Solvent Complexes. Table 2 summarizes the ^{23}Na chemical shifts of a variety of solid solvent complexes, together with their bonding features as revealed by X-ray diffraction studies.[22–25,40–43] The static ^{23}Na NMR studies showed that all of these compounds gave single resonance lines, consistent with X-ray diffraction data in which solvent molecules such as H_2O, methanol, acetone, etc. are coordinated to the central sodium ions as an octahedral or a nearly octahedral arrangement.[22–25,40–43]

Figure 2 illustrates the ^{23}Na MAS NMR spectra of some sodium complexes with 1,4-dioxane. Many of

a) s stands for single line; f.o. stands for the first-order split signal. b) DX and DMF stand for 1,4-dioxane and *N,N*-dimethylformamide, respectively. c) Data from potassium complex.

these complexes are efflorescent. In fact, the ^{23}Na MAS NMR spectra of $NaClO_4$–$3C_4H_8O_2$ complex gave three kinds of peaks whose relative peak intensities are significantly varied among three kinds of preparations (Figure 2D—F). The peak a is readily ascribed to the ^{23}Na NMR peak of uncomplexed $NaClO_4$, as compared with the peak position of $NaClO_4$ crystal (Fig. 2C). The peak c is assigned to the presence of Na^+ ion dissolved in a concentrated solution, because this peak is visible only for samples containing a wet fraction. In addition, it is emphasized that this sharp signal is still present in the static ^{23}Na NMR spectra. Accordingly, the peak b is unambiguously ascribed to the Na^+ ions complexed with 1,4-dioxane. By contrast, $NaIO_4$–$3C_4H_8O_2$ complex gave no residual peaks corresponding to the peaks a and c of $NaClO_4$–$3C_4H_8O_2$ complex (Fig. 2B). It is noteworthy that the ^{23}Na chemical shifts of these complexes are significantly displaced as compared with those of uncomplexed inorganic salts (Table 2).

Complexes with Small Ligand Molecules. In contrast to the cases of the solvent complexes described above, the sodium ions of the present complexes are coordinated to hydroxyl, carbonyl or ether moieties of small ligand molecules. The electric field gradient around the sodium ions is virtually zero as viewed from the appearance of single lines in the static ^{23}Na NMR, except for the case of 2-aminoethanol–sodium iodide(1/1) in spite of different type of oxygens around the sodium ions. For the latter, the bonding feature is that of an irregular geometry of 7 coordination which would cause non-zero quadrupole coupling constant (see Table 2).[28]

Complexes with Ionophores. Figure 3 illustrates the ^{23}Na MAS NMR spectra of crystalline sodium complexes with a variety of naturally occurring ionophores whose chemical structures differ substantially among them (see Fig. 4, for chemical structure[55]). Clearly, the ^{23}Na NMR signals of NaSCN complexes of nonactin, tetranactin, and valinomycin were displaced upfield by 16, 22, and 21 ppm, respectively, upon complex formation as compared with those of uncomplexed NaSCN, and the extent of the displacements

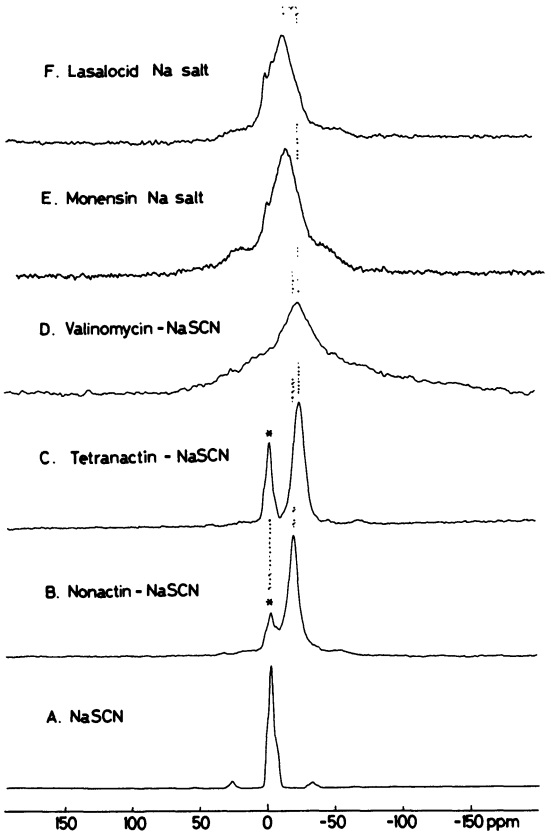

Fig. 3. 79.35 MHz MAS ^{23}Na NMR spectra of the sodium complexes with naturally occurring ionophores in the solid state. The peaks asterisked in Fig. 3B and C are from uncomplexed NaSCN.

of peaks in these cases is much larger than that of the solvent complexes described above (Table 2).

Figure 5 shows the ^{23}Na MAS NMR spectra of the sodium complexes with cryptands in the solid state (see Fig. 4). Again, it is clear that the ^{23}Na signals are displaced upfield by complexation with these cryptands and 18-crown-6 (spectrum not shown), consistent with the data of the naturally occurring ionophores (Table 2).

Ab Initio Calculation. Figure 6 summarizes the interaction energies and gross orbital charges of Na^+ ions complexed with H_2O or $H_2C{=}O$ molecules to form octahedra (a) and (b), respectively, or to form the plane (c). We consider the complexes (a) and (b) as models of the solvent complexes and complexes with ionophores, and the complex (c) as crown ethers. The total interaction energy (ΔE) was decomposed into the terms of polarization (PL), electrostatic (ES), charge transfer (CT), exchange (EX), and mixed term (mix) by the procedure of Morokuma et al.[56] Obviously, the interaction energy arises mainly from the electrostatic (ES) interaction and achieves the minimum value at about the Na–O distance of 2.4 Å, consistent with the experimental finding. The achieved stabilization energy increases in the following order: octahedral H_2CO<planar H_2O<octahedral H_2O. The largest amount of electron transfer from the ligand molecules to the 3p orbital of the Na^+ ion occurs at the bond length larger than 2.4 Å, and decreases with the following order: octahedral H_2O>octahedral $H_2C{=}O$>planar H_2O. Figure 7 summarizes the interaction energy and gross orbital charge of the Na^+ ion complexed with a H_2O molecule with various orientation. Similar results were obtained for the interaction with $H_2C{=}O$ molecule (data not shown).

Discussion

Tables 1 and 2 show that the range of the ^{23}Na chemical shifts of inorganic salts and sodium complexes so far studied is about 60 ppm and these chemical shifts can be used as a diagnostic means of characterization of these compounds. These characteristic shifts, however, cannot be obtained by solution NMR spectra, because dissolution of these solid samples in solvents results in the disruption of the crystalline structure formed by ionic interactions.

It is noteworthy that the ^{23}Na NMR peak of $NaBPh_4$ resonates at −51.7 ppm (Table 1). This peak position is surprisingly high for a Na^+ ion. In contrast to Na^+ ions, the ^{23}Na chemical shift of Na^- ion is solvent-independent:[14-17] −61.9 ppm in $MeNH_2$, −61.8 ppm in 12-crown-4 and −63.1 ppm for the gas state. In

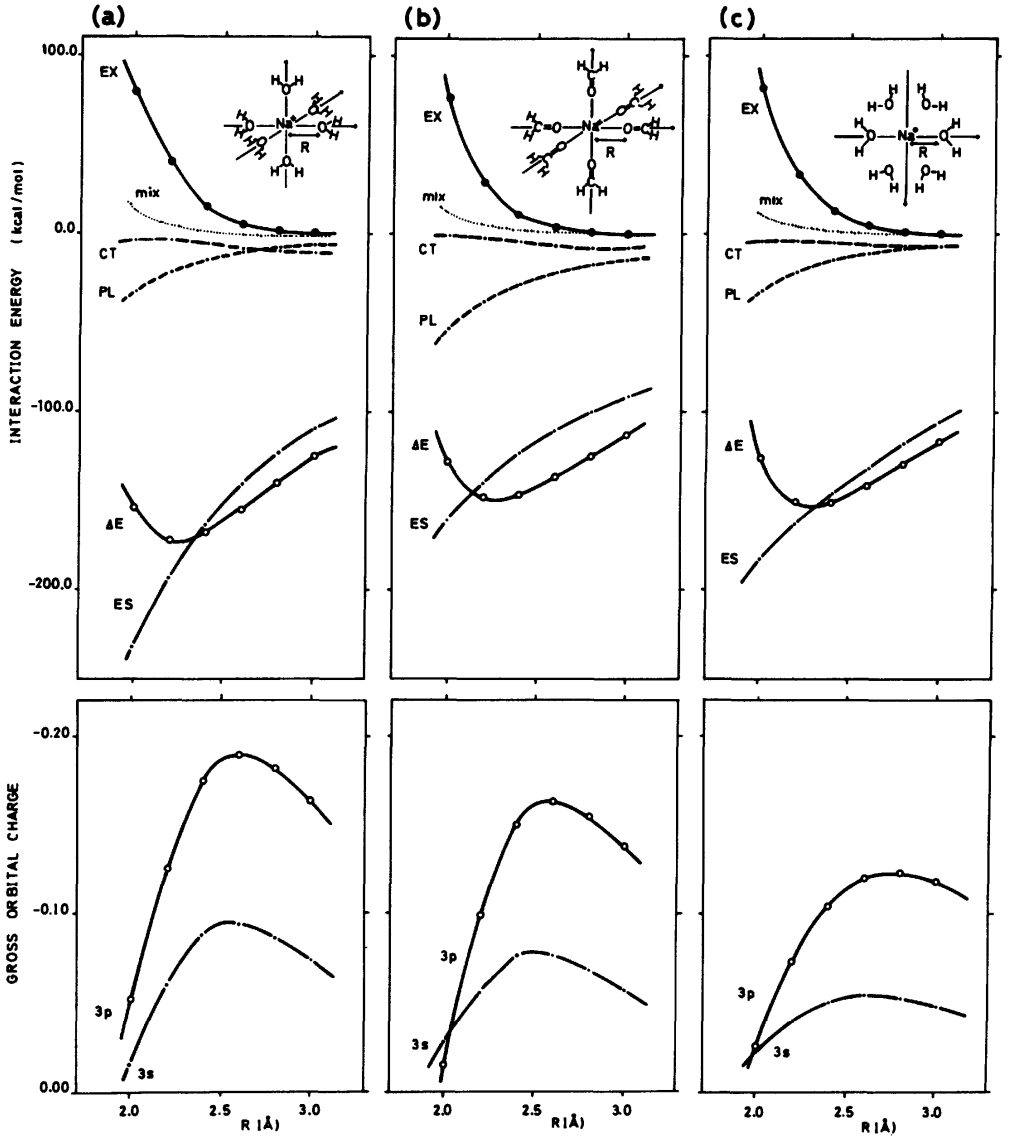

Fig. 6. The interaction energies and gross orbital charges of Na^+ ions complexed with H_2O and $H_2C{=}O$ molecules to form octahedron (a) and (b), respectively, or to form plane (c) as a function of the Na–O distance R (Å).

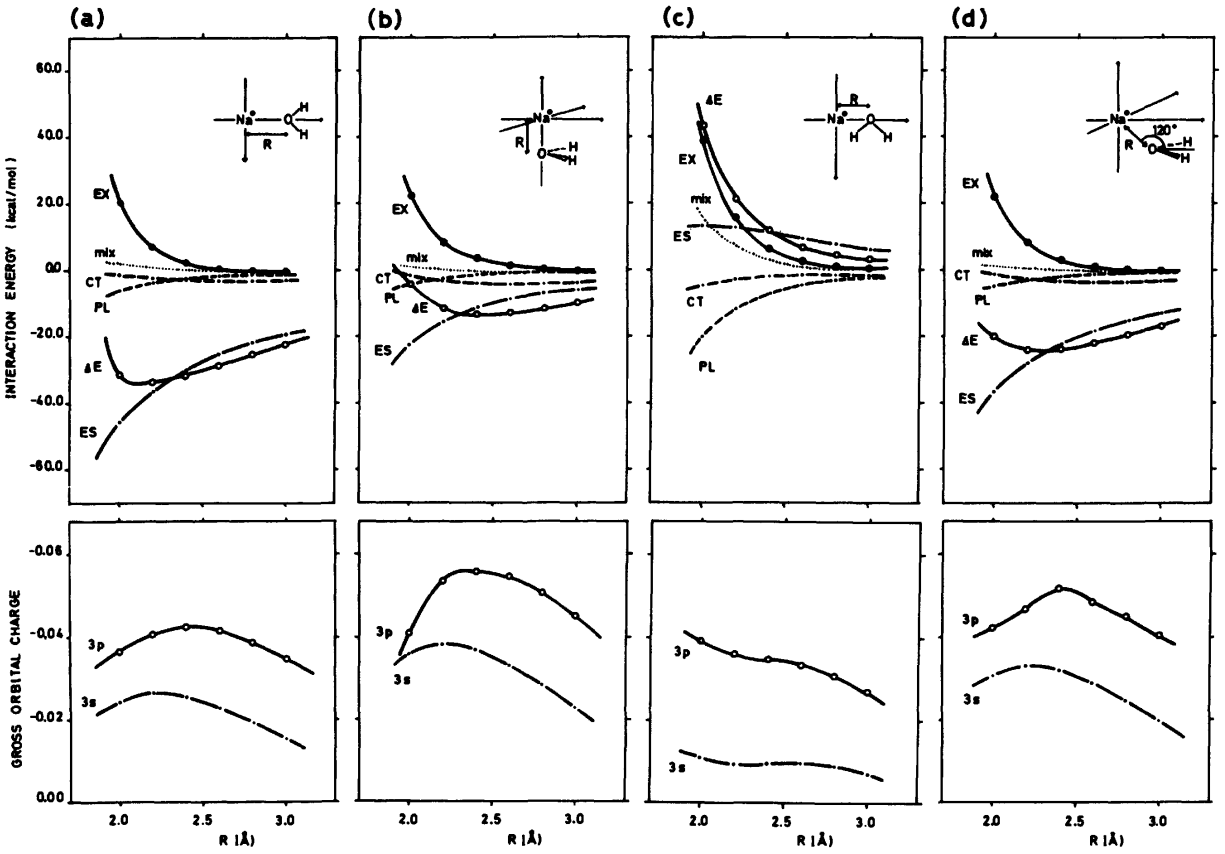

Fig. 7. The interaction energies and gross orbital charges of Na^+ ions complexed with a H_2O molecule with various orientation.

connection with this, Malli and Fraga[57] showed that the changes in nuclear shielding constants of Na^-(gas) with respect to Na^+(gas) are relatively small, amounting to a shielding of only 7.7 ppm for the addition of two 3s electrons to gaseous Na^+ to form Na^-(gas). Thus, it is possible to estimate the ^{23}Na chemical shift of Na^+(gas) as −55.4 ppm, on the basis of the data mentioned above. Accordingly, the electronic structure of the Na^+ cation in $NaBPh_4$ crystal seems to be very similar to that of the gaseous Na^+ ion, as manifested from a very small deshielding (+3 ppm). On the contrary, the large downfield shifts (≈+60 ppm) of a number of inorganic salts could be interpreted in terms of a large paramagnetic shielding contribution due to the presence of the 3p electron transferred from the counteranions, by analogy with the case of the ion-solvent interaction. As to the latter, the ^{23}Na chemical shifts can be correlated with the Gutmann donor strength of the solvents over a range of almost 20 ppm.[58]

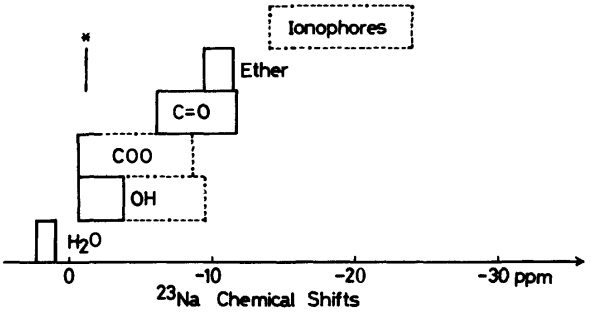

Fig. 8. Schematic representation of the displacements of the ^{23}Na chemical shifts as related to the type of ligand molecules. The data shown by the thick and dotted lines correspond with the complexes whose Na-O distance is in normal region (2.3—2.5 Å) and is larger than this range, respectively. The diagram asterisked arose from $NaIO_4$-$3C_4H_8O_2$ whose chemical shift is significantly lower than that of the other complexes indicated by the "ether".

In Figure 8, we summarized the range of the ^{23}Na chemical shifts of various sodium complexes as a function of the type of ligand molecule. For the complexes with mixed ligands, we plotted the range of the ^{23}Na chemical shifts by the type of ligands whose bonding numbers are larger than 3. In addition, we expressed the ^{23}Na chemical shifts of these complexes whose Na-O distances are in the normal range (2.3—2.5 Å) and are larger than this range by the thick and dotted lines, respectively. The following three features emerge from closer examination of Fig. 8 and Table 2.

First, the ^{23}Na chemical shifts of $Na_2SO_4 \cdot 10H_2O$, $Na_2HAsO_4 \cdot 7H_2O$, and NadAMP·$6H_2O$ are the same, 1.0—2.3 ppm, within the experimental error, regardless

of the variety of the counter-anions. Further, the ^{23}Na chemical shifts of four sodium complexes ($NaClO_4$, $NaBF_4$, NaI, and NaSCN) with 1,4-dioxane are the same, regardless of the different kinds of counteranions. These findings are rationalized by assuming that the Na^+ ions of these complexes are complexed with six (octahedral) H_2O molecules with Na–OH_2 distance 2.35—2.48 Å for the former,[40-42] and are complexed by six dioxane molecules with an average Na–O distance of 2.43 Å for the latter.[22] Accordingly, the counteranions have no direct effect upon the ^{23}Na chemical shifts because they are not directly coordinated to the sodium ions. It is not clear, however, why the ^{23}Na signal of the $NaIO_4$ complex appears at such a surprisingly lower field (−2.9 ppm). It is probable that the Na–O distance of this crystal might be different from the others, although no X-ray diffraction study is available. In a similar manner, the ^{23}Na chemical shift of $Na(CH_3COO)3H_2O$ is very close to the value of the sodium ions coordinated by six aqua ligands, because the Na ion in this case is coordinated by five H_2O molecules and one COO moiety.

Second, the ^{23}Na NMR signals of sodium complexes coordinated to COO or OH groups apprears at almost the same position (or slightly at higher field by 1—2 ppm) as those of the sodium complexes with H_2O (see Fig. 8). On the contrary, the ^{23}Na chemical shifts are displaced upfield by 5—10 ppm when the sodium ions are complexed with ether or the C=O moieties of ligands. Third, the ^{23}Na chemical shifts are significantly displaced upfield when the Na–O distances of the complexes are increased, as encountered for a variety of complexes with ionophores whose size of cavity is more preferrable to cations of larger ionic radii like potassium ions. In addition, the observation of the ^{23}Na chemical shift of trisodium nitrilotriacetate hydrate at rather higher field (−8.7 ppm) as H_2O and COO ligands could be interpreted in terms of the presence of a longer Na–O distance as compared with that of the other complexes.

A theoretical interpretation of the chemical shifts for alkali halide crystals was successfully performed by Kondo and Yamashita[59] and Ikenbery and Das[60] who took into account the overlap between the np-orbital of the metal and the outermost s- and p-orbitals of the halide ions. This approach, however, is not convenient for our purpose, because we are mainly concerned with a relation between the ^{23}Na chemical shifts and the magnitude of electron transfer from the ligand molecules. Alternatively, Bloor and Kidd showed that the paramagnetic term of the ^{23}Na chemical shifts amounts to ca. −270 ppm per electron donated to a 3p orbital of the sodium atoms,[17] using Schneider and Buckingham's "atom in a molecule" method.[61] The calculated electron density of 3p orbital at R=2.5 Å is 0.19, 0.16, and 0.11 for the coordinations of octahedral six H_2O (a), octahedral six H_2C=O (b) and planar six H_2O (c) molecules, respectively, as illustrated in Fig. 6. The resultant ^{23}Na chemical shifts for the models (a), (b), and (c) are −4, −12, and −25 ppm, respectively, by taking into account the fact that the paramagnetic shielding constant for the cases (a), (b), and (c) are −51, −43, and −30 ppm, respectively, following the formula of Bloor and Kidd[17] and the ^{23}Na chemical shift of the gaseous Na^+ ion is estimated as −54 ppm when referred to 1 M NaCl, as described already. The calculated ^{23}Na chemical shifts thus obtained are in good agreement with the experimental data, if the models (a), (b), and (c) are considered as representing the sodium complexes with ligands of H_2O, acetone or DMF, and 18-crown-6, respectively. Obviously from the data of Fig. 6, the electron density in the 3p orbital is decreased when the Na–O distance is increased further from 2.5 Å as in the cases of the complexes with ionophores, resulting in the upfield displacements of the ^{23}Na signals as a result of a reduction in the paramagnetic shielding contribution.

The extent of the electron transfer would be much influenced by the relative orientation of the lone-pair orbitals with respect to the direction of the Na–O vector, as shown in Fig. 7. Accordingly, the electron transfer is minimal for the arrangement of Na–H_2O as shown in Fig. 7(c), in which the lone-pair orbitals are perpendicular to the Na–O vector. On the contrary, the magnitude of the electron transfer is maximum for the arrangement of Fig. 7(b), although stabilization is not fully achieved. Similar results were obtained for the case of the Na–O=CH_2 system. For this reason, the relative orientation of the ligand molecule is a very important factor in the determination of the ^{23}Na chemical shifts in addition to the Na–O distance, because the magnitude of electron transfer is dependent on this separation. It is now obvious that the ^{23}Na chemical shifts of the sodium complexes can be well related to the extent of the electron transfer from the ligand molecules, although a more elaborate treatment is required to achieve a quantitative interpretation of the ^{23}Na chemical shifts in terms of electronic structure.[62]

Concluding Remarks

We have demonstrated that the ^{23}Na NMR signals of inorganic salts as well as a variety of sodium complexes in the solid state exhibit displacements of chemical shifts as large as 60 ppm and provide a convenient means of analyzing the following individual species, ion-ion, ion-solvent, and ion-ligand interactions which are present in the solution state. We found that these variations of the ^{23}Na chemical shifts are well related to the extent of electron transfer from the ligand molecules to the 3p orbital of the sodium ions which results in substantial deshielding due to a significant paramagnetic contribution. Accordingly, the ^{23}Na chemical shifts in the solid state are proven to be a very useful means for the characterization of these complexes as viewed from the type of ligand molecules, their relative

orientation, and the Na–O distances as well as reference data for solution NMR spectra.

The numerical calculations were carried out with a HITAC M-240H in the National Cancer Center and a HITAC M-200 H in the Institute for Molecular Sciences. This work was supported, in part, by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan. Finally, we thank Dr. G. A. Webb, University of Surrey, England, for helpful discussion.

39) The linewidths achieved by MAS experiments were less than 500 Hz for a number of inorganic salts, as reported previously (Ref. 20). Many of solvent complexes as well as complexes nonactin and tetranactin gave the linewidths of 500—1000 Hz. It appears, however, that the linewidths are increased to over 1000 Hz when the linebroadening by dipolar field from nearby proton(s) of counterions or ligands cannot

be completely removed by MAS experiments. In fact, the following complexes gave larger linewidths than 1500 Hz: Valinomycin (3000 Hz), monensin (2800 Hz), lasalocid (2100 Hz), [2.2.1] (1700 Hz) and [2.2] (2200 Hz). We found that the linewidths were in some instances significantly decreased by proton decoupling or removal of water molecules (Ref. 20). Further, the linewidths of $Na_2SO_4 \cdot 10H_2O$ and $Na_2HAsO_4 \cdot 7H_2O$ were decreased from 600 and 430 to 400 and 160 Hz, respectively, by recrystallization from D_2O solution. In this connection, it is mentioned that these linewidths studied herein were not affected by the second-order quadrupole interaction, because the quadrupole coupling constants from the static ^{23}Na NMR spectra were zero. Further, the linewidths of $NaBH_4$, $NaBPh_4$, and $NaBF_4$ are 1000, 1010, and 740 Hz, respectively, although the quadrupole coupling constants of the former two are zero and are 1.2 MHz for the latter.

Conductivity of Lithium Salts in the Mixed Systems of High Permittivity Solvents and Low Viscosity Solvents

Yoshiharu MATSUDA, Masayuki MORITA,* and Fumitsugu TACHIHARA
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwa-dai, Ube 755
(Received January 18, 1986)

Electrolytic conductivities of $LiClO_4$ and $LiPF_6$ have been investigated in the mixed systems of the high permittivity solvents and low viscosity solvents. Propylene carbonate (PC), sulfolane (S), and dimethyl sulfoxide (DMSO) were used as the high permittivity solvents, and 1,2-dimethoxyethane (DME) and tetrahydrofuran (THF) as the low viscosity solvents. The conductivity of 1 mol dm^{-3} $LiClO_4$ has a miximum in the mixed solvent with 40—80 m/o ether for every system. The conductance improvement by solvent-blending was qualitatively described in terms of a favorable combination of high permittivity and low viscosity of each component. The maximum conductivity of 1 mol dm^{-3} $LiClO_4$ increased in the order of S<PC<DMSO for the systems containing THF. The difference in the order of maximum conductivity between DME and THF was interpreted by ion-solvent interactions, whose measure is generally expressed by the donor and acceptor properties of the solvent. The $LiPF_6$ solutions had much higher conductance than those of $LiClO_4$, especially in high DME concentration regions.

A large number of aprotic organic solvent/lithium (Li) salt combinations have been examined as electrolyte solutions for Li batteries.[1] One of the basic requirements for battery electrolytes is high ionic coductivity. The conductivity of the electrolyte solution is much influenced by the permittivity and the viscosity of the solvent. The former relates to dissociation of the salt and the latter affects the motion of charged particles, or ions. With respect to these, a solvent with high permittivity and low viscosity should be suitable for the conductive electrolyte.[2] In general, however, few solvents satisfy these requirements concurrently. Hence, mixed systems consisting of two solvents, i.e., a high permittivity solvent and a low viscosity solvent, have sometimes been used for practical batteries.[3-5]

Previously, we have reported on the characteristics of some mixed electrolyte systems consisting of a high permittivity solvent and a low viscosity solvent for primary and secondary Li batteries.[6-11] As was expected, high conductivities were observed in the mixed solvent systems, and the electrode characteristics were also excellent in the mixed electrolyte systems.[8,10-13] However, both the conductance behavior and the electrode characteristics changed in response to the kinds of the solvent and the electrolyte salt.

In the present work, conductance behavior in some mixed solvent systems has been compared with one another. The high permittivity solvents used here were propylene carbonate (PC), sulfolane (S) and dimethyl sulfoxide (DMSO), and the low viscosity solvents were 1,2-dimethoxyethane (DME) and tetrahydrofuran (THF). The conductivities of $LiClO_4$ and $LiPF_6$ in the mixed systems are at first explained on the bases of the solvent permittivity and the solution viscosity. Differences in the conductance behavior among the systems are also discussed from the standpoint of the donor-acceptor properties of the solvents,[14,15] which concern the ion-solvent interactions to a great extent.

The structure of ionic solution with organic solvents has fairly been established by some workers,[16-18] but there have been few data on a comparison of the conductivities at moderate concentration of the salts.[19] This study concerns the conductivities at relatively high concentration (1 mol dm^{-3}). Thus the discussion will be rather qualitative, but be useful to develop the electrolyte of practical Li batteries.

Experimental

The purification of the solvents, PC, S, DME, and THF, was carried out as described previously.[9,11,19] DMSO was refluxed over CaH_2 and fractionally distilled.[20] The electrolytic salts were $LiClO_4$ (Ishizu Pharmaceutical) and $LiPF_6$ (Morita Chemical Industries). The solutions were prepared by dissolving the salts (normally 1 mol dm^{-3}) into the mixtures of the high permittivity solvents with the low viscosity solvents. These will be hereinafter represented by such formulas as "PC-DME/$LiClO_4$."

The conductivity of the electrolyte was measured with an AC impedance bridge (10 kHz). The relative permittivity (dielectric constant) of the solvent and the viscosity of the solution were determined by the same methods as described previously.[21] These measurements were carried out at 30 °C.

Results and Discussion

Table 1 shows the relative permittivity (ε_r), viscosity (η), donicity (DN) and acceptor number (AN) of the pure solvents. The values of DN and AN are those quoted from the literature.[1,14,15,24] PC, S, and DMSO have high permittivities as well as high viscosities. The ethers, DME and THF, are low viscosity-low permittivity solvents, whose η and ε_r are similar to each other.

Figure 1 shows the molar conductivity (Λ) of 1 mol dm^{-3} $LiClO_4$ in PC-DME, S-DME, and DMSO-DME as a function of the DME concentration (m/o) in the solvent. For every system, the conductivity in the mixed solvent was higher than that in the neat solvent. The molar conductivity became maximum at

Table 1. Selected Properties of the Solvents

Solvent	ε_r[a)]	η[a)]/10^{-3} Pa s	DN[b)]	AN[b)]
PC	66.8	2.25	15.1	18.3
S	42.5	9.87	14.8	19.0
DMSO	47.8	1.75	29.8	19.3
DME	6.92	0.40	24	(≃10)[c)]
THF	7.25	0.46	20.0	8.0

a) Measured at 30 °C. b) From references 1, 14, 15, and 24. c) 10.2 for diglyme (diethylene glycol dimethyl ether).

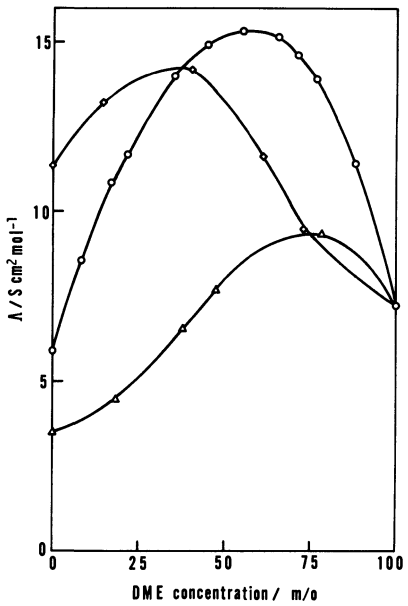

Fig. 1. Variation of the molar conductivity (Λ) of 1 mol dm^{-3} $LiClO_4$ with the solvent composition.

40—80 m/o DME. This conductivity enhancement is qualitatively explained by a favorable combination of high permittivity of PC, S, or DMSO with low viscosity of DME. The viscosity of the solution decreases with DME concentration. Thus, in the solution with relatively low DME content, the ionic mobility, or ionic conductance, increases with DME content in the solvents. On the other hand, the permittivity also decreases with DME content. This leads to an increase in the degree of ion association, which causes the conductivity to decrease, especially in the soltions with high DME content. Therefore, optimum solvent compositions are present for the conductance of these mixed electrolyte systems.

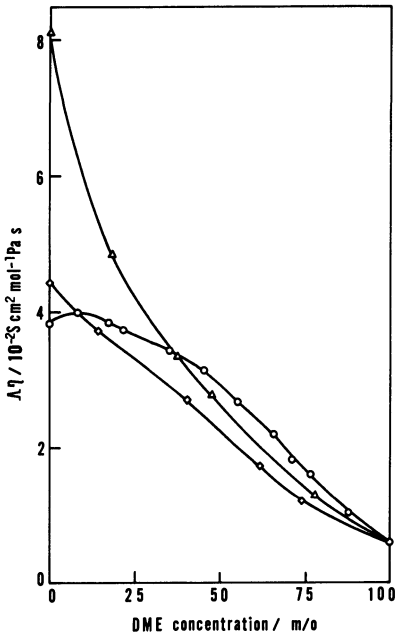

Fig. 2. Variation of the Walden product ($\Lambda\eta$) of 1 mol dm^{-3} $LiClO_4$ with the solvent composition.
○: PC-DME, △: S-DME, ◇: DMSO-DME.

Jansen and Yeager[25] have reported that the ion pair association constant K_a calculated by the Fuoss-Onsager theory was −1.0—−1.5 in PC(pure)/$LiClO_4$ at 25 °C. On the other hand, we have previously estimated the degree of association of $LiClO_4$ in the PC-DME and the PC-THF systems by using Bjerrum's equation.[9] The results showed that the degree of association would be very small (<0.1) in the solutions containing 0—40 v/o ethers, and that the ion association would significantly occur at the ether concentration range of 70 v/o or more. That is, it has been shown that the conductivity-solvent composition curves experimentally obtained in PC-DME/$LiClO_4$ and PC-THF/$LiClO_4$ were consistent with those calculated on the assumption that the conductivity is almost determined as the first approximation by the solution viscosity and the ion association.[9]

As shown in Fig. 1, there are some differences in the shape of the curve and in the DME concentration providing maximum conductivity among the three systems. This is first of all attributable to differences in the relative permittivity and the viscosity among PC, S, and DMSO. Figure 2 shows the Walden products ($\Lambda\eta$) of the 1 mol dm^{-3} $LiClO_4$ solutions as a function of DME concentration. The Walden products were approximately similar to one another in the solvents with DME concentration more than 40 m/o. The monotonous decrease of $\Lambda\eta$ with DME concentration in this region is related to the increase in ion association caused by increasing DME content in the solvents. If it is valid to assume that the conductivity is almost determined by the permittivity and the viscosity, differences in the Walden products among the solvent

systems would primarily originate in the permittivity of the solvent. The relative permittivities of the mixed solvents are shown in Fig. 3. In general, the permittivity of an binary system shows an additive property, i.e., a linear relationship between the permittivity and the composition. As shown in Fig. 3, the permittivity-composition curves for the present three systems bent downward. This is because the solvent compositions were represented by mole fractions. Relative permittivity can be assigned a significance in terms of the quantity per unit volume. In the present cases, the permittivities of the solvents varied almost linearly with the volume percent of the blended solvents.[9]

In Fig. 4, the molar conductivities of 1 mol dm^{-3} $LiClO_4$ solutions are plotted against the relative permittivities of the solvents. Since the permittivities had linear relationships to the solvent compositions, the Λ–ε_r relations also gave maximum values in the mixed systems. The ε_r providing the maximum Λ was about 30 in the systems of PC-DME and DMSO-DME, but it was 20 or less in S-DME. The relatively low Λ of 1 mol dm^{-3} $LiClO_4$ in S-DME might be attributable to the high viscosity of this system. Figure 5 shows the relation between the Walden products and the relative permittivities of the solvents. The differences in the $\Lambda\eta$–ε_r curves among the solvent systems originate probably in some characteristics of the systems, other than the permittivity and the viscosity, because the contributions of the latter parameters (ε_r and η) to the conductivity have already been reflected in the $\Lambda\eta$–ε_r relations. It must be taken into consideration that the dielectric saturation around ions[26] also affects the conductance behavior. However, this effect would be treated as a peculiar ion-solvent interaction. The ion-solvent interactions affecting the conductance behavior will be comprehensively discussed in the latter part of this section.

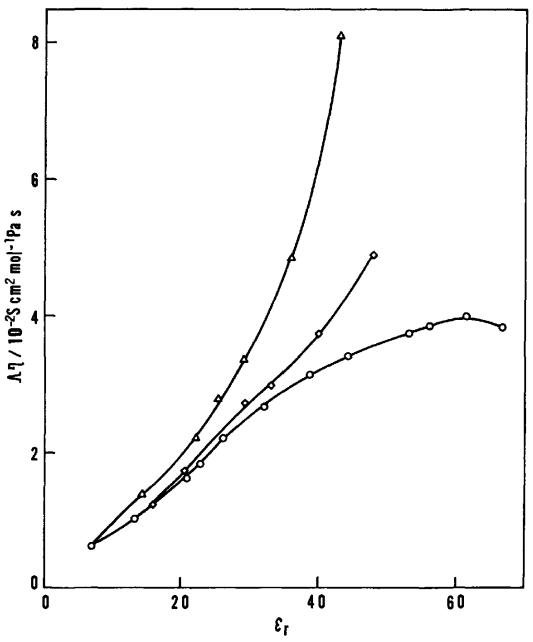

Fig. 5. Correlation between $\Lambda\eta$ of 1 mol dm^{-3} $LiClO_4$ and ε_r of the solvent.
O: PC-DME, △: S-DME, ◇: DMSO-DME.

In Fig. 5, the curve of DMSO-DME/$LiClO_4$ is almost consistent with that of PC-DME/$LiClO_4$ in the region of ε_r<40. The $\Lambda\eta$ in PC-DME tended to be unchangeable with increasing ε_r, especially in the high ε_r region. The $\Lambda\eta$ of DMSO-DME/$LiClO_4$ is higher than that of PC-DME/$LiClO_4$ in the DME

concentration region of 20 m/o or lower (ε_r>40). In S-DME, the $\Lambda\eta$ markedly increased with ε_r in the higher ε_r region (>30), compared with the PC- or DMSO-based system. This is mainly caused by high viscosity of S, since $\Lambda\eta$ in S-DME is rather lower than that in PC-DME or DMSO-DME. However, from the other point of view, it is considered that the S-DME/$LiClO_4$ system has relatively high conductance for its high viscosity.

The different $\Lambda\eta$–ε_r relations among the three systems in the low DME concentration (higher ε_r) region are explicable by the different donicities (*DN*) and acceptor numbers (*AN*) of PC, S, DMSO, and DME. According to Gutmann,[14,15] *DN* is defined as the negative ΔH-value in kcal mol^{-3} (1 cal=4.18 J) for the reaction (1) in 1,2-dichloroethane

$$D + SbCl_5 \longrightarrow D\cdot SbCl_5, \quad (1)$$

where D denotes the solvent in question. As $SbCl_5$ is a strong electron-acceptor, *DN* is a measure of the nucleophilic property of the solvent. On the other hand, *AN* is derived from the chemical shift of ^{31}P NMR of Et_3PO in the solvent under consideration. *AN* is expressed by a relative value when that of hexane is defined as 0 and the δ-value of the $Et_3PO\cdot SbCl_5$ adduct in 1,2-dichloroethane is arbitrarily normalized as 100. Thus *AN* is a measure of the electrophilic property of the solvent.

As DME has higher *DN* than PC, specific solvation (selective coordination) of DME to Li^+ comes out in the PC-DME system.[7,17] The *DN* of DMSO is higher than those of PC and DME. Thus the specific solvation of DME to Li^+ would not be expected in the DMSO-DME system. On the other hand, DME in the S-DME system would preferentially coordinate to Li^+ as in PC-DME because of the relatively low *DN* of S. Nevertheless, the Λ in S-DME was rather low compared with that in PC-DME. This result suggests that the other interactions, e.g., anion-solvent and ion-ion interactions, in the two systems differ from each other. These will be briefly discussed later again.

In Fig. 6, the molar conductivity of 1 mol dm^{-3} $LiClO_4$ in PC-THF is compared with that in PC-DME. As ε_r and η of pure THF are similar to those of DME, the variations of ε_r and η in PC-THF are also similar to those in PC-DME.[9] However, the molar conductivity in PC-THF was relatively low. In both systems Li^+ is probably coordinated by the ethers in preference to PC. It is considered that the primary solvation number of DME per Li^+ is two in PC-DME,[7] and the number of THF is four in PC-THF.[27] That is, the ionic radius of the solvated Li^+ would be larger in PC-THF than in PC-DME since there is no great difference in molecular volume between THF and DME. It is considered that there is little difference in the degree of association between the two systems containing the same concentrations of the ethers. Thus the relatively large size of

△: S-DME, ▲: S-THF.

the Li^+–THF solvate would be responsible for the lower conductance in PC-THF than in PC-DME. An analogous explanation applies to the cases of S-DME and S-THF shown in Fig. 7. The S-THF/$LiClO_4$ (1 mol dm^{-3}) system shows a conductivity maximum at THF concentration of about 60 m/o. However, the maximum value of the conductivity in S-THF is only 70% of that in S-DME. On the other hand, the conductance in DMSO-THF was appreciably high unlike the cases of PC-THF and S-THF (Fig. 8). The conductivity of $LiClO_4$ in the DMSO-THF system varied in a similar manner and in the same magnitude as in the DMSO-DME system, except for the composition region of fairly high ether concentration. This means that the ion-solvent interaction, or the solvation, in the two systems is almost equivalent to each other. As DMSO has higher *DN* than DME

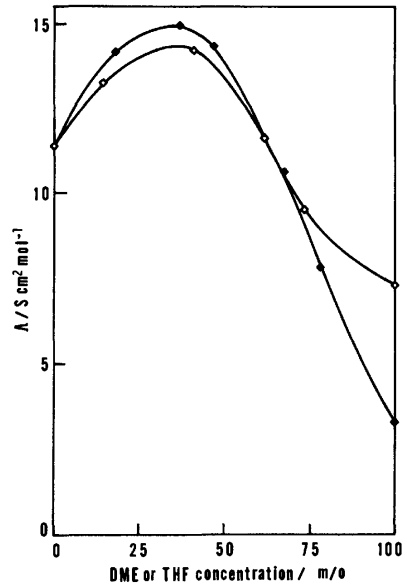

Fig. 8. Variation of Λ of 1 mol dm^{-3} $LiClO_4$ with the solvent composition.

or THF has, it is reasonable that DMSO coordinates preferentially to Li^+ in both systems. This description is consistent with the experimental results shown in Fig. 8. Besides the relatively low viscosity, the strong affinity of DMSO to Li^+, which leads to smaller size of solvated Li^+, might be related to the high conductance of $LiClO_4$ in neat DMSO compared with that in neat PC or S.

Influences of the anion on the conductance behavior of the Li salts were examined in PC-DME, S-DME, and DMSO-DME. Figures 9, 10, and 11 show the conductivity variations of 1 mol dm^{-3} $LiClO_4$ and $LiPF_6$. The solubility of $LiPF_6$ was rather low compared with that of $LiClO_4$. In S-DME, it was 1 mol

dm^{-3} or lower in the DME concentration range of < 40 or >95 m/o. The conductivity-solvent composition curves of $LiPF_6$ were almost identical to those of $LiClO_4$ in the DME concentration range up to about 40 m/o. The $LiPF_6$ solutions with high DME content showed relatively high conductance. A similar manner to this has been observed in the ether based electrolytes such as DME,[28] THF,[29,30] and 1,3-dixolane (DOL)[30] containing $LiAsF_6$ which is an analogous compound to $LiPF_6$. The reason why $LiAsF_6$ has higer conductance than $LiClO_4$ in these ether solvents has not sufficiently clarified yet.[30] The ion association will take place to a considerable extent in the ether-based electrolytes because of the low permittivity of the solvent and the relatively high concentration of the electrolyte. It is considered that the size of anion and hence the charge density at the spherical surface of anion would influence the ion-pair formation. It has been found that the two types of ion pairs may be present in solutions of high concentration or of low permittivity, i.e., solvent separated ion pairs and solvated contact ion pairs.[16,31] These are represented by the following chemical equilibria

$$(Li^+)S_n + A^- \rightleftharpoons (Li^+)S_nA^- \quad (2)$$

$$(Li^+)S_n + A^- \rightleftharpoons (Li^+A^-)S_{n-m} + mS, \quad (3)$$

where S represents a solvent molecule and A^- an anion.[1,31] It is possible that redissociation of solvent separated ion pairs occurs because of the long range nature of the coulomb force, and that the resulting free ions contribute to ionic conductance.[1] In other words, the difference in the types of ion pairs would appear in the difference of the ionic behavior, e.g., the association constants in the conventional treatment. The PF_6^- anion would be larger than ClO_4^- in its geometry[19] and hence the surface charge density of PF_6^- would be lower than that of ClO_4^-. Thus, in analogy with the $LiAsF_6$ solutions,[30] the solvent separated ion pairs would be liable to come out in the $LiPF_6$ solutions, while the contact ion pairs would be subject to form in the $LiClO_4$ solutions. These descriptions will interpret the result that the conductivities of the $LiPF_6$ solutions with high DME content were much higher than those of the $LiClO_4$ solutions.

The charge-discharge cycle characteristics of the Li electrode in S-DME/$LiPF_6$[11] and in DMSO-DME/$LiPF_6$[22] were much superior to those in the solutions containing $LiClO_4$. The $LiPF_6$ solutions consisting of the mixture of a high permittivity solvent and a low viscosity ether, which show high electrolytic conductivities, are very impressive for the practical use as the electrolytes of rechargeable Li batteries working at ambient temperatures.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60490015 from the Ministry of Education, Science and Culture.

Mechanism and kinetics of hydrogen atom transfer reaction from mesitylene (M) to triplet chloranil (^{3}CA) in 1,2-dichloroethane (DCE) at room temperature have been studied by means of picosecond (ps) and nanosecond (ns) laser flash photolysis techniques. It was found that the hydrogen transfer resulting in the formation of chloranil semiquinone radical (CAH·) proceeded through a partial charge-transfer (CT) triplet complex between ^{3}CA and M as an intermediate. No ion-pair formation was observed. The triplet complex showed transient absorption bands in the visible and near infrared regions. The association constant (K_T=28 dm^3 mol^{-1}) and lifetime (τ_C=32 ns) of the complex were estimated from a kinetic analysis for ^{3}CA quenching. From these results, combined with those of the quantum yield of CAH· formation, the first order rate constants for the hydrogen transfer and intersystem crossing in the triplet complex were estimated to be (1.7 and 1.4)×10^7 s^{-1}, respectively.

Photoinduced H atom abstraction reactions of quinones exhibit very complicated features depending on properties of H donors and solvents. Although many investigations have suggested the participation of a triplet exciplex as an intermediate, detailed studies by direct observation of short lived triplet exciplexes are still rather scarce[1-4] and desirable to elucidate the reaction mechanisms.

In a previous paper we reported the intermediation of a triplet ion pair (or exciplex with complete CT) between chloranil radical anion (CA^-) and durene radical cation (DH^+) in the course of H atom transfer from durene (DH) to ^{3}CA in DCE; i.e., a two-step mechanism via the ion pair.[1] Simultaneously, we showed the existence of a fast H atom transfer competing with the ion-pair formation. The mechanism of the fast transfer was suggested to be, substantially, also a two-step mechanism via transitory electron transfer immediately followed by a proton transfer in a collision complex with a geometrical conformation favorable to cause the fast transfer. In relation to this, it is of interest whether such a fast H atom transfer can take place commonly for the case of CA (acceptor) and other methylated benzene (donor) systems where a complete electron transfer does not occur between the donor and acceptor. Since M has an ionization potential (I_P=8.4 eV)[5] higher than that of DH (I_P= 8.03 eV),[5] it is expected that such a complete electron transfer does not take place between ^{3}CA and M.

This paper describes a laser photolysis study of H abstraction for the system of CA and M in DCE. Results indicate that the production of CAH· proceeds through the partial CT triplet complex between ^{3}CA and M, $^3(CA^{\delta-}\cdots M^{\delta+})$, but not an ion pair, and that no fast H transfer competes with the complex formation. The first-order rate constants for the H transfer and intersystem crossing in the triplet complex have been estimated by kinetic analysis.

Experimental

Transient absorption spectra were measured by the same ps and ns ruby laser photolysis systems as used previously.[1] The R636 and R406 (Hamamatsu Photonics) photomultipliers were used for the ns photolysis in the 320—825 and 500—1000 nm regions, respectively. The ground state absorption spectra were measured with a Hitachi Model 200 spectrophotometer. Chloranil (CA: Tetrachloro-*p*-benzoquinone) was the same material as purified previously.[1] The GR grade mesitylene (M: 1,3,5-trimethylbenzene) was distilled under vacuum after dried with calcium hydride or Zeolite 4A. 1,2-Dichloroethane (DCE) as a solvent was purified by the usual method. Sample solutions for ns laser photolysis were degassed by freeze-pump-thaw cycles and those for ps laser photolysis were purged with dry nitrogen gas. Transient absorption measurements were carried out at 25 °C unless otherwise stated.

Results

Ground State Complex Formation. It is well-known that the present donor-acceptor pair forms an electron donor-acceptor (EDA) complex, CA···M, in the ground state.[6] We have confirmed this in DCE by means of the electronic absorption spectroscopy. Since a large part of the CT band of the complex overlapped the absorption band of free CA in the 350—450 nm range, we determined the values of the complex formation constant (K_G=0.31±0.08 dm^3 mol^{-1}) and the extinction coefficient of the CT band at 410 nm (ε_{410}= 3270±930 dm^3 mol^{-1} cm^{-1}) at 20 °C by the Rose-Drago's method.[7] This K_G value for the M donor is smaller than that for the DH donor (0.89 dm^3 mol^{-1})[1] as expected from the difference in their ionization potentials.

Quenching Curve of ^{3}CA. The T_n—T_1 absorption of ^{3}CA was quenched efficiently by added M. The decay kinetics monitored at 510 nm obeyed the first-order rate law throughout all concentrations (1.4×10^{-3}—0.32 mol dm^{-3}) of M examined. The plot of observed decay

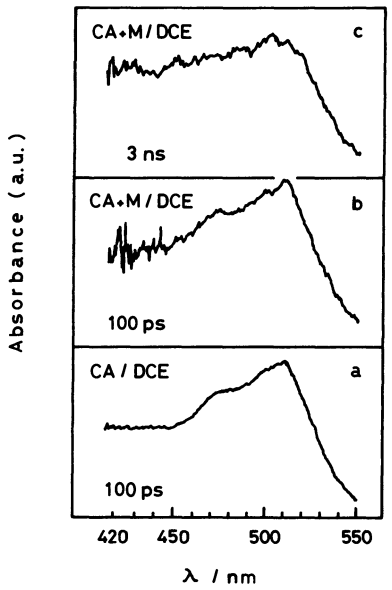

Fig. 2. Transient absorption spectra obtained by the ps laser photolysis for the solutions of CA (5.5×10^{-3} mol dm^{-3}) alone (a) and CA (5.5×10^{-3} mol dm^{-3}) plus M (0.32 mol dm^{-3}) (b and c) in DCE. Delay times: (a) 100 ps, (b) 100 ps, and (c) 3 ns. The absorbance is not corrected for the shot to shot variations of the excitation pulse intensity.

rate (τ^{-1}: the inverse of the lifetime) as a function of [M] is given in Fig. 1. The quenching curve tends to approach an asymptotic value on going to higher [M], which suggests the existence of a reverse process from a reaction intermediate such as exciplex.[8]

Picosecond Laser Photolysis. Figure 2 illustrates transient absorption spectra obtained by the ps laser photolysis. The spectrum observed for the solution of CA alone at 100 ps delay time (Fig. 2a) shows the band peaking at 510 nm, which is very similar to that of ^{3}CA obtained previously by the ns laser photolysis.[9] Since the intersystem crossing from the lowest excited singlet to the triplet state is very rapid,[1,10] the spectrum of Fig. 2a is assigned to the absorption band due to ^{3}CA. In the

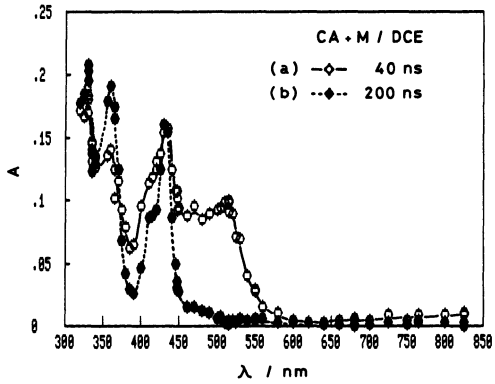

Fig. 3. Time-resolved absorption spectra obtained by the ns laser photolysis for the CA (3.0×10^{-3} mol dm^{-3}) and M (0.30 mol dm^{-3}) system in DCE. Delay times: (a) 40 ns and (b) 200 ns after the start of laser oscillation.

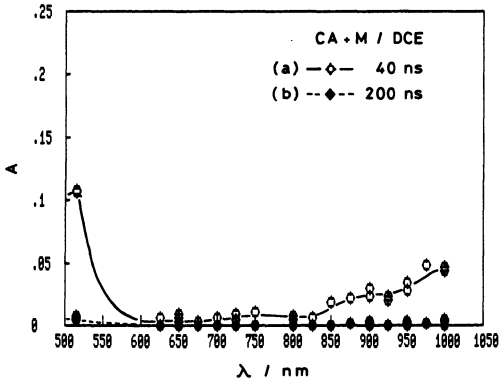

Fig. 4. Transient absorption spectra for the CA-M-DCE system in the long wavelength region. Delay times and concentrations of CA and M are the same as those in Fig. 3.

presence of M (0.32 mol dm^{-3}), the spectrum observed at 100 ps (Fig. 2b) resembles quite well with that of ^{3}CA (Fig. 2a). The spectrum at 3 ns (Fig. 2c) is also similar to that of Fig. 2a, although it shows slightly different features; the lack of vibrational structure and a slightly high absorbance in the 420—450 nm region relative to that at 510 nm. It should be noted that no absorption peaks were observed at 435 and 448 nm, which correspond to the characteristic bands of CAH· and CA^-, respectively.

Nanosecond Laser Photolysis. Time resolved absorption spectra obtained by the ns laser photolysis is given in Fig. 3. The spectrum immediately after excitation (Fig. 3a) shows an absorption band similar to that of Fig. 2c, in the 450—550 nm region. After the passage of time, this band around 510 nm disappears and strong absorption bands at 435, 360, and 325 nm, which are partly observed already in Fig. 3a, become remarkable (Fig. 3b). Among these bands, the 435 and 360 nm bands can be ascribed to CAH· produced by the H abstraction reaction by comparing them with those of CAH· observed previously in the CA and DH system[1] as well as in other related systems.[2,9] The

sharp band around 325 nm may be assigned to 3,5-dimethylbenzyl (M·) radical[11] produced by an H atom release from M, which is analogous to the formation of the benzyl-type 2,4,5-trimethylbenzyl (D·) radical observed in the CA–DH system.[1]

Figure 4 shows the transient spectra in the VIS and near IR region observed by using the R406 photomultiplier. The absorption from 800 to 1000 nm is clearly observed in the early stage after excitation, which was not detected in the absence of M. This long wavelength band disappears simultaneously with the band around 510 nm. The decay times observed at 975 as well as 1000 nm agree with that measured at 510 nm (τ=38±3 ns at 25 °C).

The decay kinetics of long lived CAH· was second-order; plot of the inverse of absorbance at 435 nm against time gave a straight line with the slope of 1.76×10^{6} s^{-1}. Using this value together with those of the molar extinction coefficient of CAH· at 435 nm ($\varepsilon_{CAH\cdot}(435)=1.0\times10^{4}$ dm^3 mol^{-1} cm^{-1})[1] and the effective length of optical path (l=0.90 cm), the second-order decay rate constant of CAH· is estimated to be 1.6×10^{9} dm^3 mol^{-1} s^{-1} at 25 °C. This value is approximately equal to that of CAH· (1.4×10^{9} dm^3 mol^{-1} s^{-1}) estimated previously in the CA–CAH_2 (tetrachlorohydroquinone)–DCE system.[9]

Determination of CAH· Yield. Under the condition of a constant laser intensity, the yield of CAH· (Φ_h) generated from ^{3}CA can be related to the following equation.

$$\Phi_h = \frac{A_{CAH\cdot}(435)/\varepsilon_{CAH\cdot}(435)}{A_{^3CA}(510)/\varepsilon_{^3CA}(510)} \quad (1)$$

where $A_{^3CA}(510)$ and $A_{CAH\cdot}(435)$ are the absorbance at 510 nm of ^{3}CA initially excited and that at 435 nm of produced CAH·, respectively, in a mixed solution of CA and M. $\varepsilon_{^3CA}(510)$ is the molar extinction coefficient of ^{3}CA at 510 nm; $\varepsilon_{^3CA}(510)=7.3\times10^{3}$ dm^3 mol^{-1} cm^{-1}.[1] On the addition of M of the concentration less than 2×10^{-2} mol dm^{-3}, the solution of CA (2.0×10^{-3} mol dm^{-3}) showed only little change (<3%) in the absorbance at 347 nm in the ground state, corresponding to little contribution of the ground state complex formation (<1%). Therefore, no correction for a small change in the concentration of the initially excited ^{3}CA was made in the photolysis at 347 nm for solutions involving a constant concentration of CA (2.0×10^{-3} mol dm^{-3}) regardless of the presence and absence of M when [M] was less than 2×10^{-2} mol dm^{-3}. At a relatively higher concentration of M in this concentration range, however, the quenching of ^{3}CA could not be neglected even at the time immediately after excitation by the laser pulse of ca. 25 ns fwhm. It was then necessary to estimate the true $A_{^3CA}(510)$ value using a separate solution as a reference. Since the absorbance change at 347 nm by the mixing of CA and M was negligible, a solution of CA alone containing the equal concentration to those of the mixed solutions could be used as a reference solution. Therefore, $A_{^3CA}(510)$ for the mixed solution can be replaced by the absorbance of ^{3}CA at 510 nm observed immediately after the excitation of the reference solution. $A_{CAH\cdot}(435)$ was obtained by observing the absorbance at 435 nm immediately after the decay of ^{3}CA in the mixed solution. CAH· did not show decay practically in the time range required for this estimation. Thus, Φ_h values were estimated to be 0.54 and 0.53 for the solutions of [CA]=2.0×10^{-3} mol dm^{-3} with [M]=4.0×10^{-3} and 1.6×10^{-2} mol dm^{-3}, respectively.

Discussion

Formation of a Partial CT Triplet Complex. As is shown in Figs. 2(b, c) and 3, no appreciable absorption band characteristic to CA^- was found around 450 nm both in ps and ns time regions. This result indicates clearly that an ion pair between CA^- and M^+ (mesitylene radical cation) is not formed in the present system,[12] contrary to the case of the CA–DH system[1] where dominant ion-pair formation takes place in the early stage after excitation. The reaction between ^{3}CA and M apparently leads to the formation of neutral radicals CAH· and M· as a result of H atom transfer from M to ^{3}CA (Fig. 3b).

The existence of intermediate complex which was suggested from the profile of quenching curve (Fig. 1) is supported also by the following results. It is expected that an EDA complex between CA and M is produced more efficiently in the triplet state than in the ground state, since ^{3}CA has a higher electron affinity than CA by the energy required for excitation from the ground to the triplet state; i.e., generally

$$E_A(^3A) = E_A(^1A) + E_T \quad (2)$$

where $E_A(^3A)$ is the electron affinity of the triplet state acceptor ^3A, $E_A(^1A)$ corresponds to that of the ground state acceptor ^1A, and E_T is the excitation energy to the triplet state. Combining Eq. 2 with the approximate relation,[13]

$$h\nu_{CT} = \text{const.} - E_A(^1A), \quad (3)$$

we can derive the following approximate equation,[2,14] assuming the same value for const.

$$h\nu_{^3CT} = h\nu_{CT} - E_T. \quad (4)$$

In Eqs. 3 and 4, $h\nu_{CT}$ and $h\nu_{^3CT}$ denote the transition energies of CT band of the ground and triplet state EDA complexes, respectively. When we use the values of E_T=2.13 eV for ^{3}CA[15] and $h\nu_{CT}$=3.02 eV (corresponding to the CT band of CA···M at 410 nm) in Eq. 4, the CT band of the triplet complex can be estimated to lie around ca. 1380 nm. The broad absorption band observed in the 800—1000 nm region (Fig. 4a),

which would have an absorption maximum beyond 1000 nm, may correspond to the CT band estimated above.

In view of the above results, we analyze the quenching data given in Fig. 1 on the basis of complex formation. Since the observed decay curves were exponential, the so called "dynamic equilibrium" would be established under the present experimental conditions.[16] In the equilibrium state, one can derive the following relation;[8,16]

$$\tau^{-1} = (\tau_0^{-1} + K_T[M]\tau_c^{-1})/(1 + K_T[M]) \quad (5)$$

where K_T is the formation constant of the triplet complex, τ and τ_0 are the decay times of ^{3}CA in the presence and absence of M, and τ_c is the lifetime of the complex. As is illustrated in Fig. 1, the experimental values of τ^{-1} are reproduced satisfactorily by the curve calculated with Eq. 5 employing the values, K_T=27.89 dm^3 mol^{-1}, τ_0=4.325 μs, and τ_c=31.55 ns which are determined by the least square method. The value of τ_0 (4.3 μs) is close to the observed one (5.6 μs) of pseudo first-order decay time of ^{3}CA in the absence of M.[9] The K_T value (28 dm^3 mol^{-1}) is significantly larger than the K_G value (0.31 dm^3 mol^{-1}), indicating that in the triplet state the complex formation is more favorable than in the ground state. This result agrees with the expectation from the larger electron affinity of ^{3}CA than CA mentioned above. Thus, the complex formation in the triplet state has been rationalized from the kinetic analysis as well as the detection of CT band.

We can estimate using the K_T value that in the equilibrium state 89% of ^{3}CA molecules are present as the triplet complex in the solution containing 0.30 mol dm^{-3} M. Hence, the intensity of absorption band around 510 nm in Fig. 3a (the spectrum at 40 ns) may be attributed mainly to the complex. That is, the triplet complex should have the absorption band around 510 nm as well as that in the near IR region. Since the absorption band around 510 nm is characteristic of ^{3}CA unit, the observed spectra in the presence of M may be assigned to the locally excited (LE) triplet state with a partial CT character; $^3(CA^{\delta-}\cdots M^{\delta+})$.

Reaction Mechanism of H Atom Transfer. In the solution of [CA]=5.5×10^{-3} and [M]=0.32 mol dm^{-3} submitted to the ps laser photolysis experiments, the absorbance due to the ground state complex reaches 38% of the total absorbance at 347 nm for the laser excitation, although CA is present by only 9% as the complex in the ground state. Under these conditions, therefore, the excellent similarity between Figs. 2a and 2b appears to indicate that a direct excitation of the ground state complex does not lead to the fast formation of CAH· as well as the ion pair.[17]

A rate constant for the formation of an outer complex can be usually approximated to be a diffusion controlled one (8.4×10^9 dm^3 mol^{-1} s^{-1} at 25 °C), so that ^{3}CA would collide with M of 0.32 mol dm^{-3} frequently enough to establish the equilibrium concerning the triplet complex formation during 3 ns delay time. Because the equilibrium in the triplet state shifts largely to the side of the complex formation (90% mole fraction), the spectrum at 3 ns (Fig. 2c) may be regarded mainly as that of the triplet complex. In addition, Fig. 2c can not be reproduced by the superposition of spectra of ^{3}CA (Fig. 2a) and CAH·. It is then implied that no CAH· is produced simultaneously with the triplet complex, if the spectrum of the triplet complex is almost the same as that of free ^{3}CA. Therefore, the fast H atom transfer competing with the formation of the triplet complex does not occur and CAH· is formed concomitantly with decrease of the triplet complex (Fig. 3).

Thus, a combination of ps and ns laser photolysis results allows us to conclude that the H atom transfer reaction proceeds via the triplet complex formation followed by H atom transfer from M to ^{3}CA in the complex. The reaction scheme may be written as follows.

$$\begin{array}{ccccc} {}^3CA + M & \overset{K_T}{\rightleftharpoons} & {}^3(CA^{\delta-}\cdots M^{\delta+}) & & \\ \tau_0^{-1}\downarrow & & k_d\downarrow & \searrow k_h & \\ CA + M & \overset{K_G}{\rightleftharpoons} & CA\cdots M & CAH\cdot + M\cdot & \end{array}$$

where τ_0 is the lifetime of ^{3}CA in the absence of M, k_d, and k_h are the rate constants for the intersystem crossing and H atom transfer processes in the triplet complex, respectively, and K_T and K_G are the equilibrium constants, respectively, as defined before.[18] The present mechanism of H abstraction is in a striking contrast with that for the case of CA and DH system where the H transfer proceeds mainly through the ion pair $CA^{\cdot-}\cdots DH^+$ formation followed by proton transfer and partly through the fast H transfer taking place competing with the ion-pair formation.[1] This difference in the mechanism seems to result from the level inversion between the zeroth order LE and CT states in the triplet complexes; i.e., the former state is lower than the latter one for the case of M donor and vice versa for the case of DH donor.

Estimation of k_h and k_d. Under the dynamic equilibrium condition between species A and B, in general, the mean rate parameter $\bar{k}$ for a certain process is given by the weighted mean of the corresponding rate parameters of A (k_A) and B (k_B) as follows:[16]

$$\bar{k} = k_A\chi_A + k_B\chi_B \quad (6)$$

where χ_A and χ_B are the mole fractions of A and B respectively. When A and B correspond respectively to ^{3}CA and $^3(CA^{\delta-}\cdots M^{\delta+})$, we can put $\bar{k}=\Phi_h/\tau$, $k_A=\phi_0/\tau_0$, $k_B=\phi_h/\tau_c$, $\chi_A=1/(1+K_T[M])$, and $\chi_B=K_T[M]/(1+K_T[M])$ for the H abstraction by ^{3}CA, so that Eq. 6 yields the following expression:

$$\Phi_h = \left(\frac{1}{1+K_T[M]}\cdot\frac{\phi_0}{\tau_0} + \frac{K_T[M]}{1+K_T[M]}\cdot\frac{\phi_h}{\tau_c}\right)\cdot\tau \quad (7)$$

Table 1. The Estimated Efficiencies (ϕ_h) of Hydrogen Transfer in the Triplet Complex along with the Observed Lifetimes (τ) of 510 nm Absorption and Yields (Φ_h) of CAH·

[CA]	[M]	τ	Φ_h	ϕ_h
10^{-3} mol dm^{-3}	10^{-3} mol dm^{-3}	ns		
2.0	4.0	297	0.54	0.56
2.0	16	103	0.53	0.54
				av. 0.55

where ϕ_0 is the efficiency of CAH· production by H abstraction of ^{3}CA from the solvent DCE, ϕ_h is the efficiency of CAH· formation from $^3(CA^{\delta-}\cdots M^{\delta+})$, and other parameters are the same as defined in Eqs. 1 and 5. According to Eq. 7, ϕ_h at each [M] can be estimated as far as Eq. 5 holds. Using the values of K_T=28 dm^3 mol^{-1}, τ_c=32 ns, τ_0=4.3 μs, and ϕ_0=0.19,[9] we obtained an average value ϕ_h=0.55 corresponding to the Φ_h values, 0.54 and 0.53, at [M]=4.0×10^{-3} and 1.6×10^{-2} mol dm^{-3}, respectively. Results are listed in Table 1. From these results, k_h=1.7×10^7 s^{-1} and k_d=1.4×10^7 s^{-1} are estimated. The k_h value is larger than the proton transfer rate constant k_p (2×10^6 s^{-1} at 20 °C) of the reaction $CA^{\cdot-}\cdots DH^+ \rightarrow CAH\cdot + D\cdot$, although the k_d value is the same order of magnitude as a corresponding rate constant k_d (1.3×10^7 s^{-1} at 20°C) of the ion pair.

Above results show clearly that the difference in nature of the intermediate complexes; i.e., the partial CT and the complete CT triplet complexes, is reflected in the rate constant of the hydrogen atom transfer between electron donor and acceptor pairs. It would be worthwhile to note that the difference by only one in the number of methyl group in the homologeous series of methylated benzene donors caused a drastic change in the mechanism of the quenching of ^{3}CA.

12) In Fig. 3b, a weak absorption band in the 450—500 nm region remains as a tail of the strong absorption band of CAH· which has no absorption band in this wavelength region.[1] The time dependence of absorbance at 448 nm showed a small rise following a fast partial decay and then decayed slowly with nearly identical behavior to that of CAH·; i.e., the second-order decay. Since the spectral profile of this band is rather similar to that of $CA^{\cdot-}$, we attempted to measure a transient photocurrent by the same way as described previously.[1] The weak current was observed in the solution containing CA (3.0×10^{-3} mol dm^{-3}) and M (0.30 mol dm^{-3}). Its decay followed exactly the second-order kinetics but its rise time (ca. 49 ns) longer than the decay time of the triplet complex did not coincide with the rise time (ca. 0.9 μs) of the 448 nm absorption band. A similar absorption band was also observed with a long life in ethyl acetate as a solvent while the transient photocurrent did not flow at all. These results indicate that the absorption band decaying slowly with approximate second-order kinetics is not due to the ion pair $CA^{\cdot-}\cdots M^+$ produced from, or in the equilibrium with, the triplet complex. If $CA^{\cdot-}\cdots M^+$ was present, the decay time of $CA^{\cdot-}\cdots M^+$ would be short as supposed from similarity with the lifetime (49 ns) of the ion pair $CA^{\cdot-}\cdots D^+$.[1] Therefore, it may be plausible to consider that the weak band gives no evidence for the formation of $CA^{\cdot-}\cdots M^+$, although the origins of this band and the photocurrent in DCE are not clear at the present stage of investigation.

17) This result suggests that the excited singlet state of the complex which should be produced by the direct excitation undergoes an immediate relaxation to the $^3(CA^{\delta-}\cdots M^{\delta+})$ and/or $CA\cdots M$ state through ISC and/or IC. It is not clear whether the direct excitation of the EDA complex affords no triplet complex. At the present stage, however, it is sufficient to note that no CAH· forms immediately after the excitation of the EDA complex.

18) The process of a relatively slow H abstraction from the solvent DCE by ^{3}CA[9] is omitted in the scheme, but for a quantitative purpose one must take this process into consideration as being included in the relaxation process of ^{3}CA with the rate constant τ_0^{-1}.

Motions of Tetramethylammonium Cations and Phase Transitions in Solid $[(CH_3)_4N]_2CdX_4$ (X=Cl, Br, I) as Studied by ^1H NMR, Powder X-Ray Diffraction, and Differential Thermal Analysis Measurements

Setsuko SATO, Ryuichi IKEDA, and Daiyu NAKAMURA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received January 31, 1986)

The temperature dependences of ^1H spin-lattice relaxation times were determined at 20 MHz for $[(CH_3)_4N]_2CdCl_4$, $[(CH_3)_4N]_2CdBr_4$, and $[(CH_3)_4N]_2CdI_4$. For the last two complexes, the frequency dependence of the relaxation time was observed above room temperature. ^1H NMR second moments were observed for the bromide complex. At room temperature, the first two complexes were found to be isomorphous with the iodide complex which forms orthorhombic crystals. Differential thermal analysis experiments revealed that these complexes undergo four, one, and one solid-solid phase transitions in the above order between ca. 80 and 430 K. Two ^1H T_1 minima were clearly observed at lower temperatures for the chloride and bromide complexes, whereas at least three ^1H T_1 minima partly overlapped with each other were detected at lower temperatures for the iodide complex. For the former two complexes, the ^1H T_1 data were well analyzed by the general method already reported. For the bromide and iodide complexes, ^1H T_1 curves observed showed a maximum above room temperature. Motions of the cation activated in these complexes are discussed in relation to the crystal field experienced by the cation.

Dynamic behavior of tetramethylammonium $(tetMA)^+$ cations in various crystalline salts has been studied fairly in detail by means of ^1H NMR techniques.[1-11] The motions of the cation contributing to ^1H spin-lattice relaxation times (T_1) around room temperature have been shown to be random reorientations of CH_3 groups about each C–N bond axis by 120°, i.e., the C_3 reorientations, and overall reorientations of the cations about the center of gravity. It has been revealed through the temperature dependence measurements of ^1H T_1 that the activation energies (E_a) for the CH_3 C_3 reorientation of the above salts except $(tetMA)CdCl_3$[11] are in a range of 15—30 kJ mol^{-1}. The widely spread values of E_a observed indicate that the potential barriers to reorient arising from interionic as well as intraionic forces contribute to E_a for the CH_3 C_3 reorientation of the cation.

When the cations are located in a weak crystal field formed by surroundings such as those in $(tetMA)_2MBr_6$ (M=Sn, Te, Pt), E_a for the CH_3 C_3 reorientation is thought to be mostly determined by the intraionic potential barrier.[10] In these crystals, the four CH_3 groups in the cation are equivalent because of the position of the cation having a high site symmetry and the E_a values observed are ca. 17 kJ mol^{-1}. If the cation is placed at a low-symmetric lattice site, however, it is supposed that the cation is somewhat distorted owing to an asymmetric crystal field and the four CH_3 groups become nonequivalent. For the distorted cations, we can expect that they show ^1H T_1 through unique motional processes different from those found for the high symmetric cations. In the present investigation, we have selected $(tetMA)_2CdX_4$ (X=Cl, Br, I) as an example of the salts having the cations distorted and the measurements of the temperature dependences of ^1H NMR parameters, X-ray powder diffraction, and differential thermal analysis (DTA) have been undertaken to obtain detailed information about the motion of the slightly distorted cations.

Experimental

Wide-line ^1H NMR absorptions were recorded to evaluate ^1H NMR second moments (M_2) at several temperatures by use of a JEOL JNM-MW-40S spectrometer operated at 40 MHz. The temperature dependences of ^1H T_1 were measured at the Larmor frequencies of 9, 12, 20, and 45.7 MHz by means of pulsed spectrometers already reported.[9,12] The conventional inversion recovery method was employed to determine T_1 values. DTA experiments were performed using a homemade apparatus.[13] For the foregoing measurements, temperatures were determined by use of copper constantan thermocouples with the accuracy of ±3 K for the wide-line NMR and ±1 K for the other measurements. X-Ray powder patterns were recorded at room temperature using a Model D-3F diffractometer from Rigaku Denki Co. equipped with a copper anticathode.

$(tetMA)_2CdCl_4$ was synthesized by slowly evaporating the solvent after mixing two methanol solutions of $2CdCl_2 \cdot H_2O$ and (tetMA)Cl in a molar ratio of 1:8.[14] $(tetMA)_2CdBr_4$ was prepared in a similar manner from the corresponding bromides. Crystals of these salts obtained were purified by recrystallization from methanol by adding a small amount of the corresponding tetramethylammonium halides. $(tetMA)_2CdI_4$ was obtained by mixing the aqueous solutions of stoichiometric amounts of CdI_2 and (tetMA)I. The colorless crystals obtained were recrystallized from water. The above crystals prepared and purified were dried over phosphorus pentaoxide in a vacuum desiccator and were sealed in glass ampoules for the measurements of NMR and DTA after evacuating ambient air and then putting in a small amount of helium exchange gas. $(tetMA)_2CdCl_4$ and $(tetMA)_2CdBr_4$ were identified by chemical analysis. Anal. Calcd for $[(CH_3)_4N]_2CdCl_4$: Cl, 35.2; C, 23.9; H, 6.0%. Found: Cl, 35.1; C, 23.7; H, 6.1%. Calcd for $[(CH_3)_4N]_2CdBr_4$: Br, 55.1; C, 16.6; H, 4.2%. Found: Br, 55.0; C, 16.7; H, 4.2%. $(tetMA)_2CdI_4$ was identified by taking X-ray powder patterns. All diffrac-

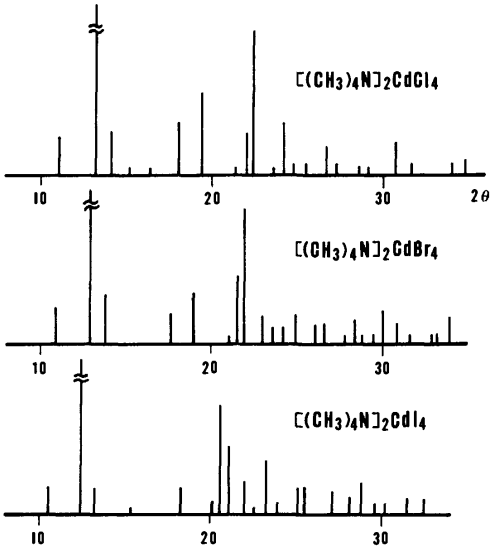

Fig. 1. X-Ray powder patterns taken at room temperature for tetramethylammonium tetrachloro- and tetrabromocadmate(II). Those of tetraiodocadmate-(II) are given for comparison.

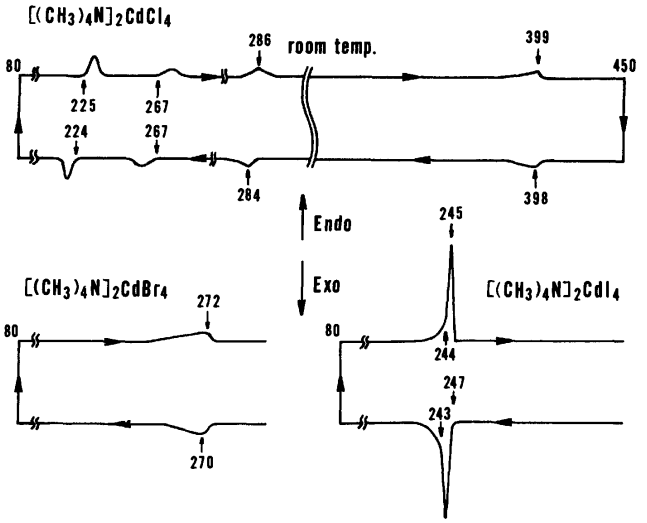

Fig. 2. DTA curves recorded for tetramethylammonium tetrachloro-, tetrabromo-, and tetraiodocadmate(II). Heat anomalies observed for tetrachlorocadmate(II) near 285 K are so small that they are enlarged about three times and shown in the figure. Temperatures measured in K are given only by figures.

tion lines detected were completely indexed in terms of an orthorhombic lattice having the lattice constants a=13.409, b=9.724, and c=16.894 Å already reported by Kallel et al.[15]

Results

From X-ray powder patterns taken at room temperature, the crystals of $(tetMA)_2CdCl_4$ and $(tetMA)_2CdBr_4$ were proved to be isomorphous with that of $(tetMA)_2CdI_4$. The powder patterns recorded for the three complexes are shown in Fig. 1. These patterns could be interpreted by the orthorhombic structure of many $(tetMA)_2MX_4$ type tetrahedral complexes[16–18] belonging to the space group *Pnma* with Z=4. The lattice constants determined were a=12.47, b=9.12, and c=15.81 Å for $(tetMA)_2CdCl_4$ and a=12.78, b=9.33, and c=16.19 Å for $(tetMA)_2CdBr_4$.

DTA curves recorded between ca. 80 and 450 K for the three complexes are shown in Fig. 2.

When $(tetMA)_2CdCl_4$ was heated from room temperature, a very small endothermic anomaly having a tail on the low temperature side appeared. The peak temperature of the anomaly was 399 K. An exothermic anomaly having a similar shape to the endothermic one and almost the same peak temperature appeared on cooling. Various methylammonium salts are known to show characteristic small heat anomalies showing no hysteresis phenomena about the peak temperature similar to the present one.[13,19–23] For these salts, we could unequivocally determine the phase transition temperature (T_{tr}) to be the peak temperature of DTA curves by comparing with the results of NQR studies which yield more accurate information about the alteration of crystal structure taking place especially in ionic crystals.[13,19–24] Accordingly, we can conclude that $(tetMA)_2CdCl_4$ undergoes a second order phase transition at 399 K.

When $(tetMA)_2CdCl_4$ was cooled from room temperature, three small exothermic anomalies appeared, the starting temperatures of which were 287, 267, and 224 K. Among these anomalies, the highest temperature one was very small. With increasing temperature, endothermic anomalies appeared at 225 and 267 K which were the initial temperatures and at 286 K determined as the peak temperature. Since the initiating temperature of the last one could hardly be determined because of its weakness and also broadness, we tentatively assigned T_{tr} of this phase transition as 286 K. Therefore, it is concluded that $(tetMA)_2CdCl_4$ undergoes three phase transitions at 286, 267, and 225 K below room temperature. Consequently, this complex experiences totally four phase transitions between ca. 80 and 450 K, yielding five structurally different solid phases.

Below room temperature, when $(tetMA)_2CdBr_4$ was cooled and warmed, an exothermic and an endothermic anomaly, respectively, appeared. Both anomalies are small and bear a strong resemblance to those observed at T_{tr} of 399 K for $(tetMA)_2CdCl_4$. They gave almost the same peak temperature. Except these, no heat anomaly could be recorded on both cooling and heating runs between ca. 80 and 430 K. Accordingly, one can conclude that $(tetMA)_2CdBr_4$ exhibits only one phase transition at 272 K, indicating the presence of two different crystalline phases.

With decreasing the temperature from room temperature, $(tetMA)_2CdI_4$ yielded a large exothermic peak which started very sharply at 247 K. From the peak

temperature, the curve returned back very sharply and almost symmetrically, but it became asymmetric from 243 K and gradually returned back to the base line with decreasing temperature. When the temperature was increased from 80 K, the base line was gradually deviated to the endothermic direction from ca. 235 K and a very sharp and large peak started from 244 K. The curve reached the maximum at 245 K, above which temperature the curve returned back to the base line very sharply. These experimental facts suggest that there exist two successive phase transitions around 245 K in the crystal of $(tetMA)_2CdI_4$. Since these phase transitions were not resolved, we could not determine T_{tr} exactly. Therefore, $(tetMA)_2CdI_4$ can be considered to undergo successive phase transitions having considerably different nature around 245 K. No heat anomaly except the above ones was recorded between ca. 80 and 450 K.

The temperature dependence of ^1H T_1 observed for $(tetMA)_2CdCl_4$ at the Larmor frequency of 20 MHz in a temperature range of 85—430 K is shown in Fig. 3. Two clearly separable T_1 minima with almost the same minimum value of 16 ms were observed. It is quite interesting that the observed T_1 curve is smooth and shows no marked anomaly at the phase transitions revealed by the DTA experiments although the gradient of the T_1 curve becomes milder just above T_{tr} of 286 K. This indicates that the phase transitions at 399, 267, and 225 K give negligible influence on the averaging of ^1H-^1H dipolar interactions in the cation.

The temperature dependences of ^1H T_1 observed for $(tetMA)_2CdBr_4$ at 12 and 20 MHz in the temperature ranges 300—465 K and 56—430 K, respectively, are

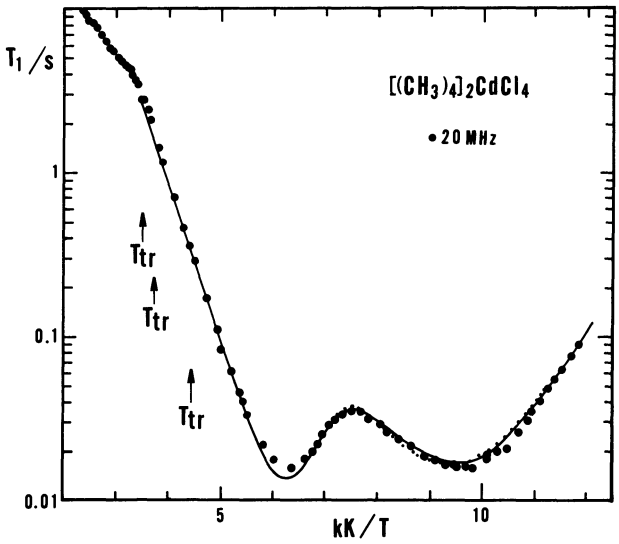

Fig. 3. Temperature dependence of ^1H T_1 observed for tetramethylammonium tetrachlorocadmate(II) at the Larmor frequency of 20 MHz (●). Solid line indicates the best fitted T_1 curve calculated based on the cationic model of C_{3v} while dotted line that based on the model of C_{2v}. Both curves agree very well with experimental values. The dotted line is written only in the temperature region where both calculated curves differ from one another. T_{tr} is the phase transition temperature determined by DTA.

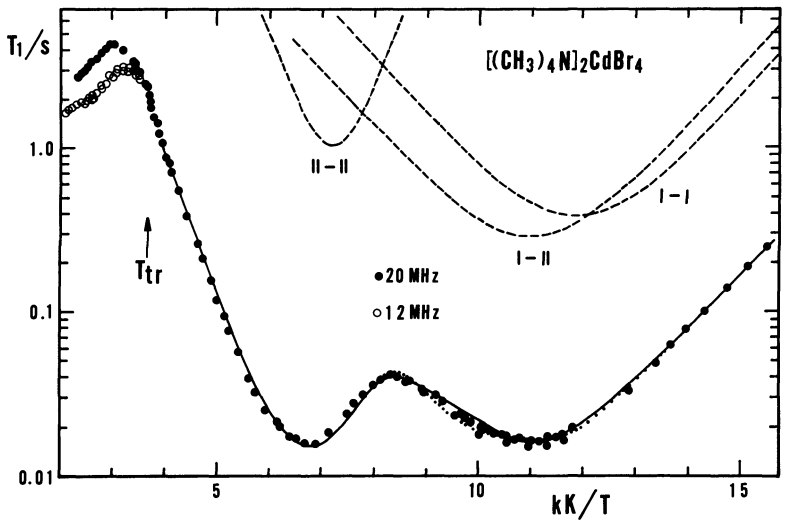

Fig. 4. Temperature dependence of ^1H T_1 observed for tetramethylammonium tetrabromocadmate(II) at the resonance frequencies of 20 (●) and 12 (○) MHz. Solid line shows the best fitted T_1 curve calculated using the cationic model of C_{3v} while dotted line that using the model of C_{2v}. The dotted curve is written only in the temperature region where both calculated curves differ from one another. Broken lines show calculated T_1 curves arising from inter-cationic dipolar interactions. Three curves were calculated for the cations between the same kind I(I-I), the different kinds I and II(I-II), and the same kind II(II-II). T_{tr} denotes the phase transition temperature determined from DTA.

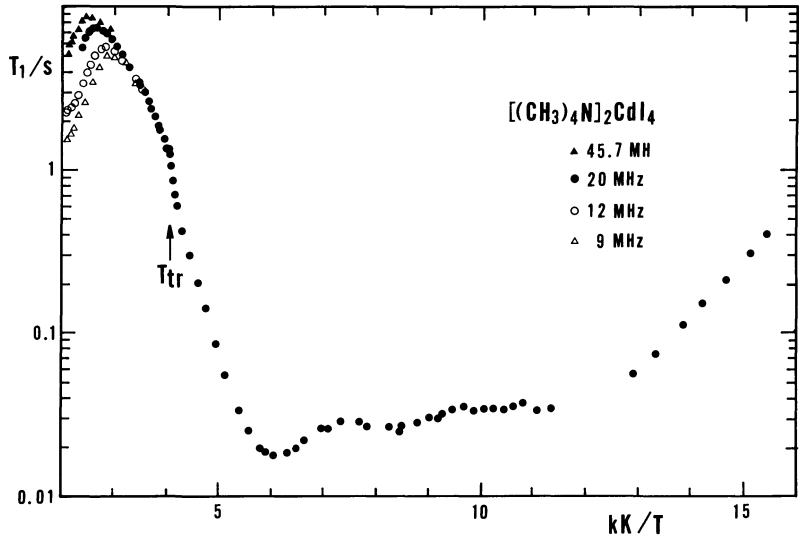

Fig. 5. Temperature dependence of ^1H T_1, observed for tetramethylammonium tetraiodocadmate(II) at 45.7 (▲), 20 (●), 12 (○), and 9 (△) MHz. T_{tr} indicates the phase transition temperature determined by DTA.

shown in Fig. 4. Two T_1 minima having almost the same minimum value of 16 ms were also obtained for this complex below T_{tr}. The T_1 curve yielding the low temperature minimum was very broad. The same is true for $(tetMA)_2CdCl_4$. Above T_{tr}, ^1H T_1 curves observed at both frequencies showed a maximum, above which temperature both T_1 values decreased almost linearly.

The temperature dependences of ^1H T_1 of $(tetMA)_2CdI_4$ measured at 9, 12, 20, and 45.7 MHz are shown in Fig. 5. T_1 observation was made in the temperature ranges of 65—430 K for 20 MHz and 300—465 K for the other three frequencies. Possibly, three or four T_1 minima partially overlapped to each other could be seen below T_{tr}. In a narrow temperature range below T_{tr} of ca. 245 K, ^1H T_1 observed at 20 MHz increased rapidly with increasing temperature and gave, above T_{tr}, a milder temperature gradient. With further increasing temperature, ^1H T_1 observed at the above Larmor frequencies yielded a maximum above which temperature each T_1 decreased almost linearly.

Discussion

It has been reported,[16-18] that half of the eight cations in a unit cell (Z=4) of the isomorphous $(tetMA)_2MX_4$ type complexes including $(tetMA)_2CdI_4$ occupies one of two kinds of nonequivalent lattice sites having low site symmetry. This means that the cation in these crystals may be distorted to some extent mainly through the electrostatic forces of the neighboring ions. In fact, the cations in the crystals of $(tetMA)_2CdI_4$ are known to be slightly distorted from T_d although the heavy atoms of the cation have very large thermal parameters.[15] In the following discussion, the same structures were roughly assumed for the cations also in $(tetMA)_2CdCl_4$ and $(tetMA)_2CdBr_4$ crystals because no atomic coordinates have been determined for these complexes as yet.

The present DTA experiments revealed the existence of phase transitions for both chloride and bromide complexes below room temperature. This means that the crystal structure of these complexes at lower temperatures is no more the same as that determined at room temperature. However, the heat anomalies recorded were so small that the structure was expected to be altered only slightly by the phase transitions. Furthermore, the ^1H T_1 data obtained show no marked anomaly at T_{tr} suggesting that the cations in these crystals keep almost the same structure from room temperature down to below 77 K.

According to the BPP theory, ^1H T_1 arising from the averaging of ^1H–^1H magnetic dipolar interactions due to molecular motions can be expressed as[25]

$$T_1^{-1} = Cg(\tau), \tag{1}$$

where

$$g(\tau) = \tau/(1+\omega^2\tau^2) + 4\tau/(1+4\omega^2\tau^2). \tag{2}$$

In these equations, C, τ, and ω denote the motional constant, the correlation time of the motion, and the angular Larmor frequency, respectively. By assuming the Arrhenius relationship for the motion, τ can be written using the activation energy E_a for the motion as

$$\tau = \tau_0 \exp(E_a/RT), \tag{3}$$

where τ_0 is the correlation time at the limit of infinite temperature.

The fact that the two T_1 minima with the same minimum value were observed for both chloride and

bromide complexes agrees very well with the crystal structure described above, showing the existence of two nonequivalent $(tetMA)^+$ cations in the crystal. Conceivable motional modes of the cation contributing to the T_1 minima are reorientations of the four CH_3 groups in the cation and also of the slightly distorted cation as a whole about its real and/or fictitious C_2 and C_3 symmetry axes. A possible explanation of the fairly deep T_1 minimum of 16 ms determined for each of the two nonequivalent cations is that all of these motional modes of each cation give a T_1 minimum at almost the same temperature and contribute as a whole to the T_1 minimum. This is because the ^1H T_1 minimum of the cation arising from these motional modes can be roughly estimated as 14 ms,[3] although this is obtained by assuming that all bond angles in the cation are tetrahedral and the bond lengths of C–H and C–N are 1.09 and 1.50 Å, respectively.[1]

$(tetMA)_2CdCl_4$ and $(tetMA)_2CdBr_4$ yielded very gentle gradients of $\log T_1$ vs. T^{-1} plots on the cold side of the lower temperature T_1 minimum. By using Eqs. 1—3, we roughly estimated E_a as 9 and 6.5 kJ mol^{-1} for the chloride and bromide complexes, respectively, from each slope. These values are too small to be considered mostly resulting from the CH_3 C_3 reorientation by the following reasons. The potential barriers for the internal CH_3 rotation in the cation have been estimated as 19.3 and 17.6 kJ mol^{-1} for $(tetMA)_2PtCl_6$ and $(tetMA)_2PtBr_6$, respectively, from the study of vibrational spectra.[26,27] For molecules having CH_3 groups in a similar situation to that of the cation, the torsional barriers of CH_3 groups in $(CH_3)_3N$ and $(CH_3)_4C$ molecules are reported to be 18.5 and 18.0 kJ mol^{-1}, respectively.[28,29] Moreover we also already obtained E_a for the CH_3 C_3 reorientation of the cation in $(tetMA)_2MBr_6$ (M=Sn, Te, Pt) crystals as 15.4, 17.8, and 18.4 kJ mol^{-1} respectively.[10]

In previous papers,[9,10] we explained shallow T_1 minima with extremely low E_a values ($\approx$8 kJ mol^{-1}) appearing at lower temperatures for $(tetMA)_2TeCl_6$, $(tetMA)_2PtCl_6$, and $(tetMA)_2MBr_6$ (M=Sn, Te, Pt) by the small-angle reorientation of the four CH_3 groups about their respective C_3 axis. However, this process can be permitted only for the cation placed in a highly symmetrical and weak crystal field such as that in the above complexes. This is because the correlated reorientation of the four CH_3 groups is an important condition for this motion. Since the cations in the present complexes are located at low symmetric lattice sites, their structure must be deformed from a tetrahedron. Therefore, the small-angle reorientation seems to be unsuitable for the explanation of the present T_1 minima with small E_a appearing at lower temperatures. For the cations deformed to some extent such as those in the present complexes, it can be expected that E_a for one or two CH_3 groups in the cation may be much lower than that for the others. This is because hindering barrier for the CH_3 C_3 reorientation is considered to be formed mainly by the intraionic forces.

For the present complexes, the CH_3 C_3 and overall reorientations give T_1 minima at almost the same temperature, where the condition necessary for the conventional treatment by Albert et al.[3] is not fulfilled. This indicates that this usual method cannot be used here. To interprete the present T_1 data, we employed the method of T_1 calculation reported by Takeda et al.,[30] which had been used for the interpretation of the data observed for neopentane. In this method, pairwise addition of intra- and inter-methyl ^1H magnetic dipolar interactions is taken for randomly jumping ^1H–^1H vectors through the respective CH_3 C_3 reorientations and also the reorientations of the whole cation about its C_2 and C_3 axes. Since jumping of each ^1H–^1H vector is regarded as representable by a Markov process, no correlation between these motions is considered as like in the case of the more convenient and widely used method developed by Albert et al.[3]

In the following analysis of T_1, the presence of two kinds of nonequivalent $(tetMA)^+$ cations is assumed in accordance with the crystal structure isomorphous with $(tetMA)_2CdI_4$ and the other $(tetMA)_2MX_4$ type complexes.[15–18] In the structure, each cation is placed on a mirror plane of the unit cell, indicating that there exist two equivalent carbon atoms in the cation. This means that each cation has two or three nonequivalent CH_3 groups. For favorable cases, the cations having C_{2v} or C_{3v} symmetry can be placed on the lattice sites. Therefore, the present T_1 calculation was performed for the two models of the cations having C_{2v} or C_{3v} symmetry so far as the motion of CH_3 groups is concerned. In other words, the geometry of the cation was roughly assumed to be T_d but the motional states of the four CH_3 groups to satisfy the above symmetry. The stable positions of hydrogen atoms were fixed at the all-staggered conformation,[27] and for C–H and C–N bond lengths the foregoing values were used.[3]

As the first model, we consider the cation having C_{2v} symmetry only in the motional states of the four CH_3 groups. Namely, two pairs, each of which consists of "equivalent" CH_3 groups, have different jumping rates and activation energies for the CH_3 C_3 reorientations from one another. For overall cationic reorientations, we assumed the presence of two kinds of nonequivalent C_2 reorientations about one genuine C_2 and two pseudo C_2 axes of the cation and, for simplicity, a single kind of C_3 reorientation about the four pseudo C_3 axes.

As the second model, we assumed the cation having C_{3v} symmetry in the same sense as above. In this model, we assumed that one CH_3 group of the cation has a more frequent jumping rate and a lower activation energy for the C_3 reorientation than the other three groups. The whole cationic motions are considered to consist of C_3 reorientations about the unique C_3 axis and the other three pseudo C_3 axes, and of C_2

reorientations about the three equivalent pseudo C_2 axes of the cation. In general, these reorientational modes should have different correlation times with the temperature dependence expressed by Eq. 3. However, the overall cationic C_3 and C_2 reorientations were reasonably assumed to have the same τ_0 and the same assumption could be made on the two kinds of CH_3 C_3 reorientations as well.

For the first C_{2v} model, the 12×12 transition matrix D[30] to calculate the intra CH_3 relaxation rate due to random jumpings of the ^1H–^1H vectors is given by

$$D = \begin{pmatrix} A & B & B' & B' \\ B & A & B' & B' \\ B' & B' & A' & B \\ B' & B' & B & A' \end{pmatrix}, \tag{4}$$

where

$$A = \begin{pmatrix} a_0 & a_1 & a_1 \\ a_1 & a_0 & a_1 \\ a_1 & a_1 & a_0 \end{pmatrix}, \qquad A' = \begin{pmatrix} a_0' & a_1' & a_1' \\ a_1' & a_0' & a_1' \\ a_1' & a_1' & a_0' \end{pmatrix}, \tag{5}$$

$$B = -\begin{pmatrix} \omega_2 & \omega_3' & \omega_3' \\ \omega_3' & \omega_2 & \omega_3' \\ \omega_3' & \omega_3' & \omega_2 \end{pmatrix}, \qquad B' = -\begin{pmatrix} \omega_2' & \omega_3' & \omega_3' \\ \omega_3' & \omega_2' & \omega_3' \\ \omega_3' & \omega_3' & \omega_2' \end{pmatrix}. \tag{5'}$$

In these equations,

$$a_0 = 2\omega_{CH_3} + 8\omega_3' + \omega_2 + 2\omega_2', \tag{6}$$

$$a_1 = -(\omega_{CH_3} + \omega_3'), \tag{7}$$

$$a_0' = 2\omega^*_{CH_3} + 8\omega_3' + \omega_2 + 2\omega_2', \tag{8}$$

$$a_1' = -(\omega^*_{CH_3} + \omega_3'). \tag{9}$$

Here, ω_{CH_3} and ω_{CH_3}* are the jumping rates of the C_3 reorientations of two nonequivalent CH_3 groups, and ω_2, ω_2', and ω_3' denote the jumping rates of the whole cationic reorientations about the C_2, pseudo C_2, and pseudo C_3 axes, respectively. These jumping rates were assumed to be the reciprocals of the correlation times of these motions.

The transition matrix due to jumping of the inter CH_3 ^1H–^1H vectors was calculated in a similar manner as used by Takeda et al.[30] Since diagonalization of these transition matrices which could be algebraically done for the T_d symmetric molecule was difficult for the present systems, it was carried out numerically using a FACOM-M382 computer in the Computation Center of Nagoya University.

Correlation times for the respective motional modes at a fixed temperature were calculated using Eq. 3 by substituting suitable trial values of E_a and τ_0. The numerical D matrix can be expressed in terms of these correlation times. By diagonalizing the D matrix thus constructed, we obtained a set of non-trivial eigenvalues which were reciprocals of the correlation times for the normal modes of reorientations for the intra CH_3 ^1H–^1H vectors at the temperature. The calculation for the D matrix of the jumping of the inter ^1H–^1H vectors was performed analogously. Finally, ^1H T_1 was obtained by the following equation,

$$T_1^{-1} = \sum_\ell K_\ell \left(\frac{\tau_\ell}{1+\omega^2\tau_\ell^2} + \frac{4\tau_\ell}{1+4\omega^2\tau_\ell^2} \right), \tag{10}$$

where τ_ℓ and K_ℓ indicate the correlation time of the ℓ-th normal mode associated with intra and inter ^1H–^1H vector jumpings and a constant depending on the mode and the structure as well, respectively. K_ℓ can be calculated numerically using the equations given by Takeda et al.[30]

T_1 values in a wide range of temperature were calculated as above by changing seven unknown parameters i.e., five E_a and two τ_0 values. From the T_1 curves calculated here, we selected several curves which agreed roughly with the observed values obtained from the cold side of the T_1 minimum, and derived approximate values of the unknown parameters.

For the other T_1 curve appearing at higher temperatures, the same method of calculation was applied. However, the T_1 curve having a rather steep slope may be interpreted by the usual "undistorted" cation. Therefore, the calculation was performed by simply assuming that all CH_3 groups in the cation are equivalent even in their motion. This results in the reduction of the number of unknown parameters.

The theoretical T_1 curve for the second model of the cation with C_{3v} symmetry for the motion of the CH_3 groups could be obtained similarly using the D matrix given by

$$D = \begin{pmatrix} A' & B_1 & B_2 & B \\ B_2 & A' & B_1 & B \\ B_1 & B_2 & A' & B \\ B & B & B & A \end{pmatrix}, \tag{11}$$

where

$$A = \begin{pmatrix} a_0 & a_1 & a_1 \\ a_1 & a_0 & a_1 \\ a_1 & a_1 & a_0 \end{pmatrix}, \qquad A' = \begin{pmatrix} a_0' & a_1' & a_1' \\ a_1' & a_0' & a_1' \\ a_1' & a_1' & a_0' \end{pmatrix}, \tag{12}$$

$$B_1 = -\begin{pmatrix} \omega_2' & \omega_3' & \omega_3 \\ \omega_3 & \omega_2' & \omega_3' \\ \omega_3' & \omega_3 & \omega_2' \end{pmatrix}, \qquad B_2 = -\begin{pmatrix} \omega_2' & \omega_3 & \omega_3' \\ \omega_3' & \omega_2' & \omega_3 \\ \omega_3 & \omega_3' & \omega_2' \end{pmatrix},$$

$$B = -\begin{pmatrix} \omega_2' & \omega_3' & \omega_3' \\ \omega_3' & \omega_2' & \omega_3' \\ \omega_3' & \omega_3 & \omega_2' \end{pmatrix}. \tag{13}$$

In these matrices,

$$a_0 = 2\omega_{CH_3} + 2\omega_3 + 6\omega_3' + 3\omega_2', \tag{14}$$

$$a_1 = -(\omega_{CH_3} + \omega_3), \quad (15)$$

$$a_0' = 2\omega_{CH_3}^* + 2\omega_3 + 6\omega_3' + 3\omega_2', \quad (16)$$

$$a_1' = -(\omega_{CH_3}^* + \omega_3'). \quad (17)$$

Here, ω_{CH_3} and ω_3 are the jumping rates of the ^1H–^1H vectors for the CH_3 C_3 and the whole cationic C_3 reorientations about the unique C_3 axis of the cation, respectively. $\omega_{CH_3}^*$ is the jumping rate of the other CH_3 C_3 reorientation while ω_3' and ω_2' denote those of the whole cationic reorientations about the other three pseudo C_3 and the three pseudo C_2 axes, respectively.

Since these ^1H–^1H vector reorientations in the cations should also average the interionic dipolar interactions which might be small, the interionic contribution to T_1 was roughly estimated by evaluating the difference of the inter-cationic second moment ΔM_2 between those in the rigid lattice and in the isotropically rotating state. The second moment M_2 in the rigid lattice could be roughly estimated for the present complexes by placing the T_d cations in the crystalline lattice isomorphous with $(tetMA)_2CdI_4$. From this model, we could calculate inter-protonic distances between protons belonging to the different cations. The interionic M_2 averaged by rapid ionic rotations was obtained by use of the method reported by Andrew and Eades.[31] In both crystals, there are two kinds of the cations I and II, which are considered to perform isotropic rotation with quite different correlation times from each other. Then, T_1 for the cation I giving rise to the low temperature minimum is expressed by[32,33]

$$T_1^{-1} = \frac{2}{3}\gamma^2\Delta M_2 g(\tau_{iso}) + \frac{2}{3}\gamma^2\Delta M_2' g(\tau_{iso}/2), \quad (18)$$

where γ and τ_{iso} indicate the gyromagnetic ratio of a proton and the correlation time of the isotropic rotation of the cation I, respectively.

The first term of Eq. 18 comes from the ^1H dipolar interactions between the cations I and II, while the second arises from those between protons belonging to the same kind of the cations I. The values of ΔM_2 and $\Delta M_2'$ calculated were 0.64 and 0.48 G^2, respectively. To evaluate τ_{iso} which is assumed to be expressed by Eq. 3, let the T_1 minimum temperature for the first term of Eq. 18 be equal to that of the observed low temperature one. Then, the temperature dependence of τ_{iso} was roughly estimated from the slope of the $\log T_1$ vs. T^{-1} curve. For the cation II yielding the high temperature T_1 minimum, the interionic T_1 can be given only by the second term of Eq. 18. $\Delta M_2'$ for this cation was calculated as 0.18 G^2 and τ_{iso} was obtained in the same way as for the cation I. The interionic contribution to the calculation of ^1H T_1 was taken into account only for $(tetMA)_2CdBr_4$ because it was turned out to be very small and the observed ^1H T_1 for $(tetMA)_2CdCl_4$ was assumed to be well explained only by intraionic contribution.

The refinement of the foregoing calculation was finally performed by changing the values of the adjustable parameters by stepwise finely to obtain the resultant best fitted T_1 curve which was the sum of the low and high temperature T_1 curves calculated separately as above. The evalution of the degree of fitting was determined by inspection.

The most appropriate T_1 curves calculated for the two kinds of the models of the cation are shown in Figs. 3 and 4 for the chloride and bromide complexes, respectively. The adjustable parameters giving rise to these T_1 curves are shown in Table 1. From these results, it is difficult to determine which model is more suitable for the present complexes. This is because both models provided the T_1 curves interpreting the observed T_1 data very well. However, it can be said that the observed T_1 curve having a normal minimum value but unusually small E_a can be explained by the motionally distorted T_d cation.

The values of E_a derived from the low temperature T_1 curve indicate that there is a distinct difference between the reorientations of the two kinds of CH_3 groups in the cation. It is noteworthy that E_a for the CH_3 reorientation whose rate is given by $\omega_{CH_3}^*$ is rather insensitive to the shape of the T_1 curve for both complexes and also for the choice of the model of the cation when E_a is larger than ca. 12 kJ mol^{-1}. On the other hand, the other E_a values listed in Table 1 gave an appreciable change on the shape of the curve when they were altered more than 0.5 kJ mol^{-1}. The larger E_a values of $(tetMA)_2CdCl_4$ than those of $(tetMA)_2CdBr_4$ obtained from both models are understandable by considering the size effect of the anion. Namely, the cations in the latter complex are thought to be more loosely packed in the crystal than those in the former crystal.

The T_1 curve observed for $(tetMA)_2CdI_4$ below room temperature is quite different from those of the foregoing two complexes, although the three complexes are isomorphous at room temperature. This difference may be due to the phase transition located at ca. 245 K, which exhibits a large heat anomaly suggesting a drastic change of the crystal structure. Therefore, the appearance of many T_1 minima successively in the low temperature phase is possibly attributed to the existence of more than two nonequivalent cations and/or CH_3 groups in the cation yielding their T_1 minima due to reorientations appearing in a fairly wide range of temperature. For this complex, E_a values were roughly estimated from the linear portions on the hot and cold sides of the T_1 curve below T_{tr} as 20.7 and 6.5 kJ mol^{-1}, respectively. Very small E_a of 6.5 kJ mol^{-1} was obtained also for this complex in the very low temperature region.

A T_1 decrease with increasing temperature was observed for both $(tetMA)_2CdBr_4$ and $(tetMA)_2CdI_4$ above room temperature, indicating the presence of at least one new relaxation process at higher temperatures.

Table 1. Best Fitted Activation Energies E_a and Correlation Times τ_0 for ^1H-^1H Vector Jumping Rates of the Cation in Tetramethylammonium (tetMA) Tetrachloro- and Tetrabromocadmate(II) Yielding High and Low Temperature T_1 Curves

Compound	High temp side			Low temp side		
[Motional model]	Jumping rate	E_a/kJ mol^{-1}	τ_0/s	Jumping rate	E_a/kJ mol^{-1}	τ_0/s
$(tetMA)_2CdCl_4$						
$[C_{3v}]$	ω_{CH_3}	17.5	3.3×10^{-12}	ω_{CH_3}	7.5	2.5×10^{-12}

	ω_3	19.7		ω_3	10.8	
		19.7	3.3×10^{-14}	ω_3'	18.0	6.3×10^{-14}
	ω_2	18.1		ω_2'	13.0	
$[C_{2v}]$	ω_{CH_3}	17.5	3.3×10^{-12}	ω_{CH_3}	8.1	1.7×10^{-12}
				ω_{CH_3}*	>12.0	
	ω_3	19.7		ω_2	11.0	
		19.7	3.2×10^{-14}	ω_2'	13.0	3.3×10^{-14}
	ω_2	18.0		ω_3'	14.5	
$(tetMA)_2CdBr_4$						
$[C_{3v}]$	ω_{CH_3}	14.0	1.3×10^{-11}	ω_{CH_3}	5.1	1.1×10^{-11}
				ω_{CH_3}*	>12.0	
	ω_3	17.5		ω_3	9.8	
		17.5	1.3×10^{-13}	ω_3'	12.7	3.3×10^{-14}
	ω_2	14.5		ω_2'	15.0	
$[C_{2v}]$	ω_{CH_3}	14.0	1.3×10^{-11}	ω_{CH_3}	5.7	8.3×10^{-12}
				ω_{CH_3}*	>12.0	
	ω_3	17.5		ω_2	9.5	
		17.5	1.3×10^{-11}	ω_2'	12.5	3.3×10^{-12}
	ω_2	14.5		ω_3'	12.5	

In these temperature regions, a clear frequency dependence of ^1H T_1 was observed for both complexes. However, the ratios of T_1 values determined at different frequencies and at the same temperature are much smaller than those of squared resonance frequencies. We determined M_2 for $(tetMA)_2CdBr_4$ at 450 K and yielded 0.5 G^2 which was almost the same as the value of 0.6 G^2 obtained at 302 K. This indicates that the T_1 decrease observed is difficult to explain through the magnetic dipolar relaxation mechanism.

It has been reported[34,35] that even bulky octahedral complex anions such as $[PtCl_6]^{2-}$ and $[PtBr_6]^{2-}$ reorient quite frequently at high temperatures and this motion appreciably shortens spin-lattice and also spin-spin relaxation times of the quadrupolar halogen nuclei. In the present complexes, rapid motions of the complex anions can be also expected to take place at high temperatures and the quadrupole resonance frequencies of iodine and bromine in both complexes are nearer to the NMR frequencies than that of chlorine in $(tetMA)_2CdCl_4$. Quadrupolar relaxation of iodine and bromine nuclei can provide an important relaxation process for ^1H in the cation through magnetic interactions between ^1H and halogen nuclei when the quadrupolar relaxation time becomes shorter than ^1H T_1 at high temperatures. This relaxation mechanism named dipolar relaxation of the second kind[36] seems to be the main origin of the frequency dependent T_1 decrease observed at higher temperatures.

The Microwave Spectrum of Ethyl Isoselenocyanate

Takeshi SAKAIZUMI,* Kazuyuki IIDA, Osamu OHASHI, and Ichiro YAMAGUCHI
Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102
(Received February 12, 1986)

The microwave spectra of two isotopic species (^{80}Se and ^{78}Se) of ethyl isoselenocyanate were measured in the frequency region of 10—28 GHz. Only a-type R-branch transitions in the ground vibrational state were identified. The rotational constants in MHz were obtained; $A=15140\pm23$, $B=1090.443\pm0.016$, and $C=1029.261\pm0.016$ for ^{80}Se species and $A=15112\pm28$, $B=1099.865\pm0.012$, and $C=1037.745\pm0.012$ for ^{78}Se species. The plausible structure of ethyl isoselenocyanate has deduced from the observed rotational constants to be the synperiplanar form with a plane of symmetry.

The microwave spectra of ethyl isocyanate[1] and ethyl isothiocyanate[2] have been reported and their structures have been determined to be planar synperiplanar conformers. A large increase in the C-N-C angle is seen when the oxygen atom of isocyanato group is replaced with a sulfur atom.[1,2] A similar trend is seen for the H-N-C angle of HNCO (124°),[3] HNCS (132°),[4] and HNCSe (143°)[5] and the C-N-C angle of CH_3NCO (140°)[6,7] and CH_3NCS (147.5°, 153°).[6,8] Recently, the C-N-C angle of methyl isoselenocyanate (CH_3NCSe)[9] has been found to be 157°. This angle is larger by about 10° than that of methyl isothiocyanate (CH_3NCS).

Franklin et al.[10] have reported the infrared spectrum of ethyl isoselenocyanate without inferring its geometrical conformation. It is very interesting to see what effect an atom heavier than oxygen or sulfur can produce on a molecular structure, particularly on the rotational conformation and the C-N-C angle.

The microwave spectra of two isotopic species (with ^{80}Se and ^{78}Se) of ethyl isoselenocyanate (CH_3CH_2NCSe) were measured in the frequency region between 10 and 28 GHz and assigned to a-type R-branch lines in the ground vibrational state. The rotational constants are reported and the molecular structure is discussed.

Experimental

Ethyl isoselenocyanate was prepared from ethyl isocyanide by refluxing in chloroform with finely divided black selenium for about 48 h.[11] Ethyl isocyanide was produced by adding silver cyanide to ethyl iodide and then adding potassium cyanide and water to the mixture.[12] Ethyl isoselenocyanate was purified by vacuum distillation and identified by comparing its infrared spectrum with the reported one.[10]

The spectrometer employed was a conventional 100 kHz square-wave Stark modulation type with a phase-sensitive detector. The microwave source was a HP8672A microwave synthesizer which was controlled by a HP9872A/S computer.

The temperature of the sample cell was kept between 0 and −10° to avoid any decomposition of the sample during the measurement of the spectrum. The absorption line widths could be kept at less than 1.5 MHz by cooling the sample cell, while the widths were about 2 to 3 MHz at room temperature.

Results and Discussion

There are four possible rotational conformers to be considered for ethyl isoselenocyanate as shown in Fig. 1. The calculation of the rotational constants for these four rotamers, using the assumed structural parameters, showed that all rotational conformers were nearly prolate symmetric top rotators, with Ray's

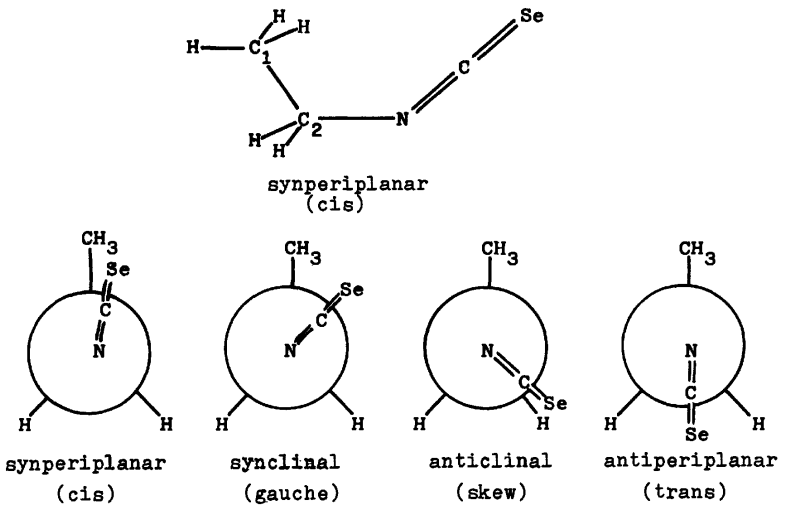

Fig. 1. Four possible rotational conformers and the numbering of carbon atoms on ethyl isoselenocyanate.

asymmetry parameter κ less than -0.99. Therefore, the rotational spectra for all four possible conformers were expected to have absorption lines with frequency intervals close to the quantity of (B+C), characteristic for a spectrum of near prolate symmetric top molecules. The ethyl isoselenocyanate has many isotopic species of selenium atom, among which ^{80}Se and ^{78}Se are dominant. The abundance ratio of ^{80}Se to ^{78}Se is about 2 and at higher frequency sides of each absorption line of ^{80}Se species, the absorption lines of ^{78}Se species were expected to appear with the intensities of about one half of the corresponding line intensities of ^{80}Se species.

The first survey of the spectrum in the frequency region of 18 to 24 GHz at the Stark field between 5 and 20 V cm^{-1} found groups of the strong lines with the frequency interval of about 2100 MHz; these were ascribed to ^{80}Se species. Groups of lines with the intensities of about one half of the corresponding line intensities of ^{80}Se species were found at frequencies higher by about 200 MHz than the absorption frequencies of ^{80}Se species. These weaker lines were assigned to ^{78}Se species.

a) $\Delta\nu=\nu_{obsd}-\nu_{calcd}$. *) Not included in the least-squares fitting.

The typical spectra of ^{80}Se and ^{78}Se species observed with the Stark field of 10 $V cm^{-1}$ are shown in Fig. 2. The $K_{-1}=2$ doublet lines were observed at the Stark field of 30 $V cm^{-1}$ as shown in Fig. 3(b). The $K_{-1}=2$ lines show a first-order Stark effect because the value (−0.991) of Ray's asymmetry parameter in ethyl isoselenocyanate is very close to −1.00. The assignments of the $K_{-1}=0$ and 1 transition lines were based on the second-order Stark effect.

In the first place, the 27 absorption lines of $J=5\leftarrow4$ to $J=13\leftarrow12$ with $K_{-1}=0$ and 1 for ^{80}Se species in the ground vibrational state were fitted to obtain the preliminary rotational and centrifugal distortion constants. These were employed to predict and assign the other transition lines with K_{-1} values larger than 2. The 75 transition lines of ^{80}Se species in the ground vibrational state were used to determine the rotational parameters, including the centrifugal distortion terms up to sextic contributions. The results are given in Tables 1, 2, and 3, together with the results of ^{78}Se species, which were obtained by analyzing the spectrum in the same way as for ^{80}Se species.

The values of −5.83 and −5.94 u Å^2 of inertia defect (Δ) for ^{80}Se and ^{78}Se species in Table 4 suggest that there are a plane symmetry and four hydrogen and heavy atoms in the ethyl isoselenocyanate molecule locate out-of-plane and in-plane, respectively. This means that there are two possible rotamers, synperiplanar and antiperiplanar forms. The observed values of P_b and Ray's asymmetry parameters for ^{80}Se and ^{78}Se species are very close to the ones calculated for synperiplanar form, but very different from the ones for antiperiplanar form, as shown in Table 4. Furthermore, the observed rotational constants A, B, and C are comparable with the ones calculated for synperiplanar conformer.

The above discussion has led to the conclusion that the spectrum assigned in this work is due to a synperiplanar rotational conformer of ethyl isoselenocyanate. This rotational conformer has been formed in ethyl isocyanate[1] and ethyl isothiocyanate.[2]

Three structural parameters, ∠C-N-C, r(C-N), and r(N=C), have been fitted to all the observed rotational constants of B and C for ^{80}Se and ^{78}Se species. The results are listed in Table 5. Other structural parameters were transferred from ethyl isocyanate,[1] ethyl isothiocyanate,[2] and carbonyl selenide.[13] The observed and calculated rotational constants obtained from the structural parameters in Table 5 are given in Table 6.

The derived values of the bond lengths, r(C-N) and r(N-C), are in agreement with those of similar compounds within less than 0.01 Å, as shown in Table 7.

Production of Carbon Monoxide by Direct Thermal Splitting of Carbon Dioxide at High Temperature

Yutaka NIGARA and Bernard CALES*,†
Research Institute for Scientific Measurements, Tohoku University, Sendai 980
†Centre de Recherches sur la Physique des Hautes Températures CNRS 45045 Orléans Cédex, France
(Received March 4, 1985)

The direct thermal decomposition of carbon dioxide CO_2 to produce carbon monoxide CO have been studied as a mean of conversion and storage of a thermal energy, such as the solar heat, into a gaseous fuel. The process under investigation consists to displace the dissociation equilibrium of carbon dioxide by a selective pumping of oxygen at high temperature through a semipermeable membrane. Large amounts of carbon monoxide have been produced after the extraction of the oxygen arising from the CO_2 dissociation with the aid of a membrane made of calcia-stabilized zirconia. The variations of the flow of CO evolved from the reactor vs. temperature and oxygen partial pressure are in good agreement with the theoretical variations that may be deduced from the general equations of electrochemical transport in stabilized zirconia. Thereby, the efficiency of this process appears to be directly limited by the low oxygen permeation rate through the material used as oxygen selective membrane.

In the last past years, many investigations have been devoted to the conversion and storage of primary energies, such as the solar heat.[1] Indeed, although inexhaustible, the solar energy is subject to considerable variations with the lattitude and also to diurnal or seasonal variations. Accordingly, the utilization of solar energy on a large scale needs its conversion into a convenient form for a subsequent use. Various ways have been investigated, in which the solar radiation could be used either through quantum effects, this is the case of the solar cells for a direct conversion to electricity[2] and the hydrogen production via a water photoelectrolysis process,[3] or as a source of thermal energy for a thermochemical conversion and storage.[4] Recently another approach has been considered, in which the solar heat could be used to perform a direct thermal splitting of water at high temperature and to produce hydrogen.[5,6] This process implies to separate the hydrogen and the oxygen arising from the steam dissociation, in order to avoid the recombination reactions at lower temperatures. This may be achieved at high temperature with the use of a membrane semipermeable to oxygen while impervious to other gaseous components.[7] Such a membrane must be characterized by a mixed, ionic and electronic, electrical conductivity and located in a gradient of oxygen chemical potential,[6] as shown in Fig. 1. The ionic component σ_i of the conductivity allows the oxygen to diffuse through the membrane as O^{2-} ions, while the electronic component σ_e ensures an internal partial short-circuit which is required for the reactions of oxygen exchange at the two electrolyte-gaseous phase interfaces (Fig. 1).

On using calcia-stabilized zirconia as oxygen semipermeable membrane, noticeable amounts of hydrogen have been produced by this technique.[6] However, the efficiency of such a process is unavoidably limited by the low dissociation rate of water vapor, which reaches only 4% about at 2300 K under normal pressure conditions. Thus, the use of a gaseous component characterized by a higher dissociation rate would be more convenient. Carbon dioxide CO_2 seems

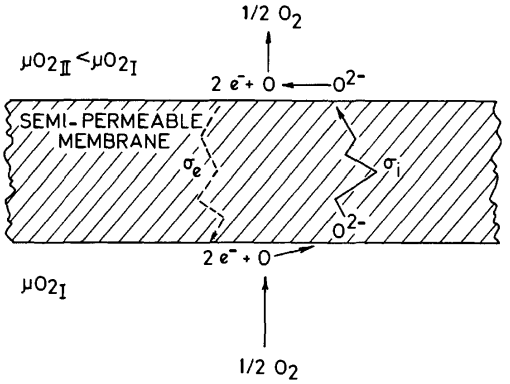

Fig. 1. Schematics of a membrane semipermeable to oxygen located between two different oxygen chemical potentials μO_2(I) and μO_2(II).

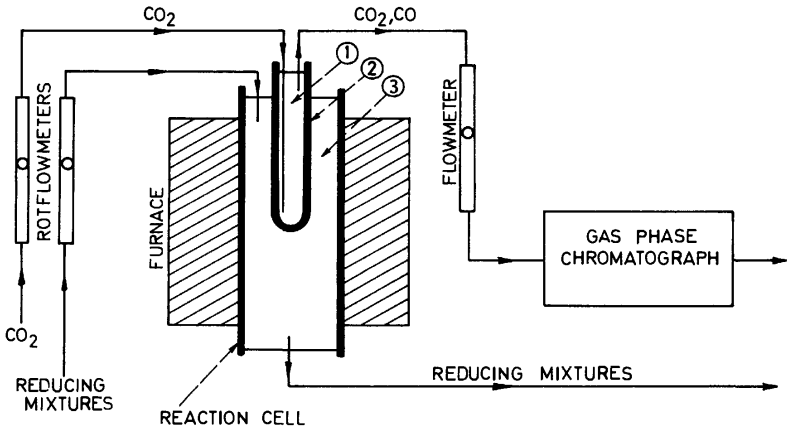

Fig. 3.Schematic illustration of the experimental set-up. ①: compartment I, ②: oxygen semipermeable membrane, ③: compartment II.

to be a good candidate owing to the potential applications of the gaseous fuel CO[2] which may be obtained by direct thermal splitting of CO_2. Moreover, the energy balance of the decomposition reaction is more propitious in the case of carbon dioxide than for water vapor.

The total quantity of energy ΔH required for the decomposition of one mole of CO_2 (or one mole of H_2O) may be supplied by means of a thermal energy $T\Delta S$ and/or an additional energy, such as a mechanical or an electrical energy, corresponding to the free enthalpy term ΔG[8] so that:

$$\Delta H = \Delta G + T\Delta S.$$

The temperature dependence of the various energies ΔH, ΔG, and $T\Delta S$ involved for the dissociation of one mole of CO_2 or one mole of H_2O may be deduced from the classical thermodynamic relationships and are depicted in Fig. 2. It clearly appears that, at high temperature, a major part of the total energy ΔH may be supplied by means of a thermal energy corresponding to $T\Delta S$. Furthermore, $T\Delta S$ is equal to 66% of the total energy required for the decomposition of one mole of CO_2 at 2250 K and only 50% in the case of one mole of H_2O at the same temperature.[8]

The purpose of the present work was to investigate the possibility of production of CO by direct thermal splitting of carbon dioxide on using a calcia-stabilized zirconia wall as oxygen semipermeable membrane.

Experimental

The experimental set-up mainly consists of a reaction cell, a laboratory built high temperature furnace working under oxidizing conditions,[9] a gas phase chromatograph and gas flowmeters (Fig. 3).[10]

The reaction cell is chiefly made up of a closed-end tube of calcia-stabilized zirconia, 2 mm thick and 10 mm in inner diameter, which acts as oxygen semipermeable membrane. Its chemical composition corresponds to 0.9 ZrO_2-0.1 CaO and the concentrations of the main impurities are ; 0.18 wt% Fe_2O_3, 0.81wt% SiO_2, 0.33wt% MgO, and 0.3 wt% Al_2O_3. The cell is located inside the high temperature furnace, the heating elements of wich are made of partially stabilized zirconia which allows the zirconia tube to be heated at temperatures up to 2500 K. However, owing to the difficulty of temperature measurements in the center of the reaction cell and to the thermomechanical characteristics of the cell itself, the usefull temperature range has been reduced to approximately 1700—2100 K.

The inner part of the zirconia tube, compartment I, is fed with pure carbon dioxide, with a flow-rate of 1000 $cm^3 h^{-1}$, under isobaric conditions (10^{-1} MPa). In the hot zone of the cell, carbon dioxide partially dissociates and the oxygen arising from the dissociation reaction diffuses through the zirconia wall into compartment II. The oxygen partial pressure in compartment II, pO_2(II), must be much lower than the oxygen partial pressure in compartment I, pO_2(I), that is fixed in dynamical conditions by the dissociation equilibrium of carbon dioxide. This has been conveniently achieved, in the present study, by the use of CO-CO_2 mixtures which allow to vary the oxygen partial pressure pO_2(II) in a large range, independently of the oxygen flux through the membrane. The flow-rate of CO-CO_2 mixtures in compartment II is equal to 18.5×10^3 $cm^3 h^{-1}$.

After migration of oxygen, the composition of the dissociated gas phase is checked out by chromatography at the gas outlet of compartment I.

Under stationary conditions, the mass flow balance implies that the flow of carbon monoxide D_{CO} evolved from the compartment I is twice the flow of oxygen D_{O_2}, through the effective permeation area S of the zirconia membrane, which is given by :

$$D_{co} = 2D_{O_2} = 2J_{O_2} \cdot S \qquad (1)$$

where J_{O_2} is the flow of oxygen per unit area of the semipermeable membrane.

From the measurement of temperature gradients along the zirconia tube,[10] the effective permeation area has been estimated to about 4 cm^2.

Theoretical Considerations

The partial current density $\vec{J_k}$ arising from the flow of charged species k in a solid electrolyte located in a chemical potential gradient is derived from the general equations of electrochemical transport and is given by:[11]

$$\vec{J_k} = -\frac{\sigma_k}{z_k q}\overrightarrow{\nabla \eta_k}, \tag{2}$$

where σ_k is the partial electrical conductivity of the electrolyte, z_k the valence of particles k and q the electronic charge. $\overrightarrow{\nabla \eta_k}$ denotes a gradient of electrochemical potential which results from gradients of chemical potential $\overrightarrow{\nabla \mu_k}$ and electrical potential $\overrightarrow{\nabla V}$:[12]

$$\overrightarrow{\nabla \eta_k} = \overrightarrow{\nabla \mu_k} + z_k q \overrightarrow{\nabla V}.$$

In the case of stabilized zirconia, the electrochemical transport at high temperature arises from the motion of both O^{2-} ions and electrons.[13] The total current density $\vec{J_t}$ is then the sum of the contributions due to ionic species $\vec{J}_{O^{2-}}$ and electrons $\vec{J_e}$. It is deduced from Eq. 2 and writes:

$$\vec{J_t} = \frac{\sigma_e}{q}\overrightarrow{\nabla \eta_e} + \frac{\sigma_i}{2q}\overrightarrow{\nabla \eta_{O^{2-}}}, \tag{3}$$

where σ_i and σ_e denote the partial ionic and electronic conductivities of stabilized zirconia.

Moreover, on assuming that the thermodynamic equilibrium between ionic and electronic species:

$$O^{2-} \rightleftharpoons 1/2\, O_2 + 2e^-$$

remains locally undisturbed by the partial current flows, it is possible to relate the total current density $\vec{J_t}$ to the chemical potential gradient of oxygen $\overrightarrow{\nabla \mu_{O_2}}$ by the following relationship:[11]

$$\vec{J_t} = \frac{\sigma_t}{q}\overrightarrow{\nabla \eta_e} + \frac{\sigma_i}{4q}\overrightarrow{\nabla \mu_{O_2}}, \tag{4}$$

where σ_t is the total conductivity of the material ($\sigma_t = \sigma_i + \sigma_e$).

Under stationary conditions, if no electrical current flows through an external circuit, the total current density in the material would be equal to zero and it follows from Eqs. 2 and 4:[11]

$$\vec{J}_{O^{2-}} = -\vec{J_e} = \frac{\sigma_e}{4q} t_i \overrightarrow{\nabla \mu_{O_2}}, \tag{5}$$

where t_i denotes the ionic transference number of stabilized zirconia ($t_i = \sigma_i/\sigma_t$).

Owing to the very wide electrolytic domain of stabilized zirconia,[14] the ionic transference number t_i is close to unity in large ranges of temperature and oxygen partial pressure. In the same domain, the electronic conductivity writes:[15]

$$\sigma_e = \sigma_e^\circ \exp(-\Delta E/k_B T)\, pO_2^{-1/4}, \tag{6}$$

where σ_e° is a constant, ΔE the activation energy, k_B the Boltzmann constant and pO_2 the oxygen partial pressure of the surrounding atmosphere. From the different values reported in the litterature, Heyne and Beekmans[15] have proposed a mean value of 3.7 eV for the activation energy of the n-type electronic conductivity of stabilized zirconia.

Combining Eqs. 5 and 6 with the condition $t_i \simeq 1$, the ionic current $J_{O^{2-}}$ through a stabilized zirconia membrane is obtained after integration over the thickness L of the membrane and is given by:

$$J_{O^{2-}} = \frac{k_B T}{qL}\sigma_e^\circ \exp(-\Delta E/k_B T)[pO_2(II)^{-1/4} - pO_2(I)^{-1/4}], \tag{7}$$

where $pO_2(I)$ and $pO_2(II)$ are the oxygen partial pressures at the two electrolyte-gaseous phase interfaces.

The oxygen flow J_{O_2} through the membrane is then derived from Eq. 7:

$$J_{O_2} = \frac{k_B T}{4qFL}\sigma_e^\circ \exp(-\Delta E/k_B T)[pO_2(II)^{-1/4} - pO_2(I)^{-1/4}], \tag{8}$$

where F is the Faraday constant.

The flow of carbon monoxide D_{CO} evolved from the reactor is directly related to J_{O_2} [Eq. 1] and would then obey the same dependences against temperature and oxygen partial pressures.

Results and Discussion

The composition of the gas phase evolved from compartment I is plotted in Fig. 4 vs. the cell temperature, for different values of the ratio CO_2/CO of the reducing mixtures flowing in compartment II. For CO_2/CO ratio lower than 10, the amount of produced carbon monoxide increases rapidly with the cell temperature. At 1954K, in the most reducing conditions ($CO_2/CO = 0.01$), which corresponds to an oxygen partial pressure $pO_2(II)$ of about 10^{-11} MPa, 21.5 mol% of carbon dioxide have been converted to CO.

Such a value is much higer than the dissociation rate of CO_2 which is expected to reach 1.2% at the same temperature without any transfer of oxygen through a semipermeable membrane. Thus, under the influence of the selective pumping of oxygen through the zirconia wall, the thermodynamical equilibrium

$$CO_2 \rightleftharpoons CO + 1/2\, O_2 \tag{9}$$

is strongly displaced to the right hand side.

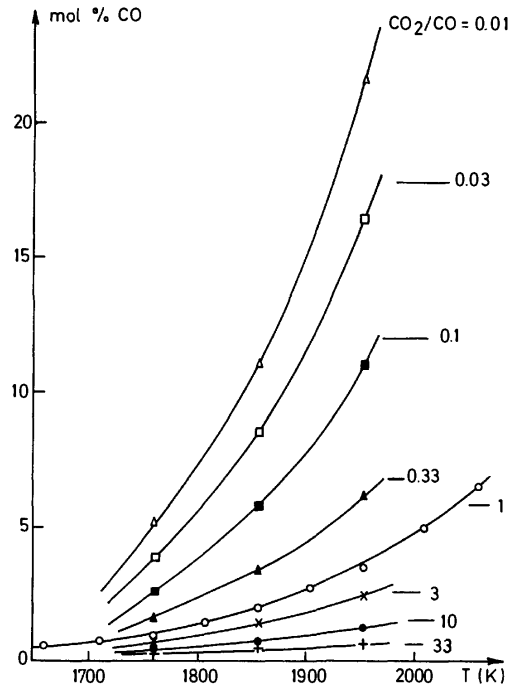

Fig. 4. Variations of the concentration of CO in the gas phase evolved from compartment I against temperature, for different composition of the $CO-CO_2$ mixtures flowing in compartment II.

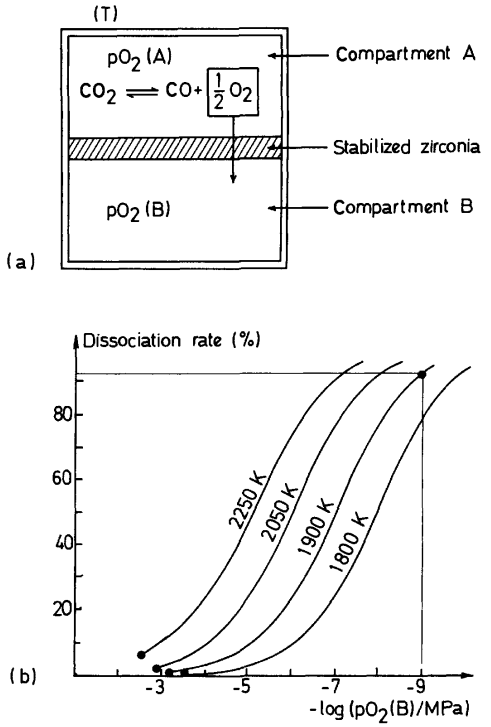

Fig. 5. Schematic of a reaction cell working under static conditions (a) and variations of the dissociation rate of CO_2 obtained with such a cell versus $pO_2(B)$ (b), after Ref. 8.

Nevertheless, due to the dynamical conditions used in the present technique, only a fraction of the introduced carbon dioxide is converted to CO. Indeed, let us consider a reaction cell working under static conditions and made up of a stabilized zirconia wall which separates two compartments A and B having the same volume (Fig. 5a). The calculated values of the dissociation rate of CO_2 that may be reached under these conditions are plotted in Fig. 5b as a function of the oxygen partial pressure $pO_2(B)$ fixed in compartment B before the experiment.[8] At a given temperature, the oxygen arising from the dissociation reaction would flow through the zirconia membrane until the oxygen partial pressures $pO_2(A)$ and $pO_2(B)$ are equal. Thus, at 1900 K, for an oxygen partial pressure $pO_2(B)$ initially fixed at 10^{-9} MPa, 93% about of the introduced carbon dioxide would be converted to CO before the system reaches the thermodynamical equilibrium.[8]

In the present case, the oxygen partial pressure $pO_2(I)$ in compartment I is smaller than the value predicted by the dissociation equilibrium of CO_2, owing to the oxygen transfer through the membrane. It has been however derived from the equilibrium constant K relative to equilibrium (9).

$$K = \frac{pCO\ pO_2(I)^{1/2}}{pCO_2} \qquad (10)$$

where the partial pressure of carbon monoxide, pCO, has been deduced from the CO content measured by chromatography in the gas phase evolved from compartment I.

The oxygen partial pressure $pO_2(II)$ is fixed by the $CO-CO_2$ mixtures. Due to the high buffer capacity of these mixtures, for CO_2/CO ratio higher than 0.03, the oxygen partial pressure $pO_2(II)$ is not affected by the oxygen transfer through the membrane. For CO_2/CO ratio smaller than 0.03, the quantity of oxygen flowing through the zirconia wall is high enough to slightly modify the composition of the $CO-CO_2$ mixtures and small corrections may be applied in the calculation of $pO_2(II)$.[10]

The flow of carbon monoxide D_{CO} evolved from compartment I has been plotted in Fig. 6 against the difference of oxygen partial pressures $\Delta pO_2^{-1/4} = [pO_2(II)^{-1/4} - pO_2(I)^{-1/4}]$, for three temperatures. The flow of CO appears to be directly proportional to $\Delta pO_2^{-1/4}$, since the log D_{CO} vs. log $\Delta pO_2^{-1/4}$ plots are characterized by straight lines, the slopes of which are not far from to unity. Owing to the proportionality relationship between D_{CO} and J_{O_2} [Eq. 1], this is in good agreement with the theoretical dependence of the oxygen flux J_{O_2} against $\Delta pO_2^{-1/4}$, predicted by Eq. 8.

Furthermore, according to Eq. 8, the semi-permeability coefficient, which is defined as the ratio of the oxygen flux to the difference $\Delta pO_2^{-1/4}$, varies with the temperature according to an Arrhenius law (Fig. 7), the activation energy of which amounts to about 3.55 eV. Such a value agrees with the mean activation energy for the n-type electronic conductivity of stabilized zirconia proposed by Heyne and Beekmans

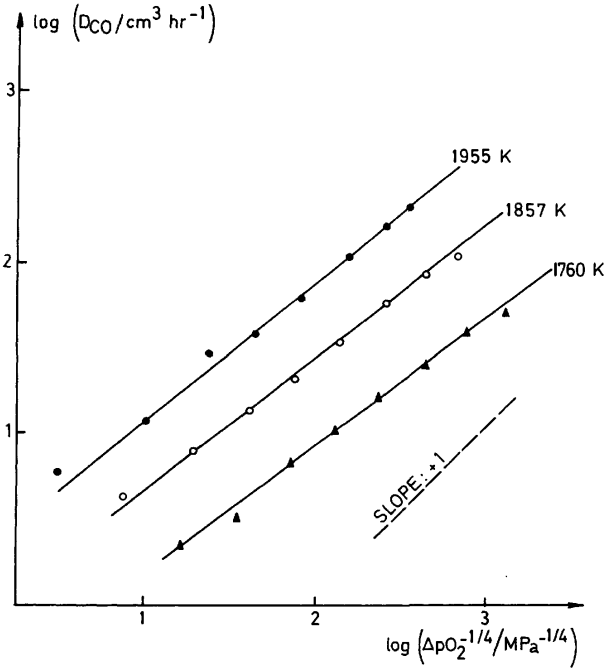

Fig. 6. Dependence of the flow of CO evolved from the reactor on the difference $\Delta pO_2^{-1/4}$.

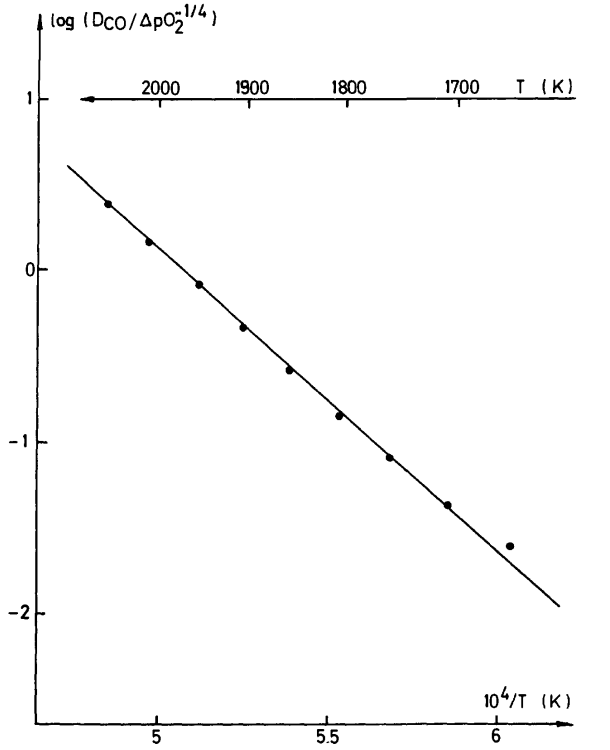

Fig. 7. Variation of the ratio $D_{CO}/\Delta pO_2^{-1/4}$ vs. temperature.

(3.7 eV).[15]

These two results clearly show that the oxygen flow J_{O_2} and the flow D_{CO} evolved from the compartment I correspond to the maximum flows that it is presently possible to obtain, since they directly depend on the specific characteristics of the oxygen semipermeable membrane. Thus, the efficiency of the process under investigation appears to be primarily limited by the low value of the electronic conductivity of the stabilized zirconia wall.

Indeed, the general expression of the current density $\vec{J}_{O^{2-}}$ due to the motion of O^{2-} ions in an oxide solid electrolyte [Eq. 5] may also be written:[16]

$$\vec{J}_{O^{2-}} = \frac{\sigma_t}{4q} t_i t_e \overrightarrow{\nabla \mu_{O_2}} \qquad (11)$$

where t_e is the electronic transference number of the material ($t_e=\sigma_e/\sigma_t=1-t_i$).

Thereby, the oxygen flux J_{O_2}, and consequently the amount of produced carbon monoxide, would be maximum for equal ionic and electronic transference numbers ($t_i=t_e=0.5$). The material used as oxygen semipermeable membrane would present equal ionic and electronic conductivities in the range of oxygen partial pressure [pO_2(I), pO_2(II)].

In the case of stabilized zirconia, such a behavior is observed for an oxygen partial pressure which is much smaller than pO_2(I) and pO_2(II) and rises from 10^{-21} MPa at 1673K to 10^{-13} MPa at 2073K.[17]

Conclusion

The present study has demonstrated the possibility of production of CO by direct thermal splitting of carbon dioxide at high temperature and extraction of oxygen by means of a semipermeable membrane.

On using calcia stabilized zirconia (10 mol% CaO) as oxygen semipermeable membrane, about 100 to 200 $cm^3 h^{-1}$ of CO have been produced at 1960 K for a CO_2 consumption of 1000 $cm^3 h^{-1}$. The variations of the flow of CO evolved from the reaction versus the cell temperature and the difference $\Delta pO_2^{-1/4}$ agreed with the theoretical variations deduced from the general equation of electrochemical transport in stabilized zirconia. Therefore, such a process appears to be very interesting with respect to energy conversion applications.

Various parameters could allow to appreciably increase the quantities of produced carbon monoxide. This would be the case on using a semipermeable membrane with a smaller thickness and/or a larger permeation area. Nevertheless, the efficiency of the process is primarily controlled by the electrical properties of the material used as oxygen selective membrane. Thus, in the present case, any improvement of this technique is submitted to an enhancement of the electronic conductivity of stabilized zirconia.

Fluorite type solid solutions may be observed between zirconia ZrO_2 and ceria CeO_2, which is known to exhibit an electronic conductivity, in large range of composition.[18] The addition of a third oxide, the cation of which has a lower valency than zirconium Zr(IV) or cerium Ce(IV) ions, such as yttria Y_2O_3, could enhance the ionic conductivity of these compounds. The study of the electrical properties of the solid

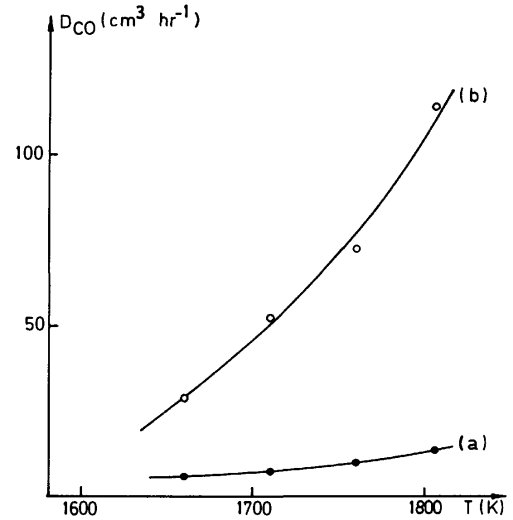

Fig. 8. Variations of the flow of CO evolved from the reactor against temperature in the case of a calcia stabilized zirconia membrane (a) or a ceria-doped stabilized zirconia memberane (b). The composition of the CO-CO_2 mixture in compartment II corresponds to $CO_2/CO=1$.

solutions of the ternary ZrO_2-CeO_2-Y_2O_3 system has shown that they would present, in the temperature and oxygen partial pressure ranges of interest for this process, a mixed electrical conductivity with equivalent ionic and electronic components.[19] Moreover, the solid solution containing about 20 mol% of cerium oxide CeO_2 appears to be the most suitable for this application.[16] This has been confirmed by preliminary results obtained on using such a solid solution as oxygen selective membrane. The flows of CO produced with the aid of either "pure" stabilized zirconia or ceria-doped stabilized zirconia as semipermeable membrane are compared in Fig. 8. They clearly indicate that the solid solution of the ZrO_2-CeO_2-Y_2O_3 system is characterized by a higher oxygen semipermeability. The use of this material in a process of thermal energy conversion and storage based on the direct thermal splitting of CO_2 is thus very promissing and presently under investigation.

Synthesis, Ion-Exchange Properties and Analytical Applications of Tin(IV) Tungstovanadophosphate

Syed Ashfaq NABI and Weqar Ahmad SIDDIQUI*,†
Chemistry Department, Faculty of Education, Post Box 18758, University of Sebha, Libya
†Department of Chemistry, Aligarh Muslim University, Aligarh-202001, India
(Received June 15, 1984)

Samples of tin(IV) tungstovanadophosphate have been synthesized under varying conditions and their ion-exchange properties are studied. Among the various samples of tin(IV) tungstovanadophosphate, sample $TTVP_7R$ is chosen for detailed study and its ion-exchange properties are compared with sample $TTVP_7$. Both the compounds are synthesized in excess of acid, i.e. at pH less than zero. Sample $TTVP_7$ is synthesized by adding 0.025 mol dm^{-3} sodium metavanadate, 0.025 mol dm^{-3} sodium tungstate and 1.0 mol dm^{-3} phosphoric acid to 0.1 mol dm^{-3} tin(IV) chloride in the volume ratio of 1:1:1:1 at pH=0. Sample $TTVP_7R$ was prepared by refluxing the precipitate of sample $TTVP_7$ in the reaction mixture. The chemical and thermal stabilities of this material have been determined. The reproducibility of the material is also checked. Distribution coefficients for numerous metal ions in formic acid-sodium formate buffer systems of different pH were determined. The utility of the material has been demonstrated by achieving a number of binary and ternary separations on its small columns.

Synthetic inorganic ion exchangers have attracted attention because of their versatility in separation science and in many other fields of diverse nature. The inorganic ion-exchange materials which have been synthesized and studied till now are mostly single and double salts of metals. In many instances it has been found that double salts exhibit ion-exchange properties and they are thermally and chemically more stable than single salts. For example tin(IV) vanadotungstate[1] has been found to behave entirely different from tin(IV) tungstate,[2] tin(IV) vanadate,[3] and tin(IV) phosphate.[4] It is our prediction that by incorporating three different types of anions in the matrix, the exchange properties of the material may be improved further. It is with this view in mind we have synthesized tin(IV) tungstovanadophosphate and studied its ion-exchange properties. The following pages summarize our findings in this direction.

Experimental

Reagents. Tin(IV) chloride pentahydrate (Reachim), sodium tungstate (BDH), sodium metavanadate (Riedel Germany), and phosphoric acid (BDH) were used for the synthesis of the material. All other chemicals were of analytical reagent grade.

Apparatus. Spectrophotometric studies were performed using spectrophotometer GS 866D (E. C.). ELICO Model LI-10 pH meter was used for pH measurements and Stanton thermobalance type H_4 for TGA. A temperature controlled shaker SICO was used for shaking.

Synthesis. Samples of tin(IV) tungstovanadophosphate were synthesized by mixing aqueous solutions of the appropriate reagents. The solutions used for the synthesis were 0.025 mol dm^{-3} in sodium tungstate, 0.025 mol dm^{-3} in sodium metavanadate, 0.5 mol dm^{-3} in phosphoric acid (1.0 mol dm^{-3} in phosphoric acid for the synthesis of samples $TTVP_7$ and $TTVP_7R$) and 0.1 mol dm^{-3} in tin(IV) chloride. Conditions of synthesis for different samples are indicated in Table 1. The pH for the sample solution in each case was adjusted by adding either concentrated hydrochloric acid or dilute sodium hydroxide solutions. The precipitate so formed was then allowed to settle down for 24 h at room temperature (25±2°C), washed several times with demineralized water (DMW) to remove excess reagent and finally

filtered under suction. It was then dried at 40 °C in an oven. The material was then immersed in DMW where it was broken into fine particles with slight evolution of heat. The material was then converted into hydrogen form by keeping it into 0.1 mol dm^{-3} nitric acid solution for 48 h. Excess of acid was removed by washing with DMW. Sample $TTVP_7R$ was prepared by refluxing the precipitate of sample $TTVP_7$ for 6 h in a mixture of 0.1 mol dm^{-3} sodium tungstate, 0.1 mol dm^{-3} sodium metavanadate and 1.0 mol dm^{-3} phosphoric acid in the volume ratio of 1:1:1. Concentrated hydrochloric acid was also added in sufficient quantity to adjust the pH of the mixture less than zero. The mixture was then allowed to cool. The supernatant liquid removed and the product was washed several times with water and finally filtered, dried, and converted into hydrogen form as described above. To check the reproducibility of the exchanger six sets of samples $TTVP_7$ and $TTVP_7R$ were prepared. Results are given in Table 2.

Ion-Exchange Capacity. The ion-exchange capacity of samples of tin(IV) tungstovanadophosphate was determined by column method.[3] The hydrogen ion liberation capacity with different mono and bivalent ions is reported in Table 3.

pH Titration. The titrations for samples $TTVP_7R$ and $TTVP_7$ were performed in NaOH-NaCl and KOH-KCl systems using the method.[5] The pH titration curves are shown in Figs. 1 and 2.

Thermal Treatment. The thermogravimetric analysis of tin(IV) tungstovanadophosphate in hydrogen form was performed at a heating rate of 10 °C min^{-1}. The resulting thermogram is shown in Fig. 3. To examine the effect of heating on the ion-exchange capacity, the material in the hydrogen form was heated at different temperatures (40, 100, 200, 400, 500, 600, and 800 °C) for 1 h in a muffle furnace.

Chemical Stability. The chemical stability of samples $TTVP_7R$ and $TTVP_7$ was studied in a number of solvents (0.1 to 4 mol dm^{-3} of HNO_3, HCl and H_2SO_4, 60% $HClO_4$, 1 mol dm^{-3} oxalic acid, 0.5 mol dm^{-3} aqueous NH_3, and 0.1 mol dm^{-3} NaOH) of analytical interest. One half gram of the ion-exchange material was equilibrated with 50 cm^3 of the solvent at room temperature (25±2 °C) and kept for 24 h with occasional shaking. Tin, tungsten, vanadium, and phosphorus in the solutions were determined spectrophotometrically using standard methods[6-9] respectively.

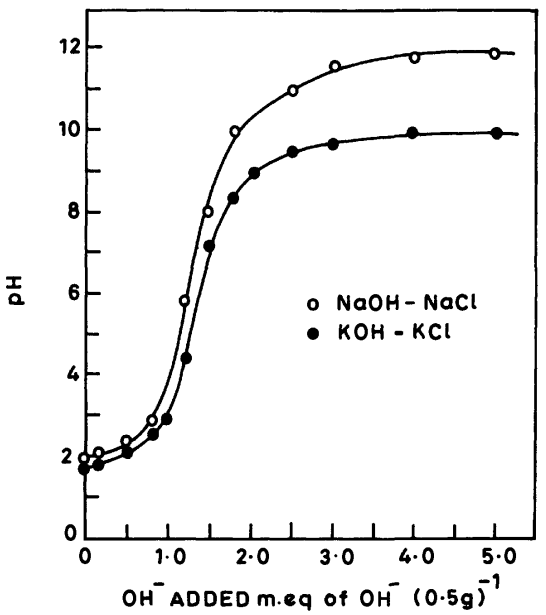

Fig. 1. pH Titration curves of tin(IV) tungstovanadophosphate (Sample $TTVP_7R$).

Chemical Composition. For the determination of chemical composition of various samples of tin(IV) tungstovanadophosphate, 0.2 g of the material was dissolved in hot concentrated hydrochloric acid. It was then diluted to

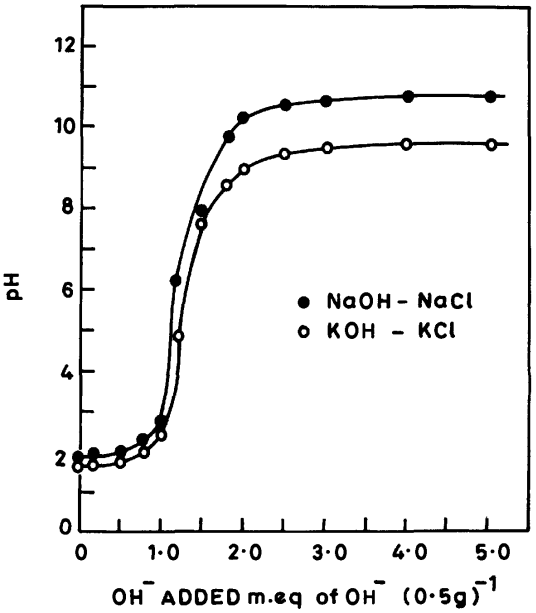

Fig. 2. pH Titration curves of tin(IV) tungstovanadophosphate (Sample $TTVP_7$).

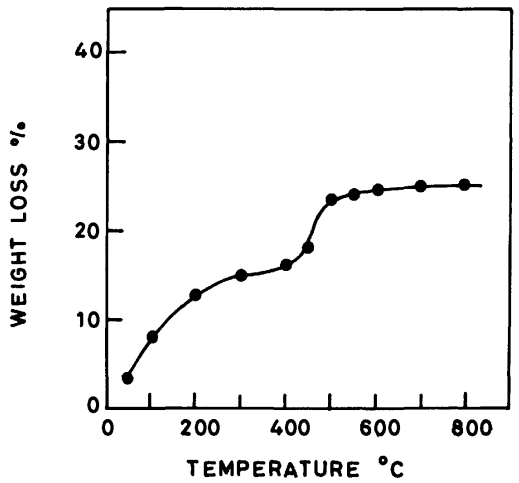

Fig. 3. Thermogram of tin(IV) tungstovanadophosphate($TTVP_7R$) in H^+ form.

100 cm^3 with DMW. Tin was determined spectrophotometrically[6] while tungsten and vanadium were determined by gravimetric[10] and titrimetric[11] methods respectively. Phosphate was determined titrimetrically using the standard method.[12]

Equilibrium Study. Equilibrium times for the adosorption of bivalent, tervalent, and quadrivalent metal ions (Mg^{2+}, Ba^{2+}, Cu^{2+}, Ni^{2+}, Al^{3+}, Fe^{3+}, Pr^{3+}, Zr^{4+}, and Th^{4+}) on tin(IV) tungstovanadophosphate ($TTVP_7R$, 50—100 mesh) in hydrogen form were determined by the earlier described method.[13]

Distribution Coefficient. Distribution coefficients of a number of metal ions in water and formic acid-sodium formate buffer systems of varying pH were determined. One half gram of the exchanger in hydrogen form (50—100 mesh) were added in 25 cm^3 cation solution in a 250 cm^3 Erlenmeyer flask. Concentration of metal ion in the solution was adjusted in such manner that it did not exceed 3% of the total ion-exchange capacity of the exchanger. The flask was then shaken in a shaker incubator at 25±2°C for 6 h. The amount of cation left in the solution after equilibrium was determined titrimetrically using 0.002 mol dm^{-3} EDTA as titrant. The K_d values were calculated according to the formula.[14] The results are given in Fig. 4.

Quantitative Separations of Metal Ions. Quantitative separations of some important metal ions of analytical utility were achieved on the columns of tin(IV) tungstovanadophosphate. Two grams of the exchanger in hydrogen form (50—100 mesh) was taken into a glass column of i. d. 0.6 cm. DMW was first run and then the mixture of metal ions was poured and allowed to be adsorbed. The metal ions were then eluted separately using suitable eluting reagents and determined by EDTA titrations. The flow rate of the effluent was maintained 1 $cm^3\,min^{-1}$ throughout the elution process. Results of separations achieved have been reported in Table 4.

Results and Discussion

Table 1 shows that the ion-exchange capacity of tin(IV) tungstovanadophosphate depends on the conditions of synthesis, that is on the mixing volume ratio of the reactants, the pH at which the precipitation is done and also on the refluxion. The maximum ion-exchange capacity [1.5 meq (dry g)$^{-1}$] is observed in the case of sample $TTVP_1$ prepared by mixing reagents in the volume ratio of 1:1:1:1 at pH 1. However, when the sample is prepared using the same ratio at pH less than zero, the capacity is found to increase significantly from 1.5 to 2.06 meq (dry g)$^{-1}$ (sample $TTVP_7$). It is interesting to observe that on refluxing the same product ($TTVP_7$) in a mixture of sodium metavanadate, sodium tungstate and phosphoric acid, the capacity of the final product ($TTVP_7R$) is further increased to some extent and it becomes chemically more stable. Both the refluxed product ($TTVP_7R$) and the unrefluxed product ($TTVP_7$) show reproducible properties as it is evident from the data given in Table 2.

It is clear from Table 3 that the hydrated radii of alkali metals and alkaline earths have no significant effect on the ion-exchange capacity of tin(IV) tungstovanadophosphate. The refluxed and the unrefluxed product both behave in a similar manner. The highest capacity is observed for Ba^{2+} ion [2.6 meq (dry g)$^{-1}$]. The order of exchange capacity for alkali metals, however, is as follows:

Sample $TTVP_7R$: $K^+ > Rb^+ > Li^+ > Na^+$

Sample $TTVP_7$: $K^+ > Rb^+ > Li^+ > Na^+$

In the case alkaline earths the same order is followed for both the ion-exchange materials

$$Ba^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+}$$

A comparison of the ion-exchange capacity of different tin(IV) based ion exchangers at 25±2°C shows

that tin(IV) tungstovanadophosphate ($TTVP_7R$) is much superior to other exchangers such as tin(IV) phosphate [(1.44 meq (dry g)$^{-1}$],[4] tin(IV) tungstate [0.58 meq (dry g)$^{-1}$][2] and tin(IV) vanadate [0.85 meq (dry g)$^{-1}$].[3] It is also interesting to note that stannic tungstovanadophosphate has higher ion-exchange capacity and chemical stability as compared to double salts such as tin(IV) vanadophosphate [1.98 meq (dry g)$^{-1}$].[1] The pH titration curves (Figs. 1 and 2) show that tin(IV) tungstovanadophosphate behaves as a monobasic acid. The uptake of ion depends on the pH of the solutions. The adsorption of K^+ is greater than

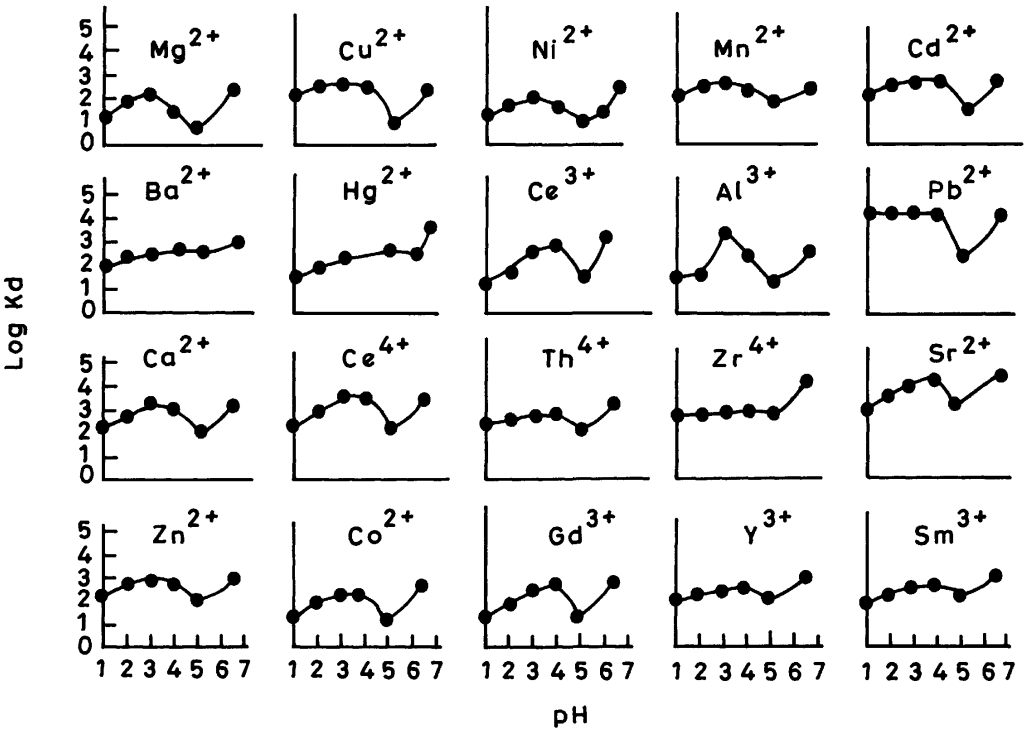

Fig. 4. Effect of pH of the solvent(formic acid–sodium formate system) on the adsorption of metal ion.

Na^+ in the pH region 2.5—10.

Tin(IV) tungstovanadophosphate has been found to be fairly stable in moderately concentrated nitric acid, hydrochloric acid, sulfuric acid, and perchloric acid. A comparison of the chemical stability data shows that the refluxed sample ($TTVP_7R$) is more stable than the unrefluxed one ($TTVP_7$). Equilibration study demonstrates the equilibrium is reached within 2 h of shaking for most of the metal ions studied except Cu^{2+} and Th^{4+} which take at least 4 h.

Thermogram of tin(IV) tungstovanadophosphate (Fig. 3) shows a continuous loss in weight upto 500 °C. A sharp weight loss upto a temperature of 250 °C may be due to removal of water molecules. It can also be inferred that the decomposition of tin(IV) tungstovanadophosphate starts after 250 °C and continues upto 500 °C. The gradual loss in weight in this temperature region is probably due to the loss of vanadium and phosphorus by volatilization. This conclusion is also supported from the ion-exchange capacity data [I. E. C. at 400 °C=0.2 meq (dry g)$^{-1}$ and at 500 °C=0.1 meq (dry g)$^{-1}$]. As vanadium and phosphorus contents of the material reduces the capacity becomes smaller and smaller. On increasing the temperature beyond 500 °C, the weight becomes constant due to the formation of stable tin oxide. The exchange capacity, therefore, reduces to a negligible value [0.4 meq (dry g)$^{-1}$].

Some interesting features are observed regarding the adsorption of metal ions on tin(IV) tungstovanadophosphate in sodium formate—formic acid buffer systems. It has been found that the pH of the buffer system affects the adsorption critically. It is apparant from Fig. 4 that the adsorption of metal ions on tin(IV) tungstovanadophosphate in sodium formate—formic acid buffer system vary with the pH. An increase in the pH of buffer system causes higher adsorption of almost all metal ions as expected. In the case of Zr^{4+}, the K_d value remains constant upto pH 5 and then increases sharply as the pH is increased. However, in other buffer systems studied, i. e. sodium citrate-citric acid and sodium acetate-acetic acid, distribution coefficients of metal ions do not vary with the pH of the buffer systems. This is also observed that the K_d values of metal ions are usually much more higher in demineralized water than in sodium formate-formic acid systems. The separation potentiality of tin(IV) tungstovanadophosphate has been demonstrated by achieving some important and difficult separations of metal ions quantitatively on its small columns.

Sphalerite and Calamine contain 0.1 to 0.5% of Cd^{2+}.[15] The binary separation of Cd^{2+}–Zn^{2+} may be utilized for the recovery of Cd^{2+} from these ores. Th^{4+}, Ce^{4+}, and Ca^{2+} may be eluted by different concentration of acid which can be applied for separation of these metal ions in cheralite[16] using tin(IV) tungstovanadophosphate columns.

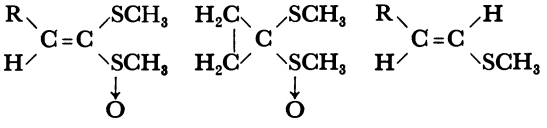
(Received December 18, 1985)

Synopsis. In the electrolytic reduction of organic sulfur compounds of general formular RCH=C$\begin{smallmatrix}\diagup\text{SMe}\\ \diagdown\text{S(O)Me}\end{smallmatrix}$, the substrates with R=aryl are much easier to reduce than those with R=alkyl, and the former substrates afford the desulfinylated compounds, E-isomers of RCH=CH(SMe), in good yields, but the later substrates do not give the corresponding desulfinylated compounds.

The title compounds, 1-methylsulfinyl-1-methylthio-1-alkenes (**1**), exhibit extremely interesting properties in their synthetic and mechanistic aspects.[1-5] Interestingly our preceding work[6] has shown that there is a sharp difference between the electrolytic and nonelectrolytic methods in the reduction of (*E*)-1-methylsulfinyl-1-methylthio-2-phenylethene (**1a**); the electrolytic reduction gives the desulfinylated compound, (*E*)-1-methylthio-2-phenylethene ((*E*)-**2a**), whereas the reduction with lithium aluminium hydride affords 2-phenyl-1,1-bis(methylthio)ethane.[1]

In the present work, the influence of a substituent group on the electrolytic reduction of **1** at a mercury electrode was examined in nonaqueous acetonitrile (MeCN) or *N*,*N*-dimethylformamide (DMF) containing excess phenol as a proton donor. The substrates investigated in this work are as follows.



1a—h **1i** **2a—h**

a : R=C_6H_5,
b : R=*p*-$CH_3OC_6H_4$
c : R=*m*-$CH_3OC_6H_4$
d : R=*p*-FC_6H_4
e : R=1-naphthyl
f : R=2-naphthyl
g : R=$(CH_3)_3C$
h : R=$HOCH_2C(CH_3)_2$

Experimental

The substrates, **1a—h**, were prepared from methyl methylthiomethyl sulfoxide (FAMSO) and the corresponding aldehydes according to the publised method[1] and **1i** was synthesized from FAMSO and 1,2-bis(tosyloxy)ethane according to a method described in the literature.[4] Verification of the substrates was made by ^{1}H NMR spectroscopy and by comparision of the physical properties with published values.

Nonaqueous acetonitrile solutions were prepared from predeoxygenated MeCN and tetrabutylammonium tetrafluoroborate (TBAB) or tetrabutylammonium perchlorate (TBAP) which were purified and dried as described previously.[6] Nonaqueous *N*,*N*-dimethylformamide solutions were prepared from the predeoxygenated DMF and TBAB or tetrabutylammonium iodide (TBAI). DMF was purified in a manner similar to that described in the literature.[7] TBAI was recrystallized twice from acetone and dried in vacuo at 80°C for 3 d. The concentration of the supporting electrolyte was 0.1 mol dm^{-3}.

Controlled potential macroelectrolysis and polarography were carried out, using the same experimental set-up and procedure as reported in the previous paper.[6]

Indirect electrolysis of **1g** using phenanthrene as a mediator was carried out at the stirred mercury pool cathode of −2.8 V vs. Ag/Ag$^+$ in MeCN/TBAB without proton donor.

Results and Discussion

Polarography. d.c. Polarograms of **1a—f** in MeCN/TBAP or DMF/TBAI in the presence of excess phenol exhibited three waves. The third reduction wave is ascribed to the further reduction of the reduction products, **2a—f**, since controlled potential macroelectrolysis of **1a—f** at the plateau potential of the first wave afforded **2a—f** in high yields, respectively (vide infra). The half-wave potentials of the first reduction wave ($E_{1/2}$) of **1a—i** in MeCN/TBAP in the presence of excess phenol are summarized in Table 1, together with the results in DMF/TBAI. Among the substrates with R=substituted phenyl, **1a—d**, these $E_{1/2}$ seem to depend on the substituent constant sigma. The substrates with R=naphthyl, **1e** and **1f** were easy to reduce by 80—100 mV compared with **1a**. This can be interpreted in terms of stabilization of the le-reduction product due to the high delocalization of the charge of the radical anions of **1e** and **1f** through 1- and 2-naphthyl groups. On the other hand, the substrates with R=alkyl, **1g** and **1h**, were much more difficult to reduce than **1a**, but **1i** was not reducible in the accessible potential region.

Macroelectrolysis. Controlled potential macroelectrolyses of **1a—h** at the plateau potential of the first reduction wave at the stirred mercury pool electrode were conducted in MeCN/TBAB or DMF/TBAI in the presece of excess phenol. Table 2 summarizes the isolated yields of (*E*)-**2**, in which the coulometric *n*-values (electrons molecule^{-1}) also are included. The table shows that the substrates with R=aryl, **1a—f**, afford the desulfinylated compounds, (*E*)-**2a**–(*E*)-**2f**, in good yields, whereas the substrates with R=alkyl, **1g** and **1h**, do not give the corresponding desulfinylated compounds, **2g** and **2h**, but a complex mixture of products. The stereochemical structure of (*E*)-**2a**–(*E*)-**2f** was determined on the basis of the NMR spectra of their olefinic protons. The NMR spectra of the H exhibited

Table 1. Half-wave Potentials for the First Reduction Wave of **1a—i** in MeCN Containing 0.1 mol dm^{-3} TBAP and DMF Containing 0.1 mol dm^{-3} TBAI in the Presence of Excess Phenol at 27 °C[a)]

Substrate	$E_{1/2}$ in MeCN/V[b)]	$E_{1/2}$ in DMF/V[c)]
1a	−2.16	−1.41

1i	no wave	

a) Concentrations of substrates and proton donor were 1.0—1.3×10^{-3} mol dm^{-3} and 4 times that of the substrate, respectively. b) Vs. Ag/0.1 mol dm^{-3} $AgNO_3$ in MeCN reference electrode. c) Vs. Ag/AgI 0.1 mol dm^{-3} TBAI in DMF reference electrode.

Table 2. Results of Controlled Potential Electrolysis of **1a—h** at the First Reduction Potential at an Hg Pool Cathode in Nonaqueous Media Containing Excess Phenol

Substrate	Electrolyte system	n-Value	Yield of (*E*)-**2**/%
1a	MeCN/0.1 mol dm^{-3} TBAB	3.6	85
	DMF/0.1 mol dm^{-3} TBAI	3.5	78
1b	MeCN/0.1 mol dm^{-3} TBAB	3.5	87
1c	MeCN/0.1 mol dm^{-3} TBAB	3.6	73
	DMF/0.1 mol dm^{-3} TBAI	3.4	78
1d	MeCN/0.1 mol dm^{-3} TBAF	3.5	79
1e	MeCN/0.1 mol dm^{-3} TBAB	4.2	80
	DMF/0.1 mol dm^{-3} TBAI	3.6	76
1f	MeCN/0.1 mol dm^{-3} TBAB	3.9	78
	DMF/0.1 mol dm^{-3} TBAI	3.4	78
1g	MeCN/0.1 mol dm^{-3} TBAB	2.1	0
1h	MeCN/0.1 mol dm^{-3} TBAB	2.1	0

the AB quartet splitting with J=15.3 Hz (cf. for (*Z*)-**2a**, AB_q J=10.6 Hz[8)]). Perusal of the NMR spectra of the reaction mixture indicated that no *Z*-isomers were produced in any experiment.

Table 2 also shows that there is no significant difference with regard to the product yield and the n-value between MeCN and DMF.

Indirect reduction of **1g** by means of the phenanthrene anion radical showed a catalytic current in the polarogram of phenanthrene in MeCN/TBAP. Nevertheless, the indirect macroelectrolysis of **1g** in MeCN/TBAB at −2.8 V vs. Ag/Ag$^+$ did not give **2g**. The indirect macroelectrolysis of **1i** was not undertaken because no catalytic current was observed.

The coulometric n-values for **1a—f** were 3.4—4.2, suggesting that the methylsulfinyl anion resulting from the cleavage of the carbon–sulfur bond will undergo further reduction to produce methanethiol. The production of methanethiol was confirmed experimentally: Benzyl methyl sulfide was isolated though low in yield (22% for **1a**) when the catholyte was allowed to react with benzyl bromide after the electrolysis.

In conclusion, polarography of organic compounds of general formular $\begin{matrix}R\\H\end{matrix}\!\!\searrow\!C{=}C\!\!\begin{matrix}\swarrow SMe\\\searrow S(O)Me\end{matrix}$ showed that $E_{1/2}$ for the first reduction wave in MeCN or DMF containing excess phenol as a proton donor is slightly dependent on the kind of R in **1** when R is an aryl group, whereas the substrates with R=alkyl are much more difficult to reduce than those with R=aryl. The electrolytic reduction of the substrates with R=aryl involves selective cleavage of one carbon-sulfur bond, resulting in formation of (*E*)-1-methylthio-2-arylethenes, (*E*)-**2a**–(*E*)-**2f**, in good yields with the consumption of about 4 electrons molecule^{-1}. On the other hand, the substrates with R=alkyl did not afford the corresponding desulfinylated compounds although about 2 electrons molecule^{-1} were consumed during the electrolyses. Neither could the corresponding desulfinylated compound be obtained by indirect electrolysis of **1g** by means of phenanthrene anion radical.

(Received February 6, 1986)

Synopsis. Fluorescence lifetimes measured for 9-methylanthracene in supersonic free jets confirm the occurrence of nonradiative decay at the vibrationless level of S_1 that has been suggested from the measurement of the fluorescence yield. The nonradiative decay constants in the isolated and condensed phases have been compared from the viewpoints of relative positions of S_1 and T_2 levels and of the magnitude of the energy gap.

The fluorescence quantum yield (Φ_f) and lifetime (τ_f) for 9-substituted anthracenes strongly depend on temperature and medium.[1-8] In solution this behavior has been explained in terms of the intersystem crossing (ISC) from S_1 to T_2 lying above S_1. A recent measurement in supersonic free jets[9] showed that Φ_f of 9-methylanthracene(9MA) at the vibrationless level of S_1 is only 0.57 although the molecule is supercooled, making a sharp contrast to a Φ_f-value of unity at 77 K in the condensed phase.[1] On the basis of the solvent and pressure effects on the ISC rate, Tanaka et al. have suggested that S_1 should lie above T_2 in the isolated state as predicted from a large blue shift of the 0-0 band.[10] The fluorescence behavior of other 9-substituted anthracenes in solution and vapor phases has been interpreted similarly in terms of a S_1–T_2 level inversion model.[11] In the present work, in order to confirm these suggestions, the fluorescence lifetimes of 9MA in supersonic free jets have been measured and the heavy atom effect in the rare gas clusters has been investigated as well, along with the additional lifetime measurements in solutions. The radiative and nonradiative decay constants (k_r and k_{nr}) in the isolated and condensed phases were estimated, and the values of k_{nr} were compared from the viewpoints of relative positions of S_1 and T_2 levels and of the magnitude of the energy gap.

Experimental

9MA purchased from Tokyo Kasei was purified by column chromatography. The apparatus and the measurement system for laser induced fluorescence studies of jet-cooled molecules at the Institute for Molecular Scienece were described previously.[12] 9MA heated to ca. 80 °C in a furnace was expanded into vacuum with a carrier gas through a 150 μm nozzle.

The fluorescence lifetime in solution was measured by a time-correlated single photon counting system at Kyoto Institute of Technology.[13] Solvents of a spectroscopic grade were used. The composition of EPA was 5:5:2 in volume for diethyl ether, isopentane, and ethyl alcohol. Sample solutions of 2.5×10^{-5} mol dm^{-3} were deaerated by freeze-pump-thaw cycles.

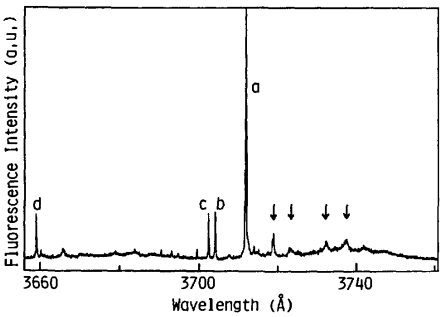

Fig. 1. The fluorescence excitation spectrum of 9MA expanded with 600 torr of Ar. The arrows indicate the Ar cluster bands of 9MA where the fluorescence lifetime was measured.

Table 1. Fluorescence Lifetimes for 9MA and Its Ar Clusters in Supersonic Free Jets

Bare 9MA		Ar Cluster	
Band position cm^{-1}	τ_f ns	Band position cm^{-1}	τ_f ns
26939 (a)	18.7	26891	11.6
26995 (b)	25.8	26859	13.2
27008 (c)	23.2	26797	13.3
27328 (b)	15.6	26758	14.3

Results and Discussion

The fluorescence excitation spectrum of 9MA expanded with 600 Torr (1 Torr=133.322 Pa) of Ar is shown in Fig. 1. The electronic origin band (a) of bare 9MA is located at 371.2 nm with a blue shift exceeding 1000 cm^{-1} from the corresponding transition in solution. The bare 9MA bands (a,b,c,d) are in good agreement with those reported by other investigators.[14,15] The Ar cluster bands on the longer-wavelength side of the origin band become prominent as the Ar pressure is increased.

Fluorescence lifetimes for the bare and cluster bands are listed in Table 1. τ_f for the 0-0 band is 18.7 ns while Zeweil et al. have obtained a value of 21 ns.[15] The vibronic bands b and c have longer lifetimes, and the vibronic band d has a shorter lifetime. Such an irregular change in the lifetime for 9MA, as well as for anthracene,[16] with an excess vibrational energy was observed in a wider range of excess energy.[15] The existence of longer lifetimes of 25.8 and 23.3 ns for b and c bands indicates that the lifetime of 18.7 ns for the 0-0 band contains the contribution from a nonradiative decay process besides radiative one. Sonnenschein et al.

Table 2. Radiative and Nonradiative Decay Constants for the S_1 Electronic Origin of Jet-Cooled 9MA and the Solution Values

Medium	temp °C	λ_{0-0}[a] nm	Φ_f	τ_f ns	k_r $\times10^7\,s^{-1}$	$k_r\cdot(1/n^2)$ $\times10^7\,s^{-1}$	k_{nr} $\times10^7\,s^{-1}$
Isolated		371.2	0.57[b]	18.7[c]	3.1		2.3

obtained a value of Φ_f=0.57 for the 0–0 band of jet-cooled 9MA.[9] The present lifetime data are consistent with their result, concerning the occurrence of nonradiative decay from the vibrationless level of S_1. The radiative and nonradiative decay constants in solution and in free jet are compared in Table 2. Although the radiative decay constant for the jet-molecule is fairly smaller than that in solution, these values become comparable, after correcting for the refractive index, i.e. multiplying by $1/n^2$.[17]

The nonradiative decay route is the ISC from S_1 to T_2. In solution k_{nr} decreases as the S_1 energy is lowered from pentane to toluene since the S_1–T_2 energy gap increases when $S_1<T_2$.[5,10] The long lifetime in EPA at 77 K reflects only a radiative decay constant as indicated by the fluorescence quantum yield of unity at this temperature.[1]

Since an apparent activation energy of ca. 800 cm^{-1} has been obtained from the temperature dependence of k_{nr} in pentane and the S_1–T_2 gap has been estimated to be ca. 400 cm^{-1} by considering the shift of S_1 due to the temperature dependence of a dielectric constant,[7] the blue shift of ca. 1000 cm^{-1} in going from pentane solution to the isolated state probably results in the elevation of the S_1 energy above the T_2 level. This S_1–T_2 level inversion will enable energetically the ISC to occur in the isolated 9MA even though 9MA is supercooled.

Another evidence for the level inversion is provided by the fluorescence behavior of the rare gas clusters of 9MA. The fluorescence lifetimes at the Ar cluster bands are shorter compared with the value at the vibrationless bare band. If the vibrationless level of S_1 of bare 9MA lies below T_2, this result can not be understood since the lowering of the S_1 energy level by cluster formation will leave the ISC channel closed. Furthermore, when Kr or Xe was used as a carrier gas, no cluster bands were observed. This finding does not necessarily mean that no clusters are formed. On the contrary, it is reasonable to consider that Kr and Xe clusters are formed but their fluorescence intensities are very low since the ISC rates are extremely raised. In fact, as the pressure of Kr or Xe increases the 0–0 band intensity of the bare 9MA decreases significantly, indicating the formation of 9MA-Kr or Xe atom van der waals clusters which exhibit very short-lived excited states. These observations on the clusters of 9MA contrast with the case of 9-cyanoanthracene (9CNA).[12] For 9CNA its cluster bands with Ar, Kr, and Xe were detected and those lifetimes were almost identical with that (28 ns) of the vibrationless bare band, indicating the absence of the heavy-atom effect. In a supersonic free jet the fluorescence yield at the vibrationless level of bare 9CNA was found to be unity.[9] These results for 9CNA indicate that the ISC from S_1 to T_2 is energetically prohibited since $S_1<T_2$, and hence the heavy-atom effect was not observed. Conversely, for 9MA where the ISC route is open in the isolated state ($S_1>T_2$), the heavy-atom effect by Kr or Xe enhances the ISC rate remarkably. The shortened lifetime for the Ar clusters of 9MA may be ascribed to the change in the Franck-Condon factor between S_1 and T_2 caused by the decrease in the S_1–T_2 energy gap under the condition of $S_1>T_2$ because the heavy-atom effect by Ar, if any, seems to be insignificant.[18]

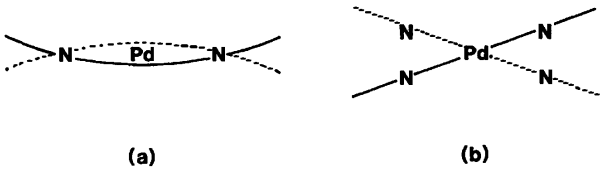
The Crystal Structure of Bis(2,2′-bipyridyl)palladium(II) Picrate $[Pd(bpy)_2](pic)_2$. A Novel "Bow" Distortion

Shūichi MAEDA, Yuzo NISHIDA, Hisashi ŌKAWA,* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received December 10, 1985)

Synopsis. The title complex crystallized in the triclinic space group $P\bar{1}$ with a=8.228(2), b=13.493(2), c=7.753(1) Å; α=96.96(1), β=106.16(1), γ=99.99(1)°; Z=1. The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method to R=0.0366. It is found that picrate ions above and below the $[pd(bpy)_2]^{2+}$ cation stack with the bpy molecules and that this stacking leads to a novel bow distortion of the cation.

It is known that the bis(2,2′-bipyridyl)palladium(II) ion ($[Pd(bpy)_2]^{2+}$) is essentially planar, but is slightly distorted from a rigorous plane because of interligand steric repulsion.[1] Two types of distortions, i.e., bow and twist (Fig. 1), have been found for the cation. It seems that the type of distortion depends upon the counter ion, and bow distortion has been found for the salt with the tetracyano-*p*-quinonedimethane anion ($TCNQ^-$).[3,4] It is presumed that the stacking between bpy and $TCNQ^-$ is associated with the unique bow distortion. In this study, the crystal structure of $[Pd(bpy)_2](pic)_2$ with the 2,4,6-trinitrophenolate ion (picrate ion, pic^-) has been determined and discussed in terms of the noncovalent interaction between the bpy molecule of the $[Pd(bpy)_2]^{2+}$ cation and the pic anion.



(a) (b)

Fig. 1. Schematical representation of (a) bow and (b) twist distortions.

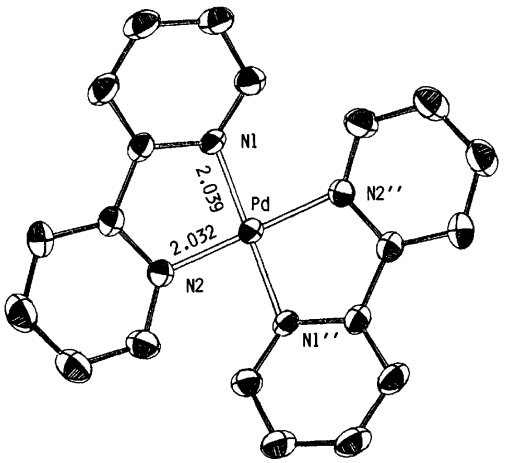


Fig. 2. Molecular structure of $[Pd(bpy)_2]^{2+}$ with bond distances.

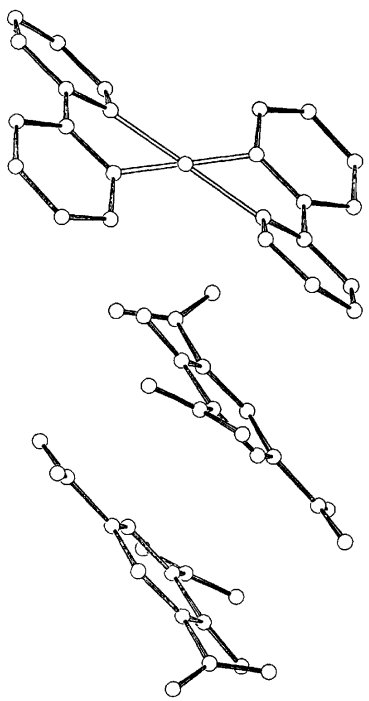

Fig. 3. Perspective view of the crystal packing.

Experimental

Preparation. $[Pd(bpy)_2](pic)_2$ was obtained as yellow crystals by the reaction of bis(2,2′-bipyridyl)palladium(II) perchlorate (1.25 g) and 2,4,6-trinitrophenol (1 g) in water. Anal. Found: C, 44.05; H, 2.39; N, 15.96%. Calcd for $C_{32}H_{20}N_{10}O_{14}Pd$: C, 43.83; H, 2.53; N, 15.97%. Single crystals were obtained by slow crystallization from a dilute methanolic solution.

X-Ray Analysis. A crystal with dimensions of 0.2×0.2×0.3 mm was used for the X-ray analysis. The unit-cell parameters and intensities were measured on a Rigaku AFC-5 Automated Four-circle Diffractometer with graphite monochromated Mo $K\alpha$ radiation (λ=0.71609 Å) at 291 K. The intensity data were collected by the 2θ—ω scan technique with a scan rate of 6° min^{-1}; they were corrected for the Lorentz and polarization effects, but not for absorption (μ=7.0 cm^{-1}). A total of 3821 reflections within the $2<\theta<55°$ range were collected, of which independent 3377 reflections ($|F_o| \geq 3\sigma(F_o)$) were employed in the solution and refinement.

Crystal Data: $[Pd(C_{10}H_8N_2)_2](C_6H_2N_3O_7)_2$, F.W.=874.99, triclinic $P\bar{1}$, a=8.227(2), b=13.493(2), c=7.753(1) Å; α=96.96(1), β=106.51(1), γ=99.99(1)°; D_m=1.81, D_c=1.81 g cm^{-3}, Z=1.

The structure was solved by the heavy-atom method, assuming the position of the palladium atom at (0,0,0), and was refined by the block-diagonal least-squares method to the final R value of 0.0366. The final atomic coordinates, the anisotopic temperature factors of the non-hydrogen atoms, a full list of bond distances (Å) and angles (°), and the complete F_o—F_c data are deposited as Document No. 8630 at the Office of the Editor of the Bulletin of the Chemical Society of Japan. All the calculations were carried out on a M-200 computer

at the Computer Center of Kyushu University using the local version[5] of the UNICS system.[6] The atomic-scattering factors were taken from the International Tables for X-Ray Crystallography.[7]

Results and Discussion

A perspective drawing of the $[Pd(bpy)_2]^{2+}$ cation is shown in Fig. 2, together with the bond lengths. The palladium atom lies at the center of the complex molecule; the mean Pd–N distance is 2.04 Å which is close to the previously reported Pd–N distances of the NO_3^-[8,9] and $TCNQ^-$[3,4] salts. The angles of N1–Pd–N2 and N1–Pd–N2″ are 78.9° and 101.1° respectively.

The $[Pd(bpy)_2]^{2+}$ cations are separated by pair of picrate ions, which are stacked with each other in a head-to-tail manner with an interplane distance of 3.41 Å, as is shown in Fig. 3. The picrate anions above and below the cation also stack with the bpy molecule with an interplane distance of ca. 3.57 Å. The picrate oxygens are located at the apical sites of the metal; however, the considerably long Pd–O distances (3.20 Å) suggest that there is no appreciable bonding.

In spite of the planar configuration of the PdN_4 part, the whole of the cation is not planar, and the two pyridine rings within one ligand are tilted by 21.3° to cause the bow distortion. Probably this distortion is attributable to the bpy/pic stacking interaction in the crystal. That is, when the pic stacks with the bpy, the nitro groups at the 2- and 6-positions exert a steric effect so as to bend the bpy molecule. So far as we know, this complex is only the second example of a bow distortion in the $[Pd(bpy)_2]^{2+}$ cation.

Di-*n*-octyl Phenyl Phosphonate: A Plasticizer of Poly(vinyl chloride) Matrix Membrane Electrodes Behaving As a Li^+-selective Agent

Kazuhisa HIRATANI,* Tatsuhiro OKADA, and Hideki SUGIHARA
Industrial Products Research Institute, Higashi 1-chome, Yatabe-machi, Tsukuba-gun, Ibaraki 305
(Received November 7, 1985)

Synopsis. PVC matrix membrane electrodes, which are composed of dioctyl phenylphosphonate (DOPP) as a plasticizer and potassium tetrakis(4-chlorophenyl)borate (KTCPB) as a lipophilic anionic additive, without any other ionophore, exhibit appreciable Li^+-selectivity. The electrode has selectivity coefficients (log k^{Pot}_{LiM} for Li^+ over Na^+ up to -1.2, over K^+ up to -1.8, over Mg^{2+} up to -1.8, and over Ca^{2+} up to -1.2. The detection limit for Li^+ was about 5.0×10^{-5} mol dm^{-3}.

During the last decade much attention has been focused on the use of neutral carrier compounds as membrane components; they can be used together with different plasticizers in ion-selective membrane electrodes, especially for alkali and alkaline earth metal ions.[1] A number of neutral carriers for ion-selective electrodes have been reported thus far, such as noncyclic polyethers,[2,3] crown ethers,[4] and bis-crown ethers.[5] Moreover, the effects of the plasticizers on the behavior of the ion-selective electrodes have also been investigated, and the change in the selectivity coefficients brought about by plasticizers, together with neutral carriers, have been observed.[6] However, in order to discriminate among cations within a given group of the periodic system, the influence of the solvent/plasticizer with neutral carrier sensors has been considered of minor importance.[7] In this paper, we wish to report on the phenomenon that the selectivity for cations within a given group of the periodic system without any other neutral carrier changes completely depending on the kind of plasticizer.

Experimental

Materials. The plasticizers, dioctyl phenylphosphonate (DOPP) and *o*-nitrophenyl octyl ether (NPOE), and potassium tetrakis(4-chlorophenyl)borate (KTCPB), were commertially available (Dojin Lab.) and were used without further purification. Poly(vinyl chloride) (PVC) (degree of polymerization $n \fallingdotseq 1100$), which was also commertially available from Wako Pure Chemical Industries, Ltd., was used after the polymer had been dissolved in tetrahydrofuran (THF), followed by reprecipitation in methanol.

Preparation of Electrodes. A plasticizer (250 mg), PVC (100 mg), and KTCPB (3 mg) were dissolved in 4 ml of THF. The solution was then poured into a Petri dish (42 mm in diameter) which was held horizontally on a mercury pool, and the THF was evaporated slowly at room temperature. A transparent homogeneous membrane ca. 0.2 mm thick was thus obtained. A disk of the polymeric membrane 5 mm in diameter was cut out from the membrane obtained and was then mounted on an Orion model 92 electrode body for electromotive force (EMF) measurements. The cell assemblies of the ion-selective electrode were as follows: Ag/ AgCl/ 10^{-2}mol dm^{-3} LiCl//membrane// test solution/ 1 mol dm^{-3} $LiOCOCH_3$/ sat. KCl/AgCl/Ag, where a silver-silver chloride electrode in a double-junction configuration was used as the external reference electrode.

EMF-Response Measurements. Test solutions were prepared from analytical-grade chlorides of alkali and alkaline earth metals and deionized water (specific conductivity 5×10^{-7} $\Omega^{-1}cm^{-1}$). The EMF response of the testing solutions at 25 °C was measured with an Orion model 701A digital ionanalyzer (input impedance 10^{13} Ω) and was recorded by means of a strip-chart recorder and a printer. The time for the electrode to attain the stationary potential value within ±1 mV for the lapse of 30 sec. was referred to as the response time. The potentiometric selectivity coefficient $k^{Pot}_{i,j}$ of the i ion over the j ion was determined by the separate-solution method.[8] The concentrations of interference ions referred to by this calculation ranged from 10^{-1} to 1 mol dm^{-3}.

Results and Discussion

Figures 1 and 2 show the plots of the EMF response vs. the logarithm of ion activity (log *a*) when DOPP and NPOE respectively were used as plasticizers. In both cases, the PVC membrane electrodes show a near-Nernstian response for the ions examined except for those with a low EMF response. The electrode exhibits a marked Li^+-selectivity over Na^+, K^+, Mg^{2+}, and Ca^{2+} when DOPP is used, whereas the K^+-selectivity over Li^+, Na^+, Mg^{2+}, and Ca^{2+} is obtained when NPOE is used. When KTCPB was not included in the membranes, the near-Nernstian response for cations was not observed; rather, the response for anions was observed in the case of NPOE.[9] It has been reported

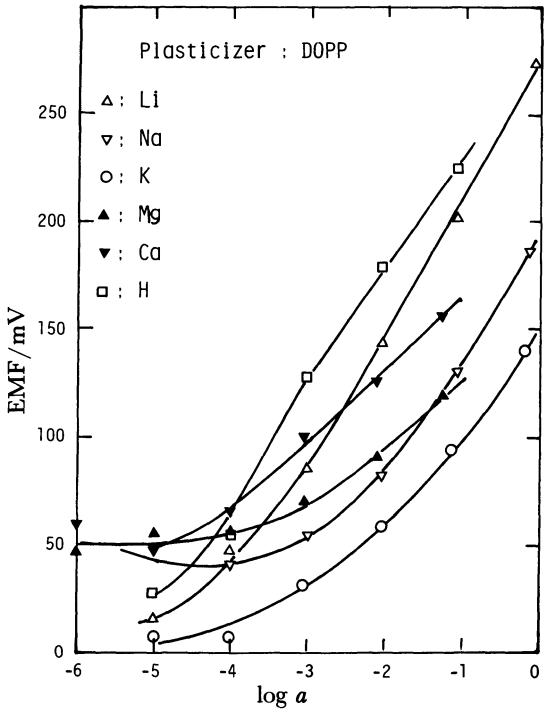

Fig. 1. EMF response of the PVC membrane containing DOPP (71 wt%) and KTCPB (3 wt%) (25 °C).

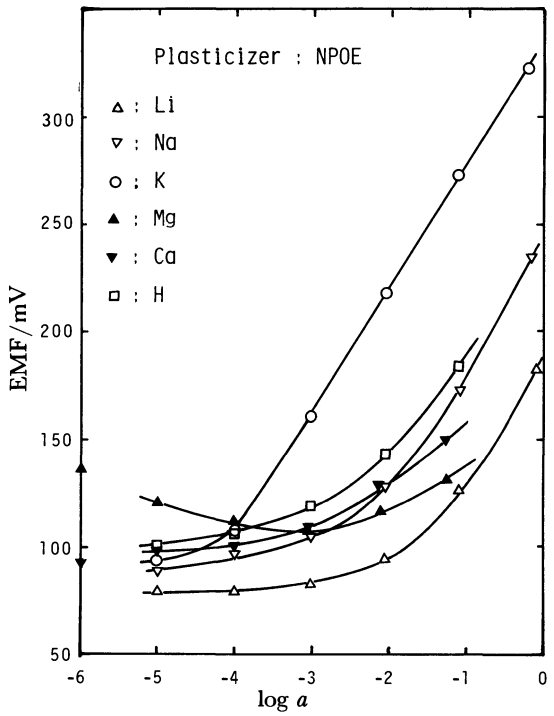

Fig. 2. EMF response of the PVC membrane containing NPOE (71 wt%) and KTCPB (3 wt%) (25 °C).

that DOPP is favorable for Ca^{2+}-selective electrodes containing an organophosphate salt-carrier.[10] It is also well known that a membrane based on tetraphenylborate in nitrobenzene or related solvents, e.g., NPOE, shows a monotonic preference for large over small cations, that is, for lipophilic over hydrophilic cations,[11] as is depicted in Fig. 2. However, when DOPP and KTCPB were used without any other ionophore, the electrode has appreciable selectivity coefficients for Li^+ over Na^+, K^+, Mg^{2+}, and Ca^{2+}. Apparently, DOPP can reverse its ion-selectivity from large to small alkali ions, that is, from lipophilic to hydrophilic cations.

Furthermore, the effect of the mixing of the plasticizers, DOPP and NPOE, on the selectivity coefficients for cations was investigated. The results are also summarized in Fig. 3. The mixing ratios apparently influence the selectivity for cations. The Li^+-selectivity is still retained even when the mixture composed of 3 wt% of DOPP and 68 wt% of NPOE is present in the membrane, as if DOPP hehaved as a Li^+-ionophore. This fact reminds us that certain organic phosphorous compounds and other compounds can improve ion-selectivity in the membrane electrodes.[13–15] It should be noted that the membrane electrode composed of a mixture of NPOE 57 wt% and DOPP 14 wt% as plasticizers has maximum selectivity coefficients for Li^+ over Na^+ of up to −1.3 compared with the other electrodes shown in Fig. 3. Thus, it is a new finding that appreciable Li^+-selectivity appears when a PVC membrane containing DOPP and KTCPB, without any other ionophore, is used.

We wish to thank Professor Toshiyuki Shono and Dr. Keiichi Kimura of Osaka University for their valuable discussions and suggestions.

The Synthesis of 3-Aryl-5-dialkylamino-1,4,2-dithiazol-1-ium Salts

Isao SHIBUYA* and Katsumi YONEMOTO
National Chemical Laboratory for Industry, Yatabe, Ibaraki 305
(Received December 24, 1985)

Synopsis. *N*-(Dialkylthiocarbamoylthio)arenecarboxamides, prepared by acylation of the corresponding *S*-dialkylthiocarbamoyl-substituted sulfenamides, cyclized with dehydration in a strong acidic media to form a number of 3-aryl-5-dialkylamino-1,4,2-dithiazol-1-ium salts in good yields.

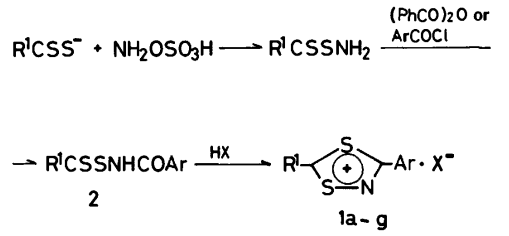
The syntheses and reactions of 1,2- and 1,3-dithiolium cations have been investigated extensively, and their results have been summarized in some excellent reviews.[1-3] The synthesis of 3,5-diaryl-1,2,4-dithiazolium cations, the aza analogs of 1,2-dithiolium, were generalized by Liebscher and the author, and their reactivity has also been studied.[4-7] These five-membered heterocyclic cations are very reactive toward nucleophiles and produce many kinds of derivatives. Therefore, it can be anticipated that 1,4,2-dithiazolium cations, the aza analogs of 1,3-dithiolium, are also reactive and lead to many derivatives. It is interesting to investigate their syntheses and reactivies.

Recently, Paton et al prepared 3-aryl-5-methylthio derivatives by methylation of the corresponding 1,4,2-dithiazol-5-thiones;[8] however, by this method the dithiazol-5-thiones are given only in poor yields.

In addition, Sammes et al prepared 3-aryl-5-dialkylamino compounds quite recently by the reaction between sodium dithiocarbamate and α-chloro oxime *O*-sulfonate,[9] however the chloro oxime sulfonates are special reagents and not available easily.[10]

We now report that a number of 1,4,2-dithiazolium cations were obtained in high yields by another simple method. The approach to preparing 3-aryl-5-dialkylamino-1,4,2-dithiazol-1-ium salts, (**1**), was attained via the pathway shown as Scheme 1, which could be postulated based on the synthetic route of the corresponding 1,3-dithiolium salts.[11]

N-(Dialkylthiocarbamoylthio)arenecarboxamides, (**2**), the precursors for **1**, could not be obtained directly by a reaction of dithiocarbamic acids with *N*-bromoarenecarboxamides; however, the dithiocarbamic acids led to sulfenamides upon treating with hydroxylamine-*O*-sulfonic acid in aqueous sodium hydroxide. The sulfenamides were acylated smoothly with benzoic anhydride to give *N*-benzoyl sulfenamides, while other aroyl compounds were also accessible by treating with aroyl chlorides. Cyclization of **2** was carried out with dehydration in a strong acidic media to afford white crystalline compounds of **1a—g**. Their mps, yields, and analytical data are summarized in Table 1, and satisfactory analytical results were obtained for all products. The IR spectrum of **1a** was almost superimposable to that of 2-diethylamino-4-phenyl-1,3-dithiolium perchlorate. Two absorptions, at δ=166.79 and 192.47, are assignable to the C-3 and C-5 carbons of 1,4,2-dithiazolium ring, respectively. These were observed in the ^{13}C NMR spectrum of **1a**, and the spectral data agreed with the results of Sammes.[9] These facts showed that **1a** is identical with 3-phenyl-5-diethylamino-1,4,2-dithiazol-1-ium perchlorate, and it was found that a number of 3-aryl-5-dialkylamino compounds, **1a—g**, could be obtained in good yields using a simple method, Scheme 1. This process is more convenient and applicable than the two when 1,4,2-dithiazolium salts are supposed to be versatile intermediates to lead to various heterocycles. A study concerning the reaction of the 1,4,2-dithiazolium salts with nucleophiles is in progress.



Scheme 1.

Experimental

***S*-Diethylthiocarbamoyl-Substituted Sulfenamide.** Into an aqueous solution (10 ml) of sodium diethyldithiocarbamate trihydrate (2.30 g, 0.01 mol) was added with stirring at a temperature below 10 °C an aqueous solution (10 ml) of hydroxylamine-*O*-sulfonic acid (1.70 g, 0.015 mol), neutralized with sodium hydroxide. The resulting precipitate was separated by filtration and air-dried. The crude product was dissolved in dichloromethane and filtered to remove any insoluble substance. The solvent was evaporated under a reduced pressure to give 1.56 g of the sulfenamide; yield 95%, mp 30—31 °C. ^1H NMR ($CDCl_3$) δ=1.26 (6H, t), 3.08 (2H, br s), 3.80 (4H, br q); IR (KBr): 3336, 3248, 2979, 2932, 1571, 1493, 1420, 1354, 1274, and 1205 cm^{-1}. Found: C, 36.77; H, 7.42; N, 16.80%. Calcd for $C_5H_{12}N_2S_2$: C, 36.59; H, 7.36; N, 17.05%.

Other *S*-dialkylthiocarbamoyl-substituted sulfenamides were also accessible in the same manner as described above almost quantitatively.

***N*-(Diethylthiocarbamoylthio)benzamide (2a). Reaction with Benzoic Anhydride:** Into a solution of *S*-diethylthiocarbamoyl-substituted sulfenamide (1.64 g, 0.01 mol) in chloroform (10 ml), benzoic anhydride (2.71 g, 0.012 mol) was added. The reaction mixture was then kept at 50 °C for 2 h. After removing the solvent under a reduced pressure, the resulting residue was washed with an excess of ether and recrystallized from ethanol to give 2.09 g of **2a**; yield 78%, mp 129 °C. ^1H NMR ($CDCl_3$) δ=1.34 (6H, br t), 3.87 (4H, br), 7.56 (3H, m), and 8.03 (2H, m). IR (KBr): 3315, 2980, 2935, 1672, 1503, 1455, 1423, 1278, and 710 cm^{-1}. Found: C, 53.85; H, 6.02; N, 10.40%. Calcd for $C_{12}H_{16}N_2S_2O$: C, 53.70; H, 6.01; N, 10.44%.

Reaction with Benzoyl Chloride: A solution of *S*-diethylcarbamoyl-substituted sulfenamide (0.82 g, 5 mmol) and

Table 1. 3-Aryl-5-dialkylamino-1,4,2-dithiazol-1-ium Salts, (**1a—g**)

benzoyl chloride (1.05 g, 7.5 mmol) in ether (20 ml) was vigorously stirred with 2 mol dm^{-3} aqueous sodium hydroxide (20 ml) for 3 h at a temperature below 10 °C. The resulting precipitate was filtered, and recrystallized from ethanol to give 0.85 g of **2a**; yield 32%. Other *N*-benzoyl sulfenamide were given in 30—41% using the same procedure mentioned above.

Preparation of 3-Aryl-5-alkylamino-1,4,2-dithiazol-1-ium Salts (1a—g). To a solution of an *N*-benzoyl sulfenamide (0.01 mol) in acetic anhydride (20 ml), 70% perchloric acid (1 ml) or 40% tetrafluoroboric acid (2 ml) was added dropwise with stirring. The reaction mixture was kept at 60 °C for 2 h. After cooling to room temperature, the mixture was poured into an excess of ether to afford a white powder and recrystallized from acetonitrile to give **1a—g**. Their mps, yields, and analytical results are given in Table 1.

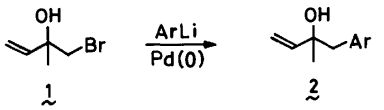
Palladium(0)-Catalyzed Coupling Reaction of Isoprene Bromohydrin with Aromatic Organolithium Reagents

Shuki ARAKI, Masayuki OHMURA, and Yasuo BUTSUGAN*
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received January 28, 1986)

Synopsis. Palladium(0)-catalyzed reaction of isoprene bromohydrin with aromatic organolithium reagents selectively gave good yields of coupling products without rearrangement.

In our continuous study on the reaction of isoprene bromohydrin (1-bromo-2-methyl-3-buten-2-ol) (**1**) with organometallic reagents, we have recently reported the coupling reaction of **1** with Grignard reagents in the presence of a palladium(0) catalyst which gives exclusively vinyl-group-migrated products. With phenylmagnesium bromide, for example, **1** selectively gave 2-phenyl-4-penten-2-ol in 85% yield.[1] It is interesting to examine the palladium(0)-catalyzed coupling of **1** with organometallics other than Grignard reagent, because isoprene bromohydrin (**1**) shows diverse reaction behavior in the transition-metal-catalyzed coupling with various types of organometallic reagents.[2] We now report the palladium(0)-catalyzed reaction of **1** with aryllithium reagents which yields, in contrast with the reaction of Grignard reagents,[1] non-rearranged coupling products (**2**) with high selectivity (Eq. 1).



1 2 (1)

When the reaction of 1 with phenyllithium was conducted in the presence of a catalytic amount (0.1 mol%) of tetrakis(triphenylphosphine)palladium, 2-methyl-1-phenyl-3-buten-2-ol (**2a**) was obtained selectively in 53% isolated yield. No other coupling products could be found in the reaction mixture. In the absence of the catalyst, a mixture of **2a** and 2-methyl-4-phenyl-2-buten-1-ol (*E*/*Z* 52/48) was formed in the ratio 76:24 in 85% combined yield.

Results for other aryllithium reagents are summarized in Table 1, which shows that a variety of aryllithiums (phenyl, *p*-tolyl, 2-furyl, 2-thienyl, and 2-pyrrolyl) all give coupling products (**2a—f**) without rearrangement. However, the reactions of **1** with alkyl- and allyllithium reagents such as butyl- and prenyllithium in the presence of the Pd(0) catalyst gave complex product mixtures. For example, the coupling of **1** with prenyllithium under the similar reaction conditions described above gave complex mixture of products in which no trace of linalool could be found.

The present procedure provides a facile and synthetically useful method for introducing a 2-hydroxy-2-methyl-3-butenyl group, an isoprenoid C_5 synthon, to an aromatic nucleus.

Experimental

General. Infrared spectra were recorded on a JASCO IRA-1 spectrophotometer. ^{1}H NMR spectra were recorded on a Hitachi R-24A spectrometer (60 MHz) or on a Varian XL-200 spectrometer (200 MHz) with Me_4Si as internal standard. Mass spectra were determined using a Hitachi M-52 instrument at 20 eV. GLC analyses were performed on a Yanaco G1800 gas chromatograph equipped with a column packed with Apiezon grease L on Uniport B (15%). Elemental analyses were performed at the Elemental Analysis Center of Kyoto University. For Kugelrohr distillation, a Shibata GTO-250R glass tube oven was used.

Table 1. Pd(0)-Catalyzed Reaction of **1** with Aryllithiums

Aryllithium	Product	Yield/%
	**2a**	53
	**2b**	86
	**2c**	60
	**2d**	78
 a)	**2e**[b]	92
	**2f**	70

a) Prepared by the lithiation of 3-methylthiophene.[4] b) Mixture of the products coupled at the 5- and 2-positions of 3-methylthiophene (7 : 3).

Palladium(0)-Catalyzed Coupling Reaction of Isoprene Bromohydrin (1) with Aryllithium Reagents. The following reaction with 2-furyllithium represents the general procedure. Tetrakis(triphenylphosphine)palladium (12 mg, 0.01 mmol) was added to a solution of 2-furyllithium, prepared from furan (680 mg, 10 mmol) and a hexane solution of butyllithium (1.6 M, 6.3 cm^3, 10 mmol (1 M=1 mol dm^{-3})) in ether (10 cm^3) according to the literature method,[3] and the mixture was stirred at 0 °C for 10 min. A solution of 1 (330 mg, 2 mmol) in ether (2 cm^3) was then added at 0 °C and the mixture was left overnight at room temperature. The reaction was quenched by the addition of saturated aqueous ammonium chloride and the product was extracted with ether. The extracts were dried (Na_2SO_4) and the solvent was evaporated. The residue was distilled (Kugelrohr) (bp 115 °C/ 18 Torr; 1 Torr≈133.322 Pa) to give a colorless oil (182 mg, 60%), which was found pure 2c by glc and ^{1}H NMR analyses.

The reactions with other aryllithium reagents were similarly carried out. Lithiation of thiophene,[4] 3-methylthiophene,[5] and 1-methylpyrrole[6] was performed according to literature. The structures of the coupling products (**2a—f**) were deduced by their spectral and analytical data, except for **2a** which was confirmed by the direct comparison with an authentic sample.[1]

2-Methyl-1-(*p*-tolyl)-3-buten-2-ol (2b): Bp 110 °C/3 Torr;

IR (neat) 3420, 2980, 1644, 1516, 1110, 920, and 812 cm^{-1}; ^1H NMR ($CDCl_3$) 1.29 (s, 3H, CH_3), 1.64 (bs, 1H, OH), 2.34 (s, 3H, CH_3), 2.80 (AB q, J=14 Hz, 2H, CH_2), 5.07 (dd, J=10, 2 Hz, 1H olefin), 5.14 (dd, J=17, 2 Hz, 1H, olefin), 6.00 (dd, J=17, 10 Hz, 1H, olefin), 7.13 (m, 5H, Ph); MS m/z 176 (M^+); Found: C, 81.47; H, 9.24%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

1-(2-Furyl)-2-methyl-3-buten-2-ol (2c): Bp 115 °C/18 Torr; IR (neat) 3430, 2980, 1642, 1594, 1504, 1146, 1010, 926, and 728 cm^{-1}; ^1H NMR (CCl_4) 1.22 (s, 3H, CH_3), 1.76 (bs, 1H, OH), 2.81 (s, 2H, CH_2), 5.00 (dd, J=10, 2 Hz, 1H, olefin), 5.21 (dd, J=17, 2 Hz, 1H, olefin), 5.92 (dd, J=17, 10 Hz, 1H, olefin), 6.08 (m, 1H, furan H-3), 6.27 (m, 1H, furan H-4), 7.32 (m, 1H, furan H-5); MS m/z 152 (M^+); Found: C, 70.96; H, 8.04%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

2-Methyl-1-(2-thienyl)-3-buten-2-ol (2d): Bp 120 °C/5 Torr; IR (neat) 3450, 2980, 1642, 1372, 1223, 1150, 994, 922, and 692 cm^{-1}; ^1H NMR ($CDCl_3$) 1.34 (s, 3H, CH_3), 1.73 (bs, 1H, OH), 3.06 (s, 2H, CH_2), 5.15 (dd, J=10, 2 Hz, 1H, olefin), 5.22 (dd, J=17, 2 Hz, 1H, olefin), 6.03 (dd, J=17, 10 Hz, 1H, olefin), 6.90 (m, 1H, thiophene H-3), 7.00 (m, 1H, thiophene H-4), 7.22 (m, 1H, thiophene H-5); MS m/z 168 (M^+); Found: C, 64.67; H, 7.37%. Calcd for $C_9H_{12}OS$: C, 64.25; H, 7.19%.

2-Methyl-1-(4-methyl-2-thienyl)-3-buten-2-ol and 2-Methyl-1-(3-methyl-2-thienyl)-3-buten-2-ol (2e) (7:3 Mixture): Bp 110 °C/ 3 Torr; IR (neat) 3450, 2980, 1642, 1370, 1120, 992, 920, 850, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) 1.32 (s, 2.1H, CH_3), 1.33 (s, 0.9H, CH_3), 1.73 (bs, 1H, OH), 2.19 (s, 0.9H, CH_3), 2.22 (s, 2.1H, CH_3), 2.99 (s, 2H, CH_2), 5.12 (dd, J=10, 2 Hz, 1H, olefin), 5.21 (dd, J=17, 2 Hz, 1H, olefin), 6.01 (dd, J=17, 10 Hz, 1H, olefin), 6.69 (bs, 0.7H, thiophene H-3), 6.76 (bs, 0.7H, thiophene H-5), 6.85 (d, J=5 Hz, 0.3H, thiophene H-4), 7.12 (d, J=5 Hz, 0.3H, thiophene H-5); MS m/z 182 (M^+); Found: C, 65.78; H, 7.88%. Calcd for $C_{10}H_{14}OS$: C, 65.89; H, 7.74%.

2-Methyl-1-(1-methyl-2-pyrrolyl)-3-buten-2-ol (2f): Bp 130 °C/ 5 Torr; IR (neat) 3500, 2980, 1642, 1490, 1298, 1088, 1018, 920, and 704 cm^{-1}; ^1H NMR ($CDCl_3$) 1.32 (s, 3H, CH_3), 1.92 (bs, 1H, OH), 2.81 (AB q, J=15 Hz, 2H, CH_2), 3.57 (s, 3H, NCH_3), 5.11 (dd, J=10, 2 Hz, 1H, olefin), 5.18 (dd, J=17, 2 Hz, 1H, olefin), 5.99 (dd, J=17, 10 Hz, 1H, olefin), 6.04 (m, 1H, pyrrole H-3 or H-4), 6.11 (m, 1H, pyrrole H-4 or H-3), 6.60 (m, 1H, pyrrole H-5); MS m/z 165 (M^+); Found: C, 72.52; H, 9.21%. Calcd for $C_{10}H_{15}NO$: C, 72.69; H, 9.15%.

Biomimetic Application of Natural Valinomycin and Nonactine Ionophores to Artificial Transport of Amino Acid Salts[1)]

Hiroshi TSUKUBE,* Kentaro TAKAGI, Tatsuo HIGASHIYAMA, Tadashi IWACHIDO, and Naomi HAYAMA
Department of Chemistry, College of Liberal Arts & Science, Okayama University, Okayama 700
(Received February 3, 1986)

Synopsis. Biological valinomycin and nonactine ionophores showed new and interesting transport abilities for important amino acid salts in the biomimetic membrane systems, which are of biological interest and of practical significance.

Valinomycin and nonactine are typical biological ionophores,[2)] which strongly bind K^+ ion in their macrocyclic cavities and effectively transport it across a biomembrane. A variety of investigations of molecular structures, biological activities, and other chemical properties of these ionophores have been investigated, but most of them have focussed only on K^+ cation transport phenomena.[3)]

Here we present a new biomimetic application of biological valinomycin and nonactine ionophores to the artificial membrane transport, in which amino acid derivatives are transported as anionic or cationic guest species. Although valinomycin and nonactine ionophores are believed to act as K^+ ionophores, we found that they showed excellent transport abilities for several amino acid guest salts. Their transport properties are compared with those of synthetic biscrown **3** and cryptand **4** (Fig. 2), because they are known to form three dimensional complexes with K^+ cation.[4)] Typical transport results, obtained by using a $CHCl_3$ liquid membrane, are summarized in Table 1.

Valinomycin **1** and nonactine **2** effectively transported several amino acid derivative anions together with alkali metal cations in the same direction, as observed in some biological amino acid symport systems.[5)] Table 1 demonstrates that valinomycin showed higher transport efficiencies than nonactine and other synthetic ionophores. Its transport properties were significantly controlled by combination of guest anion and cotransported cation. Optimal combination of Cs^+ and *N*-benzoylphenylalanine anion(Bz–Phe$^-$) provided suitably stable "valinomycin-guest anion-cotransported cation" type complex and allowed high transport efficiency.[6)] Since other employed ionophores had favourable combinations of guest salts, an effective transport of a given amino acid salt could be realized by appropriate choice of the employed ionophore and cotransported cation. These results clearly reveal new and potential transport functionalities of well-known bio-ionophores.

Table 1 also indicates that valinomycin **1** and nonactine **2** hardly mediated transport of amino acid ester salts, though the NH_3^+-moiety of amino acid ester has an ionsize similar to that of K^+ cation. Since synthetic ionophores **3** and **4** mediated transport of amino acid ester salts, the rigid backbones and bulky residues of biological valinomycin and nonactine ionophores would prevent stable complexations with guest ammonium cations of bulky amino acid esters.

The present results provide new and significant insights of biological and practical membrane transport systems. Other types of biological ionophores may offer further interesting transport functionalities for a new series of guest species, though several struc-

tural modifications are required to suppress their high toxicities.

Experiments

1. Materials. Valinomycin, bis-crown, and cryptand ionophores were purchased from Aldrich, Dojindo, and Merck, respectively. Nonactine, obtained from Fluka, contained about 25% monactine. Special cares are required for usages of valinomycin and nonactine ionophores, because of their high toxicities. Other employed reagents were also commercially available and used without further purifications.

2. Transport Procedures. The transport experiments were carried out at room temperature in a U-tube glass cell (2.0 cm, i.d.) as reported before.[7] The ionophore in $CHCl_3$ (12 ml) was placed in the base of the U-tube, and two aqueous phases(5 ml, each) were placed in the arms of the U-tube, floating on the $CHCl_3$ membrane. The membrane phase was stirred with a magnetic stirrer. The amounts of amino acid derivative anions or cations transported into Aq. II phase were determined by spectroscopic method. Initial transport rates calculated are summarized in Table 1.

This research was supported in part by a Grant-in-Aid from the Ministry of Education, Science, and Culture.

Titrations by Temperature Difference Electrode: Entropy Titrations

Tamio IKESHOJI
Government Industrial Research Institute, Tohoku; Nigatake 4-2-1, Sendai 983
(Received October 25, 1985)

Synopsis. A new type of potential-difference titration which has a relation with the entropy change of a reaction in a titrated solution was demonstrated using a Hg^{2+}–EDTA reaction on an Hg electrode. The potential difference between two identical electrodes, one kept at a different temperature from that of the solution, was monitored during titration. This difference changed from a minimum to a maximum at the equivalent point.

Many titrations concern Gibbs free-energy changes of reactions in titrated solutions. Some titration methods concern only enthalpy changes during reactions. A typical example of titrations concerning Gibbs free-energy changes is a potential-difference titration method in which the potential differences change due to Gibbs free-energy changes, i.e. the equilibrium constants of the reactions during titrations. Therefore, the equilibrium constants which this method concerns must be sufficiently large to determine the equivalent points and the equilibrium constants. In this note, the new type of titration method that is given mainly concerns entropy changes of reactions instead of the equilibrium constants. It is expected to be possible to precisely determine the equivalent points, even though the equilibrium constants are small, and to also calculate the entropy changes using only one titration curve. In ordinary potential-difference (OPD) titrations, entropy changes are calculated from at least two titration curves at different temperatures.

The new method presented here is one type of potential-difference titration in which the potential difference between two identical electrodes (one of which is kept at a different temperature from the titrated solution, called a "temperature difference electrode (TDE)") is monitored during titrations. The temperature of the other electrode is kept equal to that of the solution. In typical cases the potential difference during TDE titration is expected to change sharply from a minimum to a maximum at an equivalent point.[1] A sharp drop in potential was observed at this equivalent point in the case of OPD titration in which the electrode potential was monitored against a reference electrode in an iso-thermal condition. Since the configuration of these two identical electrodes was equal to that of a non-isothermal galvanic cell, their potential difference could be interpreted by the theory of non-isothermal galavanic cells containing a complexation reaction.

A demonstration of TDE titrations was performed using an Hg/Hg^{2+} electrode with disodium dihydrogen ethylenediaminetetraacetate ($EDTAH_2Na_2$) as a ligand for Hg^{2+}. This was done because the potential of Hg/Hg^{2+} is sufficiently stable to measure the small potential difference during TDE titration.

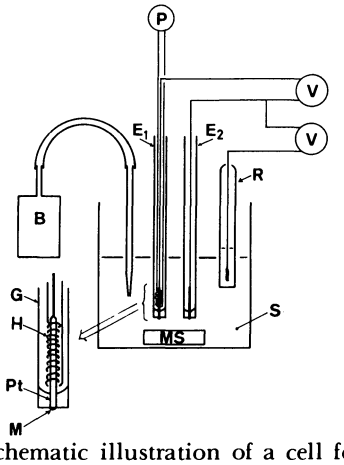

Fig. 1. Schematic illustration of a cell for temperature difference electrode titrations.
B: Motor driven syringe-burette, E_1: temperature difference electrode, E_2: the same type electrode as E_1 without a heater, H: small heater, G: glass tube, M: mercury hanging on Pt, P: power supply for small heater H, Pt: platinum rod, R: reference electrode, S: solution titrated, V: high impedance voltmeter.

Experimental

If a measurement cell for TDE titrations is built well, it will probably be complicated since it must have two compartments at different temperatures and a stirrer which can make all parts of the solution uniform. In this type measurement, the simple cell illustrated in Fig. 1 was used. Two electrodes, consisting of Pt rods (1 mmϕ) on which mercury was hanging, were placed in the cell. One of the electrodes was a TDE in which a small heater of chromel wire (13 Ω) insulated by Teflon was wrapped around the Pt rod in order to make the temperature of the TDE higher than the solution. Since the surface temperature of the TDE was a function of the current passing through this small heater and the speed of the magnetic stirrer, both were kept constant at 150 mA and ca. 150 rpm during titrations. A solution of 50 cm^3 containing $Hg(NO_3)_2$ (0.05 mmol) and sodium nitrate (1 mol dm^{-3}) at pH 1.3 or 2.2 adjusted by nitric acid were titrated by $EDTAH_2Na_2$ solution (0.01 mol dm^{-3}) with a motor-driven syringe-burette (ca. 0.2 $cm^3\,min^{-1}$) of TOA HSM-10A titrator. The cell was placed in a water bath kept at 29°C. The electrochemical system used here is, therefore, written as Hg (29°C)/Hg^{2+}, EDTA, $NaNO_3$/Hg(29°C+ΔT), where 29°C+ΔT is the surface temperature of the mercury of the TDE. The potential difference between two mercury electrodes hanging on the Pt rods and that between the mercury electrode at 29°C and an Ag/AgCl reference electrode which was used in the OPD titrations for comparison were monitored by a computer (HP-9845) with two high-impedance voltmeters (Hokuto HA-104 and ORION 811), a digital voltmeter (HP-3455A), and a scanner (Takeda TR-7216). All measurements were carried out at room temperature (29—30°C).

Results and Discussion

The potential difference measured during the TED

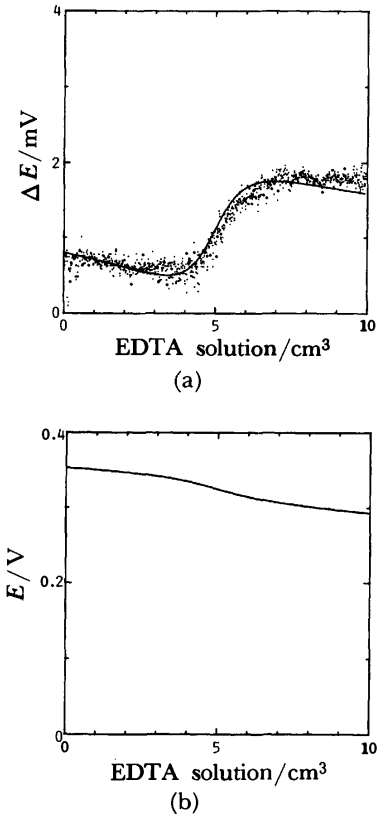

Fig. 2. Titration curves at pH 1.3. (a) by temperature difference electrode. (b) by ordinary potential difference titration.

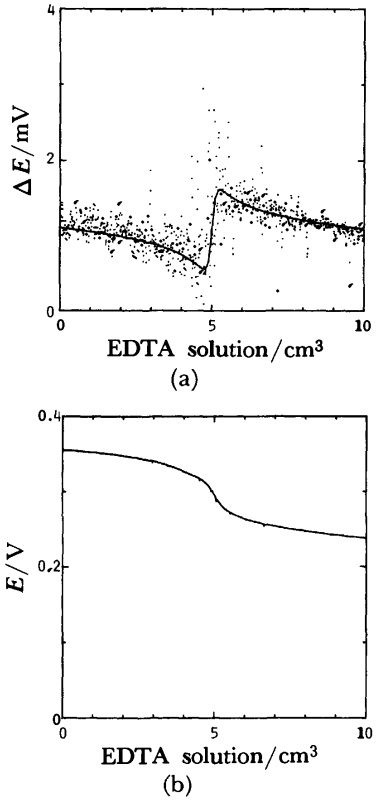

Fig. 3. Titration curves at pH 2.2. (a) by temperature difference electrode. (b) by ordinary potential difference titration.

titrations at pH 1.3 and 2.2 are plotted by dots in Figs. 2(a) and 3(a), and titration curves measured by the OPD ones in the same conditions are shown in Figs. 2(b) and 3(b).

An equivalent point for Hg^{2+} could be determined as the midpoint between the minimum and maximum peaks in the TDE titration curves. At pH 1.3, the equivalent point was determined to be 5.2 cm^3 in titrant volume from the TDE titration curve and 5.0 cm^3 from the OPD one. The difference was nearly within the experimental error. At pH 2.2 it was 5.0 cm^3 for both titration curves. The equivalent points can be seen more clearly in the TDE titration curves than in the OPD curves if measurements are performed under lower noise conditions. From the TDE and OPD titration curves at pH 1.3, regions where the apparent equilibrium constants of the complexation reaction were low, it was confirmed that a sharper change in the potential difference could be observed in case of TDE titration than in the case of OPD titration, even if the equilibrium constant was low. This is because the change in the potential difference during a TDE titration is not only due to the equilibrium constant, but also due to an entropy change of the complexation reaction.

