The Cyclodextrin-Quinone Inclusion Compounds in an Aqueous Solution at 77 K. II. 9,10-Phenanthrenequinone and Acenaphthenequinone

Akira KUBOYAMA* and Sanae Y. MATSUZAKI
National Chemical Laboratory for Industry, Tsukuba Research Center,
Yatabe, Ibaraki 305
(Received February 23, 1985)

A complex formation between cyclodextrins (CD's) and the two *o*-quinones (9,10-phenanthrenequinone (PHQ) and acenaphthenequinone (ANQ)) in a water-ethylene glycol 1:1 mixture glassy solution at 77 K was investigated using the nπ* phosphorescence spectra of these quinones. It was considered on the basis of the observed results that PHQ forms a 1:1 complex with γ-CD and ANQ a 2:1 complex with β-CD. The structures of these complexes are discussed. It was found that complexes between γ-CD and the PHQ- and ANQ-naphthalene charge-transfer complexes are also formed.

Previously. we studied the complex formation[1] between CD's and the *p*-quinones (9,10-anthraquinonesulfonates and 1,4-naphthoquinones) in an aqueous solution at 77 K, using the nπ* phosphorescence spectra of the quinones.[2] *o*-Quinones show various characteristic organic reactions like *p*-quinones. The CD-*o*-quinone complex formation may play an important role in some of these reactions. Previously, we studied the nπ* phosphorescence spectra of the *o*-quinones,[3] 9,10-phenanthrenequinone (PHQ) and acenaphthenequinone (ANQ) in organic solvents at 77 K. These spectra are sensitive to the environment around the α-dicarbonyl groups and are thought to be useful in an investigation of complex formations between CD's and the quinones.

In this work complex formations between CD's and these *o*-quinones were investigated under the same conditions as those used in the previous work.[1] Naphthalene (NA), an electron-donor to the quinones was also used as a third component.[4] Heretofore, only one study[4a] of the complex formation between CD's and a charge-transfer complex has ever, to our knowledge, been reported.

Experimental

Measurements. The phosphorescence spectra, their excitation spectra and lifetimes were obtained using an Aminco 500 spectrofluorophotometer equipped with a phosphoroscope and a photon counter (PM tube 1P28) at 77 K.[2] The solvent of the water-ethylene glycol 1:1 mixture (H_2O-EG) which forms a glassy state at 77 K was mainly used. Two cooling-speeds of the sample solutions (fast and slow) were used.[2]

Materials. PHQ and ANQ were purchased from Tokyo Kasei Kogyo Co. PHQ and ANQ were purified by the zone-melting method and vacuum sublimation, respectively (mp 209.5—210.5 °C and 262 °C). Scintillation grade NA of Merk Co., α-, β-, and γ-CD of Tokyo Kasei Kogyo Co., nonfluorescent water of Dojin Yakukagaku Kogyo Co., ethylene glycol especially prepared for chromatography by Nakarai Chemical Co., spectrograde hexane of Tokyo Kasei Kogyo Co., spectrograde heptane of Dojin Yakukagaku Kogyo Co., and analytical grade 1-chlorobutane of Nakarai Chemical Co. were used without further purification.

a: 9,10-phenanthrenequinone, b: acenaphthenequinone, ——: heptane (a), hexane (b), — —: 1-chlorobutane, ----: H_2O-EG. The concentrations of the quinones in the solutions are all lower than 3×10^{-4} M (In all the figure captions M denotes mol dm^{-3}). In Fig. 2—7 all the solutions used are of the fast-cooling unless otherwise described. In Fig. 2—6 the phosphorescence spectra of 9,10-phenanthrenequinone and acenaphthenequinone were obtained at the 420 and 312 nm excitation, respectively, unless otherwise described.

Results and Discussion

As is seen in Fig. 2, the phosphorescence spectra of PHQ and ANQ are observable in an H_2O–EG solution at 77 K, but the phosphorescence intensity of PHQ is very weak. The phosphorescence spectra of these quinones may be assigned to the $n\pi^*$ spectra, as they clearly show a CO-stretching vibrational structure alone. Also, their observed lifetimes[5] are short. From these spectra, no spectral changes can be observed under the irradiation of the exciting light, and no concentration dependence can be observed.

A *b*-shift in the spectrum of the 1-chlorobutane solution compared with that in the normal paraffin solution is ca. 790 and 830 cm^{-1} in PHQ and ANQ, respectively. The shift in the H_2O–EG solution is ca. 990 and 1620 cm^{-1} in PHQ and ANQ, respectively (Table 1). This difference in the *b*-shift between PHQ and ANQ in the H_2O–EG solution can be explained as follows. The large *b*-shift in ANQ is due to the formation of a strong hydrogen bond between ANQ and water. On the other hand, the *b*-shift in PHQ indicates that the phosphorescence is due to the PHQ molecules forming a hydrogen bond with ethylene glycol. This bond is weaker than that between PHQ and water. The PHQ molecules forming the hydrogen bond with water show no phosphorescence because their T_1 state is $\pi\pi^*$, in contrast to that of the former.[5,6] The weakness of phosphorescence of PHQ in the H_2O–EG solution is perhaps due to the proportion of the PHQ molecules forming the hydrogen bond with ethylene glycol, being far smaller than that of the PHQ molecules forming the hydrogen bond with water. The phosphorescence spectra of these quinones show no change in the presence of α-CD.

In PHQ, a spectral change can be observed only in the presence of γ-CD. As is seen in Fig. 3, the broad 0-0 peak of the phosphorescence spectrum of the γ-CD complex shifts to the red by 180 cm^{-1} in comparison with that of the free PHQ molecules, and the second peak which is sharper than the 0-0 peak is

Table 1. Peak Wavelengths, λ, of the Phosphorescence Spectra

	Solvent	λ/nm
PHQ	Hexane	588.5, 602
	1-Chlorobutane	562.5
	H_2O–EG	556
(+γ-CD)[a]	H_2O–EG	562.5, 578
(+γ-CD+NA)[a]	H_2O–EG	573
ANQ	Heptane	579
	1-Chlorobutane	552.5
	H_2O–EG	529.5
(+β-CD)[a]	H_2O–EG	553, 571
(+γ-CD+NA)[a]	H_2O–EG	544, 548, ≈551, 561.5

a) For example, (+γ-CD) denotes the solution containing γ-CD. NA denotes naphthalene.

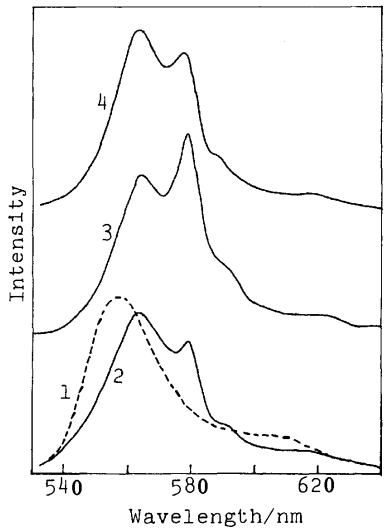

Fig. 3. Phosphorescence spectra of 9,10-phenanthrenequinone in the H_2O–EG solutions containing γ-CD at 77 K.
1: 2.4×10^{-4} M, 2: 1.2×10^{-4} M + γ-CD(1.9×10^{-3} M), 3 and 4: 2.4×10^{-4} M + γ-CD(3.7×10^{-3} M) (4:sector-speed slow).

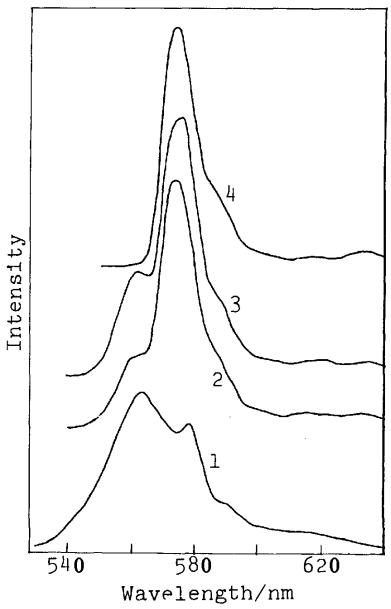

Fig. 4. Phosphorescence spectra of 9,10-phenanthrenequinone in the H_2O–EG solutions containing γ-CD and naphthalene at 77 K.
1: 1.2×10^{-4} M + γ-CD(1.9×10^{-3} M), 2 and 3: 8.6×10^{-5} M + γ-CD(1.3×10^{-3} M) + NA (5.8×10^{-5} M) (3: sector-speed slow), 4: 8.6×10^{-5} M + γ-CD(1.3×10^{-3} M) + NA(3.3×10^{-4} M) (In Fig. 4 and 6 NA denotes naphthalene).

observed at wavelengths longer by 450 cm^{-1} than the 0-0 peak. The relative intensity of the second peak to the 0-0 peak decreases with a decrease in the sector speed of the phosphoroscope. It increases a little in slow cooling compared to that with fast cooling. Furthermore, the relative intensity of the second peak increases considerably with a twofold increase in the concentration of both PHQ an γ-CD. From these results, the 0-0 and the second peak are thought to be due to a complex in the solution and a crystalline phase, respectively. The above-mentioned r-shift of the phosphorescence 0-0 peak of the complexes in comparison with that of the free PHQ molecules may be due to the weakening or destruction of the hydrogen bond between PHQ and ethylene glycol.

As is seen in Fig. 4, in the presence of γ-CD and NA, PHQ shows a relatively sharp phosphorescence 0-0 peak at wavelengths longer by 340 cm^{-1} than the above-mentioned 0-0 peak of the γ-CD–PHQ complex. This r-shift and sharpening of the spectrum is thought to be due to the formation of a complex between γ-CD and the PHQ–NA charge-transfer complex and may indicate a weakening of the beforementioned hydrogen bond between PHQ and ethylene glycol or γ-CD in the presence of NA. The intensity of this phosphorescence is considerably stronger than that of the γ-CD–PHQ complex, and its observed lifetime (4.7 ms) is close to that (5.5 ms)[3] of PHQ in the hexane solution. It is considerably shorter than that of the free PHQ molecules.[5]

In ANQ, as is seen in Fig. 5a, the phosphorescence spectrum shifts to the red by ca. 800 cm^{-1} and becomes sharper in the presence of β-CD, while in the presence of γ-CD, as is seen in the spectrum 1 of Fig. 6, a weak shoulder appears at almost the same position as the spectrum observed in the presence of β-CD in the phosphorescence spectrum of the free ANQ molecules. The large r-shift of the spectrum in the presence of β-CD might indicate that the beforementioned strong hydrogen bond between ANQ and water is considerably weakened or destroyed due to the complex formation. The observed phosphorescence lifetime (17 ms) is considerably shorter than that (26 ms) of the free ANQ molecules.[5,7]

As is seen in Fig. 5a, in the presence of β-CD the phosphorescence spectrum of the free ANQ molecules and a weak shoulder which is at wavelengths longer by ca. 570 cm^{-1} than the strong 0-0 peak of the complex appear clearly in fast cooling. From a comparison between the spectra in Fig. 5a and 5b it can be seen that the relative intensity of the phosphorescence spectrum of the complex to that of the free ANQ molecules is far weaker in the low-concentration solution of β-CD than that in the high-concentration solution. In the low-concentration solution it is considerably stronger in slow cooling than in fast cooling. Though in the low-

(a) ——: 7.4×10^{-5} M, ---- and ——: 7.4×10^{-5} M $+\beta$-CD(2.0×10^{-3} M)(----: slow cooling), (b) ---- and ——: 7.4×10^{-5} M$+\beta$-CD (6.7×10^{-4} M) (----: slow cooling).

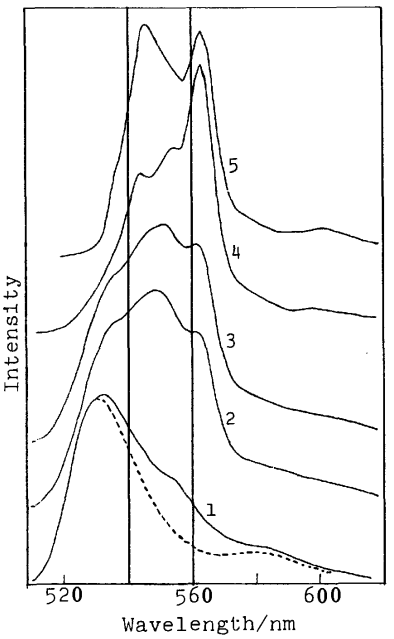

Fig. 6. Phosphorescence spectra of acenaphthenequinone in the H_2O–EG solutions containing γ-CD and naphthalene at 77 K at the 330 nm excitation.
1: 1.0×10^{-4} M$+\gamma$-CD(1.9×10^{-3} M), 2: 6.7×10^{-5} M $+\gamma$-CD (1.2×10^{-3} M)+NA (6.7×10^{-5} M), 3: 9.8×10^{-5} M$+\gamma$-CD(1.8×10^{-3} M)+NA(9.5×10^{-5} M), 4: 6.1×10^{-5} M$+\gamma$-CD(1.5×10^{-3} M)+NA(3.3×10^{-4} M), 5: 1.0×10^{-4} M$+\gamma$-CD(1.9×10^{-3} M)+NA(2.0×10^{-3} M). The dotted line spectrum is the same as the broken line spectrum in Fig. 5a.

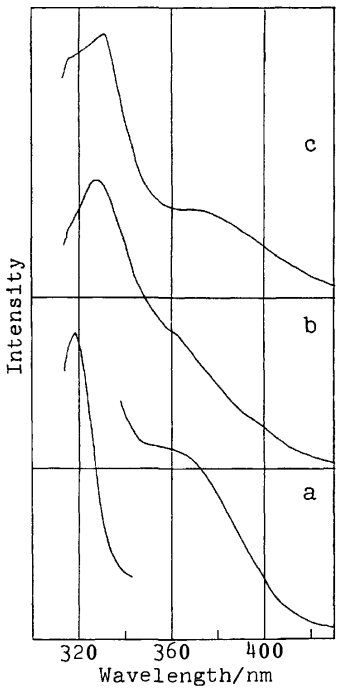

Fig. 7. Phosphorescence excitation spectra of acenaphthenequinone in the H_2O–EG solutions containing γ-CD and naphthalene at 77 K.
The solution used for the spectrum a is the same as that for the broken line spectrum in Fig. 5a, and the solution used for the spectrum b and c is the same as that for the spectrum 5 in Fig. 6. Monitoring wavelength: a 529 nm, b 561.5 nm, c 544 nm.

concentration solution the concentration of β-CD is three times lower than that in the high-concentration solution, the concentration of β-CD is one order higher than that of ANQ. On the other hand, no similar concentration-dependent features can be observed in the γ-CD–PHQ complex. These results suggest that the β-CD to ANQ ratio in the complex is not one-to-one but probably two-to-one, while that in the γ-CD–PHQ complex is one-to-one.

In the solution in which the concentrations of ANQ and β-CD are both about two times higher than those in the solution used for the solid-line spectrum in Fig. 5a, the relative intensity of the before-mentioned long-wavelength shoulder to the 0-0 peak of the complex in the spectrum obtained is close to that in the above-mentioned spectrum, contrary to the case of the γ-CD–PHQ system. In view of this result and the before-mentioned cooling-speed dependence of that relative intensity, the long-wavelength shoulder might not be due to the β-CD–ANQ complex in a crystalline phase but due to that in the solution, the structure of which is different from that of the complex showing the strong 0-0 peak, and in which the α-dicarbonyl group of ANQ is in more hydrophobic circumstances than that in the latter complex.

In the presence of NA, no shift in the phosphorescence spectrum of the β-CD–ANQ complex occurs, but the relative intensity of the phosphorescence spectrum of the free ANQ molecules to that of the complex markedly increases in the presence of NA. This result may be due to a decrease in the concentration of β-CD to form the complex with ANQ, resulting from a complex formation between β-CD and NA.[8] As is mentioned before, ANQ shows only a slight spectral change in the presence of γ-CD, while marked spectral changes are observed in the presence of NA in addition to that of γ-CD, as is seen in Fig. 6. These spectral changes are thought to be due to a complex formation between γ-CD and the quinone–NA charge-transfer complex. In the spectrum 2 two new peaks (one broad and one sharp peak) appear at 548 and 561.5 nm, respectively, in comparison with the spectrum 1. In the spectrum 3 and 4, another broad peak appears at ca. 551 nm. In the spectrum 4 and 5, a sharp peak appears at 544 nm. From a comparison between the spectra 2—5, it is thought that there are two kinds of the complexes, and that one of them shows the broad and the sharp peak at 548 and 561.5 nm in the solution and the crystalline phase, respectively, and the other one shows the broad and the sharp peak at ca. 551 and 544 nm in the solution and the crystalline phase, respectively. The latter complex is thought to be formed in the solutions containing NA in high concentrations, compared with the former complex. In the two excitation spectra of the above-mentioned two sharp peaks at 544 and 561.5 nm in Fig. 7, the two $\pi\pi^*$ absorption peaks at 328 and 325 nm, respectively, are at considerably longer wavelengths than that of the free ANQ molecules at 317 nm. This is thought to be due to a charge-transfer interaction between ANQ and NA in the γ-CD complexes.

As is mentioned before, since the phosphorescence spectra of the γ-CD–PHQ and β-CD–ANQ complex in the solution are at considerably shorter wavelengths and are far broader than those of these quinones in the normal paraffin solutions, the two α-dicarbonyl groups of these quinones in the complexes are thought not to be mostly in the hydrophobic cavity of the CD's; in other words, these complexes do not take the equatorial form.[9] This is reasonable in view of the α-dicarbonyl groups being hydrophilic. In view of the dimensions (ca. 11.6 and ca. 9.1 Å, respectively) of PHQ[10] and ANQ[11] along the direction perpendicular to the symmetry axis, the γ-CD–PHQ and β-CD–ANQ complexes cannot also take the axial form.[9,12] In these complexes the CD molecules are thought to partly cover the hydrophobic parts of the PHQ and ANQ molecules. In the complexes between γ-CD and the quinone–NA charge-transfer complexes also, the γ-CD molecules

are thought to partly cover the hydrophobic parts of the charge-transfer complexes.

Kinetic Study of Liquid-Phase Esterification with Sulfonic Acid Cation-Exchange Resin of the Macroreticular Type. I. Heterogeneous-Pseudohomogeneous Resin Catalysis[1)]

Shoichi SHIMIZU* and Choichiro HIRAI
Department of Industrial Chemistry, College of Industrial Technology, Nihon University, Izumi-cho, Narashino, Chiba 275
(Received May 25, 1985)

The rates of the esterification of octanoic acid with 1-butanol catalyzed by macroreticular sulfonated ion-exchange resin were measured by the use of a batch reactor. The effects on the rate were investigated for variations in the amount of the catalyst, the temperature, and the reactant alcohol concentrations as well as those of water and butyl octanoate. From these data, it is considered that alcohol and water solvate the matrix-bound sulfo groups, and so this esterification system consists of a heterogeneous reaction catalyzed by un-ionized sulfo groups and a pseudo-homogeneous reaction catalyzed by solvated protons; in other words, catalysis by sulfonic acid resin is both heterogeneous and pseudo-homogeneous in liquid-phase esterification.

In organic reactions catalyzed by acids or bases, the use of ion-exchange resins as catalysts offers the following advantages over that of homogeneous catalysts:[2-4)] (1) the resins are easily separated from the reaction mixture, (2) undesirable side reactions are frequently avoided, (3) resin catalysis can afford a degree of selectivity unattainable in homogeneous catalysis, (4) resins permit operation in either continuous or batch processes, and (5) corrosion is eliminated or reduced significantly. Therefore, experimental studies of the use of resin as catalysts have been carried out on many reactions. The major groups of these reactions are acetal-formation, dehydration, esterification, etherification, hydration, hydrolysis, and isomerization. The range of practical application of ion-exchange catalysts has, consequently, been extended. Theoretical problems in ion-exchange catalysis have also been discussed in several reviews.[5-7)]

The esterification of acids with alcohols, which is one of the most active areas for the application of resin catalysis, has usually been catalyzed by the use of a sulfonic acid cation-exchanger and has been carried out in both gas[8-10)] and liquid phases.[11-22)] Kinetic studies of the esterification have been reported in numerous reports on the reaction. In gas-phase esterification, it is known that the experimental data agree well with the estimate obtained by the use of a Langmuir-Hinshelwood model, which demonstrates that the resin catalysis is heterogeneous.[8,10)] In the case of liquid-phase esterification, several authors have preferred Helfferich's classical explanation[23)] based on a pseudo-homogeneous system assumption,[11,13-21)] although others have reported that the kinetics of heterogeneous catalytic reactions provide a satisfactory fit of the data.[12,21)] At present, there is no unified opinion about the liquid-phase catalysis with sulfonic acid resin, as has been mentioned above. Gates and his co-workers, however, pointed out that an excess of water or alcohol can shift the catalytic species from the more active undissociated sulfonic acid (general acid catalysis) to the less active solvated proton (specific acid catalysis), which was substantiated by a series of fundamentally important investigations of the dehydration of 2-methyl-2-propanol,[24)] olefin and paraffin formation from butyl alcohols,[25)] and benzene propylation.[26)] Recently, Gomzi et al.[21)] studied the kinetics of the esterification of acetic acid with 1-butanol catalyzed by sulfonic acid resin of the standard type; they reported that the best model for explaining the reaction rate with a partially wet ion-exchanger (27% water contents) is obtained by assuming a pseudo-homogeneous system, while the kinetics of a dry one is best represented by a model derived from assumptions based on a heterogeneous system. However, in the report of Gomzi et al.[21)] the catalytic species in these reactions were not mentioned at all.

In this work we have measured the kinetics of the esterification of octanoic acid with 1-butanol catalyzed by macroreticular sulfonic acid resin (Amberlyst 15) in order to clarify the catalysis by the resin in liquid-phase esterification. Furthermore, this work should help to elucidate the selectivity behavior of the resin catalyst in relation to the alkyl-chain length of normal fatty acids, which was reported in the preceding paper.[22)]

Experimental

Catalyst Preparation and Materials. A macroporous sulfonated copolymer of styrene and divinylbenzene was prepared from commercial ion-exchange resin, Amberlyst 15. The resin, 0.59—0.84 mm particles, was washed with distilled water and cycled between the hydrogen and sodium forms according to a conventional column method. The hydrogen-form resin to be used as a catalyst was dried in an oven at a temperature below 110 °C to 5.81% water and then stored in a desiccator in sealed vials over silica gel. The ion-exchange capacity was 4.99 meq/g of dry resin.

Guaranteed reagent-grade octanoic acid and butyl

octanoate were used without further purification. The toluene and 1-butanol were purified by distillation, and then the former was dried over anhydrous magnesium sulfate.

Reaction-Rate Measurement. The esterification with an ion-exchanger as a catalyst was usually measured at 80±0.05 °C in a 100-ml three-necked flask equipped with a magnetic stirrer (about 250 rpm) and a condenser, and heated in an oil bath. In all experiments, the volume of the reaction mixture, consisting of octanoic acid, 1-butanol, and toluene as a diluent, was kept constant at 30 ml. A timer was started on the addition of the catalyst to the reactor, and 40-μl samples were removed by using a microsyringe at appropriate time intervals and then transferred to individual capped microtubes containing a toluene solution of hexadecane as an internal standard. For gas-chromatographic (GC) analysis, samples of about 1—2 μl were taken from these microtubes. The only product detected, except water, was butyl octanoate. Therefore, the rates were determined from the ester analyses. The molar concentrations of the ester in each original sample were obtained by determining the ratio of the areas of the ester peaks to that of the hexadecane peak and by comparing these with the calibration curves.

The instrument used to carry out the GC analyses and the operating conditions were described in detail in an earlier paper.[22]

Results

Catalyst Amount and Temperature Dependence of Apparent Rate Constant. For determining the order of octanoic acid, the half-life periods were measured under the following conditions: initial concentration of 1-butanol, 7.29 mol dm^{-3}; amount of resin, 1.50 g. Figure 1 shows that the dependence of the rate on the concentration of acid is first-order under these experimental conditions. In addition, it is confirmed, by a comparison with the order obtained in the preceding study,[22] that the toluene used as a diluent does not affect the order. The rate of reaction is represented by

$$r = k'_{obsd}[F]. \quad (1)$$

As is shown in Fig. 2, the pseudo-first-order rate constants, k'_{obsd}, were directly proportional to the amount of the resin catalyst. Hence, the specific rate constant, k_{obsd}, was introduced

$$k_{obsd} = k'_{obsd}/M. \quad (2)$$

The logarithm of k_{obsd} vs. the reciprocal of the absolute temperature, that is, the Arrhenius-type plot, is shown in Fig. 3. As can be seen from the figure, a good straight line was obtained. From the slope of this line, an apparent activation energy of about 14 kcal† mol^{-1} was estimated; this is consistent with the finding of a previous work[22] that neither bulk diffusion nor pore diffusion is a limiting step.

Effects of Alcohol, Water, and Ester. The influence of the concentration of 1-butanol upon the reaction rate is shown in Fig. 4, while the cases of water and butyl octanoate instead of 1-butanol are represented in Figs. 5 and 6 respectively. Water inhibited the reaction, as is shown by the results of Fig. 5, but the ester did not affect the rate over the present range of experimental conditions. In all the

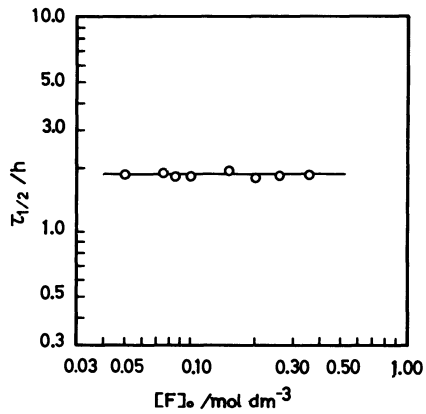

Fig. 1. Relationship between initial concentration of octanoic acid ($[F]_o$) and half life of esterification ($\tau_{1/2}$).

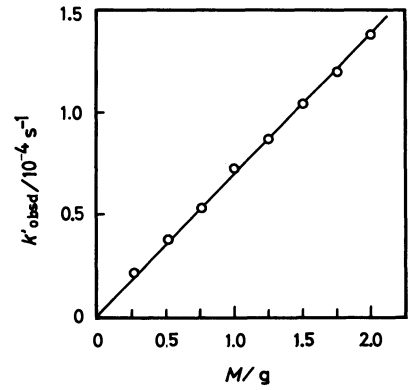

Fig. 2. Dependence of pseudo-first-order rate constant (k'_{obsd}) on amount of Amberlyst 15 (M).

† 1 cal=4.184 J.

runs denoted in Figs. 4—6, the initial concentration of octanoic acid and the amount of resin were held constant at 0.150 mol dm^{-3} and 1.75 g respectively. The ester-concentration increments from 0.0200 to 0.0400 mol dm^{-3}, divided by the time required for the reaction progress, were set equal to the reaction rates for each solution composition at a conversion of 20% and were adopted as the kinetic data, since a short induction period appeared rarely and an initial reaction rate could not be employed.

Discussion

Evaluation of Effects of Resin Swelling and the Dielectric Constant of the Reaction Medium on the Rate. Amberlyst 15, which consists of aggreates of very small gelular microspheres, presumably consists of about 20% divinylbenzene.[27] At cross-linker levels above 12%, the resin matrix exhibits great resistance to swelling.[2] Therefore, it is considered[22,27,28] that the gelular microspheres are not greatly swollen by the reaction medium and that only the sulfo groups residing on the surface of the microspheres[29] are available for a catalytic reaction. This conclusion is supported by the curve shown in Fig. 4, for if 1-butanol causes a swelling of the microsphere gel network,[30] the number of directly accesible sulfo groups should decrease with the decrease in its concentration in a reaction solution, and the catalytic activity of the resin should consequently diminish. All this is contrary to the observed curve. From the above evaluation of the resin swelling, it seems that the assumption of Helfferich[23] can not be applied in this case.

The results obtained from Figs. 4 and 5 can not be used in the treatment of the solvent effects for a reaction between a neutral dipolar molecule and a positive ion as the rate-controlling step, because the plot of ln k_2 against $1/D$ is found to be nonlinear.

Nature of the Acid Site in the Resin and Kinetic Analysis. It is considered from Fig. 5 that the product water solvates the matrix-bound sulfo groups and then depresses the catalytic rate.[12,24,25,27,31] Appropriate polar molecules such as alcohol may also participate in a similar solvation to water.[32] Since the ester did not inhibit the reaction, and since the solvating power of the toluene used as a diluent is negligibly small, it is considered that water and alcohol behave as solvating agents under the present reaction conditions. These solvation equilibria may be written as

$$\alpha A + \text{Ⓟ-}SO_3H \overset{K_{sol}^{(A)}}{\rightleftarrows} \text{Ⓟ-}SO_3^-/\alpha A/H^+, \quad (3)$$

$$\beta W + \text{Ⓟ-}SO_3H \overset{K_{sol}^{(W)}}{\rightleftarrows} \text{Ⓟ-}SO_3^-/\beta W/H^+. \quad (4)$$

The solvated protons also become catalytic agents.[33] However, it is thought that the specific activity of the hydrated protons is negligible compared with that of those solvated with alcohol; therefore, this esterification system consists of a heterogeneous reaction catalyzed by matrix-bound sulfo groups which are not ionized and a pseudo-homogeneous reaction by

protons solvated with alcohol.

Based on these considerations and the fact that the reaction was first-order in its concentration of fatty acid, the following reaction mechanism may be assumed

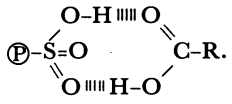
$$F + Ⓟ\text{-}SO_3H \xrightarrow{k_{het}} Ⓟ\text{-}SO_3H \cdots F, \quad (5)$$

$$A + Ⓟ\text{-}SO_3H \cdots F \underset{}{\overset{K_{het}}{\rightleftarrows}} E + W + Ⓟ\text{-}SO_3H, \quad (6)$$

$$F + Ⓟ\text{-}SO_3^-/\alpha A/H^+ \overset{K^{(A)}_{phom}}{\rightleftarrows} Ⓟ\text{-}SO_3^-/\alpha A + HF^+, \quad (7)$$

$$A + HF^+ + Ⓟ\text{-}SO_3^-/\alpha A \xrightarrow{k^{(A)}_{phom}} E + W + Ⓟ\text{-}SO_3^-/\alpha A/H^+. \quad (8)$$

Reaction (5) corresponds to the chemisorption of octanoic acid on the acid site in the resin, and it appears that the fatty-acid molecule is associated with the un-ionized sulfo group by means of the formation of a doubly hydrogen-bonded structure:[34]



If the $Ⓟ\text{-}SO_3H \cdots F$ and HF^+ species are present in very small amounts, which implies $K_{het} \gg 1 \gg K^{(A)}_{phom}$, the following equation can be set up

$$[Cat] = [Ⓟ\text{-}SO_3H] + [Ⓟ\text{-}SO_3^-/\alpha A/H^+] + [Ⓟ\text{-}SO_3^-/\beta W/H^+]. \quad (9)$$

For the two equilibria (3) and (4), it is possible to write as follows:

$$[Ⓟ\text{-}SO_3^-/\alpha A/H^+] = K^{(A)}_{sol}[A]^{\alpha}[Ⓟ\text{-}SO_3H], \quad (10)$$

$$[Ⓟ\text{-}SO_3^-/\beta W/H^+] = K^{(W)}_{sol}[W]^{\beta}[Ⓟ\text{-}SO_3H]. \quad (11)$$

The substitution of (10) and (11) into (9) gives

$$[Ⓟ\text{-}SO_3H] = [Cat]/(1+K^{(A)}_{sol}[A]^{\alpha}+K^{(W)}_{sol}[W]^{\beta}). \quad (12)$$

The rate of the heterogeneous reaction which contains the chemisorption reaction (5) as its rate-determining step is represented by

$$r_{het} = k_{het}[F][Ⓟ\text{-}SO_3H]M. \quad (13)$$

Equation (13) may be transformed into

$$r_{het} = \frac{k_{het}[F][Cat]M}{1+K^{(A)}_{sol}[A]^{\alpha}+K^{(W)}_{sol}[W]^{\beta}}. \quad (14)$$

For the pseudo-homogeneous reaction, where only the protonated form of fatty acid HF^+ reacts with alcohol at a measurable rate, the rate equation is given by

$$r_{phom} = k^{(A)}_{phom}[A][HF^+][Ⓟ\text{-}SO_3^-/\alpha A]M. \quad (15)$$

Equilibrium (7) can be expressed by

$$[HF^+][Ⓟ\text{-}SO_3^-/\alpha A] = K^{(A)}_{phom}[F][Ⓟ\text{-}SO_3^-/\alpha A/H^+], \quad (16)$$

and by using Eqs. (10), (12), and (16) r_{phom} is given as follows:

$$r_{phom} = \frac{k^{(A)}_{phom}K^{(A)}_{phom}K^{(A)}_{sol}[F][A]^{\alpha+1}[Cat]M}{1+K^{(A)}_{sol}[A]^{\alpha}+K^{(W)}_{sol}[W]^{\beta}}. \quad (17)$$

Therefore, the total reaction rate is expressed by

$$r = \frac{\{k_{het}[F]+k^{(A)}_{phom}K^{(A)}_{phom}K^{(A)}_{sol}[F][A]^{\alpha+1}\}[Cat]M}{1+K^{(A)}_{sol}[A]^{\alpha}+K^{(W)}_{sol}[W]^{\beta}}. \quad (18)$$

The straight line in the plot of [W] vs. $1/r$ in Fig. 5 indicates that the sulfo groups are solvated by one molecule of water per group at values of [W]<4 mol dm^{-3}: $\beta=1$. Therefore, the data shown in Figs. 4 and 5 were compared with the values calculated from Eq. (18), in which $\beta=1$ had been substituted. In order to determine the optimum values of $k_{het}[Cat]$, $k^{(A)}_{phom}K^{(A)}_{phom}[Cat]$, $K^{(A)}_{sol}$, and $K^{(W)}_{sol}$ for integral values of the α exponent ranging from one to three, the sum of the squares of deviations of the predicted rates from the observed ones has been calculated with a computer. The most precise representation is given by

$$r = \frac{\{k_{het}[F]+k^{(A)}_{phom}K^{(A)}_{phom}K^{(A)}_{sol}[F][A]^2\}[Cat]M}{1+K^{(A)}_{sol}[A]+K^{(W)}_{sol}[W]}, \quad (19)$$

where the values of $k_{het}[Cat]$, $k^{(A)}_{phom}K^{(A)}_{phom}[Cat]$, $K^{(A)}_{sol}$, and $K^{(W)}_{sol}$ were 2.85×10^{-4} s^{-1} g^{-1}, 5.66×10^{-6} dm^3 mol^{-1} s^{-1} g^{-1}, 0.769 dm^3 mol^{-1}, and 5.30 dm^3 mol^{-1} respectively. In view of the polarity of 1-butanol and water, it seems reasonable that the equilibrium constant, $K^{(W)}_{sol}$, is greater than the $K^{(A)}_{sol}$.

When the values calculated from Eq. (19) are compared to the data in Figs. 4 and 5, the agreement between the observed and calculated values is satisfactory. These results give support to the assumptions that this esterification involves both the heterogeneous and pseudo-homogeneous catalyses and that, in the heterogeneous one, the rate-determining step is the chemisorption reaction of fatty acid. As may be seen from Fig. 4, at the lower alcohol concentrations the rate of the heterogeneous reaction catalyzed by the un-ionized sulfo groups[35] substantially governs the total reaction rate, while at the higher ones the rate is roughly equal to that of a pseudo-homogeneous reaction catalyzed by the solvated protons with alcohol.

It is considered that, since the positions of equilibria (3), (4), and (7) are affected by the reaction temperature, the activation energy for both the heterogeneous and pseudo-homogeneous reactions are different from the apparent one estimated from the slope of the straight line in Fig. 3. Furthermore, it is presumed that the selectivity behavior of the resin catalyst related to the alkyl-chain length of normal fatty acids, which was reported in the preceding paper,[22] is due to differences in the rate constant, k_{het}, for the heterogeneous chemisorption

reaction (5).

35) The proportion of the un-ionized sulfo groups is given by

$$[Ⓟ\text{-}SO_3H]/[Cat] = 1/(1+K_{sol}^{(A)}[A]+K_{sol}^{(W)}[W]).$$

For example, when the concentrations of 1-butanol are 2.00, 6.00, and 10.00 mol dm^{-3}, the proportions are calculated to be 0.371, 0.173, and 0.113 respectively. From these proportions and the values of r_{het} and r_{phom} for each solution composition, it is considered that the un-ionized sulfo groups are very active compared to the solvated protons with alcohol.

Simulation of Absorption Spectra of Polyenes Produced in PVA Film by Heating and Kinetics of Polyenes Formation

Kazunori MARUYAMA, Michio TAKÉ, Nobuyuki FUJII, and Yoshié TANIZAKI*
Department of Materials Science and Technology, Technological University of Nagaoka, Nagaoka, Niigata 949-54
(Received June 24, 1985)

Characteristics of absorption spectra of heated PVA film could be simulated as combinations of absorption spectra of free polyenes corresponding to the type $-(CH=CH)_n-$ (n=1—13). The change in concentrations of polyenes produced in PVA films was calculated by means of simulation. Each polyene $-(CH=CH)_n-$ was assumed to be produced by a first order reaction with rate constant k_n with respect to the concentration of $-(CH=CH)_{n-1}-$. k_n values (n=1—13) at several temperatures were obtained. Arrhenius plots of k_n from straight lines, giving activation energies 57—63 kJ mol^{-1} for the reaction catalyzed by H_3PO_4 and 94—100 kJ mol^{-1} for that by H_2SO_4. The activation entropies are negative in both cases.

At the initial stage of heating, thermal decomposition of poly(vinyl alcohol) [PVA] leads to formation of polyene structures in main polymer chains.[1] The authors have already assigned peaks and bands in absorption and excitation spectra of heated PVA films to 0←0, 1←0, and 2←0 π-π* transitions of $-(CH=CH)_n-$ type polyenes and $-(CH=CH)_n-CO-$ type polyenones.[2] These types are distinguished from each other according as the spectrum is accompanied with a fine structure or not; the former shows a fine structure and the latter a broad band. Under certain conditions, the type of polyenes is preferentially produced. In such cases, a proper combination of absorption spectra of free polyenes is expected to reproduce the experimental spectrum, provided that the concentration of polyenones produced may be disregarded relative to that of polyenes. Moreover, by using the concentration of polyenes determined by simulation, a kinetic study on the polyenes formation is expected to be made.

The present purpose is to simulate absorption spectra of polyenes produced in heated PVA film and to try a kinetic study on the polyenes formation.

Experimental

The PVA used was a commercial one (Koso Chemical Co., Ltd.), of which the average polymerization degree was 1400 and the alkaline saponification was 99—100%. Ten grams of PVA powder was dissolved in distilled water of 200 cm^3 at 90 °C and the solution was poured on a horizontal plate of glass. After it was dried at room temperature for 10 d, a PVA film about 100 μm thick was obtained. This film was kept for 2 h at 80 °C, digested in a mixed solution of 0.1 M(1 M=1 mol dm^{-3}) $NaBH_4$ and 0.1 M NaOH for 1 d to reduce the carbonyl group contained, and then washed successively with 0.05 M HCl solution and with distilled water.

Subsequently, the PVA film was digested in 0.05 M H_3PO_4 or 0.05 M H_2SO_4 solution for 1 d and then dried at room temperature. The PVA film thus treated was fixed on a metal holder and heated in a heating compartment at a constant temperature in a 0.5 dm^3 min^{-1} flow of nitrogen. After a period of time, it was taken out from the compartment and cooled rapidly to room temperature by keeping the holder in contact with a metal plate, and then the absorption spectrum of the film was measured. The above-mentioned procedure from heating to absorption measurement was repeated until the maximum absorbance became 2.0.

Absorption spectra were measured on a Shimadzu UV-360 spectrophotometer, and simulation and kinetic calculation were carried out with a micro computer, an NEC model-N6300 system.

Results

Simulation. The solid line in Fig. 1 shows an example of absorption spectra of PVA film heated at 170 °C. The arrows in Fig. 1 indicate positions of 1←0 transition peaks for respective n values which were already assigned to π-π* transitions of polyenes, $-(CH=CH)_n-$, produced along polymer chains.[2]

A simulation for the spectrum was made as follows by combination of absorption spectra of free polyenes corresponding to $-(CH=CH)_n-$ with n=1—13. The absorption spectra of free polyenes[3-7] were shifted in wave number so that the 1←0 transition peaks were in accord with those assigned by the authors.[8] As for the absorption coefficients of polyenes, reported values[9] were used. Figure 2 shows examples of the shifted absorption spectra of $H(CH=CH)_nH$ used for the simulation where n=6 and 13.

In order to determine concentrations of 13 polyenes produced in the heated PVA film, the following 13 simultaneous equations were solved so that calculated absorbances at 13 wavelengths λ_m (m=1—13) agreed with those observed:

$$A_{obsd}(\lambda_m) = \sum_{n=1}^{13} C_n \cdot \varepsilon_n(\lambda_m) \cdot d \quad (\text{for } m=1\text{—}13), \qquad (1)$$

where $A_{obsd}(\lambda_m)$ is the absorbance observed at λ_m, C_n, and $\varepsilon_n(\lambda_m)$ are the concentration and molar absorption coefficient of $-(CH=CH)_n-$ at λ_m, respectively, and d is the film thickness.

The simulated spectrum is shown by the dotted

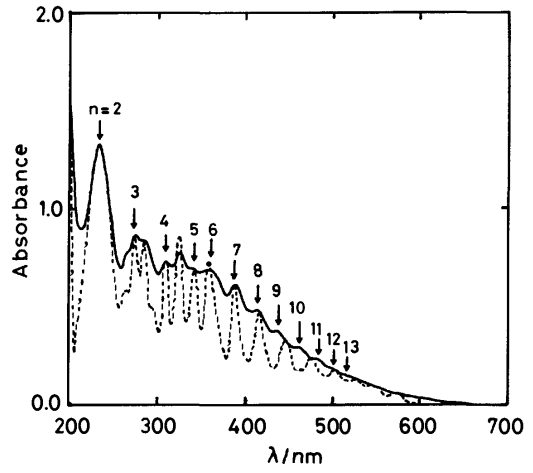

Fig. 1. Absorption spectrum of the heated PVA film (solid line) and that by simulation (dotted line). PVA film was digested in 0.05 M H_3PO_4 solution and heated at 170 °C for 40 min. n indicates conjugation number and arrows indicate 1←0 positions of $-(CH{=}CH)_n-$.

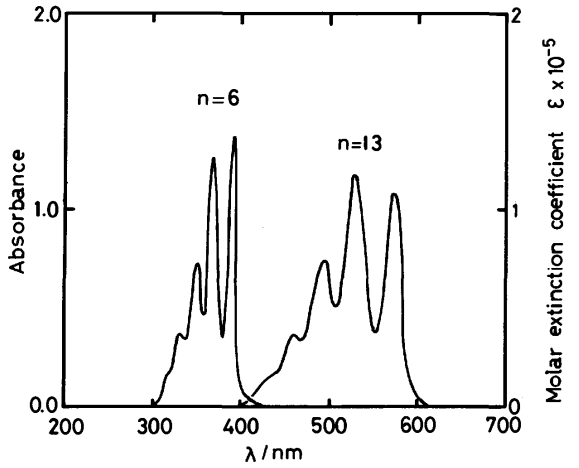

Fig. 2. Shifted absorption spectra of $H(CH{=}CH)_nH$. The concentration of each polyene is 1 mmol dm^{-3} and the film thickness is 100 μm.

line in Fig. 1. It is in good agreement with the observed absorption maxima in the region 200—400 nm.

Strictly speaking, the absorption spectra (solid lines) in Fig. 1 should be a mixture of spectra of polyenes and polyenones. But the concentrations of polyenones were disregarded for the simulation, because the excitation spectra of this sample film indicated that the intensities of polyenones were very low compared to those of polyenes.[2]

The concentrations of polyenes calculated by the present simulation, which are given in Fig. 3, are very low and decrease with increasing conjugation number n.

Kinetics. It has been pointed out that the concentrations of polyenones produced in the heated

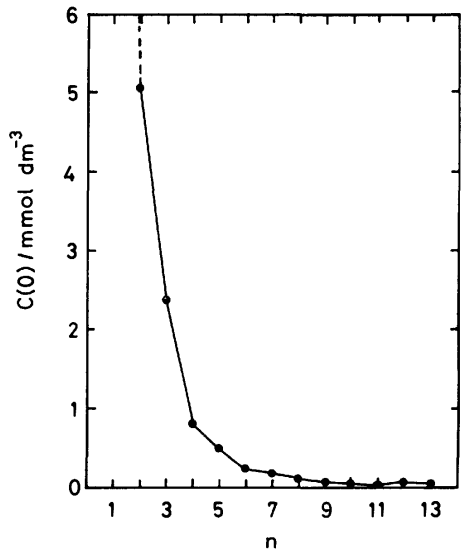

Fig. 3. Concentrations of calculated polyenes produced in the heated PVA film whose absorption spectrum is shown in Fig. 1. The concentration of monoene (n=1) is 2.95×10^{-1} mol dm^{-3}.

PVA film are much lower than that of polyenes when HCl, H_2SO_4, or H_3PO_4 is used as a catalyzer.[2] For such cases, therefore, a kinetic study on the polyenes formation could be made by repeating the heating process and absorption measurement as described in the Experimental section.

Figure 4 shows the change of absorption spectra of a PVA film with heating time at 170 °C. The concentrations of polyenes $-(CH{=}CH)_n-$ were determined from the well fitted simulation curves. The marks in Fig. 5 indicate the concentrations of polyenes thus obtained for n=2—6 against heating time. The concentration of each polyene increases rapidly according as the specimen is heated.

Since the concentrations of polyenes are very low at the initial stage of the heating, it is reasonable to consider that each polyene is formed by a dehydration of the PVA unit adjacent to the polyene as follows:

$$-(CH{=}CH)_{(n-1)}-CH_2CH(OH)- \xrightarrow{k_n} -(CH{=}CH)_n- + H_2O.$$

Accordingly, the concentration of PVA monomer unit $-CH_2CH(OH)-$, $C(0)$, is calculated by

$$C(0) = C(0)_0 - \sum_{n=1}^{13} n\cdot C(n), \qquad (2)$$

where $C(0)_0$ is the initial concentration of PVA unit, which was calculated to be 30.1 mol dm^{-3} from the volume and weight of PVA film before heating, and $C(n)$ is the concentration of $-(CH{=}CH)_n-$. Values of log $C(0)$ at various heating temperatures were plotted against heating time in Fig. 6. The plots give

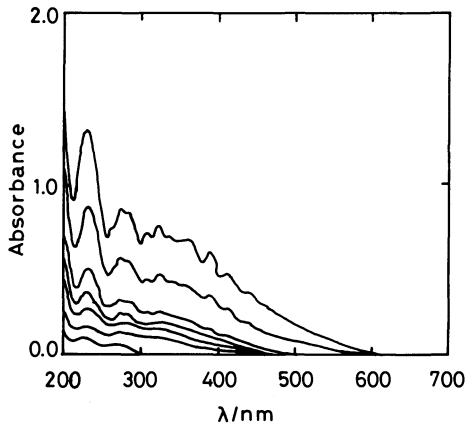

Fig. 4. Absorption spectra of PVA film (106 μm thick) which was digested in 0.05 M H_3PO_4 and heated at 170 °C for 0 (the lowest line), 5, 10, 15, 20, 30, and 40 min (the highest line) respectively.

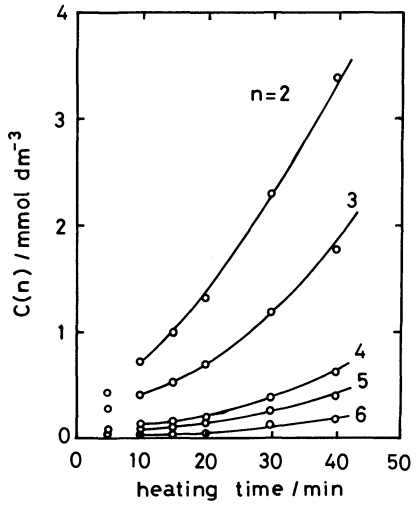

Fig. 5. Comparison of observed concentrations of polyenes (n=2—6) with calculated ones at 170 °C. Marks are experiments, lines are obtained by calculations using the rate constants shown in Table 1 and the concentrations of polyenes at 10 min of heating time as initial condition of the calculation.

straight lines in all cases for 160, 170, 180, and 190 °C. This indicates that the polyene formation is of the first order as a whole.

Assuming that each polyene of $-(CH{=}CH)_n-$ is formed by a first order consecutive reaction, we may handle the following 14 differential equations

$$\left.\begin{aligned} &d[C(0)]/dt = -\sum_{n=1}^{13} k_n[C(n-1)], \\ &d[C(n)]/dt = k_n[C(n-1)] - k_{n+1}[C(n)] \\ &\qquad\qquad (\text{for } n=1—12), \\ &d[C(13)]/dt = k_{13}[C(12)]. \end{aligned}\right\} \quad (3)$$

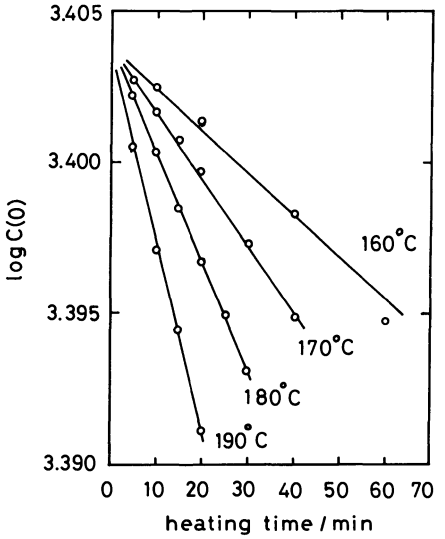

Fig. 6. Relation of log $C(0)$ and heating time at 160, 170, 180, and 190 °C.

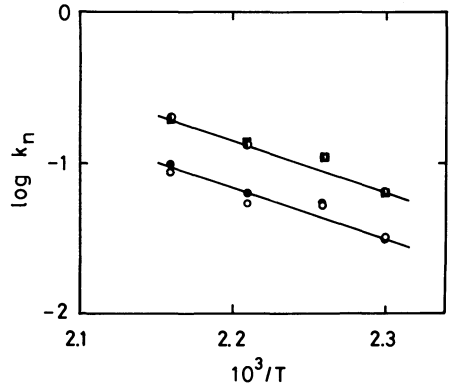

Fig. 7. Arrhenius plots of k_n for PVA film containing H_3PO_4. ○: k_3, ●: k_4, ◐: k_5, ■: k_6.

Such simultaneous differential equations could be solved numerically by the Runge-Kutta method with trial values for rate constants k_1—k_{13}. The most reliable rate constants k_1—k_{13} were determined by making calculated concentrations of polyenes fit experimental ones. The rate constants thus obtained are summarized in Table 1. The calculated curves in Fig. 5, which have been obtained by using the rate constants in Table 1, are in good agreement with the experimental concentrations of polyenes.

Figure 7 shows some of the Arrhenius plots for k_n (n=3—6). They make straight lines for respective rate constants and, therefore, activation energies of the polyenes formation can be calculated. They are summarized in Table 2 together with other activation parameters.

Tables 3 and 4 also shows rate constants k_1—k_{13} and activation parameters determined for the case using H_2SO_4 as a catalyst.

Discussion

Simulation. As shown in Fig. 1, the simulated spectrum reproduces well the experimental one with respect to the number and wavelengths of peaks in the region 200—400 nm. Nevertheless, the simulated spectrum does not agree with the absorption minima. Two reasons for this disagreement are conceivable: One is that the broad bands of polyenones form the foundation of the spectrum although the concentrations of polyenones have been judged to be low from the excitation spectra, and the other is concerned with the matter of valleys of the spectrum, which is considered as the determinant. The valleys of the reported spectra of $H(CH{=}CH)_nH$[5] are deeper than those of $CH_3(CH{=}CH)_nCH_3$.[10] Considering that the polyenes in the PVA film are formed from part of the polymer chains, their spectra should resemble those of substituted polyenes, $CH_3(CH{=}CH)_nCH_3$, rather than $H(CH{=}CH)_nH$. In fact, the excitation spectrum of tetraene produced in the heated PVA film[2] shows shallower absorption minima than the reported spectrum of $H(CH{=}CH)_4H$[5] as shown in Fig. 8. The absorption spectra of $CH_3(CH{=}CH)_nCH_3$, however, could not be used for the present simulation, because the spectrum of each polyene described in the report is part of itself. For that reason, such a spectrum with very deep constrictions as shown in Fig. 2 was obliged to be adopted for all the polyenes under consideration.

In the longer wavelength region over 400 nm, the simulated spectrum does not reproduce the number and wavelengths of absorption peaks. One reason is that the absorption spectrum of octaene has been used for $-(CH{=}CH)_n-$ of n=9—13.

Kinetics. For evaluation of k_n, 30.1 mol dm^{-3} was used as the initial concentration of PVA monomer unit. Taking into consideration the free water remaining in the PVA film before heating, we should assign $C(0)_0$ a smaller value than 30.1 mol

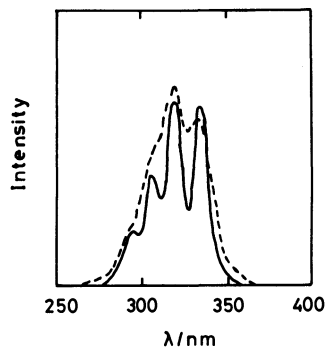

Fig. 8. Shifted absorption spectrum of $H(CH{=}CH)_4H$ (solid line) and the excitation spectrum of heated PVA film monitored at 383 nm (dotted line).

dm^{-3}. Further, the concentration of monoene, $C(1)$, is not so reliable as those for n=2—7, because the intensity of the absorption shoulder at 200 nm was adopted in the simulation instead of that of the absorption maximum of monoene. However, the unreliabilities of $C(0)_0$ and $C(1)$ influence only k_1 and k_2, having no effect on the other constants k_3—k_{13}. Because, for instance, if 25.0 mol dm^{-3} is used for $C(0)_0$ instead of 30.1 mol dm^{-3}, the value of k_1 is changed to 2.492×10^{-4} from 1.326×10^{-4} min^{-1}, but the k_2—k_{13} values are not changed and kept almost the same as shown in Table 1.

The values of k_8—k_{13} also are less reliable for the reason that the concentrations of polyenes for n=8—13 in PVA were calculated without using the absorption data for longer conjugate polyenes than tridecaene. For the same reason, there is a disagreement of the simulated spectrum with the experimental one in the longer wavelength region over 400 nm.

A few kinetic studies have been reported about the degradation of PVA by heating. Yamaguchi et al.[11] investigated the first order rate constant for degradation of PVA by the thermobalance method. According to their report, activation energies for degradation of commercial PVA powder are about 96—230 kJ mol^{-1}, which are affected by the polymerization degree, the degree of oxidation of PVA, and others. Perepelkin and Borodina[12] postulated that the change in transmittance of PVA film was dependent on the decrease in concentration of PVA monomer unit, and determined the activation energy to be 67—176 kJ mol^{-1} for the PVA film containing CH_3COONa and 192—263 kJ mol^{-1} without CH_3COONa. In the present study, as shown in Tables 2 and 4, the activation energies are 53—64 kJ mol^{-3} for the reaction catalyzed by H_3PO_4, and 94—100 kJ mol dm^{-3} for H_2SO_4, which are comparatively low, probably reflecting the effect of catalyzers.

The activation entropies in Tables 2 and 4 are negative, suggesting some sterical restriction operating in the transition state of the polyenes formation. The difference in numerical values of activation energy and entropy between Tables 2 and 4 may be taken to suggest a difference between the roles of H_3PO_4 and H_2SO_4 as catalysts.

8) Since the peak maximum of monoene, -CH=CH-, was not detected in the measured absorption range (190—800 nm) in this study, the spectrum of *trans*-$CH_3(CH=CH)$-CH_3 was used as it was, i. e., without any shifting applied for the simulation. Since both 0←0 and 1←0 transitions of tetraene and pentaene were observed in the experimental spectrum, the experimental spectra of $H(CH=CH)_nH$ (n=4 and 5) were shifted so that both the absorptions of 0←0 and 1←0 agreed with their experimental positions.

9) The molar absorption coefficent of $H(CH=CH)_4H$ was not described in Ref. 6; the molar coefficient of $CH_3(CH=CH)_4CH_3$ given in Ref. 10 was used. Since the molar absorption coefficient of heptaene reported for the 1←0 transition (33000) is so small compared with those of hexaene (127000) and octaene (112000), the average value (119500) for hexaene and pentaene was used as the absorption coefficient of heptaene.

Base-Catalyzed Hydrolysis of Acetylcholine Chloride in the Presence of Cationic and Nonionic Surfactants

Masayuki NAKAGAKI and Shoko YOKOYAMA*
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-shimoadachi-cho, Sakyo-ku, Kyoto 606
(Received July 15, 1985)

The base-catalyzed hydrolysis of acetylcholine chloride (Ach) in the presence of cationic and nonionic surfactants was investigated. The rate of hydrolysis of Ach was determined by following the disappearance of Ach spectrometrically. At a constant pH of 9.0, addition of dodecyltrimethylammonium chloride (DTAC) at concentrations below the critical micelle concentration results in a large decrease in the apparent rate constant for the hydrolysis of Ach, k_{app}. The plot of k_{app} against the concentration ratio of DTAC to Ach ($C_{DTAC}/[D]_0$) gives a break point at $C_{DTAC}/[D]_0=1$. This is considered to be due to the formation of 1:1 complex between Ach and DTAC. In the presence of heptaoxyethylene dodecyl ether (HED)-DTAC mixed micelles, k_{app} decreases with the mole fraction of DTAC, in contradistinction to the usually presupposed electrostatic effect. This is because Ach molecule penetrates into the micellar phase and is shielded from the attack by OH^- for hydrolysis. The decrease of k_{app} has been successfully interpreted on the basis of the data on the distribution of Ach between the micellar and aqueous phases.

A number of studies[1-7] on the hydrolysis of acetylcholine chloride (Ach) have been carried out, particularly in relation to the effect of pH and temperature, salt effect, and the enthalpy of hydrolysis of Ach. Nogami et al.[8] have revealed the influence of sodium dodecyl sulfate (SDS), a surfactant, on the hydrolysis of Ach. The reaction in the presence of surfactants is also interesting from the viewpoint of micellar catalysis. No kinetic analysis of the hydrolysis in the presence of SDS has, however, been carried out yet.

A kinetic study on the base-catalyzed hydrolysis of Ach in the presence of anionic and nonionic surfactants has been reported in our previous paper,[9] in which the relevant rate constant is explained well by taking into consideration both the distribution of Ach between the aqueous and micellar phases and the electrostatic effect operating on the micelle surface.

In this paper, we report a further kinetic study on the base-catalyzed hydrolysis of Ach in the presence of a cationic surfactant and mixed micelles composed of cationic and nonionic surfactants; this study has been conducted by taking into account both the accurate critical micelle concentration (cmc) of surfactant in the presence of Ach[10] and the distribution of Ach between micellar and bulk phases.[11]

Experimental

Materials. Acetylcholine chloride (Ach) and heptaoxyethylene dodecyl ether (HED) are the same as those used for our previous paper.[9] Dodecyltrimethylammonium chloride (DTAC) obtained from Nakarai Chemicals Co. was purified as previously described.[10,11]

Method of Measurement. The rate of hydrolysis of Ach was obtained as the disappearance rate of Ach at pH 9.0 and 25 °C. The concentration of Ach was determined spectrometrically as previously described.[9,11]

Results

Effect of DTAC Concentration on the Hydrolysis of Ach. The apparent rate constant for the hydrolysis, k_{app}, is defined as

$$k_{app} = \frac{1}{t} \ln \frac{[D]_0}{[D]}, \quad (1)$$

where $[D]_0$ and $[D]$ are the concentrations of Ach at the beginning and at time t, respectively. Plots of $\ln([D]_0/[D])$ vs. t are shown in Fig. 1, where the percent hydrolyzed of Ach is also included on the right side of the ordinate. In all cases, good proportionality is observed. The hydrolysis of Ach in the presence of DTAC can, therefore, be characterized as a first order reaction. The relation between the rate constant evaluated from the slope shown in Fig. 1 and the concentration of DTAC is shown in Fig. 2. In Fig. 2, each curve has a break point and this point

is found to correspond to the cmc of DTAC in the presence of Ach: 14.4, 15.2, and 15.5 mmol dm^{-3} for Ach at 10, 5, and 3 mmol dm^{-3}, respectively.[10] The value of k_{app} decreases largely at the lower concentration region and again above the cmc.

We have carried out the present experiment very carefully. Therefore, the conclusion that the break points actually exist, may be drawn in conjunction with the experimental error (note that the error for the three measurements of hydrolysis rate is within ±1.5%, that for the distribution of Ach between the micellar and aqueous phases[11] being within ±2.0%) and the solubilization into the micelle.

Effect of DTAC-HED Mixed Micelles on the Hydrolysis of Ach. For the case of the presence of DTAC-HED mixed micelle (X_{DTAC}=0.2) with

varying concentration, values of ln ($[D]_0/[D]$) for Ach of $[D]_0$=5 mmol dm^{-3} are plotted in Fig. 3 against t according to Eq. 1.

The values of k_{app} obtained from the plots shown in Fig. 3 are plotted in Fig. 4 against the total concentration of surfactants, C_t. The values of k_{app} in the presence of HED alone[9] and of DTAC alone are shown together in Fig. 4. In the presence of DTAC–HED mixed micelle (X_{DTAC}=0.2), no break point, unlike the case of DTAC alone, can be found because the value of cmc is as low as 0.1 mmol dm^{-3} for this system in the presence of 5 mmol dm^{-3} Ach.

On the other hand, the effect of the composition of DTAC–HED mixed systems at a total concentration of 20 mmol dm^{-3} was also examined. Plots of ln ($[D]_0/[D]$) vs. t are shown in Fig. 5, and the values of k_{app} obtained from Fig. 5 are given in Fig. 6(a). The value of k_{app} decreases with the mole fraction of DTAC.

Discussion

Effect of Concentrations of Ach and DTAC on the Hydrolysis of Ach. It is found from Fig. 2 that k_{app} decreases greatly in the lower concentration region below the cmc and that the inclination becomes the steeper, the lower the concentration of Ach. Therefore, the values of k_{app} are plotted against the concentration ratio of DTAC to Ach, ($C_{DTAC}/[D]_0$), in Fig. 7, and it is found that all the three curves in Fig. 2 give the same curve that has a break point at $C_{DTAC}/[D]_0$=1. This would indicate that Ach is stabilized by the formation of 1:1 complex with DTAC, because the attack of OH^- is suppressed. Furthermore, k_{app} decreases again above the point

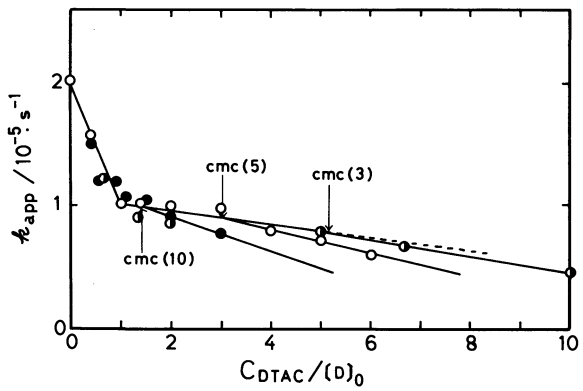

Fig. 7. Relation between k_{app} and concentration ratio of DTAC and Ach ($C_{DTAC}/[D]_0$).
$[D]_0$: ◑ 3, ○ 5, ● 10 mmol dm^{-3}.

corresponding to the cmc. Ach would form a complex with free ions of DTAC, and the complex would be solubilized into the micelle above the cmc.

The decrease of k_{app} above the cmc suggests that the rate of hydrolysis of Ach in the micellar phase is very small. This is considered to be due to the sequence that the acetyl group of Ach enters the palisade layer of the DTAC micelle[11] and is protected from the hydrolysis; hence the base-catalyzed hydrolysis of Ach in the DTAC micellar phase cannot be interpreted in terms of the electrostatic effect in contrast to the case[9] of Ach and sodium dodecyl sulfate.

Effect of DTAC-HED Mixed Micelles on the Hydrolysis of Ach. Ach is distributed between the micellar and bulk phases. The apparent rate constant, k_{app}, for the hydrolysis of Ach is, therefore, written as a sum of two terms

$$k_{app} = k(f) + k(m), \tag{2}$$

where $k(f)$ and $k(m)$ are the rates of hydrolysis in the aqueous and micellar phases, respectively. Equation 2 is rewritten as follows by taking into account the distribution ratio f between the aqueous and micellar phases and the concentrations of OH^-, $[OH^-]_f$, and $[OH^-]_m$:

$$\left.\begin{aligned} &k_{app} = k_{2\,app}[OH^-]_f = k_{2f}f[OH^-]_f + k_{2m}(1-f)[OH^-]_m \\ &\text{or} \\ &k(f) = k_{2f}f[OH^-]_f,\ k(m) = k_{2m}(1-f)[OH^-]_m, \end{aligned}\right\} \tag{3}$$

where $[OH^-]_f$ and $[OH^-]_m$ are the concentrations of hydroxide ion, k_{2f} and k_{2m} are the second order rate constants for the hydrolysis of Ach in the aqueous and micellar phases, respectively, and f is the distribution ratio of Ach in the aqueous phase, that is, $f=[D_f]/[D_t]$ where $[D_t]=[D_f]+[D_m]$ and $[D_f]$ and $[D_m]$ are the concentrations of Ach in the aqueous and micellar phases, respectively. When the total concentration of surfactants, C_t, is lower than the cmc, namely $C_t<$cmc, Eq. 3 reduces to

$$k_{2\,app} = k_{2f} \quad (\text{for } C_t<\text{cmc}), \tag{4}$$

since $f=1$ and $[OH^-]_m=0$.

The apparent rate constants for the hydrolysis of Ach in the presence of DTAC–HED mixed micelles are represented by the solid line in Fig. 6(a). The distribution ratios[11] of Ach in the aqueous phase, $f=[D_f]/[D_t]$, in the presence of DTAC–HED mixed micelles are given in Fig. 6(b).

If it is postulated that all DTAC molecules form mixed micelles with HED, the value of k_{2f} will be 2.02 $mol^{-1}\,dm^3\,s^{-1}$ as obtained from the result[9] in the absence of surfactant. The values of $k(f)=k_{2f}f[OH^-]_f$ are calculated and represented by the dotted line in Fig. 6(a), which indicates that the apparent rate of hydrolysis is nearly equal to the rate in the aqueous phase, implying that Ach in the micellar phase is not hydrolyzed with significant rate, i.e., $k_{2m}\approx 0$. This means that Ach molecules are bound so tightly to DTAC micelle[11] as to be prevented from hydrolysis. These are consistent with the result[11] that the binding constant for Ach to DTAC–HED mixed micelles increases, whereas f decreases with the mole fraction of DTAC in opposition to the expectation on the basis of the electrostatic repulsion between Ach cation and the mixed micelle caused to be charged positive by DTAC.

The small value of k_{app} in the presence of DTAC alone is due to both the existence of free DTAC and the occurrence of the interaction between Ach and DTAC in the aqueous phase.

The decrease of k_{app} with the mole fraction of DTAC is considered to be due to the decrease of f shown in Fig. 6(b). The deviation of the experimental result from the dotted line is considered to be due mainly to the existence of a small quantity of free DTAC in the aqueous phase. If the percentage of free DTAC to total added DTAC for the formation of mixed micelle is 5% at $X_{DTAC}=0.8$, the value of k_{app} is expected to be $1.424\times10^{-5}\ s^{-1}$ from the relationship between the rate constant and the concentrations of Ach and DTAC shown in Fig. 7, and the value thus obtained is consistent well with the experimental value; namely, when $(C_{DTAC}/[D]_0)\leqq 1$, the relation between k_{app} and $(C_{DTAC}/[D_f])$ is written as

$$k_{app} = k^0_{app} - 0.5\,k^0_{app}\frac{C_{DTAC}}{[D_f]} \quad \left(\text{for } \frac{C_{DTAC}}{[D_f]}\leqq 1\right), \tag{5}$$

because the value of k_{app} at $(C_{DTAC}/[D_f])=1$ is equal to $(1/2)k^0_{app}$ and the decrease of k_{app} is proportional to $(C_{DTAC}/[D_f])$ as can be seen in Fig. 7, where k^0_{app} is the value of k_{app} in the absence of free surfactant. By substituting $C_{DTAC}=20\times0.8\times0.05=0.8$ (mmol dm^{-3}), $[D_f]=5\times0.785=3.925$ (mmol dm^{-3}), and $k^0_{app}=k^0(f)=2.02\times10^{-5}\times0.785=1.586\times10^{-5}$ (s^{-1}), the value of k_{app} is obtained as $1.424\times10^{-5}\ s^{-1}$.

We have reported[12] that all sodium dodecyl sulfate molecules will form mixed micelles with HED. Although we have not studied the DTAC–HED system, it is reported[13] that the formation of mixed micelle with cationic surfactant is harder than that with anionic surfactant. Therefore, the presence of a small quantity of free DTAC is reasonable.

Finally, the values of $k(f)(=k_{2f}f[OH^-]_f)$ for the region above the cmc given by the dotted lines in Fig. 2(a) have been calculated by using the values of k_{2app} at the cmc as the values of k_{2f}. The dotted lines indicate that the apparent rate of hydrolysis decreases with decreasing value of f. This suggests that the complex formed between Ach and DTAC is solubilized into the micelle above the cmc. The existence of break point in Fig. 2(a) is, therefore, confirmed.

Conclusion

The apparent rate constant, k_{app}, for base-catalyzed hydrolysis of Ach is caused to decrease greatly by the presence of DTAC. This is considered to be due to Ach interacting with DTAC in the aqueous phase. In the presence of DTAC–HED mixed micelles, k_{app} decreases with the mole fraction of DTAC. The decrease of k_{app} is considered to be due to the sequence that the rate constant for the hydrolysis in the micellar phase is approximately zero and that the distribution ratio of Ach in the aqueous phase decreases with the mole fraction of DTAC. This

sequence is, in turn, caused by the sequence that the Ach molecule penetrates into the micelle and is shielded from the attack by OH^- for hydrolysis. It is concluded that the base-catalyzed hydrolysis of Ach in the positively charged micelle is not interpreted in terms of the electrostatic effect, in contrast to the acid-catalyzed hydrolysis of Ach in the negatively charged micelle.

Stability Constants and Some Other Properties of the Lanthanoid Nitrate Complexes with Tri-, Tetra-, and Pentaethylene Glycols

Yoshiyuki HIRASHIMA,* Koji KANETSUKI, Ikuo YONEZU, Noriyuki ISOBE, and Jiro SHIOKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565
(Received May 10, 1985)

The lanthanoid nitrate complexes of tri-, tetra-, and pentaethylene glycols (EO3, EO4, and EO5) exhibited anomalous stability trends attributed to structures similar to those of crown complexes. The stability constants of the EO4 and the EO5 complexes decreased with an increase in the atomic number of the lanthanoid in contrast to the lanthanoid complexes with most other ligands. A maximum stability was found at europium for EO3 complexes. The decomposition temperatures of EO3 complexes were higher than those of the corresponding EO4 and EO5 complexes. The yields of the solid complexes in reactions of the lanthanoids with EO5 decreased with an increase in the atomic number of the lanthanoid (with some exceptions). The separation factors observed for fractional precipitation using EO5 as the separating reagents were comparable to those reported regarding reagents practically used for lanthanoid separation.

Macrocyclic polyethers, so-called crown ethers and so on, have received increasing attention in recent years because of their specific interaction with several cations. Relatively few reports[1-5] are concerned with the interaction of noncyclic polyethers with cations. The lanthanoid complexes of polyethylene glycols and glymes have been synthesized by the present authors.[6-8] The mutual separation of lanthanoids by fractional precipitation using tetraethylene glycol has also been reported.[9] According to structure analyses,[10-12] polyethylene glycols in lanthanoid complexes form ring-like structures similar to those of crown compounds, and the mode of coordination of a nitrate ion varies with a change in the number of oxygen atoms in the polyethylene glycols.

It would be interesting to investigate the stability of lanthanoid nitrate complexes with polyethylene glycols since the selectivities of the glycols are expected to be unique, as those of the crown compounds.[13-15] This is due to a similar structure. This paper reports on the stability constants and some other properties of lanthanoid complexes with tri-, tetra-, and pentaethylene glycols.

Experimental

Materials. The lanthanoid nitrates and their complexes were prepared by the method described in a previous report.[8] The composition of the complexes used in this investigation was $Ln(NO_3)_3 \cdot HO(CH_2CH_2O)_nH$ (Ln: lanthanoid element, n=3, 4, or 5). Tri-, tetra-, and pentaethylene glycols were the same as those in the previous paper,[8] and are denoted as EO3, EO4, and EO5, respectively.

Measurements of Decomposition Temperature and Solubility of the Complexes. The decomposition temperatures of the complexes were determined on a Yanagimoto micro melting-point apparatus. The procedure for solubility measurements was as previously described.[8]

Determination of Stability Constants. The EO4 and EO5 Complexes: The stability constants of the EO4 and EO5 complexes were determined by measuring the solubilities of the complexes in ethyl acetate containing different concentrations of EO4 and EO5. The following equilibrium was attained in solutions. The complex partly dissociated into the parent nitrate and EOn (n=4 or 5).

$$Ln(NO_3)_3 \cdot EOn \rightleftharpoons Ln(NO_3)_3 + EOn \quad (1)$$

Therefore, the apparent solubility (S), which was observed directly, is regarded to be the sum of the solubility of the undissociated complex (S_0) and the concentration of $Ln(NO_3)_3$ ([M]) arising from the dissociation, that is $S = S_0 + [M]$. The value of S was varied with a change in the concentration of EO4 or EO5 because [M] is related to the concentration of EOn by Eq. 2 though S_0 is invariant.

$$K = \frac{S_0}{[M] \cdot [EOn]}, \quad (2)$$

where K and [EOn] represent the stability constant and the concentration of EOn, respectively. Equation 2 can be rewritten as Eq. 3 since $[M] = S - S_0$ and $[EOn] = [M] + L$.

$$K = \frac{S_0}{(S-S_0)(S-S_0+L)}, \quad (3)$$

where L is the initial concentration of EOn. Equation 4 is derived from Eq. 3.

$$S^2 + L \cdot S = S_0(2S+L) + (S_0/K - S_0^2) \quad (4)$$

A plot of $(S^2 + L \cdot S)$ against $(2S+L)$ gave values for S_0 and K.

The EO3 Complexes: The stability constants of the EO3 complexes were determined by measurements of apparent molecular weights in solutions, since a determination of stability by measuring the solubility was difficult, owing to the very large solubilities of the complexes. The measurement of the molecular weights were carried out by vapor osmometry. The stability constant was calculated using Eq. 5.

$$K = \frac{\alpha^2 \cdot C_0}{1-\alpha}, \quad (5)$$

where α and C_0 represent the degree of dissociation and the formal concentration of the complex dissolved in acetone, respectively. The value of α was calculated from the

observed molecular weight (M_o) and the formula weight (FW) of the complex using the equation $\alpha=(FW/M_o)-1$.

The stability constants of the EO3 complexes of some lanthanoids (La, Eu, and Lu) and yttrium were also determined by measurements of the proton NMR spectra of acetone-d_6 solutions. The signals of the oxyethylene protons of EO3 shifted upon complexing with metals. The relation between the dissociation degree of the complex (α) and the shift is expressed in Eq. 6.

$$\Delta a = (1-\alpha)\cdot\Delta A, \quad (6)$$

where Δa is the magnitude of the actually observed shift and ΔA is a value to be observed when all of the EO3 is complexed. A combination of Eq. 6 with Eq. 5 gives Eq. 7.

$$\Delta a = \Delta A - \sqrt{\Delta A/K}\cdot\sqrt{\Delta a/C_0} \quad (7)$$

A plot of Δa against $\sqrt{\Delta a/C_0}$ gave values for K and ΔA. The stability constants obtained by NMR measurement were roughly in accordance with those obtained by measurements of the molecular weight.

Determination of the Yield of the Solid Complexes. Ten cm^3 of a 0.05-M ethyl acetate solution of a hydrated lanthanoid nitrate was added to an equal volume of an ethyl acetate solution of EO5 in a 50-cm^3 flask with a glass stopper (1 M=1 mol dm^{-3}). The concentration of the EO5 solution was 0.025, 0.05, or 0.1 M. The water content of the mixed solution was adjusted to the desired value by dehydration or by the addition of water. The flask was shaken for 2 h in a water bath thermostatted at 25.0+0.5 °C. The complex was then deposited immediately after mixing or during the shaking. A solid complex was filtered out with sintered glass. The amounts of lanthanoid in the filtrate and in the solid complex were determined separately by EDTA titration. The yield of the solid complex (Y) was defined as

$$Y = (\mathrm{Ln})_s/((\mathrm{Ln})_s + (\mathrm{Ln})_f),$$

where $(\mathrm{Ln})_s$ and $(\mathrm{Ln})_f$ are the amounts of lanthanoid in the solid complex and filtrate, respectively.

Determination of the Separation Factor. The procedure for the determination of the separation factor was nearly the same as that for the determination of the yield, except the former treated the two-lanthanoid systems, which contained two different lanthanoids. The initial concentrations of individual lanthanoids and EO5 were all 0.0125 M. The separation factor between two lanthanoids (Ln1 and Ln2), $S_{Ln1,Ln2}$ is defined as follows:

$$S_{Ln1,Ln2} = \left(\frac{Ln\,1}{Ln\,2}\right)_s \Big/ \left(\frac{Ln\,1}{Ln\,2}\right)_f, \quad (8)$$

where (Ln1/Ln2) is the molar ratio of the two lanthanoids in the solid complex or filtrate. The amounts of individual lanthanoids in each phase were determined by absorption spectrophotometry, fluorescent X-ray analysis, or atomic absorption analysis.

Results and Discussion

Stability Constants of the Complexes. Figure 1 indicates that the stability constants of the EO4 and the EO5 complexes decreased with increasing atomic

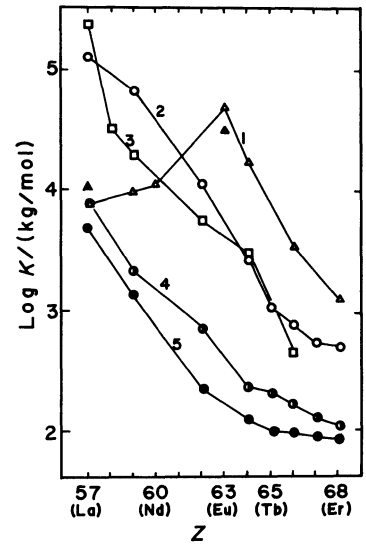

Fig. 1. Stability constants (K) of the lanthanoid nitrate complexes with EO3, EO4, and EO5.

number of the lanthanoid and that those of the EO3 complexes exhibited a maximum at europium. The stability trends are considerably different from those of lanthanoid complexes, most other ligands showing higher stabilities for the heavier lanthanoids. Similar trends have been reported for complexes of crown compounds by Izatt et al.[13] and Massaux et al.[14,15] The stabilities of most other lanthanoid complexes depend mainly on the charge density of the lanthanoid ion, and accordingly increase with a decrease in the ionic radius. On the other hand, the specific selectivities of crown compounds for several cations have been explained on the basis of the concept of the fitness between the size of the cation and the cavity of the crown ether. The unique stability trends observed here are also considered to be attributed to the ring-like structures formed by the ligands.[10-12] The diameter of the cavity of the ring-like structure in an EO4 or EO5 complex was estimated to be about 270 pm by assuming that the conformation for C-C-O-C-C in the glycol is G-T-T-G (G: gauche, T: trans), which was reported to be the most stable one for poly(oxyethylene) derivatives in the metal complexes.[16] The cavity size is larger than the diameter of a La^{3+} ion (ca. 250 pm) which is the largest among the lanthanoid ions; correspondingly, the EOn chain in a lanthanoid complex is deformed from an ideal structure and is strained to maintain the Ln–O distance at a length suitable for coordination. The decrease in the ionic radius of the

lanthanoid increases the strain in the EO*n* chain and, hence, reduces the stability of the complex.

Triethylene glycol (EO3) in the complex surrounds only half of the lanthanoid ion and forms a ring-like structure with a bidentate nitrate. In addition, the distance between the two coordinating oxygens of the nitrate is rather short compared with those between the adjacent oxygens of EO*n*'s in the complexes. These situations make it possible for the coordinating oxygen atoms in the EO3 complexes to be located closer to the central metal ions without significant repulsion among the oxygen atoms or a serious strain in the glycol chain, than those in the EO4 or EO5 complexes. The contribution of the effect of charge density is, therefore, relatively large in the EO3 complexes as in the lanthanoid complexes with most other ligands. This is especially true for those of the lighter lanthanoids, while the effect of the strain in the EO3 chain becomes significant for complexes of heavier lanthanoids. The former effect increases and the latter decreases the stability with a decrease in the ionic radius of the lanthanoid. A maximum stability at europium is considered to result from a balancing of the above opposing effects.

The above results suggest that other noncyclic compounds, which would form ring-like structures in the complexes, could also exhibit specific selectivities for lanthanoids. The stability trends of the EO*n* complexes are different from those of many other lanthanoid complexes and demonstrate that the polyethylene glycols can be useful for lanthanoid separation, especially in a combined use with other separating reagents.

Figure 1 also demonstrates that the stability constants of the EO4 complexes decrease with an increase in the water concentration in a solution (curves 2, 4, and 5). A similar stability drop was also observed for EO3 and EO5 complexes, though only a qualitative investigation was carried out for a few of the complexes. The decrease in the stability is attributed to a competitive coordination of the water and the glycol to the lanthanoid, and necessitates the dehydration of the solution for a syntheses of some of the complexes.

Decomposition Temperature. All the complexes were decomposed to evolve gas (explosively) and to be blackened upon heating. As shown in Fig. 2, the decomposition temperature, T_d, of an EO3 complex is higher than those of the corresponding EO4 and EO5 complexes. This temperature became lower with an increase in the atomic number of the lanthanoid, except for lanthanum and praseodymium. The T_d of the EO4 complex became lower with an increasing atomic number of the lanthanoid from lanthanum to dysprosium (Z=66). It remained nearly constant for elements between dysprosium and lutetium. On the other hand, the T_d of the EO5

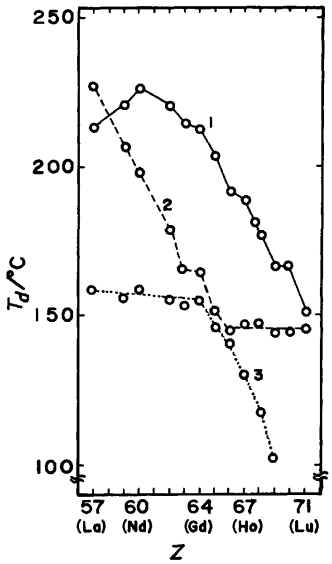

Fig. 2. Decomposition temperatures (T_d) of the lanthanoid nitrate complexes with EO3, EO4, and EO5. 1: EO3 complex, 2: EO4 complex, 3: EO5 complex. Z: atomic number.

complex between lanthanum and gadolinium is nearly constant, and it lowers from gadolinium complex to the heavier lanthanoid complexes. The difference in the decomposition trends of EO4 and EO5 complexes between the lighter and heavier lanthanoids is probably related to different crystal structures. This was previously suggested by a powder X-ray analysis.[8]

Fractional Precipitation. The use of tetraethylene glycol (EO4) in the fractional precipitation of lanthanoids was reported by the present authors.[9] From data regarding the solubilities and stability constants of the complexes, pentaethylene glycol (EO5) was also expected to be useful for the separation of lanthanoids. Figure 3 shows the yields of the solid complexes in a reaction of lanthanoid nitrates with EO5. The yield generally decreased with an increase in the atomic number of the lanthanoid, with a few exceptions, and increased with an increasing initial molar ratio of EO5 to the lanthanoid (EO5/Ln). When the molar ratio was two or unity the yields were nearly the same. They were higher than 95% for elements between lanthanum and gadolinium ((EO5/Ln)=2) or for elements from lanthanum to neodymium ((EO5/Ln)=1). When the molar ratio was 1/2, the yield for cerium, praseodymium, neodymium, and samarium was higher than 50% (ca. 60%), though the yield was not expected to exceed 50% assuming that only a 1:1 complex was deposited. The actual Ln/EO5 ratios in the solid complexes of these elements were larger than 1.0. It was in accordance with the report[8] that the ratio in the solid complex was larger than unity unless EO5

was always in excess. The yield for lanthanum was lower than 50% in contrast to those for the other elements (Ce–Sm). The unique behavior of the lanthanum complex is attributed to the fact that only the 1:1 complex is deposited for lanthanum even when the nitrate is in excess.

The yields decreased for all the lanthanoids with an increase in the water content of the solution, as is shown in Fig. 4. The effect of water was greater for lanthanoid with a higher atomic number; and therefore, the difference in the yield among individual lanthanoids was enhanced by the addition of water. The yield was higher than 90% for elements from lanthanum to holmium in an anhydrous system, and ranged from 97.8% (for lanthanum) to 0.6% (for holmium) in a system containing 0.125 M H_2O. In a system of 0.5-M water content, the yield became 0% for europium and heavier lanthanoids, but was still higher than 80% for lanthanum, cerium, and praseodymium.

The above variation in the yield is consistent with the solubility data regarding complexes previously reported,[8] since the larger solubility of the complex results in the lower yield. The solubility generally decreases with an increase in the atomic number of the lanthanoid and with an increase in the water content of the solution. The anomalous behavior at cerium or the lower yield of the cerium complex (compared with the yield of praseodymium complex) reflects the larger solubility of the cerium complex. The yields shown in Fig. 4 are lower than those estimated from the solubility data assuming that equilibrium is attained. The lower yields are attributed to the fact that the equilibria are not entirely reached within two hours because the yields increased when they were determined after three days or longer.

The difference in the yield among individual

EDTA[c]	10.81	2.0	3.1	1.4	1.02	4.8	2.25	3.6	1.8
D2EHPA[d]	6.72	1.7	5.0	2.2	1.6	3.2	2.0	2.1	2.1

a) Anhydrous system. b) System containing 0.0625 M H_2O. c) The values for EDTA were estimated from the stability constants of the complexes.[17] d) The values for D2EHPA were estimated from the distribution ratios.[18]

elements suggests the possibility of lanthanoid separation by fractional precipitation with EO5. The separation factors, $S_{Ln1,Ln2}$, were determined for several two-lanthanoid systems to evaluate the ability of EO5 for the separation of lanthanoids. Table 1 lists the separation factors obtained in this study, together with those reported for systems using EO4,[9] ethylenediaminetetraacetic acid (EDTA)[17] and bis(2-ethylhexyl) hydrogenphosphate (D2EHPA).[18] The value of $S_{Ln1,Ln2}$ were larger than unity except for the La-Pr, reflecting the trend of the yields that they were generally higher for lighter elements. The apparently anomalous value for a La-Pr pair is also reasonable considering that the yield of the lanthanum complex was lower than that of the praseodymium complex when EO5/Ln was 1/2. The separation factors observed for the systems containing water were higher than those for the anhydrous systems with two exceptions (La-Pr and Pr-Nd). The increase of the separation factors upon the addition of water is attributed to an enhancement of a difference in the yield among the individual elements described above. The separation factors obtained here were, like those for EO4, comparable to those for EDTA and D2EHPA which are the excellent reagents practically used for the separation of lanthanoids in ion-exchange and solvent-extraction processes, respectively. These results demonstrate that EO5 has an excellent separating ability.

The results also show that EO4 and EO5 are good precipitants for lanthanoid separation, though the loss of the solvent would be a serious problem regarding practical applications. A fractional precipitation may be favorable in some cases (for example, in the separation into two groups), since the procedure is simple and no special apparatus is required, though nowadays it is not popular because of the difficult procedures during multi-stage operation.

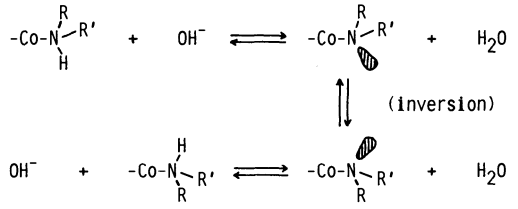
Metal Complexes of Amino Acids. XV. Racemization and Deuteration of Bis(biguanide)sarcosinatocobalt(III) Complex

Hiroshi KAWAGUCHI,* Mizuki MATSUKI, Tomoharu AMA, and Takaji YASUI
Department of Chemistry, Faculty of Science, Kochi University,
Akebono-cho, Kochi 780
(Received June 11, 1985)

All four possible optical isomers ($\Delta(S)$, $\Delta(R)$, $\Lambda(S)$, and $\Lambda(R)$) of the bis(biguanide)sarcosinatocobalt(III) ion, $[Co(sar)(Hbg)_2]^{2+}$, were isolated and characterized by their absorption, CD, and ^1H NMR spectra. The optically active $[Co(sar)(Hbg)_2]^{2+}$ ion in a basic aqueous solution showed a loss of CD intensity due to racemizations at both the chiral cobalt center ($\Delta \rightleftarrows \Lambda$) and the asymmetric nitrogen center ($R \rightleftarrows S$). The rate of an $R \rightleftarrows S$ change was ca. 50 times slower than that of a $\Delta \rightleftarrows \Lambda$ change. The rate of deuteration (H→D) at the asymmetric nitrogen atom was slower than those of other sarcosinato complexes. The ratio k_{H-D}/k_{inv} was about 10^2—10^3. The rates of racemization ($\Delta \rightleftarrows \Lambda$) for the $[Co(amino\ acidato)(Hbg)_2]^{2+}$ ion series increased in the order L-valine<L-alanine<glycine<sarcosine.

The tris(biguanide)cobalt(III) ion, $[Co(Hbg)_3]^{3+}$ [where biguanide (imidodicarbonimidic diamide) has the chemical formula $NH_2C(=NH)NH-C(=NH)NH_2$], is more reactive compared with $[Co(N)_6]$ type complexes containing amino and/or imino nitrogens as donor atoms, such as $[Co(en)_3]^{3+}$.[1] The racemization of an optically active $[Co(Hbg)_3]^{3+}$ complex was investigated in an aqueous solution and a twist mechanism has been proposed on the basis of the fact that the value of the probability factor was very small from the point of view of a unimolecular type change.[2] However, another type study was conducted for *fac*-$[Co(Ph-Hbg)_3]^{3+}$, where Ph-Hbg is $C_6H_5-NHC(=NH)NH-C(=NH)NH_2$, in which a bond-rupture mechanism was proposed regarding the intramolecular racemization process.[3] Previously, we found that optically active $[Co(am)(Hbg)_2]^{2+}$ complexes (am denotes amino acidate anion) racemize more rapidly compared to $[Co(Hbg)_3]^{3+}$ and $[Co(am)_3]$ complexes.[4,5] $[Co(am)(Hbg)_2]^{2+}$ complexes are of interest from the point of view of the reaction mechanism.

On the other hand, the kinetics of racemization and deuteration at an asymmetric nitrogen in an aqueous solution have been studied for several cobalt(III) complexes containing sarcosine (Hsar)[6,7] or *N*-methylethylenediamine (Me-en).[8] For these complexes, deuteration rates were several orders of magnitude faster than racemization rates, and both reaction processes could be described by a similar rate law, $R=k[OH^-][complex]$. A mechanism which has been proposed by Buckingham and Sargeson to account for these results is shown in Scheme 1.[8] The reactivities (proton exchange and inversion) at secondary nitrogen centers in *mer*-$[Co(dien)_2]^{3+}$ [9] and $[CoX(trenen)]^{n+}$ [10] complexes were also studied and are discussed in connection with racemization and deuteration at the nitrogen centers of the complexes described above.



Scheme 1.

$[Co(sar)(Hbg)_2]^{2+}$ ion provides four possible optically active isomers ($\Delta(R)$, $\Lambda(R)$, $\Delta(S)$, and $\Lambda(S)$) arising from two chiral centers (cobalt and sarcosinate nitrogen). In this paper we describe the isolation of the four isomers, the kinetics of racemization at these two chiral centers, and the kinetics of deuteration at the nitrogen centers of coordinated sarcosinates. In addition, we also report on rate data regarding racemization for $[Co(am)(Hbg)_2]^{2+}$ complexes, where am is glycinate, L-alaninate, and L-valinate anions.

Experimental

Preparation, Separation, and Optical Resolution. Bis(biguanide)sarcosinatocobalt(III) Chloride: An isomeric mixture of bis(biguanide)sarcosinatocobalt(III) perchlorate was prepared according to the method described in a previous paper.[4]

About six grams of $[Co(sar)(Hbg)_2](ClO_4)_2$ was dissolved in warm water (ca. 50 cm^3). The solution was poured into a SP-Sephadex C-25 column (4.7 cm×90 cm, Ba^{2+} form) and the adsorbed band was developed with a 0.2 M (M=mol dm^{-3}) $BaCl_2$ solution. Developing was repeated on the same column using a micropump until the adsorbed band completely separated into two bands (E-1 and E-2 in the order of effluence). Each eluting solution from the two bands was concentrated to a small volume under reduced pressure at 35—40 °C. Then, methanol was added to the concentrated solution and deposited barium chloride was filtered off. The filtrate was again evaporated and the remaining $BaCl_2$ was eliminated by the addition of methanol to the concentrated solution by the same procedure as described above. Finally, the methanolic solution was evaporated almost to dryness and the complex was extracted with hot methanol. A crude complex,

obtained by evaporating the extracted solution to dryness, was recrystallized from a small amount of water after adding a mixture of methanol-ethanol (1:3). The deposited crystals were filtered and washed with a mixture of methanol-ethanol (1:3) containing a little water and then with ethanol. The crystals were dried in air.

$(-)^{CD}_{480}$-$\Lambda(S)$- and $(+)^{CD}_{480}$-$\Lambda(R)$-[Co(sar)(Hbg)$_2$]Br$_2$·C$_2$H$_5$OH·H$_2$O: A solution containing 5.0 g (0.0075 mol) of K_2Sb_2(d-tart)$_2$·3H$_2$O in ca. 150 cm^3 of warm water was slowly added to an aqueous solution containing 6.3 g (0.015 mol) of the E-1 racemate, $\Lambda(S)\Lambda(R)$-[Co(sar)(Hbg)$_2$]Cl$_2$, in ca. 150 cm^3 of water without scratching the side of the vessel. The mixed solution was kept in a refrigerator for 1—2 h. The diastereomer (sparingly soluble in water) became deposited in red needle-like crystals and was filtered and washed with ice-water until the color of the filtrate turned almost colorless. They were then dried in air. The yield was 6.1 g.

The diastereomer (powdered in a mortar) was suspended in ca. 150 cm^3 of warm water together with a Dowex 1-X8 resin (Br^- form, 150 cm^3 in wet). The mixture was stirred vigorously until the color of the solution changed to red, and then filtered. The same procedure was repeated several times until the diastereomer completely disappeared. All of the red solutions were combined and concentrated using a rotary evaporator. Methanol, ethanol, and a few drops of concentrated NaBr solution were added to this concentrated solution. Red needle-like crystals were filtered, washed with 80% ethanol, and dried under reduced pressure. The crystals were recrystallized from a little warm water upon adding a few drops of concentrated NaBr solution, methanol, and ethanol (in this order). The yield was 2.7 g. Found: C, 18.52; H, 4.91; N, 27.02%. Calcd for $CoC_9H_{28}N_{11}O_4Br_2$=$(-)^{CD}_{480}$-$\Lambda(S)$-[Co(sar)(Hbg)$_2$]Br$_2$·C$_2$H$_5$OH·H$_2$O: C, 18.86; H, 4.92; N, 26.88%. $\Delta\varepsilon_{560}$=+3.275, $\Delta\varepsilon_{480}$=−5.349.

The $(+)^{CD}_{480}$-$\Lambda(R)$ isomer was obtained as follows. The filtrate obtained upon a separation of the above diastereomer was evaporated under reduced pressure at 35—40 °C. A large amount of methanol was added to the concentrated solution. Deposited potassium chloride was filtered off and the filtrate was again evaporated to dryness. The obtained crude complex was dissolved in water, and then the chloride salt was converted to a bromide salt using a short column containing a Dowex 1-X8 resin (Br^- form). After a concentration of the bromide solution, a crude complex was obtained upon the addition of methanol and ethanol to the concentrated solution. Recrystallization was carried out by the same method as that for the $(-)^{CD}_{480}$-$\Lambda(S)$ isomer. The yield was 1.6 g. $(+)^{CD}_{480}$-$\Lambda(R)$-[Co(sar)(Hbg)$_2$]Br$_2$·C$_2$H$_5$OH·H$_2$O. $\Delta\varepsilon_{560}$=−3.350, $\Delta\varepsilon_{480}$=+5.405.

$(-)^{CD}_{485}$-$\Lambda(R)$- and $(+)^{CD}_{485}$-$\Lambda(S)$-[Co(sar)(Hbg)$_2$]Br$_2$·H$_2$O: The optical resolution of the E-2 racemate ($\Lambda(R)\Lambda(S)$-[Co(sar)(Hbg)$_2$]Cl$_2$) was made by the same method used for the E-1 isomer. The $(-)^{CD}_{485}$-$\Lambda(R)$ isomer was obtained from the less soluble diastereomer. Found: C, 15.97; H, 4.32; N, 29.27%. Calcd for $CoC_7H_{22}N_{11}O_3Br_2$=[Co(sar)(Hbg)$_2$]Br$_2$·H$_2$O: C, 15.95; H, 4.21; N, 29.23%. $\Delta\varepsilon_{563}$=+2.851, $\Delta\varepsilon_{485}$=−5.754. For the $(+)^{CD}_{485}$-$\Lambda(S)$ isomer, $\Delta\varepsilon_{563}$=−2.932, $\Delta\varepsilon_{485}$=+5.814.

Other complexes examined here were prepared and resolved according to a method described in the literature[4] and were found to be analytically pure. $(-)^{CD}_{478}$-[Co(gly)(Hbg)$_2$]Br$_2$·1.5H$_2$O ($\Delta\varepsilon_{478}$=−4.79), $(-)^{CD}_{473}$-[Co(L-ala)(Hbg)$_2$]I$_2$·H$_2$O ($\Delta\varepsilon_{473}$=−4.81), $(+)^{CD}_{475}$-[Co(L-ala)(Hbg)$_2$]Br$_2$ ($\Delta\varepsilon_{475}$=+5.19), $(-)^{CD}_{473}$-[Co(L-val)(Hbg)$_2$]Cl$_2$·1.5H$_2$O ($\Delta\varepsilon_{473}$=−5.67), $(+)^{CD}_{475}$-[Co(L-val)(Hbg)$_2$]Br$_2$·3.5H$_2$O ($\Delta\varepsilon_{475}$=+5.28).

Racemization. All the chemicals used were of a reagent grade, and deionized water was degassed before use. The racemization reactions (at the chiral cobalt center and at the asymmetric nitrogen center) were followed spectrophotometrically with the use of a JASCO J-22 spectropolarimeter. A reaction vessel with a jacket and a water-jacketed cell mounted in a cell holder of the spectropolarimeter were thermostated at a constant temperature (±0.1 °C) with circulating water from a constant-temperature bath. During the experiments, the temperatures of the reaction vessel and the cell were checked with a thermistor thermometer (Takara D-221), and the pH of the reaction solution in the vessel with a Toa TSC-10A pH meter. The reaction was started by adding a buffer solution (5.0 cm^3) with stirring to the complex solution (20.0 cm^3) in the reaction vessel. About 3 cm^3 of this solution was quickly transfered to the cell in order to record the loss of the CD intensity at a suitable wave-length (485 nm for the sarcosinato complex and 475 nm for the glycinato, L-alaninato, and L-valinato complexes). The following conditions were set. For the racemization at the chiral cobalt center; pH 7.5—9.0 (Na_2HPO_4-KH_2PO_4, H_3BO_3-NaCl-$Na_2B_4O_7$, and $NaHCO_3$-Na_2CO_3 buffers), complex concentration (1.2—3.6)×10^{-3} M, ionic strength 0.15—1.0 ($NaClO_4$), temperature 25—35 °C. For the racemization at the asymmetric nitrogen center of the $[Co(sar)(Hbg)_2]^{+2}$ complex; pH 9.0—10.1 ($NaHCO_3$-Na_2CO_3 buffer), complex concentration (2.0—3.0)×10^{-3} M, ionic strength 0.15 ($NaClO_4$), temperature 30—40 °C.

For both of the racemization processes, plots of $\ln[(L_0-L_{eq})/(L_t-L_{eq})]$ vs. time, where L represents CD intensity at the subscripted time, gave straight lines over three half-lives, from which the pseudo-first-order rate constant k' (s^{-1}) were obtained. Analyses of the kinetic data were carried out on an NEC-9801F computer using the least-squares methods. In each of the rate analyses, the value of the standard error was within ±2% of the rate constant.

Deuteration. The deuteration reactions were carried out for both the $\Delta(S)$- and $\Delta(R)$-$[Co(sar)(Hbg)_2]^{2+}$ complexes in D_2O solutions buffered with D_3BO_3-NaCl-$Na_2B_4O_7$, and were followed with a ^{1}H-NMR spectrometer (JEOL MH-100). All the solutions were 0.104 M in complex concentration. The reaction was started by an addition of 1.0 cm^3 of $Na_2B_4O_7$-D_2O(0.0015 M) to the complex solution in 1.0 cm^3 of D_3BO_3(0.2 M)-NaCl(0.045 M)-D_2O in a thermostat at a constant temperature (40, 45, or 50 °C). About 0.5 cm^3 aliquot of the reaction solution was quickly transfered to a NMR tube which was kept in the probe of the spectrometer throughout the run at a constant temperature (40, 45, or 50 °C). The pD of the reaction solution in the vessel was checked using a Toa TSC-10A pH meter. The formulae, pD=pH+0.4[11] and K_{D_2O}=0.195K_w[12], were used to evaluate [OD$^-$].

pH Titration. In order to obtain the pK_a value for the $[Co(am)(Hbg)_2]^{2+}$ complex, the complex solution (1.00×10^{-2} M) was titrated with carbonate-free sodium hydroxide in an atmosphere of nitrogen at 30.0 °C using a

Results and Discussion

Four Isomers of the Bis(biguanide)sarcosinato-cobalt(III) Ion. The $[Co(sar)(Hbg)_2]^{2+}$ ion, which contains a chiral cobalt and an asymmetric nitrogen, gives four possible optical isomers ($\Delta(S)$, $\Delta(R)$, $\Lambda(S)$, and $\Lambda(R)$). Figure 1 shows two of the isomers, $\Delta(S)$ and $\Delta(R)$, that are different from each other only with respect to their configurations about the nitrogen atom. The cobalt-biguanide ring is a six-membered plane with π-electrons[14-16] and the cobalt-sarcosine ring is almost planar (within 6°).[17] The N-CH_3 group of the sarcosinato ligand is different in a chemical environment regarding the $\Delta(S)$ and $\Delta(R)$ configurations. The N-CH_3 group is perpendicular to one of the biguanide planes in the $\Delta(R)$ configuration, but is coplanar to that plane in the $\Delta(S)$ configuration. A similar situation is found for the $\Lambda(R)$ and $\Lambda(S)$ isomers which are antipodes of the $\Delta(S)$ and $\Delta(R)$, respectively.

The ^1H NMR spectra of the E-1 and E-2 racemates (measured in D_2O) are given in Fig. 2. As the deuteration of the NH proton of the sarcosinato ring is slow, even in neutral D_2O, N-CH_3 proton resonance is observed as a doublet signal due to coupling with the NH proton at 2.25 ppm (J=6 Hz) for E-1 and at 2.02 ppm (J=6 Hz) for E-2. The methyl signal of E-2 lies in a higher field than that of E-1. Hence, in E-2 the methyl group should be in a shielding position with respect to one of the biguanide rings with π-electrons; it occupies a position perpendicular to the biguanide plane. This indicates that the E-1 and E-2 racemates can be assigned to $\Delta(S)\Lambda(R)$ and $\Delta(R)\Lambda(S)$, respectively.

The -CH_2- moiety of the sarcosinato ring in E-1 gives a doublet signal centered at 3.48 ppm (J=8 Hz) while coupling with an NH proton. After a deuteration of the NH proton, the doublet signal

changes to a singlet one, indicating that the two protons of $-CH_2-$ are in same magnetic environment. However, the two protons of the $-CH_2-$ moiety in E-2 are in a different environment, and the resulting AB system is further coupled to the proton on the adjacent nitrogen atom to give an eight-line ABX spectrum: H_A=3.61, H_B=3.21 ppm ($J_{H_A-H_B}$=17, J_{NH-H_A}= 7, and J_{NH-H_B}=8 Hz).

The absorption and CD spectra for isomers of the $[Co(sar)(Hbg)_2]^{2+}$ complex are shown in Fig. 3 and their numerical data are listed in Table 1. The E-1 and E-2 racemates, which are diastereomeric to each other, show a slightly different absorption spectra in the first d-d band region. A similar behavior was observed for the diastereomers of the $[Co(sar)(en)_2]^{2+}$ complex.[7] In the first absorption band region, each of the four isomers of $[Co(sar)(Hbg)_2]^{2+}$ shows two CD bands of opposite signs with higher intensity in the higher energy side (Fig. 3). The CD curves of the

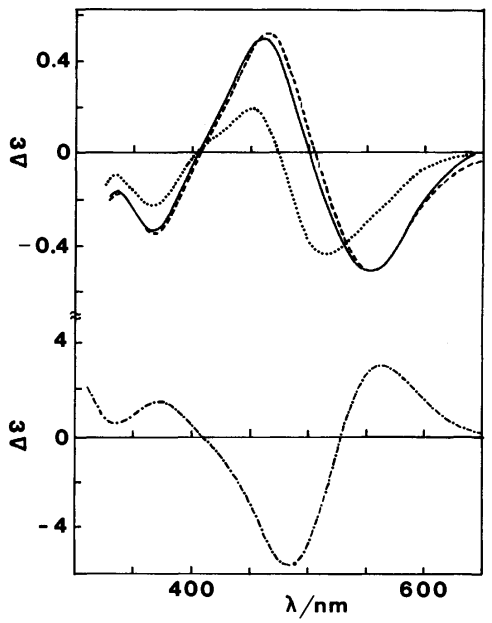

Fig. 4. Configurational and vicinal CD curves of $[Co(sar)(Hbg)_2]^{2+}$: $[\Lambda(R)+\Lambda(S)]/2$ (—·—), $[\Lambda(R)-\Lambda(S)]/2$ (·····). The CD curve of the reaction solution at the pseudo-equilibrium state (——), and the CD curve calculated for the mixture of the $\Lambda(R)$ and $\Delta(R)$ isomers with the $\Lambda(R)/\Delta(R)$ value of 1.22 (----).

$(-)^{CD}_{480}$-E-1 and $(+)^{CD}_{480}$-E-1 isomers are exactly symmetrical to each other, indicating that these isomers are in an enantiomeric relationship. The same relationship is found between the $(-)^{CD}_{485}$-E-2 and $(+)^{CD}_{485}$-E-2 isomers. Previously, the Λ configuration was assigned to $[Co(am)(Hbg)_2]^{2+}$ complexes which exhibited the same CD sign patterns as shown for the $(+)^{CD}_{480}$-E-1 and $(+)^{CD}_{485}$-E-2 isomers in Fig. 3.[4] From the CD and ^1H NMR data, the structures of four isomers of the isolated $[Co(sar)(Hbg)_2]^{2+}$ complex were assigned as follows: $(-)^{CD}_{480}$-E-1, $\Delta(S)$; $(+)^{CD}_{480}$-E-1, $\Lambda(R)$; $(-)^{CD}_{485}$-E-2, $\Delta(R)$; $(+)^{CD}_{485}$-E-2, $\Lambda(S)$.

The $(-)^{CD}_{436}$-$[Co(R\text{-}sar)(NH_3)_4]^{2+}$ ion shows three CD peaks of alternating sign (−, +, −) in the first absorption band region.[6] It is known that the "vicinal" CD curve of the $[Co(sar)(en)_2]^{2+}$ ion is quite similar to the CD curve of the $[Co(sar)(NH_3)_4]^{2+}$ ion.[7] As shown in Fig. 4, the halved difference of the CD curves of the $(-)^{CD}_{485}$-E-2 and $(-)^{CD}_{480}$-E-1 isomers of $[Co(sar)(Hbg)_2]^{2+}$, showing an R-vicinal contribution of asymmetric nitrogen, is similar to the CD spectrum of $[Co(R\text{-}sar)(NH_3)_4]^{2+}$ except for relative peak intensities. This similarity can be taken as additional evidence for our assignment of the absolute configuration of the isomers.

Racemization at the Cobalt Center of $[Co(sar)(Hbg)_2]^{2+}$ Ion. The optically active isomers of the $[Co(am)(Hbg)_2]^{2+}$ ions gradually lost their CD intensities in a weak basic aqueous solution without any change in their absorption spectra.[5] Figure 5 shows the time-course change of the CD intensities at 485 nm when $\Delta(R)$- and $\Lambda(R)$-$[Co(sar)(Hbg)_2]^{2+}$ ions were used as starting materials at pH 8.15 and 35.0 °C. After ca. 80 min, both of the isomers gave a weak residual CD with a positive sign. The loss of the residual CD was very slow under these conditions. However, a CD loss in the second step occurred at a considerable rate in the higher pH region.

A portion of the reaction solution mentioned above was neutralized with 0.1 M HCl at the pseudo-equilibrium state. The neutralized solution gave a CD curve that was slightly different from the vicinal CD (Fig. 4). If the neutralized solution contains only the $\Lambda(R)$ and $\Delta(R)$ isomers, the ratio $\Lambda(R)/\Delta(R)$ at the pseudo-equilibrium state can be calculated from the CD intensities at 485 nm in Figs. 3 and 5. The value

a) Phosphate buffer. b) Calculated from the values of both the pseudo-first-order rate constants (k') and the equilibrium constants ($\Delta(R)/\Lambda(R)$). The values of $\Lambda(R)/\Delta(R)$: 1.18 (run 4), 1.20 (run 5), 1.14 (run 6), 1.22 (other runs). c) Calculated from the data of $k_{\Delta(R)-\Lambda(R)}$ (at 30 °C). μ=0.15 except for the run of 4 and 5.

is estimated to be 1.22. The CD curve calculated for a mixture of the $\Lambda(R)$ and $\Delta(R)$ isomers with a $\Lambda(R)/\Delta(R)$ value of 1.22 coincides exactly with the spectrum of the neutralized reaction solution (Fig. 4). Moreover, in the present sarcosinato complex, both the "configurational effect" (Δ or Λ) and the "vicinal effect" (R or S) contribute to the observed CD spectrum in the d-d band region. Also, the "vicinal effect" makes a relatively small contribution to the observed CD. These considerations show that the large CD loss in the first step can be attributed to a racemization of $\Delta(R)\rightleftarrows\Lambda(R)$ and that the small CD loss in the second step can be attributed to a racemization of $R\rightleftarrows S$.

The progress of the $\Delta(R)\rightleftarrows\Lambda(R)$ change was followed by a loss of the CD intensity at 485 nm. Each of the $\Delta(R)$ and $\Lambda(R)$ isomers was used as a starting material under the same conditions, and the average value of the $[CD]_{eq}$ (CD intensity at the pseudo-equilibrium state) was used for a kinetic analysis. The values of the equilibrium constant ($\Lambda(R)/\Delta(R)$) are invariable within experimental error under conditions of pH 7.5—8.5 and 25—35 °C. The mean value is 1.22±0.03, indicating that the $\Lambda(R)$ isomer is favored. The value of $\Lambda(R)/\Delta(R)$ is reported to be 5.58 for the $[Co(sar)(en)_2]^{2+}$ complex. The stereoselectivity is smaller in the bis(biguanide)-cobalt(III) complex, since a smaller steric interaction might be expected because of the nearly planar biguanide chelate rings.

In Table 2, the rate constants, $k'_{\Delta(R)-\Lambda(R)}$, of the $\Delta(R)\rightarrow\Lambda(R)$ change, which are calculated from values of both the pseudo-first-order rate constants (k') and the equilibrium constants ($\Lambda(R)/\Delta(R)$), are summarized. The values of $k_{\Delta(R)-\Lambda(R)}(=k'_{\Delta(R)-\Lambda(R)}/[OH^-])$ are regarded as essentially constant in the lower pH region (<8.0); however, the values increase with a pH above ca. 8.5. Namely, the rate deviates from a first-order-relationship with $[OH^-]$ in a higher pH region. As the biguanide which is coordinated to a cobalt(III) ion dissociates its proton in a basic aqueous solution,[18] the following equilibrium is established for the $[Co(sar)(Hbg)_2]^{2+}$ ion:

$$[Co(sar)(Hbg)_2]^{2+} \overset{k_{a1}}{\rightleftharpoons} [Co(sar)(Hbg)(bg)]^{+} + H^{+} \overset{k_{a2}}{\rightleftharpoons} [Co(sar)(bg)_2] + 2H^{+} \quad (1)$$

(The pK_a values are listed in Table 3.) Deprotonation equilibrium was established much faster than the racemization equilibria of $\Delta\rightleftarrows\Lambda$ and $R\rightleftarrows S$. Therefore, the "$\Delta(R)\rightleftarrows\Lambda(R)$" change is described by Eq. 2.

$$\begin{bmatrix} \Delta(R)\text{-}[Co(sar)(Hbg)_2]^{2+} \\ +H^{+}\uparrow\downarrow-H^{+} \\ \Delta(R)\text{-}[Co(sar)(Hbg)(bg)]^{+} \\ +H^{+}\uparrow\downarrow-H^{+} \\ \Delta(R)\text{-}[Co(sar)(bg)_2] \\ \Delta(R) \end{bmatrix} \rightleftharpoons \begin{bmatrix} \Lambda(R)\text{-}[Co(sar)(Hbg)_2]^{2+} \\ +H^{+}\uparrow\downarrow-H^{+} \\ \Lambda(R)\text{-}[Co(sar)(Hbg)(bg)]^{+} \\ +H^{+}\uparrow\downarrow-H^{+} \\ \Lambda(R)\text{-}[Co(sar)(bg)_2] \\ \Lambda(R) \end{bmatrix} \quad (2)$$

The deviation of the data from a first-order-relationship with $[OH^-]$ may be explained by a

higher reactivity of the higher order conjugate-base species which are expected to be present in considerable concentration in a higher pH region (>9.0). Similar deviations have been found regarding racemization rates for other (amino acidato)bis-(biguanide) complexes and for $[Co(Hbg)_3]^{3+}$ [19] and $[Co(Ph\text{-}Hbg)_3]^{3+}$ [3] complexes. Hereafter, we only discuss experimental data obtained in a lower pH region where the rate law is described as $R = k_{\Delta(R)-\Lambda(R)}[OH^-][complex]$.

The rate constants of the $\Lambda \rightarrow \Delta$ change for other (amino acidato)bis(biguanide)cobalt(III) complexes are summarized in Table 4. These data were obtained in a pH region where the rates show a first order dependence on $[OH^-]$. The diastereomeric equilibrium constants, $K = \Delta(L)/\Lambda(L)$, of [Co(L-amino acidato)$(Hbg)_2]^{2+}$, which were calculated from CD data in the d-d band region, were essentially constant under the present experimental conditions (25—35 °C, pH <8.5). The constants are 0.803±0.010 and 0.504±0.005 for the L-alaninato and L-valinato complexes, respectively. In Table 2, an increase in

ionic strength from 0.15 to 1.0 caused a decrease in the rates of the $\Delta(R) \rightarrow \Lambda(R)$ change (about 20%). Further, as shown for the case of the $[Co(gly)(Hbg)_2]^{2+}$ complex (Table 4), the rates of the $\Lambda \rightarrow \Delta$ change depend on the type of buffer and the rate decreases in the phosphate buffer. This result may be due to a difference in the formation constant of the ion pair between the complex and each of the buffer anions. It is supposed that the ion pair no longer reacts with OH^- at a rate comparable to that of the original complex. The same results were also obtained for the other complexes studied here.

Ray and Dutt proposed a twist mechanism for the racemization of the $[Co(Hbg)_3]^{3+}$ ion in a neutral aqueous solution on the basis of an abnormally lower probability factor; a large value of $\Delta S^{\ddagger}$ with a negative sign.[2] However, in the $[Co(am)(Hbg)_2]^{2+}$ series the activation entropies, $\Delta S^{\ddagger}$, are positive. The racemization rates for a series of the $[Co(am)(Hbg)_2]^{2+}$ ion increase in the order L-valine<L-alanine<glycine< sarcosine; an alkyl-substitution on the nitrogen atom of glycine increases the rate and an alkyl-substitution on the α-carbon atom decreases the rate. A higher reactivity of the sarcosinato complex is not favorable to the twist mechanism because the transition state of the twist mechanism for the sarcosinato complex is expected to be higher in energy than that for the glycinato complex due to the intramolecular repulsion. One of the possible mechanisms may be a bond-rupture mechanism through the conjugate-base species. However, it is not clear which bond severs, Co–O(sarcosine) or Co–N(biguanide).

Racemization and Deuteration at the Asymmetric Nitrogen Center. The racemization rates at the asymmetric nitrogen center ($R \rightleftarrows S$) in the $[Co(sar)(Hbg)_2]^{2+}$ ion were obtained from the CD loss of the second step at 485 nm. Kinetic data are summarized in Table 5. The constancy of $k_{rac} = k'/[OH^-]$

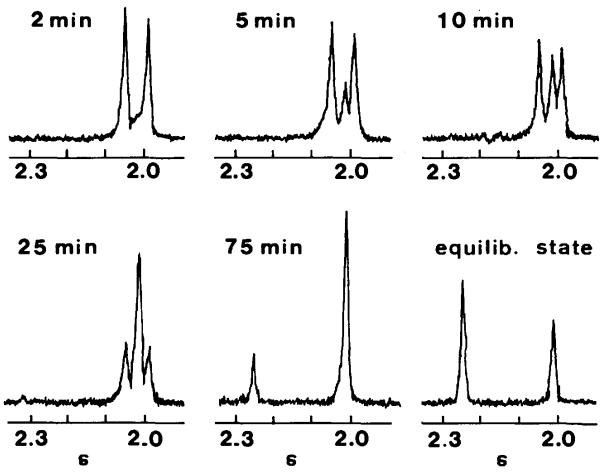

Fig. 6. Deuteration at the sarcosinato-N atom in the $\Delta(R)$-$[Co(sar)(Hbg)_2]^{2+}$ ion as followed by the collapse of the methyl doublet to a singlet (pD=6.98, 39.6 °C). An appearance of the singlet peak at 2.25 ppm is ascribed to the formation of the $\Lambda(R)$ isomer.

in a pH region of 9.0—10.0 (35 °C) indicates that the rate law is given by $R=k_{rac}[OH^-][complex]$. As the values of pK_{a1} and pK_{a2} (deprotonation equilibrium constants) are 8.84 and 10.32, respectively, this result shows that the rate of the $R\rightleftarrows S$ change for each of the species in deprotonation equation (1) is not greatly different. In Table 6, the rate constants for deuteration on the sarcosinato NH proton of $\Delta(S)$- and $\Delta(R)$-$[Co(sar)(Hbg)_2]^{2+}$ are listed. The kinetic data were obtained by following the collapse of the methyl doublet signal to a singlet as the NH proton exchanged with D^+. Part of a typical set of data for the $\Delta(R)$ isomer is shown in Fig. 6. Plots of $\ln[(\text{doublet peak height})_t/(\text{total peak height})]$ vs. time were linear for two half-lives. As the deuteration rates of NH protons observed in other complexes[6-10,20] show a first-order dependence on $[OD^-]$ concentration, the deuteration runs studied here were also analyzed according to the rate law $R=k_{H-D}[OD^-]\times[complex]$. In Table 6, the deuteration rate for the $\Delta(S)$ isomer is about 3 times slower than that for the $\Delta(R)$ isomer. The NH proton of the sarcosinato in the $\Delta(S)$ isomer, which lies in a position perpendicular to one of the biguanide rings, is more effectively hindered with the biguanide ring than in the $\Delta(R)$ isomer. Thus, the kinetic results described above can be interpreted if the rate-determining step is the nucleophilic attack of OD^- on the NH proton. (The rate of deuteration is faster enough than that of the $\Delta\rightleftarrows\Lambda$ change. See Tables 2 and 6.) The small rate constant of the $R\rightleftarrows S$ change compared with that of the deuteration implies that deuteration takes place with a substantial retention of the configuration.

The $[Co(sar)(en)_2]^{2+}$ complex shows no racemization at the cobalt center even in a basic aqueous solution.[7] In the $[Co(sar)(Hbg)_2]^{2+}$ ion, the rate of the $\Delta\rightleftarrows\Lambda$ change is faster than that of the $R\rightleftarrows S$ change. The rates of the $R\rightleftarrows S$ change and deuteration at the nitrogen center are ca. 10^4 and ca. 10^4—10^5 times slower than those for the $[Co(sar)(NH_3)_4]^{2+}$ ion, respectively. However, the ratio of k_{H-D}/k_{inv}, where the k_{H-D} and $k_{inv}(=k_{rac}/2)$ denote the rate constants of the deuteration and inversion at the asymmetric nitrogen center, is ca. 10^2—10^3 for the $[Co(sar)(Hbg)_2]^{2+}$ ion. Although both the rates of the inversion and the H→D change at the nitrogen center for $[Co(sar)(Hbg)_2]^{2+}$ are much slower than those of other sarcosinato complexes, the present kinetic results regarding the asymmetric nitrogen center can be interpreted by a mechanism proposed by Buckingham and Sargeson (Scheme 1).[6-10] Recently, the racemization at the asymmetric nitrogen center of $[Co(Me\text{-}en)(acac)_2]^+$, where the acac ring is also planar structure with π-electrons such as the biguanide ring, has been studied. It was found that the second rate constant is 1.2×10^{-2} M^{-1} s^{-1} for the $\Lambda(R\rightleftarrows S)$ change at 25.1 °C.[21] This value is about 10^4 times smaller than that of $[Co(Me\text{-}en)(NH_3)_4]^{3+}$. These results indicate that the racemization rate at the coordinated asymmetric nitrogen center is extremely affected by the natures of coexisting ligands such as Hbg or $acac^-$, both of which produce a planar chelate ring with π-electrons.

(Received June 20, 1985)

For the measurement of manganese(II)-ion activity, manganese(II) ion-selective electrodes were prepared and tested. As electrodes, heterogeneous membranes were prepared by dispersing sensitive materials, such as manganese sulfide, manganese borate, or manganese dibenzyldithiocarbamate, in silicone rubber, poly(vinyl chloride), or poly(vinyl acetate). A manganese chloride solution (0.1 mol dm^{-3}) was used as the internal reference solution, along with an Ag/AgCl internal reference electrode. The manganese(II) ion-selective electrodes thus made were then examined in terms of their response curves, response times, the effect of the pH, the variation in the response slopes with the temperature, and selectivity coefficients. The response time of the manganese dibenzyldithiocarbamate electrode was within 15 s in the concentration range of 10^{-8}—10^{-1} mol dm^{-3}. The response slope was 33.14 mV/pMn^{2+} in the linear part, and the coefficient of correlation was 0.999. The selectivity coefficients were examined by the separate-solution method.

In recent years, a number of books[1-3] and review articles[4-7] on various aspects of ion-selective electrodes have appeared. In spite of great recent progress in the study of ion-selective electrodes, however, very few manganese(II) ion-selective electrodes have been developed.[8-10] To measure the manganese-ion activity, several manganese(II) ion-selective electrodes have been prepared and tested.

Experimental

Apparatus and Reagents. A digital pH/mV meter, Model PT 3D (Toyo Kagaku Sangyo Co., Ltd.), was used to make the potential measurements (Fig. 1). All the reagents were of an analytical-reagent grade(Wako Pure Chemical Industries). Redistilled water was used in all experiments.

Manganese(II) Ion-Selective Electrode Preparation. Sensitive materials were synthesized as shown below. Manganese sulfide (type α) was formed by the addition of ammonium sulfide to manganese chloride and heated as Eq. 1. Manganese sulfide (type β+γ) was formed by the addition of hydrogen sulfide as in Eq. 2. Manganese hydrogenorthoborate was obtained by the addition of borax to manganese sulfate, while manganese dibenzyldithiocarbamate was obtained by the addition of sodium dibenzyldithiocarbamate to manganese chloride, as in Eqs. 3 and 4 respectively.

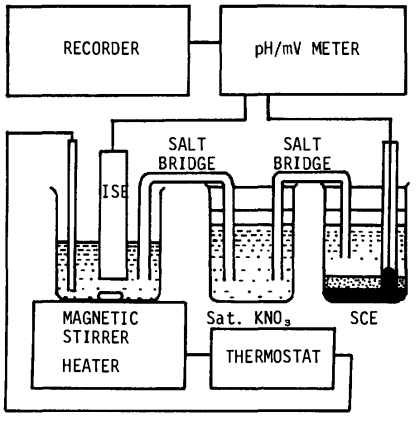

Fig. 1. Apparatus for measurement of potential.

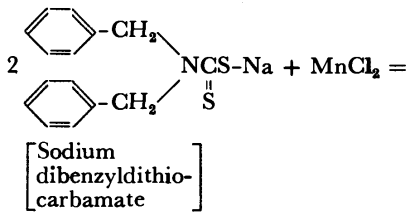
$$(NH_4)_2S + MnCl_2 = MnS \text{ (type } \alpha) + 2NH_4Cl \quad (1)$$

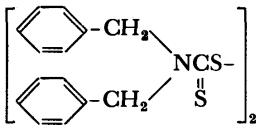
$$H_2S + MnCl_2 = MnS \text{ (type } \beta+\gamma) + 2HCl \quad (2)$$

$$Na_2B_4O_7 + 2MnSO_4 + 5H_2O = 2MnH_4(BO_3)_2 + 2NaHSO_4 \quad (3)$$

(Borax) [Manganese hydrogen-orthoborate]



[Sodium dibenzyldithio-carbamate]



(4)

[Manganese dibenzyldithio-carbamate]

The analytical data on manganese dibenzyldithiocarbmate are shown in Table 1. The analytical data agree reasonably well with the calculated values.

Heterogeneous membranes were prepared with these manganese salts by using, at room temperature, vulcanized silicone rubber (Toshiba RTV silicone rubber), poly(vinyl

Table 1. Ultimate Analysis of Manganese Dibenzyldithiocarbamate

Found	4.54	58.64	4.53	10.41

chloride), or poly(vinyl acetate) as the matrix in a weight ratio of manganese salt to the matrix of 1 to 4. The membranes were left to stand in the air for at least 12 h. Then a suitable section (a circle with a radius of 7 mm) of the membranes was attached to the end of the glass tubing with epoxy-resin-series adhesive. A solution of 0.1 mol dm^{-3} manganese chloride was used as the internal reference solution. Finally the silver-silver chloride electrode was inserted. The manganese(II) ion-selective electrodes were conditioned in a 0.1 mol dm^{-3} manganese chloride solution for 12-h periods and then stored at room temperature in a 0.1 mol dm^{-3} manganese chloride solution. The structure of the manganese(II) ion-selective electrode is shown in Fig. 2.

An electrochemical cell is as follows:

$$\underbrace{\oplus Ag|AgCl,\ Mn^{2+},\ Cl^-|\begin{matrix}\text{Activity}\\\text{Sensitive}\\\text{Material}\end{matrix}}_{\text{Manganese(II) ion-selective electrode}}$$

$$\underbrace{|Mn^{2+},Cl^-|}_{\text{Sample solution}}\underbrace{|K^+,\ Cl^-,\ AgCl|Ag\ominus}_{\text{Reference electrode}}$$

Results and Discussion

Response Curve. The responses of 10 manganese ion-selective electrodes were examined. The manganese-ion activity was calculated by means of the Debye-Hückel limitting equation. Figure 3 shows the response of a manganese(II) ion-selective electrode, with manganese sulfide (type α) as the sensing material. The slope of the E vs. manganese-ion activity was 28.49 mV/decade in the linear part of 10^{-4} to 10^{-1} mol dm^{-3}, and the coefficient of correlation was 0.998. Figure 4 shows the response of a manganese(II) ion-selective electrode with manganese dibenzyldithiocarbamate. The slope of the E vs. manganese-ion activity was 33.14 mV/decade in the linear part of 10^{-6} to 10^{-1} mol dm^{-3}, and the coefficient cf correlation was 0.999.

Response Slope. The response slopes of manganese(II) ion-selective electrodes are summarized in Table 2. The response slopes of manganese sulfide (type α) in silicone rubber, manganese sulfide (type β+γ) in silicone rubber, manganese sulfide (type β+γ)-silver sulfide in poly(vinyl acetate), and manganese dibenzyldithiocarbamate in silicone rubber are close to the Nernstian slope (29.57 mV/decade at 25 °C). With these electrodes, the slopes of E vs. the manganese-ion activity in the linear parts were 28.49 mV/decade, 28.52 mV/decade, 28.85 mV/decade, and 33.14 mV/decade respectively. The lower limits of the linear range were 10^{-4} mol dm^{-3} for the electrode with manganese sulfide (type α) in silicone rubber, manganese sulfide (type β+γ) in silicone rubber, and manganese sulfide (type β+γ)-silver sulfide in poly(vinyl acetate), and 10^{-6} mol dm^{-3} for the electrode with manganese dibenzyldithiocarbamate in silicone rubber.

Response Time. The response times (according to the definition of IUPAC[11]) of the manganese(II) ion-selective electrodes were also considered (Figs. 5 and 6). The response times of the electrodes with manganese sulfide (type α) were within 15 s in

a) Separate-solution method. The selectivity coefficients were calculated from the e.m.f. of a solution containing the manganese(II) ion, at activity 10^{-2} mol dm^{-3}, and a solution containing the interfering ion, at activity 10^{-2} mol dm^{-3}.

the concentration range of 10^{-3}—10^{-1} mol dm^{-3}, 1 min in 10^{-4} mol dm^{-3}, and 2 min in 10^{-5} mol dm^{-3}. The response time of the electrode with manganese dibenzyldithiocarbamate was within 15 s in the concentration range of 10^{-8}—10^{-1} mol dm^{-3}.

Effect of pH. Figure 7 shows the results obtained when the manganese ion was determined with a manganese(II) ion-selective electrode (manganese dibenzyldithiocarbamate) in solutions of various pH values obtained by adding nitric acid or sodium hydroxide. Manganese ions could be determined accurately at pH 2.5—5.5.

The Variation in the Response Slopes with the Temperature. The variation in response slopes with the temperature were also considered (Fig. 8). Over the range of 0—60 °C, the 10^{-2} mol dm^{-3} manganese ion could be determined with the manganese(II) ion-selective electrode [manganese sulfide (type α)]. The experimental value of 0.1095 mV/decade per 1 °C was in good agreement with the calculated value of 0.09922 mV/decade per 1 °C. Similar results were obtained with an electrode with manganese dibenzyldithiocarbamate.

Selectivity Coefficient. The selectivity coefficients of manganese(II) ion-selective electrodes to the several ions, such as the zinc ion, the copper ion, the nickel ion, the chromiun ion, and the lead ion, were examined by means of the separate-solution method (Table 3). The selectivity coefficients were calculated by the separate-solution method from the following relationship:

$$\log K_{MN}=\frac{E_2-E_1}{2.303RT/2F}$$

K_{MN} : Selectivity coefficient
E_1 : Electrode potential in the presence of the M ion
E_2 : Electrode potential in the presence of the N ion
M : Manganese ion
N : Interfering ion
R : Gas constant
T : Absolute temperature
F : Faraday's constant

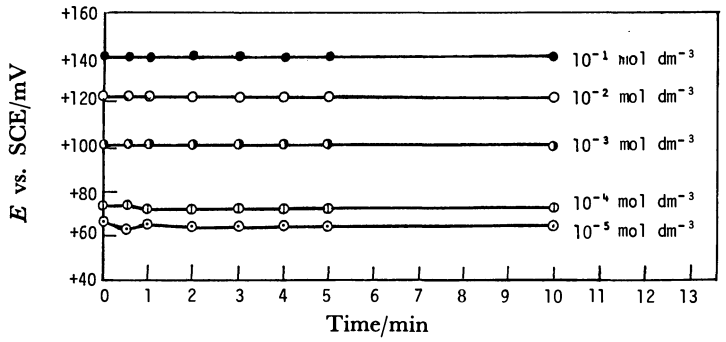

Fig. 5. Response time of manganese(II) ion-selective electrode [manganese sulfide (type α)].

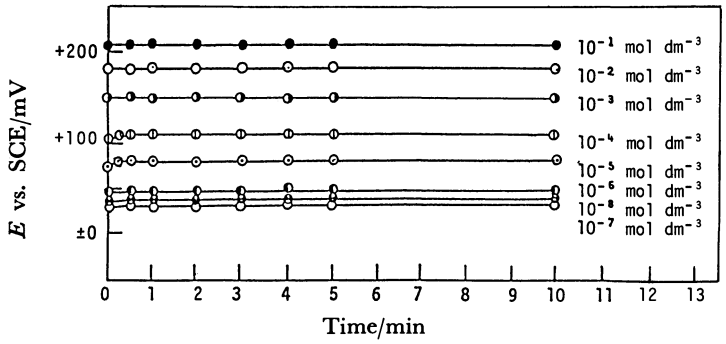

Fig. 6. Response time of manganese(II) ion-selective electrode (manganese dibenzyldithiocarbamate).

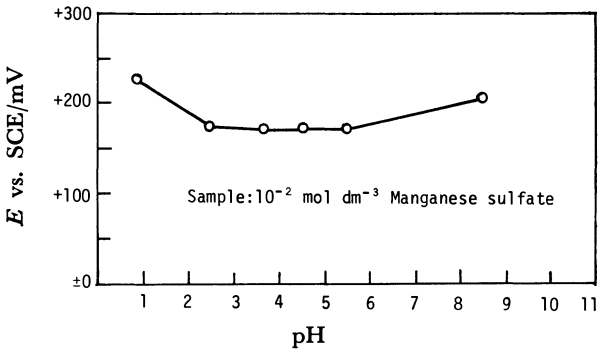

Fig. 7. Effect of pH on manganese(II) ion-selective electrode (manganese dibenzyldithiocarbamate).

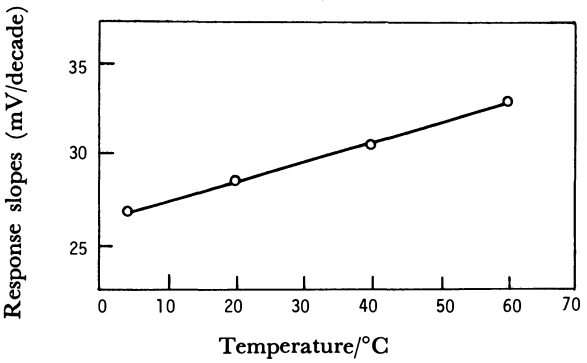

Fig. 8. The variation of response slopes by temperature on manganese(II) ion-selective electrode [manganese sulfide (type α)].

Four types of manganese(II) ion-selective electrodes [manganese sulfide (type α), manganese sulfide (type β+γ), manganese sulfide (type β+γ)-silver sulfide, and manganese dibenzyldithiocarbamate] were tested. The selectivities for monovalent cations (the sodium ion and the potassium ion) were better than those of divalent cations with the manganese sulfide (type α) and manganese sulfide (type β+γ) electrodes. The selectivity coefficients, 2.6×10^{-3}—4.2×10^{-2}, for interfering ions were obtained when the manganese dibenzyldithiocarbamate electrode was used. The electrode potentials were reproducible within 3 mV in 7—10 replicate runs.

Absolute Configuration and Circular Dichroism Spectrum of *all-cis*(NO_2,*N*,*O*)-(−)$^{CD}_{450}$[$Co(NO_2)_2(gly)_2]^-$ Complex

Shuhei FUJINAMI,* Hiroshi MIYAMAE,† Takahiro MIURA, and Koichi FUSHIMI†
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
†Department of Chemistry, Faculty of Science, Josai University,
Sakado, Saitama 350
(Received July 4, 1985)

An X-Ray analysis of *all-cis*(NO_2,*N*,*O*)-(−)$^{CD}_{450}$K[$Co(NO_2)_2(gly)_2]\cdot 1/2H_2O$ has been carried out. The crystal form is trigonal, $P3_121$, with a=10.747(1), c=18.589(4) Å and Z=6. The structure was refined by a block-diagonal least-squares method to a final R value of 0.047 for 3207 independent reflections with $|F_o|>3\sigma(|F_o|)$. The absolute configuration of the (−)$^{CD}_{450}$[$Co(NO_2)_2(gly)_2]^-$ ion has been determined to be $\Delta(R)$. By comparing the CD spectrum of $\Delta(R)$-[$Co(NO_2)_2(gly)_2]^-$ with that of a related $\Lambda(R)$-[$Co(NO_2)_2$(en)(ox)]$^-$ complex, the optical activities of these complexes have been concluded to be derived largely from helical distributions of chelate rings.

In a previous paper,[1] the CD spectrum of $\Lambda(R)$-*all-cis*(*C*,*N*,*O*)-(+)$^{CD}_{500}$[$Co(CN)_2(gly)_2]^-$ was reported and compared with that of $\Delta(R)$-*cis*-(−)$_{589}$[$Co(CN)_2$(ox)(en)]$^-$,[2] where the absolute configuration due to a helical ring pair is designated with Δ or Λ,[3] and the absolute configuration due to the distribution of donor atoms around a metal ion, with R or S.[4] The CD spectra of these complexes resemble each other due to the common R configuration. This result can not be anticipated from a dynamic coupling model regarding optical activity in transition metal complexes since the contribution from the chelate rings is usually evaluated by second-order perturbation[5] and that from the donor atoms by fourth-order perturbation.[6]

In order to clarify the optical activity derived from a chiral arrangement of donor atoms, we attempted to investigate the CD spectra of *all-cis*(NO_2,*N*,*O*)-[$Co(NO_2)_2(gly)_2]^-$ (*N* and *O* represent donor atoms of glycinato). This complex is composed of the same donor atoms as those of *cis*-[$Co(NO_2)_2$(ox)(en)]$^-$.[2] Since the ligand field strength of NO_2^- is weaker than that of CN^-, a CD spectral comparison between the dinitro complexes affords further information on the optical activity due to the arrangement of donor atoms. The *all-cis*(NO_2,*N*,*O*)-[$Co(NO_2)_2(gly)_2]^-$ complex has already been prepared by a reaction of $[Co(NO_2)_6]^{3-}$ with glycine, and resolved into optical antipodes with cinchonine by Celap et al.[7,8] However, the complex will later be prepared and optically resolved by other methods during this study. The absolute configuration of *all-cis*(NO_2,*N*,*O*)-(−)$^{CD}_{450}$[$Co(NO_2)_2(gly)_2]^-$ has been determined by an X-ray analysis in order to facilitate an analysis of the CD spectra.

Experimental

Preparation and Optical Resolution. One *cis*(NO_2) isomer of [$Co(NO_2)_2(gly)_2]^-$ has been isolated by Matsuoka et al.[9] In this study, the complex was prepared by a method described in the literature[9] with a few modification. Potassium nitrite (15 g, 0.18 mol) and glycine (15 g, 0.20 mol) were dissolved in 80 cm^3 of water. The solution was mixed with a solution containing $CoCl_2\cdot 6H_2O$ (10 g, 0.042 mol, in 30 cm^3 H_2O) and aerated for 12 h. Deposited orange needle-like crystals were filtered, and the filtrate was diluted to 3 dm^3 with water and poured onto a column of Dowex 1-X8 resin in Cl^- form (200—400 mesh, ϕ4×25 cm). The column was washed with water and the adsorbed species were eluted with 0.05 mol dm^{-3} KCl. Two bands, corresponding to univalent species, were collected in each fraction. The isomers are labelled E1 and E2 according to the order of elution. The fractions were concentrated with simultaneous removals of the eluting agent. After additions of ethanol, the solutions were kept in a refrigerator in order to precipitate the crystals. The absorption spectrum of the orange needle-like crystals deposited from the reaction mixture was identical with that of the E1 isomer. Found for E1: C, 14.14; H, 2.43; N, 16.51%. Calcd for K[$Co(NO_2)_2(C_2H_4O_2N)_2$]: C, 14.21; H, 2.38; N, 16.57%. Found for E2: C, 13.83; H, 2.61; N, 16.66%. Calcd for K[$Co(NO_2)_2(C_2H_4O_2N)_2]\cdot 0.5H_2O$: C, 13.84; H, 2.59; N, 16.14%. The infrared and absorption spectra of E1 were identical with those of the known isomer.[9]

The E2 isomer was optically resolved by the following procedure: (+)$^{CD}_{520}$[Co(ox)$(en)_2$]I (1.03 g, 2.6 mmol) and silver acetate (0.434 g, 2.6 mmol) were shaken in water (6.3 cm^3) at 60 °C for 10 min. Silver iodide was filtered and washed with 2 cm^3 of hot water and crystals containing the E2 isomer (1.35 g, 3.9 mmol) were dissolved in the above-mentioned filtrate combined with the washings. Upon scratching the wall of the vessel without cooling, an orange diastereoisomeric salt was separated. The mixture was allowed to stand for 15 min at room temperature; then the crystals were filtered. The less-soluble diastereoisomeric salt was repeatedly recrystallized from hot water (50 °C) until the $\Delta\varepsilon$ value became constant. The obtained salt was converted into potassium salt by column chromatography using Dowex 50W-X8 in a K^+ form (ϕ2×5 cm). The less-soluble diastereoisomeric salt contained (+)$^{CD}_{450}$[$Co(NO_2)_2$-$(gly)_2]^-$. The filtrate from which the less-soluble diastereoisomeric salt had been removed was also passed through a column, and a single crystal of K(−)$^{CD}_{450}$-[$Co(NO_2)_2(gly)_2]\cdot 0.5H_2O$ was obtained from the effluent and subjected to an X-ray analysis.

Spectral Measurement. Absorption and CD spectra

Table 1. Crystal Data

$K[Co(NO_2)_2(gly)_2]\cdot 1/2H_2O$	F.W.=317.2
Trigonal	Space group $P3_121$
a=10.747(1)	c=18.589(4) Å
Z=6	U=1859.3(4) Å^3
μ(Mo $K\alpha$)=1.79 mm^{-1}	D_x=1.699 g/cm^3

were recorded with a Hitachi 323 recording spectrophotometer and a JASCO J-40C automatic spectropolarimeter, respectively.

X-Ray Measurement. Crystal data are given in Table 1. Reflections were collected in a θ—2θ scan mode ($2\theta_{max}$=60°) with monochromated Mo $K\alpha$ radiation on a Rigaku AFC-5. 4187 reflections ($h\geqq 0$, $k\geqq 0$, $l\geqq 0$) were measured in which 3207 reflections, including Bijvoet pairs with $|F_o|\geqq 3\sigma(|F_o|)$, were used for a structural determination. Intensities were corrected for Lp factors, but not for absorption and extinction. Calculations were carried out on a FACOM M-160F computer at Josai University with the UNICS-III program.[10] Complex atomic scattering factors were taken from tables.[11]

Structure Determination. The structure was solved by heavy-atom and Fourier methods. Potassium atoms were located at only one special position (on a twofold axis), at the beginning. This is consistent with three K atoms per unit cell. Later, the remaining cation was found at a general position with 1/2 occupancy. One of the NO_2 groups exhibited two different orientations; each orientation was weighted at 0.5. A block-diagonal least-squares refinement with anisotropic thermal parameters for non-H atoms and isotropic parameters for H atoms reduced the R value to 0.047 (R_w=0.044 with $w=1/[\sigma^2+0.02(F_o)^2]$). The absolute structure was determined by comparing Bijvoet pairs. These are given in the F_o—F_c table.[12]

Results and Discussion

Spectral Characterization. There are five possible geometrical isomers in $[Co(NO_2)_2(gly)_2]^-$. Celap et al.[7] have isolated four isomers, except a *cis(NO$_2$)-trans(O)* isomer, from a reaction mixture of $[Co(NO_2)_6]^{3-}$ with glycine. Two isomers were isolated by column chromatography in this study. One isomer (E1) was identified with the *cis(NO$_2$)-trans(N)* isomer, and another isomer (E2) with the *all-cis(NO$_2$,N,O)* isomer from spectral data. The $(-)^{CD}_{450}$-*all-cis(NO$_2$,N,O)* isomer shows two CD peaks with opposite signs in the $^1A_{1g}\rightarrow{}^1T_{1g}$ (Oh) transition region (19400 cm^{-1}, $\Delta\varepsilon$=+0.3; 22400 cm^{-1}, $\Delta\varepsilon$=−1.4), as shown in Fig. 1.

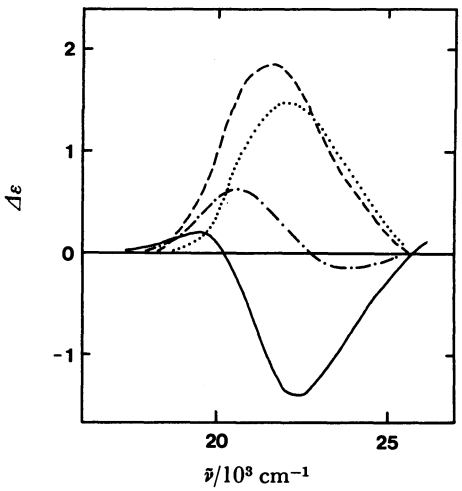

Fig. 1. CD spectra and calculated configurational curves.
a. *all-cis(NO$_2$,N,O)-Δ(R)*-$(-)^{CD}_{450}[Co(NO_2)_2(gly)_2]^-$ (——), b. *cis-Δ(R)*-$(+)_{589}[Co(NO_2)_2(ox)(en)]^-$ (----), c. $\Delta\varepsilon(R)=[\Delta\varepsilon(a)+\Delta\varepsilon(b)]/2$ (—·—), d. $\Delta\varepsilon(\Lambda)=[\Delta\varepsilon(b)-\Delta\varepsilon(a)]/2$ (·····).

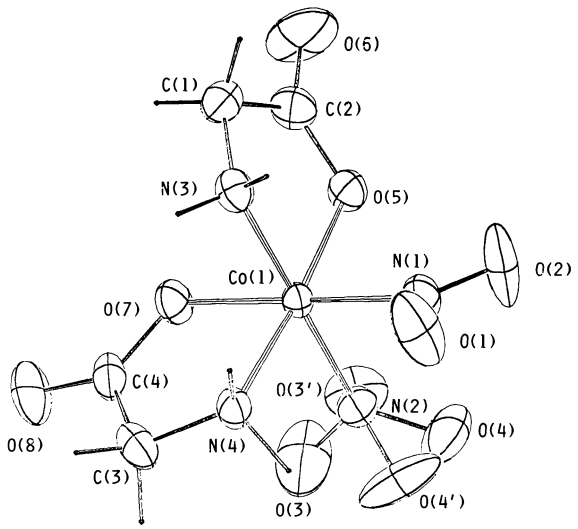

Fig. 2. Perspective view of the *all-cis(NO$_2$,N,O)*-$[Co(NO_2)_2(gly)_2]^-$ complex with atomic numbering.

Description of the Structure. Final atomic parameters are listed in Table 2. A perspective drawing of the complex anion is drawn in Fig. 2 with atomic numbering. Interatomic distances and angles are listed in Table 3. The geometrical arrangement of ligands around a cobalt ion coincides with the assignment based on spectral data; the cobalt ion is in an octahedral coordination with two bidentate glycinate ions and two unidentate nitro ions. Each of the chemically identical ligating atoms occupy cis positions on the octahedron, i.e. *all-cis(NO$_2$,N,O)*. The octahedral arrangement around a metal ion is much distorted, since there are discernible differences, even in the chemically identical bond distances around a metal ion. The differences, Co–N(NO_2), Co–N(gly), and Co–O are 0.025, 0.024, and 0.019 Å, respectively. The bond angles around a metal ion are spread at an octahedral face comprizing N(1), N(3), and N(4). The absolute configuration of helical chelate rings is described as Λ; accordingly the chiral arrangement of donor atoms, as R.

One nitro group which occupies the site trans to the oxygen atom of glycinate ion ligates with a particular orientation. However, the other nitro group trans to the nitrogen atom of glycinate ion exhibits two different orientations in disorder. The geometry of the former nitro group is normal compared with related compounds,[13–15] while the bond angle, ∠ONO, of the latter group is somewhat smaller than that of the former group. The geometry of the glycinato groups is very similar to that observed in related complexes.[16] The bite angles of glycinate ions are 84.9 and 86.0°, and the dispositions of Co atom from mean planes of glycinate ions are 0.496(8) and 0.226(0) Å, respectively.

Crystal packing (viewed down a*) is illustrated in Fig. 3, and intermolecular distances are listed in

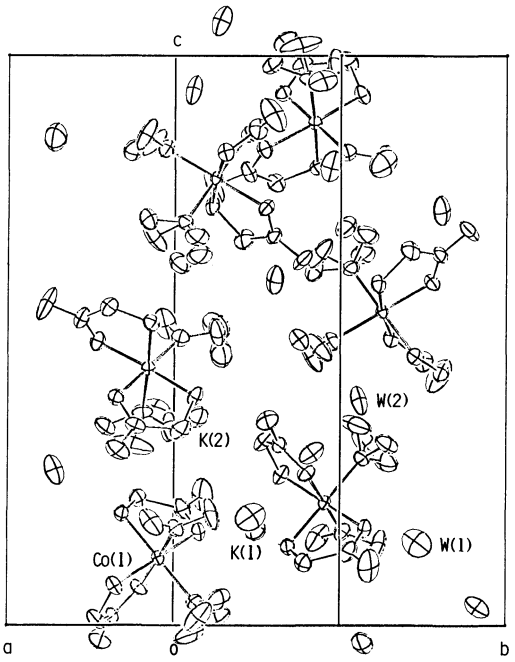

Fig. 3. Crystal packing diagram viewed down a*.

Table 4. The crystal comprises potassium cations, complex anions and water molecules in a complicated three-dimensional network of ionic and hydrogen bonds. Potassium ions are accomodated in two different environments in disorder. Half ions, K(1), are surrounded by eight oxygen atoms in a square prism while the remaining ions, K(2), by seven oxygen atoms in a monocapped octahedron. The low occupation of K(2) may be due to the short distance between the equivalent K(2) ions (2.58 Å). The K(1) ion exists near the O(1) atoms, as shown in Table 4, and an ionic bond is suggested to exist between them. On the other hand, there is no favorable atom near the oxygen atoms of the nitro group which ligates the site trans to the nitrogen atom of the glycinate ion. This is the reason for the disorder of the orientation in the nitro group.

Optical Activity of *all-cis(NO$_2$,N,O)*-[Co(NO$_2$)$_2$(gly)$_2$]$^-$. Two optical sources can be considered for the isomer as in *all-cis(C,N,O)*-[Co(CN)$_2$(gly)$_2$]$^-$;[1] a helical chelate rings and a chiral arrangement of donor atoms. The *cis*-[Co(NO$_2$)$_2$(ox)(en)]$^-$ complex also has two sources of optical activity. Since the absolute configuration of (+)$_{589}$[Co(NO$_2$)$_2$(ox)(en)]$^-$ has been assigned to $\Lambda(R)$,[2] the $\Delta(R)$-[Co(NO$_2$)$_2$(gly)$_2$]$^-$ isomer is pseudo-diastereoisomeric with the $\Lambda(R)$-[Co(NO$_2$)$_2$(ox)(en)]$^-$ isomer, judging from a description of the absolute configurations. Therefore, the contribution curve due to the R configuration can be formally evaluated by adding the two observed CD curves, as shown in Fig. 1. The resultant curve shows positive and negative peaks from the lower frequency, the positive one being dominant. The contribution curve due to the Λ configuration, which is calculated by subtraction (curve d in Fig. 1), exhibits a positive peak. The peak is twice as intense as the dominant peak in the R configurational contribution curve. Therefore, the helical ring pair is a more important optical source than the chiral arrangement of donor atoms in dinitro complexes.

The obtained result disagrees with that for the *all-cis*(C,N,O)-[$Co(C)_2(N)_2(O)_2$]-type complex in which most of the optical activity is derived from a chiral arrangement of donor atoms. These findings can be explained as follows; the difference in the ligand field strength between the cyano and the N donor atoms of glycinato is very large, while the difference between the nitro and the N donor atoms of glycinato is small. Consequently, the asymmetric field due to the donor atoms in dinitro complexes becomes weaker than that in dicyano complexes.

Atoh et al.[17] have found that *trans*(P,N)-[Co(acac)$(edpp)_2$]$^{2+}$ and [Co(acac)(en)(dppe)]$^{2+}$, which have two possibilities for the sources of optical activity (like the present complexes), exhibit CD spectra that are different from each other (edpp=(2-aminoethyl)diphenylphosphine; dppe=1,2-bis(diphenylphosphino)ethane). They concluded that the chiral arrangement of donor atoms is not the dominant source of the optical activity in the phosphine complexes. This fact can also be attributed to the ligand field strength of phosphine, similar to that of ethylenediamine.

Mason[6] has applied a dynamic coupling model to the optical activity of complexes with chiral arrangements of donor atoms. However, his application is incompatible with the present results. Though the dynamic coupling model demands that the optical activity is intimately related to polarizabilities of the donor atoms, the present results show that the optical activity derived from a chiral arrangement of donor atoms is intimately related to crystal field strengths of donor atoms rather than polarizabilities.

Adsorption of Cobalt(II) Ions on Crystalline Hydrous Titanium Dioxide Fibers at 298 to 423 K

Yū Komatsu,* Yoshinori Fujiki, and Takayoshi Sasaki
National Institute for Research in Inorganic Materials, 1-1 Namiki,
Sakura-mura, Niihari-gun, Ibaraki 305
(Received July 26, 1985)

The distribution of cobalt(II) ions between crystalline hydrous titanium dioxide fibers and aqueous solutions has been investigated. The adsorption behavior of cobalt(II) ions is explained in terms of their ion exchange with hydrogen-ions in the fibers. The distribution coefficients of cobalt(II) ions, K_d, increased with increasing temperature at 298—373 K. Slopes of the plots of log K_d vs. pH for 398—423 K were ca. +1.6, which was somewhat lower than those for 298—373 K: +2.0. X-Ray powder diffraction patterns indicate that the fibers hold a layer structure up to 373 K but change to anatase or its precursor above this temperature.

Many papers have been published on the treatment of radioactive wastes with inorganic ion exchangers.[1-3] The previous work in this laboratory has demonstrated that crystalline hydrous titanium dioxide fibers, $H_2Ti_4O_9 \cdot nH_2O$,[4] adsorb alkali metal ions,[5] alkaline earth metal ions,[6] and divalent transition metal ions[7] in weak acid solutions at 298 K. The logarithm of distribution coefficient, log K_d, for each metal ion increases proportionally with the pH of the aqueous phase if the concentration of hydrogen ions in the solid phase is kept substantially constant.

Removal of cobalt(II) ions from cooling water is indispensable for safe operation in an atomic power plant. The present paper deals with the adsorption of cobalt(II) ions on the hydrous titanium dioxide fibers. Distribution coefficients of cobalt(II) ions were measured as a function of pH at 298—423 K; in addition, X-ray powder diffractometry was performed to obtain information about the chemical and structural changes of the solid phase.

Experimental

Titanium dioxide used was of 99.9% purity. Distilled and deionized water was used throughout this work. All the other reagents were of analytical grade.

Crystalline potassium tetratitanate fibers, $K_2Ti_4O_9$, were synthesized by a flux method.[4] The average size of the fibers was 1 mm in length and 0.01 mm in diameter.

Figure 1 shows the flow sheet of a process for synthesizing crystalline hydrous titanium dioxide fibers. About 15 g portion of the fibers was filled in a glass column with an inner diameter of 25 mm, and washed with 20 dm^3 of water to remove residual K_2MoO_4. Subsequently, 1 mol dm^{-3} hydrochloric acid was passed through the column to convert $K_2Ti_4O_9$ into an H^+ form according to the reaction:

$$K_2Ti_4O_9 + nH_2O + 2H^+ \rightarrow H_2Ti_4O_9 \cdot nH_2O + 2K^+. \quad (1)$$

The fibers were treated with the acid solution until the concentration of potassium ions in the effluent became less than 1×10^{-5} mol dm^{-3}. Potassium concentrations were measured by atomic absorption spectrophotometry. The resulting product was washed with water and dried over a saturated NaCl solution (relative humidity: 70%) to a constant weight.

Aqueous standard solutions of cobalt(II) ions were prepared by dissolving cobalt(II) chloride in water. The concentration of cobalt(II) ions was determined by EDTA titration.

Figure 2 gives the flow sheet of adsorption measurement of cobalt(II) ions on the fibers. Adsorption experiments were carried out in batchwise operations in an aluminium box thermostated at temperatures between 298 and 423 K. Twenty-cm^3 stoppered glass tubes (298—373 K) or teflon tubes (398—423 K) were used to equilibrate the solid (0.1 g) with the aqueous solutions (10 cm^3) containing cobalt(II) ions. The Teflon tubes were covered with an aluminium block to seal them tightly (Fig. 3). The initial concentration of cobalt(II) chloride was 1×10^{-4} mol dm^{-3},

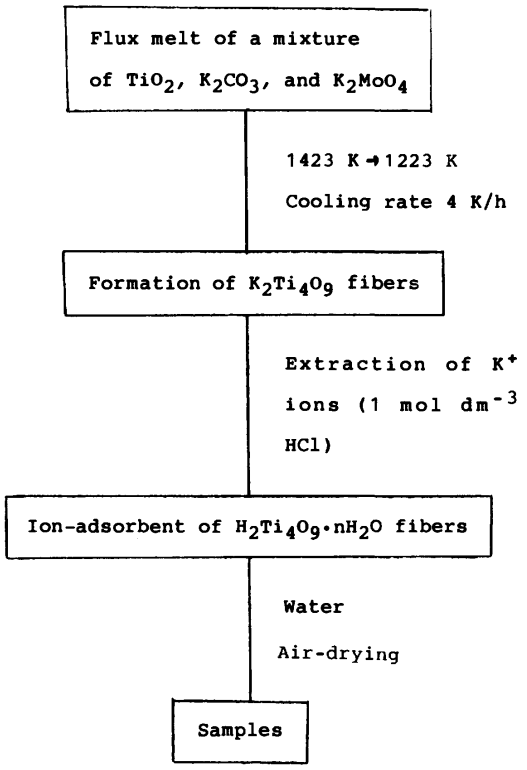

Fig. 1. Flow sheet of a process for synthesizing crystalline hydrous titanium dioxide fibers.

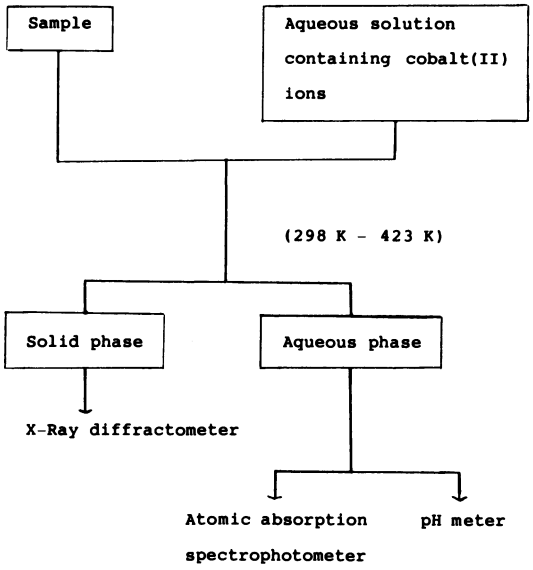

Fig. 2. Flow sheet of adsorption of cobalt(II) ions on the crystalline hydrous titanium dioxide fibers.

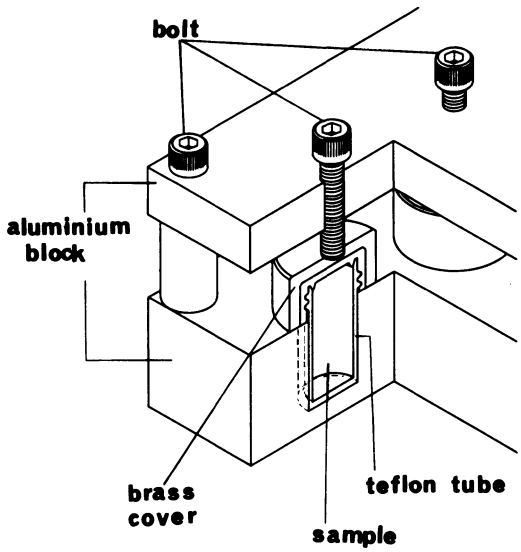

Fig. 3. Schematic diagram of the apparatus for ion exchange.

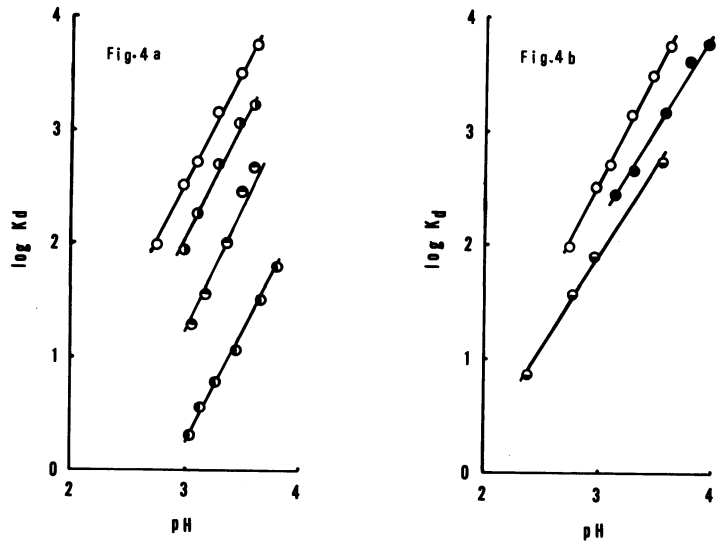

Fig. 4. Distribution coefficients of cobalt(II) ions as a function of pH in the aqueous phase at various temperatures.
The ion exchanger is 0.1 g of $H_2Ti_4O_9 \cdot nH_2O$. The aqueous solution is 10 cm^3 of hydrochloric acid solution with an initial cobalt(II) concentration of 1×10^{-4} mol dm^{-3}. Fig. 4a (◐: 298 K, ◓: 323 K, ◑: 348 K, and ○: 373 K). Fig. 4b (○: 373 K, ●: 398 K, and ◒: 423 K).

and the pH was adjusted with hydrochloric acid. The glass or teflon tubes were kept in the thermostated box, and shaken gently by hand once 1 d. The reaction times were 21 d (298 K), 10 d (323 K), or 4 d (348, 373, 398, and 423 K). Ion-exchange equilibrium was confirmed to be attained under these conditions. The fibers were separated by centrifugation for 10 min at 4000 rpm. The concentration of cobalt(II) ions in the aqueous solution was determined using a Hitachi 180—80 polarized Zeeman atomic absorption spectrophotometer. The pH of the solution was measured with a TOA HM-20E pH meter. X-Ray powder diffraction patterns were obtained by using a Rigaku Denki RAD-2B diffractometer with Cu $K\alpha$ radiation.

Results

The distribution coefficient, K_d, was calculated as

$$K_d = \frac{C_1/g}{C_2/cm^3}, \quad (2)$$

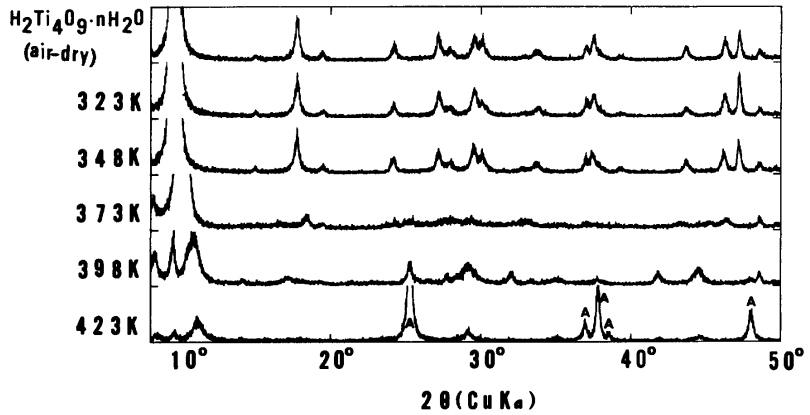

Fig. 5. X-Ray powder diffraction patterns of the solid samples treated with aqueous solutions at six different temperatures.
A: anatase.

where C_1 is the amount of adsorbed cobalt(II) ions per 1 g of the solid, and C_2 is the concentration of cobalt(II) ions per 1 cm^3 of the aqueous solution.

Figure 4 gives the plots of log K_d vs. pH in the aqueous phase for six different temperatures. In these experiments, the concentration of hydrogen ions in the solid phase was held substantially constant before and after the adsorption of cobalt(II) ions. The slopes of the log K_d–pH lines were about +2 below 398 K. Figure 4 also shows that the slopes of the lines for 398 and 423 K were somewhat lower than +2. X-Ray powder diffractometry was then applied to clarify the cause of the differences in slopes (Fig. 5).

The fibers treated below 373 K showed almost the same diffraction patterns as the original fibers. This fact indicates that the structure of the fibers remain virtually unchanged at 348 K or below. Therefore, the adsorption of cobalt(II) ions on the fibers under these conditions can be represented by the ion-exchange reaction:

$$m\mathrm{Co^{2+}(aq)} + \mathrm{H_2Ti_4O_9 \cdot nH_2O(s)} \rightarrow 2m\mathrm{H^+(aq)} + \mathrm{Co}_m\mathrm{H}_{2(1-m)}\mathrm{Ti_4O_9 \cdot nH_2O(s)}, \quad (3)$$

where the subscripts "aq" and "s" denote the aqueous and solid phases, respectively, and $0<m<1$.

The layer structure of the crystalline hydrous titanium dioxide is characterized by a very strong 200 reflection with an interplanar spacing, $d(200)$, of ca. 0.91 nm.[8] The corresponding peak of the solid treated at 373 K was observed at 0.86 nm; all the other peaks disappeared almost completely. The presence of this peak suggests that the poorly crystallized phase formed at 373 K has a layer structure similar to that of hydrous titanium dioxide.

The solids treated at 373 K or below remained fibrous, but those treated at 398—423 K turned powdery. The powdery samples showed X-ray diffraction patterns different greatly from those of fibrous ones. The three reflections appeared at 8° to 12°; furthermore, the peaks of anatase-type titanium dioxide appeared, and their intensities increased with an increase in temperature of the solution. That is, a part of hydrous titanium dioxide, $H_2Ti_4O_9 \cdot nH_2O$, dehydrates to give anatase under the above conditions:

$$\mathrm{H_2Ti_4O_9 \cdot nH_2O} \rightarrow 4\mathrm{TiO_2} + (n+1)\mathrm{H_2O}. \quad (4)$$

The three peaks described above are assigned to an intermediate phase which is formed in the course of conversion of hydrous titanium dioxide to anatase.

Table 1. Summary of the Values of $d(200)$ Determined by X-ray Powder Diffractometry and Distribution Coefficients of Cobalt(II) Ions at pH 3.0

Temperature / K	$d(200)$ / nm	K_d
298	0.91	0.22
323	0.91	1.36
348	0.91	2.10
373	0.86[a]	2.54
398	—	2.16
423	—	1.90

a) Strictly speaking, this peak cannot be assigned to the 200 reflection because this sample was not a crystalline material.

Discussion

The hydrous titanium dioxide fibers have a layer structure similar to that of potassium tetratitanate.[4] Table 1 summarizes the $d(200)$ values and distribution coefficients of cobalt(II) ions at pH 3.0. As the temperature was increased between 298 and 373 K, the

distribution coefficient also increased. At 373 K, the crystalline hydrous titanium dioxide fibers converted into the poorly crystallized phase with an interlayer distance considerably smaller than that of the crystalline fibers. The amount of adsorbed cobalt(II) ions must be influenced by the variations of both the temperature and structure of the fibers. It is, however, difficult to evaluate the extent to which these two factors affect the partition of cobalt(II) ions between the solid and aqueous phases.

The distribution coefficient of cobalt(II) ions reached a maximum at 373 K (Table 1). However, this temperature cannot be regarded as optimum for adsorption of cobalt(II) ions. As the temperature was raised above 373 K, the hydrous titanium dioxide changed into the intermediate phase and/or anatase to a greater extent with a result that the K_d values decreased with increasing temperature. In view of the fact that the layer structure is stable to heating in the air up to 573 K,[9] the presence of high-temperature solutions evidently accelerates both chemical and structural changes of the fibers in the closed tube. There is a fear of the unfavorable conversion of the poorly crystallized phase formed at 373 K into anatase or its precursor if minor modification in experimental conditions is made. On the other hand, the layer structure of the fibers remains almost unchanged below 373 K. Accordingly, a reaction temperature between 348 and 373 K is recommended especially when the fibers are used as an adsorbent for a long period. If the present fibers are used as an adsorbent for cobalt(II) ions, conditions under which $H_2Ti_4O_9 \cdot nH_2O$ does not change to other phases should be determined prior to adsorption runs.

The authors are very grateful to Professor Tatsuya Sekine of the Science University of Tokyo and Professor Mitsuo Abe of the Tokyo Institute of Technology for their valuable discussions during this work and to Mr. Yasuji Masuda, Dr. Takashi Akahane, Mr. Toshiaki Wada and Mr. Hajime Haneda of this institute for the assistance with the experimental work.

The Ion-Association Sorption and Extraction of Metal Thiocyanate Complexes to Cellulose Acetate Polymer and Organic Solvents. Similarity in Distribution Mechanisms

Takashi HAYASHITA† and Makoto TAKAGI*
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received July 30, 1985)

The sorption and extraction of heavy metal thiocyanate complexes from an aqueous solution were studied for a cellulose acetate polymer and conventional organic solvents. The ease of metal sorption to solid cellulose acetate correlated well with the ease of metal extraction to liquid glycerol triacetate. The distribution behavior of ammonium thiocyanatozincate complexes was studied in detail and compared among cellulose acetate, isobutyl methyl ketone, and glycerol triacetate. The chemical processes involved in the metal distribution to the organic phase were found to be essentially the same for these three media. Thus, cellulose acetate was conveniently considered a polymer solvent. The results were discussed in relation to metal-selective hyperfiltration through cellulose acetate membranes.

In the course of our study of metal-selective separation by means of polymer membranes,[1-4] we outlined an idea of metal-selective hyperfiltration. The principle of metal separation is based on a metal-selective sorption of ion-association complexes to the membrane phase and a subsequent transport of the sorbed metal species through the membrane by some coupling processes with a solvent flow under hydraulic pressure.[3,4] The sorption of heavy metal thiocyanate complexes to polymers took place predominantly on polymers of medium polyarity, such as cellulose acetate (CA) and polyacrylonitrile. An equilibrium study indicated that the sorption obeys the Langmuir adsorption isotherm and the Nernstian distribution law at high and low metal loadings respectively. An analysis of the Nernstian-type distribution suggested that the nature of the sorption to the polymer (CA) is essentially similar to that of the conventional liquid–liquid extraction of the metal-complex species. The permeability under hydraulic pressure of metal thiocyanate and iodide complexes through CA membranes correlated well with the sorptivity of metal species, suggesting a solvent flow-coupled permeation by the sorbed metal species. The present paper includes an extended study of metal sorption on a polymer (CA) and its comparison with liquid–liquid extraction, since their understanding is essential for the development of metal-selective hyperfiltration membranes.

Experimental

Reagents. The cellulose acetate (acetyl content 39.8%; ASTM viscosity, 3s) was obtained from Eastman Chemicals. The other reagents were reagent-grade commercial products and were used without further purification. Cellulose acetate powders finer than 50 mesh were used in the sorption experiments.

Sorption and Extraction. Sorption experiments were done by the procedure previously described.[3] Liquid–liquid extraction was carried out in a conventional manner. Ten to fifteen min mechanical shaking was enough to attain equilibrium. The volumes of the organic and aqueous solutions after equilibration were measured. The concentrations of the metal complexes were determined by means of atomic absorption spectrophotometry with a Japan Jarrel Ash Co. AA-1 instrument.

The sorption and extraction of metal complexes were estimated by means of the degree of sorption (or extraction) (E) and the distribution ratio (D):

$$E=\frac{[M]_i-[M]_f}{[M]_i}\times 100 \quad (1)$$

$$D=\frac{[M]_i-[M]_f}{[M]_f}\times\frac{V_w}{W_m}, \quad (2)$$

where $[M]_i$ and $[M]_f$ are the initial and final metal concentrations respectively, in an aqueous solution; V_w is the volume of the aqueous solution (ml) after equilibrium, and W_m is either the weight of CA (g) or the volume of the organic solution (ml) after equilibrium. In this definition, the dimensions of the metal-distribution ratio are not the same for sorption (to CA) and extraction (to organic solvent). Therefore, where a clear distinction between the two distribution constants should be made, D' is used for the volume-based liquid-liquid distribution ratio. The weight-based D value may be converted to the volume-based D' value by dividing it by the density of the dry polymer (1.25 g/cm^3 for CA) at the first approximation. The D and D' values are thus not very different numerically, and one can use either value for a direct comparison of the effectiveness of metal sorption and extraction.

Results and Discussion

Previous studies indicated that the sorption of metal thiocyanate complexes took place readily for

a) Ten ml of a 0.5 M (1 M=1 mol dm^{-3}) NH_4SCN solution containing 0.5 mM metal nitrate (pH 1.0, adjusted by HNO_3) were shaken with 10 ml of triacetin (TA), methyl isobutyl ketone (MIBK), and 1,2-dichloroethane (DCE). b) Twenty ml of a 0.5 M NH_4SCN solution containing 0.5 mM metal nitrate (pH 1.0, adjusted by HNO_3) were shaken with 2.0 g of CA powder. Data taken from Reference 4.

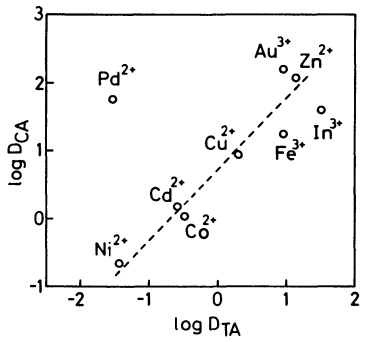

Fig. 1. Correlation between distribution ratios for the sorption and extraction of metal thiocyanate complexes. D_{CA}, distribution ratio in water–CA; D_{TA}, distribution ratio in water–TA. Conditions are similar to those in Table 1.

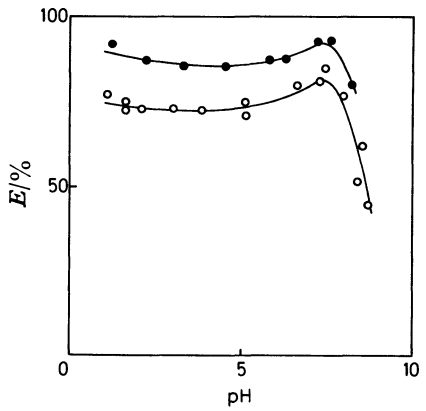

Fig. 2. Effect of pH on the sorption and extraction of zinc thiocyanate complexes. Sorption to CA (○): Twenty ml of 0.25 M NH_4SCN solution containing 0.5 mM $Zn(NO_3)_2$ were used. The pH was adjusted by adding HCl or KOH. The amount of CA was 2.0 g. Extraction to TA (●): 10 ml of 0.25 M NH_4SCN solution containing 0.5 mM $Zn(NO_3)_2$ were used. The volume of TA was 10 ml.

CA and polyacrylonitrile, but not for cellulose and poly(vinyl chloride).[3,4] In order to compare such sorption behavior with solvent-extraction systems, the extraction of metal thiocyanate complexes was investigated by using organic solvents of a related chemical structure. The results are shown in Table 1, along with the sorption data for CA. Oxygen-containing organic solvents, such as isobutyl methyl ketone (MIBK) and triacetin (TA, glycerol triacetate), have a high extraction ability. On the other hand, 1,2-dichloroethane shows little extraction ability. Such behavior is general in ion-association extraction systems.[5]

It is noteworthy that the sorption behavior of metal thiocyanate complexes on solid polymers correlates well with the liquid–liquid metal extraction. That is, CA effectively exhibits an "extraction" ability similar to those of oxygen-containing organic solvents, while poly(vinyl chloride) has little sorption ability, just like dichloroethane liquid–liquid extraction systems, Figure 1 shows the correlation of the distribution ratios between the sorption by cellulose acetate and the extraction by triacetin. The correlation is approximately linear except for palladium. This strongly suggests the similarity of metal-partition mechanisms between the solid polymer matrix and the structurally related organic solvent. The cause of the departure from the linearity for palladium is not apparent at present. It is possible, though, that a local micro-structure of the polymer matrix helps enhance the sorptivity of some particular metal complexes. A "cation chelation mechanism" has recently been described for the sorption of metal complexes by polyether-type polyurethane foam.[6,7]

The effect of the pH on the sorption and extraction of zinc thiocyanate complexes is shown in Fig. 2. The pH-E(%) profiles are quite similar for TA and CA. The E(%) values stay almost constant at pH 1—6 but drop sharply at pH>7.5. The latter effect is due to the hydrolysis of metal ions in the bulk solution.[3] As has been reported previously,[3,4] the zinc ion becomes sorbed on CA as ammonium thiocyanate complexes with an average composition of $(NH_4)Zn(SCN)_3$–$(NH_4)_2Zn(SCN)_4$ under weakly acidic conditions. The sorption and extraction were not studied under low pH conditions (pH<1) to avoid possible ester hydrolysis. However, the proton is known to act as a counter cation in such ion-association complexes as the trihydrated hydronium ion, and the

increase in proton concentration is considered to enhance the sorption and extraction,[8,9] which may, in fact, be reflected in the increased metal extractions in the lower pH region.

The relationship of the distribution ratio and the zinc concentration (total concentration) in an aqueous solution at equilibrium is shown in Fig. 3. The figure shows that the sorption and extraction ability for zinc thiocyanate complexes increases in this order; MIBK>CA>TA. The metal distribution ratio for cellulose acetate is about five times higher than that for the triacetin extraction system at an ammonium thiocyanate concentration of 0.5 M. The similar is the case at 0.25 M ammonium thiocyanate. Thus, CA is substantially a better sorbent or extraction solvent than is TA for collecting zinc(II) thiocyanate complexes from aqueous solutions. This is quite interesting because it means that a "solid" polymer can be a better "extraction solvent" than its liquid analogue.

Figure 3 also shows that the distribution ratio

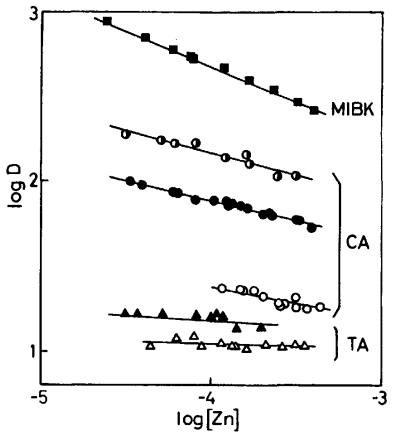

Fig. 3. Variation of zinc distribution ratio as a function of (total) zinc concentration in aqueous solution. Sorption to TA: Twenty ml of aqueous solution containing $Zn(NO_3)_2$ in various concentrations were shaken with 0.5—2.0 g CA. The aqueous solution contained NH_4SCN in concentrations 0.25 M (○), 0.50 M (●), and 0.75 M (◑). Extraction to TA and MIBK: Ten ml of aqueous solution containing $Zn(NO_3)_2$ in various concentrations were shaken with 5 ml TA or 2 ml MIBK. The aqueous solution contained NH_4SCN in concentrations 0.25 M (TA, △), 0.50 M (TA, ▲), and 0.50 M (MIBK, ■).

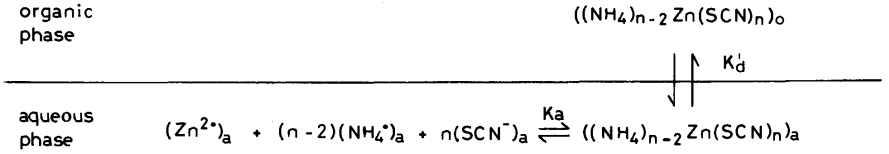
decreases as the aqueous zinc concentration increases. For conventional solvent-extraction systems, such behavior is usually considered to indicate the dissociation of extracted ion-association complexes in an organic solution, and it is particularly common for liquid-liquid extraction using solvents with a moderate dielectric constant.[10] It is conceivable that a similar dissociation reaction is taking place in the CA polymer matrix. In fact, Oren et al. studied the sorption behavior of metal halogeno complexes by using open-cell polyurethane foam and confirmed the dissociation of the extracted ion-association species in the foam.[11] However, in our sorption system, as we showed in a previous paper,[3] the polymer (CA) has a maximum sorption capacity (the maximum load of metal according to the Langmuir adsorption isotherm) for each ion-association-complex sorption system.[3] Therefore, the saturation effect, which should lead to a decrease in D similar to that observed in Fig. 3, may not be negligible under the relevant conditions. Calculations according to the Langmuir adsorption equilibria indicated, however, that the saturation effect is quite negligible under the conditions shown in Fig. 3. Thus, the behavior of CA, being in line with that of MIBK and TA (Fig. 3), further strengthens the idea that CA serves as a "polymer solvent" for the extraction of ion-association complexes.

The mechanism of the sorption of metal species to CA was compared with that of extraction to the organic solvent with a related structure (TA). Scheme 1 shows a simplified model of metal distribution. The sorption and extraction of ammonium thiocyanatozincate complexes were studied at a relatively low metal loading in the organic phase. Under such conditions, both sorption and extraction can be treated according to the Nernstian distribution law, which gives these expressions, 3—5:[3,4]

$$\log \beta D' = (n-2)\log[NH_4^+]_a + n\log[SCN^-]_a + \log K_a K_d' \quad (3)$$

$$D' = [(NH_4)_{n-2}Zn(SCN)_n]_o / ([Zn^{2+}]_a + [Zn(SCN)^+]_a + \cdots\cdots + [Zn(SCN)_m^{2-m}]_a) \quad (4)$$

$$\beta = 1 + K_1[SCN^-]_a + K_1K_2[SCN^-]_a^2 + \cdots\cdots + K_1K_2\cdots\cdots K_m[SCN^-]^m \quad (5)$$



Scheme 1. Model for zinc thiocyanate complex distribution among organic and aqueous solutions.

where K_m stands for the mth successive complex formation constant in an aqueous solution.

Equation 3 indicates that the coordination number n of the extracted metal species can be determined from the plots of log $\beta D'$ vs. log $[SCN^-]_a$.

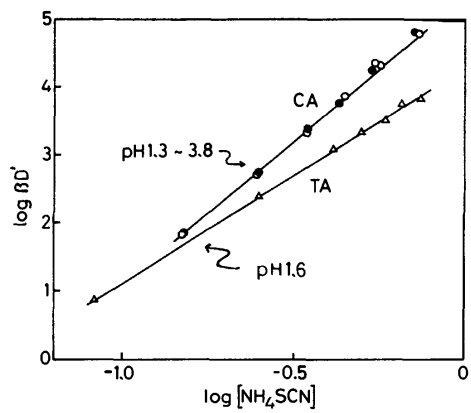


Fig. 4. Sorption and extraction of zinc thiocyanate complexes as a function of aqueous NH_4SCN concentration. Plots according to Equation 3. Sorption to CA (○,●): Twenty ml of aqueous NH_4SCN solution (○, pH 1.3; ●, pH 3.8. adjusted by HNO_3) containing 0.5 mM $Zn(NO_3)_2$ were used. The amount of CA was 2.0 g. Extraction to TA(△): Ten ml of aqueous NH_4SCN solution containing 0.5 mM $Zn(NO_3)_2$ (pH 1.6, adjusted by HNO_3) were used. The volume of TA was 10 ml.

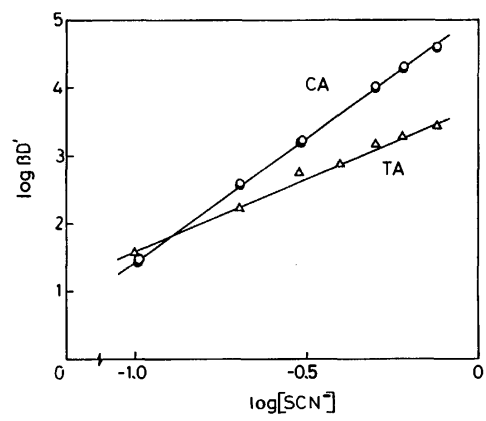

Fig. 5. Sorption and extraction zinc thiocyanate complexes as a function of aqueous SCN^- concentration. Plots according to Equation 3. Sorption to CA (○,●): Twenty ml of aqueous NH_4SCN solution (pH 1.6, adjusted by HNO_3) containing 0.5 mM $Zn(NO_3)_2$ were used. Total concentration of ammonium ion was adjusted to 0.75 M by NH_4NO_3. The amount of CA was 1.0 g (●) and 2.0 g (○). Extraction to TA (△): Twenty ml of aqueous NH_4SCN solution containing 0.5 mM $Zn(NO_3)_2$ (pH 1.6, adjusted by HNO_3) were used. Total concentration of ammonium ion was adjusted to 0.75 M by NH_4NO_3. The volume of TA was 5 ml.

Figure 4 shows one such plot, where the concentration of ammonium thiocyanate is varied (in this case, $[NH_4^+]_a=[SCN^-]_a=[NH_4SCN]_a$ in Equation 3). For the sorption on CA, the D' in Equation 3 was replaced by D. Figure 5 shows a similar plot, where $[NH_4^+]_a$ is maintained constant at 0.75 M and $[SCN^-]_a$ is varied. Figure 4 gives n values of 3.2 and 2.6 for the metal distributions to CA and TA respectively. Figure 5 similarly gives n values of 3.5 (CA) and 2.5 (TA). The sorbed or extracted metal species, therefore, seem to have average compositions of $(NH_4)_{1.2-1.5}Zn(SCN)_{3.2-3.5}$ in CA and $(NH_4)_{0.5-0.6}$-$Zn(SCN)_{2.5-2.6}$ in TA.

As regards the similarity (as extraction solvents) between CA and carbonyl group-containing solvents (MIBK and TA), it seemed that it would be interesting to obtain some insight into the solvation of the extracted metal complex in the solid polymer. A solvation number (m) or a number of solvent (S) molecules associated with the extracted complex species may be defined by Equation 6:

$$((NH_4)_{n-2}Zn(SCN)_n)_a + m(S)_o \quad ((NH_4)_{n-2}Zn(SCN)_n \cdot mS)_o \qquad (6)$$

where the suffixes "a" and "o" denote the aqueous and organic phases respectively. To obtain a rough measure of the m number, zinc thiocyanate complexes were extracted by an "inert" solvent, 1,2-dichloroethane, to which a variable concentration of MIBK or TA was added. Pure 1,2-dichloroethane does not extract the metal species at all, as shown in Table 1. A conventional manipulation then gives Expression 7 for the metal-distribution ratio (D) between the aqueous and the "active" solvent (S)-doped 1,2-dichloroethane phases:

$$\log D = m \log [S]_o + \text{constant} \qquad (7)$$

where $[S]_o$ stands for the molar concentration of the active solvent (MIBK or TA) in 1,2-dichloroethane.[12]

Equation 7 indicates that m is obtained as a slope of a linear plot, log D vs. $[S]_o$. Figure 6 shows such plots, from which the m value is determined to be 5.0 for both MIBK and TA. Although a TA molecule contains three carbonyl (or CH_3CO-) functional groups, it is most likely acting as a monofunctional carbonyl compound, as is MIBK. Since the nature of CA as an extraction solvent is between MIBK and TA (Fig. 3), it is quite probable that zinc thiocyanate complexes are stabilized by at least five carbonyl functional groups from CA in the polymer matrix.

In conclusion, there is now ample evidence that CA behaves just like ordinary carbonyl group-containing solvents, such as MIBK and TA, in "extracting" metal-complex species. Halogeno and pseudohalogeno complexes are especially easy to extract. Interestingly, CA membranes (including the

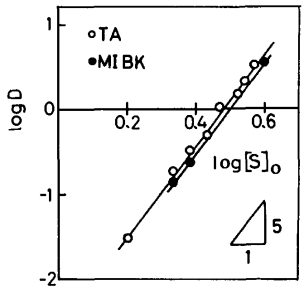

Fig. 6. Determination of solvation number according to Equation 7. Ten ml of 0.5 M NH_4SCN containing 0.5 mM $Zn(NO_3)_2$ were shaken with 10 ml of 1,2-dichloroethane containing TA or MIBK in variable concentration. The pH was adjusted to 1.0 by HNO_3.

hyperfiltration membrane) are quite similar to CA powders in such sorption properties.[13] In the light of these findings, it is no accident that CA membranes exhibit peculiar permeation characteristics to such metal complexes under hyperfiltration conditions.[1-4] At present, CA is the only polymer material which is a good sorbent for metal complexes and which can at the same time, be fabricated into hyperfiltration membranes. It is hoped that an understanding of the mechanism of metal sorption will give impetus to the development of a variety of polymer materials for the fabrication of metal-selective hyperfiltration membranes.

12) The expression can be derived in a manner similar to that of Expression 3. The constant includes the extraction equilibrium constant for Reaction 6 as well as those equilibrium constants in an aqueous solution concerning the formation of zinc thiocyanate complexes and ion-association complexes. The constant is also a function of the concentration of ammonium and thiocyanate ions in an aqueous solution. Therefore, if the concentrations of ammonium thiocyanate and an active solvent are in a large excess of the zinc ion, and if the ammonium thiocyanate concentration is kept constant, the metal distribution ratio D becomes a function of only $[S]_o$.

Chemistry of 1,2-Thiaphosphole 2-Sulfides. II. Reactions of 1,2-Thiaphosphole 2-Sulfides with Some Nucleophiles

Hideyuki TANAKA, Takao SAITO, and Shinichi MOTOKI*
Department of Chemistry, Faculty of Science, Science University of Tokyo,
Kagurazaka, Shinjuku-ku, Tokyo 162
(Received April 1, 1985)

5-*t*-Butyl-1,2-thiaphosphole 2-sulfides reacted with alcohols, thiols, and amines to give the 1,4-adducts, 2-alkoxy-, 2-(*p*-tolylthio)-, and 2-alkyl(aryl)amino-1,2-thiaphosphol-3-ene 2-sulfides, respectively. However, the reactions of 5-phenyl-1,2-thiaphosphole 2-sulfides with cyclohexyl- and arylamines afforded 1,2,3-dithiaphosphorins.

Previously, we reported the synthesis of 2,9-dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-sulfides **A** and their thermolysis generating 1,2-thiaphosphole 2-sulfides **B** and α,β-unsaturated thiones **C**.[1] The sulfides **B** are unique intermediates containing phosphorus and sulfur in their unsaturated heterocyclic ring, and they have been found to undergo cycloaddition reactions with various dienophiles.[1] Meanwhile, interest is being shown in π-bonded phosphorus compounds such as methylenephosphine sulfides, -(S=)P=C , and related compounds.[2] Their reactions with some alcohols (as nucleophile) were also reported recently.[3]

Accordingly, it appeared of interest to investigate further reactions of **B**. The reaction with some nucleophilic reagents is reported in the present paper.

Results and Discussion

Reactions of Phosphabicyclo Compounds 1 with Alcohols, Phenols, Thiols, and Amines. Treatment of **1** with alcohols (phenols) afforded no product on refluxing in benzene. However reactions took place readily in the presence of NEt_3 to give the 1,4-adducts (**5**) of alcohols toward **3** along with thione (**4**) dimers **6**[1,4] (Scheme 2, Table 1). The reaction of **1** with cyclohexanol was carried out in refluxing xylene in the presence of NPr^n_3, since the reaction was slow in refluxing benzene.

The elemental analyses and the mass spectra indicated that **5** were 1:1 adducts of **3** and the alcohols. The adducts **5** showed strong IR absorption due to the P-O linkage at about 1000 cm^{-1}. In the ^1H NMR spectra,[6] H-4 and H-5 protons resonated at δ=6.8—6.9 and 4.2—4.3 with the coupling constant 3.0—3.5 Hz and the H-4 proton exhibited a large H-P coupling constant (J_{HP}=50—55 Hz)(Table 2). The ^{13}C NMR spectra[7] showed a signal of the C-3 olefinic carbon at δ=140—142 with a large C-P coupling constant (J_{CP}=100—107 Hz), suggesting a direct bonding of the P-C(3). Chemical shifts of signals assigned to the C-4 and C-5 carbons and their coupling constants are summarized in Table 2.

The reactions of **1** with *p*-toluenethiol or primary and secondary amines gave similarly the 1,4-adducts **7** or **8** along with **6** (Table 1). The structures of **7** and **8** were determined as described above for **5**[6,7] and the ^1H and ^{13}C NMR spectral assignments are listed in Table 2.

Table 2 shows that the magnitudes of the C-P coupling constants $J_{C(3)P}$ of **5**, **7**, and **8** are in the order of **5**>**8**>**7**. This result is in accord with the observation, reported previously, that the C-P coupling constants ($^1J_{CP}$) of the structurally related phosphorus compounds, 3-phospholene 1-sulfides,

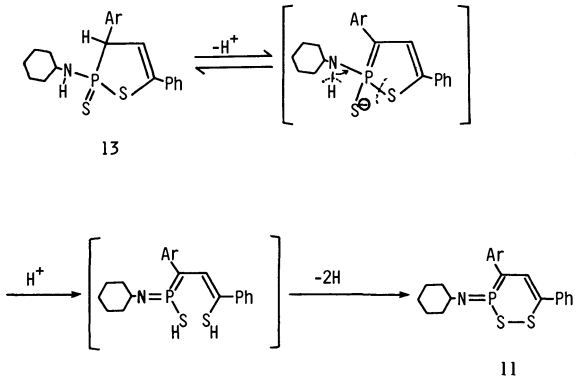
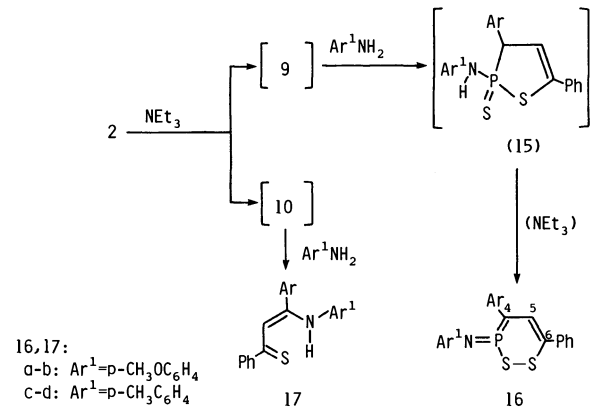


Scheme 4.



Scheme 5.

^1H NMR spectrum showed signals of the H-3 proton at δ=4.88 (J_{HH}=4.0 Hz, J_{HP}=15.0 Hz) and of the H-4 proton at δ=6.35 (J_{HH}=4.0 Hz, J_{HP}=36.0 Hz). These spectral patterns are similar to those of 1,2-thiaphosphol-4-ene 2-sulfide **14** reported previously[9] (Table 4). In the ^{13}C NMR spectrum, the resonance at δ=60.7 (J_{CP}=61.0 Hz) is assigned to the saturated C-3 carbon atom directly bonded to the phosphorus atom. Signals of the unsaturated carbons, C-4 and C-5, appeared at δ=120.4 (J_{CP}=4.9 Hz) and 141.8 (J_{CP}=11.0 Hz), respectively.

The mass spectrum of **11a** showed a molecular ion peak at *m/z* 397 [M$^+$] and an ion peak of [M$^+$ −2S] at *m/z* 333 as a base peak. The IR spectrum revealed no NH absorption band. The ^1H NMR spectrum exhibited a doublet of H-5 proton at δ=6.94 (J_{HP}=34.0 Hz) and the ^{13}C NMR spectrum displayed three signals at δ=161.3 (J_{CP}=81.8 Hz), 117.1 (J_{CP}= 11.0 Hz), and 169.2 (J_{CP}=14.7 Hz)(Table 5).

These spectral data support the proposed structures **11** and **13**. The compounds **11** were found to be very stable, probably due to the resonance stabilization of the dithiaphosphorin ring system. Treatment of **13** with NEt_3 produced **11** instead of the corresponding 1,4-adducts. A probable pathway for the formation of **11** from **13** is illustrated in Scheme 4.

The reactions of **2** with aromatic amines (*p*-anisidine, *p*-toluidine) afforded 3-amino-2-propene-1-thiones **17**[10] and 1,2,3-ditiaphosphorins **16** in contrast to the reactions with cyclohexylamine (Scheme 5, Table 3). This result is interesting but the dehydrogenation step to form **17** is still ambiguous.[11]

The accelerating effect of NEt_3 in these reactions is remarkable and the following three rationales can be considered: (1) The amine accelerates the dissociation of **A** into **B** and **C**. (2) The amine activates the nucleophiles. (3) The amine interacts with **A** at the positive center, the phosphorus atom, to activate **A** toward the nucleophiles. When the solution of **1** and the amine in benzene was heated in the absence of the nucleophiles, the solution turned greenish-blue. A benzene solution of **2** also colored even at room temperature on adding the amine. These observations suggest the generation of the monomeric thiones **C** (or dimers) and **B**. On the other hand, previously reported cycloaddition reactions of **A** with dienophiles (Scheme 1) were also found to be accelerated on addition of the amine. On the basis of these findings, the rationale (1) is considered to be most probable. However, the possibilities of (2) and (3) still remain, especially for the reactions of **1**.

Experimental

All melting points are uncorrected. IR spectra were measured on a Hitachi Model 260—10 spectrometer. ^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 spectrometer in $CDCl_3$ solution using Me_4Si as an internal standard (^1H; at 100 MHz, ^{13}C; at 25 MHz). ^{31}P NMR spectra were recorded at 40 MHz on a JEOL

JNM-FX 100 spectrometer using 85% H_3PO_4 as an external standard. Mass spectra were recorded on a Hitachi double focusing mass spectrometer (RMU-7M) operating at an ionizing potential of 70 eV. 2,9-Dithia-1-phosphabicyclo[4.3.0]nona-3,7-diene 1-sulfides **1** and **2** were prepared according to the previously described method.[1]

General Procedure for the Reactions of the Phosphabicyclo Compounds 1 or 2 with Nucleophilic Reagents (Alcohols, Phenols, Thiols, and Amines) to Afford 1,4- or 1,2-Adducts, 5, 7, 8, and 13: A solution of **1** (3 mmol) and a nucleophilic reagent (10 mmol) in 20 cm^3 of dry benzene (xylene) and 15 cm^3 of NEt_3 (NPr^n_3) was refluxed under a nitrogen atmosphere for 2—20 h until the phosphabicyclo compound **1** was consumed, as indicated by TLC (Reaction times are shown in Tables 1 and 3). After evaporation of the solvent the residue was chromatographed on silica gel (Wakogel C-200) with benzene–hexane (1:1) as an eluent to afford the adduct. Recrystallization from ethanol gave the adduct as colorless crystals. The reaction of **2** to afford **13** was carried out without NEt_3.

2-Benzyloxy-5-*t*-butyl-3-(*p*-tolyl)-1,2-thiaphosphol-3-ene 2-Sulfide (5a): IR (KBr) 2970, 1375, and 1000(P–O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.07 (s, 9H), 2.35 (s, 3H), 4.29 (dd, 1H, J_{HH}=3.4 Hz, J_{HP}=9.5 Hz), 5.06—5.28 (m, 2H), 6.85 (dd, 1H, J_{HH}=3.4 Hz, J_{HP}=52.0 Hz), and 6.93—7.54 (m, 9H); MS *m/z* (rel intensity) 388 (M^+, 18), 332 (17), 282 (22), 241 (55), 225 (47), 192 (28), 91 (100), and 57 (24). Found: C, 64.68; H, 6.23%. Calcd for $C_{21}H_{25}OPS_2$: C, 64.92; H, 6.49%.

2-Benzyloxy-5-*t*-butyl-3-phenyl-1,2-thiaphosphol-3-ene 2-Sulfide (5b): IR (KBr) 2970, 1370, and 990(P–O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.04 (s, 9H), 4.28 (dd, 1H, J_{HH}=3.5 Hz, J_{HP}=9.5 Hz), 5.06—5.28 (m, 2H), 6.88 (dd, 1H, J_{HH}=3.5 Hz, J_{HP}=54.0 Hz), and 7.00—7.68 (m, 10H); MS *m/z* (rel intensity) 374 (M^+, 16), 318 (17), 268 (25), 227 (42), 211 (30), 178 (37), 91 (100), and 57 (25). 5-*t*-Butyl-3-(*p*-chlorophenyl)-2-cyclohexyloxy-1,2-thiaphosphol-3-ene 2-Sulfide (5f): IR (KBr) 2970, 2950, 2860, 1370, and 985(P–O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.11 (s, 9H), 1.14—2.36 (broad m, 10H), 4.29 (dd, 1H, J_{HH}=3.0 Hz J_{HP}=9.8 Hz), 4.54—4.92 (broad m, 1H), 6.83 (dd, 1H, J_{HH}=3.0 Hz, J_{HP}=54.0 Hz), 7.28 (d, 2H, J_{HH}=9.0 Hz), and 7.54 (dd, 2H, J_{HH}=9.0 Hz, J_{HP}=1.5 Hz); MS *m/z* (rel intensity) 400 (M^+, 2), 319 (100), 262 (45), 245 (9), 229 (14), and 57 (44). Found: C, 56.54; H, 6.12%. Calcd for $C_{19}H_{26}OPS_2Cl$: C, 56.92; H, 6.54%.

5-*t*-Butyl-2-phenoxy-3-(*p*-tolyl)-1,2-thiaphosphol-3-ene 2-Sulfide (5g): IR (KBr) 2970, 1370, and 900(P–O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.07 (s, 9H), 2.39 (s, 3H), 4.35 (dd, 1H, J_{HH}=3.2 Hz, J_{HP}=9.8 Hz), ≈6.9 (dd, 1H, J_{HH}=3.2 Hz, J_{HP}≈50 Hz), 6.94—7.38 (m, 7H), and 7.64 (dd, 2H, J_{HH}=8.0 Hz, J_{HP}=1.5 Hz); MS *m/z* (rel intensity) 374 (M^+, 7), 318 (100), 281 (9), 225 (71), 192 (22), 161 (17), and 57 (35). Found: C, 64.13; H, 6.12%. Calcd for $C_{20}H_{23}OPS_2$: C, 64.14; H, 6.19%.

5-*t*-Butyl-2-phenoxy-3-phenyl-1,2-thiaphosphol-3-ene 2-Sulfide (5h): IR (KBr) 2970, 1370, and 905(P–O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.07 (s, 9H), 4.36 (dd, 1H, J_{HH}=3.2 Hz, J_{HP}=9.3 Hz), ≈6.9 (dd, 1H J_{HH}=3.2 Hz, J_{HP}≈50 Hz), 6.88—7.50 (m, 8H), and 7.60—7.84 (m, 2H); MS *m/z* (rel intensity) 360 (M^+, 7), 304 (100), 267 (11), 211 (88), 178 (23), 147 (28), and 57 (56). Found: C, 63.62; H, 5.86; S, 17.72%. Calcd for $C_{19}H_{21}OPS_2$: C, 63.31; H, 5.87; S, 17.79%.

5-*t*-Butyl-3-(*p*-chlorophenyl)-2-phenoxy-1,2-thiaphosphol-3-ene 2-Sulfide (5i): IR (KBr) 2970, 1370, 905(P–O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.08 (s, 9H), 4.37 (dd, 1H, J_{HH}=3.1 Hz, J_{HP}=10.0 Hz), ≈6.9 (dd, 1H, J_{HH}=3.1 Hz, J_{HP}≈50 Hz), 6.86—7.48 (m, 7H), and 7.70 (dd, 2H, J_{HH}=9.0 Hz, J_{HP}=1.7 Hz); MS *m/z* (rel intensity) 394 (M^+, 7), 338 (100), 301 (7), 245 (58), 212 (16), 181 (16), and 57 (84). Found: C, 57.88; H, 5.08%. Calcd for $C_{19}H_{20}OPS_2Cl$: C, 57.79; H, 5.10%.

5-*t*-Butyl-2-(*p*-tolylthio)-3-(*p*-tolyl)-1,2-thiaphosphol-3-ene 2-Sulfide (7a): IR (KBr) 2970 and 1375 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.81 (s, 9H), 2.29 (s, 3H), 2.41 (s, 3H), 4.43 (d, 1H, J_{HH}=2.0 Hz), 6.64 (dd, 1H, J_{HH}=2.0 Hz, J_{HP}=55.0 Hz), 6.96—7.40 (m, 6H), and 7.74 (d, 2H, J_{HH}=9.0 Hz); MS *m/z* (rel intensity) 404 (M^+, 14), 372 (2), 348 (3), 281 (60), 225 (100), 193 (61), 192 (33), 123 (11), and 57 (76). Found: C, 62.17; H, 6.04%. Calcd for $C_{21}H_{25}PS_3$: C, 62.34; H, 6.23%.

5-*t*-Butyl-3-phenyl-2-(*p*-tolylthio)-1,2-thiaphosphol-3-ene 2-Sulfide (7b): IR (KBr) 2975 and 1375 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.83 (s, 9H), 2.28 (s, 3H), 4.44 (d, 1H, J_{HH}=2.5 Hz), 6.65 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=54.5 Hz), 6.98—7.48 (m, 7H), and 7.74—7.92 (m, 2H); MS *m/z* (rel intensity 390 (M^+, 26), 358 (2), 334 (3), 267 (63), 211 (100), 178 (49), 123 (14), and 57 (91). Found: C, 61.23; H, 5.84; S, 24.55%. Calcd for $C_{20}H_{23}PS_3$: C, 61.51; H, 5.94; S, 24.63%.

5-*t*-Butyl-3-(*p*-chlorophenyl)-2-(*p*-tolylthio)-1,2-thiaphosphol-3-ene 2-Sulfide (7c): IR (KBr) 2970 and 1375 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.83 (s, 9H), 2.30 (s, 3H), 4.44 (d, 1H, J_{HH}=2.5 Hz), 6.65 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=54.0 Hz), 6.98—7.22 (m, 4H), 7.34 (d, 2H, J_{HH}=9.0 Hz), and 7.78 (d, 2H, J_{HH}=9.0 Hz); MS *m/z* (rel intensity) 424 (M^+, 6), 392 (1), 368 (1), 301 (15), 245 (27), 212 (12), 123 (12), and 57 (100). Found: C, 56.91; H, 5.32%. Calcd for $C_{20}H_{22}PS_3Cl$: C, 56.52; H, 5.22%.

5-*t*-Butyl-2-cyclohexylamino-3-(*p*-tolyl)-1,2-thiaphosphol-3-ene 2-Sulfide (8a): IR (KBr) 3260 (NH), 2970, 2940, 2850,

and 1365 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.80—1.80 (broad m, 9H), 1.11 (s, 9H), 1.84—2.12 (broad m, 1H), 2.35 (s, 3H), 3.02 (broad d, 2H, J_{HP}=12.0 Hz), 4.25 (d, 1H, J_{HH}=2.0 Hz), 6.83 (dd, 1H, J_{HH}=2.0 Hz, J_{HP}=52.0 Hz), 7.11 (d, 2H, J_{HH}=8.0 Hz), and 7.67 (d, 2H, J_{HH}=8.0 Hz); MS *m/z* (rel intensity) 379 (M^+, 1), 346 (4), 225 (7), 192 (5), 98 (100), and 57 (8). Found: C, 62.86; H, 8.14; N, 3.58%. Calcd for $C_{20}H_{30}NPS_2$: C, 63.29; H, 7.97; N, 3.69%.

5-*t*-Butyl-2-cyclohexylamino-3-phenyl-1,2-thiaphosphol-3-ene 2-Sulfide (8b): IR (KBr) 3200 (NH), 2970, 2940, 2850, and 1365 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.80—1.80 (broad m, 9H), 1.13 (s, 9H), 1.84—2.16 (broad m, 1H), 2.93 (broad d, 2H, J_{HP}=12.0 Hz), 4.31 (d, 1H, J_{HH}=2.0 Hz), 6.83 (dd, 1H, J_{HH}=2.0 Hz, J_{HP}=52.0 Hz), 7.12—7.40 (m, 3H), and 7.60—7.84 (m, 2H); MS *m/z* (rel intensity) 365 (M^+, 1), 332 (4), 211 (6), 178 (5), 98 (100), and 57 (11). Found: C, 62.58; H, 7.84; N, 3.53%. Calcd for $C_{19}H_{28}NPS_2$: C, 62.43; H, 7.72; N, 3.83%.

5-*t*-Butyl-3-(*p*-chlorophenyl)-2-cyclohexylamino-1,2-thiaphosphol-3-ene 2-Sulfide (8c): IR (KBr) 3300 (NH), 2970, 2940, 2860, and 1370 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.80—1.80 (broad m, 9H), 1.12 (s, 9H), 1.88—2.20 (broad m, 1H), 2.96 (broad d, 2H, J_{HP}=11.7 Hz), 4.30 (d, 1H, J_{HH}=2.5 Hz), 6.86 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=52.2 Hz), 7.26 (d, 2H, J_{HH}=9.0 Hz), and 7.70 (d, 2H, J_{HH}=9.0 Hz); ^{31}P NMR ($CDCl_3$) δ=90.3 (ddd, J_{PH}=52.2, 11.7, and 11.7 Hz); MS *m/z* (rel intensity) 399 (M^+, 1), 366 (3), 300 (1), 245 (4), 212 (5), 98 (100), and 57 (18). Found: C, 57.35; H, 6.95; N, 3.48; P, 7.28; S, 16.20%. Calcd for $C_{19}H_{27}NPS_2Cl$: C, 57.06; H, 6.80; N, 3.50; P, 7.74; S, 16.03%.

2-Butylamino-5-*t*-butyl-3-(*p*-tolyl)-1,2-thiaphosphol-3-ene 2-Sulfide (8d): IR (KBr) 3270 (NH), 2960, 2850, and 1365 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.70—1.62 (m, 7H), 1.12 (s, 9H), 2.35 (s, 3H), 2.72—3.08 (m, 3H), 4.30 (d, 1H, J_{HH}=3.5 Hz), 6.76 (dd, 1H, J_{HH}=3.5 Hz, J_{HP}=52.0 Hz), 7.13 (d, 2H, J_{HH}=9.0 Hz), and 7.58 (d, 2H, J_{HH}=9.0 Hz); MS *m/z* (rel intensity) 353 (M^+, 4), 320 (1), 296 (2), 281 (1), 225 (16), 192 (9), 72 (100), and 57 (13). Found: C, 61.00; H, 8.35; N, 3.81%. Calcd for $C_{18}H_{28}NPS_2$: C, 61.16; H, 7.98; N, 3.96%.

2-Butylamino-5-*t*-butyl-3-phenyl-1,2-thiaphosphol-3-ene 2-Sulfide (8e): IR (KBr) 3210 (NH), 2960, 2850, and 1360 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.64—1.62 (m, 7H), 1.12 (s, 9H), 2.68—3.20 (m, 3H), 4.30 (d, 1H, J_{HH}=2.5 Hz), 6.83 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=51.0 Hz), 7.19—7.44 (m, 3H), and 7.54—7.78 (m, 2H); MS *m/z* (rel intensity) 339 (M^+, 2), 306 (2), 282 (2), 267 (1), 211 (12), 178 (1), 72 (100), and 57 (17). Found: C, 60.13; H, 7.89; N, 4.27%. Calcd for $C_{17}H_{26}NPS_2$: C, 60.14; H, 7.72; N, 4.13%.

2-Butylamino-5-*t*-butyl-3-(*p*-chlorophenyl)-1,2-thiaphosphol-3-ene 2-Sulfide (8f): IR (KBr) 3280 (NH), 2960, 2860, and 1365 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.60—1.77 (m, 7H), 1.12 (s, 9H), 2.60—3.21 (m, 3H), 4.30 (d, 1H, J_{HH}=2.5 Hz), 6.82 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=51.0 Hz), 7.28 (d, 2H, J_{HH}=8.0 Hz), and 7.65 (d, 1H, J_{HH}=8.0 Hz); MS *m/z* (rel intensity) 373 (M^+, 2), 340 (1), 316 (1), 301 (1), 245 (6), 212 (6), 72 (100), and 57 (21). Found: C, 54.61; H, 6.83; N, 3.53%. Calcd for $C_{17}H_{25}NPS_2Cl$: C, 54.60; H, 6.74; N, 3.75%.

5-*t*-Butyl-2-piperidino-3-(*p*-tolyl)-1,2-thiaphosphol-3-ene 2-Sulfide (8g): IR (KBr) 2970, 2945, 2850, and 1370 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (s, 9H), 1.24—1.76 (broad m, 6H), 2.34 (s, 3H), 3.06—3.54 (broad m, 4H), 4.33 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=2.5 Hz), 6.81 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=53.5 Hz), 7.09 (d, 2H, J_{HH}=7.5 Hz), and 7.55 (d, 2H, J_{HH}=7.5 Hz); MS *m/z* (rel intensity) 365 (M^+, 2), 332 (3), 225 (8), 192 (5), 84 (100), and 57 (8). Found: C, 62.78; H, 7.85; N, 3.60%. Calcd for $C_{19}H_{28}NPS_2$: C, 62.43; H, 7.72; N, 3.83%.

5-*t*-Butyl-3-phenyl-2-piperidino-1,2-thiaphosphol-3-ene 2-Sulfide (8h): IR (KBr) 2970, 2945, 2850, and 1365 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (s, 9H), 1.20—1.83 (broad m, 6H), 2.94—3.58 (broad m, 4H), 4.36 (dd, 1H, J_{HH}=2.0 Hz, J_{HP}=2.5 Hz), 6.86 (dd, 1H, J_{HH}=2.0 Hz, J_{HP}=53.0 Hz), 7.18—7.50 (m, 3H), and 7.53—7.81 (m, 2H); MS *m/z* (rel intensity) 351 (M^+, 1), 318 (3), 294 (1), 211 (7), 178 (7), 84 (100) and 57 (10). Found: C, 61.60; H, 7.61; N, 3.71%. Calcd for $C_{18}H_{26}NPS_2$: C, 61.51; H, 7.40; N, 3.98%.

5-*t*-Butyl-3-(*p*-chlorophenyl)-2-piperidino-1,2-thiaphosphol-3-ene 2-Sulfide (8i): IR (KBr) 2970, 2945, 2850, and 1375 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.12 (s, 9H), 1.20—1.72 (broad m, 6H), 2.96—3.52 (broad m, 4H), 4.32 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=1.5 Hz), 6.86 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=48.0 Hz), 7.26 (d, 2H, J_{HH}=8.0 Hz), and 7.64 (d, 2H, J_{HH}=8.0 Hz); MS *m/z* (rel intensity) 385 (M^+, 1), 352 (2), 245 (3), 212 (4), 84 (100), and 57 (16). Found: C, 56.34; H, 6.66; N, 3.59; S, 16.33%. Calcd for $C_{18}H_{25}NPS_2Cl$: C, 56.02; H, 6.53; N, 3.63; S, 16.61%.

5-*t*-Butyl-2-(*p*-methoxyphenylamino)-3-(*p*-tolyl)-1,2-thiaphosphol-3-ene 2-Sulfide (8j): IR (KBr) 3150 (NH), 2960, and 1370 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (s, 9H), 2.35 (s, 3H), 3.70 (s, 3H), 4.27 (d, 1H, J_{HH}=2.0 Hz), 5.14 (broad d, 1H, J_{HP}=7.0 Hz), 6.64 (d, 2H, J_{HH}=8.0 Hz), 6.84 (d, 2H, J_{HH}=8.0 Hz), 6.88 (dd, 1H, J_{HH}=2.0 Hz, J_{HP}=54.0 Hz), 7.14 (dd, 2H, J_{HH}=8.0 Hz, J_{HP}=3.0 Hz), and 7.72 (d, 2H, J_{HH}=8.0 Hz); MS *m/z* (rel intensity) 403 (M^+, 100), 371 (1), 346 (11), 281 (20), 250 (26), 225 (80), 192 (22), 123 (95), and 57 (40). Found: C, 62.33; H, 6.47; N, 3.45%. Calcd for $C_{21}H_{26}NOPS_2$: C, 62.51; H, 6.49; N, 3.47%.

5-*t*-Butyl-2-(*p*-methoxyphenylamino)-3-phenyl-1,2-thiaphosphol-3-ene 2-Sulfide (8k): IR (KBr) 3210 (NH), 2960, and 1365 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (s, 9H), 3.70 (s, 3H), 4.28 (d, 1H, J_{HH}=3.5 Hz), 5.16 (broad d, 1H, J_{HP}=7.0 Hz), 6.64 (d, 2H, J_{HH}=9.0 Hz), 6.83 (dd, 1H, J_{HH}=3.5 Hz, J_{HP}=54.0 Hz), 6.83 (dd, 2H, J_{HH}=9.0 Hz, J_{HP}=2.0 Hz), 7.20—7.36 (m, 3H), and 7.70—7.88 (m, 2H); MS *m/z* (rel intensity) 389 (M^+, 68), 357 (1), 333 (6), 267 (18), 236 (15), 211 (76), 178 (17), 123 (100), and 57 (42). Found: C, 61.41; H, 6.37; N, 3.31%. Calcd for $C_{20}H_{24}NOPS_2$: C, 61.67; H, 6.21; N, 3.60%.

5-*t*-Butyl-3-(*p*-chlorophenyl)-2-(*p*-methoxyphenylamino)-1,2-thiaphosphol-3-ene 2-Sulfide (8l): IR (KBr) 3220 (NH), 2970, and 1370 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (s, 9H), 3.72 (s, 3H), 4.28 (d, 1H, J_{HH}=2.5 Hz), 5.18 (broad d, 1H, J_{HP}=8.0 Hz), 6.66 (d, 2H, J_{HH}=9.0 Hz), 6.84 (dd, 1H, J_{HH}=2.5 Hz, J_{HP}=52.5 Hz), 6.84 (dd, 2H, J_{HH}=9.0 Hz, J_{HP}=2.0 Hz), 7.30 (d, 2H, J_{HH}=8.0 Hz), and 7.78 (dd, 2H, J_{HH}=8.0 Hz, J_{HP}=1.0 Hz); MS *m/z* (rel intensity) 423 (M^+, 55), 391 (2), 367 (5), 301 (9), 270 (9), 245 (35), 212 (10), 123 (100), and 57 (57). Found: C, 56.27; H, 5.48; N, 3.05; S, 15.48%. Calcd for $C_{20}H_{23}NOPS_2Cl$: C, 56.66; H, 5.47; N, 3.30; S, 15.12%.

2-Cyclohexylamino-5-phenyl-3-(*p*-tolyl)-1,2-thiaphosphol-4-ene 2-Sulfide (13a): IR (KBr) 3200 (NH), 2950, and 2860 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96—2.20 (broad m, 10H),

2.36 (s, 3H), 3.08—3.64 (broad m, 2H), 4.88 (dd, 1H, J_{HH}=4.0 Hz, J_{HP}=15.0 Hz), 6.35 (dd, 1H, J_{HH}=4.0 Hz, J_{HP}=36.0 Hz), and 7.08—7.68 (m, 9H); MS *m/z* (rel intensity) 399 (M^+, 12), 366 (12), 300 (6), 238 (25), 237 (58), 205 (19), and 98 (100). Found: C, 66.40; H, 6.55; N, 3.21%. Calcd for $C_{22}H_{26}NPS_2$: C, 66.14; H, 6.56; N, 3.51%.

2-Cyclohexylamino-3,5-diphenyl-1,2-thiaphosphol-4-ene 2-Sulfide (13b): IR (KBr) 3175 (NH), 2940, and 2850 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96—2.20 (broad m, 10H), 3.08—3.64 (broad m, 2H), 4.51 (dd, 1H, J_{HH}=4.0 Hz, J_{HP}=15.5 Hz), 6.32 (dd, 1H, J_{HH}=4.0 Hz, J_{HP}=36.0 Hz), and 7.08—7.60 (m, 10H); MS *m/z* (rel intensity) 385 (M^+, 5), 352 (9), 286 (6), 224 (4), 223 (100), and 98 (86). Found: C, 65.34; H, 6.36; N, 3.44; S, 16.63%. Calcd for $C_{21}H_{24}NPS_2$: C, 65.43; H, 6.27; N, 3.44; S, 16.63%.

6-*t*-Butyl-3-[*t*-butyl(thiocarbonyl)]-2,4-bis(*p*-tolyl)-3,4-dihydro-2*H*-thiin (6a): IR (neat) 2970 and 1370 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.08 (s, 9H), 1.24 (s, 9H), 2.18 (s, 3H), 2.30 (s, 3H), 3.73 (dd, 1H, J_{HH}=2.4, 6.4 Hz), 4.33 (dd, 1H, J_{HH}=2.4, 6.4 Hz), 4.58 (d, 1H, J_{HH}=6.4 Hz), 5.87 (d, 1H, J_{HH}=6.4 Hz), and 6.72—7.35 (m, 8H); MS *m/z* (rel intensity) 436 (M^+), 218 (27), 161 (100).

6-*t*-Butyl-3-[*t*-butyl(thiocarbonyl)]-2,4-diphenyl-3,4-dihydro-2*H*-thiin (6b): IR (neat) 2970 and 1370 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.07 (s, 9H), 1.25 (s, 9H), 3.77 (dd, 1H, J_{HH}=2.8, 6.4 Hz), 4.33 (dd, 1H, J_{HH}=2.8, 6.8 Hz), 4.63 (d, 1H, J_{HH}=6.8 Hz), 5.88 (d, 1H, J_{HH}=6.4 Hz), and 6.40—7.33 (m, 10H); MS *m/z* (rel intensity) 408 (M^+, 2), 204 (38), and 147 (100).

6-*t*-Butyl-3-[*t*-butyl(thiocarbonyl)]-2,4-bis(*p*-chlorophenyl)-3,4-dihydro-2*H*-thiin (6c): IR (neat) 2970, 1370, and 1100 (C=S) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.08 (s, 9H), 1.24 (s, 9H), 3.74 (dd, 1H, J_{HH}=4.0, 6.9 Hz), 4.43 (dd, 1H, J_{HH}=4.0, 11.0 Hz), 4.66 (d, 1H, J_{HH}=11.0 Hz), 5.87 (d, 1H, J_{HH}=6.9 Hz), and 6.40—7.20 (m, 8H); MS *m/z* (rel intensity) 476 (M^+), 238 (25), and 181 (100).

General Procedure for the Reactions of the Phosphabicyclo Compounds 2 with Amines to Afford 11, 16, and 17: A solution of **2** (3 mmol) and amine (10 mmol) in dry benzene (20 cm^3) and NEt_3 (15 cm^3) was stirred at room temperature under a nitrogen atmosphere until the phosphabicyclo compound **2** was consumed as indicated by TLC (2 weeks). The solvent was removed and the residue was chromatographed on silica gel (Wakogel C-200) with benzene–hexane (2:3) as an eluent. The solvent was evaporated and the residue was recrystallized to give the products as red crystals (**11**, **16**; from hexane–ethanol, **17**; from ethanol).

3-Cyclohexylimino-6-phenyl-4-(*p*-tolyl)-1,2,3-dithiaphosphorin (11a): IR (KBr) 2940 and 2850 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.84—2.56 (broad m, 9H), 2.40 (s, 3H), 4.40—4.80 (m, 2H), 6.94 (d, 1H, J_{HP}=34.0 Hz), 7.12—7.76 (m, 7H), and 8.06 (d, 2H, J_{HH}=9.0 Hz); MS *m/z* (rel intensity) 397 (M^+, 9), 364 (38), 333 (100), and 251 (33). Found: C, 66.73; H, 6.10; N, 3.34%. Calcd for $C_{22}H_{24}NPS_2$: C, 66.47; H, 6.09; N, 3.52%.

3-Cyclohexylimino-4,6-diphenyl-1,2,3-dithiaphosphorin (11b): IR (KBr) 2940 and 2860 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90—2.48 (broad m, 9H), 4.28—4.80 (m, 2H), 6.94 (d, 1H, J_{HP}=34.0 Hz), 7.20—7.84 (m, 8H), and 8.04—8.36 (m, 2H); MS *m/z* (rel intensity) 383 (M^+, 15), 350 (41), 319 (57), and 237 (100). Found: C, 65.70; H, 5.92; N, 3.77%. Calcd for $C_{21}H_{22}NPS_2$: C, 65.77; H, 5.78; N, 3.65%.

3-(*p*-Methoxyphenylimino)-6-phenyl-4-(*p*-tolyl)-1,2,3-dithiaphosphorin (16a): ^1H NMR ($CDCl_3$) δ=2.44 (s, 3H), 3.83 (s, 3H), 6.80—7.00 (m, 2H), 7.16—7.68 (m, 9H), 7.37 (d, 1H, J_{HP}=34.0 Hz), and 8.20 (d, 2H, J_{HH}=9.0 Hz); MS *m/z* (rel intensity) 421 (M^+, 21), 357 (100), and 138 (52). Found: C, 65.83; H, 4.76; N, 2.90%. Calcd for $C_{23}H_{20}NOPS_2$: C, 65.54; H, 4.78; N, 3.32%.

3-(*p*-Methoxyphenylimino)-4,6-diphenyl-1,2,3-dithiaphosphorin (16b): ^1H NMR ($CDCl_3$) δ=3.84 (s, 3H), 6.80—7.00 (m, 2H), 7.20—7.70 (m, 10H), 7.42 (d, 1H, J_{HP}=34.2 Hz), and 8.12—8.40 (m, 2H); ^{31}P NMR ($CDCl_3$) δ=114.6 (d, J_{PH}=34.2 Hz); MS *m/z* (rel intensity) 407 (M^+, 4), 343 (100), and 138 (40). Found: C, 65.10; H, 4.41; N, 3.10; S, 15.28%. Calcd for $C_{22}H_{18}NOPS_2$: C, 64.85; H, 4.45; N, 3.44; S, 15.74%.

6-Phenyl-3-(*p*-tolylimino)-4-(*p*-tolyl)-1,2,3-dithiaphosphorin (16c): ^1H NMR ($CDCl_3$) δ=2.36 (s, 3H), 2.40 (s, 3H), 6.96—7.64 (m, 9H), 7.37 (d, 1H, J_{HP}=34.0 Hz), 8.09 (d, 2H, J_{HH}=9.0 Hz), and 8.18 (d, 2H, J_{HH}=8.0 Hz); MS *m/z* (rel intensity) 405 (M^+, 8), 371 (7), and 341 (100). Found: C, 68.70; H, 4.63; N, 3.10%. Calcd for $C_{23}H_{20}NPS_2$: C, 68.12; H, 4.97; N, 3.45%.

4,6-Diphenyl-3-(*p*-tolylimino)-1,2,3-dithiaphosphorin (16d): ^1H NMR ($CDCl_3$) δ=2.37 (s, 3H), 7.04—7.76 (m, 12H), 7.42 (d, 1H, J_{HP}=34.0 Hz), and 8.12—8.40 (m, 2H); MS *m/z* (rel intensity) 391 (M^+, 13), 357 (3), and 327 (100). Found: C, 67.49; H, 4.36; N, 3.58%. Calcd for $C_{22}H_{18}NPS_2$: C, 67.50; H, 4.63; N, 3.58%.

3-(*p*-Methoxyphenylamino)-1-phenyl-3-(*p*-tolyl)-2-propene-1-thione (17a): ^1H NMR ($CDCl_3$) δ=2.32 (s, 3H), 3.69 (s, 3H), 6.65 (d, 2H, J_{HH}=9.0 Hz), 6.78 (s, 1H), 6.83 (d, 2H, J_{HH}=9.0 Hz), 6.96—7.44 (m, 7H), 7.60—7.88 (m, 2H), and 15.85 (broad s, 1H); MS *m/z* (rel intensity) 359 (M^+, 61), 358 (82), 326 (9), and 252 (100). Found: C, 76.45; H, 5.90; N, 3.54%. Calcd for $C_{23}H_{21}NOS$: C, 76.85; H, 5.89; N, 3.90%.

3-(*p*-Methoxyphenylamino)-1,3-diphenyl-2-propene-1-thione (17b): ^1H NMR ($CDCl_3$) δ=3.68 (s, 3H), 6.62 (d, 2H, J_{HH}=9.0 Hz), 6.76 (s, 1H), 6.79 (d, 2H, J_{HH}=9.0 Hz), 7.29 (m, 8H), 7.68—7.80 (m, 2H), and 15.86 (broad s, 1H); MS *m/z* (rel intensity) 345 (M^+, 64), 344 (100), 312 (7), and 238 (89). Found: C, 76.51; H, 5.62; N, 3.88%. Calcd for $C_{22}H_{19}NOS$: C, 76.49; H, 5.54; N, 4.05%.

1-Phenyl-3-(*p*-tolylamino)-3-(*p*-tolyl)-2-propene-1-thione (17c): ^1H NMR ($CDCl_3$) δ=2.22 (s, 3H), 2.32 (s, 3H), 6.64—7.36 (m, 11H), 6.76 (s, 1H), 7.60—7.80 (m, 2H), and 15.81 (broad s, 1H); MS *m/z* (rel intensity) 343 (M^+, 60), 342 (96), 310 (12), and 252 (100). Found: C, 80.62; H, 6.11; N, 3.80%. Calcd for $C_{23}H_{21}NS$: C, 80.43; H, 6.16; N, 4.08%.

1,3-Diphenyl-3-(*p*-tolylamino)-2-propene-1-thione (17d): ^1H NMR ($CDCl_3$) δ=2.22 (s, 3H), 6.72 (d, 2H, J_{HH}=9.0 Hz), 6.77 (s, 1H), 6.90 (d, 2H, J_{HH}=9.0 Hz), 7.14—7.38 (m, 8H), 7.68—7.80 (m, 2H), and 15.83 (broad s, 1H); MS *m/z* (rel intensity) 329 (M^+, 49), 328 (78), 296 (11), and 238 (100). Found: C, 79.88; H, 5.79; N, 4.07%. Calcd for $C_{22}H_{19}NS$: C, 80.20; H, 5.81; N, 4.25%. The ^1H NMR spectrum is identical with that reported by Quiniou et al.[9]

The authors wish to thank Dr. Jun Uzawa for measuring the ^{31}P NMR spectra and also Messrs.

Toshiaki Kubota, Yoichi Sawayanagi, and Etsuji Takanobu for technical assistance.

Isopropylidenation of Raffinose[1)]

Toshiki OTAKE* and Junko TSUKAHARA
Department of Food and Nutrition, Yamanashi Gakuin Junior College,
2-4-5, Sakaori, Kofu 400
(Received April 23, 1985)

A reaction of raffinose with an excess amount of 2,2-dimethoxypropane and *p*-toluenesulfonic acid as a catalyst in *N,N'*-dimethylformamide, followed by acetylation, gave seven kinds of mono-, di, or tri-*O*-isopropylideneraffinose peracetates with at least five kinds of minor products. A reaction of raffinose with a limited amount of 2,2-dimethoxypropane gave a new isopropylidene derivative with some of the derivatives described above. The isopropylidenation occurred at 1′,2-, 2,3-, 2″,3″-, 3,4-, 3″,4″-, and 4″,6″-positions. The structures of these compounds were established by ^{1}H and ^{13}C NMR analyses.

The importance of cyclic acetals for the selective blocking of hydroxyl groups in carbohydrate chemistry has long been recognized.[2)] However isopropylidenation of nonreducing sugars like sucrose and raffinose with acetone and an acidic catalyst had been unsuccessful. In 1975, Khan and Mufti[3–5)] investigated the reaction of sucrose with a combination of DMP,*1 DMF,*2 and TSA*3 called reagent A. They obtained 4,6-*O*-isopropylidenesucrose and 1′,2:4,6-di-*O*-isopropylidenesucrose. The author[6)] has reported the isopropylidenation of 6,6′-di-*O*-palmitoylsucrose with reagent A. The main product was 1′,2-*O*-isopropylidene-6,6′-di-*O*-palmitoylsucrose.

Salam[7,8)] has reported that treatment of raffinose (**1**) with benzylidene bromide in pyridine followed by acetylation gave 3″,4″-*O*-benzylideneraffinose nonaacetate and 1′,2:4″,6″-di-*O*-benzylideneraffinose heptaacetate, and that treatment of **1** with reagent A yielded 4″,6″-*O*-isopropylideneraffinose in 21% yield. This paper will deal with mono-, di-, or tri-*O*-isopropylideneraffinose peracetates acetalated at 1′,2-, 2,3-, 2″,3″-, 3,4-, 3″,4″-, or 4″,6″-positions using reagent A.

