3′-Allyl-3′-(phenylsulfinyl)spiro[5α-cholestane-3,2′-oxirane] (4j). Chlorohydrin (**3**); mp 107—108 °C (AcOEt-hexane); 88% yield; IR (KBr): 3450 (OH), 1085, 1060, 1025 (SO) cm^{-1}; ^{1}H NMR δ=0.65 (3H, s), 0.87 (6H, d, J=7 Hz), 0.91 (3H, d, J=7 Hz), 0.97 (3H, s), 2.66 (2H, d, J=6.5 Hz), 5.08—5.50 (1H, m), 5.71—6.13 (1H, m), 6.44—6.94 (1H, m), 7.3—7.9 (5H, m); MS m/z (%): 474 ([M−PhSOH]$^+$, trace), 456 (4), 438 (9), 421 (5), 43 (100). Epoxy sulfoxide (**4j**); 88% yield; mp 114—116 °C (MeOH-H_2O); IR (KBr): 1095, 1060 (SO) cm^{-1}; ^{1}H NMR δ=0.68 (3H, s), 0.88 (6H, d, J=7 Hz), 0.92 (3H, d, J=7 Hz), 1.03 (3H, s), 4.60—5.50 (3H, m), 7.4—7.8 (5H, m); MS m/z (%): 438 ([M−PhSOH]$^+$, 100), 397 (44), 369 (9); Found: C, 78.70; H, 9.93; S, 5.62%. Calcd for $C_{37}H_{56}O_2S$: C, 78.67; H, 9.99; S, 5.68%.

General Procedure for the Preparation of Epoxide (5) from α,β-Epoxy Sulfoxide (4): The synthesis of 3′-hexylspiro[cyclohexane-1,2′-oxirane] (**5a**) is described. To a solution of n-BuLi (0.1 mmol) in 0.2 ml of dry THF at −70 °C under N_2 was added a solution of **4a** (0.1 mmol) in 0.2 ml of dry THF through a syringe with stirring. The reaction mixture was stirred for 5 min, then the reaction was quenched by adding sat. aq NH_4Cl and the whole was extracted with ethyl acetate. The organic layer was washed with sat. aq NH_4Cl and dried over Na_2SO_4. The product was purified by silica-gel column chromatography to give **5a** as a colorless oil in 89% yield. IR (neat): 2970, 2940, 2860, 1470, 1445, 910 cm^{-1}; ^{1}H NMR δ=0.90 (3H, t, J=6 Hz), 1.0—2.2 (20H, m), 2.73 (1H, t, J=6 Hz); MS m/z (%): 196 (M$^+$, 1), 153 (4), 125 (19), 98 (100).

2,3-Epoxy-3-methyl-1-phenylbutane (5b). Colorless oil; IR (neat): 1260, 1035 cm^{-1}; ^{1}H NMR δ=1.34, 1.41 (each 3H, s), 2.92 (3H, m), 7.30 (5H, m); MS m/z (%): 162 (M$^+$, 6), 147 ([M−CH_3]$^+$, 35), 119 (52), 91 (100).

1-Cyclohexyl-1,2-epoxyheptane (5c). 5c-L: Colorless oil; IR (neat): 2960, 2940, 2870, 1470, 1450, 1390, 1260, 885, 855, 830, 820, 790 cm^{-1}; ^{1}H NMR δ=0.91 (3H, t, J=6 Hz), 1.0—2.1 (19H, m), 2.64 (1H, m, $W/2$=13 Hz) 2.93 (1H, m, $W/2$=12 Hz); MS m/z (%): 196 (M$^+$, 2), 113 (44), 95 (58), 81 (100); Found: m/z 196.1818. Calcd for $C_{13}H_{24}O$: M, 196.1825. **5c-P:** Colorless oil; IR (neat): 2970, 2940, 2870, 1470, 1450, 925, 900, 890, 875 cm^{-1}; ^{1}H NMR δ=0.90 (3H, t, J=6 Hz), 1.2—2.0 (19H, m), 2.47 (1H, m, $W/2$=10 Hz), 2.75 (1H, m, $W/2$=10 Hz); MS m/z (%): 196 (M$^+$, 2), 113 (44), 95 (58), 81 (100); Found: m/z 196.1831. Calcd for $C_{13}H_{24}O$: M, 196.1826.

3′-Benzylspiro[cyclohexane-1,2′-oxirane] (5d). Colorless oil; IR (neat): 3040, 2940, 2860, 1610, 1495, 1450, 740, 695 cm^{-1}; ^{1}H NMR δ=1.2—1.9 (10H, m), 2.94 (3H, m, $W/2$=14 Hz), 7.31 (5H, m, $W/2$=3 Hz); MS m/z (%): 202 (M$^+$, 7), 173 (20), 159 (35), 105 (100), 91 (73); Found: m/z 202.1345. Calcd for $C_{14}H_{18}O$: M, 202.1355.

2,3-Epoxy-1-(4-methoxyphenyl)-3-methylbutane (5f). Colorless oil; IR (neat): 1255, 1040 cm^{-1}; ^{1}H NMR δ=1.33, 1.40 (each 3H, s), 2.85 (3H, m), 3.82 (3H, s), 6.88, 7.18 (each 2H, d, J=9 Hz); MS m/z (%): 192 (M$^+$, 43), 177 ([M−CH_3]$^+$, 8),

163 (32), 149 (77), 121 (100); Found: *m/z* 192.1130. Calcd for $C_{12}H_{16}O_2$: M, 192.1149.

3′-(4-Methoxybenzyl)spiro[cyclohexane-1,2′-oxirane] (5g). Colorless oil; IR (neat): 1250, 1040 cm^{-1}; ^1H NMR δ=1.3—1.9 (10H, m), 2.88 (3H, m), 3.83 (3H, s), 6.88, 7.20 (each 2H, d, J=8 Hz); MS *m/z* (%): 232 (M^+, 20), 203 (23), 189 (34), 121 (100); Found: *m/z* 232.1463. Calcd for $C_{15}H_{20}O_2$: M, 232.1462.

2,3-Epoxy-3-methyl-1-(1-naphthyl)butane (5h). Colorless oil; IR (neat): 1260, 1030 cm^{-1}; ^1H NMR δ=1.36, 1.48 (each 3H, s), 3.06—3.56 (3H, m), 7.4—8.2 (7H, m); MS *m/z* (%): 212 (M^+, 33), 197 ($[M-CH_3]^+$, 7), 183 (17), 153 (83), 141 (100); Found: *m/z* 212.1196. Calcd for $C_{15}H_{16}O$: M, 212.1199.

5,5-Diphenyl-4,5-epoxy-1-pentene (5i). Colorless oil; IR (neat): 1270, 1030 cm^{-1}; ^1H NMR δ=2.16 (2H, bt, J=6.5 Hz), 3.51 (1H, t, J=6.5 Hz), 5.06 (1H, m, $W/2$=9 Hz), 5.19 (1H, m, $W/2$=6 Hz), 5.77—6.08 (1H, m), 7.2—7.6 (10H, m); MS *m/z* (%): 236 (M^+, 7), 207 (7), 194 (34), 165 (100); Found: *m/z* 236.1203. Calcd for $C_{17}H_{16}O$: M, 236.1200.

3′-Allylspiro[5α-cholestane-3,2′-oxirane] (5j). Colorless oil; IR (neat): 1650, 1265 cm^{-1}; ^1H NMR δ=0.67 (3H, s), 0.87 (6H, d, J=7 Hz), 0.92 (3H, d, J=7 Hz), 1.00 (3H, s), 2.2—2.4 (2H, m), 2.85 (1H, t, J=6 Hz), 5.0—5.3 (2H, m), 5.88 (1H, dddd, J=6.5, 6.5, 10, 17.5 Hz); MS *m/z* (%): 440 (M^+, 6), 400 (83), 381 (41), 55 (100), 43 (100); Found: *m/z* 440.4009. Calcd for $C_{31}H_{52}O$: M, 440.4014.

General Procedure for the Preparation of Allylic Alcohols (6) from α,β-Epoxy Sulfoxides (4): The synthesis of (*E*)-2-methyl-4-phenyl-3-buten-2-ol (**6b**) is described. To a solution of *n*-BuLi (0.6 mmol) in 0.3 ml of dry THF at −70 °C under N_2 was added a solution of epoxy sulfoxide (**4b**) (0.2 mmol) in 0.3 ml of dry THF with stirring. The reaction mixture was stirred for 5 min; then the reaction was quenched by adding sat. aq NH_4Cl. The whole was extracted with ethyl acetate and after the usual work-up, the product was purified by silica-gel column chromatography to give **6b** as a colorless oil in 76% yield. IR (neat): 3360 (OH) cm^{-1}; ^1H NMR δ=1.44 (6H, s), 6.37 (1H, d, J=16 Hz), 6.62 (1H, d, J=16 Hz), 7.2—7.5 (5H, m); MS *m/z* (%): 161 ($[M-H]^+$, 30), 126 (32), 91 (100).

(*E*)-1-Styryl-1-cyclohexanol (6d). Mp 65—66 °C (hexane); IR (KBr): 3400 (OH) cm^{-1}; ^1H NMR δ=1.1—2.0 (10H, m), 6.36 (1H, d, J=16 Hz), 6.67 (1H, d, J=16 Hz), 7.1—7.6 (5H, m); MS *m/z* (%): 202 (M^+, 69), 184 ($[M-H_2O]^+$, 24), 159 (100); Found: C, 83.09; H, 9.00%; *m/z* 202.1353. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.79%; M, 202.1356.

(*E*)-4-(4-Methoxyphenyl)-2-methyl-3-buten-2-ol (6f). Mp 57—59 °C (hexane); IR (KBr): 3370 (OH) cm^{-1}; ^1H NMR δ=1.42 (6H, s), 3.83 (3H, s), 6.24 (1H, d, J=16.5 Hz), 6.54 (1H, d, J=16.5 Hz), 6.88, 7.33 (each 2H, d, J=8 Hz) MS *m/z* (%): 192 (M^+, 42), 177 ($[M-CH_3]^+$, 100), 159 (24), 121 (90); Found: C, 75.07; H, 8.28%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

(*E*)-1-(4-Methoxystyryl)-1-cyclohexanol (6g). Colorless oil; IR (neat): 3400 (OH) cm^{-1}; ^1H NMR δ=1.0—1.8 (10H, m), 3.82 (3H, s), 6.22 (1H, d, J=16 Hz), 6.58 (1H, d, J=16 Hz), 6.87, 7.33 (each 2H, d, J=9 Hz); MS *m/z* (%): 232 (M^+, 46), 214 ($[M-H_2O]^+$, 7), 189 (54), 121 (100); Found: *m/z* 232.1466. Calcd for $C_{15}H_{20}O_2$: M, 232.1462.

(*E*)-2-Methyl-4-(1-naphthyl)-3-buten-2-ol (6h). Colorless oil; IR (neat): 3370 (OH) cm^{-1}; ^1H NMR δ=1.49 (6H, s), 6.40 (1H, d, J=16 Hz), 7.2—8.2 (8H, m); MS *m/z* (%): 212 (M^+, 52), 197 ($[M-CH_3]^+$, 26), 179 (77), 152 (34), 141 (100); Found: *m/z* 212.1204. Calcd for $C_{15}H_{16}O$: M, 212.1200.

1,1-Diphenyl-2,5-pentadien-1-ol (6i). Mp 52—54 °C (MeOH-H_2O); IR (KBr): 3380 (OH) cm^{-1}; ^1H NMR δ= 5.08—5.37 (2H, m), 6.23—6.68 (3H, m), 7.1—7.5 (10H, m); MS *m/z* (%): 236 (M^+, 8), 218 ($[M-H_2O]^+$, 1), 183 (5), 165 (4), 105 (100); Found: *m/z* 236.1192. Calcd for $C_{17}H_{16}O$: M, 236.1200.

3β-(1,3-Butadienyl)-5α-cholestan-3α-ol (6j). Mp 84—86 °C (MeOH-H_2O); IR (KBr): 3500 (OH) cm^{-1}; ^1H NMR δ=0.66 (3H, s), 0.87 (6H, d, J=6.5 Hz), 0.90 (3H, d, J=6.5 Hz), 0.99 (3H, s), 5.0—5.4 (2H, m), 5.7—6.0 (1H, m), 6.1—6.6 (2H, m); MS *m/z* (%): 440 (M^+, 12), 422 ($[M-H_2O]^+$, 16), 407 (10), 43 (100); Found: *m/z* 440.3999. Calcd for $C_{31}H_{52}O$: M, 440.4014.

Isomerization of the Epoxide (5e-P) into Allylic Alcohol (6e). To a solution of LDA (0.2 mmol) in 0.2 ml of dry THF was added a solution of butyl phenyl sulfoxide (0.2 mmol) in 0.2 ml of dry THF under N_2 at −70 °C. After 10 min, a solution of **5e-P** (0.2 mmol) in 0.4 ml of dry THF was added to the mixture and stirred at −70 °C for 5 min. The reaction was quenched with sat. aq NH_4Cl. After the usual work-up, the allylic alcohol (**6e**) and the starting material (**5e-P**) were obtained in 25 and 75% yield, respectively.

The authors are grateful to Dr. S. Saito, Tanabe Seiyaku Co., Ltd., for the elemental analysis and Miss Sawabe, Mrs. Yamatani and Miss Ohne of this laboratory for NMR and MS measurements.

Regioselective Carboxylation of Silicon-Stabilized Allylic Carbanions and the Synthetic Utility of 2-Silyl-3-butenoates

Hidemitsu UNO
Advanced Instrumentation Center for Chemical Analysis, Ehime University, Bunkyo-cho 2-5, Matsuyama 790
(Received March 10, 1986)

Carbanions of allylic dimethylphenylsilanes show remarkable regioselectivity toward both carboxylation with carbon dioxide and methylation with methyl iodide. Methylation of these compounds occurred preferentialy at α position, although allyltrimethylsilane and allyltriphenylsilane are known to give γ selectivity toward the same electrophiles. Moreover, their aluminum "ate" complexes react with carbon dioxide regioselectively at the α position irrespective of methyl substitution pattern of the allylic moieties. The α-carboxylated allylic silanes proved to be useful synthons of 3-(methoxycarbonyl)allyl anions after esterification.

Regioselectivity in the reaction of unsymmetrical allylic carbanions with electrophiles has been discussed from both theoretical and synthetic points of view by numerous investigators[1] and is still subtle because it depends upon not only inherent characters of allylic carbanions, i.e. charge densities and HOMO coefficients, but also counter metal cations, solvation, steric effects, and transition states. Many efforts have been made to attain preferable regiochemistry. For example, predominant location of the counter cations was successfully achieved by charge repulsion,[2] intramolecular chelation,[3] and transmetallation[4] including "ate" complexation.[5] Accessibility of electrophiles to the carbanionic centers was well controlled by "hard-soft" interaction,[6] steric effects,[7] and transition state.[7] Although similar methodologies could be generally applied for the regiochemical control of silicon-stabilized allylic carbanions, γ-regioselectivity was frequently realized mainly because of steric factors.[8] Tsai and Matteson[9] have reported an exclusive α selectivity in reactions of 3-trimethylsilyl-2-propenyl-boronate. Similar results[10] have been reported in the reaction of η^3-trimethylsilylallyltitanium(III) compound, [Ti(η^5-cp)$_2$(η^3-1-trimethylsilylallyl)]. Success of these reactions may be ascribed to location of very bulky counter cations on the γ carbon. While the effects of counter cations at the transition state have been frequently discussed,[8] the roles of substituents on silicon atom have never been considered. We have already reported that aluminates of dimethylphenylsilyl-stabilized allylic carbanions reacted with carbon dioxide regioselectively at α position.[11] In this report, we describe the further results about the effects of substituents on a silicon atom.

Results and Discussion

Regioselectivity in Nucleophilic Reaction of Silyl-Stabilized Allylic Carbanions. Alkylation of silyl-stabilized carbanions bearing alkali metals as counter cations has been reported to occur preferably at γ position because of the steric hindrance and the large γ charge densities. For example, lithiated allyltriphenylsilane (**1b**) reacted with methyl iodide exclusively at γ position as well as the corresponding trimethylsilyl derivatives.[8a,8f,8l] The lithiated derivative of allyldimethylphenylsilane (**1c**), however, was found to react predominantly at α position to give a mixture of (1-methyl-2-propenyl)dimethylphenylsilane (**1h**) and (1-butenyl)dimethylphenylsilane (**2c**) (**1h**/**2c** =80/20) (Eq. 1). Also, moderate α selectivity was observed in 1-methyl-2-propenylsilane **1h** (**1l**/**2h**= 64/36). Allylmethyldiphenylsilane (**1d**), of which α position could be more hindered than **1c**, still showed α selectivity (**1m**/**2d**=73/27).

According to MINDO/3 calculation for a carbanion of allylsilane,[12] α selectivity was predicted under orbital control conditions, while γ selectivity under charge control conditions. From orbital cosideration, stabilization of an adjacent carbanion by a silyl group is attributable to p-σ* hyperconjugation.[13] In allyldimethylphenylsilane (**1c**), the energy level of the σ*

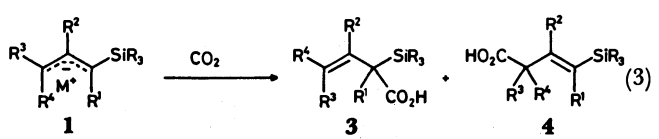
a) Isolated yield. b) Ref. 8b. c) Isolated yield of the regioisomeric mixture. d) Not determined. e) Stereoisomeric ratio was determined to be Z/E=>10/1 by the ^1H NMR (400 MHz) analysis after methylation with diazomethane.

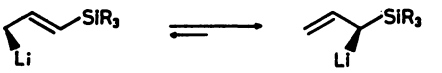
orbital of Si-Me bond would be lowered by the conjugation with a phenyl group (Fig. 1).[14] Therefore, the interaction between p orbitals of an allylic carbanion moiety and the σ^* antibonding orbital might be increased and larger HOMO coefficient at α carbon was expected than that of allyltrimethylsilane (**1a**). Moreover, the charge density at the α carbon might be increased according to the electron-attracting character of a phenyl group. Allyltriphenylsilane (**1b**) would show the reverse selectivity because of not only large steric hindrance but the lack of the low lying sp^3-σ^* orbital. Indeed, it was reported that methylation of **1b** occurred exclusively at the γ carbon[8a] and that moderate γ selectivity (α/γ=35/65) was observed in the alkylation of **1a** with alkyl iodides. On the other hand, preferential α methylation was observed if the silicon atom had both methyl and phenyl groups (**1c**: α/γ=80/20, **1d**: α/γ=73/27). Allylic carbanions stabilized by a dimethylphenylsilyl or methyldiphenylsilyl group were no longer γ selective in the reaction with methyl iodide, a "soft" electrophile. In the next, we will focus the discussion on the regioselectivity in the carboxylation of silyl-substituted allylic carbanions with carbon dioxide, which is classified to a "hard" electrophile.

Carboxylation of the lithiated derivatives of allyltriorganosilanes was carried out at −78 °C by reverse addition of the carbanion solution to give a regioisomeric mixture in moderate to good yields (Eq 3 and Table 1). In Entries 1—6, moderate γ regio-



1 3 4 (3)

selectivity (**3**/**4**=12/88—29/71) was observed. The γ selectivity could be well explained in terms of the 6-membered cyclic transition state if the equilibrium between the α-lithio allylic silanes and γ-lithio vinylic silanes was assumed to lie to the formers (Eq. 4).



(4)

This assumption was supported by the fact that carboxylation of butenylsilane **1j** occurred preferably at the carbanion center bearing a methyl substituent to give exclusively γ carboxylated compounds **4j** in good yield, although this position is sterically disadvantageous (Entry 10). On the other hand, the reaction of (1-methyl-2-propenyl)dimethylphenylsilane (**1h**) showed lower regioselectivity (Entry 8, **3h**/**4h**=45/55).[15] It is known that a methyl substituent increases the charge density on the γ carbon to the methyl group because of its electron-donating character. Therefore, lithium counter cation would tend to be localized at the γ position to the methyl group. Opposite effects between methyl and dimethylphenylsilyl groups described above would be the reason for the low selectivity in 1-methyl-2-propenylsilane **1h**. On the other hand, cooperative effects of both substituents to give the high γ regioselectivity in **1j** and **1k**.

We turned our attention to effects of counter cations. Corriu and his co-workers[8b] reported that α-carboxylated compound **3b** was preferably obtained (**3b**/**4b**=85/15) in the reaction of the Grignard reagent prepared from 3-bromo-1-triphenylsilylpropene. The similar result (**3c**/**4c**=83/17) was obtained in the carboxylation of the Grignard reagent prepared from 3-bromo-1-(dimethylphenylsilyl)propene.[8b] As the carboxylation of the Grignard reagents would also be thought to proceed via 6-membered cyclic transition state, the different selectivity between lithio and magnesio derivatives might be interpreted if we would assume that the magnesium counter cation would be localized mainly at the γ position by the electronic repulsion with the silyl group. Though the respective electronegativity values of magnesium and lithium were given as 1.2 and 1.0, a magnesium counter cation might be more positive than a lithium counter cation

because the former had another highly polarized magnesium-halogen bond.[16]

In order to obtain the α-carboxylated products in high selectivity, we examined the effects of additives to lithio derivatives of allylic silanes. As high α selectivity was reported in the reaction of lithiated allyltrimethylsilane with acetophenone in the presence of $MgBr_2$,[8f] carboxylation was carried out according to the similar manner to give a regioisomeric mixture (**3a**/**4a**=83/17). In the course of the reaction, it was ambigous whether the actual intermediate was a magnesio derivative or a magnesium "ate" complex, because the magnesium-bromine bond was accounted to undergo transmetallation reaction with alkyllithiums.

As aluminum "ate" complexes were reported to show marked regioselectivity in the reaction with various electrophiles,[5] we attempted to utilize this method to the carboxylation. The allylic aluminum "ate" complex, which was generated in situ by adding triethylaluminum to the lithiated allyltrimethylsilane, reacted smoothly with CO_2 to give a regioisomeric mixture which consisted of **3a** and **4a** (**3a**/**4a**=75/25). By chromatographic separation, pure α-carboxylated compound **3a** was obtained in 35% yield (Table 1). The low isolated yield seemed to be attributable to instability of **3a**. During the isolation and purification, **3a** slowly decomposed to give 2- and 3-butenoic acid. Once **3a** was isolated as solids, it could be stored in a freezer without decomposition for several weeks. Allyltriphenylsilane (**1b**) gave a mixture of α- and γ-carboxylated compounds (**3b**/**4b**=70/30). On the other hand, carboxylation of dimethylphenylsilyl derivative **1c** occurred exclusively at the α position to give 2-(dimethylphenylsilyl)-3-butenoic acid (**3c**) in good yield (Entry 3). Similar high α selectivity was realized in the reaction of "hybrid" allylsilanes (Entries 4—7). Low yields obtained in the reaction of **1e** and **1g** (Entries 5 and 7) could be ascribed to anionic polymerization and poor metallation. A methyl substituent on the allyl moiety proved to have no influence on the regioselectivity if the dimethylphenylsilyl group was employed as an anion-stabilizing group. Silanes **1h**, **1i**, and **1j** were carboxylated regioselectively at α position to give α-silyl β,γ-unsaturated carboxylic acids in good yields (Entries 8, 9, and 10). It is noteworthy that 2-butenylsilane **1j** gave *Z*-isomer of 2-(dimethylphenylsilyl)-3-pentenoic acid (**3j**) in good selectivity (*Z*/*E*=>10/1) (Entry 10). 3-Methyl-2-butenylsilane **1k** (Entry 11) did not show the existence of any carboxylated compounds. Similar results were also obtained in the reactions of (1,2-dimethyl-2-propenyl)-, (2-methyl-2-butenyl)-, and (1-methyl-2-butenyl)dimethylphenylsilanes of which lithiation seemed to occur insufficiently. Though there is some limitation that this method could not be applied for highly-substituted allylic silanes, this method is very useful for the preparation of α-silyl β,γ-unsaturated carboxylic acids.

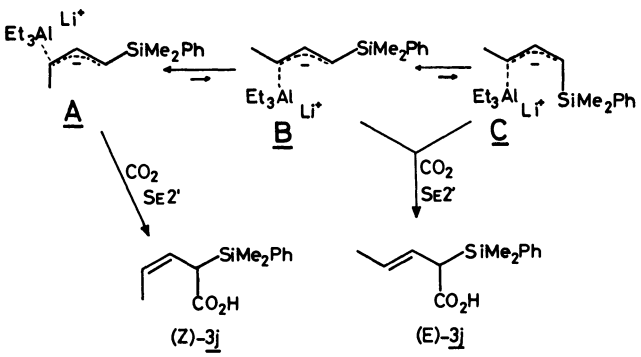


Fig. 2. Proposed carboxylation mechanism.

The remarkable α regioselectivity and stereoselectivity may be interpreted by applying the similar postulation described in the alkylation except for the case of **1g**. The reaction mechanism is discussed about 2-butenyldimethylphenylsilane (**1j**) as a representative case including both problems. There might be a conformational equilibrium of the allylic aluminate generated by adding Et_3Al to the lithiated derivative of 2-butenylsilane **1j** (Fig. 2). In the equilibrium, triethylaluminum would be localized at γ position by steric and/or electrostatic repulsions with the silyl group. Since 2-butenyllithium was reported to exist preferably as an "S"-shape comformer in a THF solution,[17] the conformer **A** would be more faborable than the "W"-shape conformer **B**. Another "S"-shape conformer **C** seemed to be disadvantageous because of the steric interaction between the bulky silyl group and a γ-allylic proton. Indeed, all vinylic silanes obtained in the reaction at γ position had trans geometry and no generation of cis vinylic silanes was observed in all cases irrespective of the species of counter cations. As aluminum "ate" complexes were considered to be in a saturated coordination state, 6-membered cyclic transition state might not participate even in the reaction of carbon dioxide. Therefore, it is suitable to consider that S_E2' type reaction via the conformer **A** would occur on the α carbon which had the large HOMO coefficient to afford *cis*-2-(dimethylphenylsilyl)-3-pentenoic acid (**3j**).

By treatment with CH_2N_2, α-carboxylated allylic silanes were converted to the corresponding methyl esters which proved to be useful for introduction of 3-(methoxycarbonyl)allyl groups.[11] We have demonstrated the utility of methyl 2-(dimethylphenylsilyl)-

a) Isolated yield. b) Only E isomer. c) Diastereomeric mixture (ca. 1:1). d) Cyclic trimers of methyl pyruvate was obtained and **5j** was recovered in a 57% yield. e) Tin tetrachloride was employed instead of $TiCl_4$. f) Isolated yield of the corresponding hydroquinone diacetate after treatment with pyridine and acetic anhydride. g) During the purification by column chromatography the double bond of **18** migrated to give a mixture (**18**/**19**=1/5.8). h) The diastereomeric ratio was estimated to be 73:27 by the NMR analysis.

3-butenoate (**5c**) in the total syntheses of 1*H*-3,4-dihydronaphtho[2,3-*c*]pyran-5,10-dione antibiotics[18] and anthracyclinones.[19] α-Silyl β,γ-unsaturated esters (**5h** and **5j**) can be prepared only by our method[20] and are synthetically more valuable.

Lewis Acid-Mediated Reaction of Allylic Silanes 5 with Electrophiles. In the presence of $TiCl_4$, **5h** prepared from **3h** in quantitative yield reacted smoothly with electrophiles at γ position as expected[21] (Table 2). The reaction with chloromethoxymethane was

carried out in the presence of $TiCl_4$ (1 equiv) at −78°C to give a crude mixture which consisted of almost only (*E*)-**7**. After column chromatography, pure (*E*)-**7** was obtained in 77% yield. α-Chloroethyl phenyl sulfide, isobutyraldehyde, and methyl pyruvate were also reacted smoothly to give trans α,β-unsaturated esters (**8**; 73%, **10**; 48%, and **12**; 96%). The reaction of acetylquinone **14** occurred at the quinone nucleus to afford **15**, which was isolated as the corresponding hydroquinone diacetate **15a** after treatment with acetic anhydride and pyridine. In this reaction $SnCl_4$, as a milder Lewis acid than $TiCl_4$, was employed instead of $TiCl_4$ because the quinone **14** was a very good Michael acceptor. Isobutyryl chloride was also employed to give δ-oxo, α,β-unsaturated ester **17** which was isolated by column chromatography in a 54% yield without the double bond migration. Similarly, (*Z*)-**5j** also reacted with various electrophiles at γ position in the presence of a Lewis acid to give 3-substituted *trans*-pentenoates in good yields (Table 2). Pure (*Z*)-**5j** employed in this reaction was readily prepared from the corresponding (*Z*)-carboxylic acid **3j** which was purified by recrystallization. It is noteworthy that isobutyryl chloride reacted with **5j** to give only α,β-unsaturated ester **18**. During the isolation by column chromatography the double bond of **18** mostly migrated to give a mixture (**18**/**19** = 1/5.8). In Entry 8, **5j** was recoverd in a 57% yield instead of the expected compound **13**. Under the applied reaction conditions methyl pyruvate reacted with itself to give a cyclic trimer. The remarkable contrast between the reaction of **5h** and **5j** (Entries 7 and 8) could be attributed to the steric difference at their γ carbons. In any reactions of **5j**, diastereoselectivity could not be observed in spite of all our efforts. The lack of high selectivity might be considered as follows. The reaction of (2-butenyl)trimethylsilane probably proceeds via acyclic transition state to exibit the selectivity whereas in that of **5j**, cyclic transition state might participate since the reagent has a carbonyl group which could coordinate the Lewis acid.

In both reactions of **5h** and **5j**, only (*E*)-olefins were obtained. This *E* selectivity could be easily interpreted if we assumed **5h** and **5j** would take the similar conformation as that of **5c** described in the preliminary report (Scheme 1).[11]

Experimental

All melting points were measured with a Yanagimoto micromelting point apparatus and are uncorrected. ^1H NMR spectra were observed with Hitachi R-600 (60 MHz), JEOL-PS-100 (100 MHz), and/or JEOL-GX-400 (400 MHz) spectrometers with TMS as an internal standard. IR spectra were measured with a JASCO IRA-1 and/or Hitachi 270-30 spectrometers. Mass spectra were measured with Hitachi M-80B spectrometer. Column chromatography was performed using Wakogel C-200. Diethyl ether and THF were distilled from sodium benzophenone ketyl and stored over sodium wire. Dichloromethane was distilled from calcium hydride and stored over 4A molecular sieves. Other solvents were used after simple distillation otherwise noted. Allylic silanes; **1c** (bp 93°C/2.27 kPa), **1d** (bp 85°C/27 Pa), **1e** (bp 112°C), **1f** (bp 80—84°C/667 Pa), **1g** (bp, 147°C), **1h**[22] (bp 106°C/2.67 kPa), and **1i** (bp 110°C/3.07 kPa), were prepared from chlorosilanes and the Grignard reagents. 2-Butenylsilane **1j** (bp 106°C/2.67 kPa) and 3-methyl-2-butenylsilane **1k**[22] (bp 115—118°C/2.00 kPa) were prepared from the silyllithium and allylic halides.

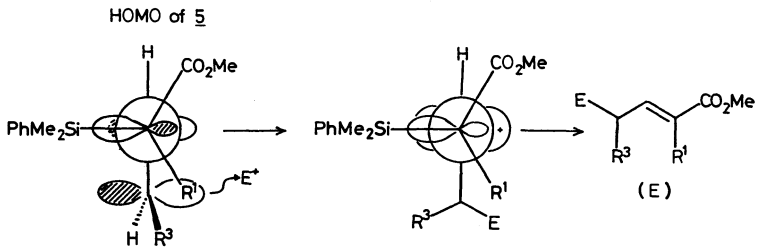
Lithiation of Allylic Silanes. Following methods A and B are applicable for almost cases except for **1e**, and give similar results. For the lithiation of **1e** method C was employed to privent from Michael addition to a vinyl group.

Method A: An allylic silane (1 equiv) and *N,N,N',N'*-tetramethylethylenediamine (TMEDA, 1.5 equiv) were placed in a three-necked flask fitted with a stopcock, a rubber serum cap, and a thermometer. The vessel was filled with nitrogen. After addition of THF (3 ml/1 mmol) the mixture was cooled to −78°C by Dry Ice acetone bath and then *t*-BuLi (pentane solution, 1.5 equiv) was added dropwise. After the addition the mixture was gradually warmed to −40°C and stirred at −40—−30°C for 1 h.

Method B: To a THF solution (3 ml/1 mmol) of an allylic silane (1 equiv) and TMEDA (1.5 equiv) was added *n*-BuLi (hexane solution, 1.5 equiv) under −70°C. The mixture was gradually warmed up to −15°C and allowed to stand for 2 d in a freezer (−15°C).

Method C: To a THF solution (3 ml/1 mmol) of an allylic silane (1 equiv) and TMEDA (1.5 equiv) was added MeLi (ether solution, 1.5 equiv) at −20°C. The mixture was allowed to stand for 3 d in a freezer (−15°C).

Methylation of Allyldimethylphenylsilane 1c. To an orange yellow solution of lithiated **1c** prepared by method A (**1c**, 880 mg, 5 mmol) was added MeI (1.42 g, 10 mmol) at −78°C. The resulted white suspension was allowed to warm to 0°C and then aq NH_4Cl was added. The reaction mixture was extracted with ether. The ethereal phase was wash-



Scheme 1.

ed with brine and dried over Na_2SO_4. After the solvent was evaporated, the residue was simply purified by being passed through a short silica-gel column (hexane–ether). From the ^1H NMR spectrum (400 MHz), the mixture was proved to consist of the starting silane **1c** (32%), **1h** (53%), and **2c** (15%). Separation of the methylated compounds from **1c** was achieved by preparative GPC (Japan Analytical Industry, LC-08, JAI-1H (20 mmID × 60 cm) +JAI-2H (20 mmID× 60 cm)) using $CHCl_3$ as a carrier solvent to give 672 mg (65%) of **1h** (80%) and **2c** (20%). Isomer ratio of the purified products was almost unchanged from the crude one. **1h**: ^1H NMR ($CDCl_3$, 400 MHz) δ=0.30 (6H, s), 1.08 (3H, d, J=17.3 Hz), 1.87 (1H, t-quintet, J=7.3, 1.6 Hz), 4.83 (1H, dt, J=17.1, 1.8 Hz), 4.89 (1H, dt, J=10.4, 1.5 Hz), 5.89 (1H, ddd, J=17.1, 10.4, 7.3 Hz), 7.39 (3H, m), and 7.54 (2H, m). **2c**: ^1H NMR ($CDCl_3$, 400 MHz) δ=0.35 (6H, s), 1.04 (3H, t, J=7.3 Hz), 2.19 (2H, m), 5.80 (1H, d, J=18.3 Hz), 6.21 (1H, dt, J=18.3, 5.6 Hz), 7.39 (3H, m), and 7.54 (2H, m).

Methylation of (1-Methyl-2-propenyl)dimethylphenylsilane (1h). The reaction of **1h** (380 mg, 2 mmol) was carried out in the similar manner as described above. By the NMR analysis of the reaction mixture, it was estimated to consist of **1h** (67%), **1l** (21%), and **2h** (12%). **1l**: ^1H NMR ($CDCl_3$, 400 MHz) δ=0.29 (6H, s), 1.02 (6H, s), 4.73 (1H, dd, J=17.4, 1.5 Hz), 4.91 (1H, dd, J=10.7, 1.5 Hz), 5.84 (1H, dd, J=17.4, 10.7 Hz), 7.38 (3H, m), and 7.53 (2H, m). **2h**: ^1H NMR ($CDCl_3$, 400 MHz) δ=0.35 (6H, s), 1.02 (3H, t, J=7 Hz), 1.68 (3H, m), 2.16 (2H, quintet, J=7 Hz), 5.40 (1H, m), 7.38 (3H, m), and 7.53 (2H, m).

Methylation of Allylmethyldiphenylsilane (1d). The reaction of **1d** (476 mg, 2 mmol) was carried out in the similar manner. By the NMR analysis of the reaction mixture, it was proved to consist of **1d** (65%), **1m** (18%), and **2d** (7%). **1m**: ^1H NMR ($CDCl_3$, 400 MHz) δ=0.58 (3H, s), 1.19 (3H, d, J=7.3 Hz), 2.34 (1H, m), 4.95 (2H, m), 5.98 (1H, ddd, J=17.1, 10.4, 7.0 Hz), 7.40 (6H, m), and 7.57 (4H, m). **2d**: ^1H NMR ($CDCl_3$, 400 MHz) δ=0.65 (3H, s), 1.08 (3H, t, J=7.5 Hz), 2.25 (2H, m), 6.00 (1H, d, J=18.6 Hz), 6.28 (1H, dt, J=18.6, 5.6 Hz), 7.40 (6H, m), and 7.57 (4H, m).

Carboxylation of Lithiated Allylic Silanes. General Procedure: Dry CO_2 gas (through a $CaCl_2$ column) was bubbled into THF (5 ml/1 mmol) at −78°C under argon. A solution of the lithiated allylic silane was slowly introduced into the THF solution absorbing CO_2 at −78°C by a stainless steel transfer tube. The color of the lithiated allylic silane (yellow or orange yellow) rapidly faded to give a clear colorless solution. The reaction was quenched by adding an aqueous NH_4Cl solution and acidified by 5% HCl. The reaction mixture was extracted with ether. The ethereal phase was washed with brine and dried over Na_2SO_4. After the solvent was evaporated in vacuo at room temperature, the residue was chromatographed on silica gel (hexane/CH_2Cl_2/ether=1/1/0—1/1/0.1).

Carboxylation of Allylic Aluminates. General Procedure: A hexane solution of triethylaluminum (ca. 1.4 M[†]) was slowly added to the solution of the lithiated allylic silane at −78° C untill the color of the solution became almost colorless. The mixture was stirred for additional 10 min and then dry CO_2 gas was slowly introduced to the solution at −78° C. After a large excess amount of CO_2 was absorbed, the solution was gradually warmed to 0° C and stirred for 15 min. After being recooled to −30° C, the reaction mixture was poured into a cold aq NH_4Cl solution (ca. −10° C) and then ether was added. The mixture was acidified by cold 5% aq HCl until both phases became clear. The organic phase was separated and the aqeous phase was extracted twice with ether. The combined organic phase was washed twice with cold 5% aq HCl and brine and dried over Na_2SO_4. After the solvent was evaporated in vacuo at ambient temperature, the residue was chromatographed on silica gel (hexane/CH_2Cl_2/ether=1/1/0—1/1/0.1).

2-(Trimethylsilyl)-3-butenoic Acid (3a): Colorless crystals (ether/hexane); mp 72—73° C; ^1H NMR ($CDCl_3$) δ=0.13 (9H, s), 2.95 (1H, d, J=10 Hz), 4.76—5.08 (2H, m), 6.00 (1H, dt, J=16, 10 Hz), and 9.02 (1H, broad s). Found: C, 53.31; H, 8.97%. Calcd for $C_7H_{14}O_2Si$: C, 53.12; H, 8.92%.

4-(Trimethylsilyl)-3-butenoic Acid (4a): A colorless oil; ^1H NMR ($CDCl_3$) δ=0.08 (9H, s), 3.13 (2H, d, J=6 Hz), 5.76 (1H, d, J=19 Hz), 6.09 (1H, dt, J=19, 6 Hz), and 10.90 (1H, broad s); IR (neat) 2960 (broad s), 1714 (vs), 1616 (m), 1418 (m), 1250 (s), 862 (s), and 840 cm^{-1} (s).

2-(Triphenylsilyl)-3-butenoic Acid (3b):[8b] Colorless prisms (benzene/hexane); mp 179—180° C; ^1H NMR ($CDCl_3$) δ=3.75 (1H, d, J=10 Hz), 4.80—5.10 (2H, m), 6.02 (1H, dt, J=16, 10 Hz), 7.20—7.80 (15H, m), and 10.0 (1H, broad s); IR (KBr) 300 (broad s), 1675 (vs), 1425 (vs), 1200 (s), and 1115 cm^{-1} (vs).

4-(Triphenylsilyl)-3-butenoic Acid (4b):[8b] Colorless crystals (benzene/hexane); mp 157—158° C; ^1H NMR ($CDCl_3$) δ=3.31 (2H, d, J=5 Hz), 6.10 (1H, dt, J=16, 5 Hz), 6.36 (1H, d, J=16 Hz), 7.2—7.7 (15H, m), and 10.30 (1H, broad s).

2-(Dimethylphenylsilyl)-3-butenoic Acid (3c): Colorless crystals (ether/hexane); mp 48—49.5° C; ^1H NMR ($CDCl_3$) δ=0.42 (6H, s), 3.04 (1H, d, J=10 Hz), 4.56—4.96 (2H, m), 5.87 (1H, dt, J=17, 10 Hz), 7.16—7.50 (5H, m), and 10.58 (1H, broad s); IR (neat) 3200 (broad m), 1690 (vs), 1430 (s), 1255 (s), and 1120 cm^{-1} (s). Found: C, 65.47; H, 7.44%. Calcd for $C_{12}H_{16}O_2Si$: C, 65.41; H, 7.31%.

4-(Dimethylphenylsilyl)-3-butenoic Acid (4c): A colorless oil; ^1H NMR ($CDCl_3$) δ=0.35 (6H, s), 3.14 (2H, d, J=5 Hz), 5.83 (1H, d, J=19 Hz), 6.10 (1H, dt, J=19, 5 Hz), 7.20 (5H, m), and 11.35 (1H, broad s); IR (neat) 3000 (broad s), 1700 (vs), 1420 (s), 1245 (s), and 1100 cm^{-1} (s).

2-(Methyldiphenylsilyl)-3-butenoic Acid (3d): Colorless crystals (ether/hexane); mp 65—68 °C; ^1H NMR (CCl_4) δ=0.65 (3H, s), 3.35 (1H, d, J=10 Hz), 4.45—4.85 (2H, m), 5.75 (1H, dt, J=16, 10 Hz), 6.9—7.5 (10H, m), and 10.53 (1H, s); IR (KBr) 3000 (broad s), 1680 (vs), 1430 (s), 1315 (s), 1200 (s), and 1100 cm^{-1} (s). Found: C, 71.97; H, 6.43%. Calcd for $C_{17}H_{18}O_2Si$: C, 72.30; H, 6.42%.

4-(Methyldiphenylsilyl)-3-butenoic Acid (4d): Colorless crystals (ether/hexane); mp 93—96° C; ^1H NMR ($CDCl_3$) δ=0.62 (3H, s), 3.21 (2H, m), 6.09 (2H, m), 7.1—7.6 (10H, m), and 10.56 (1H, broad s); IR (KBr) 2900 (broad m), 1700 (vs), 1420 (vs), 1245 (vs), 1220 (vs), and 1110 cm^{-1} (s). Found: C, 72.42; H, 6.56%. Calcd for $C_{17}H_{18}O_2Si$: C, 72.30; H, 6.42%.

2-(Dimethylvinylsilyl)-3-butenoic Acid (3e): A colorless oil; ^1H NMR ($CDCl_3$) δ=(6H, s), 2.92 (1H, d, J=10 Hz), 4.9 (2H, m), 5.9 (4H, m), and 9.0 (1H, broad s); IR (neat) 2950 (broad s), 1685 (vs), 1405 (s), 1250 (s), 905 (s), and 840 cm^{-1} (vs).

4-(Dimethylvinylsilyl)-3-butenoic Acid (4e): ^1H NMR ($CDCl_3$) δ=0.20 (6H, s), 3.18 (2H, d, J=5 Hz), 5.3—6.4 (5H, m), and 9.4 (1H, broad s); IR (neat) 2950 (broad s), 1700 (vs), 1610

[†] 1 M=1 mol dm^{-3}.

(s), 1405 (s), 1250 (vs), and 840 cm^{-1} (vs).

2-(Dimethyl-*p*-tolylsilyl)-3-butenoic Acid (3f): Colorless crystals (ether/hexane); mp 50—51 °C; ^1H NMR ($CDCl_3$) δ=0.39 (6H, s), 2.32 (3H, s), 3.06 (1H, d, J=10 Hz), 4.6—5.0 (2H, m), 5.85 (1H, dt, J=16, 10 Hz), 7.10 (2H, d, J=8 Hz), 7.34 (2H, d, J=8 Hz), and 9.46 (1H, broad s); IR (CCl_4) 2960 (broad s), 1690 (vs), 1250 (s), and 1110 cm^{-1} (vs). Found: C, 66.44; H, 7.77%. Calcd for $C_{13}H_{18}O_2Si$: C, 66.62; H, 7.74%.

2-(*t*-Butyldimethylsilyl)-3-butenoic Acid (3g): A colorless oil; ^1H NMR ($CDCl_3$) δ=0.08 (6H, s), 0.95 (9H, s), 2.93 (1H, d, J=10 Hz), 4.70—4.92 (2H, m), 5.84 (1H, dt, J=16, 10 Hz), and 10.98 (1H, broad s); IR (neat) 3080 (broad s), 1690 (vs), 1630 (m), 1405 (m), 1250 (m), 1200 (m), 1075 (m), 835 (m), and 815 cm^{-1} (m).

2-Methyl-2-(dimethylphenylsilyl)-3-butenoic Acid (3h): Colorless crystals (ether/hexane); mp 103—105° C; ^1H NMR ($CDCl_3$) δ=0.39 (6H, s), 1.20 (3H, s), 4.59 (1H, d, J=17 Hz), 4.84 (1H, d, J=10 Hz), 6.20 (1H, dd, J=17, 10 Hz), 7.0—7.3 (5H, m), and 11.65 (1H, broad s); IR (KBr) 2960 (broad m), 1680 (vs), 1628 (m), 1430 (m), 1410 (m), 1280 (vs), 1260 (s), 1112 (s), 914 (s), 832 (m), 812 (vs), 738 (m), and 700 cm^{-1} (s). Found: C, 66.40; H, 7.93%. Calcd for $C_{13}H_{18}O_2Si$: C, 66.62; H, 7.74%.

4-(Dimethylphenylsilyl)-3-pentenoic Acid (4h): A colorless oil; ^1H NMR ($CDCl_3$) δ=0.40 (6H, s), 1.67 (3H, m), 3.15 (2H, d, J=7 Hz), 5.92 (1H, m), 7.1—7.5 (5H, m), and 10.08 (1H, broad s); IR 2960 (broad s), 1712 (vs), 1620 (m), 1430 (s), 1250 (s), 1216 (m), 1114 (s), 910 (m), 834 (s), 816 (s), 776 (s), 732 (s), and 702 cm^{-1} (s).

3-Methyl-2-(dimethylphenylsilyl)-3-butenoic Acid (3i): Colorless crystals (ether/hexane); mp 65—67° C; ^1H NMR ($CDCl_3$) δ=0.48 (6H, s), 1.62 (3H, s), 3.04 (1H, s), 4.74 (1H, m), 4.84 (1H, m), 7.20—7.35 (3H, m), 7.35—7.55 (2H, m), and 10.5 (1H, broad s); IR (KBr) 2900 (broad s), 1680 (vs), 1425 (s), 1250 (vs), 1115 (vs), 810 (vs), and 700 cm^{-1} (vs). Found: C, 66.33; H, 7.86%. Calcd for $C_{13}H_{18}O_2Si$: C, 66.62; H, 7.74%.

3-Methyl-4-(dimethylphenylsilyl)-3-butenoic Acid (4i): ^1H NMR ($CDCl_3$) δ=0.39 (6H, s), 1.80 (3H, s), 3.12 (2H, s), 5.51 (1H, s), 7.1—7.6 (5H, m), and 8.27 (1H, broad s); IR (neat) 2960 (broad s) 1710 (vs), 1622 (m), 1430 (m), 1252 (s), 1114 (m), 836 (s), 730 (s), and 702 cm^{-1} (s).

***cis*-2-(Dimethylphenylsilyl)-3-pentenoic Acid (3j):** Colorless crystals (ether/hexane); mp 84—88° C; ^1H NMR ($CDCl_3$) δ=0.43 (6H, s), 1.27 (3H, d, J=6 Hz), 3.37 (1H, d, J=10 Hz), 5.40 (1H, dq, J=10, 6 Hz), 5.59 (1H, t, J=7 Hz), 7.2—7.6 (5H, m), and 8.40 (1H, broad s); IR (KBr) 2900 (broad m), 1675 (vs), 1430 (s), 1310 (vs), 1250 (s), 1195 (s), 1120 (s), 820 (s), and 725 cm^{-1} (vs). Found: C, 66.38; H, 7.87%. Calcd for $C_{13}H_{18}O_2Si$: C, 66.62; H, 7.74%.

2-Methyl-4-(dimethylphenylsilyl)-3-butenoic Acid (4j): A colorless oil; ^1H NMR ($CDCl_3$) δ=0.36 (6H, s), 1.29 (3H, d, J=7 Hz), 3.20 (1H, m), 5.88 (1H, d, J=19 Hz), 6.10 (1H, dd, J=19, 6 Hz), 7.3 (5H, m), and 10.5 (1H, broad s); IR (neat) 2960 (broad s), 1710 (vs), 1614 (m), 1430 (s), 1250 (s), 116 (s), 824 (s), 732 (s), and 700 cm^{-1} (s).

2,2-Dimethyl-4-(dimethylphenylsilyl)-3-butenoic Acid (4k): Colorless crystals (ether/hexane); mp 62—64 °C; ^1H NMR ($CDCl_3$) δ=0.40 (6H, s), 1.35 (6H, s), 5.84 (1H, d, J=19 Hz), 6.20 (1H, d, J=19 Hz), 7.25 (m, 5H), and 11.1 (1H, broad s); IR (KBr) 2900 (broad s), 1685 (vs), 1295 (s), 1250 (s), 1110 (s), 995 (s), 840 (vs), 730 (vs), and 700 cm^{-1} (vs). Found: C, 68.01; H, 8.47%. Calcd for $C_{14}H_{20}O_2Si$: C, 67.70; H, 8.12%.

Methyl 2-(Dimethylphenylsilyl)-3-butenoate (5c). To a solution (ether) of **3c** (3.749 g, 17 mmol) was added an ethereal solution of CH_2N_2 under 0° C until the solution became slightly yellow. After ether was evaporated in vacuo, the residue was chromatographed on silica gel (CH_2Cl_2/hexane) to give 2.952 g (74%) of **5c** as a colorless oil; ^1H NMR ($CDCl_3$) δ=0.38 (6H, s), 3.10 (1H, d, J=10 Hz), 3.48 (3H, s), 4.64—5.00 (2H, m), 5.93 (1H, dt, J=17, 10 Hz), and 7.25—7.5 (5H, m); IR (neat) 2950 (m), 1630 (m), 1430 (s), 1315 (s), 1250 (s), 1165 (vs), 1135 (s), 1115 (vs), 835 (vs), 810 (s), and 695 cm^{-1} (s); MS (20 eV) m/z (rel intensity) 234 (M^+, 15), 203 (4), 151 (19), 135 (81), and 68 (100).

Methyl 2-Methyl-2-(dimethylphenylsilyl)-3-butenoate (5h): A colorless oil; ^1H NMR (CCl_4) δ=0.31 (6H, s), 1.19 (3H, s), 3.41 (3H, s), 4.60 (1H, dd, J=17, ≈1 Hz), 4.81 (1H, dd, J=11, ≈1 Hz), 6.16 (1H, dd, J=17, 11 Hz), and 7.13 (5H, m); IR (neat) 2960 (m), 1720 (vs), 1635 (m), 1440 (s), 1245 (vs), 1120 (vs), 905 (s), 840 (s), 820 (s), 790 (s), 745 (s), and 710 cm^{-1} (s); MS (20 eV) m/z (rel intensity) 248 (M^+, 21), 233 (6), 217 (7), 151 (13), 135 (69), and 82 (100).

Methyl 3-Methyl-2-(dimethylphenylsilyl)-3-butenoate (5i): A colorless oil; ^1H NMR ($CDCl_3$) δ=0.43 (6H, s), 1.66 (3H, s), 3.08 (1H, s), 3.54 (3H, s), 4.88 (2H, m), and 7.40 (5H, m); IR (neat) 2956 (m), 1724 (vs), 1638 (m), 1434 (s), 1250 (s), 1152 (vs), 1118 (s), 838 (s), 816 (s), 734 (m), and 702 cm^{-1} (s); MS (20 eV) m/z (rel intensity) 248 (M^+, 8), 233 (5), 217 (4), 151 (9), 135 (69), and 82 (100).

Methyl *cis*-2-(Dimethylphenylsilyl)-3-pentenoate (5j): A colorless oil; ^1H NMR ($CDCl_3$) δ=0.39 (6H, s), 1.32 (3H, d, J=7 Hz), 3.39 (1H, d, J=11 Hz), 3.52 (3H, s), 5.40 (1H, dq, J=11, 7 Hz), 5.65 (1H, t, J=11 Hz), 7.36 (3H, m), and 7.49 (2H, m); IR (neat) 2950 (m), 1720 (vs), 1430 (s), 1305 (vs), 1250 (vs), 1150 (vs), 1115 (s), 835 (s), 810 (s), 725 (s), and 695 cm^{-1} (vs); MS (20 eV) m/z (rel intensity) 248 (M^+, 12), 217 (3), 151 (6), 135 (55), and 82 (100).

Methyl *trans*-2-(Dimethylphenylsilyl)-3-butenoate: Typical ^1H NMR signals: δ=5.21 (1H, dq, J=15, 6 Hz) and 5.59 (1H, ddq, J=15, 9, 2 Hz).

Reaction of 5. General Procedure: To a CH_2Cl_2 solution (20 ml/1 mmol) of **5** (1 equiv) and an electrophile (1.2 equiv) was added a CH_2Cl_2 solution of $TiCl_4$ (1 M solution, 2.4 equiv) at −78° C with stirring. The reaction was continued under the conditions listed in Table 2. The reaction mixture was quenched with water and extracted with ether or CH_2Cl_2. The organic phase was washed with brine, and dried over Na_2SO_4. After the solvent was removed, the residue was chromatographed on silica gel (hexane/ether or hexane/CH_2Cl_2).

Methyl 5-Methoxy-2-methyl-2-pentenoate (6): A colorless oil; ^1H NMR (CCl_4) δ=1.76 (3H, s), 2.32 (2H, q, J=7 Hz), 3.20 (3H, s), 3.30 (2H, t, J=7 Hz), 3.59 (3H, s), and 6.50 (1H, t, J=7 Hz); IR (neat) 2952 (m), 1720 (vs), 1652 (m), 1438 (m), 1228 (s), 1152 (s), and 1118 cm^{-1} (s); MS (20 eV) m/z (rel intensity) 158 (M^+, 1), 127 (37), 126 (93), 113 (17), 111 (15), 95 (18), and 82 (100).

Methyl 5-Methoxy-4-methyl-2-pentenoate (7): A colorless oil; ^1H NMR (CCl_4) δ=0.74 (3H, d, J=7 Hz), 2.19 (1H, m), 2.85 (2H, d, J=7 Hz), 2.89 (3H, s), 3.26 (3H, s), 5.30 (1H, d, J=16 Hz), and 6.35 (1H, dd, J=16, 7 Hz); IR (neat) 1726 (vs), 1660 (m), 1438 (m), 1276 (s), 1198 (s), 1178 (s), and 1150 cm^{-1} (s); MS (70 eV) m/z (rel intensity) 158 (M^+, 1), 137 (8), 127 (13), 113 (7), and 82 (100).

Methyl 2-Methyl-5-phenylthio-2-hexenoate (8): A colorless oil; ^1H NMR ($CDCl_3$) δ=1.24 (3H, d, J=7 Hz), 2.13 (3H,

d, J=1 Hz), 2.35 (2H, m), 3.35 (1H, m), 3.67 (3H, s), 5.70 (1H, m), and 7.35 (5H, m); IR (neat) 1720 (vs), 1650 (s), 1440 (s), 1226 (vs), 1150 (vs), 748 (s), and 694 cm^{-1} (s); MS (70 eV) m/z (rel intensity) 250 (M^+, 10), 219 (2), 141 (38), and 137 (100).

Methyl 4-Methyl-5-phenylthio-2-hexenoate (9): A diastereomeric mixture; a colorless oil; ^1H NMR (CCl_4) δ= 1.12 (3H, m), 1.16 (3H, m), 2.25 (1H, m), 3.23 (1H, m), 3.62 (3H, s), 5.70 (1H, d, J=16 Hz), 6.82 (1H, m), and 7.18 (5H, m); IR (neat) 2972 (m), 1724 (vs), 1656 (s), 1440 (s), 1276 (s), 1196 (s), 1178 (s), 748 (m), and 694 cm^{-1} (m); MS (70 eV) m/z (rel intensity) 250 (M^+, 7), 219 (2), 141 (3), and 137 (100).

Methyl 5-Hydroxy-2,6-dimethyl-2-heptenoate (10): A colorless oil; ^1H NMR ($CDCl_3$) δ=0.95 (6H, m), 1.80 (1H, m), 1.95 (1H, broad), 2.20 (3H, m), 2.30 (2H, m), 3.60 (1H, m), 3.69 (3H, s), and 5.80 (1H, m); IR (neat) 3468 (broad m), 2964 (s), 1720 (vs), 1648 (m), 1440 (m), 1230 (s), 1154 cm^{-1} (s); MS (20 eV) m/z (rel intensity) 154 (M^+−MeOH, 3), 126 (5), 111 (100), and 82 (31).

Methyl 5-Hydroxy-4,6-dimethyl-2-heptenoate (11): A diastereomeric mixture; a colorless oil; ^1H NMR ($CDCl_3$) δ=0.90 (6H, d, J=6 Hz), 1.08 (3H, d, J=7 Hz), 1.65 (1H, m), 2.45 (1H, broad s), 2.48 (1H, m), 3.16 (1H, m), 3.62 (3H, s), 5.72 (1H, d, J=16 Hz), and 6.80 (1H, m); IR (neat) 3476 (broad s), 2964 (s), 1724 (vs), 1658 (m), 1440 (m), 1282 (s), 1198 (m), 1178 (m), 1156 (m), and 994 cm^{-1} (m); MS (70 eV) m/z (rel intensity) 186 (M^+, 0.2), 155 (1), 114 (100), and 82 (41).

Dimethyl 5-Hydroxy-2,5-dimethyl-2-hexenedioate (12): A colorless oil; ^1H NMR ($CDCl_3$) δ=1.36 (3H, s), 1.76 (3H, s), 2.46 (2H, d, J=7 Hz), 3.30 (1H, broad), 3.61 (3H, s), 3.68 (3H, s), and 6.47 (1H, t, J=7 Hz); IR (neat) 3500 (broad m), 2956 (m), 1722 (vs), 1648 (s), 1440 (s), 1224 (vs), 1154 (vs), and 1120 cm^{-1} (s); MS (20 eV) m/z (rel intensity) 216 (M^+, 0.2), 185 (7), 184 (3), 157 (5), 125 (42), and 114 (100).

Methyl 4-(3-Acetyl-4-hydroxy-5-methoxy-1-oxo-1,2-dihydro-2-naphthyl)-2-methyl-2-butenoate (15): ^1H NMR ($CDCl_3$) δ=2.20 (3H, broad s), 2.23 (3H, s), 2.50 (2H, m), 3.55 (1H, m), 3.65 (3H, s), 3.98 (3H, s), 6.90 (1H, m), 7.4 (3H, m), and 17.05 (1H, s).

Methyl 4-(1,4-Acetoxy-3-acetyl-5-methoxy-2-naphthyl)-2-methyl-2-butenoate (15a): Colorless crystals (CH_2Cl_2/ether); mp 149—151° C; ^1H NMR ($CDCl_3$) δ=2.15 (3H, broad s), 2.31 (3H, s), 2.39 (3H, s), 2.47 (3H, s), 3.49 (2H, m), 3.62 (3H, s), 3.87 (3H, s), 5.50 (1H, m), 6.85 (1H, m), and 7.35 (2H, m); IR (KBr) 1764 (vs), 1714 (vs), 1652 (m), 1574 (s), 1440 (s), 1366 (s), 1270 (s), 1212 (vs), 1186 (vs), 1144 (s), and 1070 cm^{-1} (m); MS (70 eV) m/z (rel intensity) 429 (M^++1, 2), 428 (M^+, 8), 344 (52), 326 (20), and 270 (100). Found: C, 64.21; H, 5.70%. Calcd for $C_{23}H_{24}O_8$: C, 64.48; H, 5.64%.

Methyl 4-(3-Acetyl-4-hydroxy-5-methoxy-1-oxo-1,2-dihydro-2-naphthyl)-2-pentenoate (16): A diastereomeric mixture; ^1H NMR ($CDCl_3$) δ=0.75 (3H of one diastereomer, d, J= 7 Hz), 1.15 (3H of another, d, J=7 Hz), 2.2 (3H, m), 2.5 (1H, m), 3.1 (4H, m), 3.98 (3H, m), 5.5 (1H, d, J=16 Hz), 6.5 (1H, m), 7.4 (3H, m), 17.15 (1H of one diastereomer, s), and 17.24 (1H of another, s).

Methyl 4-(1,4-Diacetoxy-3-acetyl-5-methoxy-2-naphthyl)-2-pentenoate (16a): Colorless crystals (CH_2Cl_2/ether); mp 146—148° C; ^1H NMR ($CDCl_3$) δ=1.45 (3H, d, J=7 Hz), 2.25 (3H, s), 2.33 (3H, s), 2.49 (3H, s), 3.63 (1H, m), 3.66 (3H, s), 3.80 (3H, s), 5.88 (1H, d, J=16 Hz), 6.80 (1H, m), and 7.2 (3H, m); IR (KBr) 1764 (vs), 1722 (vs), 1704 (vs), 1650 (m), 1574 (s), 1368 (vs), 1270 (vs), 1198 (vs), and 1064 cm^{-1} (s); MS (70 eV) m/z (rel intensity) 429 (M^++1, 9), 428 (M^+, 32), 386 (80), 344 (97), 326 (78), 312 (52), 270 (100), and 267 (99). Found: C, 64.34; H, 5.75%. Calcd for $C_{23}H_{24}O_8$: C, 64.48; H, 5.64%.

Methyl 2,6-Dimethyl-5-oxo-2-heptenoate (17): A colorless oil; ^1H NMR ($CDCl_3$) δ=1.12 (6H, d, J=7 Hz), 1.86 (3H, s), 2.65 (1H, m), 3.44 (2H, d, J=7 Hz), 3.73 (3H, s), and 6.97 (1H, t, J=7 Hz); IR (neat) 2968 (m), 1712 (vs), 1652 (m), 1440 (s), 1256 (vs), 1122 (s), 1092 (vs), and 1038 cm^{-1} (s); MS (20 eV) m/z (rel intensity) 184 (M^+, 3), 153 (10), 152 (5), 141 (35), 114 (41), 113 (52), 109 (24), 82 (44), and 71 (100).

Methyl 4,6-Dimethyl-5-oxo-2-heptenoate (18): ^1H NMR ($CDCl_3$) δ=1.2 (9H, m), 2.70 (1H, m), 3.55 (1H, m), 3.75 (3H, s), 5.95 (1H, d, J=15 Hz), and 6.95 (1H, dd, J=15, 8 Hz).

Methyl 4,6-Dimethyl-5-oxo-3-heptenoate (19): (19/18=5.8/1); ^1H NMR ($CDCl_3$) δ=1.10 (6H, d, J=7 Hz), 1.70 (3H, s), 3.30 (2H, d, J=7 Hz), 3.4 (1H, m), 3.75 (3H, s), and 6.80 (1H, t, J=7 Hz); IR (neat) 2972 (m), 1742 (vs), 1672 (vs), 1440 (m), 1236 (m), 1200 (s), 1172 (s), and 1046 cm^{-1} (m); MS (20 eV) m/z (rel intensity) 184 (M^+, 1.4), 153 (3), 152 (3), 141 (100), and 113 (42).

Methyl 5-Hydroxy-2-methyl-5-(4-nitrophenyl)-2-pentenoate (20): A pale yellow oil; ^1H NMR ($CDCl_3$) δ=1.80 (3H, s), 2.65 (3H, m), 3.74 (3H, s), 5.00 (1H, t, J=6 Hz), 6.80 (1H, t, J=7 Hz), 7.57 (2H, d, J=9 Hz), and 8.23 (2H, d, J=9 Hz); IR (neat) 3464 (broad m), 2950 (m), 1710 (vs), 1650 (m), 1604 (m), 1522 (vs), 1440 (s), 1348 (vs), 1282 (vs), 1064 (s), 856 (s), 734 (s), and 702 cm^{-1} (m); MS (20 eV) m/z (rel intensity) 234 (M^+-MeO, 22), 217 (45), 158 (51), 152 (88), 122 (85), 115 (81), and 114 (100).

Methyl 5-Hydroxy-4-methyl-5-(4-nitrophenyl)-2-pentenoate (21): A diastereomeric mixture (73/27); a pale yellow oil; ^1H NMR ($CDCl_3$) δ=1.01 (3H of major isomer, d, J=6.6 Hz), 1.04 (3H of minor isomer, d, J=7.0 Hz), 2.66 (1H, m), 2.75 (1H, m), 3.70 (3H of minor isomer, s), 3.71 (3H of major isomer, s), 4.70 (1H of major isomer, d, J=6.6 Hz), 4.85 (1H of minor isomer, d, J=5.1 Hz), 5.79 (1H of minor isomer, dd, J=15.7, 1.1 Hz), 5.81 (1H of major isomer, dd, J=15.7, 1.1 Hz), 6.96 (1H, dd, J=15.7, 8.0 Hz), 7.49 (2H, d, J=9 Hz), and 8.18 (2H, d, J=9 Hz); IR (neat) 3460 (broad m), 2976 (m), 1722 (vs), 1658 (m), 1606 (m), 1522 (vs), 1440 (m), 1348 (vs), 1282 (s), 1200 (m), 1178 (m), 1034 (m), and 862 cm^{-1} (m); MS (20 eV) m/z (rel intensity) 234 (M^+−MeO, 11) 217 (14), 188 (17), 158 (26), 152 (100).

The author wishes to thank Prof. Kazuhiro Maruyama, Prof. Yoshinori Yamamoto, Dr. Yoshinori Naruta, and Prof. Hitomi Suzuki for their guidance and valuable discussions. The author also wishes to thank Dr. Hiroyuki Furuta for the measurement of 400 MHz NMR. Gifts of chlorosilanes from Shin-etsu Chemical Co. are greatly appreciated.

(Received March 12, 1986)

Alcohols in cyclohexane give their methyl ethers in high yields by the use of a combination of dimethyl sulfate and alumina. Some diols and dicarboxylic acids adsorbed on alumina react with dimethyl sulfate and produce the corresponding monomethyl ethers and esters in high selectivities.

The utilization of solid adsorbents such as alumina and silica gel as a reaction media represents one of the recent advances of organic syntheses.[1-3] The use of solid adsorbents is advantageous to milder reaction conditions, simpler work-ups and higher selectivities. We have successfully applied solid adsorbents to the acetylation of alcohols and phenols,[4] the selective monomethyl esterification of dicarboxylic acids,[5] and the selective reduction of dicarbonyl compounds.[6] We then extended this approach to the methylation of various compounds containining hydroxyl groups.

Alcohols, phenols and carboxylic acids are methylated with dimethyl sulfate in the presence of alkali. Sodium hydroxide is used for the methylation of glucose,[7,8] 1-(2,5-dihydroxyphenyl)ethanone,[9] *m*-hydroxybenzaldehyde[10] and gallic acid.[11] Potassium hydroxide and potassium carbonate are also used for the methylation of benzoic acid derivatives.[12,13] We report here the successful methylation of alcohols with dimethyl sulfate in which the alcohols were converted to the ethers in high yields by the addition of alumina instead of alkali to the reaction system. Diols and dicarboxylic acids were selectively monomethylated by a modified method. Details of these reactions are described in this paper.

Results and Discussion

Methylation of Alcohols, Phenols and Carboxylic Acids. Primary, secondary and tertiary alcohols were quantitatively converted to the corresponding methyl ethers as shown in Table 1. Phenols were converted in lower yields, and further low yields were found for carboxylic acids. The yields of methylated compounds of phenols and carboxylic acids hardly increased even though a large amount of dimethyl sulfate was used. In the absence of alumina alcohols, phenols, and carboxylic acids were not methylated with dimethyl sulfate at all.

In the methylation of benzyl alcohol Merck's neutral aluminum oxide and silica alumina (28.6% Al_2O_3) were also effective, and gave benzyl methyl ether in yields of 52 and 41%, respectively, under the same reaction conditions described in Table 1.

Selective Monomethylation of Diols and Dicarboxylic Acids. Table 2 shows the reactions that proceeded to give, selectively, monomethylated compounds in high yields. It was confirmed that no reactions took place in the absence of alumina. In the conventional method using potassium carbonate,[13] 55% methyl hydrogen terephthalate and 24% dimethyl terephthalate were formed at the point of a 79% conversion of terephthalic acid. It shows a typical example of a two-stage reaction proceeding via the intermediate methyl hydrogen terephthalate.

It is reasonable to assume that dicarboxylic acids are chemisorbed on alumina as monocarboxylate anions and that there carboxyl groups are left in positions

Table 1. Methylation of Alcohols, Phenols, and Carboxylic Acids[a]

a) Each experiment was carried out at room temperature in cyclohexane (8 mL) using the adsorbed sample (1 g), which held diol (0.467 mmol/g-alumina) or diarboxylic acid (0.400—0.467 mmol/g-alumina). In the case of diols 12 mol eq of dimethyl sulfate, and in the case of dicarboxylic acid 1.5 mol eq of dimethyl sulfate was used. b) Determined by GLC, GSC, and/or HPLC. c) In 1,4-dioxane. d) In formamide. e) In DMF solution in the absence of alumina. f) Using potassium carbonate according to the usual method[13)] in the absence of alumina.

remote from the alumina surface.[5)] A low yield (12%; see Table 1) for methyl esterification of benzoic acid, which is strongly adsorbed on alumina,[14)] indicates that the carboxylate anion has a very low reactivity toward dimethyl sulfate. The high selectivities for monomethyl esterification of dicarboxylic acids adsorbed on alumina might be due to the much higher reactivities of free carboxyl groups than those of carboxylate anions.

Experimental results suggested that the adsorbed molecules of aliphatic dicarboxylic acids align with their axis perpendicular to the adsorbent surface in a closed-packed rigid array.[5)] Selective monomethyl esterification of aliphatic dicarboxylic acids is attributable to the characteristic adsorption mode which protects the carboxyl groups being adsorbed on alumina, but not those in the free state, from the attack of dimethyl sulfate. With the aid of this protecting effect, the terminal chlorination of octanoic acid adsorbed on alumina was attained.[15)]

In contrast to the carboxylic acids, mono-alcohols adsorbed on alumina were methylated with dimethyl sulfate to produce the corresponding ethers almost quantitatively as shown in Table 1. This result means that the hydroxyl group became reactive with dimethyl sulfate by adsorption on alumina. IR and inelastic electron tunneling spectroscopy proved that alcohols are chemisorbed on alumina as alkoxides or the species in which O–H bonds are strongly polarized.[16,17)] The selective monomethylation of diols is attributable to their adsorption states in which the hydroxyl groups at one end of the molecule are activated through chemisorption on alumina to react with dimethyl sulfate, and suggests that there free hydroxyl groups are left in positions remote from alumina surface.

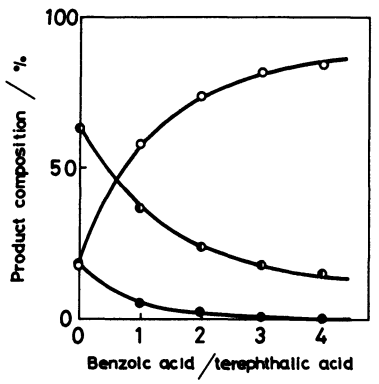

Fig. 1. Effect of benzoic acid addition on methylation of terephthalic acid on alumina. (○): Terephthalic acid, (◐): methyl hydrogen terephthalate, (●): dimethyl terephthalate. Dimethyl sulfate: Terephthalic acid=3:1 (mole).

Effect of Benzoic Acid Addition on Reactivity of Terephthalic Acid. Benzoic acid was added to cyclohexane suspension of alumina adsorbing terephthalic acid. The reactivity of terephthalic acid toward dimethyl sulfate decreased with increasing amounts of benzoic acid, as shown in Fig. 1. A desorption of terephthalic acid into cyclohexane was not detected.

Carboxylic acids exist stably in a dimer state in a solution as well as in a crystal. Benzoic acid in cyclohexane (98 mmol L^{-1}) was confirmed to be in a dimer state on the basis of the IR absorption spectrum, which has only a band at 1695 cm^{-1} assignable to dimeric acid in the reagion of C=O streching vibration. Benzoic acid added to the reaction system probably forms acid dimers by using the free carboxyl groups of terephthalic acid adsorbed on alumina. This gives rise to the decrease in the reactivities of terephthalic

acid.

In 1,4-dioxane or formamide, the adsorbed terephthalic acid was hardly converted to methyl hydrogen terephthalate (see Table 2). This is, perhaps, due to the solvation of free carboxyl groups which impedes the attack of dimethyl sulfate.

Experimental

Materials. Alumina (the reference catalyst of the Catalysis Society of Japan; JRC-ALO-5), Merck's neutral aluminum oxide 90 for column chromatography and silica alumina (28.6% Al_2O_3: JRC-SAH-1) were dried at 110 °C for a day and stored in a desiccator. Cyclohexane was dried by refluxing with calcium hydride and distilled. Other materials were commercially available and used without further purification.

Preparation of Adsorbed Sample. Diols were adsorbed on alumina by the following procedure: One gram of alumina was added to an ether solution of diol in which 0.467 mmol of diol was contained; then, ether was eliminated under a reduced pressure.

Dicarboxylic acids were adsorbed on alumina according to a previously reported procedure: One gram of alumina powder was added to 10 mL of a 1% solution of acid in DMF, the mixture was allowed to stand for 8 h; then, the alumina was filtered off and dried.[5]

Reaction Procedure. Alcoholes, phenols, and benzoic acid: Typically, 1.0 g of alumina, 54.3 mg (0.467 mmol) of 1-heptanol and 706 mg (5.60 mmol) of dimethyl sulfate was added to 8 mL of cyclohexane, and refluxed for 2 h. Then, the alumina was filtered off and eluted with ethyl acetate. After the eluate was concentrated, the product was analyzed by GLC. The analysis showed that a 1-methoxyheptane product was obtained at about 99% yield.

Diols and Dicarboxylic Acids: About 6.4 mL (5 g) of cyclohexane and 0.5 g of the adsorbed sample were placed in a reaction vessel. A calculated amount of dimethyl sulfate was introduced and the reaction was started with vigorous stirring at room temperature. Subsequent procedures were the same as those for mono-alcohols, except for washing the eluate with an alkali solution. The products were analyzed by GLC, GSC and/or HPLC.

[2+4] and [6+4] Type Cycloaddition Reactions of 1-Ethoxycarbonyl-1*H*-azepine and 1-Ethoxycarbonyl-1*H*-1,2-diazepine with 3,4,5,6-Tetrachloro-1,2-benzoquinone

Katsuhiro Saito,* Toshio Mukai,† and Shigenori Iida†
Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
†Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980
(Received March 14, 1986)

The reaction of 1-ethoxycarbonyl-1*H*-azepine with 3,4,5,6-tetrachloro-1,2-benzoquinone at room temperature gave a [6+4]-type cycloadduct as the major product and two kinds of [2+4]-type cycloadducts. In this reaction the diketone moiety of the benzoquinone derivative was used as the 4π component to form ether linkages. The [6+4]-type cycloadduct became rearranged to one of the [2+4]-type cycloadducts by heating at 90 °C. The same reaction, but using 1-ethoxycarbonyl-1*H*-1,2-diazepine, afforded two kinds of [2+4]-type cycloadducts. An electronic attraction between the oxygen atoms of the benzoquinone derivative and the carbons in the 2 and 7-positions of the azepine derivative is considered to be one of the driving force of the [6+4]-type cycloaddition reaction. The [2+4]-type cycloadducts are regarded to be formed via inverse electron demand Diels–Alder reactions.

Unsaturated heterocyclic compounds have attracted the attention of chemists from the viewpoint of their synthetic utility and an elucidation of their electronic nature. Five-membered unsaturated heterocyclic compounds such as furan, pyrrole, or thiophene derivatives are known to have aromaticity due to the contributions of lone-pair electrons of the heteroatoms to construct a 6 π-electron aromatic structure.[1] On the other hand, seven-membered unsaturated heterocyclic compounds such as oxepine, azepine, or diazepine derivatives are olefinic compounds because of a lack of the above-type contribution.[2] The five-membered unsaturated heterocyclic compounds proceed substitution and addition reactions,[3] but the seven-membered unsaturated heterocyclic compounds proceed mainly valence isomerization[4] and addition reactions[5] as olefinic compounds.[3]

While a lot of details have been published in connection with the reactions of five-membered unsaturated heterocyclic compounds,[3] reports concerning the addition reactions of seven-membered unsaturated heterocyclic compounds are relatively few in number. One of the reasons is considered to be the instability of these seven-membered unsaturated heterocyclic compounds; and also, the stable derivatives of these heterocyclic compounds are limited to only a few kinds.[4,5]

Azepine and diazepine derivatives are known to react with olefins possessing electron-withdrawing groups to give [2+4], [4+2], and [4+6]-types of cycloadducts.[5] The reaction positions of azepine and diazepines in a [2+4]-type cycloaddition is limited to their 4 and 5 positions; the yields of a [4+6]-type cycloaddition reaction is low. Exceptional cases are the dimerization reactions.[5a,b,c] The authors have investigated addition reactions of azepine and diazepine derivatives with variable olefins and organosilane compounds.[5i,j,k] Also studied were the addition reactions of azepine and diazepine derivatives with 3,4,5,6-tetrachlo-1,2-benzoquinone (**3**), typical of the class of dienes displaying a reverse electron demand in Diels–Alder reactions.[6] The cycloaddition reactions proceeded not through the olefinic part but through the diketone moiety of **3** to give [2+4]- and [6+4]-type cycloadduts forming the ether linkages. Here, we wish to report on the results of these reactions.

Result

1-Ethoxycarbonyl-1*H*-azepine (**1**) was allowed to react with one molar equivalent of 3,4,5,6-tetrachloro-1,2-benzoquinone (**3**) in benzene at room temperature for 70 min to give three kinds of colorles crystals **4**, **5**, and **6** in the yields of 46, 16, and 8%, respectively. The same reaction, but using 1-ethoxycarbonyl-1*H*-1,2-diazepine (**2**) at room temperature for 3.5 h, afforded two kinds of colorless crystals **7** and **8** in yields of 10 and 4%, respectively, along with an intractable black oily material. Products **5** and **6** were stable during heating and recovered completely even after being heated at 180° C for 24 h in benzene in a sealed tube. On the other hand, product **4** rearranged to **6** in a 63% yield upon being heated at 90° C for 4 h in benzene. Products **7** and **8** did not changed at all upon being heated at 130° C for 15 h in benzene in a sealed tube, but turned to black intractable materials upon heating at 180 °C for 10 h.

Reaction of **1** with 1,2-naphthoquinone (**9**) at room temperature for 4 d resulted in a quantitative recovery of **1**. Reactions of **1** and **9** at elevated temperatures of 70 and 110° C for 5 d gave the recovery of **1** in 30 and 0% yields, respectively, along with balck intractable materials. The same reaction of **2** with **9** gave almost the same results as the above.

The structures of the products were deduced on the basis of their spectral properties as follows. The elemental analyses and the molecular-ion peaks in the mass spectra showed that all of the products were 1:1 addition products of **1** or **2** with **3**. The fact that the IR spectra of these products showed no absorption of carbonyl group, except those due to the ester groups, indicates that **1** and **2** reacted with **3** at its oxygen atoms to form the ether linkages.

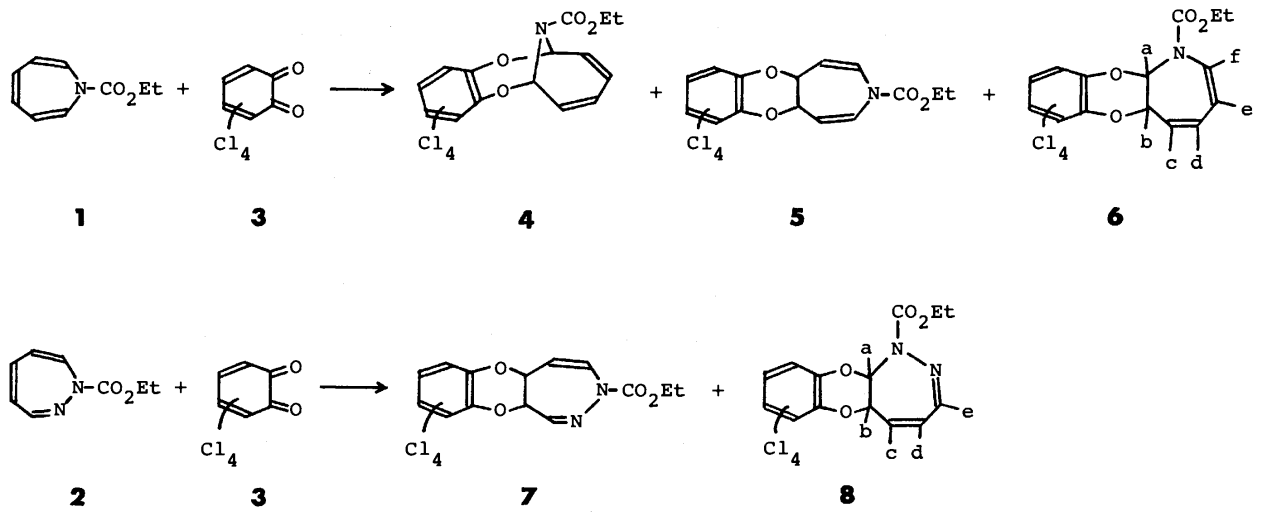

Fig. 1.

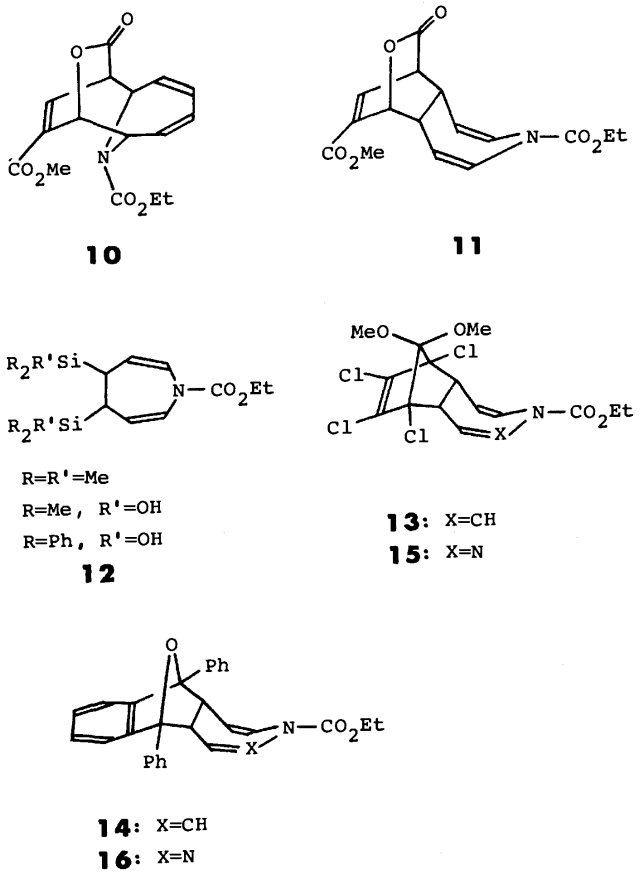

Fig. 2.

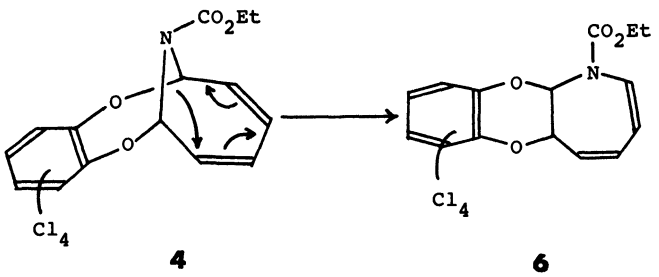
The structures of **4** and **5** were determined mainly on the basis of their NMR spectral properties, which show that these adducts are symmetric compounds. This suggests that the 2 and 7 positions or the 4 and 5 positions of **1** were involved in these reactions. The chemical shift (δ=6.04) and the broad singlet nature of the olefinic protons of **4** closely resembled those features of the olefinic protons of the skeletary analogous compound (**10**)[5i,j] and the azepine dimers. Similarly, the chemical shift (δ=7.06) and the coupling constant (9.0 Hz) of the olefinic protons of **5** had a likeness to those parameters of a similar compound (**10**,[5i,j] **11**,[5i,j] **12**,[5k] **13**,[5i,j,l] **14**[5f,m]). The broad singlet peak at δ 4.97 of **5** was considered to contain absorptions due to the other two olefinic protons and the two methine protons. On the basis of this spectroscopic data, the structures of **4** and **5** were determined as shown in the figure. The electronegativity of the oxygen atoms accounts for the observed lower field resonance of the bridgehead protons of **4** and **5** compared to **10**, **11**, **12**, **13**, and **14**.

The structure of **6** was assigned mainly on the basis of its NMR spectral properties, employing the double-resonance technique. The two continued methine protons (H_a, H_b) and four olefinic protons (H_c–H_f) and the coupling constants between these olefinic protons suggested that **6** contains a seven-membered ring.[5k,7] Dreiding models demonstrate that the diheadral angle between H_a and H_b should be approximately 60° for a cis-configuration and 170° for a trans-configuration. The small coupling constant between H_a and H_b (ca. 2 Hz) indicates that **6** is a cis-adduct of **1** with **3**.[7] The structure of **6** was confirmed by the formation of **6** from **4**, since the transformation of **4** to **6** can be quite reasonably attributed to a thermally allowed 1,5-carbon migration.[8]

The structures of **7** and **8** were also determined mainly on the basis of their NMR spectral properties and were confirmed by a comparison of these data with those of analogous compounds such as **15**,[5i,j] **16**,[5i,j] and **6**. The low field shift of the bridgehead protons of **7** and **8** in their NMR spectra compared to **15** and **16** can be explained using the same reason as that proposed for **5** and **6**.

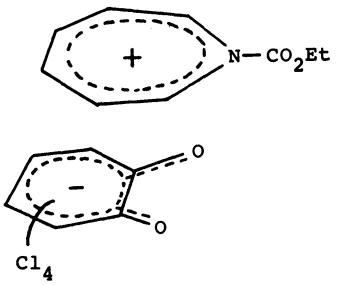
Discussion

Adduct **6** can be regarded as a secondary product, thermally derived from **4**. However, the fact that the



4 6

Fig. 3.



17

Fig. 4.

addition reaction of **1** with **3** proceeded at room temperature and that the isomerization of **4** to **6** required prolonged heating, seem to prove that **6** was the primary product of a [2+4]-type cycloaddition reaction of **1** with **3**.

The major adduct **4** was formed via a [6+4]-type cycloaddition of **1** with **3**. As previously mentioned, azepine derivatives are known to proceed a [6+4]-type addition reactions in low yields.[5] Furthermore, to our knowledge, no example can be found for [6+4]-type cycloadditions, in which **3** reacts as a **4** π-component. The possibility of a participation of a charge-transfer complex such as **17** can be proposed. The above possibility seems to be negated by the fact that no absorption due to a charge-transfer complex could not be observed in the UV spectrum of a mixture of **1** and **3**.

The major formation of the [6+4]-type cycloaddition product can be regarded as the result of an elctronic attraction between the oxygen atoms of **3** and the carbon atoms in the 2 and 7 positions of **1** as shown in Fig. 5.[8] It is well-known that oxygen atoms of carbonyl groups are negatively charged and a molecular orbital calculation has shown that the azepine has the lowest electron density at the carbons in the 2 and 7 positions.[9]

The adducts **5**, **6**, **7**, and **8** are considered to be formed via reverse electron demand [4+2]-type cycloaddition reactions,[8] in which the HOMO of **1** or **2** interact with the LUMO of **3**. The low energy level of the LUMO of **3** promotes an interaction with the HOMO of **1** or **2**; as a result, it stimulates the addition reactions.[10]

Experimental

All melting points were uncorrected. NMR spectra were measured with a Varian HA-100 or Hitachi R-20B spectrometer with tetramethylsilane as an internal standard. UV and IR spectra were measured with Hitachi 220A and DS-701G spectrometers, respectively. Mass spectra were measured with a Hitachi M-52 spectrometer. Wako Gel C-200 and Wako Gel B5F were used for column and thin-layer chromatography, respectively.

Reaction of 1 with 3. A mixture of **1** (1650 mg, 10 mmol) and **3** (2460 mg, 10 mmol) in benzene (10 ml) was stirred at room temperature for 70 min. After evaporating of the solvent, the crystals **4** (1860 mg, 46%) were separated by filtration and the filtrate was chromatographed on silica gel to give crystals **5** (637 mg, 16%) and crystals **6** (315 mg, 8%) in this order by the use of pet ether–benzene (2:3). The crystals were recrystallized from cyclohexane to give pure crystals.

IR (KBr): 3030, 2980, 1730 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.36 (t, CH_3, J=7.0 Hz), 4.31 (q, CH_2, J=7.0 Hz), 5.11 (narrow m, H_b), 5.28 (dd, H_e, J_{de}=7.5, J_{ef}=8.6 Hz), 5.39 (bd, H_c, J_{bc}= 2.1, J_{cd}=11.9 Hz), 5.91 (ddd, H_d, J_{cd}=11.9, J_{de}=7.5, J_{bd}=2.1 Hz), 6.63 (narrow m, H_a), 6.87 (d, H_f, J_{ef}=8.6 Hz).

Reaction of 2 with 3. A mixture of **2** (1660 mg, 10 mmol) and **3** (2460 mg, 10 mmol) in benzene (10 ml) was stirred at room temperature for 3.5 h. After evaporating of the solvent, the residue was chromatographed on silica gel to give crystals of **7** (415 mg, 10%) and **8** (165 mg, 4%), in this order, by the use of benzene–ether (4:1). The crystals were recrystallized from benzene to give pure crystals.

7: Mp 183—184°C. Found: C, 40.67; H, 2.56; N, 6.73%. Calcd for $C_{14}H_{10}O_4N_2Cl_4$: C, 40, 81; H, 2.45; N, 6.80%. Mass *m/z* (rel intensity): 412 (M^+, 11), 166 (65), 107 (50), 94 (100), 81 (71). IR (KBr): 3030, 2980, 1740 cm^{-1}. ^1H NMR ($CDCl_3$)

δ=1.40 (t, CH_3, J=7.0 Hz), 4.40 (q, CH_2, J=7.0 Hz), 4.93 (ddd, H_c, J_{ac}=2.5, J_{ac}=2.1, J_{cd}=6.5 Hz), 5.22 (dd, H_b, J_{ab}=2.5, J_{bc}=3.1 Hz), 5.30 (dd, H_d, J_{cd}=6.5, J_{de}=10.3 Hz), 7.07 (dd, H_a, J_{ab}=2.5, J_{ac}=2.5 Hz), 7.49 (d, H_e, J_{de}=10.3 Hz).

8: Mp 209—211 °C. Found: C, 41.03; H, 2.41; N, 6.86%. Calcd for $C_{14}H_{10}O_4N_2Cl_4$: C, 40.81; H, 2.41; N, 6.80%. Mass *m/z* (rel intensity): 412 (M^+, 14), 166 (50), 107 (44), 94 (83), 81 (100). IR (KBr): 3030, 2980, 1720 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.41 (t, CH_3, J=7.0 Hz), 4.45 (q, CH_2, J=7.0 Hz), 5.08 (narrow m, H_b, J_{bc}=2.1 Hz), 5.90 (ddd, H_d, J_{dc}=11.2, J_{db}=2.0, J_{de}=5.5 Hz), 5.98 (dd, H_c, J_{cb}=2.0, J_{cd}=11.2, J_{ce}=2.0 Hz), 6.88 (narrow m, H_a), 7.25 (dd, J_{de}=5.5, J_{ec}=2.0 Hz).

Thermal Rearrangement of 4 to Form 6. A solution of **4** (40 mg) in benzene-d_6 (0.3 ml) was heated at 90 °C for 4 h and subjected to preparative thin layer chromatography on silica gel using pet ether–benzene 1:1 as a developing solvent to give crystals **6** (R_f=0.65, 25 mg, 63%).

The authors are indebted to Honorable Professor Tadashi Sasaki of Nagoya University for his kind suggestions.

10) The energy level of the LUMO of **9** is considered to be higher than that of **3**. The bigger energy difference between the HOMO of **1** and the LUMO of **9** (ΔE_2) comparing to that between the HOMO of **1** and the LUMO of **3** (ΔE_1) explains the inertness of **9** to **1**. The same explanation can be applied to the [6+4] type cycloaddition reaction as shown below.

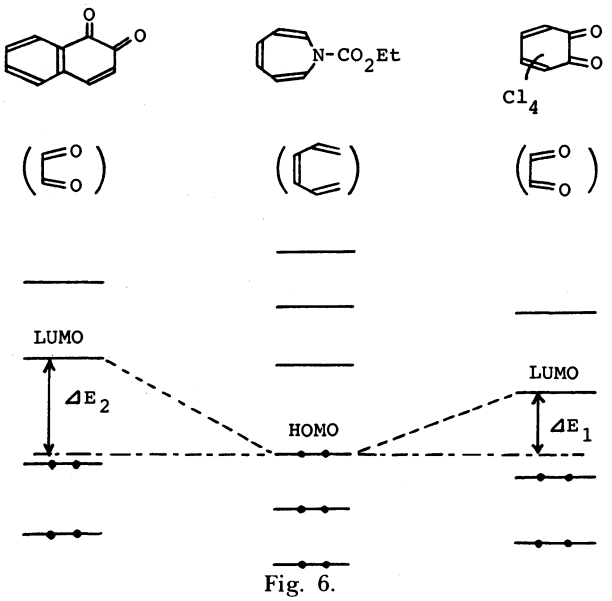

Fig. 6.

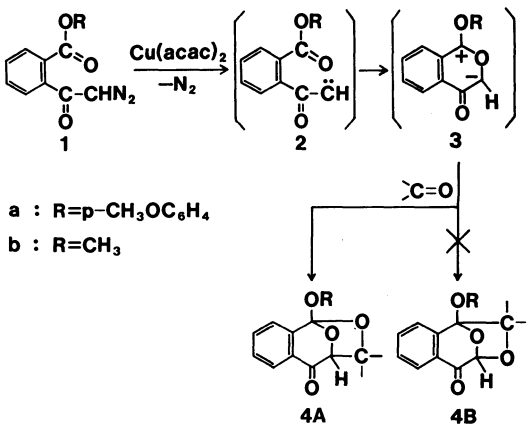
Formation and Reaction of Carbonyl Ylides. Production of 2:1-Cycloadducts of 2-Benzopyrylium-4-olates with Carbonyl Compounds

Toshikazu IBATA* and Jiro TOYODA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received March 22, 1986)

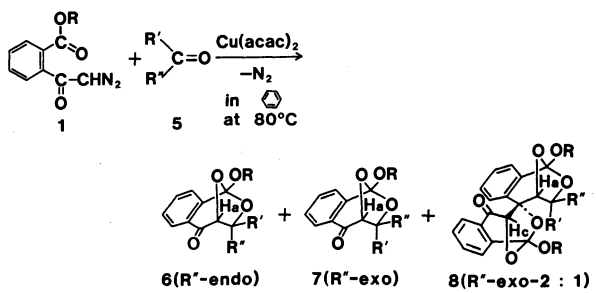
The $Cu(acac)_2$-catalyzed decomposition of *o*-(diazoacetyl)benzoates in the presence of carbonyl compounds such as benzaldehydes, acetophenones, acetone, fluorenone, and anthraquinone gave 2:1-adducts of the corresponding 2-benzopyrylium-4-olate (**3**) and the carbonyl compound, together with 1:1-adducts. The 2:1-adducts were confirmed to be produced by the cycloaddition of **3** toward the carbonyl group of the 1:1-adducts which have bulky aryl groups on exo-direction. The product ratios of the 2:1-adducts were explained according to the MNDO calculation.

In recent years the chemistry of carbonyl ylide has been studied extensively from the theoretical and synthetic interests.[1] The authors have developed the formation of carbonyl ylide through the carbene-carbonyl reaction[2,3] and reported the 1,3-dipolar cycloaddition with ethylenic,[3,4] and acetylenic compounds.[3,5] In the previous paper of this series, we have reported the $Cu(acac)_2$-catalyzed decomposition of *o*-(diazoacetyl)-benzoates (**1**) in the presence of carbonyl compounds to give not **4B** but **4A** type of cycloadducts of the carbonyl ylide intermediate, 1-(*p*-methoxyphenoxy)-2-benzopyrylium-4-olate (**3a**: R=*p*-$CH_3OC_6H_4$) and 1-methoxy-2-benzopyrylium-4-olate (**3b**: R=CH_3), with carbonyl compounds.[6] The reactions with carbonyl compounds of medium reactivity were found to yield 2:1-adducts containing two molecules of **3** and a molecule of carbonyl compound besides usual 1:1-adducts. In this paper the structure of the 2:1-adducts of **3** with various carbonyl compounds and the substituent effect on the yield of the 2:1-adducts in the reactions of substituted benzaldehydes and acetophenones were discussed.



Results and Discussion

The $Cu(acac)_2$-catalyzed decomposition of *p*-methoxyphenyl *o*-(diazoacethyl)benzoate (**1a**) in the presence of two molar equivalents of *p*-anisaldehyde (**5a**) in benzene solution at 80°C gave a 2:1-adduct of 1-(*p*-methoxyphenoxy)-2-benzopyrylium-4-olate (**3a**) and **5a** in 25% yield together with the corresponding *endo*- and *exo*-1:1-adducts. The 2:1-adduct (**8a**) has three methine proton signals at δ 4.04 (d, Ha), 4.65 (d, Hb=R′), and 5.25 (s, Hc) in which the two doublet signals are shown to couple each other. The similarity of the coupling pattern of two doublets of the 2:1-adduct (**8a**) with that of the *exo*-1:1-adduct (**7a**)[7] suggests that in **8a** and **7a** these methine protons (Ha and Hb) have the same configuration. That is, small coupling constants *J*ab, 1.5 Hz for **8a** and 1.3 Hz for **7a**, and their chemical shifts of Hb, δ 4.65 for **8a** and δ 4.63 for **7a** are quite similar. But the chemical shifts of Ha are separated by 0.5 ppm in **7a** and **8a**. This indicates that the magnetic environment of Ha are different in these two compounds. This suggests that the 2:1-adduct is produced by the second attack of **3a** on the carbonyl group of the *exo*-1:1-adduct (**7a**). The position of the second attack is inferred from the usual behavior of carbonyl compounds toward **3**.[6] In fact a similar 2:1-adduct (**9**) was observed in the reaction of **3b** (R=CH_3) with acenaphthylene.[8] In this case the second attack of **3b** has been confirmed to occur on the carbonyl group of a 1:1-adduct of **3b** and acenaphthylene, on the basis of the X-ray crystallography of **9**. Benzaldehyde was also found to give 2:1-adduct (**8b**) having an *exo*-phenyl group on bicyclic dioxolane ring system together with the corresponding 1:1-adducts (Table 1, Run b).



In order to explain the absence of *endo*-2:1-adduct in these reaction products, the MNDO calculation[9] for the *endo*-1:1-adduct (**6b**) and *exo*-1:1-adduct (**7b**)

a) Signals are all singlet. b) Only high field signals of aryl protons (Hd) are shown. c) Complex multiplets were observed together with other aromatic proton signals.

was undertaken. From the previous work, these cycloadditions were found to proceed through the interaction controlled by carbonyl ylide-HOMO and carbonyl compound-LUMO.[6b,10] In this cycloaddition the interacting molecular orbitals of carbonyl compounds are C=O π^*. The energy levels and atomic orbital coefficients of the C=O π^* do not show significant difference for the *endo*- (**6b**) and *exo*-1:1-adduct (**7b**) as is seen in Fig. 1. Therefore, difference in the reactivity of two 1:1-adducts can not be explained in this aspect. The small reactivity of **6b** possibly be attributed to the steric factor. The *endo*-adduct (**6b**) has a phenyl group in the vicinity of the carbonyl group which is the reaction center of the second cycloaddition. The free rotation of the phenyl group of the *endo*-adduct (**6b**) hinders the developement of sp^3 orbital of C-O bond during the approach of the second **3a** to the C=O double bond, and presumably suppresses the reactivity of **6b**.

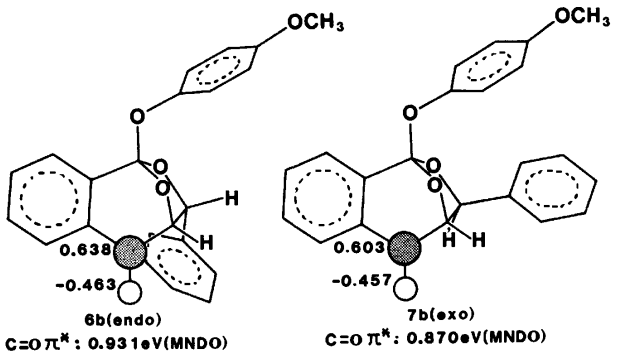

Fig. 1. The energy levels and atomic orbital coefficients of C=O π^* of **6b** and **7b**.

The substituted acetophenones also gave 2:1-adducts besides the corresponding two types of 1:1-adducts in the reactions with 2-benzopyrylium-4-olate (**3a**) (Table 1, Run d, e, f). For example, acetophenone gave *endo*-Ph-1:1-adduct (**6e**), *exo*-Ph-1:1-adduct (**7e**), and 2:1-adduct (**8e**) in 13, 8, and 5% yields, respectively. The structural determination of the bicyclic dioxolane ring system of **8e** was done as follows. The 2:1-adduct (**8e**) shows a singlet signal of CH_3(=R′) at δ 1.26 which is closer to the methyl signal of *exo*-Ph-1:1-adduct (**7e**)

at δ 1.31 than to the signal of *endo*-Ph-1:1-adduct (**6e**) at δ 1.90. This indicates that the methyl group in the 2:1-adduct has *endo* configuration in the same manner as that of *exo*-Ph-1:1-adduct. In other words, phenyl group has *exo* configuration in **7e** and **8e**. These facts suggest that the 1:1-adducts (**6**) having bulky aryl groups in *endo*-direction exhibit no reactivity of cycloaddition toward **3a** depending upon the steric hindrance.

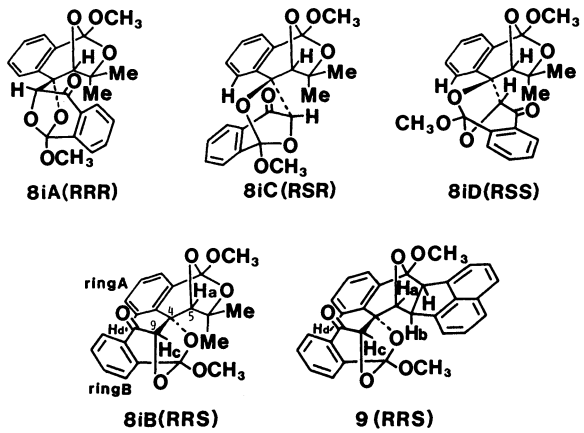
The reaction of **3a** with fluorenone also gave a 2:1-adduct in 37% yield together with a 1:1-adduct in 53% yield. In this case the CPK model shows that the fluorene ring of the 1:1-adduct does not deter the second approach of **3a** from the side of bridged oxygen of the 1:1-adduct, because the fluorene ring is fixed not to rotate like the phenyl group of **6b** described above. The reaction of 1-methoxy-2-benzopyrylium-4-olate (**3b**) with anthraquinone also gave a 2:1-adduct in 12% yield. However the structure of the 2:1-adduct is not determined yet because the 1:1-adduct have two carbonyl groups to be attacked by the second molecule of **3b** and the spectroscopic data do not characterize the structure. Acetone also gave a 1:1-adduct and a 2:1-adduct in the yields of 75 and 12%, respectively.

Stereochemistry of the Second Cycloaddition of 3. The stereochemistry of the second cycloaddition of the 2-benzopyrylium-4-olate (**3**) to the *exo*-1:1-adduct (**7**) is the next question. From the results of the previous works of this series, the regiochemistry of the second cycloaddition may be concluded to proceed in the same manner as the first cycloaddition.[6] That is, the C_1 of the benzopyryliumolate bound to the carbonyl oxygen of the 1:1-adduct. Concerning the stereochemistry of the second cycloaddition, there are four possible structures **8iA(RRR)**, **8iB(RRS)**, **8iC(RSR)**, and **8iD(RSS)** and their mirror image structures in the 2:1-adduct (**8i**) of **3b** and acetone. The CPK model inspection of these isomers reveals that the **8iB(RRS)** structure is free from the steric repulsion in the molecule. This indicates that the **8iB** is sterically the most stable one and then the most probable structure of the four possible ones.

The coupling constant $^3J(^{13}C, H)$ has been reported to be useful for the determination of configuration of rigid cyclic system,[11] and to be calculated using the dihedral angle according to the equation (Eq. 1).[12] The calculation of torsion angles of C_9–C_4–C_5–Ha and C_5–C_4–C_9–Hc, using the observed coupling constants $^3J(^{13}C_9$–Ha)=2.35 and $^3J(^{13}C_5$–Hc)=3.18 Hz of **8f** are 56 and 48°, respectively. These values are consistent with the values of torsion angles, 50° and 30°, estimated by the Dreiding model inspection for **RRS** structure in the possible four structures cited above.

$$^3J(^{13}C, H) = 4.26 - 1.00\cos\theta + 3.56\cos 2\theta \quad (1)$$

It also supports the above conclusion that the 2:1-adduct of **3b** and acenaphthylene has the same **RRS** structure.[8] The 2:1-adduct (**8iB**) of acetone shows a doublet signal of an aromatic proton at δ 6.19 which is at higher field by 1 ppm than the usual ones. This high field shift can not be expected from the other three structures than **8iB**. In the structure **8iB(RRS)** Hd attached to benzene ring A locates above the benzene ring B. The ring current anisotropy effect may shift the signal of Hd at higher field than usual.[8] A similar high field shift has been observed in the 2:1-adduct (**9**) of acenaphthylene and **3b** which has the same **RRS** structure.[8] This also supports the above assignment. Other 2:1-adducts of benzaldehydes and acetophenones also have similar aromatic proton signals at higher field (Table 2). From these results the stereochemistry at the C_5, C_4, and C_9 of the 2:1-adducts was confirmed to have **RRS** structure.



Reactivity of the Substituted Benzaldehydes and Acetophenones. In the reactions of **3a** with benzaldehydes, electron-attracting group like *p*-NO_2 decreases the yields of the 2:1-adducts. For example, the ratios of the yield of 2:1-adduct/1:1-adduct decreased from 0.45 (*p*-CH_3O), to 0.12 (H), and 0.006 (*p*-NO_2). On the other hand, *p*-anisaldehyde is concluded less reactive than benzaldehyde or *p*-nitrobenzaldehyde from the results of competitive reactions.[13] Similar result is also observed in the reactions of acetophenones. The reactivity of acetophenones is lower than that of benzaldehydes having the same substituent. For example, *p*-methoxyacetophenone and acetophenone gave 1:1- and 2:1-adducts in small total yields (5 and 26%) accompanying a lot of intractable tarry products. The product ratio seems to be explained by the competitive reaction between initially formed *exo*-Ar-1:1-adduct (**7**) and starting carbonyl compounds (**5**). Once a small amount of **7** is produced in the reaction system, **3** reacts with **7** or **5** competitively. The substituent effect on the reactivity of the 1:1-adducts is smaller than the effect on the reactivity of benzaldehydes and acetophenones. When electron-attracting *p*-NO_2 group is attached, benzaldehyde and acetophenone have larger reactivity than the corresponding 1:1-adduct, and then the ratios

Table 3. Melting Points and Results of Elemental Analysis of the 2:1-Adducts

Adduct	Mp	Found(%)			Calcd(%)			Molecular formula

8i	184—185	67.71	5.47		67.31	5.40		$C_{23}H_{22}O_7$

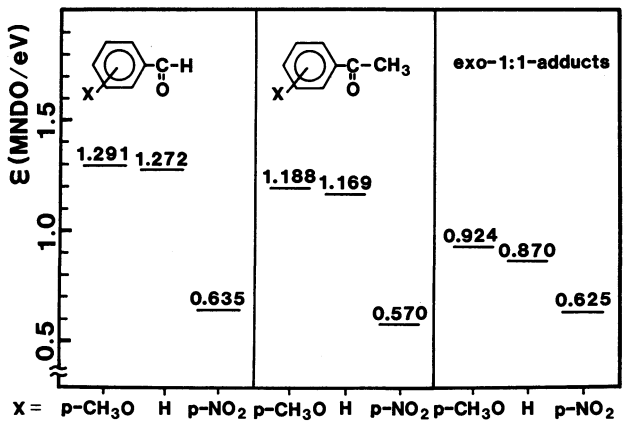

Fig. 2. The ε values of substituted benzaldehydes, acetophenones, and *exo*-1:1-adducts (**7a—c**).

of 2:1-adduct/1:1-adduct come to small. On the other hand, electron-releasing *p*-CH_3O group lowers the reactivity of the starting carbonyl compounds, and then the reactivity of anisaldehyde and the 1:1-adduct becomes comparable to give large 2:1/1:1 ratio.

The MNDO Calculation on the Energy Levels of Carbonyl Compounds. The results of MNDO calculation[9] supports the above assumption. As described previously,[6b] these cycloadditions proceed through the concerted process controlled by the carbonyl ylide-HOMO and carbonyl compound-LUMO (C=O π^*). Therefore, we can conclude that the carbonyl compound of the lower C=O π^* level have higher reactivity by decreasing the values of E(C=O π^*)−E(**3**-HOMO).[6b,10]

The C=O π^* energy levels (ε, eV) of 1,3-dipolarophiles, such as benzaldehydes, acetophenones, and *exo*-1:1-adducts (**7**), are shown in Fig. 2. The C=O π^* energy levels (ε) of benzaldehydes and acetophenones are stabilized largely by the substitution of electron-attracting *p*-NO_2 group, and are destabilized by electron-releasing *p*-CH_3O group (Fig. 2). On the other hand, the *exo*-1:1-adducts (**7a—c**) receive similar but much smaller substituent effect than benzaldehydes and acetophenones. When we compare the ε values of **7a—c** and benzaldehydes (**5a—c**), compounds (**7c** and **5c**) with *p*-NO_2 group have almost same ε values. However, the values for unsubstituted and *p*-CH_3O-substituted compounds are much smaller for **7** than for aldehydes. When we assume that the energy difference between carbonyl compound-LUMO (C=O π^*) and **3**-HOMO is the most effective factor on the reaction rate, *p*-nitrobenzaldehyde and *p*-NO_2-1:1-adduct (**7c**) should have comparable rate. However, the reaction of *p*-nitrobenzaldehyde with **3a** actually gave only 0.6% of expected 2:1-adduct (**8c**). This indicates that *p*-nitrobenzaldehyde is much more reactive than **7c**.

Other possible factors to affect the reactivity of **5c** and **7c** are as follows: (1) The atomic coefficient values of C=O π^* of **7c** and **5c**; (2) the extent of dipole-dipole interaction between **3a** and dipolarophiles, **7c** or **5c**;[10] (3) steric depression on the rate of the reaction of **7c**. In this case the factors (1) and (2) seem to be less effective than (3). The CPK model inspection reveals the large crowdedness around carbonyl group of the 1:1-adduct. Therefore, the steric depression is thought to be the most effective one. In the case of unsubstituted or *p*-CH_3O-substituted compounds, *exo*-1:1-adduct have smaller ε values than aldehydes by 0.40 eV for unsubstituted and 0.37 eV for *p*-CH_3O. The reactivity of **7a** or **7b** becomes comparable to **5a** or **5b**, under consideration of deactivation on **7** according to steric effect. Hence **3a** reacts competitively with **5** or **7** to give large values of 2:1-adduct/1:1-adduct.

Substituent effect on ε values of acetophenones is quite similar to benzaldehydes. However the small reactivities of acetophenones in comparison with those of benzaldehydes are probably caused by the steric hindrance on acetophenones, which lowers the total yields of the adducts except the case of *p*-nitroacetophenone.

Experimental

All melting points were measured on a Yanagimoto Melting Piont Apparatus and recorded without correction. The IR spectra were taken on a Perkin Elmer, model 983 in KBr pellet. The ^{1}H NMR spectra were recorded on a Varian Spectrometer, model EM390 in a $CDCl_3$ solution using TMS as an internal standard. The ^{13}C NMR spectra were measured on a Brucker NMR spectrometer, model AM360 in $CDCl_3$.

Materials. *p*-Methoxyphenyl *o*-(diazoacetyl)benzoate (**1a**)

and methyl *o*-(diazoacetyl)benzoate (**1b**) were prepared by the procedure described in the previous paper.[6b] Benzaldehydes, acetophenones, fluorenone, and anthraquinone were purified just before use by vacuum distillation or recrystallization of the commercial reagents. Benzene was purified by distillation over lithium aluminum hydride.

General Procedure of the Reaction of 3 and Carbonyl Compounds. The $Cu(acac)_2$-catalyzed decomposition of **1** was carried out according to the method described in the previous paper[6b]: A benzene solution of **1** was added drop by drop into a magnetically stirred benzene solution of 2 molar equivalents of carbonyl compound and catalytic amount (1/10 equivalent) of $Cu(acac)_2$ under reflux of benzene at 80°C in N_2 atmosphere. The reaction mixture was heated until no more N_2 was evolved (about one hour) and then the reaction products were separated by silica-gel column chromatography using benzene as an eluent. The reaction with acetone was carried out using large excess acetone because of its high volatility.

The authors express their sincere thanks to Dr. Masami Sawada and Mr. Yoshio Takai of ISIR, Osaka University for measurement and fruitful discussion on ^{13}CNMR spectra.

Structures of Agelasines, Diterpenes Having a 9-Methyladeninium Chromophore Isolated from the Okinawan Marine Sponge *Agelas nakamurai* Hoshino[1)]

Houming Wu,[2)] Hideshi Nakamura,* Jun'ichi Kobayashi, Masaki Kobayashi, Yasushi Ohizumi, and Yoshimasa Hirata†
Mitsubishi-Kasei Institute of Life Sciences, 11 Minamiooya, Machida, Tokyo 194
†Faculty of Pharmacy, Meijo University, Tempa-ku, Nagoya 468
(Received March 5, 1986)

Novel diterpenes, agelasine-A, -B, -C, -D, -E, and -F were isolated from the Okinawan marine sponge *Agelas nakamurai* Hoshino and their structures were established to be monocyclic and bicyclic diterpenes having a 9-methyladeninium unit by spectral analyses and chemical transformations.

Since Cullen and Devlin reported the isolation of agelasine, a quaternary 9-methyladenine derivative of an unidentified diterpene as a constituent of the marine sponge *Agelas dispar* in 1975,[3)] a variety of novel compounds having a polar functionality attached to a terpenoid moiety, the latter varying from acyclic sesqui to a mono or bicyclic diterpene skeleton have been isolated from marine sponges of the genus *Agelas* as bioactive metabolites. Included among these were terpenoid derivatives of hypotaurocyamine, agelasidine-A, -B and -C (**1**, **2**, and **3**)[4,5)] and seven diterpene derivatives of quaternary 9-methyladenine, agelasine-A, -B, -C, -D, and -E (**4**, **5**, **6**, **7**, **8**), agelasine-F (ageline-A, **9**), and ageline-B (**10**) isolated from the Okinawan marine sponge *Agelas nakamurai* by us[6,7)] and from a Pacific marine sponge *Agelas* sp. by Capon and Faulkner[8)] (Fig. 1). These compounds exhibited interesting bioactivities: Inhibitory effects on growth of microorganisms, contractive responses of smooth muscles and enzymic reactions of Na,K-ATPase. We

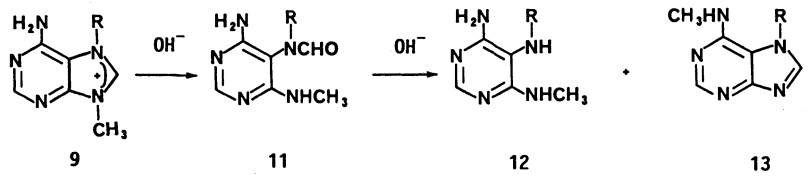
a) δ in ppm, **4**—**9** and **24** in $CDCl_3$ and **16** in DMSO-d_6.

have recently reported the isolation and structures of agelasine-A—F briefly. In this paper, we describe the structural elucidation of the compounds in detail.

Specimens of *Agelas nakamurai* were collected at Zanpa Cape, Okinawa using SCUBA (−10—−20m), frozen shortly for transportation and stored at −20° C until workup. The chloroform-soluble material of methanolic extract of the sponge was chromatographed on a silica-gel column with 3:12:2:2 chloroform–1-butanol–acetic acid–water as eluent to give two fractions. The less polar fraction was repeatedly fractionated by HPLC on a C_{18} column using a methanol–water solvent system containing 0.2 M† sodium chloride to give agelasine-A, agelasine-E and agelasine-F (ageline-A), and a mixture of agelasine-B, -C, and -D. The mixture was further repeatedly chromatographed by HPLC using a C_8 column with methanol–water containing 0.2 M sodium chloride as a mobile phase to yield agelasine-B, -C, and -D. Agelasine-A—F are ammonium salts and isolated as chloride forms. The isolation yields were 0.037, 0.1, 0.01, 0.0056, 0.031, and 0.08% for agelasine-A—F respectively, from the wet weight of the sponge.

Agelasine-A—F (**4**—**9**) showed a number of spectral features in common: Their field desorption mass spectra (FDMS) contained identical principal ions at *m/z* 422 (M^+—Cl) and their high-resolution EI mass spectra (HREIMS) exhibited the principal ions at *m/z* 421.3216, 421.3204, 421.3177, 421.3182, 421.3202, and 421.3201 (M^+—HCl), respectively, revealing the same molecular formula, $C_{26}H_{40}N_5Cl$ (Calcd for $C_{26}H_{39}N_5$: M—HCl 421.3202). Their UV spectra showed alike absorption maxima at 272 nm with very similar ε values, indicating the presence of a same UV absorbing chromophore in these components. The presence of a common main fragment ion at *m/z* 149 in their electron impact mass spectra suggested that the chromophore was composed of $C_6H_7N_5$ (HREIMS *m/z* 149.0722, Calcd for $C_6H_7N_5$: 149.0709). This was supported by the facts that their ^1H NMR spectra contained four common signals corresponding seven protons assignable to NH_2 (δ=6.76—6.98), N-CH_3 (δ=4.10) and two aromatic protons (δ=8.48—8.50, 2′-H and δ=10.91—10.94, 8′-H) and their ^{13}C NMR spectra (Table 1) possessed six common signals due to a heteroaromatic ring. The common chromophore was assigned as a

† 1 M=1 mol dm^{-3}.



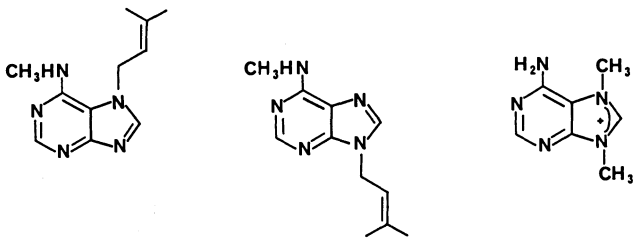
9 11 12 13

Fig. 2.

quaternary 9-methyladenine moiety on the basis of above spectral data and their following chemical behavior.

Agelasines were quite stable under acidic conditions, whereas the compounds were very unstable under basic conditions, even on a alumina column these compounds decomposed to yield less polar materials (Fig. 2). Agelasine-F (**9**), upon treatment with a base, was converted to the corresponding formamide **11**, whose ^{1}H NMR spectrum for the nitrogen-containing portion showed signals at δ 2.97 (d, 3H, J=5 Hz) for N-CH_3, 4.80 (brs, 2H) due to NH_2, and 7.96, and 8.14 (s, each 1H) assignable to the formamide group and 2′-H, respectively. Its electron impact mass spectrum (EIMS) exhibited a molecular ion at m/z 439 corresponding to a molecular formula $C_{26}H_{41}N_5O$. These data were in good agreement with literature values.[3] Furthermore, **9** was heated with 40% KOH at 110° C in a sealed tube to give two products. The less polar product was a white powder; UV absorption maximum at 272 nm (ε 8350); its ^{1}H NMR spectrum contained signals at δ 2.99 (d, 3H, J=5 Hz) for N-CH_3, 3.40 (d, 2H, J=7.5 Hz) due to N-methylene and 7.99 (s, 1H) arising from 2′-H. Lack of the signal for the formamide and the molecular ion at m/z 411 encouraged us to formulate the nitrogenous portion of the molecule as **12**. The polar product was identified as 6-N-methyl-7-alkyladenine derivative (**13**) which had been obtained by Cullen and Devlin from the cyclization of a relevant formamide with sodium hydride in N,N-dimethylacetamide. The structure was confirmed by comparing the spectral data of **13** with those of 6-N-methyl-7-prenyladenine (**14**) and 6-N-methyl-9-prenyladenine (**15**). During these chemical conversions no notable change could be found for the structure of its alkyl moiety.

The other components demonstrated identical behavior on treating with a base. The structure of nitrogenous portion of agelasines was resultantly confirmed by the comparison of the spectral data with those of 7,9-dimethyladeninium perchlorate (**16**).[9a] Above results established that agelasines contained a common polar group, quaternary 9-methyladeninium, and differed only in hydrocarbon portion which was composed of $C_{20}H_{33}$, a diterpene moiety. Further examination of the ^{1}H and ^{13}C NMR spectra of agelasines made it apparent that agelasines contained a common terminal grouping -C(CH_3)=CH-CH_2-Y, whereby the hydrocarbon portion of the molecule connected to 7-N atom of the 9-methyladenine. The E geometry of the double bond was established by their



14 15 16

Fig. 3.

high field ^{13}C NMR signals for vinyl methyls (δ=17.1—17.5). The elucidation of the structures of remaining parts for each component was performed as follows.

Agelasine-A and -B (**4**, **5**), both exhibited one vinyl proton signal, two singlet, one doublet and one vinyl methyl signals at δ 5.28 (brs), 0.79 (s), 1.02 (s), 0.73 (d, J=5.8 Hz) and 1.67 (brs) for **4** and δ 5.17 (brs), 0.70 (s), 0.97 (s), 0.76 (d, J=5.2 Hz) and 1.57 (brs) for **5**, respectively, in their ^{1}H NMR spectra and the ^{13}C NMR signals for a trisubstituted double bond at δ 123.1 (d) and 139.7 (s) for **4** and 120.3 (d), 144.3 (s) for **5**, respectively. This spectral feature is consistent with a clerodane skeleton, a bicyclic ring system. For clerodane type compounds, the ^{13}C NMR chemical shift of 5-methyl usually provides particularly valuable piece of structural evidence for the mode of ring fusion: That of the trans-isomer occurs ca. 11—12 ppm upfield from that of the cis-isomer.[10] Indeed, on inspection of their ^{13}C NMR data, it was found that **4** exhibited a diagnostic low field signal (δ=33.4) due to the angular methyl while **5** showed a high field signal for the angular methyl (δ=19.9). Therefore cis and trans fused clerodane skeleton were assigned to **4** and **5**, respectively.

Since there are four asymmetric centers for clerodane ring system, for the gross structure there are sixteen stereochemical variations, wherein only six have been reported. However **4** on treating with a mixture of hydrochloric acid and acetic acid, converted to **17a** (Fig. 4), leaving only two asymmetric centers at 8 and 9 positions. **17a** can be correlated to **18a**, **18b**, and **18c**. For **18a**[11] having *trans*-8,9-dimethyl, the three singlet methyl signals occurred at δ 0.98, while for **18b**[11] and **18c**[12] having *cis*-8,9-dimethyl, two singlet methyl signals appeared at low field (δ=0.98 for **18b**, and 0.97 and 0.98 for **18c**, respectively), the other was at somewhat high field (δ=0.78 for **18b** and 0.84 for **18c**). The similarity of chemical shifts for three methyl signals in **17a** (δ=0.79, 0.94, and 0.96) clearly favored

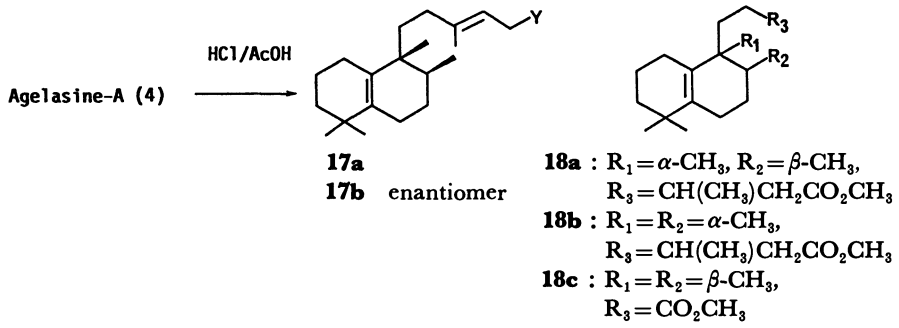


Fig. 4.

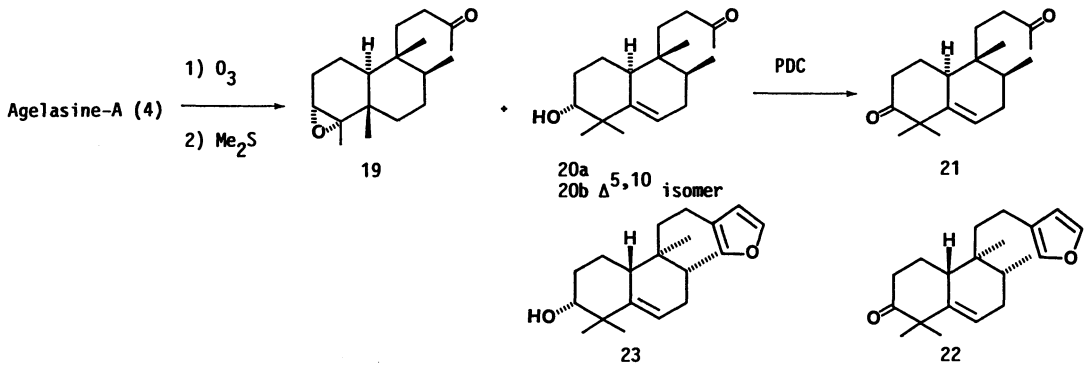

Fig. 5.

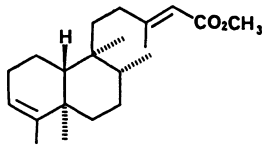
the relative stereochemistry of **18b** and **18c** over that of **18a**. Since the specific rotation of **17a** ($[\alpha]_D$ −14.7°) was same in sign to that of **18c** ($[\alpha]_D$ −52.9°), the absolute configuration of **17a** is probably identical to that of **18c**. It was confirmed by comparing **17a** with the enantiomeric **17b** which was obtained from agelasine-B (**5**). For agelasine-A, the remaining problem involved the deduction of the configuration of C-5 or C-10. Ozonolysis of **4** followed by reduction with dimethyl sulfide furnished an epoxide **19** and two olefinic alcohols **20a** and **20b** (Fig. 5), whose structures were assigned on the basis of their spectral data: **20a** showed an olefinic proton signal at δ 5.55 (m, 1H) and two ^{13}C NMR signals at δ 144.8 (s) and 118.4 (d) for a trisubstituted vinyl group while **20b** showed no olefinic proton signal and two ^{13}C NMR signals at δ 131.3 (s) and 135.1 (s) for a tetrasubstituted double bond. **20a** was oxidized with pyridinium dichromate (PDC) to yield a diketone **21**, which can be correlated to **22** obtained from a solidago diterpene via **23** by McCrindle et al.[13] The comparison of the ^1H NMR spectral data between **21** and **22** revealed close similarity. But **21** showed negative Cotton effect ($[\theta]_{293}$ −3480), which was opposit to that of **22** ($[\theta]_{291}$ +3320) suggesting that the absolute configuration of C-10 in **21** is reversed to that of **22**. Since **4** had a cis-fused decalin skeleton, absolute configurations for all asymmetric centers in **4** thus were well established. On the other hand, there were some differences in chemical shifts for methyls between **20a** and **23**; δ=0.65 (s), 0.81 (d, J=6.5 Hz), 0.94 (s), and 1.13 (s) for **20a** and 0.72 (s), 0.87 (d, J=6 Hz), 1.06 (s),



24

Fig. 6.

and 1.17 (s) for **23** respectively. This may be explained by different orientation of the hydroxyl group with respect to 10-H between them. In **23**, the hydroxyl group was situated anti and oriented axially, but in **20a** the hydroxyl group must be situated syn and adopted equatorial orientation, which was indicated by the coupling constants of 3-H proton signal at δ 3.23 (dd, J=4 and 11 Hz). This revealed that the epoxy group in **19** and the hydroxyl group in **20b** were also α-oriented.

Treatment of agelasine-B with a mixture of hydrochloric acid and acetic acid as well as agelasine-A furnished a tetrasubstituted olefinic compound. As **17b** was identical to **17a** in all respects except the sign of optical rotation ($[\alpha]_D$ +17.1°), it must be an antipode with α-dimethyl groups at 8 and 9 positions. Since agelasine-B has a trans-fused clerodane skeleton, there were only two stereochemical alternatives: 5β-methyl and 10α-proton or 5α-methyl and 10β-proton. The latter was present in methyl kolavenate (**24**)[14] (Fig. 6). The chemical shifts of four methyl signals in **5**, δ=0.70 (s), 0.76 (d, J=5.2 Hz), 0.97 (s) and 1.57 (s), were closely parallel to those of **24**, δ=0.76 (s), 0.85 (d),1.02 (s) and

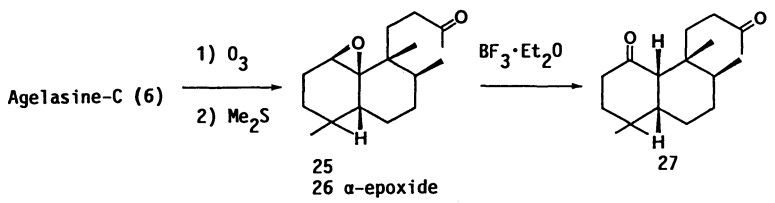


Fig. 7.

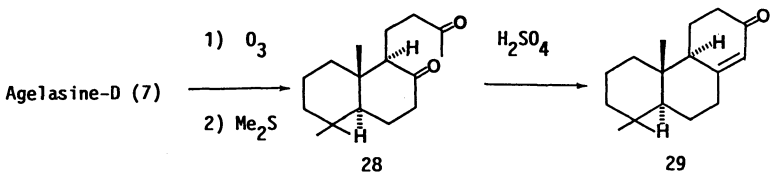

Fig. 8.

1.60 (s), and comparison of ^{13}CNMR spectrum of **5** with that of **24** revealed an excellent correlation for the relevant signals (Table 1). Since the optical rotation of **5** ($[\alpha]_D$ −21.5°) is same in sign to that of **24** ($[\delta]_D$ −58°), the absolute configuration of **5** must be identical to that of **24** at all asymmetric centers. Recently, the structure of agelasine-B (**5**) was confirmed by the synthesis of **5** from **24** by Iio et al.[15]

The ^{1}HNMR spectrum of agelasine-C (**6**) showed a vinyl proton signal at δ 5.31, three singlet methyl signals at δ 0.82, 0.84, and 0.87 and one doublet methyl signal at δ 0.79 (J=6.8 Hz). Thus a rearranged labdane skeleton with 1, 10- or 5,6-double bond was assumed for its gross structure. However, lack of a high field methyl signal, which had been observed for 9-methyl in **20a** (δ=0.65), favored the double bond arrangement at 1,10-position. An acid catalyzed rearrangement of **6** as well as **4** yielded **17a**, indicating the stereochemistry of C-8 and C-9 as illustrated in **6**. Furthermore, reductive ozonolysis workup of **6** (ozone and dimethyl sulfide) gave two epoxides **25** and **26** (Fig. 7). Both epoxides were very hindered and the attempt to reduce them with lithium triethylhydroborate was failed. Then **26** was treated with boron trifluoride etherate to yield a diketone **27** whose ^{1}HNMR spectrum contained signals for α-protons to the carbonyl group at 1-position, δ=2.12 (2-H, ddd, 1H, J=2.3, 4.4, and 13.5 Hz), 2.42 (2-H, dt, 1H, J=6.3 and 13.5 Hz) and 2.48 (10-H, d, 1H, J=5.0 Hz) besides four methyl signals at δ=0.97 (s), 1.03 (d, J=6.9 Hz), 1.17 (s) and 1.23 (s). On irradiation at δ=1.44 (8-H), the doublet methyl signal for C-8 methyl was collapsed to a singlet, whereas the α-proton signals were not affected. This result companied with the small J-value of 10-H signal (5.0 Hz) provided valid evidence for that **27** has a cis-fused decalin skeleton with a carbonyl group at **1** position. In addition, the observation of nuclear Overhauser effects between both the two singlet methyl signals at C-4 and C-9 (δ=0.97 and 1.23) and the 10-H signal (δ=2.48) required a non-steroid-like conformation for **27** which exhibited negative

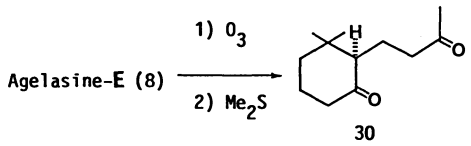

Fig. 9.

Cotton effect ($[\theta]_{298}$ −2370). On the basis of the octant rule, the absolute configuration of **27** was determined as illustrated. Since **27** might be formed from the α-epoxide **26** via a trans antiparallel hydride shift from C-1 to an incipient cationic center at 10-position and the configuration of C-5 was uneffected by the rearrangement conditions employed, the epoxy groups in **25** and **26** might be β- and α-oriented and the stereochemistry of **6** should be as illustrated.

Agelasine-D (**7**) showed three singlet methyl signals at δ 0.65, 0.79, and 0.87 and two vinyl proton signals at δ 4.43 (brs) and 4.81 (brs) for an exomethylene group which was further suggested by the ^{13}CNMR signals at δ 106.9 (t) and 149.0 (s). These data are compatible with a labdane ring system, a well studied skeleton. The stereochemistry of **7** was established by following chemical conversion (Fig. 8). Ozonolysis of **7** followed by reduction with dimethyl sulfide afforded a diketone **28**, which was treated with sulfuric acid to yield an enone **29**. Its spectral data and optical properties were identical with those of an authentic enone.[16,17]

The ^{13}CNMR spectrum of agelasine-E (**8**) showed six olefinic carbon signals at δ 108.3 (t), 115.2 (d), 122.7 (d), 136.2 (s), 146.8 (s), and 149.0 (s) due to its hydrocarbon portion, indicating the presence of three double bonds and a ring. In addition, its ^{1}HNMR spectrum contained signals at δ 5.00 (brs, 1H) and 1.57 (s, 3H) for additional group $-C(CH_3)=CH-CH_2-$, in which the geometry of the double bond was assigned to be *E* on the basis of a high field resonace of an olefinic methyl carbon (δ=15.9), leaving a terminal monocyclic moiety. The remaining ^{1}HNMR data showed two singlet methyl signals at δ 0.82 and 0.90 and an exomethylene proton signals at δ 4.53 (brd,

J=1.5 Hz) and 4.76 (brd, J=1.5 Hz) due to the terminal cyclic part. A 1-alkyl-2-methylene-6,6-dimethylcyclohexane ring system was assigned for the terminal residue. The structure of the diterpene portion in **8** was confirmed by ozonolysis results (Fig. 9). **8** was treated with ozone and worked up with dimethyl sulfide to give a diketone **30** and an unidentified compound **31** arising from the linear polyisoprenyl chain. The CD spectrum of **30** showed a negative Cotton effect ($\Delta\varepsilon_{292}$ −1.57) which was opposite to that of a known diketone having a 5*S* configuration ($\Delta\varepsilon_{296}$ +1.57),[18] indicating the absolute configuration of **8** to be 5*S*. The reduction of **31** with sodium borohydride followed by acetylation with acetic anhydride and pyridine to give 1,4-diacetoxypentane.

The spectral data of agelasine-F (**9**) was in good agreement with those of ageline-A and an identical structure was proposed for it.[8] However, the absolute configuration of **9** was independently established by a successive chemical conversions outlined as following (Fig. 10). The ozonolysis of **9** followed by reductive workup (ozone at −78° C and sodium borohydride) furnished an epoxide **32** and 1,4-pentanediol. **32** was further reduced with lithium triethylhydroborate to give a diol **33**, which was acetylated and then was submitted to dehydration with thionyl chloride/pyridine to yield a 2:1 mixture of an exocyclic olefin **35** and its endo-isomer. The mixture without separation was deacetylated with sodium methoxide to give olefinic alcohol **36**, which then was oxidized with pyridinium dichromate to yield a mixture containing a compound **37**. The mixture was treated with ozone, reduced with dimethyl sulfide and cyclized in methanolic KOH under an argon atmosphere to yield a cis-octalone **38**, which was identical in all respects with an authentic sample.[19] The CD spectrum of **38** exhibited a positive Cotton effect at 236 nm ([θ] +5800) and a negative one at 335 nm ([θ] −390) in hexane, indicating the absolute configuration of the ring junction methyl group as illustrated. On the other hand, ozonolysis of **9** (reductive workup with dimethyl sulfide) furnished an enol ether **39** and a ketone **40**. **39** may be formed via a trans-opening of an epoxide and was characterized by the carbon signals at δ 92.8 (d) and 146.9 (s). It then was treated with *p*-bromobenzoyl chloride and triethylamine to yield **41**. The structure of **41** was elucidated by the interpretation of its ^{1}HNMR spectrum and extensive homodecoupling experiments run at 400 MHz. The axial orientation of *p*-bromobenzoyloxy group and equatorial orientation of 1-methyl were indicated by the coupling constants of the proton signals at 1 and 4 position (J_{1-2a}=13 Hz and J_{3a-4}=J_{3b-4}=3 Hz). Therefore the downfield shift of the signal for 10-methyl (δ=0.93) by the benzoylation ($\Delta\delta$ 0.12) revealed that the *p*-bromobenzoyloxy group i.e. the epoxy group and 10-methyl group in **32** were situated syn. The CD spectrum of compound **40** showed a positive Cotton effect ([θ]$_{295}$ +131). Hence it could in turn be used as a standard to deduce the stereochemistry of agelasidine-B and -C.[5]

Experimental

General. All mp's were obtained on a Yanagimoto micro melting point apparatus and uncorrected. Optical rotations were measured on a Union automatic polarimeter PM-201. IR spectra were recorded on a Hitachi 260-50 spectrophotometer. ^{1}HNMR spectra were taken on JEOL FX-90Q (90 MHz), Bruker WH-270 (270 MHz), or Bruker AM-400 (400 MHz) instruments. ^{13}CNMR spectra were recorded with a JEOL FX-90Q (22.5 MHz) spectrometer. FD mass spectra and HREI mass spectra were measured on a Hitachi M-80A mass spectrometer. CD spectra were obtained on a JASCO J-40A spectrophotometer. UV spectra were taken on a Varian Cary-17 instrument.

Collection, Extraction, and Separation. The marine sponge *Agelas nakamurai* Hoshino (5 Kg, wet weight) was collected at Zampa Cape, Okinawa in 1981 using SCUBA

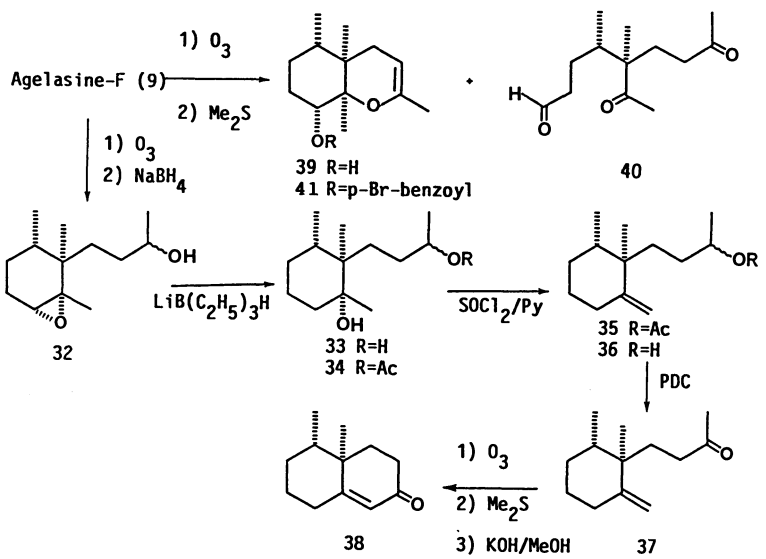

Fig. 10.

(−10—−20 m), shortly frozen and shipped via air to Tokyo, then stored at −20° C until workup. The sponge was cut into small pieces and extracted with methanol (3×40 l). The solvent was evaporated under reduced pressure to give a crude extract (195 g), which was dissolved in methanol. The methanol-soluble material (125 g) was partitioned between chloroform and water. Each 12 g of chloroform-soluble material (60 g) was chromatographed on a silica-gel column (Wako gel C-300, Wako Chemical, 50×600 mm) with 3:12:2:2 chloroform–1-butanol–acetic acid–water as eluent, monitered by TLC. The less polar fraction contained agelasidines (positive coloration with Sakaguchi reagent) and the polar fractions were consisted of agelasines (slightly positive coloration with Sakaguchi reagent and strong UV absorption). The polar fraction was purified by preparative HPLC on a C_{18} column (Nomura Chemical Co. Ltd. Develosil ODS 15/30, 21×250 mm×3) with 8:2 methanol–water containing 0.2 M sodium chloride (flow rate 28 ml min^{-1}) to give a mixture of agelasines (22 g). A part (2 g) of the mixture was separated on a C_{18} column (Develosil ODS-5, 10×250 mm) with 8:2 methanol–water containing 0.2 M sodium chloride (flow rate 4 ml min^{-1}) to yield agelasine-A (**4**, t_R=17.3 min, 170 mg), a mixture of agelasine-B, -C, and -D (t_R=18 min, 822 mg), and agelasine-E (**8**, t_R=19.8 min, 255 mg) and agelasine-F (**9**, t_R=21 min, 368 mg). The mixture was chromatographed on a C_8 column (Develosil C_8-5, 10×250 mm) using methanol–water (73:27) containing 0.2 M sodium chloride as eluent to give a mixture of agelasine-B and -D (t_R=32.3 min, 643 mg), and agelasine-C (**6**, t_R=39 min, 143 mg). The former was further separated by HPLC on a C_8 column (Develosil C_8-5, 10×250 mm) with 7:3 methanol–water containing 0.2 M sodium chloride to furnish agelasine-B (**5**, t_R=53.5 min, 220 mg) and agelasine-D (**7**, t_R=56.3 min, 24 mg).

Agelasine-A (4). Amorphous solid; mp 173—174° C; $[\alpha]_D$ −31.3° (*c* 0.59, CH_3OH); UV (CH_3OH) 272 nm (ε 8910); IR ($CHCl_3$) 3320, 3150, 2950, 1640, 1610, 1455, 1380, 1300, 1230, 1190, 1090 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.73 (d, 3H, *J*=5.8 Hz), 0.79 (s, 3H), 1.02 (s, 3H), 1.67 (brs, 3H), 1.88 (brs, 3H), 1.0—2.1 (m, 14H), 4.10 (s, 3H), 5.26 (brs, 1H), 5.41 (brt, 1H, *J*=6.5 Hz), 5.71 (brd, 2H, *J*=6.5 Hz), 6.98 (brs, 2H, exch), 8.48 (s, 1H), 10.81 (s, 1H); EIMS *m/z* 421 (M^+−HCl), 149, 150, 81, 41, 69, 55, 216, 217, 163, 298, 406; FDMS *m/z* 422 (M^+−Cl); Found: *m/z* 421.3216. Calcd for $C_{26}H_{39}N_5$: M−HCl 421.3202.

Agelasine-B (5). Amorphous solid; mp 167—170° C; $[\alpha]_D$ −21.5° (*c* 1.0, CH_3OH); UV (CH_3OH) 272 nm (ε 8240); IR ($CHCl_3$) 3370, 3160, 2960, 1640, 1610, 1590, 1460, 1385, 1300, 1240, 1195, 1090 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.70 (s, 3H), 0.76 (d, 3H, *J*=5.2 Hz), 0.97 (s, 3H), 1.57 (s, 3H), 1.86 (brs, 3H), 0.7—2.2 (m, 14H), 4.10 (s, 3H), 5.17 (brs, 1H), 5.41 (brt, 1H, *J*=6.5 Hz), 5.71 (brd, 2H, *J*=6.5 Hz), 6.84 (brs, 2H, exch), 8.50 (s, 1H), 10.89 (s, 1H); EIMS *m/z* 421 (M^+−HCl), 149, 95, 121, 107, 189, 163; FDMS *m/z* 422 (M^+−Cl); Found: *m/z* 421.3204. Calcd for $C_{26}H_{39}N_5$: M−HCl 421.3202.

Agelasine-C (6). Amorphous solid; mp 176—179° C; $[\alpha]_D$ −55.1° (*c* 2.04, CH_3OH); UV (CH_3OH) 272 nm (ε 8340); IR (KBr) 3300, 3140, 2965, 1645, 1615, 1470, 1380, 1360, 1230, 1180 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.79 (d, 3H, *J*=6.8 Hz), 0.82 (s, 3H), 0.84 (s, 3H), 0.87 (s, 3H), 0.7—2.2 (m, 14H), 4.10 (s, 3H), 5.31 (brt, 1H, *J*=6.2 Hz), 5.41 (brt, 1H, *J*=6.5 Hz), 5.70 (brd, 2H, *J*=6.5 Hz), 6.84 (brs, 2H, exch), 8.50 (s, 1H), 10.88 (s, 1H); EIMS *m/z* 421 (M^+−HCl), 149, 191, 177, 135, 122, 95, 107; FDMS *m/z* 422 (M^+−Cl); Found: *m/z* 421.3177. Calcd for $C_{26}H_{39}N_5$: M−HCl 421.3202.

Agelasine-D (7). Amorphous solid; mp 175—176° C; $[\alpha]_D$ +10.4° (*c* 1.05, CH_3OH); UV (CH_3OH) 272 nm (ε 9180); IR ($CHCl_3$) 3300, 3150, 2950, 1640, 1610, 1590, 1455, 1390, 1300, 1090, 895 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.65 (s, 3H), 0.79 (s, 3H), 0.87 (s, 3H), 0.6—2.4 (m, 16H), 1.86 (s, 3H), 4.10 (s, 3H), 4.43 (brs, 1H), 4.81 (brs, 1H), 5.41 (brt, 1H, *J*=6.5 Hz), 5.72 (brd, 2H, *J*=6.5 Hz), 6.75 (brs, 2H, exch), 8.50 (s, 1H), 10.94 (s, 1H); EIMS *m/z* 421 (M^+−HCl), 149, 81, 95, 69, 137, 109, 121, 217, 293; FDMS *m/z* 422 (M^+−Cl); Found: *m/z* 421.3182. Calcd for $C_{26}H_{39}N_5$: M−HCl 421.3202.

Agelasine-E (8). Amorphous solid; mp 180—182° C; $[\alpha]_D$ −17.1° (*c* 1.88, CH_3OH); UV (CH_3OH) 272 nm (ε 9720); IR ($CHCl_3$) 3330, 3150, 2950, 1640, 1610, 1590, 1455, 1405, 1380, 1365, 1300, 1235, 1190, 1090 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.82 (s, 3H), 0.90 (s, 3H), 1.56 (s, 3H), 1.86 (s, 3H), 0.7—2.2 (m, 15H), 4.10 (s, 3H), 4.53 (brd, 1H, *J*=1.5 Hz), 4.76 (brd, 1H, *J*=1.5 Hz), 5.00 (brs, 1H), 5.46 (brt, 1H, *J*=6.5 Hz), 5.72 (brd, 2H, *J*=6.5 Hz), 6.87 (brs, 2H, exch), 8.50 (s, 1H), 10.83 (s, 1H); EIMS *m/z* 421 (M^+−HCl), 149, 216, 81, 95, 69, 109; FDMS *m/z* 422 (M^+−Cl); Found: *m/z* 421.3202. Calcd for $C_{26}H_{39}N_5$: M−HCl 421.3202.

Agelasine-F (9). Amorphous solid; mp 178—180° C; $[\alpha]_D$ −5.5° (*c* 2.55, CH_3OH); UV (CH_3OH) 272 nm (ε 7700); IR ($CHCl_3$) 3300, 3150, 2970, 1640, 1590, 1455, 1380, 1300, 1235, 1090 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.84 (s, 3H), 0.85 (d, 3H, *J*=7 Hz), 1.57 (s, 3H), 1.59 (s, 3H), 1.86 (s, 3H), 1.0—2.2 (m, 13H), 4.10 (s, 3H), 5.02 (brs, 1H), 5.42 (brs, 1H), 5.47 (brt, 1H, *J*=7 Hz), 5.72 (brd, 2H, *J*=7 Hz), 6.87 (brs, 2H, exch), 8.50 (s, 1H), 10.83 (s, 1H); EIMS *m/z* 421 (M^+−HCl), 149, 150, 216, 217, 298, 123, 121; FDMS *m/z* 422 (M^+−Cl); Found: *m/z* 421.3201, 149.0722. Calcd for $C_{26}H_{39}N_5$ and $C_6H_7N_5$: M−HCl 421.3202 and 149.0709.

Acid Catalyzed Rearrangement of Agelasine-A (4). **4** (10 mg, 0.022 mmol) was treated with a solution of acetic acid (0.4 ml) and 12 M HCl (0.1 ml) at room temperature using HPLC to follow the reaction. After 30 min the starting meterial was converted completely to give single product. The reagents were removed in vacuo and 1 M NaCl solution (7 ml) was added. The solution was extracted with ethyl acetate (2×15 ml). The extract was concentrated to yield **17a** (10 mg, 100% theoretical). **17a**: Colorless crystals; ^{1}H NMR ($CDCl_3$, 270 MHz) δ=0.79 (s, 3H), 0.80 (d, 3H, *J*=6 Hz), 0.94 (s, 3H), 0.96 (s, 3H), 1.86 (brs, 3H), 1.0—2.0 (m, 15H), 4.08 (brs, 3H), 5.40 (brt, 1H, *J*=6 Hz), 5.67 (brd, 2H, *J*=6 Hz), 7.04 (brs, 2H exch), 8.46 (brs, 1H), 10.70 (s, 1H); ^{13}C NMR ($CDCl_3$, 67.5 MHz) δ=16.3 (q), 17.6 (q), 20.0 (t), 21.2 (q), 25.2 (t), 25.8 (t), 27.2 (t), 27.8 (q), 29.3 (q), 32.0 (q), 33.7 (d), 34.4 (t), 34.6 (s), 40.0 (t), 40.7 (s), 48.8 (t), 109.9 (s), 115.5 (d), 132.0 (s), 137.5 (s), 141.9 (d), 147.8 (s), 149.6 (s), 152.5 (s), 156.0 (d); $[\alpha]_D$ −14.7° (*c* 0.42, CH_3OH).

Ozonolysis of Agelasine-A (4). A solution of **4** (30 mg, 0.066 mmol) in methanol (3 ml) was saturated with ozone for 30 min at −78° C. The excess ozone was removed by a N_2 stream and dimethyl sulfide (0.055 ml) was added. The solution was stirred at 0° C for 30 min and room temperature overnight. The solvent was removed under reduced pressure and the residue was separated by HPLC on a C_{18} column (Develosil ODS-5, 10×250 mm) with methanol–water (8:2) to give the olefinic alcohol **20a** (4 mg, t_R=13.38 min, 22% theoretical), the epoxide **19** (1.5 mg, t_R=20.63 min, 8.3% theoretical) and the olefinic alcohol **20b** (3 mg, t_R=23.85 min, 16.6% theoretical). **20a**: A colorless syrup; ^{1}H NMR ($CDCl_3$,

90 MHz) δ=0.65 (s, 3H), 0.81 (d, 3H, J=6.5 Hz), 0.94 (s, 3H), 1.13 (s, 3H), 2.16 (s, 3H), 3.23 (dd, 1H, J=4, 11 Hz), 5.55 (m, 1H); EIMS m/z 278 (M^+), 189, 187, 119, 207, 227, 161, 224, 260. **19**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.81 (d, 3H, J=6 Hz), 0.87 (s, 3H), 1.09 (s, 3H), 1.32 (s, 3H), 2.15 (s, 3H), 2.98 (brd, 1H, J=3.5 Hz); EIMS m/z 278 (M^+), 207, 189, 149, 121, 123, 119, 109, 107, 95, 249, 221. **20b**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.83 (d, 3H, J=4.8 Hz), 0.85 (s, 3H), 1.01 (s, 3H), 1.02 (s, 3H), 2.12 (s, 3H), 3.52 (m, 1H); EIMS m/z 278 (M^+), 189, 207, 119, 135, 187, 105, 227, 260, 244, 242.

Oxidation of Olefinic Alcohol (20a). To a solution of **20a** (2.4 mg, 0.0086 mmol) in CH_2Cl_2 (1 ml), pyridinium dichromate (13 mg) was added. The reaction mixture was stirred at room temperature overnight. Diethyl ether (5 ml) was added, and then the reaction mixture was filtrated to remove the solid and concentrated under reduced pressure. The residue was purified by a short silica-gel column (hexane–ethyl acetate 17:3) to yield the olefinic diketone **21** (2 mg, 80% theoretical). **21**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.69 (s, 3H), 0.83 (d, 3H, J=6 Hz), 1.24 (s, 6H), 2.18 (s, 3H), 5.26 (m, 1H); EIMS m/z 276 (M^+), 205, 206, 163, 187, 93, 119, 121, 203, 191, 107; CD $[\theta]_{293}$ −3480.

Acid Catalyzed Rearrangement of Agelasine-B (5). **5** (10 mg, 0.022 mmol) was treated with a solution of acetic acid (0.4 ml) and 12 M HCl (0.1 ml) at room temperature for 3 h. The reaction mixture was dried in vacuo and the residue was separated by HPLC on a C_8 column (Develosil C_8-5 packed column, 10×250 mm) using methanol–water (8:2) containing 0.2 M sodium chloride as a mobile phase. The main fraction was concentrated under reduced pressure and the resultant water layer was extracted with ethyl acetate. Concentration of the extract gave **17b** (7 mg, 70% theoretical). **17b**, amorphous solid, was identical with **17a** in all respects except $[\alpha]_D^{25}$ +17.4° (*c* 0.35, CH_3OH).

Acid Catalyzed Rearrangement of Agelasine-C (6). **6** (12 mg, 0.026 mmol) was treated with a solution of acetic acid (0.48 ml) and 12 M HCl (0.32 ml) at room temperature for 3 h and worked up as above to yield **17a** (8.8 mg, 73% theoretical), which was identical with that obtained from agelasine-A, and showed $[\alpha]_D$ −15.9° (*c* 0.44, CH_3OH).