The potential difference (ΔE) observed by the TDE titrations can be expressed by

$$\Delta E = \varepsilon \Delta T,$$

where ε is a thermoelectric power of this system, since two electrodes of the TDE titrations constitute a non-isothermal galvanic cell as described in Experimental. It is well known that the thermoelectric power of a non-isothermal galvanic cell is changed from the initial thermoelectric power (ε_i) at the uniform concentrations just after changing the temperature to the final value after a Soret equilibrium is attained.[2] For the experimental conditions mentioned in this note, the final thermoelectric power might be used for an interpretation of the observed thermoelectric power because of a thin thermal boundary layer on the mercury electrode of the TDE. In this layer, a Soret equilibrium could be attained within a short time. However, the final thermoelectric power in case of cells with a complexation reaction has not been theoretically derived yet. Therefore, in this note the initial thermoelectric power is used for a calculation of the TDE titration curves. This results in only a constant shift in the TDE titration curves since the difference between the initial and final thermoelectric power for general cases is due only to the constant terms of the transport numbers and Eastman entropies.[2] The initial thermoelectric power of the non-isothermal galvanic cells is expressed by the entropy change contributed from the electrode reaction and the transported entropies.[3] When an excess amount of indifferent salts is disolved in the solution, the transported entropies are constant. Therefore, the initial thermoelectric power of a cell $M(T)/M^{n+}$, Ligand/$M(T+\Delta T)$ with an excess amount of the indifferent salts is given as[1]

$$\varepsilon_i = \left(\frac{\partial E}{\partial T}\right)_{\text{iso}} + \text{const.}$$
$$= \frac{R}{nF} \ln C_{M^{n+}} + \frac{RT}{nF}\left(\frac{\partial \ln C_{M^{n+}}}{\partial T}\right) + \frac{\partial E^\circ}{\partial T} + \text{const.}, \quad (1)$$

where R and F are gas and Faraday constants, respectively. $(\partial E/\partial T)_{\text{iso}}$ is the temperature dependence of the isothermal electrode potential (E); i.e., it is determined from the electrode potentials measured against a reference electrode at various temperatures under the condition that the electrode and the reference electrode are kept at the same temperature. The term const. in Eq. 1 arises from transported entropies, activity coefficients, etc., and is constant for an excess of indifferent salts. $C_{M^{n+}}$ is the concentration of free M^{n+} which is not complexed with the ligand. $\partial E^\circ/\partial T$ is the temperature dependence of the standard electrode potential of M/M^{n+}. This term is also constant during titration. Details of the derivation of Eq. 1 is given elsewhere.[1] If the apparent complexation reaction with ligand L is simply written as

$$M^{n+} + L \rightleftarrows M^{n+}L \quad (2)$$

with equilibrium constant K

$$K = \frac{C_{M^{n+}L}}{C_{M^{n+}} C_L}, \quad (3)$$

where $C_{M^{n+}L}$ and C_L are the concentrations of complex $M^{n+}L$, and the free ligand, respectively, $C_{M^{n+}}$ can be calculated from Eq. 3 and the mass balances among them. The first term of Eq. 1 is dependent only on K but the second term of Eq. 1 is dependent on the standard entropy change (ΔS°) of the complexation reaction. Assuming K, ΔS°, and ΔT, it is possible to calculate the TDE and OPD titration curves. From the observed curves K, ΔS°, and ΔT can be determined as follows.

K: By a curve fitting of the OPD titration curve.

ΔT: From a slope of the TDE titration curve between 0 and a half of equivalent point in the titrant volume. In this region the slope of ε_i is not sensitive for K and ΔS° changes.

ΔS°: By a curve fitting of TDE titration curve. It is also possible to determine K from peak shapes in the TDE titration curve. The sharp peak means big K. The peak difference in height is corresponding to ΔS°.

In the above way, K, ΔS°, and ΔT under these experimental conditions were determined to be: log K= 4.9, $\Delta S^\circ = -18$ J K^{-1} mol^{-1}, and ΔT=10 K for pH 1.3 and log K=6.8, $\Delta S^\circ = -25$ J K^{-1} mol^{-1}, and ΔT=5 K for pH 2.2. The differences in ΔT are due to different electrode and stirrer configurations in the cells used. The calculated TDE titration curves are shown by solid lines in Fig. 2(a) and Fig. 3(a).

Since pK of the first proton release reaction of EDTA is 2.0,[4] EDTA forms mainly $EDTAH_4$ at pH 1.3. Therefore, the main complexation reaction at pH 1.3 can be expressed as

$$Hg^{2+} + EDTAH_4 \rightleftarrows HgEDTA^{2-} + 4H^+. \quad (4)$$

From data of stability constants of $EDTAH_4$ and $HgEDTA^{2-}$ found in the literature,[4] apparent $K(=C_{HgEDTA^{2-}}/C_{Hg^{2+}}C_{EDTAH_4})$ and ΔS° in a form of reaction scheme (2) at pH 1.3 are calculated as 6.8 in log K and -40 J K^{-1} mol^{-1}, respectively. The data used here were values at 25 °C and at an ionic strength 1.0 for K and 0.1 for ΔS°. Even though a simple complexation reaction (4) was assumed here, the difference in K and ΔS° between the calculations from values found in the literature and from observed curves was not large. Thus, since it is obvious that TDE titration is related to the entropy change, it might be called "Entropy titration."

The author wishes to thank Professor Signe Kjelstrup Ratkje of The Norwegian Institute of Technology for discussions about non iso-thermal galvanic cells by irreversible thermodydnamics and Mr. Ken Nozaki of Electrotechnical Laboratory for his suggestions to this work.

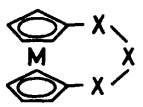
Conformational Changes of 1,2,3-Triselena- and 1,2,3-Trithia-[3](1,1′)ruthenocenophane

Sadatoshi AKABORI,* Takeshi KUMAGAI, and Masaru SATO†
Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274
†Chemical Analysis Center, Saitama University, Urawa, Saitama 338
(Received December 28, 1985)

Synopsis. 1,2,3-Triselena[3](1,1′)ruthenocenophane was obtained by the reaction of 1,1′-dilithioruthenocene with selenium powder in 22% yield. The energy barriers of the bridge reversal inversion of 1,2,3-triselena- and 1,2,3-trithia[3](1,1′)ruthenocenophane are 78.8 and 91.5 kJ mol^{-1}, respectively.

It is well-known that [3](1,1′)metallocenophanes are fluxional molecules and include bridge reversal processes. The high-temperature NMR spectra of 1,2,3-tricalcogena[3](1,1′)ferrocenophanes and their derivatives were recently interpreted as indicating the rigid nature of their medium-sized ring system.[1] For example, the activation energies required for the interconversion of 1,2,3-trithia[3](1,1′)ferrocenophane (**1**) and 1,2,3-triselena[3](1,1′)ferrocenophane (**2**) were estimated to be 80.3 and 68.4 kJ mol^{-1}, respectively. The difference in the activation energy between the two compounds is mainly attributable to the bond length of their bridge rings. In this connection, we have previously reported on the bridge reversal energy barriers of [3](1,1′)ruthenocenophane derivatives[2] containing calcogen atoms in the bridge. However, the bridge reversal energy barriers of 1,2,3-trithia[3]-(1,1′)ruthenocenophane (**3**) and 1,2,3-triselena[3](1,1′)-ruthenocenophane (**4**) have not previously been reported. It seemed interesting to compare the bridge reversal energy barriers of the metallocenophanes **1**, **2**, **3**, and **4**. Therefore, we prepared compound **3** and **4** and investigated the bridge reversal barriers in these ruthenocenophanes.



1: M=Fe, X=S
2: M=Fe, X=Se
3: M=Ru, X=S
4: M=Ru, X=Se

The reaction of 1,1′-dilithioruthenocene, which was prepared from ruthenocene and butyllithium in the presence of *N,N,N′,N′*-tetramethylethylenediamine (TMEDA), with selenium gave 1,2,3-triselena[3](1,1′)-ruthenocenophane (**4**) in 22% yield. The ^{1}H NMR spectrum of **4** in DMSO-d_6 showed the cyclopentadienyl (Cp) ring protons as an AMM′X pattern at δ 4.19, 4.79 and 5.00 as shown in Fig. 1, supporting the assigned structure. The multiplet at the highest field was assigned for H_X, due to the shielding effect of the lone pair electrons of the sulfur atoms located at the 1- and 3-positions in the bridge. Similarly, the lowest one was assigned for H_A. When the temperature was

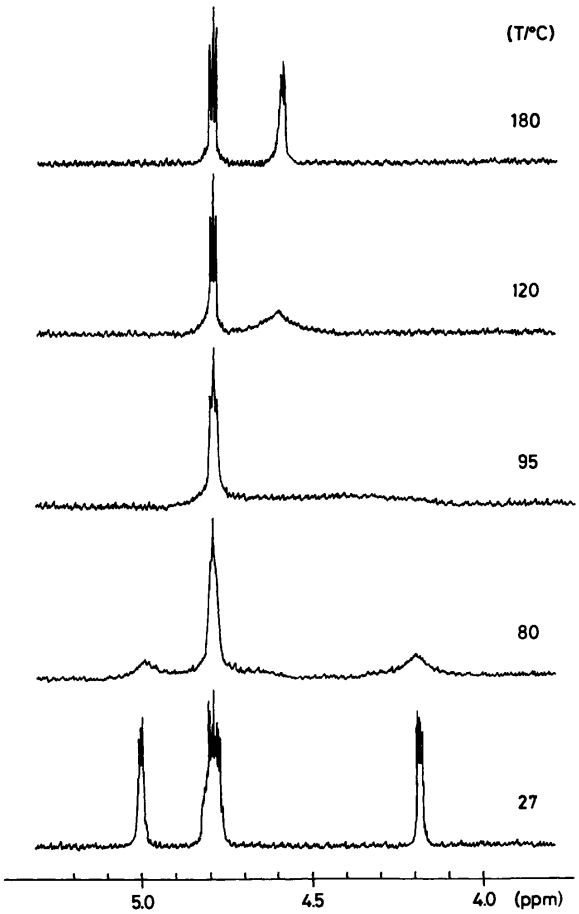


Fig. 1. Variable temperature 90 MHz ^{1}H NMR spectra of 1,2,3,-triselena[3](1,1′)ruthenocenophane in DMSO-d_6.

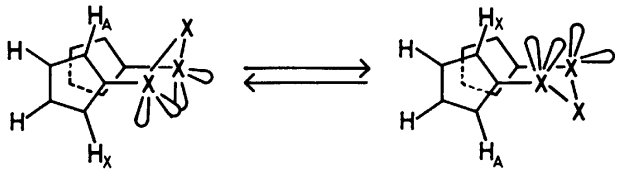
raised, these two multiplet peaks were broadened and coalesced at 95.2 °C. Above this temperature (180 °C) the broad peak due to H_α becomes sharp triplet. Also, the multiplet peak due to H_M at δ 4.79 was sharpened. The temperature dependence of the AMM′X pattern is in line with the exchange between the two α-ring protons, environments resulting from the bridge reversal inversion among conformer A and B (Fig 2). The rate of exchange k^1 at the temperature of coalescence T_c was calculated according to Gutowsky and Holm's method, from the Eq. 1,[3] where $\Delta\nu$ is the frequency separation of the resolved signals at room temperature.

$$k^1 = \pi\Delta\nu/\sqrt{2}, \quad (1)$$

$$k^1 = \kappa\frac{kT}{h}\exp\left(\frac{-\Delta G^{\ddagger}}{RT}\right). \quad (2)$$



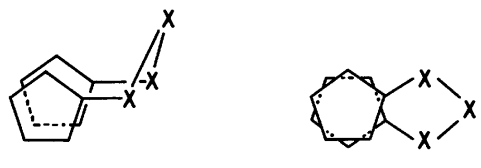
A B

Fig. 2. Bridge reversal mechanism of [3](1,1′)metallocenophane.

The values of $\Delta G^{\ddagger}$ were derived from the Eyring Eq. 2,[4] a unit transmission coefficient (k^1) being assumed. Equation 2 was transformed to Eq. 3 for the purpose of calculation.

$$\Delta G^{\ddagger} = 2.303RT_c(10.319 - \log_{10} k^1 + \log_{10} T_c) \quad (3)$$

When T_c=368 K, $k^1(s^{-1})$=161, and $\Delta\nu$(Hz)=72.6, the energy barrier for **4** was calculated to be about 75.2± 0.3 kJ mol^{-1}. This value is considerably greater than that of the bridge reversal barrier (67.2 kJ mol^{-1}) of corresponding ferrocenophane (**2**). This result is explainable by the fact that the distance between the two Cp rings of the ruthenocene nucleus was slightly longer than that of the ferrocene nucleus.[5,6] That is to say, the greater the angle of the bridge (X-X-X), the harder the bridge reversal. As shown in Fig. 3, the ^{1}H NMR spectra of 1,2,3-trithia[3](1,1′)ruthenocenophane (**3**) in DMSO-d_6 at room temperature also showed an AMM′X pattern at δ 4.28, 5.00, and 5.12. When the temperature was raised, the two multiplets of the H_A and H_X were broadened to ultimately coalesce at 170 °C. The bridge reversal barrier of **3** was calculated to be 91.5 kJ mol^{-1} ($\Delta\nu$=68.1 Hz, T_c=443 K, k^1=151 s^{-1}). The energy barrier was considerably greater than that of **4**. This result was in good agreement with the study previously reported by Abel et al. (1981).[1] They suggested that the bridge reversal barriers of [3](1,1′)-metallocenophane were correlated with the bridge length (Cp-X-X-X-Cp) determined from the covalent radii. That is, the longer the bridge length, the easier the inversion of the bridge. As the bridge length (8.56 Å) of **4** is longer than that (7.78 Å) of **3**, the value of the bridge reversal barrier of **4** is lower than that of **3**.



I II

Conformations I and II were possible as the low temperature limited conformation. For example, the structure of 1,2,3-trithia[3](1,1′)ferrocenophane took an eclipsed conformation I in a solid state and the energy of the staggered conformation II had to be higher than that of the eclipsed conformation I. Furthermore, in the [3](1,1′)ferrocenophanes, it has been proved and reported that the conformation I is the low temperature limiting conformation.[1] The conformation II is rather regarded as the transition state in the fluxional process. Accordingly, the 1,2,3-tricalcogena[3](1,1′)ruthenocenophanes (**3** and **4**) must take an eclipsed conformation as the low temperature limiting conformation.

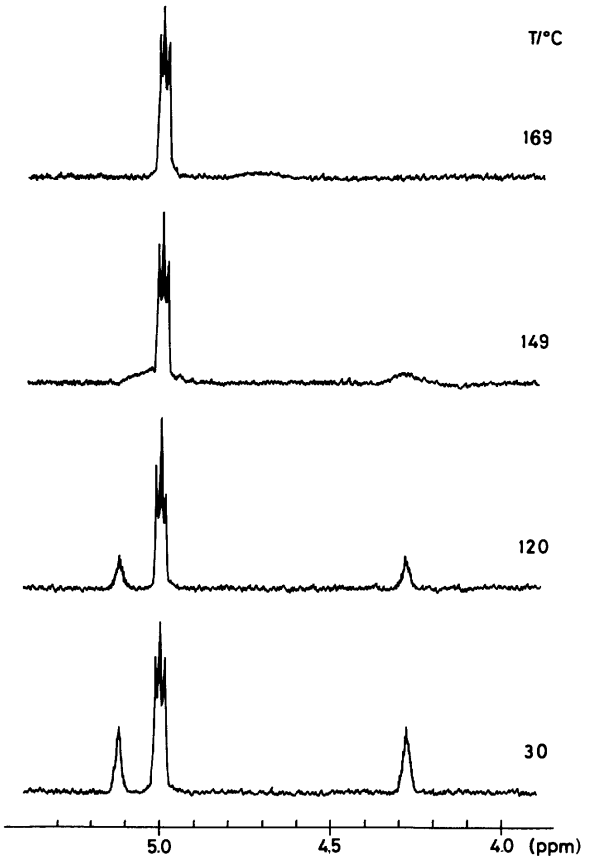


Fig. 3. Variable temperature 90 MHz ^{1}H NMR spectra of 1,2,3,-trithia[3](1,1′)ruthenocenophane in DMSO-d_6.

Experimental

1,2,3-Trithia[3](1,1′)ruthenocenophane (**3**) was prepared according to the previously reported method.[7] The variable temperature 90 MHz ^{1}H NMR of **3** and **4** were recorded in DMSO-d_6, on a JEOL FX-90 spectrometer, TMS being chosen as the internal standard. Mass spectra were taken on a Hitachi M-80 spectrometer. The melting point was not corrected.

1,2,3-Triselena[3](1,1′)ruthenocenophane (4). To a solution of ruthenocene (3.5 g, 15.2 mmol) in hexane (200 ml) was added a solution of TMEDA (5.6 ml, 37.7 mmol) and butyllithium (78.1 mmol) in hexane (50 ml) under nitrogen at a refluxing temperature. After the mixture was refluxed for 2 h, 1,2-dimethoxyethane (150 ml) and selenium powder (7.0 g, 88.6 mmol) were added to the mixture, and then refluxed for 16 h. After the mixture was cooled to room temperature, 10 ml of water was added. The supernatants were decanted and the residue was extracted with hot hexane until the extracts became colorless. The supernatants and the extracts were combined and concentrated in vacuo and the residue was chromatographed on activated alumina using a benzene : hexane (2:5) solution as the eluant. The yellow third fraction was collected and concentrated in vacuo. The residue

was recrystallized from hexane to give **4** as yellow plates in 22% yield, mp, 219.5—220.5 °C. Found: C, 25.96; H, 1.86%. Calcd for $C_{10}H_8RuSe_3$: C, 25.77; H, 1.73%. MS (70 eV), *m/z* 466 (M^+).

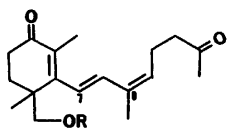
Stereospecific Synthesis of the Fungal Prohormone (±)-Trisporol B via the Palladium-Catalyzed Cross-Coupling Reaction of 1-Alkenylborane with 1-Haloalkene

Norio MIYAURA, Yoshitaka SATOH, Shoji HARA, and Akira SUZUKI*
Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received January 20, 1986)

Synopsis. The synthesis of the titled C_{18} apocarotenoid prohormone by means of palladium-catalyzed cross-coupling reaction between (*E*)-1-alkenylbis(1,2-dimethylpropyl)-borane (**10**) and (*Z*)-6-iodo-5-hepten-2-one ethylene acetal (**9**) is described. The reaction is highly stereoselective and the demanded (7*E*) and (9*Z*) double bonds are readily introduced.

The development of a simple and convenient method for the preparation of functionalized conjugated alkadienes and trienes has long been attracting much attention, since they would be promising versatile intermediates for the synthesis of naturally occurring biologically active compounds. Recently, we have reported that 1-alkenylboranes react with 1-alkenyl halides in the presence of palladium catalyst and base to give stereodefined conjugated alkadienes while preserving their *E* and *Z*-configurations.[1]

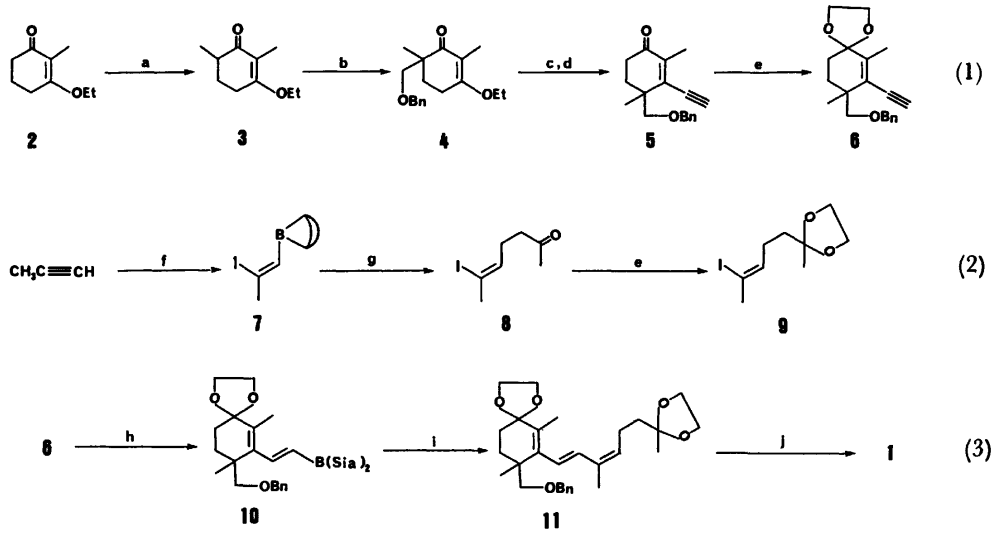
In this paper, we describe a stereospecific synthesis of the benzyl ether of a fungal prohormone (±)-trisporol B[2] (**1**, R=CH_2Ph) which involves the cross-coupling reaction between (*E*)-1-alkadienylborane (**10**) and (*Z*)-1-alkenyl iodide (**9**).



1 R = H, (±)-Trisporol B

The dienylborane derivative (**10**), required for the cross-coupling, was prepared via five steps from 2-methyl-3-ethoxy-2-cyclohexenone (**2**).[8] Thus, the methylation of **2** with lithium diisopropylamide (LDA) and methyl iodide in THF and HMPA, according to the method developed by Stork,[3] gave **3** in 91% yield as a white solid. Essentially the same procedure was applied for the benzyloxymethylation of **3** with LDA and benzyl chloromethyl ether to give **4** in 88% isolated yield. This enone **4** was then transformed into the enynone **5** by treatment with lithium trimethylsilylacetylide and the subsequent hydrolysis with aqueous hydrogen chloride. Desilylation[4] was performed with a saturated KF solution in 95% ethenol at room temperature in a quantitative yield. Subsequently, the carbonyl function of **5** was protected as its ethylene acetal. Thus, the overall yield from **2** to **6** was 56%, as shown in Eq. 1.

On the other hand, we have previously reported that the haloboration of terminal alkynes with 9-iodo-9-borabicyclo[3,3,1]nonane (B-I-9-BBN) proceeds highly regio- and stereoselectively to give the *syn*-adducts 9-[(*Z*)-2-iodo-1-alkenyl]-9-BBN's such as **7** in essentially quantitative yields, and the β-haloalkenyl-9-BBN (**7**) thus obtained reacts with α,β-unsaturated ketones via a Michael-type addition to yield haloalkenyl ketones like **8** in excellent yields.[5] This reaction sequence was applied to the synthesis of another necessary segment **9** for the cross-coupling (Eq. 2).



a) LDA, MeI b) LDA, $ClCH_2OCH_2Ph$ c) LiC≡CTMS d) KF e) EG, TsOH f) 9-iodo-9-BBN
g) MVK h) $HB(CHMe\text{-}CHMe_2)_2$ i) $Pd(PPh_3)_4$, NaOEt, **9** j) H^+

The coupling of these two fragments to **1** was carried out as outlined in Eq. 3. Namely, the enyne **6** in THF was subjected to hydroboration with bis(1,2-dimethylpropyl)borane[6] at room temperature by the usual procedure to give the dienylborane **10**. A mixture of **10** and the iodoalkene **9** in benzene containing $Pd(PPh_3)_4$[7] and sodium ethoxide was heated under reflux for 6 h in an atmosphere of nitrogen. The usual work-up and purification by TLC(silica gel-hexane) gave pure **11** in 52% yield, based on **6**. Finally, the deprotection of the ethylene acetal group with hydrogen chloride afforded the expected benzyl ether of trisporol B (**1**, R=CH_2Ph) as a pure form.

The present result clearly demonstrates that the novel two methodologies, the palladium-catalyzed cross-coupling reaction[1] and the haloboration-conjugate addition reaction,[5] both of which have been recently discovered by our group, provide a short step synthesis of trisporol B.

Experimental

The IR spectra were recorded on a Hitachi-Perkin Elmer Model 125 spectrometer. The ^1H NMR spectra of all compounds were measured with a Hitachi R-90H spectrometer (90 MHz) (solvent, $CDCl_3$; TMS as an internal reference). The measurement of mass spectra was carried out on a JEOL JMS-D 300 spectrometer (70 eV). Benzyl chloromethyl ether and trimethylsilylacetylene were commercial products and purified by distillation. THF was purified by distillation from benzophenone and sodium before use.

3-Ethoxy-2,6-dimethyl-2-cyclohexenone (3). To a solution of lithium diisopropylamide (LDA) (44 mmol) in THF (40 ml) was slowly added a solution of 3-ethoxy-2-methyl-2-cyclohexenone[8] (6.16 g, 40 mmol) in THF (20 ml) at −78 °C and the mixture was stirred for 1 h. To this solution was added HMPA (6 ml), and then methyl iodide (42 mmol) in THF (10 ml). The reaction mixture was stirred for 2 h at −78 °C, gradually warmed up to room temperature over 1 h, and then allowed to stand over night. The mixture was poured into ice water, extracted with ether, washed with brine, and dried over anhydrous $MgSO_4$. After evaporation of the solvent, the residue was chromatographed over silica gel with benzene/ethyl acetate (=10/1) to give **3** (6.1 g, 91%); Mp 49 °C; IR (nujol) 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.14 (d, 3H, J=6.6 Hz), 1.34 (t, 3H, J=7.0 Hz), 1.70 (broad s, 3H), 1.8—2.4 (m, 3H), 2.4—2.7 (m, 2H), and 4.05 (q, 2H, J=7.0 Hz). Found: m/z 168.11495. Calcd for $C_{10}H_{16}O_2$: M, 168.11501.

6-Benzyloxymethyl-2,6-dimethyl-3-ethoxy-2-cyclohexenone (4). To a solution of LDA (36 mmol) in THF (30 ml) was slowly added a solution of the enone **3** (33 mmol) in THF (20 ml) at −78 °C and stirred for 1 h. Then, HMPA (5.5 ml) and benzyl chloromethyl ether (38 mmol) in THF (10 ml) were gradually added. The reaction mixture was stirred for 2 h at −78 °C, and then warmed up to room temperature. After the solution was allowed to stand overnight, a saturated brine solution was added. The mixture was extracted with benzene, washed with brine, and dried over $MgSO_4$. The chromatography over silica gel with benzene/ethyl acetate (=15/1) gave **4** (8.3 g, 88%); n_D^{20}=1.5410; IR (film), 1625, 1460, 1385, 1360, 1240, 1115, 740, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.08 (s, 3H), 1.33 (t, 3H, J=7.0 Hz), 1.69 (broad s, 3H), 1.7—2.2 (m, 2H), 2.4—2.6 (m, 2H), 3.32 (d, 1H, J=9.0 Hz), 3.66 (d, 1H, J=9.0 Hz), 4.03 (q, 2H, J=7.0 Hz), 4.49 (s, 2H), and 7.92 (s, 5H); Found: m/z 288.17359. Calcd for $C_{18}H_{24}O_3$: M, 288.17349.

4-Benzyloxymethyl-2,4-dimethyl-3-ethynyl-2-cyclohexenone (5) and Its Acetal (6). To a solution of trimethylsilylacetylene (20 mmol) in THF (20 ml) was added a solution of butyllithium in hexane (12.5 ml, 20 mmol) at −78 °C and the solution was stirred for 30 min. Anhydrous lithium bromide (6 mmol)[9] was added all at once, and then a solution of the enone **4** (14.3 mmol) in THF (10 ml). The reaction mixture was stirred for 1 h at −78 °C, and then warmed up to 0 °C over 1 h. After the solution was stirred for 1 h at 0 °C, aqueous 2 mol dm^{-3}-HCl (20 ml) was added slowly with vigorous stirring. After 20 min, the aqueous layer was separated and extracted with ether. The combined extracts were washed with a saturated brine solution, an aqueous 5% Na_2CO_3 solution and finally again with brine. After evaporation of the solvent, the residue was dissolved in 95% ethanol (100 ml) and treated with KF (9 g) for 3 h at room temperature. The removal of ethanol in vacuo (12 mmHg) gave a mixture of the product and an excess of KF. This mixture was extracted with benzene, washed with brine, dried over $MgSO_4$, and finally chromatographed over silica gel with benzene/ethyl acetate (=20/1) gave **5** (2.7 g, 70%), mp 57 °C; IR (nujol) 3260, 2150, 2090, 1670, 1590, 1100, 1025, 843, 730, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (s, 3H), 1.99 (s, 3H), 1.6—2.6 (m, 4H) 3.36 (d, 1H, J=9.0 Hz), 3.64 (d, 1H, J=9.0 Hz), 4.53 (s, 2H), and 7.3 (s, 5H). Found: m/z 268.14526. Calcd for $C_{18}H_{20}O_2$: M, 268.14536.

A mixture of **5** (1.3 g, 4.8 mmol), ethylene glycol (6.3 mmol), trimethyl orthorformate (7 mmol), and a catalytic amount of p-toluenesulfonic acid in ether (20 ml) was stirred for 48 h at room temperature. After the usual work-up, the acetal was isolated by chromatography over silica gel with benzene/ethyl acetate (=20/1), 1.42 g (94%) of **6**; bp 160—165 °C/0.05 mmHg (the oven temperature of Kugelrohr) (1 mmHg=133.322 Pa); IR (neat) 3290, 2145, and 2095 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.14 (s, 3H), 1.9 (s, 3H), 1.5—2.1 (m, 4H), 3.13 (s, 1H), 3.34 (d, 1H, J=9.0 Hz), 3.48 (d, 1H, J=9.0 Hz), 3.99 (s, 4H), 4.52 (s, 2H), and 7.30 (s, 5H); Found: m/z 312.17185. Calcd for $C_{20}H_{24}O_3$: M, 312.17191.

(Z)-6-Iodo-5-hepten-2-one (8) and Its Acetal (9). The preparation of **8** from propyne was reported elsewhere,[5] which was protected as its ethylene acetal (**9**) by the usual procedure[10] by using ethylene glycol, methyl orthoformate, and p-TsOH in ether at room temperature. **9**: n_D^{18}=1.4980; IR (neat) 1670, 1150, 1055, 950, and 865 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.33 (s, 3H), 1.53—1.87 (m, 2H), 2.0—2.3 (m, 2H), 2.47 (s, 3H), 3.93 (s, 4H), and 5.43 (t, 1H, J=6.5 Hz).

The Benzyl Ether of (±)-Trisporol B (1, R=CH_2Ph). To a solution of **6** (1.8 mmol) in THF (2 ml) was added a solution of bis(1,2-dimethylpropyl)borane[6] in THF (4 ml of a 0.5 mol dm^{-3} solution, 2 mmol), and the mixture was stirred for 16 h at room temperature. After evaporation of the solvent in vacuo, the residue was dissolved in benzene (6 ml). To the solution of dienylborane **10** in benene thus obtained were added $Pd(PPh_3)_4$[7] (0.054 mmol), the alkenyl iodide acetal **9** (1.8 mmol) and a solution of sodium ethoxide in ethanol (1.8 ml of a 2 mol dm^{-3} solution), and then the mixture was refluxed for 6 h under N_2. After the flask was cooled to room temperature, NaOH (3 mol dm^{-3}, 2 ml) and 30%-H_2O_2 (0.5 ml) were added to decompose the unreacted borane. The product was then extracted with benzene, washed with a saturated brine solution, and dried ove $MgSO_4$. After evaporation of the solvent, the residue was chromatographed over silica gel with benzene/ethyl acetate (=10/1.5) to give **11** (0.435 g, 52%); n_D^{20}=1.4230; IR (film) 1663, 1075, 730, and 693 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.03 (s, 3H), 1.31 (s, 3H), 1.71 (s, 3H), 1.78 (broad s, 3H), 1.4—2.0 (m, 6H), 2.0—2.3 (m, 2H), 3.14 (d, 1H, J=9.0 Hz), 3.36 (d, 1H, J=9.0 Hz), 3.91 (s, 4H), 4.01 (s, 4H), 5.35 (t, 1H, J=7.0 Hz), 5.95 (d, 1H, J=16.3 Hz), 6.46 (d, 1H, J=16.3 Hz), and 7.29 (s, 5H); Found: m/z 468.28742.

Calcd for $C_{29}H_{40}O_5$: M, 468.28743.

A solution of **11** (0.101 g, 0.214 mmol) in THF (3 ml) was treated with aqueous 2 mol dm^{-3}-HCl (1 ml) for 6 h at room temperature. The product was extracted with ether, washed with brine, aqueous 5%-$NaHCO_3$, and finally with brine. TLC (silica gel) with benzene/ethyl acetate (=5/1) gave 75 mg (92%) of the benzyl ether of trisporol B (**1**, R=CH_2Ph): n_D^{20} =1.5650; λ_{max}^{EtOH}=301 nm; IR (neat) 1715, 1665, 1590, 1100, 965, 730, and 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (s, 3H), 1.81 (broad s, 3H), 1.85 (s, 3H), 2.11 (s, 3H), 2.2—2.7 (m, 6H), 3.23 (d, 1H, J=9.0 Hz), 3.51 (d, 1H, J=9.0 Hz), 4.50 (s, 2H), 5.43 (broad t, 1H, J=7.2 Hz), 6.13 (d, 1H, J=16.0 Hz), and 6.60 (d, 1H, J=16.0 Hz); Found: m/z 380.23385. Calcd for $C_{25}H_{32}O_3$: M, 380.23397.

Although we could not compare the authentic sample of benzylether of trisporol B with the product 1 (R=CH_2Ph) obtained in this work, the spectral data of our benzyl ether are quite similar to those of trisporol B previously reported,[2b] except some points due to the benzyl ether group. For instance, the characteristic bands at 1715 and 1665 cm^{-1} in IR and λ_{max}^{EtOH}=301 nm in UV owing to the conjugated enone structure are almost super-imposable with those of trisporol B (1710 and 1665 cm^{-1}, and λ_{max}^{EtOH}=298 nm).[2b] The benzyl ether has the following ^1H NMR characteristics. The chemical shifts of vinylic protons in δ (7-H=6.60, 8-H=6.13, and 10-H=5.43) and the coupling constant (J_{7-8}=16 Hz) agree almost completely with those of trisporol B: Vinylic protons; 6.63, 6.20, and 5.40. J_{7-8}=16 Hz. Moreover, the chemical shifts of four methyl groups in the former compound, δ=1.13, 1.81, 1.85, and 2.11, are in fair agreement with those of trisporol B; 1.11, 1.81, 1.89, and 2.08.

From these spectral data, the structure of our product was concluded to be the benzyl ether of the expected compound.

Complex Formation between Heptylviologen and Cyclodextrin

Masato KODAKA* and Toshio FUKAYA
National Chemical Laboratory for Industry, Tsukuba 305
(Received January 24, 1986)

Synopsis. Complex formation between heptylviologen (**1**) and cyclodextrins (α and β) was confirmed indirectly. The absorption and circular dichroism (CD) spectra of *p*-nitrophenolate aqueous solution containing α- or β-cyclodextrin were changed, when **1** was added to the solution. Contrary to **1**, methylviologen (**3**) did not give the spectral changes.

Methylviologen (**3**) has been widely used as an electron mediator (a relay compound) for hydrogen formation[1-3] and fixation of carbon dioxide.[4,5] Recently attention has been directed to viologens possessing hydrophobic groups. For example, their inclusion complexes with cyclodextrin (CD_x) increase the stability of the pyridinium moiety of the viologens to hydrogenation,[6] and the viologens are promising for electrochromic display applications.[7] Okuno et al. have estimated the complex formation between hydrophobic viologen and CD_x by the measurement of fluorescence quenching of excited $[Ru(bpy)_3]^{2+}$ by hydrophobic viologens.[6] In the case of viologens with aromatic groups, inclusion compounds can be detected by NMR and Raman spectroscopy, too.[6,7] For heptylviologen (**1**), however, the complex formation can not be detected by these spectroscopic analyses.[7]

3 R = CH_3, X = Cl

As described above, the detection of the inclusion compounds for viologens having hydrophobic groups other than aromatic ones is not so easy. In the present study, we have indirectly confirmed the complex formation between **1** and CD_x and estimated the dissociation constant.

Experimental

Heptylviologen (**1**) (Aldrich Chemical Co.), benzylviologen (**2**) (Sigma Chemical Co.), methylviologen (**3**) (Nakarai Chemicals), α-CD_x and β-CD_x (Nakarai Chemicals), tri-*O*-methyl-β-CD_x(Funakoshi Chemicals), *p*-nitrophenol (p-NP) (Wako Pure Chemical Industries), and tris(2,2′-bipyridyl)-ruthenium(II) chloride (Strem Chemicals) were used as supplied.

Absorption, circular dichroism (CD) and fluorescence spectra were taken on a JASCO UVIDEC-1 spectrophotometer, a JASCO J-20 spectropolarimeter and a JASCO FP-4 fluorescence spectrophotometer, respectively, using 10 mm cells at room temperature. All measurements were carried out at pH 9.5 (0.1 mol dm^{-3} $KHCO_3$–0.1 mol dm^{-3} Na_2CO_3 buffer solution).

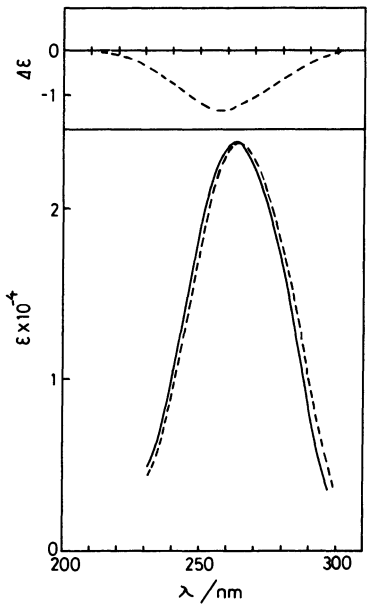

Fig. 1. Absorption and CD spectra of **1** (5×10^{-5} mol dm^{-3}) at pH 9.5.
Absorption: α-CD_x free (——); $[\alpha\text{-}CD_x]=4\times10^{-3}$ mol dm^{-3} (---).
CD: $[\alpha\text{-}CD_x]=4\times10^{-3}$ mol dm^{-3} (---).

Results and Discussion

As shown in Fig. 1, the absorption band of **1** was slightly red-shifted upon addition of α-CD_x. Corresponding to the change in the absorption spectrum, small negative Cotton effect was also observed in the CD spectrum, while **3** did not give any spectral changes. These results give the possibility that the hydrophobic chains of **1** should be included in the cavity of α-CD_x. Similar tendency was seen when β-CD_x was added into the solutions of **1** and **3** instead of α-CD_x. On the other hand, tri-*O*-methyl-β-CD_x caused little spectral change for **1**, suggesting that tri-*O*-methyl-β-CD_x has much smaller ability to form inclusion compounds.

To obtain more definitive evidence, we investigated the effect of **1** upon the absorption and CD spectra of p-NP in aqueous solution containing α-CD_x (Fig. 2). It should be noted that the addition of **1** caused appreciable changes in the spectra, which indicates that **1** undergoes complex formation with α-CD_x in competition with p-NP. On the other hand, **3** did not bring about the changes in the absorption and CD spectra. When β-CD_x was added instead of α-CD_x, similar spectral changes were observed upon addition of **1**. These findings suggest that the hydrophobic chains of **1** are included in α- or β-CD_x. The influence of tri-*O*-methyl-β-CD_x was not studied, for the spectral

CD: [α-CD$_x$]=2.5×10^{-3} mol dm^{-3}, 1 free (——); [α-CD$_x$]=2.5×10^{-3} mol dm^{-3}, [1]=5×10^{-3} mol dm^{-3} (····).

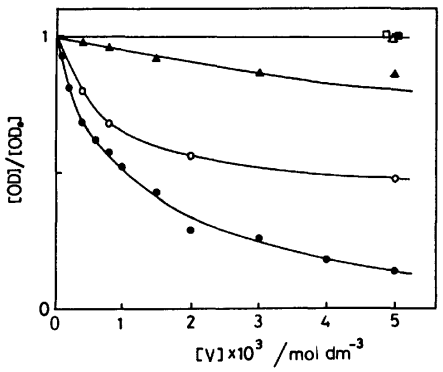

Fig. 3. Relation between relative absorbance ([OD]/[OD$_0$]) at 410 nm and concentration of various viologens ([V]) in *p*-nitrophenol/CD$_x$ solution (pH 9.5); [OD] and [OD$_0$] designate absorbance in the presence and absence of viologens, respectively.
[p-NP]=5×10^{-5} mol dm^{-3}, [CD$_x$]=5×10^{-4} mol dm^{-3}; 1/α-CD$_x$ (●), 1/β-CD$_x$ (○), 2/α-CD$_x$ (▲), 2/β-CD$_x$ (△), 3/α-CD$_x$ (■), 3/β-CD$_x$ (□).

changes of p-NP solution were small when it was added. Reasonable structure of 1/CD$_x$ (α and β) complex is shown below.

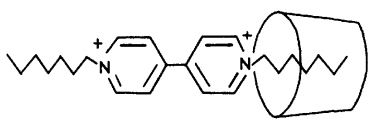

Figure 3 shows the changes in the relative absorbance of p-NP/CD$_x$ solution at 410 nm as a function of the concentration of the viologens. The results for benzylviologen (**2**) are also shown for comparison. It can be said from Fig. 3 that 1/CD$_x$ complex is more stable than 2/CD$_x$ one. From the relation in Fig. 3, we tried to estimate the dissociation constant of 1/α-CD$_x$ complex.

When the concentration of **1** is relatively higher than that of α-CD$_x$, the following two equilibriums can be expected to hold.

$$\text{p-NP} + \alpha\text{-CD}_x \rightleftarrows \text{p-NP}\cdot\alpha\text{-CD}_x \quad \text{[I]}$$

$$\mathbf{1} + \alpha\text{-CD}_x \rightleftarrows \mathbf{1}\cdot\alpha\text{-CD}_x \quad \text{[II]}$$

As the concentration of α-CD$_x$ (5×10^{-4} mol dm^{-3}) is much higher than that of p-NP (5×10^{-5} mol dm^{-3}), the dissociation constant of [I] (K_1) and that of [II] (K_2) are approximately described as follows.

$$K_1 = (p-x_1)(c-x_2)/x_1 \quad (1)$$

$$K_2 = (V-x_2)(c-x_2)/x_2 \quad (2)$$

p : total concentration of p-NP(5×10^{-5} mol dm^{-3}).
c : total concentration of α-CD$_x$(5×10^{-4} mol dm^{-3}).
V: total concentration of **1**.
x_1: concentration of p-NP·α-CD$_x$ complex.
x_2: concentration of **1**·α-CD$_x$ complex.

Eqs. 1 and 2 yield

$$K_2 = \frac{\{(p-x_1)(V-c) + K_1x_1\}x_1K_1}{\{c(p-x_1) - K_1x_1\}(p-x_1)}. \quad (3)$$

The x_1 value can be calculated from

$$x_1 = \Delta A/\Delta\varepsilon \quad (4)$$

where ΔA is the increase in the absorbance at 410 nm upon addition of CD$_x$ and **1** and $\Delta\varepsilon$ is the difference in the molar absorption coefficient between p-NP·α-CD$_x$ complex and p-NP. K_1 and $\Delta\varepsilon$ were obtained in a similar manner to that by Cramer et al.,[8] as to be 3.3×10^{-4} mol dm^{-3} and 3.4×10^{3} mol^{-1} dm^3 cm^{-1}, respectively. Therefore we could estimate K_2 from Eqs. 3 and 4 as a function of V (Fig. 4). K_2 was found to be approximately constant (ca. 2×10^{-4} mol dm^{-3}) under the conditions of $V>c$.

The complex formation between **1** and α- or β-CD$_x$ was also demonstrated by the measurement of fluorescence quenching of excited [Ru(bpy)$_3$]$^{2+}$ by **1** as reported by Okuno et al.[6] That is to say, Stern-Volmer constant ($k_q\tau$) in the presence of **1** (Fig. 5(a)) decreased much more than those in the presence of **2** or **3** (Fig. 5(b), (c)), when α- or β-CD$_x$ was added. However, tri-*O*-methyl-β-CD$_x$ did not essentially influence $k_q\tau$ values, probably due to the deficiency of ability to form inclusion complex.

As for the reduced form of **1** (cation radical), Yasuda et al. proposed an inclusion compound with β-CD$_x$, where it was more deeply situated in the cavity of β-CD$_x$.[7] Therefore we wish to mention some qualita-

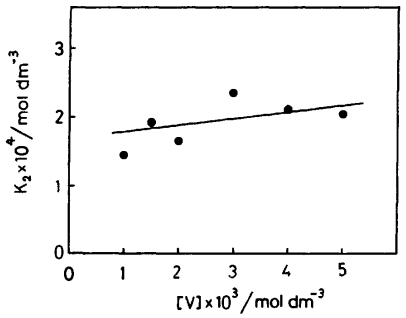

Fig. 4. Relation between dissociation constant (K_2) of 1/α-CD_x complex and concentration of 1 ([V]).

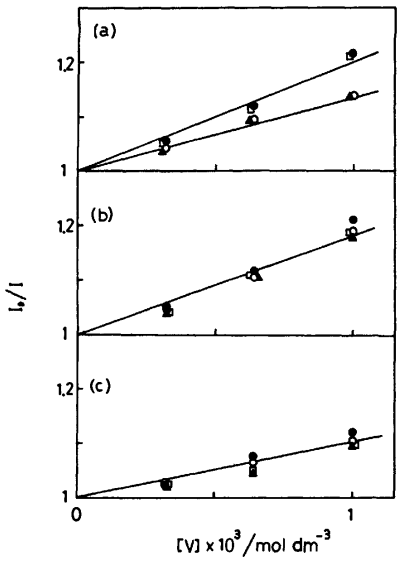

Fig. 5. Stern-Volmer plots for quenching of luminescence of $[Ru(bpy)_3]^{2+}$ (1×10^{-4} mol dm^{-3}) by viologen in the presence and absence of CD_x; (a) 1, (b) 2, (c) 3.
CD_x free (●), [α-CD_x]=2×10^{-3} mol dm^{-3} (○), [β-CD_x]=2×10^{-3} mol dm^{-3} (▲), [tri-*O*-methyl-β-CD_x]=2×10^{-3} mol dm^{-3} (□).

tive results about the reduced form of 1. When 1 was reduced with sodium dithionite ($Na_2S_2O_4$), the reduced form of 1 (purple) was precipitated in aqueous solution. In the presence of α- or β-CD_x, however, the aqueous solution of 1 turned blue by $Na_2S_2O_4$ without precipitation. Moreover, when p-NP was added to the above solution, the reduced form of 1 was again precipitated. On the other hand, when *o*-nitrophenol which is scarcely included in CD_x was added to the solution instead of p-NP, the precipitate was not formed. The findings mentioned above suggest that the reduced form of 1 is also included in α- or β-CD_x.

In the present study, the complex formation between 1 and α- or β-CD_x was definitely confirmed and the dissociation constant of the complex (1·α-CD_x) was estimated by making use of the competitive binding of 1 and p-NP with CD_x. The indirect method as shown in the present study will be useful, when the spectroscopic analyses such as absorption, NMR and Raman spectroscopy do not give fruitful information about the complex formation.

(Received January 6, 1986)

Synopsis. The coupling reaction of Grignard reagents with α,ω-dibromoalkanes took place smoothly in THF/HMPA (12:1) in the presence of a catalytic amount of copper(I) bromide and gave the products in 60—100% yields. Several α,ω-bis(vinylaryl)alkanes were prepared in reasonable yields by the application of this reaction.

The coupling reaction of Grignard reagents with alkyl halides has been known to be induced by many transition metal halides[1-5] and sometimes to proceed without catalysts.[6] Recently we have found a facile coupling reaction of Grignard reagents with α,ω-dibromoalkanes in THF in the presence of a catalytic amount of copper(I) bromide and a small amount of HMPA. Our method gives comparable or even better yields in some cases than those using Tamura-Kochi's catalyst Li_2CuCl_4,[5,7] and we have successfully applied it to the preparation of several α,ω-bis(vinylaryl)alkanes of recent interest.[8,9]

$$ArMgBr \xrightarrow[CuBr/HMPA,\ THF]{Br(CH_2)_nBr} Ar(CH_2)_nBr + Ar(CH_2)_nAr \quad (1)$$

Results are summarized in Table 1. The reverse addition of the Grignard reagent and the use of copper(I)-HMPA as catalyst are essential for this coupling. Without the catalyst, the reaction gave products in much poorer yields. In the present method, only a small amount of HMPA is enough for dissolving copper(I) bromide and the recommended volume ratio of THF/HMPA is 12. Although the copper-catalyzed Grignard coupling is wellknown,[1,4,5,7] the present procedure seems to be more useful than the previous ones for the coupling of arylmagnesium halide because of its simplicity, comparatively high yields of products, and easy availability of necessary chemicals.

The reaction was successfully applied to the synthesis of several styrene derivatives which are less easily accessible by other methods based on Friedel-Crafts acylation of diarylalkanes.[8] The reaction sequence for the synthesis of α,ω-bis(*m*-vinylphenyl)alkanes **5** and **6** is shown in Eq. 2, and results of the preparations of diolefins **5** to **9** from the corresponding Grignard reagents **1** to **4** are summarized in Table 2.

Although compound **9** may be prepared through

the Friedel–Crafts acetylation of 1,3-bis(4-biphenylyl)-propane derived from a poorly soluble aldol condensation product, 1,3-bis(4-biphenylyl)propenone, the present sequence allows its synthesis more conveniently, being carried out in a homogeneous system.

Experimental

^{1}H NMR spectra were recorded on Varian T-60A and XL-200 NMR spectrometers in $CDCl_3$ with tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi M-80A mass spectrometer. GLC analyses were done by a Shimadzu GC-4CIT gas chromatograph (OV-17, 3%, 2 m, 250—300°C). Melting points were not corrected. Tetrahydrofuran was dried with benzophenone ketyl and distilled just before use. HMPA was heated over calcium hydride for prolonged time under a nitrogen atmosphere, then distilled in vacuo and stored over molecular sieves (3A) under the same atmosphere. Commercial copper(I) bromide of highest grade was used without purification.

Coupling Reaction of Arylmagnesium Bromide with α,ω-Dibromides (General Procedure). Grignard reagent **1** was prepared in dry THF (600 ml) from *m*-bromoacetophenone ethylene acetal (130 g, 0.552 mol) and Mg turnings (16.1 g, 0.662 mol) under a nitrogen atmosphere.[10] After the completion of reaction excess Mg turnings were removed[11] and the solution was added dropwise over 1 h to a vigorously stirred mixture of dry HMPA (50 ml), 1,3-dibromopropane (55.7 g, 0.552 mol),[12] and copper(I) bromide (1.98 g, 5 mol% to the Grignard reagent) under reflux. The dark green mixture was refluxed for further 4 h with stirring, then poured into ice–HCl mixture (500 ml) to decompose organometallic compounds. The aqueous phase was extracted with benzene three times. The combined extracts were washed successively with water three times, with aq NaOH, and again with water. The mixture was dried over Na_2SO_4 and then condensed by evaporation. The residue was distilled in vacuo; *m*-(3-bromopropyl)acetophenone ethylene acetal was obtained as a thick oil in a 33.8% yield (45.4 g, 103°C/0.05 mmHg) and 1,3-bis(*m*-acetylphenyl)propane bis(ethylene acetal) as a solid residue (mp, 95—96°C) in a 60.4% yield (59.0 g).

Preparation of 1,3-Bis(*m*-vinylphenyl)propane 5 (Typical Procedure). The above bis-adduct (59.0 g) was dissolved in dioxane (500 ml) without further purification. To this solution 10% aq HCl (500 ml) was added and the mixture was stirred overnight at room temperature. The reaction mixture was extracted with benzene three times, then the combined extracts were washed with aq $NaHCO_3$ followed by water three times, dried over Na_2SO_4, and condensed by evaporation to give 1,3-bis(*m*-acetylphenyl)propane. The diketone was reduced by $LiAlH_4$ in ether and the glycol obtained was purified by column chromatography (SiO_2, cyclohexane/AcOEt=4:1—1:1). The overall yield was 43.1 g (95.5%). The glycol (4.00 g) was dehydrated by the reported method[13] to afford 1,3-bis(*m*-vinylphenyl)propane **5**, which was purified by column chromatography (SiO_2, petroleum ether/cyclohexane).[14] Yield was 2.31 g (78.0%).

Support by a Grant-in-Aid for Special Project Research (No 60035037) from the Ministry of Education, Science and Culture is gratefully acknowledged.

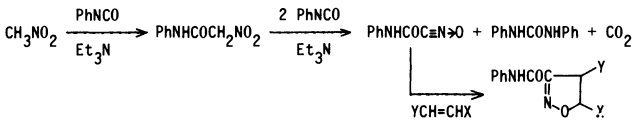
Reaction of Nitromethane with Aryl Isocyanates in the Presence of Triethylamine. A Formation of 1,3-Diaryl-5-(hydroxyimino)-imidazolidine-2,4-diones

Tomio SHIMIZU,* Yoshiyuki HAYASHI, and Kazuhiro TERAMURA
Department of Color Chemistry and Technology, Faculty of Industrial Arts, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received December 18, 1985)

Synopsis. 1,3-Diaryl-5-(hydroxyimino)imidazolidine-2,4-diones were obtained from the reactions of nitromethane with several aryl isocyanates in the presence of a trace amount of triethylamine and their structures were established from spectroscopic evidence and their chemical behavior.

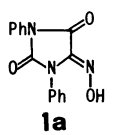
Many preparative methods of nitrile oxides by dehydration of primary nitro compounds have been known.[1-5] One of the most useful methods consists of the use of phenyl isocyanate as the dehydrating agent in the presence of a catalytic amount of triethylamine.[2a] While the reaction has been applied successfully to various types of primary nitro compounds, the reaction takes a slightly different course with nitromethane since nitromethane reacts with phenyl isocyanate to give α-nitroacetanilide.[2c] In fact, 2-isoxazoline-3-carboxanilides are formed via a cyanoformanilide *N*-oxide from the reaction of nitromethane with phenyl isocyanate in the presence of olefins and trace of triethylamine.[2c] We investigated the reaction



in expectation of obtaining a furazandicarboxanilide 2-oxide, a dimer of the cyanoformanilide *N*-oxide, in the absence of dipolarophiles. Though we could isolate none of the desired furazan oxides from the reaction mixture, we could isolate an unexpected and interesting compound. We report here the reaction in detail.

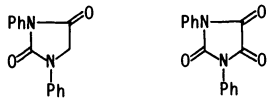
Results and Discussion

Treatment of an ethereal solution of nitromethane with two equivalents of phenyl isocyanate in the presence of a few drops of triethylamine gave colorless crystals (**1a**) in 27% yield besides a large amount of *N,N'*-diphenylurea and a small amount of phenyl isocyanate dimer. The structural assignment of **1a** as 5-(hydroxyimino)-1,3-diphenylimidazolidine-2,4-dione was based on the following results. The molecular ion



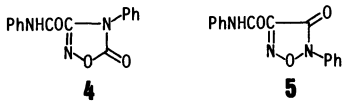
1a

peak (281.080) in the high resolution mass spectrum and the elemental analysis suggest its molecular formula as $C_{15}H_{11}N_3O_3$, formally a combination of 2 moles of phenyl isocyanate and one mole of formonitrile oxide (HCNO). Two singlets (δ 7.50 and 7.55) based on the protons of two phenyl groups and an acidic proton (δ 11.9) observed in the NMR spectrum and the formation of *N,N'*-diphenylurea by hydrolysis with ethanolic NaOH also suggested the structure of **1a**. 1,3-Diphenylimidazolidine-2,4-dione (**2**) and 1,3-diphenylimidazolidine-2,4,5-trione (**3**) were prepared by methods given in literatures for comparison. A sin-

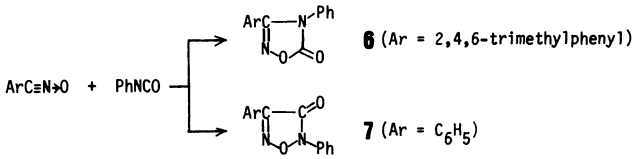


2 **3**

glet peak at δ 7.50 of phenyl protons of **3** in the NMR spectrum agreed well with that of **1a**. The product (**1a**) and the model compound (**3**) displayed carbonyl absorption peak in the IR spectra at a similar position (1730—1740 cm^{-1}). The structures of oxadiazole (**4** and **5**) are identical with those of the compounds expected from the 1,3-dipolar cycloaddition reaction of cyanoformanilide *N*-oxide with phenyl isocyanate.



4 **5**



The formation of analogous oxadiazoles (**6** and **7**) has been known in the reaction of aromatic nitrile oxides with phenyl isocyanate.[6] The possibility of the structures (**4** and **5**) for the product could be ruled out by the evidence that **6** and **7** showed its carbonyl absorption at 1770[6a] and 1720 cm^{-1},[6b] respectively. The structure (**1a**) for the product was also supported by the formation of *O*-acyl oximes (**8**) by the acylation with several acyl halides. The compounds (**8**) showed an absorption of ester group at 1770 cm^{-1} in their IR spectra which agreed well with the *O*-acyl oxime structure and not with *N*-acylated compounds (ureas) of **4** and **5**. The chemical shifts of the alkyl protons in the acyl group of **8** appeared at a field higher than that of normal ones in the NMR spectra, and the effect may be ascribed to *Z*-configuration of *O*-acyl oximes.

Analogous oximes (**1b** and **1c**) and the O-acyl oxi-

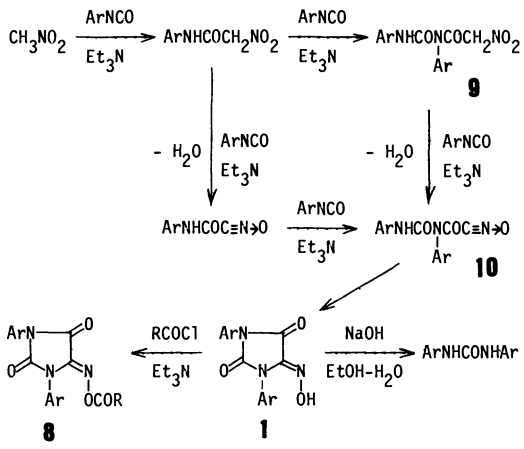
a) Yields of compounds (**1a**—**c**) were calculated on the basis of the aryl isocyanates. In the case of **8f**, the corresponding **1** (Ar=Tol-*p*) could not be isolated in crystalline state and the yield of **8f** is shown in over all yield from the isocyanate.

mes (**8f** and **8g**) were prepared by the reactions of nitromethane with some of aryl isocyanates and following acylation of the products. The results are shown in Table 1.

The mechanism of the formation of the oximes (**1**) is shown in Scheme 1; successive addition of aryl isocyanates to nitromethane gives *N*-(nitroacetyl)-*N,N'*-diarylureas (**9**), which undergo dehydration by the action of ArNCO/Et_3N to give nitrile oxides (**10**) and then, the nitrile oxides undergo intramolecular cyclization giving **1**. A similar addition of amines to nitrile oxides is well-known.[7]



Scheme 1.

Experimental

Measurements. All melting points are uncorrected. The ^1H NMR spectra were measured on a Varian T-60A instrument with Me_4Si as an internal standard; chemical shifts are given in δ units and coupling constants (J) are in herz units: s=singlet; t=triplet; q=quartet; m=multiplet; br=broad singlet. The IR spectra were determined on a Hitachi 215 infrared spectrophotometer. The high-resolution mass spectra were measured on a Hitachi M-80 mass spectrometer. A part of these spectral data for all new compounds (**1** and **8**), 1,3-diphenylimidazolidine-2,4-dione (**2**), 1,3-diphenylimidazolidine-2,4,5-trione (**3**), 4-phenyl-3-(2,4,6-trimethylphenyl)-1,2,4-oxadiazol-5(4*H*)-one (**6**), and 2,4-diphenyl-1,2,5-oxadiazol-3(2*H*)-one (**7**) are shown in Table 2. All new products gave satisfactory elemental analyses (±0.3% for C, H, and N).

Materials. Nitromethane and isocyanates were commercially available and were without further purification. 1,3-Diphenylimidazolidine-2,4-dione (**2**)[8] and 1,3-diphenylimidazolidine-2,4,5-trione (**3**)[9] were prepared according to the methods described in the literatures.

Reactions of Nitromethane with Aryl Isocyanates. Typical Procedure. A few drops of triethylamine were added to a stirred dry ethereal solution (100 ml) of nitromethane (0.1 mol, 6.1 g) and phenyl isocyanate (0.2 mol, 24 g) at room temperature and the mixture was refluxed until an evolution of carbon dioxide ceased (ca. 6 h). Upon cooling to room temperature, a white solid crystallized out of the solution was filtered off. This colorless crystalline solid is a mixture of *N,N'*-diphenylurea, 5-(hydroxyimino)-1,3-diphenylimidazolidine-2,4-dione (**1a**), and phenyl isocyanate dimer. Upon exposing to atmosphere, the colorless products yellowed gradually at the surface owing to the presence of small amount of phenyl isocyanate dimer. The phenyl isocyanate dimer and a large part of **1a** could be extracted together with a small amount of *N,N'*-diphenylurea from the crystalline mixture by a Soxlet extractor using ethyl acetate. After evaporation of the solvent, the residual crystals were mixed with 100 ml of ethanol and the mixture was refluxed for 6 h for the purpose of conversion of phenyl isocyanate dimer into ethyl *N,N'*-diphenylallophanate[10] which shows better solubility in benzene than phenyl isocyanate dimer. Then, the solvent was evaporated and the crystalline residue was recrystallized from benzene to give analytically pure **1a**. The yields and melting points were shown in Table 1 along with those of analogous compounds prepared from similar reactions of nitromethane with other aryl isocyanates. Using a stoichiometric amount (0.4 mol) of phenyl isocyanate for the reaction, the yield of **1a** was not so varied.

Acylation of 1 with Acyl Chlorides. Typical Procedure. Seven mmol of acyl chloride was added to a stirred benzene solution (80 ml) of **1** (3.5 mmol) and triethylamine (7 mmol) at room termperature. The mixture was refluxed for 4 h and, then, washed with water several times. Evaporation of the solvent from the reaction mixture in a rotary evap-

a) Compounds (**1b**, **8c**, **8d**, **8f**, and **2**) were dissolved in $CDCl_3$, the others were dissolved in DMSO-d_6. b) Spectral data of these compounds was cited from ref. 6.

orator gave crude crystalline product. The crude product was recrystallized from ethanol to give pure material of 5-(acyloxyimino)-1,3-diarylimidazolidine-2,4-dione (**8**) in the yields shown in Table 1.

Hydrolysis of 1a with Ethanolic NaOH. To a solution of sodium hydroxide (200 mg, 5 mmol) in 90% aqueous ethanol (50 ml) we added 280 mg (1 mmol) of **1a**, after which the mixture was stirred for 1 h at 50 °C. After evaporation of the solvent from the reaction mixture, the residue was treated with water and extracted with chloroform (100 ml). The organic layer was dried over anhydrous sodium sulfate. The evaporation of the solvent yielded *N,N'*-diphenylurea in 71% (150 mg) yield.

(Received February 21, 1986)

Synopsis. To investigate the role of the side chain of the 2,3-dehydroalanine (ΔAla) residue at position 4 in a cyclic tetradepsipeptide phytotoxin AM-toxin I on necrotic activity for apple leaf, [2-amino-2,3-dehydrobutanoic acid[4]] AM-toxin I was synthesized by two different routes. This analog showed no toxic activity, indicating that the side chain of the ΔAla residue can not be handled without loss of the activity.

AM-toxin I is a host-specific phytotoxic metabolite produced by *Alternaria mali*, which causes spot disease on apple leaf. The structure of AM-toxin I is a cyclic tetradepsipeptide containing a ΔAla[2] residue as shown in Fig. 1.[3] We have synthesized various analogs of AM-toxin I in order to study the relationship between structure and function (host-specific toxicity) of the toxin. According to our previous results,[4-8] for the induction of the full toxic activity, AM-toxin I requires factors such as specific ring conformation, the presence of the L-Hmb[2] and L-Amp[3] residues, and a double bond in the ΔAla[4] residue. However, significance of bulkiness of the side chain in the ΔAla[4] residue has not yet been explored. Thus, we synthesized an AM-toxin I analog (**1**) containing Δ^{Z}Abu which has a methyl group instead of a hydrogen atom in ΔAla (Fig. 1) and examined the activity of **1**.

Two synthetic routes for the cyclic peptide (**1**) are shown in Fig. 2. According to the successful synthesis of AM-toxin III and AM-toxin I analogs[6-9] using a D-amino acid residue as the precursor of ΔAla at the *N*-terminal of linear intermediates, a linear tetradepsipeptide, H-D-Thr-L-Ala-L-Hmb-L-Amp-ONSu (**6**), was selected as the precursor for the cyclization reaction. Lee et al.[10] reported that an L-Thr residue was converted to a Δ^{Z}Abu residue by the Photaki method[11] and Δ^{E}Abu was prepared similarly from an L-aThr residue, indicating that the D-Thr residue can be similarly converted to the Δ^{Z}Abu residue after cyclization. On the other hand, Ueda et al.[12] reported that cyclization of a linear tetradepsipeptide containing an L-Ser(Bzl) residue as the precursor of ΔAla residue at the *N*-terminal gave a desired cyclic tetradepsipeptide in high yield comparable to that of cyclization of a precursor containing a D-Ser residue.[13] Therefore, we also synthesized H-L-Thr(Bzl)-L-Ala-L-Hmb-L-Amp-ONSu (**7**) as a precursor of the cyclic peptide. Boc-D-Thr(or L-Thr(Bzl))-ONSu was coupled with H-L-Ala-L-Hmb-L-Amp-OH[6] to give Boc-D-Thr (or L-Thr(Bzl))-L-Ala-L-Hmb-L-Amp-OH (**2** or **3**).

	R	X
AM-toxin I	H	ΔAla
[Δ^{Z}Abu[4]]AM-toxin I (**1**)	CH_3	Δ^{Z}Abu

Fig. 1. Structure of AM-toxin I and [Δ^{Z}Abu[4]]AM-toxin I.

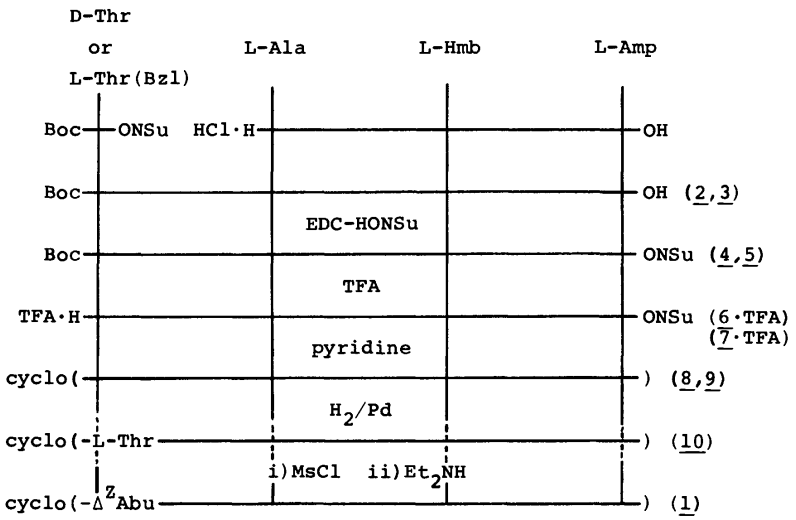

Fig. 2. Synthesis of [Δ^{Z}Abu[4]]AM-toxin I. H_2/Pd procedure was applied to L-Thr(Bzl) derivative (**9**).

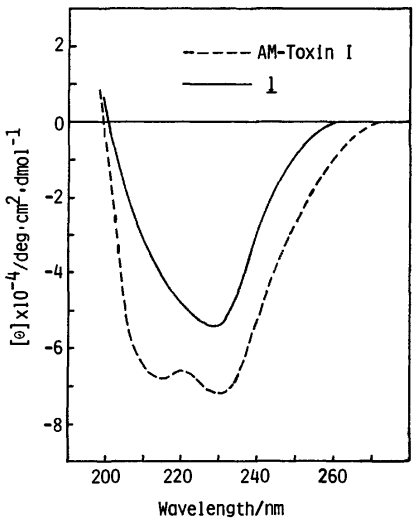

Fig. 3. CD spectra of AM-toxin I and [Δ^ZAbu^4]AM-toxin I in MeOH.

After the conversion of **2** and **3** to the corresponding active ester trifluoroacetates (**6**·TFA and **7**·TFA), their cyclizations at a concentration of 3 mM in pyridine gave cyclic peptides (**8** and **9**) in yields of 47 and 33%, respectively. The benzyl group of **9** was removed by catalytic hydrogenation. Both compounds **8** and **10** were treated with methanesulfonyl chloride and followed by diethylamine to give desired **1**. This was purified by silica-gel column chromatography followed by recrystallization. Although the yield in cyclization of **6** (D-Thr derivative) was higher than that of **7** (L-Thr(Bzl) derivative), compound **9** was converted to **1** in higher yield (16%) compared with **8** (7.2%). Noticeable difference was not observed between the total yields of **1** from **2** and **3**. Configuration of ΔAbu^4 in **1** was identified as Z form by means of ^{1}H NMR chemical shift of methyl proton in ΔAbu (1.7 ppm) compared with that reported by Lee et al.[10] (1.73 ppm for Z form and 2.05 ppm for E form).

CD spectra of **1** and AM-toxin I in methanol are shown in Fig. 3. Although AM-toxin I showed two negative ellipticity minima at 210 and 230 nm, **1** showed only a minimum at 230 nm. This result indicates that the conformation of **1** slightly differs from that of AM-toxin I.

Although minimum toxic activity of AM-toxin I for the induction of necrosis on an apple leaf (Indo) was 0.001 μg ml^{-1}, **1** did not show any toxicity at the concentration of 100 μg ml^{-1}. These results indicate that increasing the bulkiness of the side chain in the ΔAla^4 residue may result in alteration of the conformation of analog **1** and cause loss of the activity. This inactivity may also be due to the result that the unsaturated side chain of the ΔAbu residue in **1** can not react with a receptive substance in an apple leaf differing from the ΔAla residue in AM-toxin I. Combined with the results of no or very little activity of [L- or D-Ala^4]AM-toxin I,[4] the ΔAla residue in this toxin is certainly essential to induce the activity. Phytotoxic tentoxin is a cyclic tetrapeptide containing a *N*-Me-ΔPhe residue[14] and an antibacterial heptapeptide TL-119 contains a Δ^ZAbu residue in its cyclic tetrapeptide part.[15] Since the Δ^ZAbu residue in **1** can not be used as a substitute for the ΔAla residue in AM-toxin I, roles of the dehydroamino acid residues in these peptides on interactions with their receptive substances seem to be different from that of the ΔAla residue in AM-toxin I.

Experimental

Thin layer chromatography was carried out on Merck silica gel G with the following solvent systems: R_f^1,$CHCl_3$–MeOH (5:1); R_f^2, $CHCl_3$–MeOH (9:1); R_f^3, $CHCl_3$–MeOH–AcOH (95:5:1); R_f^4, $CHCl_3$–acetone (1:1). Optical rotation was measured with a Union high sensitivity polarimeter PM-71. Mass spectra were taken on a Nihondenshi mass spectrometer Model JMS-01SG-2 with a direct inlet system operating at 75 eV, CD on a JASCO J-40A spectropolarimeter, and ^{1}H NMR on a Jeol JNM-FX90Q.

Boc–D-Thr–L-Ala–L-Hmb–L-Amp–OH (2). To a solution of H–L-Ala–L-Hmb–L-Amp–OH·HCl[6] (410 mg, 0.95 mmol) and Et_3N (0.27 ml, 1.9 mmol) in a mixture (10 ml) of H_2O and dioxane (1:1) was added Boc–D-Thr–ONSu (250 mg, 0.8 mmol). The mixture was stirred at room temperature overnight. After evaporation, 10% citric acid was added to the residue. The separated oil was extracted with EtOAc, and the solution was washed with water and dried over Na_2SO_4. After evaporation, the product was obtained as an oil: Yield, 340 mg (72%); R_f^1=0.57.

Boc–L-Thr(Bzl)–L-Ala–L-Hmb–L-Amp–OH (3). Compound **3** was prepared from Boc–L-Thr(Bzl)–ONSu (610 mg, 1.5 mmol) and H–L-Ala–L-Hmb–L-Amp–OH·HCl[6] (780 mg, 1.8 mmol) as described for **2**. Compound **3** was crystallized from EtOAc–ether–petroleum ether: Yield, 800 mg (77%); mp 85—87 °C; $[\alpha]_D^{20}$ −7.2° (*c* 0.5, DMF); R_f^1=0.49. Found: C, 62.17; H, 7.50; N, 6.13%. Calcd for $C_{36}H_{51}N_3O_{10}\cdot 1/2H_2O$: C, 62.23; H, 7.54; N, 6.05%.

Boc–D-Thr–L-Ala–L-Hmb–L-Amp–ONSu (4). To a chilled solution of **2** (300 mg, 0.5 mmol) and HONSu (115 mg, 1.0 mmol) in DMF (3 ml) was added EDC·HCl (192 mg, 1.0 mmol). The mixture was stirred at 0 °C for 24 h. After evaporation, the residue was solidified by the addition of cold water and dried in vacuo: Yield, 320 mg (92%); R_f^1= 0.71. This was used to the next step without purification.

Boc–L-Thr(Bzl)–L-Ala–L-Hmb–L-Amp–ONSu (5). Compound **5** was prepared from **3** (690 mg, 1.0 mmol) as described for **4**: Yield, 770 mg (98%); R_f^2=0.70.

***cyclo*(–L-Ala–L-Hmb–L-Amp–D-Thr–) (8).** A solution of **4** (320 mg, 0.45 mmol) in TFA (2 ml) was allowed to stand at 0 °C for 30 min. After evaporation, the residual oil was solidified by the addition of ether. The powder was washed several times with ether by decantation to give H–D-Thr–L-Ala–L-Hmb–L-Amp–ONSu·TFA (**6**·TFA). This was dissolved in DMF (5 ml) and the solution was added dropwise into pyridine (130 ml) with stirring at room temperature. The stirring was continued for 3 d and the reaction mixture was evaporated. The residue was collected with the aid of water, and washed with 10% citric acid and water. This was recrystallized from DMF–EtOAc–ether; yield, 100 mg (47%); mp 242—244 °C (decomp); MS *m/z* 477 (M^+); R_f^1=0.76, R_f^2= 0.47. Found: C, 59.77; H, 7.38; N, 8.65%. Calcd for $C_{24}H_{35}N_3O_7\cdot 1/3H_2O$: C, 59.61; H, 7.36; N, 8.69%.

***cyclo*(–L-Ala–L-Hmb–L-Amp–L-Thr(Bzl)–) (9).** Compound **9** was prepared from **5** (780 mg, 1.0 mmol) as described for **8**. This was recrystallized from DMF–EtOAc: Yield, 190 mg (33%); mp 208—210 °C (decomp); MS *m/z* 567 (M^+); R_f^2=0.72, R_f^3=0.33. Found: C, 64.66; H, 7.14; N, 7.43%. Calcd for $C_{31}H_{41}N_3O_7\cdot 1/2H_2O$: C, 64.57; H, 7.34; N, 7.29%.

***cyclo*(-L-Ala-L-Hmb-L-Amp-Δ^ZAbu-) ([Δ^ZAbu^4]AM-toxin I, 1) from D-Thr Derivative (8).** To a chilled solution of **8** (67 mg, 0.14 mmol) in pyridine (3 ml) was added MsCl (0.055 ml, 0.7 mmol). After 24 h at 4°C, the solution was evaporated. The residue was solidified by the addition of cold water and washed with ether–petroleum ether (1:1) to give a powder of *cyclo*(-L-Ala-L-Hmb-L-Amp-D-Thr(Ms)-) (11): Yield, 69 mg (89%); R_f^2=0.82. This structure was confirmed by ^{1}H NMR spectrum. To a solution of 11 in DMF (1 ml) was added Et_2NH (0.026 ml, 0.26 mmol) at room temperature. The mixture was allowed to stand for 24 h at room temperature. After evaporation, the residue was solidified by the addition of cold water. This crude product (57 mg) was applied to a silica-gel column (1.1×27 cm) and eluted with $CHCl_3$–CH_3CN (1:1). The fraction was pooled and evaporated. The residue was recrystallized from EtOAc–petroleum ether: Yield, 4.6 mg (7.2%); mp 220—222°C (decomp); MS *m/z* 459 (M^+); R_f^2=0.38, R_f^4=0.34. Found: C, 62.50; H, 7.17; N, 9.21%. Calcd for $C_{24}H_{33}N_3O_6$: C, 62.72; H, 7.24; N, 9.14%.

[Δ^ZAbu^4]AM-toxin I (1) from L-Thr(Bzl) Derivative (9): Compound **9** (100 mg, 0.18 mmol) in DMF (25 ml) was hydrogenated for 4 h in the presence of Pd-black. After removal of the catalyst, the filtrate was evaporated and the residue was solidified by the addition of ether to give a powder of *cyclo*(-L-Ala-L-Hmb-L-Amp-L-Thr-) (**10**): Yield, 86 mg (100%); R_f^1=0.50. Compound **10** was treated with MsCl and Et_2NH, and then purified with a silica-gel column to give **1**; Yield, 13 mg (16%). This was identified to that obtained from **8** by mp, TLC and ^{1}H NMR spectrum.

We thank Dr. H. Nishikawa, Fukuoka University, for the measurement of CD spectra.

Practical Synthesis of 1,1′-Binaphthyl-2-carboxylic Acids via Side Chain Oxidation of 2-Methyl-1,1′-binaphthyls

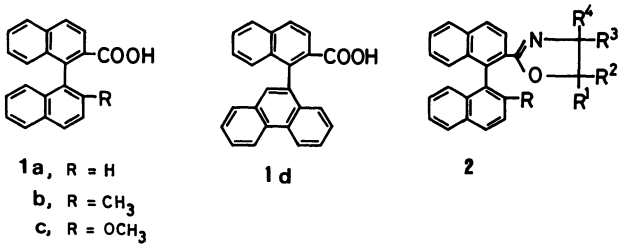
Sotaro MIYANO,* Shin-ichi OKADA, Toshiyuki SUZUKI,
Shigeru HANDA, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980
(Received January 29, 1986)

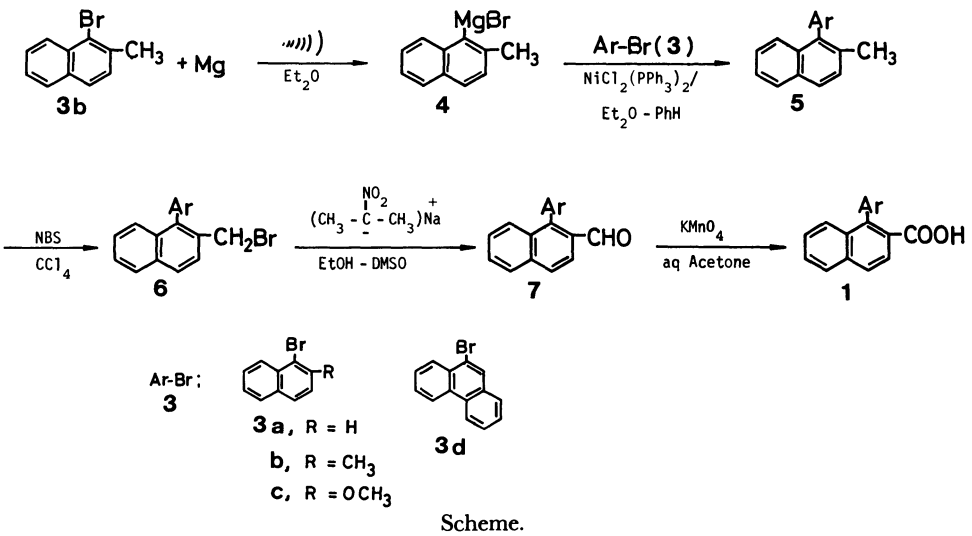
Synopsis. Four 1,1′-binaphthyl-2-carboxylic acids were obtained in 38—53% isolated yield via three-stage oxidation of 2-methyl-1,1′-binaphthyls, that is, i) NBS-bromination to benzylic bromides, ii) treatment with sodium salt of 2-nitropropane to aldehydes, and iii) $KMnO_4$-oxidation to carboxylic acids.

In the past few years, there has been an intense interest in the asymmetric reactions by means of atropisomeric binaphthyls as the chirality recognizing units.[1] The main obstacle in carrying out these reactions, however, has been the difficulty to obtain the requisite axially chiral binaphthyl skeletons.[2] In this context, 1,1′-binaphthyl-2-carboxylic acids **1** are intriguing as the starting material for elaboration of such chiral auxiliaries, considering that the carboxyl substituent should be the most helpful resort for not only optical resolutions[3] but also transformations into various functionalities.[4] Actually, Goto et al. have shown that **1b** is useful for preparation of the derivatizing agents for liquid chromatographic resolution of enantiomeric hydroxy compounds.[5] Their preparation of **1b**, however, suffered from tedious manipulations which involved the synthesis of intermediate dimethyl 1,1′-binaphthyl-2,2′-dicarboxylate. On the other hand, Meyers and Lutomski,[6] and Wilson and Cram[7] reported nucleophilic substitution of 2-oxazoline-activated 1-alkoxynaphthalenes by a naphthyl Grignard or lithium reagent to give 2-(1,1′-binaphthyl-2-yl)oxazolines **2**, which are latent binaphthyl-2-carboxylic acids. Although the procedure can be applied for the construction of axially chiral binaphthyl linkage by the use of a substrate bearing chiral alkoxyl or oxazoline group, hydrolytic regeneration of the carboxyl function from the sterically crowded **2** is not so much easy, and it is still highly-desirable to provide an alternative, operationally more simple route to **1**.

Herein we wish to report our approach to **1** which is outlined in Scheme.[8,9] Ultrasonic irradiation remarkably facilitated the reaction of **3b** with magnesium turnings in ether to form the Grignard reagent **4**. The Kumada-Tamao method[10] was successfully utilized to promote cross-coupling of **4** with bromonaphthalenes **3** to give 2-methyl-1,1′-binaphthyls **5**. The use of 1.5—1.7 molar amounts of **4** appeared to be ample excess not to leave unchanged **3**. After usual workup of the reaction, recrystallization or distillation gave pure samples of **5** (55—82% yield). The significant upfield shift of ^1H NMR of the methyl groups for **5** is consistent with the binaphthyl structure where these protons are disposed over the shielding cone of the adjacent naphthalene rings (see Experimental).

The methyl substituents of **5** were readily brominated by treatment with 1.1 equiv of *N*-bromosuccinimide (NBS) in boiling CCl_4 in the presence of a catalytic amount of benzoyl peroxide. Filtration of the precipitated succinimide from the cool reaction mixture and evaporation of the solvent left crude





Scheme.

benzylic bromides **6**, which in turn were treated with sodium salt of 2-nitropropane in DMSO–EtOH to give aldehydes **7** according to the method of Klanderman;[11] the conventional Sommelet oxidation did not work well for these bulky benzylic bromides.[12] Conversion of **7** to carboxylic acids **1** was effected by $KMnO_4$–oxidation in boiling aqueous acetone applying the method of Hall and Turner with slight modifications.[13] Pure samples of **1** were readily obtainable by recrystallization, and were characterized by elemental analysis and spectral studies.

Although the yields of **1** were moderate (38—53% based on **5**), we believe that the procedure is synthetically useful; the starting bromonaphthalenes are readily available, and any stage of the procedure does not necessarily require chromatographic purification, rendering it suitable for preparative scale synthesis of **1**.

Experimental

Materials. **3c** was prepared by treating 1-bromo-2-naphthol with NaH in DMF, followed by addition of methyl iodide and stirring overnight at room temperature, mp 85—86°C (lit,[7] mp 83—84°C). Commercial **3d** (mp 63°C) was stored over silica gel in vacuo, and **3a** was distilled before use, bp 149—152°C/16 mmHg.* **3b**[13] (bp 115—118°C/1.5 mmHg) and $NiCl_2(PPh_3)_2$[14] were prepared as described in the literature.

2-Methyl-1,1′-binaphthyls (5). The synthesis of **5d** is representative. The Grignard reagent **4** was prepared under nitrogen in a flask immersed in the water bath of an ultrasonic laboratory cleaner (53 W, 41 kHz).

To an ultrasonically irradiated mixture of magnesium turnings (7.00 g, 0.288 g-atom) in 50 ml of ether was added a solution of **3b** (37.7 g, 0.171 mol) in ether (200 ml) over 1-h period; addition of a few drops of the bromide started the reaction quite readily, which was evidenced by clouding of the ether layer with a change of the magnesium surface from dull grey to metallic. During the addition, the temperature of the water bath was allowed to rise with sonication, which kept the reaction at rapid reflux. After the addition was complete, the sonication was continued for another 2 h. The Grignard reagent was obtained as a slightly yellow slurry, which was dissolved by adding 200 ml of benzene.

The Grignard solution was transferred to another dropping funnel by means of a cannula, and then added dropwise to a magnetically stirred solution of **3d** (26.0 g, 0.101 mol) and $NiCl_2(PPh_3)_2$ (0.655 g, 1 mol% of **3d**) in 150 ml of benzene at room temperature over 1-h period. After stirred overnight at room temperature, the mixture was heated at reflux for 3 h, and then bulk of the ether was distilled off through a short Vigreux column. The cooled reaction mixture was worked up as usual.[10] Solvents were removed in vacuo, and the residue was heated up to 150°C (bath temp) at 0.1 mmHg to remove volatiles comprised mainly of 2-methylnaphthalene. The crude product was dissolved in hexane, and passed through a silica-gel pad to remove colored materials. Evaporation of the solvent and crystallization from ethanol–acetone (9:5) gave pure **5d**, 26.5 g (82%); mp 145—148.5°C; IR (KBr) 3050, 1450, 1420, 810, 740, and 720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.15 (3H, s, $-CH_3$),[15] 7.0—8.1 (13H, m, Ar-H), and 8.6—8.9 (2H, m, Ar-H). Found: C, 94.39; H, 5.93%. Calcd for $C_{25}H_{18}$: C, 94.30; H, 5.70%.

5a: **4** was prepared from 2.02 g (9.14 mmol) of **3b**, allowed to react with **3a** (1.09 g, 5.27 mmol), and worked up as above. Recrystallization from hexane gave 1.11 g (79%) of **5a** which melted at 86.0—88.0°C to an opaque liquid that cleared at ca. 103°C (lit,[16] mp 120—122°C)[17]; IR (KBr) 3050, 1500, 1360, 800, 780, and 740 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.10 (3H, s, $-CH_3$) and 7.0—8.1 (13H, m, Ar-H). Found: C, 94.21; H, 6.08%. Calcd for $C_{21}H_{16}$: C, 93.99; H, 6.01%.

5b: **4** was prepared from 4.55 g (20.6 mmol) of **3b**, and then allowed to react with another 2.78 g of **3b** (12.6 mmol). Trap-to-trap distillation gave 2.17 g (61%) of **5b** as a colorless glass; bp≈200°C (bath temp)/1 mmHg (lit,[2a] 190—210°C/0.2 mmHg); ^1H NMR ($CDCl_3$) δ=1.95 (6H, s, $-CH_3\times$ 2), 6.8—8.0 (12H, m, Ar-H). Found: C, 93.21; H, 6.11%. Calcd for $C_{22}H_{18}$: C, 93.58; H, 6.42%.

5c: **4** was prepared from 2.49 g (11.3 mmol) of **3b** and allowed to react with **3c** (1.45 g, 6.12 mmol). Crystallization from hexane gave 1.00 g (55%) of **5c**; mp 118—121°C; IR (KBr) 3050, 1620, 1570, 1240, 800, and 730 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.0 (3H, s, $-CH_3$), 3.64 (3H, s, $-OCH_3$), 6.7—8.0 (12H, m, Ar-H). Found: C, 89.01; H, 6.14%. Calcd for $C_{22}H_{18}O$: C, 88.56; H, 6.08%.

Oxidation of 5 to 1,1′-Binaphthyl-2-carboxylic Acids 1. The synthesis of **1d** is representative. A mixture of **5d** (3.18 g, 10.0 mmol), NBS (1.96 g, 11.0 mmol), and benzoyl peroxide (0.1 g) in CCl_4 (70 ml) was magnetically stirred and heated at reflux for 3 h, during which almost all of **5d** had disappeared as evidenced by ^1H NMR. Precipitated succinimide was filtered off from the cool mixture, and volatiles were removed in vacuo to give crude **6d**; δ ($-CH_2Br$)/(CCl_4-$CDCl_3$)=4.09 (1H, d, J=10.3 Hz) and 4.33 (1H, d).

The bromide was dissolved in 60 ml of DMSO under nitrogen. To the stirred solution was added slowly (0.5 h) a solution prepared by adding 3.25 g (36.5 mmol) of 2-nitropropane to a sodium ethoxide in ethanol, which had been obtained by dissolving 0.58 g of sodium (25.2 mg-atom) in 35 ml of ethanol. Stirring was continued for 3 h at room temperature, and then another 3 h at 60°C. The mixture was poured into ice-water (300 ml), extracted with dichloromethane, washed successively with 2 M† HCl, 1 M Na_2CO_3, and then water, and dried over Na_2SO_4. Evaporation of the solvent in vacuo left crude **7d**; ^1H NMR ($CDCl_3$) δ=9.72 (1H, -CHO); IR (KBr) 1680 cm^{-1}.

The aldehyde was dissolved in 60 ml of acetone and heated at reflux, to which was added dropwise (0.5 h) a solution of $KMnO_4$ (2.36 g, 15.0 mmol) in 60 ml of hot water, and heating was continued for an additional 1 h. To the dark brown mixture was bubbled sulfur dioxide till it became clear accompanying deposition of white precipitate. The solid was recovered by filtration, dissolved in hot toluene (200 ml), and then filtered hot after adding small amount of activated charcoal; concentration to about a third of the volume caused crystallization of **1d** on standing, 1.84 g (53%); mp 290—291.5°C; IR (KBr) 1680 cm^{-1}. ^1H NMR (DMSO-d_6) δ=6.8—8.4 (13H, m, Ar-H), 8.6—9.1 (2H, m, Ar-H), and 12.4 (1H, br, -COOH). Found: C, 86.24; H, 4.91%. Calcd for $C_{25}H_{16}O_2$: C, 86.19; H, 4.63%.

1c: The oxidation of **5c** (9.65 g, 32.4 mmol) was carried out as above and recrystallization from water–ethanol (2:1) gave 5.64 g (53%) of **1c**; mp 258.5—260°C; IR (KBr) 1680 cm^{-1}. ^1H NMR (DMSO-d_6) δ=3.69 (3H, s, $-OCH_3$), 6.5—8.3 (12H, m, Ar-H,), and 12.2 (1H, br, -COOH). Found: C, 80.28; H, 5.06%. Calcd for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

1a: The oxidation of **5a** (1.86 g, 6.94 mmol) was carried out as above except that, after treatment with SO_2, ca. 1 l of 28% aqueous ammonia was added to dissolve the acid which deposited as an oil and then passed through a silica-gel pad to remove colored precipitates. The aq layer was

*1 mmHg=133.322 Pa.

† 1 M=1 mol dm^{-3}.

made acidic by adding conc HCl, and the acid was taken into ether. Evaporation of the solvent and recrystallization from water–ethanol (1:1) gave 0.78 g (38%) of **1a**; mp 200—201.5 °C (lit,[7] mp 200—201 °C); IR (KBr) 1680 cm^{-1}; ^1H NMR (DMSO-d_6) δ=6.8—8.2 (13H, m, Ar-H) and 12.4 (1H, br, -COOH). Found: C, 84.46; H, 4.67%. Calcd for $C_{21}H_{14}O_2$: C, 84.54; H, 4.73%.

1b: The oxidation of **5b** (1.00 g, 3.55 mmol) was carried out according to the procedure used for **5a**, affording 0.451 g (41%) of **1b** after recrystallization from water–ethanol (1:1); mp 228—230 °C (lit,[5] 233 °C); IR (KBr) 1670 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.98 (3H, s, $-CH_3$), 6.6—8.3 (12H, m, Ar-H), and 12.4 (1H, br, -COOH). Found: C, 84.32; H, 5.33%. Calcd for $C_{22}H_{16}O_2$: C, 84.59; H, 5.16%.

We are grateful for support of this work by a Grant-in-Aid for Scientific Research No. 60119001 from the Ministry of Education, Science and Culture.

Chemistry of 1,2-Thiaphosphole 2-Sulfides. III.[1] Cycloaddition Reactions with Some Acetylenic Dienophiles and Generation of Phosphorin 1-Sulfides

Hideyuki TANAKA and Shinichi MOTOKI*
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received December 20, 1985)

Synopsis. 1,2-Thiaphosphole 2-sulfides reacted with dimethyl acetylenedicarboxylate or phenylacetylene to afford 1-phosphabarrelene 1-sulfides (1-phosphabicyclo[2.2.2]octa-2,5,7-triene 1-sulfides) via phosphorin 1-sulfides.

Previously, we reported that 1,2-thiaphosphole 2-sulfides **2** generated by the thermolysis of 2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-sulfides **1** underwent cycloaddition reactions with various olefins to afford the stable 1:1 adducts **4**.[1]

Meanwhile, numerous studies have been devoted to the chemistry of phosphorin derivatives,[2] however, phosphorin 1-sulfides are little known because of their instability. Only one example was reported by Mathey et al. very recently. They treated 4,5-dimethyl-2-phenylphosphorin with an excess of sulfur in the presence of 2,3-dimethylbutadiene or dimethyl acetylenedicarboxylate (DMAD), and transiently formed phosphorin 1-sulfide was trapped as cycloadducts.[3,4]

In view of the recent investigation, we attempted the cycloaddition reactions of **1** (**2**) with acetylenic dienophiles and also expected the formation of the phosphorin 1-sulfides **6** from the adducts **5** by elimination of the bridged sulfur atom.

Results and Discussion

When the reaction of **1a—c** with DMAD was carried out in refluxing benzene, 1-phosphabarrelene 1-sulfides **7a—c** were obtained along with the other products **8a—c** (Table 1). This interesting results are explained as follows. Initially formed cycloadducts **5** are unstable under the reaction conditions and produce intermediary phosphorin 1-sulfides **6** by the elimination of the bridged sulfur atom. Subsequently, **6** react with DMAD to afford **7a—c** as reported by Mathey et al.[3] (Scheme 1).

12c	—	4.16	3.78	—	8.0	—	22.0	14.5	47.0	52.0	4.9	48.8

cated that **7a—c** were 1:1 adducts of **6** with DMAD and the structures were confirmed by the ^{1}H and ^{13}C NMR spectral data. In the ^{1}H NMR spectrum of **7a**, the methoxycarbonyl groups resonated at δ=3.43 (s, 6H) and 3.89 (s, 6H). The doublet at δ=8.26 (1H, J_{HP}=30.0 Hz) was assigned to the olefinic H(β-1) proton. The ^{13}C NMR spectrum of **7a** showed signals of the C(α-1) and C(α-2) olefinic carbons at δ=147.3 (J_{CP}=64.7 Hz) and 139.9 (2×C, J_{CP}=57.4 Hz), respectively. The large C-P coupling constants suggest that these carbons are directly bonded to the phosphorus atom. The signals of the C(β-1) and C(β-2) carbons showed small C-P coupling constants ($J_{C(\beta\text{-}1)P} \simeq 0$ Hz, $J_{C(\beta\text{-}2)P}$=2.4 Hz). The signal of C(γ) carbon appeared at δ=59.9 and showed unusual large coupling constant (J_{CP}=29.3 Hz). These spectral data are closely similar to those of the 1-phosphabarrelene 1-sulfide reported previously.[3,5] The structures of **7b, c** were determined similarly (Table 2).

On the other hand, the mass spectra indicated that **8a—c** were 1:1 adducts of **3** with DMAD and their ^{1}H NMR spectral data suggested that they would be 4*H*-thiin derivatives. However, rearranged 2*H*-thiin structures can not be excluded strictly.[6]

The reaction of **1** with an excess of phenylacetylene gave the corresponding phosphabarrelene sulfides **11a—c** regioselectively. The orientation of phenyl group was determined by the ^{1}H NMR spectrum of **11b**. In this spectrum, signals of one proton (δ=8.45, J_{HP}=30.0 Hz), three protons (CH_3), two sets of two protons (*p*-Tol-H), and seventeen protons were observed. The first signal was assigned to the H(β-1) and the remaining two protons attached to the barrelene skeleton should be linked to the C(α-2) carbon atom. Signals of the H(α-2) couldn't be distinguished from those of other aromatic protons. Similarly, the structures of **11a** and **11c** were determined.

Cycloadducts of the thiones **3** with phenylacetylene were not obtained in this case, however, the analytical and the mass spectral data of the other products **12a—c** indicated that the compounds were 1:1 adducts of **10** and the thiones **3**. The ^{13}C NMR spectrum of **12a** showed a signal of the C(6) carbon at δ=53.6 with a large C-P coupling constant (J_{CP}=48.8 Hz), suggesting a direct bonding of the C(6)-P (Table 3).[1] In the ^{1}H NMR spectra, H(4), H(5), and H(6) protons resonated at δ=6.41 (dd, J_{HH}=4.5 Hz, J_{HP}=2.5 Hz), 4.28 (ddd, J_{HH}=4.5, 10.0 Hz, J_{HP}=14.5 Hz), and 3.75 (dd, J_{HH}=10.0 Hz, J_{HP}=14.0 Hz), respectively. These spectral data are in accord with the proposed structures. The structures of **12b, c** were determined similarly (Table 3). In these cycloaddition reactions, phosphorin sulfides **10** and α,β-unsaturated thiones **3** act as 2π- and 4π-electron components, respectively. Cycloadducts of this type did not form in the reaction of **1** and DMAD. From these results, it has been found that the sulfides **2** react with phenylacetylene more rapidly than the thiones **3**, and **3** are trapped by the generating **10** rather than phenylacetylene.

The mass spectra of **12** show fragments of thiones **3** and the phosphorin 1-sulfides **10**. So the preparation of the corresponding phosphorins[4] by the thermolysis of **12** in the presence of desulfurizing agent is now under investigation.

Experimental

All melting points are uncorrected. IR spectra were measured on a Hitachi Model 260-10 spectrometer. ^{1}H and

^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 spectrometer in $CDCl_3$ solution using Me_4Si as an internal standard (^1H; at 100 MHz, ^{13}C; 25.05 MHz). ^{31}P NMR spectra were recorded at 36.21 MHz on a JEOL FX-90A spectrometer in $CDCl_3$ solution using 85% H_3PO_4 as an external standard. Mass spectra were recorded on a Hitachi double focusing mass spectrometer (RMU-7M), operating at an ionizing potential of 70 eV. Elemental analyses were performed using a Yanaco Model MT-3 CHN corder. 2,9-Dithia-1-phosphabicyclo-[4.3.0]nona-3,7-diene 1-sulfides **1** were prepared according to the previously described method.[1]

General Procedure for the Reaction of the Phosphabicyclo Compounds 1 with Acetylenic Dienophiles: A solution of **1** (2 mmol) and DMAD (7 mmol) or phenylacetylene (18 mmol) in 5 cm^3 of dry benzene was refluxed under a nitrogen atmosphere until **1** was consumed, as indicated by TLC. After evaporation of the solvent the residue was chromatographed on silica gel (Wakogel C-200) with benzene-ethyl acetate (10:1) or benzene-hexane (1:1) as an eluent to afford the products and were recrystallized from ethanol.

4,7-Diphenyl-2,3,5,6-tetrakis(methoxycarbonyl)-1-phosphabicyclo[2.2.2]octa-2,5,7-triene 1-Sulfide (7a): IR (KBr) 2970, 1740 (C=O), 1300, and 1260 cm^{-1}; ^1H NMR δ=3.43 (s, 6H, OCH_3), 3.89 (s, 6H, OCH_3), 7.22—7.62 (m, 8H, Ar-H), and 8.26 [d, 1H, J_{HP}=30.0 Hz, H(β-1)]; ^{31}P NMR δ=9.33 (d, J_{PH}=30.2 Hz); MS *m/z* 538 (M^+, 52), 506 (M^+—S, 35), 474 (15), 447 (506-$COOCH_3$, 14), 418 (11), 302 (M^+—4$COOCH_3$, 37), 271 (34), and 93 (100). Found: C,60.38; H, 4.27; S, 6.09%. Calcd for $C_{27}H_{23}O_8PS$: C, 60.22; H, 4.30; S, 5.95%.

4-Phenyl-2,3,5,6-tetrakis(methoxycarbonyl)-7-*p*-tolyl-1-phosphabicyclo[2.2.2]octa-2,5,7-triene 1-Sulfide (7b): IR (KBr) 2960, 1740 (C=O), 1280, and 1240 cm^{-1}; ^1H NMR δ=2.39 (s, 3H, CH_3), 3.42 (s, 6H, OCH_3), 3.88 (s, 6H, OCH_3), 7.08—7.56 (m, 9H, Ar-H), and 8.22 [d, 1H, J_{HP}=30.0 Hz, H(β-1)]; MS *m/z* 552 (M^+, 33), 520 (M^+—S, 21), 488 (7), 461 (520-$COOCH_3$, 9), 432 (10), 316 (M^+—4$COOCH_3$, 39), 285 (19), and 93 (100). Found: C, 60.80; H, 4.45%. Calcd for $C_{28}H_{25}O_8PS$: C, 60.87; H, 4.56%.

2,3-Benzo-7-phenyl-9,10,11,12-tetrakis(methoxycarbonyl)-8-phosphatricyclo[6.2.2.0^{1,6}]dodeca-6,10,11-triene 8-Sulfide (7c): IR (KBr) 2970, 1730 (C=O), 1285, and 1250 cm^{-1}; ^1H NMR δ=2.86 (s, 4H, $-CH_2CH_2-$), 3.44 (s, 6H, OCH_3), 3.88 (s, 6H, OCH_3), and 6.96—7.60 (m, 9H, Ar-H); MS *m/z* 564 (M^+, 70), 532 (M^+—S, 7), 500 (17), 473 (532-$COOCH_3$, 21), 444 (1), 328 (M^+—4$COOCH_3$, 48), 297 (21), 239 (54), and 93 (100). Found: C, 61.41; H, 4.56%. Calcd for $C_{29}H_{25}O_8PS$: C, 61.70; H, 4.46%.

2,3-Bis(methoxycarbonyl)-4,6-diphenyl-4*H*-thiin (8a): IR (neat) 2975, 1740 (C=O), 1260, and 1230 cm^{-1}; ^1H NMR δ= 3.58 (s, 3H, OCH_3), 3.77 (s, 3H, OCH_3), 4.87 (d, 1H, J_{HH}= 6.0 Hz), 6.08 (d, 1H, J_{HH}=6.0 Hz), and 7.00—7.60 (m, 10H, Ar-H); MS *m/z* 366 (M^+, 29), 334 (M^+—S, 13), 307 (M^+—$COOCH_3$, 100), and 289 (M^+—Ph, 53).

2,3-Bis(methoxycarbonyl)-6-phenyl-4-*p*-tolyl-4*H*-thiin (8b): IR (neat) 2950, 1720 (C=O), 1250, and 1220 cm^{-1}; ^1H NMR δ=2.26 (s, 3H, CH_3), 3.62 (s, 3H, OCH_3), 3.80 (s, 3H, OCH_3), 4.83 (d, 1H, J_{HH}=6.0 Hz), 6.08 (d, 1H, J_{HH}=6.0 Hz), and 6.83—7.60 (m, 9H, Ar-H); MS *m/z* 380 (M^+, 17), 348 (M^+—S, 19), 321 (M^+—$COOCH_3$, 100), and 289 (M^+-*p*-Tol, 35).

2,3-Bis(methoxycarbonyl)-1-phenyl-9,10-dihydro-1*H*-4-thiaphenanthrene (8c): IR (KBr) 2950, 1740 (C=O), 1260, and 1240 cm^{-1}; ^1H NMR δ=2.18—2.92 (m, 4H, $-CH_2CH_2-$), 3.68 (s, 3H, OCH_3), 3.84 (s, 3H, OCH_3), 4.77 (s, 1H), and 7.12—7.48 (m, 9H, Ar-H); MS *m/z* 392 (M^+, 30), 360 (M^+—S, 13), 333 (M^+—$COOCH_3$, 82), and 315 (M^+—Ph, 100).

3,4,5,7-Tetraphenyl-1-phosphabicyclo[2.2.2]octa-2,5,7-triene 1-Sulfide (11a): ^1H NMR δ=6.48—7.78 [m, 22H, H(α-2) and Ar-H] and 8.49 [d, 1H, J_{HP}=30.0 Hz, H(β-1)]; MS *m/z* 458 (M^+, 1), 395 (M^+—PS, 5), 356 (**10a**, 75), 324 (**10a**-S, 70), 254 (**10a**-PhC≡CH, 100), and 102 (PhC≡CH, 72). Found: C, 81.08; H, 5.08%. Calcd for $C_{31}H_{23}PS$: C, 81.20; H, 5.06%.

7-*p*-Tolyl-3,4,5-triphenyl-1-phosphabicyclo[2.2.2]octa-2,5,7-triene 1-Sulfide (11b): ^1H NMR δ=2.42 (s, 3H, CH_3), 6.56—7.40 [m, 17H, H(α-2) and Ar-H], 7.28 (d, 2H, J_{HH}=8.0 Hz, *p*-Tol-H), 7.62 (dd, 2H, J_{HH}=8.0 Hz, J_{HP}=1.5 Hz, *p*-Tol-H), and 8.45 [d, 1H, J_{HP}=30.0 Hz, H(β-1)]; MS *m/z* 472 (M^+, 10), 438 (M^+-H_2S, 4), 409 (M^+—PS, 12), 370 (**10b**, 100), 338 (**10b**-S, 98), 268 (**10b**-PhC≡CH, 83), and 102 (PhC≡CH, 98). Found: C, 81.20; H, 5.23%. Calcd for $C_{32}H_{25}PS$: C, 81.33; H, 5.33%.

2,3-Benzo-7,10,11-triphenyl-8-phosphatricyclo[6.2.2.0^{1,6}]-dodeca-6,10,11-triene 8-Sulfide (11c): ^1H NMR δ=2.98 (s, 4H, $-CH_2CH_2-$), 5.88—6.40 (m, 2H, Ar-H), and 6.60—7.60 [m, 19H, H(α-2) and Ar-H]; ^{31}P NMR δ=8.43 (t, J_{PH}= 20.3 Hz); MS *m/z* 484 (M^+, 11), 450 (M^+-H_2S, 9), 421 (M^+—PS, 21), 382 (**10c**, 25), 350 (**10c**-S, 27), 280 (**10c**-PhC≡CH, 50), and 102 (PhC≡CH, 100). Found: C, 81.83; H, 5.18; S, 6.26%. Calcd for $C_{33}H_{25}PS$: C, 81.79; H, 5.20; S, 6.62%.

3,5,7,8,10-Pentaphenyl-1-phospha-2-thiabicyclo[4.4.0]deca-3,7,9-triene 1-Sulfide (12a): ^1H NMR δ=3.75 [dd, 1H, J_{HH}= 10.0 Hz, J_{HP}=14.0 Hz, H(6)], 4.28 [ddd, 1H, J_{HH}=4.5, 10.0 Hz, J_{HP}=14.5 Hz, H(5)], 6.32—6.60 (m, 2H), 6.41 [dd, 1H, J_{HH}= 4.5 Hz, J_{HP}=2.5 Hz, H(4)], 6.72—7.52 (m, 22H), and 7.72—7.94 (m, 2H); ^{31}P NMR δ=49.39 (dddd, J_{PH}=2.5, 14.0, 14.5, 36.0 Hz); MS *m/z* 580 (M^+, 1), 356 (**10a**, 31), 324 (**10a**-S, 76), 254 (**10a**-PhC≡CH, 43), and 223 (**3a**-H, 100). Found: C, 78.52; H, 5.04; S, 11.03%. Calcd for $C_{38}H_{29}PS_2$: C, 78.59; H, 5.03; S, 11.04%.

5,10-Di-*p*-tolyl-3,7,8-triphenyl-1-phospha-2-thiabicyclo[4.4.0]-deca-3,7,9-triene 1-Sulfide (12b): ^1H NMR δ=2.26 (s, 3H, CH_3), 2.39 (s, 3H, CH_3), 3.73 [dd, 1H, J_{HH}=10.0 Hz, J_{HP}=14.0 Hz, H(6)], 4.23 [ddd, 1H, J_{HH}=4.5, 10.0 Hz, J_{HP}=15.5 Hz, H(5)], 6.32—7.44 [m, 22H, H(9) and Ar-H], 6.41 [dd, 1H, J_{HH}=4.5 Hz, J_{HP}=2.5 Hz, H(4)], and 7.75 (dd, 2H, J_{HH}= 8.0 Hz, J_{HP}=2.5 Hz, *p*-Tol-H); MS *m/z* 608 (M^+, 1), 370 (**10b**, 29), 338 (**10b**-S, 100), 268 (**10b**-PhC≡CH, 34), and 237 (**3b**-H, 56). Found: C, 78.84; H, 5.51%. Calcd for $C_{40}H_{33}PS_2$: C, 78.91; H, 5.46%.

7,15,16-Triphenyl-5,6,13,14,15,15a-hexahydro-7a-phospha-8-thiadibenzo[*a*,*j*]naphthacene 7a-Sulfide (12c): ^1H NMR δ=2.04—2.20 (m, 4H, $-CH_2-$), 2.48—2.92 (m, 4H, $-CH_2-$), 3.78 [dd, 1H, J_{HH}=8.0 Hz, J_{HP}=14.5 Hz, H(6)], 4.16 [dd, 1H, J_{HH}=8.0 Hz, J_{HP}=22.0 Hz, H(5)], and 6.50—7.70 (m, 23H, Ar-H); MS *m/z* 632 (M^+, 1), 382 (**10c**, 98), 350 (**10c**-S, 100), 280 (**10c**-PhC≡CH, 91), and 249 (**3c**-H, 51). Found: C, 79.68; H, 5.18%. Calcd for $C_{42}H_{33}PS_2$: C, 79.72; H, 5.26%.

The authors wish to thank JEOL LTD. for measuring the ^{31}P NMR spectra and also Mr. Yasuhiro Terauchi for technical assistance.

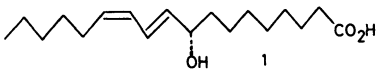
A Convenient Synthesis of (±)-Dimorphecolic Acid and Its Analogs

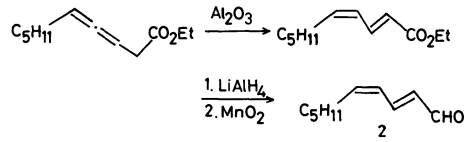
Sadao TSUBOI, Seiji MAEDA, and Akira TAKEDA*
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received January 22, 1986)

Synopsis. Dimorphecolic acid, self-defensive substances in rice plant against rice blast disease, and its analogs were prepared stereoselectively by the reaction of (2*E*,4*Z*)-2,4-decadienal with Grignard reagents.

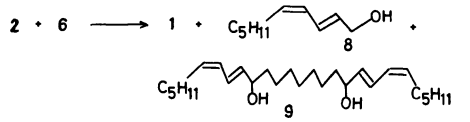
Dimorphecolic acid (**1**) is one of self-defensive substances in rice plant against rice blast disease, which were isolated by Kato et al.[1] Compound **1** is also found in oil of vegetables and is shown to possess a unique ionophore activity.[2] Recently Morota et al. reported that dimorphecolic acid isolated from Lycium chinese Mill acts as an inhibitor against angiotensin I converting enzyme (ACE), namely as a hypotensive substance.[3] Rao et al. reported the first synthesis of **1** via several steps from epichlorohydrin.[4]

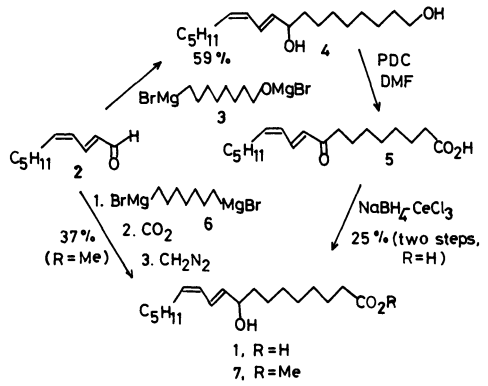


We present here a convenient synthesis of **1** via (2*E*,4*Z*)-2,4-decadienal. The synthetic sequence is shown in Scheme 1. The starting material, (2*E*,4*Z*)-2,4-decadienal (**2**) can be obtained by the reduction of ethyl (2*E*,4*Z*)-2,4-decadienoate, which was prepared by the stereoselective rearrangement of ethyl 3,4-decadienoate promoted with alumina, and the subsequent oxidation of the product.[5]



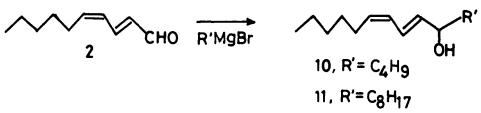
Reaction of **2** with Grignard reagent **3**[6] from 8-chloro-1-octanol gave the diol **4** in 59% yield. Oxidation of **4** with pyridinium dichromate in *N*,*N*-dimethylformamide (DMF) gave the keto acid **5**.[7] Reduction of **5** with $NaBH_4$–$CeCl_3$ in methanol afforded dimorphecolic acid (25% yield from **4**). On the other hand, one-pot synthesis of **1** was established by the reaction of **2** with 1,7-heptanediyldimagnesium dibromide (**6**)[8] followed by carboxylation and esterification (37% total yield as the methyl ester **7**). The ester **7** was converted to the benzoate, of which ^{13}C NMR data were identical with those of the literature.[1a] This carboxylation was accompanied by the formation of (2*E*,4*Z*)-2,4-decadien-1-ol (**8**) (15%) and tetraenediol **9** (42%), the reaction product of **6** with two equivalents of **2**. These compounds could be separated by HPLC or medium pressure chromatography. The present synthesis is one of rare examples[8d] of the application of di-Grignard reagents for the synthesis of natural products.





Scheme 1.

Furthermore, analogs of **1** were prepared in good yields by the reaction of **2** with Grignard reagents such as butylmagnesium bromide and octylmagnesium bromide as shown below. The biological activity of dienols **10** and **11** was examined against rice plant diseases. Neither **10** nor **11** showed any control activities against diseases such as rice blast, rice sheath blight, and rice brown spot. This fact shows clearly that a carboxyl group of **1** plays an important role for biological activity.



Although the present synthesis does not afford a high yield of **1**, the simplicity makes it more attractive than the previously reported ones.[4]

Experimental

The melting points and boiling points are uncorrected. Elemental analyses were carried out by Eiichiro Amano in our laboratory. Infrared (IR) spectra were obtained with a JASCO Model A-102 infrared spectrophotometer. High-performance liquid chromatography (HPLC) was performed with Hitachi Model 655 liquid chromatograph and Shodex Model SE-31 differential refractometer. ^1H NMR spectra (60 MHz) were recorded with a JEOL JNM-PMX60SI apparatus. ^{13}C NMR spectra were obtained with a JEOL JNM-FX100 apparatus, in $CDCl_3$ solvent. All chemical shifts are reported in δ units downfield from internal Me_4Si, and J values are given in herz. Column chromatography was accomplished with 100—200 mesh Wakogel C-200. Aldehyde **2** was prepared by the procedures described in the previous paper[5] and purified by column chromatography [silica gel, hexane–ethyl acetate (20:1—10:1)]. The purity (>95%) was checked by ^1H NMR spectrum.

(10*E*,12*Z*)-10,12-Octadecadiene-1,9-diol (4). To a mix-

ture of 73.6 mg (3.03 mg-atom) of magnesium and 0.5 ml of THF was added dropwise 0.115 ml (168 mg, 1.54 mmol) of ethyl bromide and the mixture was stirred for 1.5 h. After the dropwise addition of a solution of 8-bromo-1-octanol (316 mg, 1.51 mmol) in THF (1 ml) at 0 °C, the mixture was stirred for 30 min at 0 °C and then for 2.5 h at room temperature. At this interval 2—3 ml of THF was added. To the stirred mixture was added dropwise a solution of 152 mg (1 mmol) of **2** in 1 ml of THF at 0 °C. After the addition, the ice bath was removed and the mixture was stirred for 1.5 h. The reaction mixture was poured into aqueous NH_4Cl and extracted with ether. The organic layer was washed with water, dried over $MgSO_4$, and concentrated, and the resulting residue (410 mg) was chromatographed on 17 g of silica gel eluting with hexane–ethyl acetate–methanol (45:3:1) to give 149 mg (59%) of **4**: IR (neat) 3320 (OH), 2930, 1460, 1120, and 1060 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, J=6 Hz, CH_3), 1.33 (20H, br. S, $CH_3(CH_2)_3$, $(CH_2)_7CH_2OH$), 1.88 (2H, S, 2OH), 2.11 (2H, t, J=7 Hz, CH_2CH=CH), 3.58 (2H, t, J=6 Hz, CH_2OH), 4.15 (1H, m, $\succ$CHOH), 5.2—6.2 (3H, m, CH=CHCH=CHCHOH-), and 6.50 (1H, dd, J=10 and 15 Hz, CH=CHCHOH-). Found: C, 76.37; H, 12.27%. Calcd for $C_{18}H_{34}O_2$: C, 76.54; H, 12.13%.

Oxidation of 4 with Pyridinium Dichromate. To a solution of 1.28 g (3.40 mmol) of pyridinium dichromate[9] in 1 ml of DMF was added a solution of 160 mg (0.566 mmol) of **4** in 1.5 ml of DMF at 0 °C under an atmosphere of nitrogen. The mixture was stirred for 14 h at room temperature and then poured into water. The organic layer was extracted with ether, washed with water, dried over $MgSO_4$, and concentrated to give 124 mg of crude **5**: IR (neat) 3600—2500 (CO_2H), 1710 (C=O), 1590, 1460, and 1410 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (3H, t, J=7 Hz, CH_3), 1.25 (16H, br. S, $CH_3(CH_2)_3$, $(CH_2)_5CH_2CO_2H$), 2.33 (4H, m, CH_2CH=CH, CH_2CO_2H), 3.38 (2H, t, J=5.5 Hz, CH_2COCH=), 5.5—6.4 (3H, m, CH=CHCH=CHCO), and 7.50 (1H, dd, J=10.5 and 16 Hz, CH=CHCO). The crude **5** was used for next step without purifucation.

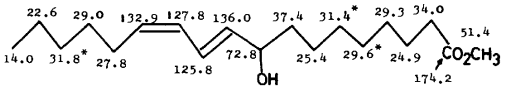
Dimorphecolic Acid (1). To a solution of 313 mg (0.84 mmol) of cerium(III) chloride in 10 ml of methanol was added a solution of 124 mg (0.421 mmol) of **5** in 5 ml of methanol. Sodium borohydride (31.9 mg, 0.843 mmol) was added in several portions at 0 °C and the mixture was stirred for 4 h at 30—35 °C, and then poured into ice water, acidified with dilute HCl, and extracted with ether. The ethereal solution was washed with water, dried over $MgSO_4$, concentrated, and chromatographed on 7 g of silica gel eluting with hexane–ethyl acetate–methanol (45:4:1) to give 40.6 mg (25% yield estimated from **4**) of **1**:[1a] IR (neat) 3300—2500 (CO_2H), 1710 (C=O), 1460, 1410, and 980 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, J=6 Hz, CH_3), 1.28 (18H, m, $CH_3(CH_2)_3$, $(CH_2)_6CH_2CO_2H$), 2.0—2.5 (4H, m, CH_2CH=CH, CH_2CO_2H), 4.1 (1H, m, $\succ$CHOH), and 5.2—7.2 (5H, m, $\{CH=CH\}_2$, CO_2H).

Methyl Dimorphecolate (7) and (6*Z*,8*E*,19*E*,21*Z*)-6,8,19,21-Heptacosatetraene-10,18-diol (9). To a mixture of 53.7 mg (2.21 mmol) of magnesium and 1 ml of THF was added dropwise a solution of 0.17 ml (257 mg, 0.996 mmol) of 1,7-dibromoheptane in 1 ml of THF at 30—35 °C over 3 h. The mixture was stirred for 1 h and then 0.18 ml (175 mg, 0.98 mmol) of hexamethylphosphoric triamide (HMPA) was added at 15—18 °C. After 30 min, a solution of 120 mg (0.788 mmol) of **2** in 1.5 ml of THF was added dropwise, and the mixture was stirred for 1.5 h and then cooled at 0 °C. Carbon dioxide dried over anhydrous magnesium perchlorate was introduced and the mixture was stirred for 3 h under an atmosphere of carbon dioxide, and then poured into aqueous NH_4Cl cooled with ice. The mixture was acidified with dilute HCl and extracted three times with ether. The ethereal solution was washed with brine, dried ($MgSO_4$), and concentrated to give 286 mg of an oil, which was treated with diazomethane in ether. After concentration, the residual oil (288 mg) was analyzed by HPLC [column, SA-I (7.5 mmϕ×25 cm); elution, hexane–ethyl acetate–acetonitrile (10:3:1), 1 ml min^{-1}]. Peaks, retention times (min), integrated percentages are as follows: 1, 6.29, 9.9%; 2, 7.78, 45.5%; 3, 8.97, 31.7%; 4, 11.4, 12.9%. Each component was separated by preparative HPLC and assigned by spectral data.

Peak 1: 1,7-dibromoheptane.

Peak 2: **9**; 41% yield; IR (neat) 3350 (OH), 2950, 1462, and 980 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (6H, t, J=6 Hz, $2CH_3$), 1.35 (26H, br. s, $2CH_3(CH_2)_3$, $(CH_2)_7CHOH$), 1.78 (2H, s, 2OH), 1.9—2.4 (4H, m, $2CH_2CH$=CH), 4.02 (2H, m, 2 $\succ$CHOH), 5.00—6.09 (6H, m, 2CH=CHCH=CHCHOH-), 6.32 (2H, dd, J=10 and 15 Hz, 2CH=CHCHOH-). Found: C, 80.37; H, 11.74%. Calcd for $C_{27}H_{48}O_2$: C, 80.14; H, 11.96%.

Peak 3: **7**;[1a] 37% yield; IR (neat) 3450 (OH), 2940, 1745 (CO_2CH_3), 1460, 1435, 1195, 1170, and 981 cm^{-1}; ^1H NMR (CCl_4) δ=0.90 (3H, t, J=5 Hz, CH_3), 1.35 (18H, br s, $CH_3(CH_2)_3$, $(CH_2)_6CH_2CO_2CH_3$), 1.9—2.4 (4H, m, CH_2-CH=CH, $CH_2CO_2CH_3$), 3.57 (3H, s, CO_2CH_3), 4.02 (1H, m, $\succ$CHOH), 5.03—6.06 (3H, m, CH=CHCH=CHCHOH-), and 6.35 (1H, dd, J=10 and 15 Hz, CH=CHCHOH). ^{13}C NMR data ($CDCl_3$, δ) were tentatively assigned.[10]



Found: C, 73.31; H, 10.80%. Calcd for $C_{19}H_{34}O_3$: C, 73.50; H, 11.04%.

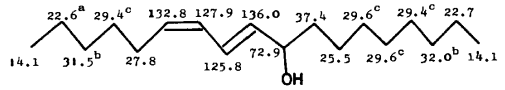
Peak 4: **8**; IR and ^1H NMR spectra were identical with those of the literature.[5]

Methyl (10*E*,12*Z*)-9-benzoyloxy-10,12-octadecadienoate was prepared in 69% yield by the treatment of **7** (23 mg, 0.0744 mmol) with benzoyl chloride (13.2 mg, 0.0941 mmol) in pyridine (0.1 ml) at 20—25 °C for 5 h. Its ^{13}C NMR data was identical with those of the literature.[1a]

(6*E*,8*Z*)-6,8-Tetradecadien-5-ol (10). To a mixture of 162 mg (6.67 mmol) of magnesium in 0.5 ml of THF was added dropwise a solution of 0.59 ml (750 mg, 5.47 mmol) of butyl bromide in 1 ml of THF, occasionally cooling with water. After 2 h, a solution of 854 mg (5.47 mmol) of **2** in 1.5 ml of THF was added dropwise at 0 °C, and then the mixture was stirred for 30 min at 0 °C. After an additional stirring for 1 h at room temperature, the mixture was poured into aqueous NH_4Cl and extracted with ether. The organic layer was washed with brine, dried over $MgSO_4$, and concentrated to give 1.21 g of crude **10**. Preparative TLC gave 0.988 g (86%) of pure **10**: IR (neat) 3370 (OH), 2950, 1460, 1375, 980, and 950 cm^{-1}; ^1H NMR (CCl_4) δ=0.90 (6H, t, J=5 Hz, $2CH_3$), 1.36 (12H, br. s, $2CH_3(CH_2)_3$), 1.8—2.5 (3H, m, CH_2CH=, OH), 4.05 (1H, m, $\succ$CHOH), 5.28 (1H, m, CH=CHCH=CHCHOH-), 5.58 (1H, m, CH=CHCHOH-), 5.86 (1H, t, J=10 Hz, CH=CHCH=CHCHOH-), and 6.39 (1H, dd, J=10 and 15 Hz, CH=CHCHOH-). Found: C, 79.74; H, 12.62%. Calcd for $C_{14}H_{26}O$: C, 79.94; H, 12.46%.

(10*E*,12*Z*)-10,12-Octadecadien-9-ol (11). A solution of 850 mg (5.58 mmol) of **2** in 1.5 ml of THF was treated with a THF solution of octylmagnesium bromide prepared from magnesium (162 mg, 6.67 mmol), 1-bromooctane (1.33 g, 6.99 mmol) and THF (1 ml), as shown in the preparation of **10**. The reaction mixture was worked up as usual to give 1.63 g of crude **11**, which was purified by preparative TLC (silica gel, hexane–ethyl acetate (2:1)) to give 1.29 g (87%) of pure **11**: IR (neat) 3370 (OH), 2950, 1460, 1380, and 980 cm^{-1}; ^1H NMR (CCl_4) δ=0.89 (6H, t, J=5.5 Hz, $2CH_3$), 1.28 (2OH, br. s, $CH_3(CH_2)_3$, $CH_3(CH_2)_7$), 1.95—2.41 (2H, m, CH_2CH=CH),

4.01 (1H, m, >CHOH), 5.26 (1H, m, CH=CHCH=CHCHOH), 5.53 (1H, m, CH=CHCHOH), 5.82 (1H, t, J=10 Hz, CH=CH CH=CHCHOH), and 6.35 (1H, dd, J=10 and 15 Hz, CH= CHCHOH-). ^{13}C NMR data ($CDCl_3$, δ).[10] Assignments of



a, b, c may be interchangeable. Found: C, 81.38; H, 12.72%. Calcd for $C_{18}H_{34}O$: C, 81.13; H, 12.86%.

Oxidation Reactions of a System Composed of Chloro(5,10,15,20-tetraphenylporphyrinato)cobalt(III) and Its π Cation Radical with Phenols

Masahiro KOHNO
JEOL Ltd., Akishima, Tokyo 196
(Received May 31, 1985)

The reactions of a system composed of chloro(5,10,15,20-tetraphenylporphyrinato)cobalt(III), [Co^{III}Cl(tpp)], and its π cation radical coordinating axially two chloride anions, [Co^{III}(tpp)$^{+\cdot}$]Cl_2, with several phenols were investigated by using ESR and optical absorption spectroscopy. The phenols were oxidized to phenoxyl radicals. The phenols investigated were classified into two groups after taking into account the differences in the reaction activities and their redox potentials, the phenols mainly reacting with [Co^{III}(tpp)$^{+\cdot}$]Cl_2 and those reacting with both [Co^{III}Cl(tpp)] and [Co^{III}(tpp)$^{+\cdot}$]Cl_2. The oxidation reactions of phenols with [Co^{III}(tpp)$^{+\cdot}$]Cl_2 were the second-order. A linear relationship between the rate constants of oxidation and the redox potentials of phenols was recognized. Active species in the reactions were determined to be composed of a chlorine radical which originates from axial ligands of [Co^{III}Cl(tpp)] and [Co^{III}(tpp)$^{+\cdot}$]Cl_2, and the porphyrin ligand of [Co^{III}(tpp)$^{+\cdot}$]Cl_2 itself. A possible mechanism for the oxidation reactions is proposed. Finally, the reaction scheme of cobalt porphyrin, ([Co^{II}(tpp)], [Co^{III}Cl(tpp)], and [Co^{III}(tpp)$^{+\cdot}$]Cl_2) with phenols is compared with oxidation reactions of phenols with horseradish peroxidase.

Peroxidase enzymes catalyze oxidation reactions of various kinds of substrates in the presence of hydrogen peroxide or substituted peroxides in biological systems. Because of the biologically important function of peroxidases, their structures, physicochemical properties, and reactivities have been extensively studied by many workers.[1] It has been known that horseradish peroxidase (HRP) takes on five different oxidation states: iron(II), iron(III), Compound II, Compound I, and Compound III, as characterized in the order of increasing oxidation states, and that Compound I is a π cation radical of iron(IV) porphyrin.[2] The π cation radicals of synthetic metalloporphyrins were prepared by chemical, electrochemical, or photochemical oxidation and their chemical natures have also been investigated.[3]

Previously, the electronic and molecular structures of chloro(5,10,15,20-tetraphenylporphyrinato)cobalt(III), [Co^{III}Cl(tpp)], were investigated by X-ray analyses, optical absorption, ^{1}H NMR, and ESR.[4-11] We have determined by ESR that [Co^{III}Cl(tpp)] is converted partially and reversibly into a paramagnetic species in chlorinated hydrocarbons by thermal and light activations.[4] This species was identified to be a π cation radical of chloro(5,10,15,20-tetraphenylporphyrinato)cobalt(III) with two axially coordinating chloride anions, [Co^{III}(tpp)$^{+\cdot}$]Cl_2.[5,6] The formation of this species in a [Co^{III}Cl(tpp)] solution was inevitable, even if a careful purification process of [Co^{III}Cl(tpp)] by column chromatography was carried out. It was recently clarified that [Co^{III}Cl(tpp)] in an aerated dichloromethane solution undergoes photooxidation to produce [Co^{III}(tpp)$^{+\cdot}$]Cl_2.[12] Hereafter, we treated the [Co^{III}Cl(tpp)] solution with a small amount of [Co^{III}(tpp)$^{+\cdot}$]Cl_2, denoted as [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl_2.

In the present study, we characterized the function of [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl_2. through an investigation of the reaction between these complexes and phenol derivatives by means of ESR and optical absorption spectroscopy and cyclic voltammetry. A possible reaction mechanism of these complexes with the phenols is proposed. Finally, the redox reaction scheme of the cobalt porphyrins with phenols is compared with that of horseradish peroxidase with phenols that is already known.

Experimental

Materials. Chloro(5,10,15,20-tetraphenylporphyrinato)-cobalt(III), [Co^{III}Cl(tpp)], was provided by Dr. K. Yamamoto of The Institute of Physical and Chemical Research.

2,6-Di-*t*-butyl-4-(3,5-di-*t*-butyl-4-oxocyclohexadienylidene)-methylphenol(PG), 2,4,6-tri-*t*-butylphenol(TBP), and 2,6-di-*t*-butyl-4-(3,5-di-*t*-butyl-4-oxo-2,5-cyclohexadienylideneamine)phenol(BIP) were prepared according to the literature.[13] 2,6-Di-*t*-butyl-4-methylphenol(BHT), 2,3-di-*t*-butyl-4-methoxyphenol(BHA), and α-tocopherol (vitamin E; VE), supplied from Wako Junyaku Co., were used without further purification.

A spin trapping reagent, nitrosodurene was supplied by Mr. N. Takahashi of Sumitomo Chemical Co. Ltd.

Preparation of Sample Solutions. Benzene was used as a solvent. [Co^{III}Cl(tpp)] was dissolved in 2×10^{-3} mol dm^{-3}. The solution of [Co^{III}Cl(tpp)] contained a small amount of the π cation radical, [Co^{III}(tpp)$^{+\cdot}$]Cl_2.[4,6] The concentration of [Co^{III}(tpp)$^{+\cdot}$]Cl_2 (2.7×10^{-5} mol dm^{-3}) was determined by comparing its ESR intensity with that of 2,2,6,6-tetramethyl-4-hydroxy-1-piperidyloxyl (98% radical) dissolved in benzene as a standard.

Concentrations of phenols (PG, BHT, TBP, BIP, and BHA) were adjusted to be 1.0×10^{-2} mol dm^{-3} and a 1% solution was employed for the VE system. All solutions were prepared just before use.

Measurements. The ESR and optical absorption spectra of the reaction mixtures were measured under deaerated

conditions in order to avoid any oxidation of the phenols. The ESR measurements were carried out with a JEOL FE-2XG spectrometer equipped with a Takeda Riken TR-5211 microwave frequency counter. The *g*-value and hyperfine coupling constant(hfcc) were calculated from the resonance frequency and the magnetic field. The optical absorption spectra were measured by a Hitachi 330 spectrophotometer using quartz cells with optical path lengths of 1 and 0.1 cm. Cyclic voltammograms were measured for the phenols (1.0×10^{-3} mol dm^{-3}) dissolved in dichloromethane with 0.1 mol dm^{-3} of tetrabutylammonium-tetrafluoroborate ($TBAF_4$). The cyclic voltammograms were recorded by a Yanagimoto P-1000H instrument at 25 °C at a scan rate of 100 mV s^{-1}. The redox potentials($E_{1/2}$) obtained from the cyclic voltammograms were checked by simultaneous polarographic measurement.

Time-dependent ESR spectra were measured using a rapid-detection system. To 0.2 cm^3 of the [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl_2 solution, which was bubbled by dry nitrogen gas, was added 0.2 cm^3 of the phenol solution (1×10^{-2} mol dm^{-3}).

Results

Reactions of [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl_2 with Phenols (PG, BHT, TBP, BIP, BHA, and VE). The ESR spectra measured before and after the addition of PG to the [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl_2 solution are shown in Fig. 1. The solid line represents the signal of [Co^{III}(tpp)$^{+\cdot}$]Cl_2.[5,6] Upon an addition of PG, the intensity of the signal decreased and a new ESR signal with doublet-triplet splittings appeared. The new signal(dotted line) was identified as a phenoxyl radical of PG (PG·) on the basis of ESR parameters; g=2.0043, a_{H1}=0.85 mT, a_{H2}=0.17 mT, which coincide with the literature values within the experimental errors.[14] Both the concentrations of the reduced [Co^{III}(tpp)$^{+\cdot}$]Cl_2 and oxidized PG were estimated to be 1.2×10^{-5} mol dm^{-3} under equilibrium states. The corresponding optical absorption spectra are shown in Fig. 2. An intense band at 406 nm (Soret band) and a moderate one at 540 nm (Q band) were determined to represent the characteristic absorption of [Co^{III}Cl(tpp)].[8] The spectrum obtained after an addition of PG showed no appreciable change in the region of the Soret and Q bands, except for a slight decrease in the absorption intensity in the region of 640—740 nm; this was interpreted to be due to a decrease in [Co^{III}(tpp)$^{+\cdot}$]Cl_2.[12] These spectral changes suggest that PG was oxidized to PG· and

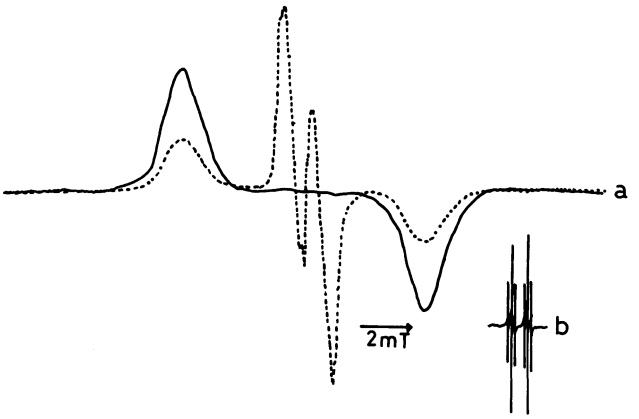

Fig. 1. a: ESR spectra measured before (——) and after (·····) addition of PG to [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl_2 in benzene at room temperature under degassed condition. b: The high resolution spectrum of center PG-phenoxyl radical.

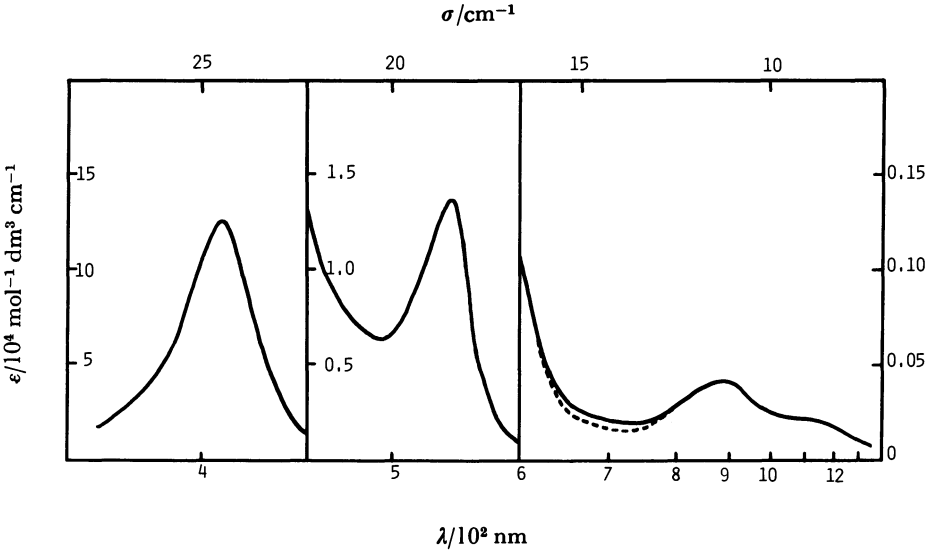

Fig. 2. Optical absorption spectra measured before (——) and after (·····) addition of PG to [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl_2 in benzene at room temperature under degassed condition.

$[Co^{III}(tpp)^{+\cdot}]Cl_2$ was reduced to $[Co^{III}Cl(tpp)]$, while the component $[Co^{III}Cl(tpp)]$ was unchanged.

In a reaction of $[Co^{III}Cl(tpp)]$-$[Co^{III}(tpp)^{+\cdot}]Cl_2$ with BHT or TBP, the phenol was oxidized to the corresponding phenoxyl radical (BHT· or TBP·),[15] and $[Co^{III}(tpp)^{+\cdot}]Cl_2$ was reduced to $[Co^{III}Cl(tpp)]$, as in the case of the PG system.

A reaction of $[Co^{III}Cl(tpp)]$-$[Co^{III}(tpp)^{+\cdot}]Cl_2$ with BIP also gave rise the formation of a phenoxyl radical (BIP·) (Fig. 3). The ESR parameters obtained from the spectrum are g=2.0036, a_N=0.21 mT, and a_H=0.104 mT. These values coincide with the reported values.[13] The concentrations of formed BIP· and the reduced $[Co^{III}(tpp)^{+\cdot}]Cl_2$ were 5.3×10^{-5} and 1.5×10^{-5} mol dm^{-3}, respectively. The concentration of formed BIP· was greater than that of reduced $[Co^{III}(tpp)^{+\cdot}]Cl_2$. This is different from the cases of the reaction with PG, BHT, or TBP. The optical spectrum of the reaction of $[Co^{III}Cl(tpp)]$-$[Co^{III}(tpp)^{+\cdot}]$-Cl_2 with BIP showed that the Soret band of $[Co^{III}Cl(tpp)]$ shifts from 406 to 410 nm with an increase in the absorption intensity. The red shift of the Soret band can be attributed to a further reduction of $[Co^{III}Cl(tpp)]$ to $[Co^{II}(tpp)]$[16] in the BIP system.

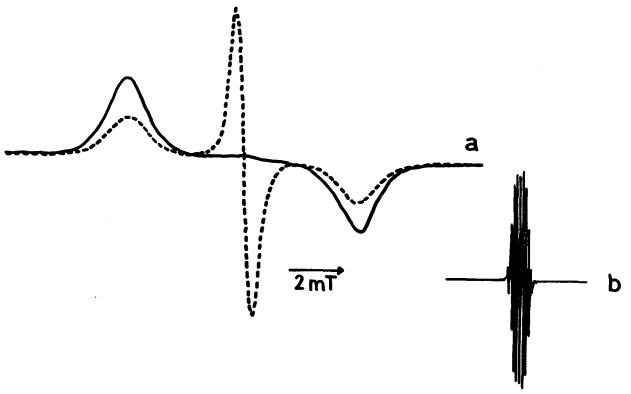

Fig. 3. a: ESR spectra measured before (——) and after (·····) addition of BIP to $[Co^{III}Cl(tpp)]$-$[Co^{III}(tpp)^{+\cdot}]Cl_2$ in benzene at room temperature under degassed condition. b: The high resolution spectrum of center BIP–phenoxyl radical.

When BHA and VE reacted with $[Co^{III}Cl(tpp)]$-$[Co^{III}(tpp)^{+\cdot}]Cl_2$, the ESR spectra of the reaction mixtures gave rise to new signals with a disappearance of the $[Co^{III}(tpp)^{+\cdot}]Cl_2$ signal. The new signals were assigned as BHA· and VE·, respectively.[17] The change in the optical absorption spectra of BHA is shown in Fig. 4. The absorption bands at 540 and 406 nm shifted to 530 and 410 nm, respectively, with an increase in absorption intensity. Furthermore, a weak band and a shoulder appeared at 1020 and 900 nm, respectively. The spectral change in the region of Q and the Soret bands indicates that a conversion of $[Co^{III}Cl(tpp)]$ to $[Co^{II}(tpp)]$ takes place in this system. The features of the ESR and optical absorption spectra show that BHA and VE react with both $[Co^{III}(tpp)^{+\cdot}]Cl_2$ and $[Co^{III}Cl(tpp)]$, as in the case of the BIP system. The appearance of new bands at the near-infrared region implies that isoporphyrin was formed. The absorption band is indeed complied with those of zinc- and iron-isoporphyrin.[18,19] For a comparison of such activities of phenols with their redox potentials, the oxidation potentials of the phenols under consideration were measured using cyclic voltammetry. The obtained potentials are listed in Table 1 with the ESR

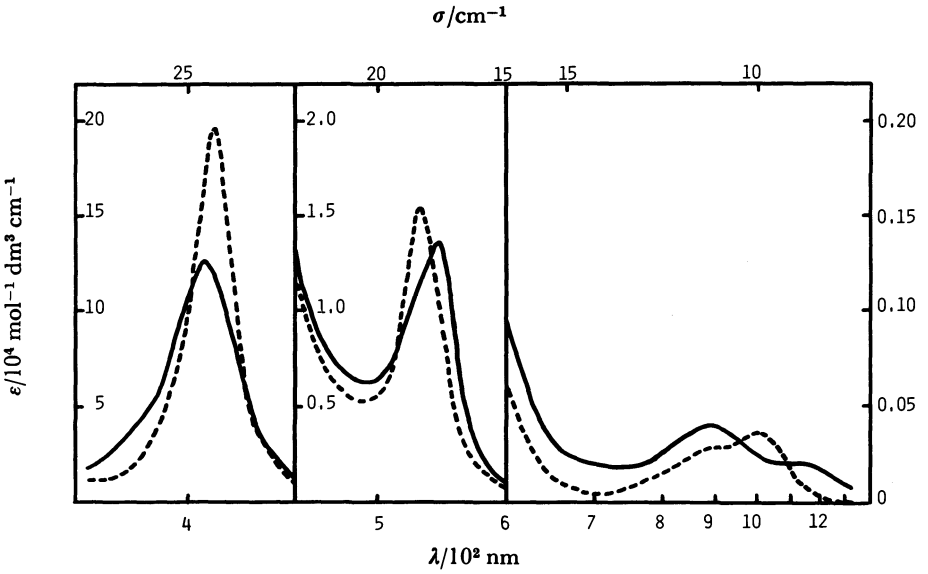

Fig. 4. Optical absorption spectra measured before (——) and after (·····) addition of BHA to $[Co^{III}Cl(tpp)]$-$[Co^{III}(tpp)^{+\cdot}]Cl_2$ in benzene at room teperature under degassed condition.

Table 1. ESR Parameters of Phenoxyl Radicals and Redox Potentials of Phenols[1] and Rate Constants(k_f) of the Reactions between [$Co^{III}(tpp)^{+\cdot}$]Cl_2 and the Phenols

parameters of all the obtained phenoxyl radicals.

Kinetics of the Reaction between [$Co^{III}(tpp)^{+\cdot}$]Cl_2 and BHA, TBP, or PG. The time-dependent ESR spectra of mixed solutions of [$Co^{III}(tpp)^{+\cdot}$]Cl_2 (2.7×10^{-5} mol dm^{-3}) with BHA in a range from 1×10^{-2} to 6.25×10^{-4} mol dm^{-3} were measured at 30 °C by using the rapid detection system combined with the method described in the Experimental section. In Fig. 5, the concentration of [$Co^{III}(tpp)^{+\cdot}$]Cl_2 estimated from the ESR signal intensities is plotted against the reaction time (in second). It is seen that the decay rates of [$Co^{III}(tpp)^{+\cdot}$]Cl_2 depend on the concentration of BHA, even in its excess range, as will be discussed later. The rate constants (k_f) for TBP and PG were determined in a similar manner as that of BHA (1×10^{-2} mol dm^{-3}) at 30 °C as is also listed in Table. 1.

The temperature dependence of a reaction between [$Co^{III}(tpp)^{+\cdot}$]Cl_2 and PG (1×10^{-2} mol dm^{-3}) was examined in order to obtain information regarding their activities. Upon increasing the temperature from 30 to 80 °C, the concentration of [$Co^{III}(tpp)^{+\cdot}$]Cl_2 decreased rapidly along with a concomitant increase in that of PG·. The enthalpy changes for [$Co^{III}(tpp)^{+\cdot}$]Cl_2 and PG· were estimated to be −1.7 and 7.1 kJ mol^{-1}, respectively, from the exponential portion.

Detection of Active Species Derived from [$Co^{III}Cl$(tpp)]-[$Co^{III}(tpp)^{+\cdot}$]Cl_2. The active species was detected using a spin-trapping method.[20] Among the various spin-trapping reagents tested for the detection, only nitrosodurene was effective to trap the

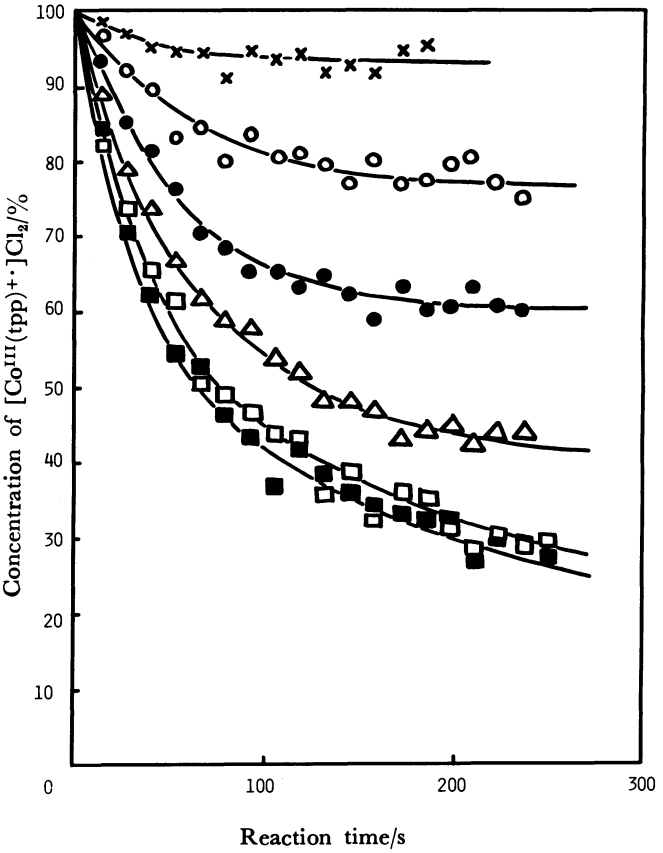

Fig. 5. Concentration decay of [$Co^{III}(tpp)^{+\cdot}$]Cl_2 in the reaction with BHA plotted against reaction time in second. Initial concentration of [$Co^{III}(tpp)^{+\cdot}$]Cl_2, 2.7×10^{-5} mol dm^{-3} and that of BHA, ■: 1.0×10^{-2}, □: 5.0×10^{-3}, △: 2.5×10^{-3}, ●: 1.25×10^{-3}, ○: 6.25×10^{-4} mol dm^{-3}, ×: blank.

species. To 1 cm^3 of the benzene solution of [$Co^{III}Cl$(tpp)]-[$Co^{III}(tpp)^{+\cdot}$]Cl_2, 3 mg of nitrosodurene was added under a degassed condition and the ESR spectrum was measured at room temperature.

The spin-trapping reaction is expressed as follows:

$$\text{R-N=O} + \text{X}\cdot \longrightarrow \text{R-N(X)-O}\cdot,$$

Scheme 1.

where X· is active species to be trapped. Figure 6 shows the ESR spectra of the spin adducts obtained by a reaction of [$Co^{III}Cl$(tpp)]-[$Co^{III}(tpp)^{+\cdot}$]Cl_2 with nitrosodurene. The spectra indicate the presence of two spin adducts (A and B). The following ESR parameters were obtained for A: one nitrogen (a_N=1.47 mT), one chlorine (a_{Cl}=0.284 mT), seven hydrogen (a_H=0.007 mT) nuclei, and for B; one nitrogen (a_N=1.47 mT) and seven hydrogen (a_H=0.007 mT) nuclei. From the ESR parameters, A was identified as a spin adduct of the nitrosodurene with a chlorine atom. The optical absorption spectrum which was measured after a reaction of [$Co^{III}Cl$(tpp)]-[$Co^{III}(tpp)^{+\cdot}$]Cl_2 with nitrosodurene in ben-

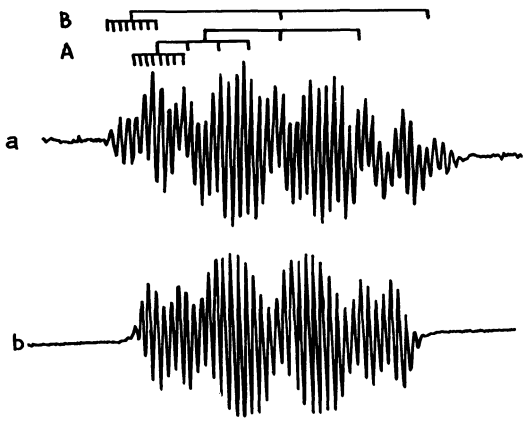

Fig. 6. ESR spectra of spin adducts (A and B) obtained from the reaction of nitrosodurene with [$Co^{III}Cl(tpp)$]–[$Co^{III}(tpp)^{+\cdot}$]Cl_2 in benzene at room temperature under degassed condition. Observed (a) and simulated for A (b) spectra.

zene at room temperature under a degassed condition showed the red shift of the Soret band, the blue shift of the Q band, and a decrease in the absorption intensity at around 600—700 nm. This spectral change was interpreted in terms of the formation of [$Co^{II}(tpp)$] from [$Co^{III}Cl(tpp)$] and [$Co^{III}(tpp)^{+\cdot}$]Cl_2. It is, thus, clear that the chlorine comes from axially coordinated chloride ligands in [$Co^{III}(tpp)^{+\cdot}$]Cl_2 and [$Co^{III}Cl(tpp)$]. This is the first case, to the auther's knowledge, that the active species in a reaction where metalloporphyrins participate has been directly detected. The second adduct B is probably a radical formed from nitrosodurene and a porphyrin ligand of [$Co^{III}(tpp)^{+\cdot}$]Cl_2.

Discussion

Based on the experiments described in the preceding section, phenols can be classified into two groups: group I (PG, TBP, and BHT) and group II (BHA, BIP, and VE). Phenols which belong to group II are more active than those of group I and are converted to phenoxyl radicals by both [$Co^{III}(tpp)^{+\cdot}$]Cl_2 and [$Co^{III}Cl(tpp)$], while phenols belonging to group I are oxidized only by [$Co^{III}(tpp)^{+\cdot}$]Cl_2. This difference in their activities can be explained in terms of the relative positions of the redox potentials of [$Co^{II}(tpp)$], [$Co^{III}Cl(tpp)$], [$Co^{III}(tpp)^{+\cdot}$]Cl_2, and phenols, as will be discussed in the following.

Regarding the oxidation process of the phenols, two oxidation mechanisms (1 and 2) have been proposed:[21]

$$POH \xrightarrow[CV_1]{-e} [POH]^{+\cdot} \xrightarrow{-H^+} PO\cdot \quad (1)$$

$$POH \xrightarrow{-H^+} PO^- \xrightarrow[CV_2]{-e} PO\cdot, \quad (2)$$

Scheme 2.

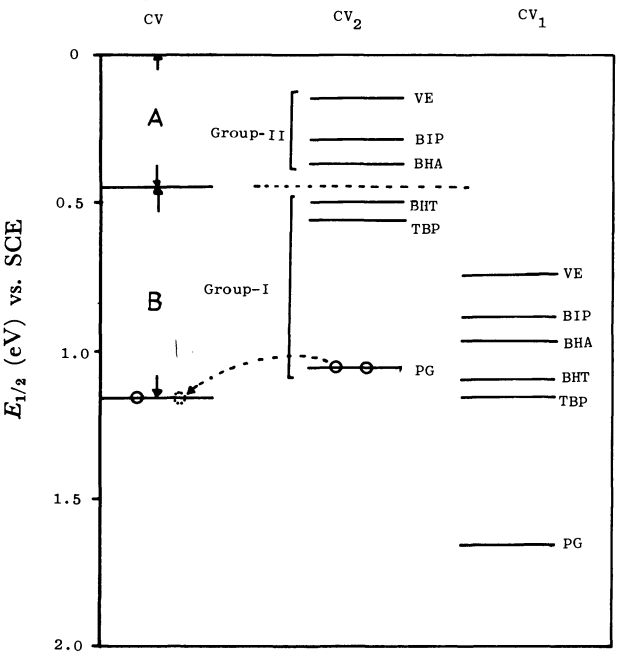

Fig. 7. Relative energy-level diagram of cobalt porphyrins and phenols. A and B represent half wave potential(CV) of [$Co^{II}(tpp)$]/[$Co^{III}Cl(tpp)$] and [$Co^{III}Cl(tpp)$]/[$Co^{III}(tpp)^{+\cdot}$]Cl_2, respectively. CV_1 represents half wave potential of phenols (POH)/phenol cation radicals ([POH]$^{+\cdot}$) and CV_2 phenolate anions (PO^-)/phenoxyl radicals ($PO\cdot$).

where phenols are abbreviated as POH. Process 1 means that first an electron is removed from phenol and then a proton is subtracted from the hydroxy group of the phenol to produce a phenoxyl radical.[22] In this process, the redox potential(CV_1) of POH/[POH]$^{+\cdot}$ obtained from a cyclic voltammogram should be the rate-determining factor. In process 2, first a proton is subtrated from the phenol, then, an electron transfer from phenolate anion follows. It has been reported[21] that the oxidation of 2,6-dimethylphenol(DMP) to diphenoquinone proceeds according to process 2 in the presence of a base(2,6-lutidine). A DMP–phenolate anion is formed through competition with the base. Such an ionic structure causes a decrease in the oxidation potential of the phenols. The redox potential (CV_2) of $PO^-/PO\cdot$ was estimated to be 0.6 eV lower than that of POH/[POH]$^{+\cdot}$(CV_1).[21]

In the present case, it is expected that the chloride anion of [$Co^{III}Cl(tpp)$] and/or [$Co^{III}(tpp)^{+\cdot}$]Cl_2 first forms an ion pair with the hydroxy proton of phenol and then process 2 proceeds predominantly. Here, we assume that in our case the oxidation potentials of phenolate anions formed are 0.6 eV lower than CV_1 of the precursor phenols. The energy-level scheme of phenols, [$Co^{III}(tpp)^{+\cdot}$]Cl_2, [$Co^{III}Cl(tpp)$], and [$Co^{II}(tpp)$] is given in Fig. 7 based on the cyclic voltammetries of these compounds. The CV_2 values of group I

phenols are lower than that of [Co^{III}Cl(tpp)]/[Co^{III}(tpp)$^{+\cdot}$]Cl$_2$[5] but higher than that of [Co^{II}(tpp)]/[Co^{III}Cl(tpp)], whereas the CV_2 values of group II phenols are higher than those of [Co^{III}Cl(tpp)]/[Co^{III}(tpp)$^{+\cdot}$]Cl$_2$ and [Co^{II}(tpp)]/[Co^{III}Cl(tpp)]. Consequently, the phenols of group I reduce only [Co^{III}(tpp)$^{+\cdot}$]Cl$_2$ but those of group II both [Co^{III}(tpp)$^{+\cdot}$]Cl$_2$ and [Co^{III}Cl(tpp)].

Possible Reaction Mechanism of [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl$_2$ with Phenols. When the concentrations of the phenols were of the same order as that of [Co^{III}(tpp)$^{+\cdot}$]Cl$_2$, the redox reaction did not proceeded. At concentrations 10^2 times higher than that of [Co^{III}(tpp)$^{+\cdot}$]Cl$_2$, however, the reaction process became spectroscopically detectable. A reaction of [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl$_2$ and PG showed that the amount of reduced [Co^{III}(tpp)$^{+\cdot}$]Cl$_2$ was equal to that of the generated PG phenoxyl radical. Furthermore, the redox reaction of [Co^{III}Cl(tpp)]-[Co^{III}(tpp)$^{+\cdot}$]Cl$_2$ by BHA proceeded depending on the concentration of BHA (Fig. 5). These facts give an indication that the reaction might be second order, as described by Eq. 1:

$$[Co^{III}(tpp)^{+\cdot}]Cl_2 + POH \rightarrow [Co^{III}Cl(tpp)] + PO\cdot + HCl \quad (1)$$

In our reaction condition, however, Eq. 1 should be reduced by the pseudo-first-order. We have tried to plot $\ln a/(a-x)$ as a function of time for the reaction with BHA (shown in Fig. 5), where a and x are initial and reduced concentration of [Co^{III}(tpp)$^{+\cdot}$]Cl$_2$, respectively. As shown in Fig. 8, before 50 s reaction time, the functions show linear relationships, but after 50 s they deviate downward from the linear relationships, which means that the reaction does not follow the pseudo-first-order reaction rate. Next, we assumed that the phenolate anion activated in part from BHA reacts with the cation radical, as discussed in process 2. This means that in Eq. 1, PO^- instead of POH takes part in the reaction. Thus, we have tried to simulate the second-order decay rates k_f of [Co^{III}(tpp)$^{+\cdot}$]Cl$_2$;

$$k_f t = \frac{1}{(a-b)} \ln \frac{b(a-x)}{a(b-x')}, \quad (2)$$

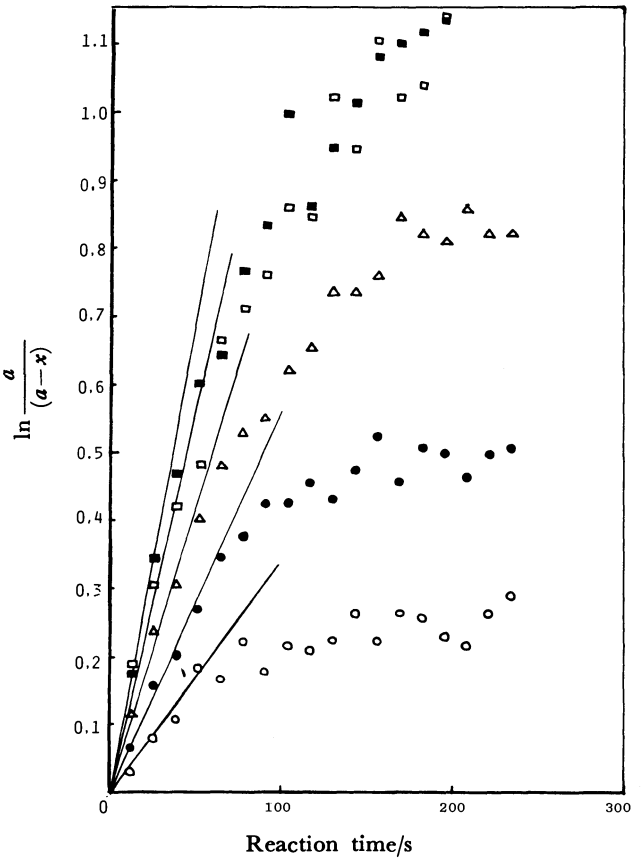

Fig. 8. In $a/(a-x)$ vs. time plot of the reaction between [Co^{III}(tpp)$^{+\cdot}$]Cl$_2$ and BHA, ■: 1.0×10^{-2}, □: 5.0×10^{-3}, △: 2.5×10^{-3}, ●: 1.25×10^{-3}, ○: 6.25×10^{-4} mol dm^{-3}.

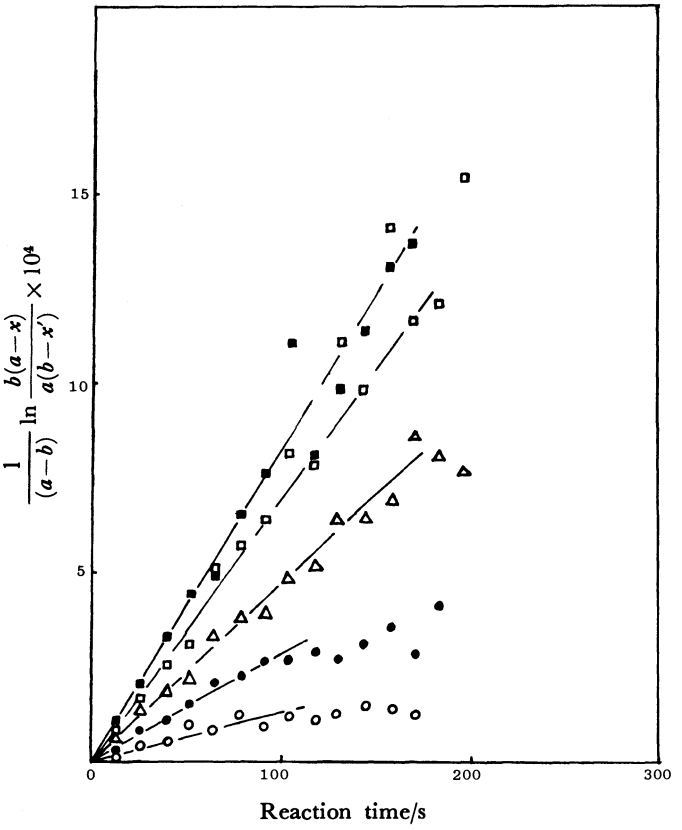

Fig. 9. $1/(a-b)\ln\{b(a-x)/a(a-x')\}$ vs. time plot of the reaction between [Co^{III}(tpp)$^{+\cdot}$]Cl$_2$ and BHA, ■: 1.0×10^{-2}, □: 5.0×10^{-3}, △: 2.5×10^{-3}, ●: 1.25×10^{-3}, ○: 6.25×10^{-4} mol dm^{-3}.

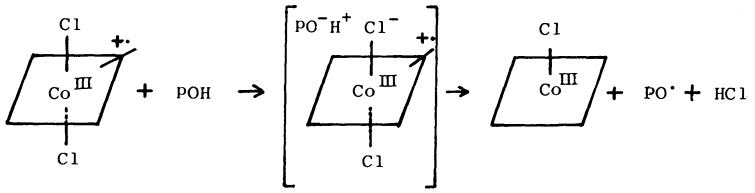
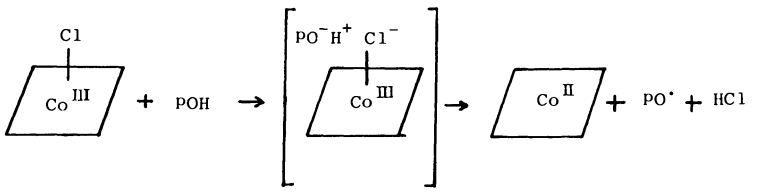
where a and x are the initial and reduced concentrations of $[Co^{III}(tpp)^{+\cdot}]Cl_2$ and b and x' are the initial and oxidized concentrations of the phenolate anion, respectively. Since b and x' are unknown, b has been substituted by trial values of 1.8 to 2.2×10^{-5} and x' is assumed to be equal to x. When the concentration of BHA anion is 2.1×10^{-5} mol dm^{-3}, the simulation accorded satisfactorily with the experimental data in whole concentration range of BHA (1.0×10^{-2}—6.25×10^{-4} mol dm^{-3}) as shown in Fig. 9. This means that the concentration of the phenolate anion is constant irrespective of the concentration change of phenol.

From these results, the reaction mechanism of $[Co^{III}(tpp)^{+\cdot}]Cl_2$ with the phenols may be written as follows:



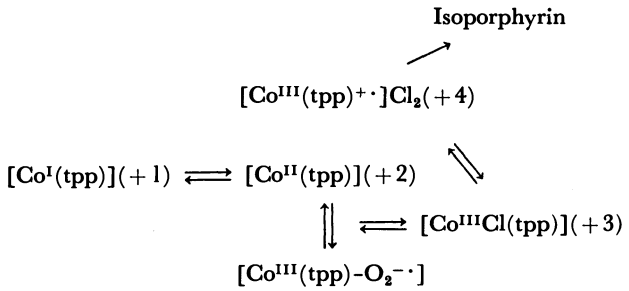
Scheme 3.

The chloride ligand of $[Co^{III}(tpp)^{+\cdot}]Cl_2$ attracts the hydroxy proton of phenol and a complex is formed, then, an electron transfer occurs from the phenolate anion to $[Co^{III}(tpp)^{+\cdot}]Cl_2$ in the complex to give a phenoxyl radical and $[Co^{III}Cl(tpp)]$. The fact that the reaction rates depend on the concentration of the phenols is related to the formation of the complex. In cases of reactions with group-II phenols, the chloride ligand of $[Co^{III}Cl(tpp)]$ also attracts its hydroxy protons. Thus, $[Co^{II}(tpp)]$ is formed through the formation of a similar complex:

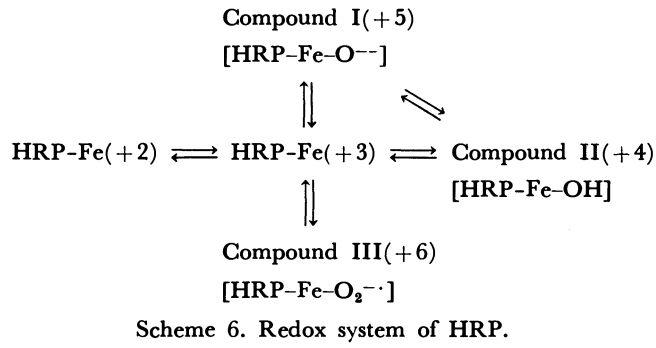


Scheme 4.

$[Co^{III}Cl(tpp)]$ and Horseradish Peroxidase(HRP). In the following we compare our results with the reaction of a typical enzyme HRP.[23] The function of $[Co^{III}Cl(tpp)]$–$[Co^{III}(tpp)^{+\cdot}]Cl_2$ and the enzymatic reaction of HRP are written in Schemes 5 and 6, respectively. The numbers in parentheses in these schemes represent the apparent oxidation states estimated on the basis of data from earlier work. $[Co^{III}(tpp)^{+\cdot}]Cl_2$ (+4) and Compound I (+5) of HRP are both π cation radicals and they perform two electron oxidation reactions. Here, we assume a correspondence of $[Co^{III}(tpp)^{+\cdot}]Cl_2$ with Compound I. Then, each of the other species in Scheme 5 can find a nice counterpart in Scheme 6. The change from $[Co^{III}(tpp)^{+\cdot}]Cl_2$ to $[Co^{III}Cl(tpp)]$ by a one-electron reduction corresponds to a reaction from Compound I to Compound II, and a change from $[Co^{III}Cl(tpp)]$ to $[Co^{II}(tpp)]$ to a reaction from Compound II to the native HRP–Fe(+3). This procedure enables us to write another correspondence: $[Co^{I}(tpp)]$ to HRP–Fe(+2), and $[Co^{III}(tpp)\text{-}O_2^{-\cdot}]$ to Compound III.[24] In our reaction system, the stable species is $[Co^{III}Cl(tpp)]$, corresponding to Compound II. The activity of $[Co^{III}Cl(tpp)]$ is considered to be due to its five-coordinate molecular structure[9] and the unique properties depending on the nature of the solvents[8] and the temperature.[10]



Scheme 5. Redox system of our case.



Scheme 6. Redox system of HRP.

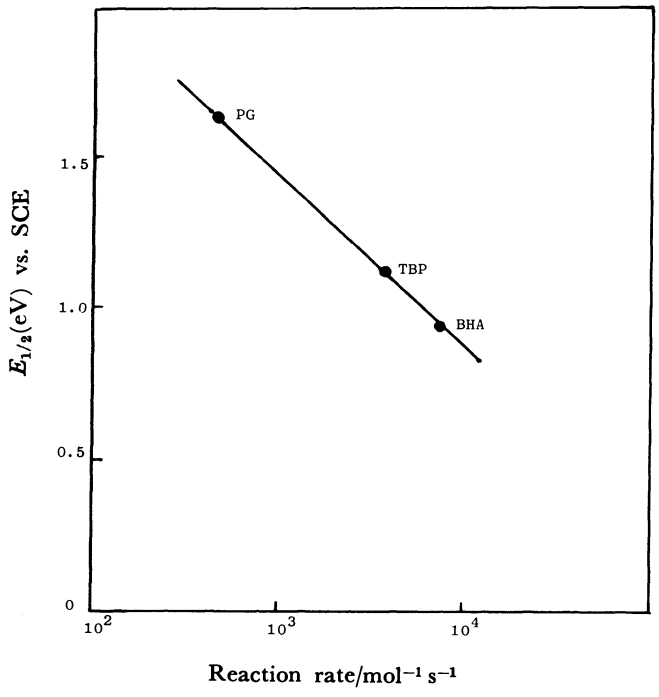


Fig. 10. Relation of reaction rates to redox potentials of phenols (PG, TBP, and BHA).

It should be noted that the active species conducting in our reactions was the chlorine radical, while the active species in the HRP system is considered to be an intermediate derived from H_2O_2.

Siga and Imaizumi[25] have reported that in the reactions of HRP-H_2O_2 and methemoglobin-H_2O_2, a phenoxyl radical formation from the phenols depends on their redox potentials. It has been found that the observed rate constants have a linear relationship with the redox potentials of the phenols. Therefore, the linear relationships shown in Fig. 10 indicate that the enzymatic reactions are correlated with the redox potentiels of the substrates. Furthermore, the concentration dependence of the rate constants shown in Fig. 9 has a similarity with that of the enzymatic reactions in which the concentration of the free radical formed depends upon that of the enzyme:[26] An excess amount of the substrates (more than 10^2 times that of the enzyme) is needed, and some activation mechanisms of the substrate are involved. Consequently, the good correspondence with [$Co^{III}Cl(tpp)$]-[$Co^{III}(tpp)^{+\cdot}$]Cl_2 and HRP suggests that knowledge of the molecular, electronic structure, and properties of [$Co^{III}Cl(tpp)$]-[$Co^{III}(tpp)^{+\cdot}$]-Cl_2 will give useful information for those of HRP.

The author wishes to express his deep gratitude to Prof. Hiroaki Ohya-Nishiguchi of Kyoto University and Dr. Kiyoko Yamamoto of The Institute of Physical and Chemical Research for their helpful discussions during the course of this study. The author is indebted to Mr. Akihiko Tajima of Ehime University for the measurements of cyclic voltammograms and useful discussions.

The Formation Process of Hydrous Gallium(III) Oxide Particles Obtained by Hydrolysis at Elevated Temperatures

Shuichi HAMADA,* Koji BANDO, and Yoshiyuki KUDO
Department of Applied Chemistry, Faculty of Science, and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received December 24, 1985)

Hydrous gallium(III) oxide was produced as monodispersed spherical particles by forced hydrolysis in the presence of sulfate ions, though they partially dissolved and recrystallized. The rate of the reaction degree was empirically expressed under the given conditions as $d\alpha/dt=1.60\alpha^{2/3}(1-\alpha)^{0.874}$, where α is the reaction degree. Polymeric hydroxo complexes were confirmed to act as precursors of the monodispersed spherical particles, judging from the fractional changes of the monomeric and polymeric species during the hydrolysis. The role of sulfate ions in the formation of hydrous gallium(III) oxide particles was discussed.

Recently, the preparation of monodispersed (hydrous) metal oxide particles has been extensively studied.[1-7] One method, the hydrolysis of metal ions at elevated temperatures, gives excellent monodispersed particles under suitable conditions. The morphology, composition, and size-distribution of the particles depend strongly, however, on several parameters, such as the concentration of metal ions, the pH, the temperature, and the kind of anion present, in the method of forced hydrolysis. Especially, a great influence of anions has usually been shown on the morphology and the composition of the particles. It has also been reported that the presence of sulfate ions in a solution is essential to produce monodispersed spherical particles of hydrous aluminium(III)[8] and chromium(III)[9] oxides. In a previous paper,[7] a remarkable effect of sulfate ions was also shown in making monodispersed spherical hydrous gallium(III) oxide particles by forced hydrolysis.

In this work, the role of sulfate ions in the formation of monodispersed hydrous gallium(III) oxide particles was studied, as was their formation process.

Experimental

Materials. All of the reagents used in this work were of a guaranteed grade and were employed without further purification. Stock solutions of gallium(III) sulfate and nitrate were prepared by dissolving the salts in doubly distilled water at room temperature, together with a known amount of the corresponding acid. These stock solutions, when kept in a cold place, did not show any visual change over three months.

Procedures. The sulfate and the nitrate solutions were prepared as the initial gallium(III) ion and acid concentrations of $[Ga^{3+}]_i=9.8\times10^{-4}$ and $[H^+]_{add}=1.0\times10^{-3}$ mol dm^{-3} respectively. The initial concentration ratio of sulfate to gallium(III) ions, $[SO_4^{2-}]_i/[Ga^{3+}]_i$, was specified as 1.9 by the use of potassium sulfate for the gallium(III) sulfate system. This composition has been confirmed as one of the optimum conditions for making monodispersed spherical particles.[7] The solutions were filtered through a membrane filter, 0.2 μm in pore size, before aging.

An aliquot of the solution was placed in a screw-capped Pyrex glass tube or a flask equipped with a condenser, and heated initially at the heating rate of 0.4 °C min^{-1},[7] followed by aging at a specified temperature (70—98 °C) in an oil bath. After the solution had been heated, particles were separated by centrifugation at 1700 g and then washed repeatedly with doubly distilled water. The morphology and size of the particles were observed with a transmission electron microscope.

The concentrations of gallium(III) and sulfate ions remaining in a supernatant solution were followed at regular time intervals after the solids had been completely separated by centrifugation at 45000 g. The supernatant solution thus obtained did not show any Tyndall cone. The total amount of gallium(III) species in the solution was determined spectrophotometrically as follows: A small portion of sulfuric acid was first added to the solution ($[H^+]\approx2.4\times10^{-2}$ mol dm^{-3}) to convert the polymeric gallium(III) species into monomeric ones, since the polymeric species did not complete the reaction with 8-quinolinol, not even within 60 min. Then all of the gallium(III) species were extracted by shaking the solution for 10 s at pH 5.1 with 10 cm^3 of chloroform, just after adding a buffer solution and a 8-quinolinol solution.

The concentration of the monomeric species was determined in the same way as above, but without the conversion process. Consequently, the concentration of polymeric gallium(III) species was estimated from the difference between the two values.

The concentration of sulfate ions in the supernatant solution was also determined colorimetrically with barium molybdate.[10]

Results

Morphology of Monodispersed Hydrous Gallium(III) Oxide Particles. Figure 1 shows the monodispersed spherical particles obtained by hydrolysis at 98 °C for 18 h. These particles were identified as amorphous-like hydrous gallium(III) oxide by means of X-ray powder diffractometry.[11]

Figures 2a—c show the change in the morphology of the particles during the reaction under the conditions shown in Fig. 1. The hydrous gallium(III) oxide was precipitated as monodispersed

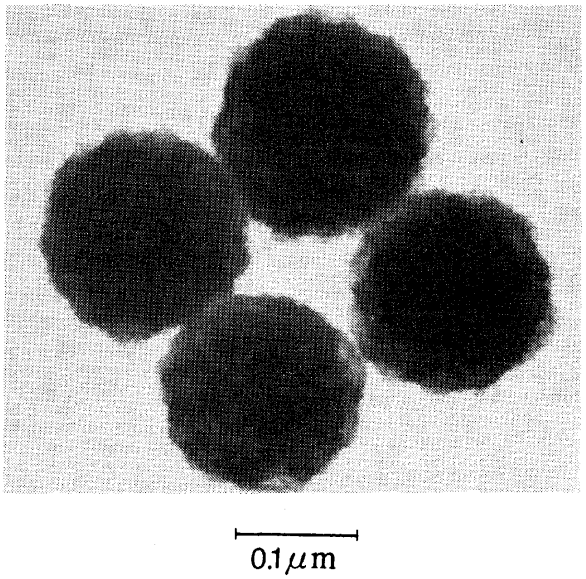

Fig. 1. Electron micrograph of monodispersed spherical hydrous gallium(III) oxide particles obtained at 98 °C. Aging conditions: $[Ga^{3+}]_I = 9.8 \times 10^{-4}$ mol dm^{-3}, $2[H_2SO_4] + [HNO_3] = 1.0 \times 10^{-3}$ mol dm^{-3}, and $[SO_4^{2-}]_I/[Ga^{3+}]_I = 1.9$ respectively.

spherical particles during a reaction for 3.5 h (Fig. 2a). The particles, however, dissolved in part after 4.5 h (Fig. 2b). Figure 2c indicates a mixture of spherical and rod-like particles which has been aged for 18 h. Such a mixture gave weak X-ray powder diffraction peaks attributable to gallium(III) hydroxide oxide. Accordingly, it is obvious that the monodispersed spherical particles became unstable as the reaction proceeded and that they were then transformed partially into crystalline particles through recrystallization.

Variations in the Fraction of Gallium(III) Species in the Supernatant Solution and in the Content Ratio of Sulfate to Gallium(III) in Particles during Reaction. Figure 3 shows the fractional change of soluble gallium(III) species during hydrolysis at 98 °C under the same conditions as are shown in Fig. 1. The fraction of gallium(III) species in the supernatant solution decreased quickly up to around 4 h, but it abnormally reached a maximum at around 4.5 h. This time corresponded to that when the particles partially dissolved (Fig. 2b).

The molar ratio of the sulfate to the gallium(III) contents, $n(SO_4^{2-})/n(Ga^{3+})$, in the particles was estimated by subtracting the concentrations of both gallium(III) and sulfate ions in the solution from their initial values, so that the value involved the amount of sulfate ions adsorbed on the surfaces. The sulfate ions incorporated in the particles were quickly excluded as hydrolysis was enhanced, as is shown in Fig. 4. A similar phenomenon has been observed in the case of hydrous chromium(III) oxide,

Change in Reaction Degree during Forced Hydrolysis. The rate of deposition of the solid phase during the growth of particles is approximately shown as:[12]

$$dP/dt = kS(C-C_s)^p \quad (1)$$

where P is the amount of solid formed; k, the apparent rate constant; S, the surface area of the particles; C, the concentration at the reaction time t; C_s, the final concentration, and p, the parameter of the concentration dependence. The P term can be expressed as mV, where m is the number of moles of gallium(III) species per unit volume and V, the volume of the particles. Thus,

$$dP/dt = mSdr/dt \quad (2)$$

where dr/dt is the radial growth rate. From Eqs. 1 and 2, the following equation can be obtained:

$$dr/dt = k'(C-C_s)^p \quad (3)$$

where k' is k/m.

On the other hand, the reaction degree, α, is defined as:

$$\alpha = (C_0-C)/(C_0-C_s) \quad (4)$$

where C_0 is the initial concentration. Accordingly, the modal diameter, r, of the monodispersed particles at t can be expressed as:

$$r = r_f\alpha^{1/3} \quad (5)$$

where r_f is the final modal diameter. Consequently, the following equation is obtained:

$$d\alpha/dt = K\alpha^{2/3}(1-\alpha)^p \quad (6)$$

where

$$K = 3k'(C_0-C_s)^p/r_f \quad (7)$$

Equation 6 was numerically integrated using the results obtained in Fig. 3. First, the parameters, p and K, were estimated as 0.874 and 1.60[13] respectively by a least-squares method using the logarithmic values of $d\alpha/dt$, α, and $1-\alpha$. Taking these values of the parameters, Eq. 6 was then integrated by the Runge-Kutta method. The solid curve in Fig. 5 displays the reaction degree thus calculated, which agreed very well with the experimental values over the wide range of reaction degrees from around 0.1 to 0.9. The rate of deposition, dP/dt or dV/dt, usually depends on the kinetic order between 1 and 2 with respect to the concentration during the growth process.[14,15] The value of the parameter p (0.874) obtained in this work was close to those presented above. Therefore, the hydrous gallium(III) oxide particles were confirmed to grow according to Eq. 1.

Fractional Changes of Monomeric and Polymeric Species in Partially Neutralized Gallium(III) Salt Solutions. The gallium(III) nitrate and sulfate solutions of 9.2×10^{-3} mol dm^{-3} containing a known amount of the corresponding acid were titrated very slowly with a potassium hydroxide solution of the

same concentration at room temperature. The arrows in Fig. 6 display points at which visual precipitation occurred. The two titration curves were almost identical, except at the later stages. Such a discrepancy in pH values at the later stages can be considered to arise from the replacement of sulfate ions incorporated in the precipitates by hydroxyl ions as neutralization proceeds. In the gallium(III) sulfate solution, however, precipitates appeared at an earlier stage (pH 2.9) ($[H^+]_{add}/[Ga^{3+}]_i=0.13$), while precipitation was retarded up to pH 4.8 ($[OH^-]_{add}/[Ga^{3+}]_i=2.5$) in the nitrate solution.

Such a clear difference in the precipitation process indicated that sulfate ions exerted a remarkable effect on the formation of hydrous gallium(III) oxide. Hek et al.[13] observed similar facts in aluminium(III) salt solutions.

The amounts of monomeric and polymeric aluminium(III) species have also been determined.[14-17] Turner[14] defined the respective amount on the basis of reactivity to 8-quinolinol. The definition for the monomeric and polymeric gallium(III) species was taken to be the same as that for aluminium(III). Furthermore, Iwase et al.[21] confirmed that a dimer, $[M_2(OH)_2]^{4+}$, was also easily extractable with 8-quinolinol, so that the term "monomer" will include this dimer hereafter.

The gallium(III) nitrate and sulfate solutions (9.2×10^{-3} mol dm^{-3}) were carefully neutralized with vigorous stirring to minimize the heterogeneity of the pH in the solutions; then, both the species were estimated in order to reveal their behavior, depending on neutralization. Figure 7 displays the fractions of the monomeric and polymeric species in the gallium(III) nitrate solution as a function of the degree of neutralization. The monomeric species was gradually polymerized as neutralization proceeded, while a solid phase did not appear in this $[OH^-]_{add}/[Ga^{3+}]_i$ range, even when a great amount of polymeric species existed.

On the contrary, the gallium(III) sulfate solution showed different features in the fractional change of the species, as is shown in Fig. 8. Precipitates appeared at a fraction of about 0.4 of the polymeric species. These results indicated that the precipitation of the polymeric gallium(III) species was enhanced in the presence of sulfate ions, combined with those produced on titration. This effect also takes place at forced hydrolysis, not only in the partially neutralized solutions.

Fractions of Monomeric and Polymeric Gallium(III) Species in Solutions during Forced Hydrolysis. Figures 9 and 10 show the changes in the fractions of the soluble gallium(III) species and the precipitates during the forced hydrolysis of the nitrate and the sulfate solutions at 98 °C. Though nearly identical fractions of the polymeric species were initially indicated in both salt solutions, the fraction of the monomeric species gradually decreased as it was converted into the polymeric species at an earlier stage of hydrolysis in the nitrate solution. The concentration ratio of the monomeric to the polymeric species, [monomer]/[polymer], decreased continuously as the hydrolysis was enhanced.

On the other hand, in the sulfate solution the precipitates appeared at an earlier stage of hydrolysis, even at a low fraction of the polymeric species. The [monomer]/[polymer] ratio gradually increased except around 4.5 h, while the fraction of the monomeric species changed similarly to that in the nitrate solution. These results clearly indicate that sulfate ions promote the deposition of hydrous gallium(III) oxide as spherical particles.

Symbols: □; Monomer, ○; polymer, ●; precipitate, △; [monomer]/[polymer] ratio. Aging conditions: $[Ga^{3+}]_i = 9.8 \times 10^{-4}$ mol dm^{-3}, $[HNO_3] = 1.0 \times 10^{-3}$ mol dm^{-3}.

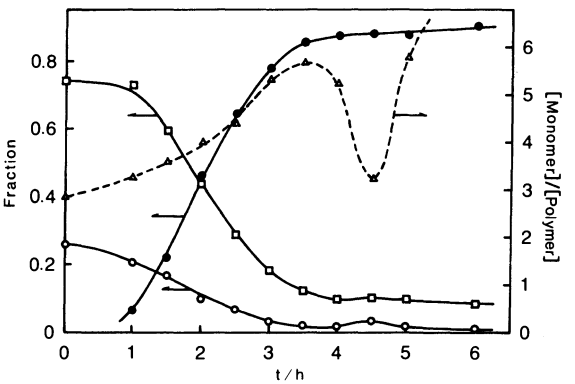

Fig. 10. Fractions of mono- and polynuclear hydroxogallium(III) complexes and precipitate during hydrolysis of sulfate solution at 98 °C. Symbols: □; Monomer, ○; polymer, ●; precipitate, △; [monomer]/[polymer] ratio. Aging conditions: $[Ga^{3+}]_i = 9.8 \times 10^{-4}$ mol dm^{-3}, $2[H_2SO_4] + [HNO_3] = 1.0 \times 10^{-3}$mol dm^{-3}, and $[SO^{2-}]_i/[Ga^{3+}]_i = 1.9$ respectively.

Discussion

On the formation of monodispersed spherical particles of amorphous hydrous aluminium(III) and chromium(III) oxides, it has been confirmed that polynuclear hydroxo and/or hydroxosulfato complexes act as precursors of such particles in the presence of limited amounts of sulfate ions.[8,9,22,23] The monodispersed spheres of hydrous gallium(III) oxide have also been clearly indicated to consist of polymeric species of hydroxo complexes.

According to the mass balance during the deposition of the solid phase, the following equation can be obtained:

$$df_{ppt}/dt = -df_{mono}/dt - df_{poly}/dt \quad (8)$$

Table 1. Rates of Change in Precipitate, Monomer, and Polymer Fractions in a Sulfate System

Reaction time / h	df_{ppt}/dt / h^{-1}	$-df_{mono}/dt$ / h^{-1}	$-df_{poly}/dt$ / h^{-1}
1.0	0.263	0.166	0.082
1.5	0.402	0.298	0.107
2.0	0.415	0.316	0.104
2.5	0.342	0.259	0.082
3.0	0.222	0.166	0.050
3.5	0.092	0.077	0.014

where f_{ppt}, f_{mono}, and f_{poly} are the fractions of the precipitate, the monomer, and the polymer respectively. Table 1 shows the values of the above three terms at different times in the sulfate system; these values were obtained from the respective fraction curves calculated by the least-squares method (Fig. 10). The results in Table 1 indicate that the values of $-df_{mono}/dt$ are 2.0—5.4 times those of $-df_{poly}/dt$. This fact implies that the reaction change in the monomer rather controlled the overall growth rate of the particles. However, a direct deposition of the monomer is unlikely, for the [monomer]/[polymer] ratio should decrease if the particles grow through this process. The [monomer]/[polymer] ratio may increase through a rapid degradation of the polymer, followed by a slow deposition of the monomer. This process is also unlikely, however, because the rate of the degradation of the polymer is usually not so fast.

Thus, the following reaction path, through slow polymerization and fast deposition steps, seems reasonable in the sulfate system:

$$\text{Monomer} \xrightarrow{\text{slow}} \text{Polymer} \xrightarrow{\text{fast}} \text{Amorphous particles.} \quad (9)$$

The first step can be accompanied by a build-up of the polymer as:

$$\text{Polymer}_{(a-b)} + b\,\text{Monomer} \longrightarrow \text{Polymer}_{(a)} \quad (10)$$

where $\text{Polymer}_{(a-b)}$ and $\text{Polymer}_{(a)}$ refer to species of a lower and higher degree of polymerization respectively.

On the other hand, a direct deposition of the polymer is hardly acceptable in the nitrate system, because the solid phase does not appear, even in the cases of large fractions of the polymer-for instance, around 0.5 at 2 h, as is indicated in Fig. 9. Additionally, the [monomer]/[polymer] ratio may decrease if the monomer species are polymerized faster than the deposition of the polymer, but this process is also improbable judging from the difference in df_{poly}/dt and df_{ppt}/dt at the early stages of the polymerization (up to 2 h) and of the deposition.

As is shown in Fig. 9, the rates of deposition

(df_{ppt}/dt) are comparable to those of the decrease in the polymer fraction ($-df_{poly}/dt$) after around 3 h. It has been reported in a previous paper[7] that only rod-like crystalline particles of gallium(III) hydroxide oxide were produced through the forced hydrolysis of the nitrate solution under the same conditions except for the kind of anion. Taking these facts into account, the rate of the particle growth would seem to be governed by that of the degradation of the polymer, and the monomer and/or low molecular-weight hydroxo complexes would seem to act as actual precursors of the crystalline particles. This process is supported by the fact that the [monomer]/[polymer] ratio increased again after 3.5 h and then returned to 2.8 at the final stage of forced hydrolysis (24 h).

Ruff and Tyree[24] expressed the cationic polymers of hydroxogallium(III) complexes as having a linear structure of $[Ga_{n+1}(OH)_{2n}]^{(n+3)+}$. They estimated, on the basis of pH measurements of a perchlorate solution, that the degree of polymerization, n, varied up to around 21 at the $[OH^-]_{add}/[Ga^{3+}]_i$ ratio of 1.75. Contrary to this, however, a much higher degree of polymerization (64) was observed by the light-scattering technique under the same conditions.[24] Patterson and Tyree,[25] by an isopiestic method, also estimated the degree of polymerization as 84 at the $[OH^-]_{add}/[Ga^{3+}]_i$ ratio of 2.0. It can be expected to have a feature similar to the hydrolysis of gallium(III) ions at elevated temperatures, though specified degrees of polymerization could not be obtained in this work.

Highly-polymerized hydroxogallium(III) complexes tend to reduce their large positive charges by converting the OH^--bridges in the polymers into O^{2-}-bridges. Cyclic structures composed of a hexamer unit are also possible, as are those of polymeric hydroxo complexes,[26] which have less positive charges than those of the linear structure for the same degree of polymerization. These highly-charged cationic polymers can more easily associate with sulfate ions compared with univalent anions, such as nitrate and perchlorate, while gallium(III) ions form sulfato complexes[27] in part. Hester and Plane,[28] by means of a Raman spectroscopic techique, have suggested that the sulfatogallium(III) complexes exist as outer-sphere complexes rather than as inner-sphere complexes. The sulfate ions thus paired with the polymers would effectively reduce the positive charge of the polynuclear hydroxo complexes and promote further polymerization.

After the nuclei were generated, their positively-charged surfaces would strongly adsorb sulfate ions in an acidic solution.[8] Then fine colloidal particles of hydrous gallium(III) oxide would easily associate according to the Schulze-Hardy rule, in addition to the surface nucleation of the polymeric species. Hek et al.[16] have confirmed, on the basis of the replacement behavior of labeled sulfate ions, that sulfate ions were incorporated in amorphous precipitates of hydrous aluminium(III) oxide as an adsorbed, but tightly-bound, state. The rapid exclusion of sulfate ions, as is shown in Fig. 4, would support this consideration. Such a spontaneous exclusion of sulfate ions may originate from the substitution by hydroxyl groups as the hydrolysis is enhanced. Hydrous aluminium(III) oxide particles also easily excluded the incorporated sulfate ions upon dialysis or repeated washings, and were transformed into crystalline α-AlOOH at elevated temperatures.[8,29]

In addition, there should be important conditions to obtain the monodispersed particles of hydrous gallium(III) oxide. As one of them, an appropriate formation rate of polynuclear hydroxo complexes is essential to gain a suitable supersaturation, leading to proper nucleation rates, whereas in general hydrolysis reactions take place faster than condensation.[30] These conditions have been shown in connection with the heating rate and the starting composition of the solutions.[7] The interfacial energy of embryos would be reduced according to the amount of sulfate ions adsorbed on the surfaces and would control the nucleation rate, in addition to the secondary surface-nucleation rate, though the detailed mechanisms are still not clear. This effect was distinctly reflected in the morphology of the particles during the forced hydrolysis of gallium(III) ions.[7] If many sulfate ions existed in the solutions ($[SO_4^{2-}]_i/[Ga^{3+}]_i > 2.0$), only polydispersed particles were produced because of the fast deposition rates.

Electrochemical Properties of Electropolymerized Poly(1-pyrenamine) Films

Noboru Oyama,* Kazuhiko Hirabayashi, and Takeo Ohsaka
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received December 25, 1985)

The electropolymerization of 1-pyrenamine (PA) in an acetonitrile solution led to the polymeric film formation on electrode surfaces. The chemical, spectroscopic, electrical and electrochemical characterization of the resulting poly(1-pyrenamine) (PPA) films was carried out. The number-average molecular weight of the PPA film, measured by gel permeation chromatography, was 1.8×10^3, corresponding to the degree of the polymerization of ca. 8. The PPA films were polymer-anion composites which contained ca. 0.3 anions (e.g., BF_4^-) per repeating aromatic unit, which is considered to be composed of three PA molecules. The oxidized form of the PPA film displayed the ESR response. The g factor was 2.0082 and the concentration of radical in the PPA film was determined to be 4.8×10^{19} e^-g^{-1}. The conductivities of the PPA films in the dry state at 300 K were in the range 10^{-11}—10^{-10} S cm^{-1}. The PPA film was electroactive in an aqueous solution as well as in a non-aqueous solution. The cyclic voltammetric responses depended on pH of aqueous solutions and supporting electrolyte in non-aqueous solutions. The thickness(ϕ) of the PPA film and the surface concentration(Γ) of the electroactive site in the PPA film were proportional to the amount (Q) of the charge passed during the electrolysis (when $Q<$ ca. 120 mC cm^{-2}). The volume concentrations of the electroactive site were 9.7×10^{-4} and 1.7×10^{-3} mol cm^{-3} for the PPA films prepared in the $NaClO_4$ and $TBABF_4$ (tetrabutylammonium tetrafluoroborate) electrolytes, respectively. From the normal pulse voltammetric, potential-step chronoamperometric and potential-step chronocoulometric experiments of the PPA films in a 0.2 M $NaClO_4$ aqueous solution (pH 1.0), the effective apparent diffusion coefficient (D_{app}) for the diffusion-like charge transport within the PPA films, and the standard rate constant (k°) and anodic transfer coefficient (α_a) of the heterogeneous electron-transfer reaction between the In_2O_3 electrode and the electroactive site in the PPA film were estimated to be $(1.5\pm0.5)\times10^{-10}$ cm^2 s^{-1}, $(1.9\pm0.4)\times10^{-5}$ cm s^{-1} and 0.67 ± 0.03, respectively.

In a series of recent papers,[1-9] we have reported (i) the preparation of polymeric films by electropolymerization of aniline, phenol and their derivatives, (ii) the electrochemical, spectroscopic, electrical and physicochemical characterization of the prepared polymeric films, and (iii) the applications of the polymer film-coated electrodes as "hybrid electrode materials." It has been demonstrated therein that whether or not the polymer film formation occurs and the structures and properties of the prepared films depend on the kind of the monomer used for polymerization as well as the experimental conditions used in their preparations (e.g., solvent, electrode material, supporting electrolyte, pH of electrolytic solution, current density, temperature, and electrolysis mode (potential sweep electrolysis, potentiostatic electrolysis, galvanostatic electrolysis, etc.)). Also, it has become apparent that one could prepare the polymeric films, chemical preparations of which are not always easy or in some cases very difficult, relatively easily by electropolymerization of commercially available reagents.

Along this line of investigation, the studies on the electropolymerization of polynuclear aromatic hydrocarbons containing hydroxyl or amino groups (e.g., 1-pyrenamine, 1-naphthylamine, and 1-naphtol) have been also started. The film formation during the electro-oxidation of a variety of polynuclear aromatic hydrocarbons has been previously observed by Peover and White,[10,11] and more recently the comprehensive study concerning their electropolymerization has been done by the IBM research group.[12-16] For polynuclear aromatic hydrocarbons containing hydroxyl or amino groups, only a few papers[17,18] concerning the electropolymerization of these compounds have appeared recently. The electrochemical oxidation of polynuclear aromatic amines (e.g., 1-naphthylamine,[19-21] 2-fluorenamine,[22] 10-phenyl-9-anthracenamine[23] and 9-(arylamino)anthracene[24]) has been recently studied by several investigators whose attention has been mainly directed to the mechanism of the formation of the dimeric products soluble in the electrolytic solutions used. Little attention has been paid to the formation of the polymeric films on the electrode surface, although the film formation has been obviously observed in some cases.[19,20] It would be worthwhile to examine the effect of a nucleus other than benzene in the electropolymerization of the aromatic amines and phenols.

In the present paper, we will report the preparation of the polymeric films by electropolymerization of 1-pyrenamine in an acetonitrile solution and the electrochemical, electrical, physicochemical and spectroscopic characterization of the resulting polymer films. It is demonstrated that the prepared polymeric films possess some interesting properties which differ from those obtained for the polymeric films[1-9,25-38] (e.g., polyaniline and polyphenol) prepared from mononuclear aromatic monomers with hydroxyl and/or amino groups.

Experimental

Materials. 1-Pyrenamine (PA)(Aldrich) was purified by

the following way: The commercially available PA reagent was dissolved in acetonitrile and then insoluble materials were filtered out, then the solvent was evaporated off and the resultant PA solids were purified by ordinary recrystallization techniques from hexane. Pyrene of reagent grade (Wako Chemical Co.) was purified by recrystallization from benzene. Acetonitrile (Wako) was distilled by ordinary technique after dehydration on molecular sieves (3A 1/16, Wako). Sodium perchlorate ($NaClO_4$) (Kanto Chemical Co.), tetrabutylammonium tetrafluoroborate ($TBABF_4$), tetrabutylammonium perchlorate(TBAP) (Tokyo Kasei Co.), tetraethylammonium chloride (TEACl) (Wako) which were used as supporting electrolytes were reagent grade. Tetrabutylammonium hexafluorophosphate($TBAPF_6$) (used as supporting electrolyte) was prepared from tetrabutylammonium bromide and potassium hexafluorophosphate and purified by recrystallization from H_2O/C_2H_5OH mixture. The basal-plane pyrolytic graphite(BPG) (Union Carbide Co.) and In_2O_3 were used as working electrodes. All other chemicals were reagent grade and were used without further purification.

Apparatus and Procedures. The electropolymerization and electrochemical measurements were conducted by using a standard three-electrode, two-compartment electrochemical cell. The electrode assembly consists of a BPG (or an In_2O_3) electrode as working electrode, a sodium chloride saturated calomel electrode(SSCE) as reference electrode and a spiral platinum wire as counter electrode. For cyclic voltammetry, potential-step chronoamperometry, potential-step chronocoulometry and normal pulse voltammetry, a home-made instrument was employed along with an X-Y recorder(Watanabe Co.).[39,40] The amounts (Γ) of the electroactive site in the electropolymerized poly(1-pyrenamine) (PPA) films were estimated in units of mol cm^{-2} by measuring the area of cyclic voltammograms(for the redox reaction of PPA film) obtained at slow potential scan rates(1—5 mV s^{-1}) in a 0.2 M (1 M=mol dm^{-3}) $NaClO_4$ aqueous solution (pH 1.0).[39-41] The molar concentration (in units of mol cm^{-3})of the electroactive site was calculated from the Γ thus obtained using the measured thicknesses of the PPA films. The electropolymerization of PA was carried out by a potential-sweep electrolysis and/or a constant potential electrolysis in an acetonitrile solution containing 5 or 10 mM PA+0.2 M supporting electrolyte (mainly $NaClO_4$ or $TBABF_4$). The film thicknesses of the resulting PPA films were measured with a Surfcom 550A (Surface Texture Measuring Instrument, Tokyo Seimitsu). An IR absorption spectroscopy (A-302 Infrared Spectrophotometer, Japan Spectroscopic Co., LTD.) was used to identify the PPA films formed on electrodes. ESR spectra were taken on JES-FEIX ESR Spectrometer for the oxidized forms of the PPA films. The conductivities (σ) of the PPA films in dry state were measured by using two-point probe technique at ambient temperature (300K) by means of d.c. power supply (Metronix Corp., Model 5126) and d.c. microvolt ammeter (Toa Electronic LTD., Model PM-18R). The weight- and number-average molecular weights of the PPA films were estimated by means of gel permeation chromatography by using narrow molecular weight polystyrene standards (Waters Assoc., Inc., Milford, Mass) as probe for measuring resolution and calibration.

Results and Discussion

Cyclic Voltammetric Behavior of PA Monomer. Typical cyclic voltammograms of PA at BPG electrode in an acetonitrile solution containing 0.2 M $TBABF_4$, and 10 mM PA are shown in Fig. 1 where the cyclic voltammograms of pyrene in the same supporting electrolytic solution are given for comparison. PA electro-oxidizes irreversibly and produces complicated cyclic voltammograms. The voltammograms contain multiple peaks which are broad and overlapping. In the first forward scan of the potential, the several anodic peaks were obtained at ca. 0.6, 0.95, 1.2, and 1.4 V vs. SSCE (at 50 mV s^{-1}). During the first reverse scan, the ill-defined cathodic peaks corresponding to the anodic peaks observed during the forward scan and the well-defined one at ca. 0.3 V were observed. In the second forward scan, the anodic peak corresponding to the cathodic one at 0.3 V was obtained at ca. 0.4 V. This paired anodic and cathodic peaks correspond to the redox reaction of the polymeric products being formed on the electrode surface. The oxidation potential (ca. 0.4 V) of the polymeric products is lower than that (ca. 0.6 V) of parent PA. Such a behavior seems to be a general feature of a number of families of homologous oligomers of aromatic compounds.[13,42] According to the fact,[13,42] the dimer or any higher oligomer is more easily oxidized than parent monomer. The

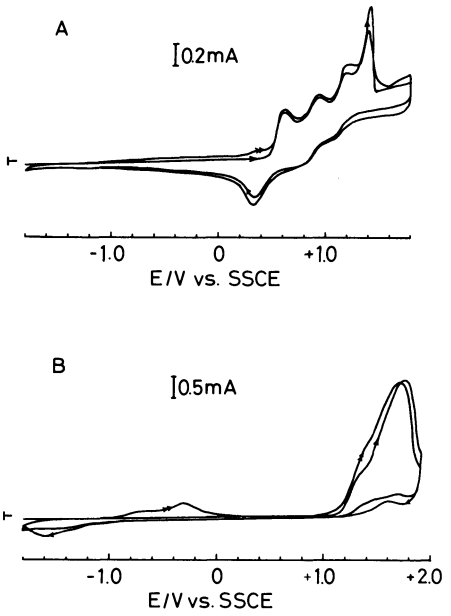

Fig. 1. Typical cyclic voltammograms of (A) PA and (B) pyrene at BPG electrodes in acetonitrile solutions under an atmosphere of nitrogen. Solution composition: (A) 10 mM PA+0.2 M $TBABF_4$, (B) 10 mM pyrene+0.2 M $TBABF_4$. Scan rate: 50 mV s^{-1}. Electrode area: 0.17 cm^2. The arrow indicates the direction of potential scan.

increase in the peak currents with successive potential scans indicates the build-up of the electroactive polymeric products on the electrode.

The cyclic voltammetric response of PA is considerably different from that for pyrene in that (i) the voltammetric responses are more complicated than those for pyrene, (ii) the first oxidation peak (ca. 0.6 V vs. SSCE) is much less positive than that (ca. 1.3 V) for pyrene, and (iii) the redox response of the polymeric product is observed at ca. 0.35 V, which is considerably negative compared with that (ca. 0.9 V) for the polymeric product from pyrene. Of course, PA as well as pyrene electro-oxidize and produce the respective polymeric films on electrode surfaces. The cyclic voltammetric data for pyrene shown in Fig. 1 are in good agreement with those reported previously by Diaz et al.[15]

By holding the electrode potential at the potential which is slightly over the first oxidation peak potential(typically this is 0.75 V vs. SSCE), the formation of the polymeric film on the electrode surface was observed. The electrolyses at more positive potentials (e.g., 1.0 V vs. SSCE) did not give the substantially different results: The cyclic voltammetric responses and IR spectra of the PPA films prepared by the electrolyses at 0.75 and 1.0 V vs. SSCE were the same. However, the electrolyses at much more positive potentials (e.g., 1.8 V vs. SSCE) did not lead a significant film formation on electrode surfaces. Thus, in the experiments mentioned below, the electrolysis was carried out at the potential which is slightly over the first oxidation peak potential. The typical cyclic voltammograms of this case are shown in Fig. 2. As the potential scan was cycled, the anodic peak current at 0.65 V decreased, while the new peaks at 0.35 and 0.45 V increased slowly. As a result, the formation of a purplish black thin film was observed on the electrode surface. The oxidized form of the film was purplish black and the reduced form was yellow. The redox response corresponding to the polymer film produced on the electrode surface was observed at ca. 0.3 V, when after the electrolysis the electrode was washed with benzene and then transferred into the supporting electrolytic solution containing no PA (0.2 M $NaClO_4$ aqueous solution, pH 1.0). The voltammetric response remained substantially unchanged even after the potential scan cycling of several hours.

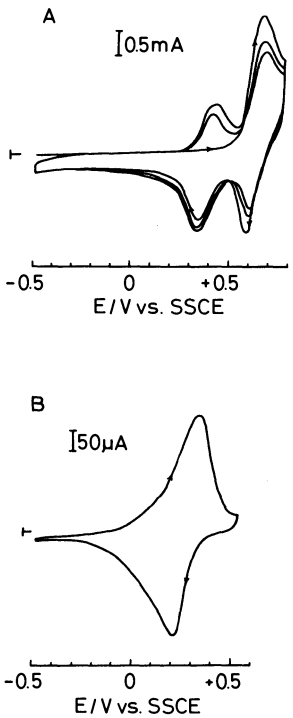

Fig. 2. (A) Typical cyclic voltammograms of PA at a BPG electrode in an acetonitrile solution containing 5 mM PA+0.2 M $TBABF_4$. Scan rate: 5 Vs^{-1}. Electrode area: 0.17 cm^2. (B) Cyclic voltammogram representing the electroactivity of the PPA film deposited on a BPG electrode in a 0.2 M $NaClO_4$ aqueous solution (pH=1.0). Scan rate: 50 mVs^{-1}.

Spectroscopic, Electrical and Chemical Characterization of PPA Film. The IR spectra of the PPA films formed on the In_2O_3 electrodes during the anodic oxidation of PA are shown in Fig. 3 in which the IR spectrum of PA monomer is also shown for comparison. These IR spectral data are summarized in Table 1. In the case of the oxidized form of the PPA film, the observation of the peak at 1660 cm^{-1}

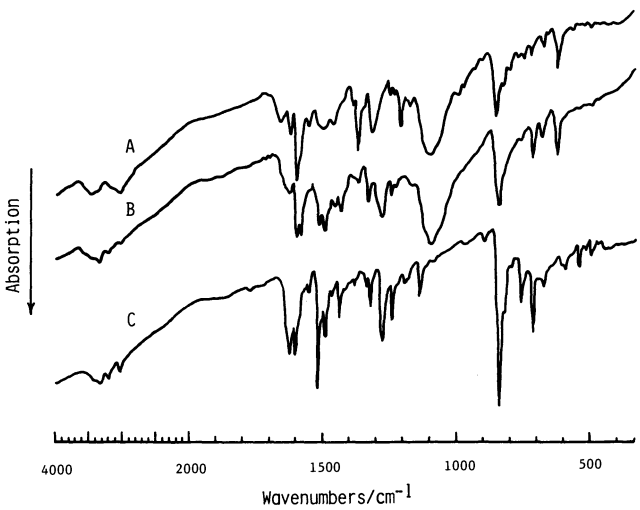

Fig. 3. IR spectra of (A) the oxidized form and (B) the reduced form of the PPA film and (C) PA monomer. The oxidized form of the PPA film was prepared on an In_2O_3 electrode by a constant-potential electrolysis (at 0.75 V vs. SSCE) in a 0.2 M $NaClO_4$ acetonitrile solution containing 10 mM PA and 10 mM pyridine. The reduced form was prepared by reducing electrochemically the oxidized form deposited on electrodes at −0.5 V vs. SSCE in a 0.2 M $NaClO_4$ aqueous solution (pH=1.0).

Table 1. IR Spectra of PPA Films and PA Monomer
(Fundamental Vibrations, Frequencies in cm^{-1})

Compound	Vibration mode[c,d,e]						
	ν(C=C)	ν(C-H)	γ(C-H)	ν(C=N)	ν(C-N)	ν(N-H)	ClO_4^-

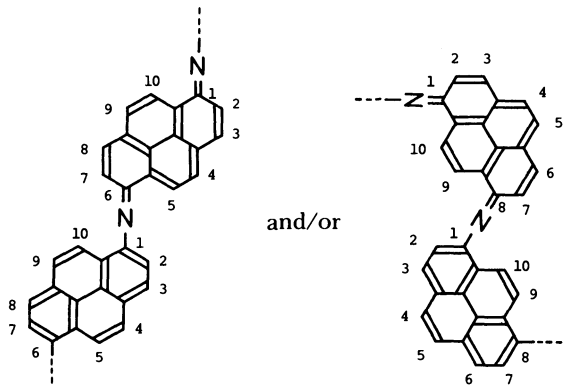
a) The oxidized form of the PPA film was prepared on an In_2O_3 electrode by a constant-potential electrolysis at 0.75 V vs. SSCE in an acetonitrile solution containing 10 mM PA+10 mM pyridine+0.2 M $NaClO_4$. b) The reduced form of the PPA film was prepared by reducing electrochemically the oxidized form deposited on electrodes at −0.5 V vs. SSCE in a 0.2 M $NaClO_4$ aqueous solution(pH 1.0). c) ν=Stretching vibration. d) γ= Out-of-plane bending vibration. e) Absorption intensity (not quantitative); s(strong), m(medium) and w(weak). f) No absorption. g) Absorption was observed as "shoulder".

corresponding to the stretching of the C=N bonds seems to point to polymers based on imine links of the type C-N=C.[43,44] This absorption peak was not observed with the reduced form of PPA as well as PA monomen The relatively strong absorption peaks at 1280 cm^{-1} which are ascribable to the stretching of C-N bonds[43,44] were observed with PA monomer and the reduced form of PPA, while in the case of the oxidized form the corresponding absorption peak was observed slightly as a "shoulder". The strong absorption peaks at 1100 cm^{-1} observed in the spectra of the oxidized and reduced forms of the PPA film are assigned to the presence of ClO_4^- ions,[43,44] which were used as an electrolytic anion during the film formation. The absorption peaks due to the N-H stretching at 3330—3350 cm^{-1} were observed for the oxidized and reduced forms of the PPA film and PA monomer. The other absorption peaks shown in Table 1 (i. e., ν(C=C), ν(C-H), and γ(C-H)), which are common to the PPA films and PA monomer, are characteristic of the various vibration modes of the C-H and C-C bonds of the aromatic nuclei.[43,44] From these results, the electropolymerization of PA seems to proceed via the formation of the C-N=C bonds and the C-NH-C bonds. In this point, the electropolymerization reaction of PA may be similar to that proposed recently for aniline and its derivatives.[2-4,6,7,27,30,46]

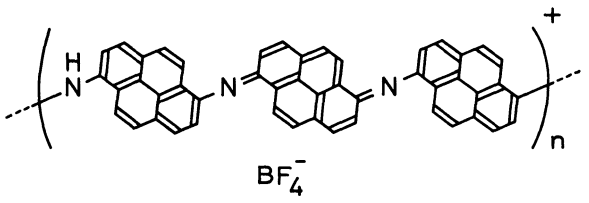
For the electropolymerized films of aniline and its derivatives,[2-4,6,7,46] an analysis of the absorption peak pattern between ca. 900 and 700 cm^{-1} which arises from the C-H out-of-plane bending modes[43,45] enabled us to assign correctively the substitution pattern of the aromatic ring and to elucidate the structures of the films. A fairly good correlation between the positions of the absorption bands and the substitution pattern in terms of numbers of adjacent hydrogen atoms was found for the condensed aromatic ring series (i.e., benzene, acene and phen series).[43,45,47,48] However, no conclusive results on the basis of the same idea were obtained for pyrene, which is a peri-condensed hydrocarbon. Recently, the empirical rules connecting substitution pattern and bond positions in a broad variety of substituted pyrenes (137 pyrene derivatives) has been suggested by Hansen and Berg.[49] According to their empirical rules, along with the above-mentioned discussions about the linkage between PA units in the PPA film, it can be concluded that the electropolymerization of PA proceeds via the coupling of the aromatic rings at the 1- and 6-positions and/or the 1- and 8-positions as follows:



and/or

On the basis of the concept of radical cation dimerization, Bargon et al.[13] have recently suggested that the polypyrene, the polymeric product resulting from the electropolymerization of pyrene, is made up of 1,6-pyrenediyl and/or 1,8-pyrenediyl units. The PPA films were soluble in dimethyl sulfoxide and *N*,*N*-dimethylformamide(DMF). The weight- and number-average molecular weight ($\bar{M}_w$ and $\bar{M}_n$) of the PPA films were estimated by means of gel permeation chromatography (solvent: DMF). The values of $\bar{M}_n$ and $\bar{M}_w$ were 1.8×10^3 and 3.0×10^3, respectively which correspond to the degree of polymerization of 8 and 14, respectively. Note that the true molecular weight of the PPA film may be smaller than that estimated on the basis of polystyrene standards (as mentioned above), because PA is more rigid than styrene.

The elemental analysis of the PPA film (oxidized form) prepared in the $TBABF_4$ acetonitrile solution indicated that the weight percents of C, H, N, and BF_4^- in the PPA film are 78.07, 3.76, 5.72, and 12.45%, respectively which correspond to the molar ratios of 15.9(C), 9.1(H), 1.0(N) and 0.35(BF_4^-) (relative to the molar numer of N). This fact indicates that the PPA films are polymer-anion composites which contain ca. 12% BF_4^- by weight. From these molar ratios of C, H, N, and BF_4^- a possible structure of the repeating aromatic unit of the PPA film may be predicted as follows:



The molar ratios of C, H, N, and BF_4^- for the repeating unit structure predicted above are 16.0, 8.3, 1.0, and 0.33, respectively, which are in fair agreement with the experimental elemental analysis. Thus, the PPA film contains ca. 0.3 BF_4^- anions per repeating aromatic unit which is thought to be composed of three PA molecules. Further, it is worth noting that the elemental composition is somewhat hydrogen-rich. This may suggest that the double bonds of the pyrene rings of the PPA are partially hydrogenated, as previously proposed for the hydrogen-rich elemental compositions of the polymers prepared by the electropolymerization of polycyclic aromatic hydrocarbons such as pyrene and fluorene.[15]

In Fig. 4 is shown the ESR spectrum of the oxidized form of the PPA film. The ESR spectrum consists of a simple, symmetrical, narrow line with Lorentzian shape. The peak-to-peak line width was 0.90 mT at room temperature. The *g* factor measured against a 2,2-diphenyl-1-picrylhydrazyl radical standard was 2.0082. The concentration of radical in the PPA film was determined to be 4.8×10^{19} $e^- g^{-1}$, which is compared to the value ($(1-7)\times10^{19}$ $e^- g^{-1}$) for polyaniline[50,53] (oxidized form) and that (1.4×10^{19} $e^- g^{-1}$) for polyacetylene.[51] Assuming that the elemental composition of the PPA is $C_{48}H_{25}N_3(BF_4)_1$, it is thought that there is one unpaired electron per ca. 17 repeating units. Even after the reduction of the oxidized form of the PPA film by the chemical procedure (using the reductants such as $Na_2S_2O_4$ and C_2H_5SH) or by the electrochemical one (by holding the PPA-coated electrode at the potetial at which the PPA film could be reduced), no NMR spectra of the reduced form (as well as the oxidized form) of the PPA film were obtained.

The conductivities (σ) of the PPA films in the dry state, measured at 300 K by using the two-point probe technique, were in the range 10^{-11}—10^{-10} S cm^{-1} for both oxidized and reduced forms irrespective of the supporting electrolytes used (i.e., $NaClO_4$ and $TBABF_4$). Also, the σ values were nearly independent of the presence or absence of pyridine in the electrolytic solution. Note that the σ values for the PPA films are about 6 to 10 orders of magnitude smaller than those obtained for the other electropolymerized films, for example, the σ values (10^{-4}—10^{-1} S cm^{-1}) for polyaniline, poly(*o*-phenylenediamine) and poly(*N*-methylaniline).[3,5,53] Further, the

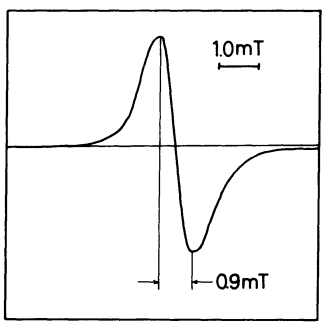


Fig. 4. ESR spectrum of the oxidized form of the PPA film at 298 K. The oxidized form of the PPA film was prepared by the same procedure as shown in Fig. 3.

following fact should be noted: In the case of the polyaniline films which were equilibrated with aqueous solutions of different pH's, washed in acetonitrile, and then dried under vaccum, changing pH from 0 to 6 has been reported to decrease σ by 6 orders of magnitude,[53] whereas in the case of the PPA film the slight dependence of σ on pH was observed, i.e., the σ values of the PPA films treated at pH 1.0 and 12.0 were ca. 10^{-10} and 10^{-12} S cm^{-1}, respectively. Such significant differences in the σ values and their pH dependences are considered to originate from the difference in the basic structures of the PPA and polyaniline, that is, the former contains polynuclear aromatic rings, while the latter contains mononuclear aromatic rings.

Electrochemical Response of PPA Film. Figure 5 shows the correlation between the thickness (ϕ) of the PPA film and the amount (Q) of the charge passed during the anodic oxidation of PA. In this case, the films were prepared by the anodic oxidation of PA at 0.75 V vs. SSCE in an acetonitrile solution containing 0.2 M $NaClO_4$ (or $TBABF_4$), 10 mM PA and 10 mM pyridine. The ϕ's are proportional to Q when $Q<$ca. 120 mC cm^{-2}. The proportionality constant of ϕ to Q is 4.2×10^{-3} cm^3 C^{-1} for the PPA film prepared in the $NaClO_4$ electrolyte and 1.9×10^{-3} cm^3 C^{-1} for that prepared in the $TBABF_4$ electrolyte. Thus, under the conditions of the same amount of the charge passed, the PPA film prepared in the $NaClO_4$ electrolyte is over twice thicker than that in the $TBABF_4$ solution. Such an observed proportionality is surprising in view of the fact that the film-forming reaction was accompanied by the formation of soluble, purplish products as can readily be seen from the colored (purplish) electrolytic solution. The similar proportionality of ϕ to Q has been also obtained in the electropolymerization of the other aromatic monomers (e.g., aniline,[1] N-methylaniline,[5] o-phenylenediamine[5] and N,N-dialkylanilines[6,7]), irrespective of the apparent observation of the production of the soluble products. The proportionality constants obtained for the PPA films are 5—10 times larger than that obtained for the electropolymerization of aniline. At any rate, the data shown in Fig. 5 indicate that the PPA film thickness can be arbitrarily controlled by the charge passed during the electrolysis.

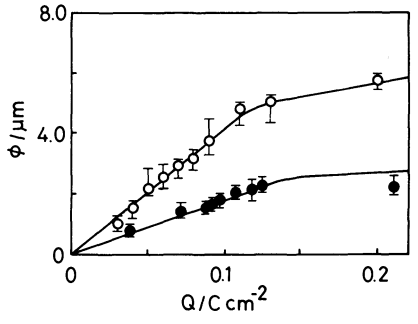

Fig. 5. Correlation between the PPA film thickness (ϕ) and the amount (Q) of the charge passed during the anodic oxidation of PA. The PPA films were prepared on BPG electrodes by a constant-potential electrolysis at 0.75 V vs. SSCE in acetonitrile solutions. Solution composition: (○) 10 mM PA+10 mM pyridine+0.2 M $NaClO_4$; (●) 10 mM PA+10 mM pyridine+0.2 M $TBABF_4$. Widths of error bars indicate uncertainties in thickness measurements.

Figure 6 shows the correlation between the Γ value and Q, where the Γ indicates the surface concentration of electroactive site in PPA films, measured by cyclic voltammetry in an aqueous $NaClO_4$ solution (pH 1.0). The Γ's are proportional to Q when $Q<$ca. 120 mC cm^{-2}. Thus, from the results shown in Figs. 5 and 6, the volume concentrations of electroactive site in the PPA films were estimated to be 9.7×10^{-4} and 1.7×10^{-3} mol cm^{-3} for the PPA films prepared in the $NaClO_4$ and $TBABF_4$ solutions, respectively. In this case, the current efficiency for the preparation of the PPA films was 30—40 per cent. This value is considerably high compared with those (several per cent) for polyaniline,[1] poly(N-methylaniline),[5] and poly(o-phenylenediamine)[5] films. It is interesting that the correlations between ϕ and Q, and Γ and Q depend on the supporting electrolyte used in the PPA film formation and as a result the volume concentrations of the electroactive site in the PPA films are different. This may probably be due to the different

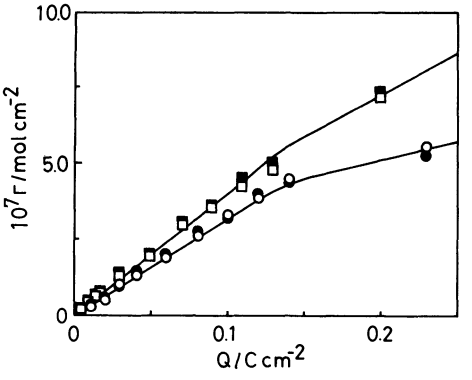

Fig. 6. Correlation between the surface concentration (Γ) of electroactive site in the PPA films and the amount (Q) of the charge passed during the anodic oxidation of PA. The PPA films were prepared by the same procedure as shown in Fig. 5. (□, ■): the PPA films prepared in the $NaClO_4$ electrolyte, (○, ●): the PPA films prepared in the $TBABF_4$ electrolyte. The estimation of the Γ values was conducted by measuring the area of cyclic voltammograms (for the redox reaction of the PPA film) obtained at the potential scan rate of 2 mVs^{-1} in a 0.2 M $NaClO_4$ aqueous solution (pH=1.0). The open and solid symbols indicate the Γ values estimated from the integration of the anodic and cathodic currents, respectively, of the cyclic voltammograms of the PPA films.

morphology of the PPA films formed in the different supporting electrolytes. The PPA films prepared from the $NaClO_4$ electrolyte appeared rough to the naked eye, while those from the $TBABF_4$ electrolyte appeared more lustrous. The latter PPA films were more adhesive to the electrode surface. Thus it may be thought that the PPA film prepared from the $NaClO_4$ electrolyte is more porous than that from the $TBABF_4$ electrolyte, so that the PA monomers can more easily penetrate the PPA film prepared from the $NaClO_4$ electrolyte to reach the electrode surface than that prepared from the $TBABF_4$ electrolyte. This is apparent from the Q vs. t curves obtained during the electrolysis at a constant potential (see Fig. 7).

The PPA films are electroactive in an aqueous solution. The pH-dependences of the cyclic voltammograms of the PPA films are shown in Fig. 8. For the PPA of Γ=2.2×10^{-9} mol cm^{-2}, corresponding to ca. 20 monolayers based on a monolayer coverage of ~10^{-10} mol cm^{-2}, the cyclic voltammetric response is similar to that obtained for the solution-phase redox species the electrode reaction of which is reversible, that is, the voltammograms are diffusion-like with broad peaks and diffusional tails and the cathodic and anodic peak currents are almost the same (Fig. 8A). The anodic and cathodic peak potentials (E_p^a and E_p^c) shifted to the negative potential with increasing pH (Fig. 9). The dependences of E_p^a and E_p^c on pH are complicated, indicating that proton (H^+) and electron (e^-) take part in the electrode reaction of the PPA film and in this case the numbers of H^+ and e^- involed in the electrode reaction vary with pH of the solution. However, in an acidic solution (pH<4.0) the slopes of E_p^a (and E_p^c) vs. pH plots are about −60 mV/pH. This suggests that the overall electrode reaction of the PPA film is the H^+/e^- reaction in an acidic

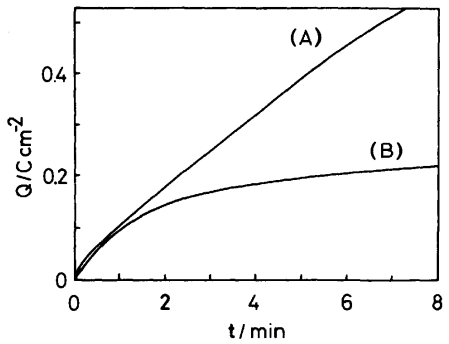

Fig. 7. Potential-step chronocoulometric responses for the anodic oxidation of PA at a BPG electrode in acetonitrile solutions. Solution composition: (A) 10 mM PA+10 mM pyridine+0.2 M $NaClO_4$; (B) 10 mM PA+10 mM pyridine+0.2 M $TBABF_4$. Electrode area: 0.17 cm^2. The electrode potential was stepped from 0.0 to 0.75 V vs. SSCE.

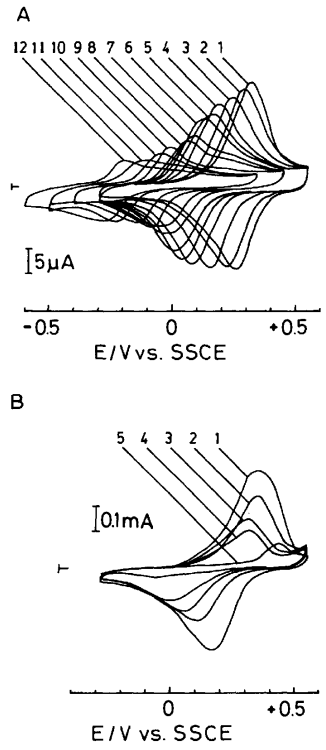

Fig. 8. Cyclic voltammetric responses of the PPA films on BPG electrodes in 0.2 M $NaClO_4$ aqueous solutions of various pH's. The Γ values of the PPA films: (A) 2.2×10^{-9} mol cm^{-2}; (B) 9.7×10^{-8} mol cm^{-2}. Scan rate: 100 mV s^{-1}. Electrode area: 0.19 cm^2. The PPA films were prepared by the same procedure as shown in Fig. 5. The numbers on respective cyclic voltammograms indicate pH values.

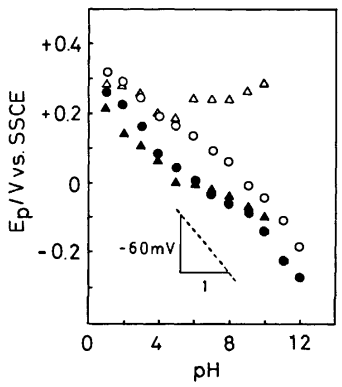

Fig. 9. Typical pH-dependences of the anodic and cathodic peak potentials of the cyclic voltammograms of the PPA films. The Γ values of the PPA films: (○, ●) 2.2×10^{-9} mol cm^{-2}, (△, ▲) 9.7×10^{-8} mol cm^{-2}. The open and solid symbols indicate the anodic and cathodic peak potentials (E_p^a and E_p^c), respectively. Other experimental conditions are the same as in Fig. 8.

aqueous solution. For the thicker film of $\Gamma = 9.7\times10^{-8}$ mol cm^{-2} corresponding to ca. 1000 monolayers, the cyclic voltammetric response is considerably complicated, compared with that for the thin film (Fig. 8B). In this case, the cyclic voltammetric response depended on the scan rate of the potential. The similar behavior has been also observed for the other electroactive electropolymerized films (e.g., polyaniline film[1,25,28]). It seems to be the reason for such a behavior that the PPA film contains the redox sites with slightly different redox potentials and/or its electrode reaction involves any chemical process which actually determines the rate of the overall electrode reaction at the time scale of the measurements. The decreases in the peak currents with increasing pH, shown in Fig. 8, are associated with the fact that a proton addition-elimination reaction is involved in the overall electrode reaction of the PPA film itself, as mentioned above. The magnitude of the peak currents reflects the apparent rate of the overall electrode reactions which decreases with a decrease in the concentration of proton. In this case, these decreases were found to be due to neither the dissolution of the PPA film on electrodes nor its chemical change to any electroinactive compounds (when soaked in alkaline solutions) from the following facts: The Γ values for a given PPA film-coated BPG electrode, measured in the solutions of different pH's, were the same within experimental errors. The coloration of the solution due to the dissolution was not observed. The IR spectra of the PPA films, which were equilibrated with the aqueous solutions of pH1.0 and 12.0 and then dried under vacuum, were essentially the same.