Results and Discussion

Reaction of **1** with DMP in a molar ratio of 1:20 and TSA in DMF for 80 min, gave a mixture of isopropylidene(Ip) derivatives of **1**. By thin-layer chromatography(TLC), the complete consumption of **1** was confirmed. On a silica-gel TLC of the acetylation product of the above reaction mixture (developed four times with an admixture of diethyl ether and hexane (4:1 or 5:1)), at least seven spots were separately observed. They were designated in R_f's order (high to low) as **2** to **8**. After recycling column chromatography of the acetates about 35 times on an open column of silica gel eluted with a solvent system of diethyl ether and hexane or diisopropyl ether and hexane, the seven acetates were isolated as pure or almost pure forms on a TLC, and at least five minor components were also separated as almost pure forms. Yields of the seven acetates were 0.8 (**2**), 4.0 (**3**), 3.4 (**4**), 3.5 (**5**), 25.4 (**6**), 3.5 (**7**), and 5.5% (**8**), respectively. The major component was **6**. Compounds **3**, **6**, **7**, and **8** were crystallized as needles, respectively. From an elementary analysis, and ^{1}H and ^{13}C NMR analyses of acetyl methyl proton signals and methyl and quaternary carbon signals of the Ip-groups (Tables 1 and 2), the degree of isopropylidenation was estimated as shown in Table 3. Figure 1 shows schematic spectra of the acetates in the region of methyl and quaternary carbons of the Ip-group. By following common signals on the spectra of the eight compounds, at

*1 2,2-Dimethoxypropane, *2 *N,N'*-Dimethylformamide, *3 *p*-Tolueneesulfonic acid.

least, six sets of signals were distinguished. Compound **9** will be described later. Each set consists of signals of two methyl carbons and one quaternary carbon in the same Ip-group. The Ip-groups corresponding to each set were designated as Ip-1 to Ip-6. The mean δ-values of the carbons in each Ip-group are as follows: Ip-1, δ=26.26, 27.82, and 109.85; Ip-2, δ=26.62, 26.81, and 111.02; Ip-3, δ=26.57, 26.68, 110.23; Ip-4, δ=23.93, 25.43, and 101.51; Ip-5, δ=26.20, 26.91, and 111.57; Ip-6, δ=18.50, 29.38, and 98.79. Possible assignments of the Ip-groups to each compound are as follows: **2**, Ip-1, Ip-2, and Ip-4; **3**, Ip-1, and Ip-4; **4**, Ip-2, Ip-4, and Ip-6; **5**, Ip-3, Ip-4, and Ip-6; **6**, Ip-4 and Ip-6; **7**, Ip-5 and Ip-6; **8**, Ip-6; **9**, Ip-1.

6	Di	7	4	2
7	Di	7	4	2
8	Mono	9	2	1
9	Mono	9	2	1

The structure of each compound was established by ^{1}H NMR with the aid of the 180° pulse-τ-90° pulse method[9,10] or others. The signal of the free induction decay of the 90° pulse was recorded and Fourier-transformed. At a τ-value of 0.15 s, the intensity of methylene-proton signal was almost zero, and methine protons showed negative signals. At a τ-value of 0.30—0.35 s, the intensities of methine-proton signals were low (positive or negative) and methylene protons showed positive signals.

First-order analyses of the eight compounds are summarized in Tables 4-1 and 4-2. Signals of the glycosylated methylene (H-6a and H-6b), Ip-*O*-methylene and methine protons are in a region between 3.3 and 4.3 ppm. Signals of acetoxy-substituted methylene and methine protons adjacent to the methylene group (H-5, H-5′, and H-5″) are in a region between 4.3 and 4.5 ppm, while signals of anomeric and other acetoxy-substituted methine protons fall in a region over 4.6 ppm.[11,12]

From the high-field shifts of H-4″ and H-6″ (2H), **8** was estimated to be 4″,6″-*O*-isopropylideneraffinose nonaacetate. Two symmetric proton signals, centered on 5.25 ppm, are regarded as signals of H-2″ and H-3″. This pattern is caused by a similar environment of the two protons:

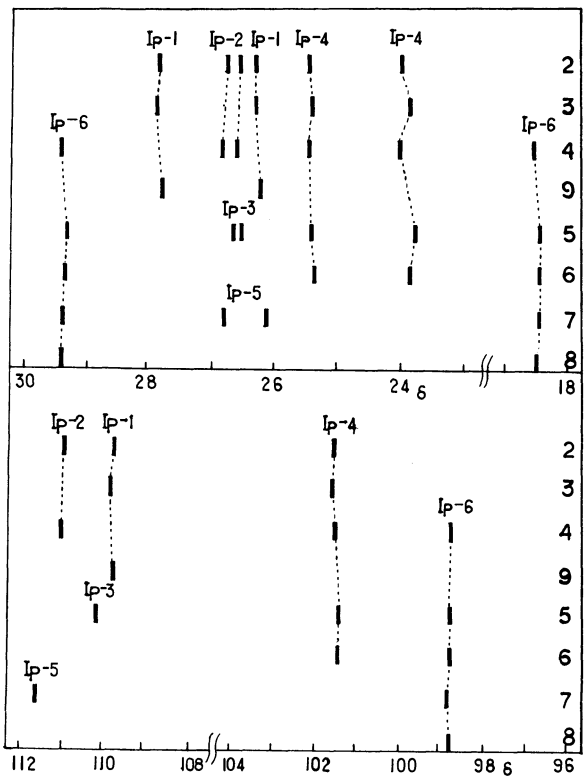

Fig. 1. Schematic ^{13}C NMR spectra of methyl (δ 18—30) and quaternary carbons (δ 96—112) of the Ip-group.

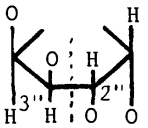

Other acetoxy-substituted methine signals (H-2, H-3, H-4, H-3′, and H-4′) were well analyzed, confirming the structure. Compounds having Ip-6 (**7**, **6**, **5**, and **4**) are also regarded as 4″,6″-*O*-isopropylidene derivatives. On a ^{1}H NMR spectrum of 6″-*O*-tritylraffinose decaacetate,[11] the coupling constants, $J_{5'',6''a}$ and $J_{5'',6''b}$ were 5 and 7 Hz, respectively. The small values of the corresponding coupling constants in the case of **8** may be caused by the rigid structure of the 4″,6″-*O*-Ip-ring.

In the case of **7**, the presence of a 4″,6″-*O*-isopropylidene group was confirmed by high-field shifts of the corresponding protons. A doublet and a triplet at 3.52 and 4.09 ppm were confirmed to be the signals of H-2 and H-3 by the decoupling method. Thus, **7** is expected to be 2,3:4″,6″-di-*O*-isopropylideneraffinose heptaacetate.

On a ^{1}H NMR spectrum of **6**, high-field shifts of H-1′ (2H) and H-2 were observed in addition to the high-field shifts of H-4″ and H-6″ (2H). Signals of acetoxy-substituted methine protons, H-3, H-4, H-3′, and H-4′ were wholly analyzed. A broad singlet of two protons centered on 5.25 ppm was assigned to the complex signals of H-2″ and H-3″. Thus, the main product **6** was confirmed to be 1′,2:4″,6″-di-*O*-isopropylideneraffinose heptaacetate. The Ip-4 type products, **2**, **3**, **4**, **5**, and **6** should be 1′,2-*O*-Ip-derivatives.

In the case of **5**, high-field shifts of H-1′ (2H), H-2, H-4″, and H-6″ (2H) were observed. All the signals involving acetoxy-substituted methine protons in a region over 4.6 ppm, H-3, H-4, H-3′, and H-4′ were wholly analyzed. At a τ of 0.15 s, in the 180° pulse-τ-90° pulse method, symmetric two-proton signals centered on 4.12 ppm were observed and assigned to the complex signals of H-2″ and H-3″. The assignments were supported by homonuclear correlated two-dimentional ^{1}H NMR.[13] A signal at 5.29 ppm (H-1″) correlated with a signal at 4.14 ppm

Table 4-1. Chemical Shifts (δ ppm) on ^{1}H NMR Spectra of the *O*-Isopropylideneraffinose Peracetates

	H-1 d	H-2 dd	H-3t(dd)		H-4t(dd)	H-6a dd	H-6b dd

to be assigned to H-2″, and a signal at 3.46 ppm (H-4″) correlated with a signal at 4.12 ppm to be assigned to H-3″. Thus, **5** was regarded as 1′,2:2″,3″:4″,6″-tri-*O*-isopropylideneraffinose pentaacetate, and Ip-3 is 2″,3″-*O*-Ip-group.

On a spectrum of **4**, high-field shifts of H-1′ (2H), H-2, H-3, H-4, H-4″, and H-6″ (2H) were recognized. In a region between 5.1 and 5.4 ppm, signals of acetoxy-substituted methine protons, H-1″, H-2″, H-3′, H-3″, and H-4′ were observed. The complex signals of H-2″ and H-3″ had almost the same symmetric pattern as that on the spectrum of **8**. Thus, **4** was recognized as 1′,2:3,4:4″,6″-tri-*O*-isopropylideneraffinose pentaacetate. Compound **2**, which also had an Ip-2 type Ip-group, was assumed to be a 3,4-*O*-isopropylidene derivative of **1**.

In the case of **3**, signals of five acetoxy-substituted methine protons, H-2″, H-3, H-3′, H-4, and H-4′ and an anomeric proton, H-1″ were observed in the region between 4.8 and 5.4 ppm. Signals of H-1′ (2H), H-2, and H-3″ were in a high field. Although the assignment of H-4″ could not be achieved due to the absence of an H-4″ signal in the region above 4.6 ppm, the high-field shift of H-4″ was clear. Thus, **3** is regarded to be 1′,2:3″,4″-di-*O*-isopropylideneraffinose heptaacetate, and Ip-1 is assumed to be a 3″,4″-*O*-isopropylidene group.

In the case of **2**, acetoxy-substituted methine protons were H-2″, H-3′ and H-4′. High-field shifts of H-1′ (2H), H-2, H-3, and H-4 were clearly recognized. Signals of H-3″ and H-4″ should be in the region between 4.3 and 4.5 ppm. Compound **2** was recognized as 1′,2:3,4:3″,4″-tri-*O*-isopropylideneraffinose pentaacetate.

In the above reaction, six types of isopropylidenation were observed. The main types were 4″,6″- and 1′,2-*O*-isopropylidenation. Isopropylidenations at 3′,4′-, and 4′,6′-positions were not found.

A reaction of **1** with DMP in a molar ratio of 1:6.5 in the presence of TSA in DMF for 80 min., also gave a mixture of Ip-derivatives without a free form of **1**. After recycling column chromatography of the corresponding acetates (about 30 times on a silica-gel column using the same method as for the former reaction), compounds, **3**, **6**, **8**, and **9** were isolated as pure or almost pure forms. A minor component and a mixture consisting of two components were also obtained. The yields of the four acetates were 1.7 (**3**), 11.3 (**6**), 10.6 (**8**), and 2.3% (**9**), respectively.

On ^{1}H and ^{13}C NMR spectra of **9**, 9 signals of acetyl methyl protons, 2 signals of Ip-methyl carbons and one signal of a quarternary carbon in an Ip-group were observed as shown in Table 1. Thus, **9** was estimated to be a mono-*O*-Ip-derivative, and the chemical shifts of the Ip-methyl carbons and the quaternary carbon in the Ip-group showed that **9** is 3″,4″-*O*-isopropylideneraffinose nonaacetate (Fig 1).

Table 5. Elementary Analysis, Optical Rotation ($[\alpha]_D^{20}$) in Chloroform, Melting Point, and R_f and R_2 on TLC of the *O*-Isopropylideneraffinose Peracetates

	Found (%) C	Found (%) H	$[\alpha]_D^{20}$	(c)	Mp(θ_m/°C)	R_f*	R_2*2
2	53.26	6.55	+ 59.50°	(1)	—	0.53	1.00

Calcd for $C_{39}H_{54}O_{21}$ (**8** and **9**): C, 50.76; H, 5.90%, for $C_{38}H_{54}O_{23}$ (**3**, **6**, and **7**): C, 51.94; H, 6.19%, for $C_{37}H_{54}O_{25}$ (**2**, **4**, and **5**): C, 53.23; H, 6.52%.

*1TLC was performed with diethyl ether–hexane (4:1) in a quadruplicated development.

*2R_2: migration length of **X**/ that of **2**.

In the acetoxy-substituted methine-proton region on a ^{1}H NMR spectrum of **9**, H-2, H-2″, H-3, H-3′, H-4, and H-4′ signals were observed. Due to an overlapping of the signals assignments of H-3″ and H-4″ could not be achieved; however **9** is difinitely regarded as a 3″,4″-*O*-Ip-derivative. Increases in mono-*O*-Ip-derivatives and decreases in tri-*O*-Ip-derivatives (compared to a high-DMP reaction) were reasonable.

Experimental

General Methods. Melting points were determined in capilary tubes and were uncorrected. Optical rotations were measured with a Japan Spectroscopic DIP-SL polarimeter. The ^{1}H and ^{13}C NMR spectra were recorded at 200 MHz (for ^{1}H) with a Varian XL-200 and at 300 MHz (for ^{1}H) with a Varian XL-300 spectrophotometer in deuteriochloroform with tetramethylsilane as an internal standard. With ^{1}H NMR, the spectral width was 2000 Hz (16000 data points) for the 200-MHz instrument and 4000 Hz (32000 data points) for the 300-MHz instrument. With ^{13}C NMR, the spectral width was 11574.1 Hz (16364 data points) and 16501.7 Hz (32000 data points). Acquisition times were 4.0 s for ^{1}H NMR and 0.7—0.97 s for ^{13}C NMR. Sixteen-times accumulation for ^{1}H NMR and 512-times accumulation for ^{13}C NMR were used. In the 180° pulse-τ-90° pulse method, the post delay (interval of the end of acquisition and 180° pulse) was 5 s, and the range of τ was 0.05—0.35 s TLC was performed on silica-gel plates (Art. 5554, DC-Alufolien Kieselgel 60 F_{254}, in a thickness of 0.2 mm, Merck) developed with a solvent system of 1-butanol–acetic acid–water (4:1:1.7) for the free Ip-derivatives and a solvent system of diethyl ether–hexane (4:1 or 5:1) in quadruplicated development for the *O*-isopropylideneraffinose peracetates. Open-column chromatography of the acetates was achieved on a silica-gel

column (Wakogel C-200, Wako Pure Chemical Ind. Ltd.) eluted with diethyl ether–hexane (4:1 or 5:1). Recycling took place 30—35 times. Samples added to the column were dissolved in chloroform. The weight of the adsorbent that was used was about 20 times that of the submitted sample and the volume of eluting solvent was about 30 times that of the adsorbent (vol/wt). The eluent was divided into 50—60 fractions. Each fraction was inspected by TLC, and the fractions having the same R_f values were collected and dried for further inspection. An admixture of diisopropyl ether and hexane (3:1) was applied for the separation of **4** and **5**.

Isopropylidenation of 1 and Acetylation of the Reaction Products. To a solution of **1** (5.0 g, 0.01 mol as dehydrated material), 0.5 g of TSA and 25 ml (d=0.85, ca. 0.2 mol) of DMP in a "high-DMP reaction" and 8 ml (0.065 mol) of DMP in a "low-DMP reaction" in 250 ml of DMF were added and each mixture was settled for 80 min at room temperature. The solution was then neutralized with IR-410(OH) resin, filtered, and concentrated. The resultant syrupy residue was then acetylated with acetic anhydride (12 ml) in pyridine (20 ml). The reaction mixture was concentrated to give a syrupy product. The product was dissolved in chloroform and added to a silica-gel column. After recycling chromatography above-described, each reaction product of the high- and low-DMP reaction was divided into the isolates, **2** to **8** in the high-DMP reaction, and **3**, **6**, **8**, and **9** in the low-DMP reaction. The combined yields of the high- and low-DMP reaction were 4.03 g (46%), and 2.42 g (26%), respectively.

Elementary Analysis and Physical Data of the *O*-Isopropylideneraffinose Peracetates. The elementary analysis and physical data of 1′,2:3,4:3″,4″-tri-*O*-isopropylideneraffinose pentaacetate (**2**), 1′,2:3″,4″-di-*O*-isopropylideneraffinose heptaacetate (**3**), 1′,2:3,4:4″,6″-tri-*O*-isopropylideneraffinose pentaacetate (**4**), 1′,2:2″,3″:4″,6″-tri-*O*-isopropylideneraffinose pentaacetate (**5**), 1′,2:4″,6″-di-*O*-isopropylideneraffinose heptaacetate (**6**), 2,3:4″,6″-di-*O*-isopropylideneraffinose heptaacetate (**7**), 4″,6″-*O*-isopropylideneraffinose nonaacetate (**8**), and 3″,4″-*O*-isopropylideneraffinose nonaacetate (**9**) were summarized in Table 1, 2, 4, and 5. The weights obtained and yields were as follows; (i) high-DMP reaction: **2** 72.1 mg (0.8%), **3** 348 mg (4.0%), **4** 297 mg (3.4%), **5** 302 mg (3.5%), **6** 2227 mg (25.4%), **7** 309 mg (3.5%), and **8** 479 mg (5.5%); (ii) low-DMP reaction: **3** 159 mg (1.7%), **6** 1066 mg (11.3%), **8** 1000 mg (10.6%), and **9** 215 mg (2.3%).

The authors wish to thank Mr. Katsuhiko Kushida, Varian Instrument Ltd., for determining the NMR spectra.

Geometrical Isomerism of Phenylhydrazones of α-Keto Esters. II. *p*-Substituted Phenylhydrazones of Ethyl Pyruvate and 2,4-Dinitrophenylhydrazones of Some α-Keto Esters[1)]

Fumihide Ishibashi,* Takeo Nashima,* Junko Nishino, Ikuko Kobayashi, Yoshinori Ichihara, Yoshimi Kitagawa, Shigeko Sasaki, Masako Yoshikawa, Atsuko Matsuoka, and (late) Keiko Yamamoto

Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka 543

(Received June 17, 1985)

Each geometrical isomer of various substituted phenylhydrazones of ethyl pyruvate and 2,4-dinitrophenylhydrazones of some α-keto esters was isolated in a pure state. Partial isomerizations of the *E*-isomers of the former hydrazones to the *Z*-isomers took place by keeping solutions of the hydrazones in organic solvents containing C, H, and Cl in the dark. An *E*- or *Z*-structure was assigned to each molecule on the basis of IR and ^{1}H NMR spectra. In all cases, isomers with higher R_f-values on a silica gel TLC (using benzene as a developing solvent) involved an intramolecular hydrogen bonding between the imino hydrogen and the ester carbonyl oxygen. Thus, the *Z*-structure was assigned. An *E*-structure was assigned to other isomers with lower R_f-values. The present assignment is, thus, entirely the same as that proposed in a previous investigation.

Previously, we[1)] reported on the isolation of each geometrical isomer of 2,4-dinitrophenylhydrazones (DNPHs) of some pyruvic esters. *E*- and *Z*-configurations were assigned to the isomers on the basis of IR, visible, and ^{1}H NMR spectroscopy, thus correcting Van Duin's[2)] assignment.

This investigation stimulated us to reexamine the geometry of some of the hitherto-known substituted phenylhydrazones of the α-keto esters. With regard to the hydrazones reported in the present paper, their separation into individual isomers and the assignment of an *E*- or *Z*-structure to each of the isomers have scarcely been described in the literature. The reported melting points of the hydrazones, in most cases, are probably those either of a mixture of *E*- and *Z*-isomers, or of the more stable isomer of the two.[3,4)]

In the present work, we report on the preparation of some *p*-substituted phenylhydrazones of ethyl pyruvate and DNPHs of ethyl glyoxylate and ethyl benzoylformate, the fractional isolation of each geometrical isomer of the above hydrazones, and structural assignments of an *E*- or *Z*-configuration, by means of the previously mentioned method.[1)] In addition, the relative stability of each isomer compared to its geometrical counterpart is also discussed.

1c=Me,	*p*-ClC_6H_4	**2c**=C_6H_5,	2,4-$(NO_2)_2C_6H_3$
1d=Me,	*p*-$NO_2C_6H_4$		

Experimental

All the melting points are uncorrected. Visible and IR spectra were recorded on a Hitachi Recording Spectrophotometer ESP-3 and a Hitachi-Perkin-Elmer IR-Spectrometer-225, respectively. ^{1}H NMR spectra were recorded on a Hitachi-Perkin-Elmer R-20B operating at 60 MHz.

Geometrical isomers showing higher R_f-values on a silica gel TLC plate using benzene as the developing solvent are called α-isomers, and those with lower R_f-values are called β-ones for all the geometrical isomer pairs of hydrazones,† in common, studied in the present investigation.

Preparation of Ethyl 2-(*p*-Tolylhydrazono)propanoate (1a). **1a** was prepared from ethyl pyruvate, *p*-tolylhydrazine hydrochloride and sodium acetate in an aqueous ethanol solution according to the general procedure.

Fractional Isolation of Each Geometrical Isomer of 1a. Crude **1a** (11.0 g), as it was prepared, was treated with petroleum ether and an insoluble precipitate was separated by filtration. The filtrate was evaporated and the residue was chromatographed on silica gel using benzene as an eluting solvent. The α-isomer (1.3 g), obtained from the first eluting fraction, melted at 43.5—43.7 °C after recrystallization from aqueous methanol. The β-isomer was isolated from the second portion of the eluate which was combined with the precipitate obtained above (weight 9.3 g), and melted at 107.7—108 °C after recrystallization from petroleum ether containing a small volume of ethanol.

Partial Isomerization of the β-Isomer of 1a to the α-Isomer. A solution of 13.2 g of the β-isomer of **1a** in 55 ml of trichloroethylene was allowed to stand for 24 h in the dark. After removing the solvent, the residue was chromatographed on silica gel to yield 6.9 g and 5.6 g of the

† An isomer with a smaller retention volume (higher R_f-value) was called an α-isomer by Van Duin[2)] and an A-isomer by Moriwaki et al.[5)] The other isomer was called a β-isomer and a *B*-isomer, respectively.

α- and β-isomers, respectively. Partial isomerizations were also carried out in 1,2-dichloroethane and chloroform.

Preparation of Ethyl 2-(Phenylhydrazono)propanoate (1b) and Ethyl 2-(*p*-Chlorophenylhydrazono)propanoate (1c), Fractional Isolation of Each Geometrical Isomer of the Above Hydrazones, and Partial Isomerization of the β-Isomers of 1b and 1c to the Corresponding α-Isomers. The above operations were all carried out in essentially the same way as described for **1a**.

Preparation of Ethyl 2-(*p*-Nitrophenylhydrazono)propanoate (1d). **1d** was prepared in a yield of 70% by the reaction of ethyl pyruvate with *p*-nitrophenylhydrazine in 50% acetic acid according to the usual procedure. The product consisted exclusively of the β-isomer.

Partial Isomerization of the β-Isomer of 1d to the Corresponding α-Isomer. A solution of the β-isomer of **1d** in 1,2-dichloroethane was irradiated with sunlight for 24 h to yield a mixture of the isomers in an α to β ratio of 1:0.4.

Yields of the α- and β-isomers of **1** in the syntheses and results of partial isomerization of the β-isomers of **1** to the α-ones are summarized in Tables 1 and 2, respectively.

Preparation of Ethyl 2-(2,4-Dinitrophenylhydrazono)acetate (2b). **2b** was synthesized according to the method described by Cope et al.[3] After a separation of the crude product into the α- and β-isomers by means of chromatography, the ratio of the yields of the α-isomer to the β-one was ca. 3:1.

Preparation of Ethyl 2-Phenyl-2-(2,4-dinitrophenylhydrazono)acetate (2c). Ethyl benzoylformate, synthesized by the oxidation of mandelic acid with potassium permanganate and subsequent esterification, was treated with 2,4-dinitrophenylhydrazine either in an ethanol-sulfuric acid solution or in an aqueous hydrochloric acid solution. The ratios of the yield of the α-isomer to that of the β-one were 3.7:1 under the former reaction conditions and 1.8:1 under the latter ones, as determined after chromatographic separation of the crude products.

Results and Discussion

Isolation of Geometrical Isomers. Since each of the *p*-substituted phenylhydrazones (**1a—d**) studied, when formed from the reactants, consisted overwhelmingly of the β-isomer (as seen in Table 1), the corresponding α-isomer was obtained as follows. In the case of **1a**, **1b**, or **1c**, the β-isomer was dissolved in organic solvents consisting of C, H, and halogen such as chloroform, 1,2-dichloroethane, trichloroethylene, bromoform, or chloroform–benzene, and left in the dark at room temperature. At a higher temperature (or with sunlight) the reaction was accompanied by a significant degradation of the hydrazones. A conversion of the β-isomer to α-one occurred so extensively that the isolation of the latter became facile by means of chromatography. It is quite interesting that when a sample of the β-isomer was dissolved in ethanol, benzene, carbon tetrachloride, or tetrachloroethylene and kept in the dark, no appreciable isomerization to the α-isomer was observed.

On the other hand, even if a solution of the β-isomer of **1d** in any one of the above solvents consisting of C, H, and halogen was left in the dark, no appreciable amount of the α-isomer was observed in the resulting equilibrium mixture. However, the irradiation of a 1,2-dichloroethane or trichloroethylene solution of **1d** with sunlight or UV light caused the equilibrium to shift toward the formation of the α-isomer.

In the preparation of **2c**, the ratio of the yield of

the α-isomer to β-one was larger during a reaction in an ethanol–sulfuric acid solution than in an aqueous hydrochloric acid solution. The observation was similar to that seen in the case of **2a** reported in the previous investigation.[1]

In a solution of **2a—c** in methanol, ethanol or chloroform, no interconversion between the α- and β-isomers occurred in the dark.

Melting points, analytical data, crystalline forms and R_f-values for compounds **1** and **2** are listed in Tables 3-a and 3-b, respectively.

Assignment of *E*, *Z*-Structure. Data regarding visible, IR, and ^{1}H NMR spectra for **1** and **2** are listed in Table 4. Several points are seen from the Table. (1) Visible spectra for all the hydrazones, except for **2b**, show absorption maxima for the α-isomers at longer wavelengths than those for the corresponding β-isomers. In the case of **2b**, the absorption maximum for the α-isomer lies at a wavelength that is slightly shorter than that for β-one. (2) The extinction coefficient at the absorption maximum is greater for α-isomers of **1a**, **1b**, **1c**, and **2b** than for the corresponding β-one; the reverse is true for the remaining hydrazones. (3) The ester carbonyl stretching bands in the IR spectra in Nujol mulls appear at smaller wavenumbers for α-isomers of **1b**, **1d**, **2a**, and **2b** than for the corresponding β-ones. This is in agreement with results obtained in the previous study.[1] On the other hand, the reverse is true in the case of **1a**, **1c**, and **2c**. Those observations have not yet been consistently explained. (4) However, the imino stretching bands in Nujol mulls appear at smaller wavenumbers for α-isomers for all the hydrazones studied than those for the corresponding β-ones. (5) Furthermore, the IR spectra in 0.01 M (1 M=1 mol dm^{-3}) carbon tetrachloride solutions for all hydrazones without exception reveal both carbonyl and imino stretching absorptions at smaller wavenumbers for α-isomers than for the corresponding β-ones. The same results are obtained even at dilutions of 10 times. (6) Finally, chemical shifts (in ppm) shown by imino protons in the ^{1}H NMR spectroscopy are larger by about δ 1.9 to 4.4 for α-isomers for all the hydrazones studied than those for the corresponding β-isomers.

From all of the above observations, it can be said

that each α-isomer involves an intramolecular hydrogen bonding between the imino hydrogen and the ester carbonyl oxygen. Accordingly, it can be concluded that the *Z*-structure should be assigned to the α-isomer and the *E*-structure to the β-one. This conclusion is the same as that shown in the previous paper.

Recently, using our assignment method, Cracknell et al.[7] reported structural assignments of an *E*- or *Z*-structure to geometrical isomers of phenylhydrazones of benzocyclobutene-1,2-dione.

We also examined the behavior of ^{1}H NMR signals of an imino proton for **1** in a polar solvent such as methanol (**2** was insufficiently soluble in methanol). This was compared with that in a nonpolar solvent such as carbon tetrachloride (Table 4). By changing the solvent from carbon tetrachloride to methanol, the imino proton signal flattened somewhat as a result of an exchange of protons between the hydrazone and the solvent molecule. Also, the signal appeared at a lower magnetic field in methanol than in carbon tetrachloride. It is noted from this comparison that the imino proton signals exhibited almost the same tendency in a methanol solution as in a carbon tetrachloride solution. Thus, in the first place, the imino proton signals of all the *Z*-isomers appeared in either solution at a lower magnetic field than those of the corresponding *E*-isomer. This suggests that an intramolecular hydrogen bonding exists in the *Z*-isomer, but not in the *E*-isomer, even in a polar solvent. Secondly, in the case of *E*-isomers, as the electronegativity of the *p*-substituent in the phenyl group becomes larger, the imino proton signal appears at a lower magnetic field in both solvents. This observation might be rationally interpreted in terms of the normal effect of electronegativity on the chemical shift of a proton.

Stability to Isomerization. Each of the individual geometrical isomers studied in the present investigation did not isomerize as it was kept in a pure state either upon irradiation with UV light or upon heating the sample to cause melting. The latter observation is contrary to that made by Katsuki et al.[8] regarding the behavior of the DNPHs of a few of α-keto acids. Also, during recrystallization from methanol or ethanol in the dark (or under dim light) isomerization took place to such a slight extent that samples were obtained practically in pure states. Only for cases **1a**, **1b**, and **1c** did isomerization take place to an ultimate equilibrium in several organic solvents consisting of C, H, and halogen even in the dark.

Studies of Polystyrene-Based Ion-Exchange Fiber. V. Immobilization of Microorganism Cells by Adsorption on a Novel Fiber-Form Anion Exchanger†

Toshio YOSHIOKA* and Masaharu SHIMAMURA
Fibers Research Laboratories, Toray Industries, Inc.,
Sonoyama, Otsu 520
(Received June 19, 1985)

Immobilization of microorganism cells by adsorption on a new polystyrene-based ion-exchange fiber has been studied. Microorganism cells, such as yeasts, bacteria, and actinomycetes, were well adsorbed on the anion-exchange fibers through an electrostatic force. The adsorption capacity for the cells became much greater as the water-holding capacity of the fibers increased. The adsorption and desorption behavior of the cells was different between actinomycetes and yeasts, and also between strong and weak anion-exchange fibers. The enzyme activities of the immobilized actinomycetes containing glucose isomerase and yeasts containing L-aminolactam hydrolase were ca. 70 and 60% of those of the native cells respectively. The stability of the immobilized yeasts in the hydrolysis of DL-cyclic lysine anhydride was also investigated.

Recently immobilization of microorganism cells as well as enzymes has been intensively studied from a view point of their use as bioreactors in industry. Microorganism cells have been immobilized by adsorption on a support and entrapment in a matrix.[1-3]

In the previous paper,[4] we have reported that the polystyrene-based ion-exchange fiber, IONEX, can be used as a support for immobilization of some enzymes such as invertase and glucose isomerase. The ion-exchange fiber exhibits good capacity for adsorbing macromolecular ionic substances; this is attributable to its large surface area.[5-7] These findings led us to investigate the possible use of the ion-exchange fiber as the support for the immobilization of microorganism cells.[8] In the present paper, immobilization of some microorganism cells including yeasts and bacteria by adsorption on IONEX is described.

Experimental

Polystyrene for ion exchange as the predominant *sea* ingredient and polypropylene for reinforcement as the *island* ingredient were spun into composite filaments having an *islands-in-a-sea* type sectional structure shown in Fig. 1, by the conventional method.[5] Following the introduction of a crosslinking group, IONEX with various ion-exchange groups were prepared by the introduction of the corresponding ion-exchange group into the polystyrene part according to the procedure described in the previous paper.[5] The resulting fibers had a diameter of ca. 30 μm in the dry state. The ion-exchange capacities of the fibers were found to be ca. 90% of the theoretically calculated values. A cation IONEX in the Na form or an anion IONEX in the Cl form was immersed in a bath of deionized water at room temperature for a sufficient period of time to reach saturation. The fiber was centrifugally dehydrated at 3000 r.p.m. for five minutes. Immediately thereafter, the wet weight (W) of the fiber was measured. The water content of the fiber was determined from the following equation:

$$\text{Water content} = (W - W_0)/W_0,$$

where W_0 is the weight of the completely dry fiber. The water content means the water-holding capacity of the fiber and it was controlled by chosing the conditions of the crosslinking reaction.[5-7] The water content becomes higher as the degree of crosslinkage is lowered.

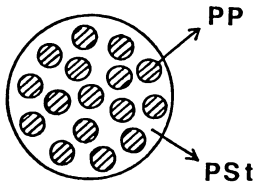

Fig. 1. Schematic cross section of composite fiber. PSt: polystyrene, *sea* ingredient; PP: polypropylene, *island* ingredient.

Actinomycetes with the activity of glucose isomerase (G-actinomycetes; *Streptomyces phaeochromogenus*) and yeasts (P-yeasts; *Saccharomyces cerevisiae*) were obtained from Nagase Sangyo Co., Ltd. and Nitushin Seifun Co., Ltd. (Japan) respectively. Yeasts with the activity of L-aminolactam hydrolase (H-yeasts; *Cryptoccus laurentii*), bacteria (R-bacteria; *Achromobacterobae*), and bacteria (E-bacteria; *Escherichica coli*) were kindly supplied from Basic Research Laboratories, Toray Ind., Inc. (Japan).

The adsorption of the microorganism cells was carried out by the following procedure. An ion exchanger of 100 mg in the Cl or Na form was added to 0.02—0.05% cell suspension, and the mixture was shaken at 20 °C for 1 h. The adsorption capacity of the microorganism cells to the ion exchanger was evaluated by measuring the concentration of the cells remaining in the suspension before and after the adsorption treatment by optical-density measurements at 550 nm. Glucose isomerase activity was determined as described in the previous paper.[4] One unit (U) of L-aminolactam hydrolase was defined as the amount of the enzyme which produced 1 μ mole of L-lysine per hour at 40 °C in 10 wt/vol% DL-cyclic lysine anhydride (CLA) solution of pH 8.0 containing 0.625 mM $MnCl_2$ (1 M=1

† A preliminary report of this work was presented in *Polym. Prepr. Jpn.*, **32**, 1855 (1983).

mol dm^{-3}).

Results and Discussion

Adsorption of Microorganism Cells. The first experiment was carried out using G-actinomycetes, H-yeasts, R-bacteria, and P-yeasts as the test microorganism cells to test whether microorganism cells were adsorbed on IONEX. The results are summarized in Table 1. E-Bacteria of 25 mg and 4 mg were also adsorbed from 0.115% cell suspension (20 °C, 4 h) on 100 mg of anion IONEX having a dimethylaminomethyl group with a water content of 7.0 and Amberlite IRA-938 respectively. It can be seen from Table 1 that the microorganism cells are not adsorbed on cation IONEX with a sulfo group, but well adsorbed on anion IONEX. They are slightly adsorbed on the macroreticular-type anion-exchange resin (Amberlite IRA-938). These results suggest that the outer walls of the microorganism cells are negatively charged and are adsorbed on anion exchangers by an electrostatic force.

Figure 2 shows the relation between the cell adsorption capacity and the water content of anion IONEX. The adsorption capacity was dependent on the water content of the fiber, but independent of the kind of anion-exchange group. The adsorption capacity of the actinomycetes and bacteria was lower than that of the yeasts. This can be ascribed to the difference in the cell size. The strong anion IONEX with water contents of 1.0 and 4.0 had adsorption capacities of 60 and 700 mg g^{-1} for P-yeasts respectively. The adsorption capacity of the yeasts on the fiber can be geometrically evaluated from their volumes and surface areas. We assume, as a first-order approximation, that the spherical yeasts with a diameter of 6 μm are most closely adsorbed on the surface of the cylindrical endless fiber with a variable

diameter according to the water content (30 μm in dry state). The adsorption capacities for the fibers with water contents of 1.0 and 4.0 are calculated to be 680 and 1020 mg g^{-1} respectively. In the case of the yeasts, the experimental values of the adsorption capacity are generally lower than the calculated ones. This discrepancy is explained by assuming that the adsorption capacity is reduced by the repulsion between the cells, rather than that the adsorption capacity is not saturated because of the low concentration of the cells. On increasing the water content of the fiber, the adsorption capacity is considered to increase rapidly and to approach the calculated capacity since the adherent force of the cells to the fiber is enhanced by their affinity for water and it inhibits the repulsion between the cells.

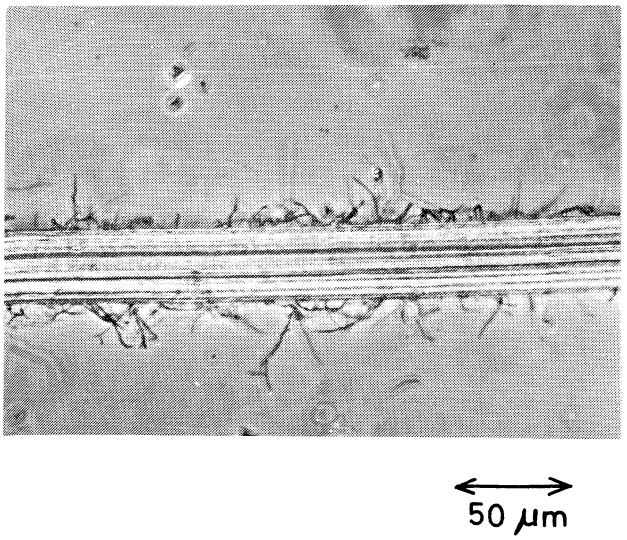

Fig. 3. Adsorption process of G-actinomycetes on strong anion IONEX in 0.05 M $NaHCO_3$ solution (pH 8.2).

Adsorption and Desorption Behavior of Microorganism Cells. Figure 3 presents the adsorption process of G-actinomycetes on the strong anion IONEX. The extreme part of the cells adheres on the fiber surface at first when the fiber is added to the cell suspension. The whole of the cell adheres on the fiber surface on shaking.

Figures 4 and 5 show G-actinomycetes and H-yeasts adsorbed on the strong anion IONEX. The yeasts were easily desorbed from the strong anion IONEX in a 10 wt% NaCl or lysine aqueous solution (Fig. 6). However, vigorous shaking was needed for desorption of G-actinomycetes even in 10 wt% NaCl. The results suggest that the ionic strength in a solution controls the adsorption and desorption properties for the cells in the case of a strong anion exchanger. The fiber is considered to shrink and lose the electrostatic force in a solution with a high ionic strength. The reason why this change of the

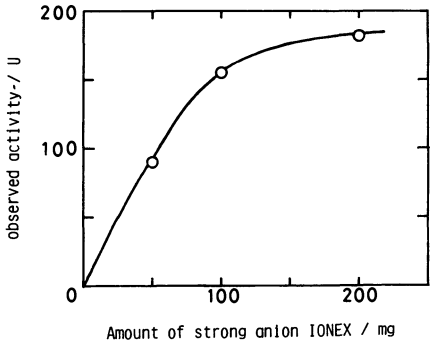

Fig. 7. Observed activity of glucose isomerase vs. amount of strong anion IONEX (water content, 4.0). Immobilization was carried out in 25 ml of 0.05 M $NaHCO_3$ (pH 8.2) containing G-actinomycetes of 260 U, 50 mg (20 °C, 1 h).

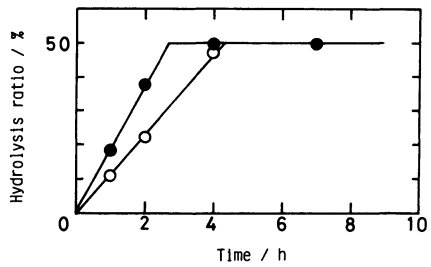

Fig. 8. Hydrolysis ratio of DL-CLA as a function of time. Native or immobilized cells were placed in 10 ml of 10 wt/vol% DL-CLA solution (pH 8.0) containing 0.625 mM $MnCl_2$ and shaken at 40 °C. ●: Native H-yeasts (17.5 mg), 1455 U, ○: immobilized H-yeasts (17.5 mg) on 500 mg of weak anion IONEX with amino group, 845 U.

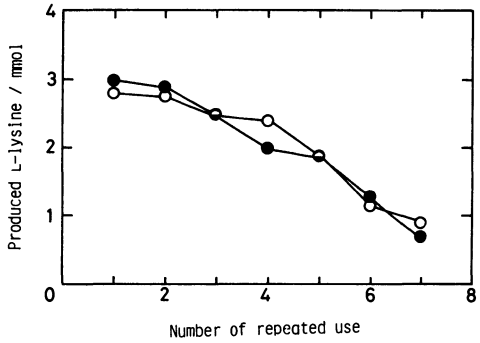

Fig. 9. Stability of immobilized H-yeasts in hydrolysis of DL-CLA by a repeated batch method. Immobilized H-yeasts (1.75 mg) on 25 mg of weak anion IONEX with amino group were placed in 8 ml of 10 wt/vol% DL-CLA solution (pH 8.0) containing 0.625 mM $MnCl_2$ and shaken at 40 °C for 40 h. 0.7 mg of native H-yeasts produced 2.45 mmol of L-lysine on the same conditions. The open and closed circles represent two separate experimental data.

electrostatic force does not readily cause the desorption of the actinomycetes can be attributed to the difference in the adsorption state. That is, the actinomycetes have a much larger contact area with the fiber than the yeasts, as seen in Figs. 4 and 5, so that the former is not so easily desorbed from the fiber as the latter. In the case of the weak anion IONEX, no appreciable desorption of the yeasts was observed in a 10 wt% lysine aqueous solution. They were partially desorbed from the fiber in a 10 wt% NaCl aqueous solution and extensively in a 1 M NaOH. Therefore, the adsorption and desorption properties of the cells for a weak anion exchanger are affected by the pH of a solution rather than by the ionic strength. This is considered to be due to the fiber shrinking more as the pH in a solution is raised. The adsorption and desorption properties for R-bacteria were the same as for H-yeasts.

Immobilization of Microorganism Cells.

Figure 7 shows the correlation between the amount of the strong anion IONEX and the glucose isomerase activity of the fiber when a fixed amount of G-actinomycetes is used in the immobilization. The activity yield was relatively high at ca. 70%.

The hydrolysis of DL-CLA was carried out by using the native H-yeasts with the activity of L-aminolactam hydrolase and the immobilized H-yeasts on the weak anion IONEX with the amino group, as is shown in Fig. 8. The activity yield was ca. 60%. Next, the stability of the immobilized H-yeasts in the hydrolysis of DL-CLA was investigated by a repeated batch method (40 °C, 40 h). The plots of the L-lysine produced vs. the number of repeated use are given in Fig. 9. It can be seen from Fig. 9 that the half life of the immobilized H-yeasts is ca. 240 h. The decrease in activity can be attributed to the inactivation of the enzyme since no appreciable desorption of the yeasts was observed during the reaction. The weak anion IONEX for the support can be repeatedly used by immobilizing new H-yeasts after the desorption

treatment in a 1 M NaOH aqueous solution when the activity of the immobilized H-yeasts decreases.

Conclusion

1. The microorganism cells are well adsorbed on anion-exchange fiber. On increasing the water content of the fiber as well as its surface area, the adsorption ability for the immobilization becomes much larger.
2. The adsorption and desorption behavior is dependent upon the kind of microorganism cells and also upon the basicity of the anion-exchange fiber.
3. The immobilization of the microorganism cells by adsorption on the fiber gives a high enzyme activity.

The authors would like to express their appreciation to Dr. Taturo Kawaguchi, Mr. Michihiko Tanaka, and Dr. Masaki Nishino for their continuous encouragement throughout this work. They are also much obliged to Mr. Kazuo Teramoto for his advice on the chemical treatments and to Mr. Seiichi Yoshikawa and other collaborators for the preparation of the composite fibers. The authors also wish to thank Toray Industries, Inc., for making this study possible.

A Novel Friedel-Crafts Type Reaction of 2-Chlorothiophene with Some Active Aromatic Compounds[1)]

Tyo Sone,* Ryoji Yokoyama, Yohko Okuyama, and Kazuaki Sato
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received June 20, 1985)

2-Chlorothiophene (**1**) was found to easily react with certain active aromatic compounds (**2**) in the presence of $AlCl_3$ under mild conditions, yielding the corresponding 2-arylthiophenes (**3**) and 5-chloro-2,2′-bithienyl (**5**) as the main products. With compounds more reactive than **1**, the formation of **3** predominated. Reactions of **1** with aryl alkyl ethers, for example, afforded the corresponding **3** in 44—83% yields in one step.

It has been generally assumed that a chlorine atom that is directly attached to a thiophene ring is inert[2)] and cannot be replaced by an aryl group under Friedel-Crafts conditions as is true for aryl chlorides that are inert.

In contrast to this fact, Ramsey et al. have reported the polymerization of chlorothiophenes by $AlCl_3$–$CuCl_2$, which involves a nuclear coupling along with the elimination of HCl.[3)] We recently found that in the presence of a cation-exchange resin, 2-chlorothiophene (**1**) reacted with anisole (**2d**) to give 2-(*p*-methoxyphenyl)thiophene (**3d**) and its derivatives, although the yield was low.[4)] We also found that $AlCl_3$ catalyzed a Friedel-Crafts reaction involving 2,5-dichloro-3-(chloromethyl)thiophene with simple benzene derivatives and unexpectedly afforded corresponding 4-aryl-3-arylmethyl-2-chlorothiophenes as the major products.[5)]

These findings suggest that chlorothiophenes can be sufficiently activated to couple with reactive aromatic compounds (**2**) under appropriate acidic conditions. This prompted us to investigate an $AlCl_3$-catalyzed reaction of **1** with **2**. In the present paper we wish to report the results.

The reaction was carried out by adding one mole equiv of $AlCl_3$ to an equimolar mixture of **1** and **2** in CH_2Cl_2 under ice-cooling. This reaction was instantaneous in most cases (as shown by a color change and the evolution of HCl gas) and came to completion upon briefly heating at ca. 40 °C. Through the reaction with **2**, the corresponding 2-arylthiophenes (**3**) and 5-chloro-2,2′-bithienyl (**5**) were obtained as the main products. On occasions, the 2,4-diarylthiophenes (**4**) and its tetrahydrothiophene derivatives (**7**) were isolated from the products. In many cases, the presence of isomers due to the

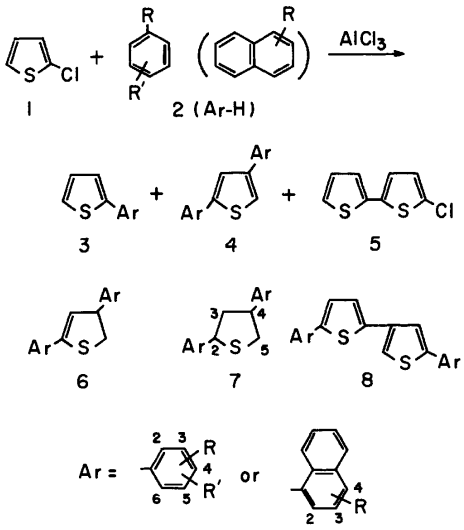
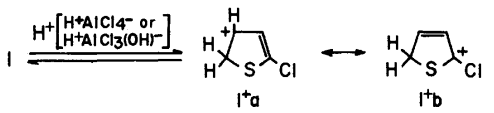


Scheme 1.

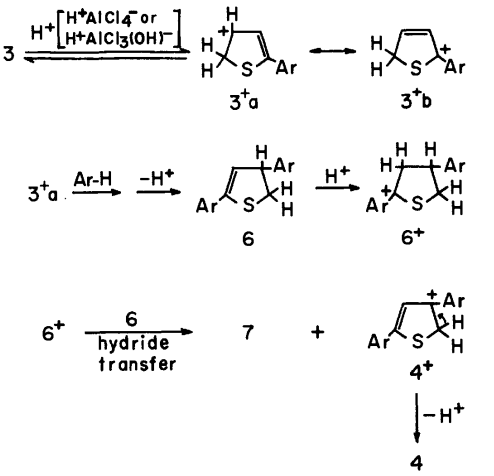
position of the substituent(s) on the aromatic ring, the dihydrothiophene derivatives (**6**) of **4**, and the coupling products of **3**, probably 5,5′-diaryl-2,3′-bithienyls (**8**),[6] were also suggested in the products (MS, NMR, and/or TLC). The results are summarized in Table 1.

The yields of the products and the product distribution depend on the relative reactivities of **2** and **1** towards electrophiles and the mole ratio of **2** to **1**. Thus, with substrates less reactive than **1**, predominantly the self-condensation of **1** occurred. For example, in a reaction with benzene (**2a**), **5** was obtained as the sole isolable product in ca. 40% yield, which had been prepared from 2-iodothiophene in seven steps.[7] With reactive substrates such as aryl alkyl ethers, the coupling of **1** with aromatic rings predominated, yielding **3** as expected. This sometimes further reacted with **2** (or **3**) to give **4**, **6**, and **7** (or **8**). An increasing mole ratio of **2** produced higher yields of **4** and its analogs.

The structures of the products were confirmed by their physical and spectral data, elemental analyses and/or direct comparisons with the authentic samples. Authentic samples of 2-(4-methoxy-1-naphthyl)- (**3i**) and 2-(2-ethoxy-1-naphthyl)thiophenes (**3j**) were conveniently prepared by Grignard cross-coupling between 2-thienylmagnesium iodide and the corresponding 1-iodo-4- or 1-iodo-2-alkoxynaphthalene using nickel(II) acetylacetonate as a catalyst.[8] Usually, compounds, **4**, **6**, and **7**, were obtained as mixtures from the products. The presence of the three compounds was readily shown by the MS spectra of the mixtures. It was difficult to separate the mixtures into their components, but 2,4-bis(*p*-methoxyphenyl)thiophene (**4d**) and 2,4-bis(2,4-dimethoxyphenyl)tetrahydrothiophene (**7g**) could be isolated from mixtures which were produced in



Scheme 2.



Scheme 3.

reactions of **1** with excess anisole (**2d**) and with excess resorcinol dimethyl ether (**2g**), respectively. The structure of **4d** was established by a comparison of its melting point and UV spectral data with that reported in the literature.[9] The structure of **7g** was assigned on the basis of spectral data and elemental analyses. The MS [*m/z* 360 (M^+, 100%)] and UV spectra [λ_{max} (MeOH) 231 (4.29), 277 (3.78)] suggested the presence of two dimethoxyphenyl units in the molecule of **7g**, neither of which was in conjugation. The ^{1}H NMR spectrum ($CDCl_3$) exhibited, besides a resonance involving six protons of the two aromatic groups, the characteristic peaks for a 2,4-disubstituted tetrahydrothiophene ring in the aliphatic region;[10] a two-proton multiplet (δ 1.93—2.63) and signals (δ 3.03 and 3.21) ascribable to the AB part of an ABX spin system corresponding to 3- and 5-methylene protons. A one-proton multiplet (centered at δ ca. 3.7) and a quartet (δ 5.02, the X part of the ABX system) were ascribable to the 4- and 2-methine groups, respectively. Although 2,4-disubstituted tetrahydrothiophenes exist in two diastereomeric forms, cis and trans, and in each case there are many conformational isomers as a result of the so-called pseudorotation, a detailed examination of the structure of **7g** was not further undertaken. An attempted dehydrogenation of **7g** to **4g** with chloranil was unsuccessful. The dihydrothiophene derivatives (**6**) could not be isolated, but the ^{1}H NMR spectra of the

mixtures showed the olefinic proton absorption (δ ca. 6.0) expected for **6**.[11]

A probable mechanism for the formation of **3** is shown in Scheme 2; this requires an initial protonation of **1** to form 2-chlorothiophenium ion **1**$^+$**b** as the electrophile. It is widely accepted that $AlCl_3$, when contacted with water in moist air, forms species such as $H^+AlCl_3(OH)^-$, which act as proton sources. In this reaction, once a small amount of **3** had been formed, the reaction could provide HCl, which, together with $AlCl_3$, would prompt a further reaction. Thiophenium ions produced from several thiophene derivatives have been observed directly by means of ^1H NMR spectroscopy.[12] We have also confirmed the presence of the ion **1**$^+$ in an $AlCl_3$-HCl-CH_2Cl_2 system at $-40\,^\circ C$ by a direct NMR spectroscopic observation.[13] With less reactive substrates than **1**, the carbonium ion **1**$^+$**b** attacks, instead of the substrate, another molecule of **1**, generating **5** as the main product. 100% Orthophosphoric acid (PPA) failed to cause a reaction with anisole at room temperature; this is probably due to the lower catalytic activity or a smaller acid strength of PPA than that of $H^+AlCl_3(OH)^-$ and/or $H^+AlCl_4^-$.

The protonation of **3** produces carbonium ions, **3**$^+$**a** and **3**$^+$**b**. An attack of **3**$^+$**a** upon an aromatic substrate, followed by proton elimination, gives the corresponding dihydrothiophene **6**. A hydride transfer from **6** to **6**$^+$ affords the tetrahydrothiophene **7** and the carbonium ion **4**$^+$, which then yields the 2,4-diarylthiophene **4** by the elimination of a proton (Scheme 3). Compound **8** can be formed analogously to **4**.

In conclusion, it was found that in the presence of $AlCl_3$ **1** was sufficiently activated to react with various active aromatic compounds under mild conditions, giving the corresponding 2-arylthiophenes (**3**) as the major products. The results are of interest not only from a theoretical viewpoint concerning the unusual reactivity of the chlorine atom of **1**, but also from a preparative one. Thus, a series of 2-arylthiophenes with alkoxyl group(s) on the aromatic ring not readily accessible by the known procedures[14] was prepared in one step by this reaction using **1** as a starting substance in moderate to good yields.

Experimental

All melting and boiling points are uncorrected. The NMR, UV, IR, and MS spectra were obtained on Hitachi R-22 (90 MHz, TMS as an internal reference), Hitachi EPU-2A, Hitachi EPI-S2, and Hitachi UMU (70 eV) spectrometers, respectively.

2-Chlorothiophene (**1**) was prepared by a method described in the literature.[19] Commercial $AlCl_3$ was used without special precautions against moisture. The authentic 5-chloro-2,2′-bithienyl (**5**),[4] 2-phenylthiophene (**3a**),[20] and 2-(*p*-methoxyphenyl)thiophene (**3d**)[4] were prepared according to the literature.

Reaction of 2-Chlorothiophene (1) with Resorcinol Dimetyl Ether (2g) (Typical Procedure). Pulverized $AlCl_3$ (2.7 g, 20 mmol) was added in portions to ice-cooled solutions of **1** (2.4 g, 20 mmol) and **2g** (2.8 g, 20 mmol) in CH_2Cl_2 (10 ml) over 2—3 min periods. Exothermic reactions occurred with the appearance of a coloration of the reaction mixtures. Also, the temperature of the mixtures rose to ca. 20 °C. The reaction mixtures were stirred in the ice-bath for 30 min, then at room temperature for 60 min, and finally at the reflux temperature of the solvent for additional 30 min. An evolution of HCl gas was observed during the reactions. Reaction mixtures were poured into ice-water (ca. 70 ml) and extracted with $CHCl_3$ (20 ml×3). The extracts were combined, washed successively with water, 5% $NaHCO_3$ solution, and water, and dried (Na_2SO_4). After the removal of the solvent and small amounts of the starting substances by distillation, the residues were chromatographed (silica gel/benzene–hexane (3:2)) to afford 2-(2,4-dimethoxyphenyl)thiophene (**3g**; 2.4 g) and an oily mixture (0.14 g) of 2,4-bis(2,4-dimethoxyphenyl)thiophene (**4g**), 2,4-bis(2,4-dimethoxyphenyl)dihydrothiophene (**6g**), and 2,4-bis(2,4-dimethoxyphenyl)tetrahydrothiophene (**7g**).

When **1** was reacted with three equivalent moles of **2g** in the presence of an equimolar amount of $AlCl_3$, the yield of the oily mixture increased; for the mixture, bp 215—220 °C/1×10^{-3} mmHg (1 mmHg≈133.322 Pa). MS *m/z* (rel. intensity) 356 (M$^+$ for **4g**, 100), 358 (M$^+$ for **6g**, 22), 360 (M$^+$ for **7g**, 37). Found: C, 66.82; H, 6.13%. The oily mixture was diluted with a mixture of MeOH and acetone and left standing in the cold to give **7g**.

3g: Colorless viscous oil, bp 124—126 °C/5×10^{-4} mmHg. MS *m/z* 220 (M$^+$, 100). UV λ_{max} (MeOH) 226 sh (4.07), 279—287 (4.09), 310 (4.05). ^1H NMR (CCl_4) δ=3.71, 3.80 (s, 3H each, OCH_3), 6.25—6.5 (m, 2H, Ar-H), 6.8—7.5 (m, 4H, Ar-H). Found: C, 65.53; H, 5.50%. Calcd for $C_{12}H_{12}O_2S$: C, 65.43; H, 5.49%.

7g: Colorless fine needles, mp 113—114 °C (from MeOH). MS *m/z* 360 (M$^+$, 100). UV λ_{max} (MeOH) 231 (4.29), 277 (3.78). ^1H NMR ($CDCl_3$) δ=1.93—2.63 (m, 2H, 3-H_aH_b), 3.03, 3.21 (ABX m J_{ab}=9.1 Hz, J_{a4}=5.7 Hz, J_{b4}=10.7 Hz, 2H, 5-H_aH_b), 3.58~ (m, overlapped partly with the OCH_3 peaks, 4-H), 3.76, 3.79 (s, 6H each, OCH_3) 5.02 (ABX q, $J_{a4}+J_{b4}$=16.4 Hz, 1H, 2-H), 6.38—6.56 (m, 4 H, Ar-H) 7.13—7.23, 7.50—7.59 (m, 1H each, Ar-H). Found: C, 66.55; H, 6.78%. Calcd for $C_{20}H_{24}O_4S$: C, 66.63; H, 6.71%.

Reaction with Anisole (2d). The reaction mixture which was obtained by the reaction of **1** (30 mmol) with 5 mol equiv of **2d** and 1 mol equiv of $AlCl_3$ was poured into ice-water. 2,4-Bis(*p*-methoxyphenyl)thiophene (**4d**; 1.4 g, mp 211—220 °C), thus precipitated, were filtered off and washed with $CHCl_3$ (10 ml). The organic layer was separated from the filtrate and combined with the washing. After the usual work-up and the removal of solvents and starting substances by distillation, the residue was chromatographed (silica gel/benzene–hexane (3:1)) to give 2-(*p*-methoxyphenyl)thiophene (**3d**; after recrystallization from MeOH, 1.7 g, mp 109—110 °C) and 2,4-bis(*p*-methoxyphenyl)tetrahydrothiophene (**7d**; 0.4 g, oil, MS *m/z* 300

(M^+, 20), ^1H NMR (CCl_4) δ=2.0—2.7 (m, 2H), 3.0—3.4 (m, 2H), 3.5~ (m, overlapped in part with the OCH_3 peaks), 3.82 (s, 6H), 4.4—4.9 (m, 1H), 6.7—7.6 (m, 8H)). The presence of the corresponding diarylbithienyl (**8d**) and 2,4-bis(*p*-methoxyphenyl)dihydrothiophene (**6d**) was also suggested to be in the product by an MS spectral analysis.

4d: Colorless leaflet, mp 219—221 °C (from *N,N*-dimethylformamide). MS *m/z* 296 (M^+, 100). UV λ_{max} (EtOH) 267 (4.60), 292 sh (4.28), 310 sh (3.98) (lit,[9a] 265 (4.56), 300—330 (4.18—4.04)).

Reaction with *o*-Methoxytoluene (2e). Chromatography (silica gel/benzene–hexane (1:2)) of the crude product gave an unseparable mixture of the two isomeric 2-(methoxytolyl)thiophenes (**3e**; mp 58—67 °C, the ratio= 85:15 (NMR)) together with small amounts of **5** and a mixture of the corresponding diarylthiophenes (**4e**; MS *m/z* 324 (M^+, 100)).

3e (as a mixture): Pale yellow crystals, mp 67—70 °C (from hexane). MS *m/z* 204 (M^+, 100). ^1H NMR (CCl_4) δ=2.11, 2.15 (s each, 3H, CH_3), 3.76 (s, 3H, OCH_3), 6.6—7.4 (m, 6H, Ar–H). Found: C, 70.31; H, 5.94%. Calcd for $C_{12}H_{12}OS$: C, 70.55; H, 5.92%.

Reaction with *m*-Methoxytoluene (2f). The crude products were chromatographed (silica gel/benzene–hexane (1:1)) to give an unseparable mixture of the two isomeric 2-(methoxytolyl)thiophenes (**3f**; oil, the ratio=70:30 (NMR)) together with small amounts of **5** and a mixture of the corresponding diarylthiophene (**4f**) and diaryldihydrothiophene (**6f**) (MS *m/z* 324 (M^+ for **4f**, 31), 326 (M^+ for **6f**, 26)).

3f (as a mixture): Pale yellow viscous oil, bp 100—110 °C/2×10^{-3} mmHg. MS *m/z* 204 (M^+, 86). ^1H NMR (CCl_4) δ=2.31 (s, 3H, CH_3), 3.74, 3.86 (s each, 3H, OCH_3), 6.5—7.5 (m, 6H, Ar–H). Found: C, 70.68; H, 5.91%. Calcd for $C_{12}H_{12}OS$: C, 70.55; H, 5.92%.

Reaction with 1-Methoxy- (2i) or 2-Ethoxynaphthalene (2j). The crude products were chromatographed (silica gel/hexane–$CHCl_3$ (3:1)) to afford 2-(4-methoxy-1-naphthyl)- (**3i**) or 2-(2-ethoxy-1-naphthyl)thiophene (**3j**), respectively. The IR spectra were identical with those of the authentic samples which were prepared as described below, and the mixed melting points exhibited no depression.

3i: Colorless plates, mp 50—51 °C (from MeOH). MS *m/z* 240 (M^+, 100). UV λ_{max} (MeOH) 218 (4.57), 238 sh (4.37), 310 (4.02). ^1H NMR ($CDCl_3$) δ=4.00 (s, 3H, OCH_3), 6.83 (d, 1H, Ar–H), 7.1—7.3 (m, 2H, Ar–H), 7.3—7.6 (m, 4H, Ar–H), 8.1—8.5 (m, 2H, Ar–H). Found: C, 75.15; H, 5.01%. Calcd for $C_{15}H_{12}OS$: C, 74.97; H, 5.03%.

3j: Pale yellow needles, mp 58—59 °C (from MeOH). MS *m/z* 254 (M^+, 100). UV λ_{max} (MeOH) 232 (4.71), 283 (3.80), 294 (3.81), 337 (3.60). ^1H NMR (CCl_4) δ=1.24 (t, *J*=6.6 Hz, 3H, $OCH_2\underline{CH_3}$), 4.04 (q, *J*=6.6 Hz, 2H, $O\underline{CH_2}CH_3$), 6.9—7.4 (m, 6H, Ar–H), 7.6—7.8 (m, 3H, Ar–H). Found: C, 75.85; H, 5.62%. Calcd for $C_{16}H_{14}OS$: 75.56; H, 5.55%.

Preparation of 2-(4-Methoxy-1-naphthyl)- (3i) and 2-(2-Ethoxy-1-naphthyl)thiophenes (3j) by the Grignard Cross-Coupling. The procedure was a modification of the method used for the preparation of arylnaphthalenes from iodonaphthalenes.[8] A solution of 2-iodothiophene (7.6 g, 36 mmol) in dry ether (40 ml) was added under a nitrogen atmosphere to magnesium turnings (0.87 g, 36 mmol) in a flask at such a rate that a gentle reflux was maintained (ca. 20 min). After an additional 1-h heating, the resulting Grignard solution was diluted with dry benzene (20 ml). To the refluxing solution was added a solution of 1-iodo-4-methoxynaphthalene[21] (3.4 g, 12 mmol) and nickel(II) acetylacetonate (31 mg) in dry benzene (20 ml). The reaction mixture was stirred for 1 h at the reflux temperature. After cooling, the mixture was treated with an aqueous NH_4Cl solution (20%, 100 ml), and the aqueous layer was extracted with benzene (20 ml×2). The combined organic layers were washed with water and dried. After a removal of the solvents, the crude reaction products were chromatographed (silica gel/hexane–$CHCl_3$ (3:1)) to give 2,2′-bithienyl (mp 32.5—33.5 °C; 0.8 g) and crude **3i** (mp 46—49 °C; 2.4 g, 88%) in order of decreasing R_f values. This was recrystallized from MeOH to afford the analytical sample (mp 50—51 °C).

2-(2-Ethoxy-1-naphthyl)thiophene (**3j**) was prepared similarly by the reaction of 2-thienylmagnesium iodide and 1-iodo-2-ethoxynaphthalene[22] in 75% yield. Mp 58—59 °C (from MeOH).

Preparation of 2-(2,4-Dimethylphenyl)thiophene (3c) by Gomberg Reaction. Compound **3c** was prepared by a reaction of thiophene with 2,4-dimethylbenzenediazonium acetate according to the procedure of Beaton et al.[18b] Purification of the crude product by chromatography (silica gel/CCl_4) followed by distillation afforded **3c** (13%) as a colorless oil. Bp 61—63 °C/1×10^{-4} mmHg. MS *m/z* 188 (M^+, 100). UV λ_{max} (EtOH) 229 (4.03), 268 (4.03); ^1H NMR (CCl_4) δ=2.29 (s, 3H, CH_3), 2.31 (s, 3H CH_3), 6.90—7.23 (m, 6H, Ar–H). Found: C, 76.40; H, 6.39%. Calcd for $C_{12}H_{12}S$: C, 76.55; H, 6.42%.

Replacement of the Activated Nitro Group by a Phenylthio Group

Hideyoshi MIYAKE* and Kimiaki YAMAMURA
Department of Chemistry, College of General Education, Kobe University,
Tsurukabuto, Nada-ku, Kobe 657
(Received June 22, 1985)

The nitro group, activated by a carbonyl group, alkoxycarbonyl group or a phenyl group, can be replaced by a phenylthio group in the reaction with benzenethiol or its potassium salt. This reaction proceeds in the electron transfer mechanism, and is applicable to the general syntheses of α-phenylthio ketones, α-phenylthio carboxylic esters and α-phenylthio alkylbenzenes from primary nitro compounds.

Primary aliphatic nitro compounds can be prepared in various methods.[1] Recently, the attractive methods of acylation,[2] alkoxycarbonylation,[3] and arylation[4] of the primary nitroalkanes have been reported, and those reactions proceed under mild conditions with high yields due to the strong electron withdrawing inductive effect and the electron acceptability of the nitro group. However, the target molecule in organic synthesis is usually nitro-free one. Therefore, the conversion of the nitro compound into nitro-free one has a considerable value. The replacement of the nitro group by hydrogen is the only useful method which is applicable to α-nitro ketone and α-nitro carboxylic ester.[5] We wish to describe the replacement of the nitro group by a phenylthio group. By this reaction, two-step conversion of primary nitro compound into α-phenylthio ketone, α-phenylthio carboxylic ester and α-phenylthio alkylbenzene become possible (Eq. 1).

$$\underset{\mathbf{1}}{R^1CH_2NO_2} \longrightarrow \underset{\mathbf{2}}{R^1CHNO_2} \longrightarrow \underset{\mathbf{3}}{R^1CHSPh} \qquad (1)$$

$PhCH(NO_2)CH_2CH_2CH_3$ **2h**	1.5	120 °C, 1 h,	**3h** 13
$CH_3CH_2CH(NO_2)CO_2C_2H_5$ **2i**	1.5	120 °C, 1 h,	**3i** 7

a) 3 equiv of PhSH was used. b) Isolated yield. c) 0.1 equiv of *m*-DNB was added.

Replacement of the Nitro Group Under Basic Conditions. When potassium benzenethiolate was used instead of benzenethiol the replacement also proceeded. This method is favorable for the compounds which do not have the sensitive functionality to a nucleophile. The results are shown in the Table 3. The nitro compound, such as **4**, which was synthesized by the Michael addition of a nitro compound, did not give **5** by the reaction with PhS^-, because retro Michael type elimination predominated and it gave **6** in 61% yield (Eq.5). In order to avoid such elimination, the carbonyl group of **4** must be protected (**2j** in Table 3).

$$\underset{\textbf{4}}{PhCH(NO_2)CH_2CH_2C(O)CH_3} \not\longrightarrow \underset{\textbf{5}}{PhCH(SPh)CH_2CH_2C(O)CH_3} \qquad (5)$$

$$\textbf{4} \longrightarrow PhSCH_2CH_2C(O)CH_3\ 61\%\ (\textbf{6})$$

When the nitro compound has an alkoxycarbonyl group, reaction at lower temperatures and addition of AIBN are favorable to avoid the destruction of the alkoxycarbonyl group.

This basic procedure was not appropriate to the replacement of the nitro group of α-nitro ketone due to the nucleophilicity of PhS^- (see Eq. 2), and the yield of the sulfide was lower than that of the neutral procedure (Table 2).

Table 3. Replacement of the Nitro Group by the Phenylthio Group Under Basic Conditions (Eq. 4)

$R\text{-}NO_2$	Conditions	Yield of 3/%[e]
2g	100 °C 1 h	**3g** 77
	120 °C 2.5 h[a]	76
2h	120 °C 2 h	**3h** 72
2i	60 °C 2 h[b]	**2i** 58
$PhCH(NO_2)CH_2CH_2C(O)CH_3$ **2j**	80 °C 3.5 h	**3j** 74
2e	60 °C 1 h[c]	**2e** 17
	60 °C 1 h[c,d]	28

a) 0.1 equiv of *m*-DNB was added. b) 0.25 equiv of AIBN was added. c) 0.5 equiv of AIBN was added. d) Et_3N was used instead of *t*-BuOK. e) Isolated yield.

Mechanism. These reactions (neutral and basic) were accelerated by a small amount of radical initiator such as AIBN, and completely inhibited (neutral) or decelerated (basic) by a small amount of *m*-dinitrobenzene(*m*-DNB). These results and the solvent effect suggest the electron transfer mechanism, which was well established for the replacement of the nitro group.[1] Equations 6—9 show the mechanism of the replacement of the nitro group under basic conditions.

$$PhS^- + R\text{-}NO_2 \longrightarrow PhS\cdot + R\text{-}NO_2^{\cdot-} \quad (6)$$

$$R\text{-}NO_2^{\cdot-} \longrightarrow R\cdot + NO_2^- \quad (7)$$

$$R\cdot + PhS^- \longrightarrow R\text{-}SPh^{\cdot-} \quad (8)$$

$$R\text{-}SPh^{\cdot-} + R\text{-}NO_2 \longrightarrow R\text{-}SPh + R\text{-}NO_2^{\cdot-} \quad (9)$$

However, the mechanism of the reaction under neutral conditions is not apparent. We think, there are two possible mechanisms. One of them involves the equilibrium of Eq 10, followed by Eqs. 6—9. The other one involves the cation radical of benzenethiol which was suggested by Hashiyama and co-workers for the reaction with glycidate.[9] However, we cannot distinguish them up to the present and the mechanism is now under investigation.

$$RhSH \rightleftharpoons PhS^- + H^+ \quad (10)$$

$$PhSH + R\text{-}NO_2 \longrightarrow [PhSH^{\cdot+} + R\text{-}NO_2^{\cdot-}] \longrightarrow R\text{-}SPh + HNO_2 \quad (11)$$

Experimental

Materials. Nitro compounds were prepared according to the reported procedures.[1-4,10]

General Procedure for the Replacement of the Nitro Group by a Phenylthio Group Under Neutral Conditions. The nitro compound (3 mmol), benzenethiol (9 mmol) and AIBN (3 mmol) were dissolved in HMPT (7 ml) and the mixture was stirred at 90—130 °C for 0.5—1 h (see Table 2). The reaction mixture was poured into water and extracted with ether. The organic layer was washed with water, dried with $MgSO_4$, concentrated under reduced pressure, and purified by column chromatography on silica gel.

General Procedure for the Replacement of the Nitro Group by a Phenylthio Group Under Basic Conditions. Benezenethiol (9 mmol) and *t*-BuOK (4.5 mmol) were dissolved in HMPT (7 ml), and the nitro compound (3 mmol) was added to that solution and the mixture was stirred at appropriate temperature for 1—3.5 h (see Table 3). The reaction mixture was poured into 0.5 M HCl (30 ml (1 M=1 mol dm^{-3})) and extracted with ether. The organic layer was washed with water, dried with $MgSO_4$, concentrated under reduced pressure, and purified by column chromatography on silica gel.

Identification of the Sulfides. The sulfides were identified by ^1H NMR and IR spectra. Some of them (**3a**, **3b**, **3d**, **3e**, **3f**, **3g**, and **3i**) were compared with the data reported.[11,12]

2-Methyl-2-phenylthio-2-butanone (3c): ^1H NMR ($CDCl_3$) δ=1.05 (dd, 6H, J=7 Hz, 3 Hz), 1.04 (d, 3H, J=7 Hz), 2.7—3.2 (m, 1H), 3.85 (q, 1H, J=7 Hz), 7.0—7.7 (m, 5H); IR (neat) 2970, 1708, 1438, 1010 cm^{-1}; Anal. ($C_{12}H_{16}OS$) C, H.

1-Phenyl-1-(phenylthio)butane (3h): ^1H NMR ($CDCl_3$) δ=0.85 (t, 3H, J=6 Hz), 1.0—1.6 (m, 2H), 1.7—2.1 (m, 2H), 4.10 (t, 1H, J=7 Hz), 6.9—7.3 (m, 10H); IR (neat) 3060, 3030, 2960, 1480, 1453, 1438, 1050 cm^{-1}; Anal.($C_{16}H_{18}S$) C, H.

4,4-Ethylenedioxy-1-phenyl-1-(phenylthio)pentane (3i): ^1H NMR ($CDCl_3$) δ=1.30 (s, 3H), 1.5—2.3 (m, 4H), 3.7—3.9 (m, 4H), 4.10 (t, 1H, J=7 Hz), 7.0—7.5 (m, 10H); IR (neat) 2940, 1455, 1440, 1365 cm^{-1}; Anal.($C_{19}H_{22}O_2S$) C, H.

The present work was partially supported by the Research Aid of the Inoue Foundation for Science.

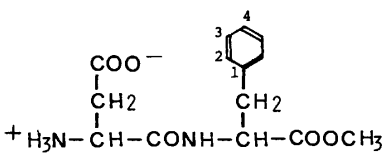
Raman and Solid State NMR Study on an Inclusion Compound of Aspartame with Cyclodextrin

Shin-ichiro TAKAHASHI,* Ei-ichiro SUZUKI, Yusuke AMINO, Nobuya NAGASHIMA, Yoshifumi NISHIMURA,† and Masamichi TSUBOI†

Central Research Laboratories, Ajinomoto Co., Inc. Suzuki-cho, Kawasaki-ku, Kawasaki 210
†Faculty of Parmaceutical Sciences, The University of Tokyo,
Hongo, Bunkyo-ku, Tokyo 113
(Received June 24, 1985)

A crystal of inclusion compound of Aspartame (α-L-aspartyl-L-phenylalanine methyl ester, APM) with β-cyclodextrin (β-CD) was obtained from their aqueous solution. The Raman spectrum of this crystal indicates some differences from the spectral sum of APM and β-CD. An analysis of these spectral differences suggests that the phenyl moiety of APM is included in the cavity of β-CD in the inclusion compound. In addition, a Raman spectroscopic study of APM with ^{15}N-substitution and N-deuteration indicates that the peptide backbone of APM undergoes some conformational change on APM going into the inclusion compound. Solid state ^{13}C CP MAS- and gated-decoupling MAS-NMR spectra for the inclusion compound indicate that the phenyl ring rotates at a higher frequency than 270 MHz, that the Phe Cβ and phenyl ring C1 move at the frequency of about 270 MHz, and that the molecular motion of the other parts of APM occurs at lower frequency than 270 MHz.

APM (Scheme 1) is a dipeptide sweetener. We have recently succeeded in obtaining a crystal of an inclusion compound of APM with β-CD which has a higher dissolving rate into H_2O than APM itself. For finding out the mechanism of such a change in that property, a single crystal X-ray diffraction study of the inclusion compound would be powerful. Unfortunately, however, our attempt to obtain a sufficiently large crystal has not so far been successful. Other methods such as Raman spectroscopy[1,2] and solid-state ^{13}C NMR spectroscopy[3–5] may also be useful. We have used the Raman method to elucidate the inclusion mechanism of APM–β-CD and the solid-state ^{13}C NMR method to determine the rate of motion of APM molecule. Such studies would provide not only new pieces of information on the particular inclusion compound now in question but also data for constructing a general view of the CD inclusion compounds, in conjunction with comparison our results with others' for different guest molecules.



Scheme 1 APM

Experimental

Materials. Crystals of inclusion compound of APM with β-CD was prepared from their aqueous solutions, i.e., 6.7×10^{-2} M(=mol dm^{-3}) of APM and 5.5×10^{-2} M of β-CD in water were sealed in a flask and stirred gently at 60 °C for 15 min. The solution was cooled gradually and kept at 4 °C for two weeks. The crystals formed of the compound were precipitated, collected by filtration and dried in a desiccator at room temperature. The composition of this crystal was found by means of an amino acid analyzer, ^1H NMR and Karl Fischer's analysis to be 1:1:6 of APM:β-CD:water. Phenylalanine-^{15}N was obtained from SHOKO Co., Ltd. Phenylalanine-^{15}N methyl ester hydrochloride (**1**) was prepared by the thionyl chloride method. *N*-benzyloxycarbonyl-β-benzyl-L-aspartyl-L-phenylalanine-^{15}N methyl ester (**2**) was synthesized from β-benzyl-*N*-benzyloxycarbonyl-L-aspartate and **1** via dicyclohexylcarbodiimide in the presence of triethylamine in chloroform. α-L-Aspartyl-L-phenylalanine-^{15}N methyl ester (**3**) was prepared from **2** by hydrogenation at room temperature in the presence of 2% palladium charcoal in aqueous methanol. **3** was purified by YMC-PAK SH-343 column chromatography using methanol/0.1 M phosphate buffer pH 5.0 (30:70 by vol) as eluent. The fraction of **3** was collected, concentrated three times with a rotary evaporator, desalted by a SEP-PAK C18 cartridge, and lyophilyzed to dryness.

Apparatus. Raman spectra were recorded on a JASCO R-800 spectrometer. The 514.5 nm exciting line from an argon ion laser (NEC model GLS 3300) was used. Wavenumbers were calibrated against the spontaneous emission (521 cm^{-1}) of Ar^+.

Solid state ^{13}C NMR was recorded on a JEOL GX-270 spectrometer operating at 67.8 MHz and on a JEOL FX-60 spectrometer at 15.1 MHz.

Results

Raman spectra of the inclusion compound of APM with β-CD and their mechanical mixture are shown in Fig. 1. The Raman bands assigned to the APM molecule in the inclusion compound indicate some frequency differences from those of free APM. Thus the bands at 819, 1005, and 1197 cm^{-1} of free APM are shifted to 825, 1002, and 1207 cm^{-1}, respectively, and the bands at 747, 765, 890, and 971 cm^{-1} are caused to disappear. From a comparison with Raman bands of toluene,[6] the shifted bands can be assigned to the normal vibrations at ν_1, ν_{12}, and ν_{13} of monosub-

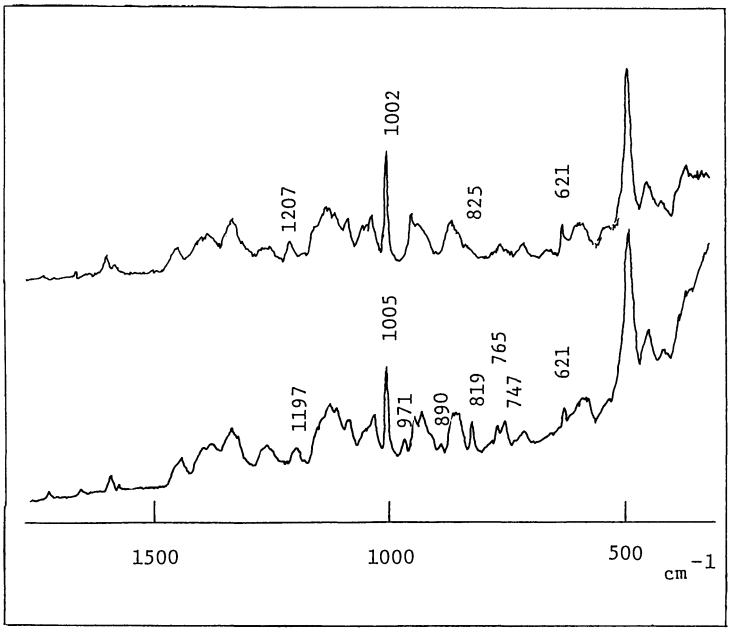


Fig. 1. Raman spectra of the inclusion compound of Aspartame with β-CD (top) and their mechanical mixture (bottom).

Table 1. Raman Bands/cm^{-1} of APM and the Inclusion Compound of APM with β-CD

APM	Inclusion compound	Assignment[a)]
819	825	ν_1
1005	1002	ν_{12}
1197	1207	ν_{13}
747	Disappear	
765	Disappear	
890	Disappear	
971	Disappear	

a) Normal vibration of monosubstituted benzene.

Table 2. Raman Bands/cm^{-1} in 600—100 cm^{-1} of APM and Its Derivatives

APM	Asp-Phe-^{15}N-OMe	N-deuterated APM
621	621	621
747	747	745
819	816	812
890	890	886
971	967	960
1005	1005	1004

stituted benzene, respectively. Results of such observations are summarized in Table 1. The observed shifts suggest that the phenyl ring of APM gets located in the cavity of β-CD on the formation of the inclusion compound. The Raman bands observed in the 600—1000 cm^{-1} range with Asp-Phe-^{15}N-OMe and N-deuterated APM are shown in Table 2. The band at 971 cm^{-1} of normal APM is shifted to 967 cm^{-1} on ^{15}N-substitution and to 960 cm^{-1} on N-deuteration. The band width of the 960 cm^{-1} line of N-deuterated APM has been found to increase and this is probably because the band of amide III is overlapping here. The Raman band around 940 cm^{-1} of polypeptides has been assigned to the backbone stretching vibration,[7] and its frequency is reported to be sensitive to the backbone conformation.[8-10] The ^{15}N and N-deuteration shifts of the band (971 cm^{-1}) indicate that it is assignable to this backbone stretching vibration. The disappearance of the band in the inclusion compound suggests that when APM is included in the cavity of β-CD, its backbone undergoes a conformational change.

The 67.8 MHz solid state ^{13}C CP MAS-NMR spectra of the inclusion compound crystal of APM with β-CD and their mechanical mixture are shown in Fig. 2. The observed resonances are assigned by comparing with the spectrum in aqueous solution. The line widths of resonances of the atoms in APM are found larger than those of β-CD in the inclusion compound, especially, the resonances of phenyl ring Cl and Phe Cβ are too broad to be detected. Figure 3a shows a 67.8 MHz ^{13}C gated-decoupling MAS-NMR spectrum of the inclusion compound. In general, resonances of nuclei of higher frequency motion shoud be sharper than those of lower one in this method. A comparison of Figs. 2 (upper) and 3a indicates that the resonances of the phenyl ring carbons except Cl become obviously sharper on gated-decoupling. This fact indicates that the phenyl ring in the cavity of β-CD is rotating rapidly, whereas the other part of the molecule is moving slowly Figure 3b shows a 15.1 MHz solid state ^{13}C CP

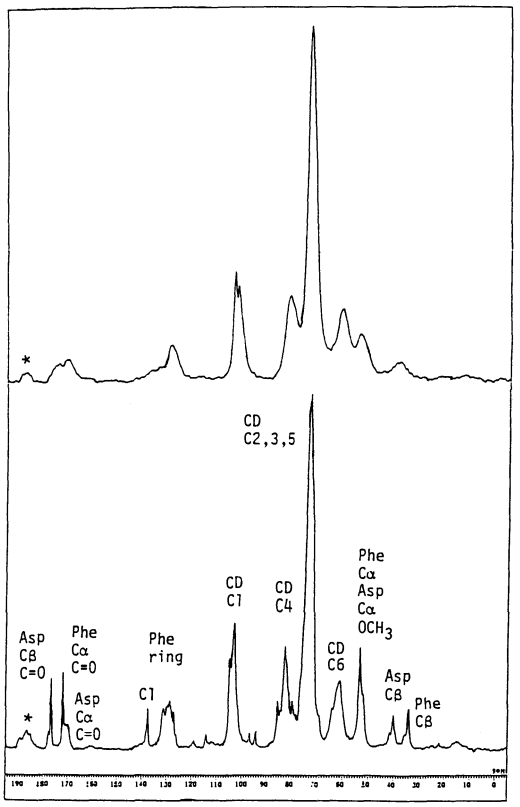

Fig. 2. 67.8 MHz solid state ^{13}C CP MAS-NMR spectra of the inclusion compound of APM with β-CD (top) and their mechanical mixture (bottom). (* denotes spinning side band)

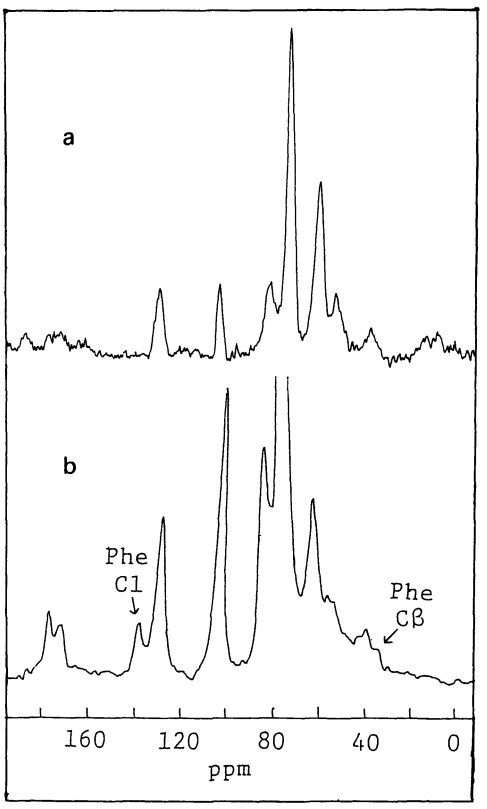

Fig. 3. (a) 67.8 MHz solid state ^{13}C gated-decoulping MAS-NMR spectrum of the inclusion compound of Aspartame with β-CD. (b) 15.1 MHz solid state ^{13}C CP MAS-NMR spectrum of the inclusion compound of Aspartame with β-CD.

MAS-NMR spectrum of the inclusion compound. The resonance of phenyl ring Cl carbon is now found sharper than that at 67.8 MHz, and the resonance of Cβ of Phe residue is detectable here, although its *S/N* ratio is very low. This phenomenon can be explained in terms of the formula proposed by Rothwell and Waugh.[11] In their paper the Hamiltonian of a two-spin system (I=^{1}H and S=^{13}C) is written as

$$H=-\omega_{0I}I_z-\omega_{0S}S_z-2\omega_1 I_x\cos\omega_{0I}t+d.d., \quad (1)$$

where ω_{0I} and ω_{0S} are the Larmor frequencies of I and S, respectively ω_1 is rf irradiation intensity, and *d.d.* is the term of the dipole-dipole interaction between I and S. If the motion of spin I takes place with a frequency ω_{0I} in the order of magnitude, the line width of the resonance of spin S should be large because I_x of the third term of Eq. 1 decays rapidly during the CP condition. Thus the large line widths of the resonances of Phe Cβ and phenyl ring Cl in 67.8 MHz ^{13}C NMR and the smaller one in 15.1 MHz indicate that the molecular motions of Phe Cβ and phenyl ring Cl occur at about 270 MHz (^{1}H Larmor frequency in 67.8 MHz ^{13}C NMR). In summary, it may be concluded that the phenyl ring is considered to rotate at higher frequencies than 270 MHz, that the Phe Cβ and phenyl ring Cl move at about 270 MHz, and that the molecular motions of the other parts of APM occurr at lower frequencies than 270 MHz in the inclusion compound.

Discussion

It is an interesting problem to find out what type and magnitude of distortions a guest molecule will undergo on being brought it into an inclusion compound with CD. Several pieces of information have been obtained on this point:[2-5] For example Sato et al.,[2] examined in 1979 some CD inclusion compounds of azo dyes in aqueous solutions. They detected frequency shifts for some Raman lines, and assigned them to Ph-N stretching and ring vibrations of the dye molecules having been brought into the inclusion compounds. There have been a number of reports on the broadening of signals of guest molecules in solid state ^{13}C NMR studies of their inclusion compounds with CD. In general, there may be two possible causes for such broadening: chemical shift dispersion and molecular mobility.[12]

Hall and Lim[13] demonstrated, by the deuterium quadrupolar echo method, that benzene-d_6 molecule is rapidly rotating around the six-fold symmetry axis in the cavity of CD where it is included.

By the use of the particular type of guest molecule, our present study has enlightened several new aspects of the problem. It should be pointed out, first of all, that our present study was made on a crystal in which 100% of the guest molecules are considered to be in the regular inclusion sites. At the same time, however, the guest molecules may be involved in an inter-molecular interaction, besides the interaction with CD, in such a crystal. In our present study some localized changes in the guest molecule have been suggested. Thus, the phenyl group is considered to be located in the CD cavity but seems to rotate rapidly in the cavity. The other part of the molecule seems to be moving slowly (<270 MHz), probably because this part is located outside the CD cavity and fixed by an inter-molecular interaction with the adjacent APM molecule. The inbetween portion, involving the Phe Cβ and Cl atoms, seems to be moving with a medium rate (close to 270 MHz). Probably because of its environmental change, on going from free to included APM, the Raman lines assignable to the phenyl group showed frequency shifts. Of them, the strong and sharp line at 1005 cm^{-1} is considered to be caused by the phenyl ring breathing vibration of the phenylalanine residue. This Raman line is always prominent in the Raman spectrum of a protein as long as it contains phenylalanine residues.[14] A review of such Raman spectra reveals that its frequency is generally insensitive to the conformation of the protein molecule and to the intra-molecular environment of the phenylalanine residue.[15] It is therefore noteworthy that this is shifted from 1005 to 1002 cm^{-1} on going from free to included APM. From this amount of frequency shift, as well as those given in Table 1, we shoud be able to derive a set of force constant changes of the phenyl group on going from free APM to the APM located in the CD cavity. This, however, is not yet to be done.

In conclusion, we have been able to ensure by Raman examination that the phenyl ring is included in the cavity of β-CD in the inclusion compound of APM with β-CD, and by solid state ^{13}C NMR that the phenyl ring rotates rapidly in the cavity.

We thank Dr. Kenzo Deguchi (JEOL NM Group Application Lab.) for the measurement of 67.8 MHz solid state ^{13}C NMR spectra and Dr. Tadashi Yoshida (Government Industrial Development Laboratory, Hokkaido) for the measurement of 15.1 MHz solid state ^{13}C NMR spectrum, and Professor Akiko Hirakawa (Univ. of Tokyo) for discussions.

Selective Preparation of Fluorene Derivatives Using the *t*-Butyl Function as a Positional Protective Group[1)]

Shoji KAJIGAESHI,* Toshiya KADOWAKI, Akiko NISHIDA, and Shizuo FUJISAKI
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
(Received July 8, 1985)

Several 4-substituted 2,7-di-*t*-butylfluorene derivatives (**3**) were prepared by electrophilic substitutions of 2,7-di-*t*-butylfluorene (**1**). 4-Substituted fluorene (**4**), such as 4-bromo- (**4a**), 4-methyl (**4e**), and 4-acetylaminofluorene (**4j**), were obtained by the trans-*t*-butylations of **3**. Although we attempted to synthesize 1,8-disubstituted fluorene from 3,6-di-*t*-butylfluorene (**2**) which was derived from 2,2′-diiodo-4,4′-di-*t*-butyldiphenylmethane (**5**), by the same methods, we obtained only 2,7-disubstituted fluorene derivatives (**8**); it turned out electrophilic substitutions of **2** gave 2,7-disubstituted 3,6-di-*t*-butylfluorene derivatives.

It is difficult to prepare 4-substituted fluorenes by direct electrophilic substitutions on the fluorene ring because such substitutions occur predominantly at the 2- or 2,7-positions having the highest electron density. Therefore, 4-substituted fluorenes usually have been prepared via 4-fluorenonecarboxylic acid, the dehydrated fused-ring compound of diphenic acid, in a tedious synthetic procedure.[2)]

Recently, Tashiro[3)] have reported that many kinds of aromatic compounds can be selectively prepared by using *t*-butyl function as a positional protective group. We now report a convenient preparation of the 4-substituted fluorenes by electrophilic substitutions of 2,7-di-*t*-butylfluorene (**1**) and subsequent Lewis acid-catalyzed trans-*t*-butylations, using the Tashiro's method. Furthermore, we report also an attempted preparation of 1,8-disubstituted fluorenes by electrophilic substitutions of 3,6-di-*t*-butylfluorene (**2**) which is prepared from diphenylmethane via several steps.

Results and Discussion

Electrophilic Substitutions of 2,7-Di-*t*-butylfluorene (1). Although starting material **1** has been prepared from the reaction of fluorene with *t*-butyl chloride in the presence of $AlCl_3$ in nitrobenzene/carbon disulfide,[4)] this method is not so appropriate because of contamination of 2-*t*-butylfluorene. Now we could obtained **1** by the $AlCl_3$/Nitromethane-catalyzed *t*-butylation[3)] of fluorene with 2,6-di-*t*-butyl-*p*-cresol in good yield under mild conditions.

The reactions of **1** with electrophiles afforded 4-substituted 2,7-di-*t*-butylfluorenes (**3**) regioselectively. In these reactions, the electrophilic attack to **1** did not occur at 1-, 3-, 6-, and 8-positions in the fluorene ring blocked by the bulky *t*-butyl groups. Thus, the reaction of **1** with bromine in the presence of iron powder in carbon tetrachloride gave 4-bromo-2,7-di-*t*-butylfluorene (**3a**). The reaction of **1** with iodine, periodic acid, and sulfuric acid in acetic acid/carbon tetrachloride at 70—80 °C gave 4-iodo-2,7-di-*t*-butylfluorene (**3b**). 4-Chloromethyl-2,7-di-*t*-butylfluorene (**3c**) was obtained by the $ZnCl_2$-catalyzed chloromethylation of **1** with chloromethyl methyl ether. The reaction of **1** with fuming nitric acid in acetic anhydride/acetic acid at −40 °C to −20 °C gave a

mixture of 4-nitro-2,7-di-*t*-butylfluorene (**3d**) and 7-nitro-2-*t*-butylfluorene. Compound **3d** was separated from the mixture by column chromatography over alumina (Scheme 1).

Attempts to synthesize 4-acetyl and 4-chloro derivatives of **1** were unsuccessful. Furthermore, any 4,5-disubstituted products were not obtained by the electrophilic substitutions of **1**. It seems that 4-substituent prevent further substitution of electrophile on 5-position owing to its steric hindrance.

Several derivatives **3** were also obtained from the subsequent reactions of **3c** and **3d**. The reduction of **3c** with $LiAlH_4$ in tetrahydrofuran afforded 4-methyl-2,7-di-*t*-butylfluorene (**3e**). The reaction of **3c** with NaCN in acetonitrile afforded 4-cyanomethyl-2,7-di-*t*-butylfluorene (**3f**), and subsequent hydrolysis of **3f** gave 4-carboxymethyl-2,7-di-*t*-butylfluorene (**3g**). 4-Hydroxymethyl-2,7-di-*t*-butylfluorene (**3h**) was also obtained by treating **3c** with $AgNO_3$ in water/acetone. And then, the reduction of **3d** with tin and hydrochloric acid in ethanol gave 4-amino-2,7-di-*t*-butylfluorene (**3i**). 4-Acetylamino-2,7-di-*t*-butylfluorene (**3j**) was obtained from **3i** and acetic anhydride.

Trans-*t*-butylations of 3. $AlCl_3$-catalysed trans-*t*-butylations[3] of **3a, 3e,** and **3j** were carried out at 50 °C for 3—6 h in benzene to afford the desired 4-bromofluorene (**4a**), 4-methylfluorene (**4e**), and 4-acetylaminofluorene (**4j**), respectively (Scheme 2).

Compounds **4a**[5] and **4j**[6], have already been prepared from 4-fluorenonecarboxylic acid by means of successive conversion of the functional groups. However, our method is more useful because these compounds can be prepared in only three steps from fluorene as starting material which is easily available. Although **4e** have been obtained by passing 2,2-dimethylbiphenyl over Pd–charcoal at 450 °C,[7] the above preparative conditions are too severe as an experimental procedure in laboratory in comparison with our method.

While we tried to prepare other derivatives **4** from **3** except above **3a, 3e,** and **3j**, these products **4** were not obtained because the trans-*t*-butylation of **3** with $AlCl_3$ in benzene did not proceed satisfactory owing to the deficient electron densities in the fluorene ring substituted with electron-attractive groups, or the products were difficult to isolate from the reaction mixture.

Synthesis of 3,6-Di-*t*-butylfluorene (2). The preparations of 1,8-disubstituted fluorene are also difficult by direct electrophilic substitutions to the fluorene ring because of the same reason described about the preparation of 4-substituted fluorenes. From the facts that several **4**'s were obtained from **1**, we also expected that 1-substituted and 1,8-disubstituted 3,6-di-*t*-butylfluorenes may be obtained by electrophilic substitutions of **2** in which the bulky *t*-butyl groups should block 2-, 4-, 5-, and 7-positions in the fluorene ring.

Thus, 2,2′-diiodo-4,4′-di-*t*-butyldiphenylmethane (**5**) was prepared by iodination of 4,4′-di-*t*-butyldiphenylmethane[8] with iodine, periodic acid, and sulfuric acid in acetic acid, and then by heating **5** with activated copper powder[9] crude **2** was obtained in fairly good yield. Furthermore, in order to obtain pure **2**, the crude **2** was oxidized with bubbling oxygen in the *N,N*-dimethylformamide solution in the presence of Triton B to afford 3,6-di-*t*-butyl-9-fluorenone (**6**) which can be easily purified by recrystallization. And then **6** is reduced with $NaBH_4$ in ethanol to give 3,6-di-*t*-butyl-9-fluorenol (**7**). The pure **2** could be obtained by reduction of **7** with hydroiodic acid in acetic acid as colorless columnar crystals (Scheme 3).

Electrophilic Substitutions of 3,6-Di-*t*-butylfluorene (2). The reaction of **2** with *N*-bromosuccinimide in propylene carbonate at 70—75 °C gave a dibromo-substituted 3,6-di-*t*-butylfluorene (**8a**). Compound **8a** was also obtained from the reaction of **2**

with bromine in carbon tetrachloride in the presence of iron powder. When **2** was treated with chlorine in carbon tetrachloride in the presence of iron powder, a dichloro-substituted 3,6-di-*t*-butylfluorene (**8b**) was obtained. The reaction of **2** with fuming nitric acid and sulfuric acid in acetic anhydride at 10—20 °C afforded a dinitro-substituted 3,6-di-*t*-butylfluorene (**8c**). Furthermore, the reduction of **8c** with zinc powder and aqueous $CaCl_2$ in ethanol gave a diamino-substituted 3,6-di-*t*-butylfluorene (**8d**). Then a bis(acetylamino)-substituted 3,6-di-*t*-butylfluorene (**8e**) was obtained by acetylation of **8d** with acetic anhydride. It could be confirmed that products, **8a, 8b, 8c, 8d,** and **8e** were all symmetrical-type compounds by their ^1H NMR spectra which showed only two singlets in aromatic regions.

Subsequently, the trans-*t*-butylations of **8a, 8b,** and **8e** were carried out in the usual way. However, all resultant products were 2,7-disubstituted fluorenes. That is, the reactions of **8a, 8b,** and **8e** with $AlCl_3$ in benzene at 50 °C gave 2,7-dibromofluorene[10] (**9a**), 2,7-dichlorofluorene[10] (**9b**), and 2,7-bis(acetylamino)-fluorene[11] (**9e**), which were identical with authentic samples, respectively.

Because it can not be considered that 1,8-groups of 1,8-disubstituted 3,6-di-*t*-butylfluorene (**10**) immigrate into the 2,7-positions under the treating conditions, the substitution reactions with electrophiles should proceed at the 2,7-positions. Thus we recognized the above compounds, **8a—e**, as 2,7-disubstituted 3,6-di-*t*-butylfluorenes. That is, it turned out that although the 2,7-positions in **2** have been blocked by bulky *t*-butyl groups the electrophilic attack to **2** occurs predominantly at 2,7-positions having the highest electron density,[12] rather than at the 1,8-positions which are not hindered sterically (Scheme 4).

Furthermore, ^1H NMR spectra of the acetylamino compounds, **3j, 4j, 8e,** and **9e**, in CF_3COOH showed two acetylmethyl signals due to the two conformers

which appear at room temperature on the NMR time scale by the restricted rotation around the N-CO bond. We have already investigated about the *cis*, *trans*-isomerism of the protonated ring-substituted acetanilides by measurements of their NMR spectra in CF_3COOH.[13]

Experimental

All melting points are uncorrected. NMR spectra were determined on a JEOL-MH-100 spectrometer with Me_4Si as internal standard. IR spectra were measured as KBr pellets on a Nippon Bunko IR-A spectrometer.

2,7-Di-*t*-butylfluorene (1). To a solution of fluorene (34.0 g, 0.2 mol) and 2,6-di-*t*-butyl-*p*-cresol (44 g, 0.2 mol) in nitromethane (300 ml) was added at 10—15 °C $AlCl_3$-nitromethane catalyst [$AlCl_3$ (40 g, 0.3 mol)/nitromethane (60 ml)] over a period of 40 min. After the reaction mixture was stirred for 15 min more, it was poured into a large amount of ice-water. The aqueous layer was extracted with ether and the combined organic phase was washed with water, and concentrated to remove nitromethane. The residue was dissolved in ether, washed with 10% NaOH solution to remove *p*-cresol, and then washed with water, dried over $MgSO_4$, and evaporated in vacuo to obtain a black oily product which was column-chromatographed on alumina using benzene as an eluent to give **1**; yield: 46 g (83%); colorless needles; mp 120—122 °C (from ethanol) (lit,[4] mp 122—123 °C). IR (KBr): 1257 cm^{-1} (*t*-C_4H_9); ^1H NMR ($CDCl_3$) δ=1.38 (18H, s, *t*-C_4H_9×2), 3.87 (2H, s, 9-CH_2), 7.39 (2H, d, J=7 Hz, 3- and 6-H), 7.58 (2H, s, 1- and 8-H), and 7.68 (2H, d, J=8 Hz, 4- and 5-H). Found: C, 90.45; H, 9.50%. Calcd for $C_{21}H_{26}$: C, 90.59; H, 9.41%.

4-Bromo-2,7-di-*t*-butylfluorene (3a). To a mixture of **1** (4.5 g, 16 mmol) and catalytic amount of iron powder in CCl_4 (20 ml) was added dropwise a solution of bromine (2.8 g, 18 mmol) in CCl_4 (5 ml) at 5—8 °C under stirring. After the reaction mixture was stirred for more 3 h at 15—20 °C, it was poured into water. The mixture was extracted with ether, and the ether solution was washed with 10% NaOH solution, dried over $MgSO_4$, and evaporated in vacuo to afford the residue which was recrystallized from ethanol to give **3a** as colorless needles; yield: 5.4 g (95%); mp 125—127 °C. IR (KBr): 1260 cm^{-1} (*t*-C_4H_9); ^1H NMR ($CDCl_3$) δ=1.39, 1.41 (each 9H, s, *t*-C_4H_9×2), 3.96 (2H, s, 9-CH_2), 7.48—7.72 (4H, m, H_{arom}), and 8.60 (1H, d, J=8Hz, 5-H). Found: C, 70.57; H, 7.03%. Calcd for $C_{21}H_{25}Br$: C, 70.58; H, 7.05%.

4-Iodo-2,7-di-*t*-butylfluorene (3b). To a solution of **1** (2.3 g, 8 mmol) and iodine (1.0 g, 4 mmol) in a 2:1 acetic acid-CCl_4 (12 ml) was added 98% H_2SO_4 (0.2 ml) and water (1.6 ml), and the mixture was heated for 3 h at 70—80 °C. After the reaction mixture was poured into water, it was extracted with ether. The ether solution was washed with $NaHSO_3$ solution to remove unreacted iodine, and washed with Na_2CO_3 solution and then with water, and dried over $MgSO_4$. The solution was evaporated in vacuo to leave the residue which was recrystallized from ethanol to give **3b** as yellow needles; yield: 2.8 g (87%); mp 109—110 °C. IR (KBr): 1260 cm^{-1} (*t*-C_4H_9); ^1H NMR ($CDCl_3$) δ=1.40 (18H, s, *t*-C_4H_9×2), 3.88 (2H, s, 9-CH_2), 7.44—7.92 (4H, m, H_{arom}), and 8.74 (1H, d, J=8 Hz, 5-H). Found: C, 62.34; H, 6.12%. Calcd for $C_{21}H_{25}I$: C, 62.38; H, 6.23%.

4-Chloromethyl-2,7-di-*t*-butylfluorene (3c). A mixture of **1** (7 g, 25 mmol), chloromethyl methyl ether (8 g, 0.1 mol), and $ZnCl_2$ (1.7 g, 13 mmol) was stirred for 20 min at room temperature. The reaction mixture was poured into water, extracted with ether, and dried over $MgSO_4$. The ether solution was evaporated in vacuo to give the residue which was recrystallized from hexane affording **3c** as colorless needles; yield: 5.1 g (62%); mp 90—93 °C. IR (KBr): 1260 cm^{-1} (*t*-C_4H_9); ^1H NMR ($CDCl_3$) δ=1.36 (18H, s, *t*-C_4H_9×2), 3.88 (2H, s, 9-CH_2), 5.00 (2H, s, CH_2Cl), 7.28—7.68 (4H, m, H_{arom}), and 9.94 (1H, d, J=8 Hz, 5-H). Found: C, 80.92; H, 8.23%. Calcd for $C_{22}H_{27}Cl$: C, 80.93; H, 8.33%.

4-Nitro-2,7-di-*t*-butylfluorene (3d). To a solution of **1** (2.3 g, 8 mmol) in acetic anhydride (40 ml) was added dropwise at −40—−20 °C a mixture of fuming HNO_3 (1 g) and acetic acid (1.15 g) over a period of 30 min under stirring. After the reaction mixture was stirred for 2 h more at −20—0 °C, it was poured into an ice-cold water. The precipitated solid was filtered, washed with water, and column chromatographed on alumina using petroleum benzine as an eluent to give **3d** in the second fraction; yield: 0.6 g (22%); yellow needles; mp 135—137 °C (from ethanol). IR (KBr): 1255 (*t*-C_4H_9), 1340, 1520 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=1.36, 1.38 (each 9H, s, *t*-C_4H_9×2), 3.89 (2H, s, 9-CH_2), 7.34 (1H, d, J=8 Hz, 6-H), 7.49, 7.66, 7.80 (each 1H, s, H_{arom}), and 7.94 (1H, d, J=8 Hz, 5-H). Found: C, 77.77; H, 7.73; N, 4.05%. Calcd for $C_{21}H_{25}NO_2$: C, 77.98; H, 7.79; N, 4.33%.

4-Methyl-2,7-di-*t*-butylfluorene (3e). To a solution of **3c** (0.5 g, 1.5 mmol) in tetrahydrofuran (10 ml) was added a small portions of $LiAlH_4$ (0.07 g, 2 mmol) under stirring, and the mixture was refluxed for 5 h and then allowed to stand. To the solution was added a 3:2 tetrahydrofuran-water (2 ml) and then a few drops of diluted H_2SO_4. The reaction mixture was extracted with ether, washed with water, and dried over $MgSO_4$. The ether solution was evaporated in vacuo to give **3e** as colorless needles; yield: 0.38 g (87%); mp 133—135 °C (from ethanol). IR (KBr): 1260 cm^{-1} (*t*-C_4H_9); ^1H NMR ($CDCl_3$) δ=1.34 (18H, s, *t*-C_4H_9×2), 2.68 (3H, s, CH_3), 3.84 (2H, s, 9-CH_2), 7.06—7.54 (4H, m, H_{arom}), and 7.70 (1H, d, J=8 Hz, 5-H). Found: C, 90.08; H, 9.70%. Calcd for $C_{22}H_{28}$: C, 90.35; H, 9.65%.

4-Cyanomethyl-2,7-di-*t*-butylfluorene (3f). To a solution of **3c** (3.9 g, 12 mmol) in acetonitrile (60 ml) was added a solution of NaCN (1.2 g, 24 mmol) in water (3 ml). After the mixture was refluxed for 3 h, it was poured into water. The precipitated solid was filtered, washed with water, and recrystallized from ethanol to give **3f** as colorless crystals; yield: 3.1 g (83%); mp 186—187 °C. IR (KBr): 1260 (*t*-C_4H_9), 2240 cm^{-1} (CN); ^1H NMR ($CDCl_3$) δ=1.36 (18H, s, *t*-C_4H_9×2), 3.82 (2H, s, 9-CH_2), 4.04 (2H, s, CH_2CN), and 7.20—7.56 (5H, m, H_{arom}). Found: C, 86.81; H, 8.74; N, 4.23%. Calcd for $C_{23}H_{27}N$: C, 87.01; H, 8.57; N, 4.41%.

4-Carboxymethyl-2,7-di-*t*-butylfluorene (3g). To a solution of **3f** (3.7 g, 12 mmol) in ethylene glycol (60 ml) was added a solution of NaOH (4.8 g, 0.12 mol) in water (30 ml). The mixture was heated for 30 h at 150—160 °C with an oil bath and then poured into water. The precipitated solid was dissolved in hot water and filtered off under

heating. After the filtrate was acidified with hydrochloric acid, the resultant precipitate was filtered and recrystallized from hexane to give **3g** as colorless crystals; yield: 1.7 g (41%); mp 177—178 °C. IR (KBr): 1255 (t-C_4H_9), 1700 cm^{-1} (CO); ^1H NMR ($CDCl_3$) δ=1.36 (18H, s, t-C_4H_9×2), 3.88 (2H, s, 9-CH_2), 4.04 (2H, s, CH_2COOH), 6.36 (1H, br.s, COOH), 7.24, 7.55, 7.62 (each 1H, s, H_{arom}), 7.42, and 7.80 (each 1H, d, J=9 Hz, 5- and 6-H). Found: C, 81.96; H, 8.44%. Calcd for $C_{23}H_{28}O_2$: C, 82.10; H, 8.39%.

4-Hydroxymethyl-2,7-di-*t*-butylfluorene (3h). To a solution of **3c** (1.6 g, 5 mmol) in acetone (24 ml) was added a solution of $AgNO_3$ (2.3 g, 13 mmol) in water (10 ml). The mixture was refluxed for 12 h and then acetone was distilled. The residue obtained was extracted with ether, washed with water, and dried over $MgSO_4$. The ether solution was evaporated in vacuo to give **3h** as colorless needles; yield: 0.4 g (27%); mp 150—151 °C (from petroleum benzine). IR (KBr): 1265 (t-C_4H_9), 3280 cm^{-1} (OH); ^1H NMR ($CDCl_3$) δ=1.36 (18H, s, t-C_4H_9×2), 3.82 (2H, s, 9-CH_2), 5.04 (2H, s, CH_2OH), and 7.24—7.60 (5H, m, H_{arom}). Found: C, 85.43; H, 9.30%. Calcd for $C_{22}H_{28}O$: C, 85.66; H, 9.15%.

4-Amino-2,7-di-*t*-butylfluorene (3i). To a solution of **3d** (3.23 g, 10 mmol) and concentrated hydrochloric acid (d=1.19; 10 ml) in ethanol (50 ml) was gradually added tin powder (2.37 g). After the mixture was refluxed for 1 h, it was poured into a large amount of ice-cold water, basified with 10% NaOH solution and extracted with chloroform. The chloroform solution was washed with water, dried over $MgSO_4$, and evaporated in vacuo to give **3i** as pink prisms; yield: 2.8 g (95%); mp 148—150 °C (from methanol). IR (KBr): 1265 (t-C_4H_9), 3350, 3450 cm^{-1} (NH_2); ^1H NMR ($CDCl_3$) δ=1.36, 1.39 (each 9H, s, t-C_4H_9×2), 3.85 (2H, s, 9-CH_2), 4.01 (2H, br.s, NH_2), 6.68, 7.02, 7.52 (each 1H, s, H_{arom}), 7.33, and 7.55 (each 1H, d, J=9 Hz, 5- and 6-H). Found: C, 85.74; H, 9.29; N, 4.67%. Calcd for $C_{21}H_{27}N$: C, 85.95; H, 9.28; N, 4.77%.

4-Acetylamino-2,7-di-*t*-butylfluorene (3j). To a solution of **3i** (1.17 g, 4 mmol) in benzene (20 ml) was added acetic anhydride (0.8 ml). The mixture was stirred at 40—50 °C for 15 min and then poured into water. The resultant precipitate was filtered, washed with water, and recrystallized from hexane to give **3j** as colorless needles; yield: 1.3 g (95%); mp 189—190 °C. IR (KBr): 1270 (t-C_4H_9), 1650 (CO), 3230, 3300 cm^{-1} (NH); ^1H NMR (CF_3COOH) δ=1.42 (18H, s, t-C_4H_9×2), 2.18, 2.60 (total 3H, s, $COCH_3$), 3.73, 3,83 (total 2H, 9-CH_2), 7.17—7.68 (5H, m, H_{arom}), 8.85, and 9.70 (total 1H, br.s, NH). Found: C, 82.29; H, 8.74; N, 4.26%. Calcd for $C_{23}H_{29}NO$: C, 82.34; H, 8.71; N, 4.18%.

4-Bromofluorene (4a). A solution of **3a** (1.08 g, 3 mmol) and $AlCl_3$ (0.04 g, 0.3 mmol) in benzene (18 ml) was stirred at 50 °C for 6 h, and then the mixture was quenched with water. The organic layer was extracted with ether, washed with water, dried with $MgSO_4$, and evaporated in vacuo at 100 °C to leave t-butylbenzene. Compound **4a** was obtained from residue as colorless needles; yield: 0.33 g (45%); mp 55—57 °C (from methanol) (lit,[5] 59 °C). ^1H NMR ($CDCl_3$) δ=3.86 (2H, s, 9-CH_2), 6.96—7.56 (6H, m, H_{arom}), and 8.56 (1H, d, J=8 Hz, 5-H). Found: C, 63.59; H, 3.72%. Calcd for $C_{13}H_9Br$: C, 63.70; H, 3.70%.

4-Methylfluorene (4e). A solution of **3e** (0.58 g, 2 mmol) and $AlCl_3$ (0.03 g, 0.2 mmol) in benzene (12 ml) was stirred at 50 °C for 4 h, and then it was treated and worked up as described above to afford **4e** as colorless crystals; yield: 0.1 g (30%); mp 68—70 °C (from methanol) (lit,[7] 70.4—71.2 °C). ^1H NMR ($CDCl_3$) δ=2.73 (3H, s, CH_3), 3.93 (2H, s, 9-CH_2), and 7.17—7.98 (7H, m, H_{arom}). Found: C, 93.34; H, 6.65%. Calcd for $C_{14}H_{12}$: C, 93.29; H, 6.71%.

4-Acetylaminofluorene (4j). To a solution of **3j** (0.67 g, 0.2 mmol) in benzene (30 ml) was added $AlCl_3$ (0.87 g, 6.6 mmol). After the reaction mixture was stirred for 3 h at 50 °C, it was treated and worked up as described above to give **4j** as a light brown crystals; yield: 0.42 g (94%); mp 197—198 °C (from benzene) (lit,[6] 199—200 °C). IR (KBr): 1630, 1650 (CO), 3160, 3220 cm^{-1} (NH); ^1H NMR (CF_3COOH) δ=2.21, 2.64 (total 3H, s, $COCH_3$), 3.86, 3.97 (total 2H, s, 9-CH_2), 7.18—7.71 (7H, m, H_{arom}), 8.98, and 9.76 (total 1H, br.s, NH). Found: C, 80.40; H, 5.88: N, 6.38%. Calcd for $C_{15}H_{13}NO$: C, 80.69; H, 5.87; N, 6.27%.

2,2′-Diiodo-4,4′-di-*t*-butyldiphenylmethane (5). To a solution of 4,4′-di-t-butyldiphenylmethane (17.6 g, 63 mmol), periodic acid (7.6 g, 34 mmol), water (35 ml), and 98% H_2SO_4 (4.9 ml), and the mixture was poured into ice-water, it was extracted with ether. The ether solution was washed with $NaHSO_3$ solution to remove iodine, and washed with Na_2CO_3 and then with water, and dried over $MgSO_4$. The solution was evaporated in vacuo to leave the residue which was column-chromatographed on alumina using petroleum benzine as an eluent to give **5**; yield: 17.6 g (54%); colorless plates; mp 88—90 °C (from ethanol). IR (KBr): 1260 cm^{-1} (t-C_4H_9); ^1H NMR ($CDCl_3$) δ=1.28 (18H, s, t-C_4H_9×2), 4.20 (2H, s, CH_2), 6.76 (2H, d, J=8 Hz, 6- and 6′-H), 7.20 (2H, dd, J=2 and 8 Hz, 5- and 5′-H), and 7.76 (2H, d, J=2 Hz, 3- and 3′-H). Found: C, 46.61; H, 4.91%. Calcd for $C_{20}H_{24}I$: C, 46.35; H, 4.67%.

3,6-Di-*t*-butylfluorene (2) by Ullmann Reaction of 5. To melted **5** (30 g, 60 mmol) was added slowly the activated copper powder[13] (30 g, 0.47 mol) and the mixture was heated at 230 °C for 4 h. After cooling, the reaction mixture was extracted with acetone and the acetone solution was filtered to remove the copper powder. The filtrate was concentrated in vacuo to give crude **2** as oily material; yield: 30 g (95%).

3,6-Di-*t*-butylfluorenone (6). To a solution of crude **2** (15 g, 54 mmol) in dimethylformamide (150 ml) was added Triton B (4 ml), and oxygen gas was bubbled into the reaction mixture with heating at 90 °C. The above mixture was poured into the water, acidified with dil. hydrochloric acid, and extracted with benzene. The benzene solution was evaporated in vacuo to give **6** as yellow needles; yield: 10 g (65%); mp 208—209 °C (from petroleum benzine). IR (KBr): 1250 (t-C_4H_9), 1700 cm^{-1} (CO); ^1H NMR ($CDCl_3$) δ=1.36 (18H, s, t-C_4H_9×2), 7.16 (2H, dd, J=8 and 2 Hz, 2- and 7-H), 7.62 (2H, d, J=2 Hz, 4- and 5-H), and 7.64 (2H, d, J=8 Hz, 1- and 8-H). Found: C, 86.19; H, 8.41%. Calcd for $C_{21}H_{24}O$: C, 86.25; H, 8.27%.

3,6-Di-*t*-butyl-9-fluorenol (7). Sodium borohydride (7.5 g, 0.2 mol) was added to the solution of **6** (10.2 g, 35 mmol) in ethanol (400 ml). The mixture was heated and stirred for 30 min until **6** was dissolved perfectly. The reaction mixture was evaporated in vacuo, and to the residue was added water, and then it was extracted with

benzene. The benzene solution was washed with water, dried with $MgSO_4$, and evaporated in vacuo to give **7** as colorless prisms; yield: 9.6 g (93%); mp 120—123 °C (from ethanol). IR (KBr): 1255 (t-C_4H_9), 3240 cm^{-1} (OH); ^1H NMR ($CDCl_3$) δ=1.32 (18H, s, t-C_4H_9×2), 1.76 (1H, br.s, OH), 5.38 (1H, br.s, 9-H), 7.28 (2H, dd, J=8 and 2 Hz, 2- and 7-H), 7.48 (2H, d, J=8 Hz, 1- and 8-H), and 7.64 (2H, d, J=2 Hz, 4- and 5-H). Found: C, 85.48; H, 9.02%. Calcd for $C_{21}H_{26}O$: C, 85.66; H, 8.90%.

3,6-Di-*t*-butylfluorene (2) from 7. To a solution of **7** (13.2 g, 45 mmol) in acetic acid (550 ml) was added hydroiodic acid (57%, 53 g, 0.24 mol) and the mixture was refluxed for 2 h. The reaction mixture was poured into ice-cold water, extracted with ether. The ether solution was washed with $NaHSO_3$ solution, Na_2CO_3 solution, and water, and then dried with $MgSO_4$. The solution was evaporated in vacuo to leave the residue which was recrystallized from ethanol to give **2** as colorless prisms; yield: 11 g (90%); mp 82—83 °C. IR (KBr): 1260 cm^{-1} (t-C_4H_9); ^1H NMR ($CDCl_3$) δ=1.42 (18H, s, t-C_4H_9×2), 3.82 (2H, s, CH_2), 7.35 (2H, dd, J=8 and 2 Hz, 2- and 7-H), 7.48 (2H, d, J=8 Hz, 1- and 8-H), and 7.82 (2H, d, J=2 Hz, 4- and 5-H). Found: C, 90.34; H, 9.39%. Calcd for $C_{21}H_{26}$: C, 90.59; H, 9.41%.

2,7-Dibromo-3,6-di-*t*-butylfluorene (8a). a) To a solution of **2** (1.1 g, 4 mmol) in dry propylene carbonate (26 ml) was added NBS (1.4 g, 8 mmol) and the mixture was heated for 6 h at 70—75 °C under stirring. The reaction mixture was poured into water, and the precipitated solid was filtered, washed with water and recrystallized from ethanol; yield: 1.6 g (92%); colorless prisms; mp 177—180 °C. b) To a solution of **2** (0.28 g, 1 mmol) in carbon tetrachloride (4 ml) with a small amount of iron powder was added the solution of bromine (0.48 g, 3 mmol) in carbon tetrachloride (2 ml) dropwised for 20 min at 35—40 °C and the reaction mixture was stirred for more 30 min at the same temperature. After the mixture was poured into water, it was extracted with ether, washed with 10% NaOH solution and then water, dried with $MgSO_4$ and concentrated in vacuo to give **8a** as colorless prisms; yield: 0.35 g (80%); mp 177—180 °C. IR (KBr): 1240 cm^{-1} (t-C_4H_9); ^1H NMR ($CDCl_3$) δ=1.60 (18H, s, t-C_4H_9×2), 3.74 (2H, s, CH_2), 7.67 and 7.75 (each 2H, s, 1,8- and 4,5-H). Found: C, 57.63; H, 5.56%. Calcd for $C_{21}H_{24}Br_2$: C, 57.82; H, 5.55%.

2,7-Dichloro-3,6-di-*t*-butylfluorene (8b). Into a solution of **2** (0.56 g, 2 mmol) in carbon tetrachloride (8 ml) with a small amount of iron powder was bubbled chlorine gas for 30 min at 30 °C. After the reaction mixture was poured into water, it was extracted with ether, washed with 10% NaOH solution and water, and dried with $MgSO_4$. The ether solution was concentrated in vacuo to give **8b** as colorless prisms; yield: 0.58 g (84%); mp 155—157 °C (from ethanol). IR (KBr): 1240 cm^{-1} (t-C_4H_9); ^1H NMR ($CDCl_3$) δ=1.53 (18H, s, t-C_4H_9×2), 3.70 (2H, s, CH_2), 7.43 and 7.76 (each 2H, s, 1,8- and 4,5-H). Found: C, 72.42; H, 6.97%. Calcd for $C_{21}H_{24}Cl_2$: C, 72.62; H, 6.97%.

2,7-Dinitro-3,6-di-*t*-butylfluorene (8c). To a solution of **2** (1.4 g, 5 mmol) in acetic anhydride (26 ml) was added the mixture of fuming nitric acid (1.3 g, 20 mmol) and concd sulfuric acid (1.3 g) dropwised for 2 h at 15—20 °C. The precipitated solid as filtered, washed with water and then ether, and recrystallized from petroleum benzine to give **8c** as slight yellow crystals; yield: 0.8 g (45%); mp 246—247 °C. IR (KBr): 1240 (t-C_4H_9), 1350, 1515 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=1.51 (18H, s, t-C_4H_9×2), 3.90 (2H, s, CH_2), 7.48 and 7.91 (each 2H, s, 1,8- and 4,5-H). Found: C, 68.55; H, 6.63; N, 7.44%. Calcd for $C_{21}H_{24}N_2O_4$: C, 68.46; H, 6.57; N, 7.60%.

2,7-Diamino-3,6-di-*t*-butylfluorene (8d). To a solution of **8c** (1.2 g, 3.3 mmol) in ethanol (78%, 50 ml) was added $CaCl_2$ aqueous solution (0.5 g, 0.7 ml) and zinc powder (14 g, 0.2 mol). After the mixture was refluxed for 2 h, zinc powder was filtered off. The filtrate was concentrated in vacuo to give **8d** as white crystals. This crystals were washed with water and dried under reduced pressure; yield: 1.0 g (98%); mp 185—188 °C (decomp). IR (KBr): 1240 (t-C_4H_9), 3360, 3470 cm^{-1} (NH_2); ^1H NMR ($CDCl_3$) δ=1.44 (18H, s, t-C_4H_9×2), 3.48 (4H, br.s, NH_2×2), 3.60 (2H, s, CH_2), 6.54 and 7.32 (each 2H, s, 1,8- and 4,5-H). This product was unstable in atmosphere so that it was analyzed as the acetyl compound (**8e**).

2,7-Bis(acetylamino)-3,6-di-*t*-butylfluorene (8e). To a solution of **8d** (0.8 g, 2.5 mmol) in benzene (10 ml) was added acetic anhydride (0.3 g, 2.8 mmol), and the mixture was stirred for 20 min at 40—50 °C. The precipitation solid was filtered and washed with benzene to give **8e** as white crystals; yield: 0.9 g (93%); mp 333—336 °C (decomp) (from chloroform). IR (KBr): 1240 (t-C_4H_9), 1650 (CO), 3240 cm^{-1} (NH); ^1H NMR (CF_3COOH) δ=1.56 (18H, s, t-C_4H_9×2), 2.30, 2.66 (total 6H, br.s, $COCH_3$), 3.94, 3.98 (total 2H, br.s, CH_2), 7.40, 8.16 (each 2H, br.s, 1,8- and 4,5-H), 9.23, 9.37, and 9.95 (total 2H, br.s, NH). Found: C, 76.41; H, 8.16; N, 7.13%. Calcd for $C_{25}H_{32}N_2O_2$: C, 76.49; H, 8.22; N, 7.14%.

Trans-*t*-butylation of 8. A solution of **8** (3 mmol) and $AlCl_3$ (8 mg, 0.6 mmol) in benzene (15 ml) was stirred at 50 °C for 30 min, and then the mixture was quenched with water. The organic layer was extracted with ether, washed with water, dried with $MgSO_4$, and evaporated in vacuo at 100 °C to leave t-butylbenzene.

2,7-Dibromofluorene (9a). Yield: 43%; colorless prisms mp 166—168 °C (from ethanol) (lit,[10] 167—168 °C). ^1H NMR ($CDCl_3$) δ=3.72 (2H, s, CH_2), 7.34, 7.42 (each 2H, d, J=9 Hz, 3,6- and 4,5-H), and 7.49 (2H, s, 1- and 8-H).

2,7-Dichlorofluorene (9b). Yield: 37%; colorless prisms mp 122—125.5 °C (from ethanol) (lit,[10] 126 °C). ^1H NMR ($CDCl_3$) δ=3.86 (2H, s, CH_2), 7.36 (2H, dd, J=2 and 8 Hz, 3- and 6-H), 7.51 (2H, d, J=2 Hz, 1- and 8-H), and 7.63 (2H, d, J=8 Hz, 4- and 5-H).

2,7-Bis(acetylamino)fluorene (9e). Yield: 56%; white crystals mp 285—286 °C (from ethanol) (lit,[11] mp 281 °C). IR (KBr): 1360 ($COCH_3$), 1650 (CO), 3040, 3220 cm^{-1} (NH); ^1H NMR (CF_3COOH) δ=2.40, 2.65 (total 6H, br.s, $COCH_3$), 3.98, 4.04 (total 2H, br.s, CH_2), 7.40 (2H, br.d, J=8 Hz, 3- and 6-H), 7.62 (2H, br.s, 1- and 8-H), and 7.77 (2H, br.d, J=8 Hz, 4- and 5-H).

The authors wish to thank Drs. Shigeki Nagai, Yoshiaki Ishida, and Mr. Tsuyoshi Arai, Ube Research Laboratory, Ube Industries LTD., for the elemental analyses.

Cerium or Ruthenium Catalyzed Oxidation of Alcohols to Carbonyl Compounds by Means of Sodium Bromate

Shigekazu KANEMOTO, Hiroki TOMIOKA, Koichiro OSHIMA,* and Hitosi NOZAKI
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received August 22, 1985)

Sodium bromate has been found to be effective oxidant for oxidation of alcohols in the presence of cerium or ruthenium compounds in biphase reaction. Selective oxidation of secondary alcohols was performed in the presence of primary ones using cerium(IV) ammonium nitrate (CAN) or cerium(IV) sulfate (CS) as catalyst. For instance, treatment of 1,10-undecanediol with CS/$NaBrO_3$ provided 11-hydroxy-2-undecanone in 82% yield. Ruthenium catalyzed biphase oxidation of alcohols with sodium bromate provided the corresponding aldehydes or ketones in good to excellent yields.

Transition metal catalyzed oxidation of alcohols to carbonyl compounds has been widely studied.[1] A variety of oxidants such as *t*-butyl hydroperoxide,[2] bis(trimethylsilyl) peroxide,[3] chloramine-T[4] were employed with many transition metals. In contrast to these procedures with organic oxidants, there are few efficient methods using inorganic oxidants for the oxidation of alcohols because of their insolubility in organic solvents. Here we wish to report two methods which utilize sodium bromate as an oxidant: (1) Cerium(IV) ammonium nitrate catalyzed selective oxidation of secondary alcohols in the presence of primary ones and (2) ruthenium(III) chloride catalyzed oxidation of hydroxyls to carbonyl compounds.

(1) Cerium Catalyzed Selective Oxidation of Secondary Alcohols in the Presence of Primary Ones.[5] Although cerium(IV) ion oxidation of organic compounds has been widely studied, application of cerium(IV) ammonium nitrate (CAN) oxidation of alcohols to organic synthesis has been limited because of the large quantities of reagents required and the lack of generality of the reaction.[6] Here we wish to report that under CAN catalysis sodium bromate oxidizes secondary alcohols[11] into ketones in excellent yields and certain diols are thus converted into the expected keto alcohols with high selectivity.

Treatment of secondary alcohols with a suspension of sodium bromate in aq acetonitrile ($CH_3CN:H_2O$= 7:3 v/v) at reflux gave the corresponding carbonyl compounds in good to excellent yields. Variations in catalysts and oxidants have been examined with cyclododecanol as the substrate. Cerium(IV) ammonium nitrate and cerium(IV) sulfate[12] were equally active as catalyst, while cerium(III) chloride and cerium(IV) oxide were inactive. Sodium bromate was far superior to other oxidants tried. The results for the oxidation of cyclododecanol in aq CH_3CN in the presence of 10 mol% CAN with several oxidants are given in order of oxidant, reaction conditions, and % yield of cyclododecanone: *t*-BuOOH, 15 h at 80 °C, 13%; 30% H_2O_2, 5 h at 80 °C, 7%; *N*-methylmorpholine *N*-oxide, 5.5 h at 80 °C, 0%. Although the longer reaction period was required, the amount of cerium(IV) and sodium bromate could be reduced from 0.1 and 1.0 mol to 0.035 and 0.35 mol, respectively per 1.0 mol of cyclododecanol without decrease of the yield of cyclododecanone.

As shown in Table 1, wide variety of secondary alcohols could be easily oxidized to ketones. Primary alcohol, however, was recovered practically unchanged. On treatment of 1-dodecanol (1.0 mmol) with cerium(IV) sulfate[13] (0.035 mmol) and sodium bromate (0.35 mmol) in aq acetonitrile at reflux for 30 min[14] dodecanal was obtained in only 2% yield along with 92% recovery of starting alcohol. Olefinic moiety even in the remote position from hydroxyl group interrupts the oxidation (run 9).[15] It is worth noting that the oxidation proceeds smoothly even with the substrates undergoing C-C bond fission upon treatment with stoichiometric amount of CAN (run 4, 5, and 6).[10,16]

It was anticipated that the treatment of primary,

Table 1. Oxidation of Secondary Alcohols

$$\underset{(2.0\ \text{mmol})}{RR'CHOH} \xrightarrow[NaBrO_3\ (2.0\ \text{mmol}),\ \text{aq. } CH_3CN,\ 80\,^\circ C]{(NH_4)_2Ce(NO_3)_6\ (0.2\ \text{mmol})} RR'CO$$

Run	Alcohol	Reaction Time/h	Product	Yield/%[a]

	CAN (10)	1.0	6.5		87

a) Reactions were performed on 1.0 mmol scale in aq CH_3CN at 80 °C. b) Isolated yields unless otherwise specified. The underlined figures refer to the yields determined by glpc relative to an internal standard. c) Cerium(IV) sulfate. d) Two hydroxy compounds (1.0 mmol each) were employed.

secondary diols with this technique would afford hydroxy ketones arising from selective oxidation at the secondary carbon.[17,18] This was indeed the case as demonstrated by the reactions summarized in Table 2. The selectivity was excellent except the case of 1-[*p*-(hydroxymethyl)phenyl]ethanol. In this particular substrate, the secondary hydroxyl group reacts only three times the rate of primary one.

The system is also effective for the oxidation of a primary, primary 1,4-diol. For instance, treatment of 2,3-bis(hydroxymethyl)bicyclo[2.2.1]heptane with cerium(IV) ammonium nitrate–sodium bromate provided the corresponding γ-lactone in a good yield. The reaction presumably proceeds via the lactol.

(2) Ruthenium Catalyzed Oxidation of Alcohols to Carbonyl Compounds. In recent years oxidation reactions using ruthenium as a key atom have been extensively developed. Among them, ruthenium complex, $RuCl_2(PPh_3)_3$ proved to be an efficient oxidant for chemoselective oxidation of primary alcohols.[18] Moreover, ruthenium catalyzed reactions with oxidants such as bis(trimethylsilyl) peroxide,[3] amine *N*-oxide,[4] *t*-butyl hydroperoxide,[19] hypervalent iodine compounds,[20] molecular oxygen,[21,22] have been reported. We chose sodium bromate as an oxidant which proved to be an effective and inexensive oxidant for oxidation of hydroxyl substrates to the corresponding carbonyl compounds.[23]

Secondary alcohols were added to a biphase solution of ruthenium trichloride hydrate and sodium bromate in water and 1,2-dichloroethane (H_2O:$ClCH_2CH_2Cl$=1:1 v/v). The mixture was heated at reflux to yield the corresponding carbonyl compounds in good to excellent yields (Reaction Conditions B). Variations in catalysts and reaction conditions have been examined with cyclododecanol as a substrate. Ruthenium trichloride hydrate, tris(triphenylposhine)ruthenium(II) dichloride, and dodecacarbonyltriruthenium(0) were equally active as catalyst and cyclododecanone was obtained quantita-

tively with each catalyst. Reaction was accelerated by phase transfer catalyst such as quaternary ammonium salt (Reaction Conditions A). For instance, cyclododecanol was easily oxidized to cyclododecanone even at 25 °C within 30 min (>99% yield), in the presence of tetrabutylammonium bromide. Some representative examples are shown in Table 3.

In contrast, $RuCl_3 \cdot nH_2O$ or $RuCl_2(PPh_3)_3$ catalyzed oxidation of primary alcohols resulted in the formation of the desired aldehydes in poor yields along with carboxylic acids and esters. Dodecacarbonyltriruthenium(0) catalyzed reaction (Reaction Conditions D), however, has solved this problem and converted primary alcohols into aldehydes in good yields. In the case of former ruthenium chloride compounds, hydrochloric acid generated during the reaction catalyzes the transformation of the resultant aldehydes into hemiacetals or gem-diols which are oxidized further to esters or carboxylic acids. The use of the buffer solution (pH=10) instead of water prevented these side reactions and provided us with a simple method for the selective formation of aldehydes (Reaction Conditions C).

Table 3. Oxidation of Alcohols with Ruthenium Compounds

Run	Alcohol	Conditions[a]	Reaction Time/h	Yield[b]/%
1	Cyclododecanol	A	0.5	>99
		B	1.0	97

16	Geraniol	C	1.5	78
17	Benzyl alcohol	C	1.5	81

a) Reactions were performed under these conditions A: $RuCl_3 \cdot nH_2O$ (5.0 mol%), n-Bu_4NBr (3.0 mol%), H_2O/CH_2Cl_2=2 ml : 2 ml, 25 °C. B: $RuCl_3 \cdot nH_2O$ (5.0 mol%), H_2O/CH_2ClCH_2Cl=2 ml : 2 ml, 70 °C. C: $RuCl_3 \cdot nH_2O$ (5.0 mol%), a buffer solution/CH_2Cl-CH_2Cl=2 ml : 2 ml, 70 °C. The buffer solution (pH 10) is prepared by mixing equal volume of 0.2 M aq Na_2CO_3 and 0.2 M aq $NaHCO_3$. (M=1 mol dm^{-3}) D: $Ru_3(CO)_{12}$ (5.0 mol%), H_2O/CH_2ClCH_2Cl=2 ml: 2 ml, 70 °C. b) Isolated, purified yields unless otherwise noted. c) Glpc yields using an internal standard. d) Transformation of olefin to bromohydrin was observed (23%). e) Dodecanoic acid (20%) and dodecyl dodecanoate (22%) were also obtained.

Experimental

Infrared spectra of neat liquid film samples were determined on a Hitachi grating infrared spectrometer 215, or JASCO IR-810, mass spectra and exact mass on a Hitachi M-80. NMR spectra were recorded on a Varian EM-390, or Varian XL-200 spectrometer using TMS as an internal standard unless otherwise noted. Multiplicity is designed as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. Preparative TLC plates were prepared with Merck kiesel-gel PF_{254}. Column chromatography was carried out with silica-gel (Wakogel C-200) at atmospheric pressure.

General Procedure for the Oxidation of Secondary Alcohols with Cerium(IV) Ammonium Nitrate (CAN)/$NaBrO_3$: Cyclododecanol (0.37 g, 2.0 mmol) and catalytic amount of CAN (0.11 g, 0.2 mmol) were added to a suspension of sodium bromate (0.30 g, 2.0 mmol) in aq acetonitrile (CH_3CN/H_2O=7/3 v/v, 12 ml). The whole was heated at reflux for 30 min and the resulting yellow suspension was diluted with ether (20 ml). After extraction with ether (10 ml×2), organic layer was washed with sat. $NaHCO_3$ and brine successively, and dried over sodium sulfate. Concentration and purification by preparative TLC (hexane–ethyl acetate=10:1) gave cyclododecanone (0.36 g, 98%).

Oxidation of 3-(2-Hydroxyethyl)cyclopentanol: The diol (0.23 g, 1.8 mmol) and CAN (0.1 g, 0.18 mmol) were added to a suspension of sodium bromate (0.27 g, 1.8 mmol) in aq acetonitrile. The whole was heated at reflux for 30 min and the solvent was removed under reduced pressure. The residue was diluted with ethyl acetate and poured into water. After extraction with ethyl acetate, the combined organic layer was dried over sodium sulfate. Concentration followed by purification by silica-gel column chromatography (hexane–ethyl acetate=3:1) gave 3-(2-hydroxyethyl)-cyclopentanone (0.20 g, 89%).

Oxidation of 1,10-Undecanediol with Cerium(IV) Sulfate (CS)/$NaBrO_3$: The diol (0.37 g, 2.0 mmol) and CS (0.07 g, 0.2 mmol) were added to a suspension of sodium bromate (0.3 g, 2.0 mmol) in aq acetonitrile (10 ml) and the whole was refluxed for 2 h. Extractive workup and purification by silica-gel column chromatography (hexane–ethyl acetate=2:1) gave 11-hydroxy-2-undecanone (0.32 g, 86%).

General Procedure for the Oxidation of Secondary Alcohols with $RuCl_3/NaBrO_3$ in the Presence of a Phase Transfer Reagent (Reaction Conditions A): Tetrabutylammonium bromide (ca. 10 mg) and a solution of cyclododecanol (0.18 g, 1.0 mmol) in dichloromethane (2.0 ml) were added successively to a solution of sodium bromate (0.15 g, 1.0 mmol) and ruthenium trichloride (0.01 g, 0.05 mmol) in deionized water (2.0 ml). The mixture was stirred at 25 °C and the alcohol was consumed completely within 30 min. The resulting dark brown solution was diluted with ether, then poured into ice cooled sat. sodium hydrogensulfite. After extraction with

ethyl acetate (20 ml×2), the combined organic layer was dried over sodium sulfate and concentrated. The residual oil was purified by silica-gel column chromatography (hexane–ethyl acetate=10:1) to yield cyclododecanone (0.18 g) quantitatively.

General Procedure for the Oxidation of Alcohols with $RuCl_3/NaBrO_3$ without a Phase Transfer Catalyst (Reaction Conditions B): A solution of cyclododecanol (0.18 g, 1.0 mmol) in 1,2-dichloroethane was added to a mixed solution of sodium bromate (0.15 g, 1.0 mmol) and ruthenium trichloride (0.01 g, 0.05 mmol) in deionized water (2.0 ml). The mixture was stirred at 70 °C for 3 h. Workup and purification by silica-gel column chromatography gave cyclododecanone in quantitative yield.

General Procedure for the Oxidation of Primary Alcohols with $RuCl_3 \cdot nH_2O/NaBrO_3$ (Reaction Conditions C): Sodium bromate (0.15 g, 1.0 mmol) and ruthenium trichloride (0.01 g, 0.05 mmol) were dissolved in the buffer solution (2.0 ml, pH=10). 1,2-Dichloroethane (1.0 ml) was added and the whole was stirred for 30 min at 25 °C. A solution of 1-dodecanol (0.19 g, 1.0 mmol) in 1,2-dichloroethane (1.0 ml) was added and the resulting mixture was stirred for 20 min at 70 °C. Workup and purification gave dodecanal in 86% yield.

General Procedure for the Oxidation of Primary Alcohols with $Ru_3(CO)_{12}/NaBrO_3$ (Reaction Conditions D): A solution of 1-dodecanol (0.19 g, 1.0 mmol) in 1,2-dichloroethane (2.0 ml) was added to a solution of dodecacarbonyltriruthenium(0) (0.01 g, 0.05 mmol of ruthenium element) and sodium bromate (0.3 g, 2.0 mmol) in deionized water (2.0 ml). The whole was stirred for 1 h at 70 °C and the mixture was poured into ice-cooled water and extracted with ethyl acetate. Purification by preparative TLC gave dodecanal (0.13 g) in 68% yield.

Polymer-Protected Metal Complex for Gas Separation. I. A Solution of Polystyrene-Protected Aluminium Copper(I) Halide as Water-Resistant Carbon Monoxide Absorbent

Hidefumi HIRAI,* Susumu HARA, and Makoto KOMIYAMA
Department of Industrial Chemistry, Faculty of Engineering,
The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received August 10, 1985)

Carbon monoxide absorbents composed of linear polystyrene (PSt), aluminium halide, copper(I) halide, and toluene are prepared. The toluene solutions of polystyrene-protected aluminium copper(I) chloride (PSt-$AlCuCl_4$) rapidly absorb CO at 20 °C under 1 atm (initial partial pressure of CO: 0.90 atm) and the equilibrium molar ratio of absorbed CO to the charged CuCl is 0.78. On the elevation of the temperature from 20 °C to 82 °C under 1 atm, the absorbed CO is released completely. The absorption-release cycles are repeated many times without measurable decrease in the absorbing capacity. The CO absorbing capacities of toluene solutions composed of aluminium halides, copper(I) halides, and polystyrene decrease as follows: $AlCl_3$-CuCl system> $AlBr_3$-CuBr system$\gg AlI_3$-CuI system=0. The CO absorbing activity of the toluene solution of PSt-$AlCuCl_4$ remains virtually unchanged on the contact of the solution with nitrogen gas containing 10 mol% water to the charged CuCl (water content: 9000 ppm), when the molar ratio of phenyl residue of polystyrene (number-averaged degree of polymerization: 420, 50, or 4.0) to $AlCuCl_4$ is unity or larger. This result is markedly in contrast with the fact that the activity of the toluene solution of $AlCuCl_4$ without polystyrene significantly (25%) decreases on the contact.

The importance of carbon monoxide (CO) as one of chief raw materials in chemical industry is increasing.[1,2] Carbon monoxide is usually produced as gas mixtures with nitrogen, hydrogen, oxygen, methane, carbon dioxide, and water[3] by steam reforming of hydrocarbons, partial oxidation processes, and coal gasification. Thus, separation of CO from gas mixtures is significant.

Copper liquor and cryogenic separation processes are known as CO separation methods.[3] Recently, a separating process using an absorbent, which takes advantage of selective complex formation of a double salt, aluminium copper(I) chloride ($AlCuCl_4$), with CO in toluene, has been proposed.[4] With this absorbent, CO is separated under mild conditions and the absorbent is stable against oxygen and carbon dioxide.[4,5] However, the CO absorbing activity of the absorbent rapidly and irreversibly decreases on the contact with gas mixture containing water, since $AlCuCl_4$ vigorously reacts with water as follows.[6,7]

$$H_2O + 2AlCuCl_4 \longrightarrow HCl + AlCuCl_4Al(OH)Cl_2 + CuCl \quad (1)$$

$$AlCuCl_4Al(OH)Cl_2 \xrightarrow{\Delta} HCl + AlCuCl_4AlOCl \quad (2)$$

Thus, the water content in feed gas mixtures must be reduced to 1 ppm or less by pretreatment for CO separation in industry.[4]

In a preliminary communication,[8] the authors showed that a solution composed of linear polystyrene (PSt), copper(I) chloride (CuCl), aluminium chloride ($AlCl_3$), and toluene reversibly absorbed CO under mild conditions and in addition was stable against water vapor.

This paper reports the results of detailed study on the toluene solutions of polystyrene-protected $AlCuCl_4$ (PSt-$AlCuCl_4$). The effects of the degree of polymerization and the amount of polystyrene on the water resistivity are revealed. The CO absorbing activities of the absorbents composed of $AlCuCl_4$ and other polymers are also shown. Furthermore, the infrared spectra of the PSt-$AlCuCl_4$ complex in the presence and the absence of CO are presented. The mechanism of protection of $AlCuCl_4$ by polystyrene in the CO absorbents is discussed.

Experimental

Materials. Linear polystyrene, purchased from Wako Pure Chemical Co. or prepared in toluene by use of benzoyl peroxide as initiator, was reprecipitated using the chloroform-methanol system and was dried in vacuo for 12 h at 60 °C. The number-averaged degrees of polymerization (DP_n) of these polystyrenes were 420 and 50, respectively, as estimated from the number-averaged molecular weight (M_n) and weight-averaged molecular weight (M_w): $M_n=4.4\times10^4$ and $M_w=1.5\times10^5$ for the first polystyrene, and $M_n=5.2\times10^3$ and $M_w=1.2\times10^4$ for the second one. The molecular weights were determined by gel permeation chromatography using columns of TSK-GEL, G5000H+G3000H, Toyo Soda Manufacturing Co. Styrene oligomer of DP_n 4.0, which contained oligomers of degrees of polymerization 2, 3, 4, 5, 6, 7, and 8 in 16, 27, 23, 16, 10, 5, and 3 mol%, respectively, was obtained from Toyo Soda Manufacturing Co.

Poly[oxy(2,6-dimethyl-1,4-phenylene)], $M_n=3.2\times10^4$ and $M_w=2.4\times10^5$, and polybutadiene (45% vinyl and 55% *cis* and *trans*-1,4), $M_n=4.5\times10^3$, respectively, were purchased from Scientific Polymer Products and Aldrich Chemical Co. Styrene-butadiene block copolymer composed of 41.6 wt% styrene part and 58.4 wt% butadiene part and hydrogenation product (Kraton-G 1650) of styrene-butadiene block copolymer composed of 30 wt% of styrene part and 70 wt%

of butadiene part were obtained from Asahi Chemical Industry Co. and Shell Co., respectively. Alternating copolymer of styrene and methyl methacrylate was prepared by photopolymerization in the presence of boron chloride.[9]

Aluminium chloride (Kishida Chemical Co.) was purified by sublimation. Copper(I) chloride (Koso Chemical Co.) was reprecipitated from an aqueous concentrated hydrochloric acid solution by the addition of distilled water, followed by washing successively with ethanol and diethyl ether, and then dried overnight in vacuo at 100 °C. Aluminium bromide, copper(I) bromide, aluminium iodide, and copper(I) iodide were commercially (guaranteed grades) obtained and were used without further purification. Titanium(IV) chloride and tin(IV) chloride were purified by distillation.

Toluene and benzene were distilled after being dried over metallic sodium. Chlorobenzene was dried over diphosphorus pentaoxide and was distilled.

Carbon monoxide and nitrogen gas, which had the purities of 99.95 and 99.999%, respectively, were passed through columns of molecular sieves 3A immediately before use.

Preparation of CO Absorbents. Carbon monoxide absorbents were prepared by heating polymer, aluminium halide, copper(I) halide, and aromatic solvent at 50 °C for 4 h. The charged molar ratio of CuCl to $AlCl_3$ was kept constant at unity unless otherwise noted.

For example, the preparation procedure for toluene solution of PSt-$AlCuCl_4$ was as follows. 2.08 g (20 mequiv in phenyl residue) of linear polystyrene, 2.67 g (20 mmol) of $AlCl_3$, 1.98 g (20 mmol) of CuCl, and 20 cm^3 (192 mmol) of toluene were placed in a 100 cm^3 flask and were heated at 50 °C for 4 h under dry nitrogen with stirring by use of a magnetic stirrer. The nitrogen in the flask was several times replaced with fresh dry nitrogen during the preparation.

Toluene solution of $AlCuCl_4$ without polystyrene was prepared in a similar manner as above, except for the absence of polystyrene.

Absorption and Release of CO. The absorption of CO by the absorbent, continuously stirred by use of a magnetic stirrer, from CO-N_2 mixture (the total pressure: 1 atm) was carried out at room temperature under 1 atm using the apparatus depicted in Fig. 1. The amount of absorbed CO was determined at room temperature under 1 atm by a gas burette (6) using toluene as leveling liquid (7). During the first 10 min, the CO-N_2 mixture was made to flow over the absorbent (1), stirred magnetically in the flask, by a gas-circulating pump (5) (Iwaki Co., BA-106TN). The initial partial pressure of CO was in the range of 0.8 to 1.0 atm and the decrease of the partial pressure of CO during CO absorption was at most 0.07 atm.

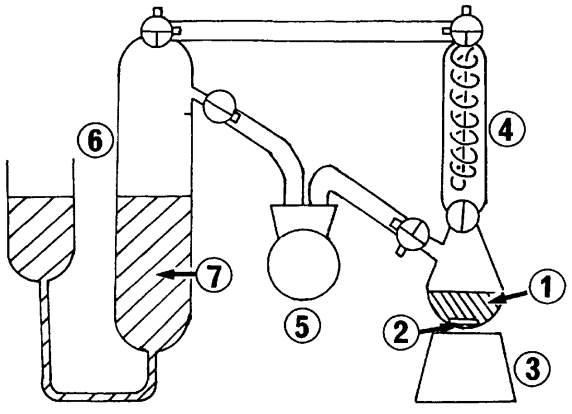

Fig. 1. Apparatus for measuring the amount of carbon monoxide absorbed by the absorbents or released from them; 1: CO absorbent, 2: rotor, 3: magnetic stirrer, 4: Dimroth condenser, 5: gas-circulating pump, 6: gas burette, 7: leveling liquid (toluene).

The release of CO from the absorbent was accomplished by heating the absorbent and the amount of released CO was determined by the gas burette ((6) in Fig. 1). Toluene vapor, produced from the absorbent on heating, was refluxed by a Dimroth condenser (4). After CO was released, the absorbent was cooled to room temperature under dry nitrogen, and then the second absorption by the absorbent was carried out by the same method as described above.

Contact of the Absorbent with Water Vapor. The contact of the absorbent with water vapor was effected by circulating 5000 or 10000 cm^3 of N_2 gas, containing 10 mol% water to the charged CuCl, over the absorbent for 10 min by use of a gas-circulating pump. During the contact, the absorbent was continuously stirred using a magnetic stirrer (Fig. 1, (3)). The N_2 gas containing water vapor was prepared by the introduction of distilled water into 5000 or 10000 cm^3 of evacuated vessel using a microsyringe, followed by the addition of dry nitrogen in an amount required to make the total pressure atmospheric.

After the contact with water, the gas phase in the flask was replaced by dry nitrogen, and then the following CO absorption was carried out.

Infrared Spectroscopy. Infrared spectra were taken with a Japan Spectroscopic Co. Model A-3 recording spectrophotometer by use of a KBr cell. Specimens were toluene solutions of PSt-$AlCuCl_4$ before and after the contact with CO under atmospheric pressure for 1 h.

Results

Preparation of CO Absorbent. The color of polystyrene (PSt) immediately changed from white to orange when aluminium chloride, copper(I) chloride, linear polystyrene, and toluene were mixed in a flask. The toluene solutions were reddish brown in the early stage of the preparation, and gradually became dark brown.

The CO absorbents were thoroughly homogeneous at the charged molar ratio unity of CuCl to $AlCl_3$. When the charged molar ratio of CuCl was larger than unity, however, CuCl in excess precipitated as white to gray powder in the mixture. In all the CO absorbents described hereinafter, the charged molar ratios of copper(I) halides to aluminium halides were maintained at 1.0.

Toluene and benzene solutions of $AlCuCl_4$ without

polystyrene were black and brown homogeneous solutions, respectively.

Chlorobenzene solutions of PSt-$AlCuCl_4$ were prepared from $AlCl_3$, CuCl, polystyrene, and chlorobenzene as homogeneous dark brown solutions. The charged molar ratio of phenyl residue in polystyrene to CuCl was 1.0. In the absence of polystyrene, however, considerable amounts of gray precipitates were formed under reddish brown solutions and homogeneous absorbents were not obtained.

Toluene solution of polystyrene-protected aluminium copper(I) bromide complex was prepared as homogeneous solution from aluminium bromide, copper(I) bromide, polystyrene, and toluene. In the case of polystyrene-protected aluminium copper(I) iodide complex in toluene, however, the resulting mixture was composed of precipitates and a reddish brown solution.

CO Absorbing and Releasing Activities of PSt-$AlCuCl_4$ Complex in Aromatic Solvents. Figure 2 shows the absorption of CO at 20 °C under 1 atm by the absorbent composed of 0.96 g (7.2 mmol) of $AlCl_3$, 0.72 g (7.3 mmol) of CuCl, 0.67 g, (6.4 mequiv in phenyl residue) of linear polystyrene (DP_n: 420), and 10 cm^3 (96 mmol) of toluene. As depicted by the open circles, the absorbent rapidly absorbs CO and the equilibrium molar ratio of the absorbed CO to the charged CuCl is 0.85. On the elevation of the temperature of the absorbent from 20 °C to 82 °C, almost all the absorbed CO is released in 5 min from the absorbent to the vapor phase.

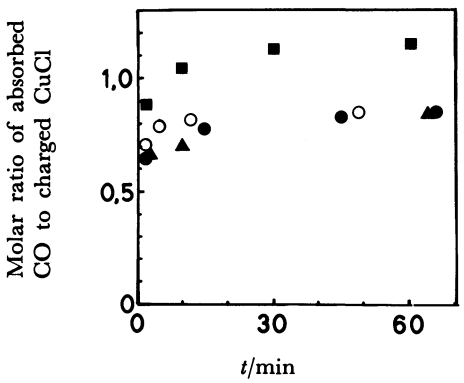

Fig. 2. Absorption of carbon monoxide at 20 °C under 1 atm by toluene or chlorobenzene solutions of polystyrene-$AlCuCl_4$: The first absorption by the toluene solution (○), the second absorption by the toluene solution which was heated to 82 °C to release CO after the first absorption (●), the third absorption by the toluene solution (▲); the first absorption by the chlorobenzene solution (■); For the toluene solution, $[AlCl_3]_0=[CuCl]_0=0.73$ and [phenyl residue of polystyrene (DP_n: 420)]$_0$=0.64 mol dm^{-3} in 10 cm^3 of toluene, and the initial $P_{CO}=1.0$ atm. For the chlorobenzene solution, $[AlCl_3]_0=[CuCl]_0=$ [phenyl residue of polystyrene (DP_n: 420)]$_0$=1.0 mol dm^{-3} in 22 cm^3 of chlorobenzene, and the initial volume of the gas mixture is 3000 cm^3 with initial pressures of CO and N_2, 0.9 and 0.1 atm, respectively.

In the second absorption, which is carried out after the cooling of the absorbent to 20 °C under dry nitrogen, the absorbent rapidly absorbs CO again as shown by the solid circles in Fig. 2. The equilibrium molar ratio of the absorbed CO to the charged CuCl is 0.85, which is exactly identical with the value (0.85) of the first absorption. The equilibrium molar ratio of the absorbed CO to the charged CuCl in the third absorption (the solid triangles) is also 0.85.

Table 1 shows the equilibrium molar ratios of the absorbed CO to the charged copper(I) halide for the various absorbents prepared from aluminium halides, copper(I) halides, polystyrene (DP_n: 420), and toluene. The absorbing capacities of the absorbents are as follows:

$AlCl_3$-CuCl system>$AlBr_3$-CuBr system $\gg$ AlI_3-CuI system=0.

Solid squares in Fig. 2 depict the absorption of CO by the chlorobenzene solution of PSt-$AlCuCl_4$ complex. The equilibrium molar ratio (1.15) of the absorbed CO to the charged CuCl is larger than the value (0.85) of the toluene solution even though the initial partial pressure of CO (0.9 atm) is smaller than the value (1.0 atm) for the toluene solution.

Effect of Water Vapor on CO Absorbing Activity of Toluene Solutions of PSt-$AlCuCl_4$ Complex. Open circles in Fig. 3 depict the absorption of CO from 1500 cm^3 of CO-N_2 mixture (initial partial pressure of CO: 0.80 atm) under 1 atm at 20 °C by the absorbent composed of 2.98 g (22.3 mmol) of $AlCl_3$, 2.22 g (22.4 mmol) of CuCl, 2.33 g (22.4 mequiv in phenyl residue) of polystyrene (DP_n: 420), and 15 cm^3 (144 mmol) of toluene. The absorption of CO is rapid and the equilibrium molar ratio of the absorbed CO to the charged CuCl is 0.71. On the elevation of the temperature from 20 °C to 95 °C,

Table 1. Molar Ratios of Equilibrium Amounts of the Absorbed CO to the Charged Copper(I) Halide for Toluene Solutions of Aluminium Halide (AlX_3) and Copper(I) Halides (CuX) with of without Polystyrene (PSt)[a)]

Absorbent	Halogen (X)		
	Cl	Br	I
PSt-AlX_3-CuX	0.78	0.45	0.00
AlX_3-CuX	0.83	0.45	—

a) CO absorbing conditions; at room temperature under 1 atm; the initial volume of the gas mixture is 3000 cm^3 and the initial pressures of CO and N_2 are 0.9 and 0.1 atm, respectively; $[AlX_3]_0=[CuX]_0=$ [phenyl residue of polystyrene]$_0$=1.0 mol dm^{-3}; the subscript 0 is used to designate the charged concentration; number-averaged degree of polymerization of polystyrene: 420.

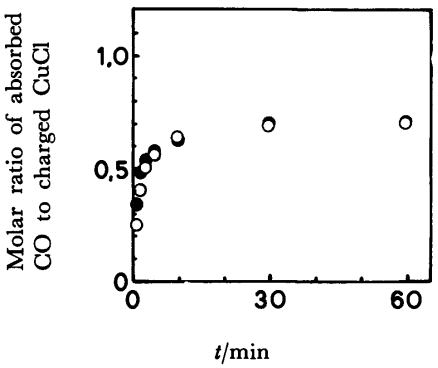

Fig. 3. Effect of water vapor on the CO absorbing activity of toluene solution of polystyrene-$AlCuCl_4$; the first absorption (○); the second absorption after the contact of the solution with 10 mol% water to the charged CuCl (●); CO absorbing conditions, 20 °C under 1 atm; the initial volume of the gas mixture is 1500 cm^3 and the initial pressures of CO and N_2 are 0.8 and 0.2 atm, respectively; $[AlCl_3]_0=[CuCl]_0=$[phenyl residue of polystyrene (DP_n: 420)]$_0$ $=1.5$ mol dm^{-3} in 15 cm^3 of toluene.

almost all the absorbed CO is released.

After being cooled to 20 °C under dry nitrogen, the absorbent is contacted with 5000 cm^3 of nitrogen containing 10 mol% water to the charged CuCl (water content: 9000 ppm) for 10 min. In the following CO absorption, the absorbent quickly absorbs CO from 1500 cm^3 of CO-N_2 mixture (initial pressure of CO: 0.80 atm), as shown by the solid circles in Fig. 3. The equilibrium molar ratio of the absorbed CO to the charged CuCl is 0.71, which is identical with the value (0.71) for the absorbent prior to the contact with water vapor. No decrease in the CO absorbing activity was detected at all even after the repeated (five times) contacts of the absorbent with water vapor. Thus, the water vapor exhibits no measurable deactivation effect on the absorbent containing polystyrene (DP_n: 420) equimolar in phenyl residue to the charged CuCl.

Table 2 shows the effects of the degree of polymerization and the amount of polystyrene used on the water resistivity of the toluene solution of PSt-$AlCuCl_4$ complex. Here, the ratio of the amount of CO absorbed by the absorbent after the contact with water vapor (10 mol% to the charged CuCl) to the value before the contact is used as an index of the water resistivity of the absorbents.

When the charged molar ratio of the phenyl residue of polystyrene (DP_n: 420) to CuCl is larger than unity, no decrease in the activity is observed after the contact with 10 mol% water to the charged CuCl. At the molar ratios 0.5 and 0.1, however, the CO absorbing activity decreases by 6 and 8%, respectively, after the contact. The decrease of the CO absorbing activity of the absorbents, even at the molar ratio 0.5 or 0.1, is much smaller than that

Table 2. Effects of the Degree of Polymerization and the Amount of Polystyrene (PSt) on the Water Resistivity of Toluene Solution of PSt-$AlCuCl_4$[a]

50	1.0	1.01
4	1.0	0.99
—	0	0.75

a) $[AlCl_3]_0=[CuCl]_0=1.0$ mol dm^{-3}. CO absorbing conditions: at room temperature under 1 atm; the initial volume of the gas mixture is 1500 cm^3 and the initial pressures of CO and N_2 are 0.8 and 0.2 atm, respectively. b) Number-averaged degree of polymerization. c) The charged molar ratio of phenyl residue in polystyrene to CuCl. d) The ratio of the equilibrium amount of the absorbed CO after the contact of the absorbent with water vapor to the value before the contact. The charged molar ratio of water to CuCl is 0.10.

(25%) of the toluene solutions of $AlCuCl_4$ without polystyrene.

At the charged molar ratio 1.0 of the phenyl residue of polystyrene to CuCl, no measurable decrease of the CO absorbing activity of the absorbents by the contact with water vapor is observed irrespective of the degree of polymerization (420, 50, and 4.0) of polystyrene.

CO Absorbing Activity and Water Resistivity of Toluene Solution of $AlCuCl_4$ without PSt. As shown by the open circles in Fig. 4, the toluene solution of $AlCuCl_4$ without polystyrene rapidly absorbs CO from 1500 cm^3 of CO-N_2 mixture (initial partial pressure of CO: 0.80 atm) at 20 °C under 1 atm and the equilibrium molar ratio of the absorbed CO to the charged CuCl is 0.68. Almost all the absorbed CO is released when the absorbent is heated to 80 °C. The CO absorbing activity remains constant on repeated absorption-release cycles, as long as sufficiently dried CO is used.

However, the activity of the absorbent without polystyrene rapidly decreases on the contact with water vapor. The equilibrium molar ratio (0.51) of the absorbed CO to the charged CuCl after the contact of the absorbent with N_2 gas containing 10 mol% water to the charged CuCl (the solid circles in Fig. 4) is much smaller than that (0.68) before the contact.

After the second contact with 10 mol% water to the charged CuCl, the equilibrium molar ratio of the absorbed CO to the charged CuCl is further decreased

to 0.30.

The activity of the absorbent without polystyrene did not change on the contact with oxygen. The contact was carried out under 1 atm of oxygen for 1 h at room temperature, while the absorbent was magnetically stirred.

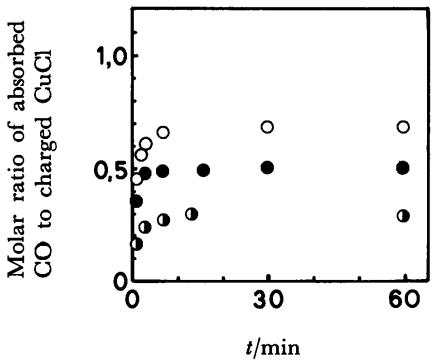

Fig. 4. Effect of water vapor on the CO absorbing activity of toluene solution of $AlCuCl_4$ without polystyrene; the first absorption (○); the second absorption after the contact of the solution with 10 mol% water to the charged CuCl (●); the third absorption after the second contact with 10 mol% water (◑); CO absorbing conditions, 20 °C under 1 atm; the initial volume of the gas mixture is 1500 cm^3 and the initial pressures of CO and N_2 are 0.8 and 0.2 atm, respectively; $[AlCl_3]_0=[CuCl]_0=1.5$ mol dm^{-3} in 19 cm^3 of toluene.

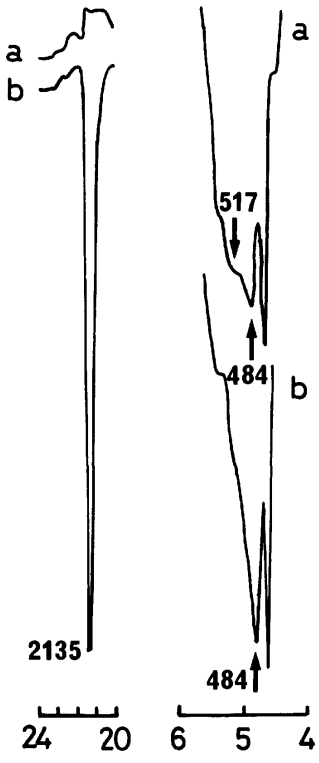

Fig. 5. Partial IR spectra of toluene solution of polystyrene–$AlCuCl_4$ before the contact with CO (a) and after the contact (b); $[AlCl_3]_0=[CuCl]_0=$[phenyl residue of polystyrene (DP_n: 420)]$_0=1.0$ mol dm^{-3}.

Infrared Spectra of the Solution of PSt-$AlCuCl_4$ with or without Absorbed CO. In the absence of CO, the solution of PSt–$AlCuCl_4$ exhibits a strong absorption at 484 cm^{-1} and a shoulder peak at 517 cm^{-1} as shown in Fig. 5, (a). All other signals are assignable to polystyrene and toluene.

When the absorbent absorbs CO, a strong and sharp absorption band appears at 2135 cm^{-1} and the band at 517 cm^{-1} weakens, as shown in Fig. 5, (b). The band at 2135 cm^{-1} is due to stretching vibration (ν_{CO}) of the absorbed CO. Otherwise, no change in the spectrum is observed on the CO absorption.

In benzene and chlorobenzene solutions of $AlCuCl_4$, ν_{CO} bands were observed at 2132 and 2135 cm^{-1}, respectively. No band assignable to the absorbed CO was observed for toluene itself without $AlCuCl_4$, which was stored under CO for 1 d.

CO Absorbents Composed of Various Polymers and $AlCuCl_4$. Homogeneous toluene solution of polymer–$AlCuCl_4$ complex was prepared using poly[oxy(2,6-dimethyl-1,4-phenylene)] or hydrogenated styrene-butadiene block copolymer (Kraton G) instead of polystyrene. These absorbents slowly absorbed CO as depicted by the open circles and solid circles in Fig. 6.

When polybutadiene, styrene-butadiene block copolymer, or alternating copolymer of styrene and methyl methacrylate were used, however, aggregates were formed and homogeneous solutions were not obtained. These aggregates showed no absorption of CO under 1 atm at 20 °C.

CO Absorbing Activities of the Absorbents with-

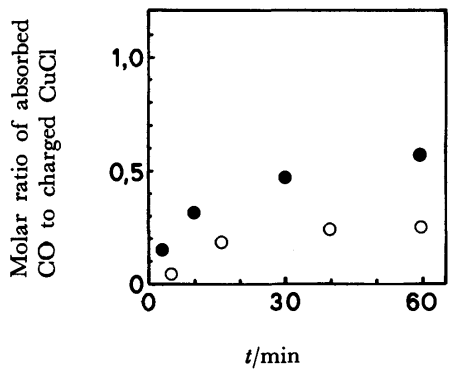

Fig. 6. Absorption of carbon monoxide at 20 °C under 1 atm CO by toluene solutions of $AlCuCl_4$ with poly[oxy(2,6-dimethyl-1,4-phenylene)] (○) or hydrogenated styrene-butadiene block copolymer (●): for the absorbent with poly[oxy(2,6-dimethyl-1,4-phenylene)], $[AlCl_3]_0=[CuCl]_0=1.3$ and [phenyl residue of the polymer]$_0=1.6$ mol dm^{-3} in 20 cm^3 of toluene; for the absorbent with hydrogenated styrene–butadiene block copolymer, $[AlCl_3]_0=[CuCl]_0=0.7$ and [phenyl residue of the polymer]$_0=0.25$ mol dm^{-3} in 40 cm^3 of toluene.

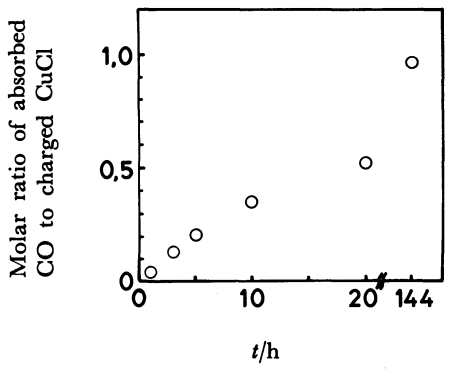

Fig. 7. Absorption of carbon monoxide at 20 °C under 1 atm CO by toluene suspension of CuCl composed of 25.0 mmol of CuCl and 20 cm^3 of toluene.

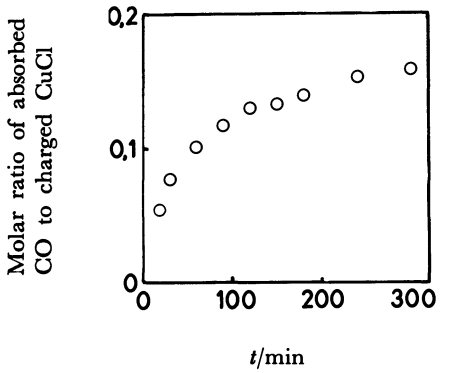

Fig. 8. Absorption of carbon monoxide at 30 °C under 1 atm by concentrated hydrochloric acid solution of CuCl composed of 3.0 mmol of CuCl and 20 cm^3 of aqueous HCl solution (12 mol dm^{-3}); the initial volume of the gas mixtures is 3000 cm^3 and the initial pressures of CO and N_2 are 0.9 and 0.1 atm, respectively.

out $AlCl_3$. In the absence of $AlCl_3$, CuCl does not dissolve in toluene either in the presence or the absence of polystyrene, and only toluene suspension of CuCl is obtained. The suspension without polystyrene slowly absorbs CO and the molar ratio of the absorbed CO to the charged CuCl is 0.04 at 60 min and 0.97 at 144 h under 1 atm at 20 °C, as shown in Fig. 7.

Concentrated hydrochloric acid solution of CuCl also slowly absorbs CO and the molar ratio of the absorbed CO to the charged CuCl is 0.10 at 60 min and 0.16 at 300 min, as shown in Fig. 8.

Dark reddish brown solution prepared from 0.85 g (8.2 mequiv in phenyl residue) of linear polystyrene (DP_n: 420), 1.55 g (8.2 mmol) of titanium(IV) chloride, 0.81 g (8.2 mmol) of CuCl, and 20 cm^3 of toluene did not absorb CO. Yellow solution from 0.95 g (9.1 mequiv in phenyl residue) of linear polystyrene (DP_n: 420), 2.39 g (9.2 mmol) of tin(IV) chloride, 0.91 g (9.2 mmol) of CuCl, and 20 cm^3 of toluene did not absorb CO either. In both cases, considerable amounts of precipitates were formed under homogeneous solutions.

Discussion

Formation of PSt-$AlCuCl_4$ Complex. Copper(I) chloride, which hardly dissolves in toluene alone, satisfactorily dissolves in toluene in the presence of $AlCl_3$ equimolar to CuCl. When the molar ratio of CuCl to $AlCl_3$ is larger than unity, CuCl present in excess forms precipitates. These results definitely show that CuCl and $AlCl_3$ form a double salt $AlCuCl_4$ in a molar ratio 1:1. Formation of $AlCuCl_4$ in toluene either in the presence or the absence of polystyrene was further confirmed by the infrared absorption band at 484 cm^{-1} (Fig. 5 (a)), which was assigned to antisymmetric stretching mode ν_a of $AlCl_4^-$ residue in $AlCuCl_4$.[10]

In the CO absorbents composed of polystyrene, $AlCl_3$, CuCl, and aromatic solvents, polystyrene and $AlCuCl_4$ form a polymer complex PSt-$AlCuCl_4$. This is shown by the fact that chlorobenzene solution of $AlCuCl_4$ was homogeneous only in the presence of polystyrene. Here, aromatic rings of polystyrene formed charge-transfer complexes with $AlCuCl_4$, which satisfactorily dissolved in chlorobenzene. In the absence of polystyrene, however, considerable portion of $AlCuCl_4$ precipitated, since the equilibrium constant for the charge-transfer complex formation between $AlCuCl_4$ and chlorobenzene was small due to small electron donating ability of chlorobenzene (ionization potential (I_p): 9.60 eV).[11] Toluene, which had a larger electron donating ability (I_p: 9.18 eV)[11] than chlorobenzene, efficiently formed charge-transfer complex with $AlCuCl_4$, resulting in a homogeneous toluene solution of $AlCuCl_4$ even in the absence of polystyrene.

The formation of the PSt-$AlCuCl_4$ complex has been further confirmed by a very strong charge-transfer band in the 380—500 nm region.[12] Such a charge-transfer band has not been found in a toluene solution of $AlCuCl_4$ without polystyrene.

Marked difference in absorption spectra between the $AlCuCl_4$-PSt system and the $AlCuCl_4$-toluene system indicates that the PSt-$AlCuCl_4$ complex involves interactions of two aromatic rings of polystyrene with $AlCuCl_4$. Probably an aromatic ring in polystyrene interacts with the Cu(I) ion in $AlCuCl_4$ and another aromatic ring interacts with the $AlCl_3$ part in the same $AlCuCl_4$ molecule.[11] The interaction between polystyrene and $AlCuCl_4$ is promoted by the chelate effect of these two types of interactions. The proposed conformation of the PSt-$AlCuCl_4$ complex is consistent with the result of crystallography on the $AlCuCl_4$-benzene complex,[13] where a benzene molecule interacts with the Cu(I)

ion in $AlCuCl_4$. Alternatively, two aromatic rings of polystyrene can interact with the two Cl atoms of the $AlCl_3$ part of $AlCuCl_4$ in the PSt-$AlCuCl_4$ complex.

When poly[oxy(2,6-dimethyl-1,4-phenylene)] and hydrogenated styrene-butadiene block copolymer were used in place of polystyrene, homogeneous solutions were obtained also by the interactions between the aromatic rings of the polymers and $AlCuCl_4$. Formation of the aggregates on the usage of polybutadiene and the alternating copolymer of styrene and methyl methacrylate, respectively, were associated with cross-linking of polybutadiene by cationic polymerization with $AlCl_3$ catalyst and the coordination of the ester groups in the alternating copolymer to $AlCl_3$.

CO Absorption by Solutions of PSt-$AlCuCl_4$ Complex. The frequency (2135 cm^{-1}) of the stretching vibration for the CO absorbed by the toluene solution of PSt-$AlCuCl_4$ (Fig. 5) is smaller than the value (2143 cm^{-1})[14] for free CO by about 10 cm^{-1}. This fact shows that CO absorption by the PSt-$AlCuCl_4$ absorbent is attributable to the coordination of CO to Cu(I) ion in $AlCuCl_4$. The coordination results in π-back donation from the Cu(I) ion to CO, reducing the bond order of C-O bond in CO.[14]

On the coordination of CO to the Cu(I) ion in $AlCuCl_4$, the aromatic ring of polystyrene or the toluene molecule, which is originally interacting with Cu(I) ion, is liberated from the Cu(I) ion and instead CO coordinates to the resultant unoccupied coordination site.[15] The larger equilibrium amount of the absorbed CO for the chlorobenzene solution of PSt-$AlCuCl_4$ than that for the toluene solution (Fig. 2) is consistent with this argument, since the ligand exchange from chlorobenzene to CO is easier than that from toluene to CO. The coordination of chlorobenzene to the Cu(I) ion in $AlCuCl_4$ is weaker than that of toluene, because of smaller electron donating ability (I_p=9.60 and 9.18 eV, respectively, for chlorobenzene and toluene).

Both the CO absorption rate and the amount of absorbed CO for the toluene solution of PSt-$AlCuCl_4$ complex (Fig. 2) are much larger than those of the concentrated hydrochloric acid solution of CuCl (Fig. 8). Formation of the double salt between $AlCl_3$ and CuCl decreases the electron density on the Cu(I) ion, which enhances the electron donation from CO to the Cu(I) ion, and promotes the coordination of CO to the Cu(I) ion.

The halogen dependence for the amount of CO absorbed by the toluene solutions of PSt-$AlCuX_4$ (Cl>Br $\gg$ I=0) (Table 1) is identical with that for the coordination of CO to copper(I) halides.[16] As the electronegativity of halogen decreases, the electron density on the Cu(I) ion in $AlCuCl_4$ increases and thus the capacity of CO absorption decreases.

In the coordination of CO to Cu(I) ion in $AlCuCl_4$, electron donation from CO to the Cu(I) ion makes predominant contribution, and the contribution of back donation from the Cu(I) ion to CO is less important. The ν_{CO} (2135 cm^{-1}) of the CO coordinating to the Cu(I) in $AlCuCl_4$ is larger than the ν_{CO} (2063 cm^{-1} in water,[17] and 2080 cm^{-1} in methanol)[18] of CO coordinating to CuCl. The back donation is suppressed by the decrease of electron density on the Cu(I) ion due to the formation of double salt $AlCuCl_4$.

In addition to the promotion of CO coordination to the Cu(I) ion by decreasing electron density on the ion, $AlCl_3$ in the solutions of PSt-$AlCuCl_4$ accelerates the CO absorption by dissolving CuCl, which is not soluble in toluene alone, with the formation of the double complex. CO absorption of homogeneous toluene solution of PSt-$AlCuCl_4$ complex (Fig. 2) is much faster than that by the toluene suspension of CuCl (Fig. 7).

Protection of $AlCuCl_4$ by PSt. The toluene solution of PSt-$AlCuCl_4$ shows no measurable deactivation on the repeated contacts with 10 mol% water to the charged CuCl (Fig. 3). This is markedly in contrast with significant decrease of the absorbing capacity of the toluene solutions of $AlCuCl_4$ without polystyrene. The amount of the $AlCuCl_4$ deactivated by water in the absence of polystyrene, estimated from the decrease in the CO absorbing capacity, is about twice in mole as large as that of the water (Fig. 4). This result is consistent with the irreversible reaction between $AlCuCl_4$ and water expressed by Eqs. 1 and 2.

No deterioration of the toluene solution of PSt-$AlCuCl_4$ on the contact with water vapor is probably due to the protection of $AlCuCl_4$ against water by the hydrophobic field of polystyrene. As described above, polystyrene and $AlCuCl_4$ form a polymer complex, in which two aromatic rings of polystyrene interact with one $AlCuCl_4$ molecule. The interactions of the two aromatic rings function cooperatively, and thus the interaction between aromatic ring and the $AlCl_3$ moiety is largely enhanced due to chelate effect. As the result, the $AlCl_3$ moieties, which otherwise rapidly react with water, are sufficiently protected by the aromatic rings of polystyrene. The water vapor remains in the gas phase here.[19]

In case of the toluene solution of $AlCuCl_4$ without polystyrene, however, protective effects of toluene on $AlCuCl_4$ are not so large, since the chelate effect does not take place. Water vapor promptly penetrates into the absorbent and hydrolyzes the $AlCuCl_4$.[19]

No dependence of the water-resistivity of CO absorbent on the degree of polymerization of polystyrene used (Table 2) indicates that the water resistivity of the absorbent is not attributable to the

increase of the viscosity of the absorbent resulting from the addition of polystyrene.

The proposed mechanism of water resistivity of the absorbent is also supported by the fact that water-resistive CO absorbent can be prepared by use of 1,3-diphenylpropane, a low molecular weight model of polystyrene, as solvent.[20]

Reciprocal Space Expansion in the Analysis of X-Ray Scattering Intensities from Liquid Carbon Tetrachloride

Keiko NISHIKAWA* and Takao IIJIMA
Department of Chemistry, Faculty of Science, Gakushuin University,
Mejiro, Toshima-ku, Tokyo 171
(Received May 31, 1985)

The concept of "reciprocal space expansion" has been applied in the analysis of the X-ray scattering intensity from liquid carbon tetrachloride. The results obtained by using the bcc local lattice structure model show very good agreement with the experimental intensity in the small-s region, where ghost peaks are inevitably introduced by the "real space expansion" usually adopted.

The analysis of the X-ray scattering intensity from a liquid by constructing a "local lattice structure model" is usually carried out by means of the formulation put forward by Narten and his co-workers.[1,2] This formulation is based on the theory developed by Debye and Menke[3] and by Warren,[4] i.e., the expansion of the scattering intensity in terms of the interatomic distances, r_{ij}, in the real space (see Eq. 2). Therefore, hereafter, we will name Narten's expression for the "local lattice structure model" the "real space expansion."

This method was applied to liquid carbon tetrachloride.[5,6] The body-centered-cubic local lattice structure formed by the head-tail head-tail packing of the carbon tetrachloride molecules with a nearest neighbor distance of 5.9 Å accounted for the experimental intensity beyond s=1.2 Å^{-1} ($s=4\pi\sin\theta/\lambda$, 2θ: scattering angle, λ: wavelength of X-rays).

As was pointed out in a previous paper,[5] the limitations of the real space expansion for the local lattice structure model arise from the unreasonable connection of the discrete structure region and the continuum one, as the sudden onset of the continuum region inevitably leads to spurious peaks in the small-s region. The use of a larger discrete-structure region is, on the other hand, difficult practically because of the slow convergence of the real space expansion for small values of s. The small-s region, however, contains information on the long-range structure of liquids. Thus it is important to investigate the scattering intensities in this region more carefully.

In the case of the real space expansion of the bcc model for liquid carbon tetrachloride,[5] the ghost peak and valley appearing at 0.5 and 0.8 Å^{-1} respectively are distinguishable from the inherent peaks beyond $s\simeq$1.3 Å^{-1} (see Fig. 2(a)). However, in some simulation studies of the structure of liquids, ghost peaks may be misunderstood as inherent peaks. Moreover, due to the ghost peaks, the usefulness of the local lattice structure model itself has often been devaluated.[7,8]

To overcome the difficulty in the real space expansion, a method called "reciprocal space expansion" was applied to liquid carbon tetrachloride; the results were reported in a previous letter by the present authors.[6] The details are described in the present paper.

Formulation of the "Reciprocal Space Expansion"

The Poisson summation formula[10] states that, for the functions $\eta(\boldsymbol{k})$ and $\phi(\boldsymbol{r})$, that are mutually related by a Fourier transform, we have

$$\sum_{\mu}\phi(\boldsymbol{a}_{\mu})=\frac{1}{v}\sum_{\nu}\eta(\boldsymbol{b}_{\nu}), \tag{1}$$

where $\boldsymbol{a}_{\mu}$ is the lattice-point vector in real space, $\boldsymbol{b}_{\nu}$ is that in the corresponding reciprocal space, and v is the volume of the unit cell in the real space. The notations μ and ν are the representations of a set of three indices.

The total coherent scattering intensity per molecule, as formulated by the real space expansion, is given by,[5]

$$I=\sum_{i}\sum_{j}f_{i}f_{j}\frac{\sin(sr_{ij})}{sr_{ij}}\exp(-l_{ij}^{2}s^{2}/2), \tag{2}$$

where f_i is the atomic scattering factor of the i-th atom and l_{ij} is the root mean-square deviation of the mean interatomic distance, r_{ij}. The summation for j is over all atoms of the sample, while that for i is over the atoms of the central molecule. By employing the Prins relation, $l_{ij}^2=2Dr_{ij}$,[11] Eq. 2 becomes

$$I=\sum_{\alpha,\alpha'}\sum_{\mu}f_{\alpha}f_{\alpha'}\frac{\sin(s|\boldsymbol{a}_{\mu}+\boldsymbol{a}_{\alpha\alpha'}|)}{s|\boldsymbol{a}_{\mu}+\boldsymbol{a}_{\alpha\alpha'}|}\exp(-Ds^{2}|\boldsymbol{a}_{\mu}+\boldsymbol{a}_{\alpha\alpha'}|), \tag{3}$$

where $\boldsymbol{a}_{\mu}$ is the lattice-point vector and $\boldsymbol{a}_{\alpha,\alpha'}$ is the vector which connects α and α'-th atoms in a unit cell (see Fig. 1). Let us define $\phi(\boldsymbol{r})$ by means of the following relation:

$$\phi(\boldsymbol{r})=\exp(-Ds^{2}|\boldsymbol{r}+\boldsymbol{a}_{\alpha\alpha'}|)\frac{\sin(s|\boldsymbol{r}+\boldsymbol{a}_{\alpha\alpha'}|)}{s|\boldsymbol{r}+\boldsymbol{a}_{\alpha\alpha'}|}. \tag{4}$$

By the Fourier transform of the $\phi(\boldsymbol{r})$, $\eta(\boldsymbol{k})$ is given as follows, where $(\boldsymbol{r}+\boldsymbol{a}_{\alpha,\alpha'})$ is replaced by $\boldsymbol{r}'$,

$$\eta(\boldsymbol{k}) = \int \exp(-Ds^2r')\frac{\sin(sr')}{sr'}\exp(i\boldsymbol{k}\cdot\boldsymbol{r})d\boldsymbol{r}$$
$$= \int \exp(-Ds^2r')\frac{\sin(sr')}{sr'}\exp(i\boldsymbol{k}\cdot\boldsymbol{r}')\times\exp(-i\boldsymbol{k}\cdot\boldsymbol{a}_{\alpha\alpha'})d\boldsymbol{r}'$$
$$= \frac{2\pi Ds}{k}\left[\frac{1}{(Ds^2)^2+(s-k)^2}-\frac{1}{(Ds^2)^2+(s+k)^2}\right]\times\exp(-i\boldsymbol{k}\cdot\boldsymbol{a}_{\alpha\alpha'}), \quad (5)$$

k being the absolute value of $\boldsymbol{k}$. Accordingly, by the use of the Poisson sum formula given by Eq. 1,

$$I = \sum_{\alpha,\alpha'}\sum_{\nu}{}' f_\alpha f_{\alpha'}\exp(-i\boldsymbol{b}_\nu\cdot\boldsymbol{a}_{\alpha\alpha'})\times\frac{2\pi Ds}{vb_\nu}\left[\frac{1}{(Ds^2)^2+(s-b_\nu)^2}-\frac{1}{(Ds^2)^2+(s+b_\nu)^2}\right], \quad (6)$$

is derived. The prime over the summation sign denotes omission of the $\boldsymbol{\nu}$=(0 0 0) term[9].

Next, let us examine the term $\sum_{\alpha,\alpha'} f_\alpha f_{\alpha'}\exp(-i\boldsymbol{b}_\nu\cdot\boldsymbol{a}_{\alpha\alpha'})$ for the bcc model of carbon tetrachloride. The atoms numbered from 1 to 5 are included in the stoichiometric unit (a molecule) placed at the origin (see Fig. 1). Therefore, the summation for α is over the atoms numbered from 1 to 5, while the summation for α′ is over the atoms numbered from 1 to 10. Let $\boldsymbol{R}$ be the vector which connects the center of the molecule at the origin with that of the nearest neighboring molecule, which in this case is given by

$$\boldsymbol{R} = \left(\frac{a}{2},\frac{a}{2},\frac{a}{2}\right) \quad (7)$$

where a is the lattice constant of the bcc unit cell. Then, we obtain the following relation,

$$\sum_{\alpha=1}^{5}\sum_{\alpha'=1}^{10} f_\alpha f_{\alpha'}\exp(-i\boldsymbol{b}_\nu\cdot\boldsymbol{a}_{\alpha\alpha'}) = \sum_{\alpha=1}^{5}\sum_{\alpha''=1}^{5} f_\alpha f_{\alpha''}\exp(-i\boldsymbol{b}_\nu\cdot\boldsymbol{a}_{\alpha\alpha''})[1+\exp(-i\boldsymbol{b}_\nu\cdot\boldsymbol{R})], \quad (8)$$

where the first term in parentheses corresponds to the correlation among the atoms in the central molecule (1—5) and where the second term is that between the two molecules in a unit cell (1—5 and 6—10 in Fig. 1). With a little manipulation of Eq. 8, we have

$$\sum_{\alpha,\alpha'} f_\alpha f_{\alpha'}\exp(-i\boldsymbol{b}_\nu\cdot\boldsymbol{a}_{\alpha\alpha'}) = [f_C^2+4f_{Cl}^2+\sum_{i=2}^{5}2f_Cf_{Cl}\cos(\boldsymbol{b}_\nu\cdot\boldsymbol{a}_{C\text{-}Cl(i)}) + \sum_{\substack{j,k=2\\ j>k}}^{5}2f_{Cl}^2\cos(\boldsymbol{b}_\nu\cdot\boldsymbol{a}_{Cl(j)\text{-}Cl(k)})]\times[1+\exp(-i\boldsymbol{b}_\nu\cdot\boldsymbol{R})]. \quad (9)$$

Finally, we must consider the correction for the term of $\boldsymbol{a}_\mu=\boldsymbol{0}$. In Eqs. 3 and 6, the mean-square deviations of the intermolecular distances are also given by the Prins relation. It is necessary to replace them by the intramolecular mean-square amplitudes, which are known more exactly. Then, the correction term, ΔI_{intra}, becomes

$$\Delta I_{intra} = 8f_Cf_{Cl}[\exp(-l_{C\text{-}Cl}^2s^2/2)-\exp(-Dr_{C\text{-}Cl}s^2)]\frac{\sin(sr_{C\text{-}Cl})}{sr_{C\text{-}Cl}} + 12f_{Cl}^2[\exp(-l_{Cl\text{-}Cl}^2s^2/2)-\exp(-Dr_{Cl\text{-}Cl}s^2)]\frac{\sin(sr_{Cl\text{-}Cl})}{sr_{Cl\text{-}Cl}}, \quad (10)$$

where $l_{C\text{-}Cl}$ and $l_{Cl\text{-}Cl}$ are the root mean-square amplitudes for the distances $r_{C\text{-}Cl}$ and $r_{Cl\text{-}Cl}$, respectively.

From Eqs. 6, 9, and 10, the total coherent intensity of the bcc model for carbon tetrachloride is given by

$$I = \frac{1}{v}\sum_{\nu}{}'\frac{2\pi Ds}{b_\nu}\left[\frac{1}{(Ds^2)^2+(s-b_\nu)^2}-\frac{1}{(Ds^2)^2+(s+b_\nu)^2}\right]\times[f_C^2+4f_{Cl}^2+\sum_{j=2}^{5}2f_Cf_{Cl}\cos(\boldsymbol{b}_\nu\cdot\boldsymbol{a}_{C\text{-}Cl(j)}) + \sum_{\substack{j,k=2\\ j>k}}^{5}2f_{Cl}^2\cos(\boldsymbol{b}_\nu\cdot\boldsymbol{a}_{Cl(j)\text{-}Cl(k)})][1+\exp(-i\boldsymbol{b}_\nu\cdot\boldsymbol{R})] + \Delta I_{intra}. \quad (11)$$

For $\boldsymbol{b}_\nu$ expressed by $\left(\frac{2\pi h}{a},\frac{2\pi k}{a},\frac{2\pi l}{a}\right)$, the value in parentheses $[1+\exp(-i\boldsymbol{b}_\nu\cdot\boldsymbol{R})]$ is equal to 2 when $h+k+l$ is even and zero when $h+k+l$ is odd. This corresponds to the extinction rule of the bcc lattice.

In practical calculation the following values were used; the intramolecular parameters, $r_{C\text{-}Cl}$, $r_{Cl\text{-}Cl}$, $l_{C\text{-}Cl}$, and $l_{Cl\text{-}Cl}$, were the values obtained by means of gas electron diffraction,[12] the lattice constant of the bcc unit cell was 6.81,[5] and D was 0.036 Å.[5] (Note that the definition of D in Ref. 5 is that of $2D$ of the present paper.)

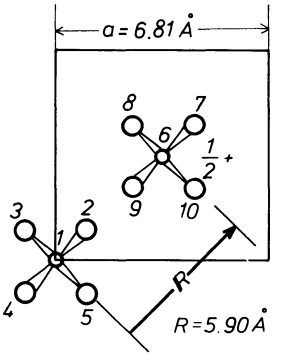

Fig. 1. The arrangement of carbon tetrachloride molecules in a bcc unit cell.

Results and Discussion

The results of the application to carbon tetra-

chloride based on the bcc local lattice structure are shown in Fig. 2(b). For comparison, the results of the "real space expansion" are shown in Fig. 2(a).[5] The total coherent intensity is adopted, because it distinguishes the discrepancy between the experimental and the simulated intensities in the small-s region. The dots represent the experimental intensities,[13] while the monotonically decreasing broken curves are the calculated self-scattering

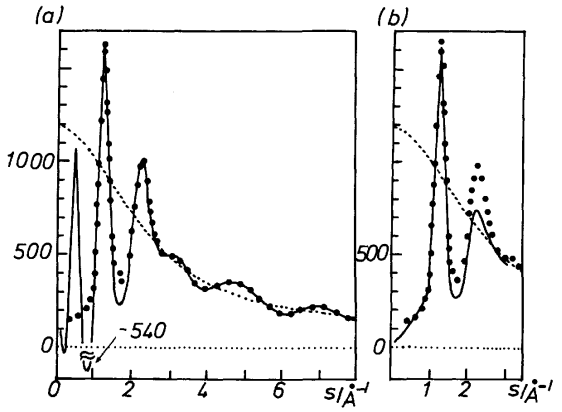

Fig. 2. Total coherent intensity (in electron unit) of liquid carbon tetrachloride. The curves described by dots are experimental intensity.[13]
(a): The solid curve is the calculated intensity based on the bcc model by the use of the "real space expansion."
(b): The solid curve is the calculated intensity based on the bcc model by the use of the "reciprocal space expansion."

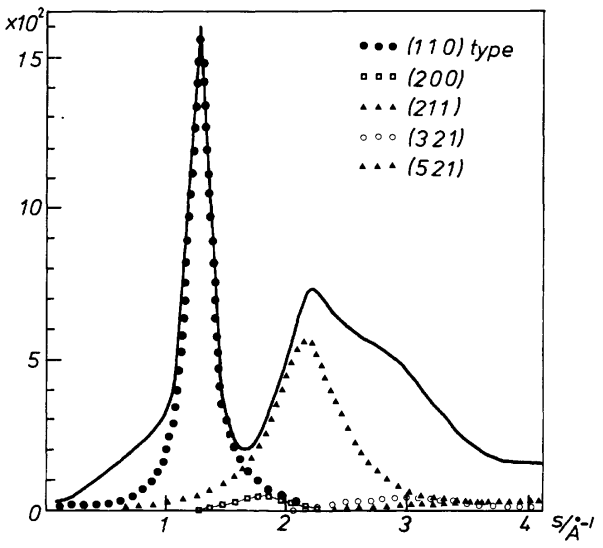

Fig. 3. contribution of each reciprocal lattice point. The solid curve is the calculated total coherent intensity. The Lorentzian-like curves are contributions from {1 1 0}, {2 0 0}, {2 1 1}, {3 2 1}, and {5 2 1} lattice points, respectively. The difference between the solid curve and the sum of the contributions from the reciprocal lattice points is the contribution of ΔI_{Intra}.

intensities. The solid curve in Fig. 2(a) is the calculated intensity based on the bcc model.[5] The agreement is very good up to $s \simeq 20$ Å^{-1}, although not shown in this figure. The intensity in the small-s region ($s < 1.2$ Å^{-1}), however, shows discrepancies, which are due to the inherent ghost peaks of the "real space expansion."

The solid curve in Fig. 2(b) is the intensity calculated by the use of the "reciprocal space expansion" based on the bcc model. In this calculation reciprocal lattice points up to $\nu=(6\ 0\ 0)$ ($b_\nu = 5.54$ Å^{-1}) are included. The calculated curve is in very good agreement with the experimental intensity in the region of s less than 1.5 Å^{-1}. However, the convergence becomes worse with the increase in the scattering parameter, s, contrary to the case with the "real space expansion."

Figure 3 shows the contribution of each reciprocal lattice point to the calculated total coherent intensity (solid curve). The Lorentzian-like curve with the peak at $s \simeq 1.3$ Å^{-1} is the contribution from the {1 1 0} reflections, which contain 12 equivalent reflections with the magnitude of b_ν 1.305 Å^{-1}. The next peak is due to the {2 0 0} reciprocal points, whose contribution is relatively small in this bcc structure. It should be noticed that the main feature of the total coherent intensity is almost entirely determined by the {1 1 0} and the {2 1 1} reflections; that is, the former form the first peak at $s = 1.3$ Å^{-1}, while the latter form the second peak at $s = 2.3$ Å^{-1}. The difference between the solid curve and the sum of the contributions from the reciprocal lattice points in the range of $s < 1$ Å^{-1} and $s > 2$ Å^{-1} is the contribution of ΔI_{intra} (see Eq. 11). As the magnitude of b_ν increases, the widths of the Lorentzian-like curves rapidly become wider. This corresponds to the fact that the convergence becomes worse with the increase in the scattering parameter, s. By the reciprocal space expansion, the intensities for s values ranging up to about 2 Å^{-1} can be well simulated. For some molecular liquids, the scattering intensity near $s \approx 0$ Å^{-1} has a finite value. This is caused by the density fluctuation of the liquids.[14] This fluctuation was not included in the present formulation by the local lattice structure model. Thus, the calculated intensity is not necessarily in agreement with the experimental values at $s \approx 0$ Å^{-1} for a liquid with large density fluctuations.[15]

With the use of both the "reciprocal space expansion" and the "real space expansion", the observed scattering intensity of liquid carbon tetrachloride is satisfactorily accounted for over the whole range of the parameter s on the basis of the bcc local lattice model.

In simulation studies for the diffaction intensity of liquids, there have been many cases where the calculated intensities can not simulate the observed

intensities. In these cases, there are two possibilities; one is that the structure model itself is not adequate, and the other is that the ghost peaks because of the inevitable result of the "real space expansion" are disturbing the inherent peaks. In this paper, the problem of the ghost peaks of the "real space expansion," which appears in the small-s region is solved by the introduction of the "reciprocal space expansion." By the use of both expansions, the application of the "local lattice structure model" becomes more promising in the study of the structure of liquids.

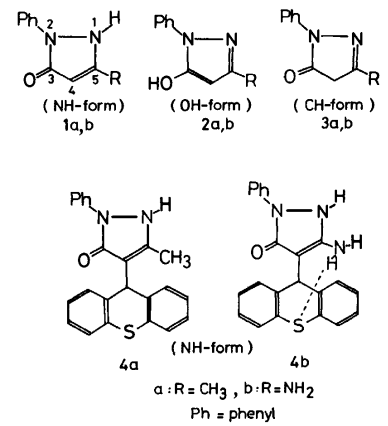
Crystal and Molecular Structure of 3-Pyrazolone Derivatives. III.[1] 5-Amino-2-phenyl-4-(9*H*-thioxanthen-9-yl)-1,2-dihydro-3*H*-pyrazol-3-one

Michio KIMURA
Niigata College of Pharmacy, 5829 Kamishin'ei-cho, Niigata 950-21
(Received June 20, 1985)

The crystal and molecular structure of 5-amino-2-phenyl-4-(9*H*-thioxanthen-9-yl)-1,2-dihydro-3*H*-pyrazol-3-one has been determined by the X-ray diffraction method to establish the predominant tautomeric form of the 3-pyrazolone ring in the solid state. The title compound, $C_{22}H_{17}N_3OS$, crystallizes in the space group $P2_1/c$ with lattice parameters: a=18.179(4), b=8.333(1), c=11.961(7) Å, β=95.88(3)°, and Z=4. The 5-amino group is intramolecularly hydrogen-bonded to the sulfur atom of the thioxanthene ring (N-H···S=3.284 Å). In the packing structure, molecules are linked to each other through hydrogen bonds between the NH of amino and C=O groups [2.849 Å] and the NH moiety and C=O group [2.939 Å] of the 3-pyrazolone ring.

3-Pyrazolone derivatives have important uses in medicine as analgesics and antipyretics and in color photography as magenta dye-formers.[2] The tautomerism in 2,5-disubstituted 3-pyrazolone[3–6] has been the subject of much work since Konn's synthesis[7] appeared as the first example of this class. In the course of studying the reactivity of 5-methyl- and 5-amino-2-phenyl-1,2-dihydro-3*H*-pyrazol-3-one, which has three possible tautomeric forms (designated as the NH-, OH-, and CH-forms (**1a,b**, **2a,b**, and **3a,b** in Scheme 1)), according to the position of the labile proton), it has been reported that these 3-pyrazolone derivatives undergo dehydration at the 4-position of the active methylene of the 3-pyrazolone ring with the OH group of 9*H*-xanthen-9-ol or 9*H*-thioxanthen-9-ol to form the condensed products (**4a,b**).[8] Generally, 3-pyrazolone derivatives[3,5] exist predominantly as the CH-form in nonpolar solvents, while the other tautomers, the OH- and NH-form, are formed as the polar character of the solvent is increased. On the other hand, in the crystalline state, additional tautomeric forms are expected to emerge due to the strong hydrogen bonding or other intermolecular forces. X-ray diffraction studies have elucidated that the preferred tautomeric form in the solid state of 5-methyl-2-phenyl-1,2-dihydro-3*H*-pyrazol-3-one is a 1:1 mixture of the NH- and OH-form(**1a** and **2a**),[9] its condensed product 5-methyl-2-phenyl-4-(9*H*-thioxanthen-9-yl)-1,2-dihydro-3*H*-pyrazol-3-one (**4a**),[8] the NH-form, and 5-amino-2-phenyl-1,2-dihydro-3*H*-pyrazol-3-one, the CH-form (**3b**).[1]

The purpose of the present work is to establish the three-dimensional structure and the preferred tautomeric form of 5-amino-2-phenyl-4-(9*H*-thioxanthen-9-yl)-1,2-dihydro-3*H*-pyrazol-3-one in the crystal, and to compare them with those of 5-amino-2-phenyl-2,4-dihydro-3*H*-pyrazol-3-one(**3b**) In the packing structure of **3b**, the molecules are linked to each other by two kinds of hydrogen bonds between the NH_2 and CO groups (2.995 and 3.170 Å) to form a two-dimensional hydrogen bond network parallel to the ac-plane, while the different hydrogen bonds could be expected from the NH_2 and CO groups of the title compound (**4b**). One of the main goals of this work was to examine the possibility of the presence of strong intramolecular hydrogen bonds between the NH_2 group and other intramolecular hydrogen bond acceptors in **4b**, because there are three hydrogen bond donors (NH_2 and NH of the 3-pyrazolone ring) in contrast to one acceptor of the C=O group requiring two hydrogen donors.



Scheme 1.

Experimental

The title compound (**4b**) was prepared by the method described previously,[8] and it was recrystallized by the slow evaporation of an EtOH-CH_3Cl solution at room temperature. The crystal used for the X-ray measurement was a cleaved piece with approximate dimensions of 0.20×0.25×0.30 mm. A preliminary examination of the crystal, carried out on a Rigaku automated, four-circle diffractometer, showed it to be monoclinic with the space group $P2_1/c$. The unit cell parameters at room temperature were refined by the least-squares fit using the Bragg angles of 24 reflections ($30° < 2\theta < 40°$).

Crystal Data: $C_{22}H_{17}N_3OS$, M 371.45, monoclinic, space group $P2_1/c$, a=18.179(4), b=8.333(1), c=11.961(7) Å, β=95.88(3)°, V=1802.3 Å^3, D_c=1.37 g cm^{-3} for Z=4, μ=16.8 cm^{-1}.

The intensity data were collected at room temperature on a diffractometer utilizing nickel-filtered Cu $K\alpha$ radiation (λ=1.54178 Å). The θ—2θ scan mode was employed. The scan rate was 6° min^{-1} in 2θ, and the scan range in θ was varied by 1.2°+0.15° tanθ. Backgrounds were counted for 5 s at both ends of the scan with an offset of 50% of the scan range from the calculated position of the $K\alpha$ peak. The intensities of the three standard reflections measured after every 57 reflections, showed a drop of 1% over the period of data collection, but no correction was made. A total of 2634 unique reflections was measured (2θ<125°), of which 2342 were observed. The standard deviations in the structure amplitudes, $\sigma(F_o)$, were derived from the counting statistics. Lorentz and polarization corrections were applied, but no absorption correction was made.

Solution and Refinement of the Structure

The structure was solved by the direct method (MULTAN),[10] determining the phases of the 200 reflections with $|E_o|$>1.84. The E-map computed from the phases with the largest combined figure of merit (2.65) revealed all the non-hydrogen atoms. The structure was refined by the block-diagonal least-squares method. The function minimized was $\sum w(|F_o|-|F_c|)^2$, where w=1 for 0<$|F_o|\leq$20 and $w=(20/|F_o|)^{-2}$ for $|F_o|$>20. An initial refinement using individual isotropic temperature factors for the non-hydrogen atoms led to a conventional $R=(\sum||F_o|-|F_c||)/\sum|F_o|$ of 0.117. After successive refinement with anisotropic temperature factors for the non-hydrogen atoms, all the hydrogen atoms were readily located in the difference Fourier map; these atoms were then included in the further refinement with isotropic temperature factors. The efinement was completed after 6 cycles. The final values of R and $R_w=(\sum w|F_o|-|F_c|)^2/\sum w|F_o|^2)^{1/2}$ were 0.048 and 0.050 respectively. At the final cycle, the largest shift of any parameters of the non-hydrogen atoms was less than 10% of the standard deviations, while that of the hydrogen atoms was 13%. The largest peak in the final difference map, 0.2e Å^{-3}, was located near the sulfur atoms. The final atomic positional and thermal parameters* are given in Table 1. The atomic scattering factors for the S, O, and C atoms were taken from "International Tables for X-Ray Crystallography," (1974)[11a] while the factors for H were those of Stewart, Davidson and Simpson.[12] Computations were performed using the crystallographic program system *UNICS*.[13]

* Tables of the anisotropic thermal parameters, the coordinates of the hydrogen atoms, the observed and calculated structure factors and the bond distances involving hydrogen atoms are deposited at the Chemical Society of Japan, Document No. 8606.

Results and Discussion

The molecular structure and the atom labeling of **4b** are presented by the *ORTEP*[20] drawing in Fig. 1. The bond distances and angles are given in Table 2. The present study has shown that the predominant tautomeric form of the title compound in the solid state adopts the NH-form (**4b**). The structure of the benzene rings in the peripheral of the 3-pyrazolone and in the thioxanthene rings has normal values [C–C$_{(av)}$=1.381 and 1.392 Å, and C–C–C$_{(av)}$=120.0°]. In Fig. 2, the geometry of the 3-pyrazolone ring observed in **4b** is compared with those of **1a, 2a, 3b,** and **4a**.[1,8,9] As may be seen in Fig. 2, the C–C and C–N bond distances in the 3-pyrazolone ring reflect

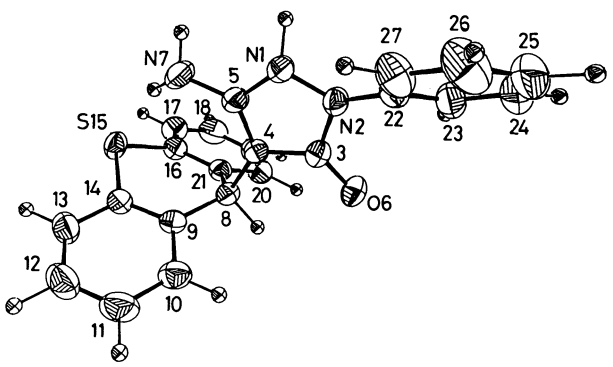

Fig. 1. Molecular structure (*ORTEP* drawing)[20] of the title compound (**4b**). Non-hydrogen atoms are drawn as thermal ellipsoids with 50 % probability level and hydrogen atoms as spheres of arbitrary radius.

Table 2. Bond Distances (l/Å) and Angles (ϕ/°) in **4b**, with Estimated Standard Deviations in Parentheses

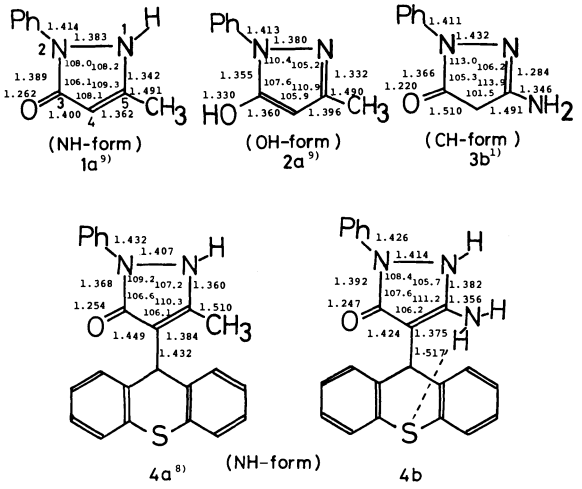

Fig. 2. The selected bond distances and angles of the 3-pyrazolone ring of **1a**, **2a**, **3b**, and **4a,b**. The stadard deviations are described in Table 2.

their predominant tautomeric forms, which are slightly shorter or longer than the normal value (1.44—1.53 and 1.35—1.36 Å respectively).[11b] The N1–C5, C4–C5, and C3–C4 bond distances are significantly different from each other in the NH-, OH-, and CH-forms (**1a**, **4a,b**, **2a**, and **3b**), showing the differences in the degree of the delocalization of the π electrons in the 3-pyrazolone ring. The C4–C5 bond distances are shorter in the NH-form (1.362, 1.384(6), and 1.375(4) Å for **1a**, **4a**, and **4b** respectively) than in the OH-form (1.396 Å for **2a**) and the CH-form (1.491(5) Å for **3b**), indicating the double-bond character of the C4–C5 in the NH-form. On the other hand, the short C3–C4 distances in the NH-form (1.400, 1.449(6), and 1.424(4) Å for **1a**, **4a**, and **4b** respectively), compared with the value of the single bond (1.510(5) Å) in the CH-form, appears to be caused by the conjugation with the C4–C5 double bond. The N1–C5 bond distances in the OH- and

CH-forms (1.332 and 1.284(5) Å for **2a**, and **3b** respectively) are shorter than the corresponding values of the NH-form (1.342, 1.360(6), and 1.382(4) Å for **1a**, **4a**, and **4b** respectively), reflecting their double-bond character. The N1–N2, N2–C3 (in the NH- and CH-form), and C3–OH bonds (in the OH-form) have typical single bond distances in the ranges of 1.383(5)—1.432(5), 1.355(5)—1.392(4), and 1.330(5) Å respectively. The C=O distances in the NH-form (**1a** and **4a,b**), 1.262, 1.254(6), and 1.247(4) Å respectively, are slightly longer than that (1.220(5) Å) in the CH-form(**3b**). These facts show the electron delocalization of the (O=C–C=C–) conjugation system in the NH-form.

Regarding the hydrogen bond, 5-methyl-2-phenyl-1,2-dihydro-3*H*-pyrazol-3-one exists in two crystallographycally independent molecules in the crystal, one in the NH-form (**1a**) and the other in the OH-form (**2a**), which are characterized by the hydrogen bonds of O–H···O (2.48 Å) and N–H···N (2.80 Å)[9] respectively. The **4a** molecules are packed with hydrogen bonds between the NH and CO groups (2.799(6) Å) to form endless chains along the c-axis in the crystal.[8] In the case of 5-amino-2-phenyl-2,4-dihydro-3*H*-pyrazol-3-one (**3b**), however, the molecules are linked together by two kinds of hydrogen bonds between the NH_2 and CO groups (2.955(5) and 3.170(5) Å) to form a network of hydrogen bonds parallel to the ac-plane.[1] It is shown that one NH of the amino group in **4b** is intramolecularly hydrogen bonded to the sulfur atom of thioxanthene (N–H···S= 3.284(3) Å). Another NH of the amino group forms an intermolecular hydrogen bond with the CO group of the neighbouring molecule (2.849(4) Å), which is also linked to the NH group of the 3-pyrazolone ring (2.939(3) Å) to form a sheet parallel to the ac-plane, as is shown in Fig. 3.

Scheme 2 shows the four chemical species (three neutral tautomers-**1a,b**, **2a,b**, and **3a,b**, and one cation-**5a,b**) in the equilibrium state in an acid solution. The structure of the 5-substituted 3-pyrazolone corresponding to **5a,b** has been established by IR, UV, and NMR spectroscopy,[14] which has shown that all three tautomeric form (OH-, NH-, and CH-forms) possess a common cation (**5a,b**). The complete equations for these equilibria have been given by a simple equation, because the CH-form is much less basic than the OH- and NH-forms.[15] As the molecular structures of **1a**, **2a**, **3b**, and **4a,b** have been established by the X-ray diffraction method, a plausible mechanism by which the tautomers are trapped in the crystal is as follows. Each NH- or OH-form is trapped in crystals by shifting the equilibrium from the common cation (**5a,b**) by electron transfer, as is shown in Scheme 2. The thioxanthene-bearing forms (**4a,b**) exist as the NH-form is a result of the removal of a proton from the protonated carbonyl group, as is shown in Scheme 2. The CH-form of **4a,b** can not participate in hydrogen bondings in crystals like the **1a** and **2a** types because of the low basicity of the pyridine-like nitrogen atom in the 3-pyrazolone ring.

The best least-squares planes, together with the displacement of atoms from the best planes and the dihedral angles between these planes were calculated. It is well known that the dihedral angle (butterfly angle) of the related thioxanthene nucleus is quite sensitive to alterations in the electronegativity of its substituents,[16] as may be seen in the change in the dihedral angle on going from phenothiazine (158.5°) to thioxanthen-9-ol (132.4°). The value (148.6°) of **4b** is in good agreement with the 143.4° value of **4a**

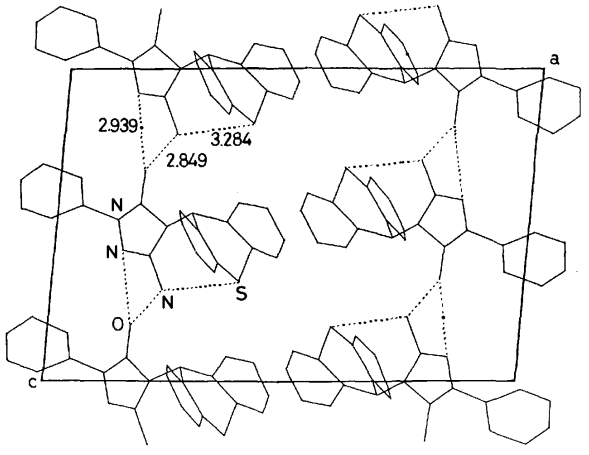

Fig. 3. Crystal structure projected along the b axis. Hydrogen bonds between molecules are shown by broken lines.

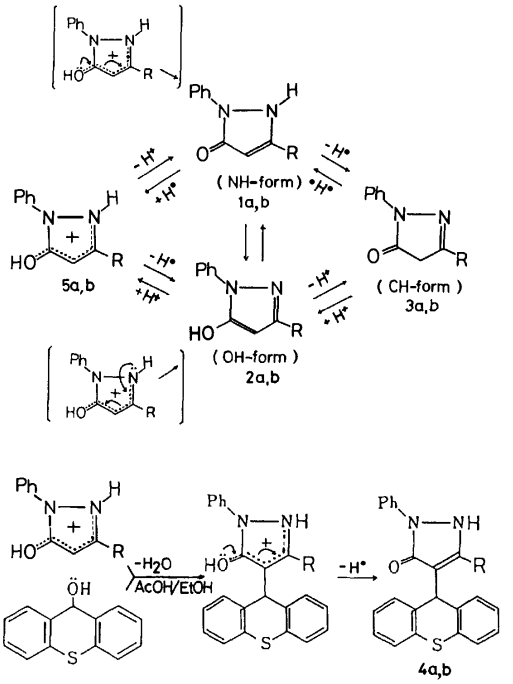

Scheme 2.

within the limits of experimental error. A final point of particular interest concernes the dihedral angles between the planes of 3-pyrazolone and phenyl rings; 47.0° for **4b**, which are to be compared with the values 47.8°, 23°, 38°, and 1.7° for **4a**, **1a**, **2a**, and **3b** respectively. These values show that the dihedral angles are different in spite of having the same tautomeric form, and that of the CH-form is significantly different. The conformation of the phenyl group in the present compounds may be mainly affected by the packing of molecules in the crystal.

The author is grateful to Professor Masao Kakudo, Professor Noritake Yasuoka, and the staff of the Crystallographic Research Center, Institute for Protein Research, Osaka University, for the use of the diffractometer and computing facilities. The author's thanks are also due to Professor Ichizo Okabayashi, Niigata College of Pharmacy, for his valuable discussions.

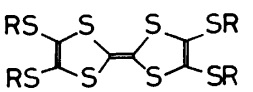
Crystal Structure and Physical Properties of (TTM-TTF)$I_{2.47}$

Peiji Wu,† Takehiko Mori,* Toshiaki Enoki, Kenichi Imaeda,
Gunzi Saito,†† and Hiroo Inokuchi
Institute for Molecular Science, Okazaki 444
†† Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo 106
(Received June 28, 1985)

The X-ray crystal structure analysis of a novel organic conductor (TTM-TTF)$I_{2.47}$ (TTM-TTF: tetrakis-(methylthio)tetrathiafulvalene) shows that the donors with an almost flat structure are stacked face-to-face to form columns. The iodine lattice composed of I_3^- columns is incommensurate with the donor lattice. The measurements of resistivity, thermoelectric power, and ESR show a metal-insulator transition around 100 K. This transition is attributed to the Peierls type phase transition. The quasi-one-dimensional electronic structure is supported by the arrangement of the donor molecules in the crystal and the calculated anisotropy of transfer integrals.

It has been demonstrated that in organic conductors an enhancement in the dimensionality is required to stabilize the metallic states and to design organic superconductors. Among the organic conductors including BEDT-TTF (bis(ethylenedithio)tetrathiafulvalene), two-dimensional conductors which are metallic down to liquid helium temperature and even superconductors have been discovered.[1-3] The investigations of the crystal structures and electronic structures have indicated that the side-by-side intermolecular interaction of these BEDT-TTF compounds is comparable to a face-to-face interaction.[4-6] This characteristic property is considered to come from the four outer sulfur atoms attached to the tetrathiafulvalene(TTF) skeleton. For the purpose of developing organic donors directed toward organic superconductors, it is important to investigate the influence of the outer alkyl groups in other alkylthio-substituted TTF's on the dimensionality of the electronic systems.

As a part of the investigation of uncapped tetrakis(alkylthio)-substituted TTF (TTC_n-TTF) (Scheme), where "uncapped" means that each outer ethylene group of BEDT-TTF is replaced by two separated alkyl groups, we have prepared a variety of charge-transfer complexes including tetrakis(methylthio)tetrathiafulvalene (TTC_1-TTF=TTM-TTF).[7,8] Among them the iodine complex (TTM-TTF)I_x showed the highest conductivity. In the present report, we deal with the crystal structure, electric conductivity, thermoelectric power, ESR spectra, and electronic structure of this iodine complex.



TTC_n-TTF R=C_nH_{2n+1}
TTM-TTF R=CH_3

Scheme.

† On leave from the Institute of Chemistry, Academia Sinica, Beijing, China.

Experimental

The iodine complex was prepared by the following three methods; (1) electrocrystallization of the donor with tetrabutylammonium triiodide as an electrolyte in a mixed solvent of benzene and methanol, (2) direct mixing of the donor and the electrolyte in dichloromethane and methanol, and (3) direct reaction of the donor with iodine molecules in dichloromethane and methanol.

X-Ray photographs with the use of Cu $K\alpha$ radiation confirmed that all these methods gave the same complex. The results of elemental analysis showed the iodine/donor ratio x to be close to 5/2 or 12/5. The exact estimation by means of an X-ray investigation indicated x=2.47. Anal. Calcd for $C_{10}H_{12}S_8I_{2.47}$: C, 17.11; H, 1.72; S, 36.53; I, 44.64. Found: C, 16.91; H, 1.73; S, 36.95; I, 44.67.

Oscillation photographs along the crystal needle axis displayed ununiformly spaced layer lines (Fig. 1), which indicated the presence of a superlattice structure characteristic of iodine complexes.[9] This superlattice structure was considered to be composed of donor and iodine subcells. Among these layer lines the scatterings from the iodine subcell were neglected in the course of the structure analysis.

The intensity data of the donor subcell were collected at room temperature with a Rigaku automated four circle diffractometer using monochromatized Mo $K\alpha$ radiation by the ω-2θ scan technique. Since the intense scatterings from the iodine subcell were neglected and the iodine subcell was approximately commensurate with the donor subcell, the accuracy of the intensity data was limited. Only 664 independent reflections of 2112 accessible reflections ($2\theta \leq 50°$) were recorded with sufficient accuracy ($|F_o| \geq 3\sigma(|F_o|)$). Cell parameters were determined from least squares applied to 25 reflections with $25° < 2\theta < 30°$.

In the course of the structure determination, first the b-axis projection, which corresponds to the projection along the crystal needle axis, was deduced from the Patterson systhesis using the $h0l$ reflections. Since the $h0l$ reflections of the donor subcell was common to that of the iodine subcell, the position of the iodine column in the b axis projection was also determined. Then the three-dimensional structure was derived from this projection. In

Table 1. Atomic Parameters

the three-dimensional structure analysis the iodine atoms were considered to be distributed randomly along the b direction. The three-dimensional structure was refined by the block diagonal least squares method. Anisotropic thermal parameters were adopted for non H atoms. Hydrogen atoms were not included in the refinement. Final refinement gave R=0.099 and R_w=0.126, where $w=1/[\sigma^2(F_o)+0.000225F_o^2]$. The positional parameters are listed in Table 1. The F_o—F_c table and the anisotropic temperature parameters are deposited as Document No. 8604 at the Office of this Bulletin.

The dc resistivity of the single crystal was measured by the four-probe method using gold paint. The anisotropy of the resistivity was measured by the combined use of the Montgomery method and the two-probe method. The thermoelectric power along the b axis was measured by attaching a single crystal with gold paint or carbon paint to two boron nitride heat sinks.[10] ESR data were obtained with an X-band spectrometer Varian E112 equipped with an Oxford Instruments ESR 9 continuous flow helium cryostat.

Results

Among the ununiformly spaced layer lines of the oscillation photograph along the crystal needle axis, the layer line with a spacing of 3.978 Å was attributed to the donor subcell, because the observed high conductivity suggests that the donor molecules form a columnar structure along the crystal needle axis. Weissenberg photographs and the investigation using a four-circle diffractometer determined the crystal data of the donor subcell to be: monoclinic, $C2/c$, a=24.78(1), b=3.978(2), c=22.65(1) Å, β=115.50(5)°, V=2015(2) Å^3, and Z=4. The b axis corresponds to the crystal needle axis.

Iodine species reported to exist in solids include I_2, I^-, I_3^-, I_5^-.[9] In addition to the scatterings from the donor subcell, the oscillation photograph along the b axis displayed layer lines at 0.233, 0.412, 0.823, 1.234, and 1.647 reciprocal lattice units of the donor subcell, b/d (Fig. 1). All these layer lines were composed of well-defined spots even at room temperature, and no diffuse layer was observed. This observation indicates the three-dimensional order of the iodine atoms.

The layer lines at 0.233 and 1.647 are weaker than the donor layer lines and the layer lines at 0.412 and 0.823 are weaker still. The layer line at 1.234 is comparable to that of the donor subcell and is attributed to the average spacing of the iodine atoms along the b axis. Since the resulting atom spacing 3.224 Å is shorter than twice of the I^- ionic radius, 4.3 Å, the presence of an I^- column is excluded. This is also consistent with the supposition that if the iodine existed as I^-, the charge on the donor should be unrealistically large.

The layer lines at 0.412, 0.823, 1.234, and 1.647 form a series with a lattice constant b'=9.670(6) Å. This lattice constant is three times as large as the above-mensioned iodine average spacing. It is documented that I_3^-, which is the most common iodine species, has a repeat period of 9.4—9.7 Å in the iodine column.[9] Therefore, this subcell spacing indicates the presence of the I_3^- column. The existence of the I_5^- column, which displays a repeat period of about 15.5 Å,[9] is excluded.

The layer line at 0.233 is not due to the two-fold structure of this iodine subcell which should appear at 3.978 Å/2×9.670 Å=0.206. This layer line is attributed to the convolution of the intense iodine layer line and the donor layer line, b/d=1.234—1.0= 0.234.

The ratio of b to b′ determines the iodine content to be $x=6b/b'$=2.468(3). The scatter of x among the samples prepared by different methods is too small to be detectable by X-ray investigations. The stoichiometry associated with x=2.47 is between TTM-TTF$_5$I$_{12}$ (x=2.4) and TTM-TTF$_2$I$_5$ (x=2.5); the iodine subcell is incommensurate with the donor subcell.

Since no additional scattering is found in the k=0 Weissenberg photograph, the iodine subcell corresponds to the donor subcell in the a*c* plane. The crystal data of the iodine subcell were determined by the combined use of Weissenberg photographs and a four circle diffractometer: triclinic, a'=24.97, b'=9.670, c'=48.95 Å, α'=111.55, β'=112.38, γ'=94.60°, and V=9827 Å^3. This subcell is related to the donor subcell by the equations: $\mathbf{a^{*\prime}=a^*}$, $\mathbf{b'//b}$, $\mathbf{2c^{*\prime}=c^*}$.

The 5th layer line of the iodine subcell at 2.06 was not clearly distinguishable from the second layer of the donor subcell. Moreover the iodine subcell gave poorer quality scatterings than did the donor subcell. Therefore analysis of the intensity data was not attempted for the iodine subcell.

The crystal structure is shown in Figs. 2 and 3. The donor molecule TTM-TTF is almost flat similarly to other TTM-TTF complexes such as (TTM-TTF)(HCBD) and (TTM-TTF)AsF$_6$,[7,8] although its neutral structure is strongly deformed to be nonplanar.[8] The donor molecules are stacked

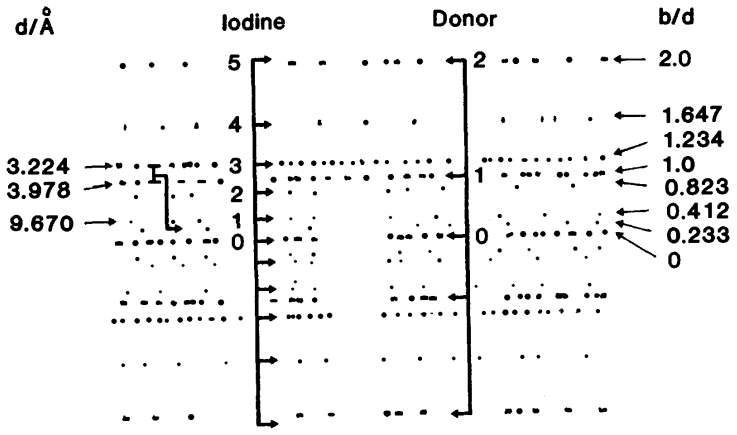

Fig. 1. Schematic representation of the oscillation photograph along the b axis. On the right side is shown b/d: the inverse of d (Å), multiplied by b=3.978 Å.

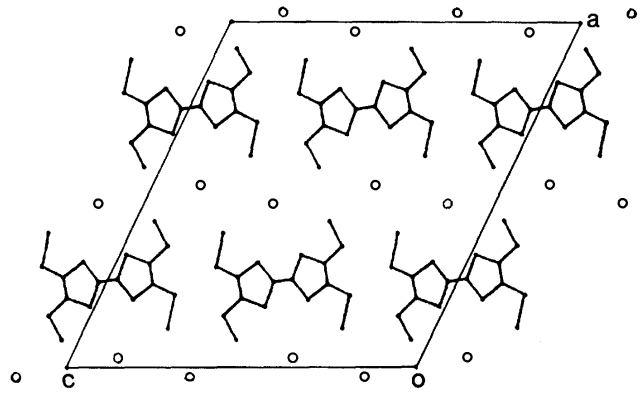

Fig. 2. Crystal structure: projection along the b axis. The white circles designate ioldine columns.

face-to-face to form a column along the b axis. The interplanar spacing is 3.58 Å and there is no shorter sulfur-to-sulfur contact than the van der Waals distance (3.7 Å) (Fig. 3). The mode of intermolecular overlap is, however, favorable to the orbital overlap (Fig. 4);[5] the adjacent molecules are displaced from each other by 1.37 Å along the long molecular axis.

There are comparatively short intercolumnar sulfur-to-sulfur contacts between the outer sulfur atoms (Fig. 3). The donor molecules form conducting sheets parallel to the bc plane in association with the short sulfur-to-sulfur contacts, and these sheets are separated from each other by the anions. The long axis of the molecule is almost parallel to this sheet.

This exhibits a striking contrast to the BEDT-TTF compounds. In all BEDT-TTF complexes whose crystal structures have been known so far, the molecular long axis is almost perpendicular to the sheet, and the intermolecular contacts at the molecular long sides are as important as the face-to-face interaction for the electron transfer.

As for TTM-TTF the terminal methyl groups extending to the direction perpendicular to the molecular long axis (see Fig. 2) block the contacts at the molecular long sides. In addition, the presence of the anions are also disadvantageous for the intermolecular interactions perpendicular to the molecular long axis in the ac plane. Since the outer sulfur atoms are instead exposed to the adjacent donors at the molecular short sides, the sheet of the donors extends through the contacts at the molecular short sides.

The b axis resistivity is shown in Fig. 5. The resistivity at room temperature is in the range of 7—10×10^{-3} Ωcm. The resistivity slightly decreases as the temperature is lowered down to 155 K, where it exhibits a broad minimum. Below 100 K the resistivity steeply increases in an activated manner with E_a=0.028 eV. The anisotropy of the resistivity is estimated to be $\rho_b:\rho_c:\rho_a=1:50:4000$.

The thermoelectric power is negative (−9 μV/K) at room temperature and decreases slightly to 155 K (−10 μV/K) (Fig. 6). Around this temperature the thermoelectric power has a broad minimum and increases below this temperature.

The magnetic susceptibility associated with the ESR intensity is almost constant from room temperature to 155 K (Fig. 7). In the temperature region between 155 and 100 K, the susceptibility decreases, but the temperature dependence is too gradual to be fitted to an activation-type formula. Below 100 K the susceptibility behaves in an activated manner with E_a=0.022 eV. This value agrees with the activation energy of the resistivity in this temperature region. Judging from the behavior of both the resistivity and the susceptibility, a metal-insulator transition is considered to take place at T_c=100 K.

The ESR linewidth is 56 G at room temperature and with a decrease in temperature decreases linearly

like that of other halides and pseudohalides of TTF derivatives.[11] This large linewidth suggests the presence of conducting sheets where the spin relaxation is allowed through interchain hoppings. The g-value (H//a*) is almost constant (2.003) through all the measured temperature region, and is close to the free electron value.

Discussion

From the stoichiometry (TTM-TTF)$I_{2.47}$ and the presence of the I_3^- species established by the X-ray investigation, the charge on a donor molecule is estimated to be n=0.823. This value is consistent with that in the estimation from the intramolecular bond lengths of the donor.[4] In general TTM-TTF tends to be slightly more positively charged in charge-transfer complexes in comparison with BEDT-TTF.

In order to estimate the anisotropy of the electron transfer, intermolecular overlap integrals of the highest occupied molecular orbital (HOMO) have been calculated on the basis of molecular orbital calculations.[5,6] The intermolecular overlap in the column is -14.7×10^{-3} and the intercolumnar overlap along the c axis is 0.88×10^{-3}. If transfer integrals t are assumed to be proportional to the intermolecular

overlaps, the anisotropy of the transfer integrals are obtained, $t_c/t_b=0.06$.

In a quasi-one-dimensional band, the ratio of the conductivity is roughly proportional to the square of the transfer integrals,[12] $(\sigma_c/\sigma_b)\simeq(ct_c/2bt_b)^2$. Thus σ_c/σ_b is evaluated to be 0.03, in agreement with the observed anisotropy 0.02.