Ozonolysis of Agelasine-C (6). Ozone was bubbled in the solution of **6** (70 mg, 0.15 mmol) in methanol (50 ml) at −78° C for 1 h. The excess ozone was removed by N_2 flow. Dimethyl sulfide (1 ml) was added, then the solution was allowed to warm up to 0° C and then room temperature (in 30 min each). The reaction mixture was dried under reduced pressure and the residue was submitted to silica-gel column chromatography (hexane–ethyl acetate 95:5) to furnish two epoxides **25** and **26** (9 mg, 21% and 13 mg, 31% theoretical, respectively). **25**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.68 (s, 3H), 0.79 (s, 3H), 0.93 (d, 3H, J=7.2 Hz), 1.06 (s, 3H), 2.15 (s, 3H), 3.04 (brd, 1H, J=4 Hz), 1.0—2.7 (m, 14H); EIMS m/z 278 (M^+), 207, 263, 189, 137, 119; $[\alpha]_D^{25}$ −36.7° (*c* 0.60, CH_3OH). **26**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.64 (s, 3H), 0.86 (s, 6H), 1.03 (d, 3H, J=7.2 Hz), 2.16 (s, 3H), 2.91 (brd, 1H, J=4 Hz), 1.0—2.6 (m, 14H); EIMS m/z 278 (M^+), 207, 163, 137, 83, 55, 67, 95, 105, 119, 121; $[\alpha]_D^{25}$ +6.5° (*c* 1.85, CH_3OH).

Reaction of 26 with Boron Trifluoride Etherate. A solution of **26** (3.5 mg, 0.013 mmol) in anhydrous benzene (1.5 ml) was treated with boron trifluoride etherate (0.1 ml) for 10 min at room temperature. The solution was diluted with ethyl acetate (5 ml) and extracted with aqueous sodium hydrogencarbonate (10%, 10 ml), then washed with brine (10 ml), and dried under anhydrous sodium sulfate. Evaporation left a residue, which was submitted to silica-gel column chromatography (hexane–ethyl acetate 85:15) to yield the diketone **27** (1.5 mg, 43% theoretical). **27**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.97 (s, 3H), 1.03 (d, 3H, J=6.9 Hz), 1.13 (s, 3H), 1.23 (s, 3H), 2.12 (ddd, 1H, J=2.3, 4.4, 13.5 Hz), 2.17 (s, 3H), 2.26 (m, 2H), 2.42 (dt, 1H, J=6.3, 13.5 Hz), 2.48 (d, 1H, J=5 Hz); EIMS m/z 278 (M^+), 207, 125, 151, 208, 95, 109, 152, 119, 161, 189; CD $[\theta]_{298}$ −2370.

Ozonolysis of Agelasine-D (7). A solution of **7** (5 mg, 0.011 mmol) in methanol (0.5 ml) was treated with ozone at −78° C for 30 min. After removing excess ozone, dimethyl sulfide (0.03 ml) was added, then the solution was kept at 0° C for 30 min and at room temperature for 3 h. Evaporation of the solvent left a residue, which was submitted to silica-gel column chromatography (hexane–ethyl acetate 85:15) to afford the diketone **28** (1.5 mg, 52% theoretical). An additional amount (ca. 18 mg) was obtained from the ozonolysis of the mixture of agelasines. **28**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.72 (s, 3H), 0.84 (s, 3H), 0.95 (s, 3H), 2.08 (s, 3H), 1.0—2.8 (m, 16H); ^{13}C NMR ($CDCl_3$, 22.5 MHz) δ=14.6 (q), 16.3 (q), 19.0 (t), 21.7 (q), 24.0 (t), 29.9 (q), 33.6 (q), 33.7 (t), 39.2 (t), 42.0 (t), 42.6 (t), 42.7 (s), 42.8 (t), 54.2 (d), 63.2 (d), 208.9 (s), 211.9 (s); IR ($CHCl_3$) 1710 cm^{-1}; EIMS m/z 264 (M^+), 249, 81, 95, 67, 55, 121, 139, 231; $[\alpha]_D^{25}$ −28.5° (*c* 1.5, CH_3OH).

Conversion of 28 to the Enone (29). Concentrated sulfuric acid (0.13 ml) was added dropwise to the solution of **28** (16 mg, 0.061 mmol) in methanol (2.4 ml). The solution was heated to boiling, then cooled, diluted with water (15 ml) and extracted with diethyl ether (2×15 ml). Evaporation of the solvent left a residue, which was submitted to silica-gel column chromatography (hexane–ethyl acetate 9:1) to give the enone **29** (12.2 mg, 76.2% theoretical): Colorless crystals; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.80 (s, 3H), 0.87 (s, 3H), 0.92 (s, 3H), 5.88 (brs, 1H); ^{13}C NMR ($CDCl_3$, 22.5 MHz) δ=15.1 (q), 18.6 (t), 20.4 (t), 21.9 (q), 21.9 (t), 33.3 (s), 33.5 (q), 36.7 (t), 38.9 (s), 39.2 (t), 41.7 (t), 51.5 (d), 53.9 (d), 125.7 (d), 165.7 (s), 199.4 (s); IR ($CHCl_3$) 1680 cm^{-1}; EIMS m/z 246 (M^+), 110, 137, 123, 231; $[\alpha]_D^{25}$ +36.0° (*c* 0.5, CH_3OH); UV (CH_3OH) 242 (ε 20050), 310 nm (360); CD $[\theta]_{242}$ +38460, $[\theta]_{317}$ −8720.

Ozonolysis of Agelasine-E (8). A solution of **8** (26 mg, 0.057 mmol) in methanol (3 ml) was saturated with ozone at −78 °C for 30 min. After removing the excess ozone dimethyl sulfide (0.075 ml) was added, then the solution was allowed to warm up to 0° C (30 min) and room temperature overnight. The reaction mixture was dried under reduced pressure and the residue was submitted to silica-gel column chromatography (hexane–ethyl acetate 85:15) to yield the diketone **30** (10 mg, 90% theoretical) and the compound **31** (5.1 mg). **30**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 270 MHz) δ=0.79 (s, 3H), 1.09 (s, 3H), 2.12 (s, 3H), 1.5—2.6 (m, 11H); ^{13}C NMR ($CDCl_3$, 22.5 MHz) δ=18.3 (t), 21.8 (q), 23.1 (t), 29.5 (q), 39.5 (t), 39.7 (s), 41.4 (t), 42.6 (t), 60.1 (d), 208.6 (s), 213.0 (s); IR ($CHCl_3$) 1710 cm^{-1}: EIMS m/z 196 (M^+), 181, 111, 163, 139, 121, 95; CD $[\theta]_{292}$ −5174, $\Delta\varepsilon_{292}$ −1.57.

Reduction and Acetylation of 31. **31** (5 mg) was reduced with sodium borohydride (10 mg) in methanol (1.5 ml), workup in usual way to give a crude product, which was purified by silica-gel column chromatography (chloroform–methanol 9:1) to yield 1,4-pentanediol (4.5 mg), which was acetylated with acetic anhydride (0.1 ml) and pyridine

(0.1 ml) to give 1,4-diacetoxypentane.

Ozonolysis of Agelasine-F (9) with Sodium Borohydride Reduction. A solution of **9** (50 mg, 0.11 mmol) in methanol (3 ml) was treated with ozone at −78° C for 15 min. After removing the excess ozone, sodium borohydride (105 mg, in three portions) was added. The reaction mixture was stirred and allowed to warm up to 0° C and room temperature (in 30 min each), then was neutralized with acetic acid. Removing solvent left a residue, which was submitted to silica-gel column chromatography (chloroform–methanol 95:5) to furnish the epoxide **32** (13.8 mg, 54% theoretical) and 1,4-pentanediol (3 mg). **32**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.77 (d, 3H, J=6 Hz), 0.88 (s, 3H), 1.20 (d, 3H, J=5 Hz), 1.24 (s, 3H), 2.98 (brs, 1H), 3.76 (brq, 1H, J=7 Hz); ^{13}C NMR ($CDCl_3$, 22.5 MHz) δ=15.9 (q), 18.1 (q), 20.8 (q), 23.5 (q), 24.2 (t), 25.9 (t), 33.3 (d), 33.6 (t), 34.4 (t), 38.4 (s), 62.5 (d), 62.8 (s), 68.8 (d); EIMS m/z 212 (M^+), 197, 126, 109, 153, 167, 179.

Reduction of the Epoxide 32. A solution of **32** (13 mg, 0.061 mmol) in anhydrous THF (1 ml) was treated with lithium triethylhydroborate (1 M, 0.5 ml) under nitrogen atmosphere and the reaction mixture was stirred at room temperature overnight. The solvent was evaporated and the residue was dissolved in a solution of chloroform and methanol (15 ml, 95:5). The solution was passed through a short silica-gel column to give the pure diol **33** (11 mg, 84% theoretical): Amorphous solid; mp 121.5—123 °C; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.88 (d, 3H, J=6 Hz), 0.90 (s, 3H), 1.22 (d, 3H, J=6.5 Hz), 1.26 (s, 3H), 3.68 (m, 1H); EIMS m/z 214 (M^+), 196, 181, 178, 170, 163, 138, 96, 149.

Acetylation of 33. A mixture of **33** (8 mg, 0.037 mmol), acetic anhydride (0.1 ml), triethylamine (0.1 ml) and 4-dimethylaminopyridine (1 mg) was stirred at room temperature for 1 h. The product was purified by silica-gel column chromatography (ethyl acetate–hexane 15:85) to yield the monoacetate **34** (8.5 mg, 88% theoretical): A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.85 (d, 3H, J=6 Hz), 0.88 (s, 3H), 1.21 (d, 3H, J=6.5 Hz), 1.25 (s, 3H), 2.02 (s, 3H), 4.78 (hexalet, 1H, J=6 Hz); EIMS m/z 256 (M^+), 239, 196, 181, 178, 163, 154, 149, 136, 138.

Dehydration of 34. A solution of **34** (8 mg, 0.031 mmol) in pyridine (1 ml) was treated with thionyl chloride (0.1 ml) at −5° C for 15 min. The reaction mixture was diluted with diethyl ether (5 ml), quenched with water (5 ml) and then separated. The aqueous layer was extracted with diethyl ether (5 ml). The combined ether layer was dried over anhydrous sodium sulfate and concentrated to give a residue, which was chromatographed on a silica-gel column (hexane–ethyl acetate 85:15) to give a mixture of the *exo*-olefin 35 and its *endo*-isomer with a ratio 2:1 (total 7.5 mg): A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.84 (d, 3H, J=6 Hz), 0.85 (s, 3H×1/3), 0.91 (s, 3H×2/3), 1.20 (d, 3H, J=6.5 Hz), 2.01 (s, 3H), 4.54 (d, 1H×2/3, J=2 Hz), 4.78 (brd, 1H×2/3, J=2 Hz), 4.84 (hexalet, 1H, J=6 Hz), 5.40 (brs, 1H×1/3); EIMS m/z 239 (M^++1), 123, 178, 149, 136.

Deacetylation of 35. A solution of **35** and its isomer (7 mg, 0.029 mmol) in methanol (1 ml) was treated with 1 M sodium methoxide (0.5 ml in three portion) under nitrogen atmosphere, then silica-gel column chromatography of the product gave a mixture of **36** and its *endo*-olefin isomer (5 mg): A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=3.73 (hexalet, 1H, J=6 Hz), 4.54 (d, 1H×2/3, J=2 Hz), 4.78 (brs, 1H×2/3), 5.40 (brs, 1H×1/3); EIMS m/z 196 (M^+), 123, 178, 163, 121.

Oxidation of 36. To a solution of **36** and its *endo*-olefin isomer (5 mg, 0.026 mmol) in anhydrous dichloromethane (1 ml) pyridinium dichromate (10 mg) was added and the reaction mixture was stirred under nitrogen atmosphere for 6 h, then it was diluted with diethyl ether (5 ml) and filtrated to remove the solid. The filtrate was passed through a short silica-gel column and concentrated to yield the olefinic ketone **37** and its *endo*-olefin isomer (3 mg): A syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.84 (d, 3H, J=6 Hz), 0.88 (s, 3H×1/3), 0.90 (s, 3H×2/3), 2.12 (s, 3H), 4.54 (d, 1H×2/3, J=2 Hz), 4.79 (brs, 1H×2/3), 5.40 (brs, 1H×1/3); EIMS m/z 194 (M^+), 123, 176, 161.

Conversion of 37 to the Octalone 38. A solution of **37** and its isomer (3 mg, 0.015 mmol) in methanol (1 ml) was saturated with ozone at −78° C for 5 min. After removing the excess ozone, dimethyl sulfide (0.007 ml) was added, then the reaction mixture was allowed to warm up to 0° C and room temperature (in 30 min each). After removing the solvent and excess reagent under reduced pressure, 5% KOH aqueous solution (0.1 ml) and methanol (1 ml) were added. The solution was refluxed for 3 h under argon atmosphere, then cooled to room temperature. Evaporation left a residue, which was chromatographed on a silica-gel column (hexane–ethyl acetate 85:15) to yield the octalone **38** (1 mg), which was further purified by TLC (hexane–ethyl acetate 85:15). ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.91 (brs, 3H, J=6Hz), 1.11 (s, 3H), 5.74 (brs, 1H); EIMS m/z 178 (M^+), 136, 163, 121, 107; CD $[\theta]_{335}$ −390, $[\theta]_{236}$ +5800.

Ozonolysis of Agelasine-F (9) with Dimethyl Sulfide Reduction. Ozone was bubbled in a solution of **9** (59 mg, 0.11 mmol) in methanol (3 ml) at −78° C for 30 min. After removing the excess ozone, dimethyl sulfide (0.5 ml) was added, then the solution was allowed to warm up to 0° C and room temperature (in 30 min each) and stirred overnight. Usual workup and HPLC separation (Develosil 60-3, 10× 250 mm, benzene–acetone 90:10) furnished the enol ether **39** (7.6 mg) and the aldehyde **40**. **39**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.80 (d, 3H, J=6.5 Hz), 0.93 (s, 3H), 1.24 (s, 3H), 1.67 (d, 3H, J=1.5 Hz), 3.68 (brs, 1H), 4.32 (m, 1H); ^{13}C NMR ($CDCl_3$, 22.5 MHz) δ=16.2 (q), 18.0 (q), 18.8 (q), 20.0 (q), 25.2 (t), 29.0 (t), 30.3 (t), 32.1 (d), 35.7 (s), 74.8 (d), 79.6 (s), 92.8 (d), 146.9 (s); EIMS m/z 210 (M^+), 149, 125, 123, 109. **40**: A colorless syrup; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.85 (d, 3H, J=7 Hz), 1.03 (s, 3H), 2.11 (s, 6H), 9.75 (t, 1H, J=2 Hz); EIMS m/z 226 (M^+), 107, 123, 121, 142, 147, 165, 183; CD $[\theta]_{296}$ +130.

***p*-Bromobenzoylation of 39.** A mixutre of **39** (5 mg, 0.024 mmol), triethylamine, *p*-bromobenzoylchloride (20 mg) and anhydrous benzene (0.5 ml) was stirred at room temperature overnight. Usual workup and silica-gel column chromatography (hexane–ethyl acetate 96:4) yield the ester **41** (2.5 mg), a colorless syrup; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.83 (d, 3H, J=6.6 Hz), 1.05 (s, 3H), 1.18 (s, 3H), 1.35 (dm, 1H, J= 13 Hz), 1.53 (dq, 1H, J=13, 4 Hz), 1.70 (s, 3H), 1.73 (dm, 1H, J=13 Hz), 1.78 (dm, 1H, J=17 Hz), 1.82 (m, 1H), 1.96 (dd, 1H, J=17, 5 Hz), 2.13 (tt, 1H, J=13 and 3 Hz), 4.19 (brd, 1H, J=5 Hz), 5.06 (brt, 1H, J=3 Hz).

Treatment of 9 with Sodium Carbonate. A solution of **9** (5 mg, 0.0011 mmol) in water (2 ml) was treated with 2 M sodium carbonate aqueous solution (0.01 ml) for 2 h, and then it was extracted with ethyl acetate. Concentration of the extracts gave the formamide **11** (5 mg, 100% yield): Amor-

phous solid; UV (CH_3OH) 260 (ε 4360), 270 (pH 2, 9160), 260 nm (pH 11, 8930); ^1HNMR ($CDCl_3$, 90 MHz) δ=2.97 (d, J=5 Hz), 4.14 (d, 3H, J=7 Hz), 4.80 (brs, 2H), 7.96 (s, 1H), 8.14 (s, 1H); EIMS m/z 439 (M^+), 396.

Hydrolysis of 9 with KOH. A mixture of **9** (10 mg, 0.0022 mmol), methanol (2 ml) and 40% KOH aqueous solution (1 ml) was heated in a sealed tube at 115° C for 3 h. The reaction mixture was dried under reduced pressure to give a residue, which was submitted to TLC separation (chloroform–methanol 95:5) to yield the less polar product **12** (0.5 mg, 6% yield) and the polar product **13** (4 mg). **12**: Amorphous solid; UV (CH_3OH) 272 nm (ε 8350); ^1HNMR ($CDCl_3$, 90 MHz) δ=2.99 (d, 3H, J=5 Hz), 3.40 (d, 2H, J=7.5 Hz), 7.99 (s, 1H); EIMS m/z 411 (M^+), 396, 139. **13**: UV (CH_3OH) 272 nm (ε 8520), 277 (8360), 282 (pH 2); ^1HNMR ($CDCl_3$, 90 MHz) δ=3.10 (d, 3H, J=5 Hz), 4.87 (d, 2H, J=7 Hz), 7.85 (s, 1H), 8.55 (s, 1H); EIMS m/z 421 (M^+), 406, 298, 149.

Preparation of 6-*N*-Methyl-7-prenyladenine (14), 6-*N*-Methyl-9-prenyladenine (15), and 7,9-Dimethyladeninium Perchlorate (16). Compounds **14**, **15**, and **16** were prepared by the methods described in literatures.[9] **14**: Amorphous solid; mp 157—158° C; UV (CH_3OH) 272 (sh, ε 12300), 277 nm (12600); IR (KBr) 1670, 1615, 1580, 1480, 1460, 1390, 1350 cm^{-1}; ^1HNMR ($CDCl_3$) δ=1.84 (s, 3H), 1.85 (s, 3H), 3.08 (d, 3H, J=4.8 Hz, NMe), 4.85 (d, 2H, J=6.2 Hz, NCH_2), 5.30 (brs, 1H, NH), 5.40 (t, 1H, J=6.2 Hz, =CH), 7.80 (s, 1H, 8-H), 8.48 (s, 1H, 2-H); ^{13}CNMR ($CDCl_3$) δ=18.2 (q), 25.6 (q), 28.1 (q, NMe), 45.8 (t, NCH_2), 112.2 (s, C-5), 119.0 (d, =CH), 139.6 (s, =C), 143.6 (d, C-8), 151.6 (s, C-6), 153.0 (d, C-2), 159.6 (s, C-4); EIMS m/z 217 (M^+). **15**: Crystals; mp 110—111° C; UV (CH_3OH) 267 nm (ε 16300); IR (KBr) 3280, 2920, 1615, 1580, 1400, 1330, 1305, 1225 cm^{-1}; ^1HNMR ($CDCl_3$) δ=1.80 (s, 6H), 3.19 (d, 3H, J=4.9 Hz, NMe), 4.73 (d, 2H, J=6.0 Hz, NCH_2), 5.42 (t, 1H, J=6.0 Hz, =CH), 6.12 (brs, 1H, NH), 7.69 (s, 8-H), 8.42 (s, 2-H); ^{13}CNMR ($CDCl_3$) δ=17.7 (q), 25.3 (q), 27.4 (q, NMe), 40.2 (t, NCH_2), 117.8 (d, =CH), 119.6 (s, C-5), 138.3 (s, =C), 138.7 (d, C-8), 148.7 (s, C-6), 152.8 (d, C-2), 155.3 (s, C-4); EIMS m/z 217 (M^+). **16**: Rods; mp 293—294° C; UV (CH_3OH) 212 (ε 12900), 272 nm (8080); IR (KBr) 3410, 3100, 1675, 1620, 1140, 1110, 1080, 620 cm^{-1}; ^1HNMR (DMSO-d_6) δ=3.86 (s, 3-H, 9-NMe), 4.17 (s, 3H, 7-NMe), 7.93 (brs, 2H, NH_2), 8.40 (s, 1H, 2-H), 9.59 (s, 1H, 8-H); EIMS m/z 163 (M^+-HClO_4).

The authors acknowledge Dr. Takaharu Hoshino of Mukaishima Biological Station, Hiroshima University for his kind identification of the marine sponge, Professor Tatsuo Miyazawa and Mr. Kaoru Wakamatsu of The University of Tokyo for 400 MHz ^1HNMR measurements, and Professor Takashi Tokoroyama of Osaka City University for ^{13}CNMR data of methyl kolavenate. We also thank Mr. Zengo Nagahama for his assistance to collect the sponges and Miss Reiko Abe for her technical assistance.

Synthetic Study on Peptide Antibiotic Nisin. II. The Synthesis of Ring B[1)]

Koichi FUKASE, Tateaki WAKAMIYA, and Tetsuo SHIBA*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received March 5, 1986)

Synthesis of a cyclic sulfide moiety ring B in peptide antibiotic nisin was successfully achieved by desulfurization from a corresponding disulfide peptide with tris(diethylamino)phosphine. The configuration on β-carbon atom of *threo*-3-methyl-D-cysteine residue in the disulfide peptide was retained through the reaction to give a desired natural *threo* form of methyllanthionine.

Peptide antibiotic nisin was isolated from culture broth of *Streptococcus lactis* by Mattick and Hirsh in 1947,[2)] and Berridge et al. in 1952.[3)] Nisin shows several biological activities such as antibacterial activity against Gram-positive microorganisms, particularly *Clostridium botulinum*, as well as antimalarial activity, and so on.[4)] Nisin is now in practical use widely in European countries as an important food preservative but not as a chemotherapeutic agent because of low solubility at physiological pH value.

In 1971, quite unique and complicated structure of nisin was proposed by Gross and Morell as shown in Fig. 1.[5)] It is composed of thirty-four amino acid residues including three dehydroamino acids and five lanthionines which construct cyclic moieties via sulfide bond. These five ring parts were named A, B, C, D, and E respectively from *N*-terminal in the molecule.

From the standpoint of a synthetic interest in such a complicated peptide as well as an elucidation on structure-activity relationship of nisin, we started the synthetic study of this antibiotic, and have already accomplished the synthesis of ring A.[6)]

In the synthetic study of ring A, we could establish an advantageous preparative method of cyclic lanthionine peptide by an elimination of one sulfur atom from a corresponding cystine peptide using tris(diethylamino)phosphine [$P(NEt_2)_3$] as desulfurization reagent[7)] (Fig. 2). According to the application of this procedure, synthesis of ring B (Fig. 3) was now carried out as shown in Fig. 4.

threo-3-Methyl-D-cysteine required for this synthesis was prepared from D-threonine by use of our novel method via 2-aziridinecarboxylic acid derivative.[8)] Mercapto groups on L-cysteine and *threo*-3-methyl-D-cysteine residues were protected with acetamidomethyl (Acm) and trityl (Trt) groups, respectively as in ring A synthesis. These protecting groups can be readily removed with I_2 oxidation in methanol to form a cyclic disulfide compound directly.[9)] Since *S*-tritylation is better than *S*-acetamidomethylation in convenience on manipulation and in yield on reaction, the mercapto group of precious *threo*-3-methyl-D-cysteine residue was protected with trityl group. The protected linear tetrapeptide **7** was first prepared successively from the *C*-terminal by stepwise elongation with either a mixed anhydride method or an active ester method. The peptide **7** thus obtained was then subjected to I_2 oxidation. The monomeric disulfide **8** was satisfactorily obtained by high dilution method. In order to confirm the formation of monomer, the molecular weight of the compound **8** was measured by mass spectrometry (*m/z* 504; calcd 504).

In the synthetic study of ring A, the desulfurization reaction was successfully carried out in *N*,*N*-dimethylformamide (DMF). Thus the desulfurization reaction of disulfide **8** was first performed in DMF. Although we could obtain the desired monomeric sulfide peptide **9**, whose molecular weight was confirmed by mass spectrometry (*m/z* 472; calcd 472), the yield did not exceed 30% even though under the

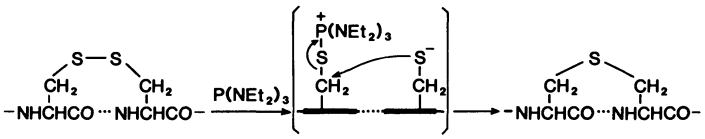

Fig. 2. The reaction mechanism of the desulfurization.

optimum conditions used in the case of ring A synthesis (Table 1). In order to improve the reaction conditions in the present case, we examined effects of the solvent, reaction temperature, amount of $P(NEt_2)_3$, and concentration of the substrate (Table 1). Among general organic solvents tested, benzene and DMF can be utilized while other solvents such as dioxane, THF, $CHCl_3$, ethyl acetate, CH_3CN, and so on were not suitable because of considerable occurrence of undesirable side reactions.

In view of reproducibility in yield, easiness in purification of the reaction product, and readiness of preparation of absolute solvent, benzene is better than DMF as reaction solvent in the present study. The yield was improved when desulfurization reaction was performed under higher dilution as far as it reached to the optimum at 0.62 mM (1 M=1 mol dm^{-3}) at room temperature as shown in Table 1. Thus, the cyclic sulfide peptide **9** was satisfactorily obtained in a 57% yield.

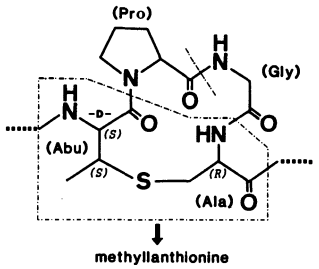

Fig. 3. The chemical structure of the ring B part in nisin.

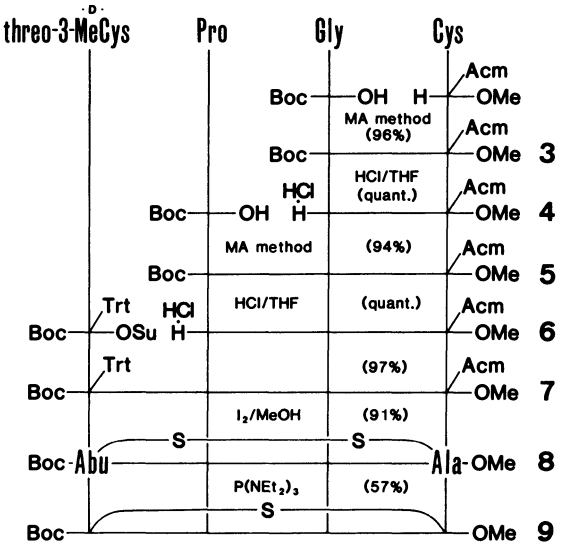

Fig. 4. The synthetic scheme of the protected ring B.

In the case of ring B preparation, it is very important to investigate about two possible desulfurization pathways (Fig. 5). When the reaction proceeds via path (a), the configuration on β-carbon atom of *threo*-3-methyl-D-cysteine is retained to give a *threo* form of methyllanthionine i.e., natural form in nisin. On the other hand, the reaction via path (b) will cause an inversion of the configuration on the β-carbon of 3-methylcysteine residue to form *erythro*-methyllanthionine.

Amino acid analysis of the hydrolyzate of the final product **9** clearly indicated the sole formation of desirable *threo*-methyllanthionine[10] residue via path (a) (Fig. 6). This result can be explained by following two plausible reasons; i) because of steric hindrance of 3-methyl group in *threo*-3-methyl-D-cysteine residue, the nucleophilic attack took place selectively at the sulfur atom of L-cysteine residue, ii) thiolate anion of 3-methylcysteine residue is more stable than that of cysteine residue.

Thus, ring B in nisin was successfully synthesized, verifying a possibility for preparation of *threo*-methyllanthionine peptide from a disulfide peptide composed of *threo*-3-methyl-D-cysteine and L-cysteine by the desulfurization with $P(NEt_2)_3$. Based on the synthetic studies of rings A and B, we could confirm that the desulfurization is very versatile method for the preparation of lanthionine peptide in general. In fact, we recently applied this method successfully to the synthesis of ring C as well as conjunctive ring D–E moiety in nisin, whose results will be reported soon elsewhere.

Experimental

All melting points are uncorrected. The FD-MS spectra were obtained with a JEOL JMS-01SG-2 spectrometer on silicone emitter. Specific rotations were obtained with a Perkin-Elmer 141 polarimeter. Amino acid analyses were carried out with a Hitachi KLA-5 analyzer. Sample for the amino acid analysis was hydrolyzed with constant boiling

Table 1. Yields of Compound **9** on Various Reaction Conditions

Solvent	Concn/mM	$P(NEt_2)_3$	Temp/°C	Reaction time/h	Yield/%
DMF	2.3	40 eq	50	96	28
DMF[a)]	2.4	20 eq	50	96	24

C_6H_6	0.31	40 eq	25	48	53

a) The optimum conditions in the case of ring A synthesis.

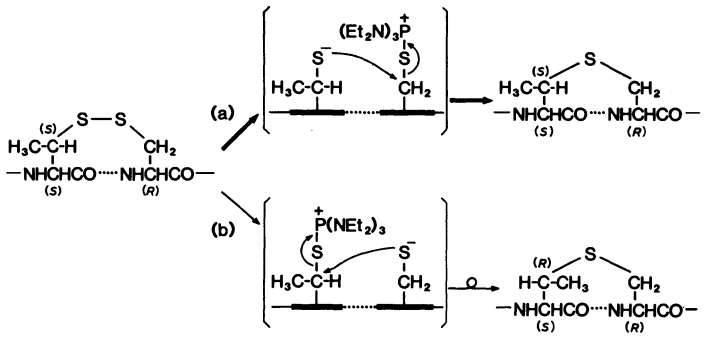

Fig. 5. Plausible desulfurization pathways in ring B preparation.

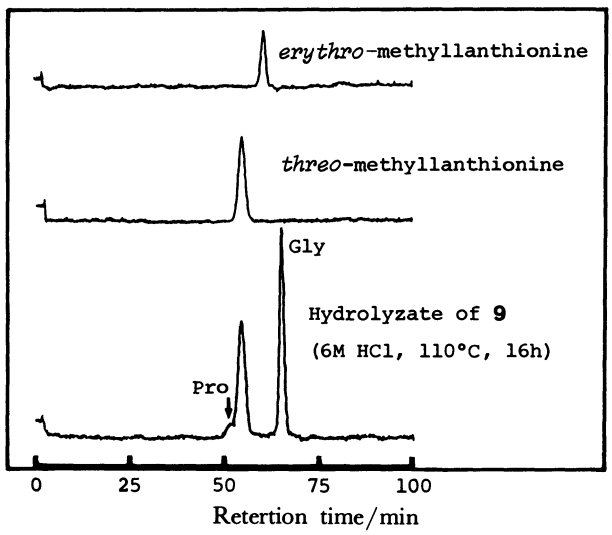

Fig. 6. Amino acid analysis of compound **9**. Column: Hitachi #2618 resin (0.9×25 cm, 55°C), buffer: 0.20 M sodium citrate (pH 3.0).

6 M HCl in a sealed tube at 110°C for 16 h.

H-3-Me-D-Cys(Trt)-OH (1). *threo*-3-Methyl-D-cysteine[8] (11.6 g, 85.9 mmol) and triphenylmethanol (22.3 g, 85.9 mmol) were dissolved in 150 ml of trifluoroacetic acid. The clear solution was allowed to stand at room temperature for 15 min and then trifluoroacetic acid was removed in vacuo. To an ether solution of the residue was added 10% aqueous sodium acetate until pH of the aqueous layer became 5 to precipitate H-3-Me-D-Cys(Trt)-OH (**1**). The precipitate collected was washed with water and ether: Yield 31.7 g (97.8%). A part of the product was recrystallized from ethanol and ether to obtain an analytical sample: Mp 163—164°C; $[\alpha]_D^{17}$ −28.9°(*c* 1.00, MeOH).

Found: C, 69.98; H, 6.23; N, 3.55; S, 8.16%. Calcd for $C_{23}H_{23}NO_2S \cdot H_2O$: C, 69.85; H, 6.37; N, 3.54; S, 8.11%.

Boc-3-Me-D-Cys(Trt)-OH·DCHA (2). To a suspension of the compound **1** (3.07 g, 8.14 mmol) in 60 ml of methanol were added di-*t*-butyl dicarbonate (2.10 g, 9.80 mmol) and triethylamine (0.906 g, 8.95 mmol). After stirring at room temperature overnight, the reaction mixture was concentrated in vacuo and the residue was dissolved in ethyl acetate. The solution was washed with 10% aqueous citric acid and saturated sodium chloride solutions. The organic layer was dried over $MgSO_4$ and then concentrated in vacuo. An oily residue thus obtained was dissolved in hexane to which dicyclohexylamine (1.77 g, 9.76 mmol) was added. After the reaction mixture was cooled in an ice bath, the precipitate was filtered: Yield 5.10 g (95.1%). A part of the product was recrystallized from ethyl acetate and hexane to obtain an analytical sample: Mp 186.5—187°C; $[\alpha]_D^{23}$ −83.0° (*c* 1.07, MeOH).

Found: C, 72.72; H, 8.29; N, 4.27; S, 4.81%. Calcd for $C_{40}H_{54}N_2O_4S$: C, 72.91; H, 8.26; N, 4.25; S, 4.87%.

Boc-Gly-Cys(Acm)-OMe (3). To a solution of Boc-Gly-OH (20.0 g, 114 mmol) in 80 ml of DMF were added ethoxycarbonyl chloride (12.4 g, 114 mmol) and triethylamine (11.5 g, 114 mmol) under cooling in an ice-salt bath. After the reaction mixture was stirred in the chilled bath for 50 min, a solution of HCl·H-Cys(Acm)-OMe[13] (23.1 g, 95.2 mmol) and triethylamine (9.63 g, 95.2 mmol) in 200 ml of DMF was added. The solution was stirred under cooling in an ice bath for additional 20 min and then kept at room temperature overnight. The reaction mixture was concentrated in vacuo to the residue, which was dissolved in chloroform, and washed with 10% aqueous citric acid, saturated sodium hydrogencarbonate, and saturated sodium chloride solutions. The organic layer was dried over $MgSO_4$ and then concentrated in vacuo to give an oily product: Yield 33.3 g (96.2%); $[\alpha]_D^{18}$ −9.50° (*c* 2.78, $CHCl_3$).

Found: C, 45.30; H, 6.94; N, 11.21; S, 8.72%. Calcd for $C_{14}H_{25}N_3O_6S \cdot 1/2H_2O$: C, 45.15; H, 7.04; N, 11.28; S, 8.61%.

HCl·H-Gly-Cys(Acm)-OMe (4). Protected dipeptide **3** (33.3 g, 91.6 mmol) was dissolved in 290 ml of 4.67 M hydrogen chloride in THF. The solution was allowed to stand at room temperature for 1 h, and then diluted with 2 l of ether. After cooling in an ice-salt bath for 1 h, the supernatant was decanted to separate dipeptide hydrochloride precipitated. The hydrochloride **4** thus obtained was dried over NaOH in vacuum desiccator and then subjected to the following reaction without purification.

Boc-Pro-Gly-Cys(Acm)-OMe (5). Ethoxycarbonyl chloride (11.0 g, 101 mmol) and triethylamine (10.2 g, 101 mmol) were added to a solution of Boc-Pro-OH (21.7 g, 101 mmol) in 70 ml of DMF under cooling in an ice-salt bath. To the mixture stirred in the chilled bath for 15 min was added a solution of dipeptide hydrochloride **4** (91.6 mmol) and triethylamine (9.27 g, 91.6 mmol) in 210 ml of DMF. The reaction mixture was stirred for 1 h and then concentrated in vacuo. The residue was dissolved in chloroform and the solution was washed with 10% aqueous citric acid, saturated sodium hydrogencarbonate, and saturated sodium chloride solutions. The organic layer was dried over $MgSO_4$ and then concentrated in vacuo to give an oily product: Yield

39.6 g (93.8%); $[\alpha]_D^{18}$ −55.1° (*c* 1.04, $CHCl_3$).

Found: C, 48.47; H, 7.26; N, 11.70; S, 6.75%. Calcd for $C_{19}H_{32}N_4O_7S \cdot 1/2H_2O$: C, 48.60; H, 7.08; N, 11.93; S, 6.83%.

HCl·H–Pro–Gly–Cys(Acm)–OMe (6). Protected tripeptide **5** (15.3 g, 33.2 mmol) was dissolved in 110 ml of 4.67 M hydrogen chloride in THF to give tripeptide hydrochloride which was obtained in a quantitative yield after the same treatment as mentioned in the preparation of **4**.

Boc-3-Me-D-Cys(Trt)–Pro–Gly–Cys(Acm)–OMe (7). Boc-3-Me-D-Cys(Trt)-OH·DCHA (**2**) (20.0 g, 30.4 mmol) was treated with ethyl acetate and 10% aqueous citric acid. Ethyl acetate layer separated from the aqueous layer was washed with water and dried over $MgSO_4$. The oily residue obtained by vacuum concentration was dissolved in 120 ml of THF. To the solution were added *N*-hydroxysuccinimide (3.50 g, 30.4 mmol) and dicyclohexylcarbodiimide (6.26 g, 30.4 mmol) under ice cooling. The mixture was stirred at 0°C for 40 min and then at room temperature for 2 h. *N,N'*-Dicyclohexylurea precipitated was filtered off and the filtrate was concentrated in vacuo. The oily residue dissolved in 30 ml of chloroform was added to a solution of tripeptide hydrochloride **6** (33.2 mmol) and triethylamine (3.36 g, 33.2 mmol) in 60 ml of chloroform. After stirring at room temperature overnight, the mixture was concentrated in vacuo. Ethyl acetate was added to the residue and an insoluble material was filtered off. The filtrate was washed with 10% aqueous citric acid, saturated sodium hydrogencarbonate, and saturated sodium chloride solutions. The organic layer dried over $MgSO_4$ was concentrated in vacuo. The oily residue was washed by trituration with hexane several times to remove off unreacted Boc-3-Me-D-Cys(Trt)-OH and then precipitated from ethyl acetate and hexane: Yield 24.2 g (97.2%); mp 76—80°C; $[\alpha]_D^{28}$ −39.5° (*c* 1.03, $CHCl_3$).

Found: C, 60.91; H, 6.52; N, 8.38; S, 7.61%. Calcd for $C_{42}H_{53}N_5O_8S_2 \cdot 1/2H_2O$: C, 60.85; H, 6.57; N, 8.45; S, 7.73%.

Boc–3-Me-D–Cys–Pro–Gly–Cys–OMe (8). To a solution of protected linear tetrapeptide **7** (620 mg, 0.757 mmol) in 150 ml of methanol was added I_2 (576 mg, 2.27 mmol) in 23 ml of methanol under vigorous stirring. The oxidation was carried out at room temperature for 1 h and stopped by an addition of 0.2 M sodium thiosulfate solution until the color of I_2 disappeared. The reaction mixture was concentrated in vacuo and the residue was suspended in water. Extraction with chloroform was repeated three times and the extract was concentrated in vacuo after drying over $MgSO_4$. The oily residue thus obtained was crystallized from ethyl acetate and hexane: Yield 345 mg (90.3%); mp 177—179°C; $[\alpha]_D^{28}$ +38.1° (*c* 0.950, $CHCl_3$); FD-MS, *m/z* 504 (M^+).

Found: C, 46.49; H, 6.33; N, 10.71; S, 12.12%. Calcd for $C_{20}H_{32}N_4O_7S_2 \cdot 1/2H_2O$: C, 46.77; H, 6.48; N, 10.91; S, 12.48%.

Boc–D–Abu–Pro–Gly–Ala–OMe (9). To a solution of **8** (100 mg, 0.198 mmol) in 320 ml of anhydrous benzene was added tris(diethylamino)phosphine[7] (1.96 g, 7.94 mmol). The reaction mixture was stirred at room temperature for 2 d and then concentrated in vacuo. The residue was dissolved in ethyl acetate and washed with 10% aqueous citric acid and saturated sodium chloride solutions three times, respectively. Organic layer was dried over $MgSO_4$ and concentrated in vacuo. An oily residue obtained was applied to Sephadex LH-20 column (1.8×56 cm) and eluted with DMF. The column-chromatographic purification was repeated twice to give the product **9** as powder: Yield 53 mg (57%). A part of the product was recrystallized from ethyl acetate to obtain an analytical sample: Mp 206—207.5°C (decomp); $[\alpha]_D^{16}$ +62.8° (*c* 0.931, DMF); FD-MS, *m/z* 472 (M^+). Amino acid analysis: Melan (0.92), Pro (1.01), Gly (1.00).

Found: C, 49.09; H, 7.05; N, 11.18; S, 6.39%. Calcd for $C_{20}H_{32}N_4O_7S \cdot H_2O$: C, 48.97; H, 6.99; N, 11.42; S, 6.54%.

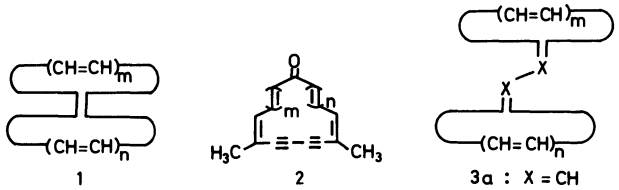
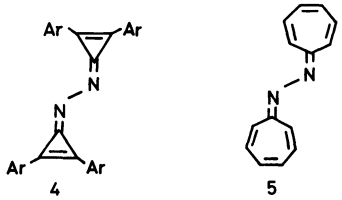
(Received March 7, 1986)

The diaza analogs of 7-13-, 7-15-, 7-17-, 13-13-, 13-15-, 15-15-, and 19-19-fulvadiene derivatives were synthesized through the reaction of 2,4,6-cycloheptatrienone and the corresponding bisdehydroannulenones with hydrazine dihydrochloride. The ^{1}H NMR and electronic spectra of these compounds are discussed in connection with tropicity.

Bicyclic polyenes containing a cyclic cross-conjugated π-electron system of the fulvalenes of type 1 have been extensively investigated.[1] The convenient synthesis of the bisdehydroannulenones of type **2**[2] in satisfactory yield made it possible to prepare the heptafulvalenes[3] and the pentafulvalenes[4,5] using **2** as the starting material.





Recently, a number of vinylogous fulvalenes (fulvadienes) of type **3a** have been studied.[6] We were interested in a synthesis of the diaza analogs **3b** of the system; only known examples are the diaza analogs **4**[7] and **5**[8] of the triatriafulvadiene and the heptaheptafulvadiene, respectively, in which both rings are the same.

We considered that the diazafulvadienes containing different-membered rings might cause π-electron polarization across the azine group. For example, the diaza 7-13- **9**[9] and 13-15-fulvadiene **13** will be expected to exhibit π-electron polarization from 7- and 15-membered ring to 13-membered rings to form zwitterionic forms **9a** and **13a**, respectively, in which all rings are [4n+2]π-electron systems and are potentially diatropic. To examine this, preparation of the diazafulvadienes having inner ring protons as marks would be desirable. In this paper, we describe synthesis

and properties of some of the hepta-derivatives **7** (**9**—**11**) and the large-ring ones **8** (**12**—**15**).

Results and Discussion

Synthesis. The synthesis was accomplished by the reaction of the bisdehydroannulenones **2** with hydrazine dihydrochloride in the presence of 2,4,6-cycloheptatrienone (**6**), usually giving rise to the diaza hepta- **7** and large-ring derivatives **8**. Thus, the reaction of a mixture of the ketone **6** and one of the following annulenones, 5,10-dimethyl-6,8-bisdehydro[13]annuleone,[2a] 5,10-dimethyl-6,8-bisdehydro[15]annulenone,[2b] and 7,12-dimethyl-8,10-bisdehydro[17]annulenone[2b] with hydrazine dihydrochloride in methanol–tetrahydrofuran at room temperature gave the diaza 7-13- **9** (5.0%), 7-15- **10** (3.0%), and 7-17-fulvadiene **11** (6.6%), respectively. In the first two cases, bis-condensation products, the diaza 13-13- **12** (24%) and 15-15-fulvadiene **14** (3.6%) were formed, but rather surprisingly, the diaza 7-7-fulvadiene was not obtained in any above reactions. The diaza analog **13** of 13-15-fulvadiene was obtained (2.9%) by the reaction of a mixture of [13]- and [15]-annulenones with hydrazine dihydrochloride. Compounds **12** and **14** were also prepared by the reaction of [13]- and [15]annulenones with hydrazine, respectively. The diaza 19-19-fulvadiene **15** (1.4%) was obtained by the reaction of 7,12-dimethyl-8,10-bisdehydro[19]annulenone[2b] with hydrazine in the presence of **6**; however the diaza 7-19-fulvadiene was not detected in the reaction mixture. The diaza 17-17-fulvadiene also was not detected in the reaction mixtures of the [17]annulenone with hydrazine in the presence of **6** or in the absence of **6**. These diazafulvadienes **9**—**15** thus obtained were recrystallized from hexane–benzene or hexane–chloroform to afford

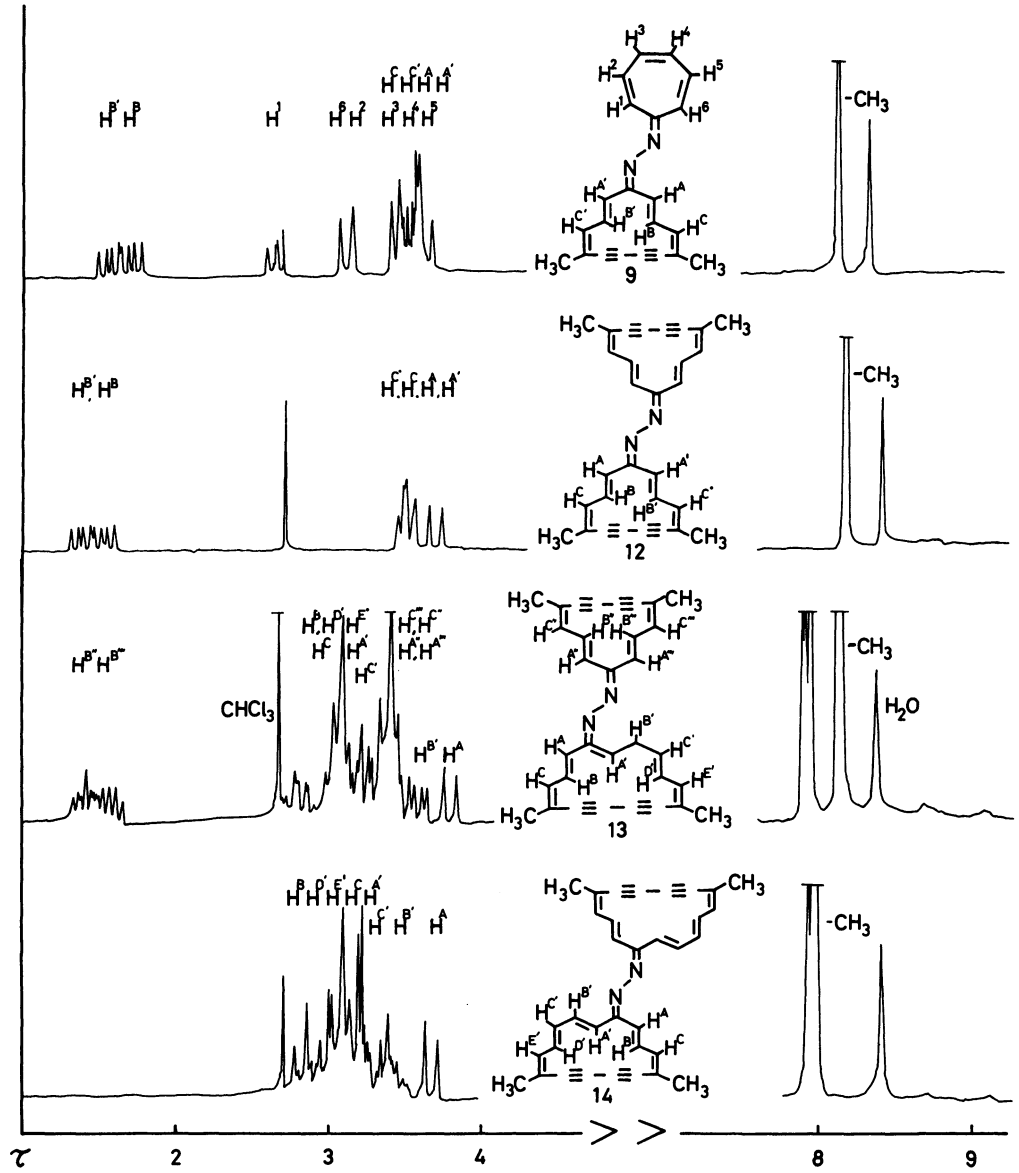

Fig. 1. The 200 MHz ^{1}H NMR spectra of the diazafulvadienes **9**, **12**, **13**, and **14** in $CDCl_3$.

deep colored (dark reddish or dark purple), unstable crystals, which were gradually decomposed at room temperature to diffused light under air.

Electronic Spectra. The electronic absorption maxima (in tetrahydrofuran) of these diazafulvadienes **9**—**15** are listed in Table 1. In two series compounds, hepta-derivatives **9**—**11** and large-ones **12**—**15**, it is clear that the most intensive maxima exhibit an almost regular bathochromic shift as the ring size increases. Thus, the occurrence of the same sort of alternation along with increasing ring size between the maxima of [$4n$−2] and of [$4n$]systems, as has been observed for annulenes and dehydroannulenes [($4n$−2)π-systems absorbing at longer wavelengths than the ($4n$)π-systems],[10] is not observed, suggesting that these diazafulvadienes are atropic, as revealed by examination of ^{1}H NMR spectra (vide infra).

The electronic absorption maxima of these diazafulvadienes **9**—**15** in trifluoroacetic acid (TFA) are listed in Table 2. It is evident that protonation with this acid causes the shift of the maxima to longer wavelength in every case and gives the corresponding protonated (or deuteronated when TFA-d_1 is used) specics **9'**—**15'**, in which **9'** was brown in color, **10'** blue, **11'** green, **12'** brown, **13'** reddish purple, **14'** blue, and **15'** brown. Neutralization of the protonated large-ring species **12'**—**15'** with aqueous sodium hydrogencarbonate resulted in regeneration of **12**—**15**, respectively. However, standing the solutions of the protonated hepta-species **9'**—**11'** resulted in a change, and the diazafulvadiene **9**—**11** were not recovered from them on quenching.

a), b) Assignments may be reversed in each group (see Experimental). c) At 270 MHz.

9—**14** are listed in Table 3, together with those of their deuteronated species **9′**—**14′**, obtained in deuteriochloroform solution admixed with a few drops of TFA-d_1. Individual assignments, some of which are tentative, were made on the basis of multiplicities, coupling constants, and the assumption that protons in a similar environment resonate at similar field, and were clarified by decoupling experiments where necessary. The ^{1}H NMR spectra of only the diaza 7-13- **9**, 13-13- **12**, 13-15- **13**, and 15-15-fulvadiene **14** are illustrated in Fig. 1. As we see from Table 3 and Fig. 1, the downfield and upfield shifts of the olefinic protons as well as the methyl protons are not observed in the spectrum of the diaza 7-13-fulvadiene **9**, as compared with the resonances of the corresponding protons in the spectrum of the diaza 13-13-fulvadiene **12**, which is not expected to polarize since both rings are the same. Similarly, the olefinic and methyl protons of **13** resonate at the almost same field as those of the resonances of the corresponding protons of the diaza 13-13- **12** and 15-15-fulvadiene **14**. These facts show that both **9** and **13** do not exhibit π-electron polarization across the azine group to form polar structures **9a** and **13a**. On the other hand, the spectra of the deuteronated species **9′** and **12′**, which are illustrated in Fig. 2, show the downfield or upfield shifts of olefinic resonances. In the spectrum of **9′**, the proton resonances of the 7-membered ring appear in lower field (Δ−0.6 ppm), and the outer proton resonances of the 13-membered ring in higher field (Δ+1 ppm), as compared with the resonances of the corresponding olefinic protons of **9**. In the spectrum of **12′**, the much larger downfield shift (Δ−1.5 ppm) of the inner proton resonances, as compared with the resonances of the corresponding protons of **12**, is seen. These facts suggest that the 7-membered ring in **9′** is diatropic, while the 13-membered ring in both **9′** and **12′** is paratropic, and the dicationic forms **9a′** and **12a′** contribute to the structures **9′** and **12′** as resonance hybrid to some extent, respectively.

As we can see from Table 3, the upfield and downfield shifts of the proton resonances of the large ring are not seen in the spectrum of the diaza 7-15-fulvadiene **10**, as compared with the resonances of the corresponding protons of the diaza 15-15-fulvadiene **14**.

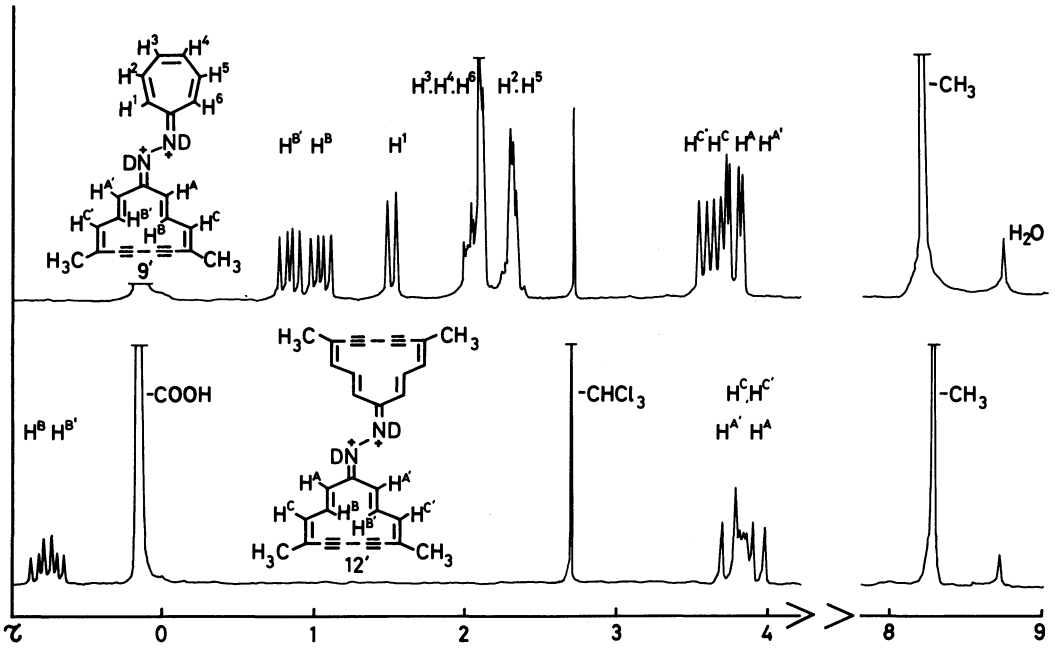

Fig. 2. The 200 MHz ^{1}H NMR spectra of the deuterated species **9'** and **12'**.

Thus, the compound **10** also does not exhibit π-electron polarization. The olefinic protons of both the diaza 7-17- **11** (Table 3) and the diaza 19-19-fulvadiene **15** (see Experimental) resonate in normal region, and these are also polyolefinic molecules. On the other hand, the deuteronated species, **10'**, **11'**, **13'**, and **14'** show that the downfield or upfield shifts of the olefinic proton resonances as well as the methyl proton resonances, as compared with the corresponding proton resonances of the respective diazafulvadienes **10**, **11**, **13**, and **14** (Table 3). In the spectra of the deuteronated species **10'** and **11'**, the protons of the 7-membered ring resonate at low field, indicating that the ring is diatropic. In **10'**, **13'**, **14'**, the inner protons of the 15-membered ring resonate at high field, and the outer and methyl protons at low field, indicating the 15-membered ring in **10'**, **13'**, and **14'** being diatropic. Conversely, the inner protons of the 13- and 17-membered rings in **11'** and **13'** resonate at low field, and the outer and methyl protons at high field, indicating the 13- and 17-membered rings in **11'** and **13'** being paratropic. These results also suggest that the similar dicationic forms as those (**9a'** and **12a'**) depicted for **9'** and **12'**, contribute to the structures of the species **10'**, **11'**, **13'**, and **14'**.

Experimental

Melting points are uncorrected. IR spectra were measured on Hitachi 260-50 spectrophotometer as KBr disk; only significant maxima are reported. Electronic spectra were recorded on Hitachi 220-A spectrophotometer in nm, in tetrahydrofuran solution. Mass spectra were measured with JMS-D 200 spectrometer at 75 eV using a direct inlet system or JMS-D spectrometer equipped with field desorption system. ^{1}H NMR spectra were taken on Varian XL-200 (200 MHz) or JEOL GX-270 (270 MHz) spectrometer, and refer to solution in $CDCl_3$, unless otherwise stated, in τ-values with TMS as an internal standard. The coupling constants (J) are given in Hz. The individual assignments were made on the basis of multiplicities and coupling constants, and were further clarified by decoupling experiments where necessary. Alumina (II—III) was used for column chromatography. Progress of most reactions was monitored by TLC using precoated Merck silica-gel plates. Preparative plate chromatography was carried out on 20×20 cm silica-gel plates (Merck, 0.5 or 2 mm thick). Evaporation of solvents was performed under water aspirator pressure, and sodium sulfate was used as drying agent.

1-(2,4,6-Cycloheptatrienylidene)-2-(5,10-dimethyl-2,4,10,12-tridecatetraene-6,8-diynylidene)hydrazine (9) and 1,2-Bis(5,10-dimethyl-2,4,10,12-tridecatetraene-6,8-diynylidene)hydrazine (12). A soln of hydrazine dihydrochloride (170 mg, 1.62 mmol) in water (2 ml) was added in one portion to a stirred soln of 2,4,6-cycloheptatrienone (**6**) (170 mg, 1.60 mmol) and 5,10-dimethyl-6,8-bisdehydro[13]annulenone[2a] (300 mg, 1.44 mmol) in methanol (80 ml) and tetrahydrofuran (THF) (20 ml) at 40 °C, and stirring was continued overnight at the same temperature. After an aqueous 10% sodium hydrogencarbonate soln was added (pH 7—8), the mixture was poured onto water and extracted with chloroform. The combined extracts were washed with brine, and dried. After solvent removal, the residual dark red liquid was chromatographed on alumina (4.0×7.0 cm). The early fractions eluted with hexane–chloroform (3:2) gave a red solid, which was purified by preparative plate chromatography (4 times, benzene–chloroform as eluent). The fast-moving, first band gave the diaza 13-13-fulvadiene **12** (140 mg, 24%). Recrystallization from hexane–tetrahydrofuran afforded purple needles: Mp 189—190 °C (decomp); MS m/z 412 (M^+, 16%) and 32 (100); mol wt 412.5; ^{1}H NMR (200 MHz) τ=1.39 (dd, 16, 10, 2H, $H^{B'}$), 1.54 (dd, 17, 10, 2H, H^B), 3.49 (d, 10,

2H, H^C), 3.50 (d, 10, 2H, $H^{C'}$), 3.54 (d, 16, 2H, $H^{A'}$), 3.71 (d, 17, 2H, H^A), 8.19 (s, 6H, CH_3), 8.20 (s, 6H, CH_3), and see Fig. 1; (CF_3COOD in $CDCl_3$, 200 MHz) τ=−0.76 (dd, 16.5, 10, 2H, H^B), −0.67 (dd, 16.5, 10, 2H, $H^{B'}$), 3.77 (d, 16.5, 2H, $H^{A'}$), 3.84 (d, 10, 2H, H^C), 3.85 (d, 10, 2H, $H^{C'}$), 3.91 (d, 16.5, 2H, H^A), 8.28 (s, 12H, CH_3), and see Fig. 2.

Found: C, 87.16; H, 5.95; N, 6.81%. Calcd for $C_{30}H_{24}N_2$: C, 87.34; H, 5.87; N, 6.79%.

The later fractions eluted with hexane–chloroform (2:3) gave a red liquid, which was purified by preparative plate chromatography (4 times, benzene–chloroform as eluent). The fast-moving, second band gave the diaza 7-13-fulvadiene **9** (23 mg, 5.0%). Recrystallization from hexane afforded red cubes: Mp 141—142 °C; MS *m/z* 310 (M^+, 41%) and 190 (100); mol wt 310.3; IR 2170 (–C≡C–) and 975 cm^{-1} (trans C=C); UV: see Tables 1 and 2; ^1H NMR (200 MHz) τ=1.58 (dd, 17, 10, 1H, $H^{B'}$), 1.73 (dd, 17, 10, 1H, H^B), 2.59—2.68 (m, 1H, H^1), 3.10—3.19 (m, 2H, H^2, H^6), 3.45 (d, 10, 1H, H^C), 3.46 (d, 10, 1H, $H^{C'}$), 3.49—3.63 (m, 3H, H^3, H^4, H^5), 3.53 (d, 17, 1H, H^A), 3.66 (d, 17, 1H, $H^{A'}$), 8.18 (s, 6H, CH_3), and see Fig. 1; (CF_3COOD in $CDCl_3$, 200 MHz) τ=0.87 (dd, 16, 10, 1H, $H^{B'}$), 1.07 (dd, 16, 10, 1H, H^B), 1.50—1.56 (m, 1H, H^1), 1.98—2.13 (m, 3H, H^3, H^4, H^6), 2.24—2.38 (m, 2H, H^2, H^5), 3.58 (d, 10, 1H, $H^{C'}$), 3.67 (d, 10, 1H, H^C), 3.77 (d, 16, 1H, H^A), 3.79 (d, 16, 1H, $H^{A'}$), 8.20 (s, 6H, CH_3), and see Fig. 2.

Found: C, 85.30; H, 5.90; N, 9.01%. Calcd for $C_{22}H_{18}N_2$: C, 85.13; H, 5.85; N, 9.03%.

The Diaza 13-13-Fulvadiene 12 from Bisdehydro[13]annulenone. A soln of hydrazine dihydrochloride (50 mg, 0.48 mmol) in water (1 ml) was added in one portion to a stirred soln of bisdehydro[13]annulenone[2a] (152 mg, 0.73 mmol) in methanol (100 ml) and THF (17 ml) at room temperature and stirring was continued overnight. The mixture was worked up as described above. The residue, after solvent removal, was chromatographed on alumina (3.7×7.5 cm). The fractions eluted with benzene gave the diaza 13-13-fulvadiene **12** (110 mg, 73%).

1-(2,4,6-Cycloheptatrienylidene)-2-(5,10-dimethyl-2,4,10,12,-14-pentadecapentaene-6,8-diynylidene)hydrazine (10) and 1,2-Bis(5,10-dimethyl-2,4,10,12,14-pentadecapentaene-6,8-diynylidene)hydrazine (14). A soln of hydrazine dihydrochloride (260 mg, 2.48 mmol) in water (2 ml) was added in one portion to a stirred soln of the ketone **6** (255 mg, 2.40 mmol) and the bisdehydro[15]annulenone[2b] (563 mg, 2.40 mmol) in methanol (180 ml) and THF (50 ml) at room temperature and stirring was continued overnight. The mixture was worked up as in the isolation of **9** and **12**. The residual red liquid, after solvent removal, was chromatographed on alumina (3.7×12.5 cm). The fractions eluted with hexane–benzene (1:4—1:9) gave a red solid, which was further purified by preparative plate chromatography (5 times, benzene as eluent). The fast moving, purple band gave the diaza 15-15-fulvadiene **14** (20 mg, 3.6%). Recrystallization from hexane–benzene afforded purple needles: Mp 171—172 °C (decomp); MS (field desorption method) *m/z* 464 (M^+); mol wt 464.6; IR 2170 (–C≡C–) and 975 cm^{-1} (trans C=C); UV: see Tables 1 and 2; ^1H NMR (200 MHz) τ=2.91 (dd, 16, 11, 2H, H^B), 3.04 (dd, 16, 11, 2H, $H^{D'}$), 3.15 (d, 11, 2H, $H^{E'}$), 3.19 (d, 11, 2H, H^C), 3.20 (d, 15.5, 2H, $H^{A'}$), 3.31 (dd, 16, 5, 2H, $H^{C'}$), 3.50 (dd, 15.5, 5, 2H, $H^{B'}$), 3.70 (d, 16, 2H, H^A), 7.96 (s, 6H, CH_3), 8.01 (s, 6H, CH_3), and see Fig. 1; (CF_3COOD in $CDCl_3$, 270 MHz) τ=2.16—2.96 (m, 10H, H^A, $H^{B'}$, H^C, $H^{C'}$, $H^{E'}$), 4.82—5.60 (m, 6H, $H^{A'}$, H^B, $H^{D'}$), 7.64 (s, 6H, CH_3), and 7.71 (s, 6H, CH_3).

Found: C, 87.04; H, 5.86; N, 6.15%. Calcd for $C_{34}H_{28}N_2$: C, 87.89; H, 6.08; N, 6.03%. Attempts to improve the elemental analysis failed.

The following fractions eluted with benzene gave a semi-solid, which was further purified by preparative plate chromatography (5 times, benzene as eluent). The fast-moving, second band gave the diaza 7-15-fulvadiene **10** (24 mg, 3.0%). Recrystallization from hexane afforded red cubes: Mp 130—131 °C; MS *m/z* 336 (M^+, 100%); mol wt 336.4; IR 2170 (–C≡C–), 1640 (C=N), and 975 cm^{-1} (trans C=C); UV: see Tables 1 and 2; ^1H NMR (270 MHz) τ=2.49—2.59 (m, 1H, H^1), 2.74 (d, 16, 1H, $H^{A'}$), 2.86—2.91 (m, 1H, H^6), 2.95 (dd, 16, 11, 1H, H^B), 2.97 (dd, 15.5, 10, 1H, $H^{D'}$), 3.15 (d, 10, 1H, $H^{E'}$), 3.17—3.24 (m, 2H, H^3, H^4), 3.20 (d, 11, 1H, H^C), 3.50—3.71 (m, 2H, H^2, H^5), 3.55 (dd, 15.5, 5, 1H, $H^{C'}$), 3.64 (d, 16, 1H, H^A), 3.66 (dd, 16, 5, 1H, $H^{B'}$), 7.99 (s, 3H, CH_3), and 8.02 (s, 3H, CH_3); (CF_3COOD in $CDCl_3$, 200 MHz) τ=1.50—1.67 (m, 1H, H^1), 1.76—2.39 (m, 8H, $H^{B'}$, $H^{C'}$, $H^{E'}$, H^2, H^3, H^4, H^5, H^6), 2.83 (d, 11, 1H, H^C), 3.06 (d, 16, 1H, H^A), 4.11 (dd, 16, 11, 1H, H^B), 4.31 (dd, 16, 11, 1H, $H^{D'}$), 6.06 (d, 16, 1H, $H^{A'}$), 7.47 (s, 3H, CH_3), and 7.54 (s, 3H, CH_3).

Found: C, 85.44; H, 6.07; N, 8.36%. Calcd for $C_{24}H_{20}N_2$: C, 85.68; H, 5.99; N, 8.33%.

The Diaza 15-15-Fulvadiene 14 from Bisdehydro[15]annulenone. A soln of hydrazine dihydrochloride (93 mg, 0.86 mmol) in water (2 ml) was added in one portion to a soln of [15]annulenone[2b] (413 mg, 1.76 mmol) in methanol (120 ml) and THF (60 ml). After stirring overnight at room temperature, the mixture was worked up as in the isolation of **9** and **12**. The residual dark red liquid, after solvent removal, was chromatographed on alumina (4.2×13 cm). The fractions eluted with hexane–benzene (1:4) gave a red solid, which was further purified by preparative plate chromatography (5 times, benzene–chloroform as eluent). The fast-moving, second red band gave the diaza 15-15-fulvadiene **14** (28 mg, 6.9%).

1-(2,4,6-Cycloheptatrienylidene)-2-(7,12-dimethyl-2,4,6,12,14,16-heptadecahexaene-8,10-diynylidene)hydrazine (11). A soln of hydrazine dihydrochloride (210 mg, 2.00 mmol) in water (2 ml) was added in one portion to a stirred soln of the ketone **6** (215 mg, 2.03 mmol) and bisdehydro[17]-annulenone[2b] (496 mg, 1.91 mmol) in methanol (200 ml) and THF (80 ml) at room temperature and stirring was continued overnight at the same temperature. Then a further quantity of the ketone **6** (80 mg) in methanol (5 ml) was added and the mixture was stirred for further 8 h. The mixture was worked up as in the isolation of **9** and **12**. The residual red liquid, after solvent removal, was chromatographed on alumina (4.0×12.5 cm). The fractions eluted with benzene–chloroform (4:1—2:3) gave a brown solid, which was further purified by preparative plate chromatography (6 times, chloroform as eluent). The fast moving, second band gave the diaza 7-17-fulvadiene **11** (46 mg, 6.6%). Recrystallization from hexane–chloroform afforded purple needles: Mp 209 °C (decomp); MS *m/z* 362 (M^+, 100%); mol wt 362.4; IR 2190 (–C≡C–), 1620 (C=N), and 1000 cm^{-1} (trans C=C); UV: see Tables 1 and 2; ^1H NMR (200 MHz) τ=2.38 (dd, 15, 11, 1H, H^B), 2.42 (dd, 16, 11, 1H, $H^{B'}$), 2.56 (dd, 16, 11, 2H, H^D, $H^{D'}$), 2.57—2.60 (m, 1H, H^1), 3.16—3.22 (m, 1H, H^6), 3.34—3.77 (m, 8H, H^C, $H^{C'}$, H^E, $H^{E'}$, H^2, H^3, H^4, H^5), 3.46 (d, 15, 1H, H^A), 3.76 (d, 16, 1H, $H^{A'}$), and 8.14 (s, 6H, CH_3); (CF_3COOD in $CDCl_3$, 200 MHz)

τ=1.25 (dd, 15.5, 10, 2H, H^D, $H^{D'}$), 1.44 (dd, 15.5, 11, 2H, H^B, $H^{B'}$), 1.69—1.75 (m, 1H, H^1), 2.04—2.20 (m, 3H, H^3, H^4, H^6), 2.32—2.42 (m, 2H, H^2, H^5), 3.63 (d, 10, 2H, H^E, $H^{E'}$), 3.87 (dd, 15.5, 11, 1H, H^C or $H^{C'}$), 3.93 (dd, 15.5, 10, 1H, H^C or $H^{C'}$), 3.98 (d, 15.5, 2H, H^A, $H^{A'}$), and 8.20 (s, 6H, CH_3).

Found: C, 85.88; H, 6.20; N, 8.04%. Calcd for $C_{26}H_{22}N_2$: C, 86.16; H, 6.12; N, 7.73%.

The Reaction of Bisdehydro[17]annulenone with Hydrazine Dihydrochloride. The reaction of the bisdehydro[17]-annulenone with hydrazine dihydrochloride was carried out under the exactly same conditions as those for the preparation of the diaza 13-13-fulvadiene **12**; however the diaza 17-17-fulvadiene was not obtained.

1,2-Bis(7,12-dimethyl-2,4,6,12,14,16,18-nonadecaheptaene-8,10-diynylidene)hydrazine (15). A soln of hydrazine dihydrochloride (225 mg, 2.14 mmol) in water (3 ml) was added in one portion to a stirred soln of the ketone **6** (230 mg, 2.17 mmol) and bisdehydro[19]annulenone[2b] (606 mg, 2.11 mmol) in methanol (150 ml) and THF (80 ml), and stirring was continued for 7 h at the room temperature. Then a further quantity of the ketone **6** (50 mg) in methanol (5 ml) was added and the mixture was stirred for further 15 h. Then the mixture was worked up as in the isolation of **9** and **12**. The residual red liquid, after solvent removal, was chromatographed on alumina (4.0×12 cm). The fractions eluted with benzene–chloroform (9:1—3:7) gave a red solid, which was further purified by preparative plate chromatography (5 times, chloroform as eluent). The fast-moving, second band gave the diaza 19-19-fulvadiene **15** (16 mg, 1.4%). Recrystallization from hexane–benzene afforded purple microcrystals: Mp 146—147 °C (decomp); MS (field desorption method) *m/z* 568 (M^+); mol wt 568.7; IR 2175 (-C≡C-), 995, and 970 cm^{-1} (trans C=C); UV: see Tables 1 and 2; ^1H NMR (200 MHz) τ ca. 2.50—3.08 (m, 4H, olefinic H), 3.10—3.76 (m, 20H, olefinic H), 7.82 (s, 3H, CH_3), 7.90 (s, 3H, CH_3), 7.96 (s, 3H, CH_3), and 8.00 (s, 3H, CH_3). In this reaction the diaza 7-19-fulvadiene was not obtained.

1-(5,10-Dimethyl-2,4,10,12-tridecatetraene-6,8-diynylidene)-2-(5,10-dimethyl-2,4,10,12,14-pentadecapentaene-6,8-diynylidene)hydrazine (13). A soln of hydrazine dihydrochloride (220 mg, 2.10 mmol) in water (2 ml) was added in one portion to a stirred soln of bisdehydro[13]annulenone (421 mg, 2.02 mmol) and bisdehydro[15]annulenone (642 mg, 2.74 mmol) in methanol (160 ml) and THF (80 ml) at room temperature and the mixture was stirred for 6 h. After a further quantity of hydrazine dihydrochloride (100 mg) in water (2 ml) was added, stirring was continued for further 19 h at room temperature. Then the mixture was worked up as in the isolation of **9** and **12**. The residual dark red liquid, after solvent removal, was chromatographed on alumina (4.0× 12.5 cm). The early fractions eluted with hexane–benzene (2:3) gave the diaza 13-13-fulvadiene **12** (70 mg, 17%). The following fractions eluted with hexane–benzene (3:7) gave a red solid, which was further purified by preparative plate chromatography (6 times, benzene as eluent). The fast moving, second band gave the diaza 13-15-fulvadiene **13** (26 mg, 2.9%). Recrystallization from hexane–benzene afforded purple plates: Mp 160—161 °C (decomp); MS (field desorption method) *m/z* 439 (M^+); mol wt 438.5; IR 2160 (-C≡C-) and 980 cm^{-1} (trans C=C); UV: see Tables 1 and 2; ^1H NMR (200 MHz) τ=1.45—1.64 (m, 2H, $H^{B''}$, $H^{B'''}$), 2.72—3.51 (m, 10H, $H^{A'}$, $H^{A''}$, $H^{A'''}$, H^B, H^C, $H^{C'}$, $H^{C''}$, $H^{C'''}$, $H^{D'}$, $H^{E'}$), 3.61 (dd, 16.5, 7, 1H, $H^{B'}$), 3.83 (d, 16.5, 1H, H^A), 7.96 (s, 3H, CH_3), 7.99 (s, 3H, CH_3), 8.12 (s, 3H, CH_3), 8.17 (s, 3H, CH_3), and see Fig. 1; (CF_3COOD in $CDCl_3$, 200 MHz) τ=0.50 (dd, 15.5, 11, 1H, $H^{B''}$ or $H^{B'''}$), 0.70 (dd, 15.5, 11, 1H, $H^{B''}$ or $H^{B'''}$), 1.28 (dd, 15, 7, 1H, $H^{B'}$), 1.98—2.35 (m, 3H, H^A, H^C, $H^{E'}$), 2.44 (dd, 15.5, 7, 1H, $H^{C'}$), 3.11—3.81 (m, 7H, $H^{A'}$, $H^{A''}$, $H^{A'''}$, H^B, $H^{C''}$, $H^{C'''}$, $H^{D'}$), 7.42 (s, 3H, CH_3), 7.67 (s, 3H, CH_3), and 8.21 (s, 6H, CH_3).

Found: C, 87.36; H, 6.14; N, 6.65%. Calcd for $C_{32}H_{26}N_2$: C, 87.64; H, 5.98; N, 6.39%.

The later fractions eluted with hexane–benzene (1:4—1:9) gave the diaza 15-15-fulvadiene **14** (29 mg, 3.0%).

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60540321, from the Ministry of Education, Science and Culture.

Insertion of Sulfur Trioxide into the N-Si Bond of Anilinotrimethylsilane. An Improved Method for the Preparation of Free Phenylamidosulfuric Acid[1)]

Fujio KANETANI,* Eiji OKADA, and Kenji NEGORO
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Saijo, Higashi-Hiroshima 724
(Received March 13, 1986)

The reaction between anilinotrimethylsilane (**1**) and a variety of sulfonating agents [SO_3, $ClSO_3H$, trimethylsilyl chlorosulfate (**5**), dioxane-sulfur trioxide complex, ethyl chlorosulfate (**10**)] has been studied. With SO_3, **5**, or a dioxane-sulfur trioxide complex a sulfur trioxide molecule was inserted selectively into the N-Si bond of **1** to yield trimethylsilyl phenylamidosulfate (**2**), which on treatment with acetic acid, trifluoroacetic acid, or methanol gave free phenylamidosulfuric acid (**3**). The reaction of **1** with $ClSO_3H$ afforded **3** directly, but the product was contaminated with slight amounts of anilinium hydrogensulfate and anilinium chloride. The reaction of **1** with **10** yielded a mixture containing dianilinium (4-sulfonatophenylamido)sulfate, 4-aminobenzenesulfonic acid, and ethyl phenylamidosulfate as major products (after desilylation). The reaction of **1** with **5** has been found to provide an improved method for preparing **3**.

Arylamidosulfuric acids ($ArR^1R^2N^+SO_3^-$) have long been believed, but not yet proved, to be intermediates in the sulfonation of aromatic amines.[2-5)] In a previous paper,[6)] one of us (F. K.) has reported the first definite preparation and characterization of some arylamidosulfuric acids. The method of preparation used simply involves the addition of ice-cold concentrated hydrochloric acid to a saturated aqueous solution of an appropriate ammonium arylamidosulfate, followed by filtration and drying of the product. This method, however, rather requires technical skillfulness for obtaining the product of high purity; therefore, it is desirable to develop a more convenient method for preparing free arylamidosulfuric acids.

In view of their great tendency to undergo thermal rearrangement and reactions with Lewis bases, such as water, alcohols, amines, etc., it is highly desirable that arylamidosulfuric acids should be generated in an inert organic medium under mild conditions and isolated in a high purity without any purification. We considered that the silyl esters ($ArR^1NSO_3SiR^2_3$) would meet such requirements and be the most promising precursor of the free arylamidosulfuric acids.

To our knowledge, there is no report on the silyl esters of arylamidosulfuric acids, although several reports[7-9)] have appeared on the aliphatic counterparts. We, therefore, decided to examine the reation of anilinotrimethylsilane (**1**) with several sulfonating agents with the aim of preparing trimethylsilyl phenylamidsosulfate (**2**) and have found that a sulfur trioxide molecule is inserted into the N-Si bond of **1** to yield the desired silyl ester **2**, which, on treatment with an appropriate desilylating agent such as trifluoroacetic acid, directly gives pure phenylamidosulfuric acid (**3**) very easily.

Results and Discussion

Reaction of Anilinotrimethylsilane (1) with Sulfur Trioxide. The reaction of **1** with sulfur trioxide at −15°C for 8 h, followed by the treatment with trifluoroacetic acid gave the desired phenylamidosulfuric acid (**3**). HPLC analysis revealed that sulfur trioxide was inserted exclusively into the N-Si bond; the ring-sulfonation products were detected but in traces. In contrast, the same reaction at room temperature (17°C) for 4 h led to the formation of 4-aminobenzenesulfonic acid and (4-sulfophenylamido)sulfuric acid in addition to **3**.

$$\underset{\mathbf{1}}{C_6H_5NHSi(CH_3)_3} + SO_3 \xrightarrow[-15^\circ C]{} \underset{\mathbf{2}}{[C_6H_5\overset{+}{N}HSi(CH_3)_3]\,SO_3^-} \xrightarrow{CF_3COOH} \underset{\mathbf{3}}{C_6H_5NH_2{}^+SO_3^-}$$

Reaction of 1 with Chlorosulfuric Acid. When chlorosulfuric acid was added dropwise to a solution of **1** in 1,2-dichloroethane at −20°C, **3** separated out directly. This product, however, was contaminated with slight amounts of anilinium hydrogensulfate and anilinium chloride as indicated by HPLC and IR spectroscopy, and also by tests for sulfate and chloride ions. The anilinium hydrogensulfate arose probably

$$\mathbf{1} + ClSO_3H \xrightarrow[-20^\circ C]{} \mathbf{3} + \underset{\mathbf{4}}{(CH_3)_3SiCl}$$

from aniline and sulfuric acid, which are commonly present as contaminants in **1** and chlorosulfuric acid, respectively. Great difficulty in obtaining very pure starting materials and the lack of methods for purifying **3** make this reaction less valuable for the preparation of pure **3**.

Reaction of 1 with Trimethylsilyl Chlorosulfate (5). Sundermeyer and his collaborators[10)] have prepared several trimethylsilyl esters of alkylamidosulfuric acids in yields of 70—90% by the reaction of (alkylamino)trimethylsilane with **5**. Our preliminary experiments showed that, with anilinotrimethylsilane (**1**), the use of much lower temperature is essential, or else

$$R^1R^2NSi(CH_3)_3 + \underset{\mathbf{5}}{ClSO_3Si(CH_3)_3} \xrightarrow[r.t.]{CH_2Cl_2} R^1R^2NSO_3Si(CH_3)_3 + \mathbf{4}$$

ring sulfonation occurs appreciably. Thus, a solution of **5** in dichloromethane was added dropwise to a solution of **1** in the same solvent at −10—−15 °C and the mixture was stirred at −10—−15 °C for 7 h; after removal of insoluble material,[11] the filtrate was treated with trifluoroacetic acid to give analytically pure phenylamidosulfuric acid (**3**) in yields of 62—71%. When the desilylating process was omitted, trimethylsilyl phenylamidosulfate (**2**)[12] was isolated from the reaction mixture.

$$\underset{\mathbf{1}}{C_6H_5NHSi(CH_3)_3} + \underset{\mathbf{5}}{ClSO_3Si(CH_3)_3} \xrightarrow[-10\ -\ -15°C]{} \underset{\mathbf{2}}{C_6H_5NHSO_3Si(CH_3)_3} + \mathbf{4}$$

Acetic acid and methanol, as well as trifluoroacetic acid, can be used as a desilylating agent. As for methanol, however, its use in excess must be avoided; otherwise phenylamidosulfuric acid first formed will react with the excess methanol at room temperature to yield anilinium methyl sulfate (**6**).

$$\underset{\mathbf{3}}{C_6H_5NH_2{}^+SO_3{}^-} + CH_3OH \xrightarrow[r.t.]{} \underset{\mathbf{6}}{C_6H_5NH_3{}^+CH_3OSO_3{}^-}$$

Reaction of Aniline with Trimethylsilyl Chlorosulfate (5). The reaction of aniline with **5** in a 1:1 molar ratio produced a mixture consisting of trimethylsilyl phenylamidosulfate (**2**) (16%), phenylamidosulfuric acid (**3**) (51%), anilinium hydrogensulfate, and anilinium chloride. The latter two anilinium salts arose probably from the hydrolysis of **5** by adventitious water during the reaction. Simchen and his

$$C_6H_5NH_2 + \mathbf{5} \longrightarrow \left[\ C_6H_5\overset{H}{\overset{|}{N}}\!\!-\!\!\overset{O}{\overset{\|}{S}}\!\!-\!\!Cl \quad (O\text{–}Si(CH_3)_3)\ \right] \longrightarrow$$

$$C_6H_5NH_2{}^+SO_3Si(CH_3)_3 + Cl^- \begin{cases} \xrightarrow{} \underset{\mathbf{2}}{C_6H_5NHSO_3Si(CH_3)_3} + HCl \\ \xrightarrow{} \underset{\mathbf{3}}{C_6H_5NH_2{}^+SO_3{}^-} + \mathbf{4} \end{cases}$$

collaborator have repoted[13] that the action of **5** on *N,N*-diethylaniline with ice-cooling gives an *N,N*-diethylanilinesulfur trioxide adduct (**7**), which rearranges to 4-(diethylamino)benzenesulfonic acid at room temperature.

$$C_6H_5N(C_2H_5)_2 + \mathbf{5} \longrightarrow \underset{\mathbf{7}}{C_6H_5N(C_2H_5)_2{}^+SO_3{}^-} + \mathbf{4}$$

$$\mathbf{7} \xrightarrow[r.t.]{} 4\text{-}(C_2H_5)_2NH^+C_6H_4SO_3{}^-$$

The reaction of aniline with **5** in a 2:1 molar ratio at −10—−15 °C yielded anilinium phenylamidosulfate (**8**) in a 87% yield; the same result was obtained when the direction of addition of both reagents was inverted. HPLC analysis showed the absence of the ring sulfonation; in addition, tests with acidic aqueous silver nitrate and barium nitrate solutions were practically negative. These facts indicate that the reaction proceeds probably as follows.

$$2\ C_6H_5NH_2 + \underset{\mathbf{5}}{ClSO_3Si(CH_3)_3} \longrightarrow \left[\ C_6H_5NH_2 \rightarrow C_6H_5\overset{H}{\overset{|}{N}}\!\!-\!\!\overset{O}{\overset{\|}{S}}\!\!-\!\!Cl \quad (O\text{–}Si(CH_3)_3)\ \right]$$

$$\longrightarrow \underset{\mathbf{8}}{C_6H_5NHSO_3{}^-C_6H_5NH_3{}^+} + \mathbf{4}$$

Reaction of 1 with Dioxane–Sulfur Trioxide Complex. Kricheldorf and his collaborator[8] have prepared trimethylsilyl *N*-methylbenzylamidosulfate in 77% yield by reaction of *N*-methyl-*N*-(trimethylsilyl)-benzylamine[9] with dioxane–sulfur trioxide. In our case, the reaction of **1** with dioxane–sulfur trioxide (−20 °C, 2 h) in 1,2-dichloroethane and subsequent desilylation with trifluoroacetic acid gave a mixture consisting of the desired product **3**, 4-aminobenzenesulfonic acid, and anilinium hydrogensulfate. The sulfate salt arose undoubtedly from the hydrolysis of unconverted **1** and the dioxane–sulfur trioxide in the course of workup; therefore, lengthening of the reaction time would lead to an increase in the yield of **3**, and removal of the insoluble by-products from the reaction mixture before the desilylation would permit the isolation of **3** in a pure state without any additional purification.

$$C_6H_5NHSi(CH_3)_3 + \text{dioxane–}SO_3 \rightleftharpoons C_6H_5\overset{+}{N}HSi(CH_3)_3 \quad (SO_3^-) + \text{dioxane}$$

$$\underset{\mathbf{2}}{C_6H_5NHSO_3Si(CH_3)_3} \xrightarrow{H^+} \underset{\mathbf{3}}{C_6H_5NH_2{}^+SO_3{}^-}$$

Reaction of 1 with Ethyl Chlorosulfate (10). The reactions between aromatic as well as aliphatic amines and alkyl chlorosulfates have been studied by several investigators.[14,15] It has been found that, for example, in the reaction of aniline with **10**, *N*-ethyl- and *N,N*-diethylaniline, phenylamidosulfate, *N*-ethylphenylamidosulfate, and 4-aminobenzenesulfonic acid are formed in varying proportions, which depend on the reaction conditions used. Yaguzhinskii and Berlin[15] have investigated the reaction of anilines with alkyl chlorosulfates in some detail and found that the corresponding alkyl *N*-alkylphenylamidosulfates were also formed.

By analogy with these findings, the reaction of anilinotrimethylsilane **1** with **10** had been expected to yield the desired product **3**; actually, however, **3** was formed in only a trace. Thus, treatment of **1** with **10** in

dichloromethane at −10—−15 °C for 1 h and at reflux for 3 h yielded a solid product, which was identified as dianilinium (4-sulfonatophenylamido)sulfate; treatment of the filtrate with acetic acid gave another precipitate, which was found to be 4-aminobenzenesulfonic acid contaminated with slight amounts of 2-aminobenzenesulfonic acid and a disulfonic acid, and a trace of **3**. In addition, ethyl phenylamidosulfate and its *N*-ethyl derivative were isolated from the desilylation mixture.

Experimental

All reactions were carried out in oven-dried glassware under a dry nitrogen atmosphere by use of Schlenk-tube techniques. All solvents were dried over appropriate drying agents. Aniline was dried over KOH pellets and distilled under reduced pressure. Triethylamine was dried over KOH and distilled. Chlorotrimethylsilane was distilled (bp 57.0—57.5 °C). Trifluoroacetic acid and chlorosulfuric acid were of reagent grade and used as purchased. Sulfur trioxide was obtained from 60—65% fuming sulfuric acid by distillation. IR spectra were recorded on a Hitachi 215 spectrophotometer; ^{1}H NMR spectra were obtained on a JNM-PMX 60 instrument. High-performance liquid chromatography (HPLC) was carried out on a Toyo Soda HPLC-803D instrument by using a TSK-GEL ODS-120T (4.6 mm ×25 cm)column and a 0.05 M Na_2HPO_4 (pH 7.0) aqueous solution containing 1% of CH_3CN as the eluant; peaks were monitored at 240 nm on a UVIDEC-100-IV. TLC was performed on Cellulose mikrokristallin (E Merck) plates by using dioxane–water (3 : 1 v/v) as a developing solvent; spots were visualized by diazotization with nitrous gases and spraying with 1% sodium 1-naphthol-4-sulfonate and subsequent exposure to ammonia. Samples for HPLC and TLC analyses were prepared by dissolving the products in aqueous NaOH.

Preparation of Anilinotrimethylsilane (1). To a stirred solution of chlorotrimethylsilane (24.0 g, 0.220 mol) in cyclohexane (100 ml) was added at 5 °C over 10 min a solution of triethylamine (22.2 g, 0.220 mol) in cyclohexane (15 ml). After the mixture had been stirred for 1 h, aniline (20.5 g, 0.220 mol) was added at 5—6 °C over 30 min, and stirring was continued for further 7 h. The mixture was filtered and evaporated. The residue was fractionally distilled under reduced pressure to give **1** (23.5 g, 65%): Bp 103.7—104.5 °C/21 Torr† (lit, 106-107 °C/24 Torr);[16] 95% purity as determined by GLC;IR (neat) 3405, 1605, 1503, 1388, 1295, 1253, 900, 838, and 690 cm^{-1}.

Preparation of Trimethylsilyl Chlorosulfate (5). Sulfur trioxide (71.0 g, 0.89 mol) was added with stirring to chlorotrimethylsilane (96.3 g, 0.89 mol) at −35 °C. The mixture was then allowed to warm to room temperature, heated at 50 °C for 10 min, and distilled in vacuo to yield **5** (145.8 g, 87%): Bp 73.0—74.0 °C/18 Torr (lit, [17] 66 °C/12 Torr).

Reaction of 1 with Sulfur Trioxide. To a stirred solution of **1** (2.50 g, 15.1 mmol) in 1,2-dichloroethane (55 ml) was added at −15 °C over 30 min a solution of SO_3 (1.21 g, 15.1 mmol) in 1,2-dichloroethane (15 ml). After being stirred for 8 h at −15 °C, the mixture was filtered and the filtrate was treated with CF_3COOH (1.72 g, 15.1 mmol) at −15 °C for 2 h. The solid produced (1.19 g, 45.5%) was collected by filtration, washed with 1,2-dichloroethane, and dried in vacuo. The product was identified as phenylamidosulfuric acid (**3**) by comparison of its IR spectrum and HPLC data with those of the authentic sample prepared in previous work.[6]

Reaction of 1 with Chlorosulfuric Acid. To a stirred solution of **1** (2.56 g, 15.5 mmol) in 1,2-dichloroethane (55 ml) was added at −20 °C over 30 min chlorosulfuric acid (1.81 g, 15.5 mmol). The mixture was then stirred for 8 h at −20 °C. A precipitate produced was collected by filtration under dry nitrogen, washed with 1,2-dichloroethane, and dried in vacuo to give **3** (2.55 g, 95%). HPLC analysis and tests with acidic aqueous $Ba(NO_3)_2$ and 0.05 M $AgNO_3$ solutions indicated the contamination with slight amounts of anilinium hydrogensulfate and anilinium chloride.

Reaction of 1 with 5. Trimethylsilyl chlorosulfate (**5**) was redistilled directly into a dropping funnel under reduced pressure (bp 75.0—75.5 °C/23 Torr). A solution of this ester (3.43 g, 18 mmol) in CH_2Cl_2 (5 ml) was added with stirring to freshly distilled anilinotrimethylsilane (**1**) (bp 104.5—106.0 °C/22 Torr) (2.97 g, 18 mmol) in CH_2Cl_2 (20 ml) at −10—−15 °C over 30 min. The mixture was stirred at this temperature for further 7 h and filtered. The filtrate was then treated at −10—−15 °C for 3 h with CF_3COOH (2.00 g, 18 mmol) to give a white solid, which was collected by filtration, washed with CH_2Cl_2, and dried in vacuo to yield pure phenylamidosulfuric acid **3** (2.0 g, 64%); IR (KBr) 1545 (NH_2^+), 1497, 1480, 1360 (SO_3^-), 1302, 1256 (SO_3^-), 1050 (SO_3^-), 875, 765, and 685 cm^{-1}. Found: C, 41.63; H, 4.17; N, 8.26%. Calcd for $C_6H_7O_3NS$: C, 41.61; H, 4.07; N, 8.09%. This product gave no turbidity with aqueous $Ba(NO_3)_2$; its homogeneity was proved by HPLC analysis.

Isolation of Trimethylsilyl Phenylamidosulfate (2). The reaction of **1** with **5** was carried out as described above. The reaction mixture was filtered and evaporated in vacuo. Distillation of the residue yielded **2** as a colorless liquid boiling at 119 °C/ca. 1 Torr; IR (film) 3285 (NH), 2965, 2900, 1605, 1503, 1345 (SO_2), 1258 ($Si(CH_3)_3$), 1175 (SO_2), 950 (SiOSi), 845, 765, and 698 cm^{-1}; treatment of this compound with CF_3COOH yielded phenylamidosulfuric acid **3**.

Formation of Anilinium Methyl Sulfate (6) on Treatment of 2 with Excess of Methanol. The reaction between **1** (2.60 g, 15.7 mmol) and **5** (2.29 g, 15.7 mmol) was carried out as described above. After removal of a white precipitate (0.85 g), the filtrate was treated with methanol (1.00 g, 31.4 mmol) at −10—−15 °C. A white solid rapidly separated out, as the methanol was added.[18] While the mixture was stirred for further 1.5 h, the solid gradually disappeared and colorless crystals, in turn, separated out as thin plates; this compound (1.26 g, 39%) was identified as **6** by comparison of its melting point (130—131 °C) and IR spectrum with those of an authentic sample.[19] Found: C, 41.09; H, 5.04; N, 6.65%. Calcd for $C_7H_{11}O_4NS$: C, 40.97; H, 5.40; N, 6.83%.

Reaction of Aniline with 5 in a 1 : 1 Molar Ratio. To a stirred solution of **5** (2.14 g, 11.3 mmol) in CCl_4 (20 ml) was added a solution of aniline (1.06 g, 11.3 mmol) in CCl_4 (20 ml) at −10—−15 °C over 30 min. After the mixture had been stirred for 7 h at −10—−15 °C, a precipitate (**A**) thus formed (1.26 g) was collected by filtration. Treatment of the filtrate with acetic acid (0.68 g; 11.3 mmol) for 3 h at −10—−15 °C yielded another precipitate (**B**) (0.34 g).

Precipitate **A**: Neutralization of this material with aqueous NaOH gave sodium phenylamidosulfate; its identity was verified by HPLC analysis and by comparison of its IR

†Torr=133.322Pa.

spectrum with that of an authentic sample; tests with aqueous $Ba(NO_3)_2$ and $AgNO_3$ indicated the contamination with anilinium hydrogensulfate and anilinium chloride.

Precipitate **B**: Its IR spectrum was identical with that of an authentic sample of **2** and its HPLC showed a single peak ascribable to **2**.

Reaction of Aniline with 5 in a 2:1 Molar Ratio. To a stirred solution of aniline (1.69 g, 18.2 mmol) in CCl_4 was added a solution of **5** (1.72 g, 9.1 mmol) in the same solvent (5 ml) over 30 min at −10—−15 °C. After the mixture had been stirred for 3 h at −10—−15 °C, the resulting precipitate was collected, washed with CCl_4, and dried in vacuo to give anilinium phenylamidosulfate (**8**) (2.12 g, 87%). Recrystallization from water gave the pure salt; its IR spectrum was identical with that of an authentic sample. Found: C, 54.33; H, 5.24; N, 10.27%. Calcd for $C_{12}H_{14}O_3N_2S$: C, 54.12; H, 5.30; N, 10.52%.

Reaction of 1 with Dioxane–Sulfur Trioxide. To a stirred solution of 1,4-dioxane (1.00 g, 11.4 mmol) in 1,2-dichloroethane (20 ml) was added a solution of SO_3 (0.78 g; 9.74 mmol) in 1,2-dichloroethane (20 ml) over 1 h at −10 °C. To this mixture was added with stirring a solution of **1** (1.61 g; 9.74 mmol) in 1,2-dichloroethane (20 ml) over 30 min at −20 °C. After having been stirred for an additional 2 h at −20 °C, the mixture was filtered. The filtrate was then treated with CF_3COOH (1.50 g, 13 mmol) at −5 °C for 3 h; the solid thus formed was collected, washed with 1,2-dichloroethane, and dried in vacuo, giving phenylamidosulfuric acid (**3**) (1.1 g; 65%).

Reaction of 1 with Ethyl Chlorosulfate (10). To a stirred solution of **1** (2.28 g; 13.8 mmol) in CH_2Cl_2 (20 ml) was added a solution of **10** (2.00 g; 13.8 mmol) in CH_2Cl_2 (10 ml) at −10—−15 °C over 30 min. After having been stirred for an additional 2 h, the mixture was allowed to warm to room temperature, and then refluxed for 3 h. A white solid (**A**) (0.45 g) was collected, washed with CH_2Cl_2, and dried; the combined filtrate and washings were treated with CH_3COOH at −10—−15 °C for 3 h to yield a solid (**B**). After the solid (**B**) had been filtered off, the filtrate was washed with water repeatedly, dried over Na_2SO_4, and evaporated to give a semi-solid (**C**), which probably is a mixture of ethyl phenylamidosulfate and ethyl *N*-ethyl-*N*-phenylamidosulfate.

Solid **A**: IR (KBr) 3270 (NH), 1601, 1501, 1230 (SO_3^-), 1162 (SO_3^-), 1125, 1033 (SO_3^-), 900, 835, 740, and 682 cm^{-1}; the IR spectrum of its sodium salt was identical with that of an authentic sample of disodium (4-sulfonatophenylamido)-sulfate.[20]

Solid **B**: The IR and NMR spectra of its sodium salt agreed with those of an authentic sample of sodium 4-aminobenzenesulfonate; HPLC analysis revealed the contamination with slight amounts of 2-aminobenzenesulfonic acid and aminobenzenedisulfonic acid, and with a trace of **3**.

Residue **C**: IR (KBr) 1603, 1503, 1360 (SO_2), 1165 (SO_2), 1008, 915, 752, and 695 cm^{-1}. ^1H NMR (DMSO-d_6) δ=1.0 (t, CH_3), 1.23 (t, CH_3), 3.65 (q, OCH_2), 4.08 (q, NCH_2), and 7.48 (m, ArH).

One of the authors (F. K.) thanks Prof. Dr. H. Schmidbaur for the laboratory facilities during his stay at Anorganisch-Chemisches Institut der Technischen Universität München on sabbatical leave.

Rearrangement Approaches to Cyclic Skeletons. IV. The Total Synthesis of (±)-Pinguisone and (±)-Deoxopinguisone Based on Photochemical [1,3] Acyl Migration of a Bicyclo[3.2.2]non-6-en-2-one[1]

Tadao UYEHARA,* Yasuhiro KABASAWA, and Tadahiro KATO
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-Aoba, Sendai 980
(Received March 14, 1986)

The total synthesis of (±)-Pinguisone (**2**) and (±)-deoxopinguisone (**3**), [5—6] fused-ring sesquiterpenes, has been achieved starting from 1-methoxy-3,4,5-trimethylbenzene. 1-Methoxy-4,5,*endo*-8-trimethylbicyclo[2.2.2]-non-5-en-2-one (**9**) was prepared selectively via facial selective Diels–Alder reaction of the diene derived from the benzene and 2-chloroacrylonitrile. Ring enlargement of **9** using $(CH_3)_3SiCHN_2$ and BF_3 etherate gave the corresponding bicyclo[3.2.2]oct-6-en-2-one (**8**). The photochemical [1,3] acyl migration of **8** gave the [5—6] fused-ring compound (**7**). The fourth methyl was introduced selectively by the conjugate addition of $(CH_3)_2CuLi$ to the spiro[bicyclo[4.3.0]non-8-ene-3,2′-[1,3]dioxolan]-7-one prepared from **7**. Each furan ring of **2** and **3** was constructed via the corresponding butenolide derived from the γ-keto acid by acid-catalyzed dehydration.

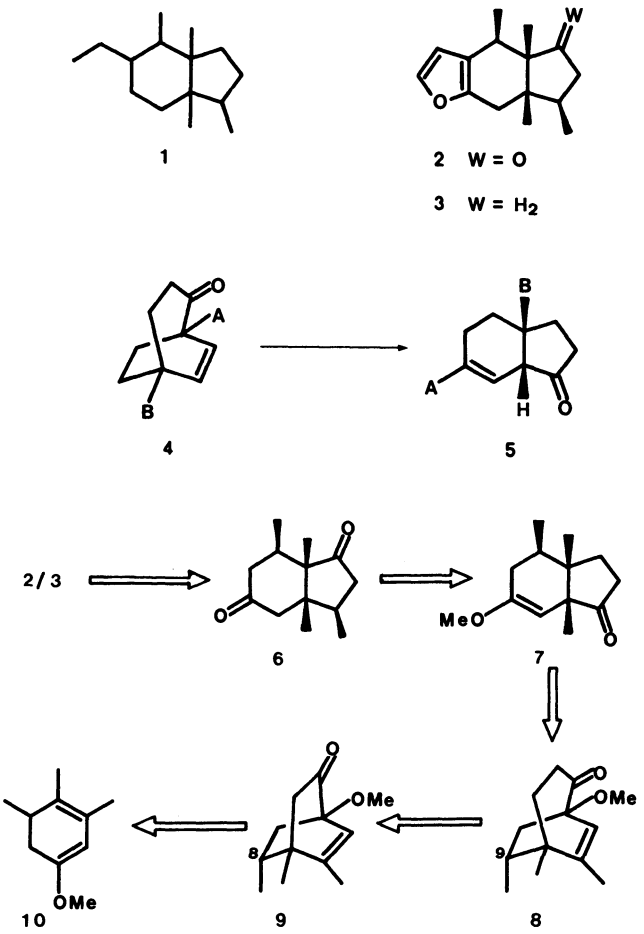
Pinguisane-type sesquiterpenes, possessing the unusual terpene skeleton (**1**),[3] have been found from various kinds of liverworts; such as pinguisone (**2**)[4] from *Aneura pinguis* (L.) Dum.[4b] and deoxopinguisone (**3**)[5] from *Ptilidium ciliare* (L.) Nees.[5a] These compounds are of particular interest in the total synthesis[6] since they have novel tricyclic furan skeletons with a cis-junction between the five- and six-membered rings and four adjacent cis-located methyl groups. Already it has been found that such polymethylated compounds do not belong to the simple cis-fused ring system whose convex and concave sides are predictable with ease.[6]

In connection with our program to develop methods for stereoselective syntheses of [*m*—*n*] fused-ring terpenoids from bridged bicyclic systems,[7] we have explored the photochemical reactions of bicyclo[3.2.2]-non-6-en-2-ones (**4**) and found a practical route to *cis*-bicyclo[4.3.0]non-4-en-7-ones (**5**) based on [1,3] acyl migration.[2] In this paper we describe the total synthesis of (±)-pinguisone (**2**) and (±)-deoxopinguisone (**3**), as the first application of this photochemical transformation to natural product syntheses.

Results and Discussion

Our synthetic plan is outlined in Scheme 1. The diketone **6**, possessing four adjacent cis methyl groups, should be an important precursor of the natural products. A key step in this plan is photochemical transformation of the bicyclo[3.2.2]non-6-en-2-one (**8**) to give the [5—6] fused ring system (**7**). The ketone **8** would be derived from the bridged bicyclooctenone **9** by ring enlargement. The stereochemistry of the 8-methyl of **9** should be controlled at the stage of cycloaddition to give the precursor of **9** by the approach of a ketene equivalent from the less hindered side to the diene **10**.

1-Methoxy-3,4,5-trimethyl-1,4-cyclohexadiene (**11**) was prepared from the corresponding anisole by dissolved metal reduction.[8] When **11** was heated with

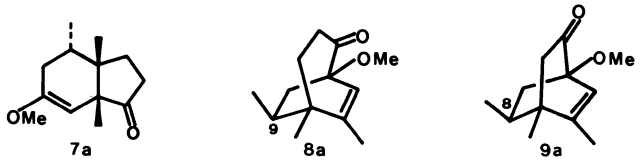


Scheme 1.

2-chloroacrylonitrile at 90°C in toluene, the 1,3-diene **10** was generated in situ and a mixture of the 1,4-addition products was obtained in 77% yield. Treating of the mixture with ethanolic sodium sulfide and potassium hydroxide[9] followed by Collins oxidation gave a ca. 10 to 1 mixture of **9** and **9a** in 57% yield. Prolongation of the treatment with sodium sulfide gave a large amount of the alcohols derived from **9** and **9a**. ^1H NMR spectrum of **9**, purified by HPLC,

shows the signals due to the 8-methyl at δ 0.89, whereas that of the isomer **9a** exhibits the corresponding signals at δ 1.01. This high-field shift of the former means that **9** is the 8-*endo*-methyl isomer. Their ^{13}C NMR spectra are also informative; that of **9** shows representative signals at δ 144.7 (5-C, s) and 47.7 (3-C, t) while those of **9a** are the singlet at δ 149.0 (5-C) and the triplet at 41.1 (3-C). These difference should be caused by the steric repulsion between the 5-carbon and the 8-*endo*-methyl in **9** and that between the 3-methylene and the 8-*exo*-methyl in **9a**.

Treatment of **9** with trimethylsilyldiazomethane and boron trifluoride etherate[10] in dichloromethane at −78 °C followed by desilylation with potassium carbonate in aqueous methanol gave the ring-enlargement product **8** in 79% yield. At higher temperature than −73 °C, the yield of **8** decreased definitely.

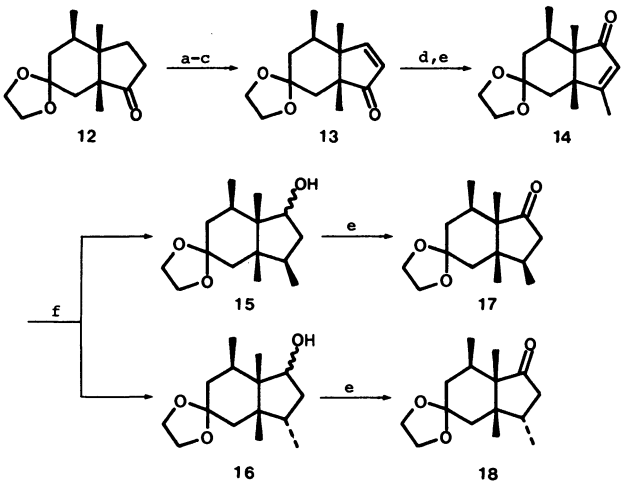


Photochemical transformation of **8** to give the cis [5—6] fused-ring system **7** was carried out in 59% yield by irradiation of its tetrahydrofuran (THF) solution using a high-pressure mercury lamp through a Pyrex filter. In practice, the mixture of **9** and **9a** was converted into a mixture of **7** and **7a** and then the desired ketone **7** was isolated by silica-gel column chromatography.

The enol methyl ether **7** underwent disproportionation slowly upon standing at ambient temperature. Terefore, **7** was treated with 2-ethyl-2-methyl-1,3-dioxolane and *p*-toluenesulfonic acid (TsOH) in benzene to give the acetal **12**, a remarkably stable compound.

In order to introduce the fourth methyl group stereoselectively, we first attempted the dissolved metal reduction route as shown in Scheme 2. The ketone **12** was converted into the α,β-unsaturated carbonyl compound **13** in 61% yield by successive treatment with 1) lithium diisopropylamide (LDA) and *S*-phenyl benzenethiosulfonate[11] and 2) sodium periodate in aqueous methanol, followed by 3) pyrolysis with calcium carbonate in toluene at 90 °C. Treatment of **13** with methyllitium and then with pyridinium chlorochromate (PCC)[12] gave the oxidative rearrangement product **14** in 79% yield. Reduction of **14** with lithium and *t*-butyl alcohol in liquid ammonia–THF gave the mixtures of the isomeric alcohols (**15** and **16**) in 33 and 58% yields, respectively. Each of them was converted quantitatively into the corresponding ketone by PCC oxidation in the presence of sodium acetate.

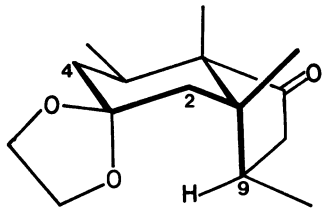
Stereochemistry of the fourth methyl group of the ketones **17** and **18** were determined on the basis of their ^{1}H NMR spectra. The spectrum of **17** shows the signals



Scheme 2. Preparation of the *cis*-tetramethyl-*cis*-perhydroindanone (**17**).[a)]
a) (a): LDA, $PhSSO_2Ph$, THF, (b): $NaIO_4$, MeOH–H_2O, (c): $CaCO_3$, PhMe, 90 °C, (d): MeLi, ether, (e): PCC, NaOAc, CH_2Cl_2, (f): Li, NH_3, *t*-BuOH, THF.

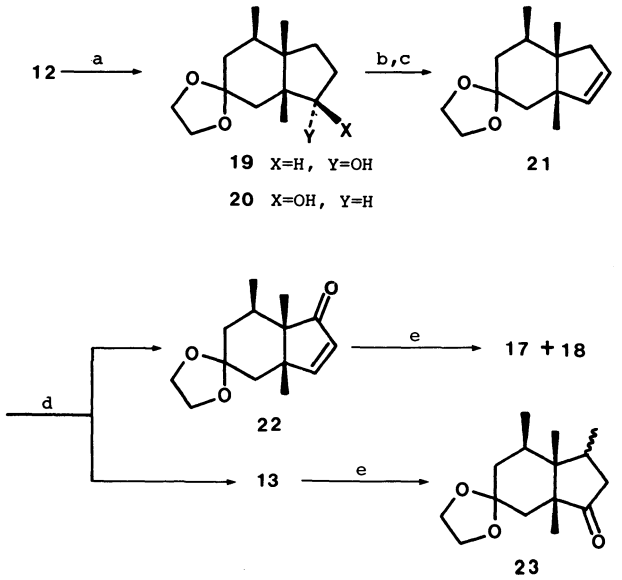
due to the 9-methine proton at δ 3.04. On the other hand, the signals due to the corresponding proton of **18** appear at the higher field than δ 2.5. This remarkable difference means the presence of large deshielding effect to the proton of **17**.

The 200 MHz NMR spectrum of **17** suggests that its presumable conformation is **17a**, as depicted. The coupling pattern of the 5-methine proton (δ=2.07, $J_{5,4}$= 13.0 and 3.8 Hz) reflects that this is an axial proton of a chair cyclohexane ring. The spin–spin coupling between one of the 4-protons (δ=1.49, $J_{4,5}$=3.8 Hz and $J_{4,2}$=2.3 Hz) and one of the 2-protons (δ=1.75, $J_{2,4}$= 2.3 Hz) should be the "W"-shape long-range coupling. This means both of the protons are present at the equatrial positions of a chair six-membered ring. Thus, the C_1–C_9 bond should be axial-like and the 9-proton approaches to the axial-like oxygen of the acetal part. The nonbonding distance between this oxygen and the 9-proton is estimated to be ca. 1.9 Å based on Dreiding model study. The low-field shift of the 9-methine proton signals should be caused by this steric compression. The isomer **18** may have a different conformation from that of **17**. The ^{13}C NMR spectrum of **17** shows the signals due to the methine carbons

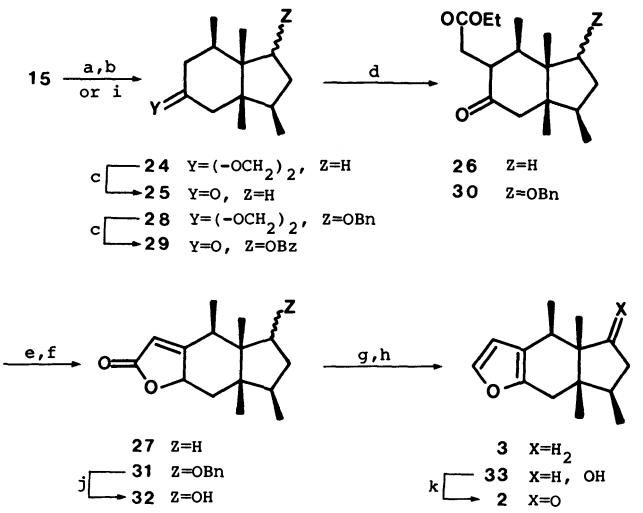


17a

at δ 30.3 and 29.2 while that of **18** exhibits the corresponding ones at δ 36.9 and 32.2. These remarkable



Scheme 3. An alternative route to the *cis*-tetramethyl-*cis*-perhydroindanone (**17**).[a)]
a) (a): $LiAlH_4$, ether, (b): MsCl, Py, (c): *t*-BuOK, DMSO, (d): CrO_3-3,5-DMP, CH_2Cl_2, (e): $(CH_3)_2CuLi$, ether.



Scheme 4. Completion of the synthesis of (±)-pinguisone (**2**) and (±)-deoxopinguisone (**3**).[a)]
a) (a): NaH, CS_2, THF, then MeI, (b): $(n\text{-Bu})_3SnH$, PhMe, reflux, (c): HCl, H_2O-acetone, (d): LDA, ICH_2CO_2Et, THF-HMPA, (e): K_2CO_3, MeOH-H_2O, (f): TsOH, PhH, reflux, (g): DIBAH, THF, (h): 1 M H_2SO_4, (i): NaH, $PhCH_2Br$, $(n\text{-Bu})_4NI$, DME, (j): BBr_3, CH_2Cl_2, (k): $(Ac)_2O$, DMSO.

differences also suggest the conformational difference between **17** and **18** and the presence of the large steric compression in the former.

Catalytic hydrogenation of **14** using 5% palladium on charcoal in ethanol gave a 1 to 1 mixture of **17** and **18**.

In order to prepare the ketone **17** selectively, an alternative route was examined (Scheme 3). Reduction of **12** with $LiAlH_4$ gave the alcohols **19** and **20** in 82 and 17% yields, respectively. Treatment of the methanesulfonate (mesylate) of **19** with potassium *t*-butoxide in DMSO gave the olefin **21** in 95% yield (from **19**), whereas **21** was not derived from the mesylate of **20**. Allylic oxidation of **21** with chromium trioxide-3,5-dimethylpyrazole complex[13] at −20 °C gave a 9 to 2 mixture of the ketones **22** and **13** in 79% yield. Reaction of this mixture with lithium dimethylcuprate(I) formed a mixture of **17** and **18**, in a ratio of 94 to 6, in 76% yield and **23**, derived from **13**, in 17% yield. Remarkable stereoselectivity of the conjugate addition to **22** is caused by steric approach control due to the steric bulk of the acetal. Reduction of the mixture of **17** and **18** by $LiAlH_4$ gave the alcohols (**15** and **16**) quantitatively.

The final stages of the (±)-deoxopinguisone (**3**) synthesis is shown in Scheme 4. The alcohols **15** were converted into the xanthates.[14] Treatment of them with tributyltin hydride in toluene gave the deoxo derivative **24** in 84% yield from **15**. Cleavage of the acetal yielded the ketone **25** (97%). The kinetic enolate of **25** generated by treating with LDA was reacted with ethyl iodoacetate in THF–hexamethylphosphoric triamide (HMPA)[15] to produce **26**, alkylated at the appropriate position, in 63% yield and 26% recovery of **25**. Hydrolysis of **26** and then heating under reflux with TsOH in benzene[16] gave the butenolide **27** in 72% yield. Reduction of **27** with diisobutylaluminium hydride (DIBAH) followed by an acid work-up produced a colorless oil, in 69% yield, whose ^1H NMR was identical with that of natural deoxopinguisone (**3**).

In order to prepare (±)-pinguisone (**2**) from **15**, the hydroxyl group was protected as a benzyl ether (**28**, 92%), and the synthetic route of (±)-deoxopinguisone was traced as shown in Scheme 4. The 1,3-dioxolane was cleaved by hydrochloric acid in acetone to yield **29** in 91% yield. Selective alkylation of **29** by treating with LDA and ethyl iodoacetate gave **30** in 68% yield and 24% recovery of **29**. Hydrolysis of **30** followed by the treatment with TsOH provided the butenolide **31** in 52% yield. Cleavage of the benzyl ether by boron tribromide[17] in dichloromethane at 0 °C gave **32** in 82% yield. DIBAH reduction of **32** follwed by an acid work-up gave the furan **33** in 66% yield. Oxidation of **33** with DMSO–acetic anhydride[18] provided the ketone, as a colorless oil (62%), whose spectral characteristics were identical with those of natural pinguisone ((+)-**2**, lit[4a,6b] mp 63 °C).

Thus, we have demonstrated that the photochemical [1,3] acyl migration of the bicyclo[3.2.2]nonenone system is incorporated into the synthetic route of the [5—6] fused-ring sesquiterpenes.

Experimental

General. Boiling points are uncorrected. Melting points were determined with a Yamato MP-21 capillary melting point apparatus and are uncorrected. UV and IR spectra (in CCl_4, unless otherwise mentioned) were recorded on Hitachi

Model 323 and 215 spectrometers, respectively. ^{1}H NMR spectra (in CCl_4, unless otherwise noted) were obtained on JEOL JNM-PMX60, Varian EM-390 90 MHz, and/or Varian XL-200 NMR specrometers, using tetramethylsilane as an internal standared. ^{13}C NMR spectra (in $CDCl_3$) were recorded on a JEOL FX 90Q NMR spectrometer. The mass spectral studies were conducted using a Hitachi M-52 spectrometer. THF and ether were distilled from benzophenone ketyl under argon, immediately prior to use. 1,2-Dimethoxyethane (DME) was distilled from lithium aluminium hydride under argon immediately prior to use. Dichloromethane was distilled from P_2O_5 and stored on 4A molecular sieves. Benzene and toluene were distilled from P_2O_5 and stored over sodium wire. *S*-Phenyl benzenethiosulfonate,[11] *N*-nitroso-*N*-trimethylsilylmetylurea,[19] and PCC[20] were prepared by using literature procedures. All reactions were monitored by analytical TLC using E. Merck precoated silica gel $60F_{254}$ plates. Column chromatography was carried out with E. Merck silica gel 60 (70—230 mesh ASTM). HPLC was performed on a Warters Associates Model R-401 liquid chromatograph using a 25 cm×8 mm stainless-steel column packed with Lichrosorb SI 100. Analytical VPC was carried out using a Hitachi 663-50 gas chromatograph, outfitted with a 3 m×3 mm stainless-steel column packed with 10% FFAP on 60/80 Uniport B.

1-Methoxy-4,5,*endo*-8-trimethylbicyclo[2.2.2]oct-5-en-2-one (9). To a solution of 9.85 g (62.9 mmol) of 1-methoxy-3,4,5-trimethyl-1,4-cyclohexadiene (**11**)[8] in 10 ml of toluene were added 11.0 g (125.7 mmol) of 2-chloroacrylonitrile and 0.23 g (2.1 mmol) of hydroquinone. The mixture was heated at 90 °C overnight, cooled, and concentrated. Distillation of the residue (bp 118 °C/0.1 Torr (1 Torr=133.322 Pa)) yielded 11.55 g (48.2 mmol, 77%) of a mixture of the isomeric addition products as a pale yellow oil which solidified upon standing.

A solution of 4.52 g (18.8 mmol) of the adducts was added to a mixture of 6.8 g (28.3 mmol) of sodium sulfide, 3.9 g (56.5 mmol) of potassium hydroxide, and 9.4 ml of water. After heated under reflux for 8 h, the reaction mixture was diluted with water, and extracted with three portions of ether. The extracts were combined, washed with water and saturated brine, and dried over $MgSO_4$. Evaporation of the solvent, followed by chromatography of the residue (2.83 g) using 100 g of silica gel (8:1 then 3:1hexane–ethyl acetate) gave 1.84 g (9.47 mmol, 50%) of a mixture of **9** and the *exo*-8-methyl isomer **9a** and 0.24 g (1.22 mmol, 7%) of the alcohols, which were converted quantitatively into **9** and **9a** by Collins oxidation. The ratio of **9** and **9a**, 10 to 1, was determined by VPC (200 °C). Pure **9** and **9a** were obtained by repeated HPLC (10:1 hexane–ethyl acetate). **9**: Colorless oil; IR 1740 (s) cm^{-1}; ^{1}H NMR δ=0.89 (3H, d, J=6.9 Hz), 1.06 (1H, dd, J=12.4 and 4.5 Hz), 1.17 (3H, s), 1.6—2.0 (1H, m), 1.81 (3H, d, J=1.5 Hz), 1.87 (2H, broad s), 2.19 (1H, dd, J=12.2 and 9.8 Hz), 3.40 (3H, s), and 5.82 (1H, broad s); ^{13}C NMR δ=209.8 (s), 144.7 (s), 122.1 (d), 84.3 (s), 52.9 (q), 47.7 (t), 42.1 (s), 38.3 (d), 37.1 (t), 19.5 (q), 19.3 (q), and 19.1 (q); MS (25 eV) m/z (rel intensity) 194 (M$^+$, 1), 166 (8), and 137 (100). Found: C, 74.11; H, 9.52%. Calcd for $C_{12}H_{18}O_2$: C, 74.19, H, 9.34%. **9a**: Colorless oil; IR 1745 (s) cm^{-1}; ^{1}H NMR δ=1.01 (3H, d, J=6.9 Hz), 1.10 (3H, s), 1.35 (1H, dd, J=10.5 and 4.4 Hz), 1.5—1.9 (3H, m), 1.80 (3H, d, J=1.5 Hz), 2.12 (1H, d, J=18.3 Hz), 3.83 (3H, s), and 5.75 (1H, broad s); ^{13}C NMR δ=209.2 (s), 149.0 (s), 122.3 (d), 84.1 (s), 52.9 (q), 41.3 (s), 41.1 (t), 36.9 (t), 35.9 (d), 18.8 (q), 17.5 (q), and 16.0 (q); MS (25 eV) m/z (rel intensity) 194 (M$^+$, 21) and 103 (100).

Ring Enlargement of 9 Using $TMSCHN_2$ and BF_3 Etherate. Preparation of 1-Methoxy-5,endo-6,9-trimethylbicyclo-[3.2.2]non-6-en-2-one (8). In a flask equipped with a Dry Ice condenser were placed 4.59 g (25.67 mmol) of *N*-nitroso-*N*-trimethylsilylmethylurea and 5 ml of pentane. To the mixture was added 2.0 ml of 20% aqueous potassium hydroxide solution at 0 °C. After 1.5 h stirring at 0 °C, the organic layer was diluted with pentane, separated, washed with water, and dried over Na_2SO_4. This solution was concentrated carefully to ca. 2 ml, and diluted with 6.6 ml of dichloromethane. To a solution of 446.6 mg (2.3 mmol) of **9** in 8.9 ml dichloromethane was added 0.41 ml (3.45 mmol) of BF_3 etherate at −78 °C under argon and the mixture was stirred for 5 min. To this reaction mixture was added that $TMSCHN_2$ solution over a period of 30 min. After 1 h stirring, to the solution was added 20 ml of saturated aqueous $NaHCO_3$ solution. The mixture was allowed to warm to room temperature with stirring. After 2 h stirring the organic layer was separated, washed with saturated brine, dried over $MgSO_4$, and concentrated in vacuo. The residual oil was a mixture of **8** and its α-silylated derivatives. This mixture was diluted with 4.5 ml of methanol and treated with 0.3 g of K_2CO_3 and 1.5 ml of water for 2 h at room temperature. After dilution with water, the mixture was extracted with ether. The extracts were combined, washed with water and brine, and dried over $MgSO_4$. Evaporation of the solvent, followed by silica-gel chromatography (20 g; 8:1 hexane–ethyl acetate) of the residue (611.3 mg) gave 378.3 mg (1.82 mmol, 79%) of **8**: Colorless oil; UV (cyclohexane) 302 nm (ε 186); IR 1725 cm^{-1};^{1}H NMR δ=0.93 (3H, d, J=6.5 Hz), 1.06 (3H, s), 1.1—2.1 (4H, m), 1.75 (3H, d, J=1.5 Hz), 2.2—2.8 (3H, m), 3.15 (3H, s), and 5.47 (1H, broad s); ^{13}C NMR δ=205.0 (s), 144.6 (s), 124.3 (d), 82.4 (s), 51.3 (q), 40.7 (t), 40.4 (s), 38.6 (t), 37.9 (t), 35.2 (d), 24.1 (q), 21.7 (q), and 20.0 (q); MS (25 eV) m/z (rel intensiity) 208 (M$^+$, 13) and 147 (100). The 2,4-DNP derivative: Mp 146.5—147 °C. Found: C, 58.74, H, 6.37; N, 14.45%. Calcd for $C_{19}H_{24}N_4O_5$: C, 58.75; H, 6.23; N, 14.42%.

Photochemical Transformation of 8 into 4-Methoxy-*r*-1,*c*-2,*c*-6-trimethylbicyclo[4.3.0]non-4-en-7-one (7). A solution of 203.9 mg (1.15 mmol) of **8** in 100 ml of THF was placed in an immersion well equipped with a Pyrex filter and degassed by sonication. The solution under nitrogen was irradiated using a 100-W Rikou high pressure Hg lamp for 4 h. From the crude photolysate (208.6 mg), 120.0 mg (0.58 mmol, 59%) of **7** was isolated by column chromatography (15 g of SiO_2; 20:1 hexane–ethyl acetate). **7**: Colorless oil; IR 1740 (s) and 1675 (m) cm^{-1}; ^{1}H NMR δ=0.89 (3H, s), 0.98 (3H, s), 1.02 (3H, d, J=6.3 Hz), 1.4—2.3 (7H, m), 3.49 (3H, s), and 4.27 (1H, broad s); MS (25 eV) m/z (rel intensity) 208 (M$^+$, 30) and 137 (100).

***r*-1,*c*-5,*c*-6-Trimethylspiro[bicyclo[4.3.0]nonane-3,2′-[1,3]-dioxolan]-9-one (12).** A mixture of 38.1 mg (0.19 mmol) of **7**, 0.5 ml each of 2-ethyl-2-methyl-1,3-dioxolane and benzene, and 3 mg of TsOH was allowed to stand at room temperature for 2 d. This reaction mixture was diluted with ether, washed successively with saturated aqueous $NaHCO_3$ and NaCl solutions, and dried over $MgSO_4$. Concentration followed by chromatography (1.5 g of SiO_2; 5:1 hexane–ethyl acetate) gave 43.3 mg (99%) of **12** as colorless prisms. **12**: Mp 66.5—67.5 °C; IR 1745 (s) cm^{-1}; ^{1}H NMR δ=0.83 (3H, s), 0.90 (3H, s), 0.93 (3H, d, J=1.5 Hz), 1.1—1.3 (9H, m), and 3.4—4.0 (4H, m); ^{13}C NMR δ=220.6 (s), 107.5 (s), 64.2

(t), 63.7 (t), 54.1 (s), 40.8 (s), 38.9 (t), 37.2 (t), 33.5 (t), 33.3 (d), 28.6 (t), 22.9 (q), 168. (q), and 14.0 (q); MS (25 eV) *m/z* (rel intensity) 238 (M^+, 18) and 113 (100). Found: C, 70.61; H, 9.47%. Calcd for $C_{14}H_{22}O_3$: C, 70.56; H, 9.47%.

***r*-1,*c*-5,*c*-6-Trimethylspiro[bicyclo[4.3.0]non-7-ene-3,2'-[1,3]dioxolan]-9-one (13).** To a solution of 0.11 ml (2.5 mmol) of diisopropylamine in 2 ml of dry THF, prepared under argon, was added 0.47 ml (0.78 mmol) of 1.56 M† hexane solution of *n*-BuLi at 0°C, stirred for 10 min, and cooled to −78°C. To this LDA solution was added a solution of 166.5 mg (0.70 mmol) of **12** in 2 ml of THF via a double-ended needle, and kept at −78°C for 15 min. To the enolate solution was added a solution of 175.0 mg (0.70 mmol) of *S*-phenyl benzenethiosulfonate in 2 ml of THF. After stirring at −78°C for 1 h and then at room temperature for an additional hour, the reaction was quenched by addition of saturated aqueous ammonium chloride, and extracted with three portions of ether. The ethereal extracts were combined, washed with saturated aqueous $NaHCO_3$ and saturated brine, and dried over $MgSO_4$. Evaporation of the solvent, followed by chromatography (5 g of SiO_2; 30:1 benzene–ethyl acetate) of the residue (256.6 mg) gave 199.1 mg (0.57 mmol, 82%) of the α-phenylthio ketone as a colorless oil. This ketone was dissolved in a mixture of 11 ml of methanol and 1.4 ml of water and treated with 134 mg (0.63 mmol) of sodium periodate at room temperature overnight. The reaction mixture was poured into saturated aqueous $NaHCO_3$ solution, and extracted with three portions of dichloromethane. The combined extracts were washed with saturated brine and dried over $MgSO_4$. After removal of the solvent, the residue (249.5 mg) was purified by chromatography (10:1 benzene–ethyl acetate) to give 196.5 g (0.54 mmol, 95%) of a mixture of the sulfoxides. To a solution of the sulfoxides in 6 ml of toluene was added 0.1 g of $CaCO_3$. The mixture was heated at 90°C for 12 h and then under reflux for 6 h. After filtration through an alumina layer, concentration of the filtrate gave 174.1 mg of a colorless oil. Chromatography on silica gel (5 g; 5:1 hexane–ethyl acetate) gave 99 mg (0.42 mmol, 78%) of **13**: Colorless needles; mp 58—60°C; IR 1720 (s) cm^{-1}; ^1H NMR δ=0.95 (3H, s), 0.97 (3H, d, *J*=6.0 Hz), 1.00 (3H, s), 1.37 (1H, d, *J*=14.1 Hz), 1.3—1.8 (3H, m), 2.00 (1H, dd, *J*=14.1 and 1.0 Hz), 3.8 (4H, m), 5.89 (1H, d, *J*=5.7 Hz), and 7.35 (1H, d, *J*=5.7 Hz); MS (25 eV) *m/z* (rel intensity) 236 (M^+, 16) and 113 (100). Found: C, 71.45; H, 8.45%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%.

***r*-1,*c*-5,*c*-6,9-Tetramethylspiro[bicyclo[4.3.0]non-8-ene-3,2'-[1,3]dioxolan]-9-one (14).** To a solution of 99 mg (0.42 mmol) of **13** in 10 ml of dry ether was added 0.49 ml (0.63 mmol) of 1.3 M methyllithium solution in ether at 0°C under argon and stirred for 30 min. To the reaction mixture was added saturated aqueous ammonium chloride solution and extracted with three portions of ether. The combined extracts were washed with water and saturated brine, and dried over $MgSO_4$. After removal of the solvent, the remaining oil (97.2 mg) was chromatographed on silica gel (3 g; 5:1 then 2:1 hexane–ethyl acetate) to yield 94.8 mg (0.38 mmol, 90%) of the allylic alcohols. To a solution of these alcohols in 3 ml of dichloromethane were added 62 mg of sodium acetate and 164 mg (0.76 mmol) of PCC at room temperature, and the mixture was stirred for 2.5 h. After addition of 4 ml of ether, the solution was decanted from the black solid. The residue was washed in turn with several portions of ether. The combined ethereal extracts were passed through a silica-gel layer to give 92.8 mg of a colorless oil. Chromatography (3 g of silica gel; 5:1 hexane–ethyl acetate) of the oil gave 83.5 mg (0.33 mmol, 87%) of **14**: Colorless oil; IR 1715 (s) and 1625 (m) cm^{-1}; ^1H NMR δ=0.86 (3H, d, *J*=7.1 Hz), 0.89 (3H, s), 0.99 (3H, s), 1.2—1.6 (3H, m), 1.7—2.1 (2H, m), 2.01 (3H, d, *J*=1.5 Hz), 3.83 (4H, m), and 5.51 (1H, brosd s).

***r*-1,*c*-5,*c*-6,*c*-9- and *r*-1,*c*-5,*c*-6,*t*-9-Tetramethylspiro[bicyclo[4.3.0]nonane-3,2'-[1,3]dioxolan]-7-ols (15 and 16, Respectively).** To a flask containing 60.1 mg (0.24 mmol) of **14** were added ca. 30 ml of ammonia, distilled from sodium, 0.5 ml (5.3 mmol) of *t*-butyl alcohol, 5 ml of THF, and 16 mg (2.4 mmol) of litium at −78°C under argon. The mixture was allowed to warm to room temperature very slowly, and treated with water. This mixture was extracted with ether, and the extracts were combined, washed with water and saturated brine, and dried over $MgSO_4$. After evaporation of the solvent, silica-gel chromatography (8 g; 5:1 hexane–ethyl acetate) of the residue (83 mg) gave 20.3 mg (0.08 mmol, 33%) of the less polar alcohols (**15**) and 35.9 mg (0.14 mmol, 58%) of the more polar alcohols (**16**).

***r*-1,*c*-5,*c*-6,*c*-9-Tetramethylspiro[bicyclo[4.3.0]nonane-3,2'-[1,3]dioxolan]-7-one (17).** To a solution of 5.2 mg (0.02 mmol) of **15** in 0.5 ml of dichloromethane were added 40 mg (1.32 mmol) of PCC and 10 mg of sodium acetate. After 11 h stirring, to the reaction mixture was added 3 ml of ether and the ethereal solution was filtered through a silica-gel layer. Concentration of the filtrate gave 8.3 mg of an oil. Chromatography on silica gel (1 g; 10:1 hexane–ethyl acetate) gave 5.1 mg (0.02 mmol, 100%) of **17**: Mp 58.5—59°C; IR 1735 (s) cm^{-1}; ^1H NMR δ=0.60 (3H, s), 0.73 (3H, d, *J*=6.9 Hz), 0.76 (3H, s), 0.88 (3H, d, *J*=6.8 Hz), 1.31 (1H, d, *J*=14.9 Hz), 1.35 (1H, dd, *J*=13.8 and 13.0 Hz), 1.49 (1H, ddd, *J*=13.8, 3.8, and 2.3 Hz), 1.73 (1H, dd, *J*=19.3 and 11.0 Hz), 1.75 (1H, dd, *J*=14.9 and 2.3 Hz), 2.07 (1H, ddd, *J*=13.0, 6.9, and 3.8 Hz), 2.47 (1H, dd, *J*=19.3 and 9.0 Hz), 3.04 (1H, ddq, *J*=11.0, 9.0, and 6.8 Hz), 3.8—4.6 (4H, m); ^{13}C NMR δ=219.8 (s), 108.4 (s), 64.7 (t), 63.4 (t), 55.9 (s), 45.7 (s), 41.8 (t), 38.3 (t), 38.1 (t), 30.3 (d), 29.2 (d), 19.2 (q), 15.7 (q), 13.8 (q), and 8.2 (q); MS (25 eV) *m/z* (rel intensity) 252 (M^+, 2) and 113 (100). Found: C, 71.59; H, 9.70%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%.

***r*-1,*c*-5,*c*-6,*t*-9-Tetramethylspiro[bicyclo[4.3.0]nonane-3,2'-[1,3]dioxolan]-7-one (18).** Alcohols **16** (7.8 mg, 0.03 mmol) was treated with PCC (40 mg) and sodium acetate (10 mg) dry CH_2Cl_2 (0.5 ml) at room temperature for 11 h. A workup similar to that employed for the synthesis of **17** gave a colorless oil (8.1 mg). Chromatography on silica gel (1.4 g; 10:1 hexane–ethyl acetate) gave 7.8 mg (0.03 mmol, 100%) of pure **18**: Colorless needles; mp 63—64°C; IR 1740 (s) cm^{-1}; ^1H NMR δ=0.89 (3H, s), 0.97 (3H, d, *J*=6.6 Hz), 1.10 (3H, d, *J*=7.5 Hz), 1.17 (3H, s), 1.1—1.6 (4H, m), 1.6—2.5 (4H, m), and 3.6—4.0 (4H, m); ^{13}C NMR δ=220.6 (s), 109.3 (s), 64.6 (t), 62.9 (t), 55.2 (s), 44.3 (s), 41.1 (t), 38.1 (t), 37.6 (t), 36.9 (d), 32.2 (d), 20.2 (q), 17.4 (q), 16.1 (q), and 12.5 (q); MS (25 eV) *m/z* (rel intensity) 252 (M^+, 4) and 113 (100).

Reduction of 12. Preparation of *t*-1,*t*-5,*t*-6-Trimethylspiro[bicyclo[4.3.0]nonane-3,2'-[1,3]dioxolan]-*r*-8-ol (19). To a suspension of 92 mg (2.42 mmol) of $LiAlH_4$ in 4 ml of dry ether was added a solution of 577.2 mg (2.42 mmol) of **12** in 3 ml of ether at 0°C. After 5 min stirring, to the reaction mixture were added successively 0.09 ml of water, 0.09 ml of 15% aq NaOH, and 0.27 ml of water. After stirring

† 1 M=1 mol dm^{-3}.

until a granular precipitate was formed, $MgSO_4$ was added to the mixture and filtered. Concentration of the filtrate gave 578.5 mg of a colorless oil. Chromatography on silica gel (20 g; 3:1 hexane–ethyl acetate) gave 475.1 mg (1.98 mmol, 82%) of **19** and 101.9 mg (0.42 mmol, 17%) of the C-9 isomer (**20**). **19**: Colorless oil; IR 3480 (m), 2980 (s), and 2890 (m) cm^{-1}; ^1H NMR δ=0.81 (3H, s), 0.84 (3H, s), 0.88 (3H, d, J=6.8 Hz), 1.0—2.3 (9H, m), 3.62 (1H, dd, J=6.0 and 3.5 Hz), 3.74 (1H, broad s), and 3.8—4.0 (4H, m); ^{13}C NMR δ=108.9 (s), 83.0 (d), 64.4 (t), 64.0 (t), 49.5 (s), 44.6 (s), 40.1 (t), 38.8 (t), 33.7 (t), 33.7 (d), 32.2 (t), 27.4 (q), 17.0 (q), and 15.4 (q); MS (25 eV) m/z (rel intensity) 240 (M^+, 19) and 113 (100). Found: C, 69.96; H, 10.24%. Calcd for $C_{14}H_{24}O_3$: C, 69.96; H, 10.07%. **20**: IR 3640 (w) and 3500 (w) cm^{-1}; ^1H NMR δ=0.6—2.0 (10H, m), 0.73 (3H, s), 0.79 (3H, s), 0.82 (3H, d, J=6.3 Hz), 3.7—4.0 (4H, m), and 4.6 (1H, m), ^{13}C NMR δ= 108.8 (s), 74.5 (d), 64.6 (t), 63.3 (t), 47.7 (s), 44.3 (s), 38.8 (t), 33.4 (d), 31.7 (t), 28.8 (t), 17.8 (q), and 14.2 (q); MS (25 eV) m/z (rel intensity) 240 (M^+, 13) and 113 (100).

r-1,c-5,c-6-Trimethylspiro[bicyclo[4.3.0]non-8-ene-3,2′[1,3]-dioxolane] (21). To a solution of 475.0 mg (1.98 mmol) of **19** in 10 ml of pyridine was added 0.18 ml (2.37 mmol) of methanesulfonyl chloride at 0 °C, and the mixture was allowed to warm to room temperature. After stirring overnight, the mixture was diluted with saturated aqueous NH_4Cl solution and extracted with ether. The ethereal solution was washed successively with water and saturated brine, dried over $MgSO_4$, and then concentrated to give 632.6 mg of the crude mesylate as a pale yellow oil.

To a solution of this oil in 10 ml DMSO was added 490 mg (4.37 mmol) of potassium t-butoxide under a nitrogen atmosphere, and the mixture was stirred overnight at room temperature. After addition of 20 ml of saturated aqueous NH_4Cl, the mixture was extracted with three portions of ether. The ethereal extracts were combined, washed with water and saturated brine, and dried over $MgSO_4$. Evaporation of the solvent gave 436.8 mg of a yellow oil. Silica-gel column chromatography (10 g; 15:1 hexane–ethyl acetate) of the oil gave 418.8 mg (1.88 mmol, 95%) of **21**: Colorless oil; IR 3070 (w) and 1090 (s) cm^{-1}; ^1H NMR δ=0.82 (3H, s), 0.84 (3H, d, J=6.0 Hz), 0.88 (3H, s), 1.2—2.0 (5H, m), 2.12 (2H, m), 3.8 (4H, m), 5.30 (1H, dt, J=6.0 and 2.2 Hz), and 5.52 (1H, dm, J=6.0 Hz); MS (25 eV) m/z (rel intensity) 222 (M^+, 95) and 113 (100). Found: C, 75.74; H, 10.16%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

Allylic Oxidation of 21. Preparation of r-1,c-5,c-6-Trimethylspiro[bicyclo[4.3.0]non-8-ene-3,2′-[1,3]dioxolan]-7-one (22). Chromium trioxide (3.76 g, 37.6 mmol) was placed in a reaction flask, dried at 40 °C in vacuo (0.2 Torr) overnight, and dissolved in 32 ml of dry CH_2Cl_2. To this solution was added 3.64 g (37.6 mmol) of 3,5-dimethylpyrazole bellow −20 °C (ice–methanol bath) and stirred for 15 min. A solution of **21** (418.8 mg, 1.88 mmol) in dichloromethane (1 ml) was added to the solution of the complex and stirred for 4 h at −20 °C. Into the reaction flask was poured 16 ml of 5 M aqueous sodium hydroxide solution and the mixture was stirred for 1 h at 0 °C. To the mixture was added 100 ml of ether, and the organic layer was separeted. The ethereal solution was washed with three portions of water, two portions of 0.5 M hydrochloric acid, and a portion of saturated brine, and then dried over $MgSO_4$. Removal of the solvent under reduced pressure gave 1.38 g of white solids. Silica-gel chromatography (30 g; 5:1 hexane–ethyl acetate) gave 305.5 mg (1.29 mmol, 69%) of a 9 to 2 mixture of **22** and **13**. Repeated HPLC (10:1 hexane–ethyl acetate) gave pure **22** as colorless needles. **22**: Mp 74.0—75.0 °C; IR 1715 (s) cm^{-1}; ^1H NMR δ=0.85 (3H, d, J=6.8 Hz), 0.90 (3H, s), 0.97 (3H, s), 1.2—1.5 (2H, m), 1.6—1.8 (2H, m), 1.92 (1H, dq, J=8.3 and 6.8 Hz), 3.83 (4H, m), 5.74 (1H, d, J=5.9 Hz), and 7.22 (1H, d, J=5.9 Hz); MS (25 eV) m/z (rel intensity) 236 (M^+, 51) and 221 (100). Found: C, 71.36; H, 8.62%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%.

Reaction of 22 and Lithium Dimethylcuprate(I). An Alternative Route to 17. To a suspension of 1.47 g (7.69 mmol) of copper(I) iodide in 25 ml of ether was added dropwise 10.5 ml (1.42 M, 14.88 mmol) of ethereal methyllithium at 0 °C under argon, and the mixture was stirred for 5 min. To this clear solution was added a solution of the 9 to 2 mixture of **22** and **13** (294.1 mg, 1.24 mmol) in ether (2 ml). After stirring 2 h at 0 °C, this reaction mixture was poured into 60 ml of saturated aqueous NH_4Cl solution and extracted with ether. The extracts were combined, washed successively with water and saturated brine, and dried over $MgSO_4$. Evaporation of the solvent gave 309.9 mg of a colorless oil. Chromatography (10 g of silica gel; 10:1 hexane–ethyl acetate) of the oil gave 238.6 mg (0.95 mmol, 76%) of a mixture of **17** and **18**, in a ratio of 94 to 6, and 54.3 mg (0.22 mmol, 17%) of **23**.

Lithium Aluminium Hydride Reduction of a Mixture of 17 and 18. An Alternative Route to 15. To a suspension of 50 mg (1.32 mmol) of $LiAlH_4$ in 5 ml of dry ether was added a solution of 238.6 mg (0.95 mmol) of the mixture of **17** and **18** derived from **22**, in 5 ml of ether at 0 °C. After 5 min stirring, to the reaction mixture were added successively 0.05 ml of water, 0.05 ml of 15% aq NaOH, and 0.15 ml of water. After stirring for 30 min, to the mixture was added $MgSO_4$ and filtered through a Celite layer. Concentration of the filtrate gave 239.3 mg of colorless needles. Chromatography (14 g of silica gel; 5:1 hexane ethyl acetate) of the products gave 225.9 mg (0.89 mmol, 94%) of **15**, as a ca. 1:1 mixture of the C-7 epimers, and 14.4 mg (0.06 mmol, 6%) of **16**.

r-1,c-5,c-6,c-9-Tetramethylspiro[bicyclo[4.3.0]nonane-3,2′-[1,3]dioxolane] (24). Sodium hydride (50% dispersion in mineral oil, 64 mg, 1.34 mmol) was washed with three portions of THF under argon, and suspended in 2 ml of THF. To this mixture was added a solution of 225.9 mg (0.89 mmol) of **15** and 20 mg of imidazole in 3 ml of THF, and heated under reflux for 30 min. After addition of 0.27 ml (4.49 mmol) of carbon disulfide, the mixture was heated under reflux for 2 h and then cooled to room temperature. To the resulting yellow solution was added 0.27 ml (4.34 mmol) of iodomethane, and the mixture was stirred for 5 min. Saturated aqueous NH_4Cl solution was added, and extracted with three portions of ether. The extracts were combined, washed with water and saturated brine, and then dried over $MgSO_4$. Removal of the solvent gave 350 mg of a yellow oil. Chromatography (10 g of silica gel; 10:1 hexane–ethyl acetate) of this oil gave 300.4 mg (0.87 mmol, 98 %) of the xanthates as a colorless oil.

To a boiling solution of 0.25 ml (0.92 mmol) of tributyltin hydride in 5 ml of toluene was added a solution of 244.2 mg (0.71 mmol) of the xanthates in 3 ml of toluene and the reaction was continued for 6 h. The reaction mixture was concentrated in vacuo and then the residue was chromatographed on 10 g of silica gel (10:1 then 5:1 hexane–

ethyl acetate) to give 145.4 mg (0.61 mmol, 86%) of **24**: Colorless oil; IR 1105 (s) cm^{-1}; ^1H NMR δ=0.62 (3H, s), 0.78 (3H, d, J=7.1 Hz), 0.79 (3H, s), 0.84 (3H, d, J=6.5 Hz), 1.0—2.0 (9H, m), 2.65 (1H, m), and 3.6—3.9 (4H, m); MS (25 eV) m/z (rel intensity) 238 (M^+, 2) and 113 (100). Found: C, 75.76; H, 11.22%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99%.

***r*-1,*c*-5,*c*-6,*c*-9-Tetramethylbicyclo[4.3.0]nonan-3-one (25).** To a solution of 127.6 mg (0.54 mmol) of **24** in 2 ml of acetone was added 0.5 ml (4.34 mmol) of 1 M hydrochloric acid at room temperature, and the mixture was allowed to stand for 4 h. To the solution was added 30 ml of ether, the aqueous layer was removed. The organic layer was washed successively with saturated aqueous $NaHCO_3$ and NaCl solutions and then dried over $MgSO_4$. The solvent was removed carefully, and the residue was chromatographed (10 g of silica gel; 10:1 hexane–ethyl aetate) to yield 100.4 mg (0.52 mmol, 97%) of **25** as a volatile oil. **25**: IR 1710 (s) cm^{-1}; ^1H NMR δ=0.74 (3H, s), 0.89 (3H, d, J=6.2 Hz), 0.93 (3H, d, J=6.0 Hz), 0.96 (3H, s), and 1.0—2.0 (10H, m); MS (25 eV) m/z (rel intensity) 194 (M^+, 2) and 109 (100). The 2,4-DNP derivative of **25**: Mp 159.0—160.0° C. Found: C, 60.89; H, 7.21; N, 14.91%. Calcd for $C_{19}H_{26}N_4O_4$: C, 60.95; H, 7.00; N, 14.96%.

Ethyl *r*-1,*c*-2,*c*-6,*c*-7-Tetramethyl-4-oxobicyclo[4.3.0]non-3-yl Acetate (26). LDA was generated from 0.18 ml (1.30 mmol) of diisopropylamine and 0.18 ml (1.04 mmol) of 1.5 M butyllithium in 4 ml of THF at −78° C. To this solution were added 0.5 ml of hexamethylphosphoric triamide (HMPA) and a solution of 100.4 mg (0.52 mmol) of **25** in 2 ml of THF at 0° C, and the mixture was stirred for 30 min at 0° C. To the enolate solution was added 0.12 ml (1.04 mmol) of ethyl iodoacetate, and the mixture was allowed to stand at 0° C for 4 h. Saturated aqueous NH_4Cl solution was added, and the mixture was extracted with three potions of ether. The extracts were combined washed with two portions of water and a portion of saturated brine, and then dried over $MgSO_4$. Concentration of the solution gave 183.4 mg of a yellow oil. Silica-gel chromatography (12 g; 10:1 then 5:1 hexane–ethyl acetate) gave 92.3 mg (0.33 mmol, 63%) of **26** and 13.4 mg (0.07 mmol, 13%) of **25**. **26**: Colorless oil; IR 1735 (s), and 1715 (s) cm^{-1}; ^1H NMR δ=0.7—3.0 (11H, m), 0.77 (3H, s), 0.88 (3H, d, J=6.5 Hz), 1.05 (3H, s), 1.25 (3H, t, J=6.5 Hz), and 4.04 (2H, q, J=6.5 Hz).

Preparation of *r*-4,*c*-4a,*c*-7,*c*-7a-Tetramethyl-4,4a,5,6,7,7a,-8,8a-octahydroindeno[5,6-*b*]furan-2-one (27). Into a flask containing 22.9 mg (0.082 mmol) of **26** were added 3 ml of methanol, 0.7 ml of water, and 60 mg of K_2CO_3. This mixture was stirred at room temperature overnight, and then acidifed with 6 M HCl. The aqueous solution was extracted with three portions of ether. The ethereal extracts were combined, washed with saturated brine, dried over $MgSO_4$, and then concentrated to give 18.3 mg of a colorless oil. A solution of the oil and a small amount of TsOH in benzene (20 ml) was placed in a flask equipped with a Soxhlet extracter containing 3A Molecular sieves and heated under reflux for 2 d. The benzene solution was washed with saturated aqueous $NaHCO_3$ and NaCl solutions, and dried over $MgSO_4$. Evaporation of the solvent gave 21.0 mg of a yellow oil. Column chromatography (3 g of silica gel; 10:1 then 5:1 hexane–ethyl acetate) gave 13.8 mg (0.059 mmol, 72%) of **27**: Colorless needles; mp 89—90°C; IR 1800 (m) and 1765 (s) cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.72 (3H, s), 0.73 (3H, s), 0.97 (3H, d, J=7 Hz, 7-Me), 1.16 (3H, d, J=6.7 Hz, 4-Me), 1.18 (1H, dd, J=13.7 and 10.4 Hz), 1.2—2.05 (4H, m), 2.28 (2H, m), 2.39 (1H, dd, J=13.7 and 6.5 Hz), 4.93 (1H, dddd, J=11.2, 6.7, 1.3 and 1 Hz), and 5.69 (1H, dd, J=2.0 and 1.3 Hz); MS (25 eV) m/z (rel intensity) 234 (M^+, 42) and 109 (100). Found: C, 76.58; H, 9.36%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

(±)-Deoxopinguisone (3). A 1.5 M solution of DIBAH in hexane (0.06 ml) was added to a solution of 13.8 mg (0.059 mmol) of the butenolide **27** in 2 ml of THF at −20°C under an argon atmosphere, and the mixture was stirred for 5 min. To the solution was added 1 M sulfuric acid and the mixture was stirred at 0°C for 30 min. The reaction mixture was diluted with water and extracted with ether. The ethereal extracts were washed with saturated aqueous $NaHCO_3$ and NaCl solutions, and dried over $MgSO_4$. Evaporation of the solvent gave 11.8 mg of a colorless oil. Column chromatography (2 g of silica gel; hexane) of the oil gave 8.9 mg (0.041 mmol, 69%) of (±)-**3**: Colorless oil; IR 2960 (s), 2885 (s), 1645 (w), 1510 (w), 1475 (m), 1460 (m), 1388 (sh), 1385 (m), 1165 (w), 1142 (m), 1045 (m), 903 (m), and 725 (s); ^1H NMR ($CDCl_3$) δ=0.73 (3H, s), 0.82 (3H, s), 0.85 (3H, d, J=6.5 Hz), 1.12 (3H, d, J=7.2), 1.3—2.7 (8H, s), 6.16 (1H, d, J=1.8 Hz), and 7.20 (1H, dd, J=1.8 and 1.0 Hz); ^1H NMR (CCl_4) δ=0.74 (3H, s), 0.83 (3H, s), 0.89 (3H, d, J=6.5 Hz), 1.12 (3H, d, J=7.2 Hz), 1.0—2.7 (8H, m), 6.02 (1H, d, J=1.8 Hz), and 7.06 (1H, dd, J=1.8 and 1.0 Hz). MS (25 eV) m/z (rel intensity) 218 (M^+, 11), 161 (7), 119 (17), and 118 (100).

7-Bezyloxy-*r*-1,c-5,*c*-6,*c*-9-tetramethylbicyclo[4.3.0]nonan-3-ones (29). Sodium hydride (50% dispersion in mineral oil, 50 mg, 1.08 mmol) was washed with dry DME under argon and then suspended in 2 ml of DME. To this suspension was added a solution of 22.9 mg (0.09 mmol) of **15**, 166.6 mg (0.45 mmol) of tetrabutylammonium iodide and 0.05 ml (0.45 mmol) of α-bromotoluene in 3 ml of DME and the mixture was heated under reflux overnight. To this solution was added saturated aqueous NH_4Cl solution, and the mixture was extraced with three portions of ether. Combined extracts were washed with water and saturated brine, and then dried over $MgSO_4$. Concentration of the solution followed by chromatography (3 g of silica gel; 20:1 hexane–ethyl acetate) of the residue (55 mg) gave 28.6 mg of the isomeric mixture of the benzyl ethers (**28**) as a colorless oil.

A mixture of 28.6 mg (0.083 mmol) of **28**, 1 ml of acetone, and 0.3 ml of 1 M HCl was allowed to stand at room temperature for 2 h. The mixture was diluted with 20 ml of ether, washed with saturated $NaHCO_3$ and NaCl solutions, and then dried over $MgSO_4$. Concentration of the solution gave 25.8 mg of a colorless oil. Chromatography of (3 g of silica gel, 20:1 then 10:1 hexane–ethyl acetate) the oil gave 22.7 mg (0.076 mmol, 91%) of **29** as the 1:1 mixture of the C-7 epimers. Each of the stereoisomers was separated by repeated HPLC (20:1 hexane–ethyl acetate). **29a**: Colorless oil: IR 1720 (s) cm^{-1}; ^1H NMR δ=0.72 (3H, s), 0.88 (3H, d, J=6.8 Hz), 1.01 (3H, s), 1.04 (3H, d, J=6.8 Hz), 1.2—2.8 (8H, m), 3.70 (1H, dd, J=6.8 and 4.5 Hz), 4.38 (1H, d, J=12.0 Hz), 4.42 (1H, d, J=12.0 Hz), and 7.18 (5H, broad s); MS (25 eV) m/z (rel intensity) 209 ($M^+-C_7H_7$, 28) and 161 (100). **29b**: Colorless oil: IR 1725 (m) cm^{-1}; ^1H NMR δ=0.88 (3H, d, J=6.0 Hz), 0.90 (3H, s), 0.91 (3H, d, J=6.0 Hz), 1.06 (3H, s), 1.2—2.5 (8H, m), 3.49 (1H, dd, J=7.7 and 3.5 Hz), 4.40 (1H, d, J=12.0 Hz), 4.42 (1H, d, J=12.0 Hz), and 7.21 (5H, broad s); MS (25 eV) m/z (rel intensity) 300 (M^+, 2), 209 ($M^+-C_7H_7$, 28) and 161 (100).