Figure 10 shows the typical normal pulse voltammograms for the oxidation of the PPA film on an In_2O_3 electrode in a 0.2 M $NaClO_4$ solution (pH 1.0). The PPA film was the electropolymerized one in the $NaClO_4$ acetonitrile solution. The plots of the anodic limiting current (i_{lim}) of these normal pulse voltammograms against the inverse square root of the sampling time (τ) were found to be linear (Fig. 11), indicating that the limiting currents were diffusion-controlled.[39,40] Thus the values of the apparent diffusion coefficients, D_{app}, for the charge-transport process within the PPA films were obtained from the slope of the i_{lim} vs. $\tau^{-1/2}$ plot by using the Cottrell equation, as has been done for other surface-confined polymers[39,40]: $D_{app}=1.3\times10^{-10}$ cm^2 s^{-1} (for anodic process). The potential-step chronoamperometric and chronocoulometric experiments (PSCA and PSCC) gave also the D_{app} values: from PSCA, the D_{app} values were determined to be 2.0×10^{-10} and 1.2×10^{-10} cm^2 s^{-1} for anodic and cathodic processes, respectively and from PSCC, the D_{app} values were determined to be 1.9×10^{-10} and 1.0×10^{-10} cm^2 s^{-1} for anodic and cathodic processes, respectively. The D_{app} values estimated by these different procedures are almost the same within experimental errors. These values of D_{app} are about 1—2 orders of magnitude smaller than those previously reported for other electroactive electropolymerized films.[1,8,52] Furthermore, from the analysis[39,40] of the rising part of the normal pulse voltammograms shown in Fig. 10, the standard rate constant (k°) and the anodic transfer coefficient (α) of the heterogeneous electron-transfer reaction were estimated to be $(1.9\pm0.4)\times10^{-5}$ cm s^{-1} and 0.67 ± 0.03, respectively.

The PPA films are also electroactive in a non-

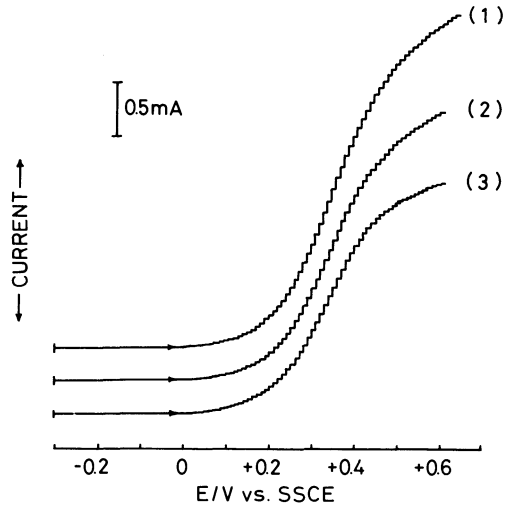

Fig. 10. Typical normal pulse voltammograms for the oxidation of the PPA film on an In_2O_3 electrode in a 0.2 M $NaClO_4$ aqueous solution (pH 1.0). The PPA film was prepared by the same procedure as in Fig. 5. Concentration of the electroactive site in the PPA film: 1.75×10^{-3} mol cm^{-3}. Thickness of the PPA film: 1.1×10^{-4} cm. Sampling time (τ): (1) 5, (2) 8 and (3) 10 ms. Electrode area: 0.16 cm^2.

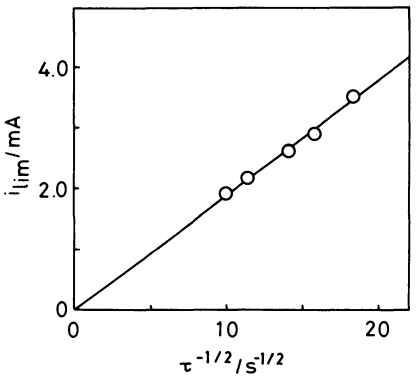

Fig. 11. Normal pulse voltammetric Cottrell plots of limiting current (i_{lim}) vs. (sampling time)$^{-1/2}$ for the oxidation of the PPA film on an In_2O_3 electrode in a 0.2 M $NaClO_4$ aqueous solution (pH 1.0). Other experimental conditions are the same as in Fig. 10.

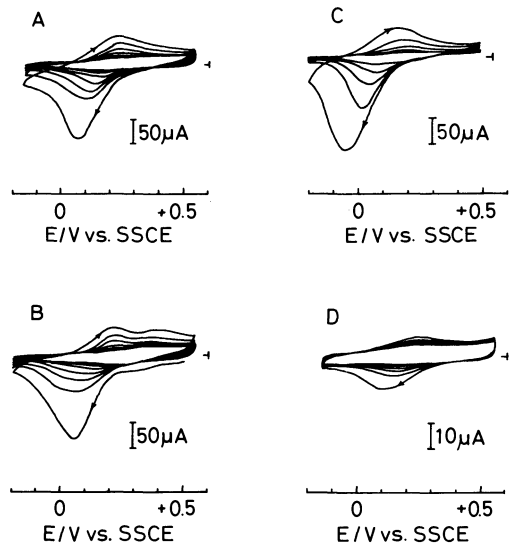

Fig. 12. Cyclic voltammetric responses of the PPA films on BPG electrodes in acetonitrile solutions containing different supporting electrolytes. Supporting electrolyte (0.2 M): (A) $TBABF_4$, (B) TBAP, (C) TEACl, and (D) $TBAPF_6$. Scan rate: 50 mVs^{-1}. Electrode area: 0.17 cm^2. The arrow indicates the direction of potential scan. The PPA films in (A)—(D) were prepared on BPG electrodes by a constant-potential electrolysis at 0.75 V vs. SSCE in acetonitrile solutions containing 10 mM PA+10 mM pyridine+0.2 M supporting electrolyte ((A) $TBABF_4$, (B) TBAP, (C) TEACl, and (D) $TBAPF_6$). In respective electrolysis, the amount of the charge passed was 30 mC cm^{-2}.

aqueous solution. For example, the cyclic voltammetric responses of the PPA film in acetonitrile solutions containing different supporting electrolytes are shown in Fig. 12. The peak current decreased with the cycling of potential scan, probably because of the relatively large solubility of the reduced form of the PPA film in an acetonitrile. The cathodic and anodic peak potentials seem to vary with the supporting electrolyte. The redox response of the PPA film in the acetonitrile solutions may be regarded as the so-called electrochemical doping-undoping process,[54,55] that is, the uptake/exclusion of the supporting electrolytic ions into/out of the film which is coupled to the electrode reaction proper of the PPA film. As mentioned above, the protons take part in the electrode reaction of the PPA in an aqueous solution and the bond formation (during the cathodic process) and cleavage (during the anodic process) of the N-H bonds occurs. Thus, the electrode reactions of the PPA film in aqueous and non-aqueous solutions are considered to be different from each other.

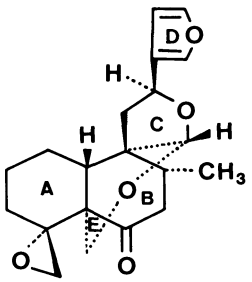
(Received January 17, 1986)

The crystal structure of an isomer of Teucrin P_1 isolated from *Teucrium gnaphalodes* has been determined by the X-ray method. Crystal data: orthorhombic, $P2_12_12_1$, a=13.849(4), b=15.545(3), c=7.896(2) Å, Z=4. The final R value is 0.048 for 1247 observed reflections with $F_o>2\sigma(F_o)$. The structure is disordered, and two kinds of components (molecules) with different conformations coexist in the crystal. The major component exists with a probability of 0.74, while the minor one with 0.26. A tetrahydropyran ring in the former takes a boat form, while the latter a chair form, indicating that in this complex fused-ring system a boat form of the tetrahydropyran ring is more stable than a chair one. The conformation of the major component is the same as that of naturally occurring Teucrin P_1, apart from the orientation of a furan ring.

Teucrin P_1 with the trans-clerodane skeleton shows significant antifeeding activity against insects. It has been isolated from two different species, *T. gnaphalodes*[1] and *T. polium*,[2,3] in the family of Labiatae. The absolute structure of Teucrin P_1 isolated from *T. gnaphalodes* (abbreviated as TPG below) has been obtained by X-ray analysis and spectroscopic methods.[1] The X-ray analysis confirmed that ring **A** has a chair conformation and ring **B** and ring **E** take boat conformations.[1]



Scheme

It is interesting that $[\alpha]_D$ of TPG, −13.0°, is different from that of Teucrin P_1 from *T. polium* (abbreviated as TPP), +6.6°. The difference may reflect the boat/chair conformational difference of such **A**, **B**, and **E** rings in the skeleton of Teucrin P_1.

An isomer of TPG (abbreviated as TPG isomer) has been obtained by a chemical treatment which is expected for generating the conformational changes on ring **B** and/or **E**.[4] The $[\alpha]_D$ of TPG isomer is +2.9° and is rather close to that of TPP.

Therefore the X-ray structure analysis of TPG isomer is undertaken to make clear what kind of conformational change induces the shift of $[\alpha]_D$ as well as to obtain a clue to elucidate the conformation of TPP.

Experimental

TPG isomer was prepared by treating TPG in solution of hexamethylphosphoric triamide and tetrahydrofuran under the catalysis of lithium diisopropylamide at 253 K for 55 min., and crystallized from ethyl acetate solution.[4] Colorless rod crystals were obtained, in which a crystal with approximate dimensions of 0.5×0.4×0.8 mm was selected for the X-ray measurement.

Crystal Data: $C_{20}H_{24}O_5$, M=344.39, orthorhombic, $P2_12_12_1$, T=297 K, a=13.849(4), b=15.545(3), c=7.896(2) Å, V=1699.9(8) Å^3, Z=4, D_c=1.34 g·cm^{-3}, μ(Cu $K\alpha$)=7.41 cm^{-1}, F(000)=736.

A Rigaku four-circle diffractometer with graphite-monochromated Cu $K\alpha_1$ radiation (1.5405 Å) was used. The unit cell parameters were determined from 10 reflections with $13°\leqq 2\theta \leqq 21°$. Intensity data with $2\theta \leqq 115°$ were collected with the θ—2θ scan technique. The θ scan rates and background counting time at both ends of a scan were: 6.0° min^{-1} and 6.7 s for $0°\leqq 2\theta \leqq 60°$; 3.0° min^{-1} and 13.4 s for $60°\leqq 2\theta \leqq 85°$; 1.5° min^{-1} and 26.8 s for $85°\leqq 2\theta \leqq 100°$; 1.0° min^{-1} and 40.2 s for $100°\leqq 2\theta \leqq 115°$. The scan width was $\Delta\theta=(1.5+0.15\times\tan\theta)°$. 1367 reflections were collected, among which 120 reflections less than $2\sigma(F_o)$ were considered as unobserved. No intensity decreases of 3 standard reflections (002, 400, and 120) were observed during the experiment. Lorentz and polarization effects were corrected but no absorption correction was made.

The structure was determined by the direct method (*MULTAN* 78).[5] The absolute configuration of TPG isomer was conformed with that of TPG. The refinement was carried out by the block-diagonal least-squares method (*HBLS* VII).[6] The function minimized was $\sum w(|F_o|-|F_c|)^2$, and the weighting scheme was $w=[\sigma^2(F_o)+0.0042|F_o|^2]^{-1}$ at the final stage. In the course of the refinement, disorders were found at O(3) and O(4) atoms on ring **E** and **C** respectively. There are a major site (with higher probability of occurring, O(3A) and O(4A)) and a minor site (with lower one, O(3B) and O(4B)) for each of the two disordered O atoms. Their occupancies were estimated from the ratio of the integrated electron densities around each site, and the occupation ratio of O(3) is found to be

identical with that of O(4). The occupancies of the major sites and the minor sites, 0.74 and 0.26 respectively, were fixed throughout the course of the refinement.

All the hydrogen atoms except for those attached to the carbon atoms directly bonded to the disordered O atoms with smaller occupancies are found in the difference Fourier map, and included in the refinements. The isotropic temperature factors of the H atoms are fixed to the equivalent temperature factors[7] of the corresponding carbon atoms to which they are bound. The final R and R_w are 0.048 and 0.064 respectively for 1247 reflections with $|F_o|>2\sigma(F_o)$. Atomic scattering factors were taken from International Tables for X-Ray Crystallography, VOL. IV.[8] The final atomic parameters with B_{eq}'s are given in Table 1.* All the computations were carried out on a FACOM M200 at Nagoya University Computation Center.

* The anisotropic thermal parameters of non-hydrogen atoms, the parameters of hydrogen atoms and the observed and calculated structure factors are preserved at the Chemical Society of Japan (Document No. 8634).

Discussion

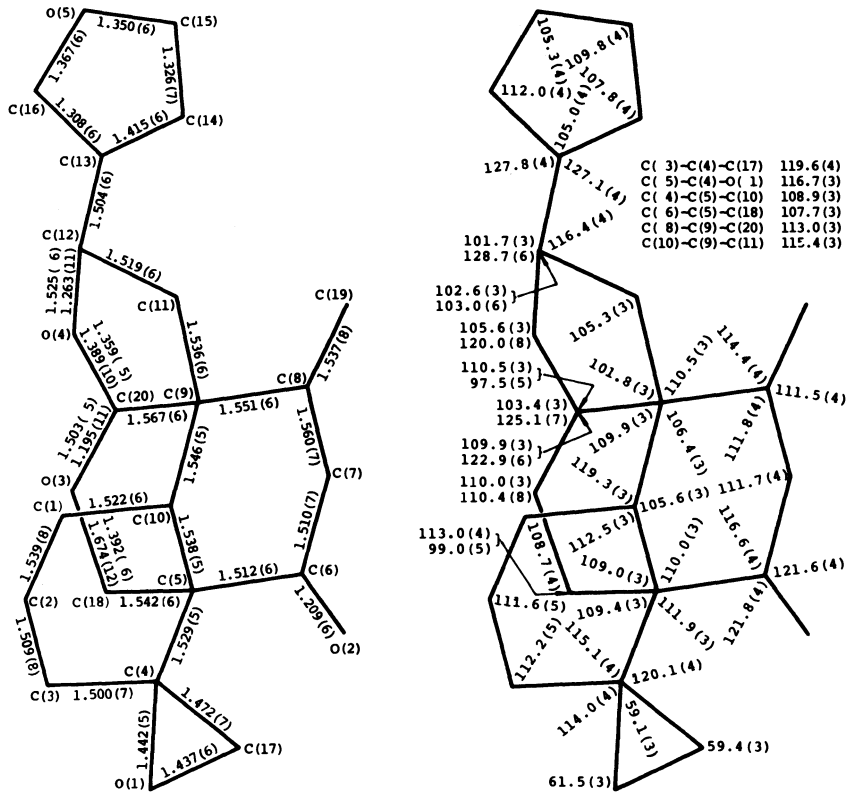
The bond distances and angles are shown in Fig. 1, together with the numbering of atoms.

Extraordinariness occurs in the bond distances and angles concerning the disordered atoms O(3) and O(4). The bond distance of O(3B)–C(18) 1.674(12) Å is longer by about 0.20 Å than that of the normal O–C bond; while O(3B)–C(20) and O(4B)–C(12) distances, 1.195(11) Å and 1.263(11) Å respectively, come to short by about 0.20 Å as compared with the normal value. The large deviations from the tetrahedral angle are found in the bond angles of O(4B)–C(12)–C(13), 128.7(6)° and O(3B)–C(20)–O(4B), 125.1(7)°. Such extraordinariness will partly be due to the errors brought about by the small occupancies for O(3B) and O(4B). On the contrary, there is not a significant anomaly for the distances and angles concerning O(3A) and O(4A).

The disorder occurring at O(3) generates two different conformations on ring **E**, a boat conformation when O(3) is at the major site (O(3A)), and a chair conformation when at the minor site (O(3B)). The disorder of O(4) also affects the conformation of the five-membered ring **C**, although it always keeps an envelope shape. In the case of the major shape corresponding to O(4A), C(12) is out of the O(4A)–C(20)–C(9)–C(11) plane by 0.55(2) Å, whereas in the minor shape containing O(4B), C(20) is displaced by 0.47(3) Å from the plane defined by O(4B)–C(12)–C(11)–C(9).

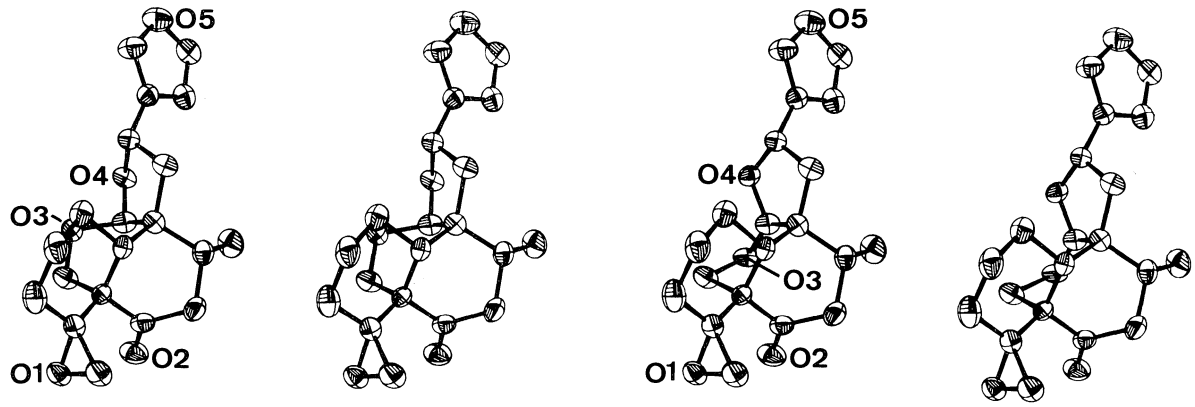
On the molecular structure, four combinations are possible if the disorders are taken into account. However, the molecules in the crystal will take either the structure with ring **E** in a boat conformation (major) and ring **C** in the major shape or that with ring **E** in a chair conformation (minor) and ring **C** in the minor shape, if the two unreasonable combinations, O(3A)–O(4B) and O(3B)–O(4A), are excluded for the reasons described below. First, the combination of O(3A) and O(4B) may readily be rejected because of the too small angle of O(3A)–C(20)–O(4B), 75.5°. Then, as for the combination of O(3B) and O(4A), it is difficult to judge which combination, O(3B)–O(4B) or O(3B)–O(4A), is more rational only from the information of the corresponding bond angles, O(3B)–C(20)–O(4B) 125.1(7)° and O(3B)–C(20)–O(4A) 126.6(6)° respectively. However, it can also be reasonably excluded taking account of the equality between the occupation ratios of O(3) and O(4), because the existence of this combination in the crystal will make the ratios unequal in the absence of the conformer with O(3A) and O(4B).

Therefore, the conformations of the rings of the major component are ring **A**, chair; ring **B**, boat; ring **E**, boat; and ring **C**, envelope with C(12) at the flap. Those of the minor one are ring **A**, chair; ring **B**,



(a) (b)

Fig. 1. (a) Bond distances (l/Å) and (b) bond angles (ϕ/°) for the major component (upper) and the minor component (lower). The estimated standard deviations are in parentheses.



(a) (b)

Fig. 2. Stereoscopic drawing: (a) the major component and (b) the minor component. Atoms are drawn with 50% probability thermal ellipsoids.

boat; ring **E**, chair; and ring **C**, envelope with C(20) at the flap. The *ORTEP* II[10] drawing of the major and minor components are shown in Fig. 2.

The gross structure of the major component is the same as that of TPG, so far as the conformation of each ring is concerned. They differ only in the orientation of ring **D** with respect to ring **C**, but they can be related by a rotation of about 180° around the bond of C(12)–C(13).

The conformational change of ring **E**, from boat to chair, is induced in the naturally occurring molecule by the chemical reaction described above, and the consequent change of the puckering of ring **C** occurs to generate TPG isomer (here referring to minor

component) that has $[\alpha]_D$ of +2.9°. During the crystallization, however, the conformation of TPG isomer transforms to that of TPG. This shows that the molecule with ring **E** in a boat conformation (major) is more stable than that with ring **E** in a chair one (minor), though the opposite result has been expected by the conformational analysis (*MM2*).[4,9] The most stable structure anticipated by the conformational analysis possesses chair conformations for both ring **E** and ring **B**.

As for TPP, its structure may be different from those of TPG and TPG isomer, because its $[\alpha]_D$ (+6.6°) is remarkably different from that of TPG (−13.0°) and also shows a significant difference from that of TPG isomer (+2.9°). Therefore we expect that TPP might possess a chair conformation for ring **B**.

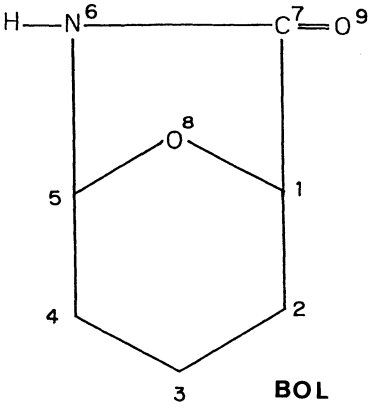
(Received February 13, 1986)

The crystal structures of the bicyclic oxalactam, 8-oxa-6-azabicyclo[3.2.1]octan-7-one(BOL) and the 4(*e*)-bromo-substituted derivative(Br-BOL) were determined by the X-ray diffraction method. Crystal data: (BOL) $P2_12_12_1$, a=10.926(3), b=9.115(2), c=6.280(2) Å, Z=4; (Br-BOL) $P2_12_12_1$, a=10.708(3), b=11.053(3), c=6.208(2) Å, Z=4. Refinements were carried out by the full-matrix least-squares method. R values are; (BOL) 0.050 for 601 reflections, (Br-BOL) 0.028 for 866 reflections. Both structures are quite similar to each other. The packing scheme of BOL is essentially the same as that of Br-BOL. Molecules are linked by N-H···O hydrogen bonds around a two-fold screw axis, giving rise to infinite chains extended along the c axis.

A bicyclic oxalactam, 8-oxa-6-azabicyclo[3.2.1]octan-7-one(abbreviated as BOL), is an interesting starting material for new functional polymers with permselectivity. The anionic solution polymerization of BOL leads to a high molecular weight polyamide (poly(BOL)) and the resulting poly(BOL) is easily cast to a hygroscopic membrane which has an excellent permeability for water and permselectivity for solutes of different sizes in an aqueous solution.[1-3] It may also be used as a component for graft and block copolymers.[4-6]



BOL

Anionic polymerization of BOL is known to proceed through the N^6–C^7 scission of the amide group.[1,2] The mechanism is the same as that in common lactams. On the other hand the cationic oligomerization of BOL was recently confirmed by the X-ray and NMR analyses of the resulting dimer [abbreviated as $(BOL)_2$],[7,8] to proceed through the C^5–N^6 scission of the amide group in the monomer unit.

The reactivity of such a novel bicyclic oxalactam should be closely related to the molecular structure. Therefore the 4-bromo-substituted derivative, 4(*e*)-bromo-8-oxa-6-azabicyclo[3.2.1]octan-7-one(abbreviated as Br-BOL), was synthesized in order to obtain an information on the structural and electronic effects upon their reactivity.[9] In this paper the structures of BOL and Br-BOL determined by the X-ray diffraction method were described.

Experimental

The BOL crystals obtained from a hexane solution were colorless plates and Br-BOL crystals grown from an ethyl acetate solution were colorless needles. The X-ray intensity data were collected on a Rigaku four-circle diffractometer, using graphite monochromated radiation; Cu $K\alpha$(λ=1.5405 Å) for BOL and Mo $K\alpha$(λ=0.70926 Å) for Br-BOL. Unit cell dimensions were obtained by the least-squares fit using 11 reflections with $40°<2\theta<56°$ for BOL and 14 reflections with $27°<2\theta<38°$ for Br-BOL. Crystal data and experimental conditions are shown in Table 1.

Both structures were solved by the direct method (*MULTAN* 80).[10] The refinement was carried out by the full-matrix least-squares method(*FMLS*).[11] The function minimized was $\sum w(|F_o|-|F_c|)^2$. After the anisotropic refinements of non-hydrogen atoms, all the hydrogen atoms were picked up on the difference-Fourier maps, and were included in the refinement with the isotropic temperature factors. The final R values were 0.050(R_w= 0.069) for BOL, and 0.028(R_w=0.035) for Br-BOL, respectively. The weighting scheme adapted was $w=(\sigma^2(F_o)+a|F_o|^2)^{-1}$ for the observed reflections with a=0.0 for BOL and 0.002 for Br-BOL. All the scattering factors were taken from the International Tables for X-Ray Crystallography, Vol. IV.[12] The atomic parameters of the non-hydrogen atoms with equivalent temperature factors(B_{eq})[13] are given in Table 2.* All the calculations were carried out on a

†† On leave from Institute of Physics, Chinese Academy of Science, Beijing, China.

* The anisotropic thermal parameters of non-hydrogen atoms, the parameters of hydrogen atoms, the equations of best-planes, and the tables of the observed and the calculated structure factors were kept at the Chemical Society of Japan(as Doc. No. 8637).

Results and Discussion

The bond distances and angles of BOL and Br–BOL are given in Fig. 1, with the numbering of atoms. The corresponding bond distances and angles between BOL and Br–BOL are in good agreements with each other, except for the C(3)–C(4) distance and the C(4)–C(5)–O(8) angle. The C(3)–C(4) distance of BOL seems slightly longer than that of Br–BOL. The C(4)–C(5)–O(8) angle, 108.6(3)°, of BOL is larger than that of Br–BOL, 105.7(4)°. The C(4)–C(5)–O(8) angle of BOL is similar to the corresponding ones in $(BOL)_2$,[7] 108.7(3) and 107.8(4)°, in which two molecules are included in the asymmetric unit, and the BOL skeleton is conserved at a terminus. The C(1)–C(7)–O(9) angle is smaller than the N(6)–C(7)–O(9) angle in both BOL and Br–BOL. These angles are, however, almost equal in the BOL moieties of $(BOL)_2$; that is, 127.3(4) and 127.1(4)° for ∠C(1)–C(7)–O(9), and 127.9(4) and 126.9(4)° for ∠N(6)–C(7)–O(9).

Stereoscopic views of BOL and Br–BOL drawn by *ORTEP* II[14] are shown in Fig. 2. The overall structures of both molecules are quite similar with each other, and they are also almost the same as the structures of the BOL moieties in $(BOL)_2$. The six-membered ring including C(1), C(2), C(3), C(4), C(5), and O(8) takes a chair conformation in each

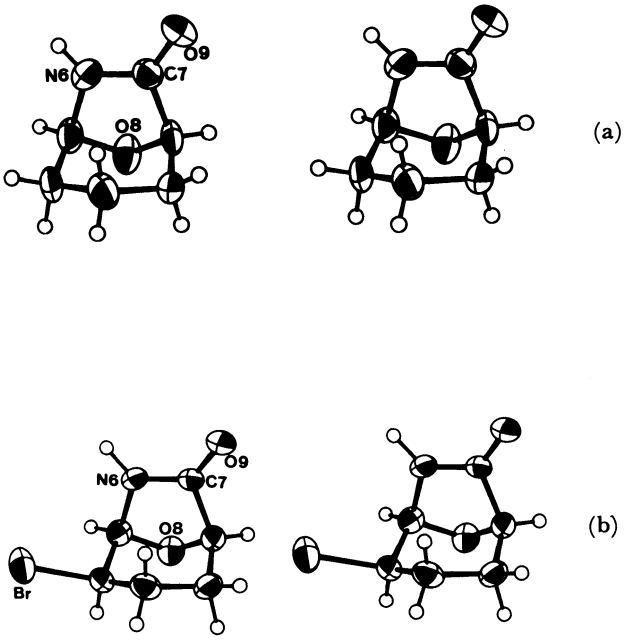

Fig. 2. Stereodrawings of (a) BOL and (b) Br–BOL. Atoms are drawn with 50% probability thermal ellipsoids.

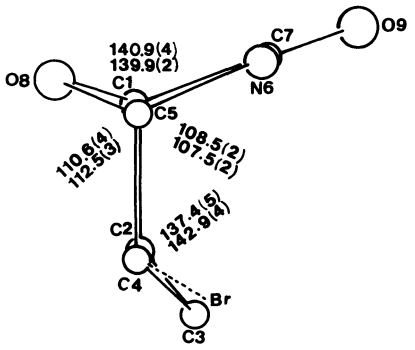

Fig. 3. Selected dihedral angles among the best-planes. Definitions are: plane I C(1), C(7), N(6), C(5), and O(9); plane II C(1), O(8) and C(5); plane III C(1), C(2), C(4) and C(5); plane IV C(2), C(3) and C(4). BOL upper, and Br–BOL lower.

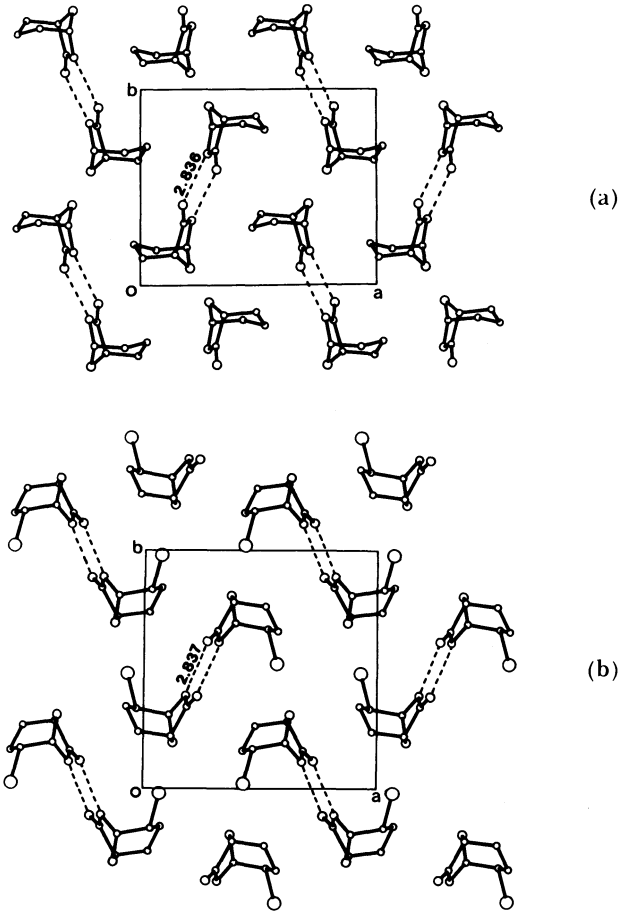

Fig. 4. Crystal structures of (a) BOL and (b) Br–BOL, projected along the c axis. Broken lines show the hydrogen bonds.

molecule. The C(1), C(7), N(6), C(5), O(8) five-membered ring shows an envelope conformation, with the O(8) out of plane[deviation: −0.604(5) Å for BOL and −0.59(1) Å for Br-BOL]. The Br atom is in equatorial with respect to the six-membered ring in Br-BOL. The molecule consists of four planes: plane I defined with C(1), C(7), N(6), C(5), and O(9); plane II C(1), O(8), and C(5); plane III C(1), C(2), C(4), and C(5); plane IV C(2), C(3), and C(4). The selected dihedral angles among the planes in the present two compounds are given in Fig. 3. A significant difference is found in the dihedral angles between the plane III and IV. The corresponding ones in $(BOL)_2$ are 139.7(5) and 140.6(5)°, which are intermediate between the present two compounds. Therefore marked changes on the molecular geometry of BOL skeleton are not observed by the substitution of Br at C(4), though the substitution may have significant effects on the intermolecular interactions due to the bulkiness and the strong electronegativity of the Br atom.

The packing of molecules in BOL and Br-BOL are drawn in Figs. 4(a) and (b), respectively. The packing schemes of both crystals are essentially the same, thus the present two compounds are isostructural. The elongation of the period of the b axis of Br-BOL, as compared with that of BOL, appears to be occured by the substitution of the bulky Br atoms, with the direction of C(4)-Br roughly parallel to the b axis. The hydrogen bonds occur between N(6)···O(9^{i}) 2.836(4) Å in BOL and N(6)···O(9^{ii}) 2.837(5) Å in Br-BOL. [Symmetry code: (i) $1.5-x$, $1-y$, $0.5+z$; (ii) $1.5-x$, $-y$, $0.5+z$] The H···O and ∠N-H···O are 1.99(5) Å and 167(5)° for BOL and 1.84(6) Å and 143(4)° for Br-BOL. Molecules are linked by hydrogen bonds around a two-fold screw axis, giving rise to infinite helical chains extended along the c axis.

Critical Behavior of the Correlation Function of Fluids Composed of Polar Diatomic Molecules

Masaharu OHBA and Kiyoshi ARAKAWA*
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received February 17, 1986)

A critical behavior of fluids composed of polar diatomic molecules is studied by the use of the Ornstein-Zernike (OZ) theory of critical phenomena extended to the interaction site model. Firstly, the asymptotic forms of the atom-atom direct correlation functions $c_{\alpha\gamma}(r)$ for the polar fluids at large separation are obtained, which are valid off the critical point. Then, the OZ hypothesis that the asymptotic forms of $c_{\alpha\gamma}(r)$ do not change near and at the critical point is examined, and the critical behavior of the total correlation function is investigated. It is found to be completely analogous to the case of simple fluids. The relation between the OZ hypothesis and some integral equation theories is also discussed.

Properties of polar fluids are extensively explored on the basis of the interaction site model.[1-6] Recently, a phase diagram of the polar hard dumbbell fluid was obtained by the use of the interaction site approximation (ISA) of RISM-1, and the existence of the critical point was shown in the phase diagram.[7] It is interesting to investigate the behavior of the atom-atom pair correlation function near and at the critical point. In the case of simple fluids, it has been found that the Ornstein-Zernike (OZ) theory of critical scattering gives qualitatively correct results. An extension of the OZ theory to the primitive model of ionic fluids was performed, and the theory showed that the critical behavior of the pair correlation function of the ionic solutions is similar to that of simple fluids.[8]

In this paper, we attempt to extend the OZ theory to the interaction site model and to analyze the critical behavior of the atom-atom pair correlation function of polar fluids by using the OZ theory. In the next section, the asymptotic forms of the atom-atom direct correlation function at large separation are obtained, which is valid off the critical point. In the last section, the critical behavior of the atom-atom pair correlation function is investigated under the assumption that the atom-atom direct correlation function near and at the critical point is similar in its form to the obtained asymptotic formula.

The Asymptotic Forms of the Atom-Atom Direct Correlation Functions.

The system considered is a fluid composed of polar diatomic molecules whose bond length is l. The charges $+q$ and $-q$ are sited on the centers of atoms of the molecule. The total potential energy of the fluid is assumed to be the sum of all intermolecular interactions. The intermolecular interaction between the i-th and j-th molecules is given by

$$U(i,j) = \sum_{\alpha}\sum_{\gamma} u_{\alpha\gamma}(|\boldsymbol{r}_i^{\alpha} - \boldsymbol{r}_j^{\gamma}|), \tag{1}$$

where $u_{\alpha\gamma}(|\boldsymbol{r}_i^{\alpha} - \boldsymbol{r}_j^{\gamma}|)$ is the interaction potential between the α-th atom of the i-th molecule and the γ-th atom of the j-th molecule. $\boldsymbol{r}_i^{\alpha}$ denotes the position of the α-th atom of the i-th molecule. The atom-atom interactions are given as

$$u_{\alpha\gamma}(r) = u^{\mathrm{sr}}(r) + \frac{q_{\alpha}q_{\gamma}}{4\pi\varepsilon_0 r}, \tag{2}$$

where ε_0 is the dielectric constant of the vacuum. $u^{\mathrm{sr}}(r)$ is the short-range part of the potential including the repulsive and the dispersion forces. For simplicity, we assume that the short-range part of the potential is independent of α and γ.

The site-site Ornstein-Zernike (SSOZ) equation in Fourier transform space is given as

$$\tilde{\boldsymbol{h}} = \tilde{\boldsymbol{\omega}}\tilde{\boldsymbol{c}}\tilde{\boldsymbol{\omega}} + \rho\tilde{\boldsymbol{\omega}}\tilde{\boldsymbol{c}}\tilde{\boldsymbol{h}}, \tag{3}$$

where ρ is the number density of molecules and $\tilde{\boldsymbol{h}}$, $\tilde{\boldsymbol{c}}$, and $\tilde{\boldsymbol{\omega}}$ are matrices of Fourier transforms of the atom-atom total correlation function $h_{\alpha\gamma}(r)$, the atom-atom direct correlation function $c_{\alpha\gamma}(r)$, and the intramolecular pair correlation function $w_{\alpha\gamma}(r)$, respectively. The Fourier transform of $w_{\alpha\gamma}(r)$ is

$$\tilde{\omega}_{\alpha\gamma}(k) = \delta_{\alpha\gamma} + (1-\delta_{\alpha\gamma})\frac{\sin kl}{kl}, \tag{4}$$

where $\delta_{\alpha\gamma}$ is the Kronecker delta. Here, we introduce the total correlation function of the center of atoms $h_{\mathrm{s}}(r)$ and the total correlation function of charges $h_{\mathrm{d}}(r)$, which are defined as

$$h_{\mathrm{s}}(r) = \{h_{++}(r) + h_{+-}(r)\}/2, \tag{5}$$

and

$$h_{\mathrm{d}}(r) = \{h_{++}(r) - h_{+-}(r)\}/2. \tag{6}$$

$c_{\mathrm{s}}(r)$ and $c_{\mathrm{d}}(r)$ are also defined in a similar manner. Then, the matrix equation Eq. 3 separates into two scaler equations as follows,

$$\tilde{h}_{\mathrm{s}}(k) = (1+\tilde{w})^2\tilde{c}_{\mathrm{s}}(k) + 2\rho(1+\tilde{\omega})\tilde{c}_{\mathrm{s}}(k)\tilde{h}_{\mathrm{s}}(k), \tag{7}$$

and

$$\tilde{h}_{\mathrm{d}}(k) = (1-\tilde{\omega})^2\tilde{c}_{\mathrm{d}}(k) + 2\rho(1-\tilde{\omega})\tilde{c}_{\mathrm{d}}(k)\tilde{h}_{\mathrm{d}}(k), \tag{8}$$

where $\tilde{\omega}=\sin kl/kl$. From Eqs. 7 and 8, we have

$$\tilde{c}_{\mathrm{s}}(k) = \frac{\tilde{h}_{\mathrm{s}}(k)}{(1+\tilde{\omega})^2+2\rho(1+\tilde{\omega})\tilde{h}_{\mathrm{s}}(k)}, \tag{9}$$

and

$$\tilde{c}_{\mathrm{d}}(k) = \frac{\tilde{h}_{\mathrm{d}}(k)}{(1-\tilde{\omega})^2+2\rho(1-\tilde{w})\tilde{h}_{\mathrm{d}}(k)}. \tag{10}$$

For polar fluids, an asymptotic form of $h_{\alpha\gamma}(r)$ at large r off the critical point is[4,5]

$$h_{\alpha\gamma}(r) \simeq \frac{E}{r^6} + \frac{F}{r^7} + O(r^{-8}), \tag{11}$$

where E and F are constants independent of the indices α and γ. From Eq. 11, the small k expansion of the Fourier transform of $h_{\alpha\gamma}(r)$ is expressed as

$$\tilde{h}_{\alpha\gamma}(k) = \tilde{h}^{\mathrm{reg}}_{\alpha\gamma} + \tilde{h}^{\mathrm{sing}}_{\alpha\gamma}. \tag{12}$$

The regular term $\tilde{h}^{\mathrm{reg}}_{\alpha\gamma}$ and the singular term $\tilde{h}^{\mathrm{sing}}_{\alpha\gamma}$ are given by

$$\tilde{h}^{\mathrm{reg}}_{\alpha\gamma} = \tilde{h}(0) + k^2h^{(2)}_{\alpha\gamma} + k^4h^{(4)}_{\alpha\gamma} + O(k^6), \tag{13}$$

and

$$\tilde{h}^{\mathrm{sing}}_{\alpha\gamma} = E'k^3 + F'k^4\ln k + O(k^5), \tag{14}$$

where E', and F' are constants independent of indices α and γ. In Eq. 13, we use the fact that $\tilde{h}_{\alpha\gamma}(0)$ is independent of indices α and γ. By inserting Eqs. 12—14 into Eqs. 5 and 6, we have

$$\tilde{h}_{\mathrm{s}}(k) = \tilde{h}^{\mathrm{reg}}_{\mathrm{s}} + \tilde{h}^{\mathrm{sing}}_{\mathrm{s}}, \tag{15a}$$

$$\tilde{h}^{\mathrm{reg}}_{\mathrm{s}} = \tilde{h}(0) + k^2h^{(2)}_{\mathrm{s}} + k^4h^{(4)}_{\mathrm{s}} + O(k^6), \tag{15b}$$

$$\tilde{h}^{\mathrm{sing}}_{\mathrm{s}} = E'k^3 + F'k^4\ln k + O(k^5), \tag{15c}$$

and

$$\tilde{h}_{\mathrm{d}}(k) = \tilde{h}^{\mathrm{reg}}_{\mathrm{d}} + \tilde{h}^{\mathrm{sing}}_{\mathrm{d}}, \tag{16a}$$

$$\tilde{h}^{\mathrm{reg}}_{\mathrm{d}} = k^2h^{(2)}_{\mathrm{d}} + k^4h^{(4)}_{\mathrm{d}} + O(k^6), \tag{16b}$$

$$\tilde{h}^{\mathrm{sing}}_{\mathrm{d}} = O(k^5). \tag{16c}$$

By inserting Eqs. 15 and 16 into Eqs. 9 and 10, and by expanding the right hand side of Eqs. 9 and 10, we can obtain a small k expansion of $\tilde{c}_{\mathrm{s}}(k)$ and $\tilde{c}_{\mathrm{d}}(k)$. The results are as follows,

$$\tilde{c}_{\mathrm{s}}(k) = \tilde{c}^{\mathrm{reg}}_{\mathrm{s}} + \tilde{c}^{\mathrm{sing}}_{\mathrm{s}}, \tag{17a}$$

$$\tilde{c}^{\mathrm{reg}}_{\mathrm{s}} = c^{(0)}_{\mathrm{s}} + k^2c^{(2)}_{\mathrm{s}} + k^4c^{(4)}_{\mathrm{s}} + O(k^6), \tag{17b}$$

$$\tilde{c}^{\mathrm{sing}}_{\mathrm{s}} = C'k^3 + D'k^4\ln k + O(k^5), \tag{17c}$$

and

$$\tilde{c}_{\mathrm{d}}(k) = \frac{A}{k^2} + c^{(0)}_{\mathrm{d}} + O(k), \tag{18}$$

where $c_{\mathrm{s}}^{(0)}=\tilde{h}(0)/4(1+\rho\tilde{h}(0))$, $C'=E'/4(1+\rho\tilde{h}(0))$, $D'=F'/4(1+\rho\tilde{h}(0))$ and

$$A = \frac{36h^{(2)}_{\mathrm{d}}}{l^2(l^2+12\rho h^{(2)}_{\mathrm{d}})}. \tag{19}$$

Thus, the asymptotic forms of $c_{\mathrm{s}}(r)$ and $c_{\mathrm{d}}(r)$ off the critical point are given as

$$c_{\mathrm{s}}(r) \simeq \frac{C}{r^6} + \frac{D}{r^7} + O(r^{-8}), \tag{20}$$

and

$$c_{\mathrm{d}}(r) \simeq \frac{A}{4\pi r} + O(r^{-4}). \tag{21}$$

$h_{\mathrm{d}}^{(2)}$ is expressed in terms of the dielectric constant ε as[4-6]

$$4q^2h^{(2)}_{\mathrm{d}} = \frac{\mu^2}{9\rho}\left(\frac{\varepsilon-\varepsilon_0}{y\varepsilon}-3\right), \tag{22}$$

where $\mu=ql$ is the magnitude of the dipole moment of molecules, $y=\rho\mu^2/9\varepsilon_{\mathrm{O}}k_{\mathrm{B}}T$, k_{B} the Boltzmann constant and T the absolute temperature. Thus, we have

$$A = -\frac{3y\varepsilon-\varepsilon+\varepsilon_0}{3y(\varepsilon-\varepsilon_0)}\cdot\frac{q^2}{\varepsilon_0k_{\mathrm{B}}T}. \tag{23}$$

Equations 20 and 21 are the result of this section. The first term of Eq. 21 with Eq. 23 was already given in a different way.[9] Equation 20 and the second term of the right hand side of Eq. 21 are new results.

The Critical Behavior of Correlation Functions.

Here, we set up the hypothesis of the OZ theory for the system considered in this paper by assuming that the asymptotic forms of the atom-atom direct correlation function does not change near and at the critical point. Thus, the asymptotic forms near and at the critical point are given as

$$c_{\mathrm{s}}(r) \simeq O(r^{-6}), \tag{24a}$$

and

$$c_{\mathrm{d}}(r) \simeq \frac{A}{4\pi r} + O(r^{-4}). \tag{24b}$$

We define a new function $c_{\mathrm{e}}(r)$ by

$$c_{\mathrm{e}}(r) \equiv c_{\mathrm{d}}(r) - \frac{A}{4\pi r}. \tag{25}$$

From Eq. 24b, $c_e(r) \simeq O(r^{-4})$ as $r \to \infty$. Then, the Fourier transforms of $c_s(r)$ and $c_e(r)$ can be expressed as

$$\tilde{c}_s(k) = c_s^{(0)} + k^2 c_s^{(2)} + O(k^3), \tag{26}$$

and

$$\tilde{c}_e(k) = c_e^{(0)} + O(k), \tag{27}$$

where $c_s^{(0)}$, $c_s^{(2)}$ and $c_e^{(0)}$ are expressed as follows:

$$c_s^{(0)} = \int c_s(r) d\boldsymbol{r},$$

$$c_s^{(2)} = -\frac{1}{6}\int r^2 c_s(r) d\boldsymbol{r},$$

and

$$c_e^{(0)} = \int c_e(r) d\boldsymbol{r}.$$

The compressibility equation is

$$\rho k_B T \kappa_T = 1 + \rho \tilde{h}(0), \tag{28}$$

where κ_T is the isothermal compressibility of the fluid. This equation shows that in the approach to the critical point $\tilde{h}(0)$ tends to infinity. Thus, from Eq. 9, we have

$$c_s^{(0)} = \tilde{c}_s(0) \to 1/(4\rho_c), \tag{29}$$

where ρ_c is the number density at the critical point. This result confirms that $c_s^{(0)}$ is analytic at the critical point. However, the analyticity of $c_s^{(2)}$ and $c_e^{(0)}$ is not verified in general. Thus, the present OZ hypothesis for this system is expressed mathematically as follows: $c_s^{(2)}$ and $c_e^{(0)}$ are analytic near and at the critical point.

From Eqs. 7 and 8, we have

$$\tilde{h}_s(k) = \frac{(1+\tilde{\omega})^2 \tilde{c}_s(k)}{1-2\rho(1+\tilde{\omega})\tilde{c}_s(k)}, \tag{30}$$

and

$$\tilde{h}_d(k) = \frac{(1-\tilde{\omega})^2 \tilde{c}_d(k)}{1-2\rho(1-\tilde{\omega})\tilde{c}_d(k)}. \tag{31}$$

By inserting Eqs. 26 and 27 together with Eq. 23 into Eqs. 30 and 31, we have

$$\tilde{h}_s(k) = \frac{4c_s^{(0)} + (4c_s^{(2)} - 2l^2 c_s^{(0)}/3)k^2 + \cdots}{(1-4\rho c_s^{(0)}) + (\rho l^2 c_s^{(0)}/3 - 4\rho c_s^{(2)})k^2 + \cdots}, \tag{32}$$

and

$$\tilde{h}_d(k) = \frac{(Al^4/36)k^2 + \cdots}{3y\varepsilon/(\varepsilon-\varepsilon_0) - (\rho l^2/3)(c_e^{(0)} - l^2 A/20)k^2 \cdots}. \tag{33}$$

By taking Eq. 30 into consideration, the compressibility equation Eq. 28 can be expressed as

$$1 - 4\rho c_s^{(0)} = (\rho k_B T \kappa_T)^{-1} = \kappa_T^0/\kappa_T, \tag{34}$$

where $\kappa_T^0 = (\rho k_B T)^{-1}$ is the isothermal compressibility of the ideal gas. Equation 34 shows that $(1-4\rho c_s^{(0)}) \neq 0$ off the critical point. Thus, the asymptotic forms of $h_s(r)$ and $h_d(r)$ off the critical point obtained from the Eqs. 32 and 33 return to Eq. 11. However, since $(1-4\rho c_s^{(0)}) \to 0$ with the approach to the critical point, we obtain from Eq. 32.

$$h_s(r) \simeq \frac{c_s^{(0)}}{\pi(\rho l^2 c_s^{(0)}/3 - 4\rho c_s^{(2)})} \cdot \frac{1}{r} \cdot \exp(-\alpha r), \tag{35}$$

and

$$\alpha = \sqrt{\frac{1-4\rho c_s^{(0)}}{\rho l^2 c_s^{(0)}/3 - 4\rho c_s^{(2)}}} \to 0. \tag{36}$$

Thus, we find that $h_s(r)$ becomes a long-range function, that is, $h_s(r) \sim O(r^{-1})$ in the vicinity of the critical point. On the other hand, it is found from Eq. 33 that the asymptotic form of $h_d(r)$ at large r does not change at the critical point. This shows that near and at the critical point the density fluctuation diverges but the charge fluctuation remains finite. Identifing the correlation length ξ with α^{-1}, we obtain the critical exponent relation $2\nu = \gamma$. ν and γ are defined as

$$\kappa_T^0/\kappa_T \propto \varepsilon^{-\gamma}(1+\cdots),$$

and

$$\xi \propto \varepsilon^{-\nu},$$

where $\varepsilon = |(T-T_c)/T_c|$ and T_c is the critical temperature. These results are quite analogous with the case of simple fluids, which is in accordance with the prediction of Stell.[10]

Let us consider the relation of the OZ theory with integral equation theories. The ISA consists of the SSOZ equation Eq. 3 and the ISA closure given by

$$h_{\alpha\gamma}(r) = -1, \quad r < \sigma_{\alpha\gamma} \tag{37a}$$

and

$$c_{\alpha\gamma}(r) = -u_{\alpha\gamma}(r)/k_B T, \quad r > \sigma_{\alpha\gamma} \tag{37b}$$

where $\sigma_{\alpha\gamma}$ is the hard-sphere diameter of atoms. For the fluid composed of polar hard dumb-bells with the same diameter σ, Eqs. 37a and 37b can be expressed as

$$\begin{cases} h_s(r) = -1, & r < \sigma \\ c_s(r) = 0, & r > \sigma \end{cases} \tag{38}$$

and

$$\begin{cases} h_d(r) = 0, & r < \sigma \\ c_d(r) = -q^2/4\pi\varepsilon_0 k_B T r. & r > \sigma \end{cases} \tag{39}$$

Thus, the ISA satisfies the OZ hypothesis introduced in this section. Equations 7 and 38 becomes the PY-like integral equation of RISM-1[11,12] for neutral hard dumb-bell fluids (HDF), and so the quantity $(1-4\rho c_s^{(0)})$ is the same as that of the solution of the PY-like integral equation for HDF. Since the critical point does not exist for HDF, no critical point can be observed in the correlation function of the polar hard dumb-bell fluids in the ISA. However, if the phase behavior is investigated through the energy equation instead of the compressibility equation, it is possible to detect the critical point. In fact, Morriss and Isbister showed the existence of the critical point through the energy equation. The circumstances are quite similar to the case of the restricted primitive model of ionic solutions.[8] Since $h_s(r) \neq h(r)^{HDF}$ in the other approximations (for example, PY-like and HNC-like approximations), the critical point will be observed in the correlation function by using these approximations. The critical behavior obtained through these approximations will be different from the result in this work, because these approximations do not satisfy the OZ hypothesis presented here.

Appendix
The Critical Behavior of Nonpolar Fluids Composed of Homonuclear Diatomic Molecules.

The critical point of nonpolar fluids composed of homonuclear diatomic molecules was recently detected through the compressibility equation by using the PY-like integral equation of RISM-1.[13]

The asymptotic form of the atom-atom direct correlation function for this system off the critical point is expressed as[9]

$$c(r) \simeq -u(r)/k_B T \sim O(r^{-6}). \quad \text{as } r \to \infty \tag{A1}$$

Hereafter, the indices α and γ are omitted, because the atom-atom functions for this system are independent of the indices. For this system, the OZ hypothesis is expressed as follows: the first two coefficients of the small k expansion of the Fourier transform of $c(r)$ are analytic near and at the critical point. Thus, we have

$$\tilde{c}(k) = c^{(0)} + k^2 c^{(2)} + \cdots, \tag{A2}$$

where

$$c^{(0)} = \int c(r) d\boldsymbol{r},$$

and

$$c^{(2)} = -\frac{1}{6}\int r^2 c(r) d\boldsymbol{r}.$$

Then, from the similar discussion described in the last section, we have the same equations as Eqs. 35 and 36 in the approach to the critical point.

PY-like approximation for fluids interacting through the short-range interaction satisfies the OZ hypothesis presented in this appendix, and so it is found that the asymptotic form of $h(r)$ given by the PY-like approximation is $h(r) \sim O(r^{-1})$ at the critical point. On the other hand, HNC-like approximation does not satisfy the OZ hypothesis, and thus the critical behavior is different from that given by the PY-like approximation. In fact, we have found that $h(r)$ decays as r^{-2} in the HNC-like approximation, which is the same as that for simple fluids interacting through the short-range interactions.[14]

†Chemotherapy Divison, National Cancer Center Research Institute, Tsukiji 5-Chome, Chuo-ku, Tokyo 104
(Received February 27, 1986)

High-resolution solid-state ^{13}C NMR spectra of a variety of (1→3)-β-D-glucans in the solid state were recorded by means of cross polarization-magic angle spinning (CP-MAS) NMR spectroscopy. We found that the C-1 and C-3 peak-positions of these glucans are significantly displaced (up to 8 ppm) depending upon variety of samples used. Interestingly, these glucans obtained by lyophilization or spray-drying possess regular secondary structures as detected by displacements of the conformation-dependent ^{13}C chemical shifts. In fact, at least four kinds of molecular conformations were distinguishable by ^{13}C NMR spectroscopy. Gel-forming ability of linear (1→3)-β-D-glucans, however, was related to the presence of a single particular conformation without involving any other form. By contrast, gel-formation was noted for a branched glucan whose conformation is similar to that of a linear glucan without gel-forming ability. Further, conformation of all these linear and branched (1→3)-β-D-glucans turned out to be the same when solid samples were prepared by lyophilization from DMSO solution.

It is well known that linear and branched (1→3)-β-D-glucans (Fig. 1) function as structural components in the cell walls of many plants and microorganism and also act as reserve polysaccharides.[1] Physical properties of (1→3)-β-D-glucans isolated from various sources are thus widely different: low molecular weight laminaran is water-soluble glucan, while pachyman (from *Poria cocos*) is not; curdlan (from *Alcaligenes faecalis*) is known to form elastic gel when aqueous suspension is heated at a temperature above 54 °C.[2,3] On the contrary, some fungal branched (1→3)-β-D-glucans such as lentinan (from *Lentinus edodes*) and schizophyllan (from *Schizophyllum commune*) form nonelastic gel without heating.[4] Our previous high-resolution ^{13}C NMR studies showed that these gel-structures are composed of rather flexible single-helical chains, a part of which being associated to give physical cross links such as multiple-helical junction-zones or these aggregates.[5–9] On the contrary, acid-degraded lower molecular weight fractions of these glucans ($\overline{DP}_n$<20 for linear glucans) are freely soluble in water.[6–8] In this connection, it is interesting to note that anti-tumor activity of these glucans is related to their solution properties:[10,11] higher molecular weight fractions with gel-forming ability are biologically active but water-soluble fraction is not.

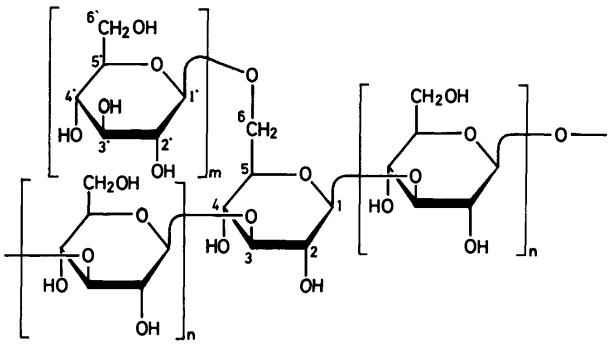

Fig. 1. Primary structures of linear and branched (1→3)-β-D-glucans: $m=0$, $\overline{DP}_n=540$, curdran; $m=0$, $\overline{DP}_n=38$, laminaran; $m=1$, $n=50$, pachyman; $m=1$, $n=2.5$, lentinan; $m=1$, $n=3$, HA β-glucan.

Accordingly, it appears that such a physical property might be also related to a secondary or tertiary structure of these glucans in addition to the degree of branching. As to the former, however, no detailed analysis for this purpose has been made, because these glucans obtained as spray-dried powder or lyophilized solid are naturally not at crystalline state and no X-ray diffraction study can be applied without extensive annealing of samples.[13,14] In addition, it is not yet clear whether or not glucans thus obtained do take any regular secondary structure. In order to reveal conformational features of noncrystalline as well as crystalline samples, high-resolution solid-state ^{13}C NMR spectroscopy has recently proven to be very useful for a various types of molecular systems.[15,16] The displacements of ^{13}C chemical shifts of backbone carbons (up to 8 ppm) are thus well related to variation of nearby torsion angles of respective carbons under consideration. In particular, the ^{13}C chemical shifts of the C-1 and C-X carbons of various types of glucans at the glycosidic linkages are well related to the torsion angles of the C-1–O_{gly} (ϕ) and C-X–O_{gly} (ψ), respectively.[17,18] Thus, conformational features of cellulose,[19–26] chitin,[27,28] (1→3)-β-D-,[29,30] and (1→4)-α-D-glucans[31] have been analyzed by the data of high-resolution

^{13}C NMR spectroscopy.

In this paper, we aimed to examine secondary structures of a variety of (1→3)-β-D-glucans from various sources by means of cross polarization-magic angle spinning (CP-MAS) ^{13}C NMR spectroscopy. First of all, we found that these glucans take various kinds of regular secondary structures, as viewed from the linewidths and displacements of ^{13}C NMR peaks, depending upon molecular weights and a manner of sample preparation. In fact, at least four kinds of different conformations can be distinguished by displacements of the C-1 and C-3 ^{13}C chemical shifts: form I (curdlan-type), form II (laminaran-type), form III (laminaripentaose-type), and form IV (DMSO-adduct). Then, it is found that paramylon granules which is over 90% crystalline is not consisting of molecular chains with a single conformation but a composite of several conformers. Further, conformational features of these glucans in the gel state were examined by observation of high resolution ^{13}C NMR spectra.

Experimental

Materials. Table 1 summarizes trivial names, degree of polymerization, physical properties, and sources of isolation for a variety of (1→3)-β-D-glucans studied in this paper. Lower-molecular-weight (1→3)-β-D-glucans were prepared from curdlan ($\overline{DP}_n$=540) by hydrolysis with formic acid or sulfuric acid by the method previously described.[10] Gel-filtration patterns of these preparations ($\overline{DP}_n$=14, 20, 82, and 131) on a Sephadex G-150 or Sepharose CL-4B column each gave a symmetrical peak. Curdlan with $\overline{DP}_n$=380 was obtained from the culture filtrate of *Alcaligenes faecalis* under different fermentation time. Numerically averaged degree of polymerization ($\overline{DP}_n$) was determined by the method of Manners et al.[32] The above-mentioned glucans were supplied by Takeda Chemical Industries, Osaka, Japan. Pachyman[33] was obtained from Sclerotium of *Poria cocos wolf* (Bukuryu) purchased from Shihira Shoten Ltd., Tokyo (by courtesy of Dr. G. Chihara of this Institute). Paramylon[34] (from *Euglena gracilis*) was a generous gift from Professor B. A. Stone of La Trobe University, Australia. Lentinan[35] was a generous gift from Dr. G. Chihara. Laminaran with $\overline{DP}_n$=38 (as determined by gel-filtration chromatography) was purchased from Nutritional Biochemical Corporation, Ohio, USA. Fractionated lower oligomers of (1→3)-β-D-glucans, laminaritriose, laminaripentaose, and laminariheptaose (Lot No. 407191), were purchased from Seikagaku Kogyo, Ltd., Tokyo, Japan. Isolation of fungal (1→3)-β-D-glucan, HA β-glucan (from *P. ostreatus (Fr.)* Quél.),[36] was reported previously. Some of these glucans were once dissolved in DMSO solution and lyophilized to obtain samples of DMSO-adduct. Curdlan gel was obtained by heating aqueous suspension (20 mg) at a temperature at 60 °C and cooling at an ambient temperature. Gels of fungal (1→3)-β-D-glucans were obtained by hydration of samples (20 mg) with excess water. To prepare gel samples for high resolution ^{13}C NMR spectroscopy, a few drops of concd NaOH solution were added stepwise to achieve 0.05 M.

^{13}C CP-MAS NMR Spectroscopy. Single contact 75.46 MHz ^{13}C CP-MAS NMR spectra were recorded on a Bruker CXP-300 spectrometer equipped with a CP-MAS accessory. Solid samples were contained in an Andrew-Beams type rotor machined from perdeuterated poly (methyl methacrylate), and spun as fast as 3—4 kHz. 90° pulse width was 5 μs and repetition time was 4 s. Spectra were usually accumulated 1000—2000 times. Chemical shifts were calibrated indirectly from the signal of liquid benzene (128.5 ppm) and converted to the value from tetramethylsilane.

Table 1. Characteristics of (1→3)-β-D-Glucan Samples Used

Sample No.	Trivial Name	Appearance	Linear or branched	$\overline{DP}_n$[a]	Solution properties in aqueous medium	Sources
1	Curdlan	Powder	Linear	540	Elastic gel	*Alcaligenes faecalis*
2	Curdlan	Powder	Linear	380	Elastic gel	*Alcaligenes faecalis*
3	Pachyman	Powder	Linear	250	Nonelastic gel	*Poria cocos*
4	Laminaran	Powder	Linear	38[b]	Not soluble	*Laminaria species*

a) Determined by the method of Manners et al. b) By gel filtration chromatography. c) Single species.

Results

Figure 2 shows the ^{13}C CP–MAS NMR spectra of four representative linear (1→3)-β-D-glucans in the solid state. These glucans are classified into three groups as viewed from peak-positions of the C-3 (and C-2,5) carbons (Table 2): (1) pachyman and curdlan giving the C-3a peak at 89.6±0.3 ppm, (2) laminaran showing the C-3b peak (at 85.5 ppm) (in addition to a minor peak of the C-3a (89.6 ppm)), and (3) paramylon exhibiting the three peaks, the aforementioned C-3a, and C-3b, and an additional C-3c (82.4 ppm). The spread of the C-3 NMR signals in paramylon (C-3a -C-3c) turned out to be about 8 ppm, as shown in Table 2. The C-1 peak, on the other hand, appears as a singlet in most cases, but as a doublet peak in paramylon. Next, we illustrate the ^{13}C CP–MAS NMR spectra of branched (1→3)-β-D-glucans isolated from various fungi in the solid state (Fig. 3). Here, the presence of two distinct peaks is evident in the C-3 region: the C-3a peak position of lentinan is exactly the same as that of curdlan or pachyman within the experimental error (±0.3 ppm), whereas the C-3b peak position of HA β-glucan is identical to that of laminaran (Table 2). Again, the spectral profile of the C-2 and C-5 region of HA β-glucan resembles that of laminaran (Fig. 2). In Fig. 4, we demonstrate how the ^{13}C NMR peak profiles are varied with their numerically averaged degree of polymerization ($\overline{DP}_n$) of acid-degraded curdlan. Apparently, the glucans with $\overline{DP}_n$ 380 exhibit

significant amount of the C-3b signals, although the peak height of the C-3a peak is higher than that of the C-3b peak.

In Figure 5, we summarized the ^{13}C CP-MAS NMR spectra of lower-molecular-weight oligomers, laminaritriose, laminaripentaose and laminariheptaose. Interestingly, all the ^{13}C NMR signals of these oligomers are identical within the experimental error (±0.3 ppm) by going from trimer to heptamer, except for the ^{13}C NMR signals arising from anomeric carbons of the terminal residues (peaks C-1a, and C-3a). The C-3 ^{13}C NMR peak positions of these oligomers (91 ppm) are significantly displaced downfield by about 1—2 ppm as compared with the corresponding peaks of curdlan, pachyman and lentinan, although the other carbon signals are identical to those of curdlan.

Further, Figure 6 summarizes the ^{13}C CP-MAS NMR spectra of a variety of (1→3)-β-D-glucans lyophilized from DMSO solution. The most notable feature is that DMSO molecule is incorporated into these polysaccharides as a quantitative manner (1/2 DMSO molecule per single residue), as manifested from the observed peak intensities. The linewidth of the C-3 peak as well as others is rather small for the samples prepared from DMSO solution as compared with that of samples lyophilized from aqueous medium. In addition, the peak positions of the C-3 signals were distinct from those of other preparations (Table 3) as shown in Figs. 1—3. On the contrary,

the C-1 signals are in many instances split into two separate peaks.

Finally, we recorded the ^{13}C NMR spectra of these (1→3)-β-D-glucans in the presence of excess water, as shown in Fig. 7. Interestingly, the ^{13}C NMR peaks of elastic gel of curdlan were well resolved at this higher frequency (75 MHz), in contrast to our previous observation at lower frequency (25 MHz).[6,7] Nevertheless, no ^{13}C NMR signals could be seen at neutral pH, in the case of nonelastic gels consisting of branched (1→3)-β-D-glucans. Consistent with our previous observation, ^{13}C NMR signals from these gel samples became visible when small amount of NaOH

Table 4. ^{13}C Chemical shifts of (1→3)-β-D-Glucans in the Gel and Solution State (ppm from TMS)

	Gel			soln
	Curdlan	HA β-glucan	Lentinan	
C-1	104.0	104.5, 102.9	104.3, 102.9	102.7
C-2	73.5	73.4	73.5	73.5

C-6	61.4	61.1	61.2	61.0

(less than 0.2 M) was added. Again, the ^{13}C NMR chemical shifts of these samples were found to be identical among various types of (1→3)-β-D-glucans such as curdlan, lentinan and HA β-glucan, in the gel state (Table 4), although conformations of these glucans in the solid state are quite different. It appears that the peak position of the C-3 carbon in the gel state is slightly displaced upfield (2 ppm) as compared with that of the solid state. On the contrary, these peaks are more distinct from those of the homogeneous aqueous solution ($\overline{DP}_n$=14).

Discussion

Conformational Features in the Solid State. As previously demonstrated, ^{13}C chemical shifts of backbone carbons for a various types of molecular systems such as polysaccharides, polypeptides, and ionophores are significantly displaced (up to 8 ppm) together with their local conformations as described by a set of nearby torsion angles.[15,16,37-41] The advantage of ^{13}C NMR spectroscopy over other method is that conformational analysis can be done equally for noncrystalline as well as crystalline molecules. For polysaccharides, it is useful to examine displacements of ^{13}C NMR signals of carbons at the glycosidic linkages (C-1 and C-X carbons), because these ^{13}C signals are sensitively varied with any conformational change.[17,18,25] In fact, the maximal splitting of the C-3 chemical shifts

of (1→3)-β-D-glucans is found to be as large as 8 ppm for paramylon (Table 2).

Interestingly, curdlan, pachyman, and lentinan gave rise to almost identical spectral features (Fig. 2) and these ^{13}C chemical shifts are identical within the experimental error (±0.3 ppm) (Table 2) in spite of differences in the primary structure. In particular, curdlan is completely a linear glucan containing no other linkage than β-(1→3)-linkages with $\overline{DP}_n$=540, while pachyman ($\overline{DP}_n$=250) contains a branch for every 50 β-(1→3)-linked glucose residues and one or two internal β-(1→6)-linkages. Lentinan, on the other hand, is a branched (1→3)-β-D-glucan with two branches for every five residues. In a similar manner, two different kinds of glucans, laminaran (linear) and HA β-glucan (branched), gave identical spectral patterns whose peak positions of these two glucans are the same within the experimental error but distinct from those of the glucans as mentioned above (see Figs. 2 and 3, and also Table 2). These data indicate that the presence (or the degree of) of branching at the C-6 position does not affect secondary structures of these branched glucans in the solid state as compared with that of the linear glucans, although this factor plays dominant role in gelation conditions of the former.[5,8] In addition, the ^{13}C NMR peak positions are the same among lower molecular oligomers, laminaritriose, laminaripentaose and laminariheptaose (Fig. 5 and Table 2). Further, the ^{13}C chemical shifts are identical among lyophilized samples from DMSO solution (Table 3). These findings strongly indicate that (1→3)-β-D-glucans so far studied take regular ordered conformations in spite of lacking in any treatment to improve the degree of crystallinity. Otherwise, it is expected that very broad envelope of ^{13}C NMR signals whose linewidths are as large as 8 ppm should be observed, because random coil form in the solid state is considered to be superposition of any conceivable several kinds of conformations.[42]

It is now possible to claim that at least four types of conformations for these (1→3)-β-D-glucans can be distinguished by the aforementioned characteristic displacements of the C-1 and C-3 peaks due to the conformation-dependent ^{13}C chemical shifts. For the sake of convenience, we tentatively classified conformations of these polysaccharides into the following four forms, I—IV, as viewed from the C-1 and C-3 peak-positions (Tables 2 and 3). Naturally, spectral patterns of the C-2 and C-5 peaks also could be varied to some extent by going from one form to another. On the basis of the aforementioned discussion, it is now clear that paramylon is not consisting of a single conformation but is a composite of at least three kinds of different conformations, as judged from the C-1 and C-3 ^{13}C chemical shifts (Table 2): form I (laminaripentaose-type), form III (laminaran-type) and an additional conformation giving rise to the peak at 82.4 ppm for the C-3 carbon. In fact, Marchessault et al. found that these split signals were converted to a single peak as a result of conformational change due to hydration.[30] Obviously, this kind of conformational heterogeneity seems to be essential to achieve better crystalline packing of paramylon granules, by analogy with the cases of higher crystalline samples as in cellulose[19-26] and polyethylene.[43,44] In this connection, crystallinity of paramylon granules is highest (≈90%) among a series of (1→3)-β-D-glucans.[45] By contrast, crystallinity of curdlan powder is only 30%[45] which does not require the presence of conformations more than the single species, as judged from the ^{13}C NMR signals.

In this connection, it is worthwhile to point out that conformation of native curdlan obtained as surface matter stripped from the colonies grown on solid culture of *Alcaligenes faecalis* is essentially the same as that of alkaline regenerated curdlan reported herein, as judged from the similarity of the ^{13}C NMR spectra,[29] in contrast to the similar pair of native and regenerated celluloses.[19-26]

The C-3 ^{13}C NMR signals of laminariheptaose and laminaripentaose (form I) are resonated at the lowermost region (91.2±0.2 ppm) and are clearly distinguishable from those of other three forms as shown in Tables 2 and 3. In fact, this peak is displaced downfield by 1.6 ppm with respect to that of curdlan and pachyman (form II)(89.6±0.3 ppm). For this reason, conformation of higher-molecular-weight (1→3)-β-D-glucan ($\overline{DP}_n$=250), curdlan and pachyman, is not always identical to that of lower-molecular-weight glucans (DP_n=3, 5, and 7). Instead, the torsion angles ψ might be different to some extent as viewed from the difference in the C-3 signals, although the ϕ angle might be the same as indicated in the similarity of the C-1 signals among these glucans.

On the other hand, the C-1 and C-3 ^{13}C chemical shifts of laminaran and HA β-glucan are resonated at 103.2 and 85.7 ppm (C-3b of Figure 3), respectively, and these peak positions are resonated significantly at higher field, as compared with those of the forms I and II (Table 2). The presence of this form is ascribed to its lower molecular weight in the case of linear (1→3)-β-D-glucans as in laminaran ($\overline{DP}_n$=38). This view was further confirmed by the fact that lower-molecular-weight acid-degraded curdlans, whose $\overline{DP}_n$'s are between 14 and 131, contain significant amount of this form (40—10%), as seen from Fig. 8 where relative proportion of the form II (C-3a) is plotted against $\overline{DP}_n$'s (thus, contribution of the form III (C-3b) is 100-contribution of the form II %). In a similar manner, paramylon does not form a gel. Accordingly, lower-molecular-weight (1→3)-β-D-glucans

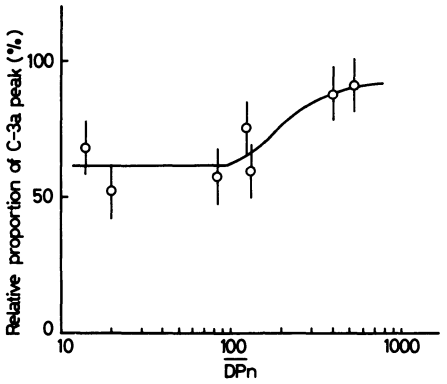

Fig. 8. A plot of the relative proportion of the C-3a peak (form II) against $\overline{DP}_n$.

taking either the forms I or III do not have gel-forming ability. In this connection, it is probable that molecular weight of HA β-glucan is rather low as in laminaran on the basis of the C-3 ^{13}C peak position (Fig. 3). Nevertheless, molecular weight of this sample estimated from a study of gel permeation chromatography is an order of 10^6 (unpublished finding). As to molecular weights of branched glucans, however, caution must be exercised about reliability of data, because aggregation phenomenon leading to infinite gel network at neutral pH or lower alkaline (<0.2 M NaOH) state would make apparent molecular weight significantly overestimated (infinite for gel!). To make situation more complicated, gelation condition as a function of molecular weight is strongly modified for branched glucans as compared with that of linear glucans. In particular, a lower-molecular-weight fraction of lentinan (fraction IV, M.W. 16200) was found to be gel-forming in spite of its lower molecular weight.[8] An explanation for this is that number of physical cross links is effectively increased for branched glucans.[8]

Alternatively, Marchessault et al.[30] suggested that the differences in the degree of hydration might strongly modify the spectral patterns of (1→3)-β-D-glucans as described above. This view, however, is not necessary true for an interpretation of the conformational heterogeneity as encountered for a variety of samples listed in Table 1, because there appears no distinct change about the degree of hydration among the samples of lyophilization or spray-drying, which were kept long time at an ambient temperature. It is also worthwhile to consider the difference in the degree of branching between lentinan and HA β-glucan. Lentinan has two branches for every five D-glucose residues,[11] while HA β-glucan has one branch for every four D-glucose residues[36] (see Fig. 1). Accordingly, there appears no direct relation between the degree of branching and molecular conformations so far elucidated.

As described already, lyophilized samples from DMSO solution take a regular conformation as manifested from observation of relatively narrow ^{13}C NMR signals. In particular, the C-1 ^{13}C signals of these samples are split into doublet signal at 105.8 and 104.0 ppm (Fig. 6). As an interpretation of this splitting, it is natural to postulate that there exist two kinds of different conformers in this form (form IV), although peak splitting of the C-3 ^{13}C signal is not pronounced. Alternatively, conformation of two chains is identical but splitting of peak is distinguishable by the effect of hydrogen bonding to one of chains with DMSO molecule.

Conformations in the Gel State. It appears that the ^{13}C NMR linewidths of the gel samples recorded at 75 MHz are much narrowed and excellent spectral separation is achieved in this study of higher frequency (especially at the region of C-2, 4, and 5) (Fig. 7). The observed linewidths in this case, however, are about 100 Hz and the extent of line narrowing as compared with the data of 25 MHz is about 30% for the C-1 and C-3 signals. This observation might be mainly ascribed to a plausible reduction in the number of effective cross links formed by multiple helical junction zones or aggregate of these regions, because the present spectra were recorded at a lower concentration (20 mg ml^{-1}) (one fifth of those of low frequency measurements). Naturally, the ^{13}C chemical shifts of gel samples in this study are in good agreement with our previous data.[4-9] However, more accurate data about the ^{13}C chemical shifts were obtained in this study because of much improved separation of peaks. Thus, it is now clear that the ^{13}C NMR peaks of curdlan gel are displaced downfield by 1.3 and 3.0 ppm for the C-1 and C-3 carbons, respectively, from those of water-soluble low-molecular-weight glucan taking random coil conformation, but the rest of peaks is unchanged by going from the gel to random-coil form (Table 4).

In spite of obvious differences in the conformations between curdlan (and lentinan) and HA β-glucan in the solid state, we found that exactly the same spectral features were observed between the two samples in the gel state (Fig. 7). In our previous papers,[5,29] we concluded that conformation of flexible molecular chains in curdlan, which is visible by high resolution ^{13}C NMR spectroscopy, is identical to that of the solid state. However, closer examination of the ^{13}C chemical shifts of these gel samples (Tables 2 and 4) shows that the C-3 ^{13}C chemical shifts of the gel samples appear at the midpoint of those of forms II and III, although no appreciable change was noted for the rest of peaks. The displacements of peaks in each case are 2—3 ppm and can be regarded as significant change, even if contribution of a plausible experimental error

(<1 ppm) is taken into account.[46] This finding implies that a sort of conformational rearrangement in association with hydration is required to form gel when solid samples of linear glucans with form II or of branched glucans with form II or III were used. It is conceivable that conformational change would be induced when these samples are hydrated to some extent. Consistent with this view, existence of polymorphic structures depending on humidity or hydration was demonstrated for curdlan by means of X-ray diffraction study.[12,30]

Concluding Remarks.

We found that (1→3)-β-D-glucans obtained either from lyophilization or spray-drying take regular secondary conformations as viewed from high-resolution solid-state ^{13}C NMR spectroscopy, in spite of inherent poor crystallinity. Obviously, this is the major advantage of the ^{13}C NMR spectroscopy as a new means of conformational elucidation complementary to X-ray diffraction. It is demonstrated that these secondary forms can be classified into at least four forms, on the basis of the conformation-dependent displacements of peaks at the C-1 and C-3 carbons. As a result, we concluded that paramylon with crystallinity of over 90% is not consisting of molecular chains of single conformation but a composite of at least three different conformers. In addition, we found that gelation property of linear glucans is related to the presence of particular conformation in the solid state. This view, however, must be modified to some extent in branched glucans, because gelation condition is not simple as in linear glucans.

We are grateful to Takeda Chemical Industries for providing us with curdlan and its acid-degraded samples, Dr. Goro Chihara for gift of lentinan and pachyman, and Professor B. A. Stone for gift of paramylon.

46) In this connection, it is important to consider a plausible contribution from the difference in molecular packing, by going from the solid to gel state, to the displacements of the ^{13}C chemical shifts (2—3 ppm for the C-3 carbon). As a means to estimate the extent of molecular packing, VanderHart compared the ^{13}C chemical shifts of *n*-alkane of different crystalline structure but the same molecular conformation and showed a separation of peaks 1.3 ppm in the resonance position of the internal methylene resonance.[47] In a same manner, Sorita et al. noticed the difference of the ^{13}C chemical shift due to molecular packing as large as 0.9 ppm for the system of *cyclo*- and *n*-alkanes.[48] Accordingly, it is obvious that such a contribution by molecular packing, if any, cannot well explain the observed displacements of peaks. Moreover, it is pointed out that significant displacements of peaks by going from the solid to gel state is limited to the C-3 peak alone, and the rest of peaks is unchanged within the experimental error. Therefore, it is reasonable to ascribe the significant displacements of peaks to a plausible conformational change, as treated in the present article.

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received December 25, 1985)

Biferrocene and ferrocenylruthenocene react with $HgCl_2$ to give very stable adducts. Large quadrupole splitting values (2.93 mm s^{-1} for biferrocene–$2HgCl_2$ and 2.99 mm s^{-1} for ferrocenylruthenocene–$5HgCl_2$, both at 78 K) indicate the presence of a direct interaction between the Fe and Hg atoms. The stabilities of their adducts suggest a chelating effect between the Fe and Fe or Fe and Ru atoms in biferrocene or ferrocenylruthenocene, respectively.

All attempts in preparing a stable adduct of mononuclear ferrocene with a Lewis acid such as Hg^{2+}, Sn^{4+}, and I^+ have been unsuccessful, whereas a number of the corresponding ruthenocene adducts were reported to be very stable.[1–4]

It was recently shown in our previous reports that [2]ferrocenophane derivatives react with various Lewis acids such as Sn^{4+}, Hg^{2+}, and I^+ to give stable adducts containing a chemical bond between the Fe and Lewis acid atoms.[5–7] The stabilities of [2]ferrocenophane adducts were ascribed to the distorted structure of [2]ferrocenophane which makes the nonbonding e_{2g} electrons of the iron atom in ferrocene easier to be ligated to a Lewis acid atom.

The other category of ferrocene derivatives which can provide a stable adduct with a Lewis acid, may be expected in binuclear metallocene derivatives, because their adducts with a Lewis acid are stabilized by a chelating effect of the binuclear ferrocene derivatives if they have a suitable molecular structure.[8] Fortunately, a number of binuclear ferrocene derivatives have been synthesized and reported in connection with studies of the mixed-valence state of iron atoms in their monocation salts. For instance, biferrocenium triiodide shows a so-called trapped valence state, while biferrocenylenium pentaiodide shows an averaged valence state.[9–11] It is also expected that ferrocenylruthenocene derivatives can provide much more stable adducts with a Lewis acid than the binuclear ferrocenes and that the electronic state of iron atoms in the adducts may provide information about the chelating effect.

Experimental

Materials. Biferrocene,[12] biferrocenylene,[13] diferrocenylmethane and diferrocenylethane,[14] 1,12-dimethyl[1.1]ferrocenophane,[15] [2.2]ferrocenophane,[16] ferrocenylruthenocene,[17] and ferrocenylruthenocenylmethane[18] were prepared by the methods reported previously.

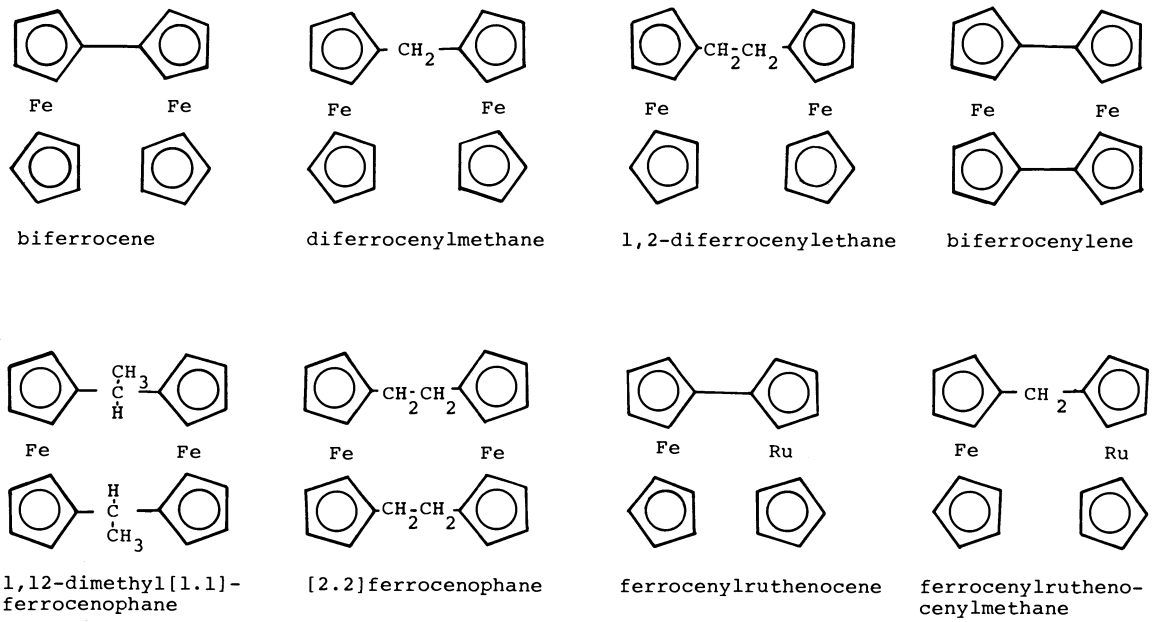
Adducts of diferrocenylmethane, 1,2-diferrocenylethane, ferrocenylruthenocene and ferrocenylruthenocenylmethane with $HgCl_2$ were prepared in diethyl ether by a similar method to that used in the case of biferrocene–$2HgCl_2$ adduct.[8] Found: C, 25.71; H, 2.71%. Calcd for biferrocene–$2HgCl_2$, $C_{20}H_{18}Fe_2Hg_2Cl_4$: C, 26.29; H, 1.97%. Found: C, 12.52, H, 0.99; Fe, 5.54%. Calcd for diferrocenylmethane–$6HgCl_2$, $C_{21}H_{20}Fe_2Hg_6Cl_{12}$: C, 12.99; H, 1.10; Fe, 4.78%. Found: C, 13.02; H, 1.09; Fe, 5.51%. Calcd for 1,2-diferrocenylethane–$6HgCl_2$, $C_{22}H_{22}Fe_2Hg_6Cl_{12}$: C, 13.05; H, 1.10; Fe, 5.08%. Found: C, 14.17; H, 1.27%. Calcd for ferrocenylruthenocene–$5HgCl_2$, $C_{20}H_{18}FeRuHg_5Cl_{10}$: C, 13.55; H, 1.03%. Found: C, 22.96; H, 2.02%. Calcd for ferrocenylruthenocenylmethane–$2.5HgCl_2$, $C_{21}H_{20}FeRuHg_{2.5}Cl_5$: C, 22.75; H, 1.82%.

Reaction products of biferrocenylene, 1,12-dimethyl[1.1]ferrocenophane and [2.2]ferrocenophane were prepared in ethanol instead of diethyl ether because of better solubility, by following a method similar to that used for the biferrocene–$2HgCl_2$ adduct. The dark green precipitates that formed were filtered, washed with ethanol or diethyl ether and dried in a vacuum. Found: C, 16.86; H, 1.13; Hg, 54.00%. Calcd for biferrocenylenium$(HgCl_3^-)(HgCl_2)_3$, $C_{20}H_{16}Fe_2Hg_4Cl_9$; C, 16.11; H, 1.07; Hg, 53.86%. Found: C, 20.51; H, 1.71%. Calcd for 1,12-dimethyl[1.1]ferrocenophanium$(HgCl_3^-)(HgCl_2)_{2.5}$, $C_{24}H_{24}Fe_2Hg_{3.5}Cl_8$: C, 20.65; H, 1.70%. Found: C, 27.74; H, 2.31%. Calcd for [2.2]-ferrocenophanium$^{2+}(HgCl_3^-)_2$, $C_{24}H_{24}Fe_2Hg_2Cl_6$: C, 27.26; H, 2.37%.

Measurements. ^{57}Fe-Mössbauer measurements were carried out using a ^{57}Co(Pt) source moving in a constant acceleraion mode. The values of the isomer shifts were described with respect to metallic iron foil. The experimental error of the isomer shifts (I.S.) and quadrupole splittings (Q.S.) was ± 0.02 mm s^{-1}. Cyclic voltammograms were obtained by using a Hokuto Denko HB-107A function generator and a Hokuto Denko HA-201 potentiostat combined with a standard three-electrode configuration. A working electrode of platinum button-(Beckman) and an Ag/AgCl reference electrode were connected via a salt bridge containing (0.1 mol dm^{-3}) $[(C_4H_9)_4N]ClO_4$ in CH_3CN.

Results and Discussion

Biferrocene reacts with a large excess of $HgCl_2$ in diethyl ether, giving deep-red precipitates thought to be biferrocene–$2HgCl_2$, based on an elemental analysis. The adduct is stable in air for a long time (more than 200 d) at room temperature, while ferrocene–$7HgCl_2$ changes immediately into a ferricinium salt.[19] Other biferrocene derivatives, such as



1′,1‴-dihalobiferrocene 1′,1‴-dialkylbiferrocene, react with $HgCl_2$ to give paramagnetic green precipitates. The results of Mössbauer spectroscopic studies of these precipitates show that these biferrocene are oxidized by $HgCl_2$, probably because of a steric hindrance of the substituents and that they give a trapped-valence state for each monocationic ferricinium salt.

Typical Mössbauer spectra of a biferrocene–$2HgCl_2$ adduct and the biferrocene itself, are shown in Fig. 1 and Mössbaur parameters are listed in Table 1. The Q.S. value (2.93 mm s^{-1} at 78 K) found in the biferrocene–$2HgCl_2$ adduct is a little smaller than that of [2]ferrocenophane–$3HgCl_2$ adduct (3.29 mm s^{-1} at 78 K)[6] but still larger than that of the original biferrocene. The results indicate that the biferrocene–$2HgCl_2$ adduct should have Fe–Hg bonds, as already verified in the $HgCl_2$ or $SnCl_4$ adducts of [2]ferrocenophane.[5,6]

A little lower Q.S. value and large stability of the

Ferrocene–$7HgCl_2$ [b]	275	2.94	0.45

a) Data were taken from Ref. 10. b) Data were taken for the fresh sample reported in Ref. 19.

biferrocene-$2HgCl_2$ adduct compared with ferrocene-$7HgCl_2$[19] suggest that biferrocene reacts with $HgCl_2$ as a chelating agent.

It is found that biferrocene reacts with $SnCl_4$ to give only green-colored precipitates in which iron atoms are not ligated to Sn^{4+} ions but partially oxidized to a mixed-valence state (Q.S. values, 2.26 and 0.29 mm s^{-1} at 78 K).[20] Also, biferrocene is oxidized to a dicationic biferricinium salt in the reaction with $SbCl_5$ (Q.S., 0.25 mm s^{-1} and I.S., 0.55 mm s^{-1} at 78 K, which are characteristic of ferricinium-like iron(III)). Although [2]ferrocenophane reacts with other Lewis acid species, such as $CdCl_2$, $ZnCl_2$, $CoCl_2$, to give corresponding adducts with them,[21] biferrocene does not react with these Lewis acids. The results may be interpreted by assuming that Hg^{2+} ions are a softer acid than Sn^{4+} and Sb^{5+} atoms, and that the e_{2g} electrons in biferrocene cannot be ligated to Lewis acids harder than Hg^{2+}.

Diferrocenylmethane and 1,2-diferrocenylethane also react with $HgCl_2$ as in the case of biferrocene, giving orange-yellow precipitates with a color that is very similar to that of ferrocene-$7HgCl_2$. The products are less stable than the biferrocene-$2HgCl_2$ adduct; i.e., they change color to blue-green after being allowed to stand at room temperature for several days after preparation. However, they are much more stable than the ferrocene-$7HgCl_2$ adduct which completely changes from orange-yellow to blue-green within a day.

The results indicate that the diferrocenylmethane- and 1,2-diferrocenylethane-$6HgCl_2$ adducts have Fe-Hg bonds, although the bonds seem to be a little weaker than the Fe-Hg bond in the biferrocene-$2HgCl_2$ adduct. Actually, the doublet component with a large Q.S. value decreases and a broad-line component with a small Q.S. value increases in their Mössbauer spectra (Fig. 2), if the compounds are placed in air for several days.

Biferrocene, 1,12-dimethyl[1.1]ferrocenophane and [2.2]-ferrocenophane react with $HgCl_2$ in ethanol giving dark-green paramagnetic precipitates. The ^{57}Fe-Mössbauer spectra of these reaction products are shown in Fig. 3, and the Mössbauer parameters are also listed in Table 1. A smaller Q.S. value (1.87 mm s^{-1} at 78 K) compared with that of biferrocenylene (2.44 mm s^{-1} at 78 K) was found and assigned to an averaged valence state of Fe(II) and Fe(III) as expected from the dark color of the adduct. The Q.S. value is close to that of biferrocenylenium

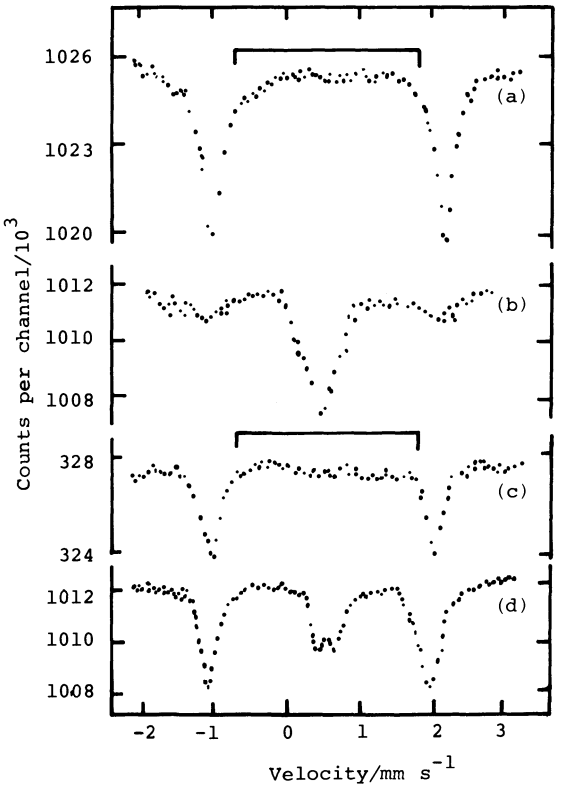

Fig. 2. Mössbauer spectra at 78 K of (a) diferrocenylmethane-$6HgCl_2$ adduct immediately, (b) 7 d after preparation, (c) 1,2-diferrocenylethane-$6HgCl_2$ adduct immediately, (d) 7 d after preparation. Peak position of diferrocenylmethane and 1,2-diferrocenylethane is shown.

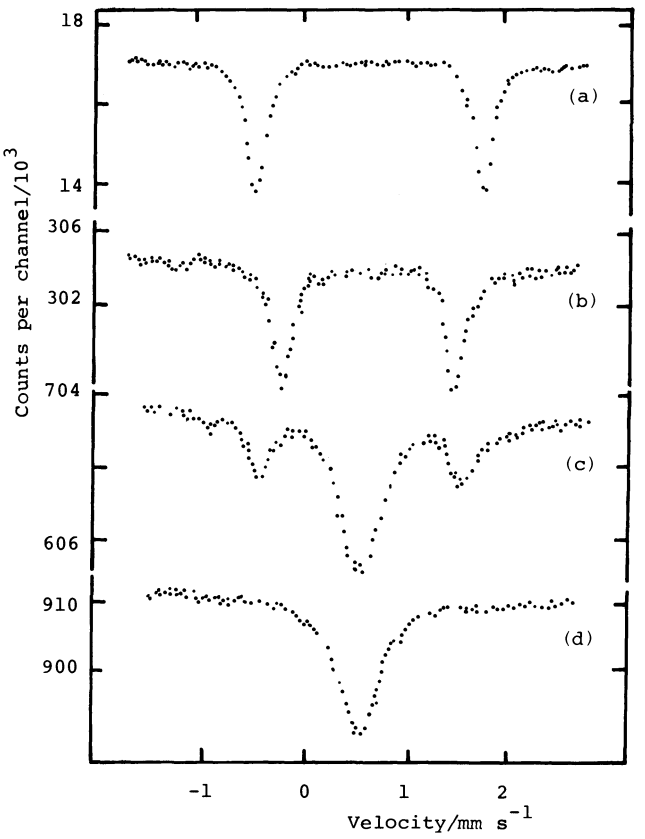

Fig. 3. Mössbauer spectra at 78 K of (a) biferrocenylene, and reaction products of (b) biferrocenylene, (c) 1,12-dimethyl[1.1]ferrocenophane, (d) [2.2]ferrocenophane with $HgCl_2$.

pentaiodide (1.756 mm s^{-1} at 4.2 K), which is known to show a typical averaged valence state.[10]

Magnetic susceptibility measurements showed that the monocationic biferrocenylenium salt is paramagnetic. The effective magnetic moment in a temperature range from 78 K to 120 K was found to be 2.02 BM, also close to the value characteristic of binuclear ferrocene derivatives in an averaged valence state (e.g., 1.90 BM for biferrocenylenium pentaiodide).[10] The results indicate that biferrocenylene is partially oxidized by $HgCl_2$ to form an averaged valence state of a monocationic biferrocenylenium salt.

The 1,12-dimethyl[1.1]ferrocenophane–$HgCl_2$ product showed two quadrupole splitting doublets (Q.S.; 1.93 mm s^{-1}. I.S.; 0.52 mm s^{-1} and Q.S.; 0.0 mm s^{-1}, I.S.; 0.53 mm s^{-1} at 78 K). These values are almost the same as those for the monocationic 1,12-dimethyl[1.1]ferrocenophanium triiodide salt.[10] This fact suggests that an interaction takes place between the iron atom, however, the interaction is not as strong as that of biferrocenylenium.

[2.2]Ferrocenophane reacts with $HgCl_2$ in ethanol giving dark green precipitates which are expressed as [2.2]ferrocenophanium^{2+}($HgCl_3^-$)$_2$. In the Mössbauer spectra of this compound, only a broad singlet peak is observed, suggesting that [2.2]ferrocenophane is oxidized by $HgCl_2$ completely to a dicationic [2.2]ferrocenophanium species.

In the cyclic voltammograms of biferrocenylene and 1,12-dimethyl[1.1]ferrocenophane, two kinds of one-electron oxidation peaks (0.26_5 and 0.85_5 V for biferrocenylene,[22] 0.38 and 0.61 V for 1,12-dimethyl-[1.1]ferrocenophane) were observed, while only one two-electron oxidation peak (0.42 V) was found in that of [2.2]ferrocenophane. The difference between the first and second half-wave potentials, $\Delta E_{1/2}$, has often been used as a parameter of the interaction between the Fe–Fe atoms in binuclear ferrocene derivatives. The fact that a larger value of $\Delta E_{1/2}$ (0.59 V) is observed in the biferrocenylene than the value (0.23 V) found in 1,12-dimethyl[1.1]ferrocenophane, is in accordance with the results of Mössbauer spectroscopic studies on binuclear ferrocenophanes' monocationic salts.

It can be concluded that doubly-bridged ferrocenophanes react with $HgCl_2$ gving only a ferricinium salt and not an adduct containing an Fe–Hg chemical bond. The reason that biferrocene, diferrocenylmethane, and 1,2-diferrocenylethane form adducts with $HgCl_2$ can be explained by assuming a more flexible molecular structure compared with the rigid structure of biferrocenylene, 1,12-dimethyl[1.1]ferrocenophane and [2.2]ferrocenophane. A large conformational change in such a way that the two Fe atoms are ligated to the $HgCl_2$ may occur, for instance, in biferrocene–2$HgCl_2$ but such a change can not be allowed in a rigid structure of binuclear ferrocenophanes.

Based on this speculation, more stable $HgCl_2$ adducts were prepared using ferrocenylruthenocene derivatives. The results of the cyclic voltammography of ferrocenylruthenocene show two one-electron oxidation peaks (E_{ox}; 0.45 and 0.92 V), one is ascribed to an oxidation of ferrocene-type iron atoms (0.45 V) and the other is to that of a ruthenocene-type ruthenium atoms (0.92 V); i.e., Ru atoms are oxidized less easily than Fe atoms by $HgCl_2$ in this compound. It is known that ruthenocene itself reacts with various kinds of Lewis acids such as I_2, $SnCl_4$, $SbCl_5$, and $HgCl_2$, to give relatively stable products containing a chemical bond between Ru and the Lewis acids.[1-4]

Ferrocenylruthenocene reacts with a large excess of $HgCl_2$ in diethyl ether giving diamagnetic orange-yellow precipitates. The product, expressed ferrocenylruthenocene–5$HgCl_2$, is more stable in air than biferrocene–2$HgCl_2$. The biferrocene–2$HgCl_2$ adduct changes color to green-blue upon standing at 80 °C for 2hr, while the color of ferrocenylruthenocene–5$HgCl_2$ remains upon standing under the same conditions.

Typical Mössbauer spectra of ferrocenylruthenocene and its $HgCl_2$ adduct are shown in Fig. 4. The Q.S. value of ferrocenylruthenocene is 2.36 mm s^{-1} at 78 K as shown in Table 1, which is nearly the same as that of biferrocene (2.33 mm s^{-1} at 78 K), suggesting there is no direct effect of ruthenocenyl group on Fe atoms in ferrocenylruthenocene.

A larger Q.S. value is observed in ferrocenylruthenocene–5$HgCl_2$ adduct (2.99 mm s^{-1} at 78 K) compared with the value of the original ferrocenylruthenocene.

Ferrocenylruthenocenylmethane reacts with $HgCl_2$

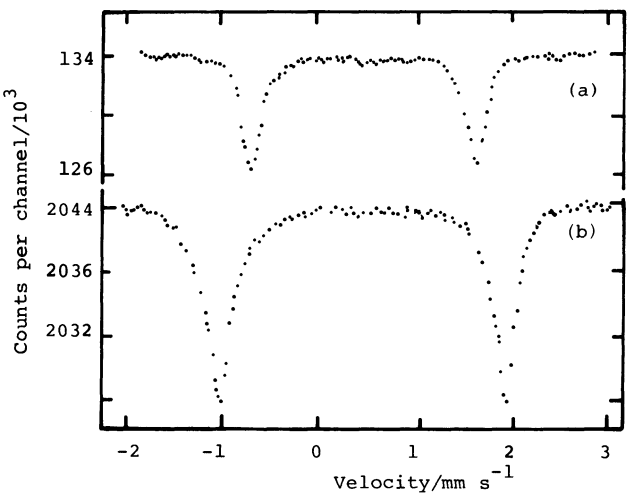

Fig. 4. Mössbauer spectra of (a) ferrocenylruthenocene and (b) its $HgCl_2$ adduct, both at 78 K.

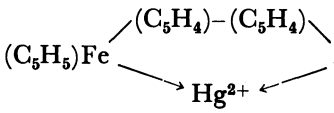
in diethyl ether, giving a diamagnetic orange-yellow product. The Q.S. value found in this adduct (2.84 mm s^{-1} at 78 K) is a little smaller than those of binuclear ferrocene derivatives-$HgCl_2$ adducts or ferrocenylruthenocene-5$HgCl_2$ adduct, but still larger than that of the original ferrocenylruthenocenylmethane (2.44 mm s^{-1} at 78 K). The results indicate that the ferrocenylruthenocenylmethane adduct has an Fe-Hg bonding, although the bond should be a little weaker than the Fe-Hg bond in the $HgCl_2$ adduct of ferrocenylruthenocene.

Actually, the $HgCl_2$ adduct of ferrocenylruthenocenylmethane is not as stable as the $HgCl_2$ adduct of ferrocenylruthenocene. After being allowed to stand in air for several days after preparation, the color of the adduct gradually changed into blue-green, as in the case of diferrocenylmethane-6$HgCl_2$ and 1,2-diferrocenylethane-6$HgCl_2$ adducts. The reason that ferrocenylruthenocenylmethane forms a less stable adduct can be explained by the larger distance between the Ru and Fe atoms in the molecule compared in the ferrocenylruthenocene molecule; i.e., the distance of Fe-Ru atoms may be too large to make a stable chelation like ferrocenylruthenocene-5$HgCl_2$ adduct.

The facts that ferrocenylruthenocene can provide a more stable adduct than biferrocene and ferrocenylruthenocenylmethane with $HgCl_2$ and that the Q.S. value is similar to that of biferrocene-2$HgCl_2$ adduct, also suggest a possibility of chelation,



rather than a monodentated donation such as $-(C_5H_5)Ru\rightarrow Hg^{2+}\leftarrow Fe(C_5H_5)(C_{10}H_8)(C_5H_5)Ru\rightarrow Hg^{2+}\leftarrow Fe(C_5H_5)-$. It is tentatively concluded in this study that ferrocenylruthenocene and biferrocene form very stable adducts with $HgCl_2$ because of an appropriate distance between the Fe-Ru or Fe-Fe atoms for chelation to take place in these adducts. However, further studies must be conducted to provide direct evidece to prove the chelating bond in the adducts.

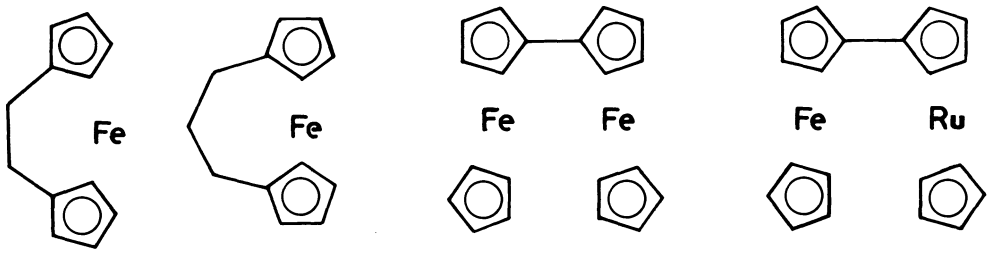
Mössbauer Spectroscopic Studies of Tin(IV) Halide Adducts with Ruthenocene and with [2]Ferrocenophanes

Masanobu WATANABE, Izumi MOTOYAMA, and Hirotoshi SANO*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received Junuary 13, 1986)

Adducts of tin(IV) halide with [2]ferrocenophane were prepared by treating SnX_4 (X=Cl or Br) with [2]ferrocenophane in hexane. The adducts were studied by means of ^{57}Fe- and ^{119}Sn-Mössbauer spectroscopy and other physicochemical measurements. Anomalously large quadrupole splittings (3.49 mm s^{-1} for [2]ferrocenophane-1.5$SnCl_4$ adduct and 3.47 mm s^{-1} for [2]ferrocenophane-1.5$SnBr_4$ adduct, both at 78 K) found in the ^{57}Fe-Mössbauer spectroscopy and organotin(IV) species (e.g., isomer shift value, 2.14 mm s^{-1} for the [2]-ferrocenophane-1.5$SnCl_4$ adduct and 2.10 mm s^{-1} for the [2]ferrocenophane-1.5$SnBr_4$ adduct, both at 78 K) found from the ^{119}Sn-Mössbauer spectroscopy suggest that a direct chemical bonding between Fe and Sn atoms is formed in the [2]ferrocenophane adducts, as the Ru-Sn bonding in the ruthenocene-1.5$SnCl_4$ adduct (isomer shift value, 2.08 mm s^{-1} at 78 K).



[2]Ferrocenophane [3]Ferrocenophane Biferrocene Ferrocenylruthenocene

Mann et al. reported that yellow-colored ruthenocene-tin(IV) halide adducts are prepared by the reaction of ruthenocene with $SnCl_4$ or $SnBr_4$ in a CCl_4 solution under nitrogen.[1] Based on the results of the IR spectra of these adducts, they proposed that the probable formula for the yellow products is $[(Cp)_2Ru\text{-}SnX_2\text{-}Ru(Cp)_2]^{2+}(SnX_5^-)_2$, where X=Cl or Br and Cp=C_5H_5, although no information was given about the ^{119}Sn-Mössbauer spectroscopy. The yellow SnX_4 adducts of ruthenocene are not as stable as the HgX_2 adducts of ruthenocene, in which Hg-Ru bonding is observed in X-ray analytical measurements.[2]

All attempts to prepare stable adducts of ferrocene with tin(IV) halide have been unsuccessful; e.g., ferrocene reacts with $SnCl_4$ giving not an adduct but only a paramagnetic ferricinium salt.

It has been shown in our recent reports that [2]ferrocenophanes react with various Lewis-acid species such as Hg^{2+}, Cd^{2+}, H^+, I^+, and Cl^+, giving their adducts by ligating electrons of iron atoms to the Lewis acids.[3-6] For instance, ^{57}Fe-Mössbauer spectroscopic studies of the [2]ferrocenophane-3$HgCl_2$ adduct show an anomalously large quadrupole splitting (Q.S.) value (3.29 mm s^{-1} at 78 K), suggesting a direct chemical bond between Fe^{2+} and Hg^{2+} atoms. The stability of [2]ferrocenophane-3$HgCl_2$ is ascribed to "naked" electrons around the iron atoms because the cyclopentadienyl rings are inclined by a bridged structure. In the case of the [2]ferrocenophane-$I^+I_3^-$ adduct, a direct interaction was verified by a single-crystal X-ray structural analysis; a similarly large Q.S. value is found in this adduct.[6]

From the similarity to ruthenocene-1.5SnX_4 adducts, it is expected that [2]ferrocenophane derivatives can provide a stable adduct of $SnCl_4$. The present study was planned to clarify the structure of the stable adducts of [2]ferrocenophane with SnX_4 (X=Cl or Br) and to provide further information about the chemical state of iron and tin by means of ^{57}Fe- and ^{119}Sn-Mössbauer spectroscopy.

Experimental

Materials. Biferrocene,[7] [2]ferrocenophane,[8] and [3]ferrocenophane[9] were prepared by the methods previously reported. The adduct of tin chloride with [2]ferrocenophane was prepared by the following method. To a solution of [2]ferrocenophane dissolved in dry hexane, a hexane solution of $SnCl_4$ was added in a nitrogen-filled dry box equilibrated with P_4O_{10}, and the produced red-orange precipitates were filtered, washed with a large excess of hexane, and dried under vacuum. The purity of the adduct was confirmed by elemental analysis: Found; C, 23.41; H, 2.77; Sn, 29.07%. Calcd for [2]ferrocenophane$(SnCl_4)_{1.5}$-(H_2O), $C_{12}H_{14}FeSn_{1.5}Cl_6O$: C, 23.19; H, 2.25; Sn, 28.67%. The red-orange product of [2]ferrocenophane with $SnBr_4$

was obtained by the same conditions as in the case of $SnCl_4$ adduct. The $SnBr_4$ adduct is very hygroscopic. Found: C, 16.21; H, 1.92%. Calcd for [2]ferrocenophane-$(SnBr_4)_{1.5}$-$(H_2O)_3$, $C_{12}H_{18}FeSn_{1.5}Br_6O_3$: C, 15.59; H, 1.95%. Reaction products of [3]ferrocenophane, biferrocene and ferrocene were obtained by the same procedure as described in the case of [2]ferrocenophane-1.5$SnCl_4$ adduct, but the color of the precipitates was dark-green characteristic of ferricinium salts. All the products prepared in the reactions of [2]-, [3]ferrocenophane and ferrocene with tin halides are so hygroscopic that the elemental analysis and IR spectroscopic data show an appreciable amount of water in each final product (as described in each empirical formula), even after keeping the samples in a desiccator. Found: C, 27.43; H, 2.93; Sn, 26.13%. Calcd for [3]ferrocenophanium-$(SnCl_4)_{1.25}(H_2O)_{1.5}$, $C_{13}H_{17}FeSn_{1.25}Cl_5O_{1.5}$: C, 26.96; H, 2.94; Sn, 25.64%. Found: C, 30.67; H, 2.44%. Calcd for biferrocenium$(SnCl_4)_{1.75}$, $C_{20}H_{18}Fe_2Sn_{1.75}Cl_7$: C, 29.07: H, 2.20%. Found: C, 20.10; H, 2.05; Sn, 28.85%. Calcd for ferricinium$(SnCl_4)_{1.5}(H_2O)_2$, $C_{10}H_{14}FeSn_{1.5}Cl_6O_2$: C, 19.58; H, 2.28; Sn, 29.05%. The adducts of [2]ferrocenophane-1.5$SnCl_4$ are hardly soluble in most organic solvents but are soluble in *N,N*-dimethylformamide. The solution shows only an absorption spectrum of [2]ferrocenophane, while the other precipitates such as [3]ferrocenophane-1.25$SnCl_4$ are soluble in *N,N*-dimethylformamide. The resulting green-colored solution gives an absorption spectra similar to that of the ferricinium salts.

Ruthenocene reacts with a large excess of $SnCl_4$ in dry hexane under nitrogen giving a yellow adduct. Found: C, 20.28; H, 1.78%. Calcd for ruthenocene$(SnCl_4)_{1.5}$, $C_{10}H_{10}RuSn_{1.5}Cl_6$: C, 19.29; H, 1.61%.

Measurements. ^{57}Fe-Mössbauer measurements were carried out by using a ^{57}Co(Pt) source moving in a constant acceleration mode, while ^{119m}Sn-Mössbauer spectra were measured against a $Ca^{119m}SnO_3$ source. The velocity calibration was made by the resonance lines of an ^{57}Fe-enriched metallic-iron absorber against the ^{57}Co(Pt) source. The isomer shift (I.S.) for ^{57}Fe was taken with respect to metallic iron and that for ^{119}Sn was descrided with respect to a $BaSnO_3$ absorber. The experimental error of the I.S. and Q.S. values were estimated to be within ± 0.02 mm s^{-1}.

Results and Discussion

The ruthenocene-1.5$SnCl_4$ adduct is not very stable and the yellow color gradually changes into green-yellow upon standing at room temperature for several days in air after preparation. The adduct is soluble in CH_3CN and gives a yellow solution. An absorption band at 360 nm in its fresh solution rapidly decreases in intensity while standing in air, and an absorption band characteristic of ruthenocene appears at 310 nm within a few minutes after preparing the solution. This is ascribed to a dissociation of the adduct into ruthenocene and $SnCl_4$.

The ^{119}Sn-Mössbauer parameters of the adducts and related compounds are listed in Table 1 and typical ^{119}Sn-Mössbauer spectra of $Ru(Cp)_2$-1.5$SnCl_4$ and related compounds are shown in Fig. 1. Measure-

ments of the ^{119}Sn-Mössbauer spectra for the $SnCl_4$ adducts were limited to within a temperature range below 150 K because of their small recoil-free fraction. In the spectrum measured at 78 K of $Ru(CP)_2$-1.5$SnCl_4$, two kinds of chemical states of the tin(IV) species (I.S., 0.56 and 2.08 mm s^{-1}) were observed. The component with a higher I.S. value (2.08 mm s^{-1}) was ascribed to an organotin(IV) species and the other broad component with a lower I.S. value (0.56 mm s^{-1}) to a rather ionic $SnCl_5^-$ species, respectively. This was based on the systematics of the ^{119}Sn-Mössbauer spectroscopic parameters found in tetravalent organotin or organometallic tin chlorides and hexachlorotin(IV) species.

Mann et al. has already proposed $[(Cp)_2Ru\text{-}SnCl_2\text{-}Ru(Cp)_2]^{2+}(SnCl_5^-)_2$ as one of the probable structures for the yellow adduct on the basis of the IR spectroscopic studies.[1] In an analogy to the conclusion, it was also confirmed from the results of a ^{119}Sn-Mössbauer spectroscopic study that the component having a higher I.S. value is ascribable to a tin(IV) species of $(Cp)_2Ru\text{-}SnCl_2\text{-}Ru(Cp)_2$ and the lower one to $SnCl_5^-$.

Ferrocene reacts with $SnCl_4$ giving paramagnetic green precipitates. The ^{119}Sn- and ^{57}Fe-Mössbauer spectra of the product are shown in Figs. 2 and 4, respectively. In the ^{57}Fe-Mössbauer spectrum of this product, a broad singlet peak observed indicates the

		2.26	0.50

presence of the ferricinium-like iron atoms as expected from the dark-green color of the product. The ^{119}Sn-Mössbauer spectrum shows that there are three components ascribed to two kinds of Sn(IV) species (I.S., 0.18 and 0.80 mm s^{-1}) and to a kind of Sn(II) species (I.S., 4.07 mm s^{-1}) at 78 K. The presence of Sn(II) peak suggests that ferrocene may be oxidized by $SnCl_4$ giving ferricinium salt, expressed as $[(Cp)_2Fe^+]_2(SnCl_3^-)(SnCl_5^-)(SnCl_4)(H_2O)_4$ in accord with the elemental analysis data.

Biferrocene, one of the typical binuclear ferrocene derivatives, is also known to react with $HgCl_2$ giving a more stable adduct than that of ferrocene. Biferrocene reacts with $SnCl_4$ in a hexane solution giving green-black paramagnetic precipitates. ^{57}Fe-Mössbauer spectroscopic measurements indicate that there are two kinds of iron atoms, one of which is ferrocene-like (Q.S., 2.26, I.S., 0.50 mm s^{-1}) and the other is ferricinium-like (Q.S., 0.29, I.S., 0.54 mm s^{-1}, at 78 K), showing a trapped-valence state. ^{119}Sn-Mössbauer spectroscopic measurements show that there are three components ascribed to two kinds of Sn(IV) species, ($SnCl_5^-$ and $SnCl_4 \cdot nH_2O$: I.S., 0.86 and 0.22 mm s^{-1} at 78 K, respectively) and to a kind of Sn(II) species ($SnCl_3^-$: I.S., 4.01 mm s^{-1} at 78 K). The spectral shape is similar to that of ferrocene-1.5$SnCl_4(H_2O)_2$. The product is expressed by a formula, (biferrocenium$^+$)$_2(SnCl_3^-)(SnCl_5^-)(SnCl_4)_{1.5}$, based on an elemental analysis.

It is reported that cyclopentadienyl rings are separated by 3.32 Å from each other in ferrocene molecules, and by 3.68 Å in ruthenocene molecules.[10,11] The larger separation of the Cp rings in ruthenocene provides a good explanation for the fact that ruthenocene can easily donate the e_{2g} electrons of the ruthenium atom to a Lewis acid, such as $SnCl_4$, $HgCl_2$, giving a stable coordination compound.[1,2,12]

Recently, the structure of the [2]ferrocenophane was investigated by an X-ray analysis and it was found that the crystals of [2]ferrocenophane are orthorhombic with a=12.444(2), b=19.969(4), c=7.467(1), space group, P_{bca}. The two five-membered rings are tilted 22.2° with respect to one another. The cyclopentadienyl rings are largely separated by 3.60 Å (in maximum) from each other,[13] and this value corresponds to that of ruthenocene (3.68 Å).[11]

[2]Ferrocenophane reacts with a large excess of $SnCl_4$ in dry hexane under the same condition as in the case of ruthenocene-1.5$SnCl_4$, giving an orange-yellow adduct with a formula of [2]ferrocenophane-1.5$SnCl_4(H_2O)$. This adduct is not as stable as the ruthenocene-1.5$SnCl_4$ adduct and its color gradually changes into dark-blue (ferricinium salt) upon standing in air at room temperature for a few hours, while the ruthenocene-1.5$SnCl_4$ adduct keeps its color for several days. The adduct of [2]ferrocenophane with $SnCl_4$ is soluble in *N*,*N*-dimethylformamide giving a solution exhibiting the original absorption spectrum of [2]ferrocenophane. This suggests a dissociation of the adduct into [2]ferrocenophane and $SnCl_4$.

The ^{119}Sn- and ^{57}Fe-Mössbauer spectra of this adduct are illustrated in Figs. 1, and 3, respectively. Anomalously large Q.S. values (3.49 mm s^{-1} at 78 K, 3.40 mm s^{-1} 300 K) are observed for the [2]ferrocenophane-1.5$SnCl_4$ adduct compared with that of [2]ferrrocenophane itself (2.41 mm s^{-1} at 78 K). The anamalously large Q.S. values are good evidence for a direct interaction between Fe and Sn atoms in this adduct, as already verified in the $HgCl_2$, I_2, $CdCl_2$ adducts with [2]ferrocenophane.[3-6]

The ^{119}Sn-Mössbauer spectra of [2]ferrocenophane-1.5$SnCl_4$ (Fig. 1) exhibit two peaks corresponding to two kinds of chemical states of the tin(IV) species (I.S., 0.54 mm s^{-1} and 2.14 at 78 K). Based on the assumption that the recoil-free fraction of both the tin atoms should become approximately equal at lower temperatures, the value of the areal intensity of the lower I.S. component is about two times larger than that of the higher I.S. component at 40 K to 4.2 K. Therefore, it seems reasonable to ascribe the component with higher I.S. (2.14 mm s^{-1}) to (Cp′)$_2$Fe-$SnCl_2$-Fe(Cp′)$_2$-type tin(IV) species and the other broad component with a lower one (I.S., 0.54 mm s^{-1} at 78 K) to a rather ionic $SnCl_5^-$-type tin(IV) species, in the ^{119}Sn-Mössbauer spectroscopic study of ruthenocene-1.5$SnCl_4$ adduct. A similar conclusion is obtained for [2]ferrocenophane-1.5$SnBr_4$ adduct. [2]Ferrocenophane reacts with directly $SnBr_4$ in hexane solution to give orange-yellow precipitates, with a formula of [2]ferrocenophane$(SnBr_4)_{1.5}(H_2O)_3$. Both the [2]ferrocenophane-tin(IV) halide adducts are hygroscopic. The $SnBr_4$ adduct is more hygroscopic than the $SnCl_4$ adduct and its orange-yellow color changes into black in an hour on standing in air at room temperature.

^{57}Fe- and ^{119}Sn-Mössbauer spectroscopic studies on the $SnBr_4$ adduct show an anomalously large quadrupole splitting (3.47 mm s^{-1} at 78 K, see in Fig. 3) for the iron atom and the presence of two kinds of chemical states of tin(IV) atoms (I.S., 0.92 mm s^{-1} for $SnBr_5^-$-type and 2.10 mm s^{-1} for $[(Cp')_2Fe-SnBr_2-Fe(Cp')_2]^{2+}$-type, at 78 K), respectively.

1,1,2,2-Tetramethyl[2]ferrocenophane also reacts with $SnCl_4$, giving an orange-yellow adduct. An anomalously large Q.S. value (3.43 mm s^{-1} at 78 K) is also observed by means of ^{57}Fe-Mössbauer spectroscopy, and two kinds of chemical state of tin(IV) species are found by means of ^{119}Sn-Mössbauer spectroscopy for this adduct.

These ^{119}Sn-Mössbauer results of [2]ferrocenophane–1.5$SnCl_4$ or –1.5$SnBr_4$ adducts are very similar to that of the $SnCl_4$ adduct of ruthenocene. Therefore, these adducts may be expressed as $[(Cp')_2Fe-SnX_2-Fe(Cp')_2]^{2+}(SnX_5^-)_2$, where X=Cl or Br. Similar direct chemical bonds between Fe and Sn atoms (Fe–Sn–Fe) were previously reported in $[Fe(Cp)(CO)_2]_2^{2+}(SnCl_2^{2-})$ by O'Connor and Corey.[14]

The magnetic susceptibility measurement shows that the adducts of [2]ferrocenophane–1.5$SnCl_4$ and –1.5$SnBr_4$ are diamagnetic at temperatures from 78 to 300 K, indicating no possibility of an oxidation of [2]ferrocenophane to a [2]ferrocenophanium cation. However, the color of these adducts gradually changes from orange-yellow to black upon standing at room temperature. These black substances are paramagnetic, probably because [2]ferrocenophane is oxidized by SnX_4 forming [2]ferrocenophanium cations.

On the other hand, [3]ferrocenophane, in which the two Cp rings are slightly inclined to each other (ca., 9°), reacts with $SnCl_4$ giving green-black precipitates. The effective magnetic moment (μ_{eff}) for these precipitates was found to be 2.60 BM; this is a characteristic value for normal ferricinium salts. The ^{57}Fe-Mössbauer spectrum of this salt is shown in Fig. 4-B, where a broad singlet peak is observed (I.S., 0.52 mm s^{-1} at 78 K), and the ^{119}Sn-Mössbauer spectrum (see in Fig. 2-B) also suggests the presence of three types of tin species, ascribed to two kinds of Sn(IV) components (I.S., 0.25 and 0.77 mm s^{-1}, assigned to $SnCl_4 \cdot nH_2O$ and $SnCl_5^-$, respectively) and to a kind of Sn(II) component (I.S., 3.99 mm s^{-1}, assigned to $SnCl_3^-$). The results indicate that the reaction product with [3]ferrocenophane with $SnCl_4$ is expressed as $[(C_5H_4)_2C_3H_6Fe^+]_4(SnCl_3^-)_2(SnCl_5^-)_2(SnCl_4)(H_2O)_6$, in accord with elemental analysis data.

All the results obtained in the present study lead to the conclusion that ruthenocene and [2]ferrocenophanes give adducts with SnX_4, containing coordination bonds between the ruthenium or iron atoms in metallocene and tin atoms. The coordination bonds may be stabilized by a decreased steric hindrance of Cp-rings both in ruthenocene and [2]ferrocenophanes; that is, the longer separation between the Cp-rings both in ruthenocene and [2]ferrocenophane than in ferrocene will make the e_{2g}-electrons of the metallocene easier to be ligated to SnX_4.

Lauher and Hoffmann suggested that the energy levels of frontier orbitals such as e_{2g}, a_{1g}, and e_{1g} in ferrocene depend on the bending angle of the molecule around iron atoms, ∠Cp–Fe–Cp.[15] For instance, one of the split e_{1g} levels goes down while the a_{1g} level and one of the split e_{2g} levels go up, as the angle decreases from 180°. It is not unreasonable to assume that the energy levels cross each other more dramatically if the iron atoms are involved in the ligation to a Lewis acid, giving an increased Q.S. value compared with that of the original [2]ferrocenophane.

(Received January 6, 1986)

Two types of the mixed complexes indicated in the title have been synthesized, and their crystal and molecular structures of the lanthanum (**1**) and the europium (**2**) complexes have been determined by the X-ray diffraction method. Both **1** and **2** are monoclinic, space group $P2_1/n$, and $Z=4$. **1**, $a=17.354(7)$, $b=23.336(4)$, $c=10.955(2)$ Å, $\beta=96.04(2)°$, final R value calculated from 4870 reflections is 0.069; **2**, $a=29.846(7)$, $b=20.070(3)$, $c=14.057(3)$ Å, $\beta=92.13(2)°$, final R value calculated from 7811 reflections is 0.077. In **1**, the central metal atom is octa-coordinated, and is in a dodecahedral geometry, where all *O,O'*-diisopropyl dithiophosphato ligands (iPr_2dtp) span m-edges of the dodecahedron, chelating through both of the respective sulfur atoms. Dimethyl sulfoxide (dmso) ligands occupy the apexes of the other m-edge. In **2**, the europium(III) metal atom of the cationic species is hepta-coordinated and is in a pentagonal-bipyramidal geometry where two oxygen atoms of dmso ligate from respective ends of the axis and one oxygen atom of the remaining dmso from the equatorial direction. The central metal atom of the anion is octa-coordinated and is in a dodecahedron; where all m-edges are spanned by iPr_2dtp ligands. The solid and the acetonitrile solution of **2** is orange in color due to the charge-transfer band ($\lambda_{max}=415$ nm; $\varepsilon_{max}=1.5\times10^2$ dm^3 mol(Eu)$^{-1}$ cm^{-1}).

In previous papers, some of the present authors have reported on the syntheses and the structures of some mixed complexes of *O,O'*-diisopropyl dithiophosphate (iPr_2dtp), and benzamide (bza),[1,2] *N,N*-dimethylacetamide (dma),[3] or dibutyl sulfoxide.[4] Pinkerton has also published a study about the mixed complexes of *O,O'*-diethyl dithiophosphate (Et_2dtp) and triphenylphosphine oxide (Ph_3PO).[5] It is an interesting fact that, in these complexes sulfur atoms ligate to the central lanthanoid atom tightly in spite of the "hard acid" character of the metal.[6]

Moreover, in a series of the dialkyl dithiophosphates mixed complexes of lanthanoid elements, the molecular structures of the lighter and heavier elements are not the same. For example, in the case of the iPr_2dtp–bza mixed complexes, lanthanum(III), through gadolinium(III), form the $[M(iPr_2dtp)_3(bza)_2]$ types and gadolinium(III), through ytterbium(III), the $[M(iPr_2dtp)_2(bza)_3](ipr_2dtp)$ types.[1,2] In cases of the Et_2dtp–Ph_3PO mixed complexes, the former types are formed for lanthanum(III), through praseodymium(III), and the latter types for the rest of lanthanoid elements.[5]

In order to add such examples, we have tried to synthesize a series of the lanthanoid mixed complexes of iPr_2dtp and dimethyl sulfoxide (dmso) and obtained the two types of the complexes indicated in the title: Type **1** complexes were obtained for lanthanum and neodymium, and Type **2** complexes for europium. As shown in the title formula, a Type 2 complex includes an anionic complex, $[M(iPr_2dtp)_4]^-$, like the dibutyl sulfoxide adduct[4] in place of the free $(R_2dtp)^-$ ion (where R=ethyl or isopropyl), which is found in the R_2dtp–bza or Ph_3PO mixed complexes of the heavier lanthanoids.[2,5]

Another problem regarding the type of complex is the coordination sites of the oxygen atoms. As shown in a dodecahedral iPr_2dtp–dma[3] mixed complex, two oxygen atoms take neighbouring positions on one m-edge of the dodecahedron, which is expected to be the preferable situation because the same kind of the ligating atoms are apt to locate nearer,[7] if no steric hindrance occurs.[3] However, as no other example of the type of complex has been found yet, other than the iPr_2dtp–dma type, this time we tried to synthesize the iPr_2dtp–dmso mixed complexes of lanthanoid elements since dmso is relatively small in size and is polar.

To clarify the above-mentioned problems, we determined the structures of the title complexes by the X-ray diffraction technique using single crystals.

Experimental

Synthesis of Tris(*O,O'*-diisopropyl dithiophosphato)bis(dimethyl sulfoxide)lanthanum(III) (1). The $Na(iPr_2dtp)$ was obtained from phosphorus pentasulfide and 2-propanol by the Livingstone's method used to prepare $Na(Et_2dtp)$.[8] Lanthanum(III) chloride heptahydrate (0.49 g, 1.3 mmol) and $Na(iPr_2dtp)$ (1.27 g, 5.4 mmol) were mixed in 30 cm^3 of 2-propanol and refluxed for 30 min. After cooling, a deposited curdy matter was filtered off, and dmso (0.20 g, 2.6 mmol) was added to the filtrate. After being warmed to about 65 °C for 10 min, the solution was concentrated to about 10 cm^3 using a vacuum rotary

evaporator at about 60 °C. The solution, thus obtained, was left standing at about 5 °C overnight in a refrigerator; the crude product was precipitated. When more dmso was added in the process, no crystals were obtained by this method; even if the standing solution was more concentrated, the sirupy liquid did not become solidified. The crude product was dissolved in benzene (about 30 cm^3) and a little insoluble matter was filtered off. The filtrate was concentrated to about 5 cm^3 by a rotary vacuum evaporator at about 70 °C, and was left standing in a refrigerator (10 °C) for several days; pure crystals precipitated. They were washed with benzene, and dried in a vacuum desiccator on silica gel. Yield, 0.5 g (40%).

The neodymium(III) complex was obtained by the same way from its chloride. Yield from 0.45 g (1.3 mmol) of the metal chloride heptahydrate, 0.9 g (70%). Anal. ($MC_{22}H_{54}O_8P_3S_8$) M, C, H, S. (M=La or Nd).

The Synthesis of [Bis(*O,O'*-diisopropyl dithiophosphato)-tris(dimethyl sulfoxide)europium(III)][tetrakis(*O,O'*-diisopropyl dithiophosphato)europate(III)] (2). Europium(III) chloride hexahydrate (0.61 g, 1.7 mmol) and Na(iPr$_2$dtp) (1.6 g, 6.7 mmol) were dissolved in 25 cm^3 of 2-propanol and refluxed for 20 min. After cooling, the residue was filtered off and was added to the filtrate 0.31 g (0.40 mmol) of dmso. The solution was warmed to 65 °C for about 10 min to complete the reaction and was concentrated to about 5 cm^3 using a rotary vacuum evaporator at about 60 °C. The obtained solution was left standing overnight and the deposited curdy matter was filtered off. When the filtrate was kept in a refrigerator for several days, pure crystals were precipitated. These were separated, washed with 2-propanol, and dried in a vacuum desiccator. Yield, 0.65 g(43%). Anal. ($EuC_{42}H_{102}O_{15}P_6S_{15}$), Eu, C, H, S.

Intensity-Data Collection. Crystals with the dimensions of 0.4×0.3×0.3 mm^3 (all apexes were cut off) (**1**), and of 0.4 mm ϕ in sphere (**2**) were used for the respective measurements. The crystallographic data, some experimental conditions to obtain the intensity data, and the final R values[9] obtained by applying the anisotropic temperature factors are tabulated in Table 1. The reflections were collected on a Rigaku AFC-6A automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation, the ω-scan technique being employed (scan speed 4° min^{-1}). The intensities were corrected for the Lorentz and polarization factors, but no correction was made for absorption and extinction.

Structure Determination. The structure was solved by the heavy-atom method. The positions of the metal, phosphorus, and sulfur atoms were deduced from a three-dimensional Patterson map; the other non-hydrogen atoms were located successively by the repeated Fourier syntheses. Their positional, isotropic and then anisotropic thermal parameters were refined by the block-diagonal least-squares method using the local version of the UNICS program.[10]

S(8), C(21), and C(22) of a dmso ligand of **1**, and S(17), C(17), C(18), and S(16) of the dmso ligand of **2** are found to be disordered, and are divided into two. Their positions and occupancy factors were refined with the fixed S–C bond length (1.799 Å). Most of the isopropyl groups of the both compounds showed quite large thermal parameters and gave some abnormal bond lengths if refined without any restrictions. We tried to divide them into disordered structures, but failed. Therefore, they were refined with a fixed geometry, assuming O–C, C–C, O···C, and C···C lengths to be 1.41, 1.53, 2.50, and 2.40 Å, respectively. These procedures were carried out by the blocked full-matrix least-squares method using the SHELX-76 program.[11]

Such ambiguity of positions of peripheral alkyl groups is often encountered in a structural determination of lanthanoid(III) O,O'-dialkyl dithiophosphato complexes.[1-5]

All the calculations were carried out on a HITAC M-280H computer at the Computer Center of the University of Tokyo. The atomic scattering factors were taken from the tables.[12]

Other Measurements. The infrared absorption spectra of the samples were obtained by means of a JASCO A202 grating infrared spectrophotometer, using Nujol and hexachloro-1,3-butadiene mull. The visible absorption spectra of the complexes were measured with a Hitachi 124 spectrophotometer.

a) The equivalent isotropic temperature factors were computed using the following expression; $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\theta)$. The B_{ij}'s are defined by; $T=\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$. b) The probability of the occupancy of each position was as follows: S(8A), C(21A), and C(22A), 70.4; S(8B), C(21B), and C(22B), 29.6%.

scheme of the atoms are shown in Figs. 1 (for **1**), 2, and 3 (for **2**). The schematic presentations to show the configurations of the ligating atoms around the respective metal atoms are shown in Figs. 4 (for **1**), and 5 (for **2**). The crystal packing diagrams of **1** and **2** are shown in Figs. 6 (for **1**), and 7 (for **2**).

Both of the crystals consist of discrete molecules or ions: No bridging is found between them.

In **1**, the lanthanum(III) atom is octa-coordinated and is in a dodecahedral geometry where each iPr_2dtp ligand spans m-edge forming a four-membered chelate ring. Two oxygen atoms of the dmso ligands occupy the apexes of the remaining m-edges. The average deviation of the central metal and the ligating atoms from the respective average trapezium planes is 0.063 Å (the maximum deviation (to O(8)) is 0.119 Å) and the dihedral angle between the two trapezia is 88.2°. The phosphorus atoms of the iPr_2dtp ligands as well as the sulfur atoms of the dmso ligands are also almost on the respective trapezium plane (average deviation of the six phosphorus and two sulfur atoms are 0.144 Å).

The average bond lengths of La–S and La–O of **1** are 3.01(1), and 2.42(3) Å, respectively. These values are comparable to those of La(iPr_2dtp)$_3$(dma)$_2$ (3.02(2), and 2.42(1) Å),[3] and to those of La(Et_2dtp)$_3$(Ph_3PO)$_2$ (3.05(4), and 2.44(2) Å).[5] The expected bond lengths of La–S and LaO are 3.00 and 2.51 Å, respectively, according to Shannon's ionic radii ($r_{La(III)}$ (octa coordinated), $r_{O(2-)}$, and $r_{S(2-)}$ are 1.160, 1.35, and 1.84 Å, respectively).[14] Therefore, compared with the calculated values, the La–S length of **1** is about the same; however, its La–O length is much shorter as was found in La(iPr_2dtp)$_3$(dma)$_2$.[3]

Complex **2** consists of a cationic and anionic species. All the metal atoms are almost on the (101) plane.

In the cation, the central europium(III) atom is hepta-coordinated and is in a pentagonal-bipyramidal geometry where four sulfur atoms of two iPr_2dtp ligands and one oxygen atom of a dmso molecule take the equatorial positions. The dmso oxygen atoms occupy both ends of the axis. The average positional deviations of the central metal and the five equatorially ligated atoms (from their average plane) is 0.069 Å (the maximum deviation is 0.126 Å for O(17)). The respective angles between the axial Eu(1)–O(15) or Eu(1)–O(16) bondings to the average pentagone plane are 88.2 and 88.3°. The average bond lengths of Eu–S and Eu–O are 2.880(8) and 2.249(8) Å, respectively. Although the former value is comparable to the calculated bond length, 2.85 Å, the latter is shorter by 0.11 Å than the sum of Shannon's ionic radii, 2.36 Å ($r_{Eu(III)}$ (hepta-coordinated) is 1.01 Å). The same tendency was observed in the average M–S and M–O bond lengths of the cationic complexes of the same type of geometry, [M(iPr_2dtp)$_2$(bza)$_3$](iPr_2dtp): 2.83(2) and 2.27(2) Å for M=Tb, and

a) The isotropic temperature factors of the atoms below the line were fixed. The equivalent isotropic temperature factors were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\theta)$. The B_{ij}'s are defined by: $T=\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$. b) The probability of the occupancy of each position was as follows: S(16A), 77.5; S(16B), 22.5; S(17A), C(17A), and C(18A), 54.4; S(17B), C(17B), and C(18B), 45.6%.

2.80(2) and 2.23(3) Å for M=Er,[2] whereas corresponding bond lengths calculated with Shannon's ionic radii are 2.82, 2.33, 2.78, and 2.29 Å, respectively ($r_{Tb(III)}$ and $r_{Er(III)}$ are 0.98 and 0.945 Å for hepta-coordination).

The equatorial Eu–O bond length (2.260(9) Å) is longer than both of the axial Eu–O ones (2.244(10) Å (both)) in this species, too, as in the case of the other same type of complexes above mentioned.[2]

In the anion, the central metal atom is octa-

coordination situations. The peak of **2** is broader than that of **1**. The ν_{as}(P-S) band appeared in 600—700 cm^{-1} region of **2**, splits into three peaks, while that of **1** into two peaks. The isostructural neodymium(III) complex shows almost the same infrared spectral pattern as that of **1**.

As in the case of $Eu(iPr_2dtp)_3(bza)_2$,[1] complex **2** is orange in color due to a charge-transfer band in both its solid and its acetonitrile-solution. The absorption spectra of the solution of **2**, as well as those of some other europium(III) complexes , are shown in Fig. 9. As shown in the figure, although the wavelength with maximum absorption of the band of **2** is about the same as that of $Na[Eu(iPr_2dtp)_4]$, or of $Eu(iPr_2dtp)_3(bza)_2$ (about 415 nm),[1] the absorpion coefficient of **2** at the wavelength, 1.5×10^2 dm^3 $mol(Eu)^{-1}$ cm^{-1}, is much smaller than those of the other europium complexes above mentioned.[1]

The authors are greatly obliged to the Shin-Etsu Chemical Ind. Co., Ltd., for aiding this study by presenting highly pure lanthanoid oxides. The

(Received January 7, 1986)

The preparation, separation, and characterization of isomeric complexes of type $[CoN_6]^{3+}$, containing one, two, or three molecules of NH_3, en, dien, trien, and tetren (n=0, 1, 2, 3, and 4, respectively for $H_2N(CH_2CH_2NH)_nH$) are reported. All the possible five stereoisomers for $[Co(NH_3)(en)(dien)]^{3+}$ and six stereoisomers for $[Co(en)(trien)]^{3+}$ have been successfully isolated, but only three of four possible geometrical isomers could be obtained for $[Co(NH_3)(tetren)]^{3+}$. These were characterized by electronic, circular dichroism (CD), and $^{13}C\{^1H\}$ NMR spectroscopy. Conformational analyses were, also, carried out and the stability, or formation of each isomer at the equilibrium state, is discussed from the calculated strain-energy data and experimental formation ratios.

Linear polyamines, $H_2N(CH_2CH_2NH)_nH$ (n=1—5)[1] coordinate to metal ions and the resulting coordination compounds contain only the five-membered chelate rings which are the most frequently found in metal complexes. Table 1 lists all the complexes of $[CoN_6]^{3+}$-type containing the polyamine ligand(s) and NH_3 (n=0).

Presently we are reporting the isomerism of the complexes, V, VI, IX, and X (Table 1). In the course of this study, the structures of both the geometrical isomers of $[Co(NH_3)_3(dien)]^{3+}$ have been determined by three-dimensional X-ray analysis.[6] The $^{13}C\{^1H\}$ NMR spectrum of the mer isomer was also reported.[12] The isomers of the complex, $[Co(NH_3)(en)(dien)]^{3+}$ are newly prepared in the present study. $[Co(NH_3)_2(trien)]^{3+}$ and $[Co(NH_3)(tetren)]^{3+}$ were prepared by Basolo[8] and Schlessinger,[13] respectively. $[Co(en)(trien)]^{3+}$ was studied by Schaefer and Brubaker.[10] However, all of their isomers were not isolated in these studies. Recently, we succeeded in isolating not only the six cis isomers, but also all of the three possible trans isomers of $[Co(NH_3)_2(trien)]^{3+}$.[9]

Isolation of each isomer was mainly performed by column chromatography on Sephadex ion exchanger.[14] The empirical elution rules that we reported,[15] were often effectively used for the assignment of geometrical isomers.

Experimental

Materials. The amines, $H_2N(CH_2CH_2NH)_nH$ (n=1—4) were obtained from Wako Pure Chemical Industries, LTD. and all other chemicals commercially available were used without further purification unless otherwise stated.

(i) $[Co(NH_3)_3(dien)]X_3$: To 25 cm^3 of a 3 M (=mol dm^{-3}) aqueous ammonia solution, 1.3 g of *mer*-$[CoCl_3(dien)]$,[16] 5 g of NH_4Cl, and 0.2 g of activated charcoal were added, and the mixture was stirred for 2 h. The activated charcoal

a) All the possible existent conformational isomers, based on the configuration about a secondary amine nitrogen are included.

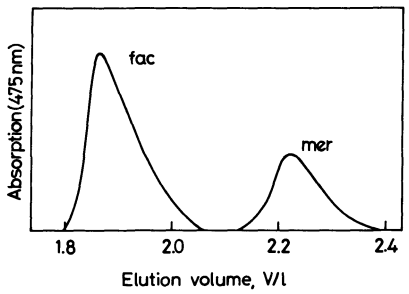

Fig. 1. Elution curve of $[Co(NH_3)_3(dien)]^{3+}$. ϕ2.7×140 cm SP-Sephadex (C-25); 0.18 M Na_2SO_4.

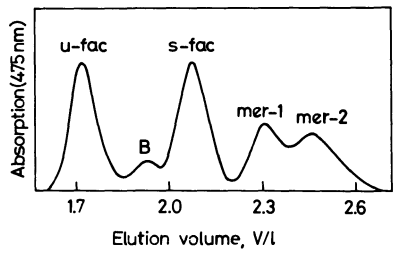

Fig. 2. Elution curve of $[Co(NH_3)(en)(dien)]^{3+}$. ϕ2.7×140 cm SP-Sephadex (C-25); 0.18 M Na_2SO_4.

was filtered off and the filtrate was acidified with hydrochloric acid. The resulting solution was diluted with a large amount of water and passed over a pre-column of SP-Sephadex (C-25).[14] A portion of the SP-Sephadex charged with the product was poured on the top of an SP-Sephadex column (ϕ2.7×140 cm) and the adsorbed complexes were eluted with 0.18 M Na_2SO_4. The elution curve is shown in Fig. 1. The effluents of two elution bands were separately collected and diluted with 0.01 M HCl about twenty times, and then each diluted solution was passed through a short column of SP-Sephadex previously conditioned with 1 M HCl and the complex was adsorbed on it. After the adsorbed column being washed with a large amount of 0.01 M HCl to remove sodium ions, the complex isomer was eluted with 1 M HCl. The chlorides of the complex were obtained by evaporating the eluate to dryness under reduced pressure, over P_2O_5 and NaOH.

(ii) $[Co(NH_3)(en)(dien)]X_3$: (*a*) To 25 cm^3 of a 0.5 M aqueous ammonia solution, 1.5 g of *s-fac*-$[CoCl(en)(dien)]Cl_2$,[17] 5 g of NH_4Cl, and 0.2 g of activated charcoal were added, and the suspension was stirred for 12 h.

(*b*) Using *mer*-$[CoCl_3(dien)]$ as a starting material: The mixture of 0.52 g of *mer*-$[CoCl_3(dien)]$, 0.26 g of en·2HCl, and 10 cm^3 of a 0.5 M aqueous ammonia solution was stirred for 48 h with 0.05 g of activated charcoal. The reaction products were processed in a similar manner a in (*i*). The resulting elution curves are shown in Fig. 2. The u-fac isomer was separated into two bands by elution with a 0.15 M sodium (+)tartratoantimonate(III) solution. The chlorides of each isomer were obtained as in (*i*). The B band is that of *fac*-$[Co(NH_3)_3(dien)]^{3+}$.

(iii) $[Co(en)(trien)]X_3$: $[Co(en)(trien)]Cl_3$ was prepared from $[CoCl_2(trien)]Cl$ and ethylenediamine, following the method of Schaefer and Brubaker.[10] The resulting

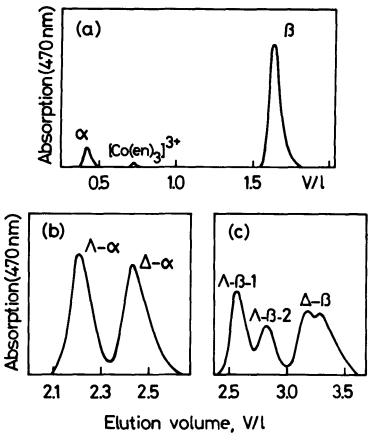

Fig. 3. Elution curves of $[Co(en)(trien)]^{3+}$. ϕ2.7×130 cm SP-Sephadex (C-25); (a) 0.1 M Na_3PO_4, (b) 0.18 M sodium (+)tartrate, (c) 0.13 M sodium (+)tartratoantimonate(III).

solution of the chloride mixture was subjected to SP-Sephadex chromatography (Fig. 3a). The α isomer easily isomerizes to the β isomers in an alkaline solution. Each isomer was resolved as shown in Fig. 3b and c. The two optically active β isomers could be more effectively isolated from each pure *racemic* β isomer, which was previously separated from each other by recycling chromatography using a mixture of 0.15 M Na_2SO_4 and 0.01 M HCl as eluent.

(iv) $[Co(NH_3)(tetren)]X_3$: (*a*) $[Co(NH_3)(tetren)]Cl_3$ was prepared from $[CoCl(NH_3)_5]Cl_2$ and tetren·5HCl, as described below. The ligand hydrochloride was purified twice by recrystallization from water. To 20 cm^3 of concentrated aqueous ammonia solution containing 2.5 g of $[CoCl(NH_3)_5]Cl_2$,[18] 4.3 g of tetren·5HCl and 0.5 g of activated charcoal were added, and the mixture was stirred for 15 h. The filtrate was diluted with 0.01 M HCl and passed through an SP-Sephadex column. The elution curve is shown in Fig. 4a, where the A, C-1, and C-2 bands were assigned to those of the isomers of $[Co(NH_3)(tetren)]^{3+}$ from their $^{13}C\{^1H\}$ NMR spectra and the others to those of impurities. These C-1 and C-2 bands were not separated by the elution with a neutral or basic eluent. The C-2 isomer formed also by the isomerization of the C-1 in an aqueous solution, but it was difficult to obtain purely because of its low formation ratio and low stability. The optical resolution of the C-1 isomer was attained by elution with 0.15 M sodium (+)tartratoantimonate(III) in a similar manner as in Fig. 3b.

(*b*) $[CoCl(tetren)](ClO_4)_2$[19] was allowed to react with liquid ammonia. Since only one geometrical isomer (C in the preceding (*a*)) could be obtained from "α-$[CoCl(tetren)](ClO_4)_2$,"[19] the following compound was used as starting material in order to get other isomers. The filtrate, in Method B of House and Garner,[19] after removing the first precipitated tetrachlorozincate(II) salt was allowed to stand for a month. The additionally formed tetrachlorozincate(II) crystals were changed to the perchlorate salt. To about 20 cm^3 of liquid ammonia, 1 g of the perchlorate was added. The excess ammonia was allowed to evaporate (slowly) at room temperature. An aqueous solution of the

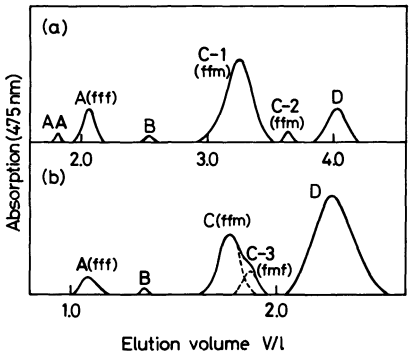

Fig. 4. Elution curves of $[Co(NH_3)(tetren)]^{3+}$ from different origin. $\phi 2.7 \times 140$ cm SP-Sephadex (C-25); (a) 0.15 M Na_2SO_4–0.01 M HCl, (b) 0.18 M Na_2SO_4.

orange residue was passed through an SP-Sephadex column (Fig. 4b). In Fig. 4b, the B and D bands are those of impurities. The C-3 isomer was completely separated into two portions by the elution with a 0.15 M sodium (+)tartratoantimonate(III) solution.

(*c*) The reaction of $[Co(NO_3)(NH_3)_5](NO_3)_2$ with tetren in DMSO (70—80 °C), and the reaction of $[CoCl(tetren)]ZnCl_4$ with ammonia in the presence of NH_4Cl and activated charcoal in an aqueous solution, were also used. Their chromatograms were similar to that in Fig. 4a.

Physical Measurements. Absorption spectra were obtained with a Union Giken SM 401 spectrophotometer equipped with a 1 cm quartz cell at 25 °C. The sample solutions contained the complex ions in 10^{-3}—10^{-2} M concentrations. CD spectra were measured for an approximately 10^{-3} M solution of each isomer in 0.01 M HCl, with a JASCO model J-20 or J-40 spectropolarimeter using a 1 cm cell. $^{13}C\{^1H\}$ NMR spectra were recorded on a JEOL JNM-FX60 spectrometer at a probe temperature of 35 °C. The solvent used was a 0.01 M HCl solution. Dioxane in D_2O in a coaxial inner tube was used as an external reference for all samples.[20]

Identification of Compositions. $^{13}C\{^1H\}$ NMR spectra were measured for the prepared metal complexes. The expected number of carbon atoms and/or the symmetry of the isomer was confirmed from their relative intensities of carbon signals. Elemental analyses were also performed for the hexacyanocobaltates of newly isolated isomers, which could be easily isolated from the solution due to their low solubilities. The agreement between the calculated and found values was within the usual limit of variation of elemental analysis.

Results and Discussion

Figures 5—8 show the possible geometrical and conformational isomers of the complexes, V, VI, IX, and X. The two isomers of $[Co(NH_3)_3(dien)]^{3+}$, the s-fac and two mer isomers of $[Co(NH_3)(en)(dien)]^{3+}$, and the fff isomer of $[Co(NH_3)(tetren)]^{3+}$ have plane-symmetric, that is, nonresolvable structures, but the others can be resolved into their optical isomers. As can be seen from Figs. 1—4, we could isolate all the

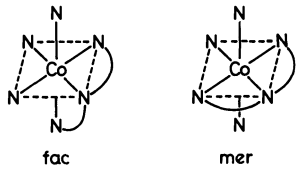

Fig. 5. Possible geometrical isomers of $[Co(NH_3)_3(dien)]^{3+}$.

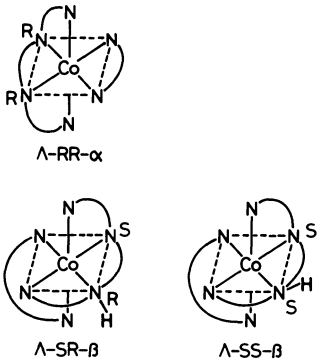

Fig. 7. Possible geometrical and conformational isomers of $[Co(en)(trien)]^{3+}$.

possible number of stereoisomers, i.e., 2, 5, and 6 for $[Co(NH_3)_3(dien)]^{3+}$, $[Co(NH_3)(en)(dien)]^{3+}$, and $[Co(en)(trien)]^{3+}$, respectively, but only three of four possible geometrical isomers of $[Co(NH_3)(tetren)]^{3+}$. All the four fmm conformational isomers, which were different in the configuration of two secondary nitrogen atoms in the center of the meridional structures, could not be isolated in the present study. The structure of each isomer was assigned mainly on the basis of the elution order[15] and $^{13}C\{^1H\}$ NMR spectrum.

The empirical elution rules predict that the complex isomer with higher ability to associate with eluent anions is eluted faster than the other(s).

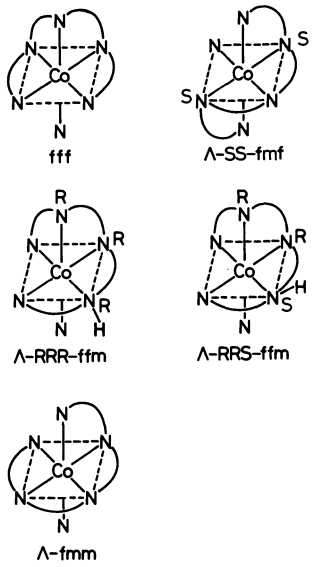

Fig. 8. Geometrical and conformational isomers of [Co(NH$_3$)(tetren)]$^{3+}$.
The absolute configuration, *R* or *S* of the central nitrogen atom of tetren in the ffm isomers, was determined assuming that the priority[24] of the *facial* structure as substituent is higher than that of the *meridional* structure. All the four possible existent conformational isomers were abbreviated for the fmm structure.

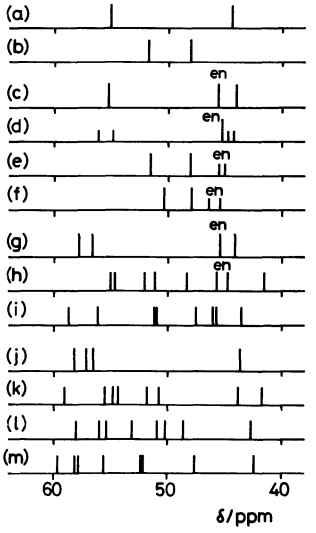

Fig. 9. Diagramatic representation of the $^{13}C\{^1H\}$ NMR spectra of $[CoN_6]^{3+}$-type complex isomers. (a) *fac*-; (b) *mer*-[Co(NH$_3$)$_3$(dien)]Cl$_3$; (c) *s-fac*-; (d) *u-fac*-; (e) *mer-1*-; (f) *mer-2*-[Co(NH$_3$)(en)(dien)]Cl$_3$; (g) α-; (h) β-1-; (i) β-*2*-[Co(en)(trien)]Cl$_3$; (j) *fff*-; (k) *fmf*-; (l) *ffm*(C-1)-; (m) *ffm*(C-2)-[Co(NH$_3$)(tetren)]Cl$_3$. The signals with "en" are those of ethylenediamine.

Therefore, it can be easily explained that the fac of [Co(NH$_3$)$_3$(dien)]$^{3+}$ (Fig. 1), the u-fac and then the s-fac of [Co(NH$_3$)(en)(dien)]$^{3+}$ (Fig. 2), the α of [Co(en)(trien)]$^{3+}$ (Fig. 3), and the fff isomer of [Co(NH$_3$)(tetren)]$^{3+}$ (Fig. 4), elute faster than the other isomers with meridional structures.

Figure 9 shows the diagramatic representation of $^{13}C\{^1H\}$ NMR spectra of all the present isomers. Since the aforementioned isomers including *mer*-[Co(NH$_3$)(en)(dien)]$^{3+}$ (C_s symmetry), and α-[Co(en)(trien)]$^{3+}$ (C_2 symmetry), have two equivalent carbons, the number of the NMR signals is reduced to one-half of that of the other asymmetric isomers. The two carbon atoms of ethylenediamine in *mer*-[Co(NH$_3$)(en)(dien)]$^{3+}$ are not equivalent and therefore show two different signals at the corresponding magnetic field. In general, the NMR signal of the carbon adjacent to a primary nitrogen atom appears at higher magnetic field than those adjacent to a secondary nitrogen atom.[21] This tendency is more pronounced in the fac configuration than in the mer, because of the less-strained valence angles about the secondary nitrogen atom of the former. Thus such isomeric structures are easily distinguished with each other in terms of the NMR signals.

The structures of the two β-[Co(en)(trien)]$^{3+}$ isomers, β-*1* and β-*2*, were assigned to (*Λ-SS,Δ-RR*) and (*Λ-SR,Δ-RS*), respectively, by comparison of their NMR signals with those of *cis*-β-[Co(NH$_3$)$_2$-(trien)]$^{3+}$.[8] The spectra of the C-1 isomer in Fig. 4a was very similar to that of (*Λ-RRS,Δ-SSR*)-*ffm*-[CoCl(tetren)](ClO$_4$)$_2$, the structure of which was determined by X-ray analysis.[22] Therefore, the C-1 was assigned to the above structure and the C-2 to (*Λ-RRR,Δ-SSS*)-ffm structure. The optical resolution of these isomers is consistent with assignment to the resolvable structures.

The data of absorption spectra in the visible region are summarized in Table 2 together with those of CD spectra (Fig. 10) of the optically active isomers. The positions of the first and second absorption maxima of the complexes are normal as those for the $[CoN_6]^{3+}$-type ones. The molar extinction coefficients, ε of the isomers with *meridional* structure are larger than those of the *facial* ones. It may be attributed to the distorsion from a regular octahedron in mer isomers. The absolute configurations of the optically active isomers were assigned according to the sign of the dominant CD component at the first absorption band region, that is, the plus sign to the *Λ* configuration.

Table 3 shows the results of the conformational analysis for all the possible isomers of the relevant complexes. The strain-energy minimization calculation was carried out by using a modification of the computer program of Boyd.[9b,23] A tendency, that fac isomers or structures are less-strained in angle bending and more-strained in torsional interaction

than mer ones, can be seen for the isomers except $[Co(NH_3)(tetren)]^{3+}$. Among the isolated isomers of each complex, there is a good correlation between the formation ratio and the strain energy, considering the statistical effects on some configurational structures. The strain-energy differences are rather small among the isomers of the complexes, the entire set of isomers of which could be isolated from the reaction mixtures.

Unambiguous assignment of the *mer*-$[Co(NH_3)(en)(dien)]^{3+}$ was difficult to make either from the conformational analysis, or from the elution order, or from the $^{13}C\{^1H\}$ NMR spectroscopy.

fmm-1-$[Co(NH_3)(tetren)]^{3+}$(*Λ-SSS*)	4.5	14.1	17.6	33.8	70.0
fmm-2-$[Co(NH_3)(tetren)]^{3+}$(*Λ-SSR*)	4.4	12.0	27.0	23.6	67.0
fmm-3-$[Co(NH_3)(tetren)]^{3+}$(*Λ-SRS*)	4.3	10.4	28.3	24.3	67.3
fmm-4-$[Co(NH_3)(tetren)]^{3+}$(*Λ-SRR*)	4.3	11.0	20.6	33.9	69.8

The $[Co(NH_3)(tetren)]^{3+}$ complexes, the hitherto undetected fmm isomers will be much more strained than all the others from strain energy calculation. Even if the fmm isomers existed in the solution, it would be hard to detect or isolate them, because of their small content and low stability.

Thus, among the isomers of $[CoN_6]^{3+}$-type listed in Table 1, only those of fmm type of $[Co(NH_3)(tetren)]^{3+}$ remained to be detected and isolated.

Paramagnetic Shifts of DMF and DMA by Uranium(V)

Toshie HARAZONO and Hiroshi FUKUTOMI*
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology,
O-okayama, Meguro-ku, Tokyo 152
(Received January 11, 1986)

Paramagnetic shifts of DMF (*N,N*-dimethylformamide) and DMA (*N,N*-dimethylacetamide) induced by U(V) were studied by the ^1H and ^{13}C NMR spectroscopy. It was found that the ^1H and ^{13}C NMR signals of bulk DMF and DMA exhibited the paramagnetic shifts to the higher field by U(V). Positive pseudocontact shift and negative contact shift for both DMF and DMA are discussed on the basis of the electronic structure of U(V) complexes. The values of magnetic susceptibilities of U(V) complexes are also presented.

Paramagnetic shifts induced by lanthanoid compounds have been extensively studied since the pioneer work of Hinckley,[1-4] while a little of information are available for actinoid compounds. Some diketonato complexes of U(IV) having the electron configuration of $5f^2$ were found to induce the shift of ^1H and ^{13}C NMR signals of ligands,[5-8] and the ^1H signals of U(IV) $(allyl)_4$ were also found to shift to the higher field.[9,10] On the other hand, there are very few studies on the paramagnetic shift by U(V) which has the $5f^1$ electron configuration, since U(V) is extremely unstable in aqueous solution owing to its rapid disproportionation. We found that U(V) was formed by photoreduction of $[UO_2(dmf)_5]^{2+}$,[11,12] $[UO_2(dma)_5]^{2+}$,[13] and $[UO_2(dmso)_5]^{2+}$,[14] and the resulting U(V) was stable over several hours in acid-free organic solvents in the dark. This has enabled the determination of the paramagnetic shift by U(V) in solution reported in this paper. In the previous paper,[11] we reported briefly the result of paramagnetic shift of DMF owing to the fast exchange between the first coordination sphere of U(V) and the bulk solvent. It is the purpose of this paper to investigate the paramagnetic shifts of DMF and DMA by U(V) in more detail and to elucidate the mechanism of spin localization.

Experimental

The $[UO_2(dmf)_5](ClO_4)_2$ and $[UO_2(dma)_5](ClO_4)_2$ complexes were prepared by the same methods so far reported.[15] Elemental analysis was performed by using a Shimadzu CHN-1A analyzer. Calcd for $[UO_2(dmf)_5](ClO_4)_2$: C, 21.59; H, 4.23; N, 8.39%. Found: C, 20.98; H, 4.10; N, 8.39%. Calcd for $[UO_2(dma)_5](ClO_4)_2$: C, 26.56; H, 5.01; N, 7.74%. Found: C, 26.65; H, 5.00; N, 7.65%. Reagent grade DMF and DMA were distilled twice under vacuum and stored over 3A molecular sieves. Benzene and acetone-d_6 (CD_3COCD_3, Merck 99%) were of analytical grade and used without further purification. NMR shift reagents $Pr(fod)_3$ (fod=6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionate) and $Eu(fod)_3$ (Dojin) were dried in a vacuum dessicator over phosphorus pentoxide. $[UO_2(dmf)_5]^+$ and $[UO_2(dma)_5]^+$ solutions were prepared by irradiation of $[UO_2(dmf)_5](ClO_4)_2$ in DMF and $[UO_2(dma)_5](ClO_4)_2$ in DMA, respectively with the light of 365 nm from a 500 W ultrahigh-pressure mercury lamp (Ushio USH 500D). The U(V) concentration was determined spectrophotometrically by using a Shimadzu UV-210A spectrophotometer, where the values of 45.5 $M^{-1}cm^{-1}$ (M=mol dm^{-3}) at 755 nm and 45.4 $M^{-1}cm^{-1}$ at 760 nm were used for the molar extinction coefficients of the U(V)-DMF[12] and U(V)-DMA[13] complexes,respectively. NMR spectra were recorded on a JEOL JNMFX-100 FT NMR spectrometer equipped with a disc system NM-3974. Acetone-d_6 was used as an internal lock for the measurement of paramagnetic shifts. In the measurement of magnetic susceptibility, D_2O and benzene were used as an external lock and internal standard, respectively.

Results

The magnetic susceptibility of U(V) was determined by Evans' method,[16] the equation of which is given by

$$\frac{\Delta H}{H_0} = \frac{2\pi}{3}\Delta\kappa, \quad (1)$$

where H_0 is the external magnetic field, ΔH is the difference in chemical shift of the signal of benzene between reference and sample solutions containing benzene, and $\Delta\kappa$ is the difference in volume magnetic

susceptibility between reference and sample solutions. The results are shown in Table 1.

For the ^{1}H and ^{13}C NMR spectra of bulk DMF and DMA in the absence of U(V)–DMF and U(V)–DMA complexes respectively, assignments of DMF and DMA signals were performed by using $Pr(fod)_3$. In the following descriptions, hydrogen and carbon atoms with subscripts, e.g. H_1, C_3, correspond to the atoms of positions 1, 3, in Figs. 1 and 2. Since the pseudocontact term is a principal term for Pr(III),[17]

the chemical shifts of each atom, which are induced to the higher field by Pr(III), can be calculated by using the McConnell and Robertson equation[18] on the assumption that a principal axis passes through Pr···O=C. Experimental results of chemical shift of DMF are given in Table 2 and shows close agreement with the theoretical values. It was found that the NMR signals of bulk DMF exhibited the paramagnetic shift to the higher field by U(V), especially in signals of H_1 and C_3. Figures 3 and 4 show the plots of ^1H and ^{13}C chemical shifts of DMF vs. $[U(V)]/[DMF]_t$ at 25 °C, where $[DMF]_t$ denotes the total DMF concentration, and each plot gives a straight line. The value of the slope is expressed as nS, where n is the number of ligands coordinated to U(V). The number of coordinated dmf in the U(V)-DMF complex has not yet been determined, but 5 is most likely. In Figs. 5 and 6, the nS values of ^1H and ^{13}C signals are plotted as a function of temperature, respectively. With respect to the chemical shift of DMA, similar plots are given in Figs. 7 and 8, which also show the paramagnetic shift to the higher field by U(V), especially in the C_4 signal. The nS values were nearly constant at a temperature range from 25 to 0 °C.

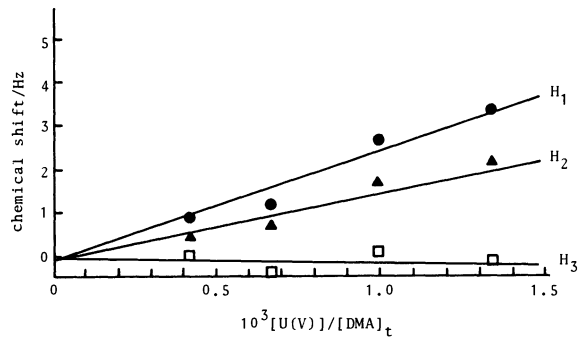

Fig. 7. Plots of ^1H chemical shifts of DMA vs. $[U(V)]/[DMA]_t$ at 25 °C. $[UO_2(dma)_5^{3+}]=0.40$ M, $[DMA]_t=7.53$ M.

Discussion

The values of magnetic susceptibilities of the U(V)-DMF and U(V)-DMA complexes are fairly large and are well consistent with that of the U(V)-TEP complex (2014×10^{-6}, TEP=triethyl phosphate).[19] The chemical shift induced by U(V) is expected to involve three terms, i. e. contact shift (CS), pseudocontact shift (PCS), and complex formation shift (CFS).[17] The CFS corrections for the U(V)-DMF and U(V)-DMA complexes were estimated by using $[UO_2(dmf)_5]^{2+}$ and $[UO_2(dma)_5]^{2+}$, respectively, which are diamagnetic complex ions having the $5f^0$ electron configuration. In the DMF complex, the CFS correction is negligibly small for H_1 and H_2 signals, and a small correction is required for H_3 signal (0.95 ppm for $[U(V)]/[DMF]_t=1$).[20] However, the information of CFS for ^{13}C is not available, and the CFS correction was neglected for ^{13}C on the basis of the fact that CFS is very small for aliphatic compounds.[17] As seen in Figs. 5 and 6, a fast ligand exchange region[21] appears at temperatures above 0 °C, and the ligand exchange comes gradually down below 0 °C. This was also confirmed by the temperature dependence of linewidths ($1/T_2-1/T_{2a}$), where T_2 and T_{2a} are the transverse relaxation times for the ^1H NMR signal (H_3 in Fig. 1) in the presence and the absence of U(V), respectively. The fact that the change in chemical shift with temperature is particularly large in C_3 signal as seen in Fig. 4 definitely indicates that the oxygen atom of DMF coordinates to U(V). Therefore, the structure of the U(V)-DMF complex shown in Fig. 1 seems to be most likely from the analogy to the Pr(III) complex.[22] On the assumption that the above structure is correct and the spin density (ρ) is the same in both methyl groups of DMF, the paramagnetic shift by U(V) is divided into CS and PCS terms. The results are listed in Table 3, where A represents a hyperfine coupling constant. The values of PCS are positive, and the nagative values of CS result in the positive

$A = \rho Q$. $Q = -22.5$ gauss. ( ): corrected value.

hyperfine coupling constant and the negative spin density on the C atoms of DMF. It should be noted that the contact term has the largest absolute value at C_3 which is the nearest C atom to U(V). A DMF molecule is regarded as a conjugated system in which π orbitals of C=O and -N and pseudo π orbitals by hyperconjugation of two methyl groups are conjugated, and the unpaired electron of U(V) might be transferred to ^1H and ^{13}C of DMF through π electrons. Paramagnetic shifts of DMF by $Eu(fod)_3$ were also studied and divided into two terms as well as the U(V)-DMF complex. The results are listed in Table 4. Negative values of PCS and positive values of CS are just the opposite of the U(V)-DMF complex. This means that the anisotropy of manetic susceptibility or g tensor of U(V) ($\chi_{//} > \chi_{\perp}$, $g_{//} > g_{\perp}$) is the opposite of that of Eu(III).

Almost the same discussion can be applied to the U(V)-DMA complex. The CFS corrections are negligible for all the ^1H signals and are small for C_1, C_2, and C_3 signals. The C_4 signal requires the correction of 7.6 ppm for $[U[V)]/[DMA]_t = 1$.[23] As seen in Fig. 8, the change in chemical shift is most large in the C_4 signal, and this indicates that the oxygen atom of C=O coordinates to U(V). The proposed structure of the U(V)-DMA complex is illustrated in Fig. 2. The paramagnetic shift by U(V) consists of two terms, CS and PCS. The results are listed in Table 5. The signs of CS and PCS are the same as those of the U(V)-DMF complex. The absolute value of CS of C_4 is smaller than those of C_1, C_2, and C_3. If the bond length between U and O in U····O=C is slightly shorter than 2.33 Å which is the U····O bond length of U····O=C in $[UO_2(CF_3CO)_2CH]_2THF$ (THF= tetrahydrofuran),[24] the absolute value of CS of C_4 will become larger than those of CS of other carbon atoms as well as the case of U(V)-DMF. The results of the paramagnetic shifts of DMA by $Eu(fod)_3$ are given in Table 6.

Table 6. Values of S, PCS, and CS for the $Eu(fod)_3$-DMA Complex at 25 °C

	S	PCS	CS
	ppm	ppm	ppm
H_1	−11.0	−29.2	18.2
H_2	−5.4	−23.6	18.2
H_3	−11.8	−41.2	29.4
C_1	−11.9	−40.8	28.9
C_2	−1.9	−30.8	28.9
C_3	−20.5	−56.1	35.6
C_4	49.6	−135	185

It may be noted that the separation of paramagnetic shifts by U(V) into the CS and PCS terms was performed for the first time in this paper.

Partial Molar Enthalpy of Solution for Tris(2,4-pentanedionato)cobalt(III) in Mixed Solvents of Water and Dimethyl Sulfoxide

Yasuki YOSHIMURA,* Nobuyoshi SATO, and Makoto KIKUCHI
Laboratory of Chemistry, College of Humanities and Social Sciences, Iwate University, Ueda, Morioka 020
(Received January 16, 1986)

The solubility (X_s) of tris(2,4-pentanedionato)cobalt(III) ([Co(acac)$_3$]) in mixed solvents of water and dimethyl sulfoxide (DMSO) with various compositions was determined over the temperature range 20—60 °C. It was found that the experimental values of X_s could be satisfactorily fitted to $\ln X_s = A(1/T) + B\ln T + C$ and the partial molar enthalpy of solution ($\Delta\bar{H}_s$) at 25 °C for [Co(acac)$_3$] was estimated from slopes of the solubility curves. When $\Delta\bar{H}_s$ was plotted against the mole fraction of DMSO (X_{DMSO}), a clear maximum was found at about X_{DMSO}=0.3. This composition profile of $\Delta\bar{H}_s$ is discussed in connection with the internal pressure of a mixture of water and DMSO. A method to estimate an approximate value of the partial molar enthalpy of hydrophobic hydration ($\Delta\bar{H}_h$) in an aqueous DMSO mixture of [Co(acac)$_3$] is also presented by using the solubility data in mixtures with a lower X_{DMSO} than 0.14.

In studies on the solvent extraction of various metal chelates, it has been found that the role of organic solvents can be successfully interpreted by the aid of the regular solution theory in terms of the solubility parameters of organic solvents.[1] However, an application of the regular solution theory to the aqueous phase in solvent-extraction systems is unreasonable because of strong interactions between solutes and water molecules such as the hydrogen bonding and association of water molecules due to hydrogen bonding among them.

Recently, Yamamoto applied a scaled particle theory to an interpretation of the thermodynamic properties of tris(2,4-pentanedionato)chromium(III) ([Cr(acac)$_3$]) in an aqueous solution.[2] Awano et al.[3] have found that the composition dependence of the partition coefficients of some tris(2,4-pentanedionato) chelates between heptane and mixed solvents of water and dimethyl sulfoxide (DMSO) can be explained in terms of the internal pressure of aqueous DMSO mixtures.

The thermodynamic properties of tetraalkylammonium salts[4—10] and some nonelectrolytes[11—14] in mixtures of water and aprotic solvents have been investigated rather extensively. Especially, Somsen et al.[7,9,10] have shown that the composition dependence of the enthalpy of solution for tetraalkylammonium salts in mixtures of water and aprotic solvents, such as DMSO and *N*,*N*-dimethylformamide (DMF), can be interpreted in terms of an effect of the organic solvents on the hydrophobic hydration of the solutes in the mixtures.

In tris(2,4-pentanedionato) chelates, central metal ions are octahedrally surrounded by three 2,4-pentanedionate anions and two oxygen atoms of the anion combine with the central metal ions. Since six methyl groups reside on the periphery of the chelates, these chelates may be expected to exhibit a hydrophobic property. In connection with the solvent extraction of metal chelates, it is interesting to examine the behavior of such chelates both in water and in mixtures of water and organic solvents such as DMSO.

Thus, in this study, tris(2,4-pentanedionato)cobalt(III) ([Co(acac)$_3$]), which is inert to exchange or substitution reactions of ligands and is fairly soluble in water,[15] was chosen as a model chelate and its solubility in water and in aqueous DMSO mixtures was determined over the temperature ranges 5—60 °C and 20—60 °C, respectively. From these data, the partial molar enthalpy of solution ($\Delta\bar{H}_s$) for [Co(acac)$_3$] was estimated and the effect of DMSO on $\Delta\bar{H}_s$ and on the hydrophobic hydration of [Co(acac)$_3$] is discussed.

Experimental

Materials. [Co(acac)$_3$] was obtained from Dojin Chemical Laboratories Ltd. and recrystallized from a water–acetone mixture (60% acetone by volume). The ultraviolet and visible absorption spectrum of the purified [Co(acac)$_3$] in ethanol agreed with values found in the literature.[16]

Commercial DMSO (spectrophotometric grade reagent, Dojin Chemical Laboratories Ltd.) was dried over calcium hydride for a week and distilled under reduced pressure. Middle fractions were collected and stored over a molecular sieve (type 4A). The water content in the purified DMSO, measured by Karl Fischer titration, was about 0.06% by weight. The purified DMSO was placed in a dry box whose humidity was kept below 20% with silica gel. Mixtures of water and DMSO were prepared by weight; preparations were carried out in the dry box. Redistilled water was used.

Solubility Measurement. The apparatus shown in Fig. 1 was used to saturate a given sample solution with [Co(acac)$_3$]. A sufficient amount of [Co(acac)$_3$] and about 50 cm^3 of a sample solution were placed in the apparatus, which was thermostated at the desired temperatures to within ±0.1 °C. The mixture was stirred with a magnetic stirrer for about 48—72 h at each temperature. At appropriate time intervals, the saturated solution was passed through an absorbent cotton filter by injecting dry air. A volume of the saturated solution suitable for subsequent spectroscopic measurements was transferred by

pipette into a 5 or 10 cm^3 volumetric flask which had been previously weighed. The total weight of the flask and the saturated solution was weighed. If $[Co(acac)_3]$ precipitated during weighing, 1 cm^3 of DMSO was added to the saturated solution in order to dissolve the precipitation. After letting the flask stand for 30 min in an incubator kept at 25±0.5 °C, water was added to the mark at 25 °C; this solution was further diluted with water to give an absorbance between 0.2 and 0.6 at 324 nm.

The concentration (C mol dm^{-3}) of $[Co(acac)_3]$ in the above final solution was calculated by using the absorbance at 324 nm (A) from

$$C = (A-0.0011)/\varepsilon d, \quad (1)$$

where εd was 8.37×10^3 mol^{-1} dm^3. The solubility in molality units (S_m mol kg^{-1}) was calculated from the weight of the saturated solution, the degree of dilution, and C.

The absorbance of $[Co(acac)_3]$ at 324 nm was not entirely affected by the presence of 5% DMSO by volume. Since in all cases, the volume fraction of DMSO in the final solution for measuring A was less than 1%, Eq. 1 settled in water was used throughout.

The temperature of the saturated solution was increased from 20 to 60 °C (from 5 to 60 °C for water) at 5 °C intervals. It was found that $[Co(acac)_3]$ attained equilibrium within 24 h at each temperature. Solubility measurements were carried out at least 3 times for equilibration times of 48—72 h at each temperature.

In solubility measurements for mixtures with a DMSO content of $X_{DMSO}\geq0.4$ (X_{DMSO} is mole fraction of DMSO), the saturated solution could not be passed rapidly through a cotton filter at the increased temperature because of the adhesion of a solid $[Co(acac)_3]$ to the cotton filter. In this case, a further measurement was not carried out.

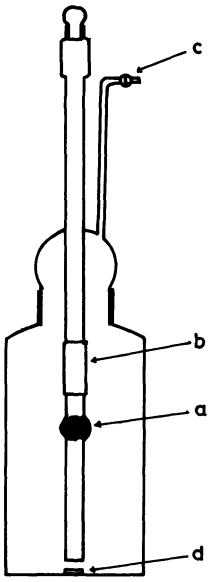

Fig. 1. Apparatus for solubility measurement. a: Filter filled with absorbent cotton, b: Silicone tube, c: Stop-cock for injecting air, d: Magnetic stirring bar.

Results

The S_m values of $[Co(acac)_3]$ in water are listed in Table 1. Errors denote deviations at a 95% confidence level and are less than 2%. In order to confirm whether $[Co(acac)_3]$ is hydrolyzed in water or not, independent measurements were carried out for two saturated solutions. The solubility was obtained from the absorbance at 324 nm in one measurement and from that at 593 nm in the other. The separately obtained S_m values closely agreed with each other (see Table 1). Furthermore, when the saturated solution equilibrated at 60 °C was allowed to attain equilibrium again at 25 °C, the solubility value at 25 °C was reproducible within the experimental error (see the lowest line in Table 1). These results show that $[Co(acac)_3]$ is not decomposed over the temperature range studied.

The S_m values in mixtures of water and DMSO are given in Table 2. The solubility data at 25 °C were reproducible within the experimental error when the solutions at the end of experiment at the highest temperature were allowed to attain equilibrium at 25 °C. This result shows that the evaporation of water or DMSO during the equilibration produced no detectable effect.

Discussion

Partial Molar Enthalpy of Solution of $[Co(acac)_3]$ ($\Delta\bar{H}_s$). The S_m values of $[Co(acac)_3]$ were converted to solubility in mole fraction (X_s) and then ln X_s was plotted against $1/T$. In Fig. 2 typical plots are

a) Error denotes deviation at 95% confidence level.

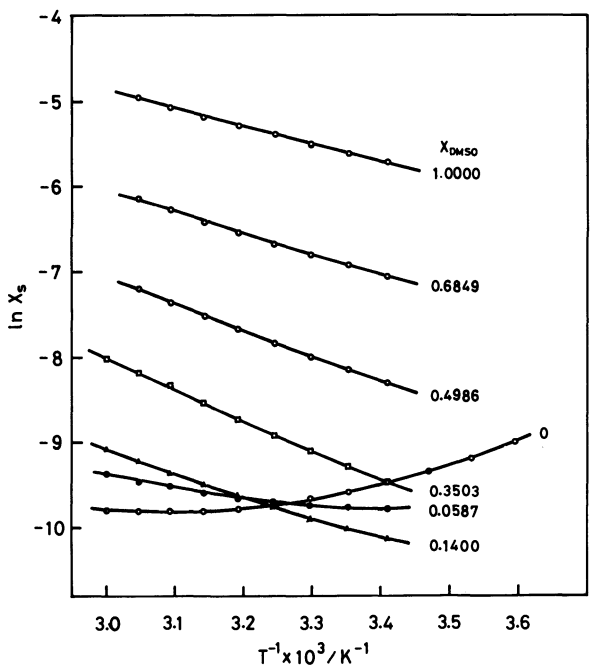

Fig. 2. Typical plot of ln X_s vs. $1/T$ for [Co(acac)$_3$] in water–DMSO mixture.
Solid lines are solubility curves calculated by Eq. 2.

shown. The solubility curve in water passed through a minimum at about 55 °C. Yamamoto has also found a similar minimum in the solubility curve of [Cr(acac)$_3$] in water.[2)]

The minima of the solubility curves in aqueous DMSO mixtures are obviously shifted to lower temperatures with increases in X_{DMSO} (40—45°C for X_{DMSO}=0.0160; 35 °C for X_{DMSO}=0.0272). In mixtures with a composition $X_{DMSO} \geq 0.0587$, the minimum was no longer distinct over the temperature range studied.

For representing solubility curves, all experimental values were fitted to

$$\ln X_s = A(1/T) + B \ln T + C, \quad (2)$$

where A, B, and C are fitting parameters. Equation 2 could reproduce the X_S values within errors of ±1% in all cases. In Table 3 the values of the fitting parameters in Eq. 2 are given. The values of $\Delta\bar{H}_s$ at 25 °C can be estimated by combining Eq. 2 with

$$\Delta\bar{H}_s = RT^2(d \ln X_s/dT). \quad (3)$$

The upward curvature in the low-temperature region of the solubility curves in water and in mixtures with a lower DMSO content might be related to the hydrophobic hydration of [Co(acac)$_3$]. (A discussion on hydrophobic hydration will be presented subsequently.) In order to confirm whether the solubility curves can be regarded as straight lines or not, an attempt was also made to fit the solubility data in mixtures of $X_{DMSO} \geq 0.1940$ to the

following equation over the whole temperature range studied.

$$\ln X_s = a(1/T) + b \quad (4)$$

The correlation coefficients (γ)** were higher than 0.998.

The values of $\Delta\bar{H}_s$ estimated by combining Eqs. 4 and 3 agreed fairly well with the values obtained using Eq. 2 (see Table 4). While this result shows that the solubility curves in these mixtures are practically straight, in the subsequent discussion, $\Delta\bar{H}_s$ estimated by Eq. 2 is used from the standpoint of consistency.

Effect of DMSO on $\Delta\bar{H}_s$ of [Co(acac)$_3$]. When $\Delta\bar{H}_s$ was plotted against X_{DMSO}, a clear maximum was observed at about X_{DMSO}=0.3 (Fig. 3). A similar maximum has been found for various properties of aqueous DMSO mixtures such as the enthalpy of mixing,[17] the viscosity,[18] and the internal pressure.[19] The maximization recognized for these properties has been interpreted in terms of a strong interaction between water and DMSO[18,19] or a marked rigidifying effect of DMSO on the water structure.[17,20,21] However, the cause of the maximization seems not to have been definitely established. Thus, in this discussion, an attempt is made to relate the composition profile of $\Delta\bar{H}_s$ to a certain property of the aqueous DMSO mixtures; also, the appearance of a maximum in Fig. 3 is not discussed in detail.

The composition dependence of the enthalpy of transfer of a hydrophobic solute from water to aqueous mixed solvents can be attributed to the enthalpy of cavity formation.[22] The partial molar enthalpy of cavity formation ($\bar{H}_c$) is related to the internal pressure (P_i) by[23]

$$\bar{H}_c = (\bar{V}_c - a^3 N\pi/6)(R/82.05)P_i, \quad (5)$$

where $\bar{V}_c$ and a are the partial molar volume of cavity formation and the hard-sphere diameter of the solute, respectively, N is Avogadro's number, and R is 8.314×10^{-3} kJ mol^{-1} K^{-1}.

Since data for P_i of aqueous DMSO mixtures are available,[19] it is significant to relate the composition

** The correlation coefficient is given by

$$\gamma = \Sigma\{(x_i-\bar{x})(y_i-\bar{y})\}/\sqrt{\Sigma(x_i-\bar{x})^2\Sigma(y_i-\bar{y})^2},$$

where $\bar{x}$ and $\bar{y}$ are means of x_i and y_i, respectively.

profile of $\Delta\bar{H}_s$ to that of P_i. First, the deviation of $\Delta\bar{H}_s$ from the ideal behavior in aqueous DMSO mixtures ($\delta\Delta\bar{H}_s$) can be defined as

$$\delta\Delta\bar{H}_s = \Delta\bar{H}_s - \{X_{DMSO}\Delta\bar{H}_s(DMSO) + (1-X_{DMSO})\Delta\bar{H}_s(H_2O)\}, \quad (6)$$

where (DMSO) and (H_2O) denote the values of $\Delta\bar{H}_s$ in DMSO and in water, respectively. Second, if it is assumed that $\bar{V}_c$ is approximately constant over the whole composition range, on the basis of Eq. 5, $\delta\Delta\bar{H}_s$ can be represented by

$$\delta\Delta\bar{H}_s = (\bar{V}_c - a^3N\pi/6)(R/82.05)\delta P_i, \quad (7)$$

where

$$\delta P_i = P_i - \{X_{DMSO}P_i(DMSO) + (1-X_{DMSO})P_i(H_2O)\}.$$

Figure 4 shows the good linear correlation between $\delta\Delta\bar{H}_s$ and δP_i which is expected from Eq. 7 (γ=0.980). Values of δP_i were calculated from values found in the literature for P_i[19] and $\delta\Delta\bar{H}_s$ values were read from a smooth curve of $\delta\Delta\bar{H}_s$ vs. X_{DMSO} which is not shown in the figure. Thus, the composition profile of $\Delta\bar{H}_s$ of [Co(acac)$_3$] can be linearly related to the composition dependence of P_i of aqueous DMSO mixtures. A definite explanation of the maximization observed in the composition profile of P_i can also be expected to clarify the cause of the maximum of $\Delta\bar{H}_s$.

The above assumption concerning $\bar{V}_c$ is not strictly valid since $\bar{V}_c$ is usually calculated using Eq. 5 with an $\bar{H}_c$ value estimated on the basis of the scaled particle theory.[23] However, the linear correlation between $\delta\Delta\bar{H}_s$ and δP_i in Fig. 4 shows that the influence of a change in $\bar{V}_c$ with the solvent composition on Eq. 7 is negligible.

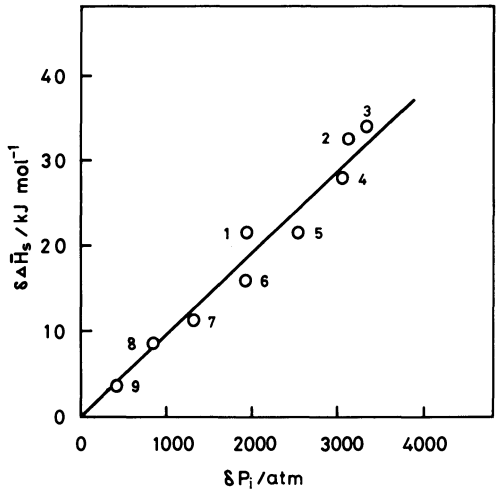

Fig. 4. Correlation between $\delta\Delta\bar{H}_s$ of [Co(acac)$_3$] and δP_i in water–DMSO mixture.
$\delta\Delta\bar{H}_s$ denotes deviation of $\Delta\bar{H}_s$ from ideal behavior defined by Eq. 6. X_{DMSO} is as follows: 1) 0.1; 2) 0.2; 3) 0.3; 4) 0.4; 5) 0.5; 6) 0.6; 7) 0.7; 8) 0.8; 9) 0.9.

In the derivation of Eq. 7, the partial molar enthalpy of interaction ($\bar{H}_i$) is not taken into account; that is, the contribution of $\delta\bar{H}_i$ to $\delta\Delta\bar{H}_s$ is ignored ($\delta\bar{H}_i$ is also defined by a similar equation to Eq. 6). The type of interaction between [Co(acac)$_3$] and water seems to differ from that between [Co(acac)$_3$] and DMSO. While an estimation of $\bar{H}_i$ is difficult, the result in Fig. 4 suggests that a change in $\bar{H}_i$ with solvent composition is approximately proportional to the solvent composition, that is, $\delta\bar{H}_i \fallingdotseq 0$.

Estimation of the Partial Molar Enthalpy of Hydrophobic Hydration ($\Delta\bar{H}_h$) for [Co(acac)$_3$]. The upward curvature at the low-temperature region of the solubility curves in Fig. 2 can be attributed to the hydrophobic hydration of [Co(acac)$_3$].[24] Shinoda has pointed out that the plot of ln X_s against $1/T$ for a hydrophobic solute in water gives a straight line at sufficiently high temperatures because of a disappearance of hydrophobic hydration.[24] The present observation that the minimum in the solubility curves is shifted to lower temperatures with increasing X_{DMSO} suggests that DMSO weakens the hydrophobic hydration of [Co(acac)$_3$].

In an attempt to estimate $\Delta\bar{H}_h$, the straightening of the solubility curve was regarded as an indication of the disappearance of hydrophobic hydration. Thus, the solubility data in aqueous DMSO mixtures with $X_{DMSO} \leq 0.14$ were fitted to Eq. 4 in limited temperature regions and the partial molar enthalpy of solution without hydrophobic hydration ($\Delta\bar{H}'_s$) was estimated from the slopes. The values of $\Delta\bar{H}_h$ were obtained by subtracting $\Delta\bar{H}'_s$ from $\Delta\bar{H}_s$.

In Table 5, $\Delta\bar{H}'_s$ and $\Delta\bar{H}_h$ are listed. For $X_{DMSO} \leq 0.0272$, errors of $\Delta\bar{H}'_s$ estimated from deviations at the 95% confidence level of the slopes in Eq. 4 were extremely large because of the narrow temperature region in which $\Delta\bar{H}'_s$ was estimated; hence, the $\Delta\bar{H}_h$ values should be regarded as being

Table 5. Partial Molar Enthalpy of Solution without Hydrophobic Hydration ($\Delta\bar{H}'_s$) and Partial Molar Enthalpy of Hydrophobic Hydration ($\Delta\bar{H}_h$) at 25 °C of [Co(acac)$_3$]

X_{DMSO}	$\Delta\bar{H}'_s$/kJ mol^{-1} a)	$\Delta\bar{H}_h$/kJ mol^{-1} b)
0.0160	4.4±2.8 (50—60 °C)	−13.7
0.0272	9.4±5.6 (50—60 °C)	−15.1
0.0587	13.5±1.8 (45—60 °C)	−10.3
0.0957	18.2±2.1 (40—60 °C)	−8.4
0.1400	23.3±1.5 (35—60 °C)	−5.4

a) Values were estimated from slopes of straight lines obtained by fitting solubility data to Eq. 4 in the temperature regions given in parentheses and errors were estimated from deviation at 95% confidence level of the slopes. b) $\Delta\bar{H}_h = \Delta\bar{H}_s - \Delta\bar{H}'_s$. The values of $\Delta\bar{H}_s$ are given in Table 4.

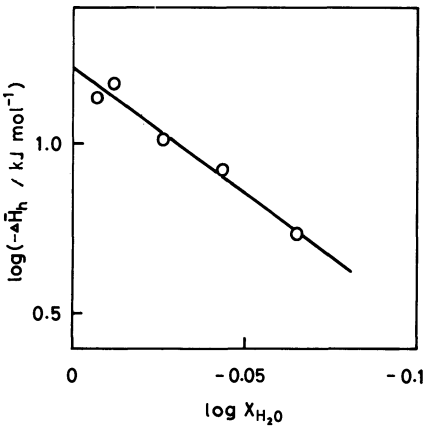

Fig. 5. Correlation between $\log(-\Delta\bar{H}_h)$ of $[Co(acac)_3]$ and $\log X_{H_2O}$ in water–DMSO mixture.

approximate. Nevertheless, it is worth noting that the differences between $\Delta\bar{H}_s$ and $\Delta\bar{H}'_s$ for mixtures with a lower X_{DMSO} than 0.14 are beyond the experimental errors. Therefore, the $\Delta\bar{H}_h$ values in Table 5 are significant.

According to Somsen et al.,[7,9,10] $\Delta\bar{H}_h$ in aqueous DMSO mixtures can be expressed by

$$\Delta\bar{H}_h = \Delta\bar{H}_h(H_2O)X^n_{H_2O}, \quad (8)$$

where $\Delta\bar{H}_h(H_2O)$ and X_{H_2O} are $\Delta\bar{H}_h$ in water and the mole fraction of water, respectively. In an earlier paper of Somsen et al.,[7] n was considered to denote the number of water molecules forming clathrate-like cages around hydrophobic sites or parts of a solute molecule. However, in a later paper, it was shown that n is not unambiguously defined by their model.[9] We consider that n is a measure of the magnitude of the decrease in $\Delta\bar{H}_h$ with X_{H_2O}. The values of $\log(-\Delta\bar{H}_h)$ are plotted against $\log X_{H_2O}$ in Fig. 5, which shows the validity of Eq. 8 (γ=0.984).

The value of $\Delta\bar{H}_h(H_2O)$ for $[Co(acac)_3]$, obtained from the intercept, is -16.7 ± 1.2 kJ mol^{-1}. Shinoda has estimated the $\Delta\bar{H}_h(H_2O)$ of benzene, methylbenzene, and ethylbenzene to be -31.5, -36.1, and -42.3 kJ mol^{-1}, respectively.[24] At present, the validity of $\Delta\bar{H}_h(H_2O)$ for $[Co(acac)_3]$ can not be discussed in terms of values from the literature for various compounds because of the difficulty in estimating $\Delta\bar{H}_h(H_2O)$. The present result suggests that the adoption of mixed solvents is useful for an estimation of $\Delta\bar{H}_h(H_2O)$. A further examination in mixed solvents of water and various organic solvents will be carried out.

The authors wish to thank Dr. Toshiki Wakabayashi for his valuable discussions and useful suggestions during this work.

Organopalladium(II) Complexes Containing Carbon-Bonded Heterocycles as a Ligand

Kiyoshi ISOBE,* Kazuharu NANJO, Yukio NAKAMURA, and Shinichi KAWAGUCHI†
Department of Chemistry, Faculty of Science, Osaka City University,
Sumiyoshi-ku, Osaka 558
†School of Medicine(Premedical Building), Kinki University,
Sayama-cho, Minamikawachi-gun, Osaka 589
(Received January 18, 1986)

Oxidative addition reactions of 2-chloropyridine, 2,6-dichloropyridine, 2-chloropyrazine, and 2-chlorobenzothiazole with tetrakis(triphenylphosphine)palladium(0) gave [{PdCl(R)(PPh_3)}$_2$] or *trans*-[PdCl(R)(PPh_3)$_2$] depending on the nature of the carbon-bonded heterocycles R. They are all stable and the chloride ligand is readily replaced by other halides and pseudohalides. These novel organopalladium(II) complexes were characterized by the analytical and molecular-weight data together with IR, ^{1}H NMR and ^{13}C NMR spectra, and the 2-pyridyl-bridged dinuclear structure of [{PdBr(C_5H_4N-C^2)(PPh_3)}$_2$] was previously revealed by X-ray analysis. Both of the dinuclear and mononuclear 6-chloro-2-pyridylpalladium(II) complexes catalyze the cross coupling reaction between 2,6-dichloropyridine and methylmagnesium bromide to afford 2-methyl-6-chloropyridine selectively. The mononuclear 6-chloro-2-pyridylpalladium(II) complexes react with carbon monoxide to form the acyl complexes.

The σ-pyridyl complexes are of considerable current interest in connection with adsorption of pyridine on metal surfaces during the catalytic reactions,[1] and a fair number of these complexes have been prepared with cobalt(III),[2] gold(I),[3] titanium(III),[4] rhenium(I),[5] palladium(II),[6] and other metals.[7] We also have extensively developed σ-pyridyl nickel(II)[8] and palladium(II)[9] complexes. In the course of the studies, both the mononuclear and the dinuclear 2-pyridyl palladium(II) complexes were important starting materials for preparation of the mixed-ligand complexes containing both the pyridyl ligand and the *O,O'*-chelated or *O*-unidentate β-diketonate anion.[10] This paper describes more detailed results on the preparation, characterization and some reactivities of palladium(II) complexes containing the σ-carbon-bonded pyridyl as well as pyrazinyl and benzothiazolyl ligands. The molecular structure of a dinuclear complex [{PdBr(μ-C_5H_4N-C^2, N)(PPh_3)}$_2$] has previously been reported.[11]

Experimental

Air-sensitive materials were handled under a nitrogen atmosphere unless otherwise stated. Solvents were redistilled under nitrogen and other reagents purged with nitrogen before use. Tetrakis(triphenylphosphine)palladium(0), Pd(PPh_3)$_4$, was prepared by Coulson's method.[12] Tertiary phosphines, halopyridines, 2-chloropyrazine, 2-chlorobenzothiazole, and Grignard reagents were purchased and used without further purification.

Preparation of [{PdX(R)(PPh_3)}$_2$] (R=C_5H_4N-C^2, X=Cl (1a) or Br (1b), and R=$C_4H_3N_2$-C^2, X=Cl (7)) and *trans*-[PdCl(R)(PPh_3)$_2$] (R=C_5H_3(6-Cl)N-C^2 (2a) or C_7H_4SN-C^2 (6)) by the Oxidative Addition. To a solution of Pd(PPh_3)$_4$ (4.21 g, 3.63 mmol) in toluene (50 cm^3) was added ca. ten times molar amount of 2-chloropyridine (4.12 g), 2-bromopyridine (5.74 g), or 2-chloropyrazine (4.16 g) and the mixture was heated to 90 °C for 10, 3, and 10 h, respectively. After standing for 5h at room temperature, yellow precipitates of **1a**, **1b**, and **7** were obtained in 60, 55, and 79% yields, respectively. Complexes **2a** and **6** were obtained in a similar manner by using 2,6-dichloropyridine or 2-chlorobenzothiazole as alkyl halide. A refrigerator was utilized for depositing precipitates from the reaction mixture. The yields were 95 (**2a**) and 80% (**6**).

Preparation of [{PdX(R)(PPh_3)}$_2$] (R=C_5H_4N-C^2, X=I (1c), N_3 (8a), NCO (8b), NCS (8c), or NCSe (8d), R=C_5H_3(6-Cl)N-C^2, X=N_3 (10a), NCO (10b), or NCS (10c)) and *trans*-[PdX(C_5H_3(6-Cl)N-C^2)(PPh_3)$_2$] (X=Br (2b), I (2c), N_3 (9a), NCO (9b), or NCS (9c)) by the Halide Substitution Reactions. Compound **1a** (0.14 g, 0.15 mmol) was dissolved in dichloromethane (50 cm^3) and methanol (20 cm^3) was added to the solution. Then a methaol solution (20 cm^3) of sodium iodide (4.5 g, 30 mmol) was added and the mixture was heated to 40 °C for 2 h. Dichloromethane was evaporated under reduced pressure and yellow crystals separated were filtered. The yield of **1c** was 80%. In a similar manner yellow dinuclear complexes **8** and **10** and white mononuclear complexes **2** and **9** were obtained by the halide substitution reactions of **2a** or **3a** with sodium bromide, iodide, pseudohalides and potassium selenocyanate. Solubility of sodium cyanate is low in methanol and aqueous methanol (1:3 by volume) was used as solvent. Yields of the metathesis reactions were 73 (**8a**), 65 (**8b**), 83 (**8c**), 52 (**8d**), 53 (**10a**), 48 (**10b**), 59 (**10c**), 90 (**2b**), 85 (**2c**), 81 (**9a**), 79 (**9b**), and 63% (**9c**), respectively.

Preparation of [{PdX(C_5H_3(6-Cl)N-C^2)(PPh_3)}$_2$] (X=Cl (3a), Br (3b), or I (3c)). To a suspension of **2a** (0.18 g, 0.23 mmol) in acetone (30 cm^3) was added dropwise an 0.05 cm^3 portion of 30% aqueous solution of hydrogen peroxide (ca. 0.44 mmol) by means of micropipette and the mixture was stirred. The initially white suspension turned yellow gradually. Stirring was continued for 24 h and the yellow precipitate was filtered. The yield of **3a** was 96%. Complexes **3b** and **3c** were derived from **3a** by the halide substitution reactions in 90 and 87% yields, respectively.

Complexes **3a—c** were also prepared via an alternative route. The perchlorato complex[9a] [{$PdClO_4$(C_5H_3(6-Cl)N-C^2)(PPh_3)}$_2$](0.12 g, 0.10 mmol) was dissolved in dichloro-

methane (50 cm^3). To the solution was added methanol (20 cm^3) followed by a methanol solution (20 cm^3) of a large excess amount of sodium chloride (1.8 g), bromide (3.1 g) or iodide (4.5 g), and the mixture was heated to 40 °C for 2 h. Dichloromethane was then evaporated under reduced pressure to precipitate crystals of **3a**, **3b**, and **3c** in 32, 83, and 89% yields, respectively.

Preparation of *trans*-[PdCl(C_5H_3(6-Cl)N-C^2)(PEt_3)$_2$] (4a), *trans*-[PdCl(C_5H_3(6-Cl)N-C^2)($PPhMe_2$)$_2$] (4b), and *trans*-[PdNCO(C_5H_3(6-Cl)N-C^2)(PEt_3)$_2$] (11). In order to prevent oxidation of phosphines during long-time reactions by a trace of oxygen accompanied by cylinder nitrogen, an argon atmosphere was employed for preparation of these complexes. Triethylphosphine (0.07 g, 0.63 mmol) or phenyldimethylphosphine (0.09 g, 0.63 mmol) was added to a suspension of complex **2a** (0.16 g, 0.21 mmol) in diethyl ether (20 cm^3), and the mixture was stirred at room temperature for 20 h to result in a clear colorless solution. After addition of petroleum ether (20 cm^3), the solution was cooled in a Dry Ice–methanol bath for 3 h to precipitate white crystals, which were filtered promptly. The yields of **4a** and **4b** were 40 and 60%, respectively. In a similar manner **11** was obtained in a 14% yield by the reaction of **9b** with triethylphosphine.

Preparation of [{PdCl(C_5H_4N-C^2)(PEt_3)}$_2$] (5). Triethylphosphine (0.06 g, 0.52 mmol) was added to a suspension of **1a** (0.13 g, 0.13 mmol) in diethyl ether (20 cm^3) and the mixture was stirred under argon at room temperature for 20 h to obtain a clear colorless solution, which was concentrated to 3 cm^3 by evaporation under reduced pressure and poured onto a column (ϕ1.5 cm×30 cm) of Aluminiumoxid 60 PF_{254} (Type E by Merck). Petroleum ether (150 cm^3) was used as an eluent to remove free triethyl- and triphenylphosphines. The complex was eluted by dichloromethane (70 cm^3) and the yellow solution was concentrated. Complex **5** was obtained in a 50% yield by adding petroleum ether to the concentrate.

Preparation of *trans*-[PdX(C_5H_3(6-Cl)N-C^2-CO)(PPh_3)$_2$] (X=Cl (12a), Br (12b), I (12c), or NCS (12d)). Carbon monoxide was bubbled through a tetrahydrofuran solution (50 cm^3) at room temperature containing ca. 0.1 mmol of **2a** (0.078 g), **2b** (0.082 g), **2c** (0.087 g), or **9c** (0.108 g). The colorless solution turned yellow on reaction. After evaporation under reduced pressure, diethyl ether was added to the concentrate (10 cm^3) to separate out yellow crystals. The CO bubbling was continued for 1, 5, 48, and 170 h in the case of X=I, Br, Cl, and NCS to attain the 73 (**12a**), 85 (**12b**), 80 (**12c**), and 82% (**12d**) yields, respectively.

All of the newly-prepared complexes were purified by recrystallization from dichloromethane–methanol (for **1**, **2**, **3**, **6**, **7**, **8**, **9**, and **10**), diethyl ether–petroleum ether (for **4**, **5**, and **11**), chloroform–diethyl ether (for **12a**, **12b**, and **12d**), or dichloromethane–diethyl ether (for **12c**).

Reactions of 2a with Chlorine, Iodine, and Methyl Iodide. Gaseous chlorine was passed for 10 min through a solution of **2a** (0.11 g, 0.13 mmol) in dichloromethane (20 cm^3). The initially colorless solution turned red. A 10 cm^3 portion of the solution was poured onto a column of Kieselgel 60 F_{254} (Merck). Diethyl ether was used as an eluent to isolate 2,6-dichloropyridine, which was identified by IR and ultraviolet spectra and elemental analysis. Found: C, 40.36; H, 2.11; N, 9.31%. Calcd for $C_5H_3NCl_2$: C, 40.58; H, 2.04; N, 9.46%. To the other 10 cm^3 portion of the red solution was added diethyl ether (40 cm^3) and the mixture was left standing for 3 h to deposit red crystals, which were identified to be di-μ-chloro-dichlorobis(triphenylphosphine)dipalladium(II) on the basis of IR spectra and elemental analysis. Found: C, 49.51; H, 3.89%. Calcd for $C_{36}H_{30}P_2Cl_4Pd_2$: C, 49.18; H, 3.44%. The yield was 78%.

A dichloromethane solution (10 cm^3) containing **2a** (0.11 g, 0.13 mmol) and iodine (0.03 g, 0.12 mmol) was stirred for 4 h to deposit a yellow precipitate, which was identified as **3c** by IR spectral assay. The yield was 70%. When methyl iodide (0.02 g, 0.13 mmol) was added dropwise to a solution of **2a** in dichloromethane (20 cm^3), the initially colorless solution turned yellow. After 24 h standing, the solution was concentrated to 10 cm^3 by evaporation under reduced pressure. Methanol (30 cm^3) was added to the concentrate and the mixture was allowed to stand 2 h to separate out orange crystals, which were identified as **2c** by IR spectroscopy. The yield was 65%.

Reactions of 8a and 9a with Carbon Monoxide. Carbon monoxide was bubbled for 4 h through a solution of **8a** (0.14 g, 0.138 mmol) in a mixture (50 cm^3) of dichloromethane and THF (1:1 by volume) and the mixture was stirred for five days in a sealed vessel. The solution was then concentrated to 20 cm^3 by evaporation under reduced pressure to deposit a pale yellow crystalline precipitate in a 95% yield, which was identified as **8b** on the basis of IR spectra and elemental analysis. Found: C, 58.30; H, 3.87; N, 5.30%.

In a similar manner carbon monoxide was passed for 4 h through a solution of **9a** (0.20 g, 0.256 mmol) in THF (50 cm^3). The solvent was evaporated to 10 cm^3 and diethyl ether (20 cm^3) was added to the concentrate to deposit a brown precipitate, which was washed thoroughly with methanol and dried. Recrystallization from dichloromethane–methanol afforded white crystals which were identified as **9b**. Found: C, 64.05; H, 4.11; N, 3.12%. When carbon monoxide was passed through the solution of **9a** for more than 4 h, the solution turned red gradually. After 10 h passage, the mixture was stirred for 2 days in a stoppered vessel. Then the solution was concentrated to 10 cm^3 by evaporation under reduced pressure and diethyl ether (30 cm^3) was added to the concentrate to deposit red crystals of $Pd_3(PPh_3)_3(CO)_3$. Found: C, 57.43; H, 4.04%. Calcd for $C_{57}H_{45}O_3P_3Pd_3$: C, 57.53; H, 3.81%.

Reaction of 12b with Methanol to Afford an Ester. When methanol (10 cm^3) was added to a solution of **12b** (0.11 g, 0.123 mmol) in chloroform (20 cm^3), color of the solution turned from red to brown. After standing for 24 h, the solvent was evaporated to dryness under reduced pressure and the residue was extracted with diethyl ether. Methyl 6-chloropicolinate in ether solution was identified by ^1H NMR spectroscopy: $\delta(CH_3)$, 4.01 s; $\delta(H^4$ and $H^5)$, 7.40 m; $\delta(H^3)$, 8.00 m ppm. The yield was 60%. IR assay showed that the residue contained *trans*-dibromobis(triphenylphosphine)palladium(II) and free triphenylphosphine.

Cross Coupling Reactions of Methylmagnesium Bromide with 2-Chloropyridine and 2,6-Dichloropyridine Catalyzed by 1a, 2a, and 3a. A solution of methylmagnesium bromide (13 mmol) in THF (13 cm^3) was added dropwise to

a) The value is unreliable due to low solubility. b) Undetermined because of poor solubility. c) Determined in chloroform.

a THF solution (50 cm^3) containing **1a** (0.10 g, 0.10 mmol) and 2-chloropyridine (1.14 g, 10 mmol), but the reaction did not occur at room temperature, the solution maintaining yellow color. When the solution was heated under reflux (about 66 °C), the reaction took place, color of the solution changing via reddish brown to deep green. After the reaction for 5 h, a 10 cm^3 aliquot was evaporated under reduced pressure and the residue was extracted with diethyl ether (20 cm^3). The ether solution was concentrated to 1 cm^3 and applied to the GLC analysis. 2-Methylpyridine was identified in a 13% yield accompanied by unreacted 2-chloropyridine. Prolonged refluxing did not improve the yield of 2-methylpyridine.

A mixed THF solution (55 cm^3) containing **2a** (0.14 g, 0.183 mmol), triphenylphosphine (4.81 g, 18.3 mmol), 2,6-dichloropyridine(2.96 g 20 mmol), and methylmagnesium bromide (25 mmol) was heated under reflux for 3 h. The resulting brown solution was concentrated and made up to 50 cm^3. 2-Methyl-6-chloropyridine was identified by GLC in a 53% yield accompanied by unreacted 2,6-dichloropyridine.

A mixed THF solution (55 cm^3) containing **3a** (0.09 g, 9.14×10^{-5} mol), 2,6-dichloropyridine (2.96 g, 20 mmol), and methylmagnesium bromide (25 mmol) was refluxed for 3 h. The resulting brown solution was concentrated and made up to 50 cm^3. 2,6-Dimethylpyridine was identified in a 4% yield in this case together with 2-methyl-6-chloropyridine (58% yield) and unreacted 2,6-dichloropyridine.

Measurements. IR spectra were recorded in Nujol on JASCO IR-E (4000-650 cm^{-1}), Hitachi EPI-L (700-200 cm^{-1}) and FIS-3 (400-30 cm^{-1}) spectrophotometers. ^1H NMR spectra were taken at 100 MHz with JEOL JNM MH-100 and PS-100 spectrometers using tetramethylsilane as internal reference. ^{13}C NMR spectra were obtained at 25.0 MHz by 6000 times scan on a JEOL JNM FX-100 instrument with tetramethylsilane as external reference. ^{15}N NMR spectra were recorded at 9.04 MHz by 3000 times scan on a JEOL JNM FX-90Q spectrometer with ammonium nitrate-^{15}N aqueous solution as external reference. Mass spectra were taken with a JEOL GC-mass spectrometer JMS D-300 and gas chromatography was performed on a Yanagimoto G-180 instrument with Silicone DC-550 and nitrogen gas, injection temperature being 200 °C. The decomposition temperatures of the newly-prepared compounds were determined in a capillary tube under nitrogen. The molecular weight was measured in dichloromethane at 25 °C by vapor pressure osmometry with an instrument manufactured by Knauer in Berline, West Germany.

Results and Discussion

Although tetrakis(triphenylphosphine)nickel(0) reacted readily with halopyridines in toluene at room temperature,[8] the reactions of $Pd(PPh_3)_4$ with halopyridines did not occur at room temperature, but heating for a long time, e.g. 3 h for 2-bromopyridine and 10 h for 2-chloropyridine at 90 °C, was necessary to afford the pyridylpalladium(II) complexes in high yields. 2-Chloropyrazine and 2-chlorobenzothiazole also reacted with $Pd(PPh_3)_4$ in toluene at 90 °C to produce the σ-carbon-bonded complexes in ca. 80% yields, although the 2-benzothiazolylnickel(II) complex could not be prepared.[8] Results of elemental analysis and molecular weight determination of newly-prepared complexes are collected in Table 1.

Properties of Halogeno 2-Pyridyl and Related Complexes. The analytical and molecular-weight data for compounds **1a—c**, **3a—c**, **5**, and **7** indicate that they are essentially dinuclear, although the observed molecular weight of **1c** in dichloromethane is appreciably lower than the calculated value. The dinuclear structure with bridging halide anions is quite common among palladium(II) complexes,[13] and is usually subject to cleavage by bonor ligands to give mononuclear species.

As is seen in Table 2, the ν(Pd-X) frequencies observed for **1a—c** are not unreasonable for the bridging halides. However the dinuclear structure in these complexes is very stable and is not cleaved by excess bases such as triphenylphosphine, pyridine, and thiourea. X-Ray analysis denied the halide-bridged structure and disclosed the bridging role of the 2-pyridyl ligand in **1b** (Fig. 1).[11] A similar μ-pyridyl(C^2,N) structure was also confirmed for (μ-H)$Re_2(CO)_8$(μ-C_5H_4N-C^2,N) and (μ-H)$Re_2(CO)_7$(μ-C_5H_4N-C^2,N)(Me_3NO).[5b] Basicity of the 2-pyridyl ligand coordinated to palladium(II) was reported to be 3700 times greater than that of free pyridine.[9b] This enhanced basicity enables the stable bridging of the 2-pyridyl ligand.*1 A similar bridged structure

Table 2. Decomposition Temperatures and Some FIR Data

Complex	Decomp temp[a] °C	ν(Pd-X) cm^{-1}	ν(Pd-P) cm^{-1}
1a	196	263 m	420 s
1b	185	196 m	420 m
1c	140	144 w	420 m
2a	250 (232)	295 s	351 m
2b	240 (230)	187 s	350 m
2c	205	172 s	346 s

4b	233 (117)	292 m	348 m
5		260 s	420 m
6	197	302 s	364 w
7	197	270 m	430 m

a) Numerals in parentheses give melting points in °C. s: strong, m: medium, w: weak.

*1 The reaction of $LPd_2(CH_3CO_2)$ (L=bridging benzenethiolate derivatives) with pyridines containing electron-donating substituents (X) at the 3-position also gave $LPd_2(C_5H_3XN$-C^2,$N)$ in low yields.[6]

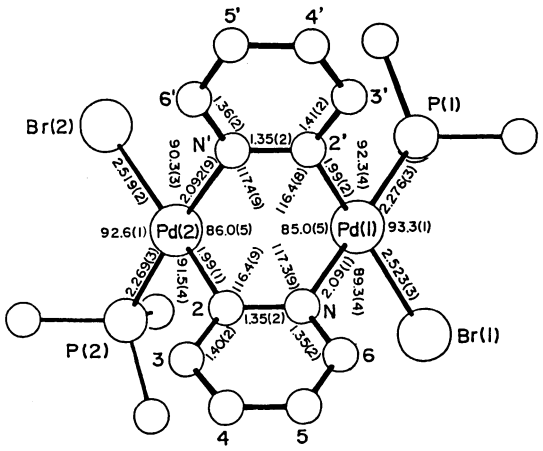

Fig. 1. Stereochemistry of *trans*-(*P*, *N*)-[{PdBr(μ-C_5H_4N-C^2,*N*)(PPh_3)}$_2$] (**1b**) viewed perpendicular to the plane containing C(2), N, C(2′), and N′. Phenyl groups are not shown for clarity, except the three carbon atoms bonded to each phosphorus atom. Important bond lengths (in Å) and angles (in degree) are also given with e.s.d.'s in parenthsses.[11]

has also been presumed for the 2-pyridyl group involved in triosmium clusters[7b] and a gold(I) complex[3] in which the 2-pyridyl ligand serves as a three-electron donor.

Complex **1a** was prepared under the same conditions as **1b**, and **1c** was derived from **1a** by the halide substitution. The patterns of ^{1}H NMR and IR spectra for **1a—c** are quite similar to each other. Furthermore, all of the IR absorption bands of these complexes in the region 1600—300 cm^{-1} are superimposable on each other within experimental errors. These facts suggest that **1a**, **1b**, and **1c** will have the identical structure. The ν(Pd–P) frequencies (in Table 2) are close to each other and the ν(Pd–Cl):ν(Pd–Br):ν(Pd–I) ratio (1:0.75:0.55) is similar to the value 1:0.75:0.61 observed for *trans*-$PdX_2(PEt_3)_2$ (X=Cl, Br, and I, respectively) and 1:0.73 for *cis*-$PdX_2(PMe_3)_2$ (X=Cl and Br).[14] Thus complexes **1a** and **1c** are considered to have the pyridyl-bridged structure analogous to **1b**. In each complex the halide anion occupies the coordination site trans to the pyridyl carbon, and the rather lower frequencies of the ν(Pd–X) vibrations are caused by the strong trans influence of the σ-carbon-bonded pyridyl ligand. Thermal stabilites of these complexes are in the sequence of **1a**>**1b**>**1c**. Stronger trans influence of the iodide anion compared with that of chloride may destabilize the Pd–C linkage.

When 2,6-dichloropyridine was used as a reagent, the mononuclear 6-chloro-2-pyridyl complexes **2a—c** were obtained. Complexes **4a** and **4b**, which were derived from **2a** by the phosphine exchange reactions, and the benzothiazolyl complex **6** are also mononuclear. When a dichloromethane solution of **2a** was allowed to stand at room temperature for a long time as weeks, one of the phosphine ligands was lost to form **3a**. A precipitate of **3a** thus produced was readily reconverted to **2a** on addition of excess triphenylphosphine, indicating that reaction (1) is reversible.

$$2[PdCl(C_5H_3(6\text{-}Cl)N\text{-}C^2)(PPh_3)_2] \rightleftarrows [\{PdCl(C_5H_3(6\text{-}Cl)N\text{-}C^2)(PPh_3)\}_2] + 2PPh_3 \quad (1)$$

By oxidizing the freed phosphine equilibrium (1) was shifted to right to obtain **3a** conveniently.[15] As was described in Experimental section, the reaction of $Pd(PPh_3)_4$ with 2,6-dichloropyridine gave **2a** exclusively without appreciable contamination with **3a** in spite of much lower solubility of the latter, indicating that the thermodynamic stability of **2a** is much higher than that of **3a**. A molecular model suggests that the dinuclear structure of **3a** analogous to **1b** is unfavorable because of the steric interaction between the chloro substituent on the pyridine ring and the benzene rings.

Mononuclear complexes **2a—c** are thermally more stable than the corresponding dinuclear complexes **3a—c**, the Cl>Br>I sequence holding again in either case, and **2a**, **2b**, **4a**, and **4b** showing clear melting points. The mononuclear complexes exhibit a single ν(Pd–X) band in the region reasonable for the terminal halide trans to the carbon-bonded organic ligand,[16] and a single ν(Pd–P) band at about 350 cm^{-1} in accordance with the trans structure. Data of ^{1}H NMR spectra included in Table 3 also support the trans structure. Thus the methyl protons of triethylphosphine in **4a** resonate at 1.11 ppm as a 1:4:6:4:1 quintet[17] with J=ca. 8.0 Hz and the methyl protons of phenyldimethylphosphine in **4b** at 1.53 ppm as a 1:2:1 triplet.[18]

As is shown in Table 3, the ring protons of triphenylphosphine in complex **1** through **7** resonate generally as two multiplets with the area ratio of 3:2 in the 7.33—7.42 and 7.45—7.86 ppm regions, respectively. The higher-field signal is assigned to the meta and para protons and the lower-field one to the ortho protons.[19] The pyridine-ring protons were assigned in a similar manner as those of the pyridylnickel(II) complexes.[8] In the case of the 2-benzothiazolyl complex **6**, signals of the hetero-ring protons overlapped with those of the benzene-ring protons.

The most remarkable feature of the ^{1}H NMR data for the 2-pyridyl complexes containing triphenylphosphine as the ancillary ligands is the up-field shift of the resonances of pyridine-ring protons at the 3, 4, and 5 positions as compared with those of uncoordinated pyridine (H^2 8.5, H^3 7.2, H^4 7.6 ppm), although the chemical shifts of pyridine-ring protons in **1a** and some other complexes such as **3a** and **4b** are so close to each other, exhibiting composite signals.

Table 3. Proton Chemical Shifts from Internal Me_4Si in CD_2Cl_2 (ppm)

Table 4. ^{13}C NMR Data for Complex **1b** and Uncoordinated Triphenylphosphine and Pyridine

Compound	Chemical shift (ppm)					Coupling constant (Hz)
$P(C_6H_5)_3$	C^1 138.3	C^2 134.4	C^3 129.2	C^4 129.3		J(P-C^1)=21, J(P-C^2)=20 J(P-C^3)=7, J(P-C^4)<1
C_5H_5N	C^2, C^6 149.7	C^3, C^5 123.6	C^4 135.5			
1b						
Phenyl carbon	C^1 138.6	C^2 143.0	C^3 135.3	C^4 139.7		J(P-C^1)=49, J(P-C^2)=11.7 J(P-C^3)=10.7, J(P-C^4)=0
Pyridyl carbon	C^2 200.5	C^3 124.5	C^4 140.3	C^5 124.4	C^6 161.7	

On the other hand, there was no significant up-field shift observed for the pyridine-ring proton resonances in the 2-pyridyl complexes containing triethylphosphine such as **5**, rhenium carbonyls,[5] and osmium clusters.[7b] Thus the up-field shift of pyridine-ring proton resonances seems to be caused by an anisotropic shielding effect of the triphenylphosphine ligand through space[20] as well as by the back-donation from palladium to the pyridine ring via the carbon atom. In fact, according to X-ray analysis of **1b**,[11] the pyridine-ring protons at the 3, 4, and 5 positions lie in the vicinity of a benzene ring of the triphenylphosphine ligand, whereas the proton at the 6 position is far from it.

Table 4 shows the ^{13}C NMR data for **1b** together with those for uncoordinated triphenylphosphine[21] and pyridine.[22] Assignment of the phenyl carbons in **1b** was readily made on the basis of J(P-C) values and also by reference to the data for the uncoordinated phosphine. It is worth noting that the J(P-C^1) value (49 Hz) is more than twice larger than the value (21 Hz) for the free ligand and that (20 Hz) for the corresponding nickel(II) complex.[8] Assignment of the pyridyl carbons in **1b** was based on

the results for *trans*-PdBr(C_5H_4N-C^2)(PEt_3)$_2$ which were obtained by the proton off-resonance and selective decoupling experiments.[9b] Pyridyl carbons are more or less deshielded on bonding to palladium(II) through C^2, and the down-field shift of C^2 is astonishingly large. The effect of coordination is quite different from the nickel(II) complexes where both the ^{13}C and ^1H signals showed up-field shifts probably due to the back donation from the metal atom. No reasonable rationalization of the palladium(II) case is possible at the present stage of investigation.

Characterization of the Pseudohalogeno σ-Pyridyl Complexes. The dinuclear pseudohalogeno complexes **8a—d** and **10a-c** were prepared by simple metathesis reactions of **1a** and **3a**, respectively, with the pseudohalides in good yields. It should be noted that the bridge-splitting reactions to give rise to anionic pyridyl complexes did not occur, but simple substitution of the halide ligands was resulted.

As is seen in Table 3, the patterns of ^1H NMR spectra for **8a—c** and the chemical shifts of pyridine and benzene-ring protons in these complexes are quite similar to each other. Compounds **10a—c** also exhibit a close resemblance to **8a—c** in the spectral patterns except for lacking of the pyridine H^6 resonance. These facts strongly suggest that all these complexes have a common bridging mode.

Complex **10c** containing the ^{15}NCS ligand (95% ^{15}N) was prepared and the ^{15}N NMR spectrum was measured in CD_2Cl_2. As Fig. 2 shows, a single doublet with J(P—N)=ca. 3.2 Hz is observed at −235.61 ppm up-field from external $NH_4{}^{15}NO_3$. The coupling constant of ^{15}N to ^{31}P situated at the trans position in *cis*-PtNCS(SCN){$P(OEt)_3$}$_2$[23] and PtNCS(SCN)($Ph_2PCH_2C(CF_3)$=CHPPh_2)[24] was found to be 91 and 53.71 Hz, respectively, whereas that of ^{15}N to the cis ^{31}P in either complex was too small to be detected. The small value of ^{31}P–^{15}N coupling constant in **10c** indicates that the N-bonded thiocyanate ligand occupies the coordination site cis to the phosphine.

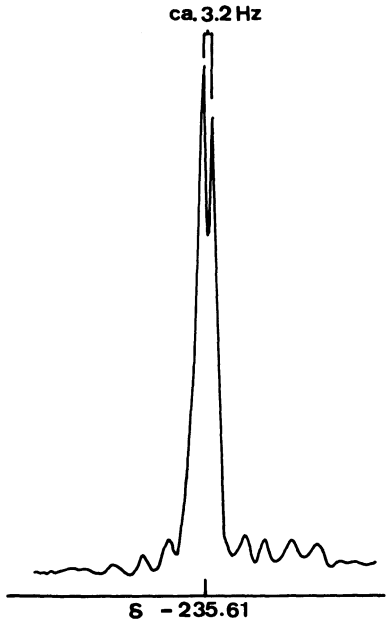

Fig. 2. ^{15}N NMR spectrum of diisothiocyanatobis(6-chloro-2-pyridyl)bis(triphenylphosphine)dipalladium(II) (**10c**) in CD_2Cl_2 by 3000 times scan at 9.04 MHz. The chemical shift is measured from external $NH_4{}^{15}NO_3$ (up-field negative).

Compounds **9a—c** were also prepared by the ligand substitution reactions of **2a**, and **11** was obtained from the reaction between **9b** and excess triethylphosphine. The trans mononuclear structure of these complexes is evidenced by the analytical and molecular-weight data in Table 1 and by the single ν(Pd-P) band around 350 cm^{-1} (Table 5). The quintet resonance at 1.09 ppm exhibited by the methyl protons of triethylphosphine in **11** (Table 3) also supports the trans structure of this complex.[17]

Infrared spectra are frequently useful in distinguishing the linkage mode of the pseudohalides in metal complexes.[25] Frequencies of the ν(CN) and ν(CS) vibrations observed for **8c**, **9c**, **10c**, and **12d** indicate that each NCS ligand in these complexes is N-bonded. Similarly the ν(CN), ν(CO), and δ(NCO) frequencies for the cyanate ligand in **8b**, **9b**, **10b**, and **11** (Table 5) are in the range assigned to N-bonding.[25] A related compound *trans*-PdNCS(C_5H_4N-C^3)(PPh_3)$_2$ was confirmed by X-ray analysis to have the N-bonded thiocyanato ligand.[26]

Reactions of the 2-Pyridylpalladium(II) Complexes. The pyridyl-palladium(II) bond is very strong and is not cleaved by methyl iodide and elementary iodine. Thus compound **2a** was merely

Table 5. Characteristic IR Data for the Pseudohalogeno Complexes[a]

a) Y=O, S, or Se. b) Indiscernible.

converted to **2c** and **3c**, respectively. Iodine seems to have shifted the mononuclear-dinuclear equilibrium analogous to Eq. 1 to right by oxidizing the freed phosphine. Benzoyl chloride did not react with **2a** in dichloromethane at room temperature. On the other hand gaseous chlorine cleaved the Pd-C bond to afford 2,6-dichloropyridine.