The dimensionality of this TTM-TTF complex is lower than that of ordinary BEDT-TTF complexes. Then it is convincing that the metal-insulator transition at $T_c=100$ K observed in the resistivity and the magnetic susceptibility is attributed to the Peierls type phase transition in the quasi-one-dimensional donor chain.

A surprising observation concerning this complex is the negative thermoelectric power at high temperatures. Halide and pseudohalide systems of the TTF family ordinarily show positive thermoelectric power, because of the hole carriers existing on the donors. In a simple tight-bindihg band the thermoelectric power changes its sign to the band center, which corresponds to the degree of charge transfer $n=1.0$. In (TTM-TTF)$I_{2.47}$, the relatively large degree of charge transfer $n=0.823$ causes the Fermi energy E_F near to the band center. Thus it is possible that the deviation of the energy band from the simple tight-binding band brings about a positive curvature at E_F in the band, leading to the negative thermoelectric power.

The negative thermoelectric power is, however, attributable to the presence of a pseudogap generated by the fluctuation in the iodine lattice. Since the iodine lattice has three-dimensional order even at room temperature, a pseudogap at E_F is induced by the periodical potential of the iodine atoms. The electronic structure at high temperatures is rather semimetallic or narrow-gap semiconductor-like than one-dimensional metallic. Such an electronic structure makes the thermoelectric power either positive or negative, depending on the difference of the carrier mobilities above and below the pseudogap.

The small increase in the resistivity and the gradual decrease in the spin susceptibility blow 155 K suggest the precursor effect of the Peierls transition. Since the iodine lattice is approximately commensurate with the donor lattice, the possibility remains that a lock-in transition may take place. The X-ray investigation which determined the average periodicity of the iodine lattice does not exclude the existence of minor iodine species other than I_3^-. Therefore, the degree of charge transfer may be changed a little from $n=0.823$, depending on temperature. Then the phase transition is possibly cooperated with the change of order in the iodine lattice and/or the degree of charge transfer. In order to confirm this speculation temperature-dependent investigation of charge transfer is desirable by means of X-ray analysis or Raman spectroscopy.

It has been suggested that the spread of the donor HOMO is related to the dimensionality of the complex.[13] As the ratio of the atomic populations of the HOMO between the outer sulfur atoms and the inner sulfur atoms P_2/P_1 increses, the dimensionality is enhanced through the increase in the transverse intermolecular overlap. The ratio P_2/P_1 is calculated to be 0.452 for TTM-TTF. This value is even larger than the 0.148 for BEDT-TTF and the 0.315 for BMDT-TTF which form conductors with two-dimensionality.[14] In TTM-TTF, however, the transverse interaction at the molecular long sides is inhibited by the methyl groups; the transverse interaction works only through the outer sulfur atoms at the molecular short sides. Thus the magnitude of the transverse interaction is small. This is the reason for the less than two-dimensional electronic structure of this TTM-TTF complex, in spite of a large P_2/P_1.

In conclusion (TTM-TTF)$I_{2.47}$ is recognized as a quasi-one-dimensional conductor with an incommensurate iodine superlattice. Since the iodine atoms have three-dimensional order, the electronic structure at room temperature is considered to be semimetallic or narrow-gap semiconductor-like. Thus the resistivity shows a slightly metallic temperature dependence, the spin susceptibility is almost constant, and the thermoelectric power shows a negative value with small temperature dependence. Around $T_c=100$ K a metal-insulator transition takes place, which is attributed to the Peierls type instability. The arrangement of the donor molecules in the crystal and the calculated anisotropy of the transfer integrals support a comparatively one-dimensional electronic structure of this complex.

The authors are grateful to Prof. H. Kobayashi and Dr. A. Kobayashi for helpful advice on the structure analysis.

Thermal Stability of Electroless Nickel-Molybdenum-Phosphorus Alloy Films

Ichiro KOIWA, Masao NISHIKAWA, Keizo YAMADA, and Tetsuya OSAKA*
Department of Applied Chemistry, School of Science and Engineering,
Waseda University, Okubo, Shinjuku-ku, Tokyo 160
(Received July 12, 1985)

The structure and the electric resistivity of electroless Ni-Mo-P alloy films, which were plated from a caustic alkali citrate-glycolic acid bath, have been investigated. The phosphorus content in deposits and the deposition rate decreased with increasing Mo-complex concentration which was formed with sodium gluconate before constructing the bath. The crystallized structure and the formation of solid solutions between the Ni matrix and the codeposited Mo were indicated by X-ray diffraction measurments for high Mo-complex concentration range. On the other hand, amorphous states appeared for the Mo-complex concentration range lower than 0.002 mol dm^{-3}. In the range less than 0.002 mol dm^{-3} Mo-complex concentration, the resistivity of as-plated Ni-Mo-P films was higher than the binary Ni-P alloy film plated from the bath without the Mo-complex. In the higher Mo-complex concentration range, the resistivity immediately reached a constant value independently of the Mo-complex concentration. After 500 and 800 °C heat treatment under vacuum, the resistivity increased with increasing Mo-complex concentration. Moreover for the higher Mo-complex concentration range, the resistivity after heat treatment became higher than that of as-plated conditions, and the increased resistivity after the heat treatment depended on the Mo content in the deposits. Therefore, the codeposited Mo tended to increase the thermal stability of the films.

Recently, some workers applied electroless Ni-P plating films to thin film resistors[1,2] taking into account some advantages of mass production capability and good cost performance as compared with those prepared by PVD[3] and thick film[4] technologies. Since the amorphous Ni-P alloy film with high phosphorus content, easily produced by electroless plating method,[5,6] has high specific resistance and low temperature coefficient of resistivity,[7] it has been applied to the fields.

The structure of electroless Ni-P films[5,6,8-12] and the structure variation by heat treatment[13-15] have been studied, but satisfactorily thermally-stabilized amorphous Ni-P films have not been reported.

It is important to improve the thermal stability of electroless Ni-P plating films in view of their application to thin-film resistors. The codeposition of a higher-melting-metal into the Ni-P film is one of the candidates to improve the thermal stability of electroless Ni alloy films. Ternary alloy films of electroless Ni-W-P[16,17] and Ni-Mo-P[18,19] have already been reported. Their thermal variation is different from that of binary Ni-P alloy films, however, the study from this viewpoint has scarcely been reported and the thermal stability of the resistivity of the ternary alloy has not been discussed in detail.

This paper describes the correlation between the structure and the electric resistivity of electroless Ni-Mo-P alloy films and discusses the effect of molybdenum codeposition into Ni-P films.

Experimental

Electroless nickel-molybdenum-phosphorus alloy films were plated from a caustic alkali citrate-glycolic acid bath whose compositions and operating conditions were listed in Table 1. Molybdenum codeposition was easily formed by complexing sodium molybdate with sodium gluconate before constructing the bath as an analogy to the method by Mallory.[20] The solution of sodium molybdate which is complexed with sodium gluconate is designated Mo-complex in the text. The ninety-six w/o α-alumina ceramics (NGK Spark Plug Co. Ltd.) were used as a plating substrate except for the differential scanning calorimetry (DSC) measurement. For the DSC measurement, the catalyzed polyimide film (25KA, Torey Co. Ltd.) was used as substrate. The repeated two step process[21] was used for catalyzing the ceramics substrate, where the sensitizer and the activator are as follows; sensitizer: $SnCl_2 \cdot 2H_2O$ 1.0 g dm^{-3}, 37% HCl 1.0 ml dm^{-3}, and activator: $PdCl_2$ 0.1 g dm^{-3}, 37% HCl 0.1 ml dm^{-3}. The film thickness was adjusted to 2 μm by controlling the deposition time. The molybdenum and phosphorus contents shown as weight percentage (wt%) were determined by an inductively coupled argon plasma atomic emission spectrophotometer (ICAP-575 MarkII, Nippon Jarrell-Ash). The resistivity of the deposits on the alumina substrate was measured by the four-probe method. The structure of the deposits was determined using an X-ray diffractometer (RAD-IIA, Rigaku Denki Co. Ltd.). Thermal analysis was made with DSC (DSC-30, Shimadzu Co. Ltd.). The samples were prepared by grinding the deposits which were peeled off the polyimide substrate. The samples were heated from room temperature up to 500 °C at a constant rate of 10 °C/min, in a nitrogen atmosphere, using 10—20 mg

Table 1. Electroless Plating Bath Compositions and Operating Conditions

Chemicals	Concentration
$NaH_2PO_2 \cdot H_2O$	0.20 mol dm^{-3}
$C_3H_4(OH)(COONa)_3 \cdot 2H_2O$	0.10
$HOCH_2COOH$	0.20
$NiSO_4 \cdot 7H_2O$	0.10
Mo-complex	0—0.015

Bath temperature 90 °C, Bath pH 9.0 adjusted by NaOH.

sample weight. The heat treatment of the deposits was made under 2×10^{-3} Pa with 10 °C/min constant heating rate from room temperature to the setting temperature afterward the sample was maintained for one hour at the setting temperature.

Results and Discussion

Deposition Rate and Film Composition of Electroless Ni-Mo-P Alloy Films. The deposition rate and film composition at various Mo-complex concentration are shown in Fig. 1. The molybdenum content in the deposits increases with increasing the Mo-complex concentration up to 0.01 mol dm^{-3}, then it reaches a constant value. The maximum Mo content, 16.8 wt%, was obtained at 0.015 mol dm^{-3} Mo-complex concentration. The deposition rate decreases with increasing Mo-complex concentration and finally no deposition occurs at the region more than 0.015 mol dm^{-3} Mo-complex concentration. In contrast to Mo content behavior, the phosphorus content decreases with increasing the Mo-complex concentration. In particular, the phosphorus content remarkably decreases until 0.0025 mol dm^{-3} Mo-complex concentration, and the phosphorus content is depressed under 2 wt% at the region more than 0.0025 mol dm^{-3} Mo-complex concentration.

Structure and Resistivity of Electroless Ni-Mo-P Alloy Films. Figure 2 shows typical X-ray diffraction patterns of the deposits at various Mo-complex concentrations in the bath. As is seen in Fig. 2, the structure of the Ni-P alloy film without Mo-complex addition is in an amorphous state; only two peaks appear due to the Al_2O_3 substrate. In the region below 0.002 mol dm^{-3}, the structure of the Ni-Mo-P alloy films is in the same amorphous state as that of the Ni-P alloy film. On the other hand, at the region more than 0.002 mol dm^{-3} Mo-complex concentration, the structure of the Ni-Mo-P alloy films changes to a crystallized state. The structural change can be due to the remarkable decrease of the P content, as is seen in Fig. 1. Since the peaks of the Ni(111) and Ni(200) planes shift to the lower angle side as compared with the pure Ni value, the interplanar spacing of the Ni-Mo-P alloy can be widened by the molybdenum codeposition. The specific resistance, ρ, and the interplanar spacing, d, of Ni-Mo-P alloys are shown in Fig. 3 as a function of Mo-complex concentration. The ρ value increases with Mo-complex concentration up to 0.001 mol dm^{-3}, and it decreases to 0.0025 mol dm^{-3}. However, the ρ value becomes constant at 100 $\mu\Omega$ cm in the crystallized region above 0.0025 mol dm^{-3}. The d value of the crystallized Ni-Mo-P alloy films increases with increasing Mo-complex concentration. The increase in d value in the crystallized states

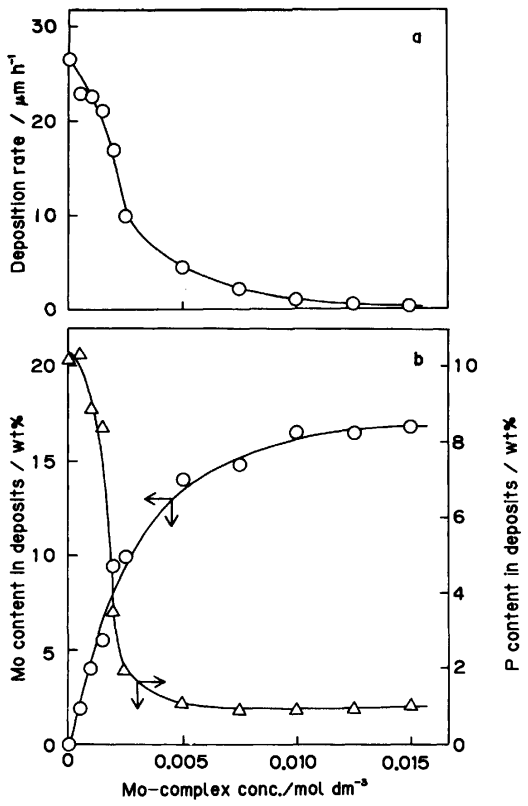

Fig. 1. Effect of Mo-complex concentration on deposition rate and film composition.

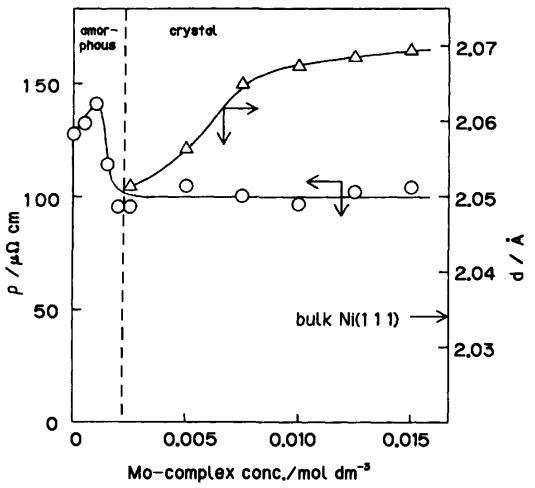

Fig. 3. Effect of Mo-complex concentration on specific resistance (ρ) and interplanar spacing (d) of Ni–Mo–P alloy films. Dashed line shows the phase change from amorphous to crystallized states.

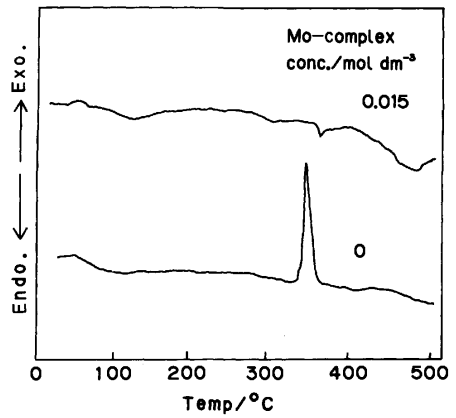

Fig. 4. DSC curves of Ni–P and Ni–Mo–P films.

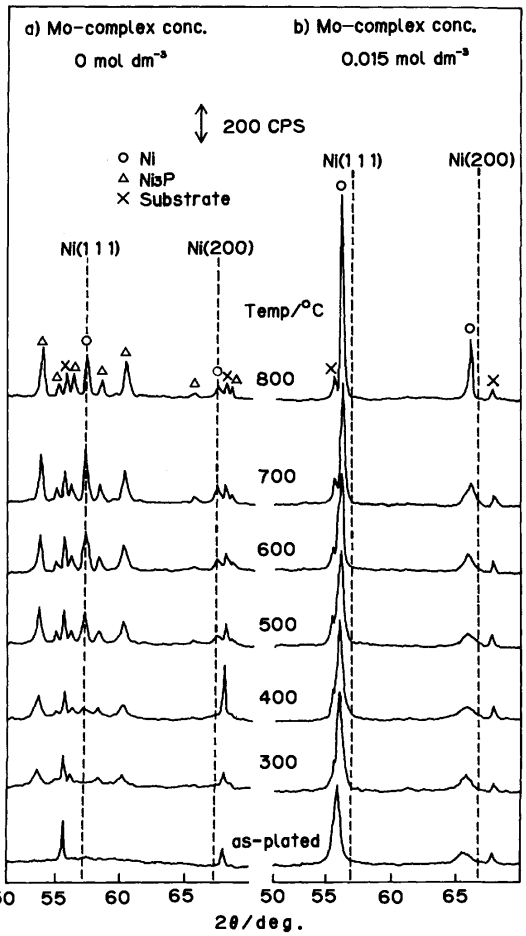

Fig. 5. X-Ray diffraction patterns for Ni–P and Ni–Mo–P alloy films at various annealing temperatures. Dashed lines show the peak positions of pure Ni.

corresponds to the increase in the Mo content with increasing Mo-complex concentration, but the ρ value of the films is independent of the increase in the Mo content. When considering that the ρ value of crystallized Ni–P alloy films with low phosphorus content generally becomes much lower than that of amorphous films,[22] the molybdenum codeposition into the Ni–P film might form a solid solution with a nickel matrix which results in the higher ρ value, in spite of the very low P content. The resistivity of as-plated Ni–Mo–P films, however, have no clear correlation with the Mo content.

Differential Scanning Calorimetry (DSC) Measurements. The DSC curves clearly show the difference between Ni–P and Ni–Mo–P deposits as is seen in Fig. 4. In the case of Ni–P film, there appears one clear exothermic peak around 350 °C, which coincides well with the previous studies.[13–15] In contrast to that of the Ni–P film, there is no obvious peak for Ni–Mo–P alloy films. In general, the exothermic peak is related to a structural change which affects the film properties such as the resistivity, and the magnetic and mechanical properties.[13–16] Therefore, the structure of an electroless Ni–Mo–P alloy film can be thermally more stable than that of a Ni–P alloy film.

Heat Treatment Effects on Properties of Electroless Ni–Mo–P Alloy Films. Figure 5 demonstrates typical X-ray diffraction patterns of the electroless Ni–P and the Ni–Mo–P alloy films after heat treatment at various temperatures. The amorphous Ni–P alloy film changes to a crystalline state and forms a Ni_3P compound on heat treatment at 300 °C. The structural change corresponds to the exothermic peak of the DSC curves as is seen in Fig. 4. The peak intensities of the Ni and Ni_3P increase with increasing heat treatment temperature. On the other hand, the electroless Ni–Mo–P alloy film, which has a crystalline structure at the as-plated conditions, maintains almost the same structure as that of an as-plated film up to 300 °C heat treatment. Moreover the peak intensities of the Ni(111) and Ni(200) plane gradually increase with the increase in the heat treatment temperature more than 300 °C. Therefore,

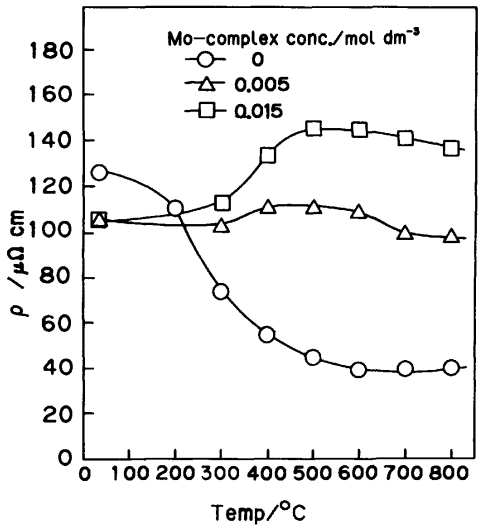

Fig. 6. Variation of specific resistance, ρ after heat treatment.

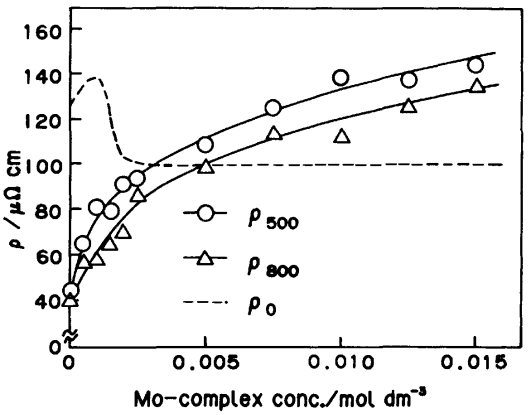

Fig. 7. Effect of Mo-complex concentration on resistivity after 500 and 800 °C heat treatment. Dashed line shows the resistivity, ρ_0 at as-plated conditions.

crystallization of electroless Ni-Mo-P alloy films is gradually proceeded by heat treatment. However, crystallization of Ni-Mo-P alloy film is much less than that of Ni-P alloy films, as has been reported previously.[13-15] The other peaks except for Ni(111) and Ni(200) planes are not observed for thermally-treated Ni-Mo-P films. The results coincide well with DSC measurement as is seen in Fig. 4. The molybdenum codeposition might inhibit the crystallization of a Ni matrix in contrast to the general Ni-P film with low phosphorus content.

Figure 6 illustrates the effect of heat treatment on the specific resistance (ρ) of Ni-Mo-P films. As is seen in Fig. 6, the resistivity of a Ni-P alloy film decreases remarkably with increasing heat treatment temperature. The decrease of Ni-P film resistivity starts in the lower heat treatment temperature range, and the decreased amount becomes larger with the increase in setting temperature. The results for a Ni-P film correspond well to those of the X-ray analysis as is shown in Fig. 5. On the other hand, the ρ value variation of electroless Ni-Mo-P alloy films is quite different from that of Ni-P alloy films, i.e., the ρ value variation is much smaller than that of a Ni-P alloy film. The resistivity of a Ni-Mo-P alloy film deposited from 0.005 mol dm^{-3} Mo-complex concentration bath is almost independent of the heat treatment temperature. Moreover, the resistivity of a Ni-Mo-P alloy film deposited from 0.015 mol dm^{-3} Mo-complex concentration bath increases with the heat treatment temperature and reaches a maximum around 500—600 °C. Such a tendency has not been observed for the binary electroless Ni-P and Ni-B alloy films. It can be concluded that the molybdenum codeposited into Ni-P film gives high stability against thermal treatment, and moreover that the Ni-Mo-P film of the higher Mo content shows the higher resistivity than that of as-plated one after heat treatment.

Figure 7 demonstrates the ρ value variation of Ni-Mo-P alloy films after heat treatment as a function of Mo-complex concentration. The resistivities after 500 °C and 800 °C heat treatments are denoted as ρ_{500} and ρ_{800}, respectively, and the dashed line indicates the resistivity value ρ_0 at as-plated conditions. The dashed line crosses solid lines of ρ_{500} and ρ_{800} values at 0.0035 and 0.005 mol dm^{-3} Mo-complex concentrations, respectively. It means that the ρ_{500} and ρ_{800} values become higher than the ρ_0 value at the region more than 0.0035 mol dm^{-3} and 0.005 mol dm^{-3} Mo-complex concentrations, respectively. The small difference of the degree of Ni matrix crystallization between 500 and 800 °C heat treatment can be observed as is seen in Fig. 5. In contrast to the poor correlation between the ρ_0 values and the Mo-complex concentration in the as-plated state, the resistivity of the heat treated Ni-Mo-P films increases with increasing Mo-complex concentration. Although no clear explanation is given for the ρ value variation of Mo codeposited Ni-P films, the molybdenum content plays one of the most important roles to determine the resistivity and the structure after heat treatment. Moreover, the codeposited molybdenum improves the thermal stability of resistivity, and it might be due to the fact that the codeposited molybdenum disturbes the structural change by heat treatment.

Conclusion

The characteristics of electroless Ni-Mo-P alloy films, which were prepared by addition of the Mo-complex into the bath, have been studied. The deposition rate and the phosphorus content decrease with increasing Mo-complex concentration. The structure of Ni-Mo-P alloy films is changed from amorphous to crystalline on increasing Mo-complex

concentration. X-Ray diffraction measurements indicate that codeposited Mo forms a solid solution with a Ni matrix. From DSC, X-ray diffraction and resistivity measurement, the Ni-Mo-P alloy film is thermally stabler than the Ni-P film. In general, a thin film resistor is actually used after heat treatment. The resistivity of the Ni-P film after heat treatment is changed abruptly by a structural transformation. Since the Ni-Mo-P films described in the text, show very stable resistivity against 400 °C heat treatment, electroless Ni-Mo-P alloy films have much advantage for the usage in thin film resistors. Under as-plated conditions, the correlation between resistivity and Mo content is not clear, however after heat treatment, the resistivity strongly depends on the Mo content, and the resistivity after heat treatment increases with increasing Mo content.

The authors wish to thank Professor Emeritus Dr. T. Yoshida, Waseda University, and Dr. K. Nihei and Mr. H. Sawai, the Research Labs, OKI Electric Industry Co. Ltd., for their encouragement of the work.

Kinetic and Equilibrium Studies of Complex Formation of Nickel(II) with Carboxylate Ligands at High Pressure. III. Nickel(II) Malonate and Nickel(II) Tartronate

Kiyotaka KOJIMA, Tohru INOUE,* Michiko IZAKI, and Ryosuke SHIMOZAWA
Department of Chemistry, Faculty of Science, Fukuoka University,
Nanakuma, Jonan-ku, Fukuoka 814-01
(Received August 16, 1985)

Kinetic and equilibrium measurements were carried out for the complexation reaction of nickel(II) malonate and nickel(II) tartronate in an aqueous solution at 20 °C and at pressures up to 100 MPa. The reaction volume, ΔV^0, and the activation volume, ΔV_f^*, for the complex formation were estimated from the pressure dependence of the stability constant and the rate constant. The results are as follows: $\Delta V^0=13.5\pm1.0$ cm^3 mol^{-1} and $\Delta V_f^*=14.7\pm0.5$ cm^3 mol^{-1} for nickel(II) malonate, and $\Delta V^0=13.3\pm0.7$ cm^3 mol^{-1} and $\Delta V_f^*=15.2\pm0.5$ cm^3 mol^{-1} for nickel(II) tartronate. The larger ΔV^0 value compared with those obtained for dicarboxylate ligands which form a monodentate complex coincides with that malonate and tartronate form a chelate complex with nickel(II) in an aqueous solution. By appropriately estimating the volume changes associated with the outer-sphere complex formation and first-bond formation, the overall volume profile for the complexation reaction was obtained. A Similar feature regarding the volume profile for the complexation of nickel(II) malonate and nickel(II) tartronate suggests that tartronate forms a bidentate chelate complex by two carboxyl groups rather than by carboxyl and hydroxyl groups.

The usefulness of the activation volume as a criterion for a mechanistic study has been progressively demonstrated since a high-pressure technique was combined with rapid-reaction techniques. Recently, many kinetic investigations have been reported for metal complexation reactions in solutions under high pressure in order to understand reaction mechanisms based on the activation volume.[1-3] Previously, we studied the complex formation reactions of nickel(II) with some carboxylate ligands in aqueous solutions under high pressure using a high-pressure pressure-jump technique.[4,5] In this present paper, we report the results obtained with nickel(II) malonate and nickel(II) tartronate systems.

In a preliminary communication,[6] we presented the kinetics of a nickel(II) malonate complexation reaction under high pressure, where only the pressure-jump relaxation data were available and the overall volume profile for the reaction could not be obtained because of the poor accuracy of the kinetically determined stability constants. Hence, in the present work, the stability constants at high pressure were determined independently.

A malonate ion has two carboxylato groups which can coordinate to a nickel(II) ion to form a six-membered chelate complex in an aqueous solution, while a tartronate ion has an additional hydroxyl group on α-carbon (see Scheme 1). Considering the molecular structure of a tartronate ion, there may be possible structures of the complex with nickel(II); six-membered chelate coordinated by two carboxyl oxygens, five-membered chelate coordinated by one carboxyl oxygen and one hydroxyl oxygen, and also tridentated chelate coordinated by two carboxyl oxygens and one hydroxyl oxygen. It will be shown below that the volume profile obtained in this study can serve to elucidate not only the rate-determining step of the reaction but also the structure of the complex.

Experimental

Reagents. Stock solutions of nickel(II) malonate and nickel(II) tartronate were prepared from nickel sulfate and respective acids according to a procedure described previously.[4] The concentration of the solution was determined by titrating with an EDTA solution standardized by a standard solution of zinc nitrate. Nickel sulfate (Wako Pure Chemicals, guaranteed grade), malonic acid (Wako Pure Chemicals, >98%), and tartronic acid (Aldrich Chemical Co., 98%) were used without further purification. Each sample solution was prepared by diluting the stock solution to the desired concentration. The pH's of the sample solutions were 6.9±0.1 for nickel(II) malonate and 6.0±0.1 for nickel(II) tartronate. In these pH ranges, most of the ligands were in a fully dissociated form, considering the pKa values of the acids; pKa$_1$=2.85 and pKa$_2$=5.67 for malonic acid,[7] and pKa$_1$=2.02 and pKa$_2$=4.24 for tartronic acid.[8]

Measurements. The stability constants of the complexes were determined from conductivity measurements according to the Fuoss-Kraus method.[9] The conductivity under high pressure was measured using a conductivity cell made by modifying an injector, which was immersed in a conventional high-pressure vessel. The concentration range of nickel(II) species employed for the conductivity measurements was 1×10^{-4}—1×10^{-3} mol dm^{-3}. Kinetic measurements were made using a high-pressure pressure-jump apparatus.[6] The concentration range of nickel(II) species for kinetic measurements was 5×10^{-4}—1×10^{-2} mol dm^{-3} for nickel(II) malonate and 5×10^{-4}—5×10^{-3} mol dm^{-3} for nickel(II) tartronate. The temperature was kept at 20.0±0.1 °C throughout the measurements and the pressure was maintained within ±0.5 MPa. As the concentration of the sample solution is expressed in molarity, in the case of measurements under pressure, corrections for the molar

concentration due to compression were made using the density data of water.[10]

Results

The complex formation reaction under consideration is represented in Scheme 1. Stability constants

$$Ni^{2+} + L^{2-} \rightleftharpoons NiL$$

L^{2-}: $CH_2(COO^-)_2$ (malonate) $CHOH(COO^-)_2$ (tartronate)

Scheme 1.

of the complexes, K, were determined from the conductivity data according to Eq. 1 using a computer iteration technique (detail of the procedure was described previously[4]).

$$\frac{F}{\Lambda} = \frac{1}{\Lambda^0} + \left(\frac{K}{(\Lambda^0)^2}\right)\left(\frac{\Lambda c\gamma_\pm^2}{F}\right), \quad (1)$$

where F is the conductivity coefficient (related to the degree of dissociation of the complex, α, by $\alpha=\Lambda/\Lambda^0F$), and other symbols have their usual meanings. Figures 1a and 1b show the plot of Eq. 1 for nickel(II) malonate and nickel(II) tartronate, respectively, at various pressures. Good linearity was observed for the whole pressure range. From the slope and intercept of these plots, the values of K were determined and are summarized in Table 1.

The present value of K for nickel(II) malonate at 0.1 MPa is in good agreement with a value found in the literature[11] ($K=1.26\times10^4$ mol^{-1} dm^3 at 25 °C and $I\rightarrow0$). For nickel(II) tartronate, the available literature value[8] is $K=2.82\times10^3$ mol^{-1} dm^3 at 20 °C and $I=0.1$. From this value, the stability constant at zero ionic strength is estimated to be 18.5×10^3 mol^{-1} dm^3 by using activity coefficient calculated from the Davies equation[12] ($\gamma_\pm\simeq0.39$ for a divalent electrolyte at $I=0.1$). Considerable disagreement is seen between this value and the present result at 0.1 MPa, the origin of which is not known.

The pressure dependence of the stability constant provides for an evaluation of the reaction volume for the complex formation according to the relation[13]

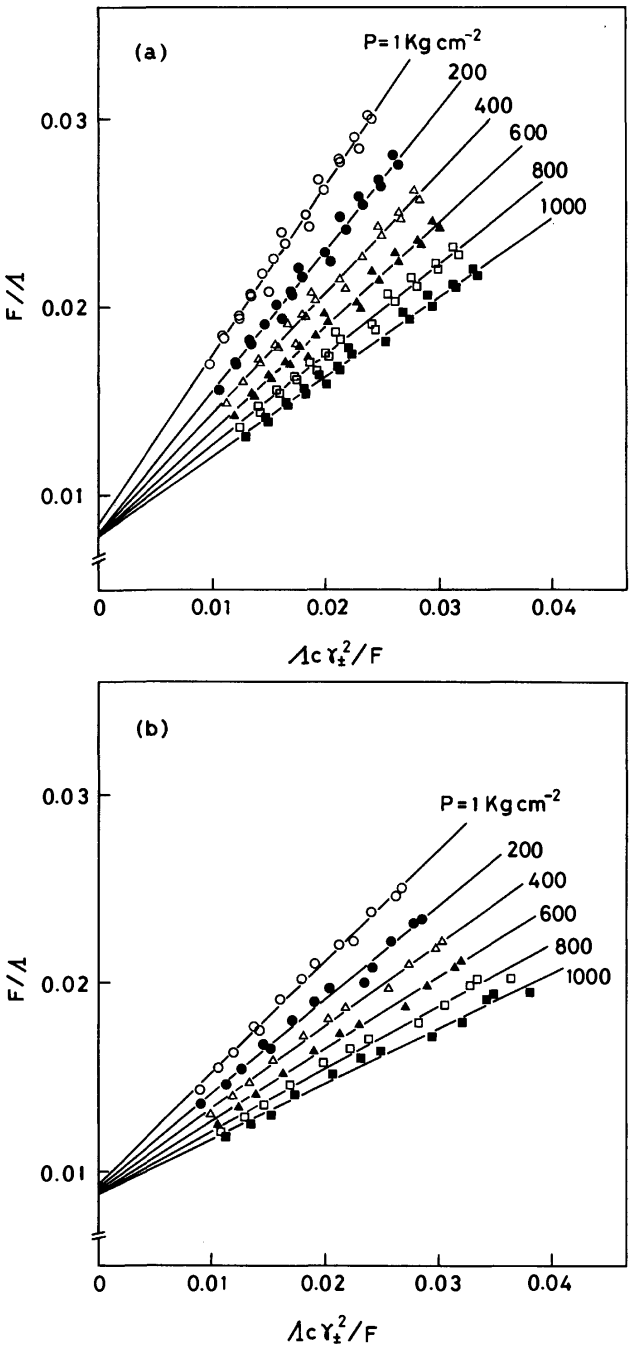

Fig. 1. Plot of conductivity data according to Eq. 1 for (a) nickel (II) malonate and (b) nickel (II) tartronate at 20 °C. Pressures are indicated in the figure.

Table 1. Stability Constants, K,[a] as a Function of Pressure at 20 °C and $I\rightarrow0$

	P/MPa					
	0.1	20	40	60	80	100

Nickel(II) tartronate	6.77 (0.42)	5.93 (0.46)	5.37 (0.32)	4.94 (0.31)	4.12 (0.32)	3.80 (0.31)

a) In 10^3 mol^{-1} dm^3. Standard deviations estimated from the least-squares analysis are given in parentheses.

$$RT\left(\frac{\partial \ln K}{\partial P}\right)_T = -\Delta V^0 - RT\kappa_0, \quad (2)$$

where ΔV^0 is the reaction volume, i.e., the change in the partial molar volume at infinite dilution accompanied by the complex formation from a nickel(II) ion and ligand, κ_0 represents the solution compressibility, and other symbols have their usual meanings. In Eq. 2, $-RT\kappa_0$ is the correction term for the compression required when the concentration is expressed in terms of molarity and has a value of 1.1 $cm^3 mol^{-1}$[13a] for the present case. A plot of log K against pressure is shown in Fig. 2a, and log K shows a linear pressure dependence over the studied pressure range. From the slope of a straight line fitted using a least-squares method, the reaction volumes for nickel(II) malonate and nickel(II) tartronate were estimated according to Eq. 2. They are listed in Table 4 together with those obtained for other dicarboxylate ligands.

The rate constants for the complex formation reaction were determined from the pressure-jump relaxation data. The observed relaxation process was characterized by a single relaxation time in the measured concentration range. A reciprocal relaxation time for the reaction of Scheme 1 is given by Eq. 3.[14]

$$1/\tau = k_f[\gamma_\pm^2(c_{Ni}+c_L) + 1/K], \quad (3)$$

where k_f is the rate constant of the complex formation at zero ionic strength, c_{Ni} and c_L are the equilibrium concentration of nickel(II) and ligand ions, and $\gamma_\pm$ is the mean activity coefficient of the free ions at a given ionic strength.

The values of k_f were determined from the relaxation time using Eq. 3, where c_{Ni}, c_L, and $\gamma_\pm$ were calculated from the stability constant by a previously described procedure.[4] Some examples of the obtained results are shown in Table 2. The dissociation rate constants of the complex, k_d, were determined from the relation

$$k_d = k_f/K \quad (4)$$

The values of the rate constants, thus obtained, at various pressures are summarized in Table 3.

The activation volume of the reaction was estimated from the pressure dependence of the rate constant based on a relation analogous to Eq. 2.[13] Figures 2b and 2c show plots of log k_f and log k_d against pressure. In the studied pressure range, a linear relationship was obtained between the logarithm of the rate constant and the pressure. From the slope of the straight line (fitted by a least-squares method), the values of the activation volume for the complex formation, ΔV_f^*, and dissociation, ΔV_d^*, were estimated, and are listed in Table 4.

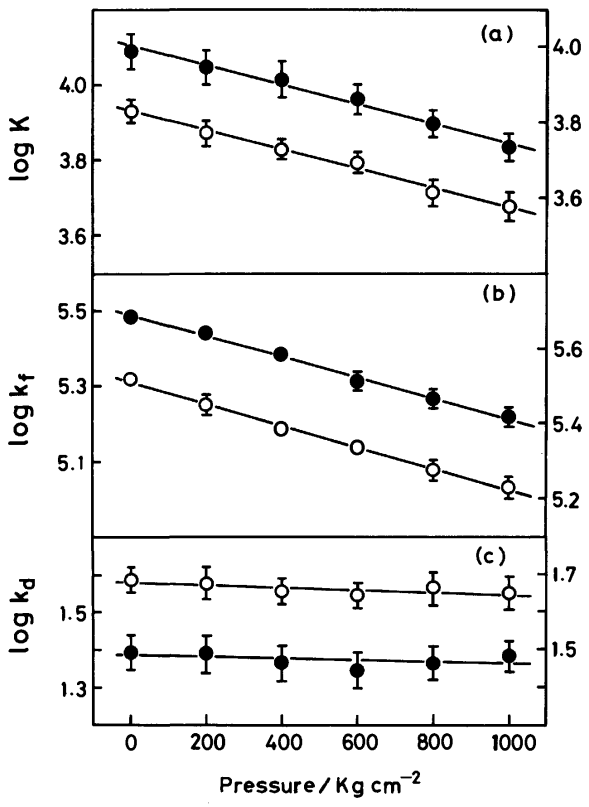

Fig. 2. Pressure dependence of (a) log K, (b) log k_f, and (c) log k_d at 20 °C: ●, nickel(II) malonate (left scale); ○, nickel(II) tartronate (right scale). Solid lines show the linear least-squares fits to the data points.

Discussion

It is considered that malonate ions form six-membered chelate complexes with nickel(II) ions in an aqueous solution, while succinate ions form monodentate complexes with nickel(II) ions rather than seven-membered chelate complexes. This may be justified from a comparison of the stability constant; the stability constant of nickel(II) succinate is much smaller than that of nickel(II) malonate. The glutarate ion and the adipate ion, which have longer methylene chains between two carboxyl groups, might also form a monodentate complexes. The difference in the structure of the complexes is reflected in the reaction volume. As can be seen in Table 4, succinate, glutarate, and adipate have similar values of ΔV^0 and are smaller than that for malonate.

The resultant volume change associated with the complex formation between metal ions and charged ligands may be divided into several contributions; i) the release of electrostriction due to the charge

neutralization, ii) the elimination of solvated water around the coordinating group accompanied by the coordination bond formation to produce free water, iii) the difference in coordination bond length between a metal-water bond and a metal-ligand bond, and iv) for a chelating ligand, the increase of free volume, which is too small to be occupied by the solvent molecule, resulting from the formation of ring structure. The contributions from i), ii), and iv) are positive for volume increase in the system, while the sign of the contribution from iii) may depend on

the nature of metal-ligand bond. Since all ligands listed in Table 4 have the same electrical charge (−2), it can be regarded that contribution i) is the same for all ligands. The smaller values of ΔV^0 for a monodentate complex than for a chelate complex may be reasonable considering contributions ii) and iv).

The value of ΔV^0 for nickel(II) tartronate is essentially the same as that for nickel(II) malonate (Table 4). Malonate ions form six-membered chelate complexes coordinated by two carboxyl oxygens. For a chelate complex formed from a tartronate ion, three different structures may be expected; a six-membered chelate coordinated by two carboxyl oxygens, a five-membered chelate coordinated by one carboxyl oxygen and one hydroxyl oxygen, or a tridentate chelate coordinated by two carboxyl oxygens and one hydroxyl oxygen. That the ΔV^0 value of nickel(II) tartronate is comparable to that of nickel(II) malonate suggests that tartronate forms a six-membered chelate complex using two carboxyl oxygens. If tartronate forms a chelate using one carboxyl and one hydroxyl group or a tridentate chelate using two carboxyl and one hydroxyl groups, then a different ΔV^0 value from malonate should be expected from the contributions ii)—iv) described above; in fact, the reaction volume of 17.8 cm^3 mol^{-1} was obtained for nickel(II) malate which forms a chelate complex coordinated by one carboxyl and one hydroxyl groups.[15]

The metal complexation reaction has been generally interpreted in terms of a stepwise mechanism which was postulated by Eigen and discussed further by Wilkins.[16] For the bidentate chelate complex (as in the present case), this mechanism is represented by Scheme 2. In this scheme, I is a free ion, II is an

$$\underset{\text{I}}{Ni(H_2O)_6^{2+} + L\text{-}L^{2-}} \overset{K_{os}}{\rightleftharpoons} \underset{\text{II}}{(H_2O)_5Ni(H_2O)L\text{-}L} \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} \underset{\text{III}}{(H_2O)_5Ni\text{-}L\text{-}L} + H_2O \overset{k_2}{\underset{k_{-2}}{\rightleftharpoons}} \underset{\text{IV}}{(H_2O)_4Ni\begin{pmatrix}L\\L\end{pmatrix}} + 2H_2O$$

Scheme 2.

outer-sphere complex, III is a monodentate complex with one end of the ligand left free, IV is a bidentate chelate complex, K_{os} is outer-sphere complex formation constant, and k's are the rate constants of the respective steps. Under the assumptions that I $\rightleftharpoons$ II is very rapid compared with other steps and that III is in a steady state, the overall rate constants are related to the rate constants of each step in Scheme 2 by the equations

$$k_f = K_{os}k_1\left(\frac{k_2}{k_2+k_{-1}}\right) \tag{5}$$

$$k_d = k_{-1}\left(\frac{k_{-2}}{k_2+k_{-1}}\right) \tag{6}$$

For the complex formation of nickel(II) malonate, the rate-determining step was assigned to the first-bond formation step (i.e., the formation of III) based on an analysis of the complexation rate constant.[17,18] This assignment is further supported from the present result that the activation volume ΔV_f^* for nickel(II) malonate is essentially the same as that for nickel(II) succinate for which the chelation process is lacking. This may also be the case for the complexation of nickel(II) tartronate, since ΔV_f^* is comparable to the other two ligands listed in Table 4. For a case in which the rate-determining step is the first-bond formation (i.e., $k_2 \gg k_{-1}$), Eqs. 5 and 6 are reduced to

$$k_f \simeq K_{os}k_1 \quad \text{and} \quad k_d \simeq k_{-1}/K_2, \tag{7}$$

where $K_2=k_2/k_{-2}$. Then, the overall activation volume can be approximately expressed by

$$\Delta V_f^* = \Delta V_{os}^0 + \Delta V_1^*, \tag{8}$$

$$\Delta V_d^* = \Delta V_{-1}^* - \Delta V_2^0, \tag{9}$$

where ΔV_{os}^0 and ΔV_2^0 are the reaction volumes for the outer-sphere complex formation and the chelate formation from monodentate intermediate, and ΔV_1^* and ΔV_{-1}^* are the activation volumes for the first bond formation and breaking.

The value of ΔV_{os}^0 is estimated to be approximately 7.2 cm^3 mol^{-1} for 2-2 electrolyte at 20 °C according to Hemmes[19] as mentioned in a previous paper.[4] Then, the values of ΔV_1^* can be estimated from Eq. 8 as follows; $\Delta V_1^*=7.5\pm0.5$ cm^3 mol^{-1} for nickel(II) malonate and 8.0 ± 0.5 cm^3 mol^{-1} for nickel(II) tartronate. These values show a close resemblance to the activation volume of the water exchange of the aquanickel(II) ion, $\Delta V_{H_2O}^*=7.2\pm0.3$ cm^3 mol^{-1}, obtained from a high-pressure NMR study.[20] This result suggests that the activated state for the first-bond formation process is the same as that for the water exchange process, where the bond between nickel(II) and leaving water molecule is loosened and somewhat lengthened.

The volume profile diagrams obtained for the complexation reaction of nickel(II) malonate and nickel(II) tartronate are shown in Fig. 3. The value of ΔV_1^0, which represents the volume difference between II and III, was estimated to be 4.3 cm^3 mol^{-1} from ΔV^0 and ΔV_{os}^0 for nickel(II) succinate.[4] This estimation is based on the facts that ΔV_1^0 corresponds to the volume change associated with the coordina-

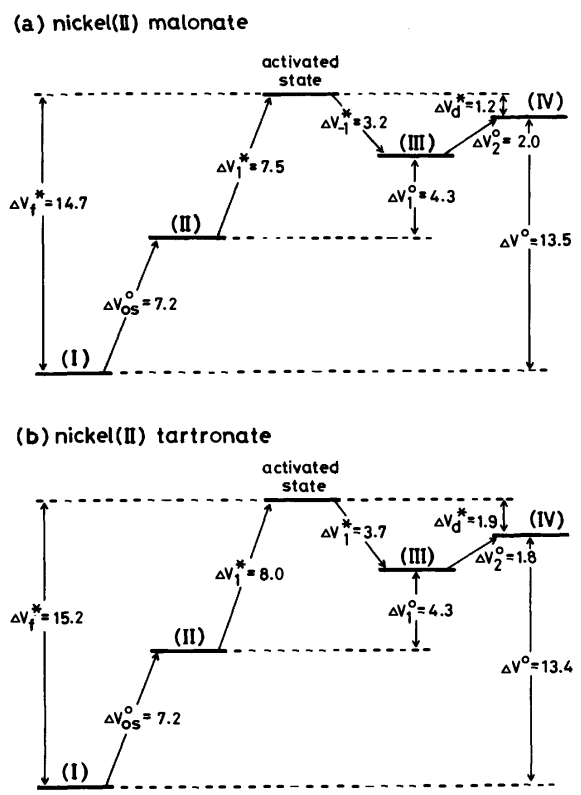

Fig. 3. Volume profile diagrams for the complex-formation reaction of nickel(II) malonate (a) and nickel(II) tartronate (b). I, II, III, and IV correspond to the species in Scheme 2. The values of volume change in $cm^3\ mol^{-1}$ are shown in the figure.

tion-bond formation by a carboxyl group after an outer-sphere complex forms, and nickel(II) succinate forms a monodentate complex coordinated by a single carboxyl group. An initial volume increase occurs due to the release of electrostriction upon forming the outer-sphere complex(II). It is followed by a volume increase due to the loosening of water-nickel(II) bonds to reach an activated state. Then, a volume decrease occurs upon going from the activated state to the monodentate complex(III) due to the completion of the coordination bond. It is again followed by a volume increase due to another coordination-bond formation to form a final chelate complex(IV). The positive ΔV_1^0 and ΔV_2^0 may be ascribed to the elimination of solvated water around the coordinating group due to the bond formation, which produces the free water and the resulting volume increase.

Features of the volume profiles for nickel(II) malonate and nickel(II) tartronate resemble each other. It is inferred from this result that the hydroxyl group on an α-carbon present in a tartronate ion has no significant role regarding both the mechanism of the complexation reaction and the final structure of the complex.

Effect of Electrochemical Pretreatment on Catalytic Activity of Bismuth Ruthenate Electrodes for Oxygen Evolution in Alkaline Solution

Chiaki IWAKURA,* Toshiyuki EDAMOTO, and Hideo TAMURA
Department of Applied Chemistry, Faculty of Engineering, Osaka University,
Yamadaoka, Suita, Osaka 565
(Received August 28, 1985)

The catalytic activity of a film-type bismuth ruthenate electrode for oxygen evolution was greatly enhanced by the electrochemical pretreatment, including potential holding and cycling. On the other hand, any appreciable enhancement in catalytic activity was not observed for a pellet-type bismuth ruthenate electrode. Such an pretreatment effect was explained on the basis of the participation of higher valence Ru species in the oxygen evolution reaction, rather than the increase of surface area.

Metallic oxides with the pyrochlore structure such as bismuth and lead ruthenates ($Bi_2Ru_2O_7$, $Pb_2Ru_2O_{7-y}$) have been of increasing interest as electrode materials in recent years. Carcia et al.[1] have first reported that bismuth ruthenate thin film electrodes, prepared by rf sputtering directly onto heated Ti substrates, showed high activity for chlorine evolution. On the other hand, Horowitz et al.[2] have lately reported that in alkaline electrolyte bismuth and lead ruthenates, prepared mainly by the alkaline solution synthesis technique, displayed significantly lower polarizations than any other catalyst for oxygen evolution and were among the best for oxygen reduction. The oxygen reduction on bismuth and lead ruthenates, prepared by conventional solid state synthesis technique, has also been reported by Egdell et al.[3]

In the course of the studies on DSA-type metal oxide electrodes for oxygen evolution, we noticed that bismuth ruthenate film electrodes showed high catalytic activity for the reaction when they were pretreated electrochemically. The pretreatment included the potential holding and cycling. To date, the electrocatalytic activation of noble metal electrodes for oxygen and chlorine evolution reactions by potential cycling has been studied rather extensively.[4–10] However, many different interpretations have been proposed for the cause of the activity enhancement. The arguments seem to be principally divided into two groups: (1) Apparent activity enhancement by the increase in surface area and (2) intrinsic activity enhancement by the surface modification. This paper describes the work on the effect of electrochemical pretreatment on catalytic activity of bismuth ruthenate electrodes for oxygen evolution in alkaline solution, supporting the second view rather than the first view.

Experimental

Film- and pellet-types of bismuth ruthenate electrodes were used in this work. The film-type electrode ($Pt/Bi_2Ru_2O_7$) was prepared by a thermal decomposition method in the following way. First, a Pt substrate (2.5_4 cm^2) was mechanically polished with emery papers (≈#2000) and then degreased with a boiling 1 mol dm^{-3} KOH aqueous solution. Next, 0.05 cm^3 of (0.05 mol dm^{-3} $BiCl_3$ and 0.05 mol dm^{-3} $RuCl_3$)-containing 20 wt% HCl aqueous solution was applied to one side of the cleaned Pt substrate, dried at temperatures below 100 °C and then heated at 700 °C in air for 10 min. Such operations were repeated for 5 times. Finally, the resulting sample was heated at 700 °C for 1 h to decompose completely. On the other hand, the pellet-type electrode ($Bi_2Ru_2O_7$) was prepared by a coprecipitation method in the following way. First, the above mixed solutions of $BiCl_3$ and $RuCl_3$ were hydrolyzed by adding concentrated ammonia water. The resulting coprecipitate was washed thoroughly with distilled water and then dried at temperatures below 100 °C. Next, the dried sample was heated at 700 °C in air for 10 min, followed by grinding to powder with an agate mortar and a pestle. After such operations were repeated for 5 times, the powder was heated at 700 °C for 12 h. Finally, the heat-treated powder was mixed with 15 wt% of a binder (mp ca. 283 °C) and then pressed at 6000 kg cm^{-2} to form a pellet (1.3_3 cmϕ, ca. 0.05 mm thick). The pellet was heated at 240 °C and water-proofed by immersing in 10 wt% polystyrene-containing benzene solution. The X-ray diffraction patterns of the surface oxides of the electrodes thus obtained correspond to the formula $Bi_2Ru_2O_{7.3}$ as indicated in the ASTM card, however, the bismuth ruthenate electrodes will be represented by $Pt/Bi_2Ru_2O_7$ or $Bi_2Ru_2O_7$ in this paper because the oxygen content is still uncertain.

All electrochemical measurements, including cyclic voltammetry and polarization measurements, were carried out at 30 °C in 1 mol dm^{-3} KOH aqueous solution unless otherwise stated. The counter electrode used was a Pt plate with large surface area. A mercury (II) oxide electrode (Hg/HgO, 1 mol dm^{-3} KOH) was mainly used as the reference electrode.

The other experimental procedures and conditions will be described in the next section.

Results and Discussion

The film-type $Pt/Bi_2Ru_2O_7$ electrode was previously anodized at a constant potential (typically 0.7 V vs. Hg/HgO) for several tens minutes (typically 40 min). For each 10 min, the potential was cycled twice in the region between 0 and 0.7 V vs. Hg/HgO with a sweep rate of 0.1 V s^{-1} in order to check the catalytic

activity. However, the potential cycling should also be regarded as a part of the pretreatment because the pretreatment effect described later was not observed in the absence of the succeeding potential cycling (see Fig. 6) and because the same effect was observed when the potential cycling was continued for much longer time (say 50 min) without the preceding constant-potential anodization.

Typical cyclic voltammograms of the $Pt/Bi_2Ru_2O_7$ electrodes with and without pretreatment are shown in Fig. 1. It is evident that the current, or the catalytic activity, for oxygen evolution is appreciably enhanced by the pretreatment. Such a current enhancement phenomenon is not explicable by the change of surface area alone, because the surface area of the pretreated electrode was found to be only about 1.3 times that of the non-pretreated electrode as the result of the surface area determination both by Zn^{2+} ion adsorption method[11] and by cyclic voltammetry[12] and because the current enhancement was observed in alkaline solutions with relatively high pH values but scarcely in acidic solutions; for example, the electrode pretreated in 1 mol dm^{-3} KOH did not reveal any enhanced activity for oxygen evolution in 0.5 mol dm^{-3} H_2SO_4.

It can also be seen from Fig. 1 that the redox peaks at around 0.4 V vs. Hg/HgO become more conspicuous after pretreatment. The redox peaks may be attributable to either Ru^{4+}/Ru^{5+} or Ru^{4+}/Ru^{6+} as reported for the $Bi_2Ru_2O_7$[3] and $Ti/(RuO_2+TiO_2)$[13] electrodes, respectively, in alkaline solutions. The current enhancement factor, which was defined as the current density at a given potential (0.7 V vs. Hg/HgO) after pretreatment divided by the current density at the same potential before pretreatment, increased as the preanodization potential increased beyond ca. 0.4 V vs. Hg/HgO where the redox peaks appeared (see Fig. 1). Furthermore, a positive correlation was observed between the current enhancement factor and the charge passed in the redox peaks. These facts suggest the important role of the mixed valence Ru species in the pretreatment effect, in agreement with the view reported for the other kinds of electrodes.[4,7,8,10]

The film-type electrodes having different oxide compositions were prepared by changing the mole ratio of $BiCl_3$ to $RuCl_3$ while the total amount of them was kept constant at 1×10^{-5} mol cm^{-2}, and their catalytic activities for oxygen evolution were measured. Figure 2 shows the plots of current density at 0.7 V vs. Hg/HgO against Bi content in the oxide layer for the $Pt/Bi_xRu_{1-x}O_y$ ($0\leqslant x\leqslant 1$) electrodes with

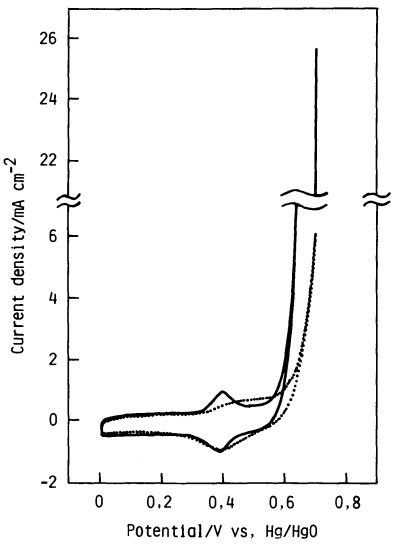

Fig. 1. Cyclic voltammograms of the film-type $Pt/Bi_2Ru_2O_7$ electrodes with (solid line) and without (dotted line) pretreatment, measured in 1 mol dm^{-3} KOH (sweep rate = 100 mV s^{-1}).

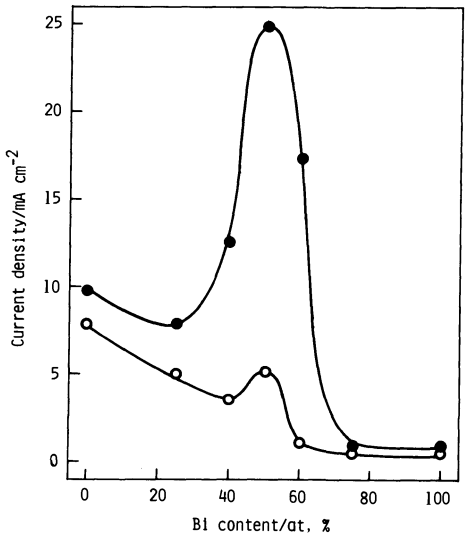

Fig. 2. Plot of current density at 0.7V vs. Hg/HgO against Bi content for the film-type $Pt/Bi_xRu_{1-x}O_y$ ($0\leqslant x\leqslant 1$) electrodes with (closed circle) and without (open circle) pretreatment.

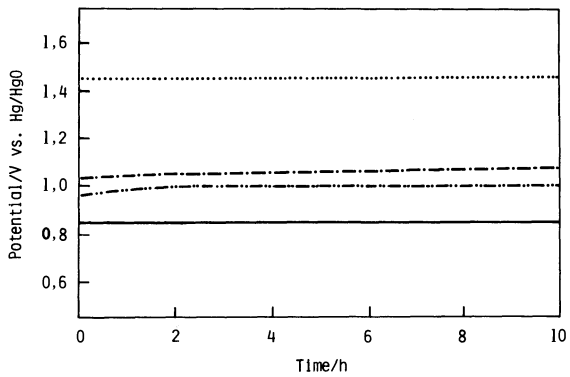

Fig. 3. Potential-time curves of the film-type $Pt/Bi_2Ru_2O_7$ and related electrodes under constant-current (0.1 A cm^{-2}) polarization in 1 mol dm^{-3} KOH. .....: Pt, —·—: $Pt/Bi_2Ru_2O_7$, —··—: Pt/RuO_2, ——: pretreated $Pt/Bi_2Ru_2O_7$.

and without pretreatment. The current for oxygen evolution has a maximum value at the oxide composition corresponding to $Bi_2Ru_2O_7$. It is to be noted that the catalytic activity for oxygen evolution of the $Pt/Bi_2Ru_2O_7$ electrode is rather low before pretreatment but is quite high after pretreatment, compared with that of the Pt/RuO_2 electrode. The superiority of the pretreated $Pt/Bi_2Ru_2O_7$ electrode over the Pt/RuO_2 electrode as well as the non-pretreated $Pt/Bi_2Ru_2O_7$ electrode in catalytic activity for oxygen evolution was confirmed by constant-current polarization measurements, as shown in Fig. 3 (see also Fig. 4). These findings suggest the special participation of Bi species in the pretreatment effect.

In contrast to the film-type $Pt/Bi_2Ru_2O_7$ electrode mentioned above, the pellet-type $Bi_2Ru_2O_7$ electrode showed no detectable pretreatment effect. Furthermore, the apparent redox peaks were observed on the cyclic voltammograms for the $Bi_2Ru_2O_7$ electrode even in the absence of pretreatment. Figure 4 shows galvanostatic polarization curves of the pellet-type electrodes together with the film-type electrodes. The pellet-type $Bi_2Ru_2O_7$ electrode exhibits the relatively high catalytic activity for oxygen evolution though it shows a steep rise in potential at high current densities, probably because of its low electrical conductivity. These observations are explained on the basis of the assumption that some Ru species exist in higher valence state on the surface of the as-prepared $Bi_2Ru_2O_7$ electrode, as well as the pretreated $Pt/Bi_2Ru_2O_7$ electrode.

The X-ray photoelectron spectroscopic (XPS) measurements were performed to get support for the above assumption. Figure 5 shows some XPS data obtained with the $Pt/Bi_2Ru_2O_7$ and $Bi_2Ru_2O_7$ electrodes. Evidently, the additional Bi peaks observed for the non-pretreated $Pt/Bi_2Ru_2O_7$ electrode in higher binding energies disappear in the case of the pretreated $Pt/Bi_2Ru_2O_7$ electrode, suggesting a valency change of Bi species in part from higher to lower oxidation states. Moreover, the Bi spectra of the pretreated $Pt/Bi_2Ru_2O_7$ electrode are similar to those observed for the $Bi_2Ru_2O_7$ electrode. On the other hand, the Ru spectra except for Ru $3d_{5/2}$ were unfortunately ambiguous for every electrode, due to the contamination by C 1s electron line at 285.0 eV. Though the further detail measurements are necessary, it appears more likely from the information obtained that the pretreatment effect is attributed to the formation of higher valence Ru species and the coexistence of Bi species may contribute to maintain the Ru species in higher valence state.

In order to prove the above view, the pretreatment effect was further examined with the other film-type electrodes ($Pt/Bi_{2-x}Co_xRu_2O_{7-y}$) prepared by partial substitution of Co^{2+} for Bi^{3+}.[14] As a result, the catalytic activity for oxygen evolution of these electrodes was found to be essentially high even before pretreatment and to increase with increasing Co content. The variation of current enhancement factor with preanodization time for the $Pt/Bi_{2-x}Co_xRu_{7-y}$ ($0 \leqslant x \leqslant 0.5$) electrodes is shown in Fig. 6. As expected, the current enhancement factor decreases with an increase in Co content. This can be explained by taking into account the valence change of Ru species by replacing Bi^{3+} with Co^{2+}, in addition to little contribution of Co oxide itself to the increased catalytic activity for oxygen evolution.

The mechanistic analysis was briefly done for the oxygen evolution reaction on the pretreated $Pt/Bi_2Ru_2O_7$ electrode and, as the result, the kinetics were found to be characterized by a Tafel slope of 0.042 V dec^{-1} and a reaction order with respect to OH^- ion of 1.12. It can therefore be presumed that the reaction mechanism as well as the rate-determining step is identical to that proposed for the

The broken line with triangles repersents a current enhancement factor vs. time curve for the $Pt/Bi_2Ru_2O_7$ electrode under constant-potential (0.7V vs.Hg/HgO) polarization.
The current enhancement factors are normalized to the values at a preanodization time of 0 min.

Ti/RuO_2 electrode,[15] in which the valence change of Ru species is virtually involved. According to such a mechanism, it is reasonable to expect that higher valence Ru species should cause modification of electron transfer rates and probably of adsorption of intermediates.

The authors wish to express their thanks to Toyo Soda Manufacturing Co, Ltd. for a financial support in a part of this work.

The Axial-Ligand Replacement of the [Tetrakis(1-methyl-4-pyridinio)-porphine]iron(III) Ion by the Cyanide Ion in a Highly Alkaline Aqueous Solution

Fumihiro ARIFUKU,* Kikujiro UJIMOTO, and Hirondo KURIHARA
Department of Chemistry, Faculty of Science, Fukuoka University,
Nanakuma, Jonan-ku, Fukuoka 814-01
(Received April 18, 1985)

The axial-ligand replacement of the [Tetrakis(1-methyl-4-pyridinio)porphine]iron(III) ion by the cyanide ion was investigated in a highly alkaline aqueous solution by means of the spectrophotometric method at 25 °C. In the course of the replacement, a protolytic equilibrium between monocyanomonoaqua- and monocyanomonohydroxo complex ions was observed; the p(K_a/mol dm^{-3}) value of the monocyanomonoaqua complex ion was found to be 12.2±1.1. In the formation of the dicyano complex ion, the rate-determining step was the second replacement of axial ligands, i.e., from the monocyano complex ion to the dicyano-complex ion; according as the pH is 11 or 13, the equilibrium constant was found to be 38.0 mol^{-1} dm^3 or 11.0, while the rate constant was 1.07×10^{-3} or 4.23×10^{-3} mol^{-3} dm^3 s^{-1}.

Iron porphyrin complexes are regarded as model compounds for studying the redox properties in the respiratory-electron-transport chain, which contains such elements as cytochromes.[1,2] In order to clarify the basic properties of iron porphyrins, we have been investigating the equilibrium situation and properties of the [Tetrakis(1-methyl-4-pyridinio)porphine]-iron(III) ion (abbreviated as Fe(III)-TMPyP) in aqueous solutions.[3] As a result of the investigation, it has been found that monomeric Fe(III)-TMPyP-$(H_2O)_2$, Fe(III)-TMPyP(OH)(H_2O), and Fe(III)-TMPyP$(OH)_2$ are, in turn, the predominant species in the solutions with pH values of pH<5.5, 5.5<pH<12 and pH>12 respectively; it has also been found that monomeric Fe(II)-TMPyP$(H_2O)_2$ and Fe(II)-TMPyP(OH)(H_2O) are predominant in the ranges of pH<11.5 and pH>11.5 respectively.

As subsequent experiments, we intended to investigate the effects of axial ligands on the redox potential. The cyanide ion was chosen as an axial ligand to investigate at first, because the preliminary experiments on the axial-ligand replacement of aqua- or hydroxo-Fe(III)-TMPyP ion by various ligands showed that only the addition of the cyanide ion induced shifts both in the position of the Soret band and in the redox potential of the central metal (Fe(III)/Fe(II)).

The substitution equilibria for various axial ligands of Fe(III)-TMPyP ions have previously been reported by Fleischer et al.,[4,5] Pasternack et al.,[6,7] Goff and Morgan,[8,9] and Weinraup et al.[10] However, for a monocyano Fe(III)-TMPyP ion in an aqueous solution, the kind of axial ligand at the trans position to CN^- can not be inferred from the descriptions in those papers or also in the paper relating to the axial-ligand replacement of Cr(III)-TMPyP by CN^-.[11]

The main purpose of the present paper is to infer the axial ligand at the trans position to the cyano group in the monocyano Fe(III)-TMPyP ion in an aqueous solution and to determine the equilibrium constant in the protolytic equilibrium between different monocyano ions and kinetic parameters for the axial replacement of the Fe(III)-TMPyP ion by the cyanide ion.

Experimental

Fe(III)-TMPyP perchlorate was prepared by metal insertion into TMPyP tetra(*p*-toluenesulfonate) (Dojindo Laboratories) with Mohr's salt according to the method of Hambright and Fleischer,[12] with a slight modification, and was stored in an about 3.5×10^{-4} mol dm^{-3} aqueous solution. All the other chemicals were of a guaranteed reagent grade (Wako Pure Chemical Industries) and were used without further purification.

The concentration of the Fe(III)-TMPyP stok solution was accurately determined spectrophotometrically by the use of a molar-absorption coefficient at 403 nm: 1.02×10^5 mol^{-1} dm^3 cm^{-1} at pH 2 and an ionic strength of 0.1 mol dm^{-3}.[6] Sample solutions were prepared by diluting the stock solution with deionized distilled water. The pH of the sample solution was then adjusted with a sodium hydroxide solution. The ionic strength was adjusted to 0.1 mol dm^{-3} with a sodium sulfate solution except when the pH was above 13.

A Hitachi 228 spectrophotometer was used for the spectrophotometric investigation. Measurements of the pH were made on a TOA HM-5B pH meter. The concentrations of the cyanide ion are expressed by the values calculated from the weight of the potassium cyanide dissolved.

The equilibrium constant and the number of protons transferred between the different monocyano complexes were obtained by spectrophotometric pH titration at a constant pCN; on the contrary, the formation constant and the number of cyanide ions transferred between monocyano and dicyano complexes were obtained by pCN titration at a constant pH.

The rate of cyano substitution was measured as follows. A small volume of a 1.00 mol dm^{-3} KCN aqueous solution, adjusted to the appropriate pH, was added quickly to a dilute Fe(III)-TMPyP aqueous solution adjusted to the

same pH as the KCN solution. The resulting mixed solution, which included a large excess of cyanide ions to Fe(III)-TMPyP, was stirred vigorously. Then, the time-course of the absorbance at the Soret peak of the dicyano complex in the mixed solution was followed on the spectrophotometer.

All the measurements were performed at 25 °C.

Results and Discussion

Time-Course of Absorption Spectra after the Addition of CN^-. Fe(III)-TMPyP species in aqueous solutions are predominantly present as a monoaquamonohydroxo complex at pH 11 and as a dihydroxo complex at pH 13.[3] A solution of potassium cyanide was added to a Fe(III)-TMPyP solution of pH 11 or 13. Figure 1 shows the time-course of the visible spectra of the Fe(III)-TMPyP solutions after the addition of KCN. The dotted lines represent the spectra of CN^--free solutions; the other lines are the spectra of the mixed solutions containing Fe(III)-TMPyP and KCN at concentrations of 1.00×10^{-5} mol dm^{-3} and 5.00×10^{-2} mol dm^{-3} respectively. At both pH 11 and 13, the Soret band shows the characteristic maximum absorption peaks for the species formed by the 1st or 2nd substitution by

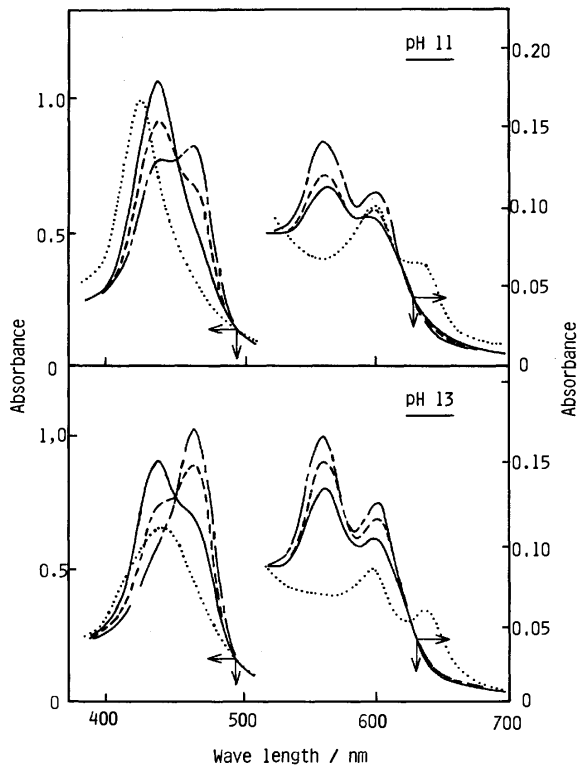

Fig. 1. The time-course of absorption spectra of Fe(III)-TMPyP aqueous solutions after addition of cyanide ion.
·····: No addition, ——: 2 min, — —: 30 min, — — —: 4 h 10 min (pH 11) or 2 h (pH 13).
Fe(III)-TMPyP: 1.00×10^{-5} mol dm^{-3}, KCN: 5.00×10^{-2} mol dm^{-3}.

CN^-. On the other hand, the Q (0—0 and 0—1) band shows the blue shift by ca. 20 nm due to the 1st substitution by CN^-, while, because of the 2nd substitution by CN^-, no shift, but an increase in the Q band, was observed. These spectral changes may be attributable to the following step-by-step substitution reactions, Eq. 1 or 2, at pH 11 or 13:

$$\underset{\text{(I)}}{\text{Fe(III)-TMPyP(H}_2\text{O)(OH)}} \rightleftharpoons \underset{\text{(II)}}{\text{Fe(III)-TMPyP(H}_2\text{O)}_2} \rightleftharpoons \underset{\text{(III)}}{\text{Fe(III)-TMPyP(CN)}_2}, \quad (1)$$

$$\underset{\text{(I')}}{\text{Fe(III)-TMPyP(OH)}_2} \rightleftharpoons \underset{\text{(II')}}{\text{Fe(III)-TMPyP(OH)(CN)}} \rightleftharpoons \underset{\text{(III)}}{\text{Fe(III)-TMPyP(CN)}_2}. \quad (2)$$

As may be seen in Fig. 1, the monocyano complexes, II and II', both have Soret bands with the same maximum absorption wavelength, 437 nm, and their Q band spectra are similar in shape.

The 2nd substitution is much slower than the 1st substitution. An electron-withdrawing property of CN^-, caused by back-donation to its empty antibonding π-orbital, probably makes the 2nd substitution slow down compared to the 1st step. Within two minutes after the addition of CN^-, the 1st step of substitution is almost complete, while the 2nd step seems to have proceeded slightly, as is shown in Fig. 1.

At pH 13, the absorption band of 437 nm (the Soret band of II') was scarcely observed after two hours, while at pH 11 the peak of 437 nm remained distinctly even after four hours. Such observation indicates that the 2nd step of substitution at pH 13 is faster than that at pH 11, even though the concentration of hydroxide ions in the pH 13 solution is about 100 times that in the pH 11 solution. If the II species is the same as II', the rate of the 2nd substitution step at pH 11 should be faster than that at pH 13. Therefore, in spite of the similarity in shape of the two absorption spectra, the II species differs from the II' species; they are identified as Fe(III)-TMPyP(H_2O)(CN) and Fe(III)-TMPyP(OH)(CN) respectively.

Acid-Dissociation Equilibrium of Fe(III)-TMPyP-(H_2O)(CN). Figure 2 shows the spectrophotometric pCN titration curves of Fe(III)-TMPyP obtained at the Soret-band maximum of the III species, 465 nm. A change in absorption attributable to an equilibrium between monocyano and dicyano complexes is observed in the pCN range from 1 to 3, and in the pCN range above 4 the absorption is gradually reduced with an increase in the value of pCN because of a dissociation equilibrium of

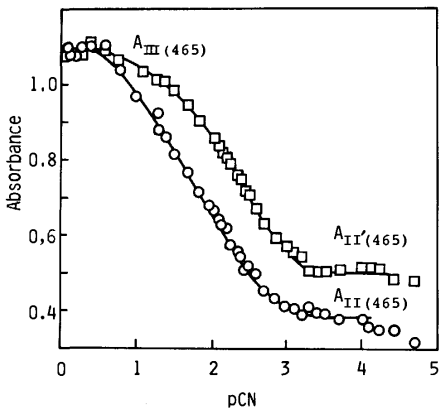

Fig. 2. Spectrophotometric pCN titration curves for Fe(III)-TMPyP in aqueous solutions at pH 11 (○) and 13 (□).
$A_{II(465)}$: Absorbance of monocyano complex at pH 11.
$A_{II'(465)}$: Absorbance of monocyano complex at pH 13.

KCN: 3.00×10^{-4} mol dm^{-3}.

the two monocyano complexes. In this figure, $A_{III(465)}$ represents the absorbance at a high concentration of CN^-, while $A_{II(465)}$ and $A_{II'(465)}$ represent the absorbances at pH 11 and 13 respectively at a low concentration of CN^-, i.e., $3<pCN<4$. Although the average values of $A_{III(465)}$ obtained separately at pH 11 and 13 virtually agreed with each other, the values of $A_{II(465)}$ and $A_{II'(465)}$ differ from one another, suggesting a change in the monocyano complex species with the pH.

Therefore, a spectrophotometric pH titration of complex solutions of pCN 3.52 was carried out over the pH range from 10.5 to 13.5 at 437 nm, which was the Soret maximum wavelength of the II and II′ species. The monocyano complexes are the predominant species in solutions with this pCN value, as is shown in Fig. 2. Figure 3 shows the titration curve thus obtained, indicating the existence of the following equilibrium between the II and II′ species:

$$\underset{(II)}{Fe(III)\text{-}TMPyP(H_2O)(CN)} \overset{K_a}{\rightleftharpoons} \underset{(II')}{Fe(III)\text{-}TMPyP(OH)(CN)} + nH^+ \quad (3)$$

$$K_a = \frac{[II'][H^+]^n}{[II]} \quad (4)$$

The value of pK_a was obtained from the data in Fig. 3 using Eq. 5:

$$\log \frac{|A_{II(437)} - A_{(437)}|}{|A_{(437)} - A_{II'(437)}|} = n\cdot pH - pK_a \quad (5)$$

A plot of the left-hand side of Eq. 5 vs. pH gives a straight line, as is shown in Fig. 4. The values of $p(K_a/\text{mol dm}^{-3})$† and n were estimated to be 12.2±1.1 and 1.02±0.09 from the slope and the intercept respectively of this straight line. Since the n value is close to unity, the equilibrium between Fe(III)-TMPyP(H_2O)(CN) and Fe(III)-TMPyP(OH)(CN) consists of one proton-transfer step. The molar absorption coefficients of the II, II′, and III species at 437 and 465 nm were also obtained from the data in Figs. 2 and 3; they are listed in Table 1.

Formation Constant of Fe(III)-TMPyP(CN)$_2$. Figure 1 indicates that the first step of CN^- substitution is rapid enough and that the second step is the rate-determining step in the presence of a large excess of CN^- to the complex. Therefore, the concentrations of the I and I′ species can be ignored except for an extremely early stage of substitution. Then, the reactions observed at pH 11 and 13 are approximately represented by:

$$II + CN^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} III \quad (6)$$

and:

$$II' + CN^- \underset{k'_b}{\overset{k'_f}{\rightleftharpoons}} III + OH^- \quad (7)$$

Table 1. Molar-Absorption Coefficients at 437 and 465 nm of Monocyano and Dicyano Complexes at pH 11 and 13

Wavelength	437 nm	465 nm
pH 11		
ε_{II}/mol^{-1} dm^3 cm^{-1}	1.15×10^5	3.87×10^4
ε_{III}/mol^{-1} dm^3 cm^{-1}	—	1.10×10^5
pH 13		
$\varepsilon_{II'}$/mol^{-1} dm^3 cm^{-1}	8.30×10^4	5.06×10^4
ε_{III}/mol^{-1} dm^3 cm^{-1}	—	1.09×10^5

† K_a is the equilibrium constant in terms of concentration.

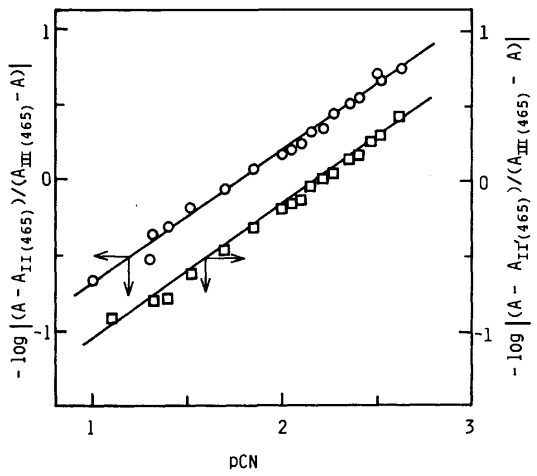

Fig. 5. Plots of left-hand sides of Eqs. 10 (○) and (11) (□) vs. pCN.

respectively, where k_f and k_f' are the formation rate constants of the III species and where k_b and k_b' are the rate constants of the reverse reactions. The values of the 2nd step-by-step formation constants of the III species at pH 11 and 13, as expressed by Eqs. 8 and 9, can be determined from the data in Fig. 2 and the molar absorption coefficient of the II and II′ species, by the use of Eqs. 10 and 11:

$$K = \frac{[\mathrm{III}]}{[\mathrm{II}][\mathrm{CN^-}]} = \frac{k_f}{k_b}, \tag{8}$$

$$K' = \frac{[\mathrm{III}][\mathrm{OH^-}]}{[\mathrm{II'}][\mathrm{CN^-}]} = \frac{k_f'}{k_b'}, \tag{9}$$

$$-\log\frac{|A_{(465)} - A_{\mathrm{II}(465)}|}{|A_{\mathrm{III}(465)} - A_{(465)}|} = pK + \mathrm{pCN}, \tag{10}$$

$$-\log\frac{|A_{(465)} - A_{\mathrm{II'}(465)}|}{|A_{\mathrm{III}(465)} - A_{(465)}|} = pK' + \log[\mathrm{OH^-}] + \mathrm{pCN}. \tag{11}$$

Figure 5 shows the linear relationship between the left-hand side of Eq. 10 or 11 and pCN. The transfer number of CN^- and the values of pK and pK' were obtained from the slope and the intercept at pCN=0 of these lines; they are listed in Table 2. The number of transferred CN^- at pH 11 is considerably smaller than unity.

Table 2. Equilibrium Constants and Number of Transfered Cyanide Ions between Monocyano and Dicyano Complexes at pH 11 and 13

	K/mol^{-1} dm^3	K'	n
pH 11	38.0	—	0.884
pH 13	—	11.0	0.919

Formation Rate Constant of the Dicyano Complex. Assuming Eq. 6 or 7 for the observed substitution, the formation rate or the III species is represented by:

$$\frac{d[\mathrm{III}]}{dt} = k_f[\mathrm{P}][\mathrm{CN^-}] - k_f\left([\mathrm{CN^-}] + \frac{1}{K}\right)[\mathrm{III}] \tag{12}$$

or:

$$\frac{d[\mathrm{III}]}{dt} = k_f'[\mathrm{P}][\mathrm{CN^-}] - k_f'\left([\mathrm{CN^-}] + \frac{[\mathrm{OH^-}]}{K'}\right)[\mathrm{III}], \tag{13}$$

where [P] is the total concentration of the complex species. In the presence of a large excess of CN^- to the complex species, therefore, the rate equation for substitution is expressed by Eq. 14 or 15 according as the pH value is 11 or 13:

$$\ln\left(\alpha - \frac{[\mathrm{III}]}{[\mathrm{P}]}\right) = \ln\alpha - k_f\beta t, \tag{14}$$

$$\ln\left(\alpha' - \frac{[\mathrm{III}]}{[\mathrm{P}]}\right) = \ln\alpha' - k_f'\beta' t, \tag{15}$$

where $\alpha = 1/(1+1/K[\mathrm{CN^-}])$, $\alpha' = 1/(1+[\mathrm{OH^-}]/K'[\mathrm{CN^-}])$, $\beta = 1/K + [\mathrm{CN^-}]$ and $\beta' = [\mathrm{OH^-}]/K' + [\mathrm{CN^-}]$.

If the formation constant of the III species and the molar-absorption coefficient of the monocyano and dicyano complexes are known, the concentration of the III species can be obtained from the observed absorbance at an appropriate wavelength using Eq. 16 or 17 according as the pH value is 11 or 13:

$$[\mathrm{III}] = \frac{\mathrm{Abs}}{\varepsilon_{\mathrm{II}}/K[\mathrm{CN^-}] + \varepsilon_{\mathrm{III}}} \tag{16}$$

or:

$$[\mathrm{III}] = \frac{\mathrm{Abs}}{\varepsilon_{\mathrm{II'}}[\mathrm{OH^-}]/K'[\mathrm{CN^-}] + \varepsilon_{\mathrm{III}}}, \tag{17}$$

where Abs is the absorbance at a certain wavelength and where $\varepsilon_{\mathrm{II}}$, $\varepsilon_{\mathrm{II'}}$, and $\varepsilon_{\mathrm{III}}$ are the respective molar-absorption coefficients of the II, II′ and III species at the same wavelength. Consequently, the rate constants, k_f and k_f' can be obtained by the use of Eqs.

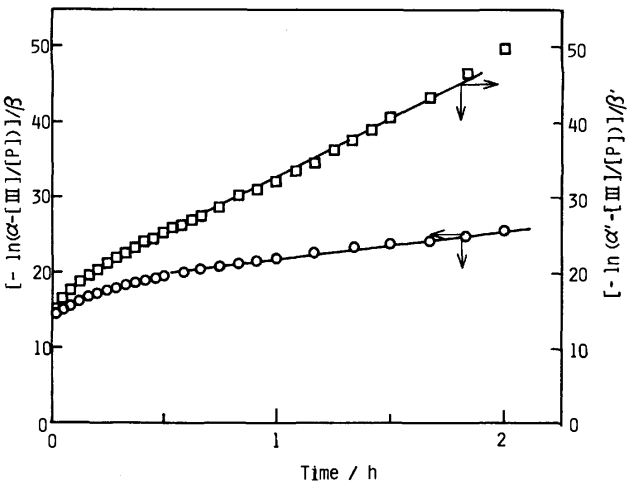

Fig. 6. Plots of $[-\ln(\alpha-[III]/[P])]/\beta$ vs. time (○ at pH 11) and $[-\ln(\alpha'-[III]/[P])]/\beta'$ vs. time (□ at pH 13).

14 and 15.

Figure 6 shows the plots of $[-\ln(\alpha-[III]/[P])]/\beta$ at pH 11 and $[-\ln(\alpha'-[III']/[P])]/\beta'$ at pH 13 against the reaction time t calculated from the data of the time-course of absorbance at 465 nm, the Soret maximum of the III species, after the addition of CN^- to a Fe(III)-TMPyP solution, in which the concentrations of the complex species and CN^- were 1.00×10^{-5} and 5.00×10^{-3} mol dm^{-3} respectively in a mixed solution. These lines show a good linearity except for the initial stage of reactions. The rate constants of formation were obtained from the slopes of these straight lines, and the rate constants of the reverse reaction, k_b and k_b' were calculated by the use of Eqs. 8 and 9. The values of the constants are listed in Table 3. The value of k_f' is almost four times that of k_f. This apparently indicates that the CN^- ion replaces the axial hydroxo ligand more easily than the axial aqua ligand in an aqueous solution, though this seems unreasonable because of the repulsion between the negative-charged ions. This finding may be interpreted in terms of the difference in the spin state of monocyano-complexes, as will be described in the next section.

Mechanisms of Substitution. The mechanism of the substitution of CN^- for the axial ligand of the Fe(III)-TMPyP species in a highly alkaline aqueous solution is summarized in Scheme 1. The solid lines express the main routes of substitution, while the dashed lines express the alternative routes.

Since the II and II′ species differ from one another, and since the pK_a value of the II species is 12.2 in the protolytic equilibrium between II and II′, the predominant monocyano species in aqueous solutions have been regarded as Fe(III)-TMPyP(H_2O)(CN) at pH 11 and Fe(III)-TMPyP(OH)(CN) at pH 13. It is considered hardly possible, because of the negative

Table 3. Rate Constants of the Axial Replacement of Monocyano and Dicyano Complexes

charge of the cyanide ion and the stronger donation of the hydroxo ligand than that of the aqua ligand, that the cyanide ion prefers to replace the hydroxo ligand rather than the aqua ligand of the monoaquamonohydroxo complex (I).[13,14] Therefore, the monohydroxomonocyano complex (II′) is probably formed first by the replacement of the species I; then the rapid protolysis[15] follows to give monoaquamonocyano complex (II) at pH 11.

In the 2nd substitution, the cyanide ion replaces the ligand at the trans position to the cyano-ligand of II′ more easily than that of II, as may be seen in Fig. 1 and Table 3. This behavior is presumably attributable to the difference in the spin states of monocyano-complexes; that is, the spin state of the II′ species, in comparison with that of II, is close to that of III.[16,17] Therefore, the 2nd substitution at pH 11 occurs via the II′ species as an intermediate; this species exists in a smaller quantity relative to the II species. Therefore, the value of the apparent rate constant, k_f, at pH 11 is smaller (seemingly by about one fourth) than the k_f' at pH 13. Similarly, it is probably ascribable to the similarity in the spin state between I′ and II′ species that the 1st substitution at pH 13 is faster than that at pH 11, as may be seen in

Fig. 1.

The authors wish to thank Miss Chie Fukuzawa for her technical collaboration and Professor Hiroko Shimada, Fukuoka University, for her valuable comments. The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 57740327) from the Ministry of Education, Science and Culture, and a grant from the Central Research Institute of Fukuoka University.

The Synthesis, Magnetic, and Spectroscopic Properties of Binuclear Iron(III) Complexes Bridged by Pyrazine, 1,1′-Tetramethylenebis(imidazol), or Bis(pyridine) Compounds Exhibiting a Spin-Equilibrium Behavior

Shoichi Ohta, Chikako Yoshimura, Naohide Matsumoto, Hisashi Okawa,† and Akira Ohyoshi*

†Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received June 5, 1985)

Five binuclear iron(III) complexes bridged by pyrazine, 1,1′-tetramethylenebis(imidazol), or bis(pyridine) compounds with the formula of $[LFe(Bge)FeL](BPh_4)_2$ have been prepared, and their spin-equilibrium behavior between high-spin($S=5/2$) and low-spin($S=1/2$) states has been investigated by means of the temperature dependences of the magnetic susceptibilities and the electronic spectra, where Bge denotes pyrazine, 1,1′-tetramethylenebis(imidazol), 4,4′-bipyridine, 4,4′-ethylenebis(pyridine), or 4,4′-vinylenebis(pyridine), L=bis(3-salicylideneaminopropyl)amine, and BPh_4^-=tetraphenylborate. The pyrazine complex is low-spin, while the bis(imidazole) and the bis(pyridine) complexes showed a spin-equilibrium between high-spin and low-spin states, accompanied by a striking thermochromism in both the solids and solutions.

Previously, we have shown that a series of iron(III) complexes with the general formula of $[FeXL]^{n+}$ ($n=0,1$) are a new family among spin-equilibrium iron(III) complexes.[1] In these complexes, the pentadentate ligand (L=bis(3-salicylideneaminopropyl)amine) is kept constant and the spin-state of iron(III) depends on the position of the sixth ligand X in the spectrochemical series; i.e., the chloro and azido complexes are high-spin, the complexes with imidazole or pyridine derivatives are spin-equilibrium, and the cyano complex is low-spin.

A number of mononuclear iron(III) complexes with spin-equilibrium, including our complexes, have been known.[1-9] However, to our knowledge, no binuclear iron(III) complex with spin-equilibrium has been reported. In this study, binuclear iron(III) complexes bridged by pyrazine, 1,1′-tetramethylenebis(imidazol), or bis(pyridine) compounds with the formula of $[LFe(Bge)FeL](BPh_4)_2$ were prepared, and their spin-equilibrium behavior was clarified by means of the temperature dependence of the magnetic susceptibilities and electronic spectra, in order to investigate the influence of the formation of binuclear species or the nature of the bridging ligand on the spin state of iron(III). The spin-equilibrium behavior of the binuclear complexes $[LFe(Bge)FeL](BPh_4)_2$ is compared with that of the corresponding mononuclear complexes $[FeXL](BPh_4)$. The schematic structures of the mononuclear $[FeXL]^{n+}$ ($n=0,1$) and binuclear $[LFe(Bge)FeL]^{2+}$ iron(III) complexes, along with the abbreviations used in this text, are shown in Fig. 1.

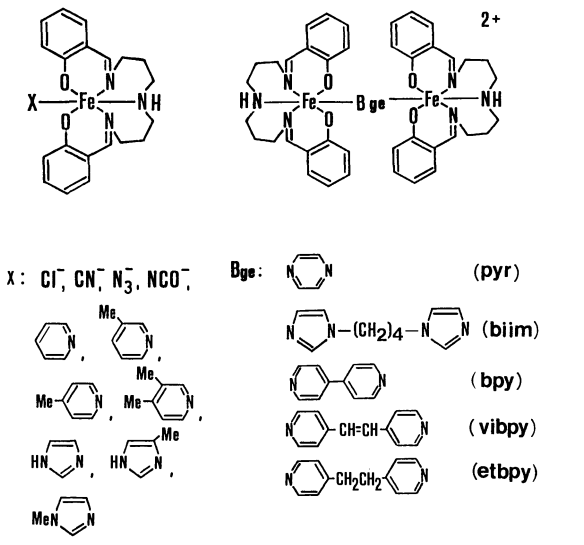

Fig. 1. Structures of mononuclear $[FeXL]^{n+}$ ($n=0,1$) and binuclear $[LFe(Bge)FeL]^{2+}$ iron(III) complexes: Bge=pyrazine(pyr), 1,1′-tetramethylenebis(imidazol) (biim), 4,4′-bipyridine(bpy), 4,4′-vinylenebis(pyridine) (vibpy), and 4,4′-ethylenebis(pyridine)(etbpy), where the abbreviations of bridging ligands Bge are given in parentheses.

Experimental

Physical Measurements. The melting points were measured on a Yanagimoto micromelting-point apparatus and uncorrected. The elemental analyses were performed by Mr. Shinichi Miyazaki at the Technical Service Center of Kumamoto University. The 100 MHz ^1H NMR spectrum was recorded on a JEOL MH 100 spectrometer; the solvent used was $CDCl_3$, and the shift measurements were made relative to $SiMe_4$. The thermogravimetric analysis was carried out on a Shimadzu TGC-20 microthermobalance at the heating rate of 5 °C min^{-1}, using ca. 20 mg of the sample. The electrical-conductivity measurements were carried out on a Denki Kagaku AOC-10 apparatus in dichloromethane solution on ca. 10^{-3} mol dm^{-3}. The reflectance spectra of the ground samples were measured on a Shimadzu UV-260 apparatus at the ambient temperature.

The temperature dependence of the electronic spectra in a dichloromethane solution was recorded with a Hitachi spectrophotometer 323, where the cell temperature was controlled by a circulating bath with a thermostat and where the sample temperature was monitored by means of a Yokogawa-Hokushin Denki digital multithermometer, Type 2572, and was kept constant within ±0.1 °C during the measurement. The magnetic susceptibilities were measured by the Faraday method in the temperature range from liquid nitrogen temperature to room temperature, according to a procedure reported previously.[10]

Syntheses. 1,1′-Tetramethylenebis(imidazol) Dihydrate. The bis(imidazole) was prepared according to the method in the literature[11] and was identified by means of elemental analysis, its mp, its ^{1}H NMR spectrum, and thermogravimetric analysis. Found: C, 53.16; H, 7.88; N, 24.80%. Calcd for $C_{10}H_{14}N_4 \cdot 2H_2O$: C, 53.08; H, 8.02; N, 24.76%. mp 56—71 °C (Ref. 58—75 °C), ^{1}H NMR ($CDCl_3$) δ=1.70 (4H, m, CH_2), 1.80 (4H, s, H_2O), 3.80 (4H, m, CH_2), 7.10 (6H, q, aromatic), mass loss 15.9 wt% (55—130 °C), Calcd for $2H_2O$:15.9 wt%.

[FeClL]. The chloro iron(III) complex as a starting material was prepared according to the method reported previously.[1]

Binuclear Iron(III) Complexes [LFe(Bge)FeL](Bph$_4$)$_2$. The binuclear iron(III) complexes bridged by pyrazine, 1,1′-tetramethylene-bis(imidazol), or bis(pyridine) compounds were obtained by mixing stoichiometric amounts of [FeClL] and the bridging ligand in a mole ratio of 2:1 and by then adding sodium tetraphenylborate to provide a counter anion, where pyrazine, 1,1′-tetramethylenebis(imidazol), 4,4′-bipyridine, 4,4′-ethylenebis(pyridine), and 4,4′-vinylenebis(pyridine) were used as bridging ligands. The syntheses of all the binuclear complexes are practically the same, so only the synthesis of the 4,4′-bipyridine complex [LFe(bpy)FeL](BPh$_4$)$_2$ will be described in detail as an example. To a solution of [FeClL] (2 mmol) in 50 cm^3 of methanol was added a solution of 4,4′-bipyridine (1 mmol). The mixture was warmed at 60 °C for 10 min and then filtered. The filtrate was added to a solution of sodium tetraphenylborate (2.5 mmol) in 10 cm^3 of methanol. The resulting crystals were filtered, washed with methanol and diethyl ether, and dried in vacuo.

Results and Discussion

Binuclear iron(III) complexes [LFe(Bge)FeL](BPh$_4$)$_2$ were prepared by mixing stoichiometric amounts of [FeClL] and the bridging ligand (Bge) in methanol and by then adding a slight excess of sodium tetraphenylborate. The elemental analytical data, melting points, molar electrical conductances in 10^{-3} mol dm^{-3} dichloromethane solutions, and colors in the solids and solutions at the ambient temperature and at the temperature of liquid nitrogen are summarized in Table 1. As shown in Table 1, the bis(pyridine) complexes showed a striking thermochromism both in the solids and solutions. On the other hand, the pyrazine complex showed no thermochromism in the solid state, and its green color is characteristic of low-spin complexes.[1]

The temperature dependences of the magnetic moments for the binuclear iron(III) complexes [LFe(Bge)FeL](BPh$_4$)$_2$ are shown in Fig. 2, where the magnetic moment per iron is given. As could be

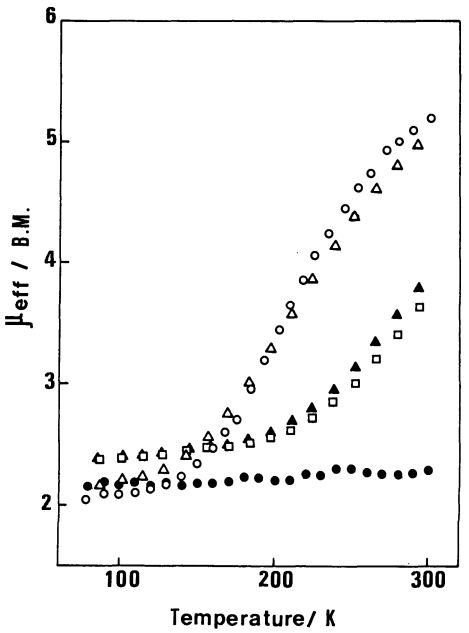

Fig. 2. Temperature dependences of effective magnetic moments for binuclear iron(III) complexes [LFe(Bge)FeL](BPh$_4$)$_2$, Bge: pyr (●), biim (○), bpy(△), vibpy(□), etbpy(▲).

a) Electrical conductance in ca. 10^{-3} mol dm^{-3} dichloromethane solutions/S mol^{-1} cm^2. b) Colors at 300 K (left) and 80 K (right); V, violet; DV, dark violet; BG, blue green; DG, dark green; G, green. c) In a dichloromethane solution.

predicted from its green color, the pyrazine complex [LFe(pyr)FeL](BPh4)2 is essentially low-spin, because the magnetic moment (ca. 2.2 BM) is in the expected range for low-spin (S=1/2) iron(III) complexes and is independent of the temperature. On the other hand, the magnetic moments for the bis(imidazole) and the bis(pyridine) complexes showed temperature dependence, indicating that the complexes exhibit a spin-equilibrium between high-spin(S=5/2) and low-spin (S=1/2) states. Since the spin-transition for these complexes takes place over a wide range of temperatures, the complexes, on the basis of König's criterion,[12] can be classified as forming a continuous type of spin-equilibrium complexes. The magnetic moments for the bis(imidazole) and 4,4′-bipyridine complexes [LFe(biim)FeL](BPh4)2 and [LFe(bpy)FeL](BPh4)2 increase gradually from a low-spin value (ca. 2.2 BM) at 80 K to a nearly high-spin value (ca. 5.3 BM) at 300 K, indicating that the spin-transition from the low-spin state to the high-spin state is almost completed in the temperature range studied. For the other two bis(pyridine) complexes, [LFe(etbpy)FeL](BPh4)2 and [LFe(vibpy)FeL](BPh4)2, the magnetic moments gradually increase from 2.3 BM at 80 K to ca. 3.7 BM at 300 K, suggesting that the spin-transition seems to be completed at a temperature higher than 300 K.

It is of interest to compare the magnetic behavior of the binuclear complexes [LFe(Bge)FeL](BPh4)2 with that of the corresponding mononuclear complexes [FeXL](BPh4). The magnetic behavior of the bis(imidazole) complex [LFe(biim)FeL](BPh4)2 can be compared with that of the mononuclear complexes with imidazole derivatives [FeXL](BPh4) (X=im, 1-meim, 2-meim). The bis(imidazole) complex showed the spin-transition between ca. 130 and 300 K, while [FeimL](BPh4) and [Fel-meimL](BPh4) are high-spin complexes between 80 and 300 K, and [Fe2-meimL](BPh4) showed the spin-transition between ca. 130 and 300 K.[1] The magnetic behavior of the bis(pyridine) complexes [LFe(Bge)FeL](BPh4)2 (Bge=bpy, etbpy, vibpy) can be compared with that of the mononuclear complexes [FeXL](BPh4) (X=py, 3-mepy, 4-mepy, 3,4-dmepy). The μ_{eff} vs. T curves for the [FeXL](BPh4) complexes (X=py, 3-mepy, 4-mepy, 3,4-dmepy) are roughly compatible with those for the [LFe(etbpy)FeL](BPh4)2 and [LFe(vibpy)FeL](BPh4)2 complexes, but are obviously different from that for [LFe(bpy)FeL](BPh4)2.

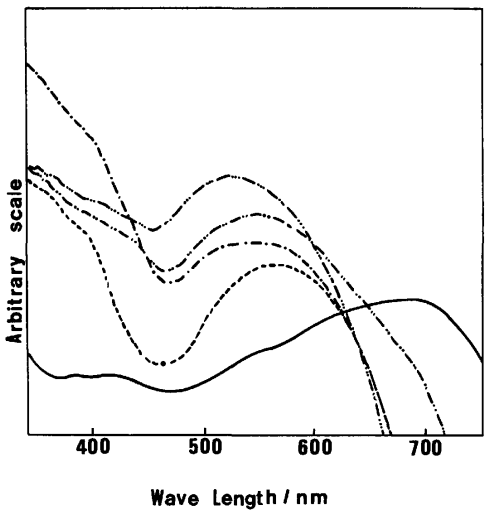

Fig. 3. Reflectance spectra for binuclear iron(III) complexes [LFe(Bge)FeL](BPh4)2, Bge: pyr(——), biim(—·····—), bpy(—·—·—), vibpy(—·—), etbpy(----).

The reflectance spectra for the binuclear complexes at the ambient temperature are shown in Fig. 3. The complexes exhibit an intense broad band in visible region. The pyrazine complex has the absorption maximum at 680 nm, while the bis(imidazole) and the bis(pyridine) complexes have the maxima around 550 nm. The results from the reflectance spectra are compatible with those from the magnetic moments at the ambient temperature.

The temperature dependence of the electronic spectra was measured in dichloromethane solutions. All the binuclear complexes except for the pyrazine complex showed thermochromic behavior. The pyrazine complex exhibits a green color in the solid and a violet color in the dichloromethane solution. The pyrazine complex showed no thermochromism in a solution, probably because the complex decomposes to form a penta-coordinated complex with the formula of [FeL](BPh4). Figure 4 shows the temperature dependence of the spectrum for [LFe(bpy)FeL](BPh4)2. The spectral patterns of the bis(pyridine) complexes are similar to each other and to those of the corresponding mononuclear complexes with pyridine derivatives.[1] At 16 °C, the spectrum for [LFe(bpy)FeL](BPh4)2 exhibits two absorptions, at 430 and 490 nm, with extinction coefficients of 8500 and 7100 $dm^3 mol^{-1} cm^{-1}$ attributable to the charge-transfer bands. With a lowering in the temperature, the absorption at 430 nm decreases in intensity and that at 490 nm shifts to a higher wavelength, accompanied by a decrease in the intensity. The temperature dependence of the electronic spectrum is probably due to the spin-equilibrium between high-spin and low-spin states, as is known for the well-characterized spin cross-over complexes.[1-9] The spectral changes are associated with two pseudo-isosbestic points at 400 and 510 nm, in which the latter is gradually displaced from 510 nm to a higher wavelength with a lowering in the temperature. The disagreement of the isosbestic points is attributable to the partial dissociation of 4,4′-bipyridine from the complex. When the spectrum was measured after having been left overnight, the absorbance was reduced by almost one

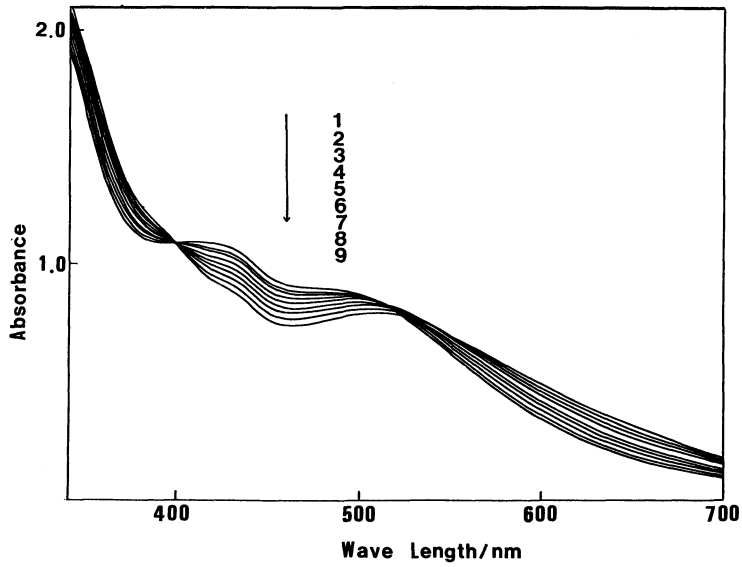

Fig. 4. Temperature dependence of electronic spectrum for $[LFe(bpy)FeL](BPh_4)_2$ in 1.257×10^{-4} mol dm^{-3} dichloromethane solution: (**1**: 16.0 °C, **2**: 13.0 °C, **3**: 10.0 °C, **4**: 7.0 °C, **5**: 4.0 °C, **6**: 1.0 °C, **7**: −2.0 °C, **8**: −5.0 °C, **9**: −8.0 °C).

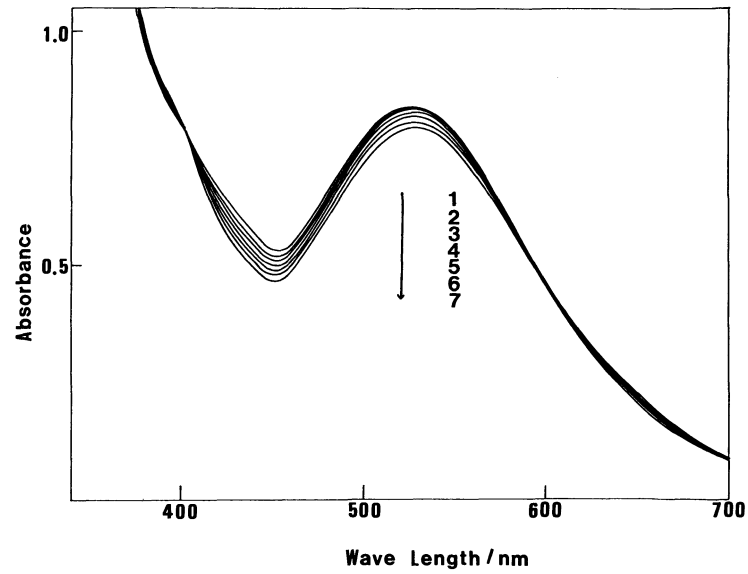

Fig. 5. Temperature dependence of electronic spectrum for $[LFe(biim)FeL](BPh_4)_2$ in 1.158×10^{-4} mol dm^{-3} dichloromethane solution: (**1**: 16.0 °C, **2**: 10.4 °C, **3**: 6.8 °C, **4**: 3.1 °C, **5**: −1.0 °C, **6**: −7.0 °C, **7**: −9.5 °C).

half, while the spectral pattern is consistent with that of the sample measured immediately after the preparation. Figure 5 shows the temperature dependence of the spectrum for the bis(imidazole) complex $[LFe(biim)FeL](BPh_4)_2$. The spectrum exhibits a band at 530 nm, which decreases in intensity with a lowering of the temperature. The spectrum changes with a set of isosbestic points at 400 and 595 nm.

We wish to thank Mr. Susumu Kohata at the Yatsushiro College of Technology for allowing us to use the Shimadzu UV-260 spectrophotometer (for the reflectance specta). This work was in part supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture (No. 59740300).

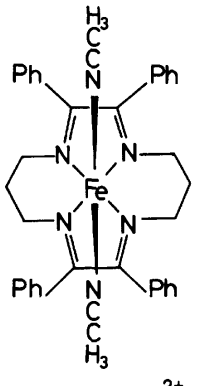
Kinetics of Axial Substitution of the Iron(II) Complex of 2,3,9,10-Tetraphenyl-1,4,8,11-tetraaza-1,3,8,10-cyclotetradecatetraene in Acetonitrile. Evidence for a Dissociative-Interchange Mechanism

Shigenobu FUNAHASHI, Naotaka UCHIYAMA, and Motoharu TANAKA*
Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received June 11, 1985)

The reaction of the iron(II) complex of 2,3,9,10-tetraphenyl-1,4,8,11-tetraaza-1,3,8,10-cyclotetradecatetraene ($[FeL(CH_3CN)_2]^{2+}$, **1**) with imidazole and thiocyanate ion in acetonitrile has been investigated spectrophotometrically at various temperatures and pressures. The axial substitution of **1** with imidazole is first order with respect to the concentration of the iron(II) complex and imidazole and the rate constant and the activation parameters are obtained as k (25.0 °C)=0.69 mol^{-1} kg s^{-1}, $\Delta H^{\ddagger}$=76±4 kJ mol^{-1}, $\Delta S^{\ddagger}$=7±13 J mol^{-1} K^{-1}, $\Delta V^{\ddagger}$=13.7±0.9 cm^3 mol^{-1}. It has been demonstrated that at higher concentration of imidazole there exists self-associated imidazole which does not react directly with the complex. The axial substitution of **1** with thiocyanate ion proceeds through the ion-association between **1** and SCN^- prior to the rate-determining step from the outer-sphere complex to the inner-sphere complex. The activation parameters for the rate-determining step were determined as follows: k^0 (25.0 °C and 0.1 MPa)=2.35 s^{-1}, $\Delta H^{\ddagger}$=86±2 kJ mol^{-1}, $\Delta S^{\ddagger}$=51±6 J mol^{-1} K^{-1}, $\Delta V^{\ddagger}$=10.1±0.2 cm^3 mol^{-1}. The positive activation volumes strongly indicate a dissociative character of the activation process.

Transition-metal complexes containing macrocyclic ligands have been investigated as models for biological molecules.[1,2] One particular interest in these model studies has been to elucidate mechanisms of solvent exchange and ligand substitution at the axial coordination site of metal complexes with macrocyclic ligands from biological interests.[3,4] There are a number of kinetic studies on axial ligand substitution reactions in six-coordinated iron(II) complexes with macrocyclic ligands,[5-21] including phthalocyanine[5-11] and porphyrins.[12-14] In such complexes the equatorial positions are occupied by four nitrogen atoms of the macrocyclic ligands and the axial sites by the ligands taking part in the relevant rate processes. Despite numerous studies, the reaction mechanism of axial substitution of iron complexes does not appear to have been proved decisively and there seems to be no mechanistic approach on the basis of the activation volumes.

We present here the results of a kinetic study on the substitution of axial acetonitrile by imidazole(Im) and thiocyanate ion in the iron(II) complex of 2,3,9,10-tetraphenyl-1,4,8,11-tetraaza-1,3,8,10-cyclotetradecatetraene ($[FeL(CH_3CN)_2]^{2+}$, **1**) at various temperatures and pressures. The overall reactions are represented by Eqs. 1 and 2.



$[FeL(CH_3CN)_2]^{2+}$, **1**

$$\mathbf{1} + 2\mathrm{Im} \rightleftharpoons [FeL(Im)_2]^{2+} + 2CH_3CN \quad (1)$$

$$\mathbf{1} + 2SCN^- \rightleftharpoons FeL(SCN)_2 + 2CH_3CN \quad (2)$$

Experimental

Materials. **Acetonitrile**: Reagent grade acetonitrile (Wako Pure Chemical Industries, Ltd.) was refluxed over P_2O_5 (2 g dm^{-3}) for longer than 3 h and distilled under dry air. Furthermore, the distilled acetonitrile was refluxed over calcium hydride (Wako) (2 g dm^{-3}) in an argon atmosphere for longer than 3 h, distilled under argon, and stored in a dry box. The amount of water contained in acetonitrile was checked by the Karl-Fisher method and it was found to be less than 2×10^{-3} mol dm^{-3}.

Imidazole: Imidazole (Wako) was purified by sublimation in vacuo (3 mmHg, 80—100 °C).

Sodium Thiocyanate: Reagent grade sodium thiocyanate (Nakarai Chemicals) was recrystallized from methanol. The crystals were washed with diethyl ether and dried for 6 h under reduced pressure. The amount of water contained in the crystals was determined to be less than 0.015 wt%.

Anhydrous Sodium Perchlorate: A sodium perchlorate solution was prepared by neutralizing reagent grade 60% perchloric acid with reagent grade anhydrous sodium carbonate. Heavy-metal impurities in the sodium perchlorate solution were precipitated as hydroxides together with active carbon at pH 8.5. After concentration of the solution crystals of sodium perchlorate hydrates were obtained by cooling the solution. Sodium perchlorate was then crystallized twice from distilled water. Anhydrous sodium perchlorate was obtained by drying the obtained sodium perchlorate hydrates at 60 °C under reduced

pressure for more than 5 h.

[FeL(CH$_3$CN)$_2$](PF$_6$)$_2$: This complex was synthesized by a procedure similar to the literature method.[22] All operations were carried out under an argon atmosphere. Yielded dark purple crystals were washed with cold methanol and then with ether. The product was purified further by chromatography (Silica gel 2308, Merck; ϕ45 mm, h 270 mm column; eluent: dry nitromethane). Recrystallization from dry acetonitrile and dry diethyl ether gave purple crystals. Anal. Calcd for $C_{38}H_{38}N_6P_2F_{12}Fe$: C, 49.39; H, 4.14; N, 9.09; Fe, 6.04. Found: C, 49.36; H, 4.08; N, 8.94; Fe, 5.95±0.03. After decomposition of the complex by heating with sodium carbonate, iron was determined by the colorimetry with 1,10-phenanthlorine. ^{1}H NMR (acetone-d_6, Me$_4$Si): 1.62 ppm (m, 4H), 2.51 (m, 6H), 4.35 (m, 8H), 7.48 (m, 20H). Visible electronic spectrum (CH$_3$CN solution): λ_{max} (ε) 551 nm (8.83×10^3 mol^{-1} dm^3 cm^{-1}), 592 nm (1.78×10^4 mol^{-1} dm^3 cm^{-1}). Half-wave potential of Fe^{2+}/Fe^{3+} for the complex 1.48 V (ΔP=64 mV, 100 mV s^{-1}). IR (KBr pellet): 1340(m), 1320(m), 1270(m), 1115(w), 1080(w), 1030(w, axial CH$_3$CN), 845(s, PF$_6^-$), 710(s).

Measurement. The reaction was started by mixing the iron(II) complex solution with an imidazole or a thiocyanate ion solution. Reactions at atmospheric pressure were followed by a stopped-flow spectrophotometer (Type RA 401, Union Giken). Reactions at high pressure up to 200 MPa were measured with a high-pressure stopped-flow apparatus with spectrophotometric detection (Type FIT 3).[23,24]

Results

Reaction of 1 with Imidazole. Under conditions with a large excess of imidazole over the bis(acetonitrile) complex, during the reaction after mixing, we observed solutions having visible absorption spectra corresponding to those of the species $[FeL(Im)_2]^{2+}$, but not corresponding to $[FeL(CH_3CN)(Im)]^{2+}$. Moreover, the final change in absorbance was independent of the concentration of imidazole and proportional to the complex concentration. Therefore, under the present experimental conditions the reverse reaction is negligible for the kinetic study and the second ligation is much faster than the first ligation of imidazole. The axial substitution of the complex with imidazole was followed at 592 nm, the maximum wavelength of the complex. The first-order plots were linear at least for 3 half-lives. Rate constants obtained at a constant concentration of imidazole (C_{Im}=0.150 mol kg^{-1}) and various concentrations of the complex (C_{FeL}=2.68—5.91×10^{-5} mol kg^{-1}) were independent of the complex concentration. The rate law is thus given by

$$-d[\mathbf{1}]/dt = k_{0(Im)}[\mathbf{1}], \quad (3)$$

where $k_{0(Im)}$ is a conditional first-order rate constant. Rate constants $k_{0(Im)}$ were obtained at various concentrations of imidazole. The plots of $k_{0(Im)}$ against the total concentrations of imidazole, C_{Im}, are shown in Fig. 1.

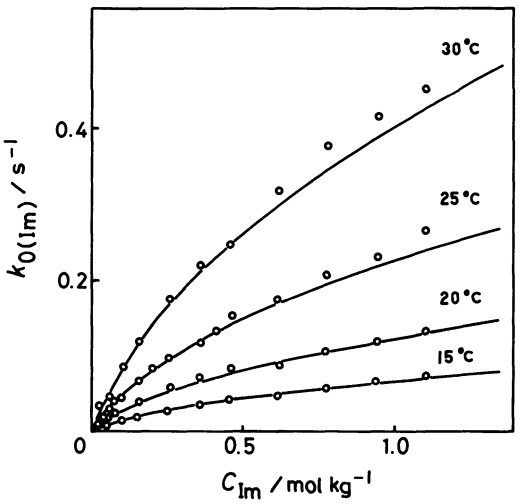


Fig. 1. Imidazole concentration dependence of first-order rate constants under atmospheric pressure at 15.0, 20.0, 25.0, and 30.0 °C. In Figs. 1—6, each point is an average of several runs. In Figs. 1, 3, 5, and 6, the soild lines were calculated by using the values obtained.

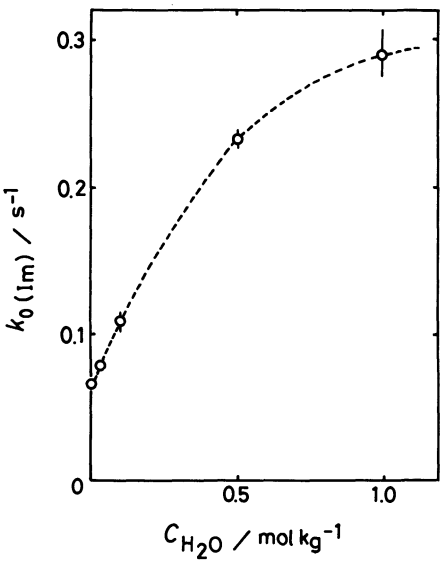

Fig. 2. Water effect on rate. C_{H_2O} is the concentration of added water. The rate constants were obtained at $C_{FeL}=5.90\times10^{-5}$ mol kg^{-1}, C_{Im}=0.150 mol kg^{-1}, and 25.0 °C.

The effect of water on the rate was checked by the addition of water (see Fig. 2). Rates drastically increase with increasing water concentration. However since water in the present reaction systems is less than 5×10^{-3} mol dm^{-3}, we believe with confidence that the presence of water, if any, does not affect our results. The rate was also not influenced by introduction of sodium perchlorate up to 0.2 mol kg^{-1}. The absence of any salt effect is

consistent with the imidazole reacting as free base.

Conditional first-order rate constants $k_{0(Im)}$ were determined at various temperatures and various pressures and they are shown as a function of imidazole concentrations in Figs. 1 and 3.

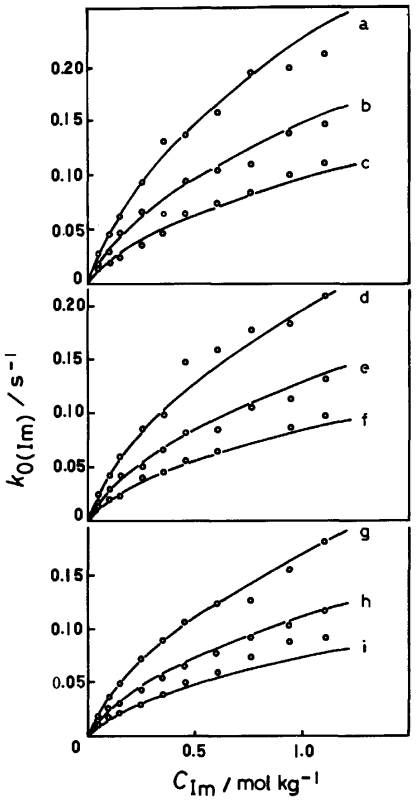

Fig. 3. Imidazole concentration dependence of first-order rate constants at 25.0 °C and nine different pressures. a: 0.1 MPa, b: 73.6 MPa, c: 147 MPa, d: 24.5 MPa, e: 98.1 MPa, f: 172 MPa, g: 49.0 MPa, h: 123 MPa, i: 196 MPa.

Reaction of 1 with Thiocyanate Ion. In a large excess of thiocyanate ion concentrations over the bis(acetonitrile) complex concentration, equilibrium 2 is much favored to the right and the reverse reaction is negligible. Under pseudo-first-order conditions, the axial substitution was followed at 732 nm, the maximum wavelength of the bis(thiocyanato) complex produced. The conditional first-

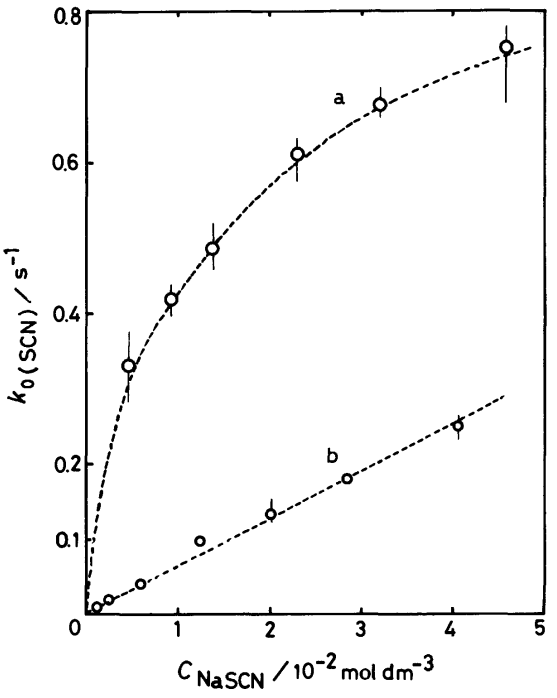

Fig. 4. Dependence of rate constant $k_{0(SCN)}$ on the total concentation of sodium thiocyanate (a) in the absence of and (b) in the presence of sodium perchlorate (C_{NaClO_4}=0.20 mol kg^{-1}).

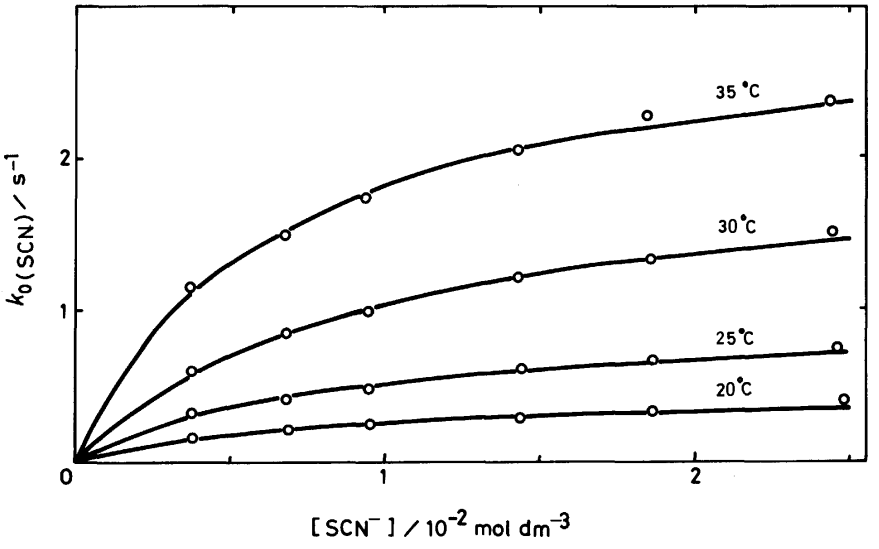

Fig. 5. Thiocyanate-ion concentration dependence of first-order rate constants at 20.0, 25.0, 30.0, 35.0, and 35.0 °C.

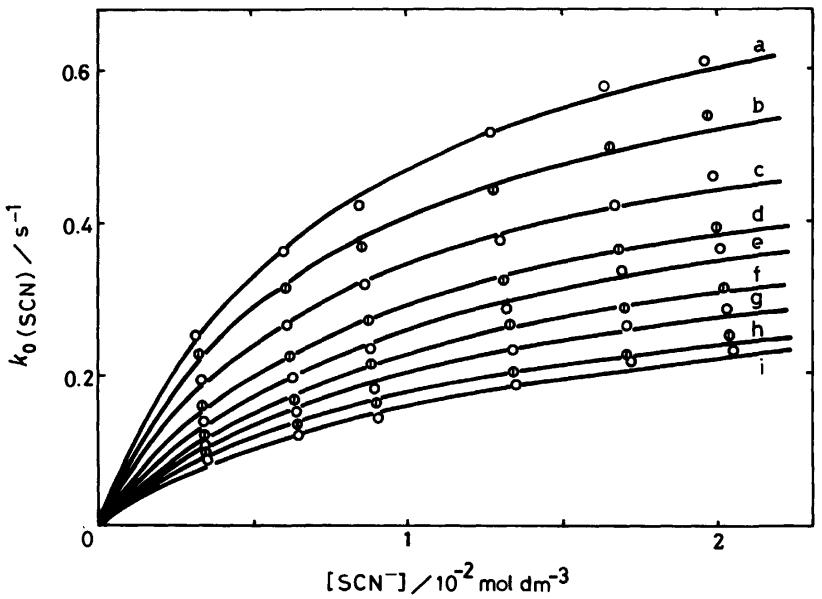

Fig. 6. Thiocyanate-ion concentration dependence of first-order rate constants at nine different pressure. a: 0.1 MPa, b: 24.5 MPa, c: 49.0 MPa, d: 73.6 MPa, e: 98.1 MPa, f: 123 MPa, g: 147 MPa, h: 172 MPa, i: 196 MPa.

order plots were excellently linear and the rate was confirmed to be first order with respect to the bis(acetonitrile) complex. Then we have

$$-\mathrm{d}[\mathbf{1}]/\mathrm{d}t = \mathrm{d}[\mathrm{FeL(SCN)_2}]/\mathrm{d}t = k_{0(\mathrm{SCN})}[\mathbf{1}], \quad (4)$$

where $k_{0(\mathrm{SCN})}$ is a conditional first-order rate constant involving the concentration of thiocyanate ion. Conditional first-order rate constants were obtained at various concentrations of thiocyanate ion both in the presence and in the absence of sodium perchlorate. As apparent from Fig. 4, in the presence of $NaClO_4$ the plot of $k_{0(\mathrm{SCN})}$ vs. the total concentration of sodium thiocyanate, C_{NaSCN}, gives a straight line through the origin, while in the absence of $NaClO_4$ the plot is leveled out with increasing thiocyanate concentration.

First-order rate constants $k_{0(\mathrm{SCN})}$ were determined as a function of thiocyanate ion concentrations at various temperatures and pressures. In Figs. 5 and 6 values of $k_{0(\mathrm{SCN})}$ are plotted as a function of the concentration of free thiocyanate ion, [SCN^-] (not the total concentration of sodium thiocyanate, C_{NaSCN}, see Discussion).

Discussion

In reaction systems showing a leveling of $k_{0(\mathrm{L})}$ with increasing concentration ([L]) of an incoming ligand, the plot of $k_{0(\mathrm{L})}^{-1}$ vs. $[\mathrm{L}]^{-1}$ gives sometimes a straight line. In this case $k_{0(\mathrm{L})}$ is expressed as follows:

$$k_{0(\mathrm{L})} = \frac{a[\mathrm{L}]}{1+b[\mathrm{L}]}. \quad (5)$$

However, the plot of $k_{0(\mathrm{L})}^{-1}$ vs. $[\mathrm{L}]^{-1}$ for the imidazole system in this work did not give a straight line. Data at higher concentration of imidazole were unable to fit to the function of Eq. 5. This behavior may be rationalized in terms of the known tendency for imidazole to make hydrogen bonding strongly with itself.[25,26] If the resulted dimer (Im_2) is assumed to be unreactive with the complex, it is possible to express the reaction as follows:

$$2\mathrm{Im} \overset{K}{\rightleftharpoons} \mathrm{Im_2}, \quad (6)$$

$$[\mathrm{FeL(CH_3CN)_2}]^{2+} + \mathrm{Im} \overset{k}{\longrightarrow} [\mathrm{FeL(CH_3CN)(Im)}]^{2+} + \mathrm{CH_3CN}, \quad (7)$$

$$[\mathrm{FeL(CH_3CN)(Im)}]^{2+} + \mathrm{Im} \overset{\text{fast}}{\longrightarrow} [\mathrm{FeL(Im)_2}]^{2+} + \mathrm{CH_3CN}, \quad (8)$$

where K refers to the dimerization constant of imidazole (Eq. 6), k is a second-order rate constant for the mono (imidazole) complex formation (Eq. 7), and the second imidazole reaction (Eq. 8) is very rapid. In a case where $C_{\mathrm{Im}} \gg C_{\mathrm{FeL}}$, we obtain

$$k_{0(\mathrm{Im})} = k\frac{\sqrt{8KC_{\mathrm{Im}}+1}-1}{4K}. \quad (9)$$

The $k_{0(\mathrm{Im})}$'s for a series of imidazole concentrations at 15, 20, 25, and 30 °C were fitted to Eq. 9 by a nonlinear least-squares program. The values of thermodynamic and activation parameters were obtained as follows: ΔH^{*}=74±3 kJ mol^{-1}, ΔS^{*}=0±9 J mol^{-1} K^{-1}, ΔH=−36±8 kJ mol^{-1}, and ΔS=−100±30 J mol^{-1} K^{-1}.

Since the plots of $\ln k$ and $\ln K$ against pressure showed linear relationships within experimental errors, the activation volume $\Delta V^{\ddagger}$ and the reaction volume ΔV can be accepted to be independent of pressure. Thus we can express k and K by Eqs. 10 and 11.

$$k = k^0 \exp(-\Delta V^{\ddagger} P/RT), \quad (10)$$

$$K = K^0 \exp(-\Delta V P/RT), \quad (11)$$

where k^0 and K^0 are constants at zero pressure, and then the conditional first-order rate constant is expressed as Eq. 12.

$$k_{0(\mathrm{Im})} = k^0 \exp(-\Delta V^{\ddagger} P/RT) \frac{\sqrt{8K^0 \exp(-\Delta V P/RT) C_{\mathrm{Im}} + 1} - 1}{4K^0 \exp(-\Delta V P/RT)} \quad (12)$$

Values of k^0, K^0, $\Delta V^{\ddagger}$, and ΔV were obtained by a nonlinear least-squares fit to all nine sets of data (201 data points): $k^0 = 0.686\ \mathrm{mol^{-1}\,kg\,s^{-1}}$, $\Delta V^{\ddagger} = 13.6 \pm 1.4\ \mathrm{cm^3\,mol^{-1}}$, $K^0 = 3.7\ \mathrm{mol^{-1}\,kg}$, $\Delta V = 1.6 \pm 4.2\ \mathrm{cm^3\,mol^{-1}}$. The final analysis of data by the least-squares program (SALS)[27] was carried out by applying simultaneously all data (341 data points) obtained at various temperatures and pressures. The parameters obtained are summarized in Table 1. The solid lines in Figs. 1 and 3 were depicted by the obtained values.

The activation volume of $13.7\ \mathrm{cm^3\,mol^{-1}}$ is considerably larger than that found for the CH_3CN exchange at Ni^{2+} ($7.3\ \mathrm{cm^3\,mol^{-1}}$), the most dissociative among solvent exchange reactions of bivalent transition metal ions.[28] Since the entering ligand, imidazole, has no charge, the electrostatic contribution to the volume change due to the interaction between the complex and imidazole is negligible. Therefore $\Delta V^{\ddagger}$ of $13.6\ \mathrm{cm^3\,mol^{-1}}$ points to a marked dissociative character of the reaction.

Figures 5 and 6 show also a falling-off of $k_{0(\mathrm{SCN})}$ with increasing concentration of the incoming ligand, $[SCN^-]$. We assume that the reaction of **1** with thiocyanate ion proceeds by the following processes:

$$\mathbf{1} + SCN^- \overset{K_{os}}{\rightleftharpoons} [FeL(CH_3CN)_2]^{2+}\cdots SCN^-, \quad (13)$$

$$[FeL(CH_3CN)_2]^{2+}\cdots SCN^- \xrightarrow{k} [FeL(CH_3CN)(SCN)]^+ + CH_3CN \quad (14)$$

$$[FeL(CH_3CN)(SCN)]^+ + SCN^- \xrightarrow{\text{fast}} FeL(SCN)_2 + CH_3CN. \quad (15)$$

Then, the conditional first-order rate constant is given by Eq. 16.

$$k_{0(\mathrm{SCN})} = \frac{kK_{os}[SCN^-]}{1 + K_{os}[SCN^-]} \quad (16)$$

The rate constant (k) of the unimolecular reaction may not be affected by ionic strength, I, while the association constant of the outer-sphere complex, K_{os}, varies as a function of ionic strength. For computation of K_{os} as described below we used the molar concentration calculated from the molal concentration with knowledge of the density of each solution at a certain temperature and pressure.[29] The ion association constant K_{NaSCN} of sodium thiocyanate in acetonitrile is available: thermodynamic constant $K_{\mathrm{NaSCN}} = 88\ \mathrm{mol\,dm^{-3}}$ at $I = 0\ \mathrm{mol\,dm^{-3}}$.[30] The ionic strength dependence of K_{NaSCN} is given by the following relations:[31]

$$K_{\mathrm{NaSCN}} = K_{\mathrm{NaSCN}} y_{\pm}^2, \quad \log y_{\pm} = -AI/(1 + BaI), \quad (17)$$

where $A = (DT)^{-3/2} \times 1.8246 \times 10^6$, $B = (DT)^{-1/2} \times 50.29 \times 10^8$, $y_{\pm}$ is a mean activity coefficient, D is the specific dielectric constant of acetonitrile of which the temperature and pressure dependence is available,[29] and a is the distance of the closest approach which is accepted to be 4×10^{-8} cm. Since, in the absence of sodium perchlorate, sodium thiocyanate exists in a very large excess (up to $5 \times 10^{-2}\ \mathrm{mol\,dm^{-3}}$), the ionic strength is controlled by the added sodium thiocyanate and then the ionic strength is given by Eq. 18.

$$I = \{-1 + (1 + 4K_{\mathrm{NaSCN}} C_{\mathrm{NaSCN}})^{1/2}\}/2K_{\mathrm{NaSCN}} \quad (18)$$

The ionic strength for each run was calculated by Eqs. 17 and 18. We have

$$k = \frac{kT}{h} \exp\left(-\frac{\Delta H^{\ddagger} - T\Delta S^{\ddagger}}{RT}\right) \quad (19)$$

K_{os} is given by Eq. 20[32]

$$K_{os} = \frac{4\pi N \text{å}^3}{3000} \exp\left\{-\frac{u(\text{å})}{kT}\right\}, \quad (20)$$

where $u(\text{å}) = z_1 z_2 e^2/\text{å}D - z_1 z_2 e^2 \kappa / D(1 + \kappa \text{å})$, $\kappa^2 = 8\pi N e^2 I / 1000 DkT$, å is the distance of the closest approach, and the other symbols have their usual meanings. The parameters ($\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and å) from the data (187 data points) of temperature dependence of $k_{0(\mathrm{SCN})}$ were computed with knowledge of values of variables such as I, $[SCN^-]$, T, and $k_{0(\mathrm{SCN})}$ with use of Eqs. 16, 19, and 20 by a nonlinear least-squares program. We

Table 1. Thermodynamic and Activation Parameters According to Eq. 6, Eq. 7, and Eq. 14[a]

Eq. 6	Eq. 7	Eq. 14
$\Delta H = -23 \pm 12$	$\Delta H^{\ddagger} = 76 \pm 4$	$\Delta H^{\ddagger} = 86 \pm 2$
$\Delta S = -67 \pm 41$	$\Delta S^{\ddagger} = 7 \pm 13$	$\Delta S^{\ddagger} = 51 \pm 6$
$\Delta V = -1.3 \pm 2.7$	$\Delta V^{\ddagger} = 13.7 \pm 0.9$	$\Delta V^{\ddagger} = 10.1 \pm 0.2$

a) Enthalpy, entropy, and volume are given by the unit in $\mathrm{kJ\,mol^{-1}}$, $\mathrm{J\,mol^{-1}\,K^{-1}}$, and $\mathrm{cm^3\,mol^{-1}}$, respectively.

obtained the following values: $\Delta H^{\ddagger}=86\pm2$ kJ mol^{-1}, $\Delta S^{\ddagger}=51\pm6$ J K^{-1} mol^{-1}, and $\mathring{a}=(6.1\pm0.3)\times10^{-8}$ cm. With knowledge of values of I, [SCN$^-$], P, and $k_{0(SCN)}$ the parameters of k^0, $\Delta V^{\ddagger}$, and $\mathring{a}$ from the data (162 data points) of pressure dependence of $k_{0(SCN)}$ were estimated with use of Eqs. 10, 16, and 20 by a nonlinear least-squares best fit. The following values were determined: $k^0=2.35\pm0.05$ s^{-1}, $\Delta V^{\ddagger}=10.1\pm0.2$ cm^3 mol^{-1}, and $\mathring{a}=(6.9\pm0.2)\times10^{-8}$ cm. The $\mathring{a}$ value of 6—7$\times10^{-8}$ cm is reasonable judging from the molecular model. The fact that the entropy of activation and the activation volume are both positive is consistent with the dissociative character of the reaction.

In the presence of a large excess of sodium perchlorate the values of K_{os} and [SCN$^-$] become smaller than in the absence of sodium perchlorate. Moreover because of the equilibrium $Na^+ + SCN^- \rightleftarrows Na^+SCN^-$, [SCN$^-$] is proportional to C_{NaSCN} in the presence of a large excess of sodium perchlorate. Therefore the term K_{os}[SCN$^-$] should be smaller than unity in Eq. 16. In this case, $k_{0(SCN)}$ is, in fact, proportional to the thiocyanate ion concentration as seen in Fig. 4b. We can calculate the ion-association constant, K_{NaClO_4}, of sodium perchlorate in CH_3CN from the data at 25.0 °C and 0.1 MPa in Fig. 4. The value of K_{NaClO_4} is evaluated to be 45 ± 5 mol^{-1} dm^3 at $I=0.057\pm0.002$ mol dm^{-3} which is reasonable as compared to the K_{NaSCN} value of 59 mol^{-1} dm^3 at $I=0.057$ mol dm^{-3} obtained from Eq. 17.

Jones and Twigg have pointed out two possible mechanisms for the substitution of axially bound dimethyl sulfoxide (Me_2SO) by imidazole at an iron (II) phthalocyanine center in Me_2SO.[5] In order to distinguish the two mechanisms they have extended their study to higher concentration range of imidazole up to 1.45 mol dm^{-3},[6] without finding the curvature which we observed in this work. This seems reasonable because imidazole dimerizes to a lesser extent in Me_2SO which is much more basic than acetonitrile.[33]

Rates of exchange of acetonitrile solvent on hexasolventoiron(II) ion are available:[28b,34] $k=6.6\times10^5$ s^{-1} (25 °C), $\Delta H^{\ddagger}=41.4$ kJ mol^{-1}, $\Delta S^{\ddagger}=5.3$ J K^{-1} mol^{-1}, and $\Delta V^{\ddagger}=3$ cm^3 mol^{-1}.[28b] The exchange rate is about 6 orders of magnitude higher than that for axial substitution in $[FeL(CH_3CN)_2]^{2+}$ primarily due to the difference in activation enthalpy. This will result from the different state of the paramagnetic high-spin hexa(acetonitrile)iron(II) and diamagnetic low-spin $[Fe(II)L]^{2+}$ ions. The activation volume for axial substitution of $[Fe(II)L]^{2+}$ is larger than that for solvent exchange and $[FeL(CH_3CN)_2]^{2+}$ reacts more dissociatively than $[Fe(CH_3CN)_6]^{2+}$ does.

25) It has been reported that the ^{1}H NMR spectrum of imidazole in dichloromethane[26a] and in benzene[26b] is strongly dependent on the imidazole concentration and on the temperature. As the imidazole concentration decreases (from 1 mol dm^{-3} to 0.2 mol dm^{-3}) the N-H resonance broadens and moves upfield, while the C-H resonances show only very minor shifts. These changes have been ascribed to the formation of strongly hydrogen-bonded

agregates of imidazole in solution.

Studies of the Hydrous Tin(IV) Oxide Ion Exchanger. V. The Sodium Isotopic Exchange Rate between the Exchanger in the Na^+ Form and Aqueous Solutions

Yasushi INOUE,* Hiromichi YAMAZAKI, and Akira OSAWA
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received July 15, 1985)

The sodium isotopic exchange rate between the hydrous tin(IV) oxide ion exchanger in the Na^+ form and aqueous solutions was determined radiochemically. When the dried exchanger was used, the rate of the first step was controlled by the rate of the equilibration of water in the exchanger with the solutions, while the second step was found to be controlled by the diffusion of sodium ions in the particles (particle diffusion). When the exchanger had been sufficiently immersed in solutions in advance, the particle diffusion controlled the rate from the beginning. From the dependency of the rate of particle diffusion on the apparent particle size and the specific surface area of the exchanger, and on the sodium-ion concentrations in the solutions, the process controlling the rate is considered to be the diffusion in the primary particles, which are formed at the initial stage of precipitation and which aggregate to form the hydrous tin(IV) oxide gel. The diffusion constants and their activation energy (35±2 KJ mol^{-1}) were also evaluated.

The ion-exchange equilibrium, the effect of thermal treatment, and other important properties were previously studied on a hydrous tin(IV) oxide ion exchanger prepared by the method recommended by the present authors.[1] Although the investigation of ion-exchange kinetics is very important for understanding the ion-exchange mechanism of the material, there has been only a little information to date. The measurement of the isotopic exchange rate of cations between the corresponding salt forms of ion exchangers and aqueous solutions is especially interesting because it provides fundamental data which are useful for elucidating ion-exchange kinetics.

This paper will deal with the results of radiochemical experiments undertaken to measure the isotopic exchange rate of sodium ions between the hydrous tin(IV) oxide in the Na^+ form and aqueous solutions of sodium salts.

Experimental

Preparation of the Exchanger in the Na^+ Form Spiked with ^{22}Na. The hydrous tin(IV) oxide prepared by the method recommended previously was classified into three particle sizes by using Japan Industrial Standard sieves; it was then converted to the H^+ form by treating it with a 0.1 mol dm^{-3} HCl solution.[1] The exchanger was air-dried and stored in a desiccator containing a saturated NH_4Cl solution. Table 1 shows the particle size and some properties of each sample. The average particle radius was estimated by approximating the particle shape to a sphere by means of this equation: $4/3\pi r^3\rho N=W$, where ρ is the density of the sample, and N, the number of particles per W g, as counted under an optical microscope.

The exchanger in the H^+ form was converted to the Na^+ form by treating it with solutions, prepared by the desired combinations of NaCl and NaOH (pH 11), with the same compositions as those used for the rate measurement. The exchanger in the Na^+ form was then labeled with ^{22}Na by equilibrating it with a ^{22}Na solution having the same chemical compositions as the above solutions for about 2 d at room temperature. After having been washed with the solutions (free from ^{22}Na) used for converting to the Na^+ form, the exchanger was used for the rate measurement (wet system), or it was dried again to a constant weight over a saturated NH_4Cl solution and then also used for the experiments (dried system).

Apparatus and the Measurement of the Isotopic Exchange Rate. All the experiments were performed in a nitrogen atmosphere. The rate was measured in solutions with the same compositions as those used for converting the exchanger to the Na^+ form, by using the same apparatus as before.[2] Otherwise, an ion-exchange reaction occurs between H^+ and Na^+ ions, since the ion-exchange capacity for Na^+ strongly depends on the pH and on the concentration of the solution.[1] A 0.2-g to 0.5-g portion of the sample was placed in the cage and immesed in 200 cm^3 of a solution of a desired composition while the cage was being rotated. The frequency of revolution was measured

with a Yokogawa, Model 2607, Photo Tachometer. The solution had been adjusted in advance to a constant temperature within ±0.1 °C. Aliquots of the solution (0.2 cm^3) were taken out at appropriate time intervals in order to measure the radioactivity with a well-type NaI(Tl) scintillation counter (Fuji Denki Model NHS-2). The time of contact of the exchanger with the solution was taken as the time elapsing between the immersion of the cage and the withdrawal of an aliquot of the solution. The fractional attainment of equilibrium, $F(t)=C_t/C_\infty$, was calculated from these results; here, C_t is the total radioactivity of the solution at time t and C_∞ at $t=\infty$. C_∞ was calculated by means of this equation: $C_\infty=CM/(M+m)$, where C is the initial total radioactivity of the exchanger, and m and M, the total amounts of Na^+ in the exchanger and in the solution respectively. Although the rate measurement is for a limited solution-volume condition, the infinite solution-volume approximation is closely obeyed under the present experimental conditions (less than 0.5 g of the exchanger per 200 cm^3 of the solutions).

The specific surface area of the sample was determined by the BET method (N_2 adsorption at −196 °C) using a Perkin-Elmer Shell Model 212D Sorptometer.

Results and Discussion

The sodium isotopic exchange rate was measured with two types of sample: (a) as dried and (b) wet. The results for each type of experiment will be described separately for convenience.

(1) Dried System. In order to ascertain the efficiency of agitation, the effect of the stirring rate on the half-exchange time was examined for pH-11 solutions of different NaCl concentrations. The time required for half-exchange ($t_{1/2}$) became shorter as the revolution rate increased, and reached a constant value at 1200 min^{-1}. Furthermore, it was confirmed that no particles were broken down during the agitation. On the basis of these results, a revolution rate of 1300 min^{-1} was adopted throughout the experiment for the dried system.

Figure 1 shows a comparison of the isotopic exchange rates in 0.01 mol dm^{-3} solutions of different sodium salts, indicating that no difference was observed in the rates between anions in the solution. This observation also held when the concentration of Na^+ was varied up to 1 mol dm^{-3}.

Figure 2 shows the influence of the sodium-ion concentration on the rate. When the concentration was higher than 0.5 mol dm^{-3}, the rate was independent of the concentration. When the concentration was less than 0.5 mol dm^{-3}, however, the rate increased with the concentration. It can be considered, from the dependence of the rate on the sodium-ion cencentration, that the rate is determined by either the diffusion of sodium ions in the adherent film (film diffusion) or by a chemical reaction at the exchange site. Since the sodium ions in the exchanger phase are in equilibrium with those in the solution phase, in the isotopic exchange reaction no concentration gradient of sodium ions exists in the film. Hence, the rate of the isotopic exchange would seem to be independent of the concentration of the sodium ion, unless the self-diffusion rate of sodium ions in solutions depends on the sodium-ion concentration. As the self-diffusion coefficients in NaCl solutions are almost constant in the concentration range lower than 1 mol dm^{-3}, the film diffusion cannot be the rate-controlling step. Furthermore, the chemical reacion in the exchanger does not appear to control the rate, because all the sodium ions in the exchanger exist as dissociated ions and, therefore, will exchange instantaneously with the incoming ions at the exchange sites.

When the exchange rate is controlled by the diffusion of ions within the particles (particle

diffusion), the sodium-ion concentration of a solution does not affect the rate, provided that the structure of the exchanger is unchanged and the change in the ionic composition of the exchanger does not affect the self-diffusion coefficients of sodium ions in the particles. Figure 3 shows the composition of the exchanger as a function of the sodium-ion concentration of the solutions. This figure suggests a strong correlation between the $t_{1/2}$ and the exchange capacity of the samples; the $t_{1/2}$ markedly changed with the sodium-ion concentration in the range lower than 0.5 mol dm^{-3}, where the capacity changed with the concentration, while it was unchanged in the concentration range higher than 0.5 mol dm^{-3}, where the capacity was nearly constant. Therefore, it appears to the present authors that the isotopic exchange rate is controlled by the particle diffusion and that the diffusion coefficients are affected by the composition of the exchanger.

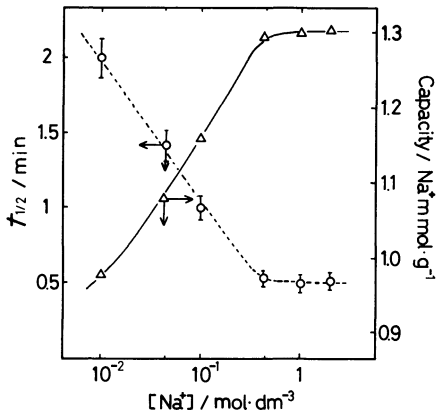

Fig. 3. Effect of Na^+ concentration on the half-exchange time and the exchange capacity (Dried system).

Figure 4 shows the results of the method called "interruption test"; the exchangers were removed from the solution for 1 h and then reimmersed. In any concentration of sodium ions, the rate immediately after reimmersion was greater than that prior to the interruption. When these findings are combined with the above discussion, it can be concluded that, in solutions of any concentration, the rate is controlled by the particle diffusion.

When the isotopic exchange rates are controlled by the diffusion of ions in spherical exchangers immersed in a well-stirred solution of approximately an infinite volume, the fractional attainment of equilibrium can be obtained by solving this equation:[3]

$$F(t) = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp\left(-\frac{\pi^2 Dn^2 t}{r^2}\right), \quad (1)$$

where D is the self-diffusion coefficient of the ions in the exchanger and where r refers to the radius of the particles. When F is less than about 0.4, Eq. 1 is approximated by a simpler form:

$$F(t) = \frac{6}{r}\left(\frac{Dt}{\pi}\right)^{1/2}, \quad (2)$$

which gives a fairly good approximation.[4] Therefore, a plot of F against the square root of the contact time must give a straight line passing through the point of origin in the region of F less than 0.4.

Figure 5 shows the effect of the particle size on the rate. A linear relation with the same slope between F and $\sqrt{t}$ held, irrespective of the particle size, but the straight lines did not pass through the point of origin; the displacement of the intercept from the origin increased with the particle size. In order to clarify the rate of the initial portion of the exchange reaciton, the effect of the particle size on the rate was

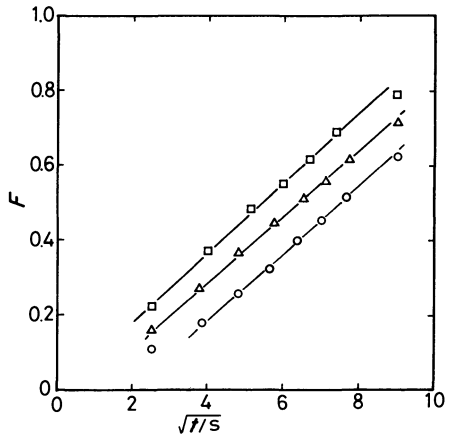

Fig. 5. Effect of particle size on the isotopic exchange rates (Dried system, I).
Temperature, 5 °C; 0.1 mol dm^{-3} Na(Cl,OH); pH, 11.0. Particle size/mesh; ○: −70+100, △: −100+145, □: −145+200.

measured under conditions of a slower rate (sodium-ion concentration, 0.01 mol dm^{-3}; revolution rate, 400 min^{-1}). The results are shown in Fig. 6. The F vs. $\sqrt{t}$ curves consist of two linear parts; the rate of exchange decreased with the particle size in the first step ($F<0.2$), but not in the second step. The latter step corresponds to the curves in Fig. 5. When the rate of this step is controlled by the particle diffusion, as has been claimed previously, the rate should depend on the particle size (Eq. 2). The experimental data, however, do not support this view. To solve the discrepancy, the specific surface area of each sample was determined; the results are shown in Table 1. This indicates that the surface areas of all the samples are the same, regardless of their apparent particle sizes. This can be understood by considering that the particles of the hydrous tin(IV) oxide are aggregates of the crystallites, subsequently called "primary particles," which have been produced at the beginning of precipitation, and that the surface area measured by the BET method is the internal surface attributable to the primary particles. If the diffusion of Na^+ within the primary particles is rate-controlling, the independence of the rate from the apparent particle size can be easily explained, since the size of the primary particles is irrelevant to the apparent particle sizes. When the shape of the primary particle is assumed to be spherical, the radius of the crystallite, r, can be calculated as $r=3/\rho S$, where ρ is the density (g cm^{-3}), and S, the specific surface area (cm^2 g^{-1}), of the exchanger. From the results in Table 1 the radius of the primary particle can be calculated to be $(4.9\pm0.3)\times10^{-7}$ cm.

Goodman and Gregg confirmed the existence of crystallites of hydrous tin(IV) oxide dried at 300 °C and determined their size ($1.5-8.0\times10^{-7}$ cm) with an electron microscope.[5] Heitner and Albu pointed out the possibility that hydrous thorium(IV) oxide is an aggregate of smaller units.[6] Hence, it is natural to consider that the particle of hydrous tin(IV) oxide consists of primary particles.

Provided the particle diffusion in the primary particles is rate-controlling, the ions should diffuse fast through the openings of the gel. In order for the ions to diffuse rapidly, these must be sufficient water in the openings. The water content of the dried sample is, however, less than that of the wet sample equilibrated with the test solutions, as is shown in Table 2. On the other hand, the rate of the penetration of the solution may reasonably be assumed to be faster into the smaller than into the larger particles. On the basis of these discussions, the rate of the first step is considered to be controlled by the rate of the equilibration of the water in the exchanger.

In conclusion, the rate of the exchange reaction on the dried system is initially controlled by the rate of the penetration of the solution into the particles, and subsequently by the diffusion rate of ions in the primary particles. In order to examine the latter step in detail, experiments were also carried out on the wet system.

(2) Wet System. In the wet system, the rate of

the exchange reaction became constant at a revolution rate greater than 1000 min^{-1}, irrespective of the sodium-ion concentration. Hence, a revolution rate of 1100 min^{-1} was adopted throughout the subsequent experiments.

Figure 7 indicates that the dependency of the rate on the sodium-ion concentration was similar to that for the dried system (Fig. 2) and that the straight lines between F and $\sqrt{t}$ in the F range smaller than about 0.5 passed through the point of origin. This relation means that the rate is controlled by the particle diffusion from the beginning of the reacion.

The effect of the particle size on the rate is shown in Fig. 8, which indicates that the rate is controlled by the diffusion of sodium ions within the primary particles, since it was independent of the particle size, in the same manner as in the second step in the dried system.

The fractional attainment of equilibrium against the square root of the time was studied in sodium-ion solutions of 0.01 and 1 mol dm^{-3} as a function of the temperature, as is shown in Fig. 9. The figure indicates that the rate of the exchange reaction increased with the temperature. The self-diffusion coefficients of sodium ions, D, were then evaluated by means of Eq. 2 from the slopes of the straight lines and the average radius of the primary particles. These values are summarized in Table 3. When log D was plotted against $1/T$, a good linearity was obtained. From the Arrhenius equation, $D = D_0 \exp(-E_a/RT)$, the activation energy, E_a, and the constant, D_0, were determined. As the activation energies obtained in solutions of 0.01 and 1 mol dm^{-3} agreed well with each other, the mechanism of the diffusion of sodium ions in the exchanger is considered to be unchanged by the compositions of the exchangers. The self-diffusion coefficients of sodium ions at 5 °C have been reported by Barrer and Rees, and by Dyer and Gill, to be 2.1×10^{-18} $m^2 s^{-1}$ in analcite and 2.0×10^{-17} $m^2 s^{-1}$ in crystalline zirconium(IV) phosphate respectively.[7,8] These values are larger than the present results. The $t_{1/2}$ is, however, considerably shorter for hydrous tin(IV) oxide (a few minutes) than for analcite and

crystalline zirconium(IV) phosphate (a few hours), because in the case of the hydrous tin(IV) oxide, the particle size practically controlling the exchange rate is smaller than the apparent particle size. Such a fast exchange rate for the hydrous tin(IV) oxide is of great practical value.

Homogeneous Asymmetric Hydrogenation Using a Chiral Phosphinite Derivative of Carbohydrates as Ligand

Mitsuji YAMASHITA,* Mineaki KOBAYASHI, Motoyuki SUGIURA, Kenji TSUNEKAWA, Tatsuo OSHIKAWA, Saburo INOKAWA,† and Hiroshi YAMAMOTO†

(Received May 16, 1985)

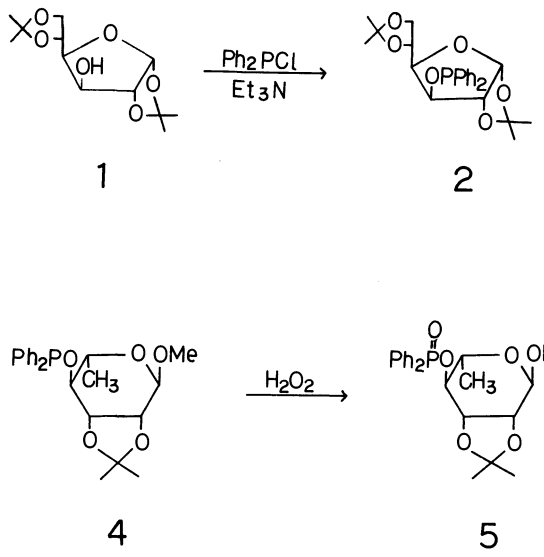
Diphenylphosphinite derivatives of sugars were conveniently synthesized by the reaction of diphenylphosphinous chloride–triethylamine with sugar derivatives. Homogeneous asymmetric hydrogenations of several prochiral olefins, i.e., (*Z*)-α-acetylaminocinnamic acid, (*Z*)-α-benzoylaminocinnamic acid, itaconic acid, tiglic acid, and their esters, were carried out using rhodium(I) catalysts with the tervalent chiral phosphorus derivative of sugars. The highest optical yields for all the prochiral substrates investigated were obtained when di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and methyl 2,3-*O*-isopropylidene-4-*O*-(diphenylphosphino)-α-L-rhamnopyranoside were used.

Homogeneous catalytic hydrogenation of olefins have been widely investigated since Wilkinson's work on chlorotris(triphenylphosphine)rhodium(I) was published.[1,2] Monosaccharides have several chiral carbon atoms in their skeletons, however, their application to homogeneous asymmetric hydrogenation of prochiral materials are found only in a few papers.[3–7] Bis-phosphinite of cellulose was used as a chiral ligand for a rhodium catalyst because of the more rigid conformation of the oxacylohexane ring than the cyclohexane ring of cyclohexane-1,2-diol.[8]

In our preceding paper we reported the asymmetric hydrogenation of a prochiral unsaturated acid such as (*Z*)-α-acetylaminocinnamic acid to afford the corresponding saturated acid in an optical yield of up to 67%, where 1,2:3,4-di-*O*-isopropylidene-6-*O*-(diphenylphosphino)-α-D-galactopyranose was revealed to be a good ligand.[9] The result suggested that the *O*-diphenylphosphino derivative of the carbohydrate afforded a higher optical yield than did the *C*-diphenylphosphino. In general, it is known that the nearer the chiral center is located to the ligand center the higher will be the optical yield on homogeneous asymmetric hydrogenation. Hence the synthesis of a dinuclear phosphorus ligand is more difficult than that of a mononuclear phosphorus ligand.[10,11] On the basis of the above standpoint much attention has been focussed on phosphinite derivatives of carbohydrate. The present paper deals with the facile synthesis of carbohydrates having a carbon–oxygen–phosphorus linkage on the hemiacetal ring and their successful application for asymmetric hydrogenation of olefins as an efficient ligand for the rhodium(I) catalyst.

Results and Discussion

Synthesis of Chiral Phosphinite Ligand from Carbohydrates. 1,2:5,6-Di-*O*-isopropylidene-3-*O*-(diphenylphosphino)-α-D-glucofuranose (**2**) was prepared from 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**1**) by treatment with diphenylphosphinous chloride in the presence of triethylamine in 73% yield. Methyl 2,3-*O*-isopropylidene-4-*O*-(diphenylphosphino)-α-L-rhamnopyranoside (**4**) was synthesized by a reported method,[9] and was oxidized with hydrogen peroxide giving oxide **5** in quantitative yield (Scheme 1) for the purpose of confirmation of compound **4**.



Asymmetric Hydrogenation of Prochiral Olefins. Asymmetric hydrogenation of prochiral olefins such as (*Z*)-α-acetylaminocinnamic acid, methyl (*Z*)-α-acetylaminocinnamate, (*Z*)-α-benzoylaminocinnamic acid, itaconic acid, dimethyl itaconate, and tiglic acid were carried out. The hydrogenation using glucose derivative **2** as the chiral ligand for di-μ-chloro-bis(cyclooctadiene)dirhodium(I) complex proceeded in 100% chemical yield for such a substrate as (*Z*)-α-acetylaminocinnamic acid to afford *N*-acetylphenylalanine. However, the optical yield was 10% with the *R* configuration, which did not improve over the previous work.[9] The results are shown in Table 1. The complex was not effective enough for the asymmetric hydrogenation.

The asymmetric hydrogenation of prochiral olefins

in the presence of di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and rhamnose **4** gave the good results summarized in Table 2. Pure dimethyl (*S*)-methylsuccinate was prepared from dimethyl itaconate. Therefore, **4** should be a better ligand for the asymmetric hydrogenation than **2**. The asymmetric hydrogenation of (*Z*)-α-benzoylaminocinnamic and itaconic acids by chloro-bis(cyclooctene)rhodium(I) in the presence of chiral ligand **4** afforded the hydrogenation product in lower optical yields than

a) The ratios of substrate to Rh(I) complex and of ligand **2** to Rh(I) complex were 25:1 and 4:1, respectively. All hydrogenations were carried out in 10 ml of benzene–ethanol (1:1, v/v) in the presence of 0.2 ml of triethylamine at room temperature under atmospheric pressure of hydrogen for 24 h.

Table 2. Asymmetric Hydrogenation of Prochiral Olefins with $[(C_8H_{12})RhCl_2Rh(C_8H_{12})]$-Ligand **4**[a]

Substrate	Product	Chemical yield/%	$[\alpha]_D^{14}$/° (Solvent)	Optical yield/%	Configuration
(*Z*)-α-Acetylaminocinnamic acid	*N*-Acetylphenylalanine	100	−22.1 (*c* 1.0, EtOH)	48	(*R*)
Methyl (*Z*)-α-Acetylaminocinnamate	*N*-Acetylphenylalanine methyl ester	96	− 8.70 (*c* 1.0, MeOH)	41	(*R*)
(*Z*)-α-Benzoylaminocinnamic acid	*N*-Benzoylphenylalanine	100	+31.1 (*c* 1.0, MeOH)	78	(*R*)
Itaconic acid	Methylsuccinic acid	100	−11.6 (*c* 4.3, EtOH)	68	(*S*)
Dimethyl itaconate	Dimethyl methylsuccinate	100	−17.0 (*c* 1.0, EtOH)[b]	100	(*S*)
Tiglic acid	2-Methylbutyric acid	100	−12.5 (*c* 1.0, EtOH)	65	(*R*)

a) The ratios of substrate to Rh(I) complex and of ligand **4** to Rh(I) complex were 25:1 and 4:1, respectively. All hydrogenations were carried out in 10 ml of benzene–ethanol (1:1, v/v) in the presence of 0.2 ml of triethylamine at room temperature under atmospheric pressure of hydrogen for 24 h. b) The value is for methylsuccinic acid, the hydrolysis product of dimethyl methylsuccinate.

Table 3. Asymmetric Hydrogenation of Prochiral Olefins with $[RhCl(C_8H_{14})_2]$-Ligand **4**[a]

Substrate	Product	Chemical yield/%	$[\alpha]_D^{14}$/° (Solvent)	Optical yield/%	Configuration
(*Z*)-α-Benzoylaminocinnamic acid	*N*-Benzoylphenylalanine	100	+3.40 (*c* 1.0, MeOH)	8	(*R*)
Itaconic acid	Methylsuccinic acid	100	−0.65 (*c* 4.3, EtOH)	4	(*S*)

a) The ratios of substrate to Rh(I) complex and of ligand **4** to Rh(I) complex were 25:1 and 2:1, respectively. All hydrogenations were carried out in 10 ml of benzene–ethanol (1:1, v/v) in the presence of 0.2 ml of triethylamine at room temperature under atmospheric pressure of hydrogen for 24 h.

that by di-μ-chloro-bis(cyclooctadiene)dirhodium(I) as shown in Table 3.

These results indicate that the efficiency of chiral phosphinite **4** is good enough for the asymmetric hydrogenation of prochiral olefins compared with the reported results using the ligand of carbohydrate derivatives.[9,12] This procedure seems to be a simple and efficient way for the asymmetric hydrogenation of prochiral olefins, especially for dimethyl itaconate, owing to the convenience in the ligand synthesis and to the improvement affording comparatively high optical yields.

Experimental

Measurements. ^{1}H-NMR spectra were measured on a Hitachi R-24 (60 MHz) spectrometer with tetramethylsilane as an internal standard, and IR spectra on a Japan Spectroscopic Co. Ltd. A-3 infrared spectrophotometer. Optical rotations were measured on Japan Spectroscopic Co. Ltd. DIP-4 digital polarimeter. Melting (measured by Yanagimoto micro melting apparatus) and boiling points are uncorrected.

Materials. The following materials were synthesized according to reported methods: (*Z*)-α-acetylaminocinnamic acid,[13] (*Z*)-α-benzoylaminocinnamic acid,[14] methyl (*Z*)-α-acetylaminocinnamate,[15] dimethyl itaconate,[15] 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**1**),[16] methyl 2,3-*O*-isopropylidene-α-L-rhamnopyranoside (**3**),[17] diphenylphosphinous chloride (bp 110 °C/0.5 mmHg[18]),[19] chloro-bis(cyclooctene)rhodium(I),[20] di-μ-chloro-bis(cyclooctadiene)dirhodium(I),[21] and methyl 2,3-*O*-isopropylidene-4-*O*-(diphenylphosphino)-α-L-rhamnopyranoside (**4**).[9]

Preparation of 1,2:5,6-Di-*O*-isopropylidene-3-*O*-(diphenylphosphino)-α-D-glucofuranose (2). Reaction of diphenylphosphinous chloride (3.0 g) with glucose **1** (3.5 g) in triethylamine for 24 h at room temperature under nitrogen atmosphere followed by filtration and evaporation in vacuo gave compound **2** (4.4 g) in 73% yield. The purity was checked by TLC on silica gel (eluent; ethyl acetate:petroleum ether=**1**:**1** v/v, R_f=0.77); $[\alpha]_D^{14}$=−12.9° (*c* 0.65, MeOH). ^{1}H-NMR ($CDCl_3$) δ=1.25, 1.30, 1.45, 1.50 (4s, 12H, $2CMe_2$), 3.8—4.2 (m, 6H, $C_{2-6,6'}$-H), 6.00 (d, 1H, *J*=4.5 Hz, C_1-H), 7.1—7.9 (m, 10H, 2Ph); IR ν_{max}^{neat} (cm^{-1}) 1440 (P-Ph), 1040 (P-O-C); MS, *m/z*, 444 (M^+, $C_{24}H_{29}O_6P$).

Oxidation of Compound 4. Oxidation of compound **4** (0.11 g) with 30% hydrogen peroxide (0.034 ml) in chloroform (2 ml)-methanol (1 ml) overnight at room temperature followed by work-up with sodium thiosulfate afforded methyl 2,3-*O*-isopropylidene-4-*O*-(diphenylphosphinyl)-α-L-rhamnopyranoside (**5**, 0.12 g) in quantitative yield. The purity was confirmed by HPLC (eluent; chloroform:methanol=20:1, retention time 6.5 min). ^{1}H-NMR ($CDCl_3$) δ=1.24 (d, 3H, *J*=5.4 Hz, C_5-Me), 1.41, 1.51 (2s, 6H, CMe_2), 3.33 (s, 3H, OMe), 3.8—4.4 (m, 4H, C_{2-5}-H), 4.79 (s, 1H, C_1-H), 7.0—8.0 (m, 10H, 2Ph); IR ν_{max}^{neat} (cm^{-1}) 1442 (P-Ph), 1225 (P=O), 1030 (P-O-C).

Found: *m/z* 419.1661. Calcd for $C_{22}H_{28}O_6P$: M+1, 419.1622.

Asymmetric Hydrogenation of (*Z*)-α-Acetylaminocinnamic Acid with Di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and Ligand 4. Asymmetric hydrogenation of (*Z*)-α-acetylaminocinnamic acid (500 mg) in anhydrous benzene (5 ml)-absolute ethanol (5 ml) was carried out using di-μ-chloro-bis(cyclooctadiene)dirhodium(I) (49 mg) and ligand **4** (160 mg) as catalyst in the presence of triethylamine (0.2 ml) under atmospheric pressure of hydrogen at room temperature for 24 h. Removal of the catalyst by passage through a column packed with ion-exchange resin Amberlite IRC-50 (H^+), followed by decolorization with activated charcoal and removal of the solvent in vacuo, gave *N*-acetylphenylalanine (100% conversion). The identification of the product was performed by ^{1}H-NMR, whose spectrum was as follows: ^{1}H-NMR ($CDCl_3$) δ=2.06 (s, 3H, COMe), 3.15 (d, 2H, *J*=6.0 Hz, $PhC\underline{H}_2$), 4.75 (t, 1H, *J*=6.0 Hz, CH), 7.1—7.4 (m, 5H, Ph); MS, *m/z*, 207 (M^+). The product had $[\alpha]_D^{14}$=−22.1° (*c*, 1.0, EtOH), which showed 48% optical yield of the *R* configuration.[22]

Removal of the catalyst from the hydrogenation mixture with ion-exchange resin Dowex 50 W (H^+) gave *N*-acetylphenylalanine methyl ester (100% conversion), which was esterified with eluent methanol.

Asymmetric Hydrogenation of Methyl (*Z*)-α-Acetylaminocinnamate with Di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and Ligand 4. Asymmetric hydrogenation of methyl (*Z*)-α-acetylaminocinnamate (500 mg) was carried out by the same method as mentioned for (*Z*)-α-acetylaminocinnamic acid using ion exchange resine Dowex 50 W (H^+) gave *N*-acetylphenylalanine methyl ester (100% conversion); ^{1}H-NMR ($CDCl_3$) δ=2.07 (s, 3H, COMe), 3.15 (d, 2H, *J*=6.0 Hz, $PhC\underline{H}_2$), 3.75 (s, 3H, OMe), 4.6—4.9 (m, 1H, CH), 6.05 (bd, 1H, *J*=7.5 Hz, NH), 6.9—7.4 (m, 5H, Ph); MS, *m/z*, 221 (M^+, $C_{12}H_{15}NO_3$). The product showed $[\alpha]_D^{14}$=−8.70° (*c* 1.0, MeOH), which indicated 41% optical yield of the *R* configuration.[23]

Asymmetric Hydrogenation of Dimethyl Itaconate with Di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and Ligand 4. Asymmetric hydrogenation of dimethyl itaconate (250 mg) in anhydrous benzene (5 ml)-absolute ethanol (5 ml) was carried out using di-μ-chloro-bis(cyclooctadiene)dirhodium(I) (32 mg) and ligand **4** (103 mg) as the catalyst in the presence of triethylamine (0.2 ml) under atmospheric pressure of hydrogen for 24 h at room temperature. Removal of the catalyst by passing a column packed with ion exchange resin Dowex 50 W (H^+), followed by decolorization with activated charcoal and removal of the solvent in vacuo, gave dimethyl methylsuccinate quantitatively, ^{1}H-NMR ($CDCl_3$) δ=1.15 (d, 3H, *J*=7.0 Hz, $C\underline{H}_3CH$), 2.1—3.3 (m, 3H, $CHCH_2$), 3.67 (s, 3H, $CHCO_2\underline{Me}$) 3.72 (s, 3H, CO_2Me). Alkaline hydrolysis of the ester at room temperature gave methylsuccinic acid, $[\alpha]_D^{14}$=−17.0° (*c* 1.0, EtOH), indicating 100% optical yield of the *S* configuration.[3,24] Treatment of methylsuccinic acid with diazomethane[25] in ether gave the dimethyl ester, $[\alpha]_D^{14}$=−6.1° (*c* 1.0, EtOH).[24]

Asymmetric hydrogenation of prochiral olefins with di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and ligand **4** gave the corresponding product as shown in Table 2. The optical yields of the products were calculated based on the reported values of optical rotation for *N*-acetyl-(*S*)-phenylalanine, $[\alpha]_D^{26}$ +46.0° (*c* 1.0, EtOH);[22] *N*-acetyl-(*S*)-phenylalanine methyl ester, $[\alpha]_D^{25}$ +21.4° (*c* 2.0, MeOH);[23] *N*-benzoyl-(*S*)-phenylalanine, $[\alpha]_D^{27}$=−40.3° (*c* 1.0, MeOH);[26] (*R*)-methylsuccinic acid, $[\alpha]_D^{18}$ +17.01° (*c* 4.41, EtOH);[3,24]

dimethyl (*R*)-methylsuccinate, $[\alpha]_D^{25}$ +6.11° (neat);[24] and (*S*)-2-methylbutyric acid, $[\alpha]_D$ +19.33°.[28]

Asymmetric Hydrogenation of (*Z*)-α-Acetylaminocinnamic Acid with Chloro bis(cyclooctene)rhodium(I) and Ligand 4. Asymmetric hydrogenation of (*Z*)-α-acetylaminocinnamic acid (500 mg) in anhydrous benzene–absolute ethanol (1:1 v/v, 10 ml) was carried out using chlorobis(cyclooctene)rhodium(I) (27 mg) and ligand **4** (60 mg) as the catalyst in the presence of triethylamine (0.2 ml) under atmospheric pressure of hydrogen at room temperature for 24 h. Removal of the catalyst and work-up as described for the asymmetric hydrogenation with di-μ-chloro-bis(cyclooctadiene)dirhodium(I) gave *N*-acetylphenylalanine (100% conversion); $[\alpha]_D^{14}$=+3.40° (*c* 1.0, MeOH), indicating an optical yield 8% of the *R* configuration.

Results for asymmetric hydrogenation with chlorobis(cyclooctene)rhodium(I) and ligand **4** were summarized in Table 3.

Asymmetric Hydrogenation of (*Z*)-α-Acetylaminocinnamic Acid with Di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and Ligand 2. Asymmetric hydrogenation of (*Z*)-α-acetylaminocinnamic acid (500 mg) in anhydrous benzene–absolute ethanol (1:1 v/v, 10 ml) was carried out using di-μ-chloro-bis(cyclooctadiene)dirhodium(I) (49 mg) and ligand **2** (178 mg) as the catalyst in the presence of triethylamine (0.2 ml) under atmospheric pressure of hydrogen at room temperature for 24 h. Removal of the catalyst and work-up as mentioned for asymmetric hydrogenation using ligand **4** gave *N*-acetylphenylalanine (100% conversion); $[\alpha]_D^{14}$=−4.50° (*c* 1.0, EtOH), optical yield of 10% of the *R* configuration.

The results obtained for several prochiral olefins are shown in Table 1.

Reactions of α-Polyhalo Ketone Tosylhydrazones with Sulfide Ion and Primary Amines. Cyclization to 1,2,3-Thiadiazoles and 1,2,3-Triazoles

Kunikazu SAKAI,* Nobuko HIDA, and Kiyosi KONDO
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received June 27, 1985)

Trichloroacetaldehyde tosylhydrazone acts as an excellent precursor of diazodithioacetate which is generated by treatment of the hydrazone with sulfide ion. This spontaneously cyclizes it to 5-mercapto-1,2,3-thiadiazole. The precursor also gives a 5-amino-1,2,3-triazole on reaction with an amine. α,α-Dichloro ketone tosylhydrazones similarly cyclize to give 1,2,3-thiadiazoles and 1,2,3-triazoles.

Heterocycles, such as 1,2,3-thiadiazoles and 1,2,3-triazoles are useful for various purposes such as modifiers of cephalosporin antibiotoics,[1] or precursors of herbicides[2] or insecticides.[3] For the synthesis of 1,2,3-heterocycles, such as 1,2,3-thiadiazoles and 1,2,3-triazoles, several methods have been developed. Among them, for example, is the preparation of 1,2,3-thiadiazoles by the 1,3-dipolar [2+3] cycloaddition of diazomethane with a thioketone as shown in Fig. 1.[4]

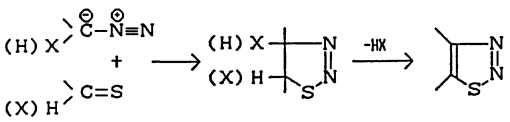

Fig. 1.

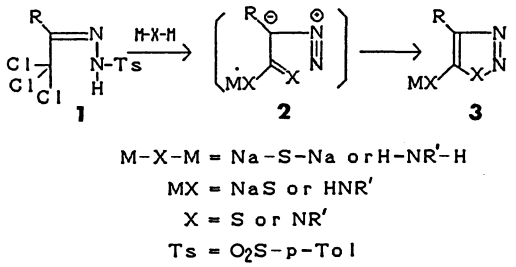
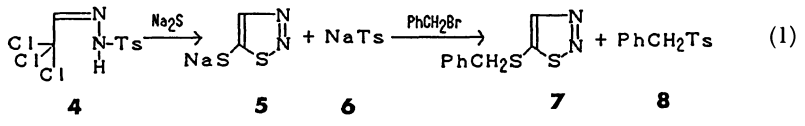
The synthesis of 1,2,3-heterocycles **3** was achieved by the intramolecular cyclization of the intermediate **2** as shown in Scheme 1. For the preparation of 1,2,3-thiadiazole **3** (X=S), diazothioacetate **2** (X=S) is considered as a potential precursor, because **2** (X=S) has the moieties of both the diazo and thiocarbonyl groups in the molecule, which are necessary for the cyclization to the 1,2,3-thiadiazole. However, the diazothioacetate **2** (X=S) is an unknown hypothetical compound, differing from the diazoacetate **2** (X=O). The intermediate **2** (X=S) is thought to be so labile that it will cyclize spontaneously to 1,2,3-thiadiazole **3** (X=S). Here, we chose the α-polyhalo ketone tosylhydrazone **1** as the precursor for the generation of the labile **2** (X=S) and cyclization to **3** (X=S). Similarly diazoacetamidinate **2** (X=NR′) will be generated from the common precursor **1** and **2** (X=NR′) will cyclize to 1,2,3-triazole **3** (X=NR′). Because, the trichloromethyl group in **1** is an equivalent of dithiocaboxylate, C(=S)-SNa, by treatment with Na_2S, and it is also an equivalent of amidine, C(=NR′)-NHR′, by the treatment with H_2NR'. On the other hand, the generation of a diazo group from tosyl hydrazone by treatment with base is well-known as the Bamford-Stevens reaction.[5] Thus, the treatment of **1** with sulfide ion or amine will induce concurrent or stepwise reactions, and will generate labile **2** which will spontaneously cyclize to **3**. Based on the above considerations and analysis, we have developed the intramolecular cyclization method successfully, and we will demonstrate the results of several reactions of α-polyhalo ketone tosylhydrazones with sulfide ion and amines to cyclize to 1,2,3-thiadiazole and 1,2,3-triazole, respectively.



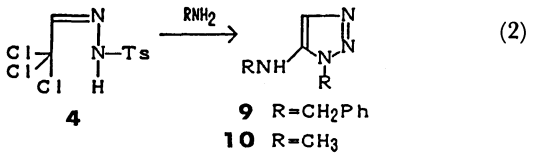
M-X-M = Na-S-Na or H-NR′-H
MX = NaS or HNR′
X = S or NR′
Ts = O_2S-p-Tol

Scheme 1.

Trichloroacetaldehyde tosylhydrazone (**4**), a precursor of the reactive intermediate **2** (X=S, MX=NaS), is a known compound and was prepared as described in the literature.[6] The cyclization reaction was carried out as follows: Into a solution of 3 equivalents of sodium sulfide nonahydrate ($Na_2S \cdot 9H_2O$) in 50% aqueous ethanol, hydrazone **4** was added. The solution was concentrated and the deposited crystals collected. Treatment of the crystals with benzyl bromide gave 5-benzylthio-1,2,3-thiadiazole (**7**) in 67% yield and benzyl *p*-tolyl sulfone (**8**) in 41% yield, as shown in Eq. 3. The result suggested that the deposited crystals were composed of sodium 1,2,3-thiadiazol-5-yl sulfide (**5**) and sodium *p*-toluenesulfinate (**6**). In practice, an attempt to separate them by fractional recrystallization from ethanol gave **5** and **6** in 60 and 84% yields. The reaction yielded the 1,2,3-thiadiazole **5** via intramolecular cyclization of the reactive intermediate **2** generated from the precursor **4**. This result encouraged us to extend the reaction using other bases, such as amines and hydroxide ion.

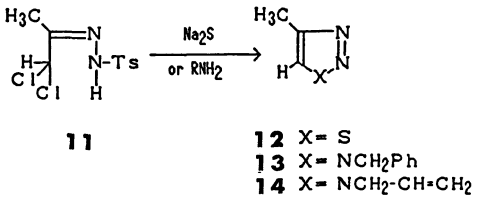


Accordingly, amines were allowed to react with **4**. Although treatment with aqueous ammonia provided no identified materials, a treatment with excess benzylamine in methanol gave 1-benzyl-5-benzylamino-1,2,3-triazole (**9**) in 30% yield, along with large amounts of mixed salts of benzylamine. With methylamine, 1-methyl-5-methylamino-1,2,3-triazole (**10**) was also afforded in 25% yield (Eq. 2).

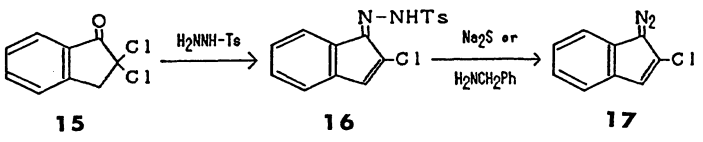


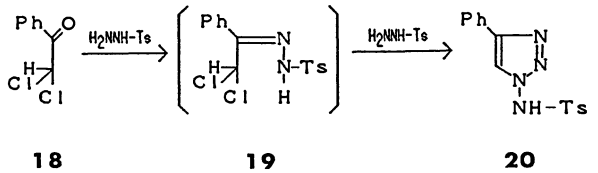
In the case of hydroxide ion, the expected reaction product of the precursor **4**, 1,2,3-oxadiazole, is known to be unstable, except for the case of sydnone.[7] In practice, treatment of **4** with sodium hydroxide solution gave no identified products.

We were next interested in the reaction of thioacetaldehyde **2** (X=S, MX=H) as the reactive intermediate. The precursor for the generation of **2** (X=S, MX=H) should be a dichloride, such as **11**. A precursor, α,α-dichloroacetone tosylhydrazone (**11**), was prepared by the same method as above for **4**.[6] By treatment of **11** with sodium sulfide, only a trace amount of 4-methyl-1,2,3-thiadiazole (**12**) was detected by NMR spectroscopy. This will be related to the volatility of the product **12**. On the other hand, reaction of **11** with excess benzylamine gave 1-benzyl-4-methyl-1,2,3-triazole (**13**), in a high yield of 84% as shown in Eq. 3. Allylamine likewise gave 1-allyl-4-methyl-1,2,3-triazole (**14**) in 83% yield. The precursor **11** also cyclized successfully.

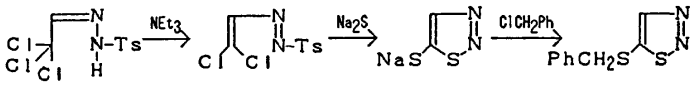


The preparation of two other α,α-dichloroketones, **15** and **18** was attempted by the cyclization reaction. By treatment with tosylhydrazine, 2,2-dichloro-1-indanone (**15**) gave 2-chloro-1-indenone tosylhydrazone (**16**) with simultaneous removal of hydrogen chloride (Eq. 4). The hydrazone **16** provided 2-chloro-1-diazoindene (**17**) as a common product, by reaction both with sodium sulfide and with benzylamine. The difficult substitution of sulfur or amine nucleophiles for a chlorine atom in **16** or **17** and stabilization of the diazo group by a benzene ring will lead to the isolation of the diazo compound **17**. On the other hand, when α,α-dichloroacetophenone (**18**) was treated with tosylhydrazine (Eq. 5), the compound isolated was unexpectedly cyclized 4-phenyl-1-(*p*-toluenesulfonamido)-1,2,3-triazole (**20**). This indicates that tosylhydrazone **19** was so labile that tosylhydrazine reacted with **19** to give **20**.



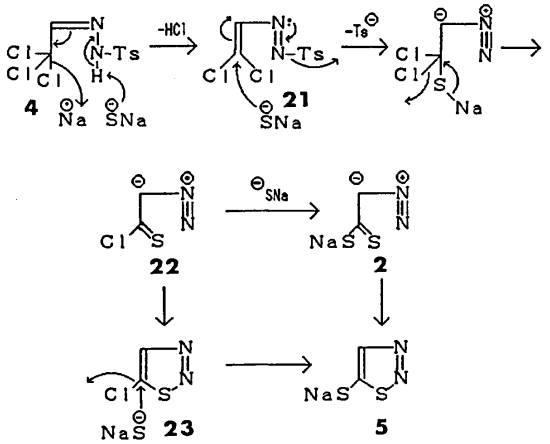


As a final example, 1,1-dichloro-2-(*p*-tolylsulfonylazo)ethene (**21**) was obtained from **4** by gentle treatment with triethylamine as reported by Bott[6] (Eq. 6). The 1,1-dichloroethenyl derivative **21** similarly cyclized to **5** by reaction with sodium sulfide; it was identified as the benzyl derivative **7**.



4 21 5 7 (6)

From the mechanistic view point, the production of 5-mercapto-1,2,3-thiadiazole (**5**) from **21** suggests that the reaction may proceed via the intermediate **21**. We can speculate that the course of the cyclization reaction is as shown in Scheme 2. According to



Scheme 2.

which, the reaction with Na_2S initiates a removal of hydrogen chloride from **4** to give a stable intermediate **21**. The addition of second sulfide ion for the substitution for chlorine atom in **21** by addition-elimination manner induces the simultaneous removal of toluenesulfinate ion to generate a diazomethane moiety to afford intermediate **22**. From **22** to the final product **5**, two routes are possible. One is that the reaction proceeds by the attack of a third sulfide ion to generate diazodithiocarboxylate **2** (X=S); alternatively cyclization may occur first, to give stable 5-chloro-1,2,3-thiadiazole (**23**). This is already known to easily substitute a sulfide ion for a chlorine atom,[8] although we could not detect it in the reaction mixture. The reaction of **4** with amines can take place by the same mechanism as shown above. However, generation of the diazo intermediate, **2** or **22**, in the course of the reaction still remains an uncertainty, because in the Bamford-Stevens reaction, the reaction conditions are generally *more drastic.*[5] *But in a particular case, such as a* monotosylhydrazone of α-diketone, it is known that the hydrazone easily gave an α-diazoketone by treatment with 0.1 M† sodium hydroxide solution at room temperature.[9] In this case the contribution of the α-carbonyl group is important for the genaration of diazo group under such mild conditions. Similarly the thiocarbonyl group may act a significant role for the smooth generation of the diazo moiety in **2** or **22**.

† 1 M=1 mol dm^{-3}.

Further detailed studies to clarify the intermediate role of the diazodithioacetate **2** are in progress.

Experimental

Measurements: All the melting points are uncorrected. NMR spectra were taken with Varian EM-390 and XL-100 instruments. Mass spectra were obtained with a Hitachi RMU-6MG instrument. IR were measured with a JASCO A-202 instrument.

Trichloroacetaldehyde Tosylhydrazone (4): This was prepared according to the method described in the literature from trichloroacetaldehyde and tosylhydrazine.[6]

Sodium 1,2,3-Thiadiazol-5-yl Sulfide (5) and Sodium *p*-Toluenesulfinate (6): To a solution of sodium sulfide ($Na_2S \cdot 9H_2O$) (18.0 g, 74.9 mmol) in 50% aqueous ethanol (40 ml) under ice-cooling, trichloroacetaldehyde tosylhydrazone (**4**) (6.31 g, 20.0 mmol) was added as powder portion wise over a period of 5 min. The stirring was continued at that temperature for 10 min and at room temperature for 1 h. The solution was then concentrated under reduced pressure at 50 °C to one third of the volume. The deposited precipitates of a mixture of **5** and **6** were collected by filtration after cooling with ice. The crystals, dried under reduced pressure in desiccator, were dissolved in ethanol (100 ml) and treated with active charcoal. Ethanol was distilled off by heating until the volume of the solution reduced to ca. 50 ml. On cooling with ice, precipitates of **6** were deposited and filtered off. The filtrate was concentrated again to a half. From the solution, **6** was crystallized again on cooling and filtered off. By complete removal of the solvent, 1.68 g of **5** was obtained (60% yield). All filtered **6** fractions were combined and totally 3.00 g of **6** was collected (84% yield).

5: IR (KBr disc); 3350, 1665, 1640, 1400, 1200, 1120, 1040, 870, 820 cm^{-1}; ^{1}H-NMR (D_2O, TSP deuterated) δ=8.2 (singlet).

5-Benzylthio-1,2,3-thiadiazole (7) and Benzyl *p*-Tolyl Sulfone (8): The dried crystalline mixture of **5** and **6** (1.00 g) obtained as above was dissolved in 50% aqueous ethanol (6 ml) and to this was added benzyl bromide (806 mg, 4.71 mmol) at room temperature. The solution was extracted with dichloromethane, after 1 h. The organic layer was washed with brine, dried over anhydrous sodium sulfate, and the solvent removed to leave 1.13 g of residue. Column chromatographic separation (silica gel, CH_2Cl_2) of the residue gave **7** (449 mg, 67% yield) and **8** (315 mg, 41% yield), respectively.

7: Mp 49—51 °C; ^{1}H-NMR ($CDCl_3$) δ=4.14 (2H, s), 7.30 (5H, s); MS (70 eV) *m/z* 208 (M^+, 2.3%), 180 (1.5%), 179 (5.3%), 147 (7.8%), 122 (15.1%), 91 (100%).

8: ^{1}H-NMR ($CDCl_3$) δ=2.39 (3H, s), 4.25 (2H, s), 6.95—7.55 (9H, m).

1-Benzyl-5-benzylamino-1,2,3-triazole (9): To a solution of trichloroacetaldehyde tosylhydrazone (**4**) (3.2 g, 10 mmol) in methanol (10 ml) under ice-cooling, was added a

solution of benzylamine (6.4 g, 60 mmol) in methanol (5 ml) dropwise. Stirring was continued at ice-water temperature for 2.5 h. Methanol was removed below 30 °C under reduced pressure. Benzene was added to the residue and the solid was crushed to a fine powder. Insoluble crystals of benzylamine salts (2.7 g) were removed by filtration and the benzene layer was washed with 1 M sodium hydroxide aqueous solution and brine. Removal of solvent after drying over anhydrous magnesium sulfate left a dark residue which was purified by column chromatography (silica gel, hexane: AcOEt=1:2) to afford **9** (0.77 g, 30% yield).

9: Mp 102—108 °C: ^{1}H-NMR (d_6-DMSO) δ=4.25 (2H, bt), 5.41 (2H, s), 6.50 (1H, bt), 6.81 (1H, s), 7.10—7.43 (10H, m): IR (KBr disc) 3050, 1670, 1600, 1500, 1450, 1290, 1240 cm^{-1}: MS (70 eV) m/z 264 (M^+, 83%), 236 (4.1%), 104 (26.0%), 91 (100%).

1-Methyl-5-methylamino-1,2,3-triazole (10): To a solution of 40% aqueous methylamine (4.7 g, 60 mmol) in water (15 ml) and methanol (10 ml) under ice-cooling, powdered trichloroacetaldehyde tosylhydrazone (**4**) (3.2 g, 10 mmol) was added portion wise. Stirring was continued at room temperature for 19 h and the product was extracted with chloroform. The organic layer was washed with brine, and dried over anhydrous magnesium sulfate. The residue (1.02 g) on removal of the solvent under reduced pressure was purified by column chromatography (silica gel, AcOEt) to give **10** (0.27 g, 25% yield).

10: Mp 61—63 °C: ^{1}H-NMR ($CDCl_3$) δ=2.83 (3H, s), 3.77 (3H, s), 4.91(1H, bs), 6.87 (1H, s): IR (KBr disc) 3050, 2810, 1440, 1310, 1280 cm^{-1}: MS (70 eV) m/z 112 (M^+, 44.6%), 83 (15.5%), 69 (41.0%), 55 (44.7%), 42 (100%).

α,α-Dichloroacetone Tosylhydrazone (11): To a solution of *p*-tosylhydrazine (6.7 g, 36 mmol) in propionic acid (30 ml), was added α,α-dichloroacetone (5.0 g, 39 mmol) and the reaction mixture was stirred at room temperature for 4 h. To this was added cyclohexane (30 ml) and the reaction mixture was cooled in ice bath. The white crystals which deposited were collected by filtration to give **11** (10 g, 94% yield).

11: Mp 137—138 °C (decomp): ^{1}H-NMR (d_6-DMSO) δ=1.85 (3H, s), 2.37 (3H, s), 7.40 (2H, m), 9.17 (1H, s), and 2.03 (3H, s), 2.37 (3H, s), 6.70 (1H, s), 7.40 (2H, m), 7.77 (2H, m): IR (KBr disc) 3230, 1600, 1340, 1170 cm^{-1}: MS (70 eV) m/z 294 (M^+, 2.3%), 155 (14.5%), 91 (100%).

Detection of 4-Methyl-1,2,3-thiadiazole (12): A solution of sodium sulfide ($Na_2S \cdot 9H_2O$)(3.00 g, 12.5 mmol) in water (7 ml) was covered with a layer of ether (12 ml), under ice-cooling, α,α-dichloroacetone tosylhydrazone (**11**) (1.48 g, 5.00 mmol) was added portion wise and stirring was continued for 19 h at that temperature. The ether layer was separated, washed with brine, and dried over anhydrous sodium sulfate. Ether was removed at atmospheric pressure at 55 °C to leave a trace of colorless residue. The ^{1}H-NMR of the residue revealed the signals due to 4-methyl-1,2,3-thiadiazole (**12**) at 2.85(s) and 8.20(s).

1-Benzyl-4-methyl-1,2,3-triazole (13): To a solution of α,α-dichloroacetone tosylhydrazone (**11**) (3.0 g, 10 mmol) in methanol (10 ml) under ice-cooling, was added a solution of benzylamine (5.3 g, 50 mmol) in methanol (5 ml) dropwise, followed by stirring at that temperature for 2 h. To the residue after removal of methanol under reduced pressure, benzene (10 ml) was added. The precipitates were crushed under ice-cooling, and removed by filtration. The benzene layer was washed with 1 M sodium hydroxide and brine, dried over anhydrous magnesium sulfate and the solvent removed leaving a dark residue. The residue was purified by column chromatography (silica gel, hexane: AcOEt=1:1) to afford **13** (1.46 g, 84% yield).

13: Mp 61—62 °C: ^{1}H-NMR ($CDCl_3$) δ=2.30 (3H, s), 5.43 (2H, s), 7.17 (1H, s), 7.21—7.37 (5H, m): IR (KBr disc) 3070, 2950, 1500, 1440, cm^{-1}: MS (70 eV) m/z 173 (M^+, 31.8%), 91 (100%), 65 (74.9%).

1-Allyl-4-methyl-1,2,3-triazole (14): To a solution of allylamine (2.9 g, 50 mmol) in methanol (15 ml), under ice-cooling, powdered dichloroacetone tosylhydrazone (**11**) was added portion wise. The mixture was stirred at that temperature for 4.5 h and at room temperature for 1.5 h. The solvent was removed under reduced pressure and replaced with dichloromethane. The solution was washed with 1 M sodium hydroxide and brine and dried over anhydrous magnesium sulfate. The residual oil on removal of solvent was purified by distillation (15 mmHg,† 100—160 °C) to give **14** (125 mg, 83%) as an oil.

14: ^{1}H-NMR ($CDCl_3$) δ=2.33 (3H, s), 4.90 (2H, dd), 5.25 (2H, m), 6.00 (1H, m), 7.30 (1H, d): IR (KBr plate) 3100, 2950, 1650, 1440, 1210, 1050, cm^{-1}: MS (70 eV) m/z 123 (M^+, 15.2%), 54 (36.1%), 41 (100%).

2,2-Dichloro-1-indanone (15): This was prepared according to the literature[10] from 1-indanone and copper(II) chloride.

2-Chloro-1-indenone Tosylhydrazone (16): 2,2-Dichloro-1-indanone (**15**) (0.54 g, 2.7 mmol) in ethanol (10 ml) was added to a solution of tosylhydrazine (0.50 g, 2.7 mmol) and 12 M hydrochloric acid (0.25 ml) and the mixture was stirred at room temperature for 20 h. The yellow crystals which deposited were collected by filtration. The filtrate was concentrated to half the volume and the crystals collected by filtration. Totally, 0.70 g of 2-chloro-1-indenone tosylhydrazone (**16**) was obtained (78% yield).

16: Mp 162—165 °C: ^{1}H-NMR (d_6-DMSO) δ=2.40 (3H, s), 6.87 (1H, s), 7.00—7.40 (5H, m): IR (KBr disc) 3450, 3250, 1600, 1345, 1170 cm^{-1}: MS (70 eV) m/z 332 (M^+, 2.1%), 176 (46.7%), 148 (93.8%), 113 (100%).

2-Chloro-1-diazoindene (17); Reaction of 16 with Benzylamine: A mixture of 2-chloro-1-indenone tosylhydrazone (**16**) (0.49 g, 1.5 mmol) and benzylamine (0.66 g, 5.9 mmol) in methanol (10 ml) was stirred under ice cooling for 1 h, at room temperature for 4 h, and finally at reflux temperature for 1 h. The solvent was removed under reduced pressure and to the residue was added a mixture of benzene and ether (v/v=1/1, 20 ml). The organic layer was washed with saturated sodium hydrogencarbonate solution and brine, and dried over anhydrous magnesium sulfate. Removal of the solvent under reduced pressure gave a residue which was separated by column chromatography (silica gel, hexane:AcOEt=1:1) to afford **16** (0.08 g, 16%) and 2-chloro-1-diazoindene (**17**) (0.07 g, 27% yield).

17: ^{1}H-NMR ($CDCl_3$) δ=6.30 (1H, s), 7.03—7.47 (4H, m): IR (KBr disc): 2100, 1505, 1430 cm^{-1}: MS (70 eV) m/z 176 (M^+, 41.7%), 148 (81.8%), 113 (100%).

2-Chloro-1-diazoindene (17); Reaction of 16 with Sodium

† 1 mmHg=133.322 Pa.

Sulfide: To a solution of sodium sulfide ($Na_2S \cdot 9H_2O$) (2.2 g, 9.0 mmol) in methanol (8 ml) was added 2-chloro-1-indenone tosylhydrazone (**16**) (1.0 g, 3.0 mmol) in methanol (10 ml) under ice-cooling and stirring was continued for 46 h at room temperature. The reaction mixture was filtered and the filtrate was concentrated until the precipitates began to deposit. The precipitates were collected by filtration. ^{1}H-NMR and IR spectra of the crystals showed that **17** was produced.

4-Phenyl-1-(*p*-toluenesulfonamido)-1,2,3-triazole (20): A mixture of α,α-dichloroacetophenone (**18**) (purchased from Aldrich Chemical Co.) (10.4 g, 60 mmol) and *p*-tosylhydrazine (5.6 g, 30 mmol) in ethanol (50 ml) was refluxed for 1 h. The crystals formed by concentration of the solution were collected by filtration after cooling with ice. The crystals of **20** were produced (1.94 g, 20% yield).

20: Mp 202—203 °C (decomp): Elemental analysis, Found: C, 57.43; H, 4.41; N, 17.58; S, 10.10%: Calcd for $C_{15}H_{14}N_4O_2S$: C, 57.31; H, 4.49; N, 17.82; S, 10.20%: ^{1}H-NMR (d_6-DMSO) δ=2.40 (3H, s), 7.17—7.87 (9H, m), 8.07 (1H, s): IR (KBr disc) 3050, 1600, 1480, 1370, 1170, 1090 cm^{-1}: MS (70 eV) *m/z* 314 (M^+, 3.8%), 171 (44.7%), 155 (52.5%), 145 (100%).

5-Benzylthio-1,2,3-thiadiazole (7) from 1,1-Dichloro-2-(*p*-tolylsulfonylazo)ethene (21): To a solution of sodium sulfide ($Na_2S \cdot 9H_2O$) (600 mg, 2.50 mmol) in water (1.0 ml) and ethanol (0.5 ml), was added 1,1-dichloro-2-(*p*-tolylsulfonylazo)ethene (**21**) (280 mg, 1.00 mmol) prepared by the method reported by Bott[6] from trichloroacetaldehyde tosylhydrazone (**4**) and triethylamine in dichloromethane at 0 °C in ethanol (0.5 ml) slowly at room temperature, and the reaction mixture was stirred for 1 h. The solution was cooled with ice and benzyl chloride was added (0.5 ml). After 1 h, ether was added and the organic layer was washed with brine, dried over anhydrous sodium sulfate, and the solvent removed under reduced pressure. Removal of excess benzyl chloride in vacuo at 60 °C gave **7** as orange crystals (94 mg, 45%).

Synthesis of Gramicidin S (GS) Analogs, [3—4-δAva]-GS and [3—4,3′—4′-Bis(δAva)]-GS (δAva=5-Aminovaleric Acid)

Shosuke SOFUKU,* Yasutaro SUGIYAMA, and Ichiro MURAMATSU
Department of Chemistry, College of Science, Rikkyo University,
Nishi-Ikebukuro, Toshima-ku, Tokyo 171
(Received July 20, 1985)

Gramicidin S (GS) analogs, [δAva$^{3-4}$]-GS and [δAva$^{3-4,3'-4'}$]-GS, were synthesized. Both of these peptides are analogs in which one or two L-leucyl-D-phenylalanyl residues of GS are replaced by one or two 5-aminovaleric acid residues. The CD spectrum of the mono-substituted analog has two troughs as that of GS. However, this analog showed almost no antimicrobial activity. Moreover, the di-substituted analog showed a CD spectrum that is ascribed to a random structure and had no antimicrobial activity.

In previous reports,[1-3] we have described the syntheses and properties of four gramicidin S (GS) analogs containing 5-aminovaleric acid residue (δAva). All of them were cyclic peptides in which each sequence of two adjacent amino acid residues is replaced by one residue of 5-aminovaleric acid. Consequently, each amide group was substituted by an ethylene group which had the same number of members in the ring as that of natural GS, *cyclo*-(Val-Orn-Leu-D-Phe-Pro)$_2$, although the side chains inevitably were lacking. Thus, it can be elucidated whether or not the original amide group in the natural peptide takes part in the intramolecular hydrogen bond. One of the analogs, [δAva$^{4-5}$]-GS, had a similar CD spectrum to that of GS, and its conformation was confirmed by ^{1}H-NMR measurement.[4] This analog showed significant antimicrobial activity against some microorganisms.[5]

In view of these results, it became of interest to obtain information about the contributions of the amide bond and side chains in Leu-D-Phe sequence of GS. Hence we undertook the synthesis and

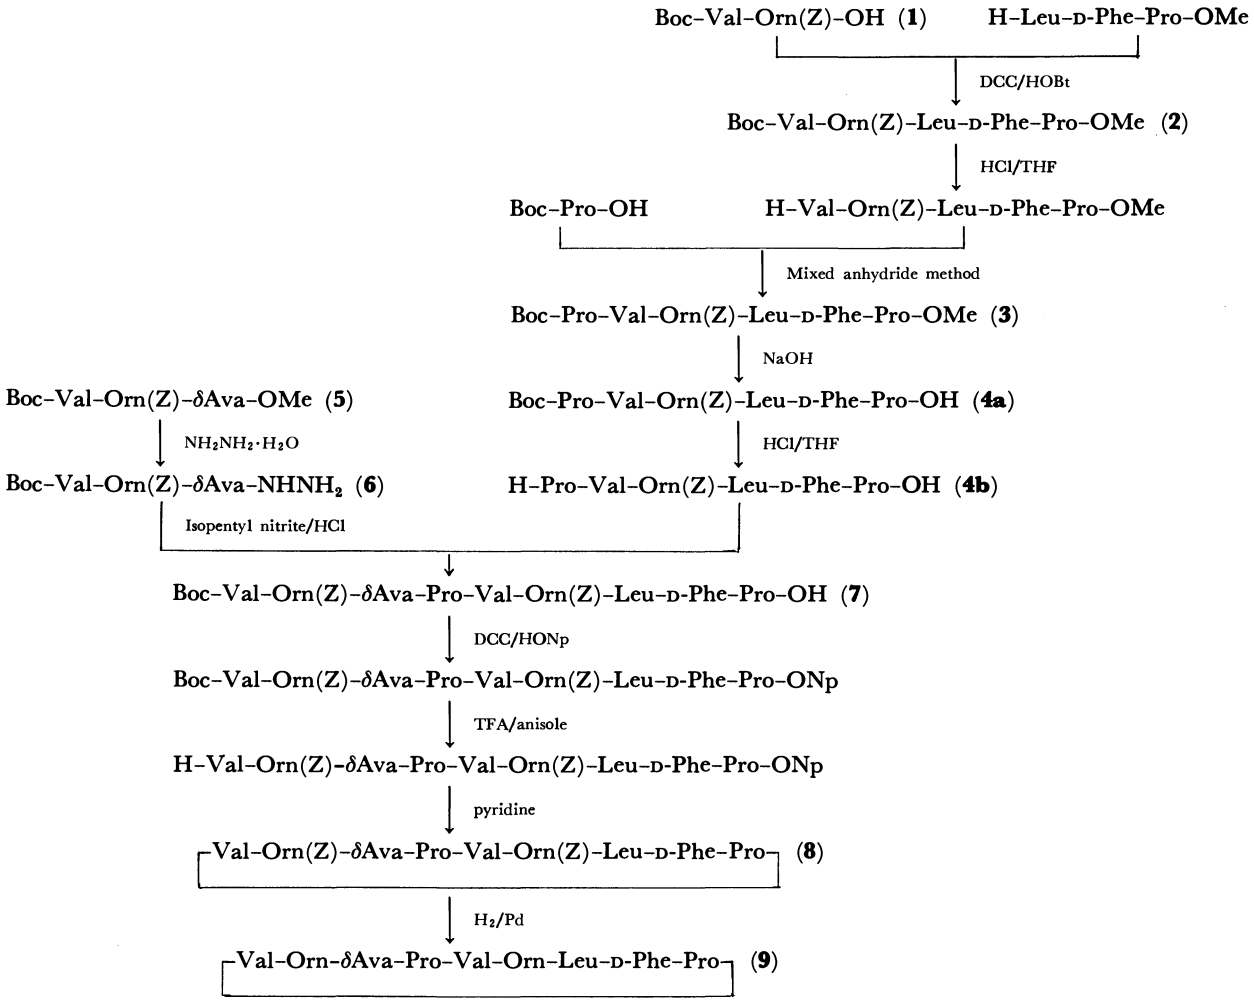

Fig. 1. Synthetic scheme for [δAva$^{3-4}$]-GS.

evaluation of the properties of [δAva$^{3-4}$]-GS and [δAva$^{3-4,3'-4'}$]-GS, as described in this paper.

Results and Discussion

The synthesis of [δAva$^{3-4}$]-GS is outlined in Fig. 1.[6] H-Leu-D-Phe-Pro-OMe was obtained by hydrogenolysis of oily Z-Leu-D-Phe-Pro-OMe which had been synthesized stepwise by the mixed anhydride method.[8] Peptides **2** and **3** were prepared by the conventional methods.[9] On the other hand, Boc-Val-Orn(Z)-δAva-OMe (**5**) was synthesized from Boc-Val-Orn(Z)-$NHNH_2$[10] and H-δAva-OMe[1] by the azide method[11] and converted to **6** by hydrazinolysis. Peptide **7** was synthesized from **4b** and **6** by the azide method.

The synthetic scheme of [δAva$^{3-4,3'-4'}$]-GS is also shown in Fig. 2. Peptide **10** was synthesized from **6** and H-Pro-OMe by the azide method. Deprotections of **10** gave **11** and **12**, respectively, which were then coupled with each other to afford **13** by the DCC-HOBt method. After purification by gel filtration on a Sephadex LH-20 with MeOH, the saponification of **13** gave **14**.

The intramolecular cyclizations of **7** and **14** were performed by the active ester method in dilute pyridine solution and the products (**8** and **15**) were purified by column chromatography. [δAva$^{3-4}$]-GS (**9**) and [δAva$^{3-4,3'-4'}$]-GS (**16**) were obtained by hydrogenolysis of **8** and **15**, respectively, and were confirmed by means of the DNSC (5-dimethylamino-1-naphthalenesulfonyl chloride) procedure[12] and paper electrophoresis.[1]

To obtain information on the conformation of [δAva$^{3-4}$]-GS and [δAva$^{3-4,3'-4'}$]-GS, CD and ORD spectra of the aqueous solutions were measured. The CD spectra of these analogs are shown in Fig. 3. The CD spectrum of the former analog has two troughs (207 and 215 nm) which are similar to those of GS although the molar ellipticity is smaller than that of GS, and the spectrum of the latter suggests a random structure. The ORD spectra of these analogs gave the same information. The minimum value in the ORD spectrum of [δAva$^{3-4}$]-GS was observed at 230 nm, the same as that of GS. The sequence of [δAva$^{3-4}$]-GS is the same as half that of GS, and this half can make the hydrogen bond maintain the β-turn, which has been indicated from the CD spectrum. From these results we predicted that [δAva$^{3-4}$]-GS may show antimicrobial activity against Gram-positive bacteria. However, as shown in Table 1, the mono-substituted analog had almost no activity, and the di-subsitituted analog had no activity at all. The partial sequence, -NH-$(CH_2)_4$-CO-Pro-Val, of these analogs corresponds to Gly-Pro-Val or D-X-Pro-Y of Type II′ in the rules for

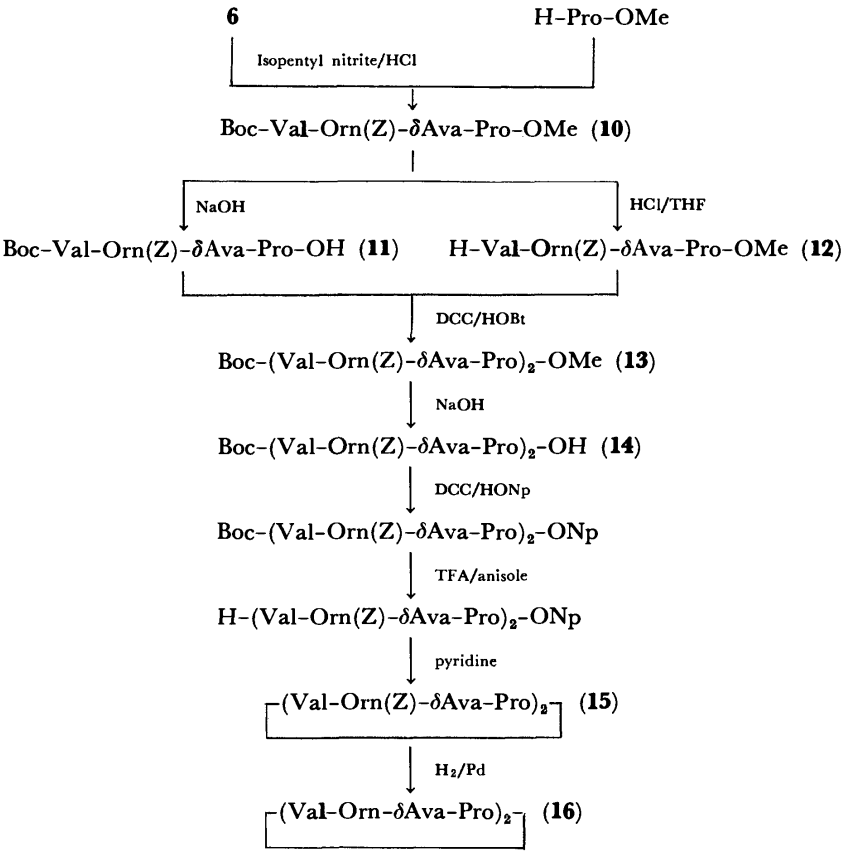

Fig. 2. Synthetic scheme for [δAva$^{3-4,3'-4'}$]-GS.

Table 1. Atimicrobial Activity of GS and its Analogs

Test organism	Minium inhibitory concentration[a]		
	GS	[δAva$^{3-4}$]-GS	[δAva$^{3-4,3'-4'}$]-GS
Sarcina lutea ATCC 9341	6.3	>100	>100
Micrococcus flavus ATCC 10240	3.1	50	>100
Corynebacterium diphtheriae P.W.8	1.6	50	>100
Bacillus subtilis ATCC 6633	6.3	>100	>100
Escherichia coli NIHJ-JC2	>100	>100	>100

a) The minimum concentration (μg/ml) was determined by the agar dilution method.

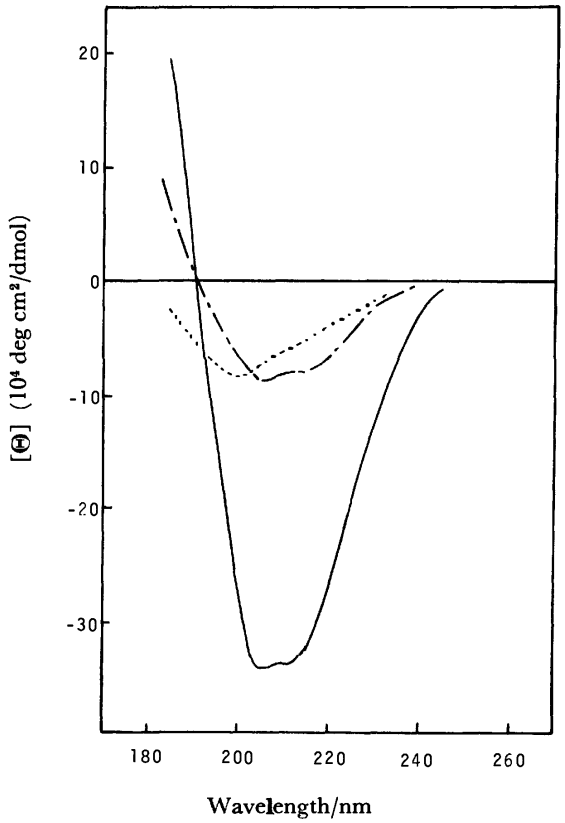

Fig. 3. CD spectra of GS·2HCl (——), [δAva$^{3-4}$]-GS·2HOAc (— — —), and [δAva$^{3-4,3'-4'}$]-GS·2HOAc (----) in water. Measurements were made using a 0.5mm quartz cell at room temperature.

β-turn proposed by Blout.[13] However, δAva has no carbonyl group at the γ-position and hence this part can not form the hydrogen bond as in the case of GS. [δAva$^{5-1'}$]-GS, in spite of the lack of an amide bond between Pro^5 and Val$^{1'}$, did exhibit some antimicrobial activity.[3] In the case of [δAva$^{4-5}$]-GS, this analog showed significant antimicrobial activity even though one of the side chains of D-phenylalanyl residues was lacking. The present results, together with these earlier findings, suggest the importance of both leucyl residue side chains in GS for the exhibition of antimicrobial activity.

Experimental

The melting points are uncorrected. The homogeneity of the synthetic compounds was confirmed by TLC on Merck silica gel F_{254} plates with following solvent systems (v/v): R_f^1, $CHCl_3$-MeOH-HOAc (9:1:1); R_f^2, *n*-BuOH-HOAc-pyridine-H_2O (4:1:1:2); R_f^3, *n*-BuOH-HOAc-H_2O (4:1:1); R_f^4, $CHCl_3$-MeOH-EtOAc (95:7:5). Amino acid analyses were performed with a JEOL automatic amino acid analyzer, after the samples had been hydrolyzed with constant-boiling HCl in evacuated sealed ampoules for 20 h at 110 °C. The molecular weight was determined with a Hitachi molecular weight apparatus model 115, using MeOH. CD spectrum was measured with a JASCO model J-20 spectrometer and is represented in term of molar ellipticity.

Boc-Val-Orn(Z)-OH (1). Boc-Val-Orn(Z)-OEt[7] (14.0 g, 28.4 mmol) was saponified in MeOH (150 ml) with 2.6 M† NaOH (44 ml) at room temperature for 20 min. The solution was neutralized with 5% citric acid and concentrated in vacuo to remove the MeOH. The aqueous phase was acidified with citric acid to pH 3 and extracted with EtOAc. The extract was dried over anhydrous Na_2SO_4 and evaporated in vacuo. The residue was recrystallized from EtOAc and hexane. Yield, 12.8 g (97.0%); mp 66—68 °C; $[\alpha]_D^{20}$ +16.2° (*c* 0.7, DMF).

Found: C, 59.27; H, 7.88; N, 9.32%. Calcd for $C_{23}H_{35}N_3O_7$: C, 59.34; H, 7.58; N, 9.03%.

Boc-Val-Orn(Z)-Leu-D-Phe-Pro-OMe (2). H-Leu-D-Phe-Pro-OMe·HCl was obtained in the theoretical yield by hydrogenolysis (Pd black in 50 ml of MeOH containing 1.8 ml of concd HCl) of oily Z-Leu-D-Phe-Pro-OMe[14] (7.8 g, 15 mmol) which had been synthesized stepwise by the mixed anhydride method from C-terminal. This deprotected peptide (15 mmol) and compound **1** (7.0 g, 15 mmol) were dissolved in THF (80 ml) containing *N*-methylmorpholine (1.75 ml, 15 mmol). Coupling was performed with DCC (3.1 g, 15 mmol) and HOBt (4.1 g, 30 mmol) at 0 °C for 2 h and room temperature overnight. After filtration of the insoluble materials, the filtrate was concentrated in vacuo. The EtOAc solution of the residue was washed successively with 5% citric acid, water, 5% $NaHCO_3$, and water, and dried over anhydrous Na_2SO_4. The solution was concentrated in vacuo and the residue was recrystallized from EtOAt and hexane. Yield, 7.3 g (58.3%); mp 159—162 °C; $[\alpha]_D^{20}$ −31.0° (*c* 1.0, DMF).

† 1 M=1 mol dm^{-3}.

Found: C, 62.92; H, 7.76; N, 10.50%. Calcd for $C_{44}H_{64}N_6O_{10}$: C, 63.14; H, 7.71; N, 10.04%.

Boc-Pro-Val-Orn(Z)-Leu-D-Phe-Pro-OMe (3). Compound **2** (5.57 g, 6.65 mmol) was dissolved in 2.3 M HCl/THF (29 ml) to remove the Boc-group. The solution was stirred at room temperature for 2 h and evaporated in vacuo. The oily residue was dried over NaOH pellets in vacuo and dissolved in DMF (20 ml) containing *N*-methylmorpholine (0.75 ml). The solution was added to the mixed anhydride solution which was prepared from Boc-Pro-OH (1.5 g, 7.0 mmol), ethyl chloroformate (0.83 ml, 8.6 mmol) and *N*-methylmorpholine (0.96 ml, 8.7 mmol) in DMF (30 ml) at −15 °C for 4 min. This reaction mixture was stirred at 0 °C 2 h and at room temperature overnight. After filtration of the mixture, the filtrate was evaporated in vacuo and the residue was triturated with water. The product was collected by filtration and washed on a funnel successively with 5% citric acid, water, 5% $NaHCO_3$ and water. The crude product was recrystallized from DMF and water. Yield, 5.45 g (87.0%); mp 208—209 °C; $[\alpha]_D^{20}$ −54.0° (*c* 1.0, DMF).

Found: C, 62.29; H, 7.60; N, 10.50%. Calcd for $C_{49}H_{71}N_7O_{11}\cdot 0.5H_2O$: C, 62.40; H, 7.69; N, 10.40%.

Boc-Pro-Val-Orn(Z)-Leu-D-Phe-Pro-OH (4a). Into the solution of **3** (5.2 g, 5.5 mmol) in THF (60 ml), 3.6 M NaOH (6.2 ml) was added. The reaction solution was stirred at room temperature for 3 h and neutralized with 5% citric acid. After removal of the solvent in vacuo, the residue was treated with 5% citric acid. The precipitate was filtered and washed with cold water on a funnel. The dried product weighed 5.15 g (100%). Mp 158—164 °C; $[\alpha]_D^{20}$ −52.5° (*c* 0.3, DMF).

Found: C, 61.98; H, 7.82; N, 10.05%. Calcd for $C_{48}H_{69}N_7O_{11}\cdot 0.5H_2O$: C, 62.05; H, 7.59; N, 10.55%.

Boc-Val-Orn(Z)-δAva-OMe (5). Boc-Val-Orn(Z)-$NHNH_2$[10] (2.5 g, 5.2 mmol) was converted to the corresponding azide with isopentyl nitrite (0.82 ml, 6.1 mmol) and 2.9 M HCl/dioxane (11.3 ml) in DMF (26 ml) at −30 °C for 15 min. Into the azide solution neutralized with Et_3N (4.8 ml) at −55 °C, the solution of H-δAva-OMe·HCl[1] (0.92 g, 5.5 mmol) and Et_3N (1.5 ml) in DMF (26 ml) was added and the reaction mixture was stirred at 0 °C for 3 d. After filtration of the insoluble materials, the filtrate was concentrated in vacuo. The AcOEt solution of the residue was treated in the same manner as described for **2**. The product was recrystallized from AcOEt and diethyl ether. Yield, 2.21 g (73.4%); mp 148—152 °C; $[\alpha]_D^{20}$ −21.3° (*c* 0.5, DMF).

Found: C, 59.78; H, 8.06; N, 10.22%. Calcd for $C_{29}H_{46}N_4O_8$: C, 60.19; H, 8.01; N, 9.68%.

Boc-Val-Orn(Z)-δAva-$NHNH_2$ (6). Compound **5** (20.2 g, 34.9 mmol) in MeOH (100 ml) was treated with 80% hydrazine hydrate (44 ml) at room temperature overnight. After evaporation of the solvent, the crystalline residue was collected on a funnel and washed with water several times. Dried crystals weighed 18.9 g (92.1%). Mp 163—165 °C.

Found: 57.03; H, 8.33; N, 13.88%. Calcd for $C_{28}H_{46}N_6O_7\cdot 0.5H_2O$: C, 57.22; H, 8.06; N, 14.30%.

Boc-Val-Orn(Z)-δAva-Pro-Val-Orn(Z)-Leu-D-Phe-Pro-OH (7). Into the solution of **6** (3.47 g, 6 mmol) in DMF (80 ml), 7.3 ml of 3.3 M HCl/THF was added and followed by isopentyl nitrite (0.9 ml, 6.7 mmol) at −15 °C. After 15 min, the reaction mixture was neutralized with Et_3N (3.4 ml) and the solution of the hydrochloride of **4b** obtained from **4a** (4.8 g, 5.2 mmol) by treatment with 2.5 M HCl/THF as described for **3** and Et_3N (0.77 ml) in DMF (40 ml) was added into the above azide solution. After the stirring for 3d at 0 °C, the filtrate was evaporated in vacuo and the residue was triturated with cold water. The product was washed on a funnel succesively with 5% citric acid, 5% $NaHCO_3$, and water. This product was purified by column chromatography on silica gel (Wakogel C-200, 3.6×40 cm) with $CHCl_3$–MeOH (97:3). The combined eluates were concentrated in vacuo and the residue was recrystallized from EtOH and diethyl ether. Yield, 2.55 g (35.9%); mp 197—200 °C; R_f[1] 0.40; $[\alpha]_D^{20}$ −28.71° (*c* 0.4, EtOH).

Found: C, 62.10; H, 7.87; N, 11.18%. Calcd for $C_{71}H_{103}N_{11}O_{16}$: C, 62.40; H, 7.60; N, 11.27%.

***Cyclo*-(Val-Orn(Z)-δAva-Pro-Val-Orn(Z)-Leu-D-Phe-Pro-) (8).** Into the solution of **7** (700 mg, 0.51 mmol) in DMF (25 ml), *p*-nitrophenol (219 mg, 1.6 mmol) and DCC (126 mg, 0.61 mmol) were added at 0 °C and the reaction mixture was stirred at room temperature overnight. After removal of the DCC, urea, and the solvent, the residue was recrystallized from MeOH–water and washed with diethyl ether. The *p*-nitrophenyl ester of **7** weighed 550 mg (72.5%), R_f[1] 0.89. Boc-group of this active ester (500 mg, 0.34 mmol) was removed with TFA (5 ml) containing anisole (0.8 ml) at 0 °C for 20 min. Evaporation of the TFA was carried out at 0 °C. An oily residue was crystallized by treatment with diethyl ether and decantation. A solution of this ester in DMF (10 ml) containing HOAc (0.1 ml) was added dropwise into pyridine (350 ml) at 58—60 °C for 2.5 h. After the stirring of the solution at 58—60 °C for 5 h, it was concentrated in vacuo. The residue was dissolved in MeOH–water (7:1) and passed succesively through columns of Dowex 1 (OH^-) and Dowex 50 (H^+). The oily product was obtained by concentration of the eluate and crystallized with diethyl ether. The recrystallization from MeOH and diethyl ether gave 77 mg (17.9%). R_f[1] 0.79; mp 165 °C; $[\alpha]_D^{18}$ −166.9° (*c* 0.6, MeOH); mol wt, found: 1240 (calcd for $C_{66}H_{93}N_{11}O_{13}$: 1247).

Found: C, 62.43; H, 7.76; N, 12.02%. Calcd for $C_{66}H_{93}N_{11}O_{13}\cdot H_2O$: C, 62.59; H, 7.56; N, 12.16%.

***Cyclo*-(Val-Orn-δAva-Pro-Val-Orn-Leu-D-Phe-Pro) (9).** Hydrogenolysis of **8** (80 mg, 0.063 mmol) was carried out in a mixture of MeOH (6 ml) containing 0.1 ml of 3 M HCl/THF and Pd black for 10 h at room temperature. After removal of the catalyst, an oily product was obtained by concentration of the filtrate in vacuo, and it was purified by chromatography on a Sephadex G-10 with 4% HOAc. The homogeneous fractions were collected and lyophilized and white crystalline peptide was obtained. Yield, 69 mg (94.9%); mp 168—169 °C; $[\alpha]_D^{22}$ −171.2° (*c* 0.3, EtOH); R_f[2] 0.63. Amino acid ratio: Val 1.89, Orn 1.91, Leu 1.02, Phe 1.02, Pro 2.07, δAva 1.09.

Found: C, 55.80; H, 8.07; N, 13.41%. Calcd for $C_{50}H_{81}N_{11}O_9\cdot 2HOAc\cdot 3H_2O$: C, 56.18; H, 8.29; N, 13.35%.

Boc-Val-Orn(Z)-δAva-Pro-OMe (10). Hydrazide **6** (3.86 g, 6.57 mmol) was converted to the corresponding azide with isopentyl nitrite (1.2 ml, 9 mmol) and 5M HCl/THF (5.3 ml) in DMF (30 ml) at −20 °C for 40 min. A solution of H-Pro-OMe·HCl (1.32 g, 8.0 mmol) and Et_3N (1.2 ml, 8.6 mmol) in DMF (20 ml) was added to the above azide solution previously neutralized with Et_3N (3.7 ml

26.6 mmol) at −50 °C. This reaction mixture was stirred at 0 °C for 3d and then added into 0.4% citric acid (750 ml), liberating an oily product. The product extracted in AcOEt was washed with water and dried over anhydrous Na_2SO_4. The solution was concentrated in vacuo and the residue was recrystallized from AcOEt and hexane. Yield, 3.93 g (88.5%); mp 87 °C; $[\alpha]_D^{20}$ −18.1° (*c* 0.7, DMF).

Found: C, 59.94; H, 8.09; N, 10.51%. Calcd for $C_{34}H_{53}N_5O_9$: C, 60.43; H, 7.90; N, 10.36%.

Boc-(Val-Orn(Z)-δAva-Pro)$_2$-OH (14). Saponification of **10** (1.96 g, 2.9 mmol) was carried out with 2.2 M NaOH (5.2 ml) in MeOH (20 ml) at room temperature for 6 h. After evaporation of the MeOH, the residue was treated with 5% citric acid and extracted with AcOEt. The oily product **11** (1.25 g, 1.9 mmol) was obtained in a 64% yield by concentration of the extract which was washed with water and dried over anhydrous Na_2SO_4. On the other hand, removal of the Boc-group of **10** (1.66 g, 2.5 mmol) was carried out with 2.3 M HCl/THF (24.5 ml) at room temperature for 2.5 h. After concentration of the reaction solution, the residual oily compound (**12**, 2.5 mmol) was dried over NaOH pellets in vacuo and used directly in the next step. The solution of above **11** and **12**·HCl in THF (30 ml) was neutralized with *N*-methylmorpholine (0.96 ml), followed by the additions of HOBt (0.5 g, 3.7 mmol) and DCC (0.42 g, 2.0 mmol). The coupling reaction proceeded at 0 °C overnight. After filtration of the insoluble materials, the filtrate was concentrated in vacuo. The residue was crystallized by treatment with water and washed successively with 5% citric acid, water, 5% Na_2CO_3, and water on a funnel. The crude product was purified by gel filtration on a Shephadex LH-20 with MeOH. The yield of **13** was 2.22 g (95.7%) and the amino acid analysis showed the composition within experimental error. Saponification of **13** (1.36 g, 1.1 mmol) was carried out with 1.3 M NaOH (4.4 ml) in DMF (30 ml) at room temperature for 2.5 h. The reaction solution was added into 0.5% citric acid (500 ml) at 0 °C. The precipitate was filtered off and recrystallized from MeOH and diethyl ether. Yield, 1.30 g (93.9%); mp 205.5—206.5 °C; $[\alpha]_D^{20}$ −23.8° (*c* 0.8, DMF); R_f^1 0.56.

Found: C, 58.11; H, 7.75; N, 11.10%. Calcd for $C_{61}H_{92}N_{10}O_{15}\cdot 3H_2O$: C, 58.17; H, 7.84; N, 11.12%.

***Cyclo*-(Val-Orn(Z)-δAva-Pro)$_2$ (15).** a) *p*-Nitrophenol (104 mg, 0.75 mmol) and DCC (152 mg, 0.74 mmol) were added into the solution of **14** (440 mg, 0.35 mmol) in DMF (10 ml) at 0 °C. After the stirring of the reaction mixture at room temperature overnight, it was filtered and the filtrate was concentrated in vacuo. The residual oily product was treated with a mixture of diethyl ether–hexane (1:1) and the crystalline *p*-nitrophenyl ester (292 mg, 0.22 mmol) of **14** was collected by decantation. In the same way as in the preparation of **8**, this active ester was used in the cyclization reaction after removal of the Boc-group. The product was dissolved in MeOH–water (7:1) and passed successively through columns of Dowex 1 (OH^-) and Dowex 50 (H^+). The eluent was removed under reduced pressure to give an oil. Chromatography on Sephadex LH-20 eluting with MeOH gave after recrystallization from aqueous MeOH 29 mg (11.5%) of **15**. Mp 202—204 °C; $[\alpha]_D^{22}$ −39.5° (*c* 0.3, MeOH); R_f^3 0.77, R_f^4 0.42; mol wt, found 1050 (calcd for $C_{56}H_{82}N_{10}O_{12}$: 1086).

Found: C, 58.87; H, 7.59; N, 11.33%. Calcd for $C_{56}H_{82}N_{10}O_{12}\cdot 3.5H_2O$: C, 58.46; H, 7.79; N, 12.17%. b) Compound **14** (1.25 g, 0.99 mmol), HOSu (245 mg, 2.13 mmol), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (320 mg, 2.06 mmol) and 3 M HCl/dioxane (0.67 ml) were mixed in DMF (8 ml) at 0 °C and the reaction mixture was stirred at room temperature overnight. After concentration of this mixture under reduced pressure, an oily residue was crystallized by the treatment with water. The dried compound weighed 750 mg (58%). Removal of the Boc-group of this *N*-hydroxysuccinimide ester, the subsequent cyclization reaction and the purification were carried out just as described in the method a. This compound gave the same properties mentioned above. Yield, 87 mg (13.1%).

***Cyclo*-(Val-Orn-δAva-Pro)$_2$ (16).** Z-groups of **15** (64.8 mg, 0.056 mmol) in MeOH (20 ml) with 3.1 M HCl/THF (0.05 ml) were removed by hydrogenolysis over Pd black for 5 h. In the same manner as with **9**, crystalline product was obtained in a 62.1% yield (36.4 mg). Mp 182—190 °C; $[\alpha]_D^{23}$ −66.7° (*c* 0.2, H_2O); R_f^2 0.37. Amino acid ratio: Val 2.03, Orn 2.04, δAva 2.14, Pro 1.78.

Found: C, 50.29; H, 8.18; N, 13.76%. Calcd for $C_{40}H_{70}N_{10}O_8\cdot 2HOAc\cdot 6H_2O$: C, 50.46; H, 8.66; N, 13.37%.

The authors express their thanks to the staff of the research laboratories of Toyo Jozo Co. for performing the elemental analyses and the microbiological assays.

Photochemical Reactions of *N*-Methyl-1,2-naphthalenedicarboximide with Alkenes. Preferential Naphthazepinedione Formation

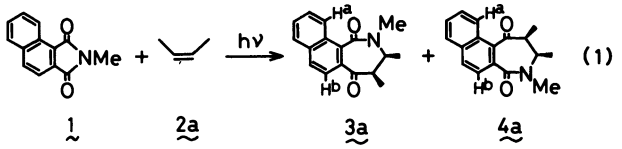
Yasuo KUBO,* Rie TODA, Kengo YAMANE, and Takeo ARAKI
Department of Chemistry, Faculty of Science, Shimane University,
Matsue, Shimane 690
(Received July 27, 1985)

Irradiation of benzene solutions of *N*-methyl-1,2-naphthalenedicarboximide (**1**) in the presence of alkenes (**2a,b,d—i**) gave two regio-isomers of naphthazepinediones (**3a,b,d—i** and **4a,b,d—i**). Stereospecificity of the naphthazepinedione formation was observed in the reaction with *cis*- and *trans*-2-butene (**2a** and **2b**). Naphthazepinediones (**3j** and **4j**) produced by the irradiation of **1** with ethyl vinyl ether (**2j**) underwent secondary photoreactions to give **7** and **8**, respectively. On the other hand, irradiation of **1** with 2,3-dimethyl-2-butene (**2k**) resulted in the formation of oxetanes (**13a,b**) and 1:1-adducts of **1** and **2k** at the carbonyl groups of **1** (**14** and **15a,b**). Irradiation of **1** with *cis*-stilbene (**2l**) afforded oxetanes (**22a,b**) and fragmentation products of oxetanes (**23a,b**, and **24**). Stern-Volmer slopes ($k_q\tau$) obtained from quenching of fluorescence of **1** by alkenes (**2a—e,k**) correlated to some extent with relative rates for disappearance of **1** in the reaction. Preferential formation of the naphthazepinedione was rationalized by the nature of the excited singlet state of **1** compared with those of other *N*-methylarenedicarboximides.