(±)-Pinguisone (2). In order to prepare 5-benzyloxy deriv-

atives of **27** (**31**), we adopted a similar procedure to that used for the synthesis of **27** from **25**. A reaction of the enolates derived from 80.2 mg (27 mmol) of **29** with ethyl iodoacetate gave 69.8 mg (0.18 mmol, 68%) of keto esters **30** as a colorless oil and 8.8 mg (11%) of the recovery. Hydrolysis of **30** (69.8 mg) followed by acid-catalyzed dehydration gave 32.0 mg (0.094 mmol, 52%) of a mixture of the butenolides (**31**). **31a**: Colorless oil; IR 1805 (s) and 1770 (s) cm^{-1}. **31b**: Colorless oil; IR 1798 (s) and 1760 (s) cm^{-1}; ^1H NMR δ=0.80 (3H, s), 0.89 (3H, s), 1.03 (3H, d, J=6.5 Hz), 1.08 (3H, d, J=6.8 Hz), 1.0—2.6 (6H, m), 3.53 (1H, dd, J=7.5 and 3.0 Hz), 4.26 (1H, d, J=12.0 Hz), 4.54 (1H, d, J=12.0 Hz), 4.68 (1H, broad dd, J=11.5 and 8.0 Hz), 5.52 (1H, dd, J=1.8 and 1 Hz), and 7.19 (5H, s).

To a solution of 12.9 mg (0.038 mmol) of **31** in 0.5 ml of CH_2Cl_2 was added 0.64 ml of 0.22 M BBr_3 solution in CH_2Cl_2 at 0°C. After 5 min stirring at 0°C, to the reaction mixture were added 0.5 ml of saturated aqueous $NaHCO_3$ solution and 20 ml of ether. The organic layer was separated, washed with saturated brine, and then dried over $MgSO_4$. Concentration of the solution gave 9.6 mg of a yellow oil. Chromatography (1.5 g of silica gel; 5:1 then 1:1 hexane–ethyl acetate) of the oil gave 7.9 mg (0.032 mmol, 83%) of a mixture of hydroxy lactones **32**. **32a**: Colorless oil: IR 3630 (w), 3450 (broad w), 1798 (m), 1760 (s), and 1750 (sh) cm^{-1}; ^1H NMR δ=0.75 (3H, s), 0.86 (3H, s), 0.96 (3H, d, J=7.0 Hz), 1.40 (3H, d, J=6.5 Hz), 4.16 (1H, dd, J=9.0 and 6.5 Hz), 4.83 (1H, broad dd, J=11.0 and 6.5 Hz), and 5.57 (1H, dd, J=1.5 and 1.5 Hz).

In a procedure similar to that employed for the synthesis of (±)-deoxopinguisone, **32** (7.9 mg, 0.032 mmol) was transformed into **33** (4.9 mg, 0.021 mmol, 66%) which was purified by silica-gel chromatography (1.5 g; 5:1 hexane–ethyl acetate). A mixture of 4.9 mg of **33**, 0.5 ml of DMSO, and 0.5 ml of acetic anhydride, was stirred overnight at room temperature. This reaction mixture was diluted with 20 ml of ether, washed with two portions of saturated aqueous $NaHCO_3$ and with a portion of saturated brine, and then dried over $MgSO_4$. Concentration of the solution followed by purification using a silica-gel column (2 g; 20:1 hexane–ethyl acetate) gave 3.0 mg (0.013 mmol, 62%) of a colorless oil (**3**) whose spectral characteristics are identical with those of natural pinguisone. (±)-**3**: IR 2980 (m), 1745 (s), 1460 (m), 1390 (m), 1152 (w), 1138 (w), 1075 (w), 1050 (w), 908 (w), and 832 (s) cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.82 (3H, s), 0.88 (3H, s), 1.06 (3H, d, J=6.8 Hz, 6-Me), 1.10 (3H, J=7.0 Hz, 3-Me), 1.90 (1H, dd, J=19.2 and 11.0 Hz, 5-H), 2.33 (1H, ddd, J= 18.2, 3.2, and 1.0 Hz, 7-H), 2.39 (1H, ddq, J=10.0, 8.0, and 6.8 Hz, 6-H), 2.71 (1H, dd, J=19.2 and 8.6 Hz, 5-H), 2.78 (1H, dd, J=18.2 and 2.0 Hz, 7-H), 2.80 (1H, broad, 3-H), 6.27 (1H, d, J=2.0 Hz, 2-H), and 7.31 (1H, J=2.0 and 0.8 Hz, 1-H).

We are grateful to Professor Yoshinori Asakawa of Tokushima Bunri University for kindly providing a copy of the ^1H NMR spectrum of natural deoxopinguisone.

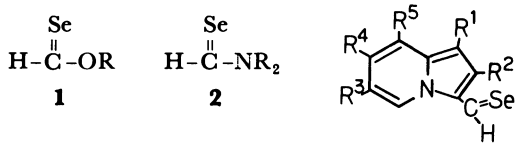
Reactions of 2,4,6-Tri-*t*-butylphenyllithium with *O*-Alkyl Selenoformates: Intermediate Formation of 2,4,6-Tri-*t*-butylselenobenzaldehyde

Akihiko Ishii, Renji Okazaki,* and Naoki Inamoto
Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received March 19, 1986)

2,4,6-Tri-*t*-butylphenyllithium reacts with *O*-alkyl selenoformates (**1**) at three different sites (i. e., the selenoformyl carbon, the selenoformyl hydrogen, and the selenium) to give 1,3,5-tri-*t*-butylbenzene, 2,4,6-tri-*t*-butylbenzaldehyde, 6,8-di-*t*-butyl-3,4-dihydro-4,4-dimethyl-1*H*-2-benzoselenin(**11**), bis(2,4,6-tri-*t*-butylphenylmethyl) di(and tri) selenides, bis(2,4,6-tri-*t*-butylphenyl) diselenide, and dibutyl diselenide depending on the reaction conditions and the alkyl group in **1**. The formation of **11** is explained in terms of the intermediacy of 2,4,6-tri-*t*-butylselenobenzaldehyde, which is trapped by condensation reaction with butylamine leading to *N*-(2,4,6-tri-*t*-butylbenzylidene)butylamine. Mechanism for the formation of these products is also discussed.

Recently much attention has been paid to the chemistry of the compounds having a multiple bond containing the third or fourth period elements. Among them are the selenocarbonyl compounds. Although sterically crowded selenoketones have been recently synthesized,[1] only a few have been reported for the selenoformyl compound. For example, selenoformaldehyde was generated by flash pyrolysis and characterized by photoelectron spectroscopy,[2] absorption,[3] or phosphorescence spectrum.[4] Selenoacetaldehyde was also characterized by microwave spectrum.[5] However, these selenoaldehydes are extremely unstable and can not exist in the monomeric form under normal conditions,[6] though selenoformaldehyde[7a] and selenobenzaldehyde[7b] have been reported to be stabilized by complexation with transition metals.

There have been isolated the compounds owning a selenoformyl group such as selenoformates **1**,[8] selenoformamide **2**,[9] and their vinylogs like indolizine-1-carboselenaldehyde **3**.[10] The selenoformyl group in these compounds, however, is stabilized by the mesomeric effect due to the lone-pair electrons on heteroatom.



1 **2** **3**

Although the thioaldehyde had also been known too unstable to be isolated, we recently reported the synthesis of 2,4,6-tri-*t*-butylthiobenzaldehyde (**4**) by reaction of 2,4,6-tri-*t*-butylphenyllithium (**5**) with *O*-ethyl thioformate.[11] Compound **4** was the first stable thioaldehyde without above-mentioned electronic stabilization by heteroatoms. In **4**, the highly reactive thioformyl group is protected by two bulky *o*-*t*-butyl groups from oligomerization and from attack by other reagents.

We undertook an investigation on the reaction of **5** with *O*-alkyl selenoformates **1** in the hope that it would also give stable 2,4,6-tri-*t*-butylselenobenzaldehyde (**6**).[12]

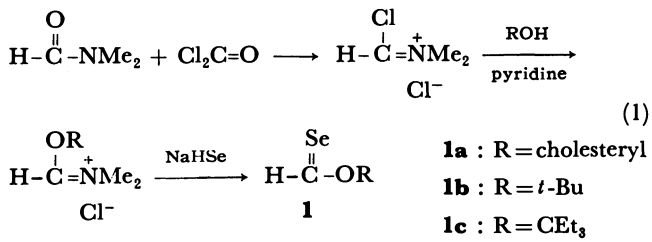
6 : X = Se

Results and Discussion

Synthesis of Selenoformates. *O*-Cholesteryl (**1a**), *O*-*t*-butyl (**1b**),and *O*-(1,1-diethylpropyl) selenoformates (**1c**) were prepared by the Barton's method (Eq. 1)[8] in 70, 22, and 6.5% yields, respectively, the latter two being new compounds.



(1)

1a : R=cholesteryl
1b : R=*t*-Bu
1c : R=CEt_3

We also tried to prepare selenoformates derived from primary alcohols (**1d**: R=ethyl; **1e**: R=2,2-dimethylpropyl). Although they existed in a reaction solution, as judged from the presence of characteristic ^{1}H NMR signals due to the selenoformyl proton at ca. δ 12 (cf., δ 12.07, 12.20, and 12.14 for **1a**, **1b**, and **1c**, respectively), they polymerized during concentration to give orange and pale orange jelly for **1d** and **1e**, respectively. The former jellied material was insoluble in organic solvents, while the latter was slightly soluble and showed a small peak due to the selenoformyl group.

The synthesis of *O*-aryl selenoformates (**1f**: R=phenyl; **1g**: R=*p*-methoxyphenyl) was also attempted, but only *N*,*N*-dimethylselenoformamide was obtained in 85 and 74% yields, respectively.

Reactions of Selenoformates 1 with 2,4,6-Tri-*t*-butylphenyllithium (ArLi, 5).† A tetrahydrofuran (THF) solution of **1** was added dropwise to **5**, prepared from

†Throughout this paper, Ar denotes 2,4,6-tri-*t*-butylphenyl.

Table 1. Reaction Products of **1a** and **1b** with **5** Prepared from **7** and Butyllithium

R	Yield/%			
	9	**10**	(n-BuSe)$_2$	**8**
Cholesteryl (**1a**)	48	4.5	62	29
t-Butyl (**1b**)	45	15	55	18

1-bromo-2,4,6-tri-t-butylbenzene (**7**) and butyllithium in THF at −78 °C, and then the reaction mixture was warmed to room temperature. The ^{1}H NMR spectrum of the reaction mixture showed the formation of 1,3,5-tri-t-butylbenzene (**8**) and a small amount of 2,4,6-tri-t-butylbenzaldehyde (**9**). ^{77}Se NMR spectra of the mixture gave signals at δ 360 and 364 for **1a** and δ 442 for **1b**. Appearance of these signals in the region of chemical shifts of selenides suggested the existence of relatively stable selenides in the crude reaction mixture. Chromatography of the reaction mixture on silica gel gave aldehyde **9**, butyl 2,4,6-tri-t-butylphenyl selenide (**10**), dibutyl diselenide, and **8** (Eq. 2, Table 1).

$$\mathrm{H\text{-}\overset{\overset{\mathrm{Se}}{\|}}{C}\text{-}OR + ArLi \xrightarrow{THF\ SiO_2} ArCHO\ (\mathbf{9}) + ArSeBu^n\ (\mathbf{10}) + (n\text{-}BuSe)_2 + ArH\ (\mathbf{8})} \quad (2)$$

Ar = 2, 4, 6-(t-Bu)$_3$C$_6$H$_2$

The fact that the amounts of aldehyde **9** and dibutyl diselenide were much increased than that before the chromatography indicates the presence of an intermediate which afforded **9** and dibutyl diselenide by hydrolysis on silica gel. The intermediate is considered to be monoselenoacetal **I** formed from the reaction of initial adduct **II** with 1-bromobutane generated in the preparation of **5** (Eq. 3). The formation

$$\mathbf{1} + \mathbf{5} \longrightarrow \underset{\mathbf{II}}{\mathrm{Ar\text{-}\overset{\overset{H}{|}}{\underset{\underset{SeLi}{|}}{C}}\text{-}OR}} \xrightarrow{n\text{-}BuBr} \underset{\mathbf{I}}{\mathrm{Ar\text{-}\overset{\overset{H}{|}}{\underset{\underset{SeBu^n}{|}}{C}}\text{-}OR}} \quad (3)$$

a : R = cholesteryl

b : R = t-Bu

of **II** is reasonable by analogy with known reactivity of formates and thioformic O-esters. The appearance in ^{77}Se NMR of two signals with similar chemical shift and intensity in the reaction of **1a** also gives support to the structure of **I**, for two diastereomers due to chiral centers adjacent to the ether oxygen should exist in **Ia**. Since some monoselenoacetals have been isolated,[8b,13] the instability of monoselenoacetal **I** is probably due to its benzylic structure with high reactivity.

Since the above results suggested that **II** reacted with 1-bromobutane before it was cleaved into selenoaldehyde **6** and ROLi, **5** was next prepared by the reaction of **7** with two equivalents of t-butyllithium in order to avoid the coexistence of an alkyl halide. Reactions of selenoformates **1** with **5** prepared in this way afforded results shown in Eq. 4 and Table 2.

Table 2. Reaction Products of **1a**, **1b**, and **1c** with **5** Prepared from **7** and t-Butyllithium

Run	**1**	Temp/°C	Yield/%				
			11	**9**	**12** (n=2,3)	**13**	**8**
1	**1a**	R.t.	—	52	—	2	37
2	**1a**	60	12	5	17, 10	Trace	35
3	**1b**	R.t.	32	13	—	2	35
4	**1b**	40	44	7	—	5	28
5	**1c**	Reflux	Trace	16	Trace	8	60

$$\mathbf{1} + \mathbf{5} \xrightarrow[THF]{-78\,^\circ C} \xrightarrow[\text{in Table 2}]{Temp.} \underset{\mathbf{11}}{\text{Se-ring}} + ArCHO\ (\mathbf{9}) + ArCH_2Se_nCH_2Ar\ (\mathbf{12}, n=2,3) + (ArSe)_2\ (\mathbf{13}) + ArH\ (\mathbf{8}) \quad (4)$$

After the reaction was conducted at −78 °C, the temperature of the reaction mixture was allowed to rise as indicated in Table 2. Although the intermediate **IIa** was stable at room temperature to give aldehyde **9** by hydrolysis (Run 1), the reaction of **1a** at 60 °C gave a new product, 6,8-di-t-butyl-3,4-dihydro-4,4-dimethyl-1H-2-benzoselenin (**11**) (Run 2). In the case of **1b**, **11** was obtained even at room temperature (Runs 3 and 4). This unusual formation of dihydrobenzoselenin **11** is very interesting since it strongly suggests the intermediacy of selenoaldehyde **6**. We previously observed that thioaldehyde **4** was very stable at room temperature, but it isomerized into dihydrobenzothiopyran **14** when heated at about 200 °C.[14] In view of this reactivity of **4**, the formation of **11** in the present

$$\underset{\mathbf{4}}{ArCHS} \xrightarrow{200\,^\circ C} \underset{\mathbf{14}}{\text{S-ring}}$$

reaction is most probably explicable in terms of intermediacy of **6**. The collapse of **IIb** occurred at a lower temperature than that of **IIa**, which indicated that t-BuO$^-$ anion was a more effective leaving group than cholesteryloxyl group. Since this is most likely explained in terms of steric acceleration, we next employed **1c** with the expectation that **IIc** could release Et$_3$CO$^-$ anion at a lower temperature than **IIb**. However, **IIc** was considerably stable and required reflux temper-

ature for cleavage, giving only a trace amount of **11**. This is probably because steric acceleration cannot overcome the intrinsic poor reactvity of Et_3CO^- anion as a leaving group.

Since the tetrahedral intermediate **II** is more stable than a similar intermediate in the reaction of **5** with *O*-ethyl thioformate which is found to be collapsed into the thioaldehyde **4** below −30°C, the conversion of **II** into the selenoaldehyde **6** seems to require higher temperatures where **6** can not exist as such and is isomerized to the dihydrobenzoselenin **11**. In order to collapse **II** into **6** at lower temperatures, hexamethylphosphoric triamide, dry HCl gas, or trimethylsilyl trifluoromethanesulfonate was added to the reaction mixture, but all of them were ineffective, the product in each case being aldehyde **9**.

Trapping of 6. Since selenoaldehyde **6** seemed to be too unstable to be isolated at ordinary temperature, some attempts to trap it were made. Since some thioketones[15a] and thioaldehydes[15b] are known to undergo the Diels-Alder reaction with dienes, 2,3-dimethylbutadiene was added to the reaction mixture with **1b** at 0°C and the resulting mixture was allowed to warm to room temperature. However, no [4+2] adduct was obtained probably because of steric congestion by Ar group; the products were dihydrobenzoselenin **11** (18%), aldehyde **9** (17%), **12** (trace), diselenide **13** (9%), and **8** (10%).

Reactions with 1,1-dimethylhydrazine were also attempted in the hope that selenoaldehyde **6** would be reactive enough to undergo condensation with the hydrazine as it was formed. Reaction in the presence of the hydrazine, however, gave no expected hydrazone **15** but ether **16** was obtained in a reasonable yield (25%).

$ArCH{=}NNMe_2$ **15** $ArCH_2OBu^t$ **16** $ArCH{=}NBu^n$ **17**

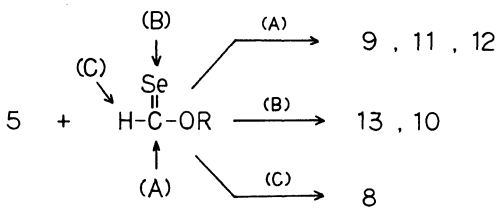
Since the ether **16** is considered to be formed by reductive cleavage of **II** by 1,1-dimethylhydrazine, the reaction with butylamine, which is a weaker reducing agent than the hydrazine, was next carried out. In this case imine **17** was obtained, though in a low yield (1.3%), along with **16** (25%).

The formation of imine **17** suggests the existence of selenoaldehyde **6** in the reaction solution, in view of similar reactivities of the corresponding thioaldehyde **4**, which reacts with butylamine at 70°C to give **17** quantitatively.[16] Furthermore this indicates that **6** has much greater reactivity toward amines than **4**, since **4** does not react with butylamine at room temperature.[17]

We consider that the formation of dihydrobenzoselenin **11** and the condensation product **17** is strong evidence for the intermediacy of selenoaldehyde **6**.

Mechanism. Since the reaction products of **5** with selenoformates **1** depend on the preparative method of **5** as described above, we classify the reactions into Case I and Case II for the convenience of the following disccussion. Case I is reactions with butyllithium as lithiating agent (Table 1) and Case II is those with *t*-buytllithium (Table 2).

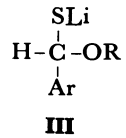
Though the reactions of selenoformate **1** with **5** afford several kinds of compounds, the formation of them can be explained by three reaction paths (A)—(C) as shown in Scheme 1. These paths correspond to reac-



Scheme 1.

tions at the selenocarbonyl carbon, the selenium, and the selenoformyl hydrogen, respectively, and the products in these paths are as follows: (A): aldehyde **9** (Cases I, II), dihydrobenzoselenin **11** (Case II), polyselenide **12** (Case II); (B): diselenide **13** (Case II), selenide **10** (Case II); (C): hydrocarbon **8** (Cases I, II). We next discuss the details of each path.

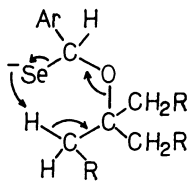
(1) Path (A). Path (A), leading to initial adduct **II**, is desirable for the formation of selenoaldehyde **6**. The fact that the reaction of **5** with *O*-ethyl thioformate gives thioaldehyde **4** at −30°C, while that with *O*-alkyl selenoformates **1** does not afford selenoaldehyde **6** under similar conditions, indicates that the initial adduct **II** in the later reaction is thermally more stable than a similar adduct **III** in the former reaction. In



III

Case I reaction, therefore, **II** is quenched by 1-bromobutane to give selenoacetal **I**, whose hydrolysis on silica gel leads to aldehyde **9** and *n*-BuSeH. Case II reactions afford dihydrobenzoselenin **11**, aldehyde **9**, and selenides **12** depending on the reaction temperature. The formation of **11** can be explained in terms of intermediacy of **6** as mentioned previously. The diselenide **12** (n=2) probably results from oxidative dimerization of selenol $ArCH_2SeH$ which is formed by reduction of **6** with RO^- anion (R=cholesteryl) having α-hydrogen. Similar reduction with an alkoxide ion having α-hydrogen has been reported for thioketones.[18] The triselenide **12** (n=3) would be an oxidative coupling product between $ArCH_2SeH$ and $ArCH_2SeSeH$ which is formed by the reaction of $ArCH_2Se^-$ anion with selenium.[19] Aldehyde **9** is thought to be formed by hydrolysis of unreacted **II** and/or by a process as shown below.

(2) Path (B). When the addition of **5** occurs on selenium of the selenocarbonyl group, adduct **IV** is



formed (Eq. 5). The intermediate **IV** is not so stable

$$\underset{\text{IV}}{\text{H-C(SeAr)(Li}^+\text{)-OR}} \longrightarrow \text{ArSeLi} + \underset{\text{V}}{\text{H-C-OR}} \qquad (5)$$

and decomposes to ArSeLi and alkoxycarbene **V**. ArSeLi thus formed is quenched by 1-bromobutane to yield **10** (Case I) or protonated to give ArSeH (Case II). ArSeH is gradually oxidized to **13** during workup. Though alkoxycarbenes have been reported to dimerize,[20] the dimer of **V** could not be found.

Such heterophilic additions of organolithium or organomagnesium reagents have been reported for thioketones and selenoketones. In the reaction of bulky 2,6-dimethylphenyllithium with di-*t*-butyl thioketone, similar decomposition of an initial adduct leading to carbenes has been observed.[21] We also reported similar formation of carbene in the reaction of 1,1,3,3-tetramethyl-2-indanselone with some Grignard reagents.[22] The bulkiness of Ar group is considered to make the decomposition even easier in the present case.

When the reaction of **1b** with **5** was carried out at −98 °C, the ratio of Se-addition/C-addition was 15/40 (Case I) or 17/26 (Case II) while the ratio of 1/10—1/20 at −78 °C. Thus the ratio of Se-addition was increased at lower temperatures. This is in keeping with the observation reported for the reaction of di-*t*-butyl thioketone with phenyllithium that the thiophilic addition is more advantageous at lower temperatures.[21]

(3) Path (C). In order to obtain direct evidence for abstraction of a selenoformyl proton of **1** by **5**, **5** was allowed to react with *O*-cholesteryl selenoformate-*d* (**1a-*d***) having a deuterated selenoformyl group. 1,3,5-Tri-*t*-butylbenzene (**8**) thus obtained (35% yield) was analyzed for deuterium content by mass spectrometry to be 6%, providing conclusive evidence for the abstraction of the selenoformyl proton. This is, to our knowledge, the first demonstration of the proton abstraction from a selenoformyl group although formyl proton abstraction from *O*-ethyl formate[23] and that from formamides and thioformamides[24] have been reported.

Although the reason for the formation of protium species ArH is not clear at the present stage, it is probably due to proton abstraction from the solvent (THF) by unreacted **5** and/or to hydrogen abstraction by 2,4,6-tri-*t*-butylphenyl radical generated by single electron transfer from **5** to **1**.

Experimental

Melting points are uncorrected. ^{1}H (90 MHz) and ^{13}C (22.49 MHz) NMR spectra were measured in $CDCl_3$ with a JEOL FX-90Q spectrometer using tetramethylsilane as an internal standard. ^{77}Se NMR spectra were recorded at 17.03 MHz with a JEOL FX-90Q spectrometer, whose chemical shifts were measured in $CDCl_3$ with dimethyl selenide as an external standard. The mass spectra were recorded with a JEOL JMS-D300 mass spectrometer. Preparative liquid chromatography (PLC) was carried out using JAI Gel 1H columm (Japan Analytical Industry) with chloroform as solvent. All reactions were carried out under argon.

Preparation of Selenoformate 1. Selenoformates (**1a**, **b**, and **c**) were prepared by the Barton's method.[8]

O-Cholesteryl selenoformate (**1a**) was obtained in 70%; mp 128—131 °C; ^{1}H NMR δ=12.07 (HC=Se) (δ=12.15 in Ref. 8); ^{77}Se NMR δ=1006. *O*-*t*-Butyl selenoformate (**1b**) (22%) was recrystallized from hexane at −30 °C; mp 50.5—51.5 °C; ^{1}H NMR δ=1.57 (9H, s, *t*-Bu) and 12.20 (1H, s, HC=Se); ^{13}C NMR δ=28.4 [C($\underline{C}H_3)_3$], 89.5 [$\underline{C}(CH_3)_3$], and 215.0 (C=Se); ^{77}Se NMR δ=1052; MS *m/z* (rel intensity) 166 (M^+, 12) and 57 (100). Found *m/z* 165.9903. Calcd for $C_5H_{10}O^{80}Se$: M, 165.9897. *O*-(1,1-Diethylpropyl) selenoformate (**1c**) (6.5%) was obtained as an orange oil after Kugelrohr distillation (70 °C, 0.05 mmHg).# ^{1}H NMR δ=0.92 (9H, t, *J*=7 Hz), 1.84 (6H, q, *J*=7 Hz), and 12.14 (1H, s, $\underline{H}C$=Se); MS *m/z* (rel intensity) 208 (M^+, 2), 99 (50), 69 (76), 57 (100), and 55 (59). Found *m/z* 208.0371. Calcd for $C_8H_{16}O^{80}Se$: M, 208.0366.

Preparation of ArLi (5). I) *n*-BuLi (1 equiv) was added to a solution of ArBr (**7**)[25] (1 equiv) in THF at −78 °C and the resulting mixture was stirred for 15 min at −78 °C before use. **5** prepared in this way is denoted as ArLi(I). II) *t*-BuLi (2 equiv) was added to the solution of **7** (1 equiv) in THF at −78 °C and the resulting yellow solution was stirred at −78 °C till the yellow color disappeared (ca. 1 h). **5** prepared by this method is denoted as ArLi(II).

Reactions of 1 with ArLi(I). (a) A solution of **1a** (0.331 g, 0.693 mmol) in THF (3 ml) was added to ArLi(I) (0.631 mmol) in THF (5 ml) at −78 °C during 5 min. The mixture was stirred at this temperature for 30 min. The yellow reaction mixture was warmed to room temperature to give an orange red solution. After stirring for 30 min at this temperature, water and ether were added. The ethereal extract was washed with water and dried ($MgSO_4$). Removal of the solvent under reduced pressure left 0.497 g of an orange solid, whose ^{77}Se NMR showed major peaks at δ 360 and 364, and other small peaks at δ 224 (ArSeBu^n, **10**), 313 (*n*-BuSe)$_2$, and 345, 349, 491, and 498 (unknown). This crude reaction mixture was subjected to chromatography (silica gel, hexane–dichloromethane 10:1). The first yellow fraction was separated again by PLC to afford ArH (**8**) (44.9 mg, 29%), dibutyl diselenide[26] (53.2 mg, 62%), and ArSeBu^n **10** (10.9 mg, 4.5%). **10** was recrystallized from ethanol giving colorless crystals. They once melted at 67.5—68.0 °C and crystallized again. These second crystals melted at 77.5—78.0 °C. ^{1}H NMR δ=0.80—1.61 [34H, m; 18H for *o*-*t*-Bu (δ=1.61), 9H for *p*-*t*-Bu (δ=1.30), 3H for ArSe(CH$_2$)$_3$-$\underline{C}H_3$ (δ=0.87, t, *J*=7 Hz), and 4H for ArSeCH$_2\underline{C}H_2\underline{C}H_2CH_3$ (m)], 2.46 (2H, t, *J*=8 Hz, ArSe$\underline{C}H_2$CH$_2$CH$_2$CH$_3$), 7.37 (2H, s, aromatic); MS *m/z* (rel intensity) 382 (M^+, 25), 367 (4), 336

1 mmHg=133.322 Pa.

(2), 311 (4), and 57 (100). Found: C, 69.08; H, 10.29%. Calcd for $C_{22}H_{38}Se$: C, 69.26; H, 10.04%. The second fraction was purified by PLC to give ArCHO (**9**)[27] (83.4 mg, 48%): Mp 189.5—190.5 °C after recystallization from methanol. ^1H NMR δ=1.32 (9H, s, *p*-*t*-Bu), 1.36 (18H, s, *o*-*t*-Bu), 7.37 (2H, s, aromatic), and 11.11 (1H, s, CHO); ^{13}C NMR δ=202.7 (CHO), 150.8, 147.4, 137.2, 36.6, 35.1, 32.6, and 31.3; MS *m*/*z* (rel intensity) 274 (M^+, 22), 259 (100), 241 (45), 217 (42), and 57 (72). Found: C, 82.94; H, 10.97%. Calcd for $C_{19}H_{30}O$: C, 83.15; H, 11.02%.

(b) A solution of **1b** (0.133 g, 0.803 mmol) in THF (1 ml) was added to ArLi(I) (0.804 mmol) in THF (5 ml) at −98 °C. The reaction mixture was stirred for 20 min at −98 °C and warmed to room temperature and to this was added aqueous ammonium chloride and ether. The ethereal extract was washed with water and dried ($MgSO_4$). Removal of the solvent gave 0.358 g of an orange oil, whose ^{77}Se NMR showed a peak at δ 442. This reaction mixture was subjected to chromatography (silica gel, hexane–dichloromethane, 10:1). The first fraction contained **8**, **10**, and dibutyl diselenide, whose yields were determined by ^1H NMR to be 18, 15, and 55%, respectively. The second fraction was **9** (87.1 mg, 40%).

Reactions of 1 with ArLi(II). (a) A THF solution of **1a** (0.474 g, 0.992 mmol) in THF (5 ml) was added to ArLi(II) (0.902 mmol) in THF (10 ml) at −78 °C during 10 min. The resulting reaction mixture was stirred for 20 min at this temperature and warmed to room temperature. To the red solution was added aqueous ammonium chloride and ether, when much red selenium was precipitated. The organic layer was washed with water and dried ($MgSO_4$). After removal of the solvent, the residue was subjected to chromatography (silica gel, hexane–dichloromethane 10:1) and PLC to give **9** (129 mg, 52%), **8** (81.2 mg, 37%), and $(ArSe)_2$ (**13**)[28] (5.2 mg, 2%). **13** was recrystallized from ethanol giving an orange crystal: Mp 251.2—253.2 °C. ^1H NMR δ=1.28 (36H, s, *o*-*t*-Bu), 1.32 (18H, bs, *p*-*t*-Bu), and 7.25 (4H, s, aromatic); ^{77}Se NMR δ=521; MS *m*/*z* (rel intensity) 650 (M^+, 7), 326 (8), and 57 (100). Found: *m*/*z* 650.2887. Calcd for $C_{36}H_{58}{}^{80}Se_2$: M, 650.2867.

The following reactions were carried out in a similar way.

(b) **1a** (0.447 g, 1.00 mmol) was reacted with ArLi(II) (1.00 mmol). The resulting reaction mixture was heated to 60 °C and stirred at this temperature for 12 h. Products were dihydrobenzoselenin **11** (40 mg, 12%), $ArCH_2Se_nCH_2Ar$ (**12**, 130 mg, from ^1H NMR *n*=2, 17%; *n*=3, 10%), **9** (14.8 mg, 5%), **13** (trace), and **8** (85.5 mg, 35%). **11** was recrystallized from ethanol to give colorless needles: Mp 180.5—181.0 °C; ^1H NMR δ=1.32 (9H, s, *t*-Bu), 1.47 (9H, s, *t*-Bu), 1.53 [6H, s, $SeCH_2C(CH_3)_2$], 2.76 [2H, s, $SeCH_2C(CH_3)_2$], 4.04 (2H, s, benzyl), and 7.35 (2H, s, aromatic); ^{13}C NMR δ=147.8, 145.9, 145.9, 131.8, 121.2, 121.3, 38.0, 35.9, 34.9, 32.8, 31.9, 31.5, 30.6, and 18.2; ^{77}Se NMR δ=89.3; MS *m*/*z* (rel intensity) 338 (M^+, 34), 323 (13), 281 (18), 229 (14), and 57 (100). Found: C, 67.36; H, 9.07%. Calcd for $C_{19}H_{30}Se$: C, 67.64; H, 8.96%. Found: *m*/*z* 338.1500. Calcd for $C_{19}H_{30}{}^{80}Se$: M, 338.1511. **12**, a mixture of selenides, was dissolved in methanol. Insoluble orange solid contained triselenide (**12**, *n*=3) as judged by mass spectroscopy and showed peaks at δ 512, 521, 619, and 719 in ^{77}Se NMR. From the filtrate was obtained diselenide (**12**, *n*=2) after repetitive recrystallization from ethanol–hexane: Yellow crystals, mp 150.0—152.0 °C. ^1H NMR δ=1.58 (36H, s, *o*-*t*-Bu), 1.30 (18H, s, *p*-*t*-Bu), 5.05 (4H, s, benzyl), and 7.33 (4H, s, aromatic); ^{77}Se NMR δ=412; MS *m*/*z* (rel intensity) 678 (M^+, 0.1), 259 (38), 243 (100), 149 (19), and 57 (93). Found: C, 67.51; H, 9.53%. Calcd for $C_{38}H_{62}Se_2$: C, 67.43; H, 9.23%.

(c) **1b** (0.113 g, 0.684 mmol) in THF (2 ml) was added to ArLi(II) (0.683 mmol) in THF (5 ml) at −78 °C. The resulting reaction mixture was warmed to room temperature and stirred at this temperature for 1 h. Products were **11** (74.5 mg, 32%), **9** (32.5 mg, 13%), **13** (5.4 mg, 2%), and **8** (58.6 mg, 35%).

(d) **1b** (0.111 g, 0.670 mmol) in THF (2 ml) was added to ArLi(II) (0.699 mmol) in THF (5 ml) at −78 °C. The resulting red reaction mixture was heated to 40 °C and stirred at this temperature for 30 min. Products were **11** (100 mg, 44%), **9** (13.6 mg, 7%), **13** (11.3 mg, 5%), and **8** (61.0 mg, 28%).

(e) **1b** (0.083 g, 0.50 mmol) in THF (1 ml) was added to ArLi(II) (0.50 mmol) at −98 °C. The reaction mixture was heated to 60 °C and to this was added water. **11** was obtained in 26% (43 mg). **8** was obtained as a mixture with **13** and ArSeH. This mixture was stirred with KOH (1 grain) in dichloromethane and methanol in order to convert ArSeH to **13**. Separation by PLC yielded **8** (30 mg, 25%) and **13** (27 mg, 17%).

(f) **1c** (0.104 g, 0.500 mmol) in THF (0.5 ml) was added to ArLi(II) (0.503 mmol) in THF (5 ml) at −78 °C. The resulting orange reaction mixture was stirred at room temperature for 12 h and at reflux for 16 h. Products were **11** (trace), **9** (22 mg, 16%), **12** (trace), **13** (13 mg, 7.8%), and **8** (74 mg, 60%).

Reaction of 1 and 5 with Hexamethylphosphoric Triamide (HMPA). (a) A solution of **1a** (0.400 g, 0.838 mmol) in THF (5 ml) was added to ArLi(II) (0.757 mmol) in THF (5 ml) at −78 °C. The yellow reaction mixture was stirred at this temperature for 1 h and was added HMPA (1.44 g, 8.00 mmol) at −78 °C. The orange reaction mixture was warmed to room temperature and stirred at room temperature for 2 d. TLC of the reaction mixture showed that **11** was not formed. Silica-gel chromatography and PLC gave **9** (76.2 mg, 37%), **12** (trace), **13** (trace), and **8** (89.7 mg, 48%).

(b) A solution of **1b** (0.172 g, 0.680 mmol) in THF (2 ml) was added to ArLi(II) (0.680 mmol) at −78 °C. The reaction mixture was warmed to 0 °C and again cooled to −78 °C. To the red orange reaction mixture was added HMPA (0.72 g, 4.0 mmol). The temperature of the resulting mixture was allowed to rise to −30 °C and stirred at this temperature for 1 h, and to this was added water. Silica-gel chromatography and PLC afforded **9** (59.9 mg, 36%), **13** (11.4 mg, 5%), and **8** (81.8 mg, 49%).

Reaction of 1a and 5 with Dry HCl Gas. A solution of **1a** (0.321 g, 0.673 mmol) in THF (5 ml) was added to ArLi(II) (0.619 mmol) in THF (5 ml) at −78 °C. The reaction mixture was allowed to rise to room temperature. The solvent was removed in vacuo and dichloromethane (15 ml) was added. The resulting reaction mixture was cooled to −78 °C and excess dry HCl gas was bubbled into it. The yellow suspension was warmed to room temperature. When dichloromethane was removed in vacuo, a gas of unpleasant smell was detected (probably hydrogen selenide, absorbed by KOH). Products were **9** (70.0 mg, 41%), **13** (trace), and **8** (83.0 mg, 54%).

Reaction of 1b and 5 with Trimethylsilyl Trifluoromethanesulfonate (TMSOTf). A solution of **1b** (0.106 g, 0.643 mmol) in THF (2 ml) was added to ArLi(II) (0.643 mmol) in THF (5 ml) at −78 °C. The reaction mixture was warmed to 0 °C. The solvent was removed in vacuo and dichloromethane (10 ml) was added. The yellow suspension

was warmed to room temperature and stirred for 18 h. TLC showed no **11**. Additional TMSOTf (0.146 g, 0.657 mmol) was added at 0 °C and the mixture was stirred for 10 h at room temperature. **9** (62.1 mg, 35%), **13** (7.8 mg, 4%), and **8** (84.2 mg, 53%) were obtained.

Trapping Reaction of 6 with Butylamine. A solution of **1b** (95.8 mg, 0.58 mmol) in THF (1 ml) was added to ArLi(II) (0.579 mmol) in THF (5 ml) at −78 °C. The reaction mixture was warmed to 0 °C and to this was added butylamine (0.422 g, 5.77 mmol) in THF (1 ml). The resulting reaction mixture was stirred for 2 h at room temperature. After the addition of water and ether, the separated ethereal layer was washed successively with dil HCl, dil aqueous sodium carbonate, and water, and dried ($MgSO_4$). After chromatographic separation, there were obtained imine **17** (2.5 mg, 1.3%), ether **16** (47.8 mg, 25%), **9** (16.2 mg, 10%), **12** (trace), **13** (12.9 mg, 7%), and **8** (62.3 mg, 48%). **17** was identified by comparing its ^{1}H NMR spectrum with that of an authentic sample.[16] **16** was recrystallized from ethanol–water to give colorless crystals: Mp 94.8—95.4 °C; ^{1}H NMR δ=1.29 (9H, s),1.34 (9H, s), 1.52 (18H, s), 4.86 (2H, s, benzyl), and 7.41 (2H, s, aromatic); MS *m/z* (rel intensity) 332 (M^+, 7.6), 259 (7.6), 247 (18), 219 (56), and 57 (100). Found: *m/z* 332.3076. Calcd for $C_{23}H_{40}O$: M, 332.3077.

An Attempt to Trap 6 with 2,3-Dimethyl-1,3-Butadiene. A solution of **1b** (0.100 g, 0.608 mmol) in THF (1 ml) was added to ArLi(II) (0.607 mmol) in THF (5 ml) at −78 °C. The reaction mixture was stirred at this temperature for 30 min and warmed to 0 °C. 2,3-Dimethyl-1,3-butadiene (0.508 g, 6.3 mmol) in THF (1 ml) was added and the resulting mixture was stirred for 2 h at room temperature. Chromatographic purification gave **11** (37.8 mg, 18%), **9** (28.4 mg, 17%), **12** (trace), **13** (8.6 mg, 9%), and **8** (69.8 mg, 47%).

An Attempt to Condense 6 with 1,1-Dimethylhydrazine. A solution of **1b** (94.4 mg, 0.602 mmol) in THF (1 ml) was added to ArLi(II) (0.602 mmol) in THF (5 ml) at −78 °C. The reaction mixture was stirred for 30 min at this temperature and warmed to 0 °C. 1,1-Dimethylhydrazine (0.364 g, 6.05 mmol) in THF (1 ml) was added and the resulting reaction mixture was stirred for 1.5 h at room temperature. Products obtained were **16** (50.7 mg, 25%), **9** (19.9 mg, 12%), **13** (16.1 mg, 18%), and **8** (80.0 mg, 54%).

O*-Cholesteryl Selenoformate-*d* (1a-*d*).** **1a-*d was prepared in 67% yield by the Barton's method, using *N,N*-dimethylformamide-d_7 (99%, Merck) instead of *N,N*-dimethylformamide in preparation of imidoyl chloride: Mp 135—137 °C (after recrystallization from hexane); ^{1}H NMR δ= 0.69—2.28 (43H, m), 2.50—2.60 (2H, bd), and 5.30—5.78 (2H, m). Selenoformyl proton was observed at δ=12.06 but negligibly small. ^{77}Se NMR δ=1000.

Reaction of *O*-Cholesteryl Selenoformate-*d* (1a-*d*) with 5. A solution of **1a-*d*** (0.319 g, 0.666 mmol) in THF (3 ml) was added to ArLi(II) (0.619 mmol) in THF (10 ml) at −78 °C. The reaction mixture was heated to 60 °C and stirred at this temperature for 20 h. Chromatographic purification afforded a mixture of ArH (**8**) and ArD (**8-*d***) (53.7 mg, 35%). The ratio of **8**/**8-*d*** was 94/6 (by mass spectrum).

Synthetic Versatility of *N*-(Silylmethyl)imines: Water-Induced Generation of *N*-Protonated Azomethine Ylides of Nonstabilized Type and Fluoride-Induced Generation of 2-Azaallyl Anions

Otohiko TSUGE,* Shuji KANEMASA, Akira HATADA, and Koyo MATSUDA

(Received March 19, 1986)

N-(Silylmethyl)imines generate *N*-protonated azomethine ylides of nonstabilized type when treated with water in HMPA, which undergo stereospecific and regioselective cycloadditions with electron-poor olefins affording *N*-unsubstituted pyrrolidines. On the other hand, fluoride-induced desilylation of the imines leads to 2-azaallyl anions which are found to be synthetic equivalents of aminomethyl anion in the Michael additions with electron-poor olefins and nucleophilic additions with carbonyl compounds.

Since Vedejs and Martinez reported the first generation of azomethine ylides from *N*-(trimethylsilylmethyl)iminium salts,[1] this reaction has been applied to organic synthesis more frequently than any other methods known for the generation of azomethine ylide 1,3-dipoles. A variety of methodologies for the preparation of *N*-(silylmethyl)iminium salts were devised,[2] and this generation method has been successfully utilized as a key reaction in the synthesis of some natural products.[3]

To be noteworthy is that this method generates nonstabilized azomethine ylides which carry no substituents capable of stabilizing the ylide centers. Even the azomethine ylides carrying no substituents at the carbons are available according to the related reactions.[4] A variety of substituents such as alkyl,[5] acyl,[6] and silyl[7] can be introduced on the nitrogen.

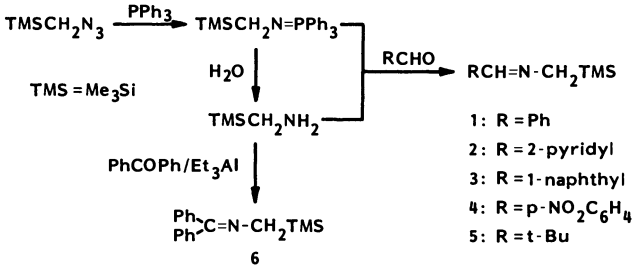
After our recent discovery of the general and convenient synthesis of *N*-(trimethylsilylmethyl)imines,[8] we have engaged in a research aiming at opening the synthetic utility of these imines. One attracting utilization is the generation of azomethine ylide 1,3-dipoles, and another is the generation of 2-azaallyl anions. So far there is no report available on the direct desilylation of *N*-(silylmethyl)imines leading to 2-azaallyl anions.[9]

The present article describes the water-induced generation of *N*-protonated azomethine ylides from *N*-(silylmethyl)imines,[10] and the desilylation of the imines without quaterization on the nitrogen leading to 2-azaallyl anions.

Results and Discussion

N-(Trimethylsilylmethyl)imines **1—5** derived from aldehydes are readily available by reactions of trimethylsilylmethyl azide with aldehydes in the presence of triphenylphosphine (Scheme 1).[8] As a good yield of trimethylsilylmethylamine is obtained from the reaction of the azide with triphenylphosphine and subsequent hydrolysis, condensations of this silylmethylamine with aldehydes can be also a convenient route to the *N*-(silylmethyl)imines **1—5**.

The azide method directly leads to *N*-(silylmethyl)imines by a simple one-flask procedure, but the imines have to be separated from triphenylphosphine oxide. This route can be conveniently applied to the synthesis of low-boiling or water-sensitive imines. On the other hand, the condensation method using trimethylsilylmethyamine needs one more step, in which the amine is separated from triphenylphosphine oxide by vacuum distillation. Accordingly, this condensation is favored when the imines can be hardly separated from triphenylphosphine oxide. Although benzophenone could not be converted into its imine **6** by either of the above two methods, **6** was successfully prepared by condensation of the silylmethylamine with benzophenone in the presence of triethylaluminum.



Scheme 1.

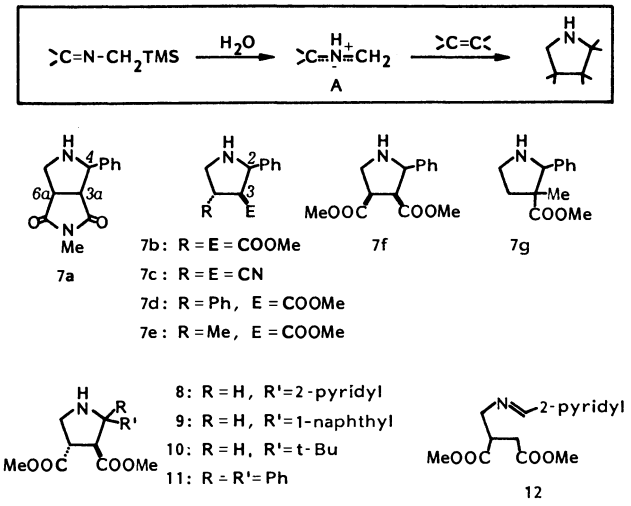
Water-Induced Generation of *N*-Protonated Azomethine Ylides of Nonstabilized Type. *N*-(Silylmethyl)imines react with water, slowly but cleanly at room temperature, in such a polar solvent as HMPA or DMF to generate *N*-protonated azomethine ylide 1,3-dipoles **A**. If electron-poor olefins are present, these ylides are captured as cycloadducts, *N*-unsubstituted pyrrolidines (Scheme 2).

N-(Benzylidene)trimethylsilylmethylamine **1** as an example was allowed to react with a variety of olefinic dipolarophiles, in HMPA in the presence of water and acetic acid for 12—24 h at room temperature, to give cycloadducts **7a—g** (Scheme 2 and Table 1). Water can be used in excess, but the use of more than five equivalents produces *N*-(benzylidene)methylamine as a tautomeric isomer of the corresponding *N*-protonated azomethine ylide. Less than one equivalent of acetic acid was employed, since acid catalyst was found to facilitate the ylide generation. Water, in this case,

Table 1. Water-Induced Cycloaddition of *N*-(Silylmethyl)imines with Olefins[a]

Imine	Olefin	Solvent	Time/h	Conditions[b]	Product	Yield/%[c]	2,3-cis/2,3-trans[d]
1	*N*-Methylmaleimide	HMPA	24	A	**7a**	100	1/2[e]
1	Dimethyl fumarate	HMPA	24	A	**7b**	100	1/1
1	Fumaronitrile	HMPA	24	A	**7c**	80	7/5
1	Methyl cinnamate	HMPA	24	A	**7d**	72	3/1
1	Methyl crotonate	HMPA	24	A	**7e**	65	2/1
1	Dimethyl maleate	HMPA	24	A	**7f**	100	3/7
1	Methyl methacrylate	HMPA	24	A	**7g**	75	4/3[f]
2	Dimethyl fumarate	THF	12	B	**8**	78	1/3
2	Dimethyl fumarate	HMPA	12	B	**12**	73	—
3	Dimethyl fumarate	HMPA	12	B	**9**	74	4/5
5	Dimethyl fumarate	HMPA	24	A	**10**	78	1/1
6	Dimethyl fumarate	HMPA	12	B	**11**	95	—

a) All reactions were carried out under nitrogen at room temperature. b) Each 1 mmol amounts of imines and olefins in 2 ml of solvent were allowed to react in the presence of: A: each 1 mmole of water and acetic acid or B: 1 mmol of water and a catalytic amount of acetic acid. c) Isolated yield. d) Determined by ^{1}H NMR. e) 3a,4-cis/3a,4-trans. f) 2,3-cis Isomer bears 3-ester cis to 2-phenyl.



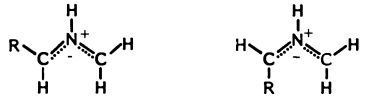
Scheme 2.

is not only a reagent neccessary for the generation of the ylide but also an inhibitor of polymerization of the dipolarophiles. When **1** is treated with *N*-methylmaleimide in very dry HMPA under nitrogen, the maleimide suffers from complete polymerization and **1** is quantitatively recovered.

Other *N*-(silylmethyl)imines **3** and **5**—**6** reacted with dimethyl fumarate under similar conditions to give the corresponding cycloadducts **9**—**11** (Scheme 2 and Table 1). Smooth generation of *N*-protonated azomethine ylide from **5** is quite interesting because this ylide is carrying no substituents which are capable of stabilizing the dipole centers.[11] Although similar reaction of the *N*-(silylmethyl)imine **2** bearing a 2-pyridyl substituent with dimethyl fumarate produced cycloadduct **8** when carried out in THF, the same reaction in HMPA afforded a Michael type product **12**. This difference will be discussed later.

The cycloadditions shown in Scheme 2 are exclusively stereospecific and regioselective, but awfully poor in stereoselectivity. In every case was formed an unseparable mixture of two stereoisomeric cycloadducts, endo and exo cycloadducts. Assignment of the stereostructures was based on $J_{3a\text{-}4}$ for **7a** or magnetic shielding of ester methyls by the adjacent phenyl moiety at the 2-position for **7b**, **7d**—**g**, and **8**—**9**. The 2-H of exo isomer (2,3-trans) of **7c** appeared in a lower field than that of endo isomer. Two isomers of **10** could not be assigned, but anyhow the isomer ratio was 1:1.

Two geometries are possible for the *N*-protonated azomethine ylide **A**, but *E*-isomer (*E*)-**A** should be much more stable than *Z*-isomer (*Z*)-**A** (Scheme 3).[12] Accordingly, two stereoisomers mentioned above are most likely to have been formed through endo and exo approaches of (*E*)-**A**.[13] Although the reason for such poor stereoselectivity can not be explained so far, there are some examples known for poor *endo*-selectivity of nonstabilized azomethine ylides.[14]



(*E*)-azomethine ylide ≫ (*Z*)-azomethine ylide

Scheme 3.

Fluoride-Induced Generation of 2-Azaallyl Anions. *N*-(Silylmethyl)imines are desilylated by a fluoride ion to generate 2-azaallyl anions **B**, which undergo cycloadditions with unactivated olefins, nucleophilic additions to carbonyl groups, or Michael additions to electron-deficient olefins (Scheme 4). Through these reactions, the anions **B** become synthetic equivalents of aminomethyl anion.

N-(Silylmethyl)imine **1** was treated with *trans*-stilbene in dry HMPA in the presence of cesium fluoride, at 80 °C for 3 d under nitrogen, to give 80% yield of 2,3,4-triphenylpyrrolidine **13** as single stereoisomer. On the basis of the very poor stereospecificity and stereoselectivity in a similar reaction of **1** with *cis*-stilbene,[15] its structure was tentatively assigned to be all-*trans*

Table 2. Nucleophilic Addition of 2-Azaallyl Anions Generated from *N*-(Silylmethyl)imines[a)]

Imine	Electrophile	Conditions[b)]	Product	Yield/%[c)]	Subsequent work-up[d)]
1	PhCHO	A	**16**	100	—
1	PhCHO	A	**17a**	88	A

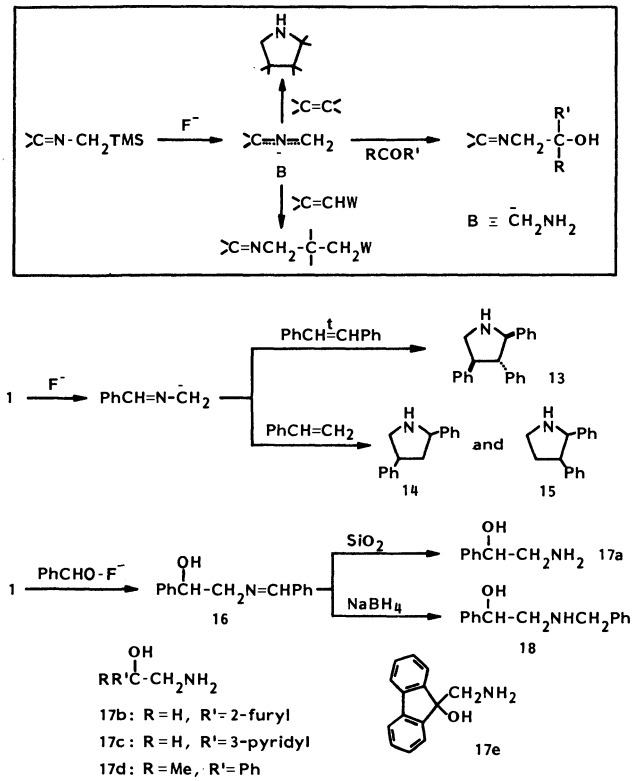
3	Benzylideneacetone	C	**23**	60	A
4	Dimethyl fumarate	C	**24**	100	—
6	Benzylideneacetone	D	**23**	77	A
6	Methyl acrylate	D	**25**	55	C

a) All reactions were carried out with equivalents of imines and electrophiles in the presence of TBAF (10 mol%). b) A: At room temperature for 48 h in DMF; B: At room temperature for 36 h in DMF in the presence of one equivalent of water; C: At 0 °C for 30 min in THF; D: At room temperature for 12 h in DMF in the presence of one equivalent of water. c) Isolated yield. d) A: Chromatographed over silica gel with MeOH–EtOAc (1:3); B: Reduced with $NaBH_4$ in MeOH at room temperature; C: Hydrolyzed with concd HCl in MeOH at room temperature and then acetylated with Ac_2O in the presence of pyridine at room temperature.



Scheme 4.

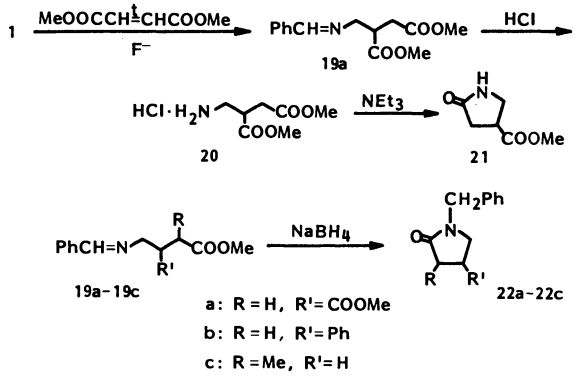
isomer that is thermodynamically most stable. Two regioisomeric cycloadducts **14** and **15** were obtained in the reaction of **1** with styrene under similar conditions, but their stereostructures could not be determined. In these reactions, a catalytic amount (0.1 equivalent) of cesium fluoride was sufficient.

As the imine **1** is inactive toward such unactivated olefins as stilbene and styrene in the presence of water, it is apparent that the reaction in the presence of cesium fluoride involves a reactive species other than *N*-protonated azomethine ylide **A**. 2-Azaallyl anion **B** will be the species involved. So we tried to capture **B** with aldehydes.

When **1** was treated with benzaldehyde in dry DMF in the presence of cesium fluoride at room temperature, a quantitative yield of 2-benzylideneamino-1-phenylethanol **16** was obtained (Scheme 4 and Table 2). This imine **16** was readily hydrolyzed into 2-amino-1-phenylethanol **17a** or reduced with sodium borohydride into its *N*-benzyl derivative **18**. The exclusive formation of **16** indicates that the 2-azaallyl anion from **1** undergoes highly regioselective nucleophilic addition with aldehydes at the carbon which was substituted with the silyl moiety. Thus, *N*-(silylmethyl)imine **1** can be a good reagent for nucleophilic aminomethylation. Therefore, similar reactions with some other carbonyl compounds were carried out. After the reactions were over, the crude reaction mixtures were subjected to column chromatography over silica gel to give hydrolyzed products, 2-aminoethanols **17b**—**e**.

Although some examples are known for the Michael addition reaction using ester-stabilized 2-azaallyl anion,[16] no nucleophilic aminomethylation using nonstabilized 2-azaallyl anion **B** has been reported so far.[17]

The 2-azaallyl anion generated from **1** and tetrabutylammonium fluoride was trapped with dimethyl fumarate at room temperature to give a regioselective Michael adduct **19a** in a quantitative yield (Scheme 5 and Table 2). One equivalent amount of water was used in this reaction, since otherwise the fumarate as a Michael acceptor readily polymerized. The adduct **19a** was hydrolyzed providing amino diester **20** which then cyclized into 2-pyrrolidinone **21** when treated with triethylamine, or it was reduced with sodium borohydride to give *N*-benzyl-2-pyrrolidinone **22a**

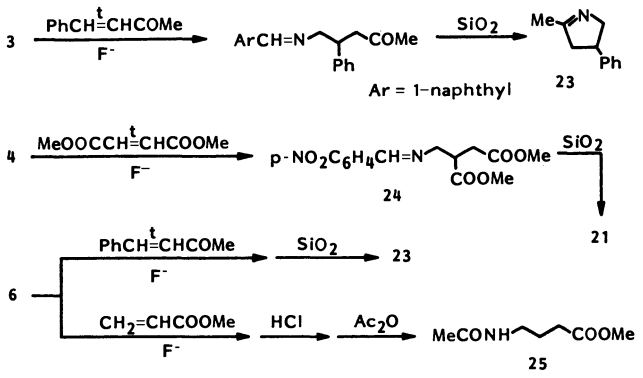


Scheme 5.

after spontaneous cyclization. Among these two sequences which look promising as a new synthetic method of 2-pyrrolidinones, the latter sequence seems more useful because all the procedures can be performed in the same flask. So the one-flask reaction was applied to some other Michael acceptors such as methyl cinnamate and methyl methacrylate to afford the corresponding *N*-benzyl-2-pyrrolidinones **22b** and **22c** (Table 2).[18]

One serious limitation is that olefins such as acrylates and methyl vinyl ketone polymerize under the reaction conditions even if water is present as an inhibitor. Such ready polymerization of olefins presumably results from the lack of stability of the 2-azaallyl anion from **1**. Therefore, several *N*-(silylmethyl)imines **3**, **4**, and **6** carrying anion-stabilizing substituents other than phenyl were examined.

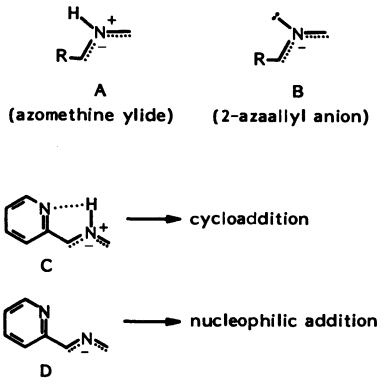
The imine **3** with a 1-naphthyl moiety was easily desilylated under very mild conditions. The anion generated underwent the Michael addition to benzylideneacetone followed by subsequent hydrolysis and cyclization providing 1-pyrroline **23** (Scheme 6 and Table 2). In this reaction, no water was needed. The 2-azaallyl anion generated from **4** also under mild conditions added to dimethyl fumarate in the absence of water to give a quantitative yield of **24**. However, the Michael addition using **3** is not highly regioselective,[19] and the anion from **4** undergoes ready oxidative coupling reaction especially if the Michael acceptor employed is not highly reactive.[20]



Scheme. 6.

So far the 2-azaallyl anion from **6** is most promising. With benzylideneacetone, 1-pyrroline **23** was obtained in 77% yield. The reaction with methyl acrylate produced 55% of methyl 4-acetamidopropanoate **25** after subsequent hydrolysis and acetylation (Scheme 6 and Table 2).

Thus, *N*-(silylmethyl)imines generate azomethine ylide 1,3-dipoles if desilylated after *N*-protonation and 2-azaallyl anions if directly desilylated. Although *N*-protonated azomethine ylides **A** and 2-azaallyl anions **B** are isoelectronic to each other, they show completely different chemical properties. Only structural difference is that the nonbonding electron pair on the nitrogen of **B** is used for the N–H bond in **A** (Scheme 7). This means that *N*-protonated azomethine ylides



Scheme 7.

A and 2-azaallyl anions **B** would be interconvertible to each other by protonation and deprotonation procedure. As described above, the reaction of imine **2** with dimethyl fumarate in THF in the presence of water produced pyrrolidine **8** which is a product expected from azomethine ylide **C**, whereas the same reaction in HMPA provided imine **12** expected from 2-azaallyl anion **D**. Probably the NH hydrogen of **C** is coordinating with the pyridine nitrogen so that the N–H bond may be weakened. In less polar solvent, THF, the hydrogen will be still sitting on the imine nitrogen, allowing the cycloaddition as azomethine ylide **C**. In highly polar HMPA, this hydrogen no longer stays on the imine nitrogen and hence the species involved is no longer azomethine ylide **C** but 2-azaallyl anion **D**. Nucleophilic addition is the reaction which actually took place.

Experimental

General. Melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C NMR spectra on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as internal standard. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 70 eV of ionization energy. Ele-

mental analyses were performed on a Hitachi 026 CHN micro analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60F-254 (Merck) or of aluminum oxide 60 F-254 type-E (Merck). Visualization was made with ultraviolet light (254 and 365 nm) and iodine. For preparative column chromatography, Wakogel C-200, C-300 (Wako), or Kieselgel 60 (230—400 mesh, Merck) was used. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Gas liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatography (Yanagimoto) with an ionization detector using a glass column (SE-30, 3×2000 mm). Micro vacuum distillation was performed with a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50°C unless otherwise stated.

Preparation of *N*-(Silylmethyl)imines 1—6. The imines were prepared according to either of the following three methods: A: Imines **1**, **2**, and **5** were prepared according to the known method using trimethylsilylmethyl azide, triphenylphosphine, and the corresponding aldehydes.[8] B: A mixture of trimethylsilylmethylamine (40 mmol) and an aldehyde (44 mmol) was stirred in ethanol (10 ml) at room temperature. The ethanol was evaporated in vacuo and the residue was dissolved in dichloromethane (20 ml). The solution was dried on magnesium sulfate and evaporated in vacuo. Crude imines **2**—**4** thus obtained all in quantitative yields were purified through vacuum distillation. C: To a solution of Et_3Al (16% in hexane, 30 ml, 30 mmol) in dry benzene (40 ml) was added trimethylsilylmethylamine (3.09 g, 30 mmol) at room temperature. The mixture was heated under reflux under nitrogen for 0.5 h. The mixture was refluxed with benzophenone (3.64 g, 20 mmol) for 1.5 h, treated with ethanol (5 ml), and poured into an aqueous solution of sodium tartrate (10%). Organic materials were extracted with dichloromethane (100 ml), the extract was dried over magnesium sulfate, and evaporated in vacuo to give almost pure **6** (5.30 g, 99%, purity 99% (GLC)).

Imines **1** (89%), **2** (72% by method A; 88% by method B), and **5** (58%) are all known compounds.[8]

3: Colorless liquid; yield 82%; bp 115—118°C/27 Pa; IR (neat) 1630, 1245, and 850 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.12 (9H, s, TMS), 3.47 (2H, d, J=1.5 Hz, CH_2), 7.2—7.5 (3H, m, Ar), 7.6—7.9 (3H, m, Ar), 8.64 (1H, t, J=1.5 Hz, N=CH), and 8.7—8.9 (1H, m, Ar); MS m/z (rel intensity, %) 241 (M^+, 51), 240 (base peak), 168 (35), 167 (23), 141 (21), and 73 (99). HRMS Found: m/z 241.1212. Calcd for $C_{15}H_{19}NSi$: M, 241.1286.

4: Colorless liquid; yield 100%; bp 107—110°C/107 Pa; IR (neat) 1600, 1250, and 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.08 (9H, s, TMS), 3.44 (2H, d, J=1, 3 Hz, CH_2), 7.70, 8.12 (each 2H, br d, Ar), and 8.08 (1H, t, J=1.3 Hz, N=CH); MS m/z (rel intensity, %) 236 (M^+, 34), 235 (74), 219 (41), 189 (22), 117 (37), and 73 (base peak). HRMS Found: m/z 236.1021. Calcd for $C_{11}H_{16}N_2O_2Si$: M, 236.0976.

6: Colorless liquid; IR (neat) 1610, 1250, and 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.03 (9H, s, TMS), 3.26 (2H, s, CH_2), and 6.9—7.6 (10H, m, Ph); MS m/z (rel intensity, %) 267 (M^+, base peak), 165 (20), 91 (29), and 73 (38). HRMS Found: m/z 267.1503. Calcd for $C_{17}H_{21}NSi$: M, 267.1442.

General Procedure for the Water-Induced Cycloadditions of *N*-(Silylmethyl)imines with Olefins Leading to 7—11. A mixture of *N*-(silylmethyl)imine and olefin (each 1 mmol) in HMPA or THF (2 ml) was stirred, under nitrogen at room temperature, in the presence of water and acetic acid. Reaction conditions are listed in Tabel 1. After the reaction was completed, the mixture was poured into aqueous sodium hydroxide and extracted with dichloromethane (15 ml×2). The combined extracts were washed with water, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel with benzene-ether. All the cycloadducts were obtained as mixtures of two stereoisomers, whose separation was unsuccessful. The results are summarized in Table 1.

7a: Colorless liquid; IR (neat) 3400, 1775, and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.11 (1H, s, NH), 2.7—3.8 (4H, m, 3a-, 6-, and 6a-H), 2.85 (1/3×3H, s, NMe), 2.98 (2/3×3H, s, NMe), 4.32 (1/3H, d, J=8.0 Hz, 4-H), 4.60 (2/3H, d, J=2.0 Hz, 4-H), and 7.1—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=24.78, 25.07 (each q, NMe), 45.91, 46.62 (each d), 48.79, 48.96 (each t, 6-C), 49.32, 53.13 (each d), 64.76, 65.52 (each d, 4-C), 126.11, 126.59, 127.28, 127.75, 128.11 128.58 (each d), 137.79, 141.31 (each s), 175.66, 178.30, 178.77, and 179.18 (each s, CON); MS m/z (rel intensity, %) 230 (M^+, 50), 119 (56), 118 (base peak), and 106 (20). HRMS Found: m/z 230.1059. Calcd for $C_{13}H_{14}N_2O_2$: M, 230.1054.

7b: Colorless liquid; IR (neat) 3400 and 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.32 (1H, br s, NH), 3.0—3.9 (4H, m, 3-, 4-, and 5-H), 3.15 (1/2×3H, s, 3-COOMe), 3.63 (1/2×3H, s, COOMe), 3.70 (3H, s, COOMe), 4.27 (1/2H, d, J=7.0 Hz, 2-H), 4.50 (1/2H, d, J=8.0 Hz, 2-H), and 7.1—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=47.14, 48.67, 50.20, 50.43, 50.90, 51.67, 51.78, 52.66, 54.89 (d), 65.87, 67.34 (each d, 2-C), 126.40, 127.05, 127.28, 127.64, 128.11 (each d), 138.37, 140.61 (each s), 172.31, 173.19, and 173.78 (each s, COOMe); MS m/z (rel intensity, %) 263 (M^+, 80), 232 (40), 204 (30), 177 (47), 144 (26), 119 (91), and 118 (base peak). Found: C, 63.89; H, 6.60; N, 5.15%. Calcd for $C_{14}H_{17}NO_4$: C, 63.87; H, 6.51; N, 5.32%.

7c: Colorless liquid; bp 150°C/400 Pa; IR (neat) 3350 and 2240 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.29 (1H, br, NH), 2.9—3.8 (4H, m, 3-, 4-, and 5-H), 4.25 (7/12H, d, J=9.0 Hz, 2-H), 4.46 (5/12H, d, J=7.0 Hz, 2-H), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR (DMSO-d_6) δ=33.02, 33.09 (each d), 50.26, (t, 5-C), 63.94, 66.99 (each, d, 2-C), 118.48, 118.77, 119.71, 120.06 (each, s, CN), 126.81, 127. 05, 127.74, 128.11, 128.52 (each, d), 137.97, and 138.26 (each s); MS m/z (rel intensity, %) 197 (M^+, 28), 119 (36), 118 (base peak), 91 (40), 89 (31), and 77 (37). Found: C, 73.23; H, 5.70; N, 21.28%. Calcd for $C_{12}H_{11}N_3$: C, 73.07; H, 5.62; N, 21.31%.

7d: Colorless liquid; IR (neat) 3320 and 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.60 (1H, br, NH), 2.9—4.0 (4H, m, 3-, 4-, and 5-H), 3.11 (3/4×3H, s, COOMe), 3.55 (1/4×3H, s, COOMe), 4.55 (1/4H, d, J=9.0 Hz, 2-H), 4.70 (3/4H, d, J=9.0 Hz, 2-H), and 7.0—7.5 (10H, m, Ph); MS m/z (rel intensity, %) 281 (M^+, 9), 131 (24), 119 (72), 118 (base peak), 117 (38), 115 (37), 103 (32), 91 (40), and 77 (30). Found: C, 77.04; H, 7.06; N, 4.72%. Calcd for $C_{18}H_{19}NO_2$: C, 76.84; H, 6.81; N, 4.98%.

7e: Colorless liquid; IR (neat) 3310 and 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10, 1.13 (3H, each d, J=6.0 Hz, 4-Me), 2.30 (1H, s, NH), 2.4—3.6 (4H, m, 3-, 4-, and 5-H), 3.16 (2/3×3H, s, COOMe), 3.61 (1/3×3H, s, COOMe), 4.44 (1/3H, d, J=8.0 Hz, 2-H), 4.46 (2/3H, d, J=8.0 Hz, 2-H), and 7.1—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=18.14, 18.32 (each q, 4-Me), 37.40, 40.39 (each d, 4-C), 50.78, 51.55 (each q, COOMe), 54.25, 54.78 (each t, 5-C), 57.71, 60.35 (each d, 3-C),

65.17, 66.40 (each d, 2-C), 126.28, 126.64, 126.93, 127.40, 127.75, 128.05, 128.22 (each d), 140.08, 142.67 (each d), 173.31, and 174.37 (each s, COOMe); MS *m/z* (rel intensity, %) 219 (M^+, 40), 119 (76), and 118 (base peak); HRMS Found: *m/z* 219.1273. Calcd for $C_{13}H_{17}NO_2$: M, 219.1258.

7f: Colorless liquid; IR (neat) 3400 and 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.33 (1H, s, NH), 3.1—3.5 (4H, m, 3-, 4-, and 5-H), 3.20 (3/10×3H, s, COOMe), 3.62, 3.63 (3H+7/10×3H, each s, COOMe), 4.39 (3/10H, d, *J*=6.0 Hz, 2-H), 4.59 (7/10H, d, *J*=6.0 Hz, 2-H), and 7.1—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=47.67, 49.85, 51.08, 51.90, 55.07, 64.76, 67.28, 126.34, 126.46, 127.22, 127.40, 128.11, 128.40, 142.84, 172.14, 172.31, 172.61, and 172.84; MS *m/z* (rel intensity, %) 263 (M^+, 8), 144 (59), 143 (21), 119 (51), 118 (base peak), 117 (32), 115 (50), 104 (25), 91 (49), and 77 (31). Found:, C, 64.14; H, 6.58; N, 5.24%. Calcd for $C_{14}H_{17}NO$: C, 63.87; H, 6.51; N, 5.32%.

7g: Colorless liquid; bp 95 °C/532 Pa; IR (neat) 3320 and 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.84 (3/7×3H, s, 3-Me), 1.37 (4/7×3H, s, 3-Me), 1.5—1.9 (1H, m), 2.2—2.7 (1H, m), 2.35 (1H, br s, NH), 2.9—3.5 (2H, m), 3.17 (4/7×3H, s, COOMe), 3.66 (3/7×3H, s, COOMe), 3.84 (4/7H, s, 2-H), 4.55 (3/7H, s, 2-H), and 7.1—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=19.96, 22.90 (each q, 3-Me), 38.16, 38.75 (each t, 4-C), 44.74, 45.62 (each t, 5-C), 51.20, 51.96 (each q, COOMe), 54.89 (s, 3-C), 68.57, 74.15 (each d, 2-C), 126.58, 127.05, 127.28, 127.46, 127.87 (each d), 139.14, 140.20 (each s), 175.60, and 177.48 (each s, COOMe); MS *m/z* (rel intensity, %) 219 (M^+, 32), 119 (79), and 118 (base peak). Found: C, 71.46; H, 8.08; N, 6.64%. Calcd for $C_{13}H_{17}NO_2$: C, 71.20; H, 7.82; N, 6.39%.

8: Colorless liquid; IR (neat) 3400, 1730, and 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.0—3.8 (4H, m, 3-, 4-, and 5-H), 3.20 (3/4×3H, s, COOMe), 3.32 (1H, s, NH), 3.66 (3H+3/4H, s, COOMe), 4.34 (1/4H, d, *J*=7.0 Hz, 2-H), 4.57 (3/4H, d, *J*=7.0 Hz, 2-H), 7.4—7.7 (3H, m, Py), and 8.40 (1H, br d, Py); MS *m/z* (rel intensity, %) 264 (M^+, 10), 145 (91), 132 (28), 126 (23), 120 (21), 119 (65), 118 (43), 117 (55), 105 (23), 92 (49), 79 (54), 78 (74), and 59 (base peak). Found: C, 59.93; H, 6.11; N, 10.32%. Calcd for $C_{13}H_{16}N_2O_4$: C, 59.08; H, 6.10; N, 10.60%.

9: Colorless liquid; IR (neat) 3400 and 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.28 (1H, br s, NH), 2.80 (4/9×3H, s, COOMe), 3.0—3.9 (4H, m, 3-, 4-, and 5-H), 3.56, 3.68 (each 5/9×3H, s, COOMe), 3.74 (4/9×3H, s, COOMe), 5.10 (4/9H, d, *J*=7.0 Hz, 2-H), 5.20 (5/9H, d, *J*=8.0 Hz, 2-H), and 7.3—8.2 (7H, m, Ar); MS *m/z* (rel intensity, %) 313 (M^+, 24), 194 (39), 193 (20), 169 (43), 168 (base peak), 167 (52), 166 (29), 165 (57), 154 (37), 153 (24), 141 (25), 139 (23), 128 (24), 127 (38), 115 (22), and 113 (22). Found: C, 69.05; H, 6.15; N, 4.68%. Calcd for $C_{18}H_{19}NO_4$: C, 68.99; H, 6.11; N, 4.47%.

10: Colorless liquid; IR (neat) 3400 and 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.93, 0.98 (each 1/2×9H, s, *t*-Bu), 1.96 (1H, br s, NH), 2.8—3.4 (6H, m, 2-, 3-, 4-, and 5-H), 3.65 and 3.67 (6H, each s, COOMe); ^{13}C NMR ($CDCl_3$) δ=26.54, 27.42 (each q, *t*-Bu), 32.41, 33.64 (each s, *q*-C), 48.55, 48.79, 49.14, 50.31, 51.02, 51.67, 52.02, 73.74 (d, 2-C), 74.50 (d, 2-C), 173.84, 174.25, 175.01, and 175.48 (each s, COOMe); MS *m/z* (rel intensity, %) 243 (M^+, 7), 186 (33), 154 (base peak), 126 (78), and 68 (38). Found: C, 59.01; H, 8.91; N, 5.81%. Calcd for $C_{12}H_{21}NO_4$: C, 59.24; H, 8.70; N, 5.76%.

11: Colorless needles; mp 140.5 °C; IR (KBr) 3400 and 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.74 (1H, br, NH), 3.0—3.7 (3H, m, 4- and 5-H), 3.24, 3.47 (each 3H, s, COOMe), 4.35 (1H, d, *J*=5.0 Hz, 3-H), and 7.0—7.6 (10H, m, Ph); MS *m/z* (rel intensity, %) 339 (M^+, 5), 220 (25), 202 (49), 195 (34), 194 (base peak), 191 (21), 170 (36), 165 (55), 144 (46), 143 (49), 117 (21), 115 (43), 104 (29), 91 (36), and 77 (53). Found: C, 70.96; H, 6.28; N, 4.21%. Calcd for $C_{20}H_{21}NO_4$: C, 70.78; H, 6.24; N, 4.13%.

12: Colorless liquid; IR (neat) 1740 and 1590 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.72 (1H, t, *J*=6.5 Hz), 3.1—3.5 (2H, m), 3.62, 3.66 (each 3H, s, COOMe), 3.87 (2H, d, *J*=7.0 Hz, NCH_2), 7.0—7.9 (3H, m, Py), 8.25 (1H, br s, CH=N), and 8.50 (1H, br d, Py); MS *m/z* 264 (M^+). Found: C, 59.23; H, 6.12; N, 10.35%. Calcd for $C_{13}H_{16}N_2O_4$: C, 59.08; H, 6.10; N, 10.60%.

Reaction of 1 with *trans*-Stilbene Leading to 13. A mixture of **1** (191 mg, 1 mmol), *trans*-stilbene (180 mg, 1 mmol), and cesium fluoride (CsF, 15 mg, 0.1 mmol) in dry HMPA (2 ml) was heated under nitrogen at 80 °C for 3 d. The mixture was poured into aqueous sodium hydrogencarbonate and extracted with dichloromethane (15 ml×2). The dichloromethane was washed with water, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel with hexane–ethyl acetate (2:1) to give **13** (239 mg, 80%): Colorless prisms; mp 64—67 °C; IR (KBr) 3340 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.20 (1H, s, NH), 3.1—3.8 (4H, m, 3-, 4-, and 5-H), 4.35 (1H, d, 2-H), and 6.8—7.4 (15H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=54.19 (d, 4-C), 54.60 (t, 5-C), 63.06 (d, 3-C), 71.04 (d, 2-C), 126.28, 126.64, 126.99, 127.28, 127.87, 128.22, 128.34, 128.87 (each d), 140.44, 142.55, and 143.02 (each s); MS *m/z* (rel intensity, %) 299 (M^+, base peak), 180 (21), 179 (25), 178 (25), 119 (25), 118 (27), and 91 (35). Found: C, 88.27; H, 7.11; N, 4.51%. Calcd for $C_{22}H_{21}N$: C, 88.25; H, 7.07; N, 4.68%.

Reaction of 1 with Styrene Leading to 14 and 15. A mixture of **1** (382 mg, 2 mmol), styrene (416 mg, 4 mmol), and CsF (30 mg, 0.2 mmol) was heated under nitrogen at 80 °C for 3 h. The same work-up as above gave **14** (152 mg, 34%) and **15** (71 mg, 16%).

14: Colorless prisms; mp 61—63.5 °C; IR (KBr) 3300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.1—2.4 (2H, m, 3-H), 2.32 (1H, s, NH), 2.9—3.7 (3H, m, 4- and 5-H), 4.39 (1H, t, *J*=7.5 Hz, 2-H), and 7.1—7.5 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=42.51 (t, 3-C), 44.80 (d, 4-C), 55.54 (t, 5-C), 62.47 (d, 2-C), 126.23, 126.46, 126.87, 127.28, 128.40 (each d), 144.01, and 144.90 (each s); MS *m/z* (rel intensity, %) 223 (M^+, 21), 119 (56), 118 (base peak), 115 (21), 91 (31), and 77 (24). Found: C, 86.05; H, 7.69; N, 6.32%. Calcd for $C_{16}H_{17}N$: C, 86.05; H, 7.67; N, 6.27%.

15: Colorless liquid; IR (neat) 3300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.9—2.5 (2H, m, 4-H), 2.40 (1H, br s, NH), 2.9—3.5 (3H, m, 3- and 5-H), 4.05 (1H, d, *J*=8.5 Hz, 2-H), and 7.0—7.3 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=35.13 (t, 4-C), 46.49 (t, 5-C), 53.94 (d, 3-C), 70.71 (d, 2-C), 126.21, 126.70, 126.94, 127.56, 128.16, 128.26 (each d), 142.63, and 142.78 (each s); MS *m/z* (rel intensity, %) 223 (M^+, 29), 119 (80), and 118 (base peak). Found: C, 86.18; H, 7.72; N, 6.45%. Calcd for $C_{16}H_{17}N$: C, 86.05; H, 7.67; N, 6.27%.

Reaction of 1 with Benzaldehyde Leading to 16. To a mixture of **1** (191 mg, 1 mmol) and benzaldehyde (106 mg, 1 mmol) in dry DMF (2 ml) was added at 0 °C tetrabutylammonium fluoride (TBAF, 1M solution in THF, 0.1 ml, 0.1 mmol). The mixture was stirred under nitrogen at room temperature for 2 d, poured into aqueous sodium hydrogencarbonate, and extracted with dichloromethane (15 ml×2). The conbined extracts were dried over magnesium sulfate and evaporated in vacuo to give crude **16** (195 mg, 100%): Colorless prisms (hexane); mp 114.5 °C; IR (KBr) 3400

and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.00 (1H, br, OH, exchanged with D_2O), 3.4—4.0 (2H, m, NCH_2), 4.95 (1H, dd, J=8.5 and 4.0 Hz, CH), 7.1—7.8 (10H, m, Ph), and 8.20 (1H, br s, CH=N); MS *m/z* (rel intensity, %) 194 (M^+, base peak), 91 (25), 89 (22), and 77 (31). Found: C, 80.10; H, 6.64; N, 6.15%. Calcd for $C_{15}H_{15}NO$: C, 79.97; H, 6.71; N, 6.22%.

General Procedure for the One-Pot Synthesis of 17. To a mixture of **1** (382 mg, 2 mmol) and carbonyl compounds (2 mmol) in dry DMF (4 ml) was added TBAF (1M in THF (1M=1 mol dm^{-3}), 0.2 ml) at 0°C. The mixture was allowed to stir under nitrogen at room temperature for 2 d, treated with aqueous sodium hydrogencarbonate, and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was filtered through a long column packed with silica gel using ethyl acetate-methanol (3:1) to give **17**. The results are summarized in Table 2.

17a: Colorless prisms; mp 54—56°C (lit,[21] mp 57°C); IR (KBr) 3200—3600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.50 (3H, br s, OH and NH_2), 2.78 (2H, m, CH_2), 4.50 (1H, dd, J=7.2 and 4.6 Hz, CH), and 7.2—7.3 (5H, br s, Ph); MS *m/z* (rel intensity, %) 118 (23), 117 (16), 107 (19), 105 (30), 91 (47), 90 (13), 89 (18), 79 (75), 78 (37), and 77 (base peak).

17b: Colorless needles; mp 85—87.5°C; IR (KBr) 2700—3300 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.70 (3H, br s, OH and NH_2), 2.88 (2H, d, J=6.0 Hz, CH_2), 4.51 (1H, t, J=6.0 Hz, CH), 6.12, 6.22, and 7.22 (each 1H, dd, 2-Furyl); MS *m/z* (rel intensity, %) 127 (M^+, 23), 98 (37), 97 (70), 69 (30), and 41 (base peak). Found: C, 56.84; H, 7.11; N, 10.95%. Calcd for $C_6H_9NO_2$: C, 56.68; H, 7.14; N, 11.02%.

17c: Colorless liquid; bp 140°C/107 Pa; IR (neat) 2800—3400 cm^{-1}; ^1H NMR (DMSO-d_6) δ=2.67 (2H, d, J=5.5 Hz, CH_2), 3.10 (3H, br, OH and NH_2), 4.55 (1H, t, J=5.5 Hz, CH), 7.30, 7.70, 8.42, and 8.49 (each 1H, dd, dt, dd, and d, respectively, 3-Py); MS *m/z* (rel intensity, %) 109 (base peak), 108 (61), 80 (13), and 53 (10). HRMS Found: *m/z* 138.0793. Calcd for $C_7H_{10}N_2O$: M, 138.0788.

17d: Colorless liquid; bp 95°C/13 Pa; IR (neat) 2800—3400 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.44 (3H, s, Me), 2.12 (3H, s, OH and NH_2), 2.75, 3.06 (each 1H, d, J=10.5 Hz, CH_2), and 7.1—7.5 (5H, m, Ph); MS *m/z* (rel intensity, %) 151 (M^+, 1), 121 (32), 105 (51), 91 (28), 78 (49), 77 (99), 51 (33), and 43 (base peak). HRMS Found: *m/z* 151.0999. Calcd for $C_9H_{13}NO$: M, 151.0996.

17e: Colorless needles; mp 134.5—135.5°C; IR (KBr) 2700—3400 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.03 (3H, br, OH and NH_2), 2.74 (2H, s, CH_2), and 7.1—7.6 (8H, m, Ar); MS *m/z* (rel intensity, %) 211 (M^+, 9), 182 (24), 181 (82), 180 (25), 153 (base peak), 152 (35), and 151 (19). Found: C, 79.66; H, 6.25; N, 6.61%. Calcd for $C_{14}H_{13}NO$: C, 79.59; H, 6.20; N, 6.63%.

Reduction of 16 with Sodium Borohydride Leading to 18. To a solution of **16** (225 mg, 1mmol) in methanol (2 ml) was added little by little sodium borohydride (38 mg, 1 mmol) under cooling with ice. After 10 min, acetone (10 ml) was added and the mixture was evaporated in vacuo. The residue was treated with water (10 ml) and extracted with dichloromethane (20 ml). The extract was dried over magnesium sulfate and evaporated in vacuo to give **18** (159 mg, 70%): Colorless needles (hexane); mp 100—101°C; IR (KBr) 2700—3200 and 1430 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.70 (2H, two d, J=7.4 and 5.2 Hz, CH_2), 3.28 (2H, br, OH and NH), 3.64 (2H, s, $PhCH_2$), 4.69 (1H, dd, J=7.4 and 5.2 Hz, CH), and 7.1—7.3 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=53.41 (t, CH_2), 56.53 (t, $PhCH_2$), 71.83 (d, CH), 125.77, 126.99, 127.28, 128.06, 128.20, 128.35 (each d), 139.56, and 142.92 (each s); MS *m/z* (rel intensity, %) 227 (M^+, 5), 121 (base peak), 118 (23), 107 (28), 92 (70), 79 (40), and 77 (49). Found: C, 79.40; H, 7.54; N, 6.21%. Calcd for $C_{15}H_{17}NO$: C, 79.26; H, 7.54; N, 6.16%.

Reaction of 1 with Dimethyl Fumarate Leading to 19a. To a solution of **1** (382 mg, 2 mmol), dimethyl fumarate (288 mg, 2 mmol), and water (32 mg, 2 mmol) in DMF (2 ml) was added TBAF (1M in THF, 0.2 ml, 0.2 mmol) at 0°C. The mixture was stirred at room temperature for 36 h and evaporated in vacuo. The residue was dissolved in dichloromethane, the dichloromethane was washed with water, dried over magnesium sulfate, and evaporated in vacuo to give **19a** (518 mg, 98%, purity: 99% by GLC): Colorless liquid; bp 145°C/53 Pa; IR (neat) 1730 and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.72 (2H, m, CH_2), 3.27 (1H, m, CH), 3.63, 3.68 (each 3H, s, COOMe), 3.84 (2H, dd, J=6.5 and 1.5 Hz, NCH_2), 7.2—7.8 (5H, m, Ph), and 8.23 (1H, d, J=1.5 Hz, CH=N); MS *m/z* (rel intensity, %) 263 (M^+, 59), 232 (66), 204 (64), 203 (30), 195 (25), 190 (56), 158 (36), 118 (60), and 91 (base peak). Found: C, 63.73; H, 6.56; N, 5.49%. Calcd for $C_{14}H_{17}NO_4$: C, 63.86; H, 6.51; N, 5.32%.

Hydrolysis of 19a into 20 and Cyclization of 20 Leading to 21. To a solution of **19a** (616 mg, 2.3 mmol) in methanol (1 ml) was added a few drops of conc HCl. After 5 min at room temperature, diethyl ether (50 ml) was added to give colorless precipitate of **20** (331 mg, 68%). This hydrochloride **20** (300 mg, 1.4 mmol) was dissolved in methanol (5 ml) and triethylamine (1 ml) was added. The mixture was heated under reflux for 2 h. The methanol was evaporated in vacuo. To the resude was added dry diethyl ether (20 ml). The ether was dried over magnesium sulfate and evaporated in vacuo to give **21** (191 mg, 94%).

20: Colorless prisms (ethyl acetate-methanol); mp 178—179.5°C; IR (KBr) 2800—3200, 1730, and 1595 cm^{-1}; ^1H NMR (DMSO-d_6) δ=2.4—3.3 (5H, m, CH_2 and CH), 3.58, 3.62 (each 3H, s, COOMe), and 8.35 (2H, br, NH); MS *m/z* (rel intensity, %) 176 (M^++1, 2), 144 (15), 115 (13), 114 (14), 102 (32), 70 (24), 56 (20), 55 (25), and 30 (base peak). Found: C, 39.84; H, 6.66; N, 6.64%. Calcd for $C_7H_{14}NO_4Cl$: C, 39.73; H, 6.67; N, 6.62%.

21: Colorless liquid; IR (neat) 3300 and 1800—1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.55 (2H, two d, J=8.5 and 7.0 Hz, 3-H), 3.0—3.8 (3H, m, 4- and 5-H), 3.72 (3H, s, COOMe), and 7.50 (1H, br, NH); MS *m/z* (rel intensity, %) 143 (M^+, 10), 116 (85), 113 (20), 101 (73), 100 (21), 87 (25), 84 (50), 83 (69), 70 (31), 59 (30), and 55 (base peak). HRMS Found: *m/z* 143.0599. Calcd for $C_6H_9NO_3$: M, 143.0582.

General Procedure for the One-Pot Synthesis of 22. To a mixture of **1** (382 mg, 2 mmol), electron-poor olefins (2 mmol), and water (2 mmol) was added TBAF (0.2 mmol) at 0°C. The mixture was stirred at room temperature for 36 h and evaporated in vacuo. The residue was dissolved in methanol (4 ml) and sodium borohydride (76 mg, 2 mmol) was added. After 10 min, acetone was added and the mixture was evaporated in vacuo. The residue was treated with water (2 ml) and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was heated under reflux in methanol for 0.5 h and the methanol was evaporated in vacuo. The crude product was chromatographed over silica gel with hexane-ethyl acetate (3:1) to give **22**. The results are summarized in Table 2.

22a: Colorless liquid; bp 150°C/267 Pa; IR (neat) 1740 and

1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.75 (2H, two d, J=9.3 and 6.7 Hz, 3-H), 3.0—3.4 (1H, m, 4-H), 3.46 (2H, two d, J=7.9 and 6.3 Hz, 5-H), 3.64 (3H, s, COOMe), 4.44 (2H, s, $PhCH_2$), and 7.1—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=33.70 (t, 3-C), 35.52 (d, 4-C), 46.15, 48.12 (each t, 5-C and $PhCH_2$), 52.02 (q, COOMe), 127.34, 127.75, 128.34 (each d), 135.56 (s), 171.96, and 172.78 (each s, COOMe and CON); MS m/z (rel intensity, %) 233 (M^+, 47), 91 (base peak), 65 (34), and 55 (27). Found: C, 66.60; H, 6.64; N, 5.97%. Calcd for $C_{13}H_{15}NO_3$: C, 66.93; H, 6.48; N, 6.01%.

22b: Colorless liquid; bp 160°C/107 Pa; IR (neat) 1690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.57, 2.89 (each 1H, dd, J=16.7 and 8.3 Hz, 3-H), 3.2—3.7 (3H, m, 4- and 5-H), 4.42, 4.56 (each 1H, d, J=14.5 Hz, $PhCH_2$), and 7.0—7.4 (10H, m, Ph); MS m/z (rel intensity, %) 251 (M^+, 78), 160 (24), 146 (22), 120 (21), 105 (98), and 91 (base peak). Found: C, 81.00; H, 6.79; N, 5.41%. Calcd for $C_{17}H_{17}NO$: C, 81.24; H, 6.82; N, 5.57%.

22c: Colorless liquid; bp 100°C/107 Pa; IR (neat) 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.23 (3H, d, J=6.0 Hz, 3-Me), 1.58 (1H, dq, J=12.3, 8.5, 8.5, and 8.5 Hz, one of 4-H), 2.0—2.7 (2H, m, 3-H and the other of 4-H), 3.14, 3.19 (each 2H, d, J=8.5 Hz, 5-H), 4.42 (2H, s, $PhCH_2$), and 7.1—7.4 (5H, m, Ph); MS m/z (rel intensity, %) 189 (M^+, 85), 107 (27), 98 (42), 92 (22), and 91 (base peak). Found: C, 76.38; H, 7.84; N, 7.25%. Calcd for $C_{12}H_{15}NO$: C, 76.15; H, 7.99; N, 7.40%.

Reaction of 3 with Benzylideneacetone Leading to 23. To a mixture of **3** (482 mg, 1 mmol) and benzylideneacetone (292 mg, 2 mmol) in dry THF (2 ml) was added TBAF (1M in THF, 0.2 ml, 0.2 mmol) at 0°C. The mixture was stirred at 0°C for 30 min and poured into aqueous sodium hydrogencarbonate. Organic products were collected in dichloromethane, the dichloromethane was dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed through a long column packed with silica gel using ethyl acetate–methanol (3:1) to give **23** (191 mg, 60%): Colorless liquid; IR (neat) 1650 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.05 (3H, s, 2-Me), 2.54 (1H, dd, J=17.5 and 7.5 Hz, one of 3-H), 2.96 (1H, m, the other of 3-H), 3.48 (1H, m, 4-H), 3.77, 4.24 (each 1H, m, 5-H), and 7.0—7.4 (5H, m, Ph); MS m/z (rel intensity, %) 159 (M^+, 28) and 55 (base peak). HRMS Found: m/z 159.1029. Calcd for $C_{11}H_{13}N$: M, 159.1047.

Reaction of 4 with Dimethyl Fumarate Leading to 24 and Then to 21. A mixture of **4** (572 mg, 2 mmol), dimethyl fumarate (288 mg, 2 mmol), and TBAF (1M in THF, 0.2 mmol) in dry THF (3 ml) was stirred at 0°C for 30 min, or the same mixture in ethanol (2 ml) was stirred at 0°C for 1 h. The resulting mixture was poured into aqueous sodium hydrogencarbonate and extracted with dichloromethane (15 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo to give **24** in quantitative yields in both cases (^{1}H NMR ($CDCl_3$) δ=2.73 (2H, m, CH_2), 3.25 (1H, m, CH), 3.63, 3.68 (each 3H, s, COOMe), 3.89 (2H, dd, J=5.5 and 1.5 Hz, NCH_2), 7.78, 8.14 (each 2H, d, Ar), and 8.28 (1H, d, J=1.5 Hz, CH=N)). Crude **24** was chromatographed through a long column packed with silica gel using ethyl acetate–methanol (5:1) to give **21** (63% yield).

Reaction of 6 with Benzylideneacetone Leading to 23. A mixture of **6** (267 mg, 1 mmol), benzylideneacetone (146 mg, 1 mmol), TBAF (0.1 mmol), and water (18 mg, 1 mmol) in DMF (2 ml) was stirred at room temperature for 12 h. The same chromatographic work-up as above gave **23** (123 mg, 77%).

Reaction of 6 with Methyl Acrylate and Subsequent Hydrolysis and Acetylation Leading to 25. A mixture of **6** (267 mg, 1 mmol), methyl acrylate (86 mg, 1 mmol), TBAF (0.1 mmol), and water (1 mmol) in DMF (2 ml) was stirred at room temperature for 12 h. The mixture was poured into aqueous sodium hydrogencarbonate and extracted with dichloromethane (15 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. To the residue dissolved in methanol (2 ml) was added concentrated HCl (0.5 ml). The mixture was stirred at room temperature for 10 min, neutralized with aqueous sodium carbonate, and extracted with dichloromethane (20 ml). The dichloromethane was dried and evaporated in vacuo. The residue was dissolved in acetic anhydride (2 ml). After pyridine (1 ml) was added, the mixture was stirred at room temperature for 2 h and poured into ice water. Organic products were extracted with dichloromethane (15 ml), the extract was dried, and evaporated in vacuo. The residue was chromatographed over silica gel with ethyl acetate–ethanol (30:1) to give **25** (88 mg, 55%): Colorless liquid; IR (neat) 3300, 1725, and 1650 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.83 (1H, m, CH_2), 1.96 (3H, s, MeCO), 2.37 (2H, t, J=6.5 Hz, CH_2COOMe), 3.29 (2H, t, J=6.0 Hz, NCH_2), 3.67 (3H, s, COOMe), and 5.90 (1H, br, NH, exchanged with D_2O); MS m/z (rel intensity, %) 159 (M^+, 11), 116 (34), 86 (71), and 43 (base peak). HRMS Found: m/z 159.0874. Calcd for $C_7H_{13}NO_3$: M, 159.0895.

Bromochlorination of Alkenes with Dichlorobromate (1−) Ion. IV.[1,2] Regiochemistry of Bromochlorinations of Alkenes with Molecular Bromine Chloride and Dichlorobromate (1−) Ion

Takeshi NEGORO* and Yoshitsugu IKEDA
Department of Chemistry, Faculty of Education, Wakayama University, Sakaedani, Wakayama 640
(Received March 25, 1986)

The regioselectivity of the addition of molecular bromine chloride to alkenes is dependent on both the steric and electronic effects of the alkyl substituent. In contrast, the regioselectivity of the addition of dichlorobromate (1−) ion to alkenes is controlled mainly by the steric effect of the substituent.

The regioselectivity of bromochlorination of phenyl- and vinyl-substituted alkenes has been shown to be markedly dependent both on the bromochlorinating agent and on the structure of alkene employed.[1-3] There have been a few investigations on the regiochemistry of bromochlorination of alkyl-substituted ethylenes with molecular bromine chloride and dichlorobromate(1−) ion, and the addition of BrCl to such alkenes as propene, 3-chloro-1-propene, and 1-hexene has been reported to give both Markownikoff and *anti*- Markownikoff adducts.[2,5] We have also reported that dichlorobromate(1−) ion reacted with propene and 3-chloro-1-propene to give two regioisomers.[1] However, no systematic study has been carried out on the bromochlorination reaction of alkyl-substituted ethylenes. As a continuation of our studies[1-3] we have carried out a study on the regiochemical effect of the alkyl substituent in the addition of molecular bromine chloride and dichlorobromate (1−) ion to various alkenes.

Results and Discussion

Reactions of a series of alkenes **3a-l** with tetrabutylammonium dichlorobromate(1−) (**1**) in dichloromethane gave the corresponding bromo chloro compounds **4a—l** and **5a—l** in good yields (Table 1 and Scheme 1). Similar reactions of methylenecycloalkanes **3m—n** with **1** also gave the corresponding bromo chloro compounds **4m—n** and **5m—n** in good yields (Table 1 and Scheme 2).

The orientation of halogen atoms in all the addition products was elucidated mainly on the basis of chemical shifts of the carbon bearing bromine and chlorine atoms in ^{13}C NMR spectra, since it has been observed that the carbon atom bearing a chlorine atom is deshielded relative to the one bearing a bromine atom.[6] Meanwhile, the structures of two regioisomers **4** and **5** have been determined by comparison of their ^{13}C NMR spectra with those of the corresponding

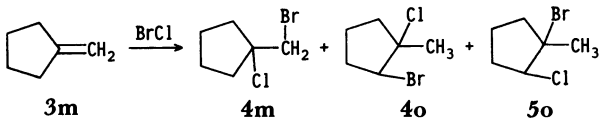
3g	36[e]	64[e]	69	**3n**	82	18	55

a) Reactions were carried out with 10 mmol of **2**, 12 mmol of alkene,and 50 ml of CH_2Cl_2 at 0°C. b) Percentages are normalized to 100%. Determined by ^{13}C NMR analysis. c) Determined by GLC analysis. d) *erythro*. e) *threo*. f) (*RS,SR*). g) (*RS,RS*).

dibromo and dichloro compounds. Control experiments revealed that all the bromo chloro compounds are stable under the reaction conditions.

Treatments of a series of alkenes **3a—l** with molecular bromine chloride (**2**) in CH_2Cl_2 also gave the corresponding bromo chloro compounds **4a—l** and **5a—l** (Table 2). The yields are lower than those in the reaction with **1** due to formation of dibromo- and dichloroalkanes. The formation of these by-products in the reaction is undoubtedly due to the attack of both Br_2 and Cl_2, which are formed from and in equilibrium with **2**, on alkenes.[7]

On the other hand, the reaction of methylenecyclopentane (**3m**) with **2** gave a mixture of 2-bromo-1-chloro- and 1-bromo-2-chloro-1-methylcyclopentanes (**4o** and **5o**, 54.5% yield by GLC analysis) as the major products. The expected bromo chloro compound **4m** (11.0% yield by GLC analysis) was a minor component (Scheme 3 and Table 2). The formation of



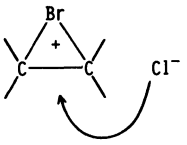
3m **4m** **4o** **5o**

Scheme 3.

both **4o** and **5o** may be due to the competing allylic halogenation which produces hydrogen halide. The hydrogen halide thus formed is considered to isomerize the terminal alkene **3m** into a more stable internal alkene **3o** (1-methylcyclopentene), to which **2** is then presumed to add. In fact, the presence of **3o** was confirmed by ^1H NMR analysis of the reaction mixture. Furthermore, the ratio of the two regioisomers (**4o**:**5o**=86:14) is the same as that observed for the reaction of **3o** with **2**. A similar reaction has been reported for the addition of bromine to **3m**.[8] Similarly, the reaction of methylenecyclohexane (**3n**) also gave a small amount of 2-bromo-1-chloro- and 1-bromo-2-chloro-1-methylcyclohexane (**4p** and **5p**).

An inspection of the data in Tables 1 and 2 clearly reveals that the regiochemistry of the addition of **1** to alkenes is strikingly different from that of the reaction of **2**. Therefore, the product-determining step must be different in these two reactions.

Regioselectivity of the Reaction of 3 with 2. The reaction with **2** can best be explained by the AdE_{C_1}-type mechanism involving the attack of chloride ion to a bridged bromonium ion intermediate **6**:[5,9] a similar intermediate has also been suggested for the bromination of alkenes with molecular bromine.[10]



(6)

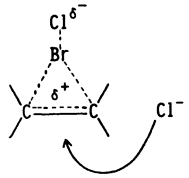
As shown in Table 2, the bromochlorination of the unsymmetrical alkenes, 1,2-dialkyl- **3f** and **3g** and 1,1,2-trialkylethylenes **3k** and **3l**, with **2** gave completely *anti* stereospecific adducts. This supports further the assumption that the intermediate in the bromochlorination of alkyl-substituted ethylenes with **2** resembles the bridged ion **6**. These results are in marked contrast to the stereoselective addition of **2** to phenyl- or vinyl-substituted alkenes, which involves a very weakly bridged ion intermediate.[2,3] Thus, the *anti* stereospecific addition of **2** to **3k** and **3l** would rule out the possibility of carbonium ion-like intermediate which is considered to be involved in the bromination of these alkenes with bromine.[10]

Both the steric and the electronic effect of the alkyl substituent on ethylene linkage would play a major role in the orientation of the approach of chloride ion on the bromonium ion intermediate **6**. As shown in Table 2, nearly the same ratio of regioisomers is given for the reactions of 1-butene (**3a**), 1-pentene (**3b**), and 1-hexene (**3c**) with **2**, which indicates the effects of linear alkyl substituents to be nearly the same. Meanwhile, the replacement of the hydrogen on ethylene by isopropyl (**3d**) or *t*-butyl (**3e**) results in the formation of an increasing amount of the *anti*-Markownikoff adduct **5d** or **5e**. This reveals clearly that the addition of **2** can be influenced by steric factors of the bulky groups.

On the other hand, the additions of **2** to 1,1-disubstituted **3h** and **3i** and 1,1,2-trisubstituted ethylenes **3j**, **3k**, and **3l** or methylenecycloalkanes **3m** and **3n** gave regioselective Markownikoff adducts **4** (Table 2).

These results imply that the attack of chloride ion on the bromonium ion intermediate **6** occurs at the more substituted carbon atom. Thus, the orientation of bromochlorination with **2** would be due to the electronic effect of the 1,1-dialkyl substituent which stabilizes the developed cationic character on the more substituted carbon atom in the intermediate **6**. A similar accumulative electronic effect of dialkyl substituent groups on the regiochemistry has previously been observed in the bromination of these alkenes in methanol.[11]

Regioselectivity of the Reaction of 3 with 1. We have previously suggested that the reaction of alkenes with **1** can be best explained by the $AdEC_2$-type mechanism involving the attack of chloride ion on the three-centered π-complex intermediate **7** with a very little charge development on the unsaturated carbon.[2,3]



(7)

Therefore, there would be a relatively small demand for electronic stabilization of the reaction center by alkyl substituents on the intermediate **7**. As expected, the amount of the *anti*-Markownikoff adduct **5** in the addition with **1** (Table 1) is generally larger than that in the addition with **2** (Table 2). Thus, the addition of **1** to linear alkyl-substituted ethylenes **3a**, **3b**, and **3c** was found to be slightly more regioselective in an *anti*-Markownikoff manner than that in the addition of **2**. Meanwhile, the replacement of the hydrogen on ethylene by an isopropyl (**3d**) or a *t*-butyl group (**3e**) results in the formation of a larger amount of the *anti*-Markownikoff adduct **5** than that in the addition of **2**. It is interesting to note that only the *anti*-Markownikoff adduct **5e** is obtained in the reaction of 3,3-dimethyl-1-butene (**3e**), as anticipated from the greater steric requirement of *t*-butyl group. The reaction of methylenecyclohexane (**3n**) with **1** also gives a regioselective *anti*-Markownikoff adduct **5n**, where the opposite orientation results from that of the reaction with **2**. All these results support that the steric effect outweighs the electronic effect of the alkyl substituent in the reaction with **1**.

However, the reaction of **1** to 1,1-dialkyl- **3h** and **3i** and 1,1,2-trialkylethylenes **3j** and **3k** or methylenecyclopentane (**3m**) gave the regioselective Markownikoff adduct **4** (Table 1). As in the reaction with **2**, the electronic effect of the 1,1-dialkyl groups would overcome partially the steric influence.

Experimental

NMR spectra were recorded on a JEOL JNM FX-60Q and a JEOL C-60HL spectrometer using TMS as the internal standard. Mass spectra were recorded on a JMS-D-300 mass spectrometer. GLC analyses were performed on a Yanako G-180 gas chromatograph with a Silicone SE-30 (5%)-Chromosorb WAW DMCS (2 m) column with helium as the carrier gas. Tetrabutylammonium dichlorobromate(1−) (**1**) was prepared by the known procedure.[12] All the organic starting materials, including the solvents, were distilled before use. Bromine chloride (**2**) was prepared by adding an equimolar amount of bromine to chlorine-carbon tetrachloride solution. 1,2-Dibromoalkanes **8a—n** were prepared by bromination of alkenes **3a—n** with bromine, respectively. 1,2-Dichloroalkanes **9a—n** were prepared by chlorination of alkenes **3a—n** with chlorine, respectively.

Reaction of Alkenes 3a—n with 1. Details of the reaction have previously been reported.[1,2] To a solution of **3** (36 mmol) in CH_2Cl_2 (50 ml) was added **1** (11.8 g, 30 mmol) at 0°C over 20 min with stirring. After the usual work-up, the products were purified by distillation. Although attempts to separate **4** and **5** were unsuccessful, these structures were determined by comparison of their ^{13}C NMR spectra with those of the corresponding dibromo and dichloro analogs.

A Mixture of 1-Bromo-2-chloro- and 2-Bromo-1-chlorobutanes (4a and 5a) from 1-Butene (3a): Bp 82°C/110 mmHg (1 mmHg=133.322 Pa); MS M^+ *m/z* (rel intensity) 170, 172, and 174 (100:135:32); ^1H NMR ($CDCl_3$) δ=1.04 (3H, t, J=6.5 Hz), 1.40—2.30 (2H, m), and 3.50—4.30 (3H, m); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5a**) δ=10.1, 11.1,* 28.4,* 28.8, 35.8, 47.6,* 54.9,* and 62.1. Although attempts to separate **4a** and **5a** were unsuccessful, these assignments were supported for dibromo and dichloro analogs as follows: 1,2-dibromobutane (**8a**), ^{13}C NMR ($CDCl_3$) δ= 11.0, 29.0, 35.6, and 54.3; 1,2-dichlorobutane (**9a**), ^{13}C NMR ($CDCl_3$) δ=10.2, 28.2, 47.8, and 62.6.

A Mixture of 1-Bromo-2-chloro- and 2-Bromo-1-chloropentanes (4b and 5b) from 1-Pentene (3b): Bp 70—72°C/ 50 mmHg; MS M^+ *m/z* (rel intensity) 184, 186, and 188 (100:134:36); ^1H NMR ($CDCl_3$) δ=0.83—2.30 (7H, m) and 3.33—4.35 (3H, m); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5b**) δ=13.3,* 13.4, 19.2, 20.2,* 36.5, 37.4,* 37.8, 48.3,* 53.2,* and 60.6. These assignments were supported for dibromo and dichloro analogs as follows: 1,2-dibromopentane (**8b**), ^{13}C NMR ($CDCl_3$) δ=13.3, 20.1, 36.3, 38.0, and 52.7; 1,2-dichloropentane (**9b**), ^{13}C NMR ($CDCl_3$) δ=13.5, 19.2, 37.1, 48.3, and 60.9.

A Mixture of 1-Bromo-2-chloro- and 2-Bromo-1-chlorohexanes (4c and 5c) from 1-Hexene (3c): Bp 95—96°C/ 50 mmHg; MS M^+ *m/z* (rel intensity) 198, 200, and 202 (100:129:31); ^1H NMR ($CDCl_3$) δ=0.93—2.40 (9H, m) and 3.50—4.30 (3H, m); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5c**) δ=13.9, 22.0,* 22.1, 28.0, 28.9,* 35.1,* 35.5, 36.5, 48.2,* 53.5,* and 60.8. These assignments were supported for dibromo and dichloro analogs as follows: 1,2-dibromohexane (**8c**), ^{13}C NMR ($CDCl_3$) δ=13.9, 21.9, 28.8, 35.7, 36.3, and 53.0; 1,2-dichlorohexane (**9c**), ^{13}C NMR ($CDCl_3$) δ= 13.9, 22.1, 27.9, 34.7, 48.2, and 61.2.

A Mixture of 1-Bromo-2-chloro- and 2-Bromo-1-chloro-3-methylbutanes (4d and 5d) from 3-Methyl-1-butene (3d): Bp 68—70°C/50 mmHg; MS M^+ *m/z* (rel intensity) 184, 186, and 188 (100:130:35); ^1H NMR ($CDCl_3$) δ=0.99 (6H, t, J=6.6 Hz), 2.00—2.57 (1H, m), and 3.63—4.33 (3H, m); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5d**) δ=15.1, 16.1,* 20.4, 21.4,* 29.6,* 30.8, 34.4, 46.1,* 61.8,* and 67.2. These assignments were supported for dibromo and dichloro analogs as follows:

1,2-dibromo-3-methylbutane (**8d**), ^{13}C NMR ($CDCl_3$) δ=15.5, 21.7, 29.9, 34.1, and 61.5; 1,2-dichloro-3-methylbutane (**9d**), ^{13}C NMR ($CDCl_3$) δ=15.6, 20.2, 30.3, 46.3, and 67.6.

2-Bromo-1-chloro-3,3-dimethylbutane (5e) from 3,3-Dimethyl-1-butene (3e): Bp 95—100°C/50 mmHg; MS M$^+$ *m/z* (rel intensity) 198, 200, and 202 (100:129:31); ^{1}H NMR ($CDCl_3$) δ=1.12 (9H, s) and 3.52—4.13 (3H, m); ^{13}C NMR ($CDCl_3$) δ=27.6, 36.3, 47.6, and 68.8. ^{13}C NMR spectra for dibromo and dichloro analogs are as follows: 1,2-dibromo-3,3-dimethylbutane (**8e**), ^{13}C NMR ($CDCl_3$) δ=27.6, 35.8, 37.0, and 69.0; 1,2-dichloro-3,3-dimethylbutane (**9e**), ^{13}C NMR ($CDCl_3$) δ=26.7, 36.2, 47.1, and 73.7.

A Mixture of *erythro*-2-Bromo-3-chloro- and 3-Bromo-2-chloropentanes (4f and 5f) from *trans*-2-Pentene (3f): Bp 71—72°C/50 mmHg; MS M$^+$ *m/z* (rel intensity) 184, 186, and 188 (100:128:32); ^{1}H NMR ($CDCl_3$) δ=1.07 (3H, t, J=6.8 Hz), 1.33—2.26 (5H, m), and 3.78—4.40 (2H, m); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5f**) δ=10.5, 11.6,* 23.4, 23.5,* 29.1,* 29.4, 51.8, 59.7,* 63.0,* and 69.0. These assignments were supported for dibromo and dichloro analogs as follows: *erythro*-2,3-dibromopentane (**8f**), ^{13}C NMR ($CDCl_3$) δ=11.4, 25.2, 30.5, 51.8, and 63.2; *erythro*-2,3-dichloropentane (**9f**), ^{13}C NMR ($CDCl_3$) δ=10.4, 22.2, 28.3, 59.5, and 68.6.

A Mixture of *threo*-2-Bromo-3-chloro- and 3-Bromo-2-chloropentanes (4g and 5g) from *cis*-2-Pentene (3g): Bp 72—73°C/50 mmHg; MS M$^+$ *m/z* (rel intensity) 184, 186, and 188 (100:132:35); ^{1}H NMR ($CDCl_3$) δ=1.07 (3H, t, J=6.9 Hz), 1.34—2.24 (5H, m), and 3.77—4.57 (2H, m); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5g**) δ=11.5, 12.6,* 21.3,* 21.5, 27.3,* 27.7, 52.2, 59.9,* 62.1,* and 68.2. These assignments were supported for dibromo and dichloro analogs as follows: *threo*-2,3-dibromopentane (**8g**), ^{13}C NMR ($CDCl_3$) δ=12.7, 21.6, 27.5, 52.2, and 62.1; *threo*-2,3-dichloropentane (**9g**), ^{13}C NMR ($CDCl_3$) δ=11.4, 20.8, 27.1, 59.7, and 67.9.

A Mixture of 1-Bromo-2-chloro- and 2-Bromo-1-chloro-2-methylpropanes (4h and 5h) from 2-Methylpropene (3h): Bp 79—82°C/90 mmHg; MS M$^+$ *m/z* (rel intensity) 170, 172, and 174 (100:132:34); ^{1}H NMR ($CDCl_3$) (the asterisk indicates **5h**) δ=1.69, 1.83* (6H, 2s), 3.63, and 3.83* (2H, 2s); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5h**) δ=30.4, 31.0,* 43.7, 55.3,* 62.3,* and 67.1. These assignments were supported for dibromo and dichloro analogs as follows: 1,2-dibromo-2-methylpropane (**8h**), ^{13}C NMR ($CDCl_3$) δ=31.9, 44.7, and 62.1; 1,2-dichloro-2-methylpropane (**9h**), ^{13}C NMR ($CDCl_3$) δ=29.6, 54.6, and 67.6.

A Mixture of 1-Bromo-2-chloro- and 2-Bromo-1-chloro-2-ethylbutanes (4i and 5i) from 2-Ethyl-1-butene (3i): Bp 65—66°C/19 mmHg; MS M$^+$ *m/z* (rel intensity) 198, 200, and 202 (100:130:35); ^{1}H NMR ($CDCl_3$) (the asterisk indicates **5i**) δ=0.90—1.14 (6H, m), 1.66—2.11 (4H, m), 3.63, and 3.87* (2H, 2s); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5i**) δ=8.2, 9.4,* 32.6, 32.9,* 37.7, 48.8,* 75.4,* and 75.8. These assignments were supported for dibromo and dichloro analogs as follows: 1,2-dibromo-2-ethylbutane (**8i**), ^{13}C NMR ($CDCl_3$) δ=9.5, 33.8, 38.2, and 75.3; 1,2-dichloro-2-ethylbutane (**9i**), ^{13}C NMR ($CDCl_3$) δ=8.2, 31.8, 48.5, and 76.1.

A Mixture of 3-Bromo-2-chloro- and 2-Bromo-3-chloro-2-methylbutanes (4j and 5j) from 2-Methyl-2-butene (3j): Bp 80—81°C/70 mmHg; MS M$^+$ *m/z* (rel intensity) 184, 186, and 188 (100:134:35); ^{1}H NMR ($CDCl_3$) δ=1.67—1.98 (9H, m) and 4.13—4.46 (1H, m); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5j**) δ=21.9,* 22.1, 27.0, 27.9,* 32.5, 33.2,* 58.4, 66.1,* 67.9,* and 71.6. These assignments were supported for dibromo and dichloro analogs as follows: 2,3-dibromo-2-methylbutane (**8j**), ^{13}C NMR ($CDCl_3$) δ=23.5, 28.0, 34.9, 59.4, and 68.2; 2,3-dichloro-2-methylbutane (**9j**), ^{13}C NMR ($CDCl_3$) δ=20.6, 26.5, 31.1, 65.2, and 71.3.

A Mixture of (*RS,SR*)-2-Bromo-3-chloro- and 3-Bromo-2-chloro-3-methylpentanes (4k and 5k) from (*E*)-3-Methyl-2-pentene (3k): Bp 68—69°C/48 mmHg; MS M$^+$ *m/z* (rel intensity) 198, 200, and 202 (100:134:28); ^{1}H NMR ($CDCl_3$) δ=0.93—1.18 (3H, m), 1.63—2.03 (8H, m), and 4.31 (1H, q, J=6.7 Hz); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5k**) δ=8.6, 9.8,* 21.7, 21.8,* 24.6, 25.2,* 36.6, 36.9,* 55.6, 63.0,* 74.4,* and 76.1. These assignments were supported for dibromo and dichloro analogs as follows: (*RS,SR*)-2,3-dibromo-3-methylpentane (**8k**), ^{13}C NMR ($CDCl_3$) δ=9.8, 23.2, 25.9, 38.4, 56.2, and 74.9; (*RS,SR*)-2,3-dichloro-3-methylpentane (**9k**), ^{13}C NMR ($CDCl_3$) δ=8.4, 20.3, 23.8, 35.2, 62.5, and 75.8.

A Mixture of (*RS,RS*)-2-Bromo-3-chloro- and 3-Bromo-2-chloro-3-methylpentanes (4l and 5l) from (*Z*)-3-Methyl-2-pentene (3l): Bp 70—71°C/48 mmHg; MS M$^+$ *m/z* (rel intensity) 198, 200, and 202 (100:132:35); ^{1}H NMR ($CDCl_3$) δ=0.93—1.18 (3H, m), 1.61—2.20 (8H, m), and 4.08—4.52 (1H, m); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5l**) δ=8.8, 9.9,* 21.5,* 21.8, 27.8, 28.7*, 32.3, 32.7,* 58.8, 66.0,* 74.7,* and 76.1. These assignments were supported for dibromo and dichloro analogs as follows: (*RS,RS*)-2,3-dibromo-3-methylpentane (**8l**), ^{13}C NMR ($CDCl_3$) δ=10.0, 23.0, 30.3, 32.4, 59.8, and 75.0; (*RS,RS*)-2,3-dichloro-3-methylpentane (**9l**), ^{13}C NMR ($CDCl_3$) δ=8.7, 20.4, 26.7, 31.8, 65.2, and 76.0.

A Mixture of 1-Bromomethyl-1-chloro- and 1-Bromo-1-(chloromethyl)cyclopentanes (4m and 5m) from Methylenecyclopentane (3m): Bp 42—43°C/5 mmHg; MS M$^+$ *m/z* (rel intensity) 196, 198, and 200 (100:132:34); ^{1}H NMR ($CDCl_3$) (the asterisk indicates **5m**) δ=1.52—2.26 (8H, m), 3.80, and 4.01* (2H, 2s); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5m**) δ=23.8, 40.6, 41.2, 52.2,* 74.9,* and 79.2. These assignments were supported for dibromo and dichloro analogs as follows: 1-bromo-1-(bromomethyl)cyclopentane (**8m**), ^{13}C NMR ($CDCl_3$) δ=23.9, 41.3, 41.4, and 74.9; 1-chloro-1-(chloromethyl)cyclopentane (**9m**), ^{13}C NMR ($CDCl_3$) δ=23.6, 39.8, 51.9, and 79.0.

A Mixture of 1-Bromomethyl-1-chloro- and 1-Bromo-1-(chloromethyl)cyclohexane (4n and 5n) from Methylenecyclohexane (3n): Bp 41—42°C/2 mmHg; MS M$^+$ *m/z* (rel intensity) 210, 212, and 214 (100:130:35); ^{1}H NMR ($CDCl_3$) (the asterisk indicates **5n**) δ=1.40—2.00 (10H, m), 3.68, and 3.92* (2H, 2s); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5n**) δ=22.1, 22.8,* 24.9, 37.3, 44.3, 55.2,* 72.5,* and 72.7. These assignments were supported for dibromo and dichloro analogs as follows: 1-bromo-1-(bromomethyl)cyclohexane (**8n**), ^{13}C NMR ($CDCl_3$) δ=23.0, 24.8, 38.0, 44.7, and 72.3; 1-chloro-1-(chloromethyl)cyclohexane (**9n**), ^{13}C NMR ($CDCl_3$) δ=21.8, 24.9, 36.4, 54.6, and 73.2.

Reaction of Alkenes 3a—n with 2. To a solution of **3** (12 mmol) in CH_2Cl_2 (50 ml) was added 5.5 ml of BrCl solution in CCl_4 (1.8 mol dm^{-3}) at 0°C over 5 min with stirring. After the solvent was removed under reduced pressure, the residues were analyzed by GLC and ^{13}C NMR. The results are given in Table 2. In all cases, GLC analyses showed the presence of 11—16% of dichloro adduct **9** and 13—19% of dibromo adduct **8** as by-products.

The reaction of 3,3-dimethyl-1-butene (**3e**) with **2** gave a

mixture of 1-bromo-2-chloro- and 2-bromo-1-chloro-3,3-dimethylbutane (**4e** and **5e**). The product composition of **4e** and **5e** was determined by ^{13}C NMR analysis: ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5e**) δ=26.8, 27.6,* 35.2, 36.3,* 37.0, 47.6,* 68.8,* and 74.6. These assignments were supported for the ^{13}C NMR data of dibromo and dichloro adducts **8e** and **9e** as described above.

The reaction of methylenecyclopentane (**3m**) with **2** gave a mixture of 2-bromo-1-chloro- and 1-bromo-2-chloro-1-methylcyclopentane (**4o** and **5o**, 54.5%), 1-bromomethyl-1-chlorocyclopentane (**4m**, 11.0%), dichloro and dibromo adducts (25.5%), and unidentified products (9.0%), as determined by GLC analysis. Although no isolation of **4o** and **5o** was carried out, the retention time of GLC agreed with that of the sample prepared by the reaction of 1-methylcyclopentene (**3o**) with **1** as follows: Bp 42—43°C/5 mmHg; MS M^+ *m/z* (rel intensity) 196, 198, and 200 (100:131:32); ^1H NMR ($CDCl_3$) (the asterisk indicates **5o**) δ=1.90, 1.96* (2s), 1.70—3.10 (m), and 4.44—4.62 (m); ^{13}C NMR ($CDCl_3$) (the asterisk indicates **5o**) δ=20.8, 21.0,* 28.5,* 28.6, 34.9,* 35.4, 39.3, 40.6,* 62.6, 70.9,* 75.1,* and 79.5. The ratio of **4o** and **5o** was shown to be 86:14 by ^{13}C NMR analysis. This product ratio is close to the product ratio (**4o**:**5o**=83:17) for the reaction of **3o** with **2** under the same reaction conditions.

^1H NMR analysis of the recovered alkenes from the reaction of **3m** (20 mmol) with **2** (10 mmol) gave 67% of 1-methylcyclopentene (**3o**) and 33% of methylenecyclopentane (**3m**) as based on the relative areas of the signals at δ=5.30 and 4.83 for the olefinic protons, respectively.

The reaction of methylenecyclohexane (**3n**) with **2** also gave a mixture of 2-bromo-1-chloro- and 1-bromo-2-chloro-1-methylcyclohexanes (**4p** and **5p**, 7.5%), **4n** and **5n** (55.2%), and dichloro and dibromo adducts (37.3%), as determined by GLC analysis. Although no isolation of **4p** and **5p** was carried out, the retention time agreed with that of the sample prepared by the reaction of 1-methylcyclohexene (**3p**) with **1** as follows: Bp 41—42°C/2 mmHg; MS M^+ *m/z* (rel intensity) 210, 212, and 214 (100:134:34); ^1H NMR ($CDCl_3$) (the asterisk indicates **5p**) δ=1.75, 1.91* (2s), 1.56—2.60 (m), and 4.35—4.70 (m).

The authors sincerely wish to thank Professor Shigeru Oae of Okayama University of Science for his kind guidance.

Carbon Monoxide Adsorbent Composed of Copper(I) Chloride and Polystyrene Resin Having Amino Groups

Hidefumi HIRAI,* Keiichiro WADA, Kazunori KURIMA, and Makoto KOMIYAMA
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113
(Received March 13, 1986)

A novel adsorbent of carbon monoxide (CO) is prepared by stirring copper(I) chloride and a macroreticular type polystyrene resin having amino groups in acetonitrile, followed by removal of the liquid phase at 5 mmHg, 80 °C. The adsorbent rapidly adsorbs carbon monoxide from 9 : 1 carbon monoxide–nitrogen mixture at 20 °C under 1 atm. The adsorbed carbon monoxide is readily desorbed by heating the adsorbent to 80 °C under 1 atm or by reducing the partial pressure of carbon monoxide to 5 mmHg at 20 °C. The CO adsorbing capacity (15.9 mmol) of the adsorbent composed of 10.0 g of the resin and 70 mmol of copper(I) chloride is 5.7 times as large as the carbon dioxide adsorbing capacity (2.8 mmol). The efficient adsorption of carbon monoxide by the present adsorbents is attributed to coordination of carbon monoxide to the copper(I) ions which coordinate the amino residues in the resin. The carbon dioxide adsorbing capacity (2.8 mmol) of the adsorbent is much smaller than that (8.3 mmol) of the resin without copper(I) chloride. The present adsorbent exhibits no measurable adsorptions of methane, nitrogen, and hydrogen at 20 °C under 1 atm, and thus is applicable to selective separation of carbon monoxide from gas mixtures containing these gases and carbon dioxide.

Carbon monoxide (CO), an important raw material in industry, is usually obtained as gas mixtures with carbon dioxide (CO_2), methane, nitrogen, and hydrogen.[1] Thus, separation of CO from gas mixtures is required for efficient utilization of CO. Considerable number of liquid absorbents of CO have been proposed.[2] However, solid adsorbents of CO have been rather few.

Active carbon exhibits adsorbing ability of CO. The adsorbing capacity for CO, however, is smaller than those for CO_2 and methane.[3] As a result, selective separation of CO from gas mixtures containing CO_2 and methane is difficult by using active carbon as adsorbent. Zeolite-supported copper(I) ions adsorbed both CO and CO_2.[4,5]

Previously, the authors reported that polystyrene resin-supported aluminium copper(I) chloride,[6,7] active carbon-supported aluminium copper(I) chloride,[8,9] and active carbon-supported copper(I) chloride[10] adsorbed CO reversibly and selectively under mild conditions.

This paper describes preparation of solid CO adsorbents composed of copper(I) chloride (CuCl) and a macroreticular type polystyrene resin having amino groups. The CO adsorbing and desorbing abilities of the adsorbents are reported. The selectivity of CO adsorption with respect to adsorptions of CO_2, methane, hydrogen, and nitrogen is presented. In addition, the results of X-ray photoelectron spectroscopy on the adsorbents are shown. The mechanism of selective adsorption of CO by the present adsorbents is discussed in terms of these results.

Experimental

Materials. A macroreticular type polystyrene resin having primary and secondary amino groups was purchased from Mitsubishi Chemical Industries (DIAION WA20; pale yellow beads of diameter 0.35—0.55 mm; ion-exchange capacity 2.5 equiv dm^{-3}; apparent density 650 g dm^{-3}). A macroreticular type polystyrene resin having carboxylate residues, a macroreticular type polystyrene resin having sulfonate residues, and a macroreticular type polystyrene resin having no functional groups were obtained also from Mitsubishi Chemical Industries: DIAION WK20 (white beads of diameter 0.35—0.55 mm; ion-exchange capacity 3.5 equiv dm^{-3}; apparent density 690 g dm^{-3}), DIAION PK208 (pale yellow beads of diameter 0.40—0.55 mm; ion-exchange capacity 1.2 equiv dm^{-3}; apparent density 745 g dm^{-3}), and DIAION HP30 (white beads of diameter 0.20—0.30 mm; surface area 570 $m^2\ g^{-1}$), respectively.

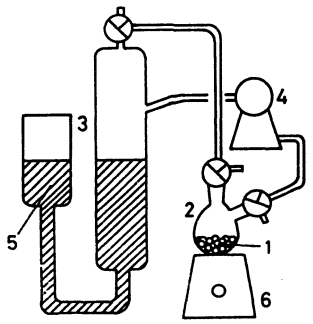

Fig. 1. Apparatus for measuring the amount of CO adsorbed by the adsorbents or desorbed from them; 1: Adsorbent, 2: flask, 3: gas burette, 4: gas pump, 5: leveling liquid (water), 6: magnetic stirrer.

Preparation of Adsorbent. 10.0 g of the polystyrene resin having amino groups and various amounts of CuCl were stirred in 80 cm^3 of solvents at 20° C for 5 h, and then the liquid phase was removed at 5 mmHg (1 mmHg=1.33×10² Pa), 80° C. In the present study, acetonitrile was used as a preparation solvent unless otherwise noted.

Adsorption and Desorption of Carbon Monoxide by the Adsorbent. Adsorption of CO by the adsorbents was carried out at 20° C under 1 atm using the apparatus depicted in Fig. 1. A flask (2) containing the adsorbent (1) under nitrogen (N_2) was connected with CO in the gas burette (3), and the adsorption was initiated by circulating the CO–N_2 mixture with the use of a gas pump (4). The uptake of CO was followed by the gas burette (3) using water as leveling liquid (5). The desorption of adsorbed CO was effected either by heating the adsorbents to 80° C under 1 atm for 10 min or by subjecting the adsorbents to a reduced pressure (5 mmHg) at

20° C for 10 min.

Adsorbing abilities of the adsorbents on carbon dioxide, methane, nitrogen, and hydrogen were measured in similar ways.

Determination of the Amounts of Copper(I) Chloride in the Adsorbents. The adsorbents were thoroughly washed with 100 cm^3 of aqueous nitric acid solution (11.8 mol dm^{-3}). The amounts of copper atoms in the resultant solutions were determined by atomic absorption spectroscopy (Shimadzu Model AA-646 spectrometer).

X-Ray Photoelectron Spectroscopy. X-Ray photoelectron spectra of the adsorbents were measured on a Shimadzu Electron Spectrometer ESCA 750 with Mg X-ray anode (8 kV, 30 mA) under a pressure smaller than 1.5×10^{-7} mmHg. Chemical shifts were determined using the $4f_{7/2}$ band of metallic gold at 84.0 eV as reference.

Results

Preparation of Carbon Monoxide Adsorbents Composed of Copper(I) Chloride and Polystyrene Resin Having Amino Groups. The adsorbents composed of CuCl and the macroreticular type polystyrene resin having amino groups were obtained as green beads. The amount of CuCl supported on the resin was 64 mmol, when the charged amounts of the resin and CuCl, respectively, were 10.0 g and 9.9 g (100 mmol), and acetonitrile was used as a preparation solvent.

Figure 2 shows a plot of the amount of CuCl supported on the polystyrene resin against the charged amount of CuCl. The charged amount of the resin is kept constant at 10.0 g. The supported amount of CuCl increases proportionally with increasing charged amount of CuCl up to the charged amount 50 mmol. Here almost all of the charged CuCl is supported on the resin. Above the charged amount 50 mmol, the supported amount is considerably smaller than the charged amount, being almost constant irrespective of the charged amount.

Adsorption and Desorption of Carbon Monoxide by the Adsorbents Composed of Copper(I) Chloride and Polystyrene Resin Having Amino Groups. Figures 3 and 4 show repeated adsorptions of CO by the adsorbents, which have been prepared from 10.0 g of the resin and 9.9 g (100 mmol) of CuCl, containing 64 mmol of CuCl. In Fig. 3 the desorption of adsorbed CO is carried out by heating the adsorbent to 80° C under 1 atm for 10 min, whereas in Fig. 4 it is achieved by subjecting the adsorbent to a reduced pressure (5 mmHg) at 20° C for 10 min.

The open circles in Fig. 3 depict the first adsorption of CO by the adsorbent from 9:1 $CO-N_2$ mixture at 20° C under 1 atm. The adsorption is rapid and the equilibrium amount of adsorbed CO is 15.2 mmol. Thus, 21 cm^3 (standard temperature and pressure) of CO is adsorbed by 1 g of the adsorbent.

The adsorbed CO is desorbed by heating the adsorbent to 80° C under 1 atm for 10 min. In the second adsorption (the closed circles), the adsorption of CO is rapid and the equilibrium amount of adsorbed CO is 9.1 mmol. In the third and the fourth adsorptions, both the rate of adsorption and the equilibrium amount of adsorbed CO are almost identical with the corresponding values in the second adsorption.

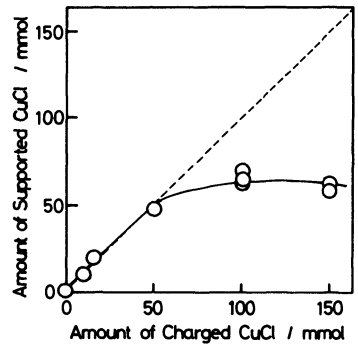

Fig. 2. Plot of the amount of CuCl supported on the polystyrene resin having amino groups against the charged amount of CuCl for the adsorbent prepared from CuCl and the resin by use of 80 cm^3 of acetonitrile as solvent: The charged amount of the resin was kept constant at 10.0 g.

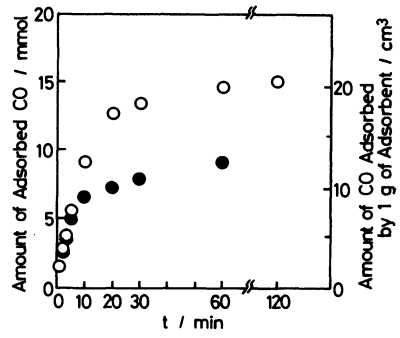

Fig. 3. Repeated adsorptions of CO from 9:1 $CO-N_2$ mixtures at 20 °C under 1 atm by the adsorbent composed of 64 mmol of CuCl and 10.0 g of the polystyrene resin having amino groups: The desorption of adsorbed CO was carried out at 80 °C under 1 atm for 10 min; the first (○) and the second (●) adsorptions.

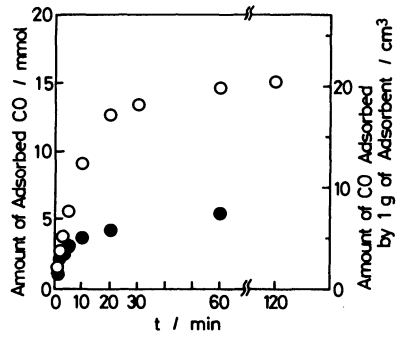

Fig. 4. Repeated adsorptions of CO from 9:1 $CO-N_2$ mixtures at 20 °C under 1 atm by the adsorbent composed of 64 mmol of CuCl and 10.0 g of the polystyrene resin having amino groups: The desorption of adsorbed CO was carried out at 5 mmHg, 20 °C; the first (○) and the second (●) adsorptions.

Table 1. Adsorbing Capacities of the CO Adsorbents Prepared from Copper(I) Chloride and Macroreticular Type Polystyrene Resins Having Various Functional Groups[a,b]

Functional group in the polystyrene resin	CO adsorbing capacity / mmol
Amino residue	15.9
Carboxylate residue	1.2
Sulfonate residue	0.8
None	2.2

a) Adsorption from 9:1 $CO-N_2$ mixture was carried out at 20°C under 1 atm. b) The adsorbents were prepared from 9.9 g (100 mmol) of CuCl and 10.0 g of the resins by use of 80 cm^3 of acetonitrile as solvent.

Table 2. Adsorbing Capacities on Various Gases for the Adsorbent Composed of 70 mmol of Copper(I) Chloride and 10.0 g of the Polystyrene Resin having Amino Groups[a]

Gas	Capacity/mmol	Amount of gas adsorbed by 1 g of adsorbent/cm^3[b]
CO	15.9	21.0
CO_2	2.8	3.7
Methane	0.0	0.0
Hydrogen	0.0	0.0
Nitrogen	0.0	0.0

a) Adsorption from 9:1 $CO-N_2$ mixture was carried out at 20°C under 1 atm. b) Standard temperature and pressure.

The open circles in Fig. 4 show the first adsorption of CO by the adsorbent, which is separately prepared. The equilibrium amount of adsorbed CO is 15.2 mmol. The adsorbed CO is desorbed by subjecting the adsorbent to a reduced pressure (5 mmHg) at 20° C for 10 min. In the second adsorption (the closed circles), the adsorption is rapid and the equilibrium amount of adsorbed CO is 5.4 mmol. Both the time courses and the equilibrium amounts of adsorbed CO in the third and the fourth adsorptions are identical with those in the second adsorption.

Adsorbing Capacities of Carbon Monoxide Adsorbents Composed of Copper(I) Chloride and Polystyrene Resins Having Various Functional Groups. Table 1 shows the CO adsorbing capacities of the adsorbents prepared from 100 mmol of CuCl and 10.0 g of the polystyrene resins having various functional groups. The capacity (15.9 mmol) of the adsorbent prepared with the use of the polystyrene resin having amino groups is much larger than the value (1.2 mmol) for the adsorbent with the resin having carboxylate residues, that (0.8 mmol) for the adsorbent with the resin having sulfonate residues, and that (2.2 mmol) for the adsorbent with the resin having no functional groups.

Selectivity of Carbon Monoxide Adsorption. Table 2 lists the adsorbing capacities of the adsorbent, composed of 10.0 g of the polystyrene resin having amino groups and 70 mmol of CuCl for various gases. The capacity (15.9 mmol) of the adsorbent for CO is 5.7 times as large as the value (2.8 mmol) for CO_2. The adsorbent exhibits no measurable adsorbing ability for methane, hydrogen, and nitrogen.

Figure 5 shows the plots of the adsorbing capacity for CO (the open circles) and the adsorbing capacity for CO_2 (the closed circles) against the amount of CuCl supported on 10.0 g of the polystyrene resin having amino groups. At the amount 0.0 mmol of supported CuCl, the resin does not adsorb CO in a measurable amount, and the adsorbing capacity for CO_2 is 8.3 mmol. The adsorbing capacity for CO largely increases with increasing amount of the supported CuCl, whereas the adsorbing capacity for CO_2 monotonously decreases. Consequently, the selectivity of CO adsorption, which is defined by the ratio of the adsorbing capacity for CO to the value for CO_2, significantly increases with increase in the supported amount of CuCl, as shown by the open squares. A selectivity 5.7 is attained at the supported amount 70 mmol of CuCl.

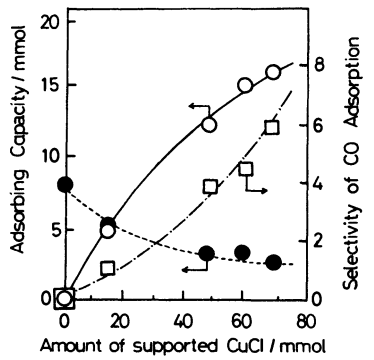

Fig. 5. Plots of adsorbing capacity (○) for CO, adsorbing capacity (●) for CO_2, and the selectivity (□) of CO adsorption against the amount of CuCl supported on the polystyrene resin having amino groups for the adsorbent prepared from CuCl and the resin by use of acetonitrile as preparation solvent: The selectivity of CO adsorption is defined by the ratio of the capacity for CO to the value for CO_2; the amount of the resin is kept constant at 10.0 g.

Effect of Preparation Solvent on the Adsorbing Capacity of the Adsorbent. Table 3 lists the CO adsorbing capacities of the adsorbents prepared with the use of various solvents. The adsorbent prepared using acetonitrile exhibits much larger capacity than the ones prepared using acetone, water, and the aqueous hydrochloric acid solution.

X-Ray Photoelectron Spectroscopy. Figure 6 shows the X-ray photoelectron spectra in the Cu_{2p} region of (a) the adsorbent composed of 65 mmol of CuCl and 10.0 g of the polystyrene resin having amino groups, (b) solid of CuCl, and (c) solid of $CuCl_2$. For the adsorbent, two bands are observed at 933 and 953 eV. The solid of CuCl also exhibits two bands at 933 and 953 eV. The spectrum for the solid of $CuCl_2$ con-

Table 3. CO Adsorbing Capacities of the Adsorbents Prepared by Use of Various Solvents[a,b]

Preparation solvent	Adsorbing capacity/mmol
Acetonitrile	15.9
Acetone	7.2
Water	6.3
Aqueous hydrochloric acid solution (1 mol dm^{-3})	5.6

a) Adsorbents were prepared from 9.9 g (100 mmol) of CuCl and 10.0 g of the polystyrene resin having amino groups with the use of 80 cm^3 of solvents. b) Adsorption from 9:1 CO–N_2 mixture was carried out at 20 °C under 1 atm.

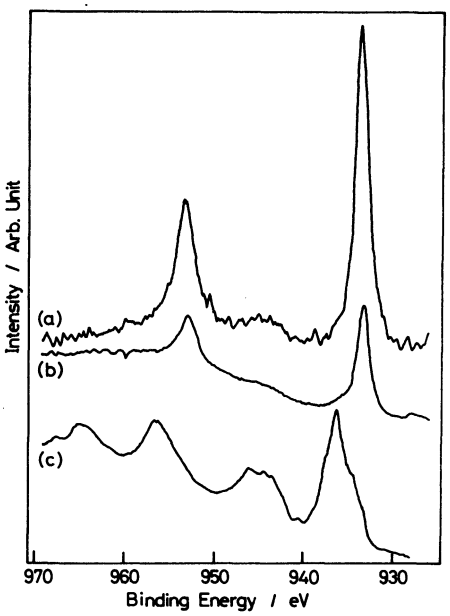

Fig. 6. X-Ray photoelectron spectra in the Cu_{2p} region for (a) the adsorbent composed of 65 mmol of CuCl and 10.0 g of the polystyrene resin having amino groups, (b) solid of CuCl, and (c) solid of $CuCl_2$.

sists of four bands at 937, 944, 957, and 964 eV.

Figure 7 depicts the X-ray photoelectron spectra in the Cl_{2p} region for (a) the adsorbent and (b) solid of CuCl. Both spectra are almost identical with each other, and are composed of a band at 200 eV and a shoulder peak around 201 eV.

Discussion

Adsorption and Desorption of Carbon Monoxide by the Adsorbents Composed of Copper(I) Chloride and Polystyrene Resin Having Amino Groups. The adsorptions of CO by the present adsorbents are ascribed to coordinations of CO to the copper(I) ions, which are complexing with the amino residues of the resin. Thus, the amount of adsorbed CO increases with increasing amount of the CuCl supported on the resin, as shown by open circles in Fig. 5.

Significance of the complexes between CuCl and the

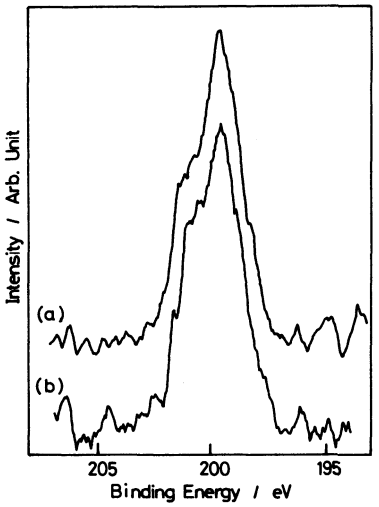

Fig. 7. X-Ray photoelectron spectra in the Cl_{2p} region for (a) the adsorbent composed of 65 mmol of CuCl and 10.0 g of the polystyrene resin having amino groups, and (b) solid of CuCl.

amino residues of the resin as the active species for the CO adsorption by the present adsorbents is definitely shown by the fact that the adsorbing capacity (15.9 mmol) of the adsorbent, prepared by use of the macroreticular type polystyrene resin having amino groups, is much larger than those (0.8—2.2 mmol) of the adsorbents prepared by use of the macroreticular type polystyrene resin having carboxylate residues, the polystyrene resin having sulfonate residues, and the polystyrene resin having no functional groups (Table 1). A methanol solution of CuCl–ethylenediamine complex absorbs CO,[11] whereas a solid of CuCl shows no measurable adsorption of CO at 20° C under 1 atm.[12]

Larger adsorbing capacity (15.9 mmol) of the adsorbent prepared by use of acetonitrile as solvent than the values (7.2 and 6.3 mmol) of the ones prepared by use of acetone and water (Table 3) is also consistent with the important role of the CuCl–amine complexes for the CO adsorption. The solubility of CuCl in acetonitrile is larger than that in acetone or in water, due to complex formation between copper(I) ion and acetonitrile.[13] Consequently, the formation of complex between CuCl and the amino residues of the resin proceeds more efficiently in acetonitrile than in acetone or in water. The small capacity (5.6 mmol) of the adsorbent obtained with the use of aqueous hydrochloric acid solution is associated with poor complex formation between CuCl and the amino residues of the polystyrene resin. In the aqueous hydrochloric acid solution, CuCl molecules dissolve in forms of $CuCl_2^-$[14] and the amino residues are present in their protonated forms. Both of these ionic species are highly stabilized by solvation with water molecules, which is unfavorable for the formations of the CuCl–amine complexes in the adsorbents.

Univalent states of virtually all the copper atoms in the adsorbents are confirmed by the fact that the

X-ray photoelectron spectrum in the Cu_{2p} region (Fig. 6 (a)) showing two bands at 953 and 933 eV is almost identical with that (Fig. 6 (b)) for the solid of CuCl. The solid of $CuCl_2$, however, exhibits satellite bands at 964 and 944 eV in addition to main bands at 937 and 957 eV (Fig. 6 (c)). Spectra in the Cu_{2p} region can be used for distinction between copper(I) species and copper(II) species.[15]

The differences (6.1 mmol and 9.8 mmol, respectively, for Figs. 3 and 4) between the equilibrium amounts of adsorbed CO in the first adsorption by the adsorbent and the values in the second and the later adsorptions correspond to the amounts of CO, which are not desorbed under the desorption conditions employed (80° C under 1 atm for 10 min and 5 mmHg at 20° C for 10 min, respectively).

When cycles involving adsorption of CO at 20° C under 1 atm and desorption of CO at 80° C under 1 atm for 10 min are repeated using the adsorbent composed of 10.0 g of the resin and 64 mmol of CuCl, 9.1 mmol of CO is separated for each of the cycles. For the cycles involving adsorption of CO at 20° C under 1 atm and desorption of CO at 5 mmHg, 20° C for 10 min, the amount of CO separated by one cycle is 5.4 mmol. In these repeated cycles, the amounts of CO separated by 1 g of the adsorbent for one cycle are 12 and 7.4 cm^3 (standard temperature and pressure), respectively.

Selectivity of Carbon Monoxide Adsorption for the Adsorbent Composed of Copper(I) Chloride and Polystyrene Resin Having Amino Groups. Much larger adsorbing capacity (15.9 mmol) on CO for the adsorbent composed of 10.0 g of the resin having amino groups and 70 mmol of CuCl than that (2.8 mmol) on CO_2 (Table 2) is highly in contrast with the adsorbing abilities of the resin itself: The adsorbing capacities of the resin on CO and on CO_2, respectively, are 0.0 and 8.3 mmol. The CuCl molecules supported on the resin are predominantly important for high selectivities of the present CO adsorbents. The adsorbents show no measurable adsorption on methane, hydrogen, and nitrogen.

The amounts of CuCl supported on the polystyrene resin having amino groups in the present adsorbents are larger than the ion-exchange capacity (38 mmol) of 10.0 g of the resin. The capacity is estimated by use of both the ion-exchange capacity per volume (2.5 equiv dm^{-3}) and the apparent density (650 g dm^{-3}) of the resin. Thus, considerable amounts of CuCl are supported on the resin without formation of complexes with the amino residues of the resin. These CuCl molecules are connected by chloride bridges with each other and with the CuCl molecules, which are complexing with the amino residues of the resin. In solids of CuCl, tetrahedrally coordinated copper(I) ions are bound by chloride bridges.[16] Consequently, layers composed of CuCl molecules are probably formed on the surface of the micropores of the resin. Even within the ion-exchange capacity of the resin, some portion of the supported CuCl is probably bound to the resin without complex formation with the amino groups, resulting in monotonous increase of adsorbing capacity with increasing amount of supported CuCl up to the amount 70 mmol (Fig. 5).

The present adsorbents efficiently adsorb CO by coordination of CO to the copper(I) ions in the complexes between CuCl and the amino residues of the polystyrene resin. In contrast, physical adsorption of CO_2 to the surface of the resin is suppressed by the layers of CuCl formed on the surface of the micropores. Chemical adsorption of CO_2 due to interactions with the amino groups of the resin is also inhibited by the complex formation between the amino groups and CuCl.

The arguments are confirmed both by the increase in the adsorbing capacity on CO and by the decrease in the adsorbing capacity on CO_2 with increasing amount of CuCl supported on the resin (Fig. 5). For the resin without CuCl, chemical and physical adsorptions of CO_2 to the resin are predominant, and the amount of adsorbed CO is zero.

The X-ray photoelectron spectroscopy on the adsorbent (Fig. 7) is consistent with formation of layers of CuCl in the adsorbents. The spectrum (a) for the chlorine atoms in the adsorbent is similar to the one (b) for a solid of CuCl. The CuCl molecules, which form layers on the surface of micropores of the resin by mutual chloride bridges, are arranged in almost the same way as those in a solid of CuCl.

The proposed mechanism of the selective adsorption of CO by the present adsorbents is supported by the fact that the adsorbents selectively adsorb ethylene with minimal adsorption of ethane.[17] There, ethylene is effectively adsorbed by the coordination to the copper(I) ions complexing with the amino groups of the macroreticular type polystyrene resin. In contrast, physical adsorption of ethane to the resin is suppressed by the layer of CuCl formed on the surface of the micropores.

In conclusion, selective carbon monoxide adsorbents are prepared from copper(I) chloride and a macroreticular type polystyrene resin having amino groups. The adsorbents are applicable to selective separation of carbon monoxide from gas mixtures containing carbon dioxide, methane, hydrogen, and nitrogen.

The authors would like to thank Dr. Yasuhiko Yoshida at Toyo University for kind assistance in the X-ray photoelectron spectroscopy.

Department of Chemistry, School of Science, Okayama University, 3-1-1, Tsushima-naka, Okayama 700
(Received February 20, 1986)

The mercury- and cadmium-photosensitized reactions of β-propiolactone (PL) have been investigated. The gaseous products from the mercury-photosensitized reaction were carbon dioxide, ethylene, carbon monoxide, ethylene oxide, acetaldehyde, and methane, while the products obtained in the cadmium-photosensitized reaction were carbon monoxide, ethylene oxide, and acetaldehyde. In the mercury-photosensitized reaction, the quantum yields of the products were independent of the lactone pressure at pressures higher than 1500 Pa, while in the cadmium-photosensitized reaction, the quantum yields of the products decreased with the increase in the lactone pressure. Several possible reaction schemes have been proposed to explain the above kinetic behavior. The mercury- and cadmium-photosensitized reactions proceed through different intermediates, that is, a triplet lactone in the former and an excited complex between an excited cadmium atom and a lactone molecule in the latter.

Recently we have studied the mercury- and cadmium-photosensitized reactions of γ-butyrolactone(BL) and found that the mercury-photosensitized reaction gives carbon dioxide, cyclopropane, and propylene, while the cadmium-photosensitized reaction gives carbon monoxide, and ethylene.[1] We concluded that the mercury-photosensitized reaction proceeds through a lactone triplet state, while the cadmium-photosensitized reaction proceeds through an excited complex between an excited cadmium atom and a lactone molecule.

The present study was undertaken to see whether other simple lactones behave similarly.

Experimental

The mercury-photosensitized reaction was carried out at 100° C in a conventional cylindrical quartz vessel, 10 cm long and 4 cm in diameter, fitted with plane quartz windows at each end. A low pressure mercury lamp (Toshiba Electric Co., germicidal lamp) made from a quartz tube was used. The 184.9 nm resonance line was filtered out by means of a Vicor filter. The light intensity absorbed by mercury atoms at 253.7 nm was determined by means of *cis*-2-butene actinometry.[2]

The cadmium-photosensitized reaction was carried out at 235° C in a cylindrical Pyrex cell, 2 cm in diameter and 20 cm long. A U-shaped cadmium discharge lamp made of Pyrex, filled with 670 Pa Ar, was used. The light intensity absorbed by cadmium atoms at 326.1 nm was determined by means of *cis*-2-butene actinometry.[3]

Product analysis was done by fractionation at −196 and −89° C, and messurement by gas buret and gas chromatography. The first portion, non-condensable at −196° C, was collected by the use of a Toepler pump. This portion consisted of carbon monoxide and methane, and it was analyzed by combustion over copper oxide at 250° C. The products in the second portion, which was not condensable at −89° C, were analyzed by means of gas chromatography, using a 6-m column of Gasukuro-pack 55 (Gasukuro Kogyo Co., LTD) at 100°C. The third portion, which was condensable at −89 °C, contained a large amount of PL; it was not analyzed.

β-Propiolsctone(PL)(Sigms Chem. Co., Grade II) was dried over a molecular sieve 4A and purified by means of trap-to-trap distillation. A known amount of liquid propiolactone was injected into a capillary by the use of a microsyringe, fully degassed by many careful freeze-pump cycles, and completely transfered to the cell. The pressure of PL in the cell was calculated by means of the perfect-gas equation.