Complexes **2a—c** and **9c** readily reacted with carbon monoxide to afford the pyridylcarbonyl complexes **12a—d**, which have the trans mononuclear structure as evidenced by the analytical and molecular-weight data as well as the existence of a single ν(Pd–P) band. Each of these complexes shows two ν(CO) bands in the frequency region reasonable for the acyl complex:[27] **12a**, 1661 and 1639 cm^{-1}; **12b**, 1663 and 1640 cm^{-1}; **12c**, 1672 and 1640 cm^{-1}, **12d**, 1673 and 1650 cm^{-1}. Compound **12b** reacted with methanol to produce methyl 6-chloropicolinate in a good yield. The reaction proceeded in the absence of base and the nucleophilic attack by the methanol molecule on the acyl carbon seems to have occurred. A proton must have been freed in this event, but the picolinate nitrogen is not protonated. Although ^{1}H NMR assay at low temperature (−40 to −60 °C) failed to detect a hydrido complex, the following sequence might be responsible for the overall reaction.

$$[PdBr(COR)(PPh_3)_2]+CH_3OH \rightarrow [PdBr(H)(PPh_3)_2]+RCOOCH_3$$

$$2[PdBr(H)(PPh_3)_2] \rightarrow [PdBr_2(PPh_3)_2]+Pd^0+2\,PPh_3+H_2.$$

The azide ligand in **8a** reacted with carbon monoxide to afford **8b**, which is the stable end product and did not react further with CO to give rise to an acyl complex, although carbonylation of the terminal azide ligand to isocyanate has been reported to occur readily for a number of metal complexes.[28] On the other hand, the mononuclear complex **9a** reacted with CO in two steps, a limited amount of CO converting the azide ligand to the isocyanate to result in **9b** and an additional amount of CO carbonylating the pyridyl ligand. The CO insertion into the Pd–pyridyl bond is appreciably slower than the reaction of the azide ligand with CO, and a small amount of $Pd_3(PPh_3)_3(CO)_3$[29] was produced by partial decomposition. Unfortunately, the product acyl complex analogous to **12d** could not be isolated in a satisfactory purity, but was characterized by the IR spectra (ν(CO)=1680 cm^{-1}).

It should be noted that only the pyridyl ligand in mononuclear complexes reacts with CO, while that in dinuclear complexes does not. The palladium–carbon bond in the latter complexes may be strengthened synergistically by the bridging of the pyridyl ligand to another metal atom through nitrogen so as to prevent CO insertion.

Cross Coupling Reactions. In recent years cross coupling reactions between organic halides and Grignard reagents have been found to be catalyzed by the nickel(II) and palladium(II) phosphine complexes.[30,31] Although $[\{NiCl(C_5H_4N\text{-}C^2)(PPh_3)\}_2]$ selectively catalyzes the cross coupling of 2-chloropyridine with methylmagnesium bromide in THF at room temperature,[8] the palladium(II) complex **1a** does not work as a catalyst under the same conditions. In refluxing THF, the catalytic coupling reaction does occur with **1a**, but the yield of 2-methylpyridine was as low as 13% when 1/100 molar amount of **1a** was added to 2-chloropyridine. Complex **3a** is more effective as a catalyst for the reaction of 2,6-dichloropyridine with methylmagnesium bromide in refluxing THF to give 2-methyl-6-chloropyridine in a 58% yield, reflecting the lability of **3a** compared with **1a**. In the presence of excess triphenylphosphine to prevent transformation of **2a** to **3a**, the mononuclear complex **2a** similarly attains the 53% yield of the product. On the other hand, the yield of 2,6-dimethylpyridine from 2,6-dichloropyridine was only 4% in the case of **3a** and was negligibly small when **2a** was used, although the nickel(II) catalyst was reported to promote the Grignard coupling of organo dihalides at both the reaction sites.[30] It is worth noting that the palladium(II) catalysts are less active but are more selective than the nickel(II) complexes for the synthesis of 2-methyl-6-chloropyridine. The selectivity of palladium(II) catalysts shown in the alkylation is analogous to that observed in the cross cou ling reactions of 2,6-dihalopyridines with $PhCH_2ZnBr$ in the presence of $Pd(PPh_3)_4$ as a catalyst.[32]

We wish to express our thanks to Mr. Junichi Gohda and Dr. Takamasa Kinoshita for elemental analyses and ^{13}C NMR measurements, respectively and to Mr. Tetsu Hinomoto of JEOL, Ltd. for ^{15}N NMR measurements.

Magnetic Circular Dichroism Spectra of Cobalt(III) Complexes in the Second d-d Absorption Band Region

Nobuko MATSUOKA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received February 24, 1986)

The MCD spectra of seventeen cobalt(III) complexes were measured in the visible and near-ultraviolet regions. Their behavior in the second d-d absorption band region were compared with those of the [Co(ox)$_x$(gly)$_y$(en)$_z$] series comprising sixteen complexes (x, y, z=0, 1, 2, 3; and $x+y+z=3$), in which a positive band had been observed on the lower-energy side of the main negative band in this region. For the present work, the positive band was found in [Co(tn)$_3$]$^{3+}$, *cis*-[Co(ox)$_2$(NH$_3$)$_2$]$^-$, *cis*-[Co(OH$_2$)$_2$(en)$_2$]$^+$, *trans*-[Co(β-ala)$_2$(en)]$^+$, *mer*- and *fac*-[Co(picol)$_3$] (picol=picolinate(1−)), and [Co(acac)$_3$]. It is pointed out that all the complexes exhibiting a positive band were the tris(chelate) or *cis*-bis(chelate) types. Therefore the origin of this band is discussed in terms of the arrangement of two or three chelate rings. A positive band was not observed for complexes containing a CO_3^{2-} ligand, even if they were a tris(chelate) or *cis*-bis(chelate) type. This is explained from a structural basis. The two complexes which had a split second d-d absorption band, *mer-trans*(NH$_3$)-[CoCO$_3$(gly)(NH$_3$)$_2$] and [CoCO$_3$(picol)(NH$_3$)$_2$], showed two negative bands in the corresponding regions to both component absorption bands, in each complex.

In a previous paper,[1] the MCD (magnetic circular dichroism) spectra of [Co(ox)$_x$(gly)$_y$(en)$_z$] series comprising sixteen complexes were reported. All complexes, except [Co(en)$_3$]$^{3+}$, showed the same MCD-spectra pattern in the spin-allowed second d-d electronic-absorption band region ($^1A_{1g}\rightarrow{}^1T_{2g}(O_h)$), despite the fact that they had various types of ligand atom constitutions and geometrical structures. Some curves are shown in Fig. 1. The spectra were composed of two bands whose signs were positive and negative, from the lower-energy side to the higher. Because other cobalt(III) complexes reported earlier[2-5] did not show a positive band in the corresponding region, the MCD behavior of the series of complexes in the previous study were quite interesting. Only a vague explanation, however, was offered for the origin of the positive band at that time. Then, the MCD spectra of many more cobalt(III) complexes containing nitrogen and oxygen atoms, like in the [Co(ox)$_x$(gly)$_y$(en)$_z$] series complexes, have been measured in order to clarify the origin of this band.

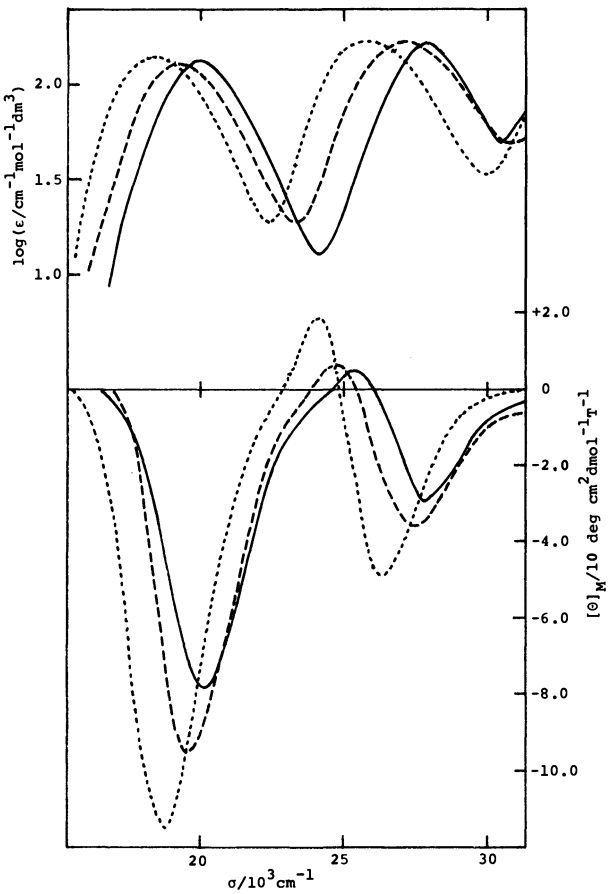

Fig. 1. Absorption and MCD spectra of C_1-*cis(O)*-[Co(gly)$_2$(en)]$^+$ (——), *fac*-[Co(ox)(gly)(en)] (— —), and C_1-*cis(N)*-[Co(ox)(gly)$_2$]$^-$ (----).

In addition, several cobalt(III) complexes, whose second d-d absorption bands were split, were reported by Shibata and his co-workers in the 1970's.[6-12] It is also interesting to know the MCD behavior of those complexes.

In the present paper, newly obtained MCD data regarding seventeen cobalt(III) complexes, including whose second d-d absorption bands are split, are described and discussed in terms of the origin of the positive MCD band.

Experimental

Materials. *mer-trans(NH$_3$)*-[CoCO$_3$(gly)(NH$_3$)$_2$], and *mer-trans(NH$_3$)*-, *mer-cis(NH$_3$)*- and *fac*-[CoCO$_3$(picol)(NH$_3$)$_2$] were prepared according to the method of Shibata et al.[6,11] All the other complexes described in this paper were synthesized by ordinary methods. The absorption and MCD data of *trans*- and *cis*-[Co(OH$_2$)$_2$(en)$_2$]$^+$ were obtained from a 10% HClO$_4$ solution of *trans*-[Co(OH)(OH$_2$)(en)$_2$](ClO$_4$)$_2$ which was provided by T. Komorita. When this solution was kept standing at room temperature for several hours, the absorption spectrum gradually changed with four isosbestic points(Fig. 2). After a week, the maximum data in the first and second d-d absorption bands of the solution approached the known data of *cis*-[Co(OH$_2$)$_2$-

$(en)_2]^{3+}$.[13,14] Then, the spectra found immediately after dissolving and measured after a week were regarded as the spectra of *trans*-$[Co(OH_2)_2(en)_2]^{3+}$ and *cis*-$[Co(OH_2)_2(en)_2]^{3+}$, respectively.

Measuremens. The electronic absorption spectra were measured by a Shimadzu UV-200 and a Hitachi 330 spectrophotometer. The MCD spectra were recorded in a magnetic field of 1.5 T with a JASCO MOE-1 spectropolarimeter. The MCD intensity is expressed in terms of molar ellipticity, $[\theta]_M$, which has the units of deg cm^2 dmol^{-1} T^{-1}. The data of $[Co(acac)_3]$ was obtained in an acetone solution, and *mer*- and *fac*-$[Co(picol)_3]$ were in a 30% $HClO_4$ solution, because they were insoluble or slightly soluble in water. The MCD and electronic absorption spectra of *trans*- and *cis*-$[Co(OH_2)_2(en)_2]^{3+}$ were recorded in a 10% $HClO_4$ solution, as mentioned above. All the other measurements were made in aqueous solutions at room temperature.

Results

The newly obtained MCD data of the seventeen cobalt(III) complexes are listed in Table 1, along with electronic absorption data. Some typical curves in the visible and near-ultraviolet regions are shown in Figs. 2—4.

As can be seen in these Figures, the shapes of the MCD spectra in the first absorption band region ($^1A_{1g}\rightarrow{}^1T_{1g}(O_h)$) are similar to those of the electronic absorption spectra, which indicates that the contribution of the B term is dominant in this region. Such a behavior has also been seen in other cobalt(III) complexes studied earlier.[1]

In the second d-d absorption-band region, however, the pattern of the MCD spectra for several complexes are different from those of the absorption spectra. The MCD behavior observed in the present work can be grouped roughly into the following three types.

In the first type, only a negative band is observed. This is, of course, the most simple pattern, and about half of the complexes listed in Table 1 belong to this type. They are $[Co(NH_3)_6]^{3+}$, $[Co(ox)(NH_3)_4]^+$, $[CoCO_3(en)_2]^+$, $[CoCO_3(NH_3)_4]^+$, *trans*-$[Co(OH_2)_2(en)_2]^{3+}$, *cis*-$[Co(OH_2)_2(NH_3)_4]^{3+}$, and *mer-cis(NH$_3$)*- and *fac*-$[CoCO_3(picol)(NH_3)_2]$.

The MCD spectra of the second type comprise two bands, a small positive band on the lower-energy side

Table 1. Absorption Maximum and MCD Extremum Data in d-d Absorption Band Region

Complex	First d-d band region		Second d-d band region	
	Absorption	MCD	Absorption	MCD
	σ[a] (log ε)[b]	σ[a] ($[\theta]_M$)[c]	σ[a] (log ε)[b]	σ[a] ($[\theta]_M$)[c]

a) Wave numbers are given in 10^3 cm^{-1}. b) Logarithms of the molar absorption coefficients are given in log(ε/cm^{-1} mol^{-1} dm^3). c) Molar ellipticities are given in 10 deg cm^2 dmol^{-1} T^{-1}. d) Shoulders.

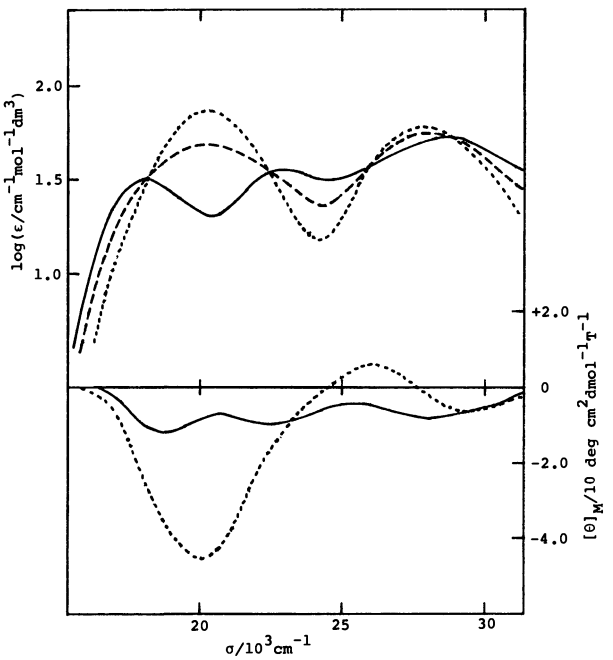

Fig. 2. Spectral change of *trans*-$[Co(OH)(OH_2)(en)_2]^{2+}$ in 10% $HClO_4$ with time: Within 1 h —— (*trans*-$[Co(OH_2)_2(en)_2]^{3+}$), after 2 d — —, and after one week ---- (*cis*-$[Co(OH_2)_2(en)_2]^{3+}$).

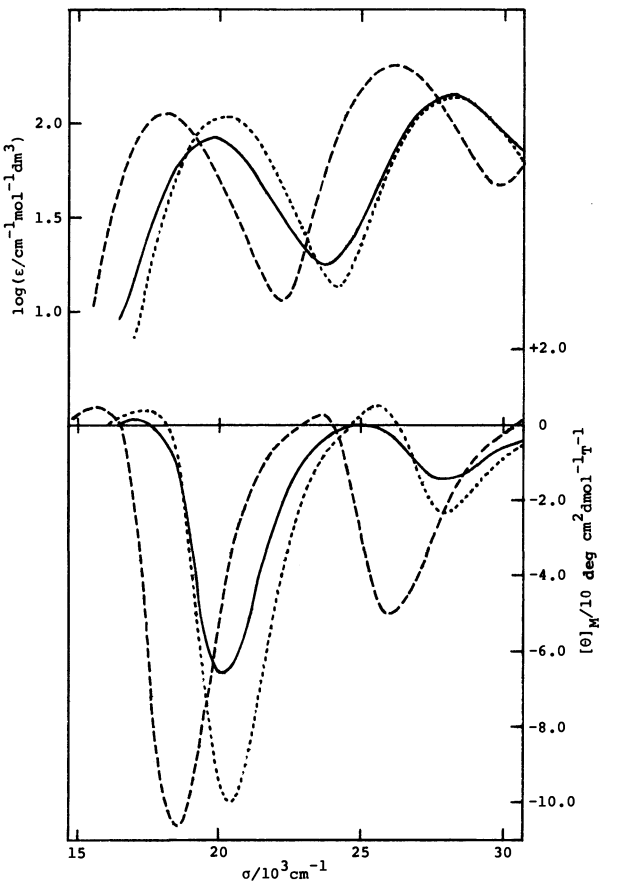

Fig. 3. Absorption and MCD spectra of $[Co(ox)(NH_3)_4]^+$ (——), $[Co(ox)_2(NH_3)_2]^-$ (— —), and $[Co(ox)(en)_2]^+$ (----).

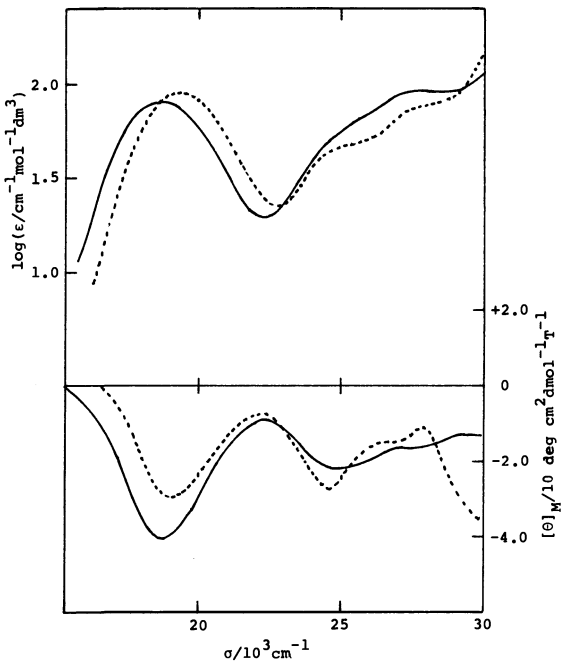

Fig. 4. Absorption and MCD spectra of *mer-trans(NH₃)*-$[CoCO_3(gly)(NH_3)_2]$ (——), and *mer-trans(NH₃)*-$[CoCO_3(picol)(NH_3)_2]$ (----).

and a large negative band on higher-energy side. This pattern is what has been seen in the $[Co(ox)_x(gly)_y(en)_z]$ series complexes.[1] In the present work, *cis*-$[Co(OH_2)_2(en)_2]^{3+}$, *trans(O)*-$[Co(\beta\text{-ala})_2(en)]^+$, *mer-* and *fac*-$[Co(picol)_3]$, *cis*-$[Co(ox)_2(NH_3)_2]^-$, and $[Co(acac)_3]$ show this type spectra.

The tris(trimethylenediamine) complexes, $[Co(tn)_3]^{3+}$, also exhibits two bands whose signs are opposite to each other. In this complex, however, the small band on the lower-energy side is negative and the dominant band on the higher-energy is positive. Since such a unique behavior of the sign of trimethylenediamine complexes has been reported elsewhere,[15] this complex is also included in the second group.

The two complexes which have a split second d–d absorption band, *mer-trans*(NH_3) form of $[CoCO_3(gly)(NH_3)_2]$ and $[CoCO_3(picol)(NH_3)_2]$, show the third type MCD behavior. They exhibit two negative bands in this region; each band is observed in a region corresponding to the component absorption band (Fig. 4).

Discussion

In the previous study on the MCD of $[Co(ox)_x(gly)_y(en)_z]$ series complexes,[1] the positive MCD band in the second d–d electronic absorption band region was suggested to be related to the presence of a coordinated carboxylato group. In the present work this assumption is also applicable for *trans(O)*-$[Co(\beta$-

ala)$_2$(en)]$^+$, *mer*- and *fac*-[Co(picol)$_3$], and *cis*-[Co(ox)$_2$(NH$_3$)$_2$]$^-$, which have coordinated carboxylato ligands and show a positive band. For [Co(ox)(NH$_3$)$_4$]$^+$, however, only a negative band is observed, in spite of the presence of two carboxylato groups. On the other hand, the two complexes which have no carboxylato ligands, [Co(tn)$_3$]$^{3+}$ and *cis*-[Co(OH$_2$)$_2$(en)$_2$]$^{3+}$, exhibit a positive band. From these facts, the previous suggestion that the origin of the positive band is connected with the presence of a coordinated carboxylato ligand will require reconsideration.

In the oxalato complexes, it is noticeable that the different types of MCD behavior is observed for a tetraammine-type complex of [Co(ox)(NH$_3$)$_4$]$^+$ (group 1), from a diammine-type complex of [Co(ox)$_2$(NH$_3$)$_2$]$^-$ and a bis(ethylenediamine)-type complex of [Co(ox)(en)$_2$]$^+$ (group 2), as can be seen in Fig. 3. The same aspect with the latter was also seen in another study on the MCD of (amino acidato)cobalt(III) complexes.[16] A positive band was observed in bis(ethylenediamine) complexes, [Co(amac)(en)$_2$]$^{2+}$, but not in tetraammine-type complexes, [Co(amac)(NH$_3$)$_4$]$^{2+}$, in which amac denotes glycinato and DL-alaninato ligands. Additionally, a positive band was not observed in the pentaammine-type complexes of [Co(Hamac)(NH$_3$)$_5$]$^{3+}$ either (Hamac=glycine, L-alanine, L-serine, L-phenylalanine and β-alanine).

In the three diaqua complexes, *trans*- and *cis*-[Co(OH$_2$)$_2$(en)$_2$]$^{3+}$ and *cis*-[Co(OH$_2$)$_2$(NH$_3$)$_4$]$^{3+}$, the positive band is observed only in *cis*-[Co(OH$_2$)$_2$(en)$_2$]$^{3+}$. Because other complexes studied to date have shown the same MCD-spectra pattern among their geometrical isomers, e.g., C_2-cis, C_1-cis and trans isomers of [Co(gly)$_2$(en)]$^+$ and [Co(ox)(gly)$_2$]$^-$ and mer and fac isomers of [Co(gly)$_3$], [Co(picol)$_3$], and [Co(ox)(gly)(en)], this difference in the MCD between the trans and cis isomers of [Co(OH$_2$)$_2$(en)$_2$]$^{3+}$ is interesting.[1]

As a result of these observations, it can be pointed out that the complexes exhibiting a positive band (group-2 complexes in the present work and the [Co(ox)$_x$(gly)$_y$(en)$_z$] series complexes in previous work) are all tris(chelate) or *cis*-bis(chelate) type. This fact leads us to a new assumption that the existence of the positive MCD band in question can be associated with a particular arrangement of two or three chelate rings.

It is reasonable to consider that the MCD behavior is affected by the arrangement of the chelate rings. For example, a D_3 or a pseudo D_3 symmetrical field would be produced around the central metal atom in tris(chelate)- and *cis*-bis(chelate)-type complexes. Then, the origin of the positive band might be associated with the electronic transition split in a D_3 (or pseudo D_3) symmetrical field caused in such a way. Namely, this band is assignable to one of the two component bands of E and A_1 in the T_{2g} (O_h) transition, which have opposite signs to each other. As an alternative explanation, it is also reasonable to consider that this band appears as a positive wing of the A term, which exhibits a dispersion-type curve, in a degenerated component of E in a D_3 (or pseudo D_3) symmetrical field. Although a full explanation can not be offered at the present stage, all experimental facts described above can be explained well from this assumption.

The tris(chelate)-type complex of [Co(en)$_3$]$^{3+}$ has not exhibited a positive band, as mentioned above. The MCD curve of this complex, however, is considerably asymmetrical and its shape suggests that a small positive band on the lower-energy side is hidden by a successive large negative band.[1]

The complexes containing a carbonato chelate ligand do not show a positive band either, even though they are the tris(chelate) or *cis*-bis(chelate) type. This might be explained in terms of distorted structures, which is brought about by a four-membered carbonato chelate ring. For example, it has been reported for [CoCO$_3$(NH$_3$)$_4$]$^+$ that the bite angle of the carbonato chelate ring is 70° and that the distance of the Co–N bond containing the nitrogen atom at a position trans to the carbonato oxygen atom is considerably longer (2.03 Å) than those containing the nitrogen atoms at the cis positions (1.93 and 1.95 Å).[17] Thus, the complexes containing a chelated carbonato ligand are inadequate for determining the MCD behavior in parallel with the other tris(chelate) or *cis*-bis(chelate) type complexes which have nearly octahedral structures.

The two complexes which have a split second d–d absorption band, *mer-trans(NH$_3$)*-[CoCO$_3$(gly)(NH$_3$)$_2$] and [CoCO$_3$(picol)(NH$_3$)$_2$], show two MCD bands in the corresponding regions (Fig. 4). Because their signs are both negative and their positions are almost the same as those of the component electronic absorption bands, each MCD band in both complexes is assignable to have a dominant B term character.

Spectroscopic and MO Study of Peptide Models for the M_{412} Intermediate of Bacteriorhodopsin. N^{ε}-Retinylidenelysyl Peptides Containing Aromatic Amino Acids

Minoru SAKURAI,* Satoshi TOMOMASA, Yûji SEIYA, Yoshio INOUE, and Riichirô CHÛJÔ
Department of Polymer Chemistry, Tokyo Institute of Technology, 12-1 Ookayama 2-Chome, Megro-ku, Tokyo 152
(Received April 30, 1985)

N^{ε}-Retinylidenelysyl peptides containing Tyr and Phe were prepared in order to investigate the effect of the surrounding microenvironment on the absorption maximum of the chromophore of bacteriorhodopsin. The absorption maximum of the retinylidene Schiff base of the lysyl peptide, Boc-Lys-Phe(or -Gly)-Tyr-OMe, was shifted to the red relative to the peptides lacking Tyr, Boc-Lys-Phe-Phe-OMe and Boc-Lys-Phe-OMe. UV and ^{13}C NMR studies on the Tyr-containing lysyl-peptide have confirmed an intramolecular interaction between Tyr and the retinylidene portion in low dielectric media. A hydrogen-bond formation of the Schiff base with a Tyr side chain is supported by a theoretical estimation of the transition energy and the shielding constants for some models of Tyr-Schiff base complexes. The side-chain conformation of the Tyr-contaning lysyl-peptide is discussed in terms of the ^{1}H NMR data. The hydrogen-bonding shift induced by Tyr was estimated as being no less than 10 nm.

Bacteriorhodopsin (bR) acts as a light-driven proton pump in the plasma membrane of halobacteria.[1] The chromophore of bR is a retinal Schiff base formed with Lys 216.[2,3] It is protonated in the initial state[4] and becomes deprotonated upon being illuminated (intermediate M_{412}).[5-7] The absorption maximum of the M_{412} is shifted considerably towards the red compared with an unprotonated retinal Schiff base, e.g., *N*-retinylidenebutylamine. This shift should be induced by neighboring amino acids of the chromophore.

Recent reports on the chemical modifications of bR[8-10] and the pH dependence of the M_{412} formation[11-14] have shown that tyrosine is one possible candidate near the Schiff base in bR. Following Engelman's model,[15] which was built on the basis of X-ray diffraction data of bR, helices A, B, and F were formed to lie close to helix G containing Lys 216 and involve several tyrosine residues. Therefore, it is interesting to study to what extent the absorption maximum is shifted by one tyrosine spatially arranged near a Schiff base using artificial pigments.

It has been demonstrated[16-18] that N^{ε}-retinylidenelysyl peptides are useful models to study specific interactions between a Schiff base and an amino acid. However, the mechanism of the spectral shift in such an artificial pigment has not been fully clarified. Preliminary consideration using the CPK model showed that several types of interactions involving a hydrogen bond are possible between Tyr and the Schiff base in tripeptide Lys(Ret)-X-Tyr, where Ret and X stand for the N^{ε}-retinylidene group and one of the common amino acids, respectively. We prepared Boc-Lys(Ret)-Phe-Tyr-OMe **1**, Boc-Lys(Ret)-Gly-Tyr-OMe **2**, Boc-Lys(Ret)-Phe-Phe-OMe **3**, Boc-Lys(Ret)-Phe-OMe **4**, where Boc is an abbreviation for a *t*-butoxycarbonyl group.

Here, we report that the absorption maximum of an unprotonated retinal Schiff base is shifted to the red by the perturbation of one tyrosine. Furthermore, we discuss the origin of the red shift on the basis of UV, ^{1}H and ^{13}C NMR spectra, and a MO calculation.

Theoretical

A ^{13}C NMR chemical shift was estimated according to a theory of Karplus and Pople[19] incorporated into the CNDO/S method.[20] The average excitation energy, ΔE, was taken as 10.0 eV. The details of the procedure were given in a previous paper.[21] The calculation of the π-π^* transition energy was carried out using the CNDO/S method. Some modifications have been proposed for the CNDO/S parameters from the originating laboratory.[22,23] According to these reports, coulomb integrals were estimated using the Nishimoto-Mataga formula and reevaluated values were used for core and bonding parameters. The lowest energy (60 configurations) of all single excitations were included in the configuration-interaction calculations.[23]

These calculations would have been computationally intractable if the entire framework of the retinylidene peptide was included. It has been shown that neglecting the C_9 and C_{13} methyl groups and the saturated carbon region of the β-ionylidene ring does not introduce any serious error to the results concerning the electronic structure.[24,25] We, therefore, approximate the retinal portion as *all-trans N*-undecapentylidenemethylamine (hereafter abbreviated as NUPM). The molecular geometry was derived from crystallographic data.[26] The other portion of the retinylidene peptide was represented by the phenol ring of Tyr. The orientation of the phenol ring to the polyene chain was determined based on a

CPK model of the peptide containing all atoms.

Experimental

All peptides were synthesized by conventional solution phase procedures, using dicyclohexylcarbodiimide as a coupling regent. The Boc group was used for α-amino group protection and methyl ester for the carboxyl group. The ε-amino group of the lysine residue was protected with a benzyloxycarbonyl group during the coupling reaction. The protecting group on the lysine side chain was removed in the final step by catalytic hydrogenation using palladium-charcoal in a methanol-acetic acid 1:1 solvent. The final products were recrystallized from ethyl acetate-hexane. All the intermediate and final products were identified by their ^{13}C NMR spectra and their purities were checked by TLC. Retinylidene peptides were prepared by keeping a mixture of *all-trans* retinal and the peptide (1:1 mole ratio) in ethanol with anhydrous potassium carbonate. The products were recrystallized from ethanol-hexane. *All-trans* retinal and *all-trans* *N*-retinylidenebutylamine-(NRB) were synthesized according to the procedure given in a previous paper.[27] All the Schiff bases were handled under a dim red light.

Absorption spectra were recorded on a Beckman model 25 spectrometer. ^{13}C NMR spectra were recorded on a JNM JEOL PS-100 spectrometer equipped with a PFT-Fourier transform system at 25.15 MHz. ^{1}H NMR spectra were recorded on a JEOL FX-400 spectrometer at 399.65 MHz. Unless otherwise noted, all spectroscopic measurments were made at 31±1 °C. Solvents (CCl_4, $CHCl_3$, and CH_3OH) used in absorption studies were spectral grade and were purchased from Tokyo Kasei Co., Tokyo. Perdeuterated dimethyl sulfoxide (DMSO-d_6), CD_3OD, and $CDCl_3$ were purchased from Merck Sharp & Dohme Canada, Ltd.

^{13}C NMR signals of the peptide portion of compounds **1**—**4** were assigned by comparisons with the spectra of their fragment peptides and the monomers.[28] The signals of the retinylidene portion were easily assigned by comparisons with the spectrum of NRB.[27,29] ^{1}H NMR resonances were assigned on the basis of their multiplet structure, selective homo-spin decoupling and a comparison with the literatures.[30,31]

The calculation was carried out with a HITAC M-200H computer system.

Results and Discussion

Identification of Retinylidenelysyl Peptides 1—4 by ^{13}C NMR and UV Spectroscopy. Figure 1 shows the ^{13}C NMR spectra of compund **1** together with that of NRB in CD_3OD. The signals corresponding to the peptide carbons (except the C_ε of Lys) were assigned by comparisons with the spectrum of compound **1'**, Boc-Lys-Phe-Tyr-OMe, under the assumption that the chemical shifts of these carbons are little changed by a Schiff base formation. The other signals were assigned by comparisons with the spectrum of NRB. As shown in Fig. 2, the signals corresponding to C_{10} and C_5 overlap with those of the $C_{2,6}$ of Tyr and Phe, respectively. There are no signals suggesting to the free retinal nor the C_ε of Lys having a free ε-amino group. This fact indicates the complete conversion of retinal to the Schiff base form. The chemical shifts of the retinylidene portion are in good agreement with those of the corresponding carbons for *all-trans* NRB. Therefore, the polyene chain was identified as an all-trans configuration. Similar results were also obtained for compounds **2**—**4**. The

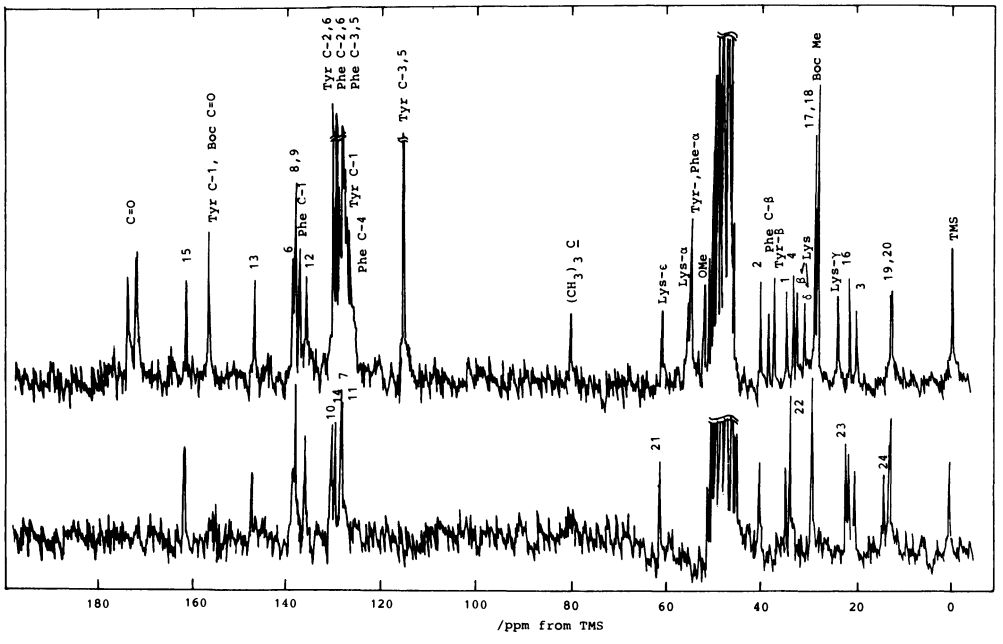

Fig. 1. ^{13}C NMR spectra of compound **1** and NRB at concd 0.1 mol dm^{-3} in CD_3OD.

peak assignments of compounds **1**—**4** are summarized in Table 1 together with those of compound **1'**, retinal and NRB.

Figure 3-a shows the absorption spectrum of compound **1** in methanol. The main peak is shifted to the blue by 15 nm compared with the *all-trans* retinal. This is consistent with the blue shift observed in the formation of NRB. The peak at 275 nm was assigned to the π-π^* transition of the aromatic rings by a comparison with the absorption spectrum of compound **1'**.

UV and ^{13}C NMR Spectra of the Retinylidene-lysyl Peptides in Low Dielectric Media. Table 2 summarizes the absorption maxima of compounds **1**—**4** and NRB in different solvents. In the halogenated solvents and in hexane, the absorption maxima of compounds **1** and **2** (which contain Tyr) were shifted to the red compared with other compounds. The concentration dependence of the absorption maximum of compound **1** was examined in carbon tetrachloride. There was no change in the band position in the observed concentration range(10^{-4}—10^{-5} mol dm^{-3}). Figure 4 shows the temperature dependence of the absorption maxima of compounds

Table 1. The Peak Assignments of Retinylidenelysyl Peptides **1**—**4**, *all-trans* NRB and *all-trans* Retinal in CD_3OD at 0.1 M[a)]

Methanol	365	364	365	364	365

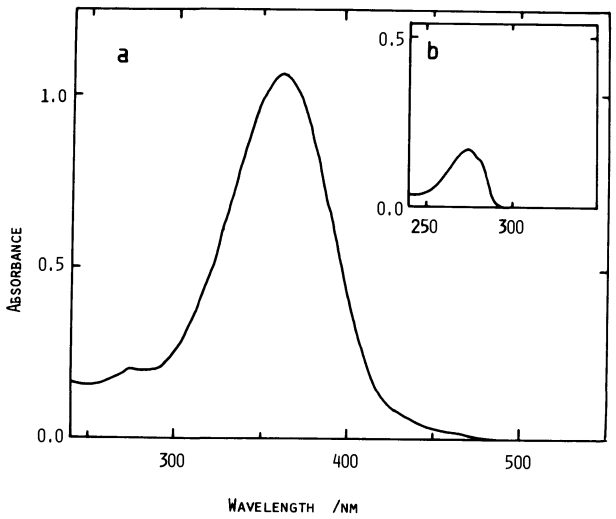

Fig. 3. (a) Absorption spectrum of compound **1** in methanol. (b) Absorption spectrum of the peptide, Boc-Lys-Phe-Tyr-OMe.

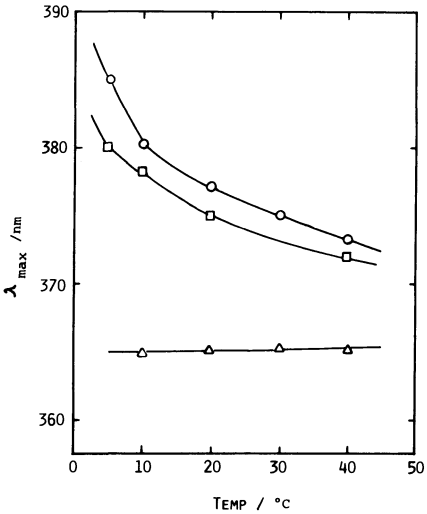

Fig. 4. Temperature dependence of the absorption maxima of compounds **1**, **2**, and **4** in carbon tetrachloride. ○: Compound **1**, □: compound **2**, △: compound **4**.

1, **2**, and **4** in carbon tetrachloride. Upon lowering the temperature from 40 to 5°, the absorption maxima of compounds **1** and **2** shifted to the red by 10 nm, but no apparent shift was detected for compound **4**. These results clearly indicate an intramolecular interaction between the retinylidene chromophore and Tyr in compounds **1** and **2**.

This interaction is also supported by the difference in the chemical shifts between compound **1** and NRB. Figure 5-a shows the chemical-shift difference($\Delta\delta$) along the polyene chain going from NRB to compound **1** in carbon tetrachloride. The magnitude of the chemical-shift difference alternates between odd- and even-numbered carbons, and the amplitude of the alternation decreases in going from the terminal nitrogen to the β-ionylidene ring. This behavior of the chemical shifts suggests an increase in the electronic polarization of the C=N bond going from NRB to compound **1**. There may be an electron-withdrawing group or a positive charge near the Schiff base nitrogen.

The absorption spectrum of a mixture of NRB and the protected tyrosine (Boc-Tyr-OMe) in carbon tetrachloride was observed. No apparent shift was detected within an observed molar ratio (Boc-Tyr-OMe/NRB) of 1—1000, with the concentration of NRB being kept constant at 3×10^{-5} mol dm^{-3}. This means that the intermolecular interaction is less

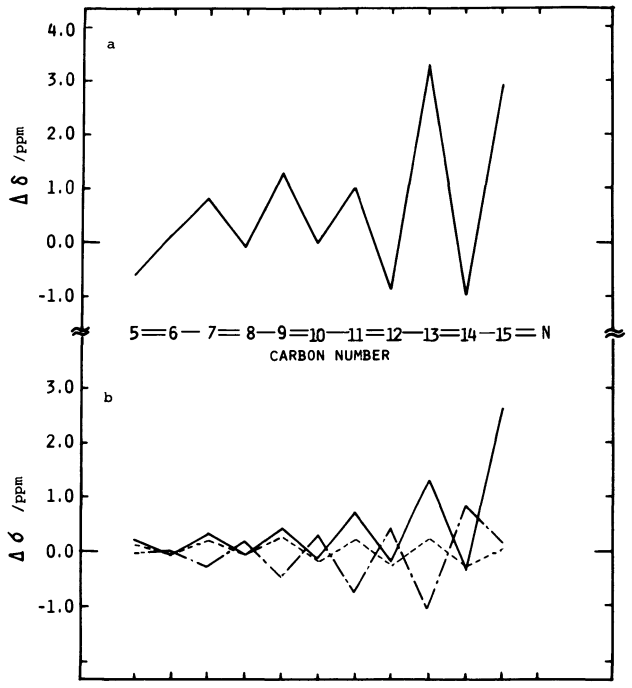

Fig. 5. Observed (a) and calculated (b) chemical shift differences of the polyene chain carbons going from the isolated Schiff base to each of the complexes as shown in Fig. 6.
(b) ——: Complex I, ——: complex II, ----: complex III.

important in a dilute solution, although a weak hydrogen-bond has been detected in more concentrated solutions (0.5 mol dm^{-3}) by IR spectra.[32] It is clear that in compounds **1** and **2** the peptide framework plays an essential role in the spatial arrangement of the tyrosine side chain to the Schiff base.

Theoretical Analysis of the UV and ^{13}C NMR Spectra of Retinylidenelysyl Peptides 1 and 2. CNDO/S calculations showed that the dipole moment of the unprotonated retinal Schiff base is directed perpendicular to the polyene axis on the polyene plane in the ground state. Bt upon excitation to the first excited state its direction becomes nearly parallel to the axis, and its magnitude increases from 2.7 to 3.7 D. Assming that a dipole-dipole type interaction is the main contributor to the spectral shift, this suggests that the π-π^* band of the Schiff base is effectively red-shifted by an electric dipole oriented antiparallel to the polyene axis. On the basis of CPK modeles of compounds **1** and **2**, three types of Tyr-Schiff base complexes were selected as association models. The geometrial configurations of these complexes are shown in Fig.6. Complexes I and II correspond to the models for a hydrogen-bond formation and stacking, respectively. In complex III, the C_1-O bond of the phenol ring is arranged parallel to the polyene axis. The phenol ring is coplanar to the polyene plane in complexes I and III.

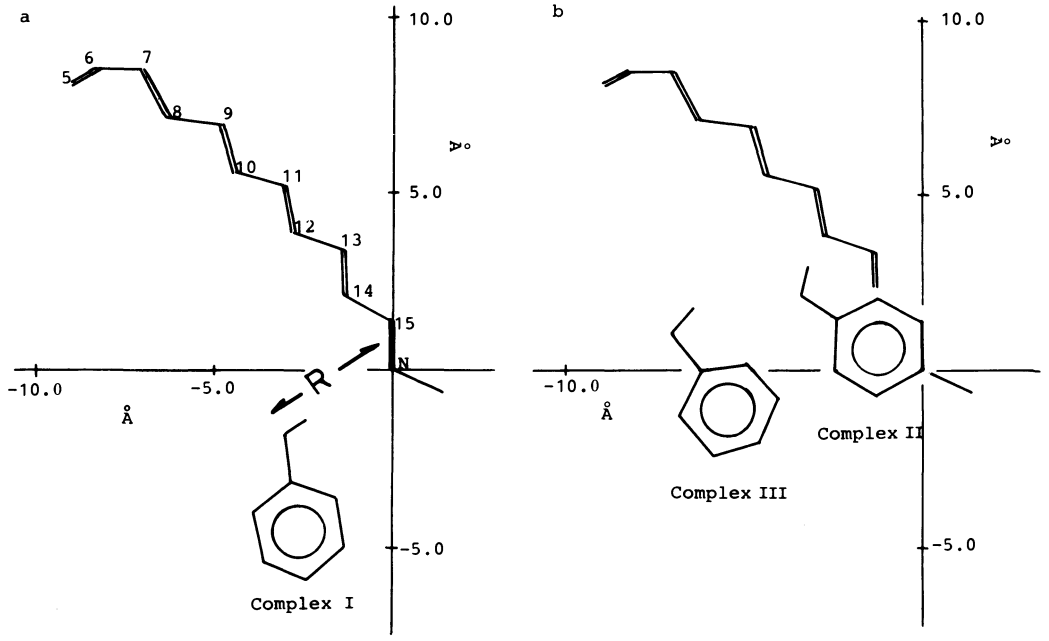

Fig. 6. The geometrical configurations of complexes between NUPM and the phenol ring assumed in the calculations.
(a) Complex I: hydrogen-bonding model. OH bond is placed on the extended line of the lone pair electron. (b) Complex II: stacking model. C_2, C_3, and C_4 of phenyl ring is placed 3 Å above C_{14}, C_{15} and N atoms, respectively. (c) Complex III: parallel model.
C_1-O bond of the phenol ring is arranged parallel to the polyene axis on the polyene plane.

Table 3. The Transition Energies, E_{tran}, of NUPM and the Complexes, and the Complex Formation Energies, ΔE_{compl}, in the Ground State

Compound	E_{tran}/eV(nm)	ΔE_{tran}/eV	ΔE_{compl}[c]/eV
NUPM	3.79(327.5)	0	—
Hydrogen bonding	3.73(331.6)	0.06	0.26
Stacking	3.69(335.7)	0.10	0.07
Parallel	3.78(328.3)	0.01	—
Compound **1**	3.31(375)[a]	0.09[b]	—

a) Observed in CCl_4 at room temperature. b) ΔE_{tran} was evaluated by subtracting E_{tran} of compound **1** from that of NRB. c) ΔE_{compl} means the energy change going from the isolated Tyr+isolated NUPM system to the complex. This was estimated by CNDO/2 method.

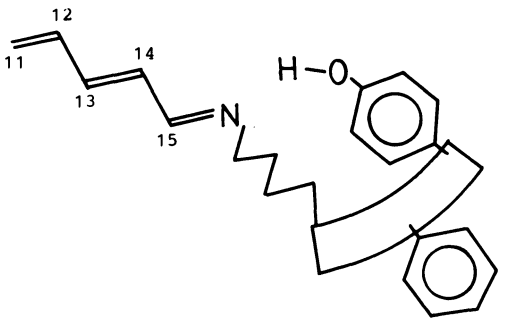

Fig. 7. Schematic representation of the overall conformation of compound **1** in low dielectric media based on CPK model considerations. The side chain of Tyr is oriented to the Schiff base. The steric hindrance about C_α–C_β bond of Phe is minimized.

Table 3 summarizes the transition energies (E_{tran}) of these complexes and NUPM, and also the complex formation energies (ΔE_{compl}) in the ground state. The complex formation energy is estimated as follows,

$$\Delta E_{compl} = E_s + E_t - E_{compl}$$

where E_s, E_t, and E_{compl} corresponds to the total energy of NUPM, the phenol ring and the respective complexes. The hydrogen bond length (R) and the O–H length were taken as 2.6 and 0.96 Å, respectively. The former value corresponds to the minimum energy structure in the ground state (determined by CNDO/2 calculations). In the other complexes, a van der Waals contact was assumed between the Schiff base and the phenol ring. The tyrosine+Schiff base system is stabilized by forming complex I or II. The transition energy decreases upon going from an isolated tyrosine (NUPM) to complex I or II. Figure 4-b shows the calculated chemical shift differences ($\Delta\delta$) going from NUPM to each of the complexes. The zigzag pattern (similar to Fig. 4-a) was reproduced in the formation of complex I. Consequently, the hydrogen-bonding model (complex I) is uniquely acceptable as an association model in compound **1**.

The hydrogen-bond length dependence was studied for the transition energy of complex I. Its values at R=2.8, 3.0 and 3.6 Å are 3.76, 3.77, and 3.79 eV, respectively. The transition energy rapidly approaches the value at an infinite bond length (3.79 eV). This explains the highly sensitive blue-shift of the absorption maxima of compounds **1** and **2** with a rise in temperature (Fig. 3). The second amino acid, Phe, of compound **1** is more bulky relative to Gly of compound **2**. The difference in the hydrogen-bond length, depending on the peptide framework, may induce a slight difference in the absorption maxima between these compounds.

NRB shows an absorption maximum at 376 nm in 2-chloroethanol,[33] which is a weaker hydrogen-bonding molecule (pK_a=14.3) relative to the tyrosine side chain (pK_a=11.1). Considering the case of NRB, a lower limit in the hydrogen-bond shift induced by a tyrosine side chain can be estimated as about 10 nm, according to the temperature dependence of the absorption maxima of compounds **1** and **2**.

Figure 7 shows a schematic representation of the overall conformation of compound **1** as predicted from the CPK model under the assumption of Tyr-Schiff base hydrogen bonding. The peptide backbone is folded to form the hydrogen bond. The side chain of Phe is exposed to the solvents.

The effect of a π-charge transfer interaction was examined in the above hydrogen-bonding system. A total charge transfer of 0.08 was found from the polyene part to the phenol ring in both the ground state and the first excited state, but the total π-charge density on the phenol ring was kept constant during hydrogen-bond formation. This means that the effect of a π-charge-transfer interaction is negligible in this system. This is in agreement with a report of Komatsu and Suzuki.[34] It seems that the hydrogen-bonding shift is chiefly induced by a dipole-dipole type of interaction between the Schiff base and Tyr.

Conformational Analysis of Retinylidenelysyl Peptide 1 by ^{1}H NMR. Table 4 summarizes the observed vicinal spin–spin coupling constants between α- and β-protons and the rotamer populations of compounds **1** and **1′**. Figure 8 shows the Newman projection of three staggered rotamers about the C_α–C_β bond of the side chain. Fractional populations P_I, P_{II}, and P_{III} were estimated by the following equations:

$$P_I = (J_{\alpha\beta A} - J_g)/(J_t - J_g) \quad (1)$$

$$P_{II} = (J_{\alpha\beta B} - J_g)/(J_t - J_g) \quad (2)$$

$$P_{III} = 1 - (P_I + P_{II}), \quad (3)$$

where $J_{\alpha\beta A(\text{or B})}$ represents the observed coupling

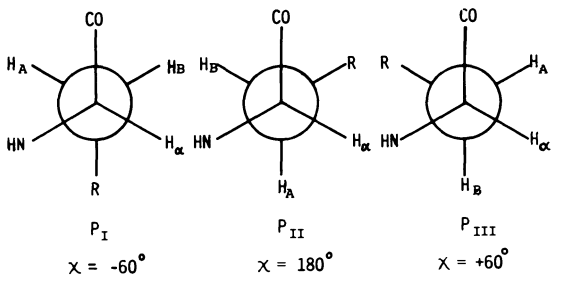

Fig. 8. Three stable rotamers about C_α–C_β bond and their notations.

Table 4. Proton Coupling Constants (Hz) and Rotamer Populations of Compounds **1** and **1′**

Compound	Residue	$J_{\alpha\beta A}$	$J_{\alpha\beta B}$	P_I	P_{II}	P_{III}
1′ a)	Phe	8.08	5.84	0.50	0.30	0.20
	Tyr	9.04	4.88	0.59	0.21	0.20
1′ b)	Phe	8.68	5.88	0.56	0.30	0.15
	Tyr	7.36	5.36	0.43	0.25	0.31
1 b)	Phe	6.60	6.00	0.37	0.31	0.33
	Tyr	8.04	5.88	0.50	0.30	0.21

a) Observed in DMSO-d_6. b) Observed in $CDCl_3$: DMSO-d_6=9 : 1.

constant between α- and βA (or βB)-protons, and J_t and J_g are the values of $^3J_{\alpha\beta}$ for the protons whose relative conformations are trans and gauche, respectively. The values of J_t and J_g are taken from Pachler's report:[35] J_t=13.56 Hz and J_g=2.60 Hz.

The relative rotamer populations of Phe in compound **1′** are almost independent of the solvent polarity. Accompanied by the formation of the Schiff base linkage, P_I decreases along with an increase in P_{III}, while P_{II} is kept constant. Consequently, three rotamers are equally populated in compound **1** in less polar solvents. This means that the side chain of Phe is randomly interconverted among the three rotamers during equilibrium. On the other hand, the rotamer population about the C_α-C_β bond of Tyr is non-random in compound **1**, with a prefered orientation of rotamer I. It seems that the conformational stability of each side chain based on a $^3J_{\alpha\beta}$ analysis is consistent with that predicted from the spatial arrangement of the side chains (Fig. 7).

In conclusion, a proximal tyrosine residue induces the red shift of the π-π^* band of an unprotonated retinal Schiff base through the hydrogen bond in a lower dielectric media. This hydrogen-bonding shift is estimated to be no less than 10 nm. The temperature coefficient, $d\lambda_{max}/dT$, was considerably large in the artificial pigments used. The hydrogen-bonding shift reached 20 nm at 5 °C. The absorption maximum of the M_{412} intermediate was shifted to the red by 47 nm compared with that of NRB in carbon tetrachloride at 30 °C. A significant part of the red shift in the M_{412} could be explained by the hydrogen-bond formation between the Schiff base and a proximal tyrosine.

The authors wish to express their thanks to Professor Isao Ando of Tokyo Institute of Technology for the use of the CNDO/2 program and his helpful discussions. We also would like to thank Dr. Shigetoshi Amiya of the Central Research Laboratories of Kuraray, Co. Ltd., Japan, for ^{1}H NMR spectra. We thank the Computer Center, Institute for Molecular Science, for the use of the HITAC M-200H computer.

^{13}C and ^{1}H NMR of α-Arylnitrones. Substituent Effects on the α-Position of α-(*p*-Substituted Phenyl)nitrones

Chino YIJIMA, Toshio TSUJIMOTO, Kohji SUDA,* and Masashige YAMAUCHI†
Department of Physical Chemistry, Meiji College of Pharmacy, 1-35-23, Nozawa, Setagaya-ku, Tokyo 154
†Faculty of Pharmaceutical Sciences, Josai University, Keyakidai, Sakado, Saitama 350-02
(Received November 26, 1985)

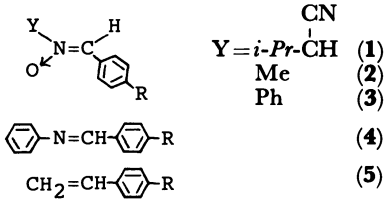
Substituent effects on the ^{13}C and ^{1}H NMR chemical shifts of the α-position of various α-(*p*-substituted phenyl)nitrones, α-phenyl-*N*-(1-cyano-2-methylpropyl)nitrones (**1**), α-phenyl-*N*-methylnitrones (**2**), and α-phenyl-*N*-phenylnitrones (**3**), have been investigated and the obtained results have been compared with data related to *N*-(*p*-substituted benzylidene)anilines (**4**) and reported data for *p*-substituted styrenes (**5**). The chemical shifts of the α-arylnitrones are well correlated with substituent constants by means of a linear combination of two empirical parameters, σ_I and σ_π. Inductive effects predominate at the α-carbon but resonance effects predominate at the α-hydrogen.

Much attention has been paid to the chemistry of nitrones because of their widely applicable reactivities.[1-3] 1,3-Dipolar cycloadditions of nitrones and their functionalizations at the α-position have great synthetic utilities.[3]

Nitrones have a positive charge on the nitrogen atom which can be delocalized between the nitrogen atom and the α-carbon atom.[1] The extent of the delocalization is naturally influenced by substituents on the α-carbon and the nitrogen. An understanding of the electronic behavior of the α-position is, therefore, one of the essential subjects in nitrone chemistry.

NMR spectroscopy is a powerfull tool for studying the electronic behavior of the nitrone function and a few attempts have been made to correlate electronic substituent constants with the chemical shifts of nitrones.[4] However, they are still lacking an adequate explanation regarding this subject. In a recent study of substituent effects on the ^{1}H and ^{13}C NMR spectra of α, *N*-diarylnitrones, Arumugam et al.[5] found a linear correlation between the chemical shifts of the α-proton ($^{1}H_\alpha$) and the Hammett σ_p parameters or the Swain-Lupton *F* and *R* parameters. Their analyses, however, have left some important problems, especially concerning the correlation with the chemical shifts of the α-carbon of a series of α-arylnitrones: the parameters they used showed no correlation with these chemical shifts which would give more direct information about the mechanisms of the transmission of substituent effects on the α-position. As a primary approach, it is necessary to decide whether this is due to the use of inappropriate parameters or to contributions from substituent effects other than inductive and resonance ones.

The present work is concerned with a systematic investigation of the effects of substituents in the phenyl ring on the α-position of various α-arylnitrones, α-(*p*-substituted phenyl)-*N*-(1-cyano-2-methylpropyl)nitrones (**1**), α-(*p*-substituted phenyl)-*N*-methylnitrones (**2**) and α-(*p*-substituted phenyl)-*N*-phenylnitrones (**3**), by means of ^{13}C and ^{1}H NMR spectroscopy. For a comparison, *N*-(*p*-substituted benzylidene)anilines (**4**) and *p*-substituted styrenes (**5**) have been investigated.



Experimental

Materials. 2-(Hydroxyamino)valeronitrile[6] and *N*-phenylhydroxylamine[7] were prepared and purified according to procedures described in the literature. *N*-Methylhydroxylamine was synthesized according to a reported method[8] with a little modification.

The nitrones used were generally prepared by the condensation of an apporopriate *N*-substituted hydroxylamine with *p*-substituted benzaldehydes in ethanol and purified by recrystallization from ethanol, ethanol-hexane or benzene-hexane.

N-(*p*-Substituted benzylidene)anilines were prepared by the literature method.[9]

Melting points (uncorrected, °C) of the compounds prepared are as follows. **1a**, 154.5—155.5; **1b**, 135—136; **1c**, 114—115; **1d**, 112.5—113.5; **1e**, 93—93.5; **1f**, 114—114.5; **1g**, 139; **1h**, 117.5—118.5; **1i**, 125—126; **2a**, 106—107 (lit, 105[10]); **2b**, 123.5—124, (lit, 120.5[11]); **2c**, 82.5—83; **2d**, 109—110; **2e**, 130—131, (lit, 127.5—128[11]); **2f**, 129.5—130; **2g**, 193—193.5 (lit, 187[11]); **2h**, 222—223, (lit, 206—207[11]); **3a**, 142—143; **3b**, 116—117; **3c**, 165—166; **3d**, 89—90, (lit, 95,[12] 85—87[4b]); **3e**, 105—106, (lit, 114,[12] 113—113.5[4b]); **3f**, 136—137; **3g**, 154—155; **3h**, 169—170, (lit, 165,[12] 161.5—162[4b]); **3i**, 133—134, (lit, 155.5—156[4b]); **3j**, 157—158, (lit, 147—149[4b]); **3k**, 193—194, (lit. 187,[12] 186—186.5[4b]); **4a**, 98—99; **4b**, 56—57, (lit, 63—64[13]); **4c**, 78—79; **4d**, 43.5—44.5, (lit, 146—147/3 mmHg[13] (1 mmHg=133.322 Pa)); **4e**, 50.5—51.5; **4f**, 42—43; **4g**, 64—65; **4h**, 73.5—74; **4i**, 76—77, (lit, 125.5—126.5[13]); **4j**, 97—98; **4k**, 91—92.

Compounds, **1a**, **1e**, **1g**, **2d**, **3c**, **3f**, **4c**, **4f**, and **4j** are new and their elemental analyses are as follows:

(**1a**) Found: C, 68.45; H, 8.01; N, 16.72%. Calcd for $C_{14}H_{19}N_3O$: C, 68.54; H, 7.81; N, 17.13%.

(**1e**) Found: C, 65.26 H, 5.95; N, 12.59%. Calcd for $C_{12}H_{13}FN_2O$: C, 65.43; H, 5.96; N, 12.72%.

(**1g**) Found: C, 51.22; H, 4.66; N, 9.91%. Calcd for $C_{12}H_{13}BrN_2O$: C, 51.25; H, 4.67; N, 9.96%.

(**2d**) Found: C, 63.01; H, 5.21; N, 9.21%. Calcd for C_8H_8FNO: C, 62.73; H, 5.28; N, 9.15%.

(**3c**) Found: C, 69.08; H, 5.20; N, 5.65%. Calcd for $C_{14}H_{13}NOS$: C, 69.11; H, 5.39; N, 5.75%.

(**3f**) Found: C, 72.58; H, 4.53; N, 6.48%. Calcd for $C_{13}H_{10}FNO$: C, 72.54; H, 4.68; N, 6.51%.

(**4c**) Found: C, 73.86; H, 5.65; N, 6.16%. Calcd for $C_{14}H_{13}NS$: C, 73.99; H, 5.77; N, 6.16%.

(**4f**) Found: C, 78.13; H, 4.79; N, 7.00%. Calcd for $C_{13}H_{10}FN$: C, 78.37; H, 5.06; N, 7.03%.

(**4j**) Found: C, 81.60; H, 4.70; N, 13.48%. Calcd for $C_{14}H_{10}N_2$: C, 81.53; H, 4.89; N, 13.58%.

NMR Measurement. The ^{13}C NMR spectra were measured at 67.8 MHz on a JEOL GX-270 spectrometer under a pulse Fourier transform mode. A spectral width of 17000—18000 Hz was used with 16K (resolution 2.4 Hz) data points. ^1H NMR spectra were obtained on a JEOL PS-100 NMR spectrometer operating at 100 MHz for **1**, at 270 MHz on a JEOL GX-270 NMR spectrometer for **2**, and at 90 MHz on a Hitachi Perkin Elmer R-22 NMR spectrometer for **3** and **4**. Sample solutions were prepared in a concentration of ca. 0.5 M (mol dm^{-3}) for ^{13}C NMR and 0.25 M for ^1H NMR spectra with $CDCl_3$ (99.8%, Merck) containing 1% TMS (tetramethylsilane) as an internal standard. Sample tubes with a 5-mm diameter were used and the probe was at room temperature.

$^{13}C_\alpha$ signals were assigned on the basis of their peak heights and the off-resonance decoupling method. $^1H_\alpha$ signals were either assigned on the basis of an integration of their peak areas or identified by a comparison of their chemical shifts with the spectral data of authentic samples.[4b,10,13]

Parametrizations of the simple HMO method were carried out on an NEC personal computer, PC-9801E, using a modified Tominaga's program.[14]

Results and Discussion

The observed ^{13}C and ^1H chemical shifts (δ) for the α-position of α-arylnitrones **1**—**3** and their substituent-induced chemical shifts (SCS) are summarized in Table 1 together with the corresponding chemical shifts and the SCS data for imines **4** and styrenes **5**.[15]

Although two geometrical isomers, *E* and *Z*, are known in several alkylnitrones,[1,16] all the nitrones used were exclusively in a *Z* configuration at room temperature and the two ortho hydrogens in the α-phenyl group situated syn to the nitrone oxygen appeared at a field lower than the rest of the aromatic hydrogens.

The chemical shifts were independent of the concentrations of the compounds used over a range of 0.1 to 2.0 M (with a smaller error than 0.05 ppm).

Table 1. $^{13}C_\alpha$ and $^1H_\alpha$ Chemical Shifts (δ) and SCS Values of α-Arylnitrones (**1**—**3**), Imines (**4**) and Styrenes (**5**)

a) δ: In ppm downfield from internal TMS. b) SCS $=\delta$(X-R)$-\delta$(X-H). c) Ref. 15.

The $^{13}C_\alpha$ signals of nitrones **1**—**3** appeared in a spectral region close to one another, and they were slightly upfield from the corresponding signals of styrenes **5** but more than 25 ppm upfield from those of imines **4**. Table 1 reveals that as the electron-withdrawing ability of substituents increases, the $^{13}C_\alpha$ signal of the nitrones moves upfield. The upfield shift caused by electron-donating *p*-substituents with a higher electronegative atom, such as OMe and SMe, is also noticeable. Such a behavior is, however, not a characteristic of nitrones alone and also observed in the corresponding chemical shifts of imines **4**[17] and styrenes **5**.[15,18]

In aromatic systems with a conjugated side chain, the range of the substituent chemical shift for the α-carbon, $^{13}C_\alpha$ SCS, is generally much narrower than that of the $^{13}C_\beta$ SCS. In the present investigation, the ranges of the $^{13}C_\alpha$ SCS for compounds **1**—**5** were all within a width of 3 ppm (Table 1).

The plots of the $^{13}C_\alpha$ SCS values of **1**—**4** against the values for styrenes exhibited good linear correlations (Fig. 1). The slopes are all larger than unity (Table 2). The magnitude of a slope should be a measure of the relative sensitivity of the α-carbon toward substituents.

The large slope for **4** may be explained by the participation of a lone pair on the nitrogen atom.

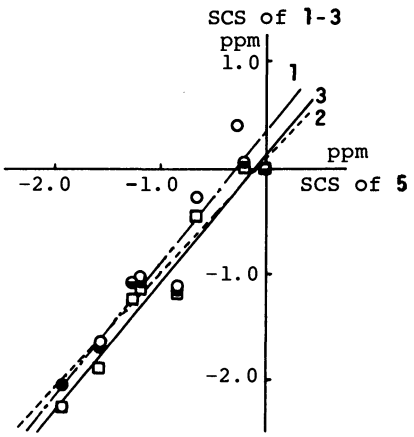

Fig. 1. Correlations of $^{13}C_\alpha$ SCS's of **1** (—○—), **2** (--●--), and **3** (—□—) with $^{13}C_\alpha$ SCS of **5**.

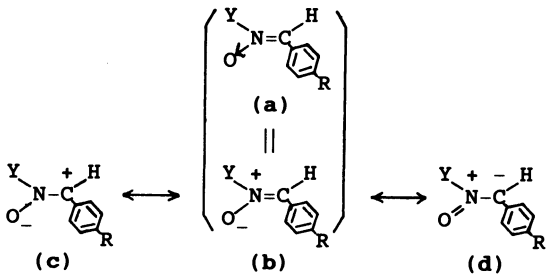
Table 2. Relative Susceptibility of **1**—**5** to Substituent Effects

X	SCS(X)/SCS(styrene)	
	^{13}C NMR	^1H NMR
1	1.28	1.78
2	1.09	1.47
3	1.23	1.34
4	1.64	1.17
5	1.00	1.00

The lone pair could shift the electron cloud around the C=N bond toward the α-carbon according to the requirement of the electron-withdrawing ability of *p*-substituents in the α-phenyl ring. The carbanionic character at the α-carbon increases with an increase in the electron-withdrawing ability of the substituent. The increased shielding at the α-carbon results in an upfield shift of the $^{13}C_\alpha$ signal.

Although nitrones are usually represented by a structure, **a** or **b**, the positive charge on the nitrogen atom is essentially delocalized between the nitrogen and the α-carbon atoms, as represented by an additional canonical structure **c**. However, the upfield shift of the $^{13}C_\alpha$ signals of nitrones **1**—**3**, which was caused by electron-withdrawing substituents, can not be rationalized by the structure of **c**. This behavior requires an explanation that the introduction of electron-withdrawing susbtituents and electron-donating substituents with an electronegative atom into the α-phenyl ring predominantly induces a "back polarized" structure **d** from **b**, or the concept of "π-polarization,"[19] in which an electron cloud around the C=N bond of **b** is withdrawn toward the α-carbon by electron-withdrawing substituents introduced in the α-phenyl group.



Although the net substituent effect at the α-carbon is smaller than that for imine **4**, this can be rationalized by the charge compensation between the normally-localized structure **c** and the "back polarized" structure **d**.

Table 3 shows the results of an HMO calculation. The Coulomb integral and the resonance integral values used for **3** and **4** are as follows: **3**[20]: h_N=0.6, h_O=1.0, k_{CN}=1.0, k_{NO}=1.5; **4**[21]: h_N=0.5, k_{CN}=1.0.

If these values used for pyridine *N*-oxides are truly applicable to a calculation for **3**, the order obtained for the α-carbon charge density, **3**>**5**>**4**, can explain

Table 3. Charge Densities and Bond Orders for **3**—**5**

	Charge density[a]	Bond order[a]	
	C_α	C_α=N or C_α=C	N→O
3	1.269	0.628	0.639
4	0.835	0.795	
5	1.000	0.911	

a) Calculated by the HMO method.

the largest upfield shift of the $^{13}C_\alpha$ chemical shift of **3**. On the other hand, the bond order for the C_α=N bond of **3** is smaller than those for the corresponding double bonds of **4** and **5**. These two estimations suggest a considerable contribution of the canonical form **d** in the structure of nitrones.

In Hammett plots of $^{13}C_\alpha$ chemical shifts vs. σ values, the slopes for α-arylnitrones **1**—**3** and imine **4** are larger than that of styrene **5** (Table 4), and the correlations are much better with σ_m than with σ_p. This and the order, $\rho_m > \rho_p$, obtained for all the compounds indicate that inductive effects are predominant at the α-carbon atom.

As shown in Table 4 and Figs. 2—4, the $^{13}C_\alpha$ SCS values for the nitrones are, expectedly, correlated much better with a linear combination of σ_i and σ_π, namely a correlation with $\rho_i\sigma_i+\rho_\pi\sigma_\pi$, than with σ_m. ρ_i and ρ_π represent empirical coefficients, and σ_π corresponds to resonance substituent constants, σ_π^+ and σ_π^-, presented by Yukawa and Tsuno,[22] having negative and positive signs for electron-donating groups and electron-withdrawing groups, respectively. The ρ_π values estimated for **1**—**5** were essentially equal to the arithmetic means of the corresponding coefficients of σ_π^+ and σ_π^- and, thus, the use of the linear combination of σ_i and σ_π is appropriate as a multivariate parameter analysis for the nitrones. Our dual-parameter analyses clealy show that inductive effects are the predominant factors in the $^{13}C_\alpha$ chemical shifts.

The relative importance of factors operating in the delocalization of the nitrone function can be estimated from the ratio, ρ_π/ρ_i (Table 5). The magnitude of the ratio, $\rho_\pi/\rho_i<0.5$, means that inductive effects are always stronger than resonance effects at the α-carbon.

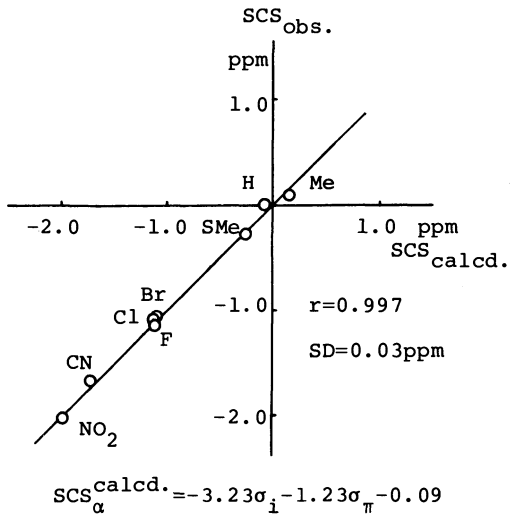

Fig. 3. Correlation between observed and calculated SCS_α for **2**.

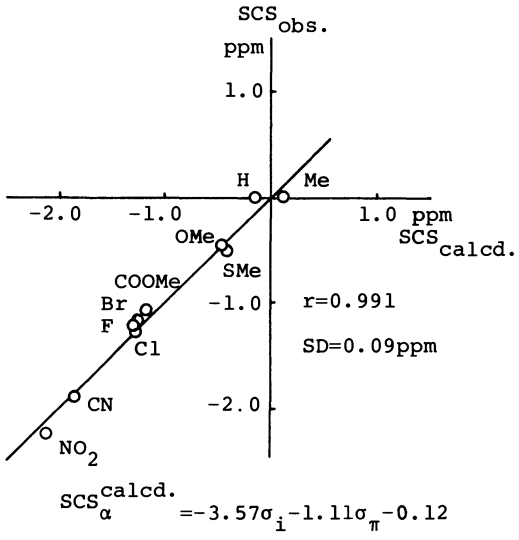

Fig. 4. Correlation between observed and calculated SCS_α for **3**.

The substituent effects of R on to the para and ipso positions, i.e. effects on to the ring carbons next and para to the C_α of nitrones, respectively, are essentially the same as those for monosubstituted benzenes.[23] The plots of SCS_1 vs. SCS_{Bz} showed a good linearity,

$$SCS_{1,para} = 0.96(SCS_{Bz}) - 0.24 \quad (r=0.996)$$
$$SCS_{1,ipso} = 0.92(SCS_{Bz}) + 0.21 \quad (r=0.997)$$

where SCS_1 and SCS_{Bz} represent the ^{13}C SCS of nitrones **1** and monosubstituted benzenes, respectively. On the other hand, no correlation was observed between $SCS_{1,ipso}$ and $SCS_{1,\alpha}$. These findings again support the above conclusion that resonance effects on the C_α through a conjugation system of a phenyl ring are minor. However, we do not suggest that the resonance effects are unimportant. The effects are rather important in nitrones, but the negative ρ_π values can not be rationalized by the canonical forms **c** and **d**. The negative ρ_π values probably result from resonance interactions of R with the nitrone function in structure **b**.

Table 5. Relative Contribution of Resonance Effects and Inductive Effects on the α-Position of **1**—**5**

X	ρ_π/ρ_i	
	^{13}C NMR	^1H NMR
1	0.49	4.0
2	0.38	4.6
3	0.31	1.8
4	0.27	25.0
5	0.17	11.0

For nitrones with an electron-donating substituent, the charge transfer between the nitrogen atom and R (**b**↔**e**) results in a decrease in the net charge density of the shortened conjugation system. On the other hand, for nitrones with an electron-withdrawing substituent, the charge transfer between the oxygen atom and R (**b**↔**f**) increases the net charge density of the extended conjugation system. These interactions result in a relatively small negative ρ_π value at the C_α since it is a nonconjugating site. The resonance effects in nitrones **1**—**3** are, therefore, more important than those in imines **4** and styrenes **5**.

The region of $^1H_\alpha$ signals of nitrones **1**—**3** lies between the corresponding signal regions of **4** and **5**, i.e., in a lower field than that of **5** but in an upper field than that of **4**. The phenomenon also can be explained by the compensating contribution of structures **c** and **d**.

In contrast with the $^{13}C_\alpha$ chemical shifts, the $^1H_\alpha$ signals of compounds **1**—**5** normally move downfield as the electron-withdrawing ability of substituents increases. This opposite behavior results from a change in the causative factors of the ^{13}C and ^1H chemical shifts. It is well accepted that for a particular nucleus the total shielding constant, σ^t, can be approximated by a sum of three terms[24]: diamagnetic contribution (σ^d), paramagnetic contribution (σ^p), and the contribution from neighboring groups per nuclei (σ'). The first term, σ^p, has been shown to contribute to 90% of total screening of a ^{13}C nucleus, and the change in the chemical shift as a function of structure may be attributed to the change in σ^p. The second term, σ^d, on the other hand, dominates the proton chemical shift.

The correlations between $^1H_\alpha$ SCS and σ values

are much better with σ_p than with σ_m in all the compounds (Table 4). This suggests that resonance effects are stronger than inductive effects at the α-hydrogen. The slopes are, however, very small and nearly one-tenth of the Hammett slopes for the $^{13}C_\alpha$ chemical shifts, reflecting intervention of one carbon between the H_α and the α-phenyl ring. Correlation analyses with $\rho_i\sigma_i+\rho_\pi\sigma_\pi$ also suggest the predominance of resonance effects in $^1H_\alpha$ chemical shifts.

The observed substituent effects on the $^1H_\alpha$ chemical shifts of nitrones **1—3** are larger than those for imine **4** and styrene **5** (Table 2). A resonance measure ρ_π is nearly constant in all the compounds but the order of the magnitude of an inductive measure ρ_i is $\rho_{i\,\text{nitrone}}>\rho_{i\,\text{imine}}$ and $\rho_{i\,\text{styrene}}\simeq 0$. Thus, the ratio ρ_π/ρ_i for the nitrones is smaller than those for imine **4** and styrene **5** (Table 5).

In summary, the $^{13}C_\alpha$ signal of α-arylnitrones shifts upfield as the electron-withdrawing ability of substituents in the α-phenyl ring increases, but the $^1H_\alpha$ signal downfield. The $^{13}C_\alpha$ chemical shifts are well correlated with a linear combination of σ_i and σ_π. Inductive effects predominate at the α-carbon and the contribution of the canonical structure **d** is the largest although its contribution is known to be small in many chemical reactions. The importance of this structure will increase with the electron-withdrawing ability of the substituent R. For the α-hydrogen, resonance effects predominate instead of inductive effects.

The authors thank Professor Masami Sawada, Scientific and Industrial Research Institute, Osaka University, for helpful discussions, and Dr. Hitoshi Takai, Fuculty of Pharmaceutical Sciences, Osaka University, for the measurement of the ^1H spectra of **3** and **4**. Thanks are also due to Mr. Tatsuya Takagi for the use of his personal computer program package for multivariate analysis.

We may analyze the substituent effects by the use of Linear Aromatic Substituent Reactivity (LArSR: $\log k/k_0=\rho_i\sigma_i+\rho_\pi^+\sigma_\pi^++\rho_\pi^-\sigma_\pi^-$) relationship, though the data have been treated as shown in the present text for the limited number of substituents. A part of the analyses is shown as follows, where substituent constants cited in ref. 22b have been used:

1: $^{13}C_\alpha$ SCS$=-3.14(\pm0.74)\sigma_i-1.47(\pm0.67)\sigma_\pi^+-1.82(\pm1.12)\sigma_\pi^--0.09(\pm0.22)$, $r=0.994$, SD=0.07 ppm, $n=9$

2: $^{13}C_\alpha$ SCS$=-3.15(\pm0.49)\sigma_i-0.93(\pm0.93)\sigma_\pi^+-1.48(\pm0.80)\sigma_\pi^--0.07(\pm0.15)$, $r=0.998$, SD=0.02 ppm, $n=8$

3: $^{13}C_\alpha$ SCS$=-3.43(\pm0.56)\sigma_i-0.58(\pm0.88)\sigma_\pi^+-1.64(\pm0.87)\sigma_\pi^--0.06(\pm0.17)$, $r=0.994$, SD=0.06 ppm, $n=10$

An alternative analysis of the $^{13}C_\alpha$ chemical shift of compounds **1—5** by means of Dual Substituent Parameter equation (DSP, $\log k/k_0=\rho_I\sigma_I+\rho_R\sigma_R$) paralleled the analysis done in the present text with comparable precisions. Some of the results are shown as follows:

1: $^{13}C_\alpha$ SCS$=-2.84(\pm0.46)\sigma_I-0.85(\pm0.36)\sigma_R-0.06(\pm0.22)$ $r=0.992$, SD=0.10 ppm, $n=9$.

2: $^{13}C_\alpha$ SCS$=-2.81(\pm0.37)\sigma_I-0.84(\pm0.43)\sigma_R-0.04(\pm0.17)$ $r=0.995$, SD=0.04 ppm, $n=8$

Synthesis of Amides and Amidines by Reaction of Carboxylic Acids and Amines in the Presence of Polyphophoric Acid Trimethylsilyl Ester (PPSE)

Shin-ichi OGATA, Amane MOCHIZUKI, Masa-aki KAKIMOTO,* and Yoshio IMAI
Department of Textile and Polymeric Materials, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received January 14, 1986)

The reaction between amines and carboxylic aicds in the presence of polyphosphoric acid trimethylsilyl ester (PPSE) has been investigated from the view point of the synthesis of amides and amidines. Benzanilide was selectively prepared from benzoic acid and aniline in the presence of PPSE and pyridine at 100 °C, whereas a mixture of benzanilide and *N,N'*-diphenylbenzamidine was obtained without the use of pyridine. The reaction at 160 °C almost exclusively gave *N,N'*-diphenylbenzamidine. Various symmetrical amidines were obtained from combinations of carboxylic acids and aromatic amines in high yields by simply heating at 160 °C with four molar amounts of PPSE. The reactions of aliphatic and aromatic amines with *N*-monosubstituted and *N,N*-disubstituted amides also afforded corresponding unsymmetrical amidines under the same conditions. The reaction mechanism is discussed in some detail.

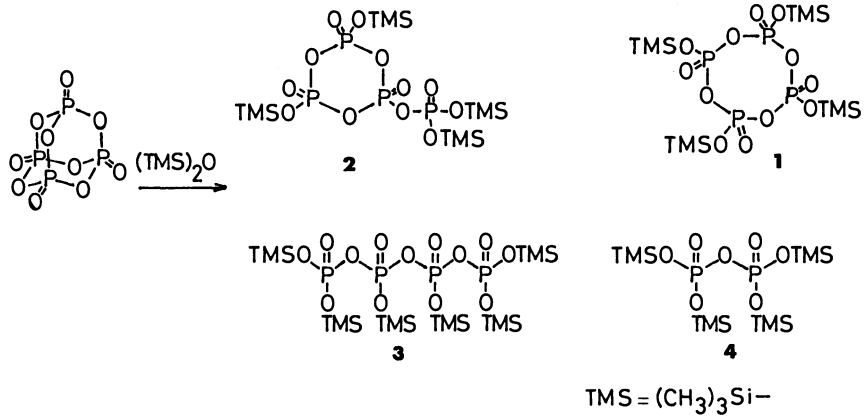
Polyphosphoric acid trimethylsilyl ester (PPSE) has been utilized extensively since its first preparation by Imamoto et al.[1] A PPSE-promoted synthesis of heterocyclic compounds[2] and nitriles from amides,[3] an unusual aldol reaction,[4] and the Beckmann,[1] pinacol-pinacolone,[5] and Pummerer rearrangements[6] have been reported. PPSE is readily prepared from diphosphorus pentaoxide and hexamethyldisiloxane, usually by heating in dichloromethane or chloroform for a short time.[1,4b] The structure of this reagent was confirmed to be a mixture of cyclotetraphosphate (**1**), isocyclotetraphosphate (**2**), linear tetraphosphate (**3**), and a small amount of pyrophosphate (**4**) on the basis of a ^{31}P NMR measurement[2a] (Scheme 1).

Although polyphosphoric acid (PPA), which has been well-known as a powerful reagent for dehydrative condensations,[7] is essentially insoluble in organic solvents, PPSE is readily soluble in various aprotic solvents such as benzene, chlorinated hydrocarbons, and sulfolane. Therefore, PPSE should be accepted as a very applicable reagent for an organic synthesis, compared with PPA. The structural and characteristic reactions of PPSE are similar to those of polyphosphoric acid ethyl ester (PPE),[8] of which a number of reactions have been presented mainly, from the view point of dehydration reactions.[9] In a comparison of these two polyphosphoric acid ester reagents, PPSE can be prepared much easier than PPE, whose preparation requires a few days from diphosphorus pentaoxide and diethyl ether.[8] Furthermore, PPSE was more reactive than PPE in some reactions.[2,4,7]

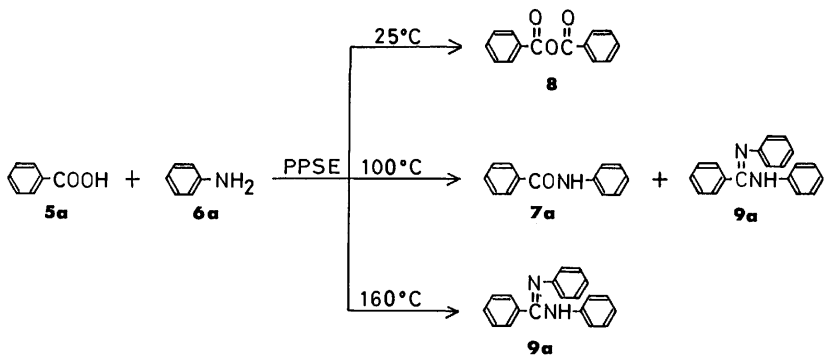
It has been demonstrated that a number of heterocyclic compounds can be easily prepared from appropriate amino compounds and carboxylic acids using PPA, PPE, and PPSE. On the other hand, the reactions of simple carboxylic acids with amines to afford acyclic compounds were only sparingly reported.[9a] Here, we wish to report on a novel synthesis of amides and amidines by a reaction of carboxylic acids and amines in the presence of PPSE.

Results and Discussion

Synthesis of Amides from Carboxylic Acids and



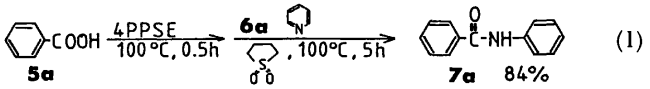
Scheme 1.



Scheme 2.

Amines. Our initial object was a synthesis of amides **7** by a direct condensation of carboxylic acids **5** and amines **6** using PPSE as condensing agent. In the beginning, the reaction between benzoic acid (**5a**) and aniline (**6a**) was conducted at the various temperatures as illustrated in Scheme 2. Results of the reactions are summarized as follows: 1) Benzoic anhydride (**8**) was the major product at 25 °C. 2) A mixture of almost the same amount of benzanilide (**7a**) and *N,N'*-diphenylbenzamidine (**9a**) was obtained at 100 °C. 3) Amidine **9a** was the only product at 160 °C.

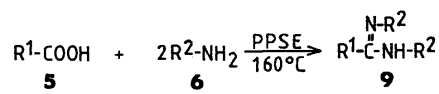
The synthesis of amidines at a high temperature will be discussed later. For the purpose of a selective formation of amide **7a**, pyridine, which should increase the nucleophilicity of aniline (**6a**), was added to the reaction system. The procedure of the amide -forming reaction was examined. Thus, 1) an equimolar amount of benzoic acid (**5a**), aniline (**6a**), and pyridine were added to four-fold molar amounts of PPSE dissolved in sulfolane at 100 °C. 2) In the first step, **5a** was treated in a PPSE solution of sulfolane for 30 min at 100 °C, and then **6a** and pyridine were added to the solution. 3) A mixture of **5a** and pyridine in a small amount of 1,2-dichloroethane was added to PPSE solution in sulfolane at 100 °C, and then **6a** was added to the solution. The yields of amide **7a** by the each procedure were 80, 84, and 49%, respectively. The reaction was also carried out in various solvents such as sulfolane, anisole, dichloromethane, and *N,N*-dimethylacetamide, and sulfolane was found to be the best solvent for this reaction (Eq. 1).



(1)

Although a detailed search was made to establish the optimum reaction conditions for amide formation, the suppression of the side reactions of amidine formation was fairly difficult. Therefore, it was concluded that this method was not so generally applicable compared with a direct synthesis of amides by the condensations of carboxylic acids with amines using some condensing agents.

Synthesis of Symmetrical Amidines from Carboxylic Acids and Amines.[10] The results of the high-temperature reaction described above have led to the suggestion that the reaction of carboxylic acids **5** with amines **6** in the presence of PPSE would be generalized to a direct synthesis of symmetrical amidines **9** as illustrated in Eq. 2. To our knowledge, the conversion of carboxylic acids and amines to amidines has been unknown except the case of cyclic amidines.[11]



(2)

Various examples of the synthesis of symmetrical amidines are summarized in Table 1. From Entry 1 to 7, a variety of carboxylic acids **5** were treated with two equivalents of aniline (**6a**) at 160 °C for 5 h without solvent. From Entry 8 to 11, benzoic acid (**5a**) with aromatic amines **6** were examined. *N,N'*-Diphenylamidines were obtained by a reaction between aniline (**6a**) and various aromatic, aliphatic, and *α,β*-unsaturated carboxylic acids in high yields. *N,N'*-Bis(*p*-nitrophenyl)benzamidine (**9k**) was obtained from benzoic acid and *p*-nitroaniline having low nucleophilicity by use of PPSE prepared from two equivalents of hexamethyldisiloxane (Entry 11). When PPSE prepared from diphosphorus pentaoxide and three equivalents of hexamethyldisiloxane was used, the reaction of the same starting compounds did not afford the corresponding amidine **9k** but gave *N*-(*p*-nitrophenyl)benzamide in 59% yield. It was observed by a measurement of the ^{31}P NMR spectra that the PPSE prepared by the former method contained a large amount of isocyclotetraphosphate **2** having an active blanched unit structure.[2a] Thus, even from nitroaniline with a low nucleophilicity, amidine **9k** can be obtained using the active PPSE. Contrary to the successful synthesis of *N,N'*-diaryl-substituted amidines **9** from aromatic amines possessing electron-donating and -withdrowing groups,

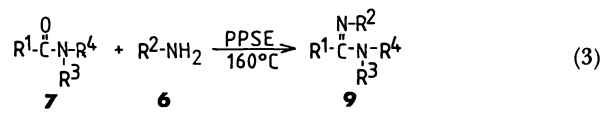
highly nucleophilic aliphatic amines gave a mixture of amidines **9** and amides **7** in low yields.

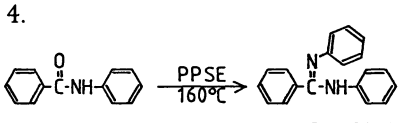
Synthesis of Unsymmetrical Amidines from Amides and Amines. In the course of the reaction between carboxylic acids **5** and aromatic amines **6**, interesting phenomena were observed. When an equimolar amount of benzoic acid (**5a**) and aniline (**6a**) were reacted in the presence of PPSE at 160 °C for 5 h, amidine **9a** was obtained in 82% yield based on aniline, and benzanilide (**7a**) was not isolated from the reaction mixture. This result suggests that the rate of formation of amidine **9a** from **7a** should be greater than the rate of formation of benzanilide (**7a**), if the intermediate to give **9a** is **7a**. To prove the reaction pathway, the reaction of benzanilide (**7a**) and aniline (**6a**) was conducted. *N,N'*-Diphenylbenzamidine (**9a**) was also obtained in 90% yield under the same conditions for the amidine formation described above. Therefore, this reaction was successfully extended to an unsymmetrical amidine synthesis as illustrated in Eq. 3.



(3)

7 **6** **9**

As summarized in Table 2, various examples of the reaction were conducted. It is interesting to note that aliphatic amines, as well as aromatic amines could be applicable in this reaction, giving moderate to excellent yields of amidines **9**, whereas aliphatic amines did not give satisfactory results in a direct synthesis of the symmetrical amidines mentioned earlier. Primary, secondary, and tertiary aliphatic amines were examined in the reaction with benzanilide (**7a**). Amidine **9o** was obtained in moderate yield from cyclohexylamine, while the product of the reaction with hexylamine was a mixture of the desired amidine **9n** and *N,N'*-diphenylbenzamidine (**9a**). In the reaction with *t*-butylamine, the amine did not react with benzanilide (**7a**) and **9a** was obtained in 87% yield based on **7a**. Amide **7a** was expected to dimerize through the reaction to give amidine **9a**, similar to the reaction of amides with PPE.[9g] Indeed, amine **7a** afforded amidine **9a** in 90% yield by simply heating at 160 °C with excess of PPSE as depicted in Eq. 4.



(4)

7a **9a** 90%

Furthermore, not only *N*-monosubstituted amides but also *N,N*-disubstituted amides could be used for this type of reaction. When the reaction of benzamide **7b** was conducted, it was found that **7b** reacted with PPSE predominantly to afford *p*-methoxybenzonitrile.[3]

Reaction Mechanism. When one discusses the mechanism of the present reaction, PPSE has two possible roles, where it acts as a silylating agent and a phosphorylating agent. Because tris(trimethylsilyl) orthophosphate, whose trimethylsilyl function seems

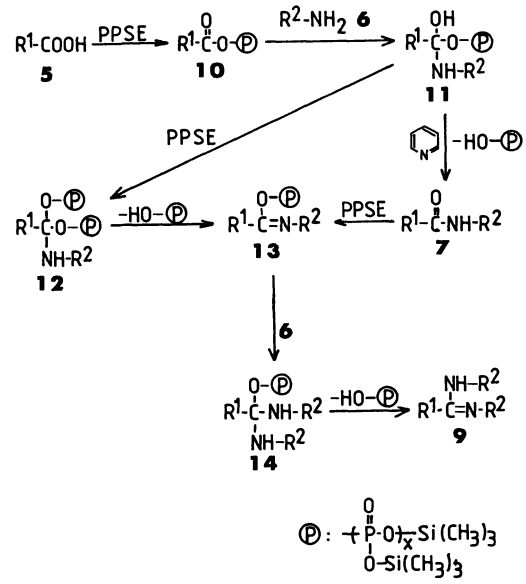
to possess almost the same reactivity as PPSE was found to be ineffective for amidine synthesis, it is concluded that phosphorylation of carboxylic acid by PPSE is the initial reaction. The mechanism is presumed as illustrated in Scheme 3. In the beginning, carboxylic acid **5** reacts with PPSE to afford mixed anhydride **10**. Amide **7** is obtained by the action of pyridine through intermediate **11**, which is produced by the reaction of **10** and amine **6**. Intermediate **11** is then phosphorylated with PPSE to afford **12**. Imidate intermediate **13** is produced by the elimination of phosphoric function from **12**. Alternatively, amide **7** is converted to **13** by the reaction with PPSE. Finally, **13** reacts with amine **6** to afford amidine **9**. Although amine **6** can react with PPSE, the reaction product (phosphoric amide and/or phosphoric acid salt of **6**) should decompose at a high temperature to liberate amine **6**, and **6** may react with **13**. Since aromatic amine should be liberated more readily than aliphatic amine at a high temperature, the reaction proceeds predominantly with aromatic amine. The reaction between benzoic acid (**5a**) and an equimolar amount of aniline (**6a**) in the presence of PPSE afforded amidine **9a** in 82% yield



Scheme 3.

based on **6a**. This result suggests that the reaction from **13** to **9** was faster than the reaction from **10** to **13**. In the reaction of amide **7a** and aliphatic amine, the only successful example was the case of cyclohexylamine. Therein, hexylamine which has high nucleophilicity should competitively react with **13** and PPSE existing in the reaction mixture, and *t*-butylamine could not attack **13** because of the steric hindrance.

Conclusion

The conventional starting materials for amidine synthesis[11] are nitriles, imidates, imidohalides, and orthoesters etc., which are essentially derivatives of carboxylic acids and/or amines. The present method offers a convenient synthesis of amidines. Thus, symmetrical and unsymmetrical amidines were synthesized directly from reactant pairs of carboxylic acid-amine and amide-amine, respectively, in the presence of PPSE. Since PPSE possesses the characteristics of a Lewis acid as well as a dehydration agent, it should be accepted as a unique reagent for dehydrative condensation reactions.

Experimental

The ^{1}H NMR spectra were determined with a JEOL C-60 HL, and the chemical shifts are given in ppm based on tetramethylsilane. The ^{31}P NMR spectra were recorded with a JEOL FX-100. Solvents such as dichloromethane were purified by the usual procedures.

Preparation of Polyphosphoric Acid Trimethylsilyl Ester (PPSE). In a 50 mL round-bottom flask, a mixture of 1.42 g (5 mmol) of diphosphorus pentaoxide, 2.56 g (16 mmol) of hexamethyldisiloxane and 3 mL of dichloromethane was heated at refluxing temperature for 30 min under a thin stream of nitrogen. After a distillation apparatus was equipped on the flask, the mixture was gradually heated to 160 °C under nitrogen. During this period, volatile compounds such as dichloromethane and excess hexamethyldisiloxane were distilled away. The residual viscous syrup was used for the following reactions.

Preparation of Benzanilide (7a). To the syrup of PPSE which was prepared from 10 mmol of diphosphorus pentaoxide and 20 mmol of hexamethyldisiloxane, 5 mL of sulfolane and 0.305 g (2.5 mmol) of benzoic acid (**5a**) were added. After the solution was stirred for 30 min, 0.2 mL (2.5 mmol) of pyridine and 0.233 g (2.5 mmol) of aniline (**6a**) were added. The reaction mixture was stirred for 5 h at 100 °C under nitrogen. The benzanilide (**7a**) was obtained by pouring the mixture into cold 1 M† NaOH solution. Yields was 0.392 g (84%): Mp 160—161 °C (161 °C[12]); IR (KBr) 3300 cm^{-1} (N-H), 1650 cm^{-1} (C=O), 1594 and 1485 cm^{-1} (aromatic).

General Procedure for the Preparation of Symmetrical Amidines (9a—k). To the syrup of PPSE which was prepared from 5 mmol of diphosphorus pentaoxide and 16 mmol of hexamethyldisiloxane, 1.25 mmol of carboxylic acid and 2.50 mmol of amine were added at 160 °C, and the solution was stirred for 5 h at the temperature under nitrogen. The crude product was isolated by pouring the reaction mixture into a 1 M NaOH solution. Recrystallization from aqueous ethanol gave pure symmetrical amidine.

The yield and melting points of the products are summarized in Table 1. The IR and NMR data of the amidines are given in Table 3.

General Procedure for the Preparation of Amidines (9l—r) from Amides 7 and Amines 6. To the syrup of PPSE which was prepared from 10 mmol of diphosphorus pentaoxide and 20 mmol of hexamethyldisiloxane, 2.5 mmol of amide and 2.5 mmol of amine were added at 160 °C. The mixture was stirred for 2 h at that temperature under nitrogen. The product was isolated by pouring the reation mixture into a 1 M NaOH solution. The pure amidine was obtained by recrystallization from aqueous ethanol.

Yields and melting points are summarized in Table 2. The IR and NMR data of the products are also given in Table 3. Analytical data of new compounds are shown in Table 4.

Reaction of Benzanilide (7a) and Hexylamine. To the syrup of PPSE, 0.591 g (3 mmol) of benzanilide (**7a**) and 0.303 g (3 mmol) of hexylamine were added at 160 °C. After the reaction was carried out as described above, the reaction mixture was poured into a 1 M NaOH solution. The solution was extracted by dichloromethane, dried over $MgSO_4$, and the solvent was evapolated. Thin-layer chromatogram (aluminum oxide, ethyl acetate/hexane= 1/10) showed two spots at R_f 0.58 and 0.51. The latter spot was the same R_f value of amidine **9a**. The mixture of these two spots, collected by columm chromatography (aluminum oxide, ethyl acetate/hexane=1/10), weighed 0.414 g and shows the following spectra: IR (KBr) 1620 cm^{-1} (C=N), 1585 cm^{-1} (aromatic), and 1220 cm^{-1} (C-N), ^{1}H NMR ($CDCl_3$) δ=0.70—1.85 and 6.50—8.00 (integration

Photochemical Reaction of 2-Aryl-1,2-benzisoselenazol-3(2*H*)-ones

Nobumasa KAMIGATA,* Hirokazu IIZUKA, Akira IZUOKA, and Michio KOBAYASHI
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University,

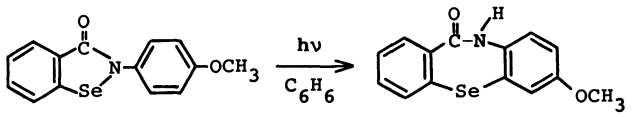
(Received January 28, 1986)

The photochemical reaction of 2-aryl-1,2-benzisoselenazol-3(2*H*)-ones (**1**) in benzene was found to give dibenzo[*b*,*f*][1,4]selenazepin-11(10*H*)-ones (**2**). On the other hand, the photochemical reaction of **1** in *t*-butyl alcohol afforded 2-(2-hydroxy-2-methylpropylseleno)benzanilide, 2-(methylseleno)benzanilide, and 2-aryl-1,2-benzisoselenazol-3(2*H*)-one 1-oxides together with the photoisomer **2**. Mechanisms for these reactions are proposed.

Attention regarding the photochemistry of five-membered heterocyclic ring systems continues to be strong because of their use in heterocycle syntheses and studies concerning the reaction mechanisms.[1] Recently, we have reported a novel photoisomerization of 2-aryl-1,2-benzisothiazol-3(2*H*)-ones to dibenzo [*b*,*f*][1,4]thiazepin-11(10*H*)-ones.[2] In our systematic investigation of the photochemical reactions of benzisothiazolinones and their analogues, we have studied the photochemical reactions of 2-aryl-1,2-benzisoselenazol-3(2*H*)-ones, selenium analogues of 2-aryl-1,2-benzisothiazol-3(2*H*)-ones. The results are described herein.

When a solution containing 2-(4-methoxyphenyl)-1,2-benzisoselenazol-3(2*H*)-one (**1a**) in benzene was irradiated under argon with 300-nm light, a single photoproduct was obtained. The assignment of this material as 7-methoxydibenzo[*b*,*f*][1,4]selenazepin-11-(10*H*)-one (**2a**) was made on the basis of spectral data.



1a **2a**

Some related 2-aryl-1,2-benzisoselenazol-3(2*H*)-ones (**1**) were also irradiated under similar conditions to give dibenzo [*b*,*f*][1,4]selenazepin-11(10*H*)-ones (**2**) as the only isolable photoproducts. The results are summarized in Table 1.

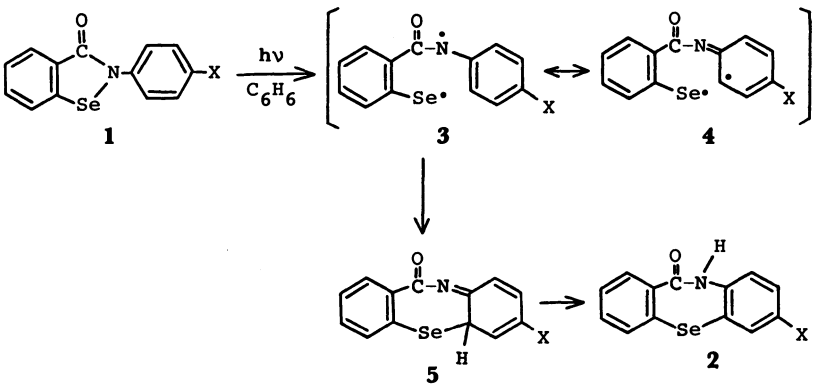
The present results show a very similar feature to that of photochemical reactions of 2-aryl-1,2-benzisothiazol-3(2*H*)-ones.[2] Therefore, the reaction mechanism of **1** is similar to that proposed in the photoisomerization of 2-aryl-1,2-benzisothiazol-3(2*H*)-ones[2] and is outlined in Scheme 1. The photoexcited **1** undergoes a homolytic cleavage of the weakest bond (Se–N) in the molecule to give biradical (**3**). The initially formed biradical recombines at the ortho-position of the *N*-aryl group to give a cyclized product (**5**). A subsequent 1,7-hydrogen shift of the intermediate **5** leads to the final product **2**. The last step of the sequence can proceed by either a thermal or photochemical hydrogen shift.

Recently, Rokach, and Hammel reported that small amounts of a photo-ring expansion product were formed together with 3-phenyl-2(3*H*)-thiazolone upon irradiation of 2-phenyl-3(2*H*)-isothiazolone.[3] However, we could not detect the corresponding 3-aryl-

Table 1. Photochemical Reaction of **1** in Benzene[a]

X in **1**		Product	Yield/%[b]
1a	OCH_3	**2a**	55
1b	CH_3	**2b**	33
1c	H	**2c**	42

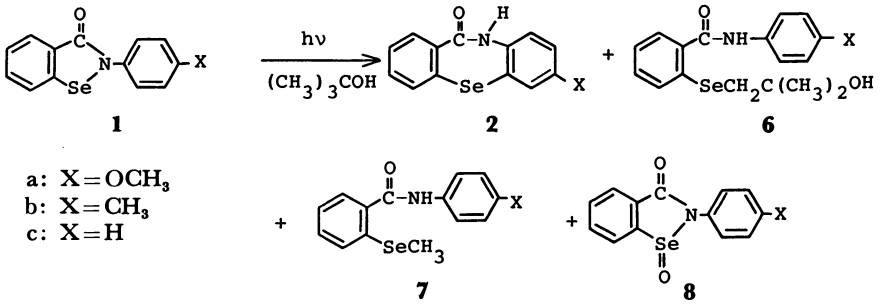
a) The irradiation was carried out on a 2.85×10^{-3} M ($1\ M = 1\ mol\ dm^{-3}$) solution of **1** in benzene under argon using a 450-W medium-pressure mercury lamp (Hanovia) through a Pyrex filter (>300 nm). b) The yields are based on the starting materials consumed.



Scheme 1.

2(3*H*)-benzisoselenazolone in the reaction mixture, as in the case similar to the photochemical reaction of 2-aryl-1,2-benzisothiazol-3(2*H*)-one reported recently from our laboratory.[2)]

Irradiation of **1** in *t*-butyl alcohol was also carried out. When a solution containing 2-(4-methoxyphenyl)-1,2-benzisoselenazol-3(2*H*)-one (**1a**) in *t*-butyl alcohol was irradiated under argon with 300 nm light, the formation of four kinds of photoproducts was indicated by a TLC analysis. The products were separated by silica-gel chromatography and were assigned as **2a**, 4′-methoxy-2-(2-hydroxy-2-methylpropylseleno)benzanilide (**6a**), 4′-methoxy-2-(methylseleno)benzanilide (**7a**), and 2-(4-methoxyphenyl)-1,2-benzisoselenazol-3(2*H*)-one 1-oxide (**8a**) on the basis of their spectral data.



1 **2** **6** **7** **8**

a: X=OCH_3
b: X=CH_3
c: X=H

The irradiation of **1b** and **1c** was also carried out in *t*-butyl alcohol in a similar way and the corresponding four photoproducts **2**, **6**, **7**, and **8** were isolated. The results are summarized in Table 2.

The mechanism of the formation of **2** is the same as that proposed regarding the photochemical reaction of **1** in benzene (Scheme 1). Photoproduct **6** seems to be formed via a homolytic cleavage of the photoproduct **2** by the secondary photo-excitation, affording the biradical **9**. The phenyl radical in the biradical intermediate **9** abstracts a hydrogen atom from *t*-butyl alcohol to give a selenyl radical (**10**) and a 2-hydroxy-2-methylpropyl radical (**11**). The homolytic recombination of these radical intermediates, **10** and **11** affords **6** (Scheme 2).

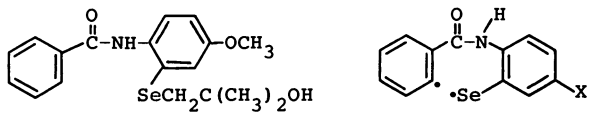
Table 2. Photochemical Reaction of **1** in *t*-Butyl Alcohol

X in **1**		Product (Yield/%[a)])					
1a	OCH_3	**2a**	35	**6a**	17	**8a**	9
1b	CH_3	**2b**	24	**6b**	8	**8b**	3
1c	H	**2c**	19	**6c**	8	**8c**	4

a) The yields are based on the starting materials consumed.

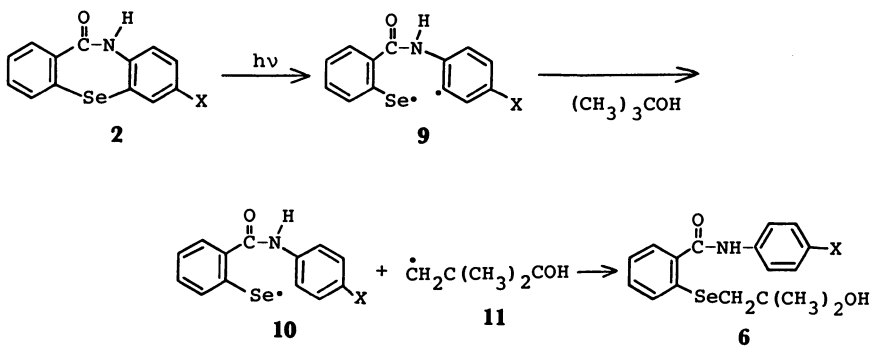
In order to obtain supporting evidence for this mechanism, the isolated **2a** was irradiated in *t*-butyl alcohol, and **6a** was obtained in 47% yield. However, **2a** did not change to **6a** in *t*-butyl alcohol by refluxing the mixture for 3 h and all of the starting material of **2a** was recovered. These findings indicate a secondary photochemical reaction route from **2** to **6**.

We could not detect such a reaction product as **12a** in the photolysis of **1a** in *t*-butyl alcohol. This indicates that **2** does not cleave homolytically to **13** but to **9**. However at present we can not propose any explanation.



12a **13**

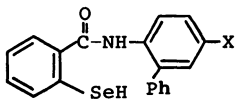
The photochemical cleavage of **2** to **9** suggests that the photochemical reaction of **1** in benzene has a



2 **9** **10** **11** **6**

Scheme 2.

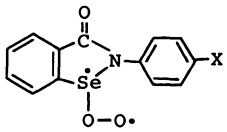
possibility of affording such a compound as **14**.



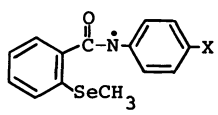
14

The absence of **14** in the photolysis of **1** in benzene means that **2** does not give **9** in a benzene solution or **9**, once formed, recombines to **2** again in a solvent cage faster than it reacts with the solvent benzene.

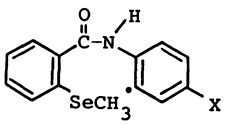
The formation of **7** is of considerable interest; however, it is very difficult to understand how the methyl group of compound **7** is introduced. It is certain that it comes from the methyl group of *t*-butyl alcohol, but the mechanism is not clear. One plausible interpretation is that formation of **7** is closely related to the formation of a photooxidized product **8**. The mechanism of the formation of **8** is a direct photooxidation, as we reported previously regarding the photochemical reaction of 2-aryl-1,2-benzisothiazolinones.[2] Another report was made by Tezuka et al.[4] The photooxidized product **8** was formed in spite of the fact that the photoreaction was carried out under argon gas. This means that a slight amount of oxygen was still present in *t*-butyl alcohol, and it oxidized **1** directly by irradiation, affording the peroxyl radical **15**. The intermediate **15** oxidized the solvent *t*-butyl alcohol and afforded selenoxide **7** and *t*-butoxyl radical. The *t*-butoxyl radical decomposed to a methyl radical and acetone, and the methyl radical attacked either the selenium atom of compound **1** to give a radical **16** or compound **2** to give a radical **17**. Either of these could abstract a hydrogen atom from *t*-butyl alcohol to give the final product **7**.



15



16



17

Experimental

Measurement. All melting points were uncorrected. IR and UV spectra were determined on a Hitachi EPI-G2 and a Hitachi 220A spectrometer. ^{1}H NMR spectra were recorded at 60 and 400 MHz using a JEOL JNM-PMX 60SI and a JEOL JNM-GX 400 spectrometer, respectively, using tetramethylsilane as an internal standard. Mass spectra were determined with a JEOL JMS-DX 300 high-resolution mass spectrometer with a JEOL JMA 5000 mass-data system with an ionization energy of 70 eV. Elemental analyses were carried out using a Perkin-Elmer 240 elemental analyzer.

Preparation of 2-Aryl-1,2-benzisoselenazol-3(2*H*)-ones (1). To a stirred solution containing 14.0 g of *o*-aminobenzoic acid and 20 cm^3 of concd hydrochloric acid in 20 cm^3 of water cooled with an ice bath under 5 °C was added dropwise to 9.0 g of sodium nitrite in 20 cm^3 of water. A solution of 2-carboxybenzenediazonium chloride resulted; this was added dropwise to a stirred solution containing sodium diselenide which was prepared in advance by the reaction of 8.8 g of selenium powder, 8.8 g of rongalite, and 4.4 g of sodium hydroxide in 60 cm^3 of water. The mixture was stirred for an additional 2 h after an initial evolution of nitrogen gas had been completed. It was confirmed that the solution was basic using litmus paper. The reaction mixture was acidified with hydrochloric acid and the precipitated solid was collected by filtration, washed with water, and dried in a desiccator to give 20.0 g (90% yield) of a crude solid of 2,2′-diselenobis[benzoic acid]; mp 293 °C (lit,[5] mp 295 °C).

A mixture of 3.0 g of 2,2′-diselenobis[benzoic acid] and 15 cm^3 of thionyl chloride was heated at reflux for 3 h. The excess thionyl chloride was removed under reduced pressure and the residual solid was recrystallized from hexane to give 3.1 g (81% yield) of pale-yellow crystals of pure 2-(chloroseleno)benzoyl chloride; mp 63—64 °C (lit,[6] mp 65 °C).

To a stirred solution containing 32 mmol of appropriate arylamine in 30 cm^3 of ether was added dropwise 3.0 g of 2-(chloroseleno)benzoyl chloride in 40 cm^3 of ether over a 30 min period, and the mixture was stirred for an additional 3 h. The solvent was removed under reduced pressure and the residue was subjected to chromatography on silica-gel using a 4:1 mixture of dichloromethane–ethyl acetate as the eluent to give pure **1**. The following compounds were prepared by this procedure.

2-(4-Methoxyphenyl)-1,2-benzisoselenazol-3(2*H*)-one (1a). Yield, 65%; mp 178—179 °C; IR (KBr) 1600 cm^{-1}(s, amide C=O); ^{1}H NMR ($CDCl_3$) δ=3.80 (3H, s), 6.90 (2H, d, J=8.4 Hz), 7.35 (2H, d, J=8.4 Hz), and 7.3—8.1 (4H, m); UV (methanol) 265 (log ε=4.57) and 325 nm (4.19); MS, *m/z* 305 (M^+), 274 225, and 184; HRMS, *m/z* 304.9924 ($C_{14}H_{11}NO_2Se$ requires 304.9954).

2-(*p*-Tolyl)-1,2-benzisoselenazol-3(2*H*)-one (1b). Yield, 65%; mp 169—170 °C; IR (KBr) 1620 cm^{-1} (s, amide C=O); ^{1}H NMR ($CDCl_3$) δ=2.37 (3H, s), 7.20 (2H, d, J=8.4 Hz), 7.52 (2H, d, J=8.4 Hz), and 7.3—8.2 (4H, m); UV (methanol) 265 (log ε=3.61) 325 nm (3.25); MS, *m/z* 289 (M^+), 274, and 209; HRMS, *m/z* 289.0017 ($C_{14}H_{11}NOSe$ requires 289.0005).

2-Phenyl-1,2-benzisoselenazol-3(2*H*)-one (1c). Yield, 86%; mp 179—180 °C; IR (KBr) 1600 cm^{-1} (s, amide C=O);

^{1}H NMR ($CDCl_3$) δ=7.20—8.13 (9H, m); UV (methanol) 260 (log ε=3.37) and 325 nm (3.30); MS, *m/z* 275 (M^+) and 195; HRMS, *m/z* 274.9845 ($C_{13}H_9NOSe$ requires 274.9849).

Photolysis of 2-Aryl-1,2-benzisoselenazol-3(2*H*)-one (1) in Benzene. A solution containing 0.65 mmol of 2-aryl-1,2-benzisoselenazol-3(2*H*)-one (**1**) in 230 cm^3 of benzene was irradiated under argon through a Pyrex filter sleeve using a 450-W Hanovia medium-pressure mercury lamp for 10 h. A removal of the solvent left a light-brown residue which was purified by silica-gel chromatography using chloroform as the eluent. Photoproduct **2** was isolated with the recovered starting material **1**. The physical, spectral data, and analyses of the photoproducts **2** are as follows:

7-Methoxydibenzo[*b,f*][1,4]selenazepin-11(10*H*)-one (2a). Mp 213 °C (from chloroform–hexane); IR (KBr) 2950—3200 (w, amide N–H) and 1650 cm^{-1} (s, amide C=O); ^{1}H NMR (DMSO-d_6) 400 MHz, δ=3.73 (3H, s), 6.92 (1H, dd, *J*=8.8 and 2.6 Hz), 7.14 (1H, d, *J*=8.4 Hz), 7.23 (1H, d, *J*=2.6 Hz), 7.37—7.64 (4H, m), and 10.39 (1H, s); MS, *m/z* 305 (M^+), 274, 225, and 210; HRMS, *m/z* 304.9951 ($C_{14}H_{11}NO_2Se$ requires 304.9954).

7-Methyldibenzo[*b,f*][1,4]selenazepin-11(10*H*)-one (2b). Mp 268—269 °C (from chloroform–hexane); IR (KBr) 2900—3200 (w, amide N–H) and 1650 cm^{-1} (s, amide C=O); ^{1}H NMR (DMSO-d_6) 400 MHz, δ=2.23 (3H, s), 7.12 (1H, d, *J*=8.4 Hz), 7.14 (1H, d, *J*=8.4 Hz), 7.39—7.41 (2H, m), 7.50 (1H, s), 7.59—7.62 (2H, m), and 10.48 (1H, s); MS, *m/z* 289 (M^+) and 209; HRMS, *m/z* 288.9991 ($C_{14}H_{11}NOSe$ requires 289.0005).

Dibenzo[*b,f*][1,4]selenazepin-11(10*H*)-one (2c). Mp 273.5 °C (from chloroform–hexane); IR (KBr) 2950—3200 (w, amide N–H) and 1650 cm^{-1} (s, amide C=O); ^{1}H NMR (DMSO-d_6) 400 MHz, δ=7.11 (1H, t, *J*=7.7 Hz), 7.22 (1H, d, *J*=7.7 Hz), 7.34 (1H, t, *J*=7.7 Hz), 7.40—7.43 (2H, m), 7.60—7.65 (2H, m), 7.68 (1H, d, *J*=7.7 Hz), and 10.59 (1H, s); MS, *m/z* 275 (M^+) and 195; HRMS, *m/z* 274.9854 ($C_{13}H_9NOSe$ requires 274.9849).

Photolysis of 2-Aryl-1,2-benzisoselenazol-3(2*H*)-one (1) in *t*-Butyl Alcohol. A solution containing 0.65 mmol of 2-aryl-1,2-benzisoselenazol-3(2*H*)-one (**1**) in 230 cm^3 of *t*-butyl alcohol was irradiated under argon through a Pyrex filter sleeve using a 450-W Hanovia medium-pressure mercury lamp for 10 h. A TLC analysis showed that four photoreaction products were formed. The solvent was removed under reduced pressure to give a light-brown residue which was purified by preparative TLC using chloroform as the eluent. Photoproducts **2**, **6**, **7**, and **8** were isolated, and the physical and spectral data of these products are as follows:

4′-Methoxy-2-(2-hydroxy-2-methylpropylseleno)benzanilide (6a). IR (neat) 2900—3000 (w, amide N–H and O–H) and 1650 cm^{-1} (s, amide C=O); ^{1}H NMR ($CDCl_3$) δ=1.33 (6H, s), 1.55 (1H, s), 3.21 (2H, s), 3.81 (3H, s), 6.90 (2H, d, *J*=9.0 Hz), 7.57 (2H, d, *J*=9.0 Hz), 7.2—8.3 (4H, m), and 8.13 (1H, s); MS, *m/z* 379 (M^+) and 306; HRMS, *m/z* 379.0700 ($C_{18}H_{21}NO_3Se$ requires 379.0684).

4′-Methoxy-2-(methylseleno)benzanilide (7a). Mp 266—267 °C (from benzene–hexane); IR (KBr) 3300 (s, amide N–H) and 1635 cm^{-1} (s, amide C=O); ^{1}H NMR ($CDCl_3$) δ=2.27 (3H, s), 3.73 (3H, s), 6.82 (2H, d, *J*=8.4 Hz), 7.42 (2H, d, *J*=8.4 Hz), 7.0—8.1 (4H, m); MS, *m/z* 321 (M^+), 306, 225, 199, and 122. Found: C, 56.24; H, 4.76; N, 3.99%. Calcd for $C_{15}H_{15}NO_2Se$: C, 56.25; H, 4.72; N, 4.37%.

2-(4-Methoxyphenyl)-1,2-benzisoselenazol-3(2*H*)-one 1-Oxide (8a). Mp 212—213 °C (from benzene); IR (KBr) 1690 (s, C=O) and 820 cm^{-1} (s, Se=O); ^{1}H NMR ($CDCl_3$) δ=3.80 (3H, s), 7.37 (2H, d, *J*=8.8 Hz), 7.50 (2H, d, *J*=8.8 Hz), 7.80—7.95 (3H, m), and 8.24 (1H, d, *J*=7.7 Hz); MS, *m/z* 321 (M^+), 305, 290, and 225; HRMS, *m/z* 320.9828 ($C_{14}H_{11}NO_3Se$ requires 320.9903).

4′-Methyl-2-(2-hydroxy-2-methylpropylseleno)benzanilide (6b). IR (neat) 3000—3500 (w, amide N–H and O–H) and 1650 cm^{-1} (s, amide C=O); ^{1}H NMR ($CDCl_3$) δ=2.00 (1H, s), 2.15 (1H, s), 2.36 (3H, s), 3.10 (2H, s), 7.12—7.95 (8H, m); MS, *m/z* 363 (M^+); HRMS, *m/z* 363.0031 ($C_{18}H_{21}NO_2Se$ requires 363.0681).

4′-Methyl-2-(methylseleno)benzanilide (7b). Mp 252.5—253.5 °C; IR (KBr) 3300 (s, amide N–H) and 1620 cm^{-1} (s, amide C=O); ^{1}H NMR ($CDCl_3$) δ=2.30 (3H, s), 2.74 (3H, s), 7.67—8.11 (8H, m), and 8.20 (1H, s); MS, *m/z* 305 (M^+) and 209; HRMS, *m/z* 305.0281 ($C_{15}H_{15}NOSe$ requires 305.0318).

2-(4-Methylphenyl)-1,2-benzisoselenazol-3(2*H*)-one 1-Oxide (8b). Mp 182—183 °C; IR (KBr) 1680 (s, C=O) and 810 cm^{-1} (s, S=O); ^{1}H NMR ($CDCl_3$) δ=2.26 (3H, s), 7.10—7.52 (8H, m); MS, *m/z* 305 (M^+); HRMS, *m/z* 305.0037 ($C_{14}H_{11}NO_2Se$ requires 304.9954).

2-(2-Hydroxy-2-methylpropylseleno)benzanilide (6c). IR (neat) 3000 (w, amide N–H and O–H) and 1650 cm^{-1} (s, amide C=O); ^{1}H NMR ($CDCl_3$) δ=1.31 (1H, s), 1.33 (6H, s), 3.13 (2H, s), 7.20—7.69 (9H, m), and 8.20 (1H, s); MS, *m/z* 349 (M^+); HRMS, *m/z* 349.0602 ($C_{17}H_{19}NO_2Se$ requires 349.0580).

2-(Methylseleno)benzanilide (7c). Mp 169—170 °C; IR (KBr) 3300 (s, amide N–H) and 1640 cm^{-1} (s, amide C=O); ^{1}H NMR ($CDCl_3$) δ=2.23 (3H, s), 7.00—7.79 (9H, m), and 7.97 (1H, s); MS, *m/z* 291 (M^+), 276, and 199; HRMS, *m/z* 291.0123 ($C_{14}H_{13}NOSe$ requires 291.0161).

2-Phenyl-1,2-benzisoselenazol-3(2*H*)-one 1-Oxide (8c). Mp 180—181 °C; IR (KBr) 1680 (s, C=O) and 810 cm^{-1} (s, Se=O); ^{1}H NMR ($CDCl_3$) δ=7.20—7.87 (10H, m); MS, *m/z* 291 (M^+); HRMS, *m/z* 291.0081 ($C_{13}H_9NO_2Se$ requires 290.9798).

Photolysis of 7-Methoxydibenzo[*b,f*][1,4]selenazepin-11-(10*H*)-one (2a). A solution containing 14 mg of 7-methoxydibenzo[*b,f*][1,4]selenazepin-11(10*H*)-one (**2a**) in 20 cm^3 of *t*-butyl alcohol was irradiated in a degassed sealed tube using a 450-W Hanovia medium-pressure mercury lamp through a Pyrex filter sleeve for 10 h. The solvent was removed under reduced pressure to give a residue which was subjected to the silica-gel preparative TLC using chloroform as the eluent. 4′-Methoxy-2-(2-hydroxy-2-methylpropylseleno)benzanilide (**6a**) 6.6 mg (47% yield) was isolated.

Syntheses of Althiomycin Analogs in Relation to Antibacterial Activities[1)]

Kaoru INAMI† and Tetsuo SHIBA*
Department of Chemistry, Faculty of Science, Osaka University,
Toyonaka, Osaka 560
(Received February 1, 1986)

Four analogs of an antibiotic althiomycin were synthesized in order to clarify the structure-activity relationships, especially with regard to two asymmetric centers and the aldoxime configuration. The antibiotic activity of de(hydroxymethyl) analog is comparable to that of the original antibiotic for Gram-positive bacteria.

Althiomycin (**1**), isolated from *Streptomyces althioticus*,[2)] inhibits the protein synthesis in both Gram-positive and negative bacteria. Recently, we achieved the total synthesis of this antibiotic.[3)] For investigation of the structure-reactivity relationships of althiomycin, we synthesized the following analogs (**2**—**5**) (Fig. 1).

First of all, the enantiomer of althiomycin, i.e., epialthiomycin (**2**), was synthesized according to the synthetic pathway of an original antibiotic (Fig. 2).

Secondly, de(hydroxymethyl) analog (**3**) was prepared from 1-[(*S*)-2-(benzyloxycarbonylaminomethyl)-2-thiazolin-4-yl-carbonyl]-4-methoxy-3-pyrrolin-2-one (**10**) which was the key intermediate of our synthetic study on althiomycin[3)] (Fig. 3). The

Fig. 1.

benzyloxycarbonyl (*Z*) group of this compound was removed with anhydrous hydrogen fluoride, followed by the coupling with the thiazole part by the azide method using potassium carbonate as the base.

Finally, we attempted to achieve the total synthesis of (*Z*)-althiomycin, which is the isomer of the natural (*E*)-althiomycin with respect to the aldoxime. (Fig. 4) The thiazole part of this compound was prepared from ethyl (*Z*)-2-(hydroxyiminomethyl)-4-thiazolecarboxylate (**11**) via successive procedures of conversion to the hydrazide with hydrazine and azidation with nitrite ester. The compound thus obtained was coupled with the thiazoline-pyrrolinone part (**5**)[3)] to give no desired product, but its bisanhydro derivative in very low yield. Therefore, we then tried to convert the natural althiomycin into its stereoisomer with anhydrous hydrogen fluoride at room temperature. Since this product was a mixture of (*E*)- and (*Z*)-althiomycins (about 1:1), the separation was performed with high-performance liquid chromatography (HPLC). The desired compound thus obtained gives two singlets at δ 8.59 and 8.09 which can be assigned as signals of the proton on C-5 in the thiazole ring and the methine proton of the aldoxime, while the original (*E*)-althiomycin gives the corresponding singlets at δ 8.37 and 8.35 in NMR respectively.[4)]

The antibacterial activities of these analogs, including the synthetic intermediate **5** of althiomycin, were shown in Table 1. This result suggests the following conclusions. The absence of the hydroxymethyl group attached to the adjacent carbon of C-2 in the thiazoline ring has no influence on the antibacterial activity of the parent antibiotic, while the inversion of the configuration of C-4 in the thiazoline ring or the aldoxime results in a significant decrease of the biological activity. The replacement of the thiazole part by benzyloxycarbonyl group gives the total loss of the antibiotic activity.

Experimental

All melting points are uncorrected. The ^{1}H NMR spectra were obtained with a Varian XL-100-15 NMR spectrometer, a JEOL FX-90Q NMR spectrometer, and a JEOL JNM-PMX 60 NMR spectrometer. The chemical shifts are given in δ, with tetramethylsilane (TMS) as the internal standard.

22.1 mmol) and dicyclohexylcarbodiimide (3.63 g, 17.6 mmol) were added and stirred at 0 °C for 2 h. After additional stirring at room temperature for 10 h, the reaction mixture was concentrated in vacuo. The residual oil was dissolved in ethyl acetate, and the insoluble material was filtered off. The filtrate was washed with saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate and concentrated in vacuo. The residue was recrystallized from ethyl acetate and hexane; yield 9.43 g (83.5%). Mp 195—196 °C (decomp). $[\alpha]_D^{20}$ +74.0° (*c* 0.978, chloroform). Found: C, 77.88; H, 5.71; N, 3.56; S, 4.10%. Calcd for $C_{50}H_{42}N_2O_4S \cdot 0.3(C_2H_5)_2O$: C, 77.92; H, 5.75; N, 3.55; S, 4.06%.

1-(*N*,*S*-Dityrityl-L-cysteinyl)-4-methoxy-3-pyrrolin-2-one (7). To a solution of 4-methoxy-3-pyrrolin-2-one (3.63 g, 32.1 mmol) in 100 ml of anhydrous THF, 60% sodium hydride (1.03 g, 25.7 mmol) was added and heated under reflux for 10 min. To the solution, *N*,*S*-dityrityl-L-cysteine 5-norbornene-*endo*-2,3-dicarboximidyl ester (**6**) (15.6 g, 21.4 mmol) was added and vigorously stirred for 50 min at room temperature. Ethyl acetate was added to the reaction mixture, and the solution was washed with saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous magnesium sulfate and concentrated in vacuo. The residue was recrystallized from ethyl acetate and hexane; yield 14.1 g (94%). Mp 206—207 °C (decomp). $[\alpha]_D^{27}$ +23.1° (*c* 1.72, chloroform). 100 MHz ^{1}H NMR ($CDCl_3$) δ=7.0—7.6 (30H, m), 4.86(1H, s), 4.84(1H, br., s), 3.78(3H, s), 3.77(1H, d, *J*=18 Hz), 3.43(1H, br., t), 3.34(1H, d, *J*=18 Hz), 2.80(1H, dd, *J*=12 Hz, 6 Hz), 2.58(1H, dd, *J*=12 Hz, 4 Hz). Found: C, 78.56; H, 5.85; N, 3.97; S, 4.55%. Calcd for $C_{46}H_{40}N_2O_3S$: C, 78.83; H, 5.75; N, 4.00; S, 4.57%.

1-[(*R*)-2-(Benzyloxycarbonylaminomethyl)-2-thiazolin-4-yl-carbonyl]-4-methoxy-3-pyrrolin-2-one (8). To a suspension of 1-(*N*,*S*-dityrityl-L-cysteinyl)-4-methoxy-3-pyrrolin-2-one (**7**) (2.50 g, 3.57 mmol) in a mixture of 12.5 ml of methanol and 8.77 ml of benzene, pyridine (0.320 ml, 3.93 mmol) and silver nitrate (670 mg, 3.93 mmol) were added and stirred for 4 h at room temperature. Hydrogen sulfide was bubbled through the reaction mixture for 30 min at room temperature. Silver sulfide was filtered off and the solution was concentrated in vacuo. The residue was dissolved in 50 ml of anhydrous ethanol and ethyl benzyloxycarbonylaminoacetimidate (842 mg, 3.57 mmol) was added to the solution. After stirring for 20 h at room temperature, the reaction mixture was concentrated in vacuo. The residue was dissolved in ethyl acetate and washed with saturated aqueous sodium hydrogencarbonate and then brine. The organic layer was dried over anhydrous magnesium sulfate and concentrated in vacuo. The residue was recrystallized from ethyl acetate and hexane; yield 660 mg (47.5%). Mp 178—179 °C (decomp). $[\alpha]_D^{27}$ −16.4° (*c* 0.335, chloroform). 100 MHz ^{1}H NMR ($CDCl_3$) δ=7.34(5H, s), 6.24(1H, mt), 5.54(1H, br., s),

5.26(1H, s), 5.25(2H, s), 4.30(2H, s), 4.26(2H, dd, J=6 Hz, 2 Hz), 3.90(3H, s), 3.62(1H, dd, J=9 Hz, 6 Hz), 3.50(1H, dd, J=9 Hz, 6 Hz). Found: C, 55.12; H, 5.06; N, 10.41; S, 8.11%. Calcd for $C_{18}H_{19}N_3O_5S \cdot 0.25H_2O$: C, 54.88; H, 4.99; N, 10.67; S, 8.14%.

1-[(4*R*)-2-[1-(Benzyloxycarbonylamino)-2-hydroxyethyl]-2-thiazolin-4-ylcarbonyl]-4-methoxy-3-pyrrolin-2-one (9). A mixture of **8** (100 mg, 0.257 mmol) and pulverized paraformaldehyde (154 mg, 5.14 mmol) in 1 ml of degassed dimethyl sulfoxide was stirred at room temperature for 7 d. After the insoluble material was filtered off, the filtrate was diluted with ethyl acetate, and washed with water. The organic layer was dried over anhydrous magnesium sulfate. The solution was concentrated in vacuo and the residue was lyophilized; yield 108 mg (100%). Mp 72—73 °C (decomp). 100 MHz ^{1}H NMR ($CDCl_3$) δ=7.33 (5H, s), 6.30 (1H, m), 5.88 (1H, m), 5.16 (1H, s), 5.13 (2H, s), 4.28 (2H, s), 4.02 (1H, s), 3.91(2H, m), 3.90(3H, s), 3.47 (1H, d, J=6 Hz), 3.34 (1H, d, J=6 Hz).

Epialthiomycin (2). To a solution of **9** (83.3 mg, 0.199 mmol) in 215 μl of anisole, anhydrous hydrogen fluoride (ca. 1 ml) was introduced within 10 min at −78 °C and stirred at 0 °C for 20 min. Hydrogen fluoride was evaporated off at 0 °C under reduced pressure for 20 min. The residual oil was dissolved in 1 ml of DMF at −78 °C, and potassium carbonate (824 mg, 5.97 mmol) was added to the solution, and then the suspension was vigorously stirred for 5 min at room temperature. Under cooling with Dry Ice-methanol bath, (*E*)-2-(hydroxyiminomethyl)-4-thiazolecarbonyl azide[3] (39.2 mg, 0.199 mmol) was added and the suspension was stirred at 0 °C for 30 min. After additional stirring at room temperature for 2.5 h, the reaction mixture was diluted with ethyl acetate, and washed with 0.1 M potassium phosphate buffer (pH 7.15) and water. The organic layer was dried over anhydrous magnesium sulfate, and concentrated in vacuo. Purification by silica-gel preparative TLC using a developing solvent chloroform–methanol 7:1 gave colorless powder; yield 19.9 mg (22.7%). Mp 174—176 °C (decomp). $[\alpha]_D^{14}$ −20.5° (c 0.073, Methyl Cellosolve). UV_{max}(methanol): 223 nm (ε 34700), 240 nm (ε 26000), and 286 nm (ε 8590). 90 MHz ^{1}H NMR(DMSO-d_6) δ=8.40 (1H, br., s, NH), 8.38 (1H, s, CH of oxime), 8.35 (1H, s, 5-H of thiazole), 6.08 (1H, mt, 4-H of thiazoline), 5.43 (1H, s, 3-H of pyrrolinone), 4.93 (1H, br.,-C<u>H</u>-CH_2OH), 4.33(2H, s, 5-H of pyrrolinone), 3.89 (3H, s, OCH_3), 3.83 (2H, m, -CH-C<u>H_2</u>OH), 3.50 (2H, t, 5-H of thiazoline). Found: C, 44.42; H, 4.48; N, 13.84; S, 12.87%. Calcd for $C_{16}H_{17}N_5O_6S_2 \cdot 0.3H_2O \cdot 0.6C_4H_8O_2$: C, 44.40; H, 4.54; N, 14.07; S, 12.88%.

De(hydroxymethyl)althiomycin (3). To a solution of 1-[(*S*)-2-(benzyloxycarbonylaminomethyl)-2-thiazolin-4-yl-carbonyl]-4-methoxy-3-pyrrolin-2-one (**10**)[3] (100 mg, 0.257 mmol) in 278 μl of anisole, anhydrous hydrogen fluoride (ca. 1 ml) was introduced within 10 min at −78 °C. After stirring at 0 °C for 20 min, hydrogen fluoride was evaporated off under reduced pressure at 0 °C for 20 min. Under cooling with Dry Ice-methanol bath, the residual oil was dissolved in 1 ml of DMF, and the solution was stirred vigorously for 5 min at room temperature. To the suspension, (*E*)-2-(hydroxyiminomethyl)-4-thiazolecarbonyl azide (50.6 mg, 0.257 mmol) was added and stirred at room temperature for 2.5 h after stirring at 0 °C for 30 min. The reaction mixture was diluted with ethyl acetate, and washed with 0.1 M potassium phosphate buffer (pH 7.15) and water. The organic layer was dried over anhydrous magnesium sulfate and concentrated in vacuo. Purification by silica-gel preparative TLC (chloroform–methanol 9:1) gave colorless solid; yield 30.7 mg (29.2%). Mp 116—117 °C (decomp). $[\alpha]_D^{14}$ +11.6° (c 0.147, Methyl Cellosolve). 90 MHz ^{1}H NMR(DMSO-d_6) δ=9.00(1H, br., d, NH), 8.33 (2×1H, s, CH of oxime and 5-H of thiazole), 6.14 (1H, mt, 4-H of thiazoline), 5.42 (1H, s, 3-H of pyrrolinone), 4.33 (2H, s, 5-H of pyrrolinone), 4.25 (2H, m, $-CH_2-\overset{N-}{\overset{\|}{C}}-S-$), 3.88 (3H, s, OCH_3), 3.40 (2H, m, 5-H of thiazoline). Found: C, 43.97; H, 4.09; N, 15.24; S, 14.01%. Calcd for $C_{15}H_{15}N_5O_5S_2 \cdot 0.5H_2O \cdot 0.4C_4H_8O_2$: C, 43.96; H, 4.34; N, 15.22; S, 14.13%.

(*Z*)-2-(Hydroxyiminomethyl)-4-thiazolecarbohydrazide (12). Ethyl (*Z*)-2-(hydroxyiminomethyl)-4-thiazolecarboxylate (**11**)[3] (1.50 g 7.50 mmol) was dissolved in 13 ml of DMF. To the solution, 100% hydrazine hydrate (8.02 ml, 0.165 mol) was added and allowed to stand at 4 °C for 20 h. To the reaction mixture, 100 ml of methanol was added and the precipitates were collected; yield 1.17 g (83.6%). Mp >220 °C. Found: C, 32.45; H, 3.30; N, 29.93; S, 17.35%. Calcd for $C_5H_6N_4O_2S$: C, 32.35; H, 3.25; N, 30.09; S, 17.22%.

(*Z*)-2-(Hydroxyiminomethyl)-4-thiazolecarbonyl Azide (13). To a suspension of the hydrazide **12** (155 mg, 0.834 mmol) in 1.25 ml of DMF, *t*-butyl nitrite (109 μl, 0.918 mmol) and 4.35 M hydrogen chloride in THF (0.420 ml, 1.80 mmol) were added at −50 °C and stirred at −30 °C for 40 min. The reaction mixture was diluted with ethyl acetate and washed with water. The organic layer was dried over anhydrous magnesium sulfate and concentrated in vacuo to give colorless needles; yield 116 mg (70.7%). Mp 118—119 °C (decomp).

(*Z*)-Althiomycin (4). Althiomycin (**1**)(148 mg, 0.337 mmol) was dissolved in ca. 5 ml of anhydrous hydrogen fluoride and stirred at room temperature for 40 min. Hydrogen fluoride was evaporated off under reduced pressure and the residue was dissolved in 2 ml of DMF. Potassium carbonate (1.40 g, 10.1 mmol) was added to the solution and the suspension was vigorously stirred for 10 min at room temperature. The reaction mixture was diluted with ethyl acetate and washed with 0.1 M potassium phosphate buffer (pH 7.15) and water. The organic layer was dried over anhydrous magnesium sulfate and concentrated in vacuo to give colorless solid. Separation and purification by HPLC (Nagel Nucleosil 7C_{18} (8 mm×250 mm), 31% aqueous acetonitrile) gave colorless solid (retention time: 5.6 min); yield 13.1 mg (8.9%). Mp 170—172 °C (decomp). $[\alpha]_D^{14}$ +10.7° (c 0.197, Methyl Cellosolve). 90 MHz ^{1}H NMR (DMSO-d_6) δ=8.59 (1H, s, CH of oxime), 8.54 (1H, br., NH), 8.09 (1H, s, 5-H of thiazole), 6.27 (1H, mt, 4-H of thiazoline), 5.43 (1H, s, 3-H of pyrrolinone), 5.14 (1H, mt, OH), 4.90 (1H, m, -C<u>H</u>-CH_2OH), 4.33(2H, s, 5-H of pyrrolinone), 3.89 (3H, s, OCH_3), 3.85 (2H, m, -CH-C<u>H_2</u>OH), 3.59 (2H, t, 5-H of thiazoline). Found: C, 43.97; H, 4.52; N, 13.43; S, 12.27%. Calcd for $C_{16}H_{17}N_5O_6S_2 \cdot 0.75H_2O \cdot 0.75C_4H_8O_2$: C, 43.96; H, 4.76; N, 13.49; S, 12.36%.

We thank the Research Laboratories of Toyo Jozo Co., Ltd. for the measurements of the antibacterial spectra of all synthetic analogs.

Palladium-Catalyzed Reaction of 2-Vinyl-2,3-dihydrobenzofurans and Chroman with Nucleophiles

Takahiro Hosokawa,* Takanori Kono, Toru Uno, and Shun-Ichi Murahashi*
Department of Chemistry, Faculty of Engineering Science, Osaka University,
Machikaneyama, Toyonaka, Osaka 560
(Received February 6, 1986)

Reaction of 2,3-dihydro-2-vinylbenzofuran with nucleophiles ($NaCH(COOEt)_2$ and $PhNHCH_3$) in the presence of palladium catalysts such as $Pd(PPh_3)_4$ and $PdCl_2(PR_3)_2$ (R=Ph and Et) gives 2-(2-butenyl)phenols (46—76% yields) in which nucleophiles are incorporated into the methyl group of the butenyl moiety. 2-Vinylchroman undergoes the same type of reaction where only the palladium complex bearing PEt_3 ligand is effective. The effectiveness of PEt_3 ligand is also observed in the reaction of 2,3-dihydro-2-isopropenylbenzofuran with diethyl sodiomalonate leading to 3-ethoxycarbonyl-4-(2-methyl-1-propenyl)-2-chromanone.

Palladium (II)-catalyzed cyclization of 2-(*trans*-2-butenyl)phenol(**1**) gives 2-vinyl-2,3-dihydrobenzofuran (**2**).[1] Since the vinyl compound has a structural unit of allylic ether, it is expected to react with nucleophiles in the presence of palladium(0) catalysts such as $Pd(PPh_3)_4$.[2] This will lead to functionalization of the methyl group in the butenyl moiety of **1** (Scheme 1). Described herein is the realization of the reduction of $PdCl_2$ complexes with excess diethyl sodiomalonate.[3] Diazopalladium(II) complex, $[PhC(N_2)]_2Pd(PEt_3)_2$ (**5**),[4] which upon heating generates $Pd(PEt_3)_2$, also serves as the catalyst to give **3a** (69%). Deethoxycarbonylation ($NaCN/LiI\cdot H_2O$/DMSO, 160 °C) of **3a** afford **6** (75%), resulting in two carbon homologation of the butenyl moiety of **1**.

b; Nu=NMePh

Scheme 1.

expectation, and an application of this procedure to 2-(*trans*-3-pentenyl)phenol (**8**) (Scheme 2).

The reaction of vinylbenzofuran **2** with diethyl sodiomalonate (1.2 equiv) in the presence of 3 mol% of $Pd(PPh_3)_4$ (THF-toluene, 110 °C, 4 h) gives a 76% yield of 4-substituted 2-butenylphenol **3a** along with its dimer **4** (10%). Palladium(II) complexes such as $PdCl_2(PR_3)_2$ (R=Ph and Et) are comparatively effective in promoting the reaction, in which palladium(0) species is generated in situ by the

Treatment of **2** with *N*-methylaniline (1.3 equiv) in the presence of $Pd(PPh_3)_4$ (3 mol%) in THF–toluene at 120 °C for 3 h gives **3b** in 46% yield (Scheme 1). The use of complex **5** bearing PEt_3 ligand affords a trace amount of **3b**. In this case, the substrate **2** largely rearranges into 2-methyl-2*H*-chromene (**7**) (46%).

2-Vinychroman (**9**), which is readily prepared by Pd(II)-catalyzed cyclization of 2-(*trans*-3-pentenyl)-phenol (**8**), undergoes the same type of alkylation with diethyl sodiomalonate (Scheme 2). In this case,

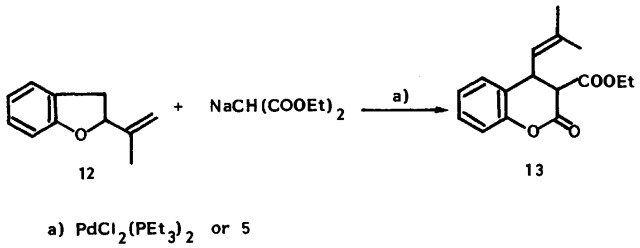
Scheme 2.

however, only the palladium complex bearing PEt_3 is effective; no reaction takes place with $Pd(PPh_3)_4$ and $PdCl_2(PPh_3)_2$, while $PdCl_2(PEt_3)_2$ affords a 63% yield of **10** along with its dimer **11** (10%). Since PEt_3 complexes are more nucleophilic than PPh_3 complexes,[5] the oxidative addition of Pd(0) into the C–O bond must be the rate-determining step in this alkylation.[6] The effectiveness of PEt_3 ligand is also observed in the reaction of dihydrobenzofuran **12** with diethyl sodiomalonate leading to coumarin **13**.



Thus, **13** is obtained in 54—64% yields with $PdCl_2(PEt_3)_2$ or **5**, while no reaction occurs with $Pd(PPh_3)_4$. In the reaction pathways shown in Scheme 3, **13** is assumed to be formed via isomerization of the intermediate π-allyl complex **14** to **15**.

Experimental

2-(*trans*-2-Butenyl)phenol (**1**) was prepared by C-alkylation of phenol with *trans*-1-chloro-2-butene (Tokyo Kasei).[1] 2-(*trans*-3-Pentenyl)phenol (**8**) was synthesized by the reaction of *o*-methoxybenzylmagnesium chloride with *trans*-2-butenyl diethyl phosphate[7] followed by demethylation.[8] The preparation of 2-isopropenyl-2,3-dihydrobenzofuran (**12**) was carried out by the reported procedure.[9]

Palladium(II)-Catalyzed Cyclization of 1 and 8. The reaction was performed by using substrate **1** or **8** (2.5 mmol), $Pd(OAc)_2$ (56.5 mg, 0.25 mmol), and $Cu(OAc)_2$ (45.0 mg, 0.25 mmol) in anhydrous MeOH (5 mL) under O_2 atmosphere (1 atm, balloon) at 36 °C. After usual workup,[1] the cyclized product was isolated by distillation followed by preparative TLC (SiO_2, hexane). **2**: Yield 62%; R_f=0.27. **9**:[10] Yield 57%; R_f=0.41.

Palladium-Catalyzed Alkylation of 2, 9, and 12 with Diethyl Sodiomalonate. Into a suspension of NaH (48 mg, 1.20 mmol) in dry THF (4 mL) was added diethyl sodiomalonate (240 mg, 1.50 mmol) at 0 °C, and the mixture was stirred for 1 h at room temperature. The resultant solution was then added by syringe to a solution of palladium catalyst (0.03 mmol) and vinyl compound **2**, **9**, or **12** (1 mmol) in dry toluene at room temperature, and the mixture was heated at 110 °C for 4 h. After cooling, the reaction was quenched by addition of water (10 mL) and ether (10 mL). The aqueous layer was neutralized by 2 M HCl(1 M=1 mol dm^{-3}) and extracted with ether (10 mL×3). The combined ethereal layer was washed with brine (20 mL×2) and dried over $MgSO_4$. Removal of the solvent followed by preparative TLC (SiO_2, hexane–EtOAc=7:3) gave the alkylated products. Their spectral and analytical data are listed below. The isolated yields of **3a** and **4** are 76 and 10% with $Pd(PPh_3)_4$, 56 and 19% with $PdCl_2(PPh_3)_2$, and 68 and 15% with $PdCl_2(PEt_3)_2$, respectively. Those of **10** and **11** are 63 and 10% with $PdCl_2(PEt_3)_2$ and 54 and 20% with $[PhC(N_2)]_2Pd(PEt_3)_2$ (**5**), respectively. The yield of **13** are 64 and 54%, with $PdCl_2(PEt_3)_2$ and **5**, respectively.

2-[*trans*-5,5-Bis(ethoxycarbonyl)-2-pentenyl]phenol (3a). Synthesis and Conformation of Aromatic Cyclic Dipeptides. Cyclo(phenylalanyl)$_2$, Cyclo(1-naphthylalanyl)$_2$, and Cyclo(2-naphthylalanyl)$_2$

Syun EGUSA,† Jun TAKAGI,† Masahiko SISIDO,*,†† and Yukio IMANISHI†
†Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606
††Research Center for Medical Polymers and Biomaterials, Kyoto University, Kyoto 606
(Received February 18, 1986)

Cyclic dipeptides of aromatic amino acids, cyclo(L-phenylalanyl)$_2$, cyclo(L-1-naphthylalanyl)$_2$, and cyclo(L-2-naphthylalanyl)$_2$ were synthesized and subjected to spectroscopic analyses using ^{1}H NMR, absorption, circular dichroism (CD), fluorescence, and fluorescence-detected circular dichroism (FDCD). The ^{1}H NMR data suggested that the 2,5-piperazinedione rings of the three cyclic dipeptides are in planar or nearly planar bowsplit boat-type conformation. The aromatic side groups of cyclo(1- and 2-naphthylalanyl)$_2$'s were found to take asymmetric configurations, one naphthyl group being folded onto the 2,5-piperazinedione ring, the other being unfolded. Strong exciton couplet was observed in CD spectra of the three compounds. The signs of the exciton splitting were opposite in the two naphthyl cyclic dipeptides. Fluorescence spectra of the two naphthyl cyclic dipeptides showed no excimer emission. The absence of strong interchromophoric interaction in the lowest excited state was also suggested by the virtual coincidence of CD spectrum with FDCD spectrum. From the above spectroscopic data, probable conformations were proposed for the naphthyl cyclic dipeptides.

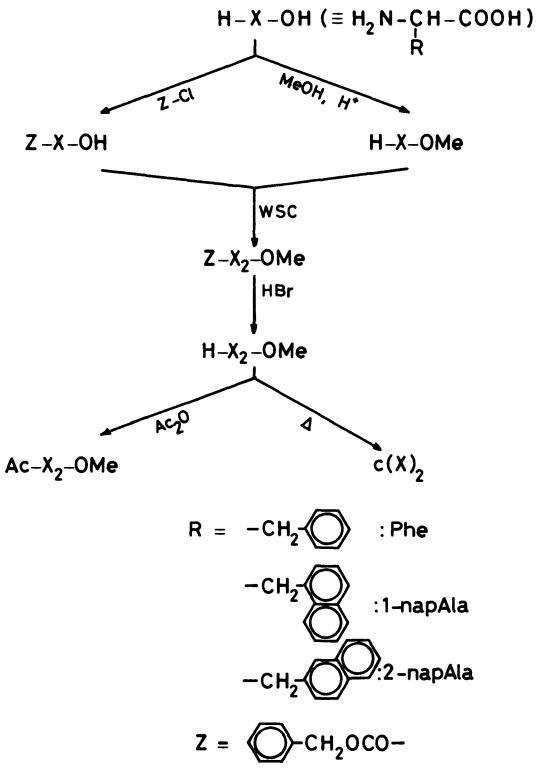
Bichromophoric systems in which conformational freedom of the two chromophores are highly restricted, have been studied and basic information on electronic properties of spatially fixed chromophoric systems has been accumulated.[1] In this respect, cyclic compounds carrying aromatic groups are especially interesting because of the rigidity of the chromophore arrangement. Bichromophoric cyclophanes,[1] cyclobutanes,[2,3] and crown ethers[4] have been reported in the past. However, few *chiral* bichromophoric cyclic compound has been reported so far.[1] The chiral bichromophoric systems are advantageous, since chiroptical spectroscopy, such as circular dichroism (CD), circularly polarized fluorescence (CPF),[5,6] and fluorescence-detected circular dichroism (FDCD)[7] provides more information on the electronic properties than that from conventional spectroscopy.

In this study, syntheses of aromatic cyclic dipeptides carrying phenyl, 1-naphthyl, and 2-naphthyl chromophores were undertaken and their conformations in solution were investigated. Cyclic dipeptides consisting of natural amino acids i.e., phenylalanine (Phe), tyrosine (Tyr), histidine (His), and tryptophan (Trp) have been studied by ^{1}H NMR, ^{13}C NMR, CD, and X-ray crystallography.[8–15] However, the aromatic groups of the natural amino acids are not suited for photochemical and photophysical investigations. In this study, artificial aromatic amino acids carrying 1- or 2-naphthyl group, L-1- and L-2-naphthylalanine (1- or 2-napAla) are employed and their linear and cyclic dipeptides are prepared.

Experimental

Meterials. Linear and cyclic dipeptides of Phe, 1-napAla, and 2-napAla were prepared by the procedure shown in Scheme 1. Optically active 1- and 2-napAla's were prepared by the optical resolution of their acetyl derivatives with acylase,[16,17] which were synthesized by the acetamidomalonate ester method. In the following, syntheses of linear and cyclic dipeptides of 2-napAla are described as typical examples.

***N*-Benzyloxycarbonyl-L-2-naphthylalanine (*Z*-2-napAla).**



Scheme 1.

2-NapAla (200 mg) was dissolved in 1 M† NaOH aqueous solution (1 ml) and cooled by ice. Benzyloxycarbonyl chloride (0.15 ml) and 1 M NaOH were added dropwise concurrently under vigorous stirring. The stirring was continued overnight and then the pH of the solution was adjusted to about 3. The organic component was extracted with ethyl acetate and the extract was dried and evaporated. The crude crystals remained were recrystallized from an ether–hexane mixed solvent. Yield 90%, mp 165—170 °C. *Z*-l-napAla: Yield 95%, mp 150—152 °C. *Z*-Phe: Yield 71%, mp 86—89 °C.

L-2-Naphthylalanine Methyl Ester Hydrochloride (2-napAla-OMe·HCl). The amino acid (200 mg) was dissolved in methanol (20 ml) containing 2 ml of 1 M HCl and refluxed for 1 h. The solvent was evaporated and the residue was recrystallized from a methanol–ethyl acetate mixed solvent. Yield 87%, mp 165 °C (gradually sublimed above 130 °C). 1-NapAla-OMe·HCl: Yield 98%, mp 143—145 °C (partially sublimed). Phe-OMe·HCl: Yield 95%, mp 159—161 °C.

***N*-Benzyloxycarbonyl-L-2-naphthylalanyl-L-2-naphthylalanine Methyl Ester [*Z*-(2-napAla)$_2$-OMe].** *Z*-2-NapAla (133 mg) was dissolved in dichloromethane (2 ml) and 2-napAla-OMe·HCl (100 mg) and triethylamine (58 µl) were added. After cooling with an ice–water bath, water-soluble carbodiimide (WSC) [1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride] (80 mg) and 1-hydroxybenzotriazole (56 mg) were added. After stirring overnight the solvent was evaporated and ethyl acetate was added. The solution was washed with 10% citric acid, aq NaCl solution, 10% $NaHCO_3$, and water and dried over sodium sulfate. The residue remained after evaporation was recrystallized from an ethyl acetate–ether mixed solvent. Yield 83%, mp 163 °C. *Z*-(1-napAla)$_2$-OMe: Yield 73%, mp 136 °C. *Z*-(Phe)$_2$-OMe: Yield 40%, mp 106—109 °C.

Cyclo(L-2-naphthylalanyl-L-2-naphthylalanyl) [c(2-napAla)$_2$]. *Z*-(2-NapAla)$_2$-OMe (177 mg) was dissolved in 25% HBr–acetic acid (3 ml) and stirred for 30 min at room temperature. The solution was concentrated under reduced pressure and a small amount of acetic acid was added again. The solution was poured into ether and the precipitate was collected and dried under vacuum. The HBr salt was then dispersed in ethyl acetate and shaked with aqueous $NaHCO_3$ solution. The organic layer was dried over sodium sulfate and the solvent was evaporated. 1-Butanol (50 ml) was added to the residue remained and the solution was refluxed for 2 d. The crystal which appeared after cooling the reaction mixture in refrigerator, was collected and washed with methanol. The cyclic dipeptide was only slightly soluble in such polar aprotic solvents as *N*,*N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and trimethyl phosphate (TMP). No appropriate solvent was found for recrystallization. Yield 55%, mp>300 °C. Found: C, 79.39; H, 5.85; N, 7.22%. Calcd for $C_{26}H_{24}N_2O_2$: C, 79.17; H, 5.62; N, 7.10%. c(1-napAla)$_2$: Yield 47%, mp 272—274 °C. Anal. Found: C, 79.30; H, 5.58; N, 7.27%. c(Phe)$_2$: Yield 32%, mp>300 °C. Found: C, 73.61; H, 6.11; N, 9.43%. Calcd for $C_{18}H_{18}N_2O_2$: C, 73.45; H, 6.16; N, 9.52%.

† 1 M=1 mol dm^{-3}.

***N*-Acetyl-L-2-naphthylalanyl-L-2-naphthylalanine Methyl Ester [Ac-(2-napAla)$_2$-OMe].** The benzyloxycarbonyl group of *Z*-(2-napAla)$_2$-OMe was removed by 25% HBr–acetic acid. The HBr salt of the dipeptide methyl ester was dissolved in acetic anhydride–triethylamine (1:1) mixture and stirred overnight. The volatile component was removed under reduced pressure and the solid remained was dissolved in ethyl acetate. The solution was washed with 1 M HCl, 10% $NaHCO_3$, and water and dried over Na_2SO_4. Evaporation gave a crude crystal which was recrystallized from an ethyl acetate–hexane mixed solvent. Mp 200—205 °C. Found: C, 73.37; H, 5.96; N, 5.98%. Calcd for $C_{29}H_{28}N_2O_4$: C, 74.34; H, 6.02; N, 5.98%. Ac-(1-napAla)$_2$-OMe: Mp 208—212 °C. Found: C, 74.37; H, 5.99; N, 6.32%.

Measurements. ^{1}H NMR (90 MHz) was recorded on a JEOL FX90Q Fourier Transform spectrometer in *N*,*N*-dimethylformamide (DMF)-d_7 over the temperature range of 50—100 °C for c(Phe)$_2$ and c(2-napAla)$_2$ and over the temperature range of −40—100 °C for c(1-napAla)$_2$. Residual peaks of the solvent were eliminated by a 180°-τ-90° pulse sequence. The peak assignment reported by Kobayashi et al.[18] was adopted. The amide NH peaks of the naphthyl dipeptides overlapped with the peaks of aromatic protons. Therefore, the coupling parameter $J_{NH-C^{\alpha}H}$, was measured from the splitting of $C^{\alpha}H$ proton band under irradiating the $C^{\beta}H$ proton. Octets were observed in the region of $C^{\beta}H$ protons for the three cyclic dipeptides, indicating the two nonequivalent $C^{\beta}H$ protons [$C^{\beta}H$(S) and $C^{\beta}H$(R)] couple with each other and with the $C^{\alpha}H$ proton. The coupling constants, $J_{C^{\alpha}H-C^{\beta}H(S)}$ and $J_{C^{\alpha}H-C^{\beta}H(R)}$, were directly read from the peak separations of the octets.

Circular dichroism (CD) was recorded on a JASCO J-20 spectropolarimeter. Fluorescence-detected circular dichroism (FDCD) was also measured on the JASCO J-20 machine, equipped with a cutoff filter for excitation light, a Hamamatsu R268 photomultiplier tube, and a preamplifier.[7] Fluorescence spectra were recorded on a Hitachi MPF-4 instrument under an autocorrection mode. The dipeptides in DMF ([Aryl group]=1.0×10^{-5} mol l^{-1}) were put into a quartz tube of diameter 5 mm, and the tube was immersed into a Dewer vessel with quartz windows. The Dewer vessel was filled with a temperature-controlled methanol. The DMF solution was bubbled with nitrogen gas for 20 min before each measurement.

Results and Discussion

^{1}H NMR Spectra. The proton NMR spectra of the three cyclic dipeptides were measured in DMF-d_7. The spectra for c(1- and 2-napAla)$_2$ are shown in Fig. 1.

Coupling parameters obtained from the spectra are collected in Tables 1 and 2. They were virtually constant over the temperature range of 50—100 °C for c(Phe)$_2$ and c(2-napAla)$_2$ and −40—100 °C for c(1-napAla)$_2$, indicating a temperature independence of the skeletal conformations of the 2,5-piperazinedione rings and of the conformer populations of the side chains for the three cyclic dipeptides.

Table 1 lists the coupling constants $J_{NH-C^{\alpha}H}$, which are related to the dihedral angle $\theta_{NH-C^{\alpha}H}$ between C^{α}–N–H plane and H–C^{α}–N plane. $\theta_{NH-C^{\alpha}H}$ is approximately equal to $\phi(N-C^{\alpha})-60°$, where ϕ is the rotational angle around N–C^{α} bond as defined by the IUPAC-IUB nomenclature committee.[19] The dihedral angles were calculated from the coupling constants by using three different equations proposed by Bystrov et al.,[20] Ramachandran et al.,[21] and Chung et al.,[22] and are listed in the same table. It is seen that the angles estimated by using the three equations differ considerably.

Skeletal conformation of cyclic dipeptides in solution is often assumed to be symmetric and have planar amide bonds. Under these assumptions, the skeletal conformation is expressed by a single angle β, which is defined as a complementary angle between the two amide planes.[12,13] A skeletal conformation with positive β is called as a bowsplit boat-type one in which the two C^{β} atoms are in extended positions out of the 2,5-piperazinedione ring. The conformation of negative β is called as a flagpole boat-type one in which the two C^{β} atoms approach with each other above the 2,5-piperazinedione ring. β is zero for a planar 2,5-piperazinedione ring. The smallest β has been reported for cyclo(*N*-methyl-L-Val)$_2$[15] to be $-41°$, while the largest β has been found in cyclo(L-proline)$_2$[23] to be 38°. Larger or smaller β leads to unacceptably small bond angles at the C^{α} atom.

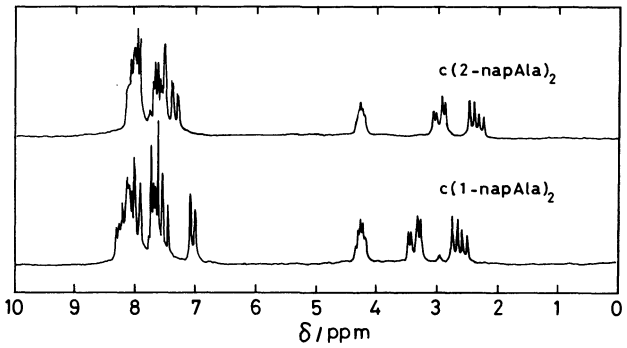


Fig. 1. Proton NMR spectra of c(1- and 2-napAla)$_2$ in DMF-d_7. Concentration=2.0 mg/0.4 ml. Temperature=30 °C for c(1-napAla)$_2$, 50 °C for c(2-napAla)$_2$.

If one allows a variation of β between ±45°, the allowed range of $\theta_{NH-C^{\alpha}H}$ is between $-20°$ and $-100°$. Hence, among the four values of $\theta_{NH-C^{\alpha}H}$ obtained as solutions of each equation of Table 1, only one is in the allowed range, which is indicated in the parentheses. If one adopts $\theta=-102°$ for c(Phe)$_2$, the bond angle $\angle$(N,C,C′) will be 97°. Similarly, if one takes $\theta=-115°$ for c(2-napAla)$_2$, the bond angle will be 85°. These small bond angles around C^{α} atom are unacceptable.

As the result of the above consideration, it was concluded that the $\theta_{NH-C^{\alpha}H}$ values lie between $-58°$ and $-39°$ for the two c(napAla)$_2$'s and between $-72°$ and $-57°$ for c(Phe)$_2$. These ranges of $\theta_{NH-C^{\alpha}H}$ correspond to the range of β between 0° and 20° for the two c(napAla)$_2$'s and between $-10°$ and 5° for c(Phe)$_2$. Therefore, the two c(napAla)$_2$'s have planar or nearly planar bowsplit boat-type skeletal conformations and c(Phe)$_2$ is in a planar conformation in DMF solution.

Little has been reported on the skeletal conformations of aromatic cyclic dipeptides. Snow and Hooker[13] calculated conformation energy and theoretical CD for c(Tyr)$_2$ and concluded that its β value was around 20°. This value is within the possible range of β for the two c(napAla)$_2$'s. On the other hand, Benedetti et al.[15] reported a result of X-ray crystallography of c(*N*-methyl-Phe)$_2$ and found that $\beta=-19°$. The large negative value may reflect the effect of *N*-methyl substituents and cannot be directly

Table 1. The Coupling Constant $J_{NH-C^{\alpha}H}$, and the Dihedral Angle $\theta_{NH-C^{\alpha}H}$, of Aromatic Cyclic Dipeptides in *N*,*N*-Dimethylformamide-d_7

Amino acid	$J_{NH-C^{\alpha}H}$[a]	$\theta_{NH-C^{\alpha}H}$/degree		
		Bystrov[c]	Ramachandran[d]	Chung[e]
Phe	≲1.0[b]	±102, ±72 (−72)[f]	[g]	±102, ±57 (−57)
1-napAla	2.9	±117, ±55 (−55)	±112, ±52 (−52)	±116, ±39 (−39)
2-napAla	2.5	±115, ±58 (−58)	±109, ±56 (−56)	±113, ±43 (−43)

a) Measured at 30 °C for c(1-napAla)$_2$ and at 50 °C for c(2-napAla)$_2$ and c(Phe)$_2$, ±0.2 Hz. b) Estimated from the linewidth of C^{α} proton signal under irradiating the C^{β} protons. c) $J_{NH-C^{\alpha}H}=9.4\cos^2\theta-1.1\cos\theta+0.4$. (Ref. 20). d) $J_{NH-C^{\alpha}H}=7.9\cos^2\theta-1.5\cos\theta+1.35\sin^2\theta$. (Ref. 21). e) $J_{NH-C^{\alpha}H}=4.3\cos^2\theta-2.9\cos\theta+4.3$. (Ref. 22). f) Value which corresponds to the allowed range of β(±45 °). g) The Ramachandran equation affords no solution.

compared with the present results.

Coupling constants $J_{C^{\alpha}H-C^{\beta}H(R)}$ and $J_{C^{\alpha}H-C^{\beta}H(S)}$ afford information on the rotamer population around $C^{\alpha}-C^{\beta}$ bond (χ_1), if the rotation is fast enough compared with the NMR time scale. Although the bulky aromatic groups is expected to retard the rotation considerably, no evidence for the restricted rotation was detected in the ^1H NMR spectra over the temperature range of −40—100 °C for c(1-napAla)$_2$ and 50—100 °C for c(2-napAla)$_2$ and c(Phe)$_2$. The coupling constants are listed in Table 2, together with the rotamer populations calculated according to the empirical equation reported by Pachler.[24]

The population of trans conformation is smaller than 20% for the three cyclic dipeptides. The small contribution of trans form is explained by a repulsive interaction between aromatic ring and the carbonyl oxygen. g^+ indicates a folded conformation in which the aromatic ring is overlapped onto the 2,5-piperazinedione ring. It should be noted that the population of the folded conformation is larger than 40% for the two c(napAla)$_2$'s and even larger for c(Phe)$_2$. The predominance of the folded conformation may be, at least partially, ascribed to an aromatic-amide interaction which has been detected by NMR spectroscopy.[25]

A CPK model examination and a preliminary result of empirical potential energy calculation for c(napAla)$_2$'s[26] suggested that the two side chains cannot take the folded conformation concurrently. Therefore, the high population of the folded conformation indicates that one side chain takes a folded conformation whereas the other is in unfolded conformations, t and g^- with a predominance of g^-. Incidentally, Benedetti et al.[15] reported that the side chains of c(*N*-methyl-L-Phe)$_2$ are in an asymmetric conformation, one being in a folded, the other in an unfolded conformation in the solid state.

To summarize the ^1H NMR results, the three aromatic cyclic dipeptides take similar skeletal and side-chain conformations. The skeletal conformation is planar ($\beta=0°$) or nearly planar bowsplit boat-type one ($\beta<20°$). The side-chains rotate rapidly within the NMR time scale and its rotamer population favors folded (g^+)-unfolded ($g^->t$) asymmetric conformations.

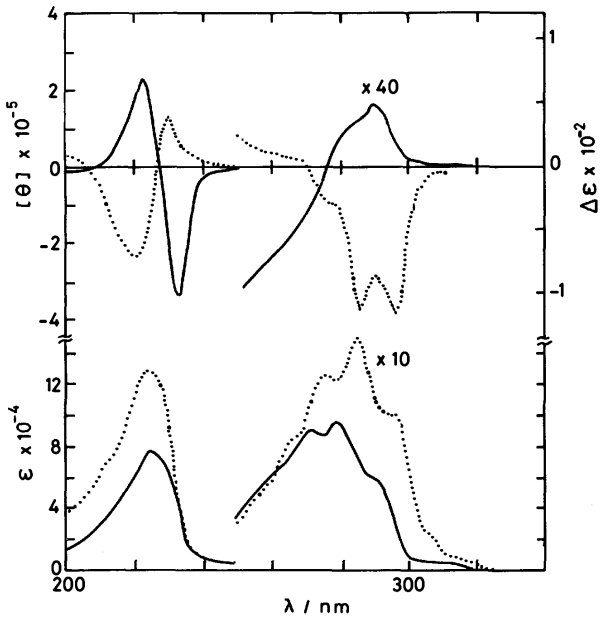

Fig. 2. CD (top) and absorption (bottom) spectra of c(1-napAla)$_2$ (·····) and c(2-napAla)$_2$ (——) in trimethyl phosphate at 25 °C. [θ] and ε are calculated with respect to two naphthyl chromophores.

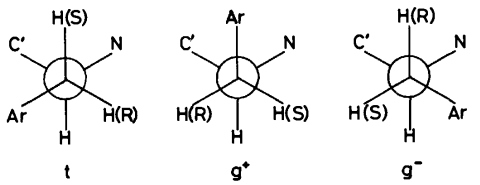
Table 2. The Coupling Constant $J_{C^{\alpha}H-C^{\beta}H}$, and the Rotamer Populations around $C^{\alpha}-C^{\beta}$ Bond in *N,N*-Dimethylformamide-d_7

Amino acid	$J_{C^{\alpha}H-C^{\beta}H(S)}$	$J_{C^{\alpha}H-C^{\beta}H(R)}$[a]	Rotamer polulations[b]		
			t	g^-	g^+
Phe	4.1	6.9	0.14	0.39	0.47
1-napAla	4.5	7.2	0.17	0.42	0.41
2-napAla	4.6	7.1	0.18	0.41	0.41

a) These coupling parameters (in Hz) were constant over the temperature range of 30—100 °C. The estimated error is ±0.1 Hz for 1- and 2-napAla's and ±0.5 Hz for Phe. b) Calculated on the basis of the Pachler's empirical equation (Ref. 24): $J_{C^{\alpha}H-C^{\beta}H(S)}=10.96\,t+2.60$, $J_{C^{\alpha}H-C^{\beta}H(R)}=10.96\,g^-+2.60$. The configurations of the three rotamers are shown below.



Absorption Spectra and Circular Dichroism. Figure 2 shows absorption and CD spectra of c(1- and 2-napAla)$_2$'s in TMP. The two cyclic dipeptides exhibit marked exciton couplets at the ^1B_b absorption band with opposite signs. The molar ellipticities are: $[\theta]_{229}=1.4\times10^5$, $[\theta]_{221}=-2.4\times10^5$ ($\Delta\tilde{\nu}=1581$ cm^{-1}) for c(1-napAla)$_2$ and $[\theta]_{233}=-3.5\times10^5$, $[\theta]_{222}=2.3\times10^5$ ($\Delta\tilde{\nu}=2127$ cm^{-1}) for c(2-napAla)$_2$. According to the exciton coupling rule,[27] the sign of exciton coupling in c(1-napAla)$_2$ indicates that the screw sense of the arrangement of ^1B_b absorption transition moment is right-handed in the conformation which contributes most significantly to the CD spectrum observed. The sign of exciton couplet in c(2-napAla)$_2$ indicates that the screw sense is left-handed in the most significant conformer.

The marked exciton couplet also suggests strong interchromophore interaction between naphthyl groups in the cyclic dipeptides. A preliminary conformational calculation[26] indicated that the center-to-center distances between two naphthyl groups in the two cyclic dipeptides are between 6—7 Å in the folded(g^+)-unfolded(g^-) side-chain conformations. The interchromophore distance is short enough to induce strong exciton couplet in the CD spectra.

The CD intensity at the ^1B_b absorption band is much more intense in the cyclic dipeptides than in the corresponding linear dipeptides which are shown in Fig. 3. No exciton couplet is seen in Ac-(1-napAla)$_2$-OMe and very weak CD is observed in Ac-(2-napAla)$_2$-OMe. The weak CD indicates a weaker interchromophore interaction in the linear dipeptides due to longer average interchromophore distances and/or an averaging of positive and negative CD spectra of a variety of conformations allowed for the linear dipeptides in solution. Absorption coefficients of the two cyclic dipeptides (Fig. 2) are smaller than those of the linear dipeptides (Fig. 3), especially for the 2-naphthyl derivatives. The hypochromicity indicates a stronger interchromophore interaction in the cyclic dipeptides than in the linear ones, suggesting that the weak CD of linear dipeptides is caused not by the averaging of positive and negative CD curves but by a weak interchromophore interaction in the linear dipeptides.

The weak chromophoric interaction in the linear dipeptides suggests that the dipeptides are in extended conformations in TMP. Rizzo and Jäckle[28] reported that linear aromatic dipeptides, such as Ac-(Trp)$_2$-NHMe, Ac-(Phe)$_2$-NHMe, and Ac-(Tyr)$_2$-NHMe, are in folded conformations in a protic solvent, 2,2,2-trifluoroethanol, and in extended ones in an aprotic solvent, tetrahydrofuran. Although it is impossible to test the above rule in the present case due to the limited solubility, the extended conformations suggested for the linear dipeptides of napAla's in TMP, which is an aprotic solvent, do not contradict the above rule.

Figure 4 shows absorption and CD spectra of c(Phe)$_2$ in TMP. A moderately strong exciton couplet is observed around 195 nm, which corresponds to the ^1B_b absorption band of the phenyl group. The interpretation of the sign of the exciton couplet of c(Phe)$_2$ is somewhat difficult due to the complexity in the direction of the ^1B_b transition moment.[29]

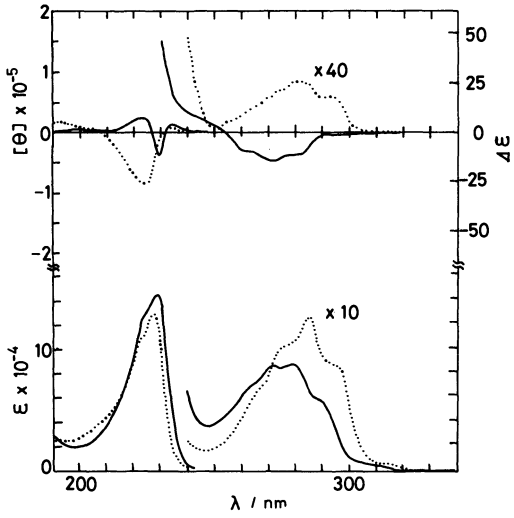


Fig. 3. CD (top) and absorption (bottom) spectra of Ac-(1-napAla)$_2$-OMe (·····) and Ac-(2-napAla)$_2$-OMe (——) in trimethyl phosphate at 25 °C. [θ] and ε are calculated with respect to two naphthyl chromophores.

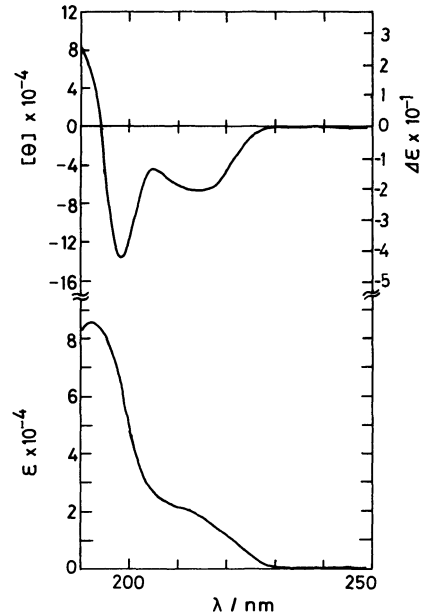

Fig. 4. CD (top) and absorption (bottom) spectra of c(Phe)$_2$ in trimethyl phosphate at 25 °C. [θ] and ε are calculated with respect to two phenyl chromophores.

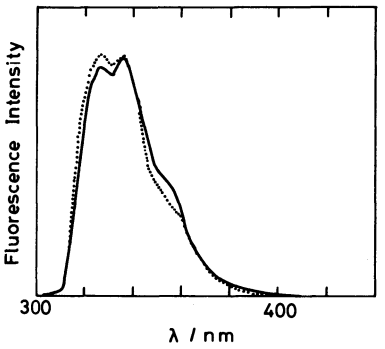

Fig. 5. Fluorescence spectra of c(l-napAla)$_2$ (·····) and c(2-napAla)$_2$ (——) in N_2-bubbled *N,N*-dimethylformamide at 25 °C. Excitation wavelength=285 nm.

Fluorescence Spectra and Fluorescence-Detected Circular Dichroism. Figure 5 shows fluorescence spectra of c(1- and 2-napAla)$_2$'s in DMF. No excimer emission was observed in the two cyclic dipeptides, indicating the inaccessibility of the two naphthyl groups connected to the 2,5-piperazinedione ring. Excimer emission was not detected even at low temperatures down to −50 °C for the two c(napAla)$_2$'s. This contrasts the case of *cis*-1,2-di(2-naphthyl)cyclobutane,[3] in which excimer emission has not been detected at room temperature, but observed at low temperatures (−20—−80 °C). The absence of excimer emission in the cyclic dipeptides indicates the rigidity of the skeletal and side-chain conformations and excludes the possibility of the folded(g$^+$)–folded(g$^+$) symmetrical side-chain conformation in the cyclic dipeptides.

No excimer was found also in linear dipeptides of 1- and 2-napAla's in DMF, suggesting, again, the extended conformation of the linear dipeptides in such aprotic solvents as TMP and DMF.

The absence of excimers in cyclic dipeptides does not contradict the observation of strong exciton couplet in CD spectra. In the latter case, one naphthyl group in the ^1B_b excited Franck-Condon state interacts with another naphthyl group, which is in the ground state, mainly by a dipole–dipole mechanism. In the case of excimer, one naphthyl group in the lowest ^1L_b excited state interacts with another naphthyl group by a mechanism including an electron-exchange interaction. The excimer formation requires a considerable distortion of molecular configuration to keep the two chromophores close to each other within ca. 3.5 Å.

The absence of strong interchromophore interaction in the lowest excited state is also evident from FDCD spectra shown in Fig. 6. FDCD spectroscopy measures a difference in fluorescence intensities (I_L^{ex}, I_R^{ex}) when excited by left- and right-circularly polarized lights, respectively, and are represented by the Kuhn's excitation dissymmetry factor g_{ex}.[7]

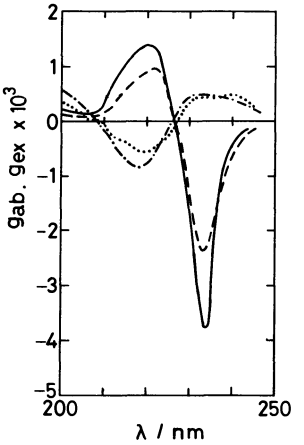

Fig. 6. FDCD spectra (g_{ex}) of c(l-napAla)$_2$ (·····) and c(2-napAla)$_2$ (----), and absorption CD spectra (g_{ab}) of c(l-napAla)$_2$ (—·—) and c(2-napAla)$_2$ (——) in trimethyl phosphate at 25 °C.

$$g_{ex} = 2(I_L^{ex} - I_R^{ex})/(I_L^{ex} + I_R^{ex})$$

The excitation dissymmetry factor should be compared with the absorption dissymmetry factor g_{ab}, calculated from CD and absorption spectra of the same sample.

$$g_{ab} = 2(\varepsilon_L - \varepsilon_R)/(\varepsilon_L + \varepsilon_R)$$

ε_L and ε_R are the absorption coefficients for left- and right-circularly polarized lights, respectively.

In Fig. 6, the absorption and the excitation dissymmetry factors of c(napAla)$_2$ coincides with each other within an experimental error, indicating the absence of any particular conformation which fluoresces predominantly. In other words, all conformers of c(l-napAla)$_2$ fluoresce equally. This, in turn, suggests the absence of any particular interaction between the naphthyl groups in the lowest excited state. The conclusion should be somewhat modified in the case of c(2-napAla)$_2$. In this case the excitation dissymmetry factor is a little smaller than the absorption dissymmetry factor, especially at the negative lobe. The smaller g_{ex} may indicate that the conformation which shows an intense CD, fluoresces less strongly than other conformers. Presumably, a conformation in which the two naphthyl groups are close to each other induces a strong exciton couplet but fluoresces little due to an enhanced nonradiative process caused by some interchromophoric interactions. However, the interaction is so small that the whole profile of the FDCD spectrum remains unchanged.

Conclusions

Possible conformations of c(1- and 2-napAla)$_2$'s are illustrated in Fig. 7. The folded(g$^+$)-unfolded(g$^-$)

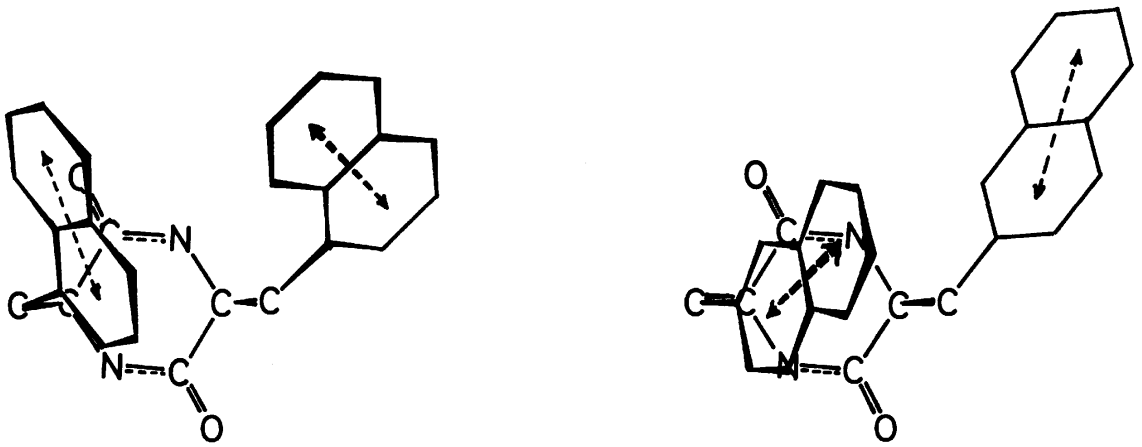

Fig. 7. Possible conformations of c(1-napAla)$_2$ (left) and c(2-napAla)$_2$ (right). The dashed arrows indicate directions of the ^1B_b transition moments.

asymmetric conformation is suggested by the ^1H NMR data and by the absence of excimer emission. The screw sense of the arrangement of the ^1B_b absorption transition moments of the two naphthyl groups is right-handed for c(1-napAla)$_2$ in a conformation which contributes most significantly to CD spectrum. It is left-handed for c(2-napAla)$_2$. The center-to-center interchromophoric distances are 6—7 Å. No particular interaction in the lowest excited state has been detected in the fluorescence and the FDCD spectra.

Stereochemistry of Hydroxymethylations of *N*-Salicylideneglycyl Dipeptide Copper(II) Complexes. A Kinetically and Also Thermodynamically Controlled Reaction

Kaoru HARADA,* Shinnichiro SUZUKI,† Hideyuki NARITA, and Hiroshi WATANABE
Department of Chemistry, University of Tsukuba, Niihari-gun, Ibaraki 305
(Received February 18, 1986)

(*N*-Salicylideneglycyl-L-valinato)copper(II) or (*N*-salicylideneglycyl-L-isoleucinato)copper(II) was treated with formaldehyde in an aqueous solution under relatively mild conditions. It was found that the resulting seryl residue was D-configuration in the early stage of the reaction. However, the configuration was inverted from D- to L-form after prolonged reaction. The epimerization reactions of authentic (*N*-salicylideneglycyl-D- or L-seryl-L-isoleucinato)copper(II) were carried out under similar conditions. These results indicate that the reaction as a whole is controlled kinetically as well as thermodynamically.

Nonenzymatic pyridoxal-catalyzed reactions of amino acids have been studied.[1-7] These are transamination, decarboxylation, racemization, and α-β bond cleavage (or formation) of α-amino acids. In these reactions, the metal complexes of the Schiff bases of amino acids with pyridoxal have been considered to be the key compounds. The presence of metal ion contributes to the formation of the Schiff base, and the resulting metal complex which has a planar geometry, facilitates the various reactions in the molecule. Because of the electron-attracting property of the metal ion in the complex, the chemical bonds around the α-carbon atom of the amino acid are activated and therefore show various interesting chemical properties in the nonenzymatic pyridoxal-catalyzed reactions of amino acids (Scheme 1).

Several studies on the activation of the α-carbon of amino acids or peptides by the formation of metal complexes have been reported. The reaction of acetaldehyde with glycine copper(II) complex in alkaline aqueous solution resulted in the formation of threonine and allothreonine.[8-11] The reaction of formaldehyde with glycylglycine copper(II) complex gave serylglycine.[12] The reaction of acetaldehyde with triglycine copper(II) complex also occurred to form threonylglycylglycine and allothreonylglycylglycine.[13]

It has been known that the reactions of aldehydes with the copper(II) complex of the Schiff base of glycine with salicyl aldehyde [aqua(*N*-salicylideneglycinato)copper(II)] proceeded smoothly to form hydroxy amino acids.[14] Alkyl halides[15] and acrylonitrile[16] react with the complex to form α-amino acids. These results indicate that the methylene group adjacent to the azomethine group in the copper complex is activated as in the pyridoxal-catalyzed reactions.[17]

In this study employing the chemical properties of *N*-salicylidene amino acid copper(II) complex, an asymmetric synthesis of a seryl residue was carried out by the hydroxymethylation of (*N*-salicylideneglycyl-L-valinato)copper(II) complex (complex **1**) under relatively mild aqueous conditions (pH 8.5, 45—80 °C) (Scheme 2). The time courses of the reaction were studied. A part of the work was already published as a short communication.[18]

When glycyl-L-valine was used, the formation of D-seryl-L-valine was larger than the corresponding diastereomer in the beginning of the reaction. Prolonged reaction, however, resulted in the formation of L-seryl-L-valine in the reaction mixture. In the case of *N*-salicylideneglycyl-L-isoleucine copper(II) complex (complex **2**), D-seryl-L-isoleucine was formed in the initial stage of the reaction, but the amount of L-seryl-L-isoleucine increased with the reaction time. The formation of D-seryl-L-valine or D-seryl-L-isoleucine in the beginning of the reaction could be explained as a sterically controlled asymmetric Knoevenagel type reaction to the glycine residue. Formaldehyde attacked the methylene group of the copper(II) complex from the less bulky side of the

planar molecule (from back side of the paper in Scheme 2).

Small amounts of the reaction mixture of Cu(sal=Gly-L-Val) and formaldehyde were withdrawn during the reaction, being treated with acid to decompose the copper complex. The resulting two diastereomers, D-seryl-L-valine and L-seryl-L-valine, and unchanged glycyl-L-valine were detected by an amino acid analyzer. The results are summarized in Table 1. The yields of seryl-L-valine increased up to 68% under the reaction conditions at 45 °C for 100 h, but the optical purities of D-serine residue decreased from 11 to 5%. At 80 °C, total yields of newly formed seryl-L-valine increase up to 78% after 6 h and then decrease gradually. In the early stage of the reaction, excess of D-seryl-L-valine was found in the reaction mixture. After 6 h, however, the content of L-seryl-L-valine increased. The increase of L-seryl-L-valine could be explained by the epimerization of the seryl residue in the dipeptide complex. The recovery of unchanged glycyl-L-valine decreased gradually and became trace amount after prolonged reaction at 80°C.

Table 2 shows the time course of the reaction of (*N*-salicylideneglycyl-L-isoleucinato)copper(II) (complex **2**) with formaldehyde at 60, 70, and 80 °C. At 60 °C, the yield of seryl-L-isoleucine reaches 63% after 15 h and the configuration of the newly formed seryl residue is D-form in the early stage of the reaction. Inversion of the configuration from D to L, however, takes place after 18 h as in the reaction of the glycyl-L-valine complex and the ratio of L-L-dipeptide to D-L-dipeptide increases gradually after longer reaction time. Similar behaviors were observed in the reactions at 70 and 80 °C. An unknown peak was detected in the reaction mixture on prolonged reaction by an amino acid analyzer. The hydrolysis of the reaction mixture showed the increase of the peak of α-(hydroxymethyl)serine. Therefore, the peak which is eluted more rapidly than the peaks of glycyl-amino acids and seryl-amino acids, was assumed to be due to α-(hydroxymethyl)seryl-L-valine (HMSV) and α-(hydroxymethyl)seryl-L-isoleucine (HMSI). Tables 1 and 2 show that the yields of HMSV and HMSI increase steadily depending on the reaction time, and the yield reaches about 20% at 80 °C. Small amounts of free amino acids such as serine, glycine, and valine or isoleucine were also found in the reaction mixtures. These amino acids formed by the hydrolysis of dipeptides during the reaction increased slowly with the reaction time. Thus the decrease of the total yield of seryl dipeptides could be caused by 1) hydrolysis of dipeptides, 2) formation of α-(hydroxymethyl)seryl dipeptides, and 3) decarboxylation, deamination, and other degradation of dipeptides.

After the reaction of complex **1** or **2** with formaldehyde, the reaction mixture was decomposed with acid and the resulting dipeptides were hydrolyzed. The amino acid mixtures were treated with 2,4-dinitroflouorobenzene and the resulting 2,4-dinitrophenyl derivatives of valine and isoleucine were separated by Celite column chromatography. The specific rotations showed that those derivatives were almost optically pure. The amino acid analysis of the hydrolyzed isoleucine exhibited no peak of alloisoleucine which would be generated by epimerization. These findings indicate that the epimerization of the dipeptide takes place only at the N-terminal amino acid and does not take place at the C-terminal of the dipeptide complex. The (D-L)-complex which is the major product of the asymmetric Knoevenagel type reaction in the early stage of the reaction, is epimerized to the (L-L)-complex under the conditions employed in the reaction, as shown in Scheme 3.

Table 2. Time Course of the Reaction of Complex **2** with Formaldehyde

Temp °C	Time h	Ser-L-Ileu/% D-L	Ser-L-Ileu/% L-L	Total yield/%	Optical purity of Ser[a]/%	HMSI[b]/%	Recovery of Gly-L-Ileu/%

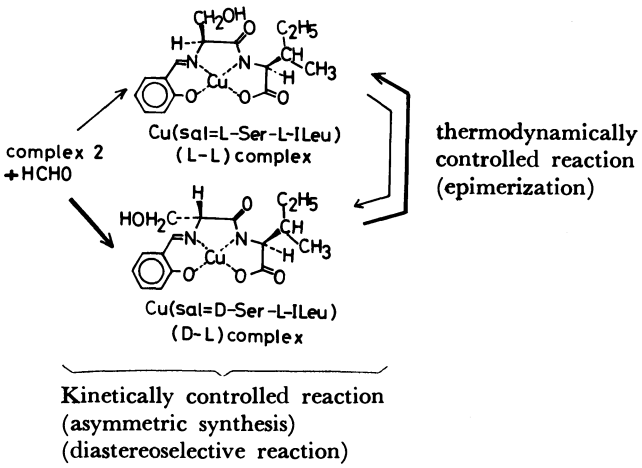

Scheme 3.

When the authentic *N*-salicylidene complexes composed of L-seryl-L-isoleucine and D-seryl-L-isoleucine were synthesized and treated at 80 °C in aqueous solution in the presence of sodium hydrogencarbonate, epimerization took place simultaneously. The time course of the reaction is shown in Table 3. Starting from (L-L)- or (D-L)-complex, epimerization reached an equilibrium after 24 h and the ratio of (L-L):(D-L) was about 6 : 4. Therefore it could be considered that the epimerization is a typical thermodynamically controlled reaction, and the first-order asymmetric transformation takes place between the two diastereomeric complexes in the reaction mixture.

The reason for the enrichment of (L-L)-complex in the equilibrium is unknown at the present stage, although the (L-L)-complex is usually considered to be less stable thermodynamically than the (D-L)-complex because of the steric repulsion between the two side chains of serine and isoleucine.

The asymmetric Knoevenagel type reaction of complex **1** or **2** with formaldehyde could be regarded as a kinetically controlled reaction. Therefore, the whole reaction is controlled by two different mechanisms, i.e. kinetically controlled reaction in the early stage of the reaction, which causes the formation of D-seryl dipeptides, and also thermodynamically controlled reaction which leads to the formation of L-seryl dipeptides in the later stage of the reaction.

a) 1 M = 1 mol dm^{-3}.

seryl dipeptides were synthesized by coupling reactions of *N*-benzyloxycarbonyl-L- or D-serine and L-valine or L-isoleucine benzyl ester using dicyclohexylcarbodiimide. Coupled products were recrystallized from ethyl acetate and petroleum ether. The yields of the products are in a range of 75—87%. The *N*-benzyloxycarbonyl dipeptide ester (1.0 g) was dissolved in a mixture of *t*-butyl alcohol and water (7:3), and the solution was applied to catalytic hydrogenolysis with 5% palladium on charcoal (1.0 g) under 1 atmosphere of hydrogen at room temperature for 6 h. After the catalyst was removed by filtration, the filtrate was evaporated to dryness under reduced pressure, and the residue was recrystallized from water and ethanol. The properties of the synthesized dipeptides are listed in Table 4. These dipeptides are chromatographically pure and the retention times of glycyl and seryl dipeptides observed by an amino acid analyzer are summarized in Table 5.

Preparations of (*N*-Salicylideneglycyl-L-isoleucinato)copper(II) and (*N*-Salicylideneglycyl-L-valinato)copper(II). Glycyl-L-isoleucine (2.5 mmol) was dissolved in a mixture of water and ethanol (2:1). To this solution, freshly distilled salicylaldehyde (2.5 mmol) and copper(II) chloride (2.5 mmol) were added. Aqueous potassium hydroxide was added to the solution, and the pH was adjusted to about 10. The solution was stirred for 15 min at room temperature. After filtration, the filtrate was evaporated to dryness under reduced pressure and purplish needles were obtained. The product was recrystallized from hot water–ethanol. molecular formula: KCu(sal=Gly-L-Ileu)· 1.5H_2O; λ_{max} 558 nm(ε=185 M^{-1} cm^{-1}); Found: C, 42.66; H, 4.30; N, 6.77%; Calcd for $C_{15}H_{20}O_{5.5}N_2CuK$ C, 42.99; H, 4.82; N, 6.69%.

(*N*-Salicylideneglycyl-L-valinato)copper(II) was synthesized from glycyl-L-valine and bis(salicylaldehydato)copper(II) in a water–ethanol (2:1) mixture by adjusting the pH value to about 9, being isolated as barium salt. Found: C, 35.94; H, 4.52; N, 6.30%; Calcd for $C_{14}H_{22}O_{7.5}N_2CuBa_{0.5}$ C, 35.73; H, 4.72; N, 5.95%.

Hydroxymethylation of (*N*-Salicylideneglycyl-L-isoleucinato)copper(II) (Complex 2) The complex 2 (7.5×10^{-5} mol) was dissolved in 45 ml of water containing 1.5 mmol of $NaHCO_3$ and the pH of the solution was about 8.5. To this solution, 35% formaldehyde (9 mmol, 0.75 ml) was added and the reaction mixture was kept at a constant temperature under nitrogen atmosphere. During the reaction, small amounts of the sample was withdrawn from the reaction mixture, and the complex was decomposed with diluted hydrochloric acid. The resulting solution was applied to a Dowex 50 column. After the column was washed with water, peptides and amino acids were eluted with aqueous ammonia (1 mol dm^{-3}). The eluate was evaporated to dryness under reduce pressure. The residue was dissolved in water and an appropriate amount of the solution was applied to an amino acid analyzer to determine the diastereomeric ratio of the newly formed dipeptide and the amount of unchanged dipeptide. The

Table 5. Chromatographic Properties of Glycyl and Seryl Dipeptides[a)]

hydroxymethylation of complex 1 was also carried out in a similar way.

Epimerization between (*N*-Salicylidene-L-seryl-L-isoleucinato)copper(II) and (*N*-Salicylidene-D-seryl-L-isoleucinato)-copper(II). *N*-Salicylidenedipeptide complexes were prepared by mixing of L- or D-seryl-L-isoleucine (7.5×10^{-5} mol), salicylaldehyde, and copper(II) chloride in an aqueous ethanol solvent with 45 ml of an aqueous solution of 1.5 mmol of $NaHCO_3$. The solution was kept at 80 °C for epimerization under nitrogen atmosphere. Small amounts of the reaction mixture were collected at varying times, being treated with a Dowex-50 column. The resulting peptides and amino acids were analyzed by an amino acid analyzer. The results are shown in Table 3.

The Synthesis of Dibenzo-Annelated Annulenes Using Reductive Coupling. Bisdehydrodibenzo[14]-, -[16]-, -[18]-, -[20]-, and -[22]annulene

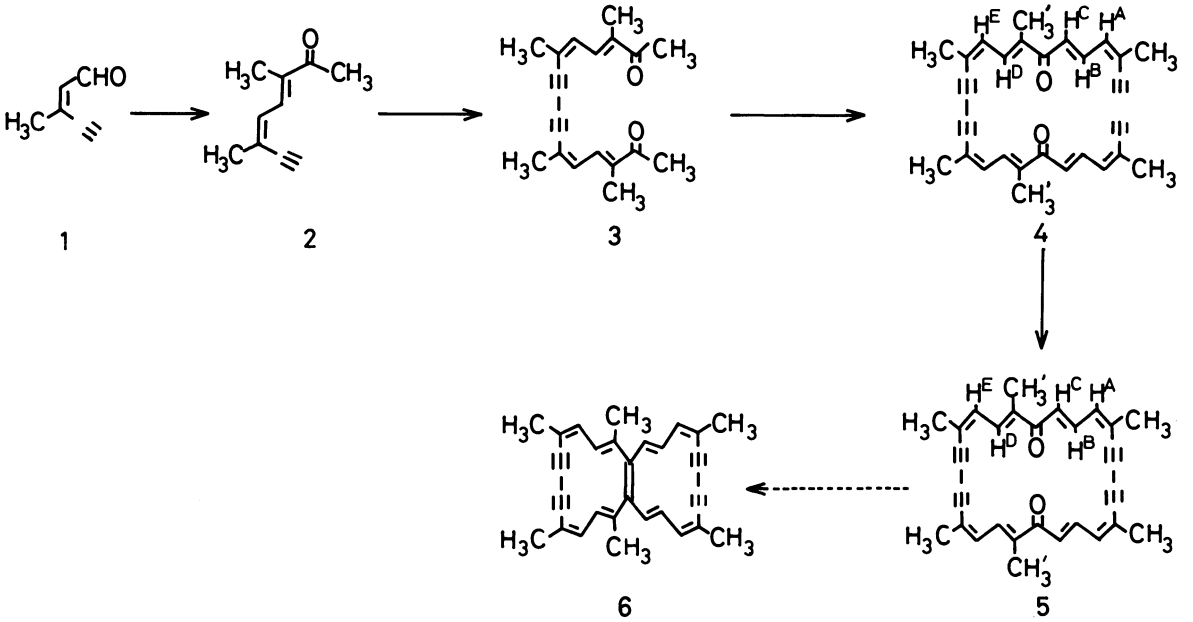
Jūro Ojima,* Koji Yamamoto,†,* Tadahito Kato, Kazuyo Wada, Yoshiharu Yoneyama, and Emiko Ejiri
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930
†Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received February 19, 1986)

Bisdehydrodibenzo[14]-, -[16]-, -[18]-, -[20]-, and -[22]annulene were synthesized by intramolecular reductive couplings using a low-valent titanium reagent. These bisdehydrodibenzo-annulenes proved to be atropic from an examination of the ^{1}H NMR spectra.

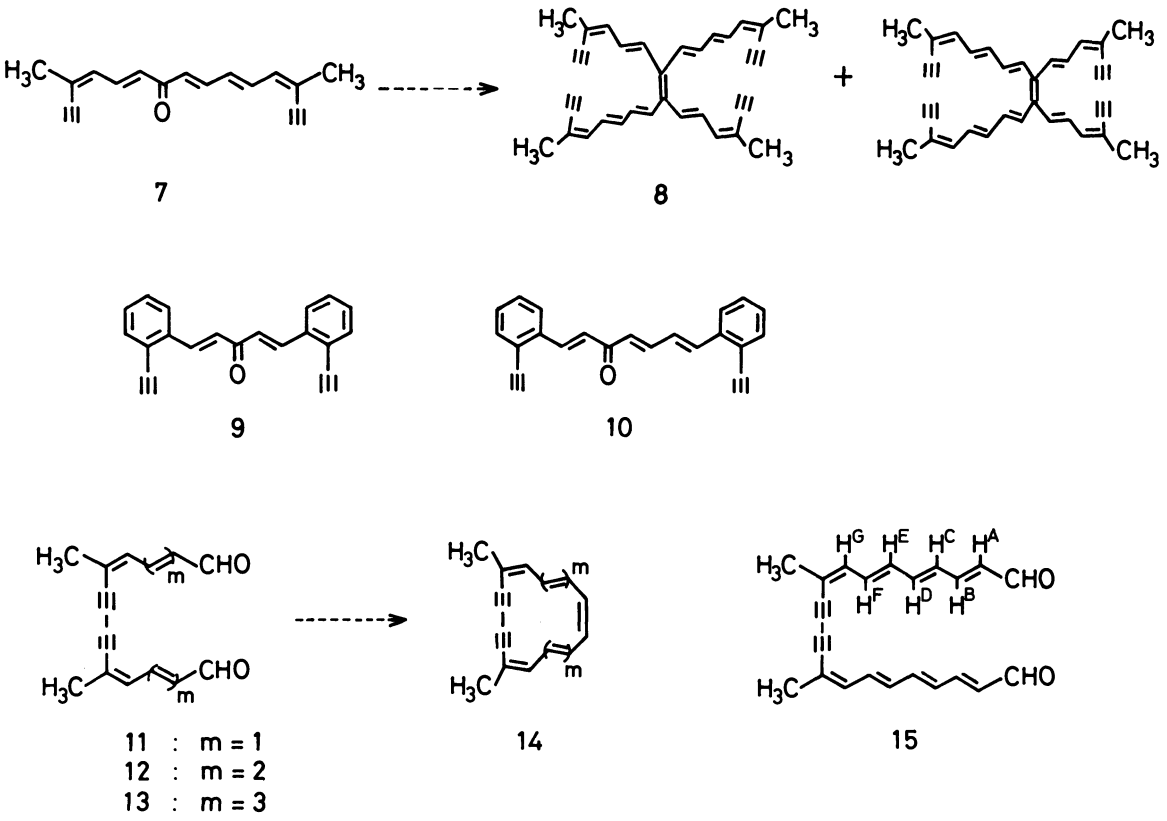
The reductive coupling of carbonyl compounds with a low-valent titanium reagent, developed by McMurry[1] and modified by several workers,[2] provides a new synthetic tool for formation of carbon–carbon double bond, which enabled chemists synthesis of a vast variety of crowded[3] or twisted[4] olefines inaccessible by usual method. In 1977, McMurry and Kees showed the potential of the method in medium- and large-ring carbocyclic synthesis by preparing cycloalkenes.[5] This intrigued us for preparation of annulenes and dehydroannulenes which usually requires lengthy reaction steps. When we commenced the present study, there had been no reports of annulene synthesis by low-valent titanium reagent, although, recently, two reports of preparation of doubly bridged [16]-[6a] and [24]annulene[6b] have appeared. In this paper, we describe attempts to prepare annulenoannulene and annulenes, and a successful synthesis of dibenzo-annelated bisdehydro-[14]-, -[16]-, -[18]-, -[20]-, and -[22]annulenes, using reductive couplings of carbonyl compounds.

Results and Discussion

Firstly, we attempted an intramolecular reductive coupling of the cyclic diketone **5**, prepared as illustrated in Scheme 1, to obtain a tetrakisdehydro-[14]annuleno[14]annulene **6**, but this attempt was unsuccessful. Then, since we had it in mind that the [4*n*]annuleno[4*n*]annulenes have not yet been known[7] and one of the desired products should be the precursor **8** of tetrakisdehydro[16]annuleno[16]annulene, we tried an intramolecular reductive coupling of the acyclic ketone **7**,[8] but some attempts did not meet with success. Thus, since the couplings using **5** and **7** gave polymeric products, we used the dibenzo-fused acyclic ketones **9**[9] and **10**[10] which are more stable than the methylated ketones **5** and **7**. However, these attempts were also unsuccessful, which led us to use more reactive aldehydes than ketones. Then we attempted intramolecular couplings of the dialde-



Scheme 1.



hydes **11**—**13**[11] to obtain the corresponding bisdehydroannulenes **14**; but the products of these reactions always gave only polymeric materials. Thus, since we learnd that these fully conjugated dialdehydes **11**—**13** or the products from them are insufferable against the reaction conditions employing $TiCl_3$ and $LiAlH_4$ in 1,2-dimethoxyethane, we tried to use the benzo-fused dialdehydes **20**, **22**—**26**. These dialdehydes were prepared by oxidative couplings of *o*-ethynylbenzaldehyde **16**[12] and/or its homologated aldehydes **17**—**19**.[13,14] The symmetrical dialdehydes **20**, **22**, **24**, and **26** were prepared from the corresponding monoaldehydes **16**—**18**, and **19**, respectively, in high yields, but the unsymmetrical dialdehydes **23** and **25** were obtained in moderate yields, since the symmetrical dialdehydes also formed. Rather surprisingly, we could not obtain the dialdehyde **21** by the oxidative coupling between **16** and **17** or by Wittig condensation with the dialdehyde **20** and 1.3 molar equivalent of [(1,3-dioxolan-2-yl)methyl]triphenylphosphonium bromide according to the procedure employed for the homologation of the aldehyde **16**.[13,14]

The intramolecular reductive couplings of these aldehydes **20**, **22**—**26** were carried out in the presence of $TiCl_3$ and $LiAlH_4$ in refluxing 1,2-dimethoxyethane under argon atmosphere, giving rise to the dibenzo-annelated bisdehydro[14]- **28**, -[16]- **29**, -[18]- **30**, -[20]- **31**, and -[22]annulene **32** in low yields. The didenzo[10]annulene **27** did not form from the dialdehyde **20**, presumably due to a severe steric strain expected for the structure.

The ^1H NMR chemical shifts of the dibenzoannulenes **28**—**32** thus obtained are listed in Table 1. The assignments of the resonances to the indiviual protons were made on the basis of multiplicities and coupling constants and the assumption that protons in a similar environment resonate at similar field, and were further clarified by the use of decoupling experiments where necessary. As we see from the Table 1, an examination of the chemical shifts suggests that these benzo-annelated annulenes **28**—**32** are atropic, since the high- or low-field shifts due to the olefinic inner or outer protons are not observed.

In conclusion, the results from this study indicate that the effectiveness of the reductive coupling in annulene synthesis greatly depends on the stability of the used conjugated carbonyl compounds and the products derived from them.

Experimental

All melting-points are uncorrected. IR spectra were measured on Hitachi 260-50 spectrophotometer as KBr disks; only significant maxima are reported. Electronic spectra were taken on Hitachi 220A spectrophotometer and recorded in nm. ε-Values are given in parentheses, shoulders being denoted by sh. Mass spectra were measured with JEOL JMS-D 200 spectrometer at 75 eV using a direct inlet system. ^1H NMR spectra were taken on JEOL FX-90Q (90 MHz) or Varian XL-200 (200 MHz) or

Table 1. ^{1}H NMR Chemical Shifts of Dibenzo-Annelated Annulenes **28**—**32** (in $CDCl_3$), Determined at 21 °C (τ Value; Internal Standard, Me_4Si)

Compd	H^A	H^B	H^C	H^D	H^E	H^F	H^G	H^H	H^I	H^J	H^K	H^L	Benzenoid H
[14]-**28**[a]	3.00—3.13	3.20—3.37	2.83										2.14—2.66
[16]-**29**[a]	1.63	(2.42—3.10)	4.18	3.99	1.08	3.96	1.11	(2.42—3.10)					(2.42—3.10)
[18]-**30**[b]	(3.26—3.34)	3.73	(3.26—3.34)	2.76	3.68								(2.01—2.62)
[20]-**31**[b]	1.75	(3.22—3.50)	2.28	(3.69—4.02)	4.30	(3.69—4.02)		(3.22—3.50)	1.54	(3.22—3.50)	(3.69—4.02)	1.52	2.61—2.98
[22]-**32**[a]	(3.30—3.54)	3.80	(3.30		3.52)	2.60	3.70						2.02—2.68

a) At 200 MHz. b) At 270 MHz.

JEOL GX-270 (270 MHz) spectrometer, and refer to solutions in $CDCl_3$, in τ-values with TMS as an internal standard. The coupling constants (J) are given in Hz. Alumina (II-III) or silica-gel (Merck) was used for column chromatography. Progress of most reactions was followed by TLC using Merck precoated silica-gel. Tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME) were distilled from sodium benzophenone under nitrogen atmosphere before use. The organic extracts were dried over anhyd sodium sulfate or magnesium sulfate prior to solvent removal.

3,6-Dimethyl-3,5-octadien-7-yn-2-one (2). This compound was prepared from 3-methyl-2-penten-4-ynal (**1**)[15] and 2-butanone as reported.[16]

3,6,11,14-Tetramethyl-3,5,11,13-hexadecatetraene-7,9-diyne-2,5-dione (3). A soln of the ketone **2** (4.40 g, 30 mmol) in methanol (42 ml) was added dropwise to a stirred soln of copper(II) acetate monohydrate (12.2 g) in pyridine (142 ml) and methanol (142 ml) during 45 min at room temp. After stirring for a further 3.5 h at the same temp, the reaction mixture was poured into water and extracted with benzene. The extracts were washed with 7% hydrochloric acid until it turned acidic, and then with aq sodium hydrogencarbonate, and dried. The residual red liquid, after solvent removal, was chromatographed on alumina (4.0×6.0 cm). The fractions eluted with benzene gave the diketone **3** (3.51 g, 80%). Recrystallization from methanol afforded yellow needles: Mp 111—113 °C (lit,[16] mp 110—112 °C).

3,8,11,16,19,24-Hexamethyl-3,5,8,10,16,18,21,23-hexaicosaoctaene-1,12,14,25-tetrayne-7,20-dione (4). A soln of the aldehyde **1** (2.60 g, 27.6 mmol) in dry benzene (8 ml) was added dropwise during 10 min to an ice-cooled, stirred soln of the diketone **3** (2.00 g 6.80 mmol) in dry benzene (40 ml) containing ethanolic sodium ethoxide (11 ml), prepared from sodium (750 mg) and abs ethanol (50 ml). After stirring for a further 4.5 h under an ice-bath, the reaction was quenched by addition of acetic acid. Then the mixture was poured onto water and extracted with benzene. The extracts were washed with aq sodium hydrogencarbonate soln and brine, and dried. The residual dark red liquid, after solvent removal, was chromatographed on alumina (4.0×12.0 cm). The fractions eluted with hexane–ether (1:1) gave the diketone **4** (2.21 g, 72.8%). Recrystallization from hexane–benzene afforded yellow needles : Mp 114 °C (decomp); MS m/z 446 (M^+, 3%) and 78 (100); mol wt 446.5; IR 3300, 3240 (-C≡CH), 2200, 2100 (-C≡C-), 1640 (C=O), 1595 (C=C), and 995 cm^{-1} (trans C=C); UV_{max} (THF) 246 sh (24200), 258 sh (26700), 284 (27000), 302 sh (27300) 353 (35400), 385 (34500), 420 nm sh (19800); ^{1}H NMR (90 MHz) τ=2.25 (dd, 15, 12, 2H, H^B), 2.50 (d, 12, 2H, H^D), 3.15 (d, 15, 2H, H^C), 3.18 (d, 12, 2H, H^A or H^E), 3.53 (d, 12, 2H, H^A or H^E), 6.57 (s, 2H, -C≡CH), 7.90 (s, 6H, CH_3'), and 8.03 (s, 12H, CH_3).

Found: C, 85.13; H, 6.80%. Calcd for $C_{32}H_{30}O_2$:C, 86.06; H, 6.77%. Attempts to improve the elemental analysis failed.

2,5,10,13,18,23-Hexamethyl-2,4,10,12,15,17,23,25-cyclohexaicosaoctaene-6,8,19,21-tetrayne-1,14-dione (5). A soln of the acyclic diketone **4** (6.00 g, 13.4 mmol) in ether (80 ml), methanol (80 ml), and pyridine (200 ml) was added dropwise during 11 h to a stirred, refluxing mixture of anhyd copper(II) acetate (20 g) in ether (1200 ml), methanol (400 ml), and pyridine (1400 ml) at 50 °C, using high-dilution apparatus. After being refluxed for a further 1 h,

the mixture was allowed to stand overnight at room temp. Then the mixture was concentrated to ca. 400 ml under reduced pressure below 35 °C, and the concentrate was worked up as for the isolation of **3**. The residual dark red liquid, after solvent removal, was chromatographed on alumina (4.0×10.0 cm). The fractions eluted with ether–benzene (1:1) gave the cyclic diketone **5** (1.50 g, 25%). Recrystallization from chloroform–ethanol afforded yellow needles: Mp 120 °C (decomp); MS *m/z* 444 (M^+, 25%) and 178 (100); mol wt 444.5; IR 2180 (-C≡C-), 1635, 1610, 1590, 1570, (C=O, C=C), 985, and 970 cm^{-1} (trans C=C); UV_{max} (THF) 253 (29500), 291 (31900), 329 sh (43900), 350 (47900), and 403 nm sh (15800); ^1H NMR (200 MHz) τ=2.45 (d, 11, 2H, H^D), 2.47 (dd, 16, 11, 2H, H^B), 3.20 (d, 11, 2H, H^A or H^E), 3.43 (d, 11, 2H, H^A or H^E), 3.54 (d, 16, 2H, H^C), 7.94 (s, 6H, CH_3'), and 7.97 (s, 12H, CH_3).

Found: C, 86.23; H, 6.31%. Calcd for $C_{32}H_{28}O_2$:C, 86.45; H, 6.35%.

An Intramolecular Reductive Coupling of The Cyclic Diketone 5. The reaction was carried out under the same conditions as those described below for the dialdehyde **23**; however no monomeric product was obtained.

3,13-Dimethyl-3,5,8,10,12-pentadecapentaene-1,14-diyn-7-one (7). This compound was prepared as reported.[8]

1,5-Bis(*o*-ethynylphenyl)-1,4-dien-3-one (9) and 1,7-Bis(*o*-ethynylphenyl)-1,4,6-heptatrien-3-one (10). These compounds were prepared as reported.[9,10]

Intermolecular Reductive Couplings of The Ketones 9 and 10. These reactions were also carried out under the same conditions as those employed for the dialdehyde **22** (vide infra); however no dimeric product was obtained.

5,10-Dimethyl-2,4,10,12-tetradecatetraene-6,8-diynedial (11) and 7,12-Dimethyl-2,4,6,12,14,16-octadecahexaene-8,10-diynedial (12). The dialdehydes **11** and **12** were prepared as reported.[11]

9,14-Dimethyl-2,4,6,8,14,16,18,20-docosaoctaene-10,12-diynedial 15 (13: *m*=3). A soln of 9-methyl-2,4,6,8-undecatetraene-10-ynal[11] (2.47 g, 14.3 mmol) in pyridine (39 ml) and methanol (39 ml) was added dropwise during 40 min to a stirred soln of copper(II) acetate monohydrate (19.2 g) in pyridine (155 ml) and methanol (155 ml) at 16 °C. After stirring overnight at room temp, the reaction mixture was worked up as in the preparation of **3**. The residual red liquid, after solvent removal, was chromatoraphed on alumina (4.0×9 cm). The fractions eluted with ether gave the dialdehyde **15** (960 mg, 39.1%). Recrystallization from hexane–benzene afforded red cubes: Mp 164—166 °C; MS *m/z* 342 (M^+, 28%) and 81 (100); mol wt 342.4; IR 2170 (-C≡C-), 1675 (-CHO), 1610, 1590, 1570 (C=C), 1010, and 990 cm^{-1} (trans C=C); UV_{max} (THF) 254 sh (16300), 264 (18200), 290 sh (18900), 302 sh (22600), 315 sh (27100), 347 sh (50000), 364 (60200), 408 (52900), and 457 nm sh (30300); ^1H NMR (90 MHz) τ=0.42 (d, 8, 2H, CHO), 2.84 (dd, 15, 10.5, 2H, H^F), 2.94—3.78 (m, 6H, H^B, H^C, H^D), 3.35 (dd, 16, 10, 2H, H^E), 3.52 (d, 10, 2H, H^G), 3.83 (dd, 15, 8, 2H, H^A), and 7.97 (S, 6H, CH_3).

Found: C, 84.42; H, 6.53%. Calcd for $C_{24}H_{22}O_2$: C, 84.17; H, 6.47%.

Intramolecular Reductive Couplings of The Dialdehydes 11—13. These reactions were carried out under the similar conditions as described for the dialdehyde **22** (vide infra); however no monomeric product was obtained.

2,3:8,9-Dibenzodeca-4,6-diyndial (20). A soln of the dialdehyde **16**[12] (2.00 g 15.4 mmol) in pyridine (31 ml) was added dropwise during 1.5 h to a stirred soln of copper(II) acetate monohydrate (31 g) in pyridine (91 ml) at 47—49 °C. After stirring for a further 2 h at the same temp, the reaction mixture was worked up as in the isolation of **3**. The residual red liquid, after solvent removal, was chromatographed on alumina (3.7×6.5 cm). The fractions eluted with hexane–ether (2:3) gave the dialdehyde **20** (1.03 g, 52%). Recrystallization from benzene afforded yellow needles: Mp 163—164 °C; MS *m/z* 258 (M^+, 100%); mol wt 258.2; IR 2270, 2200 (-C≡C-), and 1700 cm^{-1} (-CHO); UV_{max} (THF) 227 sh (57000), 235 (61900), 244 sh (57100), 261 sh (35100), 270 sh (27200), 286 sh (14100), 308 (17900), 334 (23200), and 355 nm (20000); ^1H NMR (90 MHz) τ=—0.60 (s, 2H, CHO), 1.90—2.10 (m, 2H, benzenoid H), and 2.17—2.57 (m, 6H, benzenoid H).

Found: C, 83.51; H, 3.70%. Calcd for $C_{18}H_{10}O_2$: C, 83.71; H, 3.90%.

4,5: 10,11-Dibenzo-2,12-tetradecadiene-6,8-diynedial (22). A soln of the aldehyde **17**[13] (2.00 g, 12.8 mmol) in pyridine (25 ml) was added dropwise during 1 h to a stirred soln of copper(II) acetate monohydrate (24.6 g) in pyridine (75 ml) at 52—56 °C. After stirring for a further 3 h at the same temp, the reaction mixture was worked up as in the preparation of **3**. The residual dark brown liquid, after solvent removal, was chromatographed on alumina (3.7×9 cm). The fractions eluted with hexane–ether (1:4) gave the dialdehyde **22** (1.49 g, 60%). Recrystallization from hexane–benzene afforded yellow needles: Mp 203—204 °C; MS *m/z* 310 (M^+, 17%) and 254 (100); mol wt 310.3; IR 2200 (-C≡C-), 1680 (-CHO), and 980 cm^{-1} (trans C=C) UV_{max} (THF) 224 sh (18700), 254 (32200), 277 (28500), 294 sh (24000), 330 sh (12600), and 367 nm sh (8360); ^1H NMR (90 MHz) τ=0.10 (d, 8, 2H, CHO), 1.98 (d, 16, 2H, H^B), 2.13—2.65 (m, 8H, benzenoid H), and 3.15 (dd, 16, 8, 2H, H^A).

Found: C, 85.06; H, 4.26%. Calcd for $C_{22}H_{14}O_2$: C, 85.14; H, 4.55%.

4,5: 10,11-Dibenzo-2,12,14-hexadecatriene-6,8-diynedial (23). A soln of the aldehyde **17** (2.10 g, 14 mmol) and the aldehyde **18** (2.50 g, 14 mmol) in pyridine (45 ml) and methanol (45 ml) was added dropwise during 1 h to a stirred soln of copper(II) acetate monohydrate (22 g) in pyridine (170 ml) and methanol (170 ml) at room temp, and stirring was continued for a further 16 h at the same temp. Then the mixture was worked up as in the isolation of **3**. The residue, after solvent removal, was chromatoraphed on alumina (4.5×13 cm). The early fractions eluted with hexane–ether (2:3) gave the dialdehyde **22** (0.54 g, 13%). The following fractions eluted with benzene–chloroform (4:1) gave the dialdehyde **23** (2.03 g, 43%). Recrystallization from hexane–benzene afforded yellow cubes: Mp 176—177 °C; MS *m/z* 336 (M^+, 14%) and 252 (100); mol wt 336.3; IR 2240 (-C≡C-), 1680 (-CHO), and 990 cm^1 (trans C=C); UV_{max} (THF) 235 sh (32000), 261 (40900), 271 (38300), 285 (45700), 301 (39400), 313 (40600), and 338 nm sh (32700); ^1H NMR (90 MHz) τ=0.19 (d, 7.5, 1H, H^b), 0.35 (d, 7, 1H, H^a), 2.04 (d, 16, 1H, $H^{B'}$), 2.26—2.93 (m, 11H, H^B, H^C, H^D, and benzenoid H), 3.20 (dd, 16, 7.5, 1H, $H^{A'}$), and 3.71 (dd, 14, 8, 1H, H^A).

Found: C, 85.41; H, 4.99%. Calcd for $C_{24}H_{16}O_2$: C, 85.69; H, 4.79%.

The later fractions eluted with chloroform gave the

dialdehyde **24** (vide infra) (1.08 g, 21%).

6,7:12,13-Dibenzo-2,4,14,16-octadecatetraene-8,10-diynedial (24). A soln of the aldehyde **18**[14] (363 mg, 2.0 mmol) in pyridine (4 ml) was added dropwise during 20 min to a stirred soln of copper(II) acetate monohydrate (3.8 g) in pyridine (11 ml) at 50 °C. After stirring for a further 3 h at the same temp, the reaction mixture was worked up as in the preparation of **3**. The residual yellow solid, after solvent removal, was chromatographed on alumina (3.7×9 cm). The fractions eluted with hexane–ether (3:7) gave the dialdehyde **24** (257 mg, 71%). Recrystallization from benzene afforded yellow needles: Mp 170—171 °C; MS *m/z* 362 (M^+, 10%) and 289 (100); mol wt 362.4; IR 2270, 2210 (-C≡C-), 1680 (-CHO), 1620 (C=C), and 985 cm^{-1} (trans C=C); UV_{max} (THF) 227 (24600), 269 (32800), 283 sh (30800), 300 (42400), 327 (42600), and 355 nm sh (30100); ^1H NMR (90 MHz) τ=0.28 (d, 8, 2H, CHO), 2.22—3.03 (m, 14H, H^B, H^C, H^D, and benzenoid H), and 3.65 (dd, 14, 8, 2H, H^A).

Found: C, 86.42; H, 5.29%. Calcd for $C_{26}H_{18}O_2$: C, 86.16; H, 5.01%.

6,7:12,13-Dibenzo-2,4,14,16,18-icosapentaene-8,10-diynedial (25). A soln of the aldehyde **18**[14] (2.10 g, 11.5 mmol) and the aldehyde **19**[14] (2.42 g, 11.6 mmol) in pyridine (50 ml) was added dropwise during 20 min to a stirred soln of copper(II) acetate monohydrate (46 g) in pyridine (140 ml) at 50 °C. After stirring for a further 1 h at the same temp, the mixture was poured into water, and extracted with chloroform. The combined extracts were washed with 7% hydrochloric acid until it turned acidic, water, aq sodium hydrogencarbonate soln, and brine, successively, and dried over anhyd calcium chloride. The residue, after solvent removal, was chromatographed on alumina (4.2×5.0 cm). The early fractions eluted with ether–benzene (4:1) gave the dialdehyde **24** (260 mg, 6.0%). The following fractions eluted with ether–benzene (1:1) gave the dialdehyde **25** (560 mg, 12%). Recrystallization from hexane–chloroform afforded yellow microcrystals: Mp 156—157 °C; MS *m/z* 388 (M^+, 10%) and 289 (100); mol wt 388.4; IR 2200 (-C≡C-), 1680 (-CHO), and 990 cm^1 (trans C=C); UV_{max} (THF) 225 (26300), 240 sh (22900), 272 (28000), 284 sh (30300), 300 sh (36400), 310 sh (43800), and 340 nm (45800); ^1H NMR (90 MHz) τ=0.34 (d, 8, 1H, H^a), 0.41 (d, 7.7, 1H, H^b), 2.21—3.50 (m, 16H, olefinic and benzenoid H), 3.71 (dd, 14, 8, 1H, $H^{A'}$), and 3.85 (dd, 15, 7.7, 1H, H^A).

Found: C, 86.48; H, 5.54%. Calcd for $C_{28}H_{20}O_2$: C, 86.57; H, 5.19%.

The later fractions eluted with benzene–chloroform (1:1) gave the dialdehyde **26** (vide infra) (950 mg, 19%).

8,9:14,15-Dibenzo-2,4,6,16,18,20-docosahexaene-10,12-diynedial (26). A soln of the aldehyde **19**[14] (3.48 g, 16.7 mmol) in pyridine (33 ml) was added dropwise during 1.5 h to a stirred soln of copper(II) acetate monohydrate (32 g) in pyridine (98 ml) at 52—54 °C. After stirring for a further 1 h at the same temp, the reaction mixture was worked up as in the preparation of **3**. The residual red liquid, after solvent removal, was chromatographed on alumina (3.7×12 cm). The fractions eluted with benzene-chloroform (7:3) gave the dialdehyde **26** (1.97 g, 57%). Recrystallization from hexane–tetrahydrofuran afforded red cubes: Mp 186—188 °C; MS *m/z* 414 (M^+, 59%) and 396 (100); mol wt 414.4; IR 2200 (-C≡C-), 1670 (-CHO), 1620, 1600, 1580 (C=C), 1010, and 990 cm^{-1} (trans C=C); UV_{max} (THF) 241 (33700), 253 sh (23800), 283 (33000), 296 sh (35200), 321 (55400), 359 (66600), and 383 nm sh (59600); ^1H NMR (90 MHz) τ=0.41 (d, 9, 2H, CHO), 2.26—3.60 (m, 18H, olefinic and benzenoid H), and 3.79 (dd, 17, 9, 2H, H^A).

Found: C, 86.91; H, 5.55%. Calcd for $C_{30}H_{22}O_2$: C, 86.73; H, 5.35%.

Reductive Coupling of the dialdehyde **20** was carried out under the same conditions as those indicated for the dialdehyde **22**. But no monomeric compound was obtained.

3,5-Bisdehydro-1,2:7,8-dibenzo[14]annulene (28). $LiAlH_4$ (47 mg, 1.24 mmol) was added in one portion to titanium trichloride ($TiCl_3$) (327 mg, 2.12 mmol) in dry THF (20 ml) under argon. The resultant black mixture was heated under reflux for 15 min. To the mixture, a soln of the dialdehyde **22** (248 mg, 0.80 mmol) in dry THF (10 ml) was added dropwise during 10 h and then the mixture was stirred under reflux for a further 5 h. Then after addition of ethanol (5 ml), the mixture was filtered off to remove inorganic materials and the filtrate was concentrated under reduced pressure. The residue was chromatographed on alumina (10 g). The fractions eluted with hexane–benzene (1:1) gave the dibenzo[14]annulene **28** (60 mg, 27%). Recrystallization from hexane–benzene afforded yellow plates: Mp 193—195 °C; MS *m/z* 278 (M^+, 78%) and 276 (100); mol wt 278.3; IR 2150 (-C≡C-) and 950 cm^{-1} (trans C=C); UV_{max} (isooctane) 210 sh (64500), 236 sh (21000), 244 (23900), 289 (81000), 299 (82400), 307 (85300), 337 (20300), 372 (13700), and 414 nm sh (614); ^1H NMR (200 MHz) τ=2.14 (d, 8, 2H, H^4), 2.37—2.48 (m, 4H, H^1, H^2), 2.56—2.66 (m, 2H, H^3), 2.83 (d, 16, 2H, H^C), 3.00—3.13 (m, 2H, H^A), and 3.20—3.37 (m, 2H, H^B).