In recent years, photochemistry of imides has been the subject of intensive investigations.[1] Concerning the reactions with alkenes, there are remarkable differences between the photoreactions of alicyclic imides and arenedicarboximides (especially phthalimides). Aliphatic imides undergo effective intra-[2] or inter-molecular oxetane formation,[3] illustrating its normal $n\pi^*$ carbonyl photoreactivity. In contrast, phthalimides undergo alcohol-incorporated C–C coupling at the carbonyl carbon of phthalimides (electron transfer reaction),[4] insertion of alkene into C(=O)-N bond of the imide moiety,[5] and only in a few cases oxetane formation.[6] As there has been only a little information on the effects of arene structures in the photochemistry of arenedicarboximides,[7] our studies have been focused on the effects of extended π-conjugation systems. Recently we reported the photoreactions of three types of *N*-methylnaphthalenedicarboximides with alkenes in benzene, in which the arene structure played a crucial role in determining the reaction pathways.[8] The predominant reactions of *N*-methyl-1,8- and 2,3-naphthalenedicarboximides with alkenes were cycloaddition to the aromatic C=C bond (cyclobutane formation) and oxetane formation, respectively. This paper describes the details of the photoreactions of *N*-methyl-1,2-naphthalenedicarboximide (**1**) with a variety of alkenes in benzene. In contrast to other naphthalenedicarboximides, the predominant reaction of **1** is found to be insertion of the alkene into C(=O)-N bond of the imide moiety (naphthazepinedione formation) accompanied, in some cases, by other types of reactions depending on the structure of the alkene.

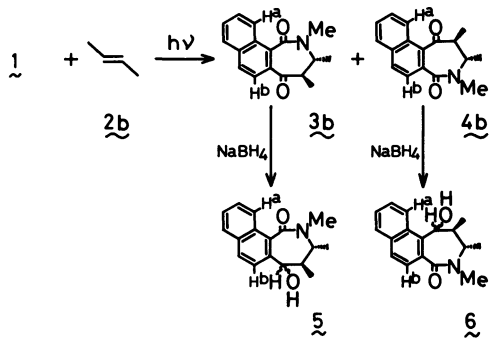
Results and Discussion

Naphthazepinedione Formation. The insertion of alkene into the C(=O)-N bond of **1**, naphthazepinedione formation, was a most typical reaction observed in the photochemistry of **1** and alkenes in benzene. For example, irradiation of a benzene solution of **1** (10 mM, 1 M=1 mol dm^{-3}) and cis-2-butene (**2a**) (100 mM) by a light of >320 nm (aq $CuSO_4$ filter) gave two regio-isomers of naphthazepinedione (**3a** and **4a**) (Eq. 1). The two isomers



1 **2a** **3a** **4a**

were readily separated by column chromatography on silica gel to give 45% of **3a** and 29% of **4a**. Irradiation of **1** with *trans*-2-butene (**2b**) also gave **3b** (46%) and **4b** (33%) (Scheme 1). Other examples of



2b **3b** **4b** **5** **6**

Scheme 1.

photoreactions of **1** and alkenes (**2c—i**) are shown in Table 1. The results indicate that the naphthazepinedione formation is characteristic of the reaction with ethylenes substituted by two or three alkyl groups and with some ethylenes substituted by

phenyl groups. No reaction was observed in the photolysis of **1** with 1-hexene (**2c**), an ethylene substituted by one alkyl group.

The structures of the naphthazepinediones, including the position of the alkyl substituent of the azepine ring, were supported by the spectral resemblance to the benzo analogues obtained by the photoreactions of *N*-methylphthalimide with the alkenes.[5] ^{1}H NMR spectra of some naphthazepinediones show coalesced signals. As the most typical example the ^{1}H NMR spectra of **4d** are shown in Fig. 1. Although signals of *N*-methyl and aromatic protons are sharp, signals of two *C*-methyl and methylene protons are broad at ambient temperature. The broad doublet signals of the two *C*-methyl protons were coalesced at 34.0 °C [(c) in Fig. 1] and changed to a more sharp singlet at higher temperatures [(d,e)]. The spectral changes probably arise from flipping of the azepine ring.

The regiochemistry of the naphthazepinediones shown in the structural formula are deduced from the following three observations: ^{1}H NMR behavior of H^a and H^b in addition to the spectral features of the reduction products. First, the H^a signals (double doublets) of **4a,b,d—i** showed low field shift (δ= 8.38—8.55) relative to those of **3a,b,d—i** (δ=≈8). This fact suggests that the H^a is close to the ketone carbonyl groups, in accord with the observations that the ketone carbonyl group exerts a stronger deshielding effect on the peri-hydrogens than the lactam carbonyl group.[5b] Second, the H^b signals (doublet) of **4a,b,d—i** were observed at slightly higher fields compared with those of **3a,b,d—i**. Third, reduction of **3b** and **4b** with sodium borohydride gave **5** and **6**, respectively (Scheme 1). The H^a signal of **5** was considerably shifted to a lower field (δ=9.10) compared with that of **6** (δ=8.25), probably due to the deshielding effect by the lactam carbonyl group remained.

The yields of the regio-isomers (**3a,b,d—i**) are generally higher than those of the other isomers (**4a,b,d—i**) except for the reaction of **1** with **2g**. Attack of alkene to the less hindered C(=O)-N bond of **1** seems to predominate over that to the other

C(=O)-N bond. In the irradiation of **1** and **2e** the ratio of the yields of the products (**3e**:**4e**) remained almost constant over the concentration region of 50 mM to 1 M of **2e**. The result may indicate that the two regio-isomers arise from the same excited state of **1**, since in the photoreactions of phthalimides and alkenes a marked concentration dependency on the ratio of the yields of products is reported when the products are generated from the distinct excited states.[6c,d]

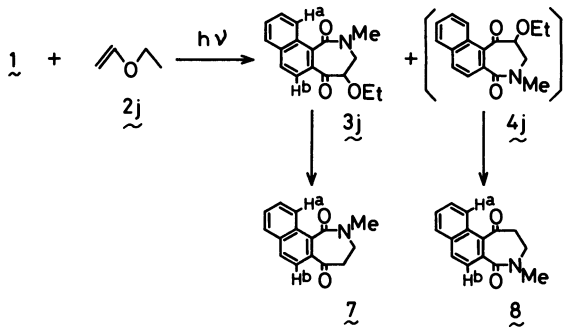
An important characteristic of the naphthazepinedione formation is stereochemical course of the reactions. Irradiation of **1** in the presence of **2a** and **2b** gave mixtures of **3a**+**4a** and **3b**+**4b**, respectively (Eq. 1 and Scheme 1). The facts that no detectable amounts of cis-trans isomerized products are observed in the irradiation of **1** with **2a** and **2b** obviously indicate the stereospecific formation of the naphthazepinedione, and suggest that the reaction occurs directly from the singlet excited state of **1**.

The stereochemistry of the products could be assigned by comparison of the coupling constants of the two methine hydrogens of the azepine ring with those of corresponding benzazepinediones, which were reported to be J=2.3 Hz for the cis-isomer and J=10.1 Hz for the trans-isomer.[5h] The products (**3a**, **3b**, and **4b**) had the coupling constants of J=3.2, 11.0, and 11.6 Hz, respectively, although the coupling constant of **4a** could not be determined. These coupling constants suggested the cis-stereochemistry for **3a** and trans-stereochemistry for **3b** and **4b** as shown in Scheme 1. The stereochemistry of the products corresponds to that of the alkenes (**2a**, **b**) used.

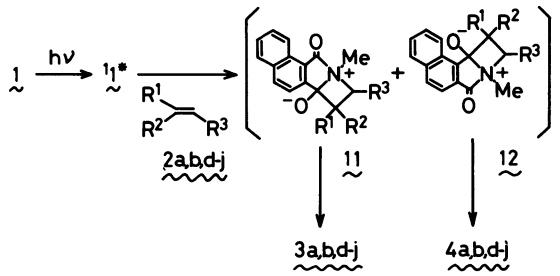
In the inter-[5e,h] and intramolecular[5i] photoreactions of phthalimides and alkenes, the stereospecificity of the benzazepinedione formation at the early stage of the photoreaction was already reported, but concomitant cis-trans isomerization of alkenes always occurred to give non-stereospecific mixtures of the products at a prolonged irradiation. No such cis-trans isomerization was observed in the photo reactions of **1** with **2a** and **2b**.

The mechanism of the cis-trans isomerization process in the reactions of phthalimides is not fully clarified.[5e] However, the isomerization may arise via a triplet biradical, an intermediate of the oxetane formation from the triplet excited state of **1**,[9] because the trans/cis ratio of 2-butene at the photosteady state is 4/1[5e] and oxetane formation has been known to occur from the triplet excited state of phthalimides.[6c,d] The fact that no isomerization is observed in the reaction of **1** seems to show a small contribution of the triplet excited state of **1** to the reaction of **1** with the alkenes.

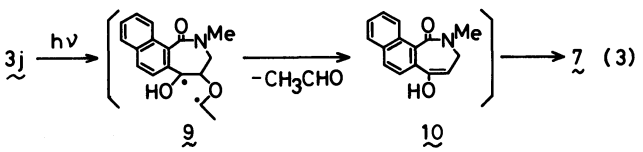
Ethyl vinyl ether (**2j**) also reacted with excited **1** to give naphthazepinediones, but secondary photoreactions were observed at the same time. Prolonged irradiation of **1** and **2j** in benzene gave **7** (43%) and **8** (26%) which however were not the primary photoproducts (Scheme 2). One of the primary products (**3j**) was isolated by the photoreaction of shorter irradiation-time. Further irradiation of **3j** in benzene quantitatively gave **7** probably through intramolecular γ-hydrogen abstraction (**3j**→**9**), followed by elimination of acetaldehyde (**9**→**10**), and tautomerization of **10** (**10**→**7**) (Eq. 3). This type of reaction series



Scheme 2.



Scheme 3.



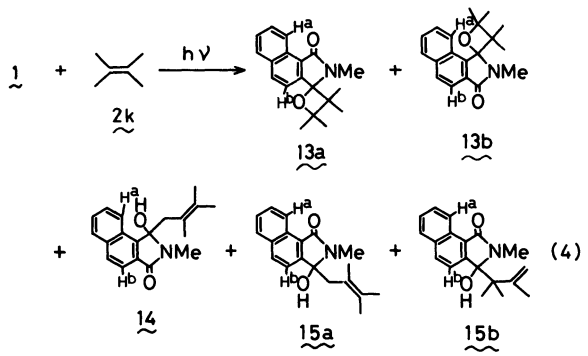
is familiar in photoreactions of benzazepinediones.[1,6a]

The naphthazepinedione formation may be rationalized by a mechanism (Scheme 3) similar to that of the benzazepinedione formation[5i] on the basis of the structures of the naphthazepinediones and the stereospecificity of the reaction. Thus, reaction of singlet excited state of **1** and alkene (**2a,b,d—j**) gave two regioisomers of intermediate (**11** and **12**) with retention of the stereochemisty of the alkene, and then C(=O)-N bond cleavage of **11** and **12** results in the formation of **3a,b,d—j** and **4a,b,d—j**, respectively.

Other Reactions. Besides the naphthazepinedione formation, two types of reactions were observed in the irradiation of **1** with 2,3-dimethyl-2-butene

(**2k**) and *cis*-stilbene (**2l**).

Irradiation of **1** and **2k** in benzene gave two regio-isomers of oxetane [**13a** (30%) and **13b** (8%)] and additional products [**14** (16%), **15a** (11%), and **15b** (9%)] (Eq. 4). The reaction is analogous to that of



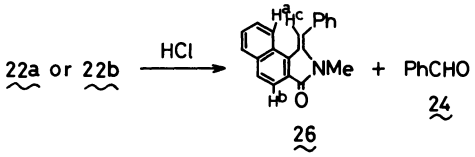
(4)

N-methylphthalimide and **2k**, and structures of the products were assigned from their spectral resemblance to the benzo analogues.[6d]

The regiochemistries of **13**—**15** were assigned on the ^{1}H NMR spectra. ^{1}H NMR spectra of the products showed characteristic double-doublets signals due to H^a in a lower field region of δ=8.47 to 9.19. The H^a signal of **13a** was shifted to a lower field (δ=9.19) compared with that of **13b** (δ=8.94) probably due to the deshielding effect from the lactam carbonyl group. The H^a signal of **15a** was likewise shifted to a lower field (δ=8.58) compared with that of **14** (δ=8.47). Attack of **2k** to the less hindered carbonyl group of **1** to give **13a** seems to predominate.

Formation of **14** and **15a, b** may be rationalized by a mechanism shown in Scheme 4, by referring the mechanism proposed by Mazzocchi and Klingler.[6d] First of all, an ion pair (**16**+**17**) is generated by electron transfer. Subsequent proton transfer gives two types of radical pairs (**18**+**19** and **20**+**19**) via path a and path b, respectively. The former pair couples to give **14** and the latter to **15a**. Another possibility is the collapsing of the ion pair (**16**+**17**) to a zwitter ionic intermediate (**21**) via path c, which converts to mainly **15b** by proton transfer.

Irradiation of **1** and **21** in benzene gave two stereoisomers of oxetane [**22a** (19%) and **22b** (19%)], a pair of unsaturated amides [**23a** (37%) and **23b** (15%)], and benzaldehyde [**24** (45%)] (Scheme 5). As reported in many cases,[10] the productions of **23a, b,** and **24** were rationalized by fragmentation of the oxetane precursor (**25**), i.e., carbonyl-alkene metathesis. Acid-catalyzed decomposition of **22a** or **22b** in methanol afforded **26** and **24** (Eq. 5).

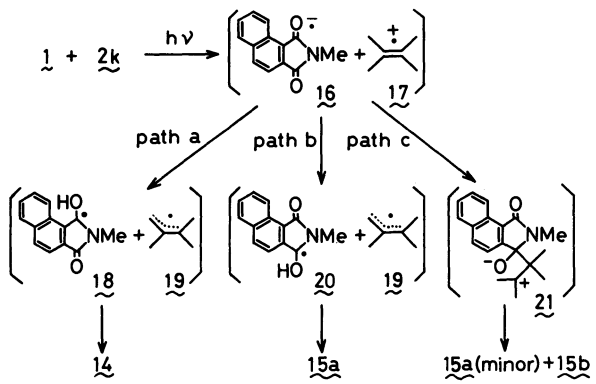


(5)

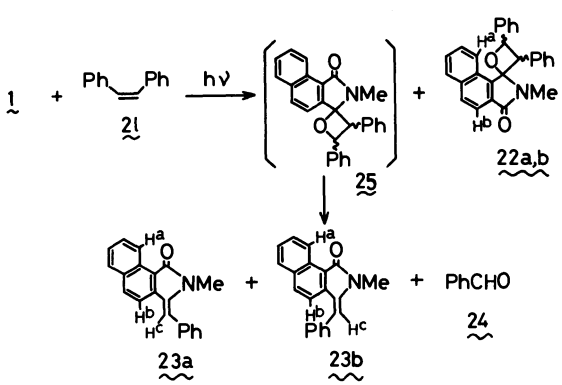
The configurations at the olefinic carbons in **23a, b** were assigned on the basis of the ^{1}H NMR spectra. First, the *N*-Me protons in **23a** were observed at a considerably higher field (δ=3.05) compared with those of **23b** (δ=3.37), probably due to the anisotropic shielding effect of the phenyl group. Second, the H^c signal of **23a** was shifted to a lower field (δ=6.83) compared with that of **23b** (δ=6.60), probably due to an anisotropic deshielding effect from the naphthyl ring current.

The positions of lactam carbonyl groups were assigned as follows: The H^a signals of **23a** (δ=9.11) and **23b** (δ=9.20) were significantly shifted to lower fields probably due to the deshielding effect of the lactam carbonyl groups, when compared with that of **26** (δ=8.55).

The regiochemistry of the oxetane precursor (**25**) of **23a, b** can be readily deduced from the structures of **23a, b**. The compound **26** was a regio-isomer of **23a, b** and its *Z*-configuration was suggested as follows: It has deshielded *N*-Me protons (δ=2.97) and shielded H^c proton (δ=7.2—7.7 mixed with arom H's). The structure of **26** allows to deduce the regiochemistry of **22a, b**.



Scheme 4.



Scheme 5.

On the basis of these structures of the products, it is possible to suppose that **2l** attacks predominantly at the less hindered carbonyl group of **1**. The stereochemical course of the reaction, however, seems to be complicated by the concomitant cis-trans isomerization of the alkene (**2l**).

A common feature between **2k** and **2l** is that **2k** has the lowest ionization (oxidation) potential among the series of ethylenes substituted by alkyl groups (**2a—e, k**) and **2l** has the lowest among the series of ethylenes substituted by phenyl groups (**2h, i, l**). The requirement of dominant electron donor-acceptor interaction has been recognized in the oxetane formation from the $\pi\pi^*$ excited state.[10,11] In this connection the formation of **14** and **15a, b** in the reaction of **1** with **2k** is rationalized by the electron transfer mechanism (Scheme 4).

Nature of the Singlet Excited State of 1 and Fluorescence Quenching. The absorption spectrum of **1** in benzene showed a broad band around 344 nm (log $\varepsilon\approx4$), which were slightly shifted to longer wavelengths ($\approx$2 nm) in ethanol. The fluorescence spectrum of **1** was obtained by using a diluted benzene solution (1×10^{-5} M) to avoid concentration quenching. The spectrum showed a strong and broad band ($\lambda_{max.}$ 430 nm, lifetime 42.0 ns at 25 °C in air-saturated benzene). The fluorescence excitation spectrum was almost identical with the absorption spectrum. These data suggest that the lowest singlet excited state of **1** is $\pi\pi^*$ in character. The energy of the excited singlet state (E_S) estimated from the absorption and fluorescence spectra was 308 kJ mol^{-1}.

Addition of aliphatic alkenes (**2a, b, d, e, k**) to the air-saturated benzene solutions of **1** (ca. 1×10^{-5} M) resulted in reduction of the fluorescence of **1** without varying the shape and the position of the maximum emission. Stern-Volmer plots of the fluorescence quenching by the alkenes (**2a—e, k**) gave straight lines against concentration of the alkenes (**2a—e, k**). Fluorescence quenching rate constants (k_q) calculated from the Stern-Volmer slopes ($k_q\tau$) using the lifetime (τ) of the fluorescence of **1** are shown in Table 2 together with ionization potentials (I_P) of the alkenes (**2a—e, k**) and relative rates for disappearance of **1** in the photoreaction with the alkenes. A good correlation was obtained between the k_q values and the relative rates for disappearance of **1**, which may indicate that the efficiency of the reaction mainly depends on the rate of reaction with excited singlet state of **1**. A correlation between the k_q values and the I_P values of alkenes is poor. This is probably due to the steric effect of the alkyl substituents, especially 1,2-dialkyl substituents, on the stage of interaction with the singlet excited state of **1**.

In summary, the most characteristic type of the reaction of **1** and alkenes was found to be naphthazepinedione formation. Other types of reactions, i.e., oxetane formation and electron

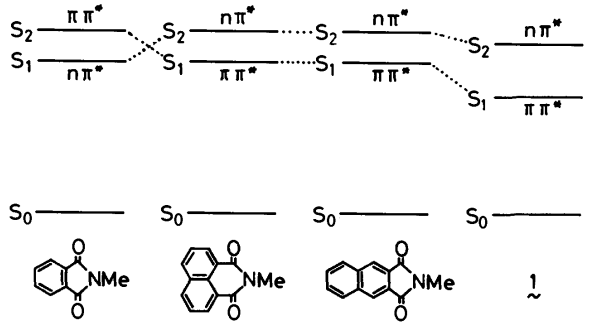


Fig. 2. Energy levels and nature of the singlet excited states of *N*-methylarenedicarboximides.

Table 2. Ionization Potentials (I_P) of Alkenes (**2a—e, k**), Stern-Volmer Slopes ($k_q\tau$) for the Fluorescence Quenching by Alkenes (**2a—e, k**),[a] Fluorescence Quenching Rate Constants (k_q),[b] and Relative Rates for Disappearance of **1** in the Photoreactions of **1** and Alkenes (**2a—e, k**) in Benzene[c]

Table 3. Lifetimes of Fluorescence (τ)[a] and Energies of the Lowest Singlet Excited States (S_1) of *N*-Methylarenedicarboximides[b]

Imide	τ/ns	Energies of S_1/kJ mol^{-1}
N-Methylphthalimide	—	335[c]
N-Methyl-**1**,8-naphthalenedicarboximide	1.0	332
N-Methyl-2,3-naphthalenedicarboximide	5.9	332
1	42.0	308

a) Conditions: at 25 °C, in air-saturated benzene. b) Estimated from the absorption and fluorescence spectra. c) Ref. 13.

transfer reaction (hydrogen abstraction), were observed only in the reactions with special alkenes (**2k**, **l**). The predominant types of reaction are found to depend largely upon the arene structure of naphthalenedicarboximides. For instance, **1**, is advantageous for the naphthazepinedione formation, but this reaction was minor for *N*-methyl-1,8- and 2,3-naphthalenedicarboximides.[8]

The results of the structure-dependent photoreactions can be explained by considering the natures of the singlet energy levels as shown in Fig. 2. The energies of the lowest singlet excited states and the lifetimes of the fluorescence of *N*-methylarenedicarboximides are shown in Table 3. The lowest and the second singlet excited states of *N*-methylphthalimide, $n\pi^*$-S_1 and the $\pi\pi^*$-S_2, respectively, are shown by referring a literature.[13] Change in the arene moiety from benzene to naphthalene alters the nature of the S_1 states from $n\pi^*$ to $\pi\pi^*$. For three *N*-methylnaphthalenedicarboximides the $\pi\pi^*$-S_1 levels were supported by the strong fluorescence and the solvent effects. The energies of $\pi\pi^*$-S_1 for 1,8- and 2,3-derivatives are virtually the same as that of $n\pi^*$-S_1 for the phthalimide. Hence, $\pi\pi^*$-S_1 of the 1,8- and 2,3-derivatives can interact with $n\pi^*$-S_2 as in the case of the phthalimide. Shorter lifetimes of the fluorescence of 1,8- and 2,3-derivatives than that for **1** as shown in Table 3 may support the stronger interaction. The predominant reaction of the 2,3-derivative is found as oxetane formation caused from the $\pi\pi^*$-S_1 strongly interacted with $n\pi^*$-S_2. The $\pi\pi^*$-S_1 level of **1** is however lowered to a "pure and simple" $\pi\pi^*$ state due to the decrease of the interaction. This nature of S_1 may be responsible for the formation of naphthazepinediones as the main products from **1**.

Experimental

The mps were measured by a Yanagimoto micromelting point apparatus, and are uncorrected. ^{1}H NMR spectra were determined on a JEOL JNM-MH-100 (100 MHz) and a JEOL JNM-GX-400 spectrometer (400 MHz) in $CDCl_3$ solution. IR spectra were obtained with a Hitachi 260-50 spectrophotometer. Mass spectra were measured on a JEOL JMS-DX-300 apparatus. Fluorescence spectra and the lifetimes were recorded by a Hitachi 650-40 spectrophotometer and a HORIBA NAES-1100 time-resolved spectrofluorometer, respectively. Microanalyses were performed on a Yanagimoto CHN corder MT-2.

Materials. *N*-Methyl-1,2-naphthalenedicarboximide (**1**)[14] were prepared by the reaction of the 1,2-naphthalenedicarboxylic anhydride[15] with methylamine and purified by chromatography (eluant dichloromethane), then by recrystallization from ethanol. Alkenes (**2a—l**) were commercially available and purified by distillation for liquid materials and by recrystallization for solid materials.

General Procedure for Irradiation and Product Isolation. UV irradiation of 25 cm^3 of N_2 purged benzene solutions containing 10 mM of **1** and 100 mM of alkenes (**2a—l**) was carried out with an Eikosha PIH 300-W high-pressure Hg-lamp through aq $CuSO_4$ filter about 1 cm in thickness (>320 nm) at ambient temperature. The reaction was monitored by TLC (Merck, Kieselgel 60 F_{254}) analyses and ^{1}H NMR measurements. After evaporation of the solvent, the residue was subjected to column chromatography [Wakogel C-200 (silica gel, 74—149 μ)]. Dichloromethane–ether was used as the eluant for the separation of the products.

Irradiation of 1 and *cis*-2-Butene (2a). ***cis*-2,3,4-Trimethyl-3,4-dihydro-1*H*-naphth[1,2-*c*]azepine-1,5(2*H*)-dione (3a)**: Mp 145—147 °C; ^{1}H NMR (400 MHz) δ=1.38 (d, *J*=7.3 Hz, 3H, NCH*Me*), 1.41 (d, *J*=7.0 Hz, 3H, COCH*Me*) 2.85 (q of d, $J_{CH\text{-}CH}$=3.2 Hz, $J_{CH\text{-}Me}$=7.0 Hz, 1H, COC*H*Me), 3.14 (s, 3H, NMe), 4.68 (q of d, $J_{CH\text{-}CH}$=3.2 Hz, $J_{CH\text{-}Me}$=7.3 Hz, 1H, NC*H*Me), 7.5—7.6 (m, 2H, Arom H), 7.83 (d, *J*=8.6 Hz, 1H, C*H*CH^b), 7.8—7.9 (m, 2H, Arom H), 7.99 (d, *J*=8.6 Hz, 1H, H^b); IR (KBr) 1683 (ketone), 1635 (lactam), 1423, 1358, 762 cm^{-1}. Found: C, 76.61; H, 6.52; N, 5.26%; M$^+$, 267. Calcd for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24%; M, 267.

***cis*-2,3,4-Trimethyl-3,4-dihydro-1*H*-naphth[2,1-*c*]-azepine-1,5(2*H*)-dione (4a)**: Mp 130—133 °C; ^{1}H NMR (400 MHz) δ=1.39 (d, *J*=7.3 Hz, 6H, NCH*Me*CH*Me*CO), 2.61 (m, 1H, COC*H*Me), 3.23 (s, 3H, NMe), 4.72 (m, 1H, NC*H*Me), 7.4—7.6 (m, 3H, Arom H), 7.8—7.9 (m, 1H, Arom H), 7.95 (d, *J*=8.6 Hz, 1H, H^b), 8.41 (dd, 1H, H^a); IR (KBr) 1682 (ketone), 1640 (lactam), 1403, 1328, 824 cm^{-1}. Found: C, 76.53; H, 6.57; N, 5.29%; M$^+$, 267. Calcd for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24%; M, 267.

Irradiation of 1 and *trans*-2-Butene (2b). ***trans*-2,3,4-Trimethyl-3,4-dihydro-1*H*-naphth[1,2-*c*]azepine-1,5(2*H*)-dione (3b)**: Mp 177—180 °C; ^{1}H NMR (400 MHz) δ=1.18 (d, *J*=7.3 Hz, 3H, COCH*Me*), 1.35 (d, *J*=6.7 Hz, 3H, NCH*Me*), 3.09 (q of d, $J_{CH\text{-}CH}$=11.0 Hz, $J_{CH\text{-}Me}$=7.3 Hz, 1H, COC*H*Me), 3.10 (s, 3H, NMe), 4.03 (q of d, $J_{CH\text{-}CH}$=11.0 Hz, $J_{CH\text{-}Me}$=6.7 Hz, 1H, NC*H*Me), 7.5—7.6 (m, 2H, Arom H), 7.84 (d, *J*=8.6 Hz, 1H, C*H*CH^b), 7.8—7.9 (m, 2H, Arom H), 8.01 (d, *J*=8.6 Hz, 1H, H^b); IR (KBr) 1698 (ketone), 1640 (lactam), 1424, 1396, 846 cm^{-1}. Found: C, 76.58; H, 6.55; N, 5.29%; M$^+$, 267. Calcd for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24%; M, 267.

***trans*-2,3,4-Trimethyl-3,4-dihydro-1*H*-naphth[2,1-*c*]azepine-1,5(2*H*)-dione (4b)**: Mp 151—154 °C; ^{1}H NMR (400 MHz) δ=1.11 (d, *J*=7.3 Hz, 3H, COCH*Me*), 1.33 (d, *J*=6.9 Hz, 3H, NCH*Me*), 2.97 (q of d, $J_{CH\text{-}CH}$=11.6 Hz, $J_{CH\text{-}Me}$=7.3 Hz, 1H, COC*H*Me), 3.14 (s, 3H, NMe), 4.11 (q of d, $J_{CH\text{-}CH}$=11.6 Hz, $J_{CH\text{-}Me}$=6.9 Hz, 1H, NC*H*Me), 7.39 (d, *J*=8.6 Hz, 1H, C*H*CH^b), 7.6—7.7 (m, 2H, Arom H), 7.87 (dd, 1H, Arom H), 7.97 (d, *J*=8.6 Hz, 1H, H^b), 8.45 (dd, 1H, H^a); IR (KBr) 1686 (ketone), 1642 (lactam), 1322, 1252, 768 cm^{-1}. Found: C, 76.49; H, 6.53; N, 5.28%; M$^+$, 267. Calcd for $C_{17}H_{17}CO_2$: C, 76.38; H, 6.41; N, 5.24%; M, 267.

Reduction of 3b and 4b. To a solution of 50 mg of **3b** in 20 cm^3 of ethanol was added 5 mg of sodium borohydride with stirring and the solution was kept overnight at room temperature. Then, the solution was poured into 10 cm^3 of 0.1 M-hydrochloric acid and extracted with 20 cm^3 of chloroform. The extract was washed several times with water and dried over magnesium sulfate. After

evaporation of the solvent, the residue was chromatographed (eluant dichloromethane–ether) to give **5** (60%).

Reduction of **4b** (50 mg) by sodium borohydride as described above gave **6** (60%).

5-Hydroxy-2,*r*-3,*t*-4-trimethyl-2,3,4,5-tetrahydro-1*H*-naphth[1,2-*c*]azepin-1-one (5): Mp 187—190 °C; ^{1}H NMR δ=1.02 (d, 3H, COCH*Me*), 1.10 (d, 3H, NCH*Me*), 2.1—2.5 (m, 1H, CH), 2.85 (s, 3H, NMe), 2.9—3.0 (m, 2H, *H*COH), 4.9—5.1 (m, 1H, NC*H*Me), 7.3—7.8 (m, 5H, Arom H), 9.10 (m, 1H, H^a); IR (KBr) 3220 (OH), 1612 (lactam), 1401, 842, 770 cm^{-1}. Found: C, 76.07; H, 7.25; N, 5.23%; M$^+$, 269. Calcd for $C_{17}H_{19}NO_2$: C, 75.81; H, 7.11; N, 5.20%; M, 269.

1-Hydroxy-*r*-2,*t*-3,4-trimethyl-2,3,4,5-tetrahydro-1*H*-naphth[2,1-*c*]azepin-5-one (6): Mp 260—262 °C; ^{1}H NMR δ=0.61 (d, 3H, NCH*Me*), 1.19 (d, 3H, COCH*Me*), 2.1—2.5 (m, 1H, CH), 2.8—3.0 (m, 2H, *H*COH), 3.05 (s, 3H, NMe), 4.5—4.7 (m, 1H, NC*H*Me), 7.2—7.9 (m, 5H, Arom H), 8.25 (m, 1H, H^a); IR (KBr) 3290 (OH), 1611 (lactam), 1401, 1088, 763 cm^{-1}. Found: C, 76.10; H, 7.28 N, 5.23%; M$^+$, 269. Calcd for $C_{17}H_{19}NO_2$: C, 75.81; H, 7.11; N, 5.20%; M, 269.

Irradiation of 1 and Isobutene (2d). 2,4,4-Trimethyl-3,4-dihydro-1*H*-naphth[1,2-*c*]azepine-1,5(2*H*)-dione (3d): Mp 149—151 °C; ^{1}H NMR δ=1.28 (d, 6H, CMe_2), 3.23 (s, 3H, NMe), 3.42 (s, 2H, CH_2), 7.4—8.0 (m, 5H, Arom H), 7.96 (d, 1H, H^b); IR (KBr) 1708 (ketone), 1652 (lactam), 1392, 1088, 778 cm^{-1}. Found: C, 76.57; H, 6.54; N, 5.29%; M$^+$, 267. Calcd for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24%; M, 267.

2,2,4-Trimethyl-3,4-dihydro-1*H*-naphth[2,1-*c*]-azepine-1,5-(2*H*)-dione (4d): Mp 151—153 °C; ^{1}H NMR δ=0.8—1.7 (coalesced br s, 6H, CMe_2), 2.9—3.2 (coalesced br s, 1H, 1H of CH_2), 3.30 (s, 3H, NMe), 3.7—4.2 (coalesced br s, 1H, 1H of CH_2), 7.36 (d, 1H, C*H*CH^b), 7.4—7.7 (m, 2H, Arom H), 7.7—7.9 (m, 1H, Arom H), 7.89 (d, 1H, H^b), 8.48 (dd, J=3.9, 8.0 Hz, 1H, H^a); IR (KBr) 1705 (ketone), 1648 (lactam), 1475, 1403, 842, 774 cm^{-1}. Found: C, 76.48; H, 6.50; N, 5.27%; M$^+$, 267. Calcd for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24%; M, 267.

Irradiation of 1 and 2-Methyl-2-butene (2e). 2,3,4,4-Tetramethyl-3,4-dihydro-1*H*-naphth[1,2-*c*]azepine-1,5(2*H*)-dione (3e): Mp 141—143 °C; ^{1}H NMR δ=0.98 (s, 3H, CMe), 1.22 (d, 3H, CH*Me*), 1.27 (s, 3H, CMe), 3.00 (s, 3H, NMe), 4.17 (q, 2H, C*H*Me), 7.3—7.8 (m, 5H, Arom H), 7.87 (d, 1H, H^b); IR (KBr) 1695 (ketone), 1646 (lactam), 1468, 1401, 841, 759 cm^{-1}. Found: C, 77.00; H, 6.95; N, 5.03%. Calcd for $C_{18}H_{19}NO_2$: C, 76.84; H, 6.81; N, 4.98%.

2,2,3,4-Tetramethyl-3,4-dihydro-1*H*-naphth[2,1-*c*]-azepine-1,5(2*H*)-dione (4e): Mp 136—138 °C; ^{1}H NMR δ=0.88 (s, 3H, CMe), 1.21 (d, 3H, CH*Me*), 1.22 (s, 3H, CMe), 3.04 (s, 3H, NMe), 4.18 (q, 2H, C*H*Me), 7.22 (d, 1H, C*H*CH^b), 7.4—7.6 (m, 2H, Arom H), 7.6—7.8 (m, 2H, Arom H), 7.81 (d, 1H, H^b), 8.40 (dd, 1H, H^a); IR (KBr) 1680 (ketone), 1642 (lactam), 1402, 1324, 833, 763 cm^{-1}. Found: C, 76.96; H, 6.90; N, 5.00%. Calcd for $C_{18}H_{19}NO_2$: C, 76.84; H, 6.81; N, 4.98%.

Irradiation of 1 and Cyclopentene (2f). 7,7a,8,9,10,10a,11,12-Octahydrocyclopenta[*b*]naphth[2,1-*e*]-azepine-7,12-dione (3f): Mp 156—159 °C; ^{1}H NMR δ=1.2—2.2 (m, 6H), 3.13 (s, 3H, NMe), 3.3—3.6 (m, 1H, COCH), 4.0—4.3 (m, 1H, NCH), 7.4—7.6 (m, 2H, Arom H), 7.7—7.9 (m, 3H, Arom H), 8.03 (d, 1H, H^b); IR (KBr) 1698 (ketone), 1636 (lactam), 1462, 1418, 1392, 763 cm^{-1}. Found: 77.57; H, 6.31; N, 5.04%. Calcd for $C_{18}H_{17}NO_2$: C, 77.39; H, 6.13; N, 5.01%.

7,8,8a,9,10,11,11a,12-Octahydrocyclopenta[*b*]naphth[1,2-*e*]-azepine-7,12-dione (4f): Mp 143—146 °C; ^{1}H NMR δ=1.3—2.4 (m, 6H), 2.8—3.2 (m, 1H, COCH), 3.24 (s, 3H, NMe), 4.1—4.5 (m, 1H, NCH), 7.36 (d, 1H, C*H*CH^b), 7.5—8.0 (m, 3H, Arom H), 8.00 (d, 1H, H^b), 8.38 (dd, 1H, H^a); IR (KBr) 1682 (ketone), 1638 (lactam), 1459, 1402, 1328, 763 cm^{-1}. Found: C, 77.20; H, 6.25; N, 4.87%. Calcd for $C_{18}H_{17}NO_2$: C, 77.39; H, 6.13; N, 5.01%.

Irradiation of 1 and 2-Norbornene (2g). 9,10,11,11a-Tetrahydro-8,11-methano-8*H*-benzo[*b*]naphth[2,1-*e*]-azepine-7,13(7a*H*,12*H*)-dione (3g): Mp 176—179 °C; ^{1}H NMR δ=1.0—2.0 (m, 6H), 2.8—3.0 (m, 1H), 3.0—3.3 (m, 2H), 3.14 (s, 3H, NMe), 3.9—4.1 (m, 1H, NCH), 7.5—7.8 (m, 2H, Arom H), 7.9—8.1 (m, 4H, Arom H); IR (KBr) 1711 (ketone), 1634 (lactam), 1372, 838, 762 cm^{-1}. Found: C, 78.72; H, 6.39; N, 4.63%. Calcd for $C_{20}H_{19}NO_2$: C, 78.66; H, 6.27; N, 4.59%.

9,10,11,12-Tetrahydro-9,12-methano-8a*H*-benzo-[*b*]naphth[1,2-*e*]azepine-7,13(8*H*,12a*H*)-dione (4g): Mp 153—156 °C; ^{1}H NMR δ=0.9—2.0 (m, 6H), 2.7—3.1 (m, 3H), 3.21 (s, 3H, NMe), 3.9—4.1 (m, 1H, NCH), 7.35 (d, 1H, C*H*CH^b), 7.5—7.8 (m, 2H, Arom H), 7.8—8.0 (m, 1H, Arom H), 8.01 (d, 1H, H^b), 8.55 (dd, 1H, H^a); IR (KBr) 1712 (ketone), 1624 (lactam), 1383, 1362, 1096, 763 cm^{-1}. Found: C, 78.83; H, 6.36; N, 4.61%. Calcd for $C_{20}H_{19}NO_2$: C, 78.66; H, 6.27; N, 4.59%.

Irradiation of 1 and Styrene (2h). 2-Methyl-4-phenyl-3,4-dihydro-1*H*-naphth[1,2-*c*]azepine-1,5(2*H*)-dione (3h): Mp 157—159 °C; ^{1}H NMR δ=3.15 (s, 3H, NMe), 3.49 (dd, J=2, 12 Hz, 1H, PhC*H*), 4.17 (t, J=12 Hz, 1H, 1H of CH_2), 4.35 (dd, J=2, 12 Hz, 1H, 1H of CH_2), 6.9—7.6 (m, 7H, Arom H), 7.7—7.9 (m, 3H, Arom H), 7.96 (d, 1H, H^b); IR (KBr) 1702 (ketone), 1652 (lactam), 1483, 1398, 774 cm^{-1}. Found: C, 80.14; H, 5.59; N, 4.50%; M$^+$, 315. Calcd for $C_{21}H_{17}NO_2$: C, 79.98; H, 5.43; N, 4.44%; M, 315.

4-Methyl-2-phenyl-3,4-dihydro-1*H*-naphth[2,1-*c*]azepine-1,5(2*H*)-dione (4h): Mp 144—147 °C; ^{1}H NMR δ=3.27 (coalesced br s, 3H, NMe), 3.3—3.8 (coalesced br s, 1H), 4.0—4.4 (coalesced br s, 2H), 7.0—8.0 (m, 9H, Arom H), 7.94 (d, 1H, H^b), 8.45 (dd, 1H, H^a); IR (KBr) 1682 (ketone), 1652 (lactam), 1398, 1258, 834, 754 cm^{-1}. Found: C, 80.20; H, 5.61; N, 4.42%; M$^+$, 315. Calcd for $C_{21}H_{17}NO_2$: C, 79.98; H, 5.43; N, 4.44%; M, 315.

Irradiation of 1 and 1,1-Diphenylethylene (2i). 4,4-Diphenyl-2-methyl-3,4-dihydro-1*H*-naphth[1,2-*c*]azepine-1,5-(2*H*)-dione (3i): Mp 195—198 °C; ^{1}H NMR δ=2.48 (s, 3H, NMe), 4.28 (br s, 2H, CH_2), 6.8—7.9 (m, 15H, Arom H), 7.96 (d, 1H, H^b); IR (KBr) 1712 (ketone), 1656 (lactam), 1483, 1401, 772, 713 cm^{-1}. Found: C, 83.01; H, 5.55 N, 3.46%. Calcd for $C_{27}H_{21}NO_2$: C, 82.84; H, 5.41; N, 3.58%.

2,2-Diphenyl-4-methyl-3,4-dihydo-1*H*-naphth[2,1-*c*]azepine-1,5(2*H*)-dione (4i): Mp 191—193 °C; ^{1}H NMR δ=2.53 (s, 3H, NMe), 3.62 and 5.04 (coalesced br ABq, 2H, CH_2), 7.12 (d, 1H, C*H*CH^b), 7.1—7.4 (m, 13H, Arom H), 7.5—7.7 (m, 1H, Arom H), 7.79 (d, 1H, H^b), 8.51 (dd, 1H, H^a); IR (KBr) 1690 (ketone), 1658 (lactam), 1456, 1402, 758, 716 cm^{-1}. Found: C, 82.92; H, 5.38; N, 3.40%. Calcd for $C_{27}H_{21}NO_2$: C, 82.84; H, 5.41; N, 3.58%.

Irradiation of 1 and Ethyl Vinyl Ether (2j). 4-Ethoxy-2-methyl-3,4-dihydro-1*H*-naphth[1,2-*c*]azepine-1,5-(2*H*)-dione (3j): Mp 141—143 °C; ^{1}H NMR δ=1.29 (t, 3H, OCH_2Me), 3.20 (s, 3H, NMe), 3.4—4.4 (m, 5H), 7.4—7.7 (m,

2H, Arom H), 7.7—8.0 (m, 3H, Arom H), 8.00 (d, J=9 Hz, 1H, H^b); IR (in $CHCl_3$) 1710 (ketone), 1646 (lactam), 1482, 1400, 1081 cm^{-1}. Found: C, 72.32; H, 6.21; N, 5.09%; M^+, 283. Calcd for $C_{17}H_{17}NO_3$: C, 72.06; H, 6.05; N, 4.94%; M, 283.

2-Methyl-3,4-dihydro-1*H*-naphth[1,2-*c*]azepine-1,5(2*H*)-dione (7): Mp 186—188 °C; ^1H NMR δ=3.23 (s, 3H, NMe), 3.0—3.4 (m, 2H, $COCH_2$), 3.6—3.8 (m, 2H, NCH_2), 7.5—7.7 (m, 2H, Arom H), 7.8—8.0 (m, 3H, Arom H), 8.03 (d, J=9 Hz, 1H, H^b); IR (KBr) 1690 (ketone), 1638 (lactam), 1493, 1392, 1256, 764 cm^{-1}. Found: C, 75.20; H, 5.69; N, 5.94%; M^+, 239. Calcd for $C_{15}H_{13}NO_2$: C, 75.30; H, 5.48; N, 5.85%; M, 239.

4-Methyl-3,4-dihydro-1*H*-naphth[2,1-*c*]azepine-1,5(2*H*)-dione (8): Mp 151—145 °C; ^1H NMR δ=2.9—3.1 (m, 2H, $COCH_2$), 3.28 (s, 3H, NMe), 3.6—3.8 (m, 2H, NCH_2), 7.5—7.7 (m, 3H, Arom H), 7.8—7.9 (m, 1H, Arom H), 7.98 (d, J=9 Hz, 1H, H^b), 8.41 (dd, 1H, H^a); IR (in $CHCl_3$) 1696 (ketone), 1646 (lactam), 1400, 1263, 828 cm^{-1}. Found: C, 75.57; H, 5.73; N, 5.90%; M^+, 239. Calcd for $C_{15}H_{13}NO_2$: C, 75.30; H, 5.48; N, 5.85%; M, 239.

Irradiation of 1 and 2,3-Dimethyl-2-butene (2k). 2,3′,3′,4′,4′-Pentamethylspiro[3*H*-benz[*e*]isoindole-3,2′-oxetan]-1(2*H*)-one (13a): Oil; ^1H NMR δ=1.05 (s, 3H, CMe), 1.25 (s, 3H, CMe), 1.53 (s, 3H, CMe), 1.63 (s, 3H, CMe), 3.24 (s, 3H, NMe), 7.4—7.9 (m, 4H, Arom H), 7.94 (d, J=9 Hz, 1H, H^b), 9.19 (dd, 1H, H^a); IR (oil) 1692 (lactam), 1372, 1356, 1068, 942, 783 cm^{-1}. Found: C, 77.53; H, 7.32; N, 4.47%; M^+, 295. Calcd for $C_{19}H_{21}NO_2$: C, 77.26; H, 7.17; N, 4.74%; M, 295.

2,3′,3′,4′,4′-Pentamethylspiro[1*H*-benz[*e*]isoindole-1,2′-oxetan]-3(2*H*)-one (13b): Mp 168—170 °C; ^1H NMR δ=0.89 (s, 3H, CMe), 1.12 (s, 3H, CMe), 1.67 (s, 3H, CMe), 1.77 (s, 3H, CMe), 3.32 (s, 3H, NMe), 7.3—7.9 (m, 5H, Arom H), 8.94 (dd, 1H, H^a); IR (KBr) 1698 (lactam), 1418, 1384, 1038, 776 cm^{-1}. Found: C, 77.30; H, 7.21; N, 4.81%; M^+, 295. Calcd for $C_{19}H_{21}NO_2$: C, 77.26; H, 7.17; N, 4.74%; M, 295.

1-(2,3-Dimethyl-2-butenyl)-1-hydroxy-2-methyl-1,2-dihydro-3*H*-benz[*e*]isoindol-3-one (14): Mp 191—193 °C; ^1H NMR δ=1.12 (s, 3H, CMe), 1.21 (s, 3H, CMe), 1.33 (s, 3H, CMe), 2.84 (s, 3H, NMe), 2.88 and 3.08 (ABq, J=14 Hz, 2H, CH_2), 3.97 (s, 1H, OH), 7.3—8.0 (m, 5H, Arom H), 8.47 (dd, 1H, H^a); IR (KBr) 3300 (OH), 1694 (lactam), 1440, 1411, 768 cm^{-1}. Found: C, 77.46; H, 7.30; N, 4.79%; M^+, 295. Calcd for $C_{19}H_{21}NO_2$: C, 77.26; H, 7.17; N, 4.74%; M, 295.

3-(2,3-Dimethyl-2-butenyl)-3-hydroxy-2-methyl-2,3-dihydro-1*H*-benz[*e*]isoindol-1-one (15a): Mp 124—127 °C; ^1H NMR δ=1.17 (s, 3H, CMe), 1.52 (s, 3H, CMe), 1.59 (s, 3H, CMe), 2.38 and 2.73 (ABq, J=14 Hz, 2H, CH_2), 2.62 (s, 3H, NMe), 4.64 (s, 1H, OH), 7.2—7.7 (m, 5H, Arom H), 8.58 (dd, 1H, H^a); IR (KBr) 3280 (OH), 1684 (lactam), 1381, 1360, 1018, 811 cm^{-1}. Found: C, 77.50; H, 7.28; N, 4.78%; M^+, 295. Calcd for $C_{19}H_{21}NO_2$: C, 77.26; H, 7.17; N, 4.74%; M, 295.

3-Hydroxy-2-methyl-3-(1,1,2-trimethyl-2-propenyl)-2,3-dihydro-1*H*-benz[*e*]isoindol-1-one (15b): Mp 122—125 °C; ^1H NMR δ=0.94 (s, 3H, CMe), 1.03 (s, 3H, CMe), 1.96 (s, 3H, =CMe), 2.41 (s, 3H, NMe), 4.31 (s, 1H, OH), 4.52 and 4.76 (two br s, 2H, $=CH_2$), 7.2—7.7 (m, 5H, Arom H), 8.72 (dd, 1H, H^a); IR (KBr) 3350 (OH), 1682 (lactam), 1386, 1362, 1080, 824 cm^{-1}. Found: C, 77.47; H, 7.24; N, 4.78%; M^+, 295. Calcd for $C_{19}H_{21}NO_2$: C, 77.26; H, 7.17; N, 4.74%; M, 295.

Irradiation of 1 and *cis*-Stilbene (2l). One Stereoisomer of 2-Methyl-3′,4′-diphenylspiro[1*H*-benz[*e*]isoindole-1,2′-oxetan]-3(2*H*)-one (22a): Mp 187—190 °C; ^1H NMR δ=2.87 (s, 3H, NMe), 5.61 (d, J=9 Hz, 1H, OCHC*H*Ph), 6.4—6.6 (m, 2H, Arom H), 6.85 (d, J=9 Hz, 1H, OC*H*Ph), 6.9—7.1 (m, 2H, Arom H), 7.3—8.2 (m, 10H, Arom H), 8.76 (dd, 1H, H^a); IR (KBr) 1718 (lactam), 1395, 968, 768, 714 cm^{-1}. Found: C, 83.02; H, 5.65; N, 3.61%; M^+, 391. Calcd for $C_{27}H_{21}NO_2$: C, 82.84; H, 5.41; N, 3.58%; M, 391.

Another Stereoisomer (22b): Mp 255—258 °C; ^1H NMR δ=2.89 (s, 3H, NMe), 5.43 (d, J=9 Hz, 1H, OCHC*H*Ph), 6.67 (d, J=9 Hz, 1H, OC*H*Ph), 6.9—7.1 (m, 2H, Arom H), 7.2—8.1 (m, 13H, Arom H), 8.26 (dd, 1H, H^a); IR (KBr) 1711 (lactam), 1382, 954, 764, 702 cm^{-1}. Found: C, 82.97; H, 5.42; N, 3.63%; M^+, 391. Calcd for $C_{27}H_{21}NO_2$: C, 82.84; H, 5.41; N, 3.58%; M, 391.

(*Z*)-3-Benzylidene-2-methyl-2,3-dihydro-1*H*-benz[*e*]-isoindol-1-one (23a): Mp 143—146 °C; ^1H NMR δ=3.05 (s, 3H, NMe), 6.83 (s, 1H, H^c), 7.1—7.9 (m, 9H, Arom H), 7.96 (d, 1H, H^b), 9.11 (dd, 1H, H^a); IR (KBr) 1682 (lactam), 1283, 824, 751, 708 cm^{-1}. Found: C, 84.36; H, 5.49; N, 4.98%; M^+, 285. Calcd for $C_{20}H_{15}NO$: C, 84.18; H, 5.30; N, 4.91%; M, 285.

(*E*)-3-Benzylidene-2-methyl-2,3-dihydro-1*H*-benz[*e*]-isoindol-1-one (23b): Mp 136—139 °C; ^1H NMR δ=3.37 (s, 3H, NMe), 6.60 (s, 1H, H^c), 7.0—8.0 (m, 10H, Arom H), 9.20 (dd, 1H, H^a); IR (KBr) 1697 (lactam), 1434, 828, 756, 702 cm^{-1}. Found: C, 84.41; H, 5.52; N, 4.87%. Calcd for $C_{20}H_{15}NO$: C, 84.18; H, 5.30; N, 4.91%.

Acid Decomposition of 22a and 22b. To a solution of 50 mg of **22a** in 20 cm^3 of methanol was added a few drops of hydrochloric acid. After 1 d, to the solution was added 30 cm^3 of chloroform and the solution was washed successively with water, and then dried over magnesium sulfate. After evaporation of the solvent, the residue was chromatographed (eluant dichloromethane) to give **26** (53%).

Acid decomposition of **22b** (50 mg) by hydrochloric acid as described above gave **26** (58%).

(*Z*)-1-Benzylidene-2-methyl-1,2-dihydro-3*H*-benz[*e*]-isoindol-3-one (26): Mp 166—168 °C; ^1H NMR δ=2.97 (s, 3H, NMe), 7.2—7.7 (m, 7H, Arom H+H^c), 7.8—8.0 (m, 3H, Arom H), 8.55 (dd, 1H, H^a); IR (KBr) 1710 (lactam), 1378, 1086, 784, 759, 703 cm^{-1}. Found: C, 84.05; H, 5.52; N, 4.91%; M^+, 285. Calcd for $C_{20}H_{15}NO$: C, 84.18; H, 5.30; N, 4.91%; M, 285.

The authors wish to express their thanks to Dr. Atsuhiro Osuka, Kyoto University, for his help in operating the 400 MHz-NMR. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60740276 from the Ministry of Education, Science and Culture.

(Received August 12, 1985)

Oxidative addition of (chloroformyl)ferrocene to $[Pd(PPh_3)_4]$ yielded a stable acylpalladium(II) compound of $[Pd(COFc)Cl(PPh_3)_2]$ (**1**), (Fc=ferrocenyl). Complex **1** was treated with alkali metal salts of poly(1-pyrazolyl)-borates (H_nBPz_{4-n}), (Pz=1-pyrazolyl) to give complexes $[Pd(COFc)(H_nBPz_{4-n})(PPh_3)]$, (**2**, n=0; **3**, n=1; and **4**, n=2), which retained the palladium-attached ferrocenylcarbonyl structure. Reaction of **1** with 1,10-phenanthroline (phen) afforded [Pd(COFc)Cl(phen)], whereas reaction with 2,2′-bipyridine gave $[\{Pd(COFc)Cl(PPh_3)\}_2]$ as an isolable material. Transformation of the ferrocenylcarbonyl moiety took place to the ferrocenyl group on palladium, in chlorine-abstraction from **1** with $AgClO_4 \cdot H_2O$ in CH_3CN. In the temperature-dependent ^{1}H-NMR spectra, fluxional behavior was observed for the poly(1-pyrazolyl)borate groups in **2** and **3**. Electrochemical experiments were carried out for **1**—**4** in CH_3CN using platinum working electrodes, and reversible one-electron redox-couples were detected, which were attributed to the process Fe(II)⇄Fe(III) in the ferrocenyl moiety. Furthermore, electron-withdrawing effects of the [poly(1-pyrazolyl)borato]palladiocarbonyl moieties from the Fe centers were compared among these complexes, in relation to their redox potentials.

Transition-metal acyl complexes have been regarded as models of intermediates for catalytic hydroformylation and carboxylation of olefins.[1-6] It would be still worthwhile to synthesize new stable acyl complexes and to study their chemical reactivity and stability of the acyl-metal σ-bonds, in relation to the properties of coexisting other ligands and to the character of alkyl or aryl groups in the acyl moiety. In the course of our study on the properties and applications of bimetallic complexes with ferrocene moieties,[7] we performed oxidative addition of (chloroformyl)ferrocene to tetrakis(triphenylphosphine)palladium(0) $[Pd(PPh_3)_4]$ to yield a stable complex of chloro(ferrocenylcarbonyl)bis(triphenylphosphine)palladium(II) $[Pd(COFc)Cl(PPh_3)_2]$ (Fc=ferrocenyl) (**1**), which involved the well-delocalized π-system of the ferrocenylcarbonyl group. The present paper deals with the syntheses, NMR spectra, and electrochemical properties of the complex **1** and its derivatives with some chelates attached via two ligating nitrogen atoms, including poly(1-pyrazolyl)-borate groups $[H_nBPz_{4-n}]^-$ (Pz=1-pyrazolyl).[8-10] Poly(1-pyrazolyl)borate groups are a versatile and interesting class of uninegative ligands, which have been shown to confer considerable stability on organometallic complexes and have a potentiality for novel fluxionality on the basis of NMR spectroscopy. Electrochemical properties of these groups seemed to be one of key clues to their interesting character. To our knowledge, there were no reports on the electrochemistry of transition-metal poly(1-pyrazolyl)-borate complexes except Trofimenko's brief mention on the polarographic data of $[M(H_nBPz_{4-n})_2]$ (M=Fe, Co, and Cu).[9]

Results and Discussion

Syntheses and Properties of (Ferrocenylcarbonyl)palladium(II) Complexes. When the zerovalent palladium compound $[Pd(PPh_3)_4]$ was added to a benzene solution of (chloroformyl)ferrocene, the color turned into orange and the resulting yellowish orange precipitates were found to be the (ferrocenylcarbonyl)palladium(II) complex **1**. In the IR spectrum, there were a strong ν(C=O) band at 1655 cm^{-1} and a medium ν(Pd-Cl) band at 303 cm^{-1}. The ^{13}C-NMR spectrum of **1** in CD_2Cl_2 showed a weak signal for the carbonyl carbon at δ=207.9. A large signal at δ=69.8 was attributed to the unsubstituted cyclopentadienyl group, and three resonances at δ=70.5, 71.1, and 73.1 were to the monosubstituted one. The phenyl carbons in the coordinated triphenylphosphine ligands resonated at δ=129.7 (1-C), 135.0 (2-C), 128.4 (3-C), and 132.3 (4-C).

Treatment of **1** with sodium or potassium salts of poly(1-pyrazolyl)borates $[H_nBPz_{4-n}]^-$ yielded (ferrocenylcarbonyl)[poly(1-pyrazolyl)borato]palladium(II) $[Pd(COFc)(H_nBPz_{4-n})(PPh_3)]$ (**2**, n=0; **3**, n=1; and **4**, n=2). Complexes **2** and **3** were considerably air-stable both in the solid states and in common organic solvents. On the other hand, complex **4** was slowly decomposed in halogenated solvents, and solubility in other organic solvents, such as benzene and THF was a little lower than those of **1**—**3**. Similar decomposition and low solubility of palladium complexes with the H_2BPz_2 group were reported previously.[9,10] Characteristic ν(C=O) bands were observed for **2**—**4** near 1650 cm^{-1} similarly to that of **1**, supporting retention of the palladium-attached ferrocenylcarbonyl structure in these complexes. The

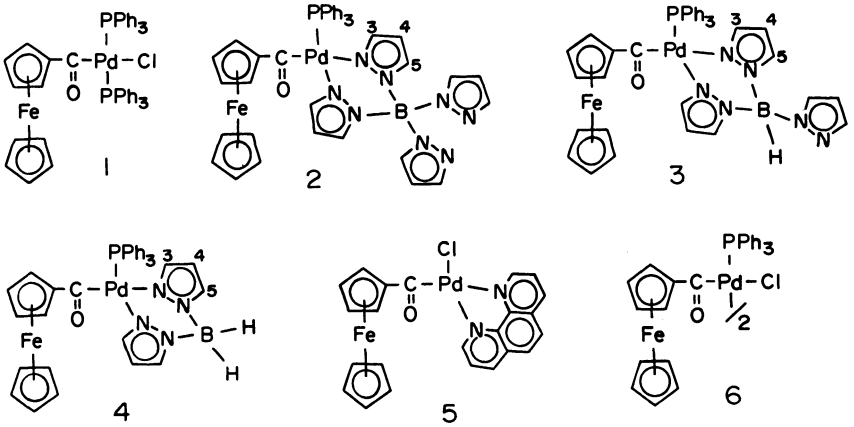
a) Measured in $CDCl_3$ at 23 °C with the CW-type JNM-MH-100 spectrometer, unless stated otherwise; δ values from TMS; signal shape and coupling constants in Hz are given in the parentheses; abbreviations used, s=singlet, bs=broad singlet, dd=doublet of doublets d=doublet, t=triplet, dt=doublet of triplets. b) At 51 °C. c) In toluene-d^8; measured with the FT-type FX-90-Q spectrometer. d) Obscured by signals for PPh_3.



$HBPz_3$ group in **3** showed a ν(BH) band at 2450 cm^{-1}, and the H_2BPz_2 group in **4** gave a characteristic $\nu(BH_2)$ pattern consisting of a slightly resolved doublet at 2395 cm^{-1} and a weak band at 2280 cm^{-1}. Visible absorption spectra of **1**—**4** in CH_3CN showed a band around 460 nm, which was associated with the mixing of a charge-transfer type transition from the Fe atom to the antibonding orbitals on the cyclopentadienyl rings and a d-d type transition.[7]

In addition, complex **1** was treated with 1,10-phenanthroline (phen), and the complex [Pd(COFc)-Cl(phen)] (**5**) was formed through displacement of

two triphenylphosphine molecules. Complex **5** was very insoluble in benzene and dichloromethane, and a ^{1}H-NMR spectrum was not obtained. In case of the reaction with 2,2′-bipyridine (bpy), the expected compound [Pd(COFc)Cl(bpy)] was not isolated, and the reaction-mixture gave a very insoluble material (**6**). Although NMR measurement was not possible, the IR spectrum confirmed retention of the ferrocenylcarbonyl group and triphenylphosphine on palladium. The elemental analysis of **6** suggested its structure to be $[\{Pd(COFc)Cl(PPh_3)\}_2]$,[11] and one mole of triphenylphosphine remained coordinated to the palladium atom in the marked contrast to the case of phen.

Chlorine-abstraction from **1** in CH_3CN was performed with hydrated silver perchlorate in expectation of a cationic complex $[Pd(COFc)(NCCH_3)(PPh_3)_2]ClO_4$, and a pale yellow material (mp, 186 °C (decomp)) of (**7**)[14] was obtained from the reaction-mixture. The IR spectrum of **7** did not show any ν(C=O) bands. There was a strong band at 1095 cm^{-1} without any significant splitting, assignable to the T_2(ClO) stretching mode of an ionic perchlorate uncomplexed. Measurement of the ^{1}H-NMR spectrum indicated retention of the ferrocenyl group and triphenylphosphine in a ratio close to 1:2. The above evidence led us to believe that the ferrocenyl group migrated to the vacant coordination-site produced, followed by dissociation of carbon monoxide from palladium.[1,2] The resulting vacant site seemed to be occupied by a water molecule.

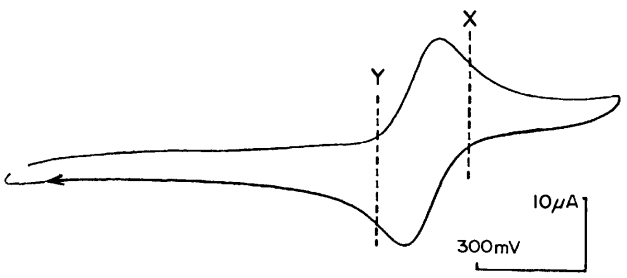


Fig. 1. Cyclic voltammogram of 10^{-3} mol dm^{-3} [Pd(COFc)(BPz_4)(PPh_3)] in CH_3CN at a scan rate of 100 mV/s.

Fluxional Behavior of (Ferrocenylcarbonyl)[poly(1-pyrazolyl)borato]palladium(II) Complexes. In ^{1}H-NMR spectra of **2** measured in $CDCl_3$ at 51 °C, four pyrazolyl groups in the BPz_4 ligand exhibited a slightly broad singlet (4H) at δ=6.32 for 4-H's and a doublet (4H) at δ=7.24 for 3-H's, as shown in Table 2. However, a signal for 5-H's was obscured by those for triphenylphosphine and was not determined explicitly. Upon cooling to −30 °C, the broad singlet for 4-H's separated into three triplets (1H, 2.0 Hz) at δ=5.71, 6.18, and 6.36, and one slightly broad singlet (1H) at δ=6.31. The 3-H protons resonated as three slightly broad singlets at δ=6.59 (2H), 6.77 (1H), and 7.06 (1H). Concerning 5-H's, two slightly broad singlets were observed at δ=7.71 (1H) and 7.93 (2H), whereas a signal of the remaining proton was not distinguished owing to overlapping with the aromatic protons in triphenylphosphine. At this temperature, coordination of the BPz_4 ligand to palladium was stereochemically rigid to give the four spectroscopically nonequivalent pyrazolyl groups. On the other hand at 51 °C, fluxional motion of the BPz_4 ligand averaged environments of all pyrazolyl groups leading to their spectroscopic equivalence.

As described previously,[15–17] the geometrical arrangement in the stereochemically rigid coordination has a square-planar structure about the central palladium atom and a boat conformation of the Pd-(pyrazolyl)$_2$-B six-membered ring. The fluxional motion for the spectroscopic equivalence of four pyrazolyl groups at high temperatures has been regarded as the "tumbling process", which involves coordination of the uncoordinated pyrazolyl group near the palladium atom, accompanied instantaneously by dissociation of the previously coordinated group and by inversion of the Pd-(pyrazolyl)$_2$-B ring.

As for the monosubstituted cyclopentadienyl group in **2**, a broad singlet at δ=3.95 was observed at 51 °C, which overlapped a signal of the unsubstituted cyclopentadienyl group.

^{1}H-NMR spectra of the [hydrotris(1-pyrazolyl)-

Table 3. Electrochemistry of Complexes **1**—**4** and Electronic Spectra of Their Oxidized Species

Complex	Electrochemical data[a]				Oxidized species	
	$E°$	ΔE_p	i_{pc}/i_{pa}	n[b]	λ_{max}	ε
	mV	mV		(Found)	nm	mol^{-1} dm^3 cm^{-1}
1	159	62	0.94	1.12	623	310
2	119	62	0.99	0.98	631	309
3	105	62	0.91	1.08	625	235
4	104	147	0.95	~1.0[c]	625	214

a) In CH_3CN; (n-Bu_4N)PF_6=0.1 mol dm^{-3}; complex=10^{-3} mol dm^{-3}; scan rate=100 mV/s; redox for the Fe(II)⇄Fe(III) couple; see the text and ref. 18. b) Number of electrons passed per complex, for anodic exhaustive electrolysis. c) Corresponding to the first step, see the text.

borato]palladium(II) **3** in $CDCl_3$ at 23 °C showed a triplet (3H) δ=6.17 for 4-H's, a slightly broad singlet (3H) at δ=7.36 for 3-H's, and a doublet (3H) at δ= 7.69 for 5-H's, indicating spectroscopic equivalence of all pyrazolyl groups and fluxional behavior of the $HBPz_3$ ligand. On cooling to −45 °C, the signals for pyrazolyl groups became broader gradually, but a slow-exchange limiting spectrum was not obtained. Similar difficult fixation of the fluxional motion of the $HBPz_3$ ligand on cooling was described previously in some [hydrotris(1-pyrazolyl)borato]palladium(II) complexes.[16,17]

^{1}H-NMR spectra of the [dihydrobis(1-pyrazolyl)-borato]palladium(II) **4** were measured in toluene-d^8 in the temperature range of 50 to −36 °C, and there was no spectral change observed. At 80 °C, the complex was decomposed slowly. Two 4-H protons at room temperature resonated as triplets at δ=5.58 and 6.00, and two 3-H protons did as a slightly broad singlet at δ=5.81 and a doublet at δ=6.13. Additional smaller coupling to ^{31}P nucleus was noticed for the signals at δ=6.00 and 6.13 in the FT-type NMR measurement, and suggested that protons for these two signals belonged to the pyrazolyl group at a trans position to the triphenylphosphine ligand. Concerning 5-H's, one proton appeared as a doublet at δ= 8.07, but the other one was obscured by overlapping with the signals of triphenylphosphine. As a whole, complex **4** did not show the fluxional motion involving bond-breaking process between palladium and pyrazolyl groups.

Electrochemistry of (Ferrocenylcarbonyl)palladium(II) Complexes. Acetonitrile solutions of complexes **1**—**4** were served for their electrochemical studies, containing 0.1 mol dm^{-3} (n-Bu_4N)PF_6 as supporting electrolyte. Working electrodes were a platinum disc and gauze for cyclic voltammetry and bulk electrolysis, respectively. Cyclic voltammogram in Fig. 1 shows a typical well-reversible redox-couple for **2**. The peak current ratio of i_{pc}/i_{pa} remained close to unity in the sweep rate of 200 to 10 mV/s, and the current function (proportional to $i_p/\sqrt{v}$) was also constant with the rate.[18] There was no current flow observed in the bulk electrolysis at the controlled potential Y in Fig. 1. On the other hand, the electrolysis at X resulted in an anodic current, which upon integration yielded charge consistent with one electron per molecule of the complex, and changed color of the solution from yellowish orange to dark brown. One-electron transfer was also confirmed by potential separation ΔE_p between oxidation and reduction peaks of the couple, which was very close to theoretical 59 mV. These findings indicated that the redox under consideration was electrochemically reversible and diffusion-controlled one-electron transfer, and that the oxidation product of **2** was stable during the time

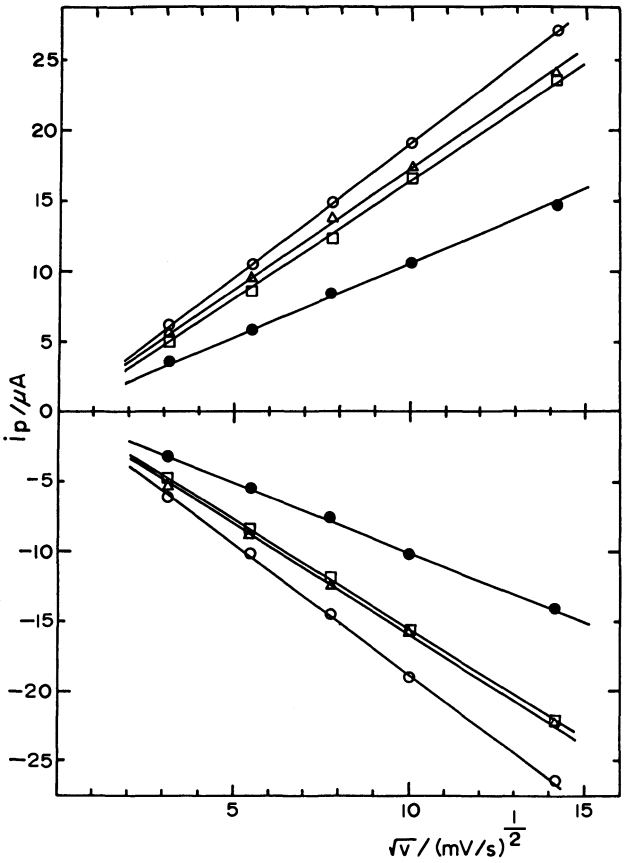

Fig. 2. Dependence of anodic and cathodic peak currents i_p of the Fe(III)/Fe(II) redoxes on the scan rate v. Concentration of complexes; 10^{-3} mol dm^{-3} ●: Complex **1**, ○: Complex **2**, △: Complex **3**, □: Complex **4**.

of the sweep.[19,20] Complexes **1** and **3** underwent analogous reversible one-electron oxidation, and the results are summarized in Table 3.

The corresponding redox-couple for **4** with the H_2BPz_2 group demonstrated that the peak current ratio i_{pc}/i_{pa} was nearly close to unity and the current function was also independent of the sweep rate similarly, whereas the peak separation ΔE_p was fairly larger than the theoretical 59 mV on the contrary. Thus, the redox couple of **4** was diffusion-controlled like the other complexes, but varying in the electrochemical reversibility, and was regarded as quasi-reversible.[19,20] Furthermore, the bulk electrolysis of **4** (10^{-3} mol dm^{-3}) was performed at a slightly more anodic potential than that of its oxidation peak, and the electrolysis was found to proceed in two steps. The current observed was ca. 9 mA at the beginning of the electrolysis and decayed following a manner of the first-order kinetics.[21] One electron passed per molecule of the complex for ca. 15 min and the current decreased to 1 mA. Then, the current was increased gradually again and approximately two more electrons passed additionally to reach

completion of the electrolysis.

Visible and near-infrared absorption spectra were observed after one-electron oxidation of the complexes **1**—**4**. In the region above 500 nm, each oxidized complex (including **4**) gave only one band detected around 625 nm. Since ferricinium cation $[Fe(C_5H_5)_2]^+$ was reported to have a characteristic band of a Ligand (e_{1u})→Fe (e_{2g}(3d)) transition at ca. 620 nm,[22] the band observed was attributable to a similar transition in the (ferrocenylcarbonyl)palladium complexes oxidized. Near-infrared absorption bands for light-induced intervalent electron-transfer were described for some heterobinuclear complexes upon oxidation,[23,24] which involved ferrocenyl groups as one component similarly to our complexes. The electron-transfer bands were expected in the range of 700 to 2000 nm, but such a band was not discernible in the spectra of **1**—**4** after one-electron oxidation.

On the basis of these results, the redox system under consideration was concluded to be the process of Fe(II)⇄Fe(III) in the ferrocenyl moiety. As for the bulk electrolysis of **4**, the Fe center was oxidized similarly at the first step and then some kinds of oxidative decomposition of the H_2BPz_2 group would occur as the second step. The oxidative decomposition of the H_2BPz_2 group seemed to be associable with some reducing ability of the group, suggested previously.[9,10]

When cyclic voltammograms of **1**—**4** were performed in a wider potential-range, an additional irreversible anodic wave appeared at a potential more than ca. 1300 mV, owing to oxidation of the Pd(II) sites.[23]

Formal redox potentials[18] $E°$ for the Fe(III)/Fe(II) couples of **1**—**4** were more anodic than that of ferrocene, and this was ascribed to electron-withdrawing effects of their palladiocarbonyl structures from the Fe redox centers. The effects of the four kinds of palladiocarbonyl structures were quite comparable. The ordering for the readiness of oxidation of the Fe centers was **4**≧**3**>**2**>**1**. Therefore, electron-withdrawing effects of the [poly(1-pyrazolyl)borato]palladiocarbonyl moieties from the Fe centers were smaller than that of the chloro(triphenylphosphine)palladiocarbonyl moiety. In addition, this parallelism indicated also that the [tetrakis(1-pyrazolyl)borato]-palladium moiety possessed greater ability for withdrawing electrons from the Fe center than the other poly(1-pyrazolyl)borate analogues, possibly owing to its larger electron-delocalization over the pyrazolyl groups.

Experimental

General Procedures and Materials. ^1H- and ^{13}C-NMR spectra were run on JEOL model FX-90-Q (FT type) and MH-100 spectrometers with tetramethylsilane as an internal standard. Temperatures of NMR samples were determined with methanol or 1,3-propanediol. IR spectra were obtained using Hitachi 285 and Shimadzu IR-450 spectrometers. Melting points were observed on a Yanagimoto MP-S3 microstage apparatus in capillary tubes and are uncorrected. Electronic spectra (260—2100 nm) were recorded on a Hitachi 323 UV-VIS-NIR spectrophotometer.

(Chloroformyl)ferrocene[25] and $M[H_nBPz_{4-n}]$ (M=Na and K)[9] were prepared according to the reported methods. Preparative and electrochemical operations were performed under dry nitrogen.

Preparation of $[Pd(COFc)Cl(PPh_3)_2]$ 1. The powder of $[Pd(PPh_3)_4]$ (850 mg) was added in portions to a benzene solution (20 cm^3) of (chloroformyl)ferrocene (230 mg) and the mixture was stirred for 24 h at ambient temperature. The resulting precipitates were collected and washed with diethyl ether. Yellowish orange microcrystals (520 mg) were obtained and characterized as **1**. Vis(CH_3CN) 450 nm (ε 625).

Preparation of $[Pd(COFc)(BPz_4)(PPh_3)]$ 2. A mixture of **1** (218 mg) and $K[BPz_4]$ (95 mg) in dichloromethane (20 cm^3) was stirred overnight. After concentration, the reaction mixture passed through a silica-gel column (200 mesh, 1.2×20 cm) to give a red fraction by eluting with dichloromethane–diethyl ether (2:1). The fraction was evaporated to dryness and the residue was recrystallized from dichloromethane and hexane, affording an orange powder (98 mg) of **2**. Vis(CH_3CN) 464 nm (ε 506).

Preparation of $[Pd(COFc)(HBPz_3)(PPh_3)]$ 3. Complex **1** (200 mg) was treated with $Na[HBPz_3]$ (63 mg) in dichloromethane (20 cm^3). After stirring for 24 h, the solvent was removed in vacuo. Then, the benzene extract was chromatographed on a silica-gel column, and a red fraction eluted by dichloromethane–diethyl ether (4:1) was evaporated to dryness. The resulting solid was recrystallized from diethyl ether and hexane to give orange microcrystals (74 mg) of **3**. Vis(CH_3CN) 464 nm (ε 441).

Preparation of $[Pd(COFc)(H_2BPz_2)(PPh_3)]$ 4. Potassium dihydrobis(1-pyrazolyl)borate $K[H_2BPz_2]$ (50 mg) was mixed with **1** (180 mg) in THF (20 cm^3), followed by stirring for 24 h at room temperature. The solvent was evaporated under reduced pressure and recrystallization of the residue from benzene and diethyl ether gave yellowish orange microcrystals (45 mg) of **4**. Vis(CH_3CN) 461 nm (ε 456).

Reaction of 1 with 1,10-Phenanthroline (phen). 1,10-Phenanthroline monohydrate (58 mg) was added to a benzene suspension (50 cm^3) of **1** (250 mg) and the mixture was stirred for 2 h. After concentration to a small volume, addition of hexane gave orange precipitates (81 mg) of **5**.

Reaction of 1 with 2,2′-Bipyridine (bpy). A mixture of **1** (250 mg) and 2,2′-bipyridine (50 mg) in benzene (50 cm^3) was stirred at ambient temperature for 2 h and the resulting precipitates were collected and washed with diethyl ether to afford pale yellow microcrystals (74 mg) of **6**.

Reaction of 1 with $AgClO_4$ in CH_3CN. An CH_3CN solution (5 cm^3) of $AgClO_4 \cdot H_2O$ (52 mg) was added dropwise to an CH_3CN suspension (20 cm^3) of **1** (200 mg). After stirring of the mixture for 2 h and evaporation under vacuum to dryness, recrystallization of the residue from dichloromethane and diethyl ether yielded pale yellow

microcrystals (130 mg), **7**.

Electrochemical Studies. Electrochemical experiments were carried out with a standard three-electrode electric circuit, using a Hokuto Denko HA-301 potentiostat and a HB-104 function generater. Acetonitrile test-solutions (20 cm^3) contained (ferrocenylcarbonyl)palladium complexes (10^{-3} mol dm^{-3}) and (n-Bu_4N)PF_6 (0.1 mol dm^{-3}) as the supporting electrolyte. The reference and auxiliary electrodes were separated from the test solution by a tube with glass frits, and the tube contained electrolytic solvent and the supporting electrolyte. Working electrodes were a Pt disc (3 mmϕ) and gauze (12 cm^2, 80 mesh) for cyclic voltammetry and bulk electrolysis, respectively. The auxiliary electrode was a Pb plate and the reference electrode was a Pt wire in a solution of [$Fe(C_5H_5)_2$] (0.01 mol dm^{-3}), [$Fe(C_5H_5)_2$]PF_6 (0.01 mol dm^{-3}), and (n-Bu_4N)PF_6 (0.1 mol dm^{-3}) in CH_3CN.

Electronic Absorption Spectra of 1—4 after One-electron Oxidation. The complexes **1**—**4** in nitrogen-deaerated acetonitrile solutions (10^{-3} mol dm^{-3}) were served for bulk electrolysis at appropriately controlled potentials. After one-electron oxidation, a syringe was used to transfer ca. 3 cm^3 of the solutions to a 10 mm quartz cuvette under nitrogen, taking care to avoid dilution with solvent in the auxiliary electrode compartment. Electronic absorption bands under consideration were observed within 5 min after completion of the electrolysis.[26] Molar absorptivities ε were evaluated from the absorbances obtained, and were based on the concentration of the complexes charged.

(Received August 22, 1985)

Eight different 1:1 charge-transfer(CT) complexes were prepared using tetrahydrobarreleno-tetracyanoquinodimethane(THBTCNQ), dihydrobarreleno-tetracyanoquinodimethane(DHBTCNQ), monobenzobarreleno-tetracyanoquinodimethane(MBBTCNQ), and dibenzobarreleno-tetracyanoquinodimethane(DBBTCNQ) as tetracyanoquinodimethane(TCNQ)-type acceptors, and tetrathiafulvalene(TTF), bis(tetramethyene)-tetrathiafulvalene(OMTTF), and tetramethyl-tetrathiafulvalene(TMTTF) as TTF-type donors. The complexes can be classified into three distinct groups, I—III, on the basis of the magnitude of both the degree of CT and the electrical resistivity of compacted powders. Group-I complexes are characterized by a small band gap semiconductivity and moderate CT, group-II complexes by low conductivity and small CT, and group-III complexes by low conductivity and complete CT. The stacking mode of the three groups of complexes are discussed, by comparing the electronic absorption spectra of the three groups of CT complexes with those of the complexes for which the crystal structures are known. A crystal structure analysis of OMTTF-DBBTCNQ revealed that it is the first example of a highly ionic CT complex of a TTF-TCNQ type with a regular mixed stacking mode. These three groups of complexes containing bulky acceptor groups will be of theoretical interest in studying the crystal properties of organic CT complexes.

Highly-conducting organic charge-transfer (CT) complexes usually have the following structural and electronic properties in the solid state:[1] (a) a uniform segregated stacking of donors and acceptors and (b) an incomplete CT between the components. Several synthetic design criteria have been proposed for obtaining a high conductivity.[1,2] Generally, an effective overlap of the planar π-electron systems is required for an efficient charge transport. As a result, two-chain organic conductors composed of donor and acceptor components have been designed mainly with planar π-systems modified two-dimensionally. Therefore, three-dimensional modifications, which lead to a destruction of the molecular planarity, have not attracted much attention so far.[2b,3] In principle, however, such modifications will affect the following essential properties in the solid state: (i) The stacking mode of the component molecules, (ii) the ionicity, and (iii) intra- and interstack interactions. We started the first systematic study regarding these points by selecting tetrathiafulvalene (TTF) and tetracyanoquinodimethane (TCNQ) as basic skeletons. These are the most widely investigated donors and acceptors. In this paper we describe the preparations and properties of the three groups of CT complexes (having a wide range of ionicity) and stress that small band gap semiconductors (including a relatively highly conducting complex (ρ=2.5×10^{-2} Ω cm)) can be prepared even from TCNQ having bulky groups. A rare example of highly ionic complexes with a mixed stacking mode was also prepared.[4]

Results and Discussion

A) Classification of CT Complexes. In this study, we aimed at obtaining rigid, bulky modifications with small electronic perturbations on TCNQ (**1a**). To this end, four barreleno-TCNQ's, **1b**, **1c**, **1d**,[5] and **1e**,[6] were synthesized in which a TCNQ moiety was incorporated into the rigid barrelene skeleton.[7] The new acceptors, **1b** and **1c**, were

prepared by the Acker and Hertler procedure[8] for the synthesis of TCNQ (Scheme 1). The first half-wave reduction potentials ($E^{r}_{1/2}$) of **1b—e** show that the acceptor strength increases gently and gradually with an increasing unsaturation in the barrelene moieties[9] (Table 1). However, the difference of $E^{r}_{1/2}$ between TCNQ **1a** and both extremes **1b** or **1e** is only +0.07 V or −0.05 V, respectively. Thus, the electronic perturbation of TCNQ caused by an introduction of bridged segments is fairly small as judged from their $E^{r}_{1/2}$ values.

$E^{o}_{1/2}$						0.33	0.26	0.25

a) Measured by cyclic voltammetry in 0.1 mol dm^{-3} Et_4NClO_4/CH_3CN at a Pt electrode.

Eight different 1:1 CT complexes were prepared using **1b—e** as acceptors and molecules of the TTF family, namely TTF (**2a**), bis(tetramethylene)-TTF (OMTTF, **2b**), and tetramethyl-TTF (TMTTF, **2c**) as donors. Their selected physical properties are compiled in Table 2. The difference between the oxidation potential ($E^{o}_{1/2}$) of donor and the reduction potential ($E^{r}_{1/2}$) of acceptor, i.e., $\Delta E^{o,r}=E^{o}_{1/2}-E^{r}_{1/2}$, is a convenient experimental measure to predict the degree of CT for a complex.[1b,2b,2d] Such intermolecular HOMO-LUMO gap, $\Delta E^{o,r}$ values, for the eight complexes are in a narrow range (+0.02—+0.22 V) since the electronic perturbation resulting from a three-dimensional modification was nearly negligible. Therefore, we expected that the ground states of all these complexes were in incomplete CT states. The degree of CT, Z, for each complex was determined by both the infrared[10] and Raman[11] spectra. We obtained values for Z (Table 2) using the frequency shifts, $\Delta\omega$, between neutral molecules and ion-radical salts for these spectra (Tables 3 and 4). The two methods which reflect the electronic structure of both the acceptor and the donor components yield estimated Z values in good agreement each other. Interestingly, the values of Z for the complexes are in a wide range (0.1—1.0) despite the narrow range of the $\Delta E^{o,r}$ values.

These CT complexes can be classified into three distinct groups, I—III, on the basis of the magnitude of both the degree of CT, and the electrical resistivity, ρ, of compacted powders. The apparent activation energies E_a for semiconduction ($\rho=\rho_0\exp(-E_a/kT)$) are also given. Group I, II, and III complexes are characterized by a relatively high conductivity with a moderate CT (small band gap semiconducting complex), a low conductivity with a small CT

(nonionic complex), and a low conductivity with a complete CT (ionic complex), respectively.

B) Electronic Spectra and Prediction of Stacking Mode. The stacking modes of the components are essential for understanding the solid-state properties of CT complexes. One of the group-III complexes, bis(tetramethylene)tetrathiafulvalene(OMTTF)-dibenzobarrelenotetracyanoquinodimethane(DBBTCNQ), crystallizes in a monoclinic lattice. However, group-I complex crystals are not suitable for X-ray structure analyses and group-II complexes gradually decomposed upon X-ray irradiation. Therefore, we estimated the stacking mode by comparing the electronic spectra of the three groups of CT complexes with those of the complexes for which the crystal structures are known. We will discuss the electronic spectra of powdered samples since they provide useful information, particularly for cases of CT complexes composed of TTF or TCNQ skeletons.[12]

For group-I complexes, we selected TTF-TCNQ as a reference complex. The two requisites, (a) and (b), for the highly conducting organic complexes, TTF-TCNQ for example, can be substantiated by the detection of a very low energy absorption band at about 3000 cm^{-1}. This was determined to be an intrastack CT transition in a segregated stack with an incomplete CT (intraband transition).[12a,13] Figure 1(a) shows the solid-state electronic spectra of TTF-THBTCNQ and TTF-DHBTCNQ as well as that of TTF-TCNQ. In addition to the similarity of the spectra between TTF-TCNQ and group-I complexes in bands B, C, and D, the presence of band A at about 4000 cm^{-1} suggests that the group-I complexes possess a segregated stacking mode. The electrical resistivity for a single crystal of TTF-THBTCNQ ($\rho=2.5\times10^{-2}$ Ω cm) is fairly low and about two orders of magnitude smaller than that for a compacted powder sample. Such small resistivity and activation energy also support the prediction of a segregated stacking mode for the group-I complexes, although more data are needed to make this argument conclusive.

Group-II complexes are characterized by their nonionic nature. Such properties closely resemble those of OMTTF-TCNQ. We estimated the value of Z as 0.25 for OMTTF-TCNQ using the nitrile stretching frequency (2216 cm^{-1}). The crystal structure shows a mixed stack of alternating donor and acceptor components.[14] As shown in Fig. 1(b)[15] we found a weak CT transition for OMTTF-TCNQ (curve d) at 5100 cm^{-1} (band E). The strong absorption bands H and I are nearly identical with the molecular absorption of neutral TCNQ and OMTTF, respectively: this is consistent with the small degree of CT of the complex. These spectral features are recognized exactly in group-II complexes (Fig. 1(b)). Hence, we expect that group-II complexes possess a mixed stacking mode.

Group-III complexes are characterized by an almost completely ionic nature. In agreement with

the complete CT, the absorption bands K, L, and M of group-III complexes were also found in the ionic salts of corresponding components, K-MBBTCNQ, K-DBBTCNQ and OMTTF-BF_4 (Fig. 1(c)). Furthermore, an additional band at 6000 cm^{-1} (band J) was observed for each of the group-III complexes, which can be assigned to a back CT transition between the anion and the cation radicals.[16] These results strongly suggest a mixed stacking mode of this group. The crystal structure of OMTTF-DBBTCNQ actually contains a mixed stacking donor and an acceptor (vide infra).

The single-crystal polarized reflection-spectra revealed that the CT band E of OMTTF-TCNQ and J of OMTTF-DBBTCNQ proved to be a transition polarized along the c-axis. This is very close to the stacking direction of the donor and the acceptor.[17] Furthermore, OMTTF-TCNQ is shown to be mostly nonionic with two CT configurations in which the lowest energy one contributes to the ground state only to a small extent, and OMTTF-DBBTCNQ to be ionic with only one CT configuration in the ground state by means of the analysis of the crystal and electronic structure.

Recently, Torrance et al. showed the simple linear relationship[16] between the energies of the CT transition ($h\nu_{CT}$) and the intermolecular HOMO-LUMO gap ($\Delta E^{o,r}$): $h\nu_{CT,neutral}=\Delta E^{o,r}+0.5$; $h\nu_{CT,ionic}=0.83-\Delta E^{o,r}$ (eV). Using this equation, we calculated the $h\nu_{CT}$ values for each complex of the three groups. These are summarized in the last two rows of Table 2 together with the observed values. The agreement is good for both the nonionic group II and the ionic group III complexes, considering the simplicity of the approximation. In addition, the calculated value for OMTTF-TCNQ (5000 cm^{-1}) is also in good agreement with the observed one (5100 cm^{-1}) (vide supra). However, for the ionic group I complexes, the agreement is relatively poor. This also supports our estimation for the stacking mode as a segregated but not a mixed type.

C) Crystal Structure of OMTTF-DBBTCNQ. OMTTF-DBBTCNQ contains a solvent molecule, benzene (see experimental section). As shown in Fig. 2, the donor and the acceptor form mixed stacking columns along the c-axis with alternating the two components. The acceptors arrange themselves in a columnar array so as to release any unfavorable steric repulsion between the bulky dibenzo-barreleno moiety on TCNQ. The mean separation distance between the π-electron frameworks of the donor and acceptor is 3.46 Å. The dihedral angle between the two planes is about 1.26°. The overlapping mode and a view of the interstack interaction are depicted in Fig. 3. The two components are shifted from the direct overlap mode as found in OMTTF-TCNQ,[14] in which the symmetry plane perpendicular to the long axis coincides nearly with each other. Interestingly, there exist no short interstack interactions of the S···S and S···N types. The shortest S···N contact distance is 4.69 Å, and is much longer than the sum of the appropriate van der Waals radii. Thus, the mixed columns in OMTTF-DBBTCNQ are completely

isolated from each other (Table 5).

Applying the bond-length-ratio procedure of Kistenmacher et al.,[18] we calculated the degree of CT as shown in Table 6. For OMTTF-DBBTCNQ, the calculated Z is 1.08, which indicates a complete charge transfer. This value is consistent with the Z determined by IR and Raman procedures. Furthermore, the donor geometry also suggests a strong ionic nature (Table 7). Thus, the difference in the central double-bond length between OMTTF and OMTTF in the complex, 0.062 Å, is comparable to that between TTF and TTF-ClO$_4$, 0.055 Å. The same procedure for OMTTF-TCNQ leads to the result that there is no charge on the donor or the acceptor. This is in good agreement with an estimation by the IR procedure.

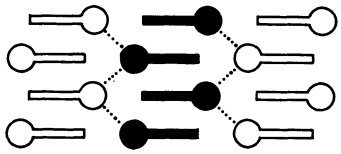
Conclusion

Usually, the ionicity of CT complexes can be controlled by selecting the donor-acceptor combination so as to change the $\Delta E^{o,r}$ values to a large extent. It should be noted that we prepared the three groups of CT complexes with a wide range of ionicity using the three dimensionally modified TCNQ's, despite the small electronic perturbation on the acceptor and the narrow range of $\Delta E^{o,r}$ values. However, another important feature in this study is that the $\Delta E^{o,r}$ values are kept small at a positive region near zero, the so-called neutral-ionic boundary.[16] Therefore, our results indicate that, in these conditions, the solid-state properties are influenced to a large extent by small steric and/or electronic perturbations in the three-dimensional modifications which influence the intra- and interstack interactions in the complexes.

Recently, Soos et al. presented experimental and theoretical aspects regarding ionicity and paramagnetism of strong organic CT complexes. One of their important results was that TMPD-TCNQF$_4$ is the first highly ionic ($Z \geq 0.9$) and paramagnetic organic CT complex to be found with a regular mixed stacking mode.[19] Although OMTTF-DBBTCNQ is found to be another example of such a highly ionic CT complex, the complex is, to best of our knowledge, the first example for the TTF-TCNQ type complexes. The Z value of 0.65 of DBTTF-TCNQF$_2$[20] is the most strong ionicity known so far in mixed-stacking mode complexes of the TTF-TCNQ type (Table 5). Interestingly, although the acceptor

strengths of MBBTCNQ and DBBTCNQ are close to that of TCNQ and much weaker than that of $TCNQF_4$,[21] the group III complexes are complete CT.

In addition, relatively highly-conducting complexes were also prepared, although our modification leads to the TCNQ's carrying the bulky groups. All these results will be of theoretical interest in studying the crystal properties of organic CT complexes.[22] Finally, this study may open an unexplored area for chemical modifications to design molecular conductors, since many variations of the barrelene skeleton are possible.[23] Furthermore, if such molecules with bulky groups pack in a crystal as shown schematically in **5**, a segregated stacking mode of CT complexes



5

will be formed. This is our model for future studies concerning new effects of three-dimensional modifications on intra- and interstack interactions, that is, the enhancement of low dimensionality and introduction of a new types of interstack interactions.

Experimental

General. All the melting points are uncorrected. Infrared spectra and electronic spectra were recorded on JASCO DS-402G and Hitachi 340 spectrometers, respectively. Each IR spectrum was calibrated with indene as the standard. Laser Raman spectra were recorded with Ar^+ (514.8 nm) excitation by using a JASCO R-800 spectrometer for samples of KBr disks or powders. Proton NMR spectra were measured by using Varian XL-100-15 and JEOL JNM-PMX-60 spectrometers. All chemical shifts are reported in parts per million (δ) relative to internal tetramethylsilane. The cyclic voltammetry was carried out at room temperature under nitrogen using Yanagimoto P-1100. The electrical resistances for the compacted pellet and the single crystal were measured with two probe and four probe methods, respectively.

Preparation of the Acceptors. 5,8-Bis(dicyanomethylene)-1,4,4a,6,7,8a-hexahydro-1,4-ethanonaphthalene (4c). A mixture of 1,4,4a,6,7,8a-hexahydro-1,4-ethanonaphthalene-5,8-dione (**3c**)[24] (2.99 g, 15.7 mmol), malononitrile (3.12 g, 47.2 mmol) and β-alanine (18 mg, 0.20 mmol) in 3.5 mL of water was stirred for 9 h at 70 °C. The crude product was recrystallized from acetonitrile to give 3.06 g (68%) of **4c** as yellow prisms: Mp 244—245 °C; ^1H NMR (CD_2Cl_2) δ=1.67 (4H, m, H-5,6), 2.88 (6H, br s, H-1,4,9,10), 3.49 (2H, br s, H-7,12), 6.33 (2H, q-like, H-2,3); IR (KBr) 2230 cm^{-1}. Found: C, 75.46; H, 4.97; N, 19.72%. Calcd for $C_{18}H_{12}N_4$: C, 75.51; H, 4.93; N, 19.57%.

1,2,3,4,4a,6,7,8a-Octahydro-1,4-ethanonaphthalene-5,8-dione (3b). The hydrogenation of **3c** with 10% Pd-C in methanol gave **3b** (93%) which continued to produce **4b**.

5,8-Bis(dicyanomethylene)-1,2,3,4,4a,6,7,8a-octahydro-1,4-ethanonaphthalene (4b). A mixture of **3b** (20 g, 0.104 mol), malononitrile (16.5 g, 0.25 mol) and β-alanine (250 mg) in 5 mL of water was stirred for 3 d at 65—75 °C. The crude product was recrystallized from acetonitrile–benzene to give **4b** (37%) as colorless needles: Mp 167—168 °C, IR (KBr) 2230 cm^{-1}; Found: C, 74.65; H, 5.53; N, 19.38%. Calcd for $C_{18}H_{16}N_4$: C, 74.98; H, 5.59; N, 19.43%.

5,8-Bis(dicyanomethylene)-1,4-dihydro-1,4-ethanonaphthalene (dihydrobarreleno-TCNQ, DHBTCNQ) (1c). A mixture of **4c** (1.01 g, 3.51 mmol), *N*-chlorosuccinimide (1.61 g, 12.0 mmol), pyridine (1.15 mL, 14.2 mmol) and dichloromethane (60 mL) was refluxed for 4 h. After the usual workup, the crude product was purified by column chromatography on silica gel. Elution with dichloromethane yielded 0.72 g (73%) of **1c** as red solids which was recrystallized from methanol: Red needles, mp 171.5—173.5 °C; ^1H NMR ($CDCl_3$) δ=1.63 (4H, AA'BB', H-5,6), 5.31 (2H, br s, H-1,4), 6.52 (2H, q-like, H-2,3), 7.41 (2H, s, H-9,10); IR (KBr) 2215 cm^{-1}; UV λ_{max} (CH_3CN) 248 (log ε 3.71), 380 (sh, 4.46), 401 (4.59), 460 nm (sh, 3.98).

5,8-Bis(dicyanomethylene)-1,2,3,4-tetrahydro1,4-ethanonaphthalene (tetrahydrobarreleno-TCNQ, THBTCNQ) (1b). The title compound was prepared as described above (67%): Golden yellow needles (recrystallized from C_6H_6–C_6H_{12}), mp 195—197 °C (decomp); ^1H NMR ($CDCl_3$) δ=1.65 (8H, m, H-2,3,5,6), 4.24 (2H, br s, H-1,4), 7.43 (2H, s, H-9,10); IR (KBr) 2213 cm^{-1}; UV λ_{max} (CH_3CN) 244 (log ε 3.68), 402 nm (4.61). Found: C, 76.10; H, 4.24; N, 19.61%. Calcd for $C_{18}H_{12}N_4$: C, 76.04; H, 4.25; N, 19.71%.

mixing solutions of donors and acceptors at 20—40 °C. The complexes usually precipitated out immediately. The 1:1 stoichiometries of donors and acceptors were determined by elemental analyses which agree with calculated values within ±0.4% for C, H, N, and S. In the case of OMTTF-DBBTCNQ, solvent molecule, benzene, was included in the crystals; elemental analysis and crystal-structure analysis indicated the molecular ratio of the components, OMTTF:DBBTCNQ:benzene, to be 1:1:1. The solvents used for the preparation of the complexes and their properties are summarized in Table 8.

Crystal Structure Analysis of OMTTF-DBBTCNQ. X-Ray data were collected on a Rigaku four-circle diffractometer of the Crystallographic Research Center, Institute for Protein Research, Osaka University. Ni-filtered Cu $K\alpha$ radiation was provided by a Rigaku rotating anode X-ray generator operated at 40 kV and 200 mV. Crystallographic data are given in Table 9. The structure was solved by direct method, using the program MULTAN 78, and refined by the block-diagonal anisotropic least-squares methods to final *R* value of 0.091. The hydrogen atoms were not included in the refinement. The atomic numbering scheme, bond lengths, and bond angles are shown in Fig. 4 and Table 10, respectively. Tables of structure factors, atomic and thermal parameters, bond lengths and angles are deposited as Document No. 8605 at the Office of the Editor of Bull. Chem. Soc. Jpn.

We are grateful to Professor Robert M. Metzger (University of Mississippi) for a critical reading of a part of the manuscript. We thank Dr. Tadaoki Mitani for valuable discussions and Dr. Kenichi Imaeda for his technical assistance on resistivity measurements. The research at Osaka was partially supported by the Grant-in-Aid for Special Research Project on Properties of Molecular Assemblies (No. 58118003) from the Ministry of Education Science and Culture.

(Received June 14, 1985)

Bis(heptafluorobutyryl) peroxide (**1**) smoothly reacted with furans and thiophenes under mild conditions to regioselectively give 2-perfluoropropylfurans and thiophenes in high yields. Mechanistically, reactions with furans or thiophenes are considered to be initiated by one-electron transfers from substrates to **1**. On the other hand, the perfluoropropylation of pyridine was proceeded by the usual free-radical substitution to a pyridinium salt by a heptafluoropropyl radical produced by the homolytic decomposition of **1**.

Recently, remarkable attention have been focused on fluoroalkyl-containing compounds due to their unique properties. However, the introduction of fluoroalkyl groups is not easy since the usual methods for alkylation can not be applied to perfluoroalkylation due to the high electronegativity of perfluoroalkyl groups. Especially, an exploration of electrophilic perfluoroalkylating agents is desired since reactions involving a perfluoroalkyl cation as an intermediate are very limited.[1] We have been studying the perfluoroalkylation of nucleophilic substrates with bis(heptafluorobutyryl) peroxide **1** via an electron-transfer process (shown in Scheme 1) and the heptafluoropropylation of electron-rich benzenes, naphthalene, anthracene, and electron-rich olefins has been achieved.[2,3]

$$\mathrm{Nu{:} + (C_3F_7CO_2)_2 \longrightarrow Nu^{\ddagger} + (C_3F_7CO_2)_2^{\cdot-}}$$
$$\longrightarrow \mathrm{Nu^{\ddagger} + C_3F_7{\cdot} + C_3F_7CO_2^- + CO_2}$$
$$\longrightarrow \mathrm{Nu{+}C_3F_7 + C_3F_7CO_2^- + CO_2}$$

Scheme 1.

In this paper, we wish to report on reactions involving bis(heptafluorobutyryl) peroxide with such heteroaromatic compounds as furans, thiophenes, and pyridines.

Results and Discussion

Two moles of furan or thiophene per mol of **1** were added to a solution of **1** in Freon-113. The mixture was degassed by a freeze-thaw cycle, sealed in an ampoule and kept at 40 °C for 3 h. Regioselectively 2-substituted furan or thiophene with a perfluoropropyl group was obtained in 98% yield and a substantial amount of perfluorobutyric acid was also formed. Several substituted furans and thiophenes

Table 1. Reactions of Furans, Thiophenes with Bis(heptafluorobutyryl) Peroxide in Freon-113 at 40 °C for 3 h

			Peroxide	Yield of the products/%[a]

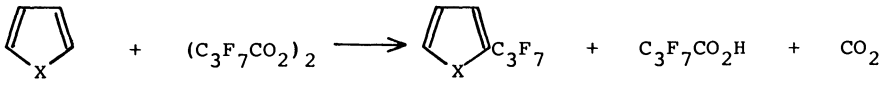
a) The yields of products are based on peroxide. b) Bis(perfluoropropyl)furans, thiophenes  .

c) Considerable amounts of polymeric compounds were obtained. d) The yield of product is based on furan.
e) Trace amount of 2-methyl-3,4,5-tris(perfluoropropyl)furan was also formed.



(X = O, S) 1 2

were also reacted with **1** and the results are summarized in Table 1. The production of perfluorobutyric acid, not heptafluoropropane (C_3F_7H), should be important from the viewpoint of synthetic chemistry; the produced perfluorobutyric acid could be recovered as a sodium salt and used again for the synthesis of peroxide **1**.

Hitherto, the direct perfluoroalkylation of heteroaromatic compounds has been carried out thermally or photochemically using perfluoroalkyl iodides.[4,5] However, these processes require high temperatures or irradiation for long periods of time. Recently, Umemoto et al. reported the perfluoroalkylation of various aromatic compounds with perfluoroalkylphenyliodonium trifluoromethanesulfonate(FITS) under mild conditions.[6] Now, peroxide **1** has also been shown to be an excellent reagent for the perfluoropropylation of furans and thiophenes under very mild conditions.

A plausible reaction mechanism for perfluoroalkylation with **1** is shown in Scheme 2; the reaction is initiated by one-electron transfers from substrates to peroxide **1**. The reactions of benzoyl peroxide with thiophene or furan via an electron-transfer process have been reported.[7,8] In an MO calculation for the substituted benzoyl peroxides, an electron-withdrawing substituent lowers the O-O antibonding energy level.[9] Thus, the energy level of the O-O antibonding of peroxide **1** should be lower than that of benzoyl peroxide due to the high electronegativity of perfluoroalkyl group. Thus, the mechanism shown in Scheme 2 involving an electron-transfer process is reasonable.[10]

The rate of decomposition of **1** should be accelerated in the presence of furans and thiophenes if the reaction is initiated by one-electron transfers from furans or thiophenes to **1**. The decomposition of **1** was followed by iodometry in the presence or absence of 5 mol of thiophenes or furan per mol of **1** and shown to be markedly accelerated by adding thiophenes or furan. The rate of decomposition of **1** was not affected by $C_3F_7CO_2H$. The results are summarized in Table 2.

When pyridine was added to a solution of **1** in

Table 2. Apparent First-Order Rate Constants for the Thermal Decomposition of 0.02 mol/l $(C_3F_7CO_2)_2$ in the Presence of 0.10 mol/l 2-Substituted Thiophenes or Furan in Freon-113

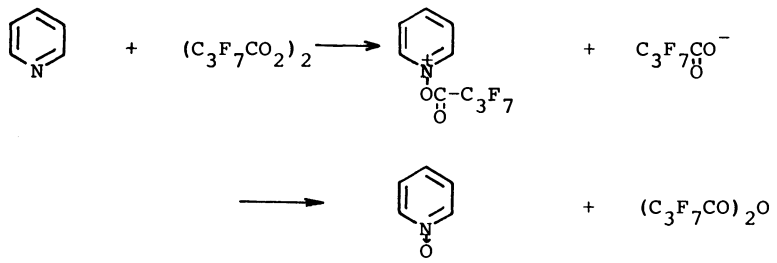
X = O, S

Scheme 2.

Freon-113, the solution turned to reddish-brown at once; the solution was maintained at 40 °C for 6 h under N_2, and the products were analyzed. Perfluoropropylpyridines were not detected and pyridinium heptafluorobutyrate and pyridine *N*-oxide heptafluorobutyrate were obtained. The reaction proceeded even at −20 °C to give pyridine heptafluorobutyrate and pyridine *N*-oxide heptafluorobutyrate. This means that the nucleophilic attack of an *N*-lone pair of pyridine on an O-O bond of **1** may be more preferential than an electron-transfer reaction from the π-orbital of pyridine to **1** observed in reactions with furan or thiophene. A similar nucleophilic attack of an *N*-lone pair on an O-O bond of benzoyl peroxides has been reported.[11]



The thermal decomposition of benzoyl peroxide in pyridine gives a mixture of 2-, 3-, and 4-phenylpyridine due to the substitution of a phenyl radical to pyridine;[12] however similar reactions with *m*-nitrobenzoyl peroxides gave an abnormally high yield of the nitrobenzoic acid and pyridine *N*-oxide.[11] The nucleophilic attack should compete more effectively with homolytic substitution when the peroxide contains powerful electron-withdrawing substituents.[11]

We have attempted a reaction with pyridinium heptafluorobutyrate which has no lone pair on the nitrogen atom with **1** in Freon-113. The results are summarized in Table 3. In the reaction of pyridinium heptafluorobutyrate with **1**, perfluoropropylpyridines were obtained. Almost the same regioselectivities ($\alpha:\beta:\gamma$=21:18:22) were observed in the perfluoropropylation of pyridinium salt, suggesting a free-radical character of this reaction as shown in Scheme 3.[13]

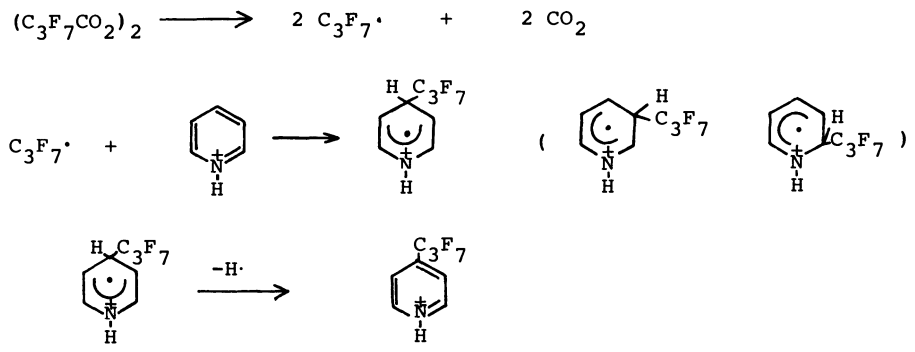
Experimental

Measurement. ^{1}H-NMR spectra were taken with a JEOL JNM-MH-100 (100 MHz) spectrometer. ^{13}C-NMR spectra were taken with a JEOL FX-60 FT-NMR spectrometer. A GC analysis was performed on Shimadzu GC-4APTF gas chromatograph. IR spectra were recorded on a JASCO A-3 spectrophotometer. GC-IR spectra were taken with a Shimadzu GC-IR-VGS-1 spectrophotometer. The Mass spectra were taken with a JEOL JMS-D300 spectrometer and a JEOL DX-500 spectrometer.

Materials. Bis(heptafluorobutyryl) peroxide was prepared from heptafluorobutyryl chloride and hydrogen peroxide in the presence of aqueous sodium hydroxide in



Scheme 3.

Table 3. Reaction Products for the Perfluoropropylation of Pyridinium Compounds with Bis(heptafluorobutyryl) Peroxide in Freon-113

	Reagent/mmol		Temp/Time	Yield of the products/%[a]	
	$PyH^+RCO_2^-$	Peroxide	°C/h	**4**	**5**
$R=C_3F_7$	2[b]	2	40/ 3	18	6

a) The yields of products are based on the pyridine consumption. b) Pyridinium heptafluorobutyrate. c) Isomer composition: $\alpha:\beta:\gamma=42:36:22$. d) 2,6-Lutidinium heptafluorobutyrate.

Freon-113 by a method described in the literature.[14]

Reaction with Furans and Thiophenes. A solution containing 2 mmol of bis(heptafluorobutyryl) peroxide and 4 mmol of furans or thiophenes in 30 g of Freon-113 was degassed and kept at 40 °C for 3 h in a sealed tube. The solution was washed with 20 mL of water. The organic layer was analyzed by GLC using internal standards and $C_3F_7CO_2H$ in aqueous layer was determined by titration.

The 2-perfluoropropylfurans and thiophenes were isolated by distillation of the reaction mixture, which was obtained by scaled-up reactions under similar conditions, and identified by IR, ^{1}H-NMR, ^{13}C-NMR, and GC-MS.

2-Perfluoropropylfuran: ^{1}H-NMR ($CDCl_3$) δ=6.60 (1H, m), 6.93 (1H, m), 7.74 (1H, m); IR (cm^{-1}) 1355 (CF_3), 1230 (CF_2); ^{13}C-NMR ($CDCl_3$) δ=111.0, 113.9, 145.9; MS *m/z* 236 (M^+), 217, 167, 148, 117, 69, 39. Exact MS: *m/z* 236.0062. Calcd for $C_7H_3F_7O$: 236.0072.

2-Perfluoropropylthiohene: ^{1}H-NMR ($CDCl_3$) δ=7.08 (1H, m), 7.34 (1H, m), 7.57 (1H, m); IR (cm^{-1}) 1350 (CF_3), 1230 (CF_2); ^{13}C-NMR ($CDCl_3$) δ=127.5, 130.2, 130.3 (t, J_{CCCF}=6.1 Hz); MS *m/z* 252 (M^+), 233, 133. Exact MS: *m/z* 251.9811. Calcd for $C_7H_3F_7S$: 251.9844.

2-Methyl-5-perfluoropropylfuran: ^{1}H-NMR ($CDCl_3$) δ= 2.24 (3H, s), 5.86 (1H), 6.42 (1H); IR (cm^{-1}) 1350 (CF_3), 1255 (CF_2); ^{13}C-NMR ($CDCl_3$) δ=13.4, 107.4, 115.0 (t, J_{CCCF}=3.7 Hz), 156.7; MS *m/z* 250 (M^+), 231, 131. Exact MS: *m/z* 250.0186. Calcd for $C_8H_5OF_7$: 250.0229.

2-Methyl-3,4,5-tris(perfluoropropyl)furan: MS *m/z* 586 (M^+).

2-Methyl-5-perfluoropropylthiophene: ^{1}H-NMR ($CDCl_3$) δ=2.54 (3H, s), 6.80 (1H), 7.26 (1H); IR (cm^{-1}) 1350 (CF_3), 1230 (CF_2); ^{13}C-NMR ($CDCl_3$) δ=15.0, 125.7, 130.3 (t, J_{CCCF}=6.1 Hz), 145.5; MS *m/z* 266 (M^+), 147, 96. Exact MS: *m/z* 265.9989. Calcd for 266.0000.

2-Methyl-bis(perfluoropropyl)thiophene: MS *m/z* 434 (M^+), 415, 315, 265, 144.

2-Methyl-bis(perfluoropropyl)furan: MS *m/z* 418 (M^+), 130.

2-Methoxycarbonyl-5-perfluoropropylfuran: ^{1}H-NMR ($CDCl_3$) 3.72 (3H, s), 6.65 (1H), 6.93 (1H); ^{13}C-NMR ($CDCl_3$) δ=50.8, 115.3, 118.0, 158.1; IR (cm^{-1}) 1740 (C=O), 1355 (CF_3), 1230 (CF_2); MS *m/z* 294 (M^+), 263, 175. Exact MS: *m/z* 294.0128. Calcd for $C_9H_5O_3F_7$: 294.0127.

2-Chloro-5-perfluoropropylthiophene: ^{1}H-NMR ($CDCl_3$) δ=7.20 (1H), 7.46 (1H); IR (cm^{-1}) 1350 (CF_3), 1230 (CF_2); ^{13}C-NMR ($CDCl_3$) δ=126.6, 129.9 (t, J_{CCCF}=6.1 Hz), 135.9. MS *m/z* 288, 286 (M^+), 169, 167, 69. Exact MS: *m/z* 285.9447. Calcd for $C_7H_2F_7SCl$: 285.9453.

2-Bromo-5-perfluoropropylthiophene: ^{13}C-NMR ($CDCl_3$) δ=118.2, 130.3, 130.7; IR (cm^{-1}) 1345 (CF_3), 1230 (CF_2). Exact MS: *m/z* 329.8952. Calcd for $C_7H_2F_7SBr$: 329.8949.

Kinetics of the Reaction with Thiophenes or Furan. Solutions of 0.02 mol/l $(C_3F_7CO_2)_2$ and 0.10 mol/l thiophenes or furan in degassed sealed tubes were immersed in a constant-temperature bath. Each sample tube was removed after appropriate time intervals and immediately immersed in the Dry Ice-acetone bath to quench the reaction; the amount of the residual $(C_3F_7CO_2)_2$ was estimated by iodometric titration. Apparent first-order rate constants were obtained from the initial slopes of the plot of the logarithm of the peroxide concentration against time.

Reaction Products with Pyridine. A solution containing 100 mmol of pyridine and 20 mmol of $(C_3F_7CO_2)_2$ in 400 g of Freon-113 in a 500-mL flask was deaerated with N_2. The flask was immersed in a bath at −20 °C for 3 d. The solution was then concentrated by evaporating the solvent under reduced pressure. A white solid (4.61 g) was obtained by the recrystallization of the residue from 2-propanol and identified as pyridinium heptafluorobutyrate on the basis of the following data; mp 54—56 °C (lit,[15] 56—58 °C), IR (cm^{-1}) 1660 (C=O), 1350 (CF_3), 1220 (CF_2); ^{1}H-NMR ($CDCl_3$) δ=8.11 (2H, m), 8.58 (1H, m), 9.14 (2H, m), 16.76 (1H, s). NaOH was added to the alcohol solution and the solution was stirred at room temperature for 3 h. After removing the alcohol, diethyl ether was added and the precipitated solid was removed. From the ether solution pyridine *N*-oxide was obtained and identified by IR, ^{1}H-, and ^{13}C-NMR.

Reaction Products with Pyridinium Heptafluorobutyrate. A solution containing 2 mmol of pyridinium heptafluorobutyrate and 4 mmol of $(C_3F_7CO_2)_2$ in 30 g of Freon-113 was stirred under N_2 at 40 °C for 6 h. The solution was then diluted with 20 mL of 5% aqueous NaOH and 20 mL of water. The organic layer was analyzed by GLC using the internal standard. The products were identified by GC-MS and isomer composition of perfluoropropylpyridines were determined by GC-IR.

Perfluoropropylpyridine: IR (cm^{-1}) 1350 (CF_3), 1230 (CF_2); MS *m/z* 247 (M^+), 228, 128, 78, 69; CI-MS *m/z* 248 (M^++1).

Bis(perfluoropropyl)pyridine. MS *m/z* 396 (M^+-19), 296, 177, 69; CI-MS *m/z* 416 (M^++1).

GC-IR (aromatic C-H bend). 2-Perfluoropropyl pyridine 750 cm^{-1} (745 cm^{-1}), 3-Perfluoropropylpyridine 780, 710 cm^{-1} (779, 714 cm^{-1}), 4-Perfluoropropylpyridine 818, 740 cm^{-1} (818, 737 cm^{-1}). Values in parenthese are perfluorodecylpyridines.[4a]

2,6-Dimethylperfluoropropylpyridine. MS *m/z* 275 (M^+) 256, 156.

2,6-Dimethylbis(perfluoropropyl)pyridine. MS *m/z* 324 ($M^+-C_2F_5$), 205, 69; CI-MS *m/z* 444 (M^++1).

The authors wish to express their thanks to Mr. Shigehiko Yamaguchi at Tsukuba Central Research Laboratory of Nippon Oil & Fats Co., Ltd. for GC-MS spectrometric measurement.

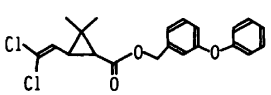
A Convenient Synthesis of Ethyl 3-(2,2-Dihaloethenyl)-2,2-dimethylcyclopropanecarboxylates and Its Modifications for cis-Isomer Enrichment[1)]

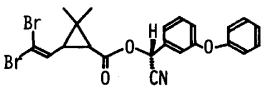
Kiyohide MATSUI,* Akira NEGISHI, Yuriko TAKAHATAKE, Kikuo SUGIMOTO, Tamotsu FUJIMOTO, Toshiyuki TAKASHIMA, and Kiyosi KONDO
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received July 19, 1985)

A synthesis of the title compounds **5** involves the reaction between 3-methyl-2-buten-1-ol and triethyl orthoacetate to produce ethyl 3,3-dimethyl-4-pentenoate, which is followed by the addition of various carbon tetrahalides to the double bond. The reaction of resulting adducts with a base affords **5** in high yields. Stereoselective preparation of the cis-isomer was achieved by the following two methods: First one involves selective transformation of ethyl 4-bromo-6,6,6-trichloro-3,3-dimethylhexanoate to ethyl 6,6,6-trichloro-3,3-dimethyl-4-hexenoate (**8a**) with piperidine followed by the selective conversion of **8a** to *cis*-2,2-dichloroethenyl compound (*cis*-**5a**). Second one is based on the stereoselective cyclization of ethyl 4,6,6,6-tetrachloro-3,3-dimethylhexanoate (*t*-BuONa/solvent/HMPA) to ethyl *cis*-2,2-dimethyl-3-(2,2,2-trichloroethyl)cyclopropanecarboxylate which is transformed into *cis*-**5a** without cis-trans isomerization.

The esters of 3-(2,2-dihaloethenyl)-2,2-dimethylcyclopropanecarboxylic acid belong to the most important class of agricultural insecticides at present.[2)] Particularly, 3-phenoxybenzyl ester of the dichloroethenyl analog (permethrin, **1a**) exibits higher activity than natural pyrethroids, moderate stability under natural conditions, and in additon, low mammalian toxicity.[3,4)] Furthermore, one optical isomer of α-cyano-3-phenoxybenzyl ester of the *cis*-dibromoethenyl analog (decamethrin, **1b**) has been known as the most powerful insecticide so far reported.[5)]



permethrin (1a)
(*cis*-, *trans*- and racemic mixture)

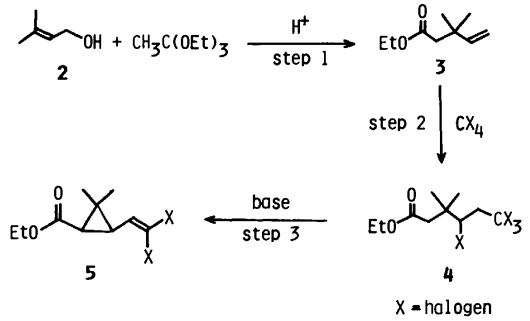


decamethrin (1b)

The known methods to prepare the acid moiety of these potent artificial pyrethroids include the followings:[6)] (1) The construction of substituted ethenyl groups by the Wittig reaction of 3-formyl-2,2-dimethylcyclopropanecarboxylate with phosphonium ylides.[7)] (2) Reaction of diazoacetates with appropriate dienes.[8)] (3) Rearrangement of substituted α-halocyclobutanones.[9)] (4) Other methods to construct ethenylcyclopropanes, for example, cyclization of 4-haloalkanoates,[10)] the Michael addition of allylic sulfones to 3-methyl-2-butenoates,[11)] addition of allenic carbenes,[12)] and addition of phosphonium ylides to 4-oxobutenoates.[13)] These methods were, however, difficult to apply to industrial production of the target compounds by following reasons: The starting materials are not readily available, the reagents required are expensive and/or the operation is tedious. Furthermore, these methods usually afforded a mixture of cis- and trans-isomers (cis/trans= 50/50—10/90).

This paper details a new and industrially acceptable method for the synthesis of ethyl 3-(2,2-dihaloethenyl)-2,2-dimethylcyclopropanecarboxylates and its modification for the stereochemically controlled preparation of the corresponding *cis*-dichloroethenyl compound.[14,15)]

The method developed herein is based on the reaction between 3-methyl-2-buten-1-ol (**2**) and triethyl orthoacetate to produce ethyl 3,3-dimethyl-4-pentenoate (step 1), and the subsequent addition of a carbon tetrahalide to the double bond (step 2). The dehydrohalogenation and cyclization of the resulting halide with a base (step 3) afford the desired cyclopropanecarboxylate **5**, as shown in the following scheme.



Scheme 1.

Preparation of Ethyl 3,3-Dimethyl-4-pentenoate 3 (Step 1). The pentenoate **3** was obtained by heating a mixture of 3-methyl-2-buten-1-ol (**2**) and triethyl orthoacetate (TEOA) in the presence of acidic catalyst under the removal of ethanol formed as the reaction proceeded.[16,17)]

The effect of various acidic catalysts on the yield of **3** was studied. Table 1 shows clearly that phosphoric acid is the best catalyst from the viewpoint of the yield and the reaction rate. When phenol was used as the catalyst, 3-methyl-2-butenyl phenyl ehter was obtained as a by-product. The formation of another by-product, i.e., 3-methyl-2-butenyl 3,3,-dimethyl-4-pentenoate (**6**), was observed in all cases in the range

Table 1. Effect of Acidic Catalysts on Preparation of 3[a]

Catalyst[b]	Reaction time	Yield of 3
	h	%
Phenol	25	76
H_3PO_4	6	81
Oxalic acid	27	65
$(CH_3)_2CHCO_2H$	23	70
$Hg(OAc)_2$	23	69
Hydroquinone	23	51

a) Molar ratio of 2:TEOA=1:2. b) The amount of the catalyst was 5.0 mol% based on 2 except for case of H_3PO_4 (1.0 mol%).

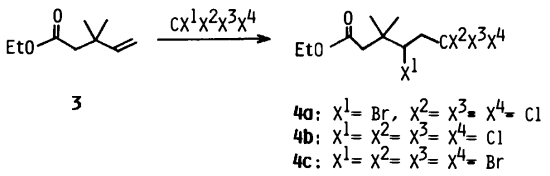
of 5—20% yields. The amount of **6** depended on the molar ratio of **2**/TEOA. The increase of the ratio of TEOA to **2** clearly suppressed the formation of **6** to improve the yield of **3** remarkably up to 89%.

Ethyl bis(3-methyl-2-butenyl) orthoacetate or tris(3-methyl-2-butenyl) orthoacetate would be the precursor of **6**. The possibility of transesterification of **3** giving **6** was excluded by the fact that heating **3** with **2** in the presence of an acidic catalyst did not afford **6**.

Thus, in order to attain the maximum yield of **3**, an excess of TEOA (preferably more than three equivalents to **2**) should be used in the presence of phosphoric acid. Most of the excess orthoacetate can be recovered by fractional distillation.

Addition of Carbon Tetrahalide to 3 (Step 2). The addition was first investigated either in the presence of a radical initiator or under irradiation.[18]

Heating a solution of **3** and AIBN in bromotrichloromethane at 104 °C for 10 h successfully induced the desired addition reaction to afford ethyl 4-bromo-6,6,6-trichloro-3,3-dimethylhexanoate (**4a**) in 89% yield. Similarly, ethyl 4,6,6,6-tetrachloro-3,3-dimethylhexanoate (**4b**) was obtained in 86% yield by refluxing a solution of **3** in carbon tetrachloride in



3

4a: X^1= Br, X^2= X^3= X^4= Cl
4b: X^1= X^2= X^3= X^4= Cl
4c: X^1= X^2= X^3= X^4= Br

the presence of BPO. Addition of carbon tetrabromide to **3** was effected by heating them with AIBN or under irradiation of visible light to afford ethyl 4,6,6,6-tetrabromo-3,3-dimethylhexanoate (**4c**) in 60% yield.

Furthermore, other radical initiators, such as transition metal-amine complexes,[19,20] were found to be good alternatives in carbon tetrachloride case. For example, heating a mixture of DMF and $FeCl_3 \cdot 6H_2O$–$BuNH_2$ complex in carbon tetrachloride at 100 °C for 15 h afforded the desired adduct **4b** in 90% yield. Other than above complex, $FeCl_2$–$BuNH_2$, CuCl–$BuNH_2$, and $Cu(CN)_2$–$BuNH_2$ were found to be also effective. In carbon tetrabromide case, the use of these metal complexes resulted low yields of **4c**.

Preparation of Ethyl 3-(2,2-Dihaloethenyl)-2,2-dimethylcyclopropanecarboxylate (5) (Step 3). This simultaneous cyclization and dehydrohalogenation were successfully achieved by treating the adduct **4** with an appropriate base as shown in Table 2. A wide variety of bases could be utilized for the preparation of dichloroethenyl compound **5a**. In the case of the tetrabromo adduct **4c**, the use of too strong bases such as *t*-BuOK and a high reaction temperature should be avoided because of decomposition of the resulting cyclopropanecarboxylate **5c**. The cis/trans ratio of **5** changed with the reaction conditions used. In general, the use of EtONa or EtOK as a base favored the formation of trans-isomer of **5**.

There was observed the formation of ethyl 2-haloethynyl-3,3-dimethylcyclopropanecarboxylate (**7**) (2—15% yields). The amount of formation of **7** increased when the reaction was carried out at high

Table 2. Preparation of 5 from Adduct 4

Adduct	Base	Solvent	Temp	Time	Product	Cis/trans	Yield
			°C	h			%

temperature or in protic solvents. In general, the reaction with the tetrabromo adduct **4c** gave more amount of the acetylenic compound, i.e., **7b** (10—15%) as compared with the case of the chloro analog (2—10%).

With respect to the reaction mechanism, we observed the formation of three intermediates **8a, 9b,** and **10a** at the beginning of the reaction of **4b** with a base. In the reaction of **4c**, detectable intermediates were only **9c** and **10b**. The ratio of the intermediates formed changed with the reaction conditions. In general, the use of *t*-alkoxide as a base favored the formation of **10**, while the reaction with ethoxide resulted in the predominant formation of **8** and **9**.

As the reaction proceeded, these intermediates formed were gradually converted to **5**. Among the intermediates, the intermediate **9** was found to be the most reactive. The rate of disappearance of **8a** was considerably lower in protic solvents than that in aprotic solvents, while the intermediate **10** was converted into **5** at a moderate rate in both solvents.

Stereoselective Preparation of *cis*-5a. The title stereocontrolled preparation becomes interesting target because cis-isomer of above new artificial pyrethroids usually exhibit enhanced insecticidal activity than trans-isomers.[21] To this end, we intended to modify the above process. At the beginning of the reaction at step *3*, three intermediates **7, 8,** and **9** were produced and were gradually converted into **5**. In order to examine the stereochemical aspect of this reaction, we planned to isolate **8a** and **9b** by the treatment of **4a** or **4b** with amines.

Fortunately, selective dehydrohalogenation was achieved. For example, the compound **8a** was prepared by treating **4a** with piperidine in benzene or DMF in 75—85% yields, whereas treatment of **4b** with pyrrolidine in toluene or DMF afforded **9b** in 87—90% yields.[22]

Cyclization of **8a** or **9b** to **5a** was carried out using a variety of bases and solvents. Typical results are summarized in Table 3. Under all conditions examined (run 1—5), the compound **9b** was transformed mainly into *trans*-**5a**. In contrast, the cis/trans ratio of **5a** derived from **8a** changed significantly depending on the reaction conditions. The treatment of **8a** with EtONa in refluxing benzene (run 6) gave **5a** with an isomer ratio of ca. 50/50, while the use of $NaNH_2$ increased the cis content to some extent (run 7). This result suggests that absence of alcohol may favor the formation of *cis*-**5a**.[23] Therefore, the ethanol formed was removed from the reaction mixture as quickly as possible by distillation to afford cis-rich **5a** (run 9). The presence of THF accelerated the cyclization, favoring formation of the cis-isomer (cf. run 7 and 8). As a result, the cyclopropane **5a** of 90% cis content was attained (run 10).

Alternative approach involving stereoselective preparation of *cis*-**10a** from **4b** was also studied. Treatment of **4b** with *t*-BuONa or *t*-BuOK gave **10a** selectively. The cis/trans ratio of the product

Table 4. Stereoselective Cyclization of **4b** to **10a**

Run	Base	Solvent	Temp °C	Yield %	cis trans
1	*t*-BuONa	Benzene/ *t*-BuOH	80	74	30/70
2	*t*-BuONa	*t*-BuOH/ HMPA	4—8	86	73/27
3	*t*-BuONa	THF/HMPA	−26	81	79/21
4	*t*-BuONa	Hexane/ HMPA	−60	88	88/12

changed dramatically depending on the solvent and reaction temperature employed. The cyclization in a mixture of benzene and *t*-butyl alcohol at the reflux temperature afforded *trans*-**10a** as the main product (cis/trans=30/70).[24] In contrast, cis-rich **10a** was obtained by carrying out the reaction in hexane in the presence of HMPA at low temperature. Table 4 shows some typical results. The observed stereoselective cyclization of **4b** to **10a** may be attributed to a solvent effect in favor of kinetic control, as no isomerization between *cis*-**10a** and *trans*-**10a** was observed under these conditions. It is worthy to note that the preferential cyclization of γ-halo ester to *cis*-cyclopropanecarboxylate is unprecedented, though the predominant formation of trans-isomer was well-known in the preparation of chrysanthemic acid.[10]

The cyclopropane **10a** (cis/trans=30/70) was transformed into **5a** (cis/trans=28/72) by treating with a base such as EtONa or DBU. Furthermore, the treatment of **10a** (cis/trans=75/25) with NaOH afforded the corresponding carboxylic acid of **5a** (cis/trans=75/25). The original stereochemical integrity was thus retained during these transformations.[25]

In contrast to **4a** and **4b**, tetrabromo adduct **4c** gave **9c** as sole product upon the treatment with DABCO or DBU. Cyclization of **9c** with bases afforded *trans*-**5b** mainly in high yields. When **4c** was treated with a *t*-butoxide ion in a common solvent, such as THF or benzene, *trans*-**10b** was produced again. The highest cis content (50%) of **5b** was obtained upon the successive treatment of **4c** with $NaNH_2$ and DBU in a mixture of *t*-butyl alcohol and hexane, hereby **10b** being the responsible intermediate (glpc).

Experimental

General. All the melting points and boiling points are uncorrected. IR spectra were recorded on a Hitachi EPI-G3 grating spectrophotometer. NMR spectra were measured with Varian HA-100 spectrometer and Hitach-Perkin-Elmer R-20B using TMS as an internal standard. Mass spectra were recorded on Hitachi RMU-6E mass spectrometer (70eV). Analytical determinations by glpc were performed on a Hitachi 163 gas chromatograph (5 mm o.d.×1 m, 2% EGA on Uniport B or diasolid ZS).

General Procedure for the Examination of the Reaction Conditions of Step 1. A catalyst (5.0 mol% except for the case of H_3PO_4 (1.0 mol%)) was added to a mixture of 3-methyl-2-buten-1-ol (**2**)[27] (4.3 g, 50 mmol) and cited amount of TEOA in Tables 1 and 2 at room temperature. The mixture was heated to 140—150 °C under removal of ethanol. The yield of ethyl 3,3-dimethyl-4-pentenoate (**3**) was determined by glpc, decahydronaphthalene being used as an internal standard.

Large Scale Preparation of the Pentenoate 3. A mixture of 43 g (0.50 mol) of **2**, 0.24 kg (1.5 mol) of TEOA and 3.4 ml (50 mmol) of phosphoric acid was heated at 140 °C with stirring for 14 h under removal of ethanol. After excess TEOA was removed, the residue was distilled to give 66 g (85%) of **3**, bp 74—78 °C/55 mmHg† (lit,[17] 35—45 °C (bath)/0.1 mmHg). ^1H NMR (CCl_4) δ=5.86 (dd, 1H), 5.1—4.7 (m, 2H), 4.06 (q, 2H), 2.19 (s, 2H) 1.22 (t, 3H), 1.12 (s, 6H). The elemental analysis gave a satisfactory result.

Ethyl 4-Bromo-6,6,6-trichloro-3,3-dimethylhexanoate (4a). Fifty milligrams of AIBN was added to a solution of 1.6 g (10 mmol) of **3** in 5.0 ml of bromotrichloromethane. The mixture was heated at 104 °C for 10 h. After the unreacted bromotrichloromethane was removed, the residue was distilled to give 3.2 g (89%) of **4a**, bp 102—105 °C/0.1 mmHg. IR (neat): 1730, 1225, 1200, 1155, 1035, 960, 805, 710, 655 cm^{-1}. ^1H NMR (CCl_4) δ=4.49 (dd, 1H), 4.08 (q, 2H), 3.4—3.15 (m, 2H), 2.60 (d, 1H), 2.23 (d, 1H), 1.23 (t, 3H), 1.23 (s, 3H), 1.13 (s, 3H). MS *m/z*: 353 (M^+), 41 (base). Found: C, 33.83; H, 4.35%. Calcd for $C_{10}H_{16}BrCl_3O_2$: C, 33.88; H, 4.55%.

Ethyl 4,6,6,6-Tetrachloro-3,3-dimethylhexanoate (4b). A mixture of 6.2 g (40 mmol) of **3**, 50 ml of carbon tetrachloride and 50 mg of BPO was heated at 80 °C for 20 h under argon atmosphere. After having been cooled to room temperature, the reaction mixture was washed with aq $NaHCO_3$ and water. The mixture was dried ($MgSO_4$) and distilled to give 11 g (86%) of **4b**, bp 107—108 °C/0.15 mmHg. IR (neat): 1730, 1180, 1130, 1090, 975, 800, 685 cm^{-1}. ^1H NMR (CCl_4) δ=4.37 (dd, 1H), 4.07 (q, 2H), 3.40—2.85 (m, 2H), 2.56 (d, 1H), 2.22 (d, 1H), 1.27 (t, 3H), 1.22 (s, 3H), 1.13 (s, 3H). MS *m/z*: 308 (M^+), 46 (base). Found: C, 38.91; H, 5.07; Cl, 45.84%. Calcd for $C_{10}H_{16}Cl_4O_2$: C, 38.74; H, 5.20; Cl, 45.74%.

Addition of Carbon Tetrabromide to 3. **a) Using AIBN as a Radical Initiator:** Fifty milligrams of AIBN was added to a mixture of 1.6 g (10 mmol) of **3** and 3.3 g (10 mmol) of carbon tetrabromide. The mixture was heated at 120 °C for 5 h under argon atmosphere. The crude product was purified by chromatography (silica-gel column) to give 3.0 g (60%) of ethyl 4,6,6,6-tetrabromo-3,3-dimethylhexanoate (**4c**). IR (neat): 1735, 1220, 1150, 1032, 610 cm^{-1}. ^1H NMR (CCl_4) δ=4.35 (q, 1H), 4.07 (q, 2H), 3.55 (m, 2H), 2.61 (d, 1H), 2.27 (d, 1H), 1.32 (s, 3H), 1.28 (t, 3H), 1.21 (s, 3H). MS *m/z*: 324 (M^+), 88 (base). Found: C,

† 1 mmHg≈133.3 Pa.

24.87; H, 3.25; Br, 65.60%. Calcd for $C_{10}H_{16}Br_4O_2$: C, 24.62; H, 3.31; Br, 65.51%.

b) Addition under Irradiation: A mixture of **3** (0.78 g) and carbon tetrabromide (3.3 g) continuously purged with argon, was irradiated with a 100 W sunlight lamp for 10 h at room temperature. The resulting darkbrown oil was purified by chromatography (silica-gel column) to give **4c** (1.5 g).

Ethyl 3-(2,2-Dichloroethenyl)-2,2-dimethylcyclopropanecarboxylate (5a). The THF solution of **4a** [0.71 g (2.0 mmol)] (5 ml) was added dropwise to 0.45 g of *t*-BuOK in 15 ml of THF and the mixture was heated under reflux for 2 h. After an additional 0.11 g of *t*-BuOK was added, the mixture was heated under reflux for 1 h. The mixture was poured into aq NH_4Cl and extracted with ether. The ether extract was dried ($MgSO_4$) and concentrated in vacuo. Distillation gave 0.35 g (74%) of **5a**, bp 80—83 °C/0.8 mmHg (lit,[8] 119—120 °C/15 mmHg). IR (neat): 1730, 1182 cm^{-1}. ^1H NMR (CCl_4) δ=6.22 (d, *cis*-H) 5.56 (d, *trans*-H) (total 1H, cis/trans=45/55), 4.05 (bq, 2H), 2.35—1.4 (m, 2H), 1.4—1.05 (m, 9H). MS *m/z*: 236 (M^+), 91 (base). Found: C, 50.44; H, 5.83; Cl, 29.63%. Calcd for $C_{10}H_{14}Cl_2O_2$: C, 50.65; H, 5.95; Cl, 29.90%. The cis- and trans-isomers could be separated by chromatography (silica-gel column). The ^1H NMR spectra of them are identical with those reported.[28] The fore-cut (45 mg) at the above distillation was composed with **5a** and ethyl *trans*-2-(2-chloroethynyl)-3,3-dimethylcyclopropanecarboxylate (**7a**). The acetylenic ester **7a** was alternatively prepared from **5a** by the treatment with NaH in THF-HMPA at room temperature for 14—26 h. *trans*-**7a** (from *trans*-**5a**): Bp 66 °C/1 mmHg. Yield 75%. IR (neat): 2220, 1735, 1280, 1170, 1050 cm^{-1}. ^1H NMR (CCl_4) δ=4.04 (q, 2H), 1.81 (d, 1H), 1.58 (d, 1H), 1.28 (s, 3H), 1.24 (t, 3H), 1.20 (s, 3H). MS *m/z*: 200 (M^+), 127 (base). Found: C, 59.95; H, 6.48; Cl, 17.42. Calcd for $C_{10}H_{13}ClO_2$: C, 59.86; H, 6.53; Cl, 17.67. *cis*-**7a** (from *cis*-**5a**): Yield 28%. ^1H NMR (CCl_4) δ=4.04 (q, 2H), 1.58 (s, 2H), 1.30 (s, 3H), 1.23 (t, 3H), 1.16 (s, 3H). MS *m/z*: 200 (M^+), 127 (base).

The formation of the intermediates **8a** and **10a** was observed at the beginning of the reaction by glpc analysis.

Cyclopropanecarboxylate 5a from the Carbon Tetrachloride adduct 4b. Typical Procedure 1 (*t*-BuONa/THF): A suspension of 4.2 g (22 mmol) of *t*-BuONa in 80 ml of dry THF was cooled to 5 °C. A solution of 3.1 g (10 mol) of the adduct **4b** in 20 ml of dry THF was added dropwise to the above susepnsion and the mixture was stirred at ca. 5 °C for 3 h. The mixture was neutralized with dry HCl in ether and filtered. The filtrate was diluted with ether, washed with water and dried ($MgSO_4$). Distillation gave 2.2 g (92%) of a mixture of *cis*- and *trans*-**5a**, bp 73—78 °C/0.6 mmHg. The cis/trans ratio was 50/50 based on NMR analysis.

Typical Procedure 2 (EtONa/EtOH): To an ethanolic EtONa (prepared from Na metal (1.0 g, 44 mmol) and dry ethanol (80 ml)) was added dropwise, while cooling with ice, 20 ml of an ethanolic solution containing 6.2 g (20 mmol) of **4b**. The mixture was stirred for 1 h at room temperature, then heated under reflux for 1.5 h. The mixture was worked up and distillation of the crude product gave 4.5 g (94%) of **5b**, bp 72—74 °C/0.4 mmHg. The cis/trans ratio was 34/66 based on the glpc analysis (2% EGA, 120 °C).

Ethyl 3-(2,2-Dibromoethenyl)-2,2-dimethylcyclopropanecarboxylate (5b). An ethanolic solution (5 ml) of EtONa (0.62 g) was added dropwise to 1.5 g (3 mmol) of **4c** in 16 ml of dry ethanol under ice cooling. The mixture was warmed to room temperature and stirred for 6 h. An additional 2.5 ml of ethanolic EtONa (about 0.3 g) was added, and the mixture was stirred for another 12 h. The mixture was worked up and distillation gave 0.77 g (79%) of **5b**, bp 98—101 °C/0.4 mmHg (lit,[29] 95—97 °C/0.4 mmHg). IR (neat): 1725, 1223, 1175 cm^{-1}. ^1H NMR (CCl_4): δ=6.72 (bd, *cis*-H), 6.10 (d, *trans*-H) (total 1H, cis/trans=2/8), 4.10 (q, 2H), 2.3—1.5 (m, 2H), 1.5—1.1 (m, 9H). MS *m/z*: 253, 41 (base). Found: C, 37.07; H, 4.40; Br, 49.27%. Calcd for $C_{10}H_{14}Br_2O_2$: C, 36.84; H, 4.33; Br, 49.02%. The fore-cut (74 mg) was mainly composed with *trans*-**7b**. Yield 10%. IR (neat): 2220, 1735 cm^{-1}. ^1H NMR (CCl_4): δ=4.05 (q, 2H), 2.0—1.4 (m, 2H), 1.5—1.0 (m, 9H). MS *m/z*: 245 (M^+), 41 (base).

Ethyl 4,6,6-Trichloro-3,3-dimethyl-5-hexenoate (9b). A solution of pyrrolidine (0.71 mg) in toluene was added to a toluene solution of **4b** (1.6 g). The mixture was stirred at 100—110 °C for 4 h and worked up. Distillation gave 1.2 g (87%) of **9b**, bp 87—90 °C/0.12 mmHg. IR (neat): 1735, 1613, 1220, 1035, 880 cm^{-1}. ^1H NMR (CCl_4) δ=5.96 (d, 1H), 4.85 (d, 1H), 4.06 (q, 2H), 2.41 (d, 1H), 2.23 (d, 1H), 1.23 (t, 3H), 1.11 (s, 6H). Found: C, 44.18; H, 5.39; Cl, 38.65%. Calcd for $C_{10}H_{15}Cl_3O_2$: C, 43.90; H, 5.53; Cl, 38.87%.

Ethyl 6,6,6-Trichloro-3,3-dimethyl-4-hexenoate (8a). Piperidine (5.1 g, 60 mmol) was added dropwise to a solution of ethyl 4-bromo-6,6,6-trichloro-3,3-dimethylhexanoate (**4a**) (11 g, 30 mmol) in benzene (45 ml) at room temperature. The mixture was refluxed for 5 h, diluted with ether, and washed (water, 1 M HCl(1 M=1 mol dm^{-3}), aq $NaHCO_3$, water) and dried ($MgSO_4$). Distillation afforded 7.0 g (85%) of **3a**, bp 82—83 °C/0.5 mmHg. IR (neat): 1730, 1615, 1225, 1175, 1030 cm^{-1}. ^1H NMR (CCl_4) δ=6.26 (d, 1H, *J*=15 Hz), 5.96 (d, 1H, *J*=15 Hz), 4.01 (q, 2H), 2.26 (s, 2H), 1.21 (t, 3H), 1.19 (s, 6H). Found: C, 44.12; H, 5.35; Cl, 38.11%. Calcd for $C_{10}H_{15}Cl_3O_2$: C, 43.90; H, 5.53; Cl, 38.87%.

Rearrangement of 8a to 9b. A solution of **8a** (1.1 g, 4 mmol) in xylene was heated at 130 °C for 5 h under argon atmosphere. The solution was concentrated in vacuo and the residue was distilled to give 0.93 g of a colorless oil which was composed of **9b** (90%) and a by-product (10%). The by-product separated by chromatography (silica-gel column) was identified to be 4-(2,2-dichloroethenyl)-2,2-dimethyl-4-butenolide. Mp 26.5—28.0 °C (lit,[30] 27.0—28.0 °C). IR (neat): 1790, 1625, 1235, 1160, 1000, 920 cm^{-1}. ^1H NMR (CCl_4) δ=5.50 (d, 1H), 4.78 (d, 1H), 2.33 (d, 1H), 2.25 (d, 1H), 1.21 (s, 3H), 1.05 (s, 3H).

Ethyl 3-(2,2-Dichloroethenyl)-2,2-dimethylcyclopropanecarboxylate (5a) from 8a and 9b (Typical Procedures). From Ethyl 4,6,6-Trichloro-3,3-dimethyl-5-hexenoate (9b). A solution of 0.55 g (2.0 mmol) of **9b** in dry ethanol (2.0 ml) was added dropwise to a solution of Na methal (57 mg, 2.5 mmol) in dry ethanol (10 ml). The mixture was stirred at room temperature for 5 h, cooled with ice and then neutralized by adding dry HCl in ether. The mixture was concentrated to one-tenth its original volume and diluted with ether. The mixture was poured into ice water,

and the ethereal layer was washed (aq $NaHCO_3$, brine) and dried ($MgSO_4$). Distillation gave 0.44 g (92%) of **5a**, bp 75—76 °C/0.25 mmHg. cis/trans=22/78 (glpc, 2% EGA).

From Ethyl 6,6,6-Trichloro-3,3-dimethyl-4-hexenoate (8a). **a) $NaNH_2$/THF**: A solution of the compound **8a** (0.41 g, 1.5 mmol) in dry THF (1.5 ml) was added dropwise to a suspension of $NaNH_2$ (78 mg, 2 mmol) in 20 ml of dry THF. The mixture was heated under reflux with stirring for 5 h poured into ice-water. The aqueous mixture was extracted with ether, washed (aq $NaHCO_3$, brine) and dried ($MgSO_4$). Distillation afforded 0.35 g (98%) of **5a**, bp 72—74 °C/0.2 mmHg. cis/trans=71/29 (glpc).

b) EtONa/Hexane-THF: Dry THF (6 ml) was added to a hexane suspension (20 ml) of EtONa (15 mmol). Then, a solution of **8a** (2.7 g, 9.9 mmol) in hexane (4 ml) was added dropwise to the suspension at the boiling temperature. Ethanol formed was azeotropically removed during the reaction. After 8 h the reaction mixture was worked up as described above. Distillation gave 2.2 g (94%) of **5a**, bp 77—80 °C/0.3 mmHg. cis/trans=90/10 (glpc).

Ethyl 2,2-Dimethyl-3-(2,2,2-Trichloroethyl)cyclopropanecarboxylate (10a). **a) *t*-BuONa/PhH**: To a mixture of *t*-BuOH (60 ml) and dry benzene (30 ml) was added portionwise Na metal (0.28 g, 12 mmol). The resulting mixture was heated under reflux until Na metal disappeared. A benzene solution (5 ml) of **4b** (3.1 g, 10 mmol) was added dropwise and the mixture was stirred for 2 h. Then, the reaction mixture was acidified by introducing dry HCl, diluted with water and extracted with ether. The ethereal layer was washed (aq $NaHCO_3$, brine) and dried ($MgSO_4$). Distillation afforded 2.0 g (74%) of **10a**, bp 78—80 °C/0.1 mmHg. cis/trans=30/70 (glpc). IR (neat): 1730, 1180, 1135, 765 cm^{-1}. ^1H NMR spectrum of trans-isomer (CCl_4) δ=4.08 (q, 2H), 2.85—2.65 (m, 2H), 1.72 (bq, 1H), 1.36 (d, 1H), 1.24 (t, 3H), 1.24 (s, 3H), 1.20 (s, 3H). ^1H NMR spectrum of cis-isomer (CCl_4) δ=4.06 (q, 2H), 3.2—2.95 (m, 2H), 1.7—1.5 (m, 2H), 1.26 (t, 3H), 1.24 (s, 6H). Found: C, 43.80; H, 5.41; Cl, 38.87%. Calcd for $C_{10}H_{15}Cl_3O_2$: C, 43.90; H, 5.53; Cl, 38.87%.

b) *t*-BuONa/Hexane-HMPA: Powdered *t*-BuONa (7.2 g, 75 mmol) was added portionwise to a solution of **4b** (16 g, 52 mmol) and HMPA (10 ml) in dry hexane (50 ml) at −60 °C over a period of 50 min. The mixture was stirred for additional 7 h under cooling and for 12 h at room temperature. Then the mixture was worked up. Distillation gave 12 g (88%) of **10a**, bp 80—83 °C/0.5 mmHg. cis/trans=88/12 (glpc).

Attempted Isomerization between *cis*- and *trans*-10a. **a) *t*-BuONa/Hexane-HMPA**: Powdered *t*-BuOK (30 mg) was added to a solution of *trans*-**10a** (0.54 g) and HMPA (0.40 ml) in hexane (2.0 ml) at −60 °C. The mixture was stirred for 5 h at the temperature and then for 15 h at room temperature. Glpc analysis showed no trans-cis isomerization of **10a** at each temperature.

b) LDA/THF: A solution of LDA in THF (0.40 ml, 0.20 mmol) was added to a solution of *cis*-**10a** (0.54 g) in dry THF (2.0 ml) at −10 °C. The mixture was stirred for 6 h at the temperature and then for 12 h at room temperature. Glpc analysis indicated no cis-trans isomerization.

Ethyl 3-(2,2-Dichloroethenyl)-2,2-dimethylcyclopropanecarboxylate (5a) from 10a. A solution of **10a** (cis/trans=30/70) (2.7 g, 9.9 mmol) in dry ethanol (20 ml) was added dropwise to an ethanolic NaOEt (prepared from Na metal (0.25 g, 11 mmol) and dry ethanol (80 ml)). The mixture was heated under reflux for 5 h. The reaction mixture was worked up as described above. Distillation afforded 1.9 g (80%) of **5a**, bp 75—76 °C/0.25 mmHg. cis/trans=28/72 (glpc).

3-(2,2-Dichloroethenyl)-2,2-dimethylcyclopropanecarboxylic Acid from 4a. A solution of **4a** (cis/trans=75/25) (9.6 g, 35 mmol) in ethanol (5 ml) was added dropwise to a solution of NaOH (6.0 g, 0.15 mmol) in water (30 ml) and ethanol (5 ml). The mixture was heated at 100 °C for 5 h under vigorous stirring. The reaction mixture was washed with ether. The aqueous layer was acidified with concd HCl and extracted with ether–AcOEt (2:1). The latter organic layer was washed with brine and dried ($MgSO_4$). Distillation gave 6.3 g (86%) of the desired acid as a viscous oil, bp 105 °C/0.3 mmHg. cis/trans=75/25 (glpc after esterification with CH_2N_2).

Ethyl 4,6,6-Tribromo-3,3-dimethyl-5-hexenoate (9c). An ethanolic solution of EtONa (prepared from Na metal (94 mg, 4.1 mmol) and dry ethanol (5 ml)) was added dropwise to an ice-cooled solution of ethyl 4,6,6,6-tetrabromo-3,3-dimethylhexanoate (**4c**) (2.0 g, 4.1 mmol) in dry ethanol (10 ml). After 2 h the reaction mixture was worked up as described above. Distillation afforded 0.85 g (51%) of **9c**, bp 130—133 °C/0.3 mmHg. IR (neat): 1730, 1600, 1225, 1150, 1030 cm^{-1}. ^1H NMR (CCl_4) δ=6.64 (d, 1H), 4.95 (d, 1H), 4.12 (q, 2H), 2.38 (bd, 2H), 1.4—1.1 (m, 9H). Found: C, 29.78; H, 3.65; Br, 58.67%. Calcd for $C_{10}H_{15}Br_3O_2$: C, 29.51; H, 3.71; Br, 58.91%.

Ethyl 3-(2,2-Dibromoethenyl)-2,2-dimethylcyclopropanecarboxylate (5b). **a) EtONa/EtOH**: A solution of **4c** (0.41 g, 1.0 mmol) in dry ethanol (1.5 ml) was added dropwise to an ethanolic EtONa (prepared from Na metal (30 mg, 1.3 mmol) and dry ethanol (5 ml)) at room temperature. After 3 h the reaction mixture was worked up and distillation gave 0.27 g (83%) of **5b**, bp 95—98 °C/0.3 mmHg. cis/trans=20/80 (NMR).

b) *t*-BuONa and DBU/*t*-BuOH-Hexane: To an ice-cooled solution of **4c** (9.8 g, 20 mmol) in *t*-BuOH (40 ml) and hexane (20 ml), $NaNH_2$ (1.2 g, 31 mmol) was added portionwise. The mixture was stirred for 1 h at 4—5 °C and for 1 h at room temperature. Then, DBU (3.1 g, 21 mmol) was added to the mixture at 4—5 °C. The mixture was stirred at room temperature for 45 min then heated under reflux for 5 h. After acidified with 1 M HCl, the mixture was evaporated in vacuo. The residue was extracted with ether and the ethereal solution was washed (aq $NaHCO_3$, brine) and dried ($MgSO_4$). Distillation gave 5.7 g (87%) of **5b**, bp 88 °C/0.1 mmHg. cis/trans=50/50 (NMR).

Catalytic Action of Iron and Manganese Ions in the Photochemically-Induced Oxidation of D-Fructose with Atmospheric Oxygen

Koji ARAKI* and Shinsaku SHIRAISHI*
Institute of Industrial Science, The University of Tokyo,
7-22-1, Roppongi, Minato-ku, Tokyo 106
(Received July 20, 1985)

D-Fructose is susceptible to photochemically-induced oxidation by atmospheric oxygen in the presence of a catalytic amount of iron or manganese cations in a neutral to weakly basic pH range. Metal hydroxide does not precipitate from a solution in this pH range because of the high sequestering ability of D-fructose. Upon irradiation of Pyrex-filtered light, D-fructose degraded into D-erythrose and other fragments. This reaction is shown to proceed by coupling with an oxidation-reduction cycle involving a metal cation, i.e., the photooxidation of D-fructose by M(III) and the subsequent reoxidation of the resultant M(II) by atmospheric oxygen.

It is well recognized that trace amounts of transition metal cations like Cu(II), Mn(II), and Fe(III) often play key roles in many biological activities.[1] Among them, the ability of saccharides to sequester metals in aqueous solutions has been drawing considerable interest because of their physiological and chemical importance and the possible applications of metal-saccharide systems to clinical use.[2-4] However, the photochemical properties of metal-saccharide systems are not yet well understood. Recent reports from our and other laboratories have shown that the photochemically-induced oxidation of monosaccharides by transition metals leads to a degradation of saccharides with selective C–C bond cleavage.[5-8] For instance, the photooxidation of D-fructose in an acidic $FeCl_3$ solution causes a C_2—C_3 bond cleavage of D-fructose via the formation of an Fe(III)–D-fructose complex to give D-erythrose in nearly 90% yield.[7] In a preceding letter, we showed that D-fructose and D-glucose are susceptible to photochemically-induced oxidation by atmospheric oxygen in the presence of a catalytic amount of transition-metal ions in the neutral pH range.[9] The catalytic action of transition metals for the oxidation and oxygenation of organic substrates with atmospheric oxygen is a subject of current interest.[10] Thus, the results of our research might have physiological and chemical importance. Therefore, we further extended our study to clarify the role of metal ions in this type of reaction. Here, we wish to report on more detailed aspect of the catalytic action of iron and manganese ions in the photochemically-induced oxidation of D-fructose in neutral to weakly basic solution.

Experimental

Materials. D-Erythrose and D-fructose were obtained from Aldrich Chem. Co. and Wako Pure Chem. Ind. Ltd., respectively. Other chemicals were also obtained commercially, and some of them were purified by conventional methods prior to use.

Photoirradiation. Sample solutions were freshly prepared using deionized water. The pH of solutions were adjusted to appropriate values by the addition of a concd NaOH solution. Photoirradiation was carried out at 20 °C by one of the following three methods.

1) 70 ml of a solution whose pH was initially adjusted to 9.6 was placed in a reaction vessel and internally irradiated by a 100 W high-pressure mercury lamp (Type UM-102, Ushio Electric Inc.) through a Pyrex-made water jacket. During irradiation, the solution was magnetically stirred and air was continuously bubbled from the bottom of the vessel. As the pH of the solution gradually decreased during photoirradiation, small amounts of concd NaOH solution were added every hour during irradiation to keep the solution within the pH range 6 to 9.6.

2) 500 ml of the solution was placed in a larger reaction vessel fitted with a pH electrode and irradiated using the same procedure described above. The pH of the solution was monitored by a TOA HM-20B pH meter and was kept constant during irradiation by a controlled addition of a 2 M[11] NaOH solution with a HSM-10A pH stat (Toa Electronics Ltd.).

3) 3 ml of the solution in a quartz cell was degassed by three freeze-thaw cycles and then irradiated by light of a known wavelength and energy (1—2.3×10^{-2} W) in a JASCO CRM-FA spectro-irradiator with a 2 kW Xenon lamp.

Analyses of the Irradiated Solutions. Syrup obtained from the irradiated solution was analyzed by previously described methods; D-fructose by high-performance liquid chromatography and D-erythrose by gas-liquid chromatography after acetylation of the syrup.[7] D-Erythrose could also be isolated from the syrup by column chromatography with anion-exchange resins (Hitachi Gel #3019N, Hitachi Ltd.; 300×20 mm; CH_3OH). Formic acid in the solution was determined according to a method of Isbell et al.[12] The irradiated solution was treated with cation-exchange resins (Amberlite IR-120, H^+-form, Rohm & Haas) and then extracted three times with ether. The amount of ether-extractable acid, which was identified to be formic acid after converting to *p*-bromophenacyl formate (mp 99—101 °C; lit, 99—100 °C[13]), was determined by titration with a 0.2 M NaOH solution.

Other Measurements. UV-visible spectra were recorded by a JASCO UVIDEC-505 spectrophotometer at 20 °C and electron-spin-resonance (ESR) spectra were measured at room temperature by a JEOL JES-FE3X

spectrometer operated in the X band.

Titration of 30 ml metal-D-fructose solutions were carried out pH-metrically at 25 °C by the addition of 0.1 M NaOH at a rate of 0.5 ml min^{-1} under an anaerobic atmosphere or 0.13 ml min^{-1} under an aerobic atmosphere.

Results

Photoirradiation in the Presence of Metal Salts. Though addition of concd NaOH solutions to acidic $FeCl_3$, $MnCl_2$, or $CuCl_2$ solutions usually resulted in a formation of a colloidal precipitate of metal hydroxide, no precipitate was formed in the presence of a large excess of D-fructose. The solutions remained clear even in the weakly acidic to basic pH range, demonstrating the ability of D-fructose to sequester metal cations in aqueous media.

Seventy millilitre of a solution containing D-fructose (2.8×10^{-2} mol) and a catalytic amount of metal chloride (1.4×10^{-4} mol) was irradiated by Pyrex-filtered light (method 1, see Experimental section). The pH of the solution initially adjusted to 9.6 was kept within the range between 6 to 9.6 during irradiation. Though the formation of a brown colloidal precipitate was observed at the end of irradiation in the presence of $FeCl_3$ or $FeCl_2$, no precipitate was formed even after 24 h of irradiation in the presence of $MnCl_2$. Irradiation in the presence of $CuCl_2$ led to the deposition of metallic copper on the surface of the water jacket at an early stage of the reaction and no light was transmitted to the solution thereafter. Results are summarized in Table 1. Though D-erythrose was the main oxidation product, its yield markedly decreased in the case of $MnCl_2$. No reaction proceeded without photoirradiation or in the absence of any of the metal salts or oxygen.

Oxidation-reduction Cycle of Iron and Manganese Ions. We showed in a preceding letter that the irradiation of an $FeCl_3$–D-fructose solution at pH 9.6 under anaerobic conditions caused the reduction of Fe(III) into Fe(II) and a subsequent aeration of the irradiated solution led to the oxidation of Fe(II) to Fe(III) again.[9] Spectral changes shown in Fig. 1(a) confirm the photoreduction and subsequent oxidation of Fe(II) ion. Similar experiments were carried out for the $MnCl_2$–D-fructose system. A $MnCl_2$ (2×10^{-3} M)–D-fructose (0.4 M) solution was adjusted

Table 1. Photoirradiation in the Presence of Metal Chloride at 20 °C

Metal Chloride	Irradiation Time/h	D-Fructose Oxidized 10^{-3} mol	D-Erythrose Formed 10^{-3} mol
$FeCl_3$[a]	12	9.1	6.7 (74%)[b]
$FeCl_2$[a]	12	8.5	6.2 (73%)
$MnCl_2$[a]	24	15.4	8.7 (56%)
$CuCl_2$	6	0	0

A 70 ml of the D-Fructose(2.8×10^{-2} mol)–metal chloride (1.4×10^{-4} mol) solution was irradiated by the method 1.

a) Ref. 9, b) Conversion based on the D-fructose oxidized (mol%).

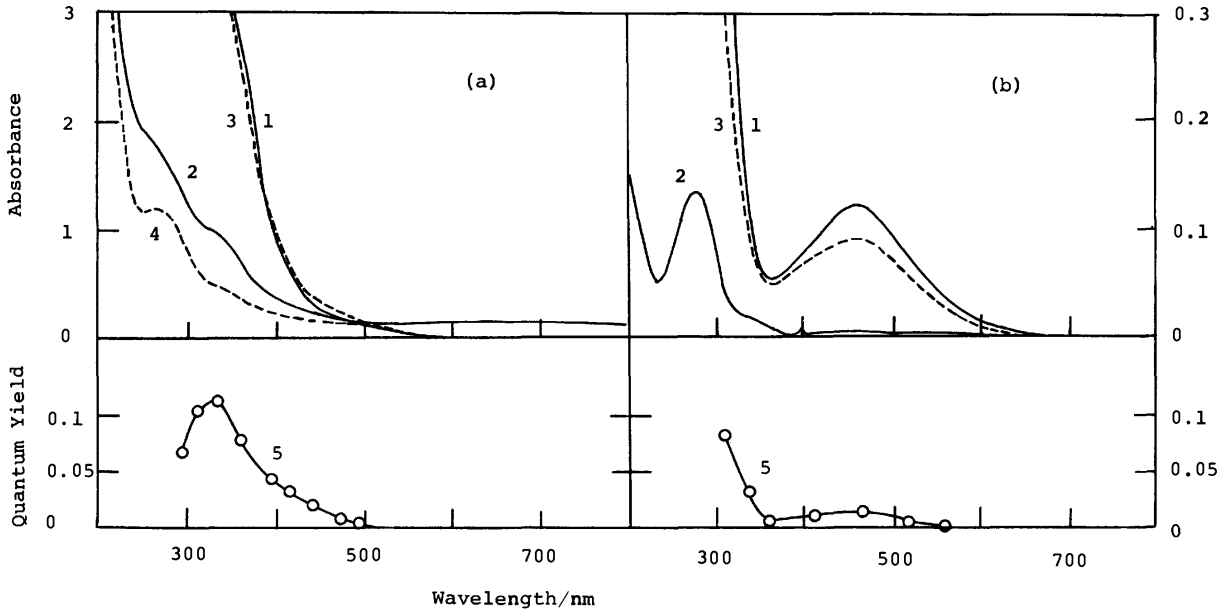

Fig. 1. Absorption and Action Spectra of (a) $FeCl_3$ (2×10^{-3} M)- and (b) $MnCl_2$ (2×10^{-3} M)–D-Fructose (4×10^{-1} M) Sloutions at pH 9.6 and 20 °C.
Initial solution(1) was irradiated for 30 min under anaerobic conditions(2), and then the solution was aerated(3). Spectrum (4)represents the $FeCl_2$(2×10^{-3} M)–D-fructose (4×10^{-1} M) solution at pH 9.6 prepared under anaerobic conditions, and curves(5) shows the quantum yields of the reduction of M(III) at different wavelengths.

to pH 9.6 by the addition of concd NaOH under an aerobic atmosphere. The colorless solution became slightly reddish and the d-d transition-band characteristics for the high-spin Mn(III) state were observed at 400—500 nm (Fig. 1(b)).[14] No signal was observed in the ESR spectrum of the solution, further supporting the formation of Mn(III) species.[15] Photoirradiation after deaerating the solution gave a clear colorless solution, showing practically no absorption in the visible region. The ESR spectrum of the irradiated solution showed a sextet signal, confirming the formation of a high-spin octahedral Mn(II) complex.[15] The aeration of the irradiated solution again made the solution faintly reddish and the ESR signal disappeared. Thus, it was shown that a photochemically-induced reduction of Mn(III) to Mn(II) and subsequent oxidation to Mn(III) by atmospheric oxygen does take place in the presence of a large excess of D-fructose in a weakly basic pH range without forming any precipitate. The action spectrum of the reduction of Mn(III) obtained by method 3 is also shown in Fig. 1(b).

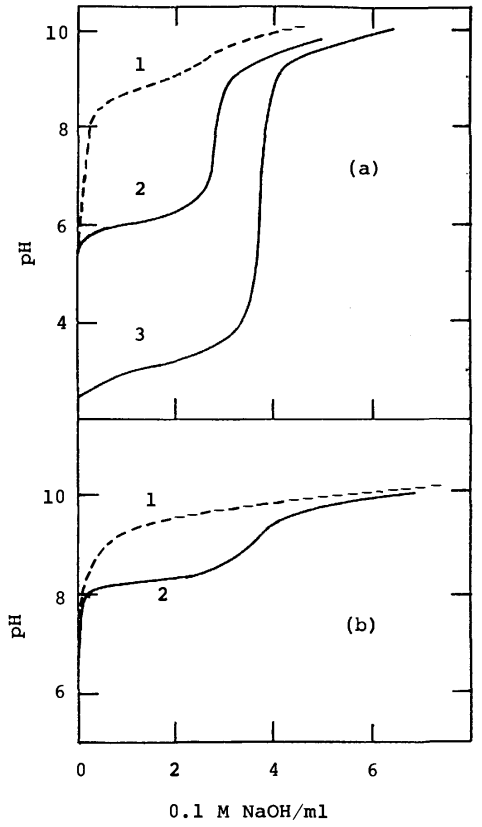

Fig. 2. Titration Curves of Metal Chloride(4×10^{-3} M)-D-fructose(8×10^{-1} M) Solutions(30 ml) by 0.1 M NaOH at 25 °C.
(a): 1. $FeCl_2$ under anaerobic, 2. $FeCl_2$ under aerobic, and 3. $FeCl_3$ under aerobic atmosphere. (b): 1. $MnCl_2$ under anaerobic, and 2. $MnCl_2$ under aerobic atmosphere.

To study the oxidation process of Fe(II) and Mn(II) further, $FeCl_3$-, $FeCl_2$-, and $MnCl_2$-D-fructose solutions were titrated using a 0.1 M NaOH solution under anaerobic or aerobic atmosphere (Fig. 2). When $FeCl_2$ was titrated in an oxygenated solution, Fe(II) was oxidized to Fe(III) at around pH 6. However, the oxidation of Mn(II) was observed only above pH 8 under similar conditions.

Effect of pH on the Reaction. Since the pH of a solution is an essential factor for the photochemically-induced oxidation of monosaccharide in the presence of transition-metal ions, the effect of pH on the reaction was further studied for $FeCl_3$-D-fructose systems. For this purpose, 500 ml of the $FeCl_3$(1×10^{-3} mol)-D-fructose(2×10^{-1} mol) solution was irradiated for 120 h with a controlled addition of a small amount of 2 M NaOH in order to maintain the pH of the solution more strictly (method 2). Without the addition of 2 M NaOH, the pH of the solution (initially adjusted to 9.6) decreased to about 3 after 12 h of irradiation. The irradiation of a solution whose pH was below 6.8 resulted in the formation of a colloidal precipitate within 24 h. The amounts of 2 M NaOH required to maintain the initial pH of the solution during irradiation are shown in Fig. 3 and the irradiation results are summarized in Table 2. A considerable amount of 2 M NaOH was consumed to maintain the pH of the solution and the yield of D-erythrose in the oxidation products markedly decreased, especially when irradiated at a higher pH. This suggested the formation of acids as oxidation products. Formic acid was detected from the ether-extract of the irradiated solution.

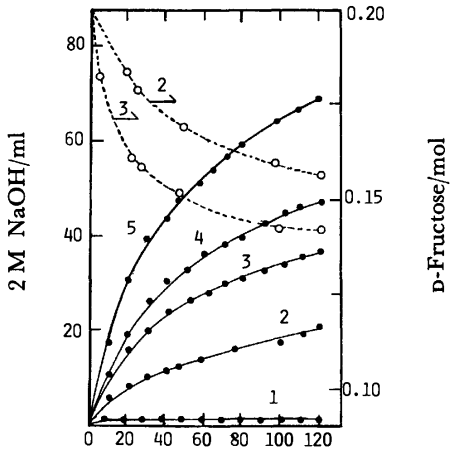

Fig. 3. Time Cource of the Photooxidation of D-Fructose (2×10^{-1} mol/500 ml) by Method 2 in the Presence of $FeCl_3$ (1×10^{-3} mol) at 1. pH 6.8, 2. pH 7.2, 3. pH 7.8, 4. pH 8.4 and 5. pH 9.0.
(—●—): 2 M NaOH required to maintain the initial pH, and (—○—): D-fructose.

Table 2. Effect of pH on the Photochemically-Induced Oxidation of D-Fructose in the Presence of $FeCl_3$ at 20 °C

pH	D-Fructose oxidized 10^{-3} mol	D-Erythrose[a] $/10^{-3}$ mol	NaOH consumed $/10^{-3}$ mol	Formic Acid $/10^{-3}$ mol
6.8	49	27 (55%)	5	5
7.2	44	18 (41%)	42	12
7.8	54	18 (33%)	74	19
8.4	80	12 (15%)	99	31
9.0	92	6 (7%)	133	38

A 500 ml of the D-fructose(0.2 mol)-$FeCl_3$(1×10^{-3} mol) solution was irradiated by the method 2 (see Experimental) for 120 h.

a) Conversions based on the D-frucotse oxidized are given in parentheses(mol%).

Discussion

Catalytic Action of Iron and Manganese Ions. Titration curves in Fig. 2 show that Fe(III) exists as $[Fe^{III}(OR^-)_3]$ at neutral to weakly basic pH in the presence of a large excess of D-fructose, where OR^- represents OH^- or a dissociated form of D-fructose. Fe(II) is supposed to exist as Fe^{2+} or to some extent as $[Fe^{II}(OR^-)]^+$ at around pH 9. These results are essentially the same as those in the absence of D-fructose (pK_a=6 for $[Fe^{III}(OH^-)_2]^+ + OH^- \rightleftarrows [Fe^{III}(OH^-)_3]$, and pK_a=9.2 for $Fe^{2+} + OH^- \rightleftarrows [Fe^{II}(OH^-)]^+$).[16,17] However, no precipitate was formed in this pH range in the presence of D-fructose, and both Fe(III) and Fe(II) remained in the solution.

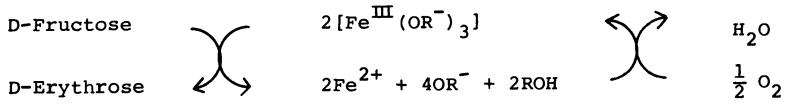
The oxidation of Fe(II) by atmospheric oxygen in the presence of D-fructose was shown to take place at an appreciable rate above pH 6 in the dark (Fig. 2). This result is consistent with the fact that the oxidation-reduction potential of Fe(III)/Fe(II) decreased at a higher pH of the solution. Several studies have shown that the rate of oxidation of Fe(II) strongly depends on the hydroxide ion concentration. The half-lives of Fe^{2+} in an air-saturated solution at pH 8 is estimated to be 45 s.[17,18] This oxidation process can be written as follows at a neutral pH,

$$2Fe^{2+} + 1/2O_2 + 6HOR \longrightarrow 2[Fe^{III}(OR^-)_3] + 4H^+ + H_2O,$$

where ROH represents H_2O or D-fructose. Therefore, the pH of the solution decreases upon the oxidation of Fe(II).

When D-fructose is degraded by a photochemically-induced oxidation with Fe(III) in a acidic medium under either an aerobic or an anaerobic atmosphere, 2 mol of Fe(III) is required to oxidize 1 mol of D-fructose into D-erythrose.[7] The irradiation of D-fructose solutions at a neutral pH in the presence of a small amount of $FeCl_3$ also caused the degradation of D-fructose, mostly into D-erythrose. However, the amount of D-fructose oxidized or D-erythrose formed is much more than that of Fe(III) (Table 1). The reaction requires the presence of oxygen, a small amount of iron ions, and irradiation with light. Irradiation in the absence of oxygen caused only a reduction of Fe(III) into Fe(II) without a detectable decrease in D-fructose. This was because the amount of iron ion in a solution was quite small compared to that of D-fructose. Therefore, the reaction was concluded to involve a photochemically-induced oxidation with atmospheric oxygen by coupling with the oxidation-reduction cycle of iron ions (Scheme 1). Little difference was observed for reactions in the presence of different iron species at the beginning ($FeCl_3$ and $FeCl_2$). Also Fe(II) was shown to be oxidized to Fe(III) by atmospheric oxygen at an appreciable rate at neutral pH. These facts further support the mechanism shown above, and the results shown in Fig. 1(a) also confirm that the oxidation-reduction cycle of iron is operative and repeatable. The photochemical process of the reaction was the reduction of Fe(III) into Fe(II) with a concomitant oxidation of D-fructose to D-erythrose. The highest quantum yield of the process was observed at 300—350 nm, showing that the exitation of the ligand-to-metal charge transfer (LMCT) band of Fe(III) was the key step of the process.[19] The results are substantially the same as those of reactions in acidic media.[7]

It was noted in relation to the results shown in



Scheme 1.

Table 2 that the irradiation of a solution whose pH was below 6.8 resulted in the formation of a colloidal precipitate. In this pH range, Fe(III) was supposed to exist in part as $[Fe^{III}(OR^{-})_2]^{+}$ in the solution, and the relative instability of this species toward hydrolysis compared to that of $[Fe^{III}(OR^{-})_3]$ may have been responsible for the precipitate formation.

It was also shown that manganese ions underwent a photoreduction from Mn(III) to Mn(II) and a subsequent reoxidation to Mn(III) due to atmospheric oxygen in the presence of a large excess of D-fructose at a weakly basic pH without the formation of any precipitate. Mn(III) and other higher oxidation states of manganese ion were interpreted to be involved in biological electron-transfer reactions.[20] However, relatively few Mn(III) complexes are known to be stable and soluble in aqueous solutions due to their high affinity toward hydroxide ions.[21,22] D-Fructose showed a good sequestering ability toward Mn(III), and Mn(III) species were formed with an appreciable rate above pH 8 under an aerobic atmosphere and remained in solution. The action spectrum of the reduction of Mn(III) at 260—650 nm showed that light of shorter wavelengths was more effective though a small maximum was observed at a region corresponding to the d-d transition band of Mn(III) (Fig. 1(b)). As the LMCT band of the Mn(III) species has been reported to be at 200—220 nm with a large extinction coefficient,[14] the excitation of the LMCT band is suggested to be most effective for the reduction of Mn(III), being consistent with that of Fe(III).

Effect of PH on the Catalytic Action of $FeCl_3$. The photooxidation of D-fructose by Fe(III) in an acidic media shows a high selectivity and gives D-erythrose in a nearly 90% yield via the formation of a D-fructose–Fe(III) complex.[7] As the reoxidation of Fe(II) does not proceed at an appreciable rate in an acidic solution, the pH of a solution should be kept above 6 for the oxidation-reduction cycle of iron ions to operate. However, the selectivity of the reaction to yield D-erythrose markedly decreased at a higher pH (Table 2). Though the yield of D-erythrose still complised more than a half of D-fructose oxidized at pH 6.8, the formation of formic acid and other acid products predominated in a more basic pH range. Aldonic acids, formic acid, and other acid products along with carbon dioxide were the common oxidation products of aldoses and ketoses with oxygen in highly alkaline solutions or with hydrogen peroxide.[23,24] Hydroxyl radical is thought to be involved in these reactions. The autoxidation of cellulose in alkaline conditions is known to be more extensive in the presence of transition-metal cations, and the photoirradiation of a cellulose-transition metal system leads to the formation of radical species.[25,26] Therefore, a free-radical process might be involved in the formation of acid products rather than a direct electron transfer from D-fructose to the Fe(III) via a complex formation. And this process becomes more dominant at a higher pH.

Thus, a catalytic amount of transition-metal cations in neutral to weakly basic solutions is shown to cause the photochemically-induced degradation of D-fructose in the presence of atmospheric oxygen. Cox et al. have noted that the presence of Fe(II) in freshly opened ampoules of "Imferon" (the ferric-dextran preparation frequently used for the treatment of iron-defficient anemia) is responsible for the hypotensive side effect of this preparation and that an exposure to the atmosphere abolishes this side effect.[27] This observation may be understood from the results presented here, i.e., the reduction of Fe(III) during the storage and reoxidation of Fe(II) by atmospheric oxygen in the presence of dextran. Furthermore, the results might have a wide variety of biological and physiological importance,[28] since saccharides and transition-metal cations are widely distributed in nature.

The Asymmetric Ullmann Coupling Reaction of (*S*)-2,2′-Bis(1-bromo-2-naphthoyloxy)-1,1′-binaphthyl Revisited. Formation of 24-Membered Optically Pure Cyclic Dimer as Well as 12-Membered Cyclic Monomer

Sotaro MIYANO,* Shigeru HANDA, Masayuki TOBITA, and Harukichi HASHIMOTO

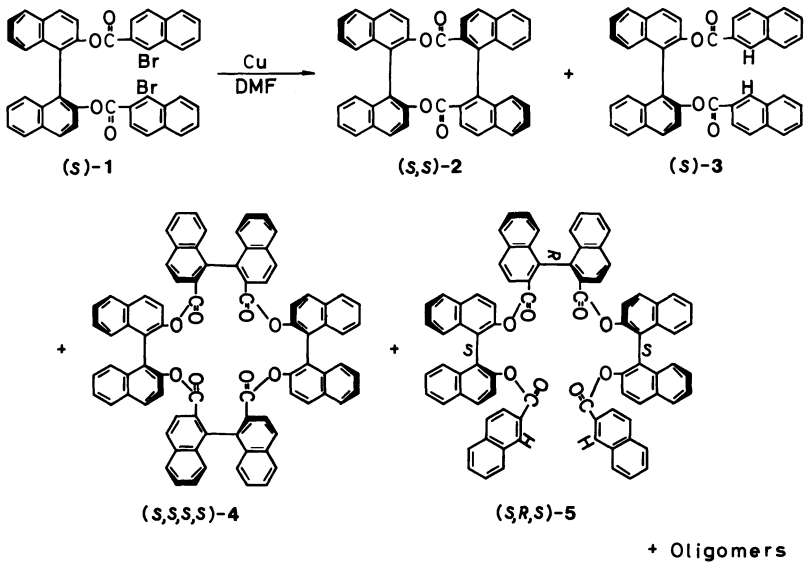
(Received August 28, 1985)

The copper-promoted Ullmann reaction of the title diester proceeded with high stereoselectivity to give 24-membered optically pure cyclic dimer of (*S,S,S,S*)-configuration as well as 12-membered monomeric cycle of (*S,S*)-configuration. The reaction also gave reduced, open-chain dimer enriched in (*S,R,S*)-diastereomer over (*S,S,S*)-counterpart (17% d.e.). Stereochemical course to the cyclic dimer was discussed considering the result that the intermolecular Ullmann coupling of chiral alcohol esters of 1-bromo-2-naphthoic acid poorly induced axial chirality in the joining of the two naphthyl units.

Recently, much attention has been centered on the asymmetric reaction by the use of axially chiral biaryls as the chirality-recognizing auxiliaries,[1] and thus there has been an increasing interest in the construction of the requisite atropisomeric biaryl skeleton via a route other than optical resolution of the racemate.[2]

In our previous papers,[3] we have reported that the Ullmann reaction of axially chiral 1,1′-binaphthyl-2,2′-diol diester (*S*)-**1** proceeds with complete diastereoselectivity to give intramolecularly coupled 12-membered monomeric cycle (*S,S*)-**2** in a 36% isolated yield without formation of (*S,R*)-diastereomer (Scheme 1). It was also implied that 24-membered cyclic dimer **4**, which was obtained only in a small amount from the reaction conducted under dilution conditions, was likely to have a rather high diastereomeric purity (87—100% d.e.) of (*S,S,S,S*)-configuration.[3b] Here we wish to report that the cyclic dimer is obtainable in a 10% yield as a precipitate from a benzene solution of an Ullmann reaction mixture in essentially optically pure state, and also wish to discuss the stereochemical course of the copper-promoted coupling reaction of (*S*)-**1** to the cyclic dimer.



Scheme 1.

Results and Discussion

Isolation of Optically Pure Cyclic Dimer (*S,S,S,S*)-4. In order to gain more information on the stereochemistry of the cyclic dimer, here again we repeated the copper-promoted Ullmann reaction of (*S*)-**1** under conditions intended to promote the intermolecular coupling; a mixture of (*S*)-**1** and an activated copper powder in a small volume of DMF was heated at gentle reflux with vigorous stirring. Debromination was completed within 5 h, and HPLC of the crude reaction mixture showed the presence of several components which had the

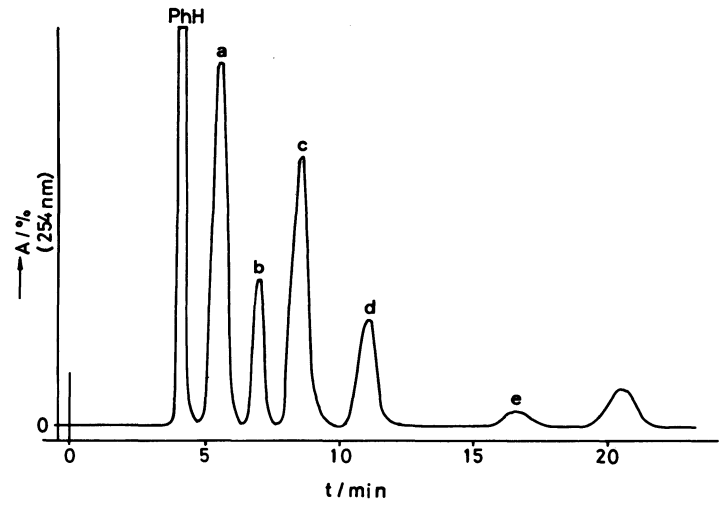


Fig. 1. HPLC of the Ullmann reaction mixture of (*S*)-**1**.
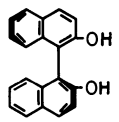
Conditions: microcolumn (0.5 mm (i.d.) × 10 cm) packed with JASCOSIL SC-01 eluted with 2% aq CH_3CN (8 μl/min). **a**, (*S,S*)-**2**; **b**, (*S*)-**3**; **c**, (*S,S,S,S*)-**4**; **d**, (*S,S,S*)- and (*S,R,S*)-**5**; **e**, tentative cyclic trimer(s).

retention volumes identical to those of, in the order of elution, (*S,S*)-**2**, (*S*)-**3**, cyclic dimer **4** obtained in the previous work,[3b] and open-chain dimer **5** (Fig. 1). The authentic sample of **5** was comprised of a 52:48 mixture of (*S,S,S*)- and (*S,R,S*)-**5**,[4] showing that these diastereomers were not differentiated on the HPLC conditions. The component eluting the 5 th on HPLC (**e** in Fig. 1) was tentatively assigned to cyclic trimer(s) (see Experimental).

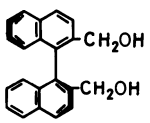
Attempted cryoscopy of the Ullmann reaction mixture in benzene was unsuccessful because of the deposition of a white precipitate on cooling a rather dilute solution. Unexpectedly but to our pleasure, we found that the precipitate showed only one peak on HPLC which had the same retention volume as that of the cyclic dimer **4**. Thus, the component of $[\alpha]_{436}^{24}$ −293±4° (PhH) was isolated in a 10% yield by standing a benzene solution of the reaction mixture at ambient temperature for 2 d followed by filtration of the precipitate deposited. The benzene filtrate was then subjected to silica-gel chromatographies to allow the isolation of (*S,S*)-**2** (12%), an extra amount of cyclic dimer **4** of $[\alpha]_{436}^{24}$ −296±3° (PhH) (1.2%), and open-chain dimer **5** (3.6%).

Discrepancies in optical rotations of the samples of **4** recovered above and the one obtained in the previous work by a column chromatography ($[\alpha]_{436}^{24}$ −291° (PhH)) should be regarded within the limits of the experimental error accompanying the measurement of them. These samples showed IR spectra superimposable on each other. From these results there seemed to be little chance that concentration of a particular stereoisomer among the possible cyclic dimers **4** had occurred during the isolation process.

Stereochemistry of the precipitated cyclic dimer **4** was unequivocally established to be optically pure (*S,S,S,S*)-**4** as follows: Treatment of the sample with lithium aluminium hydride (LAH) gave only two diols, (*S*)-1,1′-binaphthyl-2,2′-diol ((*S*)-**6**) and (*S*)-2,2′-bis(hydroxymethyl)-1,1′-binaphthyl ((*S*)-**7**). Optical



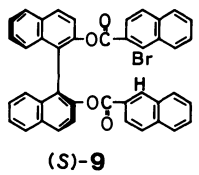
(*S*)-**6**



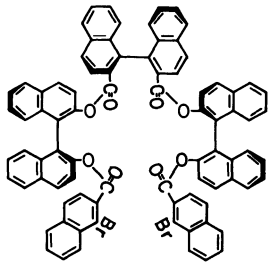
(*S*)-**7**

rotations of these diols compare well with those claimed for enantiomerically pure specimens.[5] The homochirality of (*S*)-**7** was further confirmed by ^1H NMR study of the α-methoxy-α-(trifluoromethyl)-phenylacetic acid (MTPA) ester in the presence of Eu(fod)$_3$ shift reagent.

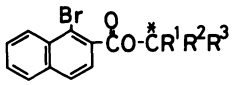
Stereochemical Course of the Ullmann Reaction of (*S*)-1 to (*S,S,S,S*)-4. Reaction path to cyclic dimer **4** inevitably requires initial bimolecular coupling of (*S*)-**1** to open-chain dibromo dimer **8**. It may be reasonable to assume that this kind of intermolecular coupling should afford a diastereomer mixture of (*S,S,S*)- and (*S,R,S*)-**8** (Eq. 1), the former being slightly in excess as a closely related coupling of (*S*)-**9** to **5** induced (*S*)-axial chirality only in a 4% diastereomeric excess (Eq. 2).[4] It was also reported that *C*-chiral alcohol esters (**10**) of 1-bromo-2-naphthoic acid poorly induced axial chirality in the Ullmann coupling of the two naphthyl units.[6]



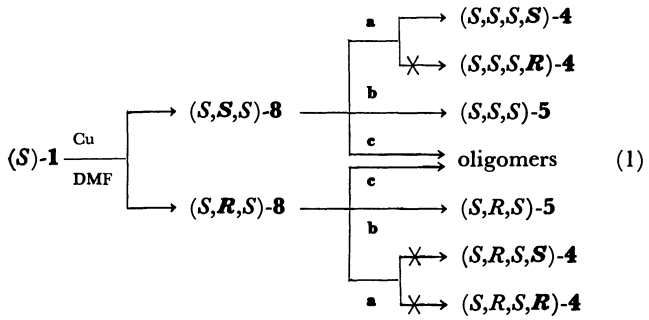
(S)-9



(S,S,S)-8

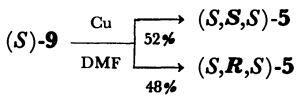


10



(1)

a: Intramolecular coupling, **b**: Reduction, **c**: Intermolecular reactions. (Bold italic letter indicates newly formed 1,1′-binaphthyl linkage in the said reaction.)



(2)

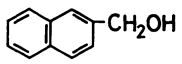
A rational conclusion deduced from the argument above is that intramolecular cyclization of **8** is allowed only for (*S,S,S*)-diastereomer to (*S,S,S,S*)-**4** without forming (*S,S,S,R*)-**4**, but not allowed for (*S,R,S*)-**8** which should give (*S,R,S,S*)- or (*S,R,S,R*)-**4** (Eq. 1). Although it is not easy to unequivocally explain the exclusive formation of (*S,S,S,S*)-**4**, inspection of the CPK molecular models of the intermediate dibromo dimers **8** and the possible cyclic dimers **4** gives some indication.

Conformationally identical 1,1′-binaphthyl axes in (*S,S,S*)-**8** seem to bring the two bromine substituents in a position to allow ring closure to cyclic dimer, while in (*S,R,S*)-**8** the coupling sites are disposed rather separated each other by intervening three 1,1′-binaphthyl moieties.

The models also show that (*S,S,S,S*)-**4** has the most symmetrical, and the least sterically crowded structure among the four possibilities; four sets of 1,1′-binaphthyl moieties are all staggered to each other as schematically illustrated in Fig. 2, which is a top view looking down along the axes of four 1,1′-binaphthyl linkages where the hatched naphthalene rings locate closer to the eyes.

On the other hand, naphthalene planes **a** and **b**, and **c** and **d** in (*S,S,S,R*)-**4** are respectively disposed face to face to each other in a close vicinity, thus imposing steric repulsion between the edges of the rings **c** and **e** (Fig. 3). Similar situation to this is valid for the (*S,R,S,S*)-counterpart. The (*S,R,S,R*)-disposition seems to be the least comfortable because every naphthalene ring faces to another causing four sets of collision among edges of the eight naphthalene rings (Fig. 4).

Stereochemistry of Open-chain Dimer 5. Treatment of the recovered **5** with LAH gave (*S*)-**6**, 2-naphthalenemethanol **11**, and **7**. On the basis of the



11

optical rotation of the diol **7**, the diastereomeric excess of the open-chain dimer **5** should be 17% enriched in (*S,R,S*)-**5** over (*S,S,S*)-diastereomer.[7] This stereochemical bias in **5** is qualitatively understandable as follows: Among the plausible reactions of the dibromo dimers **8** are intramolecular ring closure to cyclic dimers **4** and reduction to open-chain dimers **5**, as well as further intermolecular reactions to oligomeric products (Eq. 1). Assuming that the other conditions are equal, (*S,R,S*)-**8** should have more chance than (*S,S,S*)-**8** to be reduced to the open-chain dimer ((*S,R,S*)-**5**), because it lacks the exit to the corresponding cyclic dimer **4** as stated above.

In conclusion, we have shown here that 24-membered optically pure cyclic dimer (*S,S,S,S*)-**4** is

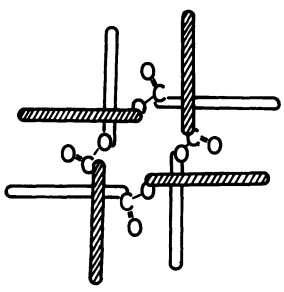


Fig. 2. (*S,S,S,S*)-4.

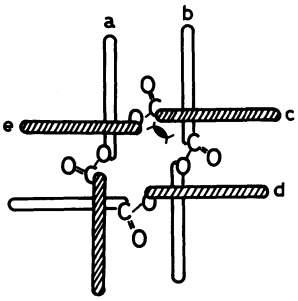

Fig. 3. (*S,S,S,R*)-**4**.

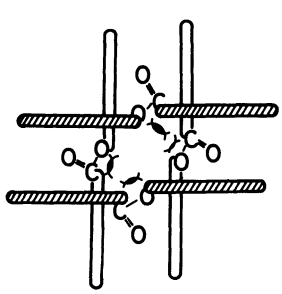

Fig. 4. (*S,R,S,R*)-**4**.

easily obtainable in a 10% yield as a precipitate from a benzene solution of an Ullmann reaction mixture of (*S*)-**1**. Recently, macrocyclic compounds with chiral cavity such as chiral crown ethers and cyclodextrins have been receiving considerable attention because of their high ability for chiral recognition of guest molecules.[8] CPK molecular models show that the 24-membered (*S,S,S,S*)-**4** confines a cavity just fit to accommodate a molecule of the size of benzene nucleus (Fig. 2), and investigation of the host-guest interaction involving the cycle is now under way.

Experimental

General directions are given in Ref. 3b. A JASCO FAMILIC-100 instrument was routinely utilized for the HPLC analyses of various binaphthyl derivatives encountered in this study using a 0.5 mm(i.d.)×10 cm microcolumn packed with JASCOSIL SC-01 (ODS) eluted with CH_3CN–H_2O.

(*S*)-**1** was prepared as before[3b] from (*S*)-**6** ($[\alpha]_D^{22}$ −34.8° (*c* 0.985, THF)) and 1-bromo-2-naphthoyl chloride; mp 178—179 °C (uncor.); $[\alpha]_D^{22}$ +34.3° (*c* 1.13, acetone).

Ullmann Reaction of (*S*)-1. To a mixture of (*S*)-**1** (3.00 g, 3.99 mmol) and activated copper powder (prepared from 3.0 g of Cu (47 mg-atom)) was added 20 ml of DMF. The mixture was magnetically stirred and heated to gentle reflux under nitrogen. After 5 h reaction, the mixture was worked up as before[3b] to give a pale yellow organic residue, 2.31 g (97.7% yield calculated as **2**), $[\alpha]_D^{24}$ −48.6° (*c* 0.803, PhH).

Isolation of (*S,S,S,S*)-4 by Precipitation: A 1.25 g sample of the Ullmann product was dissolved in 30 ml of hot benzene. The solution was allowed to stand for 2 d at ambient temperature to give a white precipitate. The material settled out was recovered by filtration, washed with small portions of benzene, and dried in vacuo (≈100 °C/10^{-1} mmHg) to give (*S,S,S,S*)-**4** as a white powder; 0.133 g (0.112 mmol); $[\alpha]_{436}^{24}$ −293±4° (*c* 0.152, PhH); IR (KBr) 1745 cm^{-1}. Found: C, 84.81; H, 4.43%. Calcd for $C_{84}H_{48}O_8$: C, 85.12; H, 4.08%.

The cyclic dimer (57 mg) was boiled with 0.1 g of LAH in 30 ml of ether for 5 h. After usual work-up, products were separated by preparative TLC (silica gel, $CHCl_3$/AcOEt(4/1)).

(*S*)-**6**: 21 mg; $[\alpha]_D^{24}$ −34.3° (*c* 1.14, THF).

(*S*)-**7**: 25 mg; $[\alpha]_{546}^{24}$ −83.2° (*c* 1.25, acetone). MTPA esters of (*S*)-**7** and racemic **7** were prepared by treatment with (*R*)-MTPA chloride. ^{1}H NMR studies of the esters in $CDCl_3$ in the presence of varying amounts of Eu(fod)$_3$ indicated that the (*S*)-**7** should be more than 98% e.e.[3b]

Stereochemistry of (*S,R,S*)-5: The benzene filtrate, which had been removed of the precipitate of (*S,S,S,S*)-**4**, was subjected to a silica-gel column chromatography ($CHCl_3$ (1% EtOH)) to give 0.157 g of (*S,S*)-**2**, $[\alpha]_D^{24}$ −452° (*c* 0.613, PhH) (lit,[3b] −457.6° (*c* 0.507, PhH)).

Column effluent fractions which were mostly comprised of cyclic dimer **4** and open-chain dimer **5** were further subjected to TLC separation (silica gel, $CHCl_3$ (1% EtOH)) to give (*S,S,S,S*)-**4** (15 mg, $[\alpha]_{436}^{24}$ −296±3° (*c* 0.147, PhH)) and (*S,R,S*)-**5** (46 mg). The latter was treated with LAH to give (*S*)-**6** (18 mg, $[\alpha]_D^{24}$ −34.2° (*c* 0.352, THF), (*S*)-**7** (11 mg, $[\alpha]_{546}^{24}$ +14.6° (*c* 0.518, acetone), and **11** (6 mg).

Similar preparative TLC of another fraction of the column effluent gave the component corresponding to **e** in Fig. 1, 14 mg, $[\alpha]_D^{24}$ +26.3° (*c* 0.909, PhH), which was tentatively assigned to cyclic trimer(s) on the basis of the HPLC elution pattern, a chemical transformation, and IR spectral studies: The cyclic structure was confirmed by the fact that LAH treatment of the sample gave only two spots on TLC (silica gel, $CHCl_3$/AcOEt(4/1)) which corresponded to (*RS*)-**6** (R_f 0.18) and (*RS*)-**7** (R_f 0.67), respectively. IR absorption (KBr disk) of the ester carbonyl function was precisely compared with those of cyclic monomer and dimer as follows, and it seemed that release of ring strain reduced the absorption frequency of the cyclic trimer(s).

(*S,S*)-**2**	1752.4 cm^{-1}
(*S,S,S,S*)-**4**	1744.7 cm^{-1}
Tentative cyclic trimer(s)	1742.9 cm^{-1}

We are grateful for support of this work by Takeda Science Foundation.

The Crystal and Molecular Structure of 12-Bromo[2.2][2.2]triple-Layered Paracyclophane

Yosuke KOIZUMI, Toshihiro TOYODA, Kunio MIKI,† Nobutami KASAI,†,* and Soichi MISUMI*
The Institute of Scientific and Industrial Research, Osaka University,
Ibaraki, Osaka 567
† Department of Applied Chemistry, Faculty of Engineering, Osaka University,
Suita, Osaka 565
(Received August 29, 1985)

The molecular structure of 12-bromo[2.2][2.2]paracyclophane has been determined by means of X-ray diffraction. The crystal is orthorhombic, space group *Pbcn*, a=12.768(1), b=11.515(1), c=13.074(1) Å, Z=4. The structure was solved by the heavy-atom method, and refined anisotropically by the block-diagonal least-squares procedure; R=0.062. The Br-C····C-H axis of the central benzene ring lies on a crystallographic two-fold axis. The outer benzene rings take a boat form, and the central benzene ring is twisted.

Among the molecular structures of multi-layered paracyclophane, only that of tetramethyl quadruple-layered paracyclophane has been reported, hitherto.[1] As to the structure of triple-layered ones, a preliminary result on isomers of tetramethyl triple-layered paracyclophanes has been presented, but the structure was reported disordered.[2] This paper deals with the first example of the molecular structure of a triple-layered one, 12-bromo[2.2][2.2]paracyclophane, determined by means of X-ray diffraction. A brief sketch of the structure has been described previously.[3]

Experimental

Crystal Data. $C_{26}H_{25}Br$, M=417.42, orthorhombic, space group *Pbcn*(No. 60, absent reflections, $0kl$: $k=2n+1$, $h0l$: $l=2n+1$, $hk0$: $h+k=2n+1$), a=12.768(1), b=11.515(1), c=13.074(1) Å, V=1922.1(2) Å^3, D_m=1.42 g cm^{-3}(by floatation in an aqueous solution of $ZnBr_2$), D_c=1.46 g cm^{-3} for Z=4.

Colorless octahedral crystal with approximate dimensions of 0.4×0.5×0.6 mm was mounted on a Rigaku automated, four-circle diffractometer. Zr-filtered Mo $K\alpha$ radiation(λ=0.71069 Å) was used.

Intensity data were collected by the θ—2θ scan technique at a 2θ rate of 2° min^{-1}. The scan range was from $\{2\theta(\alpha_1)-1.0\}$ to $\{2\theta(\alpha_2)+1.0\}$°. Backgrounds were counted for 15 s at both ends of a scan. Three standard reflections measured after every 50 reflections to monitor the stability and orientation of the crystal showed no significant decay throughout the data collection. A total of 1762 reflections was observed out of 2520(sin θ/λ<0.7). Usual Lorentz and polarization corrections were made but absorption correction was ignored [μ(Mo)=23.5 cm^{-1}].

Structure Solution and Refinement

Since the space group is *Pbcn* and the unit cell contains four molecules, the molecule must lie on a special position, either two-fold axis or a center of symmetry. The structure was established by the heavy-atom method. The position of the bromine atom was found by the Patterson function. All the carbon atoms could be located on a Fourier map computed by using approximate phases based on the bromine atom. The structure was refined anisotropically by the block-diagonal least-squares procedure (*HBLS* V).[4] The function minimized was $\sum(\Delta F)^2$. Hydrogen atoms were located on a difference Fourier map, which were included in the refinement with isotropic temperature factors. The R value converged to 0.062. Final atomic parameters are listed in Table 1.††

Atomic scattering factors were taken from International Tables for X-Ray Crystallography.[5] Computations were done mainly on a NEAC 2200—500 computer at the Computation Center, Osaka University, and at the final stage an ACOS 850 computer was used at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

Results and Discussion

The molecular structure(*ORTEP*)[7] is drawn in Fig. 1 with the numbering scheme of non-hydrogen atoms. Bond distances and bond angles are given in Fig. 2. The molecule has a two-fold axis symmetry. The Br, C(13), C(14), and H(14) atoms lie on a crystallographic two-fold axis. Three benzene rings are displaced slightly in a helical way from the eclipsed position (Fig. 3a). The C(5)–C(4) and C(12)–(13) bonds projected onto the least-squares plane of the central benzene ring make an angle of 4.1°, and similarly the C(12)–C(13) and C(4′)–C(3′) bonds form 6.4°.

The outer benzene ring has a boat form (Fig. 3b). The bending angle p_1, i.e. the dihedral angle between the plane defined by the C(4), C(5), C(7), and C(8) atoms (Plane 1) and that formed by the C(3), C(4), and C(8)(Plane 2) is 12.0°, and the p_2, the dihedral angle between the plane made by the C(5), C(6), and C(7) atoms (Plane 3) and the Plane 1 is 12.1°. These are approximately equal to the corresponding angles in [2.2]paracyclophane [12.6°][8] and its derivatives[9,10] and tetramethyl quadruple-layered paracyclophane [12.5 and 12.9°].[1] The C(2)–C(3) bond makes an angle q_1 of 11.0° with the Plane 2, and the C(6)–C(9) bond an angle q_2 of 11.7° with the Plane 3. These values are almost the same as those of the [2.2]paracyclophanes. Six C–C bond distances in the outer ring are equal and have normal values [av. 1.393 Å]. Among the bond angles, the C(4)-C(3)-C(8) and C(5)-C(6)-C(7) angles [117.3(5) and 117.0(5)°], which are the angles at the bow and stern of the boat form, are smaller than 120°, whereas the other four angles have normal values [120.4(5) to 121.0(5)°].

The central benzene ring is twisted. The dihedral angle between the plane defined by the C(11), C(12), C(13), and C(14) atoms and that by the C(11′), C(12′), C(13), and C(14) is 5.1°. Bond distances in this ring seem normal, however, inner angles at the C(11) [117.6(5)°] and C(12) atoms [115.3(6)°] are much smaller, whereas that at the C(13)[124.1(6)] is larger than 120°. The C(1)–C(12′) bond bends by 6.6° away from the plane defined by the C(11′), C(12′), and C(13) and the C(10)–C(11) bond by 4.7° away from the C(11)-C(12)-C(14) plane (Fig. 3(b_2)).

In the ethylene bridges, two C_{sp^3}–C_{sp^3} bonds are equal in length[1.578(8) and 1.582(8) Å], which are comparable to those in 4,7-dimethy[2.2]paracyclophane[1.587(12) Å],[9] 4,7,13,16-tetramethyl[2.2]paracyclophane[1.580(10) Å],[9] and tricarbonylchromium complex of [2.2]paracyclophane[1.595(4) Å].[10] Torsional angles around the C(1)–C(2) and C(9)–C(10) bonds are 12.5 and 17.6°, respectively.

Because of the deformation of the outer and central benzene rings closest nonbonded atomic distances between these rings are observed between the C(6) and C(11) atoms [2.744(7) Å] and between the C(3) and C(12′)[2.754(7) Å] (Fig 3(b_2)). The nonbonded

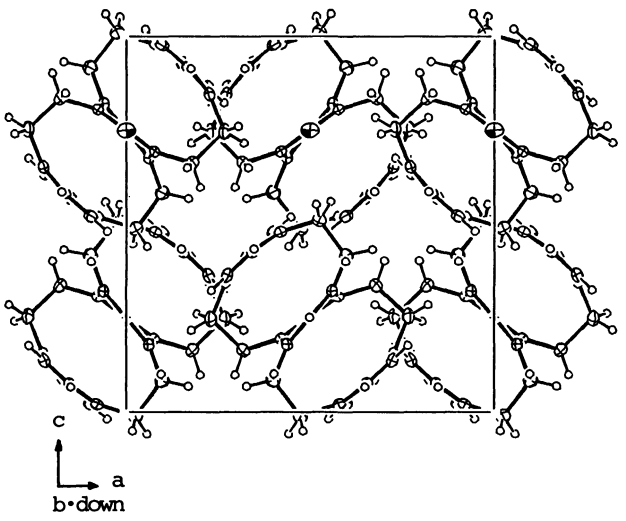

Fig. 4. Crystal structure projected along the b axis.[7]

distance between the Br and the pseudo-gem proton, H(4) is a large value, 3.26(6) Å, which is equal to or rather larger than the ordinary van der Waals contact. In other words, the Br substitution provides little effect on the geometry of the present hydrocarbon, triple-layered paracyclophane. Among the nonbonded Br···H distances the closest is 2.66(6) Å of Br···H(4).

Crystal Structure. The packing of molecules in the crystal is shown in Fig. 4. Molecules are packed rather loosely. The closest intermolecular contact is observed between C(4)(x, y, z) and C(10)(−0.5+x, 0.5−y, 1−z)[3.753(8) Å].

Effect of Pressure on the Pre-Steady-State Kinetics of the Hydrolysis of *p*-Nitrophenyl Pivalate Catalyzed by α-Chymotrypsin

Syoichi MAKIMOTO, Keizo SUZUKI, and Yoshihiro TANIGUCHI*
Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603
(Received July 10, 1985)

The pre-steady-state of the hydrolysis of *p*-nitrophenyl pivalate (pNPT) catalyzed by α-chymotrypsin (α-CHT) in Tris buffer solutions was measured up to 2.4 k bar at 25 °C. The reaction was initiated by substrate binding, and followed by acylation and deacylation processes. From the pressure dependence on the dissociation constants (K_s), the volume change ΔV_{K_s} was -14 ± 1 cm^3 mol^{-1}. From the pressure dependence on the rate constants (k_{acyl} and k_{deacyl}) of the acylation and deacylation processes, the activation volumes $\Delta V^{\neq}_{acyl}$ and $\Delta V^{\neq}_{deacyl}$ were -24 ± 1 and -2 ± 1 cm^3 mol^{-1}, respectively. The reaction mechanisms of α-CHT are discussed in terms of the reaction and activation volumes.

α-Chymotrypsin (α-CHT) is a well-known endoproteinase which hydrolyzes the peptide bonds at the C end of hydrophobic amino acid residues. It also catalyzes the cleavage of amides of individual amino acids and all other carboxylic acid derivatives, in addition to that of polymeric amides. A number of kinetic studies of this enzyme have been performed on the overall reaction rates (k_{cat}/K_M) or the steady-state kinetic parameters (k_{cat}, K_M).[1,2] However, the parameters by themselves are not sufficient to represent the microscopic rate or equilibrium constant for the elementary reactions of this enzyme. In order to obtain an insight into the mechanism of an α-CHT catalysis, the thermodynamic parameters[3] of individual reaction rate processes, as shown by Eq. 1, are necessary, especially through pre-steady-state kinetic measurements.

$$E + S \underset{K_s}{\rightleftharpoons} ES \xrightarrow{k_{acyl}} ES' + P_1 \xrightarrow{k_{deacyl}} E + P_2. \quad (1)$$

Here E, S, ES, ES′, P_1, and P_2 denote an enzyme, a substrate, an enzyme-substrate complex, an acyl-enzyme, a first leaving group, and a second leaving group, respectively, and K_s, k_{acyl}, and k_{deacyl} represent the dissociation constant of the ES complex, the acylation rate constant, and the deacylation rate constant, respectively.

Activation volumes or reaction volumes, evaluated from the pressure dependence of chemical reactions, are useful parameters for determining the differences in the reaction mechanisms.[4] From recent studies of trypsin,[5] carboxypeptidase A,[6] thermolysin,[7] and α-CHT[8] catalysis, it has been shown that these parameters also provide important information on enzyme reactions.[9]

Regarding the studies concerning the reaction mechanism of an enzyme under high pressure, the effects on pressure inactivation must be removed from the pressure effect on the reaction rate, as an enzyme protein becomes inactivated by a high-pressure treatment. Miyagawa and Suzuki[10] indicated that there is no loss of the activity of α-CHT in a pH 7.8 Tris buffer solution up to 3 kbar from measurements of enzyme activity after a pressure treatment. It has been clarified that α-CHT undergoes a reversible pressure inactivation from the rate of the hydrolysis of phenyl esters catalyzed by α-CHT up to 3 kbar.[8a] Therefore, it is necessary to check the true active enzyme concentration ($[E]_a$) directly under high pressure in order to study the reaction mechanism. These $[E]_a$ values can be stoichiometrically determined[11] by means of the pre-steady-state kinetics in the hydrolysis of *p*-nitrophenyl ester catalyzed by α-CHT.

In the present work, first the $[E]_a$ values at each pressure up to 2.4 kbar at 25 °C were determined from the measurements of the pre-steady-state in a hydrolysis reaction of *p*-nitrophenyl pivalate (pNPT) catalyzed by α-CHT. After the removal of the effect on the pressure inactivation of the enzyme, the reaction mechanism of α-CHT is discussed in terms of the volume change during substrate binding and the activation volumes of the acylation and deacylation processes.

Experimental

Materials. α-Chymotrypsin (α-CHT)(3× crystallized, Sigma Chemical Co.) was used without further purification. *p*-Nitrophenyl pivalate (pNPT) was recrystallized five times from hexane, mp 94.5—95.2 °C (lit,[12] 94—95 °C). The demineralized water was distilled. Acetonitrile was distilled over diphosphorus pentaoxide before use.

Apparatus and Procedure. The method for measuring the rate of hydrolysis reactions under high pressure has been described in a previous report.[13] The rate was measured at pH 7.8 in a 0.005 M† Tris-HCl buffer solution up to 2.4 kbar at 25±0.5 °C. The pressure dependence on the pH value was negligible, since the volume change of the dissociation process was -1 cm^3 mol^{-1}.[14] The rate of the hydrolysis of the pre-steady-state was determined by a change in the optical density (400 nm). This was attributable to the λ_{max} of the *p*-nitrophenolate ion formed as a product, monitored by means of a Hitachi 340 type

† 1 M=1 mol dm^{-3}.

spectrophotometer. It takes 45 seconds (on the average) for a compression up to a certain experimental pressure after mixing an ester and α-CHT solutions in a high-pressure cell.

Stock solutions of the enzyme (9.0×10^{-4} M) were prepared daily in a 0.01 M sodium acetate buffer. Each enzyme solution that was stored below 4 °C during use, was stable for at least 48 h.[11] Total substrate concentrations ($[S]_o$ were varied from 7.5×10^{-6} to 2.5×10^{-5} M, and the total enzyme concentration ($[E]_o$) was 4.5×10^{-6} M.

Results

The equilibrium and rate constants (K_s, K_M, k_{acyl}, and k_{deacyl}), determined by assuming a pre-steady-state, and $[E]_a$ values were analyzed by the following modified Bender's method.[11] Under the conditions of $[E]_o \ll [S]_o$, and $k_{acyl} \gg k_{deacyl}$ for a *p*-nitrophenyl ester substrate,[11] a typical plot of P_1 formation at each pressure as a function of time (t), obtained by spectrophotometry, is shown in Fig. 1. It can be represented by an equation of the form:

$$P_1 = At + B(1-e^{-Ct}) \tag{2}$$

$$A = \frac{k_{deacyl}[E]_a[S]_o}{[S]_o+K_M} + k_s([S_o]-[E_o]) \tag{3}$$

$$B = \frac{[E]_a[S]_o^2}{([S]_o+K_M)^2} \tag{4}$$

$$C = \frac{k_{acyl}[S]_o}{[S]_o+K_s} \tag{5}$$

$$K_M = K_s k_{deacyl}/k_{acyl}. \tag{6}$$

Here k_s denotes the rate constant of the spontaneous hydrolysis of the ester. The K_s and k_{acyl} are obtained by the least-squares method from Lineweaver-Burk plots (Eq. 7, Fig. 2) of the obtained C from the curvature of the initial "burst" of P_1 (Fig. 1).

$$\frac{1}{C} = \frac{K_s}{k_{acyl}}\cdot\frac{1}{[S]_o} + \frac{1}{k_{acyl}}. \tag{7}$$

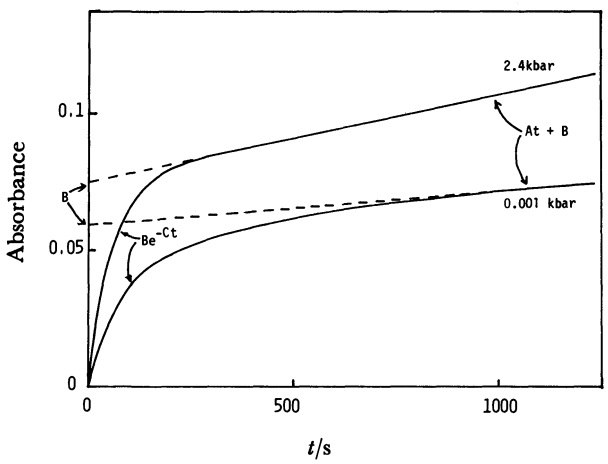

Fig. 1. The α-CHT-catalyzed hydrolysis of pNPT at 25 °C and two pressures, pH 7.8 (0.005 M Tris). Each ester concentration is 2.5×10^{-5} M.

K_M and k_{deacyl} are obtained by the same method (Eq. 8, Fig. 3) of the obtained A from a part of the straight line in Fig. 1.

$$\frac{1}{D} = \frac{1}{A-k_s([S]_o-[E]_o)} = \frac{K_M}{k_{deacyl}[E]_a}\cdot\frac{1}{[S]_o} + \frac{1}{k_{deacyl}[E]_a}. \tag{8}$$

On the other hand, B can be obtained from the intercept by extrapolating the above straight line (Fig. 1). As K_M values, being independent of $[E]_a$,

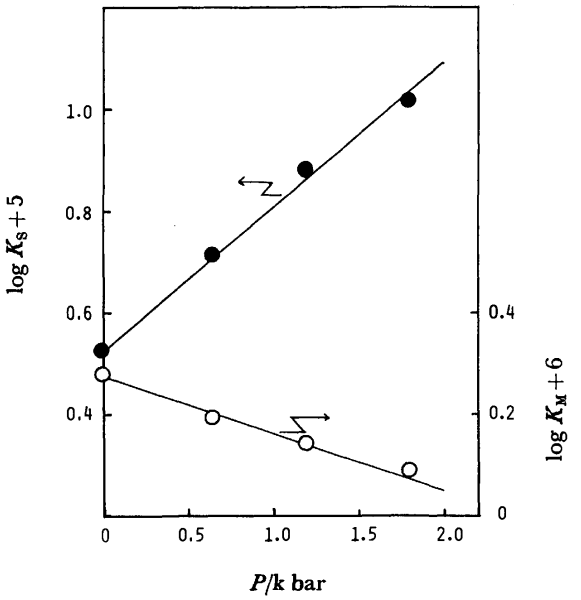

Fig. 4. Log K_S and log K_M vs. pressure at 25 °C.

(1.23×10^{-6} M—1.89×10^{-6} M) at each pressure are smaller than an $[S]_0$ value of 2.5×10^{-5} M. The B value corresponds to $[E]_a$ in Eq. 4. The values of $[E]_a$ and the enzyme purity (E_p) (calculated from the ratio of $[E]_a$ to the $[E]_0$ at each pressure) are summarized in Table 1. These values tell us that there is no loss in activity of α-CHT within ±5% by a compression of up to 2.4 kbar. The rate constants, corrected by the $[E]_a$ and the values of K_M and K_s at each pressure, are shown in Table 2.

From the linear relations of the logarithms of K_s, K_M, k_{acyl}, and k_{deacyl} vs. the pressure established for pNPT in Figs. 4 and 5, the volume changes (ΔV_{K_s} and ΔV_{K_M}) and the activation volumes ($\Delta V^{\ddagger}_{acyl}$ and $\Delta V^{\ddagger}_{deacyl}$) accompanying each process are summarized in Table 3.

Discussion

The established overall enzyme reaction of α-CHT with a tetrahedral intermediate (ET, ET′) in the acylation or deacylation step is given by Eq. 9.

$$E + S \underset{K_s}{\rightleftharpoons} ES \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} ET \xrightarrow{k_2} \underset{+\ P_1}{ES'} \overset{k_3}{\underset{k_{-3}}{\rightleftharpoons}} ET' \xrightarrow{k_4} E + P_2 \quad (9)$$

(k_{acyl} over the first arrow; k_{deacyl} over the second)

As the k_1 step is rate limiting in the acylation process of a p-nitrophenyl ester substrate,[15] the observed k_{acyl} is given by Eq. 10.

$$k_{acyl} = k_1. \quad (10)$$

While, in a deacylation step, the rate constant is given by Eq. 11,

$$k_{deacyl} = K_3 k_4, \quad (11)$$

where $K_3 = k_3/k_{-3}$.

Substrate Binding. The volume change accompanying the formation of a Michaelis complex ($-\Delta V_{K_s}$) is 14 cm^3 mol^{-1}. This value is discussed in

terms of the weak intermolecular interactions of noncovalent bonds (ΔV_{inter}) and of the conformational change of the enzyme itself (ΔV_{conf}) for the incorporation of pNPT in a binding site.

$$-\Delta V_{K_s} = \Delta V_{Inter} + \Delta V_{conf}. \quad (12)$$

The driving force of the incorporation of pNPT into the binding site is mainly the hydrophobic interaction between pNPT and α-CHT. The size of the binding site is approximately 1.0—1.2 nm×0.55—0.65 nm×0.33—0.45 nm determined by the X-ray study of Steiz et al.[16] The van der Waals radius of the pivaloyl group over 0.5 nm[17] is too large to incorporate it into a binding site of this enzyme at a depth of 0.33—0.45 nm. This pocket corresponds to the radius of the isopropyl group which removes the methyl group from the pivaloyl group. Therefore, we consider that a hydrophobic interaction between the binding site of α-CHT and the isopropyl group can be formed. The volume change accompanying the transfer of an isopropyl group from the water medium (the process of the formation of hydrophobic interaction) is 3.03 $cm^3\,mol^{-1}$. This was determined from the difference in the corresponding volume change (between 5.47 cm^3mol^{-1} for isobutyl alcohol and 2.44 $cm^3\,mol^{-1}$ for methyl alcohol). These were determined from the density data of an aqueous alcohol solution.[18]

Therefore, the value of ΔV_{conf} is 11 $cm^3\,mol^{-1}$, accompanying the incorporation of a nonspecific substrate like pNPT into α-CHT. On the other hand, in our previous paper[8b] it was reported that ΔV_{conf} is negligibly small during the incorporation of a specific substrate as *N*-Ac-L-Trp-amide (ATA). The difference in ΔV_{conf} between nearly zero for ATA and about 11 $cm^3\,mol^{-1}$ for pNPT obtained in this work may be considered to be the specific (ATA)-nonspecific (pNPT) substrate with a bulky pivaloyl group.

Acylation Process. Taniguchi and Suzuki[8a] reported that the $\Delta V^{\neq}_{acyl}$ for the hydrolysis of 2-valeryloxy- and 2-heptanoyloxy-benzoic acids catalyzed by α-CHT are −20 and −21 $cm^3\,mol^{-1}$, respectively. A $\Delta V^{\neq}_{acyl}$ of −24 $cm^3\,mol^{-1}$, found in our work, agrees with the above data. From Eq. 10, $\Delta V^{\neq}_{acyl}$ corresponds to the volume change for the process from ES to ET. The k_1 process is characterized by a large decrease in volume in contrast to a volume increase of 15 $cm^3\,mol^{-1}$ for the k_2 process[8b] in acylation. According to the single-proton-transfer (SPT) mechanism[19] (Fig. 6), the following four interactions may be mainly formed at the transition state in a k_1 process.

(1) The formation of a covalent bond between the oxygen atom of Ser-195 and the carbonyl carbon atom of the substrate, (2) the charge concentration at the carbonyl oxygen atom of the substrate and at the nitrogen atom of the imidazole ring of His-57, the formation of two hydrogen bonds (H-bonds) (3) between the oxygen atom of Ser-195 and nitrogen atom of imidazole ring of His-57, and (4) between the nitrogen atom of above ring and the oxygen atom of Asp-102, take place simultaneously. It is reported that the volume changes accompanying the formation of each interaction for model systems are −10 cm^3mol^{-1} for covalent bond,[20] −5 $cm^3\,mol^{-1}$ for H-bonding,[8b] and −5.5 $cm^3\,mol^{-1}$ for charge concentration,[8b] respectively. Accordingly, the large negative volume change of −24 $cm^3\,mol^{-1}$ is considered to correspond to the sum of the volume decreases for interactions (1)—(4).

Deacylation Process. The $\Delta V^{\neq}_{deacyl}$ (−2 $cm^3\,mol^{-1}$) is consistent with the data of Lockyer et al.[21] (−2 $cm^3\,mol^{-1}$). It is reported[21] that the values of $\Delta V^{\neq}_{deacyl}$ for other *p*-nitrophenyl esters are −6—−4 for acetate and −3 $cm^3\,mol^{-1}$ for isobutylate. From an average volume change of −4 $cm^3\,mol^{-1}$, the slightly negative volume decrease takes place in the deacylation process. From Eq. 11, the $\Delta V^{\neq}_{deacyl}$ is given by Eq. 13.

$$\Delta V^{\neq}_{deacyl} = \Delta V_{K_3} + \Delta V^{\neq}_{4}. \quad (13)$$

According to the SPT mechanism, we showed the initial state (ES′) of the deacylation process, ET′, and the expected transition state in Fig. 7. Interactions of (1)—(8) may be possible to form between ES′ and the transition state through the ET′. Because a volume change of −4 cm^3mol^{-1} is small, in spite of the

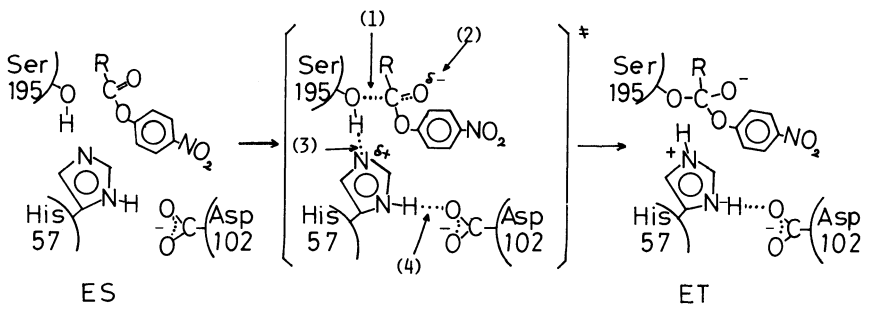

Fig. 6. Schematic drawing of the reaction mechanism of α-CHT on the process of ET formation.

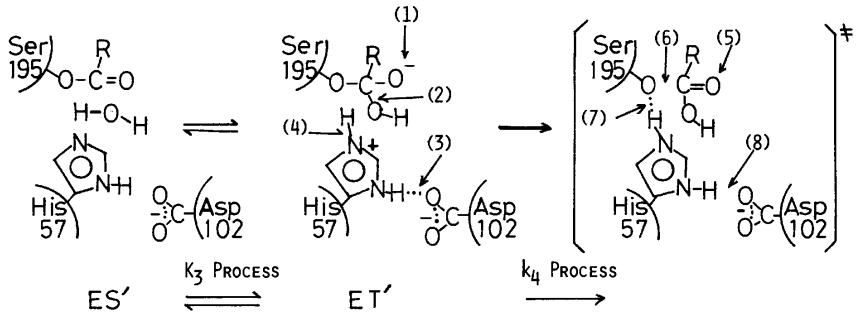

Fig. 7. Schematic drawing of the reaction mechanism of α-CHT on the process of deacylation.

formation of many interactions, the volume changes for some interactions are expected to cancell each other. Those interactions are considered to be (1)—(8) interactions, except (7) in Fig. 7, for the following reason.

At first, there was no contribution from the volume change during (1) hydration and (5) dehydration at the carbonyl oxygen atom for a reverse reaction, and (3) the formation and (8) the cleavage of one H-bond between the nitrogen atom of imidazole ring of His-57 and the oxygen atom of Asp-102. Also, similar volume changes may be expected to (2) [the formation of a covalent bond between the oxygen atom of H_2O and the carbonyl carbon atom of the substrate], and (6) [the cleavage of a covalent bond of ET′ for the formation/cleavage of C-O covalent bond]. The volume change for (4) [a proton transfer between the oxygen atom of H_2O and the nitrogen atom of imidazole of His-57, accompanying a cleavage/formation of a H-bond], may be cancelled out. Accordingly, the volume change for (7) [the formation of a H-bond between the oxygen atom of Ser-195 and nitrogen atom of imidazole ring of His-57] is considered to correspond to the experimental value of $-4\ cm^3\ mol^{-1}$.

The Regulation of Emulsion Polymerization with Fluorocarbon-Hydrocarbon Emulsifiers Mixture

Kazufumi KATO,* Kunio ESUMI, and Kenjiro MEGURO
Department of Applied Chemistry and Institute of Colloid and Interface Science,
Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received July 10, 1985)

The emulsion polymerization of styrene using a mixture of sodium dodecyl sulfate (SDS) and lithium fluorooctane sulfonate (LiFOS) has been studied. The polymerization rate decreased upon increasing the mole fraction of LiFOS, and was dependent on the solubilized amount of styrene in mixed surfactant solutions of SDS and LiFOS. The particle size increased upon increasing the mole fraction of LiFOS on the whole, and the molecular weight of the polymer formed in latices decreased upon increasing the mole fraction of LiFOS. Furthermore, the molecular-weight distribution of the latex polymer formed in mixed emulsifier solutions was considerably wider than that of the latex polymer formed in a single-emulsifier solution. It was confirmed from the above results that LiFOS had a repressive effect on the polymerization rate, and that it affected the number of particles and the molecular weight in the emulsion-polymerization process.

In the process of emulsion polymerization, the emulsifier plays an important role for the following two reasons: 1) It offers sites for polymerization, as does the micelle being acted upon for the solubilization of a monomer, and 2) It produces a stability of the synthetic latex, which has been influenced by the nature of the emulsifiers being used in the synthesis.[1-3] During emulsion polymerization, mixtures of emulsifiers have been generally used. However, a systematic study regarding the effect of emulsifier mixtures on emulsion polymerization was limited to nonion-nonion or nonion-anion hydrocarbon type surfactant systems.[4-6]

Recently, fluorocarbon surfactants have been given attention due to their peculiar natures: A low affinity for both water and oil and a good resistance against acidic, alkaline, oxidative, and reductive reagents. The surface tension of fluorocarbon surfactants is lower than that of hydrocarbon surfactants at an air-water interface, and fluorocarbon surfactants have higher surface activities.[7-11]

Suzuki et al. investigated the effect of the addition of a fluorocarbon surfactant on the micellization of hydrocarbon surfactants using the solubilization of the keto-enol tautomerism of *p*-benzoylacetanilide. They observed that the addition of a fluorocarbon surfactant was effective to expulse any materials solubilized in the micelles of a hydrocarbon surfactant by forming a mixed micelle.[12] This expulsive effect of a fluorocarbon surfactant would be interesting for the study of emulsion polymerization and, in particular the process of nucleation for a latex particle.

In this work, the emulsion polymerization of styrene in the presence of mixtures of fluorocarbon and hydrocarbon surfactants was studied by measuring the polymerization rates, particle sizes and molecular-weight distributions. The emulsifiers employed were sodium dodecyl sulfate (SDS) and lithium fluorooctanesulfonate (LiFOS).

Experimental

Materials. Potassium fluorooctane sulfonate ($C_8F_{17}SO_3K$) was repeatedly washed with water to remove water-soluble impurities, then dried at 80 °C. To prepare a lithium salt of fluorooctane sulfonate, fluorooctanesulfonic acid ($C_8F_{17}SO_3H$) was obtained by the distillation of the potassium salt in the presence of sulfuric acid (95%, guaranteed grade sample) at 180 °C, 10 mmHg. Then, it was neutralized by lithium hydroxide. Thus obtained lithium fluorooctane sulfonate ($C_8F_{17}SO_3Li$; LiFOS) was purified by repeated crystallization from dioxane after an extraction with ethanol. The purity of this sample was confirmed by an elemental analysis and by a surface tension measurement.

Sodium dodecyl sulfate (SDS) for biochemical use (Wako Pure Chemical Industries Ltd.) was purified by crystallization twice from ethanol, and was carefully dried in vacuo for 60 h before use. The purity of the sample was confirmed by the same method mentioned above.

Styrene was distilled twice under a dried nitrogen atmosphere, and was stored in a refrigerator under nitrogen before use.

For an initiator, potassium peroxodisulfate ($K_2S_2O_8$) was an analytical grade supplied by Wako Pure Chemical Industries Ltd.

Water was purified by a Milli-Q Water-Purification System.

Procedure. Each emulsion polymerization run was made using a batch process in a one-liter glass reactor fitted with a metal screw, thermometer and facilities for charging and sampling. A typical polymerization recipe is shown in Table 1. Emulsifiers (SDS and LiFOS) were mixed by two

Table 1. Emulsion Polymerization Recipe

Ingredients	Grams	Moles
Styrene	50	0.48
Water	250	13.9
Potassium peroxodisulfate	0.2	0.00755
Emulsifiers (SDS, LiFOS)	—	0.02

procedures. In the first procedure, while maintaining the same total moles of the emulsifiers, the mixed ratios of SDS and LiFOS were varied shown in Table 1.

In the second procedure, surfactant mixtures were prepared by adding various quantities of LiFOS to a definite quantity of SDS, whereas the total concentration of the mixed emulsifiers changed in each reaction system. Before the polymerization, water and emulsifiers were added to the reactor at room temperature, then a styrene monomer was added. After that, the reaction flask was immersed in a constant temperature bath which was adjusted to 60±1 °C under a nitrogen atmosphere. The mixture was stirred at 250 min^{-1}. After rising up the temperature to 60 °C, an initiator was added to the contents in the reactor.

The samples for determinations of conversion, particle size, and molecular-weight distribution were collected with pipettes at fixed intervals. The procedure for the determination of the conversion was as follows. To terminate the polymerization reaction, 5 cm^3 of a *p*-benzoquinone methanol solution (1.5 g dm^{-3}) as an inhibitor was added to 5 cm^3 samples in glass bottles. Then, the unreacted styrene monomer, methanol, and water were evaporated at 70 °C and the conversion percentages of styrene to polystyrene were estimated by measuring the dried samples on the assumption that the (monomer+polymer)/water was constant throughout the reaction.

In order to determine the particle sizes and the molecular-weight distributions after a reaction time of 90 min, the samples were rapidly cooled in cold water (0 °C). Particle sizes and size distributions were determined by transmission electron microscopy (TEM) and by submicron particle sizer (MARVERN AUTOSIZER MODEL-700). Measurements were carried out under the following conditions: The temperature was 25.0 °C, the refractive index was 1.33, and the viscosity was 0.8909cP.

The weight-average molecular-weights and the molecular weight distributions of each polystyrene latex sample were determined using gel permeation chromatography.

The solubilized amounts of ethylbenzene as a substitute for styrene in the mixed surfactant solutions were measured by means of a spectrophotometer at a wavelength of 262.6 nm at 25 °C.

Results and Discussion

Before the emulsion polymerization of styrene in the presence of SDS and LiFOS, it was necessary to confirm the stability of the emulsion particles being prepared with an aqueous mixture of LiFOS and SDS in the polymerization process. In order to evaluate the stability of the emulsion particles in each surfactant component, a percentage of coagulum was used which was estimated by the ratio of coagulum to the total amount of residue in a defined volume for each emulsion after a 90 min reaction time during the polymerization process. From the above experiments, only a few visible coagulums were observed and the coagulation ratios were below 1% for every mixed ratio of the emulsifiers. This result suggests that mixtures of SDS and LiFOS at every ratio were suitable for the stabilization of the emulsion polymerization of styrene.