Results and Discussion

The Mercury-Photosensitized Reaction. Since the vapor pressure of PL is low at room temperature, it is necessary to elevate the reaction temperature in order to obtain sufficient vapor pressure. As was been mentioned above, the mercury-photosensitized reaction was studied at 100° C. The thermal decomposition at this temperature and the direct photolysis at 253.7 nm were found to be negligible. The major volatile products observed in the mercury-photosensitized reaction of PL were carbon dioxide, ethylene, carbon monoxide, acetaldehyde, ethylene oxide, and methane. The yields of these products increased linearly with increase in the resction time and the light intensity, showing that they are primary products. The quantum yields of all products except for carbon monoxide and methane increase with the increase in the lactone pressure up to 1500 Pa, while they are independent of the lactone pressure above 1500 Pa. The increase in the rate of product formation with the increase in the lactone pressure at pressures below 1500 Pa may be explained in terms of the increase in the rate of the energy transfer from $Hg(^3P_1)$ to lactone with the increase in the lactone pressure and/or in terms of the increase in the absorption intensity by mercury atoms as a results of the pressure broadening of the absorption line. The relative yields of products are shown in Fig. 1 as a function of the lactone pressure. Ethylene is always formed in amounts equimolar with carbon dioxide. The relative yields of ethylne oxide and acetaldehyde reach a constant value of about 0.12 above 1500 Pa, and fall slightly at lower pressures, while that of carbon monoxide decreased rapidly with the increase in the lactone pressure below 1500 Pa and reaches an almost constant value of at pressures higher than 1500 Pa. (Methane was found at pressures lower than 5000 Pa. The yield of methane decrease with the increase in the

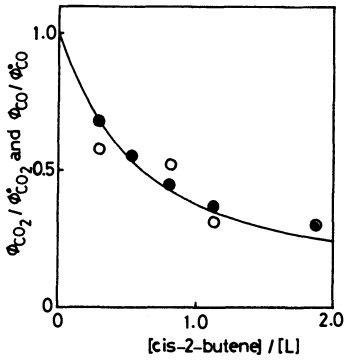

Fig. 2. Quantum yields of CO_2 (●) and CO (○) in the mercury-photosensitized reaction of PL in the presence of *cis*-2-butene.

lactone pressure and reached zero at about 5000 Pa)

When *cis*-2-butene was added to lactone, the quantum yields of carbon dioxide and carbon monoxide decreased as the quantum yield of *trans*-2-butene formation increased with the increase in the *cis*-2-butene pressure. From the slope of the reciprocal plot of the quantum yield of *trans*-2-butene vs. the lactone/*cis*-2-butene ratio, the quenching efficiency of lactone relative to that of *cis*-2-butene was estimated to be 0.62. Figure 2 shows the effect of *cis*-2-butene on the yields of carbon dioxide and carbon monoxide. The solid line shows the relative quantum yields calculated using the relative quenching efficiency of lactone obtained above. As Fig. 2 shows, the decrease in the quantum yields observed in the presence of *cis*-2-butene can be explained by the competitive quenching of the triplet mercury atom by lactone and *cis*-2-butene.

When oxygen was added to lactone, the quantum yields of the products decreased. For example, when 1333.3 Pa of oxygen was added to 4000 Pa of lactone, the following ratios of yields were obtained:

ϕ/ϕ°=0.87 (carbon dioxide), 0.75 (ethylene), 0.82 (ethylene oxide), and 0.85 (acetaldehyde). Here, ϕ° is the quantum yield in the absence of oxygen. These values are in good agreement with the ratio (0.81) calculated using the following relative quanching efficiencies of lactone and oxygen:

$$\sigma(\text{lactone})/\sigma(\textit{cis}\text{-2-butene}) = 0.62$$
$$\sigma(\text{oxygen})/\sigma(\textit{cis}\text{-2-butene}) = 0.45^{4)}$$

The decrease in the quantum yields can again be explained by the Competitive quenching of the triplet mercury atoms by lactone and oxygen. These findings show that the nature of the formation of these products was not affected by the addition of *cis*-2-butene and oxygen.

In order to explain the experimental results, the following set of reactions is proposed:

$$Hg(^1S_0) + h\nu(253.7\text{ nm}) \longrightarrow Hg(^3P_1), \quad (1)$$
$$Hg(^3P_1) \longrightarrow Hg(^1S_0) + h\nu(253.7\text{ nm}), \quad (2)$$
$$Hg(^3P_1) + L \longrightarrow Hg(^1S_0) + {}^3L, \quad (3)$$
$${}^3L \longrightarrow CO_2 + C_2H_4, \quad (4)$$
$${}^3L \longrightarrow CO + C_2H_4O^*, \quad (5)$$
$$C_2H_4O^* \longrightarrow CH_4 + CO, \quad (6)$$
$$C_2H_4O^* + L \longrightarrow \triangle_O + L, \quad (7)$$
$$C_2H_4O^* + L \longrightarrow CH_3CHO + L, \quad (8)$$
$$C_2H_4O^* + L \longrightarrow \text{other products}. \quad (9)$$

Here, ^3L denotes triplet lactone, while $C_2H_2O^*$ is an energy-rich intermediate. From this mechanism, the following equations can be derived:

$$\frac{\phi C_2H_4}{\phi CO_2} = 1.0, \quad (10)$$
$$\frac{\phi\triangle_O}{\phi CO_2} = \frac{k_5}{k_4}\frac{k_7[L]}{k_6+(k_7+k_8+k_9)[L]}, \quad (11)$$
$$\frac{\phi CH_3CHO}{\phi CO_2} = \frac{k_5}{k_4}\frac{k_8[L]}{k_6+(k_7+k_8+k_9)[L]}, \quad (12)$$
$$\frac{\phi CO}{\phi CO_2} = \frac{k_5}{k_4}\left(1+\frac{k_6}{k_6+(k_7+k_8+k_9)[L]}\right). \quad (13)$$

These equations show that the yield of ethylene is equal to that of carbon dioxide, and that the relative yields of acetaldehyde and ethylene oxide increase with the increase in the lactone pressure and reach a constant value at higher pressures, while the relative yield of carbon monoxide decreases with the increase in the lactone pressure and becomes constant (k_5/k_4) at higher pressures. These pressure dependences are consistent with those observed (Fig. 1). The decrease in the yield of methane observed (Fig. 1) is parallel to that of carbon monoxide at lower pressures, as was predicted by the above reaction mechanism. From the constant values of the relative yields at higher pressures, some ratios of

Table 1. Ratios of Rate Constants

$k_5/k_4=0.38$
$k_7/(k_7+k_8+k_9)=k_8/(k_7+k_8+k_9)=0.33$
$k_7:k_8:k_9=1:1:1$

rate constants are obtained; they are listed in Table 1.

The fate of the $C_2H_4O^*$ formed in Reaction (5) at high pressures requires some comment. Reactions (7) and (8), simple rearrangements (or stabilizations) to acetaldehyde and ethylene oxide, are suggested as the sources of these products, and because the sum of ethylene oxide and acetaldehyde was always less than carbon monoxide, Reaction (9) is suggested.

One possibility for Reaction (9) is a reaction with lactone to give higher products which were not observed.

Another possibility is the formation of vinyl alcohol, CH_2=CHOH, which would probably have been lost by polymerization before or during analysis. Although vinyl alcohol is about 84 kJ mol^{-1} less stable thermodynamically than acetaldehyde, the formation of either compound through the biradical($\cdot CH_2CH_2O\cdot$) which is considered to be formed from $C_2H_4O^*$ before formation of acetaldehyde in the thermal decomposition of ethylene oxide[5] should be quite exothermic; both would require hydrogen transfer through three-membered transition states, which might be about equally probable:

$$\overset{\cdot\cdot}{CH_2}CH\text{–}O \longrightarrow CH_3CHO, \quad (14)$$
$$\overset{\cdot\cdot}{H}$$

$$CH_2\text{–}CH\text{—}O \longrightarrow CH_2{=}CHOH. \quad (15)$$
$$\overset{\cdot\cdot}{H}$$

As Table 1 shows, the rate of Reaction (9) is equal to that of Reaction (8). This seems to show that the second case is more possible, although the existence of vinyl alcohol has not been reported in the reaction of ethylene with the oxygen atom,[6] the mercury-photosensitized reaction of ethylene oxide,[7] etc.[8,9]

From the above mechanism, the following relationship can be derived:

$$\frac{\phi CO}{\phi\Delta_0+\phi CH_3CHO}=\frac{k_7+k_8+k_9}{k_7+k_8}+\frac{2k_6}{k_7+k_8}\frac{1}{[L]}. \quad (16)$$

From the slope of the line shown in Fig. 3, $2k_6/(k_7+k_8)$=906 Pa was obtained. As is shown in Table 1, $k_7=k_8$. Therefore, $k_6/k_7=k_6/k_8$=906 Pa. The experimental value of k_6/k_7 gives $k_6=7.14\times10^7$ s^{-1} when 7.9×10^4 s^{-1} is adopted as the kinetic collision frequency at 1 Pa snd 100° C and when a collision deactivation efficiency of unity is assumed for lactone.

The excess energy of energized intermediate ($C_2H_4O^*$) can be estimated using

$$k_6(E)=A\left(1-\frac{E_a}{E}\right)^{s-1}, \quad (17)$$

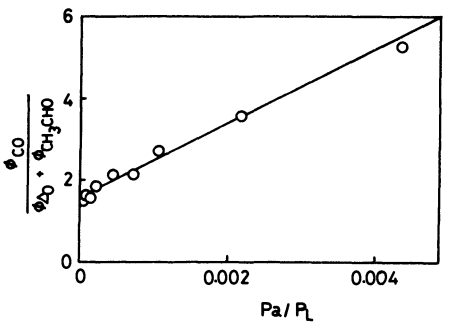

Fig. 3. Plots of $\phi_{CO}/(\phi_{\Delta_0}+\phi_{CH_3CHO})$ against the reciprocal of lactone pressure.

Here, k (E) is the rate constant for the decomposition of $C_2H_4O^*$ when the excess energy is E; A is the frequency factor, E_a is the critical energy, and s is the number of effective oscillators in the molecule. Using the experimental value of k_6 and substituting $A=10^{14.34}$ S^{-1} and E_a=240.2 kJ mol^{-1} (taken from the experiment of Mueller and Walters[8]) and s=8 (about half of the number of the modes of vibration of ethylene oxide), the value of E was found to be 272 kJ mol^{-1}. This excess energy corresponds to about 78% of the enthalpy change for the following reaction, which is estimated to be 351 kJ mol^{-1} by using the standard enthalpies of formation (ΔH_f°=−282.8 (propiolactone), −52.7 (CO), and −110.0 kJ mol^{-1} (ethylene oxide) and the excitation energy of mercury (E_T=469 kJ mol^{-1});

(18)

A comparison of the vibrational energy distribution in different systems is given in Table 2. It is evident that the major portion of the excess energy goes to the product with the most vibrational degree of freedom.

The reactions of oxygen atoms with ethylene in the gas phase[6] and in a liquid nitrogen solution[10] have been reported, and it was concluded that the primary step of the reactions involves the direct addition of an oxygen atom to the double bond to form an energy-rich intermediate ($C_2H_4O^*$) which then undergoes further reactions.

Cvetanovic pointed out[6] that there is a significant similarity among the following different modes of the decomposition of ethylene oxide: The thermal,[8] photolitic,[9] mercury-photosensitized decompositions,[7] and the decomposition of the energy-rich molecule formed in the reaction of oxygen atoms with ethylene in the gas phase.[6] As Table 3 shows, the product distribution in the present case is much simpler than those in the other cases mentioned above, and it is rather similar to that for the reaction of oxygen atoms with ethylene in a liquid nitrogen solution. It seems to be interesting that the fate of $C_2H_4O^*$ in the present case is very similar to that in the reaction of oxygen atoms with ethylene in the liquid phase.[10]

The Cadmium-Photosensitized Reaction. The cadmium-photosensitized reaction was carried out at 235°C to get a sufficient vapor pressure of cadmium. The thermal decomposition of PL occurred at this temperature and gave carbon dioxide and ethylene. Under the irradiation of the cadmium-resonance line, we obtained carbon monoxide, ethylene oxide, and acetaldehyde besides carbon dioxide and ethylene. The amounts of carbon dioxide and ethylene were almost the same as those obtained from the thermal decomposition. We checked the influence of carbon dioxide and/or ethylene on the cadmium-photosensitized reaction, and found that the quantum yields of carbon monoxide, ethylene oxide, and acetaldehyde are independent of the pressure of the carbon dioxide (and/or ethylene) added, if the competitive quenching of the triplet cadmium atoms by lactone and carbon dioxide (and/or ethylene) is taken into account. Therefore, the influence of the thermal decomposition on the results of the cadmium-photosensitized reaction was regarded as negligible. The rate of the cadmium-photosensitized reaction decreases more rapidly than that of the thermal decomposition with a decrease in the reaction temperature. Therefore, the cadmium-photosensitized reaction was difficult to study at temperature lower than 235°C.

The major products obtained in the cadmium-photosensitized reaction of PL were carbon monoxide, ethylene oxide, and acetaldehyde. The yields of these products increased linearly with the reaction time,

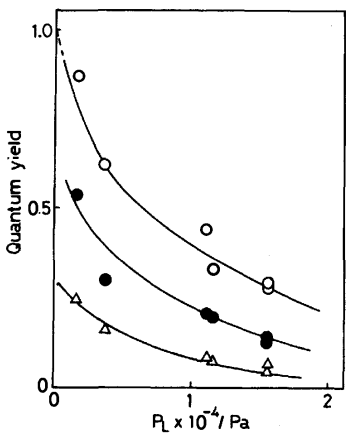

Fig. 4. Pressure dependence of quantum yields of CO (○), ethylene oxide (△), and acetaldehyde (●) in the cadmium-photosensitized reaction of PL.

showing that these are primary products. The quantum yields of these products are shown in Fig. 4 as a function of the lactone pressure. All of them decrease with an increase in the lactone pressure, showing the operation of the collisional deactivation process. This pressure dependence is quite different from that in the mercury-photosensitized reaction. Furthermore, in contrast with the mercury-photosensitized reaction, carbon dioxide and ethylene were not obtained, and the sum of ethylene oxide and acetaldehyde yields almost equals the carbon monoxide yield at low pressures (methane was not obtained even at low pressures).

These findings indicate that the cadmium-photosensitized reaction of PL proceeds through a different intermediate from that in the mercury-photosensitized reaction.

As has been mentioned previously,[1] the triplet state of BL seems to lie at about 440 kJ mol^{-1} above the ground state. If the energy of the triplet state of PL is similar to that of BL, the triplet state of PL is formed in the mercury-photosensitized reaction, as has been mentioned above ($Hg(^3P_1)$ has an energy of 469 kJ mol^{-1}), but it can not be formed by reaction with $Cd(^3P_1)$, which has an energy of only 367 kJ mol^{-1}. This probably accounts for the difference between the mercury- and cadmium-photosensitized reactions of PL.

In order to explain the experimental results, the following set of reactions is proposed:

$$Cd(^1S_0) + h\nu(326.1\ nm) \longrightarrow Cd(^3P_1), \quad (19)$$

$$Cd(^3P_1) \longrightarrow Cd(^1S_0) + h\nu(326.1\ nm), \quad (20)$$

$$Cd(^3P_1) + L \longrightarrow CdL^*, \quad (21)$$

$$CdL^* \longrightarrow Cd(^1S_0) + CO + C_2H_4O^*, \quad (22)$$

$$CdL^* + L \longrightarrow Cd(^1S_0) + 2L, \quad (23)$$

$$C_2H_4O^* \longrightarrow \triangle O, \quad (24)$$

$$C_2H_4O^* \longrightarrow CH_3CHO, \quad (25)$$

$$C_2H_4O^* + L \longrightarrow \text{other products}. \quad (26)$$

Here, CdL* stands for a transient complex between an excited cadmium atom and a lactone molecule, and $C_2H_4O^*$ is an energy-rich intermediate. The large pressure dependence of the quantum yields for the product formation is explained by Reaction (23). This mechanism is almost the same as that proposed for the cadmium-photosensitized reaction of γ-butyrolactone,[1] and of γ-valerolactone and α-methyl-γ-butyrolactone.[11]

From the above mechanism, the following equations can be derived:

$$\frac{\phi CO}{\phi\triangle_O} = \left(1+\frac{k_{25}}{k_{24}}\right) + \frac{k_{26}}{k_{24}}[L], \quad (27)$$

$$\frac{\phi CO}{\phi CH_3CHO} = \left(1+\frac{k_{24}}{k_{25}}\right) + \frac{k_{26}}{k_{25}}[L]. \quad (28)$$

Plots of $\phi_{CO}/\phi_{\triangle O}$ and ϕ_{CO}/ϕ_{CH_3CHO} vs. the lactone pressure are presented in Fig. 5. The values of k_{25}/k_{24} obtained from the intercepts and the slopes of the straight lines in Fig. 5 are in good agreement with one another within the limits of experimental error

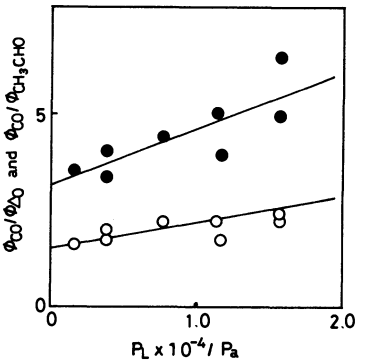

Fig. 5. Plots of $\phi_{CO}/\phi\triangle_O$ (●) and ϕ_{CO}/ϕ_{CH_3CHO} (○) against lactone pressure.

(2.1±0.1). This demonstrates that the above scheme is reasonable.

The intermediate, $C_2H_4O^*$, is similar to that in the mercury-photosensitized reaction. Since methane was not found even at low pressures, as has been mentioned above, the excess energy of $C_2H_4O^*$ in the cadmium-photosensitized reaction seems to be considerably smaller than that in the mercury-photosensitized reaction. As has been described above, the cadmium-photosensitized reaction are always accompanied by a rapid thermal decomposition at 235°C. Therefore, we could not obtain more detailed data, and further quantitative discussion of the cadmium-photosensitized reaction does not seem to be justified.

Selective Formation of 2-Phenylethanol in the Homologation of Benzyl Alcohol

Kazuhiro WATANABE,* Kiyoshi KUDO, Sadayuki MORI, and Nobuyuki SUGITA
Institute for Chemical Research, Kyoto University, Gokanosho, Uji, Kyoto 611
(Received March 8, 1986)

High selectivity of 2-phenylethanol (87%) in the homologation of benzyl alcohol was obtained with cobalt-ruthenium mixed catalyst. The formation of toluene as the major by-product was suppressed by adding water at low reaction temperature. Bromide as promoter was more effective for the homologation than chloride or iodide. From in situ IR observation, $[Co(CO)_4]^-$, which was active species for the homologation, was found to be produced by the dissociation of $[CoH(CO)_4]$ but not by the disproportionation of $[Co_2(CO)_8]$ under the reaction temperature employed (120 °C). It was also revealed that ruthenium chloride as precatalyst was converted into a bromocarbonyl complex of ruthenium under the homologation conditions.

The homologation of benzyl alcohol to 2-phenylethanol is an important reaction because the latter can be dehydrated to styrene. This reaction was first reported by Wender and his co-workers.[1] Their results showed that the hydrocarbon, toluene, and the homologous alcohol, 2-phenylethanol, were formed in a ratio of about 2:1. Based on the effects of substituents on aromatic ring, they postulated[2] that the homologation (Eq. 1) and the reduction (Eq. 2)

$$C_6H_5CH_2OH + CO + 2H_2 \longrightarrow C_6H_5CH_2CH_2OH + H_2O, \quad (1)$$

$$C_6H_5CH_2OH + H_2 \longrightarrow C_6H_5CH_3 + H_2O, \quad (2)$$

proceeded via the same intermediate. In spite of their studies, the selectivity of the homologation products were insufficient and toluene derivatives were major products. Up to now, higher molar ratio of 2-phenylethanol to toluene in this homologation was only reported in a patent.[3] Thus the main aim of this work is to improve the selectivity of the homologation step.

It has been known[4] that cobalt-catalyzed methanol homologation is promoted by iodide such as methyl iodide and by the addition of ruthenium as co-catalyst. So, we explored optimum reaction conditions for the homologation of benzyl alcohol with this mixed catalyst and halides as promoters. We also discussed the reaction mechanism.

Experimental

All materials other than solvent were commercially available and used without further purification. Solvent, 1,4-dioxane, was distilled over a Na-Pb alloy under nitrogen atmosphere. Hydrogen was commercial material (purity: above 99%) and carbon monoxide was prepared in our laboratory (purity: above 98%). Apparatus and procedure were similar to those used previously.[5,6]

Result and Discussion

Preliminary Experiments. At first, we investigated the effect of various halides as promoters on the homologation of benzyl alcohol. By the use of hydriodic acid as promoter at high temperature (180 °C), toluene was obtained preferentially and 2-phenylethanol in much lower yield under the reaction conditions employed (Run 1 in Table 1). Wender and his co-workers suggested[2] that toluene was formed through the radical mechanism involving benzyl radical. Carbon-metal bond is generally weak, for instance, 105 kJ mol^{-1} in $[C_6H_5CH_2Mn(CO)_6]$[7] and 92 kJ mol^{-1} in $[C_6H_5CH_2Co(Saloph)(py)]$,[8] so that this bond in

a) Reaction conditions: Total pressure, 300 kg cm^{-2} at room temp ($H_2/CO=2/1$); benzyl alcohol, 7 M; $Co(AcO)_2$, 0.23 M; $RuCl_3$, 0.023 M; 1,4-dioxane, 2 ml; reaction time, 4 h. b) Added as its aqueous solution, 1 M = 1 mol dm^{-3}. c) Total yield of 2-phenylethanol and phenylacetaldehyde. The selectivity of homologous compounds is shown in the parentheses. d) H_2O was added at the same concentration as that of hydrobromic acid used in Runs 5 to 8.

$[C_6H_5CH_2Co(CO)_4]$ is considered to be weak. Thus, the benzyl radical is supposed to be formed by homolysis of benzylcobalt complex and the reaction mechanism of toluene formation is considered as Eq. 3 to Eq. 7. On the other hand, if benzylcobalt complex (**1**)

$$C_6H_5CH_2OH + HX \rightleftharpoons C_6H_5CH_2X + H_2O \quad (3)$$
X : halogen atom

$$C_6H_5CH_2X + [Co(CO)_4]^- \rightleftharpoons [C_6H_5CH_2Co(CO)_4] + X^- \quad (4)$$
1

$$\mathbf{1} \rightleftharpoons C_6H_5CH_2\cdot + \cdot Co(CO)_4 \quad (5)$$
2 **3**

$$\mathbf{2} + [CoH(CO)_4] \rightleftharpoons C_6H_5CH_3 + \mathbf{3} \quad (6)$$

$$\mathbf{2}\ \mathbf{3} \rightleftharpoons [Co_2(CO)_8] \quad (7)$$

undergoes CO insertion followed by hydrogenolysis (Eqs. 8 and 9), phenylacetaldehyde is produced which

$$\mathbf{1} + CO \rightleftharpoons [(C_6H_5CH_2CO)Co(CO)_4] \quad (8)$$
4

$$\mathbf{4} + H_2 \rightleftharpoons C_6H_5CH_2CHO + [CoH(CO)_4] \quad (9)$$

is rapidly converted into 2-phenylethanol by ruthenium catalyst as shown later. 2-Phenylethanol and toluene are produced via the same intermediate, that is, benzylcobalt complex. Therefore, the suppression of homolytic cleavage (Eq. 5) or of the hydrogen abstraction reaction (Eq. 6) should improve the selectivity of 2-phenylethanol. Benzyl radical may also be formed by homolysis of benzyl iodide (Eq. 10).

$$C_6H_5CH_2I \rightleftharpoons C_6H_5CH_2\cdot + \cdot I \quad (10)$$

In order to suppress the radical cleavage such as Eq. 5 or Eq. 10, the reaction was carried out without iodide at low temperature (120 °C). Under these reaction conditions, 2-phenylethanol was a major product (Run 2 in Table 1) but its selectivity was not sufficient. By-products other than toluene were dibenzyl ether, ethylbenzene and benzyl acetate. The yield of dibenzyl ether was about 2% and that of ethylbenzene about 0.1% through the all runs. Benzyl acetate was formed by the reaction of benzyl alcohol with acetate anion originating in a precatalyst, cobalt(II) acetate, since benzyl acetate could not be detected by using octacarbonyldicobalt instead of cobalt(II) acetate. 1,2-Diphenylethane, the coupling product of benzyl radical, was also obtained in small amount through all runs. This result suggests the existance of benzyl radical.

Table 1 shows the effect of halides as promoters at low reaction temperature (Runs 3—5). Hydrobromic acid was more effective than hydrochloric acid for both the yield and selectivity of 2-phenylethanol. Hydriodic acid enhanced the conversion of benzyl alcohol but toluene was preferentially obtained. This implies that homolysis of benzyl iodide occurs to produce benzyl radical. From above results, we chose bromide as promoter and examined the effects of other reaction variables on the homologation.

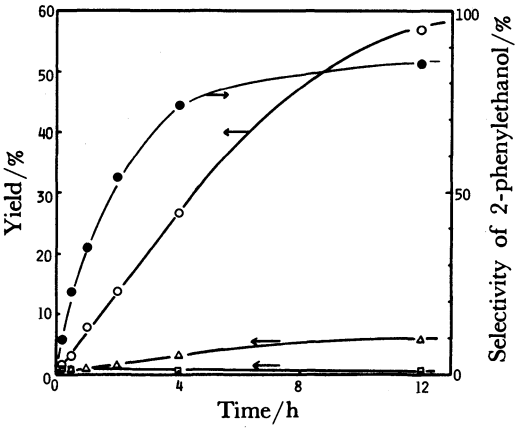

Fig. 1. Time dependent products yield in benzyl alcohol homologation. Reaction temp, 120 °C, total pressure, 320 kg cm^{-2} at 120 °C, (H_2/CO=2/1); benzyl alcohol, 7 M; HBr, 0.2 M as aqueous solution; $Co(AcO)_2$, 0.23 M; $RuCl_3$, 0.023 M; 1,4-dioxane, 10 ml. Total pressure was kept constant during the reaction. ○: 2-Phenylethanol, △: toluene, □: phenylacetaldehyde and ●: selectivity of 2-phenylethanol.

Effects of Temperature. Table 1 also shows that the yield of toluene decreases and the selectivity of 2-phenylethanol increases as the reaction temperature decreases from 180 °C to 120 °C (Runs 5—7). At 100 °C, the activity of catalyst for the homologation fell down and dibenzyl ether was obtained as the major by-product (yield: 4%). Thus, the optimum temperature for the high selectivity of the homologation step was about 120 °C.

The time-yield curves of 2-phenylethanol, phenylacetaldehyde and toluene at 120 °C are shown in Fig. 1. From these curves, it is suggested that phenylacetaldehyde is the intermediate for the formation of 2-phenylethanol (Eqs. 11 and 12). Figure 1 also shows

$$C_6H_5CH_2OH + CO + H_2 \longrightarrow C_6H_5CH_2CHO + H_2O \quad (11)$$

$$C_6H_5CH_2CHO + H_2 \longrightarrow C_6H_5CH_2CH_2OH \quad (12)$$

that the selectivity of 2-phenylethanol increases with the reaction time. As discussed later, this phenomenon is explained by the increase in the concentration of water which is produced by the reaction of benzyl alcohol with hydrogen bromide (Eq. 3, X=Br).

Effect of Ruthenium Concentration. The addition of ruthenium is known[4] to improve the selectivity of ethanol in methanol homologation and we proved[5] that its effectiveness was ascribed to the high reactivity on the hydrogenation of acetaldehyde. Figure 2 shows that ruthenium is also effective for improving the selectivity of 2-phenylethanol on account of the fast hydrogenation of phenylacetaldehyde. This fast hydrogenation of phenylacetaldehyde implies that the decarbonylation of phenylacetaldehyde affording toluene

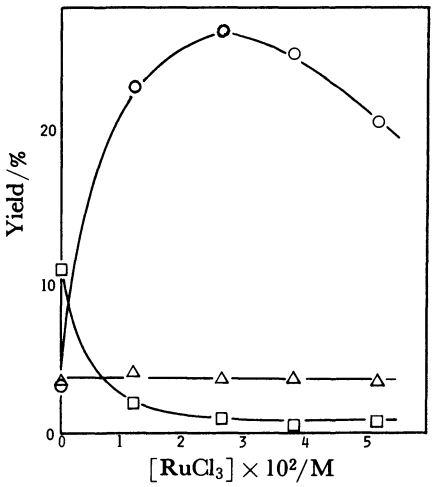

Fig. 2. Effect of ruthenium concentration on benzyl alcohol homologation. Reaction conditions were the same as those of Fig. 1, except ruthenium concentration and reaction time (4 h). ○: 2-Phenylethanol, △: toluene, □: phenylacetaldehyde.

is ruled out.

An optimum concentration of ruthenium existed and the yield of 2-phenylethanol decreased by the addition of ruthenium in large excess. This phenomenon was also observed in the case of methanol homologation.[6] As in the previous report,[5] this phenomenon is interpreted as resulting from the consumption of halogens which coordinate to ruthenium species (see later).

Effect of H_2O. As shown earlier, the concentration of water had an effect on the selectivity of 2-phenylethanol. In order to examine the effect of water in detail, we employed $C_6H_5CH_2Br$ as promoter instead of hydrobromic acid in this and the following experiments. The effect of $C_6H_5CH_2Br$ on the homologation was similar to that of HBr (Runs 5 and 9 in Table 1). [$Co_2(CO)_8$] was employed as catalyst precursor to avoid the formation of benzyl acetate.

From the results of in situ IR observation as shown later, water enhances the dissociation of [$CoH(CO)_4$] (Eq. 13). (An oxonium ion reacts rapidly with bromide anion which is produced by Eq. 4 affording water and hydrogen bromide as shown in Eq. 14).

$$[CoH(CO)_4] + H_2O \rightleftharpoons [H_3O]^+ + [Co(CO)_4]^- \quad (13)$$

$$[H_3O]^+ + Br^- \rightleftharpoons H_2O + HBr \quad (14)$$

When the initial concentration of water was lower than 2.0 M, both the yield and selectivity of 2-phenylethanol increased with the water concentration but the total yield of 2-phenylethanol and toluene was independent of it (Fig. 3 and Runs 1—3 in Table 2). Water inhibits the hydrogen abstraction reaction of benzyl radical from [$CoH(CO)_4$] (Eq. 6) because the concentration of [$CoH(CO)_4$] decreases with the initial concentration of water on account of the shift of equilibrium 13 to the right. On the other hand, addition of water in excess (higher than 2.0 M) diminished the total yield of 2-phenylethanol and toluene (Fig. 3) due to the shift of equilibrium 3 to the left. The selectivity of 2-phenylethanol, however, became not to be affected by the initial concentration of water (Runs 4, 6, and 7 in Table 2). Therefore, equilibrium 13 lies far to the right.

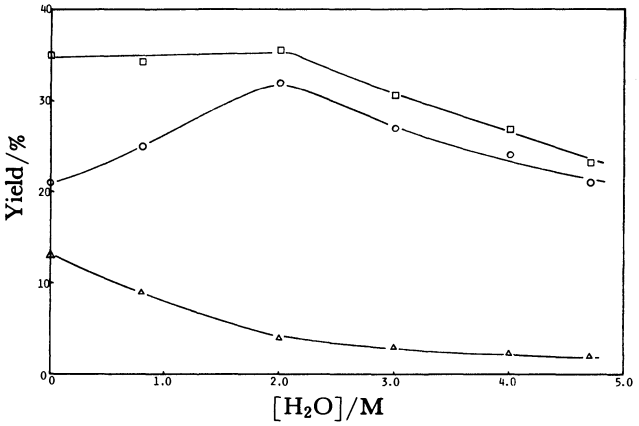

Fig. 3. Effect of H_2O concentration on toluene formation. Reaction conditions were the same as those of Table 2. ○: 2-Phenylethanol, △: toluene, □: total yield of 2-phenylethanol and toluene.

Table 2. The Effect of H_2O

Run	[H_2O]/M	Yield/%	
		$C_6H_5CH_2CH_2OH$[a]	$C_6H_5CH_3$
1	0[b]	22 (59)	13
2	0.8	25 (67)	9.2
3	2.0	32 (83)	4.1
4	3.0	27 (85)	3.1
5[c]	3.0	41 (87)	4.0
6	4.0	24 (84)	2.6
7	4.7	21 (85)	2.3

Reaction conditions: Reaction temp., 120 °C; total pressure, 320 kg cm^{-2} at 120 °C (H_2/CO=2/1); benzyl alcohol, 7 M; $Co_2(CO)_8$, 0.11 M; $RuCl_3$, 0.029 M; benzyl bromide, 0.21 M; 1,4-dioxane, 10 ml; reaction time, 4 h; the consumed gas was supplied during the reaction. a) The selectivity of 2-phenylethanol is shown in the parentheses. b) $Ru_3(CO)_{12}$, 8.8×10^{-3} M. c) Reaction time, 8 h.

As the reaction proceeded, the concentration of water increased by Eq. 3 and the selectivity of 2-phenylethanol increased as shown in Fig. 1. When the reaction was carried out for long period (12 h), one of the minor by-products, dibenzyl ether, was obtained in lower yield (0.5%) than that obtained for 4 h (1.4%). This result is due to the progress of the reverse reaction in equilibrium 15 since the concentration of water

$$2\,C_6H_5CH_2OH \rightleftharpoons C_6H_5CH_2OCH_2C_6H_5 + H_2O \quad (15)$$

increases and that of benzyl alcohol decreases with proceeding of the reaction. Thus the highest selectivity of 2-phenylethanol (87%, Run 5 in Table 2) was achieved, when the homologation was carried out for

4	2/1	19 (55)	3.0	7.0

Reaction conditions: Total pressure, 320 kg cm^{-2} at 120 °C; H_2O, 2.0 M; other reaction conditions were the same as those of Table 2. a) Partial pressure ratio. b) The selectivity of 2-phenylethanol is shown in the parentheses.

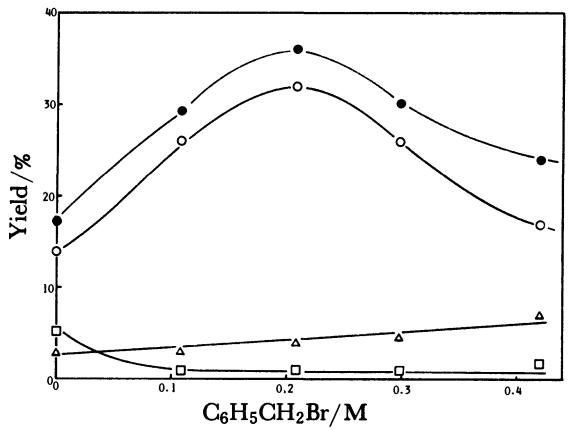

Fig. 4. Effect of benzyl bromide concentration on benzyl alcohol homologation. Reaction conditions were the same as those of Table 3. ○: 2-Phenylethanol, △: toluene, □: phenylacetaldehyde, ●: total yield of 2-phenylethanol and toluene.

long period under the optimum reaction conditions for its selectivity.

Effect of Benzyl Bromide and Partial Pressure of CO to H_2. Benzyl bromide promoted both the reactions of the homologation (Eq. 1) and the reduction (Eq. 2), when the initial concentration of benzyl bromide was lower than 0.2 M (Runs 1—3 in Table 3). The total yield of 2-phenylethanol and toluene, however, decreased with the initial concentration of benzyl bromide higher than 0.2 M (Fig. 4). These results indicate that the rate of benzylcobalt complex formation is retarded when the benzyl bromide is added in large excess. This is due to the suppression of the forward reaction of Eq. 4 by the high concentration of bromide anion. Although suppressing the forward reaction of Eq. 4 should lead to repression of the yield of toluene, that of toluene increased with the initial concentration of benzyl bromide. This implies that toluene is also produced via homolysis of benzyl bromide.

Figure 4 also shows that the hydrogenation of phenylacetaldehyde is slower in the absence of bromide than in the presence of it. As shown later, under the reaction conditions, ruthenium chloride as precatalyst was converted into chlorocarbonyl complex in the absence of bromide and into bromocarbonyl complex in the presence of it. Consequently, the former is supposed to be less reactive for the hydrogenation of phenylacetaldehyde than the latter.

Concerning the partial pressure ratio of CO to H_2, the highest yield and selectivity of 2-phenylethanol were found by using a CO to H_2 ratio of about 1:2 (Table 4). High partial pressure of H_2 increased the yield of toluene (Run 1 in Table 4) on account of high concentration of $[CoH(CO)_4]$ by equilibrium 16.

$$[Co_2(CO)_8] + H_2 \rightleftharpoons 2[CoH(CO)_4] \quad (16)$$

While low partial pressure of H_2 retarded the rate of hydrogenation of phenylacetaldehyde (Run 4 in Table 4) and also retards the formation of $[CoH(CO)_4]$ in equilibrium 16. In this case, homolysis of Co–Co bond in $[Co_2(CO)_8]$, the bond energy of which is very low (61 kJ mol^{-1}),[9] may occur to form cobalt carbonyl radical (Eq. 17). This radical abstracts $[Co(CO)_4]$ from

$$[Co_2(CO)_8] \rightleftharpoons 2\cdot Co(CO)_4 \quad (17)$$

benzylcobalt complex to afford benzyl radical (Eq. 18)

$$[C_6H_5CH_2Co(CO)_4] + \cdot Co(CO)_4 \rightleftharpoons C_6H_5CH_2\cdot + [Co_2(CO)_8] \quad (18)$$

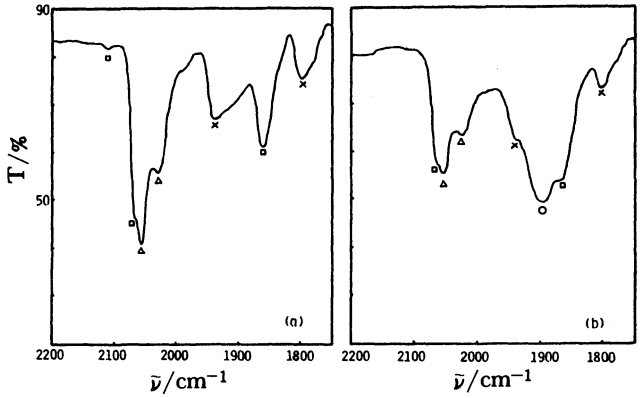

Fig. 5. IR spectra of $[Co_2(CO)_8]$, $[CoH(CO)_4]$ and $[Co(CO)_4]^-$ under high pressure of syngas. Conditions: total pressure, 125 kg cm^{-2} at 120°C (H_2/CO=2/1). Peaks ascribed to O: $[Co(CO)_4]^-$, □: $[Co_2(CO)_8]$, Δ: $[CoH(CO)_4]$, ×: benzyl alcohol. (a) solvent: benzyl alcohol, (b) solvent: benzyl alcohol-H_2O-1,4-dioxane (50:1:0.5 volume ratio).

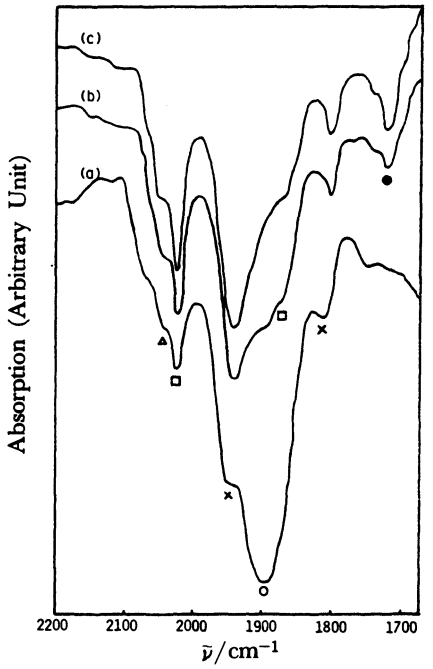

Fig. 6. IR spectra of $[Co_2(CO)_8]$ with benzyl bromide under high pressure of syngas in benzyl alcohol-H_2O-1,4-dioxane (50:1:0.5 volume ratio). Conditions: benzyl bromide, 0.04 M (bromide/Co=0.5). Peaks ascribed to O: $[Co(CO)_4]^-$, □: $[Co_2(CO)_8]$, Δ: $[CoH(CO)_4]$, ●: phenylacetaldehyde, ×: benzyl alcohol. Spectra were observed under (a) 120 kg cm^{-2} (H_2/CO=2/1) at 25°C, (b) 125 kg cm^{-2} at 100°C and (c) 127 kg cm^{-2} at 120°C.

because the yield of toluene increases, although very little, with decreasing partial pressure of H_2 (Runs 3 and 4 in Table 4).

In Situ IR Observation. The respective infrared spectral changes of $[Co_2(CO)_8]$ and $RuCl_3$ as catalyst precursors were followed under high pressure of syngas (H_2/CO=2/1) from room temperature (25°C) to

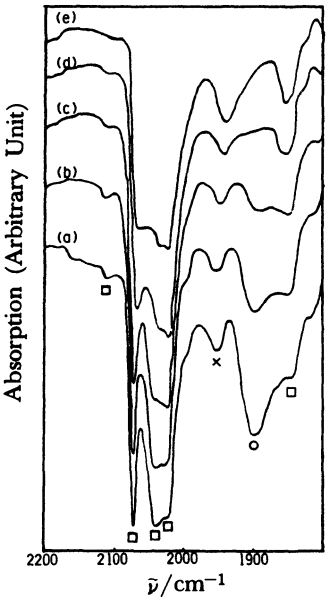

Fig. 7. IR spectra of $[Co_2(CO)_8]$ under high pressure of CO. Conditions: solvent: benzyl alcohol-H_2O-1,4-dioxane. Peaks ascribed to O: $[Co(CO)_4]^-$, □: $[Co_2(CO)_8]$, ×: benzyl alcohol. Spectra were observed under (a) 30 kg cm^{-2} of CO at 25°C, (b) 32 kg cm^{-2} at 50°C, (c) 33 kg cm^{-2} at 70°C, (d) 34 kg cm^{-2} at 100°C and (e) 35 kg cm^{-2} at 120°C.

optimum reaction temperature (120°C). Typical spectra are shown in Figs. 5—7. Figure 5 illustrates that, at 120°C, the characteristic absorption of $[Co(CO)_4]^-$, **5**, at 1890 cm^{-1} [10] is not observed without adding water (Fig. 5-(a)) but observed with adding water (Fig. 5-(b)), with the characteristic bands of $[Co_2(CO)_8]$, **6**, (2105, 2068, 2024, and 1860 cm^{-1})[11] and those of $[CoH(CO)_4]$, **7**, (2053 and 2030 cm^{-1}).[11] When benzyl bromide and water were added to this system, the absorption of **5** diminished as temperature was raised (Figs. 6-(a) and (b)) and ultimately disappeared at 120°C (Fig. 6-(c)). On the other hand, the absorption of phenylacetaldehyde (at 1700 cm^{-1}) increased (Fig. 6-(a) to (c)). This result indicates that **5** is active species for the homologation as reported previously.[5]

It is known that $[Co_2(CO)_8]$ reacts with water to afford **5** and Co(II) ion by disproportionation (Eq. 19).[12] This disproportionation occurred at low tem-

$$3[Co_2(CO)_8] + 12H_2O \rightleftharpoons 2\{[Co(H_2O)_6]^{2+}[Co(CO)_4]_2^-\} + 8CO \quad (19)$$

perature (25—75°C, Figs. 7-(a) to (c)) but did not at high temperature (100—120°C, Figs. 7-(d) and (e)). From above results, under the homologation conditions, **5** is deduced to be formed by the dissociation of **7** (Eq. 13), that is, the addition of water causes the large dissociation of **7** to produce **5**. Hence, the homologation is accelerated and formation of toluene is suppressed.

It was found from in situ IR observation that

$RuCl_3$ was converted into dichlorodicarbonylruthenium (absorption bands: 2150, 2070, and 2030 cm^{-1})[13] without adding hydrobromic acid and into dibromodicarbonylruthenium (absorption bands: 2135 and 2165 cm^{-1})[13] with adding it (HBr/Ru=2) at 120°C under syngas pressure. Although the number of bromide coordinating to ruthenium is obscure under the homologation conditions, bromoruthenium complex is more active for the hydrogenation of 2-phenylacetaldehyde than chlororuthenium complex (see Fig. 4). When ruthenium is added in excess to the homologation system, the concentration of bromide (HBr or $C_6H_5CH_2Br$) significantly decreases by the coordination to ruthenium and consequently the rate of phenylacetaldehyde formation promoted by bromide is retarded.

The authors wish to thank Messers. Yukio Ichikawa and Mitsuo Yasumoto for the contribution of manufacturing in situ high-pressure IR cell and assembling the high-pressure experimental equipments.

Relationship between Donor and Acceptor Numbers and Intrinsic Molecular Properties from Gas-Phase Ion Equilibria

Kenzo HIRAOKA
Faculty of Engineering, Yamanashi University, Takeda 4, Kofu 400
(Received March 12, 1986)

Molecular and bulk solvent properties of protic and aprotic solvent molecules were discussed in the respects of donor numbers (DN) and acceptor numbers (AN) proposed recently by Gutmann, and the intrinsic molecular properties obtained from gas-phase ion equilibria measurements. For aprotic solvent molecules, good correlations are generally found between the gas-phase thermochemical data and both of DN and AN. This indicates that DN and AN for aprotic solvents well reflect the intrinsic molecular properties. On the other hand, the correlations for H_2O and lower alcohols are not good. This is due to the more effective enhancement effect in the intermolecular interactions for protic solvents than for aprotic solvents.

Several empirical parameters have been proposed for characterizing the solvent properties. Grunwald and Winstein proposed the Y value as a scale for the ionizing properties of solvents.[1] This was based on a comparison of the rate constant for the solvolysis of t-butyl chloride in one solvent with that in the reference solvent mixture of 80% ethanol and 20% water.

Kosower introduced the Z value which characterizes the ionizing property of solvent.[2-4] This value is based on the UV spectra of 1-ethyl-4(methoxycarbonyl)-pyridinium iodide. The charge-transfer energy of this compound in a particular solvent was considered as an empirical measure of the ionizing property.

The E_t values proposed by Dimroth and Reichhardt[5,6] are based on the solvent sensitivity of optical absorption of a 4-(1-pyridinio)phenolate due to the intramolecular charge-transfer transition. All these parameters, Y, Z, and E_t, are known to be a good measure for the acceptor properties of solvents.[7]

In order to obtain a solvent-independent representation for the donor ability of a molecule, the donor numbers (DN) were introduced by Gutmann and Wychera.[8] The donor number is defined as a molar enthalpy value for the reaction of the donor (D) with $SbCl_5$ as a reference acceptor in a 10^{-3} M† solution of 1,2-dichloroethane.[7]

$$D + SbCl_5 = D\cdot SbCl_5 \qquad (1)$$
$$(-\Delta H_{D\cdot SbCl_5} = DN)$$

Recently, an empirical parameter for the acceptor properties of solvents has been proposed by Mayer et al.[9,10] which is based on the ^{31}P NMR chemical shift in triethylphosphine oxide in the respective pure solvent. In constrast to classical solvent parameters such as dielectric constant, dipole moment, or polarizability, the acceptor number (AN) allows the interpretation of numerous solvent dependent NMR-, IR, Raman-, UV-spectroscopic, and kinetic data.

The extended donor-acceptor concept presented by Gutmann[7] can be applied to very weak (electrostatic) as well as to strong (covalent or coordinate) interactions, because in both cases rearrangement of the charges in the interacting species takes place. The objective of this work is to investigate the molecular and solvent properties of protic and aprotic solvent molecules by examining the relations between the donor and acceptor numbers and gas-phase thermochemical data which represent the intrinsic molecular properties.

† 1 M=1 mol dm^{-3}.

Discussion

DN's vs. Gas-Phase Proton Affinities. In the determination of DN's, the adducts of $D\cdot SbCl_5$ are formed in a 1:1 molar ratio with all donor molecules.[7] Thus DN's represent molecular donicities rather than donicities for bulk solvents.

The gas-phase proton affinity (PA) is defined as the negative of the enthalpy change for the protonation Reaction (2).

$$A + H^+ = AH^+, \quad -\Delta H^\circ = PA(A) \qquad (2)$$

Namely, the proton affinity is a measure of the Brönsted basicity. On the protonation, a sort of coordinate bond is formed between A and H^+, i.e., $A\rightarrow H^+$. Thus the proton affinity may also be regarded as a scale of the gas-phase Lewis basicity.

Figure 1 shows the relationship between the gas-phase PA's[11] and DN's[7] for protic and aprotic solvent molecules. A fair correlation is seen between these two parameters for aprotic solvent molecules. This indicates that PA's could be a measure of molecular donicity for aprotic solvents.

Contrary to the aprotic solvent molecules, the correlation is not good for protic solvent molecules. The H_2O, CH_3OH, and C_2H_5OH molecules have about the same DN's. This means that the bond energies of D–$SbCl_5$ is more or less the same for D= C_2H_5OH, CH_3OH, and H_2O. On the contrary, proton affinities for these compounds are quite different. The smallest value of the PA for H_2O is due to the localization of positive charge in three protic hydrogens in H_3O^+. Almlöf and Wahlgren examined the electronic structure of H_3O^+ by ab initio MO calculations.[12] They deduced an HOH angle of 117° and net positive charges on H and O of 0.328 and 0.015, re-

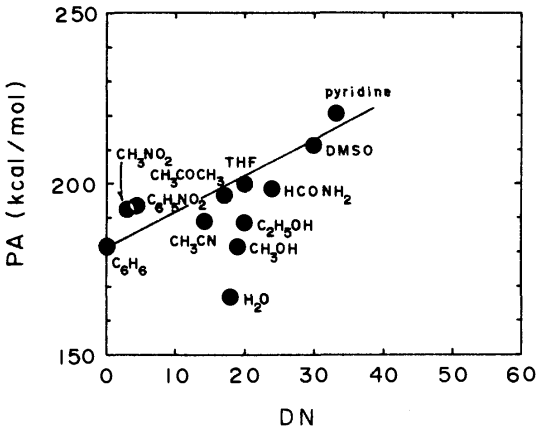

Fig. 1. Relationship between donor numbers (DN's) and gas-phase proton affinities (PA's) for protic and aprotic solvents. THF: tetrahydrofuran, DMSO: dimethyl sulfoxide.

spectively. Nearly all the positive charge in H_3O^+ is on three hydrogen atoms. In the protonated alcohols, the positive charge can be more delocalized owing to the electron-donating ability of the alkyl, making the value of PA larger than H_2O. As shown in Fig. 1, alcohols are seen to approach to the correlation curve for aprotic solvents as the alkyl gets larger. Thus the gas-phase proton affinities may be used for the measure of the molecular donicities for aprotic solvents and higher alcohols. However, PA's cannot be the measure of the molecular donicities for water and lower alcohols, and may be not for ammonia and lower amines, either.

DN's vs. Bond Energies of L_i^+ and K^+ with Solvent Molecules Measured in the Gas Phase. Figure 2 shows the relationship between DN's and the bond energies ($-\Delta H°$'s) of the complexes L_i^+·D and K^+·D for D=various protic and aprotic solvents.[13]

Since L_i^+ and K^+ have inert closed shells, they refuse the acceptance of electrons from the solvent molecule, D. Thus the stabilization of the clusters of L_i^+·D and K^+·D comes from electrostatic and polarization interactions.[14]

As shown in Fig. 2, a fair correlation is found between DN and $-\Delta H°$ for aprotic solvents, except for pyridine.

For the complex of the alkali ion M^+ with pyridine, the two stable structures may exist as shown below.

(I) (II)

The structure (I) assumes the importance of the ion-dipole interaction. The relatively large dipole moment of pyridine (μ_D=2.2 D) is mainly due to the large size of

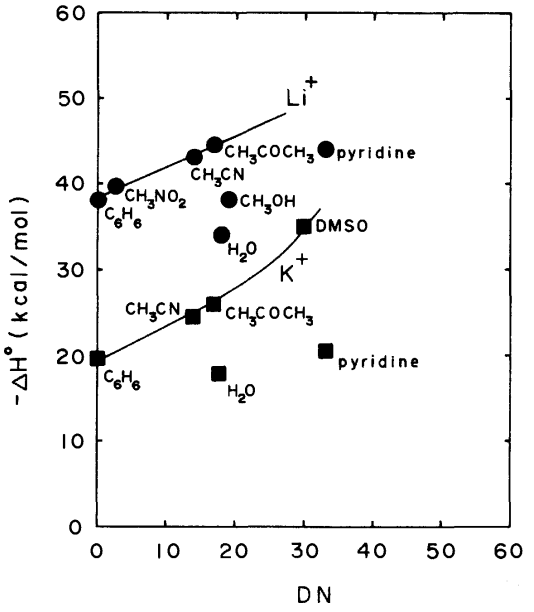

Fig. 2. Relationship between donor numbers (DN's) and enthalpy changes ($\Delta H°$'s) for reaction: M^++ solvent=M^+(solvent), measured in the gas phase. M^+=L_i^+ and K^+. $-\Delta H°$ corresponds to the bond energy of the cluster M^+---solvent. DMSO: dimethyl sulfoxide.

the molecule, i.e., pyridine is a rather soft Lewis base. Thus the interaction of the molecule with hard Lewis acids such as L_i^+ and K^+ could not be so strong as would be expected from the large μ_D of pyridine. In addition, the exchange repulsion between the closed shells of alkali ions and the lone pair plus diffuse π electrons of the pyridine molecule would make the interaction of the structure (I) less favorable. This might explain the deviation of pyridine from the correlation curve.

If the bond energy of the structure (I) is small, the complex may prefer the structure (II), in which the stabilization is due to the ion-quadrupole interaction. Such a structure is found to be most stable for the complex of K^+ with benzene.[15,16]

As the case of PA vs. DN, the protic solvents deviate from the correlation curve for aprotic solvents. In Fig. 2, the deviation of H_2O is larger than CH_3OH. This suggests that the ion-induced dipole moment interaction plays an important role for the stabilization of the bonds of M^+·D. The polarizability of CH_3OH(3.25 Å^3) is larger than that of H_2O(1.45 Å^3) while the dipole moment of CH_3OH(1.70 D) is smaller than that of H_2O(1.84 D). Although the data points are rather scarce, it may be worthwhile nothing that the DN's which represent the measure of the mainly covalent (or coordinate) bond strengths can also be a good measure for the electrostatic bond strengths for aprotic solvents.

AN's vs. Gas-Phase Acidities. The gas-phase acidity scale may be given by the enthalpy change $-\Delta H°_{acid}$ of Reaction (3),

$$AH = A^- + H^+ \qquad (3)$$

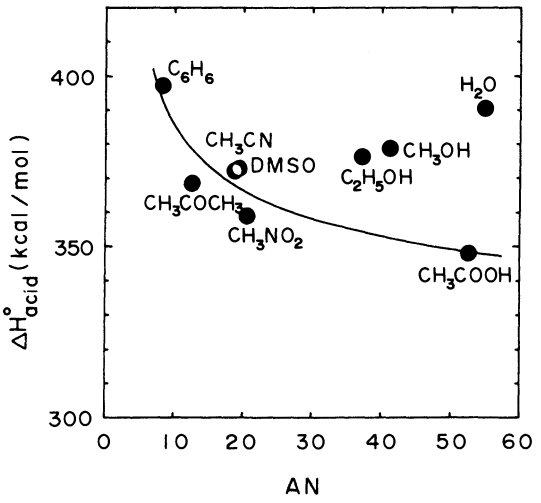

Fig. 3. Relationship between acceptor numbers (AN's) and gas-phase acidities ($-\Delta H^\circ_{acid}$) for protic and aprotic solvents. DMSO: dimethyl sulfoxide.

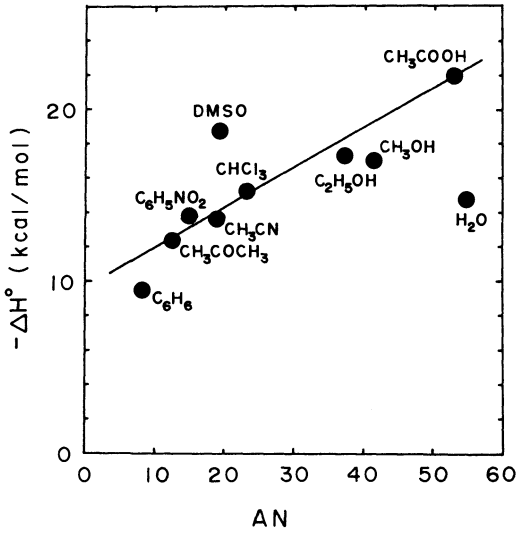

Fig. 4. Relationship between acceptor numbers (AN's) and enthalpy changes (ΔH°'s) for reaction: Cl^-+solvent=Cl^----solvent, measured in the gas phase. $-\Delta H^\circ$ corresponds to the bond energy of the cluster Cl^----solvent.

$-\Delta H^\circ_{acid}$=DH°(A-H)+IP(H)−EA(A) where DH°(A-H) is the bond energy of A-H, IP(H) is the ionization energy of the hydrogen atom, and EA(A) is the electron affinity of the radical A. Any molecule containing a hydrogen atom is potentially a proton donor, or Brönsted acid. For the complex of an acceptor AH and a donor D, $A\text{-}\overset{\delta-}{H}\cdots\overset{\delta+}{D}$, the stronger interaction may be expected for AH which has a larger gas-phase acidity (smaller value of $-\Delta H^\circ_{acid}$).

Figure 3 shows the relationship between $-\Delta H^\circ_{acid}$[17] and AN's for protic and aprotic solvents. A fair correlation exists between these two parameters for aprotic solvents, i.e., $-\Delta H^\circ_{acid}$ decreases with an increase of AN. However, just the opposite correlation is found for protic solvents, i.e., $-\Delta H^\circ_{acid}$ *increases* with an increase of AN in the order $C_2H_5OH \rightarrow CH_3OH \rightarrow H_2O$. This is ascribed to the fact that AN is a measure of the acceptor ability for the bulk solvent rather than that for a free molecule (see the following section).

AN's vs. Bond Energies of Cl^- with Solvent Molecules Measured in the Gas Phase. Figure 4 shows the relationship between AN's and bond energies of Cl^- with protic and aprotic solvents.[13]

A good correlation is seen for aprotic solvents and acetic acid as the case of gas-phase acidities vs. AN's. These results suggest that there is some correlation between the gas-phase acidity and the bond strength of the complex AH···Cl^-. Actually it is already pointed out that the bond strength of AH···X^- increases with the acidity of AH where X^- corresponds to halide or O_2^- ion.[18,19,20] An approximate correlation of the bond strength with the gas-phase acidity can be expected on the grounds that the bond strength of the bond AH···X^- should be related to D($A^-\cdots H^+$) since the bridging H atom in the complex must carry appreciable positive charge induced by the negative ion X^-.

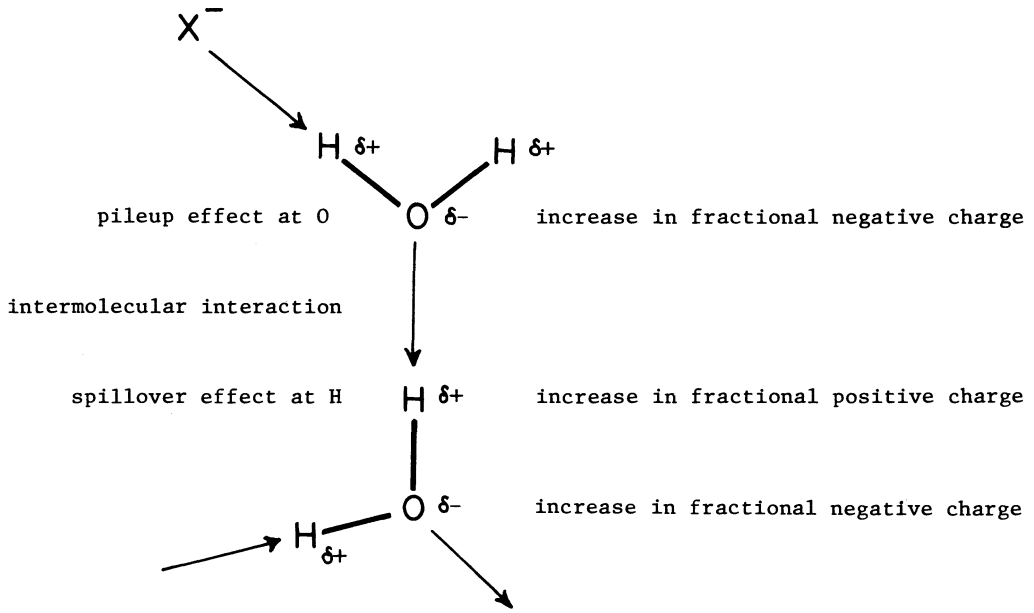
Contrary to a good correlation observed for aprotic solvents, just the opposite correlation is found for protic solvents, i.e., $-\Delta H^\circ$ *decreases* with an increase of AN in the order $C_2H_5OH \rightarrow CH_3OH \rightarrow H_2O$. The H_2O molecule which has the largest AN as a solvent has the least $-\Delta H^\circ$. This is somewhat puzzling because the larger AN suggests the stronger bond of AH···Cl^- as is observed for aprotic solvents. This must be due to the characteristic solvent properties which arise from the intrinsic molecular properties. The stepwise solvation enthalpies $\Delta H^\circ_{n-1,n}$ for Reaction (4),

$$\text{Ion(solvent)}_{n-1} + \text{solvent} = \text{Ion(solvent)}_n \qquad (4)$$

and the heats of solvation ΔH°_s are related as

$$\Delta H^\circ_S = \sum_{n=1}^{n=N} \Delta H^\circ_{n-1,n}(\text{Ion(solvent)}_n) - \sum_{n=2}^{n=N} \Delta H^\circ_{n-1,n}(\text{solvent})_n \qquad (5)$$

The value of $\Delta H^\circ_{n-1,n}$ (Ion(solvent)$_n$) and $\Delta H^\circ_{n-1,n}$ (solvent)$_n$ converge at $n=N$. It may be reasonable to assume that the solvent of large AN is a good solvent for negative ions, namely, AN and $-\Delta H^\circ_s$ correlate with each other. The large value of AN for H_2O suggests that the value of $-\Delta H^\circ_s$ is also large. The small value of $-\Delta H^\circ$ for H_2O (Fig. 4) is understandable because of the low gas-phase acidity of the H_2O molecule. When the H_2O molecule interacts with the ion, the H_2O molecule is polarized. The polarized H_2O molecule would enhance the further hydrogen bonding with the H_2O molecule in the outer shell. This enhancement effect would extend from inner ligands to outer ligands in the shells surrounding the core ion and thus make the value of $-\Delta H^\circ_s$ ultimately large. This kind of enhancement effect may be envisaged more clearly by the donor-acceptor concept, i.e., the spillover effect of the acceptor and the pileup



effect of the donor.[7] As an example, the interaction between a negative ion X^- and water molecules is shown above in a version of pileup and spillover effects.

A donor-acceptor interaction leads to increasing polarities of the bonds originating from the donor and acceptor atoms, respectively. Increasing polarity is related to an increase in fractional positive charge at the acceptor atom and an increase in fractional negative charge at the donor atom. The original decrease of fractional positive charge at the acceptor atom due to both the charge-transfer and polarization effects is overcompensated by passing over the negative charges, including part of those originally situated at the accepter atom to other areas of the acceptor molecule. In this way the fractional negative charges of other nuclei in the acceptor component are increased, in particular those terminating the acceptor molecule. This has been described as the spillover effect of negative charge from the acceptor atom. The original loss of negative charge at the donor atom by charge transfer toward the acceptor molecule is overcompensated by attracting electronic charge from other parts of the donor molecule to the donor atom. In this way the electron density at the donor atom is increased with appropriate changes of fractional nuclear charges in other areas of the donor component. This has been termed by the pileup effect of negative charges at the donor atom.

The enhancement effect for alcohols may be weaker than that for H_2O. The induced charge in the alcohol molecule is more or less dispersed in the alkyl, and this makes the net negative charge on the oxygen atom smaller. The charge dispersion leads to the weaker intermolecular interactions for alcohols. Thus the value of $-\Delta H_s^\circ$ or $-\sum_{n=1}^{n=N}\Delta H_{n-1,n}^\circ$ (Ion(solvent)$_n$) for alcohol may be expected to be smaller than that for H_2O. In fact, a positive enthalpy change (2.0 kcal mol^{-1}) is found for the transfer of Cl^- from H_2O to CH_3OH.[23] Figure 5 shows the n dependence of the sum of the stepwise solvation of the Cl^- ion $-\Delta H_{0,n}^\circ$ (i.e. $-\sum_{n=1}^{n=n}\Delta H_{n-1,n}^\circ$ (Cl^-(solvent)$_n$) for solvents=H_2O and CH_3OH up to n=4 or 5.[14,24] The value of $-\Delta H_{0,n}^\circ$ for CH_3OH is larger than that for H_2O up to n=5. This is reasonable because the first solvation shell around the Cl^- ion is composed of more than 5 solvent molecules[20,25] and the interaction of Cl^- with ligand molecules in the first shell is stronger (or nearly equal) for CH_3OH than for H_2O mainly due to the larger gas-phase acidity of CH_3OH than that of H_2O. In the cluster ion which is composed of several solvation shells, the strength of the intermolecular interactions between molecules belonging to the neighboring solvation shells would become stronger for H_2O than for alcohols, because of the greater enhancement effect for H_2O than for alcohols. This effect would make the ultimate value of $-\Delta H_s^\circ$ for H_2O larger than that for alcohols. The

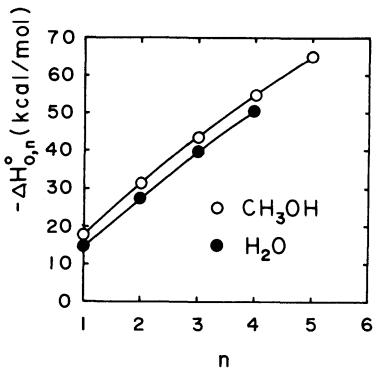


Fig. 5. The n dependence of the sum of the stepwise solvation enthalpies $\Delta H_{n-1,n}^\circ$ for reaction: Cl^-(solvent)$_{n-1}$+solvent=Cl^-(solvent)$_n$. $\Delta H_{0,n}^\circ=\sum_{n=1}^{n=n}\Delta H_{n-1,n}^\circ$ (Cl^-(solvent)$_n$). Solvents=H_2O and CH_3OH.

strong and extensive enhancement effect expected for H_2O suggests that the number N in Eq. 5 for H_2O is larger than that for alcohols.

The relatively small values of AN for aprotic solvents compared to protic solvents may partly due to the less effective enhancement effect. The positive charge in the aprotic solvent molecule can be well dispersed in the hydrophobic groups and the electrostatic intermolecular interactions must be weaker than those for protic solvents. Thus the solvation shells surrounding the core ion may not grow so large as the case of protic solvents, i.e., the number N for the aprotic solvent may be generally smaller than those for the protic solvents.

Concluding Remarks

The relationships between DN's and AN's and intrinsic molecular properties from gas-phase ion equilibria are studied.

For aprotic solvents, good correlations are generally found between DN's and AN's and intrinsic molecular properties. Since DN's represent the molecular properties, good correlations between DN's and intrinsic molecular properties are reasonable. It is of interest that there are also good correlations between intrinsic molecular properties and AN's which represent the bulk solvent properties. This indicates that AN's for aprotic solvents reflect more or less the molecular properties. From the observed good correlations and relatively small values of AN's, it is tentatively concluded that the negative ions in aprotic solvents are solvated by only a restricted number of ligands. We think that the negative ion in aprotic solvents is composed of rather tight single solvation shell which is further solvated by sorrounding solvent molecules only weakly. In such a case, the molecular properties of solvent molecules would be reflected on the AN's.

For protic solvents, just the opposite correlations between AN's and intrinsic molecular properties are found compared to those for aprotic solvents. This may be mainly due to the extensive solvation of ions in protic solvents owing to the enhancement effects in the intermolecular interactions, i.e., the formation of multiple solvation shells which is realized by the pileup and spillover effects of protic solvent molecules. The enhancement effects are the most prominent for H_2O.

Production of Cyclohexene and Reactive Sulfur Species in Vapor-Phase Catalytic Oxidative Dehydrogenation of Cyclohexane with Carbonyl Sulfide

Masamichi AKIMOTO,* Yoshinori KASHITA, and Hiroo NIIYAMA
Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received March 12, 1986)

The vapor-phase catalytic oxidative dehydrogenation of cyclohexane with COS over SiO_2 and Al_2O_3 catalysts (e.g., $C_6H_{12}+COS \rightarrow C_6H_{10}+CO+H_2S$) has been investigated with respect to the production of cyclohexene and cyclohexadiene as well as the mechanism of the dehydrogenation reaction. The representative value of the combined yield of cyclohexene+cyclohexadiene is 8.0% and the combined selectivity to these two products at this yield obtained is 34.0%. These values are comparable to the values 8.0 and 30.8% reported in a recent Japanese patent. The comparison of the catalytic performance between two types of flow fixed-bed reactors demonstrates that the role of solid catalysts is to decompose COS into CO and sulfur, which then dehydrogenates hydrocarbons through a homogeneous mechanism. The results of the kinetic analysis of these reactions, together with the simulation of the overall catalytic reaction system, suggest a contribution of atomic sulfur to the oxidative dehydrogenation of cyclohexane in a conventional flow fixed-bed reactor.

The vapor-phase catalytic oxidative dehydrogenation of cyclohexane (C_6H_{12}) to cyclohexene (C_6H_{10}) is of industrial importance for the production of adipic acid and ε-caprolactam. A number of challenging works have been reported on the production of C_6H_{10} through the oxidative dehydrogenation with gaseous oxygen: Cr_2O_3–CeO_2–K_2O/Al_2O_3,[1] SiO_2–TiO_2–CeO_2,[2] native zeolites,[3] metal ion-exchanged zeolites,[4,5] group 2 metal silicates,[6] and polyquinones[7] have been employed as catalysts. A recent Japanese patent[8] also proposed the production of C_6H_{10} through a similar catalytic oxidative dehydrogenation, but the yield and selectivity to C_6H_{10} reported are as low as 8.0 and 30.8%, respectively, although a noble bimetallic catalyst Ru–Rh/SiO_2 is employed at 773K.

We have investigated the vapor-phase catalytic oxidative dehydrogenation of lower paraffinic hydrocarbons and arylalkyl compounds with COS.[9,10] In this oxidative dehydrogenation, COS is catalytically decomposed to CO and sulfur, which then abstracts hydrogen atoms from these hydrocarbons to give unsaturated hydrocarbons and H_2S.[10]

$$COS \longrightarrow CO + S \qquad xS \longrightarrow S_x (x = 2, 4, 6, \cdots) \quad (1)$$

$$C_nH_{2n+2} + 1/xS_x \longrightarrow C_nH_{2n} + H_2S \quad (2)$$

One of the characteristic features of this dehydrogenation, compared with the conventional oxidative dehydrogenation with gaseous oxygen, is that the difference in reactivity of hydrocarbons is small between paraffinic and olefinic hydrocarbons, as shown by the reaction of butane and *trans*-2-butene over SiO_2 at 873K (e.g., conversion: butane 30% and *trans*-2-butene 48%).[9] Hence we expected to produce C_6H_{10} with high yield and selectivity by the vapor-phase catalytic oxidative dehydrogenation of C_6H_{12} with COS. In the present work, we have tried to find the best reaction conditions for the selective production of C_6H_{10} and have then elucidated the nature of sulfur species responsible for the oxidative dehydrogenation through kinetic analysis of the reactions involved, and by simulation of the overall catalytic reaction system.

Experimental

Reaction and Catalysts. Vapor-phase oxidative dehydrogenation of C_6H_{12} was carried out with a conventional flow fixed-bed reactor at atmospheric pressure (1 Torr= 133.322 Pa). The reactor system comprised a 15-mm-i.d. quartz tube, 470-mm long, and a concentric thermowell. The reactor was heated with a cylindrical electric furnace. Raschig rings (2×2 mm) were added above and below the catalyst bed. Guaranteed reagent grade C_6H_{12} and commercially available COS of greater than 97.5 vol% purity (Matheson Co., CO_2 1.4 vol%, N_2+CO 0.6 vol%, CS_2 0.19 vol%, O_2 0.10 vol% and H_2O 0.01 vol%) were used without further purification. Nitrogen (purity>99.99 vol%) was used as the diluent. The standard total feed rate was held constant at 150 (NTP) $cm^3 min^{-1}$; the standard feed composition was 10 vol% each of C_6H_{12} and COS. The catalysts employed are SiO_2 (20—40 mesh) and the referenced Al_2O_3 catalysts of the Catalysis Society of Japan (JRC-ALO-1 and -4). SiO_2 catalyst was prepared by the calcination of hydrated silica gel at 1073K in air for 5 h. Silica sol (Snowtex-O, Nissan Chemical Industries Ltd.) was used as the catalyst source. The BET surface area is 182 $m^2 g^{-1}$ (SiO_2), 176 $m^2 g^{-1}$ (JRC-ALO-1),[11] and 174 $m^2 g^{-1}$ (JRC-ALO-4),[11] respectively.

Analysis. The reaction products were analyzed by gas chromatography with helium as the carrier gas. Two columns in series, 2.0 m of Porapak R (50—80 mesh, 358K) and 2.0 m of molecular sieve 13X (60—80 mesh, room temperature), were used for the analysis of the gaseous reaction products (N_2, COS, CO_2, CO, CS_2, and H_2S). The liquid products (C_6H_{12}, C_6H_{10}, cyclohexadienes, and benzene) were analyzed with 6.0 m of PEG 6000 (20 wt% on Celite 545, 60—80 mesh, 338K). The yield of H_2S was always calculated on the basis of COS fed.

Results

Production of Cyclohexene. Table 1 summarizes the results of catalytic oxidative dehydrogenation of C_6H_{12} with COS over SiO_2 at different reaction temperatures. Preliminary studies indicated that the yields of C_6H_{10} and benzene (C_6H_6) are not restricted by the equilibrium of these reactions (e.g., K_p=661 and 2.61×

Table 1. Results of the Catalytic Oxidative Dehydrogenation of Cyclohexane with COS over SiO_2

Reaction temperature	Conversion of C_6H_{12}	Yield/%			Selectivity to $C_6H_{10}+C_6H_8$	Conversion of COS[a]	Conversion to CO+S	Yield of H_2S
K	%	C_6H_{10}	C_6H_8	C_6H_6	%	%	%	%

Catalyst: JRC-ALO-4 Al_2O_3 1.0 g. Total feed rate: 150 (NTP) $cm^3\,min^{-1}$ (C_6H_{12} 10 vol% fixed). a) The conversion to the side reaction ($2COS \rightarrow CO_2+CS_2$) is included. b) Yield of H_2S calculated from the yields of C_6H_{10}, C_6H_8, and C_6H_6. c) A small amount of CH_4 (yield=0.3—0.5%) was formed.

10^{12} for C_6H_{10} and C_6H_6 formations, respectively, at 900K[12]). Preliminary experiments showed that no significant change with time in the catalytic activity or selectivity took place during the reaction over SiO_2 and Al_2O_3 catalysts at 723—923K. The conversion of C_6H_{12} was negligibly small at 673K: the conversion of COS to CO+S was nearly 0%, but the oxidative dehydrogenation took place at 723K, at which temperature the catalytic conversion of COS to CO+S was initiated (Table 1). The olefinic product in the oxidative dehydrogenation at 723K was only C_6H_{10}, but the formation of C_6H_6 was seen at 773K and the yields of these two products increased with further rise in reaction temperature. The formation of 1,3-cyclohexadiene (C_6H_8) was seen only at 873K, but its yield was as low as 0.1%.

Figure 1 shows the variation of the conversion of C_6H_{12}, the yields of $C_6H_{10}+C_6H_8$ and C_6H_6 and the combined selectivity to $C_6H_{10}+C_6H_8$ as a function of the conversion of COS to CO+S at 873K. The conversion of C_6H_{12} and the yield of C_6H_6 were 4.4 and 1.7% at a conversion to CO+S of 7.4%, but they increased markedly at higher conversions and reached 44.5 and 38.5%, respectively, at 80.8%. In contrast, the combined selectivity to $C_6H_{10}+C_6H_8$ decreased from 61.4% to 12.1% with such an increase in the conversion to CO+S. The combined yield of $C_6H_{10}+C_6H_8$ showed a maximum at ca. 50% (Fig. 1). The combined yield and selectivity to $C_6H_{10}+C_6H_8$ at the conversions to CO+S of 40.0 and 59.3% were 8.0 and 34.0% and 8.4 and 22.1%, respectively (Fig. 1). It should be noted that the conversion of C_6H_{12}, the yields of $C_6H_{10}+C_6H_8$ and C_6H_6 and the combined selectivity to $C_6H_{10}+C_6H_8$

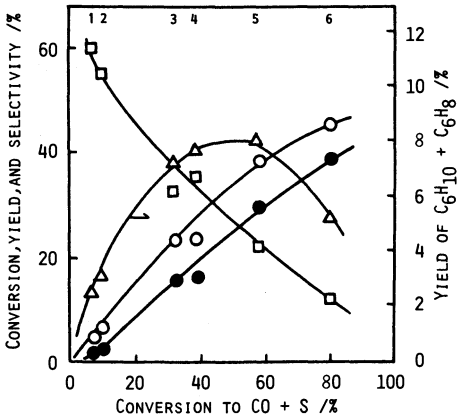

Fig. 1. Variation of the conversion of cyclohexane, the yields of cyclohexene+cyclohexadiene and benzene, and the selectivity to cyclohexene+cyclohexadiene as a function of the conversion of COS to CO+S.

are determined by the conversion of COS to CO+S, regardless of the catalysts employed (Fig. 1).

The catalytic oxidative dehydrogenation of C_6H_{12} was carried out at 873K with JRC-ALO-4 Al_2O_3 at various COS/C_6H_{12} feed ratios (Table 2). When the COS/C_6H_{12} volumetric feed ratio was 5/10, the con-

a) The reactor shown in Fig. 2 was employed. Catalyst: JRC-ALO-4 Al_2O_3 2.0 g. Feed-1: COS 15 (NTP) $cm^3\,min^{-1}$+N_2 80 (NTP) $cm^3\,min^{-1}$. Feed-2: C_6H_{12} 15 (NTP) $cm^3\,min^{-1}$+N_2 40 (NTP) $cm^3\,min^{-1}$. b) The conversion to the side reaction ($2COS \rightarrow CO_2+CS_2$) is included. c) Negligible. d) Yield of H_2S calculated from the yields of C_6H_{10}, C_6H_8, and C_6H_6. e) Yield of CH_4 is 0.2%.

version of C_6H_{12} was 20.7% and the combined yield of $C_6H_{10}+C_6H_8$ was 5.7%. But, they increased to 38.0 and 8.4% at a COS/C_6H_{12} feed ratio of 10/10 and then decreased to 34.0 and 5.1%, respectively, at 15/10. The yield of C_6H_6 showed a similar behavior. In contrast, the combined selectivity to $C_6H_{10}+C_6H_8$ decreased from 27.5% to 15.0% with such a change in the COS/C_6H_{12} feed ratio (Table 2). For the selective production of C_6H_{10}, the COS/C_6H_{12} volumetric feed ratio of 10/10 seems to be optimum at 873K. The observed values of the yields of H_2S (Table 2) give us some information about the mechanism of the oxidative dehydrogenation of C_6H_{12}. That is, the yields of H_2S calculated from the yields of dehydrogenation products (C_6H_{10}, C_6H_8, and C_6H_6) are always greater than the experimentally observed yields of H_2S, although the latter yields of H_2S are always comparable to the values of the conversion of COS to CO+S (Table 2). Similar results were obtained over JRC-ALO-1 and -4 Al_2O_3 at 873K (Fig. 1), but not over SiO_2 at 723—873K (Table 1). These results indicate that a large portion of the C_6H_8 formed, but not C_6H_{12} or C_6H_{10}, was thermally dehydrogenated to C_6H_6 when the amount of sulfur evolved was smaller than that of hydrocarbons.

Mechanistic Studies. In order to elucidate the role of solid catalysts and the mechanism of oxidative dehydrogenation, the catalytic oxidative dehydrogenation of C_6H_{12} with COS was carried out with a special reactor shown in Fig. 2. In this reactor, only the mixture of COS and N_2 is allowed to come into contact with solid catalyst and the resulting gaseous product containing sulfur is then mixed with another gaseous mixture ($C_6H_{12}+N_2$) in the absence of catalyst. The temperature of the reactor in which the homogeneous reaction of sulfur with C_6H_{12} takes place is always kept to nearly equal to that for the catalytic decomposition of COS. The results obtained at 823 and 873K over JRC-ALO-4 Al_2O_3 are summarized in Table 3. At these two reaction temperatures, the oxidative dehydrogenation of C_6H_{12} always took place to produce C_6H_{10}, C_6H_8, and C_6H_6 with formation of H_2S. Moreover, the values of the conversion of C_6H_{12}, the yields of $C_6H_{10}+C_6H_8$ and C_6H_6, and the combined selectivity to $C_6H_{10}+C_6H_8$ at 873K (Table 3) are nearly equal to the values (8.3, 4.2, 4.1, and 50.6%, respectively) expected from the conversion of COS to CO+S (14.3%)

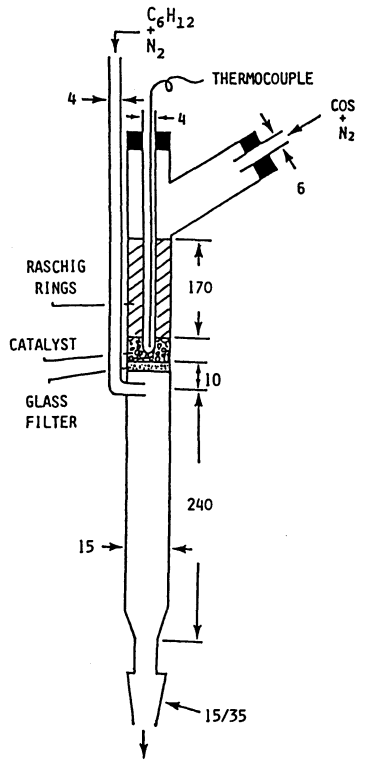

Fig. 2. A schematic figure of the reactor employed in the vapor-phase homogeneous reaction of sulfur with cyclohexane. The dimensions of the reactor are given in millimeters.

in Fig. 1. As discussed later, these results support the view that the role of solid catalyst is to decompose COS into CO and sulfur, which then dehydrogenates hydrocarbons through a homogeneous mechanism. The yield of H_2S at 823K (8.4%) is nearly the same as that calculated from the yields of C_6H_{10}, C_6H_8, and C_6H_6 (8.1%) (Table 3). This indicates that no thermal dehydrogenation of C_6H_8 to C_6H_6 took place during the oxidative dehydrogenation of C_6H_{12} at 823K.

Kinetic Studies. We estimated the rate constants for the catalytic decomposition of COS to CO+S and for the dehydrogenation of C_6H_{12} and C_6H_{10} with S_2 and then predicted the nature of sulfur species responsible for the dehydrogenation by simulation of the overall catalytic reaction system. Based on the present mechanistic findings, we propose the following reactions for the catalytic oxidative dehydrogenation of

C_6H_{12} with COS at 823K.

$$COS \longrightarrow CO + S \quad xS \longrightarrow S_x (x=2, 4, 6, \cdots) \quad (1)$$
$$2COS \longrightarrow CO_2 + CS_2 \quad (3)$$
$$C_6H_{12} + 1/xS_x \longrightarrow C_6H_{10} + H_2S \quad (4)$$
$$C_6H_{10} + 2/xS_x \longrightarrow C_6H_6 + 2H_2S \quad (5)$$

We use Reaction 5 instead of two consecutive reactions ($C_6H_{10}+1/xS_x \rightarrow C_6H_8+H_2S$, $C_6H_8+1/xS_x \rightarrow C_6H_6+H_2S$) since the yield of C_6H_8 was always negligible at 823K (Tables 1 and 3). In a conventional fixed-bed reactor, Reactions 1 and 3 take place at the surface of solid catalysts, whereas Reactions 4 and 5 occur homogeneously. In these kinetic studies, we employed JRC-ALO-4 Al_2O_3 catalyst. The reaction order with respect to COS in Reaction 1 was approximately 0.8 at 823K and the chemical equilibrium was always established for Reaction 3, as shown later. Thus, the rate equations derived for these reaction steps are as follows:

$$d[COS]/d(W/F) = -k_{01}[COS] \quad (6)$$
$$K_{p1} = [CO_2][CS_2]/[COS]^2 \quad (7)$$
$$d[C_6H_{12}]/d(V/F) = -k_1[C_6H_{12}][S_x] \quad (8)$$
$$d[C_6H_{10}]/d(V/F) = k_1[C_6H_{12}][S_x] - k_2[C_6H_{10}][S_x] \quad (9)$$
$$d[C_6H_6]/d(V/F) = k_2[C_6H_{10}][S_x] \quad (10)$$

Here k_{01}, k_1, and k_2 are rate constants for Reactions 1, 4, and 5, respectively, and K_{p1}, W, V, and F are equilibrium constant of Reaction 3, weight of catalyst, void volume in the catalyst bed, and total feed rate of reactant mixture. The parentheses in Equations 6, 7, 8, 9, and 10 denote the concentration of reactant species in mol fraction units. The density of JRC-ALO-4 Al_2O_3 was determined with liquid C_6H_{12} and a measuring cylinder: the relation V/F(min)=8.03×10^{-5} W/F(g-catalyst·min·g-mol^{-1}) was obtained at 823K. Equation 10 shows that the rate-controlling step for the formation of C_6H_6 from C_6H_{10} is the oxidative dehydrogenation of C_6H_{10} to C_6H_8, not that of C_6H_8 to C_6H_6.

Estimation of k_{01} and K_{p1}. Figure 3 shows the effect of the contact time on the conversion of COS over JRC-ALO-4 Al_2O_3 at 823K. At a contact time of 15.0 g-catalyst·min·g-mol^{-1}, the conversion to CO+S was 5.8%, but it increased for longer contact times of the reaction and levelled off at 15.0% between 150 and 300 g-catalyst·min·g-mol^{-1}. In contrast, the conversion to CO_2+CS_2 was nearly constant at 30.3—30.8% between 15.0 and 300.0 g-catalyst·min·g-mol^{-1}. Hence one could say that the chemical equilibrium for the catalytic decomposition of COS to CO_2+CS_2 is readily established even at very short contact times of the reaction, whereas that for the decomposition to CO+S is established only above 150 g-catalyst·min·g-mol^{-1}. At these reaction conditions, the sulfur species formed at equilibrium is of S_2 type (Reaction 11).[13] Using the composition of the gaseous product at 300 g-catalyst·min·g-mol^{-1}, the equilibrium constants for Reactions 3 and 11 were calculated to be 8.07×10^{-2}

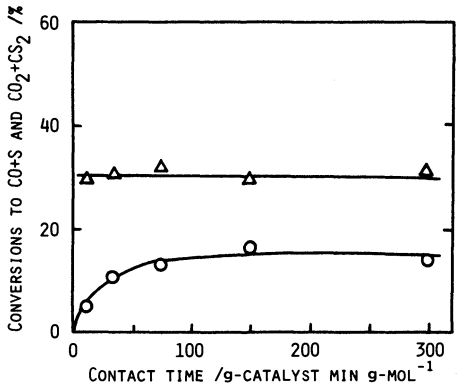

Fig. 3. Effect of contact time on the catalytic conversion of COS.
Catalyst: JRC-ALO-4 Al_2O_3. Reaction temperature: 823K. Total feed rate: 150 (NTP) cm^{-3} min^{-1} (COS 10 vol%, N_2 90 vol%).
○: Conversion to CO+S, △: Conversion to CO_2+CS_2.

$$COS \underset{}{\overset{K_{p2}}{\rightleftharpoons}} CO + 1/2S_2 \quad (11)$$

and 2.40×10^{-2}, respectively. These values agree well with the thermodynamically calculated values (K_{p1} =2.29×10^{-1}, K_{p2}=2.21×10^{-2}).[12] At a contact time of 15.0 g-catalyst·min·g-mol^{-1}, the conversions to CO+S and CO_2+CS_2 and rate of the conversion to CO+S were 5.8 and 30.5% and 3.87×10^{-4} g-mol·g-catalyst^{-1}·min^{-1}, respectively. With these values and Equation 12, the rate constants k_{01} and k_{02} were

$$d[CO]/d(W/F) = k_{01}[COS] - k_{02}[CO][S_2] \quad (K_{p2}=k_{01}/k_{02}) \quad (12)$$

estimated to be 6.14×10^{-3} and 2.56×10^{-1} g-mol·g-catalyst^{-1}·min^{-1} at 823K.

Estimation of k_1 and k_2. The rate constants for the oxidative dehydrogenation of C_6H_{12} and C_6H_{10} with S_2 were estimated at 823K by the kinetic analysis of these reactions by using the reactor shown in Fig. 2. Here COS was decomposed at 467.3 g-catalyst·min·g-mol^{-1} over JRC-ALO-4 Al_2O_3 at 823K and the evolved sulfur (S_2) was reacted with C_6H_{12} at 823K (Table 4). From Equations 8 and 9, the following equation can be derived; here x, y, and k are the fractional conversion of C_6H_{12}, the fractional yield of C_6H_{10}, and k_2/k_1, respectively:

$$y = \frac{1}{(k-1)}[(1-x) - (1-x)^k] \quad (13)$$

The averaged value of k was thus estimated to be 27.1 at 823K (Table 4).

The value of k_1 for the reaction of C_6H_{12} with S_2 was estimated by the kinetic analysis of the reaction by using the same reactor (Fig. 2). By integration of Equation 8, the following equation is obtained:

Table 4. Determination of k

$v/F^{a)}$/min	Conversion of C_6H_{12}/%	Yield/%[b]			k/—
		C_6H_{10}	C_6H_6	H_2S	
4.67×10^{-2}	5.1	2.8	2.3	9.2	26.0
2.32×10^{-2}	4.8	2.9	1.9	8.4	23.1
1.74×10^{-2}	3.3	2.1	1.2	4.9	29.1
0.83×10^{-2}	1.9	1.4	0.5	3.2	30.0

a) Reaction temperature: 823K. Catalyst: JRC-ALO-4 Al_2O_3 2.0 g. Feed-1 : COS 15 (NTP) $cm^3\,min^{-1}$+N_2 80 (NTP) $cm^3\,min^{-1}$ (W/F=467.3 g-catalyst·min·g-mol^{-1}). Feed-2 : C_6H_{12} 15 (NTP) $cm^3\,min^{-1}$+N_2 40 (NTP) $cm^3\,min^{-1}$. The conversion of COS to CO+S is 9.5%. a) v is the volume of reactor below the catalyst bed. This volume was changed by adding Rasching rings (2×2 mm). b) Yield of C_6H_8 is negligible.

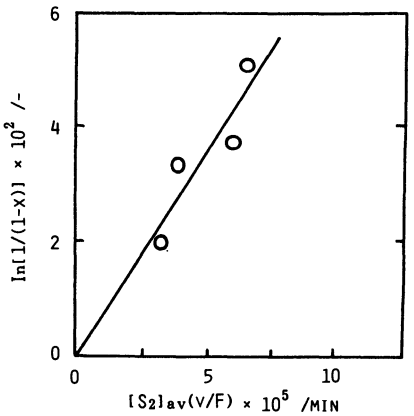

Fig. 4. Determination of k_1 based on Equation 14. Catalyst: JRC-ALO-4 Al_2O_3 2.0—10.0 g. Reaction temperature: 823K. Feed-1: 95—475 (NTP) $cm^3\,min^{-1}$ (COS/N_2=3/16, fixed. W/F=467.3 g-catalyst·min·g-mol^{-1}). Feed-2: 55—275 (NTP) $cm^3\,min^{-1}$ (C_6H_{12}/N_2=1/3, fixed). v: 17.10—32.92 cm^3.

$$k_1 = \frac{\ln[1/(1-x)]}{[S_2]_{av}(v/F)} \qquad (14)$$

Here $[S_2]_{av}$ is the logarithmically averaged value of the concentration of diatomic sulfur throughout the homogeneous reaction zone and v is its volume. By changing the amount of catalyst, the volume of the homogeneous reaction zone, and the feed rates of the respective gaseous mixtures at the fixed concentration of C_6H_{12} at the inlet of the homogeneous reaction zone (10 vol%), the relation between $\ln[1/(1-x)]$ and $[S_2]_{av}(v/F)$ at 823K was determined (Fig. 4). From the slope of the straight line in Fig. 4, k_1 for the dehydrogenation of C_6H_{12} with S_2 was estimated to be 7.38×10^2 min^{-1} at 823K. With this value of k_1 and k=27.1, k_2 for the dehydrogenation of C_6H_{10} with S_2 was calculated to be 2.00×10^4 min^{-1} at 823K.

Simulation of Catalytic Reaction System. Assuming the participation of S_2 in the oxidative dehydrogenation and no gaseous volume change during the reaction, we simulated the catalytic oxidative dehydrogenation of C_6H_{12} with COS over JRC-ALO-4 Al_2O_3

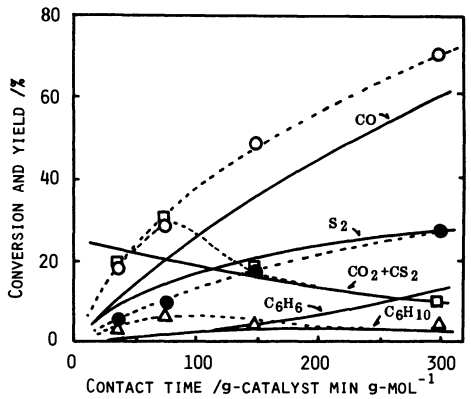

Fig. 5. Simulation of the catalytic oxidative dehydrogenation system.

$k_0=6.14\times10^{-3}$ g-mol·g-catalyst^{-1}·min^{-1}, $K_{p1}=8.07\times10^{-2}$, $k_1=7.38\times10^2$ min^{-1}, $k_2=2.00\times10^4$ min^{-1}.
○: Conversion of COS to CO+S, □: Conversion of COS to CO_2+CS_2, △: Yield of C_6H_{10}, ●: Yield of C_6H_6.

at 823K in the conventional fixed-bed reactor using Equations 6, 7, 8, 9, and 10 and the values of k_{01}, K_{p1}, k_1, and k_2 obtained above. The calculation was made by the Runge-Kutta Gill method. The calculated catalytic performance versus the contact time of the reaction is shown in Fig. 5. The calculated values of the conversion of COS to CO_2+CS_2 and the yield of C_6H_{10} are nearly equal to the experimentally observed values, especially at the contact time of 150—300 g-catalyst·min·g-mol^{-1}. However, there is a big difference between the calculated and observed values of the conversion of COS to CO+S and the yield of C_6H_6 although these two kinds of values similarly increase with increasing the contact time of the reaction. For example, the calculated (observed) values of the yield of C_6H_6 are 1.7 (9.1), 5.7 (17.0), and 14.2% (27.4%), respectively, at the contact time of 75,150, and 300 g-catalyst·min·g-mol^{-1}, and those of the conversion of COS to CO+S at these contact times are 19.6 (28.4), 36.3 (48.3), and 60.1% (70.5%), respectively (Fig. 5). The most striking difference between the calculated and observed values is the much greater yields of sulfur (2.0—24.0% at W/F=10—300 g-catalyst·min·g-mol^{-1}) in the calculated result (Fig. 5). In this oxidative dehydrogenation, the yield of sulfur was always negligible, as shown by the nearly stoichiometric formation of H_2S (Tables 1, 2, and 3).

Assuming the participation of atomic sulfur in the oxidative dehydrogenation, we have again simulated the catalytic reaction system at 823K, in which, however, only the values of k_1 and k_2 are increased to nearly 36 times k_1 and k_2 values employed in Fig. 5. In agreement with the experimental observation, the

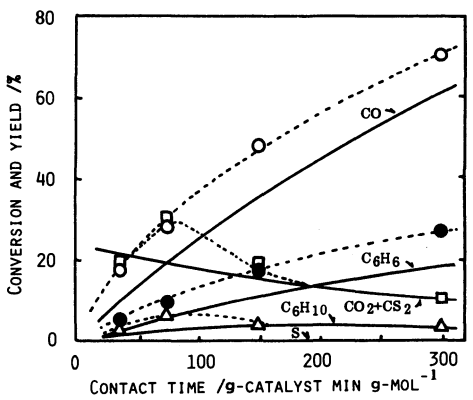

Fig. 6. Simulation of the catalytic oxidative dehydrogenation system.
Reaction conditions and symbols used are the same as those in Fig. 5.
$k_0=6.14\times10^{-3}$ g-mol·g-catalyst^{-1}·min^{-1}, $K_{p1}=8.07\times10^{-2}$, $k_1=2.66\times10^4$ min^{-1}, $k_2=7.20\times10^5$ min^{-1}.

yield of sulfur in this calculation is always negligible within the contact time of the reaction studied (Fig. 6). Both the calculated values of the yields of C_6H_{10} and C_6H_6 increased to be nearer to the observed values than the case in Fig. 5: the calculated values of the yield of C_6H_6 at the contact time of 75, 150, and 300 g-catalyst·min·g-mol^{-1} are 7.1, 10.8, and 18.8%, respectively. In contrast, the values of the conversions of COS to CO+S and CO_2+CS_2 remained unchanged in this calculation (Fig. 6).

Discussion

We first discuss the role of solid catalyst and the mechanism of the oxidative dehydrogenation of C_6H_{12} with COS. But, we do not refer here to the mechanism of the catalytic decomposition of COS since it was already reported.[14] Although the yield of C_6H_8 over SiO_2 was negligibly small between 723 and 823K, the observed behavior of the yields of C_6H_{10} and C_6H_6 with rising reaction temperature, i.e., formation of C_6H_{10} at 723K, that of C_6H_{10} and C_6H_6 at 773K, and the increase in the yields of these two products with further rise in reaction temperature (Table 1) suggest that the oxidative dehydrogenation of C_6H_{12} with COS proceeds through the following consecutive reaction steps.

$$C_6H_{12} \xrightarrow{-2H\cdot} C_6H_{10} \xrightarrow{-2H\cdot} C_6H_8 \xrightarrow{-2H\cdot} C_6H_6 \qquad (15)$$

Both the convex behavior of the yield of $C_6H_{10}+C_6H_8$ against the conversion of C_6H_{12} and the decrease in the selectivity to these two products with increasing conversion of C_6H_{12} (Fig. 1) support this reaction scheme.

The occurrence of the catalytic oxidative dehydrogenation of C_6H_{12} with COS in the special reactor, in which only COS contacts with the catalyst and the evolved gaseous sulfur reacts with C_6H_{12} in the absence of solid catalyst (Table 3, Fig. 2), indicates that the role of solid catalysts is to decompose COS into CO+S and that the evolved sulfur can dehydrogenate C_6H_{12}, C_6H_{10}, and C_6H_8 even in the absence of solid catalysts. Since the values of the conversion of C_6H_{12}, the yields of $C_6H_{10}+C_6H_8$ and C_6H_6, and the combined selectivity to $C_6H_{10}+C_6H_8$ at 873K obtained with the special type reactor were nearly equal to the values at 873K obtained with the conventional fixed-bed reactor (Table 3, Fig. 1), we believe that the oxidative dehydrogenation of C_6H_{12} with sulfur proceeded homogeneously also in the conventional fixed-bed reactor. The decisive effect observed of the conversion of COS to CO+S on the conversion of C_6H_{12} and the product distributions (Fig. 1) supports this view. The heterogeneous-homogeneous reaction mechanism for the catalytic oxidative dehydrogenation of C_6H_{12} with COS proposed in the present work agrees with the reaction mechanism for the cases of ethylbenzene and paraffinic hydrocarbons reported.[9,10] The representative values of the combined yield and selectivity to $C_6H_{10}+C_6H_8$, 8.0 and 34.0%, obtained in the present work (Fig. 1) are comparable to those, 8.0 and 30.8%, reported in a recent Japanese patent.[8]

Next we discuss the nature of sulfur species responsible for the oxidative dehydrogenation of C_6H_{12}. Although the calculated values of the conversion of COS to CO+S and CO_2+CS_2 and the yields of C_6H_{10} and C_6H_6 in the simulation at 823K did not always agree with the experimentally observed values, the behavior of these calculated values versus the contact time of the reaction is similar to that of the observed values (Figs. 5 and 6), thus supporting the reasonability of the simulation method employed in the present work. The big difference between the calculated and observed values of the conversion of COS to CO+S at 823K (Figs. 5 and 6) must have been caused by the low estimation of the value of the rate constant k_{01} for the catalytic decomposition of COS to CO+S at 823K. We believe that by the use of a larger value of k_{01} ($>6.14\times10^{-3}$ g-mol·g-catalyst^{-1}·min^{-1}) not only the calculated value of the conversion of COS to CO+S but also that of the yields of C_6H_{10} and C_6H_6 can be increased to be much nearer to the observed values than those in Fig. 6.

The most important implication suggested by the results of simulation concerns the nature of sulfur species responsible for the oxidative dehydrogenation of C_6H_{12}. The agreement of the negligibly small yields of sulfur between the calculated and observed values caused by the assumption of the participation of atomic sulfur and the rise of the values of the rate constants for the dehydrogenation of C_6H_{12} and C_6H_{10} with sulfur (k_1 and k_2) by 36 times (Figs. 5 and 6) suggests that the sulfur species responsible for the oxidative dehydrogenation in the conventional fixed-bed reactor is mainly of atomic type, although some degree of the contribution of diatomic sulfur to

the reaction can not be rejected. This view can be supported by the following discussion based on the Evans & Polanyi rule (Equation 16).[15]

$$\Delta E = -\alpha\Delta Q \quad (\alpha=0.25) \tag{16}$$

Where ΔE and ΔQ are the differences in activation energy and heat of reaction, respectively. The heat of formation of S_2 from atomic sulfur ($S \rightarrow 1/2S_2$) is ca. 40 kcal[†]·atom^{-1}.[16] When we assume that ΔQ is equal to 40 kcal·atom^{-1}, the value of $e^{-\Delta E/RT}$ at 823K is calculated to be 417. This means that the reactivity of atomic sulfur is at the greatest nearly 400 times greater than that of diatomic one in exothermal reactions. The value of the relative reactivity to C_6H_{12} and C_6H_{10} of atomic sulfur to diatomic sulfur employed in the present work, 36, is smaller than the calculated one, 417. This supports our view concerning the nature of the sulfur species responsible for the dehydrogenation reactions. In the present work, the relative degree of contribution of atomic and diatomic sulfurs to the oxidative dehydrogenation of C_6H_{12} was not determined.

(Received January 8, 1986)

Color reactions among amino glycoside antibiotics such as gentamicin (GM), a metal ion such as uranium(VI), and *o*-hydroxyhydroquinonephthalein (Qnph) as a xanthene dye were studied by using a preconcentration technique based on membrane filtration. A simple, new, and highly sensitive spectrophotometric determination of GM has been established by using a preconcentration to collect Qnph–uranium(VI)–GM ternary complex. Beer's law is obeyed over the range 0—5.4 μg of GM in 5 cm^3 of dimethyl sulfoxide at 565 nm, and the apparent molar absorptivity for GM is 4.2×10^5 dm^3 cm^{-1} mol^{-1} with a Sandell sensitivity of 0.0013 μg cm^{-2} GM at 565 nm. The procedure is about 2.5-fold as sensitive as the method employing aqueous medium, and is applicable to determination of GM in calf serum.

We have already reported a simple and highly sensitive spectrophotometric determination of antibiotics such as neomycin, toburamycin (TOB),[1] streptomycin (SM),[2] cephalexin, ampicillin,[3] and minocycline[4] which uses *o*-hydroxyhydroquinonephthalein (Qnph) and uranium(VI), manganese(II), palladium(II), or zirconium(IV) in the presence of surfactants without solvent extraction. Alykov[5] reported a determination of amino glycoside antibiotics which uses Pyrocatechol Violet (PV), aluminium(III), and amino glycoside antibiotics ternary complex in water–ethanol (7:3) medium. But, most of these methods are somewhat unsatisfactory for gentamicin (GM) in respect of sensitivity and selectivity, and thus their application to biological samples has scarcely been carried out.

On the other hand, we have already reported[6] a new and sensitive spectrophotometry of micro quantities of papaverine hydrochloride as organic bases which resorts to a preconcentration technique based on membrane filtration of the 2,4,5,7-tetrachlorofluorescein (T.Cl.fl.)–palladium(II)–papaverine hydrochloride ternary complex.

In this research, a color reaction was studied of amino glycoside antibiotics by utilizing the Qnph–metal ion–amino glycoside colored formation with a metal ion and Qnph, and suitable conditions were established for the spectrophotometric determination of microquantities of GM by using a preconcentration technique based on the use of membrane filter to collect the Qnph–uranium(VI)–GM ternary complex. The proposed method was applied to an assay of GM in calf serum.

Experimental

Reagents and Materials. GM (Shionogi Co., Ltd.; manifested potency 612 μg mg^{-1}) and uranium(VI) solutions (5.0×10^{-4} mol dm^{-3}) were prepared as described in our previous report.[1] Qnph methanol solution (5.0×10^{-4} mol dm^{-3}) and Walpole buffer solution (sodium acetate–acetic acid) were prepared according to our previous reports,[1,6] and 0.05% methyl cellulose (MC, 1500 cps, Kishida Chemical Co., Ltd.) solution was prepared by dissolving MC in water. All the other materials and reagents were of analytical grade and were used without further purification. Doubly deionized water was used.

Apparatus. A Shimadzu model UV-160 or 240 recording spectrophotometer with 1.0 cm silica cells was used to record absorption spectra and for absorbance measurements. A Hitachi-Horiba F-7AD glass electrode pH meter was used for pH measurements. A Toyo TM 4 membrane filter (nitrocellulose membrane, 25 mm in diameter and 0.2 μm in pore size) and a Toyo KGS-25 filter holder were used.

Standard Procedure. A GM solution containing 0—5.4 μg of GM was placed in a 10 cm^3 volumetric flask; to this were added 0.5 cm^3 of 0.05% MC solution, 2.0 cm^3 of acetate buffer solution (pH 5.0), 2.0 cm^3 of 5.0×10^{-4} mol dm^{-3} uranium(VI) solution, and 1.0 cm^3 of 5.0×10^{-4} mol dm^{-3} Qnph solution. The mixture was diluted to the mark with water, agitated well (aqueous solution A), and kept at 20—25 °C for 10 min together with a reference solution (Qnph–uranium(VI) solution, aqueous solution B). Aqueous solutions A and B were each filtered with a membrane filter, and then the filtered substances were washed with about 10 cm^3 of water. The membrane filters were dissolved in 5 cm^3 of dimethyl sulfoxide (DMSO), and then the absorbance of DMSO solution A was measured at 565 nm against DMSO solution B as a reference. The concentration of GM was determined by using a calibration curve.

Results and Discussion

Color Reaction, Absorption Spectra, and Effects of Dyes and Metal Ions. The absorption spectra of Qnph solution (DMSO solution C), Qnph–uranium(VI) binary complex solution (DMSO solution B), and Qnph–uranium(VI)–GM ternary complex solution (DMSO solution A) are shown in Fig. 1. The absorption maximum of DMSO solution A is around 565 nm, and the magnitude of absorbance at 565 nm is proportional to the concentration of GM.

Application of Xanthene Derivatives for Analytical Chemistry, Part LVI. Part LV, Y. Fujita, I. Mori, K. Fujita, T. Tanaka, Y. Koshiyama, H. Kawabe, *Chem. Pharm. Bull.*, **34**, 2236 (1986).

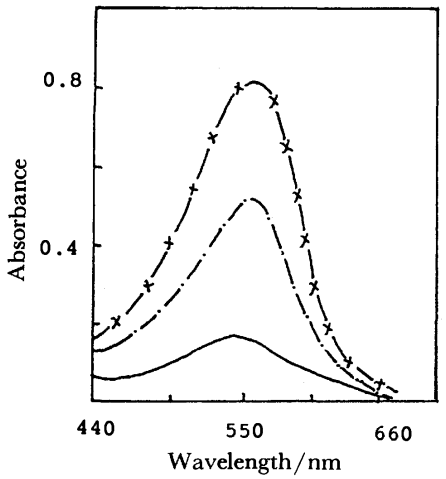

Fig. 1. Absorption spectra of Quph-uranium(VI)-GM DMSO solution (DMSO solution A), Quph-uranium(VI) DMSO solution (DMSO solution B) and Qnph DMSO solution (DMSO solution C). Uranium(VI): 1.0×10^{-4} mol dm^{-3}; Qnph: 5.0×10^{-5} mol dm^{-3}; Reference: DMSO.
——: DMSO solution C, —·—·—: DMSO solution B, —×—: DMSO solution A.

The effects of xanthene dyes and metal ions in this reaction system were also examined by measuring the absorbance of xanthene dye-metal ion-GM DMSO solution against the xanthene dye-metal ion DMSO solution. In respect of sensitivity, stability, and selectivity, Qnph as a xanthene dye and uranium(VI) as a metal ion are superior to the other xanthene dyes-salicylfluorone (Sal.fl), phenylfluorone (Phfl), *o*-hydroxyhydroquinonesulfophthalein (Qn.sul.ph), Gallein (Gall), Xylenol Orange (XO), and PV- and the other metal ions such as molybdenum(VI), tungstic acid (W(VI)), palladium(II), and lanthanum(III). These results are given in Tables 1 and 2. Next, color reactions between the Qnph-uranium(VI) solution and various amino glycoside antibiotics were compared by measuring the absorbance at 565 nm against DMSO solution B. Of the various amino glycoside antibiotics tested, the color reactions for GM and TOB are most sensitive. The results are given in Table 3.

On the basis of these results, GM was chosen for the purpose of fundamental investigations on the determination of amino glycoside antibiotics using Qnph and uranium(VI).

Effect of pH. A constant and maximum difference of absorbance between DMSO solutions A and B was obtained in the pH range from 4.8 to 5.2 when the final solution was adjusted with 2.0 cm^3 of 2.0×10^{-1} mol dm^{-3} sodium acetate-acetic acid buffer solution.

Effect of Surfactants. The effect of surfactant on the preconcentration technique using a membrane filter was examined for various surfactants. Although DMSO solutions A and B in the absence of surfactant are lacking in reproducibility and sensitivity, the presence of a small amount of MC (1500 cps), a nonionic surfactant, is most effective of the various surfactants: poly(*N*-vinylpyrrolidone) (PVP, K-15), poly(vinyl alcohol) (PVA, n=2000), MC, and sodium dodecyl sulfate (SDS). A maximum and constant absorbance of DMSO solution A was observed addition of 0.4—0.6 cm^3 of 0.05% MC solution in a final volume of 10 cm^3.

Table 1. Effect of Dyes[a]

Ampicillin	610.0	350	0.420	100.0
Adenosine Triphosphate	380.0	150	0.163	38.8
Chondroitin Sulfate (Sodium)	500.0	—	0.488	116.2
N-Hexadecylpyridinium (Chloride)	3.0	2	0.580	138.1
Sulfisomidin	139.2	100	0.450	107.1

a) GM taken: 2.7 μg/5 cm^3; uranium(VI): 1.0×10^{-4} mol dm^{-3}; Qnph: 5.0×10^{-5} mol dm^{-3}; MC: 0.5 cm^3 of 0.05% MC solution/10 cm^3; pH: 5.0; reference: Qnph–uranium(VI) DMSO solution (DMSO solution B).

Effects of Qnph and Uranium(VI) Concentrations. The effect of Qnph and uranium(VI) concentrations on the standard procedure was examined by varying the molar ratio of Qnph to uranium(VI) and measuring the absorbance at 565 nm with the amounts of uranium(VI) and GM kept constant. The molar ratio of uranium(VI) 2 to Qnph 1 is most effective for the determination of GM. Accordingly, all further works were carried out with 1.0×10^{-4} mol dm^{-3} uranium(VI) and 5.0×10^{-5} mol dm^{-3} Qnph in the final volume of 10 cm^3.

Effects of Membrane Filters and Organic Solvents. Effects of organic solvent-soluble membrane filters and water miscible organic solvents in this reaction system were examined according to our previous report.[6] Nitrocellulose of 0.20 μm pore size is most effective of the pore sizes tested: 0.10, 0.20, 0.30, 0.45, 0.65, and 0.80 μm. DMSO is the best in respect of sensitivity and reproducibility.

Calibration Curve and Reproducibilty. Beer's law holds in the concentration range up to 5.4 μg of GM in the final volume of 5 cm^3 DMSO. The sensitivity, according to Sandell's scale, is 0.0013 μg cm^{-2} for GM at 565 nm, and the apparent molar absorptivity was calculated to be 4.2×10^5 dm^3 mol^{-1} cm^{-1}. The coefficient of variation (CV) for 5 replicate determinations was 1.6% for 2.7 μg of GM.

Interference of Foreign Substances. The interference of various ions and substances was examined for the determination of 2.7 μg 5 cm^{-3} of GM. Coexistence of a metal ion such as iron(III) or copper(II) causes positive errors, though the interference can be suppressed by addition of nitrilotriacetic acid (NTA) as a masking agent. Coexistence of oxalate, or phosphate, or fluoride ion, or protein interferes with carrying out the reaction. Glycine, D-glucose, glutamic acid, salicylic acid, or ampicillin does not interfere when present in 300- to 3000-fold excess over GM. These results are summarized in Table 4.

The effect of various agents was investigated to suppress the interference of protein in this proposed method using membrane filter. Sulfosalicylic acid is most suitable, because pH adjustment of sample solution is easy and because the effect of metal ions is partially masked by its addition, of the agents tested: methanol, trichloroacetic acid, sulfosalicylic acid, tungstic acid, perchloric acid, etc.

Composition of Complex. The molar ratio of GM to uranium(VI) in the Qnph–uranium(VI)–GM ternary complex was estimated to be 1:2 by the molar ratio method. The molar ratio of the Qnph–uranium(VI) complex mixture in the presence of GM was 1:2 as determined by the continuous variation and molar ratio methods. Thus, though further investigation is necessary, the colored ternary complex formed in this reaction system appears to be a ternary complex with a ratio Qnph 1: uranium(VI) 2: GM 1 in DMSO solution.

Recovery of GM Added to Calf Serum. Recovery of GM added to calf serum (Nakarai Chemical Co., Ltd.) was examined by the proposed method. A satisfactory result was obtained in the following way: Exactly 0.5 cm^3 of calf serum containing up to 0—54 μg of GM was taken, 2.0 cm^3 of 3.0% sulfosalicylic acid

Table 5. Analytical Results of GM or TOB Added to Calf Serum[a]

	Amounts of antibiotics		Recovery/%[b]
	Added/μg	Found/μg[b]	
Gentamicin (GM)	1.36	1.44	105.6
	2.72	2.90	106.6
Toburamycin (TOB)	1.46	1.48	101.4
	2.92	3.04	104.1

a) Calf serum taken: 0.5 cm³. b) Average from 5 determinations.

solution was added to this solution, and the mixture was filtered by using a membrane filter. The filtrate was diluted to 10 cm³ with water, and 1.0 cm³ of this diluted solution was taken, and then the GM content was determined according to the standard procedure. The results are given in Table 5. The experimental results were in good agreement with these given in our previous report[4] and those obtained according to other methods.[7,8]

In conclusion, this proposed spectrophotometric determination of GM by the membrane filter preconcentration technique is more than 2.5-fold as sensitive as the method employing aqueous medium,[3] and 30-fold as sensitive as the method using PV–aluminium(III) complex.[5] The proposed method is simple, rapid, sensitive, and reproducible as compared with the Qnph–uranium(VI) aqueous method,[1] the PV–aluminium(III) method,[5] and other methods.[7,8]

Although further investigation is necessary, this preconcentration method using membrane filter may be available as a new, highly sensitive, and simple analytical procedure for various pharmaceutical and biological samples.

Presented at the 106th Annual Meeting of the Pharmaceutical Society of Japan, Chiba, April (1986).

The authors are grateful to Dr. T. Nishino of this university for supplying gentamicin.

Comparison of ESR Signal Intensities of Some Binuclear Copper Complexes

Kunio NAKANO,* Hiroshi TADANO, So OSHIGE, Nobuaki WADA, Mari YAMAGUCHI, and Heijiro OJIMA†
Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro 3, Toshima-ku, Tokyo 171
†Aichi Kyoiku University, Igaya-cho, Kariya 448
(Received February 13, 1986)

ESR signal intensities of two kinds of binuclear copper complex were measured by the two-step integral method with a multi-mode resonator cavity. The intensities standardized with $CuSO_4 \cdot 5H_2O$ are the proper values for these substances, and can be compared with each other. The intensities of oxamide type complexes (A-group) were a few tens of percent of the intensity of $CuSO_4 \cdot 5H_2O$, while the intensities of binuclear complexes having a bridge of two oxygens (B-group) were less than one percent. This suggests that the two coppers in each binuclear molecule interact, and that the magnitude of the interaction of the B-group can be considered to be much greater than that of the A-group.

Although the electron spin resonance (ESR) spectra of many substances have been determined, there are not so many examples of quantitative measurements of ESR signal intensity. An ESR signal is usually recorded in derivative shape of an absorption curve, and there are some instances of quantitative analysis by using the peak-to-peak height of the signal.[1–15] However, the peak-to-peak height method cannot be used except in the case of sharp and symmetrical signals. Hence, the two-step integration method was attempted for quantitative measurements and gave good results for general signals.[16,17] After this, a few instances of the integration method have been seen.[18–21] The wave height of a two-step integral curve, however, varies with changes in the measuring conditions; and it cannot be normalized for the microwave output power, although normalization for the other measuring conditions is possible.[22] Moreover, the Q-value of a sample varies in its signal intensity, and thus the signal intensities of samples having different Q-values cannot be compared with each other even if determined under the same measuring conditions. To make such comparison between different species possible two-step integral method using a multi-mode resonator (double cavity) was devices.[23]

A sample and a standard substance were put into each hole of two sample holes of the double cavity, and the wave heights of two-step integral were measured under same-phase and anti-phase of magnetic modulation. This method made it possible to obtain the proper ESR signal intensities of various substances. These proper values can be considered to have the same sort of significance as that of such properties as molar absorption coefficient, magnetic moment and molar heat. The ESR signal intensities of some binuclear copper complexes are reported in the present paper.

Experimental

Apparatus. The ESR apparatus used was a JES-ME3X (Japan Electron Optics Laboratory Co. Ltd.) which had been partially modified in its phase sensitive detector circuit.[24] The multi-mode cavity resonator was a TE_{105} mode type (JES-MCX-1, JEOL). Its cavity had two sample holes and in each hole was set a quartz adapter to minimize the variation of sample position by reinsertion.[24] Into one of two holes was inserted a sample and into the other a standard. Magnetic modulation applied to the two holes could be switched to the same-phase or to the anti-phase.

A signal was integrated by a hand-made integrator in which two operational amplifiers were employed.[16] The wave height of the two-step integral curve was measured by a process similar to the method for measuring limiting current in polarography. Quartz tubes of 5 mm outside diameter to just fit the adapter were used for the sample tube.

Materials. The binuclear copper complexes were synthesized by one of the present authors.[25–30] The complexes measured and their symbols are listed in Table 1. From a few mg to about 20 mg of $CuSO_4 \cdot 5H_2O$ were used as standards. Mononuclear copper complexes measured for comparison were extra pure grade or were prepared from extra pure reagents. The samples used for measurements were fine grain or powder.

Measurements. Figure 1 shows each signal example of A-group and B-group. They were measured with a single cavity. As B-4 was measured under ten-fold greater sensitivity than A-6, the signal of B-4 was much smaller than that of A-6.

The method of calculation was as follows. Sample a and sample b are inserted into the two holes, hole 1 and hole 2, of the double cavity, respectively. When the magnetic modulation of the two holes is in the same phase, the wave heights of the two-step integral curve is represented as h_s, and when in the anti phase, it is represented as h_a, then,

$$h_s = I_a + \alpha I_b \quad (1)$$

$$h_a = \beta(I_a - \alpha I_b) \quad (2)$$

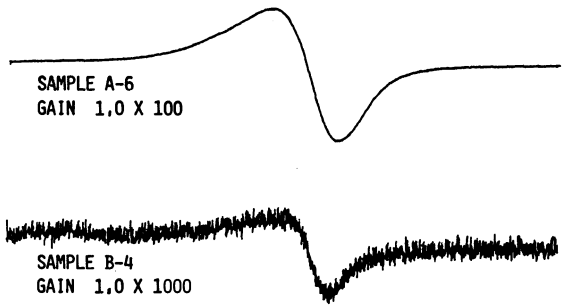

Fig. 1. Examples of ESR signal of binuclear copper complexes. Magnetic field: 3100±1000 gauss, magnetic moduration width: 6.06 gauss, microwave frequency: 9.42 GHz, microwave output power: 6.0 mW, crystal current: 0.4 mA, sweep time: 10 min, at room temperature.

B- 9	μ-Bis[*N*-(2-pyridylmethyl)hydroxoacetamido]dicopper(II)	26)

a) Obtained similarly to the complex A-5 using 1,10-phenanthroline instead of 2,2′-bipyridine in the complex A-5. b) Derived from the complex A-1 or A-3 using pyridine- or 4-methylpyridine.

while I_a and I_b are respectively the wave heights of sample a and sample b in hole 1 in the same phase, α is the ratio of the wave heights in hole 1 and hole 2, and β is the ratio of the wave heights of the same sample in the same phase and in the anti phase. Figure 2 shows an example of an original curve (1), the 1st step integral curve (2), and the 2nd step integral curve (3), and the determination of h_s and h_a are also shown in the figure.

The following equation is obtained from Eqs. 1 and 2.

$$\frac{I_a}{I_b} = \frac{\alpha(h_s + h_a/\beta)}{h_s - h_a/\beta} \tag{3}$$

I_a and I_b vary considerably with changes in the measuring conditions and in the Q-value of the sample; however, the ratio I_a/I_b is maintained almost constant. Therefore, if sample b is a standard, the signal intensity of sample a can be obtained by Eq. 3.

$CuSO_4 \cdot 5H_2O$ was employed as the standard substance in the present experiments. If n mg of $CuSO_4 \cdot 5H_2O$ are taken as a standard and m mg of binuclear complex are taken as a sample, the ratio γ of copper atoms to those in the standard is

$$\gamma = \frac{2m}{M} \cdot \frac{249.7}{n} \tag{4}$$

M: molecular weight of the binuclear complex.

The ESR signal intensity of copper in the sample is given by

$$I = \frac{1}{\gamma} \cdot \frac{I_a}{I_b} \tag{5}$$

All measurements were carried out at room temperature. Measuring conditions of the spectrometer were as follows: Sweep width of the magnetic field was 3100±1000 gauss, sweep time was 1 min, magnetic modulation width was 6.06 gauss, the microwave frequency was 9.4 GHz and its output power was 6.0 mW, and the crystal current was 0.4 mA. The cavity constants, α and β, were revaluated when the cavity and the adapters were reset.

The relative standard deviation of repeated measurements of a sample was generally within a few %, when the shape of the signal was favorable. However, when the signal was very small, as in the B-type complex, the number of significant figures of the intensity I was only one. Moreover, when the two wings of a signal curve did not coincide with the base line, the precision decreased. However, noise with short periods scarcely affected the precision, since it was canceled out by integration. The relative standard deviations of the signal intensities obtained in the present work except for the B-group were within a few %, and even the maximum deviation was less than 10%.

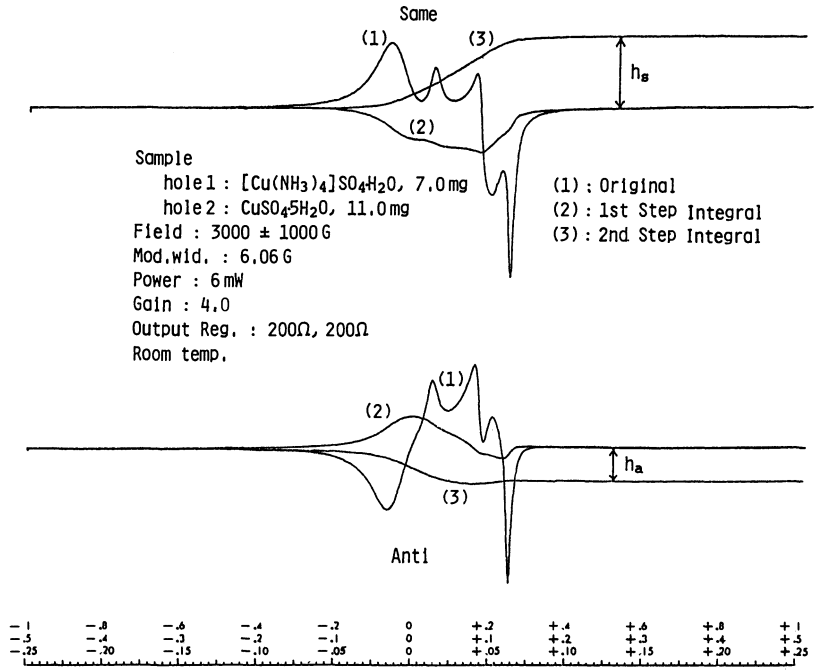

Fig. 2. An example of integrated curves of ESR signal with double cavity.
h_s: Wave height in same phase. h_a: Wave height in anti phase.

Results and Discussion

The results obtained for the ESR signal intensities I standardized with $CuSO_4 \cdot 5H_2O$ are tabulated in Table 2. The table also includes the magnetic moment μ measured previously by one of the present authors. In addition, the signal intensities of a few mononuclear copper complexes are also listed. The data are compiled and presented in Fig. 3; and when roughly classified, they show that, although the intensities of mononuclear complexes are almost 1, those of the A-group are a few tens of % and those of B-group under 1% of the copper sulfate crystals. This suggests that the two unpaired electrons of the two copper atoms in a molecule partly make a pair through bridging atoms. The interaction can be considered to be stronger in the B-group (two-oxygen bridge) than in the A-group (oxamide bridge).

With respect to the compounds A-1 to A-18, those whose chelate ring adjacent to the bridging ring has fine members have about half the I value of those having six members. Thus, it can be considered that the copper–copper interaction of a five-membered ring is stronger than that of a six-membered ring, since the larger strain of the six-membered ring more strongly affects the delocalization of π-electrons through the bridging atoms. The same tendency can be seen in the compounds from A-33 to A-47, that is, the I values of the compounds of l=2 (five-membered ring) are smaller than those of l=3 (six-membered ring). However, that the values of l=6 (nine-membered ring) are smaller than those of l=3 may suggest that the structural strain is

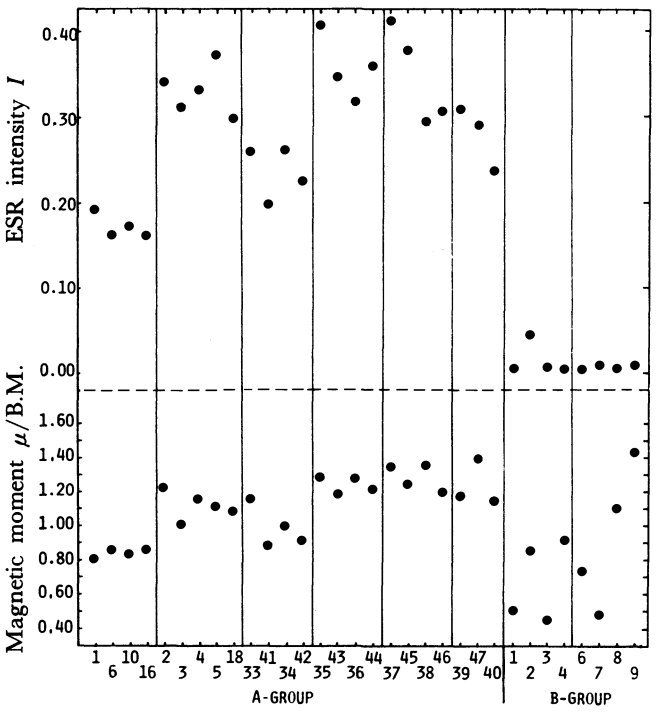

Fig. 3. ESR signal intensities and magnetic moments of binuclear copper complexes.

rather smaller than in the six-membered ring. The number of members of the chelate ring on the opposite side of the bridging ring does not seem to have obvious effect on its signal intensity.

The values of magnetic moment μ of binuclear complexes shown in Fig. 3 are smaller than the value of

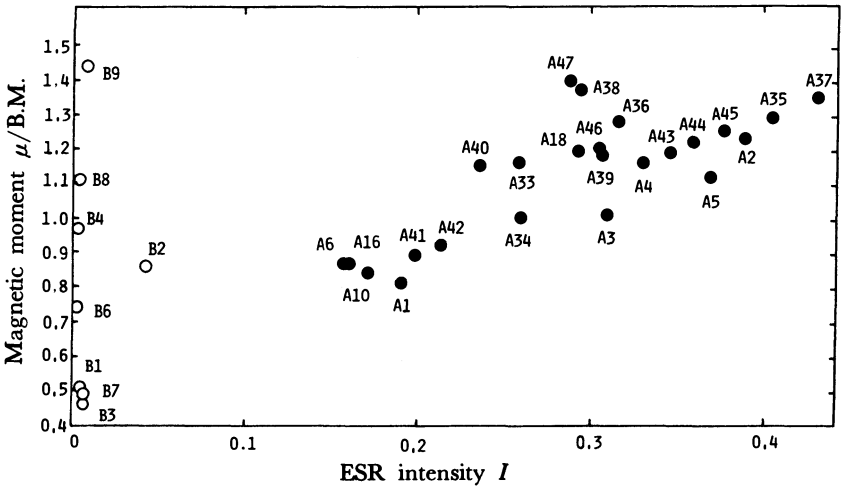

Fig. 4. Relationship between the ESR signal intensities and the magnetic moments of binuclear copper complexes.

the general mononuclear copper complex, which is about 1.9. Although the values of five-membered rings are smaller than those of six-membered rings as in the relationship in the case of ESR signal intensity, no significant difference between six or seven-membered ring and nine-membered rings can be seen. Moreover, although the ESR intensities of the B-group are much smaller than those of the A-group, there is no great difference in the magnetic moments of the A-group and B-group. The relationship between the signal intensities and magnetic moments is shown in Fig. 4. A considerable correlation is exhibited between I and μ in the A-group, but such correlation cannot be seen in the B-group. The reason for this is not yet understood.

Conclusion

The two-step integral method using a multimode cavity made it possible to obtain the intensities of ESR signals of samples relative to a standard substance, regardless of the measuring conditions and the Q-values of the samples. It can be considered that the accurate determination of an ESR signal intensity as a proper value of a species is very important. In the present work the ESR signal intensities of some binuclear copper complexes were measured as the first examples. The results showed that the intensities of the binuclear copper complexes of the A-group (oxamide type) were a few tens of percent of the intensity of copper sulfate crystals, while those of B-group (binuclear complexes bridged with two oxygen atoms) were less than one percent of copper sulfate. This difference may have been caused by the magnitude of interaction between the two copper atoms in binuclear molecule. On the other hand, the difference in the magnetic moments between the A-group and B-group was not notable. However, as the interaction between the two copper atoms of a B-group compound is generally supposed to be stronger than that of an A-group compound due to their structures, the ESR signal intensity can be considered to be more useful than the magnetic moment for estimating the interaction between these atoms.

(Received February 14, 1986)

Copper complexes of the title ligand (taec) of the general formula $Cu_2(taec)X(ClO_4)_3$ (X=F, Cl, Br, I, HCOO, CH_3COO, NO_2) were prepared and characterized. The formation constants for $[Cu_2(taec)]^{4+}+X^-=[Cu_2(taec)X]^{3+}$(X=F, Cl, Br, I) were determined spectrophotometrically in aqueous solution. The stabilities of the halogen-copper bonds were greatly enhanced relative to those of ordinary halogenocopper complexes, the order of the formation constants being Cl>Br>I>F. This result can be explained as that the anion is trapped in a cavity formed by two copper ions and the methylene chains of taec molecule, thereby the stability of the bound anion is enhanced and the fitness of the size of anion to the cavity is the most important factor for the formation constant.

A number of tetraazamacrocycles with pendant arms on the nitrogen atoms were synthesized and characterized in recent several years because of their specific complexation behavior and structural interest of their metal complexes.[1-6] In the preceding papers,[7,8] we reported the synthesis and characterization of dicopper(II) complexes of taec(*N,N',N'',N'''*-tetrakis(2-aminoethyl)cyclam). The crystal structure analyses revealed that in $Cu_2(taec)(ClO_4)_4$ and $Cu_2(taec)Br(ClO_4)_3$ each copper ion is coordinated by the two ring nitrogens and the two pendant nitrogens forming a nearly square planar coordination entity, but the coordination modes of ligand are entirely different between these complexes as depicted in Fig. 1. In both cases one of the axial sites is open for coordination on each copper, but the other site is hindered with ligand methylene groups. In $Cu_2(taec)(ClO_4)_4$ both axial coordination sites are open toward the outside of the molecule in opposite direction so that perchlorate oxygen weakly coordinates to each copper, whereas in $Cu_2(taec)Br(ClO_4)_3$ the axial coordination sites face to each other allowing the bromide ion to be bound by both coppers. This structure is in good harmony with the facts that the addition of excess sodium perchlorate to a concentrated solution of $Cu_2(taec)Br_4$ does not yield the tetrakis(perchlorate) but invariably precipitated the bromide tris(perchlorate) and the Cu-Br bond is very stable toward hydrolysis relative to ordinary Cu-Br bonds. Being interested in these results, in this study we have newly prepared a series of complexes of the formula, $Cu_2(taec)X(ClO_4)_3$ (X=F, Cl, I, HCOO, CH_3COO, NO_2), and discussed the nature of Cu-X bonds in terms of stability constants and electronic spectra.

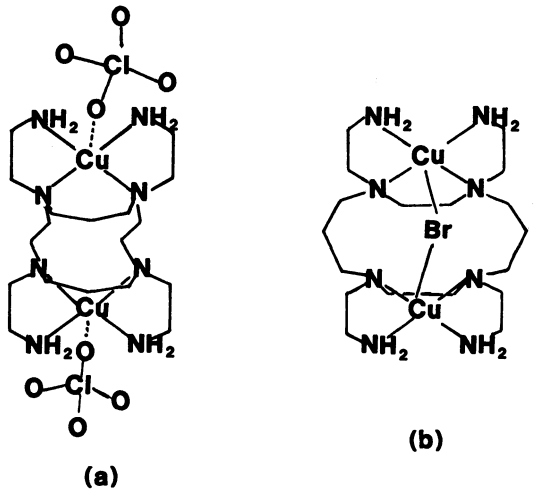

Fig. 1. Schematic drawing of the molecular structures of (a) $Cu_2(taec)(ClO_4)_4$ and (b) $Cu_2(taec)Br(ClO_4)_3$, where uncoordinated perchlorate ions are omitted.

Experimental

Preparation. The preparative methods for taec and $Cu_2(taec)Br(ClO_4)_3$ were already reported in the preceding papers.[7,8]

Complexes, $Cu_2(taec)X(CLO_4)_3$ (X=F, Cl, I, HCOO, CH_3COO, NO_2), were prepared by similar procedures from $Cu(ClO_4)_2\cdot 6H_2O$, taec, and NaX. The procedure for $Cu_2(taec)F(ClO_4)_3\cdot 2H_2O$ is shown below as an example.

$Cu_2(taec)F(ClO_4)_3\cdot 2H_2O$. To an aqueous solution of $Cu(ClO_4)_2\cdot 6H_2O$ (185 mg, 0.5 mmol) and taec (93 mg, 0.25 mmol) was added NaF (82 mg, 2 mmol), and the mixture was heated at 80 °C for 20 min. The resulting blue solution was filtered. When the filtrate was allowed to stand for about 6 h, blue needles were separated. Leaving the mixture for longer period may result in contamination of purple crystals ($Cu_2(taec)(ClO_4)_4$). The crude product was recrystallized from aqueous solution by adding NaF (≈ 50 mg). The crystals were collected, washed with methanol, and desiccated over P_2O_5. Yield; 175 mg (85%). Found: C, 25.60; H, 5.73; N, 13.23; Cu, 14.87%. Calcd for $C_{18}H_{48}N_8O_{14}Cl_3FCu_2$: C, 25.35; H, 5.67; N, 13.14; Cu, 14.90%

$Cu_2(taec)Cl(ClO_4)_3\cdot H_2O$. Blue fine crystals. Yield; 177 mg (85%). Found: C, 25.37; H, 5.25; N, 13.25; Cu, 14.87%. Calcd for $C_{18}H_{46}N_8O_{13}Cl_4Cu_2$: C, 25.39; H, 5.44; N, 13.16; Cu, 14.93%.

$Cu_2(taec)I(ClO_4)_3$. Violet needles. Yield; 210 mg (91%). Found: C, 23.32; H, 4.69; N, 11.95; Cu, 13.48%. Calcd for $C_{18}H_{44}N_8O_{12}Cl_3ICu_2$: C, 23.37; H, 4.79; N, 12.11; Cu, 13.74%.

$Cu_2(taec)(HCOO)(ClO_4)_3$. Blue needles. Yield; 196 mg (93%). Found: C, 26.73; H, 5.43; N, 13.15; Cu, 15.07%. Calcd for

Measurements. Electronic spectra were measured with a Shimazu MPS-5000 Multipurpose Spectrophotometer.

Infrared spectra were obtained with a Hitachi Grating Infrared Spectrophotometer Model 215 on KBr disk.

Magnetic susceptibilities were measured by the Faraday method. The apparatus was calibrated by use of $[Ni(en)_3]S_2O_3$. The susceptibilities were corrected for the diamagnetism of constituent atoms by use of Pascal's constants. Effective magnetic moments were calculated from the equation, $\mu_{eff}=2\sqrt{2(\chi-N\alpha)T}$, where χ is atomic magnetic susceptibility, and $N\alpha=60\times10^{-6}$ cgs emu.

Determination of stability constants. The equilibrium constants for $[Cu_2(taec)]^{4+}+X^- \leftrightarrows [Cu_2(taec)X]^{3+}$ (X=F, Cl, Br, I) were determined by a spectrophotometric method.[9] Absorbances of aqueous solutions containing $Cu_2(taec)X(ClO_4)_3$ (2×10^{-3}, 1×10^{-3}, 4×10^{-4}, 2×10^{-4}, 1×10^{-4}, and 5×10^{-5} M) and $NaClO_4$ (1×10^{-2} M) were measured in 1 cm or 10 cm cell at 30°C, where M=mol dm^{-3}. The spectrum of $Cu_2(taec)(ClO_4)_4$ (1×10^{-3} M) was also measured to determine its molar extinction coefficients at the same condition as the above. The constants K were obtained by exploiting the relations,

$$\varepsilon_a(a-x) + \varepsilon_b x = D$$
$$(a-x)/x^2 = K,$$

where a and $a-x$ are initial and equilibrium concentrations of $[Cu_2(taec)X]^{3+}$, respectively; D is optical density of the solution; and ε_a and ε_b are molar extinction coefficients of $[Cu_2(taec)X]^{3+}$ and $[Cu_2(taec)]^{4+}$, respectively, the former of which were determined by measuring the absorbances of solutions containing $[Cu_2(taec)X]^{3+}$ (1×10^{-3} M) and the excess of X^- (10^{-2}—10^{-3}). Reasonable K values were obtained from the data in the range 600—640 nm, and those at 620 nm were chosen as the best values, which are listed in Table 1.

Results and Discussion

The binuclear structure of the present complexes is obvious judging from the elemental analyses and the crystal structures of $Cu_2(taec)Br(ClO_4)_3$ and $Cu_2(taec)(ClO_4)_4$.[8] However, as seen in Table 1 magnetic moments are not subnormal, and obey Curie-Weiss law in 80—300 K with very small negative Weiss constants, implying that there is no significant magnetic interaction between the copper ions.

Infrared spectra of all the complexes showed bands at 3400—3200, 3000—2900, 1580—1500, and 1050—1150 cm^{-1} whcih can be assigned to the ν(NH), ν(CH), $\delta(NH_2)$, $\delta(CH_2)$, and $\nu(ClO_4^-)$, respectively,[10] and many small bands in the 1400—650 cm^{-1} region forming a complicated pattern. The spectra of the F^-, Cl^-, Br^-, and I^- complexes closely resemble each other, suggesting similar molecular structures. The spectra of the NO_2 and RCOO (R=CH_3, H) complexes differ from each other and from those of the halogeno complexes in detail in the 1400—650 cm^{-1} region, and the bands due to the axial ligands overlapped with those of the equatorial ligand (taec), hence no definite assignments were feasible.

As shown in Table 1 the ligand field bands of $Cu_2(taec)X(ClO_4)_3$ are generally lower in wave number than that of $Cu_2(taec)(ClO_4)_4$ in nujol mull spectra. When the complexes are dissolved in water, the bands of tris(perchlorate) complexes are blue-shifted in more or less degree, whereas that of the tetrakis(perchlorate) is red-shifted though it still maintains the highest ν_{max} values among those complexes. These shifts should be due to the hydrolysis of the axial ligands. Judging from the degree of the blue-shift, it seems that the halogeno complexes are hydrolyzed very little in spite of the general view that halogeno copper(II) complexes are readily hydrolized in water.[11] On the other hand, the other complexes of $Cu_2(taec)X(ClO_4)_3$ are considerably hydrolized. In the case of tetrakis(perchlorate) it is most likely that the weakly coordinated perchlorate ions in crystal[7] are fully replaced by water molecules.

In order to make the above view quantitative we have determined the formation constants K of the halogeno complexes spectrophotometrically, and the results are listed in Table 1.[12]

$$K = [Cu_2(taec)X^{3+}]/[Cu_2(taec)^{4+}][X^-]$$

Chung et al. determined the complexation constants between mononegative ions and some macrocyclic tetraamine copper(II) complexes, and found that they fell in the range of 1—10 for the cases of Cl^- and Br^- ions.[13] These values are comparable to the first formation constants (k_1) of Cl^- and Br^- ions with Cu^{2+} (log k_1=0.08 and −0.055 respectively). Thus, the presently obtained K values are larger than those values by a factor of 10^4—10^5 (cf. Table 1). Such an amazing stability should be attributed to a special steric arrangement of the coordination site. In fact, the X-ray analysis of Cu_2(taec)Br$(ClO_4)_3$ demonstrated that the bromide ion is linked by the two copper ions and hedged by nondonating atoms of taec molecule like being trapped in a cavity.[8] Thus, the environment around the coordinated halide ion will become somewhat similar to that in a nonpolar solvent so that the copper-halide bond is greatly stabilized. It is also to be noted that the K values decrease in the order, Cl>Br>I>F. This can also be rationalized in terms of the fitness of the anion to the cavity. In the present case fluoride ion seems to be too small for the cavity to get the largest enhancement of stability. In view of the above results the present complexes may be a model for active sites of some metal enzymes possessing specific selectivity and reactivity which are not found in ordinary synthetic metal complexes.

(Received January 31, 1986)

Complexation of silver(I) with glycinate (gly^-) and β-alaninate (β-ala^-) ions have been studied by potentiometry and calorimetry in 0.2 mole fraction (55.0%w/w) dioxane-water mixture containing 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium at 25 °C. Potentiometric titration curves obtained were well-explained in terms of formation of [AgL], $[AgL_2]^-$, and $[AgHL]^+$ (L^-=gly^- or β-ala^-) in both systems, together with $[Ag(OH)L]^-$ in the Ag(I)-β-alanine system, and their formation constants were determined. Enthalpies of formation of the complexes in the mixed solvent, as well as in water containing the same ionic medium, were calorimetrically determined on the basis of the formation constants potentiometrically determined. Solubilities and enthalpies of solution of the neutral [AgL] (L^-=gly^- and β-ala^-) complexes and some related compounds were determined in water and the mixture, the Gibbs energies of transfer, ΔG_t°, of silver(I) ion and proton from water to the mixture being also determined by potentiometry. By combining the thermodynamic quantities thus obtained, thermodynamic quantities of transfer of single species from water to the mixture were evaluated. Compared to the enthalpy, ΔH_t°, and entropy, ΔS_t°, of transfer of a neutral species, the ΔH_t° and ΔS_t° values of any charged species were significantly large with the negative sign for cations and positive one for anions. As to neutral species, [HL] and [AgL], the relation, $\Delta G_t^\circ > \Delta H_t^\circ \cong 0$ and $\Delta S_t^\circ < 0$, was found, suggesting that the [AgL] complexes have a similar zwitterionic structure to that of glycine and β-alanine zwitterions.

Complex formation equilibria between silver(I) ion and amino acids have so far been studied in water.[1] In a previous paper,[2] we also reported the formation of glycinato (gly^-) and β-alaninato (β-ala^-) complexes of Ag(I) in water, and suggested that the metal ion was coordinated with the amino nitrogen atom within [AgL] and $[AgL_2]^-$ (L^-=gly^- and β-ala^-) but with the carboxylato oxygen atom within $[AgHL]^+$.

In water-rich dioxane-water mixtures, although metal ions and ligands are expected to be preferentially solvated with water, complexation in some metal-ligand systems, such as nickel(II)-ethylenediamine,[3] nickel(II)-glycinate[4] and copper(II)-ethylenediamine systems,[5] are appreciably different from those in water, due perhaps to a partially destroyed hydrogen-bonding structure of bulk water in the mixture compared to that in water.

Silver(I) ion which tends to have a linear coordination structure with ligands may show a different solvent effect on complexation from that of the bivalent transition metal ions having an octahedral coordination structure.

In this work, therefore, we investigated the complexation of silver(I) ion with glycinate and β-alaninate ions by potentiometry and calorimetry in water and in 0.2 mole fraction dioxane-water mixture, and solvent effects on the thermodynamic quantities of formation of the metal complexes in these solvents are discussed. Solubilities and enthalpies of solution of the [AgL] (L^-=gly^- and β-ala^-) complexes and some related compounds were also determined in these solvents. The Gibbs energies of transfer of Ag^+ and H^+ from water to various dioxane-water mixtures were potentiometrically determined. By combining the thermodynamic quantities thus obtained, thermodynamic quantities of transfer of single species from water to the 0.2 mole fraction dioxane-water mixture were evaluated.

†Present address: Department of Chemistry, Texas A & M University, Colledge Station, Texas 77840, U.S.A.

Experimental

Reagents. All chemicals used were of reagent grade. *Lithium glycinate* and *lithium β-alaninate* were prepared by mixing equimolar amounts of glycine or β-alanine and lithium hydroxide in methanol and recrystallized twice from methanol, and then dried at 100 °C in a vacuum oven. *Sodium β-alaninate* was prepared with sodium methoxide by a similar procedure to that used for lithium β-alaninate. *Silver(I) glycinate* and *silver(I) β-alaninate* were prepared by dissolving silver(I) nitrate in aqueous glycine or β-alanine solution, and then by adding sodium hydroxide in the solution. The silver(I) glycinate and silver(I) β-alaninate crystals thus prepared were filtered, washed with methanol and ether, and then dried in vacuum in a dark desiccator at room temperature.

Other chemicals were prepared and purified as described elsewhere.[2,6,7]

Measurements. Potentiometric and calorimetric measurements were carried out in a room thermostated at (25.0±0.2) °C. All test solutions prepared for the measurements contained 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium.

Formation constants were determined by potentiometric measurements which were carried out in a liquid paraffin bath controlled at (25.00±0.02) °C. A test solution containing metal, ligand and hydrogen ions was titrated with a lithium hydroxide solution, and pH of the test solution was determined by using a glass electrode in combination with an Ag-AgCl electrode as a reference. The method of measurements was the same as that described in previous papers.[2-7]

Enthalpies of complexation were calorimetrically determined by measuring in a water bath thermostated at

(25.000±0.007)°C. An initial test solution contained silver(I) and ligand ions, and hydrogen ions of relatively low concentration, and was titrated with a perchloric acid solution. Details of measurements were described elsewhere.[3-5,8,9]

The Gibbs energies of transfer of silver(I) ion and proton from water to dioxane-water mixtures were potentiometrically determined by using an Ag-AgCl and a glass electrodes, respectively, in combination with an Ag-AgCl electrode as a reference, and the total concentrations of the relevant ions were kept constant with varying solvent composition in a test solution.

Solubilities of the mono(glycinato)- and mono(β-alaninato)silver(I) complexes were determined in water and in the 0.2 mole fraction dioxane-water mixture, each solution containing 3 mol dm^{-3} $LiClO_4$ and a small amount of glycine or β-alanine in order to prevent hydrolysis of the metal ion, after the solution was equilibrated for more than two weeks in a thermostated room at (25.0±0.2)°C. Concentrations of silver(I) ion in these solution at equilibrium were gravimetrically determined as AgCl. Net concentrations of the [AgL] (L^-=gly$^-$ and β-ala$^-$) complexes in the solutions were calculated by taking into account the distribution of the glycinato and β-alaninato complexes of silver(I) in each solvent.

Enthalpies of solution of the mono(glycinato)- and mono(β-alaninato)silver(I) complexes and related species were measured by dissolving a given amount of crystals of the relevant species in water and in the mixture, each containing 3 mol dm^{-3} $LiClO_4$. Procedures of the measurements and analysis of data were described in a previous paper.[9]

Determination of Formation Constants and Enthalpies. In advance of determining formation constants and enthalpies of complexation of metal ion with ligands, protonation constants and enthalpies of protonation of each ligand had been determined by potentiometry and calorimetry, respectively. The thermodynamic quantities thus obtained were kept constant in the course of the analysis of the formation constants and enthalpies of formation of the glycinato and β-alaninato complexes of Ag(I). Details of the analysis of potentiometric and calorimetric data were described previously.[3-5]

Results and Discussion

Potentiometric titration curves obtained for silver(I) glycinate and β-alaninate systems in the 0.2 mole fraction dioxane-water mixture are depicted in Figs. 1 and 2, respectively. The potentiometric data were first analyzed by the same graphical procedure as that used in a previous work.[2] For both systems, the graphical analysis indicated the formation of [AgL], $[AgL_2]^-$, and $[AgHL]^+$ over the pH range 3—10. In the silver(I)-β-alaninate system, the formation of $[Ag(OH)L]^-$ was also indicated at pH>8. Formation constants of these complexes were refined by the least-squares method, the

Table 1. The Least-Squares Refinements of Overall Formation Constants, $\log\beta_{pqr}$, of the $[Ag_pH_qL_r]^{(p+q-r)+}$ (L^-=gly$^-$ or β-ala$^-$) Complexes in the 0.2 Mole Fraction Dioxane-Water Mixture Containing 3 mol dm^{-3} $LiClO_4$ as a Constant Ionic Medium at 25 °C
$\beta_{pqr}=[Ag_pH_qL_r^{(p+q-r)+}]/[Ag^+]^p[H^+]^q[L^-]^r$

	Species	Glycinate	β-Alaninate
$\log\beta_{011}$	$[HL]^{a)}$	10.22[b)]	10.86(0.03)
$\log\beta_{021}$	$[H_2L]^+$	13.81[b)]	15.84(0.03)
$\log\beta_{111}$	$[AgHL]^+$	10.93(0.04)	11.63(0.03)
$\log\beta_{101}$	$[AgL]$	3.77(0.01)	4.02(0.22)
$\log\beta_{102}$	$[AgL_2]^-$	7.76(0.01)	8.31(0.03)
$\log\beta_{1-11}$	$[Ag(OH)L]^-$	—	−6.97(0.3)

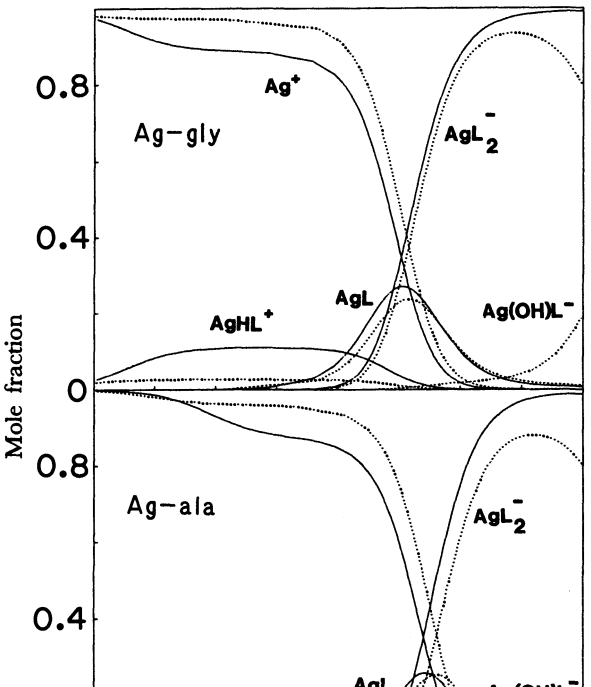

Fig. 3. Distribution of species for the silver(I) glycinate and β-alaninate systems in the 0.2 mole fraction dioxane-water mixture (the solid lines) and in water (the broken lines), both solutions containing 5 and 25 mmol dm^{-3} of silver and ligand ions, respectively, in each system.

results being summarized in Table 1, together with the protonation constants of the ligands. As seen in Figs. 1 and 2 by the solid lines, the theoretical titration curves calculated by using the formation constants in Table 1 well fitted the experimental points over the whole pH range examined in each metal-ligand system. The distribution of species of the silver(I) glycinate and β-alaninate systems in the mixture is shown in Fig. 3.

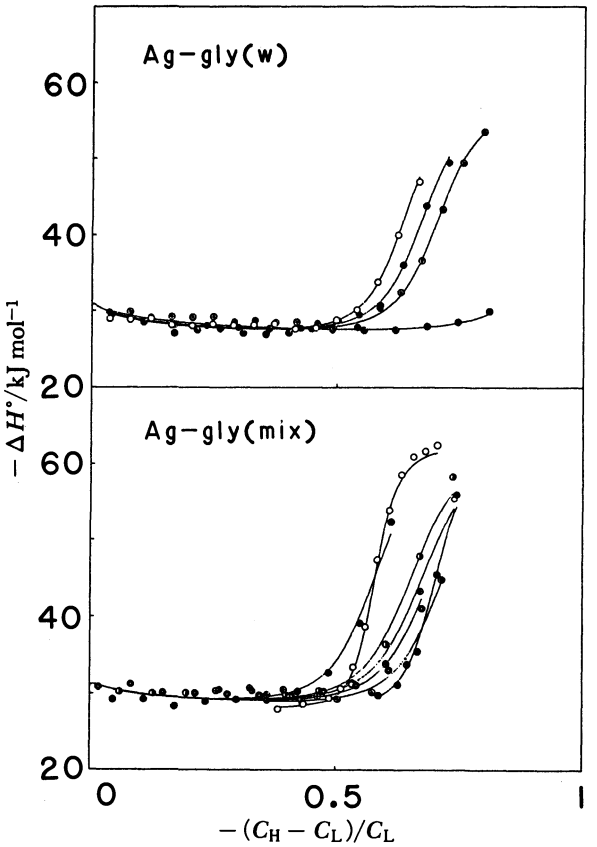

Fig. 4. Calorimetric titration curves of the silver(I)-glycinate system in water and in the 0.2 mole fraction dioxane-water mixture. Initial concentrations of the metal and ligand ions, C_M/mmol dm^{-3} and C_L/mmol dm^{-3}: 15.57, 31.81 (◎); 15.28, 43.09 (⊙); 14.77, 43.46 (●) and 15.21, 47.44 (○) in water and 5.098, 14.64 (⊕); 5.019, 14.91 (◑); 5.476, 15.40 (◉); 4.779, 15.98 (◎); 6.355, 17.18 (⊙); 12.56, 35.21 (●) and 16.41, 56.09 (○) in the mixture.
The solid lines show the calculated curves obtained by using the constants in Tables 1 and 2.