Found: C, 94.92; H, 4.92%. Calcd for $C_{22}H_{14}$:C, 95.14; H, 4.86%.

3,5-Bisdehydro-1,2:7,8-dibenzo[16]annulene (29). To a stirred, refluxed soln of $TiCl_3$ (0.61 g, 3.95 mmol) in 1,2-dimethoxyethane (DME) (40 ml) was added $LiAlH_4$ (90 mg, 2.38 mmol) in one portion under argon, and the mixture was refluxed for 30 min. To this mixture was added a soln of the dialdehyde **23** (0.50 g, 1.49 mmol) in DME (20 ml) during 8 h with stirring under reflux, and stirring was continued for a further 5 h under reflux. Then the reaction mixture was passed through Hyflo Super-Cel and washed with DME. The filtrate was concentrated, and the concentrate was extracted with benzene. The residue, after solvent removal, was chromatographed on silica-gel (20 g). The fractions eluted with hexane–benzene (4:1) gave the dibenzo[16]annulene **29** (90 mg, 20%). Recrystallization from hexane–benzene afforded red needles: Mp 159—161 °C; MS *m/z* 304 (M^+, 36%) and 306 (100); mol wt 304.3; IR 2200 (-C≡C-) and 960 cm^{-1} (trans C=C); UV_{max} (isooctane) 298 (77900), 308 sh (83900), 319 (93900), 390 (49700), 433 sh (24900), and 462 sh (16700); ^1H NMR (200 MHz) τ=1.08 (dd, 16, 10, 1H, H^E), 1.11 (dd, 16, 9, 1H, H^G), 1.69 (d, 16, 1H, H^A), 2.42—3.10 (m, 10H, H^B, H^H, and benzenoid H), 3.96 (dd, 15, 8, 1H, H^F), 3.99 (t, 10.5, 1H, H^D), and 4.18 (t, 10, 1H, H^C).

Found: C, 94.84; H, 5.17%. Calcd for $C_{24}H_{16}$:C, 94.70; H, 5.30%.

3,5-Bisdehydro-1,2:7,8-dibenzo[18]annulene (30). To the refluxing mixture of $LiAlH_4$ (47 mg, 1.24 mmol) and $TiCl_3$ (327 mg, 2.12 mmol) in dry DME (20 ml), prepared as described above, was added dropwise a soln of the dialdehyde **24** (290 mg, 0.80 mmol) in dry DME (10 ml)

during 6 h under argon and the mixture was stirred under reflux for a further 5 h. After work up as in the isolation of **29**, the residue was chromatographed on alumina (15 g). The fractions eluted with hexane-benzene (4:1) gave the dibenzo[18]annulene **30** (37 mg, 14%). Recrystallization from hexane-benzene afforded brown needles: Mp 261—263 °C; MS *m/z* 330 (M^+, 3%) and 302 (100); mol wt 330.4; IR 2200 (-C≡C-) and 960 cm^{-1} (trans C=C); UV_{max} (isooctane) 269 sh (22600), 284 sh (31400), 323 sh (70000), 342 (84300), 360 sh (33300), 417 (14800), 435 (14600), and 460 nm sh (8990); ^1H MNR (270 MHz) τ=2.01 (d, 8, 2H, H^4), 2.15 (d, 8, 2H, H^1), 2.48 (t, 8, 2H, H^3), 2.62 (t, 7.5, 2H, H^2), 2.76 (dd, 16.5, 6.5, 2H, H^D), 3.26—3.34 (m, 4H, H^A, H^C), 3.68 (d, 16.5, 2H, H^E), and 3.73 (dd, 16.5, 10, 2H, H^B).

Found: C, 94.42; H, 5.30%. Calcd for $C_{26}H_{18}$: C, 94.51; H, 5.49%.

3,5-Bisdehydro-1,2:7,8-dibenzo[20]annulene (31). To the black mixture of $TiCl_3$ (0.5 g, 3.3 mmol) and $LiAlH_4$ (75 mg, 2.0 mmol) in dry DME (40 ml), prepared as described above, a soln of the dialdehyde **25** (0.49 g, 1.26 mmol) in dry DME (20 ml) was added dropwise during 8 h and stirring was continued for a further 5 h under reflux. Then the mixture was worked up as in the isolation of **29**. The residue, after solvent removal, was chromatographed on silica-gel (20 g). The fractions eluted with hexane-benzene (2:1) gave the dibenzo[20]annulene **31** (40 mg, 8.7%). Recrystallization from hexane-dichloromethane afforded black cubes: Mp 300 °C (decomp); MS *m/z* 356 (M^+, 67%) and 339 (100); mol wt 356.4; IR 2200, 2150 (-C≡CH) and 990 cm^{-1} (trans C=C); UV_{max} (isooctane) 293 sh (46900), 320 sh (106000), 333 (121000), 413 sh (23300),435 (12600), 462 sh (19500), and 498 nm sh (14700); ^1H MNR (270 MHz) τ=1.52 (d, 16, 1H, H^L), 1.54 (dd, 16, 12, 1H, H^I), 1.75 (d, 16, 1H, H^A), 2.28 (dd, 16, 8, 1H, H^C), 2.61—2.98 (m, 8H, benzenoid H), 3.22—3.50 (m, 4H, H^B, H^J, H^G, H^H), 3.69—4.02 (m 3H, H^D, H^F, H^K), and 4.30 (dd, 12, 10, 1H, H^E).

Found: C, 94.24; H, 5.65%. Calcd for $C_{28}H_{20}$: C, 94.38; H, 5.66%.

3,5-Bisdehydro-1,2:7,8-dibenzo[22]annulene (32). To the refluxing mixture of $LiAlH_4$ (47 mg, 1.24 mmol) and $TiCl_3$ (327 mg, 2.12 mmol) in dry THF (20 ml), prepared as described above, was added dropwise a soln of the dialdehyde **26** (330 mg, 0.80 mmol) in dry THF (10 ml) during 10 h under argon and the mixture was stirred under reflux for a further 5 h. After work up as in the preparation of **28**, the residue, after solvent removal, was chromatographed on alumina (10 g). The fractions eluted with benzene gave the dibenzo[22]annulene **32** (12 mg, 4.0%). Recrystallization from hexane-benzene afforded brown needles: Mp ca. 300 °C (decomp); MS *m/z* 382 (M^+, 12%) and 57 (100); mol wt 382.4; IR 2200 (-C≡C-) and 980 cm^{-1} (trans C=C); UV_{max} (isooctane) 278 sh (28100), 297 (43200), 355 (113100), 420 sh (12600), 445 (15500), 464 (15100), and 501 nm sh (8200); ^1H NMR (200 MHz) τ=2.02 (d, 8, 2H, H^4), 2.18 (d. 8, 2H. H^1), 2.49 (t, 8, 2H, H^3), 2.60 (dd, 16, 11, 2H, H^F), 2.68 (t, 8, 2H, H^2), 3.30—3.54 (m, 8H, H^A, H^C, H^D, H^E), 3.70 (d, 16, 2H. H^G), and 3.80 (dd, 16, 10, 2H, H^B).

Found: C, 94.40; H, 5.69%. Calcd for $C_{30}H_{22}$: C, 94.20 H, 5.80%.

Active Carbon-Supported Copper(I) Chloride as Solid Adsorbent for Carbon Monoxide[1)]

Hidefumi HIRAI,* Keiichiro WADA, and Makoto KOMIYAMA
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received January 7, 1986)

An active carbon-supported copper(I) chloride (CuCl) is prepared by stirring active carbon in aqueous hydrochloric acid solution of CuCl, followed by removal of the liquid phase under 6 mmHg at 100 °C. The resulting solid rapidly adsorbs carbon monoxide (CO) at 20 °C from 9:1 CO-N_2 mixture under 1 atm (the CO partial pressure 0.9 atm) and the equilibrium molar ratio of adsorbed CO to CuCl is 0.88. All of adsorbed CO is promptly desorbed either by reducing CO partial pressure to 0.4 mmHg at 20 °C or by elevating temperature from 20 °C to 120 °C under 1 atm (the CO partial pressure 0.9 atm). Reversible adsorption-desorption cycles are repeated four times without measurable decrease in the adsorbing capacity. The adsorbing capacity of the active carbon-supported CuCl is much larger than either that of CuCl solid or that of active carbon. Effective CO adsorption by the present adsorbent is attributed to formation of complex between CO and CuCl, which is highly dispersed on the surface of active carbon.

Efficient methods for separation of carbon monoxide (CO) from gas mixtures are important in industry, since almost all CO sources are gas mixtures with nitrogen, hydrogen, methane, and carbon dioxide.[2)] Many liquid absorbents for CO were proposed.[3-5)] However, reports on solid adsorbents for CO have been scanty. Solid adsorbents have an advantage over liquid absorbents that pressure-swing methods are available for separation of CO. In addition, CO separated from gas mixtures by use of solid adsorbents is free from contamination with solvent vapor.

Although a Y-type zeolite-supported copper(I) ion adsorbed CO,[6)] the interaction between CO and the copper(I) ion was so strong that adsorbed CO could not be sufficiently desorbed even at the CO partial pressure 10^{-4} mmHg (1.0 mmHg=1.33×10^2 Pa). A patent[7)] claimed that copper(I) ion supported on zeolites, which had high ratios of silica to alumina, had CO adsorbing abilities. The amount of adsorbed CO was rather independent of CO partial pressure at the partial pressure larger than 10 mmHg.

Previously, the authors reported that aluminium copper(I) chlorides supported both on polystyrene resin[8)] and on active carbon[9,10)] reversibly adsorbed CO under mild conditions.

In this paper, preparation of active carbon-supported copper(I) chloride (CuCl) as solid CO adsorbents is reported. Their CO adsorbing and desorbing abilities as well as effects of preparation solvent on the ability are shown. Pore size distribution, BET surface area, and distribution of CuCl of the adsorbents are also described. Mechanism of effective and reversible adsorption of CO is discussed on the basis of these results.

Experimental

Materials. Active carbon was obtained from Kureha Chemical Industry Co. (Petroleum pitch, BAC G-70R, Lot No. 810117, average diameter ca. 0.7 mm) and was subjected to a reduced pressure (6 mmHg) at 200 °C for 5 h. Copper(I) chloride (guaranteed grade) was purchased from Koso Chemical Co. All other metal salts and solvents were commercially obtained.

Carbon monoxide gas and nitrogen gas, which had purities of 99.95 and 99.999%, respectively, were passed through columns of molecular sieve 3 A immediately before use.

Preparation of CO Adsorbents. A predetermined amount of CuCl was magnetically stirred in 15 cm^3 of various solvents under dry nitrogen at room temperature for 1 h, and then 10 g of the active carbon was added to the mixture. After stirring the mixture for 1 h, the liquid phase was removed at 6 mmHg, 100 °C for 1 h.

Solid of CuCl without active carbon was prepared as white powder in the same way as described above except for the absence of the active carbon.

Determination of the Amount of CuCl in the Adsorbent. The adsorbent was thoroughly washed by stirring for 24 h at room temperature in four portions of aqueous hydrochloric acid solution (3 mol dm^{-3}, total volume 2000 cm^3). Total amount of copper atoms in the solution was determined by atomic absorption spectroscopy (Shimadzu Co., model AA-646).

Measurements of Pore Size Distribution and BET Surface Area. Pore size distribution in the adsorbent was determined from desorption isotherm of nitrogen at 77 K by the method of Dollimore.[11)] The method takes advantage of capillary condensation theory and is based on the assumption of cylindrical pores with radii r. The value $\Delta v/\Delta r$ is obtained as a function of r, where Δv is sum of volume for the pores having radii between r and $r+\Delta r$. Desorption isotherm of nitrogen at 77 K was measured on a Calroerba Co. Sorptomatic Series 1800.

The BET surface area was measured by nitrogen adsorption at 77 K with a Micromeritics Instrument Model 2200A Rapid Surface Area Analyzer.

Electron Microscopy and X-Ray Microanalysis. Scanning electron microscopy and X-ray microanalysis on the beads of the adsorbents were carried out by use of a Hitachi Micro Scanning X-ray Analyzer Model X-650, which had resolution ability of X-ray image around 100 Å. The beads

were embedded in epoxy resin, and the composites were cut with a stainless steel cutter and then were coated with gold so that cross-sections of the beads were irradiated by electron beam. The distributions of copper and chlorine atoms were evaluated from intensity of characteristic X-ray.

Measurement of CO Adsorption and Desorption. Adsorption of CO from CO–N_2 mixtures by the adsorbents was achieved at 20 °C under the atmospheric pressure using the apparatus depicted in Fig. 1. Uptake of CO was followed by a gas burette (3) using water as leveling liquid (5). The flask (2) containing the adsorbent (1) under nitrogen was connected with CO in the gas burette, and the adsorption was initiated by circulating the gases with the use of a gas pump (4). The circulation was effected for the first 10 min at a rate of 30 $cm^3 s^{-1}$ in order to mix the gas phase sufficiently.

Desorption of the adsorbed CO was carried out either by reducing the total pressure in the flask to 0.4 mmHg at 20 °C for 10 min or by heating the adsorbent to 120 °C under 1 atm for 10 min.

Results

Preparation of Active Carbon-Supported CuCl. Active carbon-supported CuCl adsorbents were obtained as black beads. The amount of CuCl supported on 10 g of the active carbon was 14.1 mmol, as determined by atomic absorption spectroscopy, when the charged amount of CuCl was 15.0 mmol and 15 cm^3 of aqueous hydrochloric acid solution (3 mol dm^{-3}) was used as preparation solvent. Thus, 94% of the charged CuCl was supported on the active carbon under these conditions.

BET surface area of the active carbon-supported CuCl composed of 14.1 mmol of CuCl and 10 g of the active carbon is 744 $m^2 g^{-1}$. This value is about 70% of the value (1044 $m^2 g^{-1}$) for the original active carbon.

Figure 2 depicts pore size distribution either in the present adsorbent (the solid line) or in the original active carbon (the broken line). The ordinate ($\Delta v/\Delta r$) approximately corresponds to number of pores. The number of pores with radii smaller than 10 Å for the present adsorbent is significantly smaller than the value for the original active carbon. In contrast, the number of pores with radii larger than 10 Å is almost identical with the value for the original active carbon.

Figure 3 shows scanning electron micrographs of a cross-section of a bead of the active carbon-supported CuCl. Waved white lines depict the distributions of copper atoms (a) and chlorine atoms (b) along the white straight lines on the cross-section. Both copper atoms and chlorine atoms are uniformly distributed in the bead. No deposition of CuCl is observed either on the surface of the bead or inside the bead.

Adsorption and Desorption of CO by the Active Carbon-Supported CuCl. Figure 4 shows repeated adsorption-desorption cycles using the active carbon-supported CuCl by temperature change. The adsorbent rapidly adsorbs CO on the contact with 9:1 CO–N_2 mixture at 20 °C under 1 atm (the region I-a), and the amount of CO adsorbed in 10 min is 11.8 mmol. An equilibrium is attained in 30 min, where the amount of adsorbed CO is 12.4 mmol. This value corresponds to molar ratio 0.88 of adsorbed CO to supported CuCl: 24 cm^3 (standard temperature and pressure) per 1 g of the adsorbent.

All of the adsorbed CO is desorbed in 10 min to the gas phase, as followed with the use of the gas burette, by heating the adsorbent to 120 °C at 1 atm (the region I-d in Fig. 4).

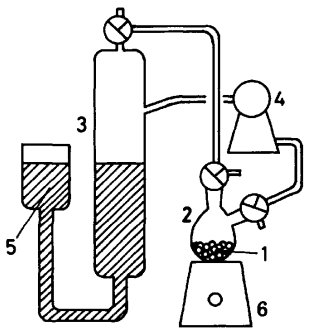

Fig. 1. Apparatus for measuring the amount of CO adsorbed by the adsorbents or desorbed from them. 1: adsorbent; 2: flask; 3: gas burette; 4: gas pump; 5: leveling liquid (water); 6: magnetic stirrer.

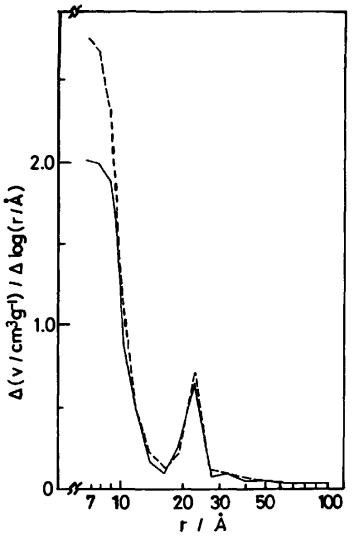

Fig. 2. Pore size distributions in the active carbon-supported CuCl (——) and the original active carbon (----): Δv is sum of volume for the pores having radii between r and $r+\Delta r$; the active carbon-supported CuCl was prepared from 15.0 mmol of CuCl and 10 g of the active carbon using 15 cm^3 of aqueous hydrochloric acid solution (3 mol dm^{-3}) as solvent, and contained 14.1 mmol of CuCl.

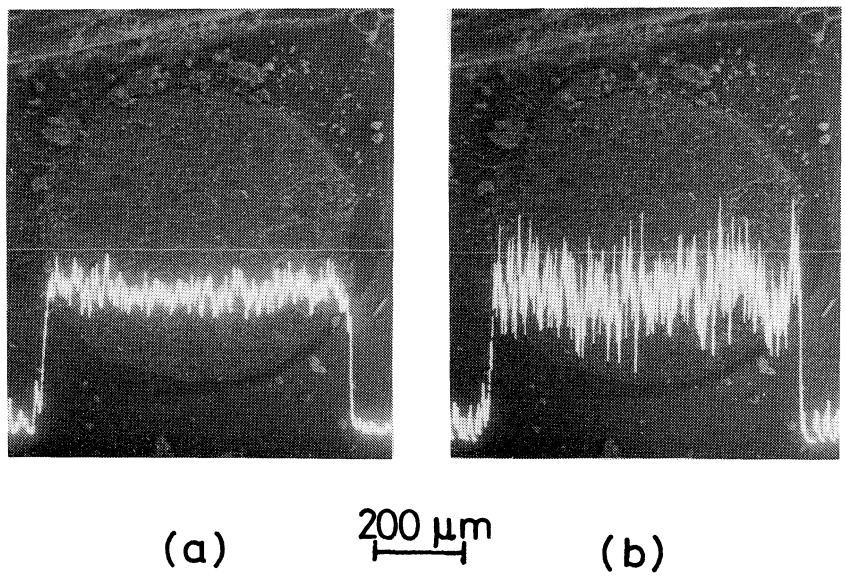

Fig. 3. Scanning electron micrographs for the cross-section of the active carbon-supported CuCl composed of 14.1 mmol of CuCl and 10 g of the active carbon: The waved white lines show distributions of copper atoms (a) and chlorine atoms (b) along the corresponding white straight lines.

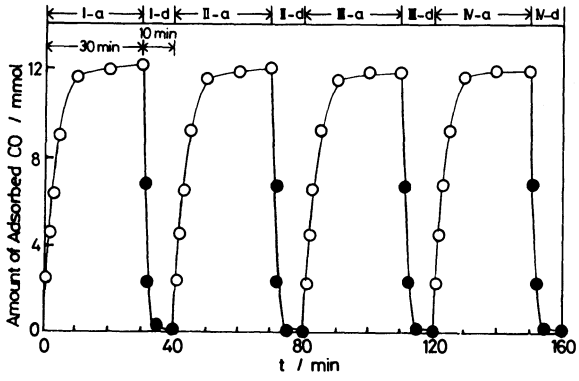

Fig. 4. Time courses of repeated CO adsorption-desorption cycles by the active carbon-supported CuCl using a change in temperature: CO adsorptions (○) from 9 : 1 $CO-N_2$ mixtures were carried out at 20 °C under 1 atm, and desorptions (●) of adsorbed CO were effected by heating the adsorbent to 120 °C under 1 atm for 10 min; the adsorbent was composed of 14.1 mmol of CuCl and 10 g of the active carbon.

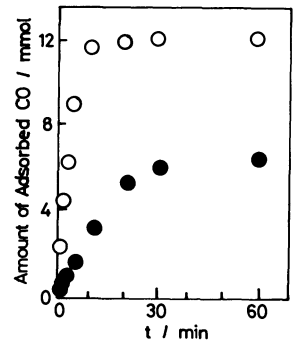

Fig. 5. CO adsorption and absorption from 9 : 1 $CO-N_2$ mixtures at 20 °C under 1 atm by the active carbon-supported CuCl (○) and by 2 mol dm^{-3} aqueous hydrochloric acid solution of CuCl (●): The charged amount of CuCl was 15.0 mmol.

On the next contact with 9:1 $CO-N_2$ mixture, the adsorbent rapidly adsorbs CO, as shown in the region II-a in Fig. 4, and the time course is almost identical with that in the first adsorption. The equilibrium amount of adsorbed CO is 12.4 mmol (24 cm^3 per 1 g of the adsorbent). The adsorption-desorption cycles are repeated four times without measurable deterioration.

Adsorption-desorption cycles for the present adsorbent were successfully carried out also by use of partial pressure change of CO in place of temperature change. Almost all of the adsorbed CO was rapidly desorbed by subjecting the adsorbent to a reduced pressure (0.4 mmHg) at 20 °C. In the following adsorptions, the time courses were virtually the same as the ones depicted by the open circles in Fig. 4. The cycles were repeated four times without measurable decrease in the adsorbing capacity.

As shown in Table 1, CO adsorbing capacity (12.4 mmol) of the active carbon-supported CuCl is much larger than either that (0.0 mmol) of the solid of CuCl or that (3.3 mmol) of the active carbon without CuCl. The capacity (6.5 mmol) of the aqueous hydrochloric acid solution of CuCl is about half of the value (12.4 mmol) of the active carbon-supported CuCl. The rate of adsorption for the active carbon-supported CuCl is much larger than that for the aqueous hydrochloric acid solution of CuCl, as depicted in Fig. 5.

Table 1. Adsorbing Capacities of the CO Adsorbents and Absorbent[a)]

Adsorbent or absorbent	Amount of CuCl / mmol	CO adsorbed in 60 min	
		Amount / mmol	Molar ratio to CuCl
Active carbon-supported CuCl[b)]	14.1	12.4	0.88
Solid of CuCl	15.0	0.0	0.00
Original active carbon[b)]	—	3.3[c)]	—
Hydrochloric acid solution of CuCl	15.0	6.5	0.43

a) At 20 °C; initial volume of gas mixture 1500 cm^3; initial partial pressures of CO and N_2, respectively, were 0.9 and 0.1 atm. b) Active carbon, 10 g. c) The value was measured using helium, in place of N_2, as balance, since the magnitudes of adsorptions of CO and N_2 to the active carbon were comparable with each other, and adsorption of helium was negligibly small.

Table 2. CO Adsorbing Capacities of Solid Adsorbents Composed of Various Copper(I) Halides and the Active Carbon[a)]

Copper(I) halide	Equilibrium amount of adsorbed CO / mmol
CuCl	12.4
CuBr	9.5
CuI	1.7

a) At 20 °C, under 1 atm; initial volume of gas mixture 1500 cm^3; initial partial pressures of CO and N_2, respectively, were 0.9 and 0.1 atm; the adsorbents were prepared from 15.0 mmol of copper(I) halide and 10 g of the active carbon using 15 cm^3 of 28% ammoniacal aqueous solution as solvent.

Table 2 lists CO adsorbing capacities of the adsorbents prepared from the active carbon and various copper(I) halides by use of 28% ammoniacal aqueous solution as solvent. The capacity decreases in the following order: CuCl>CuBr $\gg$ CuI. The adsorbing capacities (0.8, 0.9, and 0.9 mmol, respectively) for the adsorbents prepared from 10.0 g of the active carbon and 15.0 mmol of either sodium chloride, zinc chloride, or magnesium chloride were small.

Effect of Preparation Solvent on CO Adsorbing Capacity. Figure 6 depicts the dependence of the CO adsorbing capacity of the active carbon-supported CuCl on the concentration of aqueous hydrochloric acid solution used as preparation solvent. The concentration of CuCl in the solution is kept constant at 1.0 mol dm^{-3}. The adsorbing capacity of the active carbon-supported CuCl increases with increasing concentration of aqueous hydrochloric acid solution up to the concentration 1.0 mol dm^{-3}. At the concentration larger than 1.0 mol dm^{-3}, however, the capacity is constant irrespective of the concentration.

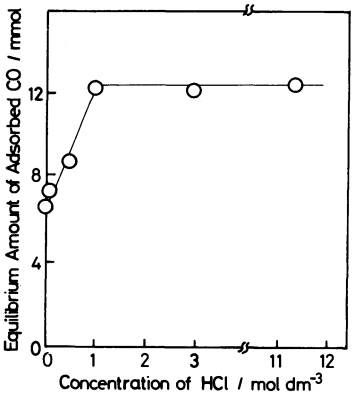

Fig. 6. Dependence of CO adsorbing capacity of the active carbon-supported CuCl on the concentration of aqueous hydrochloric acid solution used as preparation solvent; $[CuCl]_0 = 1.0$ mol dm^{-3}.

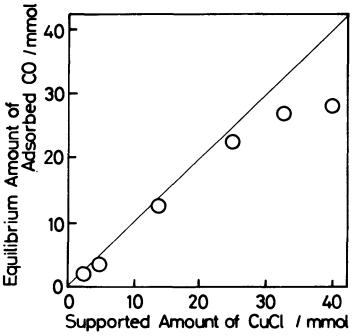

Fig. 7. Plot of CO adsorbing capacity of the active carbon-supported CuCl against the supported amount of CuCl.
Active carbon 10 g; the straight line is theoretical one calculated under the assumption that the supported CuCl forms 1 : 1 complex with CO.

Table 3 shows the CO adsorbing capacities of the active carbon-supported CuCl prepared by using various solvents. The adsorbent prepared using aqueous hydrochloric acid solution exhibits much larger adsorbing capacity and larger ratio of adsorbed CO to supported CuCl than those of the ones prepared using water, acetonitrile, and toluene.

Effect of Supported Amount of CuCl on CO Adsorbing Capacity. As shown in Table 4, both the ratio of the supported amount of CuCl to the charged amount and BET surface area of the active carbon-supported CuCl decrease with increasing charged amount of CuCl. Here, the amount of the active carbon is kept constant at 10 g.

Figure 7 depicts plot of CO adsorbing capacity of the active carbon-supported CuCl against the charged amount of CuCl. When the supported amount is smaller than 25 mmol, all the experimental points

Table 3. CO Adsorbing Capacities of the Active Carbon-Supported CuCl Prepared by Using Various Preparation Solvents[a)]

Solvent	Ratio of supported CuCl to charged CuCl	Amount of adsorbed CO / mmol	Molar ratio of adsorbed CO to supported CuCl
Aqueous hydrochloric acid solution (3 mol dm^{-3})	0.94	12.4	0.88
Water	0.70	5.6	0.64
Acetonitrile	0.87	6.1	0.47
Toluene	0.69	1.3	0.13

a) At 20 °C; initial volume of gas mixture 1500 cm^3; initial partial pressures of CO and N_2, respectively, were 0.9 and 0.1 atm; the adsorbents were prepared from 15.0 mmol of CuCl and 10 g of the active carbon using 15 cm^3 of one of the solvents.

Table 4. Supported Amounts of CuCl, Ratios of the Supported CuCl to the Charged CuCl, and BET Surface Areas for the Active Carbon-Supported CuCl Prepared from 10 g of the Active Carbon and Various Amounts of CuCl[a)]

Amount of CuCl / mmol		Ratio of supported CuCl to charged CuCl	BET surface area / $m^2 g^{-1}$
Charged	Supported		
0.0	0.0	—	1044
2.5	2.5	0.99	897
5.0	4.8	0.96	887
10.0	9.3	0.93	811
15.0	14.1	0.94	744
20.0	18.2	0.91	661
30.0	24.9	0.83	676
40.0	33.2	0.83	565
50.0	40.5	0.81	531

a) 15 cm^3 of 3 mol dm^{-3} aqueous hydrochloric acid solution was used as preparation solvent.

satisfactorily fit the theoretical line (the solid straight line) calculated under the assumption that the supported CuCl forms 1:1 complex with CO. At the supported amount larger than 25 mmol, however, CO adsorbing capacity is considerably smaller than the value estimated under the assumption.

Discussion

Preparation of the Active Carbon-Supported CuCl. Significant decrease of the BET surface area of the active carbon on the formation of the active carbon-supported CuCl adsorbents (Table 4) shows that CuCl is supported on the surface of the active carbon in the adsorbents. There, CuCl molecules probably exist in both monomeric and dimeric forms, resulting in effective adsorption of CO. Formation of large aggregates of CuCl is unlikely, since solid of CuCl shows no measurable adsorbing ability (Table 1) at 20 °C under the CO partial pressure 0.9 atm.

The proposed structure of the adsorbent involving CuCl in monomeric and dimeric forms is consistent with pore size distribution (Fig. 2) which indicates the presence of CuCl in the pores having radii smaller than 10 Å. The number of these micro-pores in the adsorbents is much smaller than that for the original active carbon, whereas the number of pores with radii larger than 10 Å is almost identical with each other. Molecular dimensions of monomeric form of CuCl and its dimeric form, respectively, are approximately 3.4 Å×3.4 Å×4.5 Å and 3.4 Å×3.9 Å×6.7 Å. These dimensions are evaluated from the bond length (2.05 Å)[12] of the Cu–Cl bond in solid of CuCl and the ionic radii (0.74 Å for copper(I) ion and 1.67 Å for chlorine anion).[12]

These arguments are further supported by the result of X-ray microanalysis (Fig. 3) showing uniform distribution of CuCl in the beads of the adsorbents without formation of any deposits of metal salts. Gradual decrease of BET surface area of the active carbon with increasing amount of supported CuCl (Table 4) is also consistent with them.

Rough estimation using the decrease (300 $m^2 g^{-1}$) of the BET surface area for the adsorbent composed of 10 g of the active carbon and 14.1 mmol of CuCl indicates that one molecule of CuCl occupies around 35 $Å^2$ of the surface area of the active carbon.

CO Adsorbing and Desorbing Ability of the Active Carbon-Supported CuCl. By use of the active carbon-supported CuCl, CO separation is successfully achieved both by temperature-swing method (Fig. 4) and by pressure-swing method. All the CO adsorbed at 20 °C under 1 atm (the CO partial pressure 0.9 atm) is desorbed both by heating the adsorbent to 120 °C under 1 atm and by reducing CO partial pressure to 0.4 mmHg at 20 °C. The amount of CO separated with the use of the present adsorbent for each of the cycles involving CO adsorption at 20 °C under 1 atm and desorption at 120 °C or for each of the cycles involving adsorption at 20 °C under 1 atm and desorption at 0.4 mmHg, 20 °C is

24 cm^3 (standard temperature and pressure) per 1 g of the adsorbent.

Complete desorption of adsorbed CO for the present adsorbent is highly in contrast with the fact that CO adsorbed by Y-type zeolite-supported copper(I) ion is not effectively desorbed even at 10^{-4} mmHg.[6] Desorption of CO, which is adsorbed by the adsorbent composed of copper(I) ion and zeolites having high SiO_2/Al_2O_3 ratios, is also difficult, as indicated by rather small dependence of the amount of adsorbed CO on CO partial pressure.[7]

The amount of CO adsorbed by 1 g of the active carbon-supported CuCl composed of 24.9 mmol of CuCl and 10 g of the active carbon is 38 cm^3 (standard temperature and pressure). The value is 2.4 times as large as the value (16 cm^3) for the adsorbent composed of copper(I) ion and high SiO_2/Al_2O_3 ratio zeolite.[7]

Mechanism of CO Adsorption by the Active Carbon-Supported CuCl. Much larger adsorbing capacity (12.4 mmol) of the active carbon-supported CuCl than both the value (0.0 mmol) for CuCl solid and that (3.3 mmol) for the active carbon (Table 1) shows that the presence of both of CuCl and active carbon is essential for the effective adsorption of CO by the active carbon-supported CuCl.

In the present adsorbent, CO is adsorbed by formation of 1:1 complex with the CuCl supported on the active carbon. This is clearly seen by the satisfactorily straight line with a slope unity for the plot between the CO adsorbing capacity and the supported amount of CuCl (Fig. 7). Deviation of the plot from the straight line at the supported amount 25 mmol or larger is ascribed to formation of small aggregates of CuCl at such large supported amounts. Furthermore, quite small capacities of the active carbon-supported sodium chloride, zinc chloride, and magnesium chloride confirm that the copper(I) ions are active species of CO adsorption by the present adsorbent. A possibility that surface of the active carbon treated with CuCl in aqueous hydrochloric acid solution has a CO adsorbing ability is ruled out by the independence of the capacity from the concentration of aqueous hydrochloric acid solution in the concentration range from 1.0 to 11.2 mol dm^{-3} (Fig. 6).

The order (CuCl>CuBr$\gg$CuI) in the CO adsorbing capacities of the active carbon-supported copper(I) halides (Table 2) is identical with that for copper(I) halides in various solvents.[13]

Effective adsorbing ability of the active carbon-supported CuCl is attributed to sufficient dispersion of CuCl on the surface of the active carbon, which produces vacant coordination sites at the copper(I) ions. Both the adsorbing capacity and the ratio of adsorbed CO to supported CuCl for the active carbon-supported CuCl prepared by use of aqueous hydrochloric acid solution are larger than the corresponding values for the ones prepared by use of acetonitrile, water, and toluene (Table 3). Aqueous hydrochloric acid solutions effectively dissolve CuCl in the form of $CuCl_2^-$,[14] whereas CuCl exhibits small solubility in acetonitrile or water, and virtually no solubility in toluene. When active carbon is stirred in hydrochloric acid solution of CuCl, most of the $CuCl_2^-$ ions, which are solvated with water, are supported on the surface of the active carbon due to mutual interactions. In the active carbon-supported CuCl obtained after evaporation of the liquid phase, CuCl molecules are satisfactorily dispersed on the surface of the active carbon. With the use of acetonitrile and water, however, the amount of CuCl supported on the active carbon is smaller due to small solubility of CuCl in them, and dispersion of CuCl molecules in the resultant adsorbents is poorer. The adsorbent prepared by use of toluene exhibits the smallest ability.

These arguments are further confirmed by the fact that the adsorbing capacity increases with increasing concentration of hydrochloric acid up to 1.0 mol dm^{-3}, when the charged amount of CuCl is 1.0 mol dm^{-3} (Fig. 6). One molecule of CuCl requires one molecule of hydrogen chloride for the formation of $CuCl_2^-$.

Adsorption of CO by the active carbon-supported CuCl is faster than that by a hydrochloric acid solution of CuCl (Fig. 5). This is due to the fact that diffusion of CO in liquid phase, which is rate-determining in the absorption by the solution, is not required for the present solid adsorbent to adsorb CO from gas phase.

In conclusion, the active carbon-supported CuCl is a solid adsorbent of CO having high abilities with respect to both adsorption and desorption. CO is efficiently adsorbed by the formation of complex with the CuCl, which is highly dispersed on the surface of the active carbon.

(Received June 22, 1985)

The chromatographic separation of rare earth elements was studied using newly-synthesized chelating resins which have EDTA (ethylenediaminetetraacetic acid) and DTTA (diethylenetriaminetetraacetic acid) pendant groups. The chromatography using EDTA- and DTTA-chelating resins gave excellent separation results, while the IDA-chelating resin was not satisfactory. The DTTA-type resin was especially effective, allowing highly purified rare earth elements to be recovered. The separation efficiency of each resin was attributed mainly to the difference in its complexing capability among rare earth ions. Prior to experimentation, the chromatographic conditions were assessed and optimized by computer simulation based on newly introduced equations. The simulation results were effective in the case of Pr^{3+}/Nd^{3+} for determining the experimental conditions. An analysis of the experimental results helped to elucidate the mechanism of the chromatographic separation while using the simulation results.

Lanthanum and cerium can be separated from other rare earth elements by a precipitation-filtration method; but the other 12 rare earth elements cannot be easily separated by such a simple chemical method. Many studies have been made on the separation of rare earth elements using solvent extraction and ion exchange.[1] In the field of analytical chemistry, it has been known that several organic ligands are capable of forming specific complexes with rare earth elements. Typical examples of such organic ligands are amine-*N*-polyacetic acids, such as NTA (nitrilotriacetic acid), EDTA (ethylenediaminetetraacetic acid) and DTPA (diethylenetriaminepentaacetic acid). Their stability constants are as high as 5 to 20 in terms of a logarithmic value (log *K*).

Differences in the values of their stability constants among the rare earth elements are expected to be sufficiently large for chromatographic separation. Several studies have been conducted on the separation of rare earth elements with such chelating resins as iminodiacetate resin,[2,3] *N*-methyliminodiacetate resin[4] and nitrilophosphonic resin.[5]

The authors have previously reported on results regarding studies of the selective bromination of *m*-divinylbenzene (*m*-DVB).[6] A bromination method was developed by referring to the selective addition reactions of various amines to *p*-DVB.[7] Follow-up and industrial application studies of that reaction have been made.[8] An attempt was also successfully made to synthesize chelating resins with pendant groups that are structurally similar to EDTA and DTTA (diethylenetriaminetetraacetic acid).[9] This paper describes the excellent results of our investigation on the chromatographic separation of rare earth elements using the newly-prepared resins, and comparing them with the obtained results using a known IDA (iminodiacetic acid)-chelating resin.

Prior to experimentation, the separation conditions of the chromatography were assessed and optimized by a computer simulation based on newly introduced equations. Although various simulation methods were known, the method introduced in this study is characterized by its easy procedure for finding a solution. The simulation results help to elucidate the chromatographic separation mechanism of rare earth elements.

Experimental

Synthesis of Chelating Resins. The procedures for synthesizing the resins followed that of previous reports.[9]

An IDA-chelating resin was synthesized from a copolymer of *m*-divinylbenzene (*m*-DVB) with vinylbenzyl chloride (VBC).[10,11] The backbone structure of a resin must be suitably designed in order to develop a greater chelate-forming capability. This capability of a resin is considered to depend primarily on the stability constant of the pendant group and secondarily on the crosslinking and rigidity of the polymer chain. Notably, there is a larger steric hindrance against pendant groups adjacent to DVB units in a resin. The monomer sequences of copolymers (VBC/*p*-DVB and VBC/*m*-DVB) were calculated based on the probability theory[12] of radical polymerization (Table 1). The formation of DVB–DVB chains in a polymer is most important from the standpoint of polymer-chain rigidity. The DVB–DVB and DVB–VBC sequences are

Table 1. Sequence Distributions in Copolymers of DVB(M_1) Isomers with VBC(M_2)

Copolymer	A[a]	B[a]
$P_2\{M_1M_1\}$	1.7	0.8
$P_2\{M_1M_2\}$[b]	41.6	18.2
$P_2\{M_2M_2\}$	56.7	80.9
$P_3\{M_1M_1M_1\}$	0.13	0.07
$P_3\{M_1M_1M_2\}$[b]	3.2	1.5
$P_3\{M_2M_1M_2\}$	19.2	8.4

a) A and B are copolymers of VBC with *p*-DVB and *m*-DVB, respectively, where $[M_1]/[M_2]=0.118$. b) $P_2\{M_1M_2\}$ consists of both diads M_1M_2 and M_2M_1, and $P_3\{M_1M_1M_2\}$ both triads $M_1M_1M_2$ and $M_2M_1M_1$.

believed to cause a steric hindrance against chelation. The probability of a DVB–DVB sequence is 0.8% for *m*-DVB and 1.7% for *p*-DVB. *m*-DVB also gives a lower probability (18.2%) for DVB–VBC chain formation than *p*-DVB (41.6%). Thus, *m*-DVB was selected as the crosslinking agent. IDA groups could be introduced into the resin by the reaction of a copolymer of *m*-DVB and VBC (*m*-DVB/VBC by wt.=1:10) with diethyl iminodiacetate (IDAE), followed by hydrolysis. It took approximately 8 h for the reaction to be completed. The resin produced had a cation-exchange capacity of 4.3 meq g^{-1}.

An EDTA-chelating resin was synthesized by the amination of a copolymer [**II**] of *m*-(1,2-dibromoethyl)-styrene (*m*-DBS) [**I**] and *m*-DVB (*m*-DVB/*m*-DBS by wt.=2.5:7.5) with IDAE, followed by hydrolysis (Fig. 1). Amination while synthesizing an EDTA-chelating resin [**IV**] was not as easy as during IDA-chelating resin synthesis. One side reaction was the elimination of HBr from the 1,2-dibromoethyl group of a DBS unit, resulting in the formation of a double bond. The obtained resin had a cation-exchange capacity of 3.9 meq g^{-1}.

DTTA-chelating resin synthesis was performed by the preparation of a copolymer [**VI**] consisting of a monomer [**V**] and *p*-DVB (*p*-DVB/monomer [V] by wt.=2:8), followed by the *N*-carboxymethylation of the amino groups with bromoacetic acid (Fig. 2). Copolymer [**VI**] had an anion-exchange capacity of 6.2 meq g^{-1}. If conversion rates for the monomer [V] and *p*-DVB were both 100%, the anion-exchange capacity of the copolymer [**VI**] should be 7.5 meq g^{-1} at its maximum. The chelating resin [**VII**] obtained after *N*-carboxymethylation had a cation-exchange capacity of 5.1 meq g^{-1}.[9]

Separation Studies. Chelating Resins: Each of the chelating resins was classified between 100-mesh and 200-mesh with sieves. The classified resins were washed (twice with a 0.1 mol dm^{-3} aqueous NaCl solution and then with 0.1 mol dm^{-3} hydrochloric acid).

Reagents: Salts of rare earth elements, rare earth chlorides, were of commercially available grade (purity: 99.9% or higher). Each salt was weighed and dissolved in deionized water. Other reagents were of commercially available guaranteed grade.

Analysis: The concentrations of rare earth elements in a solution were determined by an automatic-recording luminescence spectrophotometer, manufactured by Shimadzu Corporation. The pH values of the solutions were measured with a pH meter (model HM-18B) and a glass electrode (model GST-155C9 manufactured by Toa Elec-

tronics Ltd.).

Separation Procedure: Liquid chromatography was performed at 95 °C in a jacketed Pyrex column with an internal diameter of 10 mm and a length of 1 m (Figs. 5—10) or 2 m (Fig. 11). The concentration and amount of feed and the flow rate in each experiment are listed in Table 2. A chelating resin, which was converted to the OH^- form by an alkaline solution at pH=10, was embedded into this column. The resin bed was washed with de-ionized water to remove any remaining alkali from the column. A solution containing two rare earth elements at equal molar concentrations whose pH was adjusted using hydrochloric acid was fed into the column. Then, 0.1 mol dm^{-3} hydrochloric acid was added to the column and 2 cm^3 fractions of the eluate were collected by means of a fraction collector. The pH and concentrations of the rare earth elements were measured for each fraction.

Results and Discussion

Simulation of Separation for Determining the Experimental Conditions and Analyzing the Experimental Results. The equilibrium reactions involved in this chromatography consisted of the following two types: (i) Dissociation of amine-*N*-polyacetic acids fixed to a resin (acid-base reaction) and (ii) chelate formation of rare earth ions on the resin.

A well-known method for determining equilibrium is to introduce multidimensional equations using the equilibrium constant K. The equations give a plural of roots and it was generally hard to choose the correct root. An alternative method is to determine the concentrations in an equilibrium state by minimizing the Gibbs' free energy.[13,14] This method was more complicated, so both methods were unsuitable for the chromatography simulation.

Therefore, we devised a new method[15,16] in which each reaction was expressed as an addition reaction, and the "reduction potential strength" was used to evaluate the reaction thermodynamically. This method enabled the concentration of each chemical species to be readily determined for any equilibrium state of a system of plural reactions. Here, it is briefly explained.

In this study, a completely dissociated form of a resin-bound chelating group, denoted as R-$(COO^-)_n$, was adopted as an acceptor (Eq. 3) instead of a non-dissociated form, R-$(COOH)_n$. An addition of protons can generally be expressed as

$$\text{R-}(\text{COO}^-)_n + l\,\text{H}^+ \longrightarrow \text{R-}(\text{COO}^-)_{n-l}(\text{COOH})_l, \quad (1)$$

where n and l are integers safisfying $n \geqq l \geqq 1$. n=2 for an IDA type and n=4 for EDTA and DTTA types.

The addition of a rare earth ion to the acceptor can be expressed as

$$\{[\text{R-}(\text{COO})_n]^{n-}\}_m + \text{RE}^{3+} \longrightarrow \{[\text{R-}(\text{COO})_n]_m \cdot \text{RE}\}^- \quad (2)$$

where n=2 and m=2 for an IDA type. n=4 and m=1 for EDTA and DTTA types. The above two kinds of equations are referred to as individual reactions, where R-$(COO)_n^{n-}$ can be considered, apriori, to be suitable as an acceptor for both addends, H^+ and RE^{3+}, in the systems of this study. It was also reported[16] that amine-*N*-polyacetic acids such as EDTA complexed effectively with rare earth ions in an acceptor form as represented by Eq. 2. Taking advantage of the above expressions and reduction-potential strengths results in easier calculations and more definite determinations of the thermodynamics of a system involving plural exchange reactions, inclusive of the adsorption-desorption of rare earth ions and an acid-base reaction.

The protonation to a conjugate base and chelate formation are both generally expressed in a unified form:

$$\text{A} + \nu \cdot \text{X} \longrightarrow \text{D}. \quad (3)$$

where A is the acceptor of an addend X, D is an adduct and ν is the stoichiometric coefficient of an addend X. 'A' can refer to a carboxylate ion of an amine-*N*-polyacetic acid ligand; 'X' can refer to a rare earth ion or a proton and 'D' can be a complex of a rare earth ion with a carboxylate ion or a non-dissociated acid. The equilibrium relationship of Eq. 3 can be expressed as follows by using thermodynamic relations[17]:

$$\Delta\mu_x = \Delta\mu^\circ_{\text{D}} + \frac{RT}{\nu} \ln \frac{a_{\text{A}}}{a_{\text{D}}}. \quad (4)$$

Here, $\Delta\mu_x$ is termed the "reduction potential strength" and is defined by the chemical potential μ_x and standard chemical potential μ°_x as

$$\Delta\mu_x \equiv \mu^\circ_x - \mu_x. \quad (5)$$

$\Delta\mu^\circ_{\text{D}}$ is the "standard reduction potential strength" and is defined as

$$\Delta\mu^\circ_{\text{D}} \equiv \mu^\circ_x - \frac{(\mu^\circ_{\text{D}} - \mu^\circ_{\text{A}})}{\nu}. \quad (6)$$

Suppose that a system contains several kinds of

acceptor species A and N kinds of the addend X. The concentration ratio of an arbitrary adduct species D, which is a mixed-ligand complex of a given i-th species of A with L_j units of any j addend of X(j=1,2,…,N), to the remaining non-complexed i-th species can be expressed as Eq. 7[18]:

$$T_{i,Lj} = \exp\left(\frac{S_p - L_p}{RT}\right), \tag{7}$$

where

$$S_p = \sum_{j=1}^{N} \sum_{n_j=1}^{L_j} \nu_{i,n_j} \Delta\mu^\circ_{i,n_j} \tag{8}$$

and

$$L_p = \sum_{j=1}^{N} \sum_{n_j=1}^{L_j} \nu_{i,n_j} \Delta\mu_{i,n_j}. \tag{9}$$

Here, n_j is the stepwise number of additions of any addend j and L_j is the cumulative number of additions.

The introduced distribution function, Eq. 7, seems to be complicated, but it can be easily solved numerically since it always increases monotonously and leads to only one solution for any case.

Simulations were executed according to the following imaginary separation procedures: (1) An alkaline solution was supplied to a column packed with an EDTA-chelating resin, so as to dissociate amine-*N*-polyacetic acid groups of the resin; (2) An imaginary solution containing Nd^{3+} and Pr^{3+} was passed through the column and (3) the rare earth chelates were decomposed by supplying an acid solution. The first, second and third procedures are called "regeneration," "adsorption," and "development," respectively. Computations using an ECLIPS minicomputer manufactured by Data General Co., Ltd. were executed step-by-step for each imaginary plate formed by subdividing a packed column. In this procedure, Eq. 7 was repeatedly applied according to the reported treatment of multi-stage equilibrium.[19] The $\Delta\mu^\circ_{i,n_j}$ for rare earth ions and for H^+ are summarized in Tables 3(a)[20] and 3(c).[21] S_P for H^+ in Eq. 8 is shown in Table 3(b) and L_p is dependent on the concentrations of two addends (H^+ and RE^{3+}) in each plate of chromatography.

The results of simulated separation conditions in the chromatography can be summarized as follows:

1. A resin bed can be regenerated with an alkaline solution at pH>11.
2. A resin bed can be regenerated not only with a less alkaline solution but with a weakly acidic (pH>4) solution. It is hardly regenerated with a solution at pH<4.
3. Asorption bands can be developed at pH<2.
4. The concentrations of eluted rare earth ions are correlated positively with the acid concentration in the developing solution.

Table 3(a). $\Delta\mu^\circ_{i,n_j}$ for Protonation to the Conjugate Bases of Amine-*N*-polyacetic Acids

(kJ mol^{-1})

Amine-*N*-polyacetic acid	$\Delta\mu^\circ_{i,n_j}$[a]

Lu^{3+}	—	113.1	—

a) The j refers to a rare earth ion. Values of $\Delta\mu^\circ_{i,n_j}$ were calculated using the stability constants of the rare earth ions listed in Ref. 21.

Examples of the simulation results, selected to determine a favorable experimental condition, are illustrated in Figs. 3 and 4.

When a solution has pH=10 (Fig. 3), the dissociation degree of EDTA groups within the resin is 83%. At pH=4 (Fig. 4) it is only 54%. In view of a reported observation,[16] it was originally expected that the rare earth ions could not be effectively adsorbed after a regeneration procedure at pH=4. However, it was predicted from simulation results that rare earth ions could be adsorbed when the solution was at pH=4 as well as at pH=10. At

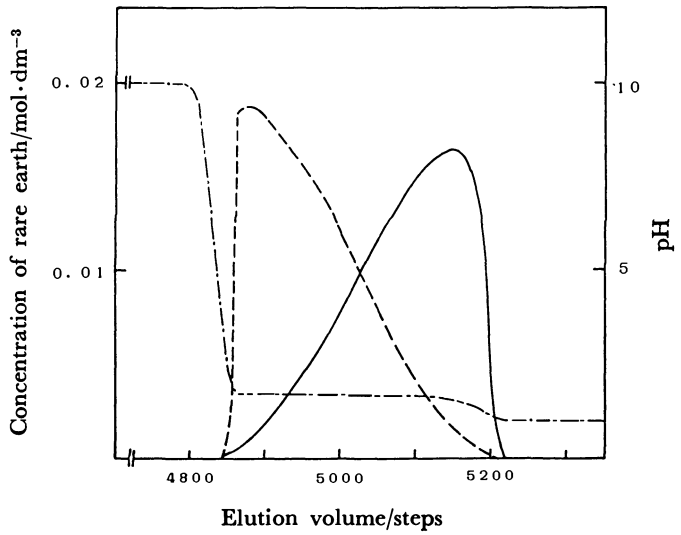

Fig. 3. Simulation of the separation of rare earth ions with EDTA-chelating resin. (The adsorption band is regenerated at pH=10 then developed with 0.1 mol dm^{-3} HCl.) ——: pH, ----: Pr^{3+}, ——: Nd^{3+}.

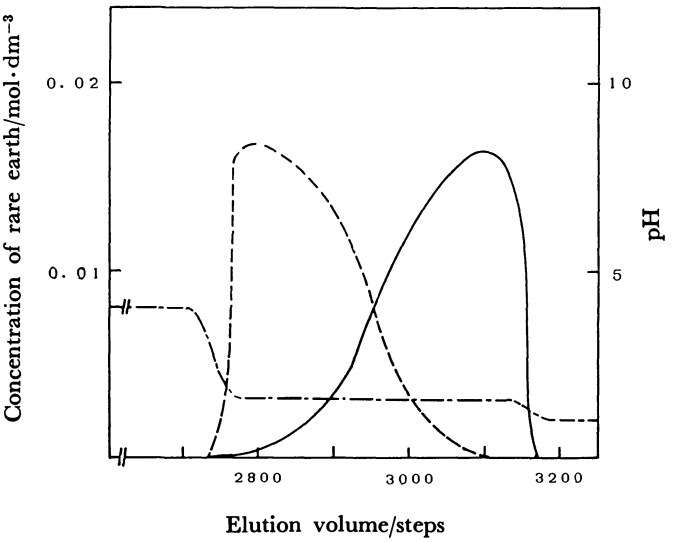

Fig. 4. Simulation of the separation of rare earth ions with EDTA-chelating resin. (The adsorption band is regenerated at pH=4 then developed with 0.1 mol dm^{-3} HCl.) ——: pH, ——: Pr^{3+}, ——: Nd^{3+}.

pH=4, two of the four carboxyl groups of an EDTA moiety were not dissociated. As a rare earth ion approaches the EDTA moiety, two nondissociated protons seem to be exchanged for a rare earth ion, allowing it to form a complex. The S_p of the second proton addition to the conjugate base of EDTA is 81.7 kJ mol^{-1} whereas the S_p of the complex formation of Pr^{3+} and Nd^{3+} with EDTA that are identical to the $\Delta\mu^{\circ}_{i,n_i}$ in these cases are as large as 93.9 and 95.1 kJ mol^{-1}. This might explain quantitatively why protons can be replaced by Pr^{3+} and Nd^{3+}.

The step number (the number of simulation calculations in which the imaginary solution phase is shifted downwards as the acid solution descends) at which rare earth ions begin to elute, is about 4840 when the adsorption band is initially regenerated at pH=10 (Fig. 3). The corresponding step number is 2750 when it is initially regenerated at pH=4(Fig. 4). It is noted that in the case of EDTA groups, the ratio of the dissociation degree at pH=10 to that at pH=4 is 1.5; also, the corresponding ratio of the step numbers for rare earth ions to start being eluted is 1.7. Thus, the former ratio does not agree with the latter ratio. It was then considered (on the basis of material balance) what determines the ratio of the step numbers for rare earth ions to start being eluted. The elution volume at the break-through point is defined by the resin volume and the rare earth ion concentrations in the solid and liquid phases.
That is,

$$V_f = \frac{C_{R,r}}{C_{R,s}} V_r \tag{10}$$

where V_f is the elution volume at the break-through point, V_r the resin volume, and $C_{R,r}$ and $C_{R,s}$ the rare earth ion concentrations in the solid and liquid phases. The ratio $C_{R,r}/C_{R,s}$ should be expressed by the proton concentrations in the respective regions as

$$\frac{C_{R,r}}{C_{R,s}} = \frac{[C_{H,r}]_B - [C_{H,r}]_F}{[C_{H,s}]_B}, \tag{11}$$

where $[C_{H,r}]_B$ and $[C_{H,s}]_B$ are the solid- and liquid-phase proton concentrations in the rare earth band and $[C_{H,r}]_F$ the solid-phase proton concentration in the front region. From Eqs. 10 and 11, the following equation is derived:

$$V_f = \frac{[C_{H,r}]_B - [C_{H,r}]_F}{[C_{H,s}]_B} V_r. \tag{12}$$

Calculations of V_f from Eq. 12 for regenerations at pH=10 and pH=4 give a value of 1.75 for the ratio of V_f. This value is almost equal to the value described above as the ratio of the step numbers for rare earth ions to start being eluted. The reason why the ratio of V_f at pH=10 to that at pH=4 is much larger than unity is that $[C_{H,r}]_F$ at pH=4 is almost three-times that at pH=10 while the $[C_{H,r}]_B$ at pH=4 is only two-times that at pH=10. $[C_{H,s}]_B$ does not change very much with the pH.

A rear boundary reaction is completed by bringing a sufficient amount of acid into contact with chelated rare earth ions. The acid concentration at the rear boundary is closely related to the liquid-phase concentration of rare earth ions in the adsorption band. The total concentration of the rare earth ions is about 110 mmol dm^{-3} when developed using 0.5 mol dm^{-3} hydrochloric acid whereas this concentration is about 20 mmol dm^{-3} with 0.1 mol dm^{-3} hydrochloric acid (Fig. 4).

The actual experimental conditions were set so that the pH of the regenerating solution was 10 and the acid concentration of the developing solution was 0.1 mol dm^{-3}.

Results of Experiments. A chromatographic separation of rare earth elements was carried out using each of the three different chelating resins under the computer-simulated conditions.

The result of a chromatographic separation of La^{3+} and Nd^{3+} with an IDA-chelating resin is shown in Fig. 5. The result was good, reflecting the large difference in the potential strengths of La^{3+} and Nd^{3+}, which is shown to be 6.3(kJ mol^{-1}) from Table 3(c). But Pr^{3+} and Nd^{3+} were slightly separated with IDA-chelating resin in Fig. 6. The result indicated that the difference $\Delta(\Delta\mu^\circ_{i,n_j})$ of the potential strengths $\Delta\mu^\circ_{i,n_j}$ between Pr^{3+} and Nd^{3+} with the IDA-chelating resin was small (see Table 4), as expected from the $\Delta(\Delta\mu^\circ_{i,n_j})$ with the corresponding acid (IDA) shown in Table 3(c).

(kJ mol^{-1})

	IDA	EDTA	DTTA
Nd^{3+}/Pr^{3+}	0.17	0.88	0.92

Separation between Pr^{3+} and Nd^{3+} was more effectively attained with the EDTA-chelating resin prepared from m-DBS (Fig. 7). The potential difference $\Delta(\Delta\mu^\circ_{i,n_j})$ between both ions with the corresponding acid (EDTA) was 1.2 kJ mol^{-1}, larger than that of IDA (0.4 kJ mol^{-1}). Figure 8 shows even better separation result using the DTTA-chelating resin prepared from styrenetriamine monomer (**V**), than that using the EDTA-chelating resin. The potential difference of these ions with DTPA, whose structure is similar to DTTA, is 2.1 kJ mol^{-1} and is larger than that with EDTA. The potential-strength differences with the chelating resins observed in Fig. 6 to Fig. 8 (listed in Table 4) were all smaller than expected from the differences obtained with the corresponding amine-*N*-polyacetic acids. The reduction of the potential-strength differences is considered to be due to a steric hindrance of a polymer network to all the three acids and a chemical structure difference between DTPA and the resin-bound DTTA moiety. The other separation experiments for pairs of Eu^{3+}/Gd^{3+} and Ho^{3+}/Eu^{3+} with a DTTA-type resin gave the results shown in Figs. 9 and 10, respectively. The potential strength of Ho^{3+} is not

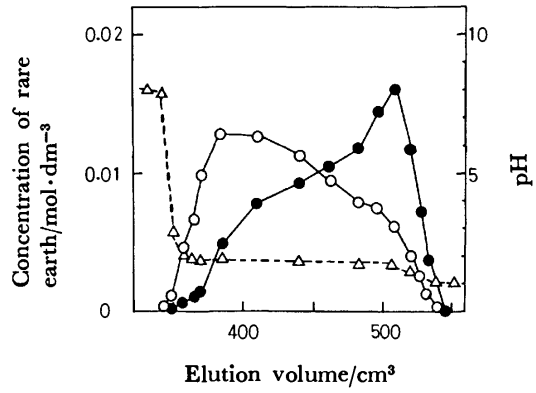

Fig. 10. Separation of Ho^{3+} and Eu^{3+} with DTTA-chelating resin. △: pH, ○: Ho^{3+}, ●: Eu^{3+}.

known and Fig. 10 is the first result of Ho^{3+} separation attempted with a DTTA-type chelate resin. The adsorbability of the Gd^{3+}/Eu^{3+} pair was contrary to that expected from the $\Delta(\Delta\mu^\circ)$ listed in the right column of Table 3(c). Several possible causes can be considered. The potential strengths of rare earth elements which have higher atomic numbers than Sm are similar to each other and no explicit tendency between the potential strengths and the atomic numbers has been observed for almost all amine-*N*-polyacetic acids. Moreover, structural distinction between DTPA and DTTA is necessary to be considered. Additional experimental results and theoretical considerations are necessary; these are presently being collected for our future reports.

Figure 11 shows the results using a longer separation column packed with a DTTA-chelating resin; the separation of Pr^{3+} and Nd^{3+} was further improved, compared with the shorter-column experiment shown in Fig. 8. Highly purified Pr^{3+} and Nd^{3+} could be recovered from almost half of the adsorption bands as well as from the neighborhoods of the front and rear boundaries. Comparing the results in Figs. 8 and 11, the volumes of the mixed-ion zone, where Pr^{3+} and Nd^{3+} were not fully (though partially) separated from each other, were not much different. It is, thus, recognized that with a longer separation column, more fractions containing highly-purified rare earth ions can be recovered. In elution chromatography the concentrations of separated materials in effluents generally decrease with an increasing length of the separation column. The concentration of rare earth ions recovered in Fig. 11 was nearly equal to that in Fig. 8 due to displacement chromatography. The fractions from 850 to 1370 cm^3 of the elution volume (Fig. 11) were analyzed by an Argon-plasma spectrometer to determine the purity of each constituent. Two fifths of the fractions had purity values ranging from 99.99 to 99.999%. Near the rear boundary, the purity of Nd^{3+} ions seemed to be higher than 99.999% since it tended to be higher in a later fraction; however, no accurate analytical value greater than 99.999% was obtained in the measurement. An analysis of kinetics is indispensable for any discussion of chromatography and results always strongly depend on the speed of adsorption-desorption or ligand exchange. In this study, the height of an imaginary plate used in the simulation was converted to the volume of the effluent under the experimental conditions by comparing the separation profiles.

Conclusion

The separation of rare earth ions was studied with synthesized amine-*N*-polyacetic acid type chelating resins.

(1) Satisfactory separation results were obtained in experiments by displacement chromatography using EDTA- and DTTA-chelating resins.

(2) Highly-purified rare earth ions could be recovered more efficiently using a longer separation column.

(3) Systems comprising five equilibrium reactions were analyzed using the concept of reduction potential strength and a novel distribution function. A prediction made on the basis of

simulation results matched the results of separation experiments in the case of Nd^{3+}/Pr^{3+} with good precision.

(4) The step number at which rare earth ions began to elute depended on the pH of the regenerating solution; the total concentration of the rare earth ions depended on the acid concentration of the developing solution.

(5) Several rare earth ions could be separated using a DTTA-chelating resin most efficiently. However, much remains to be done before quantitatively discussing the observed differences in $\Delta(\Delta\mu^\circ)$ between the chelating resins and the corresponding amine-*N*-polyacetic acids.

The authors would like to sincerely thank Prof. Teiji Tsuruta of the Science University of Tokyo for his instructions regarding the synthesis of the starting material and the polymer used in preparing the DTTA-chelating resin, and for his helpful suggestions regarding the characterization of the chelating resins. The authors also would like to thank Prof. Manabu Seno of the University of Tokyo for his suggestions regarding equilibrium and separations studies using chelating resins.

(Received April 7, 1985)

The title compound, $C_{34}H_{18}$, has been obtained by reducing violanthrone B, a byproduct in the synthesis of violanthrone. Its structure has been determined by on X-ray analysis. The space group is $P2_1/c$, with unit-cell dimensions a=25.78(1), b=3.807(5), c=19.975(8) Å, β=96.55(3)°, and Z=4. The structure was solved by the direct method and refined by a block-diagonal least-squares method to an R value of 0.076 on the basis of 1242 independent reflections. The molecules are largely distorted from a planar structure owing to a steric repulsion between the intramolecular overcrowded hydrogen atoms. Also, they are stacked face-to-face to form a column structure along the b-axis.

The title hydrocarbon, violanthrene B, was obtained by reducing violanthrone B, a byproduct in the synthesis of violanthrone. Although its structure has been assumed to be I, a confirmation by X-ray analysis is still necessary to elucidate the reaction mechanism.[2-7] Futhermore, it is very interesting to examine the molecular deformations of such overcrowded hydrocarbons as I to IV, which have very short H···H contacts. The structure of II,[8] III,[9] and IV[10] have already been reported.

*2) Diphenanthro[5,4,3-*abcd*: 5′,4′,3′-*jklm*]perylene (DPP)
*3) Anthra[2,1,9,8-*hijkl*]benzo[*de*]naphtho[2,1,8,7-*stuv*]pentacene (1,11-BisoVEB)

Scheme

Experimental

The title compound was prepared by a previously reported conventional method.[11] The crystals used for X-ray work were grown from an *o*-dichlorobenzene solution. Crystal data are as follows: $C_{34}H_{18}$; M.W. 426.5; monoclinic; a=25.78(1), b=3.807(5), c=19.975(8) Å, β=96.55(3)°, and U=1948(3) Å^3; D_x=1.455 g cm^{-3}; Z=4; space group $P2_1/c$; μ(Cu $K\alpha$)=6.44 cm^{-1}. The intensity data were collected on a Rigaku automated four-circle diffractometer with the $\omega/2\theta$ scan technique, the scanning rate being 2°(2θ) min^{-1}. The dimensions of the crystal used for the data collection were 0.05×0.2×0.5 mm. A total of 2984 independent reflections were measured up to 2θ=125°, using graphite monochromated Cu $K\alpha$ radiation, of which 1242 reflections were ($|F_o|>3\sigma(|F_o|)$). Corrections for Lorentz and polarization factors were made, but not for absorption.

Structure Determination

Systematic absences of $h01$, $l=2n+1$, and $0k0$, $k=2n+1$ indicated the space group to be $P2_1/c$. The structure was solved by a direct method using the MULTAN 78 program.[12] Two disordered molecules with equal occupancies appeared on E-maps as shown in Fig. 1. The disordered structure was refined to R=0.162 by full-matrix least-squares with the SHELX 76 program,[13] but a further refinement based on this model was impossible. A new ordered model with a space group of Pc was constructed from the $P2_1/c$ structure by removing the crystallographic center of symmetry. The refinement was carried out by least-squares. The R value converged to 0.16. Another ordered model ($P2_1/c$) was constructed by

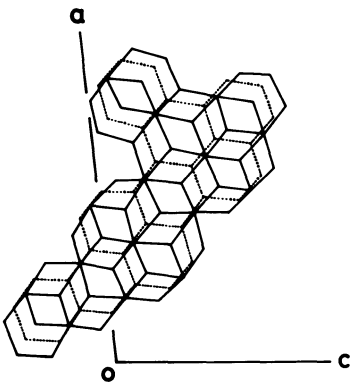

Fig. 1. The false disorderd structure (solid lines) found on the E-map and the true ordered one (dotted lines).

a) The equivalent isotropic temperature factors were computed using the following expression: $B_{eq}=1/3\sum_{i,j} a_i a_j a_i^* a_j^*$.

averaging two positions of the corresponding atoms of the disordered molecules as shown with dotted lines in Fig. 1; however, no peaks were found at the atomic positions. This model ($P2_1/c$) coincides to the Pc model if a slight difference between two crystallographically independent molecules is neglected and the origin in the Pc model is shifted so that the molecules are related by a center of symmetry. Six cycles of refinement on this model brought the value of R to 0.076, where the thermal parameters for the carbon atoms were assumed to be anisotropic and the unit weight was applied to F_o. No peaks higher than 0.3 eÅ^{-3} were found on the final defference map. The final R was 0.076 with a maximum Δ/δ of 0.5. The atomic-scattering factors were taken from the International Tables for X-ray Crystallography.[14] The final atomic parameters and their estimated standard deviations are listed in Table 1. Lists of the observed and calculated structure factors, parameters of the hydrogen atoms and anisotropic thermal parameters for non-hydrogen atoms are kept in the office of the Chemical Society (Document No. 8632). Computations were performed on the M-280H computer at the Computer Center of the University of Tokyo.

Results and Discussion

The present study has established the structure of I. Figure 2 illustrates the crystal structure viewed along the b axis. The numbering scheme is indicated in Fig. 3, together with the deviations of the atoms from the mean plane of the molecule. The bond lengths and angles are listed in Tables 2 and 3, respectively. The mean bond length of the outer bonds is slightly shorter than that of the inner lengths and the three bonds around each carbon atom are nearly coplanar. These facts have also been found for some polycyclic

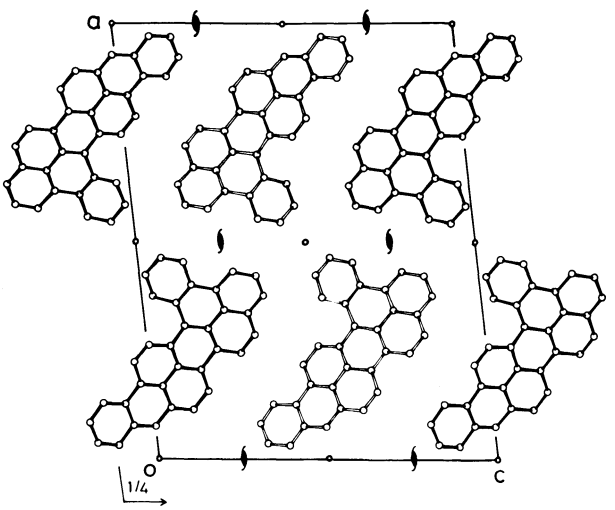

Fig. 2. A projection of the crystal structure along the b axis.

aromatic hydrocarbons.[8,9,10] Figure 4 shows a perspective drawing of the molecule. This molecule is greatly distorted from a planar conformation because of the repulsion betwen the crowded hydrogen atoms, known as an 1,7 interaction. The steric repulsion between H(23) and H(27) is mainly released by the enlargement of the C(24)–C(25)–C(26) angle and the twisting of the C(23)–C(24) and C(27)–C(26) bonds around the line C(24)···C(26) as defined in ref. 10. The angle of C(24)–C(25)–C(26) (α), the twisting angle of C(23)–C(24)···C(27)–C(26) (β) and the nonbonded C···C distances (C(24)···C(26))

a) A and B indicate the crystallographically independent molecules. b) A and B molecules occupy the same site in a ratio of 2:1.

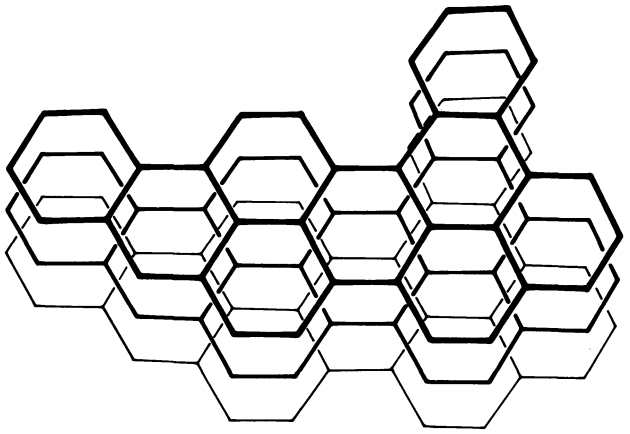

Fig. 5. Overlapping mode of the molecules.

are listed together with those of several related molecules in Table 4. Similar values were observed for the nonbonded C···C distances of the molecules. Although α in VEB is similar to that of the BPT, β resembles that of B molecules of 1,11-BisoVEB. In BPT, the expansions of the two C–C–C angles neighbouring the referred C–C–C angle also, somewhat, contributes to the relief of such a repulsion. Their angles are both 124° in BPT, whereas they are 121 and 122° in VEB. The twisting of C(23)–C(24) against the mean plane of the molecule is larger than that of C(26)–C(27) since terminal rings with C(23)–C(24) are easily bent at the bond of C(19)–C(24). The ring makes an angle of 21° to the mean molecular plane. Such bent rings are found in TBP(II),[8] where two benzene rings are bent at the bonds indicated by arrows in the scheme. On the other hand, additional (shaded) benzene rings prevent such bending in the cases of DPP (III) and 1,11-BisoVEB(IV).[9,10] The molecules are stacked face-to-face to make column structures along the *b*-axis. Figure 5 shows the overlapping mode of the molecules. The interplanar spacing (3.69 Å) is larger than the usual value. There is no unusual short contact between the molecules.

Reactivity of Electrons Produced in Gamma-Irradiated Zeolite Toward Several Electron Scavengers

Chiyoko NAKAZATO* and Takahiro MASUDA
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University,
Fukasawa, Setagaya-ku, Tokyo 158
(Received December 19, 1985)

Relative rates of reaction of electrons produced in gamma-irradiated zeolite (Molecular Sieve 13X) with several electron scavengers were determined by competition kinetics using dinitrogen monoxide as a reference compound. A part of the electrons produced in irradiated zeolite have been disclosed to be quasi-free from the feature of their reactivity toward electron scavengers that the reactivity is similar to that of quasi-free electrons found in irradiated liquid 2,2-dimethylpropane. An analysis based on competition kinetics has provided a value 9.8×10^{12} dm^3 mol^{-1} s^{-1} as the lower limit on the rate constant for the reaction of quasi-free electrons with positive holes produced in irradiated zeolite.

A compound adsorbed on the surface of a solid is radiolyzed through a reaction induced by excitation energy transferred from an irradiated solid[1-6] and formation of electron and positive hole has been investigated by ESR or product analysis using electron or hole scavengers.[7-15] A synthesized zeolite, Molecular Sieve 13X, is an interesting adsorbent because of its highly ordered structure and large capacity of adsorption. The solid can be taken as an immobile solvent if the size of an adsorbate is small enough to enter a supercavity of zeolite. Reactions occurring in the system are considered approximately as those in solution, and kinetics used for reactions in solution will be applicable. The property of electrons produced in a solid insulator such as zeolite is interesting in connection with its reactivity. The present study was carried out to clarify the property and reactivity of electrons generated in irradiated zeolite. By using several electron scavengers and adopting kinetics for reactions in solution, it has been found that at least two kinds of electrons react with adsorbates, one showing a reactivity toward a series of electron scavengers similar to that of quasi-free electrons produced in liquid 2,2-dimethylpropane.[16,17]

Experimental

Zeolite (Molecular Sieve 13X; abbreviated to MS) was obtained from Nippon Kuromatokogyo K. K. The specific surface area is 1030 m^2 g^{-1}. Dinitrogen monoxide, sulfur hexafluoride, and methyl chloride were purchased from Takachiho Kagakukogyo K. K. Carbon tetrachloride and trichloroethylene were of spectrograde from Merck. Ethyl bromide was obtained from B. D. H.

About 12 g of MS was degassed in a quartz vessel at 600 °C for 24 h under a pressure below 10^{-3} Pa and divided to six ampules attached to the vessel in ca. 2 g each. A scavenger was introduced into the ampules through breakable seals with a vacuum line. After standing for 24 h, the ampules were irradiated by ^{60}Co gamma rays to a total dose of 1.34×10^4 Gy. The amount of molecular nitrogen formed from dinitrogen monoxide was determined by gas chromatography. Calculation for kinetic analysis was carried out with the aid of microcomputer PC-8001 (Nippon Electric Co.).

Results and Discussion

Formation of Molecular Nitrogen from MS-N_2O System. As shown in Fig. 1a, the G-value for formation of molecular nitrogen, $G(N_2)$, increases with increasing amount of N_2O introduced into an ampule and approaches a limiting value 2.8 at approximately 5×10^{-5} mol of N_2O per g of MS. The nitrogen formation is explained in terms of the reactions

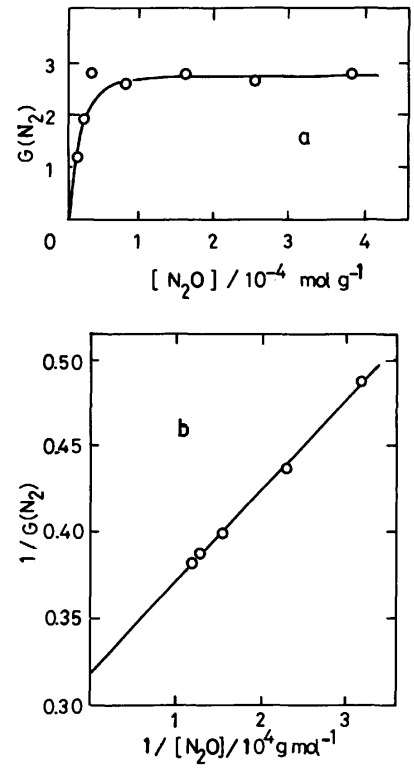

Fig. 1. a. Dependence of $G(N_2)$ on adsorbed amount of N_2O. Dose, 1.34×10^4 Gy. b. Competition plots of $1/G(N_2)$ vs. $1/[N_2O]$.

$$MS \rightsquigarrow MS^+ + e^-, \quad (1)$$

$$e^- + MS^+ \longrightarrow MS^*, \quad (2)$$

$$e^- + N_2O \longrightarrow N_2 + O^-_{ad}, \quad (3)$$

where MS^+ denotes a positive hole produced in γ-irradiated MS. From these reactions, we have

$$1/G(N_2) = 1/G_e(1+k_2[MS^+]/k_3[N_2O]). \quad (I)$$

Plotting $1/G(N_2)$ vs. $1/[N_2O]$ gave a straight line as shown in Fig. 1b, for which the observed values in Fig. 1a were not used for the plotting but the values obtained from the curve were used. Thus, a slope of 5.30×10^{-6} and an intercept of 0.32 were obtained with a correlation coefficient of 0.9988. G_e can be calculated from the intercept as 3.1, which agrees with the limiting $G(N_2)$, 2.8, within an experimental error. The slope will give k_2/k_3 if $[MS^+]$ can be estimated properly. Essentially the concentration of positive hole, $[MS^+]$, should be expressed by a steady state concentration but the estimation is very difficult. A lower limit of k_2/k_3, however, can be evaluated if the total concentration of positive hole produced in MS during irradiation is used as $[MS^+]$ instead of the steady state concentration. The total concentration of MS^+ can be calculated from G_e and the total dose by assuming $G_e=G(MS^+)$. In the present experimental conditions, it is 3.9×10^{-6} mol g^{-1} and hence 4.2 is obtained as k_2/k_3. If it is assumed that the rate constant for the reaction of quasi-free electron with N_2O in liquid 2,2-dimethylpropane, 2.3×10^{12} dm^3 mol^{-1} s^{-1}, is applicable to k_3, the lower limit of the rate constant for the reaction of electron with positive hole in MS is 9.8×10^{12} dm^3 $mol^{-1}s^{-1}$. Sulfur hexafluoride is known to react with quasi-free electron with the rate constant of 1.98×10^{14} dm^3 mol^{-1} s^{-1} in liquid 2,2-dimethylpropane[17] and the electron produced in γ-irradiated MS was found to react with SF_6 85 times as fast as with N_2O, as described below. The positive hole in MS is thought to have at least the same reactivity as SF_6. The steady state concentration of MS^+, therefore, would be less than 1.9×10^{-7} mol g^{-1}.

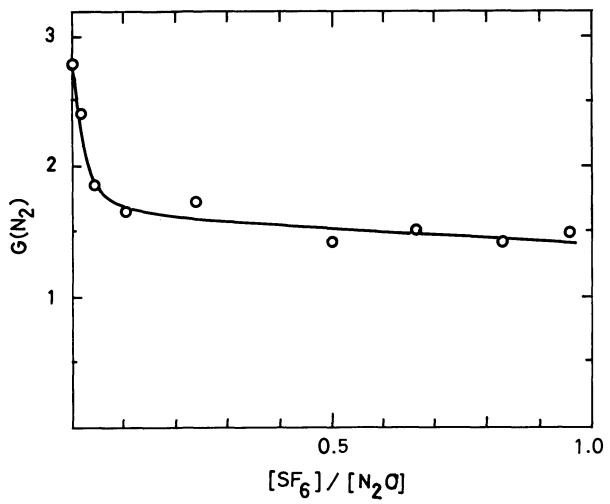

Fig. 2. Decrease in $G(N_2)$ in the presence of SF_6. $[N_2O]$, 4×10^{-4} mol g^{-1}.

Competition between N_2O and a Second Scavenger toward Electron Produced in MS. Addition of a second scavenger gives rise to decrease in the yield of molecular nitrogen formed from N_2O in irradiated MS. In Fig. 2, an effect of SF_6 on $G(N_2)$ is shown. The decrease in $G(N_2)$ is understood in terms of the competition between Reactions 3 and 4:

$$e^- + S \longrightarrow S^- \text{ or product(s)}, \quad (4)$$

where S denotes an electron scavenger added to the system as a competitor of N_2O such as SF_6. The competition kinetics is expressed by

$$1/\Delta G(N_2) = 1/G_e(1+k_3[N_2O]/k_4[S]), \quad (II)$$

where $\Delta G(N_2)$ is the difference of $G(N_2)$ between those observed in the absence and presence of the second scavenger, and G_e is the primary yield of electrons for which N_2O and the second scavenger compete with each other. As shown in Fig. 3, plots of $1/\Delta G(N_2)$ vs. $[N_2O]/[S]$ give a straight line. The relative reactivity of S to N_2O is obtained from the slope of the straight line. Results obtained for several electron scavengers are summarized in Table 1,

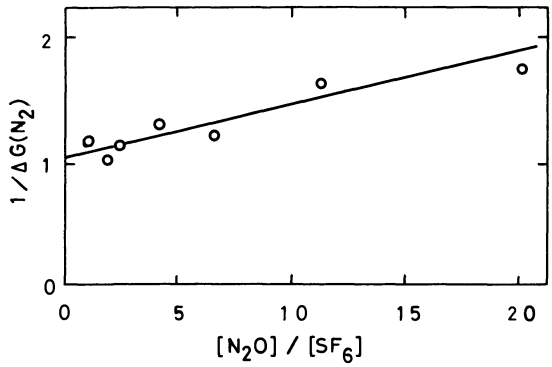

Fig. 3. Competition plots of $1/\Delta G(N_2)$ vs. $[N_2O]/[SF_6]$.

Table 1. Relative Rate Constants for Reactions of Electron with a Series of Electron Scavengers in Zeolite and Nonpolar Liquids

	k_4/k_3		
	MS	2,2-Dimethylpropane	Hexane
SF_6	85	86[a]	0.6[a]
C_2HCl_3	23	25.2[a]	1.3[a]
CCl_4	12.8	12.6[b]	0.7[a]
C_2H_5Br	0	0.1[b]	0.8[a]
CH_3Cl	0	0[c]	

a) Ref. 17. b) Ref. 16. c) Ref. 18.

together with values reported for electrons formed in irradiated nonpolar liquids. Accurate determination has failed for C_2H_5Br and CH_3Cl, because of their poor reactivity. A comparison of relative reactivities between MS and other systems indicates that the trend observed for MS is similar to that for 2,2-dimethylpropane. This suggests that the energy state of the elecron produced in MS is probaly very close to that of quasi-free electron generated in 2,2-dimethylpropane. The intercept of the straight line in Fig. 3 gives the initial yield of electrons witch react with N_2O or SF_6. Values from 0.85 to 1.1 were obtained by the experiments with SF_6, C_2HCl_3, and CCl_4. They are apparently inconsistent with the saturated $G(N_2)$, 2.8. As seen in Fig. 2, there remains a $G(N_2)$ which cannot effectively be depressed by the addition of SF_6. Similarly, a residual $G(N_2)$ was observed for the other scavengers. Since the size of the entrance to a supercavity of Molecular Sieve 13X allows the passage of a molecule below 0.8 nm in diameter, N_2O, SF_6, C_2HCl_3, and CCl_4 can enter the supercavity and hence the difference in molecular size does not explain the results. It will be explained on an assumption of two kinds of electrons, whose reactivities are different from each other. If it is assumed that the second electron, e_2^-, reacts with N_2O and SF_6 with a ratio of rate constants different from k_4/k_3, Eq. III is derived as follows:

$$e_2^- + N_2O \longrightarrow N_2 + O_{ad}^-, \quad (5)$$

$$e_2^- + SF_6 \longrightarrow \text{product(s)}, \quad (6)$$

$$G(N_2) = G_1\{k_3[N_2O]/(k_3[N_2O]+k_4[SF_6])\} + G_2\{k_5[N_2O]/(k_5[N_2O]+k_6[SF_6])\}, \quad (III)$$

where G_1 and G_2 denote the initial G-values of the first and the second electron, respectively. A computer simulation provides a curve shown in Fig. 2, by adopting $G_1=1.2$, $G_2=1.6$, $k_4/k_3=85$, and $k_6/k_5=6.7$. The curve appears to fit the experimental points fairly well. The first electron is considered to be quasi-free because its tendency in reactivity toward several electron scavengers is similar to that found in liquid 2,2-dimethylpropane by Allen et al.[16,17] The different reactivity of the second electron may be understood in terms of the different potential barriers at adsorption sites. Essentially the electrons generated in MS may be identical but the reactivity toward adsorbate is possibly affected by the potential barrier at adsorption site. The oxygen atoms of the SiO_2 network and Na^+ ions are considered as the possible candidates for the two kinds of adsorption sites where quasi-free electrons react with adsorbates. The reaction rate of the electron that reacts at the former site may be low due to its relatively high potential barrier, which is favorable for N_2O but not for the other scavengers. On the other hand, the potential barrier may be negligible at the latter site. However, further confirmation is indispensable for this speculation.

Infrared Multiple-Photon Decomposition of β-Propiolactone

Shunzo YAMAMOTO,† Yo-ichi ISHIKAWA,* and Shigeyoshi ARAI
†Department of Chemistry, School of Science, Okayama University,
3-1-1, Tsushima-naka, Okayama 700
The Institute of Physical and Chemical Research, Wako, Saitama 351-01
(Received February 3, 1986)

The infrared multiple-photon decomposition of β-propiolactone was found to give only ethylene and carbon dioxide with the same yield as the products, where the material balance was above 90%. This result suggests that the unimolecular decomposition into ethylene and carbon dioxide is a unique reaction channel of the compound at highly vibrationally excited states. It was shown that the decomposition probability was strongly dependent on the fluence but slightly dependent on the pressure.

It has been well-established in several studies that there are two nonradical unimolecular reaction modes in the thermal decomposition of cyclobutanone:

$$\longrightarrow C_2H_4 + CH_2CO, \quad (1)$$

$$\longrightarrow \triangle + CO. \quad (2)$$

The decomposition of this compound, induced by the intense infrared radiation from a CO_2 laser, has been widely investigated to obtain information on the energy distribution of highly vibrationally excited molecules, particularly, molecules whose energies are larger than either or both of the dissociation limits.[1-4]

It is possible for β-propiolactone to undergo three different ring cleavages, where each gives two stable molecules:

$$\longrightarrow C_2H_4 + CO_2, \quad (3)$$

$$\longrightarrow CH_3CHO + CO, \quad (4)$$

$$\longrightarrow CH_2CO + H_2CO. \quad (5)$$

The thermal decomposition of β-propiolactone in the temperature range of 205—255 °C has been found to be a first-order reaction and to yield only ethylene and carbon dioxide in equal amounts.[5] In the present study we have carried out the infrared multiple-photon decomposition of this compound in order to examine the possible contribution of Reaction (4) or (5) under the excitation conditions at high laser fluences.

Experimental

All the samples were irradiated with the R(20) line (1078.59 cm^{-1}) of the 9.6-μm CO_2 band from a Lumonics 103 TEA laser using and N_2-free lasing medium. The pulse profile showed a fwhm of about 80 ns without tailing. The laser-beam divergence was 2 mrad. The laser was operated in a multiple transverse mode; the intensity distribution across the beam was almost flat within a deviation of 10%.

The laser irradiation was performed in two beam geometries, i.e., mildly-focused and tightly-focused (Fig. 1). A cylindrical cell (2.5 cm diameter and 5 cm long) equipped with KBr windows at both ends was used in the former geometry. The laser beam was mildly focused by a BaF_2 lens with a focal length of 100 cm after passing through a Teflon iris with a 10-mm diameter. The irradiation fluence was controlled by setting the cell at a certain distance from the lens along the beam. The fluence inside the cell could be regarded as being nearly homogeneous along the beam. A cylindrical cell (2.5 cm diameter and 10 cm long) was used with the latter geometry, where the beam was tightly focused at the center of the cell by a BaF_2 lens with a focal length of 7.5 cm. The fluence was extremely inhomogeneous along the beam within the cell; the maximum fluence ϕ_f achieved at the focal point was three orders of magnitude greater than the fluences at both ends of the cell.

β-Propiolactone was purchased from Sigma Chemical Co. and purified by vacuum distillation at −98.5 °C. The sample pressure was controlled by changing the temperature of the sample reservoir connected directly to the cell, for example, 2.5 Torr (1 Torr=133.322 Pa) at the room temperature, 0.43 Torr at 0 °C, and 0.087 Torr at −22 °C.

After connecting the cell to a vacuum line, all samples were

a) Mildly focused. b) Tightly focused.

passed through the two traps and cooled to −196 and −98.5 °C. Noncondensable gases such as H_2, CO, and CH_4 at −196 °C were not detected as products of the photolysis. A large fraction of unreacted β-propiolactone was captured by the trap at −98.5 °C. The condensable gases at −196 °C were analyzed by gas chromatography using a 3-m column of Porapak-Q at 50 °C.

Results and Discussion

The enthalpy changes of Reactions (3), (4), and (5) are −2.55, 12.95, and 36.7 kcal mol^{-1} (1 kcal=4.184 kJ), respectively.[5,6] Therefore, the activation energies of Reactions (4) and (5) are expected to be considerably larger than that of Reaction (3), i.e., 45.81 kcal mol^{-1}.[5] We checked the possible occurrence of Reaction (4) or (5) in the tightly-focused irradiation of β-propiolactone, although fluence homogeneity was sacrificed. At very high fluences a certain fraction of the molecules could be excited to much higher levels than the reaction thresholds. The experimental results are summarized in Table 1 for reactant pressure of 2.5 Torr. The decomposition probability P_d used in the table is meaningful only for irradiation with a homogeneous fluence, since it depends strongly on the fluence in IRMPD.[6]

$$P_d = (N_p/N_i) \times (1/t) \quad \text{(I)}$$

where N_p represents the number of product molecules, N_i the number of reactant molecules in the irradiation volume, and t the number of laser pulses. For tightly-focused irradiation, P_d is considered to be merely the average value over the decomposition in the inhomogeneous fluence region. The laser imput energy for the tightly-focused irradiation was controlled by changing the diameter of the iris during the experiment. Table 1 tabulates the results obtained through product analyses. The IRMPD of β-propiolactone gave only ethylene and carbon dioxide as products, being similar to the pyrolysis at 205—255 °C. There was no other product, even for photolysis at a high fluence of 760 J cm^{-2}. In general, an increase in the fluence causes shifts in the vibrational energy distribution of excited molecules to the higher-energy side.[7] However, the reaction channel of β-propiolactone involves only a decomposition into ethylene and carbon dioxide, even at fairly

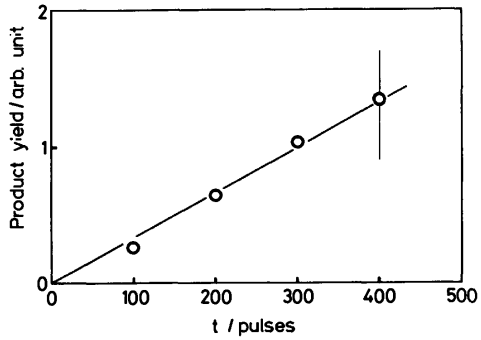

Fig. 2. Relation between product yield and laser pulse number t for multiple-photon decomposition of β-propiolactone. β-propiolactone, 2.5 Torr; fluence, 0.66 J cm^{-2}; irradiation laser wavenumber, R(20) (1078.59 cm^{-1}). The bar at 400 pulses indicates the experimental scatter.

high vibrational temperatures. When the focal fluence exceeded 760 J cm^{-2}, we observed an optical breakdown accompanied by the formation of a small amount of acetaldehyde and carbon monoxide in addition to the formation of ethylene and carbon dioxide. Acetaldehyde and carbon monoxide may be produced from electronically excited species or ionic species, because optical breakdown is essentially an electric discharge.[8]

Figure 2 shows the pulse-number dependence of the ethylene yield, where the laser fluence is 0.66 J cm^{-2}. The ethylene yield was always almost equal to the carbon dioxide yield and both yields increased linearly with the pulse number. Thus, these compounds can be produced directly from β-propiolactone. The decomposition probability was estimated to be 0.019±0.005 pulse^{-1}. Since β-propiolactone tends to be adsorbed on the walls, the adsorbed molecules on the front window might attenuate the laser intensity or decompose more efficiently than those in the gas phase. However, it may be concluded that there was no serious influence of adsorbed molecules in the present experiment. This is because the decomposition probability always remained constant throughout the irradiation period.

The material balance in the IRMPD of β-propiolactone was obtained from a comparison of the reactant consumption with the product yields. The experimental conditions were as follows: β-propiolactone pressure, 2.5 Torr; laser fluence, 0.66 J cm^{-2}; pulse number, 400 pulses. The consumption was measured with infrared absorption spectrophotometry, while the production yields of C_2H_4 and CO_2 were determined through gas chromatography. The consumption of β-propiolactone was 22.23 Torr ml, and the production yields of C_2H_4 and CO_2 were 20.25 and 21.57 Torr ml, respectively. The high material balance of 90% supports that β-propiolactone decomposes into only C_2H_4 and CO_2.

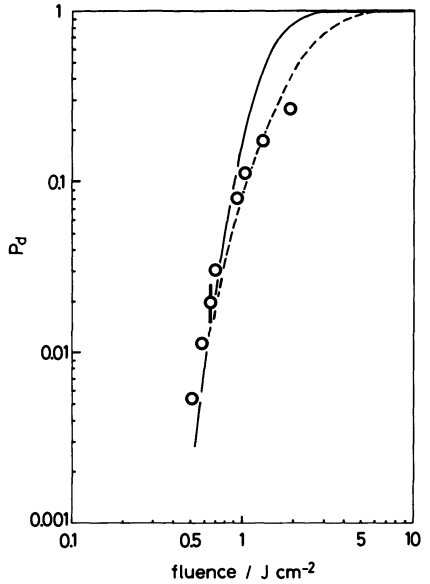

Fig. 3. Decomposition probability P_d(O) versus laser fluence observed for IRMPD of 2.5-Torr β-propiolactone. Solid curve shows the calculated P by assuming $\sigma_n=\sigma_0$. Dashed curve shows the calulated P_d by assuming $\sigma_n=\sigma_0$ ($E_n<E_a$) and $\sigma_n=\sigma_0\times n^{-0.5}$ ($E_n\geq E_a$).

The pressure effect on P_d was examined briefly in the irradiation of β-propiolactone at 2.5, 0.43, and 0.087 Torr, where the laser fluences were about 1.8 J cm^{-2}. The observed decomposition probabilities were 0.26 pulse^{-1} for 2.5 Torr, 0.18 pulse^{-1} for 0.43 Torr, and 0.17 pulse^{-1} for 0.087 Torr. Although the pressure variation was almost 30-fold, the probability changed from 0.26 to 0.17 pulse^{-1}. Thus, the pressure did not have a serious effect on the IRMPD of this compound. The slight decrease of P_d with decreasing pressure may be due to the so-called bottle-neck effect in a multiple-photon absorption process.[9]

The decomposition probability is plotted against laser fluence in Fig. 3, for a pressure of 2.5 Torr. P_d strongly depends on the laser fluence ϕ in a low fluence region, where P_d is approximately proportional to 7th power of ϕ. In a higher fluence region, however, the increase of P_d becomes much milder with increasing ϕ. Such a fluence dependence of P_d has been frequently observed for IRMPD.[10,11]

In order to obtain detailed information on infrared multiple-photon excitation (IRMPE), the absorption cross section σ_n and collisional deactivation rate $k_{d,n}$ were estimated from a simulation of the observed fluence dependence of P_d. Here, $k_{d,n}$ is a rate constant for a following collisional deactivation reaction:

$$A^*(v=n) + M \longrightarrow A^*(v=n-1) + M, \quad (6)$$

where A*(v=n) denotes the vibrationally excited molecule at level n. The method has been already reported elsewhere.[11,12] Briefly speaking, the stochastic calculation was carried out for the energy-grained master equations using assumed values of σ_n and $k_{d,n}$. The pulse was assumed to have a rectangular profile with a duration of 80 ns. The specific reaction rates during unimolecular decomposition were calculated using the QRRK theory.[13] Arrhenius parameters A=1.17×10^{16} s^{-1} and E_a=45.81 kcal mol^{-1} have been previously reported regarding a pyrolysis study of this compound.[5] The following vibrational frequencies were used for the activated complex: (100)^4 (300)^1 (500)^1 (800)^2 (1000)^1 (1200)^4 (1500)^2 (1700)^1 (3000)^4.[5] The best-fit simulation in a low fluence region was obtained for the following parameters: $k_{d,n}$=3.2×10^7×(E_n/E_a) s^{-1} and $\sigma_n=\sigma_0$=4×10^{-19} cm^{-2}. Rossi and Barker have reported that the average energy transfered per collision depends strongly on vibrational energy for azulene*.[14] This may support the assumption of the energy-dependent $k_{d,n}$ employed here. The calculated fluence depen-

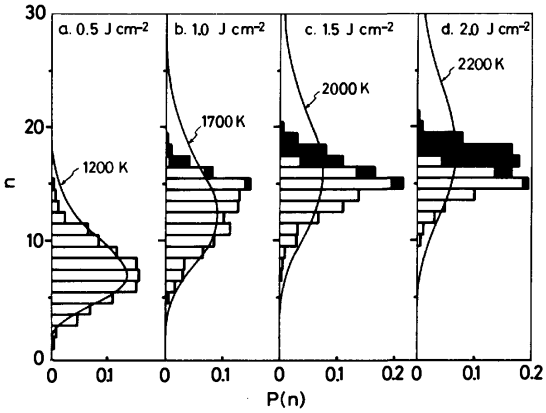

Fig. 4. Typical vibrational population distribution for β-propiolactone irradiated at various fluences. Filled areas indicate the fractions of decomposition. Solid lines show the Boltzmann distributions (Eq. II) by assuming cerain temperatures.

dence of P_d is represented by the solid curve in Fig. 3. Although the curve satisfactorily reproduces the observed dependence in the low-fluence region, there is a large discrepancy in the high-fluence region. The discrepancy may be explained in several different ways. One possible reason is that the volume irradiated in a high-fluence region is so small that the collisional quenching of excited molecules by unexcited molecules on the outer boundary of the reaction volume contributes more effectively to the reduction of P_d as compared with low fluence irradiation. Another possible reason is that a crude estimation of the absorption cross sections causes such a significant discrepancy. The absorption cross section is assumed to decrease with increasing internal energy in most of the IRMPD.[12] For example, we can improve the simulation by employing an energy-dependent absorption cross section, that is, for $E_n<E_a$, $\sigma_n=\sigma_o$; and for $E_n\geqq E_a$, $\sigma_n=\sigma_o\times n^{-0.5}$. The improved result is indicated by the dashed line in Fig. 3. At present, the simulations seem to have somewhat unavoidable uncertainties because of the lack of kinetic parameters for β-propiolactone together with an incomplete understanding of the multiple-photon absorption process. The simulation of the fluence dependence of P_d alone is thought to be insufficient to determine a unique parameter set, σ_n and $k_{n,d}$.[15]

Figure 4 shows the calculated vibrational energy distributions at various fluences, where the above-mentioned improved parameters were used. Filled areas represent the calculated decomposition fractions and solid curves represent the Boltzmann distribution $P(n)$ defined by the following equation:

$$P(n) = \frac{\rho(E_n)\exp(-E_n/kT)}{\sum\rho(E_n)\exp(-E_n/kT)} \qquad \text{(II)}$$

where $\rho(E_n)$ is the density of states at level n. The temperature was tentatively assumed as indicated in each distribution of Fig. 4. These values seem to be almost equal to the vibrational temperatures reported in IRMPD of polyatomic molecules.[16,17] The distribution estimated in the stochastic method agrees fairly well with the Boltzmann distribution in the low fluence region, where the decomposition hardly takes place. However, these two distributions do not agree with each other in the high-fluence region, where the docomposition of the molecules at vibrational levels above E_a (n=15) apparently disturbs the Boltzmann distribution. The vibrational temperature can not be defined exactly in the multiple-photon excitation, since the excitation is essentially regarded as a nonequilibrium process.

In conclusion, the reaction channel in the IRMPD of β-propiolactone is entirely a molecular decomposition into ethylene and carbon dioxide. Other decomposition channels with larger activation energies could not be observed at all during the irradiation of the compound at fluences as high as 700 J cm^{-2}. Since the pre-exponential factor A for the lowest channel has a large value of 10^{16} s^{-1}, the molecules excited to the levels above E_a (n=15) are thought to decompose rapidly before any further excitation due to light absorption.

The authors wish to express their thanks to Miss Kyoko Sugita for the computer calculations.

Ion/Molecule Reactions in Gaseous Acetone

Kenzo HIRAOKA,* Hajime TAKIMOTO, Kazuya MORISE, Takashi SHODA, and Shizuo NAKAMURA†
Faculty of Engineering, Yamanashi University, Takeda 4, Kofu 400
†ULVAC Corporation, Hagizono 2500, Chigasaki 253
(Received February 10, 1986)

The ion/molecule reactions in acetone were investigated which were induced by the electron impact. It was found that the protonated acetone reacts with an acetone molecule to produce the protonated diacetone alcohol (4-hydroxy-4-methyl-2-pentanone) and the protonated mesityl oxide (4-methyl-3-penten-2-one) through the aldol condensation reaction. It was also found that the acetone molecule isomerizes from keto to enol form in the interaction with the chloride ion. The thermochemical data for the higher-order clustering reactions of the proton and chloride ion with acetone molecules were obtained.

In recent years a number of studies have been made of the gas-phase ion/molecule chemistry of acetone.[1–5] Through these experiments, the nature and rates of formation of several reaction products have become fairly well established. Like many ionic species, the ion/molecule chemistry of acetone centers around the formation of cluster ions. MacNeil and Futrell,[2] who ionized the acetone with an electron beam, as well as Sieck[3] and Wincel,[5] who employed photons as the ionizing agents, observed a number of cluster ions at relatively high pressures. Furthermore, the species corresponding to loss of a water molecule from $H^+(CH_3COCH_3)_n$ with $n \geqq 2$ have been observed.

Lau et al. measured the equilibria and van't Hoff plots for Reaction (1).[6]

$$H^+(CH_3COCH_3)_{n-1} + CH_3COCH_3 = H^+(CH_3COCH_3)_n \quad (n-1,\ n) \qquad (1)$$

They tried to measure the (2, 3) equilibria of Reaction (1). They found that the equilibrium "constants" were not independent of pressures but decreased when the pressure of third gas CH_4 and of acetone were increased. In our previous work,[7] we observed that the intensities of ions with m/z=157 and 175 increase gradually at the expense of the $H^+(CH_3COCH_3)_2$, m/z=117, ion. These results suggest the occurrence of some unique ion/molecule reactions in gaseous acetone. However, little information was obtained so far regarding the kinetics of ion/molecule reactions in gaseous acetone. In the present work, we made extensive kinetic measurements of ion/molecule reactions in gaseous acetone. We got some evidence that acid-catalysed keto-enol isomerization of the acetone molecule followed by the formation of diacetone alcohol (4-hydroxy-4-methyl-2-pentanone) and mesityl oxide (4-methyl-3-penten-2-one) take place in gaseous acetone. The keto-enol isomerization of the acetone molecule was also found to occur in the interaction of Cl^- with the acetone molecule.

Experimental

The measurements were made with the pulsed electron beam mass spectrometer which has been described previously.[7,8] The ion/molecule reactions observed in the gas mixtures of CH_3COCH_3/He, CH_3COCH_3/CH_4, CH_3COCH_3/CCl_4/He, and $CH_3COCH_3/CCl_4/CH_4$ were studied. Small amounts of CH_3COCH_3 and/or CCl_4 were introduced into the He or CH_4 carrier gas through stainless steel capillaries (0.1 mm×1 m). 2 keV electron beam (5×10^{-9} A) was pulsed on for 50 μs and off for 3 ms. The ions escaping from the field-free ion source into an evacuated region were mass analysed by a quadrupole mass spectrometer (ULVAC MSQ-400) and collected in a multichannel analyser as a function of their arrival time after the electron pulse. The ion counts collected in a multichannel analyser were transferred to the microcomputer and the time profile of the calculated per cent of total ionization of observed ions were recorded on the x—y plotter.

Two kinds of gases, He and CH_4, were used as carrier gases in order to examine the third-body dependence on the ion/molecule reactions (see the following section). The positive ions produced in CH_3COCH_3/He and CH_3COCH_3/CH_4 are more or less the same except that the $CH_3CO^+(CH_3COCH_3)_n$ and $C_2H_5^+(CH_3COCH_3)_n$ ions are only detected in CH_3COCH_3/He and CH_3COCH_3/CH_4, respectively. Negative ions could not be detected in CH_3COCH_3/He and CH_3COCH_3/CH_4. On the contrary, strong signals of Cl^- and its clusters were observed in CH_3COCH_3/CCl_4/He and $CH_3COCH_3/CCl_4/CH_4$. The Cl^- ion is yielded from the dissociative electron capture by CCl_4.

$$e + CCl_4 = Cl^- + CCl_3 \qquad (2)$$

No other negative ions originating from acetone could be detected.

Results and Discussion

1. Acetone Containing Mesityl Oxide and Diacetone Alcohol as Impurities. Positive Ions: Figure 1 shows the temporal profile of ions observed in 4.02 Torr (1 Torr=133.322 Pa) of He containing 86 mTorr of acetone at 33.7 °C.

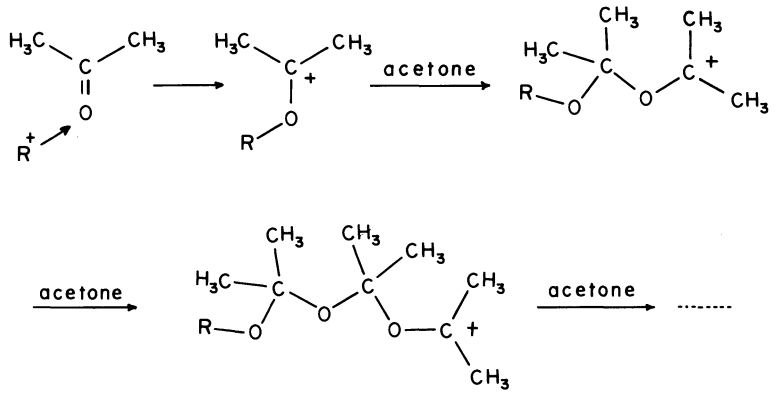
The m/z=73, 131, and 189 ions correspond to

$CH_3^+(CH_3COCH_3)_n$ with n=1 to 3. The rapid decay of the m/z=73 ion is completely accounted for by the increase of m/z=131 and 189 ions.

The ions with m/z=159 and 217, which correspond to $CH_3CO^+(CH_3COCH_3)_n$ with n=2 and 3, decrease rapidly. The rapid consumption of these ions may be due to the reactions of CH_3CO^+ with acetone molecules.[2] The ions $CH_3CO^+(CH_3COCH_3)_n$ were not detected when methane is used as a carrier gas. This indicates that CH_3CO^+ is yielded by the reaction of the primary ion $He^{+\cdot}$ with acetone molecule.

The ions with m/z=155 and 213 may be the cluster ions of $C_3H_3^+$ with acetone molecules, $C_3H_3^+(CH_3COCH_3)_n$ with n=2 and 3. The mechanism for the formation of $C_3H_3^+$ ion is not clear.

The results described above indicate that acetone has an ability to form large cluster ions with onium ions R^+=CH_3^+, CH_3CO^+, and $C_3H_3^+$. The sequence for the formation of cluster ions may be described as follows:



The reactions of onium ions with acetone molecules form polyethers. The reactions of onium ions with acetone molecules may be regarded as condensation reactions rather than clustering reactions.

The gradual increase of the ion $H_3O^+(CH_3COCH_3)_3$ with m/z=193 is observed which is yielded from water impurity. For aprotic solvent molecules B's such as acetone, acetonitrile, etc., the proton-held trimer ions $H^+(B)_3$ are known to be much less stable than the dimer ions $H^+(B)_2$.[9] Hence, the presence of a small amount of water impurity in aprotic solvents often yields quite a strong $H_3O^+(B)_3$ ion compared to $H^+(B)_3$ ion because H_3O^+ has three protic hydrogen atoms.

The gradual increase of ions with m/z=157 and 175 at the expense of the ion with m/z=117 is observed. It is evident that the ion $C_6H_{11}O^+(CH_3COCH_3)$ and some isomeric ion whose m/z is equal to the trimer ion $H^+(CH_3COCH_3)_3$ are formed from the dimer ion $H^+(CH_3COCH_3)_2$. In order to examine whether these ions are produced from acid (proton)-catalysed reactions of acetone or come from impurities contained in the acetone samples, we remeasured the ion/molecule reactions using the distilled and purified acetone samples. The apparent decrease in the growth rates of ions with m/z=157 and 175 were observed. This indicates that the gradual increase of ions with m/z=157 and 175 is due to the impurities present in the used acetone sample. It is known that under acidic or basic conditions, acetone produces diacetone alcohol and mesityl oxide by the aldol condensation reaction in the liquid phase.[10] The gradual increase in the intensities of ions with m/z=157 and 175 is likely to be due to the presence of mesityl oxide and diacetone alcohol contained in acetone as impurities.

Negative Ions: Figure 2 shows the temporal profile of negative ions observed in 4.09 Torr of He containing 0.790 Torr of acetone and 0.3 mTorr of CCl_4 at 38.9 °C.

The gradual decrease of Cl^- (m/z=35) and $Cl^-(CH_3COCH_3)$ (m/z=93) ions are observed. The decrease is compensated by the increase of m/z=151 and 209 ions. The used acetone sample contains diacetone alcohol as an impurity. As the diacetone alcohol molecule has a protic hydrogen atom, it can form a rather strong bond with Cl^- to yield $Cl^-\cdots HO(CH_3)_2CCH_2COCH_3$ (m/z=151) and its cluster with acetone (m/z=209). This explains the increase of m/z=151 and 209 ions at the expense of m/z=35 and 93 ions.

The cluster ion of Cl^- with mesityl oxide could not be detected under the present experimental conditions. This is because mesityl oxide does not have a protic hydrogen and it cannot form a strong bond with Cl^-.

The m/z=53, 111, and 169 ions correspond to $Cl^-(H_2O)(CH_3COCH_3)_n$ with n=0—2. In our previous paper,[8] we found that the third-order clustering reaction (3) with n=1 is particularly

$$Cl^-(H_2O)_{n-1} + H_2O + CH_4 = Cl^-(H_2O)_n + CH_4 \quad (3)$$

slow compared to higher order reactions ($n \geqq 2$). In

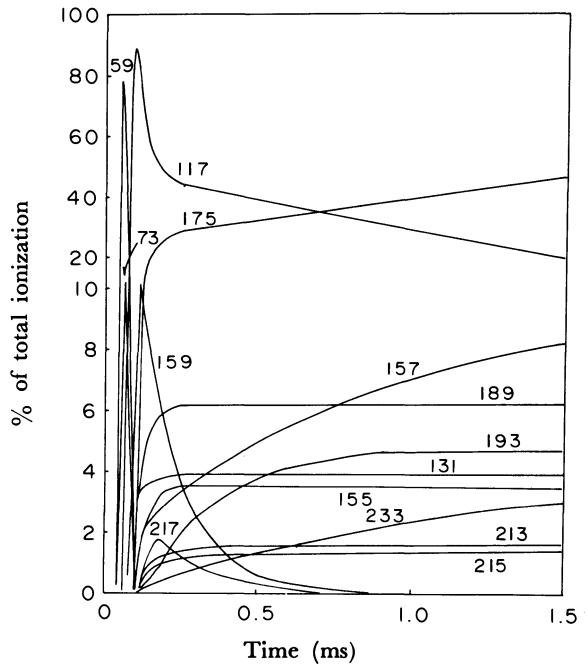


Fig. 1. Positive ions observed in a gas mixture containing 4.02 Torr of He and 86 m Torr of acetone at 33.7 °C. Acetone contains small amounts of mesityl oxide and diacetone alcohol as impurities. Mass 59 : $H^+(CH_3COCH_3)$, mass 117 : $H^+(CH_3COCH_3)_2$. The initial increase of mass 175 is due to the formation of $H^+(CH_3COCH_3)_3$. The gradual increase of mass 175 after 0.3 ms is due to the formation of $H^+(CH_3)_2C(OH)CH_2COCH_3)(CH_3COCH_3)$. Mass 233 : $H^+((CH_3)_2C(OH)CH_2COCH_3)_2$. Mass 159 : $CH_3CO^+(CH_3COCH_3)_2$, mass 217 : $CH_3CO^+(CH_3COCH_3)_3$. Mass 73 : $CH_3^+(CH_3COCH_3)$, mass 131 : $CH_3^+(CH_3COCH_3)_2$, mass 189 : $CH_3^+(CH_3COCH_3)_3$. Mass 157 : $H^+((CH_3)_2C{=}CHCOCH_3)(CH_3COCH_3)$, mass 215 : $H^+((CH_3)_2C{=}CHCOCH_3)(CH_3COCH_3)_2$. Mass 193 : $H_3O^+(CH_3COCH_3)_3$. Mass 155 : $C_3H_3^+(CH_3COCH_3)_2$, mass 213 : $C_3H_3^+(CH_3COCH_3)_3$.

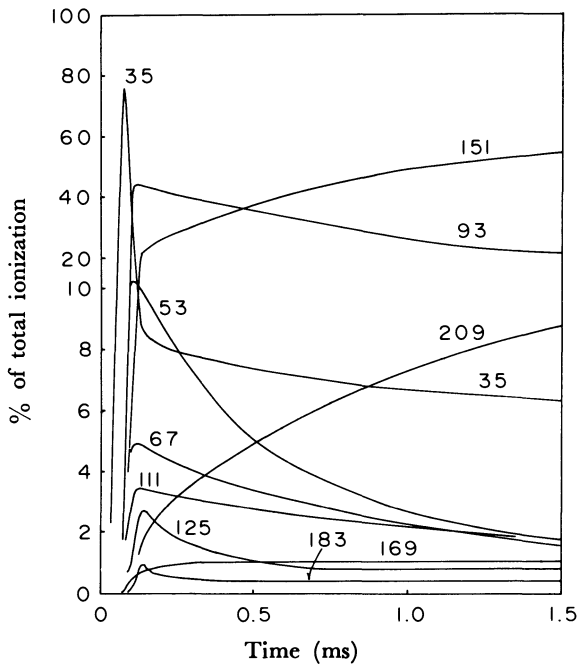

Fig. 2. Negative ions observed in a gas mixture containing 4.09 Torr of He, 0.79 Torr of acetone, and 0.3 mTorr of CCl_4 at 38.9 °C. Acetone contains small amounts of mesityl oxide and diacetone alcohol as impurities. Mass 35 : Cl^-, mass 93 : $Cl^-(CH_3COCH_3)$. The initial increase of mass 151 is due to $Cl^-(CH_3COCH_3)_2$. The gradual increase of mass 151 after 0.2 ms is due to the formation of $Cl^-((CH_3)_2C(OH)CH_2COCH_3)$. Mass 209 is mainly due to $Cl^-((CH_3)_2C(OH)CH_2COCH_3)(CH_3COCH_3)$. Mass 53 : $Cl^-(H_2O)$, mass 111 : $Cl^-(H_2O)(CH_3COCH_3)$, mass 169 : $Cl^-(H_2O)(CH_3COCH_3)_2$ and $Cl^-(H_2O)((CH_3)_2C(OH)CH_2COCH_3)$. Mass 67 : $Cl^-(CH_3OH)$, mass 125 : $Cl^-(CH_3OH)(CH_3COCH_3)$, mass 183 : $Cl^-(CH_3OH)(CH_3COCH_3)_2$ and $Cl^-(CH_3OH)((CH_3)_2C(OH)CH_2COCH_3)$.

Fig. 2, the rapid growth of $Cl^-(H_2O)$ is observed right after the electron pulse. Because the rate of reaction (3) with n=1 is slow, it is likely that $Cl^-(H_2O)$ is formed by switching Reaction (4).

$$Cl^-(CH_3COCH_3) + H_2O = Cl^-(H_2O) + CH_3COCH_3 \quad (4)$$

The ions $Cl^-(H_2O)$ and $Cl^-(H_2O)(CH_3COCH_3)$ are seen to be converted gradually to $Cl^-((CH_3)_2C(OH)CH_2COCH_3)(CH_3COCH_3)_n$ with n=0 and 1. This happens because the bond energy of $Cl^-(H_2O)$ is weaker than that of $Cl^-((CH_3)_2C(OH)CH_2COCH_3)$. The m/z=169 ion, whose intensity is independent on time, may be composed of not only $Cl^-(H_2O)(CH_3COCH_3)_2$ but also $Cl^-(H_2O)((CH_3)_2C(OH)CH_2COCH_3)$.

The m/z=67, 125, and 183 ions correspond to $Cl^-(CH_3OH)(CH_3COCH_3)_n$ with n=0—2. Methanol is a common impurity contained in acetone. The bond energies of $Cl^-\cdots CH_3OH$ and $Cl^-\cdots CH_3COCH_3$ are 17.4 and 12.4 kcal mol^{-1}(1 cal=4.184 J).[11] respectively, i.e., methanol has a greater chloride affinity than acetone. This is the reason why methanol can be readily detected by the present negative ion/molecule reactions. It should be noted that the methanol impurity could also be detected as the $CH_3OH_2^+(CH_3COCH_3)_2$ ion by the positive ion/molecule reactions when the ion source temperature was decreased. However, we found that the detection limit of methanol by positive ion/molecule reactions is about one order of magnitude lower than that by negative ion/molecule reactions under the present experimental conditions. This is because $H_3O^+(CH_3COCH_3)_3$ is thermochemically more stable than $CH_3OH_2^+(CH_3COCH_3)_2$ (i.e., the protic hydrogens of H_3O^+ are more acidic than those of $CH_3OH_2^+$) and the $H_3O^+(CH_3COCH_3)_3$ ion becomes dominant as an impurity ion under the present experimental conditions.

2. Ion/Molecule Reactions of Acetone. Positive Ions: As was described in the previous section, the used acetone contained diacetone alcohol and mesityl oxide as impurities. Although we tried to purify the sample by elaborate distillation, we could not decrease the contents of these impurities below the detection limit. We tried all available commercial acetone samples. We found that all samples measured contained detectable amounts of diacetone alcohol and mesityl oxide except the one purchased from Merck (Uvasol). The temporal profile of the positive ions observed in 4.16 Torr of CH_4 containing 0.259 Torr of acetone (Merck, Uvasol) at 46.7 °C is shown in Fig. 3. The intensities of m/z=157 and 175 ions are seen to be time-independent. This indicates that the contents of mesityl oxide and diacetone alcohol in the used acetone are below the detection limit.

The m/z=145 ion, which corresponds to $C_2H_5^+(CH_3COCH_3)_2$, is observed only when CH_4 is used as a carrier gas. The core ion $C_2H_5^+$ in the cluster may be the product ion from the ion/molecule reactions of methane.[12]

The m/z=157 ion may be the cluster ion of $C_6H_{11}O^+$ (m/z=99) with acetone. Since this ion is already produced right after the electron pulse, it may be yielded from the ion/molecule reactions induced by the primary electron irradiation. The core ion $C_6H_{11}O^+$ may have the structure $(CH_3)_2\overset{\oplus}{C}CH_2COCH_3$, which is different form that of the protonated mesityl oxide, $(CH_3)_2C{=}CHCO\overset{H\oplus}{C}H_3$ (see below).

When the ion source temperature was increased, the gradual growth of m/z=157 and 175 ions starts to be observed. Figure 4 shows the ions observed in 4.92 Torr of CH_4 containing 0.365 Torr of acetone at 104 °C. The m/z=157 and 175 ions grow gradually at the expense of the m/z=117 ion. The observed growth may not be due to the impurities because intensities of these ions are time-independent at room temperature as shown in Fig. 3. The ions seem to be produced by some ion/molecule reactions of acetone. The increase of the growth rates at higher temperature suggests the existence of energy barrier for the formation of m/z=157 and 175 ions. The growth rates increase with temperature up to ≈100 °C. Above ≈100 °C, they start to decrease and the intensities of m/z=157 and 175 ions become weaker.

It was also found that as shown in Fig. 5, the growth rates increased when the pressure of the carrier gas was decreased. This indicates that the formation of m/z=157 and 175 ions is suppressed by the third-body collision. In order to examine the

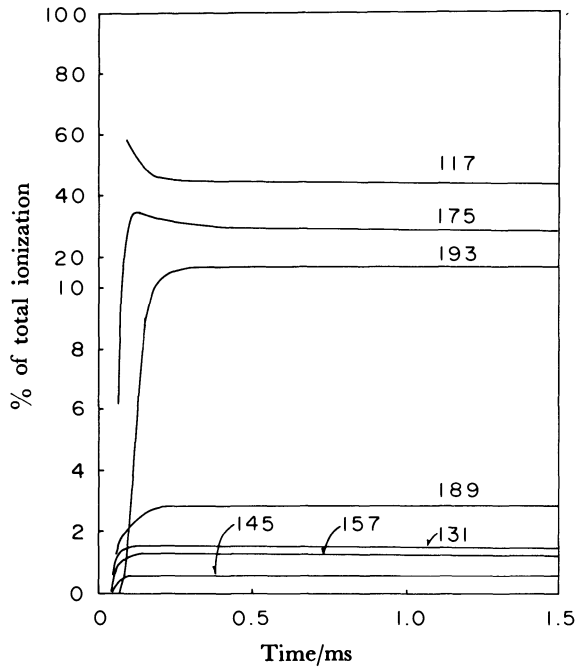

Fig. 3. Positive ions observed in a gas mixture containing 4.16 Torr of CH_4 and 0.259 Torr of acetone at 46.7 °C. Mass 117 : $H^+(CH_3COCH_3)_2$, mass 175 : $H^+(CH_3COCH_3)_3$. Mass 193 : $H_3O^+(CH_3COCH_3)_3$. Mass 131 : $CH_3^+(CH_3COCH_3)_2$, mass 189 : $CH_3^+(CH_3COCH_3)_3$. Mass 157 : $C_6H_{11}O^+(CH_3COCH_3)$. Mass 145 : $C_2H_5^+(CH_3COCH_3)_2$.

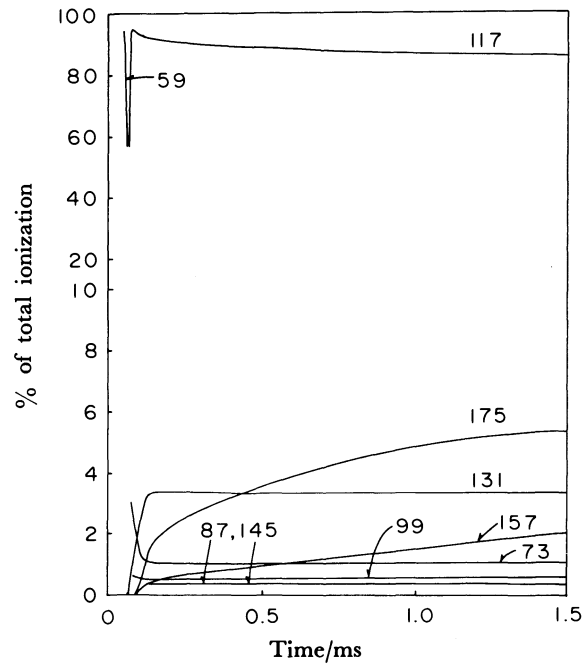

Fig. 4. Positive ions observed in a gas mixture contatining 4.92 Torr of CH_4 and 0.365 Torr of acetone at 104 °C. Mass 59 : $H^+(CH_3COCH_3)$, mass 117 : $H^+(CH_3COCH_3)_2$. Mass 73 : $CH_3^+(CH_3COCH_3)$, mass 131 : $CH_3^+(CH_3COCH_3)_2$. Mass 99 : $(CH_3)_2C^+CH_2COCH_3$. Mass 87 : $C_2H_5^+(CH_3COCH_3)$, mass 145 : $C_2H_5^+(CH_3COCH_3)_2$. The gradual increase of mass 157 and 175 may be due to the formation of $H^+((CH_3)_2C{=}CHCOCH_3)(CH_3COCH_3)$ and $H^+((CH_3)_2C(OH)CH_2COCH_3)(CH_3COCH_3)$, respectively, from the ion/molecule reactions of acetone (see text).

third-body dependence on the formation of these ions, the carrier gas was changed from CH_4 to He with keeping the ion source temperature and pressures of carrier gas and acetone constant. The apparent increase in the growth rates of these ions were observed. This may be due to the fact that helium is a less efficient third body than methane. It seems likely that m/z=157 and 175 ions are formed from the long-lived intermediate complex. The tentative reaction mechanisms for the formation of m/z=157 and 175 ions are given in Scheme 1, where M represents the third body. The clusters of species (IV) and (V) with acetone correspond to ions with m/z=175 and 157, respectively.

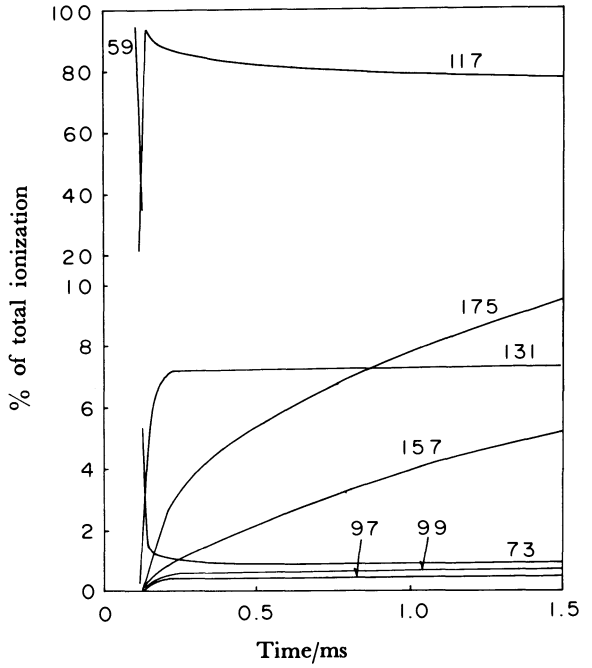

Fig. 5. Positive ions observed in a gas mixture containing 0.17 Torr of CH_4 and 0.33 Torr of acetone at 98 °C. Mass 59 : $H^+(CH_3COCH_3)$, mass 117 : $H^+(CH_3COCH_3)_2$. Mass 73 : $CH_3^+(CH_3COCH_3)$, mass 131 : $CH_3^+(CH_3COCH_3)_2$. Mass 99 : $(CH_3)_2C^+CH_2COCH_3$. Mass 97 : $C_3H_3^+(CH_3COCH_3)$. The increase of mass 157 and 175 are due to the formation of $H^+((CH_3)_2C{=}CHCOCH_3)(CH_3COCH_3)$ and $H^+((CH_3)_2C(OH)CH_2COCH_3)(CH_3COCH_3)$.

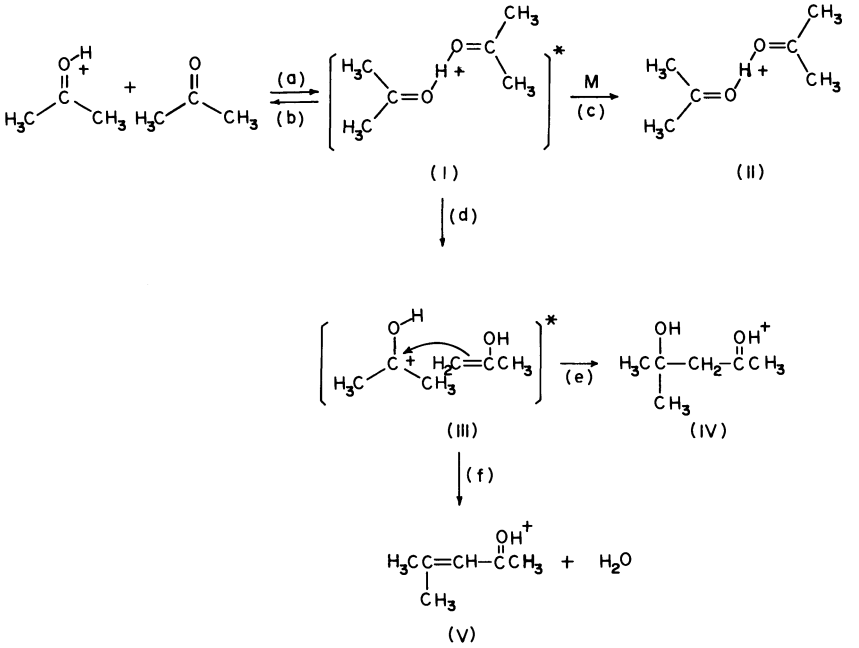
The bond energy of the proton-held acetone dimer ion is 29.6 kcal mol^{-1}.[13] Since the keto form of acetone is about 10 kcal mol^{-1} more stable than the enol form,[14] the complex (I) has more than enough internal energy for the isomerization of acetone from keto to enol form (Process (d)). The formation of the complex (III) may be followed by the formation of protonated diacetone alcohol (IV) or mesityl oxide (V). The formation of the latter species (V) is analogous to the aldol condensation reaction of acetone observed in the liquid phase.

With increase of ion source temperature ($\gtrsim$150 °C), the back dissociation reaction (b) of the intermediate complex (I) becomes prominent. This explains the decrease in the rate of the formation of m/z=157 (or 99) and 175 ions at high temperatures.

As shown in Figs. 4 and 5, the steady growth of m/z=157 ion is observed, while the intensity of m/z=99 ion is time-independent. As described in the reaction scheme given above, the m/z=157 ion is suggested to have the structure of the cluster of protonated mesityl oxide (m/z=99) with acetone. Since the protonated mesityl oxide has a protic



Scheme 1.

hydrogen atom, it can form a fairly strong hydrogen bond with acetone to give the m/z=157 ion. Since the intensity of the m/z=99 ion does not increase with time, this ion must have the different structure from the protonated mesityl oxide. We tentatively propose that the m/z=99 ion has the structure of $(CH_3)_2\overset{\oplus}{C}CH_2COCH_3$ which is produced during the primary electron irradiation. This ion is the tertiary carbonium ion and the bond of its cluster with acetone must be much weaker than that of protonated mesityl oxide with acetone.

Negative Ions: Figure 6 shows the negative ions observed in 4.07 Torr of CH_4 containing 0.287 Torr of acetone (Merck, Uvasol) and 0.2 mTorr of CCl_4. If the acetone sample contains diacetone alcohol as an impurity, the ion with m/z=151 (i.e. $Cl^-((CH_3)_2C(OH)CH_2COCH_3$) as well as its clusters with acetone molecules would be produced gradually with time. The steady intensity of ions observed in Fig. 6 indicates that the content of diacetone alcohol in the acetone sample is lower than the detection limit in the present experimental conditions.

When the ion source temperature is increased, the m/z=151 ion starts to increase as shown in Fig. 7. As described in the previous paper,[2] we think that solvent acetone molecule isomerizes from keto to enol form during the clustering reaction, as shown in Scheme 2. This reaction may be regarded as the base (Cl^- ion)-catalysed keto-enol isomerization reaction of acetone in the gas phase. In our previous work,[7] we observed that for higher order clustering Reactions (5),

$$Cl^-(CH_3COCH_3) + CH_3COCH_3 \rightleftharpoons [Cl^-(CH_3COCH_3)_2]^*$$

$$\rightarrow [CH_3COCH_3\cdots Cl^-\cdots HOC(CH_3)=CH_2]^* \xrightarrow{M} Cl^-(CH_3COCH_3)(HOC(CH_3)=CH_2)$$

Scheme 2.

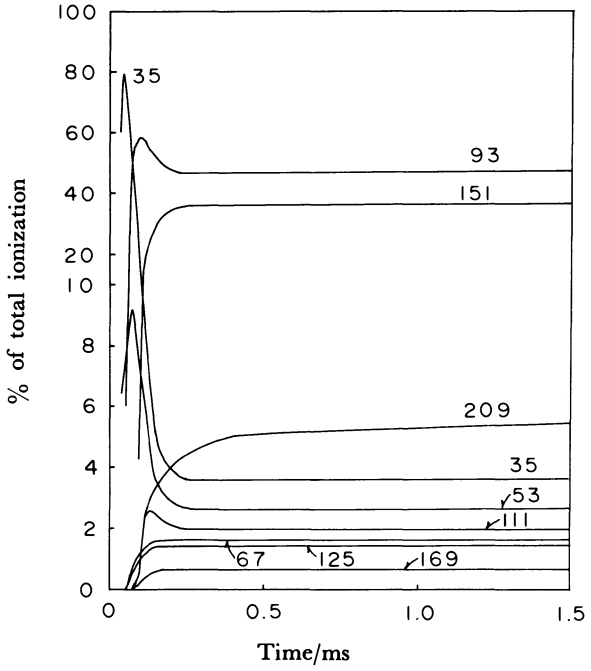


Fig. 6. Negative ions observed in a gas mixture containing 4.07 Torr of CH_4, 0.287 Torr of acetone, and 0.2 mTorr of CCl_4 at 30 °C. Mass 35 : Cl^-, mass 93 : $Cl^-(CH_3COCH_3)$, mass 151 : $Cl^-(CH_3COCH_3)_2$, mass 209 : $Cl^-(CH_3COCH_3)_3$. Mass 53 : $Cl^-(H_2O)$, mass 111 : $Cl^-(H_2O)(CH_3COCH_3)$, mass 169 : $Cl^-(H_2O)(CH_3COCH_3)_2$. Mass 67 : $Cl^-(CH_3OH)$, mass 125 : $Cl^-(CH_3OH)(CH_3COCH_3)$.

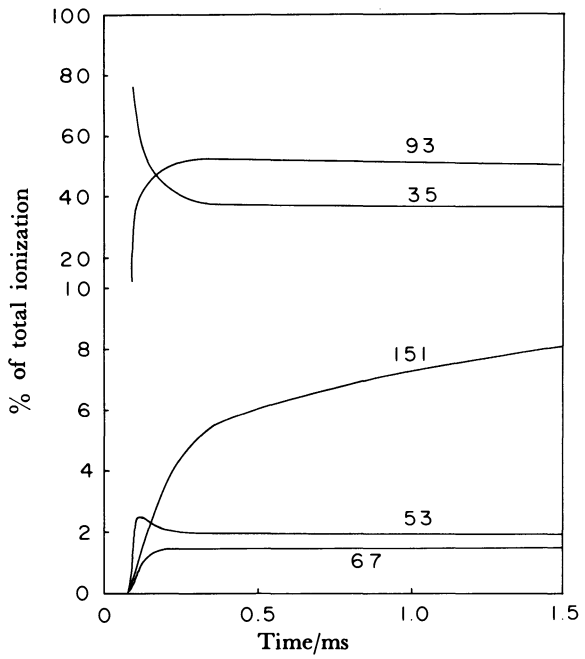

Fig. 7. Negative ions observed in a gas mixture containing 3.99 Torr of CH_4, 0.213 Torr of acetone, and 0.2 mTorr of CCl_4 at 80.5 °C. Mass 35 : Cl^-, mass 93 : $Cl^-(CH_3COCH_3)$. Mass 53 : $Cl^-(H_2O)$. Mass 67 : $Cl^-(CH_3OH)$. The initial increase of mass 151 is due to the formation of $Cl^-(CH_3COCH_3)_2$. The gradual increase of mass 151 after 0.3 ms may be due to the formation of $Cl^-(CH_3COCH_3)$ (CH_2=C(OH)-CH_3) by keto-enol isomerization of acetone.

$$Cl^-(CH_3COCH_3)_{n-1} + CH_3COCH_3 = Cl^-(CH_3COCH_3)_n \quad (5)$$

the decays of larger clusters were found to be slower at 15 °C (Fig. 8 in the Ref. 7). Since the gradual growth of larger clusters $Cl^-(CH_3COCH_3)_n$ were not observed at 30 °C in the present experiments (see Fig. 6), the acetone sample used in the previous work must contain diacetone alcohol as an impurity. We are now sure that the ions $Cl^-(CH_3COCH_3)_2$, $Cl^-(CH_3COCH_3)_3$, and $Cl^-(CH_3COCH_3)_4$ shown in Fig. 8 in Ref. 7 are more or less contaminated by $Cl^-((CH_3)_2C(OH)CH_2COCH_3)$, $Cl^-((CH_3)_2C(OH)CH_2COCH_3)(CH_3COCH_3)$, and $Cl^-((CH_3)_2C(OH)CH_2COCH_3)_2$, respectively.

The growth rate of m/z=151 ion becomes low at high ion source temperature (≈100 °C). The keto→enol isomerization reaction seems to be suppressed when the lifetime of the intermediate complex $[Cl^-(CH_3COCH_3)_2]^*$ gets short at high temperatures.

3. Equilibrium Measurements for Clustering Reactions of Proton and Chloride Ion with Acetone Molecules. Since the diacetone alcohol contained in the used acetone (Merck, Uvasol) is only a negligible amount, it was possible to measure clustering Reactions (1) and (5) without having the impurity problem. Figure 8 shows the van't Hoff plots for Reaction (1) with n=4 using the "pure" acetone sample. The van't Hoff plots of (1, 2) and (2, 3) were measured in our previous work.[7,13] The thermochemical data obtained from the van't Hoff plots are summarized in Table 1. There is a sudden decrease in the stabilities of clusters $H^+(CH_3COCH_3)_n$ between n=2 and 3. This indicates that the clusters $H^+(CH_3COCH_3)_n$ ($n \geqq 3$) are regarded as the shell $(CH_3)_2CO\cdots H^+\cdots OC(CH_3)_2$ plus surrounding ligand acetone molecules. Yamabe et al. studied the gas-phase solvation of acetone toward the proton theoretically.[9] They predicted the structure of $H^+(CH_3COCH_3)_3$ in which the proton in $(CH_3)_2CO\cdots H^+\cdots OC(CH_3)_2$ is attacked by the third molecule in the direction perpendicular to the shell plane.[9] This result suggests that the fourth acetone molecule may also approach to the proton perpendicularly from the other side of the shell plane.

Figure 9 shows the van't Hoff plots for Reaction (5) with n=2 and 3 obtained in the present work. The van't Hoff plots of (0, 1) was obtained in our previous work.[7] Contrary to the van't Hoff plots of reaction (1) (Fig. 8), the plots with n=1—3 are close with each other and the decrease in the enthalpy changes $-\Delta H^\circ_{n-1,n}$ is only gradual. This indicates that the interaction of Cl^- with ligand acetone molecules are

Table 1. Thermochemical Data for Clustering Reactions[a]

Reaction	$-\Delta H^\circ$	$-\Delta S^\circ$

mainly electrostatic.

Yamabe and Hirao investigated the stability and structure of the cluster $Cl^-\cdots CH_3CN$ by SCF computation.[15] They found that the most stable C_{3v} structure  is more stable than the C_s structure $Cl^-\cdots H\text{-}CH_2CN$ by only$\leqq$1 kcal mol^{-1}. This suggests that the bond strength of the complex $Cl^-\cdots CH_3CN$ is less affected by the change of the angle for the bending motion of Cl^- and CH_3CN species. Thus the cluster would show a considerable flexibility in the bending motion of the bond between Cl^- and CH_3CN. By analogy with $Cl^-\cdots CH_3CN$, $Cl^-\cdots CH_3COCH_3$ would also be very flexible as already pointed out in our previous paper.[8] The great flexibility of the cluster $Cl^-\cdots CH_3COCH_3$ means that the species in the cluster have appreciable freedoms of motion. This may explain the small entropy change $-\Delta S^\circ_{0,1}$ for Reaction (5).

Concluding Remarks

The reactions of protonated acetone and chloride ion with acetone molecules were investigated. It was found that mesityl oxide and diacetone alcohol which are contained as impurities in commercial acetone samples spoil the studies of ion/molecule reactions in acetone seriously. Using the relatively pure acetone, detailed kinetic studies of the positive and negative ion/molecule reactions were done. In the reactions of protonated acetone with acetone molecule, the formation of protonated mesityl oxide and diacetone alcohol are suggested. For the clustering reactions of chloride ion with acetone molecules, the equilibria could not be observed at high temperatures. We tentatively concluded that this is due to a keto-enol isomerization of the acetone ligand molecules. However, we feel that the evidences obtained in this work are suggestive rather than compelling.

The author (Kenzo Hiraoka) is greatly indebted to Professor P. Kebarle of the University of Alberta for his help. The financial support of the Grant-in-Aid from the Ministry of Education is gratefully acknowledged.

(Received December 19, 1985)

The crystal and molecular structures of (−)$_{546}$-((*R*)-alaninato)((6*R*,8*R*)-6,8-dimethyl-2,5,9,12-tetraazatridecane)cobalt(III) bromide trihydrate ((−)$_{546}$-[Co(*R*-ala)(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]Br$_2$·3H$_2$O) (**1**), derived from (−)$_{546}$-[Co(AMM)(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]$^+$ on decarboxylation, have been determined from three-dimensional X-ray counter data. In the above, AMM is an α-amino-α-methylmalonate ion. The compound crystallizes in an orthorhombic space group $P2_12_12_1$ with a=11.713 (1) Å, b=20.301 (2) Å, c=10.113 (2) Å, and Z=4. The structure was solved by the heavy-atom method followed by full-matrix least-squares and Fourier techniques. A refinement using 2168 reflections with $|F_o|>3[\sigma(F_o)]$ gave R=0.052. The absolute configuration of the complex cation is Λ in the β_2 form. The gauche conformations of two five-membered chelate rings for the tetramine are both δ, and the central six-membered chelate ring adopts a chair conformation with one methyl group axial and the other equatorial. All the secondary nitrogen atoms have S configurations except one of the terminal nitrogen atoms whose absolute configuration is R. The *N*-methyl group in an "out-of-plane" five-membered chelate ring is equatorial; however, the other in an "in-plane" five-membered chelate ring has an axial disposition. The alaninate ion coordinates to the cobalt via N and O atoms. The absolute configuration around the carbon center of the alanine was found to be R.

It is generally known that a chelated α-amino acidato ligand is not released from a cobalt(III) complex under mild basic conditions but results in epimerization of the α-carbon center.[1)]

When [Co(*R* or *S*-ala)(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]$^{2+}$, derived from [Co(AMM)(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]$^+$ on decarboxylation, was warmed under mild basic conditions, the release of alanine with a retention of the asymmetric carbon center from the cobalt(III) complex was unprecedentedly observed. In the above, ala is the alaninate ion, 1,5*R*,7*R*,11-Me$_4$-2,3,2-tet is (6*R*,8*R*)-6,8-dimethyl-2,5,9,12-tetraazatridecane, and AMM is an α-amino-α-methylmalonate ion. On the basis of this novel reaction, we have developed a new cyclic system for the asymmetric synthesis of α-amino acids by using cobalt(III) complexes containing 1,5*R*,7*R*,11-Me$_4$-2,3,2-tet as a ligand.[2)]

Some geometrical isomers, including the β_1 and β_2 modes,[3)] are possible for mixed cobalt(III) complexes of an α-amino acid and a tetramine. It is difficult to assign the geometry of these compounds by AB (electronic absorption), CD, or NMR spectra. We found that while trying to establish an asymmetric synthesis of α-amino acids using chiral cobalt(III) complexes, it is important to confirm the structure of the complex [Co(ala)(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]$^{2+}$, which easily releases alanine under mild basic conditions. Our purpose in undertaking an X-ray structure determination was to examine whether any specific stereochemical features could be observed to which the labile feature of the complex could be ascribed.

Experimental

Measurements. The electronic absorption (AB) spectra were recorded on a Shimadzu UV-210 spectrophotometer. The circular dichroism (CD) spectra were measured with a JASCO J-20 recording spectropolarimeter. Microanalyses were performed by Shonan Bunseki Center Co., Ltd.

Materials. All the reagents were of the best commercial grade and were used without further purification. 1,5*R*,7*R*,11-Me$_4$-2,3,2-tet was prepared by the previously reported method.[4)]

Preparation of (−)$_{546}$-[Co(*R*-ala)(1,5*R*,7*R*,11-Me$_4$-2,3,2)](ClO$_4$)$_2$·H$_2$O (2). (−)$_{546}$-[Co(AMM)(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]ClO$_4$·2.5H$_2$O[5)] (100 mg) was dissolved into 10 ml of 1 mol dm^{-3} hydrochloric acid and warmed on a water bath for 1 h at 60 °C. The reaction mixture was then cooled and allowed to stand overnight at room temperature. The resulting wine red crystals were collected, washed with ethanol and ether, and dried in vacuo. They were then recrystallized from a minimum amount of warm water; yield, 30 mg. Anal. Calcd for $C_{14}H_{36}N_5O_{11}Cl_2Co$: C, 29.0; H, 6.25; N, 12.1%. Found: C, 29.0; H, 6.6; N, 12.2%. ^{1}H NMR (400 MHz; solvent D_2O; standard DSS) δ=1.20 (3H, d, J 7.02 Hz, C*H*$_3$-CH), 1.45 (3H, d, J 6.41 Hz, C*H*$_3$-CH), 1.53 (3H, d, J 7.02 Hz, C*H*$_3$-CH of ala), 1.90 (3H, s, C*H*$_3$-N), 2.16 (3H, s, C*H*$_3$-N), 2.65—3.03, 3.16—3.22, 3.30—3.40 (multiplets), 3.86 (1H, q, C*H*-CH$_3$ of ala).

crystallography, we have newly prepared the bromide as follows. The perchlorate obtained above was dissolved in water and converted to the bromide form by allowing it to pass through a Dowex 2-X8 anion-exchange-resin column (100—200 mesh, Br^- form). A pure bromide salt was obtained upon evaporation of the resultant solution to near-dryness. A wine-red powder was obtained, which yielded good wine-red crystals upon recrystallization from a minimum amount of an ethanol-water solution. Anal. Calcd for $C_{14}H_{40}N_5O_5Br_2Co$: C, 29.1; H, 7.0; N, 12.1; Br, 27.7%. Found: C, 30.0; H, 6.9; N, 12.6; Br, 28.5%. The AB and CD spectra of the bromide were almost identical with those of the perchlorate.

The crystal used in the data collection was shaped into a sphere of 0.34 mm in diameter. The crystallographic and experimental data are summarized in Table 1. The diffraction data were measured on a Rigaku AFC-5 diffractometer. Three standard reflections were monitored every 50 reflections and showed no variation in intensity, for which no correction was made. The standard Lorentz, polarization, and absorption corrections were applied.

Structure Solution and Refinement. The structure was solved by the heavy-atom method and refined by a block-diagonal least-squares method. Atomic scattering factors were taken from Ref. 6. Also, the weighting scheme

$$1/w = [\sigma(\text{count})]^2 + [0.015|F_o|]^2$$

was employed. Since the tetramine was derived from (*R*,*R*)-2,4-pentanediamine,[7] the known absolute configurations of the asymmetric carbon atoms were used as internal reference asymmetric centers to determine the absolute configuration of the complex ion. The effects of anomalous dispersion were included in F_c; values of f' and f'' for Br, Co, O, N, and C were taken from Ref. 8. One of the two Br atoms, Br(2), was located at two positions. A model structure postulating the disorder of that bromine atom was refined by a full-matrix least-squares method. The thermal parameters of the subsidiary bromine atom were assumed to be the same as those of the main bromine atom. The population of the main and subsidiary bromine atoms were refined to 0.817 (6) and 0.183 (6), respectively. All the hydrogen atoms, except for those of the methyl groups and waters of crystallization, were located by assuming a tetrahedral coordination; they were all included in the final refinement with the isotropic temperature factors (R=0.054 and R'=0.054), where $R=\sum||F_o|-|F_c||/\sum|F_o|$ and $R'=(\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2)^{1/2}$. Hydrogen atom scattering factors were taken from a compilation of Stewart et al.[9] The final positional parameters along with their standard deviations are listed in Table 2. Complications of the anisotropic thermal parameters as well as observed and calculated structure factors are deposited as Document No. 8638 at the office of the Editor of Bull. Chem. Soc. Jpn. The calculations were carried out on the Hitachi M-200H computer at the Computer Center of the Institute for Molecular Science with the Universal Crystallographic Computing Program System UNICS III.[10]

Results and Discussion

Molecular Structure of $(-)_{546}$-β_2-[Co(*R*-ala)-(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]Br$_2$·3H$_2$O (1). The present structure determination of the important intermediate complex in the asymmetric synthetic system of α-alanine could establish that the cobalt ion is a slightly distorted octahedral center to which alanine is coordinated as a bidentate.

A detailed view of the complex cation is given in Fig. 1, and the intramolecular distances and bond angles are given in Tables 3 and 4. The geometry of the tetramine ligand, 1,5*R*,7*R*,11-Me$_4$-2,3,2-tet, is *Λ*-cisβ. The alaninato coordinates to a cobalt atom with N(5) and O(1) atoms in the β_2 form; the configuration of the asymmetric carbon is R. Consequently, the complex ion is represented as *Λ*-β_2-[Co(*R*-ala)(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]$^{2+}$.

The arrangement of the groups around the secondary nitrogen atoms, N(1), N(2), N(3), and N(4),

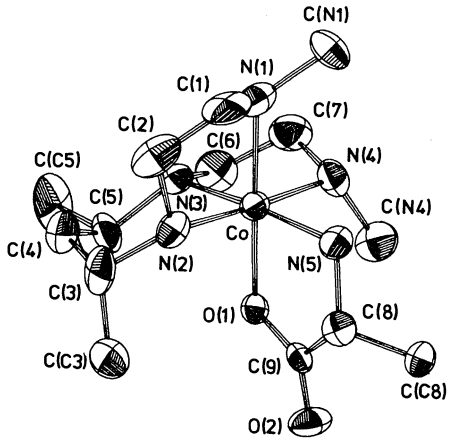

Fig. 1. ORTEP view of $(-)_{546}$-[Co(*R*-ala)(1,5*R*, 7*R*, 11-Me$_4$-2,3,2-tet)]$^{2+}$ ion with the atomic numbering scheme in an asymmetric unit.

are R, S, S, and S, respectively. The conformations of the three chelate rings of the tetramine are presented in Fig. 2-a,b,c. Both of the five-membered rings have a δ-gauche conformation with an equatorial methyl group on N(1) and an axial one on N(4). The central six-membered ring for the tetramine adopts a chair conformation with one methyl group axial, C(C3), and the other equatorial, C(C5).

The four Co–N distances of tetramine, Co–N(1), Co–N(2), Co–N(3), and Co–N(4), are not significantly different from one another, and the mean value (2.01 Å) is quite usual. The ring angles at the cobalt atom for the five-membered rings are 85.8 (6)° and 86.0 (6)° for N(1)–Co–N(2) and N(3)–Co–N(4), respectively. These are normal for cobalt(III) five-membered diamine chelate rings. The ring angle at the cobalt atom for a six-membered ring, N(2)–Co–N(3), is 91.9 (6)°. The average N–C and C–C distances of the membered nitrogen and carbon atoms are 1.49 and 1.48 Å, respectively.

The observed values of the Co–N(2)–C(3) and Co–N(3)–C(5) are 122.0 (8)° and 116.5 (8)°, significantly expanded from a tetrahedral configuration. This distortion is attributed to an interaction between the axial *C*-methyl group on C(3) and the apical O(1) atoms. The conformation of the six-membered chelate ring in the tetramine is represented diagrammatically in Fig. 3. The dihedral angles between the plane A and B (α), and B and C (β) are 35.8° and 59.0°, respectively. The value of α is considerably small, compared with a corresponding value of 40.6° in the [Co(ox)(*N*,*N'*-Me$_2$-*R*,*S*-2,3″,2-tet)]$^+$ ion,[11] which has no axial *C*-methyl group. However, it is similar to that of 36.4° in the [Co(ox)(5*R*,7*R*-Me$_2$-2,3,2-tet)]$^+$ ion,[12] which has an axial *C*-methyl group. This small α value indicates a flattened structure of the six-membered ring. The magnitude of the ring flattening of the two complexes containing axial *C*-methyl groups, [Co(ox)-(5*R*,7*R*-Me$_2$-2,3,2-tet)]$^+$ and [Co(*R*-ala)(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]$^+$, is the same in spite of a difference in the bidentate ligands, oxalato or alaninato, and additional *N*-methyl groups. Thus, although the conformation of the tetramine is not much different

from those of other analogous 2,3,2-tet complexes, the tetramine containing an *R,R*-2,4-pentanediamine unit is somewhat strained by nonbonded repulsions, including methyl substituents.

Close contacts between the *N*-methyl or *C*-methyl carbon atoms and other atoms in the complex (less than 3.5 Å) are listed in Table 5. Four close contacts between axial methyl groups and alaninato chelate ring, C(N4)–N(5) 3.30 (2) Å, C(N4)–C(9) 3.11 (2) Å, C(C3)–O(1) 3.03 (2) Å, and C(C3)–C(9) 3.42 (2) Å, were observed.

The conformation of the chelate ring for the alaninato is presented in Fig. 2-d. The five-membered ring has a slightly puckered pseudo-δ-gauche conformation (maximum deviation from the plane of best fit; N(5), 0.12 Å; C(8), 0.12 Å). In order to compare the structure of the alaninato chelate with those in reported alaninato-cobalt(III) complexes, the Cambridge Crystallographic Data File (XDC) was searched and alaninato-cobalt(III) complexes whose structures have been established on the basis of three-dimensional counter data were collected. Their selected distances, angles, and torsional angles are listed in Table 6. The bond lengths and angles in the present complex are normal compared with those in the reported complexes. The Co–N(5) distance is 1.969 (14) Å. This value is in the upper end of the reported range for the corresponding Co–N bonds (1.935—1.961 Å). The Co–O(1) distance is 1.893 (9) Å, which is normal for the Co–O bonds (the reported values are in the range 1.877—1.925 Å). The angle at the cobalt atom N(5)–Co–O(1) is 84.6 (5)°, while the reported values are in the range 83.4—86.3°. The angles Co–N(5)–C(8) and Co–O(1)–C(9) are 110.0 (7)° and 117.4 (7)°, while the reported values are in the range 106.1—110.8° and 114.3—116.8°, respectively. The torsional angle N(5)–C(8)–C(9)–O(1) is rather characteristic. The value is 17.6°; this is considerably smaller compared with those reported for the corresponding torsional angles (19.0—29.4°). This distortion is attributed to an interaction between the terminal *N*-methyl group in the tetramine part (C(N4)) and the carbon in the alanine part (C(9)). A similar distortion in the alaninato chelate has been observed in the *Λ*-*β*$_2$-[Co(*S*-ala)(*S,S*-pyht)]$^{2+}$ ion,[13] which has *N*-substituent on the terminal nitrogen of the tetramine that is similar to the present complex, whose torsional angle is 19.0°. We observed the release of alanine from the *Λ*-*β*$_2$-[Co(*S*-ala)(*S,S*-pyht)]$^{2+}$ ion when this complex was warmed under mild basic conditions; this is similar to the case of the [Co(*R*-ala)(1,5*R*,7*R*,11-Me$_4$-2,3,2-tet)]$^{2+}$ ion.

Thus, the present structure determination revealed that the important intermediate complex in the asymmetric synthetic system of α-alanine has the usual octahedral coordination geometry, although the conformation of the ligands are somewhat strained. The obtained results suggest that the labile feature of this complex should be ascribed to factors other than a stereochemical distortion of the alanine unit.

Description of the Unit Cell. The unit cell, Fig. 4, consists of four discrete complex cations, twelve bromine atoms (including eight disordered positions) and twelve waters of crystallization. In Table 7 are listed some of the important distances outside the

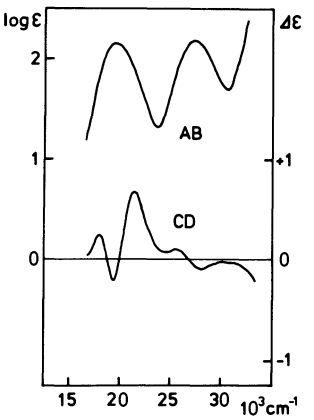

Fig. 5. Electronic absorption (AB) and circular dichroism (CD) spectra of $(-)_{546}$-[Co(*R*-ala) (1,5*R*, 7*R*,11-Me_4-2,3,2-tet)]$^{2+}$.

complex ion. Three water oxygen atoms, O(3), O(4), and O(5), and one bromide anion, Br(1), are aligned along the c-axis with distances of about 3 Å. O(4), O(5), and Br(2) (A or B) are aligned along the a-axis. There probably exists a network of hydrogen bonds between these water oxygens and the bromide anions. In addition of this network, there are N-H···Br and N-H···O hydrogen bonds between the complex ions and the water oxygen and bromide anion. An O(2) atom of the alaninato is linked to N(4) and N(5) by N-H···O hydrogen bonds at distances 2.97 (2) and 2.90 (2) Å, respectively.

Circular Dichroism and Absorption Spectra. The CD and AB spectra of $(-)_{546}$-*Λ*-β_2-[Co(*R*-ala)(1,5*R*,7*R*,11-Me_4-2,3,2-tet)]$^{2+}$ are shown in Fig. 5, and their spectral data are summarized in Table 8. It is often observed that the CD sign in the first absorption region is closely related to the absolute configurations for the dissymmetric cobalt complexes. For example, the sign of the dominant peak for the first absorption region is expected to be positive for a Λ configuration. However, the present complex has two positive and one negative cotton effects in the first absorption region. Therefore, it is difficult to assign the absolute configuration by means of CD spectroscopy.

Table 8. Electronic Absorption (AB) and Circular Dichroism (CD) Spectral Data of $(-)_{546}$-*Λ*-β_2-[Co(*R*-ala)(1,5*R*,7*R*,11-Me_4-2,3,2-tet)]$^{2+}$

AB $\tilde{\nu}/10^3$ cm^{-1} (log ε)	CD $\tilde{\nu}/10^3$ cm^{-1} (Δε)
19.5 (2.15)	17.9 (+0.24)
	19.3 (−0.20)
	21.0 (+0.67)
27.3 (2.18)	25.5 (+0.10)
	28.0 (−0.08)

The electronic absorption spectrum of the complex gives typical $[CoN_5O]^{2+}$ absorptions. The first absorption band of this complex is shifted by about 700 cm^{-1} to the lower-energy side compared to the alaninato complex of 2,3,2-tet. This indicates that an

alkyl group substitution on the tetramine nitrogen causes a weakening of the ligand field. Since the present crystal structure does not show any significant stereochemical features for the coordinated alanine part, we believe that the labile feature of this complex is closely related to the strength of the ligand field. Studies are now in progress to clarify the labile feature of amino acidato cobalt(III) complexes while hoping to establish metal-assisted asymmetric reactions.

X-Ray Photoelectron Spectroscopy of Rare Earth Halides

Yoshinori UWAMINO,* Akira TSUGE, Toshio ISHIZUKA, and Hideo YAMATERA†

(Received January 22, 1986)

Rare earth (RE) halides (fluorides, chlorides, bromides, and iodides) have been studied by X-ray photoelectron spectroscopy. The binding energies (BE's) of the RE 3d and 4d peaks for the chlorides, bromides, and iodides are related to the atomic charge calculated on the basis of Pauling's scale of electronegativity (Pauling charge). Except for Y and Lu, the observed RE 3d and 4d BE's for the fluorides are lower than those expected. For Y and Lu, the observed RE 3d and 4d BE's for all halides are related to the Pauling charge. For the fluorides and chlorides, the BE's of the ligand peak show variations with increasing atomic number of RE's and a specific "tetrad effect" is observed in plots of BE versus RE atomic number and versus $1/R$ (where R is the mean distance from the ligand atom to the neighboring RE atom), except for the BE's of the F 1s peaks from the light RE fluorides. For the iodides and bromides, no or little characteristic variations are seen in the BE's of I and Br.

Rare earths (RE's) have been studied widely by X-ray photoelectron spectroscopy (XPS).[1-6] Satellite and multiplet peaks in the 3d and 4d spectra of RE compounds have been of paticular interest.[1,3-5] Although much attention has been devoted to the energy separations between the satellite and the main peak and between the multiplet components, there has been little consideration of absolute binding energies (BE's).

Jørgensen and Berthou measured absolute BE's of the inner and outer shells of RE elements and ligands in various RE compounds.[2] However, their calibrant (C 1s peak from mounting tape) is unsatisfactory for charge correction of nonconducting materials such as RE compounds.[7] Therefore, the BE values given by them may involve some uncertainty. To discuss chemical shifts for RE elements, it is necessary to measure absolute BE's with greater accuracy. Although the RE elements show a striking similarity to one another in their chemical properties, slight differences in these properties may influence the BE's of ligands in RE compounds. Therefore, it is worthwhile measuring the BE's of such ligands.

Thus, we systematically measured the absolute BE's of the RE elements and ligands in RE oxides, sulfates, and oxalates.[6] For the oxides, appreciable differences were found in the BE's of O 1s peaks, and a specific "inclined W" form was observed in plots of BE versus $1/R$ (where R is the mean distance from the oxygen atom to the neighboring RE atom) and versus the RE oxidation potential. In the present study, we examine whether the "inclined W" pattern appears or not for RE halides. In addition, we investigate the relation between the RE BE's and the electronegativities of halogen atoms. Thus we measured the BE's of the RE elements and ligands in a series of fluorides, chlorides, bromides, and iodides of RE's (including yttrium). The results of these measurements are discussed below.

Experimental

The photoelectron spectra of the RE compounds were obtained using a JEOL JESCA-4 photoelectron spectrometer equipped with an Al $K\alpha$ X-ray source ($h\nu$=1486.6 eV). The X-ray power supply was operated at 7 kV and 40 mA. The pressure inside the sample chamber was below 5×10^{-5} Pa during the measurements. The resolution of the analyzer was set to give a full width at half-maximum (FWHM) of 1.9 eV for the Au $4f_{7/2}$ peak. The XPS data were obtained by digital accumulation using a Texas Instruments 980B minicomputer. The digital data were processed with a Hewlett-Packard 9845B desk-top computer combined with the minicomputer. Data reduction consisted of smoothing of the raw data and curve synthesis using Gaussian peak shapes. The program was written in this laboratory.[8]

RE halide samples were prepared from 99.99% RE oxides (Shin-etsu Chemical Co.). The RE fluorides were precipitated from 1% nitric acid solutions by adding hydrofluoric acid and dried at 130 °C. The RE chlorides, bromides and iodides were prepared by dissolving the RE oxides in hydrochloric acid, hydrobromic acid, and hydroiodic acid, respectively, evaporating to dryness at 90 °C on a hot plate, and then drying in vacuum at room temperature for two days. Cerium iodide was not obtained by this method; therefore spectra are lacking on this compound.

All the powder samples were pressed at 200 kg cm^{-2} using a pellet die (Hitachi Ltd.) to give circular disks about 1 mm thick and 13 mm in diameter. All samples were fixed to the sample holder by means of double-sided adhesive tape.

Results and Discussion

The 3d spectra for Y and La through Gd were measured. The $3d_{5/2}$ spectra of Y, La, Nd, and Gd are shown in Fig. 1. The spectra for Ce, Pr, Sm, and Eu were similar to those for La, Nd, Gd, and Gd, respectively. The Y 3d spectra of YF_3, YCl_3, YBr_3, and YI_3 are very similar to one another. For each of the other RE's, the RE $3d_{5/2}$ spectra of the chloride, bromide, and iodide are similar to one another, but

s) Satellite peak. a) Cerium iodide sample was not obtained.

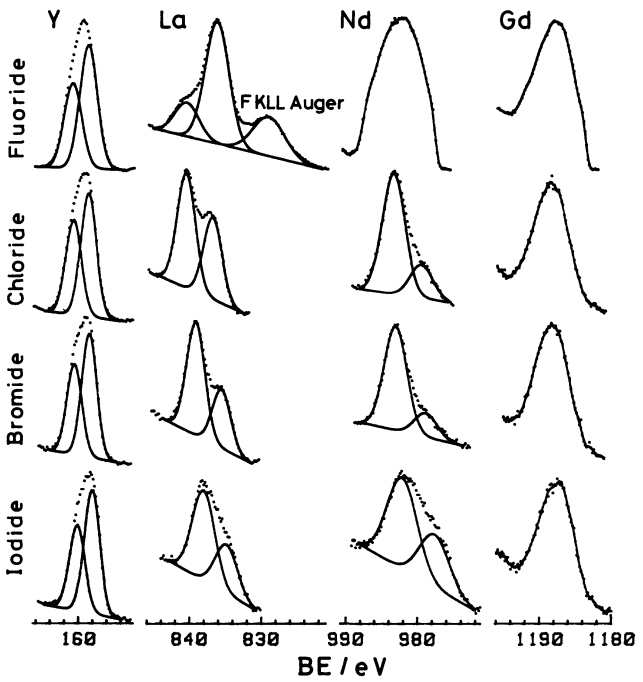

Fig. 1. Photoelectron spectra of the RE $3d_{5/2}$ level for RE halides (RE=Y, La, Nd, and Gd). Dotted lines show observed spectra. Solid lines give deconvolutions of the main and satellite peaks. Y $3d_{3/2}$ peak is shown at the higher BE site in each Y spectrum.

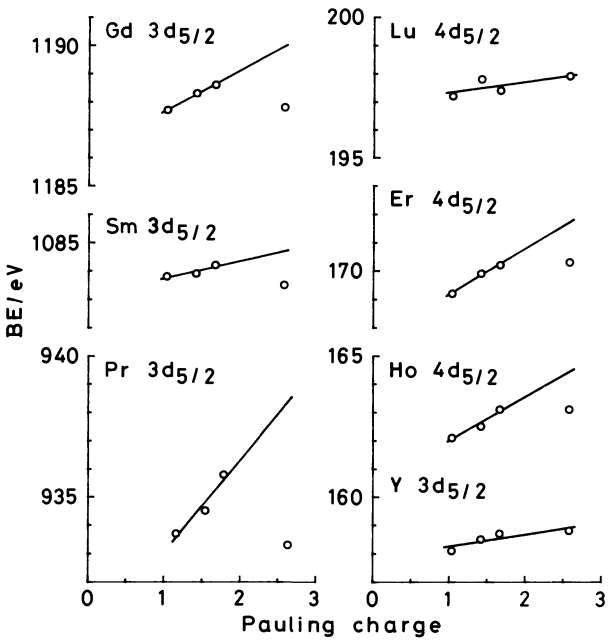

Fig. 2. Correlations of the BE's of the RE $3d_{5/2}$ and RE $4d_{5/2}$ (RE=Y, Pr, Sm, Gd, Ho, Er, and Lu) with Pauling charge for each RE halide.

rather different from that of the fluoride. The different shape of the fluoride spectra are due to the low intensity of the satellite arising from the charge-transfer transition from the ligand anion to the 4f level of RE ion.[4] Distinct satellite peaks are recognized in the Nd $3d_{5/2}$ spectra from the chloride, bromide, and iodide, but not in the spectra from the fluoride. For Gd, no distinct satellite peaks are recognized. For Nd and Gd, the FWHM's of the peaks from the fluorides are 1.3—2.0 times broader than those from the chlorides, bromides, and iodides.

The 4d spectra for all RE's were measured. The obtained spectra were similar to those given by Signorelli and Hayes[3] (the RE 4d spectra of several halides), and Suzuki et al.[4] (the RE 4d spectra of the fluorides, chlorides, and bromides of La and Ce). Satellite peaks were recognized in the La 4d spectra of the chloride and bromide. The RE 4d spectra for the halides of Tb through Yb were complex. Signorelli and Hayes have explained these complex structures by the electrostatic coupling of a 4d photohole with the unfilled 4f shell of RE.[3]

Tables 1 and 2 list the BE's of the 3d peaks and of the 4d peaks, respectively. Charging of the sample was corrected by regarding the C 1s peak from carbon contamination on the sample surface as located at 284.6 eV. The BE's of the measured satellite and multiplet peaks are also listed in Tables 1 and 2.

Jørgensen and Berthou[2] have reported the BE's of RE 3d and 4d peaks in a series of RE fluorides except for the fluorides of Dy, Ho, and Tm. The BE's of the RE 3d and 4d peaks listed in Tables 1 and 2 are 2.4—7.2 eV lower than those reported by them. The disagreement can be attributed to the difference in the calibrant used for charge correction.

In Tables 1 and 2, appreciable differences appear in the BE's of the RE 3d and 4d peaks for each RE element. Generally, chemical shifts in XPS are related to the atomic charge calculated on the basis of Pauling's scale of electronegativity (Pauling charge).[9] Figure 2 shows the dependence of the BE's of RE $3d_{5/2}$ or $4d_{5/2}$ peaks on the Pauling charge for Y, Pr, Sm, Gd, Ho, Er, and Lu (electronegativity values were quoted from Ref. 10). For Y with 4f levels far above the filled shell and Lu with a completely filled 4f shell, the BE's of Y $3d_{5/2}$ and Lu $4d_{5/2}$ peaks increase with an increase in Pauling charge for all compounds. For other RE's with a partly filled 4f shell, the BE's of RE $3d_{5/2}$ and $4d_{5/2}$ peaks increase in the order, iodide<bromide<chloride, but the peaks from the fluorides appear at lower BE's than expected. Why the solid lines in Fig. 2 show different slopes is a problem of further investigation.

The spectra of the ligands (F 1s, Cl 2s, Cl 2p, Br 3s, Br $3p_{1/2}$ and $_{3/2}$, Br 3d, I $3p_{1/2}$ and $_{3/2}$, I $3d_{3/2}$ and $_{5/2}$, and I 4d) in all RE halides were obtained. The spectrum for each RE was simple and no significant differences were observed between the ligand spectra of different RE's. Table 3 lists the BE's of the ligand peaks. The Br 3d and I 4d peaks were not resolved

Table 3. BE's (in eV) of F 1s, Cl 2s, Cl 2p, Br 3s, Br 3p, Br 3d, I 3p, I 3d, and I 4d Peaks

a) Cerium iodide sample was not obtained.

into their $d_{3/2}$ and $d_{5/2}$ peaks. Jørgensen and Berthou[2] have reported the BE's of F 1s peaks for the fluorides of Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Er, Yb, and Lu. The BE's of the F 1s peaks listed in Table 3 are 3.0—5.5 eV lower than those reported by Jørgensen and Berthou. The disagreement can be attributed to the difference in the calibrant used for charge correction.

For each RE halide, an intensity ratio of the halogen peak (F 1s, Cl 2s, Br $3p_{3/2}$, and I $3d_{5/2}$) to O 1s peak ranged from 27.0 to 8.2, after peak intensity was normalized with photoelectric cross sections,[11] mean free paths for photoelectron,[12] and efficiencies of detection of the electron. This demonstrates that the formation of halide oxides, if any, on our sample surface was not serious for the present XPS studies.

For the RE oxides, we have reported the "inclined W" pattern in the plots of the BE's of O 1s peaks versus $1/R$ and versus the RE oxidation potential.[6] The pattern is identical with the "tetrad effect"[13] that is the minute irregularity in the variation of complex formation constants[14] and unit cell volumes[15] as a function of lanthanoid atomic number. Figure 3 shows the relationships between the BE's of the F 1s, Cl 2s, Br $3p_{3/2}$, and I $3d_{5/2}$ peaks and the atomic number for lanthanoids. For the RE fluorides and chlorides, the solid lines connecting the points for La, Gd, and Lu (with spherical configurations) show that the BE of the F 1s and Cl 2s peak increases with an increase in RE atomic number. This result agrees with those shown for the BE's of O 1s peaks for the RE oxides.[6] The points for the other RE's deviate from the solid lines except for light RE fluorides. The pattern reflects electronic configurations of RE elements and is called "tetrad effect." We can not at present give a good reason for the absence of "tetrad

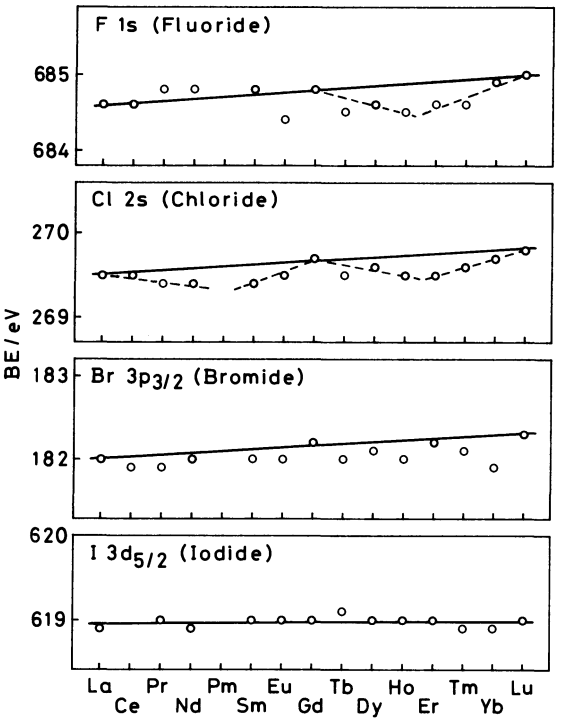

Fig. 3. BE's of the F 1s, Cl 2s, Br $3p_{3/2}$, and I $3d_{5/2}$ peaks as a function of the lanthanoid.

effect" for the fluorides of Ce through Eu. For the RE iodide and bromide, the BE's of the I $3d_{5/2}$ and Br $3p_{3/2}$ peaks show no or hardly meaningful dependence on the RE atomic number. It has been reported that the magnitude of the chemical shift for each element decreases with an increase in ionic radii.[16] The large radius of the bromide and iodide ion may be the reason for the very small chemical shift of iodine and bromine atom.

For the RE oxides, a correlation has been

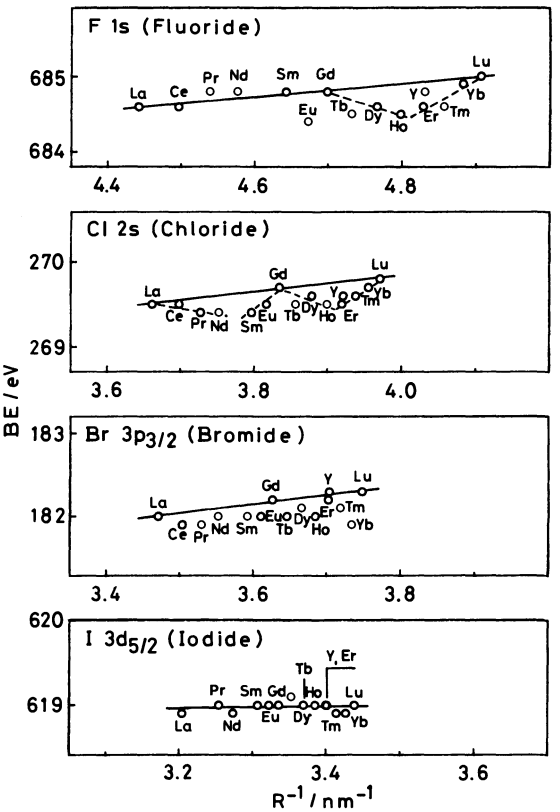

Fig. 4. Correlations of the BE's of the F 1s, Cl 2s, Br $3p_{3/2}$, and I $3d_{5/2}$ peaks with $1/R$ for each RE halide.

recognized between the BE of the O 1s peak and the mean distance from oxygen atom to the RE atom.[6] Figure 4 shows the relationships between the BE's of the F 1s, Cl 2s, Br $3p_{3/2}$, and I $3d_{5/2}$ peaks and $1/R$ for RE halides (R values quoted from Ref. 17). Solid lines were drawn so as to connect approximately the points for La, Gd, and Lu in the same manner as shown in Fig. 3. For the fluoride and the chloride, the BE's of the halogen peaks increase with an increase in $1/R$. This result agrees with those reported by Nefedov et al.[18] for the O 1s peaks for 37 kinds of oxides and the F 1s peaks for 20 kinds of fluorides. The plot for the BE's of the Cl 2s peaks show a "tetrad effect." The F 1s BE's of Gd through Lu show a similar trend. For the iodide, the BE's of the I $3d_{5/2}$ peaks show no meaningful dependence on the $1/R$. The Br $3p_{3/2}$ peaks of the bromide show a pattern intermediate between Cl 2s and I $3d_{5/2}$.

Measurements of Association Constants of Iodine with Cyclodextrins and with Iodide or Bromide Ion in Aqueous Medium, Based on Volatilization Rate of Iodine from Aqueous into Gaseous Phase

Isao SANEMASA,* Yuko NISHIMOTO, Akira TANAKA, and Toshio DEGUCHI
Department of Chemistry, Faculty of Science, Kumamoto University,
Kurokami 2-39-1, Kumamoto 860
(Received January 23, 1986)

Iodine molecules, which are volatile, are expelled from an aqueous medium into the gaseous phase by introducing an inert gas at a constant flow rate into the aqueous phase, and the amount of the released iodine is measured as a function of aeration time. In the presence of a nonvolatile solute which associates with molecular iodine, the releasing rate of the volatile solute is reduced with increasing degree of the association between both the solutes in the aqueous medium. The method was applied to the case of association of iodine with α-, β-, or γ-cyclodextrin; the formation constants of the three 1:1 complexes are $(1.5\pm0.1)\times10^4$, $(1.5\pm0.2)\times10^2$, and 24 ± 3 dm^3 mol^{-1}, respectively, at 25.0 °C and low ionic strengths. The complexation of iodine with iodide or bromide ion was also studied; the I_3^- and I_2Br^- formation constants are $(6.5\pm0.1)\times10^2$ and 16 ± 1 dm^3 mol^{-1}, respectively, at 25.0 °C and I=0.1($NaClO_4$).

The complex formation of cyclodextrin (CyD) with molecular iodine in aqueous medium is well known and association constants have been measured by the spectrophotometric,[1,2] potentiometric,[3] and solubility[4] methods. There are, however, considerable disagreements among the literature values as seen in Table 1.

A simple method for measuring association constants between volatile and nonvolatile solutes in aqueous medium has been presented and successfully used to estimate 1:1 metal acetylactonate complex formation constants.[5] The method is based on the fact that a volatile solute present in an aqueous solution can readily be driven out of the aqueous phase by an inert gas stream and that the releasing rate depends on the extent to which the volatile and nonvolatile solutes associate with each other.

Here we have used the method to determine formation constants of 1:1 complexes of iodine with α-, β-, or γ-CyDs. In order to check the reliability of the estimated values, complex formation constants of iodine with iodide or bromide ion have also been determined by the same technique.

Experimental

Materials and Preparations of Sample Solutions. Solid iodine of analytical reagent grade and cyclodextrins (α-, β-, and γ-CyD from Nakarai Chemicals) of guaranteed grade were used without further purification (γ-CyD recrystallized from water was also used). An aqueous iodine solution in the order of 1×10^{-3} M (1 M=1 mol dm^{-3}), i.e., a nearly saturated solution, was prepared by adding an excess quantity of solid iodine to 1 dm^3 of 2×10^{-4} M $HClO_4$ solution and stirring in a thermostated bath at 25 °C for a few days. Suitable portions of this iodine solution were taken out successively, and one part was used to determine the I_2 concentration by titration with a 4×10^{-3} M $Na_2S_2O_3$ standard solution using starch as an indicator and the others were diluted with water to desired iodine concentrations ranging from 10^{-5} to 10^{-4} M to prepare CyD-free sample solutions. Into the aqueous iodine solution was dissolved a suitable amount of CyD, which had been dried over phosphorus pentaoxide under vacuum, to prepare sample solutions of known CyD concentrations. The $HClO_4$ concentration in the sample solution was as low as 2×10^{-6}—2×10^{-5} M.

In runs where formation constants were to be estimated for I_2–I^- and I_2–Br^- systems, sample solutions were prepared by adding a suitable volume of an iodide or bromide stock solution which had been prepared by dissolving a dried reagent (KI, NaBr) in water. The ionic strength of the sample solution was adjusted to 0.1 with $NaClO_4$.

Apparatus and Procedures. The apparatus used to expel molecular iodine was essentially the same as the one employed in a previous work.[5]

A 50 cm^3 portion of sample solution was transferred into a $2.5\phi\times25$ cm cylindrical glass tube with a ground glass joint, which was then immersed in a bath thermostated at 25.0±0.1 °C. A gas-inlet-type adaptor was mounted on the cylindrical tube and N_2 gas was dispersed through the solution via a capillary glass tube at a constant flow rate of 60.0 cm^3 min^{-1}. The N_2 gas flow rate was controlled by a Stec Type Sec 400 mass-flow controllor, which was donated by Standard Technology Co., Ltd. (Kyoto); an accuracy within ±1% is guaranteed for this device. The N_2 gas leaving the sample solution was dispersed via a sintered glass ball through an absorbent, 20 cm^3 of 5×10^{-4} M $Na_2S_2O_3$ solution, which was placed in a $15\phi\times18$ cm cylindrical glass tube with a ground glass joint. After a fixed time, the N_2 gas stream was interrupted, the absorption vessel was replaced by another one containing the same volume of the absorbent, and the introduction of N_2 gas was resumed. This operation was repeated at regular time intervals. The amount of iodine expelled from the sample solution during the fixed time, ΔQ_{I_2}, i.e., the amount of I_2 trapped in a single absorption vessel, was determined by measuring the discoloration degree of trisulfatocerium(IV) at 312 nm according to the flow injection analysis (FIA).

The principle of the analytical method is that the

reduction of Ce(IV) by As(III) will be promoted in the presence of iodide ion as a catalyst. The FIA manifold was the same as the one previously used,[6] but the temperature of the reaction coil where the catalytic reaction occurs was set at 30 °C and the absorbent, 5×10^{-4} M $Na_2S_2O_3$, was employed as a carrier stream into which portions of a sample solution were injected. Under these conditions, we could detect iodide ions down to 1×10^{-8} M.

Results and Discussion

Formation Constants of Molecular Iodine with Cyclodextrins. The stoichiometry of α-, β-, or γ-CyD complex with molecular iodine has been established to be 1:1,[4,7,8] and thus the reactions that should be taken into account are

$$CyD + I_2 \rightleftharpoons CyD\cdot I_2,\ K_{ass}, \quad (1)$$

$$I_2(aq) \longrightarrow I_2(gas),\ k, \quad (2)$$

where K_{ass} is the association constant and k is the rate constant for expulsion of iodine molecules from the aqueous into gaseous phase. Here we assume that the iodine present in the aqueous medium is in the molecular form, that is, the hydrolysis of iodine, $I_2+H_2O \rightleftharpoons HIO+H^++I^-$, is negligible, because of its small hydrolysis constant of the order of 10^{-13}.[9]

The iodine molecules expelled into the gaseous phase are trapped successively by the absorbent, and the total amount, Q_{I_2}, is measured as a function of aeration time, t. Here, we assume that the releasing rate of I_2 at a constant N_2 gas flow rate is of first-order dependence on the concentration of this species present in the solution, and thus

$$dQ_{I_2}V^{-1}/dt = k[I_2], \quad (3)$$

where V is the volume of the aqueous phase. We have the mass-balance equations

$$C_{CyD} = [CyD] + [CyD\cdot I_2], \quad (4)$$

$$C_{I_2} = [I_2] + Q_{I_2}V^{-1} + [CyD\cdot I_2] = [I_2] + Q_{I_2}V^{-1} + K_{ass}[CyD][I_2], \quad (5)$$

where C_{CyD} and C_{I_2} are the total concentration of CyD and that of iodine, respectively. Substitution of Eq. 5 into Eq. 3 yields

$$dQ_{I_2}V^{-1}/dt = k(C_{I_2} - Q_{I_2}V^{-1})/(1 + K_{ass}[CyD]), \quad (6)$$

which becomes, on integration and with $Q_{I_2}=0$ at $t=0$,

$$\ln(C_{I_2} - Q_{I_2}V^{-1}) = -kt/(1 + K_{ass}[CyD]) + \ln C_{I_2}. \quad (7)$$

Plots of $\ln(C_{I_2}-Q_{I_2}V^{-1})$ vs. t will give a straight line

with a slope which corresponds to $-k/(1+K_{ass}[CyD])$ or to $-k$ in the absence of CyD solutes. Under the conditions that the total concentration of CyD is sufficiently large compared to the concentration of the associated complex formed, that is, $C_{CyD} \gg [CyD \cdot I_2]$, we can set [CyD] in Eq. 7 equal to C_{CyD}.

Figure 1 shows some plots constructed with the aid of Eq. 7. These plots give straight lines over the aeration time investigated, which indicates that the releasing rate of I_2 is of first-order dependence on the concentration of this species present in the solution. At a constant N_2 gas flow rate of 60.0 $cm^3\ min^{-1}$, the constant, k, was evaluated to be $(1.53\pm0.03)\times10^{-2}$ min^{-1} (an average from four replicated runs in the absence of CyD). The association constants derived for α-, β-, and γ-CyD complexes with iodine from the negative slopes of the straight lines are tabulated together with C_{CyD} and C_{I_2} in Table 1, where those reported so far in the literature are also listed.

With α-CyD, the cavity size of which is 4.7—5.2 Å, an iodine molecule can suitably be fitted with a van der Waals contact.[8] On the other hand, β- and γ-CyDs provide much less stable complexes with the guest owing to their large cavity sizes, 6.0—6.4 and 7.5—8.3 Å, respectively.

The association constants obtained by the present method are about 1.5 to 2 times as large as our previous ones[4] determined through solubility measurements. The disagreement, however, may be taken as rather small if we take it into consideration that quite different techniques were employed for the two works. The K_{ass} value determined in this work for the α-CyD complex is in reasonable agreement with that recently reported by Diard et al.[3] as a result of potentiometric measurements, while the values for β- and γ-complexes differ by one order of magnitude; their association constants decrease every one order of magnitude on going from α- to γ-CyD, while our values display a difference as much as two orders of magnitude between α- and β-CyD complexes.

It probably admits of no argument that the α-complex has the association constant as large as $1\times10^4\ M^{-1}$. The association constant for β- and γ-complexes, on the other hand, are still far from being generally acceptable. This is partially attributable to their relatively small association constants; the spectrophotometric, potentiometric, and solubility measurements are all desirable to be done under high CyD concentrations to get reliable values, β-CyD has a limited solubility in water (ca. 10^{-2} M). In view of its small association constant, some impurities which may be present in γ-CyD might cause serious errors in the estimatin of K_{ass} of γ-CyD-I_2. There is observed, however, no appreciable difference between the results obtained from purified (recrystallized from water) and untreated γ-CyD specimens, as can be seen from Table 1.

In order to make it clear whether the present method provides reasonable association constants as small as 10^2 or 10, I_2–I^- and I_2–Br^- systems were studied. The formation constant for the former system has been measured by many investigators and the latter is known for its small formation constant.

Formation Constants of Molecular Iodine with Iodide or Bromide Ion. The reactions that should be taken into account are

$$X^- + I_2 \rightleftarrows I_2X^-,\ K_{I_2X}, \tag{8}$$

$$I_2(aq) \longrightarrow I_2(gas),\ k, \tag{2}$$

where X^- denotes either I^- or Br^- and K_{I_2X} is the formation constant. An equation that allows estimation of the formation constant of I_2 with I^- or Br^- can be derived in the same way as described in the CyD–I_2 system:

$$\ln(C_{I_2} - Q_{I_2}V^{-1}) = -kt/(1 + K_{I_2X}[X^-]) + \ln C_{I_2}. \tag{9}$$

Experiments having been made under the condition that the total concentration of X^-, C_X, is sufficiently large compared to the concentration of the complex formed, we can set $[X^-]$ in Eq. 9 equal to C_X. Some examples of plots obtained with the aid of Eq. 9 are shown in Fig. 2. The plots also give straight lines

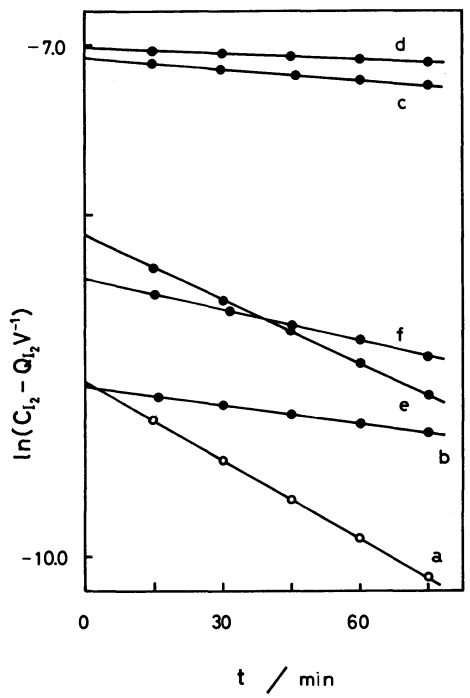

Fig. 2. The plots of $\ln(C_{I_2} - Q_{I_2}V^{-1})$ vs. t in the absence and presence of I^- or Br^-. N_2 gas flow rate 60.0 cm^3 min^{-1}; (a): $C_X=0$, $C_{I_2}=1.27\times10^{-4}$ M, (b): $C_I=5.00\times10^{-3}$ M, $C_{I_2}=1.23\times10^{-4}$ M, (c): $C_I=1.00\times10^{-2}$ M, $C_{I_2}=8.37\times10^{-4}$ M, (d) $C_I=2.00\times10^{-2}$ M, $C_{I_2}=9.01\times10^{-4}$ M, (e): $C_{Br}=2.00\times10^{-2}$ M, $C_{I_2}=2.96\times10^{-4}$ M, (f): $C_{Br}=1.00\times10^{-1}$ M, $C_{I_2}=2.31\times10^{-4}$ M.

Table 2. I_3^- and I_2Br^- Formation Constants Determined at 25 °C and I=0.1($NaClO_4$)

over the aeration time investigated. Formation constants calculated from the slopes of the straight lines for I_3^- and I_2Br^- by using the k value 1.54×10^{-2} min^{-1} determined with 0.1 M $NaClO_4$ are listed in Table 2, together with C_{I_2} and C_X.

To our knowledge, only three K_{I_2Br} values have been reported; 14.9 M^{-1} by spectrophotometry,[10] 12.2 M^{-1} from solubility,[11] and 8.35 M^{-1} through solvent extraction.[12] The present result, 16 M^{-1}, is in reasonable agreement with the first one cited; because of the lack of available literature values, it is difficult at present to judge whether the agreement is accidental or not.

With respect to K_{I_3}, on the other hand, abundant literature data are available which have been obtained by spectrophotometric,[13,14] potentiometric,[9,15] distribution,[12,16] solubility,[17,18] and conductimetric[19] methods. Some representative values are arranged in decreasing order of magnitude as follows: 768,[16] 761,[17] 7.3×10^2,[14] 725,[9] 723,[13] 714,[15] 680,[12] and 654[17] M^{-1}. If we choose 723 M^{-1} as the most reliable K_{I_3} value in accord with the recommendation by Ramette and Sandford,[20] the present result, 6.5×10^2 M^{-1}, is about 10% lower. As has been pointed out by many investigators, the I_3^- formation constant should be determined under as low iodine and/or iodide concentrations as possible. The observed K_{I_3} tends to increase with increasing iodine and/or iodide concentrations due to significant formation of higher polyiodide species such as I_5^- and I_6^{2-} in addition to I_3^-.[16,20] From this point of view, the present method, which employs very low I_2 and I^- concentrations, seems to provide rather a small I_3^- formation constant.

After all, the method proposed here can be used to determine association constants with molecular iodine, magnitudes of which are as small as the order of 10^2 or 10.

The present work was partially supported by a Grant-in Aid for Scientific Research No. 6054037 from the Ministry of Education, Science and Calture.

Vertical Concentration Distributions of Arsenic in a Reservoir and Its Sediment

Yuzo TAMARI,* Kimio NISHIMURA, Haruo TSUJI, and Yuzuru KUSAKA
Department of Chemistry, Faculty of Science, Konan University,
Higashinada-ku, Kobe 658
(Received January 24, 1986)

Vertical concentration distributions of arsenite and arsenate in a reservoir (depth, ≈31 m) and its bottom sediment (core depth, ≈18 cm) have been investigated. The concentrations of arsenite and arsenate in the water were determined by a spectrophotometric method, and those in the sediment were also determined by the same method after the following leaching-treatments of the sediment. The leaching of arsenic from the sediment was carried out by using three solutions; (1) 0.1 M† hydrochloric acid (acid-soluble fraction), (2) 1 M sodium hydroxide solution (alkali-soluble fraction), and (3) hydrofluoric and perchloric acid mixture (silicate fraction). It was found that arsenic was rich in the surface layer of the sediment, and most of it existed as arsenite fixed with iron hydroxide. Based on the analytical and leaching results of arsenic, iron, manganese, zinc, copper, and others in the reservoir and in its sediment respectively, the sedimentation process of arsenic from the reservoir and its dissolution process from the sediment have been discussed.

Arsenic is one of the most widely distributed elements in the earth's crust and in the biosphere. Arsenic is commonly considered to be intrinsically toxic to life. However, it has been recognized to be one of the essential trace elements in living organisms since 1975,[1] and has become significant for men and animals as an important element in their nutrition.[2,3] Thus, it is our concern to know the concentration of arsenic contained in drinking water or in its original reservoir.[4]

Arsenic generally exists as the following chemical species; arsine [As(−III)], elemental arsenic [As(0)], arsenite [As(III)], arsenate [As(V)], and organically-complexed arsenic. For the detailed researches of arsenic in natural water, reservoir water, and its bottom sediment, this chemical state analysis of arsenic is important. In this work, a reservoir, which is located in Hyogo Prefecture and has been used for drinking water supplies, was selected as one of the geochemical researches of arsenic. The vertical distributions of arsenite, arsenate, and organic arsenic in the reservoir and its sediment have been investigated. The concentrations of arsenite and arsenate in the water were determined by spectrophotometry.[5] The inorganic and organic arsenic in the sediment were analyzed for the solutions prepared by a chemical leaching method,[6–8] by which arsenic was released from the sediment to a solution.

Experimental

Sediment and Water Samples. A sediment sample was collected from the bottom of the reservoir of a 17.5-cm depth core, using a core sampler (Rigo Co., Ltd., model 2010). The core sample was taken in a plastic cylinder and was immediately cooled in an ice-box. It was then taken back to the laboratory within 1h. The wet core (17.5-cm length) was cut into sections, 1.5-cm in depth, and each of the divided wet core samples was then subjected to a leaching experiment without drying.

Water samples were collected from the surface to a 30.5-m depth of the reservoir. The water samples were collected in a plastic-made sampler (Rigo Co., Ltd., model 22046) and were immediately analyzed for temperature, pH, conductivity, turbidity, dissolved oxygen (D.O.), and oxidation reduction potential (O.R.P.). They were then transferred to a 2000-cm^3 polyethylene bottle after adding 33 cm^3 of 6 M hydrochloric acid to avoid the precipitation of iron (III) hydroxide. However, for the analyses of nitrate, nitrite, and ammonium ions, a part of the water sample in the sampler was transferred to a glass bottle without the addition of 6 M hydrochloric acid.

Analytical Methods. Arsenite and arsenate were determined by spectrophotometry with silver diethyldithiocarbamate, after converting the arsenic into arsine with sodium tetrahydroborate.[5] Calcium, magnesium, iron, manganese, copper, and zinc were determined by atomic absorption spectrometry. Sodium and potassium were determined by flamephotometry. Sulfide was determined by iodatimetry after converting the sulfur into hydrogen sulfide with hydrochloric acid. The other chemical species dissolved in water samples were determined by ordinary spectrophotometry and other conventional methods.[9]

Chemical Leaching Methods. The following solutions were used for fractionation into acid-soluble, alkali-soluble, and silicate fractions: (1) 0.1 M Hydrochloric acid solution[7,10,11] to dissolve sulfide, hydroxide, and some ions loosely adsorbed with sediments, but not to dissolve both lithogeneous materials derived from rocks and organically-complexed ions such as copper. (2) 1 M Sodium hydroxide solution[8] to leach some organically-bound elements or organic compounds such as humic acids. (3) Hydrofluoric and perchloric acid mixture[11,12] to decompose residual silicates and their lattice constituent elements. The preparing procedure of each fraction was as follows.

Acid-soluble fraction: Accurately weighed 2—3 g of a wet core-sediment (e.g., 2.17 g corresponds to 1.00 g of the sediment on dry basis) was placed in a 50-cm^3 centrifugal tube. Into the tube, 25 cm^3 of 0.1 M hydrochloric acid was added. The tube was then set in a hot water-bath thermostatically controlled at 40 °C, and ultrasonic waves were irradiated into the bath in order to mix and suspend the sediment particles into the acid solution. The

† 1 M=1 mol dm^{-3}.

irradiation time was for 20 min. After centrifuging the tube, the supernatant solution was filtered (filter pore size: 0.45 μm). This filtrate was saved for later analyses. Another aliquot (25 cm^3) of the fresh hydrochloric acid was then added to the residue in the tube. The mixture was again subjected to ultrasonic irradiations. This procedure was repeated five times to perfectly dissolve arsenic and other ions from the sediment.[6]

Alkali-soluble fraction: The alkali-soluble fraction was collected in a similar manner to the acid-soluble fraction. This fractionation procedure was carried out on the residue after the acid leaching.

Silicate fraction: Finally, the residue, after the alkali leaching, was transferred to a Teflon beaker, and decomposed with the mixture of 10 cm^3 of 46% hydrofluoric acid and 2 cm^3 of 60% perchloric acid. The resulting mixture was concentrated under heating until white fumes of the perchloric acid appeared. To decompose some organic compounds in the mixture, 4 cm^3 of 61% nitric acid and 2 cm^3 of 60% perchloric acid were also added, and the new mixture was again concentrated in a similar manner. The resultant solution was diluted to 50 cm^3 with 0.1 M hydrochloric acid.

Results and Discussion

Effect of Leaching Numbers on the Dissolution of Arsenic from Sediments. Figure 1 shows one of the leaching patterns of arsenic by acid- and alkali-leaching. Each shape of the patterns was a log-normal distribution, and so were those of calcium, magnesium, iron, and zinc. Therefore, it was found that these elements were effectively dissolved in the leaching solutions up to No.5.

Vertical Distribution Profiles of Several Sedimental Elements in Acid-Soluble, Alkali-Soluble, and Silicate Fractions. Table 1 summarizes the amount of each element leached out from one gram of dry sediments in each fraction. The value in parentheses represents a dissolved percentage of the element in the sediment (see the calculation formula in the footnotes in Table 1). It is noted in Table 1 that about 63—73% of total calcium went into the acid-soluble fraction throughout the entire core depth, whereas the other alkaline earth metal magnesium, alkali metals sodium and potassium (from other measurements) were poorly dissolved, e.g., 4—7% for magnesium, 0—3% for sodium and potassium. The much dissolution of calcium from the sediment can be explained from a result that the sediment is derived from detritus of rhyolite rocks which surround the reservoir of interest, because the dissolved percentages of calcium and the other elements by acid leaching of the rocks were almost same as those of the sediment.

Figure 2 is drawn from the data of Table 1, and shows the depth distribution pofiles of typical elements, arsenic and metal ions, in the core sediment. It is worth noting that arsenic, copper, zinc, and iron dissolved by the acid leaching were rich in the surface layer of the sediment and were poor in the deeper layers. A similar tendency was found in sulfide content of the sediment (this data is listed in Appendix 1).

Alkali-soluble fractions occupied considerable portions of dissolved percentages of total arsenic, copper, and zinc in the sediment. The percentages for each element were nearly constant for the entire core depth, e.g., at 11—19 μg for arsenic, 11—20 μg for copper, and 10—20 μg for zinc. It is pointed out that arsenic in the alkali-soluble fraction could not be volatilized directly as arsine from the acidified determining solution of the fraction by the addition of tetrahydroborate. Accordingly, the arsenic was determined after wet-ashing with nitric and perchloric acid mixture (see the procedure in silicate fraction of this paper). Thus the arsenic leached in the alkaline solution is probably in some form of organically-complexed arsenic, but not a simple inorganic arsenic.

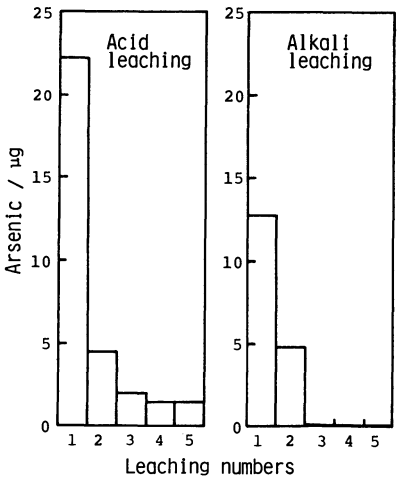

Fig. 1. Leaching patterns of arsenic by acid- and alkali-leaching treatments.
Amounts of arsenic (arsenite + arsenate) indicate to be leached from one gram of dry sediments (the core depth: 1.5—3.5 cm from sediment surface).

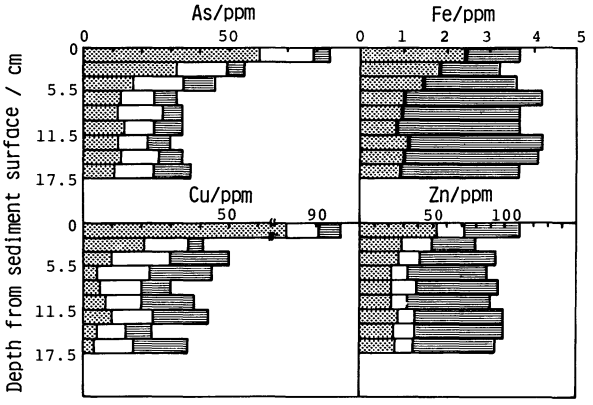

Fig. 2. Vertical distributions of concentrations of arsenic and several elements in sediments.
▨: Acid-soluble fraction, □: Alkali-soluble fraction, ▤: Silicate fraction.
Concentrations of elements in dry sediments.

In silicate fractions, the dissolved percentages of calcium and magnesium were almost constant regardless of the core depth, while those of arsenic, copper, zinc, iron, and manganese increased with the core depth.

Chemical Oxidation State of Arsenic in the Sediment. Figure 3 shows the vertical concentration distributions of arsenate and arsenite in the acid-

a) Sulfide determined as hydrogen sulfide from the sediment.

arsenite but not for arsenate. For example, the coefficients of correlation are 0.96—0.97 for Fe/As (III), Cu/As(III), and S/As(III). From these results the following discussions are made on the chemical oxidation state of arsenic in sediment.

(1) Arsenic exists rich in the surface of the sediment mainly as an arsenite species. This trace arsenite is considered to be fixed with large amounts of iron hydroxide from the following experimental results. (I) There was a good correlation between trace arsenite and large amounts of iron (see Table 2). (II) The vertical distribution curve of arsenite in the acid-soluble fraction was nearly same as that of iron (see Figs. 2 and 3). (III) Arsenite and iron were easily dissolved in the acid-soluble fraction (see Table 1). (IV) Trace arsenite is usually coprecipitated from a neutral solution with iron (III) hydroxide but not with manganese hydroxide. All the manganese in the reservoir was in the form of soluble species and not in colloidal ones such as manganese hydroxide, because the concentration of manganese determined in the water with the addition of hydrochloric acid was equal to that in the same water sample without

the additin of the acid. (V) It is not expected that the trace arsenic is coprecipitated by the formation of aluminum hydroxide, because the concentration of aluminum in the reservoir was extremely lower than that of iron (see Appendix 3).

(2) In deep layers of the sediment, arsenite fixed with iron (III) hydroxide is released from the iron by the reductive dissolution reaction of iron (III) to iron (II). This reaction is considered from the data of a good correlation between arsenite and iron dissolved from the core sediment, shown in Table 2. Similar idea on the dissolution of arsenic from lake sediments has been reported by Nakashima et al.[11] With the dissolution of the iron hydroxide, arsenite will be released from the deeper layer of the sediment to an aqueous phase, and diffuse up to the surface layer of the sediment.

(3) There is another arsenic species leached in alkali-soluble fractions. The color of the alkaline solution was light-brown, and the maximum wavelength in the absorption and fluorescence of the solution were measured respectively to be 470 and 540 nm, which correspond to probably humic acids

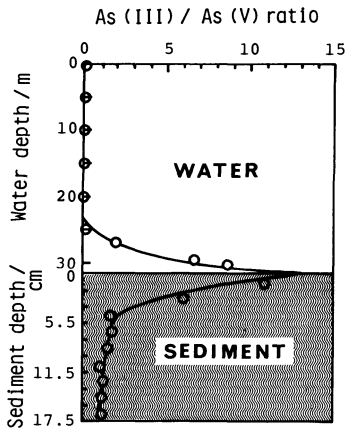

Fig. 4. Concentration ratios of arsenite to arsenate in the reservoir and its bottom sediment.
Data for sedimental arsenic are obtained from acid-soluble fractions.

or derivatives of chlorophylls. The arsenic was not vollatilized directly as arsine from the acidified alkaline solution, as already mentioned above. It can be, therefore, pointed out that the arsenic in the alkaline solution is chemically stable, and is probably organically-complexed or -bonded with

humic acids and their further decompositional products. It is worth noting that a considerable 30—40% of total arsenic content was leached out from the sediment by the alkali leaching.

Arsenite to Arsenate Ratio in Reservoir Water and Its Sediment. Figure 4 shows the ratio of As(III)/As(V) in the reservoir water and its bottom sediment. The concentrations of arsenite and arsenate in the water were quoted from Appendix 3, and those in the sediment were from the acid-soluble fraction shown in Appendix 2. As is seen in Fig. 4, the As(III)/As(V) ratio increased from the water depth of 25 m toward the bottom, which is in line with the decreasing O. R. P. values (see Appendix 3). The As(III)/As(V) in the water and in the sediment indicate a common feature that they reached maxima in the boundary layers between the two phases. On the other hand, the concentration ratio of Fe/As(III) in the bottom water, 370, was nearly equal to that in the surface sediment by acid leaching, 440. It is, therefore, considered that the formation and dissolution of the iron hydroxide coprecipitating arsenite are taking place repeatedly at the boundary layer between the water and the sediment.

The Effect of Tetraalkylammonium Ions on the Distribution of the Silicate Anions in Aqueous Solutions

Isao HASEGAWA, Kazuyuki KURODA, and Chuzo KATO*
Department of Applied Chemistry, School of Science and Engineering, Waseda University, Ohkubo, Shinjuku-ku, Tokyo 160
(Received January 30, 1986)

The effect of the addition of tetramethylammonium, (2-hydroxyethyl)trimethylammonium and benzyltrimethylammonium ions on the distribution of the silicate anions arising from the hydrolysis of tetraethoxysilane was studied by using the trimethylsilylation method. The selective formation of the octameric silicate anion with a double four-membered cage was confirmed in these solutions. It was found that tetraalkylammonium ions with three methyl groups, whether or not the other group was a methyl group, contributed to the formation of a double four-membered cage octamer.

Tetraalkylammonium ions play an important role in the structure formation involved in zeolite syntheses and constitute one of the principal factors controlling the structure of zeolite.[1] These ions also affect the distribution of soluble silicate anions in aqueous solutions. Generally, silicate anions polymerize at random in aqueous solutions; this makes the distribution of the anions very complicated. By adding tetraalkylammonium ions to the systems under appropriate conditions, however, silicate anions with specific structures are formed. In this manner, the formation of silicate species with a double three-membered cage ($Si_6O_{15}^{6-}$), a double four-membered cage ($Si_8O_{20}^{8-}$) and a double five-membered cage ($Si_{10}O_{25}^{10-}$) have been reported.[2-15]

However, several reports have described the effect of the addition of tetraalkylammonium ions with different alkyl groups or other organic cations such as pyridinium ions.[11-15] In those papers, for example, it has been described that the (2-hydroxyethyl)trimethylammonium ion ($N^+(CH_3)_3C_2H_4OH$) contributes to the formation of the double four-membered cage silicate anion (cubic octamer)[11] as well as the tetramethylammonium ion ($N^+(CH_3)_4$). However, it remains obscure why these two tetraalkylammonium ions contribute to the formation of the cubic octamer similarly.

In order to clarify the interaction between tetramethylammonium ions and silicate anions, it is necessary to study the ratio of controlled silicate species quantitatively. Previous studies by Scheler et al.[11-15] only reported the results of the selective formation of silicate anions at a few SiO_2 concentrations and cation/Si ratios by means of ^{29}Si NMR. Therefore, the purpose of this study is to investigate the effect of tetraalkylammonium ions on the silicate anions over a broader range of variable factors (SiO_2 concentration and tetraalkylammonium ion/Si ratio) by means of trimethylsilylation.

Trimethylsilylation, originally applied to silicate minerals and solutions by Lentz,[16] is an effective chemical method for the structure study of silicates[17] as well as ^{29}Si NMR spectroscopy.[18-24] ^{29}Si NMR is an extremely powerful analytical procedure for the study of silicate structure. However, some doubts remain in its quantitative analysis.[24] Trimethylsilylation has the advantage of making it easy to perform quantitative analysis by means of gas chromatography in spite of the limits imposed by the side reactions upon silylation. Although several methods are available according to the silicate samples, the Lentz method is reported to be most favorable for the trimethylsilylation of aqueous silicate solutions;[25] thus, the Lentz method was used in this study.

Experimental

Materials. Tetraethoxysilane (reagent-grade) was used as a silica source. A 10% tetramethylammonium hydroxide aqueous solution, a 50% (2-hydroxyethyl)trimethylammonium hydroxide aqueous solution, and a 40% benzyltrimethylammonium ($N^+(CH_3)_3CH_2C_6H_5$) hydroxide aqueous solution were used as the tetraalkylammonium ions. The sodium hydroxide, concentrated hydrochloric acid, and 2-propanol were all reagent grade. The hexamethyldisiloxane was obtained by the hydrolysis of chlorotrimethylsilane and was distilled once (bp 100—101 °C).

Preparation of Sample Solutions. A fixed amount of tetraethoxysilane was added to a tetraalkylammonium hydroxide solution whose concentration had been adjusted by adding deionized water. The mixture was stirred for 2 d at room temperature to complete the hydrolysis of tetraethoxysilane. In this manner, two series of sample solutions were prepared --- samples with different SiO_2 concentrations at a constant N/Si ratio (molar ratio of tetraalkylammonium ion against silica), which was 1.0, and samples with different N/Si ratios at a constant SiO_2 concentration (1.0 mol dm^{-3}). In the case of the addition of the tetramethylammonium ion, sample solutions of only the former series were prepared because of the low concentration of the tetramethylammonium hydroxide aqueous solution.

In order to compare the effects of tetraalkylammonium ions and those of alkali metal ions, sample solutions with different SiO_2 concentrations at the Na/Si ratio of 1.0, solutions to which the sodium ion had been added, were prepared in the same described above by using a 4 mol dm^{-3} aqueous sodium hydroxide solution.

Trimethylsilylation by the Lentz Method. A 2 cm^3 portion of a sample solution was added to a mixture of concentrated hydrochloric acid (6 cm^3), water (5 cm^3), 2-propanol (12 cm^3), and hexamethyldisiloxane (8 cm^3) which had been stirred for 1 h at room temperature. After the silylation had been completed by stirring the reaction mixture for 1 h at room temperature, the siloxane phase was separated and Amberlyst-15 (cation-exchange resin) was added to complete the trimethylsilylation.

Analytical Procedure. The trimethylsilylated derivatives were analyzed by means of gas-liquid chromatography. Quantitative analysis was performed with respect to SiO_4^{4-}, $Si_2O_7^{6-}$, $Si_3O_{10}^{8-}$, $Si_4O_{12}^{8-}$, and $Si_8O_{20}^{8-}$ by using tetradecane as the internal-standard substance.[26] The results are shown as SiO_2 recovery, which was the proportion of SiO_2 recovered as trimethylsilylated derivatives converted from the SiO_2 component in the starting material. (The ionic charge was omitted for the sake of simplicity in the figures of this report.) The peaks on the chromatograms were identified for the trimethylsilylated derivatives of the monomer, dimer, linear trimer, cyclic tetramer and cubic octamer by means of mass spectrometry. The chromatographic conditions were as follows: Shimadzu GC-8A apparatus, equipped with a hydrogen FID; stainless steel column (length: 6 m, internal diameter: 2.6 mm), packed with OV-17 2% Chromosorb W for 3 m and SE-30 5% Shimalite W for 3 m; oven temperature: 80 °C to 270 °C at 8 °C min^{-1}; injection temperature: 300 °C; carrier gas (nitrogen) flow rate: 50 cm^3 min^{-1}.

Results and Discussion

1. Gas Chromatograms and the Effect of Sodium Ions. Figure 1 shows typical gas chromatograms of trimethylsilylated derivatives of soluble silicate anions in (a) a sodium silicate solution and (b) a tetramethylammonium silicate solution. In the case of the sodium ion, it was found that low-molecular species such as the monomer, dimer, linear trimer, and cyclic tetramer, and also unidentified species with relatively higher molecular weights existed. This means that a random polymerization of the silicate anions occurred in the system. After adding the tetramethylammonium ion under proper conditions, however, a considerably large peak appeared, as is shown in Fig. 1(b). This peak was identified as the cubic octamer. In this way, the selective structure formation of silicate anions in the system is shown on a gas chromatogram, for almost always only one peak appeared: peaks of other species hardly ever appeared.

Figure 2 shows the variation in the silicate-anion distribution with the variation in the SiO_2 concentration at the Na/Si ratio of 1.0. With the increase in the SiO_2 concentration, the recovery of low-molecular species from the monomer to the cyclic tetramer was reduced gradually. This means that these low-molecular species polymerized and that higher molecular species were formed in the system. Although the cubic octamer existed in a small amount (the maximum recovery was 1.3% at the SiO_2 concentration of 0.7 mol dm^{-3}), it occurred in the course of the polymerization of the silicate anions because its recovery was relatively low and its lower recovery was observed in the region of higher SiO_2 concentrations, where polymerization proceeded. Therefore, in the sodium-coexisting system, silicate anions polymerize at random and there is no selective structure formation.

2. Addition of Tetramethylammonium Ions. When tetramethylammonium ions were present in a

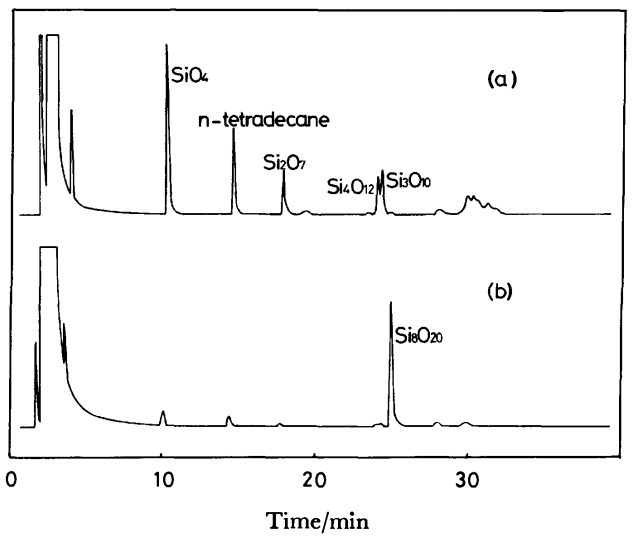

Fig. 1. Gas chromatograms of the trimethylsilylated derivatives of silicate species in (a) sodium silicate solution (Na/Si=1.0, SiO_2 concentration: 0.4 mol dm^{-3}) and (b) tetramethylammonium silicate solution N/Si=1.0, SiO_2 concentration: 0.88 mol dm^{-3}).

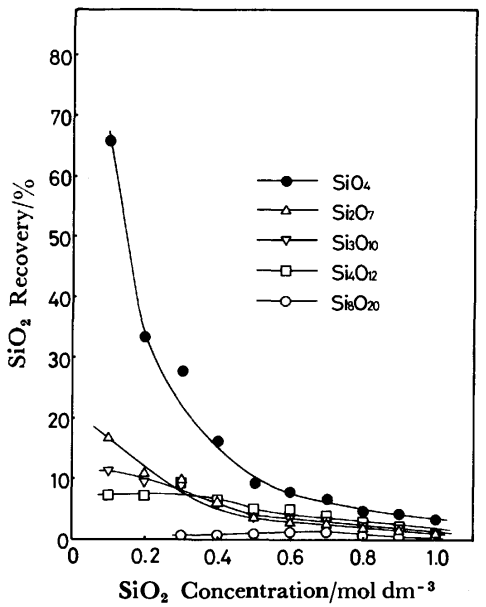

Fig. 2. Variation in the silicate-anion distribution with the SiO_2 concentration (Na/Si=1.0) in sodium silicate solution.

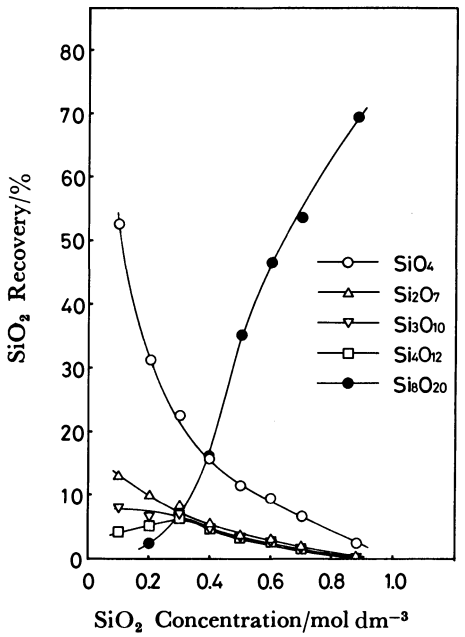

Fig. 3. Variation in the silicate-anion distribution with the SiO_2 concentration (N/Si=1.0) in tetramethylammonium silicate solution.

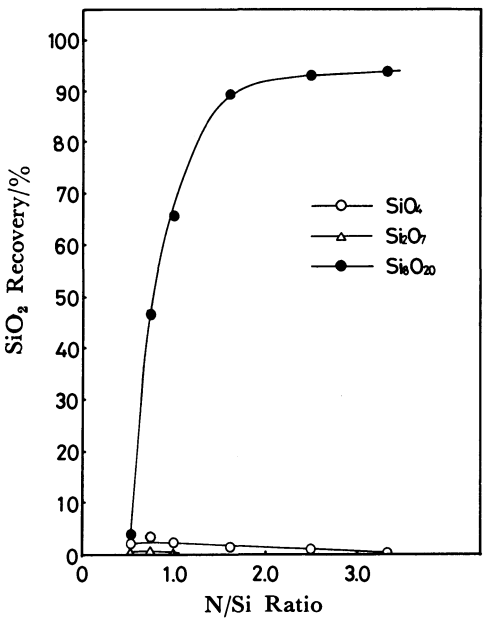

Fig. 4. Variation in the silicate-anion distribution with the N/Si ratio in 1.0 mol dm^{-3} (2-hydroxyethyl)-trimethylammonium silicate solution.

silicate solution, the silicate-anion distribution varied in a different way with the variation in the SiO_2 concentration at the N/Si ratio of 1.0, as is shown in Fig. 3. As the SiO_2 concentration increased, the recovery of low-molecular species from the monomer to the cyclic tetramer decreased. On the other hand, the recovery of the cubic octamer increased rapidly. In comparison with the results obtained from the Na_2O–SiO_2 system, shown in Fig. 2, the behavior of low-molecular species showed a similar tendency. As for the formation of the cubic octamer, however, the behavior was obviously different. This was evidently caused by the difference in the added cations. The selective formation of the cubic octamer has also been observed by Hoebbel et al., who used another silica source,[4] and a similar tendency was confirmed in this study. Thus, upon the addition of tetramethylammonium ions to aqueous silicate solutions, random polymerization did not occur, but a specified silicate skeleton was selectively formed.

3. Addition of (2-Hydroxyethyl)trimethylammonium Ions. In order to clarify the effect of another tetraalkylammonium ion, the (2-hydroxyethyl)trimethylammonium ion was employed initially. When the N/Si ratio was varied in a 1.0 mol dm^{-3} SiO_2 sample solution, the variation in the silicate-anion distribution indicated a highly selective formation of a silicate framework. As Fig. 4 shows, the low-molecular species decreased, and only the cubic octamer was formed singularly, with an increase in the N/Si ratio.

The variation in the silicate-anion distribution with the SiO_2 concentration at the N/Si ratio of 1.0 is

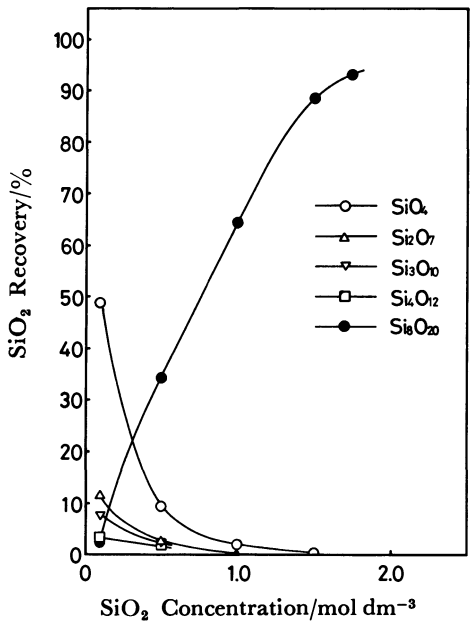

Fig. 5. Variation in the silicate-anion distribution with the SiO_2 concentration (N/Si=1.0) in (2-hydroxyethyl)trimethylammonium silicate solution.

shown in Fig. 5. The cubic octamer was formed singularly at higher SiO_2 concentrations, as was previously shown in the case of the addition of the tetramethylammonium ion. In (2-hydroxyethyl)trimethylammonium silicate solutions whose N/Si ratios were 1.0 and 2.0, the singular formation of the cubic octamer in both solutions was confirmed by Scheler et al.[11] using ^{29}Si NMR. Although the SiO_2 concentration in this work was different from that in

the earlier report, there was yet a pronounced difference in the recovery of the cubic octamer between the N/Si ratios of 1.0 and 2.0. When trimethylsilylation is used as an analytical tool, it is impossible to obtain trimethylsilylated derivatives which reflect the original distribution of the silicate anions completely, as side reactions necessarily occur. Nevertheless, the fact that the cubic octamer was recovered in a yield of ca. 90% means that virtually only the cubic octamer existed.

4. Addition of Benzyltrimethylammonium Ions. The effect of tetraalkylammonium ions with a different alkyl group was investigated by the use of benzyltrimethylammonium ion as well as (2-hydroxyethyl)trimethylammonium ions. Figure 6 shows the variation in the silicate-anion distribution with the N/Si ratio in a 1.0 mol dm^{-3} sample solution, while Fig. 7 shows the variation in the SiO_2 concentration at the N/Si ratio of 1.0. In the two cases, similar tendencies were recognized, and in both, singularly the cubic octamer was also formed. Thus, it was found that benzyltrimethylammonium ions also contributed to the formation of the cubic octamer.

From these results, it was obvious that a tetraalkylammonium ion with three methyl groups could contribute to the selective formation of the cubic octamer, even if one of the four alkyl groups was not a methyl group but was either hydrophilic or hydrophobic.

As for the structure of crystalline tetramethylammonium silicate ($Si_8O_{20}(N(CH_3)_4)_8$), a detailed structure study by means of X-ray diffraction analysis was performed by Smolin et al.[27] It remains obscure, however, how the tetramethylammonium ion contributes to the selective formation of the cubic octamer in an aqueous silicate solution. Also, several investigators have reported that the formation of silicate species with cage-like structures was affected by the structure of the tetraalkylammonium ions.[2-9] As compared with those reports, we ourselves have found that the interaction of silicate anions and tetraalkylammonium ions is not influenced by a bulky group such as the benzyl group during the selective formation and that only three methyl groups are essential for the formation of the cubic octamer, even if the other alkyl group was hydrophilic or hydrophobic. From the results in this study, it was concluded that not all four methyl groups in a tetramethylammonium ion always contribute to the selective structure formation.

The application of the trimethylsilylation technique to the early stages of the hydrolysis of tetraethoxysilane would be useful for a better understanding of this system, which requires further study.

This work was supported by the Yazaki Memorial Foundation for Science And Technology, for which help grateful acknowledgement was made.

An EXAFS Investigation of the Coordination Structure of Copper(II) Ions in Aqueous $Cu(ClO_4)_2$ and Methanolic $CuCl_2$ Solutions

Yoshichika TAJIRI and Hisanobu WAKITA*
Department of Chemistry, Faculty of Science, Fukuoka University,

(Received February 5, 1986)

The coordination structure of copper(II) ions in aqueous and methanolic solutions was investigated by means of EXAFS spectroscopy. The hexaaquacopper(II) complex in the aqueous $Cu(ClO_4)_2$ solution had an elongated octahedral structure, with four equatorial distances of 2.00 Å and two axial distances of 2.28 Å. Scarcely no axial interaction has been seen in the radial-distribution curve after the Fourier transform of the EXAFS spectrum, for the real and imaginary parts of the Fourier transformed function for the axial interactions are diminished by the interference of those for the equatorial interactions. Two distances for the equatorial interactions of the mixed-ligand chlorocopper(II) complexes in the methanolic $CuCl_2$ solution were clearly resolvable in the radial-distribution curve; they were 2.00 Å and 2.22 Å for the Cu–O and Cu–Cl interactions respectively.

Both EXAFS and X-ray diffraction methods have been used in the structural studies of metal complexes in solution.[1–10] A number of X-ray-diffraction studies have established the elongated octahedral structure of six-coordinated copper(II) complexes in solution.[1–3,7–9] However, only a few EXAFS studies[4,5] have been performed to determine the axial interaction of the octahedral structure in solution.

X-Ray-diffraction investigations have shown that the hexaaquacopper(II) complex in 1.94—3.55 mol dm^{-3} aqueous $Cu(ClO_4)_2$[1,2] and 1.386 mol dm^{-3} aqueous $CuSO_4$[3] solutions has an elongated octahedral structure with four equatorial bonds of 1.94—1.98 Å and two axial bonds of 2.34—2.43 Å, because there exist peaks caused by the $Cu-O_{eq}$ (equatorial) and $Cu-O_{ax}$ (axial) bonds in the radial-distribution function, $D(r)$.

According to Sham et al.,[4] who analyzed the EXAFS spectrum of the K-edge of copper in a 1 mol dm^{-3} aqueous $Cu(ClO_4)_2$ solution, the extremely large values of the axial distance (2.60 Å) and the Debye–Waller factor (0.12 Å) suggested that the axial ligands were loosly bonded. Sano et al.[5] mentioned, in their EXAFS study of a 0.32 mol dm^{-3} aqueous $Cu(ClO_4)_2$ solution, but without detailed analysis, that the second peak appearing at 2.46 Å in the radial-distribution curve corresponds to the $Cu-O_{ax}$ interaction.

X-Ray-diffraction studies of a 2.952 mol dm^{-3} aqueous $CuCl_2$ solution[7] and a 1.016—4.364 mol dm^{-3} aqueous $CuBr_2$ solution[8] disclosed that mixed-ligand six-coordinated aquahalogenocopper(II) complexes had elongated octahedral structures with four bonds including both $Cu-X_{eq}$ (X=Cl,Br) and $Cu-O_{eq}$ and two $Cu-O_{ax}$ bonds, although the peak due to the $Cu-O_{ax}$ bonds did not appear as a separate one. Moreover, 1.055—2.350 mol dm^{-3} methanolic $CuCl_2$ solutions[9] included nearly equivalent amounts of three copper(II) complexes, $[CuCl_n(CH_3OH)_{6-n}]$, where n=1, 2, and 3, although the peaks caused by the $Cu-O_{eq}$, $Cu-Cl_{eq}$, and $Cu-O_{ax}$ bonds overlapped with each other.