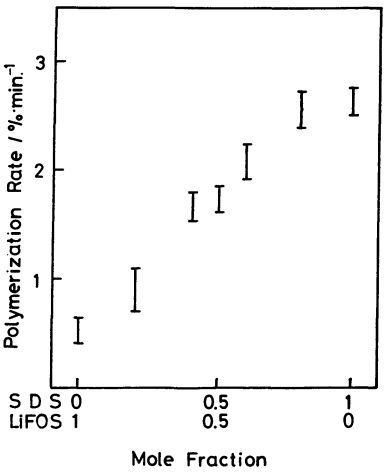

Fig. 1. The polymerization rate with mole fraction of emulsifiers; Lithium fluorooctane sulfonate (LiFOS) and sodium dodecyl sulfate (SDS), Temperature; 60 °C.

Polymerization Rate. In the first procedure, in the presence of mixtures of various mole fractions of SDS and LiFOS, the time-conversion curves in the emulsion polymerization of styrene were obtained. The polymerization rates (% min^{-1}) were calculated from the time-conversion curves in the initial period, and the results are shown in Fig. 1. The polymerization rate with SDS alone was 2.8% min^{-1} and that with LiFOS alone was 0.5% $min.^{-1}$ The polymerization rate decreased upon increasing the mole fraction of LiFOS. This result suggests that LiFOS has a depressive effect on the polymerization rates.

In the polymerization of styrene in the presence of a water-soluble initiator, the polymerization sites are considered to be in the water phase. However, a styrene monomer is only slightly soluble in water. Thus, the solubilization phenomenon of styrene in surfactant micelles became important for providing an initiation site for polymerization. Indeed, an emulsion polymerization using a styrene nearly occurred above the critical micelle concentration (cmc) in an aqueous surfactant solution.

The solubilizing power of the surfactant and the solubilized amount of monomer affect the polymerization rate in the emulsion polymerization, and it has been supported that the polymerization rate is proportional to the solubilizing power of various surfactant solutions.[13] In this work, it was assumed that the solubilized amount of ethylbenzene was similar to that of styrene in several aqueous solutions of SDS or LiFOS. The solubilized amounts of ethylbenzene were increased in proportion to the concentration of the aqueous surfactant solutions

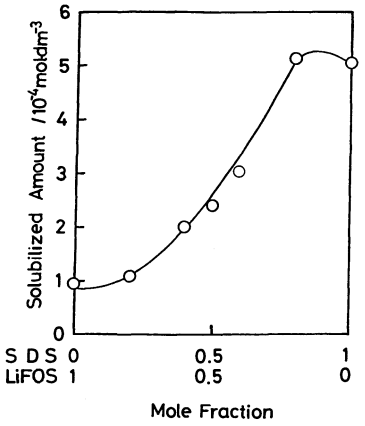

Fig. 2. Solubilized amount of ethylbenzene in mixed surfactant aqueous solution; 20 mmol dm^{-3}, Surfactants; SDS and LiFOS, Temperature; 25 °C.

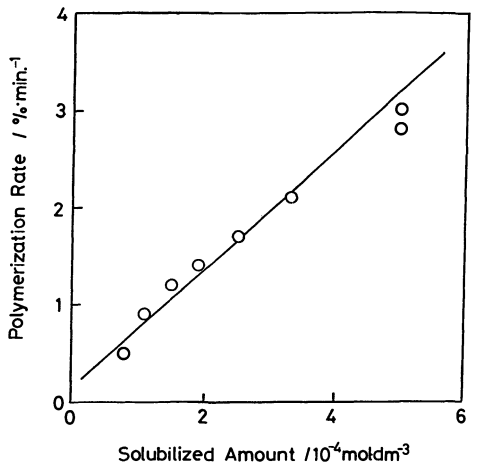

Fig. 3. Polymerization rate as a function of solubilized amount of ethylbenzene at various molar ratios of SDS and LiFOS.

above their cmc. Here, the cmc of an aqueous solution of SDS was 7.9 mmol dm^{-3} and that of an aqueous solution of LiFOS was 6.5 mmol dm^{-3}.

The solubilized amounts of ethylbenzene at total concentrations of 20 mmol dm^{-3} are shown in Fig. 2 as a function of the mole fraction. The solubilized amount in a SDS aqueous solution was about 52 mmol dm^{-3} and that in a LiFOS solution was 8 mmol dm^{-3}, whereas the solubilizing power of SDS was seven times as large as that of LiFOS. The solubilized amount of ethylbenzene decreased upon increasing the mole fraction of LiFOS, but had a maximum value at 0.8 of the mole fraction of LiFOS.

Figure 3 shows the relationship between the polymerization rates and the solubilized amounts at various mole fractions of SDS and LiFOS. As the polymerization rate is proportional to the solubilized amount, it is clear that the polymerization rate in the emulsion polymerization of styrene was influenced by the solubilized amount of styrene in the mixed-surfactant solution.

As a second procedure, an emulsion polymerization of styrene was carried out using mixed emulsifiers prepared by adding various quantities of LiFOS to a definite quantity of SDS. The obtained results are shown in Fig. 4. In this procedure, every condition in the emulsion polymerization pathway was the same as that in the first procedure except for the concentration of the emulsifiers.

These results indicate that by adding a small amount of LiFOS to SDS, the polymerization rate increases, however, a further addition of LiFOS causes the polymerization rate to decrease, compared with that for SDS alone. During the first stage, an acceleration of the polymerization rate by adding LiFOS can be correlated with an increase in the total amount of emulsifiers in the reaction system. On the other hand, a deacceleration of polymerization rate

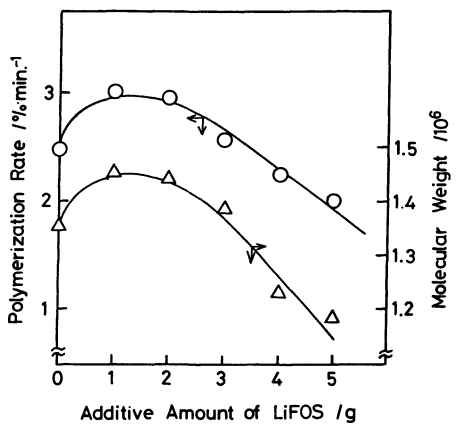

Fig. 4. The effect of additive amount of LiFOS to SDS (6.0 g) on polymerization rate and molecular weight.

occurred upon a further addition of LiFOS, in spite of an increase in the total amount of the emulsifiers. This result was almost similar to one shown in Fig. 2; the polymerization rate decreased upon increasing the mole fraction of LiFOS. This fact seems to be attributed to the expulsive effect, that added LiFOS expelles styrene radicals from the micelles in aqueous surfactants solutions, resulting in a depression of the polymerization rate.[12]

Particle Size and Particle Number Concentration. By electron micrography, the number-average particle diameter (D_n) and the polydispersity (D_w/D_n) were determined, respectively. By light scattering, the z-average particle diameter (D_z) and the polydispersity index (Pusey's Q factor) which gave an indication of the breadth of the size distribution, were determined.[14,15] These results are shown in Table 2.

The particle size of latex formed with various mixed ratios of SDS and LiFOS, which was

0.2	0.8	97.0	0.076	78.9	1.07
0	1.0	88.3	0.12	61.2	1.09

determined by both methods, has a relatively narrow distribution. From this result, the latices were determined to be exceedingly monodispersed spheres. The change in the latex particle size with the mole fraction of the emulsifiers is shown in Fig. 5.

There are many methods for measuring the particle size, and each determined average diameter provides a difference in size. The difference between the number-average diameter and the z-average diameter is caused by measurement method.[16] According to Wesslaw's experiment, the light scattering method has an upper limit in its application for a determination of the particle size; for instance, 400 nm to the size of polystyrene particles.[17]

It can be seen from Fig. 5 that all sizes are less than 400 nm. The z-average particle diameter vs. the mole fraction curve indicates, on the whole, that the particle size becomes large upon increasing the mole fraction of LiFOS. This is because the polymerization rates decrease upon increasing the mole fraction of LiFOS. Namely, when the polymerization rate is slow, the period during which the emulsion droplets and polymer particles coexist is prolonged. As a result, latex particle sizes continuously increase up to the depletion of droplets of the monomer.

Although the tendency described above regarding the z-average diameter was also observed for the number average diameters, it became much smaller. Especially, the higher the mole fraction of LiFOS was, the greater the gap between the number-average diameter and the z-average diameter became. This difference resulted from an apparent increase in the average diameter, determined by the light scattering which is capable of detecting the particle being coalesced in a suspended state.

There was a minimum value for both the average diameters at 8:2 of molar ratio of SDS and LiFOS. The z-average diameter was 56.9 nm and the number-average diameter was 61.0 nm at this mole fraction. At the same molar ratio of surfactant solutions of two emulsifiers, the solubilized amount and the polymerization rate were maximum. Thus, it was proven that the particle size increased if the mixed emulsifiers contained a small amount of LiFOS. At a high mole fraction of LiFOS, the average diameters of the latices became smaller since the polymerization rate was so slow that particle nucleation could not sufficiently progress.

The number of particles formed per cubic meter of the aqueous phase (N) was calculated from the z-average diameter or the number-average diameter, and the conversion rates. A diagram of the particle numbers plotted against the mixed emulsifiers is shown in Fig. 6. It was found that the number of particles calculated from the z-average diameter and the number-average diameter behaved similarly to each other upon a change in the mole fractions of the emulsifiers. Since latex particles are dispersed in a suspended state, the z-average diameter determined by

Table 3. The Change of Weight-average Molecular Weight (M_w) and Molecular Weight Distribution (M_w/M_n) with Mole Fraction of SDS and LiFOS

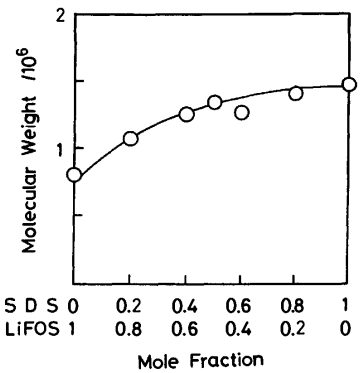

Fig. 7. The change of weight-average molecular weight with mole fraction of SDS and LiFOS.

light scattering should be used to determine the number of particles. From these results, it can be seen that the number of particles increases all over upon increasing the mole fraction of SDS. Also, it has a maximum at a molar ratio of 8:2 for SDS to LiFOS. These results can be explained by the same reasoning as mentioned above regarding particle size changes.

Molecular Weight and Its Distribution. The molecular weight of a formed latex polymer was measured after being dissolved in tetrahydrofuran by gel permeation chromatography (GPC). The same samples that were used for the particle-size measurement were used again. The weight-average molecular weights (M_w) and molecular weight distributions (M_w/M_n) of several polymer latices were calculated using Shimadzu Chromatopac C-R2AX.

Table 3 shows the weight-average molecular weights (M_w) and the molecular weight distributions (M_w/M_n), and Fig. 7 shows the change in the weight-average molecular weight with the mole fraction of mixed surfactant solutions of SDS and LiFOS. From M_w/M_n for the molecular weight distribution of the formed latices shown in Table 3, it was found that the breadth of the molecular weight distribution of the latices formed with mixed emulsifiers of SDS and LiFOS were rather broadened, compared with that of latices formed with single emulsifiers of SDS or LiFOS. These results demonstrate that the composition of emulsion and micelle in the mixed surfactant solution of SDS and LiFOS has a much wider distribution than that in a single emulsifier.

The change in the weight-average molecular weight of latex polymer against the mole fraction of a mixed surfactant solution of SDS and LiFOS is shown in Fig. 7. The molecular weight decreases upon increasing the mole fraction of LiFOS, in agreement with changes in the polymerization rate. As shown in Fig. 4, the molecular weight of the polymer latices formed with the mixed emulsifiers prepared by adding various quantities of LiFOS to a definite quantity of SDS, decreased upon adding LiFOS. The result agreed with the behavior of the polymerization rates. These results indicate that the addition of LiFOS to SDS in a mixed surfactant solution decreases the molecular weight of the latices. Accordingly, the addition of LiFOS has a repressive effect on the growth of the molecular weight of the latex polymer.

(Received July 12, 1985)

The molecular structures of the adduct of fluoreno[9,1-*bc*]pyrylium-3-olate with methyl cinnamate (**1**), $C_{25}H_{18}O_4$, and the dimerized product of fluoreno[9,1-*bc*]pyrylium-3-olate (**2**), $C_{30}H_{16}O_4$, have been determined by the X-ray diffraction method. In the adduct (**1**), the phenyl ring is situated above the fluorene ring with a dihedral angle of 64°. The product **2** has a dimeric structure with a head-to-head type *anti*-configuration, and a local two-fold symmetry. Both crystals belong to a triclinic system with a space group $P\bar{1}$. The cell constants for **1** are a=13.287(4), b=8.794(3), c=8.797(3) Å, α=109.78(3), β=82.17(3), γ=88.58(3)°, and those for **2** are a=10.401(2), b=12.425(3), c=8.564(2) Å, α=103.77(4), β=108.76(4), γ=95.06(4)°. The structure of **1** was refined to R=0.067 for 2141 reflections, and that of **2** to R=0.058 for 2301 reflections.

Pyrylium-3-olate(**5**), formed by an intramolecular carbene–carbonyl reaction of **4**, has a resonance contribution of carbonyl ylide. It has been known that **5** is an unstable and reactive species and that it undergoes a 1,3-dipolar cycloaddition reaction with acetylenic, olefinic and carbonyl compounds.[1-3] When **5** was reacted with methyl cinnamate, a 1:1 adduct(**1**) was obtained in a 66% yield.[2] The structure of **1** was assigned on the bases of an elementary analysis and NMR data.[3] $Cu(acac)_2$-catalysed decomposition of 1-diazoacetylfluorenone(**3**) in the absence of dipolarophile in absolute benzene at 80 °C yielded a crystalline compound(**2**) quantitatively (Scheme).[3] The elemental analysis and mass spectrum for **2** showed a dimeric structure. Among four possible configurations for the dimer(**2**), an NMR study rejected two *syn*-configurations. In order to confirm the structure of **1** as well as to determine either of the two *anti*-configurations, X-ray analyses of **1** and **2** were undertaken.

Results and Discussion

The molecular structures of **1** and **2** drawn by DCMS-3[4] are shown in Fig. 1. The selected bond lengths and angles are given in Table 1.[5] The present X-ray analyses have established the molecular structures of **1** and **2**. In contrast to the case of 2-benzothiopyrylium-4-olate, where it gave a head-to-tail type dimer with a *syn*-configuration,[6] fluoreno [9,1-*bc*]pyrylium-3-olate(**5**) gave a dimer (**2**) with a head-to-head type *anti*-configuration. Hence, the structural formula of **6** in Ref. 3 should be revised. The structure of **2** shows that the dimerization of **5** occurred through a bond formation between the equivalent atoms in **5**. As pyrylium-3-olate, with a carbonyl ylide resonance structure, behaves as 4π component in cycloaddition, a concerted thermal [π4s+π4s] process is not allowed for the facile dimerization of **5** according to the rule of the conservation of orbital symmetry.[7] We presume that the dimer was formed by a two-step mechanism. The transition state to *syn*-dimer, in which the carbonyl groups lie above each other, is unfavored over that of an *anti*-dimer in terms of the dipolar or electrostatic repulsion between the carbonyl groups. This electronic effect might result in the exclusive formation of an *anti*-dimer.

As seen from Fig. 1, molecule **2** has a local 2-fold symmetry. The lengths and angles of the equivalent bonds within a molecule are similar (Table 1). The six-membered ring, through which the 2-fold axis passes, has a chair form. The two six-membered rings comprizing C(7), C(8), C(9), C(14), C(15), and O(1) in **2** have envelope form; the former five atoms lie on a mean plane with an rms deviation of 0.05 Å and O(1) deviates from the plane by about 0.68 Å for each ring. The two fluorene rings of **2** are slightly bent; the dihedral angles between the two benzene rings in each fluorene ring are 16 and 15°, respectively. The proton signal exhibiting an up-field shift in the NMR spectrum of **2** might be that of the hydrogen atoms bonded to C(5A) and C(5B), which are located above the aromatic ring.

The structure of **1** shows features that are similar to those observed in **2**. The fluorene ring is bent to the same extent as in **2**; the dihedral angle between the two benzene rings is 13°. The dihedral angle between the fluorene and phenyl rings is 64°. The six-membered ring of C(7), C(8), C(9), C(14), C(15), and O(1) also takes an envelope form; the O(1) deviated by 0.79 Å from the mean plane through the former five atoms. The coupling constants of the

a) A and B represent halves of the **2** molecule. b) The value between the atoms related by the local two-fold axis within a molecule. c) Prime represents the atom of the other half within the molecule.

methine protons (J=1.7 Hz and J=6.9 Hz) seem to be consistent with ∠H-C(15)-C(16)-H=−99° and ∠H-C(16)-C(17)-H=146°, respectively.

Experimental

The formations and isolations of **1** and **2** have been reported.[3] ^{1}H NMR of **2** ($CDCl_3$) δ=4.42 (s, 2H), 6.32 (d, 2H), 6.8—8.0 (m, 12H).

Crystal Data. Adduct(**1**); $C_{25}H_{18}O_4$, M=382.4, triclinic, $P\bar{1}$, a=13.287(4), b=8.794(3), c=8.797(3) Å, α=109.78(3), β=82.17(3), γ=88.58(3)°, V=955.4 Å^3, Z=2, D_o=1.33 g/cm^3. D_c=1.33 g/cm^3. Dimer(**2**); $C_{30}H_{16}O_4$, M=440.5, triclinic, $P\bar{1}$, a=10.401(2), b=12.425(3), c=8.564(2) Å, α=103.77(4), β=108.76(4), γ=95.06(4)°, V=1001.4 Å^3, Z=2, D_o=1.46 g/cm^3, D_c=1.46 g/cm^3.

Crystallographic Measurements. The unit-cell constants and intensities of both crystals were measured with Ni-filterd Cu $K\alpha$ radiation on a Rigaku four-circle diffractometer. The intensities were measured with a θ-2θ scan technique up to 2θ=120° for **1** and 2θ=108° for **2**. The backgrounds for each reflection were measured for 5 s at both ends of the scan range. Reflections which were monitored every 100 reflections showed no significant variation in intensity during data collection. The intensities were corrected for the Lorentz and polarization factors.

Structure Determination of 1. The structure was solved by the vector-search method,[8] followed by a successive Fourier synthesis. Out of 2829 independent reflections, 2141 reflections whose intensities were greater than $3\sigma(I_o)$ were used for the refinement. The block-diagonal least-squares refinement[9] was made with anisotropic temperature factors for non-hydrogen atoms. The hydrogen atoms were located in the difference Fourier synthesis and included in a refinement with the isotropic temperature factors. Five of the strongest reflections were corrected for the extinction effect(g=3.7×10^{-6}). The weighting scheme used in the final cycle of the refinement was w=1.0 for $0<F_o\leqq 20$ and $w=[1.0+0.2(F_o-20)]^{-1}$ for $F_o>20$. The final R value was 0.067 for 2141 reflections. The final atomic parameters are given in Table 2.[5]

Structure Determination of 2. The solution and refinement of the structure of **2** was done in the same way as that of **1**. The weighting scheme used in the final cycle of the refinement was w=0.4 for F_o=0, w=1.0 for $0<F_o\leqq 7$, and $w=[1.0+0.36(F_o-7)]^{-1}$ for $F_o>7$. However, six of the

Photocatalytic Isomerization of Butenes over TiO_2. Photo-Formed Active Species and Characteristics of Reaction

Masakazu Anpo,* Masaaki Yabuta, Sukeya Kodama, and Yutaka Kubokawa
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591
(Received July 16, 1985)

It has been found that UV irradiation of powdered TiO_2 catalysts in the presence of butene molecules leads to both cis-trans and double bond shift isomerization reactions with high efficiency. In the photocatalytic isomerization the reactivity of 2-butene is much higher than that of 1-butene, being in contrast to the feature in the thermal isomerization. The addition of O_2 or NO molecules leads to the complete inhibition of photocatalytic isomerization of butenes. The effect of adsorbed water on the photocatalytic isomerization has been investigated. From these results together with the ESR measurements under UV irradiation of TiO_2 at 77 K in the presence of butene as well as O_2 or NO, the following conclusion emerges: The interaction of the photo-formed O^- species or $[Ti^{3+}\text{-}O^-]$ pairs results in opening of the C=C bond of butene, i.e. formation of a radical species, which acts as the intermediate in the photocatalytic isomerization. The O^- as well as surface OH^- species participates in the hydrogen shift, i.e. the double bond shift isomerization. Thus, the reaction mechanism which has been proposed for the photocatalytic isomerization of butene over ZnO has been confirmed over TiO_2.

Photocatalysis of powdered semiconductors has received much attention from the standpoint of photochemistry of solid surfaces as well as the possibility of utilization of solar energy. However, most studies have been mainly made with the reactions associated with the photodecomposition of water over metal loaded semiconductors.[1] In order to understand the true nature of the photocatalysis, it seems necessary to investigate the photocatalytic reactions other than the oxidation and reduction reactions. As an approach along this line, a number of workers have investigated the isomerization of alkenes over metal sulfides such as CdS[2] and ZnS[3] as well as metal oxides,[4] indicating that photocatalytic isomerization reactions proceed with higher efficiency than other photocatalytic reactions such as H_2 evolution reaction from water. In these systems only the cis-trans isomerization, i.e. geometrical isomerization proceeds.

As described previously,[5] we have found out that the double bond shift isomerization as well as geometrical isomerization of butenes is markedly enhanced over TiO_2 and ZnO under UV irradiation (band gap light). We have also proposed the mechanism for photocatalytic isomerization over ZnO catalyst on the basis of detection of reaction intermediate species by using ESR.[6] However, in the case of ZnO, the isomerization proceeds significantly in the dark even at 273 K, suggesting that separation of the photocatalytic isomerization seems to be very difficult. Accordingly, in the present work, with TiO_2 where the isomerization scarcely proceeds in the dark at room temperature, we have investigated the photocatalytic isomerization by ESR techniques as well as product analysis.

Experimental

Materials. The TiO_2 was obtained from Japan Aerosil Co. (P-25, Degussa, BET surface are: 40 m^2/g, average particle size: 0.029 μm, purity: >97%). Pure rutile type TiO_2 from Ishihara Industry Co. (BET surface area: 7.5 m^2/g, average particle size: 0.1—0.2 μm). The reactant gases (1-butene, *cis*-2-butene, and *trans*-2-butene) as well as NO gases were of extra pure grade from Takachiho Kagakukogyo Co. (purity of 1-butene: >99.1%, *cis*-2-butene: >98.9%, *trans*-2-butene: >99.8%, respectively). They were used without further purification. Commercial tank oxygen was purified by low-temperature distillation. Deionized double-distilled water was degassed by alternate freezing and thawing in vacuo. Deuterium dioxide of 99.9 mol% isotopical purity (E. Merk, Darmstadt) were used without further purification.

Apparatus and Procedure. Details of the apparatus and procedure were described in our previous papers.[5,6] The quartz cell having a volume of ca. 43 cm^3 was connected to a conventional vacuum system. Ultimate vacua of 1.33×10^{-3} Pa (1×10^{-5} Torr) were attainable. The sample of 0.3 g (P-25) or 0.6 g (rutile) was subjected to oxygen treatment at 833 K, followed by evacuation at the same temperature. The TiO_2 powder was spread on the quartz cell window, having a surface area of about 32 cm^2. The reactant butene was introduced onto the catalysts, its pressure being adjusted in the range of about 4.0 kPa (30 Torr). Then UV irradiation was carried out at 313 K using a Toshiba SHL-100UV Hg lamp with a color filter (Toshiba UV-D33S; $\lambda\cong260$—420 nm) and a water filter. Analysis of the reaction products was made by gas chromatography. Isotopic analysis of butenes was carried out with Hitachi RME-6E mass spectrometer using low-voltage electrons in just sufficient amount to produce an ion of the parent mass. ESR measurements were carried out at 77 K with a JSE-ME-1 (X-band) spectrometer. Mn^{2+} ions in MgO powders were used for *g*-values and sweep calibration. UV irradiation for ESR measurements was carried out by using a 500 W Hg lamp with a color filter (Toshiba UV-29; $\lambda\geq280$ nm).

Results and Discussion

1. Photocatalytic Isomerization of 2-Butenes over

TiO_2. As shown in Fig. 1, UV irradiation of TiO_2 in the presence of *trans*-2-butene leads to the formation of 1-butene as well as *cis*-2-butene. The yield of 1-butene increases with UV irradiation time, while that of *cis*-2-butene passes through a maximum and then slowly decreases. The rate of 1-butene formation (double bond shift isomerization) is much larger than that of *cis*-2-butene formation (geometrical isomerization). As shown in Fig. 2, similar results were obtained with *cis*-2-butene. As described previously,[5,6] no skeletal isomerization, i.e. formation of isobutene was detected. The amount of photo-formed products other than butene isomers was negligible, although small amounts of butenes were irreversibly adsorbed onto the catalysts.

The initial rates of the photoisomerization determined from the slopes of the plots of the amount reacted vs. reaction time are shown in Table 1, which includes the rates of the isomerization in the dark. It is clear that the isomerization in the dark is much slower than the photoisomerization. Furthermore, as shown in Fig. 1 after the UV irradiation ceased, no isomerization occurred. It is concluded, therefore, that the isomerization of 2-butene in the dark hardly takes place over TiO_2 at around 313 K, i. e., the observed photoisomerization of 2-butene is not associated with the thermal effect by UV irradiation. Thus, a much higher reactivity of 2-butene as compared with 1-butene shown in Table 1 has been established. Such features are completely different from those of the isomerization in the dark where 1-butene is more reactive than 2-butene.

2. Effect of the Addition of O_2 or NO Molecules upon the Photoisomerization. The addition of NO molecules leads to the complete inhibition of photoisomerization of *cis*-2-butene and *trans*-2-butene. Figure 3 shows the results for *trans*-2-butene. The inhibition was also observed in the dark isomerization of 1-butene. Lunsford et al.[7] have found that the addition of NO molecules leads to the inhibition of the dark isomerization of butene over Al_2O_3. Lunsford et al.[8] and Che et al.[9] showed that on the surface of Al_2O_3 and TiO_2 the paramagnetic NO molecules interact with exposed Al and Ti ions, respectively, by using ESR.

A similar inhibition of photoisomerization of *cis*-2-butene as well as of *trans*-2-butene was observed with the addition of oxygen. In this case the photooxidation reactions took place in place of photoisomerization. Details of the photooxidation of alkenes such as butenes have been reported elsewhere.[10]

3. ESR Measurements of the Catalysts. In connection with the inhibition of the photocatalytic isomerization caused by added O_2 or NO, ESR measurements have been carried out. The addition of O_2 onto the TiO_2 catalyst degassed at high temperature leads to the formation of O_2^- anion radicals having *g*-values, $g_1=g_{zz}=2.020$, $g_2=g_{yy}=2.0106$, and $g_3=g_{xx}=2.0046$, being in good agreement with those given in many literatures.[11] This species is very stable

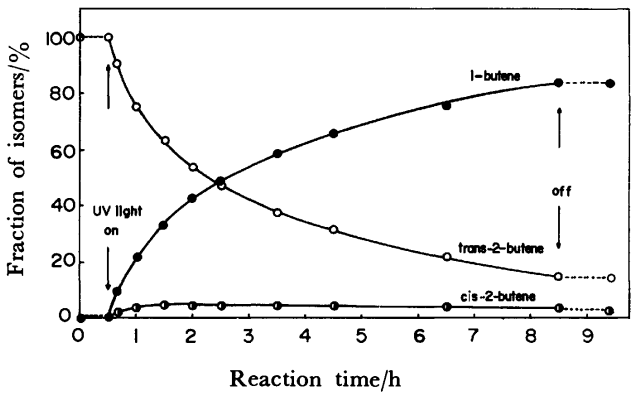

Fig. 1. Photocatalytic isomerization of *trans*-2-butene over TiO_2 catalyst at 313 K. Amount of used TiO_2 (P-25) is 0.3 g. Initial pressure of *trans*-2-butene is 4.0 kPa (30 Torr).

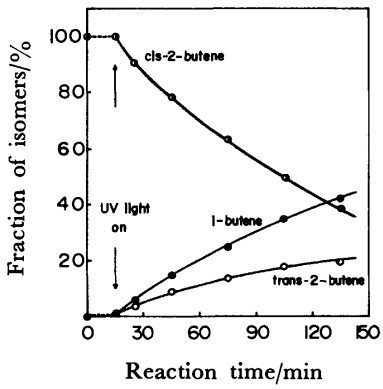

Fig. 2. Photocatalytic isomerization of *cis*-2-butene over TiO_2 catalyst at 313 K. Amount of used TiO_2 (P-25) is 0.3 g. Initial pressure of *cis*-2-butene is 4.0 kPa (30 Torr).

Table 1. Rates of Isomerization of Butenes over TiO_2 at 313 K

Catalyst	Condition	Temperature K	Initial rate/10^{-9} mol s^{-1}

even at higher temperature (up to around 373 K). Figure 4 shows the new ESR signal which appears by UV irradiation of TiO_2 at 77 K in the presence of O_2. This new signal is obtained as a differential spectrum by subtracting the spectrum of before UV irradiation from the spectrum of after UV irradiation at 77 K. This new ESR signal having g_1=2.0080 and g_2=2.0015 could be assigned to the O_3^- anion radicals, since the shape and paramagnetic parameters of the spectrum are in good agreement with those for the O_3^- anion radicals on TiO_2.[12] This suggests that the following reaction occurs on the TiO_2 under UV irradiation.

$$O^- + O_2 \rightarrow O_3^-,$$

where O^- is the photo-formed hole center. Details of the photo-formed O_3^- have been described in the previous papers.[10,13]

Figure 5 shows the ESR spectrum of the NO molecules adsorbed onto TiO_2 degassed at high temperature. As reported by a number of workers,[8-10] NO molecules adsorbed onto the solid surface shows the ESR spectrum due to partially quenching of the spin-orbit coupling. The ESR spectrum characterized by g_1=2.003 and g_2=1.920 is assigned to NO radicals coordinated with exposed Ti^{4+} ions on the surfaces.[9] This radical species can be easily removed from the surface by degassing the catalyst at around 300 K, being in agreement with previous works.[8,9,14] The high concentration of NO molecules on the surface results in the rather poorly resolved spectrum. On UV irradiation of the TiO_2 containing NO essentially no change was observed with the signal due to the radicals. Recently, Pichat et al.[15] have reported that NO molecules photodecompose over TiO_2 through the interaction with the O^- hole center as follows:

$$O^- + NO_{ad}^- \longrightarrow N_{ad} + O_{ad} + O^{2-}.$$

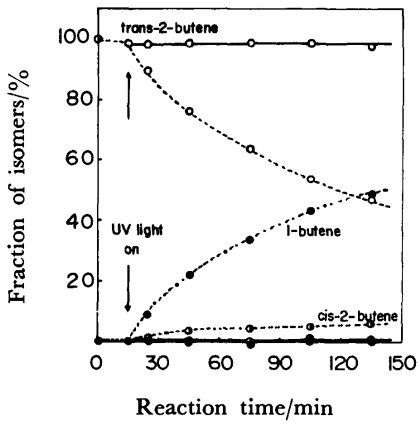

Fig. 3. Effect of the addition of NO molecules upon the photocatalytic isomerization of *trans*-2-butene over TiO_2 catalyst at 313 K. Amount of used TiO_2 (P-25) is 0.3 g. Pressures of *trans*-2-butene and NO molecule are 4.0 and 0.67 kPa, respectively. Solid lines: in the presence of NO molecules; dotted lines: in the absence of NO molecules.

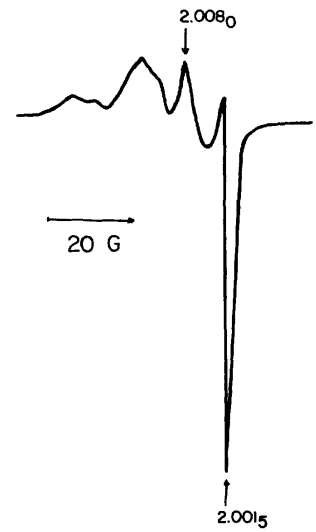

Fig. 4. ESR spectrum of photo-formed O_3^- anion radicals on TiO_2 catalyst at 77 K. Initial pressure of O_2 onto TiO_2 (rutile) is 0.33 kPa (2.5 Torr). UV irradiation was carried out at 77 K by using 500 W Hg lamp (λ>280 nm). Amount of photo-formed O_3^- anion radicals: 2×10^{-6} mol/g.

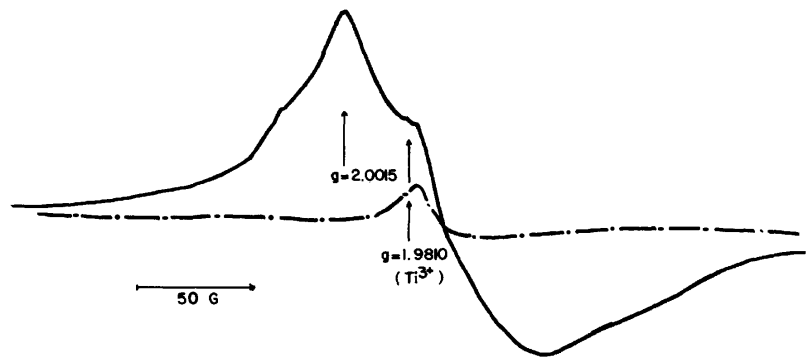

Fig. 5. ESR spectrum of adsorbed NO molecules on TiO_2 catalyst at 77 K. ESR spectra were recorded at 77 K. Amount of adsorbed NO: 2.1×10^{-5} mol/g.

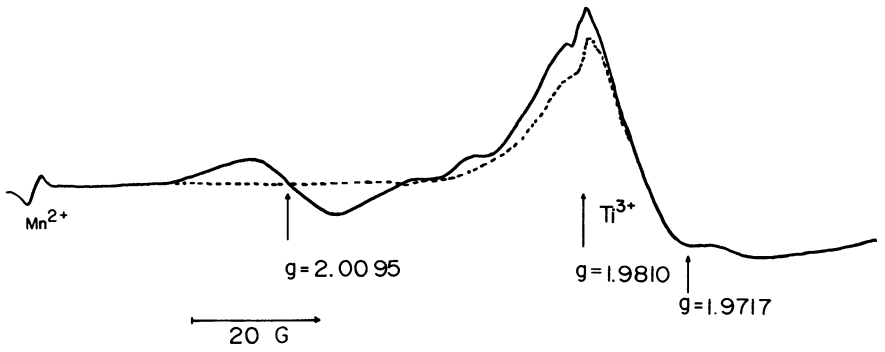

Fig. 6. ESR spectrum obtained before and after UV irradiation of TiO_2 catalyst at 77 K in the presence of adsorbed 1-butene. ESR spectra were recorded at 77 K. UV irradiation was carried out at 77 K for 30 min. Amount of adsorbed 1-butene: 1.1×10^{-5} mol/g. Dotted line: before UV irradiation; solid line: under UV irradiation.

Furthermore, as described in the previous paper,[6] the interaction of NO with photo-formed O^- species has been established. From the above considerations the following conclusions emerge: UV irradiation of TiO_2 results in formation of O^- or $[Ti^{3+}-O^-]$ pairs, although the O^- species is not detected directly by ESR, probably because of its short lifetime even at 77 K and/or incomplete removal of the degeneracy of the p-orbitals in this species, as suggested by Kazansky;[16] the O^- species thus formed interacts with NO or O_2 molecules in a manner similar with ZnO. Thus, the inhibition of the photocatalytic isomerization by added NO and O_2 is explicable.

The TiO_2 sample degassed at 833 K exhibited the ESR signal due to the Ti^{3+} ions and the O^- ions in the bulk at 77 K. The addition of butene molecules onto the catalyst at 300 K induced a slight increase in the signal due to the Ti^{3+} ions. This suggests that some fraction of Ti^{3+} ions interact with butene molecules. As shown in Fig. 6, the UV irradiation of TiO_2 in the presence of butenes at 77 K leads to the increase in the Ti^{3+} signal with UV irradiation time. Simultaneously, a broad signal with g=2.0095 appears. This signal is very unstable, and disappeared completely on raising the catalyst temperature to about 180 K. Although it is not possible to assign the species, the increase in the Ti^{3+} ion signal suggests that this unstable species might be formed through the reaction of butene with photo-formed O^- hole center. The occurrence of the photoreaction is in good agreement with the results obtained by Volodin et al.[17] who investigated the photoreduction of TiO_2 in the temperature range or 90—400 K. As shown in the preceding paper,[6] formation of a radical species has been demonstrated clearly by ESR under UV irradiation of ZnO in the presence of 1-butene at 77 K. The poorly resolved ESR spectrum may arise from the high concentration of butene adsorbed on the surface at 77 K and/or mixing of several type of radical species.

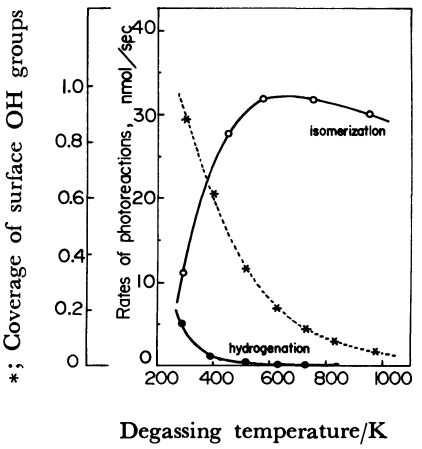

Fig. 7. Effect of the adsorbed H_2O upon the photocatalytic isomerization of *cis*-2-butene and the photocatalytic hydrogenation of $CH_3-C\equiv CH$ over TiO_2 catalyst at 313 K. H_2O vapor was adsorbed at 313 K until a pressure of 1.3 kPa (10 Torr) was reached, after which the degassing of the catalyst was carried out at each temperatures for 30 min. Initial pressure of *cis*-2-butene or $CH_3-C\equiv CH$ is 4.0 kPa (30 Torr). Coverage of H_2O was difined as ([amount of adsorbed H_2O]-[amount of desorbed H_2O])/[amount of adsorbed H_2O]. Amount of used TiO_2 (P-25): 0.3 g.

4. Effect of Remaining Water Adsorbed on the Photocatalytic Isomerization. The effect of the adsorbed water on the photocatalytic isomerization has been investigated in order to obtain further information on the active sites for the reaction. As shown in Fig. 7, the rates of photoisomerization reaction increases, passing through a maximum and then decreases. While, the increase in the degassing temperature results in the decrease in the yields of photohydrogenation of $CH_3-C\equiv CH$ (or *cis*-2-butene) where simultaneous activation of alkyne (or alkene) and H_2O is involved.[18]

When photo-formed O^- species plays a significant role in the photocatalytic isomerization, its rate is expected to increase with increasing the degassing

temperature, since the concentration of the presence of O^- species (i.e. O^{2-} ions) becomes larger. The presence of a maximum rate suggests that the surface OH^- groups is involved in the photocatalytic isomerization. From the results in Fig. 7, it is clear that on the surface of TiO_2 containing water (wet surfaces) UV irradiation leads to the photohydrogenation reactions, where simultaneous activation of alkyne (or alkene) and H_2O is involved, while on the surfaces of TiO_2 (dry surfaces) the double bond shift isomerization (1,3-hydrogen shift) occurs with high efficiency.

In order to obtain information on the role of surface OH^- groups in the photocatalytic isomerization reactions, the photoisomerization reactions of *cis*-2-butene have been undertaken over TiO_2 catalysts, which was subjected to pretreatment with D_2O followed by evacuation at 773 K. As shown in Fig. 8, deuterium substitution has no effect on the rates of double bond shift isomerization as well as cis-trans isomerization reactions. Table 2 shows the results of the distribution of D-atom in the photo-formed products and the reactant. It is clear that D-atom is incorporated into the photo-formed 1-butene, though its extent is not high. On the other hand, within the experimental error no D-atom incorporation is observed with *cis*- and *trans*-2-butene. Thus, participation of surface OH^- species in the photocatalytic isomerization is confirmed.

5. Mechanism for the Photocatalytic Isomerization of Butene. It has been reported by many workers that with TiO_2 catalysts degassed at higher temperatures (at around 900 K), the isomerization of butene proceeds via π-allyl carbanion intermediates.[19] In this mechanism the key step is abstraction of hydrogen from butene molecules, which is easier with 1-butene than with 2-butene. Such feature has been established as the characteristic of the dark isomerization. As described above, in the photocatalytic isomerization of butenes the reactivity of 2-butene is much higher than that of 1-butene, product distribution being completely different from that predicted from thermodynamic equilibrium. These clearly indicate not only that the photocatalytic isomerization reaction is kinetically controlled, as described in the previous paper,[6] but also that the active species associated with the photocatalytic isomerization is quite different from that in the dark isomerization reactions. The results of the ESR and inhibition studies described above clearly demonstrate that the interaction of photo-formed O^- species or $[Ti^{3+}-O^-]$ pair with butene molecules is involved in its photocatalytic isomerization.

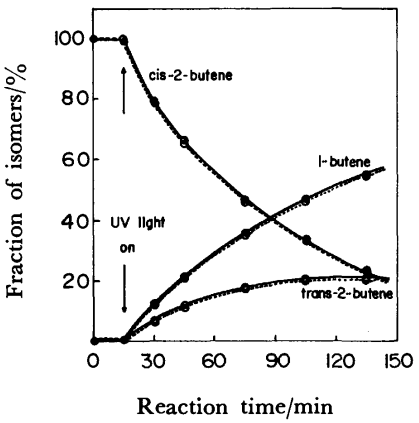

Fig. 8. Effect of the D_2O pretreatment of TiO_2 catalyst upon the photocatalytic isomerization of *cis*-2-butene over TiO_2 at 313 K. D_2O vapor was introduced onto the catalyst, kept for enough time, and then degassed at 453 K. This treatment was repeated several times. Solid lines: treated with H_2O; dotted lines: treated with D_2O. Amount of used TiO_2 (P-25): 0.3 g.

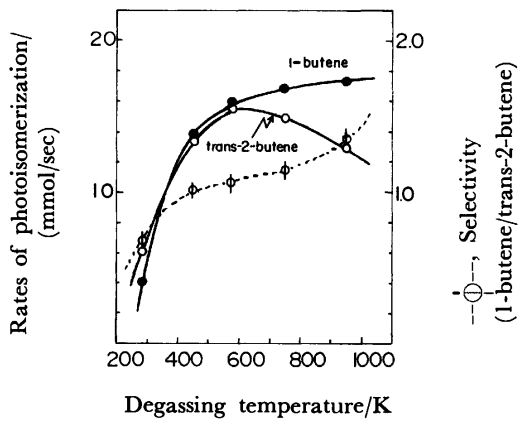

Fig. 9. Effect of the adsorbed H_2O upon the rate of photocatalytic isomerization and the selectivity of isomerization over TiO_2 at 313 K. Experimental condition is same to Fig. 7.

Table 2. Distribution of D-Atom in the Products Formed from the Photocatalytic Isomerization of *cis*-2-Butene over TiO_2 at 313 K

	Before photoreaction/%	After photoreaction/%		
	cis-2-butene	*cis*-2-butene	1-butene	*trans*-2-butene
$m/e^-=56$	96.11	92.46	84.94	93.12
$m/e^-=57$	3.89	7.54	15.06	6.88
Conversion of exchange (%)		3.65	11.17	2.99

D_2O vapor was adsorbed at 313 K until a pressure of 1.3 kPa (10 Torr) was reached, after which the evacuation was carried out at 453 K.

Recently, we have reported that the charge transfer excited states, complex, $[Mo^{5+}-O^-]^*$, of supported MoO_3 catalyst easily react with alkenes resulting in the fission of C=C bond of alkene molecule.[4b,20] It is likely, therefore, the closely existent electron and hole state, $[Ti^{3+}-O^-]$, of TiO_2 reacts with butene molecule to produce a corresponding radical species resulting from the opening of the C=C bond of butene in a manner similar to that with MoO_3 catalyst. As shown in Fig. 6, the ESR studies suggest that the photo-formed O^- species interacts with a butene molecule to form a radical species, though the spectrum is not well resolved due to high concentration of adsorbed butene.

Accordingly, it might be concluded that the photocatalytic isomerization of butene over TiO_2 proceeds according to a mechanism similar to that proposed for ZnO in the preceding paper:[6] Butene interacts with photo-formed O^- species to form a radical species. When this reverts to butene, the cis-trans isomerization will occur. The presence of H atom appears to be prerequisite for the occurrence of the double bond migration. Consequently, the more acidic the surface OH^- groups as well as the larger concentration of electron available for the neutralization of protons, the more efficient double bond migration results. As shown in Fig. 9, with increasing degassing temperature of TiO_2, the reactivity towards 1-butene formation monotonously increases. This suggests that supply of protons, i.e. the acidity of surface OH^- groups is not important in bringing about double bond migration. Accordingly, the increase in the selectivity towards 1-butene formation may be attributed to the increase in the concentration of electrons available for the neutralization of protons. Further study is necessary to clarify the nature of such an increase in the selectivity towards 1-butene formation.

Determination of the Equilibrium and Kinetic Parameters for the Surface-Redox Reaction of Hydroquinone Moiety of Adsorbed Adriamycin by Means of Numerical Simulation of d.c. Voltammogram

Tomonori KONSE, Kenji KANO, and Tanekazu KUBOTA*
Gifu Pharmaceutical University, 6-1 Mitahora-higashi 5-Chome, Gifu 502
(Received August 2, 1985)

Electrochemical equilibrium and kinetic parameters for a redox reaction caused by the hydroquinone moiety of adriamycin adsorbed on a pyrolytic graphite electrode have been determined by means of a numerical simulation of the quasi-reversible d.c. voltammograms using a theory regarding a two-step one-electron surface-redox reaction, since the electron-transfer rate constant is so small that the reversible d.c. wave can not be obtained and an analysis by a.c. voltammetry is difficult. The voltammogram was also analyzed from the viewpoint of a one-step two-electron surface-redox reaction mechanism taking into account the interaction parameters between adsorbed molecules. The analyses in terms of both mechanisms mentioned above reveal that the redox system considered here occurs through a two-step process.

The anthracycline antibiotics adriamycin and daunomycin are highly effective antitumore agents.[1] These drugs, including many new analogues and derivatives, have a dihydroxyanthraquinone structure, i.e. they contain two commonly electroactive sites: a reducible quinone moiety and an oxidizable hydroquinone moiety. The redox reaction of the quinone moiety of these drugs have been intensively investigated using various techniques, including electrochemical, in an attempt to correlate the behavior to the physiological activity of the drugs.[2-7] However, there are only a few articles concerning the redox reaction of the hydroquinone moiety. Baldwin et al.[4] have reported on a surface-redox wave of the hydroquinone moiety of adriamycin adsorbed on a carbon paste electrode. However, their analysis of the electrochemical behavior was only qualitative. One of the reasons may be related to the quasi-reversible character resulting from the small value of the electron-transfer rate constant. This character makes it difficult to estimate the equilibrium and kinetic parameters which would be obtained by an analysis of the reversible d.c. waves and a.c. voltammograms, respectively.[8,9]

In a previous paper[7] we presented a theory pertinent to the quasi-reversible d.c. voltammogram of a two-step surface-redox reaction ($O_{ad}+e \rightleftarrows S_{ad}$, $S_{ad}+e \rightleftarrows R_{ad}$), and derived a new method for determining the electrochemical equilibrium and kinetic parameters by means of a numerical simulation of d.c. voltammograms (i.e. non-linear least-squares curve fitting by the numerical calculation of current-potential curves). This new method was successfully applied to the analysis of the surface-redox reaction for the quinone moiety of adriamycin adsorbed on a basal-plane pyrolytic graphite electrode (BPGE). An excellent agreement between the equilibrium and kinetic parameters obtained from this technique and those obtained from reversible d.c. voltammograms and a.c. voltammograms indicates that the present method is very useful for determining the electrochemical parameters.

In principle, our d.c.-wave-simulation method can be employed even for surface-redox systems where the electron-transfer rate constants are so small that a direct analysis of the reversible d.c. and a.c. voltammograms is experimentally difficult. In this paper, our simulation method has been applied to the analysis of the surface-redox system of the hydroquinone moiety of adriamycin adsorbed on a BPGE. Furthermore, we have derived the theoretical equations regarding the quasi-reversible voltammetry of a one-step two-electron surface-redox mechanism ($O_{ad}+2e \rightleftarrows R_{ad}$), where the parameters describing the mutual interactions between adsorbed molecules have been taken into consideration. Then, the voltammogram was also analyzed based on the theory of a one-step mechanism. A comparison of the simulation results derived from both the mechanisms, i.e. two-step and one-step, suggests that the surface-redox system considered here obeys the above two-step mechanism.

Theoretical Treatment of Quasi-Reversible d.c. Voltammetry of Surface-Redox Reaction

At first, let us consider a one-step n-electron surface-redox reaction:

$$O_{ad} + ne \rightleftharpoons R_{ad}, \quad (1)$$

under the condition that all the electrochemical species are strongly adsorbed or immobilized on the electrode surface. Then,

$$\Gamma_o + \Gamma_r = \Gamma_t = \text{const.}, \quad (2)$$

where Γ_j's (j=o, r, and t) are the surface concentrations of O_{ad}, R_{ad}, and the total. In the following, our assumption is that the interaction between the adsorbed molecules can be expressed by using Frumkin's a-parameters (a_{ij}; i, j=O or R) and, thus, the surface activity of O_{ad} and R_{ad}, a_o and a_r, is given

by[15]

$$a_o = \Gamma_o \exp[-a_{OO} f\theta_t - a_{OR}(1-f)\theta_t] \quad (3)$$

$$a_r = \Gamma_r \exp[-a_{RR}(1-f)\theta_t - a_{RO} f\theta_t], \quad (4)$$

where $f=\Gamma_o/\Gamma_t$, and $\theta_t=\Gamma_t/\Gamma_m$, Γ_m being the maximum surface concentration. Theoretical studies regarding "reversible" d.c. voltammetry[8,11,12] and a.c. voltammetry[8] have been already reported for this type of redox system. Our formulation is, therefore, for "quasi-reversible" d.c. voltammetry.

Assuming that a surface-redox reaction occurs exclusively for adsorbed molecules and that the current-potential-surface activity characteristics can be given by the Butler-Volmer equation,[8,13] we can write:

$$i/nFA = d\Gamma_o/dt \quad (5)$$

$$= k_s a_r B_r^{-1} \exp[(1-\alpha)nF(E-E_o)/RT] - k_s a_o B_o^{-1} \exp[-\alpha nF(E-E_o)/RT], \quad (6)$$

where E_o stands for the standard redox potential of the redox couple O/R in the bulk solution, B_j (j=o,r) is the adsorption coefficient of species j at E_o, and k_s is the electron-transfer rate constant at the standard surface-redox potential, E_o'. The E_o'[8,11,12] and the electrode potential, E, are expressed by:

$$E_o' = E_o + (RT/nF) \times [\ln(B_r/B_o) - (a_{OO} - a_{RR} + a_{OR} - a_{RO})\theta_t/2] \quad (7)$$

$$E = E_i + vt. \quad (8)$$

Putting $\alpha=0.5$, a combination of Eqs. 2 to 8 leads to:

$$\psi = df_o/d\rho = m\{(1-f)\rho^{0.5} \exp(-G\theta_t/4) \exp(Jf\theta_t) - f\rho^{-0.5} \exp(G\theta_t/4) \exp[(J-G)f\theta_t]\}, \quad (9)$$

where $\psi = iRT/n^2F^2vA\Gamma_t$, $m=k_{sap}RT/nFv$, $k_{sap}=k_s \times (B_oB_r)^{-0.5}\exp[-(a_{RR}+a_{OR})\theta_t/2]$, $\rho=\exp[nF(E-E_o')/RT]$, $G=a_{OO}+a_{RR}-a_{OR}-a_{RO}$, and $J=a_{RR}-a_{RO}$. The current-potential characteristics for linear sweep voltammetry are, thus, obtained by solving Eq. 9. A standard fourth-order Runge-Kutta method was applied to resolve differential equation 9.[14] The initial conditions are $f=0$ at $\rho\to 0$ for the anodic curve and $f=1$ at $\rho\to\infty$ for the cathodic curve. To perform a numerical simulation of the d.c. voltammograms, a BASIC program was rewritten by modifying our program[7] to satisfy the above theoretical treatment. The parameters to be refined are generally k_{sap}, G (or $G\theta_t$), and J (or $J\theta_t$). When a reversible wave is obtained, the G value can be estimated from the peak current or the half-peak width of the "reversible" wave.[15] In such a case, the number of parameters will be diminished to two, k_{sap} and J.

On the other hand, in a previous paper[7] we have reported on a theoretical treatment of the quasi-reversible voltammetry for the two-step n-electron surface-redox reaction:

$$O_{ad} + ne \rightleftharpoons S_{ad} \quad \text{(1st step)}$$

$$S_{ad} + ne \rightleftharpoons R_{ad} \quad \text{(2nd step)}, \quad (10)$$

where a homogeneous interaction between the adsorbed molecules was assumed. The theoretical equations for this case are briefly given below for a comparison with those of the foregoing one-step mechanism. In this case, Eqs. 2, 5, and 6 must be rewritten as follows:

$$\Gamma_o + \Gamma_s + \Gamma_r = \Gamma_t = \text{const.}, \quad (11)$$

$$i = i(1) + i(2) \quad (12)$$

$$i(1)/nFA = d\Gamma_o/dt = k_{sap}(1)\{\Gamma_s \exp[(1-\alpha_1)nF(E-E_{o1}')/RT] - \Gamma_o \exp[-\alpha_1 nF(E-E_{o1}')/RT]\} \quad (13)$$

$$i(2)/nFA = -d\Gamma_r/dt = k_{sap}(2)\{\Gamma_r \exp[(1-\alpha_2)nF(E-E_{o2}')/RT - \Gamma_s \exp[-\alpha_2 nF(E-E_{o2}')/RT]\}, \quad (14)$$

where $i(j)$, $k_{sap}(j)$, and α_j are, respectively, the faradaic currents, the apparent rate constants at the formal standard surface-redox potentials E_{oj}', and the electron-transfer coefficients at the j-th steps (j=1 and 2). Here we define the semiquinone formation constant, K, as follows:

$$K = [S_{ad}]^2/[O_{ad}][R_{ad}] = \exp[nF(E_{o1}'-E_{o2}')/RT]. \quad (15)$$

The standard surface-redox potential, E_o', corresponding to the redox couples O_{ad}/R_{ad} is given by

$$E_o' = (E_{o1}'+E_{o2}')/2. \quad (16)$$

Equations 15 and 16 are introduced in Eqs. 13 and 14, and the resulting differential equations were numerically solved by combining them with Eqs. 8, 11, and 12. We can, thus, obtain the current-potential characteristics. In general, the parameters to be refined by a numerical simulation are $k_{sap}(1)$, $k_{sap}(2)$, K, α_1, and α_2. As we have already verified for the case of the surface-redox reaction of the quinone moiety of adsorbed adriamycin,[7] if the conditions $k_{sap}(1)=k_{sap}(2)$ and $\alpha_1=\alpha_2=0.5$ are experimentally satisfied, the parameters to be used are only two, $k_{sap}(=k_{sap}(1)=k_{sap}(2))$ and K. In addition, if the K values can be estimated from the reversible d.c. wave,[9] then only the k_{sap} needs to be refined.

Experimental

Adriamycin hydrochloride, which was donated from Kyowa Hakko Kogyo Co., and all other chemicals used

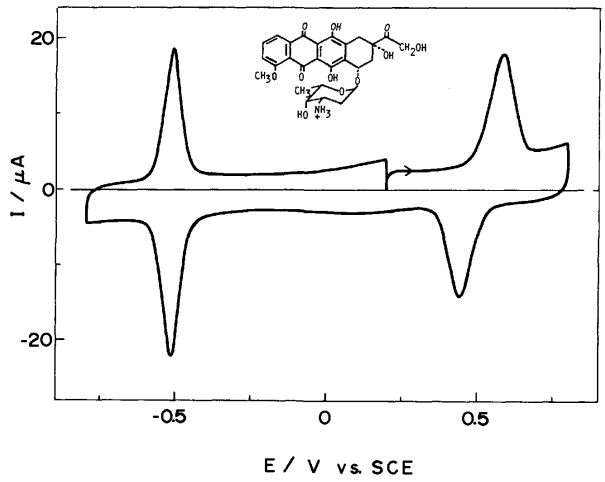

Fig. 1. Cyclic d.c. voltammograms of adriamycin adsorbed on a BPGE. Voltage scanning was done with $v=200$ mV s^{-1}. Before the measurement of cyclic voltammogram the 3.68×10^{-6} mol dm^{-3} adriamycin solution was first stirred for 1 min, then left for 1 min at $E_i=0.2$ V at 25 °C (pH=4.54, acetate buffer, $I=0.5$).

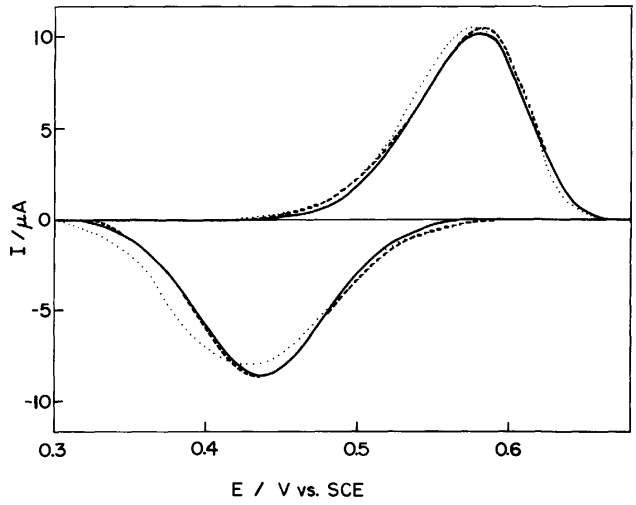

Fig. 2. Cyclic d.c. voltammograms of adriamycin adsorbed on a BPGE. Voltage scanning was done with $v=200$ mV s^{-1} under the same conditions as those in Fig. 1. The current is corrected for the base current. The broken line represents the regression curve calculated under the conditions of $k_{sap}(1)=9.49$ s^{-1}, $k_{sap}(2)=1.50$ s^{-1}, $K=0.06$, $\alpha_1=0.35$, and $\alpha_2=0.30$ for the case of the two-step mechanism. The dotted line shows the regression curve calculated under the conditions of $k_{sap}=0.187$ s^{-1}, $G\theta_t=-3.82$, and $J\theta_t=-1.20$ for the case of one-step mechanism. $E_o'=0.466$ V, $Q=4.845$ μC, and the "geometric" area of the electrode was 0.126 cm^2.

have been described elsewhere.[5-7] The electrochemical measurements and the preparation of BPGE (used as working electrodes) were, for the most part, performed as described in a previous paper.[7] The BPGE were freshly cleaved with a razor blade just before use. In the course of an analysis of the d.c. cyclic voltammograms, the base current was subtracted to determine the faradaic one. The calculation was carried out with an NEC 9801 personal computer. The computer-aided numerical simulations were done mostly performed, for the most part, as described in a previous paper.[7]

Results and Discussion

In Fig. 1 is shown a cyclic d.c. voltammogram of the adriamycin adsorbed on a BPGE in acetate buffer (pH 4.54). The voltammogram was recorded from the initial potential E_i=0.20 V to the switching potentials E_s's=0.80 and −0.80 V at a sweep rate $v=200$ mV s^{-1}, a saturated calomel electrode, SCE, being used as a reference electrode. One pair of the d.c. anodic and cathodic reversible waves at −0.50 V can be ascribed to the surface-redox reaction of the quinone moiety of adsorbed adriamycin.[3,5,6] Another pair of the quasi-reversible anodic and cathodic waves was observed at 0.60 and 0.45 V, respectively, and can be ascribed to a surface-redox reaction of the hydroquinone moiety of the substance.[4] The peak-separations of the anodic and cathodic waves on the two redox systems tell us that the electron-transfer rate constant of the hydroquinone moiety is considerably smaller than that of the quinone moiety. Actually, in a phase-selective a.c. voltammetry, the imaginary component pertinent to the redox system of the hydroquinone moiety was too small, even at the frequency as low as 100 Hz. Therefore, the analysis was difficult.

The solid line in Fig. 2 shows the d.c. voltammogram recorded from E_i=0.20 V to E_s=0.80 V at $v=200$ mV s^{-1} under the same conditions as those in Fig. 1. In Table 1 are listed the peak potentials ($E_{p,a}$, $E_{p,c}$), peak currents ($i_{p,a}$, $i_{p,c}$), half-peak widths ($\Delta E_{p/2,a}$, $\Delta E_{p/2,c}$), peak-separations ($\Delta E_p=E_{p,a}-E_{p,c}$), and $(E_{p,a}+E_{p,c})/2$ at various v, here subscripts a and c indicate anodic and cathodic waves, respectively. Upon decreasing v, ΔE_p became smaller. However, ΔE_p did not converge to zero, even at v=5 mV s^{-1}, i.e. a so-called d.c. reversible wave can not be recorded. On the other hand, the shape of the anodic wave is obviously not symmetrical with that of a cathodic one at a given v. Also, the $(E_{p,a}+E_{p,c})/2$ values shift to the cathodic side with an increasing v. These circumstances are very different from those for the quinone moiety. In the following analysis of the voltammograms, E_o' was estimated to be 0.496 V by extrapolating the v vs. $(E_{p,a}+E_{p,c})/2$ relation to v=0 within a sweep rate of 5 to 50 mV s^{-1}.

These cyclic voltammograms were then analyzed from the viewpoint of a two-step one-electron surface-redox mechanism while assuming a homogeneous interaction between the adsorbed mole-

a) The current values are normarized to $Q=4.845$ μC, assuming that i_p is proportional to Q in the narrow Q range. b) Calculated according to the theory of two-step one-electron mechanism under the conditions of $k_{sap}(1)=9.49$ s^{-1}, $k_{sap}(2)=1.50$ s^{-1}, $K=0.06$, $\alpha_1=0.35$, and $\alpha_2=0.30$ at $E_o'=0.496$ V and $Q=4.845$ μC. The values in the parentheses denote the calculated ones according to the theory of one-step two-electron mechanism under the conditions of $k_{sap}=0.187$ s^{-1}, $G\theta_t=-3.82$, and $J\theta_t=-1.20$.

cules.[7] A direct estimation of K from a reversible wave[9] is impossible in this case, and the unsymmetrical shape and the v dependence of $(E_{p,a}+E_{p,c})/2$ of the quasi-reversible waves indicate that $k_{sap}(1)\neq k_{sap}(2)$ and/or α_1, $\alpha_2\neq 0.5$.[7] For a numerical simulation of the voltammogram in Fig. 2, the following five parameters were used: $k_{sap}(1)$, $k_{sap}(2)$, K, α_1, and α_2. After repeated simulation trials, the parameters finally refined were: $k_{sap}(1)=9.49\pm1.06$ s^{-1}, $k_{sap}(2)=1.50\pm0.07$ s^{-1}, $K=0.060\pm0.009$, $\alpha_1=0.35\pm0.02$, and $\alpha_2=0.30\pm0.02$ at $Q=4.845$ μC.[16] The resultant regression curve is depicted in Fig. 2 as a broken curve. The fitting of the curves seems to be quite good. On the other hand, a numerical simulation with the three parameters, $k_{sap}(1)$, $k_{sap}(2)$, and K, was also undertaken while assuming $\alpha_1=\alpha_2=0.5$. However, the resulting regression curve did not reproduce very well the experimental one.[17]

In general, attention is necessary in a least-squares analysis based on a statistical treatment. This is in case that the parameters used are sufficiently large in number compared to those of observed points, and/or the collinearity among the parameters is large. In these cases there occurs some possibility that the refined parameter values themselves, thus derived, may be physically meaningless, though the regression curve, itself, results in a good reproduction of the observed one.[18] In order to check the validity of the parameters refined during this study, we calculated the values of $E_{p,a}$, $E_{p,c}$, $i_{p,a}$, $i_{p,c}$, $\Delta E_{p/2,a}$, $\Delta E_{p/2,c}$, ΔE_p, and $(E_{p,a}+E_{p,c})/2$ at various v by using the refined parameters described above, and compared them with the observed values. Table 1 gives the results. The calculated values and the observed values agreed well with each other.

In turn, Brown and Anson, and Kakutani et al. reported (independently) that the redox reactions of 9,10-phenanthrenequinone adsorbed on a pyrolytic graphite electrode[11] and of flavin-adenine dinucleotide adsorbed on a mercury electrode[19] can be reasonably explained by a one-step two-electron surface-redox system by taking account of heterogeneous interactions between the adsorbed molecules. Now, we would like to consider this reaction in terms of a one-step two-electron surface-redox system, since the K value (0.06) estimated above is very small. A numerical simulation was undertaken by using three parameters; k_{sap}, $G\theta_t$, and $J\theta_t$. A simulation of the voltammogram at $v=200$ mV s^{-1} (Fig. 2) resulted in $k_{sap}=0.187\pm0.02$ s^{-1}, $G\theta_t=-3.82\pm0.02$, and $J\theta_t=-1.20\pm0.15$: the regression curve is shown in Fig. 2 by a dotted curve. Also, the values of E_p, i_p, $\Delta E_{p/2}$, ΔE_p, and $(E_{pa}+E_{pc})/2$ were calculated numerically using the estimated parameters (listed in parentheses in Table 1). Although the fitting of the regression curve to the observed voltammogram is good at $v=200$ mV s^{-1}, the discrepancy between the observed and calculated values is obvious as can be seen in

Table 1. This is especially true for i_p and $\Delta E_{p/2}$ at a decreasing v. These results indicate that this redox system is not well described in terms of the one-step surface-redox reaction, even if the heterogeneous interactions between the adsorbed species are taken into account. As a result, it may be safely said that the redox reaction obeys the two-step mechanism; then, the above five parameters, refined on the basis of the two-step mechanism, can be considered to be physically significant.

It is interesting to compare the values of the equilibrium and kinetic parameters obtained for the hydroquinone moiety of the adsorbed adriamycin with those of the quinone moiety. First of all, the E'_o value of the hydroquinone part is more positive (by 1 V) than that of the quinone part (−0.498 V at pH 4.54[7]). The oxidation and the reduction of adriamycin occur at the hydroquinone and the quinone parts, respectively; thus, the hydroquinone part in the HOMO and the quinone part in the LUMO may play an important role in the oxidation and the reduction processes, respectively. Now, the difference in the above two E'_o values can be easily understood on the basis of the well-known energy-level order. In our case, however, deprotonation and protonation are coupled with the oxidation and the reduction of the hydroquinone and quinone moieties, respectively. This is because of a redox reaction in an aqueous medium. These circumstances would make it possible to reduce the difference in the two E'_o values in comparison with those expected from the HOMO and LUMO energy difference, which is correlated directly for the case of a nonaqueous medium.[20] Secondly, the semiquinone formation reaction ($O_{ad}+R_{ad}\rightarrow 2S_{ad}$) of the hydroquinone moiety in adriamycin is thermodynamically up-hill as in the case of the quinone moiety. The estimated K value (0.06) for the hydroquinone moiety corresponds to +7.0 kJ mol^{-1} in the free energy change of this reaction, $\Delta G°$, which is about 2 times as large as that of the quinone moiety (K=0.211[7]). This stability difference between the semiquinone species produced from the hydroquinone and the quinone parts might be attributable to an intramolecular hydrogen bond. In case of the semiquinone formation reaction of the quinone moiety, two hydrogen bonds formed between carbonyl groups and hydroxyl groups in adriamycin are kept in the electron transfer process. On the other hand, any one of the two hydrogen bonds should be removed due to a one-electron oxidation of the hydroquinone moiety. As a result, we can easily understand that the semiquinone species derived from the quinone part is more stable than that from the hydroquinone part. Finally, let us consider the rate constant values of $k_{sap}(1)$ and $k_{sap}(2)$. These $k_{sap}(1)$ and $k_{sap}(2)$ for the hydroquinone moiety are less than one-fiftieth and one-three hundredth of those of the quinone moiety ($k_{sap}(1)=k_{sap}(2)=5.16\times10^2$ s^{-1} at Q=4.845 μC[7,21]), respectively. The small value of k_{sap} for the hydroquinone moiety may also, in part, be ascribed to an intramolecular hydrogen-bond breakdown and/or formation in the process of a semiquinone formation equilibrium, as has been described above. This is because the activation barrier for proceeding to the semiquinone species seems to be higher for the hydroquinone moiety than for the quinone moiety, under the assumption that the barrier height is in parallel to the above-mentioned $\Delta G°$ values (chemical non-crossing rule[22]). Here note that $k_{sap}(1)$ is 6 times as large as $k_{sap}(2)$[23,24] and also α_1=0.35 and α_2=0.30 for the case of the hydroquinone moiety. This unsymmetrical nature was not observed for the hydroquinone moiety in the acetate buffer (pH 4.54) containing 9.1% *N,N*-dimethylformamide (v/v) as well as the quinone moiety in the acetate buffer.[5,7] In the former case, the analysis of the voltammograms indicates that $k_{sap}(1)=k_{sap}(2)=5.16\pm0.67$ s^{-1}, K=0.072±0.046, $\alpha_1=\alpha_2$=0.5, and E'_o=0.514 V at Q=2.301 μC. This kind of solvent effect on the kinetic parameters may also suggest the significance of inter- and intramolecular hydrogen bonds in the redox reaction. Additional work will be postponed to a future study.

We may now say, as a conclusion, that the present numerical simulation, based on a theory pertinent to the quasi-reversible d.c. voltammogram in terms of the two-step surface-redox mechanism, can be safely applied to estimate the electrochemical equilibrium and the kinetic parameters of the surface-redox system, of which the rate constants are so small that an observation of the d.c. reversible wave and the application of a.c. voltammetry are difficult. In addition, we believe that this technique can also be applied to surface-redox systems coupled with succeeding irreversible chemical reactions, such as redox reactions of the adsorbed adriamycin in neutral and alkaline media.[3,6] This is because the effect of the succeeding chemical reaction may be excluded by increasing the sweep rate,[6] then, the so-called quasi-reversible d.c. voltammograms are recorded.

We are grateful to Kyowa Hakko Kogyo Co. for kindly supplying the adriamycin. This work was supported in part by a Grant-in-Aid for Scientific Research (No. 59390012) from the Ministry of Education, Science and Culture.

23) Armstrong et al.[23] reported that the rate constant of the first step one-electron transfer would be smaller than that of the second step one-electron transfer for the oxidized flavodoxin. In connection with their report we may say that our analytical method of voltammograms gives clearly the electron-transfer rate constants of the first and second steps separately, though the application is limited to only the redox reaction of surface-attached species. Our method then seems to be very useful.

The Structure of Liquid *N*-Methylformamide by Means of X-Ray Diffraction and Ab Initio LCGO-MO-SCF Calculations

Hitoshi Ohtaki,* Sumiko Itoh, and Bernd M. Rode†
Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, 4259 Nagatsuta-cho, Midori-ku, Yokohama 227
† Institute of Inorganic and Analytical Chemistry, The University of Innsbruck, Innrain 52a, Innsbruck A-6020, Austria
(Received August 29, 1985)

The liquid structure of *N*-methylformamide (NMF) has been investigated by the X-ray diffraction method and the ab initio MO-SCF method. The structure parameters within a molecule were obtained as follows: C=O: 122(1) pm, C(methyl)-N: 145(2) pm, C(carbonyl)-N: 134(2) pm, N···O: 222(4) pm, C(methyl)···O: 278(6) pm. The intermolecular hydrogen-bonded N···O distance was estimated to be 298(11) pm. A linear and flexible chain structure was proposed for the liquid structure of NMF on the basis of scattered intensity data by the X-ray diffraction method and of interaction energies and geometries of hydrogen-bonded NMF molecules calculated by the ab initio MO calculations.

N-Methylformamide (NMF) is a methyl-substituted derivative of formamide (FA), and many physicochemical properties of NMF show intermediate values between those of formamide and *N,N*-dimethylformamide (DMF). Some properties of FA, NMF, and DMF are compared in Table 1. In spite of the increasing order of the molecular weight from FA to DMF, the boiling points, melting points and viscosities of the compounds decrease in the order FA>NMF>DMF. The trend indicates that intermolecular interaction energies may decrease in the same order. However, it must be noted that the relative dielectric constant of NMF is extremely large, 64% larger than that of FA, although the dipole moment of NMF is only 15% larger.

In previous papers we studied the liquid structures of FA[1] and DMF[2] by the X-ray diffraction method in combination with MO-SCF calculations for interaction energies between molecules and concluded that the former liquid has a relatively strong hydrogen-bonded structure through -CHO···H_2N- interactions, while the latter has an almost random structure due to weak intermolecular interactions.

In the present study we aim at determining the liquid structure of NMF in order to compare the structures of FA and DMF and to explain physicochemical properties of the amides on the basis of structural information of the liquids.

The structural investigation of NMF is also an interesting subject for biochemists, because the molecule has the -OC-NH- moiety which is found in peptides. Thus the definition of the cis- and trans-forms of an NMF molecule is given on the basis of the -CO-NH- bond in peptides (Fig. 1).

Infrared spectroscopic studies in the liquid phase[3,4] and in carbon tetrachloride solutions[5] revealed that the trans-isomer was predominant in the liquid and in the solution phase. The result agreed with that found in the gas phase by using infrared[6] and microwave[7] spectroscopies and the electron diffraction method.[8] NMR spectra obtained in the liquid phase[9] and measurements for the dipole moment of NMF in dioxane solutions[10] indicated that 90—92% of NMF molecules were present in the trans-form. Theoretical calculations[11] supported the more stable conformation of the trans-form than the cis-form of

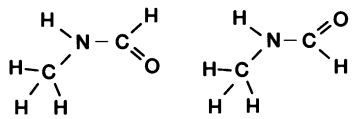
Bunger, Ed., Wiley-Interscience, New York (1970), except for the donor and acceptor numbers, which are quoted from "The Donor-Acceptor Approach to Molecular Interactions" V. Gutmann, Plenum Press, New York (1978). b) 1 cP = 10^{-3} N s m^{-2}.



trans cis

Fig. 1. *N*-Methylformamide: Definition of trans- and cis-forms.

NMF molecules. Therefore, it seems to be generally accepted that most NMF molecules exist in the trans-form in the gas and liquid phases. However, since no diffraction study has so far been examined for NMF in the condensed phase, we try to confirm the molecular conformation of NMF in the liquid state by using the X-ray diffraction method.

The energy for the hydrogen-bonds between NMF molecules was estimated by the ab initio LCGO-MO-SCF method in order to compare the strength of the intermolecular interactions in NMF with those in FA and DMF.

Experimental

Reagents. Commercially available NMF of analytical grade was dehydrated with molecular sieves and distilled in a dry nitrogen atmosphere under a reduced pressure.

X-Ray Scattering Measurements. X-Ray scattering measurements were carried out with a JEOL θ—θ diffractometer by using LiF monochromatized Mo $K\alpha$ radiation (λ=71.07 pm) at (25±2) °C. The range of the scattering angle (2θ) was from 4 to 127°. Times spent to accumulate 80000 counts were recorded over the whole angle range. The methods of data corrections and treatments were essentially the same as those described previously.[12,13] The scattering and correction factors were quoted from the literature.[14]

The reduced intensities $i(s)$ were obtained from the following equation:

$$i(s)_{obsd} = K \cdot I_{corr}(s) - \sum n_i[\{f_i(s)+\Delta f_i'\}^2+(\Delta f_i'')^2], \quad (1)$$

where n_i is the number of atom i in a stoichiometric volume V, and $f_i(s)$ denotes the atomic scattering factor at angle s. $\Delta f_i'$ and $\Delta f_i''$ are the real and imaginary parts of the anomalous dispersion of atom i, respectively. I_{corr} denotes the measured scattering intensity corrected for the back ground, absorption, polarization, multiple scattering and incoherent scattering. K is a factor for converting measured intensities to the absolute ones and was obtained by the high angle method and the Krogh-Moe-Norman method.[15,16] The radial distribution function $D(r)$ was then obtained by Eq. 2

$$D(r) = 4\pi r^2\rho_0 + 2r\pi^{-1}\int_{s_{min}}^{s_{max}} s \cdot i(s) \cdot M(s) \cdot \sin(sr)ds \quad (2)$$

where ρ_0 is the average electronic density of sample solution. s_{max} and s_{min} correspond to the maximum and minimum values of s for the Fourier transform, which are 15.7×10^{-2} and 0.6×10^{-2} pm^{-1}, respectively. $M(s)$ is a modification function and is given as follows:

$$M(s) = [\sum n_i\{(f_i(0)+\Delta f_i')^2+(\Delta f_i'')^2\}/ \sum n_i\{(f_i(s)+\Delta f_i')^2+(\Delta f_i'')^2\}] \cdot \exp(ks^2), \quad (3)$$

and the damping factor k is set to be 100 pm^2.

Theoretical reduced intensities were calculated according to Eq. 4:

$$i(s)_{calcd} = \sum n_j[\sum\sum n_{pq}\{(f_p(s)+\Delta f_p')(f_q(s)+\Delta f_q') + \Delta f_p''\Delta f_q''\} \cdot \sin(sr_{pq})/(sr_{pq}) \cdot \exp(-b_{pq}s^2)] - [4\pi R_j^3/(3V)] \cdot [3\{\sin(sR_j)-sR_j\cos(sR_j)\}/(sR_j)^3] \cdot \exp(-B_js^2) \cdot \{\sum n_i(f_i(s)+\Delta f_i') \cdot \sum n_j(f_j(s)+\Delta f_j') + \sum n_i\Delta f_i''\sum n_j\Delta f_j''\}, \quad (4)$$

where r_{pq}, b_{pq}, and n_{pq} stand for the distance, the temperature factor and the frequency factor of the p-q atom pair, respectively. R_j denotes the distance from an atom j beyond which a continuous electron distribution is assumed. A parameter B_j is introduced to avoid a sudden emergence of a continuous electron distribution at R_j. The program *KURVLR*[17] was employed for the intensity calculations. Structural parameters of each atom-pair in the system were determined by employing the least-squares method to measured intensities. The error-square sum $U=\sum w(s)\{i(s)_{obsd}-i(s)_{calcd}\}^2$ was minimized by using the program *NLPLSQ*[18], where the weighting function $w(s)$ is given to proportional to $\cos\theta/I(s)_{obsd}^2$.

Data Analysis

The procedure for determining the structural parameters of each atom-pair in the system was performed on the following assumptions:

(1) The initial structural parameters within an NMF molecule, which will be refined by the least-squares method, are assumed to be the same as those found in a DMF molecule; C=O: 122 pm, C(carbonyl)–N: 134 pm, C(methyl)–N: 145 pm. The temperature factors for these three bonds are first assumed to be 0.3×10^2 pm^2.

(2) The N–H and C(methyl)–H and C(carbonyl)–H bond distances are assumed to be 103, 109, and 109 pm, respectively, and these temperature factors are 0.1×10^2 pm^2.

(3) The methyl group has a tetrahedral form. Nonbonding interactions of H atoms are neglected except for the 3N···H and 3H···H interactions.

After corrections for spurious peaks, the experimental $s \cdot i(s)$ curve was compared with theoretical curves of the cis- and trans-isomers of NMF by using the first term of Eq. 4. The theoretical curve calculated for the trans-form showed a better agreement than that obtained from the cis-form (see Fig. 2). Intermolecular interactions were then taken into account for the least-squares fitting of the experimental data to the theoretical ones. Each molecule was assumed to link with other molecules through the –NH···OCH– hydrogen-bond. The

least-squares refinement of the data was performed for the trans- and cis-conformations of NMF molecules. In the course of the calculations a continuous electron distribution was assumed. The results are depicted in Fig. 3 for the trans- and cis-forms of NMF molecules. It is obvious from the figure that the curve calculated on the basis of the trans-conformation of NMF molecules gave a much better agreement with the experimental curve than that of the cis-conformation.

The radial distribution curve $D(r)-4\pi r^2\rho_0$ of NMF is shown in Fig. 4. The first peak at 120 pm corresponds to the C–N and C=O bonds within an NMF molecule, and the second peak around 230 pm is ascribed to the N···O and C···C nonbonding interactions within a molecule. The difference of the contribution of the isomeric conformations is expected to appear at about 280 pm for the trans-

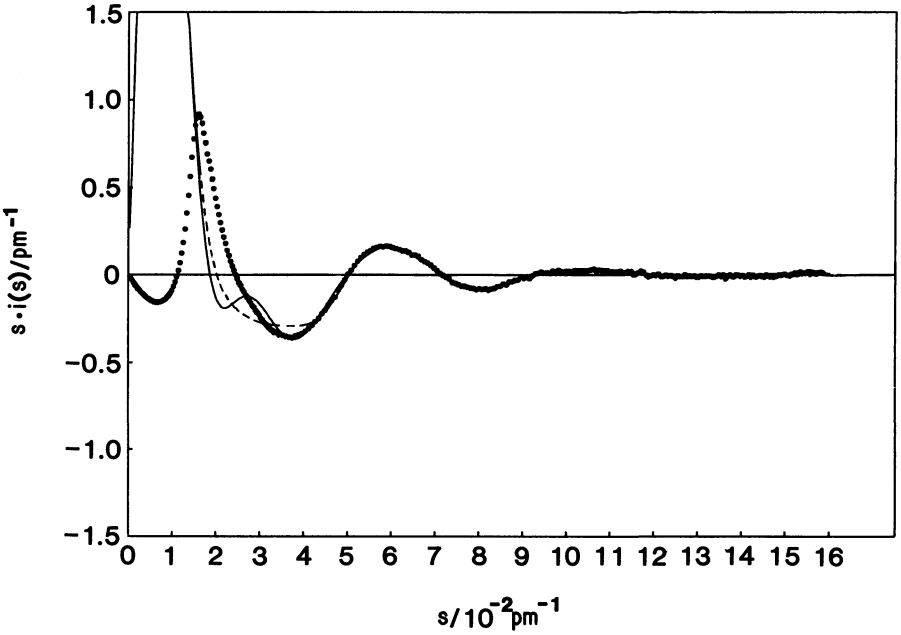


Fig. 2. Comparison between observed (circles) and the calculated $s\cdot i(s)$ corresponding to cis-(broken line) and trans-(solid line) forms. The contributions of the intermolecular N···O interaction are included.

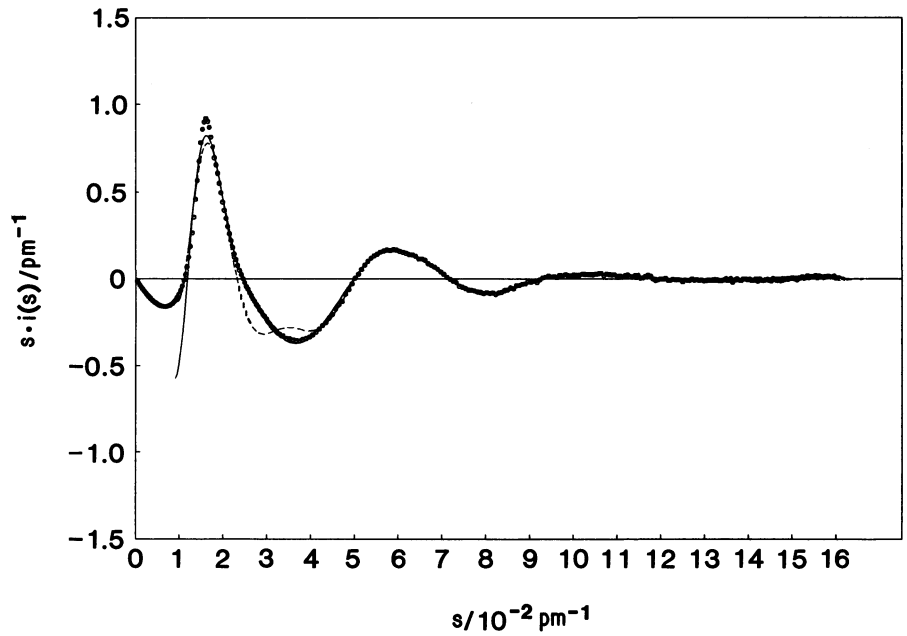

Fig. 3. Experimental (circles) and the theoretical $s\cdot i(s)$ curves for the chain structures consisting of the trans-isomer (solid line) and the cis-isomer (dashed line).

isomer and 350 pm for the cis-isomer due to the nonbonding interaction of C(methyl)···O within a molecule. On the supposition that the cis-isomer was predominant, the peak at 300 pm should be attributed only to the intermolecular N···O interaction and it was required to increase in the number of the hydrogen bonds per molecule to be 3. But even at that time, the theoretical $s \cdot i(s)$ curve showed the manifest discrepancy with the experimental one at about 4×10^{-2} pm^{-1} of s.

Therefore, we concluded that most NMF molecules in the liquid have the trans-conformation, as have been found in previous works.[4-11] The final results thus obtained for the structure parameters of NMF are listed in Table 2, together with those of FA and DMF.

Theoretical Treatment

Stabilities of the cis- and trans-conformations of an NMF molecule, as well as the interaction energies between molecules through the -NH···OCH- hydrogen bond, were investigated by the ab initio LCGO-MO-SCF method with the minimal basis sets. The bond lengths within an NMF molecule were kept at the values experimentally obtained by the present X-ray diffraction study as shown in Table 2. Total energies for the cis- and trans-conformations, both being examined for the staggered and eclipsed orientations, are shown in Table 3. The stabilities were in the order, trans(staggered)>trans(eclipsed)>cis(eclipsed)>cis (staggered), which agreed well with the result found by Sugawara, et al., using the STO-4l-G basis set.[11] The energy differences between the trans- and cis- forms were about 11 kJ mol^{-1} (0.00431 hartrees), which may be compared with the energy difference calculated by Sugawara et al. (5.7 kJ mol^{-1}).[11]

Interaction energies between NMF molecules were calculated by assuming some plausible geometries of NMF dimers which consisted of molecules of trans(staggered)-form, except for the cyclic dimer which must be constructed from molecules of the cis-form. The results are summarized in Table 4. For the calculation the counterpoise correction[19] had been performed. The energy of the hydrogen bond was the largest in the type D3 in Table 4. The cyclic dimer (D5) has the smallest interaction energy per hydrogen bond among the models examined.

Table 3. Energies of Monomers of NMF

Number	Model		Energy/hartree
M1		(cis eclipsed)	−176.47569
M2		(trans eclipsed)	−176.47679
M3		(trans staggered)	−176.48000
M4		(cis staggered)	−176.47523

1 hartree=2625.34 kJ mol^{-1}.

Table 4. Energies of Hydrogen-bonds E_h for Various Dimers of NMF

Number	Model	E_h/kJ (per H-bond)
D1		−22.16
D2		−22.16
D3		−26.76
D4		−26.35
D5		−18.40

Furthermore, the interaction energy was additive when another NMF molecule was combined with a linear dimer to form a trimer with elongation of the same conformation of the type from D1 to D4.

Intensities $s \cdot i(s)$ calculated from the models D1 to D4 gave very similar curves and all fitted well the experimental curve. Figure 3 shows the $s \cdot i(s)$ curve for the chain structure consisting of the D3 units and the continuous electron distribution are also included.

Discussion

The radial distribution curve $D(r)-4\pi r^2\rho_0$ of NMF is shown in Fig. 4, together with the curves of FA and DMF for comparison. The calculated radial distribution curve (broken line) for the chain structure using the structural parameters given in Table 2 for NMF and a continuous electron distribution satisfactory agreed with the experimental curve. In the case of NMF, the peak due to the hydrogen bonded N-(H)···O interaction appears at about 300 pm at almost the same position of that of FA, but no significant corresponding peak was observed in the case of DMF. The obtained N-(H)···O distance for NMF is compared with the value for FA[1,20,21] in Table 2. The hydrogen-bond distances are not appreciably changed between NMF and FA.

The radial distribution curve of NMF indicates a practically random distribution of molecules at a long distance $r>500$ pm, which is similar to the curve of DMF, in spite of the existence of relatively strong

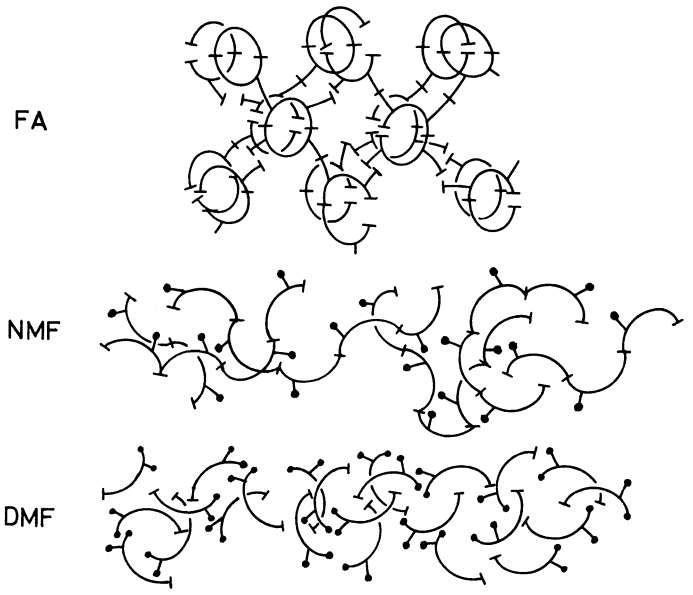

Fig. 5. Models for the liquid structures of formamide, *N*-methylformamide and *N*,*N*-dimethylformamide. —• indicates $-CH_3$, ≺ and ≺● represent $-N\langle^{H}_{H}$ and $-N\langle^{H}_{CH_3}$, respectively. ⌒ shows a hydrogen-bond between molecules.

hydrogen bonds in the system. On the contrary, FA has a three-dimensional hydrogen-bonded structure consisting of ring-dimer and chain moieties,[22] which has long-range order correlations over the ranges 350—500 pm and 700—850 pm. The energies of the hydrogen bonds in FA and NMF were estimated to be similar (E_h=−68.8[1] and −59.8 kJ mol^{-1} without the counterpoise corrections).

From the experimental results obtained by the X-ray diffraction studies and theoretical estimations for energies of hydrogen-bonds in FA,[1,22] NMF, and DMF,[2] we propose the liquid structure of these compounds as follows:

(1) Formamide has a three-dimensional structure containing the ring and chain moieties. The energy for the hydrogen-bond may be the largest among the three systems. Therefore, FA has a high boiling point and a high melting point and a large viscosity. According to most investigations from vibrational spectroscopies, however, the liquid FA has been proposed to have a chain structure.[23] This suggests that FA has a chain-like structure as the V-structure, but the time and space averaged structure (D-structure) shows a more or less crystal-like three-dimensional arrangement of molecules. So the life time of the chain moieties is suggested to be longer than that of the ring ones. A relatively high dielectric constant of FA is explained in terms of the relatively large dipole moment and the ordered structure. The ratio of the dielectric constants of FA to NMF was smaller than that expected from their dipole moments, which should be ascribed to the formation of ring-dimers in the liquid formamide in which the dipole moment is cancelled each other.

(2) *N*-Methylformamide has a hydrogen-bonded chain structure without the formation of a net-work structure. The chain may be so flexible that long-range ordered structure could not be seen from the diffraction method. Ring-dimer units hardly form in the system. The lower viscosity of NMF than FA may be explained by a slightly smaller value of the energy of the hydrogen-bond between NMF molecules, flexibility of the chain structure, and probably also by the absence of a net-work structure. The donor number and acceptor number of NMF have not been determined, but they may be similar to the corresponding values of FA.

(3) *N*,*N*-Dimethylformamide has a practically random structure, although DMF molecules interact each other through weak -HCO···HCO- hydrogen bonds. Therefore, the boiling and melting points of DMF are lower than those of FA and NMF. In spite of a larger molecular volume of DMF than those of the other two liquids, viscosity of DMF is smaller because of weaker intermolecular interactions. The relative dielectric constant is also much smaller than those of the other two solvents because of the random structure of DMF in the liquid state.

Models for the structures of FA, NMF, and DMF are depicted in Fig. 5.

The work has partially been financially supported by the Grant-in-Aid for Scientific Research (No 57470054) from the Ministry of Education, Science and Culture of Japan and the Austrian Ministry for Science and Research (Erl. Zl. 18.854/6-10/81). Computer calculations were done at the Tokyo Institute of Technology at Nagatsuta and at the University of Innsbruck.

(Received July 18, 1985)

The $[Co(S\text{-apS})(cyclen)]^{2+}$ (*S*-apS=(*S*)-1-amino-2-propanethiolate ion, cyclen=1,4,7,10-tetraazacyclododecane) complex was prepared and separated into two isomers (green and brown) by column chromatography. The crystal structure of the green isomer, $[Co(S\text{-apS})(cyclen)]ZnCl_4 \cdot H_2O$ was determined by X-ray analysis. Crystal data are as follows: monoclinic, space group $P2_1$, a=9.382(2), b=13.124(3), c=8.934(2) Å, β=91.08(3)°, and Z=2. The complex ion has a cis-octahedral geometry with the cyclen ligand coordinated in a folded, butterfly-like configuration and the bidentate *S*-apS ligand in a δ-gauche form. One of the two "planar" NH hydrogens of the macrocycle with respect to the *S*-apS ligand is directed opposite the *S*-apS chelate ring (exo), while the other "planar" and the remaining two "apical" NH hydrogens are directed to the *S*-apS ring (endo). The green isomer can be represented by *endo*(S,NH), where NH denotes the planar NH hydrogen cis to the sulfur atom. The other brown isomer was assigned as the *exo*(S,NH) configuration, where the S and NH_2 coordination sites of *S*-apS in the green isomer are interchanged with each other, remaining the configuration of the macrocycle unchanged. Reversible isomerization between the two isomers occurred in aqueous solution and the kinetics was studied at 25.4 °C in the pH range of 5.98—6.97. The isomerization obeyed a rate law of the form, $R=k[OH^-]\cdot[complex]$, and was suggested to take place with synchronous inversion at the two nitrogen atoms of the macrocycle. The relative abundance of the two isomers at equilibrium is 1.0, and the forward and reverse second-order rate constants at 25.4 °C are 6.5×10^3 mol^{-1} dm^3 s^{-1}.

In the course of circular dichroism (CD) studies of cobalt(III) complexes containing a chiral aminoalkanethio(or seleno)late-*N*,*S*(or *Se*) chelate ligand,[1] we have obtained two isomers (green and brown) of $[Co(S\text{-apS})(cyclen)]^{2+}$ (*S*-apS=(*S*)-1-amino-2-propanethiolate ion, cyclen=1,4,7,10-tetraazacyclododecane). To our knowledge, no isomers of metal-cyclen complex have been reported. The isomers are stable in acidic solution, but easily isomerize to each other in basic solution. This report is concerned with the structures, absorption and CD spectra, and isomerization reactions of these isomers.

Experimental

Preparation of $[Co(S\text{-apS})(cyclen)]ZnCl_4$ (brown isomer) and $[Co(S\text{-apS})(cyclen)]ZnCl_4 \cdot H_2O$ (green isomer). An aqueous solution (10 cm^3) containing cyclen$\cdot 2H_2SO_4$[2] (0.737 g, 2.00 mmol) and NaOH (0.32 g, 8.00 mmol) was deoxygenated by bubbling nitrogen, and then added to a deoxygenated aqueous solution (5 cm^3) of $CoCl_2 \cdot 6H_2O$ (0.397 g, 1.67 mmol) with stirring. To the resulting brownish orange solution was added a deoxygenated aqueous solution (5 cm^3) containing (*S*,*S*)-$(NH_2CH_2CH(CH_3)S\text{-})_2 \cdot 2HCl$[3,4] (0.212 g, 0.835 mmol) and NaOH (0.067 g, 1.67 mmol). The mixture was stirred under an atmosphere of nitrogen for 4 d at 30 °C, and then filtered to remove a small amount of insoluble substance. The brown filtrate was diluted with water (500 cm^3) and applied on a column (ϕ2.7 cm×30 cm) of Dowex 50 W×2 (200—400 mesh, H^+ form). By elution with 2 mol dm^{-3} HCl, a green and a brown band developed in this order. The eluate containing the green band was collected and evaporated to a small volume under reduced pressure. To the concentrate was added $ZnCl_2$ (0.5 g) in 3 mol dm^{-3} HCl (1 cm^3) to precipitate dark brown tetrachlorozincate of the complex. The precipitate was collected by filtration and washed with acetone. Yield: 0.2 g. Found: C, 23.81; H, 5.61; N, 12.60%. Calcd for $C_{11}H_{30}N_5Cl_4CoOSZn$: C, 24.17; H, 5.53; N, 12.81%.

The eluate containing the brown band was treated by the same method to yield brown plates. Yield: 0.15 g. Found: C, 24.82; H, 5.28; N, 13.19%. Calcd for $C_{11}H_{28}N_5Cl_4CoSZn$: C, 25.00; H, 5.34; N, 13.25%.

When the reaction product was chromatographed with a column of SP-Sephadex C-25 and an eluent 0.1 mol dm^{-3} Na_2SO_4—0.01 mol dm^{-3} HCl, the order of elution was reversed; the brown isomer being eluted faster than the green one.

Spectral Measurements. Absorption spectra were recorded on a Hitachi 323 or a JASCO 610B spectrophotometer, and circular dichroism (CD) spectra on a JASCO J-40CS spectropolarimeter.

Kinetic Measurements. The rate of the change in absorption spectrum was measured for a phthalate buffer solution (pH range: 5.98—6.97) of each isomer (ca. 3×10^{-3} mol dm^{-3}) at 25.4 °C. The change in absorption spectrum was recorded in the region of 800—400 nm. The reaction was followed at least three half-lives.

Crystal Structure Determination. A dark brown crystal was ground into approximate sphere 0.45 mm in diameter and mounted on an automated Rigaku four-circle diffractometer AFC-5. The cell dimensions were refined based on 20 2θ values ($20<2\theta<28°$) with λ(Mo Kα)=0.71073 Å. The crystal data are: $[Co(C_3H_8NS)(C_8H_{20}N_4)]^{2+}[ZnCl_4]^{2-} \cdot H_2O$, F.W.=546.5, monoclinic, space group $P2_1$, a=9.382(2), b=13.124(3), c=8.934(2) Å and β=91.08(3)°, V=1099.9(4) Å^3, Z=2, D_m(ether/bromoform)=1.65, D_x=1.65 Mg m^{-3}, μ=2.46 mm^{-1}. Intensity measurement was performed to 2θ=55° by θ—2θ scan technique with scan speed 6° min^{-1} (θ). The

ratio of structure factors of five standard reflections, $|F_o|/|F_o|_{initial}$, was from 0.98 to 1.06. 2814 reflections were measured and 2573 reflections with $|F_o|>3\sigma(|F_o|)$ were regarded as observed, of which 2423 reflections were unique. Lorentz-polarization and absorption corrections were applied (0.447≦transmission factor≦0.457). The structure was solved by Patterson-Fourier method. The atomic parameters were refined by block-diagonal least squares. The function minimized was $\Sigma w||F_o|-|F_c||^2$, $w^{-1}=\sigma^2(|F_o|)+(0.015|F_o|)^2$. After the introduction of anisotropic thermal parameters (R=0.050), 9 among 28 hydrogen atoms were found from the difference synthesis and others were calculated (R=0.039). The difference synthesis at this stage of the refinement showed a peak of 1.7 eÅ^{-3} with three satellite peaks of 0.7—1.0 eÅ^{-3}, suggesting positional disorder of the water of crystallization. D_m indicated one water molecule for each asymmetric unit. O(W)1 atom was included in the calculation with 0.25 occupancy factor tentatively (R=0.034). Anisotropic thermal parameter of the O(W)1 atom became non-positive definite. Thus, O(W)2, O(W)3, and O(W)4 atomic positions which separate from the most populated O(W)1 position with distances from 0.88(5) to 1.14(3) Å were added. The population parameters of four O(W) atoms were estimated by the trial and error method in such a way that each isotropic thermal parameter took nearly equal value. The R value reduced to 0.028, wR=0.035 and S=1.6.[5] All the shifts in the final cycle of the refinement were less than 0.6σ for non-hydrogen atoms except O(W). Maximum and minimum height in the final difference synthesis was 0.5 and −0.4 eÅ^{-3}. The calculations were carried out on a FACOM M-380R computer at Keio University with UNICS III program system.[6]

The absolute structure was determined by the anomalous-scattering technique. The enantiomeric structure gave R=0.032, wR=0.040 and could be rejected at the 0.005 significance level by the Hamilton test.[7] The absolute configuration of optically active apS in the present complex cation, which was obtained from $(+)_{589}$-apS·HCl,[1] was determined to be S in agreement with the assignment based on the isomer distribution and CD spectra of [Co(apS){(*R*,*R*)-1,2-cyclohexanediamine}$_2$]$^{2+}$ and related complexes.[1]

Results and Discussion

Preparation and Characterization of the Complexes. The [Co(*S*-apS)(cyclen)]$^{2+}$ complex was prepared by oxidizing Co^{II}–cyclen species with the disulfide according to the method for analogous aminoalkanethiolate-*N*,*S* complexes of cobalt(III).[8,9] The complex was separated into two isomers (green and brown) by column chromatography on Dowex 50W×2 (eluent: 2 mol dm^{-3} HCl) or on SP-Sephadex C-25 (eluent: 0.1 mol dm^{-3} Na_2SO_4—0.01 mol dm^{-3} HCl). The isomers are stable in acidic water and show no measurable change in absorption and CD spectra, but isomerize in neutral or alkaline solution to give an equilibrium mixture of the two isomers (vide infra).

The structure of the green isomer was determined by the X-ray method to be *endo*(S,NH) isomer of configuration I (vide infra, Figs. 1 and 2). We could not obtain good crystals of the brown isomer suitable for X-ray analysis. However, this isomer can be assigned to the other isomer of configuration I, *exo*(S,NH) from comparisons of the behavior in column chromatography, and the absorption and CD spectra with those of two isomers of [Co(*S*-apS)(tren)]$^{2+}$[1] (tren=tris(2-aminoethyl)amine). The steric relations of the sulfur and amine hydrogen atoms of the p- and t-isomers of [Co(*S*-apS)(tren)]$^{2+}$ can be compared to those of the *exo*(S,NH) and *endo*(S,NH) isomers of [Co(*S*-apS)(cyclen)]$^{2+}$, respectively (Fig. 2). The *exo*(S,NH) isomer of the cyclen complex and the p-isomer of the tren complex have two sets of three N–H bonds capable of forming hydrogen bonds with a sulfate ion. Thus, the isomers will be eluted faster in column chromatography than the other isomers (*endo*(S,NH) and t-isomers), since the former isomers will form a stronger ion pair with a sulfate ion than the latter ones which have no such a set of three N–H bonds.[10] The brown isomer of the cyclen complex and p-

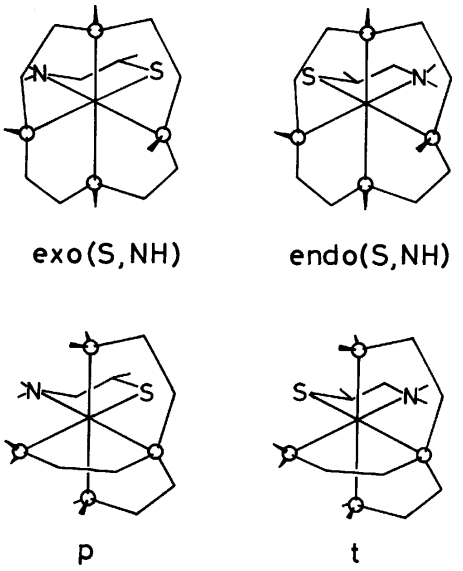

Fig. 2. Structures of *exo*(S, NH)- and *endo*(S, NH)-[Co(*S*-apS)(cyclen)]$^{2+}$, and *p*- and *t*-[Co(*S*-apS)(tren)]$^{2+}$.

isomer of the tren complex[1] are eluted faster than the other respective isomers. Thus the brown isomer can be assigned to the *exo*(S,NH) isomer. Similarity of the absorption and CD spectra between the *exo*(S,NH) and p-isomers, and between the *endo*(S,NH) and t-isomers support the assignment. The relative intensities of the two absorption components in the first absorption band region are considerably different between the two pairs of the complexes; the brown and p-isomers exhibit only a weak shoulder around 17000 cm^{-1}, while the green (*endo*(S,NH)) and t-isomers show a rather strong, distinct band in this region (Fig. 3 and Table 1). The CD spectral pattern of the green isomer resembles that of the t-isomer in the d-d absorption band region. On the other hand, the brown isomer shows a CD spectrum rather different from that of *p*-[Co(*S*-apS)(tren)]$^{2+}$. However, there is something in common between them; the spectra are weak in magnitude and complicated in pattern, and seem to consist of several components with opposite signs. Thus, all these results support the assignment of the brown isomer to *exo*(S,NH).

Figure 1 shows the two possible configurations (I and II) for cis-octahedral complexes of cyclen. Several Co^{III}-cyclen complexes have been prepared, and all of the cobalt(III) complexes whose structures have been determined by X-ray crystallography have configuration I.[2,11,12] Configuration II was found only in [NiBr(H_2O)(Me2cyclen)]Br (Me2cyclen=1,7-dimethyl-1,4,7,10-tetraazacyclododecane), where the two methyl groups are attached to the two "apical" nitrogen atoms (N(1) and N(3) in Fig. 1).[13] On the other hand, the Me2cyclen ligand takes configuration I in [Co(CO_3)(Me2cyclen)]ClO_4.[14] ^{13}C NMR spectroscopy suggests that Co^{III}-cyclen and Co^{III}-Me2cyclen complexes in solution also assume configuration I.[2,14] Examination of molecular models indicates that when a complex with cyclen (or Me2cyclen) has configuration II, steric interactions occur between the methylene groups of the macrocycle (C(3)···C(6) and C(2)···C(7) in Fig. 1). The interactions will increase as the M-N bond distances decrease. On the other hand, configuration I does not have such interactions between the methylene groups. Thus, the shorter bond distance of Co-N than Ni-N will be responsible for the preference of configuration I over II in Co^{III}-cyclen (or Co^{III}-Me2cyclen) complexes. If the brown isomer were configuration II, the strain energy would be large and the relative abundance of the isomer at equilibrium would become small. The fact that the ratio of the brown to green isomer is 1.0 also supports the assignment for the brown isomer. A similar isomerism to the *exo*(S,NH) and *endo*(S,NH)

Chelate rings A and B take a gauche, and C and D an envelope conformation. The geometry of cyclen is almost identical with those in cobalt(III) complexes investigated by X-ray analysis up to the present.[2,11,12] The hydrogen bonds listed in Table 4 do not seem to affect the conformation of the five-membered chelate rings of cyclen. In other Co^{III}-cyclen complexes, Co–N bond lengths involving N atoms on the pseudo-mirror plane (N(2) and N(4) atoms in the present complex) are by 0.02—0.04 Å shorter than others. However, the Co–N(2) bond is longer by 0.023(4) Å than Co–N(4) owing to the trans influence of the S atom.[16] The five-membered chelate ring formed by *S*-apS is δ-gauche to make the C(10)–C(11) bond in an equatorial position. The Co–N(5) bond is lengthened to avoid the short H···H contacts between the cyclen and *S*-apS ligands (see Fig. 6). A projection of crystal structure along *b* is shown in Fig. 7. Arrangement of the complex cation and $ZnCl_4^{2-}$ is NaCl type. There is an approximate

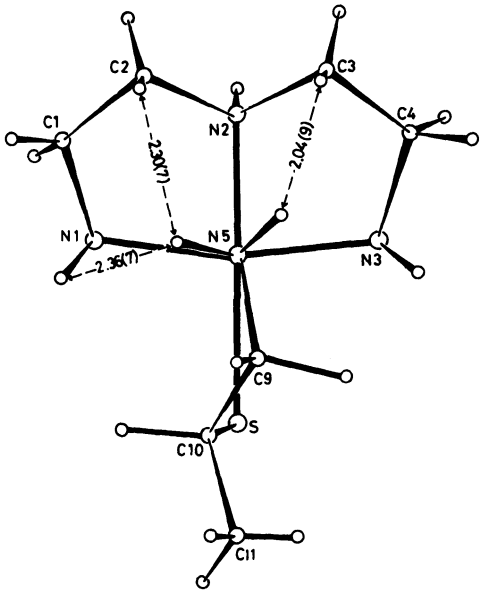

Fig. 6. The complex cation viewed along the line through the Co and N(5) atoms showing non-bonded H···H interactions between cyclen and *S*-apS ligands less than 2.4 Å, twice the van der Waals radius of the hydrogen atom.

Table 4. Intermolecular Hydrogen Bonds (Distances in Å)

A···H–B (symmetry code)	A···B	A···H	H···B
Cl(1)···H(N1)–N(1) (i)	3.268(4)	2.37(5)	1.04(5)
Cl(1)···H(N3)–N(3) (ii)	3.287(4)	2.51(4)	0.83(4)
Cl(2)···H(N5)1–N(5) (iii)	3.325(4)	2.50(5)	0.87(5)
Cl(4)···H(N5)2–N(5) (iv)	3.351(4)	2.58(6)	0.88(7)

Symmetry code: (i) $1-x$, $-1/2+y$, $-z$, (ii) $1-x$, $-1/2+y$, $1-z$, (iii) $1-x$, $1/2+y$, $-z$, (iv) $1-x$, $1/2+y$, $1-z$.

oblate spheroidal hollow, which accomodates a disordered water molecule. The shortest interatomic distance involving the hydrate O atom is 3.03(3) Å for O(W)3···Cl(2) ($-x$, $y+\frac{1}{2}$, $-z$) and only by 0.24 Å shorter than the sum of van der Waals radii.

Isomerization Reactions. Figure 8 shows a typical set of absorption spectra (800—400 nm) obtained at intervals after the brown isomer had been dissolved in water at pH 6.27 and 25.4 °C. The spectra gave an isosbestic point at 597 nm and showed a large absorbance change at 480 nm, and this wavelength was used to follow the rate. In every kinetic run, the plot of $\ln(A_t-A_\infty)$ vs. time at a constant pH gave a straight line for at least three half-lives, where A_t and A_∞ represent the absorbance at time t and at infinite time at 480 nm, respectively. The slope gave the pseudo first-order rate constant, k_{obsd}. The $k_{obsd}/[OH^-]$ ($=k_{iso}$) values are constant at 25.4 °C in the pH range of 5.98—6.97, indicating that the reaction is first-order in $[OH^-]$. The values of k_{obsd} and k_{iso} are listed in Table 5, the average value of k_{iso} being 1.3×10^4 mol^{-1} dm^3 s^{-1} at 25.4 °C. After the isomers had been equilibrated at 25.4 °C, the isomer distribution was analyzed by means of chromatography. The formation ratio of the brown to green isomer was 1.0, and no indication was observed for the formation of other isomers. The runs starting from either of the isomers gave the same result within the experimental

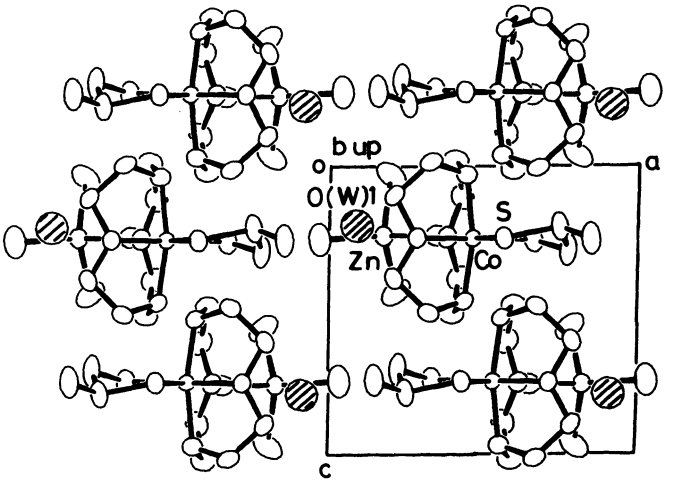

Fig. 7. A projection of the crystal structures along *b*. The hatched circles denote the O(W)1 atom. Other O(W) atoms were not drawn for simplicity.

Table 5. Rate Constants for the Isomerization of [Co(*S*-apS)(cyclen)]$^{2+}$ at 25.4 °C

pH	k_{obsd}/s^{-1}	k_{iso}/mol^{-1} dm^3 s^{-1}
5.98	$(1.22\pm0.03)\times10^{-4}$	$(1.28\pm0.03)\times10^4$
6.27	$(2.36\pm0.05)\times10^{-4}$	$(1.27\pm0.03)\times10^4$
6.74	$(7.2\pm0.2)\times10^{-4}$	$(1.31\pm0.03)\times10^4$
6.97	$(1.25\pm0.03)\times10^{-3}$	$(1.35\pm0.03)\times10^4$

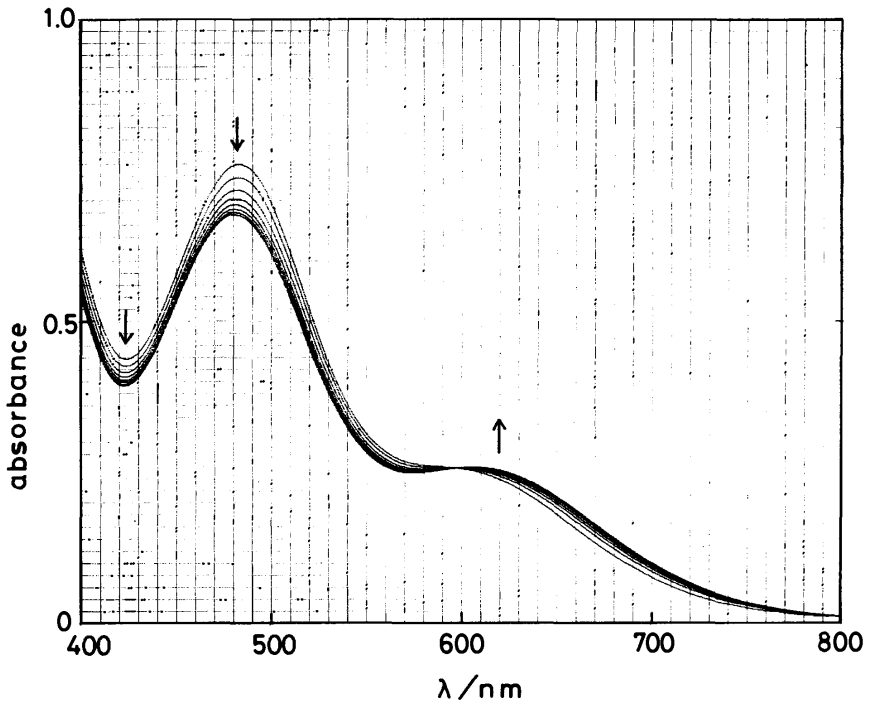

Fig. 8. Time-course changes of absorption spectrum of the brown isomer of $[Co(S\text{-apS})(cyclen)]^{2+}$ in an aqueous solution at pH 6.27 and 25.4 °C (recorded intervals: 20 min). Trends of spectral changes with time are shown by arrows.

error. The absorption and CD spectra of the equilibrated mixture agree well with those of an equimolar mixture of the two isomers. From these observations, the reaction can be expressed as

$$\text{brown isomer } (exo(\text{S,NH})) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{ green isomer } (endo(\text{S,NH})).$$

The forward and reverse second-order rate constants, k_1 and k_{-1}, are related to the rate constant, k_{iso}, and to the equilibrium constant, K, as follows:

$$k_{iso} = k_1 + k_{-1} \qquad K = \frac{k_1}{k_{-1}}.$$

From the k_{iso} and K values, the values k_1 and k_{-1} are calculated to be 6.5×10^3 mol^{-1} dm^3 s^{-1} ($k_1=k_{-1}=0.5k_{iso}$).

Inversion at an asymmetric nitrogen atom is known to be proportional to the hydroxide ion concentration[18] and the reversible isomerization is considered to occur between the two isomers (*exo*(S,NH) and *endo*(S,NH)) of configuration I. The observations decsribed above strongly suggest that the isomerization is resulted from the synchronous inversion at the two nitrogen atoms of the cyclen ring (N(2) and N(4) in Fig. 4). The isomerization can be compared to the racemization of *mer*-$[Co(dien)_2]^{3+}$. In *mer*-$[Co(dien)_2]^{3+}$, the molecular dissymmetry arises from the stereochemical relationship between the two trans NH bonds of the secondary amine nitrogen atoms in the two dien ligands. A rate constant, 2.4×10^2 mol^{-1} dm^3 s^{-1}, for the recemization of *mer*-$[Co(dien)_2]^{3+}$[19] at 35 °C is ca. 10^2 times as small as those obtained above for the isomerization of $[Co(S\text{-apS})(cyclen)]^{2+}$. An investigation is being undertaken to elucidate the effect of the sulfur donor atom on the rate of inversion at nitrogen.

Configuration II (Fig. 1) can be a possible intermediate for the isomerization reaction. The facts that (1) during the course of isomerization the absorption spectra give an isosbestic point, (2) the equilibrated mixture gives only two bands in column chromatography, and (3) only configuration I has been found by X-ray crystallography in the cobalt(III)-cyclen complexes suggest that configuration II is not stable in $[Co(S\text{-apS})(cyclen)]^{2+}$. Thus we conclude that isomerization does not involve formation of any intermediate in measurable amounts.

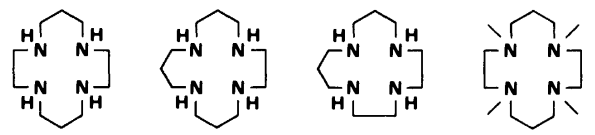
A new series of monomethyl carbonato complexes of nickel(II), cobalt(II), and copper(II) containing tetraazacycloalkanes (L) have been synthesized and characterized: Ni(L)(O_2COCH_3)(ClO_4) (L=[14]aneN$_4$ (**1**); L=[15]aneN$_4$ (**2**); L=*iso*-[14]aneN$_4$ (**3**); L=*RSRS*-Me$_4$[14]aneN$_4$ (**4**)), [Ni(*RRSS*-Me$_4$[14]aneN$_4$)(O_2COCH_3)$_2$]·$HNEt_3ClO_4$ (**5**), Cu([**14**]aneN$_4$)(O_2COCH_3)(ClO_4) (**6**), [Cu(Me$_4$[14]aneN$_4$)(O_2COCH_3)](ClO_4)·CH_3OH (**7**), and Co(L)(O_2COCH_3)(ClO_4) (L=[15]aneN$_4$ (**8**); L=Me$_4$[14]aneN$_4$ (**9**)), where [14]aneN$_4$=1,4,8,11-tetraazacyclotetradecane, [15]aneN$_4$=**1**,4,8,12-tetraazacyclopentadecane, *iso*-[14]aneN$_4$=**1**,4,7,11-tetraazacyclotetradecane, Me$_4$[14]-aneN$_4$=1,4,8,11-tetramethyl-1,4,8,**11**-tetraazacyclotetradecane, *RSRS*-=1*RS*,4*SR*,8*RS*,**11***SR*-, and *RRSS*-=1*RS*, 4*RS*,8*SR*,11*SR*-. These compounds have been obtained through CO_2 uptake reaction in basic methanol from the corresponding four-coordinate complex, [M(L)](ClO_4)$_2$. X-Ray structures of three compounds, **4**, **5**, and **6**, have been determined. Compound **4** is a five-coordinate complex with the trigonal bipyramidal geometry (Type II), in which $CH_3OCO_2^-$ is coordinated in a unidentate fashion. Compound **5** is a tetragonally distorted six-coordinate complex with two unidentate $CH_3OCO_2^-$ at axial sites (Type III). Compound **6** is also a tetragonally distorted six-coordinate complex but the $CH_3OCO_2^-$ ligand bridges two neighboring [Cu([14]aneN$_4$)]$^{2+}$ to form a linear chain structure (Type I). All the monomethyl carbonato complexes synthesized are classified into these three types on the basis of IR and/or electronic spectral data, supplemented with the X-ray results. Efficiency of the CO_2 uptake depends strongly on the coordination structure which is controlled by a combination of metal ion and tetraazacycloalkane. Differences in reactivity among the complexes of various metal ions and factors influencing the efficiency have been discussed in connection with the zinc(II) system which undergoes the most effective CO_2 uptake of this type.

Recently we reported facile CO_2 uptake by zinc(II) complexes containing tetraazacycloalkanes (L).[1] In the system, CO_2 is taken up very easily, in certain cases spontaneously from the air, as monoalkyl carbonate ion in alcohol (ROH) under mild conditions to give Zn(L)(O_2COR)(ClO_4). It is thought that square-planar coordination of a tetraazacycloalkane with an appropriate cavity size leaves the Zn^{2+} ion coordinately unsaturated and that it makes the effective uptake reaction possible. Therefore, coordination structure controlled by a combination of tetraazacycloalkane and metal ion is an important factor for such the CO_2 uptake. In this paper, we synthesized a new series of monomethyl carbonato complexes using various divalent metal ions, Co^{2+}, Ni^{2+}, and Cu^{2+}, and tetraazacycloalkanes shown below[2] in order to compare efficiency of the CO_2



uptake and to explore its factors. Aiming to investigate structural factors, single crystal X-ray analyses have been also carried out on three monomethyl carbonato complexes, [Ni(*RSRS*-Me$_4$[14]-aneN$_4$)(O_2COCH_3)](ClO_4),[3] [Ni(*RRSS*-Me$_4$[14]aneN$_4$)(O_2COCH_3)$_2$]·$HNEt_3ClO_4$,[3] and Cu([14]aneN$_4$)(O_2COCH_3)(ClO_4), which have different coordination geometries.

† Present address: Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606.

Experimental

Materials. The tetraazacycloalkanes, [14]aneN$_4$, [15]aneN$_4$, and Me$_4$[14]aneN$_4$, were purchased from Strem Chemical Inc. *Iso*-[14]aneN$_4$ was prepared according to the literature.[4] Starting nickel(II) complexes, [Ni(L)](ClO_4)$_2$ (L=[14]aneN$_4$, [15]aneN$_4$, *iso*-[14]aneN$_4$, *RSRS*-Me$_4$[14]-aneN$_4$), were prepared from the free ligands L and Ni(ClO_4)$_2$·$6H_2O$ in methanol and recrystallized from water or methanol. [Ni(*RRSS*-Me$_4$[14]aneN$_4$)](ClO_4)$_2$ was prepared by *N*-methylation of the complex, [Ni([14]aneN$_4$)](ClO_4)$_2$.[5] [Cu([14]aneN$_4$)](ClO_4)$_2$ was obtained as follows. A methanolic solution of [14]aneN$_4$ was mixed with an equimolar amount of $CuCl_2$ in methanol under stirring. After a while, addition of a methanolic solution of $NaClO_4$ to this solution gave purple precipitate, which was recrystallized from hot methanol containing a small amount of 2,2-dimethoxypropane or $NaOCH_3$. On cooling, red-purple needles came out of the solution. The same procedure was applied to the synthesis of [Cu([15]-aneN$_4$)](ClO_4)$_2$ to give blue-violet crystals. The blue-violet complex, [Cu(Me$_4$[14]aneN$_4$)](ClO_4)$_2$, was prepared by the reaction of Cu(ClO_4)·$6H_2O$ and Me$_4$[14]aneN$_4$ in methanol. FSO_3CH_3 was purchased from Wako Pure Chemical Industries, Ltd.

Ni(L)(O_2COCH_3)(ClO_4) (1, L=[14]aneN$_4$; 2, L=[15]aneN$_4$; 3, L=*iso*-[14]aneN$_4$): CO_2 gas was bubbled into a methanol solution (50—100 cm^3) of Ni(L)(ClO_4)$_2$ (1 mmol)

containing NEt_3 (1 mmol) at room temperature. After a while, a precipitate began to come out of the solution, but a stream of CO_2 was passed through the solution further for several hours. Pale pink, blue, and purple products of **1**, **2**, and **3**, were filtered and washed with methanol. Yield 89, 83, and 72% for **1**, **2**, and **3**, respectively. Found for **1**: C, 33.29; H, 6.39; N, 12.97%. Calcd for $NiClO_7N_4C_{12}H_{27}$: C, 33.25; H, 6.28; N, 12.92%. Found for **2**: C, 34.52; H, 6.16; N, 12.38%. Calcd for $NiClO_7N_4C_{13}H_{29}$: C, 34.89; H, 6.53; N, 12.52%. Found for **3**: C, 33.53; H, 6.37; N, 13.16%. Calcd for $NiClO_7N_4C_{12}H_{27}$: C, 33.25; H, 6.28; N, 12.92%.

[Ni(*RSRS*-Me$_4$[14]aneN$_4$)(O$_2$COCH$_3$)](ClO$_4$) (4) and [Ni(*RRSS*-Me$_4$[14]aneN$_4$)(O$_2$COCH$_3$)$_2$]·HNEt$_3$ClO$_4$ (5): When a stream of CO_2 was bubbled through a methanolic solution (50 cm^3) of Ni(*RSRS*-Me$_4$[14]aneN$_4$)(ClO$_4$)$_2$ (1 mmol) in the presence of an excess of NEt_3, color of the solution turned green immediately from pink-red. The solution was rotoevaporated to ca. 10 cm^3 and stood for a few days at −20 °C under CO_2 atmosphere to give green crystals of **4**. The blue complex **5** was prepared in a similar way from [Ni(*RRSS*-Me$_4$[14]aneN$_4$)](ClO$_4$)$_2$. Compound **5** was also obtained from the green methanolic solution containing [Ni(*RSRS*-Me$_4$[14]aneN$_4$)](ClO$_4$)$_2$, a large excess of NEt_3, and saturated CO_2 via configurational change of Me$_4$[14]aneN$_4$, when the solution was allowed to stand for several weeks. Found for **4**: C, 38.94; H, 6.79; N, 11.54%. Calcd for $NiClO_7N_4C_{16}H_{35}$: C, 39.25; H, 7.09; N, 11.44%. Compound **5** could not be analyzed because it decomposed rapidly in the air, but its composition is unambiguous from the X-ray analysis (vide infra).

Cu(L)(O$_2$COCH$_3$)(ClO$_4$)·*n*CH$_3$OH (6, L=[14]aneN$_4$, *n*=0; 7, L=Me$_4$[14]aneN$_4$, *n*=1): These complexes were prepared from [Cu(L)](ClO$_4$)$_2$ in the same way as described for **4**. Compounds **6** and **7** are purple and blue, respectively, and **7** was obtained as methanol solvate. Found for **6**: C, 32.61; H, 6.15; N, 12.51%. Calcd for $CuClO_7N_4C_{12}H_{27}$: C, 32.88; H, 6.21; N, 12.78%. Found for **7**: C, 38.78; H, 7.47; N, 10.64%. Calcd for $CuClO_8N_4C_{17}H_{39}$: C, 38.29; H, 7.47; N, 10.62%.

Co([15]aneN$_4$)(O$_2$COCH$_3$)(ClO$_4$) (8): A methanolic solution (50 cm^3) of [15]aneN$_4$ (5 mmol) was added to a methanolic solution (50 cm^3) of Co(ClO$_4$)$_2$·6H$_2$O (5 mmol) under a nitrogen atmosphere. Color of the solution turned red brown. After refluxing for 2 h, an excess of NEt_3 was added to the filtered solution and then CO_2 was bubbled through the solution. Pink-red crystals formed were filtered and stored under a nitrogen atmosphere to avoid air oxidation. Found: C, 34.56; H, 6.38; N, 12.28%. Calcd for $CoClO_7N_4C_{13}H_{29}$: C, 34.87; H, 6.53; N, 12.51%.

[Co(Me$_4$[14]aneN$_4$)(O$_2$COCH$_3$)](ClO$_4$) (9): A methanol solution (80 cm^3) of Me$_4$[14]aneN$_4$ (10 mmol) was added dropwise to a stirred methanol solution (50 cm^3) of Co(ClO$_4$)$_2$·6H$_2$O (10 mmol) under bubbling CO_2 at room temperature. Color of the solution became red purple and concomitantly white precipitate, presumably a salt of perchloric acid and Me$_4$[14]aneN$_4$, came out. When an excess of NEt_3 was added into the reaction mixture and CO_2 bubbling was continued, the white precipitate dissolved again and then red-purple precipitate of **9** was obtained. Yield 80%. Found: C, 39.21; H, 7.19; N, 11.43%. Calcd for $CoClO_7N_4C_{16}H_{35}$: C, 39.23; H, 7.20; N, 11.44%.

Measurements. Infrared spectra were recorded on a Jasco IR-810 or a Hitachi 295 spectrometer. Electronic spectra were measured on a Hitachi 340 spectrophotometer. Solid state spectra were taken as nujol mulls mounted between polyethylene films. ^{1}H NMR spectra were obtained on a JEOL JNM-GX400 spectrometer at 400 MHz.

Magnetic susceptibility measurements on cobalt(II) complexes were carried out at 77 K by the Hartshorn bridge method[6] (operating at 300 Hz). Tutton's salt, [Mn(OH$_2$)$_6$]-SO$_4$·(NH$_4$)$_2$SO$_4$, was used as a standard.

X-Ray diffraction data were obtained on a Rigaku AFC-5 four-circle diffractometer with use of graphite-monochromatized Mo $K\alpha$ radiation. Diffraction data were collected at room temperature for **4** and **6** but at 168 K under a nitrogen stream for **5** because it decomposed rapidly in the air at room temperature. The low-temperature measurement was made with an attached Rigaku variable-temperature apparatus using a cold nitrogen gas stream method. The procedures used for data collection were standard and have been described previously.[7] The intensity data were corrected for Lorentz-polarization effects and for absorption.

Solution and Refinement of the Structures. The structure of **4** was solved by a standard Patterson and Fourier method, whereas the direct method was used for **5** and **6**. All the structures were refined by the block-diagonal least-squares technique. The atomic scattering factors for non-hydrogen atoms were taken from Ref. 8 and those for hydrogen from Stewart, Davidson, and Simpson.[9] The effects of anomalous dispersion for non-hydrogen atoms were corrected. The weights (w) were taken as $w=[\sigma^2_{count}+(0.015|F_o|)^2]^{-1}$. All the hydrogen atoms were located by difference syntheses. Non-hydrogen and hydrogen atoms were refined anisotropically and isotropically, respectively. Calculations of the refinements for all the compounds converged smoothly.[10] All the calculations were carried out on a HITAC M-200H computer at the Computer Center of the Institute for Molecular Science with the Universal Crystallographic Computation Program System UNICS III[11] and MULTAN 78.[12]

Results

Synthesis and Characterization. Table 1 lists compounds prepared in this study along with their IR data. Monomethyl carbonato complexes are obtained by bubbling CO_2 through methanolic solutions of [M(L)](ClO$_4$)$_2$ (M=Ni^{2+}, Cu^{2+}, and Co^{2+}) containing NEt_3 as a base (Eq. 1).

$$CH_3OH + CO_2 + NEt_3 \rightleftharpoons CH_3OCO_2^- + HNEt_3^+$$
$$M(L)^{2+} + nCH_3OCO_2^- \longrightarrow M(L)(O_2COCH_3)_n^{m+} \quad (1)$$
$$(n=1,\ m=1 \text{ or } n=2,\ m=0).$$

Addition of NEt_3 was necessary in these systems, although, in some zinc(II) systems, the CO_2 uptake reaction proceeds under base-free conditions. In the systems of the nickel(II) complexes with [14]aneN$_4$ and [15]aneN$_4$, CO_2 is taken up from the air spontaneously in the presence of an equivalent amount of NEt_3 and the monomethyl carbonato

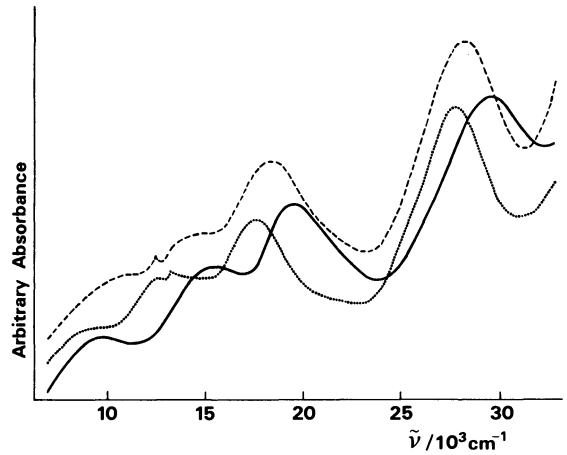

Fig. 1. Electronic absorption spectra (in methanol) of Ni([14]aneN$_4$)(O_2COCH_3)(ClO_4) (**1**) (——), Ni([15]aneN$_4$)(O_2COCH_3)(ClO_4) (**2**) (·····), and Ni(*iso*[14]aneN$_4$)(O_2COCH_3)(ClO_4) (**3**) (----).

complexes were isolated as a single product.

In contrast with the nickel(II) systems, the reactivity of $[Cu(L)]^{2+}$ toward monomethyl carbonate ions was so weak that only the starting complex, $[Cu(L)](ClO_4)_2$, was recovered when an equimolar amount of NEt_3 was present in the solution. However, when a large excess of NEt_3 was added, (monomethyl carbonato)copper(II) complexes, **6** and **7**, were successfully isolated. But we failed to isolate a desired product from $[Cu([15]aneN_4)](ClO_4)_2$ even in the presence of a large excess of NEt_3.

As to cobalt(II) complexes, it may be worth while pointing out the following observation. The cobalt(II) complex with [15]aneN$_4$ was easily oxidized by air, so that the reaction was carried out under a nitrogen atmosphere. On the other hand, the cobalt(II) complex with Me$_4$[14]aneN$_4$ was extraordinarily air stable and it underwent the uptake reaction in the air smoothly.

We pointed out previously for the zinc(II) system that stretching vibrational bands (ν_1 and ν_2) of the $-OCO_2$ group reflect a coordination mode of the monomethyl carbonato ligand.[1a] That is, in the case of unidentate $CH_3OCO_2^-$, the ν_1 band appears at higher frequencies than that of bridged $CH_3OCO_2^-$. In addition, the intensity of ν_2 is strong as compared with ν_1 in unidentate $CH_3OCO_2^-$, and vice versa in bridged $CH_3OCO_2^-$. Similar trends were also observed for the present nickel(II)- and cobalt(II)-monomethyl carbonato complexes (Table 1). The frequency difference between ν_1 and ν_2 was as much as 360 cm^{-1} in compounds **4**, **5**, and **9**, while it was at most 300 cm^{-1} in **1**—**3** and **8**. Thus, complemented with the relative band intensities, the $CH_3OCO_2^-$ ligands in complexes with Me$_4$[14]aneN$_4$ are assigned to unidentate coordination and those in other compounds to bridged coordination. However, it was difficult for copper(II) complexes to assign the coordination mode from IR data because they do not show a distinct tendency.

As shown in Fig. 1 and Table 2, the ligand field electronic spectrum of nickel(II) complex, **1**, **2**, **3**, or **5** consists of four bands except for a sharp peak due to spin-forbidden transition around 13000 cm^{-1}. Each spectrum shows clearly the splitting typical of tetragonal nickel(II) complexes in the lowest energy region (8000—15600 cm^{-1}).[13] The lowest and the second lowest energy bands are assigned to $^3E_g \leftarrow {}^3B_{1g}$ and $^3B_{2g} \leftarrow {}^3B_{1g}$, respectively, which arise from the tetragonal splitting of $^3T_{2g} \leftarrow {}^3A_{2g}$ in Oh symmetry. Thus compounds **1**, **2**, **3**, and **5** have coordination geometry of the *trans*-NiO_2N_4 type. The spectral

pattern of green compound **4** is quite different from others and indicates a five-coordinate structure.

Nujol mull solid state electronic spectra of (monomethyl carbonato)copper(II) complexes, **6** and **7**, show one broad absorption band at 19000 and 14300 cm^{-1}, respectively. The d-d band position is at lower energy than those of the corresponding square-planar four-coordinate complexes, $[Cu(L)]^{2+}$.[14] This indicates the occurrence of an axial interaction of the fifth or sixth ligand with the Cu^{2+} ion although coordination geometry of the copper(II) complexes is not clear from the electronic spectra.[15]

(Monomethyl carbonato)cobalt(II) complexes, **8** and **9**, are pale pink and red purple in color, respectively. Their electronic spectral patterns are quite different ($\tilde{\nu}_{max}/10^3$ cm^{-1}: 19.7 and 22.1 for **8**; 6.9, 13.5, 18.6, 19.9, and 20.7 for **9**). The spectral pattern of **8** resembles those of high spin octahedral cobalt(II) complexes, $[Co(OH_2)_6]^{2+}$ and $[Co(NH_3)_6]^{2+}$. On the other hand, the spectral pattern of **9** is very similar to that of high-spin five-coordinate complexes with the trigonal bipyramidal geometry, $[Co(tbcyclen)X]^+$ (X=Cl, NCS; tbcyclen=1,4,7,10-tetrabenzil-1,4,7,10-tetraazacyclododecane)[16] and $[Co(MSBen\text{-}N(C_2H_5)_2(NCS)_2]$ (MSBen-$N(C_2H_5)_2$=Schiff base derived from o-(methylthio)benzaldehyde and *N,N*-diethylethylenediamine)[17]. But the pattern of **9** differs clearly from that of a low-spin five coordinate complex having the trigonal bipyramidal geometry, [Co(CR)X]Y (X, Y=Cl, Br, I etc., CR=2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1]heptadeca-1(17),2,11,13,15-pentaene.[18] Magnetic moments for **8** and **9** have been found to be 4.09 and 4.21 μ_B, respectively. These results indicate that compound **8** is a high spin six-coordinate complex whereas **9** is a high spin five-coordinate complex.

X-Ray Structure. Partinent crystallographic parameters and final *R* indices for three analyzed compounds, **4**, **5**, and **6**, are summarized in Table 3. Their positional and thermal parameters for non-hydrogen atoms are given in Tables 4-6, respectively. Figure 2 shows X-ray structures and Table 7 lists relevant bond distances and angles.

[Ni(*RSRS*-Me_4[14]aneN$_4$)(O_2COCH_3)](ClO_4) (**4**) was found to be a mononuclear five-coordinate complex with the trigonal bipyramidal geometry (Fig. 2(a)). The macrocycle is folded and the $CH_3OCO_2^-$ ligand is coordinated in a unidentate fashion. The overall structure of **4** is essentially the same as that of the corresponding zinc(II) complex, [Zn(Me_4[14]aneN$_4$)(O_2COCH_3)](ClO_4)[1b]. All the four methyl groups of the Me_4[14]aneN$_4$ ligand are disposed toward the same side as the $CH_3OCO_2^-$ ligand. A main difference between these two structures is as follows: An angle subtended at the Ni atom by two axial bonds, Ni–N(2) and Ni–N(4), is 171.2(2)°, which is much wider than the corresponding angle of the zinc complex (166.2(1)°); Apical bonds (Ni–N(2) and Ni–N(4)) are similar in length to the in-plane ones in the nickel complex, while the formers are longer by

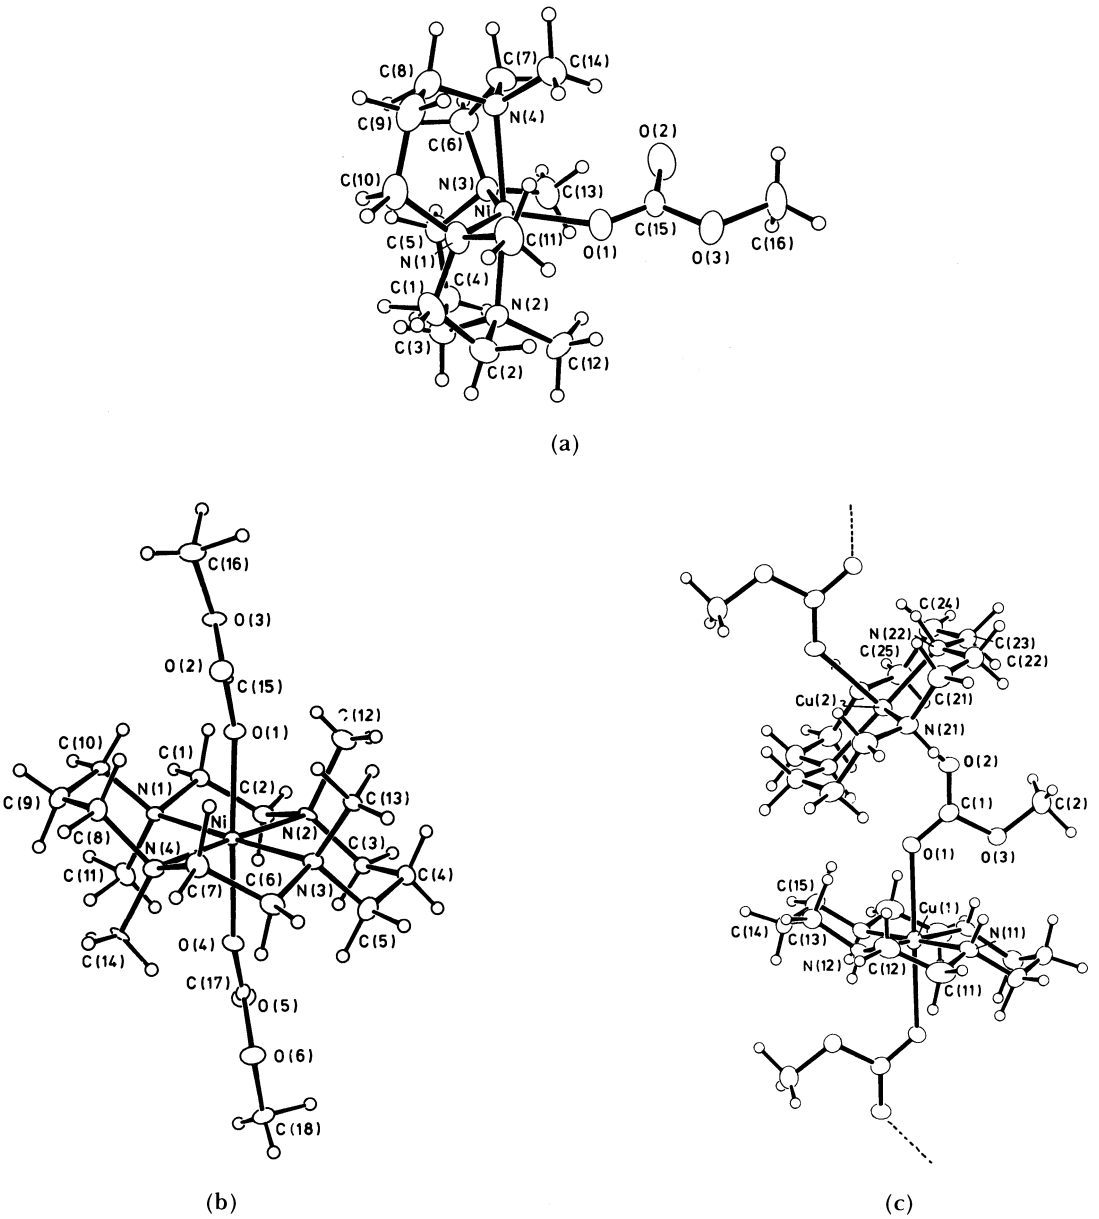

Fig. 2. ORTEP view of the structure, (a): [Ni(*RSRS*-Me_4[14]aneN$_4$)(O_2COCH_3)](ClO_4) (**4**), (b): [Ni(*RRSS*-Me_4[14]aneN$_4$)(O_2COCH_3)$_2$]·$HNEt_3ClO_4$ (**5**), (c): Cu([14]aneN$_4$)(O_2COCH_3)(ClO_4) (**6**).

ca. 0.1 Å in the zinc complex. Although the in-plane coordination bond lengths are not much different between the nickel and zinc complexes, deviations of the in-plane coordination bond angles from 120° are larger in the nickel complex than in the zinc complex.

As shown in Fig. 2(b), the structure of **5** is of the *trans*-NiO_2N_4 type with the macrocycle in a plane and with two unidentate $CH_3OCO_2^-$ occupying the axial sites. This 2:1 complex (two $CH_3OCO_2^-$'s per a metal ion) is the first example among about twenty monoalkyl carbonato complexes of M(II)–tetraaza-cycloalkane we prepared. There is an approximate inversion center at the nickel atom, although all the atoms in the complex cation are crystallographically independent. The overall skeletal structure of the macrocycle is the same as that of the most strain-free form of the [14]aneN$_4$ ligand, five- and six-membered chelate rings being in the gauche and chair conformations, respectively. The average Ni–N distance is 2.163(9) Å and is comparable to a reported value (2.16(1) Å) for [Ni_2(*RRSS*-Me_4[14]aneN$_4$)$_2$(N_3)$_3$]I.[3a] But it is about 0.1 Å longer than those found in high-spin complexes without N-methyl groups, *trans*-[NiX_2([14]aneN$_4$)].[19] This is the outcome of the *N*-methylation of [14]aneN$_4$ which causes a decrease in the ligand field strength. Monomethyl carbonato ligands are oriented parallel to the fence of the CH_3 groups on the same side, avoiding mutual steric interactions (Fig. 2(b)). Angles of Ni–O(1)–C(15) and

a) Positional parameters are multiplied by 10^4. b) See footnote in Table 4 for B_{eq}. c) Perchlorate oxygen atom.

Ni-O(4)-C(17) widen up to 156.4(4)° and 158.9(4)°, respectively.

The crystal structure of Cu([14]aneN$_4$)(O_2COCH_3)(ClO$_4$) (**6**) is isostructural with Zn([14]aneN$_4$)(O_2COCH_3)(ClO$_4$). As shown in Fig. 2(c), the $CH_3OCO_2^-$ ligand bridges adjacent Cu([14]aneN$_4$) units, forming a linear chain along the a axis. Two independent copper atoms (Cu(1) and Cu(2)) are situated at a crystallographic inversion center. Intramolecular hydrogen bonds operate between NH of [14]aneN$_4$ and the O(3) atom of the $CH_3OCO_2^-$ ligand (O(3)···HN(12)=2.40(6) Å, O(3)···HN(11)=2.60(6) Å), as in the zinc complex.

Discussion

Nickel(II) Complexes. Three types of coordination structures (I—III) are found in (monomethyl carbonato)nickel(II) complexes. Type I is a linear-chain structure with the bridging monomethyl carbonato ligand. Compounds **1**, **2**, and **3** are assigned to this type from IR and electronic spectral data. The second type (II) is a mononuclear five-coordinate structure with the unidentate monomethyl carbonato ligand and is found for compound **4**. These two types have been already known in zinc(II) complexes.[1] Type III, which is a mononuclear six-coordinate complex containing two unidentate $CH_3OCO_2^-$, has been newly found for compound **5**. As to the CO_2 uptake reaction, compounds with the structural type I were the most effective in the nickel(II) complexes as well as in the zinc(II) systems.[1] CO_2 is taken up spontaneously from the air in the system of this type to form desired monomethyl carbonato complexes. In complexes

with $Me_4[14]aneN_4$, steric constraints provided by *N*-methyl groups of $Me_4[14]aneN_4$ prevent monomethyl carbonato ligand from bridge coordination, giving structural type II or III. The $Me_4[14]aneN_4$ ligand in the *RSRS*-form folds easily to afford the type II structure, whereas *RRSS*-$Me_4[14]aneN_4$ cannot fold to form the type III complex.

As was mentioned in the experimental section, compound **5** was produced also from the solution of **4** through the nitrogen configuration inversion of $Me_4[14]aneN_4$ from *RSRS*- to *RRSS*-form. The electronic spectrum of a methanol solution of **4** containing an excess of NEt_3 and saturated CO_2 was found to change with time. The absorption maximum of the original solution at 681 nm shifted gradually toward higher frequencies, that is, toward the absorption band of **5** and reached an equilibrium position. The more NEt_3 was added, the larger and faster the band shifted. Moore et al. reported that the *RSRS*- and *RRSS*-isomers of $[Ni(Me_4[14]aneN_4)]^{2+}$ are interconvertible, and that the conversion occurs at a relatively slow rate in DMSO or DMF but rapidly in the presence of a strongly coordinating amine such as propylamine.[20] In our case, however, reverse reaction, i.e., conversion from **5** to **4** was not observed. An absorption spectrum of **5** in methanol did not change at all at least for a month. Compound **5** decomposes rapidly in the air liberating CO_2, although it is stable in a nitrogen atmosphere or in a vacuum.[21] The instability of **5** is reflected in bond angles of Ni-O-C in the monomethyl carbonato ligands. The corresponding angle in other monomethyl carbonato[1b] or carbonato complexes[22] is in the range of 122—136°, which are close to 120° expected for the oxygen atom in the sp^2 hybridization. However, the angles in **5** (157.7° in average) are by far larger.

The monomethyl carbonato ligand was successfully converted into dimethyl carbonate by treating with FSO_3CH_3 in $CDCl_3$. The formation of dimethyl carbonate was easily followed by ^1H NMR. The conversion efficiency in the present nickel(II) complexes was not much different from the case of zinc(II) complexes described previously.[1a]

Copper(II) Complexes. IR data of the (monomethyl carbonato)copper(II) complexes did not provide definite evidence for structural information. It is because an interaction of $CH_3OCO_2^-$ with $[Cu(L)]^{2+}$ is very weak. In fact, the X-ray structure of $Cu([14]aneN_4)(O_2COCH_3)(ClO_4)$ (**6**) demonstrates clearly the weakness of the interaction. As described previously, the crystal structure of **6** is isomorphous with the Zn analogue, $Zn([14]aneN_4)(O_2COCH_3)(ClO_4)$, which has been found to be one of the most effective system as to the efficiency of the CO_2 uptake among about 20 systems explored in a series of our studies. In the zinc structure, one of the Zn atoms takes an out-of-plane position,[1b] but such an out-of-plane displacement has not been found in **6** in spite of the constrained coordination environment. The double of the Cu···Cu separation (12.303(3) Å) corresponds to the length of the a axis, and is slightly longer than that of the zinc complex (12.128(2) Å). These structural informations show that the Cu-O interaction is rather weak. The Cu-O distances are as large as 2.351(6) and 2.516(5) Å, while the Zn-O lengths are 2.143(3) and 2.227(3) Å. This difference is consistent with the observation that the $CH_3OCO_2^-$ uptake by the zinc complex takes place much easier. The occurrence of such a weak interaction in copper(II) complexes was observed spectrally in a methanol solution. A d-d band of $[Cu(L)]^{2+}$ shifts to lower energies as the concentration of NEt_3 increases. Such a spectral change was observed for all the copper(II) complexes studied, $[Cu(L)](ClO_4)_2$ (L=$[14]aneN_4$, $[15]aneN_4$, and $Me_4[14]aneN_4$). The spectral change indicates that a monoalkyl carbonato adduct exists in equilibrium with the starting $[Cu(L)]^{2+}$. The d-d band shift upon addition of a large excess of NEt_3 was as much as 2400 cm^{-1} for compound **7**, whereas it was only 800 cm^{-1} for **6**. Complemented by structural data for other $Me_4[14]aneN_4$ complexes, this may indicate that the coordination geometry about Cu in **7** is of the trigonal bipyramidal type. An interaction between Cu^{2+} and $CH_3OCO_2^-$ is stronger in **7** than in **6**.

Cobalt(II) Complexes. Cobalt(II) complexes, **8** and **9**, are classified to types I and II, respectively, from the spectral and magnetic susceptibility data. Compound **8** is easily oxidized to the tervalent state and this enables discussion on the structure of **8**. When an aqueous solution of compound **8** acidified with HCl was stirred in the air, brown solid was produced. The product was identified as the most stable isomer of *trans*-[$Co^{III}Cl_2$([15]aneN_4)](ClO$_4$), in which one five-membered and three six-membered chelate rings adopt a gauche-skew-chair-chair conformational sequence.[23] Since nitrogen configurations would be retained in the process of the oxidation, the skeletal structure of [15]aneN_4 in compound **8** is considered to be the same. This overall conformation is different from that found for the corresponding zinc(II) complex in [{Zn([15]-aneN_4)}$_3$(O_2COCH_3)$_2$](ClO$_4$)$_4$, which has the [15]aneN_4 ligand in a gauche-chair-skew-chair conformation.[1b] On the other hand, compound **9** was found to be very stable in the air. The trigonal bipyramidal geometry characteristic of this particular macrocycle prevents Co(Me$_4$[14]aneN_4)$^{2+}$ from the air oxidation. To our knowledge, compound **9** is the first example that assumes a high-spin five coordinate structure in tetraaza macrocyclic cobalt(II) complexes.

Comparison of Metal Ions from the Viewpoint of the CO_2 Uptake. Among tetraazacycloalkane complexes of various metal ions studied, the zinc complexes are the most superior in the efficiency of the CO_2 uptake as monoalkyl carbonate ion. As discussed in detail in the previous paper,[1] coordinately unsaturated situation introduced by square-planar coordination of a tetraazacycloalkane ligand is the most important in the case of the zinc(II) systems. The uptake reaction by the nickel(II) systems was not so effective as the zinc(II) systems. A Ni^{2+} ion has $3d^8$ valence electron configuration and a square-planar four-coordinate structure is one of the stable geometries for nickel(II) complexes. That is, axial sites of starting nickel(II) complexes with tetraazacycloalkane are supposed to be not so reactive as those of the zinc(II) complexes. It is well known that nickel(II) complexes with tetraazacycloalkanes (L) exists in a coordinating solvent or in the presence of coordinating anions as an equilibrium mixture between square-planar four-coordinate species and five- or six-coordinate species (Eq. 2). Thermodynamic parameters of the equilibrium

$$[Ni(L)]^{2+} + nX \rightleftharpoons [Ni(L)X_n]^{m+} \quad (2)$$
$$n=1 \text{ or } 2;\ m=0\text{—}2,$$

in aqueous solution ($X=H_2O$) have been reported for various tetraaza macrocycles. The position of the equilibrium depends strongly on the kind of the in-plane ligand. For example, in the case of L=[14]aneN$_4$, only 28% of the complex exists as six-coordinate species at room temperature, while, in the case of L=[15]aneN$_4$, six-coordinate species amounts to as much as 99%.[24] A position of the equilibrium of Eq. 2 has been known to be affected by an electronic factor, that is, ligand field strength of the in-plane ligand. We tried to correlate an equilibrium constant with efficiency in the uptake of monoalkyl carbonate ion. But such a correlation was not observed in the present system. A steric factor contributes more strongly than the electronic one. In fact, the following facts are noted between [Ni(*RRSS*-Me$_4$[14]aneN$_4$)]$^{2+}$ and [Ni([14]aneN$_4$)]$^{2+}$: in aqueous solution, the former favors six-coordination over four-coordination and vice versa in the latter, while compound **5** containing the *RRSS*-Me$_4$[14]aneN$_4$ ligand is so unstable that it returns to the four-coordinate complex rapidly in the air.[21] However, the electronic effect on the uptake reaction was indeed noted in the case where ligand field strength of the macrocyclic ligand is by far stronger and, therefore, the equilibrium of Eq. 2 is shifted far to the left. [Ni(Me$_2$[13]dienatoN$_4$)]$^+$ (Me$_2$[13]dienatoN$_4$= 11,13-dimethyl-1,4,7,10-tetraazacyclotrideca-10,12-diene)[25] is such an example and it did not afford a monomethyl carbonato complex. One more fact that deserves a brief comment on the nickel(II) system, is that a nickel(II) complex containing linear tetramines such as 3,2,3-tet (3,2,3-tet=4,7-diazadecane-1,10-diamine) instead of tetraazacycloalkane undergoes the uptake of monomethyl carbonate ion. A zinc(II) complex having 3,2,3-tet never undergoes such a reaction. Possibly, this is due to the difference in coordination behavior between nickel(II) and zinc(II). Ni(3,2,3-tet)$^{2+}$ prefers a square-planar geometry and has coordinately unsaturated nature. On the other hand, Zn(3,2,3-tet)$^{2+}$ assumes a tetrahedrally distorted geometry which is more stable than a square planar form, and therefore it does not undergo further ligand uptake.

The uptake efficiency of the copper(II) complexes was the lowest among the metal ions studied. This originates from the inherently weak reactivity of axial sites of tetragonal copper(II) complexes. As described previously, the X-ray structure of compound **6** demonstrates clearly such a situation.

The cobalt(II) system is disadvantageous to the formation of monomethyl carbonato complexes because cobalt(II) complexes with four nitrogen donors are generally susceptible to oxidation. However, the Co([15]aneN$_4$) complex underwent the uptake reaction smoothly under oxygen-free conditions. The Co(Me$_4$[14]aneN$_4$) system is an exception. It forms a five-coordinate cobalt(II) complex with an extra unidentate ligand (X), CoX(Me$_4$[14]aneN$_4$)$^+$, which is exceptionally stable to oxidation. Cobalt(II) complexes resemble zinc(II) complexes in the point that they can take many different types of coordination geometries.[26] It seems that the efficiency of the cobalt complexes is not much different from that of the zinc complexes under oxygen free conditions.

21) The resulting product is orange in color indicating a four-coordinate nickel(II) complex. When this change was followed by IR spectra, bands at 1670 and 1306 cm^{-1} due to the monomethyl carbonate group disappeared gradually and a new peak appeared at 1630 cm^{-1}. This band suggested an existence of hydrogencarbonate ion. In fact, analytical data of the product was consistent with [Ni(Me$_4$[14]aneN$_4$)](O$_2$COH)(ClO$_4$): Found: C, 38.10; H, 7.04; N, 11.79%. Calcd for $NiClO_7N_4C_{15}H_{33}$: C, 37.88; H, 6.99; N, 11.78%. Therefore, the decomposition of **5** is considered to be induced by the reaction with moisture, as shown below.

$$[Ni(Me_4[14]aneN_4)(O_2COCH_3)_2]\cdot HNEt_3ClO_4 \xrightarrow[H_2O]{CO_2,\ 2CH_3OH,\ NEt_3} [Ni(Me_4[14]aneN_4)](O_2COH)(ClO_4).$$

Flow Injection Analysis of Cobalt(II) by Catalytic Oxidations of Stilbazo and Pyrocatechol Violet

Toshio Deguchi,* Atsuya Higashi, and Isao Sanemasa
Department of Chemistry, Faculty of Science, Kumamoto University,
Kurokami 2-39-1, Kumamoto 860
(Received September 4, 1985)

Catalytic oxidations of ten organic dyes with an aromatic-hydroxyl or -amino functional group have been studied in the presence of metal ions such as cobalt(II), copper(II), and vanadium(V). Of these dyes, six were found to be effectively oxidized and decolorized specifically by one of these metals. 4,4′-Bis(3,4-dihydroxyphenylazo)stilbene-2,2′-disulfonic acid diammonium salt (Stilbazo) and 3,3′,4′-trihydroxyfuchsone-2″-sulfonic acid (Pyrocatechol Violet) were found to be promising for determining trace amounts of cobalt(II). The optimum analytical conditions have been studied for these two compounds with the aid of a flow injection analysis technique. The both reagents can be used to determine cobalt(II) down to 1 ppb.

It is well known that some metal ions, particularly transition metals with different oxidation states, catalyze the oxidation reactions of an arylamine, phenol, or some dyestuffs.[1] Indeed, a number of catalytic methods using a suitable oxidant such as H_2O_2 or BrO_3^- have been reported which permit trace analysis of some transition metal ions.[2-5] Concerning with the cobalt(II) determination, the following organic chromogenic substances have been so far used; Alizarin,[6] 3-(4-sulfophenylazo)-4,5-dihydroxy-2,7-naphthalenedisulfonic acid,[7] Gallocyanine,[8] chromotropic acid,[9] diphenylcarbazone,[10] Tiron,[11] gallic acid,[12] Luminol.[13] The last two have been used for the chemiluminescent reactions, and they are generally very sensitive. The other substances have been used for the photometric method. The organic chromogenic substances listed above are helpful to search for organic dyes with similar functional group(s) that might be expected to provide new catalytic systems.

Ten kinds of organic dyes were chosen, and the possibility of their metal-catalyzed oxidations have been investigated in view of trace analyses of cobalt(II), copper(II), and vanadium(V). 4,4′-Bis(3,4-dihydroxyphenylazo)stilben-2,2′-disulfonic acid diammonium salt (Stilbazo) and 3,3′,4′-trihydroxyfuchsone-2″-sulfonic acid (Pyrocatechol Violet) appeared promising for the determination of trace amounts of cobalt(II).

A flow injection analysis (FIA) technique was employed to find the optimum analytical conditions for these two organic dyes. The technique makes many different types of analysis be easily performed by controlling reaction conditions such as mixing of reactants at a fixed rate, reaction time, and temperature of reactant, and hence, particularly suitable for kinetic method of analysis which generally takes advantage of the difference between an indicator reaction (a reaction in the absence of the metal in question) and a catalytic reaction. By the use of FIA technique, an indicator reaction can be monitored continuously and the output signal is to be recorded as a baseline on a chart, and if a catalytic reaction does take place, it appears as a signal on the baseline.

Experimental

Reagents and Materials. Distilled and deionized water was used throughout. Commercially available 1000 ppm standard solutions of cobalt(II) and the other metal ions were diluted with water (a little acidic if necessary) to prepare the working solutions. Dotite 2,2′-dihydroxyazobenzene, Stilbazo, Pyrogallol Red, Pyrocatechol Violet, Beryllon II, and di-SNADNS-4 and Wako Pure Chemical's Evans Blue, Bismarck Brown, *m*-Cresol Purple, and Cresol Red were dissolved in water to give suitable concentrations. Potassium bromate and hydrogen peroxide (30%) were used as oxidants. Buffer solutions were prepared according to the literature;[14] CH_3COOH/CH_3COONa (pH 3—6), Na_2HPO_4/KH_2PO_4 (pH 6—8) and Na_2CO_3/$NaHCO_3$ or Na_2CO_3/NaOH (pH 9—12).

Apparatus. The FIA manifold employed in determining cobalt(II) with Stilbazo or Pyrocatechol Violet as a chromogenic substance is shown in Fig. 1. The system was

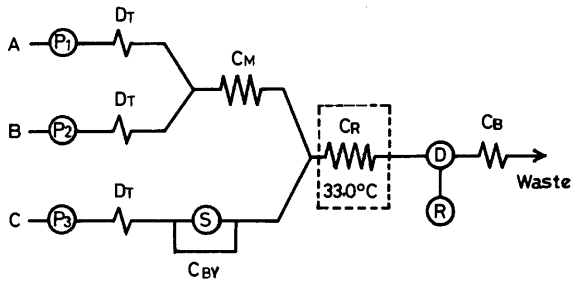

Fig. 1. Block diagram of FIA for determinations of cobalt(II) by catalytic oxidations of Stilbazo and Pyrocatechol Violet.
A: Stilbazo or Pyrocatechol Violet-hydrogen peroxide reagent solutions, B: buffer solution, C: distilled deionized water, P_1–P_3: pump, flow rates being fixed at 1 $cm^3\ min^{-1}$ (P_1), 1 $cm^3\ min^{-1}$ (P_2), and 2 $cm^3\ min^{-1}$ (P_3). D_T: damper tube(30 cm long, 2 mm i.d.), C_M: mixing coil (5 m long, 0.5 mm i.d.), C_{BY}: bypass coil (3 m long, 0.5 mm i.d.), C_R: reaction coil (4 m long, 0.5 mm i.d.), C_B: back-pressure coil(2 m long, 0.5 mm i.d.), S: sample injector(62 μl), D: detector, R: recorder.

built from Teflon tubing (i.d., 0.5 mm), Teflon connectors, two reciprocating pumps (Kyowa Seimitsu KHU-52, P_3, and KHU-W-52, double-plunger type, P_1, P_2), a spectrophotometer (Kyowa Seimitsu KLC-2290)(D), equipped with a flow-through cell (volume 8 μl, optical path-length 10 mm), a six-way loop valve injector (Seishin VHU-6)(S), and a recorder (Rikadenki R-22) (R). Elastic PVC tubes (Technicon 061 116-0536-15) of ca. 30 cm length, D_T, were placed immediately after each pump so that the pumping pulse was completely eliminated. A bypass coil, C_{BY}, which acts as a damper of sample injection shock, and a back-pressure coil, C_B, which serves to prevent the liberation of gas dissolved in reactant and carrier solutions upon heating, were incorporated into the system. The symbols, C_M and C_R, denote mixing and reaction coils, respectively.

Results and Discussion

Metal Ion-Catalized Oxidations of Organic Dyes. A suitable concentration of each chromogenic substance was prepared in pH 4 or pH 11 buffer solution in the presence of an oxidant (1.0×10^{-3} mol dm^{-3} $KBrO_3$ or 3.3% H_2O_2). To this solution a known volume of 1000 ppm metal standard solution was added with the aid of a micropipette so that the concentration of metal ion of interest became 1 ppm, and then the absorbance of the solution was followed as a function of standing time at room temperature or at an elevated temperature, if necessary. The results are summarized in Table 1. These substances listed in the Table were almost completely decolorized within 30 s in the presence of 1 ppm metal specified in the Table, while it took 30 min or more in the absence of the metal. A typical absorbance change with standing time is illustrated for Stilbazo-cobalt(II) system in Fig. 2, where the cobalt(II) concentration is lowered to 5 ppb for the sake of convenience of measuring the absorbance change with time.

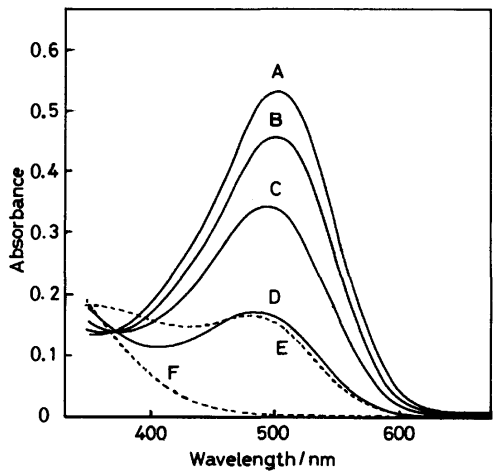

Fig. 2. Absorption spectra change with standing time. Solid line: reagent mixture of Stilbazo(1.0×10^{-5} mol dm^{-3}) and hydrogen peroxide(0.5%) at pH 11.7; A, 1.5 min; B, 15 min; C, 30 min; D, 40 min. Broken line: reagent mixture in the presence of 5 ppb cobalt at pH 11.7; E, 1.5 min; F, 15 min.

Concerning with cobalt(II) determination, Stilbazo, Pyrocatechol Violet, Pyrogallol Red, and Evans Blue are expected to be of potential utility. Among them, the first two seem better since Evans Blue is only effective at a fairly high temperature and Pyrogallol Red is of limited solubility in water.

The optimum conditions for determining trace amounts of cobalt(II) will be discussed in detail below. The experiments were carried out by using the FIA system shown in Fig. 1. The peak height recorded on a chart, which corresponds to a difference of absorbances between a metal blank and a metal-catalyzed reaction zone is a measure of analytical sensitivity.

Stilbazo Method—Effects of Operational Conditions—. The effects on the peak height were studied of such conditions as pH (9—12), concentrations of Stilbazo (4.8×10^{-5}—1.4×10^{-4} mol dm^{-3}) and hydrogen peroxide (0.05—0.6%), temperature (33, 43, 53, and 63 °C), and the FIA manifold including flow rate (P_1=P_2, 0.5—1.0 cm^3 min^{-1}; P_3, 1.0—2.0 cm^3 min^{-1}), tube length of the reaction coil (2—8 m), and sample volume (62, 91, and 110 μl). The peak height was found to (i) increase almost linearly with pH above 10, (ii) increase as the concentrations of Stilbazo and H_2O_2 increase (the peak hight become constant at Stilbazo concentrations greater than 9.6×10^{-5} mol dm^{-3} and at H_2O_2 concentrations greater than 0.15% at pH 11.9), (iii) increase by 1.4, 1.9, and 2.4 times as the temperature is raised from 33 °C to 43, 53, and 63 °C, respectively, (iv) increase with the tube length of the reaction coil to become constant at length greater than 6 m, but a longer coil tends to lead to broad peaks because of an increased axial dispersion of the sample zone, (v) increase as the flow rate decreases, but at the same time, there observed is the pronounced tailing of the peaks probably due to the adsorption of the reaction product onto the inside of the Teflon tube.

Stilbazo Method—Recommended Procedure for Cobalt(II) Determination—. Two solutions A and B are prepared; A: Stilbazo (9.6×10^{-5} mol dm^{-3})-H_2O_2 (0.15%), B: Na_2CO_3 (0.05 mol dm^{-3})-NaOH (0.006 mol dm^{-3}) mixed solution to give pH 11.9. Solutions A and B are both made to flow at the same flow rate of 1.0 cm^3 min^{-1}, while water at a flow rate of 2.0 cm^3 min^{-1}. A 62 μl portion of sample solutions which contain cobalt(II) higher than 1 ppb is injected via the loop valve injector into the carrier stream of water and mixed with the reagent stream before entering the reaction coil of 4 m which has been immersed in a thermostated bath (33 or 53 °C), and the absorbance is measured at 503 nm. A negative peak appears as a result of absorbance change due to the decolorization of Stilbazo.

Table 1. Metal Ion Catalysis in the Oxidative Decolorization of Organic Dyes

Compound examined	Oxidant	Catalyst	pH	Temperature	Color change of solution
Stilbazo 	H_2O_2	Co(II)	11	Room temp	Red ⟶ Colorless
Pyrogallol Red 	H_2O_2	Co(II)	11	Room temp	Purple ⟶ Colorless
	BrO_3^-	V(V)	4	Room temp	Orange ⟶ Colorless
Evans Blue 	H_2O_2	Co(II)	11	70 °C	Blue ⟶ Colorless
m-Cresol Purple 	H_2O_2	Cu(II)	11	70 °C	Red ⟶ Colorless
Cresol Red 	H_2O_2	Cu(II)	11	70 °C	Red ⟶ Colorless
Pyrocatechol Violet 	H_2O_2	Co(II)	11	Room temp	Violet ⟶ Colorless[a]

a) This system was studied by a batchwise technique (Ref. 15).

Stilbazo Method—FIA Responses—. Figure 3 shows typical FIA responses obtained under the recommended procedure. It will be seen that cobalt(II) down to 1 ppb can be determined. A dip is observed in front of each peak, which is caused by an injection shock. The relative standard deviation observed for analysis of 60 ppb cobalt was 0.7% (n=13), and a sampling rate of 60 samples/h was achieved.

Stilbazo Method—Interferences—. Sample solutions containing 50 ppb cobalt(II) and various concentrations of foreign ions were injected according to the recommended procedure mentioned above (the temperature of bath was set at 33 °C). The results are shown in Table 2. Zinc(II) and cadmium(II) exhibited serious interferences when present above 500 ppb. The interferences, however, were completely eliminated up to 1 ppm concentration of these metals by making a 500 ppm sodium citrate solution flow instead of water. The serious interference by EDTA is due to its stable complex formation with cobalt(II). The other ions examined have no or only slight interference so far as their concentrations do not exceed 100 to 200 times the cobalt(II) concentration.

Pyrocatechol Violet Method—Effects of Operational Conditions—. The optimum conditions were

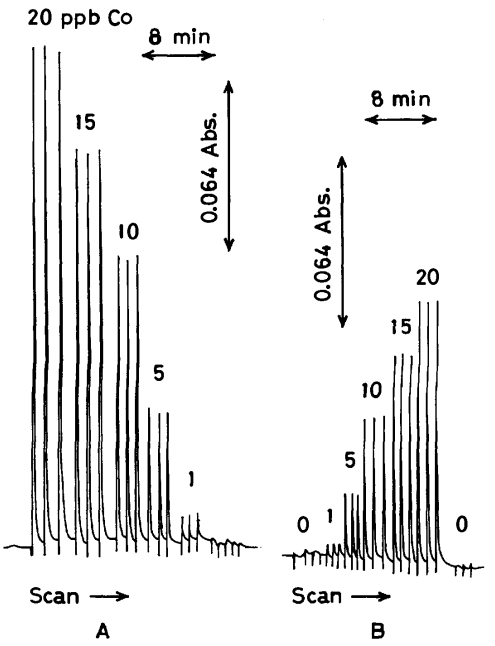

Fig. 3. Typical responses for cobalt(0–20 ppb) by FIA with Stilbazo (9.6×10^{-5} mol dm^{-3})–hydrogen peroxide(0.15%) system at 53 and 33 °C.
Experimental conditions: A, 53 °C; B, 33 °C; pH, 11.9. Other conditions and manifold as in Fig. 1.

Table 2. Effect of Diverse Ions on the Determination of 50 ppb Cobalt in the Catalytic Oxidation of Stilbazo at 33 °C

Foreign ion	Concentration/ppm	Relative error/%	Foreign ion	Concentration/ppm	Relative error/%
Al(III)	10	−4.8	Mg(II)	2	5.9
	5	0		1	3.0

	0.5	14	Citrate	50	5.5
	1	0.8*		10	0
Cd(II)	1	17	Tartrate	50	0
	0.5	9.2	Oxalate	50	9.1
	1	0*		10	0
V(V)	10	2.9	Acetate	50	0
Pb(II)	10	0	EDTA	1	−100

* These values were obtained when pumping a 500 ppm of citrate aqueous solution through the pump(P_3). A negative relative error(%) means that the peak hights of 50 ppb cobalt in the presence of the diverse ions are lower than those for 50 ppb cobalt only.

studied by changing the concentration of Pyrocatechol Violet (4.0×10^{-5}—4.0×10^{-4} mol dm^{-3}) and that of H_2O_2 (0.075—0.55%) and pH (9—12). The peak height was found to (i) increase with the concentration of Pyrocatechol Violet up to 3.0×10^{-4} mol dm^{-3} and then decrease gradually beyond this concentration, (ii) increase with H_2O_2 concentration and become constant at 0.3% H_2O_2, (iii) increase with pH and remain constant above pH 11.8, and (iv) increase by 1.4 and 1.8 times as the temperature is raised from 33 °C to 42 and 51 °C, respectively.

Pyrocatechol Violet Method—Recommended Procedure for Cobalt(II) Determination—. Two solutions A and B are prepared; A: Pyrocatechol Violet (3.0×10^{-4} mol dm^{-3})-H_2O_2 (0.3%), B: the same solution as that used in the Stilbazo method (pH=11.8). Just in the same way and at the same flow rates as the Stilbazo method, solutions A and B and water are made to flow and a 62 μl portion of sample solutions is injected and the absorbance is measured at 585 nm.

Pyrocatechol Violet Method—FIA Responses—. Figure 4 shows typical responses obtained under the recommended procedure. The sensitivity of the cobalt(II) determination is approximately in the same order as that of the Stilbazo method. The relative standard deviation observed for analysis of 25 ppb cobalt was 0.5% (n=10), and a sampling rate of 60 samples/h was achieved.

Pyrocatechol Violet Method—Interferences—. Sample solutions containing 50 ppb cobalt(II) and various concentrations of foreign ions were injected (the temperature of bath was set at 33 °C). The results are shown in Table 3. In contrast to the Stilbazo method, zinc(II) and cadmium(II) do not interfere seriously, while iron(III) and manganese(II) exhibit serious interferences. The other ions examined show only slight interferences when present 100 to 200 times the cobalt(II) concentration.

The present paper is concerned with the cobalt(II) determinations based on the catalytic oxidations of Stilbazo and Pyrocatechol Violet. We had thought that these organic substances had not been used for the cobalt(II) analysis. On writing this paper,

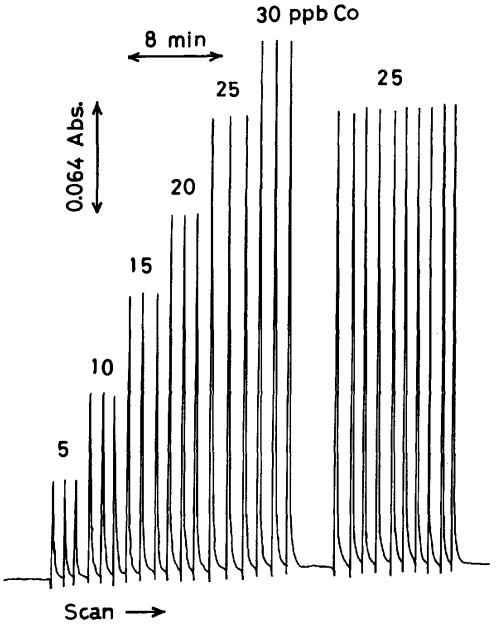

Fig. 4. Typical responses for cobalt(5—30 ppb) by FIA with Pyrocatechol Violet(3.0×10^{-4} mol dm^{-3})-hydrogen peroxide(0.3%) system at 33 °C.
Buffer solution: pH 11.8. Other conditions and manifold as in Fig. 1.

	5	−6.9	NO_3^-	50	2.3
Cu(II)	2	−2.6	SO_4^{2-}	50	3.1
	5	−8.3	Citrate	50	1.7
Pb(II)	10	−4.0	Tartrate	50	2.9
Mn(II)	2	−14	Oxalate	50	0
	5	−25	Acetate	50	1.2

A negative relative error(%) means that the peak hights of 50 ppb cobalt in the presence of the diverse ions are lower than those for 50 ppb cobalt only.

however, we found the latter reagent used for the same purpose in a batchwise technique.[15] The analytical conditions such as H_2O_2 concentration and pH are almost the same between the present work and the literature, but the concentration of Pyrocatechol Violet employed by the literature[15] is lower by one order of magnitude than the present conditions. According to the literature,[15] cobalt(II) of 0.0065 ppb can be determined. The sensitivity is higher by two orders of magnitude than that attained in the present work using FIA technique and almost comparable to that obtained based on chemiluminescence methods.[12,13] The literature method, however, seems much laborious and time-consuming since it needs measurements of reaction rates and calculations of rate constants.

The sensitivity for the cobalt(II) analysis attained in the present work using Stilbazo and Pyrocatechol Violet appears to be comparable to that reported by investigators who used aromatic chromogenic substances with two 1,3-, or 1,4-dihydroxyl group.[8]

(Received May 10, 1985)

Synopsis. The X-ray crystal structure analysis of a sulfur containing π-donor molecule, bis(ethylenedithio)-tetrathiafulvalene, (BEDT-TTF) shows that the BEDT-TTF molecule is nonplanar and that the crystal is composed of pairs of BEDT-TTF.

Recent discoveries of the superconductivities of the organic conductors based on a sulfur containing π-donor molecule, bis(ethylenedithio)tetrathiafulvalene (abbreviated as BEDT-TTF hereafter) have aroused a considerable interest.[1] The crystals of BEDT-TTF compounds show a characteristic two-dimensional (abbreviated as 2-D hereafter) array of BEDT-TTF,[2] whereas the molecular metals so far reported have 1-D stacks of planar π-donor and/or acceptor molecules. The examination of the intermolecular overlap integrals of HOMO, from which the conduction bands are formed, indicates 2-D properties of BEDT-TTF compounds.[2-4] Moreover, β-$(BEDT\text{-}TTF)_2PF_6$ has an open Fermi surface perpendicular to the direction approximately parallel to the averaged molecular plane of BEDT-TTF, which shows definitely an important role of the 2-D intermolecular interactions in the organic conductors.[5,6]

In this paper, we will report the crystal structure of the neutral BEDT-TTF molecule.

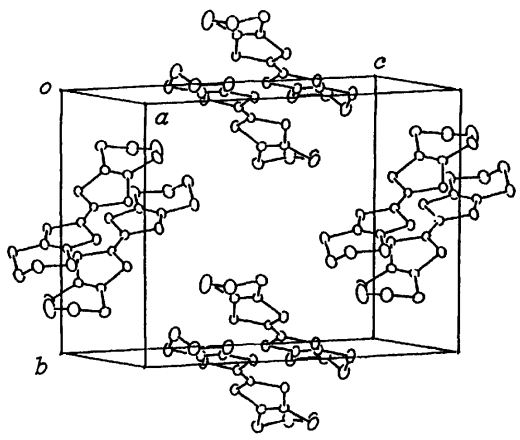

Fig. 1. The crystal structure of BEDT-TTF.

α Present address: Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106.

Results and Discussion

Crystal Data: $C_{10}H_8S_8$, M=384.7, monoclinic, space group, $P2_1/c$, a=6.614(11), b=13.985(2), c=16.646(3) Å, β=109.55(2)°, U=1449.6 Å^3, Z=4, D_x=1.76 g cm^{-3}, μ(Mo $K\alpha$)=11.6 cm^{-1}. Intensities were measured by the θ—2θ scan technique on a Rigaku automated four-circle diffractometer with Mo $K\alpha$ radiation (2θ<55°) and were corrected for usual Lorentz and polarization effects, but not for the absorption. The maximum dimension of the crystal used was 0.3 mm. The structure was solved by the direct method and refined by the least-squares procedure (currently R=0.052), using 2262 reflections ($|F_o|>3\sigma(|F_o|)$). The hydrogen atoms were refined isotropically, but the temperature factors of two of them became very large (10 Å^2 and 8 Å^2), which is probably due to the large thermal motion of the ethylene groups. Therefore, the hydrogen atoms were omitted in the final refinement. The atomic coordinates are given in Table 1.[7] The crystal structure is shown in Fig. 1.

The crystal is composed of the pairs of BEDT-TTF molecules. Similar paired structure of BEDT-TTF has also been found in the crystals of BEDT-TTF monocation salts ((BEDT-TTF)X(THF); X=ClO_4 or ReO_4).[8] The bond lengths and angles are shown in

Table 1. Atomic Parameters of BEDT-TTF

C(3)	0.4421(7)	0.2937(4)	0.0634(3)	3.3
C(4)	0.6073(8)	0.2816(4)	0.0353(3)	2.8
C(5)	−0.0354(7)	0.5356(4)	−0.2599(3)	3.3
C(6)	0.1290(7)	0.5240(4)	−0.2879(4)	2.7
C(7)	0.6767(11)	0.2173(7)	0.2197(4)	5.9
C(8)	0.8566(10)	0.2210(6)	+0.1904(4)	4.9
C(9)	−0.2893(9)	0.5803(5)	−0.4221(4)	5.8
C(10)	−0.0933(10)	0.6255(5)	−0.4309(3)	6.9

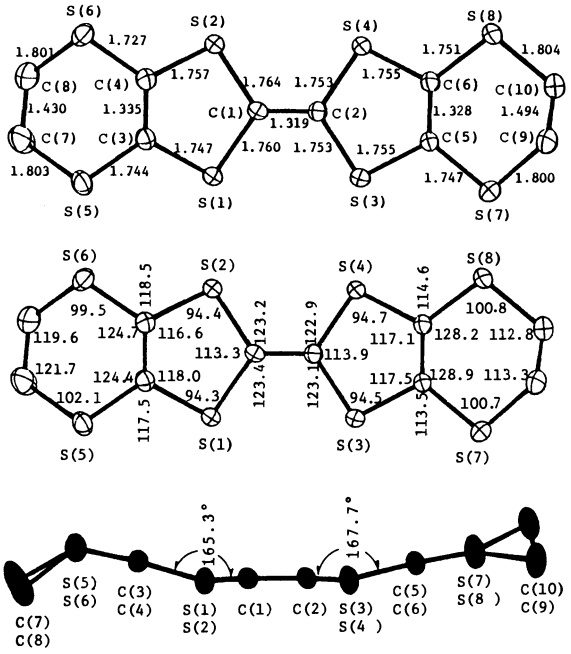

Fig. 2. Molecular structure of BEDT–TTF. Estimated standard deviations of bond lengths are 0.007—0.012 Å and those of bond angles are 0.6—1.0°.

Fig. 2. The mean bond length of C–S in the TTF skeleton is 1.751 Å and that of C=C is 1.327 Å. The structure analyses of several BEDT-TTF salts show that the C=C bonds become longer and the C–S bonds become shorter with the increasing formal charge(ρ) of BEDT-TTF$^{+\rho}$ molecule: r(C=C)=1.33 Å(ρ=0), 1.35(ρ=0.5), 1.38(ρ=1); r(C–S)=1.751(ρ=0), 1.745(ρ=0.5), 1.724(ρ=1). This is due to the symmetry of HOMO of BEDT-TTF which has nodal planes on the every C–S bond.

The BEDT-TTF molecule is nonplanar. The molecule is composed of three planes of tetrathio-substituted ethylene moieties (Fig. 2). The mode of overlapping of the paired molecules is shown in Fig. 3a. Despite of the pair structure of BEDT-TTFs, the shortest S···S distance (3.69 Å) is almost equal to the van der Waals distance (3.70 Å). Closer intermolecular contacts are found along the a axis (Fig. 3b). The sulfur atoms play a central role for the formation of the characteristic transverse intermolecular contacts. As described before, the side-by-side arrangement of BEDT-TTF is a common structural feature of the conducting BEDT-TTF salts. It is of interest that similar arrangement is also found even in the insulating neutral BEDT-TTF crystal.

Calculations were carried out partly on PANAFACOM U1300 computer of Toho University and mainly on HITAC M-200H computer at the Computer Center of The University of Tokyo, using the local version of the UNICS.[9]

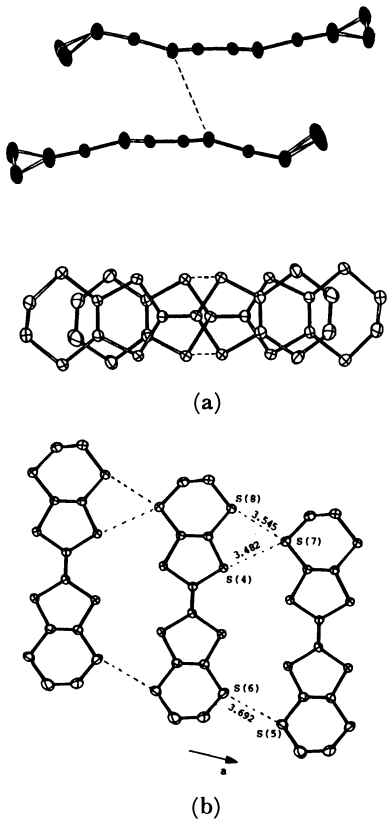

Fig. 3. (a) The mode of overlapping of the paired BEDT-TTFs. The dotted line indicates the short S···S contact (3.69 Å). (b) Molecular arrangement along the a axis.

Solid-State NMR Studies on Pillar-Interlayered Naturally-Occurring Montmorillonite

Mutsuyoshi MATSUMOTO,*,† Minoru SUZUKI, (the late) Hiroshi TAKAHASHI, and Yasukazu SAITO
Institute of Industrial Science, The University of Tokyo,
22-1, Roppongi 7-Chome, Minato-ku, Tokyo 106
(Received June 21, 1985)

Synopsis. Solid-state MAS NMR spectroscopy on naturally occurring montmorillonite has revealed that the Fe(III), contained in the octahedral layer, exerts a greater influence on octahedral Al nuclei than on tetrahedral ones. The same trend is observed in a more pronounced manner with the material intercalated with $[AlO_4Al_{12}(OH)_{24}(OH_2)_{12}]^{7+}$ cations. Mechanisms of selective peak broadening in solid-state NMR spectra are discussed.

Pillar interlayered montmorillonite (abbreviated as PILM hereafter) has attracted considerable interest since its well-defined pore structure of molecular dimension suggests promising wide applications as adsorbents[1] and catalyst supports.[2] The layer distance of PILM (ca. 0.9 nm), as determined by X-ray diffraction, is consistent with the size of $[AlO_4Al_{12}OH)_{24}(OH_2)_{12}]^{7+}$ cation introduced.[3] Direct evidence for the Al_{13} structure present in the interlayer of clay minerals was given by Plee et al.[4] with solid-state MAS ^{27}Al NMR.

The Fe(III) constituent in naturally occurring montmorillonite may exert a paramagnetic influence on solid-state MAS NMR. In the present study, Kunipia-G montmorillonites with and without the Al_{13} pillar have been examined in order to elucidate the limitation in quantitative analysis.

Kunipia-G Na-montmorillonite (abbreviated as Na-Mont), supplied from Kunimine Ind. Co., Ltd., was intercalated with Al_{13} cations and dried in an oven overnight at 393 K as previously described.[5,6] Chemical analysis was carried out by atomic absorption spectroscopy. The basal spacing was enlarged to 1.80 nm by the pillar substance, as confirmed by X-ray diffraction. Solid-state MAS ^{27}Al NMR spectra were recorded at 70.28 MHz on a JEOL FX270 NMR spectrometer. The spinning frequency of rotor was 3—4 kHz. All measurements were carried out at room temperature with $[Al(H_2O)_6]^{3+}$ as an external standard. The peak intensity was calculated by integration of the principal peak and of its spinning side bands. In deconvolving overlapping peaks, it was assumed that both the tetrahedral and octahedral Al ions would give symmetrical NMR spectra.

The crystal unit of Na-Mont is formulated according to Brindley and Sempels[7] as

$$[Na_{0.38}Ca_{0.03}Mg_{0.01}][Al_{1.59}Fe^{3+}_{0.10}Mg_{0.31}][Si_{3.86}Al_{0.14}]O_{10}(OH)_2nH_2O, \quad (1)$$

where these brackets are arranged in the order: the exchangeable cation sites, the octahedral layer ones, and the tetrahedral layer ones. As for PILM, the composition of the exchangeable cation sites is changed into

$$[(Al_{1.16}O_{0.55})^{+0.38}Ca_{0.01}Mg_{0.02}], \quad (2)$$

where the interlayered alumina is represented as

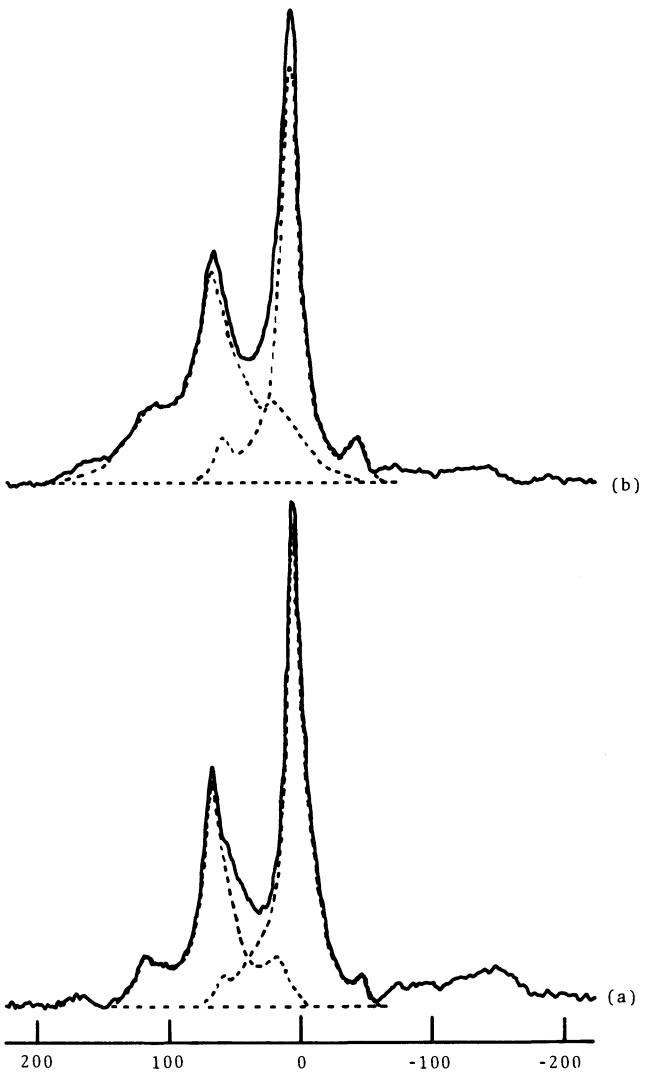

Fig. 1. Solid-state MAS ^{27}Al NMR spectra of Na-Mont (a) and PILM (b). The observed spectra are the full lines. The dotted lines are the deconvolved patterns. Resonance frequency: 70.28 MHz. Standard for δ: $[Al(H_2O)_6]^{3+}$.

† Present address: National Chemical Laboratory for Industry, 1-1, Higashi, Yatabe-machi, Tsukuba-gun, Ibaraki 305.

$(Al_{1.16}O_{0.55})^{+0.38}$.

The solid-state MAS ^{27}Al NMR spectra of Na-Mont and PILM are shown in Fig. 1 with deconvolved patterns indicated by the dotted lines. The chemical shift assignments already made for the octahedral and tetrahedral Al ions[8] are aptly applied to the peaks of 5.4 (Na-Mont) and 7.4 (PILM) ppm and of 67.0 (Na-Mont) and 66.0 (PILM) ppm, respectively.

The numbers of Al nuclei in the tetrahedral and octahedral coordinations per unit structure of Na-Mont, (Al_{tet}) and (Al_{oct}), respectively, are given from formula 1 as

$$(Al_{tet}) = 0.14, \quad (3)$$

$$(Al_{oct}) = 1.59. \quad (4)$$

The peak intensity ratio of Al_{tet}/Al_{oct} for Na-Mont should be obtained as

$$\alpha(Al_{tet})/\beta(Al_{oct}) = 0.50, \quad (5)$$

where α and β are positive coefficients which become unity when the Al nuclei involved are all detected by NMR spectroscopy. From Fig. 1, the value of β/α is obtained as 0.18. This magnitude far less than unity has certainly resulted from a rather difficult NMR detection for octahedral Al nuclei.

It is to be noted that the paramagnetic Fe(III) constituent of the naturally occurring montmorillonite is concentrated in the octahedral layer,[7] and that Al atoms are contained in the tetrahedral layer only in a small amount. Selective peak broadening due to electron-spin relaxation[9] would therefore be operative more efficiently for Al_{oct} in the same layer than for diluted Al_{tet} in a different layer.

The numbers of interlayered Al nuclei in the tetrahedral and octahedral coordinations, $\langle Al_{tet}\rangle$ and $\langle Al_{oct}\rangle$, respectively, are given from formula 2 as

$$\langle Al_{tet}\rangle + \langle Al_{oct}\rangle = 1.16. \quad (6)$$

The intensity ratio of the peak at 66.0 ppm (Al_{tet}) to that at 7.4 ppm (Al_{oct}) in Fig. 1 leads to the relationship

$$[\alpha(Al_{tet}) + \gamma\langle Al_{tet}\rangle]/[\beta(Al_{oct}) + \delta\langle Al_{oct}\rangle] = 1.3, \quad (7)$$

where γ and δ are positive coefficients not greater than unity.

The ratio of $\langle Al_{tet}\rangle/\langle Al_{oct}\rangle$ of the Al_{13} cation itself is equal to 1/12. By substituting Eqs. 3—6 in Eq. 7 we obtain

$$[\alpha(0.14) + \gamma(1/13)(1.16)]/$$
$$[\alpha(0.14)(1/0.50) + \delta(12/13)(1.16)] = 1.3, \quad (8)$$

which is simplified to

$$\delta/\gamma = 0.07 - 0.17\alpha/\gamma. \quad (9)$$

Apparently, δ/γ should be smaller than 0.07, whatever the values of α and γ may be.

Since supporting evidence for the Al_{13} structure has been obtained by solid-state NMR spectroscopy for interlayered hectorite,[4] the small magnitude of 0.07 ought to be understood in terms of the paramagnetic influence due to Fe(III) centers on the close octahedral Al nuclei of the pillar. In addition to this, the distortion factor, which has been pointed out for interlayered hectorite as becoming dominant on calcination,[4] must be taken into consideration. Moreover, any structural transformations, leading to increasing the tetrahedral sites, might occur in the pillar species partially.

Quantitative analysis of naturally occurring clay minerals by solid-state NMR spectroscopy should be undertaken with precaution against these intrinsic factors.

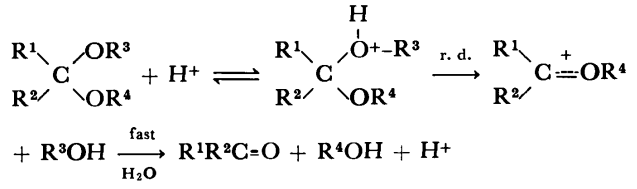
Substituent Effects in the Acid-Catalyzed Hydrolysis of Cyclic Acetals of Benzophenones

Shinya UENO, Takumi OSHIMA, and Toshikazu NAGAI*
Institute of Chemistry, College of General Education, Osaka University,
Toyonaka, Osaka 560
(Received July 18, 1985)

Synopsis. Eight 2,2-diaryl-1,3-dioxanes were prepared and the kinetic substituent effects regarding acid-catalyzed hydrolysis were studied in 80% dioxane-water(v/v) at 30 °C. The log k were well correlated with the Yukawa-Tsuno equation; log $k/k_0=-2.92(\sigma^0+0.385\Delta\bar{\sigma}_R{}^+)$($r$=0.999).

There have been numerous investigations on the acid-catalyzed hydrolysis of acetals from a mechanistic point of view.[1-3] It is generally accepted that the acetals hydrolyze by an A1 mechanism; pre-equilibrium protonation, rate-determining oxocarbenium ion formation, and fast degradation into carbonyl compound and alcohol (Scheme 1). As one part of the experimental evidence that supports the mechanism, a number of data have been collected related to kinetic substituent effects for the hydrolysis of a variety of acetals.[2] However, little is known about the cyclic acetals of benzophenones, especially with six-membered and higher ring sizes,[4] probably because of difficulties in a synthesis by traditional methods.[5]

Recently, we have discovered a facile synthetic method for cyclic and acyclic acetals of benzophenone using a redox reaction of diphenyldiazomethane(DDM) with 2,3-dichlore-5,6-dicyanobenzoquinone(DDQ) in the presence of suitable alcohols.[6-8] This discovery prompted us to synthesize cyclic acetals of benzophenones with a series of substituents and to obtain further information concerning the structure-reactivity relationship regarding the hydrolysis of acetals.



Scheme 1.

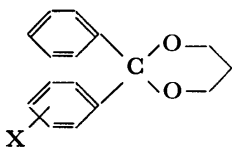
Table 1. Preparation and Hydrolysis of 2,2-Diaryl-1,3-dioxanes (**1a—h**)

Acetals	Substituents	Yields/%[a]	Mp θ_m/°C	$10^4\,k_{obsd}$ (s^{-1})[b]
1a	p-OCH_3	62	52—53	51.0
1b	p-CH_3	52	76—78	17.1
1c	m-CH_3	61	67—69	6.96
1d	p-Ph	46	154—156	4.99
1e	H	84	113—115	1.36
1f	p-Cl	55	60—61	1.13
1g	m-Cl	56	75—77	0.311
1h	m-NO_2	58	oil	0.0396

a) Isolated yields by column chromatography(Al_2O_3). b) All rates were measured in 80% dioxane-water at 30 °C under the constant HCl concentration(0.2 mol dm^{-3}).

Results and Discussion

The eight m- and p-substituted 2,2-diaryl-1,3-dioxanes (**1a—h**) were prepared and the rates of acid-catalyzed hydrolyses of these six-membered cyclic acetals were determined in 80% dioxane-water (by volume) at 30 °C (Table 1). When various values of

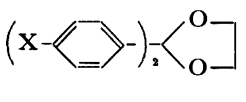


X=	X=
1a; p-OCH_3	**1e**; H
1b; p-CH_3	**1f**; p-Cl
1c; m-CH_3	**1g**; m-Cl
1d; p-Ph	**1h**; m-NO_2

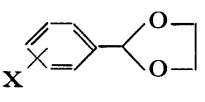
log k were correlated with the standard Hammett σ and the Brown σ^+, the σ substituent constants gave a better result (ρ=−3.10, r=0.997) than σ^+, (ρ=−2.19, r=0.974). It can be corroborated, however, that the resonance substituent effects moderately contribute to the stabilization of the transition state as evaluated from the value of the resonance reaction constant (R=0.385) in the satisfactory Yukawa-Tsuno equation.[9]

$$\log k/k_0 = -2.92(\sigma^0+0.385\Delta\bar{\sigma}_{R^+}) - 0.05 \quad (n=8,\ r=0.999)$$

In Table 2, the Hammett parameters have been collected for the hydrolysis of **1** and related cyclic acetals. The hydrolysis of **1** provided a larger negative ρ value, accompanied by increased resonance effects than that of the corresponding five-membered cyclic acetals, 2,2-diaryl-1,3-dioxolanes(**2**),[10] though a straightforward comparison is somewhat ambiguous because of the change in the solvent composition. Whereas, monoaryl substituted 1,3-dioxolanes(**3**) were more subject to both polar and resonance effects than **1**.[11]



2



3

Table 2. Hammett Parameters for Hydrolysis of **1**, **2**, and **3**

Substrates	ρ	R	No. of substituents	Solvent	r	T/C°	Ref.
1	−2.92	0.385	8	80% Dioxane	0.999	30	This work
2[a]	−2.08[b]	0.240[b]	4	20% Dioxane	0.998	25	10
3	−3.28[b]	0.457[b]	5	50% Dioxane	0.999	30	11

a) The σ^+ and σ^0 values used are the sums of the values for the two substituents. b) Original data were treated according to Yukawa-Tsuno equation.

Experimental

Materials. 1,4-Dioxane was refluxed over metal sodium and fractionated. The substituted diphenyldiazomethanes(DDMs) were synthesized by the oxidation of the corresponding benzophenone hydrazones with yellow mercury oxide as has been described.[12] Also, solid DDMs were purified by recrystallization from petroleum ether or ether. The melting points of these DDMs have been reported elsewhere.[13] The *m*-NO_2 substituted DDMs had a mp of 53—54 °C (lit,[14]; oil). The acetals (**1a—h**) were produced by a reaction of DDMs with DDQ in the presence of 1,3-propanediol according to our previous methods.[8] The structures of **1a—h** were confirmed by IR, NMR, and elemental analyses. The yields and mp are collected in Table 1.

Kinetic Measurements. The rates of hydrolysis of **1a—h** were measured in 80% dioxane-water(v/v) at a constant acid(HCl) concentration(0.200 mol dm^{-3}). The rates were measured spectrophotometrically with a JASCO UVIDEC 505 spectrophotometer by following the increase in absorption due to the benzophenone at constant temperature maintained by circulating water from a Haake constant temperature circulating bath. Pseudo-first-order rate constants (k_{obsd}) were determined from logarithmic plots of ($A_\infty - A_t$) against time. These were linear over 3 half-times.

A Novel Rearrangement of Protonated 2-Bromo-5-methylthiophene

Yukihiro YOKOYAMA, Yukihide YAMASHITA, Kensuke TAKAHASHI,* and Tyo SONE†

† Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Jonan, Yonezawa 992
(Received July 19, 1985)

Synopsis. A novel rearrangement of protonated 2-bromo-5-methylthiophene was observed in HSO_3F by means of ^1H NMR spectroscopy.

Recently we reported that well resolved ^1H NMR spectra of the cations formed from chloro- and bromothiophenes were observed in HSO_3F or HCl–$AlCl_3$-Solvent system.[1-4] We extended the observation to protonated 2-bromo-5-methylthiophene, as shown in Scheme 1. The experimental procedures were the same as those described in a previous report.[4]

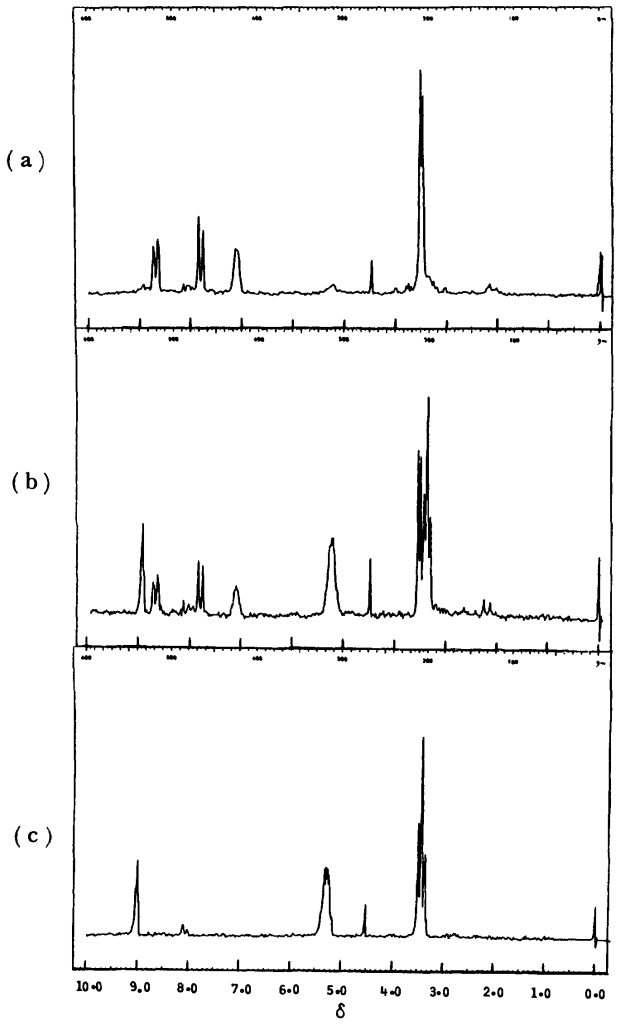

Fig. 1. ^1H NMR spectra of protonated 2-bromo-5-methylthiophene in HSO_3F at 60 MHz; (a) at −50 °C, (b) at −30 °C, and (c) at 10 °C.

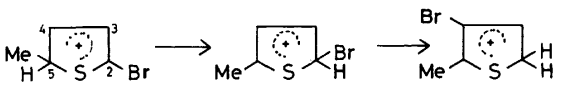
Typical examples of ^1H NMR spectra are shown in Fig. 1. The protonation of 2-bromo-5-methylthiophene gave a mixture of the two cations, 5H- and 2*H*-2-bromo-5-methylthiophenium ions at −70 °C. The former ion then underwent an irreversible 2,5-hydrogen shift and changed almost completely to the latter ion at about −50 °C (Fig. 1a), as in the case of 2-chloro-5-methylthiophenium ion.[4] When the temperature was raised to about −30 °C, however, another peculiar rearrangement appeared on the ^1H NMR spectra (Fig. 1b). This rearrangement was accomplished at about 10 °C as shown in Fig. 1c, which showed the presence of only one cation, 2*H*-4-bromo-5-methylthiophenium ion.[5] Evidence of the cation was also obtained from another route. That is, the spectral data of the cation are consistent with those observed for the cation produced from the protonation of 3-bromo-2-methylthiophene in HSO_3F, which was stable and gave an almost unchanged spectrum from −70 to 10 °C. The spectral data were also different from those obtained from the protonation of 4-bromo-2-methylthiophene in HSO_3F, which was stable from −70 to 30 °C. After the ^1H NMR measurement was carried out at 10 °C (Fig. 1c), the sample solution was poured into water and an aqueous solution was extracted by diethyl ether. Then, after the solvent was distilled off, the residue was checked by ^1H NMR. ^1H NMR spectral data were consistent with those of 2-methyl-3-bromothiophene. The spectral data of the ions are given in Table 1.

Two facts must be noted. First, the rearrangement



Scheme 1.

Table 1. ^1H Chemical Shifts of Protonated Bromomethylthiophenes in HSO_3F

Substituents	Temp °C	Chemical shift, ppm			
		2-H	3-H	4-H	5-H
2H, 2-Br, 5-Me	−50	7.11	8.68	7.80	(3.49)[a]
5H, 2-Br, 5-Me	−70	—	8.01	8.87	5.29 (2.11)
2H, 3-Br, 5-Me	−30	5.28	—	8.06	(3.31)
2H, 4-Br, 5-Me	−10	5.26	8.97	—	(3.40)

a) The values in parentheses are the chemical shifts of methyl protons.

proceeded with three clearly separated stages as given in Scheme 1 and only one species of the cation existed in a solution at a specific temperature (Fig. 1a or Fig. 1c). The mechanism of this novel rearrangement is not clear at present. However, this fact strongly suggests that the rearrangement involves an intramolecular process.[6] Second, the 2*H*-2-bromo-5-methylthiophenium ion does not rearrange to a more stable 2*H*-3-bromo-5-methylthiophenium ion, but to a 2*H*-4-bromo-5-methylthiophenium ion.

Photoinduced Hydrogen Evolution with Hydrogenase Using Bipyridinium Salts as Electron Carriers

Ichiro OKURA,* Hiroki FUJIE, Shigetoshi AONO, Tatsuya KITA, and Naruhiko KAJI
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received July 30, 1985)

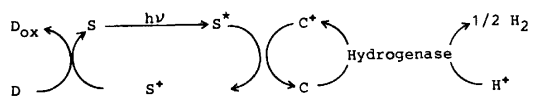
Synopsis. Photoinduced hydrogen evolution was carried out by using bipyridinium salts as electron carriers. Hydrogen evolution rate strongly depends on the type of bipyridinium salt. The order of the rate values undergoes a change by the change in the rate-determining step.

Photochemical redox systems have been proposed for solar-energy utilization.[1,2] The systems illustrated in Scheme 1, consisting of a photosensitizer (S), an electron donor (D), and an electron carrier (C), have been able to evolve hydrogen from water in the presence of hydrogenase.

The electron carrier employed almost exclusively in these studies is methylviologen, except for a few cases.[3,4] In this paper we hope to describe that some bipyridinium salts are more suitable electron carriers than methylviologen when the rate-determining step for this reaction is the photoreduction of bipyridinium salts.

Experimental

The hydrogenase from *Desulfovibrio vulgaris* (Miyazaki type) was purified according to Yagi's method.[5] The bipyridinium salts used in this experiment are listed in Fig. 1. Compounds A, B, and C were synthesized according to the literature.[6,7] The concentration of hydrogenase is not known, but it has the ability to release 19.8×10^{-6} mol of hydrogen in the following system: hydrogenase (0.5 ml)–methylviologen (1.7×10^{-4} mol dm^{-3})–$Na_2S_2O_4$ (3.8×10^{-3} mol dm^{-3}) in 6.0 ml of a 0.02 mol dm^{-3} phosphate buffer (pH 7.0) at 30 °C for 30 min. The sample solution, which consisted of zinc meso-tetraphenylporphyrintrisulfonate (Zn-TPPS$_3$), an electron carrier, 2-mercaptoethanol (RSH) as an electron donor, and hydrogenase in a phosphate buffer (pH 7.0), was deaerated by repeated freeze-pump-thaw cycles. In the photolysis with continuous irradiation, the sample in a Pyrex cell equipped with a magnetic stirrer was irradiated with light from a 200-W tungsten lamp. Light of wavelengths shorter than 390 nm was cut off by a Toshiba L-39 filter.



Scheme 1.

Results and Discussion

When an aqueous solution containing RSH, Zn-TPPS$_3$, bipyridinium salt, and hydrogenase was irradiated, hydrogen evolution at a stationary rate was observed, as is shown in Fig. 2. In these experiments an excess amount of hydrogenase was used to make the photoreduction of electron carriers the rate-determining step of the hydrogen evolution. It is evident that all the compounds shown in Fig. 1 can serve as electron carriers for photoinduced hydrogen evolution. The hydrogen-evolution rate of the system for the B electron carrier was much greater than that for methyl viologen. Under the reaction conditions where the rate-determing step of hydrogen evolution is the step of the photoreduction of electron carriers, the bipyridinium salts with low redox potentials will be favorably photoreduced. The order of the rate values, however, does not always coincide with the order of the redox potentials of the bipyridinium salts. The above results are not explained by the electrostatic effect. MV and B are positively charged, and A and C are neutral in the oxidized form. Positively charged bipyridinium salts do not always have high activity, as is shown in the case of MV. As we reported previously,[8] the back reaction (recombination of the oxidized Zn-TPPS$_3$ and reduced bipyridinium salt) may play a part in the photoinduced hydrogen evolution reaction in these systems.

By the increase in the Zn-TPPS$_3$ concentration, the rate-determining step of photoinduced hydrogen evolution is changed from the photoreduction of

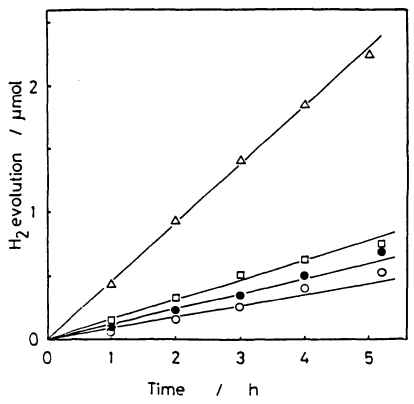

Fig. 2. Time dependence of hydrogen evolution by irradiation at 30 °C. To the solution containing RSH (2.26×10^{-1} mol dm^{-3}), Zn-TPPS$_3$ (1.00×10^{-6} mol dm^{-3}), and bipyridinum salt (8.3×10^{-5} mol dm^{-3}) 0.5 ml of hydrogenase was added and adjusted to 6.5 ml with 0.02 mol dm^{-3} phosphate buffer (pH 7.0). Bipyridinium salts are labelled in Fig. 1; ●: MV, ○: A, △: B, □: C.

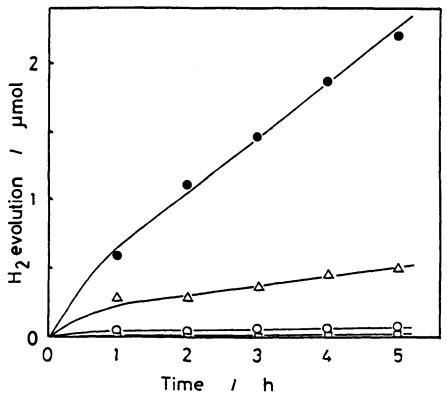

Fig. 3. Time dependence of hydrogen evolution by irradiation at 30 °C. To the solution containing RSH (2.27×10^{-1} mol dm^{-3}), Zn-TPPS$_3$ (1.00×10^{-6} mol dm^{-3}), and bipyridinium salt (8.3×10^{-5} mol dm^{-3}) 0.5 ml of hydrogenase was adjusted to 6.5 ml with 0.02 mol dm^{-3} phosphate buffer (pH 7.0). Bipyridinium salts are labelled in Fig. 1; ●: MV, ○: A, △: B, □: C.

bipyridinium salts to hydrogen evolution by reduced bipyridinium salts. Figure 3 shows the photoinduced hydrogen evolution in the region of higher concentrations of Zn-TPPS$_3$ compared with Fig. 2. In the experimental conditions of Fig. 3, it was confirmed that the rate-determining step of hydrogen evolution was the step of water reduction by reduced bipyridinium salt, for the hydrogen-evolution rate was proportional to the amount of hydrogenase used. Methylviologen shows a remarkably high activity for photoinduced hydrogen evolution. The high activity of methylviologen may be caused by the fact that methylviologen is a better substrate of the hydrogenase than are other bipyridinium salts.

From the above results, it is apparent that the photoinduced hydrogen evolution rate with the systems shown in Scheme 1 depends greatly on the type of bipyridinium salt and that the order of the rate values undergoes a change with a change in the rate-determining step.

We wish to express our appreciation to Professor Tominaga Keii and Professor Yoshio Ono for their stimulating and helpful discussions.

The Crystal Structure of a Squarylium Dye, 2,4-Bis(1,3,3-trimethyl-2-indolinylidenemethyl)cyclobutenediylium-1,3-diolate

Yoshinori KOBAYASHI,* Midori GOTO, and Masayasu KURAHASHI
National Chemical Laboratory for Industry, Yatabe-machi, Ibaraki 305
(Received August 6, 1985)

Synopsis. The crystal structure of 2,4-bis(1,3,3-trimethyl-2-indolinylidenemethyl)cyclobutenediylium-1,3-diolate has been determined. The space group is $P2_1/c$, with a=9.5115(4), b=15.712(1), c=15.174(1) Å, β=96.138(5)°, and Z=4. The molecule adopts the trans conformation.

With interest increasing in squarylium dyes as materials for effective photovoltaic devices, much attention has been paid to their solid-state structure. According to Morel et al.,[1] devices with squarylium dyes containing indoline rings have an especially high short-circuit-photocurrent yield. In order to reveal the structural feature of such compounds, an X-ray determination of the title compound (Fig. 1) was performed.

Experimental

The compound was provided by Tatsuo Sekiguchi of this laboratory. Purple needle-like crystals were obtained from a 1,2-dichloroethane solution. The cell dimensions and diffraction intensities were measured on a Rigaku AFC-4 four-circle diffractometer by using graphite-monochromated Mo $K\alpha$ radiation (λ=0.71069 Å) at room temperature. 1541 independent reflections with 2θ values up to 55° ($|F_o| \geqq 3\sigma(|F_o|)$) were used for the analysis. No correction was made for absorption.

Crystal Data: $C_{28}H_{28}N_2O_2$; M=424.54; monoclinic; space group $P2_1/c$; a=9.5115(4), b=15.712(1), c=15.174(1) Å, β=96.138(5)°; D_x=1.252 g cm^{-3} for Z=4. The structure was solved by the *MULTAN* 78 program.[2] The positions of the hydrogen atoms were obtained from the difference Fourier synthesis. The structural parameters were refined by the full-matrix least-squares method, using the *UNICS* III system.[3] Anisotropic thermal parameters were assumed for the non-hydrogen atoms, and isotropic parameters, for the hydrogen atoms. The final refinement, employing the weighting scheme of $w=(0.012|F_o|^2-0.562|F_o|+7.949)^{-1}$, led to the R value of 0.077. All the computations were carried out on a FACOM M-380 computer.

Results and Discussion

An *ORTEP* diagram[4] displaying the molecular structure is shown in Fig. 2. Table 1 lists the final atomic coordinates of the non-hydrogen atoms.[5]

The central four-membered ring (I) is planar within the limit of experimental error of 0.005 Å.

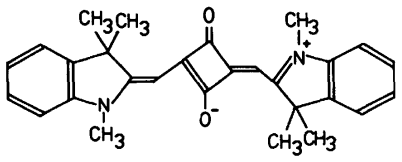

Fig. 1. One of the resonance structures of the title compound.

The indoline rings (II and III) are planar within 0.03 Å and 0.06 Å respectively. The molecule is slightly folded at the C(3) atom and is twisted along the C(16)-C(17) bond. The II and III rings make angles of 7.8° and 24.6° respectively with the I ring. The molecule is roughly planar and adopts the trans conformation.

The bond lengths of C(2)-C(3), C(3)-C(4), C(16)-C(17), and C(17)-C(18) fall in the range of those of the conjugated C-C bonds. The shorter bond lengths of N(1)-C(4) and N(2)-C(18) compared with the corresponding bonds in *N*-thioacetylindoline[6] and 3-hydroxy-2,3-diphenylindoline[7] indicate that these

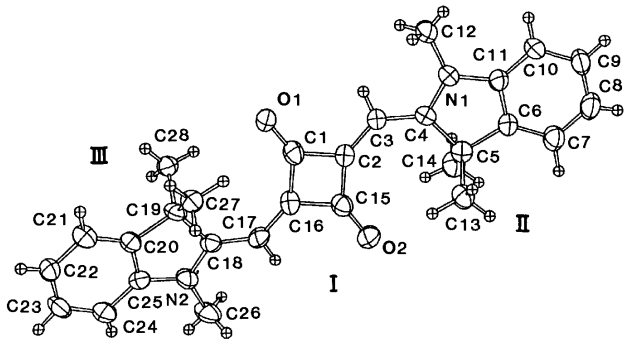

Fig. 2. Perspective view of the molecule showing the atom numbering scheme for the non-hydrogen atoms. Atoms are represented by thermal ellipsoids at 40% probability level. Hydrogen atoms are drawn at an arbitrarily small size. Selected bond lengths (l/Å) and angles (ϕ/°) are: C(2)-C(3) 1.404(12), C(3)-C(4) 1.377(12), C(16)-C(17) 1.385(12), C(17)-C(18) 1.372(12), N(1)-C(4) 1.353(11), N(2)-C(18) 1.353 (10), C(1)-C(2)-C(3) 125.1(8), C(3)-C(2)-C(15) 144.1(8), C(2)-C(4) 133.2(8), C(1)-C(16)-C(17) 143.8(8), C(15)-C(16)-C(17) 126.8(8), C(16)-C(17)-C(18) 133.1(8).

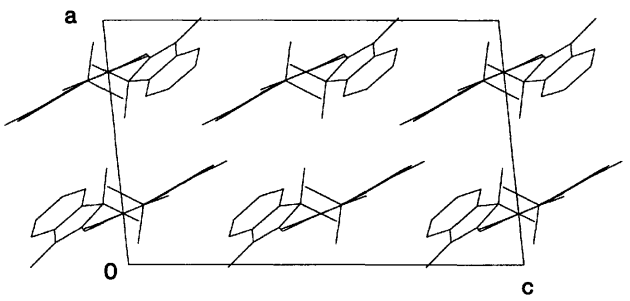

Fig. 3. Crystal structure projected along the b axis.

bonds are also involved in conjugation. The enlargement of the C(3)-C(2)-C(15), C(2)-C(3)-C(4), C(1)-C(16)-C(17), and C(16)-C(17)-C(18) angles is due to the repulsive interactions between oxygen atoms and methyl carbons, C(13), C(14), C(27), and C(28). Such interactions are suggested by the short intramolecular distances of O(1)···C(27)=3.30(1), O(1)···C(28)=3.19(1), O(2)···C(13)=3.21(1), and O(2)···C(14)=3.34(1) Å.

The crystal structure is displayed in Fig. 3. Although several short intermolecular contacts are found (O(2)···C(24)=3.27(1), C(1)···C(27)=3.51(1), and C(15)···C(28)=3.46(1) Å), the molecules are held together by van der Waals forces. The twist of the III ring from the I ring probably results from the crystal packing.

The authors would like to express their thanks to Dr. Tatsuo Sekiguchi for synthesizing the compound. They are also grateful to Drs. Yasujiro Kawabata and Kazumasa Honda for their helpful discussions.

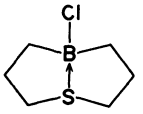
(Received September 4, 1985)

Synopsis. 5-Chloro-1-thia-5-boracyclooctane has been prepared by the hydroboration of diallyl sulfide with a chloroborane–dimethyl sulfide complex and its structure containing a sulfur–boron dative bond has been examined in detail by an X-ray crystallographic analysis.

As a part of a study on the development of useful cyclic hydroborating agents such as 9-borabicyclo-[3.3.1]nonane, 5-chloro-1-thia-5-boracyclooctane (**1**)



1

2

was synthesized. In the present paper, we wish to report on the X-ray structure determination and molecular geometry of this new heterocyclic compound.

Experimental

Preparation of 5-Chloro-1-thia-5-boracyclooctane. In a 300-ml flask cooled in a Dry Ice–acetone bath was placed a mixture of diallyl sulfide (23.0 g, 201 mmol) and pentane (100 ml). A chloroborane–dimethyl sulfide complex (200 mmol) prepared by Brown's procedure[1] was added dropwise to the vigorously-stirred solution over a period of 2 h, the temperature being kept below −20 °C. The reaction mixture was warmed to 20 °C and was stirred for another 2 h at this tempeature. After removal of the solvent, the residue was heated to 150 °C and was then distilled under reduced pressure to give 5-chloro-1-thia-5-boracyclooctane (27.56 g, 84.8% yield) as colorless crystals: Mp 50.5—51.5 °C; IR (CCl_4) 864, 1034, 1052, 1140, 1283, 1423, and 2590 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.06 (4H, t, J=7 Hz), 1.99 (4H, q, J=7 Hz), 2.59 (2H, t, J=7 Hz), and 3.02 (2H, t, J=7 Hz); MS (70 eV) m/z (%) 164 (2.85, M^+ for $BC_6H_{12}SCl^{37}$), 162 (7.65, M^+ for $BC_6H_{12}SCl^{35}$), 127 (9.85, M^+–Cl), 122 (9.94, $BC_6H_{12}SCl^{37}$-42), 120 (27.9, $BC_6H_{12}SCl^{35}$-42), and 42 (100, $CH_2CH_2CH_2$). The absence of any peak in the m/z 250—900 region indicates that this product is a monomer. Found: C, 43.70; H, 7.53; S, 19.63; Cl, 21.67%. Calcd for $BC_6H_{12}SCl$: C, 44.35; H, 7.44; S, 19.73; Cl, 21.82%.

X-Ray Measurement. A single crystal with dimensions of about 0.3×0.4×0.5 mm^3 was used. Because of the instability to air, the sample was sealed in a glass capillary tube filled with nitrogen gas. The crystallographic data were as follows: $BC_6H_{12}SCl$, mol wt 162.48, monoclinic, space group $P2_1/n$, a=11.383(7), b=11.055(5), c=6.586(5) Å, β=90.97(5)°, Z=4, D_c=1.302 g cm^{-3}, μ(Mo $K\alpha$)=6.15 cm^{-1}. The unit-cell dimensions and diffraction intensities were measured on a Rigaku four-circle diffractometer at the High-Brilliance X-Ray Laboratory of Hokkaido University, using graphite-monochromated Mo $K\alpha$ radiation. The ω—2θ scan technique was applied at an ω scan rate of 4° min^{-1}; the background was counted for 10 s at each end of the scan range. Three standard reflections, measured at intervals of every 100 reflections, showed a slight decrease in intensity with the course of data collection; the final-intensity/initial-intensity ratios were 0.93—0.94. The intensities were corrected for this damage to the sample as well as for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 50°, 1138 independent structure factors above the $3\sigma(F)$ level were selected for the structure determination.

Structure Determination

The structure was solved by the Monte Carlo direct method,[2] using the 10 reflections with the greatest $|E|$ values as the starting set. The fourth-generated random-phase set led to the correct solution; an E-map based on 301 phases revealed the locations of all the non-hydrogen atoms. The structure was refined by the block-diagonal least-squares method with anisotropic thermal parameters. After all the hydrogen atoms had been located in a difference Fourier map, further full-matrix least-squares refinements were performed including the hydrogen atoms with isotropic temperature factors and the anomalous dispersion effects of the chlorine and sulfur atoms. For these refinements, the following weighting scheme was used:

$$w=1/\{\sigma(F)^2\exp(c_1X^2+c_2Y^2+c_3XY+c_4X+c_5Y)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The c_1, c_2, c_3, c_4, and

Table 1. The Final Atomic Parameters and Estimated Standard Deviations

Atom	10^4x	10^4y	10^4z	B_{eq}[a]/Å^2

C(8)	764(4)	3571(5)	1639(7)	5.08
Cl	2315(1)	5843(1)	6195(2)	5.37

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the i-th principal axis of the thermal ellipsoid.

c_5 coefficients were evaluated from the $(\Delta F)^2$ distribution; c_1=−0.418×10^{-3}, c_2=29.8, c_3=0.241, c_4=0.388×10^{-2}, and c_5=−35.9. The final R value was 0.050. The final atomic parameters are listed in Table 1.[3]

The calculations were done on a HITAC M-280H computer at the Hokkaido University Computing Center using our own programs. The atomic scattering factors and anomalous dispersion corrections were taken from the International Tables.[4]

Results and Discussion

The obtained molecular structure is depicted in Fig. 1. The molecule has a bicyclo[3.3.0]octane skeleton where an eight-membered ring is bridged by a dative bond formed between the S(1) and B(5) atoms. As Fig. 2 shows, of the two five-membered rings, one (S(1), C(2), C(3), C(4), and B(5)) adopts an envelope conformation; the C(3) atom deviates remarkably from the C(2)–S(1)–B(5)–C(4) mean plane onto the opposite side to the C(6) and C(8) atoms. On the other hand, the remaining ring has a half-chair conformation with an approximate two-fold rotation axis through the S(1) atom; however, this conformation is not very different from the envelope one where the C(7) atom deviates from the C(8)–S(1)–B(5)–C(6) plane onto the same side as the C(2) and C(4) atoms. Accordingly, it may be said that the conformation of the present bicyclic system as a whole resembles the most stable C_s conformation of *cis*-bicyclo[3.3.0]octane (**2**).[5]

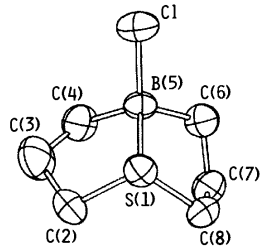

Fig. 1. A perspective view of the 5-chloro-1-thia-5-boracyclooctane molecule. Each non-hydrogen atom is represented as a thermal ellipsoid enclosing a 50% probability.

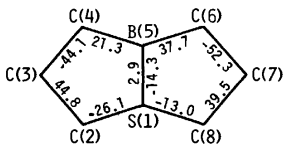

Fig. 2. The torsion angles (ϕ/°). The torsion angles relevant to atoms which form the same ring are given in the ring. The e.s.d.'s are 0.3—0.7°.

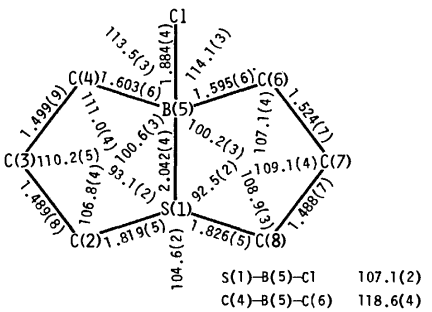

Fig. 3. The bond distances (l/Å) and angles (θ/°) and estimated standard deviations.

As Fig. 3 shows, the S(1)–B(5) bond distance is considerably longer than the S–B distances (av. 1.927 Å) in the adamantane-like compound $[CH_2(SBH_2)_2]_2$[6] in which each of the sulfur and boron atoms forms two equivalent S–B bonds. Such a long bond distance (2.04(2) Å) has already been found for the S–B dative bonds by which the two 3,4-diethyl-2,5-diiodo-1,2,5-thiadiborolene molecules form a centrosymmetric dimer.[7] The average (1.599 Å) of the B(5)–C(4) and B(5)–C(6) bond ditances lies midway between the B(sp^2)–C(sp^3) distance (1.570(4) Å) in dimethyl(methylthio)borane[8] and the B(sp^3)–C(sp^3) distance (av 1.632 Å) in lithium tetramethylborate,[9] whereas the B(5)–Cl bond distance is somewhat longer than the B(sp^3)–Cl distance (av. 1.864 Å) in boron trichloride–trimethylamine complex.[10] The S(1)–C(2) and S(1)–C(8) bond distances are almost equal to the standard S–C(sp^3) distance (1.82 Å).

Synthesis and Complexing Ability of New Type of Macrobicyclic Compounds

Yohji NAKATSUJI, Takashi KIKUI, Isao IKEDA, and Mitsuo OKAHARA*

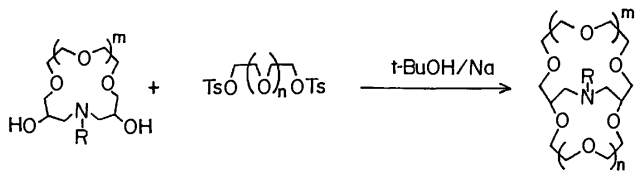
Yamada-oka, Suita, Osaka 565
(Received July 2, 1985)

Synopsis. New types of macrobicyclic compounds were synthesized from monoaza crown ethers bearing two hydroxyl groups and their complexing abilities regarding alkali metal cations were investigated.

Lipophilic monoaza crown ethers are good synthetic ionophores for the active transport of cations since they have a basic nitrogen atom as a constituent of the ring.[1] In order to improve selectivity toward a specific cation, it is necessary to design the structure of ionophores. From this viewpoint, we are reporting on the syntheses of new monoaza cryptands.[2,3]

Monoaza crown ethers (**1**)[4] bearing two hydroxyl groups, which were prepared by reactions between oligoethylene glycol diglycidyl ether and ammonia (or an appropriate primary amine), were treated with tri- or tetraethylene glycol ditosylate (**2**) in the presence of *t*-BuONa to give cryptands (**3**), generally as pale-yellow oils in fair yields (Scheme). As another route to lipophilic cryptands, *N*-unsubstituted derivatives **3a** (m=1, n=2) and **3b** (m=n=2) were easily alkylated by 1-bromodecane to afford **3h** and **3d**, respectively.

It is noteworthy that the new "Shell-shaped" cryptands **3** showed fairly good complexing abilities and selectivities in comparison with the starting crowns **1**. Derivatives with 15—17 (**3d** and **3g**) and 18—17 (**3e**) membered rings possessed selectivities



1 **2** **3**

Scheme 1.

regarding Na^+ and K^+, respectively (Table 1). A comparison of the stability constants of **3g** with those of **3d** seems to show a contribution of the electron-donating side arm to complexation.[5] Although these compounds were mixtures of stereoisomers and their separations have, so far, not been successful, the ease of preparation should be useful when they are practically used as complexing agents or carriers for a variety of cations.

Experimental

The ^{1}H-NMR spectra were taken at 100 MHz on a JEOL JNM-PS-100 spectrometer using tetramethylsilane as the internal standard. The infrared spectra were obtained on a Hitachi 260-10 spectrometer. The mass spectra were measured with a Hitachi RMU-6E mass spectrometer at an ionization potential of 70 eV.

2,5,8,11,14,17,20-Heptaoxa-23-azabicyclo[10.9.3]-tetracosane (3a): To a solution of sodium *t*-butoxide (Na: 1.0 g, 0.0435 mol) in *t*-butyl alcohol (160 ml), 1,4,7-trioxa-11-azacyclotetradecane-9,13-diol[4] (**1a**) (R=H, m=1, 4.71 g, 0.02 mol) was added and the mixture was then refluxed for 1 h. Triethylene glycol ditosylate (**2b**) (n=2, 9.17 g, 0.02 mol) in dioxane (40 ml) was added dropwise to the resulting mixture at 40 °C over a 2-h period and the mixture was further stirred for another 12 h. Insoluble matter was removed by filtration and the solvent was evaporated. The crude product was distilled in a Kugelrohr apparatus under reduced pressure (150—155 °C/0.01 Torr: 1 Torr=133.3 Pa) to give **3a** as a pale-yellow oil (2.61 g, 37%); ^{1}H-NMR ($CDCl_3$) δ=2.19 (s, 1H), 2.6—3.3 (m, 4H), 3.3—4.0 (m, 26H); MS, m/z (rel intensity) 349 (M^+, 10), 320 (9), 244 (20), 218 (20), 118 (36), 87 (58), 45 (100); IR (neat) 3320, 2855, 1455, 1350, 1245, 1100 cm^{-1}.