Calorimetric titration curves obtained for the silver(I) glycinate and β-alaninate systems are depicted in Figs. 4 and 5, respectively. Enthalpies $-\Delta H°$/kJ mol^{-1} ($=q/(\delta v C_{H,tit})$, where q and δv denote the heat evolved and the volume of an aliquot of the titrant added, respectively, at each titration point and $C_{H,tit}$ stands for the concentration of $HClO_4$ in the titrant solution) were plotted against the degree of neutralization X ($=-(C_H-C_L)/C_L$, where C_L and C_H denote the total concentration of glycine or β-alanine and hydrogen ion, respectively) of ligand in a solution. The calorimetric data in water were analyzed by using the formation constants of the complexes determined in a previous work.[2)]

As seen in Fig. 3, the formation of $[AgHL]^+$ is weak, so that the enthalpy of formation of the complex was not determined with a sufficient accuracy in each system. The enthalpy of formation of $[Ag(OH)L]^-$ was not also obtained with a reasonable reliability under the present experimental conditions.

The enthalpies of protonation of glycinate and β-alaninate ions and of complex formation of Ag(I) with glycinate and β-alaninate ions in water (w) and in the 0.2 mole fraction dioxane-water mixture (mix) obtained by the least-squares method are summarized in Table 2. The theoretical titration curves calculated by using the formation constants and enthalpies of complexes in Tables 1 and 2 are drawn by the solid lines in Figs. 4 and 5, respectively, which well reproduced the experimental points in each system.

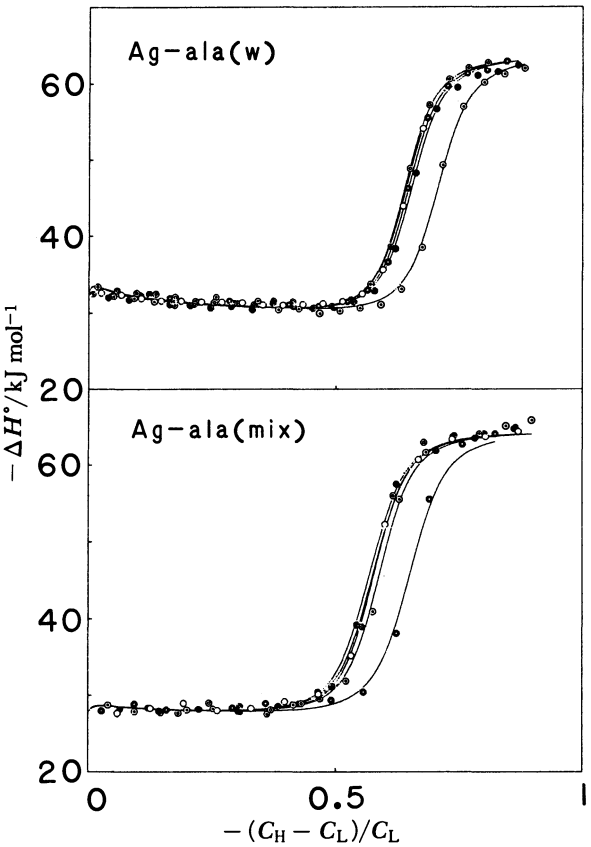

Fig. 5. Calorimetric titration curves of the silver(I)-β-alaninate system in water and in the 0.2 mole fraction dioxane-water mixture. Initial concentrations of the metal and ligand ions, C_M/mmol dm^{-3} and C_L/mmol dm^{-3}: 14.32, 43.82 (○); 15.96, 44.45 (⊙); 14.80, 44.51 (●); 14.97, 45.48 (◉) and 15.02, 46.17 (◎) in water, and 4.558, 15.13 (○); 5.203, 15.40 (◉); 4.690, 15.59 (●); 4.777, 15.70 (⊙) and 4.979, 16.55 (◎) in the mixture.
The solid lines show the calculated curves obtained by using the constants in Tables 1 and 2.

Thermodynamic quantities, $\log(K_n/\text{mol}^{-1}\,\text{dm}^3)$, ΔG_n°/kJ mol^{-1}, ΔH_n°/kJ mol^{-1} and ΔS_n°/J K^{-1} mol^{-1}, for the stepwise formation of $[H_nL]^{(n-1)+}$ (L^-=β-ala$^-$) and $[AgL_n]^{(1-n)+}$ (L^-=gly$^-$ and β-ala$^-$) are listed in Table 3, together with the difference, P_n(mix)−P_n(w) (P=log K, $\Delta G°$, $\Delta H°$, and $\Delta S°$), between the relevant quantities in water and in the mixture.

Gibbs Energies and Enthalpies of Transfer of Proton, and Silver(I), Glycinate and β-Alaninate Ions from Water to the 0.2 Mole Fraction Dioxane-Water Mixture. Changes in activities of proton and silver(I) ion in dioxane-water mixtures relative to those in water were determined by measuring emfs of a cell constructed with a glass and an Ag-AgCl electrodes in combination with an Ag-AgCl electrode as a reference, in which the total concentrations of relevant ions were kept constant with varying solvent composition. In each case of proton and silver(I) ion, the difference in emfs, ΔE=E(mix)−E(w), was obtained as a function of the concentration of dioxane in the mixtures, the result being shown in Fig. 6. As seen in Fig. 6, the ΔE values were independent of the concentrations of relevant ions, but depended on the solvent composition. Thus, ΔE is represented by Eq. 1:

$$\Delta E = (RT/F)\ln\{y(\text{mix})/y(\text{w})\} + \{E_j(\text{mix}) - E_j(\text{w})\}, \quad (1)$$

where y and E_j stand for the activity coefficient and the liquid junction potential of a species at the interface between a test solution and a salt bridge (an aqueous solution or 0.2 mole fraction dioxane-water mixture containing 3 mol dm^{-3} $LiClO_4$ as an ionic medium) and F denotes the Faraday constant. Since the difference in emfs was not influenced by the change of the composition of the salt bridge, the term $\{E_j(\text{mix})-E_j(\text{w})\}$ should be negligibly small. In these measurements, therefore, the ΔE values observed for proton and silver(I) ion could be attributed to the Gibbs energy of transfer of a relevant ion from water to the mixture:

$$\Delta G_t^\circ = RT\ln\{y(\text{mix})/y(\text{w})\} = F\Delta E. \quad (2)$$

The ΔG_t° values of proton and silver(I) ion from water to the 0.2 mole fraction dioxane-water mixture were thus obtained to be 1.9 and 3.1 kJ mol^{-1}, respectively.

Solubilities of the mono(glycinato)- and mono(β-

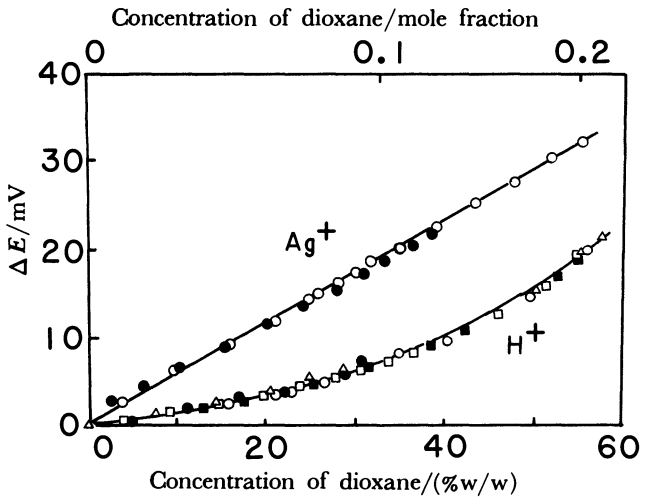

Fig. 6. Emfs obtained as a function of the dioxane concentration in dioxane-water mixtures. An aqueous solution (w) and the 0.2 mole fraction dioxane-water mixture (mix), each containing 3 mol dm^{-3} $LiClO_4$, were used as the salt-bridge solutions. Emfs measured in solutions of the same concentration of Ag^+ or H^+ ion (5—20 mmol dm^{-3}) are plotted with the same symbol.

alaninato)silver(I) complexes were determined in water and in the 0.2 mole fraction dioxane-water mixture. The net solubilities (Γ/mol dm^{-3}) of the complexes were evaluated by taking into account the distribution of species in each solution, the result being given in Table 4. The Gibbs energy of transfer of [AgL], $\Delta G_t^\circ([AgL])$, from water to the mixture was calculated:

$$\Delta G_t^\circ([AgL]) = -RT\ln\{\Gamma_{mix}([AgL])/\Gamma_w([AgL])\}, \quad (3)$$

which is related to the Gibbs energies of transfer of relevant ions, $\Delta G_t^\circ(Ag^+)$ and $\Delta G_t^\circ(L^-)$, and the Gibbs energies of formation of [AgL], ΔG_1°, in water and in the mixture given in Table 3:

$$\Delta G_1^\circ(\text{mix}) - \Delta G_1^\circ(\text{w}) = \Delta G_t^\circ([AgL]) - \Delta G_t^\circ(Ag^+) - \Delta G_t^\circ(L^-). \quad (4)$$

Since all the values except for $\Delta G_t^\circ(L^-)$ have been determined, the $\Delta G_t^\circ(L^-)$ values for glycinate and β-alaninate ions were determined.

Crystals of silver(I) glycinate and β-alaninate which were in equilibrium with the solution may involve some water molecules such as $Aggly\cdot(1/2)H_2O$.[10] In this case, the $\Delta G_t^\circ([AgL])$ value involves the contribution of the Gibbs energy of transfer of a half mole of water from water to the mixture. However, the $\Delta G_t^\circ(H_2O)$ value is about −0.4 kJ mol^{-1},[11] and thus, the contribution of water was neglected.

The enthalpies of solution of $AgClO_4$, β-alanine, sodium β-alaninate, and silver(I) glycinate and β-alaninate in water and in the 0.2 mole fraction

ΔH_s°(Naala)[c]	−19.4	−9.2	10.2

a) Concentration of [AgL] corrected by taking into account the distribution of species in each solution. b) Dissolved in solutions containing excess ligand ions to yield $[AgL_2]^-$, and the measured enthalpy of solution was corrected for the enthalpy for the reaction, $[AgL]+L^-=[AgL_2]^-$. c) Dissolved in solutions containing 0.01 mol dm^{-3} NaOH.

dioxane-water mixture are summarized in Table 4.

As to silver(I) glycinate and β-alaninate, the solubilities were too low in both solutions to directly measure the enthalpies of solution of the salts. Therefore, silver(I) glycinate (or silver(I) β-alaninate) was dissolved in a solution containing appropriate concentrations of glycine and lithium glycinate (or β-alanine and lithiun β-alaninate) in order to fully convert the species to $[AgL_2]^-$ in the solution. Thus, the measured enthalpy of solution is represented as the sum of the enthalpy of solution of [AgL], ΔH_s°([AgL]), and the enthalpy of reaction, $[AgL]+L^-=[AgL_2]^-$. Since the latter value is known, the ΔH_s°([AgL]) value was evaluated. Although the reliability of the ΔH_s°([AgL]) is low due to a low solublility of the complex in each solution, the value may account for the corresponding one calculated from the related thermodynamic quantities as will be discussed in a later section.

Since the $\Delta H_t^\circ(AgClO_4)$ and ΔH_t°(Naala) values are represented as the sum of the enthalpies of transfer of relevant ions, the $\Delta H_t^\circ(Ag^+)$ and $\Delta H_t^\circ(\beta\text{-ala}^-)$ values were obtained by subtracting the known $\Delta H_t^\circ(ClO_4^-)$ and $\Delta H_t^\circ(Na^+)$ values[9] from the $\Delta H_t^\circ(AgClO_4)$ and ΔH_t°(Naala) values, respectively.

β-Alanine exists as the zwitterion in the aqueous solutions, and thus the difference in the ΔH_s° values in these solutions corresponds to the enthalpy of transfer of the zwitterionic β-alanine.

The thermodynamic quantities of transfer of complex species were then evaluated in a following section.

Thermodynamic Quantities of Transfer of Complexes from Water to the 0.2 Mole Fraction Dioxane-Water Mixture. The Gibbs energies of protonation of β-alaninate ion in water, ΔG_{HL}°(w), and in the mixture, ΔG_{HL}°(mix), are related to the Gibbs energies of transfer of β-alanine zwitterion, ΔG_t°([HL]), proton, $\Delta G_t^\circ(H^+)$, and β-alaninate ion, $\Delta G_t^\circ(L^-)$, from water to the mixture as follows:

$$\Delta G_{HL}^\circ(\text{mix}) - \Delta G_{HL}^\circ(\text{w}) = \Delta G_t^\circ([HL]) - \Delta G_t^\circ(H^+) - \Delta G_t^\circ(L^-). \quad (5)$$

Since all the values except for ΔG_t°([HL]) have been determined, the ΔG_t°([HL]) value was evaluated. Then, the Gibbs energy of transfer of $[H_2L]^+$, $\Delta G_t^\circ([H_2L]^+)$, was successively obtained by using the corresponding relationship similar to that in Eq. 5.

Similarly, the stepwise Gibbs energies of formation of the bis(glycinato)- and bis(β-alaninato)silver(I) complexes in water, ΔG_2°(w), and in the mixture, ΔG_2°(mix), are related to the Gibbs energies of transfer of the related species in Eq. 6:

$$\Delta G_2^\circ(\text{mix}) - \Delta G_2^\circ(\text{w}) = \Delta G_t^\circ([AgL_2]^-) - \Delta G_t^\circ([AgL]) - \Delta G_t^\circ(L^-). \quad (6)$$

Since the ΔG_t°([AgL]) value has been determined by solubility measurements and the $\Delta G_t^\circ(L^-)$, ΔG_2°(w), and ΔG_2°(mix) values were also known as described in a preceding section, the $\Delta G_t^\circ([AgL_2]^-)$ (L^-=gly$^-$ and β-ala$^-$) values were evaluated.

A similar procedure was applicable for evaluation of the enthalpies of transfer of complex species. In the enthalpy relationship corresponding to Eq. 5, all the values except for $\Delta H_t^\circ(H^+)$ in the β-alanine system have been determined, thus, the $\Delta H_t^\circ(H^+)$ value was evaluated to be −22.5 kJ mol^{-1}, which is in good agreement with that (−22.7 kJ mol^{-1}) determined in the glycine system. Since the $\Delta H_t^\circ(H^+)$, ΔH_t°([HL]), $\Delta H_t^\circ(Ag^+)$, and $\Delta H_t^\circ(L^-)$ have been determined, the ΔH_t° values of $[H_2L]^+$ and $[AgL_n]^{(1-n)+}$ (n=1 and 2) were calculated. The results are summarized in Table 5, together with the corresponding entropies of transfer of species calculated from the ΔG_t° and ΔH_t° values.

Solvation Structure around Ionic Species in Dioxane-Water Mixtures. Thermodynamic quantities of transfer of ions from water to a dioxane-water mixture reflect the differences in both ion-solvent (solvation of ion) and solvent-solvent interactions in the solvents. In water, water molecules are hydrogen-bonded with each other in the bulk, and ions introduced from the gas phase to water first destroy the hydrogen-bonding water-water bonds and then are coordinated with the water molecules liberated from the structure of water

Table 5. Thermodynamic Quantities of Transfer, ΔG_t° / kJ mol^{-1}, ΔH_t° / kJ mol^{-1}, and ΔS_t° / J K^{-1} mol^{-1}, of Single Species from Water to the 0.2 Mole Fraction Dioxane-Water Mixture at 25 °C

Species	ΔG_t°	ΔH_t°	ΔS_t°
H^+	1.9	−22.7[a]	−83
gly^-	6.0	28.7[a]	76
β-ala^-	6.0	30.0	81
[Hgly][b]	6.3	1.2[a]	−17
$[H_2gly]^+$	4.1	−26.3[a]	−100
[Hala][b]	7.3	6.8	−2
$[H_2ala]^+$	3.5	−20.8	−82
Ag^+	3.1	−21.9	−84
[Aggly]	6.2	2.4	−13
$[Ag(gly)_2]^-$	10.1	28.6	62
[Agala]	6.6	1.8	−16
$[Ag(ala)_2]^-$	10.3	30.6	68

in the bulk. Similarly, ions introduced to a dioxane-water mixture may destroy both dioxane-water and water-water bonds. The bonding energies between solvent molecules in a dioxane-water mixture may be different from those in pure water, but the difference is not appreciable in the 0.2 mole fraction dioxane-water mixture because the ΔH_t° value of one mole of water molecules from water to the mixture is not significant (−0.6 kJ mol^{-1}) as compared with the corresponding ΔH_t° values of ions.[9,12] Consequently, it is postulated that thermodynamic quantities of transfer of ions from water to the dioxane-water mixture mainly reflect the change in the ion-solvent interaction in the solvents.

As seen in Table 5, compared to the ΔH_t° and ΔS_t° values of neutral species, the ΔH_t° and ΔS_t° values of cationic species, Ag^+, H^+ and $[H_2L]^+$, are significantly negative, while the ΔH_t° and ΔS_t° values of anionic species, L^- and $[AgL_2]^-$, are remarkably positive.

Negative ΔH_t° values of Ag^+, H^+, and $[H_2L]^+$ from water to the dioxane-water mixture imply that solvation energies of the ions are increased in the mixture compared to those in water. Corresponding negative ΔS_t° values of the cations suggest that solvent molecules solvating the cations are more ordered, i.e., the solvation structure is enhanced, in the dioxane-water mixture than in water. The reverse is the case for anions, L^- and $[AgL_2]^-$, which have positive ΔH_t° and ΔS_t° values. It is expected that solvation energies of the anions are decreased and solvent molecules solvating the anions are less ordered, i.e., the solvation structure is weakened, in the mixture than in water. The enhancement or weakening of solvation structure around ions may occur at the secondary or higher solvation shells because, since both donor and acceptor properties of dioxane are weaker than those of water, metal ions and ligands are expected to be preferentially solvated with water molecules in the primary solvation shell.[9]

The reason why solvation energies of cations are increased and those of anions are decreased by the addition of dioxane to water may be explained by a following consideration:

A water molecule has an oxygen atom as the electron donor (D_w) and two protons as the electron acceptor (A_w). They interact to form hydrogen-bonds in the bulk water and the equilibrium as the following equation may hold:

$$D_w + A_w = D_w\text{-}A_w, \quad (7)$$

where D_w-A_w denotes the formation of a hydrogen-bond between D_w and A_w of water molecules. It should be noted that free D_w or A_w means not only a free water molecule but also a terminal oxygen or hydrogen atom of water within a hydrogen-bonded network chain of water. The equilibrium in Eq. 7 is largely shifted toward the right hand side in pure water at room temperature.

A basic dioxane molecule may act as a donor (D_d) with a comparable donicity with water, because the donor number of dioxane (D_N=14.8) is not largely different from that of water (D_N=18.0).[13] On the other hand, the acceptor ability of dioxane (the acceptor number A_N=10.8) is much smaller than that of water (A_N=54.8).[13] Therefore, when dioxane is introduced in water, a dioxane molecule may interact with water molecules to form hydrogen-bonds through its etherial oxygen atoms as represented by D_d-A_w:

$$D_d + A_w = D_d - A_w \quad (8)$$

Thus, the formation of hydrogen-bonds between dioxane and water molecules will shift the equilibrium in Eq. 7 to result in an increase of the concentration of D_w, while the concentration of A_w decreases with decreasing mole fraction of water in the mixture.

In water-rich dioxane-water mixtures, metal ions and anionic ligands may be preferentially solvated with water molecules. Metal ions thus interact with oxygen donor atoms (D_w) and anionic ligands interact with protons (A_w) of water molecules, and thus, solvated metal ions and anionic ligands are in equilibrium with free D_w and A_w, respectively, of water. In the water-rich 0.2 mole fraction dioxane-water mixture compared to pure water, an increase of the concentration of D_w may therefore lead to an enhanced hydration structure around metal ions, while a decrease of the concentration of A_w may lead to a weakened hydration structure around anions.

In the case of glycine and β-alanine zwitterions in contrast to simple ions, the ΔH_t° value is smaller than the ΔG_t° value, so that the ΔS_t° value is negative. The same trend in the thermodynamic quantities of transfer has been observed for the [AgL] (L^-=gly^- and β-ala^-) complexes in Table 5. Therefore, we propose that [AgL] (L^-=gly^- and β-ala^-) complexes have simi-

lar zwitterionic structures, $^{+}AgNH_2CH_2COO^{-}$ and $^{+}AgNH_2CH_2CH_2COO^{-}$, to those of glycine ($^{+}H_3NCH_2COO^{-}$) and β-alanine ($^{+}H_3NCH_2CH_2COO^{-}$) zwitterions, respectively, both in water and in the dioxane–water mixture examined.

The present work has been financially supported by the Grant-in-Aid for special Project Research No. 60129031 from the Ministry of Education, Science and Calture.

Synthesis of Kaolinite-Lactam Intercalation Compounds

Yoshiyuki SUGAHARA, Shuichi KITANO, Shigeo SATOKAWA, Kazuyuki KURODA, and Chuzo KATO*
Department of Applied Chemistry, School of Science and Engineering, Waseda University,
Ohkubo, Shinjuku-ku, Tokyo 160
(Received February 21, 1986)

Intercalation compounds of kaolinite with 2-pyrrolidone and 2-piperidone have been prepared for the first time by displacing other intercalates. 2-Pyrrolidone expanded the lattice of kaolinite to 11.9 Å, while d_{001} of 12.7 Å was observed with the kaolinite-2-piperidone intercalation compound. Their IR spectra indicated the formation of a hydrogen bond between the C=O of the lactams and the OH of kaolinite. Nevertheless, their interactions were different between these two intercalation compounds. By a comparison of their behaviors, it has been concluded that the kaolinite-2-pyrrolidone intercalation compound is thermally more stable than the kaolinite-2-piperidone intercalation compound.

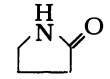
It is well-known that some clay minerals with a layer structure form intercalation compounds. Kaolinite can form intercalation compounds only with a limited number of polar molecules, whereas smectite reacts with a variety of molecules. Though some of them can react with kaolinite directly, others form intercalation compounds only in the presence of an "entraining agent" or by displacement of other intercalates.[1]

Intercalated polar molecules form hydrogen bonds with hydroxyl groups of kaolinite on the surface of the sheet. The hydroxyl groups of kaolinite show four sharp IR absorption bands at approximately 3690, 3670, 3650, and 3620 cm^{-1}. With the formation of a hydrogen bond, only the absorption bands at 3690, 3670, and 3650 cm^{-1} are perturbed, since these bands are ascribed to the vibration of the hydroxyls on the surface of the sheet and the 3620 cm^{-1} band is assigned to the inner-sheet hydroxyl.[1]

Amides are typical polar organic molecules, and some of them can be intercalated into the interlayer space of kaolinite. Many investigations were reported on the intercalation compounds with formamide (FA),[2-8] *N*-methylformamide (NMF),[4,5,8-10] *N*,*N*-dimethylformamide (DMF),[4,5,8] acetamide,[5,8,11] *N*-methylacetamide (NMA),[5,8,11] and *N*,*N*-dimethylacetamide (DMA).[5,8,11]

In their IR spectra, Ledoux and White[3] and Cruz et al.[4] observed the intensity decrease of the bands at 3690, 3670, and 3650 cm^{-1} for the hydroxyls in the intercalation compounds with FA, NMF, and DMF, while Oljenik et al.[6,11] reported that all of six amides perturbed a pair of hydroxyl bands; those at 3690 and 3670 cm^{-1} or those at 3690 and 3650 cm^{-1}. In other regions, the results showed a similar tendency; that is, an amide I band was observed at the same or a slightly higher wavenumber than liquid, and the NH stretching band was shifted to a higher wavenumber.

Lactams have NHCO group in their structures, so they can be regarded as "cyclic amides." Therefore, it is expected that an investigation of kaolinite-lactam intercalation compounds contributes to a series of studies on intercalation chemistry between kaolinite and organic molecules. In this study, 2-pyrrolidone and 2-piperidone were selected as lactams to synthesize the kaolinite-lactam intercalation compounds by a direct reaction or displacement method.



2-pyrrolidone

2-piperidone

Experimental

The kaolinite used was the API standard clay mineral No. 9 (Nesa Alta, New Mexico). The X-ray diffraction (XRD) pattern of kaolinite showed no obvious peaks due to impurities.

(1) **Direct Reaction.** A lactam was added to kaolinite at a ratio of 20 ml/1 g kaolinite. The suspension was then stirred for 72 h. The reaction was performed at two different temperatures to study the effect of the increase in the reaction temperature. One was just above the melting points of the lactams, that is, 30 °C for 2-pyrrolidone and 50 °C for 2-piperidone; the other temperature was 70 °C.

(2) **Displacement Method.** Intercalation compounds with FA, NMF, or dimethyl sulfoxide (DMSO) were used as starting materials. The lactam was added to a preformed complex with the same ratio as that in the direct reaction. The suspension was stirred for 10 min, and centrifuged. Then, the lactam was added again with the same ratio and the suspension was stirred between 0 and 96 h. The reaction temperatures were varied from 30 to 90 °C for 2-pyrrolidone and from 50 to 90 °C for 2-piperidone.

Products were analyzed by XRD (Shimadzu VD-11). The yield was calculated approximately from the proportion of the (001) peak heights of the intercalation compound, the preformed complex and the nonexpanded kaolinite.[1] The IR spectra of the products were also measured with a Shimadzu IR-435 (wavenumbers were calibrated using indene and polystyrene) using the KBr method (ca. 0.5%) after drying the products at 110 °C. Also, the IR spectra of the lactams were measured in CCl_4 (0.05 mol dm^{-3}).

Results and Discussion

In syntheses of the intercalation compounds with a direct reaction, no peaks due to intercalation compounds were observed in their XRD patterns. This indicated that lactams could not form intercalation

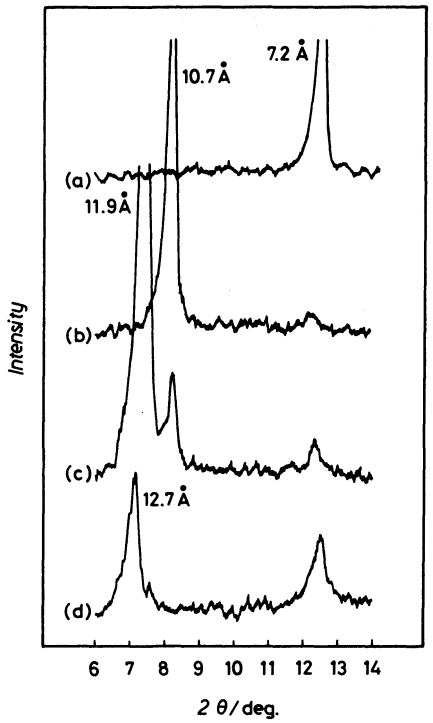


Fig. 1. X-ray diffraction patterns of (a) kaolinite, (b) kaolinite-NMF complex, (c) kaolinite-NMF complex treated with 2-pyrrolidone for 72 h, and (d) kaolinite-NMF complex treated with 2-piperidone for 72 h.

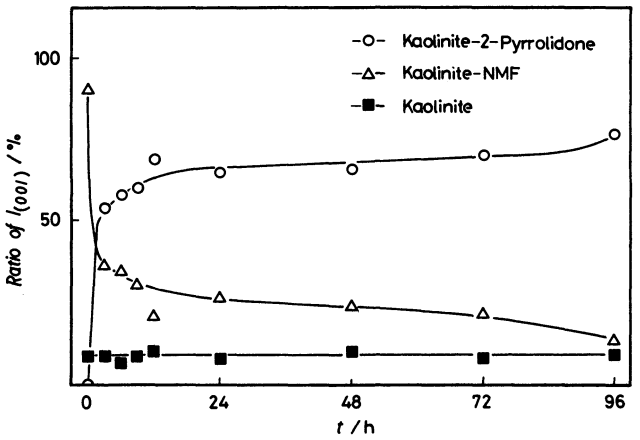

Fig. 2. The variation of the composition of the products with reaction time (t) at 30°C (kaolinite-NMF complex reacted with 2-pyrrolidone).

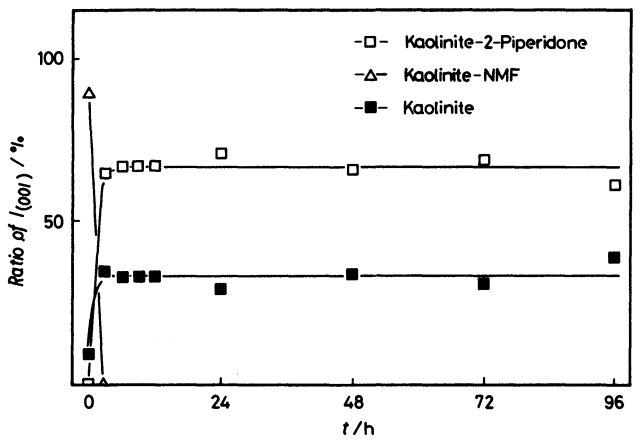

Fig. 3. The variation of the composition of the products with reaction time (t) at 50°C (kaolinite-NMF complex reacted with 2-piperidone).

compounds under these conditions. However, the possibility of intercalation with a direct reaction could not be excluded, since a relatively large molecule like DMF was intercalated directly after a long reaction period.[5]

On the other hand, intercalation compounds with 2-pyrrolidone and 2-piperidone were easily formed by a displacement reaction. The reaction temperatures were 30°C for 2-pyrrolidone and 50°C for 2-piperidone, and the reaction time was 72 h. Figure 1 shows the XRD patterns of products prepared from a kaolinite-NMF complex. In the case of 2-pyrrolidone, a new peak due to a (001) diffraction line appeared at d=11.9 Å, whereas 2-piperidone expanded the lattice of kaolinite to 12.7 Å.

It was hard to assume the orientation of lactams from their basal spacings since the conformations of their monomeric species could not be determined; 2-pyrrolidone can not be in a planner conformation, and 2-piperidone can show a few structures without strain.[12] Pyridine *N*-oxide had a six-membered ring in its structure and could be intercalated into a kaolinite lattice with a basal spacing of 12.5 Å.[5] Its orientation was assumed to be perpendicular to the plane of kaolinite. Therefore, the similar basal spacing of a kaolinite-2-piperidone intercalation compound (12.9 Å) might imply the possibility of a perpendicular orientation of lactams in the interlayer space of kaolinite. However, further work, such as neutron diffraction, is needed for a precise discussion.

Figures 2 and 3 reveal the variation of the approximate composition of the products with the reaction time. In a reaction with 2-pyrrolidone, the yield of the kaolinite-2-pyrrolidone intercalation compound was gradually augmented with an increase in the reaction time. A corresponding decrease in that of the kaolinite-NMF complex was observed during the reaction. The ratio of nonexpanded kaolinite was the same, indicating no collapse from both the preformed complex and the kaolinite-2-pyrrolidone intercalation compound to kaolinite during the reaction.

In the case of 2-piperidone, an increase in the reaction rate was observed; the X-ray diffraction line due to the kaolinite-NMF complex disappeared within 3 h and the yield of the kaolinite-2-piperidone intercalation compound did not change after 3 h. This increase of the reaction rate was ascribed to a high reaction temperature of 50°C. The ratio of the nonexpanded kaolinite increased at the beginning of the reaction.

Table 1. Effect of Reaction Temperature on the Yield of the Kaolinite-Lactam Intercalation Compounds[a)]

Lactam	Reaction Temperature			
	30°C	50°C	70°C	90°C
2-Pyrrolidone	70%	90%	93%	92%
2-Piperidone		69%	62%	30%

a) Reaction time was 72 h, and starting complex was kaolinite-NMF complex.

Since the composition was constant after 3 h, the kaolinite-2-piperidone intercalation compound was thermally stable at 50°C. Therefore, this indicates that the NMF complex partly collapsed to kaolinite during the reaction.

The effect of the reaction temperature is given in Table 1. The yield of the kaolinite-2-pyrrolidone intercalation compound increased when the reaction temperature was increased from 30 to 50°C. However, similar yields were obtained above 50°C. Since the yield of the kaolinite-NMF complex was about 90%, the kaolinite-NMF complex was completely converted to the kaolinite-2-pyrrolidone intercalation compound above 50°C during a reaction for 72 h.

In the case of 2-piperidone, yields of around 65% were obtained at 50 and 70°C. The yield was 30% at 90°C, while no differences were observed in the temperature range from 50 to 90°C with the kaolinite-2-pyrrolidone intercalation compound. A decrease in the yield at 90°C implied that the kaolinite-2-piperidone intercalation compound was thermally less stable than the kaolinite-2-pyrrolidone intercalation compound.

In addition, preparations from various preformed complexes were attempted. 2-pyrrolidone could form the intercalation compound from all of the starting complexes at 30°C. However, the formation of the kaolinite-2-piperidone intercalation compound was observed only from the FA and NMF complexes, in spite of a reaction temperature of 50°C; the DMSO complex was not converted to the intercalation compound and did not collapse to kaolinite. This fact suggested that the kaolinite-DMSO complex was much more stable than the kaolinite-2-piperidone intercalation compound at 50°C.

For measuring the IR spectra, the excess lactams adsorbed on the external surface of the particles must be removed. It is well known that intercalation compounds of kaolinite are generally unstable against washing. Therefore, the removal of the excess lactams by evaporation seemed to be suitable. Thus, the effect of the drying time on the yields of the kaolinite-lactam intercalation compounds at 110°C was initially investigated to clarify the thermal behavior of the compounds.

Figure 4 shows the results of drying the intercalation compounds at 110°C. The kaolinite-2-pyrrolidone intercalation compound used was prepared at 70°C, while the sample prepared at 50°C was used for the

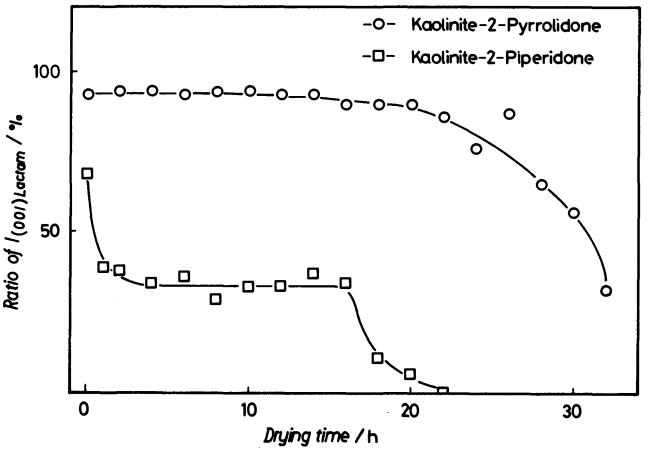

Fig. 4. The variation of the yield of the kaolinite-lactam intercalation compounds with drying time at 110°C.

kaolinite-2-piperidone intercalation compound. In the case of the kaolinite-2-pyrrolidone intercalation compound, the initial yield was retained. After 20 h, the yield of the compound began to decrease gradually.

On the other hand, the kaolinite-2-piperidone intercalation compound showed a different behavior; the yield decreased to about 30% within 1 h. Then, the compound showed the same yield for 15 h. After 18 h, the compound began to collapse again; the X-ray diffraction line of the compound disappeared after 22 h.

The difference in the initial period suggested that the kaolinite-2-piperidone intercalation compound contained at least two different kinds of arrangements of 2-piperidone in the interlayer space; 2-piperidone was present in different ways with the same d_{001} value. Also, weakly bonded 2-piperidone was unstable at a higher temperature and was deintercalated. This assumption was supported by the fact that the product prepared at 90°C showed the similar yield of 30%.

In both intercalation compounds, the products changed to a dried state during the periods, with a plateau as shown in Fig. 4. It seems that most of the lactams adsorbed on the external surface vaporize before those in interlayer spaces were deintercalated. Thus, the samples just after the plateau periods were used for IR measurements; the kaolinite-2-pyrrolidone intercalation compound was dried for 26 h (yield= 87%) and the kaolinite-2-piperidone intercalation compound was dried for 16 h (yield=34%).

Figure 5 shows the IR spectra of the products. In the case of the kaolinite-2-pyrrolidone intercalation compound (Fig. 5-c), amide I bands were observed at 1698 and 1666 cm^{-1}. The position of the 1666 cm^{-1} band was at a lower wavenumber than that of 2-pyrrolidone (Fig. 5-b). This indicated that a part of the C=O groups formed hydrogen bonds. Since the other band showed similar wavenumbers to that of 2-pyrrolidone monomer, this band was assigned to the C=O

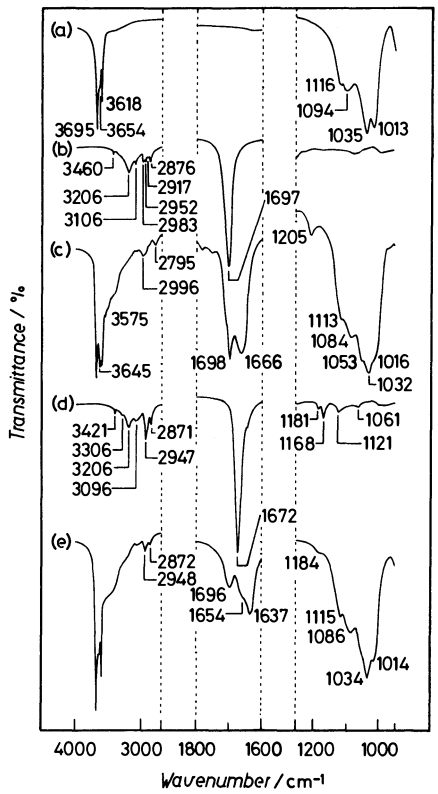

Fig. 5. IR spectra of (a) kaolinite, (b) 2-pyrrolidone (in CCl_4), (c) kaolinite-2-pyrrolidone intercalation compound dried for 26 h, (d) 2-piperidone (in CCl_4), and (e) kaolinite-2-piperidone intercalation compound dried for 16 h.

group having no hydrogen bonds with OH groups of kaolinite. In the OH region, new bands were observed at 3645 and 3575 cm^{-1}; these were ascribed to the shifted OH groups involved in the hydrogen bond. Also, a corresponding decrease of the original hydroxyl bands of kaolinite was observed; the 3695 cm^{-1} band was perturbed by 2-pyrrolidone (Fig. 5-a, c).

In terms of an Si–O stretching vibration, the spectrum (Fig. 5-c) showed a different profile from that of nonexpanded kaolinite; an intensity decrease of the 1013 cm^{-1} band and some additional shoulder bands (at 1084 and 1053 cm^{-1}) were observed. This suggested the presence of an interaction between 2-pyrrolidone and the SiO_2 surface of kaolinite.

For a measurement of the kaolinite–2-piperidone intercalation compound, a sample with a relatively lower yield (34%) was used. It should be noted that the weakly bonded 2-piperidone which was present before drying had already been deintercalated from the sample and the spectrum must have been different from that of a sample with the higher yield before drying.

The IR spectrum of a kaolinite–2-piperidone intercalation compound differed from that of a kaolinite–2-pyrrolidone intercalation compound (Fig. 5-e). The amide I band became more complicated; they split into three bands, two of which were shifted to lower frequencies than that of 2-piperidone in CCl_4 (Fig. 5-d). This implied the presence of different kinds of hydrogen bonds in the intercalation compound. In the OH region, no bands due to hydrogen-bonded OH were observed. Also, no original OH bands were clearly perturbed. This was ascribed to the low yield of the compound.

The Si–O stretching mode was slightly different from that of the kaolinite–2-pyrrolidone intercalation compound; a new band at about 1050 cm^{-1} was not clearly observed. This implied that the effect of intercalation of 2-piperidone on the Si–O stretching was similar to that of 2-pyrrolidone.

Though some similarities were observed in their IR spectra, the profiles of the bands due to C=O stretching, the yields of the compounds and their thermal stabilities were quite different between these two intercalation compounds. These facts suggest that structural differences in the lactams considerably influence the hydrogen bonds. Between two lactams, 2-pyrrolidone seems more preferable for forming an intercalation compound.

(Received March 15, 1986)

The adsorption behavior of phosphorus oxoacid, such as phosphinate, phosphonate, and phosphate, on hydrous titanium(IV) oxide in an aqueous solution was studied in detail. Hydrous titanium(IV) oxide has a pronounced activity for the adsorption of phosphonate and phosphate ions. However, phosphinate ion is little adsorbed on hydrous titanium(IV) oxide. The pH of aqueous solution remarkably affects the adsorption. Amounts of adsorbed phosphonate or phosphate ion from solutions of 500 mg l^{-1} concentration are about 0.5 mmol g^{-1} near pH 2. The Langmuir equation, applicable to the adsorption of phosphonate ion, has evaluated the maximum adsorption as being about 0.9 and 0.3 mmol g^{-1} at pHs 2 and 7, respectively. The heat of adsorption of phosphonate is −5.9 kJ mol^{-1} at pH 2. The adsorptive activity of hydrous titanium(IV) oxide for phosphonate is suppressed by coexisting ions, such as phosphate and anionic nickel(II) complexes.

In recent years, the industrial use of electroless plating has expanded rapidly. Literature data for conventional waste water treatment methods and their applicability to spent electroless nickel solution are reviewed.[1] However, most of these treatment methods are related to uptake of Ni(II). Phosphinates have been extensively used as reducing agents in the electroless plating of nickel and cobalt. During the normal plating bath operation, the concentration of phosphonate ion increases with the number of wafers plated. Nickel phosphonate has a low solubility and can precipitate under the typical bath operating conditions in solution, and the insoluble salt provides nucleation sites for spontaneous bath decomposition.[2] A commercial nickel plating bath contains nickel ion-complexing reagents, such as citrate, which serve to delay the onset of precipitation and bath decomposition. Removal of phosphonate ion from the plating solution is required for recycling use and waste water treatment on the solution.

Titanium(IV) oxide and its hydrate have been found to be excellent adsorbents for uranium in sea water[3] as well as for nickel and cobalt in aqueous citrate solution.[4] However, no studies dealing with the adsorption of phosphonate by hydrous titanium(IV) oxide have been reported.

In this paper, we report the activity of hydrous titanium(IV) oxide for the adsorption of phosphonate and other phosphorus oxoacid in aqueous solution.

Experimental

Preparation of Hydrous Titanium(IV) Oxide. Hydrous titanium(IV) oxide was prepared by the hydrolysis of titanium tetraisopropoxide at room temperature. The precipitate was filtered, washed several times with water, and dried in air at 60 °C for 20 h. The dried sample was crushed and sieved, a portion of 100 mesh pass being used in the experiment. The water content of the dried sample was determined by measuring the ignition loss at 800 °C and found to be about 18%, which corresponds to that of $TiO(OH)_2$.

The alumina and activated carbon used were commercial products of the Woelm Co. (N, Akt.I) and Takeda Yakuhin Kogyo K.K. (wH2c).

Table 1. Adsorption Activities of Adsorbents for Phosphorus Oxoacid

Adsorbate[b]	Degree of adsorption/mmol g^{-1} (%)[a]		
	Alumina	Hydrous titanium (IV) oxide	Activated carbon
Phosphinate ($H_2PO_2^-$)	0.01 (0.5)	0 (0)	0.01 (0.5)
Phosphonate ($H_2PO_3^-$)	0.55 (45)	0.79 (64)	0.26 (21)
Phosphate ($H_2PO_4^-$)	0.34 (33)	0.44 (43)	0.02 (1.6)

a) Adsorption temperature, 25 °C; time, 20 h; initial concentration of phosphorus oxoacid, 1000 mg l^{-1}. b) pH of solution: 6.60 ($H_2PO_2^-$), 2.21 ($H_2PO_3^-$), 5.00 ($H_2PO_4^-$).

Method of Adsorption. In the phosphorus oxoacid adsorption experiment, 1 g hydrous titanium(IV) oxide was put into 100 ml of a solution containing 50—1000 mg l^{-1} of phosphorus oxoacid, and then the mixture was continuously shaken for 8 h at 25 °C with a shaker. After adsorption equilibrium was attained, the solution was filtered and the phosphorus oxoacid concentration was measured. The pH of the solution was adjusted in the range 2—11 with HCl or NaOH solution.

Analysis. The analysis of phosphorus oxoacid and anions was carried out by ion-chromatography using a conductometric detector Shodex IC CD-2 (Showa Denko K.K.). Ni(II) was determined by the EDTA titration method.

Results and Discussion

Comparison of Adsorptive Activities of Adsorbents for Phosphorus Oxoacid. The results obtained for the adsorption of phosphorus oxoacid are listed in Table 1. Adsorptive activities of other adsorbents, such as alumina and activated carbon, were also examined, but their activities were considerably lower than that of hydrous titanium(IV) oxide.

As shown in Table 1, hydrous titanium(IV) oxide exhibits the highest activity for the adsorption of phosphonate and phosphate. Phosphinate is little adsorbed on the adsorbents.

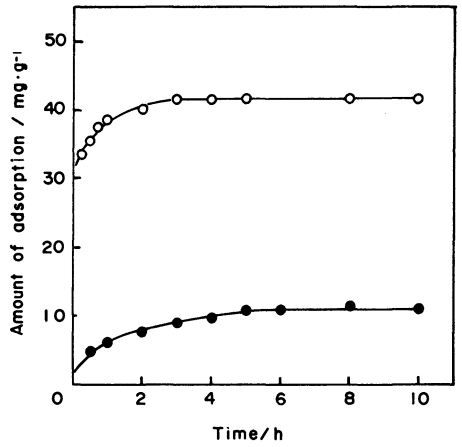

Fig. 1. Adsorbed amounts of phosphonate as a function of adsorption time.
Temperature, 25°C; phosphonate, 500 mg l^{-1}; Initial pH 2 (○), pH 8 (●).

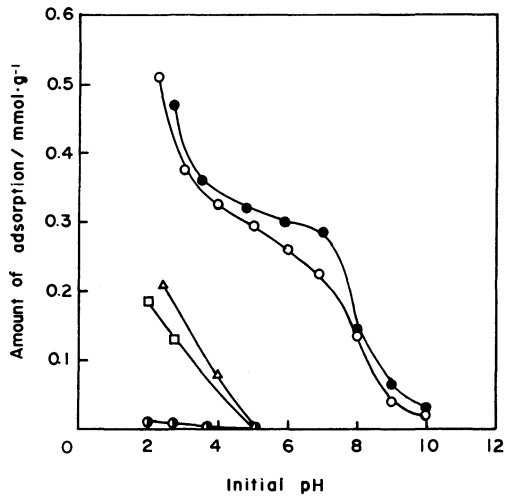

Fig. 2. Effect of pH on phosphorus oxoacid, Cl^- and SO_4^{2-} adsorption.
Adsorption time, 8 h; temperature, 25°C; phosphorus oxoacid, 500 mg l^{-1}; Cl^- and SO_4^{2-} 250 mg l^{-1}, ○: Phosphonate, ○: phosphinate, ●: phosphate, □: Cl^-, △: SO_4^{2-}.

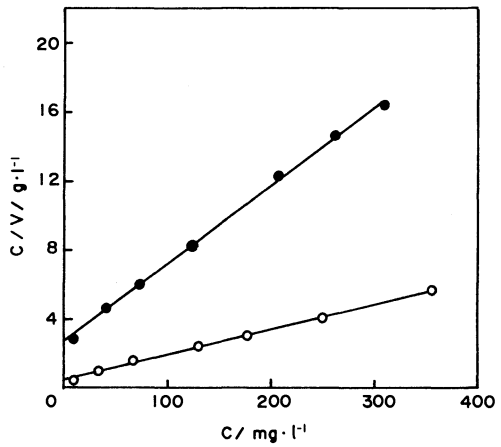

Fig. 4. Application of Langmuir equation to the adsorption shown in Fig. 3.
Initial pH 2 (○), pH 7 (●).
C is the concentration of phosphonate in solution.
V is the concentration of adsorbed phosphonate in the adsorbent at equilibrium.

Adsorption Equilibrium. The phosphonate adsorption as a function of adsorption time with hydrous titanium(IV) oxide at different pHs is shown in Fig. 1. Considerable change in the pH of solution occurs during the course of adsorption. The rate of phosphonate adsorption is faster at low pH than at high pH. Adsorption equilibrium is attained within 5 h at pH 8. The adsorption time of 8 h was chosen for subsequent experiments.

Effect of pH on Adsorption. The effect of pH on the phosphorus oxoacid adsorption by hydrous titanium(IV) oxide is shown in Fig. 2. Phosphinate is little adsorbed on hydrous titanium(IV) oxide. The adsorption of phosphonate and phosphate is much more efficient than that of Cl^- and SO_4^{2-} and remarkably dependent on the pH of solution; the amounts of adsorbed phosphonate and phosphate are both about 0.5 mmol/g-adsorbent near pH 2, decreasing with rise in pH. Hydrous titanium(IV) oxide possesses the property of amphoteric ion exchange.[5] The isoelectric point of hydrous titanium(IV) oxide, lies around pH 6[6] and it does not adsorb at higher pH than that; considerable amounts of phosphonate and phosphate are adsorbed even at the isoelectric point. The distribution of ionic species in aqueous solution was calculated for phosphonate and phosphate at various pH values.[7] With phosphonate, $H_2PO_3^-$ and HPO_3^{2-} are predominant species at pHs 5.5 and 8, respectively. With phosphate, $H_2PO_4^-$ and HPO_4^{2-} are predominant species at pHs 4.5 and 10, respectively.

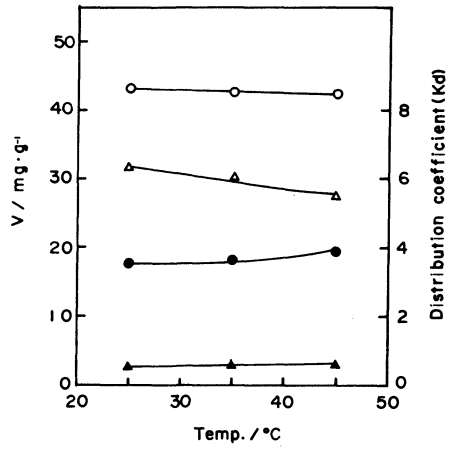

Fig. 5. Effect of temperature on phosphonate adsorption.
Adsorption time, 8h; phosphonate, 500 mg l^{-1}; Initial pH 2 (○, △), pH 7 (●, ▲).
Phosphonate adsorption (○, ●), K_d (△, ▲). V is the same as shown in Fig. 4.

The adsorption behavior of phosphonate is significantly close to that of phosphate.

Adsorption Isotherms. Figure 3 shows that adsorption of phosphonate in pHs 2 and 7. The main species of phosphonate are $H_2PO_3^-$ at pH 2 and HPO_3^{2-} at pH 7. As shown in Fig. 4, a linear relation holds between C (the concentration of phosphonate in solution) and C/V (V: the concentration of adsorbed phosphonate in the adsorption in equilibrium). This indicates that the Langmuir adsorption equation is applicable at both pHs 2 and 7. The monomolecular adsorption of phosphonate or maxmum adsorption, V_m, was calculated to be 0.88 (at pH 2) and 0.28 mmol g^{-1} (at pH 7) from the reciprocal of the slope $\Delta C/\Delta(C/V)$.

Effect of Temperature. The effect of temperature on the phosphonate adsorption by hydrous titanium(IV) oxide is shown in Fig. 5. The amount of phosphonate adsorbed is little changed with the adsorption temperature at pHs 2 and 7 in the solution. A linear relation was obtained between $1/T$ and the logarithm of the distribution coefficient (log K_d, $K_d=V/C$). The enthalpy of adsorption (ΔH_a) was calculated to be −5.9 (pH 2) and 6.8 kJ mol^{-1} (pH 7) by using the van't Hoff equation. The former value suggests that the phosphonate adsorption at pH 2 is due either to physical adsorption or ion exchange reaction. The latter value suggests that the adsorption at pH 7 does not relate to ion exchange reaction. The enthalpy change of ion exchange reaction is said to be −8.4—−12.6 kJ mol^{-1},[8] and physical adsorption is ordinaily exothermic. Anyhow, the interaction of phosphonate with hydrous titanium(IV) oxide surface is rather weak.

Effects of Coexisting Ions. Various ions such as chloride, sulfate, phosphinate, phosphate, borate, citrate, and nickel(II) citrate complexes coexist in an electroless plating solution.[9] In order to investigate

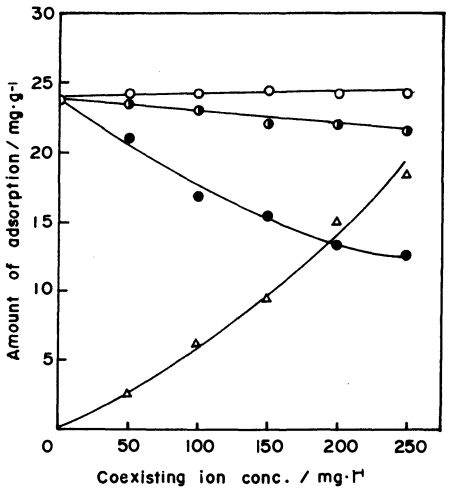

Fig. 6. Effects of coexisting ions on phosphonate adsorption.

the effect of coexisting ions, the phosphonate adsorption was measured for a solution containing 250 mg l^{-1} phosphonate ion and 0—250 mg l^{-1} coexisting foreign ions at pH 3. The results are shown in Fig. 6. The phosphonate adsorption is little affected by the coexisting ions except for phosphate. This fact suggests that phosphonate and phosphate are adsorbed on the same adsorption sites. Thus, it appears that the adsorption of phosphonate would proceeded in competition with phosphate. The phosphonate adsorption was measured with a solution containing 500 mg l^{-1} phosphonate and 0—10 mmol l^{-1} of nickel(II)

citrate (molar ratio of Ni/citrate=1) at pHs 2 and 7. The results are shown in Fig. 7. At pH 2, the phosphonate adsorption decreases slightly with increase in the nickel(II) citrate species in aqueous solution indicates that the predominant species at pH 2 is $[Ni(H_2citH)]^0$. At pH 7, both $[Ni(HcitH)]^-$ and $[Ni(citH)]^{2-}$ exist. It is found from Fig. 7 that the phosphonate adsorption decreases slightly with increase in amount of nickel(II) citrate is acidic solution, whereas it decreases remarkably in neutral solution. It may, therefore, be considerd that phosphonate and nickel(II) citrate compete for the same adsorption sites.

In conclusion, if hydrous titanium(IV) oxide is to be used for the removal of phosphonate in electroless plating solution, the process should be operated in acidic solution, and also, the oxidation of phosphinate to phosphonate or phosphate is necessary for removing residual phosphinate is spent electroless plating solution.

Magnetism, Electronic State, and Local Structure of Iron-Containing Organometallic Polymers

Tadashi SUGANO, Masaharu NOMURA,† Kunio AWAGA, POH Lee Kieng,††
Toshiaki OHTA,† and Minoru KINOSHITA*
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
†Photon Factory, National Laboratory for High Energy Physics, Ooho-machi, Tsukuba, Ibaraki 305
(Received March 10, 1986)

Schiff-base polymers were synthesized by the reaction of 2,6-pyridinedicarbaldehyde with 1,4-butane-, 1,6-hexane-, 1,8-octane-, and 1,12-dodecanediamine. Each of the polymers, when combined with iron(II) sulfate or iron(II) chloride, exhibited anomalously large magnetization and a nonlinear relation of the magnetization curve at room temperature. These iron-containing solids were found to be amorphous and, hence, the local structures around the iron atoms in the compounds were determined by the measurements of Fe K-edge X-ray absorption spectra. It was found that the iron atoms were each surrounded by six nitrogen atoms with the almost equivalent distance of 1.93±0.02Å. This was consistent with a possible geometry in which the tridentate ligand moieties of the polymers were coordinated with the iron atoms in a ratio 2 : 1. It was also found from the results of X-ray photoelectron and Mössbauer spectroscopies that the iron atoms in the solid obtained from the reaction between poly(2,6-pyridinediylmethylidynenitrilohexamethylenenitrilomethylidyne) and iron(II) sulfate were in two valence states consisted of the high spin (S=5/2) irons(III) which were responsible for the observed magnetism and the low-spin (S=0) irons(II) which gave no contribution to the magnetism.

It is of great interest to study the magnetism due to the transition-metal ions coordinated with organic ligands, because there are several organometallic compounds exhibiting ferromagnetic behavior: Bis(diethyldithiocarbamato)iron(III) chloride, T_C=4.5 K;[1,2] bis(diethyldithiocarbamato)iron(III) bromide, T_C= 1.52 K;[3] and manganese(II) phthalocyanine, T_C= 8.6 K,[4,5] where T_C is the Curie temperature. Since the magnetic interactions among metal ions are expected to be controlled by varying the structure of ligands, the length of the repeating unit of polymer chains and the kind of metal ions, there may be a possibility of finding ferromagnetic organometallic compounds with a higher T_C.

Previously, we have shown that, when the organic polymer poly(2,6-pyridinediylmethylidynenitrilohexamethylenenitrilomethylidyne) $(C_{13}H_{17}N_3)_n$ is combined with iron(II) sulfate, a solid (abbreviated as **6**-SO_4) of which the chemical composition is approximately $[Fe(C_{13}H_{17}N_3)_2]SO_4 \cdot 6H_2O$ is obtained.[6,7] This solid shows an anomalously large magnetization over the whole temperature range from 1.9 to 300 K and S-shaped magnetization curves below about 50 K.[7] In order to obtain a further insight into this magnetism, we have synthesized new compounds in which the structure of the ligand moiety and the length of the methylene chain of the polymer are varied systematically from **6**-SO_4. In addition, since all the iron-containing solids obtained have been found to be amorphous, we have measured X-ray absorption spectra in order to determine the local structure around the iron atoms in the solids. Furthermore, to reveal the valence and spin states of the iron ions in the solids, we have examined the X-ray photoelectron and ^{57}Fe Mössbauer spectra of **6**-SO_4 and found that the iron ions in this solid contribute only partially to the magnetism.

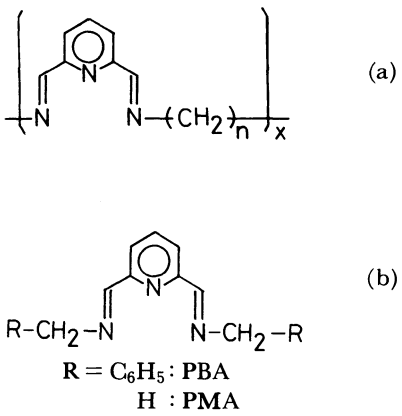

Fig. 1. Molecular structure of polymeric (a) and monomeric (b) ligands.

The present paper describes the applied field dependence of the magnetization of the iron-containing solids, the bond length and the coordination number around the iron atoms as well as their valences and spin states. The magnetic behavior of the solids will be discussed in relation to the structural and electronic properties derived from the results of X-ray absorption, X-ray photoelectron, and ^{57}Fe Mössbauer spectroscopies.

Experimental

The polymers shown in Fig. 1(a) were synthesized by the reaction of 2,6-pyridinedicarbaldehyde with 1,4-butane-, 1,6-hexane-, 1,8-octane-, and 1,12-dodecanediamine as described in the literature[6] and are abbreviated, respectively, as **4**, **6**, **8**, and **12**, according to the number of methylene groups, n. The obtained polymers were white powders and had a tendency to become fibrous upon increasing the length, n, of the methylene chain. When the polymers were treated with iron(II) sulfate or iron(II) chloride in an aqueous solution

††On leave of absence from Department of Physics, University of Agriculture Malaysia, Serdang, Salangor, Malaysia.

under a nitrogen stream, dark-violet solids were obtained. The solids were filtered off and dried over diphosphorus pentaoxide and sodium hydroxide in a vacuum desiccator. The solids are given abbreviated names: For instance, **4**-SO_4 and **8**-Cl_2 denote, respectively, solids prepared by combining polymer **4** with iron(II) sulfate and polymer **8** with iron(II) chloride. Typical results for elemental analyses are as follows; Found: C, 45.31; H, 6.57; N, 12.55; S, 5.49; Fe, 8.52%; Calcd for $[\{Fe(C_{13}H_{17}N_3)_2\}(SO_4)_{1.15}\cdot 5H_2O]_n$ (**6**-SO_4): C, 45.46; H, 6.46; N, 12.33; S, 5.37; Fe, 8.13%. Found: C, 50.40; H, 7.13; N, 11.92; Cl, 12.22; Fe, 7.81%; Calcd for $[\{Fe(C_{15}H_{21}N_3)_2Cl_{2.4}5H_2O]_n$(**8**-$Cl_2$): C, 50.21; H, 7.30; N, 11.71; Cl, 11.86; Fe, 7.78%. The water content varied to a small extent from sample to sample and the molar ratio of the sulfate or chloride ions was a little larger than the stoichiometry expected for bivalent iron ions. The latter modification of the chemical composition will be discussed below in relation to the valence state of the iron atoms.

As a reference compound for X-ray absorption measurements, two iron(II) complexes of the ligands shown in Fig. 1(b) were prepared and two ferrites γ-Fe_2O_3 (maghemite) and Fe_3O_4 (magnetite) were freshly prepared and identified by means of powder X-ray diffraction. The two complexes, [2,6-bis(benzyliminomethylene)pyridine]iron(II) bromide and [2,6-bis(methyliminomethylene)pyridine]iron(II) iodide, are abbreviated as PBA-$FeBr_2$ and PMA-FeI_2, respectively.

Fe K-edge X-ray absorption spectra were measured on powder samples sandwiched between adhesive tapes by using the EXAFS facilities installed at the beam-line 10B in Photon Factory. Extended X-ray absorption fine structure (EXAFS) oscillations were extracted by removing a cubic spline background with four sections. Bond distances and coordination numbers were determined by a single-shell curve-fitting analysis with the theoretically evaluated phase shifts.[8-10]

The infrared spectra were measured with a Perkin-Elmer PE684 infrared spectrometer. X-Ray photoelectron spectra were measured with a McPherson ESCA36 electron spectrometer by employing Mg$K\alpha$ (1253.6 eV) as the stimulating radiation. The X-ray photoelectron spectra were measured on a powder sample mounted onto an aluminum plate using a double-sided adhesive tape. The binding energies of photoelectron peaks were calibrated against that of the Au $4f_{7/2}$ peak (83.8 eV) of a thin gold film evaporated onto a sample surface in the spectrometer.

Mössbauer spectra were measured with a Shimazu MEG-2 Mössbauer spectrometer on powder samples at 77 and 300 K. Isomer shifts, quadrupole splittings and internal fields were calibrated against the six hyperfine splitting peaks of an iron metal separately measured as a reference.

The magnetization was measured with a Faraday-type susceptometer constructed in combination with a JEOL electromagnet and a Cahn 2000 electromicrobalance in the field range 0.1—0.4 T at room temperature.

Local Structure around the Iron Atoms

It is difficult to determine the molecular structure of these iron-containing solids by means of X-ray diffraction because they are found to be amorphous. Therefore, we have attempted to determine particularly the molecular structure around the iron atoms which are responsible for the magnetism, using X-ray absorption spectroscopy. Figure 2 shows the first derivative curves of the Fe K X-ray absorption near-edge structure (XANES) spectra of the solids, an iron foil, the two ferrites, and the monomeric iron(II) complexes. The spectra of the solids resemble those of monomeric complexes; this indicates that the local structures of iron-containing solids and the complexes are similar to each other. On the other hand, structures denoted by B or C split into two peaks in the spectra of the ferrites. Structure A, appearing in the pre-edge region, is attributed to quadrupolar-allowed 1s→3d transitions.[11] Its relative intensity is known to be weak for six-coordinated iron compounds, whereas it is strong for four-coordinated iron compounds.[12] The relative intensities of structure A of the iron-containing solids and complexes are similarly weaker than those of ferrites having four- and six-coordinated iron sites. Therefore, taking the chemical structure of the ligands into account, we could suggest that the iron atoms in the solids as well as those in the complexes are surrounded by six nitrogen atoms.

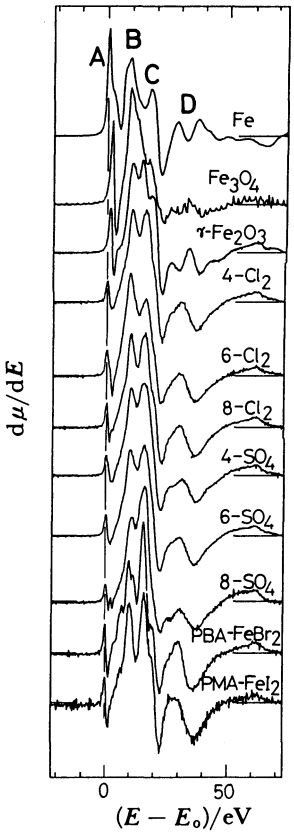

Fig. 2. First derivative $d\mu/dE$ curves of XANES spectra of an iron foil, ferrites the iron-containing solids, and the iron(II) complexes, where E is the photon energy and E_0 is the photon energy at the first maximum for the iron foil. The substances are given in abbreviated names (see the text).

Figure 3 shows a comparison among the EXAFS oscillations of iron, maghemite γ-Fe_2O_3, the iron-containing solids **6**-SO_4 and **6**-Cl_2, and the complex PBA-$FeBr_2$. It can be clearly seen that the EXAFS

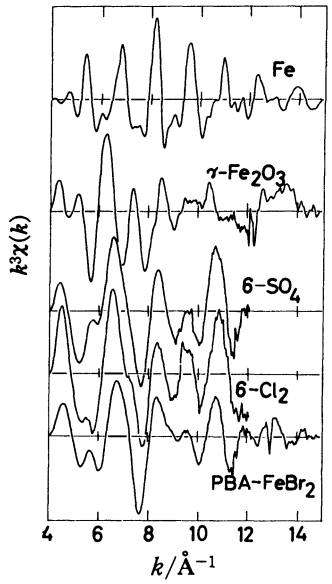

Fig. 3. EXAFS oscillations $k^3\chi(k)$ of the iron-containing solids and the iron(II) complexes.

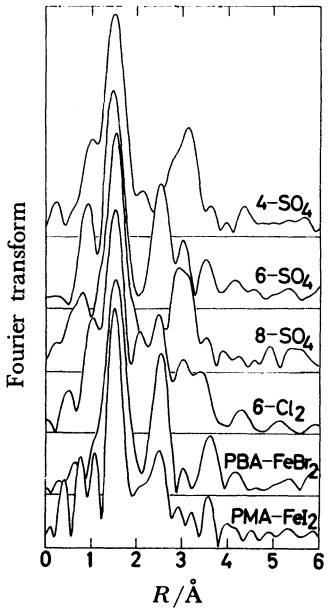

Fig. 4. Fourier transforms of EXAFS oscillations of the iron-containing solids and the iron(II) complexes.

oscillations of the solids are nearly identical to those of the complex, while they are very different from those of iron and maghemite. This behavior is quite similar to that observed in XANES spectra.

The Fourier transforms of the EXAFS oscillations, $k^3\chi(k)$ are shown in Fig. 4. The transforms for the iron-containing solids also resemble those for the complexes. The most prominent peak for the solids is located at about 1.5 Å (phase shift has not yet been corrected) and is coincident with the peak position for the complexes. This indicates that the peak corresponds to Fe–N bonds. From the chemical structure of the ligands, the peak at 2.5—3 Å could be due to Fe–C bonds.

We carried out a least-squares curve-fitting analysis by making a back-Fourier transformation of the region around the most prominent peak since it was difficult to construct reasonable structural models for second- and third-nearest neighbor atoms. The obtained bond distances are summarized in Table 1. The bond distances of the iron-containing solids are very similar to each other and are equal to those of the reference complexes within the experimental errors. Since the Fe–N bond distances in the six-nitrogen coordinated iron(II) complexes with ligands of similar molecular structure are known to be 1.9—2.0 Å,[13,14] the bond distance of 1.93±0.02 Å obtained for the iron-containing solids and the reference complexes are quite consistent with the Fe–N bond formation as expected from the molecular structure of the ligand moieties of the polymers.

The coordination number was shown to be about six for the reference complexes, although the estimated errors are somewhat large. This indicates that the present analysis which utilizes theoretical values of the phase shift instead of the experimental values is not

Table 1. The Fe–N bond Distance R and the Coordination Number N Derived from the Analysis of Fe K-edge EXAFS

Compound	R/Å (±0.02)	N (±1.0)
Monomer		
PBA-$FeBr_2$	1.93	5.9
PMA-FeI_2	1.90	5.8
Polymer		
4-SO_4	1.93	6.0
6-SO_4	1.94	5.3
8-SO_4	1.93	6.0
4-Cl_2	1.94	5.1
6-Cl_2	1.92	4.8
8-Cl_2	1.93	4.5

unreasonable for a determination of the coordination numbers for the compounds studied here. As shown in Table 1, the coordination numbers for the iron-containing SO_4-solids were found to be in the range from five to six. Although those for the Cl_2-solids are in the vicinity of five, these values seem to be underestimated to some extent in view of the similarity of the XANES and EXAFS spectra observed with all the solids and with the reference complexes. Therefore, it may be reasonable to conclude that the coordination numbers for these solids are six.

The above conclusion is further supported by the following fact. We have synthesized a polymer by reacting 1,6-hexanediamine with 1,3-benzenedicarbaldehyde instead of 2,6-pyridinedicarbaldehyde. This polymer is obtained as transparent soft lumps. We have tried to make a chelate compound of this polymer with iron(II) sulfate and chloride, but it turns out that the

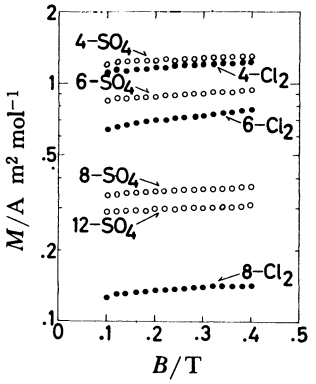

Fig. 5. Molar magnetization M of the iron-containing solids as a function of applied field strength B at room temperature.

polymer does not react with either sulfate or chloride. This implies that the tridentate structure of the ligand moiety is necessary for the polymer to form a chelate compound like **6**-SO_4; that is, the coordination number for the solids is six rather than four.

From the results mentioned above, it is concluded that the iron atoms in the solids are each surrounded by six nitrogen atoms with an almost equal distance of 1.93±0.02 Å, as observed for the iron(II) complexes in which one iron(II) ion is coordinated with two tridentate ligands. This conclusion is consistent with the 1:2 stoichiometry of Fe and the repeating units of the polymeric ligands determined by an elemental analysis. It is to be noted, at least from the results of X-ray absorption spectra, that there is no evidence for the presence of ferrite or metallic iron which would cause the ferromagnetism.

Effect of Chemical Modification of Polymers on the Magnetism

Since a magnetic interaction among the transition metal atoms is expected to be influenced by the chemical environment, particulary by the interatomic distances, we have examined the effect of chemical modifications of the length of the methylene chain and/or the anion on the magnetism of the iron-containing solids by comparing the magnetization curves at room temperature.

The length of the methylene chain does not qualitatively affect the magnetism. As shown in Fig. 5, all the iron-containing solids obtained by reacting polymers **4**, **6**, **8**, and **12** with iron(II) sulfate and iron(II) chloride exhibit magnetization curves similar to those of **6**-SO_4, i.e., a nonlinear relation to an applied field with a large magnetization, while the magnetization tends to decrease upon increasing the length, n, of the methylene chain. This indicates that only the tridentate structure is related to the large magnetization and its nonlinear relationship to the applied field.

The anions, sulfate and chloride, do not affect the magnetic behavior. Table 2 summarizes the molar magnetization of the iron-containing solids at 0.4 T. There seems to be a tendency to decrease the magnetization with a substitution of sulfate for a chloride ion. However, the magnitude of the magnetization still remains on the same order. The infrared spectra indicates that sulfate anions are only weakly or indirectly bound to the iron atoms. As shown in Fig. 6, the infrared spectrum of **6**-SO_4 exhibits the four bands attributable to sulfate ions at about 1100 cm^{-1} (ν_3) and at 610 cm^{-1} (ν_4) which are relatively strong in intensity and at 960 cm^{-1} (ν_1) and at 430 cm^{-1} (ν_2) which are very weak. Quite similar results have been obtained for all the solids containing sulfate ions. Since a free sulfate ion has a T_d symmetry, only a stretching mode (ν_3) and a bending mode (ν_4) are allowed for dipole transitions. This selection rule may be relaxed upon complex formation and the ν_1 and ν_2 modes appear with intensity, depending on the nature of the bonds formed. Simultaneously, each of bands due to ν_3 and ν_4 modes splits into two or three bands according to the occurrence of a symmetry lowering. The spectral feature observed is, therefore, characteristics of a sulfate ion that is very weakly bound to a metal ion.[15] On the other hand, a similar discussion may not be possible for monoatomic chloride anions.

Table 2. Molar Magnetization $M/A\,m^2\,mol^{-1}$ at 0.4 T and at 295 K of the Iron-Containing Solids Obtained by Reaction of the Polymers with $Fe^{II}SO_4$ or $Fe^{II}Cl_2$ (1 $A\,M^2\,mol^{-1} = 10^3$ Oe emu mol^{-1})

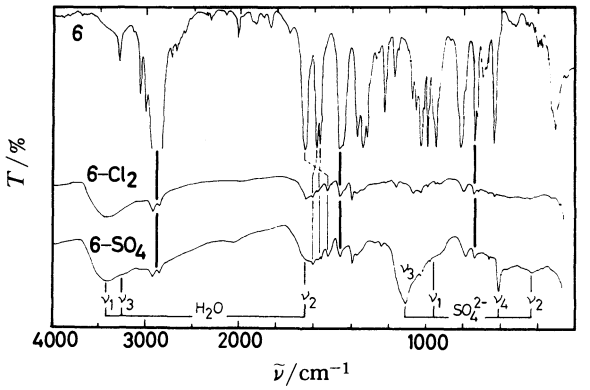

Fig. 6. Infrared spectra of **6**, **6**-SO_4, and **6**-Cl_2. The thick lines indicates the absorption bands assigned to the vibrational modes of the hexamethylene group of the polymer and the thin lines indicate those due to the tridentate moiety of the polymer. The vibrational modes of H_2O and those of SO_4^{2-} ion are also indicated. Similar results were obtained for the other polymers.

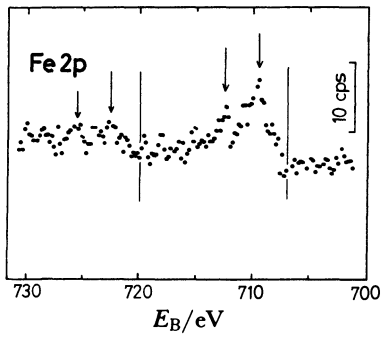

Fig. 7. Fe2p photoelectron spectrum of **6**-SO_4. Background is subtracted. The peak positions are indicated by arrows. Vertical lines represent the Fe2p peak position in metallic iron.

However, as shown in Fig. 6, a close similarity of the infrared spectra due to tridentate moieties would exclude a strong coordination of the chloride ion with the iron. Therefore, the sulfate and chloride anions in the iron-containing solids are almost isolated from iron ions and, consequently, they do not affect the magnetism.

Valence and Spin States of the Iron Atoms

Since it is important to know the valence state of the iron species in the iron-containing solids in order to discuss their magnetic behavior, we have measured the X-ray photoelectron spectra of **6** and **6**-SO_4. Figure 7 shows the X-ray photoelectron spectrum of **6**-SO_4 in the Fe2p region. The signal-to-noise ratio is not very good since the atomic fraction of the iron in **6**-SO_4 is only one-ninetieth. However, two peaks can be recognized in the $Fe2p_{3/2}$ region; also, there seem to be two peaks in the $Fe2p_{1/2}$ region. The binding energies are listed in Table 3. The binding energies of all the peaks observed shift to the higher-energy side from those of metallic iron (Fig. 7). This suggests that the iron atoms are ionized in **6**-SO_4.

The lower energy side peak in the $Fe2p_{3/2}$ region is attributed to iron(II) since its bindigng energy is close to that of tris(2,2′-bipyridine)iron(II) sulfate[16] where the iron(II) ion is associated with the six nitrogen atoms and the SO_4^{2-} ion is separated from the iron(II) ion in good agreement to that of **6**-SO_4. The binding energy of the higher energy side peak is located between the binding energies[16] of $(NH_4)_3[Fe^{III}F_6]$ and tris(8-quinolinolato)iron(III), which are six-coordinate iron(III) complexes. Therefore, this peak can be ascribed to iron(III).

It is known that the photoelectron peaks of magnetic transition-metal compounds often accompany strong satellites at positions with binding energies higher by 4 to 6 eV.[18] The energy difference between the two peaks attributed to iron(II) and iron(III) is only 3 eV. Therefore, the high energy peak can not be regarded as a satellite of the low-energy peak. In addition, the results of Mössbauer measurements described below also suggest the presence of iron(III). Thus, it is quite reasonable to attribute the high-energy peak to iron(III).

Table 3. Binding Energies of the Fe2p and N1s Core Electron Peaks in eV

Compound	$Fe2p_{1/2}$	$Fe2p_{3/2}$	N1s (fwhm)
6			399.3 (1.6)
6-SO_4	726	712.4	399.7 (2.3)
	723	709.5

$[Fe^{II}(bpy)_3]SO_4$[c]	721.6[a]	709.2[a]	
$[Fe^{III}(oxinat)_3]$[d]		711.5[a]	
$(NH_4)_3[Fe^{III}F_6]$		713.8[a]	

a) Ref. 16. b) Ref. 17. c) Tris(2,2′-bipyridine)iron(II) sulfate. d) Tris(8-quinolinolato)iron(III).

Therefore, the irons in **6**-SO_4 are in the valence states of iron(II) and iron(III). **6**-SO_4 has been prepared by reacting **6** with iron(II) sulfate under a nitrogen stream to prevent the oxidation of the bivalent iron. It should be noted that **6**-SO_4 can not be obtained by a reaction between **6** and iron(III) sulfate. Therefore, the partial oxidation seems to occur after the iron(II) has been included in the polymer chains.

The presence of two valence states explains the nonstoichiometry of the sulfate ion in **6**-SO_4 described in the experimental section. It follows from the ratio of observed intensities of the peaks that about 70% of the iron ions is in the bivalent state and about 30% is in the tervalent state. To keep charge neutrality of **6**-SO_4, the chemical composition of the relevant part is written as $(Fe^{II}SO_4)_{0.7}[Fe^{III}(SO_4)_{1.5}]_{0.3}=Fe(SO_4)_{1.15}$. This composition agrees well with that obtained by an elemental analysis.

The N1s photoelectron spectra (not shown) of **6** and **6**-SO_4 exhibit a single peak without satellite. The binding energy shifts to the higher energy in **6**-SO_4. This energy shift implies that the formal charges on the nitrogen atoms become more positive in **6**-SO_4 than in **6**. This is consistent with the coordination of the iron with nitrogen. In addition, the full-width at half-maximum (fwhm) of the N1s peak is 1.6 eV for **6** and 2.3 eV for **6**-SO_4. The line broadening observed in the latter compounds would be related to the difference in the chemical nature of the nitrogen atoms which are coordinated with the iron.

The results discussed above clearly indicate that the irons in **6**-SO_4 are in the two valence states consisting of iron(II) and iron(III). Since no evidence has been found for the presence of a magnetic moment on the organic species in **6**-SO_4, it is natural to consider that the magnetic moment in **6**-SO_4 is associated with the iron ions.

Figure 8 shows the ^{57}Fe Mössbauer spectrum of **6**-SO_4 at 77 K. It is found from a Lorentzian least-squares curve fitting analysis that the experimental

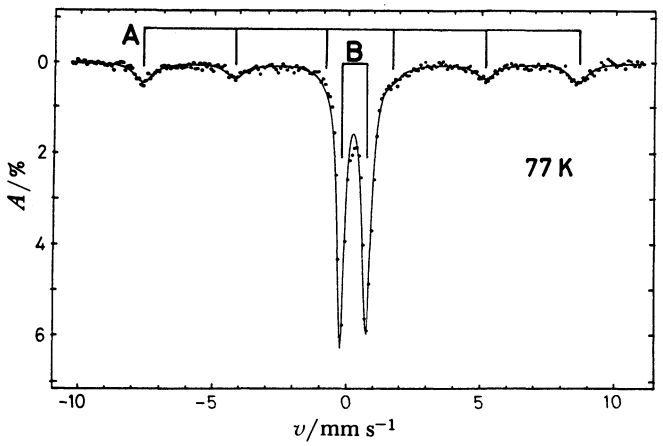

Fig. 8. Mössbauer spectrum of **6**-SO_4 at 77 K. Experimental points are shown by closed circles and the results of a Lorentzian least-squares fit is indicated by the solid line. The spectrum is composed of two subspectra denoted A and B. Stick diagrams indicate the peak positions of each subspectrum obtained by the analysis.

spectrum can well be reproduced by superimposing the subspectrum A which consists of six peaks of hyperfine splitting due to an internal field and the subspectrum B which consists of two peaks of quadrupole splitting. The absorption intensity of the Mössbauer spectra is markedly reduced at 300 K, probably due to a reduction of the recoil-free fraction. However, subspectra A and B still remain. The obtained parameters of the isomer shift δ, quadrupole splitting ΔE_q, and internal field H_i at 77 and 300 K are summarized in Table 4.

The subspectrum B can be attributed to the low-spin iron(II). The high-spin state (S=2) and the low-spin state (S=0) are possible for six-coordinate iron(II). The former possibility could be excluded on the basis of the values of the isomer shift. The isomer shift is known to be larger than 0.7 mm s^{-1} for a high-spin iron(II). Therefore, the iron(II) ions present in **6**-SO_4 have been concluded to be in a low-spin state. The iron(II) ions have no unpaired electrons in the low-spin state and, hence, does not cause an internal field. Therefore, subspectrum B should correspond to the low-spin iron(II). The quadrupole splitting of 0.96 mm s^{-1} obtained for the subspectrum B indicates the presence of an electric-field gradient induced by distortion from the octahedral symmetry, as is usually observed in low-spin iron(II) complexes with nitrogen donor ligands.[19]

On the other hand, the subspectrum A would be attributed to the high-spin state of iron(III). The presence of a hyperfine splitting in this subspectrum clearly indicates that the iron ion species have unpaired electrons. As discussed above, the possibility of high-spin iron(II) has already been eliminated. The remaining possibilities are, therefore, high-spin (S= 5/2) and low-spin (S=1/2) iron(III). These are not distinguishable from a difference in the isomer shift since the isomer shift is known to be comparable for

Table 4. Isomer Shift δ (relative to iron-metal film), Electric-Quadrupole Splittings ΔE_q, and Internal Field H_i Obtained from the Analysis of the Mössbauer Spectrum of **6**-SO_4 by the Lorentzian Least-Squares Curve Fitting

	77 K	300 K
Subspectrum A (Fe^{3+})		
δ/mm s^{-1}	0.46	0.46
ΔE_q/mm s^{-1}	−0.016	0
H_i/T	50.5±0.5	46±2
Subspectrum B (Fe^{2+})		
δ/mm s^{-1}	0.27	0.27
ΔE_q/mm s^{-1}	0.96	0.96

both states.[18] However, the internal field of 50.5±0.5 T is comparable with that of Fe_3O_4[20] and γ-Fe_2O_3[21] where iron(III) ions are in the high-spin state. In addition, this value is in good agreement with the internal field of 55 T expected for the $|M_S|$=5/2 state from the empirical relation for iron(III) ions in corundum, H_i=22$\langle S_z \rangle$.[22] Therefore, the assignment of the subspectrum A to the high-spin iron(III) is quite reasonable.

The fact that the quadrupole splitting observed for the subspectrum A is very close to zero also supports the above assignment. In the high spin-iron(III), the five d-electrons are separately distributed over the five d-orbitals so that the electron cloud becomes almost symmetric and the electric field gradient vanishes. It is known that the electron transfer between an iron atom and ligands is negligible in a high-spin iron compound[19] and that the electric field gradient is not affected very much by ligands.

The internal field is reduced to 46±2 T at 300 K, while the quadrupole splittings and the isomer shifts do not change. The reduction of internal field is quite natural, because the saturation magnetization decreases with increasing temperature.[7] A considerably large internal field, even at 300 K, indicates that the magnetic ordering would be maintained, even to a temperature higher than room temperature.

Concluding Remarks

From the discussion on the results of the X-ray photoelectron and Mössbauer spectroscopies, it is suggested that the iron atoms in **6**-SO_4 are in two valence states, consisting of the high-spin iron(III) which is responsible for the magnetism and the low-spin iron(II) which has no contribution to the magnetism. That is, only a fraction of the iron ions contributes to the observed magnetism in the iron-containing solids.

The large magnetization and its nonlinear relationship to an applied field was not only observed for **6**-SO_4 but also for the other iron-containing solids examined here. It was found that the length of the methylene chain of the polymer as well as the anions accompanying the iron ions hardly affect the

magnetism. Only the presence of the tridentate ligand moiety causes the formation of the iron-containing solids and, hence, the magnetism. This implies that the magnetic behavior observed for the iron-containing solids is not very much affected by the distance between the iron atoms coordinated with the tridentate moieties of the polymers, while the change in the length of the methylene chain may cause a variation of the distance.

This is somewhat peculiar for the large magnetization since magnetic interaction among the transition-metal ions may be influenced by their interatomic distances. X-Ray absorption measurements suggest that each of the iron ions in the solid is coordinated with two tridentate moieties of the polymers, as is expected for the stoichiometry determined by the elemental analyses. However, there remains a possibility of the presence of a small amount of iron ions which have different coordination characteristics and have escaped from observation because of limitations in the sensitivity of X-ray absorption spectroscopy for minor substances, including the same element.

The authors are greatful to Professor Takeshi Tominaga, Dr. Haruo Sato, and Dr. Motoyuki Matsuo for the measurements of the Mössbauer spectra. The authors also thank Professor Haruo Kuroda and Professor Isao Ikemoto for the use of the X-ray photoelectron spectrometer, and Professor Koichi Ohno for his valuable suggestions regarding this work.

Determination of the Solvation Number of Sodium Anion in Hexamethylphosphoric Triamide

Tetsuo SAJI,* Katsunori AOKI, Kosaku SUGA, Masamichi FUJIHIRA,* and Shigeru AOYAGUI
Department of Chemical Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received October 25, 1985)

Synopsis. Electronic absorption spectra for saturated solutions of Na in HMPA–THF mixtures with HMPA mole fractions 0.39—0.061 exhibit only a band for Na^-. A log–log plot of maximum absorbance vs. HMPA concentration has led to a numerical value 3 for the number of HMPA molecules solvating a Na^- ion.

Of stable solvated-electron species existing in solutions of alkali metals in certain amines, amides, or ethers, (free) solvated electron (e_s^-) and metal anion (M^-) have been identified by electronic spectroscopy[1] and investigated on their physicochemical properties. The solvation number of e_s^- has been determined with an interest in the nature of this specific chemical species.[2] No paper has, however, dealt with the solvation number of electron-excess species, M^-. This paper presents an indirect determination of the solvation number of Na^- in hexamethylphosphoric triamide (HMPA) from the known solvation number of Na^+ with the aid of electronic and NMR spectroscopies.

Experimental

HMPA and tetrahydrofuran (THF) were purified by the usual method in which sodium anthracenide was used to remove trace impurities.[3] Commercial sodium tetraphenylborate (NaTPB) was dried in vacuo at 60 °C for 24 h and used as a ^{23}Na source in NMR measurements. The other chemicals were commercially obtained and used without further purification. Mixing HMPA with THF at various HMPA mole fractions (x) and addition of sodium metal to pure HMPA or mixed solvents were carried out under nitrogen atmosphere. The electronic absorption spectrum of a supernatant solution was recorded after stirring the solution with excess sodium metal overnight. After additional one hour stirring of this solution, the absorbance at λ_{max} decreased slowly after stirring was stopped. However, when this absorbance for the solution was reproduced after the additional stirring of the solution, this solution was considered as a saturated solution of sodium. Mixed solvents are denoted by HMPA(x)–THF.

Electronic absorption spectra in the visible and near-IR regions were recorded at 25 °C on a Hitachi 220 and a Shimadzu MPS-50L double-beam spectrophotometers, respectively, by using a cell of 1 *mm* path length and a reference solution of THF. ^{23}Na NMR spectra were recorded at 23 °C on a Bruker CXP-300 spectrometer operating at 83.08 MHz. The chemical shifts reported are relative to external 0.1 M (1M=1 mol dm^{-3}) NaCl in D_2O, with positive sign representing a downfield shift. No signal locks were used because of broad line width.

Results and Discussion

Solvation of Na^- in HMPA–THF. The two bands at 750 and 2250 nm in the absorption spectrum of a solution of Na in HMPA have been assigned to Na^- and e_s^-, respectively.[4] Each of the spectra for the saturated solutions of Na in HMPA(0.039)–THF and HMPA(0.061)–THF exhibits only a band at 750 nm, which indicates that of the two electron-excess species only Na^- should be considered in saturated solutions of Na in HMPA(x)–THF with $0.039<x<0.061$. In view of the facts that the peak wavelengths λ_{max} for Na^- in pure HMPA and these HMPA–THF mixtures agree with one another and not with that in pure THF in the presence of cryptand (680 nm),[5] it may be safe to conclude that Na^- is solvated exclusively by HMPA molecules in solutions with $0.039<x<1$.

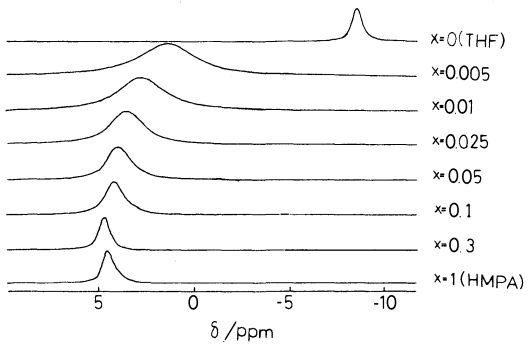

Fig. 1. ^{23}Na NMR spectra of 0.01 M sodium tetraphenylborate in HMPA–THF mixtures with varying HMPA mole fractions (x). Chemical shifts (δ) are referred to an external standard of 0.1 M NaCl in D_2O. Temperature: 23 °C.

Solvation of Na^+ in HMPA–THF. Figure 1 shows ^{23}Na NMR spectra for 0.01 M NaTPB in HMPA–THF of varying HMPA contents. An Addition of even a small amount of HMPA to THF, e.g., to x=0.005, is enough to cause a drastic change in ^{23}Na chemical shift δ, while this is not the case with the addition of THF to HMPA. These features may indicate that HMPA molecules solvate Na^+ much more strongly than THF molecules. The change in ^{23}Na chemical shift caused by a change in x may be attributed to the replacement of the THF molecules solvating Na^+ by HMPA molecules, since the observed chemical shift δ is related to the intrinsic shifts of each species i by[10]

$$\delta = \sum x_i \delta_i,$$

where x_i is the molar fraction of species i. The following discussion is based on the approximation that Na^+ is solvated selectively by HMPA molecules in HMPA(x)–THF mixtures with $0.039<x<1$.

The Sovation Number of Na^+ and Na^-. In view of the bulk dielectric constants of THF (7.4) and HMPA (30), bulk dielectric constants of HMPA(x)–THF mixtures ($0.039<x<0.061$) are expected to be 8.5—9.7 based on the volume average. A calculation with the Fuoss equation[6] for ion pair formation for a closest approach distance of about 12 Å (center to center

distance) has led to an ion pair formation constant of 2×10^2 M^{-1} at concentration 2.5×10^{-4} M for both Na^+ and Na^-, where the closest approach distance was estimated by assuming that both Na^+ and Na^- are solvated only by HMPA. The degree of ion pairing is expected to be less than 0.07, so small that ion pairing may be negligible. The following equilibrium is established in an HMPA–THF mixture saturated by Na:

$$2Na(solid) + nL \overset{K}{\rightleftharpoons} Na^+L_k + Na^-L_{n-k}, \quad (1)$$

where K is the equilibrium constant, k the solvation number of Na^+, and L stands for HMPA. The equilibrium constant is written as

$$K = [Na^+][Na^-]/[L]^n = c^2/[L]^n, \quad (2)$$

where brackets mean the concentration in molarity and $c=[Na^+]=[Na^-]$. The absorbance at λ_{max} for Na^-, A, can then be expressed by the following equation in terms of the molar absorptivity ε, the optical path length l, n, $[L]$, and K:

$$\ln A = (n/2)\ln[L] + \ln(\varepsilon l K^{1/2}). \quad (3)$$

When the total HMPA concentration $[HMPA]_0$ is much higher than c, the plot of ln A vs. $\ln[HMPA]_0$ should give a straight line whose slope and intercept on the ln A axis are $n/2$ and $\ln(\varepsilon l K^{1/2})$, respectively.[7]

Figure 2 shows that the experimental points within the concentration range of $[HMPA]_0=0.46$—0.71 M or $x=0.039$—0.061 are well fit to the following straight line obtained by the least-squares method:

$$\ln A = [(5.8\pm0.3)/2]\ln[HMPA]_0 + 2.0. \quad (4)$$

The slope of this straight line gives a round number of 6 as n, i.e., the sum of the solvation numbers for Na^+ and Na^-. This n value combined with the literature k value[8–10] of 3 leads to a numerical value of 3 for the number of HMPA molecules solvated to a Na^- ion in HMPA–THF mixtures with HMPA mole fractions ranging from 0.039 to 0.061. It is very likely that this solvation number is also valid for Na^- in pure HMPA, since the λ_{max} value for Na^- and solvation number of HMPA to a Na^+ in the HMPA–THF mixtures of the above composition are, respectively, equal and nearly equal to those in pure HMPA.

We are grateful to Mr. Yoshiharu Toida, Bruker Japan Co. for furnishing NMR spectra and to Professor Makoto Okamoto of our Institute and his group for optical providing spectra. Facilities for preliminary NMR experiments were offered by Professor Hiroshi Fukutomi of our Institute and his group.

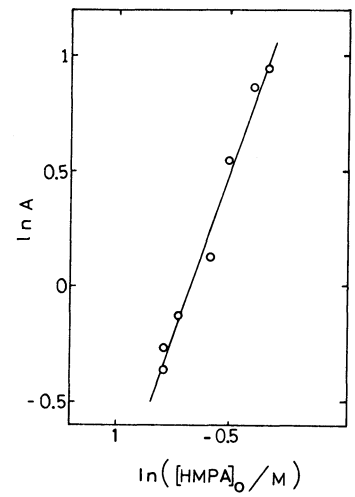

Fig. 2. A plot of the logarithmus of the absorbance at λ_{max} for Na^- (A) against the logarithmus of the total concentration of HMPA in HMPA–THF ($[HMPA]_0$). Temperature: 25 °C.

10) The change in δ in Fig. 1 gives an average value ca. 10^2 for the equilibrium constants of the successive formation of solvated Na^+ ions with $k=1$, 2, and 3, if one makes a similar assumption as was made in the paper dealing with the ^{23}Na chemical shift in H_2O_2–H_2O mixtures: A. K. Convington, T. H. Lilley, K. E. Newman, and G. A. Porthouse, *J. Chem. Soc. Faraday Trans. 1*, **69**, 963 (1973). If viscosity data of the HMPA–THF mixtures are available, the change in line width may give the T_2 values for the intermediate species with $k=1$ and 2, in a similar way as in C. Detellier, A Gerstmans, and P. Laszlo, *Inorg. Nucl. Chem. Lett.*, **15**, 93 (1979).

Nonsteroidal Antiinflammatory Drugs. V. The Crystal and Molecular Structure of (±)-(2S*)-2-[4-((1S*,2R*)-2-hydroxycyclopentylmethyl)-phenyl]propionic Acid

Tadashi HATA,* Sadao SATO, and Chihiro TAMURA
Analytical and Metabolic Research Laboratories, Sankyo Co. Ltd., 1-2-58 Hiromachi, Shinagawa-ku, Tokyo 140
(Received March 25, 1986)

Synopsis. The crystal structure of the title compound was determined by X-ray diffraction techniques and was refined to a final R index of 0.094 for 1249 reflections. The cyclopentane ring takes a half-chair conformation in which the two substituents are attached at equatorial positions. The molecules form centrosymmetric tetramers by the two hydrogen bonds through the carboxyl and hydroxyl groups.

A new antiinflammatory agent, sodium (±)-2-[4-(2-oxocyclopentylmethyl)phenyl]propionate (loxoprofen sodium) (**1**), may exhibit the inhibitory activity for prostaglandin synthesis after the conversion to an active metabolite of (+)-(2S)-2-[4-((1R,2S)-2-hydroxycyclopentylmethyl)phenyl]propionic acid.[1] Since the molecule of this metabolite has three asymmetric carbons, the eight optical isomers can be theoretically considered, wherein the above metabolite is found to be the most active. Since the structure of (±)-(2S*)-2-[4-((1R*,2R*)-2-hydroxycyclopentylmethyl)phenyl]propionic acid (cis-OH isomer) has been determined,[2] the structure determination of the title compound **2**, racemic trans-OH isomer, has been performed for comparison with the isomers and related compounds.

Experimental

Colorless prisms were grown by slow evaporation of a solution of the substance in a mixture of ether and hexane at room temperature. The lattice parameters and intensity data were collected from a 0.1×0.1×0.6 mm crystal on a Rigaku AFC-5 diffractometer with monochromated Cu$K\alpha$ radiation. Twenty reflections with $32° < 2\theta < 49°$ were used to determine the cell parameters. Space group was assigned from systematic absences. The crystal data were as follows; $C_{15}H_{20}O_3$, M=248.3, monoclinic, $P2_1/n$, a=20.275(1), b=5.479(1), c=12.005(1)Å, β=94.43(1)°, V=1329.6(3)Å^3, Z=4, D_c=1.24 gcm^{-3}, μ(Cu$K\alpha$) 6.9cm^{-1}. An ω—2θ scanning mode was employed up to 2θ=130° and 2270 reflections were measured. For the structure solution and refinement 1249 unique measurements with $F > 3\sigma(F)$ were used. No significant variation in the intensities of the three standard reflections was found. The intensities were corrected for the Lorentz and polarization factors, but not for absorptoion. The structure was solved by the direct method using MULTAN78,[3] and refined by the full-matrix least-squares method with anisotropic thermal parameters. H atom positions, except for two H atoms at C(16), were determined from a difference Fourier synthesis and refined with isotropic thermal parameters. The two remaining H atoms were placed geometrically and included in the refinements with fixed contributions to Fc. The final refinement converged at R=0.094 and R_w=0.037. The weighing sheme in the final stage was $w = 1/\sigma^2(F)$. Atomic scattering factors were taken from Ref. 4. The final fractional atomic coordinates and equivalent isotropic thermal parameters are given in Table 1.[5]

Results and Discussion

The atom labelling and the anisotropic thermal ellipsoids are shown in Fig. 1. Bond lengths and angles are given in Table 2. The C(1)–C(2) bond length of 1.354(8)Å is shorter than the normal bond length of the benzene ring due to some structural requirement and the others are all normal within the limits of experimental error.

The torsional angles of C(2)–C(1)–C(7)–C(9) and C(1)–C(7)–C(9)–O(10) of the propionic acid side chain are 122.0(6) and 126.5(7)°, respectively. These values are larger than those of 96.4 and 89.3° in ibuprofen,[6] 107.7 and 77.3° in flurbiprofen,[7] 111.7 and 90.2° in naproxen,[8] and 114.7 and 94.9° in one of the two independent molecules in the cis-OH isomer.[2] Another molecule in the cis-OH isomer has angles of 162.6

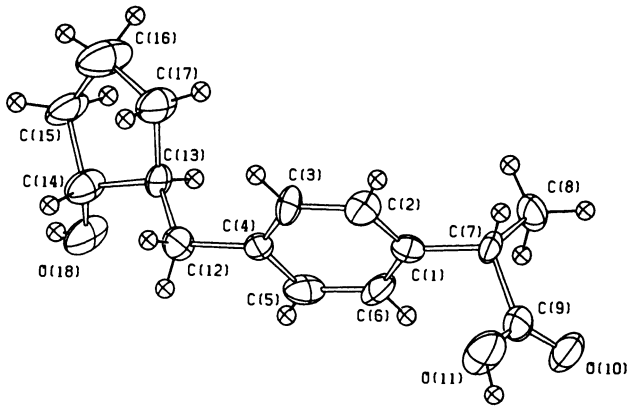

Fig. 1. ORTEP plot of the title compound with thermal ellipsoids at the 50% probability level.

and 96.2°. The former angle is larger than that in the title compound and the latter is smaller.

The cyclopentane ring adopts half-chair conformations with the two equatorial hydroxyl and methylphenyl groups, in which the C(13) and C(14) atoms are displaced by −0.27(1) and 0.31(1)Å from the plane through C(15)–C(16)–C(17). The two independent molecules of the cis-OH isomer also take half-chair forms, however, both hydroxyl groups in these molecules are attached at axial positions. The rotational angle of C(3)–C(4)–C(12)–C(13) is 86.1(8)°, compared with 100.7 and 76.6° in the two independent molecules of the cis-OH isomer. In these molecules, the steric hindrances between the benzene and cyclopentane rings are avoided in such a way that the arrangement of C(3)–C(4)–C(12)–C(13) is nearly perpendicular. The torsional angle of C(4)–C(12)–C(13)–C(14) is 162.8(5)° and the two hydrogen atoms attached at the methylene C(12) atom straddle the H(C14) atom. On the other hand, in the cis-OH isomer, the two corresponding hydrogen atoms straddle the hydroxyl oxygen atom instead of the hydrogen atom, since the oxygen atom is located on the same side of the plane through the cyclopentane ring as the H(C14) atom in the title compound.

The molecules form centrosymmetric tetramers by the two hydrogen-bonds between the carboxyl and hydroxyl groups. The O(18) atom donates the hydogen to O(10^{i}) and accepts one from O(11^{ii}) [(i) $-1/2-x$, $1/2-y$, $1/2-z$; (ii) $1/2-x$, $-1/2+y$, $1/2-z$]. The distances of these hydrogen bonds are 2.801(6) and 2.606(6)Å, respectively.

We would like to thank Dr. Atusuke Terada of The Chemical Research Laboratories of our company for providing samples.

Synthesis of β-ZrClN by Thermal Decomposition of Zirconium(IV) Amide Trichloride

Masao OHASHI,* Shoji YAMANAKA, and Makoto HATTORI
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Higashi-Hiroshima 724
(Received February 20, 1986)

Synopsis. The zirconium amide trichloride $ZrCl_3(NH_2)\cdot 7NH_3$ was prepared by the reaction of $ZrCl_4$ with liquid ammonia. On heating up to 600 °C in flowing ammonia gas, the amide was efficiently converted into β-ZrClN, whereas under vacuum it was decomposed to a different product. The decomposition processes were followed by using a quartz spring balance.

In a preceding study, we showed that a layer structured crystal β-ZrClN could be a promising candidate for electrochromic electrode, since the crystal forms a lithium intercalation compound, and exhibits reversible color changes between pale yellow green and black.[1,2]

The powder sample of β-ZrClN for the study was prepared according to a similar procedure reported by Juza and Heners:[3] Anhydrous zirconium tetrachloride was subjected to react with a dry ammonia in a silica glass tube installed horizontally in an electric furnace. The disadvantage of this procedure is that the yield of β-ZrClN is as low as 20—30%. The low yield is mainly due to the formation of the additional compound of ammonia $ZrCl_4\cdot 2NH_3$ which is easily vaporized above 400 °C[4] and physically transported to the cooler parts outside the heating zone before being decomposed to β-ZrClN.

In the present study, a new preparation method has been developed by thermal decomposition of the zirconium(IV) amide trichloride $ZrCl_3(NH_2)\cdot 7NH_3$ in an ammonia stream.

Experimental

Preparation of Zirconium Amide Chloride. Drake and Fowles[5] revealed that $ZrCl_4$ was subjected to ammonolysis to only one Zr–Cl bond in liquid ammonia, giving the zirconium amide chloride:

$$ZrCl_4 + (n+2)NH_3 \longrightarrow ZrCl_3(NH_2)\cdot nNH_3 + NH_4Cl$$

They removed the resulting ammonium chloride by washing the separated solid with liquid ammonia repeatedly. In this study, a glass apparatus was used, which was so designed that the ammonium chloride could be continuously leached out with liquid ammonia, as shown in Fig. 1. The apparatus works essentially as a Soxhlet extraction unit. Under a dry nitrogen atmosphere, about 4 g of zirconium tetrachloride purified by sublimation was placed on the glass filter E in the reaction tube D, the upper end of which is connected to a Dry Ice–methanol condenser B by a ground joint. Dry ammonia gas (99.999%) was introduced into the apparatus through the valve A and liquefied by the condenser. The liquefied ammonia comes down and reacts with the $ZrCl_4$ on the glass filter. The ammonium chloride formed by the reaction was dissolved in the liquid ammonia and leached out into the flask F connected below by a ground joint. The ammonia gas rising from the flask through the bypass C can also be liquefied by the condenser. After

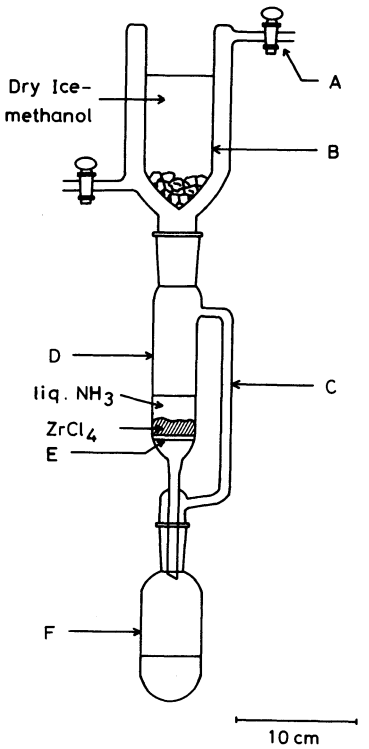

Fig. 1. Soxhlet type glass apparatus used for the preparation of zirconium amide trichloride.

refluxing for 3 h, the liquid ammonia was removed and the apparatus was purged with dry nitrogen. The amide was left on the glass filter in the form of white flocculent.

Analyses. A weighed amount of the reaction product was dissolved in 2 mol dm^{-3} sulfuric acid, and the zirconium content was determined gravimetrically as ZrO_2 after precipitation with sodium hydroxide. Nitrogen and chlorine contents were analyzed on the sulfuric acid solution by Kjeldahl and Fajans' methods, respectively.

The thermogravimetric analysis of the zirconium amide chloride was carried out by using a quartz spring balance in a vacuum and in an ammonia stream for a heating rate of 3 °C min^{-1}. The flow rate of the ammonia was 50 ml min^{-1}.

Results and Discussion

The chemical analysis of the product showed that the contents of Zr, N, and Cl were 28.1, 33.6, and 31.5%, respectively. This analytical result corresponds to the atomic ratio Zr:N:Cl=1.00:7.8:2.9, indicating that only one of the Zr–Cl bonds was subjected to ammonolysis and that the zirconium amide chloride with an approximately stoichiometric composition $ZrCl_3(NH_2)\cdot 7NH_3$ was obtained.

The thermogravimetric analysis (TG) curves of the zirconium amide chloride are shown in Fig. 2. On evacuation at room temperature for 3 h, the amide

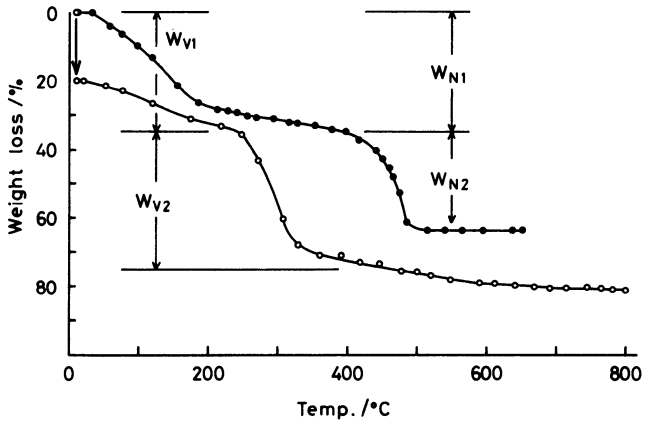

Fig. 2. Thermogravimetric curves for zirconium amide trichloride $ZrCl_3(NH_2)\cdot 7NH_3$ measured in a vacuum (○) and in an ammonia stream (●).

lost about 4 moles of ammonia, and then 3 moles of ammonia are gradually removed up to 240°C.

$$ZrCl_3(NH_2)\cdot 7NH_3 \longrightarrow ZrCl_3(NH_2)\cdot 3NH_3 + 4NH_3$$

$$ZrCl_3(NH_2)\cdot 3NH_3 \longrightarrow ZrCl_3(NH_2) + 3NH_3$$

In the second decomposition stage accompanied by a steep weight loss beginning from 280°C, white sublimate consisting of $ZrCl_4$ and NH_4Cl appeared on the cooler parts of the glass walls. Probably, the following decomposition occurs in this heating stage:

$$2ZrCl_3(NH_2) \longrightarrow ZrClN + ZrCl_4 + NH_4Cl$$

The amount of the weight loss for this reaction was calculated to be 67%. On the ammoniate formula ($ZrCl_3(NH_2)\cdot 7NH_3$) basis, this amount is reduced to 43%, which is in good agreement with the amount of the loss W_{V2} (40%). Yellow solid having the atomic ratio $Zr_{1.0}Cl_{1.0}N_{0.8}$ was obtained when the decomposition was interrupted at 450°C. The solid was very reactive and took fire when dropped into water. Irrespective of the similarity of the atomic ratio, it is apparent that the solid is different from our desired β-ZrClN which is stable in water. Similar unkown yellow solid was also found by Fowles and Pollard[6] in the course of the preliminary study of the decomposition of the zirconium amide trichloride. On further heating up to 800°C, the sample lost the weight gradually and gave black powder, which was found to be ZrN by X-ray powder diffraction analysis.

Even in an ammonia stream, the amount of the first weight loss (W_{N1}) corresponded almost to the first weight loss (W_{V1}) observed in a vacuum. However, the second weight loss began at the temperature higher by about 150°C than that of the decomposition in a vacuum. The residue obtained after the decomposition at 650°C was identified to be β-ZrClN by X-ray powder diffraction analysis. The amount of the weight loss (ammoniate formula basis) calculated on the basis of the following reaction was 22%:

$$ZrCl_3(NH_2) + 2NH_3 \longrightarrow ZrClN + 2NH_4Cl$$

Although the amount of the weight loss W_{N2} (29%) was a little larger than the calculated amount, it is apparent that the zirconium amide trichloride could be effficiently converted into β-ZrClN. It should be noted that in the ammonia stream, the decomposition temperature of $ZrCl_3(NH_2)$ is much higher than the temperature in a vacuum. It seems likely that the ammonia suppresses the decomposition of the amide, and that no sooner the $ZrCl_4$ is evolved at the higher decomposition temperature than it reacts with ammonia, forming β-ZrClN.

The resulting β-ZrClN formed lithium intercalation compound and showed changes in color from pale yellow green to black by soaking into butyl lithium solution in hexane.

Direct Evidence for the Peroxo Substitution of the Oxo Group in the Oxotitanium(IV) Porphyrin Complex in the Aqueous Solution

Masahiko INAMO, Shigenobu FUNAHASHI,† and Motoharu TANAKA†,*
Department of Chemistry, Faculty of Education, Aichi University of Education, Kariya 448
†Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received March 8, 1986)

Synopsis. Labeling experiments for IR and NMR spectra of oxo- and peroxotitanium(IV) complexes show that the oxo group of oxotitanium(IV) porphyrin is fully substituted by a peroxo group in the course of the reaction with hydrogen peroxide in the aqueous solution, i.e. the O–O bond of H_2O_2 remains intact in the peroxo complex.

In recent years interests have been focused on dioxygen complexes of transition metals for their interesting features as catalysts, reagents, or key intermediates of selective oxidation involving molecular oxygen, hydrogen peroxide, or alkyl hydroperoxide.[1] Of the high valent d^0 transition metal complexes, those of molybdenum(VI), vanadium(V), and titanium(IV) complexes are especially known to play an important role in the oxidation by peroxide species.[2] The exchange of oxygen atoms bound to the central metal ion has been investigated in order to elucidate the mechanisms of the catalytic action of these metal complexes. Modena et al. have reported that the oxygen exchange between the oxo and peroxo groups occurs in complexes containing both oxo and peroxo moiety,[3] while controversy still surrounds the mechanisms of these reactions.[4]

We have been interested in the formation of peroxo complexes in the aqueous solution and studied the kinetics of these reactions.[5] Oxo complexes of early transition metal ions react with hydrogen peroxide to give rise to the corresponding peroxo compounds with release of a water molecule:

$$\text{—M(=O)—} + H_2O_2 \longrightarrow \text{—M(O–O)—} + H_2O \qquad (1)$$

In these oxo-peroxo substitution reactions there are two possibilities: (1) The oxo group in the reactant is fully substituted by the peroxo group in hydrogen peroxide, i.e. the O–O bond of H_2O_2 remains intact in the peroxo compound, and (2) the peroxo group in the product results from both the oxo complex and hydrogen peroxide. There is, however, no direct evidence to distinguish whether the oxo group in the reactant or the oxygen atom in hydrogen peroxide is released as a water molecule. In general, oxygen exchange between the oxo complex and water in aqueous solution, i.e. oxo-oxo substitution, is very slow in comparison with the oxo-peroxo substitution[6] and mostly their rates are dependent on hydrogen ion concentration.[7,8] The latter substitution reaction has been studied on the titanium(IV) porphyrins in the organic solvent.[9] Little is known, however, about the mechanisms of this type of reaction in the aqueous solution. In this paper we will discuss the mechanism

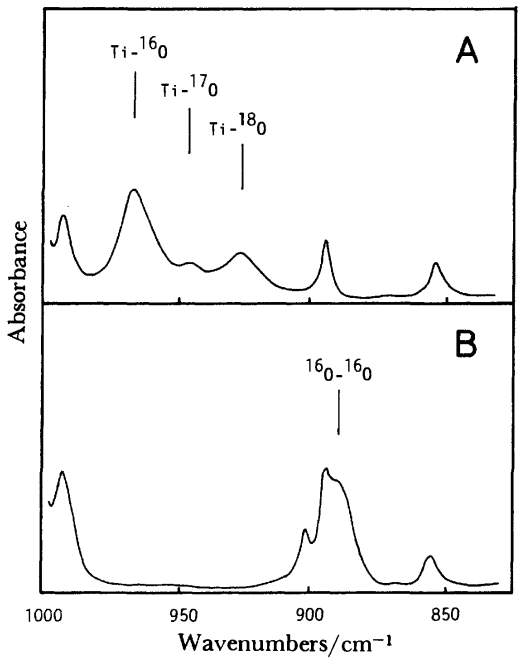

Fig. 1. Infrared spectra of ^{17}O- and ^{18}O-enriched TiO(tpyp) (A) and its peroxo derivative, Ti(O_2)(tpyp) (B), both recorded in absorbance mode. Scales of the ordinate are in arbitrary unit. The IR spectra were obtained by subtracting the spectrum of chloroform from that of the chloroform solution of each complex.

of the oxo-peroxo substitution reaction of titanium(IV) porphyrin in the aqueous solution.

Oxotitanium(IV) porphyrin, TiO(tpyp) (tpyp:5,10,15,20-tetra-4-pyridylporphine) was prepared according to the method described previously.[5c] Isotopically enriched water was purchased from C.E.A.-C.E.N.-Saclay: 35.8 wt% $^{16}OH_2$, 20.2 wt% $^{17}OH_2$, 44.0 wt% $^{18}OH_2$. The mixture involving 10 g of 0.012 mol kg^{-1} chloroform solution of TiO(tpyp) and 0.2 g of isotopically enriched water stood for ten days at 100°C in a sealed glass tube. The infrared spectrum of ^{17}O and ^{18}O labeled complex TiO*(tpyp) in chloroform, measured on a Nicolet MX-1 FT-IR spectrometer, shows three peaks due to titanium–oxygen stretching vibration (Fig. 1A); 966.5 cm^{-1} (Ti–^{16}O), 945.5 cm^{-1} (Ti–^{17}O), and 927.1 cm^{-1} (Ti–^{18}O). The measured IR spectrum was simulated to estimate the isotopic composition of the oxygen atom in TiO(tpyp) on the assumption that the absorption bands are Lorentzian and that the band widths are the same for these three peaks. The oxo group consists of 67.2% of ^{16}O, 9.2% of ^{17}O, and 23.4% of ^{18}O. Therefore 50% of oxygen

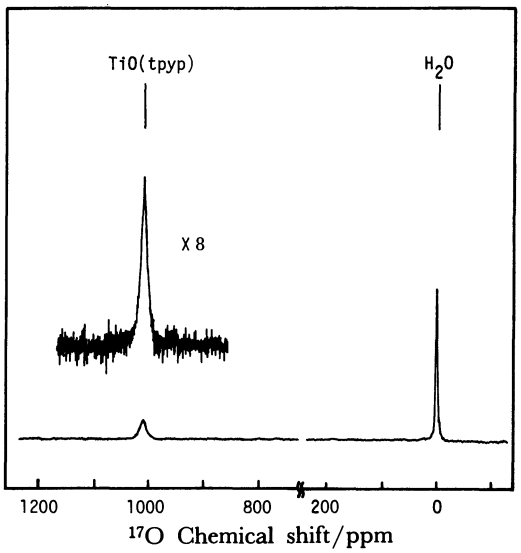

Fig. 2. 13.51-MHz ^{17}O NMR spectrum of TiO(tpyp). Chemical shifts were measured relative to the internal water. In the area of water is seen only one peak because of the proton noise decoupling.

atom of TiO(tpyp) exchanged with that of labeled water present in large excess over the complex under the present experimental conditions. Figure 2 shows the ^{17}O NMR spectrum of Ti^{17}O(tpyp) in a 2.7×10^{-2} mol kg^{-1} chloroform solution at room temperature, recorded on a JEOL FX-100 spectrometer (δ=1010 ppm, $\nu_{1/2}$=186 Hz). The extent of the oxygen exchange estimated by the integration of the ^{17}O NMR spectrum is consistent with that evaluated from the IR spectrum.

The oxo–peroxo substitution reaction in aqueous solution was accomplished by the following procedure. The titanium(IV) porphyrin complex, TiO(tpyp), is soluble in acidic aqueous solution as $[TiO(H_4tpyp)]^{4+}$, where H_4tpyp represents porphyrin ligand of which four pyridyl groups are protonated. The isotopically labeled complex was extracted from the chloroform solution to the aqueous phase at pH 1.7, and then hydrogen peroxide was added to the aqueous phase to perform the oxo–peroxo substitution. As soon as the reaction proceeded completely (<1 min),[10] the produced peroxo complex, $Ti(O_2)$(tpyp), was again extracted into the chloroform phase by neutralizing the acidic aqueous solution with sodium carbonate. This procedure can be carried out within 15 min. Addition of diethyl ether to the chloroform solution yielded the $Ti(O_2)$(tpyp) crystals. The infrared spectrum of the peroxo complex thus obtained is the same as that synthesized from nonlabeled TiO(tpyp) (See Fig. 1B). This fact indicates that this procedure afforded the nonlabeled peroxo complex. On the other hand, the control experiment showed that both oxygen exchange reactions between $[TiO^*(H_4tpyp)]^{4+}$ and bulk water and between $[Ti(O_2)(H_4tpyp)]^{4+}$ and bulk H_2O^* in acidic aqueous solution do not occur to a significant extent (<10%) for a period of 15 min under the present experimental conditions. Consequently it is concluded that the oxo group of $[TiO(H_4tpyp)]^{4+}$ is fully substituted by hydrogen peroxide to give the peroxo complex in which the oxygen atoms come entirely from H_2O_2 as shown by Eq. 2.

$$[TiO^*(H_4tpyp)]^{4+} + H_2O_2 \longrightarrow [Ti(O_2)(H_4tpyp)]^{4+} + H_2O^* \quad (2)$$

This substitution process includes both the entering of hydrogen peroxide into the inner sphere of the central titanium(IV) ion and the leaving of the oxo group which should be expelled as water or hydroxide ion. Since the titanium(IV) atom lies about 0.6 Å above the mean plane of the porphyrin skeleton toward the oxo group in the case of oxotitanium(IV) octaethylporphine in the crystalline state,[11] the similar situation will prevail in solution. In our previous paper,[5a] the associative mode of activation has been proposed for the reaction of titanium(IV) porphyrin with hydrogen peroxide on the basis of the kinetic feature, and we have put forward the acid-base catalyzed mechanism for the oxo-peroxo substitution which would include some assistance of hydrogen bonding between the oxo group of the complex and the hydrogen atom of hydrogen peroxide in the transition state. Such a mechanism is now strongly supported by the present work.

Financial support from the Ministry of Education, Science, and Culture through a Grant-in-Aid for Scientific Research (Grant No. 59430010) and a Grant-in-Aid for Special Project Research (Grant No. 60129031) is gratefully acknowledged.

Reactions of Trifluoroacetonitrile Oxide or -nitrilimines with β-Diketones and β-Keto Esters

Kiyoshi TANAKA,* Munehisa KISHIDA, Seiji MAENO, and Keiryo MITSUHASHI
Department of Industrial Chemistry, College of Technology, Seikei University, Kichijoji-Kitamachi, Musashino, Tokyo 180
(Received March 3, 1986)

Synopsis. *N*-Phenyl-*C*-(trifluoromethyl)nitrilimine cyclized with β-diketones or β-keto esters under alkaline conditions to give the corresponding 3-trifluoromethylpyrazoles with acyl or alkoxycarbonyl group at the 4-position of the ring, respectively. While trifluoroacetonitrile oxide with β-diketones provided the corresponding trifluoromethylisoxazoles, its reactions with β-keto esters gave 4-acyl-5-hydroxy-3-trifluoromethylisoxazoles as well as the expected isoxazoles without the regioselectivity.

The reaction of nitrile oxides or nitrilimines with the doubly activated methylene compounds provides a regiospecific synthesis of isoxazoles or pyrazoles with a wide variety of substituents.[1] For example, acyl group attached to methylene group is regarded as a functional group for an introduction of alkyl group into the 5-position of the azole ring. In the course of our program researching on the reactivity of the fluorinated 1,3-dipolar compounds, we now wish to describe the synthesis of 3-trifluoromethylpyrazoles or -isoxazoles having carbonyl functions through the reactions of *N*-phenyl-*C*-(trifluoromethyl)nitrilimine (**2**) or trifluoroacetonitrile oxide (**6**) with various β-diketones or β-keto esters and also to report the regioselectivity of the cycloaddition.[2]

The nitrilimine **2**, derived in situ from *N*-phenyltrifluoroacetohydrazonoyl bromide (**1**), reacted with methyl acetoacetate under alkaline conditions in methanol to give 4-methoxycarbonyl-5-methyl-1-phenyl-3-trifluoromethylpyrazole (**3a**) in fairly good yield. The pyrazole **3a** was easily transformed into 5-methyl-1-phenyl-3-trifluoromethylpyrazole (**4**) by hydrolysis followed by decarboxylation. This transformation confirmed the structure of **3a** having methoxycarbonyl group at the 4-position of the ring, indicating that cycloaddition proceeds with high regioselectivity. Similarly, **2** reacted with 2,4-pentanedione, giving rise to the corresponding acetylpyrazole **3b**. The reactions of **6**, generated in situ from trifluoroacetohydroximoyl bromide etherate (**5**), are also related to the synthesis of the acylisoxazoles **7a**, **b**, **c** from 2,4-pentanedione, dibenzoylmethane, and 1,3-cyclohexanedione,[3] respectively (Table 1). However, methyl acetoacetate produced 4-acetyl-5-hydroxy-3-trifluoromethylisoxazole (**9**), disturbing the high regioselectivity, in substantial quantity together with the expected isoxazole **8a** which was also converted into 5-methyl-3-trifluoromethylisoxazole (**10**). Although ethyl acetoacetate also produced **9** in as low as 7% yield besides **8b**, methyl benzoylacetate afforded only **8c**, accompanied by no corresponding hydroxyisoxazole.

The formation of **9** can be reasonably explained by the stepwise path involving electrophilic substitution of **6** toward the anion **11** of β-keto ester followed by intramolecular cyclization of thus formed anion **12** with the ester moiety. These ionic or hard properties are characteristic of **6** and seem to be caused by the strong electron-withdrawing effects of trifluoromethyl group.[4] On the other hand, intramolecular cyclization of the anion **12** with the acetyl group may produce the expected isoxazole **8**[5] and , however, the alternative direct formation of **8** by a concerted cycloaddition of **6** with **11** can not be still ruled out.

Experimental

All melting and boiling points are uncorrected. The IR spectra were recorded on a JASCO A-100 spectrometer. The

^{1}HNMR spectra were measured with JEOL JNM-PMX 60 spectrometer, using tetramethylsilane as an internal standard, the chemical shifts being given in δ ppm downfield. The MS spectra were obtained on a Finnigan 4023 GC-MS DS spectrometer. The bromides **1** and **5** were prepared by the methods reported in our previous papers.[6]

Preparations of 3 and 7. General Procedure. A solution of **1** (4.5 mmol) in 10 cm^3 of methanol was added dropwise to a solution of sodium methoxide (9.0 mmol) and 13.5 mmol of methyl acetoacetate or 2,4-pentanedione in 20 cm^3 of methanol. After stirring at room temperature for 2 h, 100 cm^3 of diethyl ether was added to the reaction mixture. The mixture was washed with water and brine, dried over magnesium sulfate, and evaporated to leave a residue which was placed on a column (silica gel) and eluted to give the pyrazole **3**. Product was further purified by recrystallization. The isoxazoles **7** were similarly prepared from **5** and β-diketones.

Decarboxylation of 3a and 8a. A mixture of **3a** (1.59 g, 5.6 mmol) in ethanol (25 cm^3) and 10% aqueous sodium carbonate (50 cm^3) was refluxed for 12 h. After the solvent was removed, the resulting mixture was washed with diethyl ether and dissolved in water. The aqueous solution was acidified with concd hydrochloric acid, extracted with diethyl ether, and dried over magnesium sulfate. Removal of the solvent left a solid (1.03 g). A mixture of thus obtained solid and 0.1 g of copper powder in 3 cm^3 of quinoline was heated at 190°C for 3 h and evaporated under reduced pressure to leave a residue. The residue was chromatographed on silica gel and eluted with hexane–ethyl acetate (5:1) to give 0.41 g (32%) of **4** which was further purified by preparative GLC; ^{1}HNMR ($CDCl_3$) δ=2.30 (s, 3H), 6.37 (s, 1H), 7.4 (s, 5H), IR (neat) 1590 (Ph), 1170,1130 cm^{-1} (CF_3).

Found: C, 58.57; H, 3.96; N, 12.37%. Calcd for $C_{11}H_9F_3N_2$: C, 58.41; H, 4.01; N, 12.38%.

Similar treatment of **8a** provided **10** which was collected by distillation (64%) and purified by preparative GLC. ^{1}H NMR ($CDCl_3$) δ=2.52 (s, 3H), 6.25 (s, 1H), IR (neat) 3150 (CH), 1185, 1145 cm^{-1} (CF_3).

Found: C, 39.72; H, 2.31; N, 9.28%. Calcd for $C_5H_4F_3NO$: C, 39.75; H, 2.67; N, 9.27%.

Reaction of 5 with Methyl Acetoacetate. After the similar procedures to the above using **5** (5.00 g, 18.8 mmol), methyl acetoacetate (5.95 g, 51.3 mmol), and sodium methoxide (2.77 g, 51.3 mmol), the solvent was removed to leave a residue. The residue was extracted with chloroform and then with ethyl acetate. The chloroform layer was washed with water, dried over magnesium sulfate, and evaporated. The resulting residue was distilled to give 3.44 g of a mixture of **8a** (24% yield) and methyl acetoacetate in the ratio of 17:83 (boiling range, 74—76°C/25 mmHg, 1 mmHg=133.322 Pa). The isoxazole **8a** was further separated by preparative GLC. On the other hand, the ethyl acetate layer was evaporated to give a residue which was dissolved in water. The aqueous solution was acidified with concd hydrochloric acid and extracted with diethyl ether. The extracts were dried over magnesium sulfate and evaporated to leave an oily matter which was sublimed under reduced pressure to give 0.57 g (16%) of **9**; mp 96—98°C (recrystallized from chloroform), ^{1}HNMR ($CDCl_3$–DMSO-d_6) δ=2.53 (s), 9.3 (br. s), IR(KBr) 3340 (OH), 1730 (C=O), 1150 cm^{-1} (CF_3), MS (CI, *m/z*) 196 $(M+H)^+$, 224 $(M+Et)^+$.

Found: C, 32.91; H, 2.60; N, 6.34%. Calcd for $C_6H_4F_3NO_3 \cdot 1.3H_2O$[7]: C, 32.98; H, 3.04; N, 6.41%.

In a similar manner, the reaction with ethyl acetoacetate or methyl benzoylacetate was performed and the results are summarized in Table 1.

7) Since the isoxazole **9** is hygroscopic and easily sublimed under reduced pressure, the complete drying was impossible.

Preparation of Organocalcium Halides Using Calcium Ultrafine Particle

Kunio MOCHIDA,* Sei-ichi OGURA, and Takayuki YAMANISHI
Department of Chemistry, Faculty of Sciences, Gakushuin University, 1-5-1 Mejiro, Toshima-ku, Tokyo 171
(Received March 11, 1986)

Synopsis. Organocalcium halides were prepared from organic halides and calcium ultrafine particle in good yields.

In contrast to the organomagnesium halides (Grignard reagents), the preparations and chemical reactivities of organocalcium halides have been little studied.[1] This slow progress could be due to the lack of a useful method to prepare organocalcium halides.

The formation of organocalcium halides from organic halides and calcium metal has been reported. An important problem in the preparation of organocalcium halides is the impurities in the calcium metal. Various efforts to activate calcium metal have been described.[2-4] Kawabata and co-workers have reported the preparation of organocalcium iodides and bromides by using higher-purity calcium metal than was previously available.[5-7] The reactivities of organocalcium halides, thus prepared, seem to resemble those of organolithium reagents than Grignard reagents.[7] Recently, we have reported the preparation of solvent-free organocalcium halides using calcium atoms.[1] Solvent-free organocalcium halides are highly reactive solids.

On the other hand, there are many articles in the literature concerning the unusual reactivity and chemistry of ultrafine particles (UFP).[8] These active UFP have been easily produced using a heated tungsten basket. Therefore, calcium UFP is expected to be useful for the preparation of various organocalcium halides which are unobtainable by other methods, or which can be prepared only in low yields.

In this paper, we report on a new method for the preparation of organocalcium halides from the corresponding organic halides and calcium UFP produced by a heated tungsten basket.

Results and Discussion

Calcium UFP was conveniently produced by a heated tungsten-wire basket (ca. 900 °C) in an evacuated vessel (ca. 10^{-2}—10^{-3} Torr, 1 Torr=133.322 Pa).[9] After the preparation of the calcium UFP, a desired amount of the calcium UFP was transfered to a reaction flask in an argon-filled glove box. To this reaction flask, organic halides and solvents were syringed in. All manipulations were carried out under an argon atmosphere.

The hydrolysis of the products from the reactions of calcium UFP with organic halides (RX) gave reduction products (RH) and coupling products (R-R) as the main products. These results are summarized in Table 1. It is known that the reduction product is formed quantitatively by the hydrolysis of organocalcium halides.[10,11] Therefore, the yield of the reduction product can be regarded as that of organocalcium halides.

The calcium UFP produced by a heated tungsten-wire basket is useful for the preparation of organocalcium halides in tetrahydrofuran (THF) shown in Table 1. The reaction proceeded smoothly, even at low temperatures, and the Wurtz-type coupling was relatively less important under these conditions. Yields of organocalcium halides were better than those described in the literature.[1]

The reactions of calcium UFP with octyl iodide and bromide, respectively, afforded the corresponding organocalcium halides in high yields (Runs 1 and 3). On the other hand, the reaction was restricted to octyl chloride (Run 5). The ease of reaction with calcium UFP follows the order octyl iodide>octyl bromide≫octyl chloride. The reactivity of octyl halides shown in Table 1 is consistent with that published by Bryce-Smith and Skinner,[2] and Kawabata and coworkers.[5] As shown in Table 1, the preparation of octylcalcium bromide using calcium UFP in the absence of THF was extremely difficult (Run 4). Thus, the reaction of calcium UFP with octyl bromide in toluene at 100 °C for 2 h resulted in a poorer yield. This result is clearly different from that of Kawabata and co-workers.[5-7] These authors described the reactions of alkyl halides with higher-purity calcium metal as proceeding smoothly in toluene. An initiation of the reaction was not necessarily when calcium UFP was used. Thus, calcium UFP reacted with octyl bromide in THF at −5 °C to give a 41.0% yield of octylcalcium bromide in 2 h (Run 2). This reaction started immediately at −5 °C, and was even produced at temperature as low as −78 °C in a 6.4% yield. The yields of the products from reactions of calcium UFP with octyl halides are almost constant within the temperature range examined (10—50 °C).

Calcium UFP easily reacted with cyclohexyl halides (Table 1), but the yields of cyclohexylcalcium halides were lower, as expected, than those of octylcalcium halides (Runs 6—8).

The reactions of calcium UFP with aryl iodides and bromides, respectively, afforded the corresponding arylcalcium halides in high yields (Runs 9, 10, and 14). A higher reaction temperature (50 °C) was necessary to obtain arylcalcium halides in high yields. Calcium UFP reacted selectively with the bromo substituent of *p*-dibromobenzene and *p*-bromochlorobenzene to give bromobenzene and chlorobenzene, respectively (Runs 11 and 12). No reactions of calcium UFP with chlorobenzene and 1-chloronaphthalene took place (Runs 13 and 15).

The reaction of calcium UFP with benzyl bromide gave the corresponding organocalcium halide in low yield on account of a Wurtz-type coupling as a side reaction (Run 16). The reaction was restricted to benzyl chloride (Run 17).

Although organocalcium halides are useful reagents for alkylation and arylation, the following points can be made about the usefulness of the calcium UFP method.

Table 1. Products from the Reactions of Calcium UFP with Organic Halides[a)]

Run	R-X	Solvent	Conditions	Products, Yield/%[b)]	
				R-H	R-R
1	n-$C_8H_{17}I$	THF	10°C, 2h	95.3

a) Typical reaction conditions: Organic halides, 30 mmol, Ca UFP, 10.0 mmol; THF as solvent, 20 cm³. b) Based on the calcium UFP.

(a)Reactions of calcium UFP with various organic iodides and bromides proceed smoothly under an argon atmosphere.

(b) Yields of organocalcium halides are better than those published by other workers.

(c) Low temperatures and short times are required in these reactions.

Experimental

GLC analyses were performed on a Shimadzu GC-6A or 8A gas chromatograph. NMR spectra were obtained with a Varian FT-80 A spectrometer using $CDCl_3$ as the solvent and TMS as the internal standard.

Materials. Calcium metal (granules, 99% pure, Wako Chemicals), organic halides, and other chemicals were commercially available. THF was distilled from benzophenone ketyl immediately prior to use.

Preparation of Calcium UFP. In a typical calcium UFP preparation, calcium metal (300 mg, 7.5 mmol) was vaporized in 30 min, from an aluminum oxide crucible in a tungsten filament (ca. 900°C). This apparatus was contained in a vacuum vessel (ca. 10^{-2}—10^{-3} Torr). The calcium UFP was deposited (vessel immersed in liquid nitrogen). Upon completion of a deposition, the vessel was isolated from the vacuum pump and allowed to become room temperature. The calcium UFP was weighed in an argon-filled glove box.

Reactions of Calcium UFP with Organic Halides. As a typical example, the reaction of calcium UFP with octyl bromide is described. Calcium UFP (9.0 mmol) was transferred to two-necked 50 cm³ flask equipped with a serum cap and reflux condenser. Then, THF (20 cm³) and octyl bromide (27.0 mmol) were syringed in. The reaction mixture was stirred at 10°C for 2 h under argon. After hydrolysis of the reaction mixture with dilute HCl, the organic layer was extracted with ether.

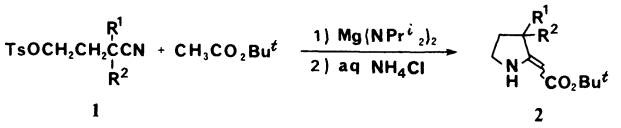
Synthesis of 2-Pyrrolidinylideneacetates by Means of a Reaction of Magnesium Ester Enolate with γ-Cyanoalkyl Tosylates

Kazuhiro KOBAYASHI* and Hiroshi SUGINOME
Organic Synthesis Division, Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received March 13, 1986)

Synopsis. We describe a new and efficient synthesis of *t*-butyl 2-pyrrolidinylideneacetate and its 3-substituted derivatives from a reaction of the magnesium enolate of *t*-butyl acetate with γ-cyanoalkyl tosylates.

In our revious paper,[1] one of the present authors reported the synthesis of 3-amino-2-alkenoates by means of a reaction of magnesium ester enolates with nitriles. It has been successfully applied to the synthesis of amino sugars such as acosamine[2] and daunosamine.[3] We now wish to report a new method for the synthesis of 2-pyrrolidinylideneacetate (**2**),[4] which is a useful intermediate for the synthesis of several biologically important natural products,[5] by the addition-cyclization sequence from the reaction of the magnesium enolate of *t*-butyl acetate with γ-cyanoalkyl tosylates (**1**).

The magnesium enolate was generated by treatment of *t*-butyl acetate with magnesium bis(diisopropylamide)[6] that had been derived from diisopropylamine and ethylmagnesium bromide (2:1) at 0 °C in diethyl ether; it was then allowed to react with **1** at that temperature. After being warmed up to room temperature, an aqueous work-up followed by distillation or chromatography on silica gel afforded *t*-butyl 2-pyrrolidinylideneacetates (**2**) in fair yields (Scheme 1).[7] We found that 4-bromobutanenitrile can also be used instead of tosylate **1a**.



1 2

Scheme 1.

The yields and the stereochemistry of **2** in the reaction of the magnesium ester enolate with various nitriles **1** are summarized in Table 1. The table indicates that the *E*/*Z* ratio of the products **2** depends on the alkyl substituents attached to the carbon atom adjacent to the cyano group of the nitrile **1**. The assignment of their configuration is based on an ^{1}HNMR analysis. The NH proton of the *Z*-form of 2 appears at around δ 7.8,[4a] owing to the intramolecular hydrogen bonding, whereas that of the *E*-form appears at around δ 6.2.

The cyclization of an ambident species **4**, which is the tautomer of the initial adduct **3** in the present reaction, may take place either at the nitrogen or at the carbon center adjacent to the *t*-butoxycarbonyl group to give **2** or an aminocyclopentene **5**, respectively (Scheme 2). The product was, however, found to be an exclusively pyrrolidine derivative **2** and no aminocyclopentene was detected.

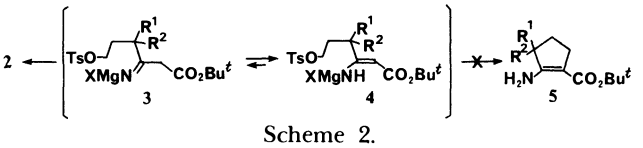
a) Isolated Yields. b) Determined by the separation of each isomer by preparative TLC on silica gel. c) 4-Bromobutanenitrile was employed instead of **1a**. d) Determined by the ^{1}H-NMR of an isolated *Z*/*E* mixture.



Scheme 2.

Attempts to obtain 2-piperidinylideneacetates from a reaction of the enolate with δ-cyanoalkyl tosylates were unsuccessful.

Experimental

The IR spectra were recorded on a Hitachi 285 spectrometer. The NMR spectra were recorded on a Hitachi R-90B spectrometer in $CDCl_3$ with TMS as an internal standard. Thin-layer chromatography was performed using Merck Silica Gel 60 GF_{254}. All solvents were used after having been dried over appropriate drying agents and distilled under nitrogen.

Preparation of the Cyanoalkyl Tosylate **1**. The cyanoalkyl tosylates **1** were prepared from the corresponding nitriles in three steps. α-Lithiated nitriles[8] were treated with 2-(1-ethoxyethoxy)ethyl bromide[9] to give alkylated nitriles, which were then deprotected with pyridinium *p*-toluenesulfonate (PPTS) in methanol. The resulting hydroxy nitriles were converted into **1** by treatment with *p*-toluenesulfonyl chloride in pyridine. The physical, spectal, and analytical data for **1** are as follows.

3-Cyanopropyl 4-Methylbenzenesulfonate (1a): R_f=0.58 (1:1 AcOEt–hexane); IR (neat) 2230, 1595, 1355, 1175 cm^{-1}; ^{1}HNMR δ=1.8—2.2 (m, 2H), 2.3—2.5 and 2.46 (m and s, combined 5H), 4.14 (t, *J*=5.7 Hz, 2H), 7.36 (d, *J*=8.1 Hz, 2H), 7.80 (d, *J*=8.1 Hz, 2H). Found: *m*/*z* 239.0609. Calcd for $C_{11}H_{13}NO_3S$: M, 239.0617.

3-Cyanobutyl 4-Methylbenzenesulfonate (1b): R_f=0.67 (diethyl ether); IR (neat) 2240, 1600, 1360, 1180 cm^{-1}; ^{1}HNMR δ=1.31 (d, *J*=7.3 Hz, 3H), 1.94 (q, *J*=6.8 Hz, 2H), 2.46 (s, 3H), 2.8 (m, 1H), 4.16 (t, *J*=6.8 Hz, 2H), 7.36 (d, *J*=8.1 Hz, 2H), 7.80 (d, *J*=8.1 Hz, 2H). Found: *m*/*z* 253.0773. Calcd for $C_{12}H_{15}NO_3S$: M, 253.0773.

3-Cyanoheptyl 4-Methylbenzenesulfonate (1c): R_f=0.68 (CH_2Cl_2); IR (neat) 2230, 1595, 1360, 1180 cm^{-1}; ^{1}HNMR

δ=0.92 (t, *J*=6.8 Hz, 3H), 1.2—2.1 (m, 8H), 2.59 (s, 3H), 2.7 (m, 1H), 4.2 (m, 2H), 7.42 (d, *J*=8.1 Hz, 2H), 7.87 (d, *J*=8.1 Hz, 2H). Found: *m/z* 295.1245. Calcd for $C_{15}H_{21}NO_3S$: M, 295.1243.

3-Cyano-3-methylbutyl 4-Methylbenzenesulfonate (1d): R_f=0.36 (1:3 AcOEt-hexane); IR (neat) 2240, 1600, 1365, 1180 cm^{-1}; ^{1}HNMR δ=1.36 (s, 6H), 1.95 (t, *J*=6.6 Hz, 2H), 2.46 (s, 3H), 4.22 (t, *J*=6.6 Hz, 2H), 7.36 (d, *J*=8.2 Hz, 2H), 7.81 (d, *J*=8.2 Hz, 2H). Found: *m/z* 267.0934. Calcd for $C_{13}H_{17}NO_3S$: M, 267.0930.

3-Cyano-3-phenylbutyl 4-Methylbenzenesulfonate (1e): Mp 51—52°C (diethyl ether-hexane); IR (KBr disk) 2240, 1600, 1365, 1180 cm^{-1}; ^{1}HNMR δ=1.72 (s, 3H), 2.34 (t, *J*=7.3 Hz, 2H), 2.45 (s, 3H), 4.1 (m, 2H), 7.3 (m, 7H), 7.71 (d, *J*=8.4 Hz, 2H). Found: *m/z* 329.1082. Calcd for $C_{18}H_{19}NO_3S$: M, 329.1086.

***t*-Butyl (*Z*)- and (*E*)-3-Methyl-2-pyrrolidinylideneacetate (2b). General Procedure.** Diisopropylamine (1.21 g, 12 mmol) was added to an etherial solution (9 ml) of ethylmagnesium bromide (6 mmol) at 0°C and the mixture was stirred for 1 h at the same temperature. To the resulting turbid solution was successively added *t*-butyl acetate (0.36 g, 3 mmol) and **1b** (0.76 g, 3 mmol) in THF (3 ml) and the mixture was allowed to warm up to room temperature. After 30 min the reaction mixture was quenched with aqueous ammonium chloride and extracted with diethyl ether. The extract was washed with brine, dried over anhydrous magnesium sulfate, filtered, and concentrated in vacuo. The oily residue was chromatographed on silica gel (1:3 AcOEt-hexane) to give (*Z*)-**2b** (R_f=0.67, 0.26 g, 44%) and (*E*)-**2b** (R_f=0.58, 0.096 g, 16%). (*Z*)-**2b**: IR (neat) 3370, 1655, 1605 cm^{-1}; ^{1}HNMR δ=1.16 (d, *J*=6.8 Hz, 3H), 1.47 (s, 9H), 1.5—2.1 (m, 2H), 2.7 (m, 1H), 3.5—3.9 (m, 2H), 4.43 (s, 1H), 7.8 (br, 1H). Found: *m/z* 197.1422. Oxidation of Cyclopentene by $RuCl_3$-NaOCl Catalyst

Hideo ORITA,* Takashi HAYAKAWA, and Katsuomi TAKEHIRA
National Chemical Laboratory for Industry, Yatabe, Ibaraki 305
(Received October 15, 1985)

Synopsis. Oxidation of cyclopentene by $RuCl_3$-NaOCl catalyst in an aqueous-organic two phase system was investigated by changing compositions of solvent system and additives to the aqueous solution. Use of acetonitrile as a cosolvent enhanced the reaction rate greatly, and addition of NaOH improved the yield of glutaric acid up to 80%.

Ruthenium tetraoxide is one of the most powerful oxidants of various organic compounds under mild condition.[1] Berkowitz and Rylander[2] reported the oxidation of various organic compounds by using ruthenium tetraoxide as a stoichiometric oxidant. In 1970, Wolfe et al.[3] reported that cyclohexene was oxidized to adipic acid (86—95%) with RuO_4 generated in situ from $RuCl_3$ and sodium hypochlorite. Foglia et al.[4] reexamined the work of Wolfe et al., and found that this procedure gave good yield of cleavage products from *acyclic* alkenes only when the oxidations were carried out with added sodium hydroxide and a *phase transfer catalyst*. Furthermore, the direct oxidation of cyclic olefines to corresponding dicarboxylic acids with RuO_2 (or $RuCl_3$)-hypochlorite oxidant was scarcely investigated.

Sharpless et al.[5] reported an improved procedure for traditional $RuCl_3 \cdot xH_2O$-IO_4^-/CCl_4-H_2O catalytic oxidation system by adding acetonitrile as a cosolvent. The effects of acetonitrile are speculated to disrupt the inactive lower valent ruthenium complexes and return the ruthenium to the catalytic cycle. Although this method is convenient, it also has several drawbacks owing to using periodate as a reoxidant; the relative high cost and high molecular weight of periodate; the precipitation of voluminous quantities of iodate as the reaction proceeds. We describe herein a convenient and effective procedure of the oxidation of cyclopentene to glutaric acid by using readily available sodium hypochlorite in the presence of a catalytic amount of $RuCl_3 \cdot xH_2O$.

Experimental

The reaction was carried out in a three necked flask equipped with a magnetic stirrer, addition funnel, and condenser. The typical experiment is as follows. The flask was charged with 90 ml of CCl_4, 10 ml of H_2O, 3.2 g of cyclopentene (47 mmol), and 0.15 g of $RuCl_3 \cdot xH_2O$ (the molar ratio of $RuCl_3$ to cyclopentene was 0.014 on calculations based on x=1). Aqueous sodium hypochlorite (100 g of 21 wt% solution, 282 mmol) with added 4 g of NaOH was added to the stirred CCl_4 solution dropwise for about 2 h while the flask was cooled by means of an ice bath. The vigorous stirring was continued until the color of the reaction solution turned black, at which time the starch iodide test for active chlorine was negative. The reaction mixture was filtered through a Celite pad in order to remove the precipitated RuO_2. After the separation of organic layer, the aqueous phase was washed with CH_2Cl_2, acidified to a pH of one with concd HCl and the solvent was removed under reduced pressure. The residual solid was extracted with ether, and the solvent was removed under reduced pressure to give 4.7 g of white powder. After esterification by BF_3-methanol reagent, gas chromatography showed that 4.4 g of glutaric acid (71 mol% yield based on charged cyclopentene) was produced. The products were also identified by IR.

Results and Discussion

Oxidation of cyclopentene by $RuCl_3$-NaOCl catalyst was investigated under various conditions and the results are shown in Table 1. The reaction time and the yield of glutaric acid were very dependent on the compositions of the organic solvent and the addtion of alkali to the aqueous solution. In the absence of alkali (Runs 1 and 2, the reaction conditions were similar to the work of Wolfe et al.[3]), or when sodium

Table 1. Oxidation of Cyclopentene by $RuCl_3$-NaOCl Catalysts[a]

Run	Solvent / ml	Alkali / g	Reaction time/h	Products

8	CCl_4, 90 CH_3CN, 10	$Na_2CO_3 \cdot 10H_2O$, 14	3.5	3.9	2.9	47

a) Cyclopentene 3.2 g, NaOCl aqueous solution 100 g (21 wt%, 282 mmol), $RuCl_3 \cdot xH_2O$ 0.15 g.

carbonate was used instead of NaOH (Run 8), the yield and selectivity of glutaric acid were relatively low. Determination by gas chromatography indicated that a considerable amount of succinic acid (about 10 mol% yield) was produced. This result indicated that the further oxidation of glutaric acid occurred. Furthermore, all of ruthenium catalyst could not be recovered as RuO_2 by means of filtration of the reaction mixture and the aqueous solution remained black even after the filtration.

The addition of NaOH (the molar ratio of NaOH to cyclopentene is 2) improved the yield of glutaric acid considerably. In these cases, all of the ruthenium catalyst could be recovered by filtration and reused easily. The effects of added NaOH are considered to depress the formation of hypochlorous acid, which often leads to the formation of chlorinated byproducts by addition to the double bond,[6] to prevent glutaric acid from the consecutive oxidation in organic layer by extraction to the aqueous layer as sodium salt, and to promote the precipitation of RuO_2 after all the consumption of charged sodium hypochlorite. Under alkaline conditions, RuO_4 is readily reduced to RuO_4^- and further to RuO_4^{2-}.[7] It was found that the molar ratio of about 2:1 NaOH to cyclopentene gave the good yield of glutaric acid. The further addition of NaOH promoted reduction of RuO_4 to RuO_4^{2-}, which is a good oxidant for alcohols but not for alkenes,[8] and then led to slower reaction and poorer yield.

When acetonitrile was used as a cosolvent of cyclopentene, the reaction rate increased greatly, and the yield of glutaric acid improved up to 82 mol% (Run 6). Although the effect of acetonitrile is not understood well in the present stage, we also speculate that acetonitrile disrupts the inactive lower valent ruthenium carboxylate complexes and makes the regeneration of RuO_4 much easier. In the work of Sharpless et al.,[5] the third solvent component, CCl_4, was necessary for the reaction. However, the solvent system which consisted of acetonitrile and water alone gave the fairly good yield of glutaric acid (Run 7) in the present work.

Although the addtion of propionitrile to the reaction mixture in place of acetonitrile also enhanced the reaction rate, the yield of glutaric acid decreased 80% of that when acetonitrile was used. Adiponitrile was not an effective cosolvent, and rather made the reaction very slow and/or incomplete. This might be due to inactivation of the catalyst owing to its strong bonding to the ruthenium.

The oxidation of other cycloalkenes with $RuCl_3$–NaOCl catalysts was also examined (the reaction conditions were the same as those of run 6 in Table 1). Cyclohexene was oxidized to adipic acid in 56 mol%, and cyclooctene to suberic acid in 36 mol%, pimeric acid in 5 mol%, and adipic acid in 5 mol%. As the ring size of cyclic olefins became bigger, and the reaction took longer time (7 h for cyclohexene and overnight for cyclooctene) and the yield of corresponding dicarboxylic acids decreased. Extention of this catalytic system to cyclododecene oxidation proved impractical, since soap formation seriously complicated reaction procedure. Cyclohexanone was oxidized under similar conditions to adipic acid in 45 mol%, glutaric acid in 1 mol%, and succinic acid in 1 mol%.

Table 2. Ruthenium-Catalyzed Oxidation of Cyclopentene with Various Reoxidants[a]

Reoxidant	Reaction time	Yield of glutaric acid/%[b]
NaOCl[c]	2 h	82
$NaClO_2$[d]	8.5 h	53
$NaClO_3$[e]	1 d	—[i]
$NaBrO_2$[f]	1 d	32
$NaBrO_3$[g]	1 d	21
$NaIO_4$[h]	1 d	68

a) Cyclopentene 3.2 g, $RuCl_3 \cdot xH_2O$ 0.15 g, CCl_4 50 ml, CH_3CN 50 ml. b) Determined by GC after esterification. c) 21 wt% NaOCl aqueous solution 100 g, NaOH 4 g. d) $NaClO_2$ 9 g in H_2O 100 ml, NaOH 2 g. e) $NaClO_3$ 7 g in H_2O 100 ml. f) $NaBrO_2 \cdot 3H_2O$ 18 g in H_2O 100 ml, NaOH 2 g. g) $NaBrO_3$ 9.5 g in H_2O 100 ml. h) Cyclopentene 1 g, $RuCl_3 \cdot xH_2O$ 0.05 g, $NaIO_4$ 15 g in H_2O 100 ml. i) Not reacted.

The ruthenium catalyzed oxidation of cyclopentene with various reoxidants was investigated and the results are tabulated in Table 2. The reaction conditions were slightly different from one to another, but not optimized. Among the reoxidants investigated, NaOCl gave the best yield of glutaric acid. Although $NaIO_4$ gave the fairly good result, reaction took longer time and the precipitation of the voluminous amounts of iodate during the reaction made the reaction system complicated.

Temperature Dependence of ^{35}Cl Nuclear Quadrupole Resonance Frequencies and Hydrogen Bonding in Some Metal(II) Hexachlorostannate(IV) Hexahydrates

Keizo HORIUCHI, Akinobu SASANE, Yoshihiro MORI, Tetsuo ASAJI,† and Daiyu NAKAMURA†,*
Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto 390
†Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received March 20, 1986)

Synopsis. The temperature dependences of ^{35}Cl NQR frequencies were observed over a fairly wide range of temperature for $MSnCl_6 \cdot 6H_2O$ [M(II)=Mg, Ca, Mn, Co, Ni] forming isomorphous crystals ($R\bar{3}$) at room temperature. These complexes yielded unusual ^{35}Cl NQR temperature dependence curves showing a positive temperature coefficient. This can be attributed to the existence of Cl···H-O type weak hydrogen bonds.

The ^{35}Cl NQR frequencies of $MSnCl_6 \cdot 6H_2O$ [M(II)= Mg, Ca, Zn, Cd, Mn, Co, Ni] were reported by Graybeal et al.[1] and independently by Brill et al.[2] For the Ca(II) and Mg(II) salts, the temperature dependence of ^{35}Cl NQR frequencies was studied and the positive temperature coefficients were found. Although Graybeal et al.[1] attributed the unusual positive temperature coefficient to the π bond character of Sn-Cl bonds,[3] their explanation seems to be implausible because no positive temperature coefficients were observed for several R_2SnCl_6 type complexes.[4] As already suggested by one of the present authors,[5] the observed positive coefficient is attributable to hydrogen bonds formed between chloride ligands and water molecules.

Recently, Kitazume et al.[6] determined the crystal structure of $CaSnCl_6 \cdot 6H_2O$ by single-crystal X-ray diffraction and NQR Zeeman effect measurements. From these studies, they concluded that the anomalous temperature dependence of ^{35}Cl NQR frequencies is due to the hydrogen bonding effect as already pointed out.[5] In order to obtain further information about the suggested mechanism which gives rise to the positive temperature coefficient, the temperature dependence study of ^{35}Cl NQR frequencies was carried out for some hexachlorostannates(IV) crystallized with hexahydrated divalent counter cations.

Experimental

Measurements of ^{35}Cl NQR frequencies were performed above 77 K by use of a modified Dean-type spectrometer described elsewhere.[7] For $NiSnCl_6 \cdot 6H_2O$, the measurements were extended down to 4.2 K by employing a homemade cryostat. Temperatures were determined using a chromel vs. alumel and a chromel vs. gold (0.03% iron) thermocouple above and below 77 K, respectively, within the accuracy of ±1 K.