Thus far no elongated octahedral structure of aquahalogenocopper(II) complexes in solution has been reported on the basis of EXAFS spectroscopy.[10]

From the consideration of the investigations described above, it seemed that it would be of interest to examine whether or not the EXAFS spectroscopy is able to "see" the axial interaction of the six-coordinated octahedral copper(II) complexes in solution. In the present paper, we attempt to analyze the structures of the copper(II) complexes in 1.019 mol dm^{-3} aqueous $Cu(ClO_4)_2$ and 0.996 mol dm^{-3} methanolic $CuCl_2$ solutions for the purpose of seeing the axial interaction by means of EXAFS spectroscopy. In order to obtain detailed information on the structure, the EXAFS data were analyzed by using not only a conventional curve-fitting method, but also the radial-distribution method to be described in the following Experimental section. The radial-distribution method used in an EXAFS study of a rhodium catalyst by Koningsberger et al.[11] seemed suitable for the analysis of the present EXAFS data, where the interatomic distances are close to each other.

Experimental

EXAFS Measurements. The EXAFS measurements were carried out by the use of synchrotron radiation using the EXAFS facilities at BL-10B of the Photon Factory in the National Laboratory for High-Energy Physics (KEK-PF). The data were collected in the range from ca. 400 eV on the lower-energy side of the Cu absorption K-edge of 8981.83 eV (λ=1.3804 Å) to ca. 1600 eV on the higher-energy side; the time for the data collection was fixed at 1 s at each measuring point.

The reference compounds, bis(acetylacetonato)copper(II) and tetramethylammonium tetrachlorocuprate(II), were prepared by the conventional methods, powdered with an agate mortar, and pressed with polyethylene powder into

films.

An 1.019 mol dm^{-3} aqueous copper(II) perchlorate solution was prepared by dissolving the copper(II) perchlorate in distilled water, which had been obtained by the reaction of copper(II) oxide with a hot perchloric acid solution and recrystallized three times from distilled water. A 0.996 mol dm^{-3} methanolic copper(II) chloride solution was prepared by dissolving copper(II) chloride crystals in absolute methanol. The concentrations of the copper(II) ion in the sample solutions were determined by the EDTA titration method. Each solution sample was put into a polyethylene pouch sandwiched by a polyacrylate holder.

Data Reduction Procedure. The EXAFS spectrum which is extracted from the observed absorption spectrum is expressed by:

$$\chi_{obsd}(k) = [\mu_{obsd}(k) - \mu_0(k)]/\mu_0(k), \quad (1)$$

where $\mu_{obsd}(k)$ is the absorption coefficient, attributed only to the K-edge of the absorption atom and where $\mu_0(k)$ is the smoothly varying background absorption coefficient, approximated by a cubic spline function.[12] k is the photoelectron wave-number and is given as $\sqrt{2m(E-E_0-\Delta E)/h^2}$, where E denotes the energy of the incident X-ray; E_0 is the theoretical energy at the absorption edge for the absorption atom, and ΔE is the correction value for the E_0 value at the absorption edge.

Analysis by the Curve-Fitting Method. The EXAFS spectrum, weighted by k^3, is converted by the Fourier transform into the Fourier transformed function, $F(r)$, in the r-space as:

$$F(r) = \int_{k_{min}}^{k_{max}} k^3 \cdot \chi_{obsd}(k) \cdot \exp(2ikr)dk = ReF(r) + iImF(r). \quad (2)$$

Moreover, the radial distribution function, $|F(r)|$, is given as:

$$|F(r)| = [ReF(r)^2 + ImF(r)^2]^{1/2}, \quad (3)$$

where $ReF(r)$ and $ImF(r)$ are the real and imaginary parts of the $F(r)$ function respectively. The structure parameters (interatomic distances, mean-square displacements, and coordination numbers) are obtained by comparing the Fourier filtered EXAFS spectrum, $\overline{\chi}(k)$, with the calculated EXAFS spectrum, $\chi_{calcd}(k)$. $\overline{\chi}(k)$ is obtained by performing the Fourier backfiltering of the peak in the $|F(r)|$ curve into the EXAFS spectrum in the k-space, while $\chi_{calcd}(k)$ is given by the single-scattering theory[13] as:

$$\chi_{calcd}(k) = \sum_j [N_j/(k \cdot R_j^2)] \cdot |f_j(\pi, k)| \cdot \sin(2kR_j + \phi_j(k)) \cdot \exp(-2R_j/\gamma) \cdot \exp(-2\sigma_j^2 k^2), \quad (4)$$

where R_j and N_j are the distance from the absorbing atom to the j-th coordination shell and the number of atoms at R_j respectively, where σ_j^2 is the mean square displacement[14] of R_j, and γ is the mean free path. $|f_j(\pi,k)|$ and $\phi_j(k)$ are the backscattering amplitude and the phase shift of the atoms in the j-th backscattering shell respectively. A curve fitting is applied to minimize the error-square sum, U ($=\sum[k^3 \cdot \overline{\chi}(k) - k^3 \cdot \chi_{calcd}(k)]^2$).

Analysis by the Radial-Distribution Method. The analysis of this method[11] is performed by using the Fourier transformed function, $F'(r)$, which is corrected for the phase shift and the backscattering amplitude as:

$$F'(r) = \int_{k_{min}}^{k_{max}} [k \cdot \chi(k)/|f(\pi, k)|] \cdot \exp(2ikr + \phi(k))dk = ReF'(r) + iImF'(r), \quad (5)$$

and using the radial-distribution function, $|F'(r)|$, given as:

$$|F'(r)| = [ReF'(r)^2 + ImF'(r)^2]^{1/2}. \quad (6)$$

The optimal values of the structure parameters are obtained by comparing the peak in the calculated $|F'(r)|$ curve with that in the observed $|F'(r)|$ curve in order to minimize the disagreement of the peak-height, -width, and -position. The calculated $|F'(r)|$ curve is obtained from $\chi_{calcd}(k)$ by the Fourier transform according to Eqs. 5 and 6, where $\chi_{calcd}(k)$ is given by substituting j (=1), γ (the initial value in the present paper, 5.0), and the initial values of the structure parameters (taken from the literature) in Eq. 4. The γ, N, R, and σ^2 parameters are allowed to vary at intervals of 0.02, 0.01, 0.001 Å, and 0.0001 Å^2 respectively.

If the EXAFS spectrum comes from one interaction, the peak in the $|F'(r)|$ curve as corrected for the phase shift and backscattering amplitude of the interaction, should coincide in position with the maximum peak in the $ImF'(r)$ oscillation.[12,15] In addition, the main peak in the $|F'(r)|$ curve and the $ImF'(r)$ oscillation should be almost symmetrical with respect to the ordinate at the position of the coincidence.[15] On the other hand, if the $|F'(r)|$ curve is inappropriately corrected for the phase shift and backscattering amplitude by taking an improper interaction into consideration, the maximum peak in the $ImF'(r)$ oscillation can not coincide in position with that in the $|F'(r)|$ curve. If the EXAFS spectrum arises from two interactions or more, the $ImF'(r)$ oscillation can be asymmetrical with respect to the ordinate around the maximum peak. The analysis of the peaks in the $|F'(r)|$ curve is as follows. The first step is to estimate the values of the structure parameters of one interaction which peaks more clearly than the other interactions in the $|F'(r)|$ curve. The next step is to subtract the $\chi_{calcd}(k)$ spectrum from the $\chi_{obsd}(k)$ spectrum. This subtraction gives the residual EXAFS spectrum, $\chi_{res}(k)$, in which the contribution of other interactions is included. Then, the third step is to analyze the peak in the $|F'(r)|$ curve of the $\chi_{res}(k)$ in a way similar to that described above by but using another set of structural parameters for an additional interaction in order to obtain the best-fit function of $\chi'_{calcd}(k)$. If a difference between the peak in the $|F'(r)|$ of the $\chi_{res}(k)$ and that of the $\chi'_{calcd}(k)$ still remains, the analysis should be repeated in a similar way by assuming further interactions.

The curve-fitting method is carried out by comparing the $\overline{\chi}(k)$ with the $\chi_{calcd}(k)$ spectra in the k-space; it needs an additional Fourier backfiltering of the peak in the $|F(r)|$ curve. On the other hand, the radial-distribution method compares the observed $|F'(r)|$ value with the calculated $|F'(r)|$ curves in the r-space and necessitates a Fourier transform of the $\chi_{calcd}(k)$. Theoretically, therefore, the two methods should give equivalent results.

Results and Discussion

Reference Compounds. The analysis of the EXAFS data makes it necessary to estimate the phase shift and the backscattering amplitude. In the present study, the phase shift and the backscattering amplitude are determined experimentally by the use of approximated equations.[16,17] The EXAFS spectra of two reference compounds, powdered $Cu(acac)_2$ (acac = acetylacetonate ion) and $[(CH_3)_4N]_2[CuCl_4]$ crystals, with known structures[18,19] were measured in order to estimate the phase shifts and backscattering amplitudes of the copper-oxygen and copper-chlorine interactions. The EXAFS spectrum, $k^3 \cdot \chi_{obsd}(k)$, and the radial distribution curve, $|F(r)|$, for the $Cu(acac)_2$ crystal are shown in Figs. 1-A and 1-B, and those for the $[(CH_3)_4N]_2[CuCl_4]$ crystal, in Figs. 1-C and 1-D. Judging from the crystal structures of these two reference compounds, we considered that the first peak in Figs. 1-B and 1-D corresponds to the first backscattering shell around the Cu^{2+} ion. Therefore, the first peak at 1.56 Å in Fig. 1-B is attributed to the interaction between copper and oxygen atoms within coordinated acetylacetonate ions,[18] while the first peak at 1.86 Å in Fig. 1-D is ascribed to the interaction between copper and chlorine atoms.[19] Performing the Fourier backfiltering over the region of the first peak in each $|F(r)|$ curve, we carried out the curve-fitting in order to obtain the phase shifts and backscattering amplitudes, using known coordination numbers and bond distances. The ΔE and γ values were fixed at 0.0 eV and 5.0 respectively, while σ^2 was allowed to vary. The crystallographic data and Fourier transform range of the reference compounds are summarized in Table 1.

Aqueous $Cu(ClO_4)_2$ Solution. The $k^3 \cdot \chi_{obsd}(k)$ spectrum and the $|F(r)|$ curve for the aqueous $Cu(ClO_4)_2$ solution are depicted in Figs. 2-A and 2-B respectively. The clear peak at 1.6 Å in the $|F(r)|$ curve can be attributed to the interaction between copper and water oxygen atoms at the equatorial site, for the first shell around the Cu^{2+} ion in this solution corresponds to the $Cu-O_{eq}$ interaction, judging from the results of X-ray diffraction.[1,2] The difference in value between the peak position in the $|F(r)|$ curve and the bond distance of the $Cu-O_{eq}$ obtained by X-ray diffraction[1] (1.94 Å) is −0.34 Å. If we use this value as the correction value for the peak position in the $|F(r)|$ curve, a peak due to the interaction between copper and water oxygen atoms at the axial site (2.43 Å, from X-ray diffraction[1]) should appear at 2.09 Å in the $|F(r)|$ curve. However, the peak found at ca. 2.1 Å is too small to be attributed to the $Cu-O_{ax}$ interaction. If the peak due to the $Cu-O_{ax}$ interaction

Table 1. Crystallographic Data and Ranges of Fourier Transforms of the Reference Compounds

Sample	k_1-range	r-range	k_2-range	N_{ref}	R_{ref}
$Cu(acac)_2$	3.0—17.0	0.80—1.90	4.5—16.0	4.0	1.95
$[(CH_3)_4N]_2[CuCl_4]$	3.0—18.0	1.11—2.22	4.5—15.0	4.0	2.22

k_1-range: the range of the Fourier transform, $Å^{-1}$; r-range: the range of the Fourier backfiltering, Å; k_2-range: the range of the curve-fitting, $Å^{-1}$; N_{ref}: coordination number; R_{ref}: interatomic distance, Å.

is small and widespread in the r-space, the peaks caused by the Cu–O_{eq} and Cu–O_{ax} interactions might not be clearly resolvable in the $|F(r)|$ curve because the bond distances of the two interactions are too close to each other. On the basis of this consideration, the curve-fitting analysis of the EXAFS data of this solution was carried out in the following way.

Performing the Fourier backfiltering over the region around the first peak (from 0.93 Å to 2.69 Å) in the $|F(r)|$ curve, we carried out the curve-fitting analysis by assuming two models; one corresponds to a two-shell model which has a six-coordinated elongated octahedral structure, as has been proposed on the basis of the results of X-ray diffraction,[1,2] while the other corresponds to a one-shell model which has a square-planar structure with four Cu–O_{eq} interatomic distances. In the course of the curve-fitting analysis, the coordination numbers were fixed at 4 for the one-shell model and at 6 (N_{eq}=4, N_{ax}=2) for the two-shell model; ΔE was also fixed at 0.0 eV. On the other hand, the γ value was allowed to vary. The γ value thus obtained changed from 5.0 (which was initially determined by the use of the $Cu(acac)_2$ crystal) to 5.4. The results of the curve-fitting analysis are listed in Table 2. The value of the error-square sum obtained from the two-shell model (7.74) is smaller than that from the one-shell model (24.08). As seen in Table 2, the interatomic distances for the Cu–O_{eq} and Cu–O_{ax} interactions obtained from the two-shell model are 2.00 Å and 2.28 Å respectively; these values are slightly different from those of the results reported by Ohtaki et al.,[1] but almost identical with those reported by Magini.[2] The difference in interatomic distance between the X-ray diffraction studies and our EXAFS data analysis may result from the uncertainties in the backscattering amplitude and phase shift used and those in the EXAFS data. The σ^2 values of the Cu–O_{eq} and Cu–O_{ax} interactions obtained are 0.0036 Å^2 and 0.0105 Å^2 respectively; they are in good agreement with the results obtained by the X-ray diffraction method.[1,14] According to the results reported by Sham et al.,[4] the interatomic distance of the Cu–O_{ax} interaction and the $[\sigma_{ax}^2/\sigma_{eq}^2]$ ratio are 2.60 Å and ca. 10 respectively. These values may be too large compared to the maxima values of the X-ray-diffraction studies (2.5 Å for the interatomic distance of the Cu–O_{ax} interaction[20] and ca. 6.5 for the $[b_{ax}/b_{eq}]$ ratio).[2,14] If the structure parameters obtained by the EXAFS method have the same quality as those obtained by the X-ray-diffraction method, the values obtained by the two methods should be close to each other.

By the theoretical calculation of the $|F(r)|$ curve for the Cu–O_{ax} interaction, which was performed independently of that for the Cu–O_{eq} interaction, the Cu–O_{ax} interaction gave a clear peak in the $|F(r)|$ curve different from that in the observed $|F(r)|$ curve. In the next step, therefore, we performed the radial-distribution analysis of the peaks in the radial-distribution curve in order to examine why the peak due to the Cu–O_{ax} interaction is scarcely seen in the curve and to reconfirm the presence of the peak. Instead of the $|F(r)|$ curve, the $|F'(r)|$ curve was used for the radial-distribution method, which was corrected for the phase shift and the backscattering amplitude. In the course of the radial-distribution analysis, the N_{eq} of the Cu–O_{eq} interaction was fixed at 4, while the γ, R_{eq}, and σ_{eq}^2 values of the Cu–O_{eq} interaction were allowed to vary simultaneously. The optimal γ value thus obtained was 5.4, in good agreement with that obtained by the curve-fitting method. The initial values of the Cu–O_{eq} interaction were 1.94 Å for R_{eq} and 0.004 Å^2 for σ_{eq}^2.

In Figs. 3-A and 3-B, the solid lines show the $|F'(r)|$ curve and the $ImF'(r)$ oscillation respectively. The peak caused by the Cu–O_{ax} interaction is scarcely seen at all in Fig. 3-A. In Fig. 3-B, the $ImF'(r)$ oscillation is slightly asymmetrical along the axis passing through the maximum peak at ca. 2.0 Å; that is, the

A: $|F'(r)|$ of the $\chi_{obsd}(k)$ (solid line), the $\chi_{calcd}(k)$ of the $Cu-O_{eq}$ interaction (dotted line). B: $ImF'(r)$ of the $\chi_{obsd}(k)$. C: $|F'(r)|$ of the $\chi_{res}(k)$ (solid line), the $\chi_{calcd}(k)$ of the $Cu-O_{ax}$ interaction (dotted line). D: $ImF'(r)$ of the $\chi_{res}(k)$.

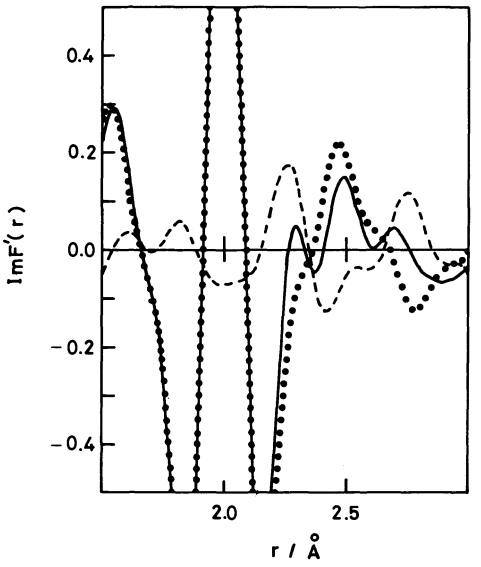

Fig. 4. The imaginary part, $ImF'(r)$ of the corrected Fourier transformed function for the aqueous $Cu(ClO_4)_2$ solution. The $ImF'(r)$ of the $\chi_{obsd}(k)$ (solid line), the $\chi_{calcd}(k)$ of the $Cu-O_{eq}$ interaction (dotted line), and the $\chi_{res}(k)$ (dashed line).

height of the peak at ca. 2.3 Å is lower than that of the peak at ca. 1.6 Å. In Fig. 3-A, the dotted line depicts the $|F'(r)|$ curve of the $\chi_{calcd}(k)$ calculated from the optimal values of the structure parameters of the $Cu-O_{eq}$ interaction. These optimal values were obtained in the r-range below about 2.0 Å in the way described in the Experimental section. When the $|F'(r)|$ curve of the $\chi_{obsd}(k)$ is compared with that of the $\chi_{calcd}(k)$, a small but clear difference is seen at ca. 2.3 Å. To analyze this difference, the residual EXAFS spectrum, $\chi_{res}(k)$, was obtained by subtracting the $\chi_{calcd}(k)$ due to the $Cu-O_{eq}$ interaction from the $\chi_{obsd}(k)$. In Figs. 3-C and 3-D, the solid lines show the $|F'(r)|$ curve and the $ImF'(r)$ oscillation of the $\chi_{res}(k)$ respectively. As the maximum peak of the $ImF'(r)$ oscillation in Fig. 3-D coincided in position with the peak in the $|F'(r)|$ curve in Fig. 3-C, the peak at ca. 2.3 Å can be ascribed to the copper-oxygen interaction. Moreover, from the analysis of this peak, we concluded that this peak was caused by the $Cu-O_{ax}$ interaction, for the coordination number obtained was about 2. Here, the initial values for N_{ax}, R_{ax}, and σ_{ax}^2 were 2, 2.43 Å, and 0.01 Å^2 respectively; they were allowed to vary simultaneously, while γ was fixed at 5.4. In Fig. 3-C, the dotted line shows the $|F'(r)|$ curve of the $\chi_{calcd}(k)$ of the $Cu-O_{ax}$ interaction. The parameter values of this interaction were obtained in the r-range below about 3.0 Å. The results of the radial-distribution method are listed in Table 2. The structure parameters obtained by this method are in good agreement with those obtained by means of the curve-fitting method.

The results of the radial-distribution method were as follows: in the case of the EXAFS spectrum corresponding to two interactions or more, the observed $ImF'(r)$ (or $ReF'(r)$) is the sum of all the $ImF'(r)$ (or $ReF'(r)$) values. If an EXAFS spectrum comes from two interactions, and if the $ImF'(r)$ oscillation due to one interaction has a sign opposite from that of the other interaction at the position of the maximum peak in the latter $ImF'(r)$ oscillation, the latter $ImF'(r)$ oscillation is reduced by the former one. Figure 4 shows the $ImF'(r)$ oscillations of the $\chi_{obsd}(k)$ (solid line), the $\chi_{calcd}(k)$ of the $Cu-O_{eq}$ interaction (dotted line),[15] and the $\chi_{res}(k)$ (dashed line). At ca. 2.3 Å, the dashed line depicts a larger positive peak than that of the solid line, for the dashed line was obtained by subtracting the dotted line (largely negative) from the solid line (barely positive). From a comparison of the $ImF'(r)$ oscillations, we can conclude that the $ImF'(r)$ oscillation due to the $Cu-O_{ax}$ interaction is diminished at the position of the peak due to the $Cu-O_{ax}$ interaction in the radial-distribution curve by the interference of the $ImF'(r)$ oscillation due to the $Cu-O_{eq}$ interaction; consequently, the peak caused by the $Cu-O_{ax}$ interaction can scarcely be seen in the radial-distribution curve.

Methanolic $CuCl_2$ Solution. The $k^3 \cdot \chi_{obsd}(k)$ value and the $|F(r)|$ curve for the 0.996 mol dm^{-3} methanolic $CuCl_2$ solution are shown in Figs. 2-C and 2-D

respectively. According to the results of an X-ray-diffraction study of the methanolic $CuCl_2$ solution,[9] the interatomic distances of the Cu–O_{eq}, Cu–Cl_{eq}, and Cu–O_{ax} interactions are very similar; hence, the corresponding peaks overlap with one another in the radial-distribution function, $D(r)$. However, the $|F(r)|$ curve for the methanolic $CuCl_2$ solution seems to show a double peak in Fig. 2-D. When two back-scattering shells consist of the same number of atoms, but of different kinds, these two distinct absorber-scatterer distances should be resolvable in the $|F(r)|$ curve as separate peaks. Therefore, the peak at ca. 1.9 Å can be attributed to the Cu–Cl interaction, because the position of this peak is close to that in the reference $[(CH_3)_4N]_2[CuCl_4]$ crystal (1.86 Å). Moreover, the shoulder at ca. 1.6 Å of this double peak may be ascribed to the interaction between copper and methanol oxygen atoms at the equatorial site, because the position of this shoulder is close to that in the reference $Cu(acac)_2$ crystal. Similarly to the aqueous $Cu(ClO_4)_2$ solution, the peak due to the Cu–O_{ax} interaction in this solution could scarcely be seen in the $|F(r)|$ curve as a separate peak. Therefore, performing the Fourier backfiltering over the region around this double peak (from 0.95 Å to 3.00 Å), we carried out the curve-fitting analysis by assuming two models; one was a three-shell model which had the same six-coordinated elongated octahedral structure as the results of the X-ray diffraction investigation,[9] while the other was a two-shell model which had a four-coordinated structure with two Cu–O and two Cu–Cl interatomic distances. In the course of the curve fitting, the coordination numbers for those interactions were fixed at 2. The results of the curve-fitting analysis are listed in Table 2. As may be seen in Table 2, the curve-fitting analysis of these two models gave similar error-square sums. Therefore, at this step, we could not conclude whether or not the average structure of the mixed-ligand copper(II) complexes in this solution was an elongated octahedron. The radial-distribution method was, therefore, used for the analysis of this solution.

In the course of the radial-distribution analysis, the coordination numbers for both Cu–O_{eq} and Cu–Cl_{eq} interactions were fixed at 2, while the γ, R, and σ^2 values for each interaction were allowed to vary. The initial values of the Cu–Cl_{eq} interaction were 2.22 Å for R and 0.006 Å^2 for σ^2. In Figs. 5-A and 5-B, the solid lines show the $|F'(r)|$ curve and the $ImF'(r)$ oscillation of the $\chi_{obsd}(k)$ value respectively. The γ value changed from 5.0 (initially determined by the $[(CH_3)_4N]_2[CuCl_4]$ crystal) to 5.4. The Cu–O_{eq} bond length may differ by only ca. 0.2 Å from the Cu–Cl_{eq} one, and the Cu–Cl_{eq} and Cu–O_{ax} interatomic distances are very close to each other; therefore, we first estimated the structure parameters for the Cu–Cl_{eq} interaction because the peak due to the

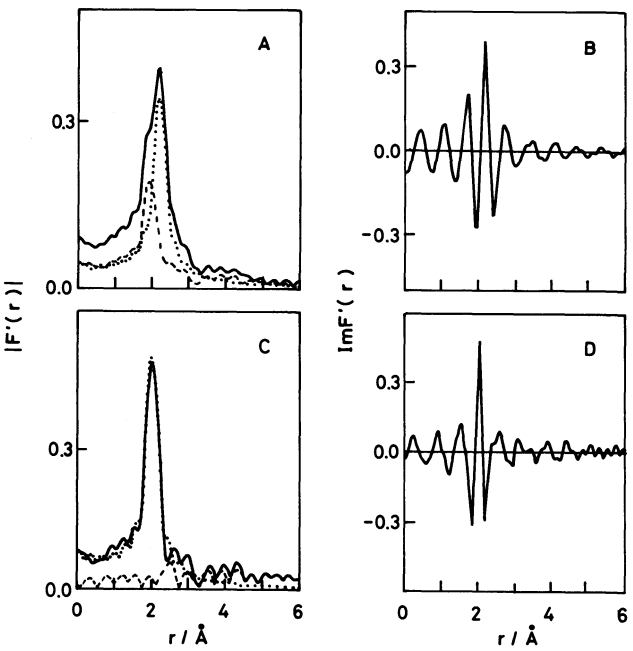

Fig. 5. The corrected radial distribution curves, $|F'(r)|$ and the imaginary parts, $ImF'(r)$ for the methanolic $CuCl_2$ solution. A: $|F'(r)|$ of the $\chi_{obsd}(k)$ (solid line), the $\chi_{calcd}(k)$ of the Cu–Cl_{eq} interaction (dotted line), and the $\chi_{res}(k)$ (dashed line). B: $ImF'(r)$ of the $\chi_{obsd}(k)$. C: $|F'(r)|$ of the $\chi_{res}(k)$ (solid line), the $\chi_{calcd}(k)$ of the Cu–O_{eq} interaction (dotted line), and the $\chi_{rem}(k)$ (dashed line). D: $ImF'(r)$ of the $\chi_{res}(k)$.

Cu–Cl_{eq} interaction was larger and clearer than those due to other interactions. Figure 5-A shows the $|F'(r)|$ curves of the $\chi_{calcd}(k)$ of Cu–Cl_{eq} interaction (dotted line) and the $\chi_{res}(k)$ (dashed line). The structural parameter values of the Cu–Cl_{eq} interaction were obtained in the r-range from ca. 2.0 Å to ca. 3.0 Å. In the $|F'(r)|$ curve of the $\chi_{res}(k)$, there existed a clear peak at ca. 2.0 Å (dashed line). From the value of this peak-position, the main contribution to this peak can be attributed to the Cu–O_{eq} interaction. Therefore, the initial values for the analysis of this peak were 1.95 Å for R and 0.004 Å^2 for σ^2. The γ value was fixed at 5.4, while R and σ^2 were allowed to vary. Figures 5-C and 5-D depict the $|F'(r)|$ curve (solid line) and the $ImF'(r)$ oscillation of the $\chi_{res}(k)$ value respectively. In Fig. 5-C, the dotted line shows the $|F'(r)|$ curve of the $\chi_{calcd}(k)$ of Cu–O_{eq} interaction, while the dashed line shows that of the remaining EXAFS spectrum, $\chi_{rem}(k)$, which is yielded by subtracting the $\chi_{calcd}(k)$ of the Cu–O_{eq} interaction from the $\chi_{res}(k)$ value. The parameter values of the Cu–O_{eq} interaction were obtained in the r-range below about 2.0 Å. A small peak around 2.4 Å in the $|F'(r)|$ curve of the $\chi_{rem}(k)$ was analyzed using the initial values of N(=2), R(=2.4 Å), and σ^2(=0.01 Å^2), where γ was fixed at 5.4, while N, R, and σ^2 were allowed to vary. The coordination number obtained

from this analysis (in the r-range from 2.2 Å to 2.6 Å) was not more than 0.3; therefore, we could not conclude that this small peak is caused by the $Cu-O_{ax}$ interaction. The results of the radial-distribution method are listed in Table 2, without the values of the $Cu-O_{ax}$ interaction.

The results obtained by the use of this method for the equatorial interactions are in good agreement with those obtained by the use of the curve-fitting method, and the values of the structure parameters obtained from both methods support well those of the X-ray diffraction study.[9] However, neither method showed any clear evidence of the $Cu-O_{ax}$ interactions of the mixed-ligand chlorocopper(II) complexes in this solution, in contrast to that of the hexaaquacopper(II) complex in the aqueous $Cu(ClO_4)_2$ solution; therefore, we could not determine whether or not the average structure of the copper(II) complexes in this solution is an elongated octahedron. Presumably, this fact results from the $Cu-Cl_{eq}$ bond length in this solution, which is very close to the $Cu-O_{ax}$ bond length, also, the former bond contributes to a large extent to the EXAFS spectrum, while the $Cu-O_{ax}$ interactions in this solution contribute to the spectrum to only a small extent. Accordingly, it might be difficult to analyze such a small contribution as that of the $Cu-O_{ax}$ interaction in this solution by means of the radial-distribution method, because the estimated errors for the structure parameters, i.e., N, R, and σ^2, of an interaction increase with an increase in the number of peaks caused by other interactions which should be subtracted.

The present EXAFS data analyses by using both methods gave similar results. The radial-distribution method is able to show an anticipated and clear peak in the $|F'(r)|$ curve as evidence of the interaction, which is diminished by the interference of other interactions. Consequently, a combined use of these two methods seems useful for further EXAFS analysis.

Sham et al.[4] explained that the diminishment of the peak due to the $Cu-O_{ax}$ interaction in an aqueous $Cu(ClO_4)_2$ solution results from the interaction having a large σ value. However, a preferable explanation may be that the diminishment of the peak due to the $Cu-O_{ax}$ interaction is caused by the interference between the imaginary and real parts of the Fourier-transformed function of the $Cu-O_{ax}$ interaction and those of the $Cu-O_{eq}$ interaction.

The authors are grateful to Professor Hitoshi Ohtaki and Dr. Toshio Yamaguchi for their valuable discussion and advice. The authors also wish to thank to Dr. Masaharu Nomura for his help and advice in the EXAFS measurements.

Kinetics and Mechanism of the Extraction of Nickel(II) with 3-Mercapto-1,5-Diphenylformazan in the Presence of 1,10-Phenanthroline or Pyridine

Kousaburo OHASHI,* Hidetoshi SHOJI, and Katsumi YAMAMOTO
Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310
(Received February 7, 1986)

The kinetics and mechanism of the extraction of nickel(II) with 3-mercapto-1,5-diphenylformazan (dithizone, Hdz) into chloroform in the presence of 1,10-phenanthroline (phen) or pyridine (py) were studied in the presence of 0.1 mol dm^{-3} or 0.2 mol dm^{-3} $NaNO_3$ at 25 °C. For the nickel(II)–dithizone–1,10-phenanthroline system, the rate-determining steps were the competitive reactions of nickel(II) with dithizonate and with 1,10-phenanthroline in an aqueous phase. The second-order rate constants for the formation of $[Ni(dz)]^+$ and of $[Ni(phen)]^{2+}$ were determined to be $(6.0\pm0.4)\times10^3$ mol^{-1} dm^3 s^{-1} and $(3.4\pm0.2)\times10^3$ mol^{-1} dm^3 s^{-1} respectively. It was suggested that $[Ni(phen)]^{2+}$ is more reactive toward dithizonate than toward 1,10-phenanthroline in an aqueous phase. The formation of $[Ni(phen)_2]^{2+}$ retards the extraction of nickel(II) with dithizone. For the nickel(II)–dithizone–pyridine system, the rate-determining step is probably the reaction of $[Ni(py)]^{2+}$ with dithizonate in an aqueous phase. The second-order rate constant for this reaction was determined to be $(1.7\pm0.3)\times10^5$ mol^{-1} dm^3 s^{-1}.

From the point of view of a selective separation and sensitive determination of metal ions, the synergistic extraction is a remarkably interesting method.[1–4]

Dithizone reacts with many metal ions to give solvent-extractable and highly colored metal complexes, whereas this extractant is less selective for metal ions. The selectivity for the extraction of metal ions with dithizone was improved by the addition of pyridine or 1,10-phenanthroline. For example, cadmium(II) was predominantly separated and determined from a mixture of cadmium(II) and zinc(II) with dithizone in the presence of 1,10-phenanthroline.[5] The extraction of nickel(II) with dithizone in the presence of 1,10-phenanthroline gave an intensely pink adduct, $[Ni(dz)_2(phen)]$, absorbing strongly in the visible range around 520 nm with a molar extinction coefficient of about 5×10^4 mol^{-1} dm^3 cm^{-1}. The above development was utilized for the sensitive determination of nickel(II).[6,7] At a pH lower than 6.0, the extraction rate of $[Ni(dz)_2]$ into chloroform is very small, but it is remarkably accelerated by the addition of 1,10-phenanthroline. In order to clarify the mechanism of the synergistic extraction of the nickel(II) ion with dithizone in the presence of 1,10-phenanthroline or of pyridine, kinetic studies of this method were carried out. The rate-determining step of the extraction of nickel(II) with dithizone was the formation of $[Ni(dz)]^+$ in an aqueous phase.[8–10] On the other hand, the rate-determining steps of synergistic extraction were found to be the competitive extraction of nickel(II) with dithizonate and that with 1,10-phenanthroline in an aqueous phase.

Experimental

Apparatus. For the determinations of the rates of the extraction reactions, the high-stirring apparatus was used.[11] An Iwaki KM shaker was used for shaking a solution in order to study the extraction equilibrium. A Hitachi 170-30 atomic absorption spectrophotometer was used for the determination of the nickel(II) ion in an aqueous phase. A Hitachi 101 spectrophotometer was used for the measurements of the absorbances of $[Ni(dz)_2(phen)]$. All the pH measurements were carried out with a Hitachi-Horiba F-7 pH meter.

Reagents. A 3-mercapto-1,5-diphenylformazan (dithizone) (Kanto Chemical Co., Inc.) was purified according to the method described in a preceding paper.[12] The chloroform solution of dithizone was prepared by dissolving a weighed amount of dithizone into chloroform just before use.

The nickel(II) stock solution was prepared by dissolving a given amount of nickel(II) nitrate hexahydrate in water. A stock solution of 1,10-phenanthroline was prepared by dissolving the weighed amount of reagent-grade 1,10-phenanthroline (Kanto Kagaku) in chloroform. Spectrophotometric-grade pyridine (Kanto Kagaku) was used without purification.

The chloroform was distilled and treated with $NH_2OH\cdot2HCl$ at pH 8 just before use.

All the other chemicals used were of a reagent-grade quality. Sodium nitrate was used to adjust the ionic strength to 0.10 mol dm^{-3} and 0.20 mol dm^{-3} for the nickel(II)–dithizone–1,10-phenanthroline and nickel(II)–dithizone–pyridine systems respectively. A potassium dihydrogenphosphate–sodium hydroxide buffer solution was used to adjust the pH of the aqueous solution. The concentration of potassium dihydrogenphosphate for the nickel(II)–dithizone–1,10-phenanthroline and nickel(II)–dithizone–pyridine systems were adjusted to 0.01 mol dm^{-3} and 0.1 mol dm^{-3} respectively.

Procedure for the Kinetics of the Extraction. The kinetics was carried out under the pseudo-first order conditions, in which dithizone is present in a large excess with respect to the nickel(II) ion. One hundred-cm^3 portions of an aqueous solution containing nickel(II) and of a phosphate buffer solution were placed in a three-necked flask. Then, a 100-cm^3 portion of a chloroform solution of dithizone containing 1,10-phenanthroline or of

pyridine was added carefully using a funnel. Before mixing, both of the solutions were thermostated at 25 °C. The solutions were vigorously stirred, and then equal volumes of two phases were removed in a test tube for a definite time interval. Each sample was centrifuged to separate the phases. The nickel(II) ion in an aqueous phase was determined by means of atomic-absorption spectrophotometry. After stirring, the pH value of an aqueous phase was measured. For the nickel(II)–dithizone–1,10-phenanthroline system, the change of the pH in an aqueous phase during the extraction reaction was within ±0.01 pH unit. The extractions were done at a constant stirring speed of 1500 rpm, because the extraction rate was independent of the stirring speed in the range greater than 1500 rpm.

Procedure for the Extraction Equilibrium. A 25-cm^3 portion of an aqueous phase containing the nickel(II) ion and a 25-cm^3 portion of a chloroform solution containing dithizone and 1,10-phenanthroline were placed in a separatory funnel. The solutions were then shaken vigorously by using an automatic shaker. After phase-separation, the nickel(II) ion remaining in an aqueous phase was determined. For nickel(II)–dithizone–pyridine, we used almost the same procedure as for nickel(II)–dithizone–1,10-phenanthroline.

Distribution Constant of 1,10-Phenanthroline. The distribution constant of 1,10-phenanthroline, K_D between chloroform and water was determined to be (1.1±0.08)×10^3 at 25 °C and I=0.10 mol dm^{-3} ($NaNO_3$) by using the same procedure as was used for dithizone.[9]

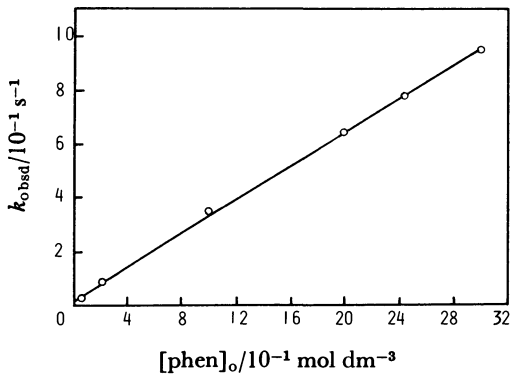

Fig. 1. Relationship between k_{obsd} and 1,10-phenanthroline concentration in the organic phase. [Ni^{2+}]: 1.90×10^{-5} mol dm^{-3}; [Hdz]: 4.80×10^{-4} mol dm^{-3}; pH: 6.0; 25 °C; I: 0.1 mol dm^{-3} ($NaNO_3$).

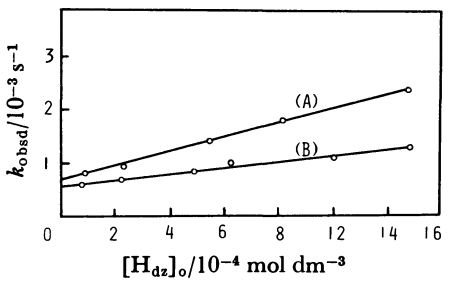

Fig. 2. Relationship between k_{obsd} and dithizone concentration. [phen]: 2.00×10^{-4} mol dm^{-3}; I: 0.1 mol dm^{-3} ($NaNO_3$); (A): pH 6.5; (B): pH 6.0.

The Kinetics of the Extraction of [Ni(dz)$_2$(phen)]. The relationship between log [Ni^{2+}]$_t$ and the extracting time appeared linear. The rate of the extraction of nickel(II) with dithizone in the presence of 1,10-phenanthroline was found to be first-order with respect to the nickel(II) ion. The pseudo first-order rate constant, k_{obsd}, was obtained by plotting log [Ni^{2+}]$_t$ vs. the time, where [Ni^{2+}]$_t$ represents the nickel(II) ion in the aqueous phase at a given time.

As is shown in Fig. 1, a plot of k_{obsd} vs. [phen]$_o$ in the chloroform phase gives a straight line with an intercept. In addition, the value of k_{obsd}, as is shown in Fig. 2, increases linearly with an increase in the dithizone concentration at a given 1,10-phenanthroline concentration. These findings suggest that the rate-determining reactions proceed through two parallel paths in an aqueous phase. One is the reaction between nickel(II) and 1,10-phenanthroline. The other is the reaction of nickel(II) with dithizone.

The rate-determining step for the extraction reaction of nickel(II) with dithizone is the reaction of nickel(II) with dithizonate, dz$^-$, in an aqueous phase. The second-order rate constant, k (rate=k [Ni^{2+}] [dz$^-$]), has been reported to be 6.1×10^3 mol^{-1} dm^3 s^{-1} at 25 °C and I=0.10 mol dm^{-3}.[9]

If they are similar to the extraction of nickel(II) with dithizone, the rate-determining reactions of the synergistic extraction occur in an aqueous phase, and the rate law for the extraction of nickel(II) with dithizone–1,10-phenanthroline system can be expressed by:

$$\frac{-d[Ni^{2+}]}{dt} = k_{phen}[Ni^{2+}][phen]_w + k_{Hdz}[Ni^{2+}][dz^-]_w. \quad (1)$$

The pseudo first-order rate constant, k_{obsd}, is represented by:

$$k_{obsd} = k_{phen}K_D{}^{phen\text{-}1}[phen]_o + k_{Hdz}K_a{}^{Hdz}[Hdz]_o[H^+]^{-1} \quad (2)$$

where k_{phen} and k_{Hdz} are the second-order rate constant, and where $K_D{}^{phen}$ (=1.1×10^3 at 25 °C) is the distribution constant of 1,10-phenanthroline between chloroform and water. A 1,10-phenanthroline species distributed into water at pH 6.0 should be predominantly present as a neutral form because of the pK_a of 4.92.[13] The value of k_{Hdz} was determined to be (6.0±0.4)×10^3 mol^{-1} dm^3 s^{-1} by using the value of the intercept in Fig. 1 and the following constants: $K_a{}^{Hdz}$=4.90×10^{-5} mol dm^{-3} [12] and $K_D{}^{Hdz}$=7.94×10^5 mol dm^{-3}.[12] The k_{Hdz} value thus obtained is approximately equal to that obtained in the previous work within the limits of experimental error.[9] The k_{phen} value was calculated to be (3.4±0.2)×10^3 mol^{-1} dm^3 s^{-1} by using $K_D{}^{phen}$=1.1×10^3 and the slope of a plot of log k_{obsd} vs. [phen]$_o$ (Fig. 1). The k_{phen} value thus obtained agrees satisfactorily with the second-order rate constant for the formation of [Ni(phen)]$^{2+}$ in an aqueous phase in the absence of dithizone.[14] The k_{Hdz} and k_{phen} values calculated from the intercept and the slope in Fig. 2 were in good agreement with the k_{Hdz} and k_{phen} values respectively obtained from the data shown in Fig. 1. Judging from these results, the first reaction of the synergistic extraction should take place in an aqueous phase. When 1,10-phenanthroline is present in a large excess to dithizone at pH 6.0, the reaction schemes in an aqueous phase are represented as follows:

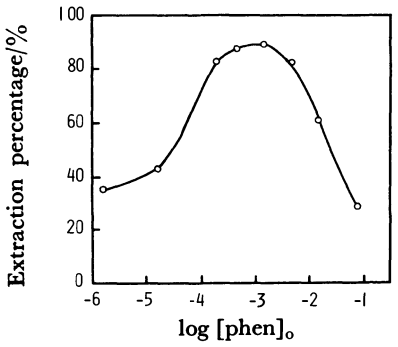

Fig. 3. Relationship between extraction percentage and 1,10-phenanthroline concentration in the presence of dithizone. [Ni^{2+}]: 1.90×10^{-5} mol dm^{-3}; [Hdz]: 4.80×10^{-4} mol dm^{-3}; pH 6.0; Shaking time: 30 min; I: 0.1 mol dm^{-3} ($NaNO_3$).

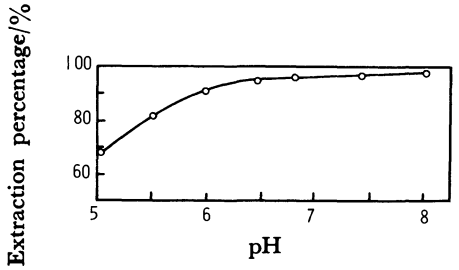

Fig. 4. Relationship between extraction percentage and pH. [Ni^{2+}]: 1.90×10^{-5} mol dm^{-3}; [Hdz]: 4.80×10^{-4} mol dm^{-3}; [phen]: 1.60×10^{-3} mol dm^{-3}; 25 °C; Shaking time: 30 min; I: 0.1 mol dm^{-3} ($NaNO_3$).

$$Ni^{2+} + phen \xrightarrow{slow} [Ni(phen)]^{2+} \quad (3)$$

$$[Ni(phen)]^{2+} + dz^- \xrightarrow{fast} [Ni(phen)(dz)]^+ \quad (4)$$

$$[Ni(phen)(dz)]^+ + dz^- \xrightarrow{fast} [Ni(phen)(dz)_2] \quad (5)$$

The reaction of $[Ni(phen)]^{2+}$ with 1,10-phenanthroline should not occur in the presence of dithizone, because $[Ni(phen)_2]^{2+}$ does not react with dithizone. The extraction of nickel(II) with dithizone takes place at a lower pH range in the presence of 1,10-phenanthroline. The acceleration effect of 1,10-phenanthroline was ascribed to the rapid formation of $[Ni(phen)]^{2+}$, based on the small K_D^{phen} value compared with the K_D^{Hdz} value, and on the lower reactivity of $[Ni(phen)]^{2+}$ toward 1,10-phenanthroline than toward dithizonate. When dithizone is in excess to 1,10-phenanthroline at pH 6.0, the following reactions should be added to Reactions (3)—(5):

$$Ni^{2+} + dz^- \xrightarrow{slow} [Ni(dz)]^+ \quad (6)$$

$$[Ni(dz)]^+ + dz^- \xrightarrow{fast} [Ni(dz)_2] \quad (7)$$

$$[Ni(dz)]^+ + phen \xrightarrow{fast} [Ni(dz)(phen)]^+ \quad (8)$$

$$[Ni(dz)_2] + phen \xrightarrow{fast} [Ni(dz)_2(phen)] \quad (9)$$

At pH 8.0, the predominant reaction path may be Reaction (6) because of the high concentration of the dithizonate distributed into an aqueous phase, even when an excess of 1,10-phenanthroline is present.

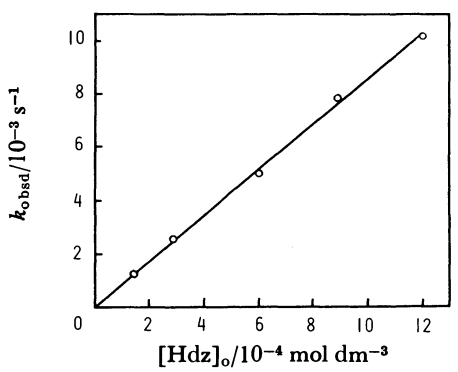

Fig. 5. Relationship between k_{obsd} and dithizone concentration. [Ni^{2+}]: 1.90×10^{-5} mol dm^{-3}; [py]: 0.20 mol dm^{-3}; pH: 6.0; 25 °C, I: 0.20 mol dm^{-3} ($NaNO_3$).

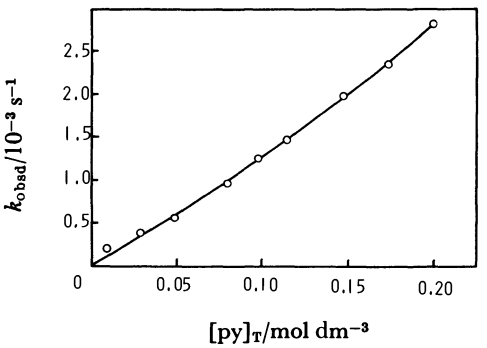

Fig. 6. Relationship between k_{obsd} and pyridine concentration. [Ni^{2+}]: 1.90×10^{-5} mol dm^{-3}; [py]: 0.2 mol dm^{-3}; pH: 6.0; 25 °C; I: 0.20 mol dm^{-3} ($NaNO_3$).

Reactions (6)—(8) should take place in an aqueous phase. The formation reaction of $[Ni(dz)_2(phen)]$ may occur in an aqueous phase and/or in an organic phase.

The effect of the 1,10-phenanthroline concentration and of the pH on the extraction of nickel(II) are shown in Figs. 3 and 4 respectively. The extraction percentage increases with an increase in the 1,10-phenanthroline concentration and the pH. In the presence of more than 1×10^{-3} mol dm^{-3} of 1,10-phenanthroline at pH 6.0, the extraction percentage decreases with an increase in the concentration of 1,10-phenanthroline. The small extraction percentage is probably to be ascribed to the formation of $[Ni(phen)_2]^{2+}$.

The Kinetics of the Extraction of $[Ni(dz)_2(py)]$. The relationship between the pseudo first-order rate constant, k_{obsd}, and the concentration of dithizone, as shown in Fig. 5, gives a straight line without an intercept, indicating that the extraction rate is first-order with respect to the concentration of dithizone. Though a plot of k_{obsd} vs. the concentration of pyridine does not give a straight line, the extraction rate increases with an increase in the concentration of pyridine (Fig. 6).

The effect of the pH on the rate for the extraction reaction of nickel(II) with dithizone in the presence of pyridine is represented by Curve (A) of Fig. 7. The dotted line (Curve (B) in Fig. 7) shows the theoretical line calculated by assuming that the rate-determining step of the extraction of nickel(II) with dithizone in the absence of pyridine is the reaction of nickel(II) with dithizonate in an

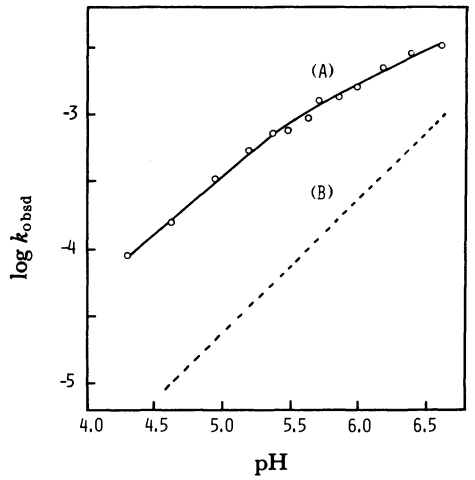

Fig. 7. Relationship between k_{obsd} and pH. [Ni^{2+}]: 1.90×10^{-5} mol dm^{-3}; [Hdz]: 8.90×10^{-4} mol dm^{-3}; [py]: 0.10 mol dm^{-3}; 25 °C; I: 0.20 mol dm^{-3} ($NaNO_3$). (A): Experimental curve; (B): Theoretical curve.

aqueous phase reacts with nickel(II) to form a nickel(II)-pyridine complex, $Ni(py)_n^{2+}$, prior to the extraction of nickel(II) with dithizone. The step-by-step stability constants of $Ni(py)_n^{2+}$ have been reported to be K_1= 8.32×10,[15] K_2=7.08,[15] K_3=3.98,[15] and K_4=1.35.[15] The K_5 and K_6 values, which are unavailable, must be very small. If the rate-determining reaction is the reaction of dithizonate with $[Ni(py)_n]^{2+}$ (n=0—4) in an aqueous phase, the rate equation can be represented by Eq. 10:

$$\frac{-d[Ni^{2+}]}{dt} = \{k_0[Ni^{2+}]+k_1[Ni(py)^{2+}]+k_2[Ni(py)_2^{2+}] + k_3[Ni(py)_3^{2+}]+k_4[Ni(py)_4^{2+}]\}[dz^-] \quad (10)$$

where k_0, k_1, k_2, k_3, and k_4 are the second-order rate constants. The pseudo first-order rate constant is represented as follows:

$$k_{obsd} = \{k_0+k_1K_1\beta+k_2K_1K_2\beta^2+k_3K_1K_2K_3\beta^3+k_4K_1K_2K_3K_4\beta^4\} \times \left\{\frac{K_a^{Hdz}\cdot[Hdz]_0}{A\cdot[H^+]\cdot K_D^{Hdz}}\right\} \quad (11)$$

where $A=1+K_1\beta+K_1K_2\beta^2+K_1K_2K_3\beta^3+K_1K_2K_3K_4\beta^4$, $\beta=[py]_T\{1+K_D^{py}+[H^+]/K_a^{py}\}^{-1}$. The values of $K_a^{Hdz}/A[H^+]$, $K_1\beta K_a^{Hdz}/A\cdot[H^+]$, $K_1K_2\beta^2K_a^{Hdz}/A\cdot[H^+]$, $K_1K_2K_3\beta^3K_a^{Hdz}/A\cdot[H^+]$, and $K_1K_2K_3K_4\beta^4K_a^{Hdz}/A\cdot[H^+]$ were calculated by introducing the following constants: K_D^{py}=0.80,[16] K_a^{py}= 5.89×10^{-6},[17] K_a^{Hdz}=4.90×10^{-5},[12] and K_D^{Hdz}=7.94×10^5,[12] Equation 11 shows that a plot of k_{obsd} vs. $[Hdz]_0$ should provide a straight line and that the rate is not first-order with respect to pyridine and the hydrogen-ion concentration. As is shown in Figs. 6 and 7, the results satisfy the above conditions. The value of k_1 which best fitted the log k_{obsd}-pH curve was found to be $(1.7\pm0.3)\times10^5$ mol^{-1} dm^3 s^{-1} at 25 °C. The value of k_0 was independently determined to be $(3.0\pm0.2)\times10^3$ mol^{-1} dm^3 s^{-1} at 0.1 mol dm^{-3} potassium dihydrogenphosphate. The value of k_2 is estimated to be $(1\pm0.8)\times10^4$ mol^{-1} dm^3 s^{-1}. It is safe to conclude that the values of k_3 and k_4 are negligibly smaller than the k_2 value. Also, the paths of the reactions of $[Ni(py)_5]^{2+}$ and

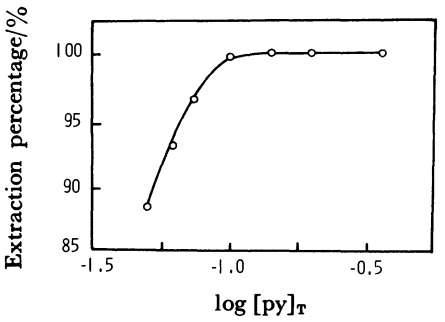

Fig. 8. Relationship between extraction percentage and pyridine concentration. [Ni^{2+}]: 1.90×10^{-5} mol dm^{-3}; [Hdz]: 4.80×10^{-4} mol dm^{-3}; pH 6.9; Shaking time: 30 min.

$[Ni(py)_6]^{2+}$ with dz^- should be omitted. On the base of these results, the reaction scheme for the synergistic extraction of nickel(II) with dithizone-pyridine can be represented by:

$$Ni^{2+} + py \xrightarrow{fast} [Ni(py)]^{2+} \quad (12)$$

$$[Ni(py)]^{2+} + dz^- \xrightarrow{slow} [Ni(dz)(py)]^+ \quad (13)$$

$$[Ni(dz)(py)]^+ + dz^- \xrightarrow{fast} [Ni(dz)_2(py)] \quad (14)$$

As the reactivity of $[Ni(py)]^{2+}$ toward dz^- was found to be about 60 times larger than that of aqua Ni^{2+} toward dz^-, the acceleration effect of pyridine on the extraction of nickel(II) with dithizone was ascribed to the formation of $[Ni(py)_n]^{2+}$.[3] It was suggested that the rate-determining step for the extraction of nickel(II) with thenoyltrifluoroacetone (tta) in the presence of pyridine was the reaction of tta with aqua Ni^{2+} and $[Ni(py)]^{2+}$ in the pH range from 1.5 to 3.9.[18] These facts further support the mechanism proposed for the extraction of nickel(II) with dithizone-pyridine.

Figure 8 represents the effect of the pyridine concentration on the extraction percentage of nickel(II) with dithizone into chloroform. In the presence of more than 0.1 mol dm^{-3} of pyridine, the complete extraction of nickel(II) was achieved with 4.8×10^{-4} mol dm^{-3} of dithizone at pH 6.9. Pyridine does not mask the extraction of nickel(II) with dithizone, even when pyridine is present in a large excess to dithizone.

As has been shown above, the rate-determining steps for the nickel(II)-dithizone-1,10-phenanthroline and nickel(II)-dithizone-pyridine systems are different from each other. This difference should result in a difference in the distribution constant between pyridine and 1,10-phenanthroline. The coordination of pyridine or 1,10-phenanthroline to the aqua nickel(II) ion probably facilitates the removal of water molecules from the central nickel(II) ion, hence accelerating the extraction rate of nickel(II) with dithizone in the presence of 1,10-phenanthroline or pyridine.

1,10-Phenanthroline behaves as a masking reagent for the extraction of zinc(II) with dithizone.[11] On the other hand, nickel(II),[1] cobalt(II),[19] and manganese(II)[20] are extracted as an adduct, $[M(dz)_2(phen)]$, with dithizone in the presence of 1,10-phenanthroline. The phenomenon

that zinc(II) does not form an adduct can not be reasonably explained by considering the difference in the softness of these metal ions as a Lewis acid. Manganese(II), cadmium(II), and zinc(II) are classified as hard, soft, and middle-class acids respectively.[21,22] Furthermore, there seems to be no relationship between the capability of the adduct formation of metal ions and the stability constants of the metal complex of dithizone and 1,10-phenanthroline. A systematical study of the kinetics of a synergistic extraction of metal ions would perhaps give more valuable guidelines for the development of a new synergistic extraction system.

The authors would like to thank Prof. Henry Freiser of the University of Arizona and Prof. Kenji Nakamura of Ibaraki University for their valuable comments and their encouragement for this work.

The Crystal and Molecular Structure of Bis(4-methylpyridine)-bis(thiocyanato)cadmium(II) in Polymeric Form, $[Cd(SCN)_2(CH_3C_5H_4N)_2]_n$

Masahiro TANIGUCHI, Mamoru SHIMOI, and Akira OUCHI*
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received February 7, 1986)

The crystal and molecular structure of the title complex was determined by a single-crystal X-ray diffraction technique. The crystal is triclinic with a space group $P\bar{1}$, a=11.323(4), b=18.383(10), c=9.284(5) Å, α=104.62(4), β=114.26(3), γ=77.71(4)°, Z=4; the final R value obtained was 0.034. All cadmium atoms are lined approximately along the [111] axis and each pair of metal atoms are bridged by two thiocyanate ions (SCN), one of which is *S*-coordinated and the other is *N*-coordinated to the same side metal atom. Also bonded with two nitrogen atoms of 4-methylpyridine (pic) ligands, the metal atom is 4*N*2*S*-hexa-coordinated and is in an octahedral geometry. The cadmium atoms, where the ligated respective pairs of N(SCN), N(pic), and S(SCN) atoms are all in a trans configuration, and the metal atoms where the ligated respective pairs of N(pic) and S(SCN) are in cis, while the pair of the N(SCN) in trans configuration, appear alternatively in the polymer chain.

A variety of polymeric structures of the metal thiocyanates and of their Lewis-base adducts are one of the interesting themes of structural chemistry, and several reports have already been published.[1] According to the soft-hard acid-base theory, cadmium is a rather soft metal, though its softness is less than that of mercury or lead.[2] Therefore, it is expected that the nitrogen as well as the sulfur atoms of a thiocyanate (SCN) ion are able to bond with cadmium easily, and that SCN-bridged polymeric complexes are stable. In fact, the cadmium(II) thiocyanate has a three-dimensional polymeric structure bridged by SCN ions,[3] and some Lewis-base adducts of cadmium(II) thiocyanate are in a variety of linear polymeric forms. For example, in *N,N'*-ethylenethiourea (2-imidazolidinethione) (etu) adduct, $Cd(SCN)_2(etu)_2$(**1**),[4] the 1*H*-1,2,4-triazole (trz) adduct, $Cd(SCN)_2(trz)_2$(**2**),[5] and the tri-*m*-tolylphosphine (tl_3P) adduct, $Cd(SCN)_2(tl_3P)$ (**3**),[6] each pair of the metal atoms, which are lined linearly, are doubly bridged by SCN ions. On the other hand, in the case of bis(2-aminoethyl)amine (ben) adduct, $Cd(SCN)_2(ben)_2$[7] each pair of metal atoms are bridged by one SCN as well as one ben ligand. In the case of 4-*t*-butyl-4*H*-1,2,4-triazole (btrz) adduct, $Cd(SCN)_2(btrz)_2$,[8] metal atoms are bridged by two N-bonded SCN ions and by three btrz ligands (alternatively) on the line.

This paper reports on the crystal and molecular structures of the title complex, $Cd(SCN)_2(pic)_2$ (pic=4-methylpyridine), determined by a single-crystal X-ray diffraction technique.

Experimental

Synthesis of Bis(4-methylpyridine)bis(thiocyanato)cadmium(II). The complex was obtained in almost the same way as that of Ahuja[9] and was recrystallized from methanol. Anal. Found: Cd, 26.99; C, 40.28; H, 3.31; N, 13.45%. Calcd for $CdC_{14}H_{14}N_4S_2$: Cd, 27.10; C, 40.54; H, 3.40; N, 13.51%. The wavenumbers of its infrared spectral bands almost coincide with the respective values of the reference.[9]

Intensity-Data Collection. A crystal with the dimension of 0.3×0.3×0.1 mm³ was used for the measurements. The crystallographic data are: $CdC_{14}H_{14}N_4S_2$, F.W. 414.82, triclinic, space group $P\bar{1}$, a=11.323(4), b=18.383(10), c=9.284(5)Å, α=104.62(4), β=114.26(3), γ=77.71(4)°, Z=4, U=1691.7(15) Å³, D_m=1.62(3), D_x=1.63 Mg m^{-3}, μ(Mo $K\alpha$)= 1.52 mm^{-1}. Reflections within a range of $3°<2\theta<50°$ were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite monochromated Mo $K\alpha$ radiation, the ω—2θ scan technique being employed (scan speed 4° min^{-1} (θ), scan width (1.10+0.5tanθ)°). The crystal was stable during exposure to X-rays. Of the 5983 reflections measured, 4652 with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination. The intensities were corrected for the Lorentz and polarization factors, but no correction was made for absorption and extinction.

Structure Determination. The structure was solved by the heavy-atom method. The positions of the cadmium, and some sulfur atoms, were deduced from a three-dimensional Patterson map; other non-hydrogen atoms were located by means of successive Fourier syntheses. Their positional, isotropic and anisotropic thermal parameters were refined by a block-diagonal least-squares method. All the hydrogen atoms were at respective calculated positions, assuming their B_{iso}'s to be 8.0 Å², and C–H bond lengths to be 1.08 Å. The final R value obtained was 0.034.[10]

All the calculations were carried out on a HITAC M-280H computer at the Computer Center of the University of Tokyo using a local version of the UNICS program.[11] The atomic scattering factors were taken from Ref. 12.

Results and Discussion

The final atomic parameters of non-hydrogen atoms are listed in Table 1; the selected bond lengths and bond angles are tabulated in Table 2.[13] A perspective drawing of the skeleton of the polymeric chain of the complex, together with the numbering scheme of the atoms, is shown in Fig. 1, the crystal

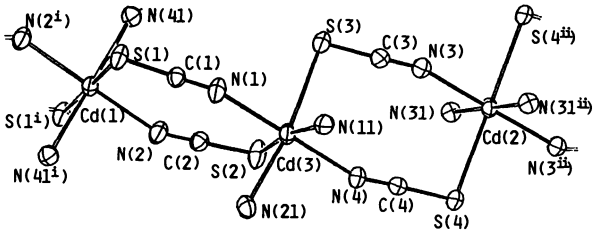

Fig. 1. A perspective drawing of the structure of the title complex with the numbering scheme. The symmetry operations are: i, $-x$, $-y$, $-z$; ii, $1-x$, $1-y$, $1-z$.

packing diagram in Fig. 2, and the numbering scheme of the pic ligand atoms in Fig. 3.

Crystallographically, there are three kinds of cadmium atoms; two of them (Cd(1) and Cd(2)) are located at the centers of symmetry (0,0,0 and 0.5,0.5,0.5), while the other one (Cd(3)) takes a position near their midpoint. All cadmium atoms are lined approximately along the [1 1 1] axis.

Along this direction, neighboring cadmium atoms are bridged by two SCN ions, one of them is *S*-coordinated and the other one is *N*-coordinated to the same side metal atom, thus forming a polymeric linear chain structure.

As two pic nitrogen atoms are also coordinated to each metal atom, the respective cadmium atoms are totally 4*N*2*S*-hexa-coordinated and are in a slightly deformed octahedral geometry. Around the Cd(1) and Cd(2) atoms, respective pairs of N(SCN), S(SCN), and N(pic) are in trans and their geometries are almost the same. Around Cd(3), respective pairs of

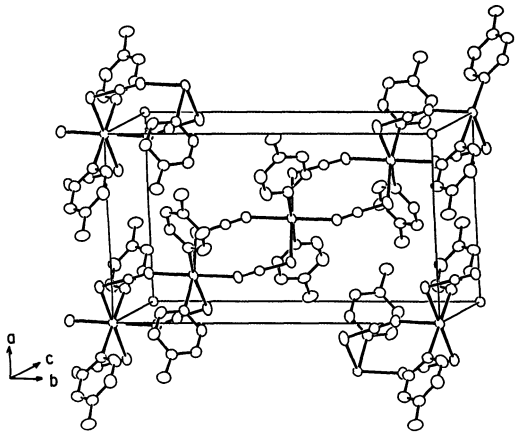

Fig. 2. Crystal packing diagram of the complex.

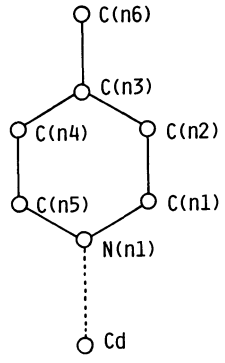

Fig. 3. Schematic presentation of the 4-methylpyridine ligand with the numbering scheme (n=1,2,3, and 4).

S(SCN) and N(pic) are in cis, while the pair of N(SCN) are in a trans configuration. Such a variation of the configuration around the cadmium atoms on the polymer chain has not been found yet for the Lewis-base adducts of cadmium thiocyanate.

The atoms of doubly bridging SCN ios, as well as the cadmium atoms on both sides, make a eight-membered ring.

They are almost on a plane: the average deviations of the atomic positions from the average plane of Cd(1), Cd(3), S(1), C(1), N(1), S(2), C(2), N(2), is 0.111 Å (maximum deviation is to S(2), 0.212 Å), while that from the average plane of Cd(2), Cd(3), S(3), C(3), N(3), S(4), C(4), N(4), is 0.100 Å (maximum deviation is to N(3), 0.244 Å). The dihedral angle between the two planes is 74.3.°.

The Cd-N(SCN) as well as Cd-N(pic) bond lengths around all cadmium atoms are not much different from each other, respectively. However, the bond length Cd-N(SCN) (2.297 Å av.[a]) is significantly shorter than that of Cd-N (pic) (2.361 Å av.). All bond lengths Cd-S are not much different from each other (2.719 Å av.), and the average bond angles of Cd-N-C(SCN) and Cd-S-C(SCN) are 158.6 and 98.4°, respectively.

As the Shannon's ionic radii of cadmium (valence (Val), 2+; and coordination number (CN), 6), sulfur (Val, 2−; CN, 6), nitrogen (Val, 3−; CN, 4) are 0.95, 1.84, and 1.46 Å, respectively, the calculated bond lengths of Cd-S and Cd-N are 2.79 and 2.41 Å.[14] Observed Cd-S lengths are not much different from the calculated one, but the observed Cd-N lengths are shorter than the calculated value. The discrepancy is probably due to the assumed Val of the nitrogen atom, which is not appropriate for atoms where the charge is significantly delocalized; the nitrogen atom in the thiocyanate ion is expected to be less negatively charged, and its ionic radius is likely to be shorter than 1.46 Å.

The bond lengths of Cd-N(SCN) and Cd-S(SCN), as well as the bond angles Cd-N-C(SCN) and Cd-S-C(SCN) in the related other cadmium thiocyanate complexes, are as follows: **1**, 2.53, 2.73 Å; 143, 109.1°; **2** , 2.330, 2.754 Å; 143.4, 96.3°; **3**, 2.28, 2.7 Å; 159, 97°.

For the title complex and **3**, the angles of Cd-N-C(SCN) are approximately 160°, Cd-N(SCN) lengths are relatively short, 2.2—2.3 Å, and Cd-S(SCN) lengths are about 2.69—2.71 Å. On the other hand, for **1** and **2**, the angle is about 140°, and Cd-N(SCN) lengths are longer than 2.3 Å, while the Cd-S(SCN) lengths are a little longer than that of the title complex. The Lewis base of **2** is coordinated to the metal atom by a nitrogen atom as the title complex, and the Cd-N(base) of **2** is shorter than that of the title complex (2.317 vs. 2.361 Å av.). From these data, the SCN bridgings of **3** and the title complex are likely to be stronger than those of **1** and **2**, and the bonding of the Lewis base with the metal atom of the title complex is weaker than that of **2**.

[a] av. means the average value. In cases of the average of the all Cd-N or S lengths, as each Cd(1 or 2)-N or S bond length shown in the table is equivalent with the one which is trans to it, the value was doubled and added to obtain the sum.

Kinetics of Ligand-Exchange Reactions in Tetrakis(acetylacetonato)-uranium(IV) in Organic Solvents

Hiroshi FUKUTOMI,* Hideki OHNO, and Hiroshi TOMIYASU
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology,
O-okayama, Meguro-ku, Tokyo 152
(Received February 10, 1986)

The kinetics of ligand-exchange reactions between tetrakis(acetylacetonato)uranium(IV) [U(acac)$_4$] (acac= acetylacetonate) and free acetylacetone Hacac in various organic solvents, $CDCl_3$, C_6D_6, and CD_3CN has been studied by ^1H NMR. The rate laws were found to change remarkably with these solvents used. The observed first-order rate constant k_{obsd} in $CDCl_3$ depended linearly on the concentration of free Hacac in the enol form as $k_{obsd}=k_s[Hacac]_{enol}$, while the plots of k_{obsd} vs. $[Hacac]_{enol}$ in C_6D_6 deviated from straight lines in higher concentrations of $Hacac_{enol}$. The exchange rate was much slower in CD_3CN than in $CDCl_3$ and C_6D_6, and k_{obsd} increased only slightly with $[Hacac]_{enol}$. Addition of dimethyl sulfoxide (DMSO) in C_6D_6 yielded the retardation of exchange rate giving a rate law $k_{obsd}^{-1}=p+q[DMSO]$, where p and q are constants. From the results obtained in these solvents, a mechanism passing through nine-coordinate intermediates was proposed.

Among quadrivalent metal ions which form eight-coordinate complexes with β-diketones, uranium(IV) has been studied most extensively. Earlier studies were much concerned with the solvent extractions of a variety of U(IV) β-diketonato complexes, [U(acac)$_4$], [U(hfaa)$_4$], [U(tta)$_4$], and [U(ba)$_4$], where hfaa=hexafluoroacetylacetonate, tta=2-thenoyltrifluoroacetonate and ba=benzoylacetonate, since the solvent extraction method has been of particular importance in the separation of actinoid elements. Despite a large number of studies little has been known with respect to the kinetics of ligand exchange reactions in the above complexes.[1,2]

Recently, we reported the kinetic results of ligand-exchange reactions in tetrakis(β-diketonato) complexes of thorium(IV), [Th(acac)$_4$],[3,4] and [Th(tta)$_4$],[5] and proposed a mechanism passing through nine-coordinate intermediates. This paper presents the results of kinetic experiments on the acac exchange between [U(acac)$_4$] and free Hacac, and the results are compared with those of earlier studies. A similar mechanism in the reactions of [Th(β-diketonate)$_4$] is also proposed in the present study.

Experimental

The [U(acac)$_4$] complex was synthesized by the same procedure as described in a earlier paper.[6] The solution of uranium(IV) chloride which was prepared by electrolytic reduction of uranyl(VI) chloride solution in 0.1 M HCl (M=mol dm^{-3}), was stirred with 0.1 M acetylacetone and the pH of the mixture was adjusted to about 4 with 0.1 M NaOH solution. A green precipitate was dried in vacuo for two days, and then recrystallized from benzene in a glove box filled with dried nitrogen. Identification of the complex was made by measurements of UV-visible and NMR spectra. Both the UV-visible and NMR spectra agreed well with those reported in a earlier paper.[7] Acetylacetone was dried over anhydrous calcium sulfate and distilled twice. Chloroform-*d* $CDCl_3$ (Merck 99%) was distilled. Acetonitrile-d_3 CD_3CN (Merck 99.95%) was dried over 4A molecular sieves and distilled. Benzene-d_6 C_6D_6 (Merck 99.6%) was dried over 4A molecular sieves and distilled. Dimethyl sulfoxide was distilled under reduced pressure. The UV-visible spectra were measured by using a Shimadzu 210 spectrophotometer with 10 mm quartz cells. The NMR spectra were recorded on a JEOL JNM-FX 100 NMR spectrometer equipped with a JNM-VT-3B temperature controller. The fraction of keto and enol isomers of Hacac in C_6D_6 were determined by area measurements of methyl proton NMR signals for keto and enol isomers in the temperature regions in which kinetic experiments were carried out.

Results

The ^1H NMR spectra of the mixture of [U(acac)$_4$] and Hacac in C_6D_6 were measured at various temperatures (Fig. 1), where the signals were assigned as follows: A and C are methine proton signals of [U(acac)$_4$] and $Hacac_{enol}$, respectively, G and F methyl proton signals of [U(acac)$_4$] and $Hacac_{enol}$, respectively, D and E methylene and methyl proton signals of $Hacac_{keto}$, and B refers to the signal of C_6D_5H involved in C_6D_6. The methyl proton signal (G) of [U(acac)$_4$] shifted to the upfield, while the methine proton signal (A) shifted to the downfield. These results agree well with those of earlier studies[8,9] suggesting that $\chi_{\parallel}$ is greater than $\chi_{\perp}$ in [U(acac)$_4$].

It can be seen in Fig. 1 that signals A, C, F, and G exhibit the broadening of line widths as the temperature goes up from 4 to 64 °C. This is attributed to the exchange of acac between [U(acac)$_4$] and $Hacac_{enol}$ as follows:

$$[U(acac)_4] + Hacac^*_{enol} \rightleftharpoons [U(acac)_3(acac^*)] + Hacac_{enol}, \quad (1)$$

where an asterisk denotes the exchanging species. Since signal G is isolated from other signals and reveals the most clear broadening, the kinetic data were determined from the line-shape analysis of signal G.

In the case of the slow exchange region,[10] the lifetime τ of the ligand at the coordination site is related with the transverse relaxation time of the exchanging nucleus by

$$1/\tau = 1/T_2 - 1/T_{2a}. \quad (2)$$

In the present study T_2 refers to the relaxation time of signal G in the reaction mixture, where acac exchanges between $[U(acac)_4]$ and $Hacac_{enol}$, and T_{2a} refers to the relaxation time of signal G in the absence of free Hacac. The first-order rate constant k_{obsd} for reaction 1 is given by the following equation.

$$k_{obsd} = 4/\tau \quad (3)$$

Application of the slow exchange region was tested by plotting k_{obsd} thus determined as a function of temperature, where the plot should obey an Arrhenius type relationship. A typical plot is shown in Fig. 2 indicating that the relaxation process is controlled by the chemical exchange at temperatures studied.

From the plots of k_{obsd} vs. the concentration of the complex (Fig. 3), the exchange reaction is found to be first-order with respect to $[U(acac)_4]$ in C_6D_6, i.e. rate$=k_{obsd}[U(acac)_4]$. In Fig. 4, the plots of k_{obsd} determined in $CDCl_3$ vs. $[Hacac]_{enol}$ give straight lines passing through the origin, which are expressed by

$$k_{obsd} = k_s[Hacac]_{enol}, \quad (4)$$

where k_s denotes the second-order rate constant. The values of k_s ($s^{-1}\,mol^{-1}\,kg$) were determined as: $(1.57\pm0.15)\times10^3$, $(2.66\pm0.30)\times10^3$ and $(4.21\pm0.55)\times10^3$ at 30, 40, and 50 °C, respectively. The corresponding plots with $[Hacac]_{enol}$ in C_6D_6 deviate from a linear relationship, but the plots of k_{obsd}^{-1} vs. $[Hacac]_{enol}^{-1}$ yield straight lines (Fig. 5) giving the following rate law.

$$k_{obsd}^{-1} = a + b[Hacac]_{enol}^{-1} \quad (5)$$

In CD_3CN, k_{obsd} changes only slightly with $[Hacac]_{enol}$

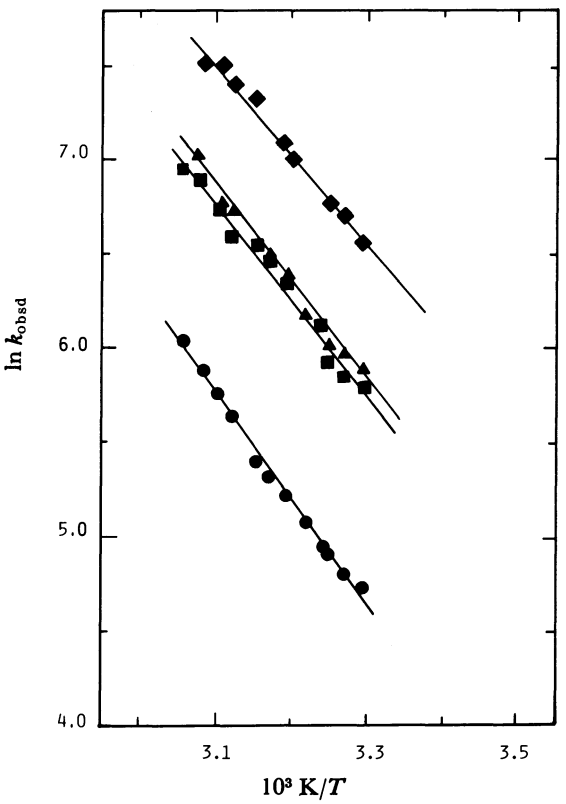

Fig. 2. Typical plots of k_{obsd} as a function of reciprocal temperature in $CDCl_3$. The concentrations of $[U(acac)_4]$ and $Hacac_{total}$ (mol kg^{-1}) are as follows: ●: 0.0317, 0.0693; ■: 0.0319, 0.182; ▲: 0.0325, 0.264; ◆: 0.0324, 0.500.

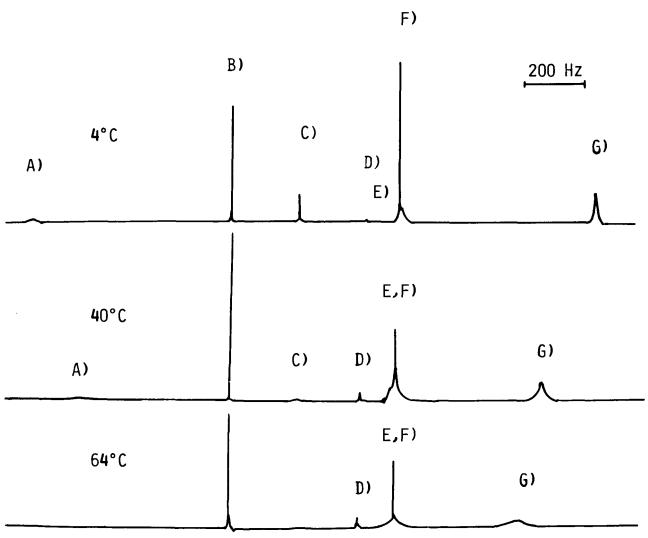

Fig. 1. ^1H NMR spectra of the mixture of $[U(acac)_4]$ and free Hacac in C_6D_6 at 4, 40 and 64 °C under the following conditions: $[U(acac)_4]=0.0496$ mol kg^{-1}, $[Hacac]=0.0128$ mol kg^{-1}.

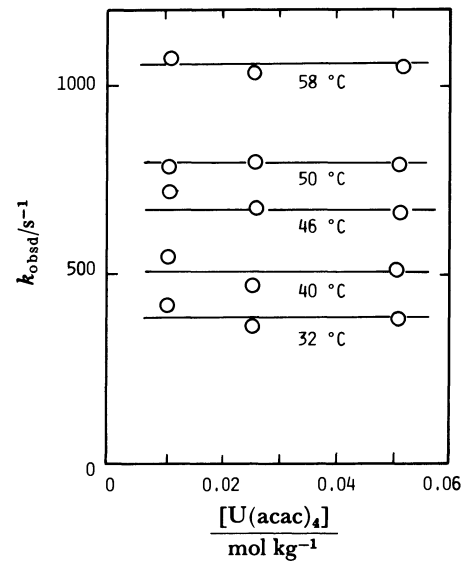

Fig. 3. The dependence of k_{obsd} on the concentration of $[U(acac)_4]$ in C_6D_6 at various temperatures. The concentration of total Hacac was kept at 0.545 mol kg^{-1}.

as is illustrated in Fig. 6.

Addition of DMSO to C_6D_6 solutions retarded remarkably the exchange rates (Fig. 7). Under the conditions [DMSO]<0.15 mol kg^{-1} in C_6D_6, plots of k_{obsd}^{-1} vs. [DMSO] are fitted to straight lines (Fig. 8) and the rate law at constant $[Hacac]_{enol}$ is expressed by

$$k_{obsd}^{-1} = p + q[DMSO]. \quad (6)$$

In the presence of high concentration of DMSO ([DMSO]≧0.5 mol kg^{-1}), k_{obsd} (s^{-1}) reaches constant values as follows: 113±14, 179±11, 241±9, and 412±16, at 40, 50, 60, and 70 °C, respectively. The concentrations of $Hacac_{enol}$ in C_6D_6 at various temperatures were calculated by using values of $\Delta H°$ (kJ mol^{-1}) and $\Delta S°$ (J K^{-1} mol^{-1}) for the equilibrium in Hacac, which were determined by the NMR method as above-described. The values obtained are −7.16±0.44 for $\Delta H°$ and −4.35±1.4 for $\Delta S°$. The $\Delta H°$ and $\Delta S°$ values used for calculation in other solvents[4] are as follows: −7.5±0.5 and 10.3±0.2 in $CDCl_3$; −1.6±0.08 and 1.38±0.30 in CD_3CN, respectively.

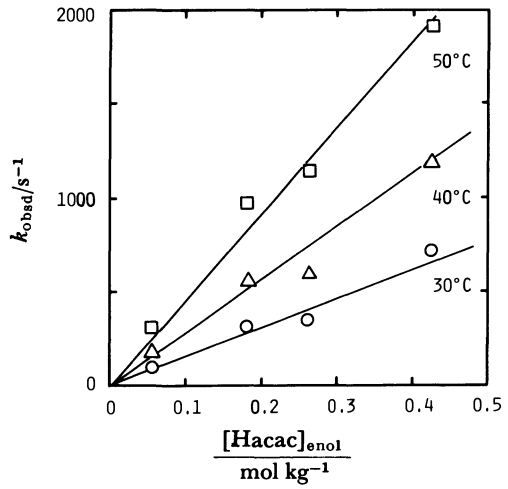

Fig. 4. Plots of k_{obsd} vs. $[Hacac]_{enol}$ in $CDCl_3$ at various temperatures. $[U(acac)_4]=0.0321$ mol kg^{-1}.

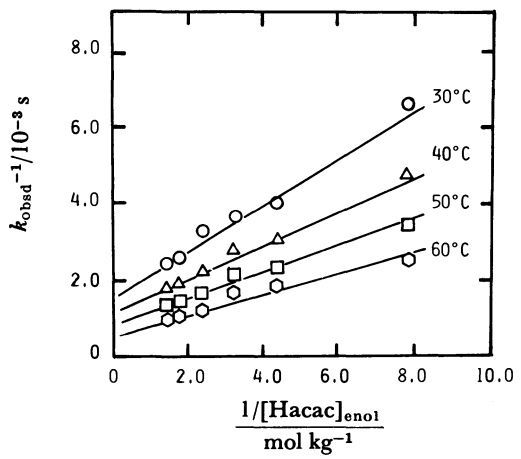

Fig. 5. Plots of k_{obsd}^{-1} vs. $1/[Hacac]_{enol}$ in C_6D_6.

Discussion

The rate laws (Eqs. 4 and 5) can be well explained by assuming the presence of a preequilibrium between $[U(acac)_4]$ and free $Hacac^*_{enol}$ prior to the acac exchange as follows:

$$[U(acac)_4] + Hacac^*_{enol} \overset{K_1}{\rightleftharpoons} [U(acac)_4 \cdots Hacac^*_{enol}], \quad (7)$$

where K_1 is the equilibrium constant and [U-

Table 1. Values of K_1, K_3, and k_2 at Various Temperatures in C_6D_6

Temperature °C	K_1 kg mol^{-1}	K_3 kg mol^{-1}	k_2 $s^{-1}\times 10^3$
40	2.72	63.8	0.901
50	2.68	40.0	1.24
60	2.69	36.6	1.69

$(acac)_4\cdots Hacac^*_{enol}]$ denotes an intermediate complex. If the acac exchange takes place only through the intermediate, k_{obsd} can be expressed by

$$k_{obsd} = \frac{k_2K_1[Hacac]_{enol}}{1+K_1[Hacac]_{enol}} \quad (8a)$$

or

$$k_{obsd}^{-1} = 1/k_2 + 1/(k_2K_1[Hacac]_{enol}), \quad (8b)$$

where k_2 refers to the rate constant for acac exchange in the intermediate, which is accompanied by a proton transfer from $Hacac^*_{enol}$ to one of the coordinated acac.

If K_1 is small enough to apply the condition $K_1[Hacac]_{enol} \ll 1$, Eq. 8 is simplified as

$$k_{obsd} = k_2K_1[Hacac]_{enol}. \quad (9)$$

Equation 9 is essentially the same as Eq. 4. This is the case for the reaction in $CDCl_3$, where $k_s=k_2K_1$, and k_2 and K_1 can not be determined independently. Under the conditions $K_1[Hacac]_{enol}\simeq 1$ with relatively large values of K_1, a linear relationship is no longer expected for the plot of k_{obsd} vs. $[Hacac]_{enol}$. On the other hand, Eq. 8b shows that the plot should be linear if k_{obsd}^{-1} is plotted against $[Hacac]^{-1}_{enol}$. This is the case for the reaction in C_6D_6, where Eq. 5 coincides with Eq. 8b, and the values of K_1 and k_2 can

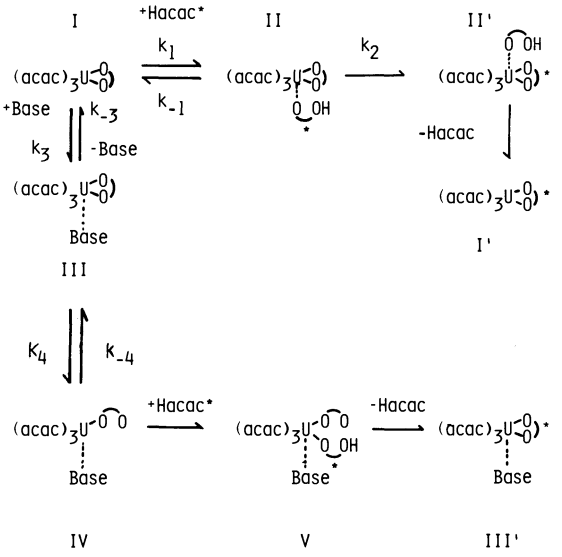

Fig. 9. Possible mechanism for the exchange of acac between $[U(acac)_4]$ and $Hacac^*_{enol}$. $\widehat{OO}$ and $\widehat{OOH}$ represent acac and $Hacac_{enol}$, respectively.

be determined. The results are listed in Table 1.

From the rate analysis, K_1 is expected to be smaller in $CDCl_3$ than in C_6D_6. This might be attributed to the difference in dielectric constant of these solvents, because K_1 is supposed to be smaller in the solvent with a larger dielectric constant, if the electrostatic interaction is responsible for the nine-coordinate adduct formation.[12]

Khvostik et al.[1] studied the kinetics of the same reaction in benzene. Although their results were not quantitative, the following data were reported: $k_2=1\times10^3$ s^{-1} and $K_1=0.4$ M^{-1} (no description of temperature was given). Compared with the present study, k_2 has the same order, but K_1 is much smaller than the values in Table 1. Since they determined the values of K_1 and k_2 from a plot of k_{obsd} vs. [Hacac] under the condition $K_1[Hacac] \ll 1$, where [Hacac] includes both keto and enol isomers, the K_1 and k_2 values obtained seem not to be correct.

We studied the ligand-exchange reactions in tetrakis(β-diketonato)thorium(IV) [Th(β-diketonate)$_4$] and proposed a mechanism passing through a nine-coordinate intermediate.[3-5] On the basis of the kinetic data and structures of Th(IV) and U(IV) β-diketonato complexes, a mechanism similar to that in Th(IV) complexes is proposed in the present study as is illustrated in Fig. 9. Addition of free $Hacac^*_{enol}$ to $[U(acac)_4]$ leads to the formation of a nine-coordinate complex (I $\rightarrow$ II), and a proton is transferred from $Hacac^*_{enol}$ to one of the coordinated acac (II$\rightarrow$II'), followed by rapid dissociation of $Hacac_{enol}$ from the coordination sphere (II' $\rightarrow$ I'). In $CDCl_3$ and C_6D_6 the pathway I $\rightarrow$ II $\rightarrow$ II' $\rightarrow$ I', which is consistent with a mechanism reported by Folcher et al. for the ligand exchange in $[U(fod)_4]$,[2] appears to be the principal

exchange pathway.

In the presence of such a free base as DMSO, another nine-coordinate complex (III) might be formed. On the assumption that complexes I, II, and III are in equilibrium and that only the pathway I → II → II′ → I′ contributes to the exchange of acac, k_{obsd} can be expressed by

$$k_{obsd} = \frac{k_2K_1[\text{Hacac}]_{enol}}{1+K_1[\text{Hacac}]_{enol}+K_3[\text{Base}]} \quad (10a)$$

or

$$k_{obsd}^{-1} = \frac{1+K_1[\text{Hacac}]_{enol}}{k_2K_1[\text{Hacac}]_{enol}} + \frac{K_3[\text{Base}]}{k_2K_1[\text{Hacac}]_{enol}}, \quad (10b)$$

where K_3 refers to the equilibrium constant for the reaction, I+Base ⇌ III. In Eq. 10b, k_{obsd}^{-1} is a linear function of the concentration of the base at constant $[\text{Hacac}]_{enol}$, and consistent with Eq. 6 obtained experimentally. In other words, the retardation effect of DMSO can be accounted for by the adduct complex formation. Additional evidence for the adduct formation came from the solvent extraction study[11] and the NMR chemical shift measurement.[2]

It should be noted, however, that k_{obsd} approaches constant values as [DMSO] increases over 0.5 mol kg^{-1}. The results suggest an alternative exchange pathway, which corresponds to the pathway I → III → IV → V → III′. The existence of two exchange processes is demonstrated clearly by the exchange reaction in CD_3CN, where k_{obsd} changes only slightly with $[\text{Hacac}]_{enol}$ (Fig. 6) giving an observed rate law

$$k_{obsd} = k_{AN} + k'_{AN}[\text{Hacac}]_{enol}. \quad (11)$$

Since CD_3CN acts as a base even though its basicity is not so strong as DMSO, the reaction might proceed via both the pathways. In the pathway I → III → IV → V → III′ the rate determining step is expected to be the bond breaking of an acac chelate ring (III → IV), because the rates of paths IV → V (coordination of Hacac^*_{enol}) and V → III′ (proton transfer) should be comparable with those of paths I → II and II → II′, respectively and hence are much faster than the observed rates in Fig. 6. Therefore, k_{obsd} can be written by

$$k_{obsd} = \frac{k_2K_1[\text{Hacac}]_{enol}+k_4K_3[CD_3CN]}{1+K_1[\text{Hacac}]_{enol}+K_3[CD_3CN]}. \quad (12)$$

If $K_3[CD_3CN] \gg (1+K_1[\text{Hacac}]_{enol})$ is assumed in CD_3CN, Eq. 12 can be simplified as

$$k_{obsd} = k_4 + \frac{k_2K_1[\text{Hacac}]_{enol}}{K_3[CD_3CN]}. \quad (13)$$

Equation 13 is consistent with Eq. 11, where

$$k_{AN} = k_4$$

and

$$k'_{AN} = k_2K_1/K_3[CD_3CN]. \quad (14)$$

The fact that the values of $k'_{AN} \approx 50$ kg mol^{-1} at 56 °C, which was determined from the plots in Fig. 6, are about hundred times smaller than those of k_2K_1 in $CDCl_3$ supports the above assumption, $K_3[CD_3CN] \gg (1+K_1[\text{Hacac}]_{enol})$. The values of k_{AN} in Fig. 6 are comparable with those of k_{obsd} obtained in the presence of high DMSO concentration in benzene, though the latter is slightly larger than the former. This fact also supports that the path III → IV controls the rates. The larger values of k_{obsd} in the presence of DMSO, as compared with k_{AN}, might be attributed to the stronger affinity of DMSO than CD_3CN toward $[U(acac)_4]$, because the adduct formation with the strong base in complex III may contribute to weaken the U(IV)–acac bonds and hence accelerate the rate in the k_4 path.

The activation parameters for the ligand-exchange reactions in $[U(acac)_4]$ are summarized in Table 2 together with those of $[Th(acac)_4]$. Similar values, particularly the large negative values of ΔS^*, suggest the similarlity in mechanism for the ligand exchange reactions in both U(IV) and Th(IV) complexes, although the pathway III → IV → V → III′ was not observed in the latter complex. In the case of ligand exchange in $[Th(acac)_4]$, the rate law was expressed by Eq. 4 under the condition $K_1[\text{Hacac}]_{enol} \ll 1$ in solvents $CDCl_3$ and CD_3CN. As compared with the results of the present study, K_1 appears relatively smaller for $[Th(acac)_4]$ than for $[U(acac)_4]$. Since the exchange rate in $[Th(acac)_4]$ is faster than in $[U(acac)_4]$ and the values of k_2K_1 for $[Th(acac)_4]$ and $[U(acac)_4]$ are 4.5×10^2 and 1.0×10^2 kg s^{-1} mol^{-1} at 20 °C in $CDCl_3$ respectively, k_2 for $[Th(acac)_4]$ is expected to be much larger than for $[U(acac)_4]$. This fact may account for that the pathway III → IV → V → III′ is observed only in $[U(acac)_4]$, because the pathway I → II → II′ → I′, whose rate is controlled by the k_2 path, is so fast in $[Th(acac)_4]$ that the probability of taking pathway III→IV→V→III′ becomes negligible. A marked difference in k_2 value might be attributed to a difference in size of these complexes: the distance between Hacac* and acac in complex II is presumed to be more favorable for the proton transfer in Th(IV) complex than in U(IV) complex.

Table 2. Activation Parameters of acac Exchange in $[U(acac)_4]$ and $[Th(acac)_4]$

Complex	Solvent	Rate constant	ΔH^* / kJ mol^{-1}	ΔS^* / J mol^{-1} K^{-1}
$[U(acac)_4]$	$CDCl_3$	$k_s(=k_2K_1)$	37.6±0.9	−69.8±3.0
$[U(acac)_4]$	C_6D_6	k_2	40.4±6.6	−62.6±2.1
$[U(acac)_4]$	CD_3CN	$k_4(=k_{AN})$	46.4±0.1	−63.6±3.5
$[Th(acac)_4]$	$CDCl_3$	k_2K_1	30.8±0.7	−81.3±2.5
$[Th(acac)_4]$	CD_3CN	k_2K_1	30.2±1.0	−97.3±3.5

The authors wish to thank Dr. Naoshi Fujiwara, Department of Medicine, Niigata University, for his helpful advice.

(Received February 22, 1986)

Nickel(II) complexes of 1,2-butanediamine(1,2-bn) and 3,3-dimethyl-1,2-butanediamine(dmbn), were prepared, and their thermal behavior was investigated in solid phase. The original complexes were all violet, octahedral diaquabis(diamine) complexes($[Ni(H_2O)_2(1,2\text{-bn/dmbn})_2]X_2$; X=Cl, Br, NO_3, or ClO_4). The 1,2-bn complexes with Cl^- or Br^- and the dmbn complex with NO_3^- showed a two-step thermochromism, violet→yellow→violet blue, upon heating. These steps correspond to structural changes to a square planar anhydride, and then to an octahedral dianiono complex. The complexes of both ligands with ClO_4^- underwent only thermal deaquation, changing into orange square planar anhydride. Other salts, the 1,2-bn complex with NO_3^- and the dmbn complexes with Cl^- or Br^-, were converted into octahedral dianiono complexes by thermal deaquation-anation which occurs in one step. The differences among the thermal reactivities of the complexes with different diamines can be understood on the basis of steric hindrance caused by the substituent groups on the diamine.

It has been well-known that the bis(*N*- or *C*-substituted ethylenediamine) complexes of Ni(II) have either an octahedral structure, $[Ni(A)_2(diamine)_2]X_2$ or $[NiX_2(diamine)_2]$(A: neutral unidentate ligand, X: univalent anion), or a square planar one, $[Ni(diamine)_2]X_2$, depending upon the structure of the diamines and the nature of X^- ions. Among the alkyl-substituted ethylenediamine complexes, in particular, two effects due to the substituent groups on the diamines seem to influence the coordination structure of the complexes. One is their inductive effect, and another is their steric hindrance. The former tends to raise the ligand field strength(l.f.s.) in the octahedral complex,[1] whereas the latter disturbs the coordination of A and X^- and thus favors the formation of square planar structure.

Both of these effects are reflected in the modes of the thermal reactions of these complexes in solid phase.[2–4] Such reactions are, in general, accompanied by distinct color changes, and can be classified into the following four types.

a) $[Ni(H_2O)_2(diamine)_2]X_2$ (Oh) $\xrightarrow[\Delta]{-2H_2O}$ $[NiX_2(diamine)_2]$ (Oh')

b) $[Ni(H_2O)_2(diamine)_2]X_2$ (Oh) $\xrightarrow[\Delta]{-2H_2O}$ $[Ni(diamine)_2]X_2$ (Sp)

c) $[Ni(H_2O)_2(diamine)_2]X_2$ (Oh) $\xrightarrow[\Delta]{-2H_2O}$ $[Ni(diamine)_2]X_2$ (Sp) $\xrightarrow[\Delta]{}$ $[NiX_2(diamine)_2]$ (Oh')

d) $[Ni(diamine)_2]X_2$ (Sp) $\xrightarrow[\Delta]{}$ $[NiX_2(diamine)_2]$ (Oh')

Here, Oh(or Oh') and Sp represent an octahedral diaqua(or dianiono) species and a square planar one, respectively.

In the case of the *N*-substituted ethylenediamine complexes, only reactions of the type (a) or (b) are observed on heating; in certain instances, no diaqua complex can be prepared at room temperature, and the square planar complex obtained scarcely show any structural change until it decomposes on strong heating. Thus it is comparatively easy to see which kind of structure(Oh, Oh', or Sp) is favored by a particular ligand. This situation is probably due to the fact that, in these complexes, the substituent groups are bound directly to the donor N atom(s) of diamines, so that they can excert highly selective influence on the stabilities of the complexes.

On the other hand, in the case of the *C*-substituted ethylenediamine complexes, thermal reactions of the type (c) or (d) often take place,[5] which include the transformation of a square planar species into an octahedral ones on heating, in addition to those of the pattern (a) or (b), so that the correlation between structure and reactivity becomes much more complicated.[7–9] In these complexes, the substituent groups are bound somewhat apart from the donor N atoms, often forming specific conformations; the mode of the thermal reaction thus seems to depend on more delicate structural factors than in the case of the *N*-substituted diamine complexes.

In continuation of these studies, thermal reactions of the nickel(II) complexes with 1,2-butanediamine or 3,3-dimethyl-1,2-butanediamine in solid phase were investigated. The obtained results will be reported in this paper.

Experimental

Materials. 1,2-Butanediamine(1,2-bn)[10] was prepared

by the reaction of 2-ethylaziridine[11] with liquid ammonia. 3,3-Dimethyl-1,2-butanediamine(dmbn)[12] was obtained by reducing 3,3-dimethyl-1,2-butanedione dioxime[13] with Raney nickel.

The complexes with these ligands were prepared by the following method. To an ethanolic solution of a nickel(II) salt, $NiX_2 \cdot nH_2O$ (X=Cl, Br, NO_3, or ClO_4), an ethanolic solution of 1,2-bn or dmbn was added in the molar ratio of 1:2.[14] The solutions were allowed to stand for several days to precipitate the desired bis-type complexes. The violet crystals obtained were collected by filtration and washed with ethanol and/or diethyl ether.

The products of the thermal reactions of these complexes were obtained by isothermal heating at the temperatures of the respective DTA peaks, using an electric furnace in static air. They were studied directly after preparation, or in carefully dried atmosphere, to avoid the occurrence of backward reactions towards the original complexes(see later).

Visual Observations of Thermochromic Changes. The mode of thermochromic color change of each complex, which usually occurs within a temperature range of several degrees, was observed by putting a small amount of finely powdered sample on the bulb of a spiral-formed thermometer, and heating it on a hot plate with a rate of ca. 5 °C min^{-1}.

Measurements. Simultaneous TG-DTA or TG-DSC measurements were carried out with a Sinku Riko TGD-3000M or a Rigaku Denki standard TG-DSC apparatus. The conditions of the runs are given in the captions of Figs. 3 and 4.

The electronic spectra in solid phase were measured by the diffuse reflectance method with a Hitachi 340 spectrophotometer equipped by reflection attachments for the visible(850—300 nm) and near IR(1400—850 nm) parts of the spectrum. The spectra at elevated temperatures were obtained by using a powder cell attached to a heating block.[15] The IR spectra were measured with a JASCO IR-A3 spectrophotometer in Nujol mulls.

Magnetic susceptibility measurements were performed with a Shimadzu Torsion Magnetometer MB-100 at room temperature.

Results and Discussion

Structure of the Original Complexes. The analytical data and magnetic moments in Table 1 show that all the complexes prepared are of the composition, $NiX_2 \cdot 2(\text{diamine}) \cdot nH_2O$ (n is 2.5 for perchlorate with 1,2-bn or 2 for others), and are high spin. The spectrum of one of them, the 1,2-bn complex with Br^-, is shown in Fig. 1 (together with those of its thermal reaction products; see later). The number of observed bands and their modes of splitting clearly indicate that the original complex has a *trans*-octahedral structure.[16,17] The spectra of the other 1,2-bn complexes and all the dmbn complexes are all similar, leading to the formulas of these complexes given in Table 1.

Thermochromism of the Complexes. Figure 2 shows the results of visual observations on the solid phase thermochromism of the complexes. All the complexes except for *trans*-$[Ni(H_2O)_2(1,2\text{-bn})_2](NO_3)_2$ change their color from violet to yellow, orange, or violet blue at a relatively low temperature (ca. 100 °C or lower). Among them, the changes observed in the 1,2-bn complexes with Cl^- and Br^- and in the dmbn complex with NO_3^- are especially remarkable, since they show a second color change from yellow to violet blue upon continued heating, leading to a two-step thermochromism(violet→yellow→violet blue).

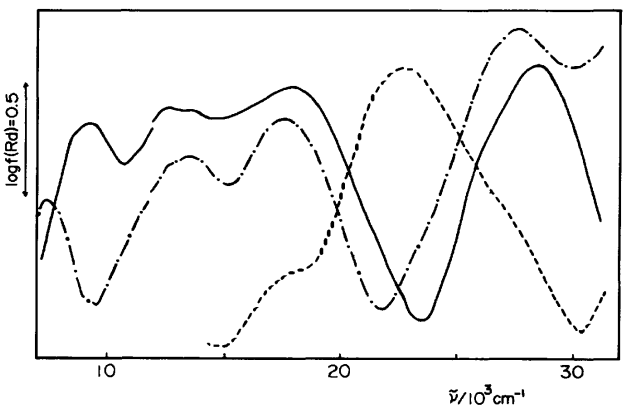

Fig. 1. Electronic spectra of *trans*-$[Ni(H_2O)_2(1,2\text{-bn})_2]Br_2$ at room temperature(——), at 100 °C(----), and at 160 °C(—·—).

a) Calculated values are in parentheses.

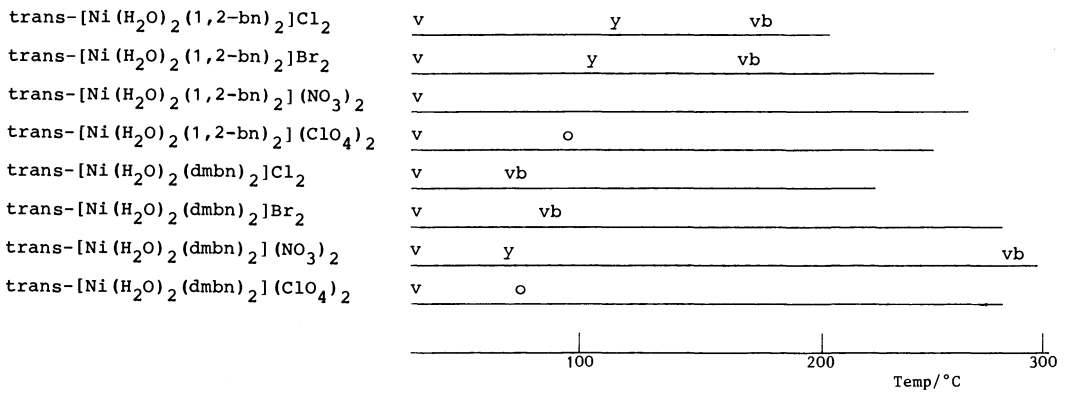

Fig. 2. Results of visual observations on the thermochromic changes of the complexes. v: violet, vb: violet blue, y: yellow, o: orange. The high-temperature colors are shown at the spots on the temperature scale(horizontal lines) where they begin to appear; the right-hand ends of the lines correspond to the decomposition points.

These color changes are reversible; in particular, the violet blue product of the dmbn complex with NO_3^- returns to yellow immeadiately on cooling. Also in the case of the 1,2-bn complexes with Cl^- and Br^-, reverse changes from violet blue or yellow to an original violet are observed on cooling for a few minutes. The violet blue product of the former complex and the yellow and violet blue products of the latter ones are thus stable only at the correspondingly elevated temperatures. The yellow product of the dmbn complex with NO_3^- could be cooled to room temperature and identified; however, it also returned to the original violet complex on standing for some days in open air. The violet blue products of the dmbn complexes with Cl^- and Br^-, and the violet one of the 1,2-bn complex with NO_3^- (anhydrous salt; see later) also revert to the original diaqua species more or less gradually.

Thermal Analyses. The results of simultaneous TG-DTA analyses for the 1,2-bn complexes with Cl^- and Br^- are shown in Fig. 3. The abrupt weight losses observed in both TG curves before 100 °C, and the corresponding endothermic DTA peaks, are due to the liberation of two moles of coordinated water, which is responsible for the color change from violet to yellow. The endothermic peaks near 160 °C(Cl^-) and 150 °C(Br^-), on the other hand, apparently correspond to the second color changes from yellow to violet blue, in which the TG curves remain flat.

Figure 4 depicts the results of TG-DTA analysis of *trans*-$[Ni(H_2O)_2(dmbn)_2](NO_3)_2$, as another example of the complexes showing the two-step thermochromism. The DTA curve at the heating rate of 2 °C min^{-1} gives no peak for the second color change (yellow→violet blue), until the complex decomposes exothermically near 260 °C. When the heating rate is increased to 8 °C min^{-1}, however, the endothermic peak begins to appear, and becomes very apparent at 10 °C min^{-1}, as can be seen in the same Figure. It is considered that this endothermic peak corresponds to the color change (yellow→violet blue).

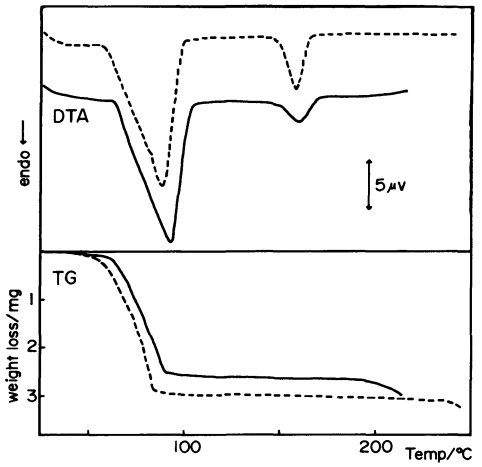

Fig. 3. TG-DTA patterns of *trans*-$[Ni(H_2O)_2(1,2\text{-bn})_2]Cl_2$(——) and *trans*-$[Ni(H_2O)_2(1,2\text{-bn})_2]Br_2$(----). Heating rate: 2 °C min^{-1}; DTA sensitivity: ±25 μV with Pt–Rh thermocouple; gas flow: N_2 at 20 ml min^{-1}; amounts of samples: 24.8 mg for chloride and 34.8 mg for bromide.

The features of TG-DTA curves of the remaining five complexes are quite similar to those of the complexes in Figs. 3 and 4, except for that the second endothermic peak does not appear. The results obtained by TG-DTA analyses of all the complexes studied are summarized in Table 2. The enthalpy changes for the reactions of the type (yellow→violet blue), also shown in Table 2, were estimated from the DSC measurements carried out separately.

Spectral Changes of the Complexes on Heating. The spectra of the 1,2-bn complexes with NO_3^- and ClO_4^- after dehydration are shown in Fig. 5. In the former case, the spectral pattern remains nearly unchanged after dehydration, showing that the *trans*-octahedral configuration is retained. In the latter case, however, there is a drastic spectral change, and a broad band characteristic to the spectrum of a square

planar Ni(II) complex appears. It is thus clear that the reactions of types (a) and (b) take place in these two cases, respectively; the reason why a distinct change in color does not occur in the former case can also be understood, since the ligands exchanged (H_2O and NO_3^-) are both O-ligands with nearly the same ligand field strength.

Figure 1 gives a comparison of the spectra of the yellow and violet blue species of the 1,2-bn complex with Br^- with that of the original violet one. The spectra of both products were measured at the elevated temperatures where the respective species form, because they change rapidly into the original complex on cooling (see above). As shown in the Figure, it is clear that the yellow product formed by dehydration has a square planar structure and the violet blue product has a *trans*-octahedral one, which is similar to that of the original violet specimen. The spectral data on the same color change, violet→yellow→violet blue, of the 1,2-bn complex with Cl^-, which are not shown, are quite similar to those in Fig. 1. In these cases, the reactions which take place are clearly of type (c).

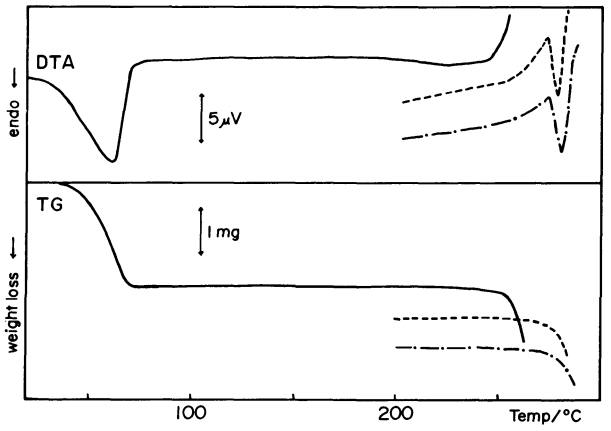

Fig. 4. TG-DTA patterns of *trans*-$[Ni(H_2O)_2(dmbn)_2](NO_3)_2$. Heating rate: 2 °C min^{-1}(run 1, ——), 8 °C min^{-1}(run 2, ----), and 10 °C min^{-1}(run 3, —·—). DTA sensitivity: ±25 μV with Pt–Rh thermocouple; gas flow: N_2 at 20 ml min^{-1}; amounts of samples: 26.5 mg for run 1, 25.8 mg for 2, and 26.3 mg for 3, respectively. The first(dehydration) step observed in run 2 and run 3 is essentially the same as that in run 1, except for a gradual shift to higher temperature like that observed with the second step.

Confirmation of the Structures of the Thermal Reaction Products. It was also tried to isolate the products of the thermal reactions and to confirm their structures separately. Although they readily revert to the original diaqua species on cooling, such reverse changes are sometimes slow enough to allow rapid measurements. In addition, they (except those of the Oh′→Sp type) can be stopped by operating in extremely dry air to avoid the reaquation of the dehydrated species. The data in Table 3 were obtained by making use of these facts; some of the spectra were obtained at high temperatures. It can be seen that all these data, and the structures deduced from them are compatible with the modes of the formation of these complexes proposed above.

The mode of coordination in the nitrato complex(Oh′) with 1,2-bn was also studied by means of its IR spectrum. In general, NO_3^- ion in a metallic complex gives rise to a weak combination band in the range of 1700—1800 cm^{-1}. When it is coordinat-

a) Calculated values are in parentheses. b) The data obtained at high temperatures are marked with.*

ed as a monodentate ion, a small splitting into two components (less than 25 cm^{-1}) takes place. When it acts as a bidentate ligand, the splitting becomes much larger(20—50 cm^{-1}).[18,19] The band at 1768 cm^{-1} in the original complex is found to split into two bands at 1752 cm^{-1} and 1773 cm^{-1} with a separation of 21 cm^{-1} after heating. This is compatible with the view that the two NO_3^- ions are coordinated at the axial positions as unidentate ligands to form the *trans*-octahedral complex.

The thermochemical changes of all the complexes observed can thus be represented by the following equations, and classified into the types (a), (b), and (c) mentioned above:

(a) *trans*-$[Ni(H_2O)_2(1,2\text{-bn})_2](NO_3)_2 \xrightarrow[\Delta]{-2H_2O}$ *trans*-$[Ni(NO_3)_2(1,2\text{-bn})_2]$

trans-$[Ni(H_2O)_2(dmbn)_2]X_2 \xrightarrow[\Delta]{-2H_2O}$ *trans*-$[NiX_2(dmbn)_2]$ (X=Cl or Br)

(b) *trans*-$[Ni(H_2O)_2(1,2\text{-bn or dmbn})_2](ClO_4)_2 \xrightarrow[\Delta]{-2H_2O} [Ni(1,2\text{-bn or dmbn})_2](ClO_4)_2$

(c) *trans*-$[Ni(H_2O)_2(1,2\text{-bn})_2]X_2 \xrightarrow[\Delta]{-2H_2O}$ $[Ni(1,2\text{-bn})_2]X_2 \xrightarrow[\Delta]{}$ *trans*-$[NiX_2(1,2\text{-bn})_2]$ (X=Cl or Br)

The data for the violet blue product of the dmbn complex with NO_3^- are lacking in Table 3, because it reverts so easily to the yellow species on cooling, at a temperature which is quite close to the decomposition point (see above and Figs. 2 and 4). The first step, violet→yellow, of its formation is, however, clearly a structural change to a square planar anhydrous complex (Table 3), and the general features of the second steps, yellow→violet blue, indicates that a type (c) reaction also takes place here.

Effects of Structures of Diamines upon Thermal Reactions. Table 4 summarizes the results on the thermal reactions of 1,2-bn and dmbn complexes, and those of 1-phenyl-1,2-ethanediamine(phenen) complexes already studied.[9] When heated, they change in one of the three ways, Oh→Oh′(type (a)), Oh→Sp(type (b)), and Oh→Sp→Oh′(type (c)). On the other hand, when the original species are square planar, they remain unchanged upon heating until decomposition; only one such example is shown in the Table, i. e., $[Ni(phenen)_2](ClO_4)_2$.

It can be seen that both 1,2-bn and dmbn complexes easily undergo deaquation-anation either in one step or in two, producing aniono complexes, retaining their octahedral configuration. Perchlorates are exceptions, undergoing deaquation to Sp only, because of the poor coordination ability of ClO_4^- ions.

The tendency of favoring an octahedral configuration observed in *C*-monosubstituted ethylenediamine complexes, such as those in Table 4, is more remarkable than that in 1,1-di- or 1,2-disubstituted ethylenediamine complexes.[3,7,20] The main reason for such a differences can be found in the magnitudes of steric hindrance caused by the substituent groups on the diamines. From NMR studies on Co(III),[21] Pt(II),[22,23] and Ni(II)[24,25] complexes with several *C*-substituted ethylenediamines, it is known that, when there is only one substituent group on the diamine, it almost always occupies the equatorial position on

Table 4. Classification of Thermal Reactions of Nickel(II) Complexes Containing *C*-Mono Substituted Ethylenediamines

	Cl	Br	NO_3	ClO_4
1,2-bn	Oh→Sp→Oh′	Oh→Sp→Oh′	Oh→Oh′	Oh→Sp
dmbn	Oh→Oh′	Oh→Oh′	Oh→Sp→Oh′	Oh→Sp
phenen[9]	Oh→Oh′	Oh→Oh′	Oh→Sp→Oh′	Sp

the plane containing two diamines at room temperature. It is clear that, in such a case, there is enough space above and below to permit the approach of the additional ligands such as water molecules and counter anions. On the other hand, in the complexes with 1,1-di- or *meso*-1,2-disubstituted ethylenediamines, at least one of the substituents in each diamine ligand is forced to occupy the axial positions.[26,27] Such a configuration generates a larger steric hindrance, preventing the approach of other ligands from the axial direction and stabilizing the square planar structure.

For the square planar species to occur in the *C*-monosubstituted ethylenediamine complexes, therefore, it is tempting to suppose that the substituent group in the diamine protruding on the equatorial plane should be so bulky that they can influence the axial coordination to some extent. In fact, except for the case of perchlorates, such a species is formed in the 1,2-bn complexes with Cl^- and Br^-, and in the dmbn complex with NO_3^-. However, since the substituent group in dmbn(i.e., $(CH_3)_3C$–) is much larger than that in 1,2-bn(C_2H_5–), the tendency observed in the complex halides is rather unexpected.

A possible explanation for this apparent anomaly is as follows. At high temperature, the conformation of the diamine chelate ring will not be rigid, and a conformational equilibrium will finally be brought about by thermal agitation, in which the equatorial group(R) on the ligand temporarily "stands up" as the axial one.[28,29] Such a "stand up" motion will occur more easily when R is small, hindering the coordination of X^- at trans positions of Ni(II), but when R is as large as $(CH_3)_3C$–, it will be hard to move in crystals, so that dianiono complexes can be formed more easily.[30] It seems probable that the occurence of such thermal deformation of the ligands is complicating the observed situations also in the case of related complexes.

The authors wish to express their thanks to Professor Eishin Kyuno and his colleagues of Hokuriku University for their kind aid in TG-DSC measurements. This work was partially supported by a Grant-in-Aid for Scientific Reseach No. 59430009 from the Ministry of Education, Science, and Culture.

References

1) If the l.f.s. is raised strongly, it is also conceivable that a crossover into the square planar(i.e., low spin) structure is brought about by this effect. In the present case, however, it seems that the steric effect is more important when the square planar structure is favored.

They show that dmbn favors the equatorial conformation much more strongly than pn.

Synthesis of the 3*H*-Azepines Utilizing the Thermolysis of Substituted Aryl Azides

Yoshihiro OHBA,* Shinji KUBO, Masaaki NAKAI, Atsunori NAGAI, and Masayo YOSHIMOTO
Department of Chemistry, Faculty of Sciences, Yamaguchi University, Yamaguchi 753
(Received October 18, 1985)

Thermolysis of several *p*-substituted aryl azides (*p*-R-$C_6H_4N_3$; R=$COCH_3$, CO_2CH_3, COPh) in methanol gave 5-substituted 2-methoxy-3*H*-azepines in moderate yields. Thermolysis of *m*-substituted aryl azides (*m*-R-$C_6H_4N_3$; R=$COCH_3$, CO_2CH_3, COPh, NO_2) gave 4-substituted 2-methoxy-3*H*-azepines and 6-substituted 2-methoxy-3*H*-azepines in good yields. In contrast, thermolysis of *p*-azidoacetophenone in piperidine gave 5-acetyl-2-piperidino-3*H*-azepine and an unusual product, 6-acetyl-2-piperidino-3*H*-azepine, and *p*-aminoacetophenone.

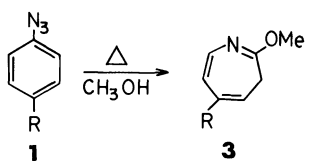
Formation of 3*H*-azepines by the thermolysis and photolysis of aryl azides in methanol is well documented.[1-3]

In general, however, many attempts at the synthesis of 3*H*-azepines by the thermolysis or photolysis of aryl azides have failed or given low yields of 3*H*-azepines. Only succeeded experiment was the photolysis of o-azidobenzoic acids[4a-c] in alcohols. It has been considered that an electron-withdrawing substituent at *m*-or *p*-position of azidobenzene apparently prevents the azepine formation by decreasing the electron density on the carbon center at which the electrophilic single nitrene attacks.[4a]

We have investigated the thermolysis of *m*-azidoacetophenone (**2a**) and *p*-azidoacetophenone (**1a**), and in a preliminary communication[5] we have shown that the thermolysis of these azides in methanol gives ring-expansion products, 3*H*-azepines, in excellent yields. We now report the thermolysis of *p*-substituted aryl azides (**1**; R=$COCH_3$, CO_2CH_3, COPh, NO_2) and *m*-substituted aryl azides (**2**; R=$COCH_3$, CO_2CH_3, COPh, NO_2) in methanol and the thermolysis of **1a** and **1c** in piperidine and morpholine.

Results and Discussion

The thermolysis of methanol solution of **1a—c** in a sealed Pyrex tube at 170 °C gave 5-substituted 2-methoxy-3*H*-azepines (**3a—c**) in moderate yields. The results are shown in Table 1. The structure of all azepines (**3a—c**) was confirmed by ^1H NMR spectroscopy. The thermolysis of 1-azido-4-nitrobenzene (**1d**) at 190 °C for 2 h gave only tar.



1 **3**

a: R=$COCH_3$
b: R=CO_2CH_3

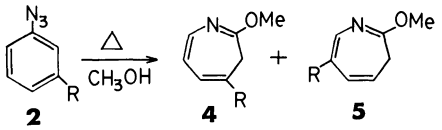
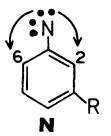
d: R=NO_2



2 **4** **5**

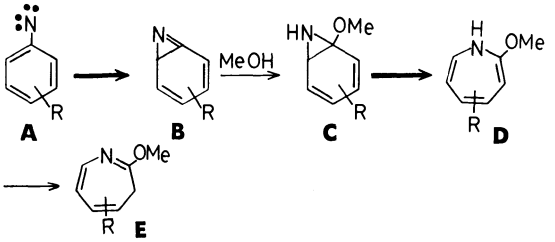
a: R=$COCH_3$
b: R=CO_2CH_3
c: R=COPh
d: R=NO_2

Thermolysis of *m*-substituted aryl azides (**2a—d**) under the similar conditions also gave 6-substituted 3*H*-azepines (**5a—d**) and 4-substituted 3*H*-azepines (**4a—d**). These results are also shown in Table 1. The observed ratio of **5a—c** to **4a—c** shows that electron-withdrawing *m*-substituent ($COCH_3$. CO_2CH_3, COPh) favor an intramolecular cycloaddition of nitrene (**N**) at C-2 position to give **5a—c**. It is



N

suggested from the failure to give 2-methoxy-3*H*-azepine in the thermolysis of azidobenzene in methanol that electron-withdrawing *m*- and *p*-substituents accelerate cycloaddition of singlet nitrene (**A**) to give azirne (**B**) and facilitate ring-expansion of (**C**) to 1*H*-azepine (**D**), which by prototropic migration yields 3*H*-azepine (**E**)(Scheme 1). In contrast with the thermolysis, the photolysis of **1a** and **2a** in methanol gave a low yields of 3*H*-azepines (**3a, 4a, 5a**). These results show that the thermolysis is superior to the photolysis for the formation of 3*H*-azepines from *m*-



Scheme 1.

Table 1. Yieldes of 3*H*-Azepines

AZIDE	R[a]	Reaction Conditions Temp/°C	Time/h	Yield of Product/% 3	4	5

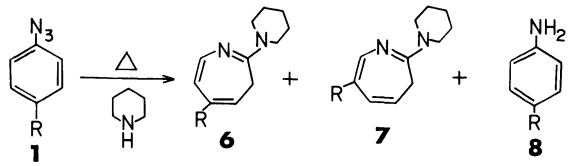
2d	*m*-NO_2	180	2		15	5

a) 
and *p*-substituted azidobenzenes.

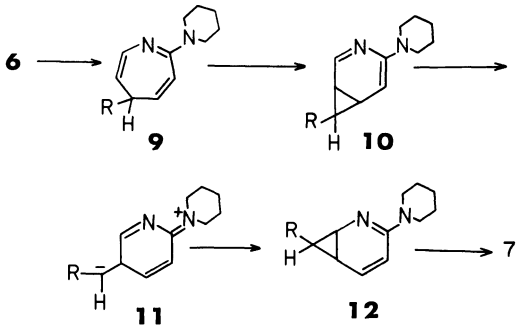
The thermolysis of **1a** in piperidine at 170 °C for 2 h gave 5-acetyl-2-piperidino-3*H*-azepine (**6a**) (10%) and unexpected product, 6-acetyl-2-piperidino-3*H*-azepine (**7a**) (13%) and a triplet product,[7] *p*-aminoacetophenone (**8a**) (22%). The thermolysis of **1c** in piperidine at 170°C for 2 h gave 6-benozyl-2-piperidino-3*H*-azepine (**7c**) (18%) and *p*-aminobenzophenone (**8c**) (27%). The thermolysis of **1a** in morpholine at 170 °C for 2 h gave 5-acetyl-2-morpholino-3*H*-azepine (**13a**) (30%), 6-acetyl-2-morpholino-3*H*-azepine (**14a**) (22%) and *p*-aminoacetophenone (**8a**) (32%). The thermolysis of **1c** in morpholine at 170 °C for 6 h gave 6-benzoyl-2-



1 **6** **7** **8**

a: R=$COCH_3$
c: R=COPh

morpholino-3*H*-azepine (**14c**) (7%) and tar. The pathway to 6-acetyl-3*H*-azepine (**7a**) must involve the bicyclic valence isomers **10** and **11** (Scheme 2). Analogous step has been postulaed[8] for the formation of 1,3-diazepine by the thermal isomerzation of 1,2-diazepine. In support of the above mechanism, the thermal isomerzation of **6a** in piperidine at 170 °C for 6 h gave **7a** (85%). The thermal isomerization of **13a** in morpholine at 170 °C for 6 h gave **14a** in 75% yield. But the thermal isomerzation of **6a** in xylene at 170 °C for 6 h gave no **7a**, and **6a** was recovered in 91% yield. These results can be explained by the existence of the dipolar transition state or intermediae (**11**) for the formation of **7a** from **6a** in piperidine. Rate constant for this valence isomerization[9] was found to be 9.45×10^{-5} s^{-1}.



Scheme 2.

Experimental

Melting points were determined in a capillary tube. IR spectra were recorded for liquids as thin films and solids as KBr discs on a Japan Spectroscopic IR-G spectrometer. UV spectra were recorded in ethanol on a Hitachi 220A spectrophotometer. ^1H NMR spectra were recorded in $CDCl_3$ at 60 MHz using a Hitachi R24-B spectrometer (Me_4Si as internal standard). Mass spectra were determined with a JEOL JMS-01SG-2 spectrometer (75 eV). Unless otherwise stated recorded yields are based on the material after separation by medium-pressure liquid chromatography (Silica-gel Woelm 32—63 μm or aluminium oxide 200—300 mesh).

Preparation of Azidobenzenes. All azides were prepared from the corresponding amines by diazotization, followed by azidation with sodium azide. Azidobenzenes (**1b, 1d, 2b,** and **2d**) were prepared according to literature.[11a-c]

***p*-Azidoacetophenone (1a)** To a solution of *p*-aminoacetophenoe (1.00 g, 7.41 mmol) in acetic acid (10 ml), concd sulfulic acid (3 ml) was added under cooling (0—5 °C), and a solution of sodium nitrite (3.00 g, 43 mmol) in water (15 ml) was added over 15 min and stirrd at 0—5 °C for 2 h. A solution of sodium azide (5.00 g, 77 mmol) in water (23 ml) was added over 2 h and stirred at 0—5 °C for 1 h and extracted with ether. The extract was washed with water and dried over Na_2SO_4. Evaporation of the extract to dryness and chromatography of residue with hexane/ethyl acetate=3:1 on silica-gel (Wako Q-22) gave 879 mg (75%) of *p*-azidoacetophenone (**1a**); Yellow needles; mp 43—44 C(lit,[11a] mp 44 °C); Anal. ($C_8H_7O_1N_3$) C, H, N. IR(KBr) 3030, 2929, 2130, 2100, 1670, and 1598 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.58 (3H, s), 7.10 (2H d, J=8 H), and 7.95 (2H, d, J=8 Hz).

Following azides were prepared similarly:

***p*-Azidobenzophenone (1c)** (90%): Yellow needles; Anal. ($C_{13}H_9O_1N_3$) C, H, N.; mp 73—74 °C(lit,[12] mp 74 °C); IR(KBr) 3040, 2900, 2130, 2100, 1658, and 1592 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.0—7.8 (9H, m).

***m*-Azidoacetophenone (2a)** (86%): Yellow oil; Anal. ($C_8H_7O_1N_3$) C, H, N.; IR(oil) 3050, 2910, 2125, 2120, 1685, and 1585 cm^{-1}: ^1H NMR ($CDCl_3$) δ=2.58 (3H, s), and 7.05—7.80 (4H, m).

***m*-Azidobenzophenone (2c)** (93%): Yellow oil; Anal.

($C_{13}H_9O_1N_3$) C, H, N.); IR(oil) 3040, 2150, 2110, 1658, 1598, and 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.10—7.90 (9H, m).

Thermolysis of *p*-Azidoacetophenone (1a). General procedure. A solution of 319 mg (1.98 mmol) of **1a** in methanol (10 ml) was sealed in a Pyrex tube and heated at 170 °C for 2 h. Evaporation of the solution to dryness gave dark brown oil which was chromatographed on silica-gel (Wako-gel Q-22) with benzene:ethyl acetate=3:1 to give 196 mg(60%) of 5-acetyl-2-methoxy-3*H*-azepine (**3a**) as yellow oil; Anal. ($C_9H_{11}O_2N_1$) C, H, N.; UV (95% C_2H_5OH) 220.0 (ε 15400) and 290 nm (sh, 1960); IR (oil) 2980, 2930, 2840, 1670, and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.38 (3H, s), 2.79 (2H, d, J=7.5 Hz), 3.73 (3H, s), 6.22 (1H, t, J=7.5 Hz), 6.52 (1H, d, J=8 Hz), 7.10 (1H, d, J=8 Hz), and 61 mg (23%) of *p*-aminoacetophenone.

Thermolysis of Methyl *p*-Azidobenzoate (1b). A solution of 102 mg (0.68 mmol) of **1b** in methanol (20 ml) was heated at 170 °C for 2 h to give 101 mg (97%) of methyl 2-methoxy-3*H*-azepine-5-carboxylate (**3b**)[4b] as yellow oil; Anal. ($C_9H_{11}O_3N_1$) C, H, N.; UV (95% C_2H_5OH) 285.0 nm (ε 2970); IR (oil) 2095, 2840, 1723, and 1627 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.74 (2H, d, J=7 Hz), 3.72 (3H, s), 3.79 (3H, s), 6.36 (1H, t, J=7 Hz), 6.48 (1H, d, J=8 Hz), 7.09 (1H, d, J=8 Hz).

Thermolysis of *p*-Azidobenzophenone (1c). Thermolysis of 256 mg (1.16 mmol) of **1c** in methanol (39 ml) at 170 °C for 4 h gave 84 mg of 5-benzoyl-2-methoxy-3*H*-azepine (**3c**) as yellow oil; Anal. ($C_{14}H_{13}O_2N_1$) C, H, N.; UV (95% C_2H_5OH) 251.0 nm (ε 15000); IR (oil) 3050, 2950, 2840, 1645, 1620, and 1595 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.76 (2H, d, J=7 Hz), 3.76 (3H, s) 5.83 (1H, t, J=7 Hz), 6.47 (1H, d, J=8 Hz), 7.06 (1H, d, J=8 Hz), 7.24—7.75 (5H, m).

Thermolysis of 1-Azido-4-nitrobenzene (1d). A solution of 360 mg (2.20 mmol) of **1d** in methanol (20 ml) was heated at 190 °C for 2 h to give no 3*H*-azepine and some tar.

Thermolysis of *m*-Azidoacetophenone (2a). A solution of 530 mg of **2a** in methanol (20 ml) was heated at 170 °C for 2 h. After the similar procedure, described for the thermolysis of **1a**, a mixture of 330 mg (61%) of 6-acetyl-2-methoxy-3*H*-azepine (**5a**) and 122 mg (22%) of 4-acetyl-2-mehoxy-3*H*-azepine (**4a**) was obtained. The yields of **5a** and **4a** were determined by ^1H NMR. The analytical samples of **4a** and **5a** were obtained by HPLC (Dupont Zorbax ODS, 15.0 cm×4.6 mm; solvent, MeOH/H_2O=1:1), giving **5a** as yellow oil; Anal. ($C_9H_{11}O_2N_1$) C, H, N.; UV (95% C_2H_5OH) 217.0 (ε 18300) and 288.5 nm (13900); IR (oil) 2990, 2940, 2840, 1658, and 1615 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.43 (3H, s), 2.66 (2H, d, J=7 Hz), 3.73 (3H, s), 5.47 (1H, dt, J=9 and 7 Hz), 6.79 (1H, dd, J=9 and 1 Hz), 7.94 (1H, d, J=1 Hz) and **4a** as yellow; oil Anal. ($C_9H_{11}O_2N_1$) C, H, N.; UV (95% C_2H_5OH) 221.0 (ε 12800) and 313.0 nm (6400); IR (oil) 2990, 2940, 2840, 1658, and 1615 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.37 (3H, s). 2.98 (2H, s), 3.70 (3H, s), 6.09 (1H, dd, J=8 and 6 Hz), 7.14 (1H, dd, J=6 and 1 H), 7.22 (1H, dd, J=8 and 1 Hz).

Thermolysis of Methyl *m*-Azidobenzoate (2b). A solution of 640 mg (3.62 mmol) of **2b** in methanol (20 ml) was heated a 170 °C for 2 h to give a mixture of 396 mg (60%) of methyl 2-methoxy-3*H*-azepine-6-carboxylate (**5b**) and 222 mg (34%) of methyl 2-methoxy-3*H*-azepine-4-carboxylate (**4b**). Analytical samples were obtained by HPLC under the same conditions used for **4a** and **5a**, giving **5b** as yellow oil; Anal. ($C_9H_{11}O_3N_1$) C, H, N.; UV (C_2H_5OH) 280.0 nm, (ε 6650); IR (oil) 2960, 2940, 2820, 1708, and 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.60 (2H, d, J=7 Hz), 3.75 (3H, s), 3.80 (3H, s), 5.40 (1H, dt, J=9 and 7 Hz), 6.74 (3H, s), 3.80 (3H, s), 5.40 (1H, dt, J=9 and 7 Hz), 6.74 (1H, dd, J=9 and 2 Hz), 8.05 (1H, d J=2 Hz) and **4b** as yellow oil; Anal. ($C_9H_{11}O_3N_1$) C, H, N.; UV (95% C_2H_5OH) 213.5 (ε 6610) and 308.0 nm (5430); IR (oil) 2960, 2910, 2825, 1704, and 1615 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.01 (2H, s), 3.73 (3H, s), 3.80 (3H, s), 6.03 (1H, dd, J=6 and 8 Hz), 7.20 (1H, dd, J=8 and 1 Hz), 7.27 (1H, dd, J=6 and 1 Hz).

Thermolysis of *m*-Azidobenzophenone (2c). A solution of 241 mg (1.08 mmol) of **2c** in methanol (10 ml) was heated at 170 °C for 4 h to give the mixture of 152 mg (62%) of 6-benzoyl-2-methoxy-3*H*-azepine (**5c**) and 58 mg (24%) of 4-benzoyl-2-methoxy-3*H*-azepine (**4c**). Analytical samples were obtained similarly. **5c**; yellow oil; Anal. ($C_{14}H_{13}O_2N_1$) C, H, N.; UV (C_2H_5OH) 245.0 (ε 9300) and 296.0 nm (9620); IR (oil) 3050, 3000, 2940, 1640, and 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.80 (2H, d, J=6 Hz), 3.80 (3H, s), 5.60 (1H, dt, J=9 and 6 Hz), 6.94 (1H, dd, J=9 and 1 Hz), 7.70 (1H, d, J=1 Hz). **4c**; yellow oil; Anal. ($C_{14}H_{13}O_2N_1$) C, H, N.; UV (C_2H_5OH) ca. 240 (sh, ε 7430) and 318.0 nm (5330); IR (oil) 3020, 2930, 2850, 1640, and 1618 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.16 (2H, s), 3.58 (3H, s), 6.06 (1H, dd, J=8 and 6 Hz), 6.94 (1H, d, J=6 Hz), 7.20 (1H, d, J=8 Hz), 7.3—7.8 (5H, m).

Thermolysis of 1-Azido-3-nitrobenzene (2d). A solution of 231 mg (1.41 mmol) of **2d** in methanol (20 ml) was heated at 180 °C for 2 h to give the mixture of 11 mg (5%) of 6-nitro-2-methoxy-3*H*-azepine (**5d**) and 36 mg (15%) of 4-nitro-2-methoxy-3*H*-azepine (**4d**). 5d; colorless oil; Anal. ($C_7H_8O_3N_2$) C, H, N.; UV (95% C_2H_5OH) 224.0 (ε 7030) and 323.0 nm (5990); IR (oil) 2980, 2940, 2850, and 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.75 (2H, d, J=7 Hz), 3.73 (3H, s), 5.48 (1H, dt, J=9 and 7 Hz), 7.00 (1H, dd, J=9 and 2 Hz), 8.43 (1H, d, J=2 Hz). **4d**; yellow oil; Anal. ($C_7H_8O_3N_2$) C, H, N.; UV (95% C_2H_5OH) 231.5 (ε 9900) and 347.5 nm (4910); IR (oil) 2980, 2930, 2840, and 1623 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.33 (2H, s), 3.76 (3H, s), 6.00 (1H, dd, J=8 and 6 Hz), 7.31 (1H, dd, J=8 and 1 Hz), 7.64 (1H, dd, J=8 and 1 Hz).

Phtolysis of *p*-Azidoacetophenone (1a) in Methanol. A solution of 500 mg (3.11 mmol) of **1a** in methanol (400 ml) was irradiated (Ushio 100 W high pressure Hg lamp with Pyrex filter) for 5 h under nitrogen to give 40 mg (8%) of **3a** and intractable tar. The reaction was monitored using HPLC,[6] and **1a** was consumed completely.

Photolysis of *m*-Azidoacetophenone (2a) in Methanol. A solution of 425 mg (2.64 mmol) of **2a** in methanol (400 ml) was irradiated under the similar conditions to give 26 mg (8%) of the mixture of **4a** (2%) and **5a** (6%). An intractable tar was also obtained, and **2a** was consumed completely.

Thermolysis of *p*-Azidoacetophenone (1a) in Piperidine. A solution of 300 mg (1.86 mmol) of **1a** in piperidine (20 ml) was heated at 170 °C for 2 h. The reaction mixture was chromatographed by medium-pressure liquid chromatography (aluminium oxide 200—300 mesh) with ethyl acetate/hexane=1:3 to give 53 mg (13%) of 6-acetyl-2-piperidino-3*H*-azepine (**7a**) as brown oil; Found: M^+, 218.1395. Calcd for $C_{13}H_{18}O_1N_2$: M^+, 218.1418.[10] UV (95%

C_2H_5OH) 231.5 (ε 13400) and 335.0 nm (22700); IR (oil) 2980, 2920, 2850, 1638, and 1602 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.46—1.78 (6H, m), 2.39 (3H, s), 2.70 (2H. d. J=7 Hz), 3.37—3.73 (4H, m), 5.23 (1H, dt, J=8 and 7 Hz), 6.88 (1H dd, J=8 and 1.5 Hz), 8.07 (1H, d, J=1.5 Hz) and 41 mg (10%) of 5-acetyl-2-piperidino-3*H*-azepine (**6a**) as brown oil; Found: N, 12.94%; Calcd for $C_{13}H_{18}O_1N_2$: N, 12.83%; UV (95% C_2H_5OH) 230.0 (sh, ε 15600) and 325.0 nm (4350); IR (oil) 2980, 2920, 2850, 1705, and 1668 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.51—1.84 (6H, m), 2.36 (3H, s), 2.77 (2H, d, J=7.5 Hz), 3.34—3.70 (4H m), 5.93 (1H, dt, J=1 and 7.5 Hz), 6.23 (1H, dd, J=8 and 1 Hz), 7.20 (1H, d, J=8 Hz), and 54 mg (22%) of **8a**.

Thermolysis of 1a in Morpholine. Thermolysis of 272 mg (1.69 mmol) of **1a** in morpholine (20 ml) a 170 °C for 2 h gave 82 mg (22%) of 6-acetyl-2-morpholino-3*H*-azepine (**14a**) as yellow oil; Found: N, 12.94%; Calcd for $C_{12}H_{16}O_2N_2$; N, 12.72%; UV (95% C_2H_5OH) 231.5 (ε 6000) and 330.5 nm (9190); IR (oil) 2940, 2890, 2840, 1636, and 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.42 (3H, s), 2.72 (2H, d, J=7 Hz), 3.25—4.11 (8H, m), 5.24 (1H, dt, J=9 and 7 Hz), 6.89 (1H, dd, J=9 and 1 Hz), 8.09 (1H, d, J=1 Hz), and 110 mg (30%) of 5-acetyl-2-morpholino-3*H*-azepine (**13a**) as yellow oil; Found: M^+, 220.1218. Calcd for $C_{12}H_{16}O_2N_2$: M^+, 220.1211.[10]; UV (95% C_2H_5OH) 233.0 (ε 7780) and 274.5 nm (6250); IR (oil) 2950, 2880, 2840, 1668, and 1563 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.37 (3H, s), 2.75 (2H, d, J=7 Hz), 3.23—3.79 (8H, m), 5.99 (1H, td, J=7 and 1 Hz), 6.32 (1H, dd, J=9 and 1 Hz), 7.22 (1H, d, J=9 Hz), and 72 mg (32%) of **8a**.

Thermolysis of 1c in Piperidine. A solution of 270 mg (1.21 mmol) of **1c** in piperidine (20 ml) was heated at 170 °C for 2 h to give 61 mg (18%) of 6-benzoyl-2-piperidino-3*H*-azepine (**7c**) as yellow oil; Found: M^+, 280.1577. Calcd for $C_{18}H_{20}O_1N_2$: M^+, 280.1575.[10]; UV (95% C_2H_5OH) 235.5 (ε 9270) and 347.0 nm (12200); IR (oil) 3010, 2930, 2850, 1625, and 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.01—1.92 (6H, m), 2.81 (2H, d, J=7 Hz), 3.23—3.95 (4H, m), 5.27 (1H, dt, J=9 and 7 Hz), 7.04 (1H, dd, J=9 and 1.5 Hz), 7.23—7.85 (5H, m), 7.89 (1H, d, J=1.5 Hz), and 64 mg (27%) of **8c**.

Thermolysis of 1c in Morpholine. Thermolysis of 191 mg (0.86 mmol) of **1c** in morpholine (10 ml) at 170 °C for 2 h gave 16 mg (7%) of 6-benzoyl-2-morpholino-3*H*-azepine (**14c**) as brown oil; Found: M^+, 282.1361. Calcd for $C_{17}H_{18}O_2N_2$: M^+, 282.1367.[10]; UV (95% C_2H_5OH) 340.5 (ε 15100) and 237.0 nm (12200); IR (oil) 2940, 2890, 2840, 1626, and 1595 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.79 (2H, d, J=7 Hz), 3.63 (8H m) 5.29 (1H, dt, J=9 and 7 Hz), 7.02 (1H, dd, J=9 and 1 Hz), 7.20—7.80 (5H, m), 7.85 (1H, d, J=1 Hz).

Thermolysis of 5-Acetyl-2-piperidino-3*H*-azepine (6a) in Piperidine. A solution of 44 mg (0.2 mmol) of **6a** in piperidine (4 ml) was heated at 170 °C for 6 h. The solution was evaporated and the residue was chromatographed by medium-pressure liquid chromatography (aluminium oxide 200—300 mesh, hexane/ethyl acetate=3:1) to give 35 mg (80%) of **7a** and no **6a**.

Thermolysis of 5-Acetyl-2-piperidino-3*H*-azepine (6a) in Xylene. A solution of 44 mg (0.2 mmol) of **6a** in xylene (4 ml) was heated at 170 °C for 6 h and the similar procedure gave 36 mg (82%) of recovered **6a** and no other products.

Thermolysis of 5-Acetyl-2-morpholino-3*H*-azepine (13a) in Morpholine. A solution of 54 mg (0.25 mmol) of **13a** in morpholine (4 ml) was heated at 170 °C for 6 h and the similar procedures described above gave 40 mg (74%) of 6-acetyl-2-morpholino-3*H*-azepine (**14a**).

The authors wish to express their thanks to Dr. Nobuo Kato of Kyushu University for mass spectral determination.

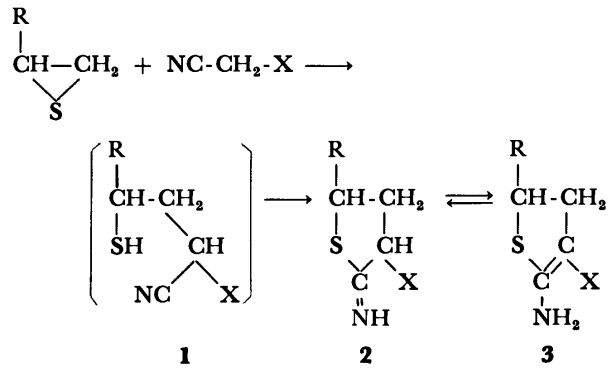
The Synthesis of Dihydro-2(3*H*)-thiophenone Derivatives

Yoichi TAGUCHI* and Yasuo SUHARA
National Chemical Laboratory for Industry, Higashi 1-1, Yatabe, Tsukuba, Ibaraki 305
(Received January 22, 1986)

The reaction of 2,2-dimethylthiirane (**4**) with diethyl malonate (**5**) in the presence of sodium ethoxide gave 3-ethoxycarbonyl-5,5-dimethyl-dihydro-2(3*H*)-thiophenone (**6**) and a polymer. The yield of **6** could be increased to 65%. The reaction of thiirane, 2-methylthiirane, 2-butylthiirane, 2-hexylthiirane, 1,2-epithiocyclohexane, and 2-phenylthiirane with **5** also gave corresponding dihydro-2(3*H*)-thiophenone derivatives. Although the reaction of an alkyl-substituted thiirane with **5** selectively gave a product formed by an attack of a carbanion at the less-hindered carbon of the thiirane ring, the major product of the reaction of 2-phenylthiirane with **5** was an isomer formed by an attack at the more hindered carbon of the thiirane ring. The reaction of **4** with ethyl acetoacetate gave 3-acetyl-5,5-dimethyl-dihydro-2(3*H*)-thiophenone selectively. A product **6** was also obtained by a reaction of **4** with **5** by using sodium hydride instead of sodium ethoxide.

It was reported that a reaction of thiiranes with ethyl cyanoacetate[1] and malononitrile[2] in the presence of a base catalyst has dihydrothiophene derivatives (**3**). The first step of these reactions was considered to be the formation of an intermediate **1** by an attack of carbanion to the thiirane ring, and a following ring closure by the reaction of thiol **1** with



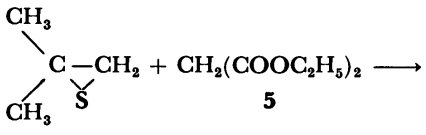
1 **2** **3**

the cyano group. This ring closure was considered to inhibit the polymerization of **1** with thiirane. Though it was reported[1] that the reaction of thiiranes with other active methylene compounds with cyano groups attached to the methylene gave only polymers, we expected that a ring closure similar to the condensation of **1** occured in the reaction of thiiranes with β-oxo-esters.

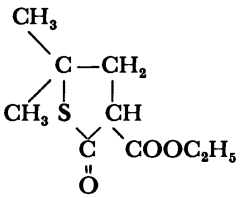
In this work, we found that the reaction of thiiranes with diethyl malonate (**5**) and ethyl acetoacetate gave dihydro-2(3*H*)-thiophene derivatives. The direction of the attack of carbanions to the thiirane rings, the effect of the structures of the thiiranes and the active methylene compounds, and the effect of the reaction conditions were studied.

Results and Discussion

The reaction of **4** with **5** in the presence of sodium ethoxide gave 3-ethoxycarbonyl-5,5-dimethyl-dihydro-2(3*H*)-thiophenone (**6**) selectively and did not give it's isomer, 3-ethoxycarbonyl-4,4-dimethyl-dihydro-2(3*H*)-thiophenone (**7**). This shows that the carbanion formed from **5** selectively attacked the sterically less-hindered terminal carbon of the thiirane; this selectivety is similar to that in a reaction of thiiranes with ethyl cyanoacetate,[1] malononitrile,[2] and the secondary amine.[6]



4 **5**



6

Table 1 shows the effects of the reaction conditions on a reaction of **4** with **5**. A product which was insoluble in water and ether was obtained, and the ^{1}H NMR and IR spectra of this product showed that it was a polymer of **4** with a few carbonyl groups. The yield of **6** decreased and the ratio of the polymer to **6** increased at lower temperatures or by using more ethanol. By using less ethanol and a great exess of **5**, the yield of **6** increased to 65% (Run 7).

Table 2 shows the products and their yields in the reactions of various thiiranes with **5**. Thiiranes have a tendency to easily polymerize such molecules as thiirane, 2-methylthiirane and 1,2-epithiocyclohexane reacted with **5** to give corresponding dihydro-2(3*H*)-thiophenones in low yield. Although a reaction of alkyl-substituted thiiranes with **5** gave a product corresponding to **6**, selectively, the major product of a reaction of 2-phenylthiirane with **5** was 3-ethoxycarbonyl-4-phenyl-dihydro-2(3*H*)-thiophenone, corresponding to **7**. The different reactivity of 2-phenylthiirane from alkyl-substituted thiiranes was cosidered to be due to a polymerization of 2-phenylthiirane by the phenyl group.

Table 1. Effect of Reaction Conditions on the Reaction of 2,2-Dimethylthiirane with Diethyl Malonate[a)]

Run	Sulfide mmol	Malonate mmol	Sodium mmol	EtOH ml	Temp °C	Time h	Yield %	Solid[b)] g
1	10	20	15	50	Reflux	1	17	0.51
2	10	20	15	50	30	1	4	0.41

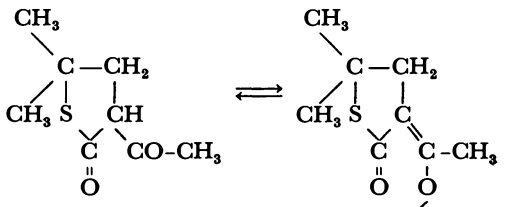
C_6H_5	H	H	18	45

a) Same reaction conditions to Run 7 in Table 1 were used.

Table 3 shows the products and their yields in the reaction of **4** with malononitrile, ethyl cyanoacetate, and ethyl acetoacetate under the same reaction conditions as that of reaction of **4** with **5** (Run 1 and Run 7 in Table 1). The reaction of **4** with diethyl methylmalonate scarcely gave the corresponding dihydro-2(3*H*)-thiophenone. In the reaction of thiiranes with ethyl cyanoacetate, Snyder and Alexander[1)] could not determine the ratio of the tautomers, **2** and **3**. It was found that the equilibrium was shifted to **3** on the basis of a ^1H NMR analysis. It was also observed that the product of the reaction of **4** with ethyl acetoacetate was a tautomeric mixture, and the ratio of the tautomers **8** and **9** was about 6:4 from an analysis of the 400-MHz ^1H NMR and ^{13}C NMR.



8 **9**

A pronounced increase in the yield was observed in a reaction of **4** with active methylene compounds having ester groups (such as **5** and ethyl acetoacetate) when an active methylene compound was used in great exess (Yield II in Table 3).

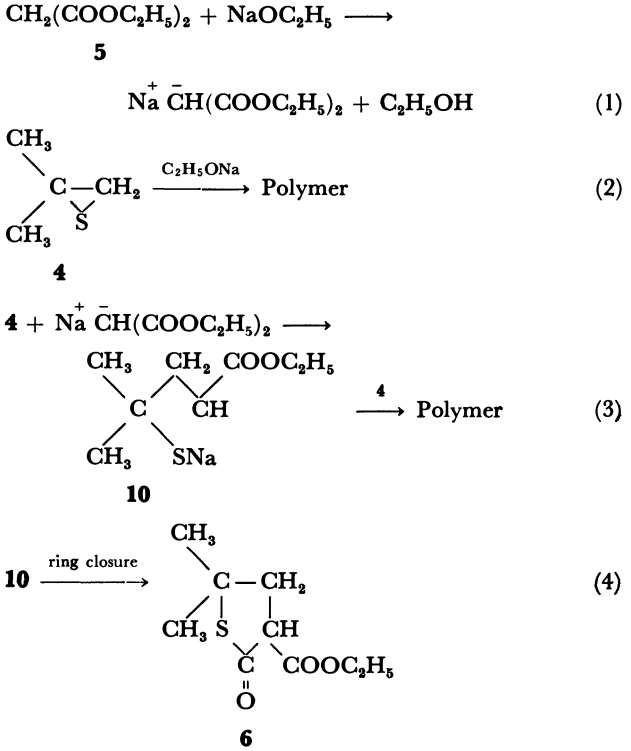
Solvent	Yield %	**5**[b] %	Solid[c] g
CH_3CN	16	38	0.36
DMSO	5	65	0.82
DMF	9	58	0.71
THF	21	38	—

a) Solvent, 15 ml; NaH, 15 mmol; **4**, 10 mmol; **5**, 20 mmol; reaction temperature, 80 °C; time, 3 h. b) Recovered after the reaction. c) Polymer of **4**.

Compound **6** could be obtained by using sodium hydride instead of sodium ethoxide. Table 4 shows the effects of a solvent on the reaction of **4** with **5** in the presence of sodium hydride. Polar solvents, such as DMF and DMSO, make the yield of **6** low, and make that of the polymer high. A better result was obtained when acetonitrile or THF was used as a solvent. The use of nonpolar solvents did not produce a good result since it could not dissolve the sodium salt of **5**. The yield in a reaction using sodium hydride was lower than that using sodium ethoxide.

The reaction of **4** with **5** was considered to involve three different reactions; 1) the polymerization of thiirane by sodium ethoxide (Eq. 2), 2) the polymerization of **8** with **4** (Eq. 3) and 3) the formation of **6** by a ring-closure reaction (Eq. 4). An intermediate **10** was very reactive and could not be detected through an analysis after the reaction. Although it was



presumed that a large amount of ethanol was favorable for an intramolecular condensation and

increased the yield of **6**, an opposite result occurred since the polymerization of **4** was accerelated by the sodium ethoxide (Eqs. 1, 2). When a large amount of active methylene compounds was used, higher effect was observed in the reaction of **4** with **5** or ethyl acetoacetate than these in the reaction of **4** with malononitrile and ethyl cyanoacetate. This was attributed to the fact that dihydro-2(3*H*)-thiophenone derivatives were more stable than dihydrothiophene derivatives having amino groups. Though **6** had active methine, and could possibly react with thiirane, its high steric hinderance was expected to disturb the reaction, because the reaction of **4** with diethyl methylmalonate scarcely gave the dihydro-2(3*H*)-thiophenone derivative.

Experimental

Measurement. GLC was carried out with a JEOL 20KF chromatograph equiped with 20% SE-30 columns. ^{1}H NMR spectra were measured with a Hitachi R-40 spectrometer. Mass spectra were measured with a JEOL D-300 GC-MS spectrometer using the CI(chemical ion) method with isobutane. IR spectra were obtained on a JASCO A302 spectrophotometer.

Materials. 2-Butylthiirane and 2-hexylthiirane were prepared as previously described.[3] 2,2-Dimethylthiirane-(4)[4], 1,2-epithiocyclohexane[4] and 2-phenylthiirane[5] were prepared according to a procedure described in the literature.

Reaction of Thiirane with 5. A typical procedure is as follows: To a solution prepared by disolving 0.70 g of sodium in 20 ml of absolute ethanol was added 6.40 g of **5** under a nitrogen atmosphere. This mixture was refluxed while 0.44 g of **4** was added dropwise over a period of one hour. Refluxing continued for more than one hour; then, the solution was poured into ice-cold water. The solution was acidified with dilute hydrochloric acid and extracted with ether. An insoluble polymeric material was filtered off and dried in vacuo. An organic layer was dried over anhydrous sodium sulfate and after the evaporation of solvent the residue was distilled in vacuo. This distillate was purified to give 3-ethoxycarbonyl-5,5-dimethyl-dihydro-2(3*H*)-thiophenone (**6**) by column chromatography on silica gel using a mixture of petroleum benzine (bp 50—90 °C) and ethyl acetate (100:1 v/v) as an eluent. IR: 1730 cm^{-1}, 1687 cm^{-1}, ^{1}H NMR δ=1.30 (t, 3H, CH_3), 1.57 (s, 3H, CH_3), 1.64 (s, 3H, CH_3), 2.17—2.76 (m, 2H, CH_2), 3.75—4.05 (quar, 1H, CH), 4.25 (quar, 2H, CH_2); QM$^+$: 203.

Thiirane, 2-methylthiirane, 2-butylthiirane, 2-hexylthiirane, 1,2-epithiocyclohexane, and 2-phenylthiirane were treated with **5**. The spectral data of these products are as follows:

3-Ethoxycarbonyl-dihydro-2(3*H*)-thiophenone. IR: 1740 cm^{-1}, ^{1}H NMR δ=1.29 (t, 3H, CH_3), 2.42—2.75 (m, 2H, CH_2), 3.20—3.70 (m, 3H, CH, SCH_2); QM$^+$: 175.

3-Ethoxycarbonyl-5-methyl-dihydro-2(3*H*)-thiophenone. IR, 1739 cm^{-1}, 1700 cm^{-1}, ^{1}H NMR δ=1.28 (t, 3H, CH_3), 1.47 (d, 1.5H, CH_3), 1.54 (d, 1.5H, CH_3), 1.80—2.95 (m, 2H, CHCO, CHS), 4.25 (quar, 2H, OCH_2); QM$^+$: 189.

5-Butyl-3-ethoxycarbonyl-2(3*H*)-thiophenone. IR: 1732 cm^{-1}, 1693 cm^{-1}, ^{1}H NMR δ=0.94 (t, 3H, CH_3), 1.30—2.00 (m, 6H, $(-CH_2-)_3$), 2.03—2.93 (m, 2H, CH_2), 3.47—3.80 (m, 1H, CHS), 3.75—4.10 (m, 1H, CHCO), 4.22 (quar, 2H, CH_2O); QM$^+$; 231.

9-Ethoxycarbonyl-7-thiabicyclo[4,3,0]nonane-8-one. IR: 1740 cm^{-1}, 1700 cm^{-1}, ^{1}H NMR δ=1.28 (t, 3H, CH_3), 1.05—2.70 (m, 9H, $(-CH_2-)_4$, CH), 3.05—3.65 (m, 2H, SCH, CHCO), 4.25 (quar, 2H, CH_2); QM$^+$: 229.

3-Ethoxycarbonyl-4-phenyl-2(3*H*)-thiophenone. IR: 1727 cm^{-1}, 1688 cm^{-1}, ^{1}H NMR δ=1.18 (t, 3H, CH_3), 3.40—4.40 (m, 4H, PhCH, CH_2S, CH_2), 7.33 (s, 5H, C_6H_5); QM$^+$: 251.

3-Ethoxycarbonyl-5-phenyl-2(3*H*)-thiophenone. IR: 1740 cm^{-1}, 1700 cm^{-1}, ^{1}H NMR δ=1.30 (t, 3H, CH_3), 2.25—3.15 (m, 2H, CH_2), 3.40—4.00 (m, 1H, CHCO), 4.25 (quar, 2H, CH_2), 4.80—5.10, 5.17—5.40 (m, 1H, PhCH), 7.25—7.60 (m, 5H, C_6H_5); QM$^+$: 251.

Reaction of 4 with Other Active Methylene Compounds. Compound **4** was reacted with ethyl cyanoacetate, malononitrile, and ethyl acetoacetate in a similar way to that for the reaction with **5**. The spectral data of these products are as follows:

2-Amino-3-ethoxycarbonyl-5,5-dimethyl-4,5-dihydrothiophene. IR: 3392 cm^{-1}, 1644 cm^{-1}, 1616 cm^{-1}, ^{1}H NMR δ=1.26 (t, 3H, CH_3), 1.51 (s, 6H, $2CH_3$), 2.83 (s, 2H, CH_2), 4.14 (quar, 2H, OCH_2), 6.00 (s, 2H, NH_2); QM$^+$: 155.

2-Amino-3-cyano-5,5-dimethyl-4,5-dihydrothiophene. IR: 3416 cm^{-1}, 1630 cm^{-1}, ^{1}H NMR δ=1.52 (s, 6H, $2CH_3$), 2.73 (s, 2H, CH_2), 4.80 (s, 2H, NH_2); QM$^+$: 202.

3-Acetyl-5,5-dimethyl-dihydro-2(3*H*)-thiophenone. IR: 1718 cm^{-1}, 1680 cm^{-1}, 1641 cm^{-1}, 1586 cm^{-1}, ^{1}H NMR (400 MHz): (keto type) δ=1.58 (s, 3H, CH_3), 1.62 (s, 3H, CH_3), 2.38 (s, 3H, $COCH_3$), 1.90—2.90 (m, 2H, CH_2), 3.90—4.20 (dd, 1H, CH). (enol type) δ=1.56 (s, 6H, $2CH_3$), 1.96 (s, 3H, CH_3-), 2.73 (s, 2H, CH_2); ^{13}C NMR: (keto type) δ=30.23, 31.25, 31.19, 42.23, 52.91, 65.77, 201.21, 202.07. (enol type) δ=19.91, 30.77(2C), 43.72, 52.63, 109.45, 166.11, 202.79; QM$^+$: 173.

The authors wish to express their thanks to Dr. Hiroshi Nakanishi and Dr. Yoshinobu Nagawa for the analysis of 3-acetyl-5,5-dimethyl-dihydro-2(3*H*)-thiophenone by 400 MHz ^{1}H NMR and ^{13}C NMR.

(Received January 24, 1986)

The halogen-abstraction reactions of carbon radicals were investigated as a model of the chain-transfer reaction in the radical polymerization of vinyl compounds. The kinetics of the halogen-abstraction reaction of carbon radicals ($(CH_3)_2\dot{C}X$, X=OC_6H_5, $OCOCH_3$, SC_6H_5, C_6H_5, and CN) from tetrahalomethanes(CBr_4, $CBrCl_3$, CCl_4) were studied in toluene at 80 °C by the ESR method using 2-(*t*-butyl)thioacrylonitrile as a spin-trapping reagent. The reactivity of these radicals for each halomethane decreased in the order X: OC_6H_5>$OCOCH_3$>SC_6H_5>C_6H_5>CN The reactivity of tetrahalomethanes for each radical decreased in the order CBr_4>$CBrCl_3$>CCl_4. Results are explained by taking into account the electron-transfer process from carbon radicals to tetrahalomethanes. Absolute rate constants of the halogen abstraction of $(CH_3)_2\dot{C}CN$ and $(CH_3)_2\dot{C}C_6H_5$ from CBr_4 and $CBrCl_3$, and of their additions to 2-(*t*-butylthio)acrylonitrile were estimated by the spin-trapping method, and they were compared with available data for similar reactions.

It has been reported that the solvent effect on the propagation rate constant k_p of vinyl esters, which have negative e values, is opposite in trend to that of methacrylates, which have positive e values. A proposal was made that the solvent effect could be explained in terms of donor-acceptor complexes of the propagating radicals with aromatic solvents[1-5] In these cases, the propagating radicals of methacrylates(e>0) were considered to be electron acceptors to the aromatic solvents and those of vinyl esters(e<0) to be electron donors to the solvents. This opposite trend in the reactivity of the propagating radicals between methyl methacrylate(MMA) and vinyl acetate(VAc) was also found in chain-transfer reactions to CCl_4 and triethylamine:[6-9] CCl_4 showed higher reactivity to the propagating radical of VAc and triethylamine to that of MMA. These facts suggest that the reactions proceed through a donor-acceptor complex formation or an electron-transfer process.

Recently, the participation of the electron-transfer process in radical reactions was pointed out in ESR studies on the reaction of the hydroxymethyl radical with CCl_4,[10,11] and in a flash photolysis on the reaction of the triethylsilyl radical with tetrahalomethanes.[12] Other examples supporting the electron-transfer process might be the chain-transfer reaction to strong transfer reagents in the radical polymerization. Since the occurrance of a net electron transfer indicates that a free radical can be converted to an ion, the finding of such a reaction seems to afford a new possibility for the reaction control of the radical polymerization. In order to investigate the possibility of the electron transfer of free radicals, we studied the reaction of free radicals with electron-accepting chain-transfer reagents, such as CBr_4 and $CBrCl_3$.

In this paper, we will repoprt an ESR study on the chain-transfer reactions of model radicals of the propagating end to tetrahalomethanes and discuss the participation of the electron-transfer process in the radical reactions. The radicals obtained by the chain-transfer reaction were trapped by 2-(*t*-butylthio)acrylonitrile which was found by Viehe as a strong radical scavenger.[13] Moreover, a new method for a determination of the rate constant of the chain transfer will be proposed.

Experimental

ESR spectra were recorded on a Japan Electron Optics Laboratory Model JES-FE 1X ESR spectrometer with a variable temperature accesory (ES-VT-3A) under irradiation with a 500 w high-pressure mercury lamp (Ushio 500) at 80 °C. A solution of azo compound 5×10^{-2} M, trapping reagent 6.4×10^{-1}—3.9×10^{-3} M, and tetrahalomethane 1.1×10^{-1}—9.8×10^{-4} M in toluene (1 ml) in a quartz sample tube (3 mmϕ) was degassed by repeated melting and freezing under vacuum and then sealed.

UV spectra were measured on a Hitachi 124 UV-visible spectrometer.

2,2′-Azobisisobutyronitrile(AIBN) was recrystallized from ethanol. 2,2′-Diacetoxy-2,2′-azopropane, 2,2′-bis(phenylthio)-2,2′-azopropane, and 2,2′-diphenoxy-2,2′-azopropane were prepared by the method of Benzing et al.[14] Azocumene was prepared from α-cumenamine and IF_5 by the method of Bartlet et al.[15] 2-(*t*-Butylthio)acrylonitrile was prepared according to the method of Viehe et al.[16]

CBr_4 was recrystallized from hexane. $CBrCl_3$(104 °C/760 mmHg(1 mmHg=133.322 Pa)) and CCl_4 (76.6 °C/760 mmHg) were purified by distillation. Hexamethylbenzene for the measurement of the electron affinity was sublimed twice. Toluene was dried and distilled by the conventional method. 2,2,6,6-Tetramethyl-1-piperidinyloxyl (Tempol)[17] was purified by recrystallization from cyclohexane.

An estimation of the kinetic parameter was carried out by a computer calculation using a nonlinear least-squares

method, computer program of which was Sals II written by Nakagawa and Koyanagi(Tokyo University Program). The simulation for the overlap of two adducts was carried out by a JEOL ESR simulation program 0398.

Results

Addition Reaction of Carbon Radicals to 2-(*t*-Butyl)thioacrylonitrile. Figure 1 shows the ESR spectrum observed under irradiation of a mixture of AIBN and 2-(*t*-butylthio)acrylonitrile, a spin-trapping reagent(T). The ESR spectrum of a triplet of triplets with hyperfine splitting constants of 0.88 and 0.28 mT due to nitrogen and two equivalent protons, respectively, was assigned to the adduct of $(CH_3)_2\dot{C}CN$ to T. Similar spectra were observed in the systems of other azo compounds and T. The hyperfine splitting constants of the adducts are shown in Table 1. The change in the ESR spectrum with reaction time shows that the concentration of the adduct became stationary within several minutes after irradiation. The signal due to the radicals (M·) of azo compounds (Eq. 1) could not be detected, indicating that the stationary concentration of M· was negligibly small compared with the adduct(MT·). Therefore, the bimolecular self-termination of M· was not taken into account in the kinetic treatment. Thus, the reactions are shown in Eqs. 1 to 4.

$$\text{M-N=N-M} \xrightarrow{I} \text{M}\cdot, \qquad I\text{: Rate} \tag{1}$$

$$\text{M}\cdot + \text{T} \xrightarrow{k_1} \text{MT}\cdot, \tag{2}$$

$$\text{MT}\cdot + \text{M}\cdot \xrightarrow{k_2} \text{Product}, \tag{3}$$

$$\text{MT}\cdot + \text{MT}\cdot \xrightarrow{k_3} \text{Product}. \tag{4}$$

The assumption of the steady state for the concentrations of M· and MT· leads to Eq. 5:

$$[\text{T}] = \frac{(k_2/k_1)[\text{MT}\cdot](1+k_3/I[\text{MT}\cdot]^2)}{1-k_3/I[\text{MT}\cdot]^2} \tag{5}$$

The relation between the stationary concentrations of MT· and T is shown in Fig. 2. The ratios, k_2/k_1 and k_3/I, were determined from Eq. 5 by a computation using the data shown in Fig. 2. The obtained ratios are shown in Table 2. The k_1/k_2 were influenced by substituents at the α-position, decreasing in the order:

$$-OC_6H_5 > -OCOCH_3 > -SC_6H_5 > -C_6H_5 > -CN.$$

The values of k_3/I changed remakably with the substituents.

Halogen Abstraction Reaction of Carbon Radicals from Tetrahalomethane. The intensity of the ESR spectra of the mixture of $CBrCl_3$, AIBN, and T was not large enough to perform a kinetic study in the absence of UV irradiation at 80 °C. Figure 3 shows the ESR spectrum observed upon irradiating the mixture. The spectrum (Fig. 3) was an overlap of two kinds of triplets of triplets, which were assigned

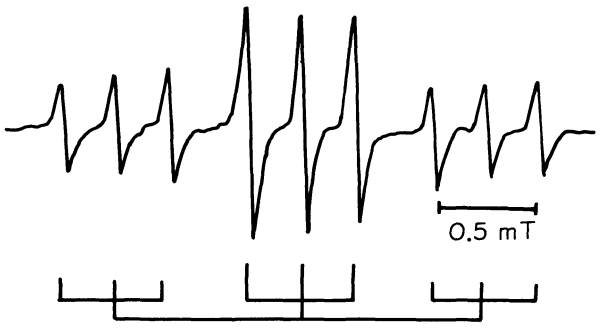

Fig. 1. ESR Spectrum observed on irradiation of a mixture of AIBN and 2-(*t*-butylthio)acrylonitrile(T) in toluene at 80 °C.
[AIBN]=5×10⁻²M, and [T]=0.64 M.

Table 1. Hyperfine Splitting Constants for Adducts Obtained by Reaction of Carbon Radicals with 2-(*t*-Butylthio)acrylonitrile[a)]

Radicals		a_H/mT	a_N/mT
$(CH_3)_2\dot{C}X$	X=-CN	0.88	0.28
	$-C_6H_5$	0.93	0.28
	$-OCOC_6H_5$	0.94	0.28
	$-SC_6H_5$	0.92	0.28
	$-OC_6H_5$	0.95	0.27

$\dot{C}Br_3$		0.77	0.26

a) 80 °C in toluene.

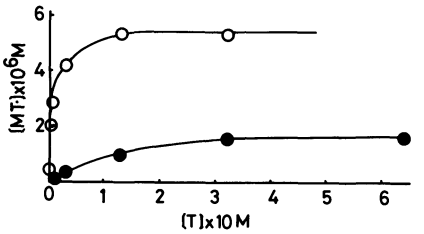

Fig. 2. Relation between MT· and T Concentrations.
○: 2,2'-Diacetoxy-2,2'-azobispropane, ●: AIBN.
[AIBN]=5×10⁻² M.

Table 2. Kinetic Data in Addition Reaction of Free Radicals $(CH_3)_2\dot{C}X$ to 2-(*t*-Butylthio)acrylonitrile[a,b)]

X	$k_1/k_2/10^{-4}$	$k_3/I/10^{10}$ M^{-2}
-CN	0.10	39
$-C_6H_5$	0.38	43
$-OCOCH_3$	3.6	450
$-SC_6H_5$	3.1	2.6
$-OC_6H_5$	4.4	2.2

a) 80 °C in toluene, [M-N=N-M]=5×10⁻² M. b) Average values of 3—5 runs(mean deviation ±50%).

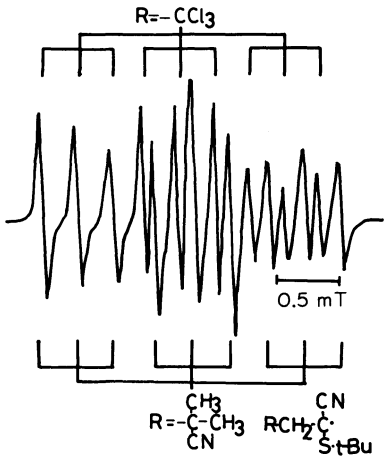

Fig. 3. ESR Spectrum observed on the UV irradiation of a mixture of $CBrCl_3$, AIBN, and 2-(*t*-buthylthio) acrylonitrile in toluene at 80 °C.
$[CBrCl_3]=8.8\times10^{-2}$ M, $[AIBN]=10^{-2}$ M, and [T]= 0.32 M.

to the adducts of the 1-cyano-1-methylethyl radical and of the trichloromethyl radical produced from AIBN and by bromine abstraction from $CBrCl_3$, respectively. Similar spectra were observed in other systems of tetrahalomethanes, azo compounds, and T. The hyperfine-splitting constants of the adducts are shown in Table 1. The reactions are illustrated in the following equations.

$$M\text{-}N{=}N\text{-}M \xrightarrow{I} M\cdot, \quad (1)$$

$$M\cdot + T \xrightarrow{k_1} MT\cdot, \quad (2)$$

$$M\cdot + RX \xrightarrow{k_x} MX + R\cdot, \quad (6)$$

$$R\cdot + T \xrightarrow{k_{1x}} RT\cdot, \quad (7)$$

$$RT\cdot + RT\cdot \xrightarrow{k_3} RTTR, \quad (8)$$

$$RT\cdot + MT\cdot \xrightarrow{k_3} MTTR, \quad (9)$$

$$MT\cdot + MT\cdot \xrightarrow{k_3} MTTM. \quad (10)$$

Since M· and R· were not observed in the ESR spectra, the self-coupling reactions of these radicals were not taken into account. A stationary state treatment on R·, RT·, and MT· gives

$$\frac{[RT\cdot]}{[MT\cdot]} = \frac{k_{1x}}{k_1}\frac{[R\cdot][T]}{[M\cdot][T]} = \frac{k_x}{k_1}\frac{[RX]}{[T]}. \quad (11)$$

Two examples of a plot of [RT·]/[MT·] vs. [RX] are shown in Fig. 4. Linear relations were observed, the ratios, k_X/k_1, being calculated from the slopes. Results are shown in Table 3. Since the signal MT· was not observed in the reactions of the radicals X=–CN, $-C_6H_5$, and $-OCOCH_3$ with CCl_4, the ratios could not be estimated. This fact indicates that k_x is too small for the ESR spectrum to be detected. From

X	k_x/k_1		
	CBr_4	$CBrCl_3$	CCl_4
-CN	4.9	0.21	—
$-C_6H_5$	2.4	0.61	—
$-OCOCH_3$	200	15	—
$-SC_6H_5$	56	5.3	0.0075
$-OC_6H_5$	210	89	2.2

a) 80 °C in toluene, $[M\text{-}N{=}N\text{-}M]=5\times10^{-2}$ M. b) Average value of 3—5 runs(mean deviation ±10%).

a comparison of k_x/k_1 for the reactions of a given radical with CBr_4, $CBrCl_3$, and CCl_4, it is concluded that rate constants for the halogen abstraction decrease in the order, $CBr_4>CCl_3Br>CCl_4$, in all reaction systems.

A remarkable difference in k_x/k_1 was found in the reactions of different radicals with a given tetrahalomethane. However, since k_1 are not considered to be constant, no information regarding k_x could be obtained from k_x/k_1.

Absolute Rate Constants for Elementary Steps. Since the kinetic parameters obtained so far were k_x/k_1, k_2/k_1, k_x/k_2 and k_3/I, absolute rate constants of each elementary processes could not be directly estimated. If the k_2 could be evaluated, k_1 and k_x could be estimated. It is difficult to directly measure k_2. However, if the self-coupling constants of M· and MT· are determined, rate constants of the cross-coupling reactions can generally be estimated as the geometrical mean of the self-coupling rate constants:[18]

$$k_2 = (k_3k_M)^{1/2} \quad (12)$$

where k_M and k_3 are the rate constants for the self-coupling reactions.

In order to estimate k_3 from k_3/I, I for each azo compound was estimated by the following method. Carbon radicals are known to be quantitatively

trapped by *N*-oxyl radical such as 2,2,6,6-tetramethyl-1-piperidinyloxyl(Tempol).[19] Accordingly, I for all azo compounds were determined from measurements of the decreasing rates of Tempol which were added to the reaction system. The rates were estimated from the change in the signal intensity of the ESR spectrum with time. The values of k_3 were calculated from k_3/I and I was thus obtained. I and k_3 are shown in Table 4. The k_3 values obtained are of the same order for all systems; this indicates that this method leads to reasonable data because k_3, which is the reaction rate constant of a diffusion-controlled reaction, should be constant, at least regarding the order of magnitude in all systems. I changed remarkably with the substituent. This change might be due to a difference in the light intensity, the molecular extinction coefficients of the azo compounds, the extent of the contribution of thermal decomposition, or the efficiency of Eq. 2.

The values of k_M for $(CH_3)_2\dot{C}C_6H_5$ and $(CH_3)_2\dot{C}CN$ have been reported in the literature.[20,21] The k_2 values for these radicals were estimated from Eq. 12 using k_3 and k_M (Table 6). Since k_M for the other radicals has not yet been reported, k_1 and k_x for only two radicals were estimated by a substitution of k_2 for k_1/k_2 and k_x/k_2 and are shown in Tables 5 and 6.

Discussion

Reactivity of Model Radicals in Addition Reaction to 2-(*t*-Butylthio)acrylonitrile and Halogen Abstraction. Since the absolute rate constants for an addition reaction(k_1) and a halogen abstraction(k_x) were determined for only two kinds of radicals, it is difficult to discuss the mechanism of the addition reaction and a chain-transfer reaction by a comparison of k_1 and k_x. However, since the bimolecular reactions between M· and MT· are diffusion-controlled in all reaction systems, k_2 are reasonably assumed to be constant, at least regarding the order of magnitude, in all reaction systems. Therefore, k_1/k_2 is considered to represent the reactivity of M· in Eq. 2. The reactivities of the radicals were influenced by substituents at the α-position; these decreased in the order:

$$-OC_6H_5 > -OCOCH_3 > -SC_6H_5 > -C_6H_5 > -CN.$$

This order shows that the radicals binding to heteroatoms have a larger reactivity than those stabilized by a phenyl or cyano group. The difference in the reactivity between $-OC_6H_5$ and $-OCOCH_3$, or between the phenyl and cyano groups, seems to be explained by the polarity of the substituent: the radicals binding to more electrodonating substituent have a higher reactivity.

Any information concerning the reactivity of model radicals in a halogen-abstraction reaction could not be obtained from k_x/k_1. However, it is possible to discuss the reactivity of a given radical with k_x/k_2 (Table 7), because k_2 is considered not to be influenced by the halomethanes used. Therefore, k_x/k_2 ratios were estimated from the k_x/k_1 and k_1/k_2 obtained in the last section. The values of k_x/k_2 are shown in Table 7, and decrease in the following order:

$$-OC_6H_5 > -OCOCH_3 > -SC_6H_5 > -C_6H_5 > -CN.$$

Table 7. Relative Rate Constants of Radicals $(CH_3)_2\dot{C}X$ in Halogen Abstractions[a]

$-SC_6H_5$	170	16	0.0075
$-OC_6H_5$	920	390	9.7

a) 80 °C in toluene, $[M\text{-}N{=}N\text{-}M]=5\times10^{-2}$ M.

This order shows that the carbon radicals binding to heteroatoms have a larger reactivity for halogen abstraction than radicals stabilized by phenyl or cyano groups. From Table 7, it is concluded that the rate constants for reaction between a given radical and tetrahalomethanes increase in the order CCl_4< $CBrCl_3$<CBr_4. For example, the reaction rate of $(CH_3)_2\dot{C}OC_6H_5$ and $(CH_3)_2\dot{C}SC_6H_5$ with CBr_4 was 10^2—10^3 times as large as that with CCl_4.

It has been reported that the activation energy of the halogen abstraction of free radicals from halomethane can be estimated from their bond dissociation energies(BDE) by the following relation[22]:

$$E = 0.055 \times [\text{BDE}] \quad (13)$$

If the preexponential factors are assumed to be the same in halogen-abstraction reactions of a given radical from tetrahalomethanes, k_x/k_1 for CBr_4 is calculated to be less than 10-times as large as that for CCl_4(C-Cl 67.9 kcal mol^{-1}(1 cal=4.184 J), and C-Br 45—57 kcal mol^{-1}),[23] the difference being much smaller than that observed. If the reaction mechanism is the same in all halogen-abstraction reactions, the preexponential factor is considered to be in the same order of magnitude[24] because tetrahalomethanes are composed of the same number of atoms. This large difference in k_x among halomethanes may be due to a difference in the reaction mechanism. Accordingly, we investigated the possibility of an electron-transfer mechanism in halogen-abstraction reactions of carbon radicals from tetrahalomethanes.

Electron-Transfer Mechanism. First, the electron affinities(EA) were estimated from the absorption spectra of their complexes with hexamethylbenzene by the method of Hatano et al.[25] Results are shown in Table 8, indicating that EA decreases in the order

$$CBr_4 > CCl_3Br > CCl_4.$$

This order is in agreement with the order of rates for halogen abstraction.

The reactivity of each radical with a given tetrahalomethanes was estimated by k_x/k_2 (Table 7), decreasing with the α-substituents in the following order:

$$\text{-}OC_6H_5 > \text{-}OCOCH_3 > \text{-}SC_6H_5 \gg \text{-}C_6H_5 > \text{-}CN.$$

The ratio for CBr_4 and $(CH_3)_2\dot{C}OC_6H_5$ which has an electron-donating group is about 2000 times as large as that for CBr_4 and $(CH_3)_2\dot{C}CN$, which has an electron-accepting group. Therefore, the electron-donating power of free radicals is considered to be an important factor for the halogen-abstraction reaction. The fact that the electron-donating character of radicals and the electron-accepting character of tetrahalomethanes seem to be important in halogen abstraction shows that this reaction might proceed through the electron-transfer process when electron-transfer from free radicals to tetrahalomethanes is thermodynamically favorable.

Table 8. Electron Affinity/eV

CBr_4	$CBrCl_3$	CCl_4
1.2	0.68	0.15

For more quantitative information on the possibility of the electron-transfer reaction, an estimation of the difference in the redox potential between halomethanes and radicals would be helpful. The reduction potentials of CCl_4 and CBr_4 are reported to be −0.78 V and −0.30 V, respectively.[26,27] Although the redox potentials of the radicals formed by a decomposition of the azo compound are not available, the oxidation potential of the hydroxymethyl radical was used which was reported to be −0.98 V.[28] The redox potentials of the radicals with an electron-donating substituent, $-OC_6H_5$, $-OCOCH_3$, and $-SC_6H_5$ are considered close to that of the hydroxymethyl radical. This value suggests that the electron transfer from these radicals to tetrahalomethane, especially CBr_4, is thermodynamically possible(ΔG=−0.6 eV for CBr_4 and ΔG=−0.2 eV for CCl_4).

Although k_x of the reaction of $(CH_3)_2\dot{C}CN$ and $(CH_3)_2\dot{C}C_6H_5$ with CBr_4 and CCl_3Br have been succesfully determined, k_x with CCl_4 was not determined, because the concentration of the adduct of $CCl_3\cdot$ was so small that the rate constants of the Cl-abstraction of these radicals could not be determined by the ESR measurement. The rate constants with CCl_4 are presumed to be less than k_x for $(CH_3)_2\dot{C}CN$ and $CBrCl_3$, being less than 10^3 M^{-1} s^{-1}. Really, k_x for the reaction of $CH_3\cdot$ with CCl_4 has been reported to be 3.3×10^2 M^{-1} s^{-1} at 65 °C.[29,30] Therefore, it is concluded that the rate constant for the halogen abstraction of these radicals from CBr_4 is more than 100 times as large as that from CCl_4. The large difference in the absolute rate constants between CBr_4 and CCl_4 is probably explained by participation of electron transfer from these radicals to CBr_4 in the halogen-abstraction reaction.

Next, we investigated the difference in k_x's for each radical between CCl_4 and $CBrCl_3$. In the $(CH_3)_2\dot{C}CN$ radical, k_x for Br abstraction from CBr_4 was 24-times larger than that for $CBrCl_3$, while in the $(CH_3)_2\dot{C}C_6H_5$ radical k_x from CBr_4 was four times larger than that from $CBrCl_3$. The ionization potential of the $(CH_3)_2\dot{C}C_6H_5$ radical is considered to be smaller than that of the $(CH_3)_2\dot{C}CN$ radical, because the cyano group is more electron-accepting than the phenyl group. Therefore, these results suggest that the electron transfer from the $(CH_3)_2\dot{C}CN$ radical to $CBrCl_3$ might be thermodynamically difficult and, that in the other three cases, electron-transfer reactions are thermodynamically favorable. This

presumption reasonably explains the smaller difference in k_x for $(CH_3)_2\dot{C}C_6H_5$ between CBr_4 and $CBrCl_3$ because in this radical the rate constants are considered to be mainly controlled by the difference in the dissociation energy of the C–Br bond between radical anions obtained by an electron-transfer reaction.

Reliability of Rate Constants. Let us discuss the reliability of k_1 and k_3. The k_1 values are $10—10^3$ times larger than the propagation rate constants of vinyl compounds.[31] This fact is reasonably explained by the fact that 2-*t*-(butylthio)acrylonitrile is a strong radical scavenger due to its stabilizing effect of captodative substituent.[13] The k_3 values are one order of magnitude smaller than those of the self-coupling reaction of carbon radicals such as $(CH_3)_2\dot{C}CN$ and $(CH_3)_2\dot{C}C_6H_5$.[20,21] This result can be reasonably explained by the stabilization of the adduct due to the capto-dative substituent effect.[13]

There are only a little available data regarding the elementary rate constants for the halogen-abstraction of carbon radicals from tetrahalomethanes, except for CCl_4:[10,11,30] k_x of the halogen abstraction reaction of $CH_3\cdot$ from $CBrCl_3$ was reported to be 2.2×10^6 M^{-1} s^{-1} at 65 °C.[30] On the assumption that the activation energy for the reaction is 5—10 kcal mol^{-1},[32] k_x at 80 °C are calculated to be the range of 3.0×10^6—4.2×10^6 M^{-1} s^{-1}. The k_x value for $(CH_3)_2\dot{C}C_6H_5$ obtained by our experiments are one order of magnitude less than the calculated values, which can be reasonably explained by the difference in the steric factor.

Thus, the spin-trapping method is considered to be applicable to a determination of the rate constants for a halogen-abstraction reaction and the chain-transfer reaction in radical polymerizations.

We thank Professor S. Nozakura for his helpful discussions and numerous suggestions for the manuscript, and Daikin Kogyo Ltd for providing IF_5.

Racemic Structures and Optical Resolutions by Preferential Crystallization of Organic Ammonium Salts of *N*-Formyl-DL-phenylalanine

Tadashi SHIRAIWA,* Hideya MIYAZAKI, Yoshihiro SAKAMOTO, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received January 24, 1986)

Racemic structures of the butylammonium salt, pentylammonium salt, benzylammonium salt, dicyclohexylammonium salt (DL-DCH salt), and 4-methylpiperidinium salt (DL-4-MP salt) of *N*-formyl-DL-phenylalanine were studied to explore the possibility of optical resolution by preferential crystallization. Free energies of formation of racemate (ΔG^F) of the DL-salts and data at eutectic points in binary phase diagrams of melting points indicate that the DL-salts form racemic compounds in the vicinity of the melting points. However, according to ΔG^F of DL-DCH and 4-MP salts and infrared spectra and solubilities of the DL- and L-salts, these DL-salts transform into conglomerates around room temperature. It is possible to resolve DL-DCH and 4-MP salts by preferential crystallization at 10 °C. Successive preferential crystallization of DL-4-MP salt at 10 °C in 1-butanol gives the D- and L-salts with optical purities of 95—100%.

DL-Phenylalanine (abbreviated as DL-Phe) has been optically resolved by emzymatic, diastereomeric, and preferential crystallization procedures. Of these procedures, the preferential crystallization procedure is useful for industrial operation, since the optical resolution can easily be achieved by providing a small amount of one enantiomer as seed crystals in a supersaturated solution of racemic modifications. Optical resolutions by this procedure have been reported on the ammonium salt,[1] ethylammonium salt,[2] isopropylammonium salt,[3] butylammonium salt,[3] 1,1,3,3-tetramethylbutylammonium salt,[2] and cyclohexylammonium salt[4] of *N*-acetyl-DL-phenylalanine. It is expected that the hydrolysis of *N*-formylphenylalanine (FrPhe) is easier than that of *N*-acetylphenylalanine. However, no optical resolution of DL-FrPhe by preferential crystallization has been reported, though DL-FrPhe has been optically resolved through its diastereomeric salts with (−)-fenchylamine.[5] This paper describes an attempt to resolve organic ammonium salts of DL-FrPhe by preferential crystallization.

The racemic structures of the butylammonium salt (DL-BA salt), pentylammonium salt (DL-PTA salt), benzylammonium salt (DL-BZA salt), dicyclohexylammonium salt (DL-DCH salt), and 4-methylpiperidinium salt (DL-4-MP salt) of DL-FrPhe were determined on the basis of free energies of racemates (ΔG^F)[2,6,7] and data at eutectic points in binary phase diagrams of melting points. The results indicated that the DL-salts form racemic compounds in the vicinity of the melting points. However, the ΔG^F values of DL-DCH and 4-MP salts suggested that the DL-salts are transformed into conglomerates at lower temperatures. This was supported by a comparison of solubilities and infrared spectra of the DL-salts with those of the corresponding L-salts. Optical resolutions of DL-DCH and 4-MP salts were attempted by preferential crystallization at 10 °C.

Experimental

Materials. DL-Phe and L-Phe were purchased from Sigma Chemicals Co., and amines from Wako Pure Chemicals Ind.

***N*-Formylation.** DL- and L-FrPhe were obtained, respectively, by formylating DL- and L-Phe in the usual way.[8] DL-FrPhe: Mp 168 °C (lit,[5] 165—166 °C). L-FrPhe: Mp 168 °C (lit,[5] 167.0 °C); $[\alpha]_D^{20}$ +75.1° (*c* 1.00, ethanol) (specific rotation of D-FrPhe[5]: $[\alpha]_D^{20}$ −75.2° (ethanol)).

Preparation of Organic Ammonium Salts. DL- or L-FrPhe (0.01 mol) and 0.01 mol of an amine were dissolved in 30 cm³ of methanol. To the solution was added 30 cm³ of diethyl ether and the salt formed was collected by filtration.

Elemental analysis and specific rotation of L-DCH salt: C, 70.32; H, 9.15; N, 7.44%; $[\alpha]_D^{20}$ +36.1° (*c* 1.00, methanol). DL-DCH salt: C, 70.35; H, 9.15; N, 7.44% (calcd for $C_{22}H_{34}N_2O_3$: C, 70.55; H, 9.15; N, 7.48%). L-4-MP salt: C, 65.55; H, 8.27; N, 9.59%; $[\alpha]_D^{20}$ +45.7° (*c* 1.00, methanol). DL-4-MP salt: C, 65.46; H, 8.27; N, 9.60% (Calcd for $C_{16}H_{24}N_2O_3$: C, 65.73; H, 8.27; N, 9.58%).

The D-4-MP salt (3.00 g) obtained from the mother liquor in the optical resolution of the DL-salt was dissolved in 15 cm³ of 1-butanol at an elevated temperature. After standing overnight around 5 °C, the salt crystallized was collected by filtration, washed with a small amount of diethyl ether, and dried; yield, 2.57 g. The recrystallization was repeated twice: Mp 167 °C; $[\alpha]_D^{20}$ −45.7° (*c* 1.00, methanol).

Optical Resolution. DL-Dicyclohexylammonium Salt: DL-DCH salt (1.221 g) was dissolved in 100 cm³ of ethanol around 40 °C to give a racemic solution with a degree of supersaturation of 161% at 10 °C. The solution was slowly cooled to 10 °C and seeded with 0.020 g of L-DCH salt. After stirring for 60—180 min at 10 °C, the salt precipitated was collected by filtration and washed with a small amount of diethyl ether. The optical purity, the yield of the optically pure modification (YOPM), and the degree of resolution of the salt obtained were determined by the equations in our previous paper.[9]

DL-4-Methylpiperidinium Salt: DL-4-MP salt (2.631 g) was dissolved in 50 cm³ of 1-butanol around 40 °C to give a racemic solution with a degree of supersaturation of 160% at 10 °C. The optical resolution of DL-4-MP salt was

carried out with this solution similarly to that of DL-DCH salt.

Successive Preferential Crystallization: DL-4-MP salt (10.560 g) was dissolved in 200 cm^3 of 1-butanol around 40 °C. The solution was slowly cooled to 10 °C and seeded with 0.050 g of L-4-MP salt. After stirring for 70 min at 10 °C, the salt precipitated was collected by filtration, and washed with a small amount of diethyl ether. DL-4-MP salt (1.268 g) was added to the filtrate, and dissolved around 40 °C. The solution was cooled to 10 °C and seeded with 0.050 g of D-4-MP salt. After stirring for 80 min, the salt precipitated was collected by filtration. The filtrate was treated similarly to above.

Preparation of Optically Active Phenylalanine: The D- or L-4-MP salt obtained by successive preferential crystallization (4.83 g) was added in 25 cm^3 of 1 mol dm^{-3} hydrochloric acid without recrystallization, and the mixture was stirred for 40 min at 5 °C. The FrPhe was collected by filtration, washed with a small amount of water, and dried: yield of each of D- and L-FrPhe 3.09 g; for D-FrPhe $[\alpha]_D^{20}$ −75.2° (*c* 1.00, ethanol); for L-FrPhe $[\alpha]_D^{20}$ +74.5° (*c* 1.00, ethanol). The D- or L-FrPhe (2.50 g) was added in 20 cm^3 of 1 mol dm^{-3} hydrochloric acid. After refluxing for 2 h, the solution was evaporated to dryness under reduced pressure around 50 °C. The residue was dissolved in 70 cm^3 of methanol, and the pH was adjusted to around 6 with ammonium hydroxide. The Phe crystallized was collected by filtration, washed with small amounts of water and methanol, and dried. D-Phe: yield 1.36 g; $[\alpha]_D^{20}$ +34.4° (*c*. 1.00, water). L-Phe: Yield 1.32 g; $[\alpha]_D^{20}$ −33.5° (*c* 1.00, water) (lit,[10] $[\alpha]_D$ −34.5° (water)).

Measurements. Specific rotations were measured with a Union Giken high sensitivity PM-101 digital polarimeter using a 0.5 dm path length quartz cell. Infrared spectra were obtained in the range 4000—400 cm^{-1} with a JASCO A-102 infrared spectrophotometer by the KBr disk method. Solubilities of DL- and L-DCH salts in ethanol and those of DL- and L-4-MP salts in 1-butanol were measured at 10 °C in a similar manner as described in our previous paper.[2] These solubilities are given in Table 1. Enthalpies of fusion and melting points were determined by use of a differential scanning calorimeter (Rigaku Denki DSC-8230). Benzoic acid, potassium nitrate, and sodium nitrate were used as standard samples to obtain enthalpies of fusion.

Table 1. Solubilities of Dicyclohexylammonium and 4-Methylpiperidinium Salts of *N*-Formylphenylalanine

Salt	Solvent	Solubility at 10 °C g/(100 cm^3 solvent)
DCH[a]	Ethanol	DL : 0.758 L : 0.561
4-MP[b]	1-Butanol	DL : 3.289 L : 1.628

a) DCH: Dicyclohexylammonium salt. b) 4-MP: 4-Methylpiperidinium salt.

Results and Discussion

Recemic Structures at Melting Piont. Racemic structures of the organic ammonium salts of DL-FrPhe were examined, since the optical resolution by preferential crystallization requires that the racemic modification is a conglomerate. The free energies of formation of racemate at melting point (ΔG^F_{mp}) of the DL-salts were calculated on the basis of the enthalpies of fusion (ΔH^f) and melting points of the DL- or L-salts.[2,6,7] These thermodynamic data are given in Table 2.

Since the ΔG^F_{mp} values of these DL-salts are negative (−2.8—−0.5 kJ mol^{-1}), it was suggested that the DL-salts would be racemic compounds or racemic solid solutions in the vicinity of the melting points and not conglomerates.[2,6]

If the DL-salts form racemic compounds, the eutectic points must be found in the mole fraction range of 0.5 to 1 in the binary phase diagrams of melting points and it is possible to calculate the mole fractions of the L-salts and temperatures for the eutectic points from the Schröder-Van Laar and Prigogine-Defay equations on the basis of the ΔH^f and melting points of the DL- and L-salts.[11] The mixtures with the mole fractions of the L-salts calculated (0.58—0.85) were prepared, and the melting points were compared with the eutectic temperatures calculated. These results are given in Table 3.

The melting points obtained agreed very closely with the eutectic temperatures calculated, and the mixtures melted at the temperatures and not over a wide range. Although the mole fractions of L-DCH and 4-MP salts at the eutectic points (about 0.5) are relatively close to 0.5 and the melting points are equal to those of their respective DL-salts, the binary phase diagrams of melting points (Figs. 1 and 2) show that the eutectic mixtures consist of the D- and L-salts in the molar ratio of about 4:6. The above results indicate that BA, PTA, BZA, DCH, and 4-MP salts have the eutectic mixtures consisting of the D-

Table 2. Thermodynamic Data for Organic Ammonium Salts of *N*-Formyl-phenylalanine

Salt	Mp/K		$\Delta H^{f\,a)}$/kJ mol^{-1}		$\Delta G^{F\,b)}_{mp}$
	DL-Salt	L-Salt	DL-Salt	L-Salt	kJ mol^{-1}
BA[c]	417	412	32.9	30.4	−2.73
PTA[d]	398	392	36.9	32.8	−2.78
BZA[e]	415	428	39.0	31.4	−1.43
DCH	483	499	63.2	61.1	−0.82
4-MP	420	440	39.5	41.3	−0.59

and L-salts in the molar ratios calculated, which leads to a clear conclusion that these DL-salts form racemic compounds in the vicinity of the melting points.

However, the mole fractions of L-DCH and 4-MP salts at the eutectic points and the absolute values of ΔG^{F}_{mp} of the DL-salts are smaller than those of the other salts. Therefore, it is suggested that the DL-DCH and 4-MP salts are unstable racemic compounds in the vicinity of the melting points.[2,7] Such an unstable racemic compound has a possibility of transformation to a conglomerate at a lower temperature,[2,7] though stable ones in the vicinity of the melting points exist in racemic compounds even around room temperature.

Table 3. Mole Fractions and Temperatures at Eutectic Points for Organic Ammonium Salts of *N*-Formylphenylalanine

Salt	Mole fraction of L-salt[a]	Temperature/K	
		Found	Calcd[a]
BA	0.84	403	404
PTA	0.85	387	386
BZA	0.70	412	412
DCH	0.60	483	483
4-MP	0.58	420	420

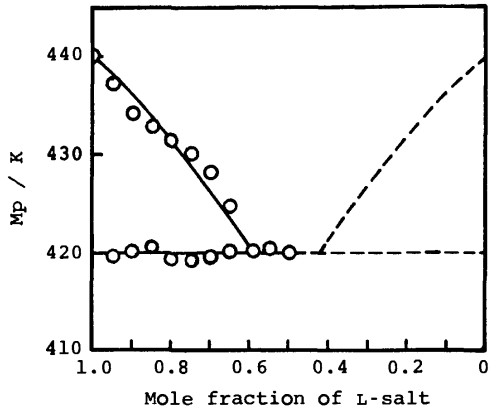

Fig. 2. Binary phase diagram of melting point of 4-methylpiperidinium salt of *N*-formylphenylalanine.

Racemic Structures Around Room Temperature. The above results suggest that DL-DCH and 4-MP salts have a possibility of existing in conglomerate around room temperature. Therefore, the transition temperatures (T_0) of DL-DCH and 4-MP salts were estimated according to previous papers;[2,7] the ΔG^{F} is zero at T_0. The T_0 obtained was 314 K for DL-DCH salt and 324 K for DL-4-MP salt. The T_0 values indicate that DL-DCH and 4-MP salts do not form racemic compounds around room temperature, since the ΔG^{F} values are positive at temperatures below T_0. The results are supported by the infrared spectra and solubilities of these DL- and L-salts; DL-DCH and 4-MP salts show infrared spectra identical with those of the corresponding L-salts, and are more soluble than the L-salts as shown in Table 1. The above results indicate that DL-DCH and 4-MP salts exist in conglomerate around room temperature, though the DL-salts form racemic compounds in the vicinity of the melting points.

Since the T_0 values estimated for DL-BA, PTA, and BZA salts are lower than 0 K and the infrared spectra of these DL-salts are different form those of the L-salts, it may be concluded that these DL-salts form also racemic compounds around room temperature.

Optical Resolution by Preferential Crystallization. Optical resolutions of DL-DCH and 4-MP salts have been attempted at 10 °C for racemic solutions with a degree of supersaturation of about 160%. The results are given in Tables 4 and 5.

It was possible to obtain the L-salts with high optical purity (93—97%) by preferential crystallization. Although the L-DCH salt obtained at resolution times of 60 and 90 min had an optical purity of over 90%, the degrees of resolution were low (22—29%). On the other hand, in the optical resolution of DL-4-MP salt, L-salt with an optical purity of 96.8% was obtained in a relatively high

a) Solvent: 50 cm³ of 1-butanol. Degree of supersaturation of racemic solution: 160%. Seed crystals: 0.020 g of L-salt. Temperature: 10 °C. b) See note in Table 4.

Table 6. Successive Preferential Crystallization of 4-Methylpiperidinium Salt of *N*-Formyl-DL-phenylalanine[a]

Run	Added amount of DL-salt / g	Resolution time / min	Salt obtained: Configuration	Salt obtained: Yield / g	Salt obtained: Optical purity / %
1	10.560	70	L	1.226	97.1
2	1.268	80	D	1.877	99.4
3	1.901	80	L	1.496	95.4
4	1.500	120	D	1.143	99.8

a) Solvent: 200 cm³ of 1-butanol. Seed crystals: 0.050 g of D- or L-salt. Temperature: 10 °C.

degree of resolution (61.0%) at time 60 min. The L-4-MP salt partially resolved is easily purified to the L-salt with high optical purity by recrystallization. For example, the L-salt with an optical purity of 84.8% ($[\alpha]_D^{20}$ +38.8° (*c* 1.00, methanol)) was recrystallized once from 1-butanol to give L-salt with purity of 100% ($[\alpha]_D^{20}$ +45.7° (*c* 1.00, methanol)) similarly to the D-4-MP salt described in the experimental section. The L-salt obtained was treated with hydrochloric acid in the usual way to give L-Phe with an optical purity of 100% ($[\alpha]_D^{20}$ −34.5° (*c* 1.00, water)). These results indicate that the optical resolution of DL-4-MP salt is more favorable for obtaining the optically active Phe than that of DL-DCH salt. The optical resolution by successive preferential crystallization of DL-4-MP salt was found to give D- and L-Phe with high optical purity. The result is given in Table 6.

The D-4-MP salts obtained had optical purities of about 100%, and the L-salts those of over 95%. These D- and L-salts gave D-Phe with an optical purity of 99.8% and L-Phe with 97.0%, respectively.

It was found from the above results that DL-DCH and 4-MP salts are conglomerates around room temperature though the DL-salts form racemic compounds in the vicinity of the melting points, and that the optical resolution by successive preferential crystallization of DL-4-MP salt gives D- and L-Phe with optical purities of obout 100%.

A Study of the Color of Coal Liquids. II. Involvement of Light, Oxygen, Phenols, and Aromatic Amines in Formation of Colored Materials from Wandoan-Coal-Derived Liquids

Shigeru FUTAMURA* and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received January 31, 1986)

Triggering materials responsible for coloring of coal liquids have been searched by comparing the structures of the colored materials derived from the neutrals, acids, and bases of the coal liquid and the nitrogenous model compounds. Basic constituents of the coal liquid are most prone to photooxidation and afford colored materials of higher molecular weight and stronger absorption in the visible region. Model compound studies suggest that they are predominantly formed in the photoinduced oxidative coupling of aromatic amines.

It has already been reported in our preceding paper that a 10 to 20-fold increase is observed in the contents of nitrogen and oxygen for the colored materials separated from the degraded Wandoan-Coal-derived liquids, compared with those of the fresh sample oils.[1] It has also been shown that they have wider absorption range from the UV to visible region and abound in the constituents of large molecular sizes.

These results further prompted us to separate neutrals, acids, and bases from the fresh sample oils and to investigate their reactivities toward oxygen and/or light. Model compounds were also photooxidized in order to disclose triggering materials responsible for coloring of the coal liquids. The structures of their photooxygenated products were compared with those derived from the constituents of the coal liquids.

In this paper, we present that the above colored materials are principally formed in the oxidative coupling of aromatic amines, minor components of coal liquids.

Experimental

The coal liquid samples used were the kerosene (bp 180—240 °C) and light oil (bp 240—340 °C) fractions of the coal liquid produced from Wandoan-Coal in the 1 t/d PDU of Sumitomo Metal Corporation's. The kerosene and light oil fractions were separated into neutrals, acids, and bases according to the procedure shown in Fig. 1 after the removal of the colored materials by vacuum distillation. The colored materials with the strongest absorption in the visible region were prepared as the methanol-eluted fractions in chromatographing through a silica-gel column the residues obtained in the vacuum distillation (2 mmHg (1 mmHg=133.322 Pa)) of the above degraded kerosene fraction (≈75 °C) and the light oil fraction (≈145 °C), respectively. The colored materials obtained in the photooxidation of the coal liquid constituents and the model compounds were treated and prepared as well as those derived from the original coal liquids.

All the solvents and the model compounds were commercially purchased. Ethanol and tetrahydrofuran of spectrograde were used as received. The following model compounds were further purified by distillation or recrystallization (purity >99%): *p*-toluidine, 2-aminobiphenyl, 1-naphthylamine, 1,2,3,4-tetrahydroquinoline, diphenylamine, isoquinoline, 1-methylindole, and 2,3-dimethylindole.

In order to trace the structural change of the coal liquid constituents or model compounds caused by aerobic irradiation, light from a 200W super-high-pressure mercury arc (Shimadzu-Bausch-Lomb) through a Toshiba glass filter (λ>310 nm) was irradiated externally to ethanol solutions (2.5×10^{-3}% v/v) of the coal liquid constituents or the model compounds in Pyrex cells. For preparation of

the photooxygenated products, light from a 400W high-pressure mercury arc (Riko Kagaku) through a 75% aqueous $NaNO_2$ solution was irradiated externally to the above sample solutions (λ>400 nm).

The UV spectra were recorded on a JASCO RC-200. Ethanol was used as solvent. The gel permeation chromatograms were obtained on a Dupont 830 liquid chromatograph equipped with a column of HSG 15+20. Tetrahydrofuran was used as carrier. The IR spectra were taken on a Shimadzu IR-420 infrared spectrophotometer.

Results and Discussion

Table 1 summarizes the abbreviations of the coal liquid components and the colored materials. Table 2 shows the chemical compositions of the kerosene and light oil fractions. Both oils contain almost the same amounts of neutrals and acids. Bases occupy only 1.6 and 3.1 weight% of each oil. Table 3 shows the elemental analyses of the kerosene fraction and the light oil fraction. These data show that nitrogen and oxygen in coal liquids are concentrated into bases and acids, respectively. Comparison of the two bases by IR confirmed that the absorption ascribed to the pyrrolic N-H stretching band can be observed at 3480 cm^{-1} for BK,[2] while the absorption of basic N-H are stronger for BL. Difference in the chemical compositions between BK and BL affects the amounts and chemical structures of the colored materials. This point will be discussed later. Absorptions ascribed to the phenolic O-H stretching band can be observed at around 3600 cm^{-1} for both of AK and AL, and they cannot be differentiated by IR.

Mechanism for Coloring of Coal Liquids. Mechanisms for oxidative degradation of coal liquids can be classified into two reaction modes as shown in Fig. 2. One is oxygen incorporation, and the other is oxidative coupling. The former reaction can be exemplified as the decomposition of hydroperoxides produced in the autoxidation of hydrocarbons, affording carbonyl compounds and alcohols. This reaction proceeds under ordinary storage conditions since the colored materials obtained contain much oxygen.[1] However, it is improbable that this reaction is responsible for formation of the colored materials with strong absorption in the visible region. On the other hand, the latter reaction affords compounds with extended conjugated systems from phenolics and aromatic amines. For example, oxidative dimerization of substituted phenols give diphenoquinones. These compounds absorb at longer wavelengths (λ_{max}=420 nm) with stronger absorption (ε=70800 M^{-1} cm^{-1}) than benzoquinones (λ_{max}=400 nm).[3] Photooxidation of 2-naphthylamine affords dibenzophenazine,[4] which can be expected to absorb at longer wavelengths than phenazine ($\lambda_{abs}\approx$440 nm). The colored materials of large molecular sizes occupy only a little less than 1 weight% of the degraded coal liquids, and these colored materials could be formed in the oxidative coupling of polar compounds at room temperature.

Structural Change Accompanied by Photooxidation of the Coal Liquid. Seven samples such as L, NL, AL, BL, (NL+AL) (5.6:1.0 weight ratio), (NL+BL) (50:1.0 weight ratio), (AL+BL) (9.3:1.0 weight ratio) were stored in the dark under oxygen at room temperature for 5 d, but all the samples were colorless and no change was observed in their UV spectra. These results show that each component of the coal liquid is rather stable under oxygen without light. Then, all the above samples were irradiated under air. Figure 3a shows that the absorption of NL at longer than 300 nm grows with irradiation time

and it levels off after 8 h. The original light oil fraction showed almost the same UV spectral change as NL. As Fig. 3b shows, increase in the absorbance in the visible region was only small on irradiating AL under air. On the other hand, BL was extremely unstable under the photooxidation conditions. As Fig. 3c shows, aerobic irradiation decreased its absorption at 280—320 nm and increased that at longer than 320 nm. The increasing rate for the absorption at 400 nm is 4 to 8 times larger for BL than for NL and AL. The UV spectrum obtained by irradiating BL under argon for 7 h (dotted line in Fig. 3c) shows that BL is sensitive to anaerobic irradiation while the absorption at longer wavelengths is much weaker than under air. These results reveal that BL is most prone to structural change induced by irradiation and that oxygen promotes the formation of chromophores with the absorption from the UV to visible region. Furthermore, on 6 h irradiation, BL comes to take almost the same spectral pattern as that of CL(Fig. 3c). All of these results suggest that BL is predominantly involved in formation of colored materials with stronger absorption in the visible region. Mixing of AL and BL had no synergistic effect on increasing the rate of the absorbance at 400 nm. This finding suggests that acid-base interaction is negligible in photoinduced formation of colored materials.

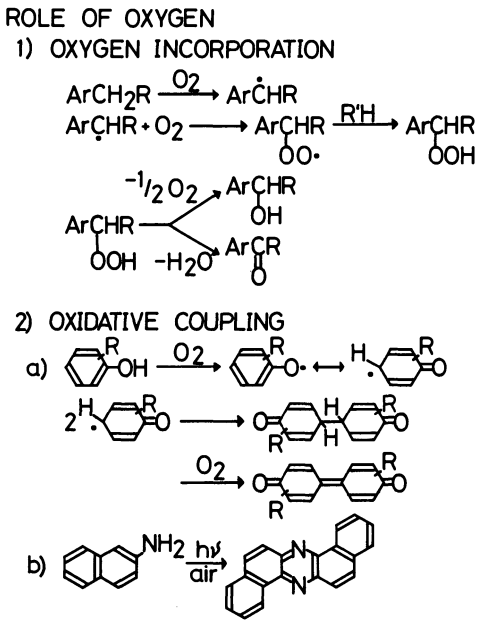

Fig. 2. Reaction modes for oxidation of coal liquids.

Comparison of Kerosene and Light Oil Fractions. The UV spectrum of the kerosene fraction remained unchanged on aerobic irradiation for 20 h. This fact coincides well with the fact that the kerosene fraction is more stable than the light oil fraction under ordinary storage conditions. NK and AK showed a similar UV spectral change on aerobic irradiation, but their absorption range did not extend to wavelengths longer than 350 nm. Aerobic irradiation of BK shifted the absorption range up to visible region, but the increasing rate of the absorbance at 400 nm was only 1/5 of that for BL. In this case, oxygen did not promote formation of colored materials. It is interesting that such difference was observed in the increasing rate of the absorption at 400 nm for pyrrole-rich BK and amine-rich BL.

Structural Change Accompanied by Photooxidation of Nitrogen Compounds. Predominant involvement of nitrogen compounds has been suggested in coloring of coal liquids, and the following model compounds have been chosen and subjected to photooxidation by taking account of the GC-MS analyses of the coal liquids used and the product analyses of the polar compounds contained in the SRC-II coal liquids.[5]: *p*-toluidine, 1-naphthylamine, 1,2,3,4-tetrahydroquinoline, diphenylamine, and iso-

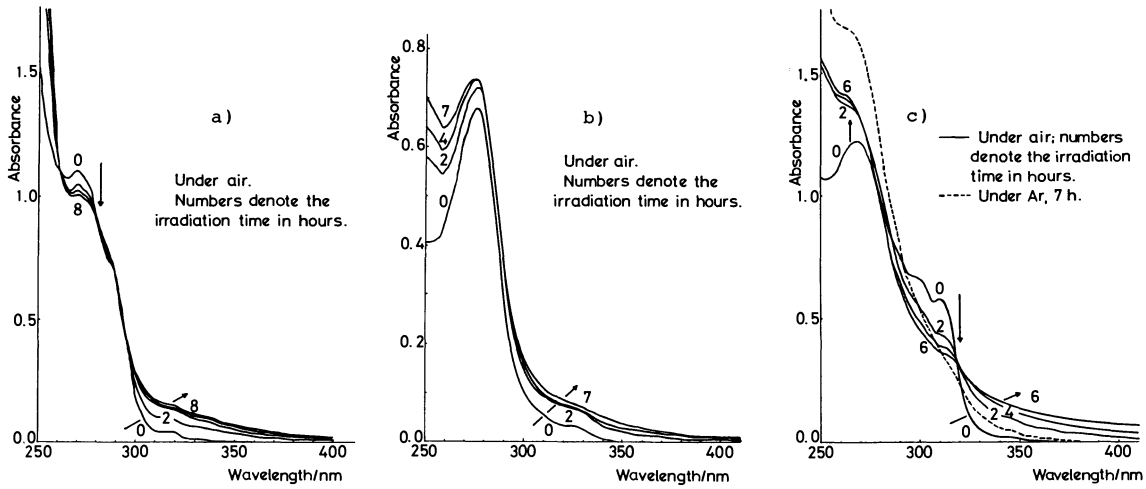

Fig. 3. UV spectral change induced by aerobic irradiation in ethanol.
a): NL, b): AL, c): BL.

quinoline. As to pyrrole-type nitrogen heterocycles, 2,3-dimethylindole and 1-methylindole have been chosen. The former compound has been reported to be deleterious in deposit formation in oil shale.[6] 1-Methylindole has been chosen as one of the *N*-alkylindoles for comparison of its reactivity toward photooxidation with that of 2,3-dimethylindole. Figure 4 shows the UV spectral changes of isoquinoline, diphenylamine, 1-naphthylamine, and 2,3-dimethylindole induced by aerobic irradiation, respectively. Any of them disappeared within 6 h, but the pattern of UV spectral change is quite different from each other. In the case of isoquinoline, no absorption can be observed at longer wavelengths. The increasing rate of the absorbance at 400 nm is 6 times larger for 1-naphthylamine and 2,3-dimethylindole than for diphenylamine. It is also interesting to note that aerobic irradiation of 1-naphthylamine for 3 h gives almost the same UV spectral pattern as that of CL.

Wright et al.[7] have alreadv pointed out that under air at 100 °C, anilines and indoles are the most reactive among the nitrogen compounds contained in the SRC-II coal liquid, and that their concentrations decrease to 1.4 and 11% after 112 d, respectively. Our results clearly show that the above compounds are photosensitive even at room temperature, forming colored materials more rapidly than aromatic secondary and tertiary amines under air.

Table 4. Weight Ratio of Colored Materials(CM)[a] to Substrate

a): Isoquinoline, b): diphenylamine, c): 1-naphthylamine, d): 2,3-dimethylindole.

Gravimetrical Analysis of the Colored Materials. Next, the structures of the colored materials were compared, taking AK, BK, *p*-toluidine, 1-naphthylamine, 1-methylindole, 2,3-dimethylindole, and 1,2,3,4-tetrahydroquinoline as substrate. Table 4 summarizes the gravimetrical analyses of the colored materials. Minor component BK affords more colored materials than AK. Among the model compounds, an unusually large amount of colored materials is obtained from 2,3-dimethylindole, suggesting considerable oxygen uptake. Among the primary amines, 1-naphthylamine seems to give more colored materials than *p*-toluidine. It may reflect their different reactivities toward oxidative coupling. Figure 5 shows the UV spectra of the colored materials obtained in the photooxidations of AK, BK, and the model compounds. CBK is stronger in absorption in the visible region than CAK, and the UV spectrum of the former is more similar to that of CK. Absorption intensity at 400 nm of the colored materials derived from the model compounds decreases in the order of NA>TOL>THQ>DMI>MI.

Comparison of Figs. 4 and 5 indicates that among the nitrogen compounds, aromatic primary amines are most responsible for coloring of coal liquids.

Elemental Analysis of the Colored Materials. Table 5 shows the results of the elemental analyses of the colored materials. CAK contains almost no nitrogen, indicating that acids contribute to a lesser extent for coloring of coal liquids. The oxygen content of CK is larger than that of CL by about 10%. It is most likely that this was induced by the different chemical compositions of pyrrole-rich BK and amine-rich BL. In fact, the colored materials derived from the indoles tend to contain more oxygen than those from the amines by 4.6—15%.

IR Analysis. Figure 6 shows the IR spectra of the colored materials. Absorption of conjugated carbonyls can be observed at around 1680 cm^{-1} for CBK and its spectral pattern coincides well with that of CK.

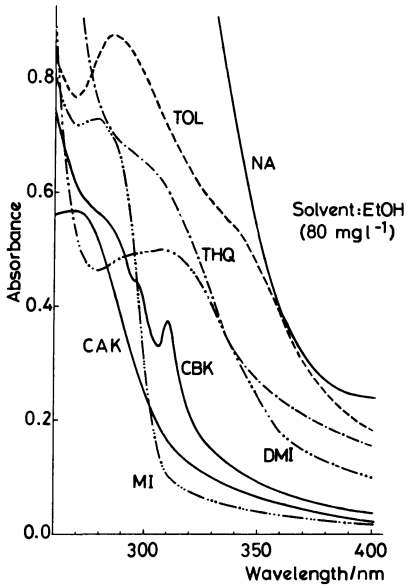

Fig. 5. UV spectra of the colored materials (concn: 80 mg l^{-1}).

Table 5. Elemental Analyses of Colored Materials(CM)[a)]

CM	C	H	N	O(diff.)
CK	60.66%	7.54%	4.91%	26.89%
CAK	61.13	6.83	0	32.04
CBK	69.53	6.91	7.72	15.84
CL	68.65	8.82	5.57	16.96
TOL	73.48	7.04	9.30	10.18
NA	79.81	4.73	7.45	8.01
THQ	75.76	6.85	8.54	8.85
MI	70.60	6.69	7.97	14.74
DMI	64.26	5.93	6.78	23.03

a) Dried in vacuo at room temperature for 6 h.

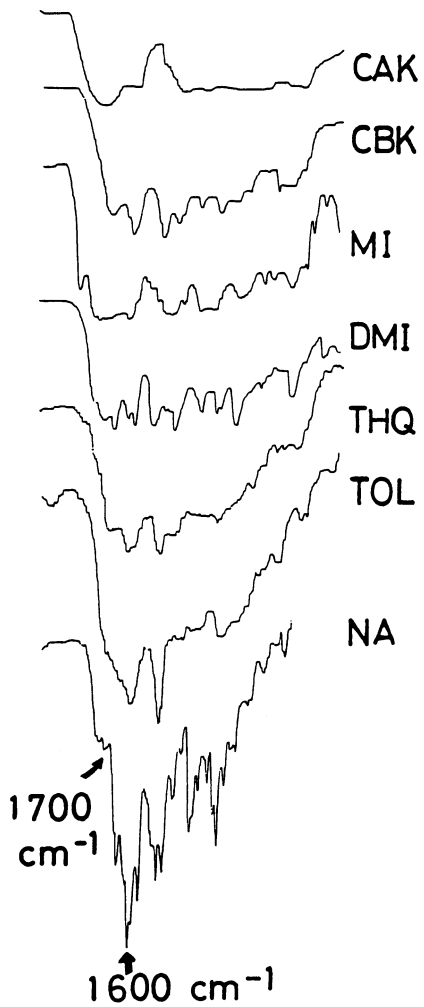

Fig. 6. IR spectra of the colored materials.

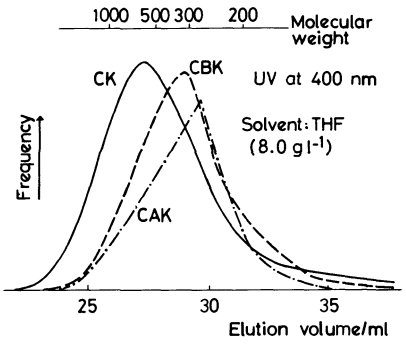

Fig. 7. GPC profiles of the colored materials derived from the kerosene fraction (concn: 8.0 g l^{-1}, detected with UV at 400 nm).

On the other hand, the carbonylic absorption of CAK shifts to higher wavenumbers. As to the model compounds, relative intensity of the absorption at 1680 cm^{-1} to that at 1600 cm^{-1} decreases in the order of MI>DMI>THQ>TOL>NA. This order is reversed against that of the UV absorption intensity at 400 nm (see Fig. 5). This fact clearly shows that the degree of photooxygenation does not parallel formation of chromophores with absorption at longer wavelengths. Therefore, it is most likely that oxidative coupling of aromatic primary amines afford colored materials of higher molecular weight with stronger absorption in the visible region.

GPC Analysis. Figures 7 and 8 show the GPC profiles of the colored materials. As to the colored materials derived from the coal liquids, nominal peak molecular weights of CK, CBK, and CAK are 580, 330, and 250, respectively (polystyrene standards). CBK is more similar to CK than CAK in molecular weight distribution. Among the colored materials derived from the model compounds, the scan of DMI extends to an area of the most highest molecular weight with a shoulder at nominal molecular weight 600. Oxidative trimers and tetramers could be formed. The molecular weight distributions of NA and TOL also suggest the formation of the constituents with higher molecular weight in the cases of 1-naphthylamine and *p*-toluidine. The scan of THQ has a wide molecular weight distribution with two peaks in the area of lower molecular weight. MI is considered to contain only a small amount of high molecular weight compounds.

All of these results show that the colored materials with the stronger absorption in the visible region tends to be of higher molecular weight.

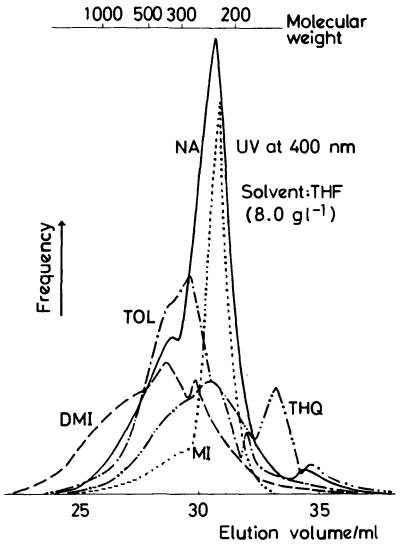

Fig. 8. GPC profiles of the colored materials derived from the model compounds (concn: 8.0 g l^{-1}, detected with UV at 400 nm).

In this paper, we have shown that coloring of coal liquids is induced by light and greatly promoted by oxygen. Bases in coal liquids are most liable to photooxidation and affords colored materials of higher molecular weight and stronger absorption in the visible region than neutrals and acids. Among the nitrogen compounds, aromatic primary amines are most deleterious and the above colored materials could be afforded predominantly in their oxidative coupling although they are only minor components in coal liquids.

This research has been entrusted by NEDO and the sample coal liquids were offered by Sumitomo Metal Corporation. The authors are very grateful to both of them.

Microheterogeniety in Aqueous Mixtures of Hydrophobic Solutes through Viscosity Studies

M. V. RAMANAMURTI, P. V. S. S. PRABHU,* and S. L. BAHADUR
Electrochemical Research Laboratories, Department of Chemistry, Banaras Hindu University, Varanasi-221 005, India
(Received May 21, 1985)

Precise viscosity data for aqueous binary mixtures of ethylene glycol (EG), 2-methoxyethanol (ME), and 1,2-dimethoxyethane (DME) at different mole fractions and at various temperatures are presented. EG behaves as a structure breaker showing negative deviation in viscosity-composition curve. Hydrophobic solutes ME and DME showed typical maximum in viscosity-composition curve in water rich region; attributed to the existence of "microheterogeniety" in these mixtures.

In order to explicate the structural arrangements at molecular level, the study of physicochemical properties of solutions would be of considerable help. With the notion to gain an insight into the molecular orientations and interactions occurring between the components of the binary mixtures, viscosities at different mole fractions of ethylene glycol (EG), 2-methoxyethanol (ME), and 1,2-dimethoxyethane (DME) in water at five different temperatures, namely 25, 30, 35, 40, and 45 °C, have been determined. Of these three solutes, EG exhibits protic character due to the two hydrogen atoms of hydroxyl groups. Obviously, in the remaining two solutes, ME and DME, succinct replacement of two hydrogen atoms of EG by electron donating methyl groups, renders them to impart quasiaprotic and aprotic characters, respectively. Also IR studies indicated that intramolecular hydrogen bonding exists in EG[1,2] and ME[2,3] molecules in the liquid state. However, it is apparent that no intramolecular hydrogen bonding is feasible in pure DME. Keeping the bifunctional nature especially of these solutes, EG, ME, and DME in view, viscosity studies of their binary mixtures with water would be of interest to elucidate the structural arrangements and molecular interactions. Although the viscosity data for these aqueous binary mixtures at 25 °C were already reported,[4-6] a thorough study on the structural details has not been dealt with.

This communication presents the viscosities of aqueous binary mixtures of EG, ME, and DME at five different temperatures viz., 25, 30, 35, 40, and 45 °C.

Experimental

Materials. Ethylene glycol, (B. D. H., AnalaR) was fractionally distilled under reduced pressure; dried over anhydrous sodium sulfate for two days and decanted. This was fractionally distilled under reduced pressure and the middle cut was collected.[7]

2-Methoxyethanol (A. R.) was treated with lithium hydride until the evolution of hydrogen gas ceased. Then it was distilled twice and the middle fraction was collected.[8]

1,2-Dimethoxyethane (Riedel-De-Haenag) was kept two days over KOH and then refluxed for 24 h. This was distilled over sodium and refluxed again for 24 h. Then the sample was distilled and middle fraction was directly used for measurements.[9]

Since these three solvents are highly hygroscopic in nature, they were kept under dry nitrogen atmosphere in order to minimize atmospheric contamination before use. Aqueous mixtures of these solvents were prepared with conductivity water (κ=0.2—0.5×10^{-6} Ω^{-1} cm^{-1}) obtained by triple distillation of water in the presence of alkaline $KMnO_4$.