A Positive Halogen Mediated Ring-Opening Reaction of 2-(α-Phenylthiobenzyl)cycloalkanol Derivatives

Masateru YASUMURA,* Ken TAKAKI, Takao TAMURA, and Kenji NEGORO
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University,
Saijo, Higashi-Hiroshima 724
(Received July 4, 1985)

Synopsis. A new ring-opening reaction of the title cycloalkanols (**1** and **3**) takes place upon treatment with *N*-chloro-succinimide and triethylamine to give ω-oxo α,β-unsaturated sulfides (**2**) in fairly good yields.

Halosulfonium salts are useful synthetic intermediates and have been used in alcohol oxidation,[1] alkaloid synthesis,[2] and many other reactions. However, in spite of their fascinating properties, sulfide derivatives, having internal nucleophiles such as hydroxyl and amino groups, have rarely been employed as substrates for halosulfonium chemistry.[3] Therefore, we undertook to study a reaction of 2-(α-phenylthiobenzyl)cycloalkanol derivatives (**1** and **3**) with a positive halogen with the hope that the internal hydroxyl group would participate in the halosulfonium center and control the reaction course and stereochemistry of the reaction. In this note we wish to describe an interesting ring-opening reaction of the cycloalkanols (**1** and **3**) with *N*-chloro-succinimide.

trans-2-(α-Phenylthiobenzyl)cyclohexanol (**1c**), a 2:1 mixture of threo and erythro isomers, was allowed to react with *N*-chlorosuccinimide (NCS), followed by treatment with triethylamine to give 7-phenyl-7-phenylthio-6-heptenal (**2c**). The product was labile but isolated rapidly by MPLC in 75% yield as a mixture of (*E*)- and (*Z*)-isomers (2:1). The structure of **2c** was determined by spectral data and by a comparison with an authentic sample. The results are summarized in Table 1. Similarly, aldehydes (**2a** and **2e**) were obtained in 10 and 64% yields, respectively. The ring-opening reaction of the tertiary substrates (**1b**, **1d**, and **1f**) took place to afford ketones (**2b**, **2d**, and **2f**). In every case, the (*E*)-isomers were the major products from the *trans*-cycloalkanols (**1**) as shown in the Table 1. On the other hand, *cis*-2-(α-phenylthiobenzyl)cyclopentanol (**3a**) (threo:erythro, 1:1) and *cis*-1-methyl-2-(α-phenylthiobenzyl)cyclohexanol (**3d**) (threo:erythro, 1:3), were also converted to ω-oxo α,β-unsaturated sulfides (**2a** and **2d**) in 60 and 68% yields, respectively. Interestingly, the stereochemistry of the products was just reversed (*E*:*Z*=1:3 in both cases). Although the stereoselectivity of the present reaction is low, these results suggest that *trans*-cycloalkanols (**1**) are changed mainly to (*E*)-isomers and *cis* derivatives (**3**) mainly to (*Z*)-isomers.

Semmelhack has reported a Grob-type ring-opening reaction of *trans*-2[bis(phenylthio)methyl]-cyclohexanol derivatives by a metal catalyst to give ω-oxo α,β-unsaturated sulfides.[4] This result prompted us to carry out a reaction of bis(phenylthio)-compound (**4**) with NCS and triethylamine. The reaction gave the ketene thioacetal (**5**), in contrast to

Table 1. Synthesis of ω-oxo α,β-Unsaturated Sulfides (**2**) from 2-(α-Phenylthiobenzyl)cycloalkanol Derivatives (**1**)

the metal-catalyzed reaction in which the α,β-unsaturated sulfide (**6**) was obtained. However, the yield was low (14%, isolated), presumably due to the decomposition of the product during workup.[5]

The ring-opening reaction mediated by NCS could be explained as follows. Cycloalkanols (**1**, **3**, and **4**) are converted to five-membered oxasulfonium salts (**7**) by a reaction with NCS,[6] which undergo a cycloelimination reaction induced by α-proton abstraction[7] to give ω-oxo α,β-unsaturated sulfides (**2**) or ketene thioacetal (**5**).

5 (R^2=SPh)

Experimental

General. *IR spectra were recorded with a Hitachi* 215 using liquid films. ^{1}H NMR spectra were obtained on a JEOL PMX-60 for a solution in $CDCl_3$ with Me_4Si as the internal standard. Mass spectra were taken with a Hitachi RMU-6D at 70 eV. Microanalyses were determined on a Yanagimoto CHN-Corder.

Material. *trans*-2-(α-Phenylthiobenzyl)cycloalkanols (**1a—f**) were prepared from the corresponding cycloalkene oxides and α-lithiobenzyl phenyl sulfide[8] (≈80%). *cis*-Cycloalkanols (**3a** and **3d**) were obtained by a base-catalyzed thiophenol addition to the corresponding 2-benzylidenecycloalkanones, followed by the reaction with $NaBH_4$ or MeMgI and separation from the trans isomer in 43 and 13% yields, respectively. *trans*-2-[Bis(phenylthio)methyl]cyclohexanol (**4**) was prepared by the reaction of cyclohexene oxide with bis(phenylthio)methyllithium in 80% yield.[8]

General Procedure for the Ring Opening Reaction of 1, 3, and 4. To a stirred solution of NCS (10 mmol) in dry dichloromethane (20 ml) was added an equimolar amount of the hydroxyl sulfide (**1**, **3**, or **4**) under N_2 with cooling (−40 °C). After 3 h, triethylamine (15 mmol) in dichloromethane (5 ml) was added dropwise and allowed to react at room temperature for 3 h. The reaction mixture was quenched with brine (10 ml), extracted with ether, and dried over anhydrous magnesium sulfate. The extract was concentrated in vacuo to give a crude product (**2** or **5**), which was purified by a MPLC (SiO_2, benzene–ethyl acetate 10:1 v/v as an eluent). Several data for the purified ring-opening products, ω-oxo, α,β-unsaturated sulfides (**2a—f**) and ketene thioacetal (**5**), are shown below.

2a: IR 1730 cm^{-1}; ^{1}H NMR δ=1.42—2.87 (m, 6H), 5.93 (t, *J*=7 Hz, 0.75 H), 6.33 (t, *J*=7 Hz, 0.25 H), 6.82—7.65 (m, 10H), 9.45—9.78 (m, 1H); MS, *m/z* 282 (M$^+$). Found: C, 76.38; H, 6.32%. Calcd for $C_{18}H_{18}OS$: C, 76.56; H, 6.42%.

2b: IR 1720 cm^{-1}; ^{1}H NMR δ=1.08—2.61 (m, 9H, at δ=2.01 acetyl methyl), 6.30 (t, *J*=7 Hz, 0.67 H), 6.78 (t, *J*=5 Hz, 0.33H), 6.42—7.72 (m, 10H); MS, *m/z* 296 (M$^+$). Found: C, 76.54; H, 6.77%. Calcd for $C_{19}H_{20}OS$: C, 76.99; H, 6.80%.

2c: IR 1730 cm^{-1}; ^{1}H NMR δ=1.17—1.90 (m, 4H), 2.83—3.40 (m, 4H), 6.02 (t, *J*=7 Hz, 0.7H), 6.35 (t, *J*=7 Hz, 0.3H), 6.77—7.42 (m, 10H), 9.53—9.77 (m, 1H); MS, *m/z* 296 (M$^+$). Found: C, 76.70; H, 6.80%. Calcd for $C_{19}H_{20}OS$: C, 76.99; H, 6.80%.

2d: IR 1715 cm^{-1}; ^{1}H NMR δ=1.27—2.80 (m, 11H, at δ=2.07 acetyl methyl), 6.03 (t, *J*=7 Hz, 0.75H), 6.35 (t, *J*=7 Hz, 0.25H), 7.00—7.42 (m, 10H); MS, *m/z* 310 (M$^+$). Found: C, 77.17; H, 7.11%. Calcd for $C_{20}H_{22}OS$: C, 77.38; H, 7.14%.

2e: IR 1730 cm^{-1}; ^{1}H NMR δ=1.12—1.92 (m, 6H), 1.92—2.78 (m, 4H), 6.05 (t, *J*=7.5 Hz, 0.6H), 6.35 (t, *J*=7.5 Hz, 0.4H), 6.92—7.40 (m, 10H), 9.55—9.75 (m, 1H); MS, *m/z* 310 (M$^+$). Found: C, 77.38; H, 7.13%. Calcd for $C_{20}H_{22}OS$: C, 77.38; H, 7.14%.

2f: IR 1715 cm^{-1}; ^{1}H NMR δ=0.86—2.73 (m, 13H, at δ=2.07 acetyl methyl), 6.06 (t, *J*=7 Hz, 0.6H), 6.36 (t, *J*=7 Hz, 0.4H), 6.73—7.66 (m, 10H); MS, *m/z* 324 (M$^+$). Found: C, 77.70; H, 7.42%. Calcd for $C_{21}H_{24}OS$: C, 77.73; H, 7.45%.

5: IR 1720 cm^{-1}; ^{1}H NMR δ=1.35—1.81 (m, 4H), 2.20—2.64 (m, 4H), 6.23 (t, *J*=7.4 Hz, 1H), 7.07—7.40 (m, 10H), 9.62 (t, *J*=1.5 Hz, 1H); MS, *m/z* 328 (M$^+$), Found: C, 69.29; H, 6.14%. Calcd for $C_{19}H_{20}OS_2$: C, 69.47; H, 6.14%.

Preparation of Authentic Samples 2c and 5. An authentic sample of **2c** was synthesized by the Peterson olefination of aldehydic acid ester ($EtO_2C(CH_2)_4CHO$) with α-phenylthio-α-(trimethylsilyl)toluene ($PhSCH(SiMe_3)Ph$)[9] and butyllithium (30%), followed by reduction ($LiAlH_4$) (80%) and PCC oxidation (80%): (Z)-**2c** (δ=6.35) predominated over *E*-isomer (δ=6.02) (9:1). Similar sequence using $(PhS)_2CHSiMe_3$[11] gave an authentic sample of **5** (δ=6.23) in 23% yield.

Thermal Dimerization of 10-Methyleneanthrone

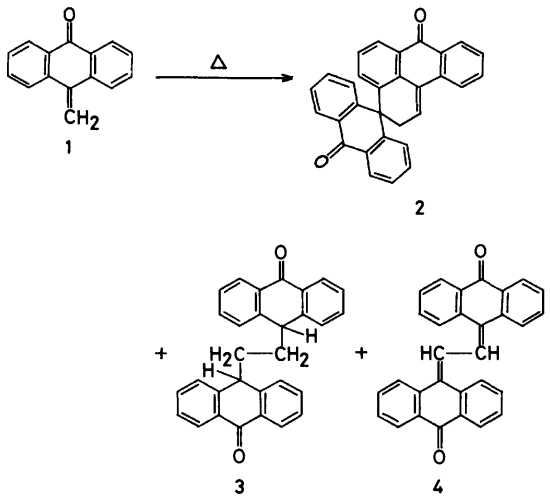
Kiyoichi HIRAKAWA,* Eriko OGIUE, Jiro MOTOYOSHIYA, and Toshio KAKURAI
Department of Chemistry, Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386
(Received July 15, 1985)

Synopsis. The thermal reaction of the title compound (**1**) gave three dimeric products which were formed via a path involving two competitive reactions, Diels-Alder and radical dimerization.

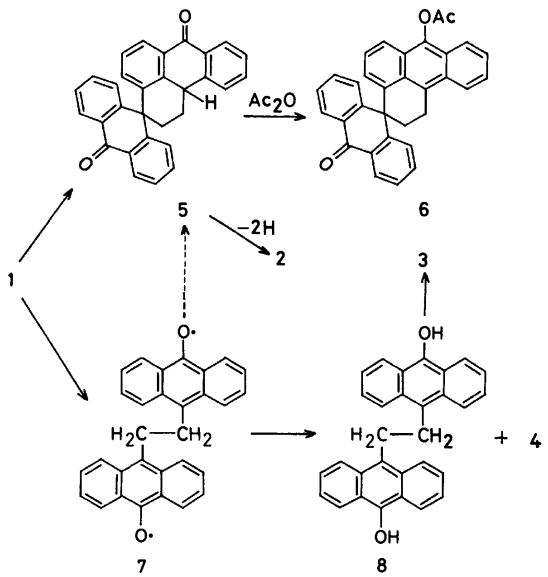
10-Methyleneanthrone (**1**) is a certain member of a class of compounds which are called "quinone methides." This system is, as a rule, unstable and is subject to reactions which form dimers, trimers, and polymers, because of the possibility that the aromatization of the cyclohexadienone portion of the molecule might supply a strong driving force for reactions.[1] However, **1** is stable and shows no tendency toward spontaneous aromatization under ordinary conditions. Such a low probability of the central ring's becoming aromatic makes its quinone methide character weak. For that reason, its chemistry has received much attention. It has been known that the base-[2] and phosphite-induced,[3,4] autoxidative,[3,5] and ketone-sensitized photochemical reactions[6] of **1** give Diels-Alder dimeric products, a dimeric peroxide, and a reductive dimeric product, respectively. Also, we previously reported that the acid-induced reaction of **1** leads to a dimeric dispiro compound, which thermally rearranged with a synchronous ring expansion.[7,8] We investigated the previously unnoticed thermal reaction of **1** and found that it undergoes thermal dimerization.

Heating compound **1** without solvent at 150 °C led to dimeric products, spiro[anthrone-10,3′(2′*H*)-benz[*de*]anthrone] (**2**), 10,10′-(1,2-ethanediyl)bisanthrone (**3**), and 10,10′-(1,2-ethanediylidene)bisanthrone (**4**) in 27, 12, and 4% yields, respectively. In a similar treatment at 180 °C, red and violet products (formulas $C_{46}H_{26}O_3$ and $C_{62}H_{34}O_4$) were obtained bisides the dimeric products, but have not yet been identified. Compounds **2** and **4** were identified by a comparison with authentic samples.[6,7] **3** was isolated as the keto rather than the enol-tautomer, the structure of which was confirmed by comparison with a sample prepared independently by the acid-induced hydrolysis of 10,10′-(1,2-ethanediyl)bis[9-anthracenol] diacetate, the reductive acetylation product of **1** with zinc and acetic anhydride. The IR spectrum of **3** indicates absorption for the carbonyl group (1665 cm^{-1}) and no hydroxy function. Its ^1H NMR spectrum reveals a triplet of H-10 and −10′ (δ 1.48). A heat treatment of **1** in refluxing xylene gave only **2**; **1** in refluxing *o*-dichlorobenzene yielded **2** along with minor products **3** and **4**. Anthraquinone was isolated in all runs and resulted from the autoxidation of **1**.

A conceivable mechanism for the thermal reaction of **1** is shown in the scheme. There would be two



competing reactions in which **1** could be consumed. One is a Diels-Alder dimerization in which **1** behaves both as a dienophile and as a diene, followed by an isomerization to **5**. Compound **5** is unstable and leads to **2** by autoxidation.[7] The other is dimerization involving the formation of biradical **7** whose disproportionation leads to **8** and **4**. Compound **8** isomerizes to a more stable keto-tautomer **3**.[9] The Diels-Alder dimerization was predominant to the radical one. The former path is supported by the following facts. The reaction of **1** in a low-boiling-point solvent such as xylene gave only **2** and in acetic anhydride afforded only **6**, acetate of **5**. Thus, at a reaction temperature below



ca. 140 °C, **1** undergoes the Diels-Alder dimerization (exclusively). No ESR signal was detected in the reaction mixture of **1** while refluxing xylene and acetic anhydride under nitrogen. Also, **3** was not detected in any reaction products at 140 °C even in a solvent labile on hydrogen abstraction, such as decalin. Therefore, it seems unlikely that the formation of **2** involves an alternative path via the intramolecular cyclization of **7** to **5**. The latter would readily be rationalized both by the formation of **3** and **4** and by the concomitant appearance of a multiline ESR signal which might be attributable to **7** in the thermal reaction of **1** without solvent under nitrogen.

10-Methyleneanthrone (**1**) behaves as a quinone methide as well as an olefin (diene or dienophile). Such a fact shows the comparative isolation of the ethylenic bond from the carbonyl group in the molecule.

Experimental

Thermal Reaction of 10-Methyleneanthrone (1). (a) Without solvent. Finely ground **1**[3] (2.06 g,10 mmol) was heated at its melting point (148 °C) in a sealed test tube for 15 min. The reaction mixture was chromatographed on silica with benzene and then with chloroform. The first fraction (benzene) contained anthraquinone (0.04 g, 2%). The second (benzene) consisted of spiro[anthrone-10,3′(2′*H*)-benz[*de*]anthrone] (**2**) (0.55 g, 27%), light yellow microcrystals (from benzene-hexane), mp 298—300 °C, identical with an authentic specimen.[7] The third (benzene) afforded 10,10′-(1,2-ethanediyl)bisanthrone (**3**) (0.24 g, 12%), colorless microcrystals (from chloroform-hexane), mp 249—251 °C (lit,[6] 245—246 °C), identical with an authentic specimen prepared independently by the method described below. The fourth eluate (chloroform) gave 10,10′-(1,2-ethanediylidene)bisanthrone (**4**) (0.08 g, 4%), orange-red microcrystals (from chloroform), mp 290—292 °C, identical with an authentic specimen.[10]

(b) In an inert solvent. A solution of **1** (1.03 g, 5 mmol) in xylene, *o*-dichlorobenzene, or decalin (30 ml) was heated under nitrogen for 30 h. The solvent was distilled off under reduced pressure, and the residue was chromatographed on silica. The results of analyses of the isolated products are as follows. The product mixture from the reaction of **1** in xylene (bp of the solution: 141 °C) gave **1** (70%) and **2** (7%). *o*-Dichlorobenzene (at 181 °C): **1** (42%), **2** (10%), **3** (1%), and **4** (trace). Decalin (at 140 °C): **1** (68%) and **2** (6%). Decalin (at 191 °C): **1** (47%), **2** (9%), **3** (1%), and **4** (trace).

(c) In acetic anhydride. A solution of **1** (1.03 g, 5 mmol) in acetic anhydride (30 ml) was heated under reflux for 1 d (bp of the solution: 139 °C). After cooling, the resulting mixture was poured into water. The crystals were collected, washed with water, and chromatographed (benzene as eluant). The first fraction gave unchanged **1** (0.85 g, 82%), and the second afforded 7′-acetoxy-1′,2′-dihydrospiro[anthrone-10,3′-[3*H*]benz[*de*]anthracene] (**6**) (0.11 g, 11%) as yellow microcrystals, mp 282—283 °C, identical with an authentic specimen.[7]

Preparation of 3. A mixture of **1** (2.06 g, 10 mmol) and zinc dust (6 g) in acetic anhydride (40 ml) was stirred and heated under reflux for 5 h. The hot mixture was filtered, and the filtrate was poured into water; the precipitate was chromatographed on silica (benzene as eluant). The first eluate afforded 9-acetoxy-10-methylanthracene (0.03 g, 1%) as light yellow needles, mp 167—169 °C (lit, 167 °C), identical with an authentic specimen.[11] The second gave 10,10′-(1,2-ethanediyl)bis[9-anthracenol] diacetate (2.17 g, 87%), light yellow needles, mp 300—302 °C (lit,[6] 295—297 °C).

A solution of the diacetate (**1**.00 g, 2 mmol) in sulfuric acid (20 ml) was allowed to stand at room temperature for 30 min. The mixture was poured into ice water (200 g), and the precipitate was collected and washed with water. Recrystallization from chloroform-hexane gave **3** (0.67 g, 81%) as colorless microcrystals, mp 261—262 °C. Its spectral data were identical to those of a specimen of **3** obtained from the ketone-sensitized photochemical dimerization of **1**.[6]

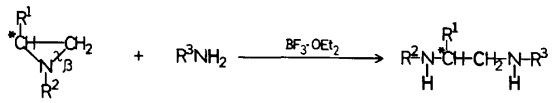
Preparation of Optically Active Piperazines from Ethyl (*S*)-2-(2-Alkyl-1-aziridinyl)acetates

Nobuhide YAHIRO* and Shigekazu ITO
Department of Industrial Chemistry, Chiba Institute of Technology,
Tsudanuma, Narashino, Chiba 275
(Received August 8, 1985)

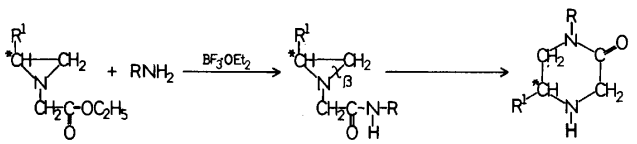
Synopsis. Reaction of ethyl (*S*)-2-(2-alkyl-1-aziridinyl) acetates with boron trifluoride etherate in a large excess of ethylamine or ammonia gives the corresponding optically active piperazines in good yields. These piperazines retain the configuration of the starting aziridines.

Optically active piperazine derivatives are usually prepared by dimerization of optically active aziridines,[1] by optical resolution of racemic piperazines,[2] or by cyclization of optically active amino acid derivatives,[3,4] but these processes are inconvenient because they involve complicated procedures. It was reported[5] that optically active aziridines react with amines under the catalytic action of boron trifluoride etherate ($BF_3 \cdot OEt_2$) to give optically active diamines:



R^1; C_2H_5, *i*-C_4H_9, R^2; H, C_2H_5, R^3; H, C_2H_5

The ring-opening reaction of an optically active aziridine (R^2=alkyl) with a nucleophilic reagent was found to proceed by β-cleavage (CH_2–N) to give the corresponding diamine retaining the configuration of the starting aziridine.[6,7] If ethyl (*S*)-2-(2-isobutyl-1-aziridinyl)acetate (**1**) is used in the above reaction, 3,6-diaza-1-ethoxy-4-isobutyl-1-octanone (R^1=*i*-C_4H_9, R^2=$CH_2COOC_2H_5$, R^3=C_2H_5) is expected to be produced. But the reaction of **1** with a large excess of ethylamine was found to give (*S*)-*N*-ethyl-2-(2-isobutyl-1-aziridinyl)acetamide (**2**) and (*S*)-1-ethyl-5-isobutyl-2-piperazinone (**3**) but no optically active diamines. In a similar procedure, optically active 2-(2-isobutyl-1-aziridinyl)acetamide (**4**) and 5-isobutyl-2-piperazinone (**5**) were prepared from **1** and ammonia:

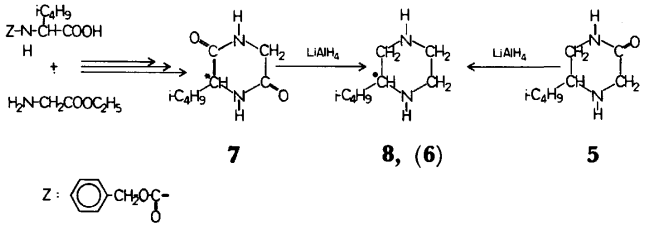


R^1=*i*-C_4H_9, **1**
R^1=C_2H_5, **9**

R^1=*i*-C_4H_9, R=C_2H_5, **2**
R^1=*i*-C_4H_9, R=H, **4**
R^1=R=C_2H_5, **10**

R^1=*i*-C_4H_9, R=C_2H_5, **3**
R^1=*i*-C_4H_9, R=H, **5**
R^1=R=C_2H_5, **11**

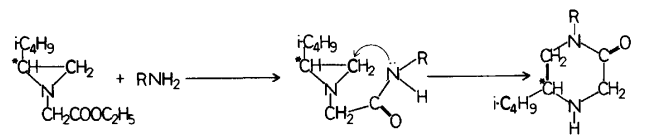
The configuration and structure of **5** were confirmed by direct comparison with an authentic sample. Optically active 2-isobutylpiperazine (**6**) was prepared by the reduction of **5** with lithium aluminium hydride ($LiAlH_4$). To determine the stereochemistry of **6**, (*S*)-2-isobutylpiperazine (**8**) was prepared by the reduction of (*S*)-3-isobutyl-2,5-piperazinedione (**7**)[3] with $LiAlH_4$:



7 **8**, (**6**) **5**

Z:

Compounds **6** and **8** showed identical ORD, CD, and IR spectra and retention times in GLC. **6**: ORD (MeOH) $[\Phi]_{205}$ +2790° and $[\Phi]_{220}$ +320°, in a positive simple dispersion curve; CD (MeOH) $[\theta]_{205}$ −350 and $[\theta]_{220}$ −110, in a negative simple dispersion curve; $[\alpha]_D^{15}$ +7.0° (*c* 2.33, EtOH); IR (neat) 3225 and 1520 cm^{-1}. **8**: ORD (MeOH) $[\Phi]_{205}$ +2850° and $[\Phi]_{220}$ +320°, in a positive simple dispersion curve; CD (MeOH) $[\theta]_{205}$ −360 and $[\theta]_{220}$ −110, in a negative simple dispersion curve; $[\alpha]_D^{15}$ +6.8° (*c* 1.07, EtOH); IR (neat) 3225 and 1520 cm^{-1}. In due course of these experiments, an effort was made in vain to determine the configuration and structure of piperadinones **3** and **5** since neither of these isomers was formed as expected. On the other hand, the reaction of **2** with $BF_3 \cdot OEt_2$ in a large excess of ethylamine was found to give **3** in a good yield. The fact that **2** and **4** gave optically active **3** and **5** with retained configuration, respectively, suggests occurrence of an intramolecular nucleophilic displacement of an intermediate acetamide derivative:



R; H, C_2H_5

Similarly, (*S*)-*N*-ethyl-2-(2-ethyl-1-aziridinyl)acetamide (**10**) and (*S*)-1,5-diethyl-2-piperazinone (**11**) were prepared from ethyl (*S*)-2-(2-ethyl-1-aziridinyl) acetate (**9**) and ethylamine.

Experimental

Materials. Ethylamine, ammonia, and $BF_3 \cdot OEt_2$ were commercial materials and were purified before use. (*S*)-2-Isobutylaziridine, with $[\alpha]_D^{25}$ −19.6° (*c* 2.02, EtOH) and bp 127—130 °C, was converted to **1**, with yield 89%, $[\alpha]_D^{25}$ +23.6° (*c* 2.63, EtOH), and 109—111 °C/17 mmHg (1 mmHg=133.322 Pa), by treating it with ethyl chloroacetate and triethylamine.[8] In a similar procedure, **9** was prepared by the reaction of (*S*)-2-ethylaziridine, with $[\alpha]_D^{25}$ −23.0° (*c* 1.54, EtOH) and bp 89—90 °C, with ethyl chloroacetate. **9**: yield 86%; bp 87—90 °C/18 mmHg; $[\alpha]_D^{25}$ +4.5° (*c* 1.02, MeOH).

Amide and Piperazine Derivatives. A large excess of ethylamine (5.4 g, 0.12 mol) and **1** (3.7 g, 0.02 mol) were placed in a stainless steel tube cooled in a Dry Ice–methanol bath, and $BF_3 \cdot OEt_2$ (0.4 cm^3) was added to the mixture. The stainless steel tube was sealed and allowed to stand at 95—98 °C. After 72 h, the reaction mixture was dissolved in benzene and washed with 10% sodium hydroxide solution. The organic layer was dried over anhydrous magnesium sulfate and the solution was distilled under reduced pressure. The product **3** (2.8 g, 76%) was obtained as colorless liquid: $[\alpha]_D^{25}$ +79.0° (*c* 0.61, EtOH); bp 106—107 °C/2 mmHg, ORD (MeOH) $[\Phi]_{300}$ +730°, $[\Phi]_{248}^{peak}$ +1880°, $[\Phi]_{243}^{trough}$ +1840°, and $[\Phi]_{220}$ +11800°, in a positive abnormal dispersion curve; CD (MeOH) $[\theta]_{223}^{trough}$ −3700 with crossover point 217 nm; IR (neat) 3275, 2940, 1635, 1496, 1465, 1430, 1304, 1213, 1164, and 791 cm^{-1}. Calcd for $C_{10}H_{20}N_2O$: C, 65.18; H, 10.94; N, 15.20%. Found: C, 64.87; H, 10.96; N, 15.19%.

In a similar procedure, **2** was prepared by the reaction of **1** with ethylamine at room temperature for 24 h. From the crude mixture (**2** and **3**), **2** was obtained by a fractional distillation: yield 54%; bp 78—80 °C/1 mmHg, $[\alpha]_D^{20}$ +31.9° (*c* 1.40, EtOH); ORD (MeOH) $[\Phi]_{300}$ +110° and $[\Phi]_{215}$ +2250°, in a positive simple dispersion curve; CD (MeOH) $[\theta]_{210}^{trough}$ −1350; IR (neat) 3300, 3050, 2960, 1650, 1535, 1332, 1293, 1251, 1168, and 828 cm^{-1}. Calcd for $C_{10}H_{20}N_2O$: C, 65.18; H, 10.94; N, 15.20%. Found: C, 64.68; H, 10.95; N, 15.33%. Compounds **4** and **5** were prepared from **1** and ammonia in similar procedures. Each product was purified by column chromatography (developing solvent MeOH/acetone) on silica gel. **4**: yield 58%; mp 78—81 °C; $[\alpha]_D^{20}$ +42.1° (*c* 0.27, MeOH); ORD (MeOH) $[\Phi]_{300}$ +570° and $[\Phi]_{215}$ +1580°, in a positive simple dispersion curve; CD (MeOH) $[\theta]_{216}^{trough}$ −650 with crossover point 205 nm; IR (KBr) 3390, 3180, 3045, 2950, 1630, 1463, 1412, 1396, 1327, 1234, 1170, 867, 782, and 705 cm^{-1}. **5**: yield 42%; mp 77—79 °C, $[\alpha]_D^{20}$ +80.9° (*c* 0.21, MeOH); ORD (MeOH) $[\Phi]_{300}$ +430°, $[\Phi]_{263}^{peak}$ +810°, $[\Phi]_{242}^{trough}$ +680°, and $[\Phi]_{220}$ +9800°, in a positive abnormal dispersion curve; CD (MeOH) $[\theta]_{221}^{trough}$ −5650 with crossover point 214 nm; IR (KBr) 3210, 2945, 1692, 1653, 1493, 1462, 1365, 1117, 916, 830, and 786 cm^{-1}. Calcd for $C_8H_{16}N_2O$: C, 61.51; H, 10.32; N, 17.93%. Found: C, 61.08; H, 10.34; N, 18.01%.

Compounds **10** and **11** were prepared from **9** and ethylamine. **10**: yield 65%; bp 88—89 °C/4 mmHg; $[\alpha]_D^{20}$ +11.2° (*c* 0.91, EtOH); ORD (MeOH) $[\Phi]_{300}$ +70° and $[\Phi]_{215}$ +1340°, in a positive simple dispersion curve; CD (MeOH) $[\theta]_{213}^{trough}$ −790; IR (neat) 3375, 3048, 2960, 1652, 1534, 1375, 1295, 1253, 1168, and 828 cm^{-1}. **11**: yield 70%, bp 104—105 °C/3 mmHg; $[\alpha]_D^{20}$ +82.8° (*c* 1.44, EtOH); ORD (MeOH) $[\Phi]_{300}$ +450°, $[\Phi]_{247}^{peak}$ +1150°, $[\Phi]_{243}^{trough}$ +1100°, and $[\Phi]_{220}$ +7200°, in a positive abnormal dispersion curve; CD (MeOH) $[\theta]_{223}^{trough}$ −2250 with crossover point 215 nm; IR (neat) 3290, 2965, 1637, 1496, 1458, 1430, 1305, 1215, 1171, 830, and 791 cm^{-1}. Calcd for $C_8H_{16}N_2O$: C, 61.51; H, 10.32; N, 17.93%. Found: C, 61.03; H, 10.39; N, 18.16%.

Reduction of 7. A solution of **7** (1.7 g, 0.01 mol) in 25 cm^3 of diethyl ether was added to a diethyl ether solution (25 cm^3) of $LiAlH_4$ (0.43 g, 0.011 mol) at 0 °C. The mixture was stirred for 48 h and the reaction was terminated by adding water. The organic layer was dried over anhydrous magnesium sulfate and the solution was concentrated under reduced pressure. The product **8** was purified by sublimation: yield 64%; mp 85—87 °C (hygroscopic); $[\alpha]_D^{15}$ +6.8° (*c* 1.07, EtOH).

The authors are grateful to Professor Masaya Yanagita for his valuable discussion and comments. This work was partially supported by a Grant-in-Aid for Scientific Research No. 60750846 from the Ministry of Education, Science and Culture.

(Received August 31, 1985)

Synopsis. To prepare L-Tyr(Me) and L-Amp (L-2-amino-5-(*p*-methoxyphenyl)pentanoic acid), their precursors cyclo(-⊿Tyr(Me)-L-Ala-) and cyclo(-⊿Amp-L-Ala-) were hydrogenated in *N,N*-dimethylformamide. The content of LL isomers in the hydrogenated products was over 94%. Mild acid hydrolysis of the hydrogenated products and subsequent recrystallization gave pure L-Tyr(Me) and L-Amp.

Unusual aromatic amino acids L-Tyr(Me)[1] and L-Amp were found in puromycin[2] and Cyl-2,[3] and AM-toxin I,[4] respectively. Both amino acids had been synthesized by us and others.[5-7] However, preparation of Ac-DL-Amp and its enzymatic resolution in the synthesis of L-Amp were troublesome and time-consuming.[7] Recently we developed a simple method for preparation of optically pure α-amino acids by asymmetric hydrogenation of cyclo(-⊿aminoacyl-L-aminoacyl-),[8] and could prepare L-2-amino-5-phenylpentanoic acid which is a constituent of AM-toxin II and its homologs in moderate yields.[9] Therefore, we intended to apply the method for preparation of L-Tyr(Me) and L-Amp. Some modification, however, seemed necessary because the method contained acid hydrolysis in the final step which might cause partial decomposition of the methoxy moiety of the L-Tyr(Me) and L-Amp side chains.[7]

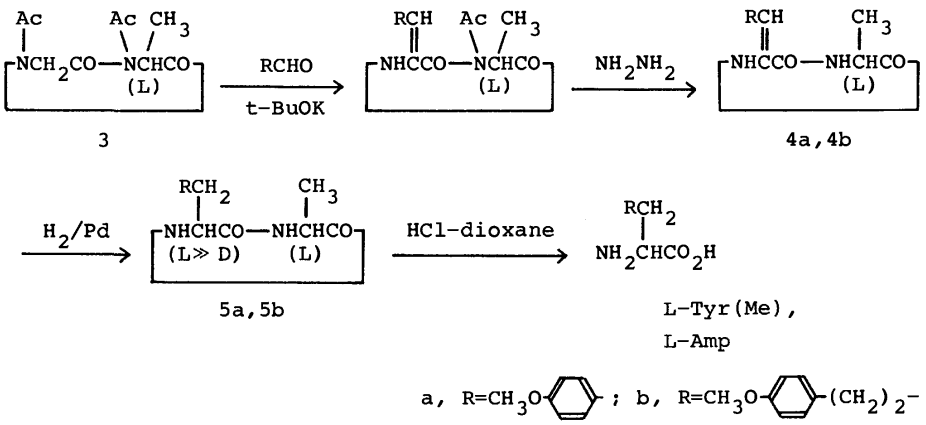
We investigated hydrolytic conditions of cyclo(-L-Tyr(Me)-L-Ala-) (**1**) using the mixture of 1—6 M HCl (1 M=1 mol dm^{-3}) and dioxane[10] as a preliminary experiment. As shown in Table 1, the conditions of 1 M HCl-dioxane (1:1), 110 °C and 72 h were adequate for **1**. Almost complete hydrolysis and negligible demethylation of the Tyr(Me) residue were observed. The conditions selected for cyclo(-L-Amp-L-Ala-) (**2**) were 0.5 M HCl-dioxane (1:1), 110 °C and 96 h.

Scheme 1 shows the route for preparation of L-Tyr(Me) and L-Amp. Compound **3** was converted into **4a** in 52% and **4b** in 40%, respectively. According to our previous papers,[8,9] Pd black and DMF were used for hydrogenation, and chiral induction (%) in hydrogenation was determined by HPLC. While the chiral induction of cyclo(-⊿phe-L-Ala-) was previously found to be of temperature dependence,[9] **4a** showed unexpectedly uniform chiral induction of about 95% between 0 °C and 50 °C. The high chiral induction of 97% at 20 °C was observed in the case of **4b**. Acid hydrolysis of the hydrogenated products (**5a** and **5b**) under the conditions found above followed by neutralization of the hydrolysates gave crude products. Pure L-Tyr(Me) and L-Amp were obtained after recrystallization in 66% from **4a** and 56% from **4b**, respectively. The total yield (34%) of L-Tyr(Me)

Table 1. Hydrolysis and Demethylation of Cyclo(-L-Tyr(Me)-L-Ala-)

Solvent	Time	Hydrolysis	Demethylation
	h	%	%
6 M HCl-dioxane[a]	24	99	24
2 M HCl-dioxane[a]	24	90	6
1 M HCl-dioxane[a]	24	69	<1
1 M HCl-dioxane[a]	72	98	2

[a] Ratio of 1—6 M HCl and dioxane is 1:1 (v/v); Temperature, 110 °C.



Scheme 1.

in the present work was lower than the reported one (62%).[6] The higher yield in the latter is due to simple modification of natural L-Tyr. On the other hand, the yield (22%) of L-Amp was comparable to that (24%) described before,[7] indicating that the present method is useful in cases where optically active natural amino acids are not available as starting materials.

Experimental

Optical rotation was measured with a Union high sensitivity polarimeter PM-71. HPLC was carried out with a Hitachi 635A liquid chromatograph and monitered at 210 nm. Amino acid analysis was performed with a Hitachi amino acid analyzer KLA-5. Thin-layer chromatography was carried out on Merck silica gel G with the following solvent systems: R_f^1, $CHCl_3$-MeOH (9:1); R_f^2, $CHCl_3$-MeOH-AcOH (95:5:1).

Cyclo(-L or D-aminoacyl-L-Ala-). Authentic samples were prepared from the corresponding Z-dipeptide-OMe according to the literature.[9] All the compounds afforded satisfactory results of elemental analysis. Cyclo(-L-Tyr(Me)-L-Ala-) (**1**): Yield, 80%; mp 274—276 °C (decomp); $[\alpha]_D^{20}$ −4.8° (*c* 1, DMF); R_f^1=0.35. Cyclo(-D-Tyr(Me)-L-Ala-) (**6**): Yield, 73%; mp 235—237 °C (decomp); $[\alpha]_D^{20}$ −17.2° (*c* 0.5, DMF); R_f^1=0.34, R_f^2=0.65. Cyclo(-L-Amp-L-Ala-) (**2**): Yield, 88%; mp 211—213 °C; $[\alpha]_D^{19}$ −31.0° (*c* 0.5, DMF); R_f^2=0.34. Cyclo(-D-Amp-L-Ala-) (**7**): Yield, 61%; mp 204—206 °C; $[\alpha]_D^{19}$ −3.5° (*c* 0.5, DMF); R_f^2=0.41.

Cyclo(-ΔTyr(Me)-L-Ala-) (4a). Compound **3** was allowed to react with *p*-methoxybenzaldehyde in the presence of *t*-BuOK. Cyclo(-ΔTyr(Me)-*N*-Ac-L-Ala-) obtained was treated with $NH_2NH_2 \cdot H_2O$ to give **4a** using the same procedure in the literature;[8] yield, 52%; mp 254—257 °C (decomp); $[\alpha]_D^{22}$ −17.0° (*c* 1, DMF); R_f^1=0.47. Found: C, 63.11; H, 5.77; N, 11.50%. Calcd for $C_{13}H_{14}N_2O_3$: C, 63.40; H, 5.73; N, 11.38%.

Cyclo(-ΔAmp-L-Ala-) (4b). This compound was prepared from **3** and 3-(*p*-methoxyphenyl)propionaldehyde; yield, 40%; mp 231-233 °C; $[\alpha]_D^{20}$ −17.5° (*c* 0.5, DMF); R_f^1=0.40. Found: C, 65.42; H, 6.66; N, 10.26%. Calcd for $C_{15}H_{18}N_2O_3$: C, 65.67; H, 6.61; N, 10.21%.

Acid Hydrolysis of Authentic Samples. A mixture of **1** and Lys·HCl (5 μmol each) was heated in a sealed tube with 1—6 M HCl-dioxane (1:1) at 110 °C for certain intervals. Lys·HCl was used as a standard for determination of hydrolysis percentage by comparison with Ala formed in hydrolysis. Amino acid analysis and calculation of demethylation were carried out as described before.[7] The results are shown in Table 1. A similar procedure was applied for **2**.

HPLC of Authentic Samples. The separation of DL and LL isomers of cyclo(-Tyr(Me)-Ala-) was performed under the following conditions: column, LiChrosorb RP-8 (4×250 mm); eluent, H_2O-CH_3CN (95:5); flow rate, 1.0 ml/min. Elution volume and relative intensity were determined as 44 ml and 99% for **6**, and 51 ml and 100% for **1**. The conditions on the separation of DL and LL isomers of cyclo(-Amp-Ala-) were as follows: column, LiChrosorb RP-18 (4×150 mm); eluent, H_2O-CH_3CN-*i*-PrOH (14:1:1); flow rate,. 1.0 ml/min. Eluent volume and intensity were 22.5 ml and 94% for **7**, and 31.2 ml and 100% for **2**.

Determination of Chiral Induction in Hydrogenation of Cyclic Dehydrodipeptides. Compound **4a** (7.4 mg, 30 μmol) in absolube DMF (8 ml) was hydrogenated in the presence of Pd black (ca. 10 mg) at 0 °C for 10 h, and an aliquot was applied to HPLC. The ratio of the DL and LL isomers in cyclo(-Tyr(Me)-Ala-) was 2.5:97.5 after correction of the apparent ratio by relative intensity. Therefore, the chiral induction (%) was calculated as 95%, and those at 25 °C and 50 °C were 97% and 94%, respectively. The chiral induction of **4b** was 97% at 20 °C.

Preparation of L-Amino Acids. **L-Tyr(Me)**: Hydrogenated product of **4a** (1.23 g, 5 mmol) was hydrolyzed with 1 M HCl-dioxane (1:1, 150 ml) at 110 °C for 3 d and evaporated in vacuo. The residue was dissolved in water (10 ml) and the solution was neutralized with Et_3N. The resulting solid was collected and washed with cold water. Dissolution of the crude product in 6 M HCl and neutralization with Et_3N gave pure L-Tyr(Me); yield, 0.65 g (66%); $[\alpha]_D^{25}$ −6.2° (*c* 1, 1 M HCl) (lit,[5] $[\alpha]_D^{29}$ −5.9° (*c* 2, 1 M HCl)). Found: C, 61.49; H, 6.71; N, 7.27%. Calcd for $C_{10}H_{13}NO_3$: C, 61.52; H, 6.71; N, 7.18%.

L-Amp: This was prepared from **4b** as described above except for hydrolysis with 0.5 M HCl-dioxane (1:1) for 4 d; yield, 56%; $[\alpha]_D^{22}$ +30.8° (*c* 1, 5 M HCl-DMF (1:1)) (lit,[7] $[\alpha]_D^{21}$ +31.8° (*c* 2, 5 M HCl-DMF). Found: C, 64.71; H, 7.61; N, 6.08%. Calcd for $C_{12}H_{17}NO_3$: C, 64.55; H, 7.68; N, 6.27%.

Mass Spectra of Tetrahydrofuran Derivatives

Hajime NAGANO,* Makiko IJIRI, Xiao Hong XU, and Michio SHIOTA
Department of Chemistry, Faculty of Science, Ochanomizu University,
Otsuka, Bunkyo-ku, Tokyo 112
(Received September 6, 1985)

Synopsis. Mass spectra of 2-(4,5-dialkyloxacyclopent-2-yl)-2-propanols exhibited a characteristic cleavage of tetrahydrofuran ring yielding an ion at *m/z* 102 ($C_5H_{10}O_2$) and/or an ion ($M^+-C_5H_{10}O_2-H$).

In the course of structure determination of magydardienediol, a diterpene isolated from *Magydaris panacifolia* (Vahl) Lange (Umbelliferae), we found a new characteristic mass spectral cleavage of tetrahydrofurans (**1**) derived from the diterpene.[1] The cleavage yielded ions at *m/z* 250 ($M^+-C_5H_{10}O_2$) and at *m/z* 167 ($M^+-C_5H_{10}O_2-CH_2CH_2CH=C(CH_3)_2$) as intense peaks. The other possible structure 2-(5-alkyl-5-methyloxacycopent-2-yl)-2-propanol expected for **1** was disproved as the mass spectra of tetrahydrofurans of the general type are well known to show an ion at *m/z* 143.[2] This difference in fragmentations shows that mass spectroscopy is efficient for the discrimination of these tetrahydrofurans.

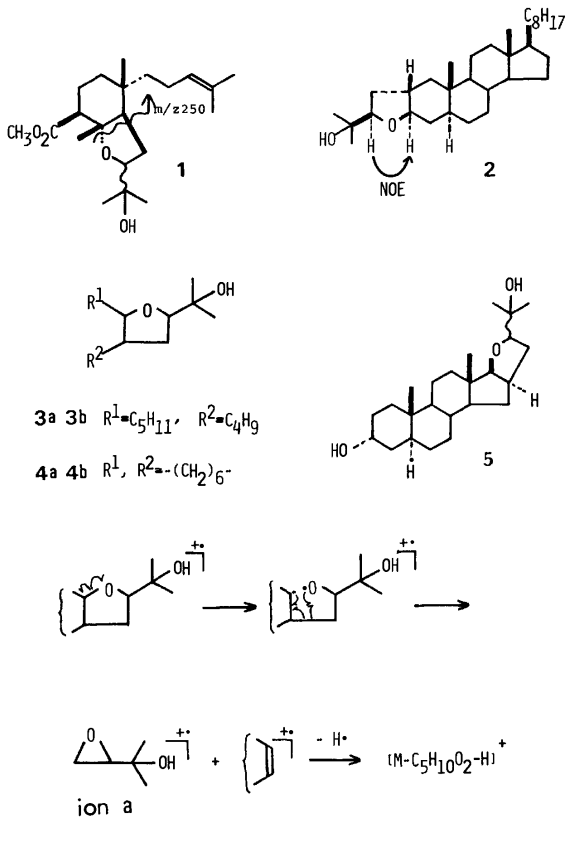
We report here the mass spectral fragmentations of tetrahydrofurans (**2—5**) which verify the cleavage of tetrahydrofuran ring mentioned above.

Tetrahydrofurans **2—5** were prepared from 5α-cholestan-3-one, 5-undecanone, cyclooctanone, and androsterone, respectively ((i) $LiN(i\text{-}Pr)_2$, $(CH_3)_2C=CHCH_2Br$, (ii) $NaBH_4$, (iii) *m*-chloroperbenzoic acid, H^+).

Mass spectrum of **2**, mp 132—134 °C, obtained at an electron beam energy of 70 eV showed a prominent peak at *m/z* 102 (relative intensity 52%) due to ion **a** ($C_5H_{10}O_2^+$). The formation of ion **a**, which was scarcely observed in the spectrum of **1**, firmly established the fragmentation process of tetrahydrofuran ring as shown in Scheme. At a lower electron beam energy (25 eV) the cleavage occurred predominantly to give the base peak at *m/z* 102 and loss of water from the molecular ion to a lesser extent. The predominancy of tetrahydrofuran ring cleavage over other fragmentations was also shown in the spectrum of **1** obtained at 18 eV (*m/z* 250 (54%) and 167 (100)).

Mass spectra of diastereomeric mixtures, **3a**, **3b**, **4a**, and **4b**, also showed an intense peak at *m/z* 102 (70 eV: **3a**(58%), **3b**(57), **4a**(53), and **4b**(53); 25 eV: **3a**(81%), **3b**(88), **4a**(87), and **4b**(100)).

In the spectra of **5** (diastereomeric mixture) fragment ions at *m/z* 273 (70 eV (77%) and 25 eV (67); $M^+-C_5H_{10}O_2-H$) and 255 (70 eV (70%), 25 eV (100); $M^+-H_2O-C_5H_{10}O_2-H$) were observed as predominant peaks, whereas the intensities of ion **a** were moderate (70 eV (21%) and 25 eV (20)). The tendency for charge to reside on the methoxycarbonyl group in **1** and the hydroxyl group at C-3 in **5** may decrease the intensities of ion **a**. In the spectra of **4a** and **4b** a fragment ion ($M^+-C_5H_{10}O_2-H$) was also observed as an intense peak at *m/z* 109 (70 eV: **4a**(72%) and **4b**(75); 18 eV: **4a**(54%) and **4b**(46)).



Scheme

Experimental

Mass spectra were measured on a JEOL DX-300 spectrometer using direct inlet system. NMR Spectra were recorded on a JEOL GX270 spectrometer in $CDCl_3$.

2α-(3-Methyl-2-butenyl)-5α-cholestan-3-one. To a solution of the enolate of 5α-cholestan-3-one (569 mg) prepared using $LiN(i\text{-}Pr)_2$ (1.5 mmole) in dry THF (5 ml) and HMPA (0.2 ml) was added a solution of 4-bromo-2-methyl-2-butene (249 mg) in THF (1 ml) at −78 °C and the solution was stirred for 3 h. After work-up as usual the product was submitted to preparative TLC to give 2α-(3-methyl-2-butenyl)-5α-cholestan-3-one (31 mg), mp 115.5—116.5 °C; IR (KBr) 1708 cm^{-1}; ^1H NMR δ=1.59 (3H, s, Me), 1.69 (3H, s, Me), and 5.06 (1H, t, *J*=6.7 Hz); ^{13}C NMR δ=45.85 (C-1), 48.07 (C-2), 45.03 (C-4), and 46.85 (C-5); Found: *m/z* 454.4141. Calcd for $C_{32}H_{54}O$: M, 454.4173.

2α-(3-Methyl-2-butenyl)-5α-cholestan-3β-ol. The above ketone (30 mg) was reduced with $NaBH_4$ (17 mg) in

ethanol to give 3β-ol (21 mg), mp 97—98 °C; IR (KBr) 3350 cm^{-1}; ^1H NMR δ=3.29 (1H, ddd, J=10.5, 10.5, and 5 Hz, 3α-H); Found: m/z 456.4416. Calcd for $C_{32}H_{56}O$: M, 456.4331.

Tetrahydrofuran 2. A solution of the 3β-ol (21 mg) and *m*-chloroperbenzoic acid (18 mg) in CH_2Cl_2 was allowed to stand at room temperature and then treated with dilute HCl to give **2** (7.6 mg); IR (KBr) 3520 and 3440 cm^{-1}; ^1H NMR δ=1.15 (3H, s, Me), 1.22 (3H, s, Me), 3.09 (1H, ddd, J=10.5, 10.5, and 4 Hz, 3α-H), and 3.83 (1H, dd, J=9 and 3.5 Hz, CH–O); HRMS: m/z 454.4170 (Calcd for $C_{32}H_{54}O$, M−H_2O, m/z 454.4173) and 102.0777 (Calcd for $C_5H_{10}O_2$, 102.0681).

Tetrahydrofurans 3a and 3b. A diastereomeric mixture of tetrahydrofurans derived similarly from 5-undecanone was separated into two fractions, **3a** (a mixture of two less polar diastereomers) and **3b** (a mixture of two polar diastereomers) using silica gel column chromatography. **3a**: an oil, IR (neat) 3450 cm^{-1}; ^1H NMR δ=0.89 (6H, m, Me), 1.105 (1.5H, s, Me), 1.109 (1.5H, s, Me), 1.21 (3H, s, Me), 3.46 (1H, m), and 3.73 (1H, m); MS (70 eV): m/z 241 (5%, M^+−Me), 238 (6, M^+−H_2O), and 153 (23, M^+−$C_5H_{10}O_2$–H); HRMS: m/z 197.1940 (Calcd for $C_{13}H_{25}O$, M−C_3H_7O, 197.1905), 153.1654 (Calcd for $C_{11}H_{21}$, 153.1644), and 102.0692 (Calcd for $C_5H_{10}O_2$, 102.0681). **3b**: an oil, IR (neat) 3450 cm^{-1}; ^1H NMR δ=0.89 (6H, m, Me), 1.10 (3H, s, Me), 1.20 (1.8H, s, Me), 1.23 (1.2H, s, Me), 3.69 (0.4H, dd, J=9.7 and 5.6 Hz), 3.78 (0.6H, t, J=7.5 Hz), and 3.91 (1H, m); MS: m/z 241 (4%), 238 (4) and 153 (19); HRMS: m/z 197.1928 and 102.0696.

Tetrahydrofurans 4a and 4b. A diastereomeric mixture of tetrahydrofurans derived from cyclooctanone was separated into two fractions, **4a** (a mixture of two less polar diastereomers) and **4b** (a mixture of two polar diastereomers). **4a**: an oil, IR (neat) 3450 cm^{-1}; ^1H NMR δ=1.10 (1.8H, s, Me), 1.11 (1.2H, s, Me), 1.21 (3H, s, Me), 3.5—3.85 (1.4H, m), 4.13 (0.6H, m); MS: m/z 212 (M^+, 0.3%); HRMS: m/z 194.1733 (Calcd for $C_{13}H_{22}O$, M−H_2O, 194.1671), 109.1011 (Calcd for C_8H_{13}, 109.1016), and 102.0693 (Calcd for $C_5H_{10}O_2$, 102.0681). **4b**: an oil, IR (neat) 3450 cm^{-1}; ^1H NMR δ=1.10 (3H, s, Me), 1.20 (3H, s, Me), 3.71 (1H, t, J=7.5 Hz), and 4.04 (1H, m); MS: m/z 212 (M^+, 1%); HRMS: m/z 197.1556, 109.1020, and 102.0707.

Tetrahydrofurans 5. The spectral data of **5** (a mixture of diastereomers), colorless plates, mp 199.5—200.5 °C, are as follows. IR (KBr) 3350 cm^{-1}; ^1H NMR δ=0.73 (1.8H, s, 18-H or 19-H), 0.78 (4.2H, s, 18-H and 19-H), 1.08 (1.8H, s, Me), 1.14 (1.2H, s, Me), 1.18 (1.8H, s, Me), 1.25 (1.2H, s, Me), 2.18 (1H, br s, OH), 2.29 (1H, br s, OH), 2.65 (1H, m,), 3.81 (0.4H, dd, J=11.3 and 4.4 Hz,), and 3.9—4.1 (2.6H, m); HRMS: m/z 376.2983 (Calcd for $C_{24}H_{40}O_3$, M, 376.2977), 273.2176 (Calcd for $C_{19}H_{29}O$, 273.2217), 255.1401 (Calcd for $C_{17}H_{19}O_2$, 255.1384), and 102.0735 (Calcd for $C_5H_{10}O_2$, 102.0681).

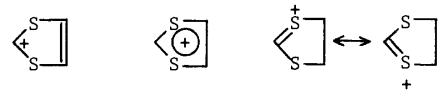
^{13}C NMR Spectra of 1,3-Dithiolan-2-ylium Ions and 2-Alkylidene-1,3-dithiolanes

Tadashi OKUYAMA* and Takayuki FUENO
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received September 9, 1985)

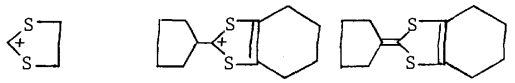
Synopsis. ^{13}C NMR spectra of various 2-substituted 1,3-dithiolan-2-ylium perchlorates **5** as well as 2-alkylidene-1,3-dithiolanes **6** are measured. Chemical shifts induced by protonation of **6** to form **5** are compared with those found with the unsaturated analogues, 1,3-dithiolylium ions, implying the aromatic charge delocalization in the latter ions.

1,3-Dithiolylium ion **1** is an unsaturated five-membered ring cation which possesses potential aromatic sextet. The stability of this ion is usually attributed to this 6π-electron delocalization (**1a**).[1] The NMR



1 **1a** **1b**

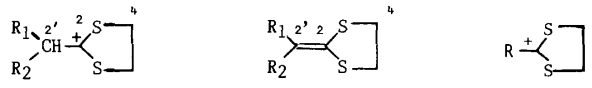
spectral data of this class of cations have been considered to support this view in one paper[2] while the other workers[3] rationalized the observed ^{13}C chemical shifts only by the sulfur conjugation (**1b**). The former paper[2] examined both ^{1}H and ^{13}C NMR spectra of **1** and the saturated analogue, 1,3-dithiolanylium ion **2**, as well as their neutral precursors. The signal of 2-H of **1** appeared at a lower field than that of **2**, whereas the chemical shift of 2-C of **1** is much smaller than that of **2**, suggesting the aromatic ring current and charge delocalization in **1**. On the other hand, the latter workers[3] compared ^{13}C NMR spectra of 2-substituted derivatives of **1** with those of their deprotonated derivatives; e. g., **3** and **4**. Chemical shift differences between **3**



2 **3** **4**

and **4** were found to be much greater at 2-C than at 4-C.

In the present investigation, we have measured ^{13}C NMR spectra of substituted 1,3-dithiolan-2-ylium ions **5** and 2-alkylidene-1,3-dithiolanes **6** in order to examine the conclusion deduced from the similar comparison between **3** and **4**. Perchlorates of **5** were



5 **6** **5**

a, $R_1=R_2=H$ **b**, $R_1=H$, $R_2=CH_3$ **e**, $R=(CH_3)_3C$
c, $R_1=R_2=CH_3$ **d**, $R_1=H$, $R_2=C_6H_5$ **f**, $R=C_6H_5$
g, $R=p\text{-}CH_3OC_6H_4$

prepared from acyl chlorides and 1,2-ethanedithiol and converted to **6** by the treatments with triethylamine.[4] ^{13}C FT NMR spectra were recorded at 27 °C on a JNM-FX 100 spectrometer operating at 25.05 MHz.[5] Spectra of **5** and **6** were measured as 5—10% solutions in CF_3COOH-CF_3COOD and $CDCl_3$, respectively. Results are summarized in Table 1.

Table 1. ^{13}C Chemical Shifts of **5** and **6**[a]

No.	R(R_1, R_2)	2-C	4-C	2-C′[b]	Others
2[c]	H	221.4	46.4

a) ppm downfield from internal TMS. Values in parentheses show the chemical shift differences between **5** and **6**. b) The carbon next to 2-C. c) Taken from reference 2.

Assignments of signals were made by comparisons with those of relevant compounds.

Resonance of 2-C of dithiolanylium ions **5** occurs at the lowest field reflecting a positive charge. Among the chemical shifts of 2-C of **5**, the largest is that of **5e** (R=*t*-Bu), decreasing in the order **5e**(*t*-Bu)>**5c**(*i*-Pr)>**5b**(Et)>**5a**(Me)>**5d**($PhCH_2$). This order coincides with that of electron-donating ability of alkyl groups to the positive center, e. g., in terms of the σ_p^+ substituent constants, and indicates decreasing order of the charge density at the positive carbon. The 2-phenyl and 2-(*p*-methoxyphenyl) cations (**5f** and **5g**) have the 2-C signals at still higher field.

2-Alkyl-1,3-dithiolanylium ion **5** is formed by protonation of 2-alkylidene-1,3-dithiolane **6**. The protonation causes large downfield (100—132 ppm) and upfield (70—77 ppm) shifts at 2-C and 2-C′ (the carbon next to 2-C), respectively, as given in parentheses in Table 1. The chemical shift of 4-C (5-C) changes only by about 9 ppm. The upfield shift of 2-C′ must mostly be due to the hybridization change from sp^2 to sp^3. The downfield shifts at 2-C and 4-C come primarily from a positive charge of the cation **5**. Similar changes in the chemical shifts of the unsaturated analogues (**3** and **4** and related dithiole derivatives) were found to be 74—89, −74—81, and 28 ppm at 2-C, 2-C′, and 4-C, respectively.[3] The changes at 2-C′ are much the same between the dithiole and dithiolane derivatives (70—80 ppm upfield shift), as expected for the same hybridization change. However, downfield shifts at 2-C and 4-C of dithiolylium ions are 30—40 ppm smaller and about 20 ppm larger than those of dithiolanylium ions, respectively. This indicates that the charge density in dithiolylium ion **1** is smaller at 2-C while greater at 4-C as compared with that in dithiolanylium ion **2**. That is, the positive charge in **1** delocalizes extensively involving the 4 and 5 carbons.

^{13}C NMR data presented by Meier et al.[3] should be taken as indicating that the positive charge delocalizes over the whole ring system of dithiolylium ion (**1a**), contrary to their conclusion.

Gas-Chromatographic Measurements of Atmospheric Sulfur Hexafluoride

Michio HIROTA* and Hisafumi MURAMATSU
Meteorological Research Institute, 1-1 Nagamine, Yatabe-machi, Tsukuba-gun, Ibaraki 305
(Received July 19, 1985)

Synopsis. From air samplings on aircraft in February and December 1982 and in February 1983, and from gas-chromatographic measurements, the background volume mixing ratio of sulfur hexafluoride(SF_6) over Japan was found to be about (0.72±0.13) ppt, where ppt=10^{-12}. Since the first observation by Lovelock in 1970 (0.03 ppt), SF_6 seems to have been increasing steadily.

Sulfur hexafluoride(SF_6) is a very stable compound which has been used for gas insulation since the 1960's[1]; it has also been used as an atmospheric tracer because a electron-capture detector(ECD) has very high sensitivity for it.

With the increasing use of SF_6, it is being accumulated in the atmosphere; its background volume mixing ratio was about 0.5 ppt in 1978.[2] Because its use as a tracer for long-range-transport experiments is not considered to be suitable, it is being replaced by C_6F_{12} and C_8F_{16}.[2] However, it can still be used as a tracer of global atmospheric circulation like CF_2Cl_2, $CFCl_3$,[3] and ^{85}Kr.[4] Furthermore, it has the anvantage that, like them, its emission is due only to man's activities.

In this paper, our preliminary findings regarding its vertical distribution in the troposphere and the time trend of its background volume mixing ratio will be reported.

Experimental

The details of our air sampling and gas-chromatographic measurements have been described in Refs. 5 and 6. Therefore, except for some changes, only a brief description will be presented here.

Sampling of Air. Air samples were collected on an aircraft (Aerocommander 685 or Cessna 404) by means of an air pump (NRK, UP-2) into stainless steel cylinders (0.3 l, Nupro SS-4JB or B-4H valves were used). The SF_6 concentration was almost constant for several months in the cylinder.

Gas-Chromatographic Measurements. SF_6 was analyzed using a Shimadzu Gas Chromatograph GC-6AM equipped with an ECD. The sample air in the cylinder was transferred into a gas sampling tube (Shimadzu MGS-4, 2 ml) and then into a glass column (3 m×5 mm o.d., 90 °C) filled with molecular sieve 5A (30—60 mesh). An ECD (^{63}Ni 10 mci) was used at 300 °C. Ultra-pure N_2(>99.9995%), which had been passed through a drier tube filled with molecular sieve 5A(1/16″ pellets), was used as the carrier gas at a flow rate of 30 ml $min.^{-1}$

SF_6 was eluted before CF_2Cl_2 and O_2. Though CF_3Cl has nearly the same retention time as SF_6, its sensitivity was about 10^2 times lower.

A reference gas was made by diluting pure SF_6 (Takachiho, >99.8%) with ultra-pure N_2 into a *tedlar* bag (20 l). The SF_6 in the *tedlar* bag was constant in a few days. By a two-step static dilution, a reference gas of SF_6 in N_2 was made. The peak height of SF_6 was proportional to the amount of SF_6 in the range from 0 to 0.33×10^{-12} g, which was equal to the amount of 25 ppt SF_6 in a 2-ml sample air. The error in repeated measurements at 1.0 ppt was ±10%. In practice, the volume mixing ratios of SF_6 were calculated from those of CF_2Cl_2[7] by making use of the fact that the peak height of SF_6 was about 20 times (20.8±0.6) higher than that of CF_2Cl_2, which was eluted about 20 s after SF_6. In the measurement of the sensitivity ratio, a mixed gas of 10 ppt SF_6 and 400 ppt CF_2Cl_2 in N_2 was used. The detection limit was 0.3 ppt (S/N~1).

Results and Discussion

The vertical distribution of SF_6 in February 1982 is shown in Fig. 1. In every flight, the Cessna 404 took off and landed at Haneda Airport. The flight courses ranged from Sendai to Hachijo-jima. As with CF_2Cl_2 and $CFCl_3$,[7] higher mixing ratios were often observed over urban areas up to an altitude of 2 km. Above 2 km, nearly constant mixing ratios were observed; the mean value (0.64 ppt) for 17 samples was considered as the background mixing ratio in the troposphere. Subsequent air samplings were performed on 20 and 21 December 1982 over the Kanto Mountains and on 7 February 1983 between Hamamatsu and Nii-Jima. Above 2 km, the mean values and standard deviations were 0.85 and 0.06 ppt for 7 samples in December 1982 and 0.83 and 0.07 ppt for 5 samples in February 1983. The mean value for the total of 29 samples and its standard deviation were 0.72 and 0.13 ppt. The increase in the mean value from February 1982 to December 1982 and February 1983 seems attributable mostly to the experimental uncertainties.

The background mixing ratios of SF_6 which were obtained in both this study and earlier works are shown in Fig. 2. The (a) value, which was obtained for the first time by Lovelock in 1970, was 0.03 ppt.[8] Observations after Lovelock have shown that the atmospheric SF_6 is increasing steadily.

The (b), (d), (g), (i), (j), and (l) values were obtained by aircraft observations. Except for the lower values of (e), (h), and (k), which were obtained in Antarctica or in the southern hemisphere, samples were obtained in the mid-latitude of the northern hemisphere. The values of this study((i), (j), and (l)) were in agreement with a higher value of Rasmussen and Khalil (0.75 ppt, (k)) which was obtained in the Pacific Northwest(≈45° N).[15]

The main sink for atmospheric SF_6 would be photodecomposition by solar ultraviolet radiation in the upper atmosphere. The rate of this process, however, must be very slow in the stratosphere, as SF_6 is photoionized only in the wavelength region below 81 nm.[16-18]

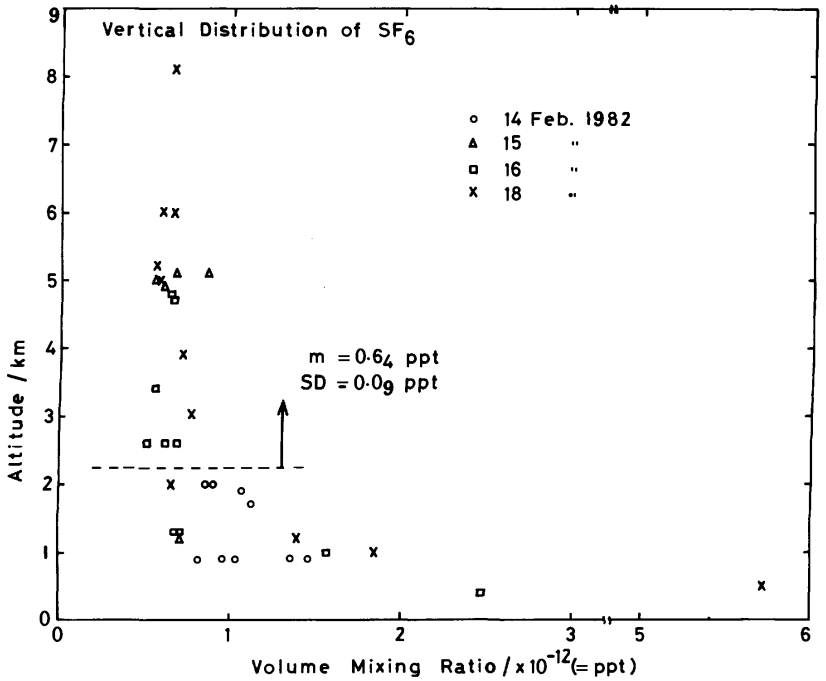

Fig. 1. Vertical distribution of SF_6.
Cessna 404 was used. Flight courses ranged from Sendai to Hachijo-jima.

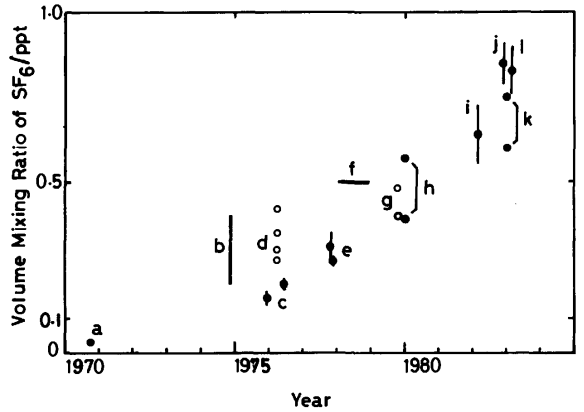

Fig. 2. Volume mixing ratios of SF_6.
○: individual value, ●: mean value and standard deviation.
In (b) and (f), only approximate values were reported. Individual values in (i) are shown in Fig. 1. In (j) and (l), samples were collected around Kanto Mts., and between Hamamatsu and Nii-jima.
(a): Lovelock,[8] (b): Elias et al.,[9] (c): Singh et al.,[10] (d): De Bortori and Pecchio.,[11] (e): Singh et al.,[12] (f): Pack et al.,[2] (g): Leifer et al.,[13] (h): Rasmussen et al.,[14] (i),(j), and (l): this study, (k): Rasmussen and Khalil[15].

The emission rate of SF_6 from gas-insulation instruments is not known. If the global mean mixing ratio is assumed to be about 0.5 ppt(≈1980), the total amount of SF_6 in the atmosphere is about 1.3×10^7 kg, assuming that the total air is 5.137×10^{18} kg.[19] The total world use was estimated to be 2.5—4.5×10^6 kg/year about 1980.[20] From these facts and also the development of SF_6 production since 1960's, a rather large part of the SF_6 may be supposed to have been released into the atmosphere in the several years since its production.

In this study, CF_2Cl_2 was used as the standard because a very dilute reference gas, such as SF_6, was not needed. However, the ratio in the senstivities of SF_6 and CF_2Cl_2 is not necessarily independent of the experimental conditions, and so further improvements are now in progress.

The Structure of Diaquatris(1,1,1-trifluoro-2,4-pentanedionato)neodymium(III)-Acetone (1/1)

Masao NAKAMURA, Reiko NAKAMURA, Kiyofumi NAGAI, Mamoru SHIMOI, Shuji TOMODA, Yoshito TAKEUCHI, and Akira OUCHI*
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received July 27, 1985)

Synopsis. The crystal and molecular structure of the title complex was determined by means of the single-crystal X-ray diffraction method. The crystal of $NdC_{18}H_{22}O_9F_9$, F.W. 697.59, is orthorhombic, with a space group *Pbna*, a=22.068(5), b=22.293(4), c=11.020(2) Å, U=5421(2) Å^3, Z=8, D_m=1.72(3), D_x=1.71 Mg m^{-3}, and μ(Mo $K\alpha$)=20.46 cm^{-1}. The central metal atom is octa-coordinated, being ligated with six β-diketonato and two water oxygen atoms, and is in a dodecahedral geometry. Two configurational isomers co-exist in the crystal, with the respective occupancy factors of 74 and 26%. In these isomers, the two chelate rings span in different ways; although the positions of all ligating oxygen atoms are the same, the chelates span two m-edges in one isomer and two g-edges in the other one.

Although the structures of some β-diketonato complexes of lanthanoids(III) have already been reported, the coordination geometry and the spanned edges of the chelate rings have been found to be diverse. For example, in $M(acac)_3(H_2O)_2$ (where M=La, Pr, or Nd; Hacac=2,4-pentanedione), the central metal atom is in a square-antiprism geometry (octa-coordinated), and the chelate ligands span square edges.[1-3] On the other hand, in $Nd(tta)_3(Ph_3PO)_2$ (where Htta=4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione; Ph_3PO=triphenylphosphine oxide), the central metal is in a dodecahedral geometry (octa-coordinated), and the ligands span one m-edge and two g-edges.[a,4] In $NH_4Pr(tta)_4\cdot H_2O$ and $(C_9H_8N)[Ce(tta)_4]$, all the ligands span g-edges and m-edges respectively.[5,6] Although 1,1,1,-trifluoro-2,4-pentanedione (Htfa) is a ligand which gives several interesting types of complexes,[7,8] few structural data about its lanthanoid complexes have yet been reported. Therefore, we have determined the structure of the title complex by the single-crystal X-ray diffraction technique.

Experimental

Single-Crystal X-Ray Analysis. The crystals of the title complex were obtained by the slow evaporation of the complex in an acetone-water mixed solvent (4:1=v/v). (The crude product was obtained by a reaction between the metal hydroxide and Htfa, as was the isomorphous lanthanum(III) complex.) Anal. ($MC_{18}H_{22}O_9F_9$, where M=La, or Nd), M, C, H. The crystal used for the structure determination was about 0.3×0.3×0.2 mm^3 in size, and was used without shaping. The reflections in the range of $3°<2\theta<60°$ were collected on a Rigaku AFC-6A automated four-circle diffractometer, with graphite-monochromated Mo $K\alpha$ radiation, by means of the ω—2θ scan technique (scan speed 4° min^{-1}; scan width, 1.30+0.5 tanθ°). The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction. Among the 8731 independent reflections collected, 3611 with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination. All the calculations were carried out on a HITAC M-280H computer at the Computer Center of the University of Tokyo, using the local version of the UNICS.[9] The scattering factors were taken from Ref. 10.

The structure was solved by the heavy-atom method. It was found that the crystal is composed of mixture of two configurational isomers. As is shown in Fig. 2, except for the common ligand (**1**), the Type A complexes include the ligands of F(21, 22A, 23A), C(21, 22A, 23A, 24A, 25), and O(21, 22) (**2A**) and F(31A, 32, 33A), C(31, 32A, 33A, 34A, 35), and O(31, 32) (**3A**), while the Type B complexes include those of F(21, 22B, 23B), C(21, 22B, 23B, 34B, 35), and O(21, 32) (**2B**) and F(31B, 32, 33B), C(31, 32B, 33B, 24B, 25), and O(31, 22) (**3B**). The probabilities of the occupancy of both types of complexes were first approximately assigned from the intensities of the atoms belonging to the respective types of ligands, and were then refined by means of the full-matrix least-squares procedure; the final occupancy factors for the type A and B complexes are 73.6(18)% and 26.4% respectively.

At the final refinement process, the positions of the seven fluorine atoms as well as the two acetone carbon atoms were fixed assuming B_{iso}=11.0. For the other atoms, except for O(AC) and C(Al), the anisotropic temperature factors were applied; the final R value[11] thus obtained was 0.066.

NMR Measurements. ^{1}H-NMR and ^{13}C-NMR spectra of the isomorphous lanthanum(III) complex were obtained by means of a Varian EM 390 NMR spectrometer and a JEOL FX90Q Fourier Transform NMR spectrometer, using the acetone-d_6 solution and TMS as the internal standards.[a]

Results and Discussion

The selected interatomic distances and bond angles are shown in Table 1.[12] A perspective drawing of the complexes in Type A is shown in Fig. 1. The schematic presentation showing the positions of the ligating atoms and of the spanning ligands, together with the numbering scheme of the ligands is shown in Fig. 2.[12]

. The central metal atom is octa-coordinated and is in a little deformed dodecahedral geometry. The chelating ligand **1**, which spans an m-edge, is common to both types of the species, while the other two ligands span in different ways; in Type A species, the ligands, **2A** and **3A**, span m-edges, but in

a) The isomorphism was checked from their powder X-ray diffraction patterns.

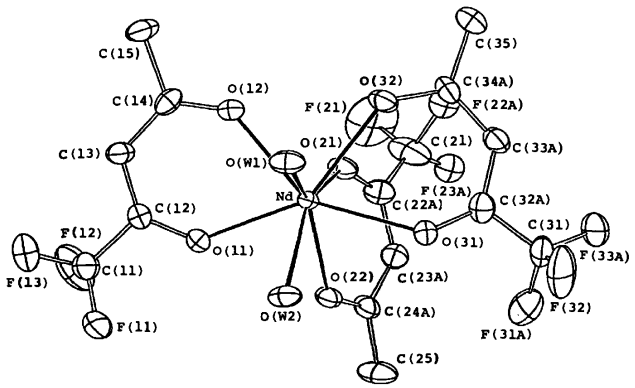

Fig. 1. A perspective drawing of Type A complex with the numbering scheme.

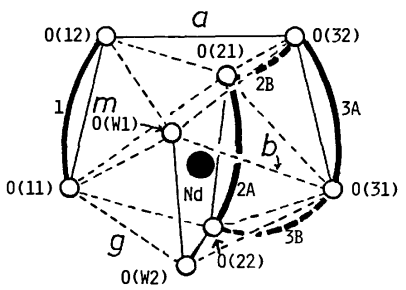

Fig. 2. Schematic presentation of the complex about the coordination geometry, with the numbering scheme of the chelating ligands (**1**, **2A**, and **3A** for Type A, and **1**, **2B**, and **3B** for Type B complex, respectively).

the Type B species, the ligands, **2B** and **3B**, span g-edges. In the chelate ring **1**, the two Nd-O bond lengths, 2.411(8) and 2.393(8) Å, are not much different from each other. On the other hand, in all the other chelate rings, the Nd-O(n1) lengths are shorter than the corresponding Nd-O(n2) ones. The Nd-O bond lengths to the coordinated water oxygen atoms are longer than those to the β-diketonato oxygen atoms. In view of the positions of O(11), O(21), and O(31), the trifluoromethyl groups of the ligands may be said to take the positions most separated from each other around the metal atom. Although the positions of all the atoms of the ligands were found, their thermal parameters, especially those of the fluorine atoms, were relatively large, probably because they are distributed around the most probable positions, respectively.

The NMR data of the isomorphous lanthanum(III) complex are as follows: ^{1}H-NMR (acetone d_6), δ=2.00 (9H, s, CH_3 of tfa), 2.10 (6H, s, CH_3 of acetone), 4.01 (4H, s, H_2O), 5.68 (3H, s, CH). ^{13}C-NMR (acetone-d_6), δ=28.8 (m, CH_3 in acetone), 29.9 (m, CH_3 in acetone-d_6), 96.1 (d, J_{CH}=146 Hz, CH), 169.1 (q, J_{CF}=31 Hz, CO(CF_3 side) of tfa), 197.3 (s, CO(CH_3 side) of tfa), 206.9 (s, CO of acetone), 120.1 (q, J_{CF}=290 Hz, CF_3). Judging from these data, the β-diketone in this complex can be said to be of the enol-type. As the peaks are all sharp, and as no splittings were found, a rapid exchange of the ligands can be expected between the two types of species in the solution at the ambient temperature (25 °C).

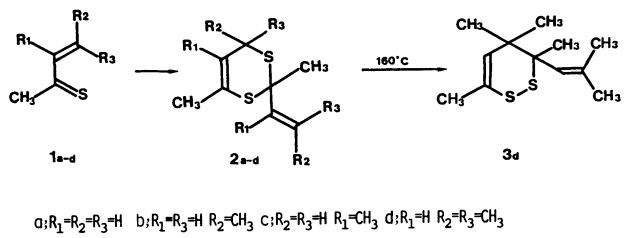
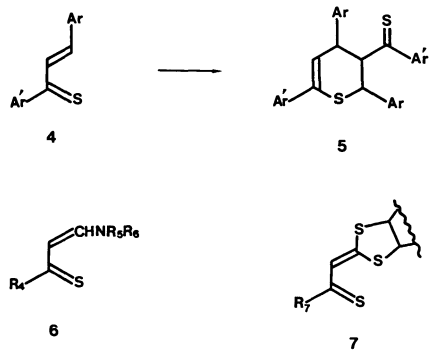
(Received June 24, 1985)

Synopsis. β-Arylthio α,β-unsaturated thioketone dimer, 3,6-diphenyl-4-arylthio-3-[2-(arylthio)ethenyl]-3,4-dihydro-1,2-dithiin, has been prepared. Thermal isomerization of 3,4-dihydro-1,2-dithiin (aryl=phenyl) afforded 6-phenyl-2,4-bis(phenylthio)-3-thiobenzoyl-3,4-dihydro-2*H*-thiopyran.

Several types of acyclic α,β-unsaturated thioketones have been reported. For example, aliphatic (**1**)[1] or aromatic (**4**)[2,3] α,β-unsaturated thioketone is unstable at room temperature and exists in the dimeric form (**2**, **3**, or **5**). In contrast, β-thioxo enamines (**6**)[4] and α-(thioacyl)ketene dithioacetals (**7**)[5] are relatively stable and exist in monomeric forms. These results suggest that the thermal stability of acyclic α,β-unsaturated thioketone is influenced by the substituent groups, particularly heteroatoms (N or S), on the β-position.[4]

As a continuation of our investigation of α,β-unsaturated thioketones,[3,6] we have examined the preparation of β-arylthio α,β-unsaturated thioketone (**9**) in order to investigate the influence of the β-arylthio group on the stability of the α,β-unsaturated thioketone (**9**), and it was found that the thioketone **9** readily dimerized into 3,4-dihydro-1,2-dithiin compounds (**10** and **12**) at room temperature and the dimer **10a** or **12a** isomerized to the thermodynamically more stable dimer, the 3,4-dihydro-2*H*-thiopyran derivative (**13a**), at elevated temperature.

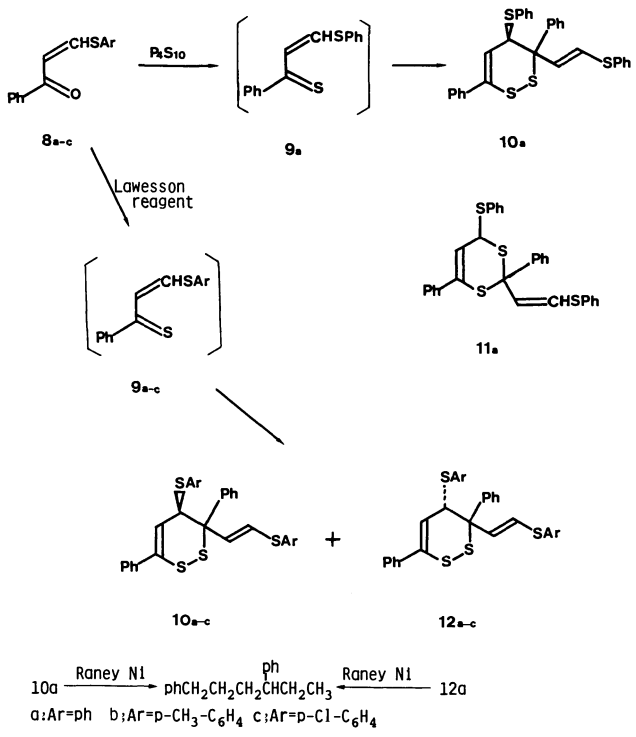




The reaction of 1-phenyl-3-phenylthio-2-propene-1-one (**8a**) with P_4S_{10} gave two products together with a large amount of tarry matter.

In the ^{1}H-NMR spectrum of one product, doublets at δ 6.13 (J=14.8 Hz) and 6.70 (J=14.8 Hz) were assigned to olefinic protons in an *E*-configuration. An assignment of the C-4 proton to the axial position is supported by the coupling constant (J=3.2 Hz) between the C-4 and the C-5 protons.[7,8] The ^{13}C-NMR spectrum exhibited two alkyl carbon signals at δ 55.2 (s) and 58.4 (d). These spectral data are in agreement with the proposed structure **10a** or **11a**. A treatment of this product with Raney nickel (W-2) gave 1,4-diphenylhexane. Therefore, this product was determined to be the 3,4-dihydro-1,2-dithiin structure **10a**.

The ^{1}H-NMR spectrum of the other product showed three olefinic protons at δ 6.33 and one methine proton at δ 4.42. In the ^{13}C-NMR spectrum appeared two alkyl carbon signals. However, it could not be determined whether the product was the 3,4-dihydro-1,2-dithiin or the 4*H*-1,3-dithiin structure.

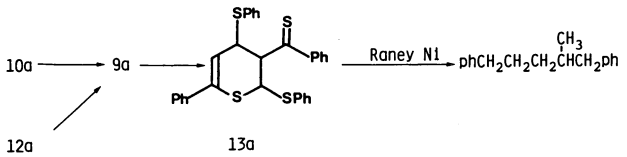


On the other hand, when **8a** was treated with Lawesson reagent while refluxing carbon disulfide, **10a** and **12a** were obtained. The structural assignment of **12a** is based on the ^{1}H-NMR spectrum and its conversion into 1,4-diphenylhexane by a Raney nickel reduction. The assignment of a C-4 proton to the equatorial position is supported by the larger coupling constant (J=5.2 Hz) between the C-4 and the C-5 protons than that of **10a** and in comparison with that of the analogous 3,4-dihydro-1,2-dithiin in the literature.[8]

3,4-Dihydro-1,2-dithiin was unstable during the course of isolation by column chromatography and recrystallization. Thus, the isolated yields were low. The thionation of other ketones **8b** and **8c** with Lawesson reagent afforded **12b** and **10c**, respectively. However, it was not possible to isolate **10b** and **12c** due to the ease of decomposition.

We observed that the color of solution (hexane, chloroform, etc) **10** or **12** turned from pale yellow to green upon heating. Thus, 3,4-dihydro-1,2-dithiin **10a** or **12a** was refluxed in hexane to give 3,4-dihydro-2*H*-thiopyran **13a** in moderate yield, respectively. The molecular ion (m/z 512) was observed in the mass spectrum. The ^{13}C-NMR spectrum exhibited a characteristic thiocarbonyl carbon signal at δ 235.5 and three methine carbon signals. Desulfurization of the dihydrothiopyran gave 2-methyl-1,5-diphenylpentane. Therefore, this compound was assigned to the proposed structure **13a**.

It would be probable that 3,4-dihydro-1,2-dithiin **10** and **12** formed by the cyclodimerization of **9** and the thermal unstable 3,4-dihydro-1,2-dithiin isomerized to the thermodynamically more stable dihydrothiopyran via a retro-Diels-Alder reaction at an elevated temperature (Scheme 1). The β-arylthio group, especially when there was only one sulfur atom, did not contributed to the stabilization of monomer **9**.



Scheme 1.

Experimental

All melting points were uncorrected. ^{1}H-NMR spectra were determined on a JEOL JNM PMX60SI or FX-100 spectrometer and ^{13}C-NMR spectra were recorded on a JEOL JNM-FX-100 spectrometer. Me_4Si was used as an internal standard. Mass spectra were measured on a Hitachi mass spectrometer RMU-7M or a JEOL JMS-DX300 or JMA-3100 mass spectrometer. 2,4-Bis(4-methoxyphenyl)-1,3-dithia-2,4-diphosphetane 2,4-disulfide (Lawesson reagent) was obtained commercially. All 1-phenyl-3-arylthio-2-propene-1-ones (**8**) were prepared according to the method of Engelhard et al.[9]

Thionation with P_4S_{10}. A suspension of 1-phenyl-3-phenylthio-2-propene-1-one **8a** (2.4 g), P_4S_{10} (1.0 g), and triethylamine (1.0 ml) in carbon disulfide (80 ml) was stirred at room temperature for 6 d. The solvent was evaporated and the residue was chromatographed on a Florisil gel by using benzene–hexane (1:1) as the eluent.

The first fraction was determined to be 3,6-diphenyl-4-phenylthio-3-[2-(phenylthio)ethenyl]-3,4-dihydro-1,2-dithiin **10a**: yellow rhombic crystals. Mp 102—104 °C. yield 3.9%. MS (22 eV) m/z: 256 ($M^+/2$, 5.8), 179 (100), 147 (3.9), 121 (11.7), 110 (18). ^{1}H-NMR ($CDCl_3$) δ=4.58 (1H, d, J=3.2 Hz), 6.13 (1H, d, J=14.8 Hz), 6.50 (1H, d, J=3.2 Hz), 6.70 (1H, d, J=14.8 Hz), 7.10—7.67 (20H, m). ^{13}C-NMR ($CDCl_3$) δ=55.2 (s), 58.4 (d), 126.3, 127.1, 127.5, 127.8, 128.4, 128.8, 129.1, 132.4, 135.0, 136.6, 137.8, 141.3. Found: C, 70.00; H, 4.72%. Calcd for $C_{30}H_{24}S_4$: C, 70.27; H, 4.66%.

The second fraction: yellow silky needles. Mp 116—117.5 °C. yield 1.8%. MS (22 eV) m/z: 256 ($M^+/2$,8), 179 (100), 147 (64), 121 (18), 115 (10), 110 (10), 103 (11). ^{1}H-NMR ($CDCl_3$) δ=4.42 (1H, d, J=4.8 Hz), [6.33 (d, J=4.8 Hz), 6.33 (s) total 3H], 7.23—7.70 (20H, m). ^{13}C-NMR ($CDCl_3$) δ=55.5 (d), 63.9 (s), 123.3, 125.9, 126.6, 127.0, 127.3, 127.9, 128.5, 128.9, 129.1, 129.8, 132.1, 132.6, 135.7, 135.9, 138.0, 138.3. Found: C, 70.03; H, 4.66%. Calcd for $C_{30}H_{24}S_4$: C, 70.27; H, 4.66%.

Thionation with Lawesson Reagent. A suspension of **8a** (2.4 g) and Lawesson reagent (2.0 g) in carbon disulfide (20 ml) was refluxed for 5 h under a nitrogen atmosphere. The solvent was removed using a rotary evaporator and the residue was passed through a short column of Florisil gel using benzene–hexane (1:1) as the eluent to give a mixture of **10a** and **12a** (yield 46%). The mixture was chromatographed on Florisil gel using benzene–hexane (1:3) as the eluent.

10a: Yield 13% (recrystallized from benzene–hexane).

12a: Yellow silky needles (recrystallized from benzene–ethanol). Mp 99.5—101.5 °C. yield 7.8%. ^{1}H-NMR ($CDCl_3$) δ=4.27 (1H, d, J=5.2 Hz), 6.23 (1H, d, J=15.2 Hz), 6.40 (1H, d, J=15.2 Hz), 6.52 (1H, d, J=5.2 Hz), 6.97—7.45 (20H, m). ^{13}C-NMR ($CDCl_3$) δ=57.1 (d), 58.4 (s), 126.1, 126.3, 126.8, 127.0, 127.3, 127.7, 127.8, 128.3, 128.6, 128.7, 128.9, 129.1, 129.8, 132.2, 134.0, 134.6, 136.0, 136.5, 138.0, 139.4. Found: C, 70.11; H, 4.57%. Calcd for $C_{30}H_{24}S_4$: C, 70.27; H, 4.66%.

4-(*p*-Methylphenylthio)-3,6-diphenyl-3-[2-(*p*-methylphenylthio)ethenyl]-3,4-dihydro-1,2-dithiin 12b: Mp 108—109 °C. yield 8%. MS (20 eV) m/z: 416 (2), 385 (6), 293 (30), 179 (100). ^{1}H-NMR ($CDCl_3$) δ=2.27 (6H, s), 4.22 (1H, d, J=5.2 Hz), 6.14 (1H, d, J=15.2 Hz), 6.50 (1H, d, J=15.2 Hz), 6.55 (1H, d, J=5.2 Hz), 6.85—7.47 (18H, m). Found: C, 71.01; H, 5.22%. Calcd for $C_{32}H_{28}S_4$: C, 71.07; H, 5.22%.

***p*-(Chlorophenylthio)-3,6-diphenyl-3-[2-(*p*-chlorophenylthio)ethenyl]-3,4-dihydro-1,2-dithiin 10c**: Mp 122—126 °C. yield 22%. MS (20 eV) m/z: 436, 408, 406, 404, 320, 318, 298, 296, 180, 144. ^{1}H-NMR ($CDCl_3$) δ=4.52 (1H, d, J=3.2 Hz), 6.10 (1H, d, J=16.0 Hz), 6.43 (1H, d, J=3.2 Hz), 6.57 (1H, d, J=16.0 Hz), 6.93—7.60 (18H, m). Found: C, 61.59; H, 3.82%. Calcd for $C_{30}H_{22}Cl_2S_4$: C, 61.95; H, 3.81%.

Reduction of 10a with Raney Nickel. To a suspension of freshly prepared W-2 Raney nickel[10] (≃10 g) in ethanol (20 ml) was added 1,2-dithiin **10a** (1.0 g) in benzene (20 ml). The mixture was stirred overnight at room temperature. The mixture was chromatographed on Wakogel C-200 using hexane as the eluent to give 1,4-diphenylhexane: yield 0.3 g (65%). MS (20 eV) m/z: 238 (M^+, 23), 131 (69), 119 (23), 105 (19), 91 (100). ^{1}H-NMR ($CDCl_3$) δ=0.62—2.63 (12H, m), 7.08 (10H). ^{13}C-NMR ($CDCl_3$) δ=12.3, 29.5, 29.9, 36.1, 47.9, 125.7, 125.9, 127.9, 128.3, 128.5, 142.7, 145.8.

Reduction of 12a with Raney Nickel. 1,4-Diphenylhexane: yield 94%.

Reduction of 13a with Raney Nickel. To a suspension of freshly prepared W-2 Raney nickel[10] (≃10 g) in benzene (100 ml) was added dihydrothiopyran **12a** (0.5 g). The mixture was stirred overnight at room temperature. Purification of the mixture by preparative TLC (Merk 5744) using benzene-hexane (1:3) as the eluent gave 2-methyl-1,5-diphenylpentane: yield 73 mg (31%). MS (70 eV) *m/z*: 238 (M^+, 17), 147 (12), 131 (12), 91 (100). ^{1}H-NMR ($CDCl_3$) δ=0.83 (3H, d), 1.17—1.93 (5H, m), 2.13—2.80 (4H, m), 7.10 (10H, s). ^{13}C-NMR ($CDCl_3$) δ=19.3 (t), 29.1 (t), 34.9 (d), 36.1 (t), 36.3 (t), 43.6 (t).

Thermal Isomerization of 10a. A suspension of **10a** (1.145 g) in hexane (100 ml) was refluxed for 9 h under a nitrogen atmosphere. The resulting deep-blue precipitate was collected by filtration and washed with ethanol. The precipitate was recrystallized from benzen-hexane to give 6-phenyl-2,5-bis(phenylthio)-3-thiobenzoyl-3,4-dihydro-2*H*-thiopyran **13a** as a deep blue needles: Mp 128—129 °C. yield 0.894 g (78%). MS (FD) *m/z*: 512 (M^+). ^{1}H-NMR ($CDCl_3$) δ=[4.46 (J=3.6, 7.0, and 0.2 Hz), 4.50 (J=3.6, 4.0, and 0.2 Hz) total 2H], 5.09 (1H, J=7.0, 0.2, and 0.1 Hz), 6.20 (1H, J=4.0, 0.2, and 0.1 Hz), 7.08—7.56 (20H, m). ^{13}C-NMR ($CDCl_3$) δ=47.2 (d), 51.2 (d), 55.6 (d), 119.5, 126.4, 126.5, 127.4, 128.9, 129.1, 129.4, 131.9, 132.1, 132.9, 133.7, 134.4, 135.6, 138.2, 145.8, 235.5. Found: C, 70.30; H, 4.56%. Calcd for $C_{30}H_{24}S_4$: C, 70.27; H, 4.66%.

Thermal Isomerization of 12a. **13a**: yield 53%.

(Received April 22, 1985)

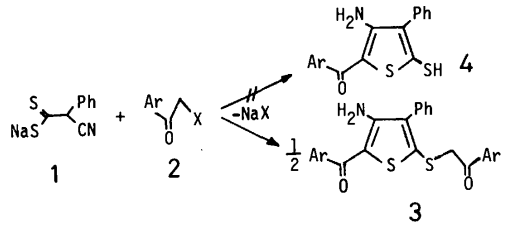
Synopsis. Highly selective cleavage of a side-chain carbon-sulfur bond of thiophene and thiazole derivatives containing acyl, cyano, and ethoxycarbonyl groups was successfully performed by electroreduction to provide the corresponding disulfides and thiols respectively in excellent to good yields.

In the course of our intensive synthetic studies of heterocyclic compounds,[1,2] we found a facile synthesis of 2-acyl-3-aminothiophene derivatives (**3**) from two equiv of α-halo ketones (**2**) and sodium cyanophenyldithioacetate (**1**) in the presence of triethylamine (Scheme 1).[3] Even though equimolar amounts of **1** and **2** were used in this reaction, **3** was always obtained and any 2-acyl-3-amino-5-mercapto-4-phenylthiophenes (**4**) were not formed.

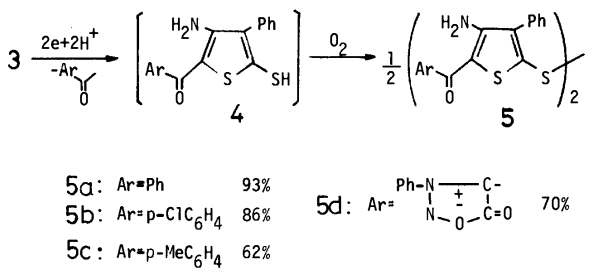
It is well known that the desulfurization of phenacyl sulfides[4] and phenacyl sulfoxides[5] can be easily achieved by chemical reduction with zinc/AcOH or alminum amalgam to provide the corresponding ketones.

Since the molecular structure of **3** is similar to phenacyl sulfides, its chemical reduction was first carried out in a manner similar to that reported.[4,5] However, our attempts to obtain **4** were not successful.

Recently, electrochemical methods have been shown



Scheme 1.



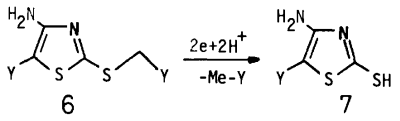
Scheme 2.

to be useful for the deprotection of sulfur moieties for organic synthesis, especially for that of natural products.[6,7] These facts prompted us to attempt the electroreduction of **3**. After several attempts, the constant current electroreduction was successfully carried out at a mercury cathode in DMF containing phenol as a proton source to give rise to **4**. In these electrolyses, after slightly excess of theoretical amount of electricity ($2.2\times96480\ C\ mol^{-1}$) had been passed, the cell voltage was found to increase remarkably and the electrolysis was stopped.

As shown in Scheme 2, the electroreduction proceeded smoothly and cleanly, and the desired **4** could be obtained as the corresponding disulfide (**5**) in good yields. The structure of **5** was determined mainly by the mass spectra together with IR and elemental analysis. The disulfide **5** showed its molecular ion peak and/or its fragments such as M^+-S, M^+-SH, and $M^+/2$. These fragmentation is well known to be characteristic of diaryl disulfides.[8]

Although a typical mesoionic compound, sydnone is interesting for its chemical, physical, and biological properties, its synthesis seems to be limitted, because the sydnone ring is unstable to acid, alkali, and heat.[9] Since the sydnone ring is also easily reduced chemically and electrochemically to decomposition products,[10] no report of the preparative electroreduction of sydnone compounds has been published except for one reported by us[11] and only a few papers deal with polarography of sydnones.[12] From this point, the electroreduction of a sydnone derivatives of **3** was also attempted. It was found that the selective reduction proceeded without any decomposition of the sydnone ring to provide pure **5d** without purification. The isolated disulfides **5** seem to be formed during the work-up by the air-oxidation of **4** once formed by the electroreduction.

At the second stage of this study, we applied this electrochemical technique to other heterocyclic compounds such as thiazoles. Three thiazole derivatives (**6**)[13] were chosen as model compounds. A highly selective electroreduction of **6** proceeded to provide the corresponding 2-mercaptothiazoles (**7**) in good yields as shown in Scheme 3. It is noticeable that disulfides **5** were always obtained as the products from thiophene derivatives **3** whereas thiols **7** were derived from thiazoles **6** in the electroreduction. In these electrolyses, reasonable amount of acetophenone derivatives, acetonitrile, and ethyl acetate were detected in the catholyte by GC analysis and any further reduction did not occur. From these results,



6 7

7a : Y=PhCO 69%
7b : Y=CN 53%
7c : Y=EtOCO 70%

Scheme 3.

the electroreduction seemed to proceed via a two-electron step.

Although **3** and **6** contain other reducible groups such as carbonyl, nitrile, and ester groups, only reductive cleavage of the C-S bond took place selectively.

Since the reduction proceeded selectively and efficiently under quite mild conditions and did not need any reducing reagent, this clean electrochemical method seems to have a potential utility for organic synthesis.

Experimental

Starting Material. Thiophene and thiazole derivatives (**3** and **6**) were prepared using the method reported previously[3] and according to the reference.[13]

General Electrolytic Procedure. An H-type electrolytic cell divided with a glass filter diaphragm was used. A mercury pool (area 7.1 cm^2) and a platinum plate were used as a cathode and anode, respectively. The catholyte was 40 ml of 0.1 mol dm^{-3} $NaClO_4$-DMF solution containing 1.5 mmol of thiophenes **3** or thiazoles **6** together with 3.0 mmol of phenol. The constant current (0.57 A dm^{-2}) was passed at ca. 20 °C.

Analysis and Isolation of Products. After the electrolysis, the catholyte was evaporated under reduced pressure below 60 °C. The residue was mixed with water and neutralized. The resulting precipitated product was collected by filtration, washed with water or ether, and dried. The catholyte was subjected to gas chromatography (PEG 20M) for analysis of acetophenones, acetonitrile, and ethyl acetate.

Bis(4-Amino-5-benzoyl-3-phenyl-2-thienyl) Disulfide (5a): Mp 174 °C (from ethanol). IR (KBr) 3500, 3300 (νNH) and 1590 cm^{-1} (νC=O). MS *m/z* 620 (M^+), 588 (M^+-S), 587 (M^+-SH), 310 ($M^+/2$), and 105 ($PhCO^+$). Found: C, 65.79; H, 3.69; N, 4.52%. Calcd for $C_{34}H_{24}N_2O_2S_4$: C, 65.78; H, 3.90; N, 4.51%.

Bis[4-amino-5-(*p*-chlorobenzoyl)-3-phenyl-2-thienyl] Disulfide (5b): Mp 138 °C (from DMF). IR (KBr): 3450, 3300 (νNH) and 1580 cm^{-1} (νC=O). MS *m/z* 660 (M^++4−S), 658 (M^++2−S), 656 (M^+-S), 655 (M^+-SH), 346 (M^++4/2), 345 (M^++2/2), 344 ($M^+/2$), 141, and 139 (p-$ClC_6H_4CO^+$). Found: C, 59.16; H, 3.23; N, 4.45%. Calcd for $C_{34}H_{22}N_2S_4Cl_2$: C, 59.21; H, 3.21; N, 4.08%.

Bis[4-Amino-5-(*p*-toluoyl)-3-phenyl-2-thienyl] Disulfide (5c): Mp 136 °C (from EtOH-DMF). IR (KBr): 3500, 3300 (νNH), 1605 and 1580 cm^{-1} (νC=O). MS *m/z* 616 (M^+-S), 615 (M^+-SH), 325 ($M^+/2+H$), and 120 (p-$MeC_2H_4CHO^+$). ^1H NMR (acetone-d_6) δ=2.44 (s, 6H, CH_3), 3.08 (broad s, 4H, NH_2), and 7.28—7.92 (m, 18H, Ar-H). Found: C, 66.54; H, 4.49; N, 4.32%. Calcd for $C_{36}H_{28}N_2O_2S_4$: C, 66.64; H, 4.35; N, 4.32%.

Bis[4-Amino-5-(3-phenyl-4-sydnonylcarbonyl)-3-phenyl-2-thienyl] Disulfide (5d): Mp 194 °C (decomp). IR (KBr): 3480, 3320 (νNH), 1775 (νC=O of a sydnone ring), and 1580 cm^{-1} (νC=O). MS *m/z* 478 (M^+-PhN-CO-NO-PhN—C-(N±C=O, O⁻)), 438 (M^+- PhN—C-(N±C=O, O⁻) — PhN—C-CO(N±C=O, O⁻)), and 189 (PhN—C-CO⁺ (N±C=O, O⁻)). Found: C, 57.61; H, 3.30; N, 10.54%. Calcd for $C_{38}H_{24}N_6O_6S_4$: C, 57.86; H, 3.07; N, 10.65%.

4-Amino-5-benzoyl-2-mercaptothiazole (7a): Mp 231 °C (from ethanol). IR (KBr): 3400, 3300 (νNH) and 1640 cm^{-1} (νC=O). MS *m/z* 236 (M^+), 235 (M^+-H), 159 (M^+-Ph), 130 ($M^+-H-PhCO$), and 105 ($PhCO^+$). Found *m/z* 236.0039. Calcd for $C_{10}H_8N_2OS_2$: 236.0077.

4-Amino-5-cyano-2-mercaptothiazole (7b): Mp 202—203 °C (from ethanol). IR (KBr): 3320, 3220, 3100 (νNH) and 2220 cm^{-1} (νC=N). MS *m/z* 157 (M^+), 130 (M^+-HCN), and 98 ($M^+-HCN-S$). Found: C, 30.60; H, 1.81; N, 26.73%. Calcd for $C_4H_3N_3S_2$: C, 30.56; H, 1.81; N, 26.73%.

4-Amino-5-ethoxycarbonyl-2-mercaptothiazole (7c): Mp 192 °C (from ethanol). IR (KBr): 3400, 3320, 3220 (νNH) and 1670 (νC=O). MS *m/z* 204 (M^+), 176 ($M^+-C_2H_4$), 159 (M^+-EtO), and 130 ($M^+-H-EtOCO$). Found: C, 35.56; H, 3.83; N 13.61%. Calcd for $C_6H_8N_2O_2S_2$: C, 35.28; H, 3.95; N, 13.71%.

We are grateful for valuable discussion with Profs. H.-J. Tien and M.-Y. Yeh of National Cheng Kung University, Taiwan, Republic of China, and thank Dr. Y. Fujimoto, Tokyo Institute of Technology and Mitsubishi Chemical Industry for MS and Hi-MS measurement.

Reaction of Tri-*n*-butyltin ω-Haloalkoxide (*n*-$Bu_3SnO(CH_2)_nX$) with Isothiocyanate

Akio BABA, Ikuya SHIBATA,* Hiroki KASHIWAGI, and Haruo MATSUDA
Department of Applied Chemistry, Faculty of Engineering, Osaka University,
2-1 Yamadaoka, Suita, Osaka 565
(Received August 8, 1985)

Synopsis. Tri-*n*-butyltin ω-haloalkoxides are useful reagents for the preparation of sulfur-containing five- and six-membered cyclic compounds combined with isothiocyanates.

We have recently reported the novel use of tri-*n*-butyltin ω-haloalkoxides (*n*-$Bu_3SnO(CH_2)_nX$ n=2,3 X=Cl, Br, I) (**1**). They are useful reagents yielding a variety of five- and six-membered heterocyclic compounds by combination with isocyanates or carbodiimides.[1] An important feature of this reaction is that **1** can be regarded as a synthon of oxiranes or oxetanes.[2] Nevertheless, in some cases, several types of compounds different from the cycloadducts of heterocumulenes with oxiranes can be obtained.

The cycloaddition of isothiocyanates to oxiranes has been investigated,[3] but in these cases, cycloadducts were obtained only by using activated isothiocyanates such as benzoyl and acetyl isothiocyanate. In other isothiocyanates such as aromatic and aliphatic isothiocyanates, no sulfur-containing cycloadduct has been obtained because of the isomerization from oxathiolanimines to oxazolidinones in the presence of oxiranes, moreover, the formation of by-products was often a problem.[4]

As a part of continuing study on synthetic use of **1**, we wish herein to report the reaction of **1** with isothiocyanates (**2**), thereby preparing five- and six-membered sulfur- containing cyclic compounds under mild condition (Scheme 1).

Treatment of *n*-$Bu_3SnO(CH_2)_2X$ with PhNCS gave a mixture of *N*-phenyl-1,3-oxathiolan-2-imine **3** and 3-phenyl-1,3-oxazolidin-2-thione **4**. The proportion of these products appeared to be dependent on the nature of substrates and solvents as shown in Table 1. The order of the reactivity of halogen species in **1** was Cl<Br<I, and the proportion of **4** was decreased in this order (entries 1, 3, and 4). The use of the chloride in hexane induced the predominant formation of **4a** (entry 1), which has not been obtained even from the cycloaddition of activated isothiocyanates to oxiranes.[3] Meanwhile, DMF, when used as a solvent,

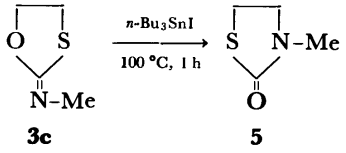
a) **1** 10 mmol, **2** 8 mmol, Temp. 40 °C, Time 1 h, b) Determined by GLC, c) 25 °C.

accelerated the reaction, and the proportion of **3a** was greater than in hexane (entries 2 and 5). Similar effects of DMF were observed in the reactions with alkyl isothiocyanates, although, the reactivity of which was low (entries 6—10).

At the initial stage of the reaction, isothiocyanates were added to **1** exothermically, and the IR absorption band of ν NCS immediately disappeared and the new band around 1600 cm^{-1} (C=N) was recognized.[5] In the case of isocyanates, two types of adducts were considered.[1] However, because of the great affinity of tin toward sulfur atoms,[6] the addition of **1** may take place only across the C=S group of RNCS as described by Davies et al.,[7] giving **A** as an intermediate (Scheme 1). In next stage, the intramolecular alkylation at the sulfur atom and at the nitrogen atom gives **3** and **4**, respectively. Although the formation of **4** was generally predominant, DMF increased the proportion of **3**. This is explained by the coordination of DMF to the tin atom in **A** as a Lewis base. The basicity of the sulfur atom adjacent to the tin is thus increased, therefore, the intramolecular S-alkylation is accelerated, giving **3** predominantly. This is not the case, however, in the case of tri-*n*-butyltin γ-halopropoxides (*n*-$Bu_3SnO(CH_2)_3X$). Compound **4d** was produced in a higher selectivity than *n*-$Bu_3SnO(CH_2)_2X$ even when DMF was used (entries 11—13).

Alternatively, the isomerization of initially formed **3** to **4** catalyzed by *n*-Bu_3SnI which is a by-product of the reaction of **1** with **2**, can be considered. However, no isomerization was recognized by the treatment of **3c** with an equimolar *n*-Bu_3SnI at 40 °C for 1 h, and **3c** was recovered quantitatively.

On the other hand, treatment of **3c** with an equimolar *n*-Bu_3SnI at 100 °C for 1 h induced the formation of the thiazolidinone **5** in 50% yield as described by Sakai et al.[8]



3c **5**

In this case, formation of **4c** could not be recognized. We thus conclude that no isomerization of **3** to **4** occurred under present conditions.

Experimental

***N*-Phenyl-1,3-oxathiolan-2-imine (3a).** *n*-$Bu_3SnO(CH_2)_2I$ (4.61 g, 10 mmol) and PhNCS (1.08 g, 8 mmol) were stirred under dry N_2 on cooling, then heat was evolved about 40 °C. The infrared spectrum showed the disappearance of the characteristic absorption band of ν NCS at 2100 cm^{-1} and the presence of a new band around 1600 cm^{-1}. After additional 5 min, DMF (5 ml) was added and the stirring was continued for 1 h at 25 °C. The addition of excess amounts of hexane on cooling induced 1.79 g of white precipitates immediately, which were filtered, washed with hexane and dried in vacuo. The precipitates contained *N*-phenyl-1,3-oxathiolan-2-imine **3a** as a mixture with **4a** (100%, **3a**:**4a**=83:17, entry 5). The **3**/**4** ratio was determined by GLC. Analytically pure sample of **3a** was obtained by column chromatography (Silica gel, $CHCl_3$). Compound **4a** was obtained as the major product from the reaction of *n*-$Bu_3SnO(CH_2)_2Cl$ (entry 1). Spectral data for **3a** was as follows; mp 65—67 °C (lit,[8] mp 65—65.5 °C); IR (KBr) 1035, 1110, 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.40 (t, 2H, $C\underline{H}_2S$), 4.50 (t, 2H, $C\underline{H}_2O$), 6.90—7.50 (m, 5H, phenyl).

Following compounds were isolated similarly.

Synopsis. The ESR spectra of polycrystalline samples of bis(*N*,*N*-dimethylformamide)tetrakis(3-ethyl-2-pyridonato)dicopper(II) and its 3-methyl-2-pyridone analogue have been measured at X-band (≈9.5 GHz) and Q-band (≈34 GHz) frequencies. The spectra are characteristic of S=1 species and the parameters (g_z 2.30, g_{xy} 2.05 and $D\approx0.29\,cm^{-1}$) are discussed in terms of the known binuclear structure.

Many binuclear copper(II) complexes are known in which two copper(II) ions are bridged by four carboxylato groups.[1,2] Analogous compounds in which nitrogen atoms are the donor atoms in the bridging unit are fewer in number,[3] and those in which the four bridges each contain one N and one O donor atom are even rarer[4] though they are well-established for other metal ions.[5]

Two complementary techniques have been customarily employed to study the electronic nature of such binuclear copper(II) compounds with the classic copper(II) acetate structure. Studies of the temperature dependence of the magnetic susceptibility generally show that the pair of copper(II) atoms are antiferromagnetically coupled, giving an $S=0$ ground state and $S=1$ level $|2J|$ above this. Application of the Bleaney and Bowers equation[6] permits evaluation of $|2J|$ and, for powder samples, an average g value. Measurement of the ESR spectra arising from those molecules within the thermally accessible $S=1$ state and application of the spin Hamiltonian (1) permit derivation of the zero-field splitting

$$\mathscr{H} = g\beta B.\hat{S} + D\hat{S}_z^2 + E(\hat{S}_x^2-\hat{S}_y^2) - 2D/3 \quad (1)$$

parameters D and E and the g values g_x, g_y, g_z if $E\neq0$, or g_z and g_{xy} if $E=0$.

It has recently been shown by X-ray methods[4] that bis(*N*,*N*-dimethylformamide)tetrakis(3-ethyl-2-pyridonato)dicopper(II) has a structure of the copper(II) acetate type but with N,O donor atom bridges. This has afforded us the opportunity of comparing the ESR parameters for such a bridging unit with those of bridges containing only O or N atoms as donors.

Experimental

The complexes $[Cu_2(3\text{-ethyl-pyr})_4(dmf)_2]$ and its 3-methyl-2-pyridone analogue were prepared as described previously.[4] Their ESR spectra were obtained as polycrystalline samples at room temperature using Varian E12 X-band (≈9.5 GHz) and Bruker ER200 Q-band (≈34 GHz) spectrometers.

Results and Discussion

The X- and Q-band ESR spectra of $[Cu_2(3\text{-ethyl-pyr})_4(dmf)_2]$ are shown in Figs. 1 and 2 respectively.

Solution of the spin Hamiltonian (1) for the situation where $D<h\nu$ and $E=0$ yields four allowed ($\Delta m_s=1$) transitions at resonance field B_{z1}, B_{z2}, B_{xy1}, and B_{xy2} given by:[7]

$$B_{z1} = (g_e/g_z)|B_0-D'| \qquad B_{z2} = (g_e/g_z)(B_0+D')$$
$$B_{xy1}^2 = (g_e/g_{xy})^2B_0(B_0-D') \qquad B_{xy2}^2 = (g_e/g_{xy})^2B_0(B_0+D')$$

where $B_0=h\nu/g_e\beta$ and $D'=D/g_e\beta$. In addition the formally forbidden $\Delta m_s=2$ transition between the $|-1\rangle$ and $|+1\rangle$ levels, the so-called half-field transition, is often observed.

Assignments of the observed transitions in Figs. 1 and 2 are summarized in Table 1 for the parameters $g_{xy}=2.05$, $g_z=2.30$, and $D=0.287\,cm^{-1}$. The values of B_{z2} and B_{xy2} are such that the transitions are virtually coincident at Q-band frequency (calculated values of 13,203 and 13,230 gauss respectively at 33.90 GHz). Consequently the low intensity B_{z2} band is hidden by the much stronger B_{xy2} band. Changing the microwave frequency to X-band enables a clear separation of these transitions to be made (Fig. 2). Conversely, the B_{z1}, B_{xy1}, and $\Delta m_s=2$ transitions could not have been unambiguously assigned from the X-band results alone because of appreciable band

Table 1. ESR Data for the Complexes[a]

	$[Cu(3\text{-ethyl-pyr})_2(dmf)]_2$		$[Cu(3\text{-methyl-pyr})_2(dmf)]_2$

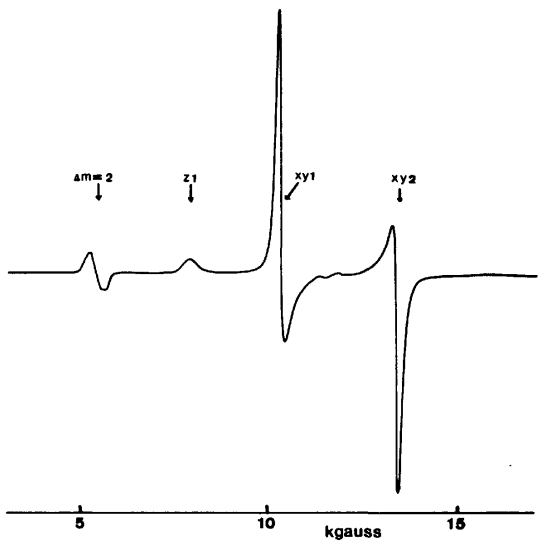

Fig. 1. Q-band ESR spectrum of $[Cu_2(3\text{-Et-pyr})_4(dmf)_2]$(kgauss=$10^{-1}$T).

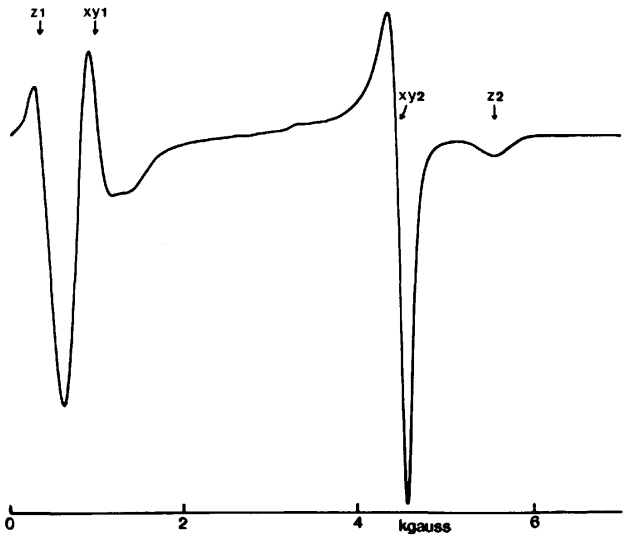

Fig. 2. X-band ESR spectrum of $[Cu_2(3\text{-Et-pyr})_4(dmf)_2]$(kgauss=$10^{-1}$T).

overlap at that frequency. However these transitions are clearly resolved and readily assigned at Q-band frequency. The advantage of measuring such spectra at more than one microwave frequency is well demonstrated by these results.

The observation that E=0, or at least too small to be evident in any splitting of the B_{xy1} and B_{xy2} bands, is in good agreement with the results of the X-ray structural determination.[4] The pairs of N and O donor atoms from the four pyridone bridges are arranged in cis-dispositions about each Cu atom and the angular and bond-length deviations from axial symmetry are small.

The ESR spectra of $[Cu_2(3\text{-methyl-pyr})_4(dmf)_2]$ are virtually identical to those disussed above, and the derived parameters and assignmens are listed in Table 1. This close similarity tallies well with the reported[4] agreement of their magnetic properties. Moreover the average g value (2.15) derived from the temperature dependence of their magnetic susceptibilities[4] is close to that (2.14) we obtain from the ESR spectra by using the expression: $g_{av}^2=(g_z^2+2g_{xy}^2)/3$.

The D values we observe ($\approx$0.29 cm^{-1}) are somewhat smaller than those (0.33—0.44 cm^{-1}) generally found for copper(II) carboxylate dimers[1,2,8] but they are larger than the values (0.1—0.19 cm^{-1}) reported[3,9] for analogous copper(II) dimers with nitrogen donor atoms in the bridges (see Table 2). It is interesting to note in this context that Brookes and Martin found $D\approx$0.27 cm^{-1} for $Cu(CH_3CO_2)L\cdot X$, where L represents the anion of 1,7-diazaindene and X=1,7-diazaindene or pyridine.[3]

The observed D value, $D_{obs}=D_{dd}+D_{exch}$, where D_{dd} arises from dipole-dipole interaction, and D_{exch} from exchange. D_{dd}, which is expected to be negative, is approximately calculated[14] from the equation based on a point dipole model, $R^3=0.65g_z^2/D_{dd}$, where R is the copper-copper distance. Use of the equation yields D_{dd}=0.207 cm^{-1}, and therefore D_{exch}=0.494 cm^{-1} for $[Cu_2(3\text{-ethyl-pyr})_2(dmf)_2]$($R$=2.55 Å). Rough correlations between D_{exch} and $|2J|$, the energy separation between the singlet ground state and the triplet first-excited state, have sometimes been made,[2,14] by means of the equation, $D_{exch}=-2J[(g_z\text{-}2)^2/4\text{-}(g_{xy}\text{-}2)^2]/8$. Use of this equation predicts a value of $|2J|$ of 198 cm^{-1}, whereas the experimental value[4] is 395

cm^{-1}. The difference between the calculated and the experimental values may be due to the approximations assumed in deriving the equations, and also to the fact that the singlet-triplet splitting is not simply related to the strength of the exchange interaction, as pointed out elsewhere.[2,15,16]

Pretreatments of Porous Silica for Improving the Activity of a Nickel-Loaded Catalyst

Masahiko Arai, Yutaka Ikushima, and Yoshiyuki Nishiyama*
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980
(Received July 15, 1985)

Nickel catalysts supported on porous silicas treated with water, ethanol, and 1-butanol were found to be more active than that supported on untreated silica for ethane hydrogenolysis and furan hydrogenation. To elucidate the reason for the activation, some surface properties of the treated silicas were examined. The treatments decreased the surface area and increased the volume of the macropores, the surface density of hydroxyl groups, and the heat of immersion in water per unit surface area. The state of nickel on the support was examined by temperature programed desorption(TPD) of hydrogen, X-ray diffraction(XRD), and scanning electron microscopy/X-ray microanalysis. The dispersion measured by XRD was not appreciably altered by the treatments, but the TPD showed more hydrogen desorbed above 150 °C from nickel on the treated supports. The activation of nickel by pretreatment of the support was ascribed to the increase of those nickel atoms which dispersed finely over the support by the increased number of surface hydroxyl groups. This was based on the number of hydroxyl groups per unit surface area. The nickel catalyst supported on the pretreated silicas showed greater thermal stability.

It is well established that the activities of supported metal catalysts are influenced by the surface properties of the supports, so that the choice of the support material is important for the preparation of the catalysts.[1] Therefore some surface modifications of the support can improve the activity of the catalysts loaded on it. Previously, we have reported that nickel and platinum catalysts loaded on porous silicas pretreated with water and alcohols are more active than those on untreated silicas.[2,3] As the impregnation of the active metal species was done from aqueous solutions, it was our anticipation that alcohol treatment, which would be expected to give the surface a hydrophobic nature, would lead to a lower dispersion of the active metal. Contrary to this anticipation, the catalytic activities of metals on alcohol treated silicas were found to be higher than those on untreated silica. As a follow-up of the previous work, the present study was undertaken to clarify the reason for the activation by the pretreatment of the support. In doing so, temperature programed desorption of hydrogen was extensively used to characterize the state of nickel on the support, as it seems to be more relevant to examine those metals which are active in catalysis.[2]

A number of researches on surface modifications of silica as well as other metal oxides have been reported in the literature.[4—10] Their concern of these authors, however, is more with the actions of modified surfaces as adsorbents and solid acid catalysts. There was little attempt made to use modified materials as supports for the metal catalyst.

Experimental

A porous silica material was used, Silbead-N obtained from Mizusawa Industrial Chemicals, Ltd. It was powdered to 32—60 mesh and treated with water at 280 °C, ethanol at 280 °C, and 1-butanol at 250 °C. Detailed procedures of these treatments were described previously.[2,3] The silica was characterized before and after the treatments by the following means. (i) The surface area was measured by the nitrogen BET method. (ii) The pore size distribution was determined by the Cranston-Inkley method using a nitrogen adsorption isotherm[11] and by a mercury porosimetry (Shimadzu-Micromeritics Pore Sizer 9300). (iii) FT-IR diffuse reflectance spectra were obtained using a mixture of the silica (ca. 5 wt%) and potassium bromide with a JEOL JIR-100 spectrometer. (iv) The heat of immersion in either water or hexane was measured at 22 °C using a Tokyo Riko TCC-21 calorimeter.

Using the treated and untreated silicas, supported nickel (5 wt%) catalysts were prepared by impregnation with nickel nitrate from its aqueous solution. The impregnated samples were vacuum dried and reduced in flowing hydrogen at 350 °C for 16 h. The state of the nickel dispersion was examined by temperature programed desorption (TPD) of hydrogen, X-ray diffraction line broadening (XRD), and scanning electron microscopy/X-ray microanalysis (SEM-XMA). For TPD, using a 5 mm i.d. quartz tube reactor operated at atmospheric pressure, ca. 0.3 g of the catalyst was exposed to flowing hydrogen of 48 ml min^{-1} at room temperature for 20 min. The adsorbed hydrogen was then desorbed by linear heating at 30 °C min^{-1} in an argon carrier at a flow rate of 40 ml min^{-1}. The catalytic activity was examined for ethane hydrogenolysis at 350 °C and furan hydrogenation at 110 and 200 °C with ethane and furan partial pressures of 16.0 and 27.7 kPa, respectively. The apparatus and procedures for the TPD and the activity test were described in detail previously.[2,3]

In the following sections, the water-, ethanol-, and 1-butanol-treated and untreated silicas will be referred to as SI(W), SI(E), SI(B), and SI(U), respectively.

Results

Effects of Treatments of Silica on the Surface Properties.

(1) Surface Area and Porosity. The BET surface area, pore volumes, and XRD data as well as the heat of immersion of the silicas are summarized in Table 1. The treatments caused the surface area to decrease to less than 1/5 of the initial value. The pores in SI(U) were mostly smaller than 5 nm in diameter and the treatments enlarged the pore diameter. Compared with

Table 1. Characterization of Treated and Untreated Silicas

	SI(U)	SI(W)	SI(E)	SI(B)
Surface area (m^2/g)	680.0	74.3	98.1	131.2
Pore volume (ml/g)				
diameter<5 nm	0.202	0.052	0.010	0.020
5—30 nm	0.021	0.063	0.142	0.220
XRD[a] 2θ (deg)	23.8	21.6	22.0	22.2
d (nm)	0.37	0.41	0.40	0.40
Heat of immersion				
in water (J/m^2)	0.218	0.616	0.422	0.417
in hexane (J/m^2)	0.246	0.335	0.200	0.276

a) A Cu $K\alpha$ ray was used. d is the corresponding interlayer spacing.

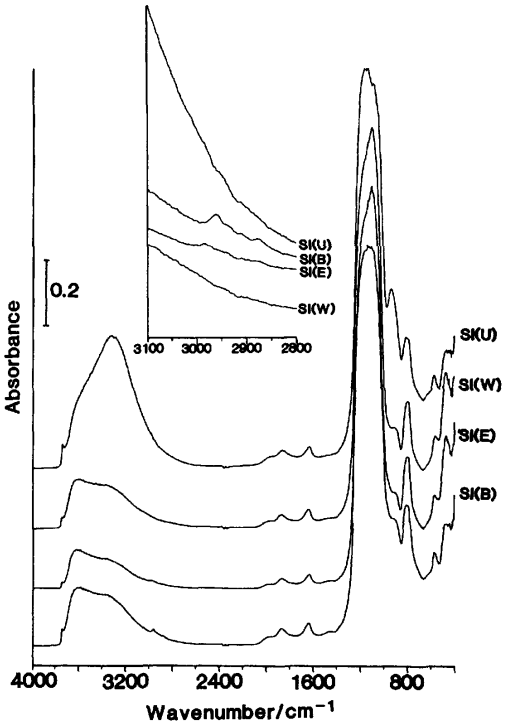

Fig. 1. FT-IR spectra for treated and untreated silicas.

SI(U), the total pore volumes of SI(W) and SI(E) were smaller by factors of 0.6—0.7 while that of SI(B) was comparable. The mercury porosimetry showed the absence of macropores larger than 30 nm even in the treated silicas. The observed maximum pore diameter was 20 nm for SI(E) and SI(B) and 30 nm for SI(W).

The XRD showed an increase in the interlayer spacing, d, with the treatments, the order of d being SI(W)>SI(E)≥SI(B)>SI(U). This suggests that the treatments caused a growth of cristobalite- and/or tridymite-like structure in the silica.

(2) Infrared Absorption Spectra. In Fig. 1, FT-IR spectra for the treated and untreated silicas are compared. The intensity of absorption of the sharp peak at 3750 cm^{-1}, of the broad band between 3600 and 2800 cm^{-1}, and of the weak band at 870 cm^{-1} was decreased by the treatments. These absorptions can be

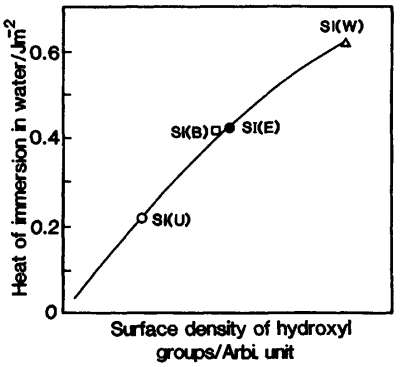

Fig. 2. A plot of heat of immersion in water versus relative surface density of hydroxyl groups.

assigned to surface hydroxyl groups. Thus the number of hydroxyl groups on the treated silicas was smaller than that on the untreated silica when compared on a unit weight basis. However, as the surface area was decreased by the treatments, the number of hydroxyl groups in unit surface area increased (see Fig. 2). In addition, the spectra of SI(E) and SI(B) have absorption bands at 1450 and 2950 cm^{-1}, which can be assigned to methyl and methylene groups. These indicate the exchange of some hydroxyl groups with alkoxyl groups on the silica surface.

(3) Heat of Immersion in Water and Hexane. The heat of immersion per unit surface area is presented in Table 1. The surface treatments caused the heat of immersion in water to increase by factors of about 3 and 2 for the water and alcohol treatments, respectively. Figure 2 shows a plot of the heat of immersion in water against the relative density of surface hydroxyl groups from FT-IR. The latter was obtained by graphically integrating the absorbance between 2600 to 3800 cm^{-1} in Fig.1 and then normalizing to the absorbance at 1640 cm^{-1} assigned to a silicon-oxygen overtone vibration.[12,13] The correlation indicates that the surface hydrophilicity was associated with the surface hydroxyl groups for the present silicas and that, contrary to expectation, the treatment by alcohols rendered the silica more hydrophilic nature. On the other hand, the heat of immersion in hexane per unit surface area was only slightly changed. It was increased by the water and 1-butanol treatments but it was decreased by the ethanol treatment.

Effect of Silica Pretreatments on the Catalytic Properties of Supported Nickel.

(1) Metal Dispersion. Figure 3 shows TPD spectra of hydrogen adsorbed on the nickel catalysts on SI(U), SI(W), and SI(B). In the present TPD experiment, the heating of the catalyst was restricted to below 350 °C to avoid thermal effects on the nickel dispersion during repeated measurements. It was found that the catalysts on the treated silicas could, as a whole, adsorb larger amount of hydrogen than that on SI(U). After the heat treatment in hydrogen at 500 and 700 °C, the total

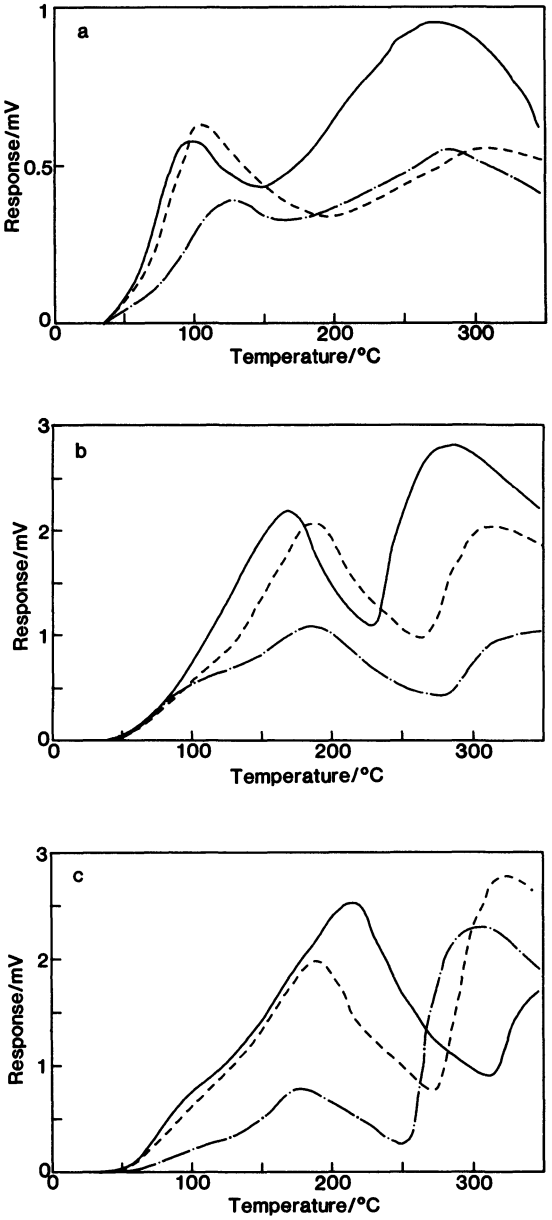

Fig. 3. TPD spectra of hydrogen adsorbed on (a) Ni/SI(U), (b) Ni/SI(W), and (c) Ni/SI(B). ——: as reduced, – – –: heated in hydrogen at 500°C for 1 h, —·—: heated in hydrogen at 700°C for 1 h.

amount of hydrogen desorbed in the TPD decreased for all the catalysts used. However, the amounts of hydrogen desorbed from nickel on the treated silicas were larger or, at least, comparable to that from the catalyst on SI(U) without the heat treatment although the TPD patterns were different.

Table 2 presents mean crystallite sizes of the supported nickel obtained by XRD, including the influence of heat treatment in hydrogen at 700°C for 1 h. It shows that the nickel crystallites in the catalysts as prepared had similar sizes although the supports used were different in the surface area, porosity, and hydrophilicity as noted above. On heat treatment, the crystallites in all the catalysts grew but the extent of growth was larger

Table 2. Mean Nickel Crystallite Size[a)]

H.T.T.[b)]	Support			
	SI(U)	SI(W)	SI(E)	SI(B)

a) Determined by an XRD line broadening, in nm. b) Heat treatment temperature. The treatment was performed in a flowing hydrogen for 1 h.

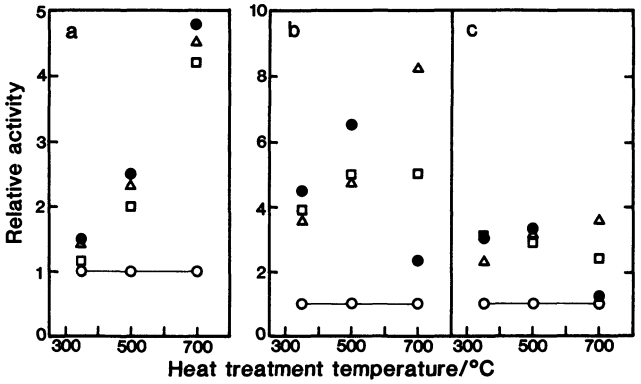

Fig. 4. Relative activities of (△) Ni/SI(W), (●) Ni/SI(E), and (□) Ni/SI(B) to (○) Ni/SI(U) for ethane hydrogenolysis at 350°C (a) and furan hydrogenation at 110°C (b) and at 200°C (c).

for the treated silicas than that for SI(U).

To see whether or not the surface pretreatment of the support caused some irregular distribution of nickel at the time of impregnation, the radial distribution of nickel on the cleaved surface of a catalyst particle was examined by SEM-XMA. The nickel distribution was found to be uniform within experimental error for all the catalysts on SI(U), SI(W), SI(E), and SI(B).

(2) Catalytic Activity. Figure 4 shows the catalytic activities of nickel supported on the treated silicas in ethane hydrogenolysis and furan hydrogenation relative to those of nickel on untreated silica. For the SI(U)-supported catalyst, the heat treatment in hydrogen at 500°C decreased the activity in ethane hydrogenolysis at 350°C by 44% and those in furan hydrogenation at 110 and 200°C by 35 and 22%, respectively; the treatment at 700°C decreased it in the same order, by 80, 68, and 60%. Though the heat treatment deactivated all the catalysts examined, those on surface-modified silicas were more stable against thermal deactivation than that on SI(U) as seen in Fig. 4.

Discussion

It is noteworthy that the structure of the silica was altered by the autoclave treatments with such alcohols as ethanol and 1-butanol as well as with water. Namely, the treatments decreased the surface area by factors less than 1/5 while they increased the volume of the pores in the range of 5-30 nm in diameter. Previous workers

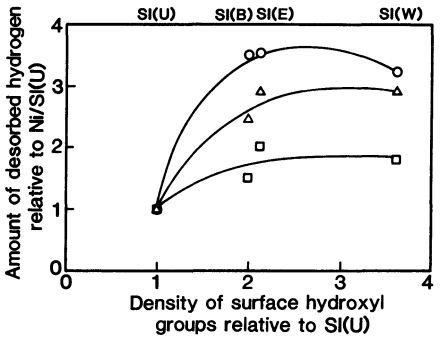

Fig. 5. Correlation between hydrogen adsorbability of supported nickel and density of surface hydroxyl groups of the supports. ○: Desorbed at 150—250 °C, △: 150—300 °C, □: 25—350 °C.

showed that the hydrothermal treatment of oxide gels including alumina and silica-alumina resulted in the change of surface area and pore structure, and it varied their catalytic properties.[10,14] On our treatments, the extent of the structural change is thought to be associated with the penetrability of the treating agent into the silica gel structure. The solvents penetrated into unstable gel caused some rearrangement of its structural units, resulting in a partial crystallization as indicated by the XRD measurements, thereby reducing its surface area.

Along with the structural change, there occurred chemical change of the silica surface on the treatments. They increased the density of hydroxyl groups on the surface. The larger heat of immersion of treated silicas in water on unit surface area basis than that of untreated one is mainly due to the increased density of the surface hydroxyl groups. Some of the surface hydroxyl groups were replaced with alkoxyl groups by the alcohol treatments as expected, but their effect on the surface properties seems small.

An interesting finding is that the pretreatments of the silica enhanced the catalytic activity of supported nickel in spite of a concurrent significant decrease in the surface area of the silica. One probable explanation is that the larger density of the hydroxyl groups on the silica surface resulted in a higher dispersion of nickel, as evidenced by the TPD of hydrogen. Figure 5 shows the plot of the amount of hydrogen desorbed against the density of surface hydroxyl groups from the FT-IR spectra, both in relative values to SI(U). It suggests that the amount of hydrogen retained on the catalyst has some correlation with the surface hydroxyl groups on the support. The hydrogen adsorbability can be related with the catalytic activity in either hydrogenolysis or hydrogenation.[2] Dispersion of nickel estimated from XRD gave no reasonable correlation with the catalytic activity. It is therefore inferred that well-dispersed nickel atoms play a main role in the catalysis and those in larger crystallites have small activity.

For all the catalysts examined, the heat treatment in hydrogen at 500 and 700 °C caused deactivation due to the sintering of the nickel crystallites as evidenced by the XRD measurements. At treatment temperatures of 500 and 700 °C, there is a possibility of an occurrence of strong nickel-support interaction, e. g., the formation of a nickel-support complex.[15,16] Nickel atoms on the treated silicas were more stable than those on the untreated one, which suggested a stronger interaction with the treated supports.

Part of the enhanced activities of the catalysts on the pretreated supports may be ascribed to their increased pore diameter, which would favor the diffusion of reactants and products in the catalyst. The contribution of pores in activity enhancement needs further study.

The present study was done using a particular kind of silica gel, so that it is natural to ask whether the pretreatments of the support are applicable to other substances as well. An additional study using two aluminas indicated that the effectiveness of the pretreatments depended on the substance used; a catalyst with Neobead-C (Mizusawa Industrial Chemicals, Ltd.) was activated by the pretreatment of the support though the extent of the activation was less marked, whereas the other with JRC-ALO-1 (Catalysis Society of Japan) was not activated to any appreciable extent.

The Photochemical Formation of the π-Cation Radical from Chloro(5,10,15,20-tetraphenylporphyrinato)cobalt(III) in Aerated Dichloromethane

(Received July 15, 1985)

Chloro(5,10,15,20-tetraphenylporphyrinato)cobalt(III), Co^{III}(tpp)Cl, in an aerated dichloromethane(DCM) solution undergoes photooxidation to produce the porphyrin π-cation radicals, $Co^{III}(tpp)^{+\cdot}Cl_2$. The formation mechanism of the π-cation radical was investigated by means of optical absorption and ESR spectroscopy: Co^{III}(tpp)Cl in DCM decomposes photochemically to yield Co^{II}(tpp) and chlorine atoms, which then abstract hydrogen atoms from DCM molecules to yield solvent radicals, $\cdot CHCl_2$, and HCl. The solvent radicals react with oxygen molecules, resulting in the generation of peroxyl radicals, which then oxidize Co^{III}(tpp)Cl to produce the π-cation radicals, $Co^{III}(tpp)^{+\cdot}Cl_2$.

In an earlier paper[1] we reported that chloro (5, 10, 15, 20-tetraphenylporphyrinato)cobalt(III), Co^{III}(tpp)Cl, in chlorinated hydrocarbon solutions is converted, partially and reversibly, into a π-cation radical of (tetraphenylporphyrinato)cobalt(III), $Co^{III}(tpp)^{+\cdot}Cl_2$, by thermal and light activations. Such behavior of Co^{III}(tpp)Cl is considered to be closely related to the enzymatic reactions of natural metalloporphyrins. In previous papers,[2,3] we reported that crystals of Co^{III}(tpp)Cl always contain a small amount of the π-cation radical and Co^{II}(tpp). This fact suggests that these oxidation and reduction products are easily formed in the process of preparing Co^{III}(tpp)Cl. The elucidation of the redox behavior of Co^{III}(tpp)Cl is expected to give useful information for an understanding of the functions of peroxidases in vivo.[4] In the present study, we examined in detail the effects of air and light on the redox behavior of Co^{III}(tpp)Cl by using optical absorption and ESR techniques. It was found from these experiments that Co^{III}(tpp)Cl in aerated DCM solutions is efficiently oxidized by irradiation of $\lambda<500$ nm to produce π-cation radicals, $Co^{III}(tpp)^{+\cdot}Cl_2$. The photochemical formation mechanism of $Co^{III}(tpp)^{+\cdot}Cl_2$ is discussed on the basis of optical and ESR measurements of the irradiated DCM solutions.

Experimental

Materials. Chloro(5, 10, 15, 20-tetraphenylporphyrinato) cobalt(III), Co^{III}(tpp)Cl, was prepared by the method previously reported[5] (Found C, 72.66; H, 3.98; N, 7.71; Co, 8.29; Cl. 4.90%).

High-purity dichloromethane (DCM) supplied from Merck Co., Inc., was used as the solvent. The concentration of Co^{III}(tpp)Cl was ca. 1.5×10^{-3} mol dm^{-3} throughout this study.

Instruments. The optical-absorption spectra were recorded on a HITACHI 330 spectrophotometer. The ESR spectra were measured by means of a JEOL FE-2XG spectrometer.

Measurements. Two portions of Co^{III}(tpp)Cl in aerated DCM solutions were preserved, in a light room or in a dark room, over a period of one month. At about one-week intervals, the optical absorption and ESR spectra of the stored solutions were measured. The spectra of Co^{III}(tpp)Cl in deaerated DCM solutions stored in the light room over the period of one week were also measured. For an examination of the effects of light on the photochemical reaction, Co^{III}(tpp)Cl in aerated DCM solutions was irradiated by using a 500 W mercury lamp as a light source, with and without cut-off filters.

The unstable radicals generated from the solvent molecules by UV irradiation were examined by means of a spin-trapping method. Nitrosodurene(3 mg), a spin-trapping reagent, was added to neat DCM(1 cm^3) in vacuo, and the mixture was irradiated.

Results and Discussion

The Optical Absorption and ESR Spectral Changes of Co^{III}(tpp)Cl in Aerated DCM Solutions Preserved in the Light Room. The optical absorption spectrum of Co^{III}(tpp)Cl[6] in DCM has a Soret band at 406 nm (ε=112000), a Q band at 543.5 nm (ε=13200), a small peak at 900 nm (ε=330), and an absorption shoulder at 1080 nm (ε=250). When the aerated DCM solution of Co^{III}(tpp)Cl was preserved in the light room for one month, the optical-absorption spectrum changed, as is shown in Fig. 1. The intensities of the absorption bands of Co^{III}(tpp)Cl gradually decreased with the preservation time, and broad absorption bands around 620 and 680 nm appeared. When methanol was added to the preserved solution, the broad absorption bands disappeared.

Since the solids of Co^{III}(tpp)Cl used for the present study contain a small amount of the π-cation radical, $Co^{III}(tpp)^{+\cdot}Cl_2$, the ESR spectrum observed for the solution of Co^{III}(tpp)Cl immediately after preparation showed a weak signal due to the π-cation radical.[1,2,7] The ESR signal increased in intensity with the preservation time. When methanol was added to the solution, the signal disappeared immediately.

On the other hand, the optical absorption spectra of Co^{III}(tpp)Cl in aerated DCM solutions preserved in the dark room did not show any appreciable changes except for a slight decrease in the absorption intensity around

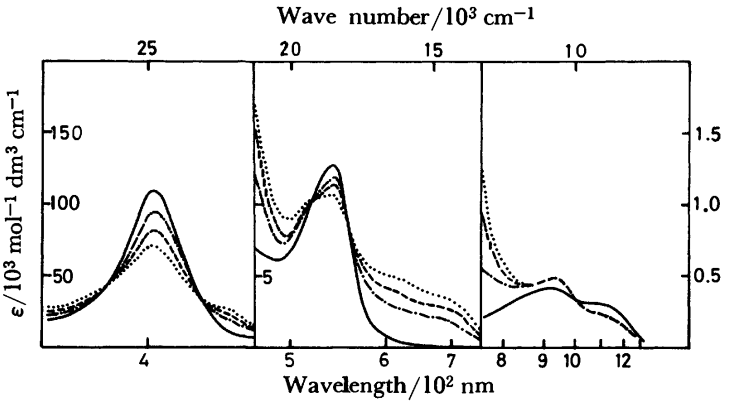

Fig. 1. Absorption spectral changes observed for aerated DCM solutions of Co^{III}(tpp)Cl preserved in the light room. Measured immediately after preparation (——), and measured after preservation for 6 (-·-·-·-), 13 (----), and 17 (·····) days in the light room.

580—720 nm. The ESR spectra of the solutions showed a considerable decrease in the signal intensity of $Co^{III}(tpp)^{+\cdot}Cl_2$. This reveals that the π-cation radical decomposes thermally, while Co^{III}(tpp)Cl does not, so long as the solution is preserved in a dark room.

From these results, we may conclude that: (1) The absorption bands around 620 and 680 nm observed for the preserved solution are to be ascribed to the π-cation radicals, $Co^{III}(tpp)^{+\cdot}Cl_2$, and (2) the π-cation radical is produced photochemically when the aerated DCM solution of Co^{III}(tpp)Cl is preserved in a light room.

Participation of Solvent Radicals in the Formation of $Co^{III}(tpp)^{+\cdot}Cl_2$. The photochemical decomposition of chlorinated hydrocarbons is well-established. In order to examine the participation of the solvent radicals in the photochemical reactions, an aerated DCM solution of Co^{III}(tpp)Cl was irradiated by a mercury lamp without and with a cut-off filter transmitting the light of $\lambda>360$ nm. Since DCM molecules absorb only the light of $\lambda<360$ nm, Co^{III}(tpp)Cl can be selectively irradiated by the use of this filter.

Figure 2 shows the ESR signal intensity of $Co^{III}(tpp)^{+\cdot}Cl_2$, represented as a function of the irradiation time. The formation rate of $Co^{III}(tpp)^{+\cdot}Cl_2$ observed for the aerated solution irradiated without a filter becomes faster than that irradiated with the filter ($\lambda>360$ nm). This result indicates that the photooxidation of Co^{III}(tpp)Cl in DCM occurs by the photolysis of both Co^{III}(tpp)Cl and DCM, as will be discussed later.

The aerated DCM solution of Co^{III}(tpp)Cl was also irradiated by the use of a mercury lamp with a cut-off filter transmitting the light of $\lambda>500$ nm. No increase in the ESR signal intensity of $Co^{III}(tpp)^{+\cdot}Cl_2$ was observed. From this observation, we may conclude that the Q-band excitation gives no oxidation product, $Co^{III}(tpp)^{+\cdot}Cl_2$.

Detection of Solvent Radicals Generated from Neat DCM. Radicals generated by the direct photolysis of neat DCM in vacuo were examined by using the spin-trapping method. When the mixture was irradiated by the use of a mercury lamp without a filter, the ESR spectrum shown in Fig. 3 was obtained. The following ESR parameters were obtained for the generated radical: One nitrogen (a_N=1.37 mT) and two hydrogen (a_H=0.86 mT) nuclei. The radical was identified as a spin adduct of nitrosodurene with the $\cdot CH_2Cl$ radical. This result clearly indicates that DCM molecules undergo the C–Cl bond cleavage upon UV irradiation to produce $\cdot CH_2Cl$ radicals and chlorine atoms.

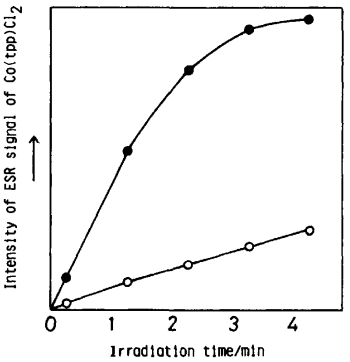

Fig. 2. ESR signal intensity of $Co^{III}(tpp)^{+\cdot}Cl_2$ generated from Co^{III}(tpp)Cl in aerated DCM solutions by irradiation with the light of $\lambda>360$ nm (○) and without filter (●).

The Optical Absorption and ESR Spectral Changes of Co^{III}(tpp)Cl in Degassed DCM Solutions Preserved in the Light Room. As is shown in Fig. 4, the optical absorption spectrum observed for the degassed DCM solution of Co^{III}(tpp)Cl preserved for one week in the light room showed a red shift of the Soret band and a blue shift of the Q band. The spectrum of pure Co^{II}(tpp) in DCM shows a Soret band at 409.5 nm (ε=295000), a Q band at 527.5 nm (ε=16200), and a band at 860 nm (ε=140). The spectral changes in Fig. 4 may be interpreted in terms of the photochemical formation of Co^{II}(tpp) by the photodissociation of the

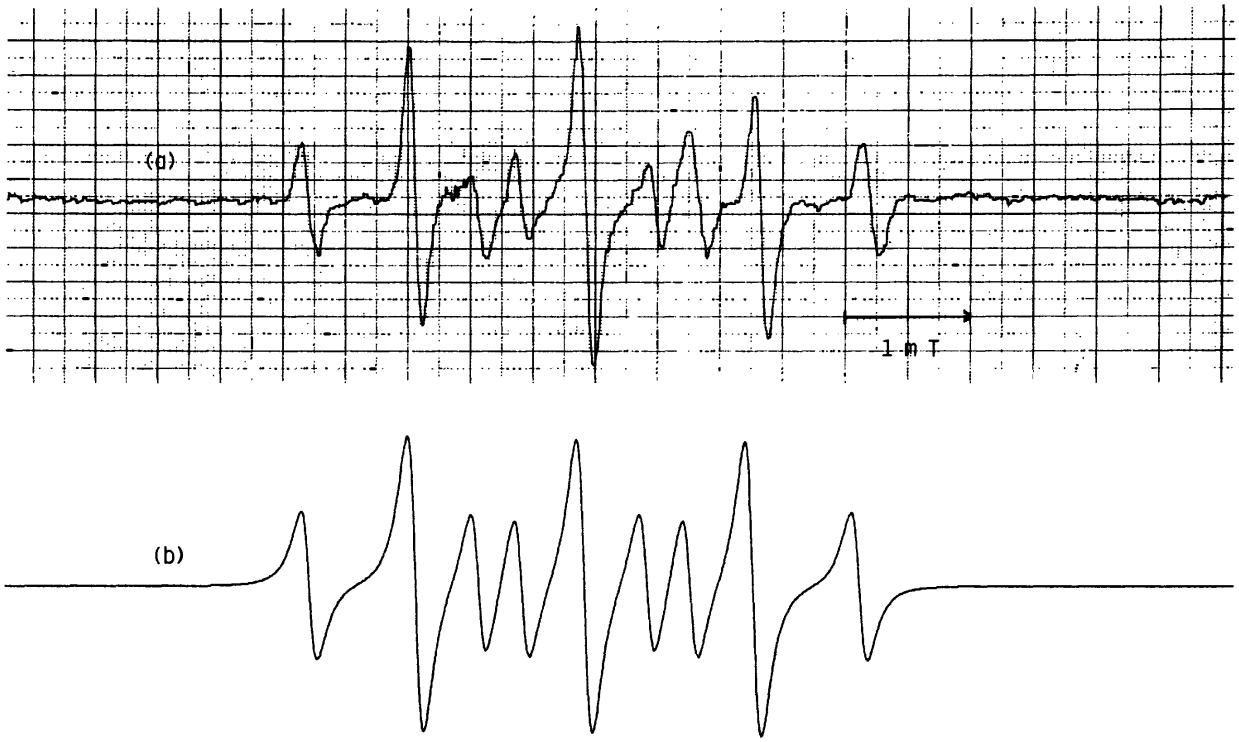

Fig. 3. ESR spectrum of spin adduct of nitrosodurene with $\cdot CH_2Cl$ radical. Observed (a) and simulated (b) spectra.

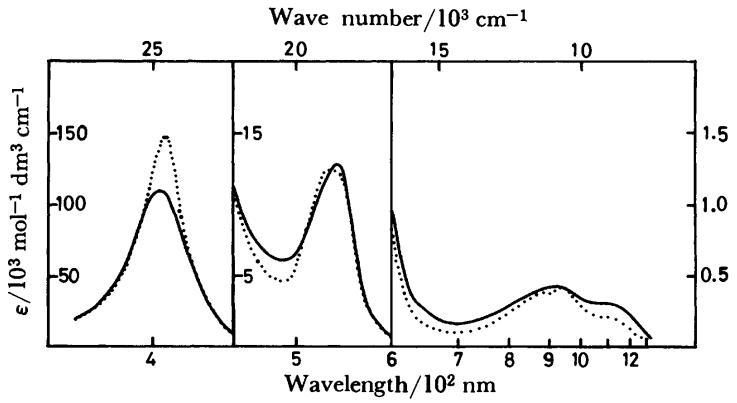

Fig. 4. Absorption spectral changes observed for degassed DCM solutions of Co^{III}(tpp)Cl preserved in the light room. Measured immediately after preparation (——) and after preservation for 7 days (·····) in the light room.

chlorine atom from Co^{III}(tpp)Cl. In fact, the ESR spectrum measured for the degassed solution stored in the light room for one week shows an increase in the signal intensity of Co^{II}(tpp).[8] No formation of the π-cation radical was observed in the degassed conditions.

Oxidation Mechanism of Co^{III}(tpp)Cl in Aerated DCM Solutions. The photoinduced homolytic Co–Cl bond cleavage of Co^{III}(tpp)Cl gives rise to the formation of Co^{II}(tpp) and chlorine atoms:[9]

$$Co^{III}(tpp)Cl \xrightarrow{h\nu} Co^{II}(tpp) + Cl\cdot \quad (1)$$

The occurrence of this reaction is demonstrated by the result that the concentration of Co^{II}(tpp) in the degassed DCM solutions of Co^{III}(tpp)Cl increases with the preservation time in the light room. The formation of the chlorine atoms in Co^{III}(tpp)Cl solutions was also detected by using another spin-trapping method.[10] Subsequently, the chlorine atoms abstract hydrogen atoms from DCM molecules to yield solvent radicals, $\cdot CHCl_2$, and hydrochloric acid:

$$Cl\cdot + CH_2Cl_2 \longrightarrow \cdot CHCl_2 + HCl \quad (2)$$

In the aerated solutions, the solvent radicals react with oxygen molecules, forming peroxyl radicals,

$CHCl_2O_2\cdot$. They oxidize $Co^{III}(tpp)Cl$ to produce π-cation radicals, $Co^{III}(tpp)^{+\cdot}Cl(CHCl_2O_2)$, which are then converted into the stable π-cation radicals of $Co^{III}(tpp)^{+\cdot}Cl_2$, presumably as a result of axial-ligand substitution.[1,11]

$$\cdot CHCl_2 + O_2 \longrightarrow [CHCl_2O_2\cdot] \quad (3)$$

$$[CHCl_2O_2\cdot] + Co^{III}(tpp)Cl \longrightarrow Co^{III}(tpp)^{+\cdot}Cl(CHCl_2O_2) \quad (4)$$

$$Co^{III}(tpp)^{+\cdot}Cl(CHCl_2O_2) + HCl \longrightarrow Co^{III}(tpp)^{+\cdot}Cl_2 + CHCl_2O_2H \quad (5)$$

It should be noted here that the formation of the peroxyl radicals is essential to give the π-cation radicals.

As revealed from the spin-trapping study, solvent molecules, CH_2Cl_2, undergoes photodecomposition with the light of $\lambda<360$ nm:

$$CH_2Cl_2 \xrightarrow{h\nu} Cl\cdot + \cdot CH_2Cl \quad (6)$$

The solvent radicals produced by the photolysis of DCM molecules may also react with oxygen molecules, forming peroxyl radicals:

$$\cdot CH_2Cl + O_2 \longrightarrow CH_2ClO_2\cdot \quad (7)$$

The radicals also oxidize $Co^{III}(tpp)Cl$ to form $Co^{III}(tpp)^{+\cdot}Cl_2$.

$$CH_2ClO_2\cdot + Co^{III}(tpp)Cl \longrightarrow Co^{III}(tpp)^{+\cdot}Cl(CH_2ClO_2) \quad (8)$$

$$Co^{III}(tpp)^{+\cdot}Cl(CH_2ClO_2) + HCl \longrightarrow Co^{III}(tpp)^{+\cdot}Cl_2 + CH_2ClO_2H \quad (9)$$

Thus, the fast formation rate of the $Co^{III}(tpp)^{+\cdot}Cl_2$ radical observed for the conditions without a filter (Fig. 2) is conducted with the two oxidation mechanisms described above. When we use the filter absorbing the light of $\lambda<360$ nm, the first five reactions (1—5) dominate the formation of the π-cation radical.

According to Reaction (1), $Co^{III}(tpp)Cl$ decomposes photochemically to produce $Co^{II}(tpp)$. However, we can not detect $Co^{II}(tpp)$ in the aerated DCM solution of $Co^{III}(tpp)Cl$ upon irradiation. This fact suggests that the oxidant radicals, such as $CHCl_2O\cdot$, $CH_2ClO\cdot$, and $HO\cdot$, which are produced from $CHCl_2O_2H$ and CH_2ClO_2H, oxidize $Co^{II}(tpp)$ to reproduce $Co^{III}(tpp)Cl$.

Conclusion

Studies on the mechanism of the formation of the porphyrin π-cation radicals, $Co^{III}(tpp)^{+\cdot}Cl_2$, from $Co^{III}(tpp)Cl$ in aerated DCM solutions in the light room have revealed that: (1) $Co^{III}(tpp)Cl$ undergoes the homolytic cleavage of the Co–Cl bond in $Co^{III}(tpp)Cl$ upon Soret-band excitation to yield $Co^{II}(tpp)$ and chlorine atoms; (2) the hydrogen abstraction of the chlorine atoms from DCM molecules produces solvent radicals, which then react with oxygen molecules to form oxidant radicals; (3) oxidant radicals are also formed by the photolysis of aerated DCM, and (4) these oxidant radicals oxidize $Co^{III}(tpp)Cl$ to produce $Co^{III}(tpp)^{+\cdot}Cl_2$.

(Received July 30, 1985)

The zero field splittings of a series of substituted benzenes and related molecules have been examined by means of optical detection of magnetic resonance (ODMR), electron paramagnetic resonance (EPR), and molecular orbital (MO) calculations. It is experimentally shown that D and E values vary remarkably depending on the type of molecule despite the similarlity in the molecular size. In particular, E varies from $+0.038$ cm^{-1} for phenylacetylene to -0.0597 cm^{-1} for aniline reflecting large differences in the spin distributions. The calculation of the zero field splittings of the molecules studied here on the basis of the Pariser-Parr-Pople-type MO's can give the values reasonably close to those obtained experimentally with a few exceptions. On the basis of the obtained results the natures of the T_1 states of substituted benzenes are characterized from the zero field splittings.

The zero field splittings (ZFS's) of the lowest excited triplet (T_1) states of aromatic molecules have been studied extensively for more than two decades.[1–18] Since in most molecules ZFS's are determined by spin-spin interactions between two unpaired electrons, the ZFS's reflect spin distributions which are directly related to the electronic wave functions of the T_1 states. One would hope to extract useful information about electronic structures of the T_1 states from the analysis of ZFS's. Yet, use of ZFS's in elucidating the electronic structures of the T_1 states of aromatic molecules has been limited so far in spite of numerous experimental data accumulated. This is due partly to the fact that the ZFS's are often not very sensitive to structural changes. In the present work we have attempted to analyze the ZFS's of substituted benzenes and related molecules with a hope of utilizing the ZFS's to characterize the electronic structures of the T_1 states.

Substituted benzenes form an attractive group of molecules for a detailed study of ZFS, because their ZFS's are markedly dependent on the nature of substituent.[2–18] This situation is quite different from the cases of other hydrocarbons such as naphthalene.[19] The triplet states of substituted benzenes are often classified as having quinonoidal (Q) or antiquinonoidal (AQ) structures. The ZFS's are expected to vary depending on whether the T_1 state is of Q type or of AQ one and an examination of the ZFS's may be helpful in characterizing their electronic structures.

The main purposes of the present work are the following. First, we compare the ZFS's of various substituted benzenes in order to find general qualitative trends. For this purpose we have supplemented the existing data by conducting optical detection of magnetic resonance (ODMR) and electron paramagnetic resonance (EPR) experiments on a series of substituted benzonitriles, anilines, and anisoles. On the basis of the obtained results we attempt to characterize the natures of the T_1 states of substituted benzenes from the ZFS's. Second, we calculate the ZFS's of the representative systems by using the semiempirical Pariser-Parr-Pople-type molecular orbitals (MO's) to see whether or not such calculations reproduce the experimentally obtained ZFS's adequately. Substituted benzenes which we examine here are divided into two groups, one having electron-attracting mesomeric groups such as -CCH, -CN, and -CHO, and the other having electron-donating inductive substituents such as $-NH_2$ and $-OCH_3$. The effects of weakly perturbing substituents such as F, Cl, and CH_3 were examined in benzonitrile, aniline, and anisole. We also studied other related molecules such as benzofuran, indole, and indazole as the examples of the molecules with very strongly mesomeric groups.

Experimental

Sample Preparation. 1,4-Dibromobenzene (DBB) was purified by recrystallization from ethanol followed by zone refining. All of the solid guest samples were purified by recrystallization and all the liquid samples were purified by distillation. Mixed crystals containing small amounts of guest molecules were grown using the standard Bridgman method starting from the melts containing approximately 2 wt% of the guest molecules.

ODMR and EPR Measurements. The ZFS's (D's and E's) of benzonitriles, anilines, and anisoles were determined from the microwave frequencies corresponding to the transitions among the zero field (ZF) spin sublevels observed by the zero field optical detection of magnetic resonance (ZFODMR)

†††Present address: Institute for Molecular Science, Myodaiji, Okazaki 444.

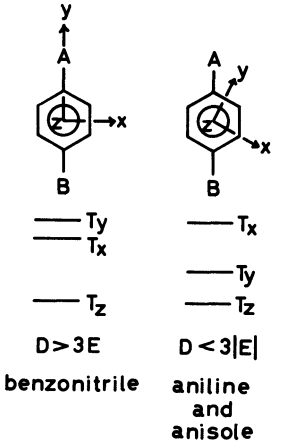

Fig. 1. Direction of axes and ZFS's of the molecules investigated in this work.

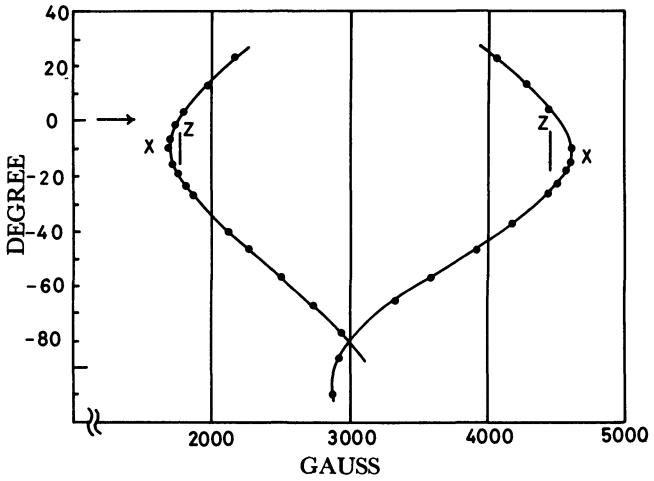

Fig. 2. Angular dependence of the EPR signals of 4-methylanisole in DBB. Magnetic field was rotated in the x-y plane of the molecule.

experiments at about 1.8 K. The experimental setup and procedures are essentially the same as those described in a previous paper.[20] The ODMR experiments were normally made under steady state illumination using the fast passage technique. The lifetimes of the substituted benzenes in DBB host range from 5 to 100 ms and we swept the frequency region of 0.1—0.5 GHz within 0.1—2 s. Normally three ODMR transitions were detected with good S/N ratios. In order to determine the sublevel schemes we also performed the EPR experiments of single crystal on a few anilines and anisoles at 4.2 K. The experimental setup and the method are similar to those described previously.[6]

Experimental Results and Qualitative Interpretation

Experimental Results. The ZFS's, D's and E's, of the molecules studied here are determined from the ZF transition energies using the spin Hamiltonian,

$$H_s = D\left(S_z^2 - \frac{1}{3}S^2\right) + E(S_x^2 - S_y^2). \quad (1)$$

When the z axis is taken perpendicular to the molecular plane, the bottom sublevel is the z sublevel. In the cases of benzonitriles and phenylacetylene with the C_{2v} symmetry we take the x and y axes as shown in Fig. 1. Then the order of the sublevels becomes y, x, and z from the top. In these molecules it is known that $T_y - T_x < T_x - T_z$ and $D > 3E$.[5] In the ortho- and meta-substituted benzonitriles the y directions are not exactly parallel to the C-CN direction. However, the above sublevel scheme is considered to be correct in all the benzonitriles studied here.

On the other hand, whether D is larger than $3|E|$ is not certain in anisoles and anilines. In most aromatic molecules D is usually larger than $3|E|$. $D > 3|E|$ was found in the case of 4-chloroaniline in xylene (X),[3,8] but the same molecule gives $D < 3|E|$ in the 1,4-dichlorobenzene (DCB) host.[8,14] Kothandaraman and Tinti also concluded $D < 3|E|$ for 4-chloroanisole.[3] One cannot make an a priori assumption about the relative magnitudes of D and $3|E|$. Here we have examined the EPR spectra of 4-methylanisole in the DBB host (Fig. 2). We have obtained the values for the field strengths of the Z stationary points, 4465 and 1755 G (1 G=10^{-4} T). These values are in good agreements with the values calculated from the D and E determined by the ODMR experiments on the assumption of $D < 3|E|$. This assignment is also confirmed by the observation that the field separation between the two in-plane stationary peaks is larger than that for the Z stationary peaks. These observations definitely show $D < 3|E|$ for 4-methylanisole. $D < 3|E|$ was also found for 4-chloroanisole[3] 4-chloroaniline, and 2-fluoroaniline in DBB.[14] Here we calculated D's and E's of other anilines and anisoles by assuming $D < 3|E|$.

Another remarkable point about the T_1 states of anilines and anisoles is the spin axis rotation whose occurrence has been confirmed in the cases of aniline in X,[11] 4-fluoroaniline in DBB,[14] and 4-chloroaniline in DCB.[14] It is quite probable that the spin axis rotation is also taking place in anilines and anisoles studied here. If this is the case, the x and y axes deviate from the molecular symmetry axes as shown in Fig. 1. The order of the sublevels determined for aniline is x, y, and z from the top and this is assumed for all anilines and anisoles studied here. The ZFS's determined in this work are tabulated in Table 1 together with those of other related systems.

The values of the ZFS's determined by the present ODMR experiments agree reasonably well with those determined by EPR at 4.2 K. However, the ZFS's determined by the ODMR experiments do not necessarily agree with the values determined by the EPR experiments at 77 K. For instance, EPR at 77 K gives D=0.1371 cm^{-1} for benzonitrile in DBB,[5] while ODMR at about 1.8 K gives D=0.1430 cm^{-1} for the same system. The ZFS's of the substituted benzenes also depend on the nature of the matrix. D and E values of aniline in DBB are considerably different from those obtained in X.[11]

General Trend of ZFS. We first discuss some notable observations about the ZFS's of substituted benzenes. Despite the similarities of the molecular size the ZFS's vary remarkably depending on the substituent. D observed here ranges from 0.1472 cm^{-1} in 4-fluorobenzonitrile to 0.1040 cm^{-1} in 4-fluoroaniline. E ranges from +0.0380 cm^{-1} in phenylacetylene to −0.0597 cm^{-1} in aniline. However, the variations of D and E in the same type of molecules are much smaller. From the results given in Table 1 we conclude the following.

1) Even weakly perturbing substituents such as F, Cl, and CH_3 affect D considerably, but their effect on E is relatively small.

Table 1. Experimental Results of E_T's, D's, and E's

Number	Guest	Host[a]	E_T	D	E	Reference

a) DBB, X, DCB, and BAC denote 1,4-dibromobenzene, xylene, 1,4-dichlorobenzene, and benzoic acid, respectively. b) The sign of the E parameter seems to be negative by analogy. c) The sign of the E parameter was determined by means of single crystal EPR. d) EPR at 4.2 K gives $D=0.102\,cm^{-1}$ and $E=-0.0535\,cm^{-1}$ for 4-fluoroaniline in DBB.[14] The value of the ZFS of 4-fluoroaniline in this table is determined by the ODMR experiment, and agrees well with the value determined by EPR. e) The sign of the E parameter was not determined. f) EPR at 77 K gives $D=0.1371\,cm^{-1}$ and $E=0.0072\,cm^{-1}$ for benzonitrile in DBB.[5] The value of the ZFS of benzonitrile in this table is determined by the ODMR experiment. As mentioned in the text, the ZFS's determined by the ODMR experiments do not necessarily agree with the values determined by the EPR experiments at 77 K. g) Present work.

2) D's of benzonitriles are relatively large compared with those of anilines and anisoles.

3) $|E|$'s of anilines and anisoles are similar and quite large, while $|E|$'s of benzonitriles are rather small.

In Fig. 3 we plot D vs. S_0—T_1 transition energy (E_T) for a series of benzonitriles, anilines and anisoles. Brinen and Orloff noted that there is a linear relation between D and E_T for a large number of polyacenes.[21] We have extrapolated their plot to the region of large E_T which is shown by a dotted line in Fig. 3. It is seen that the points for benzonitriles are located above the extrapolated Brinen Orloff line, but D's for anilines and anisoles are located below. For a series of benzonitriles D vs. E_T plot gives an approximately linear relation, but the slope is much steeper than that for the Brinen Orloff plot. It is interesting to note that the D values of benzonitriles with mesomeric substituents, polyacences (extrapolated Brinen Orloff line), and aniline and anisoles with mainly inductive substituents decrease in that order.

A detailed analysis of the ZFS's of benzene and benzene derivatives by Godfrey, Kern, and Karplus showed that the main factors determining the magnitude of D are the extent of configurational mixing and the extent of delocalization of unpaired electrons.[22] The former tends to increase D, whereas the latter to decrease D. It was shown that D calculated for the benzene triplet state with a single configuration can be very small, being $0.1\,cm^{-1}$, but a small amount of configurational mixing can increase the D drastically. In the present systems benzonitriles and phenylacetylene with more delocalization of unpaired electrons into the substituents have larger D values than anilines and anisoles with less delocalization. Therefore the main factor determining the variation of D in the present systems appears to be the extent of the configurational mixing.

In the aromatic hydrocarbons such as naphthalene, substitution by weakly perturbing substituents hardly affects D.[19] In the molecules studied here D is rather sensitive to the substitution by them. Even fluorine substitution causes a significantly large change in D. Furthermore the change in D caused by the mono fluoro substitution depends on the location of the substitution: D (para)>D (ortho)>D (meta) in benzonitrile, while D (ortho)>D (para) in aniline. It was also found that fluorine substitution at the para position produces a blue shift of E_T in benzonitrile, but a red shift in aniline. Thus the effect of fluorine substitution is opposite in these two types of molecules. These observations seem to indicate that substitution by weakly perturbing substituents changes the extent of configurational mixing considerably in the present systems.

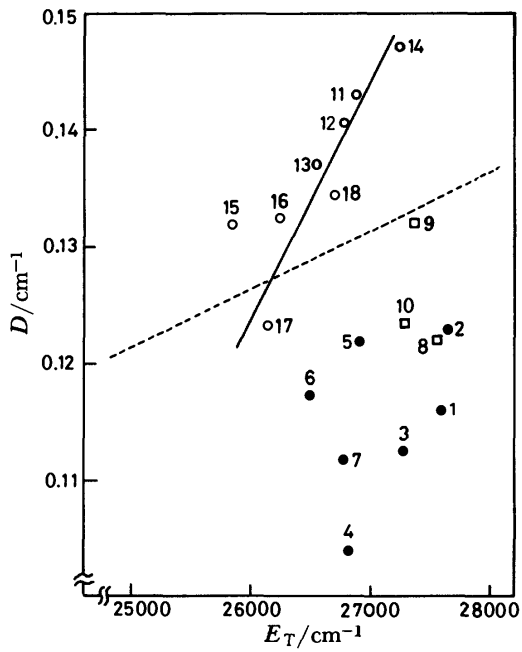

Fig. 3. Plots of D vs. E_T for a series of benzonitriles (○), anilines (●), and anisoles (□). The numbers near the data points correspond to those in Table 1. The dotted line shows the extrapolated Brinen Orloff plot.[21]

The previous investigations have shown that benzonitrile and phenylacetylene have Q structures,[5] while anilines and anisoles have AQ ones.[11,14] Anilines and anisoles studied here all have large $|E|$ values. It seems that substituted benzenes with AQ structures have large $|E|$ values.

Calculation of ZFS

The ZFS's in the lowest excited triplet states of the representative benzene derivatives have been calculated using the semiempirical Pariser-Parr-Pople-type LCAO-MO's.[23,24] The ZFS's of benzofuran, indole, 1*H*- and 2*H*-indazoles, benzimidazole, and purine were also calculated for comparison. Many calculations on the ZFS's of several molecules in their triplet states have been made successfully with various degrees of approximations.[25-34] One of the present authors (J. H.) also obtained good agreements between the observed ZFS's and the calculated ones for aromatic hydrocarbons.[25] We have used a similar procedure in the present calculation.

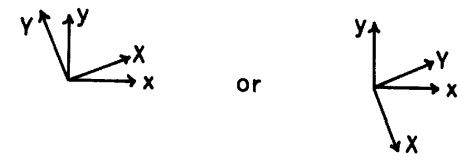
Method and Procedure. The ZFS's were evaluated from the electron spin-spin interactions, using the standard and simple approximation with only Coulomb-type integrals.[35-38] The spin-orbit interactions were ignored. The ZFS parameters, D and E, can be expressed as,

$$D = \frac{3\mu_0 g^2\beta^2}{16\pi hc}\left\langle \frac{r_{12}^2 - 3z_{12}^2}{r_{12}^5} \right\rangle, \quad (2)$$

$$E = \frac{3\mu_0 g^2\beta^2}{16\pi hc}\left\langle \frac{x_{12}^2 - y_{12}^2}{r_{12}^5} \right\rangle, \quad (3)$$

where r_{12} is the distance between two unpaired electrons. The wave functions were constructed by including configurations arising from all the single excitations relative to the ground state. For all of the molecules studied here, the overlap integrals and the electron spin-spin interactions were calculated by using double-zeta atomic orbitals by Clementi.[39]

The information obtained from the present calculation for the directions of the principal axes of the ZF tensors is not complete.[40] In fact, we cannot determine whether the direction of the principal axis of the ZF tensor corresponds to, for example,



where (x, y) and (X, Y) denote sets of the in-plane axes for the coordinate system of the molecule and for the principal axis system of the ZF tensor, respectively. This means that the absolute sign of E cannot be determined from the calculation. We therefore deduced the directions of the principal axes of the ZF tensors and the signs of E's from the experimental results.

For benzaldehyde, benzonitrile, and phenylacetylene, two-center electron repulsion integrals were estimated by the method suggested by Nishimoto.[41-43] Since the detailed knowledge of the molecular geometry is not required, two-center core integrals (β) were calculated by the method of variable β approximation[43] using the following parameters reported previously.[5,13]

Benzaldehyde:

$(-0.51P - 2.12)$ eV for C-C(ring),

$(-0.55P - 2.80)$ eV for C=O,

$(-0.51P - 1.70)$ eV for C(ring)-C(formyl group).

Benzonitrile:

$(-0.51P - 2.12)$ eV for C-C(ring),

$(-0.53P - 2.60)$ eV for C≡N,

$(-0.51P - 1.72)$ eV for C(ring)-C(cyano group).

Phenylacetylene:

$(-0.51P - 2.12)$ eV for C-C(ring),

$(-0.51P - 2.40)$ eV for C≡C,

$(-0.51P - 1.72)$ eV for C(ring)-C(ethynyl group),

where P is the bond order. In the calculations of these molecules, the ionization potentials (I's) and electron affinities (A's) for C, O, and N were taken as 86% of the values for free atoms[44] following Nishimoto (C $tr^1tr^1tr^1\pi$: I=9.60 eV, A=0.00 eV, N $tr^2tr^1tr^1\pi$: I=12.14 eV, A=1.53 eV, O $tr^2tr^2tr^1\pi$: I=15.22 eV, A=2.12 eV).[5,42] The UHF calculations using these parameters have been made previously for benzaldehyde,[13] benzonitrile,[5] and phenylacetylene[5] with satisfactory results for

spin distributions. We checked our program and procedure with naphthalene. The result of the calculation (D=0.101 cm^{-1} and E=-0.010 cm^{-1}) agreed well with the experimental result for naphthalene (D= 0.1006 cm^{-1} and E=−0.0138 cm^{-1}).[45]

The above method is not applicable to the molecules with odd π orbitals. Therefore, in the calculations of aniline, anisole, benzofuran, indole, 1*H*- and 2*H*-indazoles, benzimidazole, and purine, two-center electron repulsion integrals and β's were evaluated by using Ohno-Klopman-type[46] and Wolfsberg-Helmholtz-type[47] approximations, respectively. β for benzene was assumed to be −2.39 eV.

In the calculations of the molecules with odd π orbitals, we adopted either of the following two kinds of parameters (parameter A and B). In parameter A, we used the values given by Hinze and Jaffe[44] (C trtrtrπ: I=11.16 eV, A=0.03 eV, N tr^{2}trtrπ: I=14.12 eV, A=1.78 eV, O tr^{2}tr^{2}trπ: I=17.70 eV, A=2.47 eV) and by Dewar and Morita[48] (N trtrtrπ: I=28.59 eV, A= 11.96 eV, O tr^{2}trtrπ: I=33.90 eV, A=15.30 eV).

As described later, parameter A does not satisfactorily reproduce the observed trend of ZFS in the calculations of *N*-heterocyclic molecules with N trtrtrπ. The reason for this may be explained by the following fact. N tr^{2}trtrπ and N trtrtrπ provide one and two π electrons to π molecular orbitals, respectively. However, since in a conjugated system the π electron density on N trtrtrπ decreases substantially from 2 owing to the π electron delocalization, while the σ electron density on N trtrtrπ is estimated to increase largely from 3.[49] Thus, the value of semiempirical parameters, such as the one-center repulsion integral (I−A), for N trtrtrπ are considered to become close to those for N tr^{2}trtrπ. As a result, the observed trend of ZFS may not be reproduced with parameter A. Accordingly, in parameter B the value of I−A for N trtrtrπ is tentatively assumed to be equal to that for N tr^{2}trtrπ given by Hinze and Jaffe (I−A=12.34 eV).[44] On the other hand, since N tr^{2}trtrπ and N trtrtrπ provide one and two π electrons to π molecular orbitals, the electric fields for electrons on N tr^{2}trtrπ and N trtrtrπ approximate to those of N^+ and N^{2+}, respectively. The value of A for N^{2+} is considered to be equal to that of I for N^+. It may not be unreasonable, thus, to assume that the value of A for N trtrtrπ is nearly the same as that of I for N tr^{2}trtrπ given by Hinze and Jaffe.[44] In parameter B, for N trtrtrπ we used the value thus determined (I=26.45 eV, A=14.11 eV) and for C trtrtrπ and N tr^{2}trtrπ we used the same values as those in parameter A.

The ZFS of aniline was calculated for the conformation in which the benzene ring is hexagonal (H), Q, AQ, or skewed-antiquinonoidal (SAQ) form. The geometries of the benzene rings for the H, Q, and AQ conformations were taken from the results by Fujimura et al.[50] The geometry of the SAQ conformation was assumed to be the same as that of 4-fluoroaniline which had been predicted from the EPR study.[14] The effect of the methyl group in anisole was not taken into account in the present calculation. The ZFS of anisole was calculated with the same geometry as that of the SAQ conformation of aniline.

The geometries of indole, 1*H*-indazole, benzimidazole, and purine were taken from the results of the X-ray diffraction.[51–53] The geometries of the benzene and pyrazole moieties in 2*H*-indazole were assumed to be the same as those of the benzene ring in 1*H*-indazole and of pyrazole ring given in the reference,[51] respectively. The ZFS of benzofuran was calculated with the same geometry as that of indole.

Results and Discussion. The results of the calculations for E_T's, the D's and E's, and the directions of the in-plane principal axes of the ZF tensors (θ) are summarized in Table 2. Here θ denotes the angle between the short axis of the molecule and the principal axis of the top sublevel. It is seen

Table 2. Calculated E_T's, ZFS's, and Directions of Principal Axes of ZF Tensors

					Parameter A				Parameter B			
	E_T	D	E	θ	E_T	D	E	θ	E_T	D	E	θ

a) In benzaldehyde the principal axis of the top sublevel is nearly parallel to the C=O direction.

that the main characteristics of the observed results (Table 1) are reproduced reasonably well by these calculations with a few exceptions.

The calculated ZFS of benzaldehyde is consistent with the observed value in benzoic acid (BAC) host,[9,10,13,17] although it is very different from those obtained in many other hosts.[4,7] In the present calculation the second order effect of the spin-orbit interaction was ignored, though this effect is known to make a large contribution to the ZFS of benzaldehyde in many hosts.[4,7] In the BAC host, however, the contribution of the spin-orbit interaction is very small owing to the effect of the hydrogen bonding formation between benzaldehyde and BAC.[9,10,13,17]

The calculated D values of benzonitrile and phenylacetylene are considerably smaller than that of benzene.[25] As described in the preceding section, the smaller value of D is related to the situation that one of the singly-excited configurations relative to the ground state dominates over the other configurations in the wave function of the lowest excited triplet state. In fact, the main configuration was calculated to be dominant in benzonitrile and phenylacetylene. However, the calculated D's are somewhat smaller than the observed values. This may indicate that the present calculation underestimates the configurational mixing. The calculated E values of benzonitrile and phenylacetylene are in good agreement with the observed values. The D values calculated for aniline and anisole are in reasonable agreement with the observed values.

Although the observed absolute value of E of aniline is rather large,[11] the calculated one for the H conformation is very small. We examined the influence of distortion from H symmetry upon the ZFS of aniline for the Q, AQ, and SAQ conformations. For the Q conformation the calculated sign of the E parameter is the same as those of benzonitrile and phenylacetylene and contradicts the observation. For the AQ conformation the sign does not contradict the observation, but the calculated $|E|$ is somewhat small. From the angular dependence of the EPR signals of aniline and anisole derivatives, it was indicated that the geometries of these molecules in the lowest excited triplet states are distorted to the SAQ conformations.[11,14] The experimental results show that $|E|$'s of these molecules are relatively large. However, the calculated $|E|$ values of the SAQ conformations are still rather small. Thus the present calculation does not reproduce correctly E's of aniline and anisole.

The ZFS's of indole, indazole, and benzimidazole are reproduced well by the present calculation with parameter B. As to the observed values of E, benzofuran, indole, 1*H*- and 2*H*-indazoles, benzimidazole, and purine are divided into two groups.[6,16,18] In benzofuran, indole, and purine, $D<3|E|$,[6,18] while in 1*H*- and 2*H*-indazole and benzimidazole, $D>3|E|$.[6,16,18] This trend of the ZFS parameters is well reproduced in the present calculation with parameter B, whereas with parameter A, $D>3|E|$ was obtained for indole. The observed values of D and E of 1*H*-indazole are considerably larger than those of 2*H*-indazole.[16] This trend is also reproduced in the calculation with parameter B more clearly than with parameter A.

Summary and Conclusions

We have examined the ZFS's of a series of substituted benzenes. It is experimentally shown that D and E values vary remarkably depending on the type of molecule despite the similarity in the molecular size. In particular, E varies from $+0.038\,cm^{-1}$ for phenylacetylene to $-0.0597\,cm^{-1}$ for aniline reflecting large differences in the spin distributions. Generally speaking, the calculation of the ZFS's of substituted benzenes based on the Pariser-Parr-Pople-type MO's can give the values reasonably close to those obtained experimentally, but some more subtle points such as the difference in D between benzonitrile and aniline and large $|E|$'s of aniline and anisole are not reproduced in the present calculation. In the case of molecules with odd π orbitals we have examined two sets of parameters A and B. It was found that parameter B satisfactorily explains the observed trend of ZFS.

Structure and Optical Spectrum of $(TMTTF)_2IO_4$. The Role of Coulomb Interaction

Kyuya YAKUSHI,* Sukekazu ARATANI, Koichi KIKUCHI, Hiroyuki TAJIMA, and Haruo KURODA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 4, 1985)

The semiconductive $(TMTTF)_2IO_4$ salt was prepared by using the electrochemical method. The crystal structure was determined to be isomorphous to the metallic $(TMTTF)_2X$ salts. The polarized infrared reflectance spectra of $(TMTTF)_2IO_4$ and $(TMTTF)_2BF_4$ were measured and were interpreted on the basis of the extended Hubbard model.

Over the past few years, the bis(tetramethyltetrathiafulvalenium) salts [$(TMTTF)_2X$] have been widely studied.[1] All of these salts exhibit a metallic character as regards the temperature dependence of electrical resistivity near room temperature.[2] On the other hand, the optical spectra of $(TMTTF)_2PF_6$ and $(TMTTF)_2Br$ do not show a Drude-like spectral shape, but show a shape which suggests the localization of charges due to the Coulomb interaction.[3] We found a new semiconductive TMTTF salt, $(TMTTF)_2IO_4$, which has an isomorphous structure to other $(TMTTF)_2X$ salts. Although this salt is a semiconductor, its optical spectrum was found to be very similar to that of the metallic $(TMTTF)_2PF_6$, showing a non Drude-like spectral shape. These facts suggest that the Coulomb interaction cannot be neglected also in the metallic $(TMTTF)_2PF_6$, and if this is the case, the transfer integrals, which were given for $(TMTTF)_2PF_6$ from the analysis of its reflectance data by use of the Drude model, should be reexamined by taking account of the Coulomb interaction. In this paper we describe the characteristic structure of the TMTTF column of $(TMTTF)_2IO_4$, and estimate the band parameters of the extended Hubbard model through the analysis of the reflectance spectrum. The reflectance spectrum of the metallic $(TMTTF)_2BF_4$ was also measured for the purpose of comparison.

Experimental

The single crystals of $(TMTTF)_2IO_4$ and $(TMTTF)_2BF_4$ were obtained in the tetrahydrofuran solutions of $(n\text{-}Bu_4N)BF_4$ and $(n\text{-}Bu_4N)IO_4$ by using the electrochemical method. The temperature of the electrochemical cell was controlled to be 0 °C and the constant current, 5 μA, was applied for 2 d. The largest crystal thus obtained was of the dimension of $5\times1\times0.2\,mm^3$ for $(TMTTF)_2BF_4$ and $20\times2.5\times0.5\,mm^3$ for $(TMTTF)_2IO_4$. The low frequency electrical resistivity was measured along the a-axis by using a standard four-probe method. The electrical contacts were made by 20 μm gold wires with carbon paint onto the (001) crystal face. The reflectance measurement on the (001) crystal faces was conducted over the spectral range from 720 cm^{-1} to 25000 cm^{-1} by using the microspectrophotometric technique. The intensities of X-ray diffraction were collected with Rigaku automated diffractometer using Mo $K\alpha$ radiation in the range of 2θ from 2° to 60°. The 1107 independent diffractions which are larger than three times of the standard deviations were used for the analysis. The full-matrix-least-squares refinement reduced the R-value to 0.079.

Results and Discussion

The temperature dependence of the electrical conductivity of $(TMTTF)_2IO_4$ is shown in Fig. 1. The electrical behavior is semiconductive throughout the observed temperature region below 300 K. The room-temperature dc conductivity along the a-axis was ≈10 $\Omega^{-1}cm^{-1}$. The activation energy around 150 K was obtained to be 0.09 eV, which is about twice the values of other $(TMTTF)_2X$ salts. Among the $(TMTTF)_2X$ salts, $(TMTTF)_2IO_4$ is the first example which exhibits the semiconductive behavior at room temperature.

The crystal of $(TMTTF)_2IO_4$ belongs to the triclinic system, the space group $P\bar{1}$, the lattice constants being a=7.226(6) Å, b=7.664(3) Å, c=13.226(4) Å, α=81.99(3)°, β=96.54(4)°, γ=106.68(5)°, Z=1. The final values of the fractional coordinates were listed in Table 1. The crystal structure is isomorphous to other $(TMTTF)_2X$ salts as shown in Fig. 2, in which the two orientations, of IO_4 occupying the center of symmetry are drawn separately although those two orientations are randomly distributed. The intrastack S–S distances are significantly shorter than the interstack S–S distances.

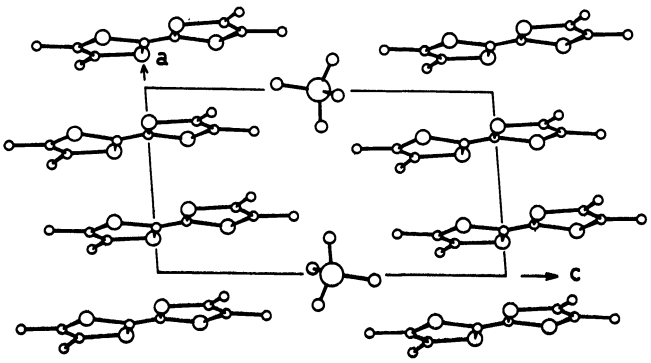

Fig. 2. Crystal structure of $(TMTTF)_2IO_4$ projected along the b-axis.

This result indicates that this salt possesses a strong one-dimensional nature like other $(TMTTF)_2X$ salts. The TMTTF molecules are stacking diadically along the a-axis. The interplanar spacings between the TMTTF molecules are listed in Table 2 together with the corresponding values of other $(TMTTF)_2X$ salts. In a $(TMTTF)_2X$ crystal, the semiconductive gap is introduced by the periodic potentials,[5] the difference of the transfer integrals,[5] and the nearest-neighbor Coulomb interaction, V,[6] if the on-site Coulomb repulsion, U, is very large as compared with the average transfer integral, t. The difference of the transfer integrals increases with the increase of the value of the difference between the interplanar spacings, $(d2-d1)$, found in a TMTTF stack, while the normalized Coulomb interaction, V/t, increases with the increase of the average spacing. The most characteristic feature of the semiconductive $(TMTTF)_2IO_4$ is that it shows the largest average spacing among the $(TMTTF)_2X$ salts hitherto investigated. This fact suggests that the Coulomb interaction, V, is

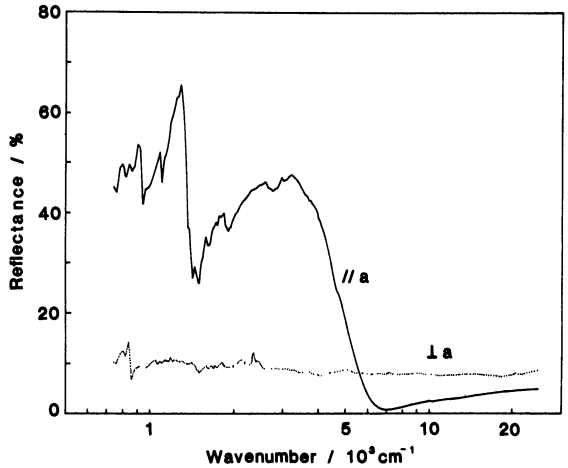

Fig. 3. Polarized reflectance spectrum on the (001) crystal face of the $(TMTTF)_2IO_4$ single crystal.

playing a dominant role in opening the band gap in $(TMTTF)_2IO_4$, although other effects may also contribute to the magnitude of the gap.

The reflectance spectrum of $(TMTTF)_2IO_4$ is shown in Fig. 3. The dispersion in the infrared region is completely polarized along the stacking axis. The spectrum is very similar to that of $(TMTTF)_2PF_6$, which was reported by Jacobsen et al.[3] We calculated the optical conductivity spectrum through the Kramers-Kronig transformation of the reflectance data. The spectrum thus obtained is shown in Fig. 4 together with the spectrum of $(TMTTF)_2BF_4$, which is known to be metallic. Four prominent peaks, A, B, C, and D were observed in the infrared region. The maximum position of the peak A is 2300 cm^{-1} for $(TMTTF)_2IO_4$ and 2100 cm^{-1} for $(TMTTF)_2BF_4$. This broad band is assignable to the charge-transfer transition from $TMTTF^{\circ}$ to $TMTTF^{+}$ or interband transition between the subbands separated mainly by Coulomb energy, V. The positions of peaks, B, C, and D are 1180 cm^{-1}, 1080 cm^{-1}, and 900 cm^{-1} both for $(TMTTF)_2IO_4$ and $(TMTTF)_2BF_4$. These peaks correspond to the a_{1g} vibrational transitions of TMTTF mixed with the charge-transfer excitation.[7] The total oscillator strength, which can be the measure of the

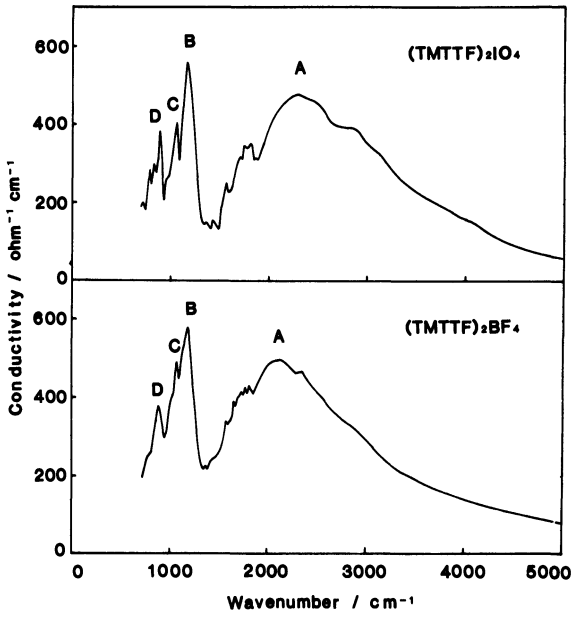

Fig. 4. Conductivity spectra in the infrared region.

magnitude of transfer integral, was obtained by the numerical integration of the conductivity curve from 0 to 10000 cm^{-1}, where the conductivity curve in the region from 720 cm^{-1} to 0 cm^{-1} was drawn by a smooth extrapolation to the dc conductivity at zero frequency. The oscillator strengths thus obtained were about 0.4 both for $(TMTTF)_2IO_4$ and $(TMTTF)_2BF_4$. This value is slightly smaller in comparison with alkali-metal-TCNQ salt, which gave the oscillator strength value of about 0.5.[8,9]

We should consider that the band-gap in $(TMTTF)_2IO_4$ arises from the electron-electron Coulomb interactions, since the one-electron theory predicts a metallic state without a gap for a diadically stacked TMTTF column. If the on-site Coulomb repulsion, U, is much larger than the average transfer integrals, t, the band-gap is introduced by the periodic potentials due to anions, by the nonequivalent transfer integrals in the diadically stacked column, and/or by the nearest-neighbor Coulomb repulsion, V. As we have already mentioned, the crystal structure of $(TMTTF)_2IO_4$ suggests the importance of V for opening a semiconductive gap. The difference of the two kinds of transfer integrals is rather small and is not likely to be the main factor. Thus, let us make a rough estimation of the band parameters, U, V, and t within the framework of the extended Hubbard model. In the case $U \gg t$, the exact solution of the 3/4-filled extended Hubbard chain predicts that $V/2t=1$ is the boundary between a metal and a semiconductor.[6] Thus, we can consider that $V>2t$ in $(TMTTF)_2IO_4$, because it is semiconductive at room temperature. No theory is known to predict the excitation energy and the oscillator strength of the optical transition in such a case. However, we could estimate the parameters in the following way. Mazumdar and Soos calculated the band structure of a one-dimensional chain in the limit of $V \gg 2t$, and concluded the optical gap to be $V+2t^2/V$.[6] Since the electronic transition (peak A) appears at about 0.3 eV, we should consider that $2t<V<0.3$ eV. From the magnetic susceptibility study, Delhaes et al.[10] proposed that $(U-V)/4t \simeq 2$ for the $(TMTTF)_2X$ salts. If we assume this relation for $(TMTTF)_2IO_4$, we obtain the following relations: $U<1.5$ eV and $2t<V<0.3$ eV. Thus the parameters in $(TMTTF)_2IO_4$ are likely to be comparable with those of K·TCNQ[8] and Rb·TCNQ[9], and consistent also with the powder optical spectrum of TMTTF-Br.[11] As shown in Fig. 4, the optical conductivity spectrum of the semiconductive $(TMTTF)_2IO_4$ is quite similar to that of the metallic $(TMTTF)_2BF_4$. This fact indicates that the band structures of these two salts are similar to each other. Mortensen et al. proposed from their thermopower studies that the apparent metallic behavior observed for several $(TMTTF)_2X$ salt comes not from the absence of a band gap but from the narrowness of their semiconductive gap.[12] According to their model, we can consider that the difference between the semiconductive $(TMTTF)_2IO_4$ and other metallic $(TMTTF)_2X$ salts exists only in the magnitude of the band gap. The similarity of the reflectance spectrum between $(TMTTF)_2BF_4$ and $(TMTTF)_2IO_4$, shown in the present study, indeed supports their model.

We thank Dr. A. Kobayashi and Dr. K. Ichida for their kind assistance to the crystal structure analysis. This work was supported by the Grant-in-Aid for the Special Project Research on "The Properties of Molecular Assemblies"(No.59112002) from the Ministry of Education, Science and Culture.

Preparation of Polymer-Protected Colloidal Dispersions of Copper

Hidefumi HIRAI,* Hidehiko WAKABAYASHI, and Makoto KOMIYAMA
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 5, 1985)

Colloidal copper dispersions are prepared by reducing copper(II) ions in water with sodium tetrahydroborate or hydrazine in the presence of various protective polymers. The polymers are poly(*N*-vinyl-2-pyrrolidone), poly(vinyl alcohol), poly(methyl vinyl ether), poly(potassium vinyl sulfate), dextrin, amylopectin, methylamylopectin, methylcellulose, ethylcellulose, and (2-hydroxyethyl)cellulose. The dispersions are black, reddish dark brown, or reddish brown homogeneous solutions, and are stable under nitrogen at room temperature for more than three months. Electron diffraction experiments indicate that copper atoms in the colloidal particles are arranged in an ordered way, which is almost identical with that in a crystal of bulk copper metal. At the charged molar ratio 40 of the monomeric residue of the protective polymer to copper(II) ion, the average diameters of the copper particles, prepared by use of sodium tetrahydroborate, range from 50 to 150 Å, depending on the polymer used. With the use of poly(*N*-vinyl-2-pyrrolidone) as protective polymer, the size of the copper particles monotonously increases with increase in the degree of polymerization of the polymer and also with decrease in the amount of the polymer.

Colloidal dispersions of noble metals such as rhodium, ruthenium, and platinum were prepared by reduction of the corresponding metal salts in the presence of protective polymers, using molecular hydrogen,[1,2] hydrazine,[3] formaldehyde,[4] sodium tetrahydroborate,[5] and alcohols[6–9] as reducing agents. These dispersions exhibited high and selective catalytic activities in hydrogenation of olefins and nitro groups. However, information on the preparation of colloidal dispersions of non-noble metals and their properties has been rather scant.

Papavassiliou and Kokkinakis[10] prepared a colloidal copper dispersion by reducing copper(II) sulfate with hydrazine in the presence of gelatin. However, concurrent precipitation took place in the reduction, and homogeneous solution was obtained only after the removal of large particles of copper by centrifugation. No information on the size of copper particles was presented there.

In a preliminary communication,[11] the authors reported that homogeneous colloidal dispersions of copper could be prepared by reducing copper(II) sulfate with sodium tetrahydroborate in the presence of poly(*N*-vinyl-2-pyrrolidone) or poly(vinyl alcohol). The resulting colloidal dispersions were highly active and selective in the hydration of acrylonitrile to acrylamide.

This paper will report preparation of colloidal copper dispersions using various kinds of protective polymers, copper salts, and reducing agents. Results of electron microscopy on the colloidal particles will be described. Furthermore, effects of degree of polymerization of protective polymers and their amounts on the size of colloidal particles will be shown.

Experimental

Materials. Poly(*N*-vinyl-2-pyrrolidone)s, amylopectin, methylcellulose (degree of methylation, 2.0), (2-hydroxyethyl)cellulose (degree of hydroxyethylation, 1.6) (from Tokyo Kasei Kogyo Co.), poly(vinyl alcohol)s (from Pure Chemicals Co.), dextrin (from Kanto Chemicals), and ethylcellulose (degree of ethylation, 1.0, from Nakarai Chemicals) were repeatedly (2—5 time) reprecipitated from aqueous solutions with the addition of acetone. Poly(potassium vinyl sulfate), β-cyclodextrin (from Nakarai Chemicals), poly(methyl vinyl ether) (from Tokyo Kasei Kogyo Co.), poly(acrylic acid), poly(2-acrylamido-2-methyl-1-propanesulfonic acid) (from Aldrich Chemical Co.), and a copolymer of methyl vinyl ether and maleic acid (methyl vinyl ether composition 0.62, from Scientific Polymer Products) were used without further purification. Soluble nylon, in which 30% of the hydrogens in the α-methylene groups with respect to the carbonyl groups in nylon 6 were substituted with diethylamino groups, was kindly provided by Toray Chemical Co. Poly(aminoethylene)[12] and methylamylopectin[13] were prepared according to the literatures. The degree of methylation with respect to glucose unit in the methylamylopectin was 1.1 as determined by ^{1}H-NMR spectroscopy.

Copper(II) sulfate from Yoneyama Chemical Co. was recrystallized three times from aqueous solution. Copper(II) chloride, copper(II) nitrate, and copper(II) acetate were obtained from Koso Chemical Co. Doubly distilled water was degassed by boiling under a reduced pressure.

Sodium tetrahydroborate (Koso Chemical Co.) was stored over silica gel and was dissolved in water immediately before use. Hydrazine hydrate and aqueous formaldehyde solution (37 wt%) were obtained from Nakarai Chemicals and Yoneyama Chemical Co., respectively. Nitrogen gas and hydrogen gas, which had purities higher than 99.9995 and 99.999%, respectively, were purchased from Nippon Sanso Co.

Preparation of Colloidal Copper Dispersion. Copper salts and various amounts of polymers were dissolved in water, and were stirred magnetically at 80 °C under nitrogen for 1 h. The stirring was made at 25 °C instead of 80 °C only for the case of poly(methyl vinyl ether), since this polymer dissolved in water at 25 °C but not at 80 °C. Then, aqueous solution of sodium tetrahydroborate, hydrazine, or formaldehyde was added to the resulting solution at 25 °C. Reduction using molecular hydrogen was carried out at 80 °C for 20 h under hydrogen pressure 37 atm.

Preparation with the use of methanol containing alkali as reducing agent was carried out as follows. Copper salts and

polymers were dissolved in 1: 1 methanol–water mixture, and the solutions were stirred magnetically at 80 °C for 1 h, and then aqueous solution of sodium hydroxide was added. The solution was further kept at 80 °C for 10 min.

Electron Microscopy. Electron micrographs of the colloids were measured on a Hitachi Model HU-12A electron microscope operated at 100 kV. Sample films were prepared under nitrogen from the colloidal dispersions on collodion films coated with a carbon layer, by evaporating the solvent to dryness.

Absorption Spectroscopy. Absorption spectra of the colloidal dispersions were taken under nitrogen on a Hitachi Model 340 spectrometer at 25 °C using 1 cm quartz cell.

Results

Preparation of Colloidal Copper Dispersions Using Sodium Tetrahydroborate as Reducing Agent. As shown in Table 1, homogeneous colloidal copper dispersions were successfully prepared by reducing copper(II) sulfate with sodium tetrahydroborate in the presence of various polymers as protective polymers. The protective polymers were poly(*N*-vinyl-2-pyrrolidone) (PVP), poly(vinyl alcohol), poly(methyl vinyl ether), poly(potassium vinyl sulfate), dextrin, amylopectin, methylamylopectin, methylcellulose, ethylcellulose, and (2-hydroxyethyl)cellulose. Here, the charged molar ratio of monomeric residue of the polymer to copper(II) sulfate was kept constant at 40.

The resulting colloidal copper dispersions were highly stable under nitrogen. For example, neither change in color nor precipitation was detected, when the colloidal dispersion with PVP of viscosity-averaged degree of polymerization (DP) 3240 was kept under nitrogen at room temperature for more than three months. On contacts with oxygen, however, the dispersions turned into yellow in a few minutes.

Stable colloidal copper dispersion was obtained even at the charged molar ratio 5 of monomeric residue of PVP (DP=3240) to copper(II) sulfate. At the charged molar ratio 1.0, however, the dispersion was less stable and considerable amounts of black precipitates were formed in 1 h.

In contrast with the formation of homogeneous colloidal dispersions in the presence of these protective polymers, black precipitates were rapidly formed in their absence. The precipitation took place immediately after the addition of sodium tetrahydroborate to an aqueous solution of copper(II) sulfate.

When poly(ethylene oxide) and β-cyclodextrin were used as protective polymers, copper particles rapidly coaggregated, and black precipitates were formed in a few minutes under virtually colorless supernatant. No reduction of copper(II) sulfate occured in the presence of poly(acrylic acid), poly(2-acrylamido-2-methyl-1-propanesulfonic acid), or the copolymer of methyl vinyl ether and maleic acid, even after the addition of sodium tetrahydroborate. Poly(aminoethylene) and soluble nylon did not dissolve in aqueous solutions containing copper(II) sulfate due to gelation.

In addition to copper(II) sulfate, copper(II) chloride, copper(II) acetate, and copper(II) nitrate were reduced with sodium tetrahydroborate in the presence of PVP, yielding homogeneous reddish dark brown, dark brown, and dark brown colloidal dispersions, respectively. The dispersion prepared from copper(II) nitrate was rather unstable, and gradually turned into yellowish green even under nitrogen.

Figure 1 shows the absorption spectrum of the colloidal copper dispersion prepared from copper(II) sulfate and PVP (DP=3240). A peak is clearly observed at

Table 2. Effects of Reducing Agents on the Formation of Colloidal Copper Dispersions Using PVP (DP=3240) as Protective Polymer[a)]

Reducing agent	Charged concentration of reducing agent (10^{-2} mol dm^{-3})	Colloid	
		Formation	Color
Sodium tetrahydroborate	*1.0*	*Yes*	*Reddish dark brown*
Hydrazine	3.3	Yes	Reddish brown
Molecular hydrogen	—[b)]	No (no reduction)	—
Ethanol	—[c)]	No (no reduction)	—
Methanol/NaOH	—[d)]	No (precipitation)	—
Formaldehyde	3.3	No (gelation)	—

a) $[CuSO_4]_0=5.0\times10^{-3}$ mol dm^{-3} and [monomeric residue of PVP]$_0=2.0\times10^{-1}$ mol dm^{-3}; solvent was water unless otherwise noted. b) Reduction was carried out at 80°C, hydrogen pressure 37 atm for 20 h. c) Copper(II) sulfate (0.15 mmol) was refluxed in 50 cm^3 ethanol for 2 h. d) Copper(II) chloride (0.15 mmol) was refluxed in 50 cm^3 of 1:1 methanol-water mixture containing sodium hydroxide (0.45 mmol) for 1 h.

Absorption spectra for the colloidal copper dispersions prepared by reduction of copper(II) sulfate in the presence of PVP (DP=3240) using (a) sodium tetrahydroborate and (b) hydrazine: $[CuSO_4]_0=5.0\times10^{-3}$, [monomeric residue of PVP]$_0=2.0\times10^{-1}$, $[NaBH_4]_0=1.0\times10^{-2}$, and [hydrazine]$_0=3.3\times10^{-2}$ mol dm^{-3}.

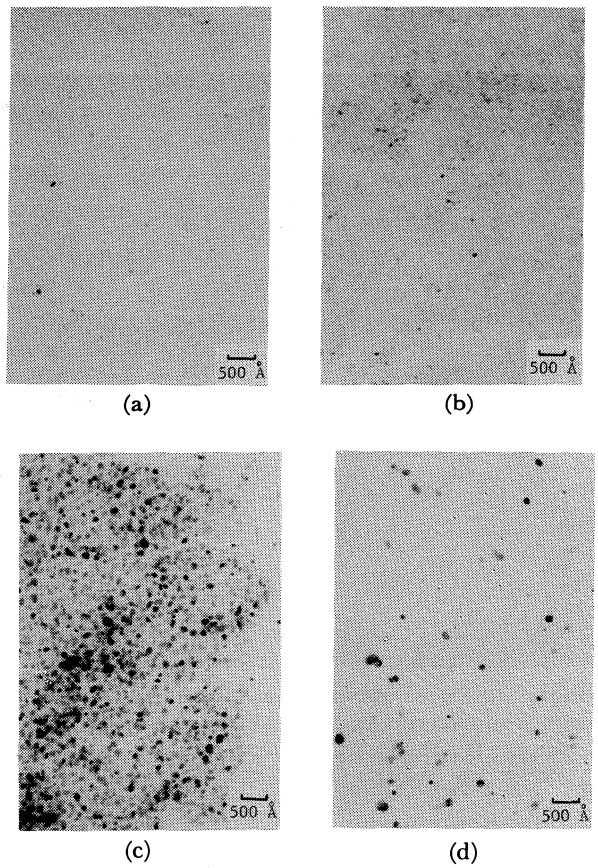

Fig. 2. Electron micrographs of colloidal copper dispersions prepared by reduction of copper(II) sulfate with sodium tetrahydroborate in the presence of (a) PVP (DP=1440), (b) PVP (DP=90), (c) dextrin, or (d) methylcellulose (×100000); $[CuSO_4]_0=5.0\times10^{-3}$, $[NaBH_4]_0=1.0\times10^{-2}$, and [monomeric residue of polymer]$_0=2.0\times10^{-1}$ mol dm^{-3}.

570 nm. Otherwise, the optical density increases with decrease in wavelength, which is ascribed to light scattering by the colloidal copper particles.

Preparation of Colloidal Copper Dispersions Using Various Reducing Agents. Table 2 shows the results of the treatment of copper(II) sulfate with various reducing agents in the presence of PVP (DP=3240). Homogeneous dispersion of copper is prepared with the use of hydrazine as well as sodium tetrahydroborate. The color of the dispersion obtained with hydrazine is reddish brown. As shown in Fig. 1, the dispersion exhibits an absorption miximum at 580 nm.

Colloidal dispersion can not be prepared with the use of the other four reducing agents. Ethanol exhibits no reducing activity on copper(II) sulfate under refluxing conditions. Hydrogen shows no reducing activity at 80°C under 37 atm either.

Refluxing of alkaline methanol-water mixture (1:1 in volume) containing copper(II) chloride for 10 min turns the color of the solution into pale reddish brown, indicating that a small amount of copper(II) ion is reduced. On prolonged reaction, however, brown precipitates are formed. The addition of formaldehyde to an aqueous solution of copper(II) sulfate and PVP results in gelation.

Electron Microscopy on Colloidal Copper Particles. Figure 2 shows the electron micrographs of the copper

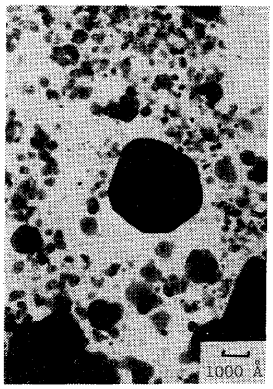

Fig. 3. Electron micrograph of copper precipitates prepared by reduction of copper(II) sulfate in the absence of polymers (×50000); $[CuSO_4]_0=5.0\times10^{-3}$ and $[NaBH_4]_0=1.0\times10^{-2}$ mol dm^{-3}.

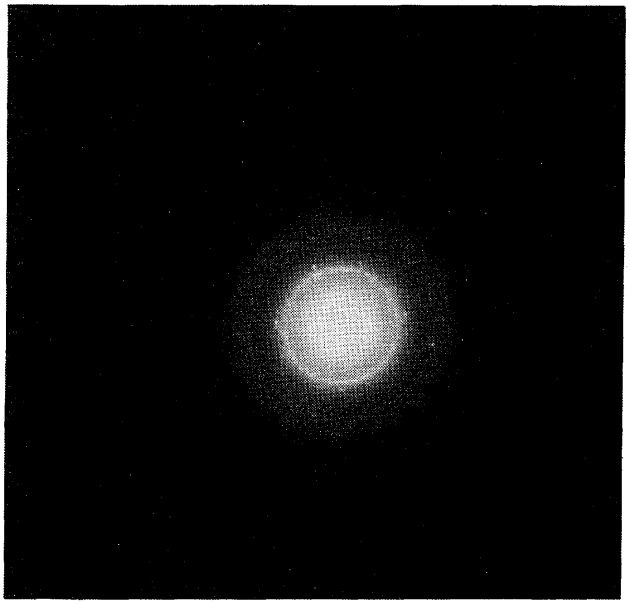

Fig. 4. Selected area electron diffraction pattern of the colloidal copper dispersion obtained by reducing copper(II) sulfate with sodium tetrahydroborate in the presence of dextrin; $[CuSO_4]_0=5.0\times10^{-3}$, $[NaBH_4]_0=1.0\times10^{-2}$, and [monomeric residue of dextrin]$_0=2.0\times10^{-1}$ mol dm^{-3}.

colloids prepared by reduction of copper(II) sulfate with sodium tetrahydroborate in the presence of various polymers. Highly dispersed particles without any aggregation are observed. For the colloid with PVP (DP=1440), for example, the particle size is distributed from 20 to 190 Å, and the average particle diameter is 100 Å. The average diameter depends on the polymer used, ranging from 50 Å for the colloid with PVP (DP=90) to 150 Å for the one with poly(vinyl alcohol) (DP=1500), as listed in Table 1.

In contrast, the diameters of the copper particles in the precipitates, obtained by the reduction of copper(II) sulfate with sodium tetrahydroborate in the absence of the polymers, were widely distributed from 40 to 3500 Å (Fig. 3).

1.93	1.00	1.09(311)	1.00

a) $[CuSO_4]_0=5.0\times10^{-3}$ mol dm^{-3}, $[NaBH_4]_0=1.0\times10^{-2}$ mol dm^{-3}, and [monomeric residue of dextrin]$_0=2.0\times10^{-1}$ mol dm^{-3}. b) Values from Ref. 14. c) Numbers in parentheses refer to *hkl* values.

Fig. 5. Electron micrograph of colloidal copper dispersion prepared by reduction of copper(II) sulfate with hydrazine in the presence of PVP (DP=3240) (×100000); $[CuSO_4]_0=5.0\times10^{-3}$, [hydrazine]$_0=3.3\times10^{-2}$, and [monomeric residue of PVP]$_0=2.0\times10^{-1}$ mol dm^{-3}.

Figure 4 depicts a selected area electron diffraction pattern for the particles in the colloidal copper dispersion prepared by reducing copper(II) sulfate in the presence of dextrin. The diffraction experiment has been carried out for the inside of a circle, which is located exactly at the center of the picture (c) in Fig. 2 and has diameter of around 400 nm. Clearly split and distinct Debye-Scherrer rings are observed. Virtually identical patterns are observed also for the dispersions with PVP and poly(vinyl alcohol). As shown in Table 3, the relative ratios for the reciprocals of the radii of the four rings are almost perfectly identical with the relative values for the lattice spacing in pure crystal of bulk copper metal.

Figure 5 shows the electron micrograph of the colloidal copper dispersion prepared by using hydrazine as reducing agent. Copper particles are much larger than those in the dispersions prepared by using sodium tetrahydroborate, and the particle diameters range from 200 Å to 1600 Å.

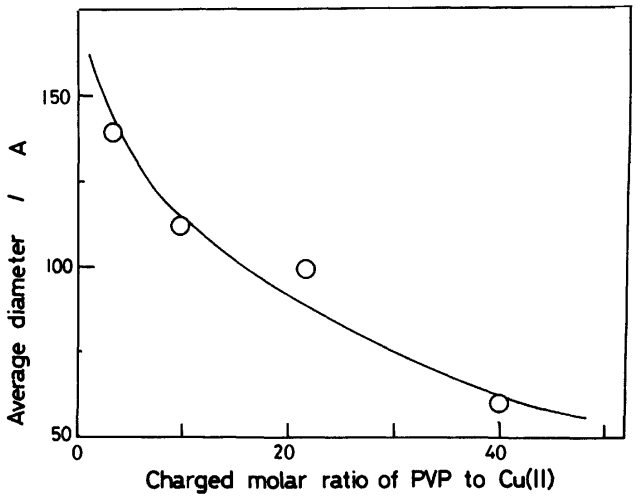

Fig. 6. Dependence of the average diameter of copper particles on the amount of PVP (DP=1440) for the colloidal dispersion prepared by reduction of copper(II) sulfate with sodium tetrahydroborate; $[CuSO_4]_0=5.0\times10^{-3}$ and $[NaBH_4]_0=1.0\times10^{-2}$ mol dm^{-3}.

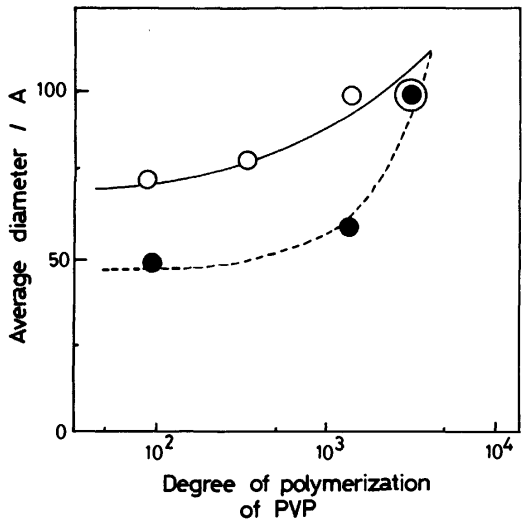

Fig. 7. Dependence of the average diameter of colloidal copper particles on the degree of polymerization of PVP for the colloidal dispersion prepared by reduction of copper(II) sulfate with sodium tetrahydroborate; [monomeric residue of PVP]$_0=1.0\times10^{-1}$ (○) or 2.0×10^{-1} mol dm^{-3} (●); $[CuSO_4]_0=5.0\times10^{-3}$ and $[NaBH_4]_0=1.0\times10^{-2}$ mol dm^{-3}.

Effects of Amount of Poly(*N*-vinyl-2-pyrrolidone) and Its Degree of Polymerization on Size of Copper Particles. As depicted in Fig. 6, the average diameter of copper particles, determined by electron microscopy, monotonously decreases with increase in the charged molar ratio of monomeric residue of PVP to copper(II) sulfate.

Figure 7 shows the plots of the average diameter of copper particles vs. the degree of polymerization of PVP. The particle size increases with increasing degree of polymerization for both the charged molar ratios 20 (○) and 40 (●) of the monomeric residue of PVP to copper(II) sulfate.

Discussion

Formation of Colloidal Copper Particles. Clearly split Debye-Scherrer rings in electron diffraction pattern in Fig. 4, which are virtually identical with those for a crystal of bulk copper metal, show that the colloidal copper particles prepared in the present study are not simple aggregates of copper atoms. Instead, the copper atoms in the particles with diameters of 20—250 Å show face-centered cubic packing in the same way as those in the copper metal. In addition, the lattice constants for the colloidal particles are almost identical with those for bulk copper metal.

Formation of copper boride is ruled out by these facts as well as by successful preparation of colloidal dispersion using hydrazine as reducing agent (Table 2).

The positions of absorption maxima (570 and 580 nm, respectively) for the colloidal copper dispersions prepared by reducing copper(II) sulfate with sodium tetrahydroborate and hydrazine in the presence of PVP (Fig. 1) is almost identical with that (580 nm) for the copper dispersion prepared by using gelatin as protective polymer.[10] The dispersion with gelatin was prepared by reduction of copper(II) sulfate with hydrazine in the presence of gelatin, followed by the removal of large copper particles by centrifugation. These absorption maxima are attributable to excitation of surface plasmon in copper particles.

Protective Polymers. The polymers successfully used as protective polymers for the preparation of colloidal copper dispersions have *N*-substituted amide, alcoholic, ethereal, or sulfate groups in the side chains (Table 1). On the formation of colloidal dispersions, the polymers first form complexes with copper(II) ions using these functional groups. Then copper(II) ions in the polymer complexes are reduced to zero valence states by sodium tetrahydroborate or hydrazine. Stability of the dispersion is attributable to the inhibition of the direct contacts of the metal particles by the polymers, which are located on the surface of the particles.[15]

Steric factors are also important for the polymers to function effectively as protective polymers. Quite a small protecting activity of poly(ethylene oxide) with alkoxyl groups in the polymer main chains, which is in contrast with sufficient protecting activity of poly(methyl vinyl ether) with alkoxyl groups in the side chains, is due to steric hindrance. β-Cyclodextrin, possessing rings composed of seven or fourteen hydroxyl groups with diameter of 6—8 Å, has a poor activity also due to steric hindrance, although poly(vinyl alcohol) shows effective protection. Soluble nylon, which has *N*-unsubstituted amide groups in the main chains and probably interacts with copper(II) ions more strongly than PVP with *N*-substituted amide groups, forms gel

with copper(II) ions.

No reduction of copper(II) ions in the presence of poly(acrylic acid), poly(2-acrylamido-2-methyl-1-propanesulfonic acid), and the copolymer of methyl vinyl ether and maleic acid is associated with the acidity of the polymer complex solution. Here, sodium tetrahydroborate added is largely used for the reactions with protons. This interpretation is consistent with the successful preparation of a colloidal dispersion using poly(potassium vinyl sulfate).

Reducing Agents. Sodium tetrahydroborate and hydrazine effectively reduce copper(II) ions, yielding colloidal copper dispersions. No reducing activity of ethanol and molecular hydrogen on copper(II) ions is in contrast with successful preparation of colloidal dispersions of noble metals from the salts using them as reducing agents.[1,2,6-9] This is attributable to much more negative oxidation-reduction potential (+0.34 eV[16]) for copper(II) ions than those for noble metals. The values for palladium(II), silver(I), and gold(III) ions, for example, are +0.92, +0.83, and +1.50 eV, respectively.[16]

Size of Colloidal Copper Particles. The size of colloidal copper particles should increase with increase in the relative rate of combination of copper atoms with copper particles, with respect to the rate of coverage of surface of copper particles by protective polymers. Thus, the particle size decreases with increasing amount of the protective polymer (Fig. 6). The decrease of the particle size with decreasing degree of polymerization of the protective polymer (Fig. 7) is associated with more rapid and effective coverage of the particles by the polymer of smaller degree of polymerization. This argument is consistent with the fact that the protecting activity of PVP on colloidal dispersions of silver increases with decreasing degree of polymerization.[17]

The authors would like to thank Mr. Koichi Adachi for valuable assistance in the electron microscope measurements.

Valence Coordinate Contributions to Zero-Point Energy Shifts Due to Hydrogen Isotope Substitutions

Takao Oi*,† and Takanobu Ishida
Department of Chemistry, State University of New York, Stony Brook, New York 11794, U.S.A.
(Received September 18, 1985)

The orthogonal approximation method for the zero-point energy (ZPE) developed previously has been applied to analyze the shifts in the ZPE, δ(ZPE), due to monodeuterium substitutions in methane, ethylene, ethane and benzene in terms of elements of $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices. The δ(ZPE) can be expressed with a reasonable precision as a sum of contributions of individual valence coordinates and correction terms consisting of the first-order interactions between the coordinates. A further refinement in the precision is achieved by a set of small number of second-order terms, which can be estimated by a simple procedure.

The zero-point energy, ZPE, of a molecule is of fundamental interest since it represents the minimum energy of the vibrating system with respect to the minimum in the potential energy surface. In the field of chemistry of isotopes, the ZPE differences between isotopically substituted molecules, δ(ZPE), are very important in the theoretical consideration of isotope effects on equilibria and also on reaction rates.

In a previous paper,[1] we developed an approximation for the ZPE expressed in terms of the first-order and second-order traces of the vibrational $\boldsymbol{H}$ matrix ($\boldsymbol{H}\equiv\boldsymbol{FG}$), i.e., Tr($\boldsymbol{H}$) and Tr($\boldsymbol{H}^2$), on the basis of a method of orthogonal expansion,

$$\mathrm{ZPE}=\frac{\hbar}{2}\lambda_{\max}^{1/2}[f\beta_0+(\beta_1/\lambda_{\max})\mathrm{Tr}(\boldsymbol{H})+(\beta_2/\lambda_{\max}^2)\mathrm{Tr}(\boldsymbol{H}^2)], \tag{1}$$

where $\lambda_{\max}$ is the largest vibrational eigenvalue of the molecule, f is the number of internal degree of freedom, and the coefficients β_0, β_1, and β_2 are simple functions of λ_0, a reference eigenvalue for a normalization purpose (Sometimes, $\eta\equiv\lambda_0/\lambda_{\max}$ is used in place of λ_0.), and ξ, the range of λ_i/λ_0 for the purpose of expansion. An advantage of this approximation method is that contributions of individual elements of the $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices to the ZPE and/or to the δ(ZPE) can be explicitly estimated, and thus the method can provide an analytical means to study correlation of the ZPE and δ(ZPE) with molecular structures and molecular forces.

The method was since tested for the ZPE's of normal paraffins[2] and for the δ(ZPE) due to the deuterium-for-hydrogen substitutions in some molecules,[3] and a linear frequency sum rule was derived.[3] Now it seems to be a due course to apply the method to study in detail relationships between δ(ZPE) and the elements of $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices.

In this paper we report on an analysis of correlation between internal valence coordinates and the ZPE shifts for monodeuterium substitutions, i.e., the d_1/d_0 pairs, in methane, ethylene, ethane and benzene. A simple equation is presented which yields the δ(ZPE) with a reasonable precision.

Computation

The isotope shift in ZPE, δ(ZPE), is defined as the ZPE of the lighter of two isotopic species of the pair minus the ZPE of the heavier. Thus, δ(ZPE) for the pair, d_1/d_0, is ZPE(d_0)−ZPE(d_1). In this paper we will treat the contributions of various valence coordinates and interactions between them to the shift in the sum of the frequencies, expressed in units of wavenumbers, $\delta\sum\omega_i$. From Eq. 1, we have

$$\delta\sum\omega_i\simeq\omega_{\max}[\beta_1\delta\sum(\lambda_i/\lambda_{\max})+\beta_2\delta\sum(\lambda_i/\lambda_{\max})^2], \tag{2}$$

where $\omega_{\max}=\lambda_{\max}^{1/2}/2\pi c$, and δ denotes the difference in the quantity that follows it between the two isotopic molecules, d_0 and d_1. If one uses the conventional units for the elements of $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices so that the eigenvalues are in units of mdyn Å^{-1}amu^{-1} (1 mdyn=1×10^{-8}N, 1 Å=1×10^{-10} m, and 1 amu=1.66057×10^{-27} kg), Eq. 2 becomes

$$\delta\sum\omega_i\simeq\beta_1'\delta\sum\lambda_i+\beta_2'\delta\sum\lambda_i^2, \tag{3}$$

where

$$\beta_1'\equiv\beta_1/\sigma\omega_{\max},\ \beta_2'\equiv\beta_2/\sigma^2\omega_{\max}^3, \tag{4a,b}$$

and

$$\sigma\equiv 4\pi^2c^2/10^5N_0 \tag{5}$$

in which c is the speed of light in cm/s and N_0 the Avogadro's number.

The term of $\sum\lambda_i$ is the first-order term and that of $\sum\lambda_i^2$ is the second-order term. Each can be explicitly written in terms of the elements of $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices, which forms the basis of our present study. Due to the Born-Oppenheimer approximation, an $\boldsymbol{F}$ matrix of a chemical species is common to all isotopic molecules. Because hydrogen is always a terminal atom (with exceptions of hydrogen-bonded structures), any motion of a hydrogen atom in a molecule does not vary many valence coordinates. Thus, many $\boldsymbol{G}$ matrix elements in $\sum\lambda_i$ and $\sum\lambda_i^2$ cancel between the isotopic pair d_1/d_0.

Let us denote the first-order term by S_1. Then,

$$S_1\equiv\beta_1'\delta\sum\lambda_i=\beta_1'[\sum_i f_{ii}\delta g_{ii}+2\sum_{i>j}\sum f_{ij}\delta g_{ij}], \tag{6}$$

†Present address: Department of Chemistry, Faculty of Science and Technology, Sophia University, 7-1, Kioicho, Chiyodaku, Tokyo 102.

Table 1. Second-Order Terms of $\delta\sum\lambda_i^2$, $A_m \equiv a_m \sum \bar{F}\delta\bar{G}$ [a]

Type(m)	a_m	$\delta\bar{G}$	$\bar{F}$	Summation [b]
1	1	$\delta(g_{ii}^2)$	f_{ii}^2	Over all coordinate number i
2	2	$\delta(g_{ii}g_{jj})$	f_{ij}^2	Over all distinct combinations of different coordinate numbers i and j
3	4	$\delta(g_{ij}g_{ij})$	$f_{ii}f_{ij}$	(same as above)
4a	2	$\delta(g_{ij}^2)$	$f_{ii}f_{jj}$	(same as above)
4b	2	$\delta(g_{ij}^2)$	f_{ij}^2	(same as above)
5	4	$\delta(g_{ii}g_{jk})$	$f_{ij}f_{ik}$	Over all distinct combinations of different coordinate numbers i, j, and k
6	4	$\delta(g_{ij}g_{ik})$	$f_{ii}f_{jk}+f_{ij}f_{ik}$	(same as above)
7	4	$\delta(g_{ij}g_{kl})$	$f_{ii}f_{jk}+f_{ik}f_{jl}$	Over all distinct combinations of different coordinate numbers i, j, k, and l

a) $\sum_m A_m = \delta\sum\lambda_i^2$. b) When more than one subscript are involved, all permutations of the same combination are counted once, except for Type 3 terms for which both $\delta(g_{ii}g_{ij})f_{ii}f_{ij}$ and $\delta(g_{jj}g_{ij})f_{jj}f_{ij}$ have to be separately considered.

where f_{ii} and g_{ii} are the diagonal elements of $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices, respectively, for the i-th coordinate, while f_{ij} and g_{ij} are the off-diagonal elements of $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices, respectively, representing the interactions between the i-th and j-th coordinates. δg_{ii} and δg_{ij} are the isotopic differences in g_{ii} and g_{ij}, respectively, i.e., the lighter (g_{ii} and g_{ij}) minus the heavier (g_{ii} and g_{ij}). The double summation in Eq. 6 is taken over all different combinations of different coordinates i and j.

Similarly, the second-order term S_2 is

$$S_2 \equiv \beta_2'\delta\sum\lambda_i^2 = \beta_2'\sum_{m=1}^{7}A_m, \tag{7}$$

where each A_m[4] is in the form of a product of a force constant factor, $\bar{F}$, and a geometric factor, $\delta\bar{G}$ as defined in Table 1.