The all complexes studied were prepared according to the method described in literature.[2] Deuterated compounds, $CaSnCl_6 \cdot 6D_2O$, $CoSnCl_6 \cdot 6D_2O$, and $NiSnCl_6 \cdot 6D_2O$, were synthesized in a dry box using deuterated hydrochloric acid and $SnCl_4$. The extent of deuteration (>95%) was checked by means of Hitachi EPI-G and 345 infrared spectrometers.

Results and Discussion

X-Ray powder patterns recorded for the complexes studied could be well interpreted by use of the reported lattice constants with the space group of $R\bar{3}$.[6,8] Only one ^{35}Cl NQR line was found in each complex studied in agreement with the crystal structure already reported. The frequencies determined at four temperatures are listed in Table 1.

The NQR frequencies observed at room temperature for the present complexes except for the Ni(II) salt agree well with the reported values.[1,2] For the Ni(II) salt, Graybeal et al.[1] reported two very closely spaced ^{35}Cl NQR frequencies. The appearance of multiplet structure for the resonance line of the Mg(II) and Ca(II) salts at lower temperatures was also pointed out by the same authors. However, only a broad single line could be observed for the Ni(II) salt at all temperatures studied and for the Mg(II) and Ca(II) salts even at lower temperatures. Although the existence of phase transitions above room temperature had been reported for the Ca(II) salt,[6] no heat anomaly was observed in the present DTA measurements up to the fade-out temperature of the NQR signal (≈390 K).

The Mg(II) and Ca(II) salts gave a very broad signal at 77 K. With increasing temperature, the signals became gradually sharp. A broad and intense ^{35}Cl NQR signal was observed for the remaining complexes at 77 K and for the Ni(II) salt even at 4.2 K. This means that no saturation effect was observed for the Ni(II) salt because of the presence of paramagnetic ions in the crystal. With increasing temperature, the resonance frequencies of these paramagnetic com-

Table 1. ^{35}Cl Nuclear Quadrupole Resonance Frequencies in Some Hexachlorostannates(IV) Crystallized with Hexahydrated Divalent Cations Observed at Several Temperatures

a) ±0.005 MHz. b) ±0.010 MHz. c) at 4.2 K.

plexes increased rather rapidly.

For $CoSnCl_6 \cdot 6D_2O$, two ^{35}Cl resonance lines in place of a single line could be observed at first. The complex freshly prepared yielded two broad resonance lines at 15.75 and 15.90 MHz at room temperature. Immediately after the first annealing at ca. 450 K, only the high frequency line could be observed. However, no resonance could be detected with the above same sample after six months. The crystals which gave only the strong and sharp low-frequency line was obtained by the second annealing at ca. 410 K. This crystalline state showing the low-frequency line was stable and the high-frequency line could not be detected any more throughout the measurements of the temperature dependence of NQR frequencies as well as even after six months. For $CoSnCl_6 \cdot 6D_2O$, the data of this crystalline state are indicated in Table 1 and in Fig. 1. No such anomaly due to annealing could be observed for $CoSnCl_6 \cdot 6H_2O$ and the other complexes studied. A similar phenomenon has been also observed for $MnPtCl_6 \cdot 6D_2O$.[7]

It is interesting to note that the resonance frequency observed at 77 K for these complexes decreases in the order of Ca(II), Mg(II), Mn(II), Co(II), and Ni(II), which approximately coincides with the order of increasing electronegativities.[9,10] According to the X-ray analysis of $CaSnCl_6 \cdot 6H_2O$, each chloride ion has three neighboring hydrogens which exist nearly on the plane including the chloride ion and perpendicular to the Sn–Cl bond axis. Let the bond axis be the z axis. Then, the three hydrogens are nearly on the xy plane. Since each hydrogen of water molecules is polarized positively, the hydrogen bearing a fractional positive charge will draw out the $3p_x$ or $3p_y$ electrons of the chloride ligand to the higher orbitals. This means that the $3p_x$ and/or $3p_y$ electron cloud will be expanded and the unbalanced p electrons of the chloride ligand decrease leading to a decrease of the ^{35}Cl NQR frequency. The lone-pair electrons of water molecules attached to a more electronegative divalent cation may be drawn out more strongly to the cation resulting in an increase of a fractional positive charge on the hydrogens. In other words, those water molecules form stronger hydrogen bonds with the chloride ligands at lower temperatures, where the motion of water molecules and/or complex anions can be neglected. This is an explanation of the correlation between the ^{35}Cl NQR frequencies observed at 77 K and the electronegativity of the divalent cations in these complexes.

With increasing the temperature from ca. 100 K, the ^{35}Cl NQR frequency of the all complexes except for the Mg(II) and Ca(II) salts increased and also its temperature coefficient became larger. This effect is remarkable especially for the Mn(II), Co(II), and Ni(II) salts which yield lower NQR frequencies at lower temperatures as can be seen in Fig. 1. The Mg(II) salt showed a maximum of the NQR frequency at ca. 450 K, above which temperature the frequency decreased with increasing temperature. The NQR frequency of the Ca(II) salts decreased with increasing temperature above 77 K. However, $CaSnCl_6 \cdot 6H_2O$ yielded a broad minimum and a maximum at ca. 250 and ca. 380 K,

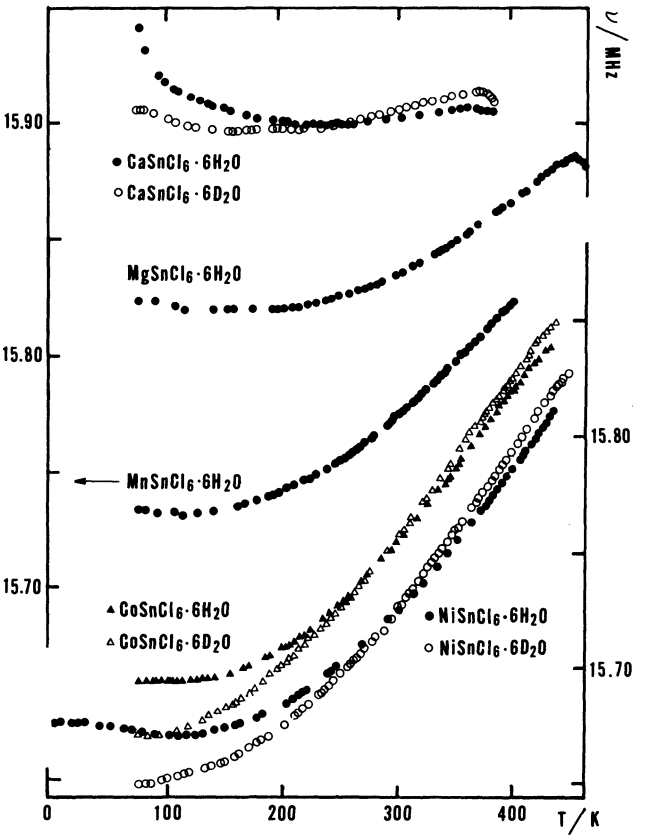

Fig. 1. Temperature dependence of ^{35}Cl NQR frequencies in the crystals of $MSnCl_6 \cdot 6H_2O$ [M(II): Mg, Ca, Mn, Co, Ni] and $MSnCl_6 \cdot 6D_2O$ [M(II): Ca, Co, Ni] observed above 77 K. For $NiSnCl_6 \cdot 6H_2O$, measurements were extended down to 4.2 K.

respectively, while $CaSnCl_6 \cdot 6D_2O$ yielded them at ca. 170 and 385 K, respectively. These results can be explained as follows.

At first, we discuss about the above results only on the usual ^1H hydrated complexes. With increasing temperature, the motions of water molecules, which are mainly librational motions are thought to be excited and the hydrogen bonding can be considered to be weakened gradually. This leads to an increase of the NQR frequency for the present type of hydrogen bonding.[5,11] For the Mn(II), Co(II), and Ni(II) complexes, the effect due to the weakening of hydrogen bonding prevails over the normal Bayer effect[12] yielding a positive temperature coefficient up to each fade-out temperature of the NQR frequencies. For the Mg(II) salt, the former effect dominates against the latter below the maximum temperature whereas the latter does above the temperature. The Ca(II) salts probably having the weakest hydrogen bonds among the present complexes show the smallest contribution to the temperature dependence from the hydrogen-bond effect. At high temperatures, the resonance frequencies of these complexes seem to converge upon ca. 15.85 MHz. This is considerably large among various complexes having $[SnCl_6]^{2-}$ ions ever studied at room temperature[2,4] and may be the resonance frequency of the complex anion crystallized with large cations. The cation size effect in complexes was already

discussed.[13]

For the deuterated analogs of the Ca(II), Co(II), and Ni(II) complexes, the temperature dependence of ^{35}Cl NQR frequencies was also studied. In these complexes, it was commonly observed that the resonance frequencies determined for each deuterated analog at lower temperatures were smaller than those of the corresponding protonated complex. However, each deuterated analog showed slightly larger NQR frequencies at higher temperatures than the corresponding protonated one. At 77 K, the frequency difference between the deuterated and protonated analogs of each kind is fairly large amounting to 20—30 kHz. The above isotope effect detected on the ^{35}Cl NQR frequencies of these complexes can be understood as described below.

Since the amplitude of the librations and/or the frequency of the reorientational motions of coordinated water molecules can be expected to be reduced by deuteration, the motionally averaged distance $\langle r_{H\cdots Cl}\rangle$ may become longer than the $\langle r_{D\cdots Cl}\rangle$.[14] Therefore, the ^{35}Cl NQR frequency in crystals having hydrogen bonds of the present type decreases by deuteration at lower temperatures where only low-frequency vibrations such as librations are considered to affect the NQR frequency. At higher temperatures where librations are well excited, however, the anharmonicity of the stretching vibration of water molecules appears as the most important origin of the isotope effect. Owing to the anharmonicity of the interatomic potential, the distance $r_{X\cdots Y}$ is assumed to be elongated by deuteration in a hydrogen bond system X–H···Y.[15] For this case, the NQR frequency of the present complexes is expected to increase by deuteration as really observed at high temperatures. This isotope effect was already pointed out from the ^{35}Cl NQR study to exist in some compounds involving O–H···Cl type hydrogen bonds.[16]

The authors are grateful to Mr. Hitoshi Ota for his help in preparing some complexes.

An ^{1}H NMR Study on the Motion of Guanidinium Cations in Some Crystals Formed with Tetrahedral or Octahedral Complex Anions Having Halide Ions as Ligands

Yoshihiro FURUKAWA and Daiyu NAKAMURA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received March 25, 1986)

Synopsis. The temperature dependences of ^{1}H NMR spin-lattice relaxation times were determined at 20 MHz for $[C(NH_2)_3]_2ZnX_4$ (X=Cl, Br), $[C(NH_2)_3]_2MCl_6$ (M=Sn, Te, Pt), and $[C(NH_2)_3]_2PtBr_6$. Above room temperature, the D_{3h} cation undergoes reorientational motion by 120° about the cationic C_3 axis. For $[C(NH_2)_3]_2TeCl_6$ crystals, two phase transitions were located at 312 and 373 K.

Recently, we studied the temperature dependences of ^{1}H NMR second moments and ^{1}H spin-lattice relaxation times (T_1) in various guanidinium (guH^+) salts involving simple salts such as guanidinium halides and the salts with D_{4h} tetrahalo complexes, such as tetrahaloaurates(III), and obtained information about the motion of the cation in solids.[1-3] From these investigations, it becomes apparent that with increasing temperature the cation undergoes 120° reorientations as a whole, i.e., the C_3 reorientation, about the principal axis of the D_{3h} cation. The observed activation energies (E_a) for this motion are distributed in a fairly wide range from 78 kJ mol^{-1} for (guH)Cl to 20 kJ mol^{-1} for the high-temperature phase and its supercooled state of (guH)$AuBr_4$. This is presumably due to the following reasons. The strength of hydrogen bonding formed between the cation and the counter anion is considered to vary to a large extent from salt to salt. Furthermore, steric hindrance to perform the C_3 reorientation may be largely determined by the loosely or densely packed crystal structure, where the size and/or the shape of the counter anion might play a crucial role. To clarify which is the most important factor, the accumulation of much more data is required. Therefore, the present investigation of ^{1}H T_1 has been undertaken for some guanidinium salts containing tetrahalo T_d and hexahalo O_h complex anions.

Experimental

$(guH)_2ZnCl_4$ and $(guH)_2ZnBr_4$ were prepared by adding the corresponding guanidinium halide to a hydrohalogenic acid solution of $ZnCl_2$ and $ZnBr_2$, respectively. Colorless crystals were obtained for both complexes. Colorless $(guH)_2SnCl_6$ and yellow $(guH)_2TeCl_6$ crystals were obtained by mixing a concd aqueous solution of (guH)Cl with concd hydrochloric acid solutions of $SnCl_4 \cdot xH_2O$ and TeO_2, respectively.[4,5] Orange colored crystals of $(guH)_2PtCl_6$ were obtained from $(guH)_2PtCl_4$ which had been synthesized in the previous work[1] by oxidizing it with chlorine gas in a concd hydrochloric acid solution. Reddish brown $(guH)_2PtBr_6$ crystals were prepared by adding a concd aqueous solution of (guH)Br to a concd hydrobromic acid solution of hexabromoplatinic(IV) acid. All samples prepared were identified by usual chemical analysis. Anal. Calcd for $[C(NH_2)_3]_2ZnCl_4$: N, 25.7; Cl, 43.3%. Found: N, 26.0; Cl, 43.6%. Calcd for $[C(NH_2)_3]_2ZnBr_4$: N, 16.6; Br, 63.3%. Found: N, 16.8; Br, 63.5%. Calcd for $[C(NH_2)_3]_2SnCl_6$: N, 18.6%. Found: N, 18.9%. Calcd for $[C(NH_2)_3]TeCl_6$: N, 18.3; Cl, 46.2%. Found: N, 18.5; Cl, 46.0%. Calcd for $[C(NH_2)_3]_2PtCl_6$: N, 15.9; Cl, 40.3%. Found: N, 16.2; Cl, 40.2%. Calcd for $[C(NH_2)_3]_2PtBr_6$: N, 10.6; Br, 60.3%. Found: N, 10.7; Br, 60.2%.

A pulsed NMR spectrometer[6] was employed for the measurements of the temperature dependence of ^{1}H T_1 observed at 20 MHz. A usual π-τ-$\pi/2$ pulse sequence was used for the determination of T_1. Differential thermal analysis (DTA) curves for $(guH)_2TeCl_6$ were recorded by use of a homemade apparatus.[7] Sample temperatures were determined within the accuracy of ±1 K using copper-constantan thermocouples.

Results and Discussion

The temperature dependences of ^{1}H T_1 observed at 20 MHz are shown in Fig. 1 for $(guH)_2ZnCl_4$ and $(guH)_2ZnBr_4$, and in Fig. 2 for $(guH)_2SnCl_6$, $(guH)_2TeCl_6$, $(guH)_2PtCl_6$, and $(guH)_2PtBr_6$. All of these complexes showed a single ^{1}H T_1 minimum above room temperature having approximately the same T_1 minimum value. The present complexes except $(guH)_2TeCl_6$ yielded usual T_1 curves explainable by the simple BPP theory.[8] The ^{1}H T_1 curve of $(guH)_2TeCl_6$ showed anomalies suggesting the presence of phase transitions.

When $(guH)_2TeCl_6$ was heated from room temperature, ^{1}H T_1 observed decreased monotonously up to ca. 315 K where it increased discontinuously. With further increasing temperature, $\log T_1$ again decreased linearly with decreasing T^{-1} although it decreased discontinuously at 373 K. Above this temperature, $(guH)_2TeCl_6$ yielded a usual BPP curve.

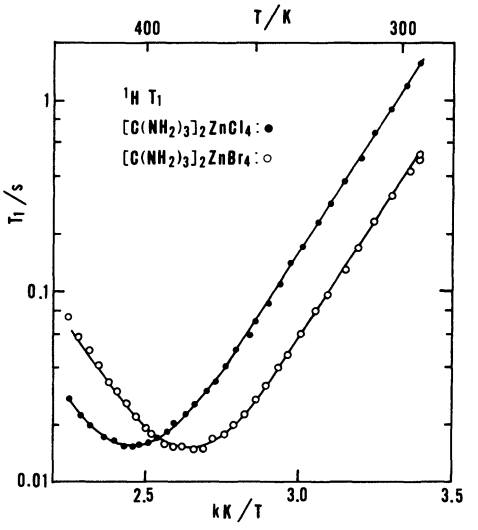

Fig. 1. Temperature dependences of ^{1}H T_1 determined at 20 MHz for guanidinium tetrachloro- and tetrabromozincate(II). Best-fitted BPP curves are depicted by solid line.

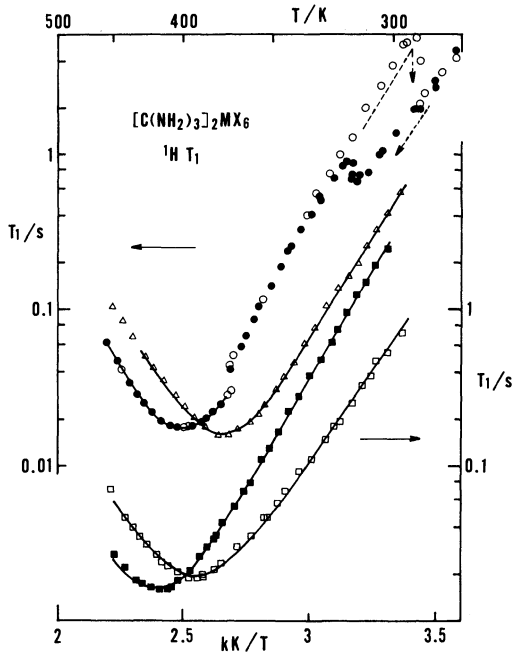

Fig. 2. Temperature dependences of ^1H T_1 determined at 20 MHz for $[C(NH_2)_3]_2SnCl_6$ (△), $[C(NH_2)_3]_2PtCl_6$ (■), and $[C(NH_2)_3]_2PtBr_6$ (□). The data of $[C(NH_2)_3]_2TeCl_6$ are also plotted by ● and ○ for the heating and cooling runs, respectively. Best-fitted curves are indicated by solid line. Broken lines with arrows show heating and cooling processes.

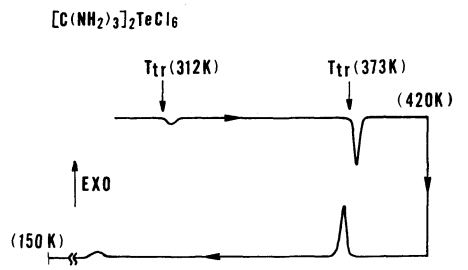

Fig. 3. DTA curves recorded for guanidinium hexachlorotellurate(IV).

When the temperature was lowered from ca. 450 K, the ^1H T_1 value observed followed the same curve down to ca. 330 K as that obtained on the heating run. Below this temperature, $\log T_1$ values obtained deviated from the curve observed on the heating run and increased almost linearly against T^{-1} down to ca. 290 K. Around this temperature, ^1H T_1 shortened drastically to the value which was observed on the heating run. Below this temperature, $\log T_1$ increased linearly with increasing T^{-1}.

To confirm the occurrence of phase transitions and to determine the phase-transition temperature, T_{tr}, DTA experiments were carried out for $(guH)_2TeCl_6$ (see Fig. 3). When the sample was heated, small and large endothermic peaks appeared at 312 and 373 K, respectively. With decreasing temperature, exothermic anomalies corresponding to the above ones were detected at 372 and near 290 K. Since the latter heat anomaly was weak and broad, a definite transition temperature could not be located on the cooling run. However, it can be said that this phase transition shows marked hysteresis phenomenon as was also observed in the foregoing T_1 experiments. Thermal hysteresis could also be detected for the high-temperature phase transition. Accordingly, it is concluded from the DTA experiments that $(guH)_2TeCl_6$ crystals undergo two first-order phase transitions at 312 and 373 K.

Table 1. ^1H T_1 Minimum Value, $T_{1\,min}$, Observed at 20 MHz, Activation Energy, E_a, and Correlation Time, τ_0, Obtained from T_1 Measurements for the C_3 Reorientation of Guanidinium Ions in the Crystals of Several Complexes

Compound (phase)	$T_{1\,min}$/ms	E_a/kJ mol^{-1}	τ_0/s
$[C(NH_2)_3]_2ZnCl_4$	16	48	3.2×10^{-15}
$[C(NH_2)_3]_2ZnBr_4$	15	48	1.0×10^{-15}
$[C(NH_2)_3]_2PtCl_6$	16	53	1.2×10^{-15}
$[C(NH_2)_3]_2PtBr_6$	19	45	5.2×10^{-15}
$[C(NH_2)_3]_2SnCl_6$	16	52	3.9×10^{-16}
$[C(NH_2)_3]_2TeCl_6$ (highest-temp.)	17	57	2.2×10^{-16}

The all complexes investigated yielded a single T_1 minimum, the values of which were in the range of 15—19 ms. These values are approximately the same as those found for various guanidinium salts already studied.[1-3,9,10] In the preceding works, those T_1 minima could be attributed to the C_3 reorientation of the cation as a whole about its principal axis on the basis of the theoretical value calculated for the cation using the geometrical values obtained by the X-ray analysis of $(guH)ClO_4$.[2,3,9,10] Therefore, each T_1 minimum detected in the present complexes can be assigned to the magnetic dipolar relaxation due to the cationic C_3 reorientations.

Since guH^+ cations include $-NH_2$ groups in which two kinds of magnetic nuclei, ^1H and ^{14}N, exist although ^{14}N nuclei have a small magnetic moment, we should take into account two kinds of magnetic dipolar interactions, ^1H-^1H and ^1H-^{14}N, to calculate motionally averaging ^1H T_1. Therefore, the observed ^1H T_1 can be written for the present complexes as,[2,8]

$$T_1^{-1} = C\left(\frac{\tau}{1+\omega_H^2\tau^2} + \frac{4\tau}{1+4\omega_H^2\tau^2}\right) + C'\left[\frac{\tau}{1+(\omega_H-\omega_N)^2\tau^2} + \frac{3\tau}{1+\omega_H^2\tau^2} + \frac{6\tau}{1+(\omega_H+\omega_N)^2\tau^2}\right]. \quad (1)$$

Here, ω_H and ω_N denote the Larmor frequencies of a proton and a ^{14}N nucleus, respectively. The motional constants, C and C', are determined by the dipolar interactions operative between protons and between the hetero nuclear spins, respectively. The correlation time, τ, of the motion is assumed to obey the Arrhenius relationship,

$$\tau = \tau_0 \exp(E_a/RT), \quad (2)$$

where E_a and τ_0 are the activation energy for the motion of the cation and its correlation time at the limit of infinite temperature.

The ^1H T_1 values observed at various temperatures for each complex except $(guH)_2TeCl_6$ were fitted to Eqs. 1 and 2 by changing the values of E_a and τ_0 as adjustable parameters. The calculation was performed using a personal computer Model PC-9801 from NEC by the least-squares method using a program written by us. For $(guH)_2TeCl_6$, the same method of fitting calculation was used for the ^1H T_1 values obtained in the highest-temperature phase. However, only the E_a values of this complex were roughly estimated from the gradient of each linear portion of $\log T_1$ vs. T^{-1} curves observed in the middle- and low-temperature phases as 60 and 42 kJ mol^{-1}, respectively. It is interesting to note that the low-temperature phase of $(guH)_2TeCl_6$, which is stable below room temperature, has the considerably smaller E_a than those estimated for the higher-temperature phases. This suggests that $(guH)_2TeCl_6$ forms more loosely packed crystals in the low-temperature phase as compared with those at the other high-temperature phases.

The best-fitted curves calculated by the least-squares method are shown by solid lines in Figs. 1 and 2. The most probable values of E_a and τ_0 are listed in Table 1 along with the observed T_1 minimum values.

For the C_3 reorientation of the cation in the crystal of $(guH)_2ZnCl_4$ and $(guH)_2ZnBr_4$, the same E_a value was observed as 48 kJ mol^{-1}. Although the anionic size of the former is smaller than the latter and the ionic characters of halide ligands estimated from the NQR frequencies reported are fairly small,[11] both complexes exhibit rather small and the same E_a value. This suggests that the size difference of the complex anions and the formation of hydrogen bonding between the cations and halide ligands give negligible effect on the hindering barrier of the cationic C_3 reorientation. Among octahedral complexes, only $(guH)_2PtBr_6$ gave fairly small E_a. This suggests that the cations placed in the large openings surrounded by the bulky anions which practically determine the lattice, can be reoriented more easily than those in the crystals of the hexachloro complexes. Hindering barrier for the C_3 reorientation of the cation due to hydrogen bonding between $-NH_2$ groups and the ligands may be neglected because $(guH)_2SnCl_6$ having more ionic ligands than $(guH)_2PtCl_6$[12] gives lower E_a. Since no information about the crystal structure of the present complexes is available, no further discussion can be made.

Vacuum Sublimation Behavior of Iron(III), Cobalt(II), Nickel(II), Copper(II), and Palladium(II) Chelates with Tetradentate *N,N'*-Disalicylideneethylenediamine and *N,N'*-Bis(1-methyl-3-oxobutylidene)ethylenediamine

Takaharu Honjo* and Kazuhiko Nukui
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920
(Received February 10, 1986)

Synopsis. A vacuum sublimation apparatus with a continuous temperature gradient (25—200°C) along the tube (50—0cm) at 2×10^{-2} Torr (1 Torr=133.322 Pa) was used. *N,N'*-disalicylideneethylenediamine, *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediamine and its metal chelates (Fe^{III}, Co^{II}, Ni^{II}, Cu^{II}, and Pd^{II}) were sublimed without thermal decomposition, while the chelates of Fe^{III}, Co^{II}, Ni^{II}, Cu^{II}, and Pd^{II} with *N,N'*-disalicylideneethylenediamine were thermally stable, but did not sublime completely.

The vacuum sublimation method is useful for the purification and separation of metal chelates of 4-anilino-3-penten-2-one, 2,4-pentanedione, dithiocarbamates, 8-quinolinol and its derivatives, dimethylglyoxime, diphenylthiocarbazone, 1-(2-pyridylazo)-2-naphthol, 5,10,15,20-tetraphenylporphyrin, and 1,1,1-trifluoro-4-(2-thienyl)-4-mercapto-3-buten-2-one.[1-3] Of the metal chelates described above, bidentate shiff base chelates of β-imino ketones, such as 4-anilino-3-penten-2-one, were accompanied by remarkable thermal decompositions during the sublimation process; however, the sublimation-recrystallization temperatures of these chelates were found in the lower-temperature region of all the chelates studied. The present research aims to investigate the tetradentate ligands of *N,N'*-disalicylideneethylenediamine and *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediamine for the purification of metals in milligram amounts (as their chelates) by a vacuum sublimator with a continuous temperature gradient under low pressure. Some of these chelates in nanogram amounts have already been evaluated by gas chromatography, mainly for Cu^{II}, Ni^{II}, and Pd^{II}.[4]

Experimental

Materials. The shiff bases of *N,N'*-disalicylideneethylenediamine and *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediamine were easily prepared by the condensation of ethylenediamine with salicylaldehyde in ethanol or with 2,4-pentanedione (directly), as described previously.[5]

Metal chelate compounds with these ligands were generally prepared by the addition of an ethanolic solution of the corresponding chelating reagent to an aqueous ammonia solution of each metal salt at room temperature, or by heating if necessary. This has been previously mentioned.[5,6] These materials were purified by recrystallization from ethanol or by vacuum sublimation before use.

Sublimation Procedure. A vacuum sublimation apparatus which provided a continuous temperature gradient (25—200°C) along the tube (50—0cm) at 2×10^{-2} Torr was used, as previously described.[1] The temperature gradient along the sublimator is shown in Fig. 1; this was obtained after thermal equilibrium for 4 h. These patterns were obtained by supplying the following electric power through the heating mantle, 16V, 8V, and 3V at 1.0A. Metal chelates were placed inside the apparatus for 5.5 h after establishing thermal equilibrium. The sublimate zone along the sublimation tube was decided from the color of the chelate and its deposition position. The thermal conditions of the sublimator were always checked from the sublimation zone of a definite amount of copper(II) acetylacetonate after sublimating it by another sublimation tube with the metal chelates to be investigated. The sublimation-recrystallization zone temperatures of copper(II) acetylacetonate (in 12-mg amounts) were 89—60°C at 0.02 Torr, 120—66°C at 0.1 Torr, and 162—158°C at 7 Torr, respectively.

Results and Discussion

The temperature range of the deposited zones, the recovery, and the colors of the various metal chelates after sublimation are summarized in Table 1.

N,N'-Disalicylideneethylenediamine, and *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediamine and its metal chelates (Fe^{III}, Co^{II}, Ni^{II}, Cu^{II}, and Pd^{II}) were sublimed without any thermal decomposition, while the chelates of Fe^{III}, Co^{II}, Ni^{II}, Cu^{II}, and Pd^{II} with *N,N'*-disalicylideneethylenediamine were thermally stable, but did not sublime completely. This fact may have been caused by the rate of sublimation of the chelate compounds, which depends upon the temperature established at the high-temperature end of the sublimator. The sublimation-recrystallization temperature of individual chelates generally increased in the following order: $Fe^{III}<Cu^{II}<Ni^{II}$, $Co^{II}<Pd^{II}$. The sublimation-recrystallization zones for metal chelates of Fe^{III}, Cu^{II}, Co^{II}, Ni^{II}, and Pd^{II} with *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediamine in varying quantities are graphically presented in Fig. 2. In general, the sublimation-recrystallization distance gave shorter values with an increase in quantity of the chelates. In cases where the recrystallization-zone pattern was not uniform, the deposition zones (where over 90% of the chelates were

found) are indicated by a thicker lines.

Representative photomicrographs of metal chelates with *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediamine deposited on the glass wall inside the sublimation tube are given in Fig. 3. Metal chelates of Co^{II}, Ni^{II}, and Pd^{II} form stereoradial needle-like crystals, and Fe^{III} chelate forms hexahedral crystals. A copper chelate forms two kinds of crystals; a purple planar needle-like crystal at the lower-temperature side, and a green plate crystal at the higher-temperature side, when sublimating it in more than 5 mg amount. Both crystals are purple in their powder states. Therefore, it is clear that sublimation is useful for the purification of milligram amounts of each metal chelate since large-sized crystals can be obtained.

Synopsis. The reaction of nickel(II) chloride hexahydrate and ethyl α-(hydroxyimino)acetoacetate with ethylenediamine or (*R*)-propylenediamine gives [diethyl *N,N'*-ethylenebis(2-hydroxyimino-3-iminobutanoato)]nickel(II) or {diethyl *N,N'*-[(*R*)-1-methylethylene]bis(2-hydroxyimino-3-iminobutanoato)}nickel(II). The nickel(II) complexes with Schiff base ligands were characterized by their electronic absorption, ^{13}CNMR, infrared, and CD spectra.

In the metal complexes with α-hydroxyimino β-diketone or its derivatives, it has been known that two coordination modes are possible for the hydroxyimino group.[1-8] Namely, the ligands coordinate to a metal ion through the nitrogen of the hydroxyimino group to form a five-membered ring or through the oxygen of the group to form a six-membered one. In the previous paper,[9] we reported some properties of the palladium(II) complexes with diethyl *N,N'*-ethylenebis(2-hydroxyimino-3-iminobutanoate), (ieaa)$_2$-en, and ethyl 3-[(*R*)-2-aminopropylimino]-2-hydroxyiminobutanoate, (ieaa)-(*R*)-pn,[10] in which the hydroxyimino group coordinates to palladium(II) ion through the nitrogens. It is of interest that the (ieaa)$_2$-en was formed as a quadridentate ligand and the (ieaa)-(*R*)-pn as a terdentate one, though a similar reaction was adopted.[9] In order to examine the difference in formation, the preparation of the nickel(II) complexes with Schiff base ligands, which are derived from the reaction of ethyl α-(hydroxyimino)acetoacetate, ieaa, with the ethylenediamine or (*R*)-propylenediamine, was attempted. The resulting nickel(II) complexes are characterized by the electronic absorption, ^{13}CNMR, infrared, and CD spectra.

Experimental

Materials. Ethyl α-(hydroxyimino)acetoacetate was prepared by nitrosation of ethyl acetoacetate with sodium nitrite according to the method of Adams.[11] Nickel(II) chloride hexahydrate and the other reagents used were obtained from the Wako Pure Chemicals Ind. Co., Ltd.

Preparation of Complexes. 1) [Diethyl *N,N'*-Ethylenebis(2-hydroxyimino-3-iminobutanoato)]nickel(II): [Ni{(ieaa)$_2$-en}]. Nickel(II) chloride hexahydrate (0.65 g, 0.005 mol) and ieaa (3.2 g, 0.02 mol) were dissolved in 70 cm^3 of 1-propanol, and 0.7 cm^3 of ethylenediamine was added to it. After reflux for 45 min, the red precipitate which appeared was collected by filtration. The crude product was recrystallized from chloroform and dried in a vacuum desiccator. The orange red needle crystals obtained were insoluble in water, but soluble in methanol, dimethyl sulfoxide (DMSO), and chloroform. Found: C, 41.97; H, 5.02; N, 14.03%. Calcd for $NiC_{14}H_{20}N_4O_6$: C, 42.14; H, 5.05; N, 14.04%.

2) {Diethyl *N,N'*-[(*R*)-1-Methylethylene]bis(2-hydroxyimino-3-iminobutanoato)}nickel(II): [Ni{(ieaa)$_2$-(*R*)-pn}]. Nickel(II) chloride hexahydrate (0.65 g, 0.005 mol) and ieaa (3.2 g, 0.02 mol) were dissolved in 80 cm^3 of absolute ethanol, and 0.8 cm^3 of (*R*)-propylenediamine and 10 drops of 28% aqueous ammonia were added to it. After reflux for 72 h, the reaction mixture was stood in a refrigerator for 48 h. The crystals which appeared were collected by filtration, washed three times with small amounts of cold ethanol, and dried in a vacuum desiccator. The red fine crystals obtained were also insoluble in water, but soluble in methanol, DMSO, and chloroform. Found: C, 43.60; H, 5.35; N, 13.70%. Calcd for $NiC_{15}H_{22}N_4O_6$: C, 43.61; H, 5.36; N, 13.56%.

Measurements. The electronic absorption spectra were recorded with JASCO UVIDEC-1 and UVIDEC-610 spectrophotometers and the CD spectra with a JASCO J-20 and J-500 spectropolarimeters. All measurements were carried out at room temperature. The ^{13}CNMR spectra were recorded in $CDCl_3$ with a JEOL JNM-FX-100 or -FX-90Q NMR spectrometer at the probe temperature. Tetramethylsilane was used as an internal reference. The infrared spectra were recorded with a Hitachi 260-50 infrared spectrophotometer using the KBr disk method. The elemental analyses were carried out in the Analysis Center of the University of Tsukuba.

Results and Discussion

Only an orange red needle crystalline complex was formed by the reaction of nickel(II) chloride hexahydrate and ieaa with ethylenediamine in 1-propanol. The elemental analytical result suggests the formation of the nickel(II) complex containing (ieaa)$_2$-en type Schiff base as a quadridentate ligand, [Ni{(ieaa)$_2$-en}], as in the case of [Pd{(ieaa)$_2$-en}].[9] Although two kinds of structure, square planar and tetrahedral, are possible for this nickel(II) complex, the ^{1}H and ^{13}CNMR spectral behaviors seem to prefer the former to the latter (vide infra). This is supported by the fact that the present nickel(II) complex exhibits a quite similar absorption spectral behavior to the square planar nickel(II) complexes with Schiff base ligands such as 3-hydroxyimino-4-imino-2-pentanone (iaa-NH),[5] 2-hydroxyimino-3-imino-1-phenyl-1-butanone (iba-NH),[6] ethyl 2-hydroxyimino-3-iminobutanoate (ieaa-NH),[12] their *N*-alkyl derivatives (iaa-NR, iba-NR, and ieaa-NR; R=CH_3, C_2H_5, *n*-C_3H_7, and so on),[5,6,12] (*R*)-*N,N'*-disalicylidene-1,2-propanediamine, and its derivatives (Fig. 1).[13,14]

For the square planar nickel(II) complex, three geometrical isomers with respect to the coordination modes of the hydroxyimino groups of the ieaa moieties are possible as shown in Fig. 2. The ^{13}CNMR spectrum of [Ni{(ieaa)$_2$-en}] exhibits eight resonance lines for the four methyl (14.1, 14.2, 17.4, and 18.5 ppm) and four

†Present address: Department of Chemistry, The 3rd Military Academy, Youngchun, 671-09, Korea.

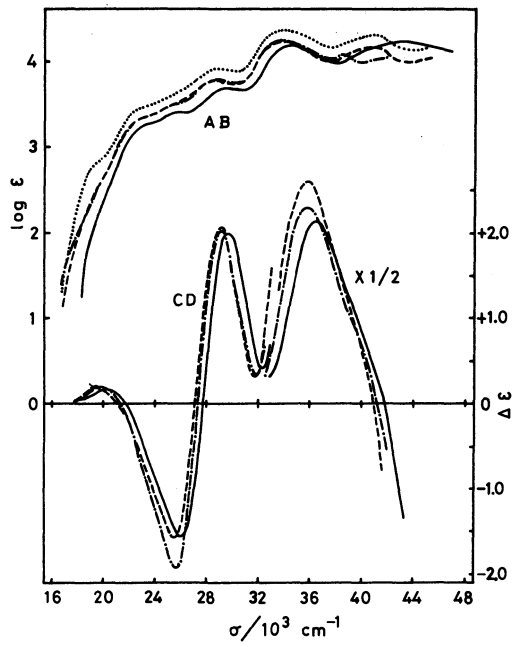

Fig. 1. Absorption spectrum of [Ni{(ieaa)$_2$-en}] in chloroform (·····), and absorption and CD spectra of [Ni{(ieaa)$_2$-(*R*)-pn}] in chloroform (------), in DMSO (—·—·—·—), and in methanol (———).

methylene carbon atoms (48.6, 59.4, 60.4, and 61.7 ppm). As seen in Fig. 2, eight resonance lines for the methyl and methylene carbon atoms are expected for the ^{13}CNMR spectrum of (b) and four resonance lines for the carbon atoms are expected for that of (a) or (c), since (b) is C_1 symmetry and (a) or (c) C_2 one. The infrared spectrum of this complex exhibits the stretching vibration bands, $\nu_{N\text{-}O}$=1260 cm^{-1}, $\nu_{C=O}$=1688 and 1706 cm^{-1}, $\nu_{Ni\text{-}N}$=503 and 541 cm^{-1}, and $\nu_{Ni\text{-}O}$=ca. 315 cm^{-1}. The infrared spectral characteristics coincide well with those of [Ni(iaa-NH)(iaa-NR)][5] or [Ni(ieaa-NR)$_2$][12] (R; H and alkyl groups), in which one ligand coordinates through the nitrogen of the hydroxyimino group and the other through the oxygen. These ^{13}CNMR and infrared spectral characteristics indicate that the present nickel(II) complex takes the form (b) in Fig. 2, namely, one of the two hydroxyimino groups coordinates to nickel(II) ion through the nitrogen to form a five-membered chelate ring and the other through the oxygen to form a six-membered one.

Nickel(II) chloride hexahydrate reacted with ieaa and (*R*)-propylenediamine in basic ethanol to give one product as in the case of [Ni{(ieaa)$_2$-en}]. The analytical result of this complex suggests that one diethyl *N,N'*-[(*R*)-1-methylethylene]bis(2-hydroxyimino-3-iminobutanoate) ligand, (ieaa)$_2$-(*R*)-pn, coordinates to a nickel(II) ion, and the nickel(II) complex exhibits a quite similar absorption spectrum to [Ni{(ieaa)$_2$-en}] (Fig. 1). Further, its infrared spectral bands also agree well with those of the (ieaa)$_2$-en complex; $\nu_{N\text{-}O}$=1255 cm^{-1}, $\nu_{C=O}$=1673 and 1710 cm^{-1}, $\nu_{Ni\text{-}N}$=506 and 538 cm^{-1}, and $\nu_{Ni\text{-}O}$=ca. 325 cm^{-1} (stretching vibrations). These facts suggest that the quadridentate ligand in [Ni{(ieaa)$_2$-(*R*)-pn}] takes a similar coordination mode to that in [Ni{(ieaa)$_2$-en}] ((b) in Fig. 2). The ^{13}CNMR spectrum

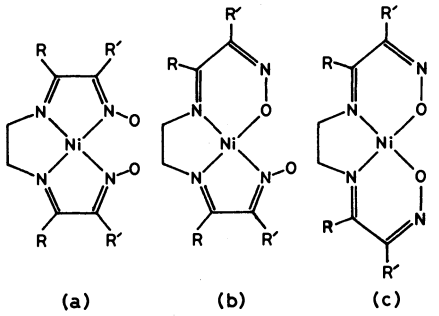

Fig. 2. Possible geometrical isomers of the square planar configuration for [Ni{(ieaa)$_2$-en}]; R=CH_3 and R'=$CO_2C_2H_5$.

of [Ni{(ieaa)$_2$-(*R*)-pn}] exhibits seven resonance lines due to the methyl carbon atoms and eight resonance ones due to the methylene carbon atoms. This ^{13}CNMR spectral behavior seems to indicate that the nickel(II) complex is a composite of two possible isomers, which are caused by the configuration due to the methyl group of the (*R*)-propylenediamine moiety of (b) in Fig. 2.

When the absorption and/or CD spectra of [Ni{(ieaa)$_2$-en}] and [Ni{(ieaa)$_2$-(*R*)-pn}] are compared with those of the square planar nickel(II) complexes with the quadridentate Schiff base ligands such as (*R*)-*N,N'*-disalicylidene-1,2-propanediamine (sal-(*R*)-pn),[10,13,14] their absorption bands are assigned as follows; the intense bands at ca. 34 and 40×10^3 cm^{-1} originate from the π-π* transitions due to the coordinated (ieaa)$_2$-en or (ieaa)$_2$-(*R*)-pn, other three intense bands at 22—29×10^3 cm^{-1} from the charge transfer, and the shoulder at ca. 19.5×10^3 cm^{-1} from the d-d transition. In the region of 18—38×10^3 cm^{-1}, the absorption and/or CD spectral patterns of [Ni{(ieaa)$_2$-en}] and [Ni{(ieaa)$_2$-(*R*)-pn}] were almost unaffected by nature of the solvents such as chloroform, dimethyl sulfoxide, methanol, and pyridine (Fig. 1).

In contrast to [Ni{(ieaa)$_2$-(*R*)-pn}], the corresponding palladium(II) complex, [Pd{(ieaa)$_2$-(*R*)-pn}], could not be formed by a reaction similar to that for the nickel(II) complex, but the palladium(II) complex with a terdentate Schiff base ligand, [Pd(Cl){(ieaa)-(*R*)-pn}], was formed.[9] This difference in the formation of the (*R*)-pn Schiff base ligand between the palladium(II) and nickel(II) complexes is presumably related to the affinity of chloride,[15] which is lower to nickel(II) ion than to palladium(II) ion, and to the adaptability of the strained quadridentate Schiff base ligand with (*R*)-propylenediamine backbone ring, which coordinates more easily to nickel(II) ion capable of taking distorted square planar structure than to palladium(II) ion.

Cyclic Peptides. XXIII.[1] Synthesis of Retro-Enantio-AM-Toxin I

Hisakazu MIHARA,* Haruhiko AOYAGI, Tamio UENO,† Tetsuo KATO, and Nobuo IZUMIYA
Laboratory of Biochemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812
† Pesticide Research Institute, College of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received March 15, 1986)

Synopsis. To characterize a receptive substance in an apple leaf of phytotoxic AM-toxin I, retro-enantiomer of the toxin was synthesized by the solution method. This analog showed no toxic activity, indicating that the specific backbone conformation of the toxin is essential for the activity.

AM-toxins are host-specific phytotoxic metabolites produced by *Alternaria mali*, which cause spot disease on apple leaves. The structure of AM-toxin I is a cyclic tetradepsipeptide as shown in Fig. 1.[2] We have synthesized various analogs of AM-toxin I and examined their necrotic activities on apple leaves in order to study the relationships between structure and activity of the toxin. We have found that the following factors are important for the induction of the full toxic activity: i) the specific ring conformation,[3] ii) bulkiness of the isopropyl side chain of the L-Hmb[4] residue at position 2,[5] iii) the exact side chain length of the L-Amp residue at position 3,[6] iv) the presence of the ΔAla residue at position 4.[7] The size of side chain of the L-Ala residue at position 1 is not critical to the toxic activity.[8] Thus, AM-toxin I holds a unique structure which can not be easily handled by chemical modifications without loss of the activity. Previously, we illustrated a scheme on interaction between AM-toxin I and a possible receptive substance in the sensitive apple leaf.[6] In this connection, we attempted to design a compound which could characterize the receptive substance.

The cycloretro-enantiomer is a cycloisomer which has unique topochemical relations to the parent cyclic peptide as follows: both are equivalent in the spatial arrangement of various side chains, but reversed in the chirality of each center and the direction of the amide bonds. As the first step of receptor study, we tried to synthesize retro-enantio-AM-toxin I (**1**, Fig. 1) and examined its necrotic activity on an apple leaf. Compared with the sequence of AM-toxin I, the retro-enantio-AM-toxin I (**1**) should have inversed chirality of each center and reversed direction of amide and ester bonds. Therefore, the retro-enantiomer contains D-Val and D-Lac instead of L-Hmb and L-Ala, respectively, in AM-toxin I. Topochemical arrangement of each side chain in **1** is equivalent to that in AM-toxin I.

The synthetic route for retro-enantiomer (**1**) is shown in Fig. 2. In a preliminary study, according to the successful synthesis of AM-toxin I—III and AM-toxin analogs,[5-8] a linear tetradepsipeptide H-D-Amp-D-Val-D-Lac-D-Dpr(Z)-ONSu (**11**), in which the ester bond was placed at the center was selected for cyclization. Cyclization of **11**, however, gave the desired cyclic tetradepsipeptide 9 in a very low yield (4%). Main product of this reaction was a 2,5-piperazinedione *cyclo*(-D-Amp-D-Val-) identified with mass spectrum and

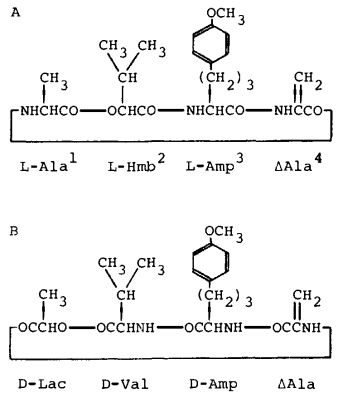

Fig. 1. Structure of AM-toxin I (A) and its retro-enantiomer (**1**, B).

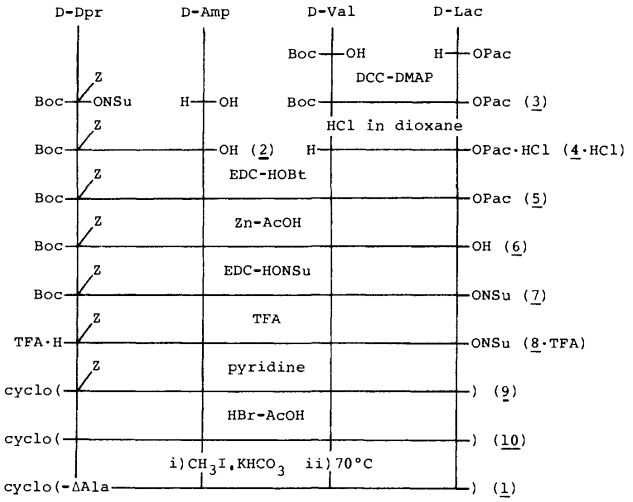

Fig. 2. Synthesis of retro-enantio-AM-toxin I.

elemental analysis. This may be due to preferential ability to form the 2,5-piperazinedione from H-D-Amp-D-Val-OR. In the previous studies,[5-8] such a by-product was not found in cyclization of linear tetradepsipeptide, e.g., H-D-Dpr(Z)-L-Ala-L-Hmb-L-Amp-ONSu.

Therefore, the sequence of a linear tetradepsipeptide as the precursor of 9 was changed to H-D-Dpr(Z)-D-Amp-D-Val-D-Lac-ONSu (**8**), in which the D-Lac residue was placed at the C-terminal to avoid the 2,5-piperazinedione formation, as shown in Fig. 2. Boc-D-Dpr(Z)-ONSu was coupled with D-Amp to give Boc-D-Dpr(Z)-D-Amp-OH (**2**). Boc-D-Val-D-Lac-OPac (**3**) was prepared from Boc-D-Val-OH and D-Lac-OPac with DCC-DMAP.[9] Boc group in **3** was removed with HCl followed by condensation with **2** to give Boc-tetradepsipeptide-OPac (**5**). After Pac group was removed with Zn-AcOH, the resulting acid (**6**) was

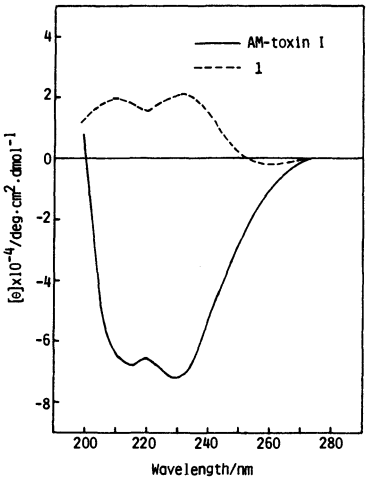

Fig. 3. CD spectra of AM-toxin I and its retro-enantiomer (**1**) in MeOH.

converted to the corresponding active ester (**7**) and its Boc group was removed with TFA to give the active ester trifluoroacetate (**8**·TFA). Cyclization of **8** at a concentration of 3 mM in pyridine gave the cyclic peptide **9** in a yield of 37% from **7**. After deprotection of Z group in **9** with HBr–AcOH, the resulting HBr salt was treated with CH_3I and $KHCO_3$[10] to give the desired **1**. The yield of **1** from **9** was 17% comparable to the yields in previous syntheses of AM-toxins.[5-8]

CD spectra of the retro-enantiomer **1** and AM-toxin I in MeOH are shown in Fig. 3. Although AM-toxin I showed double minima of negative molar ellipticities at 210 and 230 nm, **1** showed positive ones at similar wavelengths. The enantiomer of AM-toxin I, *cyclo*-(-D-Ala-D-Hmb-D-Amp-ΔAla-), should show positive bands with the same ellipticities at the same wavelengths as AM-toxin I. When the spectrum of the retro-enantiomer **1** was compared with that of the enantiomer, wavelengths of minima were similar each other but ellipticities of **1** were much smaller than those of the enantiomer. These results indicate that the conformation of **1** differs from that of AM-toxin I which should have the same conformation as the enantiomer, or the content of the common conformation is low in **1**.

Minimum toxic activity of AM-toxin I for the induction of necrosis on an apple leaf (Indo) was 0.001 μg ml^{-1}, while the retro-enantiomer **1** did not show any toxicity at the high concentration up to 100 μg ml^{-1}. The retro-enantiomer **1** contains each side chain topo-equivalently arranged to that of AM-toxin I, but the chirality of each center and the direction of the amide and ester bonds in **1** were reversed. Combined with the previous results,[3,5-8] the presence of each side chain in AM-toxin I is very important, but the direction of the amide and ester bonds, i.e., backbone conformation, also is essential to induce the toxic activity. This specific conformation[3] of AM-toxin I may confirm the exact orientation of each side chain, and then can reveal the full toxic activity.

Experimental

Thin layer chromatography was carried out on Merck silica gel G with the following solvent system: R_f^1, $CHCl_3$–MeOH (5:1); R_f^2, $CHCl_3$–MeOH (9:1); R_f^3, $CHCl_3$–MeOH–AcOH (95:5:1); R_f^4, *n*-BuOH–AcOH–pyridine–H_2O (4:1:1:2). Optical rotations were measured with a Union high sensitivity polarimeter PM-71. Mass spectra were taken on a Nihondenshi mass spectrometer Model JMS-01SG-2 with a direct inlet system operating at 75 eV, and CD on a JASCO J-40A spectropolarimeter.

Boc-D-Dpr(Z)-D-Amp-OH (2). To a solution of H-D-Amp-OH (810 mg, 3.3 mmol) and NEt_3 (0.46 ml, 3.3 mmol) in DMF (30 ml) was added a solution of Boc-D-Dpr(Z)-ONSu (1.3 g; 3.0 mmol) in DMF (5 ml). The mixture was stirred at room temperature overnight. After evaporation, 10% citric acid was added to the residue. The separated oil was extracted with EtOAc, and the solution was washed with water and dried over Na_2SO_4. After evaporation, the residue was recrystallized from EtOAc–ether–petroleum ether: yield, 1.2 g (73%); mp 141—143°C; $[\alpha]_D^{20}$ +7.9° (*c* 1, DMF); R_f^1=0.57, R_f^3=0.46. Found: C, 61.78; H, 6.86; N, 7.71%. Calcd for $C_{28}H_{37}N_3O_8$: C, 61.86; H, 6.86; N, 7.73%.

Boc-D-Val-D-Lac-OPac (3). To a chilled solution of Boc-D-Val-OH (2.2 g, 10 mmol), D-Lac-OPac[11] (2.1 g, 10 mmol) and DMAP[9] (1.2 g, 10 mmol) in CH_2Cl_2 (30 ml) was added DCC (2.1 g, 10 mmol). The mixture was stirred at 0°C for 3 h and at room temperature overnight. After evaporation, the residue was dissolved in EtOAc, washed with 10% citric acid, 4% $NaHCO_3$ and water, and dried over Na_2SO_4. After evaporation, **3** was obtained as an oil: yield, 3.4 g (83%); R_f^2=0.87, R_f^3=0.36.

H-D-Val-D-Lac-OPac·HCl (4·HCl). Compound **3** (2.9 g, 7.0 mmol) was dissolved in 4 M (1M=1 mol dm^{-3}) HCl in dioxane (20 ml). The solution was allowed to stand at room temperature for 2 h. After removal of the solvent, the evaporation was repeated several times by the addition of dioxane. The residue was crystallized by the addition of ether: yield, 2.0 g (92%); R_f^1=0.52.

Boc-D-Dpr(Z)-D-Amp-D-Val-D-Lac-OPac (5). To a chilled solution of **2** (1.2 g, 2.2 mmol), **4**·HCl (670 mg, 2.2 mmol), HOBt (450 mg, 3.3 mmol) and NEt_3 (0.31 ml, 2.2 mmol) in DMF (20 ml) was added EDC·HCl (630 mg, 3.3 mmol). The mixture was stirred at 0°C overnight. After evaporation, the residue was dissolved in EtOAc, washed with 10% citric acid, 4% $NaHCO_3$ and water, and dried over Na_2SO_4. After evaporation, the residue was recrystallized from EtOAc–ether–petroleum ether: yield, 1.5 g (83%); mp 108—110°C; $[\alpha]_D^{20}$ +35.1° (*c* 0.5, DMF); R_f^2=0.45, R_f^3=0.40. Found: C, 63.39; H, 6.79; N, 6.71%. Calcd for $C_{44}H_{56}N_4O_{12}$: C, 63.45; H, 6.78; N, 6.73%.

Boc-D-Dpr(Z)-D-Amp-D-Val-D-Lac-OH (6). To a solution of **5** (1.5 g, 1.8 mmol) in 90% AcOH (20 ml) was added Zn powder (0.5 g) at room temperature. The mixture was stirred at room temperature for 8 h. The insoluble Zn was filtered off and the filtrate was evaporated. Ten per cent citric acid was added to the residue. The separated oil was extracted with EtOAc, washed with water, and dried over Na_2SO_4. After evaporation, the residue was recrystallized from EtOAc–ether–petroleum ether: yield, 1.17 g (91%); mp 115—118°C; $[\alpha]_D^{20}$ +26.9° (*c* 0.5, DMF); R_f^1=0.55, R_f^3=0.33. Found: C, 60.64; H, 6.91; N, 7.61%. Calcd for $C_{36}H_{50}N_4O_{11}$: C, 60.49; H, 7.05; N, 7.84%.

Boc-D-Dpr(Z)-D-Amp-D-Val-D-Lac-ONSu (7). To a chilled solution of **6** (1.1 g, 1.5 mmol) and HONSu (345 mg, 3.0 mmol) in DMF (10 ml) was added EDC·HCl (575 mg, 3.0 mmol). The mixture was stirred at 0°C overnight. After evaporation, the residual solid was collected with the aid of cold water and dried in vacuo: yield, 1.2 g (98%); R_f^2= 0.53. This was used to the next step without purification.

***Cyclo*(-D-Dpr(Z)-D-Amp-D-Val-D-Lac-) (9).** A solution of **7** (1.2 g, 1.5 mmol) in TFA (5 ml) was allowed to stand

at 0°C for 30 min. After evaporation, the residual oil was solidified by the addition of ether. The powder was washed several times with ether by decantation to give H-D-Dpr(Z)-D-Amp-D-Val-D-Lac-ONSu·TFA (**8**·TFA). The powder was dissolved in DMF (10 ml) and the solution was added dropwise into pyridine (500 ml) with stirring at room temperature. The stirring was continued for 3 d and the reaction mixture was evaporated. The residue was collected with the aid of cold water, and washed with 10% citric acid and water. This was recrystallized from EtOAc-ether: yield, 330 mg (37%); mp 224—226°C (decomp); $[\alpha]_D^{20}$ +155° (*c* 0.3, DMF); MS *m/z* 596 (M^+); R_f^2=0.45, R_f^3=0.29. Found: C, 62.30; H, 6.87; N, 9.40%. Calcd for $C_{31}H_{40}N_4O_8$: C, 62.40; H, 6.76; N, 9.39%.

***Cyclo*(-ΔAla-D-Amp-D-Val-D-Lac-) (1).** Compound **9** (120 mg, 0.2 mmol) in 25% HBr in AcOH (5 ml) was allowed to stand at room temperature for 2 h. After evaporation, the residue was solidified by the addition of ether to give a powder of cyclo (-D-Dpr-D-Amp-D-Val-D-Lac-)·HBr (**10**·HBr). To a suspension of **10**·HBr in EtOAc (30 ml) were added CH_3I (2 ml) and $KHCO_3$ (400 mg), and the mixture was stirred in the dark at room temperature. The same amounts of CH_3I and $KHCO_3$ were added again 2 d later, the stirring being continued for 4 d. After removal of solvent and excess CH_3I in vacuo, the residue was suspended in EtOAc (30 ml) and the suspension was stirred at 70°C for 2 h. Insoluble material was filtered off and the filtrate was evaporated to give a crude product. The crude product was purified by silica gel column (1.1×20 cm) chromatography using $CHCl_3$-acetone (4:1) followed by recrystallization from EtOAc-ether-petroleum ether: yield, 15 mg (17%); mp 158—160°C; MS *m/z* 445 (M^+); R_f^2=0.48, R_f^3=0.36. Found: C, 61.83; H, 7.07; N, 9.01%. Calcd for $C_{23}H_{31}N_3O_6$: C, 62.01; H, 7.01; N, 9.43%.

Biological Assay. Biological assay on apple leaves (susceptible cultivar, Indo) was carried out as described previously.[6]

We thank Dr. S. Lee of this laboratory for his helpful discussion during this work, and Dr. H. Nishikawa, Fukuoka University, for the measurement of CD spectra.

Optical Resolution of Asymmetric Selenoxides by High-Performance Liquid Chromatography Using Optically Active Column

Toshio SHIMIZU and Michio KOBAYASHI*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received March 6, 1986)

Synopsis. The optical resolution of asymmetric diaryl selenoxides and the determination of the enantiomeric excess of the partially active selenoxides were found to be possible by HPLC using an optically active column.

Although optically active sulfoxides have been known for a long time, the synthesis of an optically active pure selenoxide has so far been unsuccessful. The reason for the difficulty in isolating the enantiomer of selenoxides has been attributed to either a facile racemization due to the formation of a hydrate or to a rapid pyramidal inversion of the conformation around the selenium atom. In 1983, the preparation of partially optically active selenoxides was reported for the first time, but their optical purities were only 5—11%.[1] Recently, we described a synthesis of the optically pure diastereomeric selenoxide as well as the enantiomeric selenoxide with a high optical activity.[2] The determination of the enantiomeric excess has a vital importance in studies on optical resolution. We have discovered that asymmetric diaryl selenoxides can be resolved into the antipodes and also that the optical purities of the selenoxides, in which optical rotation is unknown, can be determined by HPLC using an optically active column. Details are described in this paper.

Results and Discussion

Selenides were prepared according to published methods.[3-6] The oxidation of selenides to selenoxides was carried out with *t*-butyl hypochlorite in the presence of methanol and pyridine.[7]

An example of the general procedure is shown for the case of *p*-tolyl 2,4,6-triisopropylphenyl selenoxide (**1**). A chromatographic separation of the racemic selenoxides was performed with a Bakerbond chiral phase HPLC column RP 7103-O (250×4.6 mm) packed with DNBPG/aminopropylsilica (particle size 5 μm), similar to those which have been used for the separation of various optically active compounds,[8] using hexane containing 5 vol% of 2-propanol as the mobile phase at a flow rate of 1.0 ml min^{-1} (Fig. 1). The chromatographic separability factor of the enantiomers, α was calculated to be 1.10. The R_S value was also calculated as 1.46. The integration ratio (lower R_f/higher R_f) was 1.01. This integration value over 1.00 could be attributed to the tailing of higher R_f enantiomer.

Several diaryl and alkyl aryl selenoxides were subjected to HPLC in a similar way using an optically active column; the results are summarized in Table 1. The R_S value and the integration ratio are a measure of the capability for a chromatographic separation of the optical isomers. The R_S values of the selenoxides **1**—**6** were 1.00—1.86 and integration ratios were 1.01—1.05.

In order to investigate the effect of bulky ortho substituents to retard the rate of racemization through a conformational inversion, the separabilities of phenyl 2,4,6-trimethylphenyl selenoxide (**8**), triethyl derivative **7**, triisopropyl derivative **2**, and tri-*t*-butyl derivative **5** in the HPLC with optical active column were compared with each other. All selenoxides were found to be separable into optical isomers; however, as can be seen in Table 1, compared to selenoxides **2** and **5**, the R_S values of selenoxides **7** and **8**, which possess less bulky substituents than isopropyl or *t*-butyl groups, were small. The integration ratios of selenoxides **7** and **8** increased by over 1.00. The decrease of the chromatographic separability of latter selenoxides might be attributed to a decrease in the conformational stability. We have also attempted a resolution of alkyl aryl selenoxide **9** and benzyl aryl selenoxide **10**, which possess bulky ortho substituents. However, contrary to

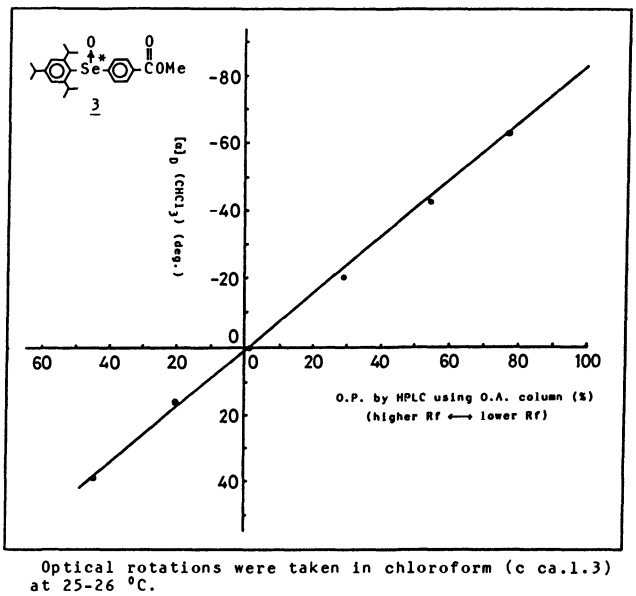
(8)		10	7.43	1.05	0.51	1.83

a) Ar is 2,4,6-triisopropylphenyl group. b) Ar′ is 2,4,6-tri-*t*-butylphenyl group. c) The volume percentage of 2-propanol in hexane used as a mobile phase. d) k_1' is the capacity ratio for the initially eluted enantiomer; $k_1'=(T_1-T_0)/T_0$. e) The chromatographic separability factor of the enantiomers, α, is the ratio of the capacity ratios of the two enantiomers; $\alpha=k_2'/k_1'$. f) R_s is the peak resolution of the two enantiomers; $R_s=2\Delta W/(W_1+W_2)$. g) The integration ratio of the two enantiomers; lower R_f/higher R_f.



Optical rotations were taken in chloroform (c ca.1.3) at 25-26 °C.

Fig. 2. Correlation of optical rotations and optical purities by HPLC using optically active column.

the diaryl selenoxides, we found that these alkyl aryl selenoxides could not be separated by HPLC using an optically active column.

A plot of the optical rotations $[\alpha]_D$ and the optical purities estimated by HPLC gave a good straight line (Fig. 2) in the case of selenoxide **3**.

In conclusion, HPLC with an optical active column is useful for indicating which selenoxide can be separable into optical antipodes and to determine their optical purities.

Experimental

All melting points were determined on a Yamato MP-21 and were uncorrected. The IR spectra were recorded on a Hitachi 260-10 Spectrometer, ^{1}HNMR spectra with TMS as an internal standard on a JEOL JNM-PMX 60, and mass spectra on a JEOL JMS-DX300 Mass Spectrometer. The optical rotations were measured on a JASCO DIP-140 digital polarimeter. Silica-gel TLC and column chromatography were performed with a Merck Kieselgel 60F_{254} and a Wako Wakogel C-200, respectively. The HPLC system consisted of a Hitachi 655 Liquid Chromatograph equipped with a Rheodyne 7125 sample injector. Elutions were monitored at 265 nm using a Hitachi 638-41 variable-wavelength UV monitor. A Hewlett-Packard 3390A reporting integrator was used to obtain accurate retention times and integration areas at a chart speed of 5 mm min^{-1}.

Materials. Selenoxides (**1**, **3**, **5**, and **9**) were the known compounds.[1,2,7]

Phenyl 2,4,6-Triisopropylphenyl Selenoxide (2): Selenide was prepared from bis(2,4,6-triisopropylphenyl) diselenide and phenylmagnesium bromide.[3] The oxidation of this selenide to selenoxide **2** was accomplished according to our published method.[7] Mp 148.5—149.5 °C (hexane). IR (KBr) ν=815 cm^{-1} (Se=O). ^{1}HNMR ($CDCl_3$) δ=0.90, 1.24, 1.30 (18H, d, J=6.8 Hz), 2.86 (1H, m), 3.73 (2H, hep, J=6.8 Hz), 6.98 (2H, s), 7.2—7.7 (5H, m). Exact MS, Found: m/z 376.1217 (^{80}Se), Calcd for $C_{21}H_{28}O^{80}Se$: 376.1305.

2-Methoxyphenyl 2,4,6-Triisopropylphenyl Selenoxide (4): Starting selenide was prepared from bis(2-methoxyphenyl) diselenide and 2,4,6-triisopropylphenylmagnesium bromide[3]

and oxidized to selenoxide **4** by *t*-butyl hypochlorite.[7] Mp 154.5—155 °C (benzene–hexane). IR (KBr) ν=825 cm^{-1} (Se=O). ^{1}H NMR ($CDCl_3$) δ=0.86, 1.18, 1.29 (18H, d, J=6.6 Hz), 2.80 (1H, hep, J=6.6 Hz), 3.56 (3H, s), 3.84 (2H, hep, J=6.6 Hz), 6.93 (2H, s), 6.7—8.1 (4H, m). Exact MS, Found: *m/z* 406.1459, Calcd for $C_{22}H_{30}O_2{}^{80}Se$: 406.1411.

4-(Methoxycarbonyl)phenyl 2,4,6-Tri-*t*-butylphenyl Selenoxide (6): A starting selenide was prepared from *p*-ethoxycarbonylphenyl selenocyanate and 2,4,6-tri-*t*-butylphenyllithium in THF[5] followed by the hydrolysis and methylation. The oxidation of the selenide to the selenoxide **6** was performed in a similar method as **4**. Mp 129—129.5 °C. IR (KBr) ν=840 (Se=O) and 1725 (C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.36 (9H, s), 1.45 (18H, s), 3.86 (3H, s), 6.97 and 7.87 (4H, ABq, J=8.6 Hz), 7.49 (2H, s). Mass, M$^+$ 476 (^{80}Se). Exact MS, Found: *m/z* 460.1916 (^{80}Se)(lack of one oxygen, Calcd for $C_{26}H_{36}O_2{}^{80}Se$: 460.1880.

Phenyl 2,4,6-Triethylphenyl Selenoxide (7): Selenide prepared from diphenyl diselenide and 2,4,6-triethylphenylmagnesium bromide[3] was oxidized to the selenoxide **7** as in the case of **4**. Mp 50.5—51.5 °C. IR (KBr) ν=820 cm^{-1} (Se=O). ^{1}H NMR ($CDCl_3$) δ=1.06 (6H, t, J=7.8 Hz), 1.18 (3H, t, J=7.8 Hz), 2.60 (2H, q, J=7.8 Hz), 2.91 (4H, q, J=7.8 Hz), 6.89 (2H, s), 7.2—7.7 (5H, m). Exact MS, Found: *m/z* 334.0841 (^{80}Se), Calcd for $C_{18}H_{22}O^{80}Se$: 334.0836.

Phenyl 2,4,6-Trimethylphenyl Selenoxide (8): Oxidation of the selenide prepared from diphenyl diselenide and 2,4,6-trimethylphenylmagnesium bromide[3] with our published method[7] gave the selenoxide **8** in good yield. Mp 82—82.5 °C. IR (KBr) ν=805 cm^{-1} (Se=O). ^{1}H NMR ($CDCl_3$) δ=2.25 (3H, s), 2.44 (6H, s), 6.81 (2H, s), 7.2—7.7 (5H, m). Exact MS, Found: 292.0287, Calcd for $C_{15}H_{16}O^{80}Se$: 292.0366

Benzyl 2,4,6-Triisopropylphenyl Selenoxide (10): Selenide prepared from bis(2,4,6-triisopropylphenyl) diselenide and benzyl magnesium bromide[3] was oxidized to the selenoxide **10** according to the published method.[7] Mp 132.5—134 °C (hexane). IR (KBr) ν=820 cm^{-1} (Se=O). ^{1}H NMR ($CDCl_3$) δ=1.04, 1.26, 1.27 (18H, d, J=6.8 Hz), 2.88 (1H, m), 3.94 (2H, hep, J=6.8 Hz), 4.38 (2H, s), 6.98 (2H, s), 6.8—7.3 (5H, m).

Optically Active 4-(Methoxycarbonyl)phenyl 2,4,6-Triisopropylphenyl Selenoxide (3): The optically active selenoxide (**3**) was synthesized by the method described in our previous paper.[2] The selenoxide samples with lower enantiomeric excess were prepared by mixing of (+) selenoxide and (−) selenoxide.

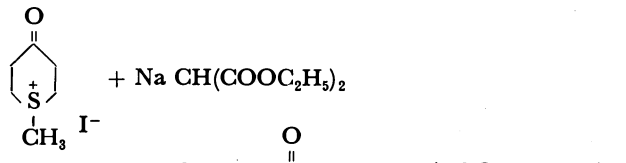
S-Alkyl-4-oxothianium Ions for the Synthesis of Cyclopentenones. Acid-Catalyzed Cyclization of Divinyl Ketones

Haruo MATSUYAMA,* Yuji TAKEI, and Michio KOBAYASHI
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received March 4, 1986)

Synopsis. A new approach to 2-cyclopentenones via an acidic cyclization of divinyl ketones by the use of S-alkyl-4-oxothianium ions as key compounds is described.

Considerable attention has been focused in recent years on cyclic sulfur compounds for the synthesis of interesting organic compounds. 4-Thianone (**1**) (R=H) is constituted of 5 carbon units and a sulfur atom as an active functional group for a ring transformation. Recently, we reported a general synthesis of 2-alkyl-3-cyclopentenones via a Ramberg-Bäcklund reaction starting from **1** (R=alkyl) as a 5 C synthon.[1] In connection with the use of **1** for the synthesis of cyclopentenones, we examined the possible route to 2-cyclopentenones (**6**) from S-alkyl-4-oxothianium ions (**2**) as shown in Scheme 1.[2] Cardwell reported that S-methyl-4-oxothianium iodide reacted with a carbon nucleophile, such as sodium diethyl malonate, to give a ring-substitution product in good yield (Eq. 1).[3]



(1)

We found that sulfonium ions (**2**) reacted smoothly with sodium ethanethiolate to give **3** in good yield (Scheme 1). In this note we illustrate the utility of S-ethyl-4-oxothianium ions (**2**) for the synthesis of 2-alkyl-2-cyclopentenones (**6**). The starting materials, 3-alkyl-4-thianones (**1**) (R=alkyl), were prepared by the alkylation of 3-methoxycarbonyl-4-thianone with alkyl halides (R-X, NaH, *N*,*N*-dimethylformamide (DMF)), followed by demethoxycarbonylation (NaCl, wet dimethyl sulfoxide (DMSO), 150 °C) (Eq. 2).[4] S-

Ethyl-4-oxothianium tetrafluoroborate (**2**) was readily prepared from **1** with Meerwein's reagent (triethyloxonium tetrafluoroborate) in dichloromethane at room temperature. It underwent a clean substitution reaction with sodium ethanethiolate in methanol (room temperature for 20 h) to form 2-alkyl-1,5-bis(ethylthio)-3-pentanone **3** (**3a**: 89%; **3b**: 69%). **3** was oxidized with sodium periodate (2.2 equiv) in methanol (room temperature for 20 h) to give 2-alkyl-1,5-bis(ethylsulfinyl)-3-pentanone (**4**) (**4a**: 82%; **4b**: 80%). Divinyl ketone (**5**) was formed by refluxing a benzene solution of **4** in the presence of calcium carbonate (3 equiv). The IR spectrum of the benzene solution showed a strong absorp-

tion band of the carbonyl group at 1680 cm^{-1}, corresponding to the vinyl ketone. An acid-catalyzed cyclization (phosphoric acid–formic acid (1:1), reflux)[5] of the divinyl ketone (**5**) gave 2-alkyl-2-cyclopentenone (**6**) (**6a**: 34%; **6b**: 22%) and its *exo*-enone isomer (**7**) (**7a**: 20%; **7b**: 10%). In our reaction system, a chemical yield of 2-cyclopentenones can be 32 to 54% because the isomerization of **7** to **6** could be accomplished by heating **7** in HCl/1-butanol at 90 °C.[6]

In conclusion, as shown in Scheme 1, S-alkyl-4-oxothianium ions (**2**) are very interesting compounds for a ring transformation of a six-membered ketone (4-thianone, **1**) to a five-membered ketone (2-cyclopentenone, **6**).

Experimental

The IR spectra were determined on a Hitachi 260-10 spectrometer. The NMR spectra were recorded on Hitachi R-20B and JEOL FX-60 spectrometers, using TMS (tetramethylsilane) as an internal standard. The mass spectra were recorded with a JEOL DMX-300 mass spectrometer. Column chromatography was performed with silica gel Wakogel C-200 and preparative TLC was carried out using silica gel $60F_{254}$ PLC plates (Merck 5717).

3-Pentyl-4-thianone (1a). Granular sodium hydride (0.36 g, 15 mmol) was added to a solution of 3-methoxycarbonyl-4-thianone[3] (1.74 g, 10 mmol) and pentyl iodide (2.97 g, 15 mmol) in dry DMF (60 ml) under an atmosphere of dry nitrogen. The mixture was stirred at ambient temperature for 20 h and then poured into water (100 ml). A normal ether work-up followed by column chromatography (hexane: ether=5:1) gave 3-pentyl-3-methoxycarbonyl-4-thianone as a colourless oil (1.76 g, 72%); Bp 138 °C/2.5 mmHg (1 mmHg=133.322 Pa); IR (neat) 1740 and 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.97 (3H, t), 1.00—1.50 (8H, m), and 2.84—3.46 (6H, m), 3.77 (3H, s); MS: *m/z* 244 (M^+).

A mixture of the β-keto ester (1.25 g, 5.1 mmol), anhydrous sodium chloride (0.33 g, 5.6 mmol) and water (0.3 ml) in DMSO (20 ml) was heated (oil bath temperature, 150 °C) for 20 h. After cooling the solution to room temperature, a normal ether work-up followed by column chromatography (hexane:ether=9:1) gave the ketone (**1a**) as a colourless oil (442 mg, 46%); IR (neat) 1705 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (3H, br t), 1.29—1.33 (8H, m), 2.60—3.10 (7H, m); MS: *m/z* 186 (M^+).

3-Benzyl-4-thianone (1b). Granular sodium hydride (0.36 g, 15 mmol) was added to a solution of 3-methoxycarbonyl-4-thianone (1.74 g, 10 mmol) and benzyl bromide (1.88 g, 11 mmol) in dry DMF (60 ml) under an atmosphere of dry nitrogen. The mixture was stirred at ambient temperature for 2.5 h and then poured into water (100 ml). A normal ether work-up followed by column chromatography (hexane:ether=5:1) gave 3-benzyl-3-methoxycarbony-4-thianone as solids (2.16 g, 82%); Mp 64.5—65.3 °C; IR (KBr) 1750 and 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.90 (5H, br s), 3.20—3.30 (3H, m), 3.69 (3H, s), 7.23 (5H, br s); ^{13}C NMR ($CDCl_3$) δ= 30.6, 37.9, 39.7, 43.4, 52.3, 64.2 (OCH_3), 126.9, 128.1, 130.4, 135.6, 170.5 (ester C=O), 204.7 (keto C=O); MS: *m/z* 264 (M^+). Anal. ($C_{14}H_{16}O_3S$) C, H.

A mixture of the β-keto ester (1.10 g, 4 mmol), anhydrous sodium chloride (0.26 g, 4.4 mmol) and water (0.22 ml) in DMSO (5 ml) was heated (oil bath temperature, 150 °C) for 20 h. After cooling the solution to room temperature, a normal ether work-up followed by column chromatography gave the ketone (**1b**) as a colourless oil (0.49 g, 60%); Bp 149 °C/2 mmHg; IR (neat) 1705 (C=O) and 1490 cm^{-1} (aryl); ^{1}H NMR ($CDCl_3$) δ=2.40—3.30 (9H, m), 7.24 (5H, br s); ^{13}C NMR ($CDCl_3$) δ=30.8, 35.0, 35.2, 43.9, 54.5, 126.3, 128.4, 129.0, 138.8, 205.5 (C=O); MS: *m/z* 206 (M^+).

2-Pentyl-1,5-bis(ethylthio)-3-pentanone (3a). A dichloromethane solution (20 ml) of 3-pentyl-4-thianone (**1a**) (408 mg, 2.2 mmol) and triethyloxonium tetrafluoroborate (500 mg, 2.6 mmol) was stirred for 20 h at room temperature. After the reaction solution was concentrated in vacuo, the residual oil was dissolved in dry methanol (10 ml). To a methanol solution (20 ml) of sodium ethanethiolate (2.8 mmol; 1.3 equiv) was added the above methanol solution of sulfonium salt (**2a**) and the mixture was stirred at room temperature for 21 h. After the removal of methanol in vacuo, a normal dichloromethane work-up to give an oil (**3a**) which was homogeneous on silica gel TLC (539 mg, 89%); IR (neat) 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (3H, t), 1.00—1.80 (14H, m containing t at 1.26 (J=7.2 Hz)), 2.30—3.00 (11H, m containing s at 2.76).

2-Benzyl-1,5-bis(ethylthio)-3-pentanone (3b). A dichloromethane solution (20 ml) of 3-benzyl-4-thianone (**1b**) (734 mg, 3.6 mmol) and triethyloxonium tetrafluoroborate (820 mg, 4.3 mmol) was stirred for 19 h at room temperature. After the dichloromethane solution was concentrated in vacuo, the residual oil was dissolved in dry methanol (10 ml). To a methanol solution (20 ml) of sodium ethanethiolate, which was prepared by the reaction between sodium metal (4.8 mmol) and ethanethiol (330 mg, 5.3 mmol), was added the above methanol solution of sulfonium salt (**2b**) and the mixture was stirred at room temperature for 22 h. After the methanol solution was concentrated in vacuo, a normal dichloromethane work-up to give an oil (**3b**) which was homogeneous on silica gel TLC (726 mg, 69%); IR (neat) 1705 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.20 (6H, t, J=6.6 Hz), 2.24—2.97 (3H, m), 7.19—7.21 (5H, m); ^{13}C NMR ($CDCl_3$) δ=14.67, 24.67, 25.97, 26.75, 32.86, 38.18; 44.80, 53.89, 126.49, 128.56, 128.81, 138.56, 210.89 (C=O).

2-Pentyl-1,5-bis(ethylsulfinyl)-3-pentanone (4a). 2-Pentyl-1,5-bis(ethylthio)-3-pentanone (**3a**) (539 mg, 2 mmol) was treated with sodium periodate (940 mg, 4.4 mmol) in methanol at room temperature for 21 h. After removal of insoluble solids, methanol solution was concentrated in vacuo and the residue was dissolved in chloroform to give **4a** (492 mg, 82%); IR (neat) 1710 (C=O), 1050 and 1020 cm^{-1} (S=O); ^{1}H NMR ($CDCl_3$) δ=0.90 (3H, br t), 1.20—1.90 (14H, m containing t at 1.35 (J=7.2 Hz)), 2.56—3.30 (11H, m containing t at 2.68 (J=7.2 Hz)).

2-Benzyl-1,5-bis(ethylsulfinyl)-3-pentanone (4b). 2-Benzyl-1,5-bis(ethylthio)-3-pentanone (**3b**) (193 mg, 0.56 mmol) was oxidized with sodium periodate (310 mg, 1.45 mmol) in methanol at room temperature for 20 h. After filtration of insoluble solids, methanol solution was concentrated in vacuo and the product was extracted with chloroform to give **4b** (151 mg, 71%); IR (neat) 1715 (C=O), 1050 and 1020 cm^{-1} (S=O).

2-Pentyl-2-cyclopentenone (6a). A benzene solution (10 ml) of **4a** (492 mg, 1.6 mmol) and calcium carbonate (480 mg, 4.8 mmol) was refluxed for 17 h. After filtration of the above solution, its IR spectrum showed a strong absorption band at 1680 cm^{-1} corresponding to vinyl ketone. After removal of benzene, phosphoric acid (8 ml) and formic acid (8 ml) were added to the residual oil and the solution was refluxed for 20 h (oil bath temperature, 100 °C). After cooling the solution to room temperature, a normal benzene work-up, followed by preparative TLC (hexane:ether=5:1) to give **6a** (83 mg, 34%) and its *exo*-enone isomer **7a** (48 mg, 20%); **6a**:[5] IR (neat) 1700 (C=O) and 1625 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ=0.90 (3H, br t), 1.00—1.70 (6H, m), 2.00—2.26 (6H, m), 7.31 (1H, m); MS: *m/z* 152 (M^+). **7a**: IR (neat) 1715 (C=O) and 1645 (C=C) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.95 (3H, br t), 1.10—1.60 (4H, m), 1.60—2.73 (8H, m), 6.16—6.60 (1H, m). Authentic **7a** was also

prepared by cross-aldol reaction between enol silyl ether of cyclopentanone (2.60 g, 16.7 mmol) and pentanal (1.59 g, 18.5 mmol) in the presence of titanium tetrachloride (1.85 ml, 16.7 mmol) in dichloromethane at −78 °C for 4.5 h in 59% yield;[7] IR (neat) 1720 (C=O) and 1645 (C=C) cm^{-1}. **6a** was obtained by heating **7a** (1.496 g, 9.87 mmol) in HCl (1 ml)/1-butanol (40 ml) at 90 °C for 19 h in 87% yield;[6] Bp 79.5—82.0 °C/5 mmHg; IR (neat) 1700 and 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.85 (3H, br t), 1.00—1.74 (6H, m), 1.86—2.66 (6H, m), 7.25 (1H, m).

2-Benzyl-2-cyclopentanone (6b). A benzene solution (5 ml) of **4b** (445 mg, 1.4 mmol) and calcium carbonate (410 mg, 4.1 mmol) was refluxed for 21 h. After filtration of the above solution, its IR spectrum showed a strong absorption band at 1680 cm^{-1} corresponding to vinyl ketone. After the removal of benzene, phosphoric acid (6 ml) and formic acid (6 ml) were added to the residual oil and the solution was refluxed for 23 h (oil bath temperature, 100 °C). After cooling the solution to room temperature, a normal benzene work-up, followed by preparative TLC (hexane:ether=1:1) to give **6b** (76 mg, 22%) and its *exo*-enone isomer **7b** (34 mg, 10%); **6b**: IR (neat) 1690 and 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.40—2.60 (4H, m), 3.40—3.60 (2H, m), 7.10—7.30 (6H, m containing s at 7.25); MS: *m/z* 172 (M^+). **7b**: IR (CCl_4) 1710 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.79—2.50 (4H, m), 2.85 (2H, t, d, *J*=6.6 and 3 Hz), 7.31—7.56 (6H, m). **7b** was prepared by aldol reaction between cyclopentanone (8.4 g, 0.10 mol) and benzaldehyde (3.56 g, 0.03 mol) in sodium hydroxide solution (sodium hydroxide (2.0 g, 0.05 mol) in 463 ml of water) at room temperature for 22 h in 53% yield;[8] Bp 115—117 °C/2 mmHg; IR (CCl_4) 1710 and 1620 cm^{-1}.

Proton Inventory of Carboxypeptidase Y-Catalyzed Reactions

Shigeru KUNUGI,* Kazuo TANABE, and Mitsuhiro FUKUDA†
Department of Applied Chemistry, Fukui University, Fukui 910
†Department of Practical Life Studies, Hyogo University of Teacher Education, Yashiro-cho, Hyogo 673-14
(Received February 13, 1986)

Synopsis. The partial solvent isotope effect of D_2O on the carboxypeptidase Y-catalyzed hydrolysis of a peptide (3-(2-furyl)acryloyl-L-phenylalanyl-L-phenylalanine) and an ester (3-(2-furyl)acryloyl-L-phenylalanine ethyl ester) was investigated. The peptide hydrolysis showed a smaller kinetic isotope effect regarding the catalytic rate constant (k_{cat}) and the second-order rate constant (k_{cat}/K_m). k_{cat} Varied linearly on the heavy-water content, indicating that one proton is essentially transferred during the rate-determining step. On the other hand, an ester hydrolysis showed a larger, nonlinear effect, indicating the possibility of a transfer of two or more protons in the rate-determining step of the ester hydrolysis, possibly the deacylation step.

Serine carboxypeptidase [EC.3.4.16.1] is a group of *exo*-protease which have a crucial serine residue in the active site.[1] It is found in tissues from mold and yeast to plants and animals as an intercellular protease.[2] Some of the enzymes of this group are now commercially available, and are largely utilized in peptide sequencing. They are also useful for peptide syntheses through an enzymatic condensation reaction.[3]

One of the characteristics of enzymes of this class is that they often show esterase and/or amidase activities besides the intrinsic peptidase activity.[4-7] This is in contrast to carboxypeptidase A,[8] a well-known metallo-carboxypeptidase from mammalian. This endopeptidase-like activity of serine carboxypeptidase raises questions about the reaction mechanism, especially for the substrate binding to this enzyme.

We have investigated some of the details of reactions of these enzymes,[6,7,9,10] including the pressure dependence of the reaction rate, and found that the two different types of activities show contrasting characters: In a neutral pH region, the apparent activity of amidase or esterase increases with the pH while that of the peptidase increases with a decreasing pH. The latter is very sensitive to pressure.

For an enzyme isolated from yeast (carboxypeptidase Y), Douglas et al.[11] observed a burst process in a the reaction with a non-specific acylating reagent, trimethylacetyl *p*-nitrophenolate. Lobb and Auld[12] reported a presteady-state process in a reaction of this enzyme with a fluorescent depsipeptide substrate. Our preliminary study[13] on a chromophoric amino acid ester substrate using a stopped-flow method also indicated the existence of a presteady-state process. Coupled with the results of a trans-peptidation study catalyzed by this enzyme,[14] these results led us to postulate a so-called three-step mechanism including the acylated enzyme (Eq.1), just as in the case of the serine protease reactions, such as α-chymotrypsin or trypsin.

However, the rates of acylation (k_2) and the deacylation (k_3) are comparable in the case of carboxypeptidase Y-catalyzed hydrolysis of the peptide.[6] Under certain conditions a burst process has been observed,

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} ES' + P_1 \xrightarrow{k_3} E + P_2 \qquad (1)$$

(E, enzyme; S, substrate; E S, enzyme-substrate complex; ES′, acyl-enzyme; P_1, product; k_1, respective rate constant)

even for the peptide substrate.[13] These are fairly different from serine protease. To find more details regarding these constituent reaction steps, we studied the partial solvent isotope effect of deuterium oxide, known as a proton inventory technique that is useful for determining the behavior of protons during reaction pocesses.[15]

Experimental

Three types of serine carboxypeptidases (carboxypeptidase Y from yeast, W from wheat and P from penicillium) were studied. They were obtained from Oriental Yeast Co., (Osaka; Lot. 21003001), Pentel Co., (Tokyo; Lot. 6930606) and the Protein Research Foundation, (Osaka; Lot. 099201), respectively. Chromophoric substrates, 3-(2-furyl)acryloyl-L-phenylalanyl-L-phenylalanine (Fua-Phe-Phe) and 3-(2-furyl)acryloyl-L-phenylalanine ethyl ester (Fua-Phe-OEt), were used as before.[6] Benzoyl-L-tyrosine-*p*-nitroanilide (Bz-Tyr-*p*NA) was from the Protein Research Foundation. 2-morpholinoethanesulfonic acid (MES) and 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid (HEPES) were from the Dohjindo Laboratories (Kumamoto, Japan). Deuterium oxide (99.85%) and sodium deuterium oxide solution in D_2O were purchased from CEA (France). The absorbance spectrum was measured using a Uvidec type-650 spectrophotometer (Nippon Bunkou Co.). The pH was measured with a Hitachi-Horiba pH meter (F-7LC) and the pD value for a D_2O solution was calculated by adding 0.4 to the value read on the meter.[15] Most of the preparation of D_2O-containing solutions was carried out under a stream of dry nitrogen gas. The atom fraction of deuterium in an H_2O-D_2O mixture was calculated on the basis of weight. For a very low content, a NMR apparatus (JEOL GX-270) was also used.

Results

Figure 1 shows the pH or pD dependence of k_{cat} on the carboxypeptidase Y-catalyzed hydrolysis of Fua-Phe-Phe (**a**) and Fua-Phe-OEt (**b**). When the optimum values were compared, the kinetic deuterium-isotope effect ((k_{cat} in H_2O)/(k_{cat} in D_2O)=k_H/k_D) for the peptide substrate was found to be about 1.6, and that for the ester substrate was about 3.5. These values are somewhat larger than those for Z-Phe-Leu and Ac-Phe-OEt reported by Hayashi's group.[16] The K_m parameter was largely unaffected by the solvent D_2O, though not shown here. Thus a comparison of the second-order rate constant (k_{cat}/K_m) can also show the approximate effect on the catalytic process; for

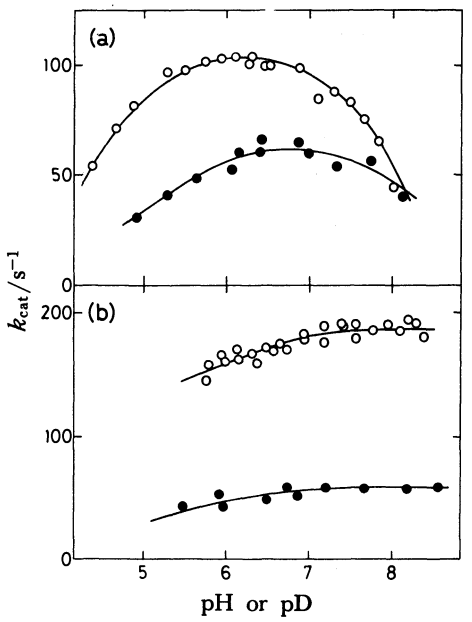

Fig. 1. The pH* dependence of k_{cat} for the carboxypeptidase Y-catalyzed hydrolysis of Fua-Phe-Phe (a) and of Fua-Phe-OEt (b). (○) in H_2O and (●) in D_2O, at 25°C.
(a) [Fua-Phe-Phe]=0.46 mM, [E]=0.17 μM in H_2O and 0.21 μM in D_2O, containing 2.5% (v/v) CH_3CN.
(b) [Fua-Phe-OEt]=0.50 mM, [E]=0.10 μM in H_2O and 0.16 μM in D_2O, containing 2.0% (v/v) CH_3CN.

carboxypeptidase W, k_H/k_D of k_{cat}/K_m was 2.44 for Fua-Phe-OEt hydrolysis (at pH=7.60 and pD=8.01) and 1.13 for Fua-Phe-Phe hydrolysis (at pH=3.95 and pD=4.35). For carboxypeptidase P, only the peptide hydrolysis could be practically measurable and the k_H/k_D of k_{cat}/K_m was 1.11 (at pH=3.87 and pD=4.46). The effect was always small for a peptide hydrolysis.

When measured in an H_2O–D_2O mixture, the k_{cat} value changed as shown in Fig. 2. In the peptide hydrolysis (**a**) the rate constant varied almost linearly with a change in the D_2O content, while the rate of ester hydrolysis (**b**) varied considerably in a concave manner. According to a simplified theoretical treatment of the proton inventory, the rate constant in an H_2O–D_2O mixture can be expressed, provided that all the protons contribute to the total effect in equal amounts,[15] as

$$k = k_{H_2O}(1-n+n\phi)^{\nu}, \quad (2)$$

where n and ν indicate the D_2O content and the number of protons concerning the rate-determining step, respectively. ϕ is a deuterium isotope effect in an elementary step. A nonlinear regression of the data showed us that the ester hydrolysis can be represented by a ϕ value of 0.54 for ν=2 (two-proton assumption) and 0.66 for ν=3 (three-proton assumption). We can mention that at least two protons take part in the rate-determining process of ester hydrolysis while only one proton is apparently concerned in the rate-determining step of the peptide hydrolysis.

Discussion

A proton inventory technique has been successfully

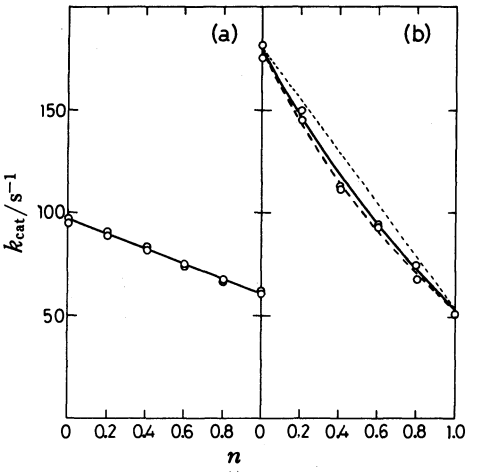

Fig. 2. The partial solvent isotope effect as a function of atom fraction of deuterium (n) for the k_{cat} of the carboxypeptidase Y-catalyzed hydrolysis of Fua-Phe-Phe (a) and of Fua-Phe-OEt (b), at 25°C. [E]=0.11 μM, containing 2.5% (v/v) CH_3CN.
(a) [Fua-Phe-Phe]=0.40 mM. (——) ν=1, ϕ=0.63.
(b) [Fua-Phe-OEt]=0.52 mM.
(——) ν=2, ϕ=0.54, (-----) ν=3, ϕ=0.66 for Eq. 2.
(----) ν=1, ϕ=0.29.

applied to the analysis of an enzyme reaction, especially for the reaction involving serine proteases. In the cases of a serine proteases such as α-chymotrypsin or elastase, a coupled movement of protons was reported for the hydrolysis of specific peptide anilide substrates,[15,17] largely related to the character of the acylation step, while most of the deacylation processes gave a very simple partial isotope effect.[15,18] The coupled movement of the protons during the acylation step of these enzymes was explained based on the so-called charge-relay mechanism involving a concerted proton movement within the Ser–His–Asp residues. This was originally postulated by Blows's group[19] on the basis of their X-ray crystallographical studies, though this mechanism (especially the existence of a very week carbonic acid side chain of Asp 102) has been recently questioned.[20]

Compared to these serine proteases, we know far less about the active site of serine carboxypeptidase. Hayashi et al.[21] showed that a His residue was crucial for the catalytic activity of carboxypeptidase Y. This gives us a picture of an active site similar to that of serine protease; a cooperative function of the Ser and His residues. We have reported after a systematic study of the steady-state kinetics of this enzyme that the peptide hydrolysis by serine carboxypeptidase is partly rate-controlled by the acylation step and that the ester hydrolysis is mostly deacylation-controlled.[6] The present results involving proton inventory indicates that the acylation reaction for these enzymes involves a transfer of one proton, probably between Ser and His residues. On the other hand, the deacylation process is more or less cooperative and a coupled movement of proton(s), in addition to the one between the hydration water and the His residue, is to be considered. Based on a new understanding of the proton movement of the serine protease reaction,[20] a mechanism including the

relaying of ptotons (not a charge) is still considered to be meaningful, especially when the substrate is bound to the active site. Therefore, the present result for carboxypeptidase Y might be explained by a coupled proton transfer occurring when the acyl part of the substrate is co-valently attached to the active site of the enzyme. However, the possibility of other mechanisms, such as a structural change of the protein or a change in the hydration state, might also be considered.

We gratefully acknowledge the advice and encouragement of Professors Norio Ise (Kyoto University) and Yoshiharu Nakamura (Fukui University) throughout the study.

Stereoselective Reduction of Symmetrical Diketones with Biological Methods. Microbial Reduction of *cis*-2,7-Decalindione

Hiroaki CHIKAMATSU,* Masatoshi TANIGUCHI, and Takamasa KANEMITSU
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received March 22, 1986)

Synopsis. The *pro-S* group of two enantiotopic carbonyl groups in *cis*-2,7-decalindione was preferentially reduced with *Rhodotorula rubra* to give (−)-(7*S*,9*R*,10*S*)-7-hydroxy-*cis*-2-decalone of high optical purity.

In the course of our investigations of the stereo-differentiating reduction of various carbonyl compounds with biological systems, two completely opposite enantiomer selectivities toward C_2-ketones,[1] which were found in a microbial reduction and a horse liver alcohol dehydrogenase (HLADH)-mediated reduction, have led us to propose the microbial "*P*-C_2-ketone rule"[2] and the HLADH "*M*-C_2-ketone rule"[3] to summarize their respective stereochemical behaviors.

Among our further studies on the symmetrical diketones,[4,5] we found that one of two enantiotopic carbonyl groups was preferentially reduced and the hydrogen attack occurred from the *Re*-face of its carbonyl plane.[5] These findings encouraged us to develop a useful methodology for asymmetric syntheses.[6] For instance, it is theoretically possible by utilizing biological stereoselectivity toward prochiral diketone, *cis*-2,7-decalindione (**1**),[7] to transfer the total amount of starting material into one chiral isomer of four molecules, enantiomers of *cis,trans*-ketol **2**[8] and of *cis,cis*-ketol **3**.[8] The HLADH-mediated reduction of **1** did indeed show differentiations between enantiotopic *pro-R* and *pro-S* carbonyl groups,[9] and diastereotopic faces of the carbonyl plane affording (−)-(7*S*,9*S*,10*R*)-7-hydroxy-*cis*-2-decalone (**2**)[10] with a good yield and high optical purity. Starting from **2**, optically pure (+)-twistane was synthesized in short steps.[5b,11]

Coupled with the opposite enantiomer selectivities toward C_2-ketone, we expected to find the opposite enantiotopic group selectivities toward the diketone **1** in the HLADH-mediated reduction and the microbial reduction.

Results and Discussion

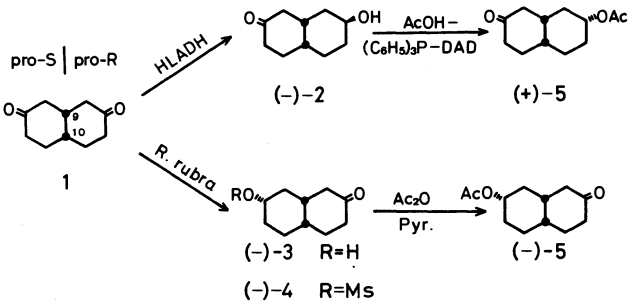
Microbial Reduction of Diketone 1. The preliminary test incubation of **1** both with *Rhodotorula rubra* and *Curvularia lunata* revealed that these microbes rapidly reduced **1** giving a ketol as the major product and sluggishly reduced it into diol(s) during further incubation. Monitoring by means of GLC indicated that the metabolite ketol was found to be *cis,cis*-ketol **3**, one of the diastereomers of (−)-*cis,trans*-ketol **2** obtained from an HLADH-mediated reduction.

Preparative-scale incubation with *R. rubra* was carried out for 68 h at 30°C. During this period, 85% of the diketone was consumed. After an extraction of the metabolite, alumina chromatography provided a 59% yield of crystalline (−)-ketol **3**, $[\alpha]_D^{25}$ −2.3°. Contrary to *R. rubra*, *C. lunata* was found to show a poor enantiotopic group selectivity, affording a 21% yield of optically inactive ketol **3**.[12]

In the ^{1}HNMR spectrum, a singlet signal at δ 3.0 ppm due to methyl protons of $-OSO_2CH_3$ exhibited by the (±)-keto mesylate **4** of (±)-ketol **3**, was clearly separated ($\Delta\Delta\delta$ 0.04 ppm) with an addition of a chiral shift reagent, Eu(facam)$_3$.[13] In case of (−)-**4** prepared from (−)-ketol **3**, such an enantiomer differential shift was not observed to give any information about the optical purity of (−)-ketol **3** as to be 100% within experimental error.

To secure information on the absolute configuration of (−)-ketol **3**, we attempted to relate it to (−)-ketol **2**, whose absolute configuration had been established as being (7*S*,9*S*,10*R*) in our labolatory.[5b]

By the method of Mitsunobu,[14] an inversion of the configuration at C-7 of (−)-ketol **2** using triphenylphosphine, diethyl azodicarboxylate, and acetic acid in tetrahydrofuran, gave (+)-keto acetate **5**, $[\alpha]_D^{24}$ +41°. This was found to be an enantiomer of (−)-**5**, $[\alpha]_D^{24}$ −40°, prepared from (−)-ketol **3** by a treatment with acetic anhydride in pyridine. Thus, the absolute configuration of (−)-ketol **3** was determined as being a (7*S*,9*R*,10*S*)-configuration.[15]



These results clearly show that *R. rubra* preferentially catches the *pro-S* carbonyl group and the hydrogen attack occurs from the *Re*-face of the carbonyl plane. The demonstrated enantiotopic group selectivity of *R. rubra* is completely opposite to that found in the HLADH-mediated process which selectively reduced the *pro-R* carbonyl group.

Experimental

Melting points are uncorrected. ^{1}HNMR spectra were determined on a JNM-60-HL and JNM-NH-100 with Me_4Si as an internal standard (δ=0). Optical rotations were measured with a JASCO-DIP-140 polarimeter. CD spectra were determined on a JASCO-J-40 spectropolarimer. GLC analyses were performed on a JGC-20K equipped with a FID using a 1 m×3 mm inside diameter column of 10% Carbowax 20M on Chromosorb W. Column-chromatography was carried out with Woelm active alumina (neutral, activity III).

Preparation of 1. The diketone **1** was prepared by the method of Anderson and Barlow,[16] mp 63—64°C (lit,[16] mp 62—64°C).

Cultured Broth. *(a). Microbe Culture*: The cultures of *R. rubra* (IFO 0889) and *C. lunata* (IFO 6288) were obtained from the Institute of Fermentation, Osaka, Japan. *(b). Culture medium*:[17] The culture medium was prepared by dissolving glucose (30 g), KH_2PO_4 (1 g), corn-steep liquor (10 g), $MgSO_4 \cdot 7H_2O$ (0.5 g), $NaNO_3$ (2 g), $FeSO_4 \cdot 7H_2O$ (0.02 g), K_2HPO_4 (2 g), and KCl (0.5 g) in 1 L of tap water and was sterillized at 123 °C for 15 min. *(c). Growth of Microbes*: 25 mL of the culture medium in a 100-mL Erlenmeyer flask was inoculated with spores of the microbe on Difco MY agar slants and was shaken for 48 h at 30 °C on a shaker. The culture was transferred into a 500 mL Erlenmeyer flask containing 200 mL of the culture medium, incubation was maintained for another 48 h at 30 °C until a sufficient mass of mycelium had developed.

Microbial Reduction of 1 with *R. rubra*. An aquous solution (40 mL) containing 1.5 g (9 mmol) of **1** was divided into eight batches of the culture broth of *R. rubra* (each 200 mL) and the mixture was incubated at 30 °C for 68 h. After the mycelium was collected by filtration through the layer of Hyflo Super Cel and extracted with chloroform, the beer filtrate was also extracted with the same solvent. The combined extracts were washed with water and dried over anhydrous magnesium sulfate. The removal of the solvent in vacuo left a metabolite mixture (1.4 g) which was analyzed by GLC to reveal that it was a 15:5:78:2 mixture of **1**, **2**, **3**, and diol(s).

The mixture was taken up in benzene and chromatographed upon 50 g of alumina. Elution with 200 mL of benzene–chloroform (10:1) afforded 50 mg of **1**. Further elution with 200 mL of benzene–chloroform (1:1), followed by 600 mL of chloroform, gave 880 mg (59% yield) of (−)-ketol **3**; mp 88—89 °C (from pentane); $[\alpha]_D^{25}$ −2.3 ° (*c* 1.6, $CHCl_3$); CD (*c* 2.4×10^{-3} mol dm^{-3}, MeOH) $[\theta]$ 290 nm −380; IR (KBr) 3400, 1690, 1060 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ= 3.6 (m, 1H, 1/2*W* 24Hz, C-7-H).

Found: C, 71.45; H, 9.57%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.39%.

(−)-Keto Mesylate 4. To a solution of (−)-ketol **3** (460 mg, 2.7 mmol) in pyridine (5 mL) was added methanesulfonyl chloride (600 mg, 5.2 mmol) at 0 °C. The mixture was allowed to stand overnight in a refrigerator. The reaction mixture was diluted with ice-water and extracted with dichloromethane. The extract was washed with dil hydrochloric acid and water, then dried over anhydrous magnesium sulfate. After the removal of the solvent in vacuo, the residue (620 mg) was recrystallized from pentane-dichloromethane to give 420 mg (62% yield) of (−)-keto mesylate **4** as flaks; mp 99—100 °C; $[\alpha]_D^{25}$ −24.4 ° (*c* 1.7, $CHCl_3$); IR (KBr) 1700, 1350, 1170, 938 cm^{-1}: ^{1}H NMR (60 MHz, $CDCl_3$) δ=4.65 (m, 1H, 1/2*W* 23Hz, C-7-H), 3.0 (s, 3H, S-CH_3).

Found: C, 53.57; H, 7.39; S, 12.98%. Calcd for $C_{11}H_{18}O_4S$: C, 53.64; H, 7.37; S, 13.02%.

(−)-Keto Acetate 5. To a solution of (−)-ketol **3** (103 mg, 0.6 mmol) in pyridine (1 mL) was added acetic anhydride (0.1 mL). The mixture was allowed to stand overnight. The reaction mixture was poured into ice-water and extracted with ether. The ethereal layer was washed with 5% hydrochloric acid and water followed by drying over anhydrous magnesium sulfate. The removal of the solvent gave 110 mg (90% yield) of (−)-keto acetate **5**; mp 82—83 °C (from pentane); $[\alpha]_D^{22}$ −40.0 ° (*c* 0.54, $CHCl_3$); IR (KBr) 1730, 1705, 1250, 1050 cm^{-1}; ^{1}H NMR (60 MHz $CDCl_3$) δ=4.75 (m, 1/2*W* 22 Hz, C-7-H), 2.0 (s, 3H, O-CH_3).

Found: C, 68.52; H, 8.69%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

Microbial Reduction of 1 with *C. lunata*. The diketone **1** (total 1.5 g, 9 mmol) was incubated for 68 h at 30 °C in eight batches. The metabolite mixture containing **1**, **2**, **3**, and diol(s) in a ratio of 8:9:80:3 was worked up according to the procedure described on the *R. rubra* reduction to afford 317 mg (21% yield) of (±)-ketol **3**; mp 101.5—102.5 °C (from pentane); $[\alpha]_D^{23.5}$ ±0 ° (*c* 1.33, $CHCl_3$).

Found: C, 71.51; H, 9.58%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

The (±)-keto mesylate **4**; mp 78—79 °C (from pentane–dichloromethane); $[\alpha]_D^{24}$ ±0 ° (*c* 1.2, $CHCl_3$).

Found: C, 53.57; H, 7.39%. Calcd for $C_{11}H_{18}O_4S$: C, 53.64; H, 7.37%.

(+)-Keto Acetate 5. To a solution of (−)-ketol **2** obtained from HLADH mediated reduction ($[\alpha]_D^{24}$−16.4 °,[5b] 170 mg, 1 mmol), triphenylphosphine (510 mg, 2 mmol), and acetic acid (120 mg, 1 mmol) in dry THF (4 mL) was added dropwise a solution of diethyl azodicarboxylate (340 mg, 2 mmol) in dry THF (2 mL). After being stirred at room temperature for 48 h, the reaction mixture was analyzed by GLC to reveal that 76% of **2** was inverted into keto acetate **5**. The solvent was removed under reduced pressure to afford a syrupy product which was taken up into ether (50 mL). An insoluble material was filtered off and the filtrate was concentrated. The resultant residue was taken up into pentane (150 mL) and a soluble portion was washed with aq sodium hydrogencarbonate. It was then chromatographed over alumina (5 g). Elution with pentane–ether (10:1) (250 mL) gave 55 mg (26% yield) of (+)-keto acetate **5**; mp 82—83 °C (from pentane); $[\alpha]_D^{24}$ +41 ° (*c* 0.73, $CHCl_3$).

Found: C, 68.58; H, 8.72%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

Tertiary Amine-Catalyzed Acyl Group-Exchange Reactions of *N,O*-Diacyl-*o*-aminophenols

Tadamitsu SAKURAI,* Shuichi YAMADA, and Hiroyasu INOUE
Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221
(Received January 27, 1986)

Synopsis. A kinetic study on the base-catalyzed acyl group-exchange reactions of *N,O*-diacyl-*o*-aminophenols was undertaken to show that the formation of the amidate ion should be the rate-determining step in these intramolecular acyl-exchange reactions, and that the electron-withdrawing power of acyl group becomes an important factor to control the relative stabilities of a pair of *N,O*-diacyl-*o*-aminophenols.

The acyl group-exchange reactions of *N,O*-diacyl derivatives of *o*-aminophenol have been extensively studied in the past because these exchange reactions have attracted attention of both theoretical and synthetic organic chemists.[1] The use of HPLC made it possible to separate and analyze quantitatively labile acyl-exchanged products and thus allowed Smith and Elrod to propose the hypothesis that the inductive effects of acyl groups attached to nitrogen or oxygen in the molecule determine the relative stabilities of a pair of *N,O*-diacyl-*o*-aminophenols.[1,2] The failure of this hypothesis to explain the relative stabilities of a pair of *N,O*-acyl-alkoxycarbonyl-*o*-aminophenols[3] prompted us to study the acyl-migration reactions whose mechanism still remains obscure.

We chose *N,O*-(*p*-substituted benzoyl)-(1-naphthoyl) derivatives of *o*-aminophenol as a new system and investigated the solvent, base (tertiary amine), and substituent effects on the rate and equilibrium constants for acyl-exchange reactions, hoping to shed light on the mechanism of these reactions.

The tertiary amine-catalyzed acyl-exchange reactions shown in Scheme 1 follow first-order kinetics in **1** ($2.5—3.3\times10^{-3}$ M, 1 M=1 mol dm^{-3}) at the amine concentration 8.6×10^{-4}—1.2 M at 30 °C (correlation coefficient r=0.990—0.999). In addition, the pseudo-first-order rate constants (k), observed typically for **1a**—**2a** pair, increase linearly in proportion to the amine concentration (r=0.996), suggesting that the reaction is first-order in both **1** and the amine. The acyl exchange was not observed in benzene and 1,2-dichloroethane without the amines, whereas the reaction proceeded to a minor extent in acetonitrile containing no amines. However, such a solvent(acetonitrile)-catalyzed reaction ($k\approx3\times10^{-5}$ min^{-1}) was shown to have a negligible effect on the observed rate constants, e.g., k=0.40 min^{-1} for the triethylamine(1.65×10^{-3} M)-catalyzed reaction of **1a** in acetonitrile. On the other hand, no HPLC peaks attributable to the conceivable intermediates could be detected during the course of the reaction under any conditions. The equilibrium constants (K) were estimated from the concentration ratios [**2**]/[**1**] at equilibrium state and the second-order rate constants (k_1) were obtained by dividing the k values by the amine concentration used. The rate and equilibrium constants thus evaluated are collected in Table 1.

First we discuss the solvent, base, and substituent effects on the rate of the acyl-migration reaction. The increased solvent polarity was found to greatly accelerate the reaction. In addition, the reaction rates have a tendency to increase with increasing the basicity of the amines and the electron-withdrawing power of the

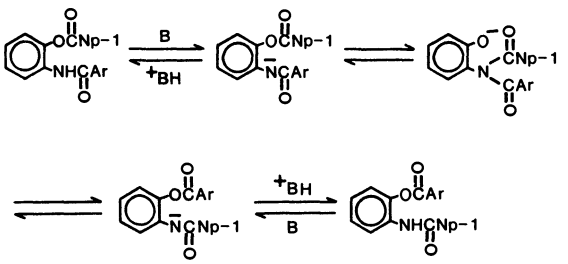
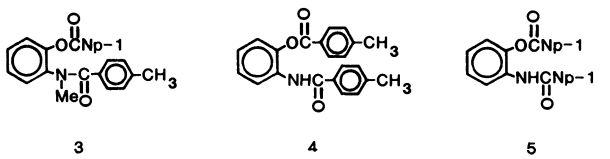
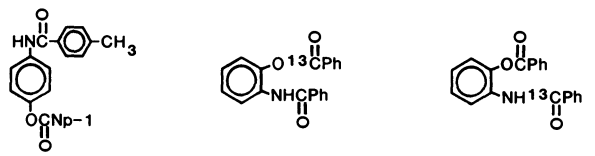
substituents R. All these observations can be nicely explained in terms of the rate-determining formation of the amidate ion. Thus we propose the mechanism shown in Scheme 2 to explain the observed acyl-exchange reactions of *N,O*-diacyl-*o*-aminophenol derivatives. Amundsen and Ambrosio[4] have previously proposed a similar mechanism but they have presented no kinetic evidence in support of their mechanism. The facts that both **1a** in acetic acid and the *N*-methyl derivative **3** in acetonitrile containing triethylamine do not undergo the acyl-exchange reaction to any extent support this mechanism. To ascertain the intra- or intermolecularity of this acyl-exchange reaction, an equimolar mixture of **1a** and **2a** was allowed to react with triethylamine in acetonitrile until the equilibrium is established. Careful HPLC analysis of the mixture indicates no formation of the crossover products **4** and **5**. In addition to the fact that the para-isomer **6** is not subject to the base-catalyzed exchange reaction in acetonitrile the result of this crossover experiment allows us to conclude that the observed acyl-migration is exclusively intramolecular reaction. Furthermore, definitive evidence for the occurrence of acyl-group migration comes from the observation of triethylamine-catalyzed exchange of ^{13}C-labeled benzoyl group between **7** and **8**. No migration of the benzoyl group was observed without the amine also in this case.



Scheme 2.



3 4 5



6 7 8

The equilibrium constants obtained for **1—2** pairs were found to decrease as the electron-withdrawing ability of the substituents R is increased. Smith and Elrod[2] have suggested that the more stable isomer should be the one with the stronger electron-withdrawing acyl group bonded to nitrogen. Because the electron-withdrawing ability of acyl groups in our system should have the following order on the basis of the p*K*a values of the corresponding carboxylic acids: *p*-$NO_2C_6H_4CO$ > 1-naphthoyl > *p*-ClC_6H_4CO > *p*-$CH_3C_6H_4CO$, only the relative stabilities of **1c—2c** pair do not conform to their proposal. We felt that the solvent polarity also plays a role in determining the relative stabilities of **1** and its isomer **2**. For this purpose **1a—2a** pair was chosen and the solvent effects on the magnitude of *K* were examined. Although there is a tendency that the increased solvent polarity shifts the equilibrium slightly to the direction of **2**, the equilibrium is not much affected by a change in solvent polarity. On the other hand, the magnitude of *K* is neither very sensitive to a change in the amine bases nor correlate with the basicity of tertiary amines used.

Although in *N,O*-acetyl-chloroacetyl-,[5] *N,O*-(1-naphthoyl)-(*p*-toluoyl)-, and *N,O*-(1-naphthoyl)-(*p*-chlorobenzoyl)-*o*-aminophenols the more stable isomer is the one with the stronger electron-withdrawing acyl group attached to nitrogen as proposed by Smith and Elrod, their hypothesis cannot predict the more stable isomer in acetyl-aroyl,[2] acetyl-alkoxycarbonyl,[3] and 1-naphthoyl-(*p*-nitrobenzoyl) derivatives of *o*-aminophenol, indicating that the inductive effects of acyl groups are not the only factor to determine which isomer is more stable. As mentioned above, however, the results of substituent effects on the magnitude of *K* demonstrate that the electron-withdrawing ability of acyl group plays a crucial role in controlling the relative stabilities of **1—2** pairs.

We expect that the equilibrium constant for the reaction of *N,O*-diacyl-*o*-aminophenol wherein the two acyl groups are the same becomes practically unity. As expected, it was estimated to be unity for **7—8** pair within the limits of experimental accuracy.

Experimental

Materials. *N*-(*p*-Substituted benzoyl)-*o*-aminophenol and *N*-(1-naphthoyl)-*o*-aminophenol were prepared by *N*-aroylation of two equiv of *o*-aminophenol with *p*-substituted benzoyl and 1-naphthoyl chlorides in dichloromethane, respectively. Recrystallization of the crude products from aqueous ethanol gave pure samples whose physical properties are the followings. *N*-Benzoyl-*o*-aminophenol, mp 167.5—168.5 °C; IR (KBr) 3400, 3000 (broad), 1640 cm^{-1}. *N*-(*p*-Toluoyl)-*o*-aminophenol, mp 157.5—158.5 °C; IR (KBr) 3410, 3080 (broad), 1640 cm^{-1}. *N*-(*p*-Chlorobenzoyl)-*o*-aminophenol, mp 180.5—181.5 °C; IR (KBr) 3200 (broad), 1630 cm^{-1}. *N*-(*p*-Nitrobenzoyl)-*o*-aminophenol, mp 206—207 °C; IR (KBr) 3280, 3120 (broad), 1650, 1520, 1350 cm^{-1}. *N*-(1-Naphthoyl)-*o*-aminophenol, mp 194.5—195.5 °C; IR (KBr) 3400, 3100 (broad), 1640 cm^{-1}.

N-Methyl-*N*-(*p*-toluoyl)-*o*-aminophenol was prepared according to the following reaction steps. The crude product obtained was recrystallized from aqueous ethanol and then from benzene-hexane affording colorless crystals, mp 140—141 °C; IR (KBr) 3100 (broad), 1620 cm^{-1}.

N,O-Diacyl-*o*-aminophenols (**1a—c**, **2a—c**, **3—5**, and **7**) were derived from the reactions between *N*-acyl-*o*-aminophenols (1 mol) and the corresponding acyl chlorides (1 mol) in the presence of triethylamine (0.9 mol) in dichloromethane. The usual work-up gave the crude products which were purified by column chromatography on silica gel (70—230 mesh, Merck) with chloroform as eluent, followed by recrystallization from benzene–hexane yielding analytical samples whose physical properties are listed in Table 2. IR and HPLC analyses of these diacyl derivatives showed them to be pure samples containing negligible amounts of the opposite isomers. Benzoyl-*carbonyl*-^{13}C chloride (99+ atom% ^{13}C, Aldrich) was employed as acylating agent to synthesize **7**.

N-(*p*-Toluoyl)-*o*-(1-naphthoyl)-*p*-aminophenol (**6**) was prepared by treatment of *N*-(*p*-toluoyl)-*p*-aminophenol (mp 212.5—214 °C, 1 mol), which was obtained from the reaction of two equiv of *p*-aminophenol with *p*-toluoyl chloride, with 1-naphthoyl chloride (1.1 mol) in the presence of triethylamine (1.1 mol) in dichloromethane. Analytical sample, listed in Table 2, was obtained by recrystallizing the crude product from ethyl acetate.

Kinetic Methods. The rate of appearance of **2a—c** or disappearance of **1a—c** was followed with a JASCO twincle HPLC apparatus equipped with an UV detector (254 nm) and a 25 cm×4.6 mm (i.d.) ODS column at 30 °C. Carefully purified acetonitrile containing 35% (by volume) distilled water was used as the developing solvent in all cases. In this developing solvent the acyl-exchange reaction proceeds to a negligible extent. Each kinetic run was carried out by analyzing 2-μl aliquots of the solutions at suitable time intervals. The concentrations of **1** and **2** were determined by employing the linear calibration curves made for each compound under the same analytical conditions.

All the pseudo-first-order rate constants (k) were determined from the following rate equation and the extent of the reaction studied was more than two half-lives, allowing us to get reliable rate constants.

$$\ln\{[\mathbf{2}]_e/([\mathbf{2}]_e-[\mathbf{2}]_t)\} = [\mathbf{1}]_0 kt/[\mathbf{2}]_e$$

where $[\mathbf{1}]_0$, $[\mathbf{2}]_t$, and $[\mathbf{2}]_e$ refer to initial concentration of **1**, concentration of **2** at time t and at equilibrium state, respectively. The acyl-exchange rate of ^{13}C-labeled **7** was determined with a JEOL FX-200 spectrometer (200 MHz) in $CDCl_3$ at 30 °C. Tetramethylsilane was used as an internal standard. Increasing concentration of **8** or decreasing concentration of **7** was estimated from the area ratio of the two signals arising from the ester (164.5 ppm) and amido (165.3 ppm) carbonyl carbons. The migration reaction of ^{13}C-labeled benzoyl group also follows first-order kinetics (r=0.997). The experimental errors in the estimated rate and equilibrium constants are of the order of about 10%.

Racemic Structures and Optical Resolution by Preferential Crystallization of Organic Ammonium Salts of (±)-Mandelic Acid

Tadashi SHIRAIWA,* Mitsuhiro NAKAMURA, Masanobu NOBEOKA, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received March 24, 1986)

Synopsis. According to a thermodynamic analysis the 4-methylpiperidinium salt of (±)-mandelic acid is a conglomerate around room temperature, though the salt forms a racemic compound in the vicinity of the melting point. A successive preferential crystallization in ethanol at 10°C yields both the (+)- and (−)-salts with optical purities of over 95%.

Mandelic acid (abbreviated as MAN) is very useful as medicines and intermediate materials, such as phenyramidol, a centrally axting muscle relaxant.[1] Optically active MAN has also been used as a resolving agent in optical resolution of racemic organic bases.[2] (±)-MAN has been optically resolved by the diastereomeric procedure using L-phenylalanine[3] and cinchonine[4] as resolving agents. However, the diastereomeric procedure requires a relatively large quantity of resolving agents. On the other hand, the preferential crystallization procedure is more useful on the industrial scale than the diastereomeric one, since optical resolution can easily be achieved by providing a small amount of one enantiomer as seed crystals in a supersaturated racemic solution. However, the optical resolution by this procedure has scarcely been reported on (±)-MAN.[5] This note describes an attempt to resolve optically organic ammonium salts of (±)-MAN by preferential crystallization.

Racemic structures of propylammonium salt ((±)-PA salt), isopropylammonium salt ((±)-IPA salt), isobutylammonium salt ((±)-IBA salt), benzylammonium salt ((±)-BZA salt), and 4-methylpiperidinium salt ((±)-4-MP salt) of (±)-MAN were determined on the basis of thermodynamic analysis,[6,7] with the results that all of these (±)-salts form racemic compounds in the vicinity of their melting points and that (±)-4-MP salt exists in a conglomerate around room temperature. An optical resolution of (±)-4-MP salt has been achieved by successive preferential crystallization in ethanol at 10°C.

Experimental

Materials. (±)- and (+)-MAN were purchased from Sigma Chemicals Co., and amines from Wako Pure Chemicals Ind.

Preparation of Organic Ammonium Salts. (±)- or (+)-MAN (0.01 mol) was dissolved in diethyl ether. After adding 0.01 mol of amine and stirring for 10 min in an ice bath, the salt formed was collected by filtration, washed with a small amount of diethyl ether, and dried. The salts obtained were recrystallized from an appropriate solvent.

(±)- and (+)-4-MP salts were recrystallized from ethanol. Elemental analysis, specific rotation, and solubility of (±)-4-MP salt: C, 66.73; H, 8.42; N, 5.56% (calcd for $C_{14}H_{21}NO_3$: C, 66.91; H, 8.42; N, 5.57%); $[\alpha]_D^{20}$ +56.0° (*c* 0.50, ethanol); 4.470 g/(100 cm³ ethanol). (±)-4-MP salt: C, 66.73; H, 8.42; N, 5.57%; 11.578 g/(100 cm³ ethanol). (−)-4-MP salt was obtained from mother liquor in the optical resolution by preferential crystallization and was recrystallized twice from ethanol: Mp 136°C; $[\alpha]_D^{20}$ −56.0° (*c* 0.50, ethanol).

Optical Resolution. (±)-4-MP salt (3.184 g) was dissolved in 25 cm³ of ethanol around 40°C to give a racemic solution with a degree of supersaturation of 110% at 10°C. The solution was slowly cooled to 10°C and seeded with 0.010 g of (+)-salt. After stirring for 20 min at 10°C, the salt precipitated was collected by filtration and washed with a small amount of diethyl ether. (±)-4-MP salt (0.112 g) was dissolved in the filtrate around 40°C. The solution was cooled to 10°C and seeded with 0.010 g of (−)-salt. After stirring for 30 min, the salt precipitated was collected by filtration. The filtrate was treated in a similar manner as above. The degrees of resolution of (+)- and (−)-salts were calculated by

$$\text{Degree of resolution}/\% = [\text{YOPM/g} \times 100]/[(\text{Operation amount of (+)- or (−)-salt/g}) - 1.447], \quad (1)$$

where YOPM is the yield of optically pure modification.[8]

Preparation of Optically Pure Mandelic Acid. The (+)- and (−)-4-MP salts (about 0.85 g) obtained in the successive resolution were treated as aqueous solutions through a 1×10 cm column of Amberlite IR-120 in the H^+ form by eluting with water; the initial (+)-salt had an optical purity of 96.5% and the (−)-salt that of 98.2%. The eluents were evaporated to dryness under reduced pressure around 40°C to give (+)- and (−)-MAN. (+)-MAN: yield 95.8%; $[\alpha]_D^{20}$ +154° (*c* 1.00, ethanol). (−)-MAN: yield 94.6%; $[\alpha]_D^{20}$ −157° (*c* 1.00, ethanol) (lit,[9] $[\alpha]_D^{20}$ −159.7° (ethanol)).

Measurements. Specific rotations were measured with a Union Giken high sensitivity PM-101 digital polarimeter using a 0.5 dm path length quarz cell. Infrared spectra were obtained in the range 4000—400 cm^{-1} with a JASCO A-102 infrared spectrophotometer by the KBr disk method. Enthalpies of fusion and melting points were determined with a Rigaku Denki DSC-8230. The solubilities of (±)- and (+)-4-MP salts and the ternary phase diagram were obtained in a similar manner as described in our previous paper.[10]

Results and Discussion

Racemic Structures. Racemic Structures at Melting Point: Free energies of formation of racemates at melting point, ΔG_{mp}^F, were calculated on the basis of

Table 1. Thermodynamic Data for Organic Ammonium Salts of Mandelic Acid

Salts	Mp/K		ΔH^{f} a)/kJ mol^{-1}		ΔG^{F}_{mp} b)	Eutectic point

4-MP h)	394	409	31.8	33.5	−1.01	0.65	393	392

a) ΔH^{f}; Enthalpy of fusion. b) ΔG^{F}_{mp}: Free energy of formation of racemate at melting point. c) These values were calculated by the Schröder-Van Laar and Prigogine-Defay equations. d) PA: Propylammonium salt. e) IPA: Isopropylammonium salt. f) IBA: Isobutylammonium salt. g) BZA: Benzylammonium salt. h) 4-MP: 4-Methylpiperidinium salt.

the enthalpies of fusion, ΔH^{f}, and melting points of (±)- and (+)-salts.[6,7] The thermodynamic data are given in Table 1.

The ΔG^{F}_{mp} values suggest that these (±)-salts are racemic compounds or racemic solid solutions in the vicinity of their melting points, since the values are negative.[6,7,10] The mole fractions and temperatures at the eutectic points were calculated from the Schröder-Van Laar and Prigogine-Defay equations.[11] Mixtures with mole fractions calculated were prepared and their melting points were compared with the eutectic temperatures calculated (Table 1). The melting points obtained agreed closely with the eutectic temperatures calculated. The mixtures melted at their respective temperatures and not over wide ranges. It is concluded from the above results that these (±)-salts form racemic compounds in the vicinity of their melting points.

The mole fractions of (+)-PA, -IPA, -IBA, and -BZA salts at their eutectic points (0.83—0.94) are close to 1, and the absolute values of ΔG^{F}_{mp} are more than 2 kJ mol^{-1}. Therefore, the above (±)-salts form stable racemic compounds.[6,7] However, (±)-4-MP salt may be an unstable racemic compound, since the mole fraction (0.65) is relatively close to 0.5 and the ΔG^{F}_{mp} is −1.01 kJ mol^{-1}.[6,7]

Racemic Structures Around Room Temperature: Unstable racemic compounds such as 4-MP salt have a possibility of transformation to conglomerate at a lower temperature.[6,7] The ΔG^{F}_{283} at 283 K of (±)-4-MP salt was calculated to examine this possibility,[6,7] a positive value (+0.26 kJ mole^{-1}) being obtained. This value indicates that (±)-4-MP salt will form no racemic compounds at 283 K. (±)-4-MP salt shows a infrared spectrum identical with that of its (+)-salt and is more soluble than the (+)-salt at 10 °C. The ternary phase diagram of solubility of 4-MP salt at 10 °C displays the pattern of a conglomerate as shown in Fig. 1.[12] The above results clearly indicated that (±)-4-MP salt exists in a conglomerate around room temperature.

The infrared spectra of (±)-PA, -IPA, -IBA, and -BZA salts are different from those of respective (+)-salts, and the ΔG^{F}_{283} values are negative. Therefore, these (±)-salts also form racemic compounds around room temperature.

Optical Resolution of (±)-4-Methylpiperidinium Salt. The optical resolution of (±)-4-MP salt by successive preferential crystallization has been carried out for a racemic solution with a degree of supersaturation of 110% in ethanol at 10 °C. The result is given in Table 2.

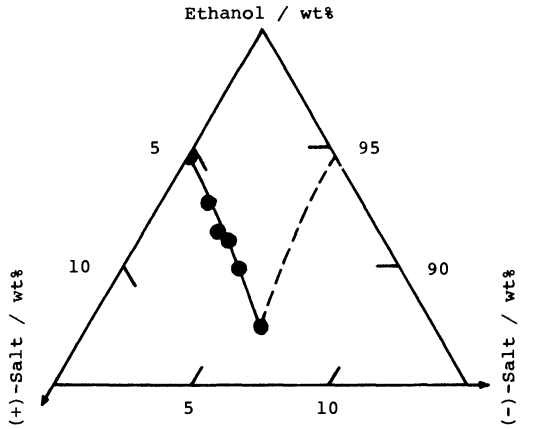

Fig. 1. Ternary phase diagram of solubility of 4-methylpiperidinium salt of mandelic acid. Solvent: Ethanol. Temperature: 10 °C.

It was possible to obtain the (+)- and (−)-salts with an optical purity of 95—100% in a degree of resolution of 62—81%. The (+)- and (−)-salts obtained gave (+)-MAN with an optical purity of 96.4% and (−)-MAN with that of 98.3%, respectively.

The optical resolution has also been carried out for a racemic solution with a degree of supersaturation of 138% to give the (+)-salt with an optical purity of around 90% at a resolution time of 5—10 min. However, the optical purity of the (+)-salt obtained at a resolution time beyond 10 min rapidly decreased with resolution time. The salt with a low optical purity is easily purified by recrystallization. The phase diagram of solubility or the solubility of the (±)-salt gives the optimum amount of ethanol which permits one to obtain the maximum yield of the optically pure salt.[13] The amount of ethanol Ws/wt% is expressed by

$$W_s = 100\, W_E \cdot W/[5000 - W_E \cdot (50 - W)], \quad (2)$$

where W_E/wt% is the amount of ethanol at the eutectic point at 10° ((+)-4-MP salt, 6.34; (−)-salt, 6.34; ethanol, 87.33 wt%) and W/wt% is the amount of the (−)-salt contained in the crystalline salt having an abundance

Table 2. Successive Preferential Crystallization of 4-Methylpiperidinium Salt of (±)-Mandelic Acid[a)]

Run	Added amount of (±)-salt	Operation amount[b)]/g		Resolution time	Salt obtained			
					Yield	Optical purity	YOPM[c)]	Degree of resolution[d)]
	g	(+)-Salt	(−)-Salt	min	g	%	g	%
1	3.184	1.592	1.592	20	0.122	(+) 95.7	0.107	73.8
2	0.112	1.538	1.645	30	0.168	(−)100	0.158	79.8
3	0.158	1.617	1.566	40	0.151	(+) 96.8	0.137	80.6
4	0.141	1.549	1.634	40	0.132	(−) 95.5	0.116	62.0

a) Solvent: 25 cm³ of ethanol. Degree of supersaturation of initial racemic solution: 110%. Seed crystals: 0.010 g of (+)- or (−)-salt. Temperature: 10°C. b) The operation amounts of the (+)- and (−)-salts in solutions were calculated on the basis of the analyses of the salts obtained in Run 1—3. c) YOPM: Yield of optically pure modification. d) Degree of resolution/%=[YOPM/g×100]/[(Operation amount of (+)- or (−)-salt/g)−1.447/g].

of the (+)-salt.

A (+)-4-MP salt with an optical purity of 28.0% (4.00 g) was recrystallized from 25 cm³ of ethanol; the amount calculated is 25.07 cm³. After dissolving the salt at an elevated temperature, the solution was stirred for 30 min at 10°C to crystallize 1.05 g of the (+)-salt with an optical purity of 99.6%; the theoretical yield of the optically pure (+)-salt is 1.12 g. An approximate (±)-salt ($[\alpha]_D^{20}$ +0.7°) was recovered in 2.89 g from the filtrate. (+)-MAN with an optical purity of 99.6% was obtained from the (+)-salt recrystallized.

The above result indicates that (±)-4-MP salt exists in a conglomerate around room temperature, though the (±)-salt forms a racemic compound in the vicinity of the melting point. It was possible to obtain the (+)- and (−)-MAN with a high optical purity by successive preferential crystallization of the (±)-4-MP salt.

Dehydrogenation of Ethylbenzene on Potassium-Promoted Iron Oxide Catalyst Containing Magnesium Oxide

Takenori HIRANO
Kasukabe Laboratory, Nissan Girdler Catalyst Co. Ltd., Ushijima 573, Kasukabe, Saitama 344
(Received March 26, 1986)

Synopsis. Among potassium-promoted iron oxide catalysts containing a minor chromia and a series of alkaline earth oxides, i.e., MgO, CaO, SrO, and BaO, the MgO-containing catalyst showed the best performance with respect to the dehydrogenation activity and the stability even at a steam-to-ethylbenzene molar ratio (H_2O/EB ratio) as low as 6.

The styrene monomer has commercially been produced by the dehydrogenation of ethylbenzene over potassium-promoted iron oxide catalysts in the presence of steam; the usual industrial catalysts consist of iron oxide, potassium carbonate and chromia:[1] known as Shell 105 or G-64A. Nowadays, styrene producers are making efforts to reduce steam consumption from a standpoint of saving energy, that is, lowering the H_2O/EB ratio has the advantage of reducing cost of styrene. Therefore, a more active and stable catalyst is desired in order to obtain an appreciable styrene yield at a low steam condition.[2] In order to modify the catalytic properties of the potassium-promoted iron oxide containing a minor chromia, various alkaline earth oxides were added to the system and the effects of these additives, especially of magnesium oxide, upon the catalytic properties were investigated. Although some patents on dehydrogenation catalysts containing alkaline earth oxides have been published,[3] few basic studies on the catalysts have been carried out.

Experimental

All the catalysts examined were prepared as follows: iron oxide (α-Fe_2O_3, 23 m^2g^{-1}), chromia (Cr_2O_3) and suitable amounts of potassium carbonate (K_2CO_3) and alkaline earth carbonate were mixed and extruded to pellets of 3.2 mm dia. and 4—6 mm length. These were crushed into 16/20 mesh granulates for activity tests at a high H_2O/EB ratio of 11.8, and were used without crushing for long-run tests at a low H_2O/EB ratio of 6. The pellets were dried at 120 °C overnight followed by calcination at 600 °C for 4 h in a muffle furnace. The reactor made of stainless steel (20 mm i.d.) was used for the activity tests at atmospheric pressure. The products were analyzed by gas-chromatography. The surface areas were measured by the BET method. The amounts of carbonaceous deposits, including polymers, were determined by trapping the CO_2 released during oxidation at 450 °C in a closed system (138 cm^3) after vacuum treatments at 250 °C for 30 min. XRD measurements were carried out on a Rigaku X-ray diffractometer with Co $K\alpha$ radiation. The pore volumes and their distributions were measured on an Amco Hg-porosimeter.

Results and Discussion

In order to evaluate the intrinsic activities of catalysts whose compositions are listed in Table 1, dehydrogenation tests on granulated (16/20 mesh) catalysts were carried out at a low conversion region, a high H_2O/EB ratio of 11.8 and in the temperature range 550—620 °C. Since the catalysts were granulated and the H_2O/EB ratio was high, the influences of the pore structure and the deposited carbon on the activity could be eliminated; all the activities reached a steady state within about 20 h after starting a run. The rates and selectivities for styrene formation at 580 °C, and the activation energies for styrene, benzene and toluene formations over various catalysts are listed in Table 1. Among the alkaline earth oxides added, only MgO enhanced the dehydrogenation activity of the potassium-promoted iron oxide without decreasing the selectivity, and CaO enhanced the selectivity although the activity was decreased. The order of promoting effect on the activity was as follows: MgO > SrO > CaO > BaO.

Changing the magnesium content in the Fe_2O_3-K_2CO_3-Cr_2O_3-MgO system, the rate and selectivity for the styrene formation were investigated as functions of the magnesium contents. The results are shown in Fig. 1, where the rate and the selectivity are plotted against the content. A plot of the rate shows a folded straight line, in which the rate increases with an increase in the content at low levels (0—4 wt%). It is almost independent of the content at high levels (4—12 wt%), although the selectivity does not show any significant change with the content. X-ray diffraction analyses of the Mg catalyst indicated that a part of the magnesium oxide was contained as a form of magnesium ferrite ($MgFe_2O_4$), the XRD patterns being shown in Fig. 2. When the MgO content was changed, as depicted in Fig. 3, the XRD peak intensity of the magnesium ferrite (d: 2.97 Å) increased with an

a) Test conditions: H_2O/EB ratio = 11.8, SV = 39100 ml g^{-1} h^{-1}, 3 g cat. b) 16/20 mesh. c) Rate of styrene formation (mol g^{-1} min^{-1}, $\times 10^5$) at 580 °C.

increase in the content below 4 wt%. It then changed little in the content range 4—12 wt%; this behavior of the peak intensity of the magnesium ferrite with the magnesium content is similar to that of the activity with the content. On the other hand, the XRD peak intensity of magnesium oxide (MgO, d: 2. 11 Å) increased linearly with the content (Fig. 3). From these results, it is guessed that the formation of magnesium ferrite on iron oxide can participate in the effect of the magunesium addition on the activity of the potassium-promoted iron oxide catalyst.

For the ethylbenzene dehydrogenation catalyst, a stable activity is required under reaction conditions as well as the activity since the catalyst is used for one or two years at any styrene plant. In order to examine the stability of the Mg catalyst, the change in activity (% EB conversion) with time was investigated at a H_2O/EB ratio as low as 6 and 620 °C. It was then compared with the changes of the K and Ca catalysts; all the catalysts (3.2 mm dia. and 4—6 mm length) were used to investigate the pore structure in addition to the activity. As shown in Fig. 4, the Mg catalyst exhibited an appreciable activity and stability under such severe conditions, while other catalysts, i.e., K and Ca, showed a significant deterioration of the activity with time.

The physical properties of the catalysts in fresh and used states are listed in Table 2; increases in both surface area and pore volume were found on the Mg catalyst after a reaction, whereas those properties of other catalysts were decreased. The mean pore diameter of the Mg catalyst was not greatly altered after a reaction, compared to those of the K and Ca catalysts. These showed remarkable enlargements of the mean pore diameter; the mean pore diameters (*mPD*) were defined by the value at the midpoint of the cumulative pore distribution curve, because all the catalysts showed nallow distributions. Since the mean pore diameter can be determined from the size of the skeletons forming the pore structure of a pellet, the extent of pore destruction under reaction conditions can be expressed by the change in the mean pore diameter. The mean pore diameters of the K and Ca

catalysts were enlarged and their surface areas were reduced; therefore, the pore skeletons, which may be constituted by iron oxide particles, of both catalysts might grow under the reaction conditions. On the other hand, the MgO catalyst exhibited little change in the mean pore diameter; hence, it is considered that the magnesium addition might prevent the pore destruction of the potassium-promoted iron oxide catalyst. From these results, it is suspected that the stability of the pore structure of the Mg catalyst might be associated with the observed stability of the activity at a low H_2O/EB condition.

The carbonaceous deposit on the catalyst was sometimes considered to deactivate the catalysts;[4] however, such a deactivating effect was not observed in this study because the deposited amounts on the K and Ca catalysts, which showed a deterioration in the long-run test, were not so large as that on the Mg catalyst, which showed little deterioration. Then, it can be presumed that the carbonaceous deposit does not exist on the active sites to inhibit the activities.

In earlier commercial dehydrogenation catalysts, MgO and CaO were used as a support.[5] Lee[6] investigated a binaly system of the iron oxide-alkaline earth oxide to find a relationship between the intrinsic activity and the first ionization energy for an alkaline earth atom. The order of the promoting effects of various alkaline earth oxides on iron oxide was as follows: BaO>SrO>CaO>MgO. This is different from the order obtained in this study. Accordingly, the promoting effect of MgO in the potassium-promoted iron oxide might be different from that in a binaly catalyst. From the results obtained in this study, the formation of magnesium ferrite in potassium-promoted iron oxide is considered to take part in the effects of a magnesium addition upon the activity and the stability of the catalyst.

In order to study the valence state in the mixed-valence binuclear ferrocenes, X-ray absorption spectra near the Fe K-edge were measured using synchrotron radiation. Well-resolved lines in the spectra obtained for ferrocene derivatives were assigned to the 1s→3d, 1s→Cp(π^*), and 1s→4p transitions, respectively, based on the molecular orbitals. There is an apparent difference in the 1s→3d transitions between trapped-valence compounds and averaged-valence compounds in the I_3^- salts of the monocation of binuclear ferrocenes. The valence states of the mixed-valence binuclear ferrocenes were also studied by X-ray photoelectron spectroscopy.

Among polynuclear organometallic mixed-valence compounds, there exist metal ions having different formal oxidation states in their individual chemical species. A growing interest has been paid to such compounds in connection with studies of superconductive materials and of biological "mixed-valence" systems.[1] The present authors have studied by Mössbauer spectroscopy the valence state for the salts of mono-oxidized binuclear ferrocene cations, in which two kinds of iron atoms, formally in the Fe(II) and Fe(III) states, are simultaneously present.[2-4]

Mössbauer spectra of the salts of mono-oxidized binuclear ferrocene cations are classified into two types; one is the trapped-valence type which contains ferrocene-like bivalent and ferrocenium-like tervalent atoms, as found in the case of triiodide salts of biferrocene[5] and 1′,1‴-dichlorobiferrocene,[4] and the other is the averaged-valence type which contains two equivalent iron atoms, as in the case of triiodide salts of 1,1″:1′,1‴-biferrocenylene,[6] 1′,1‴-dibromo- and 1′,1‴-diiodobiferrocene.[4] It has been also reported that 1′,1‴-diethyl- and 1′,1‴-dipropylbiferrocenium$^+I_3^-$ salts give rise to a transition from the averaged-valence state of iron atoms to the trapped-valence state as the temperature is lowered.[7] Although Mössbauer spectroscopy can distinguish whether or not the rate of the thermal electron transfer between two iron atoms is higher than ca. 10^{-7} s, no additional information from Mössbauer spectroscopy is available about the thermal electron transfer between the two atoms with a time scale faster than 10^{-7} s.

In the present study, X-ray absorption spectra near the edge structure (XANES) and X-ray photoelectron spectroscopy (XPS), both of which have a time scale of ca. 10^{-16} s, were measured at room temperature and at 80 K. The detailed electronic states of the iron atoms in the mixed-valence binuclear ferrocene salts are discussed by comparing the results with those obtained in Mössbauer spectroscopy of the same compounds which has a time scale of ca. 10^{-7} s.

Experimental

Commercially available ferrocene was purified by sublimation for the measurements. Other compounds were synthesized following the methods described in Refs. 4—7. The confirmed purities were >99% by means of the melting point, elemental analysis, IR, NMR, and Mössbauer spectroscopy.

Fe K-edge XANES spectra were measured at the National Synchrotron Radiation Research Facility (Photon Factory) affiliated to the National Laboratory for High Energy Physics (KEK-PF). Synchrotron radiation emitted from a storage ring, working at 2.5 GeV and ≈160 mA, was monochromated by a Si(311) channel-cut single crystal. The powdery samples were placed between two thin sheets transparent to the X-rays.[8]

XPS spectra were obtained by using Mg $K\alpha$ radiation with a Shimazu ESCA 750 spectrometer. Binding energy data were calibrated by using the binding energy of Cls photoelectron as the standard (285.5 eV). The experimental error for the binding energy was estimated within ±0.1 eV.

Results and Discussion

XANES Spectra. Ferrocene and Ferrocenium Triiodide. In the solid state, the molecular symmetry of ferrocene is known to be D_{5d}. Sohn et al. reported that the π orbitals in cyclopentadienyl (Cp) can be classified into the symmetries with the energy levels shown in Fig. 1.[9] The valence orbitals in iron atoms consist of $e_{2g}(3d)$, $a_{1g}(3d)$, $e_{1g}(3d)$, $a_{1g}(4s)$, $a_{2u}(4p)$, and $e_{1u}(4p)$. The ground state of ferrocene is also known to be $^1A_{1g}(1e_{2g})^4(2a_{1g})^2$. The ground state of the ferrocenium ion is shown to be $^2E_{2g}(1e_{2g})^3(2a_{1g})^2$ by ESR,[10] and by magnetic susceptibility measure-

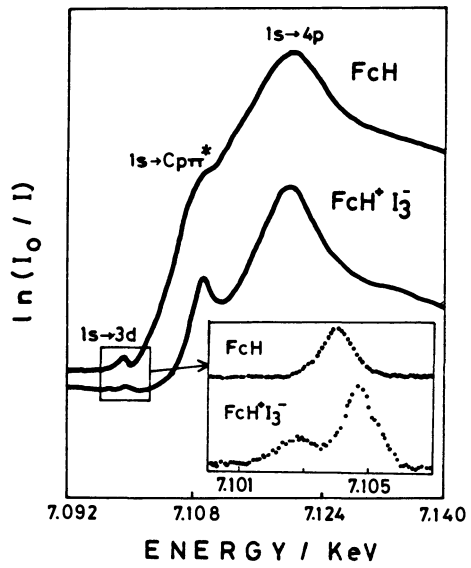

Fig. 2. The XANES spectra of ferrocene and ferrocenium$^+I_3^-$. The 1s→3d transitions are given under magnification. The pre-edge continuum background has been subtracted by smoothing the foot of the main peak.

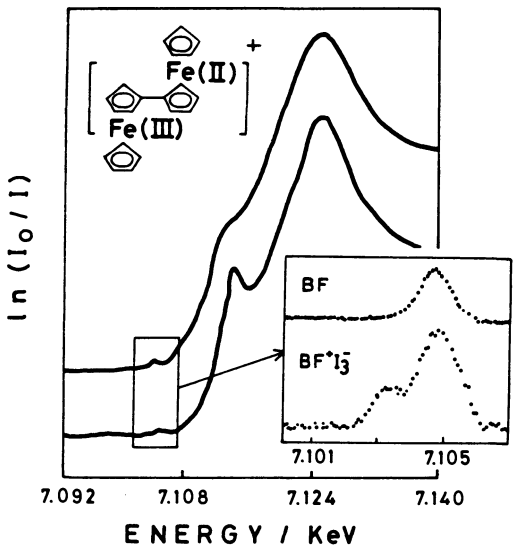

Fig. 3. The XANES spectra of BF and BF$^+I_3^-$. The weak 1s→3d transition in BF consists of a single peak, while the splitting of 1.57eV in the 1s→3d transition of BF$^+I_3^-$ is observed.

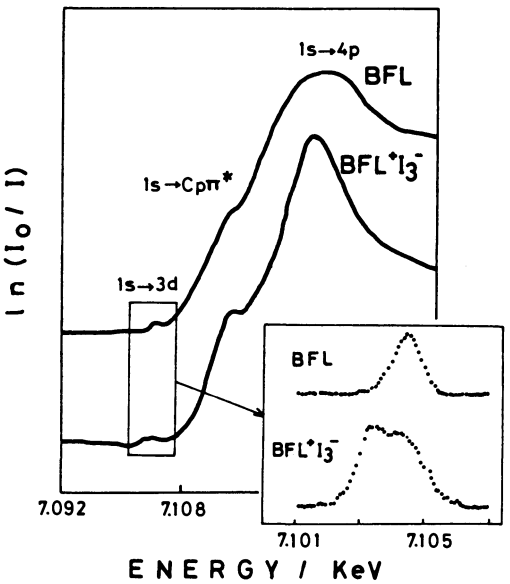

Fig. 4. The XANES spectra of BFL and BFL$^+I_3^-$. For BFL$^+I_3^-$ the splitting in the 1s→3d transition is small and the intensity of the lower energy peak is strong.

ments.[11] This state is slightly split into two Kramers doublets by spin-orbit coupling, indicating a crystal field with a symmetry lower than D_{5d}. However, since the splitting of the two Kramers doublets is estimated to be much smaller than the relevant transition energy, it is neglected in the present investigation.

Figure 2 shows the Fe K-edge XANES spectra of ferrocene and ferrocenium triiodide salt. There is a weak absorption peak below the Fe K-edge ionization threshold, followed by a shoulder on a rising absorption curve which culminates in a strong peak. In the XANES spectrum of ferrocene, the strong peak can be ascribed to the allowed transitions 1s→4p e_{1u} or a_{2u}, the lower-energy shoulder to the 1s→Cp(π^*), and the weak pre-edge peak to the dipole-forbidden (quadrupole-allowed or vibronically allowed) transition 1s→3d e_{1g}, respectively, based on the relative energy estimated in the molecular orbitals in ferrocene shown in Fig. 1.[9]

The XANES spectrum of ferrocenium ion has been compared with that of ferrocene. In Fig. 2, no energy difference is observed in the intense 1s→4p transitions between ferrocene and ferrocenium$^+I_3^-$. On the other hand, there exists a significant difference in the forbidden transition 1s→3d between ferrocene and

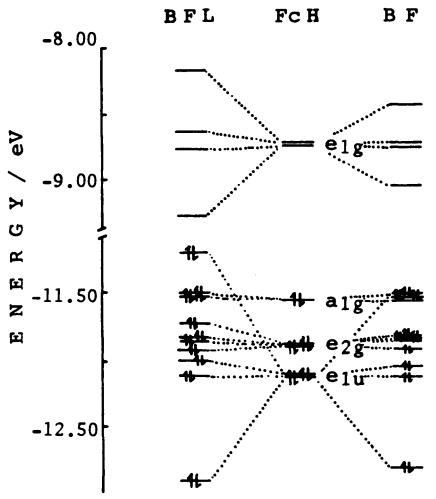

Fig. 5. The total ground-state configuration in the trans (C_{2h}) conformation of BF and in the D_{2h} point group of BFL.[12]

ferrocenium$^+I_3^-$. The weak 1s→3d transition in ferrocene consists of a single peak, while a splitting of ca. 2 eV is observed in the 1s→3d transition of ferrocenium ion. These results are explained in terms of the crystal field splitting of the ground state. The electronic ground states of the ferrocene and ferrocenium ion are $^1A_{1g}$ and $^2E_{2g}$ consisting of the $a_{1g}^2e_{2g}^4$ and $a_{1g}^2e_{2g}^3$ configurations, respectively. The 1s→3d transition of ferrocene is assigned to the transition from the 1s orbital to the unoccupied e_{1g} state; in ferrocenium ion, there are two possibilities for the 1s→3d transitions from the 1s to the unoccupied valence state e_{1g} and e_{2g}. The value of the splitting (ca. 2 eV) in the 1s→3d transitions of ferrocenium ion is roughly comparable with the crystal field splitting observed in the electronic absorption data assigned to the d-d transition which corresponds to about 25000 cm^{-1} (ca. 3 eV).[12]

Biferrocene, 1,1″:1′,1‴-Biferrocenylene and Their Triiodide Salts. Figures 3 and 4 show the XANES spectra of biferrocene (BF) and 1,1″:1′,1‴-biferrocenylene (BFL) compared with their triiodide salts, respectively. The features in the XANES spectra for the neutral species are similar to the spectral feature for ferrocene. Kirchner et al. reported on the molecular orbitals calculated for BF in the trans (C_{2h}) conformation that the net charge on the iron atom and total electron density in each d orbital of BF are similar to those of ferrocene, as shown in Fig. 5.[12] This result is consistent with the data that the isomer shift and quadrupole splitting in Mössbauer spectra of BF and BFL agree with those of ferrocene.

There is an apparent difference in the 1s→3d transition between biferrocenium$^+I_3^-$ (BF$^+I_3^-$) and 1,1″:1′,1‴-biferrocenylenium$^+I_3^-$(BFL$^+I_3^-$), as seen in Figs. 3 and 4 under magnification. The pre-edge continuum background has been subtracted by

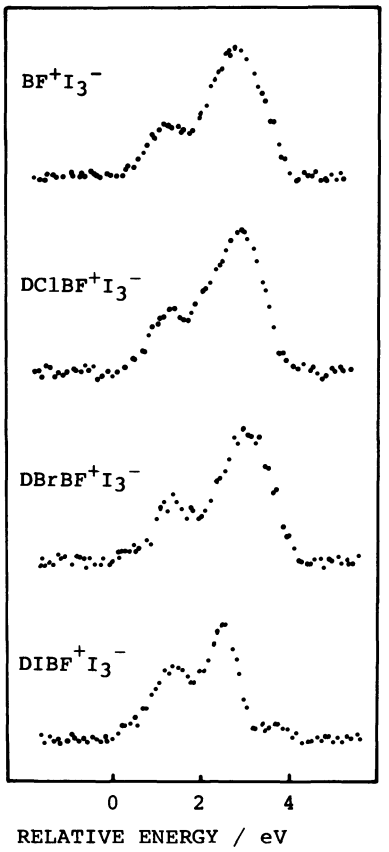

Fig. 6. The 1s→3d transition in the XANES spectra for the salts.

smoothing the foot of the main peak. BF$^+I_3^-$, which shows a trapped-valence state in the Mössbauer spectrum, exhibits an asymmetric splitting of 1.57 eV in the 1s→3d transition, while BFL$^+I_3^-$, which shows an averaged-valence state in the Mössbauer spectrum, gives a nearly symmetric splitting of 0.89 eV. These transitions are assigned to the transitions from 1s to unoccupied molecular orbitals which are mainly ascribed to the 3d orbitals corresponding to e_{1g} and e_{2g} in ferrocene.