Apparatus. Two Cannon-Ubbelohde viscometers, with flow times approximately 200 and 500 s, for water at room temperature, were calibrated[10] using pure water, methanol, carbon tetrachloride, benzene, and toluene. Viscosities of pure EG, ME, and DME so obtained at 25 °C are in excellent agreement with the literature values.[4,6,11] Thus e.g., at 25 °C η_{EG}[4]=16.84×10^{-3}, η_{ME}[5]=1.60×10^{-3}, and η_{DME}[11]=0.455×10^{-3} kg m^{-1} s^{-1}. Our values at 25 °C are η_{EG}=16.63×10^{-3}, η_{ME}=1.59×10^{-3}, and η_{DME}=0.451×10^{-3} kg m^{-1} s^{-1}.

During the course of measurements temperature constancy was ensured within ±0.01 °C. There was no need to incorporate corrections due to kinetic energy effects in the viscosity values calculated.[12]

Results and Discussion

Viscosity (η) values determined for aqueous binary mixtures of EG, ME, and DME, covering the whole range of composition, at 25, 30, 35, 40, and 45 °C are given in Tables 1, 2, and 3, respectively.

The monotonious increase in viscosity with the increase of EG content in the EG+water mixture (cf. Fig. 1) shows negative deviation from the ideal behavior indicating the structure breaking effect of the components on one another. Water has a well defined characteristic geometric structure.[13] However, EG, despite possessing a high degree of self-association through hydrogen bonding, does not have a defined geometric structure.[14,15] The autoprotolysis constant studies in these mixtures have also shown the absence of defined geometric structure in EG.[16] Therefore, the incompatibility which arises due to the dissimilarity in the basic geometric structures, as well as the differences in hydrogen bond energies results in the breakage of the

structural integrities of EG and water. Subsequently the individual water molecules will get themselves loosely associated with ethylene glycol molecules through hydrogen bonding resulting in an overall less structured solvent mixture than that expected from ideal behavior.

In case of aqueous mixtures of ME or DME, viscosity increases rapidly with the increase of solute content (ME or DME) in the mixture and reaches a maximum at a particular composition in the water-

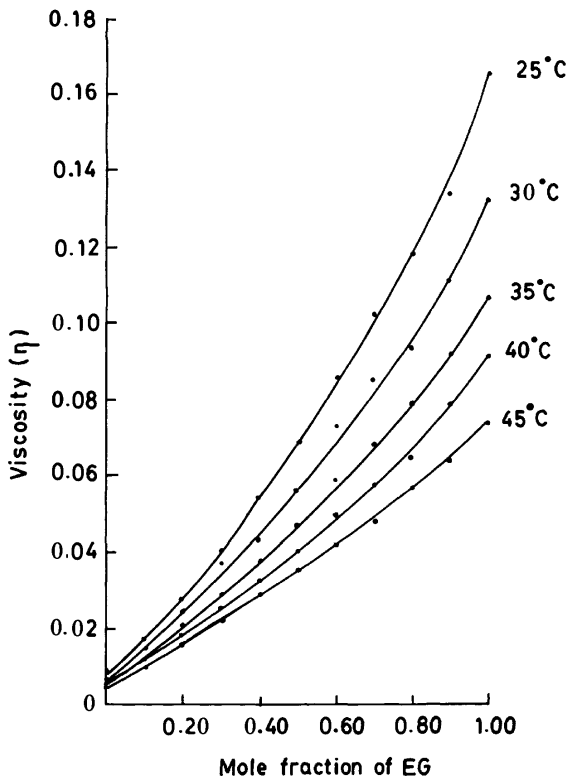

Fig. 1. Variation of viscosity (η) with the mole fraction of ethylene glycol at different temperatures.

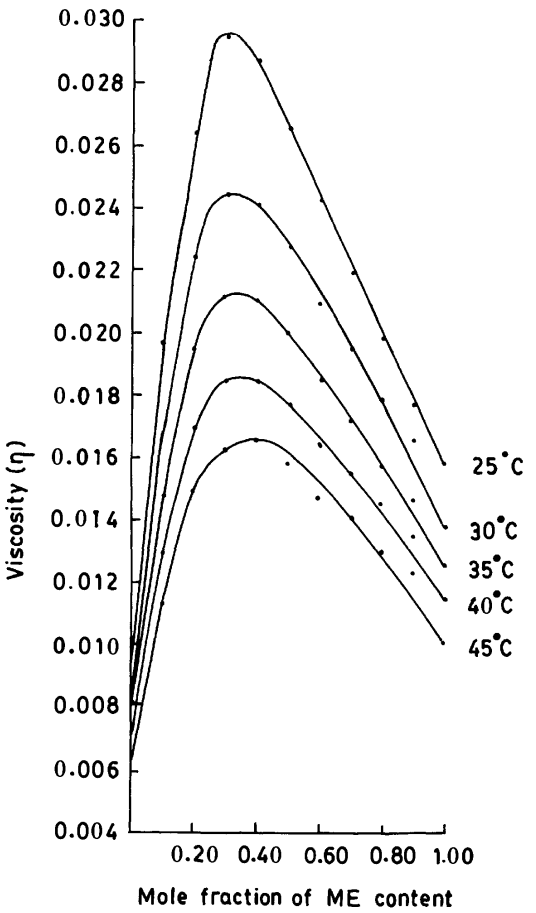

Fig. 2. Variation of viscosity (η) with the mole fraction of 2-methoxyethanol at different temperatures.

rich region (cf. Figs. 2 and 3). The viscosity maxima are nearly 2.9 and 2.0 times viscosity of water and appear around 0.30 and 0.20 mole fractions of ME and DME, respectively. Although, such a maximum, observed for aqueous mixtures of different organic solvents was attributed to the formation of an association complex,[17–20] an appropriate explanation may be given as follows. The ascending part of viscosity–composition curve (water-rich region in Figs. 2 and 3) represents structural promotion in the mixture by gradual formation of clusters of associated species. These clusters[21–27] may be formed in three different possible ways such as the association between (a) the same species (b) different species, and (c) the same species and different species simultaneously. A gradual aggregation of these different types of clusters would obviously lead to an increase in the viscosity and approach to a maximum value when aggregation is maximum. So viscosity maximum is an indication of maximum structuredness. However, the participation of different types of associated molecular species in aggregation at viscosity maximum apparently brings heterogeniety in the system (mixture). Therefore, since the observed maximum in viscosity is a consequence of aggregation of heterogeneous associated species at molecular level, this phenomenon may be termed as "microheterogeniety". The shift of viscosity maximum (Figs. 2 and 3) towards water-rich region with the addition of methyl group e.g. 0.30 mole fraction ME to 0.20 mole fraction DME in respective aqueous mixtures suggests the solvation of water into organic solute (interstitial solvation) in agreement with findings of Rohdewald and Moldner.[28]

Franks[29] has explained the structure promotion and destruction effects on the basis of the variation in $d\eta/dx$ with x (i.e. rate of change of viscosity with the change in solute content) instead of variation in η with x. The solutes, ME and DME, may be brought under the category of "structure promoters" for water-rich region, following Franks. Structural promotion 'effect' decreases with the increase in solute content and it passes through "zero structural promotion" effect (i.e. $d\eta/dx=0$) at mole fraction value corresponding to η_{max} (Fig. 4). This implies that at viscosity maximum no further structural promotion is possible. Further addition of solute decreases $d\eta/dx$ to a minimum value which indicates "structure breaking" in solute rich mixtures due to excess presence of solute. The mole fraction value corresponding to $d\eta/dx=0$ remains unaltered with change in temperature (Fig. 4).

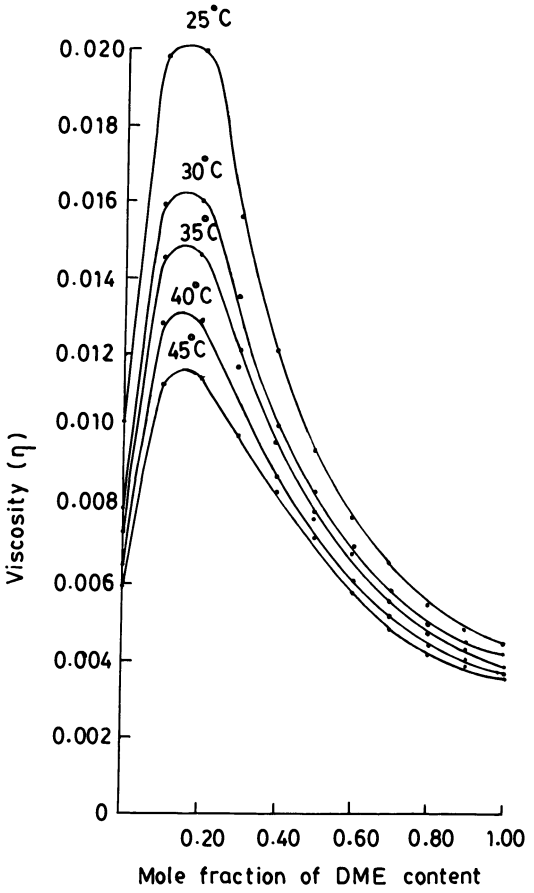

Fig. 3. Variation of viscosity (η) with the mole fraction of 1,2-dimethoxyethane at different temperatures.

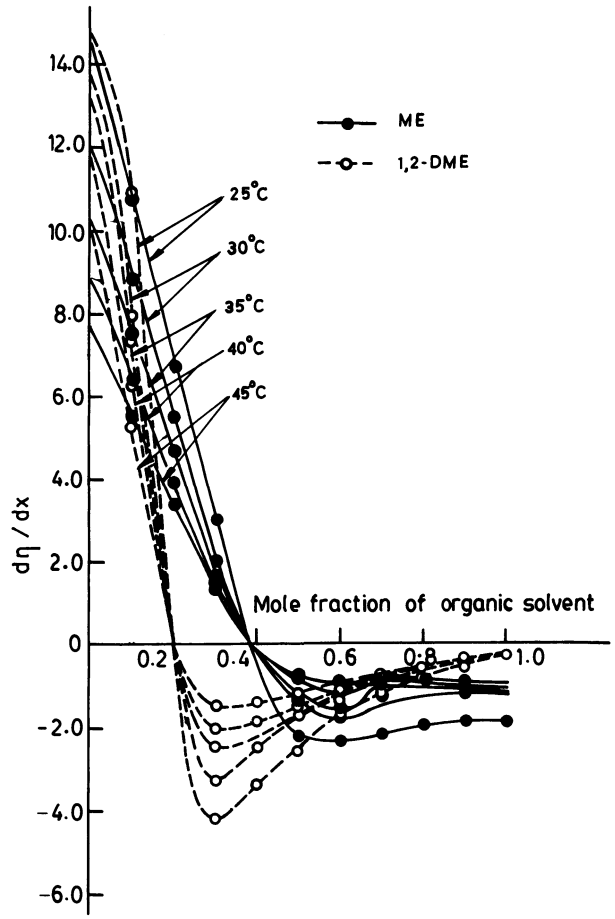

Fig. 4. Variation of first derivative ($d\eta/dx$) with mole fraction (x) of organic solvent.

These three systems have followed fairly closely the Andrade's relation[30]

$$\eta = Ae^{B/RT},$$

where B is called the "activation energy for viscous flow" and A is system specific parameter. A representative plot of variation of log η with $1/T$ for EG+water mixtures is illustrated in the Fig. 5, which clearly shows the applicability of Andrade's relation. Various other workers[31–33] also have showed that this equation is fairly applicable for several other systems.

A consideration of molecular size (S) of pure EG, ME, and DME (viz., $S_{EG}<S_{ME}<S_{DME}$) suggests that, if molecular association were not to be present the same should have been the trend in viscosity values also. A decrease in viscosity values as observed viz., $\eta_{EG}(16.63\times10^{-3}$ Kg m^{-1} s$^{-1}) > \eta_{ME}(1.59\times10^{-3}$ Kg m^{-1} s$^{-1}) > \eta_{DME}(0.0451$ Kg m^{-1} s^{-1}) can be explained on the basis of the gradual reduction of inter- and intramolecular association because of successive replacement of hydrogen atoms of hydroxyl groups in EG by methyl group.

Solvent Effect on Lifetime of Triplet Exciplex between Chloranil and Durene

Harumichi KOBASHI,* Tomoyuki KONDO, and Masa-aki FUNABASHI
Department of Chemistry, Faculty of Engineering, Gunma University,
Kiryu, Gunma 376
(Received January 9, 1986)

Synopsis. The triplet exciplex between chloranil (CA) and durene (DH) shows a decay which is associated with solvent viscosity rather than polarity, in spite of having a full charge-transfer (CT) character.

A strong dependence of the photophysical and photochemical processes of exciplexes upon solvent polarity is well-known for singlet states. However, solvent effects on the dynamic behavior of triplet exciplexes have not yet been fully investigated. The triplet exciplex with a nearly complete CT nature (CT-type triplet exciplex) or an ion pair between CA and DH has previously been reported by us for the solvent 1,2-dichloroethane (DCE).[1] Here, we report on the lifetimes of this triplet exciplex in various solvents, while paying attention to the effects of the solvent polarity and viscosity.

Experimental

The transient spectra and lifetimes of the exciplex were measured by means of nanosecond laser photolysis using a Q-switched frequency-doubled ruby laser at room temperature (20±1 °C).[1] The method used for photocurrent measurements was the same as that used before.[1] Solvents used were 1,4-dioxane (DO), benzene (BZ), diethyl ether (EE), ethyl acetate (EAC), dichloromethane (DCM), acetone (ACT), and acetonitrile (ACN). DCM was purified as follows: shaken with concd. H_2SO_4, water, aq 5% NaOH, and again water, it was then distilled twice over P_2O_5 after being pre-dried with $CaCl_2$ and stored in a brown bottle with molecular sieves (Zeolite 4A). After these treatments, it was fractionally distilled just before use. Other solvents of spectrograde (Dotite) were distilled after being dried with Zeolite 4A.

Results and Discussion

In DO, BZ, EE, EAC, and DCM (nonpolar and moderately polar solvents) the quenching of triplet chloranil (^{3}CA) by DH led to the formation of a short-lived triplet exciplex, $^3(CA^{\cdot-}\cdots DH^{\cdot+})$, having an absorption band around 450 nm, similar to that in DCE.[1] After a lapse of time, a long-lived chloranil semiquinone radical (CAH·) was observed at 435 and 365 nm in these solvents as well as in DCE.[1] Figure 1 shows the transient spectra observed in DCM as a representative of such spectral features. The first-order decay rate constants of $^3(CA^{\cdot-}\cdots DH^{\cdot+})$ were analyzed at 448 nm in the same manner as that used for the case of a DCE solution.[1]

In ACT and ACN (polar solvents) ^{3}CA quenching also led to a rapid appearance of an absorption band around 450 nm due to a $CA^{\cdot-}$ unit. However, its decay was very slow and did not obey first- or second-order kinetics. Figure 2 gives an example of the spectral change together with an oscillogram of the absorption band at 448 nm observed in ACN. Absorbance at a later stage of the time trace decays with a second-order kinetics resulting from a recombination between free $CA^{\cdot-}$ and $DH^{\cdot+}$ produced through the ionic dissociation of a relaxed and/or nonrelaxed exciplex. A fast formation of free ions and their decays (obeying second-order kinetics) were also observed through transient photocurrent measurements.[2] The decay curve at 448 nm consists of at least two components, first- and second-order decays in both solvents. However, a further detailed analysis of the decay in the polar solvents was not performed during the present stage of the investigation.

Table 1 summarized the data for the lifetimes of the triplet exciplex in various solvents. The values of $\tau_{1/e}$ in ACT and ACN are the apparent decay times of both ion pairs and free ions superposing each other. These values have only qualitative meanings for a comparison purpose with those of true exciplexes in

other solvents. It has been found that the lifetime of $^3(CA^{\mp}\cdots DH^{\pm})$ does not depend on the polarity of the solvent in a range of ε from 2.3 to 10.7, while it depends weakly upon the viscosity of the solvent. A linear correlation (factor γ=0.87) between the decay rate τ^{-1} and the parameter T/η (here, T=293 K) of the diffusion coefficient seems to indicate that τ^{-1} is affected by the easiness of the vibrational and/or reorientational motion of the exciplex associated with solvent molecules. It is known that the escape probability of the triplet exciplex, between fluorenone and 1,4-diazabicyclo[2.2.2]octane, into dissociated ions depends on the solvent viscosity.[3] In our case, however, the ionic dissociation is not involved in the exciplex decay since no transient photocurrent was gained in DO, BZ, EE, and EAC.[4] Kuz'min et al. have reported that the lifetimes of the triplet exciplexes of 2,6-diphenyl-*p*-benzoquinone with diphenylamine and triphenylamine tend to decrease with increasing ε, ranging from 2.4 to 7.3.[5] The polarity dependence of the present exciplex differs from those of the exciplexes cited above, though they are exciplexes of quinones with a full CT character. This difference in decay behavior can be attributed to a difference in the chemical species constructing the exciplex. Although there is a small difference, such a small (or no) effect of the solvent polarity seems to be consistent with the result that the intersystem crossing (ISC) or back electron transfer of CT-type triplet exciplexes is only weakly dependent on the polarity of the medium.[6]

The relaxation of our exciplex consists of two processes, ISC and a proton transfer, except for cases involving a slight ionic dissociation.[4] Then, if the rate constant of ISC can be regarded as almost constant while changing ε,[7] the dependence on η in the present exciplex might mainly reflect a change in the rate of the proton transfer (k_p). This expectation would not contradict the supposition that $^3(CA^{\mp}\cdots DH^{\pm})$ is necessary for changing its conformation through a diffusive movement upon going from the relaxed state to a state favorable for causing a proton transfer.[1] Recently, Manring and Peters have also pointed out the requirement of molecular reorientation in a triplet ion pair prior to causing a proton transfer (k_p) for the benzophenone and *N*-methyldiphenylamine system.[8] They have additionally shown in the same system that the rate constant corresponding to k_p decreases upon increasing the solvent polarity. Thus, the decay behavior of triplet exciplexes exhibits various dependences on solvents. A further study of the solvent effect on the single process of a proton transfer in our exicplex is in progress now.

We with to thank Prof. Haruo Shizuka for his interest and encouragement.

Temperature Effect on the Rhodium-Catalyzed Direct Synthesis of Ethylene Glycol from Carbon Monoxide and Hydrogen in Several Solvents

Takashi MASUDA,* Kazuhisa MURATA, Toshiaki KOBAYASHI, and Akio MATSUDA
National Chemical Laboratory for Industry, Higashi, Yatabe, Tsukuba-gun, Ibaraki 305
(Received December 26, 1985)

Synopsis. The $Rh_4(CO)_{12}$/*N*-methyl-2-pyrrolidone system is featured in that the rate of ethylene glycol (EG) formation is significantly accelerated with increasing reaction temperature. The turnover frequency of EG at 300 °C and 2000 kg/cm² ($H_2/CO=1$) is about 2000 h^{-1}. The $Rh_4(CO)_{12}$/tributylamine system also has a high catalytic activity at a high temperature.

The direct synthesis of ethylene glycol (EG) from carbon monoxide and hydrogen is interesting from the fundamental and industrial points of view. Much attention has been paid on this direct synthesis and a number of patents have appeared.[1] Clusters and complexes of group VIII elements of the periodic table such as Co,[2a] Rh, Ru, and Ir[2b] are used as catalysts. Most noteworthy is the work of Union Carbide Corporation which describes the direct synthesis of EG with rhodium catalysts. Union Carbide workers also carried out bench-scale experiments in a continuous flow unit capable of catalyst recycle.[3] Fahey[4] has reported of a Rh-catalyzed direct synthesis in tetraglyme solvent with promoters at about 2000 atm of synthesis gas. The highest turnover frequency of EG including ethylene glycol monoformate in his results was 248 h^{-1}, which is, to our knowledge, the highest rate to EG in the literature.[1-4] However, little is known about the influence of temperature on the glycol producing activity of rhodium catalyst. In the present paper, we report of remarkable temperature effects on the Rh-catalyzed formation of EG from carbon monoxide and hydrogen in nitrogen-containing solvents.

Experimental

All reagents were commercially available. All experiments were carried out in a 20 ml rocking batch reactor made of Inconel Alloy under a constant pressure. Oxygenated compounds such as methyl alcohol (MeOH), ethylene glycol (EG), methyl formate (MF), ethyl alcohol (EtOH), and ethylene glycol monoformate (EGMOF) were formed as products. The products were analyzed by gas chromatography using a Chromosorb 102 column. Sulfolane was used as an internal standard. Rates to products were given in terms of turnover frequency, defined as the number of moles of the product formed per gram-atom of metal per hour. The turnover frequency of EG, N(EG), is obtained by

$$N(EG) = \text{mol}(EG+EGMOF)/(\text{g-atom Rh})h$$

Product selectivity is defined as the carbon efficiency on the basis of reduced carbon monoxide in a product obtained. The selectivity value of EG, Sel.(EG), is obtained by

$$\text{Sel.}(EG) = \frac{2(EG+EGMOF)\times 100}{MeOH+MF+2(EtOH+EG+EGMOF)}$$

Results and Discussion

The results are summarized in Table 1. The $Rh_4(CO)_{12}$/tributylamine system has a high catalytic activity at 290 °C (Run 1). In intial patents, a number of amines have been used as promoters. Optimum EG productivities have generally been achieved at relatively low amine/rhodium ratios of 0.1—2.3.[1b] However, there have been no precedents

in which reactions in amine solvents give as high a catalytic activity as the N(EG) of Run 1.

The $Rh_4(CO)_{12}$/*N*-methyl-2-pyrrolidone (NMP) system shows a remarkable temperature effect on the formation of EG. Keim et al.[5] reported that the $Rh(CO)_2acac$/NMP system yielded EG in the hydrogenation of carbon monoxide, but without giving no rates to EG. As can be seen from Runs 2—5, the rate of EG formation is significantly accelerated by increase in reaction temperature. The N(EG) at 300 °C and 2000 kg/cm^2 of synthesis gas is about 2000 h^{-1} (Run 5). The Sel.(EG) of Run 5 is about 70%. This value of N(EG) is the highest that has ever been found with rhodium catalysts. This value is interesting from the standpoint of the cost and availability of rhodium.

The result obtained for the $Rh_4(CO)_{12}$/toluene solvent system is given in Run 6. The rate of EG formation is significantly lower than that of the $Rh_4(CO)_{12}$/NMP system (Run 2), though the rate of MeOH formation is higher than that of Run 2. This reaction in toluene at 230 °C caused precipitation of rhodium metal, which suggests that the catalyst stability in toluene is low.

Although tetraglyme and γ-butyrolactone have been used as effective solvents in the presence of promoters in the literature,[1,4] little is known about their catalytic effectiveness in the absence of promoters. The results obtained for the $Rh_4(CO)_{12}$/tetraglyme solvent system are given in Runs 7 and 8. This catalyst system also gives lower rates to EG than the $Rh_4(CO)_{12}$/NMP system (Runs 2 and 3). The reaction in tetraglyme at 250 °C gives rise to precipitates of rhodium metal.

The results obtained for the $Rh_4(CO)_{12}$/γ-butyrolactone solvent system are shown in Runs 9—11. In contrast to the results of the nitrogen-containing solvents (Runs 1—5), increase in temperature has only a small effect on the rate of EG formation, though there was no visible evidence for the formation of rhodium metal at the end of the reaction.

For γ-butyrolactone, tetraglyme, and toluene, the effectiveness order for catalyst stability is γ-butyrolactone>tetraglyme>toluene. It appears that solvents having high dielectric constants enhance the stability of the rhodium catalyst. On the other hand, a comparison of Run 1 with Runs 6 and 7 shows that tributylamine improves the catalyst stability, though the dielectric constant of tributylamine is low (2.33 at 20 °C).[6] The nitrogen atom in NMP seems to contribute to the enhancement of the catalyst activity for the EG formation, as is evident from a comparison of Run 4 with Run 11.

As shown in Table 1, the reactions in toluene, tetraglyme, and γ-butyrolactone which show low turnover frequencies of EG give colored solutions at the end of reaction. On the other hand, the reactions in nitrogen-containing solvents which show high turnover frequencies of EG give colorless solution. Watanabe et al.[7] reported that the reaction with the $Rh(CO)_2acac$/NMP system under about 500 kg/cm^2 of synthesis gas gives a colorless solution. These results are interesting in connection with the active species and the role of solvent.

This work is a part of "C_1-Chemistry Project," a National Research and Development Program of Agency of Industrial Science and Technology, Ministry of International Trade and Industry (M.I.T.I.), Japan. The authors thank Drs. Ken-ichro Bando and Ikuei Ogata for their valuable suggestions.

The Direct Preparation of Flavones from 2′-Hydroxychalcones Using Disulfides

Yukio HOSHINO,* Toshinori OOHINATA,†† and Noboru TAKENO†
Department of Natural Science, Muroran Institute of Technology, Mizumoto-cho, Muroran 050
†Department of Industrial Chemistry, Muroran Institute of Technology, Mizumoto-cho, Muroran 050
(Received December 19, 1985)

Synopsis. Flavone was obtained by a reaction of 2′-hydroxychalcone with disulfides in good yield. Among several disulfides, diphenyl disulfide gave the best result. Under the same conditions, some flavones were obtained from the corresponding 2′-hydroxychalcones in satisfactory yields.

A synthesis of flavones(**2**), which are the main materials of naturally occurring flavonoids, is usually based on the dehydrogenation of flavanones obtained by the cyclization of 2′-hydroxychalcones(**1**).[1] Flavones can also be obtained directly from **1** by use of selenium dioxide,[2] Pd-black[3] or Pd(II).[4] In a previous paper,[5] we reported that **2** could be obtained by a reaction of **1** with sulfur in *N,N*-dimethylformamide (DMF) in good yields.

We now report the new synthesis of **2** from **1** using disulfides. In this reaction a mixture of **1a** and disulfides was heated at 260—290 °C under a nitrogen atmosphere.

The effects of the disulfides on the formation of **2a** are shown in Table 1. Among four disulfides, diphenyl disulfide gave the best result. In the case of aliphatic disulfides, the low yields of **2a** may be due to the bulky carbon chains of thiyl radicals which are presumed to be formed in the course of the reaction.

Using diphenyl disulfide, nine flavone derivatives(**2b—j**) were prepared from the corresponding chalcones(**1b—j**) under the same conditions in various yields. The results are summarized in Table 2. In this and the above tables, the yields of **2** were determined by means of HPLC or GLC analyses using an absolute calibration method. For a comparison, the results of a run using flavanone(**3a**) as the starting material is also shown in Table 2.

In all cases, the conversions were complete and there was no isolable material in addition to the flavones. Table 2 shows that substituents having an electron-withdrawing effect tend to decrease the yields to a large extent. The nitroderivative(**1j** or **2j**) resinated considerably in these reaction conditions, and resulted in the lowest yield of **2j**. Although a slight increase in the yield of **2a** was observed in the case of **3a**, it can not be concluded in view of the

reaction time that there is the difference in the reactivity between **1a** and **3a**. Eventually, the varieties of the yields of **2** may depend on the stabilities or the presence of secondary decompositions of the substrates and/or the products.

Although the mechanism of this reaction is not clear at present, we believe that the reaction provides a useful route to a one-step synthesis of flavones.

Experimental

Materials and Instruments. Disulfides were of a commercial grade and were used without further purification. 2′-Hydroxychalcones were prepared according to known procedures[6] from the corresponding 2′-hydroxyacetophenones and benzaldehydes. Those physical data have already been reported,[5] except **1b**, **1g**, and **1i**. All melting points are uncorrected and ^{1}H NMR spectra were obtained with a Hitachi R-22(90 MHz) spectrometer using tetramethylsilane as an internal standard.

4-Phenyl-2′-hydroxychalcone(1b): Mp 149.5—151.0 °C, ^{1}H NMR (CCl_4) δ=6.74—7.98 (15H, m, Olefin and Aromatic), 12.60 (1H, s, 2′-OH); Found: C, 84.20; H, 5.37%. Calcd for $C_{21}H_{16}O_2$: C, 83.98; H, 5.37%.

3-Methoxy-2′-hydroxychalcone(1g): Mp 91.5—92.5 °C, ^{1}H NMR (CCl_4) δ=3.81 (3H, s, 3-OCH_3), 6.73—7.88 (10H, m, Olefin and Aromatic), 12.59 (1H, s, 2′-OH); Found: C, 75.79; H, 5.42%. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55%.

4-Chloro-2′-hydroxychalcone(1i): Mp 155—156 °C, ^{1}H NMR (CCl_4) δ=6.73—7.91 (10H, m, Olefin and Aromatic), 12.48 (1H, s, 2′-OH); Found: C, 69.26; H, 4.15; Cl, 13.64%. Calcd for $C_{15}H_{11}O_2Cl$: C, 69.64; H, 4.29; Cl, 13.70%. Flavones as authentic samples were also obtained by known procedures[1] and those physical data have already been reported.[7]

HPLC and GLC analyses were conducted using instruments by Yanagimoto High Speed Liquid Chromatograph L-2000 and Shimazu Gas Chromatograph GC-3BT, respectively.

General Reaction and Purification Procedure. In a 50 ml three-necked round-bottom flask equipped with nitrogen inlet and outlet tubes at both side necks, a mixture of chalcones(4.46 mmol) and disulfides(4.66 mmol) was placed and the center neck was sealded by a Uni-stopper. The flask was then dipped into a silicone oil bath and heated at 260—290 °C under a nitrogen atmosphere until the distilling of the formed thiols through the outlet tube ceased. The reaction mixture was then cooled at room temperature and solved in 50 ml chloroform. The yields of the flavones were determined by HPLC or GLC analyses. Then, the solvent was removed and the residue was purified by silica-gel column chromatography using dichloromethane as an eluent and crystallized from ligroin or benzene. All flavones were identified by a comparison of melting points and the IR and ^{1}H NMR spectra with those of authentic samples.

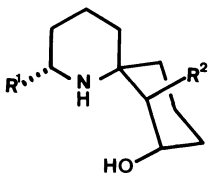
New Piperidinic Synthons via Ring Contraction. Formal Synthesis of (±)-Perhydrohistrionicotoxin

Pierre DUHAMEL,* Mitsuharu KOTERA, and Thierry MONTEIL
U.A.464 Laboratoire de Chimie Organique,
Faculté des Sciences et des Techniques de Rouen,
76130 Mont Saint Aignan, France
(Received February 10, 1986)

Synopsis. The 2,2-bifunctionalized piperidines **6** and **10** were obtained via ring contraction of the seven-membered heterocyclic enamino aldehyde **5** in nearly quantitative yield. The synthesis of 1-benzyl-1-azaspiro[5.5]undec-7-en-9-one **9** (a formal precursor of perhydrohistrionicotoxin **1b**) in 3 steps from the piperidinedialdehyde monoacetal **6**, is reported.

The histrionicotoxins, a group of unique spiropiperidinol alkaloids isolated from skin extracts of the Colombian poisonous frog "Dendrobates histrionicus," have been the subject of current synthetic investigation because of their important neurophysiological activity.[1] In particular, several successful syntheses of dodecahydro derivative **1b**, commonly named perhydrohistrionicotoxin or H_{12}-HTX, have been reported as have a number of approaches to similar compounds[2–4]. Recently a total synthesis of (±)-histrionicotoxin **1a** ((±)-HTX), the parent alkaloid of this family has been reported[5].



1a R^1 = $-CH_2CH=CH-C\equiv CH$, R^2 = $-CH=CH-C\equiv CH$

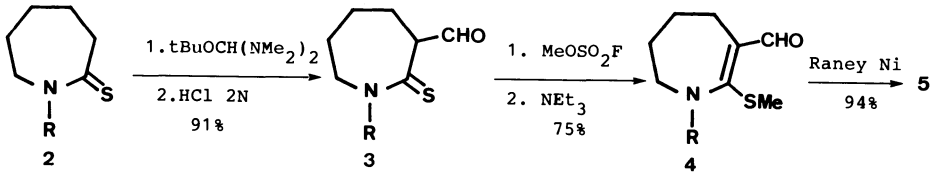
1b R^1 = C_5H_{11}, R^2 = C_4H_9

1c R^1 = $-(CH_2)_3-CH=CH_2$, R^2 = $-(CH_2)_2-CH=CH_2$

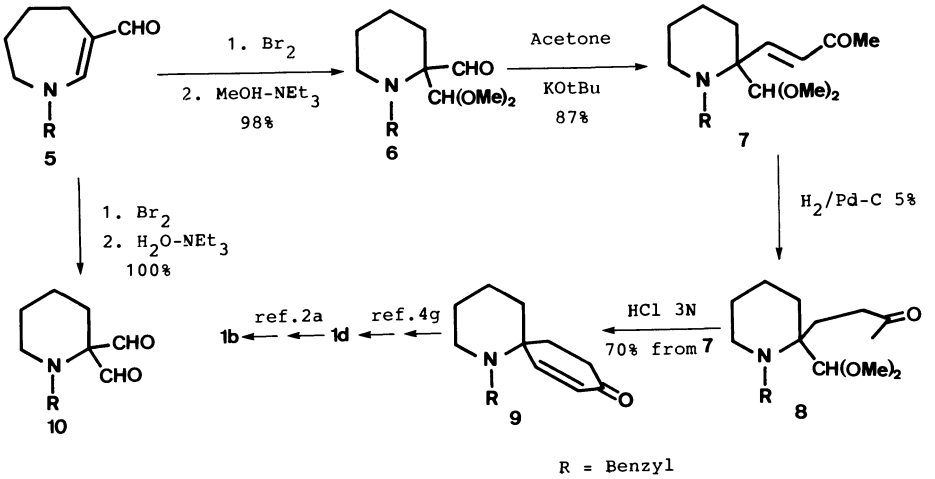
1d R^1 = H, R^2 = C_4H_9

Having developed a new strategy for the preparation of 2,2-bifunctionalized pyrrolidines and piperidines via ring contraction of heterocyclic enamines[6], we sought to further demonstrate its utility by applying it in a synthesis of **9** which is reported to be a flexible synthon for the H_{12}-HTX.[4g] We selected the heterocyclic enamino aldehyde **5**, which is available in 3 steps from the thiolactame **2**,[7] as starting material.

Formylation of **2** was carried out by Bredereck's reagent followed by hydrolysis.[8] Methylation and deprotonation of **3** afford the methylthiotetrahydroazepinecarbaldehyde **4**. Reductive desulfurization of **4** to the enamino aldehyde **5** was accomplished by deactivated Raney nickel (64% overall yield from **2**).



Upon treatment with bromine followed by triethylamine-methanol[6], the tetrahydroazepine **5** was easily transformed to the piperidinedicarbaldehyde monoacetal **6** in 98% yield. The same reaction using triethylamine-water lead to the dicarbaldehyde **10** in quantitative yield.



This ring contraction affords us a direct and effective method for the synthesis of azaspiranic enone **9**. Thus the monoacetal **6** was condensed with acetone to give the unsaturated keto acetal **7** which was hydrogenated in the presence of 5% Pd-C. The resulting saturated keto acetal **8** was hydrolyzed without isolation and spontaneously cyclized by acid work-up (3 M HCl)[9] to the azaspirannic enone **9** (60% overall yield from **5**). The same enone **9** has been converted by others[4g,2a] into depentyl H_{12}-HTX **1d** and thence H_{12}-HTX **1b**.

Experimental

General Procedure. All melting points are uncorrected. Infrared spectra (IR) were recorded on a Perkin Elmer 337 spectrophotometer and are reported in cm^{-1}. ^1H NMR spectra were taken on a Perkin Elmer R 12. ^{13}C NMR spectra were taken on a Varian CFT20. The chemical shifts (δ values) are given in parts per million relative to TMS as an internal standard in $CDCl_3$ solutions and coupling constants in hertz. Splitting patterns are designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad.

1-Benzyl-2-thioxohexahydroazepine-3-carbaldehyde 3. A mixture of **2** (35.0 g, 0.16 mol) and *t*-BuOCH(NMe_2)$_2$ (44.3 g, 0.25 mol) was heated at 140 °C for 3 h until most of *t*-BuOH had been removed by distillation. After cooling, the reaction mixture was poured into 2 M HCl (500 ml (1 M=1 mol dm^{-1})) and stirred for 2 h at room temperature. The resulting solid was collected by filtration, washed with cold water and dried on P_2O_5, providing 36.0 g (91%) of **3** which was utilized without further purification: IR (nujol) 1730; ^1H NMR 9.80 (d, J=2 Hz, 1H), 7.35 (s, 5H), 5.44, 5.88 (ABq, J=15 Hz, 2H), 3.5—3.8 (m, 3H), 1.2—2.5 (m, 6H); ^{13}C NMR 202.1, 192.3, 135.2, 128.6, 128.0, 127.7, 60.6, 56.6, 52.4, 27.3, 26.0, 23.6.

1-Benzyl-2-methylthio-4,5,6,7-tetrahydro-1H-azepine-3-carbaldehyde 4. Methyl fluorosulfate (24 g, 0.21 mol) was rapidly added to a solution of **3** (35.6 g, 0.14 mol) in CH_2Cl_2 (350 ml). The mixture was stirred overnight at room temperature. To this mixture, triethylamine (73 g, 0.72 mol) was added slowly with stirring and after 1 h, the dichloromethane was removed in vacuo. The oily residue was continuously extracted with hot hexane. **4** crystallized out on cooling (28.5 g, 75%) and was utilized without further purification: mp 88—89 °C; IR (nujol) 1610, 1510; ^1H NMR 9.92 (s, 1H), 7.30 (s, 5H), 4.73 (s, 2H), 3.15—3.4 (m, 2H), 2.2—2.5 (m, 2H), 2.25 (s, 3H), 1.25—1.6 (m, 4H); ^{13}C NMR 190.2, 168.3, 137.6, 128.7, 127.9, 127.8, 118.7, 56.5, 52.7, 25.1, 24.7, 23.2, 19.1; Anal. ($C_{15}H_{19}NOS$) C, H, N.

1-Benzyl-4,5,6,7-tetrahydro-1*H*-azepine-3-carbaldehyde 5. To about 20 g of W2 Raney nickel previously refluxed in acetone (100 ml) for 2 h was added a solution of **4** (3.9 g, 14.9 mmol) in acetone (30 ml), and the mixture was refluxed for 3 h. After cooling, the solution was decanted and the catalyst was washed six times with acetone. The decanted solution and washings were together filtered and concentrated. The resulting solid was purified by flash chromatography on silica gel with ethyl acetate as the eluant to give 3.0 g (94%) of **5**: Mp 69—70 °C (ethyl acetate); IR (nujol) 1600; ^1H NMR 8.98 (s, 1H), 7.3 (m, 5H), 6.90 (s, 1H), 4.40 (s, 2H), 3.1—3.4 (m, 2H), 2.3—2.6 (m, 2H), 1.5—1.9 (m, 4H); ^{13}C NMR 190.5, 160.3, 136.6, 128.9, 128.1, 127.3, 115.4, 63.1, 52.5, 28.2, 26.2, 23.6; Anal. ($C_{14}H_{17}NO$) C, H, N.

1-Benzyl-2-dimethoxymethylpiperidine-2-carbaldehyde 6. To a suspension of **5** (3.23 g, 15.0 mmol) in anhydrous ether (420 ml) were added at −70 °C 2.6 g (16.2 mmol) of bromine in 25 ml of cold (about −30 °C) anhydrous ether. After completion of the addition, the resulting yellow suspension of the iminium salt was stirred at this temperature for 30 min. To this suspension, a mixture of methanol (12.7 g, 0.39 mol) and triethylamine (4.55 g, 45.0 mmol) was added at −70 °C and the reaction mixture was allowed to warm to room temperature, stirred for 24 h, and filtered. The filtrate was concentrated under reduced pressure, and cold anhydrous ether (50 ml) added to the residue. The triethylamine hydrobromide was filtered and the solvent was evaporated under reduced pressure to give 4.08 g (98%) of **6** which was utilized without further purification. An analytical sample was obtained by flash chromatography on silica gel with petroleum ether/ether (9:1) as the eluant: Mp 38—39 °C (pentane); IR (nujol) 1730; ^1H NMR 9.69 (s, 1H), 7.2—7.6 (m, 5H), 4.72 (s, 1H), 3.93 (s, 2H), 3.59 (s, 6H), 2.6—2.8 (m, 2H), 1.4—2.0 (m, 6H); ^{13}C NMR 201.3, 138.5, 126.0, 125.9, 124.5, 107.1, 67.7, 56.3, 56.0, 53.6, 44.8, 24.5, 23.0, 17.9; Anal. ($C_{16}H_{23}NO_3$) C, H, N.

1-Benzylpiperidine-2,2-dicarbaldehyde 10. To a suspension of the iminium salt (1.0 mmol) in 35 ml of anhydrous ether, prepared from 213 mg of **5** and 0.17 g of bromine as above, was added at −70 °C a mixture of water (38 mg, 2.1 mmol) and triethylamine (0.5 g, 5 mmol). The reaction mixture was allowed to warm to room temperature and stirred for 3 h. The triethylamine hydrobromide was filtered and washed with a solution of triethylamine (0.5 g) in 50 ml of ether. After removal of the solvent, 25 ml of ether were added and the precipitated salt was removed by filtration. The filtrate was concentrated in vacuo to give **10** (220 mg, 100%) as a colorless oil which became discoloured with decomposition on standing at room temperature: IR (neat) 1720; ^1H NMR 9.72 (s, 2H), 7.0—7.4 (m, 5H), 3.80 (s, 2H), 2.5—2.8 (m, 2H), 1.2—1.9 (m, 6H); ^{13}C NMR 202.1, 138.9, 128.3, 128.0, 127.3, 76.2, 58.1, 46.6, 27.6, 24.9, 19.4.

(*E*)-4-(1-Benzyl-2-dimethoxymethylpiperidin-2-yl)-3-buten-2-one 7. To a suspension of *t*-BuOK (2.55 g, 22.7 mmol) in anhydrous THF (50 ml) was rapidly added at −5 °C a solution of acetone (0.95 g, 16.3 mmol) in THF (5 ml). After cooling to −10 °C a solution of **6** (1.25 g, 4, 50 mmol) in THF (10 ml) was added. The reaction mixture was allowed to warm to room temperature, stirred for 1 h and then poured into 2 M HCl (200 ml). After neutralization with Na_2CO_3, the aqueous solution was extracted with ether, dried over Na_2CO_3 and concentrated. The resulting solid was recrystallized from hexane to yield 1.24 g (87%) of **7**: Mp 117—118 °C; IR (nujol) 1670; ^1H NMR 7.2—7.5 (m, 5H), 7.18, 6.45 (ABq, J=17 Hz, 2H), 4.66 (s, 1H), 3.88, 3.71 (ABq, J=15 Hz, 2H), 3.57 (5s, 3H), 3.55 (s, 3H) 2.5—2.7 (m, 2H), 2.23 (s, 3H), 1.4—2.2 (m, 6H); ^{13}C NMR 198.2, 149.6, 140.7, 130.7, 127.7, 127.1, 125.9, 106.8, 64.5, 58.0, 57.2, 55.2, 46.5, 33.1, 26.4, 25.1, 20.3; Anal. ($C_{19}H_{27}NO_3$) C, H, N.

1-Benzyl-1-azaspiro[5.5]undec-7-en-9-one 9. A suspension of 0.22 g of 5% Pd-C in 0.3 M ethanolic KOH (20 ml) was saturated with hydrogen. A solution of enone **7** (1.58 g, 5.0 mmol) in a mixture of 0.3 M ethanolic KOH (20 ml) and ethyl acetate (25 ml) was added and the mixture hydrogenated at room temperature and atmospheric pressure until 1 equiv of hydrogen (120 ml) was absorbed (about 20 min). After filtration of the catalyst, the filtrate was concentrated at reduced pressure to about 20 ml, acidified with 3 M HCl (20 ml), concentrated again to about 20 ml. Then 3 M HCl (30 ml) was added and the mixture refluxed for 16 h. After cooling, the mixture was basified with Na_2CO_3, extracted with ether, dried over Na_2CO_3 and concentrated. The residue was purified by

flash chromatography on silica gel with petroleum ether/ether (1:1) as the eluant to yield 0.89 g (70%): Mp 57—59 °C (methanol-water); IR (neat) 1680; ^{1}H NMR 7.2—7.6 (m, 5H), 6.95 (d, br, J=10 Hz, 1H), 6.03 (d, J=10 Hz, 1H), 3.73, 3.33 (ABq, J=15 Hz, 2H), 2.0—2.8 (m, 6H), 1.3—1.9 (m, 6H); ^{13}C NMR 198.8, 160.1, 139.9, 128.8, 127.9, 127.6, 126.5, 57.3, 55.9, 45.3, 34.3, 32.2, 25.6, 21.0, 20.4; Anal. ($C_{17}H_{21}NO$) C, H, N.

(Received January 24, 1986)

Synopsis. The reductions of some cobalt(III) complexes having overall charges of −1 to +3 by the polymer-bound ferrous chelate, Fe(II)-PBDA (PBDA=vinylbenzylamine-*N,N*-diacetate-co-4-styrenesulfonate), and the effect of sodium chloride on the reduction rate have been investigated. The specific rate increases sharply with the positive charge on the Co(III) complexes by electrostatic interactions between reactant species.

In previous papers,[1-4] the reductions of macromolecular cobalt(III) complexes by some low-molecular-weight ferrous chelates have been reported. The results of kinetic studies, i.e., the acceleration and retardation of the rates of electron-transfer reactions relative to the corresponding low-molecular-weight systems, have been interpreted, essentially, by the effects of the electrostatic, steric, and hydrophobic interactions between the reactant species in the macromolecular domains.

Experimental

The preparation of (vinylbenzyl)amine-*N,N*-diacetic acid (VBDA) and a method for the copolymerization of VBDA with sodium 4-styrenesulfonate (NaSS) have been described elsewhere.[5,6] To the reaction mixture after copolymerization, dilute sodium hydoxide solution was added. The mixture was dialyzed in water for 3 d with cellulose dialyzer tubing (Nakarai Chemicals Co., MW cutoff 8,000), evapolated to dryness, grained with a mortar, and dried in vacuo at 80 °C. The sodium salt of VBDA-co-NaSS (PBDA) was obtained as a white powder. The intrinsic viscosity of an aqueous solution of PBDA was 1.3 dl g^{-1} at 25 °C. (Ethylbenzyl)amine-*N,N*-diacetic acid (EBDA) was prepared according to a similar method described elsewhere.[5] Sodium chloro[ethylenediaminetetraacetato(3−)]-cobaltate(III) (Na[CoCl(Hedta)]),[7] bis(ethylenediamine)oxalatocobalt(III) chloride ([Co(ox)(en)$_2$]Cl),[8] pentaamminechlorocobalt(III) chloride ([CoCl(NH$_3$)$_5$]Cl$_2$),[9] hexaamminecobalt(III) chloride ([Co(NH$_3$)$_6$]Cl$_3$),[10] and tris(ethylenediamine)cobalt(III) chloride ([Co(en)$_3$]Cl$_3$)[11] were prepared by the reported methods. The concentration of PBDA is represented by the monomer unit of the VBDA in the copolymer and the unit of the concentration is expressed by mol dm^{-3}. Solutions of Fe(II)-PBDA and Fe(II)-EBDA were prepared by mixing a deoxygenated buffer solution of the chelating agent with equivalent amounts of deoxygenated ammonium iron(II) sulfate solution under an atmosphere of argon. The viscosities were measured in aqueous solutions, using Ubbelohde-type viscometer at 25±0.1 °C.

The kinetic experiments were undertaken at pH 7.5—8.5 (phosphate buffer), I=0.03 (I; ionic strength), and 25±0.2 °C. The reactions were followed under pseudo-first-order conditions with a large excess of the ferrous chelate by observing the decay of the absorbances of the cobalt(III) complexes at 350—600 nm using a Yanagimoto Model SPS-1 stopped-flow spectrophotometer. The concentrations of Co(III) and Fe(II) in the reaction solutions were 1.0×10^{-4} and 1.0×10^{-3} mol dm^{-3}, respectively. The rate constants were determined from the slopes of the log (A_t-A_∞) vs time. Absorption spectra were recorded on a Hithachi Model 320 recording spectrophotometer.

Results and Discussion

The chemical structure and composition of the sodium salt of PBDA prepared is illustrated in Fig. 1. The content of the VBDA moieties on the polymer chain was also ascertained spectrometrically: e.g., examinations of the method of continuous variation and the absorption spectra for a VBDA-co-NaSS-Ni^{2+} solution were carried out. The molecular weight of this polymer-bound chelating agent was estimated to be at least 8000 since a dialysis of the copolymer solution was carried out using cellulose dialyzer tubing of MW cutoff through 8000. This molecular weight corresponds to about 4 monomer units of the chelating agent and about 33 units of the sulfonate groups on a polymer chain. This indicates that this polymer has a great number of negatively charged sulfonato groups on the polymer backbone.

In all cases for the polymer and the low-molecular-weight systems, plots of log (A_t-A_∞) vs time gave

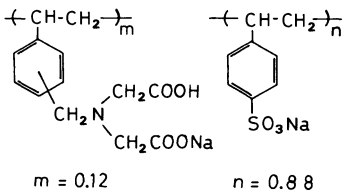

Fig. 1. Chemical structure of PBDA.

Table Pseudo-First-Order Rate Constants for the Reductions of Co(III) Complexes with the Ferrous Chelates at pH 8.0, I=0.03, and 25 °C[a]

Co(III) complex ion	Reductant	
	Fe(II)-PBDA k_p/s^{-1}	Fe(II)-EBDA k_m/s^{-1}
[CoCl(Hedta)]$^-$	1.75±0.04	1.40±0.30
[Co(ox)(en)$_2$]$^+$	42.7±2.2	17.6±0.6
[CoCl(NH$_3$)$_5$]$^{2+}$	7.6±0.4	2.1±0.04
	7.4±0.4[b]	2.2±0.1[b]
	7.6±0.8[c]	2.0±0.07[c]
[Co(en)$_3$]$^{3+}$	41.9±0.5	3.5±0.1
[Co(NH$_3$)$_6$]$^{3+}$	60.4±0.5	8.8±0.1

a) Initial concentrations are 1.0×10^{-4} mol dm^{-3} Co(III) and 1.0×10^{-3} mol dm^{-3} Fe(II). b) pH 7.5. c) pH 8.5.

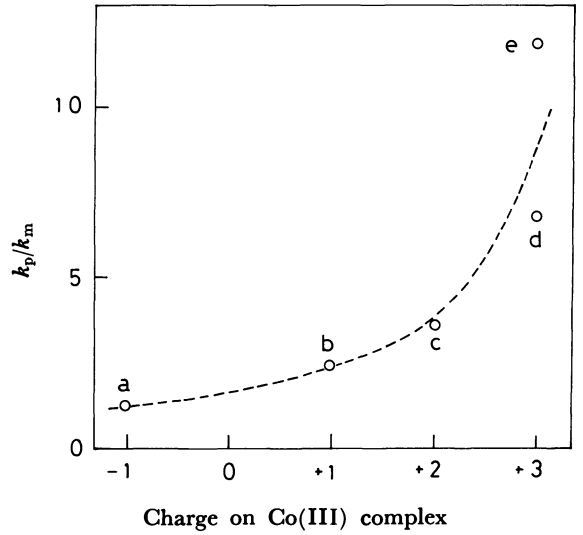

Fig. 2. Relationship between acceleration factor and the charges on the Co(III) complexes.
a: $[CoCl(Hedta)]^-$, b: $[Co(ox)(en)_2]^+$, c: $[CoCl(NH_3)_5]^{2+}$, d: $[Co(en)_3]^{3+}$, e: $[Co(NH_3)_6]^{3+}$.

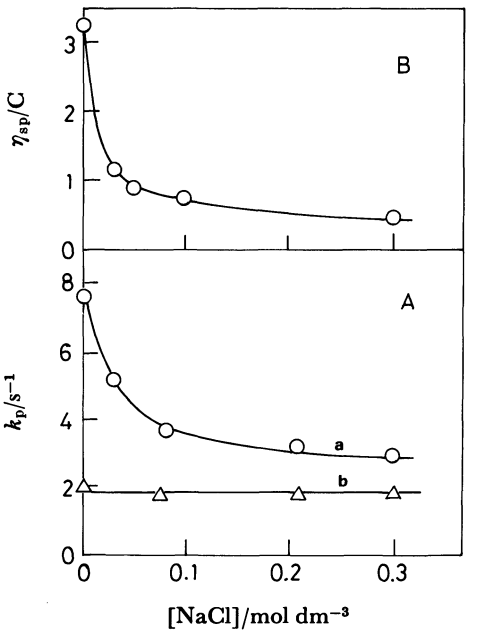

Fig. 3. Dependences of k_p on [NaCl] (A) and η_{sp}/C on [NaCl] (B).
(A): 1.0×10^{-4} mol dm^{-3} $[CoCl(NH_3)_5]^{2+}$, $I=0.03$, pH 8.0, and 25 °C. (a) 1.0×10^{-3} mol dm^{-3} Fe(II)-PBDA. (b) 1.0×10^{-3} mol dm^{-3} Fe(II)-EBDA (B): 1.0×10^{-3} mol dm^{-3} Ni(II)-PBDA, $I=0.03$, pH 8.0, and 25 °C.

straight lines for at least two-times the half-life of the reactions, indicating a first-order dependency of the rates with respect to Co(III). The pseudo-first-order rate constant for the reductions of the Co(III) complexes with a polymer-bound Fe(II)-chelate and those with a low-molecular-weight Fe(II)-chelate, k_p and k_m, respectively, are summerized in the Table. The rate constant for the reduction of $[CoCl(NH_3)_5]^{2+}$ was independent on pH in the region of pH 7.5—8.5. This suggests that no appreciable change in the chemical species of the polymer and the low-molecular-weight Fe(II)-chelates occur in this pH region. The results show explicitly that the overall charges of the Co(III) complexes are of great importance in controling the rate of the electron-transfer reactions in the polymer system; the rate constant for the negatively charged Co(III) complex with Fe(II)-PBDA was of the same order as that with Fe(II)-EBDA, whereas the rate constants for the positively-charged Co(III) complexes with Fe(II)-PBDA were greater than that of the corresponding Co(III) with Fe(II)-EBDA. The ratio of the rate constants, k_p/k_m (represented by acceleration factor) where k_p is the pseudo-first-order rate constant for a given Co(III) complex for the polymer system and k_m is that for the corresponding low-molecular-weight system, is introduced as a measure of the degree of the acceleration. The relationship between the acceleration factor and the overall charge of the Co(III) complex is represented in Fig. 2. The results show that the acceleration factor increases sharply with the positive charges on the Co(III) complexes, i.e., in the domains of the polymeric metal complex anions, a great enhancement of the specific reduction rate occurs with an increase in the positive charge on the low-molecular-weight metal complex ions. Such a charge effect might be ascribed to a large negative charge density in the domains of the Fe(II)-PBDA polymers. Namely, positively-charged inorganic Co(III) complex ions tend to concentrate within the polymer domain with an increase in their positive charge due to an electrostatic attraction between these, leading to an enhancement of the collision frequency between the reactant species. However, no appreciable decrease in the enhancement factor was observed for a reduction of the negatively charged species of $[CoCl(Hedta)]^-$ by a polymeric ferrous chelate relative to that of the monopositively charged species, $[Co(ox)(en)_2]^+$. This seems to indicate that the effect of the coulombic repulsion between the negatively charged polymer domain and a mono-negatively charged Co(III) complex is quite small or can be ignored.

The pseudo-first-order rate constant for the reduction of $[CoCl(NH_3)_5]^{2+}$ by Fe(II)-PBDA decreased rapidly with the addition of NaCl in the concentration region below 0.1 mol dm^{-3}. However, the rate constant for the low-molecular-weight system was little affected by the presence of 0—0.3 mol dm^{-3} NaCl (Fig. 3A). It is known that the local charge density in the polyion domains is greatly affected by the presence of inorganic salts.[12] For example, an addition of sodium chloride to a dilute solution of sodium 4-styrenesulfonate containing $[Ru(bpy)_3]^{2+}$ (bpy=2,2′-bipyridine), which was concentrated in the domains of the poly(4-styrenesulfonate), tended to replace by the sodium ions with an increase in the concentration of sodium chloride.[6] The results of the salt effect on the reduced viscosity of the polymer-bound Ni(II) chelate solution (Fig. 3B) also seems to account for the salt effect on the rate. For a lower salt

concentration than 0.1 mol dm^{-3}, a sharp decrease in the viscosity of the Ni(II)–PBDA solution was observed along with an increase in the salt concentration, indicating a shrinkage of the polymer chain by the shielding of the negative charge in the domains by counter ions. The explanation for the acceleration of the rate is quite similar to that for the reduction of the polymeric Co(III) complexes with low-molecular-weight Fe(II) species.

Photochemical Reaction of Tricarbonyl(η-methylcyclopentadienyl)manganese(I), [Mn(CO)$_3$(MeCp)], with 1,1′-Bis(diphenylphosphino)ferrocene, (dppfe), and X-Ray Molecular Structure Analysis of [Mn(CO)(MeCp)(dppfe)]

Satoru ONAKA

Gokiso-cho, Showa-ku, Nagoya 466
(Received February 4, 1986)

Synopsis. Photochemical reaction of MeCpMn(CO)$_3$ with (Ph$_2$PC$_5$H$_4$)$_2$Fe, (dppfe), was conducted in benzene. From the reaction mixture, the title compound [Mn(CO)(MeCp)(dppfe)] was isolated and its molecular structure was solved by X-ray analysis. ν(CO) peak at 1810 cm^{-1} of the title compound was clarified to be originated from the terminal carbonyl. Temperature-dependent ^{1}H NMR spectra were also measured for the title compound.

It is well-established that tricarbonyl(η-cyclopentadienyl)manganese(I), [Mn(CO)$_3$Cp], dissociates CO quite easily upon photolysis to yield CpMn(CO)$_2$, which, on treatment with various nucleophiles to yield CpMn(CO)$_2$L,[1] where L is phosphines, nitriles, alkadienes, and alkynes. However, the reaction with bidentate phosphine ligands has not yet been well-explored except PR$_2$(CH$_2$)$_n$PR$_2$ type ligands (n=1 and 2; R=CH$_3$ and C$_6$H$_5$) to our knowledge.[2] Recently, it was demonstrated that the dppfe-palladium complex, PdCl$_2$(dppfe), exhibits selective catalytic activity toward cross-coupling of Grignard and organozinc reagents.[3] Therefore, the reaction of **dppfe**, which is a new type of enticing bindentate ligand, with tricarbonyl(η-methylcyclopentadienyl)manganese(I)(**1**), which is a cheaper congener of CpMn(CO)$_3$, under UV irradiation was attempted with the hope of obtaining a new bimetallic compound which may exhibit intriguing reactivity.

From the photolysis of **1** with **dppfe** in benzene, two components were isolated by column chromatography. The second component eluted with benzene afforded orange-red crystals **2** by recrystallization from chloroform–hexane, which showed a strong IR peak at 1810 cm^{-1}. This peak is 24 cm^{-1} lower than that of CpMn(CO)(Ph$_2$PCH$_2$CH$_2$PPh$_2$) and 44 cm^{-1} lower than that of CpMn(CO)(Ph$_2$PCH$_2$PPh$_2$).[2] The observation posed some expectation that the CO group in **2** might be located in a bridging or semi-bridging position. ^{1}H NMR spectrum of **2** showed a broad feature in the methyl proton region at room temperature; the observation suggested some kind of dynamic process such as exchange among the conformers. These lines of structural interest motivated us to carry out X-ray molecular structure analysis of **2**.

Figure 1 shows an ORTEP view of the complex **2**, (CH$_3$C$_5$H$_4$)Mn(CO){(C$_6$H$_5$)$_2$PC$_5$H$_4$}$_2$Fe, and the atom numbering system; **dppfe** functions as a bidentate ligand. Important bond lengths and angles are listed in Table 1. The separation between Mn and Fe is 4.231(2)—4.308(2) Å, which is too far to expect any strong interaction between these two metal atoms. The distances between the carbon atom in CO and Fe atom are 3.89(1)—3.91(1) Å. This range of distance falsifies our expectation that the CO group may occupy a bridging position or a semi-bridging position rather than a terminal position. Therefore, occurance of the absorption of the carbonyl group as low as 1810 cm^{-1} for a terminal carbonyl should be originated from the strong electron-donating nature of **dppfe**. Another interesting feature of the structure of **2** is that the methyl substituent in CH$_3$C$_5$H$_4$ group extends to the same direction as that of CO in solid state, that is, the methyl and CO groups form an eclipsed conformation. Two Ph$_2$PC$_5$H$_4$ groups in **dppfe** moiety also compose an eclipsed conformation. Two C$_5$H$_4$ planes in **dppfe** moiety are almost parallel for each other and perpendicular to the C$_5$H$_4$ plane in (CH$_3$C$_5$H$_4$)Mn(CO) moiety. Mn–P distances are in

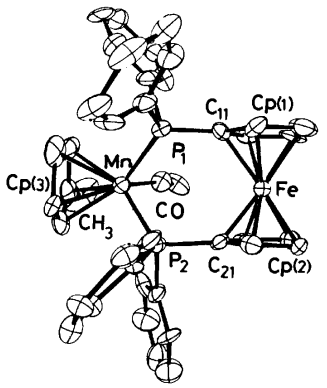

Fig. 1. An ORTEP view of MeCpMn(CO)·dppfe. Thermal elipsoids are drawn at 50% probability level.

Table 1. Important Bond Lengths and Angles

Bond, Angle	Molecule 1	Molecule 2
Mn···Fe	4.308(2) Å	4.231(2) Å
Mn–P$_1$	2.233(3)	2.209(3)
Mn–P$_2$	2.222(3)	2.214(3)
Mn–CO	1.85(1)	1.68(1)
C–O	1.12(2)	1.24(2)
Fe···CO	3.89(1)	3.91(1)
P$_1$–C$_{11}$	1.76(1)	1.94(1)
P$_2$–C$_{21}$	1.85(1)	1.82(1)
Mn···Cp(3) plane	1.80	1.76
Fe···Cp(1) plane	1.60	1.58
Fe···Cp(2) plane	1.70	1.69
CH$_3$-Cp(3)	1.57(3)	1.51(2)
∠P$_1$–Mn–P$_2$	99.5(1)°	98.2(1)°

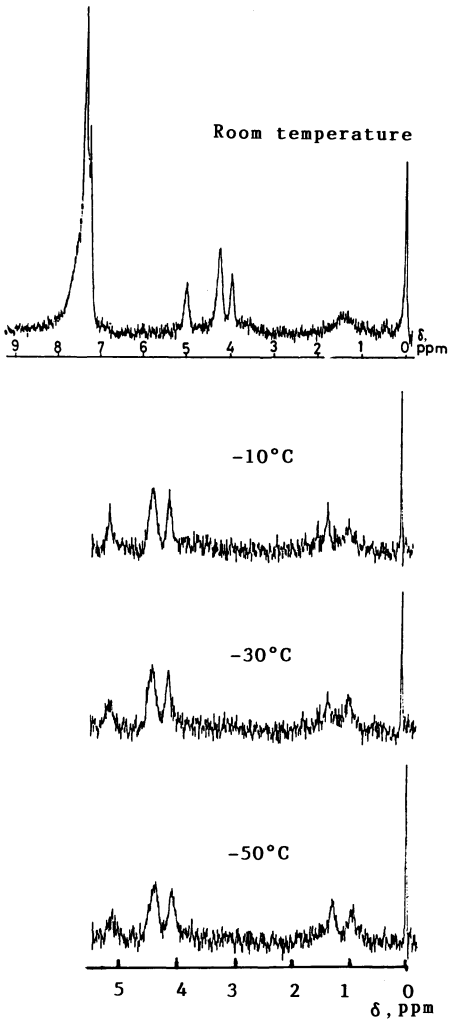

Fig. 2. Temperature-dependent ^{1}H NMR spectra of MeCpMn(CO)·dppfe in $CDCl_3$.

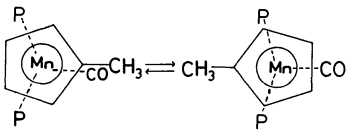
the range of 2.209(3)—2.233(3) Å, which are shorter than Pd–P distances in $PdCl_2$(dppfe) and the bond angle, ∠P–Mn–P, is 99.5(1)—98.2(1)°, which is close to 99.07° for ∠P–Pd–P in $PdCl_2$(dppfe).[3]

Figure 2 shows a temperature-dependent ^{1}H NMR spectra of **2** in $CDCl_3$; the broad feature at around δ 1.4 ppm observed at room temperature splits into two peaks with lowering the temperature. This observation clearly indicates the existence of exchange between two structures. The most plausible explanation for this dynamic process is that **2** exchanges between two conformers in solution such as shown in the Scheme.



Scheme

Experimental

Syntheses. 1.11 g (2 mmol) of **dppfe** and 410 mg (2 mmol) of **1**, which were both purchased from Strem Chemicals, Inc., were dissolved into 75 ml of benzene and this orange solution was photolyzed for 3.5 h under Ar atmosphere with a Riko 100 W high-pressure Hg lamp. The resulting yellow brown precipitate was filtered off and the solvent was vacuum-stripped from the filtrate to leave orange-red semisolid. This semisolid was dissolved into minimum amount of chloroform and was loaded on a Florisil column. First, an orange band was eluted with petroleum ether and then second orange band was eluted with benzene. From the first orange band, yellow microcrystalline product **3** was isolated by recrystallization from dichloromethane–hexane, which showed two strong ν(CO) peaks at 1920 and 1845 cm^{-1} (a Nujol mull). IR data suggest that **dppfe** functions as a monodentate ligand in **3**. Anal. Calcd for [Mn(CO)$_2$($CH_3C_5H_4$)(dppfe)], $C_{42}H_{35}FeMnO_2P_2$: C, 67.76; H, 4.74%. Found: C, 67.53; H, 4.91%. The orange-red product from the benzene eluent was recrystallized from chloroform–hexane to yield orange-red crystals **2** from which a good crystal for X-ray analysis was selected. X-Ray analysis showed that one chloroform molecule is contained for one [Mn(CO)($CH_3C_5H_4$)(dppfe)] molecule in the crystal of **2**. Anal. Calcd for $FeMnC_{41}H_{35}OP_2 \cdot CHCl_3$: C, 60.35; H, 4.34%. Found: C, 60.79; H, 4.45%. IR spectra were measured with a Jasco 701G spectrometer for Nujol mull samples and proton NMR spectra were recorded with a Hitachi-Perkin-Elmer R-20B and R-24A spectrometers (60 MHz) for $CDCl_3$ solutions.

X-Ray Analysis. A single crystal of Mn(CO)($CH_3C_5H_4$)($Ph_2PC_5H_4$)$_2$Fe·$CHCl_3$ with approximate dimensions 0.25×0.35×0.60 mm^3 was mounted on a Rigaku AFC-5 diffractometer with graphite monochromatized Mo $K\alpha$ radiation. Crystal data: monoclinic, $P2_1$, a=18.589(3), b=20.574(3), c=9.785(1) Å, β=91.46(1)°, V=3741(1) Å^3, Z=4 and μ(Mo $K\alpha$)=10.5 cm^{-1}. The structure was solved by direct method with MULTAN 78 and refined by block-diagonal least-squares method. Two independent molecules of Mn(CO)($CH_3C_5H_4$)($Ph_2PC_5H_4$)$_2$Fe and $CHCl_3$ were contained in an asymmetric unit. The final R indices were 0.057 and R_w=0.072 for 100 non-hydrogen atoms with anisotropic temperature factors based on 4838 independent reflections (2θ<50° and $|F_o|>3\sigma(|F_o|)$), which were collected by 2θ—ω scan method.[4,5] Calculations were made on the HITAC M-200H computer at the Computation Center of the Institute for Molecular Science by use of the Universal Crystallographic Computation Program System, UNICS III.[6]

The present study was supported by Grant-in-Aid for Scientific Research No. 57470036 from the Ministry of Education, Science and Culture. Thanks are also due to the Institute for Molecular Science for permission to use the AFC-5 automated X-ray diffractometer (the Instrument Center) and the computer (the Computation Center).

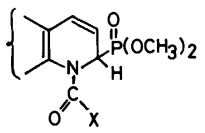
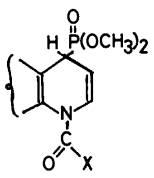
(Received February 20, 1986)

Synopsis. ^{1}H, ^{13}C, and ^{31}P NMR spectra of the products from the Reissert type reactions using acyl halides and trimethyl phosphite were measured and correlated with their structures. ^{31}P Chemical shift of dimethoxyphosphinyl group and ^{13}C chemical shift of the α-carbon atom, as well as $^{1}J_{CP}$ and $^{2}J_{PH}$, can be criteria to differentiate the 1,2- and the 1,4-adducts from each other. Thus, there NMR parameters can be a clue to elucidate the regioselectivity of the reactions.

Pyridine and similar heterocycles containing six-membered azaaromatic ring were shown to react with acyl halides and trimethyl phosphite to give the corresponding 1-acyl-1,2-dihydro-1-azaaromatic phosphonates by Akiba and co-workers.[1] In some instances, the formation of 1,4-adducts was also reported.[2,3] In relation to our recent studies[4] on the Reissert type reactions of some azaheterocycles, some diazanaphthalenes and mono- and diazaphenanthrenes were allowed to react with similar reagents and the structures of the products were elucidated by means of ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy.



1,2-Adduct



1,4-Adduct

Results and Discussion

1-Azaphenanthrene (**1**), 1,5-diazaphenanthrene (**2**), and 1,8-diazanaphthalene (**3**) were allowed to react with trimethyl phosphite in the presence of several acyl and sulfonyl chlorides. The structures of the products were determined by NMR spectroscopy in view of examining the regioselectivity (1,2- vs. 1,4-addition) of the reactions. In order to have unambiguous knowledge on the NMR spectral characteristics of the 1,2- and the 1,4- adducts, the adducts were also prepared from phthalazine (**4**), 9-azaphenanthrene (**5**), and acridine (**6**). The adducts thus obtained were used as the reference compounds of known regioselectivity. Only the 1,2-adducts are expected to be formed in the cases of (**4**) and (**5**). In contrast, acridine (**6**) should give the 1,4-adduct.

The ^{1}H, ^{13}C, and ^{31}P chemical shifts, as well as $^{1}J_{CP}$ and $^{2}J_{PH}$ spin-spin coupling constants, of these *N*-acyl-dihydroazaaromatic phosphonates are given in Table 1. The structural feature of the adducts is reflected in the NMR spectral parameters of the phosphonate parts of the molecules, i.e. ^{31}P chemical shift of dimethoxyphosphinyl group, ^{13}C chemical shift of the carbon atom directly bonded to the phosphorus atom (named α-carbon atom, hereafter), ^{1}H chemical shift of the proton on the α-carbon atom, one bond ^{13}C–^{31}P coupling constant, and two bond ^{1}H–^{31}P coupling constant.

The Chemical Shifts. In the 1,2-adducts which have the *N*-acylated nitrogen atom on the α-carbon atom, ^{31}P and α-^{13}C chemical shifts fall in the ranges of 19 to 21 ppm and 48 to 54 ppm, respectively. The ^{13}C chemical shift differences among the 1,2-adducts are relatively small. The ^{13}C chemical shift is affected far more significantly by the substituent on the nitrogen atom than the skeletal structure of the heterocycle. When the substituent on the nitrogen atom (COX) was changed from acetyl ($COCH_3$) to benzoyl (COC_6H_5), a low field shift of 1 to 1.5 ppm is generally induced.[5] Considerably larger low field shift was observed when the substituent COX was ethoxycarbonyl ($COOC_2H_5$) or diphenylcarbamoyl ($CON(C_6H_5)_2$).

Chemical shifts of the hydrogen atom on the α-carbon atom (named α-hydrogen atom, hereafter) are renging between 5.6 and 6.5 ppm in the series of the 1,2-adducts. Small but definite deviation dependent on the structure of the parent heterocyle was observed among them. Thus the ^{1}H chemical shifts of the 1,2-adducts of 1,8-diazanaphthalene (**3**) appear at a little higher fields, while those of 9-azaphenanthrene (**5**) at lower fields, than the average. As a whole, the chemical shift of α-hydrogen is more sensitive to the skeletal structure of the heterocycle than that of α-carbon. When the substituent COX was changed from acetyl to benzoyl, the ^{1}H chemical shift generally moves towards a high field in contrast to the low field shift of the ^{13}C signal of α-carbon caused by the same structural modification.[5]

The corresponding ^{31}P ^{13}C, and ^{1}H chemical shifts of the 1,4-adducts fall in the range of 23—24 ppm, 34—45 ppm, and 4.4—4.9 ppm, respectively. The ranges of the chemical shifts overlap to each other in neither cases. Therefore, the chemical shift values can be good criteria to differentiate the 1,2- and the 1,4-adducts.

The Spin-Spin Coupling Constant. The ^{1}H-decoupled spectrum of α-carbon atom is split into a doublet by the coupling with the phosphorus nucleus from which $^{1}J_{CP}$ was determined. The $^{1}J_{CP}$ values of the 1,2-adducts fall within a relatively narrow range between 149 and 154 Hz, again the difference among the 1,2-adducts not being large.

Table 2. Summary of the Characteristic Differences in NMR Spectra of 1,2- and 1,4-Adducts

NMR	1,2-Adduct	1,4-Adduct
^{31}P	19—21 ppm	23—24 ppm
$^{13}C(\alpha)$	48—54 ppm	35—45 ppm
$^{1}H(\alpha)$	5.9—6.5 ppm	4.4—4.9 ppm
$^{1}J_{CP}$	148—154 Hz	139—146 Hz
$^{2}J_{HP}$	16—21 Hz	21—26 Hz

$^{1}J_{CP}$ becomes 2—3 Hz smaller when *N*-acyl substituent is changed from acetyl to benzoyl. The $^{2}J_{PH}$ of the 1,2-adducts are ranging from 15 to 21 Hz and are considerably smaller than those of the 1,4-adducts. Those of phthalazine (**4**) adducts is around 16 Hz, being considerably smaller than the average. The $^{1}J_{CP}$'s and $^{2}J_{PH}$'s of the 1,4-adducts are 139—146 Hz and 21—26 Hz, respectively. These ranges do not overlap with the corresponding ranges for the 1,2-adducts. Therefore, the coupling constants will provide an additional clue to characterize the isomeric 1,2- and the 1,4-adducts by NMR spectroscopy.

Other NMR Parameters. The chemical shifts and the spin-spin coupling constants of other ^{1}H and ^{13}C nuclei are rather insensitive to the mode of addition. The ^{1}H and ^{13}C chemical shifts of dimethoxyphosphinyl group are almost unaffected by the change of *N*-acyl group and by the modification of ring structure, ranging 3.3 to 3.8 ppm (two lines) and 52.8 to 53.8 ppm (two lines usually), respectively. The $^{3}J_{POCH}$ values are rather insensitive to the structure of the adducts and not versatile to the discrimination of the two isomeric adducts. As expected, the carbonyl chemical shifts of the acyl groups are determined by the nature of acyl groups, i.e. 168 to 171 ppm for acetyl, 168 to 170 for benzoyl, around 157 ppm for diphenylcarbamoyl, and around 153 ppm for ethoxycarbonyl.

Experimental

Preparation of Materials. Fused 1-acyl-1,2-dihydro-2-pyridylphosphonates from **1—5** were newly prepared by the present authors by the following procedures: To an ice-cooled solution of the azaaromatic compound (9.6 mmol) dissolved in 40 ml of acetonitrile, slightly excess (10.6 mmol) of acyl chloride was added dropwise under stirring, and the whole was kept stirring for 20 min after the completion of addition. Then trimetyl phosphite (10.6 mmol) and sodium iodide (14 mmol) were added successively. The mixture was warmed to 50 °C and left standing for additional 30 min. The solvent was distilled off, and 30 ml of 5% aqueous Na_2CO_3 solution was added to the residue. The crude *N*-acyldihydroazaaromatic phosphonate(s) obtained by extracting the aqueous solution with dichloromethane. In cases when isomeric (1,2- and 1,4-) adducts were formed, they were separated by column chromatography on silica gel.

Measurement of NMR Spectra. All NMR spectra were measured on a JEOL JNM FX-90Q spectrometer in chloroform-*d* solutions at room temperature (26 °C in the probe) unless otherwise remarked. ^{1}H and ^{13}C chemical shifts were determined in reference to the signal of TMS added in the solution, and ^{31}P chemical shifts in reference to the external phosphoric acid standard.

5) In the case of the 1,2-adducts derived from isoquinoline, both the ^{1}H and the ^{13}C chemical shifts of α-carbon and the hydrogen attached on it tend to move towards low fields by the change from acetyl to benzoyl in *N*-acyl group. Thus, the quinoline- and isoquinoline-derived adducts were shown to behave apparently different from each other towards the same structural modification, and their behaviors could be explained by the difference in preferred conformation between these two series of adducts. The *N*-benzoyl-1,2-dihydroquinoline-2-phosphonateds are expected to take a favorable conformation in which the aromatic ring of the benzoyl group orient itself towards the α-carbon atom (antiperiplanar about the C(carbonyl)–N bond) to avoid the steric hindrance between the phenyl and the peri-hydrogen atom. On the contrary, a synperiplanar conformation might be favorable in the adducts of isoquinoline-like heterocycles. The fact that the C(3) and C(4) chemical shifts of the latter adducts shift towards high fields by the same change in the *N*-acyl substituent supports the preference of synperiplanar conformation.

Metal Carbonyl-Induced N-O Bond Cleavage of the Oxime Group

Makoto NITTA* and Yukio IINO
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received December 26, 1985)

Synopsis. The reaction of $[Mo(CO)_6]$ or $[Fe_2(CO)_9]$ with oxime *O*-acetate of 1,3-diphenyl-2-propen-1-one undergoes a reductive N-O bond cleavage to give an imine which dimerises and/or is hydrolyzed to ketones. The dimer, so formed, undergoes fragmentations to give pyridine and pyrimidine derivatives. Similarly, the reaction of $[Mo(CO)_6]$ with several oxime *O*-acetates, oximes, and an oxime ether were shown to give the corresponding ketones. A reaction of oxime *O*-acetates with $[Cr(CO)_6]$ or with $[W(CO)_6]$ to give the corresponding ketones was also shown to proceed very slowly.

In relation to the synthetic and mechanistic interests of a $[Mo(CO)_6]$-, $[Fe_2(CO)_9]$-, or $[Fe(CO)_5]$-induced reductive N-O bond cleavage of isoxazoles[1] and 2-isoxazolines,[2,3] we previously showed that oxime *O*-acetates, oximes, and oxime ethers can be converted to the corresponding ketones in the presence of $[Fe_2(CO)_9]$ or $[Fe(CO)_5]$ under thermal conditions or under photoirradiations.[4] The postulated mechanism involves the imine intermediate. In connection with this study, we report here that a $[Mo(CO)_6]$-induced reaction of oxime *O*-acetate of 1,3-diphenyl-2-propen-1-one gives the imine intermediate. The deoximation of several oxime derivatives using group VI metal carbonyls $[M(CO)_6]$: M=Mo, Cr, and W] are described.

The thermal reaction of oxime *O*-acetates **1** with $[Mo(CO)_6]$ in ethanol or in mosit acetonitrile under reflux afforded 1,3-diphenyl-3-propen-1-one (**2**), 1,3-diphenyl-1-propanone (**3**), 2,4,6-triphenylpyridine (**4**),[5] 2,4,6-triphenylpyrimidine (**5**),[6] (Table 1, Entries 1 and 2). The detailed reaction conditions and the yields of the products, all of which are known compounds, are summarized in Table 1.

The present reaction can be explained by the mechanism shown in Scheme 1. From an analogy of the $[Mo(CO)_6]$-induced N-O bond cleavage of isoxazoles[1] and 2-isoxazolines,[3] and the $[Fe_2(CO)_9]$-induced deoximation reaction of oxime derivatives,[4] the initial step of the reaction was shown to be a complexation of **1** to give **7**.[4] The subsequent N-O bond cleavage gives complex **8**, the nitrogen moiety of which would be reduced by the central molybdenum followed by protonation to give the imine **9** in a protic media.[4] The hydrolysis of **9** would result in the formation of **2** even by stray water. Under the present conditions, **2** was reduced to give **3** (see Experimental).

The imine **9** has been known to dimerise to give a bicyclic dimer **6**, the thermal reaction of which at 190 °C gives **4** and **5** in the presence of sulfur.[7] The thermal reaction of **6** in ethanol under reflux for 24 h afforded **4** (5%) and a trace of **5**; the starting material **6** was recovered in 95% yield. However, the

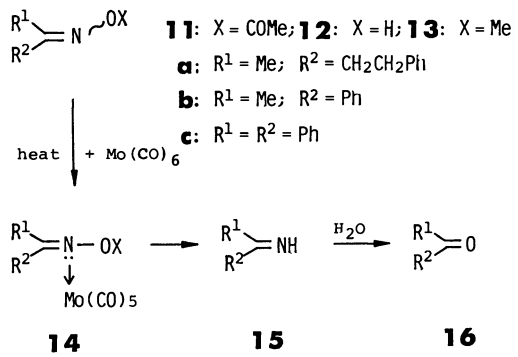
Entry	Solvent	Reaction Conditions[a]	Reaction Time/h	Product (yield/%) 2	3	4	5	6
1	EtOH	A	24	0	7	31	6	15
2	MeCN-H_2O	A	7	5	6	39	1	9
3	EtOH	B	1.5	6	0	2	0	29

a) A: A molar equivalent amount of $[Mo(CO)_6]$ was used, being heated under reflux. B: 1.2 Molar equivalent amount of $[Fe_2(CO)_9]$ was used, being heated under reflux.



Scheme 2.

fragmentation reaction of **6** was accelerated in the presence of [$Mo(CO)_6$], resulting in the formation of **4** (42%), **5** (1%), and **6** (48%) under reflux in ethanol for 24 h. A possible explanation of this fact is a complexation of the [$Mo(CO)_5$] species to the nitrogen atom of **6** to give **10**. Previously, it was suggested that [$Mo(CO)_5$] and [$Fe(CO)_4$] species can coordinate to the oxygen atom of an epoxide ring to facilitate a C–O bond cleavage.[8] The metal carbonyl species also seems to exhibit the nature of a Lewis acid. In a similar fashion, [$Mo(CO)_5$] in a possible intermediate **10** might facilitate the elimination of styrene or benzaldimine from **6**, followed by dehydrogenation to give **4** and **5**.

In relation to a previous study,[4] a reaction of **1** with [$Fe_2(CO)_9$] in ethanol was carried out. The reaction proceeded very fast compared to an [$Mo(CO)_6$]-induced reaction, and **2**, **4**, and **6** were obtained in rather low yields (Table 1, Entry 3). Thus, the reaction is very similar to an [$Mo(CO)_6$]-induced reaction (Scheme 1). The reduction of **2** to give **3** was not observed in this case.

Thermal reactions of oxime O-acetates **11a—c**, oximes **12a—c**, and an oxime ether **13c** in the presence of [$Mo(CO)_6$] afforded the corresponding ketones **16a—c**. Reaction pathways similar to that in Scheme 1 are depicted in Scheme 2. The reaction conditions and yields of the products are summarized in Table 2. The reactions of oxime *O*-acetates **11a—c** proceeded fast and the starting materials were completely consumed to give **16a—c** in good yields (Table 2, Entries 1—3). However, the reaction of the oximes and the oxime ether generally proceeded slowly and the starting materials were recovered (Entries 5—7). Thus, oxime *O*-acetates are labile compared to oximes and the oxime ether.[4] On the other hand, the reaction of **11a** with [$W(CO)_6$] or with [$Cr(CO)_6$] did not occur and **11a** was recovered (Table 2, Entry 8 or 10). Similarly, the reaction of **11c** proceeded very slowly and the corresponding ketone **16c** was obtained in low yield in addition to **11c** (Table 2, Entries 9 and 11). In the deoximation reactions of oxime derivatives, [$Mo(CO)_6$] was shown to be effective compared to [$W(CO)_6$] and [$Cr(CO)_6$] under the present conditions.

Ketimine and aldimine complexes of pentacarbonylchromium have been synthesized.[9] Furthermore, recent work by Shvo et al. clarified that ketimine and aldimine complexes of pentacarbonyltungsten can be obtained in yields ranging from 10 to 20% from a reaction of [$W(CO)_5$THF] with ketoximes and aldoximes.[10] Under the present reaction conditions, no ketimine complex of the group VI metal carbonyls was obtained.

Table 2. Deoximation of **11a—c**, **12a—c**, and **13c**[a]

Entry	Compound	Reaction Time/h	Product yield/%	Recovery/%
1	**11a**	24	**16a** (77)	0
2	**11b**	20	**16b** (60)	0
3	**11c**	10	**16c** (85)	0
4	**12a**	22	**16a** (77)	0
5	**12b**	48	**16b** (55)	13
6	**12c**	144	**16c** (81)	16
7	**13c**	27	**16c** (56)	32
8[b]	**11a**	24	**16a** (0)	90
9[b]	**11c**	14	**16c** (5)	94
10[c]	**11a**	24	**16a** (0)	98
11[c]	**11c**	14	**16c** (2)	96

a) The reactions were carried out in moist acetonitrile under reflux by using an equivalent amount of [$Mo(CO)_6$]. b) The reactions were carried out by using an equivalent amount of [$W(CO)_6$]. C) The reactions were carried out by using an equivalent amount of [$Cr(CO)_6$].

Experimental

General Procedure for the Reaction of 1,3-Diphenyl-2-propen-1-one Oxime O-Acetate 1 with [$Mo(CO)_6$] or with [$Fe_2(CO)_9$]. A solution of **1** (265 mg, 1 mmol) with [$Mo(CO)_6$] (264 mg, 1 mmol) or with [$Fe_2(CO)_9$] (437 mg, 1.2 mmol) in ethanol (3 cm^3) or in acetonitrile (3 cm^3) containing water (ca. 1 mmol) was heated under reflux until **1** was completely consumed. After removing the solvent, the residue was dissolved in benzene (10 cm^3) and filtered through Celite to remove any insoluble material. The filtrate was concentrated and the resulting residue was separated by TLC on silica gel using benzene–hexane (1/1) as a developer to give the products. The results are summarized in Table 1.

Reduction of 1,3-Diphenyl-2-propen-1-one 2 with [$Mo(CO)_6$]. A solution of **2** (104 mg, 0.5 mmol and [$Mo(CO)_6$] (264 mg, 1 mmol) in ethanol (2 cm^3) was heated under reflux for 24 h under a nitrogen atmosphere. After hexane was added to the reaction mixture, it was filtered through Celite to remove any insoluble material. The filtrate was concentrated and the resulting residue was separated by TLC on silica gel using benzene-hexane (1/1) as a developer to give **3** (58 mg, 55%) and **2** (15 mg, 14%).

Thermal Reaction of 6. A solution of **6** (42 mg, 0.1 mmol) in ethanol (1 cm^3) was heated under reflux for 24 h. After the solvent was evaporated, the residue was separated by TLC on silica gel using benzene–dichloromethane (1/1) as a developer to give **2** (2 mg, 5%), a trace of **3**, and **6** (40 mg, 95%).

Thermal Reaction of 6 in the Presence of [$Mo(CO)_6$]. A solution of **6** (42 mg, 0.1 mmol) and [$Mo(CO)_6$] (27 mg, 0.1 mmol) in ethanol (1 cm^3) was heated under reflux for

24 h. After the solvent was evaporated, the resulting residue was separated by TLC on silica gel using benzene–dichloromethane as a developer to give **2** (13 mg, 42%), **3** (1 mg, 2%), and **6** (20 mg, 48%).

General Procedure for the Deoximation Reaction of Oxime *O*-Acetates 11a—c, Oximes 12a—c, and Oxime Ehter 13c with [Mo(CO)$_6$]. A solution of oxime derivatives **11a—c**, **12a—c**, or **13c** (1 mmol) with [Mo(CO)$_6$] (264 mg, 1 mmol) in acetonitrile (2 cm^3) containing water (ca. 1 mmol) was heated under reflux for various periods of time. After the solvent was evaporated, the residue was dissolved in benzene (10 cm^3) and filtered through Celitė to remove any insoluble material. The filtrate was concentrated and the resulting residue was separated by TLC on silica gel using benzene–dichloromethane (1/1) as a developer to give the products. The reaction conditions and the yields of the products are summarized in Table 2 (Entries 1—7).

General Procedure for the Deoximation Reaction of Oxime *O*-Acetate 11a,c with [W(CO)$_6$] or with [Cr(CO)$_6$]. A solution of oxime *O*-acetate **11a,c** (1 mmol) with [W(CO)$_6$] (352 mg, 1 mmol) or with [Cr(CO)$_6$] (220 mg, 1 mmol) in acetonitrile (2 cm^3) containing water (ca. 1 mmol) was heated under reflux for various periods of time. After the solvent was evaporated, the residue was dissolved in benzene (10 cm^3) and filtered through Celite to remove a insoluble material. The filtrate was concentrated and the resulting residue was separated by TLC on silica gel using benzene-dichloromethane as any developer to give the products. The reaction conditions and the yields of the products are summarized in Table 2 (Entries 8—11).

The Determination of a Small Amount of Biological Constituent by the Use of Chemiluminescence. VII. An Attempt of Cyclic Immunoaffinity Chromatography

(Received February 4, 1986)

Synopsis. An immunoaffinity chromatography has been established by combining a chemiluminescence detector developed by the authors with two kinds of immunoaffinity columns connected in series. According to the present method, human serum albumin and ovalbumin in the range of 100 ng to 15 μg in their mixtures could be continuously and selectively determined.

It has been desired to develop an analytical technique for a sensitive, continuous, and selective determination of the desired constituents in serum.

Through immunoassay, used as a labeling reagent, a synthesized metal-complex compound having catalytic activity for a chemiluminescence(CL) reaction, was continuously carried out by the sandwich method mentioned in a previous paper. It required six operating steps and tedious labeling.[1]

So far, there have been several reports[2-5] in which the desired constituent was specially separated on an affinity column based on a biological reaction analyzed by means of a suitable detector. However, the detector used for such a measurment was not always very sensitive.

The method for a flow-injection analysis of protein was established by the authors on the basis of the phenomenon that the catalytic activity of copper(II) against a CL reaction between 5-amino-2,3-dihydro-1,4-phtalazinedione (luminol) and hydrogen peroxide(H_2O_2) is lowered in the presence of protein. According to this method, 2×10^{-4}—1×10^{-1} g dm^{-3} of protein could be sensitively determined with a detection limit of 10 ng.[6,7] A highly sensitive detector for the HPLC of protein was manufactured by making use of the same phenomenon that is described above, and the detector was shown to be also useful for the post-column detection of protein in HPLC.[7]

It was therefore expected that an immunoaffinity chromatography for the sensitive, continuous and selective determination of the desired constituents in a sample without labeling might be established by combining the CL detector with the affinity columns used for an immune reaction.

Experimental

All the reagents used were of a commercially available special grade. A 2.0×10^{-6} mol dm^{-3} copper(II) solution was prepared by diluting a 2.0×10^{-2} mol dm^{-3} copper(II) stock solution[8] with a buffer solution (pH 12.8) consisting of a 0.20 mol dm^{-3} boric acid (H_3BO_3) solution and a 0.25 mol dm^{-3} potassium hydroxide (KOH) solution. A 1.0×10^{-4} mol dm^{-3} luminol solution was prepared by use of a buffer solution (pH 10.2)(0.20 mol dm^{-3} H_3BO_3–0.20 mol dm^{-3} KOH buffer solution). A 5.0×10^{-4} mol dm^{-3} H_2O_2 solution was prepared in a manner similar to that described in a previous paper.[7] These reagents were used for the CL detector developed by the authors. Human serum albumin(HSA)(Miles Labolatolies, Inc.), bovine serum albumin(BSA)(Nakarai Chemicals, Ltd.), ovalbumin (Ova)(Sigma Chemical Co.), human serum γ-globuline-(HγG)(Sigma Chemical Co.), bovine serum γ-globulin-(BγG)(Sigma Chemical Co.), bovine serum α-globulin-(BαG)(ICN Pharmaceuticals, Inc.), and control serum(Q-PAK-Chemistry Control Serum I; Hyland) were diluted with a 8.34×10^{-3} mol dm^{-3} phosphate buffer solution(Buff-A; pH 7.3) consisting of a 2.78×10^{-3} mol dm^{-3} potassium dihydrogenphosphate solution and a 5.56×10^{-3} mol dm^{-3} disodium hydrogenphosphate solution.

Rabbit anti-HSA(DAKO) and goat anti-Ova(Cappel), respectively, were immobilized onto 2 g of porous glass beads (CPG-3000, 200/400 mesh, 29260 nm mean pore diameter, ELECTRO-NUCLEONICS, INC.) by a periodate method.[1] Each amount of anti-HSA and anti-Ova immobilized onto a gram of support was 18.5 and 3.10 mg, as determined by the CL detector developed by the authors.

A flow diagram of the immunoaffinity chromatography system equipped with the CL detector devised by the authors is shown in Fig. 1, and its operating procedure is shown in Scheme 1. Buff-A(a) was fed at a flow rate of 1.8 cm^3 min^{-1} by the pump(d)(Atto, SJ 1211) and an elluent(b)(pH 2.5; 4.2×10^{-3} mol dm^{-3} hydrochloric acid –2.5×10^{-2} mol dm^{-3} potassium chloride buffer solution) (Buff-B) was fed at a flow rate of 1.0 cm^3 min^{-1} by the pump(e)(Pharmacia High-precision Pump P-500). The porous glass beads immobilized with anti-HSA and anti-Ova were packed in a column 1(Col. 1)(15×1 mm i.d.) and a column 2(Col. 2)(15×1 mm i.d.), respectively.

A 50-mm^3 mixed solution containing HSA and Ova was

injected into the Buff-A line through the sampling loop(j) and a six-way cock(g). A sample flaction was repeatedly passed through columns 1 and 2 for 20 min by operating a four-way cock(f). Here, HSA and Ova were collected on columns 1 and 2, respectively, by an immune reaction. Then Buff-A was fed to columns 1 and 2 for 10 min by operating a four-way cock(f) to wash out coexisting constituents. Ova was eluted from column 2 by operating a six-way cock(i); then cock(i) was again operated to feed Buff-A. HSA was eluted from column 1 by operating a six-way cock(h) and then cock(h) was again operated to feed Buff-A. Ova and HSA in each eluate was detected by a CL detector(1) as mentioned in a previous paper.[7] Columns 1 and 2 were regenerated by operating the six-way cocks and by feeding Buff-A.

Results and Discussion

Four steps consisting of adsorption, washing, elution (CL detection), and regeneration were developed for optimum operation as follows: both the flow rate and the feeding time of Buff-A for adsorption and regeneration were chosen so that each analytical value of a mixed sample containing 500 ng HSA and 500 ng Ova might give a definite value; both the flow rate and the feeding time of Buff-A for washing were also chosen so that the analytical value of 500 ng BSA, as a coexisting constituent, might give a minimum value; HSA and Ova, less than 500 ng, could almost be completely eluted in 7 min from affinity columns. The chosen experimental conditions are shown in Scheme 1.

A chromatogram for the mixture consisting of 500 ng of both HSA and Ova is shown in Fig. 2. The selectivities of affinity columns 1 and 2 are indicated on the basis of the analytical values of HSA and Ova, respectively (Table 1). Each 500 ng of protein was

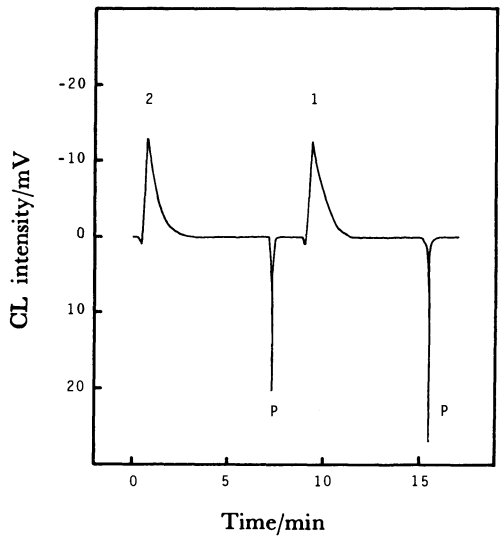

Fig. 2. Chromatogram of the mixture of HSA and Ova. 1: HSA, 2: Ova, and P: shock peak appeared owing to the exchange between the two cylinders in the pump.

Table 1. Selectivity of the Affinity Columns

Proteins (500 ng)	Column 1 (anti-HSA)	Column 2 (ati-Ova)
HSA	1.00	0.00
Ova	0.00	1.00
BSA	0.58	0.00
HγG	0.18	0.07
BγG	0.63	0.23
BαG	0.40	0.15

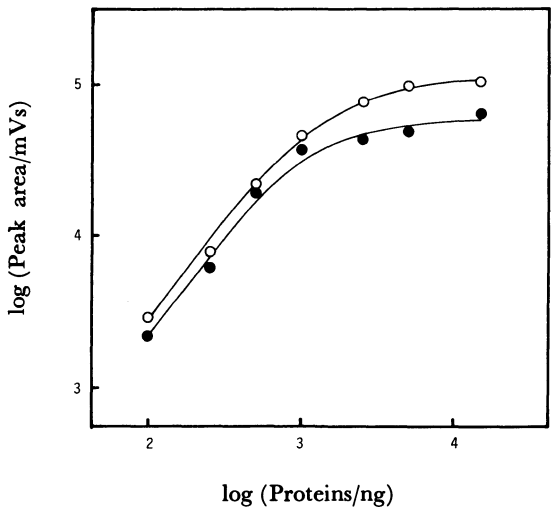

Fig. 3. Analysis of the mixture of HSA and Ova.
○: HSA and ●: Ova.

○: Analytical value obtained by use of column 1 and
●: analytical value obtained by use of column 2.

used throughout this experiment. As can be seen from Table 1, the selectivity of column 1 (immobilized with anti-Ova) was fairly good. Porous glass beads were subjected to the immobilization treatment described in a previous paper[1] in the absence of antibodies. It was charged in a column to analyze HγG. According to the obtained result, no nonspecific adsorption was obtained. This suggests that nonspecific adsorption of HγG onto an affinity column is based on a cross reaction due to the use of inpure antibodies and HγG.

The present method was applied to a mixture of HSA and Ova, and each in the range of 100 ng—15 μg could be successfully determined (Fig. 3). The difference between two calibration curves seemed to result from a difference between the amounts of immobilized antibodies. The coefficient of variation for five analyses of a mixture containing each 500 ng HSA and Ova were 5.7% for HSA and 9.3% for Ova. The time necessary for an analysis was 46 min and the affinity columns were durable for about 20 replicate analyses. The beads immobilized with antibodies were stable and available for about 3 months after their preparation. By assuming the following (1)—(3): (1) 2 g of beads are immobilized with antibodies at a time, (2) 5.9 mg of beads are charged in a column, and (3) an affinity column is durable for about 20 replicate analyses, therefore, about 6800 analyses are feasible. Thus, the present method is sufficiently economical.

To examine the applicability of the present method to a practical sample, a control serum was diluted 5000 times and to it a definit amount of HSA and Ova was added. This was followed by an analysis of the resulting three mixtures (Fig. 4). Curves I and II in Fig. 4 were obtained from columns 1 and 2, respectively. Curve I showed the sum of albumin and non-specifically adsorbed protein in the control serum and of the added HSA. Curve II passed through an original point. This meant that the added Ova alone could be selectively analyzed without being affected by the serum matrix.

Judging from these results, the present method is sufficiently applicable to a practical sample if a selective column immobilized with antibodies is available.

A New Phase-Transfer Porphyrin Catalyst for the Olefin Epoxidation

Shigeru TAKAGI, T. Ken MIYAMOTO,* and Yukiyoshi SASAKI
Department of Chemistry, Faculty of Science, The University of Tokyo,
Hongo, Bunkyo-ku, Tokyo 113
(Received December 24, 1985)

Synopsis. A new type of amphiphilic porphyrin has been synthesized and its manganese(III) complex has been used as a catalyst for the epoxidation of olefin. Catalytic oxygenation in a two-phase (CH_2Cl_2/H_2O) system has been undertaken in the absence of a phase-transfer reagent, such as benzyldimethyltetradecylammonium chloride.

During the last several years, efficient catalytic systems for the epoxidation of olefin in a two-phase (CH_2Cl_2/H_2O) system have been reported.[1,2] These synthetic model systems for the cytochrome P-450 have had several constituent elements. These elements included a hydrophobic Mn(III) porphyrin, an imidazole (or pyridine), a hypochlorite solution as an oxidant, and a phase-transfer reagent which catalyzed the transfer of an oxygen atom from hypochlorite to olefin (See Fig. 1).[3] In order to simplify the two-phase catalytic system, we developed a porphyrin catalyst toward a new amphiphilic manganese(III) salt (abb. Mn srf. **6**, Fig. 2) which had the function of a phase-transfer reagent as well as an epoxidation capability. We report here on the preparation of a new phase-transfer porphyrin catalyst (Mn srf. **6**) and its epoxidation of styrene and cyclohexene.

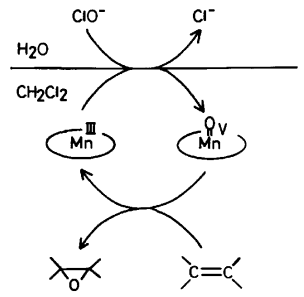

Fig. 1. The two-phase (CH_2Cl_2/H_2O) catalytic system for the olefin epoxidation.

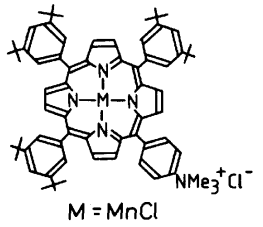

Fig. 2. Mn srf. **6**.

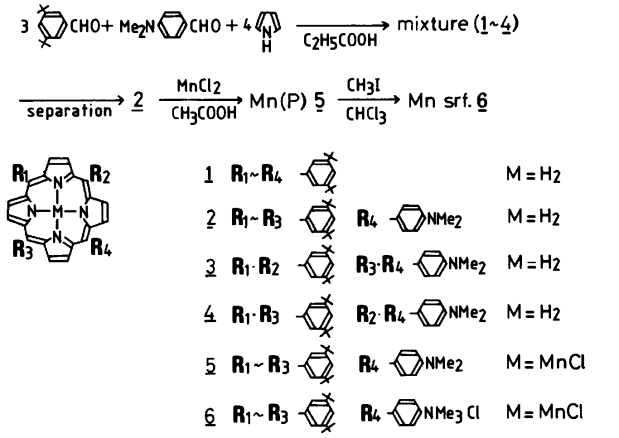

Scheme. The synthetic procedure to Mn srf. **6**.

Exprimental

The synthetic procedure to Mn srf. **6** followed that of previous work[4] and is shown in the scheme.

5,10,15-Tris(3,5-di-*t*-butylphenyl)-20-(4-dimethylaminophenyl)-21*H*,23*H*-porphyrin 2. The porphyrin **2** was synthesized by Rothemund condensation. 3,5-di-*t*-butylbenzaldehyde (76 g, 0.35 mol), 4-dimethylaminobenzaldehyde (18 g, 0.12 mol), and pyrrole (33 g, 0.49 mol) in propionic acid (1 dm^3) were heated under reflux for 2 h. Propionic acid was removed by distillation to give a mixture of porphyrins **1**—**4**. The crude mixture was dissolved in chloroform and chromatographed on an alumina (Merck Alumina 90) column with chloroform as an eluent. The porphyrins **1**—**4** were eluted and other by-products tended to be absorbed on the alumina. After the solvent was removed, the mixture of porphyrins was redissolved in benzene/hexane (1:4). The solution was poured onto a silica gel (Wako gel C-200) column prepared as a slurry in hexane. After all the material was loaded, 1:2 benzene/hexane was added. The porphyrin **1** was eluted, and the mixed solvent was passed through the column until the eluate became very pale. Then, benzene was added and the desired porphyrin **2** was eluted. The solvent was removed and dried in vacuo. Yield: 15.5 g (13%). Anal. Calcd for $C_{70}H_{83}N_5$: C, 84.54; H, 8.41; N, 7.04. Found: C, 84.24; H, 8.24; N, 7.27. ^{1}H NMR ($CDCl_3$) δ=−2.5 (2H, s, internal pyrrole H), 1.4 (54H, s, *t*-butyl H), 3.1 (6H, s, N-CH_3), 6.9—7.9 (21H, m, phenyl H), 8.7 (8H, s, β-pyrrole H).

Mn Insertion to Porphyrin 2. The porphyrin **2** (2.0 g, 2.2 mol), anhydrous $MnCl_2$ (2.0 g), CH_3COONa (2.0 g), and pyridine (20 cm^3) were dissolved in 260 cm^3 of mixed solvent ($CHCl_3/CH_3COOH$ 3:10). The solution was heated under reflux for 4 h. A Mn (III) complex **5** was extracted with $CHCl_3$ and the crude material was purified by alumina column ($CHCl_3$). The eluate was stirred with 10% hydrochloric acid. The solvent was then evaporated. Yield: 2.1 g (91%).

Preparation of the Mn srf. 6. Mn porphyrin **5** (1.0 g) was treated with methyl iodide (30 cm^3) in $CHCl_3$ under reflux for 5 h. The product was purified by chromatography as an alumina column ($CHCl_3$) eluting with 2:1 $CHCl_3/CH_3OH$. After the eluate was stirred with 10% hydrochloric acid, the solvent was removed by the evaporator. Yield: 0.4 g (37%): Anal. Calcd for $C_{71}H_{84}N_5MnCl_2$: C, 75.25; H, 7.47; N, 6.18. Found: C, 75.40; H, 7.46; N, 6.09. UV-vis. ($CHCl_3$) λ/nm ($\varepsilon/M^{-1}cm^{-1}$)[5]: 381 ($4.9\times10^4$),

Table 1. Products of a Styrene Oxidation Reaction

Total	68	(105)

406 (4.4×10⁴), 482 (7.9×10⁴), 589 (9.1×10³), 627 (1.3×10⁴).

Epoxidation Reaction. All experiments were carried out as follows. Mn srf. **6** (0.018 mmol), 4′-(imidazol-1-yl) acetophenone (65 times as many as mol of Mn srf. **6**), styrene (8 mmol, or cyclohexene), and *p*-dichlorobenzene (or cyclohexanone) as an internal standard were dissolved in 50 cm³ of dichloromethane. Then 50 cm³ of the sodium hypochlorite solution (2.9 mmol) was layed over the organic phase. The epoxidation reaction was initiated by stirring vigorously, and was carried out in an ice bath. The products were monitored by gas chromatography. A dependence of the reaction rate on the olefin concentration or on the Mn srf. **6** concentration was evidenced by control experiments. In an analysis of the kinetic experiments, the olefin concentration or the concentration of **6** was changed as listed in Table 3 or 4. Other conditions were maintained as mentioned above.

Results and Discussion

Mn srf. **6** was soluble in most organic solvents such as benzene, chloroform, *N*,*N*-dimethylformamide, ethanol and acetone etc. Mn srf. **6** was not soluble in water, but was soluble in an ethanol/water (1:5) mixed solvent. Soret bands were blue-shifted about 10 nm in methanol and ethanol/water compared with those in $CHCl_3$.[6]

The results of 2 h-oxidation of styrene and of cyclohexene are listed in Tables 1 and 2. In each reaction, epoxides were the main products. A certain amount of phenylacetaldehyde and a small amount of benzaldehyde[7] were also detected during styrene oxidation.[8] Styrene oxidation using Mn srf. **6** reached a maximum turnover number of 1200,[9] compared with that of 240[10] using a Mn complex of **1** and a phase-transfer reagent (benzyldimethyltetradecylammonium chloride). This result shows that Mn srf. **6** is superior to the Mn complex of **1** as a stable catalyst in an oxygenation reaction.[11,12]

The dependence of the reaction rate on the styrene concentration showed that a higher concentration led to a lower reaction rate (See Table 3). The catalyst concentration dependence indicated that the reaction rate changed from 8[13] (under a higher concentration, such as 0.27 and 0.37 mM) to 1.2 (under a lower concentration, such as 0.19 mM (See Table 4)).

Table 3. Dependence of the Reaction Rate on the Olefin Concentration

Styrene concentration/M[5]	Reaction rate[13]
0.06	5.6
0.24	3.7
0.41	1.8

Table 4. Dependence of the Reaction Rate on the Catalyst Concentration

Mn srf. **6** concentration/mM[5]	Reaction rate[13]
0.19	1.2
0.27	8.0
0.37	8.0

This catalytic system using Mn srf. **6** showed a unique behavior regarding the dependence of the reaction rate on the substrate concentration or on the catalyst concentration in comparison with those of other Mn(III) porphyrin catalytic systems.[2,14] The kinetic behavior of an epoxidation reaction using Mn srf. **6** could not be completely fitted by a Michaels-Menten equation, which was proposed by Collman et al.[2] At the present stage, we cannot rationalize these characteristic concentration dependencies of the reaction rate. However, our Mn srf. **6** system efficiently put olefin epoxidation into practice without using a phase-transfer reagent.

Electrochemistry of the Redox-Active Langmuir-Blodgett Films Coated on Glassy Carbon Electrodes

Masamichi FUJIHIRA* and Toshinari ARAKI
Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received January 6, 1986)

In order to study the electrochemical behavior of a redox species in the Langmuir-Blodgett (LB) film on a glassy carbon (GC) electrode, three kinds of amphiphilic redox compounds, each carrying an anthraquinone, a viologen, and a ferrocene moiety, were confined on the electrode surfaces. Prior to the deposition of the film on the electrode, surface pressure-area isotherms for a number of mixed films of the redox-active amphiphiles and arachidic acid were recorded and the stability of the monolayers was discussed. Finally, the cyclic voltammetric behavior of the LB film-modified electrodes was discussed in terms of the changes in the structure and the nature of the LB film caused by the redox reactions.

In the course of the development of the modified electrodes,[1,2] a high density of the immobilized functional species,[1] a regularity in the molecular organization,[3,4] and an ultrathinness of the coated film on the electrode surface[2,5] are of crucial importance. The LB method, the technological possibilities of which have been widely appreciated in connection with molecular engineering,[6,7] was utilized to fulfill these requirements. This technique not only ensures the molecular electrochemical devices,[3,4] but also gives some insights into the structure of the electrical double-layer.[8]

In the present work, we confined redox-active amphiphiles, such as an anthraquinone (AQS), a viologen (VS), and a ferrocene surfactant derivative (FcS), on a GC electrode by the use of the LB method, thereby organizing the desired film structure in which electroactive and electroinactive layers were assembled in a deliberate way. Arachidic acid (AA) was used to form the stable electroactive mixed layers with each redox-active amphiphile and also to build the electroinactive layers. The cyclic voltammetry of these LB modified electrodes and some of the unexpected findings therefrom are discussed in terms of i) the charge on, or in the vicinity of, the redox moieties; ii) the environment and location of the redox moieties, and iii) the change in some of these characteristics by the redox reaction and its effect on the structure and nature of the LB multilayer film.

Experimental

Materials. The redox-active amphiphiles used in the present work are shown in Fig. 1. The AQS was prepared according to the following procedure: dodecylamine was transformed into *N,N*-didodecylmethylamine by the method of Ralston et al.[9]; 2-methylanthraquinone was treated with *N*-bromosuccinimide in the presence of benzoyl peroxide in carbon tetrachloride,[10] and the resulting 2-(bromomethyl)-anthraquinone was reacted with *N,N*-didodecylmethylamine in 1,4-dioxane to yield AQS. For the preparation of FcS, the method of Ohkawara[11] for amide formation from 1,1′-ferrocenedicarboxylic acid was used, as previously.[4] The VS was synthesized according to the method of Fendler et al.[12]

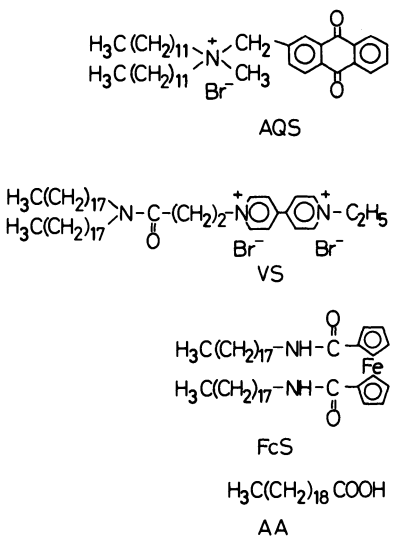

Fig. 1. The structures of the redox-active amphiphiles and a fatty acid used in this work.

Monolayer Preparation and Surface Pressure-Area Isotherms. The surface pressure-area isotherms were studied by using a commercially available Langmuir trough equipped with a film balance (Kyowa Kaimenkagaku Co.). Monolayers were obtained by spreading chloroform solutions of amphiphiles on the air-water interface of the trough and by then compressing the surface at 2 Å^2 molecule^{-1} min^{-1}. Doubly distilled water was used as the subphase; it contained no salt unless otherwise stated. The surface pressure-area isotherms were measured at 24°C.

Film Deposition on the Electrode Surface. The monolayer formed at the air-water interface was deposited at 40 mN m^{-1} on the GC disk electrode (diameter: 0.3 cm) at a dipping rate of 3 mm min^{-1}, except in the case of the pure monolayer of AQS or VS, which was deposited at 35 mN m^{-1}. Since the surface of GC is hydrophilic, little material was deposited on the first insertion of the electrode surface into the subphase, but a good coverage was obtained on the withdrawal of the electrode surface through the film. With repetitive strokes, the multilayer structure of a typical Y film was formed on the GC electrode. For the sake of accuracy, the transfer ratio was determined independently with a GC plate possessing a larger area (6 cm^2). In every case, the apparent transfer ratios for both downward and upward strokes were between 0.8 and 1.1.

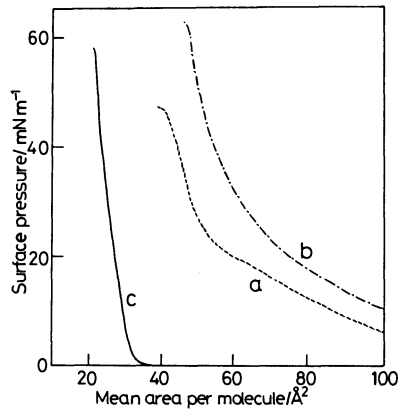

Fig. 3. Surface pressure-area isotherms of (a) VS on pure water, (b) on 0.3 mM Na_2CO_3, and (c) a mixture of VS and AA (1:3) on pure water, at 24°C.

Cyclic Voltammetry. The electrochemical characteristics of the LB film-modified GC electrodes were examined by means of cyclic voltammetry. A three-electrode configuration was employed: an SCE was used as the reference, and a platinum wire as the counter electrode, in addition to the LB film-modified working electrode. Measurements were carried out at room temperature (24°C). An aqueous solution of 0.5 M† KCl was used as the electrolyte. For the AQS-modified electrode, hydrochloric acid was added also to make the pH of the solution two, for in an acidic solution, although there are kinetic complications due to proton addition during the electron transfer, the anthraquinone derivative attached to the GC electrodes exhibits a clear two-electron and two-proton reduction peak to hydroanthraquinone.[8]

Results and Discussion

Stability of the Mixed Monolayers. The isotherms were compared between the mixed monolayer and the monolayer that contained only a redox surfactant, as is shown in Figs. 2—4. For a pure AQS monolayer, only a liquid-expanded film was formed (Fig. 2b). The mixed film of AQS and AA in the molar mixing ratio of 1:3, however, exhibited a condensed state at high surface pressures (Fig. 2c). A pure VS monolayer was unstable on the pure-water subphase (Fig. 3a). The stability was improved on an aqueous solution of 0.3 mM Na_2CO_3 (Fig. 3b). A remarkable stability was achieved by mixing with AA (Fig. 3c). A pure FcS monolayer collapsed at a low surface pressure (Fig. 4a). When mixed with AA, the film was stabilized (Fig. 4b). In all the cases mentioned above, the mixed monolayer, when compressed, formed an extremely stable monolayer, with no appreciable collapse being evident over a period of many hours. The molar mixing ratio of the

redox surfactant and AA (1:3) was chosen in view of both the film stability and the accuracy required for the electrochemical measurements.

Electrochemistry of the LB Film-Modified GC Electrode. We have concentrated our attention on two types of multilayer-deposited electrodes: in one, some AA layers as an electroinactive matrix were sandwiched between the electrode surface and the AA-redox surfactant mixed bilayer, while in the other the relative locations of the AA layers and the AA-redox surfactant monolayer were reversed. The former system is termed an N^xA^2 type, and the latter AN^x, where A, N, and x signify the electroactive AA-redox surfactant mixed layer, the electroinactive AA layer, and the number of the AA layers respectively (Fig. 5).

Figure 6 shows cyclic voltamograms for an N^3A^2 type of AQS modified electrode.* The peak separation became significant as the sweep rate increased. This irreversibility of the electrode process observed on the cyclic voltammogram makes possible the calculation of an apparent surface-reaction rate, k_s.[8,13-15] Figure 7 shows a comparison of the k's for various kinds of N^xA^2

* The electroreactivity of the redox-surfactant in N^xA^2 may need mediators in the N^x matrix, since the direct electron transfer from the electrode to the A layers through the N^x matrix seems to be impossible. As candidates for the mediators, the redox-surfactant itself diffusing into the N^x matrix and redox-active impurities such as a trace of oxygen are considered.

and AN^x electrodes. It should be noted that, in the series of N^xA^2 electrodes, k_s becomes smaller as x increases.

The VS modified electrodes behaved reversibly as long as the potential range was limited to between 0 and −0.9 V vs. SCE. The only peak observed in this region corresponds to $V^{2+}+e=V^+$ (Fig. 8). For the FcS modified electrodes, an unexpected result was obtained: no peak for ferrocene site oxidation was observed in any N^xA^2 and AN^x structure (Fig. 9). The decrease in the charging current compared with the background current for the naked GC electrode (a dashed line in Fig. 9), however, suggests a compact structure of the FcS–AA mixed film. A similar decrease in the charging current was also observed for the VS–AA mixed film (Fig. 8), but the decrease is not so enormous as that of the FcS–AA mixed film.

The formal reversible peak potential, $E°$, was estimated by the extrapolation of the E_{pa}, E_{pc} vs. v plots to v=0, where the E's are peak potentials for the anodic and cathodic sweeps and where v is the sweep rate. The definition of the formal reversible peak potential is available in the literature.[15] Figures 10 and 11 show the formal potentials of the AQS and the VS modified electrodes respectively. On the AQS modified electrodes, the $E°$ values are classified roughly according to the structure of the film: on the N^xA^2-type electrodes, whatever the number of the AA layer was, the $E°$'s were concentrated at values around −0.18 V, whereas on the AN^x-type electrodes the $E°$'s were distributed between −0.22 and −0.20 V. In Fig. 10, Q

denotes the pure AQS layer. The difference in the $E°$'s may be attributed to the electrical potential difference between the film and the solution phases. As the AA layers act as a cation-exchange membrane, the negative bias may be created between these two phases and may be effective for the shift of $E°$ for AN^x.

On the VS electrodes, however, no such regular effect of the film structure on the $E°$ in the multilayer system was observed (Fig. 11). Rather, we found a different kind of shift in $E°$ that was not encountered in the AQS modified electrodes. On the pure VS monolayer modified electrode (denoted by V), $E°=-0.48$ V, whereas on the mixed monolayer modified electrode (denoted by A), $E°=-0.54$ V. The mixing of VS with AA thus resulted in a shift of $E°$ to a more negative value. A further negative shift was observed in any type of multilayer modified electrode (−0.62 — −0.66 V). One possible interpretation for the large negative shift up to 180 mV may be an ion-pair formation of the viologen moiety with the carboxylate anion of AA rather than the membrane potential effect. The ion-pair interaction increases in a more hydrophobic environment,[16,17] such as N^xA^2 and AN^x, than in A. The ion-pair may also be formed between cationic AQS and AA, but in this case the neutral anthraquinone redox moiety does not interact directly with the carboxylate anion; therefore, the effect of the ion-pair formation on $E°$ is not so obvious as that for the VS–AA mixed film. Alternatively, the negative shift may be attributed to the less preferable dimer formation between the viologen monocation radicals resulting from the dilution of VS by mixing with AA and from the decrease in polarity[18] in the multilayer films.

An Ion-Gate Function of the VS-Modified Electrode. Figure 12 shows by the solid line, a cyclic voltammogram for an AN^4 type of VS-modified electrode over the potential range from 0 to −1.3 V for the first cycling. At ca. −1.1 V, appeared the second redox peaks corresponding to $V^+ + e = V^0$. The two pairs of peaks for viologen gradually diminished as the sweep was repeated, until finally the shape represented by the dashed line was obtained. This diminution was not observed when the potential was limited to the region with di/monovalent viologens. The disappearance of the peaks was common to any N^xA^{2-} and AN^x-type electrode except for the monolayer-modified electrodes. This phenomenon indicates that VS, when reduced to an electrically neutral state, forms a compact structure with AA in the multilayer and also makes the film more hydrophobic, so that the reoxidation of V^0 is hindered by blocking the supporting electrolyte. If this is taken into account, the inactivity of the electrically neutral FcS film described above becomes very reasonable. Recently, Tokuda, Matsuda, and their co-workers[19]

have found that the electrochemical reactivity of the LB film of a surface-active nitroxide radical deposited on an SnO_2 electrode was affected by the kinds and concentrations of ions in the solution and was diminished strongly under some conditions. Such an effect has been ascribed to the change in the structure of the LB film caused by the "salt-out" effect. Consequently, if the ion-blocking ability is controlled by changing the charge of the head group of the redox-active surfactants electrochemically, a novel function, i.e., an ion gate,[20] can be expected in the LB-modified electrode.

Taking these findings into consideration, a multilayer possessing both AQS and VS layers was fabricated on the electrode, as is shown schematically in Fig. 13. An AQS layer as the electrochemical probe was inserted between the electrode and an N^2A^2-type VS multilayer. Cyclic voltammograms of this electrode are shown in Fig. 14. In Fig. 14A, two cathodic peaks due to the AQS reduction and the first reduction of VS and the corresponding anodic peaks appeared. After the potential had been held at −1.5 V for one minute instead of the negative sweep, the first wave of viologen completely disappeared, and that of anthraquinone showed a remarkable decrease in the peak current as well (Fig. 14B). Here again, the V^0 formation in the multilayer made the viologen site itself and the anthraquinone site electrochemically inactive. The neutral compact structure and the hydrophobicity of the completely reduced N^2A^2-type VS multilayer film possibly obstructs the approach of various ions to the proximity of the anthraquinone site and therefore hinders the ions from establishing an electrochemical neutrality or an electrochemical double-layer in the LB film. If the latter effect is true, the anthraquinone site lies in a potential inadequate for the electron transfer. The further decrease in the capacitive current shown in Fig. 12 after the complete reduction of V^{2+} to V^0 and the comparison with the background current of the naked GC electrode in Fig. 8 may support this interpretation. When the electrode potential was kept at 0 V for five minutes afterwards, a total recovery of the AQS wave and a partial recovery of the VS wave were observed (Fig. 14C). One possible explanation of this observation is that a partial amount of neutral viologen is reoxidized to the initial cationic states and that the resulting partial breakdown of the compactness and hydrophobicity allows the electrochemical response of the anthraquinone site.

The authors are deeply grateful to Professors Hiroaki Matsuda and Koichi Tokuda of Tokyo Institute of Technology for their fruitful discussions and for the use of the Kyowa Kaimenkagaku Langmuir trough. We are also grateful to Mr. Katsuhiko Nishiyama and Dr. Tetsuo Saji for their gifts of FcS and VS respectively. This work was partially supported by Grant-in-Aid for Scientific Research No. 60040051 and No. 59470067 from the Ministry of Education, Science and Culture.

Solvent Effects on the $n\pi^*$ and $\pi\pi^*$ Absorption Intensities of Some Organic Molecules

Takehiro ABE* and Idowu IWEIBO†

College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received March 6, 1986)

Recently proposed experimental and theoretical expressions for the molecular electronic oscillator strength in a solution (*J. Chem. Phys.*, **83**, 1546 (1985)) have been succesfully applied to the spectral data of some nonpolar and polar organic molecules (benzoquinones, ketones, nitroalkanes, β-carotene, and substituted benzenes). In an application of the theoretical expression, the transition moment of a nonpolar solute molecule in various solvents was assumed to be approximately constant, while that of a polar solute molecule was developed on the assumptions of a first-order perturbation of the wave function and a Block-Walker reaction field. The ratio of the oscillator strength in a solution to that either in a vapor or a specified solvent was computed from both experimental data and theoretically from the transition moments. The results of the two computational modes are, generally, in good agreement for the range of compounds studied.

For an electronic transition from the ground state to the ith excited state in a solute molecule, we have recently proposed the following equations[1] for the experimental and theoretical oscillator strengths in a solution:

$$f^{\mathrm{exp}}(\mathrm{soln}) = \frac{4n}{(1+n)^2} \times \frac{10^3(\ln 10)m_e c^2}{\pi e^2 L}\int \varepsilon(\tilde{\nu})\mathrm{d}\tilde{\nu} \qquad (1)$$

and

$$f^{\mathrm{theor}}(\mathrm{soln}) = \frac{36n^4}{(1+n)^2(2n+1)^2} \times \frac{8\pi^2 m_e c}{3he^2} \times \tilde{\nu}_{0i}|\mu_{0i}(\mathrm{soln})|^2, \qquad (2)$$

where n is the refractive index of the solvent, c the speed of light in a vacuum, h the Planck constant, e the charge of a proton, m_e the mass of an electron, and L Avogadro's constant. Here, $\tilde{\nu}_{0i}$ is the wave number of the transition, $\varepsilon(\tilde{\nu})$ the molar absorption coefficient at a wave number $\tilde{\nu}$, and $\mu_{0i}(\mathrm{soln})$ the transition moment of a solute molecule in a solution. Then, the ratio of the oscillator strength in, for example, two solvents (denoted by subscripts 1 and 2), i.e., $f^{\mathrm{exp}}(\mathrm{soln}\ 2)/f^{\mathrm{exp}}(\mathrm{soln}\ 1)$, gives a ratio of the energies absorbed per unit time by the transitions, as described in a previous paper.[1]

Here, by either assuming a constant value for $\mu_{0i}(\mathrm{soln})$ or using first-order perturbation theory to find an approximate expression for $\mu_{0i}(\mathrm{soln})$, we apply Eqs. 1 and 2 to the $n\pi^*$- and $\pi\pi^*$-absorption spectral data which are available for several compounds and demonstrate that our previously proposed expressions for the oscillator strength of a molecule in a solution give fairly good results.

Theory

We can write the oscillator strength of a gaseous absorbing system as $f(\mathrm{vap})$, and the usual experimental oscillator strength in a solution (n=1) as $\bar{f}^{\mathrm{exp}}(\mathrm{soln})$. Then, from Eqs. 1 and 2 the following equations can be derived:

$$\frac{f^{\mathrm{exp}}(\mathrm{soln})}{f^{\mathrm{exp}}(\mathrm{vap})} = \frac{4n}{(1+n)^2} \times \frac{\bar{f}^{\mathrm{exp}}(\mathrm{soln})}{f^{\mathrm{exp}}(\mathrm{vap})} \qquad (3)$$

and

$$\frac{f^{\mathrm{theor}}(\mathrm{soln})}{f^{\mathrm{theor}}(\mathrm{vap})} = \frac{36n^4}{(1+n)^2(2n^2+1)^2} \times \frac{\tilde{\nu}_{0i}|\mu_{0i}(\mathrm{soln})|^2}{\tilde{\nu}^0_{0i}|\mu^0_{0i}|^2}, \qquad (4)$$

where $\tilde{\nu}^0_i$ and μ^0_i are the transition energy (in cm^{-1}) and the transition moment, respectively, of the isolated solute molecule. In a case where there are no data in the literature for $f^{\mathrm{exp}}(\mathrm{vap})$, we used equations corresponding to $f^{\mathrm{exp}}(\mathrm{soln}\ 2)/f^{\mathrm{exp}}(\mathrm{soln}\ 1)$ and $f^{\mathrm{theor}}(\mathrm{soln}\ 2)/f^{\mathrm{theor}}(\mathrm{soln}\ 1)$ instead of Eqs. 3 and 4, respectively.

In the present analysis, $\mu_{0i}(\mathrm{soln})$ are not transition moments like those formulated by Weigang[2] and Myers and Birge[3] for a system that includes a solute and many solvent molecules, but rather for a single solute molecule in a solution. Even Liptay's generalized expression[4] for $\mu_{0i}(\mathrm{soln})$ is still difficult to apply practically. We have, however, found an approximate expression for $\mu_{0i}(\mathrm{soln})$ in the following two ways:

Approximation of $\mu_{0i}(\mathrm{soln})$ for Nonpolar Solute Molecules. Since, in this case, there is usually no data in the literature for $f^{\mathrm{exp}}(\mathrm{vap})$, we have adopted an equation corresponding to the expression $f^{\mathrm{theor}}(\mathrm{soln}\ 2)/f^{\mathrm{theor}}(\mathrm{soln}\ 1)$ instead of Eq. 4. Further, for a nonpolar solute molecule, we assumed that the values of $\mu_{0i}(\mathrm{soln})$ in various solvents are approximately constant, since a solute molecule has no dipole moment. From this assumption, it follows from Eq. 2 that

$$\frac{f^{\mathrm{theor}}(\mathrm{soln}\ 2)}{f^{\mathrm{theor}}(\mathrm{soln}\ 1)} = \frac{F(\mathrm{soln}\ 2)\tilde{\nu}_{0i}(\mathrm{soln}\ 2)}{F(\mathrm{soln}\ 1)\tilde{\nu}_{0i}(\mathrm{soln}\ 1)}, \qquad (5)$$

where $F(\mathrm{soln}\ i)=36n^4/(1+n)^2(2n^2+1)^2$ and $\tilde{\nu}_{0i}(\mathrm{soln}\ i)$ are, respectively, the solvent correction factor and the transition wave number for the ith solvent. By using

†Present address: Department of Chemistry, University of Ibadan, Ibadan, Nigeria.

Eq. 3, we obtained experimental values for f^{exp}(soln 2)/f^{exp}(soln 1); these results could be compared with those of Eq. 5.

Approximation of μ_{0i}(soln) for Polar Solute Molecules. For a polar solute molecule, we formulated an approximate expression for μ_{0i}(soln) by using the Block–Walker reaction field.[5]

The ground and ith excited state of a neutral solute molecule are denoted by the wave functions Ψ_0 and Ψ_i, respectively. According to first-order perturbation theory, Ψ_i, for example, can be written as

$$\Psi_i = \Psi_i^\circ + \sum_{k\neq i} \frac{(\Psi_k^{\circ *}|H'|\Psi_i^\circ)}{E_i^\circ - E_k^\circ}\Psi_k^\circ, \tag{6}$$

where E_k° is the energy of the kth excited state (Ψ_k°) for an isolated solute molecule. The perturbation operator H' is written as[6,7]

$$H' = -\sum_j e_j \boldsymbol{R}\cdot\boldsymbol{r}_j. \tag{7}$$

Here, e_j and $\boldsymbol{r}_j$ are the charge and position vector of the jth charged particle in the solute molecule, and $\boldsymbol{R}$ is the reaction field. The expression Ψ_0 is similarly obtained by replacing i with 0 in Eq. 6. We denote, for example, the average of all values of $(E_k^\circ - E_i^\circ)$ by ΔE_i and assume that $\Delta E_i = \Delta E_0 = I_0$, as was done in a previous paper,[8] where I_0 denotes the ionization potential of the ground state of an isolated solute molecule. We then obtain the following approximate expression for μ_{0i}(soln):

$$\begin{aligned}
\mu_{0i}(\text{soln}) &= (\Psi_i^*|\Sigma e_j\boldsymbol{r}_j|\Psi_0) \\
&\approx \mu_{0i}^\circ - \frac{1}{I_0}\{\sum_{k\neq 0}(\Psi_0^{\circ *}|H'|\Psi_k^\circ)(\Psi_k^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_i^\circ) \\
&\quad + \sum_{k\neq i}(\Psi_i^{\circ *}|H'|\Psi_k^\circ)(\Psi_k^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_0^\circ)\} \\
&\quad + \frac{1}{I_0^2}\sum_{i\neq}\sum_{k\neq 0}(\Psi_0^{\circ *}|H'|\Psi_k^\circ)(\Psi_i^{\circ *}|H'|\Psi_i^\circ)(\Psi_i^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_k^\circ) \\
&= \mu_{0i}^\circ + \frac{\boldsymbol{R}}{I_0}[\{\sum_k^{all}(\Psi_0^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_k^\circ)(\Psi_k^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_i^\circ) \\
&\quad - (\Psi_0^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_0^\circ)(\Psi_0^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_i^\circ)\} \\
&\quad + \{\sum_k^{all}(\Psi_i^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_k^\circ)(\Psi_k^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_0^\circ) \\
&\quad - (\Psi_i^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_i^\circ)(\Psi_i^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_0^\circ)\}] \\
&\quad + \frac{R^2}{I_0^2}\sum_{i\neq}\sum_{k\neq 0}\left\{\frac{\boldsymbol{R}}{R}(\Psi_0^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_k^\circ)\right\} \\
&\quad \times \left\{\frac{\boldsymbol{R}}{R}(\Psi_i^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_i^\circ)\right\} \times (\Psi_i^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_k^\circ) \\
&= \mu_{0i}^\circ + \frac{\boldsymbol{R}}{I_0}\times(2Q_{0i}^\circ - \mu_{0i}^\circ\boldsymbol{p}_0^\circ - \mu_{0i}^\circ\boldsymbol{p}_i^\circ) + \frac{R^2}{I_0^2}\times\boldsymbol{R}_{0k,il}^\circ,
\end{aligned} \tag{8}$$

where $\boldsymbol{p}_0^\circ$ and $\boldsymbol{p}_i^\circ$ are the ground- and ith-excited-state electric dipole moments, respectively, of the isolated solute molecule and

$$Q_{0i}^\circ = \sum_k^{all}(\Psi_0^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_k^\circ)(\Psi_k^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_i^\circ) = (\Psi_i^{\circ *}|(\Sigma e_j\boldsymbol{r}_j)^2|\Psi_0^\circ) \tag{9}$$

and

$$\boldsymbol{R}_{0k,il}^\circ = \sum_{i\neq}\sum_{k\neq 0}\left\{\frac{\boldsymbol{p}_0^\circ}{p_0^\circ}(\Psi_0^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_k^\circ)\right\} \times \left\{\frac{\boldsymbol{p}_0^\circ}{p_0^\circ}(\Psi_i^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_i^\circ)\right\} \times (\Psi_i^{\circ *}|\Sigma e_j\boldsymbol{r}_j|\Psi_k^\circ). \tag{10}$$

If the Block-Walker reaction field[5] is written as

$$\boldsymbol{R} = \frac{\theta(\varepsilon_r)}{a^3}\boldsymbol{p}_0^\circ, \tag{11}$$

where

$$\theta(\varepsilon_r) = \frac{3\varepsilon_r \ln\varepsilon_r}{\varepsilon_r\ln\varepsilon_r - \varepsilon_r + 1} - \frac{6}{\ln\varepsilon_r} - 2 \tag{12}$$

and a and ε_r are the cavity radius of the solute molecule and the relative permittivity of the solvent, respectively, the following expression for μ_{0i}(soln) is obtained from Eq. 8:

$$\mu_{0i}(\text{soln}) = \mu_{0i}^\circ\{1 + \theta(\varepsilon_r)\times A + \theta^2(\varepsilon_r)\times B\}. \tag{13}$$

Here, A and B are characteristic of a solute molecule and are expressed as

$$A = \frac{\boldsymbol{p}_0^\circ}{a^3 I_0}\left\{\frac{2\mu_{0i}^\circ Q_{0i}^\circ}{(\mu_{0i}^\circ)^2} - \boldsymbol{p}_0^\circ - \boldsymbol{p}_i^\circ\right\} \tag{14}$$

and

$$B = \frac{(p_0^\circ)^2\mu_{0i}^\circ \boldsymbol{R}_{0k,il}^\circ}{a^6 I_0^2(\mu_{0i}^\circ)^2}. \tag{15}$$

Substituting Eq. 13 into Eq. 4 makes f^{theor}(soln)/f^{theor}(vap) a determinable quantity from experimental data, i.e., f^{theor}(soln)/f^{theor}(vap)=f^{exp}(soln)/f^{exp}(vap), so that alternatively

$$\frac{f^{exp}(\text{soln})}{f^{exp}(\text{vap})} = F(\text{soln})\times\frac{\tilde{\nu}_{0i}}{\tilde{\nu}_{0i}^\circ}\times\{1+\theta(\varepsilon_r)\times A + \theta^2(\varepsilon_r)\times B\}^2. \tag{16}$$

For relative f values in two solvents, Eq. 16 can be transformed into

$$\frac{f^{exp}(\text{soln 2})}{f^{exp}(\text{soln 1})} = \frac{F(\text{soln 2})}{F(\text{soln 1})}\times\frac{\tilde{\nu}_{0i}(\text{soln 2})}{\tilde{\nu}_{0i}(\text{soln 1})} \times \frac{\{1+\theta(\varepsilon_r\ 2)\times A+\theta^2(\varepsilon_r\ 2)\times B\}^2}{\{1+\theta(\varepsilon_r\ 1)\times A+\theta^2(\varepsilon_r\ 1)\times B\}^2}, \tag{17}$$

where $\theta(\varepsilon_r\ i)$ and $\tilde{\nu}_{0i}$ (soln i) are the Block–Walker parameter for the ith solvent and the transition energy (cm^{-1}) in the ith solvent. The squared, bracketed term $\{1+\theta(\varepsilon_r)\times A+\theta^2(\varepsilon_r)\times B\}^2$ in Eq. 16 comes from the calculation of $|\mu_{0i}(\text{soln})|^2/|\mu_{0i}^\circ|^2$ ($=|\mu_{0i}^\circ|^2|1+\theta(\varepsilon_r)\times A+\theta^2(\varepsilon_r)\times B|^2/|\mu_{0i}^\circ|^2$) in the derivation of Eq. 16. As should be clear from Eq. 13, the second and third terms in the brackets are due to the perturbation of the transition moment by the solvent. Accordingly, on

the assumption that the perturbation is small, we assume that $|\theta(\varepsilon_r)\times A+\theta^2(\varepsilon_r)\times B|<1$, i.e., that the bracketed term is always positive. Thus, a data analysis of the square roots of both sides of Eq. 16 by a multiple linear regression permits an evaluation of the constants A and B. A similar simultaneous solution of A and B in Eq. 17 also follows from the substitution of experimental values of f^{exp}(soln 2)/f^{exp}(soln 1) and of the refractive indices in the square roots of both sides of Eq. 17.

As has already been pointed out in a previous paper,[6] the present treatment neglects dispersion effects. Consequently, Eqs. 16 and 17 cannot be applied to solute molecules with no electric dipole moments.

In applying Eqs. 5, 16, and 17, we always assumed a temperature of 20°C and excluded data of solvents which were capable of forming hydrogen bonds or complexes with solutes, since such specific interactions were not considered in the derivations of these equations. Moreover, we used the spectral data reported for a solute by the same authors, since experimental values of oscillator strengths considerably vary with different authors.

Results and Discussion

nπ* Transitions. We first test the applicability of Eqs. 5, 16, and 17 from the data of some compounds whose weak electronic spectral bands are assigned to nπ* transitions. These bands are advantageous in the present consideration because of their relatively small overlaps with bands of other transitions in the spectral profiles of these compounds.

(i) *p*-Benzoquinone, 2,5-Di-*t*-butyl-*p*-benzoquinone and 4,5,5-Trimehtyl-4-phenyl-1,3-dithiolane-2-thione: Obviously 4,5,5-trimethyl-4-phenyl-1,3-dithiolane-2-thione ought to have a dipole moment owing to its molecular structure. A small experimental dipole moment of 0.81 D[9] (1 D=3.333×10^{-30} Cm) has been reported for 2,5-di-*t*-butyl-*p*-benzoquinone. This value can be predicted from a resolution of the bond moments of the substituents. Experimentally, *p*-benzoquinone does not have a dipole moment in the vapor phase but has small dipole moments (0.63—0.69 D) in a solution; it varies slightly in such solvents as hexane, dioxane, carbon tetrachloride and benzene.[10] The small and slightly varying dipole moment of *p*-benzoquinone in solvents is probably due to its molecular structure, which is not strictly planar but has a slightly chair form.[11] Accordingly, Eq. 17 was applied to the oscillator strength data of Kuboyama and his coworkers[12] on these compounds. The results are shown in Fig. 1. For each compound, the ratios of the oscillator strengths calculated to that of the standard value in a solvent are in good agreement with those observed.

(ii) Pyrazine: The experimental dipole moment of pyrazine has been reported as 0.66 D[13] in dioxane, 0.15 D[14] in carbon tetrachloride, and 0.34 D[14] in cyclohexane. Both Eqs. 5 and 17 were, therefore, applied to the reported data[3] for the nπ* absorption intensities of pyrazine. The results are shown in Fig. 2. The figure shows that calculations with Eq. 17 give a good correlation between the experimental and

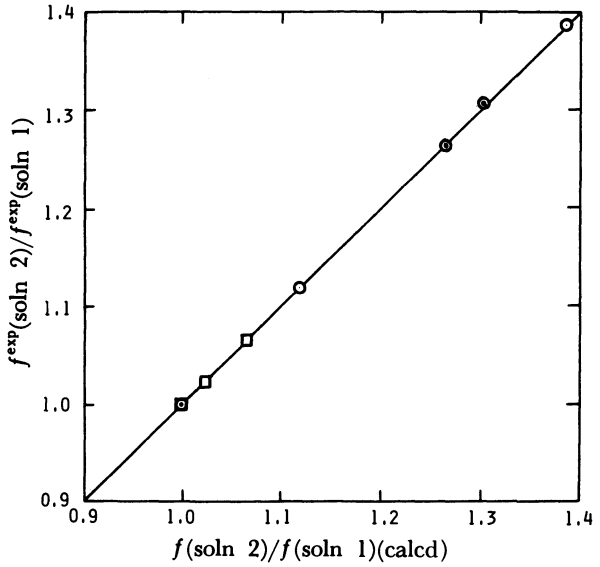

Fig. 1. Correlations between the observed and calculated values of f(soln 2)/f(soln 1) for *p*-benzoquinone (○) with heptane as the standard solvent (A=−8.584 and B=44.939), 2,5-*t*-butyl-*p*-benzoquinone (□) with cyclohexane as the standard solvent (A=−4.955 and B=−23.903) and 4,5,5-trimethyl-4-phenyl-1,3-dithiolane-2-thione (⊙) with cyclohexane as the standard solvent (A=4.153 and B=60.873).

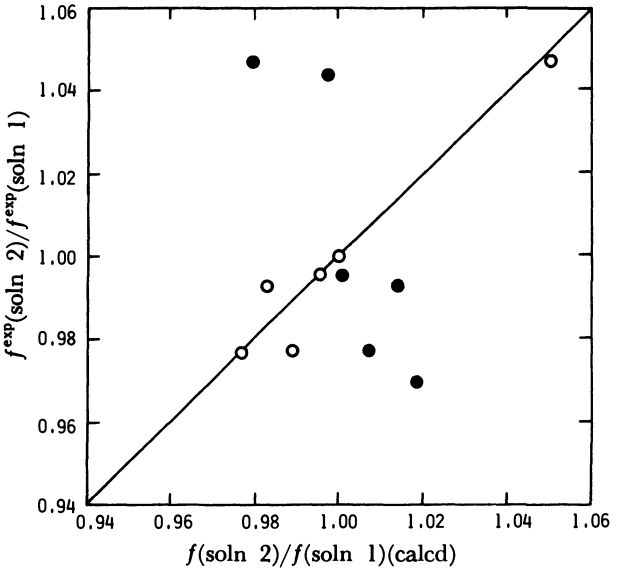

Fig. 2. Correlations between the observed and calculated values of f(soln 2)/f(soln 1) for pyrazine with cyclohexane as the standard solvent. The plots (○) denote those obtained according to Eq. 17 (A=−2.107 and B=16.989). The plots (●) denote those obtained according to Eq. 5.

calculated ratios of the oscillator strengths to the value selected as a standard; calculations with Eq. 5 give a poor correlation. Thus, it seems that the pyrazine molecule in solution does have a small dipole moment.

(iii) Ketones: In applying the equations developed in this paper to the data of Bayliss and Wills-Johnson[15] on the effects of solvents on the usual oscillator strengths of $n\pi^*$ bands of ketones and nitroalkanes, we have selectively avoided solute-solvent systems with strong tendencies to form a hydrogen bond (e.g., acetone-chloroform, water, and alcohol systems[16]) or a weak donor-acceptor complex (e.g., acetone-benzene complex[17]). Moreover, Nakashima et al.[18] have pointed out that their data for benzene were likely to contain large errors. Accordingly, for the ketones we have chosen data for 6 or 7 solvents out of a reported total of 11. By applying Eq. 16 to the data, we obtained values for A and B (Table 1) from which we calculated the ratios of f(soln)/f(vap) (Table 1) together with the observed ratios. Considering the difficulties that may attend a determination of the oscillator strengths from the experimental estimates of the values of the integral, $\int\varepsilon(\bar{\nu})d\bar{\nu}$, and the inherent approximations in the development of the present treatment, we found that all of the correlations between the observed and calculated ratios of f(soln)/f(vap) in the case of these ketones were good.

(iv) Nitroalkanes: For computations of the nitroalkanes, we chose 6 data points from a total of 11 found by Bayliss and Wills-Johnson.[15] The data gathered for benzene as a solvent were excluded since benzene forms donor-acceptor complexes with nitromethane and nitroethane.[17] The results of calculations by means of Eq. 16 are shown in Table 2. Correlations between the observed and calculated ratios of f(soln)/f(vap) are reasonably good, but are generally worse than those for the ketones. This may be due to the relatively large overlaps with bands of other transitions in the spectral profiles of these nitroalkanes.

$\pi\pi^*$ Transitions. There are only a few advantageous examples of the bands assigned to the $\pi\pi^*$ transitions because of their relatively large overlaps with bands of other $\pi\pi^*$ and/or $n\pi^*$ transitions.

(i) β-Carotene: Myers and Birge[3] have reported relative oscillator-strength values for β-carotene in various solvents. From their total of 21 data points we chose 19, excluding data points of hexadecane and decalin (mixed isomers). The relative permittivity for hexadecane is unknown. We applied Eq. 5 to these selected data points and obtained the results shown in Fig. 3. This figure shows that the correlation between the observed and calculated ratios of oscillator strengths to those for the benzene solvent is fairly good. However, all the points in Fig. 3 have a tendency to fit a steeper line. This may be due to a neglect of the dispersion effect and the solute-induced dipole (solvent dipole interaction) in the derivation of Eq. 5.

(ii) Benzene: Considering that benzene is a weak hydrogen-bonding acceptor,[16] we chose 11 data points from Macovei's total[19] of 17 for the solvent effects on

a) The oscillator strength in cyclohexane is selected as f(soln 1).

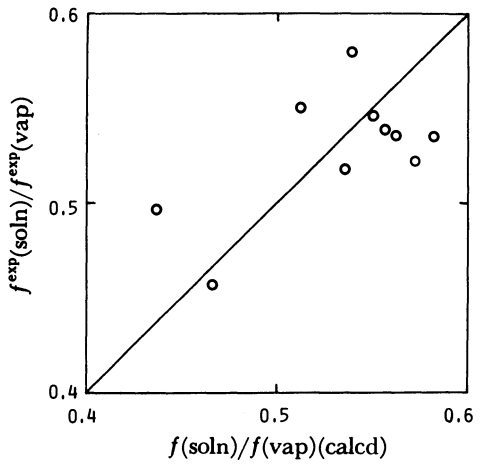

Fig. 4. Correlation between the observed and calculated values of f(soln)/f(vap) for chlorobenzene (A=−3.108 and B=7.154).

the electronic spectra of benzene and applied Eq. 5 to these data points. Values for the experimental and calculated ratios of oscillator strengths to those for the cyclohexane solvent are given in Table 3. The calculated ratios agree to a gross approximation with the corresponding observed values.

(iii) Chlorobenzene: Since chlorobenzene is a weak hydrogen-bonding acceptor,[16] we chose 10 data points from Macovei's total[20] of 19 for solvent effects on the spectral intensities of this molecule. Using f^{exp}(vap)=5×10^{-3} for chlorobenzene,[21] we applied Eq. 16 to these selected data points. The results of the calculations are summarized in Fig. 4. The figure shows that the correlation between the observed and calculated values for f(soln)/f(vap) is also fairly good.

(iv) Nitrobenzene: Macovei[22] has reported the effects of a solvent on the oscillator strength of the principal band of nitrobenzene in the near-ultraviolet region. Of his total of 22 data points, we chose only 9;

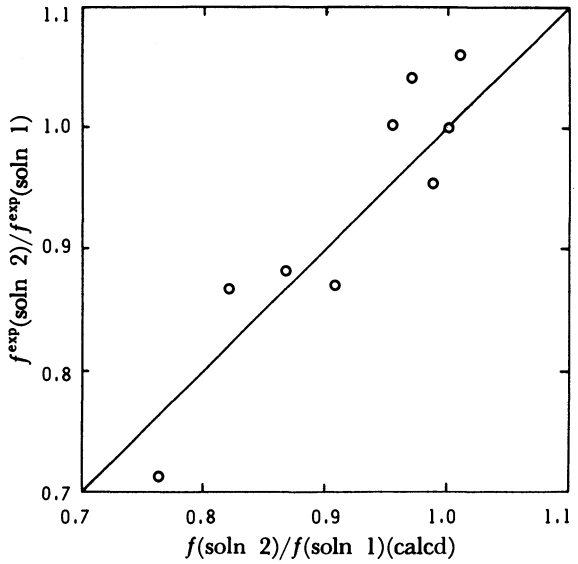

Fig. 5. Correlation between the observed and calculated values of f(soln 2)/f(soln 1) for nitrobenzene (A=−1.584 and B=2.654).

the excluded data being those of nonpolar solvents whose molecular shapes are too much long and plane. The principal band of nitrobenzene at 240 nm overlaps a weak band at 288 nm and a strong band at 193 nm.[23,24] In particular, a weak band of nitrobenzene in a solution is hidden in the principal band (Fig. 1 of Ref. 24). Macovei's data for the oscillator strengths in a solution seem not to have been corrected for a contribution from such an overlaps with the weak band. The application of Eq. 17, therefore, to Macovei's data yields the results shown in Fig. 5. The correlation between the observed and calculated values of f(soln 2)/f(soln 1) is good.

Photochemical Reactions of Pentakis(*N,N*-dimethylformamide)-dioxouranium(VI) Ions in Nonaqueous Solutions

Hiroshi FUKUTOMI,* Toshie HARAZONO, and Takashi KOJIMA
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received November 29, 1985)

Photochemical reactions of $[UO_2(dmf)_5]^{2+}$ (dmf=*N,N*-dimethylformamide) ions were investigated in DMF and acetone solutions. The photolysis product of $[UO_2(dmf)_5]^{2+}$ at the initial stage was U(V), which was so stable in acid-free organic solvents in the dark that the absorption spectrum of U(V) was easily obtained in DMF. The molar extinction coefficient of U(V) was determined to be 45.5±1.5 M^{-1} cm^{-1} (M=mol dm^{-3}) at 755 nm. The formation of U(V) seems to proceed through the intramolecular reaction (k_i) and the lower limit of k_i was determined to be about 10^7 s^{-1} from the lifetime of excited uranyl ions by using a laser flash photolysis.

With respect to photochemical reactions of uranyl ions (UO_2^{2+})[1] with organic substrates in aqueous acidic solutions, a large number of investigations were performed, especially with alcohols,[2-4] acetaldehyde,[5] and acetone.[6] In aqueous acidic solutions, the uranyl ion is reduced giving UO_2^+ as an intermediate, which immediately disproportionates to U^{4+} and UO_2^{2+}.[7,8] On the other hand, a limited number of studies were carried out in nonaqueous solutions. It was reported that U(V) was formed on irradiation of $[UO_2(tbp)_2](NO_3)_2$ in TBP (tributyl phosphate)[9] and of UO_2(18-crown-6)$(ClO_4)_2$ in acetonitrile.[10] Cauzzo et al. studied the photochemical reaction mechanism of $UO_2(NO_3)_2 \cdot 2TEP$ in TEP (triethyl phosphate),[11] and reported that U(V) formed was stable in the dark. The reaction of $[UO_2(hfac)_2]$thf (hfac=hexafluoroacetylacetonate, thf=tetrahydrofuran) was studied in hydrocarbon solvents, and the final product was considered to be U^{4+}, where the appearance of U(V) was proposed as an intermediate.[12] In order to elucidate photochemical reaction mechanisms of uranyl ions in nonaqueous solvents, the photochemical reactions of $[UO_2(dmf)_5](ClO_4)_2$ in DMF and acetone were studied, and a possible reaction mechanism including the formation of U(V) is proposed.

Experimental

Materials. The $[UO_2(dmf)_5](ClO_4)_2$ complex was prepared by the same method as reported by Lincoln et al.[12] Dimethyl sulfoxide (DMSO) and DMF were distilled twice in vacuo and stored over 3A molecular sieves. Aceone was distilled after refluxing over potassium permanganate, followed by distillation with calcium chloride, then treated with phosphorus pentaoxide, and fractionally distilled. The distillate was stored over 4A molecular sieves. ^{13}C-enriched DMF ($H^{13}CON(CH_3)_2$, Merck 90%) and acetone-d_6 (CD_3COCD_3, Merck 90%) were used without further purification. Preparation of $[U(dmso)_8](ClO_4)_4$ was performed by adding DMSO into aqueous U^{4+} solution[14] which was prepared by electrolytic reduction of uranyl perchlorate solution. Brownish green crystals were filtered and washed with diethyl ether. All other chemicals were of analytical grade and used without further purification.

Apparatus and Procedures. Elemental analysis of the complexes was carried out by using a Shimadzu CHN-1A analyzer. Calcd for $[UO_2(dmf)_5](ClO_4)_2$: U, 28.53; C, 21.59; H, 4.22; N, 8.39. Found: U, 28.50; C, 20.98; H, 4.10; N, 8.39. Calcd for $[U(dmso)_8](ClO_4)_4$: U, 18.88 C, 15.24; H, 3.84. Found: U, 18.79; C, 15.67; H, 3.65. Luminescence spectra and intensities of excited uranyl ions were measured by using a JASCO FP-550A fluorescence spectrophotometer at room temperature. Uranyl ions were excited with light of 430 nm and the luminescence intensity was measured at 522 nm. Other spectrophotometric measurements were carried on a Shimadzu UV-210A spectrophotometer. The lifetimes of excited uranyl ions were measured by using a pulsed dye laser (420 nm) with a pulse width of 6.7 ns. Sample solutions for the measurement of quantum yields were degassed under vacuum and irradiated at 25±0.1 °C with a 500 W ultrahigh pressure mercury lamp (Ushio USH-500D) at various wavelengths by using a set of appropriate filters. Sample solutions for ESR measurements were degassed in vacuo and ESR spectra were recorded on a JEOL- JES-FX3 spectrometer. All the ESR measurements were carried out during the light irradiation.

Results

Absorption Spectra of Uranium Species and a Luminescence Spectrum of the Excited Uranyl Ion. Absorption spectra of $[UO_2(dmf)_5]^{2+}$ in DMF and acetone, and a luminescence spectrum of the excited uranyl ion in acetone are illustrated in Fig. 1. The molar extinction coefficient (ε_{VI}) of the uranyl ion in

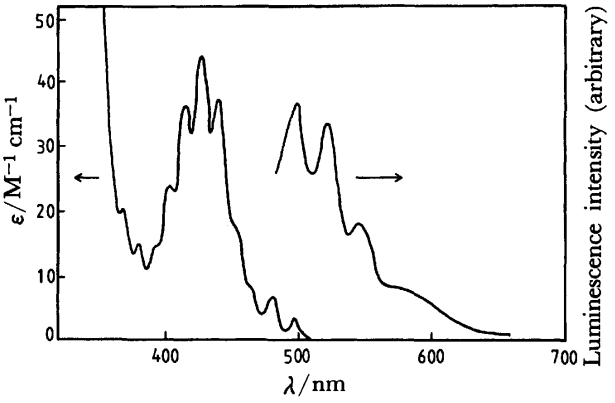

Fig. 1. Absorption spectrum of $[UO_2(dmf)_5](ClO_4)_2$ in DMF and acetone, and its luminescence spectrum in acetone.

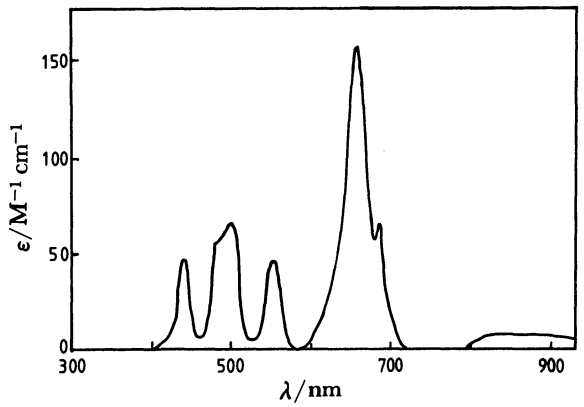

Fig. 2. Absorption spectrum of the DMF solution containing $[UO_2(dmf)_5](ClO_4)_2$ and $HClO_4$ after long-time irradiation.

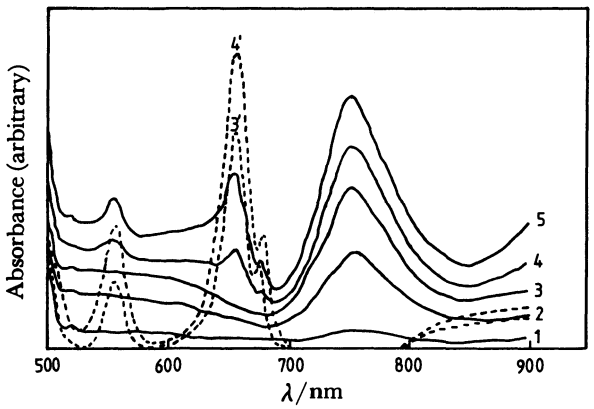

Fig. 3. Spectral changes of 0.1 M $[UO_2(dmf)_5]^{2+}$ in DMF irradiated with 365 nm light. (1): 2 min, (2): 13 min, (3): 23 min, (4): 30 min, (5): 40 min. Spectra 3′ and 4′ were obtained on addition of $HClO_4$ to solutions 3 and 4, respectively.

DMF and acetone at 426 nm was 44.4 $M^{-1}cm^{-1}$. The luminescence of the excited uranyl ion was not observed in DMF at room temperature, but observed in acetone. Figure 2 shows an absorption spectrum which was obtained after long-time irradiation of the DMF solution containing $[UO_2(dmf)_5](ClO_4)_2$ and a small amount of perchloric acid. This spectrum is well-consistent with that of the U(IV)–DMF complex (ε_{IV}= 155.7±1.5 $M^{-1}cm^{-1}$ at 657 nm) which was prepared by dissolving $[U(dmso)_8](ClO_4)_4$ into DMF or by dissolving U^{4+} into DMF (H_2O: DMF=1:99).[15] Therefore, the spectrum was identified as that of the U(IV)–DMF complex. Figure 3 shows changes in absorption spectrum of 0.1 M $[UO_2(dmf)_5](ClO_4)_2$ in DMF irradiated with 365 nm light. The appearance of a different absorption peak at 755 nm indicates the formation of a new complex (A), and then the absorption spectrum after further irradiation shows the formation of another compound (U^{IV}) which has two peaks at 558 and 657 nm. These two peaks are consistent with those of the U(IV)–DMF complex, but the peak heights are quite different. Addition of

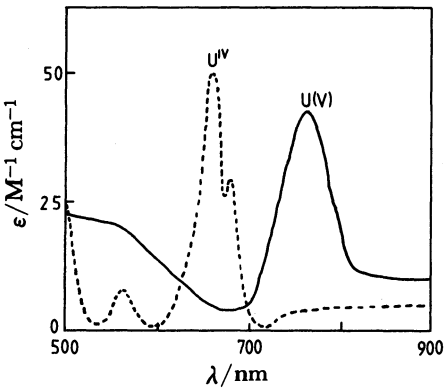

Fig. 4. Absorption spectra of U(V) and U^{IV} in DMF.

perchloric acid to the complex A solution under nitrogen atmosphere caused the rapid disappearance of complex A and the formation of U(VI)- and U(IV)–DMF complexes. Therefore, complex A was identified as the U(V)–DMF complex which disproportionated as follows:[7,8]

$$2UO_2^+ + 4H^+ \longrightarrow UO_2^{2+} + U^{4+} + 2H_2O \quad (1)$$

The concentration of U(V) was determined spectrophotometrically in the following way. An appropriate quantity of perchloric acid was added to the U(V) solution and the concentration of the resulting U(IV) was used for the determination of the U(V) concentration using the relation of 2[U(IV)]=[U(V)]. The molar extinction coefficient of U(V) at 755 nm was determined to be 45.5±1.5 $M^{-1}cm^{-1}$. The spectrum of U(V) was obtained as follows. The molar extinction coefficient of U(V) at wavelength λ, $\varepsilon_V(\lambda)$, can be evaluated by

$$\varepsilon_V(\lambda) = \varepsilon_{VI}(\lambda) + \frac{\Delta A(\lambda,t)}{\Delta C_V(t)}, \quad (2)$$

where $\Delta A(\lambda, t)$ is the absorbance change of the solution at the wavelength of λ after irradiation time t, and $\Delta C_V(t)$ is the concentration change of U(V) after t. The U(V) spectrum obtained is shown in Fig. 4.

The spectrum of U^{IV}, which is discussed later, was obtained by adding perchloric acid to the solution containing U(V) and U^{IV}, and using Eq. 3.

$$\varepsilon^{IV}(\lambda) = \varepsilon_{VI}(\lambda) + \frac{\Delta A(\lambda,t) + \{\varepsilon_{VI}(\lambda) - \varepsilon_V(\lambda)\}\Delta C_V(t)}{\Delta C^{IV}(t)}, \quad (3)$$

where $\varepsilon^{IV}(\lambda)$ and ΔC^{IV} denote the molar extinction coefficient at λ and the concentration change of U^{IV}, respectively. The absorption spectrum of U^{IV} is also shown in Fig. 4.

ESR Spectrum. Figure 5 shows the ESR spectrum of photolysis products of $[UO_2(dmf)_5](ClO_4)_2$ in the rigid DMF matrix at −170°C, where ESR measurements were carried out during the light irradiation. The ESR measurement was also carried out for $[UO_2$-

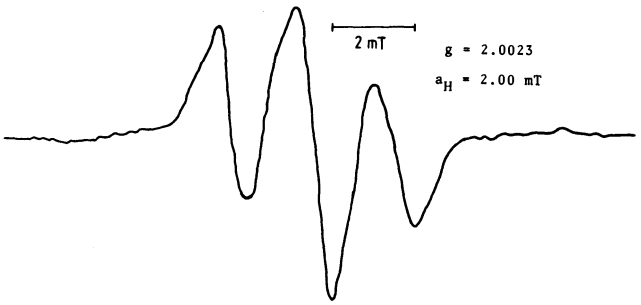

Fig. 5. ESR spectrum of the sample containing $[UO_2(dmf)_5]^{2+}$ in DMF during the irradiation at 365 nm and −170 °C. Symbols g and a_H are the g-factor (reference: Mn^{2+}) and hyperfine coupling constant, respectively.

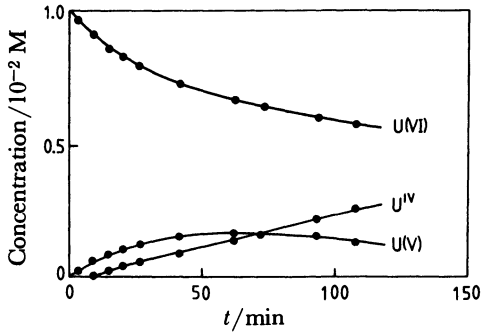

Fig. 6. Changes in the concentrations of reactant and products on irradiation of $[UO_2(dmf)_5]^{2+}$ in DMF with light of 313 nm. $[UO_2(dmf)_5^{2+}]$=0.01 M, T=25 °C.

$(dmf)_5](ClO_4)_2$ dissolved in $H^{13}CON(CH_3)_2$ at −170 °C, which shows the same ESR spectrum given in Fig. 5, and the radical species was assigned to $HCON(CH_3)$-CH_2·.[16,17] In addition, $[UO_2(dmf)_5](ClO_4)_2$ in the rigid acetone-d_6 matrix yielded the same radical.

Changes in Concentration of Uranium Species. Figure 6 shows the changes in concentration of U^{IV}, U(V) and U(VI) resulted from the irradiation of 0.01 M $[UO_2(dmf)_5](ClO_4)_2$ in DMF at 313 nm. The U(VI) concentration was estimated by subtracting ([U(V)]+[U^{IV}]) from the initial concentration of U(VI). The U(V) concentration has a maximum, and U^{IV} appears somewhat later during the irradiation, and gradually increases. These changes occur irrespective of λ of the light and the initial concentration of U(VI). The ratio of the maximum U(V) concentration to the initial U(VI) concentration is about 0.16—0.19 in the initial U(VI) concentration range of 2×10^{-3}—2×10^{-1} M. The plot of log[U(VI)] vs. irradiation time before the appearance of U^{IV} gives a first-order decay as shown in Fig. 7.

Quantum Yields. The quantum yield of U(V), Φ_V, was measured to elucidate the photochemical reaction mechanism of $[UO_2(dmf)_5](ClO_4)_2$ in DMF and acetone. Table 1 shows the dependence of quantum yields on the absorbed light intensities, and indicates

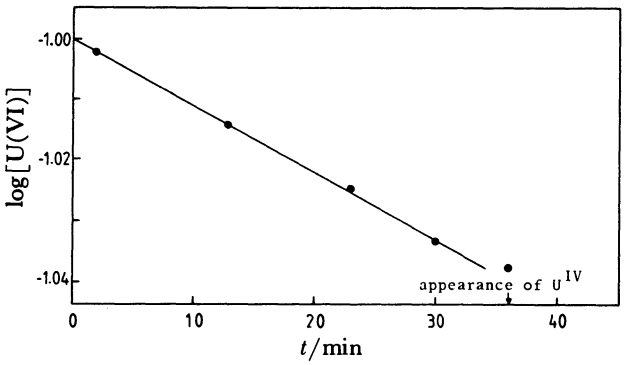

Fig. 7. Plot of log [U(VI)] vs. irradiation time. $[UO_2(dmf)_5^{2+}]$=0.10 M, λ_{irr}(wavelength of irradiating light)= 365 nm, T=25 °C.

that the quantum yield does not depend on the absorbed light intensity. The quantum yield is also independent of the initial U(VI) concentration (Table 2). Additional experiments were carried out to investigate the depencence of the quantum yield on the DMF concentration, where the solution of $[UO_2(dmf)_5](ClO_4)_2$ dissolved in the mixture of acetone and DMF was used. As a milky precipitate which was readily soluble in perchloric acid was observed with irradiation and was supposed to be hydrolysis products or polymers of U(IV), perchloric acid was added to the solution in these experiments prior to irradiation. In the acetone-DMF mixture, where the concentration of DMF was over three times higher than that of the uranyl ion, the number of coordinated DMF molecules was determined to be five by the NMR method at −50 °C. As the

donicity of DMF is larger than those of acetone and water on the basis of Gutmann's donor number,[18,19] the first-coordination sphere of the uranyl ion might be fully occupied by DMF even at 25 °C. The results are given as the quantum yield of U(IV) in Table 3. As the quantum yield of U(IV) in the photochemical reaction of the uranyl ion in acetone is less than 10^{-3} in this acid concentration range (ca. 0.02 M),[6] the chemical path of the excited uranyl ion with acetone can be neglected. As is seen in Table 3, the quantum yield was independent of the DMF concentration. Table 4 shows the dependence of the quantum yield of U(V) on the wavelength of light.

Luminescence Lifetime. Measurements of the luminescence lifetime of 0.01 M $[UO_2(dmf)_5](ClO_4)_2$ in acetone containing 0.18 M DMF were not successful because the decay of luminescence was faster than the time resolution of the instrument (50 ns), and hence the lifetime of the excited uranyl complex was estimated to be less than 50 ns.

Discussion

The absorption spectrum of U(V) obtained in this work is very similar to those produced by electrolysis of U(VI) in DMSO,[20] and by reduction of U(VI) with Eu(II) in aqueous solution.[21] However, it is very different in shape and peak position from the spectrum of U(V) in triethyl phosphate.[11] The U(V) formed by photolysis of $[UO_2(dmf)_5](ClO_4)_2$ in DMF is very stable in oxygen- and acid-free solution in the dark, and did not disproportionate. Therefore, it is considered that U^{IV} is produced by the light absorption of U(V). As no change occurs when U(V) is irradiated with light of $\lambda>520$ nm, U(V) presumably absorbs light of the charge-transfer band with short wavelength and is reduced to U^{IV}. The molar extinction coefficient of U^{IV} at 657 nm was 50.0 $M^{-1}cm^{-1}$ when U^{IV} is assumed to be a single species. The absorption spectrum of U^{IV} is very similar to that of U(IV) except for its value of the molar extinction coefficient, which is about one third of U(IV). Long irradiation of the sample solution caused a remarkable increase in base line of the absorption spectrum, especially at a short-wavelength region. This might be due to the light scattering from colloidal particles. Cauzzo et al. suggested that U(V) was in a UO_2^+ form and U^{IV} was in a UO_2 form in TEP.[11] Gritzner and Selbin reported that a brown colloidal precipitate was UO_2 in DMSO.[20] The U^{IV} formed in DMF seems similar to those so far reported. Unfortunately, the colloidal precipitate could not be isolated by centrifugation.

Mechanism. The primary photochemical reactions can be expressed as follows:

$$UO_2L_5^{2+} \xrightarrow{h\nu} (UO_2L_5^{2+})^*, \quad (4)$$

$$(UO_2L_5^{2+})^* \longrightarrow UO_2L_4^+ + \cdot L + H^+, \quad (5)$$

or

$$(UO_2L_5^{2+})^* + L \longrightarrow UO_2L_5^+ + \cdot L + H^+, \quad (6)$$

where L and ·L represent DMF and $HCON(CH_3)CH_2\cdot$, respectively. Figure 7 supports the reaction path of Eqs. 5 or 6, and means that the following reaction path, if any, in which the excited uranyl ion reacts with a product (P), can be ignored.

$$(UO_2L_5^{2+})^* + P \longrightarrow UO_2L_n^+ + P' \quad (7)$$

As the quantum yield of U(V) is independent of the absorbed light intensity, it is reasonable to assume that U(V) is formed from $(UO_2L_5^{2+})^*$, which is represented by Eqs. 5 or 6. In addition, the following reaction seems to be negligible because the quantum yield of U(V) is less than unity.

$$UO_2L_5^{2+} + \cdot L \longrightarrow UO_2L_5^+ + \cdot L^+ \quad (8)$$

The ·L radical may disappear by radical recombination or self-decomposition.

On the assumption that the formation of U(V) occurs from $(UO_2L_5^{2+})^*$, and from the fact that the quantum yield is less than unity, one would expect that the deactivation path expressed by Eq. 9 would be operative.

$$(UO_2L_5^{2+})^* \xrightarrow{k_d} UO_2L_5^{2+} \quad (9)$$

This path may include the recombination in the solvent "cage".

$$(UO_2L_5^{2+})^* \xrightarrow{k_r} (UO_2L_4^+ \cdots \cdot L \cdots H^+) \longrightarrow UO_2L_5^{2+} \quad (10)$$

The results in Table 2 suggest that the self-quenching of $(UO_2L_5^{2+})^*$, which was observed in TEP,[11] is negligible.

$$(UO_2L_5^{2+})^* + UO_2L_5^{2+} \longrightarrow 2UO_2L_5^{2+} \quad (11)$$

It is of great interest to clarify which path (Eqs. 5 or 6) being operative. As seen in Table 3, the quantum yield of U(IV) is independent of the DMF concentration, and the ESR spectrum of $[UO_2(dmf)_5](ClO_4)_2$ in acetone-d_6 irradiated at $-170°C$ gives the signal of $HCON(CH_3)CH_2\cdot$. These results might indicate that the uranyl ion directly reacts with the coordinated dmf, i.e. the photochemical reaction occurs by intramolecular reaction (Eq. 5). Miyake et al.[22] observed the ESR spectrum of U(V) in both photo- and electrolytic-reduction processes of $[UO_2(dmf)_5]^{2+}$ in DMF and found the stronger bond between uranium and oxygen in the equatorial plane than in the axial direction. This fact also supports the formation mechanism of U(V) by the intramolecular reaction.

As is shown in Fig. 1, the uranyl ion has a triplet state (T_1) around 426 nm and a charge transfer band (CT) at shorter wavelengths. The wavelength dependence of the quantum yield of U(V) indicates that the excitation to the triplet state of the uranyl ion gives better yield than that to the charge transfer band. This implies that the photochemical reaction occurs from the triplet state of the excited uranyl ion.

Since the recombination in the solvent cage usually decreases as the irradiation wavelength becomes shorter, it is expected that the quantum yield of U(V) increases. The results in Table 4 are not in accord with this expectation, and consequently suggest no appreciable recombination in the solvent cage.

The decrease in quantum yield at the charge transfer band suggests the presence of a nonradiative deactivation from the charge-transfer band, which results in a lowering of the quantum yield of intersystem crossing from CT to T_1.

From the above discussion, the photochemical reaction mechanism is described as follows:

$$UO_2(dmf)_5^{2+} \xrightarrow{h\nu} (UO_2(dmf)_5^{2+})^*, \quad (4')$$

$$(UO_2(dmf)_5^{2+})^* \xrightarrow{k_i} UO_2(dmf)_4^{+} + HCON(CH_3)CH_2\cdot + H^+, \quad (5')$$

$$\longrightarrow UO_2(dmf)_n^{+} + P,$$

$$(UO_2(dmf)_5^{2+})^* \xrightarrow{k_d} UO_2(dmf)_5^{2+}, \quad (9')$$

where n is the number of coordinated dmf. The average value of the quantum yields in Table 1 and the relation, $\Phi_V = k_i/(k_i+k_d)$, give the value of $k_d/k_i = 2.2$. The energy level diagram is shown in Fig. 8, where ISC denotes the intersystem crossing ($\Phi < 1$) and k_{dCT} is the deactivation rate constant from CT. In

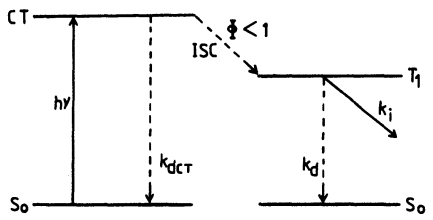

Fig. 8. Energy level diagram.

the photochemical reaction of $UO_2(NO_3)_2\cdot 2TEP$ in TEP, the ratio of the maximum concentration of U(V) to the initial concentration of U(VI) decreased as the initial U(VI) concentration increased, and it was suggested that the photoexcited U(V) disproportionated to give U^{IV} and U(VI)[11]. However, the ratio is about constant at any initial concentration of U(VI) in DMF, and no disproportionation was observed.

The photochemical reaction mechanism of $[UO_2(dmf)_5](ClO_4)_2$ in acetone is essentially the same as that in DMF except for the presence of the following luminescence path.

$$(UO_2(dmf)_5^{2+})^* \xrightarrow{k_l} UO_2(dmf)_5^{2+} + h\nu' \quad (12)$$

This might lead to the result that the quantum yield of U(V) in DMF is larger than that in acetone containing perchloric acid as is shown in Table 3, where $2\Phi_{IV}$ corresponds to Φ_V. Since the lifetime of the excited uranyl complex ion was less than 50 ns as described above, the lower limit of the k_i value is estimated to be $\approx 10^7\ s^{-1}$.

The authors wish to thank Professor Ikuzo Tanaka of the Tokyo Institute of Technology for providing a laser flash photolysis instrument. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 57470035 from the Ministry of Education, Science and Culture.

(Received December 27, 1985)

The Raman spectra of $[Co(ida)_n(dien)_{2-n}]^{(3-2n)+}$ (n=0, 1, and 2), where ida and dien denote iminodiacetate and diethylenetriamine respectively, and related complexes in the skeletal vibration region were measured in order to deduce the relation between their spectra and their geometrical structures. The Raman bands could be classified into five vibration modes: Totally symmetric stretching vibration modes (polarized bands in the 510—625 cm^{-1} region); Co-O and Co-N stretching vibration modes (depolarized bands in the 430—525 cm^{-1} region); metal-ligand skeletal breathing vibration modes (polarized bands in the 360—480 cm^{-1} region); skeletal bending deformation modes (depolarized bands in the 290—405 cm^{-1} region), and chelate ring deformation modes (polarized bands in the 220—260 cm^{-1} region). The polarized bands around 400 cm^{-1} were regarded as characteristic of the mono and bis(terdentate)cobalt(III) complexes. The mer isomers of each complex gave Raman spectra clearly different from those of the fac isomers in the stretching vibration region.

It has been accepted[1] that vibrational spectra are one of the most useful means for investigating the stereochemistry of transition metal complexes. Especially, the Raman spectra of the complexes in the skeletal vibration region, which appear in the low frequency region, reflect their structural characteristics.

The Raman spectra in the skeletal vibration region of $[Co(a)(b)(en)_2]$,[2] $[Co(a)(b)(NH_3)_4]$,[3] $[Co(a)(b)(tn)_2]$,[4] and $[Co(a)_2(NH_3)_2(en)]$,[5] where a and b stand for unidentate ligands and where en and tn denote ethylenediamine and trimethylenediamine respectively, have been measured in order to find the vibrational criteria for differentiating their geometrical configurations. Recently, the Raman spectra of the nitroammine series[6] and the complete series of the $[Co(gly)_x(ox)_y(en)_z]$-type complexes ($x+y+z=3$),[7] where gly and ox denote glycinate and oxalate respectively, have been systematically investigated in order to establish the relation between the spectra and geometrical structures among their isomers. In particular, it has been concluded that the Raman bands of the $[Co(gly)_x(ox)_y(en)_z]$-type complexes could be treated in terms of the effective symmetry, which was mainly determined by the arrangement of coordinated atoms around the cobalt(III), and could be classified into several vibration modes.

The present investigation aims at finding more general information as to the relation between the geometrical structures and the Raman spectra in the skeletal vibration region of the cobalt(III) complexes. For this purpose, the Raman spectra of $[Co(ida)_n(dien)_{2-n}]^{(3-2n)+}$ (n=0, 1, and 2), $[Co(NH_3)_3(dien)]^{3+}$, and $[Co(ida)(NH_3)_3]^+$ were measured in the low frequency region (200—800 cm^{-1}) in an aqueous solution and were compared with those of the $[Co(gly)_x(ox)_y(en)_z]$-type complexes. Furthermore, the Raman spectra of $[Co(ida)(mida)]^-$, $[Co(mida)_2]^-$, and $[Co(mida)(mdien)]^+$, where mida and mdien denote *N*-methyliminodiacetate and *N,N*-bis(2-aminoethyl)methylamine respectively, were measured and compared with those of the $[Co(ida)_n(dien)_{2-n}]$-type complexes.

Experimental

Complexes. The complexes were prepared and characterized according to the literature procedures except for $[Co(NH_3)_3(dien)]Cl_3$ (vide infra): *sym-fac*-$[Co(dien)_2]Br_3$,[8] *unsym-fac*-$[Co(dien)_2]Cl_3$,[8] *mer*-$[Co(dien)_2]Cl_3$,[8] *sym-fac*-$[Co(ida)(dien)]ClO_4$,[9] *unsym-fac*-$[Co(ida)(dien)]ClO_4$,[9] *mer*-$[Co(ida)(dien)]ClO_4$,[9] *sym-fac*-$K[Co(ida)_2]$,[10] *unsym-fac*-$K[Co(ida)_2]$,[10] *fac*-$[Co(ida)(NH_3)_3]ClO_4$,[11] *sym-fac*-Na-$[Co(ida)(mida)]$,[12] *unsym-fac*-$K[Co(ida)(mida)]$,[12] *mer*-K-$[Co(ida)(mida)]$,[13] *sym-fac*-$K[Co(mida)_2]$,[14] *unsym-fac*-$K[Co(mida)_2]$,[14] *mer*-$K[Co(mida)_2]$,[14] *sym-fac*-$[Co(mida)(mdien)]$-Cl,[15] and *mer*-$[Co(mida)(mdien)]Cl$.[15]

$[Co(NH_3)_3(dien)]Cl_3$. Two grams of $[CoCl_3(dien)]$ were dissolved in 50 cm^3 of 28% aqueous ammonia, and the solution was evaporated to dryness on a steam bath. The precipitate was then dissolved in a small amount of water and poured onto a column (40 mmϕ×600 mm) containing strong acid cation exchange resin (SP-Sephadex, C-25, Na^+ form). Having been swept with water, the band adsorbed on the column was eluted with a 0.3 mol dm^{-3} aqueous sodium chloride solution. A yellow band of the desired complex was then eluted and fractionated. It was found, from the absorption spectra of the fractions, that the middle eluates contained $[Co(NH_3)_3(dien)]^{3+}$. Then the middle fractions were combined and concentrated to a small volume, and the Raman spectrum was measured. This

complex was characterized on the basis of the electronic absorption spectrum and elemental analysis.

Measurements. The Raman spectra were recorded on a JASCO Laser Raman Spectrometer, which had been constructed specially with a double monochromator, model CT-25, a He-Ne Laser, model NEC GLS-8500, and a data processor, model DP-500 as the main components. The sample solution was excited at 632.8 nm, and the Raman spectra were calibrated with indene.

Results and Discussion

General Aspect. For the present bis(terdentate-X,N,X)cobalt(III)(X=O or N) complexes, these are three geometrical isomers, sym-fac, unsym-fac, and mer, as may be seen in Fig. 1.[8-15] Their Raman spectral data, obtained in the skeletal vibration region, are summarized in Table 1, together with those of such related complexes as $[Co(NH_3)_3(dien)]^{3+}$ and $[Co(ida)(NH_3)_3]^{+}$.

Figure 2 shows the Raman spectrum of *unsym-fac*-$[Co(dien)_2]^{3+}$ as a typical example of the bis(terdentate)cobalt(III) complexes, together with those of $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$;[7] these three complexes equally have O_h symmetry for the coordinated atoms. Their Raman frequencies, intensities, and depolarization ratios indicate that *unsym-fac*-$[Co(dien)_2]^{3+}$ has the same spectral characteristics as $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ except for a polarized band at 409 cm^{-1}. That is, the Raman bands at 546, 430—485, and 321 cm^{-1} of the unsym-fac isomer correspond to those at 495, 440, and 320 cm^{-1} of $[Co(NH_3)_6]^{3+}$ and to those at 525, 440, and 378 cm^{-1} of $[Co(en)_3]^{3+}$

	Assignment[d]	ν_{ts}(Co-L)	ν(Co-L)	ν_{br}	δ_{sbd}(L-Co-L)	δ_{crd}(Co$\overset{L}{<}_{L}$)

a) The following abbreviations are used: s, strong; m, medium; w, weak; vw, very weak; sh, shoulder; p, polarized; dp, depolarized. Numerals in the parentheses show the polarization ratio. b) This isomer seems to be facial, judging from the Raman spectral behavior. c) Ref. 7. d) ν_{ts} denotes the totally symmetric stretching vibration mode; ν, the stretching vibration mode excluding the totally symmetric one; ν_{br}, the skeletal breathing vibration mode; δ_{sbd}, the metal-ligand skeletal bending deformation mode; δ_{crd}, the chelate ring deformation mode, and L, the donor atom (N and/or O).

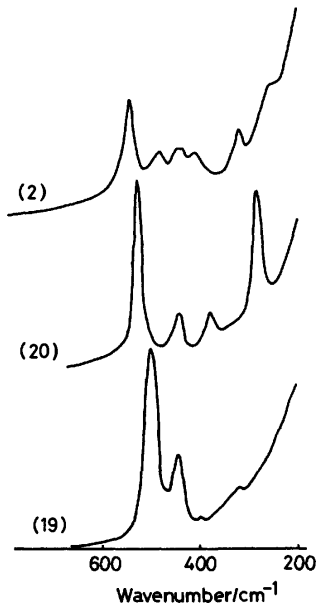

Fig. 2. Raman spectra of *unsym-fac*-[Co(dien)$_2$]$^{3+}$, [Co(en)$_3$]$^{3+}$, and [Co(NH$_3$)$_6$]$^{3+}$ (Ref. 7). Numbers in parentheses correspond to those in Table 1.

respectively, while the Raman band at 255 cm^{-1} of the unsym-fac isomer corresponds to that at 283 cm^{-1} of [Co(en)$_3$]$^{3+}$. Hence, the polarized band at 546 cm^{-1}, the depolarized bands in the 430—485 cm^{-1} region, the depolarized band at 321 cm^{-1}, and the polarized band at 255 cm^{-1} of *unsym-fac*-[Co(dien)$_2$]$^{3+}$ can be assigned to the totally symmetric metal-ligand stretching, the Co-N stretching, the metal-ligand skeletal bending deformation, and the chelate ring deformation modes respectively. The polarized band at 409 cm^{-1} of *unsym-fac*-[Co(dien)$_2$]$^{3+}$ is regarded as a band characteristic of the bis(terdentate)cobalt(III) complexes, for we could not find the corresponding band in the spectra of [Co(NH$_3$)$_6$]$^{3+}$ and [Co(en)$_3$]$^{3+}$, but could find it uniquely in the spectra of the [Co(ida)$_n$(dien)$_{2-n}$]-type complexes (Table 1). On the basis of the Raman frequency and polarization characteristics, the polarized band at 409 cm^{-1} of *unsym-fac*-[Co(dien)$_2$]$^{3+}$ is tentatively assigned to the breathing mode, which corresponds to the symmetric vibration of the overall structure of the complexes, i.e., the coupled vibration of the totally symmetric metal-ligand stretching and the chelate ring deformation. Furthermore, the good correlation between the vibration modes of *unsym-fac*-[Co(dien)$_2$]$^{3+}$ (C_2 symmetry) with those of [Co(NH$_3$)$_6$]$^{3+}$ (O_h symmetry) and [Co(en)$_3$]$^{3+}$ (D_3 symmetry)[7] suggests that the Raman spectra of the bis(terdentate)cobalt(III) complexes with linked five-membered chelate rings can be treated as a first approximation on the basis of the effective symmetry, which is mainly determined by the arrangement of the coordinated atoms around the central metal ion, as in the case of the tris-(bidentate)cobalt(III) complexes with the five-membered chelate rings.[7]

Figure 3 shows the Raman spectra of the three geometrical isomers of [Co(dien)$_2$]$^{3+}$ and [Co(ida)-

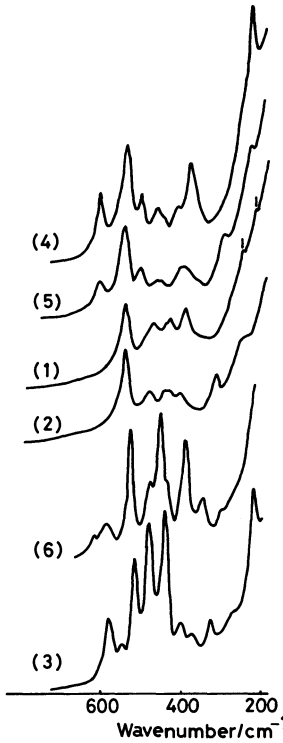

Fig. 3. Raman spectra of three geometrical isomers of $[Co(ida)(dien)]^+$ and $[Co(dien)_2]^{3+}$. Numbers in parentheses correspond to those in Table 1.

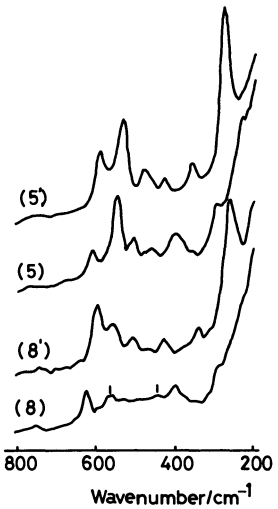

Fig. 4. Raman spectra of *unsym-fac*-$[Co(ida)(dien)]^+$ and $[Co(ida)_2]^-$. Raman spectra of C_2-*cis(O)*-$[Co(gly)_2(en)]^+$(5') and C_2-*cis(N)*-$[Co(gly)_2(ox)]^-$(8') were also shown (Ref. 7).

$(dien)]^+$. It is evident from Fig. 3 and Table 1 that the unsym-fac and sym-fac isomers of $[Co(dien)_2]^{3+}$ of the $[Co(N)_6]$-type have the same spectral characteristics except for minor differences in the low frequency region. The same thing is observed for the unsym-fac and sym-fac isomers of $[Co(ida)(dien)]^+$ of the $[Co(N)_4(O)_2]$-type (Fig. 3 and Table 1) and $[Co(ida)_2]^-$ of the $[Co(N)_2(O)_4]$-type (Table 1). Hence, we may expect that, so far as the skeletal vibrations of the fac isomers for the bis(terdentate)cobalt(III) complexes with the two linked five-membered chelate rings are concerned, the Raman spectral characteristics are predominantly determined by the arrangement of the coordinated atoms. The predominant contribution of the arrangement of the coordinated atoms to the Raman spectral characteristics is further supported by the Raman spectral characteristics of *unsym-fac*-$[Co(ida)_2]^-$ and C_2-*cis(N)*-$[Co(gly)_2(ox)]^-$ and of *unsym-fac*-$[Co(ida)(dien)]^+$ and C_2-*cis(O)*-$[Co(gly)_2(en)]^+$ (Fig. 4). Figure 4 and Table 1 show that the Raman bands at 560—625, 446, and 291 cm^{-1} of *unsym-fac*-$[Co(ida)_2]^-$ correspond to those at 560—605, 430—510, and 348 cm^{-1} of C_2-*cis(N)*-$[Co(gly)_2(ox)]^-$, while the Raman bands at 545—610, 450—505, 301, and 235 cm^{-1} of *unsym-fac*-$[Co(ida)(dien)]^+$ correspond to those of 535—600, 430—490, 360, and 276 cm^{-1} of C_2-*cis(O)*-$[Co(gly)_2(en)]^+$ respectively, irrespective of the chelate ring structure. On the other hand, the mer isomer shows Raman spectral characteristics quite different from those of the fac isomers. Figure 3 and Table 1 demonstrate that the Raman spectra of the mer isomers of $[Co(dien)_2]^{3+}$ and $[Co(ida)(dien)]^+$ exhibit several polarized bands, but no depolarized bands, in the 390—615 cm^{-1} region, while those of the fac isomers of $[Co(dien)_2]^{3+}$ and $[Co(ida)(dien)]^+$ exhibit both polarized and depolarized bands in this region. This striking difference in the Raman spectral characteristics in the stretching vibration region can be ascribed to the difference in the stretching vibration mode depending on the coordination mode whether the linked two five-membered chelate rings take the mer coordination or the fac one.

On the basis of the above discussion and the Raman spectral characteristics summarized in Table 1, the Raman spectra of the bis(terdentate)cobalt(III) complexes can be classified into five categories: Polarized bands in the 510—625 cm^{-1} region, depolarized ones in the 430—525 cm^{-1} region, polarized ones in the 360—480 cm^{-1} region, depolarized ones in the 290—405 cm^{-1} region, and polarized ones in the 220—260 cm^{-1} region which can be assigned to the totally symmetric metal-ligand stretching, the Co–N and Co–O stretching except for the totally symmetric stretching character, the metal-ligand skeletal breathing, the skeletal bending deformation, and chelate ring deformation modes respectively.

Figure 5 shows the Raman spectra of the triamminecobalt(III)-type complexes, $[Co(NH_3)_3(dien)]^{3+}$ and $[Co(ida)(NH_3)_3]^+$, together with those of related complexes. The Raman spectrum of $[Co(NH_3)_3(dien)]^{3+}$ can be better correlated to that of *sym-fac*-$[Co(dien)_2]^{3+}$ than to that of $[Co(NH_3)_6]^{3+}$. That is, the character of the linked chelate rings appears similarly in the spectra of the mono(terdentate)cobalt(III)-type complexes. Further, Fig. 5 and Table 1 demonstrate that the Raman spectral characteristics of *fac*-$[Co(ida)(NH_3)_3]^+$

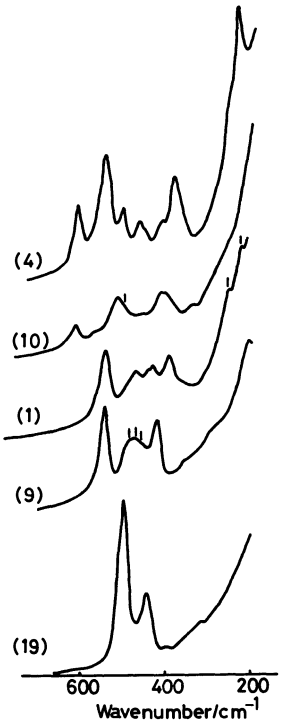

Fig. 5. Raman spectra of *sym-fac*-[Co(ida)(dien)]$^+$, *fac*-[Co(ida)$(NH_3)_3$]$^+$, *sym-fac*-[Co$(dien)_2$]$^{3+}$, [Co$(NH_3)_3$(dien)]$^{3+}$, and [Co$(NH_3)_6$]$^{3+}$ (Ref. 7). Numbers in parentheses correspond to those in Table 1.

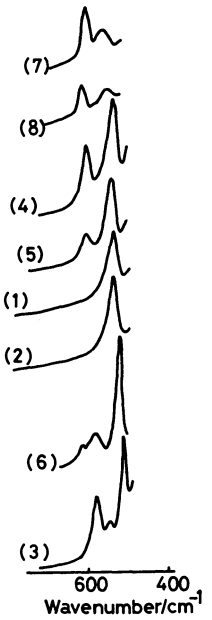

Fig. 6. Raman spectra of [Co$(ida)_n(dien)_{2-n}$]$^{(3-2n)+}$ (n= 0, 1, and 2) in the totally symmetric stretching vibration region. Numbers in parentheses correspond to those in Table 1.

are superimposed on those of the sym-fac and unsym-fac isomers of [Co(ida)(dien)]$^+$. It is interesting to note in Table 1 that the Raman spectral characteristics of [Co$(NH_3)_3$(dien)]$^{3+}$ can be correlated to those of the fac isomers of [Co$(dien)_2$]$^{3+}$ rather than to those of the mer isomer. Hence, we can expect that the dien in [Co$(NH_3)_3$(dien)]$^{3+}$ takes the facial coordination.

Finally, it should be noted that *sym-fac*-[Co$(dien)_2$]$^{3+}$ has more Raman bands than those expected from C_{2h} symmetry ($4A_g+2B_g$) because of the splitting of the chelate ring deformation mode. In crystal, *sym-fac*-[Co$(dien)_2$]Br_3 has been reported to have an "approximate" C_{2h} symmetry as a result of X-ray crystal structure analysis.[8,16] This Raman spectrum evidence implies that the sym-fac isomer is somewhat distorted structurally from C_{2h} molecular symmetry in an aqueous solution so far as the skeletal vibration characteristics are concerned.

Polarized Bands in the 510—625 cm^{-1} Region. Figure 6 shows the Raman spectra in the totally symmetric stretching vibration region. The mer isomers of [Co$(ida)_n(dien)_{2-n}$]-type complexes exhibit characteristic Raman spectra in this region. That is, each of the mer isomers of [Co$(dien)_2$]$^{3+}$ and [Co(ida)(dien)]$^+$ exhibits three polarized bands and no depolarized bands in the vibration region of lower frequencies. This is in contrast to the fac isomers, which exhibit both polarized and depolarized bands in the vibration region. The change of the depolarized bands to the polarized ones, together with the shift to the higher frequency region on going from the fac isomers to the mer ones, can be explained in terms of the strengthening of the harmonic stretching vibration characteristic of the totally symmetric stretching mode because of the diagonally connected chelate rings; in fact, the mer isomers are distorted from the regular octahedral structure, for the Co–N(imino nitrogen) bond in the mer isomers is appreciably stronger than the others.[8,17] Hence, the Raman spectral characteristics in this region can be used for the differentiation of the fac and mer isomers.

In the fac isomers, [Co$(dien)_2$]$^{3+}$ exhibits only one Raman band, whereas [Co(ida)(dien)]$^+$ and [Co$(ida)_2$]$^-$ give doublets. It is evident from the Raman frequencies of the cobalt(III) complexes with the fac coodination (Table 1) that the Raman bands can be classified into two categories: Those above 605 cm^{-1} and those below 570 cm^{-1}, and that the former can be assigned to the ν_{ts}(Co–O) mode, and the latter, to the ν_{ts}(Co–N) mode. This assignment was supported by the isotopic shift; the polarized bands near 545 cm^{-1} of the fac isomers of [Co(ida)(dien)]$^+$ and [Co$(dien)_2$]$^{3+}$ exhibited a shift to a lower frequency upon the deuteration of the amino protons.

Depolarized Bands in the 430—525 cm^{-1} Region. In this region, the Raman spectra exhibit from one to three depolarized bands, except for *mer*-[Co$(dien)_2$]$^{3+}$ and [Co(ida)(dien)]$^+$, which give no depolarized bands at all (Fig. 7). These Raman bands can be assigned to the stretching mode, excluding the totally symmetric one, by comparison with the Raman spectra of the tris(bidentate)cobalt(III) complexes.[7] Furthermore,

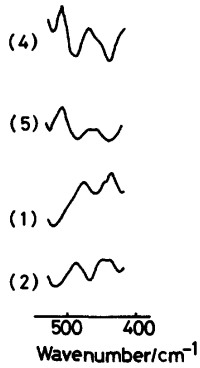

Fig. 7. Raman spectra of the fac isomers of [Co(ida)(dien)]$^+$ and [Co(dien)$_2$]$^{3+}$ in the stretching vibration region excluding the totally symmetric one. Numbers in parentheses correspond to those in Table 1.

the depolarized bands of *sym-fac*-[Co(dien)$_2$]$^{3+}$ are assigned to ν(Co–N), because the bands exhibit a large spectral shift (about 15 cm^{-1}) upon deuteration. As a whole, the Raman bands of *fac*-[Co(ida)(dien)]$^+$ and [Co(ida)$_2$]$^-$ are observed at higher frequencies (445—525 cm^{-1}) than those of *fac*-[Co(dien)$_2$]$^{3+}$ (430—485 cm^{-1}). This result implies that the Raman bands of [Co(ida)(dien)]$^+$ and [Co(ida)$_2$]$^-$ may be greatly influenced by the Co–O stretching vibration mode, for the Raman spectra of the tris(bidentate)cobalt(III) complexes have shown that the Raman bands of the ν(Co–O) mode appear at a higher frequency than those of the ν(Co–N) mode.[7]

Polarized Bands in the 360—480 cm^{-1} Region. The Raman spectra of the [Co(ida)$_n$(dien)$_{2-n}$]-type complexes in this region exhibit some unique polarized bands, as is shown in Table 1. These sorts of polarized bands have not been found in the Raman spectra of the tris(bidentate)cobalt(III) complexes;[7] they may be characteristic of the octahedral mono and bis(terdentate)cobalt(III) complexes. As has been mentioned before, these bands can be assigned to the skeletal breathing mode in the sense of the totally symmetric stretching, to which the chelate ring deformation is coupled, because the Raman bands in this region have totally symmetric vibration characteristics.

Depolarized Bands in the 290—405 cm^{-1} Region. From a comparison with the data of the tris(bidentate)-cobalt(III) complexes,[7] the Raman bands in this region have been assigned to the metal-ligand skeletal bending deformation mode. Figure 8 shows the relation between the Raman spectra of the sym-fac and unsym-fac isomers of [Co(dien)$_2$]$^{3+}$, [Co(ida)(dien)]$^+$, and [Co(ida)$_2$]$^-$ and their geometrical structures. The Raman spectra reflect the chelate ring structure (Fig. 8 and Table 1): The unsym-fac isomers have a depolarized band, the sym-fac isomers have no bands, and the mer isomers have a few bands. That is, it can be said that the combination of the chelate rings changes the metal-ligand skeletal bending deformation characteristics. This result is quite unlike that for the [Co(gly)$_x$(ox)$_y$(en)$_z$]-type complexes, each of which gives a Raman band, irrespective of the chelate ring structure, except for the [Co(ox)$_y$(en)$_z$]-type complexes, which have a major band accompanied by a very weak one.[7]

Fig. 8. Raman spectra of [Co(ida)$_n$(dien)$_{2-n}$]$^{(3-2n)+}$ (n=0, 1, and 2) in the skeletal bending deformation and the chelate ring deformation regions. Numbers in parentheses correspond to those in Table 1.

It seems to indicate that tha Raman bands in this region can be used for the differentiation of the sym-fac and unsym-fac isomers of the [Co(ida)$_n$(dien)$_{2-n}$]-type complexes.

Polarized Bands in the 220—260 cm^{-1} Region. Polarized Raman bands of the [Co(ida)$_n$(dien)$_{2-n}$]-type complexes in this region have been assigned to the chelate ring deformation mode of the coordinated terdentate ligands, because they correspond well to a sharp band near 270 cm^{-1} of the [Co(a)(b)(en)$_2$]-type complexes.[2] Unlike those in the 290—405 cm^{-1} region, the Raman bands of the [Co(ida)$_n$(dien)$_{2-n}$]-type complexes in this region do not reflect the chelate ring structure (Table 1 and Fig. 8). Rather, they belong to the same skeletal vibration modes as those of the tris(bidentate)cobalt(III) complexes with the five-membered chelate rings. A shift to the lower frequency side was noticed for the polarized band by the linkage of the chelate rings (Table 1[7]).

No polarized bands were observed on the Raman spectra of [Co(ida)(NH$_3$)$_3$]$^+$ and [Co(NH$_3$)$_3$(dien)]$^{3+}$, both of which have one linked chelate ring.

Raman Spectra of [Co(ida)$_n$(mida)$_{2-n}$]$^-$(n=0 and 1)

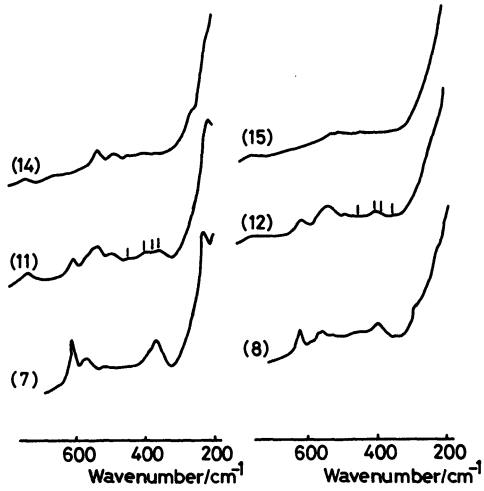

Fig. 9. Raman spectra of the fac isomers of $[Co(ida)_n(mida)_{2-n}]^-$ (n=0, 1, and 2). Numbers in parentheses correspond to those in Table 1.

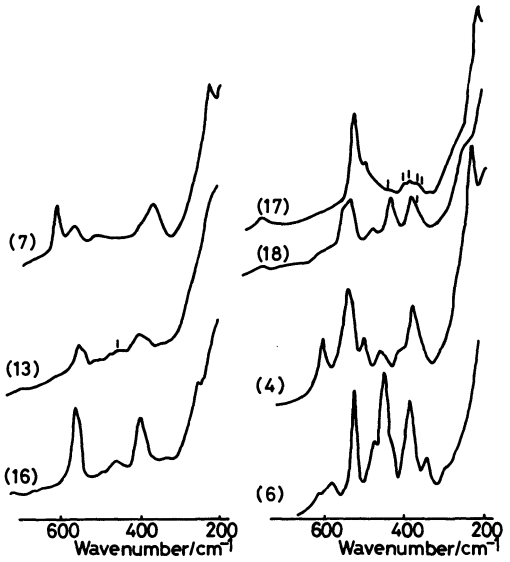

Fig. 10. Raman spectra of *sym-fac*-$[Co(ida)_2]^-$, *mer*-$[Co(ida)(mida)]^-$, *mer*-$[Co(mida)_2]^-$, *sym-fac*-$[Co(mida)(mdien)]^+$, *mer*-$[Co(mida)(mdien)]^+$, *sym-fac*-$[Co(ida)(dien)]^+$, and *mer*-$[Co(ida)(dien)]^+$. Numbers in parentheses correspond to those in Table 1.

and $[Co(mida)(mdien)]^+$ Complexes. The Raman spectra of the $[Co(ida)_n(mida)_{2-n}]^-$($n$=0 and 1) and $[Co(mida)(mdien)]^+$ complexes were measured in the skeletal vibration region as an extension of the $[Co(ida)_n(dien)_{2-n}]$-type complexes; those spectral data are also summarized in Table 1. The coordinated mida and mdien ligands are characteristic in that their conformations are somewhat restricted by the methyl group on imino nitrogen.

The Raman bands of the $[Co(ida)_n(mida)_{2-n}]$-type and $[Co(mida)(mdien)]^+$ complexes can be classified into five vibration modes as in the case of the $[Co(ida)_n(dien)_{2-n}]$-type ones.

Figure 9 shows the Raman spectra of the $[Co(ida)_n(mida)_{2-n}]$-type complexes. The replacement of a hydrogen on the imino nitrogen by a methyl group causes a marked change in the Raman spectral characteristics rather than the spectral shift anticipated in the case of the deuteration of the amino protons. At the same time, the Raman spectra become less well defined with an increase in the numbers of the methyl group in the complexes.

The Raman spectra of the sym-fac and mer isomers of the $[Co(ida)_n(mida)_{2-n}]$-type and $[Co(mida)(mdien)]^+$ complexes are shown in Fig. 10, together with those of the $[Co(ida)_n(dien)_{2-n}]$-type complexes. The Raman spectra in the stretching vibration region of the mer isomers for $[Co(ida)(mida)]^-$, $[Co(mida)_2]^-$, and $[Co(mida)(mdien)]^+$ exhibit depolarized bands. These spectral characteristics differ somewhat from the Raman spectra of the mer isomers for the $[Co(ida)_n(dien)_{2-n}]$-type complexes, which give only polarized bands. These findings suggest that the skeletal vibration characteristics of the mer isomers for the mida or mdien cobalt(III) complexes are mainly regulated by the linked chelate rings, which are folded by the restriction imposed by the methyl group on the imino nitrogen.

Finally, it should be pointed out that the two fac isomers of $[Co(mida)_2]^-$ exhibit no intense bands around 400 cm^{-1}. This may be due to the two methyl groups on the imino nitrogen atoms, which change the normal vibrations of the fac isomers by means of the fixed conformation of all of the chelate rings.

Mössbauer and DTA Studies of Superionic Conducting $AgCl$-Ag_2O-B_2O_3 Glasses

Tetsuaki NISHIDA,* Michiko OGATA, and Yoshimasa TAKASHIMA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812
(Received January 6, 1986)

A structural study of silver borate glasses containing 20 or 30 mol% AgCl and 1 mol% Fe_2O_3 has been performed by means of Mössbauer spectroscopy. The distinct decreases in the Mössbauer parameters observed in the borate glasses with Ag_2O contents higher than about 10 mol% suggest that chloride ions are covalently bonded with tetrahedral iron or boron atoms as nonbridging chlorine. On the other hand, chloride ions are considered to be ionically bonded with Ag^+ ions at the interstitial sites of the three-dimensional network composed of BO_3, BO_4, and FeO_4 units when the Ag_2O content is lower than 10 mol%. Measurements of the glass transition temperatures and the electric conductivity show a good agreement with the Mössbauer results, suggesting that mobile and electric conducting Ag^+ ions change their configurational sites from the interstitial sites which are close to Cl^- ions to different interstitial sites which are close to the nonbridging chlorine atom.

Superionic conducting glasses containing Ag^+ ions have attracted much attention because of the scientific interest in the conduction mechanism as well as their technological applications.[1-13] The high electric conductivity of these glasses, amounting to the order of 10^{-2} S cm^{-1}, has been reported to be brought about by a cation conduction due to mobile Ag^+ ions which are considered to be present at interstitial sites of the glass-network structure. (The electric conductivity of ordinary alkali oxide glasses is known to be lower than 10^{-13} or 10^{-14} S cm^{-1}.) Minami et al.[1,5,6] suggested that mobile Ag^+ ions originate from AgX (X=Cl, Br, and I) molecules and that the nature of the chemical bond between the mobile Ag^+ ion and the neighboring halide ion is completely ionic. They also suggested that the nature of the chemical bond between the Ag^+ ion originating from Ag_2O and the oxygen atom constituting the skeleton of the glass network is partially covalent. This is different from the ionic bond between the alkali metal ion and the oxygen in ordinary alkali oxide glasses. In the light of this suggestion, the latter type of Ag^+ ion has been considered to be essentially immobile. Raman and EXAFS studies of the superionic conducting glasses revealed that the mobile Ag^+ ion is tetrahedrally surrounded by four halide ions at the interstitial site, forming a microdomain or a distorted sublattice of the α-AgI phase which itself has a high electric conductivity.[9,10,12] On the other hand, Chiodelli et al.[13] ruled out the presence of a high electric-conducting α-AgI phase dispersed in the glass network, for the electric conductivity of silver borate glasses containing AgI also shows a marked increase with the Ag_2O content when the AgI content is constant, and also the conductivity of binary Ag_2O-B_2O_3 glasses is much higher than that of ordinary alkali borate glasses. The electric conductivity measurements of binary Ag_2O-B_2O_3 glasses performed by Matusita and Sakka[14] and by Tsuchiya et al.[15] revealed that the conductivity of $30Ag_2O \cdot 70B_2O_3$ glass is about 10^{-6} S cm^{-1} at 100 °C and that it is higher than 10^{-8} S cm^{-1} at room temperature. These experimental results seem to lead to the tentative conclusion that at least a part of the Ag^+ ions originating from Ag_2O also participate in the electric conduction. One possible explanation of the high electric conductivity of binary silver borate glasses is the electron hopping from the colloidal Ag^0 to the Ag^+ ions originating from Ag_2O.[15]

Mössbauer spectroscopy has been successfully used for the structural study of several glasses, such as borate,[16-20] borosilicate,[21,22] phosphate,[23,24] borophosphate,[25] germanate,[26,27] KCl-$ZnCl_2$,[28] and BaF_2-ZrF_4[29] glasses. Mössbauer and ESR studies of potassium borate glasses containing a small amount of KCl or KBr revealed that chloride and bromide ions are ionically present at interstitial sites of the three-dimensional network composed of BO_3 and BO_4 units when the alkali oxide (K_2O) content is lower than 15 mol%.[19,20] On the other hand, the chloride and bromide ions proved to be covalently bonded with tetrahedal boron or iron (Fe^{3+}), as nonbridging chlorine (-Cl) and bromine (-Br) atoms respectively, when the K_2O content is higher than 15 mol%.[19,20] These results are almost entirely consistent with the optical absorption results reported by Maekawa et al.[30]

The present Mössbauer study was carried out in order to elucidate the local structure of superionic conducting $AgCl$-Ag_2O-B_2O_3 glasses, for Mössbauer spectroscopy is a very useful method for the structural study of amorphous materials, the structural study of which is very difficult by means of ordinary diffraction methods. The differential thermal analysis (DTA) of these glasses was performed because any change in the local structure of glasses, such as a change in the coordination number of network-forming atoms or the formation of nonbridging atoms, is known to be well reflected in the glass transition temperature (T_g).[26,29,31-35]

Experimental

Silver borate glasses containing 20, 30, and 40 mol% AgCl and 1 mol% Fe_2O_3 were prepared by fusing the individual mixtures of AgCl, Ag_2O, B_2O_3, and $^{57}Fe_2O_3$, of a guaranteed

reagent grade, at 1020 °C for 3 h using an electric muffle furnace. After the fusion, each melt in a platinum crucible was quenched with ice-cold water. The yellowish brown to reddish brown glasses obtained in this way were pulverized for the Mössbauer, DTA, and electric-conductivity measurements. Mössbauer measurements were performed by means of a constant-acceleration method at room temperature. Cobalt-57 (10 mCi) diffused into a palladium foil and a metallic iron foil enriched with iron-57 were used as the Mössbauer source and the reference for the isomer shift respectively. The velocity of the spectrometer was calibrated with the spectrum of metallic iron foil. Using a least-squares method, each Mössbauer spectrum was analyzed into a quadrupole doublet with the same width and the same intensity. DTA measurements were performed at a heating rate of 5 °C min^{-1} over the range from room temperature to 700 °C, and Al_2O_3 powder was used as the standard material. Electric-conductivity measurements for each glass sample (600 mg), pressed at a net pressure of 2.6×10^6 g cm^{-2}, were performed at room temperature by applying a DC voltage of 3 V.

Results and Discussion

The Mössbauer measurements of AgCl–Ag_2O–B_2O_3 glasses containing 1 mol% Fe_2O_3 revealed that iron is present only in the Fe^{3+} state, as is shown in Fig. 1. It may also be seen from Fig. 1 that the spectrum consists of a quadrupole doublet caused by the electric field gradient at the iron nucleus. Quadrupole doublets are often observed in the Mössbauer spectra of borate glasses,[16–20] and the increase in the quadrupole splitting of Fe^{3+} suggests the decreased symmetry of FeO_4 tetrahedra, because high-spin Fe^{3+} species have a symmetric $3d^5$ electron configuration in the outermost orbital. Therefore, only the electric field gradient brought about by the neighboring atoms or ions, i.e., oxygen atoms in the oxide glasses, affects the quadrupole splitting values. The symmetry of the BO_4 tetrahedra will also be reflected in the magnitude of the quadrupole splitting, for all the Fe^{3+} ions are considered to be present at the substitutional sites of the boron atoms constituting the BO_4 tetrahedra. (The isomer shifts smaller than ca. 0.4 mm s^{-1} mean that each Fe^{3+} ion is surrounded by four oxygen atoms, just as in the case of the boron atoms constituting the BO_4 tetrahedra.) It may be seen from Fig. 1 that the linewidth (FWHM) of the Fe^{3+} absorption is much larger than those of the Fe^{2+} or Fe^{3+} absorptions in the ordinary crystalline compounds, which is usually smaller than ca. 0.4 mm s^{-1} in the case of ^{57}Fe-Mössbauer spectroscopy. The large linewidth of the Fe^{3+} absorption in the borate glasses suggests that the Fe–O (and B–O) bond lengths and also the O–Fe–O (and O–B–O) bond angles are distributed. These distributions can be described as characteristic of amorphous materials. All the Mössbauer parameters obtained in the present study are summarized in Table 1, in which the isomer shifts of Fe^{3+} are in the range of 0.27 to 0.33 mm s^{-1} and show a slight decrease with an increase in the Ag_2O content. Table 1 indicates that quadrupole splitting also decreases with an increase in the Ag_2O content. (The experimental error for the isomer shift is estimated to be ±0.01 mm s^{-1}, and the errors for the quadrupole splitting and the linewidth are estimated to be ±0.02 mm s^{-1}.) The changes in the isomer shift and the quadrupole splitting with the Ag_2O content are also shown in Figs. 2 and 3 respectively.

a) Isomer shift. b) Quadrupole splitting. c) Linewidth (FWHM).

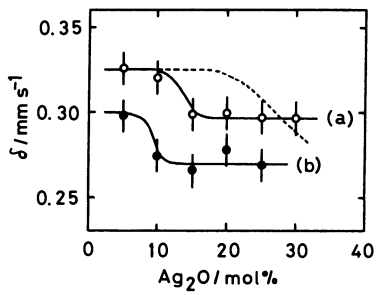

Fig. 2. Isomer shifts of Fe^{3+} in silver borate glasses containing (a) 20 mol% and (b) 30 mol% AgCl. A broken line refers to the change in the isomer shift of Fe^{3+} in K_2O–B_2O_3 glasses.[16,18]

Figure 2 demonstrates distinct decreases in the isomer shift of Fe^{3+} when the Ag_2O contents are in the ranges of 10—15 mol% and 5—10 mol% in the borate glasses containing 20 and 30 mol% AgCl respectively. The broken line shown in Fig. 2 refers to a change in the

isomer shift of Fe^{3+} in the K_2O–B_2O_3 glasses, from which the formation of a nonbridging oxygen (NBO) atom in BO_4 and FeO_4 units can be deduced when the K_2O content is equal to or higher than 20 mol%.[16,18] In the Mössbauer and ESR studies of K_2O–B_2O_3 glasses containing a small amount of KCl or KBr, the formation of nonbridging chlorine or bromine atoms was concluded on the basis of the distinct decreases in the isomer shift of Fe^{3+} and the ESR absorption intensity of Cl_2^- and Br_2^- when the K_2O content is equal to or higher than 15 mol%.[19,20] These results suggest that the formation of nonbridging chlorine atom starts when the Ag_2O content is higher than about 10 mol% in the case of silver borate glasses containing 20 or 30 mol% AgCl. The critical composition of the ternary AgCl–Ag_2O–B_2O_3 glass, where a distinct change in the isomer shift is observed, is found to be almost identical with the composition of the binary K_2O–B_2O_3 glass containing only 0.63 mol% KCl[19,20] when the Ag_2O/B_2O_3 molar ratio is compared to the K_2O/B_2O_3 ratio. That is, the molar ratio of 15/85 (=0.18) in the K_2O–B_2O_3 glass,[19,20] where it was concluded that the formation of the nonbridging chlorine atom starts, corresponds to the Ag_2O contents of about 12 and 10.5 mol% in the AgCl–Ag_2O–B_2O_3 glasses containing 20 and 30 mol% AgCl respectively. These conclusions are consistent with the results of the quadrupole splitting shown in Fig. 3, from which it is obvious that the quadrupole splitting shows a drastic decrease when the Ag_2O content is equal to or higher than 10 mol%. The broken line shown in Fig. 3 refers to a change in the quadrupole splitting of Fe^{3+} in the K_2O–B_2O_3 glasses;[16] the distinct decrease in the quadrupole splitting when the K_2O content is higher than 20 mol% is ascribed to the formation of a nonbridging oxygen atom in BO_4 and FeO_4 tetrahedral units, as has been described above. The increased quadrupole splittings of Fe^{3+} in the AgCl–Ag_2O–B_2O_3 glasses are ascribed to the substitution of the chloride ion for one of the oxygen atoms constituting the BO_4 or FeO_4 tetrahedra, or to the decreased symmetry of FeO_4 when the Ag_2O content is very low. Similar overall increases in the quadrupole splitting of Fe^{3+} have been observed in K_2O–B_2O_3 glasses containing a small number of chloride ions.[19]

DTA measurements were performed for all the glass samples prepared in the present study. The DTA curve consists of a broad exothermic peak, followed by an endothermic peak and a few exothermic peaks due to crystallization (Fig. 4). As is shown in Fig. 4, the glass transition temperature (T_g) is generally obtained from the intersection of the tangent to the broad exothermic peak and that to the following endothermic peak. All the glass transition temperatures obtained in this way are shown in Fig. 5, in which T_g shows a maximum when the Ag_2O content is about 10 mol%. It is already known that the increased coordination number of network-forming boron and germanium, in borate and germanate glasses respectively, is well reflected in the gradual increase in T_g.[26,31–35] This is probably due to the increased degree of bridging in the glass skeleton as a result of the step-by-step structural changes from BO_3 to BO_4 units and from GeO_4 to GeO_6 units in borate and germanate glasses respectively. On the other hand, the formation of nonbridging oxygen atom, i.e., a decreased degree of bridging in the glass skeleton, is known to result in a decrease in T_g.[26,34,35] Therefore, the gradual decrease in the T_g observed in the silver borate glasses with the Ag_2O contents higher than about 10 mol% is concluded to be due to the formation of a nonbridging chlorine atom in BO_4 or FeO_4 units, i.e., the formation of BO_3Cl or FeO_3Cl units.

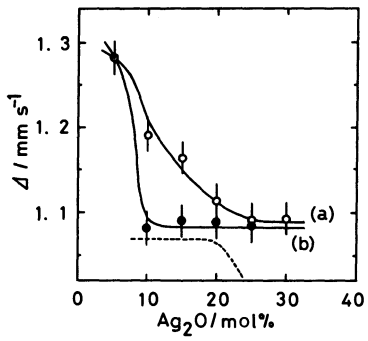

Fig. 3. Quadrupole splittings of Fe^{3+} in silver borate glasses containing (a) 20 mol% and (b) 30 mol% AgCl. A broken line refers to the change in the quadrupole splitting of Fe^{3+} in K_2O–B_2O_3 glasses.[16]

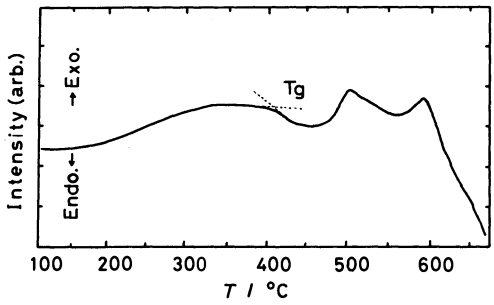

Fig. 4. DTA curve for $20AgCl \cdot 10Ag_2O \cdot 69B_2O_3 \cdot Fe_2O_3$ glass.

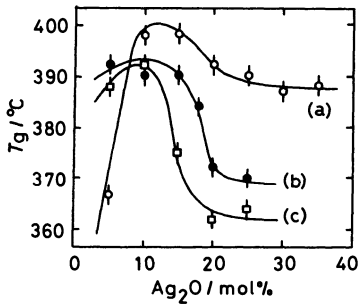

Fig. 5. Glass transition temperatures of silver borate glasses containing (a) 20 mol%, (b) 30 mol%, and (c) 40 mol% AgCl.

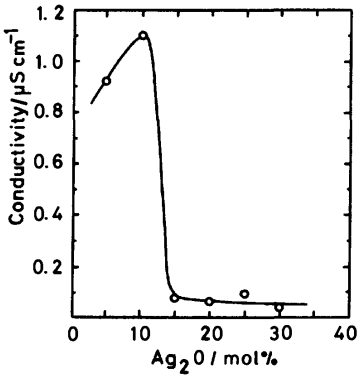

Fig. 6. Electric conductivities of silver borate glasses containing 20 mol% AgCl.

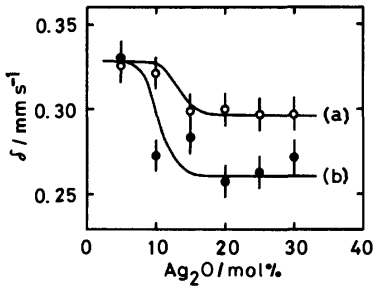

Fig. 7. Isomer shifts of Fe^{3+} in silver borate glasses containing 20 mol% AgCl. (a): Non-irrad., (b): irrad. with ^{60}Co-γ rays of 10^8 R.

This conclusion is consistent with the Mössbauer results presented above. An overall decrease in T_g with an increase in the AgCl content also supports this conclusion, because the number of nonbridging chlorine atoms will, to some extent, be proportional to the concentration of chloride ions in glasses.

The composition dependency of electric conductivity for silver borate glasses containing 20 mol% AgCl is shown in Fig. 6, which also shows a drastic change when the Ag_2O content exceeds about 10 mol%. Considering the experimental findings that the electric conductivity for binary Ag_2O–B_2O_3 glasses shows a drastic and almost linear increase with an increase in the Ag_2O content,[13–15] the remarkable decrease in the electric conductivity shown in Fig. 6 is concluded to be caused by AgCl. The drastic decrease in the electric conductivity suggests that the number of mobile Ag^+ ions decreases abruptly when the Ag_2O content exceeds about 10 mol% in the case of silver borate glasses containing 20 mol% AgCl. Considering the Mössbauer (Figs. 2 and 3) and DTA (Fig. 5) results presented above, this phenomenon can be correlated with the formation of nonbridging chlorine atoms in the silver borate glasses with an Ag_2O content higher than about 10 mol%. The number of mobile Ag^+ ions will be reduced because most of the Ag^+ ions, which were present with Cl^- ions at the interstitial sites of the three-dimensional network structure, follow the nonbridging chlorine atoms. As a result, such Ag^+ ions will become less mobile, just like the Ag^+ ions originating from Ag_2O molecules. These results are consistent with the prediction made by Minami et al.[1,5,6] that the electric conduction in AgX–Ag_2O–B_2O_3 glasses is primarily made by Ag^+ ions originating from AgX molecules. (X indicates Cl, Br, and I, as has been described above.) Their prediction will be especially valid in an Ag_2O content region in which most chloride ions are present at the interstitial sites of the three-dimensional network structure, i.e., when the Ag_2O content is lower than about 12 and 10.5 mol% in the cases of the silver borate glasses containing 20 and 30 mol% AgCl respectively. In the case of AgI–Ag_2O–B_2O_3 glasses, somewhat different results will be obtained, because the structural behavior of the I^- ion has been reported to be independent of the Ag_2O content of the glasses,[30] being contrary to the behavior of the Cl^- or Br^- ions.

Gamma-Ray irradiation experiments with silver borate glasses containing 20 mol% AgCl were performed in order to confirm the presence of nonbridging chlorine atoms in the silver borate glasses when the Ag_2O content is higher than about 10 mol%. According to the Mössbauer studies of γ-ray irradiated borate or borosilicate glasses, the irradiation is known to result in a decrease in the isomer shift of Fe^{3+} when a nonbridging oxygen atom is present in FeO_4 or BO_4 tetrahedral units.[21,36] Figure 7 shows the irradiation-induced changes in the isomer shift of Fe^{3+} in silver borate glasses containing 20 mol% AgCl. Gamma-Ray irradiations of 10^6 and 10^7 R result in gradual decreases in the isomer shifts, which are intermediate between the (a) and (b) curves. The gamma-ray irradiation of borate glasses is known to result in a reduction of Fe^{3+} to Fe^{2+} when the total iron content of the glasses is very low.[11,36] The decrease in the isomer shift shown in Fig. 7 is, therefore, ascribed to an increased *s*-electron density at the iron nucleus as a result of the charge transfer from a nonbridging chlorine atom to the neighboring iron atom constituting a FeO_3Cl tetrahedral unit. This will also be the case for a tetrahedral BO_3Cl unit.

All the experimental results obtained in the present study lead to the following conclusions. Chloride ions in AgCl–Ag_2O–B_2O_3 glasses are ionically bonded with Ag^+ ions at the interstitial sites of the three-dimensional network composed of BO_3 and BO_4 (and FeO_4) units when the Ag_2O content is lower than about 10 mol%, i.e., when the Ag_2O/B_2O_3 ratio is smaller than 15/85. On the other hand, chloride ions are covalently bonded with tetrahedral boron (or iron) atoms as nonbridging chlorine when the Ag_2O content exceeds about 10 mol%. These structural changes are concluded to affect the steric configuration of the Ag^+ ion, which is a cation conductor. That is, Ag^+ ions are considered to change their structural sites from the interstitial sites which are close to the Cl^- ions to different interstitial

sites which are close to the nonbridging chlorine atoms. The latter type of Ag^+ ions seems to be less mobile than the former, because a drastic decrease in the electric conductivity is observed when the Ag_2O content exceeds about 10 mol%.

The authors are indebted to Mr. Toshiharu Hirai of Chemical and Catalysis Industrial Corporation for his kind help in the electric-conductivity measurements. The present study was partially supported by the Itoh Science Foundation and by a Grant-in-Aid for Scientific Research (No. 60740234) from the Ministry of Education, Science, and Culture.