At this point, let us define the kinds (or the types) of coordinate and the kinds (or the types) of interaction between coordinates. What follows is more or less generally presumed in papers on chemistry of isotopes, but it is essential for the present work to spell it out. A valence coordinate system of a molecule consists of a set of groups of equivalent coordinates. Then, each of such groups is a kind (or a type). Due to the isotope-independence of $\boldsymbol{F}$ matrix, the equivalence of coordinates for the present purpose is considered unaffected by a change of molecular symmetry by an isotopic substitution. A complete set of kinds of coordinate of a given chemical species is, therefore, found by examining the most symmetric isotopic species. Thus, ethane may be said to consist of five kinds (or types) of coordinates if redundancies are freely built into the coordinate system to preserve the highest possible symmetry; C-H stretching, C-C stretching, H-C-H bending, H-C-C bending, and HC-CH torsion. We will denote the kinds (or types) of coordinate with subscripts p and q, in order to distinguish them from the coordinate numbers for which the subscripts i, j, k, and l will be used.

The interaction (pq) between two kinds of coordinate, p and q, is the sum of all equivalent interactions between all coordinates i of kind p and all coordinates j of kind q. p may be equal to q in an interaction (pq), while i cannot be equal to j in an interaction (ij). It should be noted that not all interactions between the coordinates of kind p and those of kind q are necessarily identical. In such cases, an appropriate notation will be used to uniquely define the relative positions of two coordinates involved.

To examine the various terms included in Eqs. 6 and 7 from the viewpoint of the kinds of coordinate and of interaction, it may be useful to decompose these equations into the quantities, T, defined below.

$T_1(p)$: Sum of all terms of the form $f_{ii}\delta g_{ii}$, where i is a coordinate of kind p, multiplied by β_1'. $f_p \equiv f_{ii}$.

$T_1(pq)$: Sum of all terms of the form $2\beta_1' f_{ij}\delta g_{ij}$, $i>j$, where i is a coordinate of kind p and j is a coordinate of kind q. $f_{pq}\equiv f_{ij}$.

$T_2^m(p)$: Take the sum of all second-order terms of type m (cf: Table 1) involving the diagonal force constant f_{ii}, where i is a coordinate of kind p, and multiply the sum with β_2'. Then, $T_2^m(p)$ for $m=1$ is equal to the product, and $T_2^m(p)$ for all other terms containing another force constant beside f_{ii} is one-half of the product.

$T_2^m(pq)$: Take the sum of all second-order terms of type m involving the interaction constant f_{ij}, where i is a coordinate of kind p and j is a coordinate of kind q, and multiply the sum with β_2'. $T_2^m(pq)$ is equal to the product for types 2 and 4b, and one-half the product for all other types containing another constant beside f_{ij}. For $m=6$ and 7, the rule applies to each term of force constant product.

$T_2(p)$: Total second-order contribution of the coordinates of kind p to $\delta\Sigma\omega_i$.

$T_2(pq)$: Total second-order contribution of the interactions of kind pq to $\delta\Sigma\omega_i$.

$T_2(m)$: Total contribution of the second-order interactions of type m to $\delta\Sigma\omega_i$.

$T(p)$: Total contribution of the coordinates of kind p to $\delta\Sigma\omega_i$.

$T(pq)$: Total contribution of the interactions of kind pq to $\delta\Sigma\omega_i$.

Relationships among $\delta\Sigma\omega_i$, S_1, S_2, and various T's are easily understood. Whenever a second-order term contains a product of two different force constants, each half of the term is attributed to each of the participating force constants.

The various contributions, T, to $\delta\Sigma\omega_i$ were calculated for the d_1/d_0 pairs of methane, ethylene, ethane and benzene. The $\boldsymbol{F}$ matrices and the approximation parameters used are noted in the footnotes of Tables 2—6. The expansion coefficients β_1' and β_2' were computed from Eqs. 4a,b. The parameters ξ and η

a) $\boldsymbol{F}$ matrix is taken from Hartshorn and Shiner.[5] The *c1* approximation[1] is used; k=0.77, ξ=3.614329, η=1.274406, ω_{max}=3022.31 cm^{-1} and $\delta\sum\omega_i$(exact)=1231.45 cm^{-1}. b) All T terms are in cm^{-1}. The numbers in parentheses below the wavenumber values are percent of $\delta\sum\omega_i$(exact). c) In units of Å mdyn^{-1}cm^{-1}. d) The sum of the contributions tabulated. e) The sum of all contributions, both tabulated and not tabulated. Contributions whose absolute magnitudes are less than 0.1% of $\delta\sum\omega_i$(exact) are not tabulated. f) Number in the brackets is the type of interaction, m. See Table 1 for the definition of interaction types. g) All bending coordinates are weighted by the equilibrium C-H bond length. The adjacent bends are two bends which share a C-H bond.

a) $\boldsymbol{F}$ matrix is taken from Crawford and Miller.[10] The *c1* approximation[1] is used; k=0.55, ξ=3.332543, η=1.309823, ω_{max}=3083.78 cm^{-1} and $\delta\sum\omega_i$(exact)=1164.06 cm^{-1}. b)—f) See the footnotes b)—f) of Table 2, respectively. g) The coordinate system consists of six C-H stretchings, six C-C stretchings, six CCC bendings and six in-plane wags (pw). The pw's are weighted by the equilibrium C-H bond length and CCC bends are weighted by the equilibrium C-C bond length.

Tables 2—6. Each entry of the terms T, i.e., the columns 4, 5, 6, 8, 9, and 10 in these tables, shows the magnitude of the term in cm^{-1} and, in parentheses, percent of the exact value of $\delta\Sigma\omega_i$, $\delta\Sigma\omega_i$(exact). The exact value was calculated from the eigenvalues obtained by solving vibrational secular equations. For clarity, only the coordinate and interaction types (column 1) for which the magnitude of the first-order or second-order term (column 4 or 5) is more than 0.1% of the $\delta\Sigma\omega_i$(exact) have been tabulated. Columns 4 and 5 tabulate the totals of the first-order and second-order terms, respectively, and column 6 is the sum of columns 4 and 5. Columns 7—10 will be used for detailed examination of individual contributions contained in columns 4—6.

From their definitions, $T_1(p)$ and $T_1(pq)$ may be written as

$$T_1(p) = \beta_1' n_p f_p \delta g_p, \tag{8}$$

and

$$T_1(pq) = 2\beta_1' n_{pq} f_{pq} \delta g_{pq}, \tag{9}$$

where n_p and n_{pq} are, respectively, the numbers of non-vanishing δg_{ii}, in which i is a member of p, and the number of non-vanishing δg_{ij} in which (ij) is a member of the interaction type (pq) (column 3). Because hydrogen is a terminal atom, n_p is usually unity. The larger value of n_p is possible only when two or more coordinates of the same kind share the substituted hydrogen atom (SHA).

The "Total" under the columns 4, 5, 6, 8, and 10 are, respectively, S_1 (Eq. 6), S_2 (Eq. 7), $\delta\Sigma\omega_i$ (Eq. 3), $T_2(1)$, and $S_1+T_2(1)$. A difference between "Total (approx)" and

a) $\boldsymbol{F}$ matrix is taken from Miller and Crawford.[11] The *cl* approximation[1] is used; k=1.4, ξ=4.193083, η=1.209680, ω_{max}=993.44 cm^{-1} and $\delta\sum\omega_i$(exact)=213.67 cm^{-1}. b)—f) See the footnotes b)—f) of Table 2, respectively. g) The coordinate system consists of six HCC_2 out-of-plane wags (op) and six CC-CC torsions (t) as defined in Wilson, Decius, and Cross.[9] The op's are weighted by the equilibrium C-H bond length and t's are weighted by the equilibrium C-C bond length.

"Total (exact)" is a sum of the small contributions which were individually not tabulated due to the 0.1% criterion.

In the following we will first itemize important observations one would make on these tables and then discuss each feature separately.

Observations. (1) On $\delta\Sigma\omega_i$: $\delta\Sigma\omega_i$ is within 0.1% of $\delta\Sigma\omega_i$(exact) if all contributions are counted. It is within 0.1% for all molecules, except ethylene (100.3%) and the planar vibrations of benzene (100.2%), when only those tabulated in these tables are summed up.

(2) On few entries for interaction types (pq) in column 1: Except for methane, ethylene and benzene (out-of-plane vibrations), there is no entry for the interactions in column 1, which means that $T_1(pq)$ and $T_2(pq)$ for the interaction forces do not individually contribute more than 0.1% of $\delta\Sigma\omega_i$(exact) in most cases.

(3) On the relative magnitudes of entries in columns 4, 5, and 6: By far the largest contributor is the H-X stretching coordinate. The following inequalities generally hold on the absolute magnitudes among various terms; a) $T_1(p)\gg T_2(p)$ and $T_1(pq)\gg T_2(pq)$, b) T_1(H-X stretch)$\gg T_1$(bend)$\gg T_1$(out-of-plane motion), c) many $T_1(pq)$'s vanish, and when they do not, T_1(bend)$\gg T_1(pq)$, and d) T_2(HX stretch)$\gg T_2$(p$\neq$HX-stretch).

(4) On the "Totals" for the columns: a) The S_1 and $T_2(1)$ entries (columns 4 and 8) for "approx" are respectively identical to the "exact", and b) the difference between "approx" and "exact" of S_2 (column 5) is equal to that of $\delta\Sigma\omega_i$ (column 6).

(5) On column 10: $S_1+T_2(1)$ is within 0.7% of $\delta\Sigma\omega_i$(exact) except for the out-of-plane vibrations of benzene. The sources of the errors for all molecules are identified in column 9.

First-Order Terms. Every type of coordinate that includes the SHA in the coordinate definition makes a positive contributions, $T_1(p)$, to the first-order term. The number n_p of non-vanishing δg_p (Eq. 8) is more than unity only when more than one equivalent bending coordinate share the SHA, as exemplified by methane and ethane. Expressions for $T_1(p)$ can be easily obtained. It is seen that column 7 in Tables 2—6 gives $\beta_i'\delta g_p$ (Eq. 8) and, β_i' being common to all coordinate types of a given molecule, the difference in $T_1(p)/n_pf_p$ is the difference in δg_p. For every molecule studied, all bending coordinates except CCC bends in benzene are weighted by the equilibrium C-H bond length. For stretching and angle-bending coordinates, therefore, the numbers under column 7 are equal to $\beta_i'\delta\mu_H$. For the wagging and torsional coordinates in ethylene, 65.3 for the coordinate types pw, op, and t is simply 261/4. The value for the out-of-plane wag for benzene seems to be out of place at a first glance, but actually it is not. The unusually large value is due to the artifact that the out-of-plane vibrations have been isolated for the purpose of this analysis, thus making ω_{max} for this group of motions small (993 cm^{-1}). In fact, the products of these values of $\beta_1\delta\mu_H/(\sigma\omega_{max})$ and ω_{max} fall in a relatively narrow range between 7 and 8 in units of 10^5 Å mdyn^{-1} for all molecules tested, and variation of the values is due to the difference in the k-values used for the different molecules.

The first-order contribution of an interaction type (pq) does not vanish only if 1) there is at least one member coordinate i of kind p and at least one member

coordinate j of kind q, such that $s_{iH} \cdot s_{jH} \neq 0$, where s_{iH} is the s-vector[9] for the motion of the SHA in the coordinate i, and 2) f_{ij} for such a pair ij is non-zero. Thus, δg_{pq} vanishes whenever one of p and q is a stretching coordinate.

The most common interaction type that makes a finite contribution to the first-order term is one between two bending coordinates that share the SHA.

The fact that the "Total (approx)" and "Total (exact)" for S_1 are identical for all molecules studied is accidental due to two major reasons. The first is lack of appropriate f_{ij} in the $\boldsymbol{F}$ matrix used. For instance, the interactions such as (HCH)×(in-plane wag)$_{adj.}$, in ethylene, (HCH)×(HCC)$_{adj.}$, in ethane do not contribute to the first-order term simply because the corresponding interaction constants are, somewhat strangely, missing from the particular $\boldsymbol{F}$ matrices used. The second reason is lack of adjacent bending coordinates. For example, there is no entry for the (HCC)×(HCC)$_{adj.}$ interaction in column 1 for the in-plane vibrations of benzene, due to the fact that coordinate system used happens to include six wags rather than, say, twelve HCC bends. However, the difference between the "approx" and "exact" can be made assuredly negligible as long as one includes all the important interactions for which f_{pq}'s are large.

Second-Order Contributions by Diagonal Elements of $\boldsymbol{F}$ Matrix. It is clear from Table 1 that the diagonal elements of $\boldsymbol{F}$ matrix may contribute to the second-order terms only through Types 1, 3, 4a, and 6. Further, it can be shown that $\delta(g_{ii}^2)$ does not vanish if and only if the corresponding δg_{ii} is non-zero and that $\delta(g_{ij}^2)$ does not vanish if and only if the corresponding δg_{ij} is non-zero. Therefore, the number of non-vanishing $\delta(g_{ii}^2)$ is n_p, where p is the kind of coordinate of which i is a member. The number of non-vanishing $\delta(g_{ij}^2)$ is n_{pq}, where pq is the kind of interaction of which ij is a member.

It is thus evident that $T_2^1(p)$ is always non-zero for every p which has a member involving the SHA. Furthermore, they are the largest second-order term, because both of its geometric and force constant factors involve the diagonal elements only. Because the bond-stretching force constants are larger than the bending force constants, usually by one order of magnitude, T_2^1(H–X stretch) is by far the most important contributor of all $T_2^1(p)$'s. $T_2^1(p)$ is always nagative, because β_2' is negative.

As explained earlier, many g_{ij} $(i \neq j)$ are zero, and many $\delta(g_{ij})$ vanish for monodeuterium substitutions. $T_2^3(p)$ is non-zero, only if g_{ij} and f_{ij} are both non-zero at least one coordinate i of kind p that contains the SHA and for at least another coordinate j $(i \neq j)$. Note that j may be another member of p. $T_2^{4a}(p)$ does not vanish, only if there is another coordinate j sharing the SHA with i, such that $s_{iH} \cdot s_{jH} \neq 0$. Again, j may be another member of p. The probability of non-zero $T_2^6(p)$ due to any f_{ii} is so low that we can safely disregard this term.

The sum of S_1 and $\Sigma T_2^1(p)$ (column 10 of Tables 2—6) is within 0.7% of $\delta\Sigma\omega_i$(exact) for all molecules studied with the exception of out-of-plane vibration of benzene. This offers a possibility of a means for a quick approximate calculation for δ(ZPE). A further refinement can be made if one is able to locate all major correction terms to this approximation, namely, all large terms among $T_2^m(p)$ and $T_2^m(pq)$, $m \neq 1$ (column 9, Tables 2—6).

Second-Order Contributions by Off-Diagonal Elements of $\boldsymbol{F}$ Matrix. From Table 1, it is seen that an off-diagonal element f_{ij} may make a non-vanishing contribution in all but those for $m=1$ and 4a. Due to the stringent requirements for the existence of non-zero $T_2^6(pq)$ and $T_2^7(pq)$, we can safely ignore these terms. Similarly, the likelihood of occurrence of non-zero $T_2^5(pq)$ is small and, even if it does occur, its magnitude will be small due to the fact that it contains a product of two off-diagonal force constants and one off-diagonal $\boldsymbol{G}$ matrix element. This leaves us with three types: $T_2^2(pq)$, $T_2^3(pq)$, and $T_2^{4b}(pq)$.

For a given (non-zero) f_{pq}, the process of finding major contributing terms among $T_2(m)$, $m \neq 1$, is a rather simple task once $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices become available, because one can eliminate a major portion of all possible second-order terms on the basis of vanishing δg_{ii} and δg_{ij}: When a δg_{ii} or a δg_{ij} vanishes, the corresponding $\delta(g_{ii}^2)$ or $\delta(g_{ij}^2)$ also does.

Among the non-vanishing terms of $T_2^2(pq)$, $T_2^3(pq)$ and $T_2^{4b}(pq)$, the term $T_2^3(pq)$ tends to be the largest, especially when the members i and j share the SHA because, then, the geometric factors g_{ii} and g_{ij} would become comparable. One should note that Type 3 $(m=3)$ terms contains both $f_{ii}f_{ij}\,\delta(g_{ii}g_{ij})$ and $f_{jj}f_{ij}\,\delta(g_{jj}g_{ij})$ which are different from each other. For a given (ij) both possibilities should be explored.

A Simple Correlation Formula

As noted earlier in this paper, column 10 in Tables 2—6 suggests that an approximation,

$$\delta\Sigma\omega_i \simeq S_1 + T_2(1), \tag{10}$$

gives a precision of 0.7% or better in all molecules tested except the out-of-plane vibrations of benzene. The error for the latter is unusually large simply because the major contribution for this case, $T(op)$, comes from the weak out-of-plane motion, thus making other small second-order terms $T_2(m)$, $m \neq 1$, relatively significant. The foregoing example shows that the process of estimating such a correction term is not a laborious task, even for the relatively large correction.

We made similar correlation study for some other molecules, which we did not report here, and obtained the result that Eq. 10 is a good approximation of Eq. 3.

Equation 10 may be rewritten as

$$\delta(\text{ZPE}) \simeq \frac{\hbar c}{2}\{[\beta_1'\sum_i f_{ii}\delta g_{ii} + \beta_2'\sum_i f_{ii}^2\delta g_{ii}^2] + 2\beta_1'\sum_{i>j}\sum f_{ij}\delta g_{ij}\}. \tag{11}$$

The terms within the brackets represent the contribution of various valence coordinates (diagonal elements), and the last term under the double sum is the contribution of interactions between the coordinates. It has been shown that the first-order interaction terms usually vanish, unless there are more than one adjacent bending coordinates sharing the SHA and the corresponding interaction force constant is non-zero.

Equation 11 thus implies that, usually, a fair result can be obtained only by considering the diagonal elements of $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices. This result is consistent with the result by Wolfsberg's perturbation approximation.[12] His approximation for ZPE consists of a zeroth-order term, $\hbar(f_{ii}g_{ii})^{1/2}/2$, and a correction term which consists of the off-diagonal elements as well as the diagonal ones. This zeroth-order term gives an excellent approximation, and the correction term is usually very small.

The fact that the second-order terms $T_2(m)$, $m\neq1$ in our present approximation are relatively small can be understood from Eq. 2. Every ratio λ_i/λ_{max} in Eq. 2 is much smaller than unity, except for the H-X stretching eigenvalues. The ratios for all bending modes usually lie in the range below $0.25\lambda_{max}$.[2,3] The squares of such ratios are much smaller quantities than λ_i/λ_{max}. As we have shown in this paper, a large majority of the non-vanishing terms $T_2(m)$, $m\neq1$, may be regarded as correction terms for the eigenvalues of bending modes. Since the stretching modes are well accounted for within S_1 and $T_2(1)$, the terms of $T_2(m)$, $m\neq1$, are thus second-order corrections for the small eigenvalues, and one expects such corrections to be very small. One may also reason for the smallness of these terms on the basis of relative magnitudes of $\delta\overline{G}$ and $\overline{F}$ tabulated in Table 1.

It is thus reasonable to make a general statement that Eq. 11 is a simple way to correlate the δ(ZPE) for the monodeuterium substitution and the molecular structures and forces.

Conclusion

The shift in the zero-point energy due to monodeuterium substitutions can be expressed, with the precision which is usually better than 1%, by the relation,

$$\delta(\mathrm{ZPE}) \simeq \frac{\hbar c}{2}\{[\beta'_1\sum_i f_{ii}\delta g_{ii} + \beta'_2\sum_i f_{ii}^2\delta g_{ii}^2] + 2\beta'_1\sum_{i>j}\sum f_{ij}\delta g_{ij}\}.$$

A further refinement in the precision can be achieved by a relatively simple process of estimating major correction terms among the second-order terms of Types 3, 4, and 2.

(Received July 26, 1985)

The extraction of alkaline earth metal ions has been investigated using a mixture of polyethylene glycol mono-*p*-nonylphenyl ether (PEGP; average number of oxyethylene group, 10) and 4-(1,1-dimethyl-3,3-dimethylbutyl)-2,5-dinitrophenol (2,5-dinitro-4-*t*-octylphenol, DNP; HL) in 1,2-dichloroethane. The metal extraction takes place with one molecule of deprotonated DNP (L^-) and an extraneous monoanion (X^-) for neutralization of the dicationic charge of the metal ion. The ease of extraction generally follows the order, $Ba^{2+}>Sr^{2+}>Ca^{2+}\gg Mg^{2+}$. The nature of the anion present in the aqueous phase strongly affects the extractability. For barium, the extractability decreases in the order $ClO_4^->SCN^->I^->Cl^->NO_3^-$. The composition of the extracted complexes for barium and strontium ions proportional to the metal is metal : PEGP : L^- : X^- = 1 : 1 : 1 : 1. The overall extraction constants were estimated.

Nonionic surfactant molecules with noncyclic poly(oxyethylene) chains are known to form cationic complexes with alkali and alkaline earth metal ions. The complexes can be extracted into organic solvents by forming ion pairs with suitable counter anions. Such extractions have successfully been applied to the evaluation of complexation equilibrium constants between metal ions and poly(oxyethlene) derivatives[1-3] as well as to the determination of poly(oxyethlene)-chain-containing nonionic surfactants.[4,5] The nature of the counter anion strongly influences the extractablity of such cationic complexes. Yanagida et al.[1] investigated the extractability of potassium complexes from poly(oxyethylene) derivatives and showed that the extractability varies with the anion in the order $SCN^->I^->>Br^->NO_3^->Cl^-$.

For the extraction of alkaline earth metal ions, however, only a few systematic investigations on the effect of anion have been reported.

On the other hand, a carrier mediated transport of metal ions through membranes continues to be a major concern in biological cell membrane studies as well as in industrial metal separation technology.[6] For alkaline earth metal ions, so far a combination of a lipophilic (counter) anion such as picrate and a lipophilic neutral complexing ligand such as poly(oxyethylene)-chain-containing surfactant or crown ether has been a preferred method, and few systems have a potential for the selective separation of alkaline earth metal ions on a large scale.

In the present study, a proton dissociable lipophilic molecule, 4-(1,1-dimethyl-3,3-dimethylbutyl)-2,5-dinitrophenol(2,5-dinitro-4-*t*-octylphend, DNP; HL) is used in combination with a poly(oxyethylene)-chain-containing, surfactant type neutral ligand (polyethylene glycol mono-*p*-nonylphenyl ether, PEGP; average number of oxyethylene group, 10) for the extraction alkaline earth metals. The basic features in the metal extraction equilibrium has been elucidated.

Experimental

Reagent. *p-tert*-Octylphenol was purchased from Wako Pure Chemicals Co. LTD., and dicyclohexano-18-crown-6 (DCH18C6) from Nakarai Chemicals Co. LTD. DNP was synthesized as described below. 1,2-Dichloroethane was of analytical reagent grade and used as received. Other reagents used were of the best available quality.

Synthesis of DNP. *p-tert*-Octylphenol (5.0 g) was dissolved in a mixture of chloroform (25 ml) and acetic acid (25 ml). Concentrated nitric acid (4 ml) was added dropwise with stirring at room temperature. The mixture was stirred for 30 min, then diluted with 50 ml of chloroform and washed with distilled water. The chloroform layer was dried and evaporated, and the residue was purified by passage through a silica gel column with chloroform as eluent. Yellow crystals yield 4.8 g (67%), mp 48—49 °C. Found: C, 56.76; H, 6.73; N, 9.41%. Calcd for ($C_{14}H_{20}N_2O_5$): C, 56.75; H, 6.80; N, 9.45%. H NMR ($CDCl_3$) δ=0.80 (9H, CH_3), 1.45 (6H, CH_3), 1.78 (2H, $-CH_2-$), 8.18 (2H, aromatic H).

Properties of DNP. DNP is sparingly soluble in water and readily soluble in organic solvents. The absorption spectrum of DNP in 1,2-dichloroethane shows a maximum at 360 nm, with a molar absorptivity at this wavelength of 6500 $dm^3\,mol^{-1}\,cm^{-1}$. The deprotonated anion in dichloroethane shows an absorption maximum at 460 nm with a molar absorptivity of 8500 $dm^3\,mol^{-1}\,cm^{-1}$. The proton dissociation constant of DNP (HL) was determined photometrically to be $10^{-4.5}$ in a 1: 3 (v/v) dioxane: water mixture.

Extraction Study. An aqueous solution (7 ml) containing 0.10 mol dm^{-3} alkaline earth metal salt and a pH buffer (diethanolamine-HCl) was placed in a 50-ml glass stoppered centrifuge tube. To this was added 7 ml of 1,2-dichloroethane containing 6×10^{-6}—1×10^{-4} mol dm^{-3} PEGP (or DCH18C6) and 5×10^{-6}—1×10^{-4} mol dm^{-3} DNP. The aqueous and organic solutions were equilibrated by shaking for 20 min at 25 °C. The tube was centrifuged for phase separation (3000 rpm for 15 min). The absorbances of both the organic and the aqueous phases were measured at 300-450 nm on a double beam spectrophotometer (Hitachi UV-200 type) in a 10 mm quartz cell.

Results and Discussion

The extraction equilibrium may be formulated by the following general reaction:

$$M^{2+} + n(PEGP)_o + m(HL)_o + (2-m)X^- \rightleftharpoons (M(PEGP)_nL_mX_{2-m})_o + mH^+ \quad (1)$$

where the suffix "o" refers to the species in the organic phase. The overall extraction constant K_{ex} is then defined by Eq. 2, which can be rewritten in a logarithmic form by Eq. 3, where D stands for the conventional distribution ratio of the metal ion between the two phases.

$$K_{ex} = \frac{[M(PEGP)_nL_mX_{2-m}]_o[H^+]^m}{[M^{2+}][PEGP]_o^n[HL]_o^m[X^-]^{2-m}} \quad (2)$$

$$\log D = n\log[PEGP]_o + m\log[HL]_o - m\log[H^+] + (2-m)\log[X^-] + \log K_{ex} \quad (3)$$

The special case where $m=1$, the ratio (Q) of the dissociated (L^-) and undissociated (HL) phenol concentrations in the organic phase is given by Eq. 4 in logarithmic form.

$$\log Q = \log\frac{[M(PEGP)_nLX]_o}{[HL]_o} = -\log[H^+] + n\log[PEGP]_o + \log[X^-] + \log[M^{2+}] + \log K_{ex}. \quad (4)$$

Both the D and Q values are readily obtained experimentally under various extraction conditions.

Figure 1 shows the dependence of the log Q values on the pH. As the pH of the aqueous phase is increased, the fraction of the L^- species or the extent of metal extraction increases, due to the facilitated dissocitation of HL. The extractability among alkaline earth metal ions decreases in the order $Ba^{2+}>Sr^{2+}>Ca^{2+}\gg Mg^{2+}$. The extraction of magnesium ion is negligibly small and hence is not shown in Fig. 1. In accordance with Eq. 4, all plots in Fig. 1 give straight lines having a slope of 1.0. This means that only one molecule of L^- is involved in the metal species extracted.

The dashed line in Fig. 1 indicates the extraction of calcium chloride with DNP alone (i.e., in the absence of PEGP). In this case, it is probable that DNP anion L^- acts as a bidentate chelating ligand to occupy the two coordination sites on calcium. It is interesting that here again the slope of the plot is 1.0, indicating that an anionic species (most probably Cl^-) other than L^- is involved in the extracted calcium species. This is probably related to the present extraction conditions, i.e., the presence of a large excess of metal chloride salt in aqueous solution as compared with a spectrometric concentration of the extractant phenol in the organic phase. The metal extraction ability of DNP when used by itself is poor, and calcium shown in Fig. 1 is the most easily extractable among the alkaline earth metals.

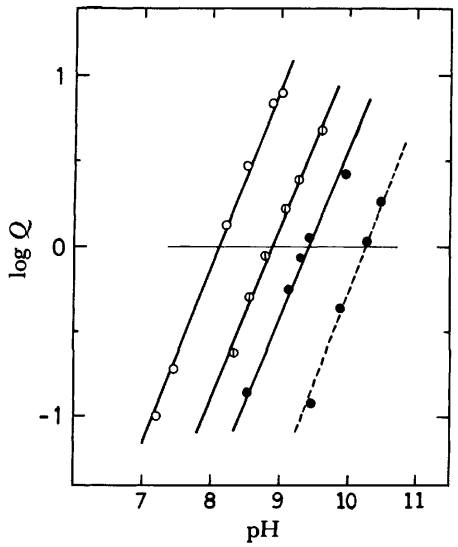

Fig. 1. Influence of pH on log Q for extraction of alkaline earth metal ions. Concentrations before equilibration: organic phase, $[PEGP]_o=5.0\times10^{-4}$ mol dm^{-3}, $[DNP]_o=6.9\times10^{-5}$ mol dm^{-3}; aqueous phase, $[MCl_2]=0.12$ mol dm^{-3}.

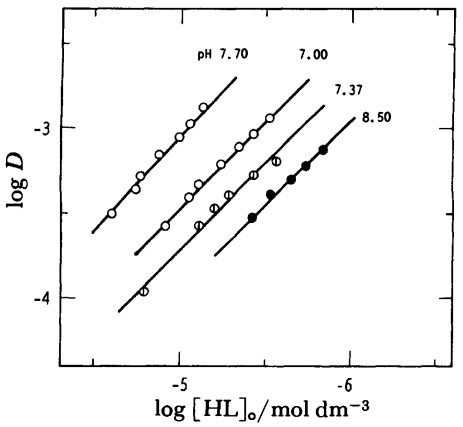

Fig. 2. Plots of distribution ratio (log D) against log $[HL]_o$ at constant pH. $[HL]_o$ stands for free DNP in organic phase. Concentrations before equilibration: organic phase, $[PEGP]_o=0.005$ mol dm^{-3}, $[DNP]_o=5.0\times10^{-6}$—1×10^{-4} mol dm^{-3}; aqueous phase, $[M(ClO_4)_2]=0.10$ mol dm^{-3}.
○, Ba^{2+}; ⊕, Sr^{2+}; ●, Ca^{2+}.

That the extracted species contain equimolecular amounts of metal ion and DNP anion has also been confirmed by the metal extraction at varying DNP concentration and constant pH. The results are shown in Fig. 2, where log D is plotted against log $[DNP]_o$. A linear relationship with a slope of 1.0 was obtained in every case.

Figure 3 shows the dependence on the concentration of PEGP for the extraction of alkaline earth metal ions.

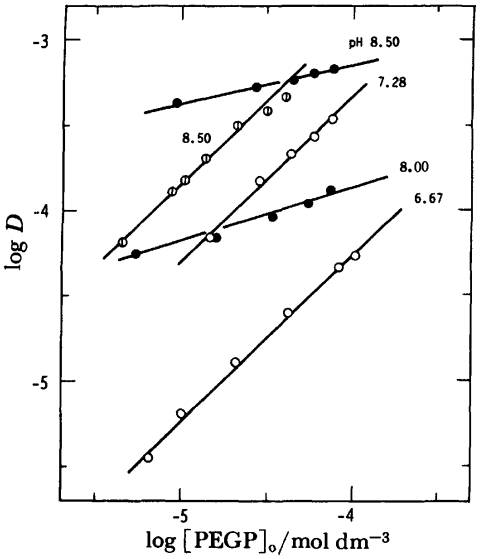

Fig. 3. Plots of distribution ratio (log D) against log [PEGP]$_0$ at constant pH. Concentrations before equilibration: organic phase, [DNP]$_0$=5.0×10^{-4} mol dm^{-3}, [PEGP]$_0$=6.0×10^{-6}—10^{-4} mol dm^{-3}; aqueous phase, [MCl_2]=0.10 mol dm^{-3}. ○, Ba^{2+}; ⊙ Sr^{2+}; ●, Ca^{2+}.

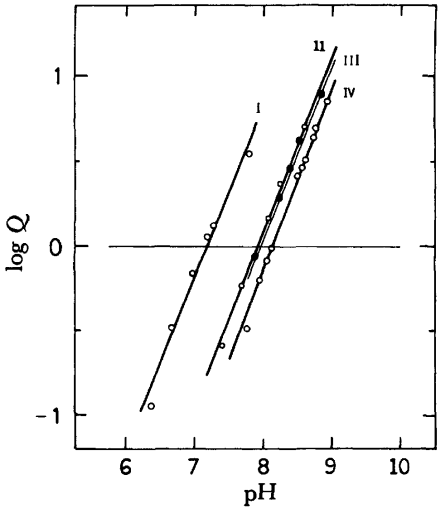

Fig. 4. Influence of pH on log Q for extraction of barium salts. Concentrations before equilibration: organic phase, [PEGP]$_0$=5.0×10^{-4} mol dm^{-3}, [DNP]$_0$=6.9×10^{-5} mol dm^{-3}; aqueous phase, [$Ba(ClO_4)_2$]=0.10 mol dm^{-3} (I), [$Ba(SCN)_2$]=0.087 mol dm^{-3} (II), [BaI_2]=0.103 mol dm^{-3} (III), [$Ba(NO_3)_2$]=0.101 mol dm^{-3} (IV).

The distribution of metal ions increases linearly with an increase in the concentration of PEGP. The slope of the plot of log D against log [PEGP]$_0$ gives a value for n in Eq. 3. As can be seen in Fig. 3, the values of the slopes for barium and strontium ions are 1.0, which indicates that both ions react with PEGP to form complexes having a composition of metal ion to PEGP ratio of 1 to 1. Considering the conformation suggested for the polyethylene glycol complex,[7,8] it is possible that the complexes in the present study assume a similar helical conformation.

On the other hand, the dependence of the calcium extraction on the PEGP concentration is different from that of barium and strontium ions; the slopes for calcium ion are 0.32 and 0.23 at pH 8.0 and 8.5 respectively (Fig. 3). The difference seems to arise from the difference in solvation by water for these ions. The calcium ion is strongly hydrated, so that the water molecule coordinated to the calcium ion are not replaced effectively by PEGP molecules, while both barium and strontium ions are easily encircled by the oxygen atoms of the poly(oxyethylene) chain in PEGP by replacing the hydration water molecules.

Finally, the effect of inorganic anions was investigated for the extraction of barium. The results are shown in Fig. 4, where log Q is plotted against pH. The extraction is influenced by the nature of the inorganic anion present in the aqueous phase. The extractability decreases in the order ClO_4^->SCN^->I^->Cl^->NO_3^-. The sequence is comparable with that observed for the extraction of alkali metal ions with poly (oxyethylene) derivatives[1] and DCH18C6.[9] The sequence is also compatible with the crystal ionic radius for these anions.[10] As may be expected, the bulkier anions are less hydrophilic and therefore promoted to be transferred into the organic phase. The effect of pH on log Q for various barium salts are similar, and a good linear relationship between pH and log Q (slope, 1.0) holds for each metal salt, as is expected from Eq. 4. This fact indicates that a barium ion is accompanied by an in oganic anion as well as by a DNP anion when extracted into the organic phase.

Based on the experimental results obtained above, the overall extraction constants for alkaline earth metal ions were calculated. The results are summarized in Table 1. Recently, Motomizu et al.[11] reported the extraction constants of inorganic anions with the Zephilamine cation. By comparing the extraction constants obtained in the present study with those reported, it is revealed that the difference among the extraction constants for the accompanied inorganic anions (in barium extraction) is very small in this study. The separation factor between perchlorate and chloride is only 6.3 in the present study, in contrast to about 1000 in the extraction with Zephilamine. From the investigation on the effect of organic anion on the extractability of sodium, potassium and calcium ions with DCH18C6, Jawaid et al.[12] concluded that the efficiency of the extraction increases with the hydrohobicity of the counter anion, while the selectivity among the accompanied anions decreases. The low anion selectivity in the present study is probably due to the high lipophilicity of DNP anion which plays a dominant role on the nature of the ion-pair complex formed in the organic phase.

In contrast to the ion-pair complex with the quater-

nary ammonium ion where there can be no direct chemical bond between the cationic center and anion, it is also possible that ion-pair complex in the present study can involve some kind of direct coordinate bond between the metal center and the accompanied anion X^-. Such a bond formation would be favored between a hard acid (alkaline earth metal ion) and a hard base (Cl^-), and helps to enhance the extractability of a chloro complex rather than an iodo or thiocyanato complex. This leads to a lowered extraction selectivity between lipophilic and hydrophilic anions. The importance of direct interaction between the alkali metal cation and the anionic group is well documented in the extraction of crown ether complexes.[13)]

In Table 1, the extraction constants with DCH18C6 are also shown. These constants were calculated on the assumption that the extraction of alkaline earth metal ions with the crown ether proceeds by the same mechanism as the extraction with PEGP. The validity of the assumption was partly justified by the plots of log Q against pH, which indicated linear relationships with a slope of 1.0 (Eq. 4). It can be seen that the extraction constants for barium and strontium ions with PEGP are close to those with DCH18C6. The similarity suggests that the extraction is governed by the nature of the counter anion rather than that of the neutral ligand, PEGP. An extracted metal species contains generally

In summary, DNP is an effective extractant for alkaline earth metal ions when used in combination with PEGP. An extracted metal species contains generally one molecule each of deprotonated DNP, inorganic monoanion, and PEGP. The extractability of the metal complex follows the order of the lipophilicity of the ions: $Ba^{2+}>Sr^{2+}>Ca^{2+}\gg Mg^{2+}$ and $ClO_4^-> SCN^->I^->Cl^->NO_3^-$. The present study, however, is limited by the use of a spectrophotometric concentration measurement ($<5\times10^{-4}$ mol dm^{-3}) of DNP and a similar concentration of PEGP. Extraction at much higher reagent concentration is still open to further research.

(Received September 6, 1985)

Monomeric (yellow) and dimeric (red) cobalt(III)-dioxygen complexes containing 1,2-bis(dimethylphosphino)ethane (dmpe) have been prepared from $[Co(dmpe)_2]^+$ and $[Co(dmpe)_2]^{2+}$, respectively, by air oxidation. The 1,3-bis(dimethylphosphino)propane (dmpp) complex afforded only the monomeric dioxygen complex by either preparative method. The crystal structures of $[Co(O_2)(dmpe)_2]B(C_6H_5)_4$ (**1**) and $[Co(O_2)(dmpp)_2]BF_4 \cdot H_2O$ (**2**) have been determined by X-ray analysis. Crystal data for **1**; monoclinic, $P2_1/a$, a=18.011(12), b=18.761(10), c=11.455(6) Å, β=107.78(4)°, V=3686(4) Å^3, Z=4, and R=0.064. Crystal data for **2**; orthorhombic, $Pbcn$, a=14.540(5), b=13.123(4), c=13.138(2) Å, V=2507(1) Å^3, Z=4, and R=0.076. The complex ions in both **1** and **2** have a trigonal-bipyramidal coordination geometry when the O_2 group bonded to the Co atom in the side-on form at a coordination site of the trigonal plane is assumed to be a unidentate ligand. Bond lengths, Co–O (1.858(7)—1.881(4) Å) and O–O (1.414(12) and 1.425(6) Å), and O–O stretching frequencies (877 and 862 cm^{-1}) indicate that both **1** and **2** are the peroxo complexes. The monomeric dioxygen complexes react immediately with SO_2 and with concd HCl to afford $[Co(SO_4)(dmpe \text{ or } dmpp)_2]^+$ and *cis*-$[CoCl_2(dmpe \text{ or } dmpp)_2]^+$, respectively. The red dimeric *trans*-$[(dmso)(dmpe)_2Co(\mu\text{-}O_2)Co(dmpe)_2(dmso)](BF_4)_4$ (dmso=dimethyl sulfoxide) complex was isolated and characterized.

Only a few monomeric cobalt(III)-dioxygen complexes have been known, in contrast to a large number of dimeric cobalt(III)-dioxygen complexes.[1] Vaska et al.[2,3] prepared $[Co(O_2)(dpee)_2]^+$ (dpee=*cis*-$(C_6H_5)_2PCHCHP(C_6H_5)_2$) and determined the molecular structure by X-ray analysis. Gray et al.[4] studied the chemical properties, formation mechanisms, and absorption spectra of this complex in some detail. In the present paper, we report new complexes of the same type, $[Co(O_2)(dmpe \text{ or } dmpp)_2]^+$ (dmpe=$(CH_3)_2PCH_2CH_2P(CH_3)_2$, dmpp=$(CH_3)_2PCH_2CH_2CH_2P(CH_3)_2$). These new complexes are highly reactive to SO_2 and HCl to afford $[Co(SO_4)(dmpe \text{ or } dmpp)_2]^+$ and *cis*-$[CoCl_2(dmpe \text{ or } dmpp)_2]^+$, respectively, while $[Co(O_2)(dpee)_2]^+$ is unreactive to SO_2 and much less reactive to HCl. In order to examine their different reactivities, we have determined the molecular structures of $[Co(O_2)(dmpe)_2]^+$ and $[Co(O_2)(dmpp)_2]^+$ and compared them with that of $[Co(O_2)(dpee)_2]^+$. A new dimeric cobalt(III)-dioxygen complex, *trans*-$[(dmso)(dmpe)_2Co(\mu\text{-}O_2)Co(dmpe)_2(dmso)]^{4+}$, and two related complexes, $[Co(CO_3)(dmpe)_2]^+$ and *trans*-$[Co(H_2O)_2(dmpe)_2]^{3+}$ are also described. A preliminary report on $[Co(O_2)(dmpe)_2]^+$ has been published.[5]

Experimental

The dmpe[6] and dmpp[7] ligands were prepared according to the literatures and handled under a nitrogen atmosphere until they formed cobalt(III) complexes. All solvents used for the preparations were deoxygenated by bubbling nitrogen for 20 min immediately before use. Absorption, ^{1}H NMR and IR spectra were recorded on a Hitachi 323 spectrophotometer, a Jeol JNM-PMX 60 spectrometer and a Jasco A-3 spectrophotometer, respectively.

Preparation of Complexes. $[Co(O_2)(dmpe)_2]BF_4$ and $[Co(O_2)(dmpe)_2]B(C_6H_5)_4$ (1). The complexes were prepared by the methods reported in a previous paper.[5]

$[Co(^{18}O_2)(dmpe)_2]BF_4$. The complex was prepared by a method similar to that for $[Co(O_2)(dmpe)_2]BF_4$.[5] The complex was yielded by exposing an ethanol solution of $[Co(dmpe)_2]^+$ to $^{18}O_2$ gas (Prochem. Co., 99% pure), instead of bubbling air.

$[Co(O_2)(dmpp)_2]BF_4 \cdot H_2O$ (2). Method a). To an ethanol solution (50 cm^3) of $Co(BF_4)_2 \cdot 6H_2O$ (588 mg, 1.73 mmol) was added an ethanol solution (5 cm^3) of dmpp (707 mg, 4.31 mmol) with stirring. After stirring for 30 min, air was bubbled into the solution for 10 h. A small amount of a white precipitate (probably the phosphine oxide) was filtered off, and the filtrate was concentrated to ca. 10 cm^3 under reduced pressure. The concentrate was chromatographed using a column (ϕ 2.5 cm×20 cm) of Toyopearl TSK-GEL. By elution with ethanol, a yellow and a pink ($Co(BF_4)_2$) band appeared. The eluate containing the yellow band was collected and concentrated to ca. 20 cm^3 under reduced pressure. To the concentrate was added diethyl ether (50 cm^3), and the solution was allowed to stand at −10 °C for 10 h, yielding yellow-orange crystals which were filtered and air-dried. Yield: 384 mg(43%). Found: C, 31.79; H, 7.28%. Calcd for $C_{14}H_{38}BCoF_4O_3P_4$: C, 32.09; H, 7.30%.

Method b). The same dmpp dioxygen complex was also yielded by a method similar to that for the dmpe complex.[5] To an ethanol solution (50 cm^3) of $Co(BF_4)_2 \cdot 6H_2O$ (1.37 g, 3.71 mmol) was added an ethanol solution (5 cm^3) of dmpp (1.06 g, 6.45 mmol) with stirring. After 1 h an ethanol solution (3 cm^3) of $NaBH_4$(140 mg, 3.71 mmol) was added to the solution. The solution was stirred for 30 min, and then air was bubbled into the solution for 10 h. The resulting solution was concentrated to ca. 10 cm^3, yielding a yellow precipitate. It was dissolved in ethanol (10 cm^3), diethyl ether (30 cm^3) was added, and the solution was allowed to stand at −10 °C for 10 h to give yellow-orange crystals. Yield: 660 mg(35%).

The complex is soluble in ethanol and acetonitrile. It is also soluble in water, but slowly decomposes to give Co(II)

species.

[(dmso)(dmpe)$_2$Co(μ-O$_2$)Co(dmpe)$_2$(dmso)](BF$_4$)$_4$. Air was bubbled into a dimethyl sulfoxide (dmso) solution (30 cm^3) of [Co(dmpe)$_2$](BF$_4$)$_2$[5] (1.06 g, 1.99 mmol) for 10 h. A red precipitate was obtained, filtered, and dissolved in dmso (5 cm^3). The solution was chromatographed with a column (ϕ 2.5 cm×20 cm) of Toyopearl TSK-GEL. By elution with dmso, a main red and a minor yellow (probably [Co(dmpe)$_2$]$^{2+}$) bands developed. The eluate containing the red band was collected and mixed with ethanol to give a red precipitate. It was filtered, washed with a mixture of ethanol and diethyl ether (1:1), and air-dried. Yield: 460 mg(37%). Found: C, 26.93; H, 6.28; P, 20.43%. Calcd for $C_{14}H_{38}B_2CoF_8O_2P_4S$: C, 26.82; H, 6.11; P, 19.76%. The complex is soluble in dmso, but hardly in other common solvents such as water or ethanol.

[Co(CO$_3$)(dmpe)$_2$]ClO$_4$·1.5NaClO$_4$·H$_2$O. To *trans*-[CoCl$_2$(dmpe)$_2$]ClO$_4$[8] (840 mg, 1.6 mmol) in a mixture (100 cm^3) of methanol and water (2:1) was added K_2CO_3(335 mg, 2.42 mmol) in water (2 cm^3). The color of the solution immediately changed from blue to orange-yellow. After stirring for 4 h, the solution was diluted with water (2 dm^3) and applied on a column (ϕ 5 cm×20 cm) of SP-Sephadex C-25. The column was washed thoroughly with water, and the adsorbed product was eluted with 0.2 mol dm^{-3} NaClO$_4$ to give a main yellow and a small blue band (the starting complex). The eluate containing the yellow band was collected and concentrated to ca. 30 cm^3 under reduced pressure. Further concentration was carried out in a desiccator over P_4O_{10} to afford yellow crystals, which were filtered, washed with a mixture (50 cm^3) of methanol and diethyl ether (1:1), and air-dried. Yield: 940 mg(80%). Found: C, 21.03; H, 5.38%. Calcd for $C_{13}H_{34}Cl_{2.5}CoNa_{1.5}O_{14}P_4$: C, 21.15; H, 4.91%. The complex is soluble in water, methanol and ethanol, but not in diethyl ether.

***trans*-[Co(H$_2$O)$_2$(dmpe)$_2$](ClO$_4$)$_3$·2H$_2$O.** To an aqueous solution (20 cm^3) of [Co(CO$_3$)(dmpe)$_2$]ClO$_4$·1.5NaClO$_4$·H$_2$O (2.19 g, 2.97 mmol) was added dropwise 60% perchloric acid (5 cm^3) with stirring. The solution was warmed at 50 °C for 2 h, and then concentrated slowly in a desiccator over P_4O_{10} to yield red crystals, which were filtered, washed with a mixture (100 cm^3) of ethanol and diethyl ether (1:1), and air-dried. Yield: 1.85 g(86%). Found: C, 19.52; H, 5.22%. Calcd for $C_{12}H_{40}Cl_3CoO_{16}P_4$: C, 19.76; H, 5.53%. The complex decomposes slowly to cobalt(II) species in neutral water, although it is stable in water acidified with HClO$_4$. This complex was assigned to the trans isomer from the ^{1}H NMR spectrum.

Reaction of [Co(O$_2$)(dmpe or dmpp)$_2$]$^+$ with SO$_2$. SO_2 gas was bubbled into an ethanol solution (50 cm^3) of [Co(O$_2$)(dmpe)$_2$]BF$_4$ (100 mg, 0.2 mmol) for 10 min. The color of the solution changed immediately from yellow to red-orange. The solution was concentrated to ca. 5 cm^3. On addition of diethyl ether (30 cm^3) the concentrate afforded an orange precipitate, which was filtered and dissolved in a mixture (2 cm^3) of acetonitrile and ethanol (1:1). The solution was applied on a column (ϕ 1.5 cm×20 cm) of Toyopearl TSK-GEL, and the adsorbed product was eluted with a mixture of acetonitrile and ethanol (1:5). The eluate containing the orange band was collected and concentrated to ca. 5 cm^3 under reduced pressure. To the concentrate was added diethyl ether (20 cm^3), and the mixture was allowed to stand at −10 °C for 10 h, yielding orange crystals of [Co(SO$_4$)(dmpe)$_2$]BF$_4$·2H$_2$O, which were filtered and washed with a mixture (20 cm^3) of diethyl ether and ethanol (2:1). Yield: 80 mg(70%). Found: C, 24.97; H, 6.31%. Calcd for $C_{12}H_{36}BCoF_4O_6P_4S$: C, 24.93; H, 6.28%. The complex was identical with that prepared from *trans*-[Co(H$_2$O)$_2$(dmpe)$_2$](ClO$_4$)$_3$·2H$_2$O and Na_2SO_4.

The [Co(O$_2$)(dmpp)$_2$]BF$_4$·H$_2$O complex reacted similarly with SO_2 to afford [Co(SO$_4$)(dmpp)$_2$]BF$_4$. Yield: 52%. Found: C, 29.46; H, 5.81%. Calcd for $C_{14}H_{36}BCoF_4O_4P_4S$: C, 29.49; H,

Reaction of $[Co(O_2)$(dmpe, dmpp, or dpee)$_2]^+$ with concd HCl. Both solid and dissolved $[Co(O_2)$(dmpe or dmpp)$_2]^+$ in ethanol reacted immediately with concd HCl at 0 °C to afford red *cis*-$[CoCl_2$(dmpe or dmpp)$_2]^+$. The same *cis*-dichloro complexes were prepared from $[Co(CO_3)$(dmpe or dmpp)$_2]^+$ with concd HCl.[9] The $[Co(O_2)$(dpee)$_2]^+$ complex reacted slowly with concd HCl at 0 °C to give a mixture of red *cis*-and green *trans*-$[CoCl_2$(dpee)$_2]^+$. The relative yield of the trans isomer increased with the reaction temperature. The $[Co(CO_3)$(dpee)$_2]ClO_4$ complex[4] afforded only the *trans*-dichloro complex by reaction with concd HCl even at below 0 °C.[9]

Crystal Structure Determination. Experimental conditions are listed in Table 1. Densities of the crystals were measured by flotation in aqueous solutions of KI. Intensity measurements were performed by a Rigaku AFC-5 four-circle diffractometer with Mo $K\alpha$ radiation (λ=0.70926 Å) monochromatized by a graphite plate. A crystal of **2** was sealed in a glass capillary with the mother liquid. The space group was uniquely determined from the Laue group and systematic absences. The intensity of reflections of **1** decreased rapidly with 2θ, and most of the reflections with $2\theta>40°$ were not observed. Corrections were made for Lorentz and polarization effects. Absorption correction was applied for **2** but not for **1**. The position of Co was deduced from the Patterson function, but the structure of **1** could not be solved by the heavy atom method because the location of Co near y=0 or 1/2 lacked the phase-determining power for reflections with $h+k$ odd in the case of $P2_1/a$. The structure was solved by direct methods with MULTAN78.[10] Starting with the positions of Co, four P and O atoms, those of the other non-hydrogen atoms were determined from the Fourier synthesis and refined by block-diagonal least-squares with anisotropic thermal parameters using UNICS III computation program system.[11] The function minimized was $\sum w||F_o|-|F_c||^2$. Complex neutral-atom scattering factors were taken from International Tables for X-Ray Crystallography.[12] The positions of 8 among 52 H atoms were found on the difference synthesis and others were calculated. Final R was 0.064 for 2421 observed unique reflections.[13] The atomic parameters of the non-hydrogen atoms are presented in Table 2.

The general position of space group *Pbcn* is eightfold. The Co atom of **2** must be on the fourfold position. Consequently the Co atom must lie on the twofold axis, because the complex does not have a center of symmetry. The position of the Co atom was deduced from the Patterson function and the orientation of the CoO_2P_4 octahedron around the twofold axis was determined by the R factor method, where the geometry of **1** was utilized. All of non-hydrogen atoms were found on the Fourier synthesis and all the H atoms except those of the water molecule were found on the difference synthesis. Positional disorder of the F atoms of BF_4^- was found. The B atom lies on the twofold axis. The population parameters for the two sets of F atoms, (F(1), F(2)) and (F(01), F(02)) were estimated to be 0.7 and 0.3, respectively by the trial and error method in such a way that the isotropic thermal parameters took nearly equal value. The F(01) atom could not be found on the difference synthesis so that it was omitted. Final R was 0.076 for 2346 unique reflections.

Results and Discussion

Preparation. Gray et al.[4] prepared $[Co(O_2)$(dpee)$_2]^+$ by two methods; one is oxidation of $[Co$(dpee)$_2]^+$ with O_2, and the other oxidation of $[Co$(dpee)$_2]^{2+}$ with air. In the present study, either oxidation of $[Co(dmpp)_2]^+$ or $[Co(dmpp)_2]^{2+}$ with air yielded $[Co(O_2)(dmpp)_2]^+$, while $[Co(O_2)(dmpe)_2]^+$ was only formed from $[Co(dmpe)_2]^+$. Oxidation of $[Co$(dmpe)$_2]^{2+}$ with air in dmso afforded a red complex whose chemical composition is $CoO(dmpe)_2(dmso)(BF_4)_2$. The $[Co(O_2)$(dmpe or dmpp)$_2]^+$ complexes are yellow in color and contain the O_2^{2-} group bonded to the Co^{3+} ion in the side-on form (vide infra). The ^{1}H NMR spectrum of the red complex in d_6-dmso is quite similar to that of *trans*-$[CoCl_2(dmpe)_2]^+$ [8] in the region of signals due to dmpe, and shows a singlet signal at 3.37 ppm assignable to the methyl protons of coordinated dmso.[14] In the IR spectrum the complex exhibits a strong band at 917 cm^{-1} which can be assigned to the S–O stretching vibration of dmso coordinated through the oxygen atom.[14] The *trans*-$[CoCl_2(dmpe)_2]^+$ complex shows no strong absorption in this region. Thus we assumed the red complex to be a dimeric μ-peroxo complex where the dmso and μ-peroxo groups occupy the trans positions to each other. No dimeric μ-peroxo cobalt(III) complex is formed with dpee and dmpp. Gray et al.[4] suggested that the dimeric μ-peroxo dpee complex is unstable for steric repulsions of the bulky dpee ligands with a solvent molecule coordinated at the position trans to the μ-peroxo group. The dmpe ligand is less bulky than dpee[15] and may be sterically favorable for formation of the dimeric μ-peroxo complex. The dmpp complex does not form the dimeric μ-peroxo complex. The instability of the dimeric dmpp complex will also be attributable to the steric reasons, since the six-membered dmpp chelate ring should be more bulky than the five-membered dmpe chelate ring and will have larger steric repulsions with other ligands. We have also attempted to prepare the dioxygen complex of 1, 2-bis(dibutylphosphino)ethane (dbpe) by two different methods described above. Both reactions proceeded quite similarly to those for dmpp and afforded only the monomeric dioxygen complex, $[Co(O_2)(dbpe)_2]^+$. The pure complex could not be isolated because the complex was highly soluble in common solvents, but the formation of only the monomer was confirmed by the ^{1}H NMR and absorption spectra. The dimeric μ-peroxo complex of bulky dbpe will also be unstable for steric reasons. Bosnich et al.[16] reported that *o*-phenylenebis(dimethylarsine) (diars) and *meso*- and *rac*-$\{(CH_3)_2AsCH_2CH_2CH_2As(C_6H_5)CH_2-\}_2$ (tetars) form both monomeric peroxo and dimeric μ-peroxo cobalt(III) complexes.

The monomeric dioxygen complexes of dmpe, dmpp and dbpe are stable in organic solvents such as alcohols

and acetonitrile, but slowly decompose in water to give cobalt(II) species. No liberation of oxygen from the complexes was observed by bubbling nitrogen into organic solutions of the complexes. Uptake of O_2 is irreversible in these complexes.

Molecular Structure. Perspective drawings of complexes **1** and **2** are shown in Fig. 1. Bond distances and bond angles are listed in Table 3. The dioxygen group in each complex coordinates to the cobalt atom in the side-on form. $[Co(O_2)(dmpe)_2]^+$ **1** has a pseudo twofold axis passing through the Co and the midpoint of the O(1)–O(2) bond axis, and the coordination geometry can be described as a trigonal-bipyramid when the O_2 group is regarded as a unidentate ligand. A similar trigonal-bipyramidal structure was report-

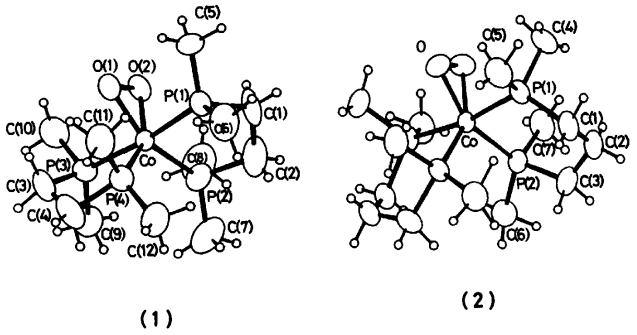

Fig. 1. ORTEP drawings of the complex cations **1** and **2** with thermal ellipsoids scaled at the 50% probability level.[17] H atoms are represented by circles of radius 0.08 Å.

ed for $[Co(O_2)(dpee)_2]^+$.[3] The O_2 ligand and P(2) and P(4) atoms form an equatorial plane, to which the P(1)-Co-P(3) axis is approximately perpendicular. The P(2) and P(4) atoms deviate by 0.03 and −0.02 Å, respectively from the plane formed by the Co, O(1) and O(2) atoms. The P(1) and P(3) atoms are 2.22 Å distant from the plane. The O-O bond distance (1.414(12) Å) is nearly the same as the values found in $[Co(O_2)(dpee)_2]^+$ (1.420(10) Å)[3] and *Δ-cis β*-$[Co(O_2)(RR$-tetars$)]^+$ (1.420 (10) Å).[18] These O-O distances are in the range of the reported values for a peroxide ion.[1] The O(1) and O(2) atoms are at essentially the same distance from the Co, and the Co-O distances (1.866(7), 1.858(7) Å) are similar to those for $[Co(O_2)(dpee)_2]^+$ (1.871(7), 1.902(7) Å)[3] and for *Δ-cis β*-$[Co(O_2)(RR$-tetars$)]^+$ (1.862(6), 1.867(7) Å)[18]. These facts indicate that the Co-O and O-O distances are not greatly affected by other ligands in a complex. The dmpe chelate ring takes a gauche conformation. The average Co-P bond distance, 2.213 (4) Å, is by 0.04—0.06 Å shorter than those in *Λ*-$[Co(en)_2(dmpe)]^{3+}$ (2.256(3) Å; en=$NH_2CH_2CH_2NH_2$)[19] and *trans(P, N)*-$[Co(edmp)_2(dmpe)]^{3+}$ (2.277(4) Å; edmp=$(CH_3)_2PCH_2CH_2NH_2$).[20] The average P-Co-P chelate angle (86.3(1)°) is by 2—4° larger than those of *Λ*-$[Co(en)_2(dmpe)]^{3+}$ (84.2(1)°) and *trans(P,N)*-$[Co(edmp)_2(dmpe)]^{3+}$ (82.7(1)°). The axial Co-P bond distances in **1** are longer by ca. 0.03 Å on average than those in the equatorial plane. It may be accounted for by trans influence of the mutually trans P donating atoms.[21] Two methyl groups C(5) and C(10) of **1** are placed over and under the O_2 group. The distance from the Co atom to the midpoint of the peroxide ion is 1.73(1) Å, which is comparable with the P-CH_3 bond length.

The structure of $[Co(O_2)(dmpp)_2]^+$ (**2**) is very similar to complex **1**. Complex **2** has a crystallographic twofold axis passing through the Co atom and the midpoint of the O-O bond. The trigonal-bipyramid around the Co atom is slightly deformed. The P(2) atom deviates by 0.37 Å from the plane formed by the Co, O, and O' atoms, and the P(1) atom is apart from the plane by 2.21 Å. All the O-O, Co-O, and Co-P bond distances are slightly longer than those of complex **1**, though not significant in view of the e.s.d.'s. The six-membered chelate ring formed by dmpp adopts a chair conformation. The C(1), C(2), and C(3) atoms of the chelate skeleton are shifted by 0.89, 0.47, and 0.89 Å, respectively from the plane through the Co, P(1) and P(2) atoms. There is no short contact between the two methyl groups C(4) and C(7), although P(1)-C(4) and P(2)-C(7) bonds are axial to the six-membered ring. Interatomic distances C(4)···C(7) and P(1)···P(2) are 3.91(1) and 3.18(2) Å, respectively.

IR Spectra. In Fig. 2 are shown IR spectra of $[Co(O_2)(dmpe)_2]BF_4$ and $[Co(^{18}O_2)(dmpe)_2]BF_4$ in the O-O stretching frequency region. The medium intensity band at 877 cm^{-1} of the O_2 complex shows the isotope shift; the $^{18}O_2$ complex gives a new band at 827 cm^{-1}. Other bands remain unchanged. The value of shift agrees well with that calculated for the O-O stretching vibration ($\Delta\nu$=50 cm^{-1}). For $[Co(O_2)(dmpp)_2]^+$, a similar medium intensity band is observed at 862 cm^{-1}. The corresponding *cis*-$[CoCl_2($dmpe or dmpp$)_2]^+$ complexes show no such bands in this region. Thus the bands at 877 cm^{-1} of the dmpe and 862 cm^{-1} of the dmpp complex can be assigned to the O-O stretching vibration. Gray et al.[4] assigned the band at 909 cm^{-1} of the dpee complex to the O-O stretching vibration. These frequencies are in the range of the reported values for a peroxide ion.[1,22]

Absorption Spectra. Figure 3 shows absorption spectra of the dioxygen complexes of dmpe, dmpp and

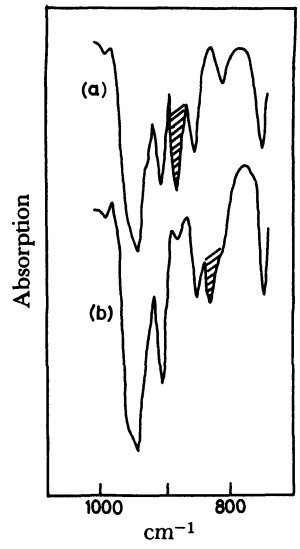

Fig. 2. IR spectra of $[Co(O_2)(dmpe)_2]BF_4$ (a) and $[Co(^{18}O_2)(dmpe)_2]BF_4$ (b).

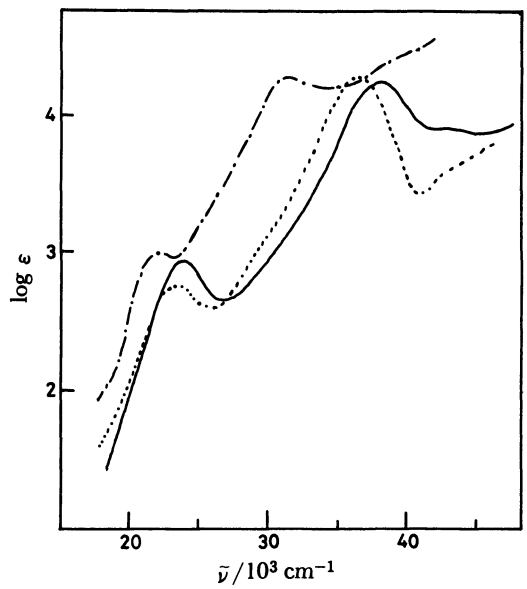

Fig. 3. Absorption spectra of $[Co(O_2)(dmpe)_2]BF_4$ (———), $[Co(O_2)(dmpp)_2]BF_4$ (·····) and $[Co(O_2)(dpee)]BF_4$ (—·—·—) in CH_3CN.

dpee. Gray et al.[4] assigned the band at 21000 cm^{-1} and the shoulder around 26000 cm^{-1} of the dpee complex to the first ($^1A \rightarrow {}^1T_1$) and the second ($^1A \rightarrow {}^1T_2$) ligand field bands, respectively, from a comparison with the spectrum of $[Co(CO_3)(dpee)_2]^+$ which has the same *cis*-$[CoO_2P_4]$ chromophore. The spectra of the dmpe and dmpp complexes are similar in pattern to that of the dpee complex, giving a peak at ca. 24000 cm^{-1} and a shoulder around 30000 cm^{-1} in the ligand field band region. The peak positions shift to high energy in the order of dpee<dmpp< dmpe complexes. This order coincides with the ranking of these phosphine ligands in the spectrochemical series.[23] Thus we have assigned the bands at 23750 cm^{-1} (log ε=2.95) of the dmpe complex and 23250 cm^{-1} (log ε=2.77) of the dmpp complex to the first ligand field band. It is not clear whether the shoulder absorption around 30000 cm^{-1} is the second ligand field band. In Fig. 4 are compared the spectrum of $[Co(O_2)(dmpe)_2]^+$ with those of $[Co(CO_3)(dmpe)_2]^+$ and $[Co(SO_4)(dmpe)_2]^+$. The latter two complexes exhibit two distinct absorption bands in the region of 20000 to 28000 cm^{-1} ($[Co(CO_3)(dmpe)_2]^+$ in water: 23530(2.96), 27100(2.98); $[Co(SO_4)(dmpe)_2]^+$ in CH_3CN: 21740(2.92), 25130(2.99) in cm^{-1} (log ε)). The two bands of each complex can be assigned to the ligand field bands, although the energy separation between them is much smaller than those of Co(III) amine complexes. The energy difference between the two ligand field bands in $[Co(CO_3)(dmpe)_2]^+$ (3750 cm^{-1}) is smaller than the half of the difference in $[Co(CO_3)(en)_2]^+$ (8250 cm^{-1}).[24] It is known that the energy differences between the two ligand field bands of phosphine[25] and arsine[16,26] cobalt(III) complexes are markedly reduced. No distinct band is observed for $[Co(O_2)(dmpe)_2]^+$ in the region of the second ligand field band of $[Co(CO_3)(dmpe)_2]^+$, although the first absorption bands of the two complexes are very similar both in intensity and peak position. When the shoulder around 30000 cm^{-1} of $[Co(O_2)(dmpe)_2]^+$ is assigned to the second ligand field band, the energy difference from the first ligand field band seems to be too large for a phosphine complex. Bosnich et al.[16] reported the absorption and CD spectra of an optically active peroxo tetrarsine complex, *Δ-cis β*-$[Co(O_2)(RR\text{-tetars})]^+$. The complex shows an absorption spectral pattern very similar to that of $[Co(O_2)(dmpe)_2]^+$ in the ligand field band region, and exhibits rather strong CD corresponding to the first ligand field band and fairly weak CD in the region from the absorption minimum to the high

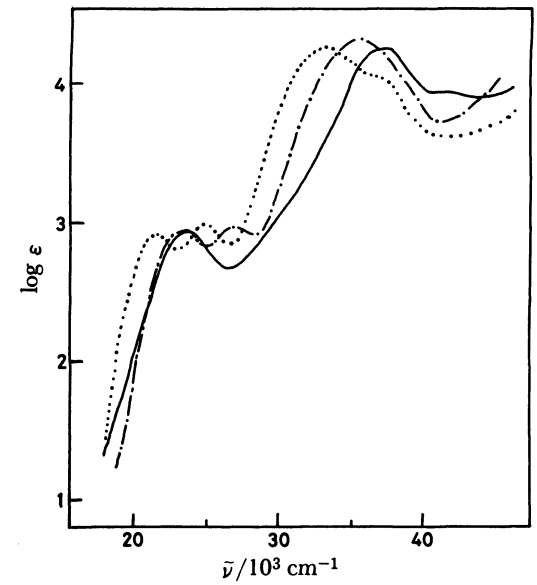

Fig. 4. Absorption spectra of $[Co(O_2)(dmpe)_2]BF_4$ (———), $[Co(CO_3)(dmpe)_2]ClO_4$ (—·—·—) and $[Co(SO_4)(dmpe)_2]BF_4$ (·····) in CH_3CN.

energy side. If the weak CD corresponds to the second ligand field band ($^1A \rightarrow {}^1T_2$) of Co(III), such a CD pattern is acceptable as a cobalt(III) complex. The second ligand field band would be so weak that it is hidden by adjacent strong absorption, although the reason is unknown. The ligand field absorption spectra of $[Co(O_2)(dmpe)_2]^+$ and $[Co(O_2)(dmpp)_2]^+$ could be understood in the same manner as that of the tetars complex.

The peroxo-bis(diphosphine) complexes show strong absorption bands in the region of 30000 to 40000 cm^{-1}. Gray et al.[4] assigned the band at 31000 cm^{-1} of $[Co(O_2)(dpee)_2]^+$ to a ligand-to-metal charge transfer transition of the type $\sigma(P) \rightarrow d\sigma^*(Co)$. The corresponding strong band is observed at 38000 cm^{-1} (log ε=4.36) and 36000 cm^{-1} (log ε=4.29) for $[Co(O_2)(dmpe)_2]^+$ and $[Co(O_2)(dmpp)_2]^+$, respectively. These bands are largely shifted to the high energy side compared with that of the dpee complex. Similar P-to-Co charge transfer bands of complexes, $[Co(en)_2(N\text{-}P)]^{3+}$ ($N\text{-}P=NH_2CH_2CH_2P(C_6H_5)_2$ or $NH_2CH_2CH_2P(CH_3)_2$)[27] and *trans*-$[Co(CN)_4(P)_2]^-$ ($P=P(C_6H_5)_3$, $P(C_6H_5)_2(CH_3)$ or $P(C_6H_5)(CH_3)_2$)[28] show a similar large shift to high energy by replacing a phenyl group on P with a methyl group.

The *trans*-$[(dmso)(dmpe)_2Co(\mu\text{-}O_2)Co(dmpe)_2(dmso)]^{4+}$ complex shows two medium intensity bands at 20000 cm^{-1} (log ε=2.93) and 25000 cm^{-1} (log ε=2.64) and a stron g band at 36000 cm^{-1} (log ε=4.67)(Fig. 5). The former two bands can be assigned to the two ligand field transitions of cobalt(III), since the spectral pattern quite resembles that of *trans*-$[Co(dmso)_2(dmpe)_2]^{3+}$ which was generated from *trans*-$[Co(H_2O)_2(dmpe)_2]^{3+}$ in dmso. While such distinct ligand field bands of a μ-peroxo cobalt(III) complex have been observed for $[(CH_3CN)(diars)_2Co(\mu\text{-}O_2)Co(diars)_2(CH_3CN)]^{4+}$[16] and $[X(cyclam)Co(\mu\text{-}O_2)(cyclam)X]^{n+}$ (X= a unidentate ligand such as H_2O or Cl^-; cyclam=1,4,8,11-tetraazacyclotetradecane),[29] a large number of amine complexes such as $[(NH_3)(en)_2Co(\mu\text{-}O_2)Co(en)_2(NH_3)]^{4+}$ show a broad, unresolved spectrum in the ligand field region.[30]

The *trans*-$[Co(H_2O)_2(dmpe)_2]^{3+}$ complex exhibits the first ligand field band split into two components, a shoulder around 20000 cm^{-1} (log ε = ca. 2.4) and a band at 23300 cm^{-1} (log ε = 2.80), and the second ligand field band at 27000 cm^{-1} (log ε = 2.96). The splitting of the first ligand field band can be anticipated from a *trans*-$[CoO_2P_4]$ chromophore. However, neither the present μ-peroxo complex nor *trans*-$[Co(dmso)_2(dmpe)_2]^{3+}$ show such splitting of the first ligand field band. Further studies will be needed for elucidating the absorption spectra of the cobalt(III) phosphine complexes.

Reactivity of Dioxygen Complexes. Both monomeric peroxo complexes of dmpe and dmpp in ethanol solutions react immediately with SO_2 at room temperature to afford $[Co(SO_4)(dmpe \text{ or } dmpp)_2]^+$, which were isolated as the tetrafluoroborate. The $[Co(O_2)(dbpe)_2]^+$ complex also reacts with SO_2, but the

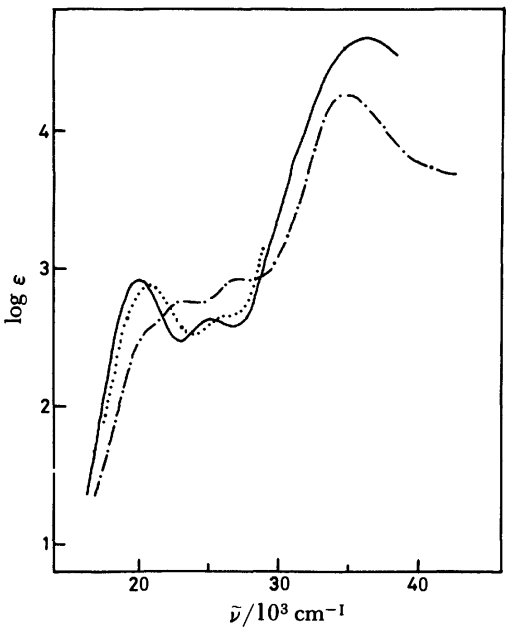

Fig. 5. Absorption spectra of $[(dmso)(dmpe)_2Co(\mu\text{-}O_2)Co(dmpe)_2(dmso)]^{4+}$ in dmso (——), and *trans*-$[Co(H_2O)_2(dmpe)_2]^{3+}$ in 0.5 mol dm^{-3} $HClO_4$ (—·—·—) and in dmso (·····).

sulfato complex could not be isolated because it decomposed to give Co(II) species during the course of isolation. Similar reactions have been reported for dioxygen complexes of cobalt(III). The $[Co(O_2)(diars)_2]^+$ complex reacts with SO_2, but the product (probably sulfato complex) can not be isolated because of the instability in the presence of SO_2.[16] Some μ-peroxo amine complexes such as $[(en)_2Co(\mu\text{-}NH_2, \mu\text{-}O_2)Co(en)_2]^{3+}$ yield μ-sulfato complexes by reaction with SO_2.[31]

On the other hand, $[Co(O_2)(dpee)_2]^+$ is quite inert toward SO_2. As described in Molecular Structure, the bond distances and angles of the Co-O_2 moiety are similar among the dmpe, dmpp and dpee complexes. As described previously the O_2^{2-} ion is surrounded by substituents on the axial P donor atoms of diphosphine ligands. The peroxide ion in $[Co(O_2)(dpee)_2]^+$ might be protected by the surrounding bulky phenyl groups against the attack of SO_2. Bulkiness of substituents on the axial P donor atoms in the $[Co(O_2)(diphosphine)_2]^+$ complex seems to be an important factor for the reactivity of the ligating peroxide ion. Thus the remarkable difference in reactivity toward SO_2 between the dpee complex and the other dmpe and dmpp complexes may be attributable to steric factors rather than electronic factors.

The peroxo complexes of dmpe and dmpp react instantly with concd HCl at 0 °C to afford red *cis*-$[CoCl_2(diphosphine)_2]^+$, while the same reaction of the dpee complex takes place very slowly and gives a mixture of green *trans*- and red *cis*-$[CoCl_2(dpee)_2]^+$. This indicates also the less reactivity of the dpee

complex. The formation of *trans*-$[CoCl_2(dpee)_2]^+$ may be related with the fact that *cis*-$[CoCl_2(dpee)_2]^+$ in ethanol isomerizes to the trans isomer (half-life=1.07 h at 53.3 °C) much faster than does *cis*-$[CoCl_2(dmpe)_2]^+$ (half-life=148 h at 55.0 °C). Detailed isomerization studies for these dichloro complexes will be reported elsewhere.

A Study on the Mechanism of the Dimerization of Quinazoline Compounds Catalyzed by Cyanide Ions

Ayako GOTO* and Takeo HIGASHINO
Shizuoka College of Pharmacy, 2-2-1, Oshika, Shizuoka 422
(Received May 22, 1985)

It was shown that an intermediate, 4,4′(3*H*,3′*H*)-biquinazolinylidene (**2a**) was isolated in the formation process of 4,4′-biquinazolinyl (**3a**) which was obtained from the reaction of quinazoline (**1a**) with potassium cyanide, and **2a** was readily oxidized to **3a** by oxygen in air. The dimerization process was studied kinetically by NMR method. The result showed that the process was essentially similar to that of the benzoin condensation. The introduction of a methyl group into the C^2-position of **1a** resulted in a lowering of the reaction rate because the activation energy of 2-methylquinazoline (**1b**) dimerization became higher compared with that of **1a** dimerization.

It has been reported by Higashino et al.[1,2] that the chemical properties of the C^4-atom of quinazoline ring system are similar to those of carbonyl carbon. These properties were observed in the following reactions; i) the reaction of quinazoline(**1a**) with cyanide ions caused a dimerization,[1] ii) the benzoin-type condensation between quinazoline(**1a**) and aromatic aldehydes in the presence of cyanide ions resulted in the formation of α-aryl-4-quinazolinmethanol,[1] and iii) the benzilic acid-type rearrangement of aryl 4-quinazolinyl ketones proceeded in the presence of sodium hydroxide in dimethyl sulfoxide.[2]

Armarego and Willette[3] found that quinazoline (**1a**) reacted with cyanide ions to give 4,4′-biquinazolinyl(**3a**), and Higashino et al.[1] reported that this dimerization involved a benzoin-type condensation and oxidation. However, since an intermediate could not be isolated in the formation process of 4,4′-biquinazolinyl(**3a**), its mechanism is unknown. We studied its dimerization mechanism of quinazoline compounds in order to obtain useful information with respect to the carbonyl-like properties of the C^4-atom of quinazoline.

In this paper, we report that a benzoin-type condensation product, 4,4′(3*H*, 3′*H*)-biquinazolinylidene (**2a**), was isolated and the reaction process was investigated in detail by NMR technique.

Experimental

Infrared(IR) spectrum was recorded on a Jasco IRA-1 grating infrared spectrophotometer. The ^1H NMR and ^{13}C NMR spectra were measured at 90 MHz and at 21 °C on a JEOL TNM-FX90QFT NMR spectrophotometer. Mass spectra were obtained on a JEOL JMS-D100 mass spectrometer. The samples were vaporized in a direct inlet system at 190 °C. Ultraviolet spectra were measured in dimethyl sulfoxide (DMSO) on a Shimadzu Recording Spectrophotometer UV-360.

Materials. Dimethyl sulfoxide and potassium cyanide were of the reagent grade. Dimethyl-d_6 sulfoxide was obtained from Merck.

Quinazoline(**1a**) was synthesized according to the method of Higashino.[4] After the crude **1a** was distilled under 15—20 mmHg (1 mmHg=133.322 Pa) and the fraction boiling at 115—125 °C was collected, it was twice passed through a column of alumina. The elution with benzene gave the pure compound, mp 48 °C, white needles. 2-Methylquinazoline(**1b**) was synthesied by the method described in the previous paper.[5] The crude **1b** was purified by the same manner as **1a** to give the pure compound, light yellow, needles, mp 41 °C.

4,4′(3*H*, 3′*H*)-Biquinazolinylidene (2a). A mixture of 3.8 mmol of **1a** and 7.7 mmol of KCN in 2 cm³ of DMSO was allowed to stand overnight under nitrogen atmosphere. The reaction mixture was poured into an ice-H_2O mixture. The separated crystals were collected and washed thoroughly with methanol and dried under reduced pressure. The crystals, mp 217—218 °C, were obtained as needles in a 70% yield. The compound **2a** had molecular formula, $C_{16}H_{12}N_4$ (*m/z*, 260(M^+)). The NMR spectrum was as follows; NMR (DMSO-d_6) $\delta(^1H)$=6.69—7.16 (8H, m), 8.73 (2H, d, J=8.0 Hz), and 6.3 (2H, bs). $\delta(^{13}C)$=113.2, 126.5, 138.0 (each s), 122.1, 127.0, 128.3, 129.0, 140.5 (each d). When **2a** was heated or allowed to stand overnight in air, it was readily oxidized to **3a**.

Oxidation of 2a with $K_3[Fe(CN)_6]$. A solution of 500 mg of $K_3[Fe(CN)_6]$ in 5 cm³ of H_2O was added to a mixture of 120 mg of **2a**, 10 cm³ of benzene and 1 cm³ of 50% NaOH, and the mixture was vigorously shaken for 1 h at room temperature. The benzene solution was dried over Na_2SO_4 and evaporation of the benzene gave **3a**.

2,2′-Dimethyl-4,4′(3*H*,3′*H*)-biquinazolinylidene (2b). The NMR data of **2b** in the reaction mixture were as follows; NMR (DMSO-d_6, 90 MHz) $\delta(^1H)$=2.60 (6H, s), 6.67—7.12 (6H, m) and 8.87 (2H, d, J=7.8 Hz). $\delta(^{13}C)$=112.8, 121.1, 125.9, 138.8 (each s), 121.6, 126.7, 128.8, 147.3 (each d), and 21.2 (q).

2,2′-Dimethyl-4,4′-biquinazolinyl (3b). The dimer, **3b**, mp 219 °C, was prepared by the same method described by Armarego and Willette.[3] The yield was 25%.

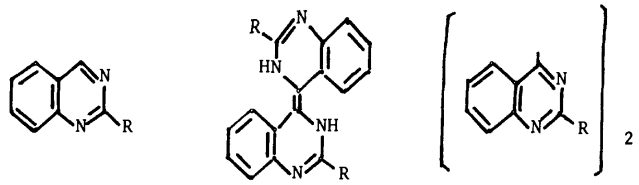
3,4-Dihydro-4-quinazolinecarbonitrile. 3,4-Dihydro-4-quinazolinecarbonitrile was synthesized according to the method of Higashino.[4]

Kinetics of Dimerization. The reaction mixture was made by mixing equal volumes (0.2 cm³) of KCN-DMSO-d_6 solution and DMSO-d_6 solution of quinazoline compound (**1**) in an NMR tube and air was replaced with N_2 after degassing. The concentrations of KCN and **1** in a mixture of 0.2 cm³ of KCN-DMSO-d_6 and 0.2 cm³ of **1**-DMSO-d_6 are represented as mol dm^{-3}. Temperature equilibration was done outside the NMR probe in a thermostat at a constant temperature±0.1 °C. These reactions were followed by integration of the signal of the hydrogen atom at C^4-position of **1a** or **1b**. The errors of integration of the hydrogen atom observed by using CH_2Cl_2

as the standard were ±1.2% for **1a** and ±2.6% for **1b**, respectively. Rate constants were calculated by a least-square computer.

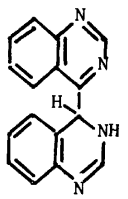
Results and Discussion

Although Higashino et al.[1] assumed that 3,4-dihydro-4,4′-biquinazoline (**2′**) (Chart 2) was a formal benzoin-type condensation product for **1a**, **2′** could not be isolated. Furthermore, it is yet unknown whether the oxidation step is caused by oxygen in atmosphere or by **1a** which may act as the hydride ion acceptor to form a reduction product such as 3,4-dihydroquinazoline.



1a: R = -H **2a**: R = -H **3a**: R = -H
1b: R = -CH_3 **2b**: R = -CH_3 **3b**: R = -CH_3

Chart 1.



3,4-Dihydro-4,4′-biquinazoline (**2′**)

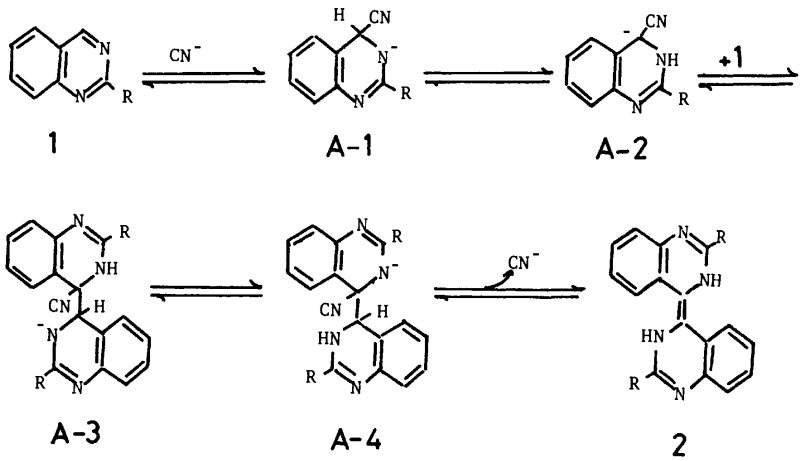
Chart 2.

When a dried dimethyl sulfoxide solution of **1a** containing potassium cyanide was allowed to stand under nitrogen atmosphere at room temperature, **2′** was not obtained, but the isomer, 4,4′(3*H*, 3′*H*)biquinazolinylidene (**2a**) was isolated. The structure of **2a** was elucidated by the spectra data (see Experimental) and the following chemical procedures. Compound **2a** was easily oxidized to **3a** not only with $K_3[Fe(CN)_6]$, but also by atmospheric oxygen at room temperature. The structure of **2a** was suggested as (*E*)-form as shown in Chart 1 on the basis of the following facts: (*E*)-Form corresponds to *trans*-stilbene and (*Z*)-form to *cis*-stilbene. Rizebos and Havinga[6] reported that *trans*-stilbene showed a longer wavelength shift of the absorption maximum (λ_{max} 295 nm, ε 27000) than *cis*-stilbene (λ_{max} 280 nm, ε 10500) because the hydrogen atoms at the ortho-positions of *cis*-stilbene interact mutually and the stilbene cannot exist in a coplanar structure either. On the other hand, Armarego and Willette[3] reported that the ultraviolet spectrum of 4,4′-biquinazolinyl(**3a**) is similar to that of **1a**, due to the restricted rotation about the 4,4′-bonds; the two halves of the molecule are not coplanar and the chromophores are not highly conjugated with one another. If the compound, **2a**, corresponds to (*Z*)-form, the hydrogen atoms at C^5-and $C^{5'}$-positions interact mutually and also it can hardly maintain a coplanar structure. However, the absorption maximum of **2a** in DMSO is at 414 nm (ε 9680), and is remarkably longer than that of **3a** (λ_{max} 320 nm, ε 7110 in DMSO). Therefore, this fact suggests that the double bonds of **2a** may be highly conjugated by maintaining a coplanar structure and it seems reasonable to assume that **2a** is in (*E*)-form.

Since the above result proved that the dimerization of **1a** in the presence of potassium cyanide gave **2a** which was oxidized to **3a**, the reaction process for the formation of **2** is assumed to be as shown in Scheme 1, which is similar to the benzoin condensation process: *N*-anion (**A-1**) formed by addition of cyanide ions to **1** would rearrange readily to carbanion (**A·2**) by a prototropic shift. Nucleophilic addition of **A-2** to quinazoline provides an intermediate *N*-anion, **A-3**, which rearranges readily to *N*-anion (**A·4**) and is finally converted to product **2** by rapid loss of CN^-. The process represented in Scheme 1 is also summarized as represented in Eqs. 1 and 2,

$$Q + C \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \textbf{A-2} \qquad (1)$$

$$\textbf{A-2} + Q \xrightarrow{k_2} P + C \qquad (2)$$



Scheme 1.

where [Q] refers to free quinazoline and C to free cyanide ions. **A·2** is the carbanion in Scheme 1, and P stands for product **2**. The presence of carbanion **A·2** is suggested from the following reasons: Hydrogen cyanide adds easily to quinazoline to produce 3,4-dihydro-4-quinazolinecarbonitrile. When 3,4-dihydro-4-quinazolinecarbonitrile in DMSO-d_6 was mixed with quinazoline and potassium hydroxide under nitrogen atmosphere in an NMR tube, the presence of **2a** was observed in the NMR diagram. This corresponds to the fact that α-hydroxyphenylacetonitrile was mixed with benzaldehyde and a base to give benzoin.[10]

Figure 1 shows the NMR diagram of the reaction mixture (0.4 cm^3) of **1a** (3.72×10^{-1} mol dm^{-3}) and KCN (4.55×10^{-2} mol dm^{-3}) in DMSO-d_6 at 25 min (A) and at 300 min (B) after mixing under nitrogen atmosphere, respectively. Since Fig. 1 shows only the presence of **1a** as the starting material and **2a** as the reaction product, it is possible to follow the reaction process kinetically by determing the time dependence of the signal of the hydrogen atom at C^4-position of quinazoline represented as * in Fig. 1. The rate constant may be derived, using a steady-state approximation in a similar manner as benzoin condensation.[7-10] That is to say, if $k_{-1}\gg k_2$, the following rate expression can be derived,

$$d[P]/dt = \frac{k_1k_2}{k_{-1}}[Q][C_0], \qquad (3)$$

where [Q] refers to free quinazoline concentration and C_0 to cyanide ion concentration. The second order rate plots with respect to quinazoline are shown in Fig. 2. Although ^{1}H NMR method may be less accurate than other spectrophotometric methods, the second order plots were fairly linear ($r>0.98$) in all cases. This is in agreement with the result that benzoin condensation is kinetically second order in benzaldehyde.[7-10] Therefore, it suggests that the process of Eq. 2, that is, addition of carbanion, **A·2**, to the carbon at C^4-position of quinazoline is rate-determing, corresponding to the result that addition of carbanion, [ArC(CN)OH]$^-$, to the carbonyl carbon of benzaldehyde is rate-determining in benzoin condensation.[7-10] It seems also reasonable to consider that the chemical properties of C^4-atom of the quinazoline ring system are similar to those of carbonyl carbon.

Furthermore, the dimerization process of **1b** was investigated in order to clarify the effect of methyl group at C^2-position of **1** on the dimerization. When **1b** was allowed to react under the same experimental conditions as the quinazoline dimerization, only 2,2′-dimethyl-4,4′-biquinazolinyl(**3b**) was obtained. The intermediate, 2,2′-dimethyl-4,4′(3*H*,3′*H*)-biquinazolinylidene(**2b**) could not be isolated because it was readily oxidized, compared with **2a**. Figure 3 shows ^{1}H NMR spectra of the reaction mixture (0.4 cm^3) of **1b** (3.17×10^{-1} mol dm^{-3}) and KCN (5.3×10^{-2} mol dm^{-3}) in

Table 1. Kinetic and Thermodynamic Parameters for the Dimerization of **1**

Parameter	**1a**	**1b**
k/(mol dm^{-3})$^{-2}$ min^{-1} at 25 °C	1.20±0.09	$7.18\times10^{-2}\pm0.88\times10^{-2}$
ΔE^*/kJ mol^{-1}	1.02×10	2.39×10
ΔG^*/kJ mol^{-1} at 25 °C	5.71×10	6.42×10
ΔH^*/kJ mol^{-1}	5.24	1.90×10
ΔS^*/J mol^{-1} T^{-1}	-1.74×10^2	-1.52×10^2

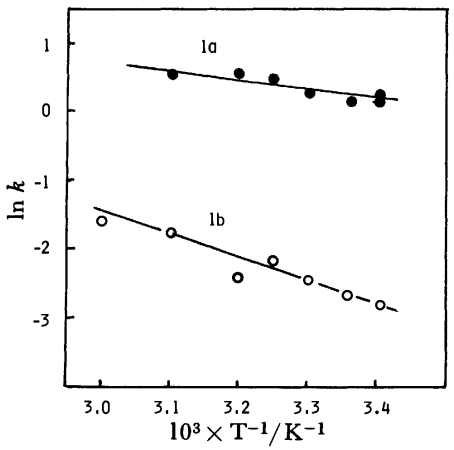

Fig. 4. Plots of ln k against T^{-1}.

DMSO-d_6 at 280 min (A) and at 1500 min (B) after mixing, respectively. Since the presence of **1b** and **2b** was observed by the NMR spectra shown in Fig. 3, the dimerization process of **1b** can be followed by ^{1}H NMR methods described above for the dimerization of **1a**. The rate was estimated by following the signal of hydrogen at C^4-position of **2b** represented as * in Fig. 3. Figure 2 shows second order rate plots for the **1b** dimerization, indicating that the rate of **1b** is lower than that of **1a**. Kinetic parameters were determined from the temperature-dependency of the rate constant, k. Plots of ln k vs. T^{-1} show an approximately linear relationship in the temperature ranges 20—45 °C for **1a** and 20—60 °C for **1b** (Fig. 4). Activation parameters, ΔE^*, ΔG^*, ΔH^*, and ΔS^* were determined (Table 1). The value of ΔE^* for the **1a** dimerization was smaller than that for the **1b** dimerization. In comparison with the parameters of benzoin condensation in methanol at 44—66 °C ($\Delta G^{\ddagger}_{298}$=94.1 kJ mol^{-1}, ΔH^*=41.8 kJ mol^{-1}, and ΔS^*=−75 J mol^{-1} T^{-1}), the values of ΔH^* and ΔG^* for both quinazolines were low. It is interesting because the reactivity of quinazoline compounds is suggested to be higher than that of benzaldehyde in regard to the benzoin condensation. Activation enthalpy, ΔH^*, for **1b** is much higher than that for **1a**, while ΔS^* at 25 °C is essentially the same. It is expected that the electrophilicity of the C^4-position of **1a** is higher than that of **1b** because electron density at the C^4-position of **1b** will increase due to the electron-donating effect of the methyl group. This expectation is compatible with the above result of activation parameters.

In conclusion, the present quantitative study verified that the dimerization process of **1** is essentially similar to the benzoin condensation process.

The authors are grateful to Professor E. Hayashi and Dr. M. Uchida of Shizuoka College of Pharmacy for many valuable discussion.

Studies of Polystyrene-Based Ion-Exchange Fiber. IV. A Novel Fiber-Form Material for Adsorption and Immobilization of Biologically-Active Proteins†

Toshio YOSHIOKA* and Masaharu SHIMAMURA
Fibers Research Laboratories, Toray Industries, Inc., Sonoyama, Otsu 520
(Received June 12, 1985)

A new polystyrene-based ion-exchange fiber (IONEX) has a large surface area per unit weight and has been studied for its ability to adsorb and immobilize biologically-active proteins. A strong cation IONEX was found to be able to effectively adsorb hemoglobin and albumin, invertase, and glucose isomerase were readily adsorbed to a strong anion IONEX. The adsorption of these proteins to IONEX was found to take place through an electrostatic force. The adsorption capacity for proteins became exceedingly large (ca. 300 mg g^{-1}) with an increase in the water-holding capacity of the fiber. The activities of the invertase and glucose isomerase immobilized to the fiber exhibited 40—50 and 75—80%, respectively, of those of native enzymes. A continuous inversion of sucrose was also carried out using immobilized invertase. From these results, this fibrous ion exchanger with a high water-holding capacity is considered to be an excellent material for the adsorption and immobilization of proteins.

In other papers we have reported the preparation methods, fundamental characteristics, and acid-base catalytic properties of a polystyrene-based ion-exchange fiber (IONEX).[1-3] The ion-exchange fiber has a large surface area and, accordingly, is expected to have a large capacity for adsorbing macromolecular ionic substances.

Recently, the immobilization of enzymes has been intensively studied and some immobilized emzymes have been used in industry. There have been many investigations regarding methods for immobilizing enzymes, such as bonding to a supporter, entrapping in a crosslinked gel, and crosslinking by a bi- or multifunctional reagent.[4] An immobilization of enzymes to an ion-exchange fiber based on poly(vinyl alcohol) has also been examined and several reports have been published.[5-7] We have undertaken an investigation regarding the immobilization of emzymes using IONEX while considering the following advantages:[8]

(1) The capacity for adsorbing macromolecular proteins is expected to be large since IONEX has a large surface area per unit weight.

(2) The yield of the activity is expected to be high because immobilization probably occurs on the surface through ionic bonding. Thus, steric hindrances for the active site of proteins and for the diffusion of the substrates would be smaller.

(3) IONEX exhibits a high mechanical strength and, thus, it can be utilized in various forms, such as a cut fiber, a knitted fabric, a woven fabric, a braid, a felt, a nonwoven fabric, and a paper.

In the present report, the adsorption and immobilization of some proteins and enzymes to IONEX are described. The importance of the water-holding capacity of the fiber for protein adsorption and enzyme immobilization is also described.

†A preliminary report of this work was presented in *Polym. Prepr. Jpn.*, **32**, 1851 (1983).

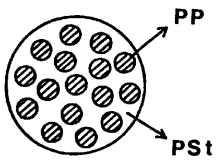

Fig. 1. Schematic cross section of composite fiber. Pst: polystyrene as *sea* ingredient; PP: polypropylene as *island* ingredient.

Experimental

Polystyrene to be converted into an ion exchanger (as the predominant *sea* ingredient) and polypropylene for reinforcement (as the *island* ingredient) were spun into composite filaments having an *islands-in-a-sea* type sectional structure (Fig. 1) by the conventional method. A cation IONEX with sulfo groups and an anion IONEX with trimethylammonio groups were prepared by the introduction of crosslinking groups and corresponding ion-exchange groups into the polystyrene part according to the procedures described in a previous paper.[1] The capacity of strong acidic- and basic-type IONEX was ca. 2.5 mequiv g^{-1}. A cation IONEX in the Na form or an anion IONEX in the Cl form was immersed in deionized water at room temperature for a sufficient period in order to reach an equilibrium water sorption. The fiber was centrifugally dehydrated at 3000 r.p.m. for five minutes, and then, the wet weight (W) was determined immediately. The water content of the fiber was determined using the following equation:

$$\text{Water content} = (W - W_0)/W_0,$$

where W_0 is the dry weight of the fiber. The water content means the water-holding capacity of a fiber. The content was controlled by choosing the conditions of the crosslinking reaction.[1-3] The water content becomes higher as the degree of crosslinking is lowered.

Hemoglobin and albumin from bovine blood and invertase from *Candia utilis* were obtained from Sigma Co. and Seikagaku Kogyo Co., Ltd., respectively. Glucose isomerase was extracted by the lysozyme methods from *Streptomyces*

phaeochromogenus supplied by Nagase Sangyo Co., Ltd. The adsorption capacity of the fiber for proteins was evaluated by measuring the concentrations of the proteins in solutions before and after an adsorption treatment by means of the copper-Folin[9] or optical-density (at 270 nm) methods. The amount of the enzyme adsorbed to the fiber (A) was calculated by subtracting the activity of the enzyme which remained unadsorbed from the activity of the added enzyme. The yield of the activity (B/A) was determined by measuring the activity of the enzyme immobilized to the fiber (B). One unit (U) of invertase activity was defined as the amount of enzyme which produced 1 μ mole of glucose per minute at 30°C in a 10 wt% sucrose solution containing a 0.01 M (1 M=1 mol dm^{-3}) phosphate buffer of pH 5.0. The activity of the native invertase was 170 U mg^{-1}. On the other hand, one unit (U) of glucose isomerase activity was defined as the amount of enzyme which produced 1 mg of fructose per hour at 60°C in a 0.5 M glucose solution (pH 8.2) containing 0.05 M $NaHCO_3$ and 0.01 M $MgSO_4$. The amount of glucose or fructose produced was determined by the polarimetric methods.[10]

Results and Discussion

Adsorption of Hemoglobin and Albumin. The adsorption of hemoglobin and albumin was carried out by the following procedures. A strong cation exchanger (20—100 mg in the Na form) was added to 10 ml of a 0.1% hemoglobin (isoelectric point; pH 6.9, molecular weight; ca. 70000) solution containing a 0.05 M phosphate buffer of pH 6.6. The mixture was then shaken at 30°C for 3 h. Similarly, a strong anion exchanger (20—100 mg in the Cl form) was added to 10 ml of a 0.1% albumin (isoelectric point; pH 4.7, molecular weight; ca. 70000) solution containing a 0.05 M phosphate buffer of pH 7.0; then, the mixture was shaken at 30°C for 3 h. The results of hemoglobin adsorption to cation exchangers and albumin adsorption to anion exchangers are summarized in Tables 1 and 2, respectively.

The adsorption capacity of a cation IONEX for hemoglobin was apparently dependent on its water content. IONEX with a water content of 1.5 exhibited an adsorption capacity of less than 20 mg g^{-1}. In contrast, IONEX with the highest water content among those tested exhibited a capacity of 300 mg g^{-1}. The granular cation-exchange resins, Amberlite IR-120B and IR-200C, and the crushed resin, Powdex PCH, were also examined for their capacity to adsorb hemoglobin. These resins had a water content in a range from 0.9 to 1.6 and showed adsorption capacities similar to that of IONEX with the lowest water content. In the case of albumin, protein was readily adsorbed to an anion IONEX having a trimethylammonio group as the ion-exchange site. The adsorption capacity was again dependent on the water content. Macroreticular-type granular anion-exchange resins, such as Amberlite IRA-900, IRA-904, and IRA-938, showed low adsorption capacities of 12—40 mg g^{-1}. Gel-type granular anion-exchange resins, Amberlite IRA-400 and IRA-401, and the crushed resin, Powdex PAO, exhibited no appreciable adsorption capacities for albumin.

The dependences on the water content of the adsorption capacities of IONEX for the proteins are shown in Fig. 2. Apparently, water in the polystyrene network of IONEX plays an important role in macromolecular protein's ability to have access to the ion-exchange site. In fact, IONEX comprises a polystyrene network crosslinked between the phenyl

Table 3. Results of Invertase Immobilization to Anion IONEX in Cl Form by Batch Method

Water content	Amount of IONEX	Adsorbed[a] enzyme (*A*)	Observed activity (*B*)	Yield of activity (*B/A*)
	mg	U	U	%
1.5	250	610	230	38
	500	1170	460	39
	1000	2125	860	40
2.5	50	625	350	56
	150	1940	1025	53
	500	2125	1140	54

a) Enzyme added: 2125 U, 12.5 mg (50 ml of 0.01 M phosphate buffer, pH 5.0), 20°C, 2 h.

groups by methylene linkages. The lattice of the network becomes wider as the degree of crosslinking is decreased; that is, the water content of the fiber increases, and thus, a macromolecule can diffuse into the network and more easily interact with the ion-exchange sites.

The higher adsorption capacity of IONEX (diameter; ca. 30 μm), compared with gel-type granular resins (diameter; ca. 500 μm) or with crushed resins (particle size; 37—250 μm) with similar water contents, would come from the larger surface area of IONEX. The surface areas of IONEX with a water content of 1.5—5.0 were 2.0—2.5 $m^2 g^{-1}$, as determined by the BET methods using nitrogen gas. On the other hand, the surface areas of the crushed resins and the gel-type granular resins were 0.5—0.8 $m^2 g^{-1}$ and less than 0.1 $m^2 g^{-1}$, respectively. In addition, the lattice sizes of the polystyrene network of IONEX are presumably larger than those of the usual styrene-divinylbenzene-based resins. This also contributes, at least in part, to the larger adsorption capacity of IONEX.

When a fiber which had adsorbed albumin was washed with distilled water and then treated with 10 wt% NaCl, more than 90% of the adsorbed protein was released. These results indicate that a protein is adsorbed to the fiber through an electrostatic force.

Immobilization of Some Enzymes. The results described above suggest the possibility of IONEX as an excellent material for the immobilization of enzymes. In order to prove this possibility, the immobilization of two enzymes, invertase and glucose isomerase, to IONEX was investigated with special reference to their activities.

Invertase (isoelectric point; pH 3.8, molecular weight; 270000) was first immobilized to an anion IONEX with two different water contents (1.5 and 2.5) by the following methods. A fixed amount of the anion IONEX in the Cl form was added to 50 ml of a 0.01 M phosphate buffer solution (pH 5.0) containing 2125 U of invertase. The mixture was shaken at 20°C for 2 h. Then, the fiber to which the enzyme was adsorbed was washed five times with distilled water and stored in the same buffer solution.

As expected, invertase was readily adsorbed to the anion IONEX and its adsorption capacity for this

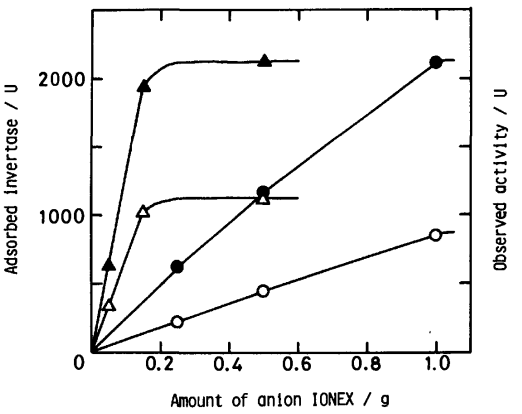

Fig. 3. Adsorbed invertase and observed activity vs. amount of anion IONEX in Cl form. Immobilization was carried out in 50 ml of 0.01 M phosphate buffer solution (pH 5.0) containing invertase of 2125U (20°C 2h). ●: Adsorbed invertase, ○: observed activity (water content of IONEX=1.5), ▲: adsorbed invertase, △: observed activity (water content of IONEX=2.5).

enzyme was greater when the water content of the ion exchanger was higher (Table 3). When the water content was 1.5, the increase in the amount of the adsorbed enzyme was almost linear to the amount of IONEX (see Fig. 3) up to 1.0 g under the conditions used. In contrast, when the water content was 2.5, saturation occured in the vicinity of 0.2 g. These results indicate that the capacity for immobilization increases by five times when the water content of the fiber increases from 1.5 to 2.5. This fact is attributable to the difference in the crosslinked structure described above. The reasons that the yield of the activity is lower than 100% are considered to be (1) that the enzyme is inactivated during the immobilization process, (2) that the active site of the immobilized enzyme is sterically hindered, and (3) that the diffusion of the substrate to the active site of the immobilized enzyme is hampered. The yield of the activity was enhanced from ca. 40% to ca. 50% when the water content of the fiber was increased from 1.5 to 2.5 (Table 3). These results may indicate that two effects, (2) and (3), are eliminated by a loosening of the crosslinked structure.

Invertase was also immobilized to anion exchangers

Table 4. Results of Invertase Immobilization to Anion Exchangers in Cl Form by Column Method

Anion exchanger	Water content	Packed[a] amount	Adsorbed[b] enzyme (*A*)	Observed activity (*B*)	Yield of activity (*B*/*A*)
		mg	U	U	%
IONEX	1.5	500	600	265	44
	2.5	150	1700	865	51
Amberlite IRA-900	1.4	1500	600	260	43

a) Column diameter: 7.5 mm. b) Enzyme added: 2125 U, 12.5 mg (50 ml of 0.01 M phosphate buffer, pH 5.0), 20 °C, 1 h.

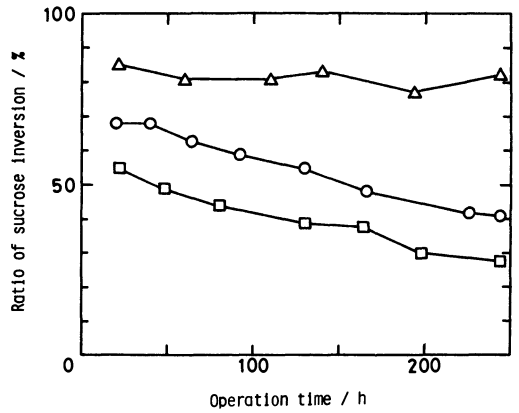

Fig. 4. Stability of immobilized invertase to continuous inversion of sucrose by a column method. 10 wt% Sucrose solution containing 0.01 M phosphate buffer of pH 5.0 was passed through the column (7.5 mmϕ) filled with the immobilized invertase at a flow rate of 50 ml h^{-1} at 25 °C.
○: 500 mg of anion IONEX with water content of 1.5 (265U). △: 150 mg of anion IONEX with water content of 2.5 (865U), □: 1500 mg of Amberlite IRA-900 (260U).

by a column method as follows. Anion exchangers were packed into a jacketed glass column with an inside diameter of 7.5 mm. The enzyme solution described above was circulated through the column at 20 °C for 1 h. The results are summarized in Table 4.

The column method gave results similar to the batch method, except that the amounts of adsorbed enzyme for IONEX with water contents (1.5 and 2.5) decreased to 55 and 85%, respectively. The decrease in the amounts of adsorbed enzyme may imply that some parts of IONEX are not utilized because of an irregular flow. The macroreticular-type resin, Amberlite IRA-900, has only one third as large an effective capacity for immobilizing invertase per unit weight as IONEX with a water content of 1.5.

Figure 4 shows the dependence on operation time of the ratio of sucrose inversion when the substrate solution was continuously passed through each column at 25 °C. The activity of an IONEX column with a water content of 2.5 decreased more slowly than that of an IONEX column with a water content of 1.5 and an IRA-900 column. The inversion ratio was not improved, although an enzyme solution with twice the decreased activity was circularly passed through each column. This fact indicates that the decrease in activity can be attributed to the inactivation of the enzyme, but not to the release of the enzyme.

Table 5. Results of Glucose Isomerase Immobilization to Anion IONEX of Water Content 4.0 in Cl Form

Amount of IONEX	Adsorbed[a] enzyme (*A*)	Observed activity (*B*)	Yield of activity (*B*/*A*)
mg	U	U	%
10	160	125	78
20	294	235	80
40	337	253	75

a) Enzyme added: 344 U (2 ml, pH 8.0), 20 °C, 6 h.

The immobilization of glucose isomerase was then examined by the following methods. A fixed amount of the anion IONEX with a water content of 4.0 in the Cl form was added to 2 ml of an extract solution (pH 8.0) of glucose isomerase. The mixture was shaken at 20 °C for 6 h. Then, the fiber to which the enzyme was adsorbed was washed five times with distilled water. The results of glucose isomerase immobilization are listed in Table 5.

Glucose isomerase was also readily adsorbed to the anion IONEX and the amount of the adsorbed enzyme was directly proportional to the amount of IONEX (up to 20 mg) under the conditions used. The yield of the activity was very high, that is, in the range from 75 to 80%. This shows that the enzyme is very stable, that the active site of the immobilized enzyme is not sterically hindered, and that the diffusion of glucose to the immobilized enzyme is not hampered.

Conclusion

1. The water content of the ion-exchange fiber as well as its surface area is very important for protein adsorption and enzyme immobilization. The adsorption capacity becomes much larger as the water content increases.

2. The immobilization of the enzymes by adsorption to the fiber gives high yields of the activity, that is, 40—50% for invertase and 75—80% for glucose isomerase.

3. The yield of the activity is improved as the water content of the fiber is increased.

The authors would like to express their appreciation to Dr. Tatsuro Kawaguchi, Mr. Michihiko Tanaka, and Dr. Masaki Nishino for their continuous encouragement throughout this work. They are also much obliged to Mr. Kazuo Teramoto for his advice on the chemical treatments and to Mr. Seiichi Yoshikawa and other collaborators for the preparation of the composite fibers. The authors also wish to thank Toray Industries, Inc., for making this study possible.

(Received June 26, 1985)

Treatment of allylic nitro compounds with sodium benzenesulfinate in the presence of 5 mol% of $Pd(PPh_3)_4$ in *N,N*-dimethylformamide (DMF) at 20—70 °C for 1—10 h resulted in the formation of allylic sulfones with predominance of kinetically controlled products. The product distribution is mainly controlled by the electronic nature of substituents of an allyl unit, and the isomerization to the thermodynamically-stable isomers is negligible. On the other hand, the palladium-catalyzed sulfonylation of allylic acetates with sodium benzenesulfinate is accompanied by the isomerization to give the thermodynamically-controlled products selectively. These results can be explained by assuming that allylic nitro compounds are more reactive to the palladium catalyst than allylic acetates and sulfones.

Allylic sulfones are useful synthetic intermediates because of ability of the sulfonyl group as an activating group for generation of an adjacent carbanion[1] and as a leaving group in substitution reactions[2] and elimination reactions.[3] Allylic sulfones have been prepared so far by following four methods as described in the recent paper,[1] method A: The displacement of allylic halides with sodium benzenesulfinate, method B: The oxidation of the corresponding allylic sulfides, method C: The replacement of an allylic hydroxyl group with sulfone with sodium benzenesulfinate,[4] method D: Oxidation of allyl sulfoxides formed via rearrangement of allyl sulfenates. We now wish to report a new method for the preparation of allylic sulfones.

Recently we have reported that allylic nitro compounds can serve as allylic electrophiles in the palladium-catalyzed allylic alkylation or amination,[5,6] and in the substitution reactions with dialkylcuprates[7] or sodium benzenethiolate.[8] In our previous communications, we reported that allylic nitro compounds were converted into allylic sulfones on treatment with sodium benzenesulfinate in the presence of 5 mol% of $Pd(PPh_3)_4$.[8,9] This provides a useful addition to the above four methods, for some kinds of allylic nitro compounds are more readily available than other conventional allylic electrophiles and the reaction gives the kinetically-controlled products.[8,9] In this paper we wish to report additional experimental data for this reaction which further extend its synthetic utility.

Results and Discussion

Cyclic allylic nitro compounds (**1**), which were readily prepared by the amine-catalyzed reaction of nitroalkanes with cycloalkanones,[10] reacted with sodium benzenesulfinate in the presence of 5 mol% of $Pd(PPh_3)_4$ to give the corresponding sulfones (**2** and **2′**) with predominance of the endo isomer. The results are summarized in Table 1.

Table 1. Preparation of Cyclic Allylic Sulfones (**2**)[a]

Run	R	*n*	Temp/°C	Time/h	Product,	Yield/%
1	H	2	20	10	**2a**,	70[b]
2	H	3	70	1	**2b**,	85[b]
3	H	3	20	10	**2b**,	70

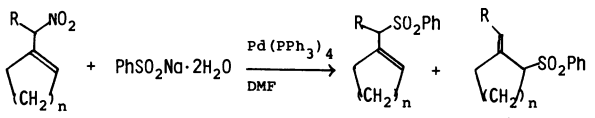
6	H	5	70	1	**2e**,	76

a) The reaction was carried out in DMF in the presence of $Pd(PPh_3)_4$ (5 mol%). b) The regio-isomer (**2′**) was also formed in 2—3% yield.



1 **2** **2′** (1)

DMF = *N,N*-Dimethylformamide

Acyclic allylic nitro compounds are also readily prepared in the same way using carbonyl compounds and nitroalkanes as cyclic cases.[10] α-Nitro olefins, which are prepared by dehydration of β-nitro alcohols[11] or nitration of olefins,[12] can be used as allylic nitro compounds because α-nitro olefins are readily isomerized on treatment with bases. A series of acyclic allylic nitro compounds (**3**) were prepared either by the base-catalyzed isomerization of 2-nitro-2-butene or by the introduction of a vinyl group into secondary nitroalkanes via the Michael addition of nitroalkanes to phenyl vinyl sulfoxide and the subsequent thermolysis.[5,6]

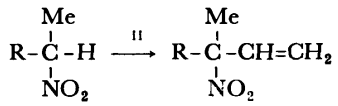
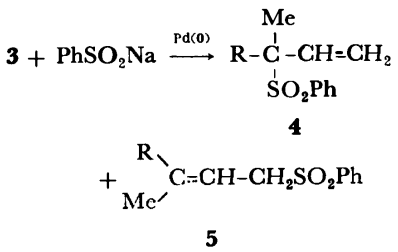
The reaction was carried out by stirring a mixture of **3** (1 mmol), $PhSO_2Na \cdot 2H_2O$ (2 mmol), and $Pd(PPh_3)_4$ (0.05 mmol) in DMF (10 ml).



3 (3)

ii) $CH_2=CH-SOPh$, DBU, CH_3CN, 25 °C, 24 h, then thermolysis

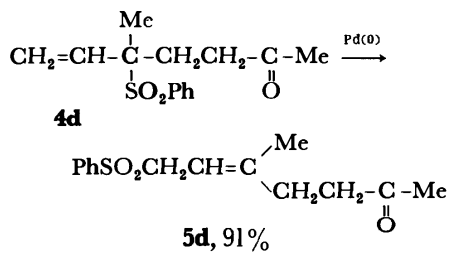
Allylic nitro compounds (**3**) underwent the palladium-catalyzed denitro-sulfonylation with sodium benzenesulfinate in the similar way as in the reaction of **1** to give allylic sulfones, **4** and **5**, in good yields. The results are summarized in Table 2.



4 + **5** (4)

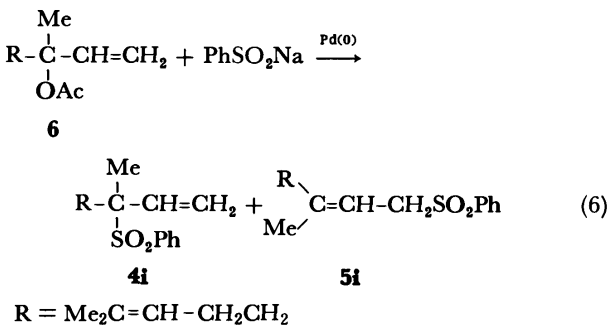
The product distribution was mainly controlled by the nature of substituents (R) in **3** and was a little affected by the reaction conditions. When R was an electron-donating group such as alkyl groups, the substitution reaction took place at the more hindered site to give the thermodynamically less stable isomer, **4**, regioselectively. When R was an electron-withdrawing group, the reverse regioselectivity was observed and **5** was obtained selectively.

Allylic sulfones are readily isomerized to the thermodynamically more stable isomers by the palladium catalyst.[4] In fact, stirring a mixture of **4d** and $Pd(PPh_3)_4$ (5 mol%) in DMF at room temperature resulted in clean isomerization to **5d**.



5d, 91% (5)

Nevertheless, **4d** was selectively obtained by the reaction of **3d** with sodium benzenesulfinate in the presence of $Pd(PPh_3)_4$. On the other hand, the palladium-catalyzed sulfonylation of allylic acetates was accompanied by the isomerization to give the thermodynamically-controlled products selectively. For example, treatment of linaryl acetate (**6**) with sodium benzenesulfinate in DMF at 70 °C in the same way as the reaction of **3** resulted in the exclusive formation of **5i**. This fact indicates that sodium nitrite which is liberated during the reaction suppresses the isomerization of the product, **4**. So the reaction was carried out in the presence of sodium nitrite (1 equiv). The results are summarized in Tables 3 and 4. Thus, addition of sodium nitrite is very effective to suppress the isomerization of the product in the sulfonylation of allylic nitro compounds and allylic acetates.



R = $Me_2C=CH-CH_2CH_2$ (6)

The sulfonylation of allylic nitro compounds (**3**) gives the kinetically-controlled product essentially when the isomerization can be ignored. However, the isomerization may occur to some extent during the sulfonylation of **3**. If the isomerization of **4** to **5** competes with the sulfonylation of **3**, the ratio of **4**/**5** may be affected by various factors. So the reaction of **3** with sodium benzenesulfinate was carried out under various conditions. The results are summarized in Tables 2 and 4. Concentration, temperature, and the nature of catalyst affect the ratio of **4**/**5** slightly. However, the reaction time does not affect the ratio of **4**/**5** (Run 19, 20). Namely, the isomerization occurs at the initial stage of the reaction. As the reaction

a) The reaction was carried out under Ar in the presence of $Pd(PPh_3)_4$ (5 mol%). b) The ratio of **4**/**5** was determined by GLC and NMR. c) $Ph_2PCH_2CH_2PPh_2$. d) Yields were not determined.

proceeds, sodium nitrite is liberated, which deactivates the palladium catalyst to generate a new palladium catalyst which catalyzes the sulfonylation of **3** but is inert to the isomerization of **4**.[13] Consequently, when the reaction was carried out in the presence of sodium nitrite (1 equiv), the isomerization could be completely suppressed to give **4** as a sole product. When the reaction was carried out at higher temperature (Run 24) or in a highly concentrated solution (Run 22, 23), it proceeds fast and the selectivity between the sulfonylation and the isomerization becomes low.

Thus, kinetically-controlled products are readily prepared from the reaction of allylic nitro compounds and thermodynamically-controlled products are obtained from the reaction of allylic acetates. It is rather difficult to get the kinetically-controlled products by the palladium-catalyzed sulfonylation of allylic acetates as shown in Table 3. It might be expected that pure **4i** might be obtained if the reaction is carried out at low temperature in the presence of sodium nitrite. However, allylic acetates were less reactive than allylic nitro compounds, and the reaction did not proceed well in the presence of sodium nitrite at low temperature.

All these facts strongly suggest that allylic nitro compounds are more reactive toward the palladium catalyst than allylic acetates or allylic sulfones. To confirm this hypothesis, the competition reaction of **7** (X=NO_2, OAc, tosyl) was carried out. The mixture of the allylic nitro compound and another electrophile was treated with sodium benzenesulfinate in the presence of $Pd(PPh_3)_4$ and the relative reactivity was estimated by measuring the amount of **7** using ^{1}H-NMR. The approximate order of relative reactivity of **7** is summarized in Table 5. Thus, higher reactivity of

Table 5. Relative Reactivity of Allylic Electrophiles (**7**)

X	Rel. Rate
NO_2	1
OAc	0.5
Ts	0.3

allylic nitro compounds than other allylic electrophiles was verified.

$$Me_2C(X)\text{-}CH{=}CH_2 + PhSO_2Na \xrightarrow{Pd(0)} \mathbf{4} + \mathbf{5} \qquad (7)$$

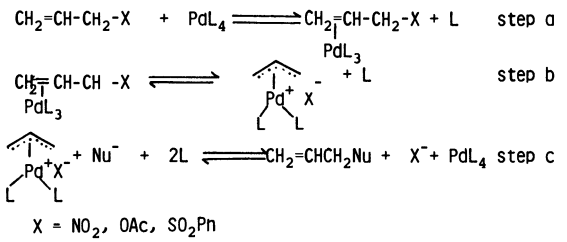
7 (X = NO_2, OAc, Ts)

Another type of competition reaction was carried out; 4-acetoxy-2-methyl-1-nitro-2-butene (**8**) was treated with sodium benzenesulfinate in the presence of $Pd(PPh_3)_4$ in DMF or tetrahydrofuran (THF)–MeOH. The results are summarized in Eq. 8. When the reaction was carried out in THF–MeOH, the acetoxyl group was selectively displaced to give **9** in 52% yield. When the reaction was carried out in DMF, both groups were displaced to give **10**. Namely, the acetoxyl group is more readily displaced than the nitro group in the reaction of Eq. 8.

$$O_2N\text{-}CH_2\text{-}C(Me){=}CHCH_2OAc + PhSO_2Na \xrightarrow{\text{THF-MeOH}} O_2N\text{-}CH_2\text{-}C(Me){=}CH\text{-}CH_2SO_2Ph \quad \mathbf{9} \qquad (8)$$

$$PhSO_2Na \xrightarrow{\text{DMF}} PhSO_2CH_2\text{-}C(Me){=}CH\text{-}CH_2SO_2Ph \quad \mathbf{10}$$

The regiochemistry of the present sulfonylation can be explained by the mechanism shown in Scheme 1, which has been proposed by Tsuji and Trost for the palladium-catalyzed allylic alkylation of allylic acetates or related reactions.[14] Three key-steps are involved there, step a: π-complexation of double bonds with PdLn, step b: elimination of X from this complex to form π-allylpalladium complex, step c: nucleophilic attack to this π-allyl complex.

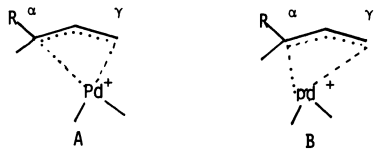


Scheme 1. The Mechanism of Palladium-Catalyzed Allylation

As the nitro group is a stronger electron-accepting group than the acetoxyl and sulfonyl groups, allylic nitro compounds are more reactive than other allylic electrophiles at step a. On the other hand, the acetoxyl group is a better leaving group than other allylic electrophiles at step b. The palladium catalyst may be used preferably for the sulfonylation of allylic nitro compounds rather than for the isomerization of allylic sulfones until the reaction is complete. As the palladium catalyst is deactivated by sodium nitrite when the reaction is complete, the sulfonylation of allylic nitro compounds gives the kinetically-controlled product selectively.

When allylic electrophiles have both the nitro and acetoxyl groups at the allylic positions as compound **8**, the regiochemistry of the leaving group is determined only at step b, and the acetoxyl group is more readily displaced by nucleophiles than the nitro group.

Product distribution is intrinsically controlled by the nature of substituents of an allyl unit. Although the steric effect plays an important role for the control of the regiochemistry of the palladium-catalyzed allylic alkylation,[15] the steric effect is a minor factor in the present sulfonylation as shown in Table 2. The regiochemical results are understood in terms of the electronic effects of the substituents of **3**. The palladium atom in the reaction intermediates may be unsymmetrically bonded to the allylic system depending on the substituents. When R is an electron-donating group, palladium lies close to the γ-carbon (intermediate A), and when R is an electron-withdrawing group, palladium lies close to the α-carbon (intermediate B).[16] The former intermediates causes the external nucleophilic attack to occur at the more weakly bonded α-carbon and the latter do it at the γ-position.[4] Hegedus and his co-workers have proposed that some kinds of palladium-assisted allylic aminations and alkylations may proceed via the σ-allyl complex rather than the cationic π-allyl complex. The regiochemical data of the present sulfonylation can also be explained by assuming that the reaction proceeds via the σ-allyl complex.[17] However, it is very difficult to distinguish these mechanisms at the present stage by the regiochemical data only.



Although the utility of the present method is well demonstrated in Tables 1 and 2, it should be emphasized that allylic nitro compounds can be used both as nucleophiles and electrophiles. Namely, electrophiles (E) and nucleophiles (Nu) can be introduced stepwise as shown in Eq. 9. The regiochemistry of both steps is well-controlled as discussed here. Considering these merits, the present method provides a useful addition to the exisiting methods for the preparation of allylic sulfones.[1]

E = Electrophiles Nu = Nucleophiles

Experimental

Preparation of Allylic Nitro Compounds. Cyclic allylic nitro compounds were prepared by heating a solution of cycloalkanones, nitroalkanes, and amines in benzene at 80 °C according to the literature.[10] Acyclic allylic nitro compounds, **3a**,[18] **3b**, **3e**, and **3g**,[6] were prepared by the Michael addition of the corresponding nitro compounds to phenyl vinyl sulfoxide and the subsequent thermolysis. **3b**: IR (neat) 1340, 1540 cm^{-1}, ^1H NMR ($CDCl_3$) δ=0.92 (3H,m), 1.3 (8H, m), 1.62 (3H, s), 2.0 (2H, m), 5.24 (1H, d, J=17 Hz), 5.28 (1H, d, J=10 Hz), 6.20 (1H, dd, J=17 and 10 Hz). **3e**: IR (neat) 1360, 1540 cm^{-1}, ^1H NMR ($CDCl_3$) δ=2.04 (3H, s), 5.26 (1H, d, J=17 Hz), 5.48 (1H, d, J=10 Hz), 6.60 (1H, dd, J=17 and 10 Hz), 7.4 (5H, m). Other allylic nitro compounds, **3c**,[6] **3d**, and **3f** were prepared by the isomerization of 2-nitro-2-butene. **3d**: IR (neat) 1700, 1530, 1350 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.61 (3H, s), 2.08 (3H, s), 2.12—2.48 (4H, m), 5.12 (1H, d, J= 10 Hz), 5.22 (1H, d, J=17 Hz), 6.12 (1H, dd, J=17 and 10 Hz). All these compounds were prepared in 70—80% yields according to the literatures.[6,18] Compound **3f** was prepared as follows: A solution of 2-nitro-2-butene (3.03 g, 30 mmol), 35%-HCHO (5.14 g, 60 mmol), and triethylamine (0.303 g, 3 mmol) in 20 ml of acetonitrile was kept at room temperature for 24 h. The reaction mixture was poured into water and extracted with diethyl ether. The usual work-up followed by distillation with Kugelrohr gave 2-methyl-2-nitro-3-buten-1-ol, 3.15 g (80%), bp 110 °C/1 mmHg (1 mmHg=133.322 Pa). This alcohol (0.74 g, 5.65 mmol) was dissolved in 10 ml of benzene and to this solution was added acetic anhydride (0.58 g, 5.65 mmol), 3 ml of pyridine and 4-

(dimethylamino)pyridine (70 mg) and the resulting mixture was stirred at room temperature for 15 h. The usual work-up followed by column chromatography (silica gel/benzene-hexane) gave **3f**, 0.86 g (88%). IR (neat) 1730, 1540, 1370 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.72 (3H, s), 2.01 (3H, s), 5.48 (2H, q, J=10 Hz), 5.52 (1H, d, J=10 Hz), 5.54 (1H, d, J=17 Hz), 6.10 (1H, dd, J=10 and 17 Hz). Found: C, 45.74; H, 6.84; N, 10.38. Calcd for $C_5H_9NO_4$ (alcohol): C, 45.79; H, 6.92; N, 10.68.

Preparation of 1-(Phenylsulfonylmethyl)cyclopentene (2a). A mixture of 1-(nitromethyl)cyclopentene (0.381 g, 3 mmol), sodium benzenesulfinate dihydrate (0.60 g, 3 mmol), and $Pd(PPh_3)_4$ (20 mg) in 11 ml of DMF was stirred at 20 °C under Ar for 10 h and then poured into water. The product was extracted with diethyl ether and the organic layer was washed with brine and water, dried with anhydrous magnesium sulfate. After the solvent was evaporated, the residue was subjected to column chromatography (silica gel/hexane-ethyl acetate) to give **2a**, 0.466 g (70%), mp (from benzene-hexane) 95—96 °C. IR ($CHCl_3$) 1313, 1152 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.86 (2H, m), 2.28 (2H, m), 2.37 (2H, m), 3.92 (2H, s), 5.50 (1H, br), 7.50—7.90 (m, 5H). Found: C, 64.70; H, 6.32. Calcd for $C_{12}H_{14}O_2S$: C, 64.84; H, 6.35. Following compounds were prepared by this procedure.

2b: Mp 63—65 °C. IR ($CHCl_3$) 1315, 1155 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.38—1.58 (4H, m), 1.86 (2H, m), 2.00 (2H, m), 3.61 (2H, s), 5.33 (1H, br), 7.44—7.83 (5H, m). Found: C, 65.92; H, 6.84. Calcd for $C_{13}H_{16}O_2S$: C, 66.07; H, 6.82.

2c: IR (neat)1310, 1155 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.44 (3H, d, J=7 Hz), 1.4—2.2 (8H, m), 3.60 (1H, q, J=7 Hz), 5.34 (1H, br), 7.40—7.82 (5H, m). MS, found; M^+, 250.1047. Calcd for $C_{14}H_{18}O_2S$: M^+, 250.1056.

2d: Mp 48—49.5 °C. IR ($CHCl_3$) 1657, 1310, 1155 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.41 (2H, m), 1.53 (2H, m), 1.80 (2H, m), 2.02 (2H, m), 2.25 (2H, m), 3.73 (2H, s), 5.50 (1H, t, J=6.5 Hz), 7.52—7.92 (5H, m). Found: C, 67.12; H, 7.19. Calcd for $C_{14}H_{18}O_2S$: C, 67.17; H, 7.25.

2e: Mp 64—65.5 °C. IR ($CHCl_3$) 1658, 1316, 1151 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.2—1.71 (8H, m), 1.84—2.40 (4H, m), 3.72 (2H, s), 5.42 (1H, t, J=8.2 Hz), 7.40—7.97 (5H, m). Found: C, 68.52; H, 7.60. Calcd for $C_{15}H_{20}O_2S$: C, 68.15; H, 7.62.

Preparation of 3-Phenylsulfonyl-3-methyl-1-butene (4a). A mixture of 3-methyl-3-nitro-1-butene (**3a**, 0.115 g, 1 mmol), sodium benzenesulfinate dihydrate (0.24 g, 1.2 mmol), and $Pd(PPh_3)_4$ (40 mg) in 10 ml of DMF was stirred at 20 °C under Ar for 10 h. The usual work-up followed by column chromatography (silica gel/hexane-ethyl acetate) gave **4a**, 0.157 g (75%). IR (neat) 1300, 1135 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.68 (3H, s), 5.08 (1H, d, J=17 Hz), 5.26 (1H, d, J=10 Hz), 6.01 (1H, dd, J=17 and 10 Hz), 7.42—7.86 (5H, m). The spectra of **5a** was also detected slightly. The ratio of **4a**/**5a** was determined by GLC to be 98/2. Following acyclic allylic sulfones (**4** or **5**) were prepared by this procedure.

4b: IR (neat) 1300, 1150 cm^{-1}, ^1H NMR ($CDCl_3$) δ=0.88 (3H, t, J=7 Hz), 1.32 (3H, s), 1.0—1.4 (8H, m), 1.8—2.04 (2H, m), 5.00 (1H, d, J=16 Hz), 5.31 (1H, d, J=10 Hz), 5.90 (1H, dd, J=16 and 10 Hz), 7.36—7.86 (5H, m). The ratio of **4b**/**5b** was determined by NMR and GLC to be 95/5. Found: C, 68.44; H, 8.64. Calcd for $C_{16}H_{24}O_2S$: C, 68.53; H, 8.63.

4c: Mp 72—75 °C. IR ($CHCl_3$) 1735, 1298, 1147 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.35 (3H, s), 2.22—2.39 (4H, m), 3.66 (3H, s), 5.08 (1H, d, J=17 Hz), 5.38 (1H, d, J=11 Hz), 5.91 (1H, dd, J=17 and 11 Hz), 7.38—7.99 (5H, m). Found: C, 59.90; H, 6.65. Calcd for $C_{14}H_{18}O_4S$: C, 59.55; H, 6.43.

4d: Mp 82—84 °C. IR ($CHCl_3$) 1715, 1302, 1148 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.34 (3H, s), 2.13 (3H, s), 2.20 (2H, m), 2.48 (2H, m), 5.06 (1H, d, J=17 Hz), 5.35 (1H, d, J=11 Hz), 5.91 (1H, dd, J=17 and 11 Hz), 7.95—7.35 (5H, m). Found: C, 62.84; H, 6.73. Calcd for $C_{14}H_{18}O_3S$: C, 63.13; H, 6.81.

4e, 5e: Treatment of **3e** (0.16 g, 0.9 mmol) in the same way as the preparation of **4a** gave the mixture of **4e** and **5e** (the ratio of **4e**/**5e**=53/47), 0.177 g (72%). Mp 117—120 °C. IR ($CHCl_3$) 1310, 1155 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.64 (Me of **5e**, s), 1.82 (Me of **4e**, s), 3.96 (CH_2 of **5e**, d, J=8 Hz), 5.32 (CH=C of **4e**, m), 5.64 (C=CH, of **5e**, t, J=8 Hz), 6.65 (C=CH of **4e**), 7.08—7.84 (10H, m). Found: C, 70.23; H, 5.91. Calcd for $C_{16}H_{16}O_2S$: C, 70.56; H, 5.92.

4f, 5f: Treatment of **3f** (0.173 g, 1 mmol) gave the mixture of **4f** and **5f** (**4f**/**5f**=51/49), 0.254 g (95%). IR (neat) 1740, 1310, 1060 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.36 (s, Me of **5f**), 1.44 (s, Me of **4f**), 1.98 (s, Ac of **4f**), 2.01 (s, Ac of **5f**), 3.90 (m, CH_2 of **5f**), 4.3—4.5 (m, CH_2O- of **4f**, **5f**), 5.22 (1H, d, J=17 Hz), 5.40 (1H, d, J=10 Hz), 5.3—5.5 (CH=C of **5f**), 5.94 (1H, dd, J=17 and 10 Hz). MS, found: M^+ 268.0736. Calcd for $C_{13}H_{16}SO_4$: 268.0767.

5g: Treatment of **3g** (0.173 g, 1 mmol) in the same way as the preparation of **4a** gave **5g**, 0.234 g (87%). No **4g** was detected in GLC and NMR. *E*/*Z* ratio was determined by GLC and NMR to be 97/3. IR (neat) 1730, 1290, 1170 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.28 (3H, t, J=7 Hz), 1.60 (3H, s), 4.01 (2H, d, J=7 Hz), 4.22 (2H, q, J=7 Hz), 6.66 (1H, t, J=8 Hz), 7.44—7.96 (5H, m). MS, found: M^+ 268.0747. Calcd for $C_{13}H_{16}SO_4$: 268.0767.

4h, 5h: A mixture of 2-nitro-2-butene (0.101 g, 1 mmol), sodium benzensulfinate dihydrate (0.4 g, 2 mmol), $Pd(PPh_3)_4$ (58 mg), dppe (20 mg), and triethylamine (0.101 g, 1 mmol) in 4 ml of DMF was stirred at 70 °C under Ar for 2 h. The usual work-up followed by column chromatography (silica gel/benzene-hexane) gave the mixture of **4h** and **5h** (**4h**/**5h**=25/75), 0.117 g (60%). IR (neat) 1305, 1150 cm^{-1}. The GLC analysis showed that the products consists of **5h** consisted of two isomers, (*E*)-**5h** and (*Z*)-**5h**, (*E*/*Z*=75/25). ^1H NMR ($CDCl_3$) δ=1.34 (Me of (*Z*)-**5h**, d, J=7 Hz), 1.42 (Me of **4h**, d, J=7 Hz), 1.65 (Me of (*E*)-**5h**), 3.7—3.9 (CH-SO_2Ph or CH_2SO_2Ph of **4h** or **5h**), 5.06—6.0 (CH=C of **4h** and **5h**), 7.4—7.9 (5H, m). The spectral data of this mixture are in good agreement with those of the literature where this sulfone was prepared by the reaction of crotyl chloride with sodium benzenesulfinate.[1] MS, found: M^+ 196.0546. Calcd for $C_{10}H_{12}O_2S$: 196.0548.

Palladium-Catalyzed Isomerization of 4d to 5d. A mixture of **4d** (0.133 g, 0.5 mmol) and $Pd(PPh_3)_4$ (0.029 g) in 2 ml of DMF was stirred at 25 °C under Ar for 30 h and poured into water. After the usual work-up, the crude product was subjected to column chromatography (silica gel/hexane-ethyl acetate) to give *E*-**5d**, 0.097 g (73%) and *Z*-**5d**, 0.024 g (18%). (*E*)-**5d**: Mp 79—81 °C, IR ($CHCl_3$) 1714, 1311, 1149 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.35 (3H, s), 2.16 (3H, s), 2.27 (2H, t, J=7 Hz), 2.51 (2H, t, J=7 Hz), 3.80 (2H, d, J=8 Hz), 5.19 (1H, t q, J=2 and 8 Hz), 7.52—7.90 (5H, m). Found: C, 63.06; H, 6.83. Calcd for $C_{14}H_{18}O_3S$: C, 63.13; H, 6.81. (*Z*)-**5d**: colorless oil, ^1H NMR ($CDCl_3$) δ=1.25 (3H, s), 2.16 (2H, t, J=8 Hz), 2.18 (3H, s), 2.42 (2H, t, J=8 Hz), 3.90 (2H, d, J=8 Hz), 5.28 (1H, t, J=8 Hz), 7.53—7.95 (5H, m).

Sulfonylation of Linaryl Acetate (6). A mixture of linaryl acetate (0.196 g, 1 mmol), $PhSO_2Na \cdot 2H_2O$ (0.22 g,

1.1 mmol), and $Pd(PPh_3)_4$ (58 mg) in 3 ml of DMF was stirred at 70 °C under Ar for 3 h. The usual work-up followed by column chromatography (silica gel/hexane–ethyl acetate) gave **5i**,[4] 0.211 g (76%). The *E*/*Z* ratio was determined by GLC to be 74/26. IR (neat) 1310, 1150 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.30 (3H, s), 1.58 (3H, s), 1.65 (3H, s), 1.98 (4H, m), 3.82 (2H, d, J=8 Hz), 5.1 (2H, m), 7.5—7.9 (5H, m). The same reaction was carried out in the presence of $NaNO_2$ (0.069 g, 1 mmol) under the same reaction conditions as above. The mixture of **4i** and **5i**, 0.203 g (73%), was obtained. The ratio of **4i**/**5i** was determined by GLC to be 80/20.

Effects of Reaction Conditions on the Ratio 4/5 A mixture of **3** (1 mmol), $PhSO_2Na \cdot 2H_2O$ (1.2 mmol), and $Pd(PPh_3)_4$ (0.059 g) in DMF (2—10 ml) was stirred under various conditions as in Table 4. The product, which was isolated by the procedures described in the preparation of **4a**, was analyzed by GLC and NMR. The yields are in the range of 70—90% in every case. The results are summarized in Table 4.

Effects of Ligands on the Ratio of 4/5. A mixture of **3b** (0.185 g, 1 mmol), $PhSO_2Na \cdot 2H_2O$ (0.24 g, 1.2 mmol), $Pd(PPh_3)_4$ (0.059 g), and dppe (0.035 g) in 5 ml of DMF was stirred at 20 °C for 15 h under Ar. The usual work-up followed by column chromatography gave the mixture of **4b** and **5b**, 0.196 g (70%). The reaction in the presence of Ph_3P (0.090 g) was carried out in the same way. The product was analyzed by GLC and NMR.

Preparation of 4c and 4d by the Reaction of 3c and 3d in the Presence of Sodium Nitrite. A mixture of $Pd(PPh_3)_4$ (0.058 g, 0.05 mmol) and sodium nitrite (0.069 g, 1.0 mmol) in DMF (4 ml) was stirred at 25 °C under Ar for 30 min. To the resulting mixture was added $PhSO_2Na \cdot 2H_2O$ (0.22 g, 1.1 mmol) and **3c** (0.188 g, 1 mmol) and stirred at 25 °C for 21 h and then poured into water. The usual work-up followed by column chromatography (silica gel/hexane–ethyl acetate) gave **4c**, 0.22 g (79%), mp 72—75 °C. The same procedure using **3d** (0.172 g, 1 mmol) gave **4d**, 0.22 g (83%), mp 82—84 °C.

Competition Reaction of Allylic Electrophiles (7). To a mixture of **7** (X=NO_2, 1 mmol) and **7** (X=OAc, 1 mmol) in 5 ml of DMF was added $PhSO_2Na \cdot 2H_2O$ (1 mmol) and $Pd(PPh_3)_4$ (58 mg) and the resulting mixture was stirred at 20 °C. After 3 h and 6 h, a portion of the reaction mixture was poured into water and extracted with diethyl ether and the organic components were analyzed by NMR. The same reaction was carried out by using **7** (X=NO_2) and **7** (X=Ts). The reactivity was estimated by the peak at δ 1.60 (Me, X=NO_2), 2.02 (OAc, X=OAc), and 2.30 (Me, X=Ts). The results are summarized in Table 5.

Sulfonylation of 4-Acetoxy-2-methyl-1-nitro-2-butene (8).[19] A mixture of **8** (0.52 g, 3 mmol), $PhSO_2Na \cdot 2H_2O$ (0.60 g, 3 mmol), and $Pd(PPh_3)_4$ (70 mg) in 10 ml of THF and 2 ml of MeOH was stirred at 20 °C under Ar for 20 h. The usual work-up followed by column chromatography (silica gel/hexane–ethyl acetate) gave **9**, 0.52 g (52%). Mp 50—52 °C. IR ($CHCl_3$) 1550, 1357, 1305, 1150 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.42 (3H, s), 3.92 (2H, d, J=8 Hz), 4.83 (2H, s), 5.64 (1H, br t, J=8 Hz), 7.40—7.88 (5H, m). Found: C, 51.66; H, 4.90; N, 5.36. Calcd for $C_{11}H_{13}NO_4S$: C, 51.75; H, 5.13; N, 5.49. The same reaction was carried out in 12 ml of DMF to give **10**, 0.53 g, (42%). Mp 136—138 °C. IR ($CHCl_3$) 1310, 1150 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.55 (3H, s), 3.82 (4H, d, J=8 Hz), 5.30 (1H, br t, J=8 Hz), 7.44—7.96 (10H, m). Found: C, 58.13; H, 5.10. Calcd for $C_{17}H_{18}O_4S_2$: C, 58.26; H, 5.18.

α-D-Glucosylation by 6-O-Acetyl-2,3,4-tri-O-benzyl-D-glucopyranose Using Trimethylsilyl Triflate and Pyridine. Synthesis of α-Maltosyl and α-Isomaltosyl α-D-Glucosides[1]

(Received July 3, 1985)

The D-glucosylation of methyl 2,3,4-tri-O-benzyl-α-D-glucopyranoside and methyl 2,3,6-tri-O-benzyl-β-D-glucopyranoside by 2,3,4,6-tetra-O-benzyl-α-D-glucopyranose using pyridine and excess trimethylsilyl triflate was carried out in dichloromethane, 1,2-dimethoxyethane, and acetonitrile. In a given solvent, the selectivity of the reaction varied depending on the type of hydroxyl group of the glucosyl acceptors. The D-glucosylation of these acceptors with 6-O-acetyl-2,3,4-tri-O-benzyl-D-glucopyranose employing this reagent system in dichloromethane proceeded with good α-selectivity irrespective of the type of the hydroxyl group. This α-D-glucosylation was applied for the synthesis of O-α-D-glucopyranosyl-(1→4)- and -(1→6)-α-D-glucopyranosyl α-D-glucopyranosides from α,α-trehalose.

Traditional glycosylation is performed with the aid of various heavy-metal compounds.[2] Several methods are, however, free from the use of such materials.[3,4] The desiloxane-promoted condensation between a 1-O-silyl derivative of 2,3,4,6-tetra-O-benzyl-α-D-glucopyranose (**1**) as a D-glucosyl donor and a silylated alcohol as its acceptor is catalyzed by strong acids such as sulfonic acids,[5] as well as a Lewis acid like trimethylsilyl triflate (TMSOTf).[6,7] Since trimethylsilyl triflate[8] is a powerful silylation reagent for a hydroxy compound, a mixture of excess trimethylsilyl triflate and a base such as pyridine (Py) was expected to bring about a condensation between **1** and an alcohol (Eq. 1) in which G denotes a 2,3,4,6-tetra-O-benzyl-D-glucosyl residue or appropriate equivalents.

$$\mathrm{GOH} + \mathrm{ROH} \xrightarrow[-2\mathrm{TfOH}\cdot\mathrm{Py}]{(2+x)\mathrm{TMSOTf}+2\mathrm{Py}} (\mathrm{GOTMS} + \mathrm{ROTMS}) \xrightarrow[-\mathrm{TMS_2O}]{x\mathrm{TMSOTf}} \mathrm{GOR} \qquad (1)$$

The results of the D-glucosylation of the protected glucosides **2** and **3** with **1** (prescribed by Eq. 1) is summarized in Table 1. The value of x, the excess of trimethylsilyl triflate (Eq. 1), was sufficient at 1.5 for the primary alcohol **2** (Entry 1) and at 2 for the secondary alcohol **3** (Entry 4) to react in dichloromethane at 0°C. Glucosylation in this solvent, however, showed poor selectivity. On the other hand, the glucosylation of **3** (Entry 5) in 1,2-dimethoxyethane exhibited a good α-selectivity but the reaction was slow. The reaction of **2** (Entry 2) in 1,2-dimethoxyethane, however, did not show any selectivity. The glucosylation of **2** (Entry 3) in acetonitrile[4] showed only moderate β-selectivity. A similar selectivity, however, was not observed in the reaction of **3** (Entry 6) in acetonitrile. Such a weak solvent-dependency of the selectivity is in contrast to the remarkable dependence of the selectivity observed in a coupling reaction between glucosyl fluoride and silylated alcohol in the presence of trimethylsilyl triflate.[4]

Expectedly,[7] in the absence of an acceptor, **1** underwent self-condensation[5] to give **9** and **10** (Entry 7).

6-O-Acetyl-2,3,4-tri-O-benzyl-D-glucopyranose (**4**), readily derived from 1,6-anhydro-β-D-glucopyranose (levoglucosan), has been used as an α-D-glucosyl donor in dehydrative glucosylation.[9] This compound was again effective for α-D-glucosylation in the glucosylation of **2** and **3** using the above-described reagent mixture (Entries 8 and 9). The α-selectivity (86%) of the glucosylation of the primary alcohol was improved

Table 1. Results of D-Glucosylation by Protected D-Glucoses Using Pyridine and Excess Trimethylsilyl Triflate

Entry	Donor GOH (equiv)	Acceptor ROH (0.1 mmol)	Solv. (0.5 ml)	Py (equiv)	TMSOTf (equiv)	x[a]	Temp °C	Time h	Glucosides GOR %(α/β)

a) x=TMSOTf(equiv)−Py(equiv) (cf. Eq. 1).

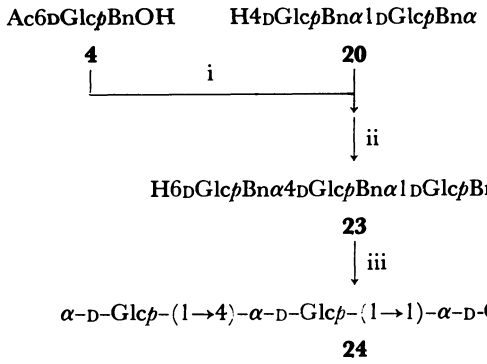

Fig. 1. Synthetic Scheme of α-Maltosyl α-D-Glucoside (**24**); Bn=—CH_2Ph (cf. Ref. 19 for the code-expression of the protected carbohydrates).

compared to the previously reported method (69%).[9]

The α-D-glucosylation described so far was then applied to the synthesis of *O*-α-D-glucopyranosyl-(1→4)- and -(1→6)-α-D-glucopyranosyl α-D-glucopyranosides (**24** and **28**) as illustrated in Fig. 1 for the case of **24**. Various kinds of unsymmetrical α,α-trehaloses have been synthesized in view of biological interests.[10-12] A short-time treatment of a solution of α,α-trehalose (**15**) in dimethyl sulfoxide with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid, followed by acetylation, gave the monoisopropylidene derivative **17** in a 57% yield. This compound was transformed into the hexabenzyl derivative **19**, which was then converted into a heptabenzyl derivative **20** via controlled benzylation. The heptabenzyl derivative **21** was prepared via tritylation of **19**. Glucosylation of **20** and **21** with **4** gave the corresponding α-glucosides **22** and **26** with good selectivity. A deprotection of these compounds afforded the unsymmetrical derivatives, **24** and **28**, of trehalose, and their C-13 were consistent with their proposed structure.

Experimental[13,14]

Compounds **5**,[15] **6**,[16] **7**,[13] **8**,[13] **9**,[5] and **10**[5] were identified with those prepared before.

Procedure for Glucosylation. Pyridine and trimethylsilyl triflate (Aldrich) were successively injected into a stirring mixture of a donor and an acceptor in a solvent at −45°C. The temperature was allowed to increase to the temperature specified in Table 1 and below. The reaction was continued for an appropriate duration. After the addition of triethylamine equimolar to trimethylsilyl trilfate, the mixture was concentrated and chromatographed using toluene–2-butanone system (gradient elution).

Methyl *O*-(6-*O*-Acetyl-2,3,4-tri-*O*-benzyl-α- and -β-D-glucopyranosyl)-(1→6)-2,3,4-tri-*O*-benzyl-α-D-glucopyranosides (11 and 12). Compound **11**, mp 80—82°C, $[\alpha]_D^{20}$ +56° (*c* 2.1, $CHCl_3$), R_f=0.35 (toluene/2-butanone=10/1), δ_C($CDCl_3$, TMS) 97.3 and 98.2 (the anomeric carbons). Compound **12**, $[\alpha]_D^{20}$ +29° (*c* 0.5, $CHCl_3$), R_f=0.33, δ_C($CDCl_3$, TMS) 98.2

and 104.1 (the anomeric carbons).

Found: **11**, C, 72.79, H, 6.64%. **12**, 72.81, H, 6.64%. Calcd for $C_{57}H_{62}O_{12}$: C, 72.90, H, 6.65%.

Methyl O-(6-O-Acetyl-2,3,4-tri-O-benzyl-α- and -β-D-glucopyranosyl)-(1→4)-2,3,6-tri-O-benzyl-β-D-glucopyranoside(13 and 14). Compound **13**, $[\alpha]_D^{20}$ +33° (*c* 1.3, $CHCl_3$), R_f= 0.38 (toluene/2-butanone=10/1), δ_C($CDCl_3$, TMS) 96.8 and 104.9 (the anomeric carbons). Compound **14**, $[\alpha]_D^{20}$ +10° (*c* 0.6, $CHCl_3$), R_f=0.33, δ_C($CDCl_3$, TMS) 102.5 and 104.9 (the anomeric carbons).

Found: **13**, C, 73.17, H, 6.69%. **14**, C, 73.15, H, 6.75%. Calcd for $C_{57}H_{62}O_{12}$: C, 72.90, H, 6.65%.

2,3-Di-O-benzyl-α-D-glucopyranosyl 2,3,4,6-Tetra-O-benzyl-α-D-glucopyranoside (19). A solution of **15** (Tokyo Kasei, 1.0 g, 2.9 mmol), *p*-toluenesulfonic acid monohydrate (100 mg) in dimethyl sulfoxide (19 ml) was treated with 2,2-dimethoxypropane (1.0 ml) at room temperature for 55 min. After the addition of triethylamine (1.5 ml), the mixture was evaporated at 85°C to give a syrup which was then treated with acetic anhydride (12 ml) and pyridine (24 ml) at room temperature. Chromatography using toluene–2-butanone system (gradient) afforded **16** (0.21 g, 12%), **17** (1.06 g, 57%), mp 80—81°C, $[\alpha]_D^{20}$ +141° (*c* 0.6, $CHCl_3$) (lit,[11] mp 79—80°C, $[\alpha]_D$ +150.5° (*c* 1.1, $CHCl_3$)), and **18** (0.61 g, 31%).

The monoisopropylidene derivative **17** (530 mg, 0.84 mmol) was heated in benzyl chloride (10.5 ml) containing potassium hydroxide (2.5 g) at 130°C for 1.0 h. Filtration and evaporation at 95°C gave a yellow oil, which was heated in 80% aq acetic acid (40 ml) at 90°C for 15 min. Evaporation and chromatography using toluene-2-butanone system (gradient) gave **19** (484 mg, 66% from **17**), $[\alpha]_D^{20}$ +92° (*c* 0.6, $CHCl_3$) (lit,[11] [α]+90° (*c* 3.09, $CHCl_3$)).

2,3,6-Tri-O-benzyl-α-D-glucopyranosyl 2,3,4,6-Tetra-O-benzyl-α-D-glucopyranoside (20). A mixture of **19** (484 mg, 0.55 mmol), silver oxide (1.66 g), anhydrous calcium sulfate (1.66 g), and benzyl bromide (0.66 ml) in chloroform (7.2 ml) was stirred at room temperature overnight.[17] Chromatography using hexane–acetone system (gradient) gave **9** (33.7 mg), **20** (387 mg, 73%), $[\alpha]_D^{20}$ +89° (*c* 1.2, $CHCl_3$), δ_C($CDCl_3$, TMS) 94.5 (2C, the anomeric carbons), **21** (72 mg, 14%), $[\alpha]_D^{20}$ +96° (*c* 1.4, $CHCl_3$), δ_C($CDCl_3$, TMS) 94.3 and 94.5 (the anomeric carbons).

Found: **20**, C, 74.42, H, 6.42%. **21**, C, 74.76, H, 6.49%. Calcd for $C_{61}H_{64}O_{11}$: C, 75.29, H, 6.63%.

2,3,4-Tri-O-benzyl-α-D-glucopyranosyl 2,3,4,6-Tetra-O-benzyl-α-D-glucopyranoside (21). A solution of **19** (70.2 mg, 0.080 mmol), and trityl chloride (120 mg) in pyridine (0.7 ml) was kept standing for 3 h at 65°C. After the addition of triethylamine (1 ml) and toluene (1 ml), the mixture was evaporated to dryness. The residue was heated in benzyl chloride (2.8 ml) containing potassium hydroxide (1.0 g) at 130°C for 2 h. After filtration and evaporation, the residue obtained was heated in aq acetic acid (80%, 4 ml) at 95°C for 0.5 h. Chromatography (toluene–2-butanone) gave **21** (60.0 mg, 78%).

O-(6-O-Acetyl-2,3,4-tri-O-benzyl-α-D-glucopyranosyl)(1→4)-2,3,6-tri-O-benzyl-α-D-glucopyranosyl 2,3,4,6-Tetra-O-benzyl-α-D-glucopyranoside (22). D-Glucosylation of **20** (143.2 mg, 0.15 mmol) with **4** (94.2 mg, 0.19 mmol) in the presence of pyridine (33.4 μl) and trimethylsilyl triflate (156.4 μl) in dichloromethane (1.4 ml) was conducted at 5 °C for 6 h. Chromatography (toluene–2-butanone, gradient) gave the impure β-anomer (ca. 20 mg, R_f=0.53 (toluene/2-butanone=10/1), δ_C($CDCl_3$, TMS) 103.2) and **22** (161.0 mg, 76%), $[\alpha]_D^{20}$ +81° (*c* 0.4, $CHCl_3$), R_f=0.49, δ_C($CDCl_3$, TMS) 94.0, 94.6, and 97.3 (the anomeric carbons). Found: C, 75.25, H, 6.57%. Calcd for $C_{90}H_{94}O_{17}$: C, 74.67, H, 6.54%.

O-(6-O-Acetyl-2,3,4-tri-O-benzyl-α-D-glucopyranosyl)-(1→6)-2,3,4-tri-O-benzyl-α-D-glucopyranosyl 2,3,4,6-Tetra-O-benzyl-α-D-glucopyranoside (26). Condensation between **4** (55.6 mg, 0.11 mmol) and **21** (100.0 mg, 0.10 mmol) in the presence of pyridine (21.6 μl) and trimethylsilyl triflate (91.4 μl) in dichloromethane (1.0 ml) at 5°C for 6 h, followed by chromatography (toluene–2-butanone, gradient) gave the impure β-anomer (ca. 10 mg, R_f=0.47 (toluene/2-butanone=10/1), δ_C($CDCl_3$, TMS) 103.2) and **26** (118 mg, 79%), $[\alpha]_D^{20}$ +93° (*c* 0.7, $CHCl_3$), R_f=0.43, δ_C($CDCl_3$, TMS) 94.3 (2C), and 97.4 (the anomeric carbons). Found: C, 75.13, H, 6.51%. Calcd for $C_{90}H_{94}O_{17}$: C, 74.67, H, 6.54%.

O-(2,3,4-Tri-O-benzyl-α-D-glucopyranosyl)-(1→4)-2,3,6-tri-O-benzyl-α-D-glucopyranosyl 2,3,4,6-Tetra-O-benzyl-α-D-glucopyranoside (23). A solution of **22** (50.3 mg, 0.035 mmol) in methanol (2 ml) and acetone (1 ml) was treated with 1.5M (1M=1 mol dm^{-3}) sodium methoxide in methanol (0.3 ml) at room temperature overnight. After neutralization with acetic acid, evaporation and chromatography (toluene–2-butanone) furnished **23** (30.2 mg, 62%), $[\alpha]_D^{20}$ +95° (*c* 1.6, $CHCl_3$), δ_C($CDCl_3$, TMS) 94.1, 94.7, and 97.1 (the anomeric carbons). Found: C, 75.19, H, 6.63%. Calcd for $C_{88}H_{92}O_{16}$: C, 75.19, H, 6.60%.

O-(2,3,4-Tri-O-benzyl-α-D-glucopyranosyl)-(1→6)-2,3,4-tri-O-benzyl-O-D-glucopyranosyl 2,3,4,6-Tetra-O-benzyl-α-D-glucopyranoside (27). Similar deacetylation of **26** (58.2 mg, 0.04 mmol) gave **27** (55 mg, 97%), $[\alpha]_D^{20}$+101° (*c* 1.5, $CHCl_3$), δ_C($CDCl_3$, TMS) 94.4 (2C) and 97.5 (the anomeric carbons). Found: C, 75.01, H, 6.50%. Calcd for $C_{88}H_{92}O_{16}$: C, 75.19, H, 6.60%.

O-α-D-Glucopyranosyl-(1→4)-α-D-glucopyranosyl α-D-Glucopyranoside (24). Hydrogenation of **23** (53.6 mg, 0.038 mmol) over palladized charcoal (10%, 40 mg) in acetic acid (6 ml) under 340 kPa of hydrogen at room temperature overnight, followed by chromatography (chloroform/methanol=1/1), gave **24** (17 mg, 81%), $[\alpha]_D^{20}$+169° (*c* 0.4, H_2O), δ_H(D_2O, TMS(ext.)) 5.61 (2H, d, *J*=3.6 Hz, H-1, H-1′), 5.85 (1H, d, *J*=3.0 Hz, H-1″), δ_C(D_2O, TMS(ext.))[18] 61.7 (3C, C-6, -6′, and -6″), 70.6 (C-4), 70.9 (C-4″), 72.0 (C-2′), 72.1 (C-2″), 72.3 (C-2), 73.0 (C-5), 73.4 (C-5″), 73.8 (C-5′), 73.9 (C-3″), 74.1 (C-3′), 74.3 (C-3), 78.2 (C-4′), 94.5 (C-1″), 94.7 (C-1′), and 101.0 (C-1). Found: C, 42.59, H, 6.19%. Calcd for $C_{18}H_{32}O_{16}$: C, 42.86, H, 6.39%.

Benzoylation of **24** (5.1 mg, 0.01 mmol) with benzoyl chloride (1 ml) and pyridine (2 ml) gave the perbenzoate **26** (13.7 mg, 82%), mp 118—119°C, $[\alpha]_D^{20}$ +202° (*c* 0.8, $CHCl_3$) (Found: C, 69.06, H, 4.64%); lit,[12] mp 121—122°, $[\alpha]_D^{21}$+217° (*c* 0.7, $CHCl_3$).

O-α-D-Glucopyranosyl-(1→6)-α-D-glucopyranosyl α-D-Glucopyranoside (28). Similar hydrogenation of **27** (70.6 mg, 0.05 mmol) gave **28** (15.2 mg, 60%), $[\alpha]_D^{20}$+144° (*c* 0.6, H_2O), δ_H(D_2O, TMS(ext.)) 5.41 (1H, d, *J*=3.6 Hz, H-1″), 5.61 (2H, d, *J*=3.5 Hz, H-1, H-1′), δ_C($CDCl_3$TMS(ext.))[18] 61.7 (2C, C-6 and C-6″), 66.6 (C-6′), 70.8 (C-4), 70.9 (2C, C-4′ and -4″), 71.8 (C-2′), 72.2 (2C, C-2 and -2″), 72.7 (C-5), 73.1 (C-5′), 73.4 (C-5″), 73.8 (C-3″), 74.1 (C-3′), 74.4 (C-3), 94.6 (2C, C-1′ and -1″), and 99.0 (C-1). Found: C, 42.76, H, 6.13%. Calcd for $C_{18}H_{32}O_{16}$: C, 42.86, H, 6.39%.

A Simple and Efficient Synthesis of Optically Active (+)-4-Demethoxydaunomycinone[1)]

Yoshikazu KIMURA, Michiyo SUZUKI, Teruyo MATSUMOTO, Rumiko ABE, and Shiro TERASHIMA*
Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229
(Received July 18, 1985)

Diels-Alder reaction of 2-chloro-1,3-butadiene with anthracene-**1**,4,9,10-tetrone was found to occur exclusively at the external ($C_{2,3}$) double bond, giving the adduct in an excellent yield. The adduct was elaborated to 5,12-dihydroxy-1,2,3,4-tetrahydro-2,6,11-naphthacenetrione. The conventional cyanohydrin formation of this sample followed by acid hydrolysis gave (±)-2,5,12-trihydroxy-6,11-dioxo-1,2,3,4-tetrahydro-2-naphthacenecarboxylic acid. The racemic acid was found to be cleanly resolved by forming a salt with (−)-*N*-methylephedrine, furnishing optically pure (*R*)-carboxylic acid. Successive treatments of the (*R*)-carboxylic acid with *N*,*N*′-carbonyldiimidazole and methylmagnesium bromide in the presence of trimethylsilyl triflate readily produced optically pure (*R*)-(−)-7-deoxy-4-demethoxydaunomycinone, the key synthetic intermediate of (+)-4-demethoxydaunomycinone.

The anthracycline antibiotics, adriamycin (**1a**) and daunorubicin (**1b**), are important antitumor agents with clinical effectiveness against various types of human solid tumors and leukemias.[2,3)] However, their utilization for cancer chemotheraphy is hampered by various undesired side effects, the most notable and serious one of which is dose-related cardiotoxicity. Based on extensive studies on analogues of **1a**, **b**,[2)] 4-demethoxyanthracyclines, 4-demethoxyadriamycin (**1c**) and 4-demethoxydaunorubicin (**1d**) have been developed as unnatural anthracyclines which could show more improved therapeutic properties than natural **1a**, **b**. Since unnatural **1c**, **d** are obtainable only by chemical synthesis, numerous synthetic efforts have been devoted to 4-demethoxyanthracyclinones (**2c**, **d**), the aglycones of 4-demethoxyanthracyclines.[4)]

In connection with our continuing synthetic studies on optically active **2c**,**d**,[1,5–10)] we have hitherto developed various preparation methods of optically active (*R*)-(−)-7-deoxy-4-demethoxydaunomycinone ((*R*)-(−)-**14**) by featuring asymmetric synthesis[5,6,10,11)] or optical resolution.[1,7,8,9,12)] The optically active α-hydroxy ketone ((*R*)-(−)-**14**) is anticipated to place a central position in the synthesis of optically active **2c**, **d**,[4a,b)] since introduction of the C_7-hydroxyl group (anthracycline numbering) into (*R*)-(−)-**14** can be achieved in a highly stereoselective manner[8)] and optically active **2d** can be readily converted to optically active **2c** by sequential bromination and substitution.[6,8)] However, considering various impracticalities including uses of expensive reagents and/or chiral sources,[5,6,8)] reactions at low or high temperatures,[6)] and also substantial loss of optical integrities observed in the synthesis of (*R*)-(−)-**14**,[6,7)] the previously explored synthetic methods[1,4–10)] seem not to be adequate for a large scale preparation of (*R*)-(−)-**14**.

We have now developed another synthetic scheme for optically pure (*R*)-(−)-**14**, starting from cheap and readily available 1,4-dihydroxyanthracene-9,10-dione (quinizalin) (**3**).

This report deals with the exploration of this novel synthetic route which is considered to be more practical and efficient than the previously reported methods[1,5–10)]

	X	Y
a:	OMe	OH
b:	OMe	H
c:	H	OH
d:	H	H

Commercially available **3** was oxidized with lead tetraacetate to give anthracene-1,4,9,10-tetrone (**4**) in 58% yield according to the reported method.[13)] The Diels-Alder reaction of **4** with 2-chloro-1,3-butadiene (chloroprene) as an enophile regiospecifically occurred at the external $C_{2,3}$-double bond, giving a 79% of 2-chloro-1,4,4a,12a-tetrahydronaphthacene-5,6,11,12-tetrone (**5a**). TLC and NMR analyses of the crude product clearly disclosed complete absence of the undesired Diels-Alder adduct which might result from the attack of chloroprene on the internal $C_{4a,9a}$-double bond of **4**. While 2-acetoxy-1,3-butadiene which had been employed as an excellent enophile in the synthesis of natural anthracyclinones (**2a**, **b**)[14)] afforded a 58% yield of the desired adduct in the Diels-Alder reaction with **4**, this diene could only be prepared in less than 10% yield according to the reported method by our hands.[15)] 2-Acetoxy-1,3-butadiene could be also prepared from methyl vinyl ketone in 38% yield by simultaneous metallation with lithium diisopropylamide and acylation with acetic anhydride. However, it is obvious that this synthetic method is not applicable to a large scale preparation of 2-acetoxy-1,3-butadiene. Therefore, chloroprene seems to be one of the best enophile for the construction of desired tetracyclic ring system such as **5a** because of its superior regioselectivity and ready availability.[16)] Since **5a** was found to be fairly unstable, it was immediately aromatized with anhyd sodium acetate in acetic acid to afford the

dihydroxyanthraquinone **6a** in 91% yield. Hydrolysis of the vinylic chloride functionality was readily accomplished with concd sulfuric acid, giving rise to 5,12-dihydroxy-1,2,3,4-tetrahydronaphthacene-2,6,11-trione (**7**)[16b,17] in 98% yield.

According to the conventional method, **7** was smoothly converted to (±)-2,5,12-trihydroxy-6,11-dioxo-1,2,3,4-tetrahydro-2-naphthacenecarboxylic acid ((±)-**9**). Thus, treatment of **7** with potassium cyanide and hydrochloric acid in acetic acid yielded the unstable cyanohydrin **8**, which without isolation was subjected to acid hydrolysis to afford (±)-**9** in 83% yield.

With a large quantity of (±)-**9** in hand, the optical resolution of (±)-**9** was first attempted. After several unsuccessful attempts, (−)-*N*-methylephedrine was found to be the best optically active amine, being neccessary for the salt formation with (±)-**9**. Treatment of (±)-**9** with (−)-*N*-methylephedrine (1.2 equiv) in ethanol gave the crude salt of (*R*)-**9** in 51% (102%)[19] yield. Two recrystallizations of the crude salt from ethanol containing a small amount of (−)-*N*-methylephedrine (0.2 equiv to the amount of the salt)[20] afforded the pure salt of (*R*)-**9** in 31% (62%)[19] yield which showed the constant melting point and optical rotation, mp 217.5—220 °C, $[\alpha]_D^{20}$ −12.0° ($CHCl_3$). The optically pure acid ((*R*)-**9**) was readily regenerated in a quantitative yield by stirring a suspension of the pure salt in aqueous hydrochloric acid. Unfortunately, the optical rotation of (*R*)-**9** could not be measured because of its extremely low solubility to almost all solvents.

While the absolute configuration and optical purity of optically active **9** could be determined by the successful synthesis of (*R*)-(−)-**14** (vide infra), the independent determination of these physical indices was examined at this stage by transforming optically active **9** into its derivatives. Thus, esterification of optically active **9** in a mixture of methanol and dimethyl sulfoxide[21] using a catalytic amount of concd sulfuric acid gave the corresponding (−)-methyl ester ((−)-**10**) in 91% yield, $[\alpha]_D^{20}$ −55.0° ($CHCl_3$), after purification by column chromatography. Further methylation of the phenolic hydroxyl groups of (−)-**10** with potassium carbonate and dimethyl sulfate in acetone, followed by purification by column chromatography, produced the (+)-dimethoxy ester ((+)-**11**) in 90% yield, $[\alpha]_D^{20}$ +11.7° ($CHCl_3$).[22] Measurement of the NMR spectrum of (+)-**11** in the presence of chiral shift reagent clearly disclosed that optically active **9** produced by the resolution was optically pure (100% ee). In order to determine the absolute configuration, (+)-**11** was further hydrolyzed under alkaline conditions to give the (+)-dimethoxy acid ((+)-**12**)[5,23] in 82% yield, $[\alpha]_D^{20}$ +16.9° ($CHCl_3$). Since (+)-**12** showing $[\alpha]_D^{20}$ +14.0° ($CHCl_3$) had been reported to belong to (*R*)-series,[5] optically active **9** was definitely established to belong to (*R*)-configuration.

Since determination of the absolute configuration and optical purity of optically active **9** was completed as mentioned above, our next attention was focused on the elaboration of (*R*)-**9** to (*R*)-(−)-**14**. At the outset, the synthesis of (*R*)-(−)-**14** from (*R*)-**9** seemed to be simply accomplished by employing one of the reported methods which could afford a methyl ketone from the corresponding acid. However, this was found to be quite refractory. After several unsuccessful attempts employing (±)-**9** as a substrate,[24] the reaction of the (±)-*N*-acylimidazole ((±)-**13**) in situ produced from (±)-**9**[25] with methylmagnesium bromide was turned out to be promising. Thus, the reaction of (±)-**9** with *N,N'*-carbonyldiimidazole (2.0 equiv) in tetrahydrofuran containing hexamethylphosphoric triamide furnished (±)-**13**. Without isolation, (±)-**13** was immediately treated with trimethylsilyl trifluoromethanesulfonate (trimethylsilyl triflate) (1 equiv) at −20 °C, then with methylmagnesium bromide at −40 °C, giving (±)-**14** in 65% yield. By applying the developed sequential reactions to (*R*)-**9**, optically pure (*R*)-(−)-**14**, $[\alpha]_D^{20}$ −90.3° ($CHCl_3$) was obtained in 58% overall yield from (*R*)-**9** by way of (*R*)-**13**.

In order to clearly elucidate several notable aspects of the explored one pot synthesis of (*R*)-(−)-**14** from (*R*)-**9**, some preliminary results obtained by using (*R*)- and (±)-**9** are summarized in Table 1. Absence of hexamethylphosphoric triamide and/or trimethylsilyl

Table 1. Preparation of (*R*)-(−)- or (±)-**14** from (*R*)- or (±)-**9** by Way of (*R*)- or (±)-**13**

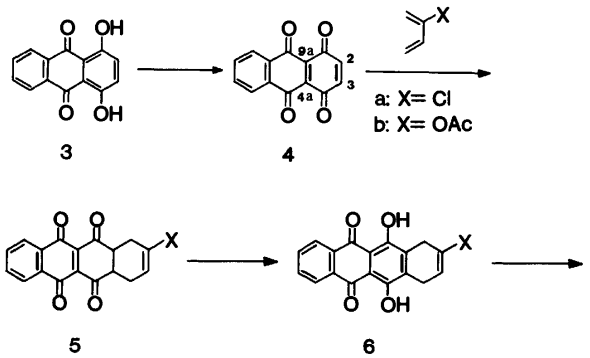
Run	**9**	Solvent[a]	Additive[b]	Reaction[c] Temp/°C	Yield of (*R*)-(−)-[d] or (±)-**14**/%
1	(*R*)-	THF-HMPA[e]	TMSOTf	−40	58
2	(*R*)-	THF	TMSOTf	−40	44
3	(*R*)-	THF	—	−20	23[f]
4	(±)-	THF-HMPA[e]	TMSOTf	−40	65
5	(±)-	THF-HMPA[e]	BF_3·OEt_2	−20	51
6	(±)-	THF-HMPA[e]	—	−20	40[f]
7	(±)-	THF	—	−20	25[f]

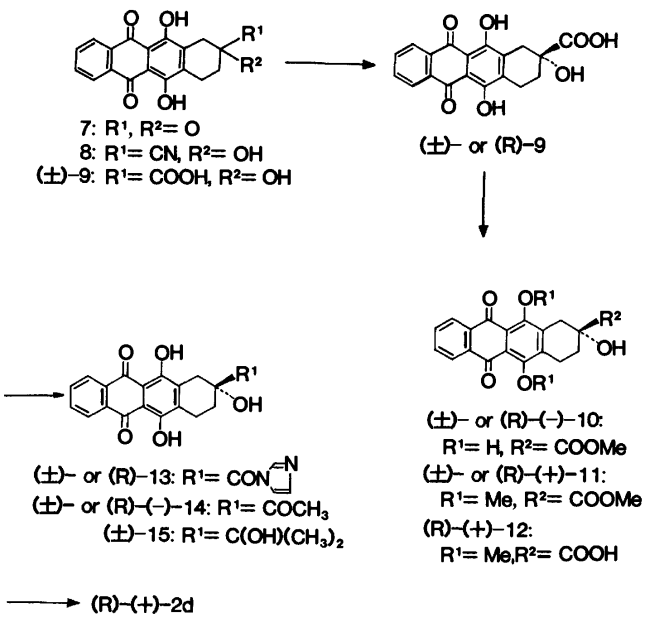
a) Tetrahydrofuran (THF), hexamethylphosphoric triamide (HMPA). b) Trimethylsilyl triflate (TMSOTf), boron trifluoride etherate (BF_3·OEt_2). c) Reaction temperature in the reaction with methylmagnesium bromide. The *N*-acylimidazole ((*R*)- or (±)-**13**) was prepared at room temperature. d) Based on (*R*)- or (±)-**9**. e) The volume ratio of THF to HMPA was 50:1. f) NMR analysis showed that this sample was contaminated with the (*R*)-(−)- or (±)-methyl ester of (*R*)-(−)- or (±)-**9** ((*R*)-(−)- or (±)-**10**) ((*R*)-(−)- or (±)-**9**/(*R*)-(−)- or (±)-**10**=9/1—4/1) (see text).

triflate in the reaction medium significantly decreased the yield of (*R*)-(−)- or (±)-**14** (see runs 1—3).
Addition of the Grignard reagent to (*R*)- or (±)-**13** began to occur at −20 °C in the absence of trimethylsilyl triflate, affording a low yield of (*R*)-(−)- or (±)-**14** (see runs 1, 3 and 4, 6). In this case, the reaction product ((*R*)-(−)- or (±)-**14**) was accompanied by a significant amount of the methyl ester ((*R*)-(−)- or (±)-**10**) ((*R*)-(−)- or (±)-**14**/(*R*)-(−)- or (±)-**10**=9/1—4/1). While the formation mechanism of (*R*)-(−)- or (±)-**10** from (*R*)- or (±)-**9** is quite obscure, the amount of (*R*)-(−)- or (±)-**10** seems to be proportional to the temperature at which the Grignard reagent was added to a solution of (*R*)- or (±)-**13**. In the reaction carried out at −40 °C, no formation of undesired (*R*)-(−)- or (±)-**10** was definitely ascertained by NMR analysis of the crude reaction product. When methylmagnesium iodide was employed as a Grignard reagent in place of methylmagnesium bromide, the tertiary alcohol ((±)-**15**) was formed in 74% yield. It is noteworthy that a negligible amount of (*R*)- or (±)-**15**, usually less than 3% yield, was produced even though a large excess of methylmagnesium bromide was employed as a Grignard reagent. This may be explained by the assumption that the magnesium salt produced by the reaction of methylmagnesium iodide is more unstable than that formed by employing methylmagnesium bromide and liberates (*R*)-(−)- or (±)-**14** in the reaction medium.

By accumulating these results described above, we have finally succeeded in preparing (*R*)-(−)- or (±)-**14** directly from (*R*)- or (±)-**9** in ca. 60% yield. Numerous synthetic approaches to anthracyclinones hitherto reported, terminate at or proceed through 1,2,3,4-tetrahydro-2,6,11-naphthacenetrione derivatives.[4,14,16b,17,26] Therefore, the explored process is anticipated to hold promise for adding the racemic or optically active C_9-α-hydroxy ketone moiety to those tetracyclic systems.

As mentioned in the introduction part, the methods for converting (*R*)-(−)-**14** to optically pure **2d**, then to optically pure **2c**, have been firmly established by us.[6,8] Accordingly, the developed overall scheme to (*R*)-(−)-**14** which can be characterized by its operational simplicity and directness is expected to facilitate a large scale preparation of optically pure **2c**, **d** more readily than the previously reported method.[4-10]





Scheme 1.

Experimental

General. All melting points were determined with a Yamato MP-21 melting point apparatus and were uncorrected. IR spectral measurements were carried out with a JASCO A-202 diffraction grating infrared spectrometer. NMR spectra were recorded with a Varian EM-390 spectrometer (90 MHz) and a Varian XL-100A spectrometer (100 MHz). All signals were expressed as ppm downfield from TMS, used as an internal standard (δ-value). Mass s_ectra were taken with a Hitachi RMU-6MG mass spectrometer. Measurements of optical rotation were performed with a Union PM-201 automatic digital polarimeter and Horiba SEPA-200 automatic digital polarimeter. Wakogel C-200 and Kieselgel 60 (Merck) were used as an adsorbent for column chromatography. All reactions were carried out using anhydrous solvents. Especially tetrahydrofuran, ether, and dioxane freshly distilled from sodium benzophenone ketyl, and dichloromethane, acetone, and pyridine freshly distilled from calcium hydride were used. Lead tetraacetate purchased from Wako Pure Chemical Industries, Ltd., was used for a reaction without further purification. Following abbreviations are used for solvents and reagents: acetic acid (AcOH), benzene (C_6H_6), chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), dimethyl sulfoxide (DMSO), ether (Et_2O), ethyl acetate (EtOAc), ethanol (EtOH), hexamethylphosphoric triamide (HMPA), hexane (C_6H_{14}), methanol (MeOH), tetrahydrofuran (THF).

Anthracene-1,4,9,10-tetrone (Quinizalin Quinone) (4). A mixture of **3** (31.9 g, 0.133 mol) and lead tetraacetate (purity 90%) (98.4 g, 0.200 mol) in AcOH (80 mL) are stirred in a mortal for 30 min. The brown precipitate was collected by filtration, washed with AcOH and H_2O, and dried over P_2O_5 in vacuo to give crude **4** (26.6 g, 84%). This was added to nitrobenzene (400 mL), and the mixture was stirred for 2 h at 70 °C, then filtered through a pad of celite. The filtrate was concentrated in vacuo below 70 °C until crystals appeared. After cooling to room temperature, the crystals were collected by filtration, washed with Et_2O, then dried in

vacuo to afford pure **4** (18.2 g, 58%), mp 210—212°C (decomp) (lit,[13] mp 208—210°C (decomp)). IR (KBr): 1700, 1685, 1645, 1595 cm^{-1}. ^1H NMR ($CDCl_3$) δ=6.87 (s, 2H, C<u>H</u>=C<u>H</u>), 7.70—8.15 (m, 4H, Ar).

2-Chloro-1,4,4a,12a-tetrahydronaphthacene-5,6,11,12-tetrone (5). Chloroprene (9.80 g, 0.111 mol) was added to a suspension of **4** (mp 210—212°C) (16.2 g, 0.068 mol) in a mixture of C_6H_6 and xylene (5 : 1) (170 mL). After reflux for 3 h, additional amount of chloroprene (3.53 g, 0.040 mol) was added to the mixture, then the whole suspension was heated at reflux for 1 h. After cooling, the crystals were collected by filtration, washed with Et_2O, then dried over P_2O_5 in vacuo, to give pure **5** (17.6 g, 79%), mp 232—234°C (decomp). A part of this sample was recrystallized from xylene to give an analytical sample of **5**, mp 232—234°C (decomp). IR (KBr): 1710, 1665, 1595 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.34—2.83 (m, 4H, 1-H_2+4-H_2), 3.39—3.81 (m, 2H, 4a-H+12a-H), 5.88 (m, 1H, C<u>H</u>=CCl), 7.76—8.22 (m, 4H, Ar). Found: C, 66,23; H, 3.34; Cl, 10.61%. Calcd for $C_{18}H_{11}O_4Cl$: C, 66.17; H, 3.39; Cl, 10.85%.

2-Chloro-5,12-dihydroxy-1,4-dihydro-6,11-naphthacenedione (6). The powdered tetrone (**5**) (mp 232—234°C (decomp)) (19.6 g, 60.0 mmol) was added to a mixture of anhyd sodium acetate (100 mg, 1.22 mmol) in AcOH (200 mL) over 15 min. After reflux for 30 min, the red crystals were collected by filtration, washed successively with H_2O, MeOH, and Et_2O, then dried over P_2O_5 in vacuo, to afford pure **6** (17.9 g, 91%), mp 285.5—286.5°C. A part of this sample was recrystallized from toluene to give an analytical sample of **6**, mp 285.5—286.5°C. IR (KBr): 1625, 1590 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.44—3.82 (m, 4H, 1-H_2+4-H_2), 6.00—6.13 (m, 1H, C<u>H</u>=CCl), 7.77—8.50 (m, 4H, Ar), 13.41 (s, 1H, ArO<u>H</u>), 13.42 (s, 1H, ArO<u>H</u>). Found: C, 65.95; H, 3.38; Cl 10.86%. Calcd for $C_{18}H_{11}O_4Cl$: C, 66.17; H, 3.39; Cl, 10.85%.

5,12-Dihydroxy-1,2,3,4-tetrahydro-2,6,11-naphthacenetrione (7). The vinylic chloride (**6**) (mp 285.5—286.5°C) (17.4 g, 53.3 mmol) was gradually added to a stirred concd H_2SO_4 (170 mL). The reaction mixture was stirred for 1 h under an exclusion of moisture ($CaCl_2$ tube), then poured onto ice-H_2O (3 L). The aqueous mixture was kept standing at room temperature for 3 d. Red powderlike crystals were collected by centrifugation and suspended in AcOH (250 mL). The acidic suspension was heated at reflux for 2 h with stirring. After cooling, the red powderlike crystals were collected by filtration, washed with MeOH, and dried over P_2O_5 in vacuo, to give **7** (16.1 g, 98%), mp > 250°C (decomp). A part of this sample was recrystallized from AcOH to give an analytical sample of **7**, mp > 250°C (decomp) (lit,[16b] mp 313—315°C, lit,[17a] mp>310°C (decomp), lit,[17b] mp> 300°C, lit,[17c] mp 296—298°C (decomp)). IR (KBr): 1730, 1620, 1585 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.68 (t, J=7 Hz, 2H, 3-H_2), 3.30 (t, J=7 Hz, 2H, 4-H_2), 3.70 (s, 2H, 1-H_2), 7.78—8.02 (m, 2H, Ar), 8.30—8.52 (m, 2H, Ar), 13.40 (s, 1H, ArO<u>H</u>), 13.50 (s, 1H, ArO<u>H</u>). Found: C, 69.92; H, 4.01%. Calcd for $C_{18}H_{12}O_5$: C, 70.13; H, 3.92%.

(±)-2-Cyano-2,5,12-trihydroxy-1,2,3,4-tetrahydro-6,11-naphthacenedione (8). Potassium cyanide (15.8 g, 24.3 mmol) was added to a suspension of **7** (mp > 250°C) (5.00 g, 16.2 mmol) in a mixture of EtOH (130 mL) and THF (170 mL) at 0°C with stirring. After stirring for 20 min, AcOH (20 mL) was added dropwise to the reaction mixture at 0°C. The whole mixture was stirred for 30 min at 0°C, then overnight at room temperature. The mixture was poured onto 3% HCl (1 L). The red powder was collected by filtration, washed with H_2O, and dried over P_2O_5 in vacuo, to afford crude **8** (4.50 g, 83%). IR (KBr): 3400, 2240, 1630, 1595, 1417, 1377, 1253, 1105, 1077, 1008, 797, 739 cm^{-1}. ^1H NMR ($(CD_3)_2CO$) δ=2.34 (t, J=6.5 Hz, 2H, 3-H_2), 3.06 (m, 2H, 4-H_2), 3.18 (d, J=18.4 Hz, 1H, one of 1-H), 3.45 (d, J=18.4 Hz, 1H, one of 1-H), 5.93 (brs, 1H, OH), 8.05 (m, 2H, Ar), 8.38 (m, 2H, Ar), 13.42 (s, 1H, ArO<u>H</u>), 13.47 (s, 1H, ArO<u>H</u>).

(±)-2,5,12-Trihydroxy-6,11-dioxo-1,2,3,4-tetrahydro-2-naphthacenecarboxylic Acid ((±)-9). A mixture of **8** (3.66 g, 10.9 mmol) AcOH (37 mL), and concd HCl (9 mL) was refluxed for 4.5 h. Additional amount of concd HCl (9 mL) was added to the mixture, and the whole mixture was heated at reflux for 5.5 h. After cooling, the red powder was collected by filtration, washed with H_2O, then dried over P_2O_5 in vacuo, to afford crude (±)-**9** (3.63 g, 94%). This was recrystallized from nitrobenzene to give pure (±)-**9**, mp 251—252°C (lit,[25] 253—258°C). IR (KBr): 3400, 3250, 1730, 1625, 1590 cm^{-1}. ^1H NMR ($(CD_3)_2SO$) δ=1.80—2.20 (m, 2H, 3-H_2), 2.57—3.00 (m, 4H, 1-H_2+4-H_2), 7.80—8.35 (m, 4H, Ar), 13.29 (s, 1H, ArO<u>H</u>), 13.31 (s, 1H, ArO<u>H</u>). Found: C, 64.03; H, 3.98%. Calcd for $C_{19}H_{14}O_7$: C, 64.41; H, 3.98%.

(*R*)-2,5,12-Trihydroxy-6,11-dioxo-1,2,3,4-tetrahydro-2-naphthacenecarboxylic Acid ((*R*)-9). Optical Resolution of (±)-9: A mixture of (±)-**9** (mp 251—252°C) (10.0 g, 28.2 mmol) and (−)-*N*-methylephedrine[17] (mp 85—86°C, $[\alpha]_D^{20}$ −30.2° (*c* 4.48, MeOH)) (6.07 g, 33.9 mmol) in EtOH (2 L) was heated at reflux for 2 h. After the hot solution was filtered, the filtrate was concentrated to a half volume and kept standing overnight at room temperature. The red crystals were collected by filtration to afford the crude salt of (*R*)-**9** (7.72 g, 51% (102%)[19]), mp 200—204°C, $[\alpha]_D^{20}$ −64.0° (*c* 0.10, $CHCl_3$). The salt was twice recrystallized from EtOH containing (−)-*N*-methylephedrine of 0.2 equiv to the total amount of the salt,[20] affording the pure *N*-methylephedrine salt of (*R*)-**9** as a red powder (4.71 g, 31% (62%)[19]), mp 217.5—220°C, $[\alpha]_D^{20}$ −12.0° (*c* 0.05, $CHCl_3$). IR (KBr): 3420, 1625, 1595 cm^{-1}. Found: C, 67.50; H, 5.60; N, 2.35%. Calcd for $C_{30}H_{31}NO_8$: C, 67.53; H, 5.86; N, 2.63%. The pure *N*-methylephedrine salt of (*R*)-**9** (1.17 g, 2.19 mmol) was added to stirred 3.6% HCl (350 mL), and the mixture was stirred at room temperature for 17 h. The red powder was collected by filtration, washed with dil HCl and H_2O, and dried over KOH at 100°C in vacuo, to give optically pure (*R*)-**9** (0.776 g, 100%), mp > 280°C. IR (KBr): 3450, 1730, 1625, 1590 cm^{-1}. MS *m/z*: 354 (M^+), 336, 291.

(±)-Methyl 2,5,12-Trihydroxy-6,11-dioxo-1,2,3,4-tetrahydronaphthacene-2-carboxylate ((±)-10). A mixture of (±)-**9** (mp 251—252°C) (506 mg, 1.43 mmol) and concd H_2SO_4 (7 drops) in MeOH (50 mL) and DMSO (10 mL) was heated at reflux for 4 h with stirring. After cooling, the reaction mixture was poured onto satd $NaHCO_3$ and extracted with EtOAc. The combined ethyl acetate extracts were washed with H_2O and satd NaCl, then dried over $MgSO_4$. Filtration and concentration in vacuo gave crude (±)-**10** as a red solid (524 mg, 100%), mp 198.5—199.5°C. This was recrystallized from toluene to afford pure (±)-**10**, mp 211.5—213.5°C. IR (KBr): 3470, 1743, 1620, 1590 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.95—2.20 (m, 2H, 3-H_2), 2.80—3.20 (m, 4H, 1-H_2+4-H_2), 3.09 (brs, 1H, OH), 3.84 (s, 3H, CH_3), 7.70—7.90 (m, 2H, Ar), 8.20—8.40 (m, 2H, Ar), 13.43 (s, 2H, ArO<u>H</u> ×2). MS *m/z*: 368 (M^+). Found: C, 65.23; H, 4.39%. Calcd for $C_{20}H_{16}O_7$: C, 65.22; H, 4.38%.

(*R*)-(−)-Methyl 2,5,12-Trihydroxy-6,11-dioxo-1,2,3,4-tetra-

hydronaphthacene-2-carboxylate ((*R*)-(−)-10). Treatments of (*R*)-**9** (mp > 280°C) (350 mg, 0.99 mmol) in the same manner as described for (±)-**10** gave crude (*R*)-(−)-**10** (345 mg, 95%) after concentration of the ethyl acetate extracts. This was purified by silica-gel column chromatography (C_6H_6/EtOAc=5/1—3/1) to afford pure (*R*)-(−)-**10** (293 mg, 81%) as red crystals, mp 206.5—210°C, $[\alpha]_D^{20}$ −55.0° (*c* 0.10, $CHCl_3$). A part of this sample was recrystallized from toluene to give an analytical sample of (*R*)-(−)-**10**, mp 210.5—211.5°C, $[\alpha]_D^{20}$ −60.0° (*c* 0.10, $CHCl_3$). IR (KBr): 3470, 1734, 1620, 1590 cm^{-1}. NMR spectrum of this sample was identical with that of (±)-**10**. Found: C, 65.21; H, 4.20%. Calcd for $C_{20}H_{16}O_7$ C, 65.22; H, 4.38%.

(±)-Methyl 2-Hydroxy-5,12-dimethoxy-6,11-dioxo-1,2,3,4-tetrahydronaphthacene-2-carboxylate ((±)-11). Anhyd potassium carbonate (150 mg, 1.09 mmol) and dimethyl sulfate (137 mg, 1.09 mmol) were added to a suspension of (±)-**10** (mp 198.5—199.5°C) (100 mg, 0.27 mmol) in Me_2CO (12 mL). After reflux for 5.5 h, the reaction mixture was filtered and the filtrate was concentrated in vacuo. The residue was dissolved in EtOAc, and the ethyl acetate solution was washed successively with satd $NaHCO_3$, H_2O, and satd NaCl, then dried over $MgSO_4$. Filtration and concentration in vacuo gave crude (±)-**11** (97.6 mg, 91%), which was purified by silica-gel column chromatography (Et_2O) to afford pure (±)-**11** as a yellow solid (78.6 mg, 73%), mp 152 and 186°C. A part of this sample was triturated with Et_2O to give an analytical sample of (±)-**11**, mp 152 and 186°C. IR (KBr): 3540, 1728, 1675 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.90—2.20 (m, 2H, 3-H_2), 2.90—3.20 (m, 4H, 1-H_2+4-H_2), 3.16 (brs, 1H, OH), 3.84 (s, 3H, CO_2Me), 3.86 (s, 3H, OMe), 3.91 (s, 3H, OMe), 7.63—7.82 (m, 2H, Ar), 8.05—8.30 (m, 2H, Ar). MS *m/z*: 396 (M^+). Found: C, 66.56; H, 5.07%. Calcd for $C_{22}H_{20}O_7$: C, 66.66; H, 5.09%.

(*R*)-(−)-Methyl 2-Hydroxy-5,12-dimethoxy-6,11-dioxo-1,2,3,4-tetrahydronaphthacene-2-carboxylate ((*R*)-(+)-11). Treatments of (*R*)-(−)-**10** (mp 206.5—210°C, $[\alpha]_D^{20}$ −55.0° (*c* 0.10, $CHCl_3$)) (50.0 mg, 0.14 mmol) in the same manner as described for (±)-**11** gave (*R*)-(+)-**11** as a yellow solid (48.5 mg, 90%) after purification by silica-gel chromatography, mp 152—154°C, $[\alpha]_D^{20}$ +11.7° (*c* 0.22, $CHCl_3$)[22] (lit,[5] mp 154—155°C). IR (KBr): 3540, 1728, 1675 cm^{-1}. ^1H NMR spectrum of this sample was identical with that of (±)-**11**. NMR spectrum of (*R*)-(+)-**11** measured in the presence of chiral shift reagent tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium(III) (Eu(hfc)$_3$) exhibited the methyl ester as a singlet at δ=6.07. Since NMR spectrum of (±)-**11** measured under the same conditions as described for (*R*)-(+)-**11** showed two singlets at δ=5.82 and 6.07, the optical purity of optically active **9** produced by the optical resolution was established to be 100% ee.

(*R*)-(+)-2-Hydroxy-5,12-dimethoxy-6,11-dioxo-1,2,3,4-tetrahydro-2-naphthacenecarboxylic Acid ((*R*)-(+)-12). Three percent potassium hydroxide (0.50 mL, 0.27 mmol) was added to a mixture of (*R*)-(+)-**11** (mp 152—154°C, $[\alpha]_D^{20}$ +11.7° (*c* 0.22, $CHCl_3$)) (70 mg, 0.18 mmol) in THF (1.4 mL) and MeOH (2.0 mL), and the mixture was stirred at room temperature for 3 h. After concentration in vacuo, the residue was diluted with satd NaCl, and the aqueous solution was washed with EtOAc. The aqueous layer was acidified (pH=2) with concd HCl, saturated with NaCl, then extracted with EtOAc. The combined organic extracts were washed with satd NaCl, dried over $MgSO_4$, and concentrated in vacuo, affording crude (*R*)-(+)-**12** (55.2 mg, 82%) as a yellow solid. Recrystallization of this sample from C_6H_{14}–EtOAc gave pure (*R*)-(+)-**12**, mp 202—207°C, $[\alpha]_D^{20}$+16.9° (*c* 0.20, $CHCl_3$) (lit,[5] mp 200—201°C, $[\alpha]_D^{20}$+13.6° (*c* 0.430, $CHCl_3$); lit,[23] mp 200—205°C, $[\alpha]_D^{20}$+14.0° (*c* 0.20, $CHCl_3$)). IR (KBr): 3440, 1715, 1675 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.92—2.29 (m, 2H, 3-H_2), 2.93—3.37 (m, 4H, 1-H_2+4-H_2), 3.91 (s, 3H, OMe), 3.94 (s, 3H, OMe), 5.76 (brs, 2H, O<u>H</u>+COO<u>H</u>), 7.60—7.84 (m, 2H, Ar), 8.00—8.30 (m, 2H, Ar). MS *m/z*: 382 (M^+), 319. Found: C, 65.32; H, 4.74%. Calcd for $C_{21}H_{18}O_7$–0.25H_2O: C, 65.20; H, 4.82%.

(±)-7-Deoxy-4-demethoxydaunomycinone ((±)-14). A mixture of (±)-**9** (mp 251—252°C) (52.7 mg, 0.15 mmol) and *N,N'*-carbonyldiimidazole (48.6 mg, 0.30 mmol) in THF (10 mL) containing HMPA (0.2 mL) was stirred at room temperature for 18 h to give a solution of (±)-**13**. Trimethylsilyl triflate (0.03 mL, 0.16 mmol) was added to the solution of (±)-**13** cooled at −20°C, and stirring was continued at −20°C for 15 min. After cooling at −40°C, an ethereal solution of methylmagnesium bromide (3 M[1] solution, 0.50 mL, 1.5 mmol) was added to the stirred reaction mixture. After stirring was continued at the same temperature for 2 h, additional amount of the ethereal solution of methylmagnesium bromide (3 M solution, 0.2 mL, total 0.7 mL, 2.1 mmol) was added to the reaction mixture. After being stirred at −40°C for 1 h, the reaction mixture was poured onto a vigorously stirred mixture of 1 M HCl (50 mL) and EtOAc (50 mL) to quench the reaction. The upper organic phase was separated, washed with satd NaCl, then dried over $MgSO_4$. Filtration and concentration in vacuo gave a red residue, which was purified by filtration through a short silica-gel column (C_6H_6/EtOAc=9/1) to give (±)-**14** as a red solid (34.0 mg, 65%), mp 194—198°C. Recrystallization of this sample from C_6H_6 gave a pure sample of (±)-**14** as a red minute crystals (29.3 mg, 56%), mp 213—215°C (lit,[6] mp 214—216°C). IR and NMR spectra of this sample were identical with those reported.[6]

(*R*)-(−)-7-Deoxy-4-demethoxydaunomycinone ((*R*)-(−)-14). Treatments of (*R*)-**9** (mp > 280°C) (50.5 mg, 0.14 mmol) in the same manner as described for (±)-**14** gave (*R*)-(−)-**14** as a red solid (29.1 mg, 58%), after extractive isolation with EtOAc and purification by filtration through a short silica-gel column, mp 195—203°C, $[\alpha]_D^{20}$ −85.7° (*c* 0.105, $CHCl_3$). This sample was recrystallized from C_6H_6 to afford pure (*R*)-(−)-**14** as a red minute crystals (23.3 mg, 46%), mp 214—216°C, $[\alpha]_D^{20}$ −90.6° (*c* 0.106, $CHCl_3$) (lit,[8] mp 218—219°C, $[\alpha]_D^{20}$−90.3° (*c* 0.106, $CHCl_3$)). IR and NMR spectra of this sample were superimposable on those of the authentic sample.[8]

(±)-2-Hydroxy-2-(1-hydroxy-1-methylethyl)-1,2,3,4-tetrahydro-6,11-naphthacenedione ((±)-15). A mixture of (±)-**9** (mp 251—252°C) (201 mg, 0.568 mmol) and *N,N'*-carbonyldiimidazole (185 mg, 1.14 mmol) in THF (40 mL) containing HMPA (0.8 mL) was stirred at room temperature for 18.5 h, to give a solution of (±)-**13**. Trimethylsilyl triflate (0.12 mL, 0.621 mmol) was added to the solution of (±)-**13** cooled at −40°C, and stirring was continued at −40°C for 20 min. An ethereal solution of methylmagnesium iodide (3 M solution, 1.9 mL, 5.70 mmol) was added to the reaction mixture at the same temperature. After stirring for 2 h, additional amount of the ethereal solution of methylmagnesium iodide (3M solution, 1.9 mL, 5.70 mmol) was added to the reaction mixture at −40°C. A reaction temper-

[1] 1 M = 1 mol dm^{-3}.

ature was gradually raised up to −20 °C, then the whole mixture was stirred at −20 °C for 5 h. Extractive isolation followed by purification by silica-gel column chromatography (C_6H_6/EtOAc=5/1) in the same manner as described for (±)-**14** afforded pure (±)-**15** (155 mg, 74%), mp 234.5—237.5 °C. IR (KBr): 3525, 1620, 1588 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.36 (s, 3H, CH_3), 1.42 (s, 3H, CH_3), 1.5—3.1 (m, 8H), 7.55—7.85 (m, 2H, Ar), 8.05—8.33 (m, 2H, Ar), 13.32 (s, 1H, ArOH), 13.36 (s, 1H, ArOH). MS *m/z*: 368 (M^+), 310.

The authors are grateful to Showa Neoprene K.K. for generous supply of 2-chloro-1,3-butadiene.

19) This yield was calculated based on (*R*)-**9** originally contained in (±)-**9**.

20) Existence of a small amount of (−)-*N*-methylephedrine (ca. 0.2 equiv to the total amount of the salt of (*R*)-**9**) was indispensable for improving purity of the salt of (*R*)-**9** by repeated recrystallizations.

21) When the esterification was carried out in the absence of dimethyl sulfoxide, only 64% yield of (−)-**10** was obtained under the similar reaction conditions. This might be due to extremely low solubility of optically active **9** in methanol.

22) This sample showed the following optical rotations in solvents other than chloroform: $[\alpha]_D^{20}$ 0.0° (*c* 0.22, Me_2CO), $[\alpha]_D^{20}$ −5.2° (*c* 0.23, MeOH), $[\alpha]_D^{20}$ −13.1° (*c* 0.25, EtOH), and $[\alpha]_D^{20}$ −23.5° (*c* 0.22, C_6H_6). Although $[\alpha]_D^{20}$ −7.8° (*c* 0.613, Me_2CO) was previously reported for this compound,[5] this rotation value should be corrected.

23) N. Ohashi, M. Muramatsu, N. Tanno, and K. Ishizumi, Japan Kokai Tokkyo Koho, JP 58-77844.

24) Before developing the efficient one-pot preparation method of (*R*)-(−)-**14** reported here, the following multi-step syntheses were found to produce (±)-**14** from (±)-**9** in rather low overall yields. Thus, esterification of (±)-**9** (concd H_2SO_4 in methanol and dimethyl sulfoxide) followed by protection of the C_9-hydroxyl group (dihydropyran-pyridinium *p*-toluenesulfonate in tetrahydrofuran or trimethylsilyl triflate-triethylamine in tetrahydrofuran) and reaction with sodium methylsulfinyl methanide in tetrahydrofuran, gave the corresponding C_9-*O*-protected methylsulfinyl ketone in ca. 60% overall yields. Successive reductive cleavage of the methylsulfinyl ketones (aluminum-amalgam in tetrahydrofuran or Raney-Ni in ethanol) and deprotection of the C_9-*O*-protective groups (pyridinium *p*-toluenesulfonate in ethanol, 50% acetic acid in ethyl acetate or 10% hydrochloric acid in tetrahydrofuran, etc.) gave (±)-**14** in 18—25% yields. On the other hand, (±)-**9** was converted to the corresponding thiol ester in 67% yield by treating with ethanethiol, magnesium ethoxide, and *N*,*N*′-carbonyldiimidazole in tetrahydrofuran. Reaction of thiol ester with lithium dimethylcuprate(I) in tetrahydrofuran at −40°C gave (±)-**14** in 23% yield.

Novel Glycosidation of 4-Demethoxyanthracyclinones by the Use of Trimethylsilyl Triflate. Syntheses of Optically Active 4-Demethoxydaunorubicin and 4-Demethoxyadriamycin[1)]

Yoshikazu KIMURA, Michiyo SUZUKI, Teruyo MATSUMOTO, Rumiko ABE, and Shiro TERASHIMA*
Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229
(Received July 18, 1985)

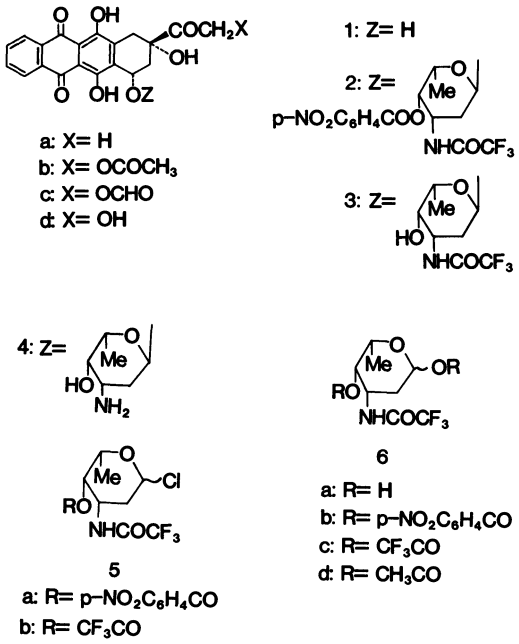
Optically pure (+)-4-demethoxydaunorubicin has been prepared by a novel glycosidation reaction of (+)-4-demethoxydaunomycinone with (−)-3-*N*-trifluoroacetyl-1,4-bis(*O*-*p*-nitrobenzoyl)-L-daunosamine in the presence of trimethylsilyl triflate, followed by sequential *O*- and *N*-deprotection reactions. Total synthesis of optically pure (+)-4-demethoxyadriamycin has been also accomplished by two different synthetic schemes, starting from (+)-4-demethoxydaunorubicin or by way of (+)-3′-*N*-trifluoroacetyl-4-demethoxyadriamycin. (+)-4-Demethoxyadriamycin prepared by our hands was fully characterized by its spectral properties.

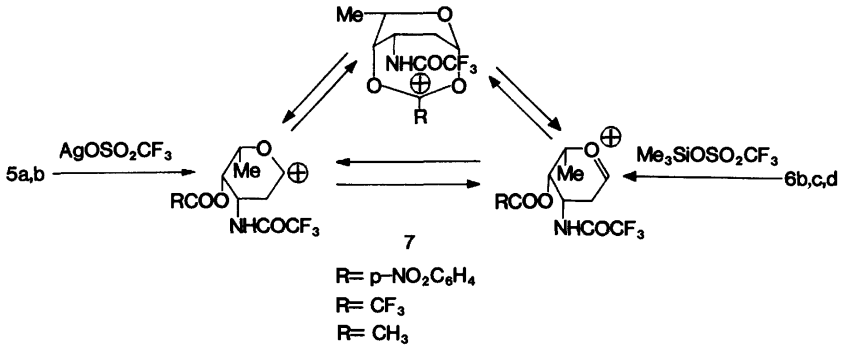
In the preceding paper,[2)] we have succeeded in exploring the simple and efficient synthetic scheme of optically pure (+)-4-demethoxydaunomycinone ((+)-**1a**). With a large quantity of (+)-**1a** in hand, our next efforts were focused on the elaboration of (+)-**1a** to unnatural 4-demethoxyanthracyclines, (+)-4-demethoxyadriamycin ((+)-**4d**–HCl) and (+)-4-demethoxydaunorubicin ((+)-**4a**–HCl). However, while an efficient glycosidation process is indispensable to the synthesis of unnatural anthracyclines such as (+)-**4a**, **d**–HCl, only a limited number of methods has been explored for glycosidation reaction in anthracycline area.

The reported methods of glycoside formation generally consist of the reactions of anthracyclinones, 1) with 1-halo-amino sugar derivatives in the presence of mercury(II) salt (Koenigs-Knorr reactions)[3)] or silver triflates,[4)] 2) with glycals derived from amino sugar derivatives in the presence of *p*-toluenesulfonic acid,[5)] 3) with 1-*O*-acyl amino sugar derivatives in the presence of tin(IV) chloride,[6a)] or *p*-toluenesulfonic acid.[6b,c)] However, these reactions seem not to be applicable to a large scale preparation of anthracyclines due to rather low yields,[3–6)] uses of unstable 1-halo amino sugar derivatives[3,4)] and toxic[3)] or expensive reagents,[4)] and lack of stereoselectivity resulting in the formation of α- and β-anomers.[3,5,6)]

We have recently explored the novel glycosidation method in which 4-demethoxyanthracyclinones are allowed to react with 1-*O*-acyl-L-daunosamine derivatives in the presence of trimethylsilyl trifluoromethanesulfonate (trimethylsilyl triflate) (TMSOTf).[1a)] This novel method has been found to produce the α-glycosides as sole reaction products which can be elaborated to optically pure (+)-**4a**–HCl and (+)-**4d**–HCl. In this full account, we wish to report the detailed procedure of the explored glycosidation reaction and the efficient synthetic schemes to (+)-**4a**–HCl and (+)-**4d**–HCl.

Development of the Novel Glycosidation Reaction and Its Application to the Synthesis of (+)-4-Demethoxydaunorubicin ((+)-4a–HCl). In order to obtain an authentic sample of (+)-3′-*N*-trifluoroacetyl-4-demethoxydaunorubicin ((+)-**3a**), and moreover, to evaluate the reported glycosidation method which could afford the desired α-glycoside most efficiently,[4b,c)] the reactions of (+)-**1a** with 1-chloro-L-daunosamine derivatives (**5a**, **b**) in the presence of silver trifluoromethanesulfonate (triflate) were examined by our hands. Treatment of optically pure (+)-**1a**[2)] with 3-*N*-trifluoroacetyl-4-*O*-*p*-nitrobenzoyl-L-daunosamyl chloride (**5a**)[3a,4b)] or 3-*N*:4-*O*-bis(trifluoroacetyl)-L-daunosamyl chloride (**5b**)[3b–d,4a)] in the presence of silver triflate, followed by 4′-*O*-deprotection under mild alkaline conditions or methanolysis, was found to give (+)-3′-*N*-trifluoroacetyl-4-demethoxydaunorubicin ((+)-**3a**) in 49 or 56% yield with 47 or 43% recovery of starting (+)-**1a**, respectively. These yields are very close to those reported.[4b,c)] With an aim to improve the yield of (+)-**3a** with decrease of the recovery of (+)-**1a**, uses of further equivalents of **5a**, **b** and/or silver triflate and additions of organic or inorganic bases to the glycosidation medium were examined.[7)] However, these attempts turned out to be ineffective for obtaining





better yields of (+)-**3a** than those described above.

After accumulating numerous unsuccessful results, a combination of (−)-3-*N*-trifluoroacetyl-1,4-bis(*O*-*p*-nitrobenzoyl)-L-daunosamine ((−)-**6b**) and TMSOTf was found to be quite promising for the glycosidation of (+)-**1a** to afford an almost quantitative yield of the desired α-glycoside, (−)-3′-*N*-trifluoroacetyl-4′-*O*-*p*-nitrobenzoyl-4-demethoxydaunorubicin ((−)-**2a**). Thus, TMSOTf (2.0—2.5 equiv) was added to a suspension of (−)-**6b**[3a] (1.2—1.3 equiv) and granulated molecular sieves 4A[8] in a mixture of dichloromethane and ether (1:1—3:1) at −40 °C, and the whole mixture was stirred at 0—5 °C to give a clear solution. Then, a dichloromethane solution of (+)-**1a**[2] (1 equiv) was added dropwise to the clear solution cooled at −15 °C. The glycosidation reaction proceeded smoothly at −15 °C to produce (−)-**2a** as a sole reaction product. After completion of the reaction, usual extractive isolation followed by filtration through a short silica-gel column gave pure (−)-**2a**[4b] in 99.5% yield, mp 171—173 °C, $[\alpha]_D^{20}$ −89.7° (dioxane). No formation of the undesired β-glycoside was definitely ascertained by the NMR spectra which exhibited the C_1'-proton as a singlet at 5.70 ppm (W_H=6.0 Hz). The α-glycoside ((−)-**2a**) was successfully elaborated to (+)-**4a**–HCl according to the reported method.[4b] Thus, mild hydrolysis with 0.1 M[†] sodium hydroxide in a mixture of methanol and dichloromethane selectively effected 4′-*O*-deprotection, resulting in the formation of (+)-**3a**[4b] in 83% yield, mp 151—153 °C, $[\alpha]_D^{20}$ +190° (dioxane). Further treatment of (+)-**3a** with 0.1 M sodium hydroxide followed by salt formation with hydrogen chloride afforded (+)-**4a**–HCl[3b,4a,b] in 77% yield, mp 184—187 °C (decomp), $[\alpha]_D^{20}$ +188° (methanol). These physical data were almost identical with those reported.[3b,4a,b] The glycoside (+)-**4a**–HCl also showed the same spectral properties as those reported.[4b]

Next, in order to examine the scope and limitation of the explored glycosidation reaction, uses of trialkylsilyl triflate and L-daunosamine derivatives other than those employed above were attempted. Triethylsilyl triflate could be similarly used as an activating reagent of (−)-**6b**, giving (−)-**2a** in 95% yield. However, the reaction of (+)-**1a** with (−)-**6b** in the presence of *t*-butyldimethylsilyl triflate afforded (−)-**2a** in only 7% yield. When (−)-3-*N*-trifluoroacetyl-1,4-bis(*O*-trifluoroacetyl)-L-daunosamine ((−)-**6c**)[3b] or *N*-trifluoroacetyl-1,4-di-*O*-acetyl-L-daunosamine (**6d**) were subjected to the glycosidation under the same conditions as those described above and the formed unstable 4′-*O*-acyl-α-glycosides were immediately hydrolyzed under mild alkaline conditions, (+)-**3a** could be obtained in 61 or 70% overall yield, respectively.

Precise reaction mechanism of the novel glycosidation is presently obscure. As mentioned above, we have already observed that the glycosidation of (+)-**1a** with **5a**, **b** in the presence of silver triflate, followed by 4′-*O*-deprotection, exclusively produced (+)-**3a** in moderate yields with recovery of (+)-**1a**. This glycosidation reaction has been explained to proceed through the cationic species **7**. Since formation of the same cationic species **7** can be reasonably expected for the explored glycosidation, the observed higher yields of (+)-**3a** might be explained by the assumption that the reactivity of **7** derived from **6b**—**d** and TMSOTf is amplified more than that derived from **5a**, **b** and silver triflate. Exclusive formation of the desired α-glycoside ((−)-**2a**) may be due to a combination of the usual steric and anomeric effects.

The developed glycosidation reaction has the following novel characteristics: 1) Almost quantitative yield of the α-glycoside ((−)-**2a**) can be obtained by using (−)-**6b** as a daunosamine derivative. 2) 1,4-Di-*O*-acyl-L-daunosamine derivatives (**6b**—**d**) show larger stability under an air and are more feasible than **5a**, **b**, and (−)-**6b** is the best amino sugar component in the light of the exclusive formation of the desired α-glycoside ((−)-**2a**). 3) TMSOTf is commercially available[9] and is more inexpensive than silver triflate. 4) Presence of ether in the reaction medium is necessary for obtaining a good yield of the glycoside. When the glycosidation is carried out by omitting ether from a reaction solvent, the yield of (−)-**2a** dramatically decreases to 20%. This might be explained by the assumption that ether can effectively stabilize a cationic species such as **7** by chelation with the lone pair of oxygen atom.[10] 5) A role of molecular sieves 4A is quite obscure, but in the absence of molecular sieves 4A, the glycosidation affords only 27% of (−)-**2a**.[11]

[†] 1 M=1 mol dm^{-3}.

As detailed above, we have succeeded in exploring the highly efficient glycosidation reaction of (+)-**1a**. Taking into account various novel aspects, the developed glycosidation reaction might be considered to be one of the best preparation methods of anthracyclines among those hitherto reported.[3-6]

Synthesis of (+)-4-Demethoxyadriamycin ((+)-4d-HCl). The natural adriamycin is well known to display more favorable therapeutic profiles than daunorubicin[13,14] against various types of human cancers. Similar more improved anticancer activities can be foreseen for unnatural **4d**-HCl than for (+)-**4a**-HCl. Therefore, synthesis of optically pure **4d**-HCl was examined by two different synthetic schemes.

One synthetic route is the elaboration of (+)-**4a**-HCl to optically pure **4d**-HCl according to the same synthetic scheme as that reported by Arcamone et al.[4a,15] By subjecting (+)-**4a**-HCl to the reported synthetic operations such as successive acetalization and bromination with triethoxymethane[16] and bromine in a mixture of methanol, dioxane, and dichloromethane, deacetalization with 0.25 M hydrobromic acid, substitution with sodium formate, hydrolysis with 5% sodium hydrogencarbonate, and salt formation with hydrogen chloride, we obtained the compound showing mp 186—189 °C (decomp) and $[\alpha]_D^{20}$ +185° (methanol) in 30% overall yield. Although the melting point of this sample was almost identical with that reported for **4d**-HCl (mp 186—189 °C (decomp)),[15] the spectral profiles (IR, NMR, MS) were found to be inconsistent with the expected structure. Especially the NMR spectrum showed a singlet at 8.40 ppm which could be assigned as a formyl group, and the molecular weight could be determined as 541 based on its MS spectrum. These spectral properties clearly suggested that this sample was not the right compound (**4d**-HCl) but (+)-14-formyloxy-4-demethoxydaunorubicin hydrochloride ((+)-**4c**-HCl). The reason why (+)-**4c**-HCl was obtained instead of the expected **4d**-HCl should be insufficient hydrolysis of the formate with 5% sodium hydrogencarbonate. As expected, further hydrolysis of (+)-**4c**-HCl with 0.1 M sodium hydroxide followed by salt formation with hydrogen chloride, readily produced desired (+)-**4d**-HCl, mp 225—228 °C (decomp) and $[\alpha]_D^{20}$ +187° (methanol). Full spectral (IR, NMR, MS) properties of this sample strongly supported the structure of (+)-**4d**-HCl.

Taking into account the result obtained above, the improved procedure for preparing (+)-**4d**-HCl from (+)-**4a**-HCl was deviced by minor modifications of the original synthetic scheme.[4a,15] Thus, successive acetalization and bromination of (+)-**4a**-HCl with trimethoxymethane and bromine in a mixture of methanol and dioxane followed by removal of the acetal by transacetalization with acetone,[16,17] substitution of the α-bromo ketone with sodium formate, hydrolysis of the formate with 0.1 M sodium hydroxide in methanol, and salt formation with hydrogen chloride, gave (+)-**4d**-HCl in 49% overall yield.[19]

In order to confirm the structure of (+)-**4d**-HCl, another synthesis of (+)-**4d**-HCl was next attempted. According to the reported method,[20] (+)-14-acetoxy-4-demethoxydaunomycinone ((+)-**1b**), mp 187—188.5 °C, $[\alpha]_D^{20}$ +181° (dioxane), was prepared from (+)-**1a** in 70% overall yield by sequential bromination of (+)-**1a** with pyridinium tribromide and substitution of the bromide with potassium acetate. Glycosidation of (+)-**1b** with (−)-**6b** in the presence of TMSOTf by the same manner as that described for (−)-**2a** readily gave the desired (−)-α-glycoside ((−)-**2b**) as a sole product in 99% yield, mp 167—170 °C, $[\alpha]_D^{20}$ −53.5° (dioxane). No formation of the undesired β-glycoside was also ascertained by the NMR analysis of the reaction product. However, simultaneous hydrolysis of the 4′- and 14-ester functions with 10% potassium carbonate (pH≈10) afforded only crude (+)-3′-*N*-trifluoroacetyl-4-demethoxyadriamycin ((+)-**3d**) in 39% yield.

Since (+)-**3d** seems to be unstable under the basic conditions (pH≈10) which is required to hydrolyze the acetoxyl group, a formyl group that can be more easily removed than an acetyl group was selected as a protective group of the 14-hydroxymethyl function. Bromination of (+)-**1a** with pyridinium tribromide, followed by substitution of the bromide with tetrabutylammonium formate,[21] gave (+)-14-formyloxy-4-demethoxydaunomycinone ((+)-**1c**) in 78% overall yield, mp 183—185 °C, $[\alpha]_D^{20}$+153° (dioxane). Glycosidation of (+)-**1c** with (−)-**6b** in the presence of TMSOTf similarly produced the corresponding α-glycoside (**2c**) as a sole product.[22] Immediate hydrolysis of **2c** with 0.1 M sodium hydroxide in methanol (pH≈8) effected the removal of the 14-*O*-formyl and 4′-*O*-*p*-nitrobenzoyl groups, giving (+)-**3d** in 73% overall yield, mp 143—148 °C, $[\alpha]_D^{20}$ +170° (dioxane).

After simultaneous protection of the C_9- and C_{14}-hydroxylic functions of (+)-**3d** by treating with trimethoxymethane,[23] the formed protected glycoside was directly treated with 0.1 M sodium hydroxide to remove C_3′-*N*-trifluoroacetyl group, then with 0.25 M hydrochloric acid to cleave the protective group(s) derived from trimethoxymethane, affording (+)-**4d**-HCl in 40% overall yield from (+)-**3d**, mp 226—229 °C (decomp), $[\alpha]_D^{20}$+190° (methanol). Spectral (IR, NMR, MS) behavior of this sample were completely identical with that of (+)-**4d**-HCl prepared from (+)-**4a**-HCl.

Based on exploration of the novel glycosidation reaction and various modifications of the reported reactions, we have succeeded in the total syntheses of (+)-**4a**-HCl and (+)-**4d**-HCl starting from (+)-**1a**. Taking into account numerous novel aspects delineated in this report, the developed overall processes seem to hold promise not only for 4-demethoxyanthracyclines but also for the whole family of natural and unnatural anthracyclines.

Experimental

General. All melting points were determined with a Yamato MP-21 melting point apparatus and a Yanaco micro melting point apparatus and were uncorrected. IR spectral measurements were carried out with a JASCO A-202 diffraction grating infrared spectrometer. NMR spectra were measured with a Varian EM-390 spectrometer (90 MHz) and a Varian XL-100A spectrometer (100 MHz). All signals were expressed as ppm downfield from TMS used as an internal standard (δ-value). Mass spectra were taken with a Hitachi RMU-6MG mass spectrometer and a Hitachi M-80A mass spectrometer (SIMS). Measurements of optical rotations were performed with a Union PM-201 automatic digital polarimeter and a Horiba SEPA-200 automatic digital polarimeter. Wakogel C-200 and Kieselgel 60 (Merck) were used as an adsorbent for column chromatography. All reactions were performed using anhyd solvents. Especially, tetrahydrofuran, ether, and dioxane freshly distilled from sodium benzophenone ketyl, and dichloromethane, acetone, and pyridine freshly distilled from calcium hydride were used. Trimethylsilyl trifluoromethanesulfonate purchased from Petrarch System Inc. (Chisso) was used without further purification. Triethylsilyl trifluoromethanesulfonate and *t*-butyldimethylsilyl trifluoromethanesulfonate were purchased from Aldrich Chemical Co. and used without further purification. Pyridinium tribromide purchased from Tokyo Kasei Kogyo Co. Ltd. was used after three repeated recrystallizations from acetic acid. The following abbreviations are used for solvents: acetic acid (AcOH), acetone (Me_2CO), benzene (C_6H_6), chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), ethanol (EtOH), ether (Et_2O), ethyl acetate (EtOAc), hexane (C_6H_{14}), methanol (MeOH), tetrahydrofuran (THF).

(−)-3-*N*-Trifluoroacetyl-1,4-bis(*O*-*p*-nitrobenzoyl)-L-daunosamine ((−)-6b). Prepared from (−)-**6a**[24] (mp 146—147 °C, $[\alpha]_D^{20}$ −127.2° (*c* 0.10, MeOH)) (lit,[3a] mp 146—147 °C) in 82% yield according to the reported method,[3a] mp 201—202 °C, $[\alpha]_D^{20}$ −117° (*c* 0.029, Me_2CO) (lit,[3a] mp 202—203 °C, $[\alpha]_D^{21}$ −125° (*c* 0.03, 95% EtOH)). IR and NMR ($(CD_3)_2SO$) spectra were identical with those reported in the literature.[3a] ^{1}H NMR ($CDCl_3$) δ=1.27 (d, *J*=6 Hz, 3H, CH_3), 2.26 (d, *J*=3 Hz, 1H, 2-*ax*-H), 2.34 (d, *J*=3 Hz, 1H, 2-*eq*-H), 4.46 (q, *J*=6 Hz, 1H, 5-H), 4.47—5.02 (m, 1H, 3-H), 5.58 (brs, 1H, 4-H), 6.51 (brd, *J*=8 Hz, 1H, NH), 6.72 (brs, W_H=6 Hz, 1H, 1′-H), 8.24—8.50 (m, 8H, Ar). Since the C_1-anomeric proton appeared as a broad singlet at δ 6.72 (W_H=6 Hz) in the NMR spectrum in $CDCl_3$, it appeared evident that (−)-**6b** solely consisted of the α-anomer.

(−)-3-*N*-Trifluoroacetyl-1,4-bis(*O*-trifluoroacetyl)-L-daunosamine ((−)-6c). Prepared from (−)-**6a**[24] (mp 146—147 °C, $[\alpha]_D^{20}$ −127.2° (*c* 0.10, MeOH)) in 51% yield according to the literature,[3c] mp 133.5—135 °C, $[\alpha]_D^{20}$ −69.5° (*c* 0.12, Me_2CO) (lit,[3c] mp 132—134 °C). IR and NMR spectra of this sample were identical with those reported in the literature.[3c] Based on the NMR spectrum in which the C_1-anomeric proton appeared as a broad singlet at δ 6.53 (W_H=6 Hz), (−)-**6c** was considered to solely consist of the α-anomer.

3-*N*-Trifluoroacetyl-1,4-di-*O*-acetyl-L-daunosamine (6d). Acetic anhydride (1 mL, 10.6 mmol) was added to (−)-**6a**[24] (mp 146—147 °C, $[\alpha]_D^{20}$ −127.2° (*c* 0.10, MeOH)) (105 mg, 0.49 mmol) in pyridine (2 mL) with stirring at room temperature. After the stirring was continued overnight, the reaction was quenched by adding H_2O to the mixture. Usual extractive isolation with $CHCl_3$ followed by purification by silica-gel chromatography (EtOAc/C_6H_6=1/4), furnished **6d** as a white caramel (126.6 mg, 87%). ^{1}H NMR ($CDCl_3$) δ= 1.15 (d, *J*=6 Hz, 1.5H, CH_3), 1.22 (d, *J*=6 Hz, 1.5H, CH_3), 1.60—2.05 (m, 2H, 2-H_2), 2.12 (s, 3H, $COCH_3$), 2.20 (s, 3H, $COCH_3$), 3.66—4.00 (m, 1H, 5-H), 4.05—4.35 (m, 1H, 3-H), 5.00—5.20 (m, 1H, 4-H), 5.80 (dd, *J*=9 and 3 Hz, 0.5 H, 1-*ax*-H), 6.28 (brs, W_H=6 Hz, 0.5H, 1-*eq*-H), 6.40—6.80 (brs, 1H, NH). Based on this NMR spectrum, it appeared evident that **5d** was a mixture of the α- and β-anomers (α/β=1). This sample was immediately used without separation of these two anomers.

3-*N*-Trifluoroacetyl-4-*O*-*p*-nitrobenzoyl-L-daunosamyl Chloride (5a). Prepared by treating (−)-**6b** (mp 201—202 °C, $[\alpha]_D^{20}$ −117° (*c* 0.029, Me_2CO)) with hydrogen chloride in Et_2O according to the literature.[4b] ^{1}H NMR ($CDCl_3$) δ= 1.20 (d, *J*=6 Hz, 3H, CH_3), 2.10—2.48 (m, 2H, 2-H_2), 4.48 (q, *J*=6 Hz, 1H, 5-H), 4.64—5.03 (m, 1H, 3-H), 5.33—5.53 (m, 1H, 4-H), 6.20—6.56 (m, 2H, 1-H+NH), 8.24 (s, 4H, Ar). This sample was directly used without further purification.

3-*N*:4-*O*-Bis(trifluoroacetyl)-L-daunosamyl Chloride (5b). Prepared by treating (−)-**6c** (mp 133.5—135 °C, $[\alpha]_D^{20}$ −69.5° (*c* 0.12, Me_2CO)) with hydrogen chloride in Et_2O according to the reported method.[3c] NMR spectrum of this sample was identical with that reported.[3c]

(+)-3′-*N*-Trifluoroacetyl-4-demethoxydaunorubicin ((+)-3a). a) **Glycosidation of (+)-1a with (−)-6b by the Use of TMSOTf:** TMSOTf (0.12 mL, 0.62 mmol) was added to a stirred suspension of (−)-**6b** (mp 201—202 °C, $[\alpha]_D^{20}$ −117° (*c* 0.029, Me_2CO)) (159 mg, 0.29 mmol) and molecular sieves 4A (0.8 g) in a mixture of CH_2Cl_2 (12 mL) and Et_2O (10 mL) at −40 °C under an argon atmosphere. The whole mixture was stirred at 0 °C for 1 h to give a clear solution, which was cooled at −15 °C. A solution of (+)-**1a**[2] (mp 184—185 °C, $[\alpha]_D^{20}$ +154° (*c* 0.10, dioxane)) (85 mg, 0.23 mmol) in CH_2Cl_2 (25 mL) was added to the stirred reaction mixture cooled at −15 °C. After stirring at −15 °C for 5 h, the whole mixture was poured onto a two-layer mixture of satd $NaHCO_3$ (150 mL) and EtOAc (80 mL) with vigorous stirring to quench the glycosidation reaction. Progress of the glycosidation could be readily monitored by TLC analysis (SiO_2: EtOAc/C_6H_6=1/4). The organic layer was separated, washed with satd NaCl (50 mL×2), then dried over $MgSO_4$. Filtration and concentration in vacuo gave a residue, which was filtered through a short silica-gel column (EtOAc/C_6H_6=1/4) to give (−)-**2a** as an orange solid (170 mg, 99.5%). The purified sample was triturated with C_6H_{14} containing a small amount of $CHCl_3$, giving pure (−)-**2a** as an orange solid (157 mg, 92%), mp 171—173 °C, $[\alpha]_D^{20}$−89.7° (*c* 0.078, dioxane) (lit,[4b] mp 171—175 °C, $[\alpha]_D^{20}$ −89.8° (*c* 0.1, dioxane)). ^{1}H NMR ($CDCl_3$) δ=1.25 (d, *J*=6 Hz, 3H, 6′-Me), 1.98—2.38 (m, 4H, 2′-H_2+8-H_2), 2.45 (s, 3H, $COCH_3$), 3.00 (d, *J*=19 Hz, 1H, 10-*ax*-H), 3.36 (d, *J*=19 Hz, 1H, 10-*eq*-H), 4.22 (s, 1H, 9-OH), 4.32—4.66 (m, 2H, 3′-H+5′-H), 5.36 (brs, 1H, 7-H), 5.51 (m, 1H, 4′-H), 5.70 (brs, W_H=6 Hz, 1H, 1′-H), 6.24 (brd, *J*=7 Hz, 1H, NH), 7.76—7.94 (m, 2H, Ar), 8.20—8.48 (m, 6H, Ar), 13.35 (s, 1H, ArO*H*), 13.68 (s, 1H, ArO*H*). These spectral properties were identical with those reported.[4b] Found: C, 55.87; H, 4.17; N, 3.94%. Calcd for $C_{35}H_{29}F_3N_2O_{13}$·0.5H_2O: C, 55.89; H, 4.02; N, 3.72%.