The splitting in the 3d orbital for averaged-valence type, BFL$^+I_3^-$, is found to be smaller than that for trapped-valence type, BF$^+I_3^-$, and the intensity of the lower-energy peak in the 1s→3d transition for BFL$^+I_3^-$ is stronger than that for BF$^+I_3^-$. These results are consistent with those obtained in Mössbauer spectroscopy, suggesting that the molecular orbital of BF$^+I_3^-$ differs from that of BFL$^+I_3^-$.

Halogenated Biferrocene Derivatives and Their Triiodide Salts. The features of the XANES spectra for halogenated biferrocenes are also similar to the spectral feature for ferrocene. Figure 6 shows the 1s→3d transitions in the XANES spectra for the salts of monooxidized biferrocene (BF$^+I_3^-$), 1′,1‴-dichlorobiferrocene (DClBF$^+I_3^-$), 1′,1‴-dibromobiferrocene (DBrBF$^+I_3^-$) and 1′,1‴-diiodobiferrocene (DIBF$^+I_3^-$).

The Mössbauer spectrum of $DClBF^+I_3^-$ shows a trapped-valence state, while the Mössbauer spectra of $DBrBF^+I_3^-$ and $DIBF^+I_3^-$ show averaged-valence states. The XANES spectrum of $DIBF^+I_3^-$ is distinguishable from the others by the ratio of the peak intensities and by the separation of the split peaks. Although it is difficult to interpret the XANES spectrum quantitatively for the averaged-valence state, the peculiar XANES spectrum for $DIBF^+I_3^-$ can be qualitatively interpreted as a fully delocalized system on two equivalent iron atoms. On the other hand, the XANES spectrum for $DBrBF^+I_3^-$ is similar to those of $BF^+I_3^-$ and $DClBF^+I_3^-$, which indicate trapped-valence states in the Mössbauer spectra. The inconsistensy of the results obtained from XANES spectra and Mössbauer spectra is explained by assuming that the rate of the thermal electron transfer between the two iron atoms in $DIBF^+I_3^-$ is higher than ca. 10^{16} s^{-1} and the rate in $DBrBF^+I_3^-$ is higher than ca. 10^7 s^{-1} but lower than ca. 10^{16} s^{-1}.

X-Ray Photoelectron Spectroscopy. Since the time scale of XPS is ca. 10^{-16} s comparable with that of XANES, XPS also affords the possibility of distinguishing the localized electronic systems from delocalized ones in the mixed-valence binuclear ferrocenes.[13] Although the XPS for ferrocene itself and ferrocenium salts has been studied for many years, there are few reports concerning the XPS for the mixed-valence binuclear ferrocenes. In the present studies, attempts were also made to interpret the XPS spectra of the mixed-valence binuclear ferrocene derivatives in comparison with those of ferrocene and ferrocenium salts.

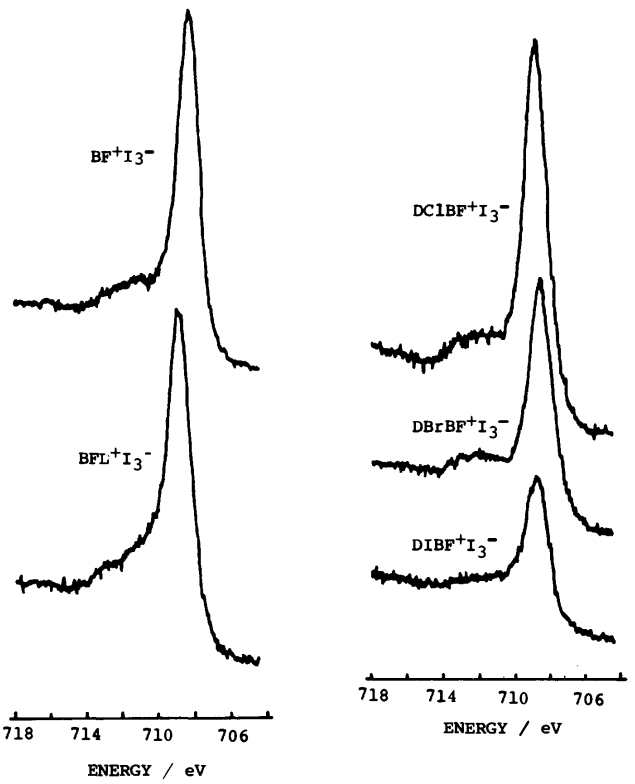

Fig. 7. The $Fe2p_{3/2}$ XPS spectra of the triiodide salts for binuclear ferrocenes.

For ferrocene a sharp band $Fe2p_{3/2}$ is observed at a binding energy of ca. 708 eV, while ferrocenium triiodide has much broader $Fe2p_{3/2}$ lines at 771 eV due to the exchange interaction of the core electrons with the unpaired valence electrons.[14] In addition, the satellite band with the broad line for ferrocenium ion is observed at 713 eV and is ascribed to the shake-up from the highest occupied orbital to the lowest unoccupied orbital.[14]

As shown in Fig. 7, the XPS spectra of the I_3^- salts of monocation of binuclear ferrocenes are found to consist of a single $Fe2p_{3/2}$ transition peak with a satellite peak. In the XPS spectra for mixed-valence binuclear ferrocenes, it is difficult to distinguish completely a sharp Fe(II) band from an Fe(III) band broadened by the exchange interaction of the core electrons with the valence electrons.

The XPS spectra of $BF^+I_3^-$, which indicates a trapped-valence state in Mössbauer spectra, are characterized by the main peak in the high energy state and the satellite peak in the low energy state. On the other hand, the satellite band in the spectrum of $BFL^+I_3^-$ which shows an averaged-valence state in Mössbauer spectra becomes broader and of lower energy than that of $BF^+I_3^-$. The fact that the position of the shake-up satellite band shifts to lower energy indicates that the splitting in the 3d orbitals for averaged-valence compounds is smaller than that for trapped-valence compounds.

Figure 7 shows the XPS spectra for halogenated compounds. In the XPS spectra of $DBrBF^+I_3^-$ and $DClBF^+I_3^-$, the satellite bands are clearly observed at the high-energy region as in the case of $BF^+I_3^-$. On the other hand, the XPS spectrum of $DIBF^+I_3^-$ is similar to that of $BFL^+I_3^-$, although the satellite band is not definitely characterized in the spectrum. These results indicate that two iron atoms of $DIBF^+I_3^-$ are equivalent in a delocalized system in the range of the time scale of 10^{-16} s and that the electrons are hopping thermally between the two unequivalent iron atoms in the rate from 10^{-7} s to 10^{-16} s in the case of $DBrBF^+I_3^-$.

In the temperature range from 80 K to 298 K, Mössbauer spectra show the trapped-valence states for $BF^+I_3^-$ and $DClBF^+I_3^-$ and the averaged-valence states for $BFL^+I_3^-$, $DBrBF^+I_3^-$ and $DIBF^+I_3^-$. The latter are known to give the averaged-valence states even at 4.2 K, whereas $BF^+I_3^-$ becomes an averaged-valence state above 298 K. From the results of Mössbauer, XANES, and XPS data, it can be concluded that the trapped-valence state becomes more stable in the order $DClBF^+I_3^- > BF^+I_3^- > DBrBF^+I_3^- > DIBF^+I_3^-$. This order can neither be explained by the order of electronega-

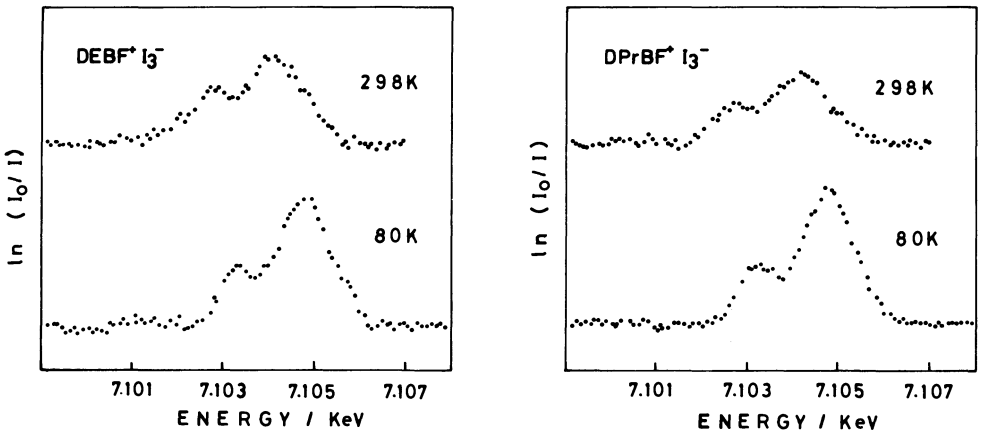

Fig. 8. The temperature dependence of the 1s→3d transition in the XANES spectra for $DEBF^+I_3^-$ and $DPrBF^+I_3^-$.

tivity for the substituted halogen atoms nor by the order of the ionic radii. It can, therefore, be presumed that the difference in electronic state between the two iron atoms is caused by the structual effect of substituents, rather than by their electronic effect.

The most prominent features of the infrared spectra are similar in binuclear ferrocenium ions because of the similarity of the molecular structures. However, there appears to be a difference in the band near 680 cm^{-1} band associated with the fulvalene moiety.[15] The disappearance of the 680 cm^{-1} band in $DIBF^+I_3^-$ reveals that the fulvalene moiety has a symmetric structure and the others, whose spectra give strong peaks at ca. 680 cm^{-1}, have an asymmetric fulvalene moiety. Although further structual studies need to be carried out, it would appear that a symmetric molecular structure is indispensable for yielding the averaged-valence state of the iron atoms.

1′,1‴-Diethyl- and Dipropylbiferrocene and their Triiodide Salts. It is found that Mössbauer spectra in 1′,1‴-diethylbiferrocenium$^+I_3^-$ ($DEBF^+I_3^-$) and 1′,1‴-dipropylbiferrocenium$^+I_3^-$ ($DPrBF^+I_3^-$) are temperature dependent, since a trapped-valence state of the iron atoms is observed at low temperatures and an averaged-valence state at room temperature.[7] The mechanism of this temperature dependence of the Mössbauer spectra has been interpreted by a change of the molecular orbitals accompanying a change in the crystal structure. This is because no-broadening cannot be ascribed to a relaxation effect adopted to the temperature dependence of the Mössbauer spectrum found in *trans*-μ-(as-indacene)bis(cyclopentadienyliron).[7,16] This interpretation was later supported by the X-ray crystal-structure determination of 1′,1‴-dipropylbiferrocenium triiodide at different temperatures.[15] The structural data indicate that the molecular orbitals are influenced more directly by the interaction between the triiodide ion and the ferrocene moiety rather by the intramolecular structural change, especially in the case of the mixed-valence compounds.

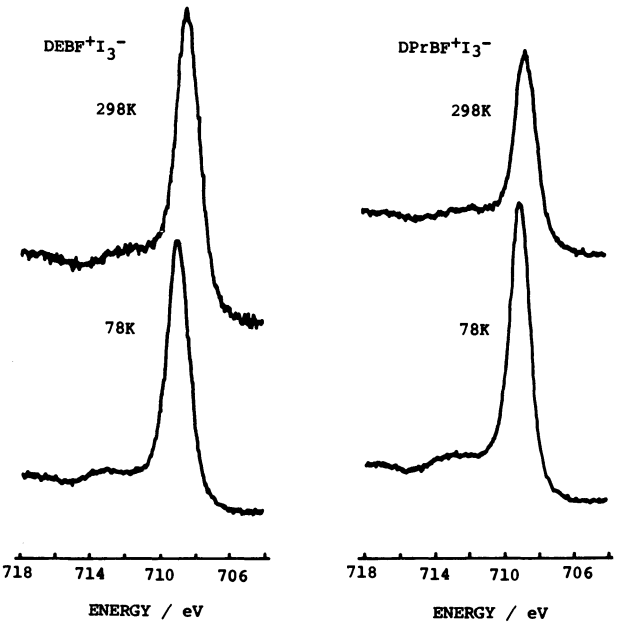

Fig. 9. The temperature dependence of the $Fe2p_{3/2}$ XPS spectra for $DEBF^+I_3^-$ and $DPrBF^+I_3^-$.

The temperature dependence of the XANES spectra for $DEBF^+I_3^-$ and $DPrBF^+I_3^-$ is shown in Fig. 8. The XANES spectra at 80 K resemble those of the trapped-valence type compounds, while the spectra at room temperature are similar to those of the averaged-valence type compounds. As shown in Fig. 9, there seems to be a slight temperature dependence of the peak assigned to $Fe2p_{3/2}$ in XPS spectra for $DEBF^+I_3^-$ and $DPrBF^+I_3^-$, that is, the satellite peaks are likely to appear at lower temperatures. This dependence is not inconsistent with the results obtained in XANES. These results lead to the conclusion that the temperature dependence of the electronic states for $DEBF^+I_3^-$ and $DPrBF^+I_3^-$ is explained by assuming a substantial change in the molecular orbital caused by the change of the crystal structure.[15]

It is concluded that there are two types of electronic states in the mixed-valence compounds. One is satisfactorily explained by a thermal electron tranfer between the two iron atoms in $DBrBF^+I_3^-$, because the Mössbauer spectra show the averaged-valence state at the studied temperature, while the feature of XANES and XPS spectra are similar to those for the trapped-valence compounds. The other is interpreted in terms of the substantial change of the molecular orbital caused by the change of the crystal structure at higher temperatures.

The XPS spectra of $I3d_{5/2}$ for mixed-valence binuclear ferrocenes are shown in Fig. 10. The XPS spectrum of $BF^+I_3^-$ consists of a single $I3d_{5/2}$ transition peak with a shoulder whose intensity is one half that of the main peak. The main peak is assigned to two negatively charged iodine atoms in the terminal position of I_3^- and the shoulder is assigned to an iodine atom at the central position of I_3^-. The charge on the triiodide ion is highly localized and the negatively charged iodine atoms in the terminal position seem to have a significant effect on the electronic states of the ferrocene moiety.

This speculation is supported by the study of the crystal structure for an analogous trapped-valence compound determined by single-crystal X-ray diffraction.[2,3] The crystal structure for 1′,1‴-dibutylbiferrocenium triiodide at 150 K, whose Mössbauer spectrum shows a trapped-valence state, reveals that one of the negatively charged iodine atoms in the terminal position in a triiodide ion is situated near the ferrocenium-like moiety. It can be presumed that the localization of the molecular orbitals should be caused by such an asymmetric structure between the triiodide ion and the ferrocene moiety.

On the other hand, the XPS spectrum of $I3d_{5/2}$ for $BFL^+I_3^-$, whose Mössbauer spectrum shows the averaged-valence state, gives an apparently symmetric peak. Since this peak broadens, it can be interpreted as a splitting between the main peak and the side peak in the XPS spectrum of $BFL^+I_3^-$ which is smaller than that of $BF^+I_3^-$. It can be presumed that the shift of the negative charge on I_3^- in $BFL^+I_3^-$ is insignificant and then the electronic effect of the counter anion on the ferrocene moiety is symmetric, which seems to be favorable to the averaged-valence state.

The XPS spectra of $I3d_{5/2}$ for halogenated derivatives are also given in Fig. 10. The spectra for $DClBF^+I_3^-$ and $DBrBF^+I_3^-$ are characterized by the broad bands, indicating that there exist various kinds of iodine atoms with different electronic states in the crystal. Unfortunately, the spectra of $DIBF^+I_3^-$ cannot be readily interpreted because of the overlap of the spectral components of the iodine atoms of I_3^- and those attached to the Cp rings.

Figure 11 shows the XPS spectra of $I3d_{5/2}$ for $DEBF^+I_3^-$ and $DPrBF^+I_3^-$. These spectra also show broad single peaks both at 78 K and 298 K. It can, therefore, be presumed that a slight difference of the interaction between the triiodide ion and the ferrocene moiety at an increased temperature gives rise to a valence fluctuation in $DEBF^+I_3^-$ and $DPrBF^+I_3^-$.

The authors are indebted to Dr. Sei'ichiro Iijima, at Research Institute for Polymers and Textiles, for his kind preparation of diethyl- and dipropylbiferrocenium triiodides, and to Professor Takaharu Ohnishi and Dr. Kazunari Domen at Research Laboratory of Resources Utilization, Tokyo Institute of Technology, for their kind help with the use of the X-ray photoelectron spectrometer and the discussion of the results. The authors are grateful to Dr. Masaharu Nomura at National Laboratory for High Energy Physics, and Messrs. Toshihiko Yokoyama, Kiyotaka

The Point of Zero Charge and the Isoelectric Point of γ-Fe_2O_3 and α-Fe_2O_3

Haruo WATANABE and Jun'etsu SETO*
Sony Corporation Research Center, 174 Fujitsuka-cho, Hodogaya-ku, Yokohama 240
(Received October 1, 1985)

The difference of the point of zero charge (PZC) and isoelectric point (IEP) values for γ- and α-Fe_2O_3 were measured and are quantitatively explained by the difference in crystal structure. Great care was taken to assure the purity of the samples and that measurements were taken under identical conditions. The PZC and the IEP for the "unhydrated" samples, were the same for each crystal structure, with the values for γ-Fe_2O_3 being more acidic, by 1.1 or 1.2 pH units, than for α-Fe_2O_3. This difference can be quantitatively explained by Parks' equation, in terms of the difference in the coordinations of the Fe^{3+} ions in the two crystal structures.

γ-Fe_2O_3 is a ferrimagnetic inverse-spinel type iron oxide, which is widely used for making magnetic recording tapes. Its surface properties have a large influence on its dispersibility in the paint, and thus on the output and noise characteristics of the tape.[1] Although the PZC and the IEP are important parameters which characterize the surface of the γ-Fe_2O_3, little work has been reported on this subject. Iwasaki et al.[2] reported an IEP at pH 6.7 for a sample with a γ-FeOOH phase. Parks' review[3] of the work on α-Fe_2O_3 shows a wide scattering of the reported values of IEP and PZC, ranging from 1.9 to 9.04. This can be attributed to variations, in the level of surface impurities, the hydration states, and in the conditions and methods of measurement.

The dependence of the IEP value on the crystal structure was reported for manganese[4] and aluminum oxides.[5] Kittaka and Morimoto[6] reported that the IEP in inverse-spinel type oxides is lower than that in normal-spinel type oxides. They explained this in terms of the coordination between the hydroxyl group and the metal ions at the surface.

The aim of the present work is to measure the inherent PZC and IEP values of acicular γ- and α-Fe_2O_3, and to provide a quantitative explanation for the difference between them. In order to obtain reliable values, care was taken to assure both the purity of the samples and the reproducibility of the measurement conditions. The control of the measurement conditions is especially important in measurements involving the state of hydration of the samples.

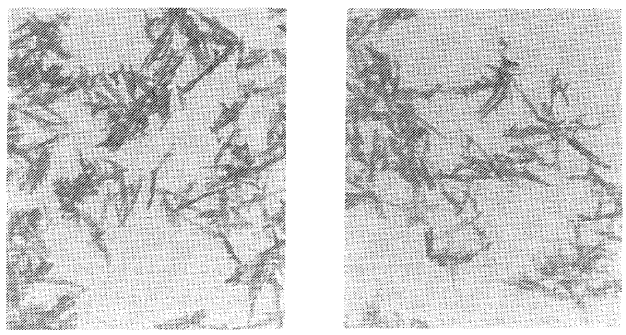
Experimental

Samples. The γ-Fe_2O_3 sample was prepared by the dehydration reduction of synthetic acicular α-FeOOH, followed by an oxidation. The α-FeOOH was prepared by the oxidation of the precipitate, formed by adding a NaOH aqueous solution to an iron (II) sulfate aqueous solution. The α-FeOOH was subjected to dehydration reduction at 350 °C under a hydrogen flow for 1 h, and then, oxidized at 250 °C under an air flow for 1 h. The product was confirmed to be spinel latticed γ-Fe_2O_3 by X-ray diffraction and had a magnetization of 73.0 emu g^{-1} as measured at room temperature by a vibrating sample magnetometer (Princeton Applied Research, Model-155). An electron micrograph of the γ-Fe_2O_3 particles is shown in Fig. 1a. The specific surface area of the γ-Fe_2O_3 particles was established as 18.6 $m^2 g^{-1}$ by the BET method of nitrogen adsorption at liquid nitrogen temperature. The atomic absorption spectrum of the γ-Fe_2O_3 particles revealed no significant metallic ion impurity, although a small amount of sulfate ion was detected. The sulfate ion content was determined from the amount of $BaSO_4$ precipitate, formed on the addition of $BaCl_2$ to a HCl solution of the γ-Fe_2O_3 particles, and was found to be 0.96 wt.%.

The α-Fe_2O_3 sample was prepared by heat treating the γ-Fe_2O_3 sample at 550 °C for 2 h in air.[7] Examination of the sample by X-ray diffraction verified it to be rhombohedral hematite. The α-Fe_2O_3 particles' specific surface area was 16.0 $m^2 g^{-1}$, which is a little smaller than that of the parent γ-Fe_2O_3 particles. Electron microscopic observation of α-Fe_2O_3 particles in Fig. 1b indicated that they retained the shape of the γ-Fe_2O_3 particles. The sulfate ion content in these samples was 0.85 wt%.

Cleaning the Samples. The samples were cleaned in 150 g batches using the following procedure. First, a water rinse in which the sample is decanted ten times with 5L of doubly-distilled water. Second, an alkali wash where the sample is decanted 3 times with 5L of KOH solution (pH 9), followed by a second water rinse. Third, the batches were electrodialized for one week, after which they were then filtered, dried at 100 °C for 24 h in an oven, and then stored in a desiccator.

Potentiometric Titration Method.[8] Batches of both samples, corresponding to 100 m^2 of total surface area, were



γ-Fe_2O_3 18.6 $m^2 g^{-1}$ (a) α-Fe_2O_3 16.0 $m^2 g^{-1}$ (b)

Fig. 1. Electron micrograph of γ-Fe_2O_3 sample (a) and α-Fe_2O_3 sample (b).

dispersed into 150 ml of about 0.01 M† KOH solution and adjusted to various values of ionic strength by the addition of KCl. The solution was then titrated potentiometrically. The titration cell was a 500 ml Pyrex flask, with a water jacket through which thermostated water was circulated to maintain the cell temperature at 20 °C. Glass and calomel electrodes, a thermometer, a microburet, and an inlet and outlet for purified nitrogen gas, were inserted into the cell through rubber gaskets. A Teflon stirring rod with Teflon blades, was also inserted into the center of the cell, through a Teflon greaseless seal. The amount of titrant added and the pH of the suspension were recorded by a Recording Auto Titrator (Hiranuma Sangyo Co., Ltd.). The titration was started at about pH 12, and 0.1 ml of the titrant, HCl standard solution, was added at 3 min intervals (because equilibrium was reached in 3 min.) The measurement was repeated 3 times and the pH values differed by less than ± 0.1 pH unit which is equivalent to an adsorption density of ± 1.0 $\mu C\,cm^{-2}$. The measurment was also carried out for solutions of different ionic strength.

Microelectrophoretic Method A lateral quartz cell with plane-parallel walls was used in the microelectrophoretic measurement. The 40 mm long cell had a rectangular cross-section whose inside dimensions were 1.0×10 mm. The electric field strength (E) was about 10 $V\,cm^{-1}$. The migration speed (u) of the particles was measured and the ζ-potential was calculated by the following formula by Smoluchowski.[9]

$$\zeta = 4\pi\eta u/\varepsilon E,$$

where ε is the dielectric constant, and η is the vicosity.

The suspension was prepared by dispersing 5 mg of the sample ultrasonically in 100 ml of aqueous solution, the pH of which was adjusted by KOH and HCl, and the ionic strength of which was adjusted to 4.0×10^{-5} M by KCl. This suspension was stored in tightly stoppered glass vessel and handled under a nitrogen atmosphere. The pH value of the suspension did not change for 20 h, which is quite adequate for measuring the IEP.

The hydration time hereafter mentioned is the time taken from the preparation of the dispersion to the measurement, that is the time during which the samples were in contact, at room temperature, with the aqueous media.

Results

The γ-Fe_2O_3 sample after washing with water contained 0.56 wt% of sulfate ions, and the α-Fe_2O_3 sample contained 0.55 wt% of sulfate ions. The γ-Fe_2O_3 sample after electrodialysis contained 0.06 wt% of sulfate ions and the α-Fe_2O_3 sample contained 0.25 wt%. The higher content of sulfate ions in the α-Fe_2O_3 sample can be explained by the migration of sulfate ions from the surface into the bulk during the heat treatment. Contamination by potassium ions, possibly introduced during the alkali washing, was found to be less than 5 ppm by the atomic absorption method. The adsorption density of the γ-Fe_2O_3 sample at the three stages of cleaning is plotted against pH in Fig. 2. The PZC is the pH value when the surface charge density is zero, and was found to be more basic after cleaning. The PZC value of the sample after alkali washing and electrodialysis, was 5.5.

Figure 3 shows the results of the potentiometric titration of the α-Fe_2O_3 sample. The PZC value of the α-Fe_2O_3, as with the γ-Fe_2O_3 sample, shifted in the basic direction during cleaning. The PZC value of the α-Fe_2O_3 sample after alkali washing and electrodialysis was 6.7.

Figures 4 and 5 show the plots of adsorption density versus pH taken at various ionic strengths, for the γ- and α-Fe_2O_3 respectively. As can be seen for an ionic strength of 1.0 M or less the curves have the same intersection point. Thus, the absence of a shift in the PZC value with variation of ionic strength was ascertained for both samples.

The ζ-potential increased with the hydration time, as shown in Figs. 6 and 7, for the γ-Fe_2O_3 and α-Fe_2O_3 samples respectively. Constant ζ-potential values were observed for both the γ- and α-Fe_2O_3 samples, for hydration times of 15 h and over, with no significant change being observed even after one week's hydration. The ζ-potentials at 0.5 h hydration are plotted

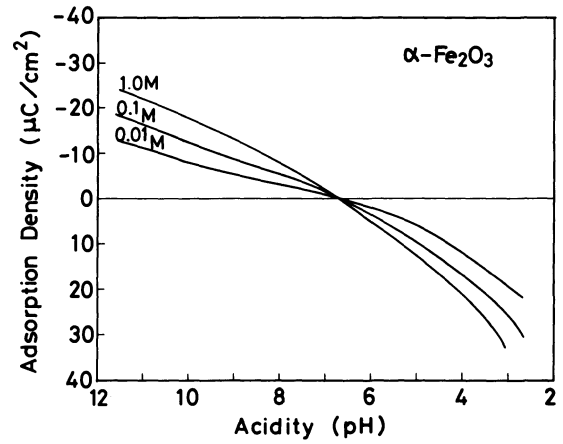

Fig. 5. Surface charge density of α-Fe_2O_3 as a function of pH: ionic strength, 0.01 M, 0.1 M, 1.0 M: temperature, 20 °C.

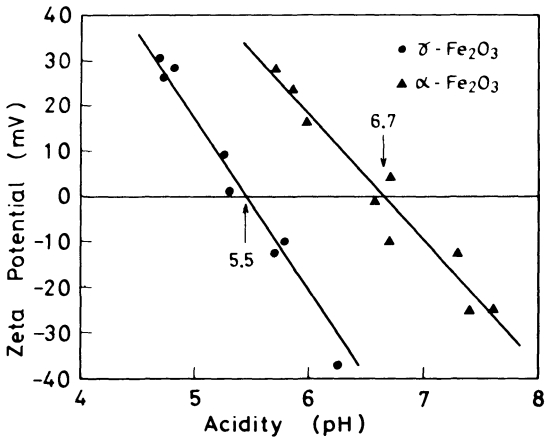

Fig. 8. Zeta potentials of γ-Fe_2O_3 hydrated up to 30 min as a function of pH: ionic strength, 4×10^{-5} M.

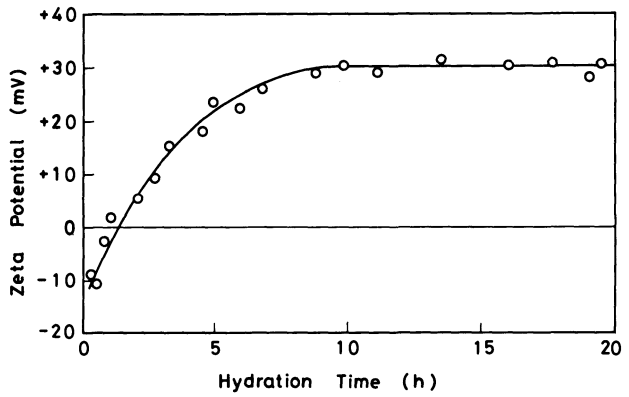

Fig. 6. Zeta potential of γ-Fe_2O_3 at pH 5.70 as a function of the hydration time.

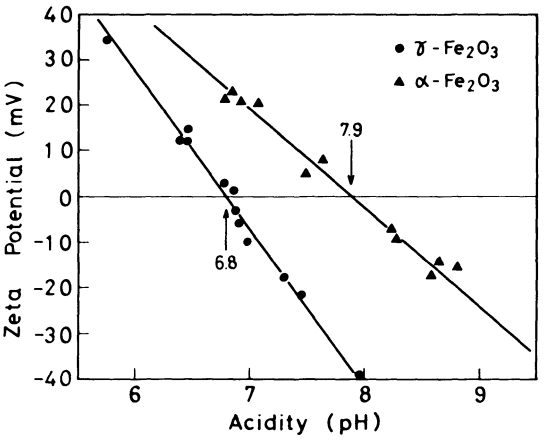

Fig. 9. Zeta potentials of γ- and α-Fe_2O_3 hydrated for 20 h as a function of pH: ionic strength, 4×10^{-5} M.

against the pH in Fig. 8. The zero point of the ζ-potential of the γ-Fe_2O_3 sample, that is its IEP, is 5.5±0.2 and that of the α-Fe_2O_3 sample is 6.7±0.2. These values, for the low hydration state, agree with the PZC values measured by potentiometric titration.

The ζ-potential of the γ- and α-Fe_2O_3 sample after 20 h hydration are plotted in Fig. 9. After 20 h hydration, the IEP of the γ-Fe_2O_3 sample was 6.8±0.2, and that of the α-Fe_2O_3 sample was 7.9±0.2. The IEPs of the γ- and α-Fe_2O_3 samples move in the basic direction by 1.3 and 1.2 pH units, respectively.

Discussion

Effect of Sulfate Ions. The PZC of the γ- and α-Fe_2O_3 samples shifts to higher values as the sulfate ion content decreases. These results correspond to those reviewed by Parks on α-Fe_2O_3[3].

The adsorption equilibrium of sulfate ions on iron oxide is represented as follows,

$$O\begin{matrix}\rangle Fe\text{-}OH \\ \rangle Fe\text{-}OH\end{matrix} + SO_4^{2-} \rightleftharpoons O\begin{matrix}\rangle Fe\text{-}O \\ \rangle Fe\text{-}O\end{matrix}\rangle S\begin{matrix}\langle O \\ \langle O\end{matrix} + 2OH^-$$

Parfitt and Smart[10] showed that this adsorption occurs at pH values less than 8. Therefore, the desorption of sulfate ions from the surface is not negligible around the pH values corresponding to the IEP and PZC of the iron oxides. The desorption of sulfate ions causes the adsorption of hydroxide ions, which results in a lowering of the pH of the suspension and thus shifts the PZC value in the acidic direction.

The PZCs obtained by potentiometric titration of the γ- and α-Fe_2O_3 samples after alkali washing and electrodialysis, coincide with the IEPs measured by the electrophoretic method for the short hydration time of 0.5 h. This suggests that the influence of the specific adsorption of ions on the particles' surface has been eliminated.

Effect of Hydration. The value of the PZC and IEP of γ-Fe_2O_3 hydrated for 0.5 h is 5.5, and the value for α-Fe_2O_3 hydrated for 0.5 h is 6.7. This value of 6.7 for α-Fe_2O_3 is nearly equal to the values reported, on natural hematite and ignited α-Fe_2O_3 by Johansen and Buchanan[11] and Iwasaki et al.[12]

The value of the IEPs of γ- and α-Fe_2O_3 increases with increasing hydration time. The IEP of hydrated γ-Fe_2O_3 is 6.8, and that of hydrated α-Fe_2O_3 is 7.9. The value of 6.8, for the hydrated γ-Fe_2O_3, is in good agreement with the value of 6.7 obtained by Iwasaki et al.[2] for γ-Fe_2O_3, containing a small amount of lepidocrocite. The IEP value of 7.9 for hydrated α-Fe_2O_3 agrees well with the 8.0 value obtained by Johansen and Buchanan.[11]

The IEPs of γ- and α-Fe_2O_3 increased by 1.3 and 1.2 pH units respectively on hydration. Parks[3] calculated that there was an average of 2.1 pH units difference, between the IEPs of the hydrated and unhydrated oxides. Johansen and Buchanan[11] reported a decrease of 1.5 pH units in the IEP after dehydration.

The difference between the value of the IEPs of γ- and α-Fe_2O_3 was 1.2 pH units for the unhydrated samples and 1.1 pH units for the hydrated sample.

The reason why the IEPs of the oxides shift to the basic direction has been considered in terms of the formation of a hydrated layer[3] and the interacting forces between adjacent hydroxyl groups[13] at the particle surface. Ahmed and Maksimov[14,15] also reported the shift of PZC on hydration, and pointed out that the hydration is remarkable, when the amount of metal ions dissolved in the aqueous media, is of the order of the surface concentration of ions.

In this measurement, hydration caused a large increase in the IEP, whereas the PZC was nearly constant for at least a number of days. This discrepancy may be due to the fact that the concentration of the suspensions used in the microelectrophoretic method was smaller by a factor of 10^3 from the concentration used in the potentiometric titration method.

Effect of Crystal Structure. The difference in IEPs of the γ- and α-Fe_2O_3 samples can be considered to be due to the difference in their crystal structures, because the shapes of the particles, their specific surface areas and the cleaning and hydration operations applied to both of the samples were the same.

The crystal structures of γ- and α-Fe_2O_3 are the same as those of γ- and α-Al_2O_3, respectively. In both oxides, the γ-type has an inverse-spinel crystal structure, and the α-type has a corundum crystal structure.[16] Kozumina et al.[5] measured the IEP's of γ- and α-Al_2O_3, prepared by calcination of a gibbsite sample and obtained IEP values of 7.4 to 8.6 for the γ-Al_2O_3 and of 9.1 to 9.2 for the α-Al_2O_3 using the streaming potential method. The average difference in IEP between γ- and α-Al_2O_3, therefore, is 1.1 to 1.2 pH units, which is similar to the average difference in the IEP values between γ- and α-Fe_2O_3.

The unit lattice of γ-Fe_2O_3 is expressed by the following formula:

$$\underset{\text{Coordination Number}=4}{Fe^{3+}_8} \quad (\underset{\text{Coordination Number}=6}{Fe^{3+}_{40/3}} \ \square_{8/3}) \quad O^{2-}_{32}$$

In the above formula a vacant lattice point is indicated by □ at the position of the coordination number 6, i.e. 6 oxygen ions adjacent to the Fe^{3+} ion. Fe^{3+} ions having coordination numbers of 4 and 6 are present in the ratio of 3:5. On the other hand, α-Fe_2O_3 is a corundum-type oxide, in which all of the Fe^{3+} ions have a coordination number of 6.

The average IEP is more acidic by 2.6 pH units for four-coordinated ions than for six-coordinated metallic ions.[3] Thus, the difference in the IEPs between the γ-Fe_2O_3 and α-Fe_2O_3 is calculated to be 2.6×3/(3+5)=

1.0, assuming that the additivity rule holds.[17] Accordingly, the IEP of γ-Fe_2O_3 is about 1.0 pH units lower than that of α-Fe_2O_3. The lower IEP values of γ-Fe_2O_3 and the IEP differences of 1.2 and 1.1 for the hydrated and unhydrated samples respectively, coincide well with the above calculation.

Conclusion

1) The PZC and IEP of the unhydrated γ-Fe_2O_3 were 5.5 and the IEP of the hydrated γ-Fe_2O_3 was 6.8.

2) The PZC and IEP of γ-Fe_2O_3 were more acidic by 1.1 and 1.2 pH units than those of α-Fe_2O_3 for the hydrated and unhydrated stages respectively.

3) These differences were explained quantitatively in terms of the crystal structure.

The authors wish to thank Dr. S. Baker of Sony Corporation Research Center for reading the manuscript.

Transport Properties of Cation-Exchange Membrane-Aqueous Electrolyte System

Yoshihiko NAGATA, Kazuyuki KOHARA, WongKang YANG, Akira YAMAUCHI, and Hideo KIMIZUKA*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 12, 1986)

Transport properties of a cation-exchange membrane-aqueous sodium chloride solution system have been studied. The membrane used was a sulfonated styrene-divinyl benzene copolymer, Neosepta C66-5T. The salt concentration was kept at 10^{-1} mol dm^{-3} on one side of the membrane and varied from 10^{-3} to 10^{-2} mol dm^{-3} on the other. The six elements of a conductance matrix have been experimentally determined according to the previous theory[1] and the membrane properties were discussed in terms of conductance elements. All the elements of the conductance matrix were positive within the concentration range studied. This would be characteristic of a cation-exchange membrane. The electrical ion conductance was greater than the diffusional ion conductance by a factor of 10 to 100. The ion-solvent coupling coefficient was much less than the interionic one, although the electroosmotic conductance was ten-times greater than the membrane conductance. The reflection coefficient was close to unity. The electroosmotic properties were also discussed in terms of the conductance matrix.

In the preceding papers,[1,2] six elements of a conductance matrix (phenomenological coefficients) were experimentally determined with the amphoteric ion-exchange membrane–aqueous electrolyte systems and the membrane properties were discussed in terms of the conductance matrix. All the transport properties in these systems could be explained in terms of the six elements. This indicates that six phenomenological coefficients are required for a characterization of a membrane–aqueous electrolyte system. It is, therefore, of interest to determine the phenomenological coefficients by using a variety of membranes and to understand how the coefficients reflect the membrane characters. Thus, a determination of the coefficients in the cation-exchange membrane-aqueous electrolyte system has been attempted. This paper describes the experimental results.

Experimental

Materials. The cation-exchange membrane used in the present study was a sulfonated styrene-divinyl benzene copolymer developed by Tokuyama Soda Co., Ltd. and coded as Neosepta C66-5T. The ion-exchange capacity was 2.45 meq. (g dry membrane)$^{-1}$, the water content 0.4 gH_2O (g dry membrane)$^{-1}$ and the thickness 0.15 mm. A pure specimen of sodium chloride as well as sucrose and twice-distilled water were used for preparing salt and sucrose solutions.

Procedures of Experiments. The experimental procedures were described elsewhere.[1] Regarding the aqueous phases separated by a membrane, the salt concentration of phase II was kept at 10^{-1} mol dm^{-3} and that of phase I was varied from 10^{-3} to 10^{-2} mol dm^{-3}. The sucrose concentration used for an osmotic flux measurement was 8.176×10^{-2} mol dm^{-3}. In the present study, current densities of 0.902×10^{-2}, 1.981×10^{-1}, and 2.971×10^{-1} mA cm^{-2} were passed through the paired Ag/AgCl electrodes of each system. The experiments were carried out at a regulated temperature of 25.0±0.1 °C.

Results and Discussion

The aim of the present work was to determine the phenomenological coefficients, g_{NaNa}—g_{ww}, in the phenomenological equation[1]

$$\begin{bmatrix} i_{Na} \\ i_{Cl} \\ Fj_w \end{bmatrix} = -\begin{bmatrix} g_{NaNa} & g_{NaCl} & g_{Naw} \\ g_{ClNa} & g_{ClCl} & g_{Clw} \\ g_{wNa} & g_{wCl} & g_{ww} \end{bmatrix} \begin{bmatrix} V-V_{Na} \\ V-V_{Cl} \\ -V_w \end{bmatrix}, \quad (1)$$

and to discuss the membrane properties in terms of the conductance matrix. In Eq. 1, the suffixes Na, Cl, and w refer to sodium and chloride ions and water, respectively. Also i denotes the ion current, j the flux, V the membrane potential, V_{Na} and V_{Cl} the pseudoequilibrium potential for sodium and chloride ions, respectively, and V_w the effective driving potential for water or the water potential. V_{Na}, V_{Cl}, and V_w are defined by

$$Z_\gamma FV_\gamma = RT \ln a_\gamma^{I}/a_\gamma^{II} - \bar{v}_\gamma \Delta P \quad (\gamma = \text{Na, Cl}) \quad (2)$$

and

$$FV_w = RT \ln a_w^{I}/a_w^{II} - \bar{v}_w \Delta P = \bar{v}_w(\Delta\pi - \Delta P), \quad (3)$$

□: G^0_{NaNa}, △: G^0_{Naw}, ○: G^0_{ww}.

respectively, where the superscripts I and II refer to phases I and II, respectively. Here, F, R, and T denote the Faraday constant, the gas constant and the absolute temperature, respectively. Also, Z is the charge number, a the activity, $\bar{v}_\gamma$ (γ=Na, Cl, w) the partial molar volume of species γ (assumed to be constant for a given system), $\Delta\pi$ the osmotic pressure and ΔP ($=P^{II}-P^{I}$) the external pressure difference.

The equation for the membrane current, I, is obtained from Eq. 1 as follows[1]

$$I = i_{Na} + i_{Cl} = -G_m(V-V_0)$$
$$= -g_{Na}(V-V_{Na}) - g_{Cl}(V-V_{Cl}) + g_wV_w, \quad (4)$$

where g_{Na}, g_{Cl}, and g_w denote the electric conductances for the permeating species Na, Cl, and w, respectively,

$$g_k = g_{kNa} + g_{kCl} \quad (k=Na,\ Cl,\ w) \quad (5)$$

G_m, the membrane conductance is given by

$$G_m = g_{Na} + g_{Cl}. \quad (6)$$

V_0, the membrane potential at zero membrane current is

$$V_0 = t_{Na}V_{Na} + t_{Cl}V_{Cl} + t_wV_w, \quad (7)$$

and t_k, the transport number of a species k, is

$$t_k = g_k/G_m. \quad (8)$$

The transport numbers can be estimated from fluxes and the membrane currents according to the relations[1]

$$i_{Na} - i^0_{Na} = t_{Na}I$$

and

$$F(j_w - j^0_w) = t_wI, \quad (9)$$

where the superscript 0 refers to the fluxes at zero membrane current. The transport number of the cation t_{Na} is plotted in Fig. 1 together with the membrane potential V_0 and the membrane conductance G_m. This figure indicates that the membrane is selective to cations and that G_m is constant in the concentration range studied. The apparent transport number $(t_{Na})_{app.}$ estimated from the membrane potential vs. the logarithmic activity relation was close to t_{Na}.

The chloride ion conductance g_{Cl} was evaluated by subtracting g_{Na} ($=G_mt_{Na}$) from G_m. The conductances, g_{Na}, g_{Cl}, and g_w ($=G_mt_w$), are plotted against the salt activity as shown in Fig. 2. In the absence of a membrane current in the external solution, Eq. 1 is reduced to

$$\begin{bmatrix} i^0_{Na} \\ Fj^0_w \end{bmatrix} = -\begin{bmatrix} G^0_{NaNa} & G^0_{Naw} \\ G^0_{wNa} & G^0_{ww} \end{bmatrix} \begin{bmatrix} V_{Cl}-V_{Na} \\ -V_w \end{bmatrix}, \quad (10)$$

where

$$G^0_{NaNa} = g_{NaNa} - G_mt^2_{Na},$$
$$G^0_{Naw} = g_{Naw} - G_mt_{Na}t_w = G^0_{wNa},$$

and

$$G^0_{ww} = g_{ww} - G_mt^2_w. \quad (11)$$

A change in the water potential, ΔV_w, under constant values of V_{Na} and V_{Cl} gives rise to changes in the fluxes, Δi^0_{Na} and Δj^0_w, which are given as

$$\Delta j^0_{Na} = G^0_{Naw}\Delta V_w$$

and

$$F\Delta j^0_w = G^0_{ww}\Delta V_w, \quad (12)$$

provided that there is no appreciable change in the activity coefficients of ions as well as the phenomenological coefficients due to the addition of sucrose into one of the two aqueous phases. G^0_{NaNa} and G^0_{wNa} may be determined by using Eq. 10 provided G^0_{Naw} and G^0_{ww} are known. The result showed that G^0_{wNa} and G^0_{Naw} are close to each other, an indication of a reciprocal relation. Figure 3 shows G^0_{NaNa}, G^0_{Naw}, and G^0_{ww} as a function of the salt concentration in phase I. The diffusional conductances g^0_k (k=Na, Cl, w), calculated according to the relation

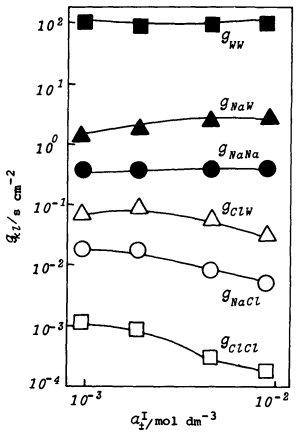

Fig. 4. Element of conductance matrix vs. mean electrolyte activity of phase I.
●: g_{NaNa}, □: g_{ClCl}, ○: g_{NaCl}, ▲: g_{Naw}, △: g_{Clw}, ■: g_{ww}.

$$g_k^0/g_k = (g_{NaNa}g_{ClCl} - g_{NaCl}^2)/g_{Na}g_{Cl} \quad (13a)$$
$$= G_{NaNa}^0/G_m t_{Na} t_{Cl}, \quad (13b)$$

are plotted in Fig. 2 together with the conductances g_k as functions of the electrolyte activity in the external solution. The value of g_k^0 can be estimated according to Eq. 13b, provided that g_k, G_m, and G_{NaNa}^0 are known.

Comparing Eqs. 11 and 5, we obtain a set of relations for estimating the elements of the conductance matrix as follows[2]

$$g_{NaNa} = G_m t_{Na}^2 + G_{NaNa}^0, \quad g_{Naw} = G_m t_{Na} t_w + G_{Naw}^0$$
$$g_{NaCl} = G_m t_{Na} t_{Cl} - G_{NaNa}^0, \quad g_{Clw} = G_m t_{Cl} t_w - G_{Naw}^0 \quad (14)$$
$$g_{ClCl} = G_m t_{Cl}^2 + G_{NaNa}^0, \quad g_{ww} = G_m t_w^2 + G_{ww}^0$$

Thus, the six elements of the conductance matrix can be estimated according to Eq. 14 after measurements of G_m, t_{Na}, t_w, G_{NaNa}^0, G_{Naw}^0, and G_{ww}^0. Figure 4 shows the six elements as functions of the mean electrolyte activity of phase I.

It can be seen in Fig. 4 that $g_{ww} > g_{Naw} > g_{NaNa} > g_{Clw} > g_{NaCl} > g_{ClCl}$ and that all the conductance elements are positive. This result is similar to that in the cation-exchange membrane-barium chloride system,[3] but differs from that in the amphoteric ion-exchange membrane-aqueous sodium chloride system,[1] $g_{ww} > g_{Naw} > |g_{Clw}| > g_{NaNa} \simeq g_{ClCl} > |g_{NaCl}|$, where g_{Clw} and g_{NaCl} are negative.

The lines in Fig. 2 indicate the values of g_k and g_k^0 calculated from g_{kl}'s (k,l=Na, Cl, w) in Fig. 4 according to Eqs. 5 and 13b, respectively. The calculated values are in good agreement with those obtained experimentally. This figure also indicates that the electrical ion conductance g_γ (γ=Na, Cl) is much greater than g_γ^0. This result agreed with that observed with the cation-exchange membrane-aqueous calcium chloride system[4] and can be ascribed to the small co-ion concentration in the membrane. In contrast, it was also reported that g_γ is much smaller than g_γ^0 in the amphoteric ion-exchange membrane-aqueous electrolyte system.[1,2] Rewriting Eq. 13a we have[1]

$$g_\gamma - g_\gamma^0 = g_{NaCl}/(1-t_\gamma). \quad (15)$$

Thus, it is seen that the positive value of g_{NaCl} in the cation-exchange membrane and the negative value of g_{NaCl} in the amphoteric ion-exchange membrane[2] are correlated to the difference between the conductive and diffusional ion conductances. Assuming the membrane controlling, we have from Eq. 15 an equation for the equivalent ion conductance[1]

$$\lambda_\gamma - \lambda_\gamma^0 = g_{NaCl}\delta/|Z_\gamma|\overline{C}_\gamma(1-t_\gamma), \quad (16)$$

where λ_γ denotes the equivalent ion conductance and λ_γ^0, that calculated from the diffution coefficient according to the Nernst-Einstein relation; δ the membrane thickness; and $\overline{C}_\gamma$, the concentration of γ ions within the membrane. Despić and Hills[5] ascribed the difference, $\lambda_\gamma - \lambda_\gamma^0$, to an electroosmotic effect. Since g_{NaCl} exhibits an interionic correlation, Despić and Hills' theory is not theoretically valid in view of nonequilibrium thermodynamics. Furthermore, the fact that the negative value of $(\lambda_\gamma - \lambda_\gamma^0)$ is observed in an amphoteric ion-exchange membrane can not be explained by Despić and Hills' theory, because the electroosmotic term is always positive.[5]

The reason why the positive and negative values of g_{NaCl} are observed in the cation-exchange membrane and the amphoteric ion-exchange membrane, respectively, has not yet been clear. However, it is of interest to point out that the negative value of g_{NaCl} in the amphotoric ion-exchange membrane is conformable with the positive cross term in phenomenological coefficients observed in an aqueous sodium chloride solution.[6]

The difference between the membrane conductance G_m and that without the electroosmotic effect, G_m' has been expressed as[1]

$$G_m - G_m' = g_v^2/g_p, \quad (17)$$

where g_v and g_p denote the electroosmotic volume-flow conductance and the hydrodynamic volume-flow conductance, respectively. Since the transport number of cations in the cation-exchange membrane is close to unity, Eq. 17 can be rewritten as

$$\lambda_{Na} - \lambda_{Na}' = \delta g_v^2/g_p \overline{C}_{Na}, \quad (18)$$

where δ is the membrane thickness and $\overline{C}_{Na}$, is the sodium ion concentration in the membrane. It has been shown in a preceding paper that under several assumptions Eq. 18 can be reduced to Despić and Hills' equation[1]

$$\lambda - \lambda' = (Fr)^2\overline{X}/8\eta, \tag{19}$$

where F denotes Faraday constant, r the capillary radius, $\overline{X}$ the counter-ion concentration in the membrane and η the solvent viscosity. It can be seen by comparing Eq. 16 with Eqs. 18 and 19 that the failure of Despic and Hills' theory lies in the replacement of λ_γ' by λ_γ^0. The electroosmotic contribution to the membrane conductance can be evaluated according to Eq. 17. The values of g_v and g_p can be estimated from g_{kl}'s given in Fig. 4 by using the relations given in the preceding paper.[1] The values of g_v and g_p were found to be almost the same as those of g_w and g_{ww}, respectively. The observed value of G_m was 0.39 S cm^{-2} in the range of concentration studied and the values of G_m' calculated according to Eq. 18 were 0.35—0.30 S cm^{-2}. On the other hand $g_\gamma(\lambda_\gamma)$ was greater than $g_\gamma^0(\lambda_\gamma^0)$ by a factor of 2 as shown in Fig. 2. These results indicate that the electroosmotic effect is not so appreciable as the diffusional effect.

The charge concentration per unit volume of the pore liquid X can be evaluated according to the relation[1]

$$X = g_v/g_p\bar{v}_w. \tag{20}$$

The value of X is given in Fig. 5. Equation 20 is equivalent to the effective charge density of a membrane proposed by Staverman.[7] The values of X were found to be 1—1.6 mol dm^{-3}, while the counter-ion concentration, $\overline{X}$, in the pore liquid evaluated from the exchange capacity and water content of the membrane was ca. 6 mole/KgH_2O. This might indicate that the counter-ions accompanying the electroosmotic flow are not all counter-ions within the membrane, as assumed in classical membrane theory.[8] The relation $X=\overline{X}$ was also assumed in Despić and Hills' theory.[5] It is interesting to note here that the ratio, $X/\overline{X}$, is near to the contribution of the electroosmotic effect in membrane conductance, $(G_m-G_m')/G_m$.

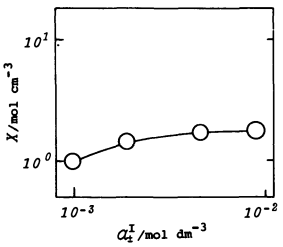

Fig. 5. Charge concentration per unit volume of the pore liquid vs. mean electrolyte activity of phase I.

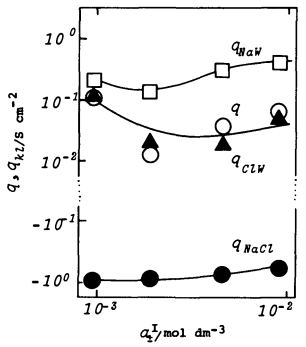

Fig. 6. Coupling coefficient vs. mean electrolyte activity of phase I.
○: q, ●: q_{NaCl}, □: q_{Naw}, ▲: q_{Clw}.

The present study deals with the three processes expressed by Eq. 1. The degree of coupling among these processes can be demonstrated by a coupling coefficient[1]

$$q_{kl} = -|g|_{kl}/(|g|_{kk}|g|_{ll})^{1/2}, \tag{21}$$

where $|g|_{kl}$ is the cofactor of an element g_{kl} in the conductance matrix. The coupling coefficients q_{NaCl}, q_{Naw}, and q_{Clw} calculated according to Eq. 21 is shown in Fig. 6. It is shown in this figure that q_{NaCl} is close to -1 while q_{Naw} and q_{Clw} are the order of 10^{-1} and 10^{-2}, respectively. This indicates that the ionic processes are more strongly coupled to each other than the coupling between ion and water transports. The remarkable difference between the diffusional and electric ion conductances reflects a strong interionic coupling. On the other hand, the ion-solvent interaction is weaker as shown in the electroosmotic effect, although it is appreciable. These facts indicate the importance of the cross coefficients in the membrane process. Thus, the cross coefficients in the phenomenological equation can not be ignored unless doing so is verified experimentally. The coupling coefficient q for the salt flow-volume flow coupling in the absence of an electric current is also shown in Fig. 6. The coefficient q is defined by

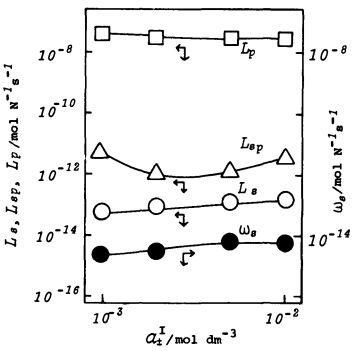

Fig. 7. Solute permeability(ω_s), thermodynamic permeability(L_s), mechanical filtration coefficient(L_{sp}) and hydrodynamic permeability(L_p) vs. mean electrolyte activity of phase I.
●: ω_s, ○: L_s, △: L_{sp}, □: L_p.

$$q = L_{sp}/(L_s L_p)^{1/2}, \tag{22}$$

where L_{sp} and L_s, and L_p are the phenomenological coefficients in the equation[1)]

$$\begin{bmatrix} \bar{v}_s J_s^0 \\ J_v^0 \end{bmatrix} = -\begin{bmatrix} L_s & L_{sp} \\ L_{sp} & L_p \end{bmatrix} \begin{bmatrix} \Delta\pi - \Delta\pi_s \\ \Delta p - \Delta\pi \end{bmatrix}. \tag{23}$$

This can be derived from Eq. 1 at a zero membrane current.[1)] In Eq. 23, the superscript 0 refers to a case where there is no membrane current; $\bar{v}_s$ denotes the partial molar volume of the salt; J_s^0 the salt flux; J_v^0 the volume flow; $\Delta\pi$ the osmotic pressure difference; Δp the external pressure difference; and $\Delta\pi_s$ the osmotic pressure difference of the salt. It is defind by[1)]

$$\bar{v}_s \Delta\pi_s = -2RT \ln a_{\pm}^{II}/a_{\pm}^{I}. \tag{24}$$

Here, $a_{\pm}$ denotes the mean activity of salt. It should be noted that the factors determining the correlation among the flow processes are not the relative magnitudes of the flows, but the coupling coefficients. For example, g_{ww} and g_w are greater than 100 and 10 times the membrane conductance, respectively, while the effects of the solvent flow on the interionic correlations are small as illustrated in the electro-osmotic effect on the membrane conductance. The ion fluxes can also be expressed by

$$\begin{bmatrix} i_{Na} \\ i_{Cl} \end{bmatrix} = -\begin{bmatrix} (g_{NaNa})_{app} & (g_{NaCl})_{app} \\ (g_{ClNa})_{app} & (g_{ClCl})_{app} \end{bmatrix} \begin{bmatrix} V - V_{Na} \\ V - V_{Cl} \end{bmatrix}, \tag{25}$$

where the subscript app refers to the apparent values, including the solvent effect.[1)] The deviation of $(g_{NaCl})_{app}$ from g_{NaCl} was comparable with that of G_m from G_m', although $(t_{Na})_{app}$ is close to t_{Na}.

Since the conductance matrix characterizes the system, all the transport properties of the membrane can be calculated from the elements of the conductance matrix. The thermodynamic solute permeability L_s, the mechanical filtration coefficient L_{sp}, the hydrodynamic permeability L_p and the solute permeability coefficient ω_s[1)] are related by

$$\omega_s = (L_s - L_{sp}^2/L_p)/\bar{v}_s. \tag{26}$$

These quantities were estimated for the present system as shown in Fig. 7. The reflection coefficient

$$\sigma = 1 - L_{sp}/L_p \tag{27}$$

was close to unity, 0.9998—0.9999, and is not plotted in this figure.

Effect of Pressure on the Adsorption and Micelle Formation of Aqueous Dodecyltrimethylammonium Chloride-Cyclohexane System

Michio YAMANAKA,*,† Makoto ARATONO, and Kinsi MOTOMURA
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received February 17, 1986)

The interfacial tension of aqueous dodecyltrimethylammonium chloride (DTAC) solution-cyclohexane system was measured as a function of pressure at concentrations around the critical micelle concentration (cmc). The derivative of interfacial tension with respect to pressure was observed to change abruptly at the cmc. The volume changes associated with the adsorption of DTAC from its monomeric and micellar states and the volume of micelle formation were calculated and compared with the corresponding ones of the aqueous DTAC solution-hexane system. It was found that the molar interfacial excess volume of the adsorbed film is slightly larger than the molar volume of micelle in the case of the cyclohexane system, while in the case of the hexane system the former is approximately equal to the latter. Further, it was concluded that the micellar particles solubilize molecules of the oil coexisting in equilibrium with the aqueous solution. It was also proved in the case of the present system that the micelle formation can be treated thermodynamically as the appearance of a macroscopic bulk phase in the solution.

In the preceding papers,[1,2] the interfacial tension of the aqueous solutions of dodecylammonium chloride (DAC) and dodecyltrimethylammonium chloride (DTAC) against hexane has been measured as a function of pressure. By applying the thermodynamic equations derived previously,[3] the volumes of adsorption of the surfactants from their monomeric and micellar states and the volume of micelle formation have been evaluated; the micelles of DAC and DTAC in equilibrium with hexane have been found to be similar in volumetric behavior to their adsorbed films at the solution/hexane interface. Further, our thermodynamic method has been proved to be useful.

On the other hand, organic liquids are known to have an influence on the critical micelle concentration and adsorption isotherm of surfactant.[4] Therefore, it is of interest to see if the above conclusions are drawn by using other organic liquid in place of hexane. Furthermore, it is important to investigate how the volumetric behavior of the micelle and adsorbed film of surfactant is affected by the organic liquid coexisting with its aqueous solution. In this work, we adopt cyclohexane as the organic liquid. The interfacial tension between aqueous DTAC solution and cyclohexane is measured as a function of pressure at various concentrations at a constant temperature.

Experimental

Dodecyltrimethylammonium chloride was prepared and purified as described in the previous papers.[2,5] Water was triply distilled from alkaline permanganate solution. Cyclohexane (Nakarai Chemicals, Ltd., UV spectrophotometric grade) was used after being distilled.

The equilibrium interfacial tension was measured by the pendant drop method[1,6] within an experimental error of 0.05 mN m^{-1}. The pendant drops were stood for 30 min to attain the thermodynamic equilibrium. The density of cyclohexane taken from the literature,[7] was used to calculate the interfacial tension at high pressures. The pressure range measured was from atmospheric pressure to the freezing pressure of cyclohexane (about 37 MPa). Temperature was kept constant at 298.15 K.

Results and Discussion

The interfacial tension γ between aqueous dodecyltrimethylammonium chloride (DTAC) solution and cyclohexane was measured as a function of pressure p at constant molality m_1 of DTAC and at 298.15 K. The γ vs. p curves at lower concentrations are shown in Fig. 1 and those at higher ones in Fig. 2. It is seen from Fig. 1 that the curves of the aqueous solutions of DTAC at concentrations below the critical micelle concentration (cmc; e.g., 21.89 mmol kg^{-1} at 0.1 MPa, see Fig. 5) are convex upward, while the curve of the pure water is linear. From Fig. 2, on the other hand, the curve at a concentration above the cmc is seen to be linear and have a very small slope compared to the curve of the pure water. At a concentration near the cmc, the curve has a linear portion, of which the upper limit is indicated by an arrow, at lower pressure.

The pressure effect on the adsorption can be visualized by plotting the slope of the γ vs. p curve, which is related directly to the volume change associated with the adsorption, against molality m_1 at several pressure values. Figure 3 shows the $\partial\gamma/\partial p$ vs. m_1 curves at 0.1, 15, and 30 MPa. It is seen that the $\partial\gamma/\partial p$ value varies with pressure in the concentration range below the cmc, while in the concentration range above the cmc it remains unvaried. Further, it is observed that the curve changes discontinuously at the cmc.

Next, let us consider the concentration dependence

† Present address: Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Fukuoka 810.

of the interfacial tension at constant pressure. In Fig. 4, the γ vs. m_1 curves, which are drawn by making use of the interpolated γ values taken from the γ vs. p curves in Figs. 1 and 2, are shown in the concentration range around the cmc. Included in this figure for comparison is the γ vs. m_1 curve of the system of aqueous DTAC solution and hexane at 0.1 MPa.[2] The γ vs. m_1 curve is observed to break at the cmc sharply enough to determine the precise value of the cmc. The dependence of the interfacial tension on pressure and concentration observed above is qualitatively similar to that made on the systems of the aqueous solutions of dodecylammonium chloride (DAC)[1] and DTAC[2] and hexane.

In Fig. 5, the cmc values obtained from the curves given in Fig. 4 and their analogs are shown as a

function of pressure and compared with those of the aqueous DTAC solution–hexane system.[2] The values of the cyclohexane system are found to be slightly different from those of the hexane system within the pressure range measured. Taking into account that the γ vs. m_1 curve of the cyclohexane system is shifted from that of the hexane system, such a difference suggests that the cyclohexane and hexane molecules take a place in the micelle formation of DTAC molecules in the aqueous solution.

According to the thermodynamic treatment developed previously,[1,3] the partial derivative of the interfacial tension with respect to pressure at constant temperature and molality shown in Fig. 3 provides the volume change per unit area associated with the adsorption of surfactant from its monomeric state, $\Delta v(1)$, at a concentration below the cmc and that from its micellar state, $\Delta v(\mathrm{M})$, at a concentration above the cmc; they are respectively defined by

$$\Delta v(1) = \Gamma_1^{\mathrm{H}}(v^{\mathrm{H}}/\Gamma_1^{\mathrm{H}} - v_1^{\mathrm{W}}) \tag{1}$$

and

$$\Delta v(\mathrm{M}) = \Gamma_1^{\mathrm{H}}(v^{\mathrm{H}}/\Gamma_1^{\mathrm{H}} - v^{\mathrm{M}}/N_1^{\mathrm{M}}), \tag{2}$$

where v^{H} is the interfacial excess volume per unit area, v^{M} the molar volume of micelle defined as the excess one with respect to the spherical dividing surface which makes the excess number of moles of water zero,[8] v_1^{W} the partial molar volume of monomeric surfactant, Γ_1^{H} the interfacial excess number of moles of surfactant per unit area, and N_1^{M} the number of surfactant ions in the micelle particle. Therefore, the curves in Fig. 3 turn out to be the $\Delta v(1)$ vs. m_1 and $\Delta v(\mathrm{M})$ vs. m_1 curves.

The values of $\Delta v(1)$ and $\Delta v(\mathrm{M})$ at the cmc, which are obtained by extrapolation, are plotted with those of the aqueous DTAC solution–hexane system[2] against pressure in Fig. 6. It is found again that the $\Delta v(\mathrm{M})$ value is independent of pressure and the $\Delta v(1)$ value depends on pressure. Further, the $\Delta v(1)$ and $\Delta v(\mathrm{M})$ values of the cyclohexane system are seen to be larger than those of hexane system. Therefore, it is possible to say that the molar interfacial excess volume of the adsorbed film at the cmc becomes slightly larger than the molar volume of micelle though their pressure dependence is similar to each other, when cyclohexane is used in place of hexane. This may be related closely to the experimental fact that the volume of interface formation of the pure water/cyclohexane interface has a larger value than that of the pure water/hexane interface.[9]

Let us now consider the volume of micelle formation $\Delta_{\mathrm{W}}^{\mathrm{M}}v$ defined by

$$\Delta_{\mathrm{W}}^{\mathrm{M}}v = v^{\mathrm{M}}/N_1^{\mathrm{M}} - v_1^{\mathrm{W}}. \tag{3}$$

The value of $\Delta_{\mathrm{W}}^{\mathrm{M}}v$ can be evaluated by use of the equation[8]

$$\Delta_{\mathrm{W}}^{\mathrm{M}}v = 2(RT/\mathrm{cmc})(\partial \mathrm{cmc}/\partial p)_T. \tag{4}$$

The $\Delta_{\mathrm{W}}^{\mathrm{M}}v$ vs. p curve obtained from the cmc vs. p curve in Fig. 5 is compared with that of the hexane system in Fig. 7. It is seen from this figure that the micelle formation in the cyclohexane system shows the volumetric behavior slightly different from that in the hexane system. Therefore, we may say that the micelle particles solubilize molecules of the oil coexisting in equilibrium with the aqueous solution.

Finally, let us examine whether the micelle particle behaves thermodynamically like a macroscopic bulk phase. Combining Eqs. 1, 2, and 3, the following equation is obtained:

$$\Delta v(1) - \Delta v(\mathrm{M}) = \Gamma_1^{\mathrm{H}}\Delta_{\mathrm{W}}^{\mathrm{M}}v. \tag{5}$$

The left side of Eq. 5 is the difference between the $\Delta v(1)$ and $\Delta v(\mathrm{M})$ values given in Fig. 6 and the right side the product of the Γ_1^{H} value, which is evaluated

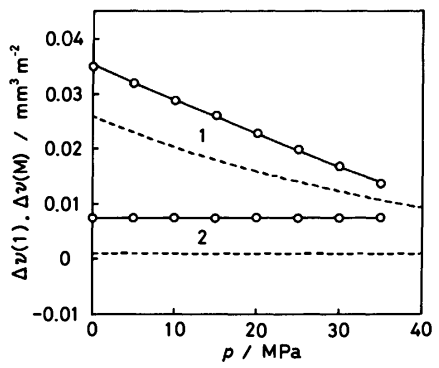

Fig. 6. Volume change associated with the adsorption from monomeric state ($\Delta v(1)$) vs. pressure and volume change associated with the adsorption from micellar state ($\Delta v(\mathrm{M})$) vs. pressure at cmc and at 298.15 K. (1): $\Delta v(1)$ vs. p, (2): $\Delta v(\mathrm{M})$ vs. p, (○): aq DTAC/cyclohexane, (— — —) aq DTAC/hexane.

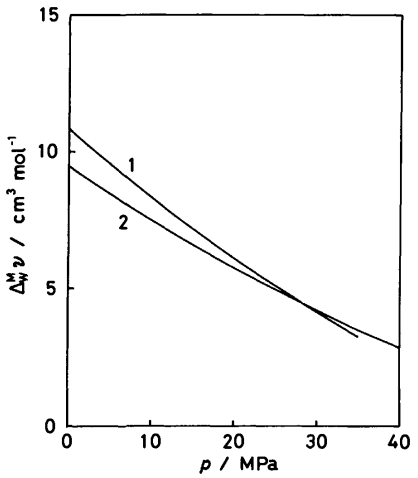

Fig. 7. Volume of micelle formation vs. pressure curves at 298.15 K. (1): aq DTAC/cyclohexane, (2): aq DTAC/hexane.

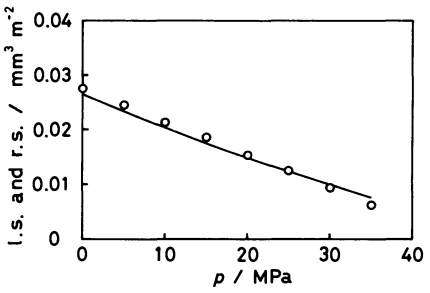

Fig. 8. Comparison between left side ($\Delta v(1)-\Delta v(M)$) and right side ($\Gamma_1^{II}\Delta_W^M v$) of Eq. 5. (○): left side, (——): right side.

from the γ vs. m_1 curve in Fig. 4, and the $\Delta_W^M v$ value given in Fig. 7; both the sides are compared in Fig. 8. They are in good agreement with each other over the entire pressure range measured. Therefore, we again arrive at the conclusion that irrespective of the phase coexisting in equilibrium with its aqueous solution, the micelle formation of surfactant can be treated thermodynamically as the appearance of a macroscopic bulk phase.[1-3,5]

The Phase Transition of 1,4-Dialkyl-1,4-diazoniabicyclo[2.2.2]octane Dibromides, C_n-DABCO-C_{n+2}-Br

Kengo IMAMURA, Jun SHIMIZU, and Takashi NOGAMI*

(Received March 13, 1986)

The phase transition of 1,4-dialkyl-1,4-diazoniabicyclo[2.2.2]octane dibromide (diquaternary salt) in which the difference in the carbon numbers of the two alkyl groups is two, was studied by means of differential scanning calorimetry, infrared absorption spectroscopy, and a study of the bromide-anion conductivities. DSC measurements revealed the existence of the metastable phase. The conversion rate from the metastable phase to the stable phase was too slow to be followed. The phase transition could be explained by the free energy-temperature relation. The temperature-dependence of the infrared absorption spectra showed that the band progressions due to two different alkyl chains disappeared at the transition temperature. This shows that the *trans*-zigzag conformation in the low-temperature phase is destroyed by the conformational change of the alkyl chain at the transition temperature. The free energy-temperature relation was also confirmed by the IR spectra. Discontinuous increases in the bromide-anion conductivities were observed at the transition temperatures. The conductivity jump was explained by the voids caused by the conformational change in the alkyl chain.

There have been extensive studies of the solid–solid phase transitions of alkanes and their derivatives[1] and of alkylammonium salts.[2] Especially, IR, Raman, and wide-line NMR spectroscopy have revealed that the transition was caused by the rotation of the alkyl chain. Two types of "rotation" have been recognized: one is the rotation of the whole molecule without changing its conformation,[3] and the other, the rotation involving conformational change.[4] In the cases of alkanes and their derivatives, the rotation of a whole molecule in the solid has long been postulated for the phase transition.[5] However, nonplanar conformers have recently been found for alkanes longer than n-$C_{21}H_{44}$ by IR spectroscopy.[6] These phase transitions have attracted much attention, because they are the best models for such fundamental chemical phenomena as the melting of materials and the glass transition temperatures of polymers.

In connection with this, we have found that a series of symmetrical 1,4-dialkyl-1,4-diazoniabicyclo[2.2.2]-octane dibromides (diquaternary salts) exhibited first-order phase transitions, with a concomitant increase in the halide-anion conductivities by two to three orders of magnitude.[7,8] The temperature dependences of the IR spectra showed that the band progressions due to the *trans*-zigzag conformation of the long alkyl chains in the low-temperature phase disappeared completely at the transition temperature.[8] This shows that the conformational change in the alkyl chain occurs at every site of the methylene carbons of the alkyl chain, contrasting with the case of the phase transitions of alkanes; band progressions did not disappear even after the transition in the alkanes. Snyder et al. reported that the conformational change in n-$C_{21}H_{44}$ occurs mainly within four carbons from either end of the molecule; the *trans*-zigzag conformation is almost retained at the central part of the molecule.[9] Thus, the phase transition of the salts of 1,4-diazabicyclo[2.2.2]octane (DABCO) is peculiar case in that the *trans*-zigzag conformation is completely destroyed. Although the transition temperatures of alkanes are a few degrees below their melting points, those of the DABCO salts are more than one hundred degrees lower than the melting points or the decomposition points. Since the phase-transition temperatures and the transition enthalpies tend to increase with the increase in the alkyl-chain length in the symmetric diquaternary salts, it is noteworthy how these properties are modified in the case of the unsymmetric salts. All of the symmetric diquaternary salts exhibited one transition temperature.[7,8] Thus, it is especially interesting to determine whether or not the phase transition takes place at several temperatures, as a result of the difference in the alkyl chains in the unsymmetric diquaternary salts. The effect of the unsymmetric substitution on the halide-anion conductivities and the IR absorption spectra are also noteworthy. As an extension of the previous studies, we have investigated the phase transitions of the unsymmetric diquaternary salts of DABCO on the basis of their differential scanning calorimetry curves, bromide-anion conductivities, and

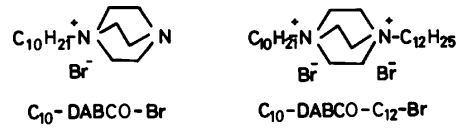
infrared-absorption spectra. The materials studied possess two long alkyl chains; the difference in their carbon numbers was fixed at two. The materials studied are shown in Fig. 1. The names of the materials are abbreviated by the numbers of alkyl carbons. For example, 4-Decyl-1-aza-4-azoniabicyclo-[2.2.2]octane bromide and 1-decyl-4-dodecyl-1,4-diazoniabicyclo[2.2.2]octane dibromide are abbreviated as C_{10}-DABCO-Br and C_{10}-DABCO-C_{12}-Br respectively. Thus, the materials in Fig. 1 can be described generally as C_n-DABCO-C_{n+2}-Br.



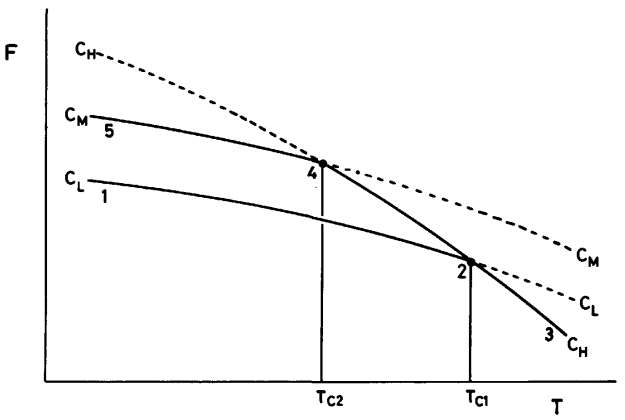


Fig. 2. Free energy (F)-temperature (T) relation of unsymmetric diquaternary salts of DABCO.

Experimental

Materials. The methyl alcohol and acetonitrile were purified as has been described before.[7,8] The ethyl acetate was washed with aqueous sodium hydrogencarbonate, and then aqueous sodium chloride, dried over magnesium sulfate, and distilled. The ethyl alcohol was distilled. The diethyl ether, DABCO, and all of the alkyl bromides were used without purification.

Syntheses of 4-Alkyl-1-aza-4-azoniabicyclo[2.2.2]octane Bromides. The synthesis of 4-alkyl-1-aza-4-azoniabicyclo-[2.2.2]octane bromide (monoquaternary salt) will be described for C_{10}-DABCO-Br as a typical example. To the acetonitrile solution (50 ml) of DABCO (5.6 g, 50 mmol) we stirred in, drop by drop, 11.05 g (50 mmol) of decyl bromide for a 30-min period, at room temperature. The solvent was then evaporated, and 500 ml of benzene was added to the residue to obtain a white precipitate. It was recrystallized from a mixed solvent of benzene (1 l) and acetonitrile (50 ml). The same procedures were adopted for the synthesis of C_{11}-DABCO-Br. In the case of C_n-DABCO-Br ($n \geqq 12$), the acetonitrile solution was directly poured into diethyl ether to obtain the crude product. It was recrystallized from ethyl acetate.

Syntheses of Unsymmetric Diquaternary Salts of DABCO. The synthesis of unsymmetric diquaternary salt of DABCO will be described for C_{10}-DABCO-C_{12}-Br as a typical example. A methanol (20 ml) solution of C_{10}-DABCO-Br (2 g, 6 mmol) and dodecyl bromide (1.49 g, 6 mmol) was refluxed for 48 h. After it had then been cooled to room temperature, it was poured into diethyl ether (500 ml) to obtain a white precipitate. The crude product was recrystallized five times from acetonitrile. Essentially the same reaction conditions were adopted for the other materials. The solvents of recrystallization were acetonitrile for C_n-DABCO-C_{n+2}-Br (n=10, 11, 12, 13, 14) and ethyl alcohol for C_n-DABCO-C_{n+2}-Br (n=15, 16).

Measurements. The measurements of the DSC, the IR absorption spectra, and the bromide-anion conductivities were made by the methods described previously.[7,8]

Results and Discussion

Syntheses of Unsymmetric Diquaternary Salts of DABCO. Unsymmetric diquaternary salts of DABCO were synthesized by two-step reactions, i.e., the synthesis of monoquaternary salt, followed by that of the diquaternary salt. In the first step, the reaction of equimolar amounts of DABCO and alkyl bromide readily gave the monoquaternary salt in 30 min at room temperature. Diquaternary salt was not obtained in this case, however, because the reaction rate from the monoquaternary salt to the diquaternary salt is much slower than that from DABCO to the monoquaternary salt. The diquaternary salt was obtained by the reaction with the monoquaternary salt with alkyl bromide under more vigorous reaction conditions in the second step. Since one nitrogen converts to N^+ in the monoquaternary salt, the lone-pair electron at the other nitrogen will be attracted by N^+ by means of Through-bond interaction.[10] This effect causes the lowering of the lone-pair MO level and the decrease in the lone-pair electron density, both of which consequently reduce the rate of the second step of the reaction. MINDO/2 calculation[11] revealed that the former effect is dominant over the latter.[12] In reality, the monoquaternary salt and alkyl bromide did not give the diquaternary salt under the same conditions as in the first step of the reaction. Only after the solution of the reactants had been refluxed for a prolonged period of time (48 h) could the diquaternary salt be obtained.

DSC Measurements. DSC measurements were made while changing the temperature by 5 °C/min. When the virgin samples were heated, single endothermic signals ($\Delta H_{en,1}$) were observed at T_{c1}. However, no reproducible T_{c1} values were obtained; they varied by several degrees in several runs. C_{12}-DABCO-C_{14}-Br and C_{16}-DABCO-C_{18}-Br exhibited three and two transitions respectively. When the samples were

Table 1. Unsymmetric Diquaternary Salts of DABCO, Transition Temperatures (T_{c1} and T_{c2}), Transition Enthalpies ($\Delta H_{en,2}$), Transition Entropies (ΔS), and Ratios of Bromide-anion Conductivities Before (σ_l) and After (σ_h) Transition

a) Since the values of T_{c1}'s are not strictly reproducible, they are shown in parentheses as only approximate values.

cooled after they had once been heated above T_{c1}, exothermic signals ($\Delta H_{exo,1}$) were observed at much lower temperatures (T_{c2}) than T_{c1}; $T_{c1}>T_{c2}$. Reproducible T_{c2}'s were obtained. The succeeding heating-cooling cycles showed reproducible endothermic ($\Delta H_{en,2}$) and exothermic ($\Delta H_{exo,1}$) signals at around T_{c2}, but did not show any signal at T_{c1}, even when DSC was measured after the samples had been kept at room temperature for weeks. The absolute values of $\Delta H_{en,1}$, $\Delta H_{en,2}$, and $\Delta H_{exo,1}$ were within the range of experimental error. The annealed sample which gives the phase transition at T_{c2} is designated as C_M; it is assumed to be a metastable phase[13] on the basis of our related studies of the phase transition of C_{10}-DABCO-C_n-Br ($13 \leqq n \leqq 22$).[14] For these systems, DSC measurements exhibited phenomena similar to those described above. However, C_M was found to be converted slowly to the stable phase (C_L) when the sample was kept at room temperature. The larger the difference in the carbon numbers of the two alkyl groups attached to DABCO nitrogens, the faster was the conversion rate from C_M to C_L. For example, the conversion rates of C_{10}-DABCO-C_{14}-Br and C_{10}-DABCO-C_{18}-Br were one week and one day respectively. Since the difference in the carbon numbers is only two in the present systems, the conversion rates are too slow to be followed. The above thermodynamic phenomena can be understood by the free energy (F)-temperature (T) relation shown in Fig. 2. In this figure, the virgin sample (C_L) follows the F-T curve from 1 to 2 when the sample is heated. Phase transition takes place at 2 (temperature: T_{c1}), and the sample follows the curve of the high-temperature phase (C_H) from 2 to 3. When the sample is then cooled, it follows the F-T curve of C_H from 3 through 2 to 4. Phase transition takes place at 4 (temperature: T_{c2}), and the sample follows the F-T curve of the metastable phase (C_M) from 4 to 5.

Part of Table 1 shows T_{c1}, T_{c2}, $\Delta H_{en,2}$, and ΔS ($=\Delta H_{en,2}/T_{c2}$). The values of T_{c1} are shown in parentheses, because they are not strictly reproducible.

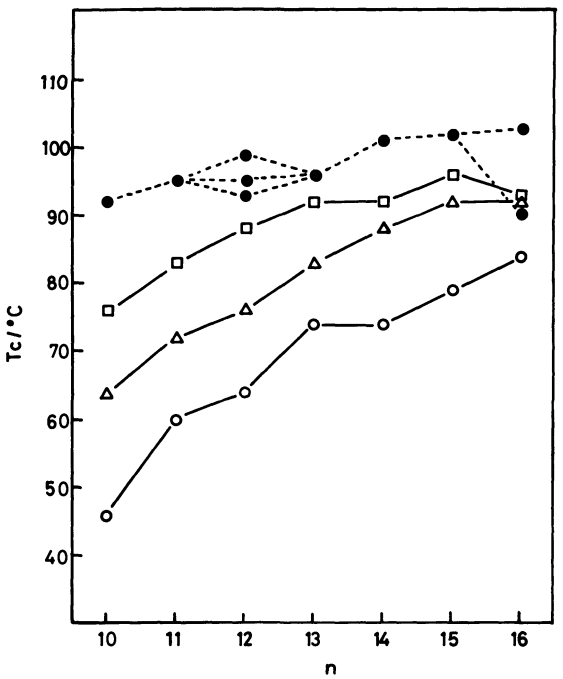

Fig. 3. The plot of the transition temperatures against the carbon numbers of alkyl groups attached to DABCO nitrogens.
○: T_{c2} for C_n-DABCO-C_{n+2}-Br, △: T_c for C_n-DABCO-C_n-Br, □: T_c for C_{n+2}-DABCO-C_{n+2}-Br, ●: T_{c1} for C_n-DABCO-C_{n+2}-Br. Since T_{c1} is not strictly reproducible, the black circles were connected with dotted lines.

They are shown only as approximate values. All of the transition temperatures were obtained from the onsets of the endothermic peaks. The characteristic points of the DSC measurements will be discussed below. Figure 3 plots the T_{c1} and T_{c2} values against the carbon numbers of the alkyl chains. This figure also shows the plots of the transition temperatures of the symmetric diquaternary salts of DABCO[8] for the sake of comparison. All of the transition temperatures tend to increase with the increase in the alkyl-chain lengths. The order of the transition temperature is as

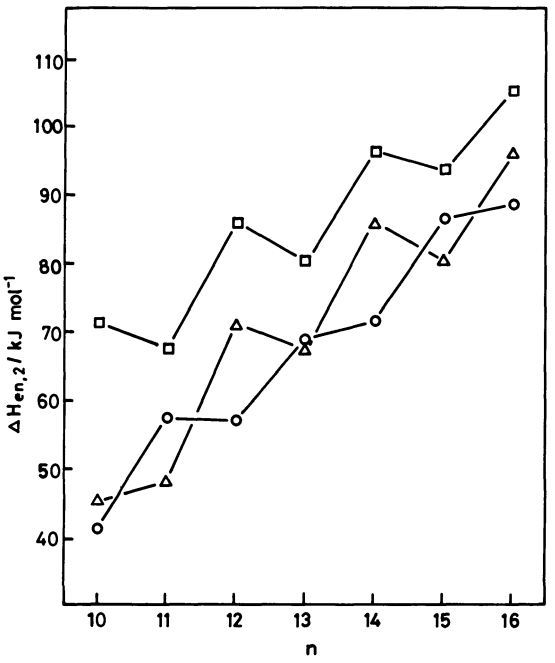

Fig. 4. The plot of the transition enthalpies ($\Delta H_{en,2}$) against the carbon numbers of alkyl groups attached to DABCO nitrogens.
○: C_n–DABCO–C_{n+2}–Br, △: C_n–DABCO–C_n–Br, □: C_{n+2}–DABCO–C_{n+2}–Br.

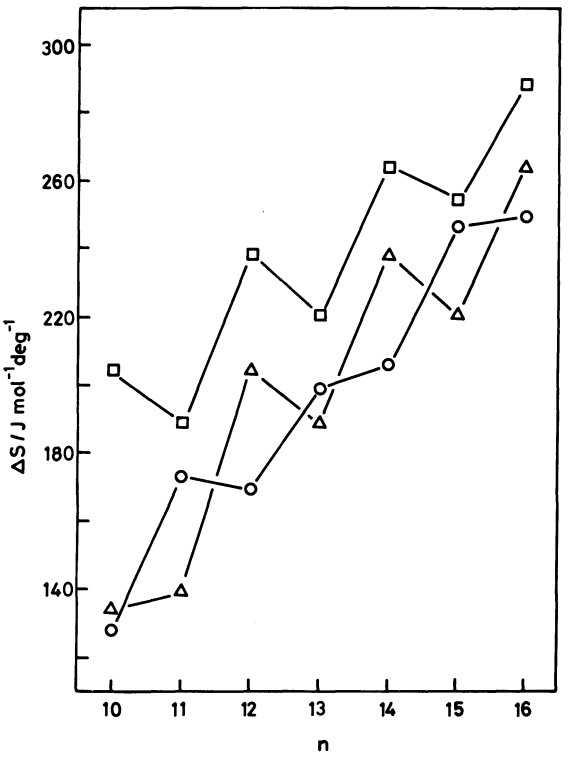

Fig. 5. The plot of the transition entropies ΔS (= $\Delta H_{en,2}/T_{c2}$) against the carbon numbers of alkyl groups attached to DABCO nitrogens.
○: C_n–DABCO–C_{n+2}–Br, △: C_n–DABCO–C_n–Br, □: C_{n+2}–DABCO–C_{n+2}–Br.

follows, if the carbon number of the alkyl group is fixed: $T_{c1}>T_c$ for C_{n+2}–DABCO–C_{n+2}–Br$>T_c$ for C_n–DABCO–C_n–Br$>T_{c2}$. An even-odd number effect of carbon was found for T_{c2}. The difference between T_{c1} and T_{c2} tends to decrease with the increase in the alkyl-chain length, but it is always in the range of 6—50 °C. Since the difference in the alkyl-chain length is only two, the general tendency of the transition temperature with the alkyl-chain length is similar to that of the symmetric diquaternary salts. The great difference in the unsymmetric salts from the symmetric salts is that the metastable phase can be found for the former salts. Figure 4 shows the plots of $\Delta H_{en,2}$ against the carbon numbers of the alkyl chains. This figure also shows the transition enthalpies of the symmetric salts[8] for the sake of comparison. An even-odd number effect of carbon was clearly observed in a reverse manner from the symmetric salts, i.e., up-down for the unsymmetric salts and down-up for the symmetric salts. $\Delta H_{en,2}$ tends to increase with the increase in the alkyl-chain length. The following order of the transition enthalpy is noteworthy, although the reason is as yet not clear; ΔH for C_{2n+2}–DABCO–C_{2n+2}–Br$>\Delta H$ for C_{2n}–DABCO–C_{2n}–Br$>\Delta H$ for C_{2n}–DABCO–C_{2n+2}–Br. ΔH for C_{2n+1}–DABCO–C_{2n+1}–Br$>\Delta H$ for C_{2n-1}–DABCO–C_{2n+1}–Br$>\Delta H$ for C_{2n-1}–DABCO–C_{2n-1}–Br. Figure 5 shows the plots of the transition entropies ($\Delta S=\Delta H_{en,2}/T_{c2}$) against the carbon numbers of the alkyl groups. This figure also shows the plot of the transition entropies of the symmetric salts for the sake of comparison.[15] The ΔS's also tend to increase with the increase in the alkyl-chain lengths. The even-odd number effect of carbon on ΔS was quite similar to that on the $\Delta H_{en,2}$ shown in Fig. 4. The transition entropies also exhibited order similar to that found for $\Delta H_{en,2}$; i.e., ΔS for C_{2n+2}–DABCO–C_{2n+2}–Br$>\Delta S$ for C_{2n}–DABCO–C_{2n}–Br$>\Delta S$ for C_{2n}–DABCO–C_{2n+2}–Br. ΔS for C_{2n+1}–DABCO–C_{2n+1}–Br$>\Delta S$ for C_{2n-1}–DABCO–C_{2n+1}–Br$>\Delta S$ for C_{2n-1}–DABCO–C_{2n-1}–Br. The numbers of sites (W) after phase transition were estimated from the $\Delta S=R\ln W$ relation, and the W's were in the range of 4.9×10^6—9.8×10^{12}.[16] Although T_{c1} could not be obtained correctly, the estimated transition entropies gave the values of W as 10^6—10^{12}. Thus, comparable structural changes seem to occur at T_{c1} and T_{c2}. The large values of W's will be discussed later, together with the IR absorption spectra.

Infrared Absorption Spectroscopy. The temperature dependence of the infrared absorption spectra was measured in order to obtain more information on the phase transition and on the metastable phase. Figure 6 shows the temperature dependence of the IR spectra of C_{14}–DABCO–C_{16}–Br for a KBr disk sample, as a typical example, when the sample is heated from room temperature to 103 °C and then cooled to room

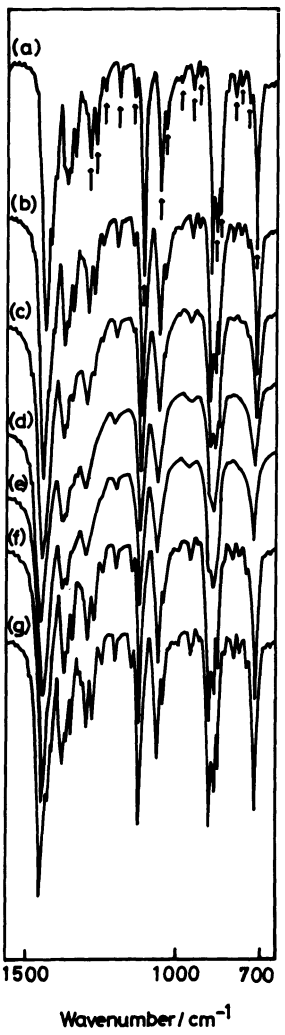

Fig. 6. Temperature dependence of the IR spectra of C_{14}–DABCO–C_{16}–Br for the KBr pellet sample.
(a): 29 °C, (b): 79 °C, (c): 98 °C, (d): 103 °C, (e): 80 °C, (f): 61 °C, (g): 33 °C. The virgin sample was heated from (a) to (d), and then cooled from (d) to (g).

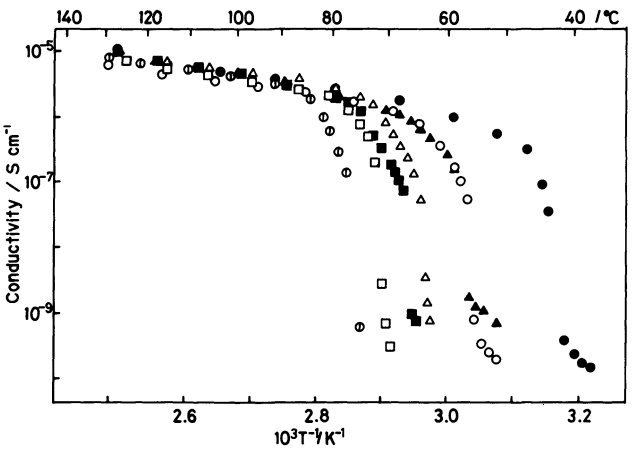

Fig. 7. Temperature dependence of the bromide-anion conductivities of C_n–DABCO–C_{n+2}–Br.
●: $n=10$, ○: $n=11$, ▲: $n=12$, △: $n=13$, ■: $n=14$, □: $n=15$, ⓓ: $n=16$.

temperature. The resulting IR spectra are shown sequentially from the top to the bottom in this figure. The IR spectra of the virgin sample (C_L) at 29 °C exhibited several structures, shown by the arrows. The absorption positions of these structures were compared with band progressions of n-$C_{15}H_{32}$ and n-$C_{17}H_{36}$,[17] which have the same numbers of CH_2 units as the alkyl groups of C_{14}–DABCO–C_{16}–Br. The good coincidence[18] leads to the conclusion that the structures in Fig. 6 can be assigned to the band progressions of the two alkyl groups.

The absorption spectra at 29 °C (a) and 79 °C (b) were not so different. When the temperature of the sample approached T_{c1} (101 °C), all of the absorptions were broadened (see Spectrum (c) at 98 °C), but the band progressions could still be seen. However, all of the band progressions disappeared at 103 °C (d). This shows that the *trans*-zigzag conformation of the alkyl groups of the low-temperature phase (C_L) is destroyed at T_{c1}. When the temperature of the sample was lowered after it had once been raised above T_{c1}, the band progression did not appear between T_{c1} and T_{c2}. For example, the absorption spectra (b) and (e) were measured at almost the same temperature, but they are quite different; the Spectrum (b) exhibited the band progressions, but (e) did not show them. This observation is consistent with the DSC result. Since the Spectrum (e) corresponds to the point between 2 and 4 on the F–T curve of the C_H phase in Fig. 2, the *trans*-zigzag conformation of the alkyl chain is still destroyed. Only after the temperature had been lowered below T_{c2} (74 °C) did the band progressions appear again (see Spectrum (f)) to convert to the C_M phase. Since no difference in the spectra was found between (a) and (g) in Fig. 6, the *trans*-zigzag conformation is assumed to be recovered in the C_M phase. However, judging from the broader powdered X-ray diffractions of the C_M phase than the C_L phase,[13] the crystallinity of the C_M phase can be said to be lower than the C_L phase. The high potential barrier between C_M and C_L prevents C_M from going back to C_L.

DSC measurements gave a large numbers of sites (W) above the transition temperature. This is consistent with the results of the IR absorption spectra. Since band progressions disappeared completely above T_{c1} or T_{c2}, the conformational change is assumed to occur at every site of the alkyl carbons. This gives rise to a large numbers of sites. Thus, the conformational changes in the present systems and previous systems[8] are quite different from those in *normal* alkanes,[9] because the *trans*-zigzag conformation still remains above the transition temperature for

the latter materials. Although the phase transitions of the diquaternary DABCO salts were ascribed to the conformational change in the alkyl groups, there is some possibility that the portion of DABCO may rotate around the N–N direction.[19] However, the present study could not confirm this possibility.

Bromide-anion Conductivities. All of the samples have already been confirmed as bromide-anion conductors.[7,8] The ionic conductivities were measured for the compressed pellet samples by an AC method. The impedance and a phase shift were measured, and the real and imaginary parts of the impedances were plotted for various frequencies (25 Hz—500 kHz). The resistance of the sample was obtained by a method described previously.[8] The temperature dependences of the bromide-anion conductivities were measured while raising the temperature of the sample slowly (about 0.5 °C min^{-1}) from room temperature; they are shown in Fig. 7. Conductivities less than 10^{-9} S cm^{-1} are below the limit of our measurements. Since the samples were dried overnight under a dynamic vacuum above T_{c1} before the measurements, they were converted to C_M phases. The proton conduction due to moisture was negligible. The following facts are noteworthy from this figure: (1) All of the samples show abrupt increases in the ionic conductivities by two to three orders of magnitude resulting from the phase transitions around T_{c2}. (2) The longer the alkyl chain, the higher the transition temperature. (3) The longer the alkyl chain, the lower the bromide-anion conductivities below T_{c2}. However, the bromide-anion conductivities were close to each other above T_{c2}, with their activation energies of about 30 kJ mol^{-1}.

The second and third characteristics above are also those of the halide-anion conductivities of the symmetric diquaternary salts of DABCO, and they may be explained as before.[8] Table 1 shows the materials and the ratios of the bromide-anion conductivities before (σ_l) and after (σ_h) the phase transition, i.e., σ_h/σ_l. The two steps of the conductivity changes were observed around T_{c2}; the first rapid increase, followed by the slower increase in the conductivities. The changes in the conductivities around T_{c2} were found to be in the range of 770—3070. However, the conductivity jumps in Fig. 7 are slightly broader than those of the symmetric diquaternary salts,[8] because the slower increases in the conductivities were not observed for the latter materials. The virgin samples (C_L) can also be expected to show an abrupt change in the ionic conductivities at T_{c1}. However, no measurement was made for this transition, because DSC measurements did not give reproducible results. Although abrupt increases in the bromide-anion conductivities were observed around T_{c2}, the transition temperatures obtained by DSC were higher than those obtained by the bromide-anion conductivities; the latter transition temperatures were defined as the middle points of the conductivity jumps. This shows that the conductivity jump starts before the considerable structural change sets in. Since ionic conductivities are sensitive to the structure, the conductivity jump takes place at the temperature region of the pre-transition where the local movement of the alkyl groups begins. Since the low-temperature phase possesses a close-packed crystal structure, the conduction pathway of the bromide anion is assumed to be narrow. However, the situation changes considerably at the transition temperature. The conductivity jump can be explained by the formation of voids caused by the onset of the movement of the alkyl chains.

Summary. The phase transitions of the unsymmetric diquaternary salts of DABCO, C_n–DABCO–C_{n+2}–Br ($10 \leqq n \leqq 16$), were studied by means of the DSC, the IR spectra, and the bromide-anion conductivities. The DSC measurements revealed the existence of the metastable phase. The temperature dependence of the IR spectra showed that, with a rise in the temperature, the band progressions in the low-temperature phase disappeared completely at T_{c1} and then appeared again at T_{c2} when the temperature was lowered after it had once been raised above T_{c1}. These results are consistent with the existence of the metastable phase. Abrupt increases in the bromide-anion conductivities by two to three orders of magnitude were found at the transition temperatures (T_{c2}). However, the conductivity jumps were slightly broader than those of the symmetric diquaternary salts. The conductivity jump at the transition temperature was explained by the formation of voids caused by the onset of the conformational change in the alkyl chains.

We are grateful to Professor Shigekazu Kusabayashi and Dr. Shunsuke Takenaka, Faculty of Engineering, Osaka University, for the use of the DSC apparatus. We are also grateful to Dr. Yasuhiko Kondo, Faculty of Engineering, Osaka University, for his suggestion that the rate difference in the quaternization reaction of DABCO may be explained by the Through-bond interaction.

11) M. J. S. Dewar and E. Haselbach, *J. Am. Chem. Soc.*, **92**, 590 (1970); N. Bodor, M. J. S. Dewar, A. Harget, and E. Haselbach, *J. Am. Chem. Soc.*, **92**, 3854 (1970).

12) MINDO/2 calculation was done for DABCO and the 4-methyl-1-aza-4-azoniabicyclo[2.2.2]octane cation (CH_3-DABCO$^+$) in order to see the quaternization effect on the lone-pair electron density of nitrogen and the orbital energy of the HOMO level. The nitrogen lone-pair electron densities of DABCO and CH_3-DABCO$^+$ are calculated to be 1.75 and 1.72 respectively; those values are not very different. Since the contribution of the nitrogen lone-pair is the largest for HOMO, the large difference in the HOMO levels ($\varepsilon_{DABCO}=-7.76$ eV, $\varepsilon_{CH_3\text{-}DABCO^+}=-13.31$ eV) is assumed to cause the large difference in the activation energy of the quaternization reaction.

13) Powdered X-ray diffractions of the virgin samples (C_L) showed several sharp diffractions. On the other hand, the annealed sample (C_M) exhibited somewhat broader diffractions. This suggests that C_M is disordered, possibly by the *gauche* conformation of the alkyl groups. This fact also supports the assumption that C_M is in a metastable phase.

14) J. Shimizu, K. Imamura, T. Nogami, and H. Mikawa, *Bull. Chem. Soc. Jpn.*, in press.

15) From the transition enthalpies and the transition temperatures shown in Ref. 8, the transition entropies (J mol^{-1} deg^{-1}) of the symmetric salts (C_n-DABCO-C_n-Br) were obtained as follows: 134 for n=10, 139 for n=11, 204 for n=12, 189 for n=13, 237 for n=14, 220 for n=15, 263 for n=16, 254 for n=17, 288 for n=18, and 311 for n=22.

16) The numbers of sites of the symmetric diquaternary salts of DABCO were estimated from the transition entropies shown in Ref. 15; they are in the range of 1.0×10^7—1.9×10^{16}.

17) R. G. Snyder and J. H. Schachtschneider, *Spectrochim. Acta*, **19**, 85 (1963).

18) Since the difference between the carbon numbers of the two alkyl groups is only two, the band progressions of the two alkyl groups have almost the same absorption positions. Thus, we could not assign the band progressions separately to the individual alkyl group.

19) We are grateful to Professor Hiroshi Suga, Department of Chemistry, Faculty of Science, Osaka University, who suggested that the portion of DABCO may rotate above the transition temperature.

(Received March 31, 1986)

The molecular structure of diphenyl-2-pyridylmethyl methacrylate has been determined by means of X-ray diffraction. Crystals are monoclinic, space group $P2_1/n$, a=10.334(2), b=22.093(3), c=8.415(1) Å, β=110.92(2)°, and Z=4. The structure was established by the direct method, and refined by the block-diagonal least-squares procedure to R=0.052 (R_w=0.064) for 1702 observed reflections. The molecule has an *antiperiplanar-synperiplanar* conformation. One of the two phenyl groups attached to the C(5) atom is *trans*, and the other phenyl and 2-pyridyl groups are *gauche* to the C(1).

Recently, in a series of studies on the molecular structures of methacrylates and their reactivties in the asymmetric selective polymerization with Grignard reagnt-(−)-sparteine derivatives, molecular structures of (*RS*)-1,2-diphenylethyl methacrylate (1,2-DPEMA),[1] (*RS*)-α-*t*-butylbenzyl methacrylate (*t*-BBMA),[1] (*RS*)-1,2,2,2-tetraphenylethyl methacrylate(TrBzMA),[2] and (1*S*,2*R*)-(+)-1-benzyl-3-dimethylamino-2-methyl-1-phenylpropyl methacrylate (ChMA)[2] have been determined by means of X-ray diffraction. In addition, in order to clarify the role of the α-substituents on the ester group in the sterospecific polymerization of diphenylmethyl methacrylate derivatives with *n*-BuLi, molecular structures of diphenylmethyl methacrylate (DPMMA),[3] 1,1-diphenylethyl methacrylate (1,1-DPEMA),[4] and triphenylmethyl methacrylate (TrMA)[4] have been determined. This paper describes the structural study on diphenyl-2-pyridylmethyl methacrylate (2-PyMA), a new diphenylmethyl methacrylate derivative, which gave a highly isotactic polymer not only by anionic polymerization but also by radical polymerization.[5]

Experimental

Colorless crystals of 2-PyMA were recrystallized from toluene. Unit-cell parameters and reflection intensities were measured on a Rigaku automated, four-circle diffractometer. Nickel-filterd Cu $K\alpha$ radiation was used.

Crystal Data. 2-PyMA, $C_{22}H_{19}O_2N$, M 329.4, monoclinic, space group $P2_1/n$, a=10.334(2), b=22.093(3), c=8.415(1) Å, β=110.92(2)° V=1794.6(4) Å^3, D_c=1.219 g cm^{-3} for Z=4, μ(Cu $K\alpha$)=6.27 cm^{-1}.

Integrated intensities were measured by the θ-2θ scan technique(2θ<110°). The 2θ scan rate and scan width were 4° min^{-1} and $\Delta 2\theta$=(2.0+0.3 tanθ)°, respectively. Backgrounds were counted for 7.5 s before and after each scan. Four standard reflections were measured after every 60 reflections, which showed no intensity decrease during the intensity measurement. The usual Lorentz and polarization corrections were applied but no correction for absorption and extinction was carried out. A total of 1702 reflections was collected($|F_o|>3\sigma(F_o)$).

Structure Solution and Refinement

The structure was solved by the direct method (*MULTAN* 78),[6] and refined by the block-diagonal least-squares procedure (*HBLS* V)[7] minimizing $\Sigma w(\Delta F)^2$. Anisotropic temperature factors were applied for nonhydrogen atoms and isotropic ones for hydrogen atoms. Atomic scattering factors were taken from

Fig. 2. Conformation about the C(5)–O(1) bond.

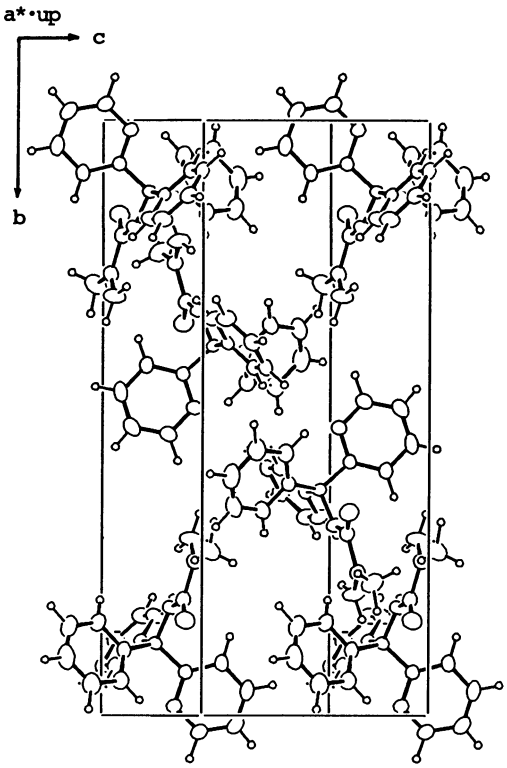

Fig. 3. Crystal structure projected along the a* axis.[10]

International Tables for X-Ray Crystallography.[8] Finally, the R value converged to 0.053 (R_w=0.064). The weighting scheme used at the final stage was $w=\{\sigma^2(F_o)-0.00438\,|F_o|+0.00170|F_o|^2\}^{-1}$ for $|F_o|>0$. σ is the standard deviation obtained by the counting statistics.

The final atomic parameters and equivalent temperature factors are given in Table 1.††† All computations were done on an ACOS 850 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

Results and Discussion

Molecular Structure. Figure 1 shows a perspective view[10] of 2-PyMA molecule with the atom labelling. Selected bond lengths and bond angles are given in Table 2, and some least-squares planes and dihedral angles in Table 3.

This molecule has an *antiperiplanar-synperiplanar (ap-sp)* structure: the conformation of the C(2)=C(3) [1.366(7) Å] and C(1)=O(2) [1.199(5) Å] double bonds about the C(1)-C(2) [1.498(5) Å] is *ap* and that of the C(1)=O(2) and the C(5)-O(1) ester bond [1.461(4) Å] about the C(1)-O(1) is *sp*, which is different from those of α-substituted diphenylmethyl methacrylates, 1,1-DPEMA and TrMA but similar to DPMMA. However, TrMA and 2-PyMA act similarly in the stereospecific polymerization; both monomers afford almost 100% isotactic polymers in the anionic polymerization, and even radical polymerization produce the isotactic polymers.[5,11] Therefore, the conformation of the C(2)=C(3) and C(1)=O(2) of the methacrylates in the solid state may not be important for the stereospecific polymerization. In solution both monomers likely take the same conformation considering from the results by ^{1}H NMR study with a shift reagent.[12]

The methacryloyl residue is planar within 0.04 Å (Plane 1), and the dihedral angle between the plane defined by the C(1), C(2), C(3), and C(4) atoms (Plane 2) and that made by the C(1), C(2), O(1), and O(2) (Plane 3) is only 1.7(2)°. Two benzene and a pyridine

††† Tables of anisotropic temperature factors, coordinates of hydrogen atoms, and the observed and calculated structure factors are kept at the Chemical Society of Japan, Document No. 8641.

rings attached to the C(5) atom are all planar within 0.01 Å. Bond lengths [av. 1.385 and 1.384 Å] and bond angles [both 120.0°] in phenyl rings are normal. The nitrogen atoms of the 2-pyridyl group is located far from the methacryl residue. The N-C(18) [1.339(4) Å] and N-C(22) [1.343(5) Å] bond lengths are respectively equal to the corresponding lengths in the pyridine molecule at 153 K [1.336 Å].[13] The C(19)-C(20) bond length [1.385(6) Å] is slightly longer than the corresponding C-C length in pyridine [1.378 Å]. The C(18)-N-C(22) angle [118.2(3)°] is slightly larger and the N-C(18)-C(19) [121.6(3)°] smaller than the C-N-C [116.6°] and N-C-C [123.7°] angle in pyridine, respectively. Among the bond angles around the C(5) atom, the C(6)-C(5)-C(18) angle [116.3(3)°] is much larger, whereas the O(1)-C(5)-C(12) [103.9(3)°] is much smaller than the tetrahedral angle.

The molecular conformation about the O(5)-C(1) bond is shown in Fig. 2. Similar to 1,1-DPEMA,[4] one of the two phenyl groups attached to the C(5) atom is trans to the C(1), and the other and the 2-pyridyl group gauche. This conformation is also similar to those of TrMA[4] and ChMA,[2] each of which has no hydrogen atom on the C(5).

Crystal Structure. The packing mode of molecules in the crystal is shown in Fig. 3[10] Close intermolecular contacts between non-hydrogen atoms of pyridine rings in adjacent molecules are observed: C(21)(x, y, z)···C(22)($-x$, $-y$, $-1-z$)=3.392(6), N(x, y, z)···C(21)($-x$, $-y$, $-1-z$)=3.435(5), and C(20)(x, y, z)···C(22)($-x$, $-y$, $-1-x$)=3.489(6) Å. The C(15)(x, y, z)···O(2) ($-1+x$, y, z) distance is also short [3.461(5) Å].

Proton Transfer Reactions in the Triplet State of Benzophenone Studied by Nanosecond Laser Flash Photolysis

Masahiko Hoshi and Haruo Shizuka*
Department of Chemistry, Gunma University,
Kiryu, Gunma 376
(Received April 1, 1986)

Proton-transfer reactions in the triplet state of benzophenone in H_2O–acetonitrile (4:1) at 20 °C have been studied by means of nanosecond nitrogen laser flash photolysis at 337 nm. The proton association (k_1) and dissociation (k_2) rates are determined to be 5.0 (±0.5)×10^9 mol^{-1} dm^3 s^{-1} and 3.3 (±0.3)×10^9 s^{-1} respectively by a transient kinetic treatment. These rates are large enough to make an acid-base equilibrium during the lifetime of the triplet state. The acidity constants (pK_a*) in the triplet state of benzophenone obtained by the transient kinetic treatment, the Ware plot, and the T_n←T_1 absorbance titration curve are the same [0.18 (±0.1)]. The pK_a* value determined by the titration method is appreciably dependent upon the delay time after the start of pulsing (the accurate value was obtained at the delay time 20 ns). There is no proton-induced quenching in the triplet state of benzophenone, since electrophilic protonation occurs at the oxygen atom in the carbonyl group. The reactive state for protonation in the triplet state is not $^3(n,\pi^*)$, but $^3(\pi,\pi^*)$, judging from the large k_1 value and the pK_a* value.

Proton-transfer reactions in the excited states of aromatic compounds are elementary processes in both chemistry and biochemistry. The acid-base properties in the excited state of aromatic compounds are closely related to electronic structure, which is considerably different from that in the ground state. A large number of studies on the acidity constants pK_a* in the excited state of aromatic compounds have been reported showing that the pK_a* values are significantly different from the acidity constants in the ground state.[1–9] It is known that the pK_a* values can be estimated by means of the Förster cycle,[1–3,10] the fluorescence titration curve,[2,3] and the triplet–triplet absorbance titration curve.[11] These methods involve the assumptions that proton transfer in the excited state is very fast and that the prototropic equilibrium may be accomplished during the lifetime in the excited state.

However, it has been shown recently that proton-induced quenching (^1k_q) is competitive with the proton-transfer reaction in the excited singlet state of naphthylamines (that is, simple acid-base equilibrium cannot be attained during the lifetime in the excited state of aromatic amines) and that a dynamic analysis containing the quenching process is, therefore, needed in order to obtain the accurate pK_a* values.[12] The dynamic analyses by means of nanosecond time-resolved spectroscopy with fluorimetry have been applied to 1-pyrenylamine,[13] 1-anthrylamine,[14] phenanthrylamines,[15] and naphthols.[16] The Stuttgart group[17] has supported our method to determine the pK_a* values of naphthylamines. Similar experimets for excited naphthols have been reported by Harris and Selinger.[18] For the proton-induced quenching mechanism, it has been demonstrated that the quenching proceeds via electrophilic protonation at one of carbon atoms of the aromatic ring in the excited singlet state, leading to proton exchange (or isotope exchange).[19] An intramolecular CT structure in the excited state is responsible for the quenching.[15,19,20] A linear relationship between the values of $\log {}^1k_q$ and the charge densities in the excited state of aromatic compounds has been shown.[20] Examples for no excited-state acid-base equilibria of aromatic compounds have been shown.[21–23] Establishment of prototropic equilibria at moderate acid concentrations have been reported for benzophenone[24,25] and phenyl ketones.[25] For the triplet state, its lifetime is relatively long enough to establish the prototropic equilibrium.[25] Very recently, it has been shown that the proton-induced quenching occurs scarcely in the triplet state of methoxynaphthalenes.[26] There has been considerable interest in photochemical and photophysical properties of aromatic compounds in the presence of protons.[27]

In the course of a study on the excited-state proton transfer reaction,[27] we became interested in the proton transfer reaction in the triplet state of benzophenone studied by nanosecond laser flash photolysis. This work was studied to answer the following questions: (1) How fast are the proton association and dissociation rates in the triplet state of benzophenone? (2) Is there really no proton-induced quenching in the triplet state? (3) How about pK_a* values in the triplet state of benzophenone determined by a transient kinetic treatment, the Ware plot, and the T_n←T_1 absorbance titration curve? (4) Which is the reactive state for protonation in the triplet state, $^3(n,\pi^*)$ or $^3(\pi,\pi^*)$?

Experimental

Materials. Benzophenone (a G. R. grade product from Tokyo Kasei) was purified by repeated recrystallizations from H_2O–EtOH mixtures. Sulfuric acid (97%, Wako) was used without further purification. Distilled water and acetonitrile (G. R. grade, Wako) were used as a H_2O–CH_3CN mixture (4:1 by volume). The concentration of benzophenone was 3.2×10^{-3} mol dm^{-3}. The pH values of samples were recorded with a pH meter (Corning M-125). The samples were thoroughly degassed by freeze-pump-

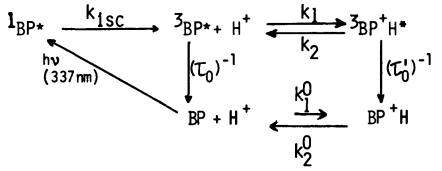
thaw cycles on a high vacuum line. All experiments were carried out at 20 °C.

Nanosecond Laser Flash Experiments. Laser flash photolysis studies were carried out using a nanosecond N_2 laser system at 337 nm (Japan Dynamic JS-1000L; pulse width 5 ns, laser power 5 mJ). The monitoring system consisted of a pulsed UXL-150D xenon lamp. A MC-20N monochromator (Ritsu) and a HTV R928 photomultiplier tube were used for the detection part. The transient signal was recorded with a transient memory (Kawasaki Electronica, MR-50E) and a 100 MHz storage oscilloscope (Iwatsu TS-8123).

Results and Discussion

Nanosecond Laser Flash Photolysis of Benzophenone. It is well known that triplet formation through intersystem crossing is very rapid (<10 ps),[28] according to the El-Sayed's rule.[29] For benzophenone (BP), a strong absorption band with a maximum at 525 nm (ε=7800 $mol^{-1}\,dm^3\,cm^{-1}$)[30] was observed just after pulsing, which decayed by first-order kinetics with a decay rate of $(\tau_0)^{-1}=7.4\times10^5\ s^{-1}$. This band is ascribed to the $T_n\leftarrow T_1$ absorption.[31,32] The protonated benzophenone triplet, ^{3}BP+H*, has a very weak absorption band at 505 nm.[25] The ^{3}BP+H* species produced in a 4 mol dm^{-3} H_2SO_4 solution decayed with a lifetime of 13 ns. The observed decay rate of triplet benzophenone (^{3}BP*) monitored at 525 nm increased significantly with an increase of proton concentration. The experimental data of the 525 nm transient absorbance (Ab) at 20 ns after the start of pulsing and the observed decay rate constants (τ_{obsd}^{-1}) or the apparent lifetimes (τ_{obsd}) in various acid concentrations are summarized in Table I. Judging from the relatively low value of absorbance at 525 nm, there is no triplet-triplet annihilation of BP under the experimental conditions. There is little or no quenching of ^{3}BP* by the counter anion SO_4^{2-}.[33]

Dynamic Analyses by Means of a Transient Kinetic Treatment. The experimental results can be accounted for by Scheme 1.



Scheme 1.

where BP and ^{3}BP* represent the ground and triplet states of benzophenone respectively, τ_0 and τ_0' the lifetimes of ^{3}BP* (in the absence of protons) and ^{3}BP+H* respectively, k_1 and k_2 the protonation and dissociation rate constants in the triplet state, respectively, and ^{3}BP+H* protonated benzophenone triplet. At the highest acidities used, the ground state of benzophenone is unprotonated,since the pK_a value in the ground state of BP is very low (−5.7).[34] when BP is excited by a laser pulse at 337 nm, ^{3}BP* is produced very quickly within 10 ps[28] via fast intersystem crossing[29] of the singlet state of benzophenone (^{1}BP*).

At first, a transient kinetic treatment for the acid-base reaction of benzophenone has been made. The decay function of $Ab(t)$ of the transient absorbance at 525 nm for ^{3}BP* can be expressed as[35]

$$Ab(t) = c(e^{-\lambda_1 t}+Ae^{-\lambda_2 t}) \quad (1)$$

where c denotes the constant and $A=(X-\lambda_1)(\lambda_2-X)^{-1}$. The decay parameters λ_1 and λ_2 are

$$\lambda_{1,2} = \frac{1}{2}[X+Y\mp\{(Y-X)^2+4k_1k_2[H^+]\}^{1/2}] \quad (2)$$

where $X=\tau_0^{-1}+k_1[H^+]$ and $Y=(\tau_0')^{-1}+k_2$. The observed decay function at 525 nm is approximately the same as the undistorted decay function of Eq. 1, since the pulse width is relatively small (5 ns). The experimental value of τ_0^{-1} ($7.4\times10^5\ s^{-1}$) was used. The values of k_1, k_2, and $(\tau_0')^{-1}$ were varied. With use of the values of λ_1 and λ_2 obtained from Eq. 2, fitting of the decay function of $Ab(t)$ was carried out. Figure 1a shows the observed and calculated results of the function $Ab(t)$ at 20 °C at the concentrations of protons (1) $8.5_2\times10^{-2}$, (2) 0.22_8, and (3) 0.52_1 mol dm^{-3}. The best fitted values of λ_1 and λ_2 as a function of $[H^+]$ are shown in Fig. 1b. The values of k_1, k_2, and $(\tau_0')^{-1}$ were determined to be 5.0 ($\pm$0.5)$\times10^9$ $mol^{-1}\,dm^3\,s^{-1}$, 3.3 ($\pm$0.3)$\times10^9\ s^{-1}$, and 7.9 ($\pm$0.7)$\times10^7\ s^{-1}$, respectively. The value of the protonation rate constant (k_1) is close to that of the diffusion rate. It is noteworthy that the value of $(\tau_0')^{-1}$ obtained is approximately the same as the decay rate constant ($7.7\times10^7\ s^{-1}$) of ^{3}BP+H* at higher acid concentrations (see Table 1). The values of k_1 and k_2 are very much greater than those of the competitive processes: i.e., $k_1\gg\tau_0^{-1}$; $k_2\gg(\tau_0')^{-1}$. That is, an acid-base equilibrium in Scheme 1 is established in the excited

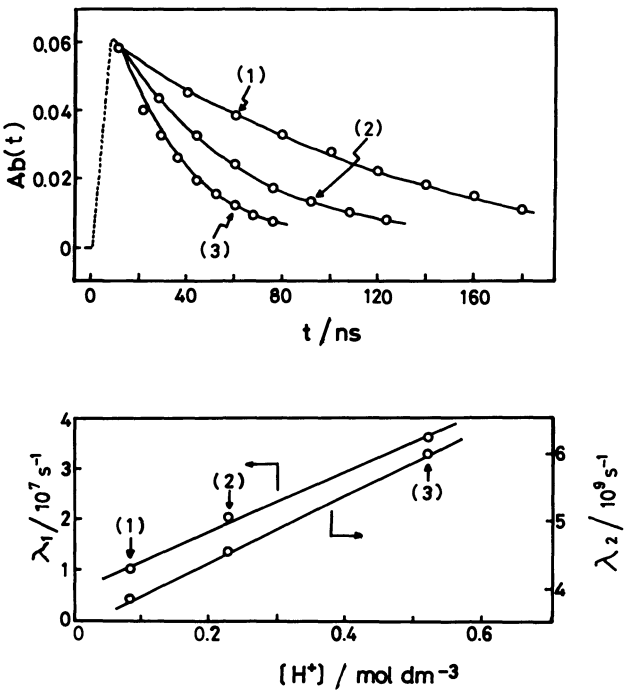


Fig. 1. (a) The decay function $Ab(t)$ of the 525 nm transient at the concentration of protons: (1) $8.5_2\times10^{-2}$, (2) 0.22_8, (3) 0.52_1 mol dm^{-3}. Circle: observed; solid curve; calculated. (b) The decay parameters λ_1 and λ_2 fitted to $Ab(t)$ as a function of $[H^+]$; e.g., (1)$\lambda_1=1.0\times10^7$s^{-1}, $\lambda_2=3.8\times10^9$s^{-1}; (2) $\lambda_1=2.0\times10^7$s^{-1} and $\lambda_2=4.5\times10^9$s^{-1}; and (3) $\lambda_1=3.5\times10^7$s^{-1} and $\lambda_2=5.9_5\times10^9$s^{-1}. For details see text.

state. The value of K_a^* ($=k_2/k_1$) was evaluated to be 0.66 mol dm^{-3}. The acidity constant of triplet benzophenone (pK_a^*) was determined to be 0.18 by means of the transient kinetic treatment. Very recently, a similar treatment has been employed in the hydrogen-atom transfer reaction from triplet naphthol to ground benzophenone.[30]

The Ware Plot. In the above section, it is shown that the prototropic equilibrium in the triplet state of BP is established within the triplet lifetime. Therefore, the Ware equation[36] can be applied to the present system. The Ware equation reads

$$\{\tau_{obsd}^{-1}-\tau_0^{-1}\}^{-1}=\{(\tau_0')^{-1}-\tau_0^{-1}\}^{-1}\left\{1+\frac{K_a^*}{[H^+]}\right\}. \quad (3)$$

The Ware plot of $(\tau_{obsd}^{-1}-\tau_0^{-1})^{-1}$ as a function of $[H^+]^{-1}$ is shown in Fig. 2. From the slope and intercept, the values of K_a^* and $(\tau_0')^{-1}$ are determined as 0.64 mol dm^{-3} and 7.5×10^7 s^{-1} respectively. The pK_a^* value is evaluated to be 0.19 from the Ware plot. As for $(\tau_0')^{-1}$ the values obtained by the decay rate constant of ^{3}BP$^+$H*, the transient kinetic treatment, and the Ware plot are approximately the same each other within experimental errors. The pK_a^* value (0.19) obtained is approximately the same as that (0.18) determined by the transient kinetic treatment.

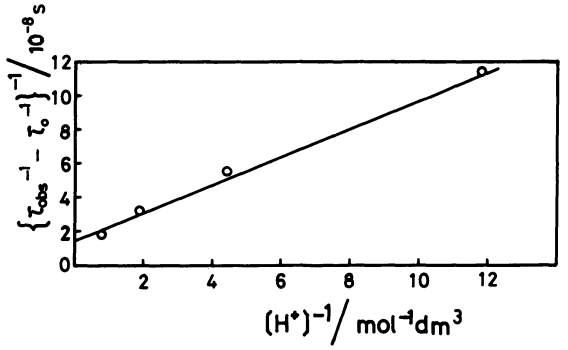

Fig. 2. The Ware plot of $[\tau_{obsd}^{-1}-\tau_0^{-1}]^{-1}$ vs. $[H^+]^{-1}$. See text.

Triplet-Triplet Absorbance Titration Curve. This method is the most popular one to estimate the pK_a^* value in the triplet state, when a prototropic equilibrium is established within the lifetime in the excited state.[11] Usually, the pK_a^* value can be estimated from the midpoint of the $T_n\leftarrow T_1$ absorbance titration curve obtained by nanosecond laser flash photolysis or microsecond flash photolysis just after pulsing. However, little attention has been paid to a relation between the pK_a^* value and the delay time to measure the titration curve. Here, it is demonstrated that there is a large dependence of the pK_a^* value upon the decay time. Figure 3 shows the dependence of the $T_n\leftarrow T_1$ absorbance titration curve on the delay time after the start of pulsing. The midpoint of the titration curve is shifted to higher pH values with an increase of the delay time. The pK_a^* value (0.18) obtained by the titration method at 20 ns after the start of pulsing is the best fit to that obtained by the transient kinetic analysis or the Ware plot. This value is positively deviated as the delay time increases, since the decay rate $[(\tau_0')^{-1}=7.7\ (\pm0.3)\times10^7\ s^{-1}]$ of ^{3}BP$^+$H* is extremely large compared to that $[\tau_0^{-1}=7.4\times10^5\ s^{-1}]$ of free ^{3}BP*. The short lifetime (13 ns) of ^{3}BP$^+$H*, the triplet benzophenone protonated at the oxygen atom of the carbonyl group, is not due to the proton-induced quenching, but the decay nature of ^{3}BP$^+$H* itself. In the triplet state of BP, electrophilic attack occurs on the oxygen atom of the carbonyl group of ^{3}BP* to produce ^{3}BP$^+$H*, since intramolecular charge migration from phenyl groups to the carbonyl group takes place appreciably in ^{3}BP* as discussed later. There is no electrophilic protonation (i.e., proton-induced quenching)[19] at one of carbon atoms of aromatic rings under the experimental conditions. The proton association and dissociation rates (k_1 and k_2) in the triplet state of BP are very fast enough to make an acid-base equilibrium within the lifetime in the excited state as stated above. Therefore, the delay time at 20 ns after the start of pulsing is a reasonable time to measure the titration curve in the present system.

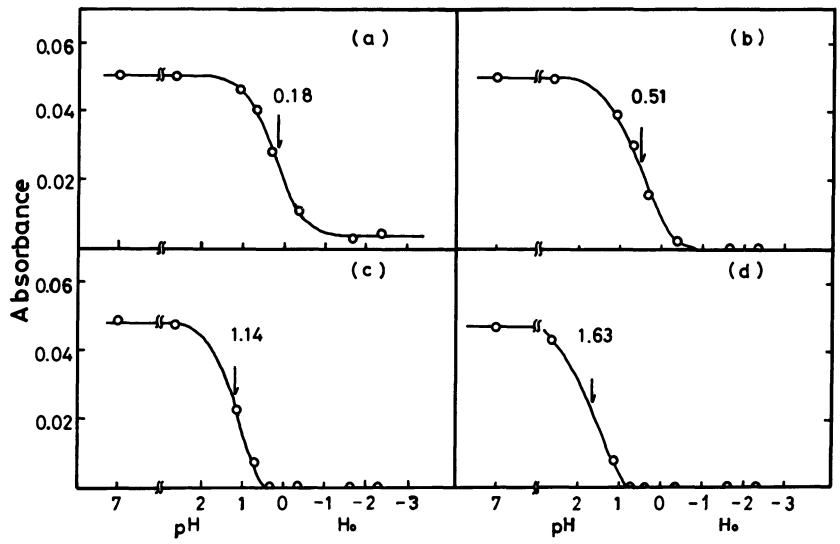

Fig. 3. The 525 nm transient absorbance curves observed at various delay times: (a) 20 ns, (b) 40 ns, (c) 100 ns, and (d) 200 ns after the start of pulsing.

Electronic Structure of Triplet Benzophenone. It is known that the lowest triplet state of BP is $^3(n,\pi^*)$ even in polar media.[37] There is a problem whether the reactive state of $^3BP^*$ for protonation is $^3(n,\pi^*)$ or $^3(\pi,\pi^*)$. In a previous paper,[25] the pK_a^* value for aromatic ketones is expressed as

$$pK_a^* = \rho^*\sigma^* + (pK_a^*)_0 \quad (4)$$

where ρ^* is equal to -1.33 and $(pK_a^*)_0$ denotes the pK_a^* value of acetophenone (0.60). The +I effect of a substituent of the carbonyl group increases the charge density (i.e., basicity) at the oxygen atom of the carbonyl group, resulting in an increase of the pK_a^* value. For BP, a positive deviation from the line according to Eq. 4 is observed.[25] The pK_a^* value of BP (0.18) has a greater value than that (-0.2) expected from its σ^* value ($+0.600$).[38] This fact cannot be explained by the difference in the lowest triplet character between $^3(n,\pi^*)$ (BP) and $^3(\pi,\pi^*)$ (phenyl alkyl ketones) in polar media. The charge density at the carbonyl group in the $^3(n,\pi^*)$ state should be smaller than that in the $^3(\pi,\pi^*)$ state, since the former state involves back charge transfer (from the carbonyl group to the phenyl ring). Both $^3(n,\pi^*)$ and $^3(\pi,\pi^*)$ states are perturbed by one another because the energy separation between them is very small in polar media, as has been discussed previously.[25,33b] The rapid rate of k_1 for protonation to $^3BP^*$ strongly supports that the reactive state of $^3BP^*$ is not $^3(n,\pi^*)$ but $^3(\pi,\pi^*)$. The $^3(\pi,\pi^*)$ state may have an intramolecular CT structure; charge migration from phenyl groups to the carbonyl group occurs in polar media, leading to a relatively high basicity in the triplet state. Thus, it can be understood that the pK_a^* value (0.18) in the triplet state of benzophenone increases drastically compared to that (-5.7)[34] in the ground state.

Concluding Remarks

The following remarks can be drawn from the results reported: (1) The protonation (k_1) and proton dissociation (k_2) rate constants in the triplet state of benzophenone in H_2O–CH_3CN (4:1) at 20 °C are determined to be $5.0\ (\pm0.5)\times10^9\ mol^{-1}\ dm^3\ s^{-1}$ and $3.3\ (\pm0.3)\times10^9\ s^{-1}$ respectively by means of a transient kinetic treatment. These rates are very much greater than those of their competitive decay processes, leading to produce an acid-base equilibrium in the excited state. (2) There is no proton-induced quenching in $^3BP^*$, because protons attack the oxygen atom of the carbonyl group. (3) The pK_a^* values for $^3BP^*$ obtained by means of the transient kinetic treatment, the Ware plot, and the $T_n \leftarrow T_1$ absorbance titration method are the same (0.18 ± 0.1) each other. The pK_a^* value determined by the titration curve depends upon the delay time to measure its curve; the accurate pK_a^* value is obtained at the delay time 20 ns after the start of pulsing. (4) The reactive state for protonation in the triplet state of benzophenone is not $^3(n,\pi^*)$ but $^3(\pi,\pi^*)$, considering the relatively large protonation rate k_1 and the pK_a^* value.

(Received April 8, 1986)

Electrocatalytic activity of oxygen reduction was strikingly improved at a GC(glassy carbon)/PPy(polypyrrole)/CoTSP((tetrasulfonatophthalocyaninato)cobalt) electrode among the other CoTSP doped polymer electrodes. The GC/PPy/CoTSP electrode was formed by electro-oxidized polymerization of pyrrole on a glassy carbon(GC) electrode in methanol solution containing CoTSP. The catalytic oxygen reduction at the GC/PPy/CoTSP electrode was mainly analyzed with RRDE technique. Oxygen reduction reaction at the GC/PPy/CoTSP electrode in 0.05 mol dm^{-3} H_2SO_4 showed ca. 0.5 V more anodic onset potential than the value obtained with a GC electrode in 0.05 mol dm^{-3} H_2SO_4 containing 10^{-3} mol dm^{-3} CoTSP. Kouteckty-Levich plot, i.e., the relation between I_{lim}^{-1} and $\omega^{-1/2}$ for the GC/PPy/CoTSP electrode gave almost the same slope of theoretical four-electron reduction at the limiting current region. It was indicated that the apparent oxygen reduction is occurred through direct four-electron exchange process. On the other hand, the GC electrode in dissolved CoTSP gave almost the same slope as of theoretical two-electron reduction. A diagnostic criterion for oxygen reduction proposed by Wroblowa et al.[19] indicated that the parallel pathways of two- and four-electron reduction exist for the GC/PPy/CoTSP electrode.

Catalytic properties of macrocyclic transition metal complexes such as metal porphyrins and phtalocyanines for an electrochemical oxygen reduction have been recognized and examined extensively by many workers.[1,2] An active, inexpensive and also stable catalyst system, however, has not yet been discovered.[14-17] In this connection, special efforts have been made to enhance the activity of electrode catalysts such as graphite by modifying their surfaces with some active materials. Utilization of modified catalytic electrode at monolayer level has not been so successful in that they lack stability and conductivity in a doped state due to an unstable and insulating nature of adsorbed species on the substrate.[3-5] Recently, incorporation of electrocatalytic materials into polymer-coated electrode has been introduced as an easy and potential means for fixing a large metal complexes as active catalyst on a substrate.[6-9] Polymer films can be deposited on an electrode by electro-oxidized polymerization simultaneously with the incorporation of active materials from the supporting electrolyte.

In this paper, we mainly adopted polypyrrole for coating glassy carbon(GC) electrode by considering the following advantages. First, pyrrole can easily be polymerized and form a fairly stable film which adheres well to the substrate. Second, polypyrrole shows a good electronic conductivity, and can be an excellent current collector and an electron shuttle. Third, polymerized polypyrrole shows an easy incorporation of dopants during the film formation.

Bull et al.[6] reported that there was no remarkable change in catalytic activity by doping FeTSP in PPy film. However, a considerable improvement on catalytic activity of O_2 reduction was observed by doping [5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrinato] metals such as CoTPPS, FeTPPS and MnTPPS in polypyrrole films.[7,8] In the previous communication,[9] we briefly surveyed some PPy modified metal porphyrins such as FeTPPS, CoTPPS, FeTSP, and CoTSP for the activity of O_2 reduction. Among these, we found that the GC/PPy/CoTSP electrode showed the highest activity with respect to an onset potential of O_2 reduction reaction. The main motivation of the paper is to throw a light on the interpretation of oxygen reduction mechanism for the GC/PPy/CoTSP electrode with RRDE (rotating ring-disk electrode) technique.

Experimental

CoTSP was synthesized and purified after an usual way,[10] and was then identified by an absorption spectrum using the same method in Refs.[11,12] Electrocatalytic activities for oxygen reduction reaction were mainly examined by rotating Pt ring-GC disk electrode (RRDE) at various rotating speeds. The ring and disk electrodes were pretreated by polishing with alumina grain (0.3 μmϕ) suspended in water. The ring-disk electrode was calibrated with the iron(II)/iron(III) couple. The value of collection efficiency, N, determined in this manner was 0.40 which was well consistent with the value of 0.40 obtained from the geometry of electrodes. An Ag/AgCl was used as a reference electrode and all the potentials for electrochemical measurements were referred to it. Pt wire was used as a counter electrode. Polymer coated CoTSP electrodes were deposited on GC by potentiostatic electropolymerization in methanol or aqueous solution containing CoTSP. The film thickness of polymer films was controlled by passing 90 mC cm^{-2}. GC/PPy/CoTSP and GC/PMP(poly(N-methylpyrrole))/CoTSP were formed at 1.2 V vs. Ag/Ag$^+$ in methanol solution containing 0.1 mol dm^{-3} monomer and 10^{-3} mol dm^{-3} CoTSP. GC/PPr(polypyrene)/CoTSP was formed at 1.2 V vs. Ag/Ag$^+$ in methanol containing

0.01 mol dm^{-3} monomer and 10^{-3} mol dm^{-3} CoTSP. GC/PAn(polyaniline)/CoTSP was formed at 0.8 V vs. Ag/AgCl in an aqueous solution containing 0.1 mol dm^{-3} monomer, 0.2 mol dm^{-3} H_2SO_4 and 10^{-3} mol dm^{-3} CoTSP. Solutions with various pH values were used as follows; 0.05 mol dm^{-3} H_2SO_4 (pH=1.2), 0.05 mol dm^{-3} KH_2PO_4+5.6×10^{-3} mol dm^{-3} NaOH (pH=6.0), and 0.025 mol dm^{-3} Na_2HPO_4+3.3×10^{-3} NaOH (pH=10.9). The intermediate hydrogen peroxide generated by two-electron reduction of O_2 was detected by ring electrode which was polarized at 1.10 V (pH=1.2), 0.82 V (pH=6.0), and 0.53 V (pH=10.9) while scanning the disk electrode potential at a scan rate of 10 mV s^{-1}.

Results and Discussion

Figure 1 shows typical O_2 reduction curves for GC/Polymer/CoTSP electrodes at 960 rpm where the background currents in N_2 atmosphere are already subtracted. GC/PPy/CoTSP, GC/PMP/CoTSP and GC/PAn/CoTSP electrodes have almost the same onset potentials at ca. 0.50 V which are the most favorable potential compared with the other two electrode systems, viz., GC/PPr/CoTSP and GC electrode in dissolved CoTSP. However, the ring current behavior of each electrode indicates that GC/PPy/CoTSP electrode is the most active oxygen reduction catalyst because of the occurrence of the four-electron transfer process to H_2O at the potential cathodic to 0.00 V. Therefore, the GC/PPy/CoTSP electrode was considered to be the most active oxygen reduction catalyst among the other polymer coated electrodes and worthwhile examining further.

Typical pH dependence of RRDE polarization curves for the GC/PPy/CoTSP is shown in Fig. 2. Oxygen reduction current at the GC/PPy/CoTSP disk electrode has onset potentials of ca. 0.50 V (pH=1.2), ca. 0.25 V (pH=6.0), and ca. 0.00 V

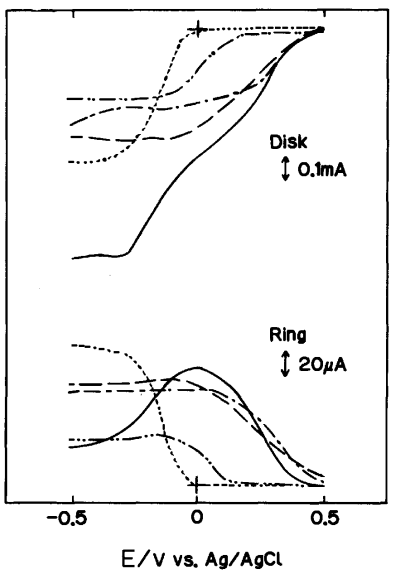

Fig. 1. Ring-disk current vs. potential curves for GC/CoTSP electrodes coated with various conductive polymers at 960 rpm in 0.05 mol dm^{-3} H_2SO_4. Film preparation conditions are indicated in the experimental section.

(pH=10.9). As proton concentration increases, the onset potentials of O_2 reduction are observed to shift to the anodic side. In the solution of pH=1.2, the disk current shows the most anodic onset potential and a relatively clear limiting current is observed. The ring current shows a peak at ca. 0.00 V, and decreases until −0.32 V at which disk current exactly shows a maximum, and finally becomes constant current. At the potential more cathodic than 0.00 V, the four-electron process seems to occur. In the solution of pH=6.0, both disk and ring current curves have an onset potential at 0.25 V. Although disk current shows a substantial increase, the ring current shows almost zero change, indicating that the direct reduction from O_2 to H_2O is dominantly involved. In the solution of pH=10.9, the two- and the four-electron process seems to occur in parallel. The following study is focused on the behavior of GC/PPy/CoTSP electrode in the acidic solution of pH=1.2.

Figure 3 shows polarization curves for O_2 reduction reaction in three different supporting electrolytes, viz., H_2SO_4, CH_3COOH, and $HClO_4$ at pH=1.2. O_2 reduction current for H_2SO_4 electrolyte keeps the highest values than those in the other electrolyte. Polarization curves for O_2 reduction curves are observed to be very sensitive to the electrolyte anions used for the O_2 reduction measurements. The reason for that is still unclear at the present stage, but the behavior of polarization curves may have a close relationship with the mobility of anions in electrolyte solutions and the polymer film resistances with anion doped states.

Polarization curve of O_2 reduction at a GC/PPy electrode without CoTSP dopants and at the GC/PPy/CoTSP electrode are compared as shown in Fig. 4. As is evident from the disk currents, an onset potential for the GC/PPy electrode is 0.0 V, which is less anodic than that for the GC/PPy/CoTSP. Ring currents for the GC/PPy/CoTSP and the GC/PPy electrodes have onset potentials at 0.50 V and 0.00 V, respectively. For the GC/PPy/CoTSP electrode, two-electron reduction of O_2 is observed to occur at ca. 0.50 V, and has peak value at 0.00 V. At the potentials cathodic to 0.00 V, four-electron reduction gradually became to be involved. On the other hand, for the GC/PPy electrode, only two-electron O_2 reduction process occurs at the potential cathodic to 0.00 V. By incorporating CoTSP into PPy film, catalytic activity of O_2 reduction is found to be highly improved.

Oxygen Reduction Mechanism at GC/PPy/CoTSP Electrode. Figure 5 shows polarization curves for the GC/PPy/CoTSP electrode. Background currents for the GC/PPy/CoTSP electrode in N_2 atmosphere are almost the same for given range of rotation speeds. The background currents at given rotation speeds are already subtracted so that the polarization curves reflect only O_2 reduction reaction. At potentials from −0.2 V to −0.3 V, the polarization curves have the plateaus and can reasonably be understood as the limiting currents. Therefore, the Kouteckty-Levich plots can be applied to these curves. According to the

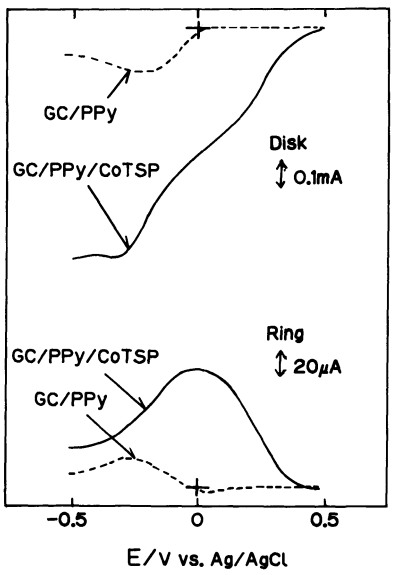

Fig. 4. Ring-disk current vs. potential curves for GC/PPy/CoTSP electrode (solid line) and GC/PPy (dashed line) formed at 1.2V vs. Ag/AgCl in 0.1 mol dm^{-3} Na_2SO_4+0.1 mol dm^{-3} pyrrole monomer at 960 rpm in 0.05 mol dm^{-3} H_2SO_4.

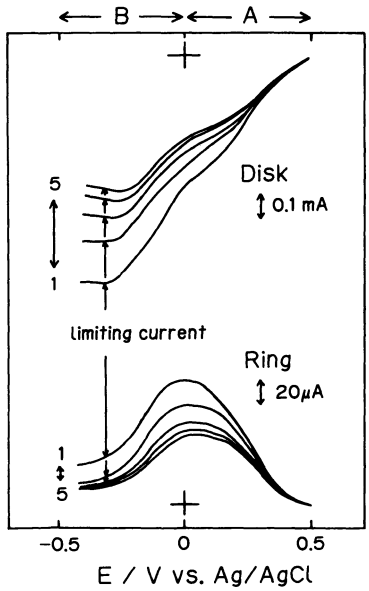

Fig. 5. Ring-disk current vs. potential curves for GC/PPy/CoTSP electrode at various rotation speeds in 0.05 mol dm^{-3} H_2SO_4 in O_2(solid lines) and N_2 (dashed line) atmosphere. The numbers 1, 2, 3, 4, and 5 correspond to 960, 610, 420, 310, and 240 rpm, respectively.

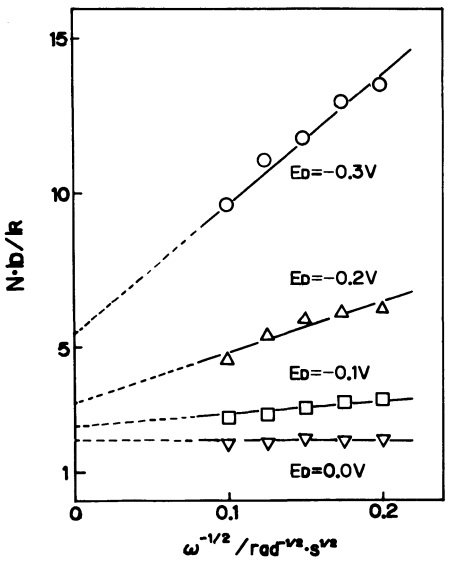

Fig. 7. NI_D/I_R vs. $\omega^{-1/2}$ plots for O_2 reduction reaction at GC/PPy/CoTSP electrode at various disk potentials in 0.05 mol dm^{-3} H_2SO_4. The disk potentials are indicated in the figure.

shape of ring currents, O_2 reduction mechanism can be discussed in two potential regions, viz., **A**: 0 V to 0.5 V, **B**: −0.50 V to 0 V. For the GC/PPy/CoTSP electrode in region **A**, O_2 reduction appears to occur from ca. 0.5 V, partly via H_2O_2, and the ring current steadily increases. In region **B**, the ring current of the GC/PPy/CoTSP electrode shows reverse behavior to that in region **A**, and the intermediate H_2O_2 gradually decreases for the GC/PPy/CoTSP electrode. It is assumed that O_2 reduction at the GC/PPy/CoTSP electrode partly became to involve four-electron transfer process at the transition potential region from **A** to **B**. Thus, for the GC/PPy/CoTSP electrode, the reaction path changed partly from two-electron process to four-electron process in this potential region.

Figure 6 shows the Kouteckty-Levich plots for the GC/PPy/CoTSP electrode and the GC electrode in dissolved CoTSP at the potential at which the limiting current was observed. The disk limiting current(I_{lim}) can generally be expressed as follows;[18]

$$1/I_{lim} = 1/I_k + 1/(I_d)_{lim} \quad (1)$$

$$(I_d)_{lim} = 0.62\,nFAD^{2/3}\nu^{-1/6}\omega^{1/2}Cb, \quad (2)$$

where $(I_d)_{lim}$, I_k, Cb, D, ν are the diffusion limiting current, the reaction controlled current, the dissolved O_2 concentration, the diffusion coefficient of O_2, the kinematic viscosity of the solution, respectively. Theoretical values for two- and four-electron reduction are calculated by using Eq.2 and the values of D and ν in Ref.[13] For both electrodes, the linear relationship between the reciprocal of limiting current and (rotation speed)$^{-1/2}$ are shown. The plot for the GC electrode in dissolved CoTSP is in good agreement with the theoretical two-electron reduction.

In contrast, for the GC/PPy/CoTSP electrode, the slope is almost the same as the theoretical four-electron reduction. The reaction controlled current is observed at the intercept with I_{lim} axis for the GC/PPy/CoTSP eletrode.

Figure 7 shows NI_D/I_R vs. $\omega^{-1/2}$ plots as a function of disk potentials. All plots yield straight lines with their intercepts above unity. The increase of the slope is observed with an increase of cathodic potential. Further information on an apparent electroreduction can be obtained from the diagnostic criterion suggested by Wroblowa et al.[19] By postulating a generalized scheme[19] for possible oxygen electroreduction at the GC/PPy/CoTSP, disk current(I_D) to ring current(I_R) ratio was derived as follows:

$$N(I_D/I_R) = 1 + 2k_1/k_2 + A + (k_{-5}/Z\omega^{1/2})A$$

where

$$A = (2k_1/k_2k_5)(k_{-2}+k_3+k_4) + (2k_3+k_4)/k_5 \quad (3)$$

$$Z = 0.62D^{2/3}\nu^{-1/6}$$

with N, D, ν, and ω are the collection efficiency, the diffusion coefficient of peroxide, the kinematic viscosity and the angular velocity of electrode. Equation 3 involves the two main reaction pathways, i.e., four-electron reduction to H_2O (k_1) and two-electron reduction to H_2O_2 (k_2). Adsorbed H_2O_2 proceeds to the following reactions; **1**. further two-electron reduction to H_2O(k_3), **2**. reoxidation to O_2(k_{-2}), **3**. catalytic decomposition of adsorbed H_2O_2 to O_2 and H_2O(k_4), **4**. desorption of adsorbed H_2O_2(k_5).

Equation 3 reduces to Eq. 4 with the intercept(J) and slope (s) of the NI_D/I_R vs. $\omega^{-1/2}$ plots.

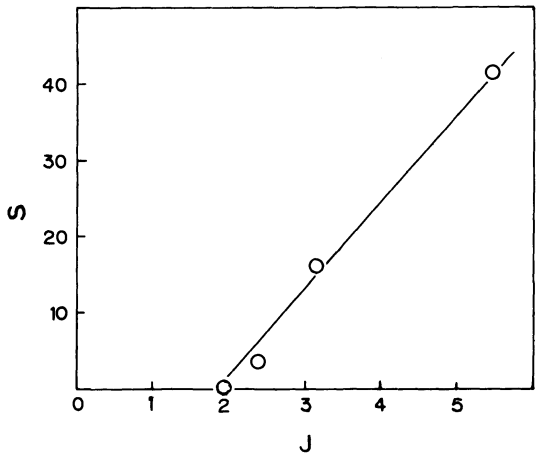

Fig. 8. Intercept(J) vs. slope (S) plot for O_2 reduction at GC/PPy/CoTSP electrode as a function of disk potentials.

$$J = 1 + 2k_1/k_2 + SZ/k_{-5} \quad (4)$$

Slope (S) was plotted against J at several disk potentials and indicated in Fig. 8. A straight line with the intercept $J'=2$ was yielded. When $k_1 \neq 0$, and k_1/k_2 is independent of potential, J vs. S plots should become linear with the intercept $J'>1$ as follows:

$$J' = 1 + 2k_1/k_2 \quad (5)$$

Hence, there is a parallel mechanism of four-electron direct reduction to H_2O and two-electron reduction to H_2O_2 process. The increase of S with an increase of cathodic potential is considered to be caused mainly by the occurrence of further oxidation from H_2O_2 to H_2O.

Cyclic Voltammograms for GC/PPy/CoTSP Electrode and GC Electrode in Dissolved CoTSP. One of the reasons of the high catalytic improvement for GC/PPy/CoTSP electrode would be deduced from the results in Fig. 9. In Fig. 9 a), a small redox peak was observed at around 0.3 V which may due to the redox reaction of CoTSP doped PPy film. The peaks are not so distinct because of the hindrance of PPy background, but they can be identified as ca. 0.31 V and ca. 0.22 V for anodic and cathodic peak potentials in N_2 atmosphere. The cathodic current peak at 0.22 V was increased when the solution was saturated with O_2. This catalytic reduction can be caused by the mediation effect of the redox couple at 0.30 V. As shown in Fig. 9b), O_2 reduction occurred at ca. 0.00 V which was far cathodic to the onset potential for the GC/PPy/CoTSP electrode. Therefore, the GC/PPy/CoTSP electrode has a favorable conditions with respect to the onset potential of O_2 reduction reaction. For the GC/PPy/CoTSP electrode, PPy matrix makes the redox potential more cathodic, which, as a result,

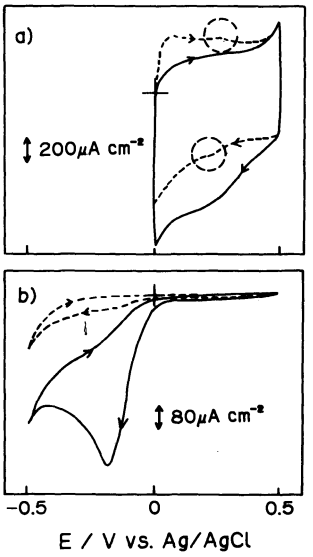

Fig. 9. Cyclic voltammograms for a) GC/PPy/CoTSP electrode and b) GC electrode in 10^{-3} mol dm^{-3} CoTSP at a scan rate of 50 mV s^{-1} in 0.05 mol dm^{-3} H_2SO_4 solution in O_2 (solid line) and N_2 (dashed line) atmosphere.

happen to form a favorable energy level of the CoTSP metal center for the formation of O_2 adduct with Co metal center of CoTSP.

The authors are indebted to Prof. Noboru Oyama and Dr. Takeo Ohsaka at Tokyo University of Agriculture and Technology for their valuable discussions and Mrs. Michiko Maeda at Japan Women's University for supplying CoTSP.

Photochemical Magnetic-Field Effects of Isoquinoline *N*-Oxide in Various Alcohols

Norisuke HATA
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157
(Received April 8, 1986)

A pronounced solvent dependence of the magnetic-field effect due to the HFI-J mechanism was found for the first time in the case of a photochemical isomerization of isoquinoline *N*-oxide into lactam (1-isoquinolone). The chemical yield of the lactam showed a minimum at a higher magnetic field as one changes the reaction medium from *t*-butyl alcohol to 2-propanol (or ethanol) and then to methanol, which was the same order as the pK_a value (*t*-butyl alcohol>2-propanol≈ethanol>methanol). Such a solvent dependence provides corroborating evidence that the photoisomerization proceeds via the S_1-born singlet radical-ion-pair intermediate, which is linked by a hydrogen bond between the N→O group in the cation radical of *N*-oxide and the OH group in the anion radical of alcohol. Another interesting finding was that, in the case of the photochemical isomerization in *t*-butyl alcohol, the chemical yield of the lactam showed distinct maxima at approximately 0.9T and 1.35T in addition to a minimum at about 0.72T. The anomalous magnetic-field effect in a high field region (>0.8T) could reasonably be explained in terms of an HFI-J mechanism by assuming the T_1-born triplet hydrogen-bonded radical-ion pair to have an electron-exchange interaction larger than that in the S_1-born singlet hydrogen-bonded radical-ion pair.