(Received March 5, 1986)

Complex formation equilibria between copper(II) and chloride ions have been studied by calorimetric and spectrophotometric titrations in dimethyl sulfoxide (DMSO) containing 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ or 1 mol dm^{-3} $LiClO_4$ as a constant ionic medium at 25 °C. Both calorimetric and spectrophotometric data obtained were well explained in terms of formation of $[CuCl_n]^{(2-n)+}$ (n=1—4) in each solution, and their formation constants, enthalpies and entropies were determined. It was found that the complexation at each step was appreciably suppressed in the $LiClO_4$ DMSO solution compared to that in the $(C_2H_5)_4NClO_4$ one, which was ascribed to the extensive formation of LiCl ion-pairs in the former solution. As well as in *N,N*-dimethylformamide (DMF),[1] positive values of stepwise ΔH_n° and ΔS_n° (n=1—3) and negative ΔH_4° values were observed in DMSO. However, the ΔS_n° (n=1, 2, and 4) values in DMSO were appreciably smaller than the corresponding ones in DMF. The result was interpreted in terms of stronger intermolecular interactions in the bulk DMSO than those in DMF. The entropies of transfer of $[CuCl_n]^{(2-n)+}$ (n=0—4) from DMF to DMSO were significantly positive. This result also suggested that DMSO is a highly associated solvent. Electronic spectra of individual copper(II) chloro complexes were extracted from the spectra measured by varying molar ratios of chloride to copper(II) ions in solution. In contrast to the electronic spectra of Cu^{2+}, $[CuCl]^+$ and $[CuCl_2]$, the spectra of $[CuCl_3]^-$ and $[CuCl_4]^{2-}$ in DMSO were not appreciably different from those in DMF, indicating that solvation of these complexes are rather weak in both solvents.

The complexation of copper(II) with chloride ions in dimethyl sulfoxide (DMSO) has so far been studied by spectrophotometry,[2,3] potentiometry,[3-5] and conductometry.[5] These works elucidated the formation of mononuclear copper(II) chloro complexes in the solvent. Although the formation constants of these complexes have been obtained, their enthalpies and entropies have not been determined in DMSO yet.

We previously reported the complex formation equilibria between copper(II) and chloride ions in *N,N*-dimethylformamide (DMF),[1] in acetonitrile[6] and in their mixtures[7] by calorimetric and spectrophotometric measurements. A large difference was found in the enthalpies of complexation in these solvents, so that the difference in the metal-solvent bonding energies was indicated to play a dominant role for solvent effect on the complexation. In this respect, the donicity of DMSO is only slightly larger than that of DMF.[8] However, DMSO is expected to be a highly associated liquid,[9] while DMF has so weak intermolecular interactions that it shows practically random distribution in the bulk.[10]

In this work, therefore, we investigated the complexation of copper(II) with chloride ions in DMSO and compared the thermodynamic quantities of complexation thus obtained with those in DMF. The thermodynamic quantities were determined in 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMSO solutions by the same methods as used in previous works.[1,6] In order to evaluate the enthalpies of transfer of each $[CuCl_n]^{(2-n)+}$ (n=0—4) complex from DMF to DMSO, the enthalpy of solution of neutral $CuCl_2$ was determined in DMSO, as well as in DMF. Similarly, the corresponding Gibbs energies of transfer ΔG_t° of each complex were evaluated on the basis of the ΔG_t° values of copper(II) and chloride ions from the literature.[11,12] Electronic spectra of individual copper(II) chloro complexes were extracted by resolving the spectra measured in DMSO by varying molar ratios of chloride to metal ions.

Experimental

Reagents. *Copper(II) Perchlorate* was prepared from copper(II) oxide and perchloric acid of super special reagent grade. The copper(II) perchlorate thus prepared were recrystallized three times from water, and $Cu(ClO_4)_2 \cdot 6H_2O$ crystals were then dried in a vacuum oven at 70 °C. *Copper(II) perchlorate DMSO solvates*, $Cu(ClO_4)_2 \cdot x$DMSO, were prepared from $Cu(ClO_4)_2 \cdot 6H_2O$ by dissolving in an ethanol-diethyl ether mixture of equal volume fractions, followed by adding DMSO to yield the DMSO solvate crystals. The crystals thus obtained were washed with acetone, recrystallized from acetone and dried in vacuum at 50 °C for several days. An electrogravimetrical analysis showed that the value of x within the crystals finally obtained was close to 5.

Dimethyl sulfoxide was refluxed over CaH_2 for about one day, then distilled twice over CaH_2 at 50 °C under a reduced pressure (260 Pa) and kept over molecular sieves 4A 1/16 in a dark bottle with a P_2O_5 drying-tube.

Other chemicals used were prepared and dried by usual procedures as described elsewhere.[1] All test solutions were prepared in a dry box over P_2O_5 under an atmosphere of nitrogen gas.

Measurements. Calorimetric and spectrophotometric measurements were carried out in a room thermostated at (25.0±0.2) °C. All test solutions prepared contained 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ or 1 mol dm^{-3} $LiClO_4$ as a constant ionic medium.

Calorimetric measurements were performed in a thermostated water-bath at (25.000±0.007) °C. 100 cm^3 of a cop-

per(II) perchlorate solution was placed in a Dewar vessel, which was filled with nitrogen gas and prevented from moisture with a P_2O_5 drying-tube, and then was titrated with either 0.2 mol dm^{-3} $(C_2H_5)_4NCl$ or 1 mol dm^{-3} LiCl DMSO solution. The concentration of copper(II) ion in the initial test solutions was varied in the range 8—40 mmol dm^{-3}. Heats of complexation at each point of titration were ranged 1—5 J with a certainty ±0.05 J and were corrected for heats of dilution of the titrant separately determined by titrating either 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ or 1 mol dm^{-3} $LiClO_4$ DMSO solution with relevant titrant solutions in advance. Details of the data treatment have been described previously.[1,13]

Electronic spectra were measured with a HITACHI 340 spectrophotometer (HITACHI) equipped with a JEC 6 electronic computer (JEOL) which recorded data at selected wavelengths. A flow cell with a light-pass length of 0.5 cm was connected with a titration vessel through teflon and glass tubes. 15 cm^3 of a $Cu(ClO_4)_2$ DMSO solution was placed in a vessel under a nitrogen atmosphere and then was titrated with either the $(C_2H_5)_4NCl$ or LiCl DMSO solution.

Analysis of Calorimetric and Spectrophotometric Data. Calorimetric data obtained were analyzed by assuming the formation of mononuclear $[CuCl_n]^{(2-n)+}$, and their formation constants and enthalpies were simultaneously determined by the least-squares method as described previously.[1,6,7,13]

The absorbance data obtained at thirty different wavelengths in the range 250—500 nm were analyzed by the same procedure as that used previously,[1,6] and the formation constants of $[CuCl_n]^{(2-n)+}$ (n=1—4) were determined together with the molar extinction coefficents of the complexes at each relevant wavelength.

Results and Discussion

Calorimetric titration curves obtained in 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMSO solutions are depicted in Figs. 1 and 2, respectively. In each solution, enthalpies $\Delta H^\circ = -q/(\delta v C_{X,tit})$ were plotted against C_X/C_M, where q, δv, C_X and C_M stand for the heat evolved, the volume of an aliquot of the titrant added and the total concentrations of chloride and copper(II) ions in a solution, respectively, at each titration point, and $C_{X,tit}$ denotes the concentration of chloride ion in the titrant solution.

The trend of variation of the titration curves was similar in both $(C_2H_5)_4NClO_4$ and $LiClO_4$ DMSO solutions over the whole range of C_X/C_M examined. In both solutions, the ΔH° values at lower $C_X/C_M<0.5$ were kept constant and were independent of the metal concentration in solutions, the $[CuCl]^+$ complex being indicated to solely form in the range. With increasing C_X/C_M up to 2, the ΔH° value then increased and changed depending on the metal concentration, so that $[CuCl_2]$ was expected to form with a more endothermicity than $[CuCl]^+$. In the range $C_X/C_M>2$, the ΔH° value gradually decreased to approach $\Delta H^\circ=0$ with an increase in C_X/C_M, the higher $[CuCl_3]^-$ and $[CuCl_4]^{2-}$ complexes being expected to form over the range.

The result of the least-squares refinement of the calorimetric and spectrophotometric data in the $(C_2H_5)_4NClO_4$ DMSO solution are summarized in Table 1.

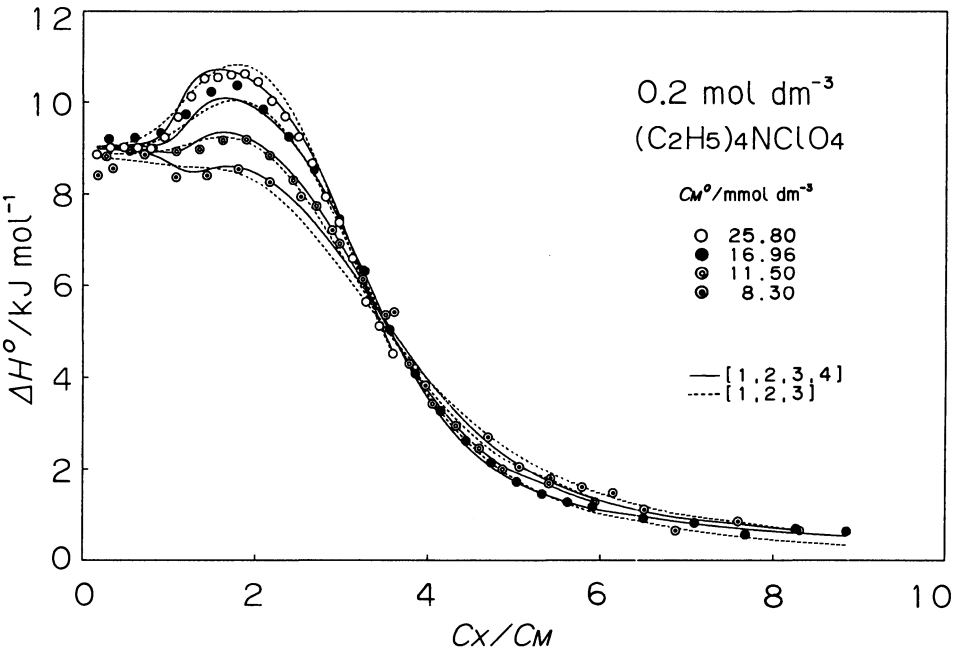

Fig. 1. Calorimetric titration curves of copper(II) chloride DMSO solutions containing 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25 °C. Initial concentrations of copper(II) perchlorate (C_M°/mmol dm^{-3}) are given in the figure. The solid and broken lines show the theoretical curves calculated by using the constants of the sets (1—4) and (1—3), respectively, in Table 1.

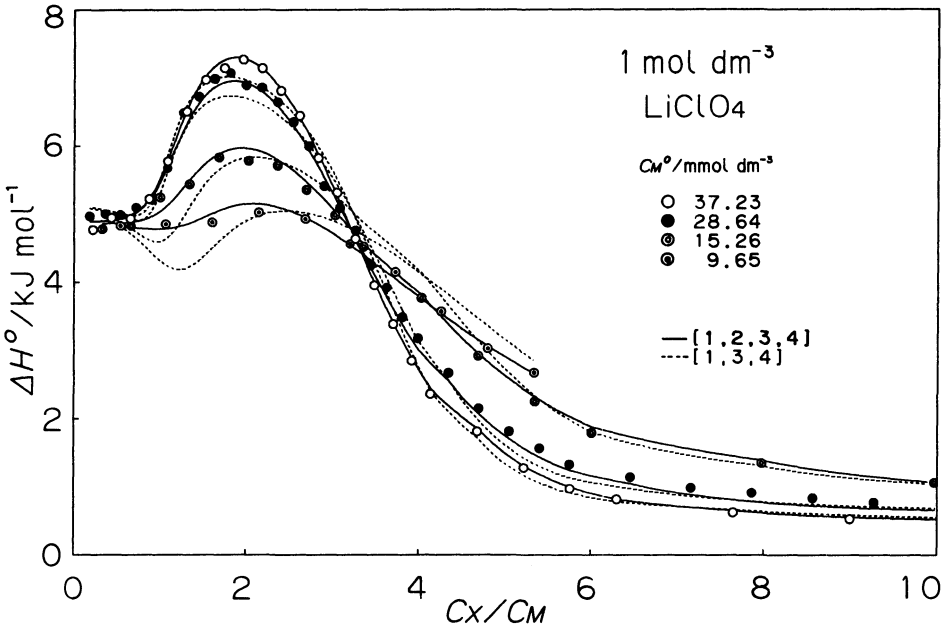

Fig. 2. Calorimetric titration curves of copper(II) chloride DMSO solutions containing 1 mol dm^{-3} $LiClO_4$ at 25 °C. Initial concentrations of copper(II) perchlorate (C°_M/mmol dm^{-3}) are given in the figure. The solid and broken lines show the theoretical curves calculated by using the constants of the sets (1—4) in Table 2 and the set (1, 3, 4), respectively.

The calorimetric data were analyzed by assuming several sets of mononuclear complexes. Among these sets examined, the set (1—4) assuming the formation of $[CuCl_n]^{(2-n)+}$ (n=1, 2, 3, and 4) gave the minimum error-square sum. However, since the $\Delta H^{\circ}_{\beta 4}$ value showed a rather large standard deviation, the $[CuCl_4]^{2-}$ complex may not appreciably form in the solution. Therefore, the set (1—3) eliminating $[CuCl_4]^{2-}$ was also examined for comparison. As seen in Fig. 1 by the broken lines, the theoretical curves calculated by using the constants of the set (1—3) in Table 1 ill fitted the experimental points, and thus it was concluded that the $[CuCl_4]^{2-}$ complex must not be neglected. In fact, as seen in Fig. 1 by the solid lines, the experimental points well fell on the theoretical curves when the four $[CuCl_n]^{(2-n)+}$ (n=1—4) complexes were taken into account. Electronic spectra measured in the solution were also indicated the formation of the four complexes and their formation constants evaluated were similar to those obtained by calorimetry.

The result of the least-squares refinement of the calorimetric and spectrophotometric data in the $LiClO_4$ DMSO solution are summarized in Table 2. In the solution, the formation constants and enthalpies of all the $[CuCl_n]^{(2-n)+}$ (n=1—4) complexes were determined with sufficient accuracy by both calorimetry and spectrophotometry. According to the result obtained by Elleb et al.[2] in the same solution by spectrophotometry, the formation of $[CuCl_2]$ was not conclusive. In fact, the distribution of species calculated by using the formation constants of the complexes in Table 2 indicated that the degree of formation of $[CuCl_2]$ was rather small. Thus, the refinement of the calorimetric data was also carried out for the set (1, 3, and 4) by eliminating the neutral complex. However, as seen in Fig. 2, the theoretical curves for the set (1—4) given by the solid lines well reproduced the experimental points, while those for the set (1, 3, and 4) shown by the broken lines ill

Values in parentheses refer to standard deviations. a) The formation of LiCl ion-pairs is taken into consideration: $\log K_{ip}=0.25$, $\Delta H^\circ_{ip}=8.5$ kJ mol^{-1}. b) The number of data points. The formation constants by spectrophotometry were obtained by using absorbance data at 30 different wavelengths. c) The error-square sum. d) The Hamilton R-factor.

fitted the experimental points, implying that the $[CuCl_2]$ complex should not be neglected. The formation constants were also evaluated from the spectrophotometric data, which were similar to those obtained by calorimetry as well.

As seen in Tables 1 and 2, a significant difference was found between the corresponding quantities in the $(C_2H_5)_4NClO_4$ and $LiClO_4$ solutions. It has been so far suggested that lithium chloride forms contact ion-pairs in DMSO,[14-16] although it is ambiguous.[17] Besides, in contrast to the $(C_2H_5)_4NClO_4$ DMSO solution, significant heats of dilution were observed when the LiCl DMSO solution was added to a DMSO solution of the relevant ionic medium. Therefore, it was expected that the LiCl contact ion-pairs appreciably formed in the LiCl titrant solution, and its formation constant and enthalpy, $\log(K_{ip}/\text{mol}^{-1}\text{dm}^3)=(0.25\pm0.07)$ and $\Delta H^\circ_{ip}=(8.5\pm0.6)$ kJ mol^{-1} (the uncertainties refer to standard deviations), respectively, were estimated by analyzing the heats of dilution of the LiCl titrant solution. Then, a further analysis of the calorimetric and spectrophotometric data obtained in the $LiClO_4$ DMSO solution was performed by knowing amount of LiCl ion-pairs formed in the solution. The formation constants and enthalpies of formation of $[CuCl_n]^{(2-n)+}$ (n=1—4) thus corrected for the formation of LiCl ion pairs are also listed in Table 2, the stepwise $\log(\beta_n/\beta_{n-1})$ values being practically the same as the corresponding values in the $(C_2H_5)_4NClO_4$ DMSO solution. Thus, it is concluded that an extensive formation of LiCl ion-pairs reduces the concentration of free chloride ions, which reflects on the unfavorable complexation of copper(II) with chloride ions in the $LiClO_4$ DMSO solution compared to that in the $(C_2H_5)_4NClO_4$ DMSO solution.

Figure 3 shows the distribution of species of the copper(II) chloro complexes in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMSO solution (the upper figure by the solid lines) and 1 mol dm^{-3} $LiClO_4$ DMSO solution (the lower figure). The distribution of species corrected for the formation of LiCl ion-pairs in the $LiClO_4$ solution is also depicted (the upper figure by the broken lines), which is similar to that in the $(C_2H_5)_4NClO_4$ solution.

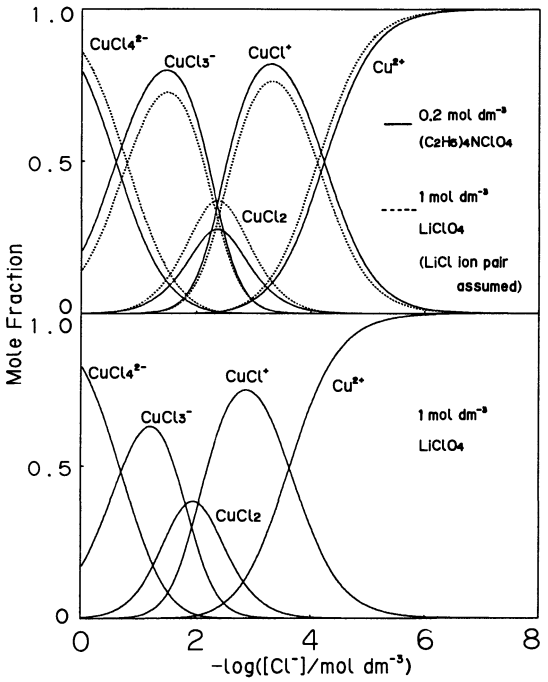

Fig. 3. Distribution of species of the copper(II) chloro complexes in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMSO solutions. The distribution of species in the $LiClO_4$ DMSO solution corrected for the formation of LiCl ion-pairs is depicted by the broken lines.

Thermodynamic quantities, $\log(K_n/\text{mol}^{-1}\text{dm}^3)$, ΔG°_n/kJ mol^{-1}, ΔH°_n/kJ mol^{-1} and ΔS°_n/J K^{-1} mol^{-1}, for the stepwise formation of $[CuCl_n]^{(2-n)+}$ in DMSO are summarized in Table 3, together with those in DMF for comparison.[1]

Formation of Copper(II) Chloro Complexes. As seen in Table 3, the thermodynamic quantities of formation of the copper(II) chloro complexes in DMSO are, in general, similar to those in DMF, as expected from strong donicities and relatively weak acceptor abilities of both solvents.[8] As well as in DMF, the positive ΔH_n° (n=1—3) values were observed in DMSO, indicating that copper(II) ion is strongly solvated in these solvents. It was found that the ΔH_n° (n=1—3) values changed in the sequence $\Delta H_1^\circ<\Delta H_2^\circ<\Delta H_3^\circ$ in DMSO but in the sequence $\Delta H_1^\circ>\Delta H_2^\circ>\Delta H_3^\circ$ in DMF. The Cu–Cl bonds are weaken within a higher $[CuCl_n]^{(2-n)+}$ complex and solvation energies of $[CuCl_n]^{(2-n)+}$ (n=1—3) become weaker with n due to an electron donation from chloride ions to the metal ion. The different trend of ΔH_n° (n=1—3) in DMSO and DMF suggests that weakening of the metal-solvent bonds within $[CuCl_n]^{(2-n)+}$ (n=1—3) with n occurs in a different manner in these solvents. The negative ΔH_4° value observed in DMSO suggests that the metal-solvent bond is very weak within $[CuCl_3(dmso)]^-$, and $[CuCl_4]^{2-}$ is not solvated in the first coordination sphere of the metal ion, the structure of the complexes being discussed in the later section.

In previous papers,[1,6] we discussed the entropies of formation of the copper(II) chloro complexes in DMF and acetonitrile in relation to the solvent-solvent interactions in the bulk. The positive and large ΔS_n° (n=1—3) values observed in DMSO suggests that DMSO molecules solvating copper(II) and chloride ions are liberated from the coordination shells of the ions, and enter the bulk solvent with a relatively high freedom.[18] However, comparing the entropy changes in DMSO (corrected for the formation of LiCl ion-pairs) with those in DMF, the ΔS_n° (n=1 and 2) values, as well as $\Delta S_{\beta 4}^\circ$, in DMSO are appreciably smaller than the corresponding ones in DMF. This suggests that the solvent-solvent interaction in DMSO is significantly different from that in DMF. It has been so far pointed out that DMSO is a highly associated liquid,[9] and DMSO oligomers are formed even in dilute DMSO solutions of benzene,[19] while DMF has only weak intermolecular interactions in the liquid state.[10] Therefore, less entropies of formation of the complexes in DMSO are attributable to larger entropy losses of the solvent molecules at entering the structured bulk phase from the coordination sphere as compared with the case of DMF which has a random intermolecular structure in the bulk. In contrast to large difference in $\Delta S_{\beta 4}^\circ$ in DMSO and DMF, the $\Delta H_{\beta 4}^\circ$ value in DMSO was even more positive than that in DMF. Thus, we propose that the effect of solvent-solvent interactions in the bulk on the thermodynamic quantities of formation of complexes in aprotic solvents reflects mainly on the entropy changes.

Thermodynamic Quantities of Transfer from *N,N*-Dimethylformamide to Dimethyl Sulfoxide. By measuring heats of solution of anhydrous $CuCl_2$ in DMSO, the enthalpies of solution for the following processes were evaluated:[6]

$$CuCl_2(c) = Cu^{2+}(s) + 2Cl^-(s);\ \Delta H_s^\circ(Cu^{2+}, 2Cl^-), \quad (1)$$

$$CuCl_2(c) = CuCl_2(s);\ \Delta H_s^\circ([CuCl_2]), \quad (2)$$

where c and s stand for the crystalline and solution states, respectively. Since the $\Delta H_s^\circ(Cu^{2+}, 2Cl^-)$ and $\Delta H_s^\circ([CuCl_2])$ values have been determined in DMF,[6] the enthalpy of transfer of copper(II) ion from DMF to DMSO, $\Delta H_t^\circ(Cu^{2+})$, was evaluated by knowing the $\Delta H_t^\circ(Cl^-)$ value from the literature:[20]

$$\Delta H^\circ_{s,DMSO}(Cu^{2+},2Cl^-) - \Delta H^\circ_{s,DMF}(Cu^{2+},2Cl^-) = \Delta H_t^\circ(Cu^{2+}) + 2\Delta H_t^\circ(Cl^-). \quad (3)$$

Similarly, the enthalpies of transfer of $[CuCl_n]^{(2-n)+}$ from DMF to DMSO, $\Delta H_t^\circ([CuCl_n]^{(2-n)+})$, were obtained from the relation:

$$\Delta H^\circ_{\beta n,DMSO} - \Delta H^\circ_{\beta n,DMF} = \Delta H_t^\circ([CuCl_n]^{(2-n)+}) - \Delta H_t^\circ(Cu^{2+}) - n\Delta H_t^\circ(Cl^-), \quad (4)$$

since all the values except for $\Delta H_t^\circ([CuCl_n]^{(2-n)+})$ have been known.

The Gibbs energies of transfer, $\Delta G_t^\circ([CuCl_n]^{(2-n)+})$ from DMF to DMSO were calculated by using the relation similar to Eq. 4 on the basis of the known $\Delta G_t^\circ(Cu^{2+})$ and $\Delta G_t^\circ(Cl^-)$ values from the literature.[11,12] The results are summarized in Table 4, together with the corresponding ΔS_t° values calculated from the ΔG_t° and ΔH_t° values.

The negative $\Delta H_t^\circ(Cu^{2+})$ value from DMF to DMSO may be attributable to the slightly larger donicity of DMSO than that of DMF.[8] Since the $\Delta H_t^\circ(Cl^-)$ value is also negative, the negative $\Delta H_t^\circ([CuCl_n]^{(2-n)+})$ values are expected from the view-point of both metal-solvent and ligand-solvent interactions of each complex.

The $\Delta G_t^\circ(Cu^{2+})$ value is more negative than $\Delta H_t^\circ(Cu^{2+})$ due to the largely positive $\Delta S_t^\circ(Cu^{2+})$ value. The ΔS_t° values of all the $[CuCl_n]^{(2-n)+}$ (n=1—4) complexes are positive. However, such positive ΔS_t° value from DMF to DMSO can hardly be explained in terms of the solely different donicities of these solvents, because the ΔS_t° values of the $[CuCl_n]^{(2-n)+}$ complex from acetonitrile to DMF, these solvents having largely different donicities, are close to zero.[6] The significantly positive $\Delta S_t^\circ([CuCl_n]^{(2-n)+})$ (n=1—4) values from DMF to DMSO may be ascribed to the difference in their intermolecular interactions in the bulk. When we consider the process of solvation of an ion which is transferred from vacuum to a solvent, the entropy of solvation of an ion, ΔS°_{solv}, should be negative as the result of formation of the solvation sphere. The stronger the metal-solvent bonds, the more negative value of ΔS°_{solv} may result. However, at the formation of solvation shell, solvent-solvent interactions in the bulk must be partially broken, and this process gives a positive value of entropy change. The more the association of solvent molecules in the bulk, the larger the positive entropy change is at the breaking of intermolecular interactions. Accordingly, the ΔS_t° value of an ion may be largely positive when the ion is transferred from a solvent randomly distributed to that associated, as such a case of transferring ions from acetonitrile to water.[21] Since DMSO has a long range intermolecular interactions,[9] and easily associates,[19] the large and positive ΔS_t° values of transfer of $[CuCl_n]^{(2-n)+}$ (n=0—4), as well as $\Delta S_t^\circ(Cl^-)$, from DMF to DMSO can be explained in terms of the different intermolecular interactions in the bulk phase.

Table 4. Thermodynamic Quantities of Transfer, ΔG_t°/kJ mol^{-1}, ΔH_t°/kJ mol^{-1} and ΔS_t°/J K^{-1} mol^{-1}, of $[CuCl_n]^{(2-n)+}$ from *N,N*-Dimethylformamide to Dimethyl Sulfoxide at 25 °C

	ΔG_t°	ΔH_t°	ΔS_t°

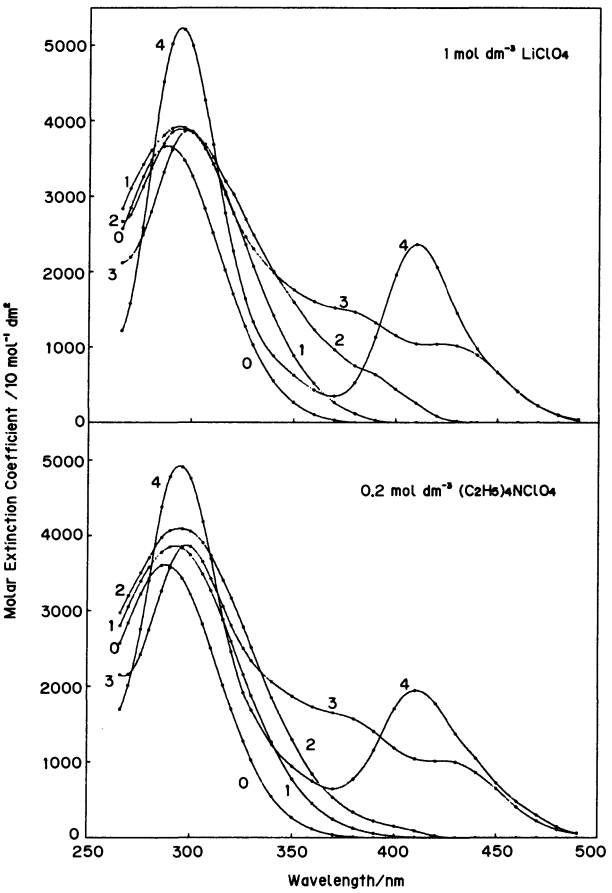

Fig. 4. Electronic spectra of individual copper(II) chloro complexes in the range 250—500 nm obtained in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMSO solutions. The numbers represent n within $[CuCl_n]^{(2-n)+}$.

Electronic Spectra of Copper(II) Chloro Complexes. Together with the formation constants, electronic spectra of individual copper(II) chloro complex-

es were extracted by resolving the spectra measured at various C_X/C_M ratios in the 0.2 mol dm^{-3} $(C_2H_5)_4NClO_4$ and 1 mol dm^{-3} $LiClO_4$ DMSO solutions and represented in Fig. 4 over the range 250—500 nm.

As well as in DMF,[1] electronic spectra of each $[CuCl_n]^{(2-n)+}$ complex obtained are practically independent of ionic media, indicating that the structures of each complex obtained are not influenced by the medium salts.

As to Cu^{2+}, $[CuCl]^+$ and $[CuCl_2]$, the absorption maximum of each species in DMSO is appreciably shifted to a longer wavelength than that in DMF, suggesting that these species are differently solvated with DMSO and with DMF. In contrast, the electronic spectra of $[CuCl_3]^-$ and $[CuCl_4]^{2-}$ in DMSO are very similar to those of relevant species in DMF,[1] and thus the metal-solvent interaction in these solvent may be very weak. According to X-ray diffraction measurements for DMF solutions of copper(II) chloride,[22] the $[CuCl_4]^{2-}$ complex has a distorted tetrahedral structure and no solvent molecule is directly coordinated to the central metal ion, and the $[CuCl_3]^-$ complex has an additional DMF molecule to form a distorted tetrahedral structure and thus the complex should be described as $[CuCl_3(dmf)]^-$. The Cu–dmf bond within $[CuCl_3(dmf)]^-$ is weaker as indicated by its longer bond-length (230 pm) than the Cu–dmf(eq) bond (201 pm) within $[Cu(dmf)_6]^{2+}$. The similar electronic spectra of $[CuCl_3]^-$ and $[CuCl_4]^{2-}$ in DMSO and in DMF suggest that these complexes have practically the same structures in both solvents and the Cu–dmso bond within $[CuCl_3(dmso)]^-$ may be as weak as the Cu–dmf bond within $[CuCl_3(dmf)]^-$.

Crystal Structure and Molecular Motion of Tetramethylammonium Hexaiodotellurate(IV)-Iodine (1/1) Compound

Hideko KIRIYAMA* and Kyoko NISHIZAKI
Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657
(Received March 31, 1986)

The crystal structure of the title compound was determined by means of X-ray diffraction. The crystal data and the final R value are: $[(CH_3)_4N]_2TeI_6 \cdot I_2$, tetragonal $I4_1/acd$, a=20.356 (3) and c=27.571 (5) Å, V=11,424 (3) Å^3, Z=16, R=0.082 for 1562 observed unique reflections. The structure consists of discrete $[TeI_6]^{2-}$ anions and Me_4N^+ cations in an arrangement analogous to the K_2PtCl_6 structure and of additional I_2 molecules bridging adjacent complex anions. The TeI_6 octahedron is considerably distorted with Te-I distances of 2.933 (2), 3.017 (2), and 2.857 (2) Å, owing to different interaction with the surrounding I_2 molecules. Two of three independent Me_4N^+ cations are orientationally disordered and distributed over each two positions. A phase transition was found at 234 K from DTA and its molar enthalpy was estimated to be approximately 2.4 kJ mol^{-1} from DSC. Proton NMR studies offered direct evidences for threefold reorientation of CH_3 groups and overall rotation of Me_4N^+ cations taking place consecutively far below room temperatures. At 234 K the spin-lattice relaxation time T_1 changes discontinuously by about one order of magnitude, suggesting the first order of transition. The activation energies of such composite reorientation in the fast regions ($\omega\tau_c \ll 1$) are 5.4 and 14.2 kJ mol^{-1} in the high- and low-temperature phases, respectively.

A large family of methylammonium hexahalometallate(IV) complexes, $[(CH_3)_nNH_{4-n}]_2MX_6$ where M=Pd, Pt, Sn, Te, X=Cl, Br, I, and n=1, 2, 3, 4 exhibit one or more phase transitions associated with molecular motion of cation groups or complex anions.[1,2] Most of them have the typical K_2PtCl_6 type structure, but some tellurate complexes of the series, especially their iodo analogues, are characterized by the unique structures different from the others.[3,4] In order to develop our study on methylammonium hexaiodotellurate(IV), $[(CH_3)_nNH_{4-n}]_2TeI_6$, the complex for n=4 was tried to prepare, but the obtained crystals did include extra iodine atoms, as encountered in $(Me_3NH)_2TeI_7$.[4] The crystal structure of the resulting octaiodotellurate complex was determined by X-ray diffraction methods to elucidate the role of extra iodine atoms and the dynamic process of cations was revealed by ^{1}H NMR experiments to connect with the phase transition newly found.

Experimental

Preparation. A saturated aqueous solution of tetramethylammonium iodide added dropwise with stirring into a hydrogen iodide solution of tellurium dioxide in a stoichiometric molar ratio yielded black precipitates. The product showed broad X-ray powder patterns because of its poor crystallinity. Most of the reflections could be roughly indexed on the basis of a cubic K_2PtCl_6 cell (space group $Fm3m$) with a=14.2 Å, but some of them remained unindexed. In order to obtain single crystals suitable for X-ray use, the precipitate was dissolved into a hot, dilute (ca. 3%) HI solution and black cubooctahedron-like crystals were grown from the filtrate. These crystals were identified with the source material from the X-ray powder patterns and confirmed to be $(Me_4N)_2TeI_8$ by chemical analyses. Unlike $(Me_3NH)_2TeI_7$, the recrystallization from an HI solution did not change the chemical constitution, therefore the original precipitate also being not hexaiodide but octaiodide.

X-Ray Structure Determination. The density was measured by pycnometry with o-xylene at 20°C; the lattice parameters and the space group were previously determined with a Weissenberg camera, reflection conditions hkl: $h+k+l=2n$, $hk0$: $h,k=2n$, $0kl$: $k,l=2n$, hhl: $2h+l=4n$, $00l$: $l=4n$ leading to $I4_1/acd$; crystal 0.2×0.2×0.25 mm^3 in size was mounted with c coincident with the goniostat axis; Rigaku AFC-4 diffractometer, graphite-monochromated Mo $K\alpha$ radiation (λ=0.7107 Å), 40 kV-200mA; unit cell parameters were refined by least-squares method using 25 2θ values ($20° < 2\theta < 24°$); intensity measurement was made up to 2θ =55° ($0 \le h \le 18$, $0 \le k \le 26$, $0 \le l \le 34$), ω—2θ scan technique, all intensities monitored by three standard reflections (0, 0, 16; 6, 4, 10; 800) every 50 reflections throughout experiments; 3629 unique reflections were measured. 1569 reflections classified as observed [$|F_o| > 3\sigma(F_o)$] used for the structure determination; Lorentz-polarization factors and absorption were corrected, empirical correction factors on F 0.996—1.091;[5] the possible positions of Te and I deduced from the E map were confirmed by the Patterson function, starting with these positions the other non-hydrogen atoms located on electron density maps, the structure refined by full-matrix least-squares on F with anisotropic thermal parameters for Te and I, and isotropic ones for N and C; H atoms were not found in difference maps and omitted in refinement, $\sum w(|F_o| - |F_c|)^2$ minimized for 72 parameters, seven reflections with low angles and strong intensities removed to avoid possible extinction effects, $w = [\sigma^2(F_o)]^{-1}$; final R=0.082, R_w=0.056 and goodness of fit S=1.86 for unique 1562 reflections, $(\Delta/\sigma)_{max}$=0.48 for Te and I, but 2.28 for C and N, maximum positive and negative electron densities, $(\Delta\rho)_{max}$ and $(\Delta\rho)_{min}$, in final difference fourier syntheses 1.90 and −2.52 e Å^{-3}, respectively.

Neutral atom scattering factors and anomalous dispersion terms were taken from International Tables for X-Ray Crystallography.[6] UNICS Program System,[7] Finger Computing System,[8] and their modifications were used for calculations at the Computation Center, Osaka University and later at the Information Processing Center, Kobe University.

Crystal Data: $[(CH_3)_4N]_2TeI_6 \cdot I_2$, F.W.=1291, tetragonal, space group $I4_1/acd$, a=20.356(3), c=27.571(5) Å, V=11,

424 Å^3, D_m(20°C)=3.01, D_x(20°C)=3.00 Mg m^{-3}, Z=16, F(000)=8992, μ(Mo $K\alpha$)=9.6 mm^{-1}.

Proton NMR Experiments. For NMR measurements, the polycrystalline sample was sealed in a glass tube with a small amount of helium gas for heat exchange. The continuous wave (CW) absorption spectrum was observed with a bridge-type spectrometer (homemade) operated at 19.4 MHz, while the spin-lattice relaxation time T_1 was measured by an induction type of pulse spectrometer (homemade) adjusted at 10.5 MHz. A conventional pulse sequence of $90°_{comb}$-τ-90° or 180°-τ-90° was selectively used. The temperature of the specimen was kept constant within ±0.5 K for the CW experiments and ±1 K for the pulse one. It was measured with a Chromel-Constantan thermocouple above 15 K and with a germanium resistance thermometer or an Au(Fe)-Chromel thermocouple below 15 K.

Thermal Analyses. Differential thermal analysis (DTA) and differential scanning calorimetry (DSC) were carried out with a Rigaku DTA & DSC apparatus. Carbontetrachloride CCl_4 of "extra pure" grade was used as a standard to calibrate the DSC scale.

Results and Discussion

Crystal Structure. The fractional coordinates and isotropic thermal parameters for non-hydrogen atoms are listed in Table 1.[9] The stereoscopic drawing viewed along $\boldsymbol{a}$ and the (001) projection with the atom numbering scheme of the structure are shown in Figs. 1 and 2, respectively.[10] Selected interatomic distances and angles are given in Table 2.

The crystal consists of octahedral anions $[TeI_6]^{2-}$, cation group Me_4N^+ and iodine molecules. The large unit cell as well as the large Z number causes the structure to appear much complicated. However, the principle of the structure is rather simple and adequately described in terms of the K_2PtCl_6 structure, when the tetragonal deformation arising from the inclusion of dumbbell like I_2 molecules and also slight displacements of all constituents are neglected. As shown in Fig. 2, the tetragonal subcell with $\boldsymbol{a}_s=(\boldsymbol{a}+\boldsymbol{b})/2$(=14.39 Å), $c_s=c/2$ (=13.79 Å) and Z_s=4 is closely related to the antifluorite structure. Octahedral $[TeI_6]^{2-}$

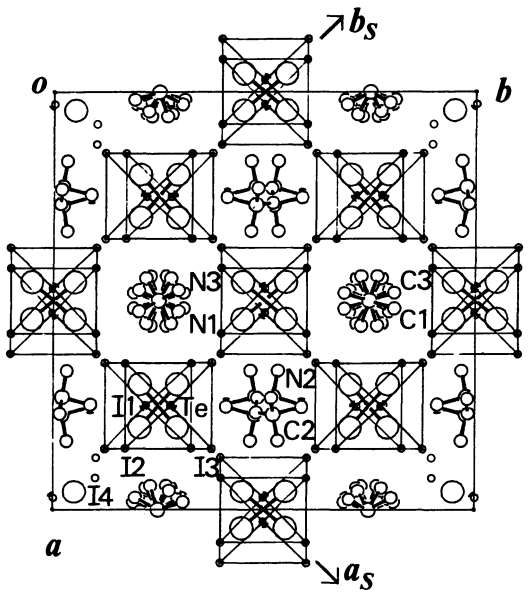

Fig. 2. The projection of the structure along [001] with the atom numbering scheme. Only one orientation for each disordered cation is shown. Atom symbols, for example, I1 denotes I(11) and C2 represents C(21), C(22) and C(24) as listed in Tables 1 and 2.

anions form a tetragonally deformed, face-centered lattice and Me_4N^+ cations occupy the eight tetrahedral holes. The subcell further contains I_2 molecules aligned parallel to a_s or b_s axis at the interstitial sites of twelve edge-centers (1/2, 0, 0) etc. and one body-center (1/2, 1/2, 1/2). Thus, the iodine molecule bridges adjacent complex anions.

Each Te^{IV} atom is coordinated octahedrally by six iodine atoms with Te–I distances of 2.933(2), 3.017(2), and 2.857(2) Å. The average value 2.94 Å is close to the typical one of 2.952(2) Å found in $(Me_3NH)_2TeI_6$.[4] The individual Te–I distances, however, are significantly different from one another, reflecting a variety of interactions with the surroundings. The arrangement of six iodine molecules around a central TeI_6 octahedron is illustrated in Fig. 3. The Te–I(2) bond is parallel to the axis of the neighboring I_2 molecule, while the other two Te–I(1) and Te–I(3) bonds are perpendicular to them. The axial I(1) atom is surrounded by two I(4) atoms with distances of 4.085(3) and 4.376(3) Å. The equatorial I(2) is close to only one I(4) atom with the shortest intermolecular I···I distance 3.261(2) Å, this being much shorter than the corresponding one (3.57 Å) in iodine crystal.[11] The remaining equatorial I(3) has also two I(4) neighbors at distances of 4.132(2) and 4.172(2) Å. A comparison of these I···I separations with the van der Waals contact 4.3 Å suggests that a remarkable interaction such as charge transfer occurs between I(2) and I(4). For this reason the Te–I(2) distance is lengthened than the normal 2.95 Å and consequently the Te–(3) bond may be shortened by some trans effect.

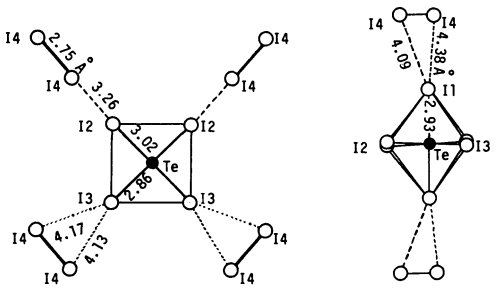

Fig. 3. The arrangement of six I_2 molecules around a central TeI_6 octahedron, (a) viewed along *c*, and (b) viewed along *b* (=*a*).

On the other hand, the intramolecular I–I length 2.748(3) Å is longer than 2.68 Å found in solid iodine. All these facts indicate that the intermolecular I···I interaction is fairly strong in the octaiodo complex relative to iodine crystals. The present X-ray analysis showed that excess iodine atoms are included as iodine molecules in contrast to $(Me_3NH)_2TeI_7$ complex where excess iodine atoms are held together as infinite linear chains.[4] To the best of our knowledge the present complex is the first example for inclusion of iodine molecules in the series of hexaiodometallate(IV) complexes.

There are three kinds of Me_4N^+ cations which are denoted by their central nitrogen atoms in Fig. 2. The N(1), N(2), and N(3) atoms are located at **8b**(222), **16f**(2), and **8a**(4) positions of $I4_1/acd$, respectively. The cation of N(3) is ordered, whereas those of N(1) and N(2) are orientationally disordered and distributed over each two configurations with the equal probability 0.5. Thus, the occupancy factors of their methyl carbons are 1 for C(3) and 0.5 for the other six from C(11) to C(24). Although the positional parameters of such disordered methyl carbons are less reliable than the ordered ones, the assigned geometry for each cation group appears to be reasonable. The mean C–N distances and the mean C–N–C bond angles around N(1), N(2), and N(3) are 1.43, 1.45, 1.49 Å and 109, 109, 112°, respectively, in agreement with 1.47 Å and the tetrahedral angle in the literature.

Phase Transition. The DTA and NMR results showed that the crystal undergoes a phase transition at 234 K, like some other members of the family. The transition enthalpy was determined approximately to be 2.4 kJ mol^{-1} from DSC. Recently, Matsuo et al. reported the transition enthalpy 1.78 kJ mol^{-1} for $(CH_3NH_3)_2SnCl_6$,[12] where no structural change was disclosed except for slight discontinuities in some lattice parameters.[13] Accordingly, the structural change caused by the transition would not be so much in the octaiodo complex also.

Dynamic Behavior of Me_4N^+ Cation Groups. The ^1H NMR spectra at the lowest temperatures of measurement showed a fine structure characteristic of the static array of nuclei, and it remained fairly well

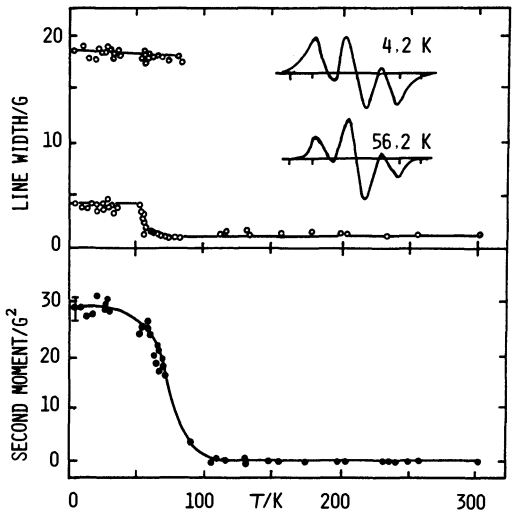

Fig. 4. The temperature dependences of ^{1}H NMR line width and second moment observed for $[(CH_3)_4N]_2TeI_8$.

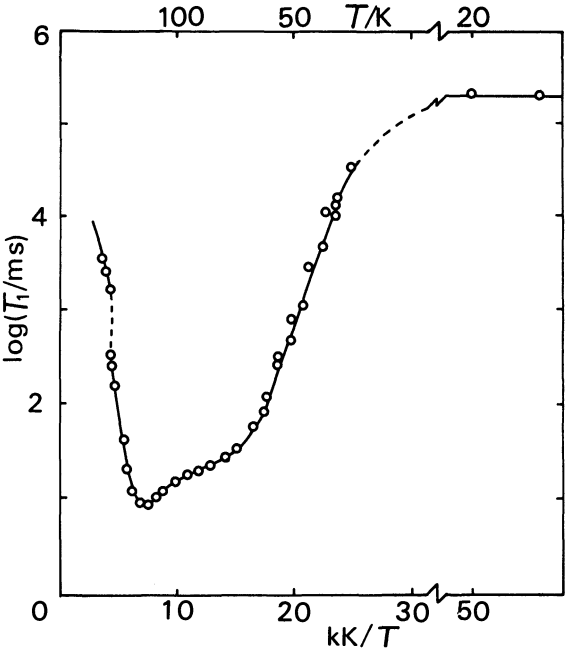

Fig. 5. The temperature variation of proton T_1 measured at 10.5 MHz for $[(CH_3)_4N]_2TeI_8$.

up to about 50 K. The line width δH_{msl} measured on the absorption derivative and the observed second moment M_2 are plotted against temperature in Fig. 4. From liquid helium temperature to 30 K δH_{msl} were 18.4±0.1(outer) and 4.0±0.1 G(inner), and M_2 was 29±2 G^2, these being close to the rigid lattice values expected for Me_4N^+ cations.[14] The spectrum was narrowed strongly between 50 and 100 K, above which the line width and the second moment were again constant at 1.5±0.1 G and 0.5±0.1 G^2, respectively. The M_2 values for various dynamic models of Me_4N^+ cations were calculated in the usual manner based on Van Vleck formula: M_2=30 G^2 for the rigid lattice; M_2=9 G^2 for the threefold reorientation of all CH_3 groups; M_2=0.5 G^2 for the isotropic reorientation of whole cations. In these calculations, the geometry of the cation was taken to be tetrahedral 109°28′ for all the bond angles, 1.47 Å for the C–N bond length and 1.10 Å for the C–H length in all-staggered conformation.[15] A comparison of these calculated values with the experimental ones indicates that all the Me_4N^+ cations reorient rapidly and isotropically far below room temperatures. As seen in Fig. 4, the narrowing process occurs in only a single step, suggesting the three fold reorientation of methyl groups consecutively followed by the overall reorientation of the cations itself.

The spin-lattice relaxation times are plotted in Fig. 5 against reciprocal temperatures. As described previously, the T_1 value changed discontinuously by one order of magnitude at 234 K, indicating the presence of a phase transition which was confirmed by thermal analyses. The T_1 vs. T^{-1} curve exhibits a deep and very broad minimum with a value of 8.5 ms at 133 K. The appearance of a shoulder on the low temperature side of the T_1 minimum may be due to reorientation of methyl groups. However, the T_1 value of the shoulder is longer than that of T_1 minimum in contrast with the usual behavior of methylammonium groups.[16] It is therefore supposed that three or more nonequivalent Me_4N^+ cations set in motion with slightly different motional parameters in the low temperature phase, causing the T_1 minimum to be shallow and consequently to be quite broad. Such a T_1 behavior seems too complicated to analyze, because of many unknown parameters included. Therefore, the activation energy for the threefold (C_3) reorientation of CH_3 groups was tentatively deduced from the positive slope ($\omega\tau_c \gg 1$) in the low temperature side of the T_1 minimum, while the value for the overall reorientation of whole cations from the negative slope ($\omega\tau_c \ll 1$): These are 6.3 and 14.2 kJ mol^{-1}, respectively. The similar T_1 minima were observed in analogous complexes of $(Me_4N)_2MX_6$ (M=Pt, Te, Sn, X=Cl, Br), and each shallow minimum in the low temperature side was successfully explained in terms of a small-angle reorientation of methyl groups of the cations.[17,18] It is not clear whether or not this is the case in the present complex, because of no sufficient evidence for it and also of unusual breadth of the T_1 minimum in comparison with those for the other analogues.

Above T_{tr} (234K), the negative slope of the T_1 curve gives the activation energy 5.4 kJ mol^{-1} for the composite reorientation of cations, which is much smaller than the corresponding value 14.2 kJ mol^{-1} below T_{tr}, reflecting more loose packing in the high temperature phase. This finding together with the discontinuity of T_1 at T_{tr} suggests that the reorientational motion of the cations is associated with the phase transition more or less.

The authors wish to express their thanks to Dr. Yuriko Yamagata for her help in part of the X-ray work and also to Dr. Taisei Yamanoto for the CW NMR data collection.

N-Hydroxy Amides. IV.[1] Synthesis and Properties of a Trihydroxamic Acid Anilide as a Model for Ferrioxamines

Kazuyuki SHIMIZU, Kazuyuki NAKAYAMA, and Masayasu AKIYAMA*
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received October 11, 1985)

A trihydroxamic acid having a 6-aminohexanoyl-3-(hydroxyamino)propanoyl sequence has been synthesized in a stepwise manner, starting with glycinanilide. The trihydroxamic acid anilide bears a good structural resemblance with *N*-benzoyl-deferriferrioxamine B (Benzoyl-DFB). A plot of the absorbance vs. the molar ratio of iron(III) to the hydroxamate group indicates the formation of a 1 : 1 intramolecular iron(III) complex for the trihydroxamic acid anilide and Benzoyl-DFB. Cyclic voltammetry also shows that the iron complexes of both compounds have similar electrochemical properties. A solid iron(III) complex was obtained when the trihydroxamic acid anilide was mixed with tris(2,4-pentanedionato)iron(III) in methanol.

There is a growing interest in natural and synthetic iron sequestering agents.[2-6] Ferrioxamines, an important class of microbial iron-transporting compounds (siderophores), are stable octahedral iron(III) complexes of linear and cyclic trihydroxamic acids (deferriferrioxamines). They show unique biological activities, such as antibiotics and growth factors.[2,4,7-9] A characteristic structural feature for these trihydroxamic acids is a repeating unit comprising 5-hydroxyamino-1-pentanamine and succinic acid.[2,8] Deferriferrioxamine B (DFB) is used as a drug for the treatment of an iron-overload disease in humans.[4,5,8,10] In this respect, it is of interest for designing and synthesizing trihydroxamic acids of a similar nature but of different molecular compositions as a model and for comparing the important properties, such as iron(III) complex formation and the electrochemical behavior between these synthetic and natural compounds.

A previous paper reported on a synthesis of an *N*-hydroxy hexapeptide anilide containing three hydroxamic acid units in the chain.[11] The hexapeptide anilide showed a rather weak iron(III) bond, owing to the close spacing between hydroxamate groups. In an attempt to provide compounds that firmly hold iron(III), the synthesis of a linear oligoamide having a 6-aminohexanoyl-3-(hydroxylamino)propanoyl sequence has been made. This paper describes the results together with an examination of iron(III) binding properties.

Results and Discussion

Synthesis. A trihydroxamic acid carrying an anilide terminal was synthesized by the reactions shown in Scheme 1. The anilide derivative was chosen in order to obtain a series of compounds as crystals. Thus, glycinanilide was coupled with *p*-nitrophenyl 3-(benzyloxyamino)propanoate H-(BzlO)Apr-ONp[12] to give *N*-[3-(benzyloxyamino)propanoyl]glycinanilide (**1**). The terminal *N*-benzyloxyamino group of **1** was acylated with 6-(Boc-amino)hexanoic acid (Boc-Ahe-OH) by a mixed anhydride procedure to give compound (**2**). The low nucleophilicity of the benzyloxyamino group allowed us to use a *p*-nitrophenyl ester without *N*-protection;[11] yet, the same benzyloxyamino group had a sufficient activity to attack a mixed anhydride. A repeated-acylation technique, needed to couple *N*-benzyloxy α-amino acid derivatives,[11] was unnecessary for the benzyloxy-β-alanyl unit. The ease of acylation is ascribed to less steric constraint around the nitrogen atom, relative to

Benzoyl-DFB

that of *N*-benzyloxy α-amino acid derivatives.[11]

A reaction cycle involving the acylation of the benzyloxyamino group with a mixed anhydride of Boc-Ahe-OH and a subsequent deprotection of the Boc-group, followed by another acylation with H-(BzlO)Apr-ONp, gave compounds **1**, **2**, **3**, **4**, and **5** in good yields. The cycle was terminated at the hexamer stage by use of Ac-(BzlO)Apr-ONp. Column chromatography at each stage provided a pure product. The desired trihydroxamic acid anilide (**6**) was obtained by catalytic hydrogenation[1,13] with Pd-C, followed by column chromatography. IR absorptions for the carbonyl groups were 1670 (sh) (-CONH-) and 1630 cm^{-1} -CON(OH)-, the latter of which is ascribed to the cis configuration.[14] ^1H NMR peaks were observed in the expected regions (Experimental). The compound was soluble in aqueous DMF but insoluble in water and methanol.

As a reference, compound Benzoyl-DFB was prepared according to a method described in the literature.[15] Molecular models reveal that there is a good structural analogy between compound **6** and Benzoyl-DFB; both compounds have a 9-atom spacing between the hydroxamic acid groups[8] and the same 7 atoms exist in the sequence between the phenyl group and the nearest hydroxamic acid moiety. These two compounds show similar solubilities.

Iron(III) Binding. DFB itself has a great affinity for iron(III), forming a 1:1 intramolecular iron(III) complex by the three hydroxamate groups.[8,15] Benzoyl-DFB was reported to form a stable iron(III) complex.[15] The formation constant of a similar complex of Acetyl-DFB[16] is as high as 10^{30}.

The complex-forming tendency of compound **6** was examined in a 50% aqueous DMF solution[17,18] using DFB as a reference compound. Plots of absorbance vs. the molar ratio of iron(III) to the hydroxamic acid groups are shown in Fig. 1. Both compound **6** and Benzoyl-DFB show a sharp inflection at a ratio of 1/3 as DFB does,[17,18] indicating the formation of the expected complex. The complex formation is also supported by its λ_{max} 435 nm and ε 2700, which are close to those of iron(III)-DFB.[16] From these results, the 9-atom spacing seems to be satisfactory for the formation of a stable complex, regardless of the position of the amide groups. In an aqueous DMF solution, a slight increase in the absorbance and a bathochromic shift of λ_{max} were observed in the iron(III) excess region (Fig. 1). Although the reason is still obscure, one explanation is that the spectral

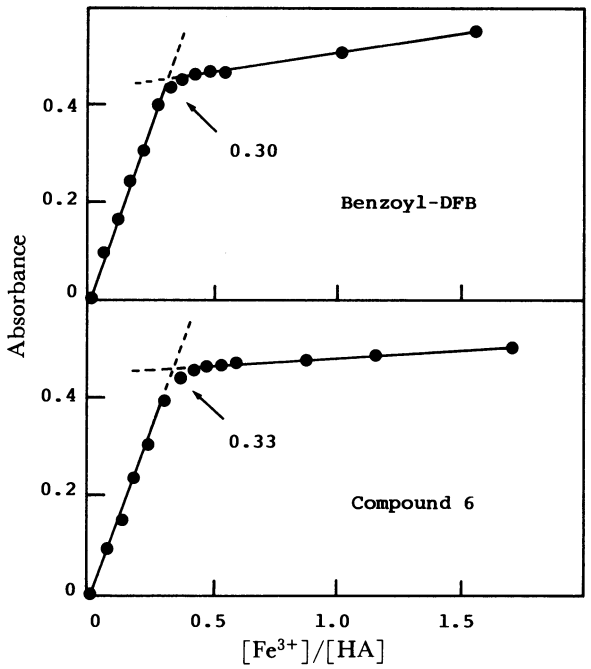

Fig. 1. Absorbance vs. the ratio of iron(III) to the hydroxamic acid (HA) units in 50% aqueous DMF solution at apparent pH=3.0 and 25 °C, ionic strength 0.1 with KNO_3. Absorbance of λ_{max} was determined for Benzoyl-DFB at 430—470 nm and for compound **6** at 423—445 nm.

changes are due to a weak interaction between free, or free and complexed iron(III) and solvent amide groups.[19]

An examination of CPK molecular models of the iron(III) complexes reveals that there are several molecular arrangements leading to a stable complex.[15] When compound **6** was mixed with tris(2,4-pentanedionato)iron(III) in methanol, the compound dissolved readily and an iron(III) complex was formed as a solid when the solvent was evaporated. The complex, soluble in water, showed a visible spectrum similar to that of ferrioxamine B.[16]

Cyclic Voltammetry. In order to determine the usefulness of compound **6** as a siderophore model, it was worthwhile to determine the electrochemical properties of the iron(III) complex. To this end, the cyclic voltammetry was carried out at a neutral pH in an aqueous solution. The results are summarized in Table 1 and some details are given in Table 2. It has been reported that DFB with iron(III) (ferrioxamine B) exhibits a reversible one-electron oxidation-reduction wave at pH 8 when a mercury electrode is used.[20]

Table 1. Results of Cyclic Voltammetry[a]

Ligand	$E_{1/2}$ vs. SCE[b]	ΔE
	mV	mV
DFB	−698[c]	60[c]
	−705	65[d]
Benzoyl-DFB	−710	35
Compound **6**	−703	35

a) Conditions: 0.05 M sodium borate-0.05 M sodium phosphate buffer, pH 8.0; ionic strength 0.5 with 1 M KCl. b) Saturated calomel electrode. c) Ref. 20. d) $i_{pc}/i_{pa}=1.00$.

Table 2. Cyclic Voltammetry Data[a]

Ligand	Scan rate	i_{pc}	i_{pa}	i_{pc}/i_{pa}
	mVs^{-1}	A	A	
Benzoyl-DFB	500	42	29	1.44
	200	21	15	1.40
	100	14	10	1.40
	50	8.5	6.0	1.40
	20	5.5	4.0	1.37
Compound **6**	500	51	38	1.34
	200	26	20	1.30
	100	17	13	1.30
	50	11	8.5	1.29
	20	6	5	1.20

a) Details of the data in Table 1.

Under present conditions with a carbon electrode at pH8, the same compound showed a slightly different value of the peak-to-peak separation (ΔE). The data may be interpreted as indicating a similar reversible redox process since $i_{pa}/i_{pc}=1.0$ and $i_{pc}\propto v^{1/2}$.[21] Half-wave potentials ($E_{1/2}$) obtained for iron(III) with compound **6** and Benzoyl-DFB are very close to that of DFB, as expected from the similar 9-atom spacing; however, the value of the peak-to-peak separation is different from that of DFB. Although a value 35 mV for both compound **6** and Benzoyl-DFB may correspond to a two-electron transfer process, it is improbable that the introduction of a phenyl group in the remote position can change the electron-transfer mode, that is, from a one-electron-transfer to a two-electron transfer. The observed small separation and the deviation of i_{pa}/i_{pc} values from unity for both compound **6** and Benzoyl-DFB are considered rather to be due to a weak adsorption of these ligands to the carbon electrode through phenyl groups; a case of weak adsorption of both reactant and product. A plot of i_{pc} vs. either v or $v^{1/2}$ from the data in Table 2 does not necessarily yield a straight line. A situation is known in which as adsorption occurs the peak separation narrows.[22]

In short, compound **6** and Benzoyl-DFB behave similarly during the formation of an iron(III) complex. Also, the complexes formed show a quasi-reversible redox wave in an electrochemical determination.

Experimental

All the melting points are uncorrected. IR spectra were obtained with a JASCO model A-302 spectrophotometer and ^{1}H NMR spectra were recorded on a JEOL JNM-FX 200 spectrometer with TMS as internal standard. HPLC was carried out with a JASCO model TWINCLE apparatus by using a column packed with a Finepak SIL C_{18}. A microanalysis was performed in the Analytical Section, Institute of Physical and Chemical Research, Saitama. TLC was carried out by using Merck precoated silica gel $60F_{254}$ plates: R_f^1, THF-hexane (5:1); R_f^2, $CHCl_3$-MeOH-C_6H_6 (6:1:3); R_f^3, $CHCl_3$-MeOH (3:1).

The iron(III) complex molar ratio was determined with a Hitachi model 320 spectrophotometer in a 50% aqueous DMF solution, as before.[17,18] 1 M=1 mol dm^{-3}.

H-(BzlO)Apr-Gly-NHPh (1). A solution containing *p*-nitrophenyl 3-(benzyloxyamino)propanoate hydrochloride[12] (2.22 g, 6.3 mmol) and Et_3N (0.64 g, 6.3 mmol) in $CHCl_3$ (15 mL) was added to a solution of glycinanilide hydrochloride (1.18 g, 6.3 mmol) and Et_3N (0.64 g, 6.3 mmol) in $CHCl_3$ (25 mL); the mixture was stirred at 30°C for 48 h. Chloroform (100 mL) was added to this and the $CHCl_3$ layer was washed with aqueous Na_2CO_3 and water, and dried (Na_2SO_4). Evaporation of the solvent gave a crude product (1.91 g, 93%). Purification by column chromatography (Wako gel C-300 with THF-hexane, 3:2 v/v) and reprecipitation from EtOAc-hexane gave a solid, 1.62 g (78%). The hydrochloride of **1** was obtained as crystals by a treatment of the solid with 3.6 M HCl in dioxane, mp 147—148°C: R_f^1=0.54, R_f^2=0.46, R_f^3=0.90. Found: C, 59.23; H, 6.12; N, 11.55%. Calcd for $C_{18}H_{21}N_3O_3$·HCl: C, 59.42; H, 6.10; N, 11.55%.

Boc-Ahe-(BzlO)Apr-Gly-NHPh (2). A mixture of Boc-Ahe-OH (0.783 g, 3.39 mmol) and Et_3N (0.342 g, 3.39 mmol) in THF (20 mL) was chilled at −12°C, and Bu^{t}OCOCl (0.442 g, 3.25 mmol) in THF (5 mL) was added and the mixture was kept at −15°C for 15 min. To this were slowly added HCl·H-(BzlO)Apr-Gly-NHPh (0.986 g, 2.71 mmol) and Et_3N (0.274 g, 2.71 mmol) in $CHCl_3$ (15 mL); the mixture kept for 3 h at −15°C and for 20 h at room temperature. After evaporation of the solvent, the residue was extracted with EtOAc (100 mL), washed with 5% $NaHCO_3$, 5% citric acid, and water, and dried (Na_2SO_4). Evaporation of the solvent gave a crude product, which was purified by chromatography (Wako gel C-300 with $CHCl_3$-MeOH). Recrystallization from THF-Et_2O- petroleum ether gave 1.03 g (70%) of **2**, mp 105—106°C: R_f^1=0.73, R_f^2=0.49, R_f^3=0.94. Found: C, 64.39; H, 7.55; N, 10.30%. Calcd for $C_{29}H_{40}N_4O_6$: C, 64.42; H, 7.46; N, 10.36%.

H-(BzlO)Apr-Ahe-(BzlO)Apr-Gly-NHPh (3). HCl·H-Ahe-(BzlO)Apr-Gly-NHPh was obtained by deprotection of **2** with 3.6 M HCl in dioxane.

A mixture of HCl·H-(BzlO)Apr-ONp (0.12 g, 0.34 mmol) and Et_3N (0.034 g, 0.34 mmol) in DMF (5 mL) was added to a solution containing HCl·H-Ahe-(BzlO)Apr-Gly-NHPh (0.161 g, 0.34 mmol) and Et_3N (0.034 g, 0.34 mmol) in DMF (10 mL); the mixture was stirred for 48 h at 30°C, and evaporated. An extraction of the residue with EtOAc, washing (aqueous Na_2CO_3 and water), drying (Na_2SO_4), solvent evaporation, and column chromatography (Wako gel C-300 with THF-hexane) afforded 0.191 g (92%) of **3** as an oil. The oily product was converted into the hydrochloride of **3** (syrup) with 3.6 M HCl in dioxane: R_f^1=0.40, R_f^2=0.39, R_f^3=0.92.

Boc-Ahe-(BzlO)Apr-Ahe-(BzlO)Apr-Gly-NHPh (4). To a mixed anhydride solution of Boc-Ahe-OH prepared as

above, was slowly added a solution of HCl·H-(BzlO)Apr-Ahe-(BzlO)Apr-Gly-NHPh (0.884 g, 1.35 mmol) and Et_3N (1.37 g, 1.35 mmol) in DMF; the mixture was kept at −16°C for 4 h, and at room temperature for 20 h. Concentration of the solution, extraction with EtOAc, washing (5% $NaHCO_3$, 5% citric acid, and H_2O), and drying (Na_2SO_4) gave a crude product (1.05 g, 94%) of **4**, which was purified by chromatography (LH-20 with MeOH) to give **4** as an oil, 0.955 g (85%): R_f^1=0.54, R_f^2=0.42, R_f^3= 0.92.

Ac-(BzlO)Apr-ONp. *O*-Benzylhydroxylamine (1.97 g, 16 mmol) in Et_2O (40 mL) was added to a solution of *p*-nitrophenyl acrylate (2.90 g, 15 mmol) in Et_2O (40 mL); the mixture stirred for 15 h at room temperature and concentrated to give an oil. The oil was acetylated with Ac_2O (10 mL) in THF (20 mL) at 70°C for 1 h and evaporated. The resulting residue was crystallized on addition of Et_2O-petroleum ether, 2.90 g (54%). Recrystallization from Et_2O- petroleum ether gave the product, 1.67 g (36%); mp 73—74°C. Found: C, 60.33; H, 5.06; N, 7.82%. Calcd for $C_{18}H_{19}N_2O_6$: C, 60.16; H, 5.33; N, 7.80%.

Ac-(BzlO)Apr-[Ahe-(BzlO)Apr]$_2$-Gly-NHPh (5). HCl·H-Ahe-(BzlO)Apr-Ahe-(BzlO)Apr-Gly-NHPh (**4'**) was obtained by deprotection of **4** with 3.6 M HCl in dioxane.

Ac-(BzlO)Apr-ONp (0.455 g, 1.27 mmol) was added to a solution of the hydrochloride (0.813 g, 1.06 mmol) and Et_3N (0.107 g, 1.06 mmol) in DMF (20 mL). The solution was stirred for 48 h at 30°C, and the solvent was evaporated to give a residue. Extraction of the residue with EtOAc, washing (aqueous Na_2CO_3 and water), drying (Na_2SO_4), and evaporation of the solvent gave a crude product of **5**. Column chromatography (Wako gel C-300 with THF-hexane) afforded 0.855 g (85%) of **5**, mp 99—101°C; R_f^1= 0.23, R_f^2=0.35, R_f^3=0.94. Found: C, 65.49; H, 7.30; N, 10.00%. Calcd for $C_{52}H_{67}N_7O_{10}$; C, 65.73; H, 7.11; N, 10.32%.

Ac-(HO)Apr-[Ahe-(HO)Apr]$_2$-Gly-NHPh (6). A mixture containing the hexaamide (**5**) (0.60 g, 0.63 mmol) and 10% Pd-C (0.12 g) in MeOH (30 mL) was subjected to hydrogenation with H_2 at 35°C for 40 h. DMF (30 mL) was added; the hot suspension was filtered. Concentration of the filtrate and column chromatography (Toyo pearl HW-40 with DMF) afforded 0.35 g (82%) of **6**, mp 175—176°C (decomp); R_f^2=0.03, R_f^3=0.44; IR, $\nu_{C=O}$ 1670 (sh) and 1630 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.35 (12H, m, $-CH_2-CH_2-CH_2-$), 2.00 (3H, s, CH_3-), 2.30 (8H, m, N-CH_2- and $-CH_2-$CO in -Ahe-), 3.00 (6H, m, $-CH_2-$CO in -Apr-), 3.70 (6H, m, N-CH_2- in -Apr-), 3.85 (2H, d, N-CH_2-CO), 7.30 (5H, m, $-C_6H_5$), 7.78 (3H, -NH-CO), 8.20 (1H, -NH-Ph), and 9.6—9.8 (3H, N-OH). Found: C, 54.62; H, 7.42; N, 14.31%. Calcd for $C_{31}H_{49}N_7O_{10}$: C, 54.77; H, 7.27; N, 14.43%.

Iron(III) Complex of 6. Tris(2,4-pentanedionato)iron-(III) (13 mg) was added to a methanolic suspension (5 mL) of **6** (26 mg). The suspension became a clear solution. The mixture was left at room temperature for 1 d, and concentrated to give a crude product, 25 mg (64%). Reprecipitation from MeOH to ether and drying under vaccum (60 °C, 1 d) gave a sample; λ_{max} 420 nm, ε=2590 (in water). Found: C, 50.38; H, 6.63; N, 11.25; Fe, 7.37%. Calcd for $C_{31}H_{46}N_7O_{10}\cdot Fe\cdot CH_3OH$: C, 50.26; H, 6.59; N, 12.82; Fe, 7.30%.

Cyclic Voltammetry. To a DMF solution containing a trihydroxamic acid ligand was added 0.90 equivalent of an aqueous $Fe(NO_3)_3$ solution. The solvent was then evaporated. To this was added a phosphate buffer solution (pH 8.2 and ionic strength 0.50 with KCl). This was filtered and adjusted to pH 8.00 with 1 M HCl.

Cyclic voltammetry was carried out for solutions, thus obtained, by generating triangular waves at an ambient temperature. A carbon electrode was used for measurements with a saturated calomel electrode as a reference and a platinum wire as an auxiliary electrode. Current-voltage curves were recorded on an X-Y recorder.

We are grateful to Prof. Noboru Oyama and Dr. Yukio Ohnuki for discussion and cyclic-voltammetry measurements.

Preparation and Complexing Properties of Crown Ether Compounds Incorporating a Ferrocene Unit at 1,2- or 1,3-Positions

Taeko IZUMI,* Katsuo SAITOU, Shigeki MATSUNAGA, and Akira KASAHARA
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received December 16, 1985)

Ten new crown ethers incorporating a ferrocene unit at 1,2- or 1,3-positions are reported. These crown ethers were synthesized by the reaction of 1,2- or 1,3-bis(hydroxymethyl)ferrocene with oligoethylene glycol ditosylate (n=1—5) with potassium t-butoxide by a high-dilution method. These new types of ferrocene crown ethers were examined for complexation behavior with alkali, alkaline earth, and transition-metal cations by solvent extraction. It was found to extract thallium ions most effectively.

Crown compounds with a ferrocene unit incorporated into a macrocyclic ring have recently received considerable attention. Polyoxaferrocenophanes,[1] polythiaferrocenophanes,[2] polyoxathiaferrocenophanes[3] and ferrocene cryptands[4] have been synthesized and their functions have been investigated. Before, we reported on the synthesis and the cation-complexing ability of ferrocene-containing oxo crown ethers.[5] Most of these ferrocenophanes and cryptands exhibit rather weak binding toward alkali metal cations, but better complexation toward silver and thallium ions. Furthermore, all of these ferrocenophanes and cryptands formed a macrocycle at the 1,1′-positions of a ferrocene ring. In this work we considered the effects of a ferrocene structure on the complexing ability of a macrocycle. We now report on the synthesis and give a survey of the complexing properties of new ferrocenophanes which contain crown-ether type units connected at the 1,2- or 1,3-positions of a ferrocene ring.

Results and Discussion

Synthesis. The following reactions were carried out in order to obtain 1,2-bis(hydroxymethyl)ferrocene (**1**) and 1,3-bis(hydroxymethyl)ferrocene (**2**) as starting materials. In connection with the synthesis of the ferrocenophanes (**4b—e**, **5a**, **6b—e**, and **7a**), it became desirable to synthesize 1,2- and 1,3-bis(hydroxymethyl)-ferrocenes (**1** and **2**) in quantity. 2-Lithio[(dimethylamino)methyl]ferrocene, which was prepared by the reaction of [(dimethylamino)methyl]ferrocene with t-buthyllithium, was condensed with paraformaldehyde to give 2-[(dimethylamino)methyl]ferrocenemethanol. The amino alcohol was quaternized by methyl iodide, this ammonium iodide was converted to ferrocene-1,2-dimethanol (**1**) by boiling with an aqueous alkali. A treatment of 1,3-diacetylferrocene with sodium hypobromite in dioxane–H_2O below 10°C led to the formation of 1,3-ferrocenedicarboxylic acid. Then, ferrocene-1,3-dimethanol (**2**) was synthesized by the usual $LiAlH_4$ reduction of the dimethyl ester, which was prepared by an acid-catalyzed esterification of 1,3-diacid. A new series of "crowned" ferrocenophanes were prepared by the synthetic sequence shown in Fig. 1.

We used a facile modification of the Williamson ether synthesis which was performed in aprotic solvents using tosylate as the leaving group, the potassium cation improved the yields by forming a template

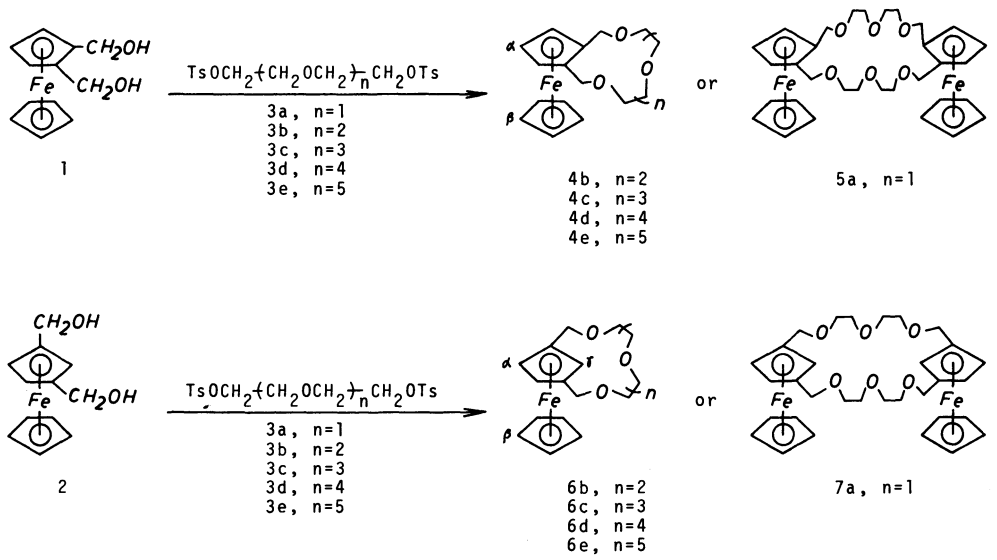

Fig. 1.

Table 1. Reaction of 1,2-Bis(hydroxymethyl)ferrocene and 1,3-Bis(hydroxymethyl)-ferrocene with Oligoethylene Glycole Ditosylates

Starting materials		Product	Yield/%	Mp θ_m/°C	Color
Ferrocene dialcohol	$TsOCH_2$-$(CH_2OCH_2)_n$-CH_2OTs				
1	n=1	**5a**	5.8	109—110	Yellow
1	n=2	**4b**	10.8	66—67	Yellow
1	n=3	**4c**	6.1	48—49	Yellow
1	n=4	**4d**	8.2	Oil	Orange
1	n=5	**4e**	7.6	Oil	Orange
2	n=1	**7a**	4.0	144—145	Yellow
2	n=2	**6b**	6.9	92—93	Yellow
2	n=3	**6c**	12.2	Oil	Orange
2	n=4	**6d**	17.3	Oil	Orange
2	n=5	**6e**	15.8	Oil	Orange

about which molecules could cyclize.[6] The reaction of diol (**1** or **2**) with the ditosylates of oligoethylene glycols (**3b—e**) in dry benzene in the presence of potassium *t*-butoxide gave crowned ferrocenophanes (**4b—e** and **6b—e**) in 5.8—10.8% yields for 1,2-ferrocenophanes or 4.0—17.3% yields for 1,3-ferrocenophanes, respectively, as yellow crystals or orange oils, along with unexpected polymeric materials (5—8 weight %). The starting materials (**1** and **2**) were recovered in every case in 40—60% yields. We tried to improve the product yields, but this could not be done by changing the reaction conditions (reaction time and solvent). Binuclear ferrocenophanes (**5a** and **7a**) were formed in the reaction of diethylene glycol ditosylate (**3a**) with **1** and **2**. This might indicate that the diethylene glycol chain (n=1) is too short to cyclize on the same cyclopentadienyl ring (1,2- or 1,3-positions). The results are summarized in Table 1. The structures of all ferrocenophanes, thus prepared, were determined on the bases of their IR, ^{1}H NMR, mass spectra and elemental analyses. The IR spectra of the ferrocenophanes showed bands caused by ether a linkage at 1090 or near 1127 cm^{-1}, by homoannular disubstituted ferrocene in 3105—3095, 1100, 1020—1000, and 820 cm^{-1} regions, and by methylene group in 2980—2920, 2880—2870, 1460—1420, and 1380—1360 cm^{-1} regions. In the ^{1}H NMR spectra, all the ferrocenophanes showed a similar pattern: methylene protons as a broad singlet at about 3.6 ppm, protons of methylene groups adjacent to the ferrocene ring at 4.26—4.39 ppm, unsubstituted cyclopentadienyl protons at 4.08—4.10 ppm as sharp singlets and substituted cyclopentadienyl protons as multiplets at 4.22—4.42 ppm. The mass spectra and the elemental analyses also confirmed the structures.

Extraction Ability. The complexing ability between synthesized polyoxaferrocenophanes (**4b—e**, **6b—e**, **5a**, and **7a**) and alkali, alkalin earths, and transition metal cations could be established by Pedersen's solvent extraction method.[7] The data are summarized in Table 2. These results indicate little or no extractability toward alkali metal cations (Li^+ and Na^+) for almost all of polyoxaferrocenophanes, except **4c** which exhibits selectivity toward the thallium cation.

Table 2. Extraction Data (Water-Dichloromethane)[a]

Compound	Extracted/%					
	Li^+	Na^+	K^+	Ba^{2+}	Tl^+	Ag^+
4b	0	2.9	0.7	5.3	14.9	Oxidation
4c	0.9	32.9	19.3	14.2	67.6	86.1
4d	4.3	4.3	13.4	19.2	66.4	Oxidation
4e	2.9	2.9	24.3	53.6	77.9	Oxidation
6b	0	0	0	10.0	4.4	Oxidation
6c	0	0	4.0	8.3	56.3	Oxidation
6d	0	0	11.4	0.7	66.3	25.7
6e	1.4	1.8	6.7	4.0	60.8	42.1
5a	0	1.8	9.0	6.4	56.2	Oxidation
7a	0	0	0	9.1	34.2	Oxidation

a) Equal volumes of water and dichloromethane, and picric acid at 7.0×10^{-5}M (1M=1 mol dm^{-3}). Concentration of ferrocenophane: 7.0×10^{-4}M. Concentration of metal nitrate: 0.1 M.

Furthermore, the extraction efficiency toward others cations (K^+, Ba^{2+}, and Tl^+) is dependent on the size of the crown ether ring in the polyoxaferrocenophanes, especially in the cases of **4b—e**. It is interesting that **4b—e** (1,2-ferrocenophanes) shows a high complexing ability compared with **6b—e** (1,3-ferrocenophanes), even though the latter has a large ring size, and even though these ferrocenophanes have similar structures. This can be explained by assuming that the proton at the 2-position of the substituted cyclopentadienyl ring of **6b—e** is more sterically hindered in the process of complexation. On the other hand, the attached position of ferrocene to the crown ether seems to influence the complexing ability. For example, 1,2-polyoxaferrocenophanes (**4b—e**) show a high complexing ability, except toward silver ions, compared with 1,1′-polyoxaferrocenophanes which were reported by Akabori et al.[1c] It should be emphasized that **4c** (n=3) has a high complexing ability toward sodium, thallium, and silver ions. It is also interesting that the extraction ability toward thallium ion shows a remarkable dependence on the cavity size in the macrocycle of **4b—e**. Binuclear polyoxaferrocenophanes (**5a** and **7a**) show a low extractability to-

ward metal cations (Li^+, Na^+, K^+, and Ba^{2+}), but show an appreciable selectivity toward thallium cations. A similar trend of affinity toward transition metal cations have been observed in hitherto reported "crowned" ferrocenophanes and these synthesized polyoxaferrocenophanes; this suggests that the iron atom of the ferrocene nucleus participates in the process of complexation. This means that the metal cation is drawn into the crown ether ring from the iron-atom side of ferrocene, even though the opposite side of the ring has less hindrance. In the case of a silver ion, the ferrocene nucleus changed to a ferricenium ion, which showed blue color in solution, upon oxidation with $AgNO_3$ (except **4c**, **6d**, and **6e**). This oxidation seems very sensitive to the crown-ring member since **4c** showed an 86.1% extractability and almost all cases showed oxidation reaction. These facts indicate that the distance between the iron atom of ferrocene and the incorporated silver cation influences the oxidation of ferrocene. A similar result was also observed in polyoxa-[1c] or polyoxathiaferrocenophanes.[3e,3f]

Experimental

Materials and Measurements. All melting points are uncorrected. Diethylene glycol, triethylene glycol and tetraethylene glycol were commercial products, pentaethylene glycol and hexaethylene glycol were prepared by reactions of tri- and diethylene glycol ditosylates with the sodium salt of ethylene glycol and diethylene glycol, respectively.[8] 1,2-Bis(hydroxymethyl)ferrocene[9] and 1,3-bis(hydroxymethyl)-ferrocene[10] were prepared as described in the literature. The other reagents employed were commercial materials or were prepared by the usual method. All inorganic compounds were reagents grade. The IR, ^1H NMR, mass, and electronic spectra were recorded on Hitachi 260-10, Hitachi R-22, Hitachi RMU-6M, and Hitachi 200-10 spectrometers, respectively.

General Procedure for Polyoxa[*n*](1,2)ferrocenophanes (5a and 4b—e) and polyoxa[*n*](1,3)ferrocenophanes (7a and 6b—e). A mixture of 1,2-bis(hydroxymethyl)ferrocene (**1**) (2.00 g, 0.0081 mol) or 1,3-bis(hydroxymethyl)ferrocene (**2**) (2.00 g, 0.0081 mol) and oligoethylene glycol ditosylate (n=1—5) (0.0081 mol) in 160 ml of dry benzene was added dropwise to a benzene solution (20 ml) of potassium *t*-butoxide (K: 0.8 g, 0.020 mol) over a period of 7 h at a refluxing temperature under nitrogen, and then further stirred for 20 h. After the solution has been cooled to room temperature, precipitated potassium tosylate was filtered off and washed with warm chloroform. Evaporation of the solvent left crude products as viscous oils; these were purified by silica-gel column chromatography. The first fraction eluted with benzene–ether (10:1) gave ferrocenophane (**5a**, **4b—e**, **7a**, and **6b—e**); the second fraction eluted with chloroform–methanol (5:1) recovered the starting dialcohol (**1** or **2**); and the last fraction eluted with chloroform–methanol (2:1) gave polymeric materials. The crude product was recrystallized from hexane. The results are summarized in Table 1.

2,5,8,22,25,28-Hexaoxa[9.9](1,2)ferrocenophane (5a). IR (KBr): 3080, 2950—2860, 1460, 1360, 1100, 1090, 1000, 820 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.53 (br-s, 16H, $-OC\underline{H_2}C\underline{H_2}O-$), 4.04 (s, 10H, Fc–$H_\beta$), 4.26 (m, 6H, Fc–$H_\alpha$), 4.36 (s, 8H, Fc–$C\underline{H_2}O-$) ppm. Thermal Racemization of Thiaheterohelicenes

Koh-ichi YAMADA, Hiroko NAKAGAWA, and Hiroshi KAWAZURA*
Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02
(Received January 27, 1986)

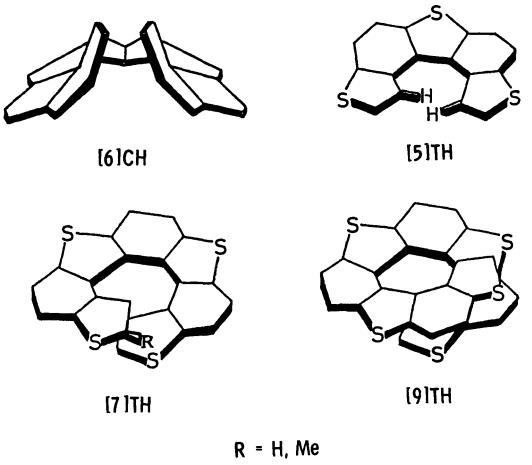
Thermal racemizations of four thiaheterohelicenes (TH) with alternant thiophene and benzene rings were examined and compared with those of carbohelicenes (CH). The racemization rate of [5]TH was very fast at room temperature, and the rates of [7]TH and [9]TH were found to be 1/5 to 1/50 times slower than the corresponding CH having a similar internal angle. The $\Delta S^{\ddagger}$ values obtained by temperature-variable experiments showed a large difference between [7]TH (-103.9 ± 4.8 JK^{-1} mol^{-1}) and [9]TH (-66.3 ± 4.0), suggesting different conformations in the transition state. CNDO calculations on the transitional conformations of [5]TH demonstrated that a geometry, such as that distorting the benzene rings, has a lower energy than a geometry such as that twisting the thiophene ring. Based upon these results, the conformations in the transition states for the THs are inferred.

Reports on the racemization of carbohelicenes (CH) were very surprising in view of the flexibility of the angularly fused benzene rings.[1] Despite their structural overcrowding, the free energies of the activation ($\Delta G^{\ddagger}$) for the reactions did not seem to be too large to override a severe transition path: [8]CH, 181.9; [9]CH, 188.3kJ mol^{-1} at 543 K. Thus, the racemization is thought to occur via an achiral transition state in which the deformations spread over the entire molecule so as to prevent a local severe strain, accompanied by much motional freedom. Lindner calculated the energy differences between the ground state and some assumed transition states for a [6]CH molecule by the π-SCF-force-field method, and argued that the most plausible geometry for a transition state is that in which the terminal portions of the molecule are in a face-to-face position with each other (Figure).[2] So far, only a few heterohelicenes, partially composed of heteroaromatics, were investigated regarding racemizations.[3] However, they were confined to hexa homologs which do not complete a full turn and, hence, do not reveal the distinct effect of heteroaromatics on the reaction.

As a part of the study on the properties and structures of thiaheterohelicene (TH), we examined the thermal racemizations of TH containing alternant thiophene and benzene rings. We wish to describe here the kinetic results of the reactions and to discuss their transition states by referring to our CNDO calculation on the transition state models. A comparison of CH with TH in the transition states is also made while focusing on the influence of the heteroaromatics.

Experimental

Syntheses[4] and optical resolutions[5] of the thiaheterohelicenes studied have been reported in the foregoing publications. Optical rotations were measured on a JASCO DIP-180 digital polarimeter or a JASCO J-20A automatic recording spectropolarimeter. Chromatograms of THs were recorded on a Waters Model 204 HPLC system. CNDO calculations[6] were performed on a FACOM M-160F computer.



Racemization reactions of chiral TH were carried out in a mesitylene solution in a tube sealed under a nitrogen atmosphere. Tubes of the solution were thermostated in an oil bath and the reaction progress was pursued by measuring the optical rotation at given time intervals. The reactions were also followed by measuring changes in the absorption spectra and HPLC peaks.

Results and Discussion

The ease of racemization depends on the winding degree of the helix, i.e. the extent of the intramolecular overlap, which can be estimated with the internal angle (IA) of the TH molecules[3] studied here: [9]TH, 465; [7]TH and 2-methyl[7]TH, 360; and [5]TH, 255°.[7] Thus, it is expected that [5]TH should racemize rapidly in solution, although the structure in crystals retains a rigid helix.[8] In fact, HPLC using a column containing (+)TAPA-bonded silica gel (TAPA: 2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)-propionic acid) could not be used to separate the enantiomers of [5]TH at −14°C. Several recyclings or a lowering of the temperature to −24°C caused a slight separation between *P* and *M* enantiomers[9] (Fig. 1). All attempts to isolate the enantiomers were, however, unsuccessful, even at lowered temperatures, suggesting a low activation energy for the racemization of [5]TH.

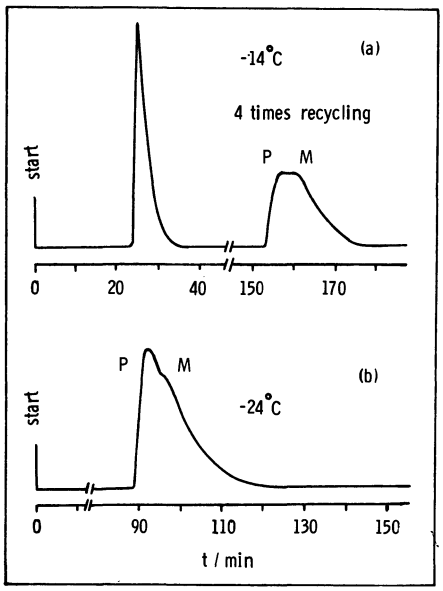


Fig. 1. Resolutions of the enantiomers of [5]TH by HPLC. (+)TAPA-bonded silica-gel column, CH_2Cl_2/n-C_6H_{14}=4/1, monitored at 254 nm, (a) flow rate 2 ml min^{-1}, and (b) 1 ml min^{-1}.

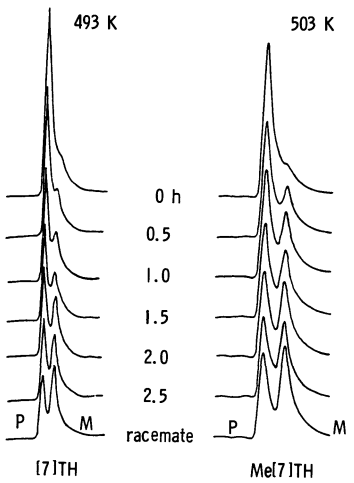

Fig. 2. Time course of HPLC peaks of [7]TH and 2-Me[7]TH. (+)TAPA-bonded silica-gel column, CH_2Cl_2/n-C_6H_{14}=1/1, flow rate 1 ml min^{-1}, and monitored at 254 nm.

Figure 2 illustrates the time course of the HPLC peaks for reactions of [7]TH and 2-Me[7]TH. During every reaction time, no peak except for those illustrated was observed, indicating that no meaningful side reaction took place and that all the changes in the optical rotations could be regarded as racemization processes.

The first-order rate constant k_r and the activation parameters were obtained from the following equations by least-squares treatments,

$$k_r = 1/2\,t \ln(\alpha_0/\alpha_t),$$
$$\Delta G^* = RT[\ln(k/h) - \ln(k_r/T)],$$
$$\Delta G^* = \Delta H^* - T\Delta S^*,$$

Table 1. k_r and ΔG^* of Racemization at 500 K

	Internal angle	$k_r \times 10^6$	ΔG^*
	deg.	s^{-1}	kJ mol^{-1}
[7]TH	360	124	162.0
Me[7]TH	360	113	162.4
[9]TH	465	0.021	198.1
[6]CH[a)]	360	668	154.3
[8]CH[a)]	480	1.10	181.9

a) The values are cited from Ref. 1.

	ΔH^*	$-\Delta S^*$
	kJ mol^{-1}	JK^{-1} mol^{-1}
[7]TH	110.0±2.8	103.9±4.8
Me[7]TH	120.7±2.8	83.3±4.6
[9]TH	164.9±2.2	66.3±4.0
[6]CH[a)]	146.4	17.6
[8]CH[a)]	171.5	19.2

a) The values are cited from Ref. 1.

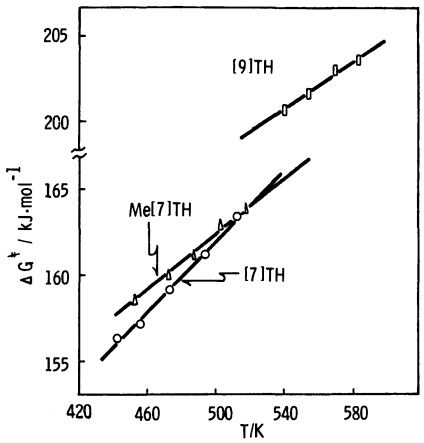

Fig. 3. Temperature dependence of ΔG^*.

where α_0 and α_t are the optical rotation at time 0 and t, respectively. The k_r's and the free energies of the activation (ΔG^*) at 500 K are tabulated in Table 1, together with the calculated IA values. The effect of a methyl substituent at the 2-position in a [7]TH molecule seems to be relatively small. It is notable that the rate of [9]TH becomes much smaller than that of [7]TH by about 1/5900 times with a large ΔG^* value by 36.1 kJ mol^{-1}. Compared with the k_r of carbohelicene having a similar IA value, the k_r of [7]TH is 1/5.4 times smaller than that of [6]CH, and [9]TH (which possesses the smaller IA than [8]CH) shows a k_r that is 1/52 times slower as a result of the larger ΔG^* by 16.2 kJ mol^{-1}. These results demonstrate that TH molecules hold more rigid skeleton than CH molecules.

The temperature dependences of ΔG^* are depicted in Fig. 3 and the activation enthalpies (ΔH^*) and entropies (ΔS^*) are listed in Table 2. As is apparent

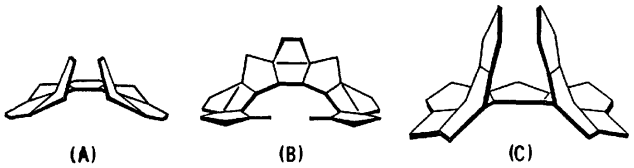

Fig. 4. The possible transitional geometries of [7]TH ((A) and (B)), and the plausible transitional geometry of [9]TH ((C)).

from the Table, a comparison between the two CHs exhibits an increasing $-\Delta S^*$ with an increasing ΔH^*. This relationship between ΔH^* and ΔS^* is generally observed in such a case as a series of homologs whose racemization could occur through the same kind of transitional geometries. On the other hand, the trend of $-\Delta S^*$ against ΔH^* in the TH series was found to be opposite; this might imply that [9]TH should take a different transitional geometry from that of [7]THs. Moreover, the most striking feature is the large difference of $-\Delta S^*$ values between CH and TH. In the racemization of a TH molecule, the entropy term contributes greatly to the free energy of the activation, suggesting a great loss of motional freedom in the transition state.

As for the transitional geometry of [7]TH racemization two conformations, (A) and (B), are thought possibly to exist (Fig. 4), as speculated in the literature.[2] Form (A) is produced by a distortion of the terminal thiophene rings, while (B) is formed by a distortion of the benzene portions. The kinetic results indicate that type (B) is more plausible since in this form the distortion should occur synchronously at the three sites to provide a greater entropy change than at the two sites in form (A). Regarding the [9]TH transition state, it may be no longer possible to hold form (B) on account of its larger extent of winding. Figure 4 (C) illustrates the plausible transitional geometry of the [9]TH racemization. In this geometry the number of the mainly distorted sites is two; this is more related to the smaller $-\Delta S^*$ value than that of [7]TH.

Finally, we attempted to obtain CNDO-calculational support for the geometries mentioned above. However, the [7]TH and [9]TH molecules are so big that the energies could not converge to definite values. For the [5]TH molecule, the total energies were attained with iterative methods for the ground-state geometry determined by an X-ray analysis, and for a planar geometry having the same bond lengths, in which the terminal hydrogens are brought into close proximity with each other: 1.36 Å (Table 3, (a) and (b)). Interestingly, the energies of both conformations were found to be close; the increase in the conjugation energy, due to the planarity, would counteract the repulsion energy between the terminal hydrogens. Thus, the transition state of the [5]TH racemization

Table 3. Total Energies (E_T) of Some Conformations of the [5]TH Molecule. Refer to Fig. 5.

Conformation	r	E_T
	Å	eV
(a) Ground State	2.11	−4141.17
(b) Plane	1.36	−4140.94
Distorted Ring		
(c) Thiophene	1.55	−4139.28
(d) Benzene	1.56	−4139.74

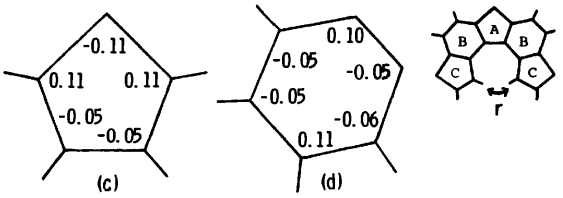

Fig. 5. Distorted conformations of [5]TH molecule. Distorted sites are (c) thiophene A ring and (d) benzene B rings. The figures in the rings are deviations (Å) from the least-squares plane.

can be supposed to be like a planar geometry.

Furthermore, a series of tentative calculations of the total energies of the [5]TH molecules was carried out using various hypothetical models in which only thiophene or benzene rings were distorted from the planar geometry. Figure 5 and Table 3 ((c) and (d)) show an example where two kinds of distorted molecules are chosen as being equal at a distance (r) between the terminal hydrogens. In every case, it was found that the energy obtained for the molecule with a distorted benzene became smaller than that of a molecule with a distorted thiophene. This implies that in order to hold the terminal moieties in the same separation, the distortion of the five-membered ring thiophene needs to have a higher energy than that of the six-membered ring benzene. This difference in the rigidity between thiophene and benzene ring might play a role in the transitional geometry of the [7]TH racemization.

In conclusion, thiaheterohelicenes manifest fairly different behaviors in thermal racemization reactions from carbohelicenes, presumably because of the existence of the heteroaromatics thiophene.

Design of the Synthetic Route for Peptides and Proteins Based on the Solubility Prediction Method. I. Synthesis and Solubility Properties of Human Proinsulin C-Peptide Fragments[1)]

Mitsuaki NARITA,* Toshihiko OGURA, Kazuhiro SATO, and Shinya HONDA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received February 25, 1986)

The usefulness of the solubility prediction method is demonstrated using relatively small peptide fragments of human proinsulin C-peptide. The propriety of the solubility prediction method for peptides having polar side chains is also examined in the following respects: (1) Peptide intermediates smaller than a heptapeptide have high solubility regardless of their $\langle P_c \rangle$ values; (2) the $\langle P_c \rangle$ values of peptide intermediates are useful for judging solubility of peptide intermediates equal to or larger than an octapeptide level; (3) the Pro residue in a central position of a peptide chain is effective for increasing peptide solubility; and (4) there is critical chain length for peptide insolubility caused by a β-sheet aggregation. A strategy suitable for the design of the synthetic route for human proinsulin C-peptide is subsequently discussed on the basis of the solubility prediction of peptide intermediates.

To achieve total synthesis of large peptides and proteins, all of the components must be soluble in coupling solvents. In many cases of protein syntheses, indeed, avoidance of insolubility of peptide intermediates in coupling solvents is claimed to be a problem of utmost importance to achieve the protein syntheses favorably.[2)] Thus, the proper design of the synthetic route based on the solubility prediction of peptide intermediates is greatly required to avoid erroneous synthetic routes. Following this concept, we are pursuing the scope of the design of the synthetic routes for peptides and proteins based on a solubility prediction method.[3)]

So far, however, it has been widely recognized that the solubility prediction of protected peptide intermediates is difficult due to the diverse individuality of their amino acid sequences since their solubility is primarily dependent on their amino acid sequences. In our recent papers,[3-10)] however, we have demonstrated that insolubility of peptide intermediates is caused by a β-sheet aggregation of peptide intermediates equal to or larger than an octapeptide level and that the temporary protection of a N-H peptide bond in a central position of a peptide chain helps improve solubility to a remarkable extent.[4)] Furthermore, we have also demonstrated that, in hydrophobic sequences found in proteins, the β-sheet aggregation plays an important role in insolubility of hydrophobic peptides and that, contrary to the general recognition that solubility of peptide intermediates is primarily dependent on their amino acid sequences, their solubility is independent on their amino acid sequences.[10)] On the basis of these results, the solubility prediction of peptide intermediates was successfully performed by making use of both the randomness of peptide structures in the solid state and the existence of tertiary peptide bonds, that is, the disturbance of a β-sheet structure.[3)] The correctness of the concept of this solubility prediction method was furthermore verified by another evidence, that is, solubility improvement by promotion of helical folding in oligopeptides based on the restriction of the values of the backbone dihedral angles ϕ and ψ of the α-aminoisobutyric acid residue.[10-12)]

The usefulness of the solubility prediction method has been previously confirmed in hydrophobic oligopeptides.[3-12)] We here demonstrate its usefulness also for relatively small peptide fragments of human proinsulin C-peptide having polar side chains and we then propose a strategy suitable for the design of the synthetic routes for the C-peptide on the basis of the solubility prediction of peptide intermediates.

Experimental

General. The uncorrected capillary melting points will be reported. The amino acid compositions of acid hydrolysates were determined with a Shimadzu HPLC LC-3A all amino acid analysis system. The acid hydrolyses of the peptides containing the Ser residue were carried out with 3M† *p*-toluenesulfonic acid[13)] for 3 d at 115 °C in evacuated, sealed tubes, and those of other peptides, with propionic acid/12M HCl (vol. ratio, 2/1)[14)] for 2 d at 115°C. Other analytical instruments and conditions were described in the previous paper.[11)]

General Procedure for Removal of the Boc Group. Boc-amino acid Pac esters (10 mmol) and Boc-peptide Pac esters (10 mmol) in 3 M HCl/AcOEt (60 ml) were stirred in an ice-chilled bath for 1.5—3 h. Then, the mixture was concentrated in vacuo, followed by the repetition of the addition and removal in vacuo of dichloromethane. The residual amino component HCl salt was used for a subsequent coupling reaction without further purification.

General Procedure for Stepwise Elongation of Peptide Chains Using DCC Activation (Preparation of the Peptides 1—6 and 10). DCC (1.2 equiv) was added to an ice-chilled, stirred mixture of a carboxyl component (1.2 equiv) and an amino component (10 mmol) in dichloromethane, a mixture of dichloromethane and DMF, or DMF (100 ml). The amino components were obtained from the corresponding HCl salt with an equivalent of NMM. For incorpora-

† 1 M=1 mol dm^{-3}.

tion of the Gln residue, instead of DCC activation, Boc-Gln-ONp (1.5 equiv) was used for chain elongation. The reaction mixture was stirred in an ice-chilled bath for 3 h, at room temperature overnight, and then subjected to ninhydrin test. When the test was positive, double and triple couplings were carried out using the carboxyl component and DCC (each 0.3 equiv). After completion of the reaction, the reaction mixture was filtered. The subsequent work-up procedure was essentially the same as those described before.[11] The synthetic results and analytical data are shown in Tables 1—3.

General Procedure for Fragment Condensation Using DCC Activation in the Presence of HOBt (Preparation of the Peptides 7—9, 11, and 12). Assembly of peptide chains by fragment condensation was carried out in DMF or a mixture of DMF and NMP. DCC (1.2 equiv) was added to an ice-chilled, stirred mixture of a carboxyl component (1.2 equiv), HOBt (1.2 equiv), and an amino component (10 mmol) in solvent (100 ml). The amino components were obtained from the corresponding HCl salts with an equivalent of NMM. The reaction mixture was stirred in an ice-chilled bath for 3 h, at room temperature for 2 d, and then subjected to ninhydrin test. When the test was positive, double and triple couplings were carried out using the carboxyl component and DCC (each 0.3 equiv). After completion of the reaction, the reaction mixture was filtered. The subsequent work-up procedure was essentially the same as those described before.[11] The synthetic results and analytical data are also shown in Tables 1—3.

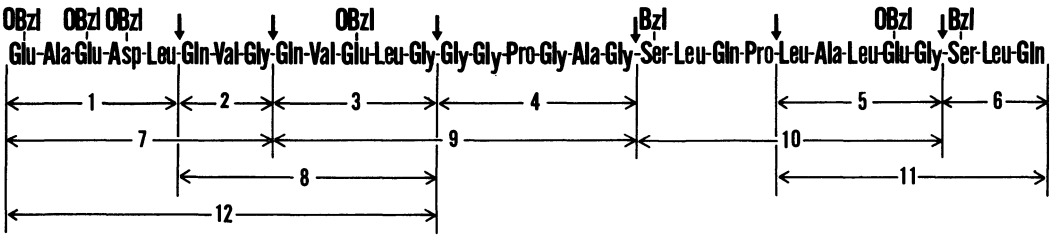
General Procedure for Removal of the Pac Group. Boc-peptide Pac esters were stirred in a mixture of AcOH using a several-fold molar excess of Zn dust at room temperature for several days. After removal of Zn residues, the filtrate was concentrated in vacuo. The residue was treated with aqueous citric acid, followed by washing with water and hexane. Completion of the reaction was examined by TLC. The residue was used for a subsequent coupling reaction without further purification.

Results

Fragmentation of Human Proinsulin C-Peptide Based on the Solubility Prediction Method. One of our purposes in this paper is to examine the propriety of the solubility prediction method for peptide intermediates having polar side chains in the following respects: (1) Peptide intermediates smaller than heptapeptides have high solubility regardless of their $<P_c>$ values; (2) the $<P_c>$ values of peptide intermediates are useful for judging solubility of peptide intermediates equal to or larger than an octapeptide level; (3) the Pro residue in a central position of a peptide chain is effective for increasing peptide solubility; and (4) there is critical chain length for peptide insolubility caused by a β-sheet aggregation.

To investigate these points, the primary structure[15] of human proinsulin C-peptide was divided into seven fragments at the points indicated by arrows in Fig. 1, where the primary structure includes side-chain-protecting Bzl groups in the Asp, Glu, and Ser residues. Figure 1 also illustrates the N- and C-terminal-protected peptide fragments **1—12** used in this study. The solubility properties of the peptides **1—12** will be discussed later on the basis of the solubility prediction method.[3]

Synthesis and Solubility Properties of Each Peptide Fragment. Starting from the Pac ester of each C-terminal amino acid residue as the amino component, the peptide fragments **1—6** and **10** were prepared by the usual stepwise elongation of the peptide chain using Boc-amino acids[16] as the acid components. The following side-chain-protected amino acids were used for the synthesis: Glu(OBzl), Asp(OBzl),



1. Boc-Glu(OBzl)Ala Glu(OBzl)Asp(OBzl)Leu-OPac
2. Boc-Gln Val Gly-OPac
3. Boc-Gln Val Glu(OBzl)Leu Gly-OPac
4. Boc-Gly Gly Pro Gly Ala Gly-OPac
5. Boc-Leu Ala Leu Glu(OBzl)Gly-OPac
6. Boc-Ser(Bzl)Leu Gln-OPac
7. Boc-Glu(OBzl)Ala Glu(OBzl)Asp(OBzl)Leu Gln Val Gly-OPac
8. Boc-Gln Val Gly Gln Val Glu(OBzl)Leu Gly-OPac
9. Boc-Gln Val Glu(OBzl)Leu Gly Gly Gly Pro Gly Ala Gly-OPac
10. Boc-Ser(Bzl)Leu Gln Pro Leu Ala Leu Glu(OBzl)Gly-OPac
11. Boc-Leu Ala Leu Gln(OBzl)Gly Ser(Bzl)Leu Gln-OPac
12. Boc-Glu(OBzl)Ala Glu(OBzl)Asp(OBzl)Leu Gln Val Gly Gln Val Glu(OBzl)Leu Gly-OPac

Fig. 1. The amino acid sequence of human proinsulin C-peptide and the N- and C-terminal protected peptide fragments **1—12** used in this study.

and Ser(Bzl).[17,18] The coupling reactions were mediated by DCC[19] throughout except for the Gln residue, which was incorporated by the active ester method[20] using Boc-Gln-ONp. Use of the Pac ester[21] at the C-terminus should have the advantage that Boc-peptide Pac ester thus prepared can be used not only as an amino component, but also as a carboxyl component since the stability of the side-chain-protecting Bzl group under removal conditions of Boc- and Pac groups has been well established.[17] Liberation of the amino groups from Boc-peptide Pac esters was performed by treatment with 3 M HCl/AcOEt, followed by treatment with NMM. Removal of the Pac group from the Boc-peptide Pac esters was performed by hydrogenolysis using Zn dust in AcOH.[22] The larger peptide fragments **7**—**9**, **11**, and **12** were subsequently prepared by the fragment condensation method after removal of the C- or N-terminal-protecting

Others, see Ref. 1). c) Number of amino acid residues of the peptide. d) DMF, NMP, DMA, DMSO, and HMPA. e) Solubility in benzene.

group of the corresponding fragment. Each fragment was coupled mainly in DMF with least danger of racemization using DCC activation in the presence of HOBt.[23] Completion of every coupling reaction was monitored by checking the reaction product with the sensitive ninhydrin test.

All of the soluble peptides were purified by repeated recrystallization, and, as a result of this purification process, each peptide gave a single peak on HPLC. The peptides **7**, **8**, and **12** which were insoluble in MeOH were purified by repeated washing with hot MeOH. Synthetic and analytical results of the peptides **1**—**12** are assembled in Tables 1—3. The amino acid and elemental analyses of the peptides shown in Tables 2 and 3 are in good agreement with the calculated values.

Solubility properties of the peptides **1**—**12** in organic solvents are also summarized in Table 4. The $<P_c>$ values of peptides shown in Table 4 indicate the randomness of each peptide fragment and they are obtained using P_c value for each amino acid residue.[3] For example, a peptide intermediate with the $<P_c>$ value above 1.00 is predicted to have a random structure in the polar solvents such as DMA, DMF, DMSO, NMP, and HMPA. According to the rule 1 of the solubility prediction method,[3] regardless of its peptide chain length, it is soluble in the polar solvents sufficiently enough to be susceptible to subsequent coupling reactions. In fact, the undecapeptide **9** has high solubility in the polar solvents, while the tridecapeptide **12** having the $<P_c>$ value of 0.86, as expected on the basis of the rule 3 of the solubility prediction method,[3] is extraordinarily less soluble in the solvents such as DMA, DMF, DMSO, NMP, HMPA, MeOH, and AcOH. With respect to the oligopeptides smaller than a heptapeptide, except for the peptides **2** and **3** containing the Gln residue, the oligopeptides **1** and **4**—**6** are easily soluble even in the moderate-polar solvents such as dichloromethane, chloroform, dioxane, and THF.

Conformations of Each Peptide Fragment in the Solid State. Conformational analysis of each peptide fragment in the solid state is interesting for the purpose of elucidating the relationship between the conformation and solubility of peptides having polar side chains. All of the peptides show strong bands at 3290—3270 cm^{-1} and 1635—1625 cm^{-1}, assigned to a typical β-sheet structure.[24] The IR absorption spectra of the peptides **4**, **9**, and **10**, which contain the Pro residue in central positions of the peptides, have strong broad shoulders at 1700—1650 cm^{-1}, indicating the disturbance of the β-sheet structure by rotation of the tertiary peptide bond plane as reported in previous papers.[3-9] The peptides **10** and **11** happen to have the very close amino acid sequences except for the Pro residue and the peptide **10** clearly shows the effect of the Pro residue in a central position of the peptide chain on the disturbance of the β-sheet structure. Analytical details will be reported elsewhere.[25,26]

Discussion

As expected from the solubility prediction of peptide intermediates, all peptide fragments **1**—**12** of human proinsulin C-peptide were prepared without difficulty by the usual stepwise elongation and fragment condensation methods, and, during the formation of the peptide fragments **8** and **12**, gelation eventually took place in a mixture of DMF and NMP along with the coupling reaction.

Regardless of the $<P_c>$ values of peptide fragments, in actuality, the peptide fragments **1**—**6** smaller than a heptapeptide are readily soluble in the polar solvents (Table 4). Most of them, except for the peptides **2** and **3** containing the Gln residue, have high solubility even in moderate-polar solvents. As reported

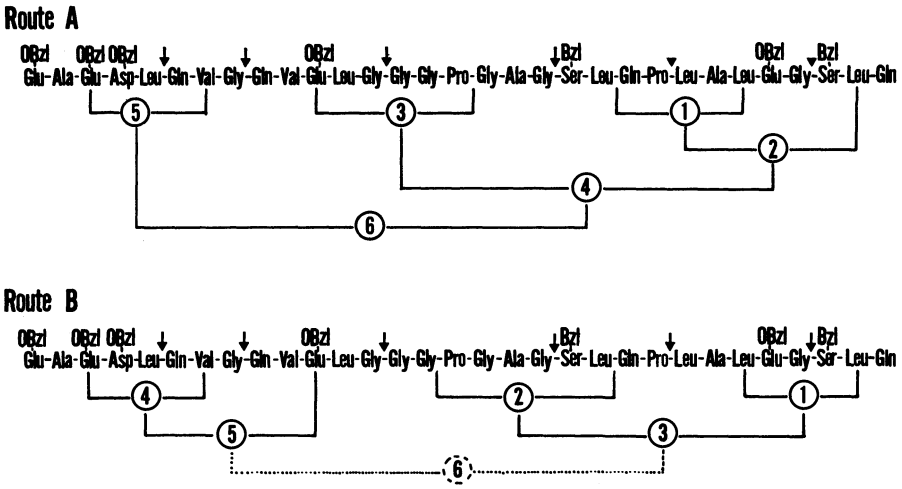

Fig. 2. Design of the synthetic routes for human proinsulin C-peptide. The number in a circle represents the order of each fragment condensation reaction.

for oligopeptides containing the Asn residue,[27] the peptides **2** and **3** have low solubility in the moderate-polar solvents probably due to hydrogen bonds through the Gln side-chain amide. The hexapeptide **4** and nonapeptide **10** are readily soluble even in the moderate-polar solvents such as dichloromethane, chloroform, dioxane, THF, and acetonitrile. The result apparently indicates that the tertiary peptide bonds (X–Pro) cause the disturbance of the β-sheet structures by the rotation of the tertiary peptide bond planes, bringing about their high solubility. The disturbance of the β-sheet structures is clearly verified by broadening of IR absorption bands in the amide I region. The solubility difference between the peptides **10** and **11** also conspicuously exhibits the effect of the Pro residue in a central position of the peptide chain on increasing peptide solubility (Table 4). Actually both the peptides have the very close amino acid sequences except for the Pro residue. On the other hand, solubility properties of the octapeptides **7**, **8**, and **11** are on a boundary. Although the peptides **7**, **8**, and **11** are soluble in the polar solvents, the peptides **7** and **8** are practically insoluble in MeOH and EtOH, and the peptide **11** is soluble only in the hot alcohols. These solubility behaviors indicate that, for the peptides containing polar side chains, critical chain length for peptide insolubility caused by the β-sheet aggregation is larger than an octapeptide level. With respect to larger peptides, the undecapeptide **9** is sufficiently soluble in the polar solvents due to the presence of the Pro residue in a central position of the peptide chain, while the tridecapeptide **12** has the $<P_c>$ value of 0.89, indicating that it is extraordinarily less soluble in the polar solvents. The peptide **12**, indeed, is actually insoluble in the polar solvents shown in Table 4 and difficult to remove the Pac group using Zn dust in AcOH. In terms of the relationship between the conformation and solubility of the peptides **7**, **8**, **11**, and **12**, the β-sheet aggregation clearly plays an important role in reducing these solubility properties.

The results and discussion mentioned above thoroughly make clear that the solubility prediction of peptide intermediates is very useful for the design of the synthetic routes for peptides and proteins. In general, assembly of the target structure by fragment condensation allows for great flexibility in the choice of the synthetic routes. In most cases of peptide and protein syntheses, for example, the Gly and Pro residues are recommended to be placed at C-termini of peptide intermediates since they are free from racemization in fragment condensation reactions. Our results clearly show that, for solving the insolubility problem of the peptide intermediates, the Pro residue should be placed in central positions of peptide intermediates. Thus, on the basis of the solubility prediction method, principally, we can design the proper synthetic route A of human proinsulin C-peptide as shown in Fig. 2. Assembled peptide intermediates in the route A are predicted to be sufficiently soluble in the polar solvents and to be susceptible to the subsequent fragment condensations **1**—**6**. All acid component candidates are also predicted to be sufficiently soluble in AcOH and to be converted to the corresponding acid components by removal of the Pac group from the peptide esters using Zn dust in AcOH. Contrary to the proper route A, if we choose the erroneous route B in Fig. 2, the acid component candidate obtained by the fragment condensation **5** is confronted with the insolubility problem on removal of the Pac group from the peptide ester using Zn dust in AcOH.

Infrared Absorption Study of Human Proinsulin C-Peptide Fragments in the Solid State[1)]

Mitsuaki NARITA,* Toshihiko OGURA, Kazuhiro SATO, and Shinya HONDA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received March 15, 1986)

In order to evaluate the propriety of the solubility prediction method for peptide intermediates having polar side chains, IR absorption spectroscopic analysis of human proinsulin C-peptide fragments was performed in the solid state. The polar amino acid residues involved in the peptide fragments are in the following: Glu(OBzl), Asp(OBzl), Gln, and Ser(Bzl). All peptide fragments except for ones containing the Pro residue exhibit a high potential for the formation of a β-sheet structure, indicating that, even when the polar side chains of the Glu, Asp, and Ser residues are protected by the Bzl group, the coil conformation parameter P_c for each amino acid residue is useful for estimating the potential for the formation of a β-sheet structure of peptide fragments smaller than critical size for development of α-helical structure in the solid state. As in the case of hydrophobic peptides, the β-sheet aggregation clearly plays an important role in reducing solubility of the peptide fragments having polar side chains. The effect of the Pro residue on the disturbance of the β-sheet structure was also observed. The ability of the short-range (polar side chain-backbone) or intraresidue interactions due to the low flexibility of the pyrrolidine ring of the Pro residue to promote helical folding in peptide fragments in the solid state was not observed for the peptide fragments corresponding to helical regions of human proinsulin.

In a previous paper,[2)] the usefulness of the solubility prediction method proposed previously by us[3)] was demonstrated taking the synthesis of human proinsulin C-peptide fragments as an example. On the basis of the solubility prediction of peptide intermediates, subsequently, a strategy suitable for the design of the synthetic route for peptides and proteins was proposed. Insolubility of peptide intermediates is essentially caused by a β-sheet aggregation formed by peptides equal to or larger than an octapeptide sequence level and their solubility is independent on their amino acid sequences and compositions.[4)] Thus, the solubility prediction method is principally based on both the randomness of peptide intermediates in the solid state and the existence of tertiary peptide bond, that is, the disturbance of the β-sheet structure by the rotation of the tertiary peptide bond plane. In order to evaluate the structural randomness of peptide chains, we have used the coil conformation parameter, P_c, for each intact amino acid residue which is determined according to the definition of Chou and Fasman.[5)] One of our purposes in this study is to examine the propriety of evaluation of the structural randomness of peptide fragments with protected polar side chains using the coil conformation parameter, P_c, obtained for each intact amino acid residue.[3)]

The correctness of the concept of the solubility prediction method was moreover verified by the another evidence that solubility improvement on oligopeptides was easily achieved by a β-sheet → helix conformational transition using the ability of the Aib residue to promote helical folding in oligopeptides.[4,6)] The ability of the Aib residue to promote helical folding was distinctly demonstrated using oligo(Leu)s and was clearly attributed to the restriction of the values of the backbone dihedral angles ϕ and ψ of the Aib residue to helical regions due to steric hindrance.[6)] These result also suggested that the restriction of the values of the backbone dihedral angles ϕ and ψ of an amino acid residue to the right-handed α-helical region (ϕ=−57° and ψ=−47°) was one of important initiation mechanisms of α-helical folding in natural proteins.[6)] In connection with the results, it is quite interesting to investigate the ability of the short-range (polar side chain-backbone) or intraresidue interactions due to the low flexibility of the pyrrolidine ring of the Pro residue to promote helical folding in peptide fragments since two helical regions of human proinsulin are included in fragments of the C-peptide.

In this paper, we report IR absorption spectroscopic analysis of human proinsulin C-peptide fragments with protecting groups in the solid state and investigate the points described above.

Experimental

Materials. Samples of human proinsulin C-peptide fragments are those prepared in the previous paper.[2)] The solid samples of the peptides **1** and **5—9** were obtained by repeated recrystallization from appropriate solvents.[2)] Those of the peptides **2—4** and **10** were obtained by repeated washing with hot methanol or ethanol. The purity of the peptides **1—10** was confirmed by the amino acid and elemental analyses. The peptides **1—3** and **5—10** which were soluble in *N,N*-dimethylformamide also gave a single peak on HPLC.

IR Measurements. The IR absorption spectra of the solid samples were recorded with a Jasco Model DS-701G spectrometer in a nujol mull.

Results

IR Absorption Spectroscopic Analysis of Each Peptide Fragment in the Solid State. parentheses in the following C-peptide represent the positions of the first and last amino acids from the N-terminal in the C-peptide. Figures 2 and 3 show the IR absorption spectra of the peptides **1**—**4**, **7**, **8**, and **10** in the solid state in the most significant spectral regions for the conformational assignments (3600—3200 cm^{-1}, amide A; 1800—1600 cm^{-1}, amide I). All of the peptides show strong bands at 3290—3270 cm^{-1} and 1635—1625 cm^{-1}, assigned to a typical β-sheet structure.[7] The absorption band at 1690 cm^{-1} of the peptides **3**, **4**, and **10** also suggests the antiparrallel β-sheet structure. The absorption band or shoulder around 1750 cm^{-1} is assigned to the Pac ester carbonyl group, while the bands around 1730, and 1706 cm^{-1} are assigned to the Bzl ester- and Boc urethane-carbonyl groups, respectively. These absorption bands were assigned by IR measurement in dichloromethane of the peptides **1**, **7**, and **8**. The Pac ketone carbonyl group is estimated to show the band around 1685 cm^{-1}, overlapped with the amide carbonyl group. Although the absorption band characteristic to the Gln side-chain amide can not clearly be assigned, the band at 1660—1655 cm^{-1} of the peptide **2**—**4**, **7**, and **10** is incidentally assigned to the Gln side-chain amide. Similar assignment was reported for the Asn side-chain amide.[8] Figure 4 represents the IR absorption spectra in the solid state of the peptides **5**, **6**, and **9**, which contain the Pro residue in central positions of the peptide chains. These IR absorption spectra are accompanied by additional strong broad shoulders at 1680—1650 cm^{-1}, indicating the disturbance of β-sheet structures by the rotation of the tertiary peptide bond planes (Gly-Pro and Gln-Pro) as reported in previous papers.[9-13] The peptide **9** happens to have, except for the Pro residue, the very close amino acid sequence with the peptide **10**, clearly showing the effect of the Pro residue in a central position of the peptide chain on the disturbance of the β-sheet structure in the peptide

9.

Discussion

All peptide fragments **1**—**4**, **7**, **8**, and **10**, except for the peptides **5**, **6**, and **9** containing the Pro residue, exhibit a high potential for the formation of the β-sheet structure. Their chain lengths range from a tripeptide to a tridecapeptide. The results indicate that, with respect to peptides having protected or intact polar amino acid residues such as the Glu(OBzl), Asp(OBzl), Gln, and Ser(Bzl) residues, the polar side chain-backbone (short-range) interactions within neighboring residues can not give rise to the disturbance of the formation of the β-sheet structure of the peptides in the solid state. The typical β-sheet structure of the higher oligopeptides **2**—**4** and **10** is also supported by the fact that these peptides have low solubility as reported previously.[2] If the short-range interactions play an important role in determing the conformation of the peptides, it is estimated that they conduct the peptides to random coil, turn, or helical structure, resulting in high solubility of the peptides.

In Table 1, the conformational parameters $\langle P_c \rangle$, $\langle P_\alpha \rangle$, and $\langle P_\beta \rangle$ of each peptide fragment are summarized. The values of $\langle P_c \rangle$,[3] $\langle P_\alpha \rangle$,[5] and $\langle P_\beta \rangle$[5] were determined according to the literatures. The low values of average coil conformation parameters, $\langle P_c \rangle$, of the peptide fragments **1**—**4** and **7**—**10** suggest that these peptides are highly structured. In actuality, all of the peptide fragments **1**—**4**, **7**, **8**, and **10**, except for the peptide **9** containing the Pro residue, exhibit the high potential for the formation of the β-sheet structure (Figs. 2 and 3). The conformational behaviors of the peptides **1**—**4**, **7**, **8**, and **10** indicate that, even when the polar side chains of the Glu, Asp, and Ser residues are protected by the Bzl group, the coil conformational parameters, P_c, obtained for each intact amino acid residue are useful for estimating the potential for the formation of a β-sheet structure of peptides smaller than critical size for development of α-helical structure in the solid state. On the contrary, the $\langle P_\beta \rangle$ values of the peptides except for **3** and **7** are very low, indicating a low potential for the formation of the β-sheet structure of these peptides. In the case of the peptides **1**, **2**, **4**, and **8**—**10** which are smaller than a critical size for development of α-helical structure in the solid state, their high $\langle P_\alpha \rangle$ values indicate a high potential for the formation of the β-sheet structure. Eventually, we can easily estimate the potential for the formation of the β-sheet structure of peptide intermediates only using their $\langle P_c \rangle$ values.

Table 1. The Values of Average Conformational Parameters $\langle P_c \rangle$, $\langle P_\alpha \rangle$, and $\langle P_\beta \rangle$ of the Peptides **1**—**10**

Peptide	$\langle P_c \rangle$	$\langle P_\alpha \rangle$	$\langle P_\beta \rangle$
1	0.85	1.37	0.70
2	0.84	1.33	0.46
3	0.88	1.07	1.03
4	0.86	1.26	0.68
5	1.22	0.69	0.81
6	1.12	0.90	0.91
7	0.95	1.10	1.06
8	0.78	1.24	0.90
9	0.93	1.12	0.92
10	0.91	1.19	0.96

The β-sheet→helix conformational transition is provoked by the change of intermolecular hydrogen bonds to intramolecular hydrogen bonds, providing high solubility of peptides. In fact, we previously showed a dramatic solubility change of oligo(Leu)s by the complete β-sheet→helix conformational transition using the great ability of the Aib residue to promote helical folding in peptides.[4,6] As well known, the β-sheet→helix conformation transition is dependent on a peptide chain length, and the critical chain length for α-helix formation in the solid state in oligopeptides is not lower than n=10 although it depends on the nature of the constituent amino acid residues.[14] On the other hand, we have demonstrated that the restriction of the values of the backbone dihedral angles ϕ and ψ of the Aib residue to helical regions is an important initiation and stabilization mechanisms of helical folding in peptides.[4,6] In this case, the restriction of the values ϕ and ψ of the Aib residue is apparently attributed to the intraresidue interactions due to steric hindrance,[15] being favorable

to helical folding in peptides. Therefore, if nucleation sites for helical folding in peptide fragments is able to predict as in the case of the Aib residue, it is useful for predicting their solubility. In certain cases, turn structures, which are mainly promoted by backbone-backbone interactions within neighboring residues, are suggested to be nucleation sites for helix formation in proteins.[16] Therefore, the polar side chain-backbone interactions within neighboring residues have the possibility to promote helical folding in oligopeptides. However, unfortunately, the octapeptides **2**, **3**, and **10** having high $<P_\alpha>$ values show the β-sheet structure in the solid state, and no ability of the short-range interactions to promote helical folding in each peptide was observed.

The estimated structure of human proinsulin indicates that the protein contains three short helices, and two of them are included in the part of human proinsulin C-peptide.[17] These helical regions are also included in the peptides **4** and **9**. However, the tridecapeptide **4** also has the β-sheet structure in the solid state, indicating no ability of the short-range interactions to promote helical folding in the peptide **4**. In the sequence analysis of helical regions in proteins, several authors[18-21] have pointed out the tendency of charged side chains to cluster at the ends of helices. Blagdon and Goodman[16] have also suggested that the proper arrangement of charged side chains stabilize helices and they have denoted the route to helix formation as a polar mechanism of initiating helices. Therefore, one of causes of no ability of the peptide **4** to promote helical folding may be attributed to the negation of negative charges at the Glu and Asp residues by their protection with the Bzl group.

In connection with the fact that the most frequently observed conformations for the Pro residue lie in the region of the backbone dihedral angles $\phi=-60°\pm10°$ and $\psi=-30°\pm20°$, and $\phi=-60°\pm10°$, $\psi=-120\pm20°$ due to the low flexibility of the pyrrolidine ring in the Pro residue,[22] in which the former is corresponding to the helical region, it is quite interesting to investigate the ability of the Pro residue to promote helical folding in the peptide **9** due to the low flexibility of the pyrrolidine ring of the Pro residue, which is one of intraresidue interactions as in the case of the Aib residue. Unfortunately, the sample of the peptide **9** in the solid state mainly shows the β-sheet structure, accompanied by an unordered structure which is caused by the rotation of the tertiary peptide bond plane (Gln-Pro) due to steric hindrance. On the other hand, IR conformational analysis of the peptide **9** in dichloromethane solution clearly indicates that the peptide **9** has successive-intramolecular hydrogen bonds, probably corresponding to a stable α-helix in solution.[23] Therefore, another procedure for the preparation of the solid sample of the peptide **9** was examined. But IR conformational behaviors of the sample obtained by reprecipitation by pouring the dichloromethane solution into hexane were essentially the same with the sample before, indicating that the α-helical structure of the peptide **9** in dichloromethane solution was not so stable enough to tolerate the phase transformation from solution into the solid state.

Infrared Absorption Study of Human Proinsulin C-Peptide Fragments in Dichloromethane[1)]

Mitsuaki NARITA,* Toshihiko OGURA, Kazuhiro SATO, and Shinya HONDA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received March 20, 1986)

In connection with the relationship between the conformation and solubility of peptide intermediates having polar side chains, IR spectroscopic conformational analysis of human proinsulin C-peptide fragments was performed in dichloromethane. The polar amino acid residues involved in the peptide fragments are Glu(OBzl), Asp(OBzl), Gln, and Ser(Bzl). Especially, the N-H stretching absorption spectra have been explored over a wide range of concentration. Based on the concentration dependence of the N-H stretching bands, it has been shown that the characteristic N-H stretching band around 3330 cm^{-1} is due to the intramolecular hydrogen bond. Intermolecular hydrogen bonding also occurs to a small extent in these peptides, giving rise to a slight concentration dependence of the N-H stretching bands. Conformational behaviors of oligopeptides having protected polar side chains of the Glu(OBzl) and Asp(OBzl) residues are just the same as those of the corresponding homooligo(Leu)s, indicating that the protected polar side chains do not disturb conformational behaviors of the oligopeptides. Conformational analysis of the peptide in dichloromethane, which contains the Pro residue and has a high potential for the formation of an α-helical structure, distinctly suggests that the Pro residue near the N-terminal in the peptide has the great ability to promote successive intramolecular hydrogen bonds, probably corresponding to the α-helical structure of the peptide.

In connection with the design of the synthetic route for peptides and proteins based on the solubility prediction method,[2-4)] it is quite interesting to investigate conformational behaviors of peptide intermediates in solution since the investigation offers useful information for the solubility prediction of peptide intermediates. In the previous paper,[4)] we reported IR spectroscopic conformational analysis in the solid state of human proinsulin C-peptide fragments. Here, we report their IR spectroscopic conformational analysis in dichloromethane, which is commonly used in conventional solid-phase peptide synthesis.[5,6)] Especially, in this paper, we give attention to the role of the Pro residue in solubility improvement of peptide fragments containing the Pro residue.

The Pro residue is well recognized to a strong helix and β-sheet breaker and plays an important role in stopping the development of helix and β-sheet structures in peptides and proteins.[7-10)] In fact, the insertion of the Pro residue into oligo(Leu)s caused "the peptide segment separation" in the solid state and achieved remarkable solubility improvement of peptides in a variety of organic solvents.[11-13)] The effect of the Pro residue on increasing solubility of peptide intermediates was also confirmed in human proinsulin C-peptide fragments.[2)]

On the other hand, the values of the backbone dihedral angles ϕ and ψ of the Pro residue are severely restricted to be $\phi=-60°\pm10°$, $\psi=-30°\pm20°$, and $\phi=-60°\pm10°$, $\psi=-120°\pm20°$ due to the low flexibility of the pyrrolidine ring in the Pro residue.[14)] In our recent papers,[15,16)] we demonstrated the great ability of the Aib residue to promote helical folding in peptides due to the short-range interactions by van der Waals repulsions and subsequently proposed that the restriction of the dihedral angles was one of important initiation mechanisms of helical folding in the natural proteins. One of our purposes in this paper is also to investigate the ability of the Pro residue to promote helical folding in oligopeptides in solution.

Experimental

Materials. Samples of human proinsulin C-peptide fragments are those prepared in the previous papers.[2)] The purity of the peptides was confirmed by the amino acid and elemental analyses. The peptides also gave a single peak on HPLC. The peptide fragments used in this study are in the following: Boc-Glu(OBzl)-Ala-Glu(OBzl)-Asp(OBzl)-Leu-OPac (**1**), Boc-Leu-Ala-Leu-Glu(OBzl)-Gly-OPac (**2**), Boc-Gly-Gly-Pro-Gly-Ala-Gly-OPac (**3**), Boc-Ser(Bzl)-Leu-Gln-Pro-Leu-Ala-Leu-Glu(OBzl)-Gly-OPac (**4**), and Boc-Ser(Bzl)-Leu-Gln-OPac (**5**).

IR Measurements. The IR absorption spectra of the samples in dichloromethane were recorded at room temperature with a JEOL Model JIR-100 FT-IR spectrometer by employing 0.5 mm- and 5 mm-path length cells with potassium bromide windows.

Results

IR Absorption Study of the Pentapeptide Fragments 1 and 2 in Dichloromethane. Conformational analysis of peptide fragments having polar side chains is quite interesting in order to elucidate the role of protected polar amino acid residues in conformational behaviors of peptide fragments in dichloromethane. As reported in the previous paper,[2)] the pentapeptides **1** and **2** are easily soluble in dichloromethane, and their IR absorption spectra are easily obtained over a wide range of concentration (1.0×10^{-4}—10^{-2} M[†]). In Fig. 1, we show the N-H stretching bands of both peptides in dichloromethane and

[†] 1 M=1 mol dm^{-3}.

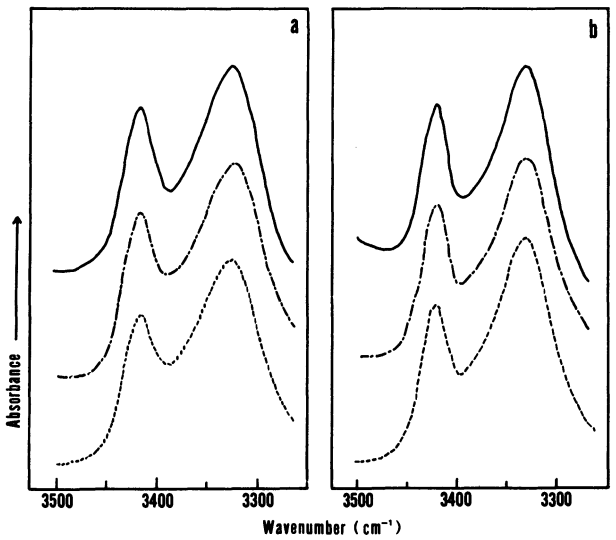

Fig. 1. Concentration dependence of the N-H stretching bands in the IR absorption spectra of the peptides **1** and **2** in dichloromethane. -----: 1.0×10^{-2} M, —·—·—: 1.0×10^{-3} M, ——: 1.0×10^{-4} M. a: The peptide **1**; b: the peptide **2**.

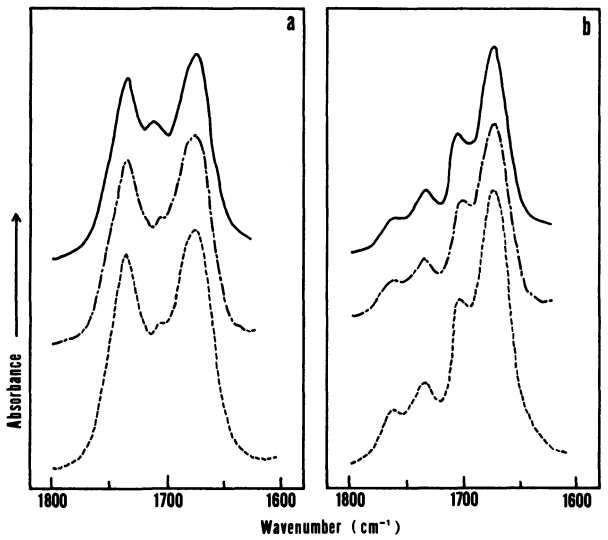

Fig. 2. Concentration dependence of the IR absorption bands in the amide I region of the peptides **1** and **2** in dichloromethane. -----: 1.0×10^{-2} M, —·—·—: 1.0×10^{-3} M, ——: 1.0×10^{-4} M. a: The peptide **1**; b: the peptide **2**.

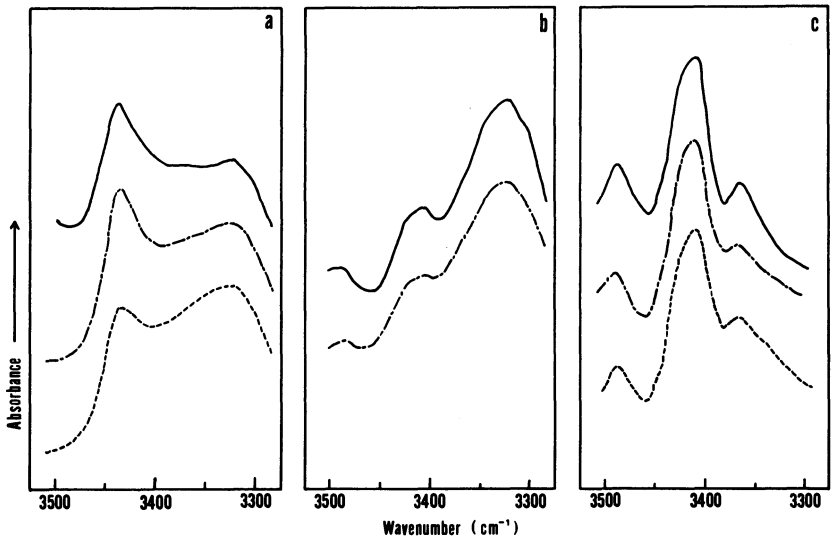

Fig. 3. Concentration dependence of the N-H stretching bands in the IR absorption spectra of the peptides **3**—**5** in dichloromethane. -----: 1.0×10^{-2} M, —·—·—: 1.0×10^{-3} M, ——: 1.0×10^{-4} M. a: The peptide **3**; b: the peptide **4**; c: the peptide **5**.

clearly see two distinct bands at 3420 and 3330 cm^{-1} over the entire concentration range. The 3420 cm^{-1} band is clearly due to the free N-H stretching vibration, while the 3330 cm^{-1} band is due to a hydrogen-bonded species.[17-19] Since the intensities of these two bands show little dependence on concentrations, the 3330 cm^{-1} band is attributed mainly to the intramolecular hydrogen-bonded species, accompanied by a slight contribution from intermolecular hydrogen bonding. The IR absorption spectra in the amide I region of the peptides **1** and **2** in dichloromethane are also illustrated in Fig. 2. The IR spectra of both peptides measured over the wide range of concentrations show the bands around 1760, 1733, 1706, and 1675 cm^{-1}, corresponding to the Pac ester carbonyl, Bzl ester carbonyl, Boc urethane carbonyl, and amide carbonyl groups, respectively. The Pac ketone carbonyl group is estimated to have the absorption band around 1685 cm^{-1}, overlapped with the amide carbonyl group. The amide carbonyl band also showed little dependence on concentration (1.0×10^{-4}—10^{-2} M).

IR Absorption Study of the Hexapeptide 3, Nonapeptide 4, and Tripeptide 5 in Dichloromethane. The IR absorption spectra in the N-H stretching region of the peptides **3**—**5** in dichloromethane (1.0×10^{-4}—10^{-2} M) are shown in Fig. 3. We also see two

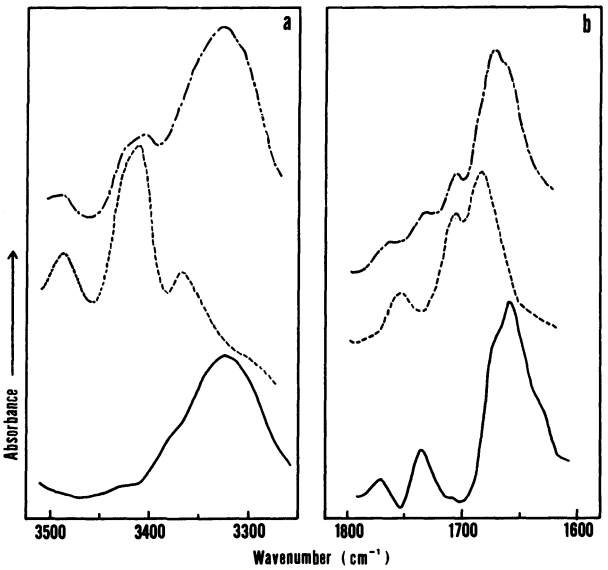

Fig. 4. IR absorption spectra in the amide A and amide I regions of the peptides **4** and **5** in dichloromethane (1.0×10^{-4} M). —·—·—: The peptide **4**, ------: the peptide **5**, ——: IR difference spectra for the peptides **4** and **5**. a: The amide A region; b; the amide I region.

distinct bands at 3435—3425 cm^{-1} and around 3370 or 3330 cm^{-1} over the entire concentration range. The peptides **4** and **5** have the additional absorption band at 3487 cm^{-1} corresponding to the side-chain amide group, which is free from hydrogen bonding. Again, the 3430 cm^{-1} band is due to the free N-H stretching vibration, while the bands around 3370—3330 cm^{-1} are due to hydrogen-bonded species. The intensities of the hydrogen-bonded band of the peptide **3** (Fig. 3a) are more dependent on concentration than the intensities of the band at 3330 cm^{-1} of the peptides **1**, **2**, **4**, and **5** (Figs. 1, 3b, and 3c), indicating that the peptide **3** is accompanied by more contribution from intermolecular hydrogen bonding than the peptides **1**, **2**, **4**, and **5**. Figures 4a and 4b show the IR absorption spectra in the amide A and amide I regions of the peptides **4** and **5** in dichloromethane (1.0×10^{-4} M). The amide carbonyl band also showed little dependence on concentration (1.0×10^{-4}—10^{-2} M) (not shown). Assignment of each band in the amide I region of the peptides **4** and **5** is essentially the same with that of the peptides **1** and **2**. In Figs. 4a and 4b, the IR difference spectra for both peptides are also represented. The spectra indicate the disappearance of the free N-H stretching vibration and clear-cut features of absorption bands at 3323 $^{-1}$ and 1658 cm^{-1}, probably assigned to the α-helical structure.[17-19]

Discussion

Contrary to the fact that the pentapeptides **1** and **2** in the solid state have the β-sheet structure,[4] in dichloromethane, the clear conformational transformation from intermolecular to intramolecular hydrogen bonding takes place in both peptides. The N-H stretching absorption band at 3330 cm^{-1} of the peptides **1** and **2** shows little dependence on concentration, indicating a slight contribution from inter molecular hydrogen bonds, which are apparently different from the intermolecular hydrogen bonds in the solid state assigned by the band at 3270 cm^{-1} (β-sheet). Their conformational behaviors both in the solid state and in dichloromethane are just the same as those of Boc-Leu_4-OBzl and Boc-Leu_5-OBzl,[20] indicating that the protected polar side chains of the Glu(OBzl) and Asp(OBzl) residues do not disturb the conformational behaviors of the pentapeptides **1** and **2** both in the solid state and in dichloromethane. Since the IR difference spectrum in dichloromethane for Boc-Leu_5-OBzl and Boc-Leu_3-OBzl suggests that the conformation formed by the intramolecular hydrogen bonds of Boc-Leu_5-OBzl appears to be a helical structure in dichloromethane,[20] the conformation of the peptides **1** and **2** is assumed to be the helical structure in dichloromethane. A little concentration dependence of the peptides **1** and **2** is assumed to be mainly due to intermolecular hydrogen bonds between the free N-H and C=O groups in the helical structure. On the other hand, Boc-Gln-Val-Glu(OBzl)-Leu-Gly-OPac **6**, which is also the partial sequence of the C-peptide, has the β-sheet structure in the solid state and it is insoluble in dichloromethane.[2,4] The insolubility represents that, in dichloromethane, the conformational transformation from intermolecular to intramolecular hydrogen bonding does not take place in the pentapeptide **6**. The insolubility is probably due to intermolecular hydrogen bonds through the Gln side-chain amide as reported for oligopeptides containing the Asn residue,[21] and the intermolecular hydrogen bonds may interrupt the conformational transformation from intermolecular to intramolecular hydrogen bonding in dichloromethane.

With respect to the role of the Pro residue in conformational behaviors of peptides containing the Pro residue, as reported in the previous papers,[2,4] the peptides **3** and **4** in the solid state, which contain the Pro residue in central positions in the peptide chains, have strong bands at 3290—3270 and 1635—1630 cm^{-1}, accompanied by strong broad shoulders at 1700—1650 cm^{-1} in the amide I region, indicating the disturbance of the β-sheet structure by the rotation of the tertiary peptide bond planes (Gly-Pro and Gln-Pro). In the solid state, the role of the Pro residue in conformational behaviors of the peptides **3** and **4** is just the same as that of oligo(Leu)s as reported in previous papers.[11-13] In dichloromethane, each Pro residue in the hexapeptide **3** and the nonapeptide **4** clearly plays a different role in conformational behaviors of both peptides. When we compare

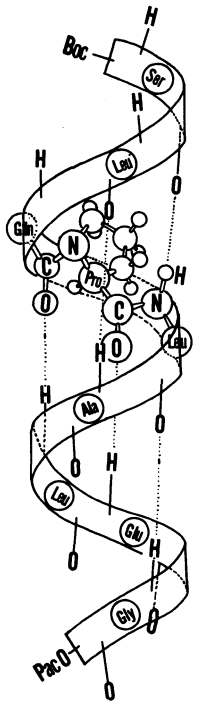

Fig. 5. α-Helical structure of the peptide **4**. Circles containing abbreviations for amino acids represent C^{α} atoms for each amino acid.

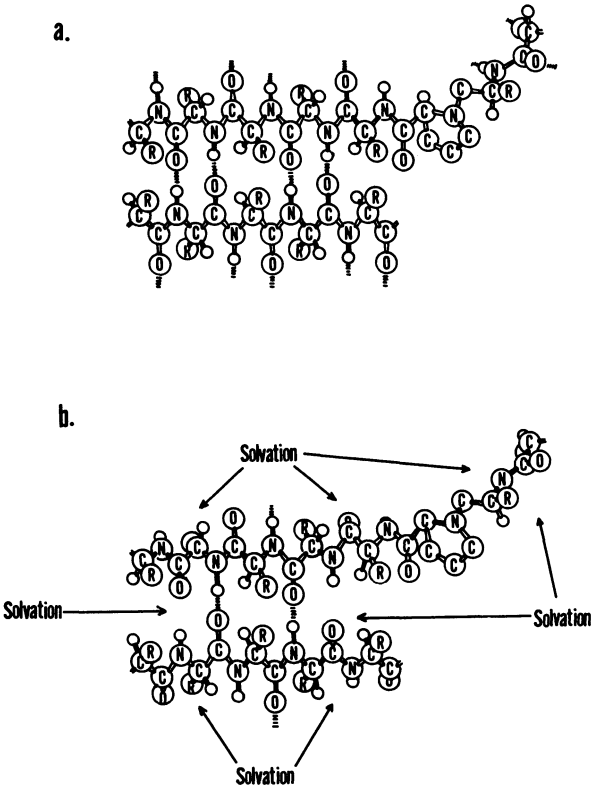

Fig. 6. Role of the Pro residue in dissolving process of the peptide **4**. a: In the solid state; b: solvating process.

solubility of the peptide **3** with that of Boc-Gly_6-OBzl,[22] the solubility improvement in the peptide **3** by the Pro residue is quite significant. The Pro residue in the peptide **3** clearly disturbs the development of the β-sheet structure in dichloromethane. The peptide **3** contains the four Gly residues, and each Gly residue can explore a large conformational space,[22,23] thus inducing a high flexibility to the peptide chain. Actually, the wide range of hydrogen bonded N-H stretching band and concentration dependence of the peptide **3** indicate that the peptide **3** in dichloromethane contains many kinds of intermolecular and intramolecular hydrogen bonds and exists in more than one conformation. On the other hand, the conformational behaviors of the peptide **4** in dichloromethane, which has polar side chains, are just the same as those of Boc-Leu_3-Pro-Leu_4-OBzl (**7**),[20] and the IR difference spectrum for the peptides **4** and **5** (Fig. 4) suggests that the peptide **4** appears to have successive-intramolecular hydrogen bonds, probably corresponding to the α-helical structure as shown in Fig. 5. This is in remarkable contrast with the fact that Boc-Leu-Ala-Leu-Glu(OBzl)-Gly-Ser(Bzl)-Leu-Gln-OPac (**8**), which is also the partial sequence of the C-peptide and has the very close amino acid sequence with the peptide **4**, has the β-sheet structure in the solid state and is insoluble in dichloromethane.[2,4] The peptides **4** and **7** have high parameters for α-helix formation, and their $<P_{\alpha}>$ values[24] are 1.12 and 1.25, respectively. In fact, the peptide **4** is included in one of helical regions in human proinsulin.[25] In comparison with the conformational behaviors of the peptide **8**, the IR difference spectra for the peptides **4** and **5** in dichloromethane clearly suggest that the Pro residue, which exists in near the N-terminal portion in the peptide having a high potential for the formation of the α-helical structure, plays an important role in helical folding in the peptide. Figure 6 represents the role of the Pro residue in dissolving process of the peptide **4**. The Pro residue in the peptide **4** clearly disturbs the development of the β-sheet aggregation in the solid state by the rotation of the tertiary peptide bond plane (Gln-Pro) and facilitates solvation of the peptide chain. Thus, the restriction of the values of the backbone dihedral angles ϕ and ψ of the Pro residue appears to promote helical folding in dichloromethane of the peptide **4**.

(Received February 27, 1986)

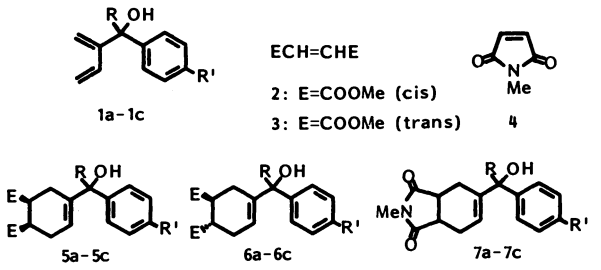
The Diels-Alder reactions of 1-aryl-2-methylene-3-buten-1-ols, readily available from chloroprene and aryl ketones, with olefinic dienophiles and subsequent electrocyclic reactions of the cycloadducts offer a new method of [6.5] annelation to benzene ring. By this way, tetrahydrofluorene skeletons bearing functional groups can be prepared. Stereochemical aspect of this sequence is also discussed.

The Diels-Alder reaction involves the interaction between diene and dienophile forming six-membered ring with an endo double bond. Therefore, two rings annelation including a six-membered ring will be established when another ring-forming reaction is performed across this unsaturated bond. Such sequential ring formation is quite limited,[1] while the double Diels-Alder cycloaddition of cross-conjugated trienes offers an annelation method of this category.[2] It is important that the sequential ring formation is to be initiated by Diels-Alder cycloaddition since this cycloaddition takes place in a highly stereoselective and stereospecific manner. The second ring formation is expected to occur also in a selective way to afford stereochemically defined fused ring systems.[3]

Our method for sequential [6.5] annelation consists of the initial Diels-Alder reactions on 1-aryl-2-methylene-3-buten-1-ols and the subsequent acid-catalized electrocyclic reactions of the cycloadducts. In the Diels-Alder steps, dimethyl maleate, fumarate, and *N*-methylmaleimide are employed as representatives for cis, trans, and cyclic olefinic dienophiles, respectively. It should be emphasized that the present method permits the introduction of several functional groups onto tetrahydrofluorene skeletons.[4]

Results and Discussion

Diene alcohols **1a—c** as starting materials in the present [6.5] annelation can be prepared from the reaction of 2-lithio-1,3-butadiene with aryl ketones.[5] Without separation of isomeric allene alcohols as side products, the Diels-Alder reaction with dimethyl maleate (**2**), fumarate (**3**), or *N*-methylmaleimide (**4**) was carried out under reflux in benzene to give the corresponding cycloadducts **5a—c**, **6a—c**, or **7a—c**, in excellent yields (Table 1). These cycloadducts were separated from the unreacted allene alcohols through column chromatography. Then, acid-catalyzed electrocyclic reaction of these cycloadducts was investigated under various conditions.[6]



a: R=Ph, R'=H; b: R=Me, R'=H; c: R=Me, R'=OMe

The maleate cycloadduct **5a** derived from benzophenone adduct **1a** was found to undergo ready cyclization, in the presence of trifluoroacetic acid (TFA) or zinc chloride, to afford a mixture of two stereoisomeric tetrahydrofluorene derivatives **8a** and **9a** together with a trace amount of diene **10a** (Entries 1—3 in Table 2). Structures of the major product **8a** and the minor one **9a** were assigned to be 3,4a-cis and 3,4a-trans isomers on the basis of coupling constants J_{3-4}, and J_{4-4a}, and also by comparison with their

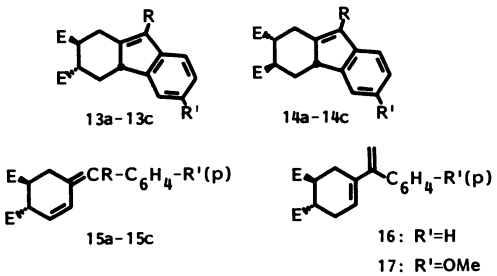
isomers **13a** and **14a** obtained from similar cyclization of fumarate cycloadduct **6a**.[7] No isomerization between **8a** and **9a** was observed under conditions of the cyclization, indicating that one of two possible conrotatory rotations has predominantly occurred to lead to this high stereoselectivity. This will be discussed later. The highest selectivity in favor for the 3,4a-cis isomer **8a** was obtained (**8a**:**9a**=95:5) when cyclization was carried out in benzene at room temperature in the presence of molecular sieves 5A (Entry 4). Although some examples for the dehydration of tertiary alcohols with molecular sieves are already known,[8] this example might be the first case in which molecular sieves are utilized in cationic cyclization reactions.

Other maleate cycloadducts **5b** and **5c** derived from acetophenone adducts **1b** and **1c** similarly cyclized within 5 min at room temperature in the presence of TFA, to give two stereoisomeric tetrahydrofluorenes **8b**+**9b** and **8c**+**9c** (Entries 5 and 7 in Table 2). However, no cyclized product was obtained when **5b** or **5c** was treated with aqueous HCl (Entries 6 and 8). 1-(1-Arylvinyl)cyclohexene **11** or **12** as a major product in this reaction was found to be a kinetically controlled product since **11** or **12** gradually isomerized into 3-methylenecyclohexene **10b** or **10c** under conditions of the dehydration. Although **10b** or **10c** underwent no cyclization, **11** or **12** cyclized on treatment with TFA leading to quantitative yield of **8b**+**9b** or **8c**+**9c**, respectively.[9]

Fumarate cycloadducts **6a**—**c** underwent cyclizations into the corresponding tetrahydrofluorene derivatives **13a**—**c** and **14a**—**c** under similar conditions (Entries 9—19 in Table 2). However, stereoselectivity between **13** and **14** was found extremely low under all the conditions employed for cyclization. This makes a striking contrast with the stereoselective cyclization of maleate cycloadducts **5a**—**c**. Formation of 3-methylenecyclohexenes **15** as side products was not critical, and 1-(1-arylvinyl)cyclohexene **16** or **17** was the only product when acetophenone adduct **6b** or **6c** was treated with aqueous HCl, respectively.



R=Ph, R'=H; b: R=Me, R'=H; c: R=Me, R'=OMe

Maleimide cycloadducts **7a**—**c** underwent similar cyclizations in the presence of TFA or molecular sieves

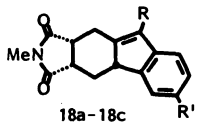
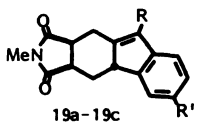
a) Solvent: DCM: dichloromethane; BZ: benzene. Catalyst: TFA: trifluoroacetic acid; MS: molecular sieves 5A. The catalyst was used in large excess in all cases. b) The ratio was determined by GLC.

5A to give two stereoisomeric octahydroindeno[1,2-*f*]isoindoles **18a—c** and **19a—c** (Table 3). Surprising is that the isomer ratio is very much dependent on the reaction conditions. The reactions in benzene in the presence of molecular sieves 5A preferentially produced 3a,4a-cis isomers **18** (**18**:**19**=71—85:29—15, Entries 4, 8, and 11). On the other hand, the reactions in the presence of TFA favored 3a,4a-trans isomers **19** rather than **18** (**18**:**19**=14—43:86—57, Entries 1—3, 6, 7, and 10). When acetophenone adduct **7b** or **7c** was treated with molecular sieves, noncyclized dehydration product **20** or **21** was formed as a side product, respectively.

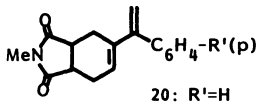


18a-18c



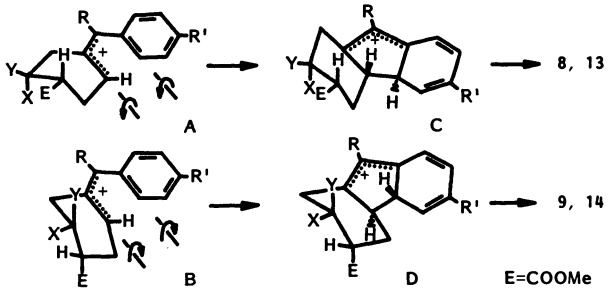
19a-19c

a: R=Ph, R'=H; b: R=Me, R'=H; c: R=Me, R'=OMe



20: R'=H
21: R'=OMe

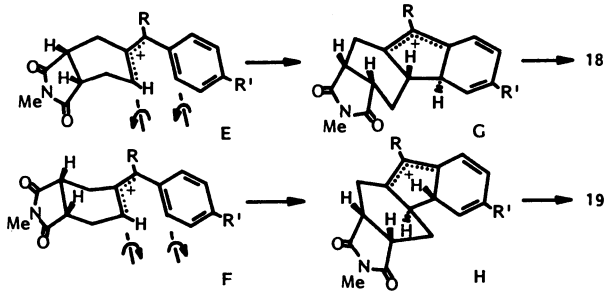
On the basis of the above results, such difference of stereoselectivity of these electrocyclic reactions may be explained as follows: as it is quite certain that the cyclization involves an aryl-substituted allyl cationic intermediate, the stereochemistry of cyclized products must have been determined at the stage of irreversible cyclization of this cation by either of two possible conrotatory rotations, clockwise and counterclockwise conrotatory rotations. Two half-chair conformations **A** and **B** (X=COOMe, Y=H) are possible for cationic intermediates from the maleate cycloadducts **5**, and they should have almost equal stability. Counterclockwise rotation of **A** leads to 3,4a-cis cyclization product **C**, while clockwise rotation of **B** forms sterically unfavorable 3,4a-trans isomer **D** whose quasi-chair six-membered ring carries an axial ester substituent at the 3-position causing considerable steric repulsion toward axial 4a-H.[10] Consequently, cyclization of **5** has predominantly occurred through counterclockwise rotation of **A** giving **8** as far major product.



On the other hand, stability of two cationic intermediates **A** and **B** (X=H, Y=COOMe) from the fumarate cycloadducts **6** is not identical. Conformer **A** bearing two ester groups at adjacent equatorial positions may be less stable than **B** with two axial ester substituents.[11] The less stable cation **A** undergoes cyclization through a transition state leading to more stable cyclization product **C**, and the more stable cation **B** to less stable product **D**. As a result, stereoselectivity between **13** and **14** was lowered.

In the case of electrocyclization of the maleimide cycloadducts **7**, cationic intermediates **E** and **F** are expected to cyclize into cyclization products **G** and **H**, respectively. During this transformation, conformation of the six-membered ring changes from a folded conformation into an envelope shape.[12] Relative stabilities should be **F**>**E** and **G**>**H**, and this situation resembles to the case of electrocyclization of fumarate cycloadducts **6**. However, difference of stability between **E** and **F** and between **G** and **H** may be relatively smaller.[13] This might be the main reason for the high dependence of stereoselectivity upon reaction conditions. Cyclization under less polar con-

ditions (e.g. use of molecular sieves in benzene) has favored the route going through more stable transition state (**E→G→18**). On the other hand, cyclization under more polar conditions (e.g. TFA in dichloromethane) has selected the route starting from more stable ionic intermediate (**F→H→19**).



Thus, the sequence of Diels–Alder reaction and electrocyclization of 1-aryl-2-methylene-3-buten-1-ols works well as a new method of [6.5] annelation. Stereoselectivity in the second electrocyclization step mainly depends upon the structure of dienophiles used in the initial Diels–Alder cycloaddition.

Experimental

General. Melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H-NMR spectra were recorded on a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C-NMR spectra on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as internal standard. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN micro analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or of aluminum oxide 60 F-254 type-E (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako), or Kieselgel 60 (230—400 mesh, Merck) was used. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Gas liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatography (Yanagimoto) with an ionization detector using a glass column (SE-30, 3×2000 mm). Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Materials and Solvents. Benzene and dichloromethane were distilled over sodium wire and calcium hydride, respectively, prior to their use. Zinc chloride was purified by crystallization from anhydrous dioxane and dried over phosphorus pentaoxide under vacuum. 1-Aryl-2-methylene-3-buten-1-ols **1a—c** were prepared according to the method previously reported.[5] They are available as mixtures with the corresponding allene alcohols (purity: **1a**: 50%; **1b**: 90%; **1c**: 95%). No separation of **1** from these mixtures is needed, but these mixtures were submitted to the following Diels–Alder cycloadditions. Other solvents such as THF, hexane, and ethyl acetate and olefins **2—4** are commercially available, and were used without further purification.

General Procedure for the Diels–Alder Reactions of 1 with 2—4 Leading to 5—7. Diene alcohols **1a—c** with the purity shown above and olefins **2—4** were heated under reflux in dry benzene (2—5 ml for 1 mmol of **1**) under the conditions listed in Table 1. The crude mixtures were condensed in vacuo and chromatographed over silica gel with hexane–ethyl acetate to give cycloadducts **5—7**. The results are summarized in Table 1.

5a: Colorless prisms (ethyl acetate–hexane); mp 113—115 °C; IR (KBr) 3500, 1725, and 1705 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.2—2.6 (4H, m, CH_2), 2.8—3.2 (3H, m, CH and OH), 3.58, 3.64 (each 3H, s, COOMe), 5.34 (1H, m, 2-H), 7.23, and 7.25 (each 5H, br s, Ph); ^{13}C-NMR ($CDCl_3$) δ=25.71, 26.36 (each t, 3- and 6-C), 39.51, 40.16 (each d, 4- and 5-C), 51.73 (2×C, q, COOMe), 82.49 (s, q-C), 124.64, 127.05, 127.46, 127.58, 127.75 (each d), 140.26, 144.60, 144.95 (each s), and 173.43 (2×C, s, COOMe); MS *m/z* (rel. intensity, %) 363 (M^+−17, 23), 362 (87), 303 (25), 302 (72), 244 (23), 243 (80), 183 (23), 165 (55), and 105 (base peak). Found: C, 72.73; H, 6.51%. Calcd for $C_{23}H_{24}O_5$: C, 72.61; H, 6.36%.

5b: (Mixture of two diastereomers): Colorless viscous oil; IR (neat) 3500 and 1725 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.61 (3H, s, Me), 2.0—3.1 (7H, m, CH_2, CH, and OH), 3.47, 3.49 (each 3H, s, COOMe), 5.86 (1H, m, 2-H), and 7.0—7.5 (5H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=25.58 (t, CH_2), 28.46, 28.80 (each q, Me), 39.52, 39.67, 39.96, 40.15 (each d, CH), 51.61, 51.80 (each q, COOMe), 76.12, 76.51 (each s, q-C), 119.24, 119.49, 125.24, 126.65, 127.92 (each d), 140.73, 140.93, 146.09 (each s), 173.33, 173.48, and 173.68 (each s, COOMe); MS *m/z* (rel. intensity, %) 301 (M^+−17, 31), 241 (50), 181 (base peak), and 105 (29). Found: C, 67.80; H, 6.91%. Calcd for $C_{18}H_{12}O_5$: C, 67.91; H, 6.97%.

5c: (Mixture of two diastereomers): Colorless viscous oil; IR (neat) 3500 and 1725 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ= 1.60 (3H, s, Me), 2.0—3.2 (7H, m, CH_2, CH, and OH), 3.51, 3.53, 3.62 (6H, each s, COOMe), 3.74 (3H, s, OMe), 5.85 (1H, m, 2-H), 6.79, and 7.24 (each 2H, br d, Ar); ^{13}C-NMR ($CDCl_3$) δ=25.58 (t, CH_2), 28.31, 28.65 (each q, Me), 39.47, 40.01, 40.10 (each d, CH), 51.56, 51.75 (each q, COOMe), 55.11 (q, OMe), 76.12 (s, q-C), 113.20, 119.05, 126.41 (each d), 138.25, 140.93, 158.22 (each s), 173.33, and 173.57 (each s, COOMe); MS *m/z* (rel. intensity, %) 348 (M^+, 13), 331 (21), 330 (base peak), 273 (21), 271 (29), 270 (61), 213 (28), 211 (91), 152 (48), and 135 (57). Found: C, 65.22; H, 7.02%. Calcd for $C_{19}H_{24}O_6$: C, 65.50; H, 6.94%.

6a: Colorless prisms (diethyl ether–hexane); mp 126—128 °C; IR (KBr) 3520, 3480, and 1720 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.0—2.6 (4H, m, CH_2), 2.7—3.0 (3H, m, CH and OH), 3.57, 3.63 (each 3H, s, COOMe), 5.34 (1H, m, 2-H), 7.22, and 7.26 (each 5H, br s, Ph); ^{13}C-NMR ($CDCl_3$) δ=27.83, 28.00 (each t, 3-and 6-C), 40.86, 41.57 (each d, 4- and 5-C), 51.72 (2×C, q, COOMe), 82.37 (s, q-C), 123.88, 127.17, 127.46, 127.81 (each d), 140.49, 144.48, 144.66 (each s), 174.84, and 175.01 (each s, COOMe); MS *m/z* (rel. intensity, %) 363 (M^+−17, 0.3), 302 (34), 243 (43), 183 (55), 165 (71), 155 (25), 105 (61), and 59 (base peak). Found: C, 72.52; H, 6.36%. Calcd for $C_{23}H_{22}O_5$: C, 72.61; H, 6.36%.

6b: (Mixture of two diastereomers): Colorless viscous

oil; IR (neat) 3500 and 1730 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.61, 1.62 (3H, each, s, Me), 2.0—3.0 (7H, m, CH_2, CH, and OH), 3.54, 3.61 (6H, each s, COOMe), 5.7—6.0 (1H, m, 2-H), and 7.0—7.5 (5H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=26.95, 27.53 (each t, CH_2), 28.24, 28.77 (each q, Me), 40.80, 41.33 (each d, CH), 51.67 (2×C, q, COOMe), 75.50, 76.15 (each s, q-C), 118.36, 118.95, 124.88, 124.99, 126.52, 127.81 (each d), 141.02, 145.60, 145.89 (each s), 174.89, and 175.07 (s). Found: C, 68.04; H, 7.07%. Calcd for $C_{18}H_{22}O_5$: C, 67.91; H, 6.97%.

6c: (Mixture of two diastereomers): Colorless viscous oil; IR (neat) 3500 and 1725 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.62 (3H, s, Me), 1.9—3.0 (7H, m, CH_2, CH, and OH), 3.55, 3.65 (each 3H, s, COOMe), 3.77 (3H, s, OMe), 5.86 (1H, m, 2-H), 6.81, and 7.26 (each 2H, br d, Ar); ^{13}C-NMR ($CDCl_3$) δ=27.30, 27.83 (each t, CH_2), 28.36, 28.94 (each q, Me), 40.98, 41.10, 41.63 (each d, CH), 51.84 (2×C, q, COOMe), 55.19 (q, OMe), 75.62, 76.21 (each s, q-C), 113.43, 118.36, 119.00, 126.35, 126.46, 128.22 (each d), 137.73, 138.09, 141.26, 158.40 (each s), and 175.07 (2×C, s, COOMe). MS *m/z* (rel. intensity, %) 348 (M^+, 16), 333 (32), 330 (55), 298 (37), 273 (26), 271 (29), 270 (85), 213 (21), 211 (base peak), 152 (54), 135 (72), and 133 (27). Found: C, 65.41; H, 7.05%. Calcd for $C_{19}H_{24}O_6$: C, 65.50; H, 6.94%.

7a: Colorless prisms (diethyl ether-hexane); mp 125—126 °C; IR (KBr) 3450, 1770, 1660, and 1600 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.9—2.7 (4H, m, CH_2), 2.86 (3H, s, NMe), 2.96 (2H, m, CH), 5.41 (1H, m, 6-H), and 7.2—7.3 (10H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=24.02 (t, 7-C), 24.85 (q, NMe), 25.39 (t, 4-C), 39.23, 39.96 (each d, 3a- and 7a-C), 81.62 (s, q-C), 124.95, 127.09, 127.09, 127.33, 127.62, 127.87 (each d), 143.90, 144.14, 145.07 (each s), 179.77, and 179.91(each s, CON); MS *m/z* (rel. intensity, %) 347 (M^+, 19), 329 (38), 165 (34), 112 (30), 105 (base peak), 80 (22), 78 (55), and 77 (91). Found: C, 76.08; H, 6.05; N, 4.18%. Calcd for $C_{22}H_{21}NO_3$: C, 76.06; H, 6.09; N, 4.03%.

7b: (Mixture of two diastereomers): Colorless viscous oil; IR (neat) 3420, 1770, and 1700 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.56, 1.58 (3H, each s, Me), 1.8—4.1 (7H, m, CH_2, CH, and OH), 2.79, 2.83 (3H, each s, NMe), 5.96 (1H, m, 6-H), and 7.23 (5H, m, Ph); ^{13}C-NMR ($CDCl_3$) δ=23.63, 23.93, 24.41 (each t, CH_2), 24.66 (q, NMe), 24.85 (t, 4-C), 27.68 (q, Me), 39.37, 39.62, 39.81 (d, CH), 75.87 (s, q-C), 119.49, 119.92, 125.24, 126.94, 128.01 (each d), 144.97, 145.31, 145.55 (each s), 179.27, 179.91, and 180.01 (each s, CON); MS *m/z* (rel. intensity, %) 285 (M^+, 5), 270 (19), 79 (36), 78 (30), 77 (69), and 43 (base peak). Found: C, 71.80; H, 6.70; N, 5.07%. Calcd for $C_{17}H_{19}NO_3$: C, 71.56; H, 6.71; N, 4.91%.

7c: (Mixture of two diastereomers): Colorless viscous oil; IR (neat) 3450, 1770, and 1690 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.54, 1.56 (3H, each s, Me), 1.8—3.2 (7H, m, CH_2, CH, and OH), 2.82, 2.85 (3H, each 3H, NMe), 3.75 (3H, s, OMe), 5.97 (1H, m, 6-H), 6.78, and 7.19 (each 2H, m, Ar); ^{13}C-NMR ($CDCl_3$) δ=23.68, 23.98 (each t, CH_2), 24.46, 24.85 (each q, Me), 24.90 (t, 4-C), 27.48, 27.87 (each q, NMe), 39.37, 39.42, 39.67, 39.86 (each d, CH), 55.21 (q, OMe), 75.29, 75.58 (each s, q-C), 113.35, 113.39, 119.14, 119.73, 126.45, 126.55 (each d), 137.12, 137.66, 145.55, 145.57, 158.42, 158.52 (each s), 179.42, 179.96, and 180.00 (each s, CON); MS *m/z* (rel. intensity, %) 315 (M^+, base peak), 300 (91), 272 (31), 192 (65), 151 (80), 135 (25), 121 (53), and 79 (23). Found: C, 68.60; H, 6.67; N, 4.55%. Calcd for $C_{18}H_{21}NO_4$: C, 68.55; H, 6.71; N, 4.44%.

General Procedure for the Acid-Catalyzed Electrocyclization of 5—7 Leading to 8—21. The Diels-Alder cycloadducts **5—7** were treated with a catalyst such as TFA, $ZnCl_2$, aqeous HCl, and molecular sieves 5A under the conditions shown in Tables 2 and 3. The amounts of catalyst and reaction solvent used for 1 mmol of **5—7** are as follows: TFA: 7—15 mmol in 6—10 ml of dichloromethane or benzene; $ZnCl_2$: 1.5—2 g in 10 ml of dichloromethane; aqeous HCl: 5 ml in 5 ml of THF. After the reaction was over, the mixture was poured into ice water and extracted with diethyl ether twice. The combined extracts were washed with aqueous sodium hydrogencarbonate, with water, dried over anhydrous magnesium sulfate, and finally evaporated in vacuo. The residue was subjected to ^{1}H-NMR and GLC analysis to know the ratio of products, and chromatographed over silica gel with ethyl acetate-hexane. All results were summarized in Tables 2 and 3.

8a: Colorless prisms (diethyl ether-hexane); mp 124—125 °C; IR (KBr) 1720 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.67 (1H, q, J=13.1 Hz, one of 4-H), 2.61 (1H, dd, J=14.8 and 6.0 Hz, one of 1-H), 2.7—3.0 (2H, m, the other of 1- and 4-H), 3.1—3.6 (3H, m, CH), 3.35 (3H, s, 2-COOMe), 3.67 (3H, s, 3-COOMe), and 7.0—7.6 (9H, m, Ar); ^{13}C-NMR ($CDCl_3$) δ=28.21, 29.58 (each t, 1- and 4-C), 43.27, 43.52 (each d, 2- and 3-C), 48.78 (d, 4a-C), 51.41, 51.90 (each q, COOMe), 119.88, 122.56, 124.56, 126.65, 127.19, 128.31, 128.79 (each d), 134.50, 137.62, 141.85, 144.92, 146.24 (each s), 172.36, and 173.29 (each s, COOMe); MS *m/z* (rel. intensity, %) 362 (M^+, 64), 303 (28), 302 (base peak), 243 (40), 242 (25), 203 (22), 202 (21), and 165 (82). Found: C, 76.36; H, 6.15%. Calcd for $C_{23}H_{22}O_4$: C, 76.22; H, 6.12%.

8b: Colorless prisms (dichloromethane-hexane); mp 188—189 °C; IR (KBr) 1725 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.39 (1H, dt, J=13.1, 13.1, and 12.2 Hz, one of 4-H), 2.01 (3H, t, J=1.8 Hz, 9-Me), 2.48 (1H, br dd, J=14.0 and 5.5 Hz, one of 1-H), 2.6—3.6 (5H, m, CH_2 and CH), 3.52, 3.68 (each 3H, s, COOMe), and 7.0—7.4 (4H, m, Ar); ^{13}C-NMR ($CDCl_3$) δ=9.69 (q, 9-Me), 27.83, 29.71 (each t, 1- and 4-C), 43.50, 43.62 (each d, 2- and 3-C), 48.32 (d, 4a-C), 51.61, 51.84 (each q, COOMe), 118.60, 122.17, 124.17, 126.52 (each d), 131.39, 139.43, 146.19 (each s), 172.43, and 173.43 (each s, COOMe); MS *m/z* (rel. intensity, %) 300 (M^+, 21), 240 (88), 182 (22), 181 (base peak), 166 (20), 165 (32), and 141 (26). Found: C, 72.07; H, 6.72%. Calcd for $C_{18}H_{26}O_4$: C, 71.98; H, 6.71%.

8c: Colorless needles (dichloromethane-hexane); mp 182—183 °C; IR (KBr) 1725 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.40 (1H, dt, J=13.0, 13.0, and 12.0 Hz, one of 4-H), 1.97 (3H, t, J=1.6 Hz, 9-Me), 2.46 (1H, br dd, J=14.0 and 5.8 Hz, one of 1-H), 2.3—3.6 (5H, m, CH_2 and CH), 3.30 (1H, dd, J=14.0 and 2.3 Hz, the other of 1-H), 3.52, 3.67 (each 3H, s, COOMe), 3.77 (3H, s, OMe), 6.74 (1H, dd, J=8.2 and 2.5 Hz, 7-H), 6.95 (1H, d, J=2.5 Hz, 5-H), and 7.07 (1H, d, J=8.2 Hz, 8-H); ^{13}C-NMR ($CDCl_3$) δ=9.70 (q, 9-Me), 27.78, 29.68 (each t, 1- and 4-C), 43.52 (2×C, d, 2- and 3-C), 48.15 (d, 4a-C), 51.51, 51.75 (each q, COOMe), 55.46 (q, OMe), 109.16, 111.64, 118.75 (each d), 130.79, 137.42, 139.17, 147.84, 157.54 (each s), 172.41, and 173.33 (each s, COOMe); MS *m/z* (rel. intensity, %) 330 (M^+, 55), 271 (27), 270 (78), 212 (31), 211 (base peak), 197 (22), 195 (20), 172 (24), 165 (29), 129 (26), and 128 (21). Found: C, 69.21; H, 6.73%. Calcd for $C_{19}H_{22}O_5$: C, 69.07; H, 6.71%.

9a: Colorless prisms (diethyl ether-hexane); mp 134—136 °C; IR (KBr) 1720 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.32 (1H, dt, J=13.0, 13.0, and 4.7 Hz, one of 4-H), 2.25 (1H, ddd, J=11.7,

5.8, 4.2 Hz, 2-H), 2.94 (1H, dd, J=13.0 and 11.7 Hz, one of 1-H), 3.13 (1H, ddd, J=13.0, 5.8, and 2.8 Hz, the other of 4-H), 3.02 (1H, dd, J=13.0 and 5.8 Hz, the other of 1-H), 3.32 (1H, dd, J=13.0 and 5.8 Hz, 4a-H), 3.47 (1H, ddd, J=4.7, 4.2, and 2.8 Hz, 3-H), 3.67, 3.78 (each 3H, s, COOMe), and 7.0—7.6 (9H, m, Ar); MS m/z (rel. intensity, %) 362 (M^+, 76), 331 (29), 330 (66), 303 (26), 302 (89), 243 (56), 242 (84), 241 (32), 217 (63), 215 (24), 203 (32), 202 (31), and 165 (base peak). Found: C, 75.98; H, 6.16%. Calcd for $C_{23}H_{22}O_4$: C, 76.22; H, 6.12%.

9b: Colorless solid; mp 120—122 °C; IR (KBr) 1720 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.13 (1H, dt, J=12.7, 12.7, and 4.5 Hz, one of 4-H), 2.03 (3H, t, J=1.6 Hz, 9-Me), 2.40 (1H, ddd, J=12.0, 5.0, and 4.0 Hz, 2-H), 2.6—3.3 (4H, m, CH_2 and CH), 3.40 (1H, m, 4a-H), 3.72, 3.76 (each 3H, s, COOMe), and 6.9—7.4 (4H, m, Ar); ^{13}C-NMR ($CDCl_3$) δ=9.89 (q, 9-Me), 24.71 (t, 4-C), 32.70 (t, 1-C), 41.81, 44.83, 45.42 (each d, CH), 51.90 (2×C, q, COOMe), 118.56, 122.22, 124.02, 126.65 (each d), 130.21, 142.04, 145.94, 146.39 (each s), 173.33, and 173.48 (each s, COOMe); MS m/z (rel. intensity, %) 300 (M^+, 13), 240 (37), 182 (26), 181 (base peak), 180 (57), 179 (25), 178 (23), 167 (36), 166 (45), 165 (85), 155 (31), 153 (27), 142 (28), 141 (46), and 115 (30). Found: C, 72.16; H, 6.80%. Calcd for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71%.

9c: This product was not separated in pure form from the mixture with **8c**. ^{1}H-NMR ($CDCl_3$, only major signals are given): δ=1.15 (1H, dt, J=12.7, 12.7, and 4.7 Hz, one of 4-H), 2.00 (3H, t, J=1.7 Hz, 9-Me), 2.40 (1H, ddd, J=12.0, 4.9, and 4.2 Hz, one of 2-H), 3.71, 3.74, 3.78 (each 3H, s, COOMe and OMe), 6.77 (1H, dd, J=8.2 and 2.5 Hz, 7-H), 6.93 (1H, d, J=2.5 Hz, 5-H), and 7.09 (1H, d, J=8.2 Hz, 8-H); ^{13}C-NMR ($CDCl_3$) δ=9.94 (q, 9-Me), 24.71 (t, 4-C), 32.84 (t, 1-C), 41.86, 44.93, 45.32 (each d, CH), 51.90 (2×C, q, COOMe), 55.55 (q, OMe), 109.35, 111.73, 118.75, 125.67, 129.867 (each d), 139.51, 139.81, 147.65, 157.50 (each s), 173.38, and 173.57 (each s, COOMe); MS m/z 330 (M^+). Found: C, 68.95; H, 6.82%. Calcd for $C_{19}H_{22}O_5$: C, 69.07; H, 6.71%.

10a—c: These products were not fully characterized because of too poor yields and unsuccessful separation from the major products. Their formation was deduced only on the basis of ^{1}H-NMR ($CDCl_3$) of crude reaction mixtures and the yields were determined by GLC analysis. **10a**: δ=5.90 (dd, J=10 and 5 Hz, 2-H) and 6.34 (dd, J=10 and 3 Hz, 1-H); **10b**: δ= 2.08 (s, Me), 5.55 (dd, J=10 and 5 Hz, 2-H), and 6.16 (br d, J=10 Hz, 1-H); **10c**: δ=2.06 (s, Me), 5.60 (dd, J=10 and 5 Hz, 2-H), and 6.18 (br d, J=10 Hz, 1-H).

11: Colorless viscous oil; IR (neat) 1730 cm^{-1} ; ^{1}H-NMR ($CDCl_3$) δ=2.2—3.2 (6H, m, CH_2 and CH), 3.67, 3.68 (each 3H, s, COOMe), 5.04, 5.22 (each 1H, s, $=CH_2$), 5.59 (1H, m, 2-H), and 7.23 (5H, br s, Ph); ^{13}C-NMR ($CDCl_3$) δ=26.37, 27.20 (each t, 3- and 6-C), 39.45, 40.23 (each d, 4- and 5-C), 51.90 (2×C, q, COOMe), 112.40 (t, $=CH_2$), 126.22, 127.39, 128.12, 128.71 (each d), 135.84, 141.55, 150.78 (each s), and 173.73 (2×C, s, COOMe); MS m/z (rel. intensity, %) 300 (M^+, 51), 269 (24), 240 (base peak), 181 (93), 180 (50), 103 (93), and 42 (20). 9) Protonation of **11** or **12** leads to the cationic intermediate which is the same to that involved in the electrocyclization of **5** forming **8** and **9**.

10) Both clockwise rotation of **A** and counterclockwise rotation of **B** lead to boat conformations, therefore these rotations were excluded.

11) It is known that, in 4,5-disubstituted cyclohexene series, 4,5-diequatorial conformer is always more stable than 4,5-diaxial isomer (N. S. Zefirov, V. N. Chekulaeva, and A. I. Belozerov, *Tetrahedron*, **25**, 1997 (1969)). However, the conformer **B** with two axial ester groups is expected to be more stable than the conformer **A** with two equatorial esters because only the axial esters can interact with the cationic centers stabilizing these centers. As a similar interaction, see G. P. Kugatova-Shemyakina and G. M. Nikolaev, *Tetrahedron*, **23**, 2987 (1967).

12) The envelope conformation can be replaced by another name, twisted half-chair conformation.

13) As the six-membered ring of **H** takes twisted half-chair conformation, the 1,3-steric repulsion between 3a-carbonyl and 4a-H is insignificant. Accordingly, the energy difference between **G** and **H** should be smaller that between **C** and **D** (X=H, Y=COOMe).

Novel Regioselective Iodination of Estradiol 17β-Acetate[1)]

C. Akira Horiuchi,* Akinori Haga, and J. Yasuo Satoh
Department of Chemistry, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171
(Received March 1, 1986)

Direct iodination of estradiol 17β-acetate (**3**) using iodine–copper(II) acetate in acetic acid afforded the 2-iodo derivative regioselectively in high yield. The iodination of **3** using several methods was discussed. On the other hand, the reaction of **3** with iodine–copper(II) bromide gave the 4-bromo derivative (**7**), not the 2-iodo compound. The reaction of 3-methoxy-17β-acetoxy-1,3,5(10)-estratriene (**4**) with iodine–copper(II) chloride–iron(III) chloride in acetic acid gave the 2- (**10**) and 4-iodo (**11**) derivative.

2-Iodoestradiols are important as synthethic intermediates and as possessors of biological activity, and also in making highly radioactive iodine isotopes. They are usually prepared either from diazotization of the corresponding 2- or 4-amino-3-methoxyestrone derivative, reduction with sodium borohydride, and then demethylation using boron tribromide,[2)] or from the reaction of estradiol (**1**) with mercury(II) acetate and iodine.[3)] However, recently the synthesis of 2-iodoestradiol (**5**) by the reaction of **1** with mercury(II) acetate and iodine in acetic acid has been questioned.[3)] More recently, Santaniello and Ferrabschi[4)] reported that the reaction of 3-methoxy-17β-acetoxy-1,3,5(10)-estratriene with mercury(II) acetate in dry acetonitrile gave the 2-iodo derivative. However, since these methods involve many steps and the demethylation results in low yield, we wished to find a method for the direct regioselective iodination of estradiol (**1**).

We have been investigating a novel iodination using iodine–copper(II) acetate, and as a first step in this research project, we reported earlier the α-iodination of ketone,[5)] the iodination of electron-rich aromatic compound,[6)] and synthesis of α-iodo carboxylic acid.[7)] Earlier, we described a novel regioselective iodination of estradiol, estriol, and estrone using iodine–copper(II) acetate to afford the 2-iodo derivative.[8)] In the present paper, we would like to report the details of this iodination. We have been now also investigated the reaction of estradiol (**1**) with iodine and some other copper(II) salts.

The reaction of **1** with iodine (1.5 mol equiv)–copper(II) chloride dihydrate (1.5 mol equiv) in acetic acid at 55°C for 35 h gave the diiodo compound **8** (mp 190—193°C) and the monoiodo compound **6** (mp 175—177°C). Compound **8** showed absorption at 1708 (C=O) and 1264 cm^{-1} (C–O) in its IR spectrum. The NMR spectrum showed a singlet at δ 7.60 (C_1–H) and a singlet at δ 2.06 ($C_{17\beta}$–OAc). Therefore, compound **8** was presumed to be 2,4-diiodoestradiol 17β-acetate. The IR spectrum of **6** showed absorption at 1708 (C=O), 1268 (C–O), and 880 cm^{-1} (–CH). This product **6** was presumed to be 2-iodoestradiol 17β-acetate, identification being based on the presence of two singlets in the NMR spectrum at δ 6.70 (C_4–H) and δ 7.50 (C_1–H), and a singlet at δ 2.06 ($C_{17\beta}$–OAc). In the case of the reaction using iodine (1.5 mol equiv)–copper(II) bromide (1.5 mol equiv), the bromo estrogen derivative **7**, mp 140—142°C was obtained. This product was presumed to be 4-bromoestradiol 17β-acetate, identification being based on the presence of two doublets in the NMR spectrum at δ 6.62 and δ 7.16. These results are summarized in Table 1 for the iodination of **1**.

On the basis of these results, it was found that (i) copper(II) acetate and copper(II) chloride were the best reagents for C_2–iodination, (ii) copper(II) chloride was more active than copper(II) acetate, and (iii) in the case of copper(II) bromide, bromination occurred at the C_4-position, not iodination at the C_2-position. Also, these results showed that copper(II) salts acted as a catalyst of acetylation of 17β-hydroxyl group.

Hence, we attempted acetylation of the hydroxyl group using copper(II) acetate-acetic acid. The reaction of **1** or **2** with copper(II) acetate in acetic acid under refluxing for 2 h gave 17β-acetoxy derivative (**3** or **4**) in good yield. The treatment of **3** with iodine–copper(II) acetate at 60°C for 10 h yielded the 2-iodo derivative **6** (89%). Moreover, the reaction of **3** with iodine–copper(II) chloride, iodine–copper(I) acetate, iodine–copper(I) chloride, iodine–thallium(I) acetate, iodine monochloride, iodine–morpholine complex, or iodine–copper(II) chloride–iron(III) chloride was carried out in a similar manner to the procedure mentioned above, and the results are presented in Table 2.

From these results, it was concluded that iodine–copper(II) acetate and iodine–copper(II) chloride are efficient and regioselective iodinating agents in com-

Table 1. Products and Isolated Yields (%) in the Iodination of Estradiol (**1**) at 60°C

parison with the other reagents. Moreover, it was found that the iodination of estradiol 17β-acetate (**3**) gave 2-iodoestradiol 17β-acetate (**6**) in good yield (80—90%). This results is also supported by our earlier finding that the iodination using iodine–copper(II) acetate of phenol occurred at the ortho-position.[6]

Thus, it is considered that in the reaction of **3** using iodine–copper(II) acetate, the copper is coordinated to the oxygen of the phenolic hydroxyl group, and then attacks at the less hindered C_2-position than the corresponding C_4-position.

We attempted the iodination of 3-methoxy-17β-acetoxy-1,3,5(10)-estratriene (**4**) with affecting the coordinating ability of the oxygen atom using iodine–copper(II) acetate or iodine–copper(II) chloride in acetic acid. The reaction resulted in the recovery of the starting material. The reaction of **4** with iodine–copper(II) chloride–iron(III) chloride in acetic acid gave the 2- (**10**) (56%) and the 4-iodo derivative (**11**) (18%).

From these results, it is considered that the iodination using iodine–copper(II) chloride–iron(III) chloride of the 3-methoxyestrogen (**4**) proceeds by an initial π-complex of iodine with the aryl ring and the more powerful Lewis acid, iron(III) chloride is no doubt attributable to the roles as a potent catalyst.

Experimental

All the melting points are uncorrected. The IR spectra were measured using a Hitachi Model 215 grating infrared spectrometer. The NMR spectra were measured using either Hitachi Model R-900 or JEOL FX200 Model Spectrometer in deuteriochloroform with TMS as an internal standard.

The high-resolution mass spectra were recorded at 75 eV on a JEOL JMS-O1SG-2 instrument with a direct inlet.

Estradiol 17β-Acetate (3). A mixture of estradiol (**1**) (3.0 g) and copper(II) acetate monohydrate (0.2 mol equiv) in acetic acid (80 ml) was stirred under refluxing for 4 h. The solvent was then removed under reduced pressure, and the residue was poured into water and extracted with ether. The ethereal solution was washed successively with aqueous sodium hydrogencarbonate and with water, dried, and concentrated. Crystallization of the residue from methanol gave plates of **3** (3.02 g, 87%), mp 216—218°C (lit,[9] 217—218°C). The IR and ^1H NMR spectra were identical with those of an authentic sample.

3-Methoxy-17β-acetoxy-1,3,5(10)-estratriene (4). A mixture of 3-methoxyestradiol (**2**) (1.0 g) and copper(II) acetate mono-

hydrate (0.2 mol equiv) in acetic acid (30 ml) was stirred under refluxing for 12 h. After a similar work-up, the resulting oil, on crystallization from methanol, gave **4** as plates (1.05 g, 92%), mp 102—103 °C (lit,[10] 103.5—104.5 °C). The IR and ^{1}H NMR spectra were identical with those of an authentic sample.

Reaction of Estradiol with Iodine and Copper(II) Chloride in Acetic Acid. Estradiol (**1**) (200 mg) in acetic acid (20 ml) was treated with iodine (280 mg) and copper(II) chloride dihydrate (188 mg) at 60 °C for 35 h. After a similar work-up, the resulting oil (322 mg) was purified by preparative TLC on silica-gel plates (2 mm layer) (Merck). Developement with benzene–ether (2:1) gave 2,4-diiodoestradiol 17β-acetate (**8**) as plates (44 mg) from methanol, mp 190—193 °C; IR (KBr): 3450, 1708, 1530, 1264, and 750 cm^{-1}; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.82 (3H, s, C_{18}–H_3), 2.07 (3H, s, $C_{17\beta}$–$OCOCH_3$), 4.70 (1H, t, J=7.5 Hz, $C_{17\alpha}$–H), and 7.60 (1H, s, C_1–H).

Found: C, 42.51; H, 4.40%. HRMS m/z 565.9770. Calcd for $C_{20}H_{24}O_3I_2$: C, 42.43; H, 4.27%; M, 565.9816.

The less polar fraction on crystallization from methanol gave 2-iodoestradiol 17β-acetate (**6**) as needles (162 mg), mp 175—177 °C; IR (KBr): 3450, 1708, 1594, 1268, 880, and 865 cm^{-1}; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.82 (3H, s, C_{18}–H_3), 2.06 (3H, s, $C_{17\beta}$–$OCOCH_3$), 4.68 (1H, t, J=7.5 Hz, $C_{17\alpha}$–H), 6.70 (1H, s, C_4–H), and 7.50 (1H, s, C_1–H).

Found: C, 54.74; H, 5.76%. HRMS m/z 440.0892. Calcd for $C_{20}H_{25}O_3I$: C, 54.56; H, 5.72%; M, 440.0850.

Reaction of Estradiol 17β-Acetate with Copper(II) Bromide in Acetic Acid. Estradiol (**1**) (100 mg) in acetic acid (10 ml) was treated with copper(II) bromide (82 mg) at 60 °C for 10 h. After a similar work-up, the resulting oil (127 mg) was purified by preparative TLC on silica-gel plates (2 mm layer) (Merck). Developement with benzene–ether (2:1) gave 4-bromoestradiol 17β-acetate (**7**) as needles (61 mg) from acetone, mp 213—215 °C; IR (KBr): 3430, 1705, 1605, 1561, 1274, and 793 cm^{-1}; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.82 (3H, s, C_{18}–H_3), 2.07 (3H, s, $C_{17\beta}$–$OCOCH_3$), 4.71 (1H, t, J=7.5 Hz, $C_{17\alpha}$–H), 6.62 (1H, d, J=8.0 Hz, C_2–H), and 7.16 (1H, d, J=8.0 Hz, C_1–H).

Found: m/z 392.1019 (M^+); 394.0926 $(M+2)^+$. Calcd for $C_{20}H_{25}O_3Br$: M, 392.0986; M+2, 394.0966.

Reaction of Estradiol 17β-Acetate with Iodine–Copper(II) Acetate in Acetic Acid. A mixture of estradiol 17β-acetate (**13**) (200 mg), iodine (242 mg), and copper(II) acetate (116 mg) in acetic acid (20 ml) was stirred at 60 °C for 10 h. The precipitated copper(I) iodide was removed by filtration, and the filtrate was poured into water and extracted with ether. After a similar work-up, the resulting oil, on crystallization from methanol, gave **6** as needles (250 mg), mp 175—177 °C.

Reaction of Estradiol 17β-Acetate with Iodine–Copper(II) Chloride in Acetic Acid. A mixture of estradiol 17β-acetate (**3**) (200 mg), iodine (242 mg), and copper(II) chloride (163 mg) in acetic acid (20 ml) was stirred at 60 °C for 50 h. After a similar work-up, the resultant oil was chromatographed on silica gel (30 g). Elution with benzene (250 ml) gave 2,4-diiodoestradiol 17β-acetate (**8**) as plates (23 mg) from methanol, mp 190—193 °C. The next fraction, eluted by the same solvent (30 ml), on crystallization from methanol gave plates of **6** (146 mg), mp 175—177 °C. The third fraction, eluted by the same solvent (30 ml), on crystallization from methanol gave plates of 4-iodoestradiol 17β-acetate (**9**) (61 mg), mp 161—164 °C; IR (KBr): 3430, 1705, 1595, 1557, 1267, and 790 cm^{-1}; ^{1}H NMR ($CDCl_3$, 200 MHz) δ=0.82 (3H, s, C_{18}–H_3), 2.06 (3H, s, $OCOCH_3$), 4.69 (1H, t, J=8.9 Hz, $C_{17\alpha}$–H), 7.20 (1H, d, J=8.8 Hz, C_1–H), and 6.84 (1H, d, J=8.8Hz, C_2–H).

Found: C, 54.24; H, 5.72%; HRMS m/z 440.0840. Calcd for $C_{20}H_{25}O_3I$: C, 54.56; H, 5.72%; M, 440.0850.

Reaction of Estradiol 17β-Acetate with Iodine Monochloride. A mixture of estradiol 17β-acetate (**3**) (200 mg) and iodine monochloride (103 mg) in acetic acid (20 ml) was stirred at 60 °C for 1 h. After a similar work-up, crystallization from methanol afforded plates of **9** (81 mg), mp 161—164 °C. From the mother liquor, recrystallization from methanol gave plates of **6** (139 mg), mp 175—177 °C.

Reaction of Estradiol 17β-Acetate with Iodine–Morpholine. A mixture of estradiol 17β-acetate (**3**) (200 mg), iodine (161 mg), and morpholine (166 mg) in methanol (40 ml) was stirred at 0 °C for 2 h. After a similar work-up, the resultant oil was chromatographed on silica gel (30 g). Elution with benzene–ether (10:1) (60 ml) gave 2,4-diiodoestradiol 17β-acetate (**8**) as plates (99 mg) from methanol, mp 190—193 °C. The second fraction, eluted by the same solvent (24 ml), on crystallization from methanol gave plates of **6** (48 mg), mp 175—177 °C. The third fraction, eluted by the same solvent (8 ml), on crystallization from methanol gave plates of **9** as plates (59 mg), mp 161—164 °C.

Reaction of 3-Methoxy-17β-acetoxy-1,3,5(10)-estratriene with Iodine, Copper(II) Chloride Dihydrate, and Iron(III) Chloride Hexahydrate. Estradiol 17β-acetate 3-methyl ether (**4**) (200 mg) in acetic acid (20 ml) was treated with iodine (232 mg), copper(II) chloride dihydrate (156 mg), and iron(III) chloride hexahydrate (247 mg) under stirring at 60 °C for 5 h. After a similar work-up, the resultant oil was chromatographed on silica gel (30 g). Elution with benzene (130 ml) gave 2-iodoestradiol 17β-acetate 3-methyl ether (**10**) as plates (154 mg) from methanol, mp 138—141 °C; IR (KBr): 1738, 1590, 1240, 878, and 860 cm^{-1}; ^{1}H NMR ($CDCl_3$, 200 MHz) δ=0.82 (3H, s, C_{18}–H_3), 2.06 (3H, s, $C_{17\beta}$–$OCOCH_3$), 3.83 (3H, s, OCH_3), 4.69 (1H, t, J=9.4 Hz, $C_{17\alpha}$–H), 6.54 (1H, s, C_4–H), and 7.64 (1H, s, C_1–H).

Found: C, 55.35; H, 5.97%; HRMS: m/z 454.1003. Calcd for $C_{21}H_{27}O_3I$: C, 55.52; H, 5.99%; M, 454.1006. The second fraction, eluted by the same solvent (40 ml) gave 4-iodoestradiol 17β-acetate 3-methyl ether (**11**) as plates (51 mg) from methanol, mp 165—167 °C; IR (KBr): 1734, 1590, 1556, 1260, 1245, and 786 cm^{-1}; ^{1}H NMR ($CDCl_3$, 200 MHz) δ=0.82 (3H, s, C_{18}–H_3), 2.06 (3H, s, $C_{17\beta}$–$OCOCH_3$), 3.87 (3H, s, OCH_3), 4.69 (1H, t, J=7.6 Hz, $C_{17\alpha}$–H), 7.25 (1H, d, J=8.50 Hz, C_1–H), and 6.66 (1H, d, J=8.50 Hz, C_2–H).

Found: C, 55.80; H, 6.12%; HRMS: m/z 454.1008. Calcd for $C_{21}H_{27}O_3I$: C, 55.52; H, 5.99%; M, 454.1006.

We are indebted to Associate Professor Sukekatsu Nozaki, Josai University, for his measurement of the high resolution mass spectra and Research Laboratories of Toyo Jozo Co., Ltd. for the elemental analyses. Thanks are also due to Associate Professor Yoshio Koike and Mr. Toshio Takayama, Kanagawa University, for the measurement of FT-NMR spectra.

Stereospecific Desulfinylation of α,β-Epoxy Sulfoxides with Butyllithium. A New Synthesis of Epoxides and Allylic Alcohols from Carbonyl Compounds[1)]

Tsuyoshi SATOH, Youhei KANEKO, and Koji YAMAKAWA*

(Received March 8, 1986)

Desulfinylation of α,β-epoxy sulfoxides, easily prepared from carbonyl compounds and 1-chloroalkyl phenyl sulfoxide, with 1 equivalent of butyllithium at low temperature gave epoxides in good yields. The similar α,β-epoxy sulfoxides having an arylmethyl group at the α-position gave 3-aryl-allylic alcohols upon treatment with excess butyllithium at −70 °C. These reactions offer a simple and useful approach to the synthesis of epoxides and 3-aryl-allylic alcohols from a carbonyl compound.

Epoxides have received considerable attention in recent years with interest concerning their synthesis, including asymmetric synthesis,[2)] their use as versatile intermediates in organic synthesis,[3)] and their use in the total synthesis of complex natural products.[4)] The preparation of epoxides are usually classified into two categories. One is the oxidation of a double bond with peroxy acids[2a,5)] or peroxides[2b)] or with NBS in the presence of water followed by a treatment with an alkali.[6)] The other is the method from ketones *via* Darzens-type condensation[7)] including sulfur ylides[8)] or arsonium ylides.[9)] The most important characteristic of the latter method is that the reaction gives epoxides with carbon–carbon bond formation.

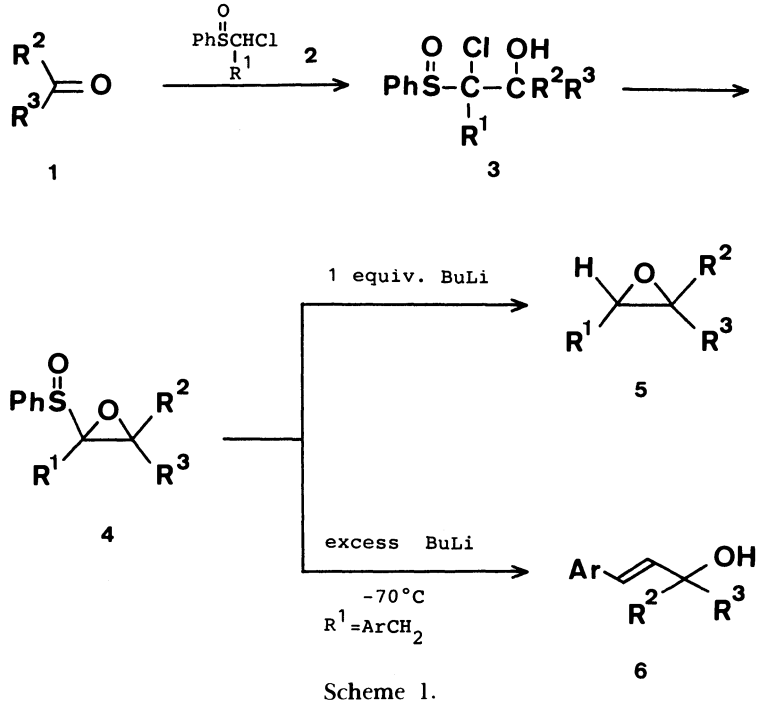
α,β-Epoxy sulfoxides (**4**) are very easily prepared in high yields and on a large scale from carbonyl compounds (**1**) and 1-chloroalkyl phenyl sulfoxide (**2**) by the Darzens-type condensation.[10)] We have reported that the β-carbon of α,β-epoxy sulfoxides (**4**) is highly reactive toward nucleophiles such as selenolates, thiolates, amines, and acetate giving dialkyl ketones,[11a)] α-sulfenylated ketones,[11b)] α-amino ketones,[11c)] and α-acetoxy ketones,[11d)] respectively, in good yields.

In the course of studies on the new synthetic methods from carbonyl compounds through α,β-epoxy sulfoxides, we found that the phenylsulfinyl group of the α,β-epoxy sulfoxides (**4**) could be easily cleaved with butyllithium (*n*-BuLi), even at −100 °C, to give epoxides (**5**) in quite good yields. This reaction leads to a novel synthetic method for the synthesis of epoxides from carbonyl compounds via α,β-epoxy sulfoxides. We also found that the α,β-epoxy sulfoxides (**4**) having an arylmethyl group at the α-position afforded 3-aryl-allylic alcohols (**6**) upon treatment with excess *n*-BuLi at −70 °C. These procedures are given in Scheme 1.

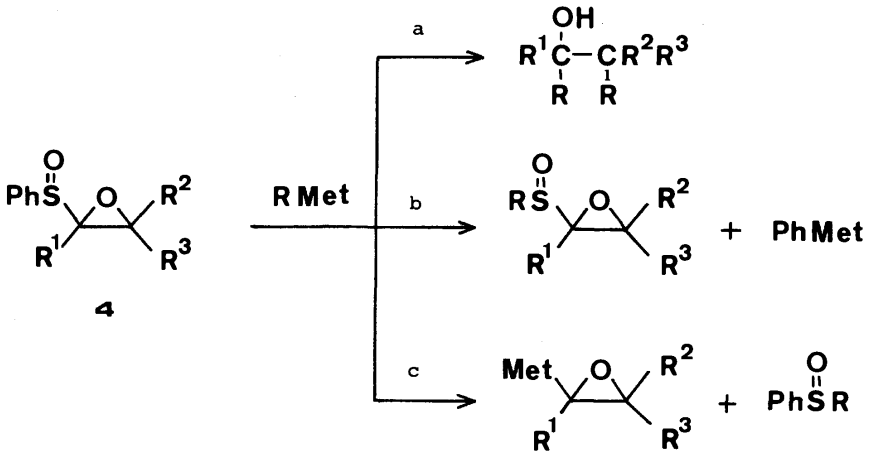
In this paper we describe details and the mechanistic aspects of these reactions.

Results and Discussion

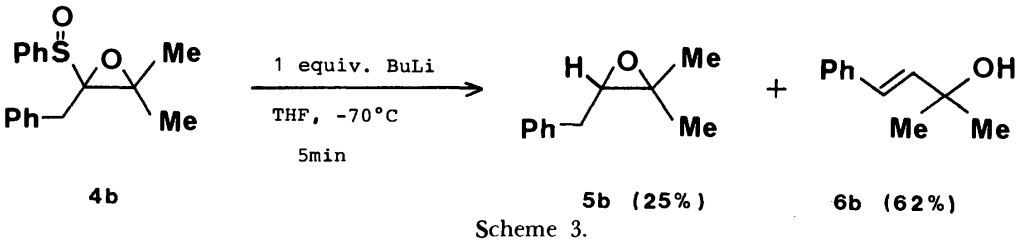
A Synthesis of Epoxides from Carbonyl Compounds



Scheme 1.



Scheme 2.



Scheme 3.

Through α,β-Epoxy Sulfoxides. If the phenylsulfinyl group of the α,β-epoxy sulfoxides (**4**) can be easily exchanged with hydrogen; this reaction offers a novel method for the epoxidation of carbonyl compounds. It has been reported that a treatment of sulfoxides with alkylmetal takes place carbon–sulfur bond cleavage.[12] In the treatment of α,β-epoxy sulfoxides (**4**) with alkylmetal, three types of reactions could be expected to take place: 1) A nucleophilic attack of a carbanion to the β-carbon of α,β-epoxy sulfoxides (**4**) (route a in Scheme 2); 2) the addition of a carbanion to the sulfinyl group leading to phenyl-alkyl exchange (route b); and 3) the addition of a carbanion to the sulfinyl group leading to the cleavage of the bond between sulfur and epoxide (route c). On the basis of this consideration α,β-epoxy sulfoxide (**4a**) was treated with 1 equivalent of *n*-BuLi in THF at −70°C. In this reaction all the starting materials disappeared within 5 min, and an 89% yield of the epoxide (**5a**) along with trace amounts of by-products and reasonable amount (about 50%) of butyl phenyl sulfoxide were obtained. This result clearly indicates that the reaction proceeded along route c shown in Scheme 2.

A search was made to find the most effective alkylmetal for this reaction. Table 1 shows the results for a treatment of α,β-epoxy sulfoxide (**4a**) with various alkylmetals, including lithium diisopropylamide (LDA) in THF at −70°C for 5 min. From these results, we decided to use *n*-BuLi throughout the study.

Next, α,β-epoxy sulfoxide (**4b**) was treated with 1 equivalent of *n*-BuLi under the same conditions as above. In this reaction a 62% yield of unexpected 3-phenyl-allylic alcohol (**6b**) along with the expected epoxide (**5b**) (25% yield) was obtained as shown in Scheme 3. The allylic alcohol (**6b**) was thought to form from the epoxide (**5b**) by isomerization with bases. When the reaction was carried out at −100°C for 5 min it was found that the desired epoxide (**5b**) was obtained in 71% yield with almost no allylic alcohol (**6b**).

Table 1. Treatment of the α,β-Epoxy Sulfoxide (**4a**) with 1 Equivalent of Alkylmetal (RMet) in THF at −70°C for 5 min

RMet	**5a** (%)	Recovered (**4a**)/%
n-BuLi	89	0
CH_3Li	43	30[a]
t-BuLi	28	Trace[a]
EtMgBr	Trace	47[a]
LDA	0	88

a) The product other than **5a** was a complex mixture.

Representative results of the treatment of α,β-epoxy sulfoxides (**4**) with 1 equivalent of *n*-BuLi are listed in Table 2. As shown in Table 2, quite good results were obtained, except for Entry 12. It should be noted that in Entries 5 and 6, diastereomers (**4e-L**) and (**4e-P**)[13] afforded (*Z*)-epoxide (**5e-L**) and (*E*)-epoxide (**5e-P**),[14] respectively, without any contamination of their isomers. In previous studies the configuration of the diastereomers of the α,β-epoxy sulfoxides (**4**) was not determined but in this study, in order to clarify the stereochemistry of this reaction, we needed to determine the configuration of **4e**.

Table 2. Synthesis of Epoxides from α,β-Epoxy Sulfoxides and 1 Equivalent of Butyllithium[19]

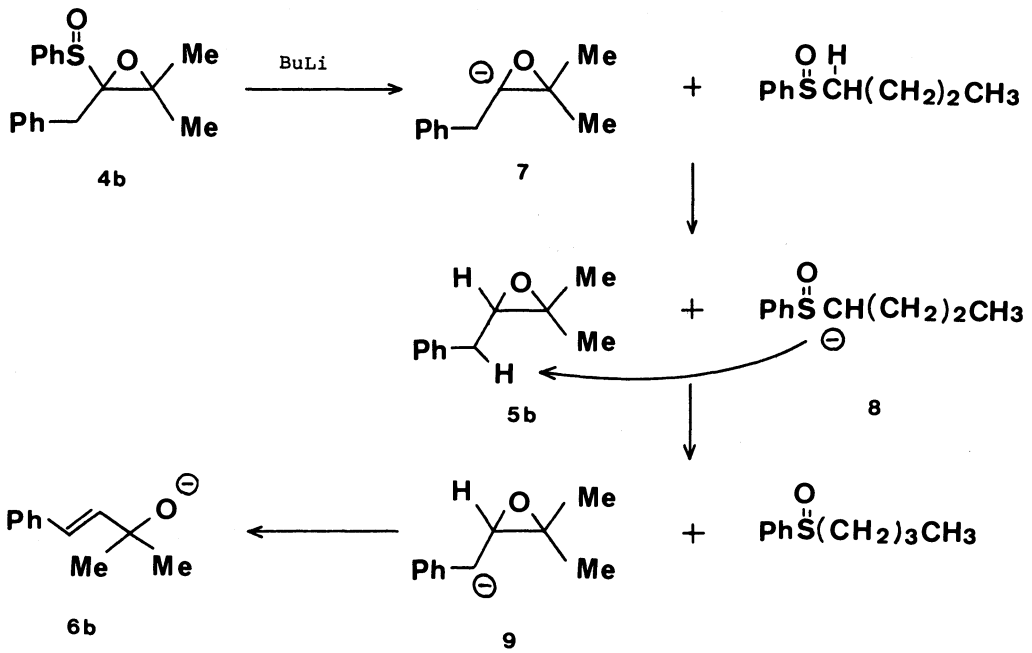
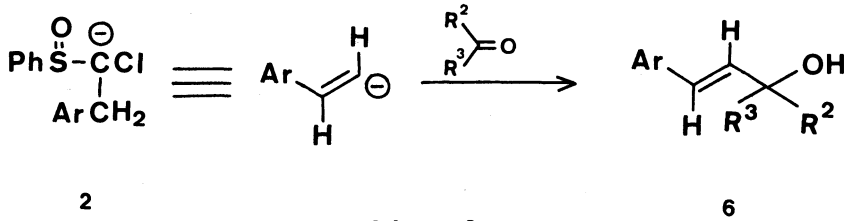
a) Isolated yields after silica-gel column chromatography. The yields in parenthesis are calculated from consumed starting material. b) The configuration was not determined. c) The configuration see Fig. 1.

The structures of these α,β-epoxy sulfoxides (**4e-L**) and (**4e-P**) were determined by the lanthanoid-induced shift[15] of their NMR spectra using tris[(heptafuluorobutanoyl)pivaloylmetanato]europium as a NMR shift reagent. Figure 1 shows the shift curves of the hydrogen on the β-carbon of the α,β-epoxy sulfoxides (**4e**), in which the differences of the chemical shift between original ones (**4e-L**:δ 4.87, **4e-P**:δ 3.79) and shifted ones (Δδ) are scaled on a vertical line and amounts (mole equivalents) of the shift reagent added are scaled on a horizontal line. From the results shown in Fig. 1, the structure of **4e-L** and **4e-P** were unambiguously determined as *E*- and *Z*-configurations, respectively. As already described, **4e-L** (*E*) and **4e-P** (*Z*) gave *Z*-epoxide (**5e-L**) and *E*-epoxide (**5e-P**); this reaction is stereospecific and the configuration of the carbon bearing the sulfinyl group was retained.

A Synthesis of 3-Aryl- and 3-Vinyl-Allylic Alcohols from Carbonyl Compounds Through α,β-Epoxy Sulfoxides. As mentioned above, a treatment of α,β-epoxy sulfoxide having a benzyl group as R^1 (**4b**) with 1 equivalent of *n*-BuLi gave 3-phenyl-allylic alcohol (**6b**) along with the epoxide (**5b**). The supposed mechanism of this reaction is shown in Scheme 4. The attack



Scheme 4.



Scheme 5.

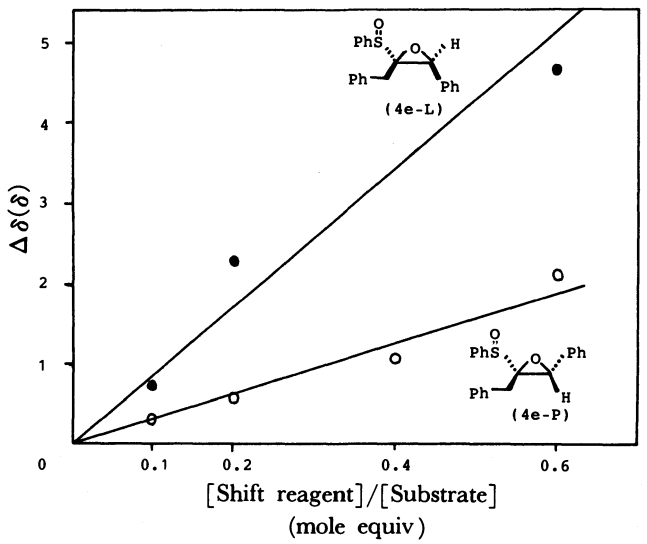


Fig. 1.

of *n*-BuLi on the sulfinyl group of **4b** leads to a carbon–sulfur bond cleavage, giving the carbanion (**7**) and butyl phenyl sulfoxide. Then, a proton transfer from the sulfoxide to **7** takes place to afford **5b** and the α-carbanion of butyl phenyl sulfoxide (**8**). As **5b** has acidic hydrogens on benzyl methylene carbon, the hydrogen is eliminated by the carbanion (**8**) giving **9**. This is isomerized to the allylic alcohol (**6b**). To make sure that the carbanion (**8**) acted as a base to isomerize the epoxide (**5**) into the allylic alcohol (**6**), the following experiment was carried out by using **5e-P** as an epoxide. To a solution of **5e-P** in THF at −70°C was added a solution of 1 equivalent of the carbanion (**8**), prepared from butyl phenyl sulfoxide and LDA. The reaction mixture was stirred for 5 min. After the usual work-up, the allylic alcohol (**6e**) and the starting material (**5e-P**) were obtained in 25 and 75% yields, respectively. From these facts it was predicted that excess bases and the higher temperature cause an acceleration of the epoxide-allylic alcohol isomerization. In fact, a treatment of **4b** with 3 equivalents of *n*-BuLi at −70°C for 5 min gave the allylic alcohol (**6b**) in 76% yield without the epoxide (**5b**).

Table 3 shows the results of the treatment of α,β-epoxy sulfoxides with excess *n*-BuLi (3—5 equivalents) in THF at −70°C for 5 min. All α,β-epoxy sulfoxides having an arylmethyl group, including an allyl group at the α-position, afforded 3-aryl-allylic alcohols (**6**) in good yields (except Entry 3). In this reaction the α,β-epoxy sulfoxides having a simple alkyl group as R^1 gave only epoxides (**5**) and no allylic alcohol was observed. The configuration of the double bond of **6** was confirmed as E by the NMR spectra.[16] It is

Table 3. Synthesis of Allylic Alcohols from α,β-Eoxy Sulfoxides and Excess Butyllithium at −70 °C[19]

noteworthy that in this reaction the carbanion of 1-chloroalkyl phenyl sulfoxide (**2**; $R^1=CH_2Ar$) acted as a β-arylvinyl carbanion equivalent as shown in Scheme 5.

In conclusion, a novel and versatile procedure for the synthesis of epoxides and 3-aryl-allylic alcohols has been developed from carbonyl compounds with carbon–carbon bond formation through α,β-epoxy sulfoxides. In regard to the accessibility of the starting materials, the simplicity and mildness of the operation, and high overall yields, the present procedure offers a simple and useful approach to the synthesis of epoxides and 3-aryl-allylic alcohols from carbonyl compounds.

Experimental

All melting points are uncorrected. Infrared (IR) spectra were measured directly on a NaCl plate or in KBr disks with a Hitachi 215 spectrometer. ^1H Nuclear magnetic resonance (NMR) spectra were measured in a $CDCl_3$ solution with a JEOL FX-100 spectrometer using Me_4Si as an internal standard. Electron-impact mass spectra (MS) were obtained on a Hitachi M-80 double-focusing spectrometer at 70 eV by direct insertion. Silica gel BW-127ZH (Fuji-Devison) containing 2% fluorescence reagent 254 and quartz column were used for column chromatography and the products having ultraviolet (UV) absorption were detected by UV irradiation.

Materials. All α,β-epoxy sulfoxides (**4**) except **4f—j** were reported in the references IIa and 11b.

Preparation of 1-Chloro-2-(4-methoxyphenyl)ethyl Phenyl Sulfoxide, 1-Chloro-2-(1-naphthyl)ethyl Phenyl Sulfoxide, and 1-Chloro-3-butenyl Phenyl Sulfoxide. These sulfoxides were prepared from chloromethyl phenyl sulfoxide with 4-methoxybenzyl chloride, 1-(chloromethyl)naphthalene, and allyl bromide according to the procedure reported previously.[11a] 1-Chloro-2-(4-methoxyphenyl)ethyl phenyl sulfoxide: Diastereomeric mixture; colorless oil; 87% yield; IR (neat): 1090, 1040 (SO) cm^{-1}; ^1H NMR δ=2.76 (dd, *J*=9, 14 Hz), 3.18 (dd, *J*=9.5, 14.5 Hz), 3.53 (dd, *J*=3, 14.5 Hz), 3.58 (dd, *J*=5, 14 Hz), 3.79 (s), 4.55 (dd, *J*=3, 9 Hz), 4.67 (dd, *J*=5, 9 Hz), 6.8—7.3 (m), 7.5—7.9 (m); MS *m/z* (%): 179 ([M−PhSO]$^+$, 100), 178 ([M−PhSOH]$^+$, 84), 134 (43), 121 (26). 1-Chloro-2-(1-naphthyl)ethyl phenyl sulfoxide: Diastereomeric mixture; colorless crystals; mp 127—129 °C (AcOEt–hexane); 40% yield; IR (KBr): 1085, 1040 (SO) cm^{-1}; ^1H NMR δ=3.06 (dd, *J*=9, 14.5 Hz), 3.36 (dd, *J*=11, 15 Hz), 4.27 (dd, *J*=4.5, 15 Hz), 4.34 (dd, *J*=2, 14.5 Hz), 4.70 (dd, *J*=2, 11 Hz), 4.93 (dd, *J*=4.5, 9 Hz), 7.3—8.1 (m); MS *m/z* (%): 314 (M$^+$, trace),

188 ([M−PhSOH]$^+$, 23), 153 (100). 1-Chloro-3-butenyl phenyl sulfoxide: Diastereomeric mixture; colorless oil; 72% yield; IR (neat): 1090, 1050 (SO) cm^{-1}; ^{1}H NMR δ=2.1—2.5 (m), 2.6—3.2 (m), 4.48 (dd, J=4, 8 Hz), 4.60 (dd, J=4.5, 8.5 Hz), 5.1—5.3 (m), 5.6—6.1 (m), 7.5—7.9 (m); MS m/z (%): 214 (M$^+$, 2), 126 ([M−C_4H_4Cl]$^+$, 100), 89 ([M−PhSO]$^+$, 26), 78 (79).

General Procedure for the Preparation of α,β-Epoxy Sulfoxide (4): The synthesis of 2,3-epoxy-1-(4-methoxyphenyl)-3-methyl-2-(phenylsulfinyl)butane (**4f**) is described. To a solution of LDA (2.2 mmol) in dry THF (3 ml) at −70 °C under N_2 was added a solution of 1-chloro-2-(4-methoxyphenyl)-ethyl phenyl sulfoxide (2 mmol) in 2 ml of dry THF dropwise through a syringe with stirring. The solution was stirred at −40 °C for 20 min and then acetone (3 mmol) was added through a syringe and the reaction mixture was stirred for additional 10 min. The reaction was quenched with sat. aq NH_4Cl and the whole was extracted with ethyl acetate. The product was separated by silica-gel column chromatography to give chlorohydrin (**3**) and recovered starting material in 49 and 37% yield, respectively. Chlorohydrin: Mp 103—105 °C (AcOEt-hexane); IR (KBr): 3400 (OH), 1035 (SO) cm^{-1}; ^{1}H NMR δ=1.26, 1.58 (each 3H, s), 3.30, 3.48 (each 1H, d, J=15 Hz), 3.83 (3H, s), 6.88, 7.30 (each 2H, d, J=9 Hz), 7.4—7.8 (5H, m); MS m/z (%): 226 ([M−PhSOH]$^+$, 29), 211 (67), 125 (40), 78 (76), 43 (100).

To a solution of the chlorohydrin (1.47 mmol) in 7 ml of MeOH and 4 ml of THF was added 30% aq KOH (6 ml) dropwise with stirring and the mixture was stirred at room temperature for 2 h. The reaction mixture was neutralized by adding NH_4Cl and the MeOH was evaporated. The residue was extracted with ethyl acetate and the product was purified by silica-gel column chromatography to give **4f** in quantitative yield. Mp 70—72 °C (AcOEt-hexane); IR (KBr): 1080, 1050 (SO) cm^{-1}; ^{1}H NMR δ=1.29, 1.83 (each 3H, s), 3.23 (2H, s), 3.73 (3H, s), 6.64, 6.72 (each 2H, d, J=10 Hz), 7.4—7.8 (5H, m); MS m/z (%): 316 (M$^+$, trace), 191 ([M−PhSO]$^+$, 31), 163 (8), 121 (100); Found: C, 68.22; H, 6.37; S, 9.95%. Calcd for $C_{18}H_{20}O_3S$: C, 68.33; H, 6.37; S, 10.13%.

3′-(4-methoxybenzyl)-3′-(phenylsulfinyl)spiro[cyclohexane-1,2′-oxirane] (4g). Chlorohydrin (**3**); colorless oil; 65% yield; IR (neat): 3400 (OH), 1080, 1035 (SO) cm^{-1}; ^{1}H NMR δ=1.0—2.4 (10H, m), 3.32, 3.44 (each 1H, d, J=15 Hz), 3.82 (3H, s), 6.7—7.0 (2H, m), 7.2—7.4 (2H, m), 7.4—7.8 (5H, m); MS m/z (%): 266 ([M−PhSOH]$^+$, 22), 209 (40), 126 (57), 78 (100). Epoxy sulfoxide (**4g**); 88% yield; colorless oil; IR (neat): 1080, 1050, 1035 (SO) cm^{-1}; ^{1}H NMR δ=1.3—2.3 (10H, m), 3.21 (2H, s), 3.73 (3H, s), 6.64, 6.77 (each 2H, d, J=10 Hz), 7.4—7.8 (5H, m); MS m/z (%): 231 ([M−PhSO]$^+$, 11), 202 (2), 121 (100).

2,3-Epoxy-3-methyl-1-(1-naphthyl)-2-(phenylsulfinyl)butane (4h). Chlorohydrin (**3**); mp 101—103 °C (AcOEt-hexane); 52% yield; IR (KBr): 3380 (OH), 1080, 1040, 1020 (SO) cm^{-1}; ^{1}H NMR δ=1.45, 1.60 (each, 3H, s), 4.02, 4.40 (each 1H, d, J=15 Hz), 7.3—8.3 (12H, m); MS m/z (%): 246 ([M−PhSOH]$^+$, 68), 231 (18), 213 (80), 141 (28), 110 (87), 43 (100). Epoxy sulfoxide (**4h**); 93% yield; colorless oil; IR (neat): 1090, 1055, 1045 (SO) cm^{-1}; ^{1}H NMR δ=1.07, 1.89 (each 3H, s), 3.50, 3.87 (each 1H, d, J=17 Hz), 7.2—7.9 (12H, m); MS m/z (%): 336 (M$^+$, trace), 211 ([M−PhSO]$^+$, 22), 169 (68), 141 (100).

5,5-Diphenyl-4,5-epoxy-4-phenylsulfinyl-1-pentene (4i). In this case alkylation of 1-chloro-3-butenyl phenyl sulfoxide with benzophenone directly gave the α,β-epoxy sulfoxide (**4i**) in 92% yield. Mp 121—123 °C (AcOEt-hexane); IR (KBr): 1640 (C=C), 1085, 1045 (SO) cm^{-1}; ^{1}H NMR δ=2.20, 2.90 (each 1H, dddd, J=1.2, 1.2, 6.5, 16 Hz), 4.36 (1H, m, $W/2$=20 Hz), 4.62 (1H, m, $W/2$=11 Hz), 4.96 (1H, dddd, J=6.5, 6.5, 10, 17 Hz), 7.2—7.8 (15 H, m); MS m/z (%): 234 ([M−PhSOH]$^+$, 41), 194 (46), 167 (71), 165 (100), 129 (80); Found: C, 75.95; H, 5.50; S, 8.90%. Calcd for $C_{23}H_{20}O_2S$: C, 76.64; H, 5.59; S, 8.89%.