Sodium hydroxide (0.1 M) (2.5 mL) was added to a solution of (−)-**2a** (mp 171—173 °C, $[\alpha]_D^{20}$ −89.7° (*c* 0.078, dioxane)) (189.0 mg, 0.25 mmol) in CH_2Cl_2 (1.5 mL) and MeOH (100 mL) with stirring at 0 °C under an argon atmosphere. The deep purple solution produced was stirred at 0 °C for 30 min. Glacial AcOH was added to the reaction mixture until the color of the solution became bright orange. Ethyl acetate (150 mL) and satd NaCl (150 mL) were successively added to the reaction mixture. The separated organic layer was washed with satd NaCl (50 mL×2), and dried over $MgSO_4$. Filtration and concentration in vacuo gave an orange residue, which was purified by silica-gel column chromatography (CH_2Cl_2/Me_2CO=9/1) to give pure (+)-**3a** as an orange crystalline solid (120 mg, 83%), mp 151—153 °C, $[\alpha]_D^{20}$ +190° (*c* 0.10, dioxane) (lit,[3b] mp 155—157 °C, $[\alpha]_D^{20}$ +188° (*c* 0.1, dioxane); lit,[4b] mp 155—156 °C, $[\alpha]_D^{20}$ +190° (*c* 0.1, dioxane)). IR (KBr): 3530, 3475, 1720 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.34 (d, *J*=7 Hz, 3H, 6′-Me), 1.80—2.38 (m, 4H, 2′-H_2+8-H_2), 2.43 (s, 3H, $COCH_3$), 2.99 (d, *J*=19 Hz, 1H, 10-*ax*-H), 3.34 (dd, *J*=19 and 1.5 Hz, 1H, 10-*eq*-H), 3.62—3.78 (m, 1H, 4-H), 4.32 (s, 1H, 9-OH), 4.10—4.42 (m, 2H, 3′-H+5′-H), 5.30 (dd, *J*=4 and 2 Hz, 1H, 7-H), 5.54 (brd, *J*=3 Hz, 1H, 1′-H), 6.67 (brd, *J*=8 Hz, 1H, NH), 7.81—7.93 (m, 2H, Ar), 8.35—8.47 (m, 2H, Ar), 13.38 (s, 1H, ArO*H*), 13.66 (s, 1H, ArO*H*). These spectra were identical with those reported.[4b]

b) Glycosidation of (+)-1a with (−)-6c by the Use of TMSOTf: Treatments of (+)-**1a**[2] (mp 184—185 °C, $[\alpha]_D^{20}$ +154° (*c* 0.10, dioxane)) (10.6 mg, 0.029 mmol) with (−)-**6c** (mp 133.5—135 °C, $[\alpha]_D^{20}$ −69.5° (*c* 0.12, Me_2CO)) (15.5 mg, 0.036 mmol) in the presence of TMSOTf (0.02 mL, 0.10 mmol) in the same manner as that described in **a**), gave the crude glycoside. This was immediately hydrolyzed with 0.1 M NaOH in MeOH to afford (−)-**3a** (10.0 mg, 61%). This sample showed an almost identical NMR spectrum with that of the pure sample obtained in **a**).

c) Glycosidation of (+)-1a with 5d by the Use of TMSOTf: Treatments of (+)-**1a**[2] (mp 184—185 °C, $[\alpha]_D^{20}$ +154° (*c* 0.10, dioxane)) (5.4 mg, 0.015 mmol) with **6d** (6.0 mg, 0.020 mmol) in the presence of TMSOTf (0.01 mL, 0.050 mmol) in the same manner as that described in **a**), followed by hydrolysis with 0.1 M NaOH and purification by silica-gel chromatography (CH_2Cl_2/Me_2CO=9/1), gave (+)-**3a** (6.2 mg, 70%). NMR spectrum of this sample was almost identical with that of pure (+)-**3a** obtained in **a**).

d) Glycosidation of (+)-1a with (−)-6b by the Use of Triethylsilyl Triflate: The same treatments of (+)-**1a**[2] (mp 184—185 °C, $[\alpha]_D^{20}$ +154° (*c* 0.10, dioxane)) (10.3 mg, 0.028 mmol) as those described in **a**), afforded (−)-**2a** (19.6 mg, 95%) after extractive isolation and purification by column chromatography. This was similarly identified by spectral (IR, NMR) comparisons.

e) Glycosidation of (+)-1a with (−)-6b by the Use of *t*-Butyldimethylsilyl Triflate: The same treatments of (+)-**1a**[2] (mp 184—185 °C, $[\alpha]_D^{20}$ +154° (*c* 0.10, dioxane)) (4.3 mg, 0.012 mmol) as those described in **a**), gave (−)-**2a** (0.50 mg, 7%), with recovery of (+)-**1a** (3.9 mg, 90%). NMR spectrum of (−)-**2a** was almost identical with that of pure (−)-**2a** obtained in **a**).

f) Glycosidation of (+)-1a with 5a by the Use of Silver Triflate: According to the reported method,[4b] a solution of silver triflate (22.0 mg, 0.086 mmol) in Et_2O (1 mL) was added to a mixture of (+)-**1a**[2] (mp 184—185 °C, $[\alpha]_D^{20}$ +154° (*c* 0.10, dioxane)) (20.9 mg, 0.057 mmol) and **5a** (26.7 mg, 0.075 mmol) in THF (4 mL) with stirring at room temperature. After being stirred at room temperature for 1 h with protection from a light, the mixture was diluted with EtOAc (20 mL), and washed with satd $NaHCO_3$ (30 mL). After drying over $MgSO_4$, filtration through a pad of celite and concentration in vacuo gave the crude product containing (−)-**2a**. Without purification, the crude glycoside ((−)-**2a**) was dissolved in a mixture of MeOH (20 mL) and CH_2Cl_2 (2 drops), and 0.1 M NaOH (0.4 mL) was added to the methanolic solution with stirring at 0 °C. After stirring at 0 °C for 20 min, the reaction was worked up in a similar manner as that described in **a**), giving a mixture of (+)-**3a** and (+)-**1a** as a red caramel after concentration of the ethyl acetate extracts. Separation by column chromatography (EtOAc/C_6H_6=1/4, then, 1/1) gave almost pure (+)-**1a** (9.8 mg, 47%) and (+)-**3a** (16.5 mg, 49%). Both samples were identified with the authentic samples by spectral (NMR) comparisons, respectively.

g) Glycosidation of (+)-1a with 5b by the Use of Silver Triflate: According to the reported method,[4a] a solution of silver triflate (20.0 mg, 0.078 mmol) in Et_2O (1 mL) was added to a mixture of (+)-**1a**[2] (mp 184—185 °C, $[\alpha]_D^{20}$ +154° (*c* 0.10, dioxane)) (20.0 mg, 0.054 mmol) and **5b** (22.0 mg, 0.067 mmol) in CH_2Cl_2 (3 ml) with stirring at room temperature. After stirring at the same temperature for 1.5 h, a solution of silver triflate (20.0 mg, 0.078 mmol) in Et_2O (1 mL) was further added to the reaction mixture, and the stirring was continued for 1 h. Usual extractive isolation followed by methanolysis in MeOH (20 mL) at 50 °C for 1 h, gave a crude mixture of (+)-**1a** and (+)-**3a**. This was separated by silica-gel column chromatography (EtOAc/C_6H_6=1/4, then 1/1), giving almost pure (+)-**1a** (8.5 mg, 43%) and (+)-**3a** (18.0 mg, 56%). Both samples were identified with the authentic samples by spectral (NMR) comparisons, respectively.

(+)-4-Demethoxydaunorubicin Hydrochloride ((+)-4a-HCl). A deep purple solution of (+)-**3a** (mp 151—153 °C, $[\alpha]_D^{20}$ +190° (*c* 0.10, dioxane)) (95.7 mg, 0.17 mmol) in 0.1 M NaOH (20 mL) was stirred at room temperature for 20 min under an argon atmosphere. After the acidity of the solution was adjusted to be pH 8 with 5 M HCl, the neutralized solution was extracted with $CHCl_3$ until a chloroform extract showed no orange color of the reaction product (ca. 70 mL×5). The combined chloroform layers were washed with H_2O (50 mL), and dried over Na_2SO_4. Filtration and concentration in vacuo gave an orange residue which was dissolved in a small amount of $CHCl_3$ and MeOH (9/1). After 0.25 M hydrogen chloride in MeOH was added to the resulting solution until the acidity became pH 3—5, Et_2O (30 mL) was added to the acidic solution to give (+)-**4a**-HCl as an orange powder (69.7 mg, 77%), mp 184—185 °C (decomp), $[\alpha]_D^{20}$ +188° (*c* 0.10, MeOH) (lit,[3b] mp 183—185 °C, $[\alpha]_D^{20}$ +205° (*c* 0.1, MeOH); lit,[4b] mp 172—174 °C (decomp), $[\alpha]_D^{20}$ +187° (*c* 0.1, MeOH)). IR (KBr): 3350, 1715, 1625, 1590, 1410, 1235, 1120, 985 cm^{-1}. ^1H NMR ($(CD_3)_2SO$) δ=1.18 (d, *J*=6 Hz, 3H, 6′-Me), 1.70—2.24 (m, 4H, 2′-H_2+8-H_2), 2.30 (s, 3H, $COCH_3$), 3.00 (brs, 2H, 10-H_2), 3.54—3.70 (brs, 1H, 4′-H), 4.24 (q, *J*=6 Hz, 1H, 5′-H), 5.00 (brs, W_H=8 Hz, 1H, 7-H), 5.32 (brs, W_H=6 Hz, 1H, 1′-H), 5.47 (d, *J*=6 Hz, 1H, 4′-OH), 5.58 (s, 1H, 9-OH), 7.75—8.05 (brs, 3H, NH_3), 7.95—8.12 (m, 2H, Ar), 8.20—8.42 (m, 2H, Ar), 13.36 (brs, 1H, ArO*H*), 13.54 (brs, 1H, ArO*H*). These IR and NMR spectra were identical with those reported.[4b] MS (SIMS) *m/z*: 498 (MH^+). Found: C, 56.34; H, 5.32; N, 2.42%. Calcd for $C_{26}H_{28}ClNO_9$-H_2O: C, 56.58; H, 5.48; N, 2.54%.

(+)-14-Acetoxy-4-demethoxydaunomycinone ((+)-1b). The same treatments of (+)-**1a**[2] (mp 184—185 °C, $[\alpha]_D^{20}$ +154° (*c* 0.10, dioxane)) (74 mg, 0.20 mmol) as those reported[19] gave (+)-**1b** as an orange solid (60 mg, 70%) after extractive isolation with CH_2Cl_2 and purification by column chromatography (EtOAc/C_6H_6=1/4). Recrystallization from a mixture of C_6H_6, Et_2O, and C_6H_{14} gave pure (+)-**1b** as orange crystals, mp 187—188.5 °C, $[\alpha]_D^{20}$ +181° (*c* 0.104, dioxane). IR (KBr): 3500, 3450, 1745, 1735, 1623, 1587 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.08 (dd, *J*=15 and 4.5 Hz, 1H, 8-*ax*-H), 2.21 (s, 3H, $COCH_3$), 2.51 (dt, *J*=15 and 2 Hz, 1H, 8-*eq*-H), 3.00 (d, *J*=19 Hz, 1H, 10-*ax*-H), 3.31 (dd, *J*=19 and 2 Hz, 1H, 10-*eq*-H), 3.43 (brs, 1H, 7-OH), 4.69 (s, 1H, 9-OH), 5.17 (d, *J*=18 Hz, 1H, one of 14-H), 5.38 (brs, 1H, 7-H), 5.42 (d, *J*=18 Hz, 1H, one of 14-H), 7.76—8.01 (m, 2H, Ar), 8.24—8.48 (m, 2H, Ar), 13.19 (s, 1H, ArO*H*), 13.52 (s, 1H, ArO*H*). MS *m/z*: 426 (M^+). Found: C, 61.86; H, 4.28%. Calcd for $C_{22}H_{18}O_9$: C, 61.97; H, 4.26%.

(+)-14-Formyloxy-4-demethoxydaunomycinone ((+-1c). A mixture of (+)-**1a**[2] (mp 184—185 °C, $[\alpha]_D^{20}$ +154° (*c* 0.10 dioxane)) (100 mg, 0.27 mmol) and pyridinium tribromide (100 mg, 0.30 mmol) in THF (10 mL) was stirred at room temperature for 2 h. A solution of tetrabutylammonium formate[21] (488 mg, 1.70 mmol) in THF (13 mL) was added to the reaction mixture. After stirring for 10 min at room temperature, the whole mixture was diluted with CH_2Cl_2 (150 ml), washed with satd NaCl (100 mL×3), then dried over $MgSO_4$. Filtration and concentration in vacuo followed by purification by a short silica-gel column (EtOAc/C_6H_6=1/4) gave crude (+)-**1c** as an orange solid (102.3 mg, 92%). Recrystallization from a mixture of $CHCl_3$, MeOH, and Et_2O gave an analytical sample of (+)-**1c** (86.7 mg, 78%), mp 183—185 °C, $[\alpha]_D^{20}$ +153° (*c* 0.11, dioxane). IR (KBr): 1735, 1720, 1625, 1590 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.14 (ddd, *J*=15, 5 and 2 Hz, 1H, 8-*ax*-H), 2.53 (dt, *J*=15 and 2 Hz, 1H, 8-*eq*-H), 3.02 (d, *J*=19 Hz, 1H, 10-*ax*-H), 3.34 (brs, 1H, 7-OH), 3.38 (dd, *J*=19 and 2 Hz, 1H, 10-*eq*-H), 4.69 (s, 1H, 9-OH), 5.26 (d, *J*=18 Hz, 1H, one of 14-H), 5.39 (brs, 1H, 7-H), 5.53 (d, *J*=18 Hz, 1H, one of 14-H), 7.78—7.98 (m, 2H, Ar), 8.24 (s, 1H, OC*H*O), 8.30—8.52 (m, 2H, Ar), 13.30 (s, 1H, ArO*H*), 13.63 (s, 1H, ArO*H*). MS *m/z*: 412 (M^+). Found: C, 59.24; H, 3.87%. Calcd for $C_{21}H_{16}O_9$-0.75H_2O: C, 59.23; H, 4.14%.

(+)-3′-*N*-Trifluoroacetyl-4-demethoxyadriamycin ((+)-3d).
a) Glycosidation of (+)-1b with (−)-6b by the Use of TMSOTf: TMSOTf (0.08 mL, 0.41 mmol) was added to a suspension of (−)-**6b** (mp 201—202 °C, $[\alpha]_D^{20}$ −117° (*c* 0.029, Me_2CO)) (90.0 mg, 0.166 mmol) and granulated molecular sieves 4A[8] (0.8 g) in a mixture of CH_2Cl_2 (9 mL) and Et_2O (3 mL) with stirring at −40 °C under an argon atmosphere. The whole mixture was stirred at 0 °C for 1 h, then cooled to −15 °C. A solution of (+)-**1b** (mp 187—188.5 °C, $[\alpha]_D^{20}$ +181° (*c* 0.104, dioxane)) (56.9 mg, 0.134 mmol) in CH_2Cl_2 (17 mL) was added to the stirred reaction mixture. After being stirred at −15 °C for 3.5 h, the whole mixture was poured onto a two-layer mixture of satd $NaHCO_3$ (100 mL) and EtOAc (50 mL) with vigorous stirring to quench the glycosidation reaction. The organic layer was separated, washed with satd NaCl (50 mL×2), then dried over $MgSO_4$. Filtration and concentration in vacuo gave a residue, which was filtered through a short silica-gel column (EtOAc/C_6H_6=1/4) to give almost pure (−)-**2b** as an orange solid (105.5 mg, 99%). The glycoside ((−)-**2b**) was further triturated with $CHCl_3$, then with C_6H_{14} to give pure (−)-**2b** (91.3 mg, 85%), mp 167—170 °C, $[\alpha]_D^{20}$ −53.5° (*c* 0.097, dioxane). IR (KBr): 3500, 3350, 1730 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.30 (d, *J*=6 Hz, 6′-Me), 2.00—2.68 (m, 4H, 2′-H_2+8-H_2), 2.22 (s, 3H, $COCH_3$), 3.10 (d, *J*=19 Hz, 1H, 10-*ax*-H), 3.44 (dd, *J*=19 and 1.5 Hz, 1H, 10-*eq*-H), 4.39 (s, 1H, 9-OH), 4.35—4.60 (m, 2H, 3′-H+5′-H), 5.10 (d, *J*=19 Hz, 1H, one of 14-H), 5.40 (brs, 1H, 7-H), 5.44 (d, *J*=19 Hz, 1H, one of 14-H), 5.54 (brs, 1H, 4′-H), 5.74 (brs, W_H=6 Hz, 1H, 1′-H), 6.31 (brd, *J*=8 Hz, 1H, NH), 7.80—7.98 (m, 2H, Ar), 8.20—8.50 (m, 6H, Ar), 13.33 (s, 1H, ArO*H*), 13.69 (s, 1H, ArO*H*). Found: C, 54.55; H, 3.86; N, 3.71%. Calcd for $C_{37}H_{31}F_3N_2O_{15}$-H_2O: C, 54.28; H, 4.06; N, 3.57%.

Ten percent potassium carbonate (0.12 mL) was added to (−)-**2b** (mp 167—170 °C, $[\alpha]_D^{20}$ −53.5° (*c* 0.097, dioxane)) (23.5 mg, 0.029 mmol) in MeOH (12 mL) at 0 °C. The deep purple solution produced was stirred at 0 °C for 4 h. Glacial AcOH was added to the reaction mixture until the color of the solution became bright orange. Usual extractive isolation and purification by silica-gel thin-layer chromatography ($CHCl_3$/Me_2CO=2/1) gave (+)-**3a** as an orange solid (6.9 mg, 39%), mp 132—135 °C. NMR spectrum of this sample was almost identical with that of (+)-**3a** obtained in **b**).

b) Glycosidation of (+)-1c with (−)-6b by the Use of TMSOTf: TMSOTf (0.10 mL, 0.52 mmol) was added to a suspension of (−)-**6b** (mp 201—202 °C, $[\alpha]_D^{20}$ −117° (*c* 0.029. Me_2CO)) (133 mg, 0.25 mmol) and granulated molecular sieves 4A[8] (0.75 g) in a mixture of CH_2Cl_2 (8 mL) and Et_2O (6 mL) with stirring at −40 °C under an argon atmosphere. The whole mixture was stirred at 3—5 °C for 1 h to give a clear solution. After cooling to −15 °C, a solution of (+)-**1c** (mp 183—185 °C, $[\alpha]_D^{20}$ +153° (*c* 0.11, dioxane)) (77.9 mg, 0.19 mmol) in THF (25 mL) was added to the reaction mixture with stirring, and the stirring was continued for 7 h at −10 °C. Extractive isolation in the same manner as described for (−)-**2a** gave crude **2c** as an orange solid in an almost quantitative yield. This was immediately subjected to deprotection reaction of the C_{14}-formyloxy and C_4′-*p*-nitrobenzoyl groups.[21]

Sodium hydroxide (0.1 M) (2 mL) was added to a solution of crude **2c** in a mixture of THF (1 mL) and MeOH (80 mL) with stirring at 0 °C under an argon atmosphere. After stirring at 0 °C for 20 min, the purple reaction mixture was neutralized to pH 7 with AcOH (1 drop). The resulting mixture was diluted with satd NaCl (100 mL) and EtOAc (100 mL). The upper organic layer was separated, washed with satd NaCl (100 mL), then dried over $MgSO_4$. Filtration and concentration in vacuo, followed by purification by filtration through a short silica-gel column ($CHCl_3$/Me_2CO=19/1→9/1) afforded pure (+)-**3d** as an orange solid (84.1 mg, 73% overall yield), mp 143—148 °C, $[\alpha]_D^{20}$ +170° (*c* 0.11, dioxane). IR (KBr): 3450, 1725, 1630, 1590, 1410 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.32 (d, *J*=7 Hz, 3H, 6′-Me), 1.80—2.38 (m, 4H, 2′-H_2+8-H_2), 2.97 (t, *J*=6 Hz, 1H, 14-OH), 3.08 (d, *J*=19 Hz, 1H, 10-*ax*-H), 3.30 (dd, *J*=19 and 1 Hz, 1H, 10-*eq*-H), 3.62—3.78 (m, 1H, 4′-H), 4.10—4.30 (m, 2H, 3′-H+5′-H), 4.38 (s, 1H, 9-OH), 4.79 (d, *J*=6 Hz, 2H, 14-H_2), 5.33 (dd, *J*=4 and 2 Hz, 1H, 7-H), 5.55 (d, *J*=4 Hz, 1H, 1′-H), 6.66 (brd, *J*=10 Hz, 1H, NH), 7.81—7.96 (m, 2H, Ar), 8.36—8.48 (m, 2H, Ar), 13.34 (s, 1H, ArO*H*), 13.65 (s, 1H, ArO*H*). Found: C, 53.84; H, 4.80; N, 2.21%. Calcd for $C_{28}H_{26}F_3NO_{11}$-H_2O: C, 53.59; H, 4.50; N, 2.23%.

(+)-14-Formyloxy-4-demethoxydaunorubicin Hydrochloride ((+)-4c-HCl). Attempted Preparation of (+)-4d-HCl According to the Reported Method:[15] Bromine (0.76 M

CH_2Cl_2 soln) (0.05 mL, 0.038 mmol) and 0.25 M hydrogen chloride in MeOH (0.1 mL) were added to a suspention of (+)-**4a**-HCl (mp 184—187 °C, $[\alpha]_D^{20}$ +188° (*c* 0.10, MeOH)) (20.0 mg, 0.037 mmol) and triethoxymethane (0.02 mL, 0.16 mmol) in a mixture of MeOH (0.3 mL) and dioxane (0.75 mL), and the whole mixture was stirred at room temperature for 1 h. A mixture of C_6H_{14} (2 mL) and Et_2O (4 mL) was added to the reaction mixture to precipitate the crude bromo acetal as an orange powder. The crude bromo acetal was collected by decantation and dried in vacuo.[16] After 0.25 M hydrobromic acid (3 mL) and dioxane (3 mL) were added to the crude bromo acetal, the whole mixture was stirred at room temperature for 22 h to liberate the α-bromo ketone.[17] A solution of sodium formate (220 mg, 3.24 mmol) in H_2O (2.2 mL) was added to the stirred solution of the α-bromo ketone. After stirring at room temperature for 24 h, the reaction mixture was diluted with 5% $NaHCO_3$ (50 mL) and extracted successively with a mixture of MeOH and $CHCl_3$ (1/2) (50 mL) and $CHCl_3$ (50 mL×4). The combined organic extracts were washed with H_2O (50 mL), and dried over Na_2SO_4. Filtration and concentration in vacuo gave a residue, which was dissolved in a mixture of MeOH and $CHCl_3$ (1/9) (2 mL). After addition of 0.25 M hydrogen chloride in MeOH (0.10 mL), Et_2O (15 mL) was added to the acidic solution to precipitate (+)-**4c**-HCl as a bright orange solid (6.0 mg, 30%), mp 186—189 °C (decomp), $[\alpha]_D^{20}$ +185° (*c* 0.040, MeOH). IR (KBr): 3400, 1725, 1620, 1590 cm^{-1}. ^1H NMR ($(CD_3)_2SO$) δ=1.18 (d, *J*=6 Hz, 3H, 6′-Me), 1.69—2.00 (m, 2H, 2′-H_2), 2.02—2.32 (m, 2H, 8-H_2), 2.92 (d, *J*=19 Hz, 1H, 10-*ax*-H), 3.20 (d, *J*=19 Hz, 1H, 10-*eq*-H), 3.44—3.69 (m, 2H, 3′-H+4′-H), 4.10—4.40 (m, 1H, 5′-H), 5.01 (brs, W_H=8 Hz, 1H, 7-H), 5.34 (brs, 3H, 14-H_2+1′-H), 5.46 (d, *J*=6 Hz, 1H, 4′-OH), 5.74 (s, 1H, 9-OH), 7.88 (brs, 3H, NH_3), 7.96—8.12 (m, 2H, Ar), 8.24—8.46 (m, 2H, Ar), 8.40 (s, 1H, C*H*O), 13.36 (brs, 1H, ArO*H*), 13.56 (brs, 1H, ArO*H*). MS (SIMS) *m/z*: 542 (MH^+).

(+)-4-Demethoxyadriamycin Hydrochloride ((+)-4d-HCl).

a) Preparation of (+)-4d-HCl from (+)-4c-HCl: Sodium hydroxide (0.1 M) (0.25 mL) was added to a solution of (+)-**4c**-HCl (mp 186—189 °C (decomp), $[\alpha]_D^{20}$ +185° (*c* 0.040, MeOH)) (12.2 mg, 0.021 mmol) in MeOH (10 mL) at 0 °C. The deep purple solution produced was stirred for 20 min at 0 °C. The reaction mixture was diluted with $CHCl_3$ (50 mL) and satd NaCl (50 mL). The chloroform layer was separated, and the aqueous layer was further extracted with $CHCl_3$ (50 mL×3). The combined organic extracts were washed with H_2O (50 mL×2), and dried over Na_2SO_4. Concentration in vacuo gave a residue, which was dissolved in a mixture of MeOH and $CHCl_3$ (1/9) (3 mL). After addition of 0.25 M hydrogen chloride in MeOH (0.15 mL), Et_2O (15 mL) was added to the acidic solution to precipitate (+)-**4d**-HCl as a bright orange solid (7.7 mg, 67%), mp 225—228 °C (decomp). NMR spectrum of this sample was almost identical with that of (+)-**4d**-HCl obtained in **c**).

b) Preparation of (+)-4d-HCl from (+)-4a-HCl by the Improved Method: A solution of (+)-**4a**-HCl (mp 184—187 °C (decomp), $[\alpha]_D^{20}$ +188° (*c* 0.10, MeOH)) (106 mg, 0.20 mmol) and trimethoxymethane (0.11 mL, 1.1 mmol) in a mixture of MeOH (2.7 mL) and dioxane (4.2 mL) was stirred at room temperature for 15 min under an argon atmosphere. Bromine (0.86 M CH_2Cl_2 soln) (0.39 mL, 0.34 mmol) was added to the reaction mixture. After stirring at room temperature for 1 h, the reaction mixture was poured onto Et_2O (60 mL) to precipitate the crude bromo acetal as an orange powder. The crude bromo acetal was collected by decantation and dried in vacuo.[16] Anhyd Me_2CO (45 mL) was added to the crude bromo acetal, and the mixture was stirred at room temperature for 1 h to liberate the α-bromo ketone.[17] A solution of sodium formate (266 mg, 3.9 mmol) in H_2O (3.3 mL) was added to the solution of the α-bromo ketone. After stirring at room temperature for 15 h, the mixture was concentrated in vacuo to give crude **3c** as an orange solid. Sodium hydroxide (0.1 M) (1.0 mL) was added to a solution of crude **3c** in MeOH (100 mL) and the mixture was stirred at 0—5 °C for 10 min. After addition of $CHCl_3$ (200 mL) and satd NaCl (200 mL), the lower organic layer was separated, and the aqueous layer was further extracted with $CHCl_3$ (100 mL×3). The combined organic extracts were washed with H_2O (100 mL×2), dried over Na_2SO_4, filtrated, then concentrated in vacuo. The residue was dissolved in a mixture of MeOH and $CHCl_3$ (1/9) (15 mL). After addition of 0.25 M hydrogen chloride in MeOH (0.50 mL), the acidic solution was diluted with Et_2O (50 mL) to give (+)-**4d**-HCl as bright orange powderlike crystals (54.0 mg, 49%), mp 225—228 °C (decomp), $[\alpha]_D^{20}$ +187° (*c* 0.030, MeOH). IR, NMR, and MS spectra of this sample were identical with those of (+)-**4d**-HCl obtained in **c**). Found: C, 53.63; H, 4.91; N, 2.09%. Calcd for $C_{26}H_{28}ClNO_{10}$-1.5H_2O: C, 54.12; H, 5.42; N, 2.43%.

c) Preparation of (+)-4d-HCl from (+)-3d: A mixture of (+)-**3d** (mp 143—148 °C, $[\alpha]_D^{20}$ +170° (*c* 0.11, dioxane)) (12.0 mg, 0.02 mmol), trimethoxymethane (1 mL), and *d*-10-camphorsulfonic acid (2 mg) in THF (3 mL) was stirred at room temperature for 2 h. The reaction mixture was poured onto 5% $NaHCO_3$ (50 mL), and extracted with EtOAc (50 mL×2). The combined organic extracts were successively washed with 5% $NaHCO_3$ (30 mL), satd NaCl (30 mL), and H_2O (30 mL), dried over Na_2SO_4, filtered, then concentrated in vacuo, giving an orange caramel which conceivably consisted of the cyclic orthoester.[23] Sodium hydroxide (0.1 M) (3 mL) was added to the concentrated residue with stirring under an argon atmosphere, and the mixture was further stirred for 45 min. The mixture was neutralized to pH 8 with 5 M HCl, and extracted with $CHCl_3$ (30 mL×5). The combined chloroform extracts were washed with H_2O (50 mL×2), dried over Na_2SO_4, filtered, then concentrated in vacuo. The residue was dissolved in a mixture of MeOH (3 mL) and 0.25 M HCl (1 mL), and the whole mixture was stirred at room temperature for overnight. After concentration in vacuo, MeOH (15 mL) was added to the residue. The methanolic solution was filtered to remove a small amount of insoluble materials, and the filtrate was concentrated in vacuo to a small volume. Addition of Et_2O (5 mL) to the concentrated methanolic solution gave (+)-**4d**-HCl as orange powderlike crystals (4.3 mg, 40%), mp 226—229 °C (decomp), $[\alpha]_D^{20}$ +190° (*c* 0.042, MeOH). IR (KBr): 3400, 1725, 1620, 1590 cm^{-1}. ^1H NMR ($(CD_3)_2SO$) δ=1.16 (d, *J*=6 Hz, 3H, 6′-Me), 1.70—2.00 (m, 2H, 2′-H_2), 2.00—2.30 (m, 2H, 8-H_2), 3.02 (s, 2H, 10-H_2), 3.40—3.68 (m, 2H, 3′-H+4′-H), 4.21 (q, *J*=6 Hz, 1H, 5′-H), 4.60 (brd, *J*=5 Hz, 2H, 14-H_2), 4.82 (d, *J*=5 Hz, 1H, 4′-OH), 5.01 (brs, W_H=8 Hz, 1H, 7-H), 5.34 (brs, W_H=6 Hz, 1H, 1′-H), 5.47 (s, 1H, 9-OH), 7.83 (brs, 3H, NH_3), 7.90—8.10 (m, 2H, Ar), 8.22—8.42 (m, 2H, Ar), 13.36 (brs, 1H, ArO*H*), 13.58 (brs, 1H, ArO*H*). MS (SIMS) *m/z*: 514 (MH^+). Found: C, 53.32; H, 5.03; N, 2.35%. Calcd for $C_{26}H_{28}ClNO_{10}$-1.75H_2O: C, 53.70; H, 5.46; N, 2.41%.

The authors are grateful to Dr. S. Penco, Farmitalia

Carlo Erba, for providing us with the spectral (IR, NMR, MS) data of 4-demethoxyadriamycin hydrochloride and for many valuable suggestions.

19) After our preliminary communication was subjected for publication,[1b] we informed our results to Drs. F. Arcamone and S. Penco, Farmitalia Carlo Erba. Replying to our letter, Dr. Penco kindly provided us IR, NMR, and MS spectra of their sample of **4d**-HCl. While the melting point and optical rotation of their sample on which those spectral properties had been recorded were not informed to us, we found that the spectra of the Falmitalia's sample were completely identical with those of our (+)-**4d**-HCl. Recently, Dr. Penco generously wrote to us that the melting point of their **4d**-HCl measured with a differential scanning calorimetry was in the range of 270—277 °C, and that the measurement of the optical rotation could not be carried out because of the intense color of **4d**-HCl.

The Diels-Alder Reactions of 2-Alkyl-5-methoxy-4-(*p*-nitrophenyl)oxazoles with Ethylenic, Acetylenic, and Azo-Type Dienophiles

Toshikazu IBATA,* Shuji NAKANO, Hiroyuki NAKAWA, Jiro TOYODA, and Yasushi ISOGAMI
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received July 20, 1985)

The Diels-Alder reactions of 2-methyl- and 2-ethyl-5-methoxy-4-(*p*-nitrophenyl)oxazoles with *N*-methyl-, *N*-ethyl-, and *N*-phenylmaleimides gave endo- and exo-adducts. When the reactions were carried out in an acetonitrile solution containing a small amount of water as an impurity, *N*-substituted 3-hydroxy-2-(*p*-nitrophenyl)-4,5-pyridinecarboximides were obtained via the decomposition of the Diels-Alder adducts, while the methanol was eliminated. The decomposition might be catalyzed by contaminated water at the initial stage of the reaction. The adducts of *N*-phenylmaleimide and *N*-ethylmaleimide were shown to undergo the retro-Diels-Alder reaction on heating at 80°C to give the starting maleimides and oxazole. Diethyl azodicarboxylate and 4-phenyl-3*H*-1,2,4-triazole-3,5(4*H*)-dione gave the corresponding single adducts. A reaction with dimethyl acetylenedicarboxylate gave *p*-nitrobenzonitrile (**10**), dimethyl 2-methyl-5-methoxy-3,4-furandicarboxylate (**11**), and tetramethyl 3,5-epoxy-3-methoxy-5-methyl-1,4-cyclohexadiene-1,2,4,5-tetracarboxylate (**12**), although the expected adduct was not isolated. These products were explained on the basis of the Diels-Alder reaction, followed by the retro-Diels-Alder reaction, thus affording **10** and **11**, which gave **12** upon cycloaddition with the second molecule of DMAD.

The cycloaddition of the five-membered aromatic heterocycles has been recognized to be one of the most convenient methods of synthesizing six-membered heterocycles.[1] Since the early work of Kondrat'eva,[2] the Diels-Alder reactions of oxazoles with ethylenic dienophiles have been studied extensively in connection with the pathway of synthesizing vitamin B_6.[3] In general, the determination of the stereochemistry of the cycloaddition is important for the mechanistic investigation of the reaction. However, scarcely no stereochemical research into the Diels-Alder reaction of oxazoles has been done because of the instability of the adducts.[4] Recently the present authors have reported a general method of synthesizing oxazoles by the BF_3-catalyzed decomposition of diazo carbonyl compounds in the presence of excess nitriles to give various types of oxazoles.[5] Of the oxazoles obtained, we chose 5-methoxy-2-methyl-4-(*p*-nitrophenyl)oxazole (**1A**) and 2-ethyl-5-methoxy-4-(*p*-nitrophenyl)oxazole (**1B**) as azadiene components of the Diels-Alder reaction for the following reasons: First, a high Diels-Alder reactivity of the oxazoles can be expected because of the electron-releasing effect of the methoxyl group on C-5,[3b,6] second, a high stability of the cycloadducts may possibly be attained by the introduction of the *p*-nitrophenyl group. The retro-Diels-Alder reaction of the adducts was also studied.

Results and Discussion

Reactions with Ethylenic Dienophiles. *N*-Substituted maleimides have been recognized as having high reactivity as dienophiles in the Diels-Alder reactions. The refluxing of an acetonitrile solution of 5-methoxy-2-methyl-4-(*p*-nitrophenyl)oxazole (**1A**) and two molar equivalents of *N*-ethylmaleimide (**2b**) for 50 h gave three products after silica-gel column chromatography of the reaction mixture. The first and successively eluted products were determined to be the expected Diels-Alder adducts on the basis of the analytical and spectral data. The IR spectra of the two products showed absorptions ascribable to the imide carbonyl near 1700 cm^{-1} and to the nitro group at 1535 and 1340 cm^{-1}, and also showed similar absorption patterns in the fingerprint region. The first product (mp 159.0—161.0 °C) has signals of the methyl and methylene protons of the *N*-ethyl group at δ 0.48 (t) and 3.14 (q) respectively in the ^1H NMR spectrum; they are considerably higher (by 0.5—0.7 ppm) than those signals of the second product at δ 1.20 (t) and 3.57 (q). The high field of the *N*-ethyl group of the first product might be attributed to the shielding effect derived from the ring-current anisotropy of the *p*-nitrophenyl group. This indicates that the adduct is the endo-adduct (**3b**). Therefore, the second product may be assigned to the exo-adduct (**4b**). The appearance of methine protons of **3b** in a lower field (δ 3.50 (d) and 3.62 (d)) than those of **4b** at δ 2.96 (d) and 3.07 (d) is also in accord with the above assignment, assuming a deshielding effect of the bridged oxygen in the endo-adduct (**3b**).[7] The X-ray structural analysis of **4b** supported the above determination.[9]

The third product was found to have a molecular formula corresponding to that of the CH_3OH elimination from the adducts, **3b** or **4b**. The ^1H NMR spectrum lacked signals of the methoxyl and methine protons observed in **3b** and **4b** but showed signals of methyl at δ 2.84, *N*-ethyl at δ 1.21 (t) and 3.75 (q), and hydroxyl at δ 7.98, besides the ABq signals of the *p*-nitrophenyl group. The IR spectrum had absorptions of the imide carbonyl group at 1690 cm^{-1}, the hydroxyl group at 3350, and the nitro group at 1505 and 1340 cm^{-1}. These spectroscopic data show that the third product is *N*-ethyl-3-hydroxy-6-methyl-2-(*p*-nitrophenyl)-4,5-pyridinecarboximide (**5b**).

The Diels-Alder adducts between 5-alkoxyoxazoles and ethylenic dienophiles, which have structures like **3b** and **4b**, have already been reported to give 3-

hydroxypyridine derivatives upon treatment with acid.[3a,3c)] The treatment of **3b** and **4b** with *p*-toluenesulfonic acid in a benzene solution readily gave **5b**. The formation of **5b** in the Diels-Alder reaction of **1A** and *N*-ethylmaleimide may also be attributed to the second attack of a protic species such as H_2O, contained in the reaction mixture, on the **3b** and **4b** produced by the cycloaddition. In order to confirm this point, the reaction was examined under various reaction conditions, with differing solvents, reaction temperatures, and reaction times (Runs bl—b5). The results show that the formation of **5b** is greatly affected by the solvent and the reaction time, but only slightly by the reaction temperature. When the reaction was carried out using a freshly distilled solvent, no decomposition to give **5b** was observed. These results suggest that the H_2O present in the solvent might function as a protic species to catalyze the decomposition of **3b** or **4b** formed at the outset. Once the decomposition started, the methanol and **5b** produced might work as catalysts. Quite similar results were obtained in the reaction of **1A** with *N*-methylmaleimide. 2-Ethyl-5-methoxy-4-(*p*-nitrophenyl)-oxazole (**1B**) also showed similar behavior in the reactions with *N*-substituted maleimides.

The preference for the endo-adducts formation in these reactions may be explained by the endo rule.[8)] However, a larger endo/exo ratio (96:3) than usual was observed in the reaction of **1B** and *N*-ethylmaleimide (Run f). One of possible explanation is as follows. The CPK-model inspection of the adducts (**3f** and **4f**) indicated that the exo-adduct (**4f**) has a steric repulsion between the C-ethyl group and imide carbonyl. This may indicate that the steric repulsion between these two groups in the transition state to the exo-adduct lowers the rate of the addition and that the *N*-ethyl substitution strengthens this tendency.

On the other hand, *N*-phenylmaleimide (**2c**) gave

a) Signals of the aromatic protons were omitted. b) Methine protons showed doublet signals unless otherwise cited. c) A singlet NH signal was at δ=3.27. d) Singlet OH signals of **5a**, **5b**, and **5c** were observed at δ=7.98, 8.03, and 8.18 respectively.

small amounts of both endo- and exo-adducts at 80 °C, and the yields decreased with the increase in the reaction temperature (100 °C). In order to clarify the course of the addition, the proceeding of the reaction between equivalent molar amounts of **1A** and **2c** was traced by monitoring the proton NMR in an NMR tube at 25 and 80 °C in C_6D_6. As a result, the rates of the formation of the endo-adduct were found to be faster than that of the exo-adduct. However, the tracing was interrupted during the course of the reaction because of the crystallization of the adducts in the NMR tube. The reaction of **1A** with *N*-ethylmaleimide (**2b**) exhibited a monotonous increase in the yields of the adducts at 25 °C, without any interruption by the crystallization of the adducts (Fig. 1a). However, at 80 °C the yield of the endo-adduct reached its maximum after 10 h and then decreased gradually, while the yield of the exo-adduct increased constantly, as is shown in Fig. 1b. This indicates that the endo-adduct is converted into the exo-adduct, probably via the retro-Diels-Alder reaction as described below.

The ratio between the adducts (**3**+**4**) and the remaining oxazole (**1A**) depends upon the reaction temperature, showing smaller values at higher temperatures. The ratios were also found to be larger for the reactions of **2b** with **1A** than for the corresponding reactions of **2c**, even though the reaction rates were faster for **2c** than for **2b** at various temperatures. The depressions of the yields of the adducts at higher temperatures may be explained on the assumption that the equilibrium between the Diels-Alder reaction and the retro-Diels-Alder reaction declines to the side of the reactants at higher temperatures.

The reaction of the oxazole (**1A**) and tetracyanoethylene gave a colorless product, which showed an absorption of the ester carbonyl group in its IR spectrum at 1758 cm^{-1}. This indicates that the product is not the expected Diels-Alder adduct (**6**), but the

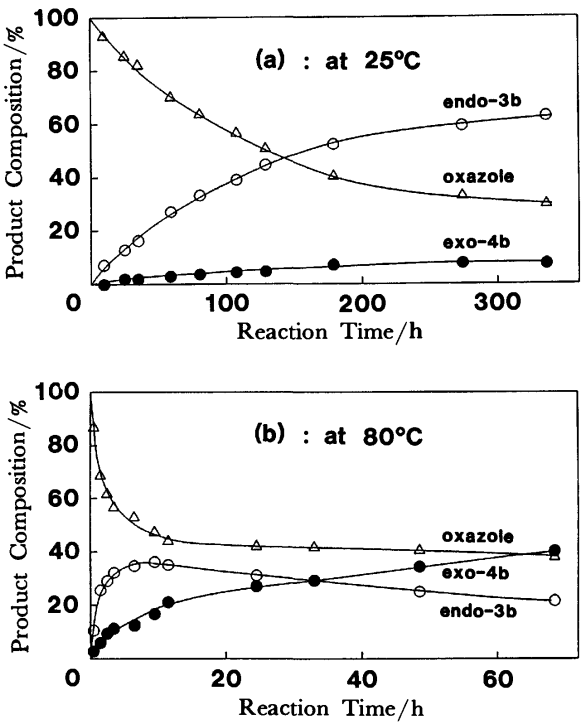

Fig. 1. Changes in the Product Composition during the Reaction of **1A** with **2b** at 25 °C (a) and 80 °C (b).

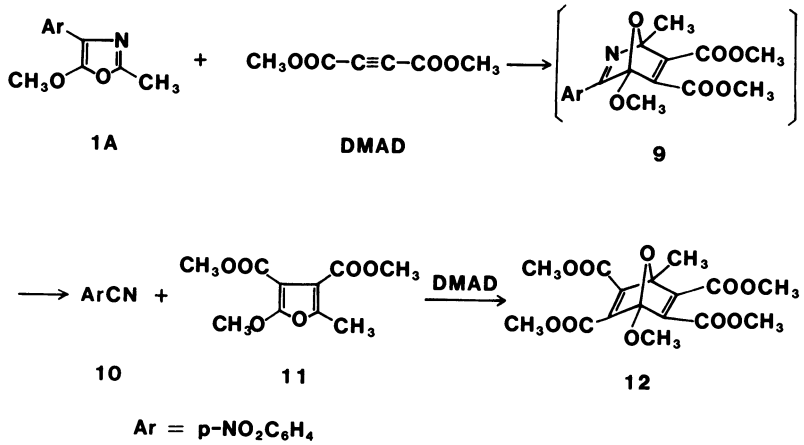
oxazole-ring-opened product obtained via the step-by-step reaction of **1A** and TCNE.[10] The results of the detailed examination of this reaction will be described elsewhere. Dimethyl fumarate and dimethyl maleate gave no adduct, the reactions with **1A** resulting in the recovery of the starting materials, even under such drastic reaction conditions as at 110 °C for 100 h in toluene.

Reactions with Azo-Type Dienophiles. The azo-type compounds have been reported to have higher Diels-Alder reactivities than the corresponding



Scheme 2.

ethylenic dienophiles.[11] Similar results were observed in the Diels-Alder reaction of oxazoles. That is diethyl azodicarboxylate[12] was found to react readily with the oxazole (**1A**) in a benzene solution at 80 °C within 48 h to give an adduct (**7**) in a fairly good yield (91%). 4-Phenyl-3*H*-1,2,4-triazole-3,5(4*H*)-dione, which is one of the most reactive dienophiles,[11b] also gave an adduct (**8**) in a high yield. However, azobenzene gave no adduct.

Reaction with Acetylenic Dienophile. As a typical example of acetylenic dienophiles, dimethyl acetylenedicarboxylate was treated with the oxazole (**1A**) in toluene at 110 °C for 50 h. This reaction did not give the expected Diels-Alder adduct (**9**)[12,13] but *p*-nitrobenzonitrile (**10**), dimethyl 2-methoxy-5-methyl-3,4-furandicarboxylate (**11**), and tetramethyl 3,5-epoxy-3-methoxy-5-methyl-1,4-cyclohexadiene-1,2,4,5-tetracarboxylate (**12**) in yields of 86, 20, and 25%, respectively. The reaction may be explained by the retro-Diels-Alder reaction of the adduct (**9**) to give *p*-nitrobenzonitrile and the furan derivative (**11**),[12, 13] followed by the second Diels-Alder reaction of DMAD on the furan (**11**) to produce the adduct (**12**).[13,14] When the reaction was carried out under milder conditions, at 100 °C for 24 h, *p*-nitrobenzonitrile and furandicarboxylate (**11**) were isolated in 30 and 34% yields respectively, along with 61% of the unreacted oxazole (**1A**). Further attempts to isolate the adduct **9** by conducting the reaction at the low temperature of 50 °C were also unsuccessful.

Retro-Diels-Alder Reaction. In order to explain the low yields of the Diels-Alder adducts between the oxazole (**1A**) and *N*-phenylmaleimide, we studied the retro-Diels-Alder reaction of the adducts **3c** and **4c** to reproduce the starting materials. During the recrystallization of the endo-adduct (**3c**), separated by the column chromatograhy of the reaction mixture, yellow crystals of *N*-phenylmaleimide (**2c**) were isolated in a pure state. When the decompositions of **3c** and **4c** were traced by means of NMR spectroscopy in a DMSO solution at 80 °C, the intensities of the signals of **3c** and **4c** decreased, with an accompanying increase in the intensities of the signals of **1A** at δ 2.41 (s, CH_3) and 4.12 (s, OCH_3) and the methine signal of **2c** at δ 7.13. After 200 h, both reaction systems gave mixtures of **1A** (**2c**), **3c**, and **4c** in about a 7:1:2 ratio. In these measurements, the thermal retro-Diels-Alder reactions of **3c** was found to be faster than that of **4c**. This may be explained by the steric repulsion in the endo-adduct. These types of retro-Diels-Alder reactions were also found for the adducts of *N*-methyl- and *N*-ethylmaleimides. However, the rates of the decomposition of these adducts were not so rapid as those of the *N*-phenylmaleimide adducts.

Experimental

The melting points were measured with a Yanagimoto Melting-point Apparatus and are presented without correction. The IR spectra were recorded on a Perkin-Elmer model 983. The ^{1}H NMR spectra were recorded in a $CDCl_3$ solution at 90 MHz on a Varian Spectrometer model EM390, using TMS as the internal standard.

Materials. 2-Alkyl-5-methoxy-4-(*p*-nitrophenyl)oxazoles were prepared by the BF_3-catalyzed decomposition of methyl (*p*-nitrophenyl)diazoacetate in the presence of acetonitrile or propionitrile, as has been described in a previous paper.[15]

5-Methoxy-2-methyl-4-(*p*-nitrophenyl)oxazole (1A): Pale yellow crystals; yield, 75%; mp 122.0—123.0 °C; ^{1}H NMR δ=2.43 (s, CH_3), 4,12 (s, OCH_3), 7.85 and 8.20 (ABq, Ar). Found: C, 56.56, H, 4.29; N, 11.90%. Calcd for $C_{11}H_{10}N_2O_4$: C, 56.41; H, 4.30; N, 11.96%.

2-Ethyl-5-methoxy-4-(*p*-nitrophenyl)oxazole (1B): Pale yellow needles; yield, 84%; mp 96.0—97.0 °C; ^{1}H NMR δ=1.36 (t, CH_3), 2.76 (q, CH_2), 4.13 (s, OCH_3), 7.92 and 8.23 (ABq, Ar). Found: C, 58.26, H, 4.87; N, 11.27%. Calcd for $C_{12}H_{12}N_2O_4$: C, 58.06; H, 4.87; N, 11.29%.

General Procedure of the Diels-Alder Reaction of 1 with Maleimides. A solution of **1** (2.0 mmol) and maleimide (2.5 mmol) in acetonitrile (or toluene) was heated at 60—110 °C for several hours, as shown in Table 1. After the evaporation of the solvent under reduced pressure, the products were separated by silica-gel column chromatography,

using benzene as the eluent.

Reaction of 1A with Diethyl Azodicarboxylate. A benzene solution of **1A** (0.23 g, 1.0 mmol) and diethyl azodicarboxylate (0.17 g, 1.0 mmol) was heated at 80 °C for 48 h. After the usual treatment, an adduct (**7**) was isolated: yield, 0.37 g; 91%; mp 116—117 °C; IR 1751 (ester C=O), 1523, and 1353 cm^{-1} (NO_2); ^1H NMR δ=1.30 (t, CH_3), 1.33 (t, CH_3), 2.46 (s, CH_3), 3.76 (s, OCH_3), 4.29 (q, CH_2), 7.81 and 8.22 (ABq, Ar).

Reaction of 1A with 4-Phenyl-3*H*-1,2,4-triazole-3,5(4*H*)-dione. A toluene solution of **1A** (0.47 g, 2.0 mmol) and 4-phenyl-1,2,4-triazoline-3,5-dione (0.35 g, 2.0 mmol) was heated at 100 °C for 9 h to give an adduct (**8**; 0.56 g, 69%): Pale yellow crystals; IR(KBr) 1730 (ring C=O), 1515, and 1355 cm^{-1} (NO_2); ^1H NMR δ=2.50 (s, CH_3), 3.73 (s, OCH_3), 7.45 (s, Ph), 7.86 and 8.39 (ABq, Ar).

Reaction of 1A with Dimethyl Acetylenedicarboxylate. A toluene solution of **1A** (0.70 g, 3.0 mmol) and DMAD (0.85 g, 6 mmol) was heated at 120 °C for 50 h. After the evaporation of the toluene under reduced pressure, the reaction products were separated by silica-gel column chromatograhy to isolate three products. The first fraction was assigned to *p*-nitrobenzonitrile (0.38 g, 86%) on the basis of a comparison of the spectral data with those of an authentic sample. The second fraction was characterized dimethyl 5-methoxy-2-methyl-3,4-furandicarboxylate (**11**): Colorless crystals; yield, 0.14 g; 20%; mp 60—63 °C; IR(KBr) 1705 cm^{-1} (ester C=O); ^1H NMR δ=2.38 (s, CH_3), 3.79 (s, OCH_3), 3.83 (s, OCH_3), and 4.06 (s, OCH_3). The third fraction was tetramethyl 3,5-epoxy-3-methoxy-5-methyl-1,4-cyclohexadiene-1,2,4,5-tetracarboxylate (**12**): Colorless oil; yield, 0.28 g; 25%; IR(liquid film) 1710 cm^{-1} (ester C=O); ^1H NMR δ=1.92 (s, 3H, CH_3), 3.61 (s, 3H, OCH_3), 3.80 (s, 6H, OCH_3), and 3.84 (s, 6H, OCH_3).

Perfluoroalkylations of Carbanions with (Perfluoroalkyl)-phenyliodonium Triflates (FITS Reagents)

Teruo UMEMOTO* and Yoshihiko GOTOH
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received August 29, 1985)

FITS reagents reacted with primary alkylmagnesium halides in THF at −78 °C to give the corresponding perfluoroalkyl(R_f)-alkanes in moderate to good yields. But an alkyl-lithium or -copper gave a poor yield of the R_f-product. The reaction of FITS with secondary or tertiary alkylmagnesium halides resulted in low yields of the products. Alkynyl-lithiums or -magnesium halides produced R_f-alkynes in favorable yields. The reaction with aryl or vinylmagnesium halide was complex and the yields of R_f derivatives were low. FITS also reacted smoothly with enolate anions of active methylene compounds such as 2-methyl-1,3-cyclopentanedione, ethyl 2-methylacetoacetate, and ethyl 2-oxocyclopentanecarboxylate in a polar solvent to afford *O*- and *C*-perfluoroalkylation products in moderate yields, ratios *O*-/*C*-Rf products depending on the reaction temperature. Anions of diethyl 2-methylmalonate and 2-nitropropane afforded *C*-R_f-compounds only.

There have been many investigations on perfluoroalkylations of organic compounds, but the perfluoroalkylations of carbanions have never been reported.[1] This may be because it was very difficult to generate electrophilic perfluoroalkyl(R_f) species, since the R_f group has an extraordinary high electronegativity.[2] We have developed (perfluoroalkyl)-phenyliodonium triflates (FITS reagents) as useful electrophilic perfluoroalkylating agents[3,4] and partly described the perfluoroalkylations of carbanions in the preliminary report.[5] After that, *C*-perfluoroalkylations of β-diketones in liquid ammonia and of 2-nitropropyl anion with iodoperfluoroalkanes under irradiation were reported by L. M. Yagupol'skii's group[6] and A. E. Feiring,[7] respectively. This paper describes perfluoroalkylations of a variety of carbanions, and *O*- and *C*-perfluoroalkylations of active methylene compounds with FITS reagents.

Results and Discussion

Reaction of Grignard Reagents with FITS. FITS reacted with several kinds of Grignard reagents to give perfluoroalkyl derivatives in varying yields.

$$R_f\text{-}\underset{\underset{\text{Ph}}{|}}{\text{I}}\text{-OTf} + \text{RMgX} \longrightarrow R_f\text{-R} + \text{PhI} \qquad (1)$$

FITS-*m* (1) (2)

(R_f=*n*-C_mF_{2m+1})

Iodobenzene was formed in 70—95% isolated yield as another product. The reaction conditions of FITS-8 with octylmagnesium bromide are shown in Table 1. The best yield (52%) was obtained when FITS was added dropwise into a solution of an equivalent amount of the magnesium bromide in THF at −78 °C (Run 1). The reaction seemed to be fast, though the reaction mixture was stirred for 2 h. The reverse addition decreased the yield in some degree (Run 2) and there was no change in the yield at lower temperatures (Run 3). FITS-8 reacted with octylmagnesium chloride under the same conditions as in Run 1 to yield the product in a 58% yield. The yield was somewhat better than that of the bromide (52%). The results and reaction conditions of the reaction with several kinds of Grignard reagents are summarized in Table 2. No difference in reactivity among different carbon numbers of the *n*-R_f groups of FITS was observed. On the other hand, there was a significant difference between primary and secondary or tertiary Grignard reagents, and the secondary and tertiary reagents remarkably hindered the reaction (Run 6 and 7). Reactions of FITS-8 with Grignard reagents of sp^2 carbons, *p*-tolylmagnesium chloride and vinylmagnesium bromide, yielded complex mixtures, from which *p*-(perfluorooctyl)toluene and (perfluorooctyl)-ethylene were isolated in low yields, respectively, along with a small amount of (perfluorooctyl)-benzene. No formation of (perfluorooctyl)benzene

5	n-$C_8H_{17}Li$	9

was observed with sp^3 or sp carbon Grignard reagents.

We examined the reaction of FITS with other organometallic compounds and showed the results in Table 3. It is worth noting that the reaction with the lithium salt was complex and the yield was very low. Grignard reagents provided the best yield of all the organometallic compounds used.

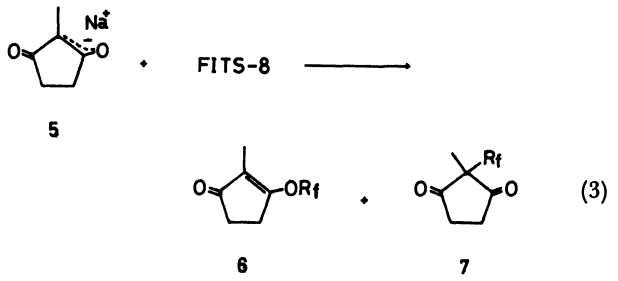
Reaction of Acetylides with FITS. FITS-8 reacted with an equimolar lithium salt of phenylacetylene in THF at −78°C to give Rf-compound **4** (R=Ph) in favorable yield (Run 1 in Table 4).

$$\text{FITS-}m + \underset{\mathbf{3}}{\text{R-C}\equiv\text{CM}} \longrightarrow \underset{\mathbf{4}}{\text{R-C}\equiv\text{C-R}_f} \quad (2)$$

M=Li, MgX

Elevated temperature, excess of the lithium salt, or the reverse addition method resulted in lowering the yield (Runs 2, 3, and 4 in Table 4). Interestingly, it was found that β-(perfluorooctyl)styrene was formed in 11, 9, and 4% yields in Runs 2, 3, and 4, respectively, which was proved to be a 1:1 mixture of cis and trans isomers by comparison with authentic samples. At present the mechanism of the formation of the R_f-styrene is quite unclear. Table 5 shows the results of the reactions with several kinds of acetylides under similar conditions as in Run 1 in Table 4. It is interesting that there was no difference between the lithium salt and the magnesium chloride of phenylacetylene in contrast to the great difference between octyllithium and octylmagnesium chloride. Furthermore, it is worth noting that the acetylides (sp carbanions) afforded good yields of the products, while the reactions of vinyl or aryl anions (sp^2 carbanions) were complex and their yields were low.

Reaction of Enolate Anions of Active Methylene Compounds with FITS. FITS was allowed to react with sodium salt of 2-methyl-1,3-cyclopentanedione **5** in DMF at 0°C for 3h, giving *O*- and *C*-perfluoroalkylated compounds **6** and **7** in 26 and 7% yields, respectively. The ^{19}F chemical shifts of α-CF_2



(3)

groups clearly reflect the structural difference between **6** and **7**. The CF_2 group bonding to the oxygen atom in **6** appears at 80.1 ppm as a multiplet, while the CF_2 bonding to the carbon atom in **7** at 112.8 ppm. The effect of solvents and reaction temperature on the perfluoroalkylation was investigated and the results are summarized in Table 6. The reaction was exothermic and other products were tarry materials. Polar solvents such as DMF and DMSO were needed for the alkylation. The reaction at room temperature in DMF or DMSO afforded only the *O*-R_f-product **6**. With a lowering of the temperature, **6** decreased, while the *C*-R_f-product **7** increased. In hydrocarbon system, a similar temperature-dependent change of the ratios of *O*/*C*-alkylation was observed in butylation of an enolate anion of ethyl acetoacetate with butyl halides.[8] The above results are very different from the photo-reaction of β-diketones with iodoperfluoroalkanes in liquid

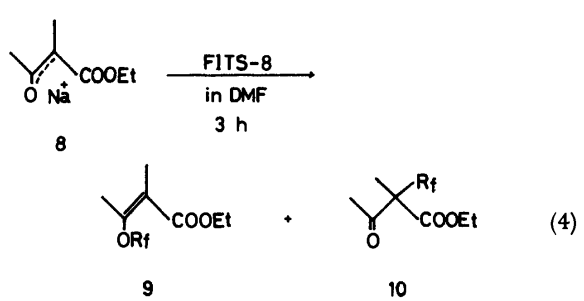
4	DMF	−55	7	31	0.23
5	DMSO	R.t.	20	0	
6	THF	−30	Trace	0	

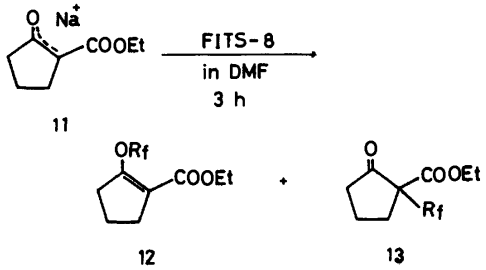
a) Reaction time 3 h.

ammonia, which gave only C-R_f-products.[6]

Similarly FITS reacted with enolate anions of β-keto esters **8** and its cyclic ester **11** in DMF at 0°C to afford C-R_f-compounds **10** and **13** as major products along with a small amount of O-R_f-compounds **9** and **12**, respectively. Both the keto esters showed analogous behavior and it is in contrast to the case of the β-diketone **5** in which the O-product **6** was a main product at 0°C. The C-products **10** and **13** increased further at lower temperatures.



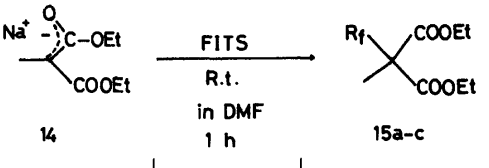
(4)



(5)

Temp/°C	**9**	**10**	**12**	**13**
0	8%	28%	8%	20%
−55	5%	36%	6%	29%

Sodium salt of diethyl 2-methylmalonate **14** reacted exothermically with FITS-8 at room temperature for 1 h to produce only a C-R_f-compound **15a** in a 24% yield. Other products were tarry materials, so their assignment was not made. In this reaction, the effect of the R_f groups was examined by using FITS-8 and -3, and FITS(F)-3*i*[9] (Eq. 6).



(6)

	R_f	Yield/%
15a	n-C_8F_{17}	24
15b	n-C_3F_7	20
15c	i-C_3F_7	3

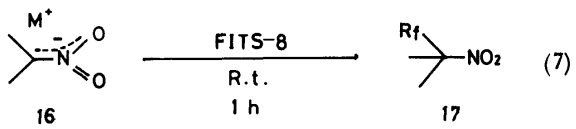
Table 7. Reaction of **16** with FITS-8[a)]

Run	**16**	Solv.	Yield of **17**/%
1	M=Na	DMSO	43
2	M=Na	DMF	33
3	M=Na	Et_2O	22
4	M=Li	DMSO	49
5	M=Li	DMF	51
6	M=Li	Et_2O	18

a) Reaction time; 1 h, temp; room temperature.

Similar yields were obtained in the cases of FITS-8 and -3 having primary R_f, but FITS(F)-3*i* bearing perfluoroisopropyl group gave a very low yield of **15c**. Thus, the secondary R_f group strongly hindered the desired reaction.

The reaction of FITS-8 with 2-nitro-2-propanide anion **16** was run in several solvents at room temperature for 1 h. The reaction occurred exothermically and yielded 2-R_f-2-nitropropane **17** only in varying yields. The results are summarized in Table 7. Polar solvents gave better yields and the lithium



(7)

salt in the polar solvents afforded somewhat better yields than the sodium salt.

FITS-8 was also treated with an enolate anion of acetophenone under several conditions to give a mixture of α-(perfluorooctyl)acetophenone and its dehydrofluorination product, 2-fluoro-2-(perfluoroheptyl)vinyl phenyl ketone in low yields (<17%). Therefore, the reaction of FITS with enol silyl ethers was much better as a synthetic method of α-(perfluoroalkyl) ketones because high yields were obtained and the reaction procedure was simple.[10)]

Experimental

^{19}F Chemical shifts are given in ppm upfield from $CFCl_3$ as an internal standard. A gas chromatograph with a column of 10% SE-30 on Chromosorb WAW DMCS was used for the isolation or analysis of the products. FITS reagents were prepared by the method described previously.[3)] Reaction solvents were purified and dried by the usual methods. All the reactions were done under argon atmosphere.

Note: FITS reagents decomposed soon in diethyl ether or sooner in THF at room temperature. Therefore, if necessary, FITS must be dissolved in the solvents at −78 °C.

Reaction of FITS with Grignard Reagents. Typical Procedure: Into a solution of 1.4 mmol of Grignard reagent (0.4—0.8 mmol ml^{-1} of THF or diethyl ether) in 13 ml of THF at −78 °C, was added 1.3 mmol of FITS reagent in several portions with stirring. After the reaction mixture was stirred at −78 °C for additional 2 h, it was quenched with aq ammonium chloride and extracted with pentane. The extract was dried with magnesium sulfate and concentrated. The desired R_f-compound was seperated from iodobenzene as another product by column chromatography of the residue on silica gel using pentane as an eluent and then distilled.

Grignard reagents were prepared from the halides in THF or diethyl ether by the usual method. The organocopper compounds used as shown in Table 3 were prepared by the methods reported.[11)]

The reaction with Grignard reagents was carried out at different temperatures in different solvents as shown in Tables 1 and 2.

In the case of the reaction of FITS-8 with benzylmagnesium chloride, the residue resulting from the extraction with ether was treated with Raney Ni (W-2)[12)] in ethanol to reduce iodobenzene to benzene, because it was difficult to seperate the R_f-product from iodobenzene by column chromatography or distillation. After the reduction, the resulting residue was distilled to give (1*H*, 1*H*-heptadecafluorononyl)benzene in a 38% yield.

The yields of the volatile R_f-products were determined by NMR or gas chromatography. Spectral data and elemental analyses of new compounds are summarized in Table 8.

Reaction of FITS with Acetylides. Typical Procedure: Into a solution of 1.32 mmol of an alkyne in 8 ml of THF at −78 °C, was dropwise added a solution of 1.32 mmol of butyllithium in 0.96 ml of hexane with stirring. The solution was stirred for additional 10 min and 1.32 mmol of FITS reagent was added in several portions into it at −78 °C. After the reaction mixture was stirred for additional 5 min at −78 °C, it was warmed to −30 °C for a period of 25 min, quenched with aq ammonium chloride, and extracted with pentane. The extract was dried with magnesium sulfate and concentrated. The residue was column-chromatographed on silica gel using pentane to give the R_f-alkyne. The yields of the volatile R_f-products were determined by NMR or gas chromatography of the concentrated extracts, as shown in Table 5. The spectral data and elemental analyses of the products are shown in Table 8.

Reaction of FITS with Enolate Anions 5, 8, 11, and 14. Typical Procedure: A solution of 2-methyl-1,3-cyclopentanedione (168 mg, 1.5 mmol) in 8 ml of DMF was added dropwise into a mixture of sodium hydride (1.7 mmol) and 5 ml of DMF with stirring. The reaction mixture was stirred for an additional 15 min at room temperature and cooled to −55 °C. Then FITS-8 (772 mg, 1 mmol) was added into the solution of the enolate anion. After an additional stirring for 3 h at −55 °C, the mixture was quenched with 3 mol dm^{-3} hydrochloric acid and extracted with ether. The organic layer was washed with water, dried with magnesium sulfate, and concentrated. Two isomers were separated by column chromatography on silica gel using a mixture of pentane and ether as an eluent and then each distillation gave 38 mg (7%) of **6** and 163 mg (31%) of **7**. Products **9** and **15c** were isolated by gas chromatography after column chromatography. Products **15a** and **15b** were isolated by column chromatography only. The results are shown in Table 6 and in Eqs. 4—6.

Reaction of FITS with 16. Typical Procedure: Sodium or lithium 2-nitro-2-propanide was prepared according to the method described in the literature.[13)] FITS-8 (1.33 mmol) was added into a solution of **16** (2.00 mmol) in 10 ml of DMF at room temperature with stirring. After an additional stirring for 1 h, some water was added into the reaction mixture and the mixture was extracted with ether. The post-

Synthesis and Reactivity of *N*-Trifluoromethyl-*N*-nitrosotrifluoromethanesulfonamide as a New Type of Trifluoromethylating Agent

Teruo UMEMOTO* and Akira ANDO†
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received September 21, 1985)

N-Trifluoromethyl-*N*-nitrosotrifluoromethanesulfonamide (TNS-Tf) was synthesized in a 58% yield by the reaction of trifluoronitrosomethane with hydroxylamine followed by the treatment with trifluoromethanesulfonyl fluoride in the presence of a base. TNS-Tf was demonstrated to be an effective trifluoromethylating agent photochemically or thermally for aromatics, thiols, disulfides, and uridine derivatives. The insertion reaction by two trifluoromethyl groups of TNS-Tf to the sulfur-sulfur bonds was observed in the reaction with disulfides having electron-withdrawing groups, giving 2 mols of trifluoromethylthio compounds. Furthermore, TNS-Tf served as a good reagent for mild and convenient in situ generation of trifluoromethylcopper complex which converted iodoaromatics to trifluoromethyl-substituted aromatics in good yields. Similarly, *N*-trifluoromethyl-*N*-nitrosononafluoro-1-butanesulfonamide (TNS-Nf) was synthesized in a 36% yield. The examination of the reactivity indicated that this type of *N*-nitroso sulfonamides became to be sources of both perfluoroalkyl radicals contained.

Much attention has been riveted to trifluoromethyl-containing compounds in the fields of medicine and agricultural chemicals because of the attractive effect of the trifluoromethyl groups on biological activity.[1] Therefore, there have been many investigations for introduction of trifluoromethyl groups into organic compounds. There have been two essential approaches, conversion of trichloromethyl or carboxy groups to trifluoromethyl groups with HF,[2,3] SbF_5,[4] or SF_4[5] and direct introduction of trifluoromethyl groups with trifluoromethyl iodide[6-17] or bromide,[18] trifluoroacetic acid or its salt.[19-21] However, the studies on the syntheses of new reactive trifluoromethylating agents were little reported.[22] Previously we presented the synthesis of *N*-trifluoromethyl-*N*-nitrosobenzenesulfonamide (TNS-B) as a new photochemical trifluoromethylating agent.[23] However the yields for trifluoromethylation were somewhat low and TNS-B was too thermal stable to act as a thermal reagent. In order to enhance the reactivity, we altered it according to our idea that the more the electronegativity of phenyl group of TNS-B rises the more the reactivity increases. Although we replaced the phenyl group of TNS-B with *p*-nitro- or 2,4-dinitrophenyl,[24] their reactivities were rather low. Thus, we expected a great variation in the reactivity by replacement of the aryl group with a perfluoroalkyl group because of its extraordinary high electronegativity.[25] As a result, we could develop a novel and effective trifluoromethylating agent. This paper describes the synthesis and reactivity of *N*-trifluoromethyl-*N*-nitrosotrifluoromethanesulfonamide (TNS-Tf) as a new type of trifluoromethylating agent.

Results and Discussion

TNS-Tf was synthesized in a 58% yield by the reaction of trifluoronitrosomethane with hydroxylamine in DMF/Et_2O (4/1) at −65 °C followed by the treatment with trifluoromethanesulfonyl fluoride at −65—−60 °C for 20 h in the coexistence of sodium hydride.

$$CF_3NO \xrightarrow[-65^{\circ}C]{NH_2OH} [CF_3N{=}NOH] \xrightarrow[NaH]{R_fSO_2F} CF_3{-}\overset{\overset{N=O}{|}}{N}{-}SO_2R_f$$

TNS-Tf (R_f=CF_3)
TNS-Nf (R_f=*n*-C_4F_9)

When trifluoromethanesulfonyl chloride was used instead of the fluoride, TNS-Tf could not be synthesized. TNS-Tf is colorless volatile liquid (mp 3.2—4 °C). Since it is stored in acetonitrile at room temperature for a long time, TNS-Tf can easily and safely be treated as an acetonitrile solution (1—0.5 mol dm^{-3}).

TNS-Tf was found to be a useful photochemical or thermal trifluoromethylating agent for aromatics, thiols, disulfides, and uridine derivatives. The reactions proceeded with evolution of gas. The photochemical reaction was carried out in acetonitrile by using a high pressure Hg lamp and biacetyl as a sensitizer. The results are summarized in Table 1. The trifluoromethylation smoothly took place in the case of electron-rich aromatic compounds and the substitution occurred preferentially at electron-rich positions as shown in Run 2. In this way, TNS-Tf has electrophilic nature. In addition, the trifluoromethylation showed a high *ortho-para* substitution ratio as shown in the reaction of acetanilide (*o*/*p*=4/1). It is in sharp contrast to classical electrophilic substitution of acetanilide (*o*/*p*=1/19 in the nitration).[26] Our method was successfully applied to the preparation of trifluoromethylated dopamine derivative (Run 6), whereas the trifluoromethylation with gaseous trifluoromethyl iodide needed an excess of the substrate and the yield was low.[27] The reaction with such activated aromatics as *p*-*t*-butylphenol and *p*-dimethoxybenzene was accompanied with the formation of considerable amount of

†Present address; Faculty of Pharmaceutical Sciences, Setsunan University, 45-1 Nagaotoge-cho, Hirakata, Osaka 573-01.

Table 1. Photochemical Trifluoromethylation with TNS-Tf

Run[a]	Substrate	Molar equiv of TNS-Tf	Time h	Product[b]	Yield[c] %	^{19}F-NMR[d]

a) Acetonitrile was used as a solvent except for Run 10 where acetone was used. b) See the experimental section for spectral data of new compounds. The known compounds were spectroscopically in agreement with authentic samples or spectral data reported. c) Yields were calculated on the basis of substrates except for Run 1 in which the yield was on the basis of TNS-Tf. d) Chemical shifts (ppm, upfield from $CFCl_3$ as an internal standard) of trifluoromethyl groups are given. e) ^{19}F-NMR yields. f) Isolated yields. g) 2,6-Bis(CF_3)-4-*t*-butylphenol as another product was isolated in a 17% yield based on the substrate (34% based on TNS-Tf). h) Yields were calculated based on TNS-Tf. i) 2,3-Bis(CF_3)-1,4-dimethoxybenzene and 2,5-bis(CF_3)-1,4-dimethoxybenzene were produced in 7 and 9% ^{19}F-NMR yields based on the substrate, respectively (14 and 18% based on TNS-Tf). Their spectral data are shown in the experimental section. j) This starting material was prepared by treating L-cystine with trifluoroacetic anhydride in trifluoroacetic acid at −10 to +10 °C. k) This starting material was prepared by treating DL-homocystine in the same manner as the case of j) followed by esterification with diazomethane. l) Ref. 24. m) Bp 60 °C/20 mmHg (1 mmHg=133.322 Pa). n) Bp 125 °C/21 mmHg [lit, 88—88.5 °C/15 mmHg, V. V. Boiko, G. M. Shchupak, and L. M. Yagupol'skii, *J. Org. Chem. USSR*, **13**, 972 (1977)]. o) Bp 120 °C/17 mmHg (lit, 108 °C/22 mmHg, J. F. Harris, Jr., USP 3522293). p) BP 106 °C/17 mmHg. q) Ref. 15.

bis(trifluoromethyl)aromatics (34% in Run 3 and 32% in Run 4, based on TNS-Tf). Accordingly, the total yields of trifluoromethylated aromatics in Runs 3 and 4 were 99 and 92% based on TNS-Tf, respectively. It indicated that TNS-Tf is an effective source of trifluoromethyl groups. Deactivated aromatics such as methyl benzoate did not give any trifluoromethylated products. Photochemical decomposition of TNS-Tf itself occurred. TNS-Tf could not trifluoromethylate such nitrogen-containing compounds as pyridine and aniline because TNS-Tf was decomposed by them.

The reaction of mercaptoacetic and 3-mercaptopropionic acids with TNS-Tf afforded (trifluoromethylthio) acetic and -propionic acids in 86 and 89% isolated yields, respectively. It is in contrast to the reaction of the phenyl analogue TNS-B, of which reaction with 3-mercaptopropionic acid yielded only a trace of the product. 1-Heptanethiol, an easily oxidizable thiol, gave a moderate yield of the product. Until now, trifluoromethylation of thiols was the photochemical or thermal action of trifluoromethyl iodide on the thiols under basic conditions.[8,15] TNS-Tf afforded a useful method for thiols or products which are unstable to basic conditions (for example Runs 9, 11, and 12).

TNS-Tf was a good reagent for the conversion of disulfides to trifluoromethylthio compounds. The yields were calculated according to the following equation. Actually the reaction of 2.73 mmol of TNS-

$$\mathbf{R\text{-}S\text{-}S\text{-}R} + \text{TNS-Tf} \longrightarrow 2\,\mathbf{CF_3\text{-}S\text{-}R}$$

Table 2. Thermal Trifluoromethylation with TNS-Tf

Run[a]	Substrate	Molar equiv of TNS-Tf	Temp °C	Time h	Product	Yield[b] %
1[c]	*t*-Butylphenol	1.0	110	22	2-CF_3-4-*t*-butylphenol[c]	69
2	$(n\text{-}C_{10}H_{21}S)_2$	1.5	80	1.5	$n\text{-}C_{10}H_{21}SCF_3$	23
3	$(SCH_2CH_2COOH)_2$	1.0	80	23	$CF_3SCH_2CH_2COOH$	47

a) Acetonitrile was used as a solvent. b) Isolated yields which were calculated on the basis of substrates. c) In addition, 2,6-bis(trifluoromethyl)-4-*t*-butylphenol was isolated in 15.5% yield.

Table 3. Preparation of 1-Trifluoromethylnaphthalene from 1-Iodonaphthalene by CF_3 Copper Complex Generated In Situ from TNS-Tf and Copper

Run	Solvent	Temp/°C	Time/h	Yield/%[b]
1	$HMPA/CH_3CN(5/2)$[a]	100	18	86
2	$NMP/CH_3CN(5/2)$[a]	100	19	93
3	$DMF/CH_3CN(5/2)$[a]	100	19	88
4	CH_3CN	Reflux	19	52

a) The amount of acetonitrile is that of acetonitrile solution (0.5 mol dm^{-3}) of TNS-Tf used. b) ^{19}F-NMR yields.

Tf with 2.28 mmol of *N*-trifluoroacetylcystine gave 3.75 mmol of the product (82% based on the disulfide, Run 11). In this way, two trifluoromethyl groups of TNS-Tf were consumed in the insertion reaction. The trifluoromethionine derivative was prepared in a 71% yield by TNS-Tf (Run 12), whereas the yield by TNS-B was 30% only. This insertion reaction followed by hydrolysis provided an effectual method for the preparation of trifluoromethionine, a competitive inhibitor of methionine activation,[28] compared with the known method[29] starting from acrylaldehyde and gaseous trifluoromethanethiol because of easiness of operation, availability of the amino acid as a starting material, high yield, and short steps.

TNS-Tf is the first to make it possible to trifluoromethylate the uridine derivative directly, giving the biologically interesting 5-trifluoromethyluridine derivative (Run 13).[1] Our method is advantageous compared with the stepwise synthesis.[17]

The thermal trifluoromethyaltion with TNS-Tf was accomplished by heating an equimolar mixture of TNS-Tf and a substrate in acetonitrile in a sealed tube. The results are shown in Table 2 and are similar to the photochemical reaction.

Interestingly, it was found that an exothermic reaction occurred with evolution of gas when a solution (0.5 mol dm^{-3}) of TNS-Tf (1 equimol) in acetonitrile was added dropwise into a mixture of activated copper powder (2 equimol) in such solvents as HMPA, NMP, DMF, and acetonitrile at room temperature. This is a good example for high reactivity of TNS-Tf. The reaction mixture resulted in an almost homogeneous brown solution. Iodonaphthalene (0.4 equimol) was added into the brown solution and the reaction mixture was heated to give trifluoromethylnapthalene in a high yield without the formation of naphthalene. Advantageously, no reduction of iodine atom by copper occurred. It is due to the complete reaction of TNS-Tf with copper. Reduction of aromatic iodides by copper was reported in the trifluoromethylation with trifluoromethyl iodide and copper.[10] The results and reaction conditions are shown in Table 3. These facts

$$\text{TNS-Tf} \xrightarrow[\text{R.t.}]{\text{Cu}} CF_3\text{–Cu Complex} \xrightarrow[\Delta]{\text{ArI}} \text{Ar–}CF_3$$

suggested that the reaction of TNS-Tf with copper formed trifluoromethylcopper complex, because it has been well-known that trifluoromethylcopper reacted with iodoaromatics to give trifluoromethyl compounds.[12,30] There have been many reports about the methods for the formation of the copper.[6,7,10,12,21,30] It was demonstrated that trifluoromethylcopper in situ generated afforded high yields and wide application for the preparation of trifluoromethyl compounds, compared with the copper transiently formed.[12,30] The reaction of trifluoromethylcopper complex generated in situ from TNS-Tf with several kinds of haloaromatics was carried out and the results are summarized in Table 4. Trifluoromethyl compounds were prepared from iodo compounds in good yields, while bromo compounds gave poor yields of the products under our conditions. Dodecyl iodide did not afford the corresponding trifluoromethyl compound under our conditions, although it was reported that trifluoromethylcopper in situ generated from trifluoromethyl iodide and copper in HMPA at 120 °C was treated with decyl iodide to give 1,1,1-trifluoroundecane in a 48% yield.[12] Our method using TNS-Tf is advantageous in generating in situ the copper complex conveniently under very mild conditions compared with the known methods which needed high tempearture or pressure reaction and removal of excess or remaining copper by filtration in a dry box.[12,30]

Table 4. Trifluoromethylation of Haloaromatics by CF_3 Copper Complex from TNS-Tf

Run	Haloaromatics	Method[a]	Product[b]	Yield/%[c]

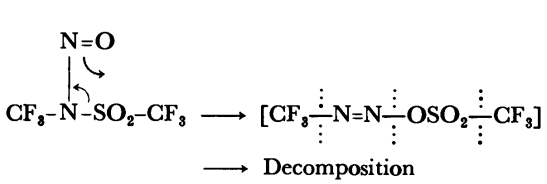
					2-C_4F_9-1,4-dimethoxybenzene	47

a) All the reactions were carried out in acetonitrile. b) See the experimental section for spectral data of new compounds. c) Isolated yields which were calculated on the basis of TNS-Tf.

We also synthesized *N*-trifluoromethyl-*N*-nitrosononafluoro-1-butanesulfonamide (TNS-Nf) in a 36% yield in a similar manner as TNS-Tf. The results of the thermal and photochemical reactions with *p*-*t*-butylphenol and *p*-dimethoxybenzene are shown in Table 5. In every case, two kinds of products, trifluoromethyl and nonafluorobutyl compounds were formed, indicating that both trifluoromethyl and nonafluorobutyl radicals were generated from TNS-Nf, probably, by homolytic fission. It suggested that both trifluoromethyl groups in TNS-Tf participated in the trifluoromethylation. The mass spectrum of the gas evolved from the photoreaction of TNS-Tf with *p*-*t*-butylphenol in acetonitrile (Run 3 in Table 1) indicated that nitrogen and hexafluoroethane were contanined in the gas as main components but dinitrogen monoxide wasn't. The formation of nitrogen and hexafluoroethane suggested the isomerization of TNS-Tf to the azo compound followed by decomposition



through the homolytic cleavage. It was reported that hydrocarbon analogues of nitrososulfonamides, *N*-alkyl-*N*-nitrosotoluenesulfonamides, easily isomerized to the corresponding azo compounds which decomposed through heterolytic fission.[31] Although the acetonitrile solution didn't contain triflic acid after the reaction, the solution became acidic. Probably it is due to the formation of sulfur trioxide as a by-product. It was reported that trifluoromethanesulfonyloxyl radical easily decomposed to release sulfur trioxide.[32]

Experimental

Melting and boiling points were uncorrected. ^1H NMR spectra were determined with a Varian HA-100 NMR spectrometer or a Varian EM 390 NMR spectrometer. ^{19}F NMR spectra were determined with a Varian XL-100A NMR spectrometer or a Hitachi R-20B NMR spectrometer. ^{19}F Chemical shifts are given in ppm upfield from trichlorofluoromethane as an internal standard. IR spectra were measured on a Jasco A-202 diffraction grating infrared spectrometer. Mass spectra were recorded on a Hitachi RMU-6MG spectrometer at 70 eV. GLC analyses were carried out with Ohkura 802 Gas Chromatograph, using a column (2 mm×3 m) packed with Silicone SE-30 (10%) on Chromosorb WAW DMCS. Riko Kagaku UVL-400P Hg lamp was used for the photoreaction. *N*,*N*-Dimethylformamide (DMF) used was distilled on a small amount of triphenylchlorosilane to remove amines contained, after drying with molecular sieve 3A.

Material. Trifluoronitrosomethane was prepared according to our method reported previously.[33]

Caution. Neat TNS-Tf or TNS-Nf must not be allowed to stand at room temperature because of possible violent decomposition and can be stored for a long time (more than one year) in a deep freezer (−20°C). As mentioned earlier, TNS-Tf can easily and safely be treated as an acetonitrile solution (1—0.5 mol dm^{-3}) at room temperature.

***N*-Trifluoromethyl-*N*-nitrosotrifluoromethanesulfonamide (TNS-Tf).** At −65 °C, trifluoronitrosomethane (16.1 g, 0.163 mol) was blown into a solution of hydroxylamine which was prepared by the treatment of hydroxylamine hydrochloride (10.9 g, 0.156 mol) with potassium *t*-butoxide (17.5 g, 0.156 mol) in 207 ml of a mixture of DMF/diethyl ether (4/1). An excess of the nitrosomethane was removed by flowing argon. After the introduction of 25.0 g (0.165 mol) of trifluoromethanesulfonyl fluoride, sodium hydride (50% in oil, 8.25 g, 0.172 mol) was added in several portions. All operations described above were performed at −65—−60 °C. The mixture was stirred for 20 h at −65 °C and warmed to −50 °C. At this temperature, pentane (20 ml) was added and then the mixture was allowed to warm to −20 °C. The mixture was poured into water and extracted with pentane (60 ml×3). The pentane solution was washed with water, dried ($MgSO_4$), and filtered. The filtrate (room temperature) was transfered to a trap cooled to −78 °C by trap-to-trap distillation in vacuo to remove high boiling materials (nujol and others) from the filtrate. Then the distillate was cooled to −90 °C—−100 °C. TNS-Tf crystallized from the solution and then was isolated as colorless crystals by removing the solvent with a syringe at the low temperature. Further purification by the trap-to-trap method in vacuo from −78 °C to −196 °C gave 22.3 g of colorless volatile crystals (58%); mp 3.2—4 °C; ^{19}F NMR ($CDCl_3$, ppm) 69.7 (3F, m, N-CF_3), 76.5 (3F, bs, SO_2CF_3); IR (neat, cm^{-1}) 1545 (N=O), 1415 (SO_2). Elemental analysis was not done because of instability at room temperature.

***N*-Trifluoromethyl-*N*-nitrosononafluoro-1-butanesulfonamide (TNS-Nf).** Trifluoronitrosomethane was allowed to react with hydroxylamine followed by the treatment with nonafluoro-1-butanesulfonyl fluoride in the same manner as the case of TNS-Tf. The reaction mixture was extracted with diethyl ether. The ethereal layer was washed with water till the aqueous layer was neutral (pH 6—7), dried ($MgSO_4$), filtered and then concentrated on an ice bath by using an aspirator. The residue (yellow oil) was purified by the trap-to-trap method at low temperature to give TNS-Nf as colorless liquid in a 36% yield. ^{19}F NMR ($CDCl_3$, ppm) 69.4 (3F, bs, CF_3N), 81.0 (3F, m, CF_3), 109.9 (2F, m, CF_2), 120.0 (2F, m, CF_2), 125.3 (2F, m, CF_2); IR (Neat, cm^{-1}) 1540 (N=O), 1420 (SO_2). Elemental analysis was not done because of instability at room temperature.

Photochemical Trifluoromethylation with TNS-Tf or -Nf. A Typical Experimental Procedure: A solution of 75 mg (0.50 mmol) of 4-*t*-butylphenol, 43.2 mg (0.50 mmol) of biacetyl, and 127.9 mg (0.52 mmol) of TNS-Tf in 2 ml of acetonitrile was degassed by a freeze-thaw cycle, sealed in a Pyrex tube equipped with a stopcock, and was irradiated under water bath cooling for 5 h with a 400W high pressure Hg lamp. The reaction mixture was chromatographed over silica gel (10% Et_2O/pentane) to give 24.9 mg (17%) of 2,6-Bis(CF_3)-4-*t*-butylphenol and 71 mg (65%) of 2-CF_3-4-*t*-butylphenol.

2,6-Bis(CF_3)-4-*t*-butylphenol: Oil; ^1H NMR ($CDCl_3$) δ=1.33 (9H, s, 3×CH_3), 5.93 (1H, broad peak, OH), 7.68 (2H, bs, ArH); ^{19}F NMR ($CDCl_3$, ppm) 61.2 (s, CF_3).

2,5-Bis(CF_3)-1,4-dimethoxybenzene: Mp 131—132 °C; ^1H NMR (CCl_4) δ=3.88 (6H, s, 2×CH_3), 7.13 (2H, s, ArH); ^{19}F NMR (CCl_4, ppm) 63.4 (s, CF_3); MS (*m/z*) 274 (M^+).

2,3-Bis(CF_3)-1,4-dimethoxybenzene: Mp 71—74 °C; ^1H NMR (CCl_4) δ=3.83 (6H, s, 2×CH_3), 7.08 (2H, s, ArH); ^{19}F NMR (CCl_4, ppm) 55.9 (s, CF_3); MS (*m/z*) 274 (M^+).

***N*-Acetyl-*O,O'*-dimethyl-6-CF_3-dopamine:** Mp 118.5—120.5 °C; ^1H NMR ($CDCl_3$) δ=1.95 (3H, s, CH_3CO), 2.93 (2H, t, $ArCH_2$), 3.48 (2H, m, CH_2N), 3.88 (3H, s, OCH_3), 3.90 (3H, s, OCH_3), 5.70 (1H, broad peak, NH), 6.81 (1H, bs, ArH), 7.07 (1H, s, ArH); IR (KBr, cm^{-1}) 3350 (NH), 1640 (C=O); MS (*m/z*) 291 (M^+).

***N*-Trifluoroacetyl-*S*-trifluoromethylcysteine:** Mp 69—72 °C; ^1H NMR ($CDCl_3$) δ=3.27—3.73 (2H, m, CH_2), 4.80—5.07 (1H, m, CH), 7.10—7.40 (1H, m, NH), 9.77 (1H, bs, COOH); IR (Nujol, cm^{-1}) 3325 (NH), 1720 (C=O).

***N*-Trifluoroacetyltrifluoromethionine Methyl Ester (*N*-Trifluoroacetyl-*S*-trifluoromethylhomocysteine):** Oil; ^1H NMR ($CDCl_3$) δ=2.27 (2H, m, CH_2), 2.93 (2H, t, *J*=7.5 Hz, CH_2), 3.80 (3H, s, OCH_3), 4.72 (1H, dt, *J*=6.0, 7.5 Hz, CH), 7.42 (1H, d, *J*=7.5 Hz, NH); IR (Neat, cm^{-1}) 3350 (NH), 1750 (sh) (C=O), 1720 (C=O). Found: C, 30.52; H, 2.85; N, 4.52%. Calcd for $C_8H_9NO_3SF_6$: C, 30.68; H, 2.90; N, 4.47%.

4-*t*-Butyl-2-C_4F_9-phenol: Oil; ^1H NMR (CCl_4) δ=1.33 (9H, s, 3×CH_3), 5.48 (1H, m, OH), 6.86 (1H, d, *J*=8.7 Hz, ArH), 7.30 (1H, d, *J*=2.4 Hz, ArH), 7.42 (1H, dd, *J*=8.7, 2.4 Hz, ArH); ^{19}F NMR (CCl_4, ppm) 81.0 (3F, t, *J*=10 Hz, CF_3), 107.6 (2F, m, CF_2), 122.3 (2F, m, CF_2), 125.3 (2F, m, CF_2); IR (Neat, cm^{-1}) 3450 (OH).

1,4-Dimethoxy-2-C_4F_9-benzene: Oil; ^1H NMR (CCl_4) δ=3.75 (3H, s, OCH_3), 3.78 (3H, s, OCH_3), 6.91 (3H, m, ArH); ^{19}F NMR (CCl_4, ppm) 81.4 (3F, bs, CF_3), 107.6 (2F, m, CF_2), 121.7 (2F, m, CF_2), 125.9 (2F, m, CF_2); IR (Neat, cm^{-1}) 2850 (OCH_3), 1590 (Ar), 1510 (Ar).

Thermal Trifluoromethylation with TNS-Tf or -Nf. A Typical Procedure: A solution of 300 mg (2.0 mmol) of 4-*t*-butylphenol and 491 mg (2.0 mmol) of TNS-Tf in 10 ml of acetonitrile was degassed by a freeze-thaw cycle, sealed in a Pyrex tube, and was heated at 110 °C for 22 h. The reaction mixture was cooled, poured into water, and extracted with diethyl ether. The ethereal layer was dried ($MgSO_4$) and concentrated in vacuo. The residue was chromatographed over silica gel (10% Et_2O/pentane) to give 88.7 mg (15.5%) of 2,6-bis(CF_3)-4-*t*-butylphenol and 300.4 mg (69%) of 2-CF_3-4-*t*-butylphenol.

Hydrolysis of *N*-Trifluoroacetyltrifluoromethionine Methyl Ester to Trifluoromethionine(*S*-trifluoromethylhomocysteine). 2 mol dm^{-3} Sodium hydroxide (1.5 ml) was dropwise added to a solution of 0.35 g of *N*-trifluoroacetyltrifluoromethionine methyl ester in 4 ml of methanol. The mixture was stirred for 5 h at room temperature. After evaporation of the solvent, a small amount of water was added to the residue and the solution was neutralized to pH=ca. 6 with hydrochloric acid. The resulting white precipitates were collected by filtration and washed with acetone. Yield 0.17 g (75%). Recrystallization from methanol gave pure crystals; mp 224—225 °C (with decomp) (lit, mp 229 with decomp),[29] ^{19}F NMR (CD_3OD, ppm) 40.9 (s, CF_3). Found: C, 29.74; H, 3.91; N, 6.78%. Calcd for $C_5H_8NO_2SF_3$: C, 29.56; H, 3.97; N, 6.89%.

Trifluoromethylation of Aromatic Iodides by Using TNS-Tf and Copper. A Typical Procedure: TNS-Tf (4 ml, 0.5 mol dm^{-3} in acetonitrile, 2.0 mmol) was dropwise added to a mixture of 250 mg (3.93 mmol) of activated copper powder[34] and 10 ml of dry *N*-methylpyrrolidinone (NMP) at room temperature under argon atmosphere. Then the mixture was stirred for 3 h at room temperature. 1-Iodonaphthalene (200 mg, 0.788 mmol) was added to the resulting brown solution which was almost homogeneous, and the mixture

was heated at 100 °C for 19 h. After addition of water and ether to the cooled reaction mixture, the resulting solution was filtered through Celite layer, and extracted with ether. Combined ethereal layer was washed with water, dried ($MgSO_4$), and concentrated at 40—50 °C under atmosphere. To the remaining crude product was added $CClBr_2CF_3$ (145.9 mg, 0.528 mmol) as an internal standard, and then the yield of 1-CF_3-naphthalene based on the relative intensity of ^{19}F NMR signal was 0.491 mmol (93%).

Isolation of Dithiolanylium Salts and Their Conversion to Ketene Dithioacetals and Ortho Esters

Tadashi Okuyama,* Wataru Fujiwara, and Takayuki Fueno
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received September 6, 1985)

Various 2-substituted 1,3-dithiolan-2-ylium perchlorates (**1**) were prepared by the reaction of 1,2-ethanedithiol with acyl chlorides in the presence of perchloric acid. Treatments of **1** with triethylamine gave 2-alkylidene-1,3-dithiolane (**2**) when the 2-substituent was a primary or secondary alkyl group. 2-Aryl derivatives of **1** were converted to ortho esters by the reaction with methanol in the presence of silver nitrate. 1,3-Dithian-2-ylium perchlorates and 2-alkylidene-1,3-dithianes were also prepared similarly from 1,3-propanedithiol.

We previously described a simple method of preparation of 2-methyl-1,3-dithiolan-2-ylium perchlorate from the reaction of 1,2-ethanedithiol with acetic anhydride in the presence of perchloric acid (Eq. 1).[1] This is extended to a general procedure by using an acyl chloride as one of starting materials (Eq. 2).

$$2(CH_3CO)_2O + HSCH_2CH_2SH + HClO_4 \longrightarrow \underset{\textbf{1a}}{CH_3\text{-}C_3H_4S_2^+}\,ClO_4^- + 3CH_3CO_2H \quad (1)$$

$$RCOCl + HSCH_2CH_2SH + HClO_4 \longrightarrow \underset{\textbf{1}}{R\text{-}C_3H_4S_2^+}\,ClO_4^- + HCl + H_2O \quad (2)$$

1 **a**, R = CH_3 **e**, R = $C_6H_5CH_2$
b, R = C_2H_5 **f**, R = C_6H_5
c, R = $(CH_3)_2CH$ **g**, R = *p*-$CH_3OC_6H_4$
d, R = $(CH_3)_3C$

The isolated salts can easily be converted to ketene dithioacetals when R is a primary or secondary alkyl group (Eq. 3) and to ortho esters when R is an aryl group (Eqs. 4 and 5).

$$\mathbf{1} + Et_3N \longrightarrow \underset{\textbf{2}}{R'R''C_3H_2S_2} + Et_3NHClO_4 \quad (3)$$

2 **a**, R′ = R″ = H
b, R′ = H, R″ = CH_3
c, R′ = R″ = CH_3
d, R′ = H, R″ = C_6H_5

$$\mathbf{1} + CH_3OH + Et_3N \longrightarrow \underset{\textbf{3}}{RC(OCH_3)S_2H} + Et_3NHClO_4 \quad (4)$$

$$\mathbf{3} + 2CH_3OH + 2AgNO_3 + 2Et_3N \longrightarrow \underset{\textbf{4}}{RC(OCH_3)_3} + AgSCH_2CH_2SAg + 2Et_3NHNO_3 \quad (5)$$

Results and Discussion

When equimolar amounts of 1,2-ethanedithiol and isobutyryl chloride were mixed together at room temperature, reaction gradually proceeded with some evolution of HCl gas. Pyridine was added in the final stage of the reaction to neutralize the mixture. A main product isolated was 2-isopropylidene-1,3-dithiolane (**2c**) instead of the thiocarboxylate expected. The monothio ester initially formed is cyclized.[2] The cyclization must be catalyzed by the HCl which is produced in the initial reaction (Eq. 6), although it partly escapes as a gas from the mixture.

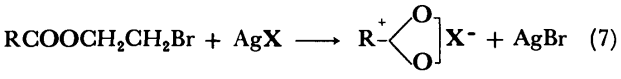
$$RCOCl + HSCH_2CH_2SH \longrightarrow RCOSCH_2CH_2SH$$
$$+ HCl \rightleftharpoons R\text{-}C(^{+}OH)(HS)\text{-}S\text{-}C_2H_4 + Cl^- \rightleftharpoons R\text{-}CH(HO)\text{-}S\text{-}C_2H_4^+$$
$$+ Cl^- \rightleftharpoons R\text{-}CH(^{+}H_2O)\text{-}S\text{-}C_2H_4 + Cl^- \rightleftharpoons \underset{\textbf{1}}{R\text{-}C_3H_4S_2^+} + Cl^- + H_2O \quad (6)$$

The pyridine must have acted as a base to abstract a proton from the β carbon of the carbocation but not to neutralize the HCl in the above example.

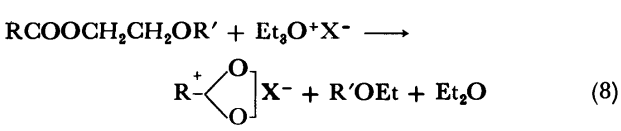
In order to isolate the carbocation as a salt from this reaction, perchloric acid (70%) was added to compensate the HCl escaped and to facilitate the cyclization. Carbenium perchlorates are usually more stable than the chlorides. Acetic anhydride was used to remove the water and to dissolve the salt. Dry ether was then added to reprecipitate the pure salt. Organic impurities which are soluble in ether are removed in this stage. All the treatments can satisfactorily be done in air and the yellow crystals obtained are practically pure as judged from the NMR spectra.

Salts of dithio carbocations were previously prepared either by hydride transfer from dithioacetals to trityl cation[3] or by dissociation of ortho thio esters.[4–6] The present new procedure involves acid-catalyzed cyclization of thiocarboxylates derived from the dithiol.

Cyclization of acyl derivatives has been used to prepare oxo carbocations.[7,8] In these cases, cyclizing agents may promote formation of the primary carbocations which attack the carbonyl oxygen (Eqs. 7 and 8).

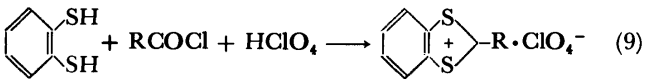


$$RCOOCH_2CH_2Br + AgX \longrightarrow R\text{-}\overset{+}{C}(O)O]X^- + AgBr \quad (7)$$



$$RCOOCH_2CH_2OR' + Et_3O^+X^- \longrightarrow R\text{-}\overset{+}{C}(O)O]X^- + R'OEt + Et_2O \quad (8)$$

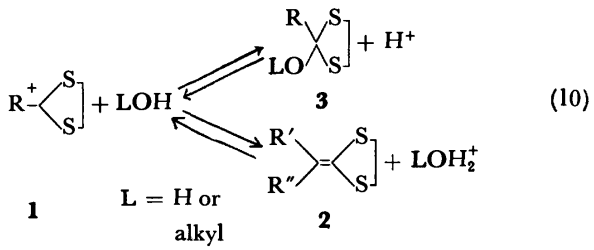
In the sulfur analogue, the mercapto group is nucleophilic enough even in strongly acidic media to attack the carbonyl carbon which is activated by acid catalysis. A closely related example found in the literature is formation of 1,3-benzodithiolylium salts from the reaction of 1,2-benzenedithiol with acyl chlorides (Eq. 9).[9]



$$\text{1,2-benzenedithiol} + RCOCl + HClO_4 \longrightarrow \text{1,3-benzodithiolylium}\cdot ClO_4^- \quad (9)$$

These unsaturated carbocations are considered to be stable because of aromatic 10π electron delocalization and have been isolated by various methods.[10]

When the dithio carbocations (**1a—c**) carrying a primary or secondary alkyl group were treated with methanol, the deprotonated product **2** was obtained as a main product rather than the methanol adduct **3**. Deprotonation from the β carbon occurs more easily than the nucleophilic reaction. This is not unexpected since we have found from kinetic investigations that deprotonation competes well with hydration in aqueous solution[11–15] and even the former predominates in some cases.[16]



$$\underset{\mathbf{1}}{R\text{-}\overset{+}{C}(S)S]} + LOH \rightleftharpoons \underset{\mathbf{3}}{R\text{-}C(OL)(S)S} + H^+ \quad (10)$$

$$\mathbf{1} + LOH \rightleftharpoons \underset{\mathbf{2}}{R'R''C(S)S} + LOH_2^+$$

L = H or alkyl

Thus, ketene dithioacetals **2** were prepared quantitatively (as seen by NMR spectra of crude product mixtures) by treating **1** with bases, tertiary amines. Typical procedures are given in Experimental Section.

Ketene dithioacetals are used as versatile intermediates for organic syntheses but general procedures for syntheses of this class of compounds are rather elaborate.[17,18] The present simple procedure starting from readily available reagents would be useful.

The recent two reports[19,20] of new methods for preparation of aryl ortho esters prompted us to examine the possibility of the carbocations **1** leading to this class of compounds. The carbocation **1** derived from benzoyl chloride gave the 2-methoxy derivative **3** by reaction with methanol (Eq. 4).[21] This cyclic ortho thioester **3** could be converted to trimethyl ortho ester **4** by the treatment with two equivalents of $AgNO_3$ in methanol in the presence of excess base (Eq. 5). This is a modification of the method of Breslow[19] where ortho trithioesters are used as a starting material. The present method requires a smaller amount (2/3) of $AgNO_3$ and is much simpler than that of Breslow[19] since preparation of ortho trithioesters is very cumbersome with formation of a large amount of gel during workup which arises from metal halide used.[22] The intermediate ortho thio ester **3** is not necessarily isolated in the present procedure. The carbocation salts **1**, which are just filtered, washed with ether, and still wet, can directly be treated with $AgNO_3$ in methanol to afford the final ortho ester **4** in a satisfactory yield. The 2-*t*-butyl cation **1d** gave the ortho ester **4d** in a low yield.

Derivatives of 1,3-dithiane seem to be prepared in a similar way. Reaction of 1,3-propanedithiol with isobutyryl chloride afforded a 1,3-dithian-2-ylium ion which absorbs light at 311 nm. The salt was then converted to 2-isopropylidene-1,3-dithiane by treatment with triethylamine. Other examples were not examined in detail but brief preliminary experiments seem to give in general satisfactory results.

Experimental

Typical procedures are given below. Other derivatives were obtained in the same way. Spectral data and boiling points are summarized in Tables 1 and 2. Temperatures are not

Table 1. Spectral Data of 2-Substituted 1,3-Dithiolan-2-ylium Perchlorates

corrected. Proton NMR spectra were recorded on a JNM C60-HL spectrometer.

2-Ethyl-1,3-dithiolan-2-ylium Perchlorate (1b). To an ice-cooled mixture of propionyl chloride (25 mmol) and 1,2-ethanedithiol (25 mmol), 70% perchloric acid (2.5 ml) was added dropwise under stirring. After 5-h reaction on an ice bath, acetic anhydride (15 ml) was added carefully (exothermic) to the viscous mixture. Dry ether (ca. 50 ml) was then added to precipitate the product, which was collected on a sintered-glass filter, washed three times with ether, and dried under reduced pressure. The yellow crystals obtained (4.8 g, 80%) were practically pure as seen by the NMR spectroscopy (Table 1).

2-Phenyl-1,3-dithiolan-2-ylium Perchlorate (1f). 1,2-Ethanedithiol (25 mmol) was added to benzoyl chloride (25 mmol) and stirred on an ice bath for 1 h. Then, 70% perchloric acid (3 ml) was added to the mixture. Stirring was continued for another 1 h at 0 °C. The solidified mixture was dissolved with acetic anhydride (15 ml) and reprecipitated by adding dry ether (50 ml). The yellow crystals were collected on a sintered-glass filter, washed with ether, and dried under vacuum. Yield was 6.2 g (88%).

2-Ethylidene-1,3-dithiolane (2b). The salt of **1b** prepared from 25 mmol of propionyl chloride was dissolved in dry acetonitrile (30 ml). The wet salt was used without drying. The solution was added to excess triethylamine (6 ml). The products were taken up in ether, washed with water, and dried over $MgSO_4$. After the evaporation of the ether, the remaining liquid was distilled. Yield, 1.8 g (55%). Anal. ($C_5H_8S_2$) C, H.

Trimethyl *p*-Methoxyorthobenzoate (4g). The perchlorate **1g**, which was prepared from *p*-methoxybenzoyl chloride (25 mmol) and still wet with ether, was dissolved in acetonitrile (30 ml), and methanol (100 ml) and triethylamine (14 ml) were added to the solution. The solution of silver nitrate (7 g) in acetonitrile (50 ml) was then introduced under stirring. After 10-h stirring at room temperature, precipitates were removed by filtration and the filtrate was concentrated to ca. 20 ml on a rotary evaporator. The products were taken up in ether, washed with aqueous $NaHCO_3$, dried over $MgSO_4$, and distilled. Yield, 2.8 g (53%). Bp 114—116 °C (5 mmHg†) [lit,[23] 114—115 °C (5 mmHg)].

Trimethyl Orthopivalate (4d). A solution of $AgNO_3$ (20 mmol) in CH_3CN (20 ml) was added to a solution of triethylamine (3.5 ml) and 2-*t*-butyl-2-methoxy-1,3-dithiolane **3d** (10 mmol) prepared from **1d**[24] in methanol (50 ml). After 12-h of stirring at room temperature, precipitates were filtered away and the filtrate was concentrated to ca. 10 ml. The products were taken up in ether, washed with aqueous $NaHCO_3$, and dried over $MgSO_4$. After evaporation of the ether, the residues were distilled with a Kugelrohr. The fraction collected at the oven temperature of ca. 80 °C and 50 mmHg was solidified on cooling (yield 0.1 g). ^1H NMR (CCl_4) δ=0.92 (s, 9H), 3.36 (s, 9H). Anal. ($C_8H_{18}O_3$) C, H.

2-Isopropylidene-1,3-dithiane. To a mixture of isobutyryl chloride (10 mmol) and 1,3-propanedithiol (10 mmol), 70% $HClO_4$ (1 ml) was added under stirring at room temperature. After 15-h stirring, acetic anhydride (10 ml) and then dry ether (50 ml) were added. Yellow precipitates collected on a sintered-glass filter were washed with ether and dissolved in CH_3CN (20 ml). The solution was added to triethylamine (3 ml). Workup in a similar way to **2b** and the Kugelrohr distillation gave 0.88 g (55%) of the fraction boiling at ca. 95 °C and 5 mmHg. ^1H NMR and IR spectra agree with those reported.[25]

†1 mmHg=133.322 Pa.

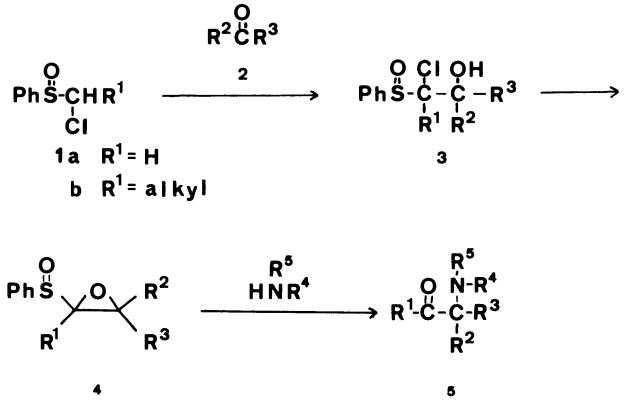
α,β-Epoxy Sulfoxides as Useful Intermediates in Organic Synthesis. III.[1] A Novel Synthesis of α-Amino Ketones and α-Amino Aldehydes by Aminolysis of α,β-Epoxy Sulfoxides

Tsuyoshi SATOH, Youhei KANEKO, Kiichi SAKATA, and Koji YAMAKAWA*
Faculty of Pharmaceutical Sciences, Science University of Tokyo, Ichigaya-funagawara-machi, Shinjuku-ku, Tokyo 162
(Received September 7, 1985)

Aminolysis of α,β-epoxy sulfoxides, easily prepared from 1-chloroalkyl phenyl sulfoxides or chloromethyl phenyl sulfoxide and carbonyl compounds, with alkyl- or arylamines afforded α-amino ketones or α-amino aldehydes in good yields. Treatment of thus obtained α-arylamino ketones with weak Lewis acid led to 2,3-disubstituted indoles.

α-Amino ketones (**5**) are valuable synthetic intermediates for drugs[2,9] or useful as building blocks for nitrogen containing heterocyclic compounds.[3] In contrast to the impressive development of the methods for the synthesis of β-amino ketones, such as Mannich reaction[4] or Michael addition of amines to α,β-unsaturated carbonyl compounds,[5] only limited numbers of methods for the preparation of α-amino ketones (**5**) are reported. Five main methods have so far been reported but they have some drawbacks. The S_N2 type displacement of α-halo ketones with amines[3,6] is useful only when regioselectively halogenated carbonyl compounds are easily available and at the same time, this reaction usually gives relatively poor yields. Reduction of acyl cyanides[7] gives only α-acylmethylamines and the Neber rearrangement[8] gives only α-amino ketones having no substituent on the nitrogen atom. Aminolysis of enediol silyl ethers[2] was reported to give less than 45% yield of α-amino ketones. Aminolysis of α,β-epoxy ethers,[9] which are synthesized from α-halo ketones, seems to be a relatively good method but only synthesis of phenyl α-amino ketones was reported.

As a consequence of the usefulness of α-amino ketones, exploration of a new procedure for the synthesis of them from readily available precursors is still required. Recently we have reported a method for the synthesis of ketones, aldehydes, and α-sulfenylated carbonyl compounds from α,β-epoxy sulfoxides (**4**).[1,10] Here we report, in detail, a new and efficient method for a synthesis of α-amino ketones and α-amino aldehydes[11] from α,β-epoxy sulfoxides and an application of this method to a synthesis of 2,3-disubstituted indoles.



Scheme 1.

Results and Discussion

Synthesis of α-Alkylamino Ketones and α-Alkylamino Aldehydes. α,β-Epoxy sulfoxides (**4**)[12] are very easily prepared in good overall yields from *chloromethyl phenyl sulfoxide* (**1a**) *or 1-chloroalkyl* phenyl sulfoxides (**1b**) and carbonyl compounds (**2**) through chlorohydrins (**3**). Few synthetic methods have already been reported[13] by using α,β-epoxy sulfoxides. We have found that the β-carbon of α,β-epoxy sulfoxides (**4**) is highly reactive to various alkyl- and arylamines to afford α-amino ketones (**5**) in good to excellent yields.[11]

Seven types of α,β-epoxy sulfoxides (**4a—g**) are selected to clarify the reactivity of **4** with various amines. The epoxides **4a—c** and **4g** have two isomers, which are expressed as L and P,[14] respectively, but the stereochemistries have not yet been determined. The epoxide (**4g**) used in this study is a mixture of L and P.

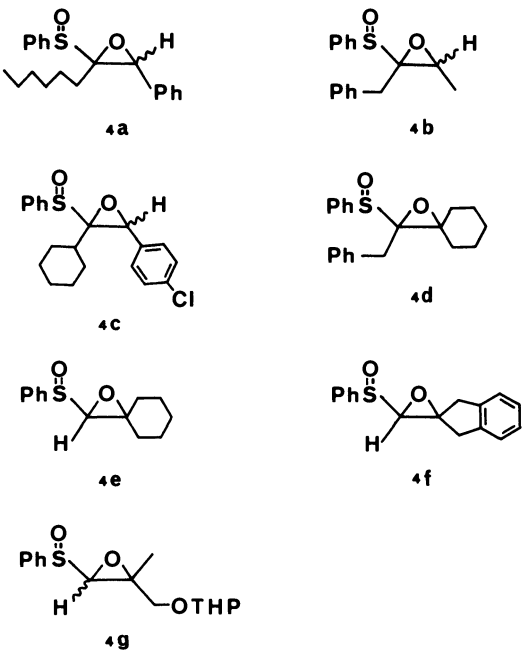


Table 1. α-Amino Ketones and Aldehydes from α,β-Epoxy Sulfoxides with Aliphatic Amines

Table 1. (Continued)

Run	Epoxy Sulfoxide	Amine[a]	Solvent	Temp	Time	α-Amino Ketone	Yield[b] %
17	**4g**	A	—	r.t.	1 d		**5q** 71

a) A: piperidine, B: morpholine, C: 1,2,3,4-tetrahydroisoquinoline, D: pyrrolidine, E: diethylamine, F: *N*-methyl-3-hydroxy-4-methoxybenzylamine, G: benzylamine. b) Isolated yields after silica gel column chromatography. c) Forty equivalents of amine was used and the concentration of the epoxy sulfoxide was 0.07 M. d) Forty-five equivalents of amine was used. e) Three equivalents of amine was used. f) Five equivalents of amine was used.

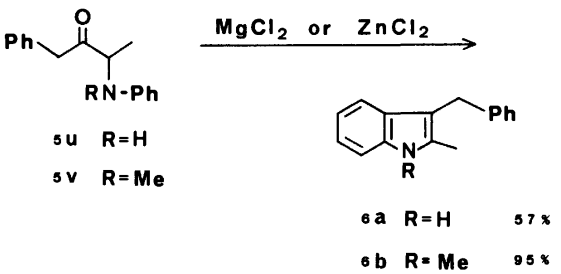
The reaction was simply conducted in an amine without solvent or in dimethyl sulfoxide (DMSO) or hexamethylphosphoric triamide (HMPA) as a solvent (0.5M† concentration of epoxy sulfoxide and 10 equivalents of amines are used unless otherwise noted) under nitrogen atmosphere.

The results of the reaction of α,β-epoxy sulfoxides (**4**) with aliphatic amines are summarized in Table 1. As shown in Table 1, aliphatic amines especially cyclic amines are very reactive to α,β-epoxy sulfoxides (**4**) giving α-amino ketones under the mild conditions in good to excellent yields. Isomers L and P showed some differences in the reactivity toward the amines but these differences are not essential problem for the practical use of this method. The epoxide having a cyclohexane ring in R^1 (**4c**) reacted slowly with amines than those having normal alkyl groups in R^1 (**4a** and **b**) due to a steric hindrance on the β-carbon of the epoxide by cyclohexyl group (see runs 1—7). The dipolar aprotic solvents known to be effective for nucleophilic bimolecular reactions[15] were used but we did not observe any solvent effect. The other conditions reported to be effective for opening of epoxides, such as the reaction with aminosilanes[16] or the reaction at alumina surface[17] were not effective in this reaction.

The results of the reaction of α,β-epoxy sulfoxides with acyclic alkylamines are summarized in runs 10 to 14. As acyclic amines are known to be less nucleophilic than cyclic amines, these reactions required much longer reaction time than those in cyclic amines and the yields were moderate to good (compare runs 1—4 with runs 10—14). The amine having a phenolic hydroxyl group, *N*-methyl-3-hydroxy-4-methoxybenzylamine, also reacted with **4a** and **b** to afford **5k** and **5m**, respectively, in moderate to good yields (runs 11 and 13). Monoalkylamines usually gave a complex mixture but only benzylamine afforded an α-benzylamino ketone (**5l**) in about 70% yield (run 12). Runs 15 to 17 show the results of the reaction of α-unsubstituted α,β-epoxy sulfoxides (**4e—g**) with piperidine to afford α-piperidino aldehydes (**5o—q**). Such complex amino aldehydes are usually very difficult to obtain but the present procedure gave α-piperidino aldehyde under the mild conditions without any problem in 70—80% yields.

Synthesis of α-Arylamino Ketones, Aldehydes and an Application of the Procedure to a Synthesis of 2,3-Disubstituted Indoles. Table 2 shows the results of the reaction of **4a**, **b**, **e**, **f** with arylamines. Since usually arylamines have a lower nucleophilic property than that of alkylamines, the reaction of arylamines with **4** required a higher temperature but the yields are still very good. α-Anilino aldehydes (**5x**) and (**5y**) were also obtained in excellent yields. In these cases it is noteworthy that aniline was very reactive to **4e** and **4f** (see Table 1, runs 15 and 16)

The present procedure has proved of value by transforming the products to heterocyclic compounds according to Scheme 2. α-Arylamino ketones have already been transformed to tetrahydrocarbazoles[3b] or substituted indoles[3c,18] but in these cases, α-arylamino ketones were derived from α-chloro ketones in about 50% yield. In our study, *N*-(1-methyl-2-oxo-3-phenylpropyl)aniline (**5u**) was heated with magnesium



Scheme 2.

chloride in Ethylcellosolve at 130°C for 1.5 h to afford 3-benzyl-2-methylindole (**6a**; mp 89—90°C)[19] in 57% yield. Similarly, **5v** was heated with zinc chloride (in this case magnesium chloride was not effective) in Ethylcellosolve at 120°C for 3 h to give 3-benzyl-1,2-dimethylindole (**6b**; mp 54—55°C)[20] in 95% yield. Since, the α,β-epoxy sulfoxide (**4b**) was synthesized from benzyl bromide, chloromethyl phenyl sulfoxide, and acetaldehyde in three steps in over 90% yield[10a] the indole (**6b**) was synthesized from these three components and *N*-methylaniline in five steps overall

† 1 M=1 mol dm^{-3}.

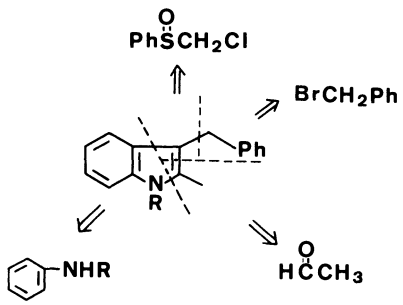

Fig. 1.

in about 80% yield (see Fig 1).

In conclusion a novel and versatile procedure for a synthesis of α-amino ketones and α-amino aldehydes has been developed from α,β-epoxy sulfoxides. In regard to the accessibility of the starting materials, the simplicity and mildness of the operation, and high yields of the products, the present method offers a simple and useful approach to α-amino ketones and α-amino aldehydes and at the same time this process contributes to the nitrogen containing heterocyclic chemistry.

Experimental

All melting points are uncorrected. Infrared (IR) spectra were measured directly on a NaCl plate or in KBr disks with a Hitachi 215 spectrometer. ^{1}H Nuclear magnetic resonance (NMR) spectra were measured in $CDCl_3$ solution with a JEOL FX-100 spectrometer using Me_4Si as an internal standard. Electron impact mass spectra (MS) were obtained on a Hitachi M-80 double focusing spectrometer at 70 eV by direct insertion. Silica gel BW-127ZH (Fuji-Devison) containing 2% fluorescence reagent 254 and quartz column were used for column chromatography and the products having ultraviolet (UV) absorption were detected by UV irradiation.

Materials. All α,β-epoxy sulfoxides (**4**) used in this study were reported in references 1 and 10. DMSO, HMPA, and all amines except *N*-methyl-3-hydroxy-4-methoxybenzylamine were dried over CaH_2 and distilled before use.

General Procedure for the Preparation of α-Amino Ketones and α-Amino Aldehydes by Aminolysis of α,β-Epoxy Sulfoxides with Amines. Method A: The α,β-epoxy sulfoxide (**4**) (0.1 mmol) was dissolved in 2 ml of an amine in dry flask under N_2 atmosphere. This reaction mixture was stirred at the appropriate temperature till the starting

material disappeared. The amine was distilled off under reduced pressure at room temperature and the residue was purified by silica-gel column chromatography with a mixture of hexane and ethyl acetate as an eluent.

Method B: The α,β-epoxy sulfoxide (**4**) (0.1 mmol) was dissolved in 0.2 ml of DMSO or HMPA in dry flask under N_2 atmosphere. To the solution was added an amine (1 mmol) and the reaction mixture was stirred at the appropriate temperature till the starting material disappeared. The reaction mixture was diluted with 50 ml of ethyl acetate and the solution was washed twice with water followed by sat. aq NaCl. The solution was dried over Na_2SO_4 and the solvent was evaporated under reduced pressure. The residue was purified by silica-gel column chromatography with a mixture of hexane and ethyl acetate as an eluent. In the cases of arylamines, usually the R_f values of the amines are very close to the products. The products were purified by silica-gel column chromatography followed by preparative thin-layer chromatography (Merck Kieselgel 60 F_{254}; 0.25 mm).

1-Phenyl-1-piperidino-2-octanone (5a). Colorless oil; IR (neat): 1710 (CO) cm^{-1}; ^1H NMR δ=0.82 (3H, t, J=6 Hz), 1.0—1.8 (14H, m), 2.1—2.6 (6H, m), 4.87 (1H, s), 7.1—7.5 (5H, m); MS m/z (%): 287 (M^+, trace), 286 ($[M-H]^+$, trace), 174 ($[M-C_7H_{13}O]^+$, 100); Found: m/z 286.2160. 3-Benzyl-2-methylindole (6a). To a 20 ml dry flask was added 38 mg (0.4 mmol) of dry $MgCl_2$ and 0.5 ml of Ethylcellosolve followed by 18 μl (0.2 mmol) of aniline. The atmosphere of the flask was evacuated and replaced with nitrogen. The suspension was stirred and heated at reflux for 15 min to give colorless clear solution. To this solution was added a solution of *N*-(1-methyl-2-oxo-3-phenylpropyl)aniline (**5u**) (36 mg; 0.15 mmol) in 0.2 ml of Ethylcellosolve and the reaction mixture was stirred and heated at 130 °C for 1.5 h. The reaction mixture was diluted with ethyl acetate and washed with water. The organic layer was dried over Na_2SO_4 and the solvent was evaporated and the residue was chromatographed on a silica-gel column (hexane : AcOEt = 20:1) to afford 19 mg (57%) of **6a** as yellow crystals. Recrystallization from AcOEt-hexane gave colorless prisms, mp 89—90 °C. IR (KBr): 3500 (NH) cm^{-1}; ^1H NMR δ=2.32 (3H, s), 4.09 (2H, s), 7.02—7.64 (10H, m); MS m/z (%): 221 (M^+, 100), 206 ([M−CH_3]$^+$, 27), 144 ([M−C_6H_5]$^+$, 43); Found: m/z 221.1194. Calcd for $C_{16}H_{15}N$: M, 221.1203.

3-Benzyl-1,2-dimethylindole (6b). To a 20 ml dry flask was added 230 mg (1.68 mmol) of dry $ZnCl_2$ and 1 ml of Ethylcellosolve and the atmosphere of the flask was replaced with nitrogen as described above. The suspension was stirred and heated at 100 °C for 10 min to give colorless clear solution. To this was added a solution of *N*-methyl-*N*-(1-methyl-2-oxo-3-phenylpropyl)aniline (**5v**) (62 mg; 0.24 mmol) in 0.5 ml of Ethylcellosolve and the reaction mixture was stirred and heated at 120 °C for 3 h. The work-up as described above gave a crude product, which was purified by silica-gel column chromatography (hexane:AcOEt=40:1) gave 55 mg (95%) of **6b** as light yellow crystals. Recrystallization from ethanol gave colorless prisms, mp 54—55 °C (lit,[20] 56.6—57 °C). IR (KBr): 740, 705 (aromatic) cm^{-1}; ^1H NMR δ=2.35 (3H, s), 3.65 (3H, s), 4.11 (2H, s), 6.92—7.50 (9H, m), MS m/z (%): 235 (M^+, 100), 220 ([M−CH_3]$^+$, 39), 158 ([M−C_6H_5]$^+$, 94); Found: m/z 235.1346. Calcd for $C_{17}H_{17}N$: M, 235.1360.

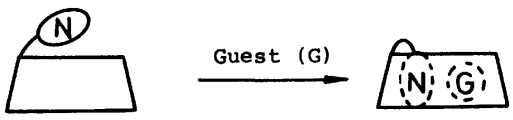
(Received September 17, 1985)

Host-guest complexation of γ-cyclodextrin bearing two 2-naphthyl moieties (**1**) has been studied by circular dichroism and fluorescence spectroscopic methods. The exciton coupling band observed in the naphthalene ^1L_a transition region shows that the two naphthyl moieties of **1** take a chiral orientation in the cavity. The guest binding of **1** changes the circular dichroism pattern, finally affording a negative band, but hardly influences the fluorescence pattern in which excimer emission is predominant. These phenomena suggest that a guest molecule is included in the cavity of **1** by extruding two naphthyl moieties from the cavity so as to make the moieties to act as hydrophobic caps. Dimethyl sulfoxide(DMSO) was found to be effective to change both fluorescence and circular dichroism patterns, increasing monomer-like emission and converting the exciton coupling pattern to a simple negative band. These results suggest that the two naphthyl moieties are not in proximal positions in DMSO-rich solutions.

Cycloamyloses (cyclodextrins, CDs) are a series of cyclic oligomers consisting of six or more α-1,4-linked D-glucopyranose units. The number of glucopyranose unit is designated by a Greek letter: α for six, β for seven, γ for eight, and so on. The smaller α- and β-CDs have been widely utilized for various purposes because of their remarkable property of forming inclusion complexes with a variety of small molecules.[1] However, the use of γ-CD has not been frequent due to its large cavity size in addition to the factor of its commercial unavailability. In recent reports of spectroscopic studies,[2-4] it was suggested that γ-CD can include two molecules of benzene or naphthalene derivatives in marked contrast to α-and β-CDs which form 1:1 host-guest complexes. The unique property of γ-CD places the basis for using γ-CD as a molecular flask which facilitates reactions by involving two reactants as shown by excimer[2] or charge-transfer complex[3] formation and dimerization.[5]

As a new extension of our works, we have prepared several γ-CD derivatives, which bear a covalently attached aromatic moiety,[6] and observed that the moiety acts as a spacer which enables the γ-CD derivatives to form 1:1 host-guest complexes by narrowing the large γ-CD cavity (Scheme 1). The complexation



N: Naphthalene

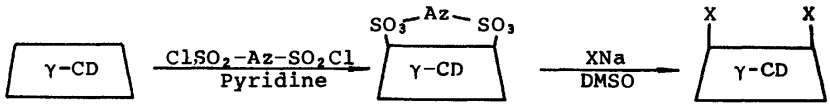
Scheme 1.

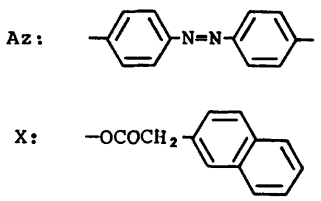
behavior of the γ-CD derivatives may be regarded as an induced-fit type of complexation since the host changes the location of the appended moiety so as to be suited for guest binding.

We now wish to describe here another induced-fit type of complexation which was observed for γ-CD bearing two 2-naphthyl moieties (**1**). The preliminary study on the complexation behavior of **1** showed that orientation and location of the appended naphthyl moieties changed by guest binding.[7] In addition to the detailed features of the binding behavior, this work is concerned with the conformational changes induced by dimethyl sulfoxide (DMSO).

Results

We prepared the compound **1** via azobenzene-capped γ-CD as shown in Scheme 2. Figure 1 shows the absorption and circular dichroism spectra of **1** in an aqueous 10% DMSO solution. The circular dichroism spectrum reveals a peak around 282 nm and a trough around 258 nm in the naphthalene ^1L_a transition region. The exciton coupling pattern indicates that the two 2-naphthyl moieties of **1** form a pair with a chiral geometry in the cavity of **1**. The spectral pattern in shorter wavelengths (^1B_b transition region) may be a decisive indicator for determining the direction of the chirality since the ^1B_b transition occurs along the long axis of naphthalene ring. However, as the measurements in the shorter wavelengths could not be achieved due to the absorption of DMSO, we used aqueous 10% ethylene glycol solutions for the purpose. The circular dichroism spectrum of this solution shows a trough at 234 nm with the molar ellipticity of 29000 and a peak at 217 nm with the molar ellipticity of 158000 associated with the naphthalene ^1B_b transition. Although the spectrum has unballanced intensities between positive and negative bands, the pattern may be regarded as that of the exciton coupling of counter-clockwise orientation of the two naphthyl moieties.[8] Its deformed shape might be due to the electronic interaction between ^1B_b and ^1L_a transitions within the naphthyl pair. The circular dichroism pattern in the ^1L_a transition region of this aqueous 10% ethylene glycol solution is the same as that of the aqueous 10%





Scheme 2.

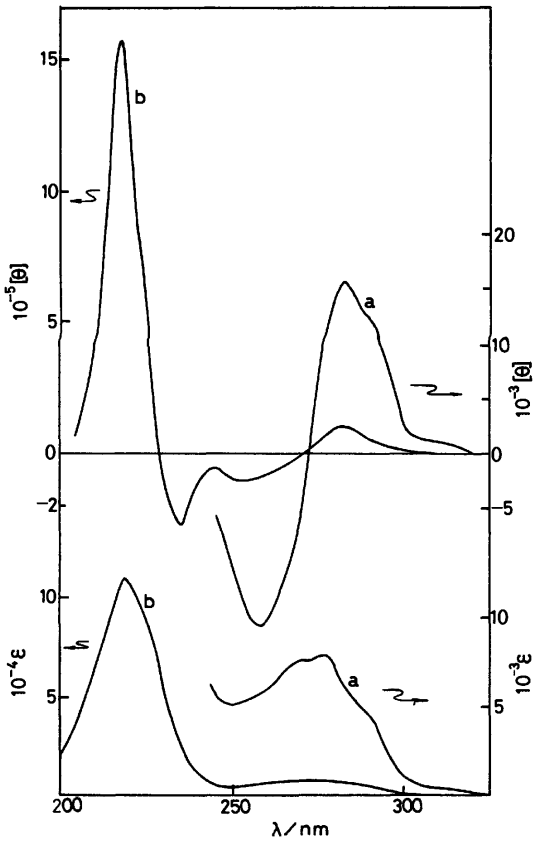


Fig. 1. Circular Dichroism (top) and absorption (bottom) spectra of **1** in aqueous 10% DMSO solution (a) and in aqueous 10% ethylene glycol solution (b). Concentrations of **1** were 6.53×10^{-5} and 7.66×10^{-6} mol dm^{-3} for the spectra a and b, respectively.

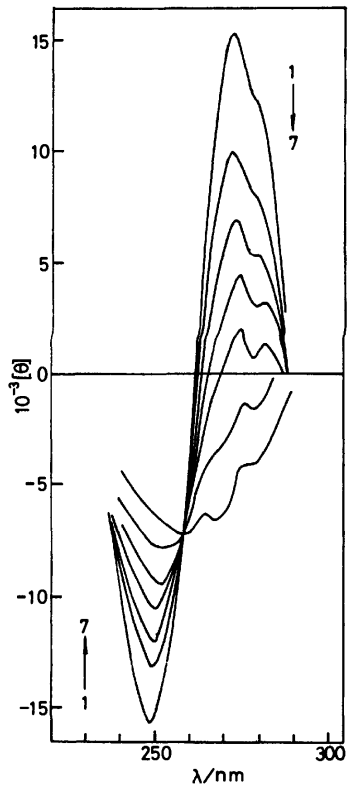

Fig. 2. Circular dichroism spectra of **1** in aqueous 10% DMSO solutions (6.53×10^{-5} mol dm^{-3}) at various cyclododecanol concentrations (1, 0.0; 2, 2.02×10^{-5}; 3, 4.04×10^{-5}; 4, 6.05×10^{-5}; 5, 8.07×10^{-5}; 6, 1.21×10^{-4}; 7, 1.81×10^{-4} mol dm^{-3}).

DMSO solution. Therefore, the orientation of the two naphthyl moieties involved in the cavity of **1** should be the same in both solutions.

The intensity of the positive peak of the exciton coupling band in the naphthalene ^1L_a transition region diminishes with increasing guest concentration. Figure 2 shows the variation of the circular dichroism pattern in the case of cyclododecanol. It is noted that the spectra have an isoellipticity point at 268 nm, this confirming that two forms of **1**, free and complexed ones are present in the present system.

The guest-induced variations of the molar ellipticity were used to obtain binding constants (K) of **1**. It was reported that the binding constant is given by Eq. 1 when circular dichroism intensity changes by guest.[9]

$$K=\frac{\theta_h-\theta_x}{(\theta_x-\theta_c)\left[C_g-C_h\dfrac{\theta_h-\theta_x}{\theta_h-\theta_c}\right]} \quad (1)$$

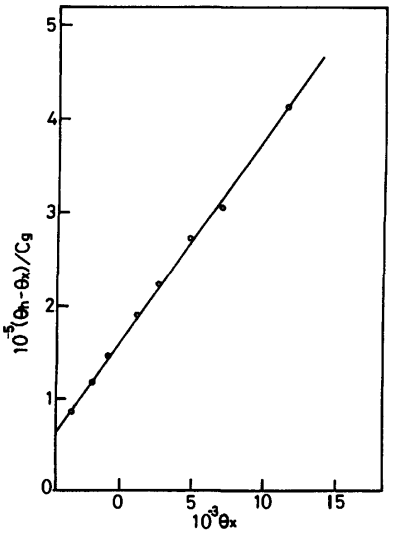

Fig. 3. The plot of $(\theta_h-\theta_x)/C_g$ as a function of θ_x in the system of **1** and cyclohexanol.

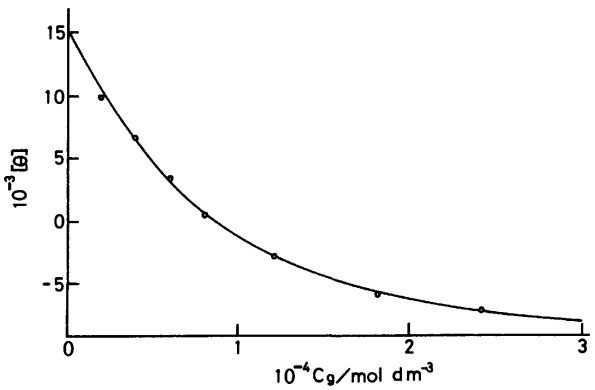

Fig. 4. The plot of $[\theta]_{282}$ of **1** in aqueous 10% DMSO solutions as a function of cyclododecanol concentration (solid line is the calculated curve for K=2.6×10^4 mol^{-3} dm^3).

Here, θ=molar ellipticity (the molar ellipticity at 282 nm in this study), θ_x for sample, θ_h for host alone, θ_c for complex, C_h=total host concentration, and C_g=total guest concentration. When guest is in large excess, we used Eq. 2 which derives from Eq. 1.

$$\frac{\theta_h-\theta_x}{C_g} = K\theta_x - K\theta_c \qquad (2)$$

Figure 3 shows the plot of $(\theta_h-\theta_x)/C_g$ againtst θ_x in the case of cyclohexanol guest. When guest is not in large excess, a curve-fitting method was used as an alternative method. Figure 4 shows the curve-fitting data for cyclododecanol guest. The binding constants obtained by these methods are listed in Table 1. The binding constants in aqueous 10% DMSO solutions are roughly in the order of guest sizes, ranging from 21.7 mol^{-1} dm^3 for cyclohexanol to 26000 mol^{-1} dm^3 for cyclododecanol. DMSO was found to influence the circular dichroism pattern of **1**, decreasing the intensity of the peak around 282 nm and finally giving a negative band around 275 nm (Fig. 5). The effect of DMSO content on guest binding was checked by using (−)-borneol as guest. Figure 6 shows the (−)-borneol-

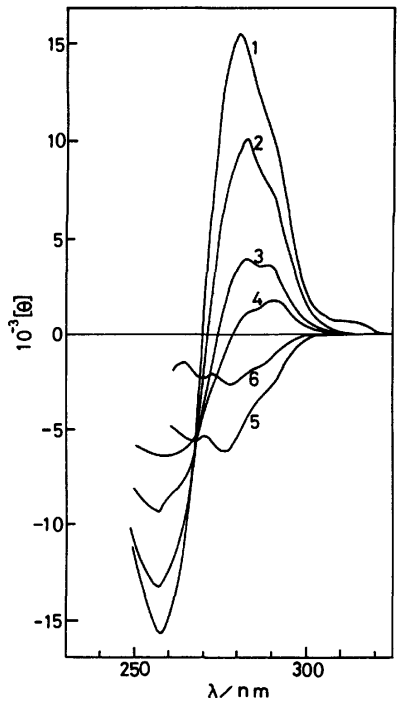

Fig. 5. Circular dichroism spectra of **1** (6.53×10^{-4} mol dm^{-3}) at various DMSO contents (1, 10; 2, 15; 3, 20; 4, 25; 5, 70; 6, 100%).

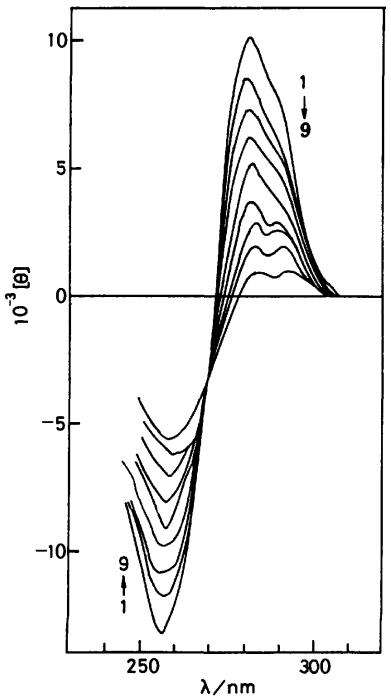

Fig. 6. Circular dichroism spectra of **1** in aqueous 15% DMSO solutions (7.54×10^{-5} mol dm^{-3}) at various (−)-borneol concentrations (1, 0.0; 2, 1.00×10^{-4}; 3, 2.00×10^{-4}; 4, 3.00×10^{-4}; 5, 4.00×10^{-4}; 6, 5.39×10^{-4}; 7, 6.98×10^{-4}; 8, 8.97×10^{-4}; 9, 11.9×10^{-4} mol dm^{-3}).

Table 1. Binding Constant of **1** at 25°C[a)]

Guest	Solvent	K/mol^{-1}dm^{3}[b)]
Cyclohexanol	10% DMSO	21.7
(−)-Menthol	10% DMSO	329
1-Adamantanecarboxylic acid	10% DMSO	507
(−)-Borneol	10% DMSO	795
	15% DMSO	1000
	20% DMSO	1500
	25% DMSO	1500
Cyclododecanol	10% DMSO	26000[c)]

a) Values were obtained by the plot of $(\theta_h-\theta_x)/C_g$ vs. θ_x except for the value for cyclododecanol which was obtained by the curve-fitting method. b) Errors are within ±15%. c) 9730 mol^{-1}dm^{3} in Ref. 7.

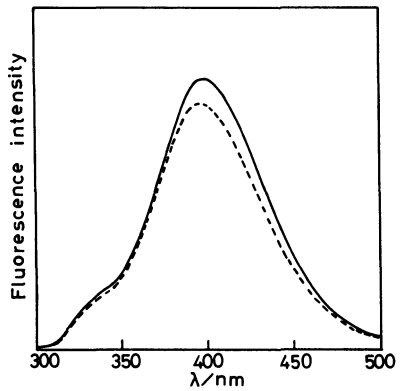

Fig. 7. Fluorescence spectra of **1** in aqueous 10% DMSO solutions (6.53×10^{-5} mol dm^{-3}) in the absence (——) and presence (----) of cyclodoecanol (2.41×10^{-4} mol dm^{-3}). Excitation wavelength is 290 nm.

dependent variation of the circular dichroism pattern of **1** in aqueous 15% DMSO solutions. The binding constans obtained in the range of 10—25% of DMSO are also shown in Table 1. The binding increased wtih increasing DMSO content until 20% DMSO. It should be noted that the analysis was limited to the solutions below 25% DMSO because of the depressed circular dichroism intensity.

Figure 7 shows the fluorescence spectra of **1** in aqueous 10% DMSO solutions, alone and in the presence of cyclododecanol. The spectra exhibit a predominant excimer emission around 400 nm and a shoulder of normal fluorescence around 330 nm. In contrast to the drastic circular dichroism changes, the fluorescence pattern was found to be hardly influenced by guest binding. However, marked changes of the fluorescence pattern was caused by increasing DMSO content (Fig. 8). This result suggests that the two naphthyl moieties of **1** in the DMSO-rich solutions are difficult to be held in the γ-CD cavity of **1** due to the weakened hydrophobic driving force.

Discussion

The synthesis of **1** was performed via γ-CD capped

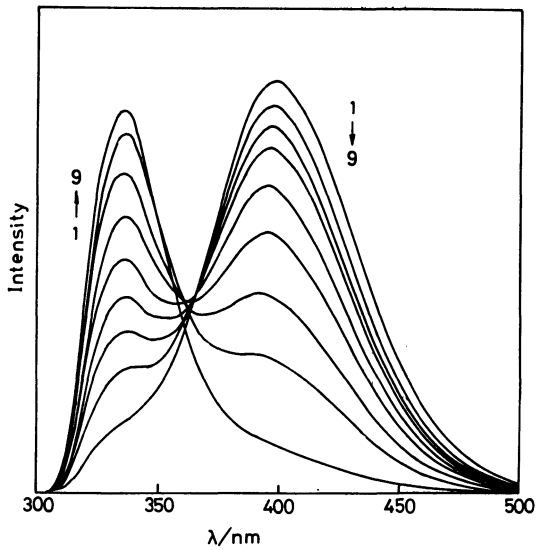

Fig. 8. Fluorescence spectra of **1** (7.54×10^{-5} mol dm^{-3}) at various DMSO contents (1, 10; 2, 20; 3, 30; 4, 40; 5, 50; 6, 60; 7, 70; 8, 80; 9, 100%).

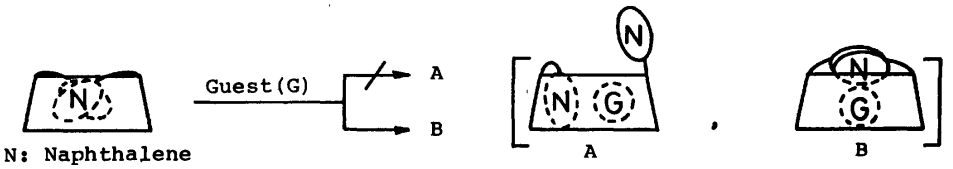
by azobenzene-4,4′-disulfonate moiety. Therefore, the positions of the two naphthyl moieties are those of primary hydroxyls sulfonated by azobenzene-4,4′-disulfonyl dichloride. When glucose units of CD ring are denoted by A, B, C, D, etc., in the order, primary hydroxyl groups of A and D glucopyranose units of β-CD were reported to be selectively sulfonated by stilbene-4,4′-disulfonyl dichloride.[10)] Similar selectivity may be expected here. The examination of Corey-Pauling-Koltun models of the present system shows that substitution is most likely to occur at A-D and A-E positions of γ-CD. However, in spite of our efforts to observe the isomeric forms of **1**, there was no indication of mixing of the isomers. Furthermore, the circular dichroism spectra of **1** at various guest concentrations had an isoellipticity point and could be analyzed based on a simple 1:1 stoichiometry, so the physical nature of the isomers should be very similar even if the present sample is composed of two isomeric forms.

We have examined guest-induced circular dichroism variations for aqueous 10% DMSO solutions. Guest binding of **1** cancelled the exciton coupling in the 250—300 nm region (Fig. 2), this phenomenon indicating that the chiral orientation of the naphthyl pair was lost by forming inclusion complexes. In contrast to this marked variation of the circular dichroism pattern, the excimer emission was hardly influenced by guest binding. These results indicate that the two naphthyl moieties are still close in the complexes. It was reported that γ-CD bearing a naphthyl moiety showed an induced-fit type of complexation (Scheme 1).[6a)] In the system, the naphthyl moiety was fixed in the cavity together with a guest molecule. If similar type of complexation occurs in the present system, the complex

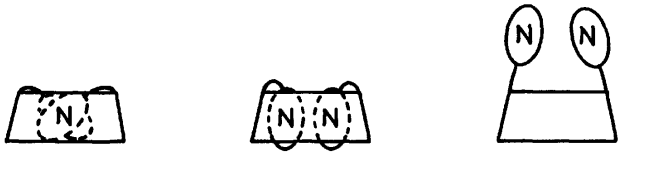


Scheme 3.

A should be formed (Scheme 3). However, the excimer emission from the complexes is not consistent with the structure A in which the face-to-face interaction between the two naphthyl moieties is not allowed. Thus, the structure B is the form which may be supported by both circular dichroism and fluorescence data. The two naphthyl moieties are likely to contact with the included guest molecule as flexible caps. It is interesting that **1** accommodates only one guest molecule in the cavity in spite of the fact that the γ-CD cavity itself is large enough to include two molecules of smaller guests. The hydrophobic naphthyl caps seem to contribute to form such 1:1 complexes.

The DMSO-enhanced binding ability of **1**, which was observed below 25% DMSO, is worthy to note since DMSO in aqueous solutions usually tends to decrease the binding ability of CDs. In the present system, the two naphthyl moieties seem to be so tightly involved in the cavity when water content is high that they are hard to be replaced by a guest molecule. Consequently, the proposed mechanism for the DMSO-enhanced binding is that DMSO increased the mobility of the naphthyl moieties so as to make the cavity suited for guest accommodation.

The fluorescence data indicate that the two naphthyl moieties are close to each other both in free and complex forms of **1** when DMSO content is low, but are located apart in pure DMSO. Figure 9 shows the plots of excimer-monomer ratio and circular dichroism intensity at 282 nm against DMSO content. It is obvious that exciton coupling is more sensitive to DMSO than excimer emission. This result suggests that the two naphthyl moieties are located still in the cavity after loosing the chiral orientation and then extruded outward from the cavity with increasing DMSO content. Thus, three forms with different geometries as illustrated below are likely to be present.



I (tense) II (quasi-tense) III (relaxed)

The two naphthyl moieties are tightly and loosely bound to the cavity in the tense and the quasi-tense forms, respectively, whereas not bound in the relaxed form.

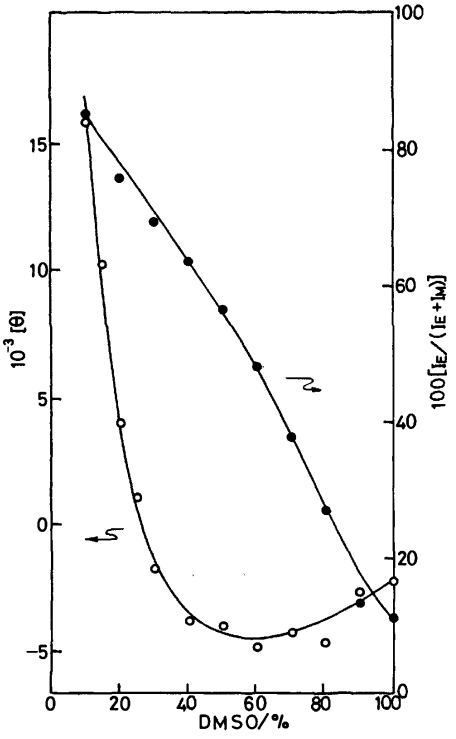


Fig. 9. Plots of excimer-monomer fluorescence ratio (I_M and I_E are intensities at 335 and 400 nm, respectively) and the molecular ellipticity at 282 nm of **1** (7.54×10^{-5} mol dm^{-3}) as a function of DMSO content.

The important aspect of the modified γ-CDs such as those bearing one and two naphthyl moieties is that native γ-CD, which is a rigid host, can be converted to flexible hosts. On this basis, various modified γ-CDs with different guest-selectivity may be designed and construction of new enzyme models, which are capable of induced-fit type of substrate binding, is now in progress.

Experimental

Materials. γ-CD was kindly gifted from Nihon Shokuhin Kako Ltd. The following commercially available guaranteed reagents were used without further purification; *p*-nitrobenzenesulfonic acid, cyclohexanol, (−)-menthol, 1-adamantanecarboxylic acid, (−)-borneol, and cyclododecanol. DMSO was Dotite-spectrosol grade.

Measurements. The circular dichroism, UV and fluorescence spectra were measured at 25 °C using a JASCO J-400X spectrodichrometer, a Shimadzu UV-250 spectrophotometer and a Shimadzu RF-500 spectrofluorophotom-

eter, respectively. The circular dichroism intensities were expressed as molar ellipticity (in degree $cm^2 dmol^{-1}$) on the basis of the total concentration of **1**. Due to the poor solubility of **1** in pure water, DMSO-containing aqueous solutions were used as solvents.

Disodium Azobenzene-4,4′-disulfonate (2). Sodium hydroxide solution (63.2 g in 150 ml H_2O) was added dropwise to the solution of *p*-nitrobenzenesulfonic acid (20.0 g, 0.0985 mol) and water (135 ml). The mixed solution was heated at 50 °C and then D-glucose solution (126 g, 0.699 mol and 150 H_2O) was added dropwise. Air was introduced into the resultant solution at room temperature for 10 h. The precipitates were collected by filtratioin, washed with 15% NaCl solution (100 ml), and recrystallized from 50% ethanol solution to give 9.6 g (25%) of **2**: ^{1}H NMR (D_2O) δ=8.14 (8H, m, Ar). Found: C, 36.46; H, 1.87; N, 7.23%. Calcd for $C_{12}H_8N_2O_6S_2Na_2$: C, 36.65; H, 2.05; N, 7.13%.

Azobenzene-4,4′-disulfonyl Dichloride (3). Thionyl chloride (8 ml) was added dropwise to the stirred suspension of **2** (9.0 g, 0.0233 mol) in *N,N*-dimethylformamide (150 ml). After vigorous stirring for 1 h, the solution was poured into ice water (280 ml). The precipitates were collected, washed with ether, and recrystallized from benzene to give 6.4 g of **3** (73%): mp 223—225 °C; ^{1}H NMR ($CDCl_3$) δ=8.20 (8H, m, Ar); IR (KBr) 1377, 1183, 655, 582, and 528 cm^{-1}; R_f=0.5 (2:1 hexane-acetone). Found: C, 38.19; H, 1.84; N, 7.24. Calcd for $C_{12}H_8S_2O_4N_2Cl_2$: C, 38.00; H, 2.13; N, 7.39.

***trans*-Azobenzene-4,4′-disulfonyl γ-CD (4).** To a stirred solution of dry γ-CD (4.0 g, 3.08 mmol) in dry pyridine (100 ml), azobenzene-4,4′-disulfonyl dichloride (1.40 g) 3.7 mmol) was added, and then heated at 60 °C for 1 h. After cooling the reaction mixture, pyridine was removed by evaporation under reduced pressure. Water addition to the residue followed by evaporation was repeated several times until no pyridine odor was detected. The resultant oily residue was dissolved in a small amount of water and subjected to Sephadex G-15 column chromatography. Recrystallization from methanol afforded the product (0.69 g, 13%) as orange powder: R_f=0.40 (5:1 CH_3CN-H_2O); Found: C, 42.93; H, 5.89; N, 1.45. Calcd for $C_{60}H_{86}N_2O_{44}S_2 \cdot 4H_2O$: C, 43.01; H, 5.66; N, 1.67.

Bis(2-naphthylacetyl) γ-CD. A mixture of **4** (0.515 g, 0.307 mmol), sodium 2-naphthylacetate (0.265 g, 1.28 mmol), and DMSO (10 ml) was stirred at 80 °C for 5 h. After cooling, the reaction mixture was poured into 500 ml of acetone. The precipitates were collected by filtration and subjected to Sephadex G-15 column chromatography. Recrystallization from water gave the desired product (0.12 g, 23%): R_f=0.48 (5:1 CH_3CN-H_2O); ^{1}H NMR (DMSO-d_6, 60 °C) δ=3.1—3.8 (48H, m, CD protons other than C_1H and OH), 4.0—4.5 (6H, m, O_6H), 4.8—4.9 (8H, br. s, C_1H), 5.8 (16H, br. s, O_2H, O_3H), 7.2—7.9 (14H, m, Ar); UV (9:1 H_2O-DMSO) (ε) 277 nm (7900); IR (KBr): 1735 cm^{-1} (CO). Found: C, 50.73; H, 6.12. Calcd for $C_{72}H_{96}O_{42} \cdot 4H_2O$: C, 50.70; H, 6.15.

We thank Dr. N. Harada of Chemical Research Institute of Non-Aqueous Solutions of this university for his variable comments about our circular dichroism results. This work was supported by Grant-in-Aid (No. 58118007) for Special Project Research from the Ministry of Education, Science and Culture.

Oxidation of Lipids. XII. Inhibition of Oxidation of Soybean Phosphatidylcholine and Methyl Linoleate in Aqueous Dispersions by Uric Acid

Etsuo NIKI,* Mitsuo SAITO, Yasuyuki YOSHIKAWA, Yorihiro YAMAMOTO, and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 18, 1985)

The activity of uric acid as a chain-breaking antioxidant was studied in the oxidations of methyl linoleate micelles and soybean phosphatidylcholine liposomes in aqueous dispersions at 37°C. Uric acid was found to act as a radical scavenger. Uric acid located in an aqueous phase could trap the radicals in an aqueous phase, but it could not scavenge radicals within the lipid region of micelles and liposomal membranes. The kinetics of the oxidations of lipids in aqueous dispersions inhibited by uric acid was discussed.

Toxicity caused by oxygen and its active species has received much attention recently in connection with its pathological effects and aging.[1-11] Aerobic organisms have an array of protective mechanisms both for preventing the formation of active oxygen species and lipid peroxidation and for repairing oxidative damage. Enzymes such as superoxide dismutase and glutathione peroxidase play an important role in the protective systems. Chain-breaking antioxidants are also important and it has been reported[12] that vitamin E is the most potent and probably the only lipid soluble, chain-breaking antioxidant in erythrocyte membranes. Water soluble ascorbic acid also acts as an antioxidant.[13-17]

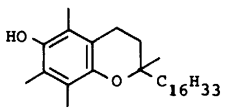
Uric acid may be another water soluble antioxidant. In 1963, Matsushita[18] found that uric acid was as effective antioxidant as α-tocopherol in the oxidation of linoleic acid in water at 37°C. Kellogg and Fridovich[19] observed that urate inhibited hemolysis of erythrocytes caused by xanthine oxidase-acetaldehyde system. Recently, Ames[20] suggested that uric acid may play a role in protecting man from oxygen radical toxicity. More recently, on the other hand, Kittridge and Willson[21] have shown that urate does not always show a protective effect against free radicals. In the course of our study on the oxidation of lipids and its inhibition, we have measured the activity of uric acid as a chain-breaking antioxidant. This paper shows convincingly that uric acid can scavenge peroxyl radicals.

Experimental

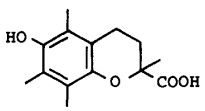
Materials. Commercial soybean phosphatidylcholine (PC) purchased from Daigo Chemicals Co. (Osaka) was purified by alumina and silica-gel columns. The purified PC gave only one spot on thin-layer chromatography and no conjugated diene was observed before oxidation. The composition of fatty acids in PC measured by gas-liquid chromatography after hydrolysis and esterification with HCl-methanol was as follows: palmitic acid 12.1%, stearic acid 1.6, oleic acid 9.6, linoleic acid 69.6, and linolenic acid 7.1 mol%. Methyl linoleate was obtained from Sigma Chemical Co. (St. Louis) and Tokyo Kasei Kogyo Co. (Tokyo) and purified by silica-gel column.

2,2′-Azobis(2-amidinopropane) dihydrochloride (AAPH) and 2,2′-azobis(2,4-dimethylvaleronitrile) (AMVN) were used as water-soluble and oil-soluble radical initiators, respectively, in order to generate initiating free radicals at a constant rate outside or within liposomes or micelles as requested. Both AAPH and AMVN were obtained from Wako Chemicals (Tokyo) and used as received. The rate of chain initiation was determined by the conventional method[22-24] from the induction period observed by the addition of a chain breaking antioxidant.

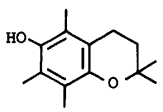
The rate of radical generation from AAPH in an aqueous phase was measured using a water soluble vitamin E model, 2-carboxy-2,5,7,8-tetramethyl-6-chromanol (CTMC), as a radical scavenger, whereas the rate of chain initiation in the lipid phase was measured using 2,6-di-*t*-butyl-4-methylphenol incorporated into lipid region of micelles or liposomes as a chain-breaking antioxidant.



α-tocopherol



CTMC



PMC

Uric acid, hypoxanthine, xanthine, purine, L-histidine, indole, and Triton X-100 were of the highest grade available commercially and used without further purification. *d*-α-Tocopherol and its models, CTMC and 2,2,5,7,8-pentamethyl-6-chromanol (PMC), were kindly supplied from Eisai Co. (Tokyo). 2,6-Di-*t*-butyl-4-methylphenol was recrystallized from ethanol.

Pure water was usually used for aqueous dispersion. In some experiments, the effect of pH of the medium was studied. Table 1 shows the buffer system used in this study.

Procedures. The liposome was prepared as follows. PC and oil soluble additives were dissolved in chloroform and the solution was taken into a small flask. The solvent was removed to obtain a thin film. An appropriate amount of 0.1 M NaCl (M=mol dm^{-3}) aqueous solution containing, when necessary, water-soluble additives was added and the film was slowly peeled off by shaking to obtain a white, milky liposome solution. An aliquot of the liposome solution was taken into a reaction vessel and immersed in a water bath which was carefully thermostated at the desired temperature.

The micelle was prepared as follows. Oil soluble additives were dissolved in benzene and the solution was taken into a 30 ml Pyrex glass ampoule. The ampoule was connected to

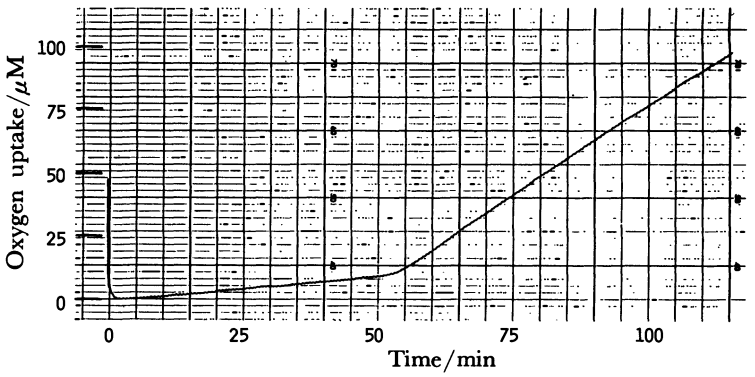

Fig. 1. Rate of oxygen uptake during the oxidation of 0.108 M methyl linoleate in 0.01 M Triton X-100 aqueous dispersion at 37°C under air in the presence of 17.7 mM AAPH and 37.3 μM uric acid. Oxygen uptake was followed by pressure transducer.

a water aspirator and benzene was removed at room temperature. Appropriate amount of methyl linoleate was added and oil-soluble materials were dissolved and then 0.01 M aqueous Triton X-100 containing, when necessary, water-soluble additives was added into the ampoule and shaken vigorously on Vortex mixer for two minutes.

The oxidation was carried out under air at 37°C. The reaction mixture was agitated with a magnetic stirrer. The rate of oxygen uptake was measured in an automatic recording gas absorption apparatus with either a pressure transducer or oxygen electrode and the rate of consumption of α-tocopherol was followed at 294 nm with high-performance liquid chromatography (HPLC) as reported previously.[15]

Results and Discussion

Oxidation of Methyl Linoleate Micelles in Aqueous Dispersion and Its Inhibition by Uric Acid. Methyl linoleate was oxidized in aqueous dispersions using Triton X-100 as a surfactant. In the absence of radical initiator, the rate of oxidation was quite slow, but the addition of AAPH induced the oxidation and methyl linoleate was oxidized at a constant rate without any noticeable induction period. When uric acid was added to the aqueous phase, the oxidation was suppressed quite markedly and after some induction period the rate of oxidation increased as shown in Fig. 1. The rate of oxidation after the induction period was as large as that in the absence of uric acid.

The pertinent results are shown in Table 2. The induction period was proportional to the uric acid concentration. The quantitative evaluation of the data in Table 2 will be discussed later in the text.

Figure 2 shows the results of oxidation of methyl linoleate micelles in aqueous dispersions of different

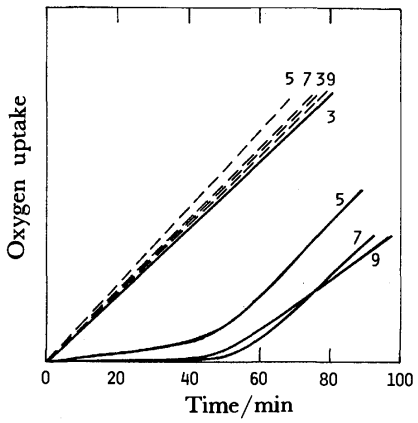

Fig. 2. Effect of pH of the medium on the inhibition of oxidation of 0.11 M methyl linoleate by 51 μM uric acid in 0.01 M Triton X-100 aqueous dispersion at 37°C under air initiated with 18 mM AAPH.
——: with uric acid, ----: without uric acid.

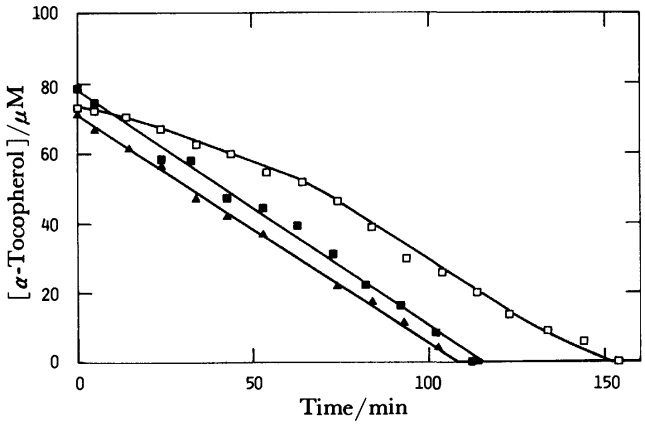

Fig. 3. Rate of disappearance of α-tocopherol during the oxidation of methyl linoleate micelle in 0.010 M Triton X-100 aqueous dispersion at 37°C under air.
■: [α-tocopherol]=78.7 μM; [uric acid]=none; [AMVN]=13.0 mM, ▲: [α-tocopherol]=71.3 μM; [uric acid]=49.9 μM; [AMVN]=10.9 mM, □: [α-tocopherol]=73.0 μM; [uric acid]=38.3 μM; [AAPH]=17.6 mM.

pH in the presence and absence of uric acid. It shows that pH of the medium has little effect in the absence of uric acid but that the antioxidant activity of uric acid depends on pH and it is not effective as an antioxidant at pH 3.

Although uric acid was an effective antioxidant, hypoxanthine, xanthine, purine, and L-histidine which have similar structures as uric acid did not suppress the oxidation of methyl linoleate in aqueous dispersions initiated with AAPH. Xanthine was not effective as an antioxidant over the pH range between 3 and 9. Indole did not suppress the oxidation of methyl linoleate in benzene solution initiated with AMVN.

Similarly, AMVN located in methyl linoleate micelles in Triton X-100 aqueous dispersions induced the oxidation. AMVN generates initiating free radicals

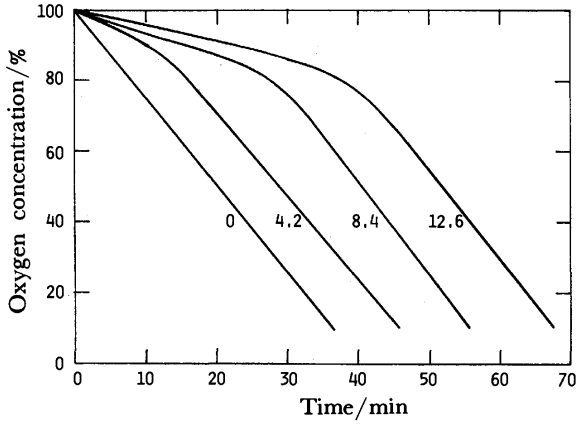

Fig. 4. Inhibition of oxidation of 1.95 mM soybean PC liposome by uric acid in 0.1 M NaCl aqueous dispersion at 37°C under air initiated with 10 mM AAPH. Rate of oxygen uptake was followed by oxygen electrode. Number show the concentration of uric acid in μM.

in the lipid region of micelles. Interestingly, however, uric acid could not suppress the oxidation when it was initiated with AMVN, suggesting that uric acid located in an aqueous phase can not scavenge radicals that are present in the lipid region of micelles, as observed for ascorbic acid.[15,16]

Figure 3 shows the rate of decay of α-tocopherol in the presence and absence of uric acid during the oxidation of methyl linoleate micelles in aqueous dispersions initiated with AAPH or AMVN. In the absence of uric acid, α-tocopherol disappeared linearly with time. In the presence of uric acid, the rate of decay of α-tocopherol was suppressed when the oxidation was initiated with AAPH, whereas uric acid had little effect on the rate of α-tocopherol consumption when the oxidation was initiated with AMVN.

Oxidation of Soybean PC Liposomes and Its Inhibition by Uric Acid. The results are summarized in Table 3 and in Fig. 4. Substantially the same results were obtained as in the oxidation of methyl linoleate micelles in aqueous dispersions. Both AAPH and AMVN induced the oxidation of soybean PC liposomes. Uric acid suppressed the oxidation initiated with AAPH, but it could not suppress the oxidation efficiently when it was induced by AMVN. The induction period was proportional to the concentration of uric acid.

Quantitative Evaluation of Antioxidant Activity of Uric Acid. The oxidation of lipids initiated with AAPH (A-N=N-A) proceeds by the following mechanism.[15-17,25,26]

Initiation:

$$\text{A-N=N-A} \xrightarrow{k_d} [\text{A}\cdot\ \text{N}_2\ \cdot\text{A}] \longrightarrow (1-e)\text{A-A} \quad (1)$$

$$\searrow\ 2e\text{A}\cdot \quad (2)$$

$$\text{A}\cdot + \text{O}_2 \xrightarrow{k_3} \text{AO}_2\cdot \quad (3)$$

Table 3. Inhibition of Oxidation of Soybean PC Liposomes by Uric Acid under Air at 37°C[a)]

$$AO_2\cdot + IH \xrightarrow{k_{inh}} \text{stable products} \quad (4)$$

$$AO_2\cdot + AO_2\cdot \xrightarrow{k_t} \text{stable products} \quad (5)$$

$$AO_2\cdot + LH \xrightarrow{k_6} AOOH + L\cdot \quad (6)$$

Propagation:

$$L\cdot + O_2 \xrightarrow{k_7} LO_2\cdot \quad (7)$$

$$LO_2\cdot + LH \xrightarrow{k_p} LOOH + L\cdot \quad (8)$$

Termination:

$$2LO_2\cdot \xrightarrow{k_t} \text{non-radical products} \quad (9)$$

The water soluble AAPH generates geminate radicals by its thermal decomposition, a portion of which recombine within the solvent cage (reaction 1) but rest of them escape from the solvent cage and become free radicals (reaction 2). They rapidly interact with oxygen to give peroxyl radicals (reaction 3). The peroxyl radicals are either scavenged by an antioxidant (IH) that is present in the aqueous phase (reaction 4), interact with another peroxyl radical to give stable products (reaction 5), or attack micelles or liposomes and abstract active, doubly-allylic hydrogens from lipids (LH) (reaction 6) to initiate free radical chain oxidation (reactions 7 and 8). As shown above, the uric acid in the aqueous phase can not scavenge radicals in the lipid region and therefore the chains are terminated by bimolecular interactions of lipid peroxyl radicals (reaction 9). Thus the oxidation proceeds by a free radical chain mechanism and one initiating radical can produce many lipid peroxides.

When the rate of chain initiation is constant, that is, when the new chains are started at a constant rate, the steady state treatment can be applied for the reaction sequence 1 to 9.

The rate of free radical generation in an aqueous phase from AAPH, $R_i(aq)$, is given by

$$R_i(aq) = 2ek_d[AAPH] = n[CTMC]/t_{inh} \quad (10)$$

where e is the efficiency of free radical production and k_d is the rate constant for the unimolecular decomposition of AAPH. The rate of radical generation in an aqueous phase can be determined from the induction period (t_{inh}) produced by CTMC. The stoichiometric number (n) of peroxyl radicals trapped by each CTMC was assumed to be 2.[15,25,27)]

On the other hand, the rate of chain initiation, that is, the rate of initial radical generation in the lipid phase, $R_i(lipid)$, was determined from the induction period produced by 2,6-di-*t*-butyl-4-methylphenol incorporated into lipid phase of micelles or liposomes.[22,23,24)] The constant n was taken as 2.[15,22,23)] If all the free radicals from AAPH produced in an aqueous phase attack micelles or liposomes, then $R_i(aq)=R_i(micelle)=R_i(liposome)$.

$$R_i(lipid) = n[IH(lipid)]/t_{inh} \quad (11)$$

The steady state treatment for the above reactions 1 to 9 gives Eqs. 12 to 14,

$$[AO_2\cdot] = \frac{R_i(aq)}{k_{inh}[IH] + (1+\alpha)k_6[LH]} \quad (12)$$

$$[LO_2\cdot] = \left(\frac{k_6[AO_2\cdot][LH]}{2k_t}\right)^{1/2} \quad (13)$$

$$= \left\{\frac{k_6[LH]}{2k_t}\cdot\frac{R_i(aq)}{k_{inh}[IH] + (1+\alpha)k_6[LH]}\right\}^{1/2} \quad (14)$$

where

$$\alpha = 2k_5[AO_2\cdot]^2/k_6[AO_2\cdot][LH] \quad (15)$$

The rate of oxidation during the induction period (R_{inh}) is given by Eqs. 16 to 18,

$$R_{inh} = k_3[A\cdot][O_2] + k_7[L\cdot][O_2] \quad (16)$$

$$= R_i(aq) + k_6[AO_2\cdot][LH] + k_p[LO_2\cdot][LH] \quad (17)$$

$$= R_i(aq) + r^2R_i(aq) + rk_p[LH]\left(\frac{R_i}{2k_t}\right)^{1/2} \quad (18)$$

where

$$r = \left(\frac{k_6[\mathrm{LH}]}{k_{\mathrm{inh}}[\mathrm{IH}] + (1+\alpha)k_6[\mathrm{LH}]}\right)^{1/2} \quad (19)$$

and k_{inh}, k_p, and k_t are the rate constants for scavenging by uric acid of peroxyl radicals derived from AAPH, propagation reaction 8, and termination reaction 9, respectively.

In the absence of an antioxidant or after the induction period, where [IH]=0, $r=(1/(1+\alpha))^{1/2}$, and the rate of oxidation (R_p) is given by Eq. 20.

$$R_p = R_i(\mathrm{aq}) + \frac{1}{1+\alpha}R_i(\mathrm{aq}) + k_p[\mathrm{LH}]\left(\frac{R_i(\mathrm{aq})}{2(1+\alpha)k_t}\right)^{1/2} \quad (20)$$

Equations 18 and 20 gives Eq. 21

$$r = \left\{\frac{R_{\mathrm{inh}}}{R_i(\mathrm{aq})} + \left(\frac{(1+\alpha)^{1/2}R_q}{2R_i(\mathrm{aq})}\right)^2 - 1\right\}^{1/2} - \frac{(1+\alpha)^{1/2}R_q}{2R_i(\mathrm{aq})} \quad (21)$$

where

$$R_q = R_p - R_i(\mathrm{aq}) - \frac{1}{1+\alpha}R_i(\mathrm{aq}) \quad (22)$$

The constant α is the ratio of the rate of reaction 5 to that of reaction 6; that is, the ratio of $AO_2\cdot$ radicals that interact with each other to those that attack lipids. The value $1/(1+\alpha)$ gives the ratio of free $AO_2\cdot$ radicals generated in the aqueous phase that attack lipids in micelles or liposomes in the absence of an antioxidant in the aqueous phase (Eq. 23), and this can be obtained from R_i(aq) and the rate of chain initiation in the lipid phase, R_i(lipid), obtained from Eq. 11. On the other hand, the values of r^2 show the fraction of free $AO_2\cdot$ radicals generated in an aqueous phase that attack lipid in micelles or liposomes instead of being scavenged by uric acid and reacting with another $AO_2\cdot$ radicals.

Since R_i(aq), R_i(lipid), R_{inh}, and R_p can be measured experimentally, and α is calculated from Eq. 24, r can be calculated from Eqs. 21 and 22. Equation 19 gives Eq. 25 and, if k_6 is known, k_{inh} can be obtained.

$$\frac{1}{1+\alpha} = \frac{k_6[\mathrm{AO_2\cdot}][\mathrm{LH}]}{2k_5[\mathrm{AO_2\cdot}]^2 + k_6[\mathrm{AO_2\cdot}][\mathrm{LH}]} \quad (23)$$

$$= \frac{R_i(\mathrm{lipid})}{R_i(\mathrm{aq})} \quad (24)$$

$$\frac{k_{\mathrm{inh}}}{k_6} = \left(\frac{1}{r^2} - 1 - \alpha\right)\frac{[\mathrm{LH}]}{[\mathrm{IH}]} \quad (25)$$

Figure 5 shows the plot of induction period observed in the presence of uric acid and CTMC. The induction period was proportional to the concentration of antioxidant and inversely proportional to that of

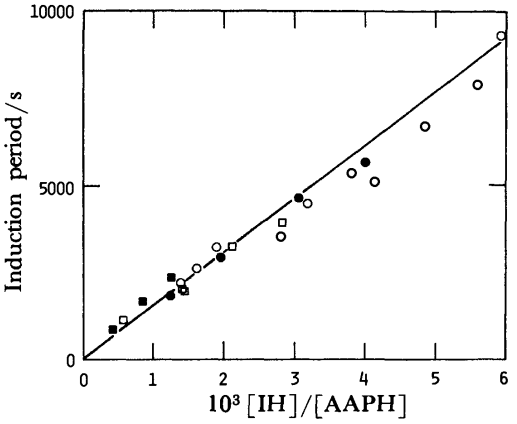

Fig. 5. Plot of induction period as a function of [antioxidant]/[AAPH] observed in the oxidations of methyl linoleate micelles and soybean phosphatidylcholine liposomes in aqueous dispersions initiated with AAPH and inhibited by uric acid and 2-carboxy-2,5,7,8-tetramethyl-6-chromanol (CTMC) at 37°C.

	Uric acid	CTMC
Micelles	□	○
Liposomes	■	●

AAPH as expected from Eq. 10. It is noteworthy that the same induction periods were observed in micelle and liposome systems. Furthermore, CTMC and uric acid gave substantially the same induction period, suggesting that both of them have same n values. Since the value of n for CTMC may reasonably be assumed to be 2,[15,25,27] the n value for uric acid must be also 2. The rate of free radical generation in an aqueous phase was obtained from Fig. 5 as

$$R_i(\mathrm{aq}) = 1.30 \times 10^{-6}[\mathrm{AAPH}] \quad (\mathrm{s^{-1}}) \quad (26)$$

In Tables 2 and 3 are shown the rates of oxidation of methyl linoleate micelles and soybean phosphatidylcholine liposomes during and after the induction period. The values of r^2 calculated from Eq. 21 are also included in Tables 2 and 3. They show that substantially all of the peroxyl radicals derived from AAPH are scavenged by uric acid before they attack lipids in micelles and liposomes. The ratio of rate constants, k_{inh}/k_6, calculated for micelle and liposome systems from Eq. 25 is also included in Tables 2 and 3 respectively. Since r values are obtained from Eq. 21 as a small difference between large numbers, these values may contain considerable error, but the average values of k_{inh}/k_6 are obtained as 5.8×10^5 and 2.2×10^4 for micelle and liposome systems respectively.

The difference between R_i(aq), R_i(micelle), and R_i(liposome) is interesting. The rates of radical production in aqueous phase are similar in micelles

and in liposome systems as shown in Fig. 5. The ratio is R_i(aq): R_i(micelle): R_i(liposome)=1.30×10^{-6}: 8.12×10^{-7}: 3.06×10^{-7}=1:0.62:0.24, when the lipid concentrations in total aqueous dispersions are about 110 and 2 mM for micelle and liposome systems respectively. This shows that under these conditions, considerable amounts of the radicals generated in an aqueous phase are terminated and only small fraction of the free radicals attack lipids and initiate chain oxidation even in the absence of an antioxidant in the aqueous region. In other words, the structure of liposomal membranes is by itself effective in protecting from the attack of oxygen radicals.

If we consider the concentration difference, it may be said that liposomes are more readily attacked than micelles by oxygen radicals. The higher k_{inh}/k_6 for micelle systems than that for liposome systems must be also ascribed to less accessibility of peroxyl radicals to lipids in micelles than to those in liposomes. These results are consistent with the previous finding that ascorbic acid can interact, although less readily than in homogeneous solution, with peroxyl radicals in liposomes whereas it can not interact with peroxyl radicals in micelles,[28] and that ascorbic acid, cysteine, and glutathione located in aqueous phase interact faster with galvinoxyl radical located in liposomes than they do with galvinoxyl located in micelles in Triton X-100 aqueous dispersions.[29] It may be noteworthy, however, that the reactivity of lipids in micelles toward radicals in aqueous phase must depend on the surfactant.

Synergistic Inhibition with Vitamin E. Ascorbic acid inhibits the oxidation synergistically in combination with vitamin E.[14,15,28,30-40] It has been shown[14,15,28,38-40] that ascorbic acid reacts with vitamin E radical to regenerate vitamin E. It was examined whether uric acid could interact with vitamin E radical and inhibit the oxidation synergistically. That the rate of disappearance of α-tocopherol during the oxidation initiated with AAPH was suppressed by uric acid (Fig. 3) must be due to the trapping by uric acid of radicals from AAPH rather than the trapping of substrate peroxyl radicals and/or α-chromanyloxyl radical from α-tocopherol and it does not necessarily indicate the interaction of uric acid with α-chromanyloxyl radical.

It has been found[28] previously that ascorbic acid in an aqueous phase can interact with chromanyloxyl radical from 2,2,5,7,8-pentamethyl-6-chromanol (PMC) located in micelles and that ascorbic acid can contribute to the inhibition of the oxidation of methyl linoleate micelles in aqueous dispersions in the presence of PMC even though the oxidation is initiated with AMVN and ascorbic acid can not scavenge lipid peroxyl radicals in the oil region. However, uric acid did not show any synergistic activity in the similar oxidation of methyl linoleate micelles in the presence of PMC initiated with AMVN. The above results and Fig. 3 suggest either that uric acid does not interact with chromanoxyl radical at all or that its rate is not fast enough to compete with the interaction of chromanoxyl radical with peroxyl radical.

Addition Reaction of 1,4-Dibromo-2,5-piperazinedione with 3,4-Dihydro-2*H*-pyran

Kuniaki ITOH* and Akira SERA
Department of Science of Material Reaction, Division of Science of Materials, Graduate School of Science and Technology, Department of Chemistry, Faculty of Science, Kobe University, Kobe 657
(Received May 4, 1985)

Reaction of 1,4-dibromo-2,5-piperazinedione (**1**) with 3,4-dihydro-2*H*-pyran (**2**) under irradiation gave 1 : 1- and **1** : 2-addition products (**3**,**4**) and corresponding secondary products (**5**—**7**). The adducts were considered to be produced separately by photoinduced free radical addition as well as concomitant ionic addition reactions.

Reactions of *N*-bromosuccinimide (NBS) with olefins are characterized as allylic brominations and additions to double bonds.[1] The majority of the NBS-reactions have been postulated to involve a free radical chain mechanisms, though different chain transfer species participate: a bromine atom[1] or a succinimidyl radical[2-4] according to the reaction conditions. Incremona and Martin[5] however, claimed that reactions of *N*-bromotetrafluorosuccinimide (NBTFS) with olefins were considerably different from those of NBS, and proposed an ionic reaction pathway for these reactions. The ionic reactivity of NBTFS was attributed to the electron-withdrawing inductive effect of the fluorine substituent of NBTFS. We have reported that irradiation of 1,4-dibromo-2,5-piperazinedione (**1**) with cyclohexene or 1-alkenes in acetonitrile gave addition products produced by a free radical mechanism. The reactions were rationalized by taking into account an initial attack of the 2,5-dioxo-1-piperazinyl radical in the olefinic double bonds to give stable radical intermediates.[6,7] However, minor intervention of a concomitant ionic addition mechanism could not be ruled out. In this paper, we describe the reaction of **1** with 3,4-dihydro-2*H*-pyran (**2**) which is more susceptible to ionic addition reactions than cyclohexene or 1-alkenes. The addition reaction of **1** to **2** was suggested to proceed by two pathways, a free radical and an ionic process, to give two types of addition products, respectively.

Results and Discussion

The photoreaction of 1,4-dibromo-2,5-piperazinedione (**1**) with 3,4-dihydro-2*H*-pyran (**2**) was carried out in acetonitrile using a high pressure mercury lamp. The photolysate was separated by silica-gel column

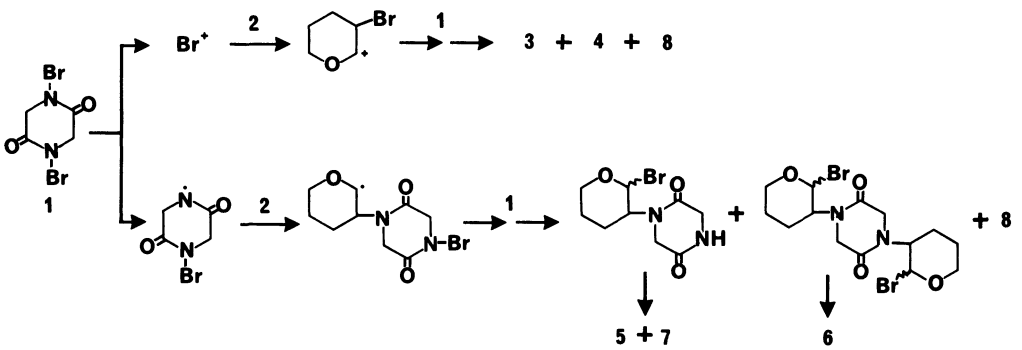
chromatography and the structures of the products were determined by elemental and spectroscopic analyses. The results are summarized in Table.

Irradiation of **1** with **2** in acetonitrile gave only 2,5-piperazinedione (**8**) as an isolable product accompanied by a large amount of polymeric products. The dione **8** was derived from **1** by either hydrogen abstraction of the 2,5-dioxo-1-piperazinyl radical intermediate or protonation on the corresponding anion.[6] The polymeric products may come from **2** via the well-known acid catalyzed polymerization. When the reaction was performed in the presence of 1,2-epoxybutane (a hydrogen bromide scavenger), the formation of the polymers was greatly depressed. In the presence of 1,2-epoxybutane, the reaction gave a considerable amount of addition products (Scheme 1). These adducts consisted of bromine-containing 1:1- and 1:2-adducts (**3** and **4**), hydroxyl group-containing 1:1- and 1:2-adducts (**5** and **6**). A substituted 3,4-dihydro-2*H*-pyran (**7**) was also produced. The bromine-containing 1:1-adduct (**3**) was rechromatographed to give isomers **3a** and **3b** (approx. 2:1).

Both **3a** and **3b** had a bromine substituent (MS), and an NH group (IR and NMR). They gave similar NMR and IR spectra which demonstrated the presence of a 2,5-dioxo-1-piperazinyl group at C_1 of the respective tetrahydropyran ring. That is, both adducts showed characteristic infrared absorptions (1690, 1445—1460, 1190—1215 cm^{-1}) of a 2,5-piperazinedione moiety, and their NMR spectra showed signals of protons on bromine-bearing carbon atoms (C_2 of the tetrahydropyran ring) [**3a**; δ=4.0—4.6, m, and **3b**; δ=4.56, br.], and those on C_1 of the tetrahydropyran ring [**3a**; δ=5.43, d, J=10 Hz (axial-H_1/axial-H_2), and **3b**; δ=5.19, J=2 Hz (axial-H_1/equatorial-H_2)]. Treatment of **3a** and **3b** with tributyltin hydride led to the same reduced product, 1-(2-tetrahydropyranyl)-2,5-piperazinedione. This observation indicated that these two 1:1-adducts are a pair of stereoisomers at the bromine-bearing carbon atom. From these results, the stereochemistry was deduced as trans for the major isomer **3a** and cis for the minor isomer **3b**.[8] The bromine containing 1:2-adduct (**4**) bore two bromine atoms (MS), and showed no NH absorption on its IR spectrum. The features of the NMR spectra of **4** were similar to those of **3a**. Thus the structure of **4** was determined as *trans,trans*-1,4-bis(3-bromo-2-tetrahydropyranyl)-2,5-piperazinedione. Neither the trans, cis, nor the cis, cis isomer was isolated.

On the other hand, the adducts **5** and **6** were determined to be 3-substituted 2-hydroxytetrahydropyran derivatives by the following spectroscopic analysis. The presence of hydroxyl groups in **5** and **6** was characterized by their IR absorption (ν_{OH} 3400 cm^{-1}) and MS peaks (M^+-H_2O and M^+-2H_2O). The adduct **5** consisted of two isomers; which were hardly separated on TLC. The NMR spectra of **5** showed complex signals indicating that it contained two configurational isomers. That is, there were two hemiacetal hydroxylic groups at δ=6.29 (a doublet, coupled with an adjacent methine proton with J=4.5 Hz) and at δ=6.42 (another doublet, coupled with another adjacent methine proton with J=6 Hz). Two respective hemiacetal methine protons were also observed at δ=4.79 (dd, J=2 and 4.5 Hz) and at δ=4.57 (dd, J=6 and 8 Hz). The former was presumed to be an equatorial hemiacetal methine proton and the latter to be an axial hemiacetal methine proton, and their coupling constants indicated the presence of axial protons on C_2, to which an equatorial 2,5-piperadinedione moiety was attached. The NMR spectra also indicated a hemiacetal structure for the 1:2-adduct **6**. The methine protons resonated at δ=4.70 as a double doublet with J=6 and 12 Hz, which may be assigned to axial protons on C_1 with adjacent axial protons on C_2 as mentioned above. The spectra of **7** were also found to be consistant with the structure given in Scheme 1.

The position of the bromine substituent(s) of the bromine-containing adducts (**3** and **4**) suggested that a species to attack the double bond of **2** was either a bromine cation to give a 3-bromo-1-tetrahydropyranyl cation, or a bromine radical to give a corresponding radical. In the presence of hydroquinone, the reaction gave **3** and **4** in almost unchanged yields, while the yields of **5**—**7** were considerably depressed. In addition, the reactions in the dark[9] afforded **3** and **4** in increased yields, while **5**—



Scheme 2.

7 in highly decreased yields. These observations may rule out the radical addition mechanism for the formation of **3** and **4**. Thus the bromine cation produced by heterolysis of the N–Br bond of **1** added to **2** to give the 3-bromo-1-tetrahydropyranyl cation, which in turn reacted with the 2,5-dioxo-1-piperazinyl anion to afford the adducts **3** and **4**. In the reaction of **1** with cyclohexene in acetonitrile under similar conditions, 2-acetylamino-1-bromocyclohexane was isolated. This was thought to be derived by a Ritter-type addition of the 2-bromocyclohexyl cation to acetonitrile.[6] However, in the present reactions, no 2-acetylamino-3-bromotetrahydropyran, a corresponding Ritter-type product, was detected.

On the other hand, the hydroxyl group-containing adducts (**5** and **6**), and the dihydropyran derivative (**7**) were presumed to be secondary products derived from other bromine-containing adducts produced through a radical addition of **1** to **2**. We had previously shown that the radical reactions of **1** with cyclohexene and 1-alkenes revealed a solvent dependent product distributions.[6,7] In carbon tetrachloride, which is a poor solvent for **1** (under essentially heterogeneous conditions), allylic bromination and bromine addition to the double bonds were the dominant processes. Contrarily, in acetonitrile (a good solvent for **1**) the radical addition of **1** to the double bonds became the main reaction path, in which the 2,5-dioxo-1-piperazinyl radical added initially to the less substituted carbon atoms of the respective double bonds to give more stable radical intermediates.[7] Tedder and Walton[10] reported that addition of a radical to a vinyl ether gave preferentially a 1-alkoxy-1-alkyl radical. Accordingly, a primary radical expected from addition of the 2,5-dioxo-1-piperazinyl radical to **2** should be a 3-(4-bromo-2,5-dioxo-1-piperazinyl)-2-tetrahydropyranyl radical. The radical thus formed would abstract a bromine atom from **1** to give 1-(2-bromo-3-tetrahydropyranyl)-2,5-piperazinedione (not isolated). 1,4-Bis(2-bromo-3-tetrahydropyranyl)-2,5-piperazinedione (not isolated) woubd be produced in a similar manner. We had observed previously that 1- and 1,4-bis(2-bromoalkyl)-2,5-piperazinediones are spontaneously hydrolyzed during chromatographic separation to give corresponding 2-hydroxyalkyl derivatives.[7] Participation of the neighboring N-function was responsible for the observed ease of hydrolysis. In the present cases, the bromine substituents of the above mentioned bromotetrahydropyranyl-2,5-piperazinediones were undoubtedly more easily hydrolyzed to give **5** and **6**, because of the hemiacetal character of the bromine-bearing carbon atoms. The substituted 3,4-dihydro-2*H*-pyran (**7**) was considered to be formed by concomitant dehydrobromination of 1-(2-bromo-3-tetrahydropyranyl)-2,5-piperazinedione.

It was suggested that in the reaction of 1,4-dibromo-2,5-piperazinedione (**1**) with 3,4-dihydro-2*H*-pyran (**2**) the two processes, the radical addition and the ionic addition, were operating concurrently to give the corresponding adducts (Table). In dark conditions, the ionic addition predominated, but the radical addition was not completely depressed. Hydroquinone decreased the yields of the radical addition products, whereas those of the ionic addition products remained unchanged. Low temperature seemed to favor the radical addition process as described in the case of NBS.[4]

Experimental

3,4-Dihydro-2*H*-pyran and 1,2-epoxybutane were dried over Molecular Sieve 4A and distilled over copper(I) chloride prior to use. Acetonitrile was dried over calcium hydride and distilled. 1,4-Dibromo-2,5-piperazinedione was prepared according to the procedure reported earlier.[11] IR spectra (KBr) were recorded with JASCO IR-A-1 and -3 spectrometers. NMR spectra were measured on JEOL JMN-PMX-60 and-PS-100 specrometers using tetramethylsilane as the internal standard. Mass spectra were obtained by an ESCO EMD-05A spectrometer. Irradiation was carried out using a Halos EHB-WU high pressure mercury arc lamp (100 W).

Reaction of 1,4-Dibromo-2,5-piperazinedione (1) with 3,4-Dihydro-2*H*-pyran (2) in the Presence of 1,2-Epoxybutane. A typical experimental procedure is described. Irradiation of a mixture containing 2.72 g (10 mmol) of **1**, 8.41 g(100 mmol) of **2**, and 1,2-epoxybutane (2.88 g, 40 mmol) in acetonitrile (50 cm^3) was carried out for 3 h at room temperature with stirring. The resulted mixture was filtered to give 2,5-piperazinedione (**8**). The filtrate was evaporated to a syrup, which was separated on a silica-gel column using benzene–acetone (4:1) as eluant. Yields are given in Table as an average of three experiments on the basis of **1** employed. Physical constants of respective products are shown below.

Synthesis of Sydnone Compounds Substituted by Heteroatom Groups at the 4-Positions

Toshio FUCHIGAMI,* Ching-Sy CHEN, Tsutomu NONAKA,* Mou-Yung YEH,† and Hsien-Ju TIEN†

(Received May 8, 1985)

A general method for the introduction of heteroatoms to the 4-position of a sydnone ring was developed. Various 4-alkylthio- and 4-arylthiosydnones were prepared in excellent yields by the reaction of 3-aryl-4-lithiosydnones (**2**) with dialkyl and diaryl disulfides. Treatment of **2** with diaryl diselenides, diphenylphosphinous chloride, and arsenic trichloride provided 3-aryl-4-(arylseleno)sydnones, (3-aryl-4-sydnonyl)diphenylphosphine and tris(3-aryl-4-sydnonyl)arsine, respectively, in good yields. It was also found that the reactivity of sydnonyl anions derived from **2** was quite different in some cases from that of the corresponding ordinary aromatic analogues, though the sydnone ring has a somewhat aromatic nature.

Sydnone is a typical mesoionic compound and has been investigated extensively because of its unique electronic structure and biological activity.[1]

As a part of a broad program to study on the synthesis of sydnone compounds and their properties, we reported the synthesis of sydnone derivatives having various kinds of heterocyclic groups at the 4-positions from derivatives of sydnone-4-carboxylic acid[2,3] and 4-(haloacety)sydnones.[4-7]

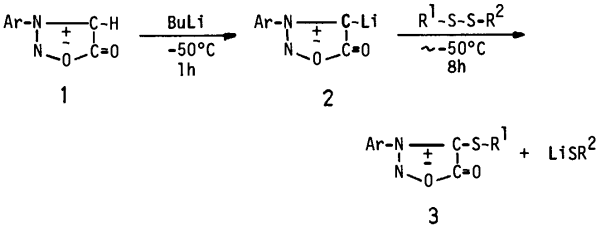
Although a number of sydnone derivatives have been prepared, relatively few studies on the direct substitution by heteroatoms at the 4-position have been reported.[8-14] All attempts to introduce electron-donating substituents such as hydroxyl, alkoxyl, and amino groups at this position have been unsuccessful so far. Recently, Masuda and Okutani have successfully introduced methylthio and phenylthio groups, i.e. analogues of an alkoxyl group, to the 4-position of sydnones by the use of dimethyl sulfoxide and methyl phenyl sulfoxide, respectively.[10] However, their method has limitation and some problems, because the yields are low except for a few cases and the reaction conditions are not so mild. Since the sydnone ring is unstable to acid, alkali, heat, oxidation, and reduction, the successful synthesis of sydnone derivatives requires quite mild reaction conditions in general. Although 4-lithiosydnone (**2**) can be easily prepared from sydnone (**1**) and butyllithium, very few synthetic studies using **2** have been reported: Especially, very few sydnone derivatives substituted by heteroatoms have been prepared from **2**.[13,14]

From these aspects, at first, a general method for the introduction of sulfur and its analogue, selenium, to the 4-position was developed using **2** as the starting material in this work. And then, some attempts to introduce phosphorus, arsenic, antimony, and tin atoms were also made.

Results and Discussion

Synthesis of 4-Alkylthio- and 4-Arylthiosydnone Compounds (3). It is known that carbanions readily react with disulfides to provide the corresponding sulfides.[15] This method seems suitable for the introduction of thio groups to carbon atoms which have active hydrogens. This prompted us to explore the possibilities of direct introduction of alkylthio and arylthio groups to the 4-position of a sydnone ring by the reaction of 4-lithiosydnone (**2**) with various disulfides. We found that the initial lithiation of sydnones and the subsequent reaction of the resulting **2** with disulfides could be run in sequence in THF below −50°C.

As shown in Table 1, 4-alkylthio- and arylthiosydnone compounds (**3**) were successfully prepared in excellent yields. Bis(2-Benzothiazolyl) disulfides provided 4-(2-benzothiazolylthio)-sydnone (**3d**) in a good yield whereas dimorpholino disulfide did not and large amount of the starting sydnone was recovered. This unsuccessful result may be attributable to higher electron density on the sulfur atoms compared with those of the other disulfides. The higher electron density may be due to the presence of the electron-donating morpholino groups. Two possible



Scheme 1.

products, 4-(2-naphthylthio)sydnone (**3e**) and 4-sydnonyl thiocyanate, were expected to be formed from **2** and 2-naphthalenesulfenyl thiocyanate, however **3e** was obtained as a sole product in a good yield as shown in Scheme 2.

This procedure seems to be an excellent general method for the preparation of 4-alkylthio- and arylthiosydnone derivatives, since the reaction proceeds

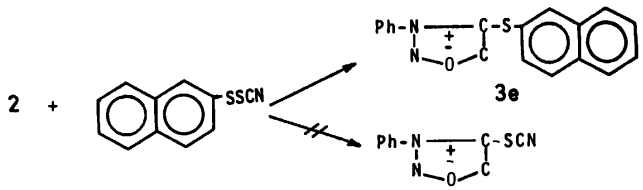

Scheme 2.

under quite mild conditions and almost pure products can be directly obtained.

Synthesis of 4-(Arylseleno)sydnones (4). We extended this process for the preparation of 4-(arylseleno)sydnones (**4**) and 4-(phenyltelluro)sydnone (**5**) using diaryl diselenide and diphenyl ditelluride, respectively. As shown in Tables 2, **4** was obtained in a good yield whereas **5** was not. Although disulfide, diselenide, and ditelluride are analogues, the reactivity of ditelluride to **2** was found to be quite different.

Scheme 3.

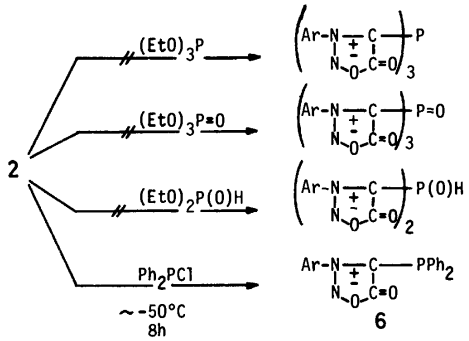
Introduction of Phosphorus Atoms to the 4-Positions of Sydnones. Since it is known that aryllithiums react with various kinds of phosphorus acid esters and halophosphorus compounds to give the corresponding compounds having a C–P bond, the following reactions were examined using **2** as shown in

Table 2. Synthesis of Sydnone Derivatives (4—7)

Compound	Yield[a] %	Mp θ_m/°C
4a	99	83—84
4b	100	90—91
5	0	—
6a	92	175—176
6b	97	164.5—165
7a	99	92
7b	100	91

a) Crude yield.

Scheme 4. 4-Lithiosydnone **2** did not react with the



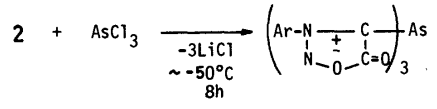
6a : Ar=Ph,
6b : Ar=p-Tolyl

Scheme 4.

phosphorus acid esters used, whereas diphenylphosphinous chloride reacted with **2** to provide 4-(diphenylphosphino)sydnone (**6**) in a good yield. These unsuccessful results may indicate that the reactivity of 4-sydnonyl anion is lower than that of ordinary aryl

anions.

Introduction of Arsenic Atom to the 4-Positions of Sydnones. Since diarylphosphinous chloride and phosphorus trichloride[13] reacted smoothly with **2**, the reaction of **2** with arsenic trichloride was successfully attempted in a similar manner to provide the corresponding tri(4-sydnonyl)arsine (**7**) which is a compound containing three sydnone rings bound to the same central arsenic atom.



7a : Ar=Ph
7b : Ar=p-Tolyl

Scheme 5.

Attempts to Introduce Tin and Antimony to the 4-Positions of Sydnones. It is known that **2** reacts with chlorotrimethylsilane to give 4-sydnonylsilane.[14] In a similar manner, the reactions of **2** with tin(II) chloride, trimethyltin chloride, antimony trichloride, and antimony pentachloride were carried out. However, all attempts were unsuccessful. Since ordinary aryllithium readily reacts with halostannanes, the unsuccessful result also clearly indicates that the nucleophilicity of 4-sydnonyl anion is weaker than that of ordinary aryl anions.

The new types of sydnone compounds thus prepared are expected to be pharmacologically active and screening tests of several biological activities of these sydnones are currently under investigation.

Experimental

^{1}H NMR spectra were recorded at 60 MHz on a Varian EM-360 spectrometer using $CDCl_3$ and Me_4Si as a solvent and an internal standard, respectively. IR spectra were obtained on a Hitachi 295 infrared spectrometer. Electron impact mass spectra were determined at 30 eV on a JEOL JMS-D100 mass spectrometer by direct introduction via solid probe.

Typical Procedure for the Synthesis of 4-Alkylthio- and Arylthiosydnones (3). Synthesis of 4-Methylthio-3-phenyl-sydnone (3a): To a stirred suspension of 6.2 mmol of 4-phenylsydnone in 10 ml of anhydrous THF was added dropwise 6.5 mmol of a solution of butyllithium in hexane (15%, 4 ml) below −50 °C. After about 1 h of stirring, a solution of 6.2 mmol of diphenyl disulfide in 5 ml of THF was added dropwise to the resulting brown solution below −50 °C. After additional 8 h of stirring, the reaction mixture was poured into ice-water. The precipitating colorless pure product, **3a** was collected by filtration, washed with water, and dried. The yield was 1.15 g; IR (KBr): 3060 (νCH of Ph), 2950 (νCH of Me), 1790, and 1770 cm^{-1} (νC=O). *m/z* 208 (M^+) and 150 (M^+−NO-CO). ^{1}H NMR: δ=2.20 (s, 3H, CH_3) and 7.67 (s, 5H, C_6H_5). Found: C, 51.99; H, 3.96; N, 13.50; S, 15.69%. Calcd for $C_9H_8N_2O_2S$: C, 51.91; H, 3.87; N, 13.45; S, 15.40%.

3-Phenyl-4-(phenylthio)sydnone (3b): A yellow solid (from ethanol). IR (KBr): 3060 (νCH of Ph) and 1770 cm^{-1} (νC=O). *m/z* 270 (M^+) and 212 (M^+−NO-CO). ^{1}H NMR δ=7.16 (s, 5H, C_6H_5S) and 7.60 (s, 5H, C_6H_5). Found: C, 62.32; H, 3.68; N, 10.44; S, 11.65%. Calcd for $C_{14}H_{10}N_2O_2S$: C, 62,21; H, 3.73; N, 10.36; S, 11.86%.

3-Phenyl-4-(*p*-tolylthio)sydnone (3c): A pale yellow solid (from ethanol). IR (KBr): 3070 (νCH of aromatic), 2930 (νCH of Me), 1790 and 1770 cm^{-1} (νC=O). *m/z* 284 (M^+) and 226 (M^+−NO-CO). ^{1}H NMR δ=2.30 (s, 3H, CH_3), 7.07 (s, 4H, *p*-MeC_6H_4), and 7.30—7.80 (m, 5H, C_6H_5). Found: C, 63.33; H, 3.97; N, 9.76; S, 11.18%. Calcd for $C_{15}H_{12}N_2O_2S$: C, 63.36; H, 4.25; N, 9.85; S, 11.28%.

4-(2-Benzothiazolylthio)-3-phenylsydnone (3d): Colorless needles (from ethanol-acetone). IR (KBr): 3070 (νCH of aromatic), 1795, and 1775 cm^{-1} (νC=O). *m/z* 239 (M^+−NO-CO). ^{1}H NMR δ=7.00—8.00 (m, aromatic C-H). Found: C, 55.08; H, 2.71; N, 12.65; S, 19.65%. Calcd for $C_{15}H_9N_3O_2S$: C, 55.03; H, 2.77; N, 12.84; S, 19.59%.

4-(2-Naphthylthio)-3-phenylsydnone (3e): The product **3e** was obtained as a pale yellow solid, which contains ethanol of crystallization after recrystallization from ethanol. IR (KBr): 3070 (νCH of aromatic), 1785, and 1765 cm^{-1} (νC=O). *m/z* 320 (M^+), 262 (M^+−NO-CO), and 46 ($EtOH^+$). ^{1}H NMR δ=1.27 (t, 3H, CH_3CH_2OH), 1.67 (s, 1H, CH_3CH_2OH), 3.75 (CH_3CH_2OH), and 7.10—8.10 (m, 12H, aromatic C-H). Found: C, 65.36; H, 4.82; N, 7.41%. Calcd for $C_{20}H_{18}N_3O_3S$: C, 65.56; H, 4.95; N, 7.63%.

4-Methylthio-3-(*p*-tolyl)sydnone (3g): Colorless prisms (from ethanol). IR (KBr): 3070 (νCH of aromatic), 2930 (νCH of Me), and 1770 cm^{-1} (νC=O). *m/z* 222 (M^+) and 164 (M^+−NO-CO). ^{1}H NMR δ=2.28 (s, 3H, CH_3S), 2.53 (s, 3H, *p*-$CH_3C_6H_4$), and 7.47 (s, 4H, *p*-MeC_6H_4). Found: C, 53.75; H, 4.59; N, 12.36%. Calcd for $C_{10}H_{10}N_2O_2S$: C, 54.04; H, 4.53; N, 12.60%.

4-Phenylthio-3-(*p*-tolyl)sydnone (3h): After reaction, the reaction mixture was poured into ice-water and was repeatedly extracted with dichloromethane. The extracts were dried over anhydrous sodium sulfate and then evaporated to give pure **3h** as brown viscous oil. IR (KBr): 3070 (νCH of aromatic), 2930 (νCH of Me), and 1780 cm^{-1} (νC=O). *m/z* 284 (M^+) and 226 (M^+−NO-CO). ^{1}H NMR δ=2.40 (s, 3H, CH_3), 7.13 (s, 5H, C_6H_5), and 7.26 (s, 4H, *p*-MeC_6H_4). Found: C, 63.23; H, 4.18; N, 9.92; S, 11.27%. Calcd for $C_{15}H_{12}N_2O_2S$ C, 63.36; H, 4.25; N, 9.85; S, 11.28%.

3-(*p*-Tolyl)-4-(*p*-tolylthio)sydnone (3i): A yellow solid (from ethanol). IR (KBr): 3070 (νCH of aromatic), 2930 (νCH of Me), 1790, and 1775 cm^{-1} (νC=O). *m/z* 298 (M^+) and 240 (M^+−NO-CO). ^{1}H NMR δ=2.30 (s, 3H, *p*-$CH_3C_6H_4S$), 2.50 (s, 3H, *p*-$CH_3C_6H_4$), 7.10 (s, 4H, *p*-MeC_6H_4S), and 7.30 (s, 4H, *p*-MeC_6H_4). Found: C, 64.20; H, 4.54; N, 9.32; S, 10.83%. Calcd for $C_{16}H_{14}N_2O_2S$: C, 64.41; H, 4.73; N, 9.39; S, 10.75%.

Synthesis of 4-(Arylseleno)sydnones (4). 3-Phenyl-4-(phenylseleno)sydnone (4a): In a manner similar to the synthesis of **3**, **4a** was obtained using diphenyl diselenide. A yellow solid (from ethanol). IR (KBr): 3075 (νCH of aromatic) and 1770 cm^{-1} (νC=O). *m/z* 318 (M^++2), 316 (M^+), 260 (M^++2−NO-CO), and 258 (M^+−NO-CO). ^{1}H NMR δ=7.20 (broad s, 5H, C_6H_5Se) and 7.35—7.75 (m, 5H, C_6H_5). Found: C, 53.03; H, 3.05; N, 8.73%. Calcd for $C_{14}H_{10}N_2O_2Se$: C, 53.01; H, 3.18; N, 8.83%.

4-Phenylseleno-3-(*p*-tolyl)sydnone (4b): A pale yellow solid (from ethanol). IR (KBr): 3070 (νCH of aromatic), 2930 (νCH of Me), 1780, and 1760 cm^{-1} (νC=O). *m/z* 332 (M^++2),

330(M^+), 274 (M^++2−NO-CO), and 272 (M^+−NO-CO). ^{1}H NMR δ=2.50 (s, 3H, CH_3), and 7.10—7.50 (m, 9H, aromatic C-H). Found: C, 54.48; H, 3.53; N, 8.35%. Calcd for $C_{15}H_{12}N_2O_2Se$: C, 54.39; H, 3.65; N, 8.46%.

Diphenyl(3-phenyl-4-sydnonyl)phosphine (6a). In a manner similar to the synthesis of **3** and **4**, **6a** was obtained using chlorodiphenylphosphine and 4-lithio-3-phenylsydnone. White yellow plates [from ethanol-acetone (2:1)]. IR (KBr): 3070 (νCH of phenyl) and 1760 cm^{-1} (νC=O). *m/z* 346 (M^+), 288 (M^+−NO-CO), and 185 (Ph_2P^+). ^{1}H NMR δ=7.40 (m,10H, C_6H_5P) and 7.55 (s, 5H, C_6H_5). Found: C, 69.62; H, 4.17; N, 7.83%. Calcd for $C_{20}H_{15}N_2O_2P$: C, 69.36; H, 4.37; N, 8.09%.

Diphenyl[3-(*p*-tolyl)-4-sydnonyl]phosphine (6b). Colorless needles [from ethanol-acetone (2:1)]. IR (KBr): 3070 (νCH of aromatic), 1780, and 1760 cm^{-1} (νC=O). *m/z* 360 (M^+), 302 (M^+−NO-CO), and 185 (Ph_2P^+). ^{1}H NMR δ=2.47 (s, 3H, *p*-$CH_3C_6H_4$) and 7.00—7.70 (m, 14H, aromatic C-H). Found: C, 70.09; H, 4.49; N, 7.65%. Calcd for $C_{21}H_{17}N_2O_2P$: C, 70.00; H, 4.75; N, 7.77%.

Tris(3-Phenyl-4-sydnonyl)arsine (7a). In a manner similar to the synthesis of **3**, **7a** was obtained using arsenic trichloride and 4-lithio-3-phenylsydnone. A pale yellow solid [from ethanol-acetone (2:1)]. IR (KBr): 3060 (νC-H of Ph), 1785, and 1760 cm^{-1} (νC=O). ^{1}H NMR δ=7.37—7.87 (m, C_6H_5]. Found: C, 51.57; H, 2.54; N, 15.21%. Calcd for $C_{24}H_{15}N_6O_6As$: C, 51. 63; H, 2.71; N, 15.05%.

Tris[3-(*p*-Tolyl)-4-sydnonyl]arsine (7b). A colorless solid [from ethanol-acetone (2:1)]. IR (KBr): 3070 (νCH of aromatic), 2940 (νCH of Me), 1790, and 1750 cm^{-1} (νC=O). ^{1}H NMR δ=2.47 (s, 9H, CH_3) and 7.30 (s, 12H, *p*-MeC_6H_4). Found: C, 54.18; H, 2.31; N, 13.95%. Calcd for $C_{27}H_{21}N_6O_6As$: C, 54.01; H, 2.53; N, 14.00%.

(Received July 11, 1985)

The introduction of thio and seleno functional groups to the 4-position of a sydnone ring was successfully attempted using 4-lithiosydnones (**2**) and 4-bromosydnones (**3**) as starting compounds. The reaction of **2** with tetraalkylthiuram disulfides, bis[alkoxy(thiocarbonyl)] disulfides, and bis[alkylthio(thiocarbonyl)] disulfides provided 4-sydnonyl dithiocarbamates, *O*-alkyl *S*-(4-sydnonyl) dithiocarbonates, and dialkyl 4-sydnonyl trithiocarbonates, respectively in good yields. In addition, treatment of **2** with thiocyanogen and selenocyanogen gave rise to bis(4-sydnonyl) sulfides (**11**) and bis(4-sydnonyl) selenides (**12**), respectively. These products, **11** and **12** were also formed by the reaction of **3** with potassium thiocyanate and selenocyanate, respectively. Furthermore, it was found that **3** reacted with selenourea and potassium *O*-ethyl dithiocarbonate under heating to provide **12** and **11**, respectively. It was also found that the reactivity of these sydnone compounds **2** and **3** was quite different in many cases from that of the corresponding ordinary aromatic analogues, though the sydnone ring has a somewhat aromatic nature.

Although a typical mesoionic compound, sydnone (**1**) has been investigated extensively because of its unique electronic structure and biological activities, a few studies on the direct substitution by heteroatoms and hetero functional groups at the 4-position have been reported.[1)]

In our previous paper,[2)] we have reported a general method for the introduction of heteroatoms such as sulfur, selenium, phosphorus and arsenic to the 4-position. For example, we found that 4-thio and 4-selenosydnone compounds were successfully prepared by the reaction of 4-lithiosydnones (**2**) with disulfides and diselenides, respectively. In these cases, reaction proceeded under mild conditions and almost pure products could be obtained directly. Since sydnones are known to be unstable to acid, alkali, heat, oxidation, and reduction, quite mild reaction conditions are necessary for the successful synthesis of sydnone derivatives in general.[3)] Therefore, the previous method for the introduction of thio and seleno groups seems to be applicable to more complicated disulfides and selenides bearing carbonyl, thiocarbonyl, and cyano groups to provide sydnone compounds having hetero functional groups containing sulfur and selenium atoms.

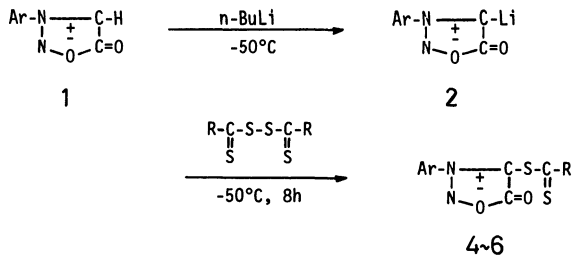
4-Bromosydnones (**3**) are easily prepared by both chemical and electrochemical halogenation of 4-unsubstitued sydnones.[4)] Although **3** is known to be useful starting compounds for the preparation of sydnone derivatives, only one paper dealing with the reaction of **3** with heteroatom compounds such as hydrogen sulfide, thiophenol, and thiourea has been reported.[5)]

From these aspects, preparation of sydnone compounds substituted by hetero functional groups at the 4-positions was attempted using **2** and **3** as starting materials.

Results and Discussion

Preparation of Sydnones Having Thiocarbonylthio Groups at the 4-Positions. It was found that the initial lithiation of sydnones (**1**) and the subsequent reaction of the resulting 4-lithiosydnones (**2**) with tetraalkylthiuram disulfides, bis[alkoxy(thiocarbonyl)] disulfides, and bis[alkylthio(thiocarbonyl)] disulfides could be run in sequence in THF below −50 °C (Scheme 1).

As shown in Table 1, 4-sydnonyl dithiocarbamates (**4**), *O*-alkyl-*S*-(4-sydnonyl) dithiocarbonates (**5**), and alkyl 4-sydnonyl trithiocarbonates (**6**) were successfully prepared in good yields.



Scheme 1.

The structures of the products **4**, **5**, and **6** were confirmed by elemental analyses and various spectral studies. In the IR spectra, C–H absorption bands (3140—3160 cm^{-1}) of the starting **1** disappeared after the reaction, while those of thiocarbonyl groups (1050—1200 cm^{-1}) newly appeared. In the MS spectra, most sydnone derivatives showed their molecular ion peaks together with their characteristic fragment peaks due to the elimination of CO and NO. The sydnones bearing an isopropyl group showed fragment peaks due to elimination of the isopropyl group but did not show their molecular ion peaks.

It is known that the reaction of ordinary aryllithiums

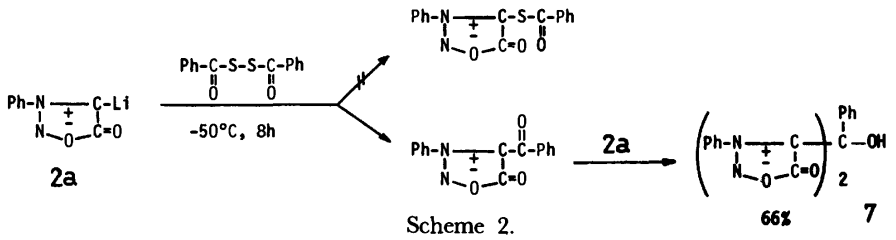

Scheme 2.

with such sulfides always gives a mixture of products because of a competing nucleophilic attack at both the sulfur atoms of the disulfide bond and the carbon atoms of the thiocarbonyl group. Recently, Cava et al.[6] have reported that an aryllithium reacts exclusively at a disulfide bond of tetraisopropylthiuram disulfide to provide aryl dithiocarbamate because the thiocarbonyl group is highly hindered to nucleophilic attack. From these points, it is noticeable that the reaction always took place at the disulfide bond selectively, regardless of the bulkiness of the alkyl substituents in the case of **2**. These results indicate that the reactivity of 4-sydnonyl anions is different from that of ordinary aryl anions.

Next, we extended this process to the preparation of 4-(benzoylthio)sydnone. The reaction was carried out in a similar manner using equimolar **2a** and dibenzoyl disulfide. However, no expected product was obtained and Phenylbis(3-phenyl-4-sydnonyl)methanol (**7**) was formed in a low yield. In this case, a large amount of the disulfide was recovered. Since **7** should be stoichiometrically formed from two mole of **2a** and one mole of the disulfide, the reaction was carried out using two equiv of **2a** to provide **7** in a moderate yield.

It is noticeable that 4-sydnonyl anions attack at a carbonyl group but do not attack the thiocarbonyl group of the disulfides used in these reactions. In order to confirm this fact further, the reaction of **2** with carbon disulfide was examined. However, the reaction did not proceed at all, though it is well-known that **2** readily reacts with carbon dioxide to provide 4-sydnonecarboxylic acid in a good yield.[7] Since carbon disulfide is much more reactive to nucleophiles than carbon dioxide, the reactivity of 4-sydnonyl anions is quite unique.

Since dithiocarbamates are known to be easily hydrolyzed by alcoholic alkali to give the corresponding thiols,[6] hydrolysis of **4**, **5**, and **6** were attempted in order to obtain 4-mercaptosydnone (**8**) which are hitherto unknown compounds. However, our attempts were unsuccessful owing to the decomposition of the sydnone ring.

Reaction of 4-Lithiosydnones (2) with Thiocyanogen and Selenocyanogen. Since the reaction of **2** with disulfides bearing a thiocarbonyl group was found to be useful for the introduction of thiocarbonylthio groups to the 4-positions of sydnones, we applied this procedure to the preparation of 4-sydnonyl thio- and selenocyanates (**9** and **10**) from thio- and selenocyanogens. Thio- and selenocyanogens were generated from potassium thio- and selenocyanates and bromine in dry THF at −50°C and the resulting solution was directly used for the reaction with **2**. When the solution of thiocyanogen was added gradually to the solution of **2** [procedure (a)], bis(4-sydnonyl) sulfide (**11**) was unexpectedly formed instead of 4-sydnonyl thiocyanate (**9**). In order to obtain the desired **9**, the reverse procedure (b) was attempted as follows: **2** was added to the solution of thiocyanogen, however the same product, **11** was obtained. No remarkable differene in the yield of **11** was observed between these two procedures employed.

In a similar manner, the reaction of **2** with seleno-

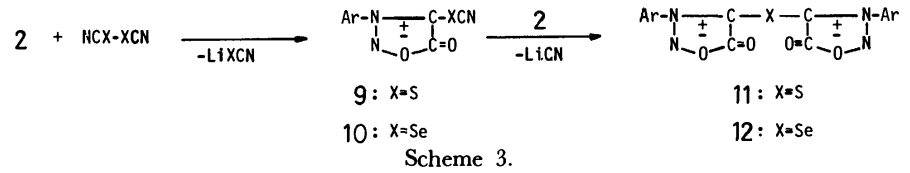
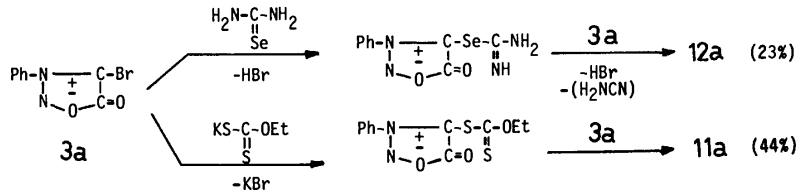


Scheme 3.



Scheme 4.

cyanogen also provided bis(4-sydnonyl) selenide (**12**) in a moderate yield as shown in Table 2.

Aryl tellurocyanates are known to be unstable and disproportionate to diaryl tellurides and tellurium dicyanate in some cases,[8] whereas aryl thio- and selenocyanates are stable and such disproportionation has not been reported. A probable mechanism for the reaction involves the formation of 4-sydnonyl thio- and selenocyanates (**9** and **10**) as primary products, which reacted further with 4-sydnonyl anions to give rise to **11** and **12**, respectively.[9]

These results clearly indicate that the reactivity of 4-sydnonyl anions is quite different from that of ordinary aromatic analogues though the sydnone ring has a somewhat aromatic nature.

Reaction of 4-Bromosydnone (3) with Selenourea. 4-Bromo-3-phenylsydnone (**3a**) was found to react with selenourea under refluxing in ethanol to give bis(3-phenyl-4-sydnonyl)selenide (**12a**). During the reaction, the precipitation of selenium metal was observed. Since ordinary aryl bromides do not react with selenourea, this reaction seems to be quite interesting.

Kato and Ohta found that 4-iodo- and bromosydnones have weak oxidizing power whereas 4-chlorosydnone does not.[5,10] Since oxidative deselenylation of selenourea is known to take place very often as well as that of thiourea, the elimination of selenium metal clearly indicates that the bromosydnone **3a** acted as oxidizing reagent in this reaction.

Table 3. Reaction of 4-Bromosydnone (**3**) with Potassium Thiocyanate and Selenocyanate

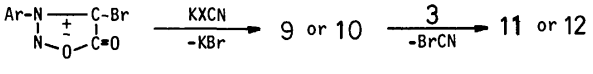
12b	*p*-Tolyl	Se	24	50

a) After recrystallization.

Reaction of 4-Bromosydnone with Potassium Thio- and Selenocyanates and Potassium *O*-Ethyl Dithiocarbonate. Because the thio- and selenocyanation of sydnones from **2** and thio- and selenocyanogen was unsuccessful, the reaction of **3** with potassium thio- and selenocyanates was attempted in order to obtain **9** and **10**, respectively. However, the reaction in DMF under heating provided sulfides **11** and selenides **12** instead of the desired products (**9** and **10**) as shown in Scheme 5. The results are summarized in Table 3.



Scheme 5.

In our earlier work,[11] we found that *N*-[α-(chloroimino)benzyl]sulfilimine easily reacted with potassium thiocyanate to provide heterocyclic sulfilimine. Although this sulfilimine has a positive halogen, such elimination of the cyanate ion was not observed.

The products **11** and **12** seem to be formed by the further reaction of 4-sydnonyl thio- or selenocyanates (**9** or **10**) once formed with additional 4-bromosydnones as shown in Scheme 5.

It was found that the sulfide **11a** was also formed by the reaction of **3a** with potassium *O*-ethyl dithiocarbonate in a similar manner. The reaction may proceed similarly to the reaction of the thio- and selenocyanate ions (Secheme 4).

It was reported that the bromine atom of bromomalonic acids could be substituted by the thiocyanate ion, although their bromine atom has a positive character.[12] These unusual reactions (Schemes 4 and 5) have never been known in the case of the corresponding ordinary aryl bromides, therefore it can be stated that 4-bromosydnone **3** has quite intriguing reactivities.

The new type of sydnone compounds thus prepared are expected to be pharmacologically active and screening tests of several biological activities of these sydnones are currently under investigation.

Experimental

NMR spectra were recorded at 60 MHz on a Varian EM-360 spectrometer using Me_4Si as an internal standard. IR spectra were obtained on a Hitachi 295 infrared spectrometer. Electron impact mass spectra were determined at 30 eV on a JEOL JMS-D100 mass spectrometer by direct introduction via solid probe.

Typical Procedure for the Preparation of Sydnones Having Thiocarbonylthio Groups at the 4-Positions (4, 5, and 6). 3-Phenyl-4-sydnonyl Dimethyldithiocarbamate (4a): To a stirred suspension of 1.00 g (6.2 mmol) of 3-phenylsydnone in 10 ml of anhydrous THF, under a dry nitrogen atmosphere, was added dropwise 4.0 ml (6.5 mmol) of a solution of butyllithium in hexane (15%) below −50 °C. After about 1 h of stirring, a solution of 1.48 g (6.2 mmol) of tetramethylthiuram disulfide in 7 ml of THF was added dropwise to the resulting brown solution below −50 °C. After additional 8 h of stirring, the yellow-brown reaction mixture was poured into ice-water. The pricipitated yellow solid was collected by filtration, washed with water, and dried: yield 1.71 g (99%); mp 145—147 °C. Recrystallization from ethanol provided 1.55 g (89%) of the pure product **4a** as yellow plates: Mp 148—150 °C; NMR ($CDCl_3$) δ=3.30 (s, 3H, $C\underline{H}_3$), 3.35 (s, 3H, $C\underline{H}_3$), and 7.63 (s, 5H, $C_6\underline{H}_5$); MS, *m/z* 281 (M^+) and 223 (M^+−NO-CO). Found: C, 46.98; H, 3.92; N, 14.93; S, 22.47%. Calcd for $C_{11}H_{11}N_3O_2S_2$: C, 46.96; H, 3.94; N, 14.93; S, 22.79%.

3-Phenyl-4-sydnonyl Diisopropyldithiocarbamate (4b): A yellow solid (from ethanol); ^1H NMR ($CDCl_3$) δ=1.31 (d, 12H, $C\underline{H}_3$), 4.0—5.0 (m, 2H, C<u>H</u>), and 7.63 (s, 5H, $C_6\underline{H}_5$); MS, *m/z* 337 (M^+), 294 (M^+−*i*-Pr), and 236 (M^+−*i*-Pr-NO-CO). Found: C, 53.37; H, 5.71; N, 12.32; S, 18.98%. Calcd for $C_{15}H_{19}N_3O_2S_2$: C, 53.39; H, 5.67; N, 12.45; S, 19.00%.

3-(*p*-Tolyl)-4-sydnonyl Dimethyldithiocarbamate (4c): A yellow solid (from ethanol); ^1H NMR ($CDCl_3$) δ=2.45 (s, 3H, *p*-$C\underline{H}_3C_6H_4$), 3.35 (s, 3H, $NC\underline{H}_3$), 3.40 (s, 3H, $NC\underline{H}_3$), 7.30 (d, 2H, Ar-H), and 7.50 (d, 2H, Ar-H); MS, *m/z* 295 (M^+) and 149 (M^+−NO-CO-C(S)NMe_2). Found: C, 48.98; H, 4.77; N, 14.10; S, 21.65%. Calcd for $C_{12}H_{13}N_3O_2S$: C, 48.80; H, 4.44; H, 14.23; S, 21.71%.

3-(*p*-Tolyl)-4-sydnonyl Diisopropyldithiocarbamate (4d): Pale pink plates (from ethanol); ^1H NMR ($CDCl_3$) δ=1.40 (d, 12H, $CH(C\underline{H}_3)_2$), 2.45 (s, 3H, *p*-$C\underline{H}_3C_6H_4$), 4.10—4.90 (br. m, 2H, C<u>H</u>), 7.30 (d, 2H, Ar-H), and 7.50 (d, 2H, Ar-H); MS, *m/z* 308 (M^+−*i*-Pr), and 250 (M^+−*i*-Pr-NO-CO). ***O*-Isopropyl *S*-(3-phenyl-4-sydnonyl) Dithiocarbonate (5a):** A yellow solid (from ethanol); ^1H NMR (DMSO-d_6) δ=1.28 (d, 6H, $C\underline{H}_3$), 5.50 (m, 1H, C<u>H</u>), and 7.70 (s, 5H, $C_6\underline{H}_5$); MS, *m/z* 253 (M^+−*i*-Pr), and 195 (M^+−*i*-Pr-NO-CO). Fond: C, 48.62; H, 4.02; N, 9.46; S, 21.39%. Calcd for $C_{12}H_{12}N_2O_3S_2$: C, 48.63; H, 4.08; N, 9.45; S, 21.64%.

***O*-Isopropyl *S*-[3-(*p*-Tolyl)-4-sydnonyl] Dithiocarbonate (5b):** A yellow solid (from ethanol); ^1H NMR ($CDCl_3$) δ=1.33 (d, 6H, $CH(C\underline{H}_3)_2$), 2.50 (s, 3H, *p*-$C\underline{H}_3C_6H_4$), 5.57 (m, 1H, C<u>H</u>), and 7.37 (s, 4H, Ar-<u>H</u>); MS, *m/z* 310 (M^+), 267 (M^+−*i*-Pr), and 209 (M^+−*i*-Pr-NO-CO). Found: C, 50.32; H, 4.53; N, 8.98; S, 20.96%. Calcd for $C_{13}H_{14}N_2O_3S_2$: C, 50.31; H, 4.55; N, 9.03; S, 20.66%.

Methyl [3-(*p*-Tolyl)-4-sydnonyl] Trithiocarbonate (6): A yellow solid (from ethanol); ^1H NMR ($CDCl_3$) δ=2.40 (s, 3H, *p*-$C\underline{H}_3C_6H_4$), 2.70 (s, 3H, $C\underline{H}_3S$), and 7.40 (s, 4H, Ar-<u>H</u>); MS, *m/z* 298 (M^+) and 240 (M^+−NO-CO). Found: C, 44.22; H, 3.26; N, 9.49; S, 32.32%. Calcd for $C_{11}H_{10}N_2O_2S_3$: C, 44.28; H, 3.38; N, 9.39; S, 32.23%.

Phenylbis(3-phenyl-4-sydnonyl)methanol (7): In a manner similar to the preparation of **4—6**, **7** was obtained in 66% yield using two equiv of 4-lithio-3-phenylsydnone and dibenzoyl disulfide. Recrystallization from ethanol provided pure **7** as a pale yellow solid (58%); mp 199—201 °C (decomp) (lit,[13] mp 203—205 °C); IR (KBr): 3240 (νOH), 3070 (νCH of aromatic), 1790 and 1710 cm^{-1} (νC=O); ^1H NMR ($CDCl_3$) δ=6.15 (s, 1H, O<u>H</u>), 7.10 (s, 5H, $C_6\underline{H}_5COH$), and 7.20—7.60 (m, 10H, $C_6\underline{H}_5$). Found: C, 64.48; H, 3.51; N, 13.06%. Calcd for $C_{23}H_{16}N_4O_5$: C, 64.48; H, 3.76; N, 13.08%.

Reaction of 4-Lithiosydnones (2) with Thiocyanogen and Selenocyanogen. General Procedure (a). To a stirred solution of 6 mmol of 4-lithiosydnone **2** in 10 ml of THF under dry nitrogen atmosphere below −50 °C, was added dropwise a solution of thiocyanogen or selenocyanogen in 15 ml of THF, which was prepared by the treatment of potassium thiocyanate or selenocyanate (20—24 mmol) with 10—12 mmol of bromine below −50 °C. After ca. 8h of stirring, the colored (violet or orange color) reaction mixture was poured into a large amount of ice-water. After the mixture had been allowed to stand for 1h, the resulting precipitates were collected by filtration and washed with water. The crude product was dissolved in ethanol-acetone (10:1) and the solution was treated with activated charcoal powder. The solution was concentrated and the remaining solution was allowed to stand overnight. The precipitated pure product was obtained by filtration.

Bis(3-phenyl-4-sydnonyl)sulfide (11a): ^1H NMR ($CDCl_3$) δ=7.40—7.93 (m, $C_6\underline{H}_5$). MS, *m/z* 354 (M^+), 296 (M^+−NO-

CO), and 238 (M^+—2NO-2CO). Found: C, 54.17; H, 2.63; N, 15.66; S, 8.94%. Calcd for $C_{16}H_{10}N_4O_4S$: C, 54.24; H, 2.84; N, 15.81; S, 9.05%.

Bis[3-(*p*-tolyl)-4-sydnonyl]sulfide (11b): ^{1}H NMR ($CDCl_3$) δ=2.50 (s, 6H, CH_3), 3.37 (d, 4H, Ar-H), and 7.70 (d, 4H, Ar-H). MS, *m/z* 324 (M^+—NO-CO) and 266 (M^+—2NO-2CO). Found: C, 56.40; H, 3.61; N, 14.59; S, 8.50%. Calcd for $C_{18}H_{14}N_4O_4S$: C, 56.54; H, 3.69; N, 14.65; S, 8.38%.

Bis(3-phenyl-4-sydnonyl)selenide (12a): ^{1}H NMR ($CDCl_3$) δ=7.40—8.10 (m, C_6H_5). MS, *m/z* 402, 400 (M^+) and 344, 342 (M^+—NO-CO). Found: C, 47.83; H, 2.23; N, 13.93%. Calcd for $C_{16}H_{10}N_4O_4Se$: C, 47.90; H, 2.51; N, 13.96%.

Bis[3-(*p*-tolyl)-4-sydnonyl]selenide (12b): ^{1}H NMR ($CDCl_3$) δ=2.55 (s, 6H, CH_3), 7.43 (d, 4H, Ar-H), and 7.73 (d, 4H, Ar-H). MS, *m/z* 430, 428 (M^+) and 372, 370 (M^+—NO-CO). Found: C, 50.27; H, 3.13; N, 13.02%. Calcd for $C_{18}H_{14}N_4O_4Se$: C, 50.36; H, 3.29; N, 13.05%.

Reaction of 4-Bromo-3-phenylsydnone (3a) with Selenourea. To a stirred solution of 1.90 g (7.8 mmol) of **3a** in 20 ml of anhydrous ethanol was added 1.00 g (8.1 mmol) of selenourea and the mixture was refluxed for 8 h. After cooling, the precipitating selenium metal (0.44 g, 69%) was filtered. The filtrate was concentrated and the remaining solution was allowed to stand overnight. The resulting precipitates were collected by filtration and 0.36 g (23%) of pure **12a** was obtained as a yellow solid.