As has been described in a previous paper,[1] the photochemical isomerization of isoquinoline *N*-oxide in ethanol was found to show a new type of magnetic-field effect in 1976, the chemical yield of the product (1-isoquinolone) having a minimum at approximately 1T. This phenomenon was successfully interpreted in terms of a hyperfine-interaction mechanism including an electron-exchange interaction (HFI-J mechanism) in the S_1-born singlet hydrogen-bonded radical ion-pair, assumed to be a transient intermediate of this reaction. In 1979 the photochemical magnetic-field effect was found to depend greatly on the pK_a of the alcohol (methanol, ethanol, 2-propanol, or *t*-butyl alcohol) used as a reaction medium; further, in the case of a *t*-butyl alcoholic solution, an anomalous field dependence of the chemical yield was observed at a magnetic field higher than 0.8T.[2] These findings were partly reported in a preliminary form.[2] The present paper will present further details of these phenomena, together with an interpretation.

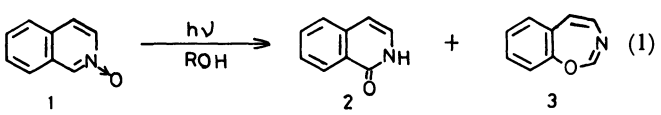
Experimental

The isoquinoline *N*-oxide **1** used as a sample was prepared and purified according to the method described in a previous paper;[1] mp 103—105 °C. The 1,3-cyclohexadiene used as a triplet quencher was a reagent-grade product of the Tokyo Kasei Kogyo Co., which was further purified by distillation; bp 80—81 °C. The methanol, 2-propanol, and *t*-butyl alcohol used as the photoreaction medium were reagent-grade products of Wako Pure Chemical Industries.

The experimental procedure was quite similar to that described proviously;[1] a 50-cm^3 portion of an alcoholic solution (methanol, 2-propanol or *t*-butyl alcohol) containing 35 mg of isoquinoline *N*-oxide in a quartz vessel (44×45×25 mm) was irradiated with a 500W Ushio super-high-pressure Mercury Lamp (USH-500D) equipped with a Toshiba filter UV-31 for 15 min in the cases of methanolic and 2-propanolic solutions (or 10 min in the case of a *t*-butyl alcoholic solution), while nitrogen was being bubbled in, in a magnetic field of 0—1.65T at room temperature. A similar experiment was also performed on a *t*-butyl alcoholic solution containing the *N*-oxide (35 mg) and 1,3-cyclohexadiene (4.80×10^{-1} mol dm^{-3}). In the case of a methanolic or 2-propanolic solution, unreacted *N*-oxide **1** and a photoproduct (lactam) **2** were separated by means of silica-gel TLC (Merck silica-gel plate $60F_{254}$; layer thickness, 2 mm; the eluent, benzene–ethanol–diethyl ether (5:1:2)). In the case of a *t*-butyl alcoholic solution, the irradiated solution was chromatographed on an alumina column (Wako activated aluminium oxide, about 300 mesh) by elution with chloroform–diethyl ether (1:3), chloroform–ethanol (40:1), and then chloroform–ethanol (20:1) to separate some decomposition products, unreacted *N*-oxide **1** and then lactam **2**. The amounts of the unreacted *N*-oxide **1** and the product **2** were determined spectrophotometrically. The UV absorption spectra were taken with a Shimadzu recording spectrophotometer, UV-220.

Results and Discussion

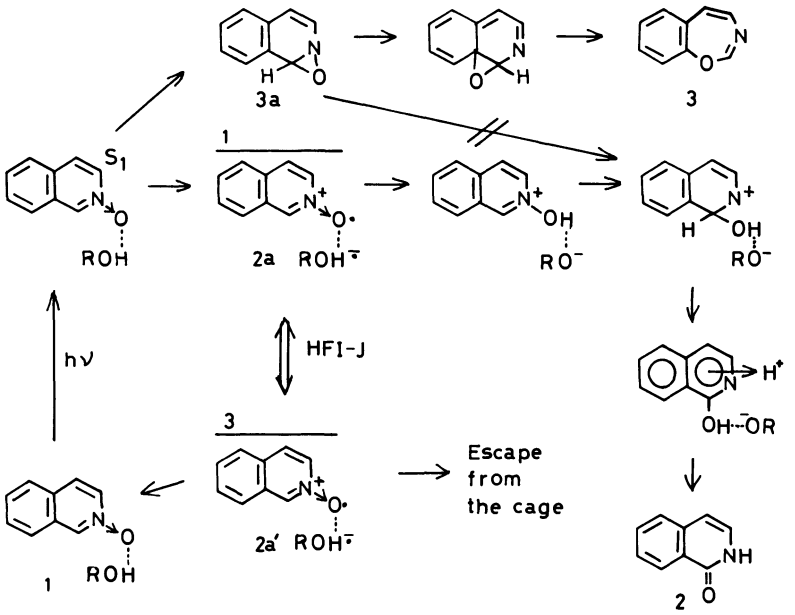
The irradiation of isoquinoline *N*-oxide **1** in hydroxylic solvent (ROH) leads to the isomerization into lactam **2** (1-isoquinolone) and 1,3-benzoxazepine **3** (Eq. 1), but the latter product **3** is quite unstable and can not be isolated.[1,3]



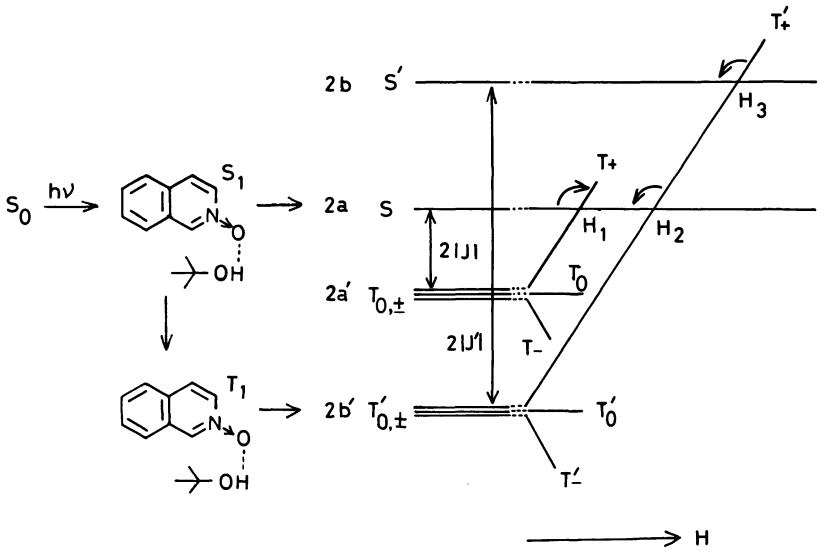
1 2 3 (1)

As has been reported previously,[1] when the photochemical isomerization of isoquinoline *N*-oxide **1** in ethanol was carried out in the presence of a magnetic field, the chemical yield of lactam **2** showed a minimum at approximately 1T (Fig. 2). In order to interpret this phenomenon, "the radical-ion-pair mechanism" (as shown in Scheme 1) has been proposed for the photoisomerization of isoquinoline

N-oxide **1** into lactam **2** in hydroxylic solvents (ROH).[1] In this scheme, the field-sensitive singlet radical-ion-pair intermediate **2a** responsible for the formation of lactam **2** was reasonably assumed to be formed by the transfer of an electron (πO:) from the excited singlet *N*-oxide (S_1) to the hydrogen-bonded alcohol (ROH). The exchange interaction between the unpaired electrons in the pair **2a** is thought to be larger than the electron-nuclear hyperfine interaction, for the radical centers are in close proximity as a result of hydrogen-bonding interaction between the radical ions. This means that, as is shown in Scheme 2, the singlet (S) and triplet ($T_{0,\pm}$) levels of the S_1-born radical-ion pair (**2a** and **2a'**) are nondegenerate, having an energy gap of $2|J|$, where J denotes the electron-exchange integral. Therefore, the hyperfine-induced intersystem crossing ($S \leftrightarrow T_{0,\pm}$) of the pair does not occur at the zero field. As can be seen from Scheme 2, however, the application of the magnetic field to this system causes a crossing of the levels of S and T_+ at a particular magnetic field, H_1. Consequently, the chemical yield of the lactam **2** as an S_1-born cage product comes to show a minimum at this field strength, H_1 (ca. 1T in Fig. 2), i.e., the magnetic-field dependence of the chemical yield of the S_1-born cage product due to the HFI-J mechanism.[4]



Scheme 1.



Scheme 2.

If this interpretation is valid, the magnetic field, H_1, should be progressively shifted to a higher field as the electron-exchange interaction in the radical-ion pair **2a** increases, because the electron-exchange interaction determines the singlet-triplet splitting ($2|J|$) of the pair.[6] The exchange integral, $J(r)$, depends exponentially on the interradical distance, r, according to:

$$J(r) = J_0\exp(-\alpha r) \quad (2)$$

where α is a parameter.[6a] In the photochemical system under consideration, the distance between the radical centers of the pair **2a** can be assumed to vary with the pK_a of the reaction medium (ROH) which is linked by hydrogen bond to the oxygen atom of the *N*-oxide. This, in turn, leads to the idea that the electron-exchange interaction is dependent on the pK_a of the alcohol used as a reaction medium. The values of pK_a of some conventional aliphatic alcohols are known to be in the following order:[7] *t*-butyl alcohol>2-propanol≈ethanol>methanol. Accordingly, the magnetic field, H_1, responsible for the minimal yield of lactam **2** can be expected to be shifted to a progressively higher field as the reaction medium is changed from *t*-butyl alcohol to 2-propanol (or ethanol) and then methanol. In order to determine whether or not this presumption is correct, therefore, the photochemical isomerizations of isoquinoline *N*-oxide in the various alcohols were examined in either the absence or presence of a magnetic field.

In the absence of a magnetic field, the chemical yield of lactam **2** was dependent on the nature of the alcohol used as a reaction medium, decreasing in this order: methanol (ca. 74%), ethanol (ca. 67%), 2-propanol (ca. 55%) and *t*-butyl alcohol (ca. 43%), where the values in parentheses are the chemical yields.

Figures 1 to 4 show the results when the chemical yield of lactam **2** in various alcohol is plotted as a function of the magnetic-field strength. In the case of a 2-propanolic solution (Fig. 3), the minimal yield (ca. 44%) was observed at approximately 1T, just as in the case of an ethanolic solution (Fig. 2) reported previously.[1] In the case of a methanolic solution (Fig. 1), the chemical yield of lactam **2** was ca. 74% at a magnetic field below 1.4T, but it decreased steeply with an increase in the field strength reaching ca. 68% at 1.62T. It may safely be concluded from this finding that a minimal yield would appear in the vicinity of

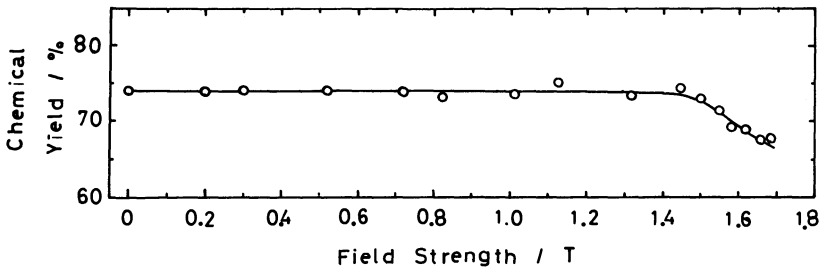


Fig. 1. Photochemical magnetic field effect of isoquinoline *N*-oxide **1** in methanol. Chemical yield of lactam **2** vs. magnetic field strength. [**1**]=4.81×10^{-3} mol dm^{-3}. Irradiation time: 15 min. Conversion: ca.18%.

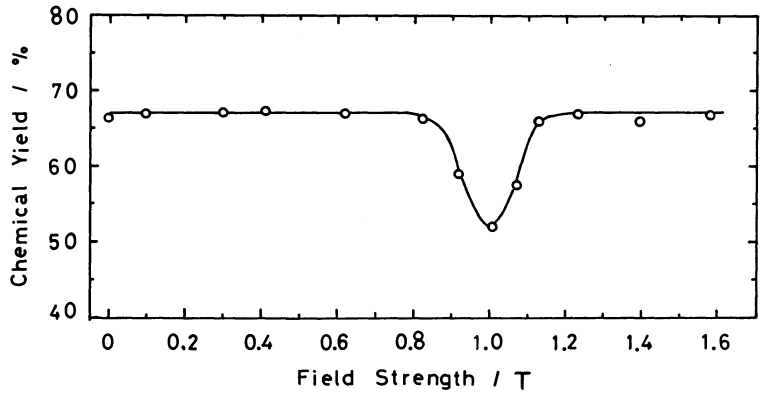

Fig. 2. Photochemical magnetic field effect of isoquinoline *N*-oxide **1** in ethanol. Chemical yield of lactam **2** vs. magnetic field strength.[1] [**1**]=4.82×10^{-3} mol dm^{-3}. Irradiation time: 10 min. Conversion: ca. 17%.

1.7T, although the measurement was not performed at a magnetic field above 1.65T because of the limited capability of the electromagnet employed in the experiment. In the case of a *t*-butyl alcoholic solution, unexpectedly, the complicating magnetic-field effect shown by Curve (a) in Fig. 4 was observed; the chemical yield of lactam **2** showed two maxima (ca. 50 and 55%), at approximately 0.9 and 1.35T, as well as a minimum (ca. 34%) at about 0.72T. The anomalous magnetic-field effect in the high-field region (>0.8T) disappeared completely upon the addition of 1,3-cyclohexadiene, C_6H_8, (triplet quencher)[8] to the reaction system, while a minimum of the chemical yield was still observed at approximately 0.75T (Curve (b) in Fig. 4). The results indicate clearly that the quencher-insensitive-field effect around 0.7T should be assigned to the HFI-J magnetic-field effect, which can itself be ascribed to the S_1-born singlet hydrogen-bonded radical-ion pair **2a**. The anomalous and quencher-sensitive magnetic-field effect will be discussed later.

The experimental results described above are, surprisingly, in fair agreement with the presumption that a minimum in the chemical yield of lactam **2** may appear at a higher magnetic field as one changes the reaction medium in the order: *t*-butyl alcohol, 2-propanol (or ethanol) and methanol. Hence, the observed solvent dependence can be taken as corroborating evidence that, as is shown in Scheme 1, the photochemical isomerization of isoquinoline *N*-oxide **1** into lactam **2** in hydroxylic solvents (ROH) occurs with the intervention of the S_1-born singlet hydrogen-bonded radical-ion pair **2a**, but it does not proceed via the S_1-born oxaziridine **3a** previously postulated as an intermediate of this reaction (cf. Ref. 1).

Next, let us discuss the anomalous field dependence of the chemical yield that is observed only in the case of *t*-butyl alcoholic solution in a magnetic field above 0.8T. As can be seen from Fig. 4, the chemical yield of lactam **2** showed distinct maxima at approximately 0.9 and 1.35T, but this effect disappeared upon the

addition of the triplet quencher. The quencher-sensitive magnetic-field effect showed, of course, the same pattern as that for the field dependence of the chemical yield of the T_1-born cage product due to the HFI-J mechanism (cf. Fig. 6 in Ref. 5).[4] This strongly suggests that the transfer of an electron (πO:) from the *N*-oxide to the hydrogen-bonded alcohol occurs not only in the S_1 state, but also in the T_1 state, to produce two kinds of field-sensitive radical-ion-pair intermediates (**2a** and **2b′**) quite similar to each other (Scheme 2). The only difference between the two pairs is the magnitude of the electron-exchange interaction. The exchange interaction in the T_1-born radical ion pair, **2b′**, should be much larger than that in the S_1-born radical ion pair, **2a**, since the maximal yields of the lactam **2** as a T_1-born cage product appear in a higher-field region compared to the minimal yield of the lactam **2** as an S_1-born cage product. For the formation of such radical-ion pairs, a hydrogen-bonding interaction between the oxygen atom of the *N*-oxide and the alcoholic solvent has to be much stronger in the T_1 state than in the S_1 state.

Kubota et al.[9] have demonstrated clearly, prior to 1972, from solvent-effect studies of the absorption (singlet–singlet and singlet–triplet) and fluorescence spectra of some heterocyclic *N*-oxides, that the hydrogen-bonding ability of the oxygen atom of the N→O group is much larger in the S_0 and T_1 states than in the S_1 state; this is in conformity with the result of molecular-orbital consideration that the charge transfer from the oxygen atom of the N→O group to the ring π-electron system is much larger in the S_1 state than in the S_0 and T_1 states. The results strongly support the idea that the T_1-born triplet hydrogen-bonded radical-ion pair **2b′** has an electron-exchange interaction (J') much larger than that (J) in the S_1-born singlet hydrogen-bonded radical-ion pair **2a**.

One may construct a schematic energy-level diagram (as is shown in Scheme 2) for the hydrogen-bonded radical-ion pairs produced from the S_1 and T_1 states, by considering that the singlet-triplet splitting ($2|J'|$) in the T_1-born radical-ion pair is greater than that ($2|J|$) in the S_1-born radical-ion pair. On the basis of this diagram, the observed photochemical magnetic-field effect of isoquinoline *N*-oxide in *t*-butyl alcohol can be reasonably interpreted in terms of an HFI-J mechanism as follows.

In the absence of an external magnetic field, the hyperfine-induced intersystem crossing ($S \rightarrow T_{0,\pm}$ or $T'_{0,\pm} \rightarrow S'$) from the S_1-born singlet or T_1-born triplet radical-ion pair (**2a** or **2b′**) does not occur at the zero field because of the large electron-exchange interaction. As a result, the S_1-born singlet hydrogen-bonded radical-ion pair **2a** mostly undergoes a geminate reaction within a solvent cage to give rise to lactam **2** as an S_1-born cage product, whereas the T_1-born triplet hydrogen-bonded radical-ion pair **2b′** undergoes a diffusive separation into the solvent bulk. However, the application of the magnetic field to this system resolves the triplet level $T_{0,\pm}$ (or $T'_{0,\pm}$) into three sublevels, T_0, T_+, and T_- (or T'_0, T'_+, and T'_-), and the T_+ (or T'_+) level approaches the S and S′ levels as the field strength increases. Consequently, a crossing of the levels of S and T_+ occurs first at the magnetic field of H_1 and the chemical yield of the lactam **2** as an S_1-born cage product becomes minimal, corresponding to a minimal yield around 0.7T (Fig. 4). A further increase in the field strength causes an intersystem crossing of $T'_+ \rightarrow S$ at the magnetic field H_2,[10] followed by a crossing from the T'_+ to S′ levels at the magnetic field H_3. As a result, the chemical yield of the lactam **2** as a T_1-born cage product comes to show maxima at the magnetic fields of H_2 and H_3, corresponding probably to maximal yields at approximately 0.9 and 1.35T (Curve (a) in Fig. 4).

In the case of a methanolic, ethanolic or 2-propanolic solution, no such anomalous field effect was observed at all at any magnetic field below 1.65T (Figs. 1 to 3). This is probably because a hyperfine-induced intersystem crossing between the T'_+ and S (or S′) levels can not occur in this field region because of a large electron-exchange interaction in the hydrogen-bonded radical-ion-pair intermediate.

Conclusion

Remarkable solvent dependences of the magnetic-field effect attributable to the HFI-J mechanism were found for the first time in the case of a photochemical isomerization of isoquinoline *N*-oxide **1** into lactam **2** in alcoholic solvents. First, the chemical yield of the lactam **2** as an S_1-born cage product showed a minimum at a particular magnetic field, which was progressively shifted to a higher field as the reaction medium (ROH) was changed from *t*-butyl alcohol to 2-propanol (or ethanol) and then methanol. Such a solvent dependence was attributable to the influence of an electron-exchange interaction on the hyperfine-induced intersystem crossing of the S_1-born singlet hydrogen-bonded radical-ion pair **2a**, assumed to be a transient intermediate of this reaction. Second, in the case of a *t*-butyl alcoholic solution, the chemical yield of lactam **2** showed two maxima in the field region of 0.8—1.4T, in addition to a minimum at ca. 0.7T. This phenomenon was also reasonably explained in terms of an HFI-J mechanism by assuming the formation of the triplet hydrogen-bonded radical-ion pair **2b′** from the T_1 state (Scheme 2). The present studies demonstrate definitely that the photochemical isomerization of isoquinoline *N*-oxide in hydroxylic solvent proceeds according to the mechanism shown in Scheme 1.

10) The fact that the chemical yield of lactam **2** shows a maximum at the magnetic field of H_2 (ca. 0.9T in Fig. 2) indicates explicitly that the intersystem crossing $T'_+ \rightarrow S$ occurs, while the $S \rightarrow T'_+$ does not. This is probably because a geminate reaction (**2a**→**2b**) of the singlet hydrogen-bonded radical-ion pair **2a** takes place much faster than the intersystem crossing $S \rightarrow T'_+$.

Basis Set Dependency of Molecular Electronic Structures

Hiroshi Ichikawa,* Keiichiro Sameshima, and Yukiko Ebisawa
Hoshi College of Pharmacy, Shinagawa-ku, Tokyo 142
(Received April 14, 1986)

The total atomic charges as well as the kinetic and potential energies calculated using 22 different basis sets were compared. It was shown that polarization functions must be added to atoms of the first row as well as the hydrogen atom in order to obtain well-balanced wave functions. The STO-*N*G (*N*=3, 4, 5, or 6) method, which is considered to give poor wave functions, is shown to give well-balanced wave functions.

It is unnecessary to say that ab initio molecular orbital (MO) theories have been frequently used in explaining various molecular properties in terms of electronic structures. Energy partitioning based on ab initio MO theories has been effectively applied in analyses of chemical bonds[1] and aromaticity.[2,3]

So far, quantum chemists have proposed various types of basis sets (i.e. MO theories). However, much effort in creating a new basis set has been devoted to the lowering of the total energy and to reproducing the observed geometries; the electron distribution has been treated less effectively. As a result, electron distributions can be greatly changed according to the type of basis set used. There have been method-to-method comparisons reported between different basis sets, mainly by the originaters of new basis sets. However, the number of such comparisons is too small for determining the general aspects of various MO theories. This paper is to show how the electronic structures and partitioned energies are dependent on the adopted basis set. For this purpose we have examined those quantities using 22 different basis sets in the GAUSSIAN-80 program.[4,5]

Partitioning of Molecular Energies

If wave functions are to provide an understanding of the behavior of electrons in a molecule, one must try to extract, in some way, information on the physically essential features of electronic energies. One of the trends along this line is energy partitioning.[6] Since in LCAO MO theory each MO is expanded by a linear combination of atomic orbitals (AO's), and since via the Fock matrix three- and four-center integrals out of the two-electron integrals can be reduced to two-center terms, the energy (E) based on either the restricted[7] or unrestricted Hartree-Fock equation[8] is *formally* expressed by the sum of monocentric (E_A) and bicentric (E_{AB}) terms,

$$E = \sum_{A} E_A + \sum_{A>B} E_{AB}. \quad (1)$$

These terms were further partitioned as

$$E_A = E_A^V + E_A^J + E_A^T \quad (2)$$

and

$$E_{AB} = E_{AB}^V + E_{AB}^J + E_{AB}^N + E_{AB}^T, \quad (3)$$

where E^V, E^J, and E^T are the one-electron potential, two-electron potential and kinetic energies of the electrons. E_{AB}^N is the nuclear-repulsion energy between atoms A and B and is, of course, one of the potential energies in the given system. A detailed calculation method has been given elsewhere.[3]

According to the method of Mulliken population analysis,[9] the kinetic and potential energies concerning electrons belonging to a specified atom, X, KE(X) and PE(X) are, respectively, defined as,

$$\mathrm{KE(X)} = E_X^T + 1/2 \sum_{A} E_{XA}^T \quad (4)$$

and

$$\mathrm{PE(X)} = E_X^V + E_X^J + 1/2 \sum_{A>B} (E_{XA}^V + E_{XA}^J + E_{XA}^N). \quad (5)$$

Since the kinetic and potential energies are considered to be basic quantities with apparent physical meanings, we examined them in addition to the total atomic charges of the Mulliken population analysis.

Results and Discussion

1. Total Atomic Charge. The Mulliken population analysis[9] is probably the most-widely applied method in the analyses of the electronic structures in the various fields of chemistry. It is important to note that the total atomic charge obtained in a Mulliken population analysis must be dependent on the basis set since any assignment of charges to atoms in a molecule is necessarily arbitrary. Therefore, the absolute charges calculated by a Mulliken population analysis also tend to be dependent on the basis set. First, we show how much they are dependent.

Figure 1 shows the total atomic charge of the hydrogen atoms of vinylamine by 22 different ab initio MO methods,[5] where a geometry optimization was carried out for each MO calculation. We also obtained results for the hydrogen of methane, which appears to be almost the same as those of H_a. It is clearly shown that the calculated total atomic charge varies significantly according to the calculation method. However, there seem to be some tendencies in the results. It can

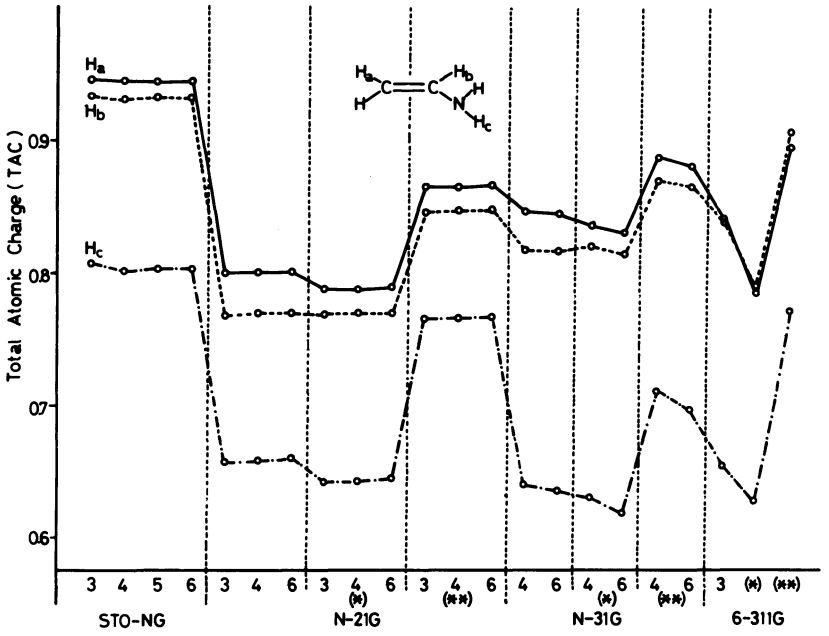

Fig. 1. Dependence of total atomic charge on basis set in hydrogen atoms of vinylamine.

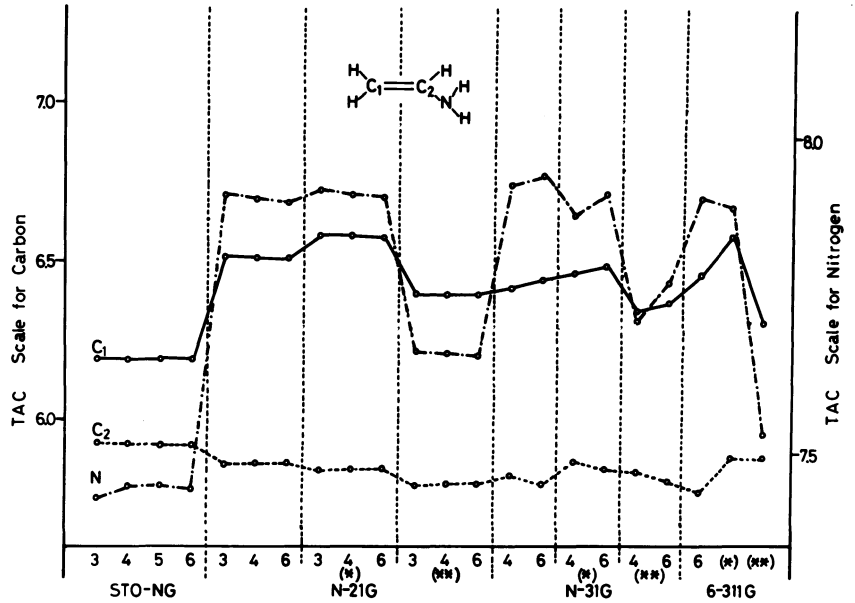

Fig. 2. Dependence of total atomic charge on basis set in carbon and nitrogen atoms of vinylamine.

be generally said that similar methods give similar electronic structures. The STO-*NG* series give almost the same total atomic charges, independently of the contraction number *N*.

In the split-valence methods, the number of the primitive gaussian functions for an inner-shell 1*s* AO has almost nothing to do with the total atomic charge of the hydrogen. "Single-star" methods generally give a total atomic charge for hydrogen that is too low, while "double-star" methods compensate such a loss of electrons on the hydrogen atoms. A good example is the difference of the results between the 6-311G* and 6-311G** methods, where the difference is most prominent.

Figure 2 shows the total atomic charges of C_1, C_2, and N for optimized structures of vinylamine. If we consider that the 6-311G** method gives the best-balanced wave function at present, any other split-

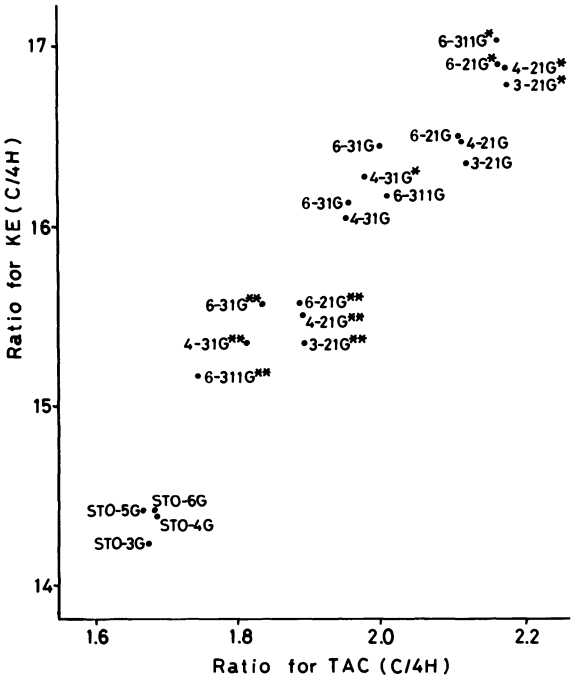

Fig. 3. Ratio of kinetic energies (C/4H) vs. ratio of total atomic charge (C/4H).

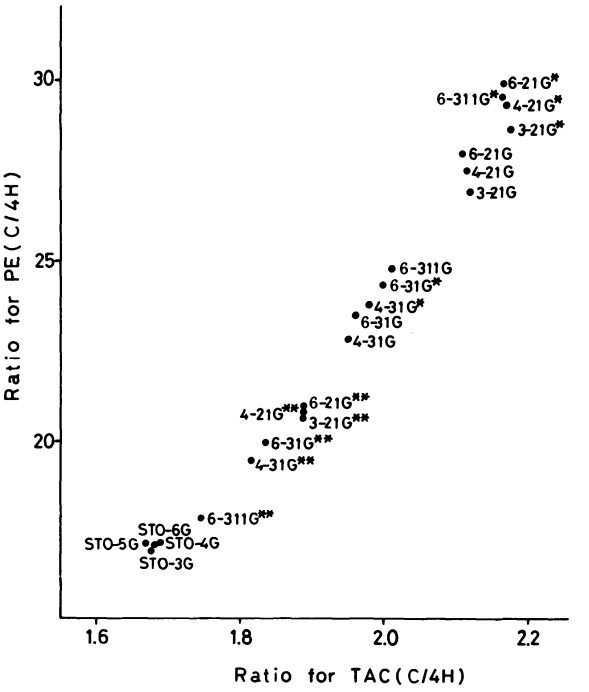

Fig. 4. Ratio of potential energies (C/4H) vs. ratio of total atomic charges (C/4H).

valence method without a "double-star" seems to produce off-balanced wave functions. Interestingly, the STO-*N*G method gives a very similar result to that of 6-311G**.

The above results suggest that the addition of polarization functions allows much freedom for electrons, resulting in a large electronic population on atoms with polarization functions. This indicates that polarization functions must be added to both the atoms of the first row and hydrogen atoms in order to obtain a well-balanced wave function. It should be stressed here that the total atomic charge obtained by STO-*N*G is very close to that obtained by 6-311G**, which is considered to be very close to the Hartree-Fock limit.

2. The Relationship between Total Atomic Charge and Partitioned Energies. Since the total energy is dependent on the basis set, a direct comparison of the partitioned energy with that of a different basis set is meaningless. As a matter of fact, we usually do not need the absolute energy, but only the relative energy or relative distribution of energy in a molecule with respect to the change of the molecular geometry. Accordingly, we examined the ratios of the total atomic charge and partitioned energies.

The horizontal axis of Figs. 3 or 4 represents the ratios of the total atomic charge of the carbon atom to the sum of those for four hydrogen atoms in methane. The ratios range from 1.685 to 2.174. It can again be said that a similar method gives similar results: a "single-star" series give results that are very different from that of 6-311G** because of an *unfair* addition of electronic freedom (only for carbon). The addition of a polarization function on hydrogen improves such a deformed wave function.

The vertical axes of Figs. 3 and 4 are for the ratios of the kinetic and potential energies, respectively. There is a close linear relationship between the ratios of the total atomic charge and that of the potential energy or the kinetic energy.

3. Basis Set Dependency of Partitioned Potential and Kinetic Energies. It was very fortunate to be able to obtain the result that STO-*N*G can reproduce a well-balanced wave function since STO-*N*G is a feasible method that can be applied to systems that are as large as those in which organic chemists show interest. We extended a similar examination in order to determine whether or not STO-*N*G gives a well-balanced wave function, regardless of the position of the bisection. Since it became clear that a similar method gives similar results, we only examined STO-3G, 3-21G, 4-31G, 6-31G*, and 6-311G**, and assumed that 6-311G** gives the best-balanced wave function out of all the methods.

Table 1 shows the results for carbon monoxide, formaldehyde, and ketene, where the ratios of the kinetic energies (KE(X)/KE(Y)) and the potential energies (PE(X)/PE(Y)) are also listed. We chose the oxygen-containing compounds as models, since such compounds are most liable to show a large depen-

dence on the basis set. Comparing those ratios, we could again conclude that the STO-3G method reproduces the results of 6-311G** very well.

Next, we examined the partitioned energies bisected by a functional group. Table 2 shows the ratios of the kinetic and potential energies of the two functional groups. The ratios are similar, independent of the method unless one of the functional groups is hydrogen. As shown in the former section, the total atomic charge of hydrogen is most susceptible to a change in the basis set: the split-valence methods and the split-valence methods with polarization functions only for first row atoms ("single-star" series) are liable to cause a low electron distribution on hydrogen resulting in a large difference in the energy ratios from the STO-*N*G or 6-311G** methods. It was again ascertained that the STO-3G method gives the closest ratios to those by the 6-311G** method in all kinds of functional partitionings.

Thus, we have obtained very instructive results regarding the choice of the basis set in a MO calculation. It is well known that the larger is the adopted basis set, the better the molecular wave function. It can be obtained simply because of the lower total energy. However, this does not apply to the electron distribution in the system. The addition of polarization functions to only first row atoms gives the most deformed wave functions. Instead, the STO-*N*G method, which was considered to give a poor wave function, was found to produce a well-balanced wave function. Recently, contour maps have been widely used in an explanation of the molecular properties and the reaction processes in cases where the shape of molecular wave function is the decisive factor.

Finally, Fig. 5 shows a comparison of the computation time (cpu time) of 22 different basis sets for some small molecules. The computer used was a HITAC

6) The method of energy partitioning was proposed and rigorously evaluated by Reudenberg (K. Reudenberg, *Rev. Mod. Phys.*, **34**, 326 (1962)). There are some problems in partitioning the total energy by an HF SCF method into mono- and bicentric terms since a Fock operator contains the potentials from three- and four-center interactions in an averaged form. However, since there are no other means to see inside of a large molecular system, this method has been frequently applied to the analysis of chemical bonds as shown in Ref. 1.

(Received April 14, 1986)

Photolyses of α-bromoanthraquinones (1-bromo-, 1,5-dibromo-, and 1,8-dibromoanthraquinones) with 366-nm light in ethanol at room temperature gave rise to the formation of debrominated 9,10-anthracenediol as a final product. This was interpreted in terms of the sequence of the formation of α-bromo-9,10-anthracenediols followed by the photochemical dehydrobromination yielding the corresponding anthraquinones with one less bromine atom than original ones. Photolysis of 2-bromoanthraquinone gave rise to the formation of 2-bromo-9,10-anthracenediol, and no dehydrobromination was observed. Combined with the values of the quantum yields of photoreduction, the results of the laser photolyses revealed that the rate constant for the hydrogen-atom abstraction from ethanol decreased as an increase of the $\pi\pi^*$ character of the lowest triplet states of α-bromoanthraquinones.

The photochemistry of quinones has been extensively studied on account of its importance in the understanding of the degradative action of light upon biological materials, photophosphorylation and the initiation of biological electron transport via excited quinones.

In connection with our recent interest in photophysics and photochemistry of aromatic carbonyl compounds, we have investigated the phosphorescences and triplet–triplet ($T'\leftarrow T_1$) absorptions of a series of halogenoanthraquinones:[1,2] Our finding is that the lowest triplet states (T_1) of α-haloanthraquinones are of mixed $n\pi^*$–$\pi\pi^*$ or $\pi\pi^*$ character, while the $n\pi^*$ triplet states are the lowest ones for β-haloanthraquinones. The much shorter lifetimes of the T_1 states and small phosphorescence quantum yields of α-haloanthraquinones were indicative that the depopulation of the T_1 states was mainly due to a special rapid nonradiative process.

Although the reason for this was not clear, a possible conjecture was that the dehalogenation of α-haloanthraquinones affects the triplet lifetimes, because we observed the formation of anthraquinone during the steady-state photolysis of 1-chloroanthraquinone in ethanol with 366-nm light. However, this is ruled out by our findings that: (1) Steady-state photolysis of α-chloroanthraquinones (1-chloro-, 1,5-dichloro-, and 1,8-dichloroanthraquinones) with 366-nm light in ethanol gave rise to the sequence of the formation of α-chloro-9,10-anthracenediols followed by the photochemical dehydrochlorination yielding the corresponding anthraquinones with one less chlorine atom than original ones and the final photoproduct was 9,10-anthracenediol. No dechlorination was observed upon the 366-nm photolysis of 2-chloroanthraquinone.[3,4] (2) The hydrogen-atom abstraction of α-chloroanthraquinones from ethanol originated from the T_1 state in spite of its mixed $n\pi^*$–$\pi\pi^*$ or $\pi\pi^*$ character, though the reactivity for hydrogen-atom abstraction decreased as an increase of the $\pi\pi^*$ character in the T_1 state.[5,6]

This paper deals with the photochemical reactions of bromoanthraquinones. Since the lifetimes of the T_1 states of α-bromoanthraquinones (1-bromo-, 1,5-dibromo-, and 1,8-dibromoanthraquinones) are much shorter than those of α-chloroanthraquinons,[1,2] the purpose of our present study is to examine the photochemical reactivity of bromoanthraquinones in order to confirm whether our previous conclusion made for chloroanthraquinones[3–6] can generally be applicable or not.

Experimental

Chemicals. The details of the methods of preparation of 1-bromo-, 2-bromo-, 1,5-dibromo-, and 1,8-dibromoanthraquinones (1-BAQ, 2-BAQ, 1,5-DBAQ, 1,8-DBAQ) have been given in our previous paper.[1] Spectral-grade ethanol (Nakarai) was used as a solvent without further purification. The sample solutions were degassed by several freeze-pump-thaw-cycles.

Steady-State Photolysis. Irradiation of bromoanthraquinones was carried out using a USH-500D super-high pressure mercury lamp. Light of 366-nm monochromatic wavelength was selected by the combination of two Toshiba color glass filters (UV-35 and UV-D35) and a filter solution ($CuSO_4 \cdot 5H_2O$, 100 g dm^{-3}; path length, 3 cm), while 313-nm light was selected by the combination of two Toshiba color glass filters (UV-29 and UV-D33S) and a filter solution ($Ni_2SO_4 \cdot 6H_2O$, 50 g dm^{-3}; path length, 2 cm). Photolysis of α-bromo-9,10-anthracenediols was performed with lights of longer wavelengths than 450 nm which were selected by the combination of a USL-500D Xe lamp, two Toshiba color glass filters (UV-35 and VY-46) and a filter solution of $CuSO_4$ (loc. cit). Absorption and fluorescence spectra were recorded using a Hitachi 200-20 spectrophotometer and a Hitachi MPF-4 fluorescence spectrophotometer, respectively. Since we observed a relatively rapid dark reaction

immediately after the photolysis of 1,8-DBAQ, the time variation of the absorption spectrum was measured with a Unisoku rapid scan spectrophotometer (USP-450), where a Xe (at 330—450 nm) and a D_2 (at 290—390 nm) lamps were used as the monitoring-light sources. Unless otherwise stated, all experiments were carried out in ethanol at room temperature and the concentrations of sample solutions were $2—5\times10^{-4}$ M (1 M=1 mol dm^{-3}). The quantum yield of the photoreduction was determined by the Hatchard-Parker's potassium trisoxalatoferrate(III) actinometry method.[7] The yield of the photoproduct was determined by measuring its absorbance. To confirm the participation of the solvent in the dehydrobromination reaction, photolysis of 1-bromo-9,10-anthracenediol was carried out in benzene-d_6 (G.R.-grade, Wako) and anthraquinone produced was analyzed by using a Shimadzu QP-1000 GC-MS spectrometer with an OV-101 wall-coated capillary column (Ionization potential, 70 eV).

Laser Photolysis. The decays of the triplet-triplet ($T'\leftarrow T_1$) absorptions of bromoanthraquinones were measured at 380 nm in ethanol at room temperature. The third harmonic (355 nm) from a picosecond mode-locked Nd^{3+}:YAG laser was used for sample excitation, and the pulse width was 15 ps. Although the details of this laser photolysis system have been given elsewhere by Sumitani and Yoshihara,[8] a minor modification was performed: The monitoring light was generated by focusing the fundamental light onto the electrode of a Xe flash lamp (FX265 B203). The detection system for the absorption spectroscopy was composed of a monochromator (Shimadzu-Baush-Lomb, 1350 grooves/mm), a photomultiplier (HTV RI 294UZC3I8), an osciloscope (Tektronix 7104 with 7A29 and 7B10 plag-in units), a photo-oscillo unit (San-ei Instrument, 5R32) and a microcomputer (NEC PC9801m). The concentrations of the deaerated sample solutions in a cell of 10-mm path length were 3.5×10^{-4}, 1.8×10^{-4}, and 1.6×10^{-4} M for 1-BAQ, 1,5-DBAQ, and 1,8-DBAQ, respectively.

Results

Steady-State Photolysis. Photoreduction of 2-BAQ in ethanol was studied by the absorption spectral change upon photolysis. Figure 1 indicates the depletion of 2-BAQ and the buildup of a photoproduct during 366-nm photolysis. The existence of an isosbestic point at 353 nm supports quantitative conversion of 2-BAQ to the product. Exposure to oxygen caused quantitative oxidation of the product back to 2-BAQ. This reaction is very similar to those of anthraquinone (AQ)[3,4,9-11] and 2-chloroanthraquinone.[4] Moreover, absorption and fluorescence spectra of the photoproduct of 2-BAQ are similar to those of 9,10-anthracenediol (AQH_2) and 2-chloro-9,10-anthracenediol. Thus one can safely conclude that the new absorption in Fig. 1 is due to 2-bromo-9,10-anthracenediol.

Photoreactions of 1-BAQ upon 366-nm photolysis gave rise to rather complicated absorption spectral changes as shown in Fig. 2-a: No isosbestic point could be seen as observed for 2-BAQ, and the absorption bands of the reactant and the products shifted to the blue during photolysis. Spectrum F with λ_{max}=382 nm was assigned to AQH_2, because absorption and fluorescence spectra of the final product were identical with those of AQH_2. Moreover, exposure to oxygen caused quantitative oxidation of the final photoproduct to AQ with λ_{max}=325 nm. On the other hand, photolysis of 1-BAQ with 313-nm light caused a simple absorption spectral change similar to that in photoreduction of 2-BAQ, that is, the depletion of 1-BAQ and the buildup of a product with λ_{max}=387 nm were observed, accompanied by an isosbestic point at 359 nm (Fig. 2-b). No spectral shifts

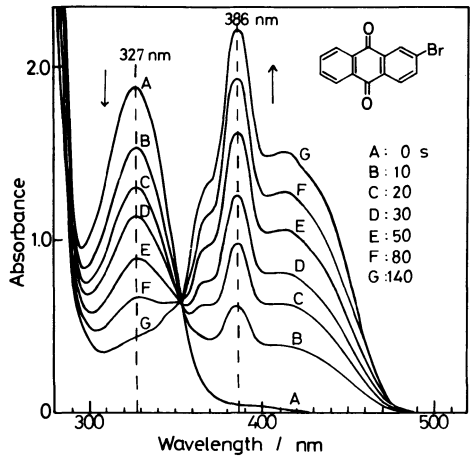

Fig. 1. Absorption spectral change of 2-BAQ in ethanol upon irradiation with 366-nm light at room temperature.

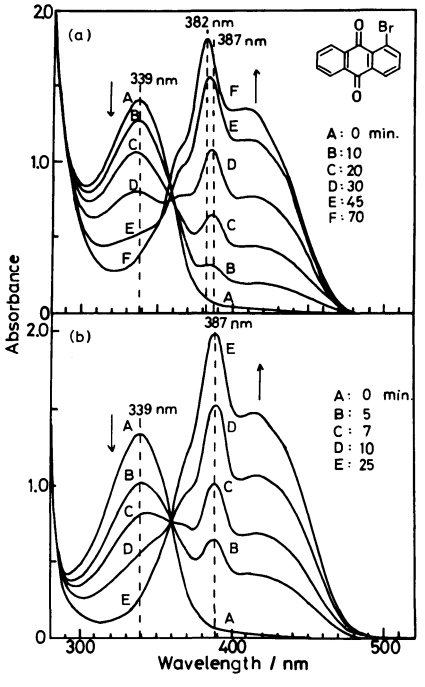

Fig. 2. Absorption spectral changes of 1-BAQ in ethanol upon irradiation with 366-nm (a) and 313-nm (b) lights at room temperature.

of the reactant and the product were observed during irradiation. (Extended photolysis gave rise to the decrease and the blue-shift in the absorption band at 387 nm). Spectrum E with λ_{max}=387 nm in Fig. 2-b is identical with Spectra B and C in Fig. 2-a, and the photoproduct can be identified as 1-bromo-9,10-anthracenediol (1-BAQH$_2$) by its reaction with oxygen on exposure to air, giving 1-BAQ.

Figure 3 shows the absorption spectral change of 1-BAQH$_2$ upon the photolysis with lights of longer wavelengths than 450 nm, indicating the formation of a product at the expense of 1-BAQH$_2$, accompanied by an isosbestic point at 348 nm. The photoproduct with λ_{max}=325 nm was identified as AQ by comparison of the absorption spectrum with that of the authentic sample of AQ. Further irradiation of this photoproduct with 366-nm light yielded AQH$_2$. The photolysis of 1-BAQH$_2$ was also performed in benzene-d_6, and the result of GC-MS analysis indicated that only AQ (not deuterated AQ) was produced.

In Fig. 4-a, we display much complicated photoreactions of 1,5-DBAQ upon 366-nm photolysis. Spectral shifts of the absorption bands of the reactant and the products can also be seen during photolysis, and the final photoproduct was AQH$_2$. (In Spectrum C, the absorption band with λ_{max}=387 nm is identical with that of 1-BAQH$_2$). However, photolysis of 1,5-DBAQ with 313-nm light gave rise to a simple reaction as shown in Fig. 4-b. The photoproduct has an absorption band with λ_{max}=393 nm which is identical with that of Spectrum B in Fig. 4-a, and the photoproduct was identified as 1,5-dibromo-9,10-anthracenediol (1,5-DBAQH$_2$), because it changed to 1,5-DBAQ on exposure to air. Further photolysis of 1,5-DBAQH$_2$ with lights of longer wavelengths than 450 nm gave a photoproduct with λ_{max}=339 nm which was identified as 1-BAQ by comparison of the absorption spectrum with that of the authentic sample (Fig. 5).

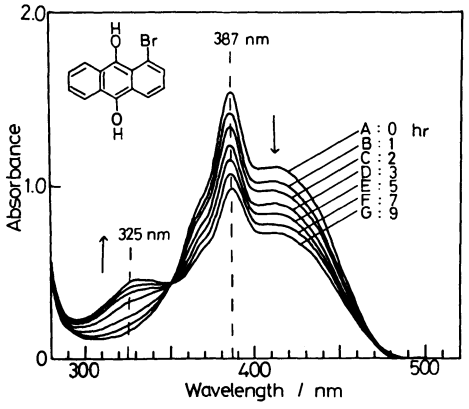

Fig. 3. Absorption spectral change of 1-BAQH$_2$ in ethanol upon irradiation with lights of longer wavelengths than 450 nm at room temperature.

The photochemical reactions of 1,8-DBAQ were not different from those of 1,5-DBAQ as shown in Figs. 6 and 7: The final photoproduct with λ_{max}=382 nm in Fig. 6-a was identified as AQH$_2$ and the absorption spectrum of the final photoproduct with λ_{max}=393 nm in Fig. 6-b was assigned to 1,8-dibromo-9,10-anthracenediol (1,8-DBAQH$_2$), because it changed to 1,8-DBAQ on exposure to air. By $\lambda \geq$450-nm excitation (Fig. 7), 1,8-DBAQH$_2$ was dehydrobrominated to 1-BAQ. By using a Unisoku rapid scan spectrophotometer, however, we observed that the absorption spectra taken immediately after the photolysis (7 or 10 min) of 1,8-DBAQ changed with time by a dark reaction (cf. Fig. 8); the absorption around 300 nm decreased and those of 1,8-DBAQ and 1,8-DBAQH$_2$ increased simultaneously, accompanied by an isosbestic point at 325 nm. (Such a spectral change was not observed for 1-BAQ, 2-BAQ, and 1,5-DBAQ.) For the sake of comparison, we also show the similar results for 1,8-

dichloroanthraquinone (1,8-DCAQ) in Fig. 9, where spectra were taken by a Hitachi 200-20 spectrophotometer (a)[3,4] and a Unisoku rapid scan spectrophotometer (USP-450) (b). Since the both results are identical with each other, the result for 1,8-DBAQ in Fig. 8 may be reliable.

In Table 1, we show the quantum yields of photoreduction of α-bromoanthraquinones upon the 313-nm photolysis. For the sake of comparison, we also show the results for α-chloroanthraquinones.[4]

Laser Photolysis. Since the T′←T$_1$ absorptions of α-bromoanthraquinones have the strong absorptions at ≈380 nm and weak one at ≈500 nm,[2] the decays of

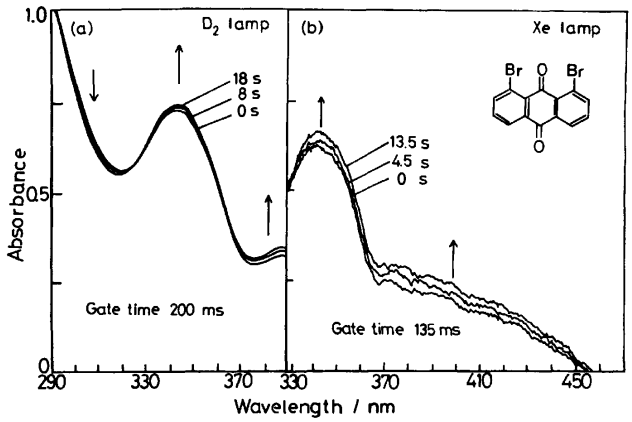

Fig. 8. Dark reactions of the complex of two 1,8-DBAQH· in ethanol at room temperature after irradiation of 1,8-DBAQ for 7 min (a) and 10 min (b), where spectra were taken by a Unisoku rapid scan spectrophotometer (USP-450) using a D_2 (a) and a Xe (b) lamps as the monitoring light sources.

the T$_1$ states were monitored at 380 nm. In Fig. 10, we display the time variation of the transient absorptions (full curves). According to the mechanism established by Wilkinson[9] and Tickle and Wilkinson,[10] the photoreduction of anthraquinone (AQ) in alcohol (R_2CHOH) is given by

$$AQ^*(T_1) \longrightarrow AQ, \quad (1)$$

$$AQ^*(T_1) + R_2CHOH \longrightarrow AQH\cdot + R_2\dot{C}OH, \quad (2)$$

$$R_2\dot{C}OH + AQ \longrightarrow AQH\cdot + R_2CO, \quad (3)$$

$$2AQH\cdot \longrightarrow AQ + AQH_2, \quad (4)$$

where AQ*(T$_1$) and AQH· are triplet anthraquinone and anthrasemiquinone radical, respectively. Since the transient absorptions decayed monotonously and the quantum yields of photoreduction were very small as shown in Table 1, the absorptions due to anthrasemiquinone radicals may be negligible. Thus, the triplet decay constant (k_T) of α-bromoanthraquinones were determined by analyzing the most probable smooth curves (broken lines) as a single exponential curve. (The first-order plots of the absorbances against time are inserted in Fig. 10 by open circles and dotted lines). The values of k_T thus obtained are also listed in Table 1, together with those for α-chloroanthraquinones.[5,6]

Discussion

The results of the steady-state photolysis indicate that only the photoreduction occurs upon the photolysis of 2-BAQ. For α-bromoanthraquinones, 313-nm photolysis yielded the corresponding bromo-9,10-anthracenediols, and no photochemical dehydrobromination was observed. However, the photolysis of α-bromo-9,10-anthracenedilols with lights of

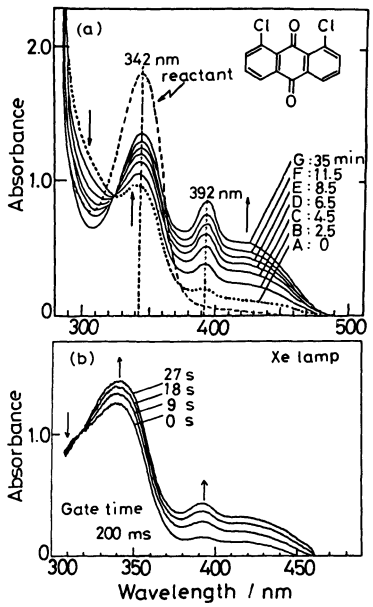

Fig. 9. Dark reactions of the complex of two 1,8-DCAQH· in ethanol at room temperature after irradiation of 1,8-DCAQ for 12 min (a) and 3 min (b), where spectra were taken by a Hitachi 200–20 spectrophotometer (a)[3,4] and a Unisoku rapid scan spectrophotometer (USP-450) (b). In the latter case, a Xe lamp was used as a monitoring light source.

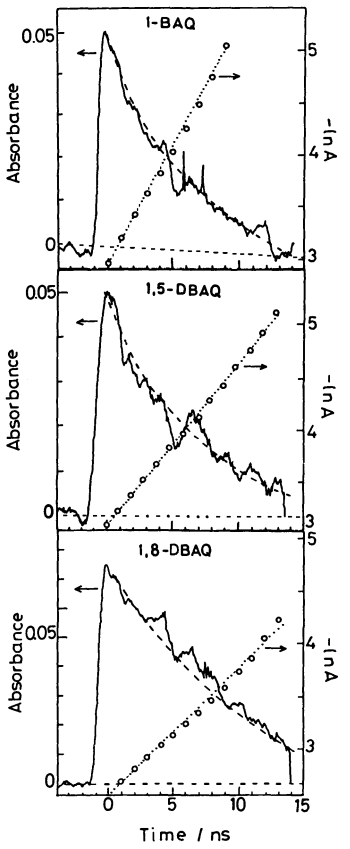

Fig. 10. Decay curves of the $T' \leftarrow T_1$ absorptions of 1-BAQ, 1,5-DBAQ, and 1,8-DBAQ (full curves), where the absorbances were monitored at 380 nm and the data represent the average of 20 shots of laser pulses. The broken lines are the most probable decay curves and their first-order plots are shown by the dotted lines.

longer wavelengths than 450 nm gave rise to the dehydrobromination yielding AQ (or 1-BAQ), accompanied by a clear isosbestic point. Since AQ and α-bromoanthraquinones (and their bromo-9,10-anthracenediols) have appreciable absorptions at 366-nm, the results of 366-nm photolyses are interpreted in terms of the following consecutive reactions, in accordance with the results for α-chloroanthraquinones:[3,4]

$$\text{1,5- or 1,8-DBAQ} \xrightarrow{h\nu} \text{1,5- or 1,8-DBAQH}_2 \xrightarrow{h\nu} \text{1-BAQ} \xrightarrow{h\nu} \text{1-BAQH}_2 \xrightarrow{h\nu} \text{AQ} \xrightarrow{h\nu} \text{AQH}_2.$$

Based on this conclusion, the decrease and the blue-shift in the absorption bands of the photoproducts upon the extended 313-nm photolyses of α-bromoanthraquinones may be due to the consecutive reactions mentioned above.

In Fig. 6-b, a clear isosbestic point can be seen. Such an isosbestic point was not observed for 1,8-DCAQ, where we observed the initial spectral increase around 300 nm instead of a small yield of 1,8-dichloro-9,10-anthracenediol (1,8-DCAQH$_2$):[3,4] By a dark reaction (cf. Fig. 9), the absorption around 300 nm decreased and those of 1,8-DCAQH$_2$ and 1,8-DCAQ increased simultaneously, accompanied by an isosbestic point at 322 nm. The decay constant of the 300-nm absorption was nearly equal to the rate constants for the formation of 1,8-DCAQH$_2$ and 1,8-DCAQ,[4] i.e., $\approx 5.8\times10^{-3}$ s^{-1}. Thus, we have assigned the 300-nm absorption to a complex of two 1,8-dichloroanthrasemiquinone radicals (1,8-DCAQH·). Actually, the rate constant for the buildup of the 300-nm absorption ($\approx 2\times10^{9}$ M^{-1} s^{-1})[4] was nearly equal to the decay constant of 1,8-DCAQH·, i.e., 5.8×10^{8}—2.2—4.1×10^{9}

Table 1. The Quantum Yields(Φ) of the Photoreduction of α-Bromoanthraquinones, Their Triplet Decay Constants (k_T) and the Rate Constants (k_r) for the Hydrogen-Atom Abstraction from Ethanol

	1-BAQ	1,5-DBAQ	1,8-DBAQ
Φ	0.04 (1.0)[a]	0.03 (0.9)[a]	0.003 (0.04)[a]
k_T/s^{-1}	2.3×10^{8} (2.3×10^{6})[b]	1.6×10^{8} (1.6×10^{6})[b]	1.2×10^{8} (4.0×10^{5})[b]
k_r/s^{-1}	9.3×10^{6} (2.3×10^{6})[b]	4.8×10^{6} (1.4×10^{6})[b]	3.6×10^{5} (1.6×10^{4})[b]

The values in parentheses are those for the corresponding α-chloroanthraquinones. a) Ref. 4. b) Refs. 5 and 6.

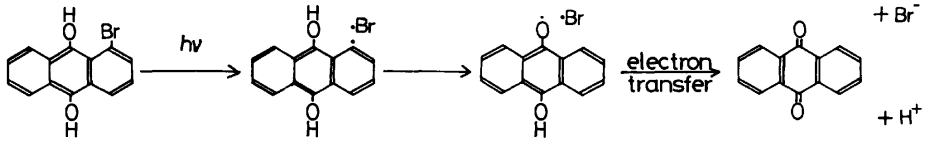
$M^{-1}s^{-1}$, though the value of the decay constant depends on the assumption of the extinction coefficient of 1,8-DCAQH·.[6]

Since we could not observe any absorption due to a complex of two 1,8-dibromoanthrasemiquinone radicals (1,8-DBAQH·) during the spectral measurements using a Hitachi 200-20 spectrophotometer, the complex of two 1,8-DBAQH· may be more unstable than that of 1,8-DCAQH·. This is consistent with our findings that: (1) The result in Fig. 8 clearly shows the existence of a relatively rapid dark reaction. (2) A clear isosbestic point was observed even for 1,8-DCAQ, when each spectrum was taken at the delay time of 20 min after the 313-nm photolysis (1 min) of 1,8-DCAQ.[4]

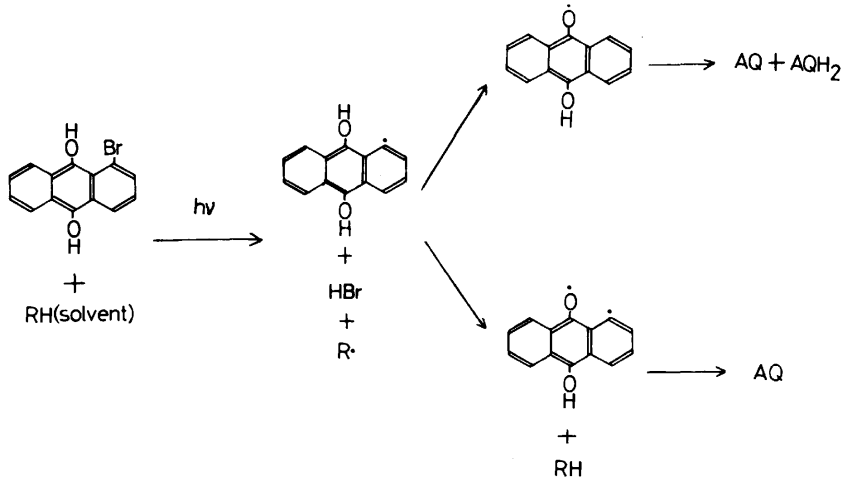
As reported in our previous paper,[4] the quantum yields of photoreduction were 1.0, 1.0, 0.9, and 0.04 for AQ, 1-chloro-, 1,5-dichloro-, and 1,8-dichloroanthraquinones, respectively. This decrease in the quantum yields as an increase of the $\pi\pi^*$ character in the T_1 states of α-chloroanthraquinones was also observed for α-bromoanthraquinones as shown in Table 1. (The value for 2-BAQ was 1.0). Thus one can safely conclude that much shorter lifetimes of the T_1 states and small phosphorescence quantum yields of α-haloanthraquinones are not due to the photoreactions but are due to the modification of the geometrical molecular structure by the interaction of the carbonyl group with halogen atom(s) at the α-positions, causing the T_1 states to be of $\pi\pi^*$ character with short lifetimes. Of course, the internal heavy-atom effect of halogen atoms may also affect the triplet lifetimes.[12]

As can be seen in Table 1, the decay constants (k_T) of the T_1 states of α-bromoanthraquinones are much greater than those of α-chloroanthraquinones.[5,6] Combined with the results of quantum yields of photoreduction, the rate constants (k_r) of hydrogen-atom abstraction from ethanol were estimated as shown in Table 1, indicating that the reactivity of triplet α-bromoanthraquinones decreases as an increase of the $\pi\pi^*$ character of the T_1 state, in accordance with our previous results for α-chloroanthraquinones.[5,6]

Since the result of GC-MS analysis indicated that only AQ (not deuterated AQ) was produced upon the photolysis of 1-BAQH$_2$ in benzene-d_6, a possible reaction mechanism may be given by Scheme 1: Namely, the homolysis of the C–Br bond may give rise to the formation of two caged radicals. If the electron transfer from the semiquinone radical to the bromine radical in the solvent cage is followed by the rapid deprotonation, it looks like that the solvent does not participate in the overall reaction. If this scheme is correct, however, the rate of dehydrochlorination of α-chloro-9,10-anthracenediols should be slower than that of dehydrobromination of α-bromo-9,10-anthracenediols, because the bond dissociation energy of C–Cl bond is expected to be larger than that of C–Br bond. This is inconsistent



Scheme 1.



Scheme 2.

with our present finding that the rates of dehydrobromination are extremely slower than those of dehydrochlorination. (The possibility of Scheme 1 may be also excluded, based on the fact that photolysis of 2-BAQH$_2$ does not give rise to the formation of AQ.)

An alternative reaction mechanism may be given by Scheme 2. However, this is also ruled out based on the discussion in our previous paper,[4] where we proposed that the dehydrochlorination of α-chloro-9,10-anthracenediols occurs via the intramolecular elimination of hydrogen chloride. Since dehydrobromination is also observed only for α-bromo-9,10-anthracenediols, the dehydrohalogenation reaction may be affected by the proximity effect of halogen(s), that is, the structural proximity of the hydroxyl group to the halogen atom(s) may make it possible to cause intramolecular elimination of hydrogen halide. The faster rates of dehydrochlorination than those of dehydrobromination support our previous suggestion[4] that an intramolecular hydrogen bonding between the hydroxyl group and the halogen atom at the α-position enhances the rate of dehydrohalogenation. This is based on the fact that the electronegativity of chlorine atom is larger than that of bromine atom, indicating that the hydrogen-bonding character (or charge-transfer character) between the chlorine atom and the hydroxyl group is larger than that between the bromine atom and the hydroxyl group. For β-halo-9,10-anthracenediols (2-chloro- and 2-bromo-9,10-anthracenediols), therefore, it is expected that the hydroxyl group and the halogen atom are located too much separately to cause the intramolecular dehydrohalogenation.

In summary, one can say that our previous conclusion made for the photochemical reactions of chloroanthraquinones is generally applicable to those of bromoanthraquinones.

We wish to express our sincere thanks to Professor Keitaro Yoshihara and Dr. Minoru Sumitani of Institute for Molecular Science for the help in the measurements of the triplet decay constants using a Nd^{3+}:YAG laser. Thanks are also due to Mr. Toshihiko Nagamura of Unisoku Co. Ltd. for the help in the measurements of the dark reactions using a rapid scan spectrophotometer.

12) Inoue et al.[13] proposed that the photoreduction originated via direct electron transfer from ethanol to triplet $\pi\pi^*$ haloanthraquinones. If this were correct, the much shorter lifetimes of the T_1 states of α-haloanthraquinones studied by us might be attributed to the formation of an exciplex between ethanol and triplet $\pi\pi^*$ α-haloanthraquinones, because the rates of photoreduction of anthraquinones were enhanced by the addition of triethylamine (TEA) and it was confirmed that the photoreduction originated via the formation of the exciplexes between TEA and the lowest triplet anthraquinones.[14] In the absence of TEA, however, no evidence for electron transfer from ethanol to the triplet α-haloanthraquinones was obtained.[5,6]

Nuclear Magnetic Resonance Studies of Copper(I) Complexes of Imidazoles. I. Their Preparation, Characterization, Equilibria, and Reaction with Carbon Monoxide

Susumu KITAGAWA* and Megumu MUNAKATA
Department of Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashi-Osaka 577
(Received December 12, 1985)

Various copper(I) complexes with monodentate imidazole(im) have been prepared from $[Cu(CH_3CN)_4]X$ ($X=ClO_4^-$ and PF_6^-) in acetone. Their characterization has principally been made by ^1H NMR spectroscopy. Binary copper(I) complexes are $[Cu(im)_2]^+$ (**2**) and $[Cu(im)_3]^+$ (**3**), while the monoimidazole complex is a ternary two- or four-coordinate complex (**1**). In contrast with **2** and **3**, quantitative formation of $[Cu(im)_4]^+$ (**4**) does not occur in acetone. Even at [im]/[Cu]<2, **2** forms more preferentially than **1**. This is due to the linear structure of **2**. **2** and **3** provide stable CO adducts, both of which display complete reversibility. The affinity for CO of **3** is much stronger than that of **2**. Pyrazole copper(I) complexes were also prepared and examined as a comparison with imidazole complexes. Monodentate pyrazole hardly gives two- and three-coordinate complexes. This is attributable to its low basicity in contrast with that of imidazole.

The presence of copper(I)–imidazole binding[1–3] in copper proteins has been demonstrated physicochemically. Keen interest in the relationship between their functions and the structure of a copper(I)–imidazole moiety has prompted the syntheses and characterizations of low-molecular weight copper(I) compounds including ligation from histidine, histamine, imidazole,[4–5] and their derivatives.[6–17] Binary copper(I) compounds having only imidazole are significant in connection with the environment of "type 3" copper moiety[1–3] in copper proteins. Two-coordinate copper(I) compounds of chelating benzimidazole-containing ligands have been isolated, where the copper atom is linearly coordinated by two nitrogen atoms.[9,14] Tetrakis(imidazole)copper(I)[4] has been isolated and the structure has been demonstrated to be tetrahedral. This geometric feature is not necessarily rare in copper(I) compounds[18–23] as well as in silver(I) and mercury(II) compounds.[24] On the other hand, no binary three-coordinate complex of imidazole has ben found. Regarding a structural model of deoxyhemocyanin,[3] the synthesis and characterization of three-coordinate imidazole complexes are of great importance; furthermore, a detailed knowledge of their behavior in solution, such as equilibria and reactivity, is valuable.

In this work, we try to challenge the preparation of various coordination copper(I) compounds of imidazole. Another purpose of this work is to explore the coordination chemistry of an imidazole–copper(I) system by inquiring into the chemical reactivity in a solution together with equilibrium. Finally, we aimed at the establishment of a methodology to investigate a copper(I)–imidazole system since ESR and the visible absorption spectroscopy are of very little use in these complexes. NMR spectroscopy is a very important tool for copper(I) complexes in solution, and helps to answer such questions as to what and how many donors are coordinated to copper(I).[25,26] Consequently, the characterizations of the imidazole–copper(I) compounds studied here are due to NMR spectroscopy.

Experimental

Materials. $[Cu(CH_3CN)_4]ClO_4$ and $[Cu(RCN)_4]ClO_4$ ($R=C_2H_5$ and C_6H_5) were synthesized from copper(I) oxide[27] and copper wire,[28] respectively. $[Cu(CH_3CN)_4]PF_6$ was also prepared by a method described in the literature.[29] The obtained compounds were all checked by elementary analysis and optical absorption method with the aid of the absorbance at 440 nm of a derived bis(2,2′-bipyridine)copper(I) in acetone (ε_{max}=4800 M^{-1} cm^{-1}(1 M=1 mol dm^{-3})).[30] Copper(I) oxide and copper wire were commercially available, refreshed with dilute HCl, washed with water and dried before use. Imidazole(im), pyrazole(pz), and 1-methylimidazole(1-meim) were commercially available. The first two were recrystallized several times from benzene and dried in vacuo, while the latter was dried over KOH and distilled at a reduced pressure.

Acetone-d_6 (Merck, 99.8%) was used as a solvent for ^1H and ^{31}P NMR measurements after drying with molecular sieves. High-purity nitrogen (99.9998%) and carbon monoxide (>99.95%) were utilized.

Preparation of Copper(I)-Imidazole Compounds. A solution of imidazole (2.0 mg, 2.9×10^{-5} mmol) and $[Cu(CH_3CN)_4]ClO_4$ (5.1 mg, 1.5×10^{-5} mmol) in 5 mL of acetone-d_6 was stirred under nitrogen for 5 min. In order to vary the ratio of [im] to [Cu], a stock solution of imidazole was added to a constant amount of copper(I). While maintaining a nitrogen atmosphere, the resultant solutions were transferred into an NMR sample tube and the NMR spectra were recorded.

Carbonylated compounds were prepared by passing carbon monoxide through a solution of imidazole copper(I) compounds. Low-pressure carbon monoxide was obtained[33] by mixing nitrogen with carbon monoxide and making adjustments with three Kusano KG-1 rotameters and three precise needle valves. The rotameters were individually calibrated throughout their ranges with nitrogen and carbon monoxide.

Physical Measurements. 200 MHz ^1H NMR spectra were obtained with a JEOL FX200 spectrometer. Between 200 and 1000 transients were accumulated using a 14-μs (90°) pulse;

8 K data points were collected over a band width of 2500 Hz. A probe temperature was set at −90 °C, being calibrated to an accuracy of ±1 °C using the temperature-dependent difference between the CH_3 and OH shifts of pure methanol. ^{31}P NMR spectra operating at 80.79 MHz were recorded: 500 transients were accumulated using an 18-μs (80°) pulse and 8 K data points were collected over a band width of 4000 Hz. The solution of copper(I) imidazole containing 50 mM copper(I) with a ratio [im]/[Cu]=2 and 3 was transferred under a nitrogen atmosphere into a sealed IR cell constructed with KBr plates having a 0.05 mm path length. The IR spectrum was recorded at 25 °C. The remaining solution was then exposed to carbon monoxide for 5 min; that solution was transferred to a sealed IR cell and the spectrum was again recorded. All the spectra were calibrated with the aid of polystyrene film.

Results and Discussion

^{1}H NMR Spectra of Imidazole Complexes of Copper(I). $[Cu(CH_3CN)_4]ClO_4$ reacts with imidazole under anaerobic conditions to give various copper(I) complexes whose formation depends upon the concentration of imidazole. All of the complexes are colorless and show no optical spectra. Thus, their formation and structural characterization were investigated by ^{1}H NMR spectroscopy.

Three metal-free imidazole signals with integrated intensities of 1:1:2 were assigned[31,32] from the downfield region to 1-H, 2-H, and 4,5-H, respectively. The coordinated imidazole generally gave four resolved signals,[6,32] with the downfield shift assigned from downfield to 1-H, 2-H, 5-H, and 4-H. Those imidazole copper(I) species in solution encounter a chemical-exchange effect at ambient temperature and exhibit four averaged broad ^{1}H NMR signals. This averaging of the signals is released when a solution is cooled to −90 °C.[30]

Formation of Binary Copper(I) Complexes. By ^{1}H NMR spectroscopy, we can distinguish the species in a solution. Figure 1 illustrates these features as a function of [im]. The metal-binding imdazole gives well resolved signals which are reproducible within, at most, ±0.02 ppm on repeated runs. Especially, imidazole C-H proton signals are good markers for a species in solution. Now we will focuss on imidazole C-H protons in the 6—9 ppm region. When a small amount of imidazole (r=[im]/[Cu]≤1) was added to $[Cu(CH_3CN)_4]ClO_4$, three signals ($A_{2,4,5}$) appeared. As [im] further increased, the new signals ($B_{2,4,5}$) increased with a decrease in the intensity of signals $A_{2,4,5}$ (Fig. 1(2)). Signals $A_{2,4,5}$ were located at the upfield region more than signals $B_{2,4,5}$. Signals $A_{2,4,5}$ are assigned to mono(imidazole)complex(**1**), while signals $B_{2,4,5}$ are attributable to bis(imidazole)complex(**2**). Complex **2** was predominantly formed by the addition of ca. two equivalent of imidazole. When more than two equivalent of imidazole was added to $[Cu(CH_3CN)_4]ClO_4$, a set of new signals($C_{2,4,5}$) appeared, located at higher field than signals for **1** and **2**. We successfully detected signals $C_{2,4,5}$ concurrently with those of **2** at [im]/[Cu]=2.5 (Fig. 1(4)). These signals $C_{2,4,5}$ were ascribed to tris(imidazole)copper(I) (**3**). Nearly equal intensities of signals B and C (Fig. 1(4)) support the quantitative formation of **2** and **3**. As [im] further increased [im]/[Cu]=3—4), signals $C_{2,4,5}$ apparently broadened, even at low temperatures, accompanying a slight upfield shift. Under these concentrations, the principal species was **3**. At an imidazole concentration greater than four equivalent, signals were further broadened, indicating a signal-averaging between the coordinated and metal-free imidazole. This broadening makes it difficult to detect tetrakis(imidazole)copper(I) (**4**). At r=4, **4** is a likely minor species. Interestingly, excess imidazole ([im]/[Cu]>4) turned a colorless solution blue at the ambient temperature. This reveals the occurrence of the oxidation of copper(I).[33] The observed ^{1}H NMR chemical shifts obtained here are listed in Table 1.

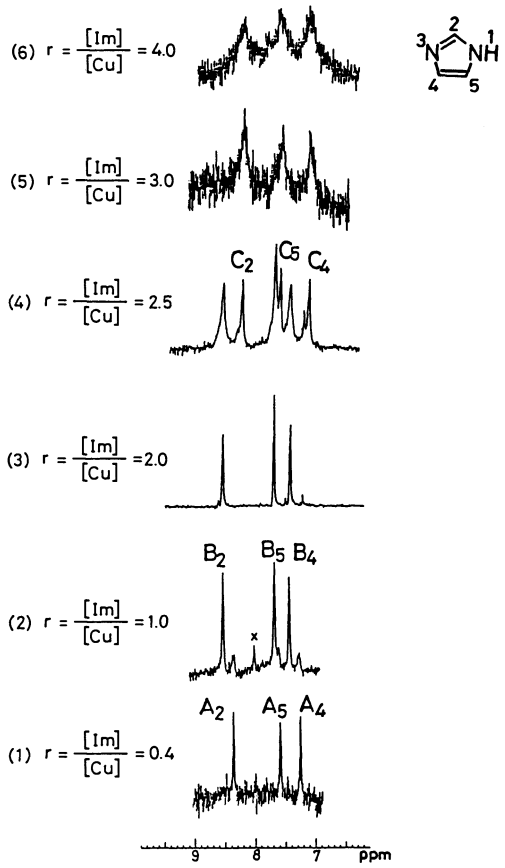

Fig. 1. ^{1}H NMR spectra at −90°C of acetone-d_6 solution of copper(I) complexes of imidazole. A, B, and C corresponds to signals of compound **1**, **2**, and **3**, respectively. Suffix denotes the assignement of proton signals of imidazole. x=impurity.

What structures have the solution species **1**—**4**? Among copper(I) complexes which have so far been

a) $[Cu(RCN)_4]ClO_4$ was used as a starting material. Solvent was acetone-d_6. b) Shifts in ppm from $Si(CH_3)_4$. Error limit, ±0.02 and ±0.04 ppm for 2,4,5-H, and 1-H, respectively. Observed nitrile shifts were catalogued in Table 2.

synthesized and characterized, four-coordinate tetrahedral species[23] are popular. Recently, various two-[7,9,14,18–22] and three-coordinate[13,34–46] copper(I) complexes have been synthesized; these types have become familiar. Two-coordinate complexes display a linear structure, while three-coordinate structures exhibit a triangular[34–43] or T-shape form,[15,44–46] the former being more preferable when the usual monodentate ligands coordinate. We have clarified the number of coordinating imidazole among **1**—**4**. Next, other ligands should be determined among solution species **1**—**3**. In our systems, potential donor ligands are ClO_4^-, CH_3CN, and acetone. The latter can be excluded from the donor groups due to its very poor coordinating ability against a soft metal ion.[47] Concerning (1) nitrile and (2) counter anion binding, we have used various starting materials of copper(I) such as $[Cu(RCN)_4]ClO_4$ (R=CH_3, C_2H_5, and C_6H_5). Also, we have demonstrated[25] that methyl proton signals of CH_3CN distinguish well between the coordinated and dissociated CH_3CN. Thus, signals of the nitriles for solutions of **2** and **3** have been examined. Table 2 shows the observed shifts of the nitriles. All of the ^{1}H signals locate at metal-free positions, indicating no coordination of acetonitrile. The imidazole signals of **2** and **3** have also been recorded as a function of R, and the obtained shifts are listed in Table 3. An inspection of Table 3 reveals that the imidazole signals of **2** and **3** show independence upon starting nitrile derivatives. Lastly, with the aid of ascorbic acid as a reducing agent, **2** was also synthesized from $Cu^{II}(ClO_4)_2$ and imidazole; such a system is free from nitrile. Both the ^{1}H NMR spectra with and without CH_3CN show that those imidazole signals[48] completely agree with each other.

Species **1** was checked, although it was the most difficult case to be characterized by NMR. **1** is formed only if $r<1$, wherein the principal species in solution are binary $[Cu(CH_3CN)_n]^+$ (n=2 or 3)[49,60] rather than **1**. Even at −90°, ^{1}H NMR spectroscopy failed to detect separated CH_3 signals of the CH_3CN ascribed to each species. This is because CH_3CN is chemically exchanged faster than the NMR time scale and its signal is averaged out. The chemical exchange is not depressed for nitrile. Table 2 reveals that only **1** gives nitrile signals different from a metal-free position. Imidazole proton signals of **1** show a nitrile-dependence as illustrated in Tables 1 and 3; these shift downfield by 0.08—0.16 ppm when a starting copper source $[Cu(CH_3CN)_4]$ is replaced by $[Cu(C_6H_5CN)_4]$. This nitrile-dependence is significantly associated with the coordination of CH_3CN in **1**. Consequently, it is concluded that the binding of nitrile occurs in **1** while not in **2** and **3**.

In order to clarify the coordination of a perchlorate ion, PF_6^- is used instead of ClO_4^-: The former possesses much less coordinating ability[24] than ClO_4^-. ^1H NMR signals of perchlorate salts of **1—3** are the same as those from their hexafluorophosphate salts. ^{31}P NMR spectra of the resultant species were measured as to whether or not the ^{31}P NMR signal shifts to the position denoting a strong association with copper(I). Both imidazole-free and imidazole-containing (two-equivalents) solutions of $[Cu(CH_3CN)_4]PF_6$ gave a single ^{31}P signal, appearing at −143.9 ppm from H_3PO_4, that are characteristic of a metal-free PF_6^-. Accordingly, the counter anion proves to be dissociated for all the species, **1—3.**

Now, we conclude that **2** and **3** are two- and three-coordinate copper(I) complexes, respectively, wherein neither nitrile nor an anion is bound to copper(I). The results regarding **2** are in good agreement with the accepted view that 1:2 complexes with monodentate ligands like NH_3[58] are truely two-coordinate in solution. **2** is possibly linear, as has been demonstrated by its X-ray structure,[7,9,14] while **3** is trigonal. This is reasonable since 1:3 complexes of copper(I) are easily formed with CN^-,[34,52] pyridine,[53,54,59] Cl^-, and CH_3CN.[55-57] **1** has at least one ligand other than imidazole. In referring to structures which have so far been demonstrated for copper(I) compounds, $[Cu(im)(CH_3CN)]^+$ or $[Cu(im)(CH_3CN)_3]^+$ is considered as a possible species. Mono-, bis-, and tris(imidazole)complexes are successfully prepared in an acetone solution; their formation and equilibria are summarized in Scheme 1. Throughout this investigation, $[Cu(CH_3CN)_4]ClO_4$ has been proven to be equivalent to $[Cu(CH_3CN)_4]PF_6$ concerning a reaction with imidazole.

It is noteworthy in Table 1 that the increase in the coordiation number from **2** to **3** causes imidazole signals to shift upfield. This is accounted for by the delocalization of a positive charge upon the imidazole ring.[6] The downfield shift upon coordination to copper(I) is attributable to a scattering of positive charge onto imidazole ring, and the increase in the number of coordinating imidazole dilutes the scattered positive charge on each imidazole ring. Chemical shifts for **1** are not directly compared with those for **2** and **3** because the former is a ternary compound.

Formation of Carbonylated Copper(I) Imidazole Complexes. When CO gas was passed into a solution of **1—3**, the resultant colorless solution gave new sharp ^1H NMR signals whose chemical shifts are different from those of the precursor (Fig. 2). The binding of CO causes an upfield shift of coordinating imidazole. The carbonylated complex (**3-a**) of **3** has been definitely determined to be $[Cu(im)_3(CO)]^+$ since dissociated imidazole signals were not observed.

We have determined the structure of a carbonylated species as well as the binary systems mentioned in the previous section. The coordinated imidazole signals of **2-a** and **3-a** showed no dependence upon the starting materials of $[Cu(RCN)_4]ClO_4$ (R=CH_3, C_2H_5, and C_6H_5), indicating no nitrile-binding in **2-a** and **3-a**. Also, no anion binding to copper(I) in **2-a** and **3-a** has demonstrated by ^1H and ^{31}P NMR for imidazole-$[Cu(CH_3CN)_4]PF_6$ systems. Consequently, these species are $[Cu(im)_2(CO)]^+$ and $[Cu(im)_3(CO)]^+$. Figure 2(3) reveals that the signal intensities of $[Cu(im)_2(CO)]^+$ and $[Cu(im)_3(CO)]^+$ are nearly equal, indicating the occurrence of only addition reaction of CO (Fig. 1(4)).

CO-bubbling into the solution of **1** gave imidazole ^1H shifts that just correspond to those of **2-a.** This is either because the carbonylated compound of **1** accidentally gives the same chemical shifts as **2-a**, or because carbon monoxide drives the equilibrium to the formation of **2-a** rather than the addition to **1.** To determine which is more probable is beyond the abilities of the present NMR method.

Decarbonylation was carried out by passing nitrogen into the solution. **3-a** is the most stable and, thus, prolonged nitrogen bubbling is required. This stability reminds us that $[Cu(dien)(CO)]^+$ [61] and $[Cu(HB(pz)_3)(CO)]^+$ [63] (dien=diethylenetriamine ;HB-$(pz)_3$=hydrotris(pyrazol-1-yl)borate). Neither compounds lose CO, even at high temperatures or in

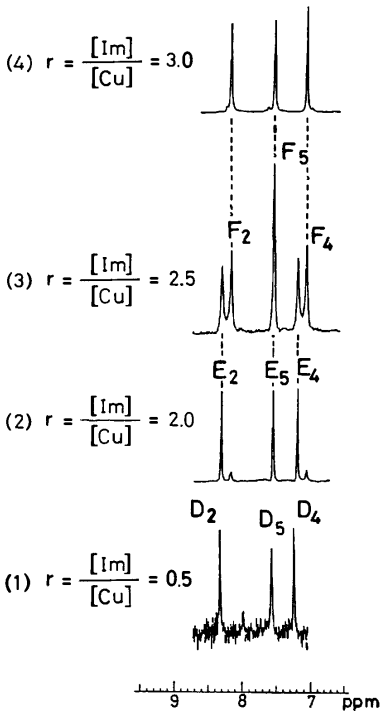

Fig. 2. ^1H NMR spectra at −90 °C of acetone-d_6 solution of copper(I) complexes of imidazole. All samples were prepared under CO atmosphere. D, E, and F correspond to signals of complexes **1-a**, **2-a**, and **3-a**, respectively. Suffix denotes the assignment of proton signals of imidazole.

vacuo in the solid state. These copper(I) complexes and **3-a** commonly have a tetrahedral structure with an N_3C donor set. The greater is the basicity of the N donor ligand, the more the electron density on copper increases.[62] Therefore, the rich electron density on copper enhance the π back-bonding and stabilize the Cu–CO bond. The basicity of dien is greater in five pK_a units[59] than that of imidazole. This gap in basicity is significantly associated with a reversible binding of CO. The carbonyl–decarbonyl cycle can be repeated many times for all a solutions of copper(I) imidazole compounds in this work, while dien system can not. The obtained reversible reactions are summarized in Scheme 1.

Sorrell et al.[7] have reported by use of IR spectra that bis(imidazole)copper(I) does not react with CO unless other bases are present in solution. On the basis of the inertness of bis(imidazole)copper(I) species, they suggest that the coordination sphere of each copper in hemocyanin is a two-coordinate; however, near one of the copper centers is an additional donor that can coordinate and promote CO binding to that copper. Indeed, three-coordinate copper(I) tends to readily provide a monocarbonyl complex, as has also been demonstrated here. However, the reactivity of bis(imidazole)copper(I) against CO appears opposite to our results. They have also illustrated that bis(pyrazole)copper(I) readily reacts with CO to produce its monocarbonyl adduct. Then, two questions arise: (1) Whether or not bis(imidazole)copper(I) reacts with CO? and (2) why there are marked difference in reactivity toward CO between copper(I) complexes of pyrazole and imidazole? In response to question (2), we point out that the difference in the ligand basicity, which contributes to the stability[7] of a precursor, is of significance. The answer to question (1) is that **2** does react with CO, contrary to Sorrell's conclusion. It should be noted that the NMR spectra were measured at different conditions from the IR spectra. The clearest difference is the temperature: −90 °C was established for the NMR measurement, while the ambient temperature was set for IR. Does this low temperature render an equilibrium shift to the formation of a carbonylated complex? For example, $[CuCl(bpy)]_2$ in acetone under a P_{co}=1 atm at 25 °C gives a monocarbonyl adduct[30] with ca. 57% yield to the precursor. This adduct was completely formed at −90 °C. Figure 2 ((2) and (3)) reveals the quantitative formation of **2-a** and **3-a**, amounts that clearly correspond to those of precursors, **2** and **3** (Fig. 1(4)), respectively. This fact was obtained at low temperature and does not exhibit any marked difference in the reactivity[7] of **2** and **3**.

In comparison with a low-temperature species, the species formed at ambient temperature were checked by the IR spectra. The stretching frequencies (ν_{co}) of the coordinated CO was measured for carbonyl complexes in an acetone solution. Fortunately, acetone gives no significant absorption bands at 2000—2200 cm^{-1}. Solutions prepared with a ratio of [im]/[Cu]=2 provided a single band at 2076 cm^{-1}, while a degassed solution gave no band in this region (Fig. 3). This band is attributable to ν_{co} of the coordinating CO. A band at 2069 cm^{-1} having the stronger intensity appeared at r=3. The band at r=2 is broader than that at r=3. The gap (7 cm^{-1}) between two bands is not large enough to be seen as two different bands, since the linewidth of those IR bands are broad. The ν_{co} band of $[CuL_3(CO)]^+$ appeared in the region lower than 2100 cm^{-1}, while that of

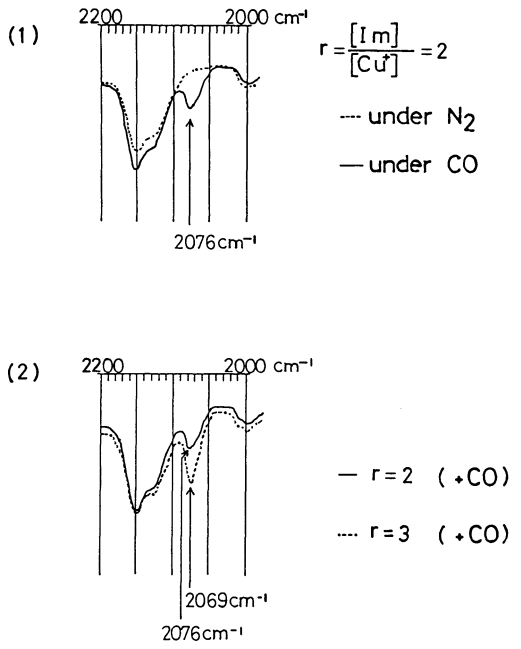

Fig. 3. Infrared spectra at 25 °C of carbonylated copper(I) complexes in acetone. The band ascribed to carbonyl stretching is indicated by an arrow together with its wave number.

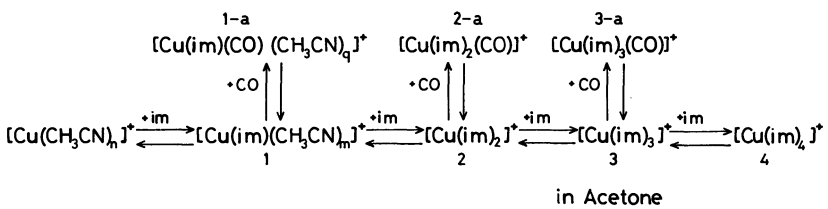

Scheme 1.

$[CuL_2(CO)]^+$ appeared in the region greater than 2100 cm^{-1} (L=pyrazole and its derivatives).[7] Accordingly to these facts, these bands were assigned to ν_{CO} of $[Cu(im)_3(CO)]^+$. Even at r=2, the detection of **3-a** indicates that **3-a**[64] forms more readily than **2-a**. The IR spectra of solution samples require a very high concentration of the coordinating CO. The concentration of 50—100 mM is 25—50 fold larger than in the case of ^1H NMR measurements. Therefore, the IR spectrum fails to detect its ν_{CO} signal when **2-a** is present as a minor species. The detection is dependent on the degree in the stability constants of the resultant CO adduct. In conclusion, **2** does react with CO, giving 100% **2-a** at −90 °C, and less **2-a** at ambient temperature.

Copper(I) Pyrazole Complexes. Similarly, copper(I) pyrazole (pz) compounds were also examined by ^1H NMR spectroscopy at −90 °C.[65] From the ^1H NMR spectra obtained at r=[pz]/[Cu]=0.5—4, various chemical exchange phenomena were found. At r=1—2, the 3-H signal was broadened accompanying with a slight shift, while 5-H and 4-H signals remain sharp. This broadening is not due to the paramagnetic copper(II) species generated by the oxidation of copper(I) species because of its selective broadening. This selective broadening is attributable to a chemical exchange[66] among $[Cu(pz)L_x]^+$ (L= another ligand, possibly CH_3CN), $[Cu(pz)_2]^+$, and L. Such a chemical exchange phenomena is in good contrast with the case of imidazole. At r=2—3, all the signals of pyrazole became broadened, indicating a chemical exchange[67] between a metal-free and coordinating ($[Cu(pz)_n]^+$; n=2 and 3) pyrazoles; thus, the presence of a considerable amount of metal-free pyrazole in solution. On the other hand, the chemical exchange rate in $[Cu(im)_n]^+$ (n=2 and 3) at r=2.5 was so slow that the ^1H NMR spectra were simultaneously observed (Fig. 1). Accordingly, the formation of $[Cu(pz)_3]^+$ is harder than that of $[Cu(im)_3]^+$. The difference between copper(I) complexes of pyrazole and imidazole is ascribed to the basicity of the ligand,[48,53] A chelating ligand of pyrazole is required if a stable and less labile copper(I)-pyrazole complexes is to be synthesized. Carbonylated copper(I) complexes of pyrazole are quantitatively formed and all their signals are sharp, revealing a slow chemical exchange.[69] Of course, the carbonyl-decarbonyl cycle is readily repeated. In summarizing these results, there was the remarkable difference in forming two-coordinate copper(I) complexes between pyrazole and imidazole. Also, no distinguishable difference between their carbonylated copper(I) complexes were detected by low temperature ^1H NMR spectroscopy.

A knowledge of the equilibria and reactivity and the accumulated ^1H NMR data on imidazole in various copper(I) complexes would contribute to an advancement in the copper(I) chemistry involving imidazole and its derivatives and an application to copper proteins.

We appreciate the assistance of Mr. Hirotoshi Konoike, Mr. Hiroki Nagai, and Mr. Norimitsu Izumi for the recording the NMR spectra. This work was supported in part by a Grant-in-Aid for Scientific Research No. 59740303 from the Ministry of Education, Science and Culture.

Although acetone is a weak ligation molecule and there is no cases where acetone binds copper(I), we cannot exclude the possibility of the ligation of acetone because large excess of acetone is present.
48) The reduction was made by refluxing the solution. These copper(I) compounds reduced by ascorbic acid definitely gave the same ^{1}H NMR signals of coordinating imidazole as those obtained from copper(I) sources. Additional signals were also observed which are easily assigned to oxidized ascorbic acid.
49) ^{63}Cu NMR spectra are available for an investigation of tetrahedrally coordinated copper(I) compounds.[26] Due to the great quadrupolar interaction, other copper(I) compounds having the lower symmetry give hardly detected ^{63}Cu NMR signal as a consequence of the broadening. By use of ^{63}Cu NMR spectroscopy, it has been demonstrated that acetone solution of $[Cu(CH_3CN)_4]ClO_4$ provides no ^{63}Cu signal, indicative of significant decomposition[50,51] of $[Cu(CH_3CN)_4]^+$ into the lower coordination form. On the other hand, its acetonitrile solution clearly gave single signal ascribed to $[Cu(CH_3CN)_4]^+$.

64) Exact addition of two equivalent of imidazole at the concentration is very difficult problem. If a slight excess of imidazole is present in solution, **3-a** may readily form under CO atmosphere.
65) A metal-free pyrazole gave three ^{1}H NMR signals at 13.1 (1-H), 7.83 (3- and 5-H), and 6.42 ppm (4-H), with relative intensities of 1, 2, and 1, respectively. In copper(I)-pyrazole systems, well-separated four signals were obtained, and the coordination shift for all pyrazole protons was appreciated, ranging from 0.11—0.43 ppm. At $r<1$, except for 1-H (13.3 ppm) very sharp signals displaying multiplets were obtained, whose assignment is 5-H (8.26), 3-H (7.94), and 4-H (6.70). The chemical shift of 4-H and 5-H signals is insensitive to the structures such as $[Cu(pz)_n]^+$ and $[Cu(pz)_m(CO)_p]^+$. On the other hand, 3-H signal is sensitive, indicative of a good probe to inquire into the structure in solution.
66) At $1\leq r\leq 2$, several exchange processes are considered from ^{1}H NMR spectra, which show characteristic broadening of 3-H signal. Possible processes are considered as follows:

$$[Cu_A(pz)L_n]^+ + [Cu_B(pz)(pz)^*]^+ \rightleftharpoons [Cu_A(pz)(pz)^*]^+ + [Cu_B(pz)L_n]^+, \quad \text{(i)}$$

$$[Cu(pz)L_x]^+ + L \rightleftharpoons [Cu(pz)L_{x+1}]^+, \quad \text{(ii)}$$

wherein L is another ligand, possibly CH_3CN. This is characteristic of copper(I)-pyrazole system.

67) The linewidth of all the signals increases with increase in r. Hence, the line-broadening of signals is attributable to the following chemical exchange processes (iii) and/or (iv).

$$Cu(pz)_2 + pz^* \rightleftharpoons Cu(pz)(pz^*) + pz \quad \text{(iii)}$$

$$Cu(pz)_3 + pz^* \rightleftharpoons Cu(pz)_2(pz^*) + pz \quad \text{(iv)}$$

68) "Stability Constants of Metal-Ion Complexes," ed by D. D. Perrin, IUPAC Chemical Data Series No. 22, Pergamon, Oxford (1979).

69) At r=1—3, three different ^1H NMR spectra were obtained. They all displayed well-separated and sharp four signals. The tentative structure of these carbonylated complexes is determined in analogy with that of copper(I)-imidazole complexes. At r=1, $[Cu(pz)(CO)L_x]^+$ (L=another ligand; x=1 or 2) forms, whose signals are assigned to 1-H (13.4 ppm), 5-H (8.27), 3-H (7.89), and 4-H (6.70). At r=2, four signals at 13.2 (1-H), 8.25 (5-H), 7.74 (3-H), and 6.68 (4-H) are ascribed to $[Cu(pz)_2(CO)_y]^+$ (possibly y=2). Finally, at r=3, $[Cu(pz)_3(CO)]^+$ gives signals at 8.25 (5-H), 7.67 (3-H), and 6.67 (4-H).

Nuclear Magnetic Resonance Studies of Copper(I) Complexes of Imidazoles. II. Their Reaction with Ethylene, Phosphite, and Isocyanides

Susumu KITAGAWA* and Megumu MUNAKATA
Department of Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashi-Osaka 577
(Received December 12, 1985)

The reaction of binary copper(I) complexes of monodentate imidazole(im) with π acceptor ligands (ethylene, triethyl phosphite, *p*-tolyl isocyanide, and phenyl isocyanide) have been carried out in acetone. The resultant copper(I) complexes have been characterized by ^{1}H and ^{31}P NMR spectroscopy. Ethylene reacts with $[Cu(im)_2]^+$ (**2**) to give $[Cu(im)_2(C_2H_4)]^+$ (**2-b**), but does not react with $[Cu(im)_3]^+$ (**3**). This shows a clear difference in reactivity between **2** and **3**. Phosphite and isocyanides give rise to a substitution reaction for im in **2** and **3**, accompanying with addition reaction. Among the copper(I) compounds prepared here, two- and four-coordinate forms show sharp ^{1}H NMR signals of coordinated im, indicating that they are in the slow-exchange regime. This proved that ^{1}H NMR spectroscopy is a useful tool to characterize diamagnetic copper(I)-imidazole complexes in solution.

Part I of this study[1] has demonstrated that binary copper(I) complexes of monodentate imidazole (im) are produced quantitatively in acetone at low temperature. Bisimidazolecopper(I) perchlorate, $[Cu(im)_2]ClO_4$ (**2**), and trisimidazolecopper(I) perchlorate, $[Cu(im)_3]ClO_4$ (**3**), are quite interesting in relation to the active site of deoxyhemocyanin,[2,3] of which copper(I) reacts with π acceptor ligands such as carbon monoxide[4] and isocyanide.[5] Furthermore, certain copper(I) complexes provide an ethylene adduct,[6,7] indicative of a possible receptor[6-8] of ethylene, which is a plant hormone. From these points of view, knowledge of such coordination chemistry as the coordination number, geometry and reactivity for π acceptor ligands of copper(I)–imidazole systems is important for an intrinsic understanding of the copper(I) active site. This manuscript is concerned with a reaction of **2** and **3** with π acceptor ligands of ethylene, phosphites, and isocyanides and their equilibrium in solution.

Experimental

Materials. Triethyl phosphite was commercially available. Its purity was checked by ^{1}H and ^{31}P NMR spectroscopy and used without further purification. Phenyl and *p*-tolyl isocyanide were synthesized from corresponding amines.[9]

Acetone-d_6 (99.8%)(Merck) was utilized as a solvent for ^{1}H and ^{31}P NMR studies after drying with molecular sieves. High-purity nitrogen (99.9998%) and ethylene (99.9%) were utilized.

$[Cu(im)_2]ClO_4$ (**2**) and $[Cu(im)_3]ClO_4$ (**3**) were prepared according to the method of Part I.[1] A 2.9×10^{-3} M (1 M=1 mol dm^{-3}) acetone solution of **2** (or **3**) was prepared under nitrogen. While maintaining a nitrogen atmosphere, a stock solution of triethyl phosphite (L) was added to the copper(I) solution in order to vary the ratio of [L]/[Cu]. The mixed solution was stirred for 30 min and then transferred into an NMR sample tube and sealed therein. Ethylene compounds were prepared by passing C_2H_4 gas through a solution of **2** (or **3**).

200 MHz ^{1}H and 80.79 MHz ^{31}P NMR spectra were obtained as previously described.[1]

Results and Discussion

Phosphites and isocyanides are good π acceptor ligands.[10] **2** and **3** react with them to give ternary copper(I) complexes; these are thermally stable, but air-sensitive. Because ternary copper(I) complexes are generally substitution labile, we should find the optimum conditions under which the objective ternary copper(I) complexes predominantly form. Of most significance is the characterization of copper(I) species in solution for the isolation of a copper(I) complex. We have demonstrated[1] that the ^{1}H NMR spectra of imidazole give coordination shift that is sensitive to the structure of copper(I) complexes; this indicated that these signals are also applicable to the inquirement of ternary copper(I) complexes in solution.

Reaction with Ethylene. The ^{1}H NMR spectra at -90 °C of **2** and **3** under ethylene atmosphere were studied as to whether they react with C_2H_4 to give adducts or not. **2** affords an ^{1}H NMR spectrum, displaying the formation of an ethylene complex (**2-b**), whose chemical shifts are presented in Table 1. **2-b** is thermally stable to a loss of ethylene. Upon the binding of ethylene,[11] no dissociation of im occured, indicating an addition reaction of ethylene. Monoolefin copper(I) compounds have recently been synthesized: A four-coordinate compound is $[Cu(HB(3,5\text{-}Me_2pz)_3)(C_2H_4)]$,[6a] ($HB(3,5\text{-}Me_2pz)_3$=hydrotris(3,5-dimethyl-1-pyrazolyl)borate), while a three-coordinate is $[Cu(biL)(C_2H_4)]^+$ (biL=1,10-phenanthroline, 2,2′-bipyridine, etc.).[6b,7] In analogy with $[Cu(biL)(C_2H_4)]^+$, **2-b** is assigned to $[Cu(im)_2(C_2H_4)]^+$. The reaction of **3** with C_2H_4 is in good contrast with that of **2**. An ethylene atmosphere did not influence the ^{1}H NMR spectrum of **3** even at -90 °C; this reveals that no formation of $[Cu(im)_3(C_2H_4)]^+$ takes place. The solution of **3** turned blue when C_2H_4 was bubbled at ambient

a) Shift in ppm, from $Si(CH_3)_4$. Error limit, ± 0.02 ppm. b) Binary complexes in Ref. 1. c) $[Cu(im)_3]^+$ does not react with C_2H_4.

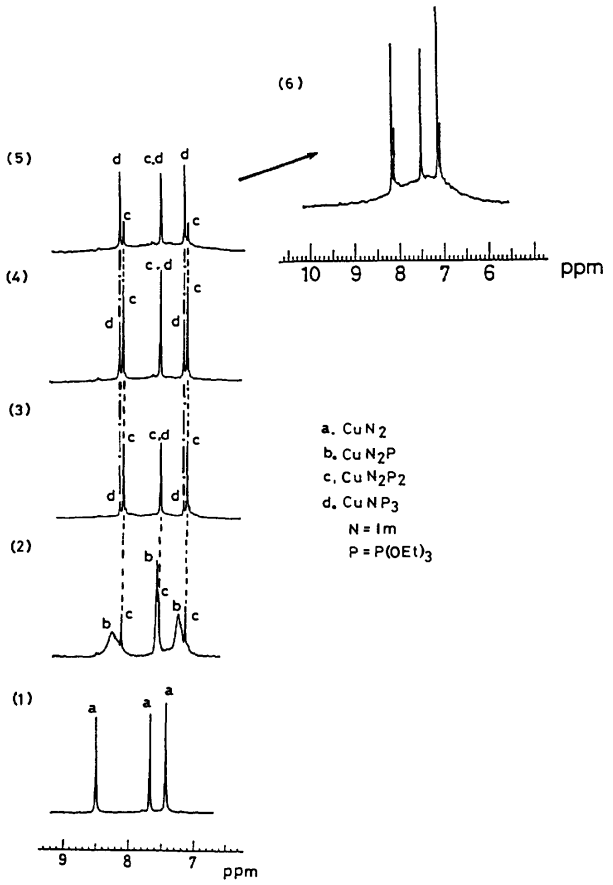

Fig. 1. ^{1}H NMR spectra at -90 °C of acetone-d_6 solution of mixed-ligand copper(I) complexes. Titration of $P(OC_2H_5)_3$ to the solution of **2**. $r=[P(OC_2H_5)_3]/[Cu^+]$: (1) 0; (2) 1.0; (3) 2.0; (4) 3.0; (5) and (6) 4.0. (6) was recorded at wider spectral width than other five spectra in order to examine the base line.

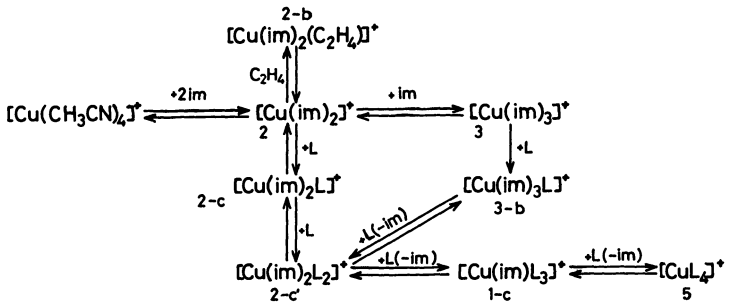
temperature for a long time. The resultant blue species were associated with copper(II) complexes. Hence, it is concluded that **3** does not react with C_2H_4.[12] In the case of a carbon monoxide atmosphere, thermally very stable $[Cu(im)_3(CO)]^+$ predominantly forms, and gives well resolved ^{1}H NMR signals.[1] The difference in the reactivity of C_2H_4 and CO against **3** is of much interest in probing the copper(I) active site in a protein.

A four-coordinate complex, $[Cu(HB(3,5\text{-}Me_2pz)_3)(C_2H_4)]$, is in good contrast with $[Cu(im)_3(C_2H_4)]^+$. This pyrazole derivative is stable even in olefin-free solvents, and the prolonged exposure of a solution to an inert atmosphere[6] is indispensable for removing the coordinated olefin. From this difference in reactivities between these two copper(I) precursors, two factors governing the affinity for C_2H_4 are considered. One is the bonding nature of N donor ligands such as imidazole and pyrazole. The basicity of imidazole is much greater than that of pyrazole. According to the Dewar-Chatt-Duncanson model,[13,14] the more basic ligand, when it binds copper(I), promotes the π back-bonding of copper(I) and results in stable bonding. Imidazole complexes are more stable than pyrazole complexes as was demonstrated regarding binary copper(I) complexes in Part I.[1] Such a stability of the binary copper(I) complex is associated with its reactivity with ethylene.

The geometry of a complex is another factor influencing the reactivity of copper(I). Tridentate chelating ligands, especially tripodal ligands, are structurally fixed, being correlated to (1) the hybridization of copper(I) orbitals to form the more stable bond with ethylene, and (2) the controlling the steric interaction between chelating groups and the fourth ligand. $[Cu(HB(3,5\text{-}Me_2pz)_3)]$ has, if present, a trigonal-pyramidal form with copper at an apex. This is indicative of the unusual structure in copper(I) chemistry. In fact, $[Cu(HB(3,5\text{-}Me_2pz)_3)]_2$ is easily dimerized to give $[Cu(HB(3,5\text{-}Me_2pz)_3)]_2$,[15] revealing that this monomer is very reactive and requires another ligand at the fourth position, giving a tetrahedral complex. In this case, the presence of ethylene as a donor is just appropriate to give a four-coordinate monomer. On the other hand, a structural change might be needed when C_2H_4 binds copper(I) of **3** to give a tetrahedral complex. A number of three-coordinate triangular copper(I) complexes have been found with monodentate ligands. Typical examples are $Na_2[Cu(CN)_3]$,[16] $[Cu(SPh)_3][BPh_4]_2$ (Ph=phenyl),[17] and $[Cu(2\text{-methylpyridine})_2]ClO_4$.[18] According to these facts, **3** at least, has a structure dissimilar to $[Cu(HB(3,5\text{-}Me_2pz)_3)]$, and is supposed to be nearly triangular. The energy barrier on the structural change from a triangular to a tetrahedral form can affect the reactivity of copper(I). It is interesting to



L=phosphite or isocyanide

Scheme 1.

consider the reaction of CO[1] in **3**, where CO readily provides its adduct. Structural factors concerning the affinity for C_2H_4 is significantly associated with the stable formation of four-coordinate ethylene adducts.[19] From this point of view, the systematic synthesis of copper(I) complexes of various tripodal imidazole- or pyrazole- containing chelates is most important in order to elucidate the relationship between the reactivity and structure of three-coordinate imidazole-copper(I) complexes.

Reaction of Phosphite and Isocyanides. We have also utilized triethyl phosphite, phenyl, and *p*-tolyl isocyanide. So long as a high pressure was not provided in the case of ethylene, the concentration was restricted to the solubility at 1 atm. On the contrary, phosphite and isocyanides are available for controlling their concentrations (from high to low) in solution. Typical example of their reaction with binary copper(I) imidazole complexes is presented in Fig. 1. Triethyl phosphite was successively added to a solution of **2** with varying r (=[$P(OC_2H_5)_3$]/[Cu]=0—4). With an increase in r ($0<r<1$), ternary compounds, $[Cu(im)_2(P(OC_2H_5)_3)_n]^+$ (n=1 and 2), successively appeared. Copper(I) complexes from two- to four-coordinate have so far been synthesized and characterized.[21] It is to be noted that copper(I) complexes of more than five-coordination hardly form. The further appearance of signals d in Fig. 1 (3)—(5) indicates the occurrence of a substitution reaction at $r>2$. Signals d are attributable to $[Cu(im)(P(OC_2H_5)_3)_3]^+$. $[Cu(im)_2(P(OC_2H_5)_3)_2]^+$ (**2-c'**) and $[Cu(im)(P(OC_2H_5)_3)_3]^+$ (**1-c**) gave sharp signals, indicating that these four-coordinate complexes undergo slow chemical exchanges, while the main signals at the condition r=1 are broad. This indicates a partial chemical exchange between **2** and **2-c**. These signals in Fig. 1 were completely assigned in analogy with those illustrated previously for binary and ternary copper(I) complexes.[1]

In order to inquire into the behavior[22] of $P(OC_2H_5)_3$, the ^{31}P NMR spectra of these solutions were measured. A single broad ^{31}P NMR signal at 120±0.5 ppm from $H_3{}^{31}PO_4$ as an external reference was observed at $r<2$ and no metal-free signal of $P(OC_2H_5)_3$ were detected in this region. This indicates that $P(OC_2H_5)_3$ is chemically exchanged among coordinated ones of copper(I) species, as confirmed by the ^1H NMR spectra (Fig. 1). On the other hand, at $r>2$ a quartet signal centered at 127 ppm appeared (J_{Cu-P}=1180 Hz), which could be easily assigned to $[Cu(P(OC_2H_5)_3)_4]^+$ (**5**).[23,24] With an increase in r, the ^{31}P signal for ternary copper(I) complexes decreases; it is then covered with the main signal of **5**, and finally disappears. Hence, it is concluded that **5** is a principal species at $r>3$ and that $P(OC_2H_5)_3$ has a high affinity for Cu(I).

At $r>3$, excess metal-free imidazole must be present in solution. However, Fig. 1 (4)—(6) apparently reveal no metal-free signals of imidazole. The wide ^1H NMR spectrum (6 kHz) exhibits a rising baseline at the region 7—9 ppm in Fig. 1 (6). This is averaged broad imidazole signals due to very rapid exchange between the bulk and the coordinated imidazole of binary copper(I) complexes.[25] Imidazoles of **2-c'** and **1-c** are free from this exchange mechanism because their sharp resonances can be simultaneously detected (Fig. 1 (5)). It is important to examine the reactions of **3** in comparison with **2**. The ^1H and ^{31}P NMR spectra were monitored when $P(OC_2H_5)_3$ was also successively added to **3**. As was expected, $[Cu(im)_3(P(OC_2H_5)_3]^+$ (**3-b**) firstly formed with a little broadening. Also, and with an increase in [$P(OC_2H_5)_3$], **2-c** and **2-c'** appeared, followed by **1-c** and **5**. These facts indicate that the reaction occurring here are all reversible. We can, thus, summarize these reactions in one part of Scheme 1.

In the case of isocyanides, the same trend in ^1H NMR signals as in Fig. 1 has been observed. $[Cu(im)_2L_2]^+$ and $[Cu(im)L_3]^+$ (L=phenyl and *p*-tolyl isocyanide) successively form with the isocyanide addition to **2**. ^1H NMR imidazole signals are sharp enough to resolve various species in solution, denoting the downfield shift more than those in the case of phosphite (Table 1). Phenyl-group signals of isocyanide accidentally collapse with each other; hence, their separations are difficult. Of course, their signal positions are shifted downfield more than those of metal-free species, indicating a coordination to

copper(I).

In conclusion, the generated species with C_2H_4 (and CO) are only adduct compounds, while in the case of phosphite and isocyanides, a substitution reaction principally occurs accompanied by a dissociation of imidazole to produce their mono-, bis-, tris-, and finally tetrakis-coordination compounds. The remarkable difference in the reactivity of **2** from **3** is also found in the case of ethylene. Concerning the ^1H NMR spectra, four-coordinate mixed-ligand complexes, such as $[Cu(im)_nL_m]^+$ (n=3 and m=1; n=2 and m=2; n=1 and m=3), are in the slow-exchange regime and are readily detected using low-temperature NMR. The lower coordination complexes encounter a chemical-exchange effect to give broad and averaged signals, indicating the labile nature of such complexes.

We appreciate the assistance of Mr. Hiroki Nagai and Mr. Katsumasa Kanai in recording of the NMR spectra. This work was supported in part by a Grant-in-Aid for Scientific Research No. 60307004 from the Ministry of Education, Science and Culture.

11) Acetone solution under ethylene gives single ethylene ^1H NMR signal with the intensities much larger than imidazole signals. This reveals the great dissolution of ethylene in acetone. Hence, ethylene ^1H NMR signal is averaged due to chemical exchange phenomena, such as

$$Cu(im)_2(C_2H_4)^* + C_2H_4 \rightleftarrows Cu(im)_2(C_2H_4) + C_2H_4.^*$$

12) Prolonged passing of nitrogen into the solution of **3** changed the colorless solution into pale blue. This blue color solution gave broad ^1H NMR imidazole signals, whose intensity is considerably weakened. When the solution of **3** remains for a long time, **3** is oxidized by O_2 contained in nitrogen, or coming from air into synthetic apparatus. Thus, **3** is very sensitive to O_2. On the other hand, CO-passing causes no change in color of the solution even for a long time, indicative of a much better stability against O_2. Under ethylene-passing, a phenomenon similar to the case of nitrogen occurs.

19) Concerning a steric interaction, the orientation of a coordinated ligand is likely to be important. CO binds Cu(I) in end-on form,[20] while C_2H_4 does in side-on one.[6,7] The latter potentially encounters steric interaction with coordinated imidazole. From this point of view, a tripodal chelate is considered to be a ligand avoiding this type interaction. This can be proved by the use of chelating systems, including these types of stuctural factors.

22) Triplet methyl and quartet methylene signals of coordinated $P(O(C_2H_5)_3)$ appear near 1 and 4 ppm, respectively. Methylene signals for **2-c**, **2-c'**, and **1-c** collapse with each other; thus, reading their shifts are difficult. Methyl signals of **2-c**, **2-c'**, and **1-c** are 1.24, 1.21, and 1.27, respectively.

25) The greater [L] becomes, the more **5** forms and metal-free imidazole increases. Under this condition, equilibria are very complicated. In addition to **2-c'** and **1-c**, binary complexes such as **3** also likely to form. Binary ones easily undergo a chemical exchange with metal-free imidazole as was demonstrated in Part I.[1]

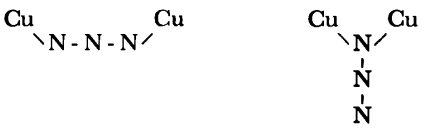
(Received December 26, 1985)

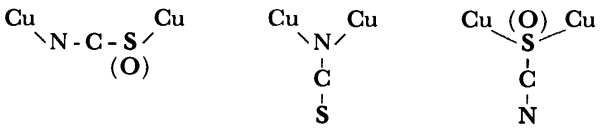
A series of di- and trinuclear copper(II) complexes containing *N,N,N',N'*-tetramethylethylenediamine (tmen), *N,N*-diethylethylenediamine(deen), 2,2'-bipyridyl(bpy) or 1,10-phenanthroline(phen) and azide, thiocyanate or cyanate ions have been prepared and characterized by their magnetic susceptibilities, infrared, electronic, and ESR spectra, and electric conductances. Magnetic susceptibility data for the dimeric complex $[Cu_2(tmen)_2(N_3)_2](ClO_4)_2$ shows the presence of a ferromagnetic interaction (Weiss constant θ=+30 K) above 150 K, whereas the two copper(II) ions are apparently non-coupled below 150 K. On the other hand, the dimeric complex $[Cu_2(bpy)_2(N_3)_2](ClO_4)_2$ shows the presence of a large antiferromagnetic exchange interaction (μ_{eff}<0.6 B.M. at room temperature). The complex $[Cu_3(tmen)_3(NCS)_3](ClO_4)_3\cdot 1.5H_2O$ is estimated to have the trimeric structure; the temperature-dependence of the magnetic susceptibility for this compound indicates the existence of an antiferromagnetic exchange interaction with a J value of $-175\ cm^{-1}$.

It is well-known that azide, thiocyanate, and cyanate ions act as a bridging ligand between metal atoms. The azide ligand can bridge two metal ions in an end-to-end fashion as in (1) or in an end-on fashion as in (2).[1-22] On the other hand,



(1) (2)

three bridging modes are available for the thiocyanate and cyanate ions ((3)—(5)).[15,23-29] Some dimeric copper complexes



(3) (4) (5)

containing these bridging groups are of particular interest as synthetic models for the natural dinuclear copper proteins and their derivatives.[9,11,12,20]

In this paper we report the preparation and characterization of dimeric and trimeric copper(II) complexes containing *N,N,N',N'*-tetramethylethylenediamine(tmen), *N,N*-diethylethylenediamine (deen), 2,2'-bipyridyl(bpy) or 1,10-phenanthroline(phen) and azide, thiocyanate or cyanate anions.

Experimental

Preparation of Copper(II) Complexes. $Cu_2(tmen)_2X_4\cdot nH_2O$ (X=N_3, NCS, and NCO), 1, 4, and 6. To a mixture of $Cu(ClO_4)_2\cdot 6H_2O$ (1.85 g, 5 mmol) and 20 cm^3 of ethanol were added tmen(0.58 g, 5 mmol) and NaX(X=N_3, NCS, or NCO, 10 mmol). The reaction mixture was stirred at room temperature for 1 h, and then allowed to stand for several hours in a refrigerator. After it had been filtered off, the precipitate was recrystallized from ethanol.

$Cu_2(deen)_2X_4\cdot nH_2O$(X=$N_3$, NCS, and NCO), 7, 9, and 10. These complexes were also prepared in the same way as that for $Cu_2(tmen)_2X_4\cdot nH_2O$, and then recrystallized from ethanol.

$Cu_2(tmen)_2(N_3)_2(ClO_4)_2$, 2 and $Cu_3(tmen)_3(NCS)_3(ClO_4)_3\cdot 1.5H_2O$, 5. Except that 4 mmol of NaX(X=N_3 or NCS) was used, the same procedure as that for the preparation of $Cu_2(tmen)_2X_4\cdot nH_2O$ was adopted. The products obtained were washed by ethanol.

12	$Cu_2(bpy)_2(N_3)_2(ClO_4)_2$	2.36	2.24	34.14	33.25	19.17	19.39
13	$Cu_2(bpy)_2(NCS)_4$	2.47	2.41	43.00	42.90	16.63	16.68
14	$Cu_2(bpy)_2(NCO)_4$	2.67	2.66	47.19	47.44	17.95	18.45
15	$Cu_2(phen)_2(N_3)_4$	2.51	2.46	44.03	43.96	33.71	34.19

The complex $Cu_2(tmen)_2(N_3)_2(NO_3)_2 \cdot 2.5H_2O$, **3** was isolated by the same way using $Cu(NO_3)_2 \cdot 3H_2O$.

$Cu_2(deen)_2(N_3)_2(ClO_4)_2$, 8. This was obtained by the same method as **2** by use of deen.

$Cu_2(bpy)_2X_4$(X=N_3, NCS, and NCO), and $Cu_2(phen)_2(N_3)_4$, 11, 13, 14, and 15. These were prepared by the same method as **1** using bpy or phen instead of tmen. Recrystallization was carried out using aqueous ethanol (1:1 by volume).

$Cu_2(bpy)_2(N_3)_2(ClO_4)_2$, 12. Except that 5 mmol of NaN_3 was used, the same method as that for the preparation of **11** was adopted. The purification was carried out by washing with ethanol.

The analytical data for the compounds described above are collected in Table 1.

Measurements. Infrared absorption spectra were measured with a JASCO A-102 infrared spectrophotometer with KBr disk. Visible absorption spectra of DMF solutions were recorded on a Hitachi 200-10 double beam spectrophotometer. Magnetic susceptibility at room temperature was determined by using a Gouy magnetic apparatus. The magnetic susceptibility measurements over the range of liquid helium temperature to room temperature were carried out by Faraday method. The instrument was calibrated with $CuSO_4 \cdot 5H_2O$. The X-band ESR spectra of powdered sample at 77 K were recorded at 9.3 GHz and 100 kHz modulation frequency with a JEOL JES-FE-1X. The g values were calibrated based on Li-TCNQ (g= 2.0025). The X-ray powder patterns were recorded by the use of a Rigaku RAD-1B diffractometer at room temperature, with the Cu-$K\alpha$ line filtered through nickel. The differential scanning calorimetry measurement was carried out by the use of Rigaku DSC 8230. A Toa Denpa Conduct Meter CM-7B was used for conductivity measurements.

Results and Discussion

Copper(II) Complexes with tmen and deen. The dimeric copper(II) complex **1** had already been prepared and characterized by Bkouche-Waksman et al.[13] The similar type of complexes (**1**—**10**) bridged by N_3^-, NCS^-, and NCO^- were newly prepared by the method described in the Experimental section. The color of crystals, magnetic moments at room temperature, IR spectral and electric conductance data are given in Table 2. The complex **1** has centrosymmetric dimeric units with two asymmetric end-to-end azide bridges.[13] However, it has been pointed out that the two copper(II) ions are magnetically non-coupled in the complex **1**.[13] The complex **7** shows the similar magnetic moment and λ_{max} due to d-d transition(Table 3) as those for **1**, hence this compound is estimated to have the dimeric structure I like the corresponding complex **1**. The magnetic moments of the complexes **2** and **8** at room temperature are higher than that of copper(II) complex having no interaction. In order to obtain detailed information on the structure of these complexes, the magnetic susceptibility of **2** was measured over the temperature range 4.2—300 K. Figure 1 shows the temperature-dependence of the magnetic susceptibility. The χ_A^{-1}—T profile in this Figure curves at about 150 K, indicating the possibility of phase transition. The differential scanning calorimetry(DSC) curve for **2** showed the existence of a single broad endotherm at ca. 138 K. These results for **2** suggest that there is a ferromagnetic exchange interaction(Weiss constant θ=+30 K) between the two copper(II) ions above ca. 150 K. However, the two copper(II) ions are essentially non-coupled below 150 K. The similar behavior was recently observed for complexes $[Cu_2(2\text{-Pca=Hist})_2(N_3)_2](ClO_4)_2$[31] and $[Cu_2(2\text{-Pca=}\beta\text{-Ala})_2(N_3)_2] \cdot 2H_2O$.[31] Thus, the complex **2** is considered to have the dimeric structure II like $[Cu_2(2\text{-Pca=Hist})_2(N_3)_2]$ $(ClO_4)_2$ with the end-on azide bridging. The splitting of ClO_4^- vibration(1090, 1115, and 1145 cm^{-1}) in IR spectrum supports the validity of this structure. The structure of **8** is

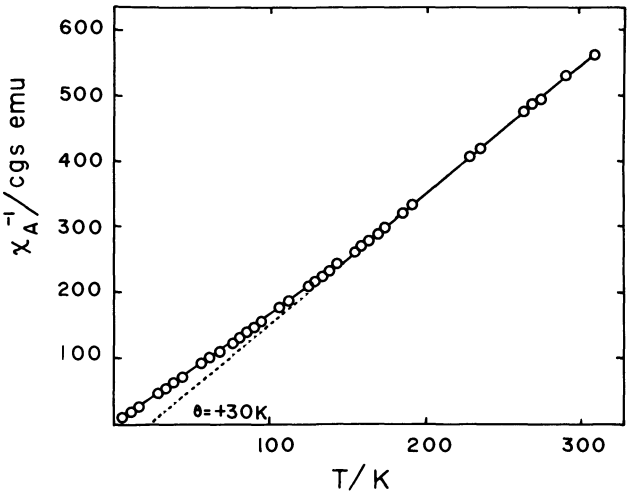

Fig. 1. Temperature-dependence of the magnetic susceptibility of **2**.

expected to be analogous to that of **2** because of its similar magnetic moment and the splitting mode of ClO_4^- (1090, 1120, and 1145 cm^{-1}) in IR spectrum. The above structures are also born out by the ESR parameters of both the complexes **2** ($g_{//}$=2.18 and $g_{\perp}$=2.07) and **8** ($g_{//}$=2.15 and $g_{\perp}$=2.05). Further, the signals due to triplet state were found at g=3.0 and g=1.2 for **8** (Fig. 2), which exhibits that the complex is a dinuclear copper(II) complex. The spectral lines in the ΔM_s=1 region of Fig. 2 are not easily interpreted. Because the sample **8** is a good crystalline solid, we consider that the amount of impurities (probably the copper(II) monomers of unknown composition) is very slight. However, the ΔM_s=1 signal in Fig. 2 may be attributed to some contaminants.

The room-temperature magnetic moments of the thiocyanate containing complexes **4** and **9** were close to the values for non-interacting or weakly interacting copper(II) complexes. The IR spectra of these complexes showed two C-N stretching vibrations of thiocyanato group in the region 2080—2125 cm^{-1} (Table 2). This suggests that there are two kinds of thiocyanato group of different bonding modes in each complex. It is pointed out that the complexes bridged by thiocyanate exhibit ν(CN) above 2100 cm^{-1}.[24)] In addition, the wavenumbers of the two ν(CN) vibrations for **4** and **9** are close to those for α- and β-$[Cu_2(NCS)_4(dmtp)_4]$[28)] which have the skeleton

, hence two Cu-NCS bonds. Thus the

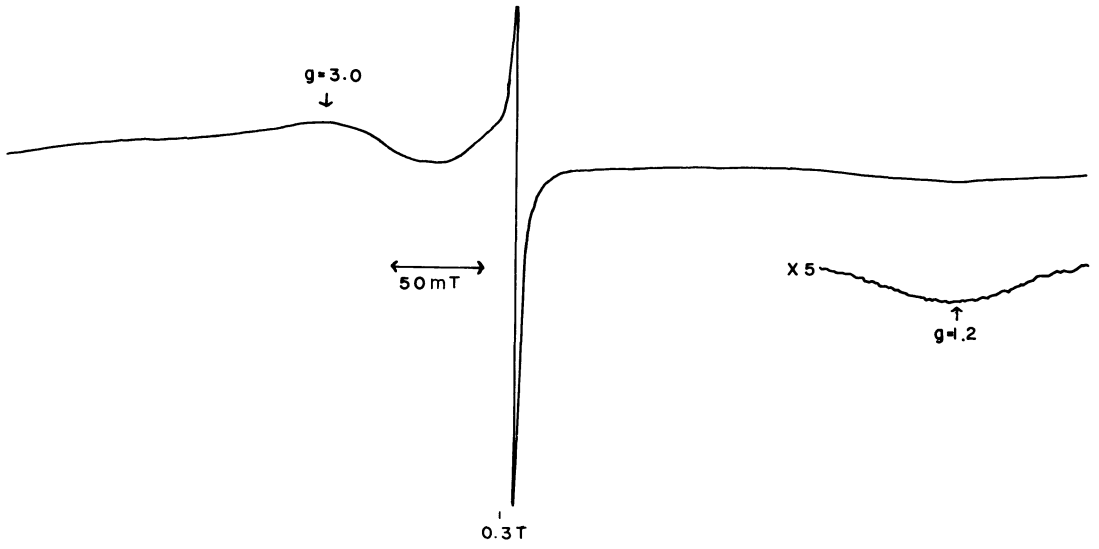

Fig. 2. ESR spectrum of **8** at 77 K.

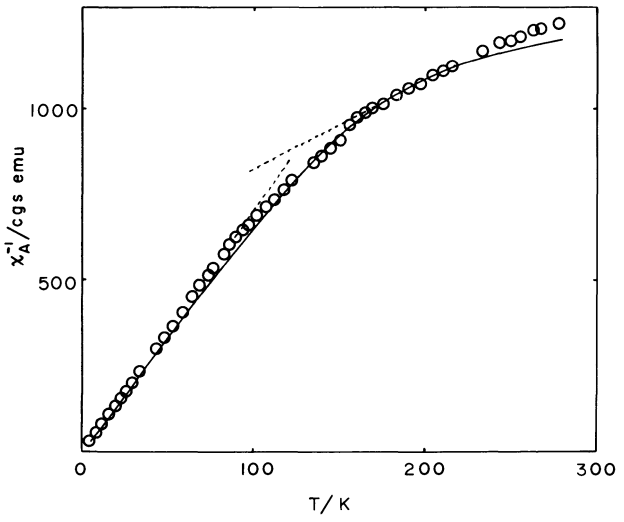

Fig. 3. Temperature-dependence of the magnetic susceptibility of **5**. The solid line shows theoretical susceptibility calculated by Eq. 1 with the parameters described in the text.

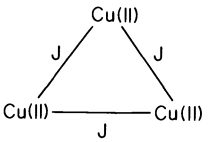

Fig. 4. Spin-spin interaction in triangular trinuclear copper(II) complexes.

complexes **4** and **9** may have the dimeric structure III. The complex **5** shows an effective magnetic moment smaller than the spin-only value at room temperature. The magnetic susceptibility was measured over the range from liquid helium temperature to room temperature. Figure 3 represents the temperature-dependence of the magnetic susceptibility. The observed susceptibility obeyed the Curie-Weiss law in the temperature range $T \gtrsim 160$ K and $T \lesssim 90$ K: the Curie and Weiss constants were determined as C_h=0.38 emu K mol^{-1} and θ_h=−210 K for the high temperature range, and C_l=0.143 emu K mol^{-1} and θ_l=0 K for the low temperature range. Furthermore, the ratio C_h/C_l is 2.7. This magnetic behavior indicates that the complex **5** is the compound containing three copper(II) ions magnetically interacted. The theoretical susceptibility, χ_A, for triangular trinuclear complex is given by a solid line in Fig. 3. The calculation of these χ_A values was carried out according to the Eq. 1[30]

$$\chi_A = \frac{Ng^2\mu_B^2}{12kT} \times \frac{1+10\exp(3J/kT)}{1+2\exp(3J/kT)} + N\alpha, \quad (1)$$

where J denotes the exchange integral between copper(II) ions as indicated in Fig. 4. Magnetic parameters were as follows: g=2.16, $N\alpha$=60×10^{-6} cgs emu mol^{-1}, J=−175 cm^{-1}. Thus the complex **5** is considered to have the triangular trimeric structure bridged by thiocyanate ions. This complex indicates the rhombic ESR spectrum with g_1=2.18, g_2=2.13, and g_3=2.07 in the ΔM_s=1 region.

The ΔM_s=2 transition in the X-band ESR spectra for cyanate containing complexes **6** and **10** was not observed at half-field. The same results were found for the thiocyanato complexes **4** and **9**. Although there are no other evidences for dimeric structure of **6** and **10**, these compounds are also supposed to have a dinuclear structure similar to III proposed for thiocyanato complexes.

The electric conductances (Table 2) of **1**, **7**, and **10** show that these complexes are non-electrolytes in DMF solutions. Accordingly, the structures in the solid state of **1**, **7**, and **10** are supposed to be

maintained in DMF. The molar conductances of **2**, **3**, and **8** are in the range found for 1:2 electrolytes, suggesting that these compounds undergo significant structural changes upon dissolution. Also, a partial dissociation of NCS^- for **4** and **9** takes place in DMF.

All of the azido complexes display an intense band at 380—390 nm(log ε, ca. 3.5) (Table 3). These bands are assigned to azide to copper CT transitions.[32,33] The CT bands are also observed for the thiocyanato complexes around 370 nm (Table 3).[33] The similar $N_3^- \rightarrow$ and $SCN^- \rightarrow$Cu CT bands are observed in metazido- and metthiocyanato-hemocyanin in which the peroxide of oxy-hemocyanin is displaced by N_3^- and NCS^-, respectively.[33]

Copper(II) Complexes with bpy and phen. The copper(II) complexes **11**—**15** were prepared by the same method as that for **1**—**10** by using 2,2′-bipyridyl or 1,10-phenanthroline. The complexes with same compositions with ours, $[Cu(bpy)(N_3)_2]$, $[Cu(bpy)(NCS)_2]$, and $[Cu(phen)(N_3)_2]$ were described by Dutta and De.[34] Bushnell and Kahn[6] reported the crystal and molecular structure of $[Cu(bpy)(N_3)_2]$,[34] which has the polymeric structure with asymmetric end-on azide bridges. No difference was observed in IR spectra of $[Cu(bpy)(N_3)_2]$ and **11**. However, the low-angle lines of X-ray powder diffraction patterns (Fig. 5) for both complexes are fairly different in location and relative intensity. This indicates a somewhat different

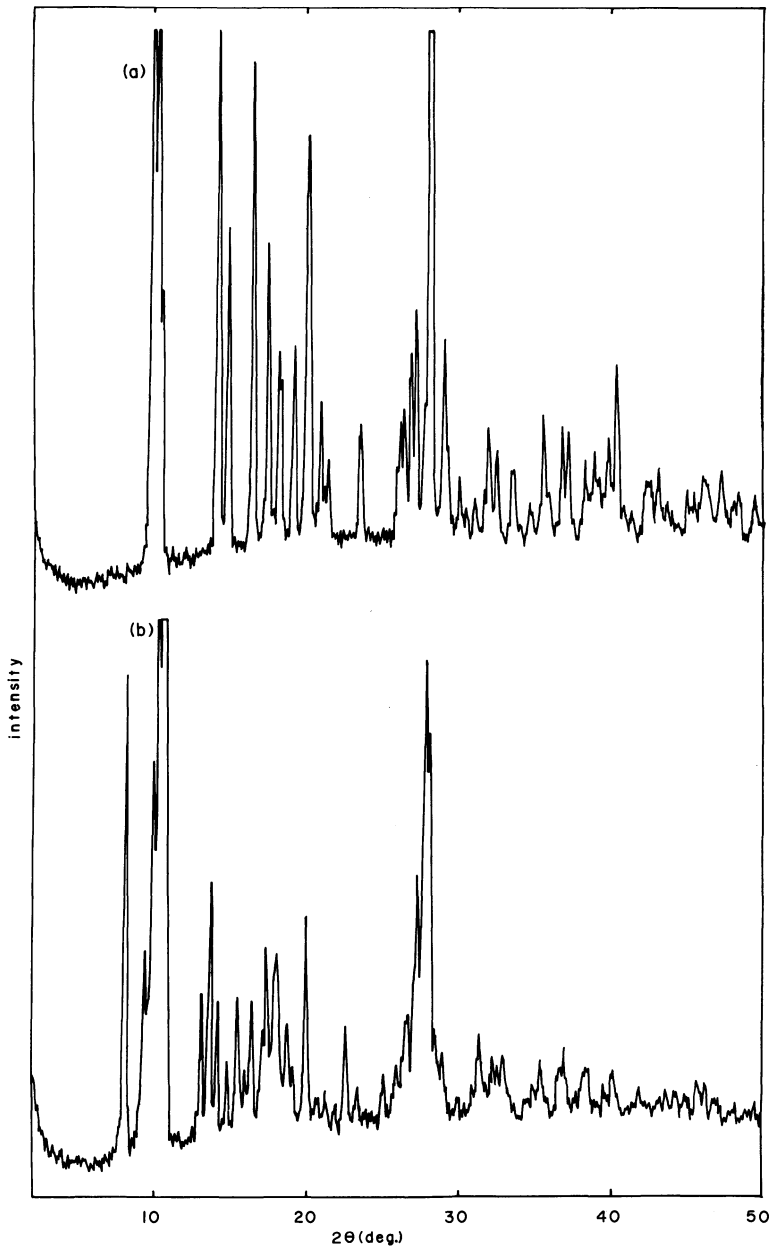

Fig. 5. Comparison of X-ray powder diffraction patterns for **11** (a) and $[Cu(bpy)(N_3)_2]$ (b).

packing arrangement in the unit cells of [Cu(bpy)$(N_3)_2$][6] and **11**. Although more precise measurements of magnetic susceptibilities and the determination of the crystal structure of **11** will be required for elucidating the difference between [Cu(bpy)$(N_3)_2$][6] and **11**, it may be suggested that **11** has a dimeric structure similar to **1**. The magnetic moment of **12** at room temperature shows 0.6 B.M. However, we consider that the compound **12** has a property near diamagnetism, since the presence of several % of paramagnetic impurities in the solid sample **12** is confirmed from the experiment on variable-temperature magnetic susceptibility. Antiferromagnetic interactions have been found in many copper(II) complexes containing end-to-end azide bridges.[8,9,11,13,22] The complex **12** is, therefore, considered to have the structure with end-to-end azide bridging. Also, we imagine that the two copper(II) coordination planes are nearly coplanar and the azide ions bridge the two copper(II) ions in the coordination planes, because the large spin-spin interaction usually operates only when the coplanality of the bridging group  is attained.[8,9,11,13,22] Thus, we consider that the diamagnetic metazido-hemocyanins[35,36] derived from the hemocyanins of *Busycon canaliculatum* and *Limulus polyphemus* contain  plane. These complexes **11**—**15** exhibit the similar behaviors as **1**—**10** in electronic spectra and electric conductances (Tables 2 and 3).

We thank Miss Sachiyo Nishi for her collaboration in the preparation of compounds. We also indebted to Dr. Isao Kusachi of Okayama University for obtaining the results of the X-ray diffraction and Mr. Sakira Kaneko of Rigaku Denki Co. for DSC measurement and his valuable disscussion. This work was supported in part by a Grant-in-Aid for Scientific Reserch (C) (No. 58540389) from the Ministry of Education, Science and Culture.

Preparation of Cubic $HZr_2(PO_4)_3$ and Related Compounds

Akira ONO* and Yoshiyuki YAJIMA
National Institute for Research in Inorganic Materials, Namiki, Ibaraki 305
(Received January 11, 1986)

A single phase of cubic $NH_4Zr_2(PO_4)_3$ with a langbeinite-type structure was prepared at 235 °C by a hydrothermal method. A series of analogous compounds containing various monovalent cations or vacancies were made by starting with cubic $NH_4Zr_2(PO_4)_3$. They are polymorphs with respect to Nasicon-type compounds and have rigid skeleton structures with interstitial spaces partially occupied by monovalent ions and water molecules. Maximum water contents of the cubic compounds decrease with increasing sizes of the monovalent ions. Proton-bearing cubic compound exhibited ion exchange reactions with NaCl and LiCl solutions at 20 °C. This suggests the existence of bottlenecks large enough for permitting diffusion of Na^+ and Li^+ ions. Low thermal expansion of cubic $NaZr_2(PO_4)_3$ was studied by high-temperature X-ray diffraction.

Phosphate compounds with the formula $AM_2(PO_4)_3$ where A is an alkali metal atom, H_3O, H, or NH_4 and M is Zr or Ti have three dimensional skeleton structures. Most of the compounds have rhombohedral Nasicon-type structures, but cubic langbeinite-type compounds are also known.[1,2] Here, Nasicon is a solid solution series of the formula $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$ ($3>x>0$), and langbeinite is a mineral formulated as $K_2Mg_2(SO_4)_3$. Recently, we have prepared cubic $AZr_2(PO_4)_3$ (abbreviated as AZP) and $Zr_4P_6O_{23}$ (abbreviated as VZP, V stands for a vacancy) by a series of heat treatments of cubic NH_4ZP under dry and hydrothermal conditions and ion-exchange reactions between HZP and alkali chloride solutions.[3] The novel cubic compounds, however, were not investigated in detail because of the presence of a considerable amount of monoclinic ZrO_2. This paper describes the preparation and properties of a single phase of cubic NH_4ZP and its related compounds. The cubic phases obtained were characterized by X-ray powder diffraction, high temperature X-ray diffraction, thermal gravimetric analysis(TG), differential thermal analysis(DTA), infrared(IR) spectroscopy and scanning electron microscopy(SEM). An analysis of complex impedance data on cubic HZP[4] will be reported in the near future.

Both cubic and rhombohedral skeleton structures consist of corner-sharing ZrO_6 octahedra and PO_4 tetrahedra with interstitial spaces partially occupied by monovalent cations. Their structures have been explained by a cubic or hexagonal packing of rods[5] consisting of a repeating sequence $A,(A),O_3ZrO_3$, O_3ZrO_3 or A,O_3ZrO_3,O_3ZrO_3, respectively, where (A) is a vacancy. Rhombohedral AZP has one M_1 octahedral site occupied by an A^+ ion and three vacant M_2 sites per formula unit. The M_1 and M_2 sites constitute a three-dimensional network. Any M_1 site is surrounded by six M_2 sites. The spaces linking the M_1 and M_2 sites are considered to be ion-pathways.[6,7]

Cubic AZP has two kinds of cation sites occupied by A^+ ions, and half of the sites are vacant in a statistical sense. Figure 1 illustrates the schematic view parallel to [111] showing the two cation sites in a large ellipsoidal cage which is bounded by a network of six 6-membered and three 4-membered rings consisting of corner-sharing ZrO_6 octahedra and PO_4 tetrahedra. The monovalent ion is surrounded by nine oxygen atoms.[2] Judging from the rapid ion-exchange reaction between cubic HZP and a LiCl or NaCl solution,[3] diffusion of Na and Li ions took place rapidly through the windows of the 6-membered rings.

Experimental

Hydrothermal syntheses were carried out in a Teflon-lined bomb of 20 cm^3 capacity. The bomb was heated in an oven at a prescribed temperature. The pressure was believed

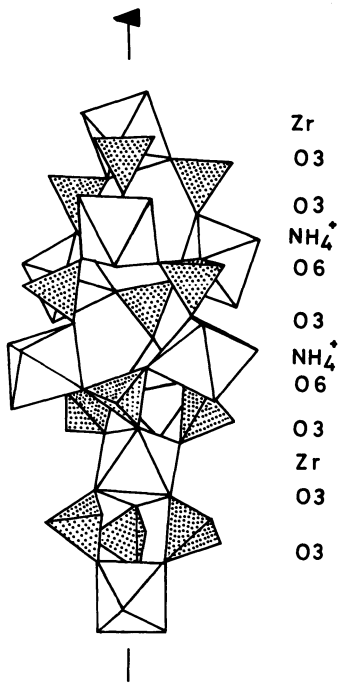

Fig. 1. The schematic view showing the framework of an ellipsoidal cage occupied by a monovalent ion. Two kinds of sites are available for an NH_4^+ ion.

to be about 0.1 to 0.2 GPa calculated from the per cent fill of the container. Two kinds of starting materials were used for the preparation of cubic NH_4ZP. The first one was obtained as follows: $ZrOCl_2 \cdot 8H_2O$, $(NH_4)_2HPO_4$, and $NH_4H_2PO_4$ were mixed in a Teflon container, and then water was added. NH_4F and NH_4NO_3 solutions of 1.5 mol dm^{-3} were also used in some experiments to promote crystallization reactions. The precipitate obtained was well homogenized by stirring with a rod made of bamboo. The Zr/P ratio of the precipitate was 2/3 judging from the mixing ratio of the starting materials. The pH values of the solutions were adjusted by changing the mixing ratio of $NH_4H_2PO_4$ and $(NH_4)_2HPO_4$, but in a few cases a dilute solution of HCl or aqueous ammonia was added to the starting materials. Experimental conditions are given in Table 1.

The other starting material was a gel obtained by mixing solutions of $NH_4H_2PO_4$ and $ZrOCl_2 \cdot 8H_2O$ under controlled pH values.[8] The gel was crystallized in a dilute HCl solution. A small amount of NH_4F or LiCl was added as a mineralizer in a few runs. Experimental conditions are summarized in Table 2.

The yields were filtered and washed with distilled water after the determination of the pH values of the solutions. The products were examined by X-ray methods, IR spectra, TG, DTA, and SEM. All the measurements were carried out on the same laboratory equipment and by the methods described previously.[3,8] Various cubic compounds were prepared from cubic NH_4ZP by the same procedure used before.[3] Chemical compositions of these cubic phases were determined by the combined data of lattice constants, IR spectra, and TG, assuming that the Zr/P ratio of all the cubic phases studied here was 2:3. To confirm the validity of this method, sodium in cubic NaZP was analyzed by the atomic absorption method. The sample was brought into solution in the mixed acid of HF and H_2SO_4.

The interplanar spacing d_{311} of cubic NaZP was measured up to 520 °C for the determination of the coefficient of linear thermal expansion. X-Ray diffraction patterns were recorded with a high-temperature X-ray powder diffractometer, JEOL, DX-COH-V2, using Ni-filtered Cu $K\alpha$ radiation with a scanning speed of 0.25° 2θ min^{-1}. The temperature was measured with a Pt-Pt13%Rh thermocouple in contact with a platinum sample holder which was also heater. Quartz was used as an internal standard. The spacing d_{310} of quartz at 520 °C was calculated by using the lattice constants given in the literature.[9] During the slow heating up to 520 °C, seven lattice constants were measured under constant temperatures, and two lattice constants during the cooling process.

Results and Discussion

Preparation of Cubic AZP. Table 1 shows the results of experiments which were carried out at 235 °C using the precipitates made in a Teflon-container. Cubic NH_4ZP was obtained as a main product under high pH values, but a minor rhombohedral phase was present when no mineralizer was used. A single phase of cubic NH_4ZP was prepared by the addition of a small amount of NH_4F. At low pH values both rhombohedral and cubic NH_4ZP were pepared, but a considerable amount of amorphous materials were obtained together with cubic and rhombohedral phases in a pH range 7—8.3.

Cubic NH_4ZP obtained in NH_4F solutions exhibited euhedral crystal forms with 0.5—1.2 μm in sizes under the SEM. At 925 °C for 25 min this compound loses NH_3 and H_2O to yield cubic VZP which has crystal forms retaining the morphology of the original cubic compound. We could not find any effects of degassing of volatile components on the crystal surfaces of VZP. This may be due to a small volume difference between NH_4ZP and VZP.

For the hydration of VZP at 340 °C and 0.1 GPa,[3] the duration was 5 h previously, but it was 9 h in the

present study that was long enough for the formation of cubic H_3OZP. The weight loss of cubic H_3OZP took place in the two temperature ranges as shown in Fig. 2A. Cubic HZP was formed after the first water loss of 3.9 wt%, and cubic VZP after the second water loss of 1.85 wt%. The TG curve of cubic HZP showed a weight gain due to absorption of moisture in the temperature range 25 to 220 °C as shown in Fig. 2B. Actually, rehydration of cubic HZP, i.e. formation of H_3OZP, occurred rapidly at 25 °C by addition of a small amount of water. Hydrated VZP ($Zr_4P_6O_{23}\cdot 4H_2O$) was obtained by the hydration of cubic VZP at 100 °C for 24 h under one atmosphere.

Preparation of cubic H_3OZP was undertaken by the hydration of VZP at 245 °C for 48 h in the Teflon-lined bomb. The material obtained showed a water loss of 1.0 wt% in the temperature range 500—900 °C,

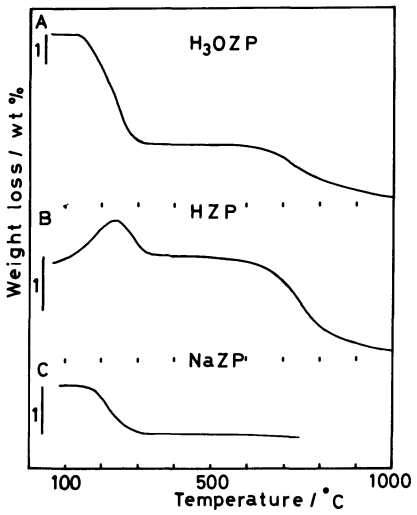

Fig. 2. TG curves of three cubic AZP.
A, C: Materials prepared hydrothermally, B: HZP heated at 500 °C and quenched to room temperature. Scale bar: 1 wt%. Heating rate: 10 °C min^{-1}.

which indicated that H_3O^+ ions occupy 60% of the available cation sites. The hydrated phase obtained was heated at 400 °C in air to prepare a proton-bearing compound which might exhibit an ion-exchange reaction with a NaCl solution at room temperature. The ion-exchange reaction, monitored by a pH meter, mainly took place within 0.5 min after the mixing of the solid and the liquid phases and was completed after 48 h. The final product did not show a weight loss above 500 °C, suggesting the complete exchange of protons by sodium ions. The sodium content of the final product is 2.7 wt% determined by the atomic absorption method. It is, therefore, concluded that sodium ions occupy 56% of the available cation sites that is in good agreement with the value obtained by the water loss datum.

Cubic LiZP was prepared at room temperature by the ion-exchange reaction between cubic HZP and a LiCl solution. In a dilute HCl solution cubic LiZP was changed to cubic H_3OZP after 80 h at 25 °C.

The results of experiments performed by using gels are summarized in Table 2. Cubic NH_4ZP was prepared together with the rhombohedral phase in most of the products. The amount of the cubic phase varied depending upon the different starting gels, and it did not show any systematic relationships to the pH values of the solutions. With respect to this problem, no rhombohedral phase was present when 1.5 mol dm^{-3} solution of NH_4F was added to the dilute HCl solution of 4 cm^3, although the pH value was below 2.0 (Table 2, 9—39). The fluorine ions in the solvent are the strong influencing factor for the formation of the cubic phase. On the other hand, the aging of a gel promoted the formation of the rhombohedral phase over the cubic phase. The result is presented in Table 2, 9—51 for the xerogel aged for 90 d at room temperature before heating.

Stability of Cubic AZP. The thermodynamical stabilities of cubic and rhombohedral AZP are

problematic because formation of the phases depend on the nature of the starting materials, the pH value and the anion species in the solution equilibrated with the solid phase. According to the previous study,[3)] however, cubic NH_4ZP crystallized at 340 °C and 0.1 GPa at the initial stage of the reaction, and was then gradually changed to the rhombohedral phase by further heating. This result indicates the instability of cubic NH_4ZP above 340 °C under 0.1 GPa.

Here, we have carried out experiments to evaluate the stability of cubic H_3OZP under hydrothermal conditions. Cubic VZP sealed in a gold capsule together with water was heated in a cold sealed pressure vessel for various times. At 350 °C and 0.1 GPa cubic H_3OZP was formed after 9 h, but it was transformed completely to the rhombohedral phase after the subsequent hydrothermal heating for 6 h. It is evident that cubic H_3OZP is a metastable transient phase at 350 °C. At 410 °C and 0.1 GPa, rhombohedral H_3OZP crystallized together with the cubic phase after 1 h. However, on further heating both phases decomposed partially to give unknown oxide compounds. Thus, both cubic and rhombohedral H_3OZP are unstable at 410 °C under 0.1 GPa. The stability ranges of cubic NH_4ZP and H_3OZP, if present, are below 350 °C under 0.1 GPa according to the available data.

Properties of Cubic AZP. X-Ray powder data of cubic VZP and NaZP are listed in Table 3. Here, the intensity (I_{obsd}) was measured as the peak height above the background. The other compounds obtained here showed similar X-ray powder patterns to those listed in Table 3 or Table 1 of the literature.[3)] Chemical formulas and lattice constants of cubic AZP prepared in hydrous conditions are listed in Table 4 together with those of anhydrous cubic compounds which were obtained by heating the hydrous compounds at 500 °C in air. The amount of zeolitic water in the hydrous AZP was estimated by the weight loss taking place mainly in the temperature range 110—300 °C. An example of TG curves is given in Fig. 2 C.

Table 4. Lattice Constants of Cubic AZP

Crystalline material	Lattice constant/Å
$NH_4Zr_2(PO_4)_3$	10.192
$H_3OZr_2(PO_4)_3 \cdot 0.1H_2O$	10.190
Na $Zr_2(PO_4)_3 \cdot 0.3H_2O$	10.205
Li $Zr_2(PO_4)_3 \cdot 0.7H_2O$	10.200
$Zr_4P_6O_{23} \cdot 4H_2O$	10.218
Na $Zr_2(PO_4)_3$	10.173
Li $Zr_2(PO_4)_3$	10.168
H $Zr_2(PO_4)_3$	10.165
$Zr_4P_6O_{23}$	10.146

Lattice constants of hydrous AZP are similar and do not show any relationships to the size of the monovalent ions. The hydrous cubic phases appear to have similar dimensions and configurations of the rigid framework structures. The lattice constant of hydrous cubic AZP is larger than that of the anhydrous one, and hydrous VZP has the largest lattice constant as listed in Table 4. These facts suggest that the lattice constant of cubic AZP may increase by the incorporation of water molecules into the vacant sites located in the large ellipsoidal cages shown in Fig. 1. If the vacant sites were completely occupied by water molecules, the lattice constant of hydrous AZP would be larger than the value given in Table 4. Since such a hypothetical highly hydrous phase could not be prepared, hydrous cubic AZP must become unstable when its lattice constant exceeded a certain value by the increasing number of water molecules in the structure. This value may be in the narrow range 10.190 to 10.205 Å for various cubic AZP. If this is true, the amount of zeolitic water is highly dependent on the size of the monovalent ion, because effects of a water molecule on the expansion of the ellipsoidal cage may be more effective when a water molecule is incorporated into the sites located nearby the larger monovalent ions. Actually, the amount of the zeolitic water in the cubic phases decrease systematically with increasing sizes of the monovalent ions as shown in Table 4.

The lattice constants of the anhydrous cubic phases increase slightly with the increasing sizes of the monovalent ions. The difference in the molar

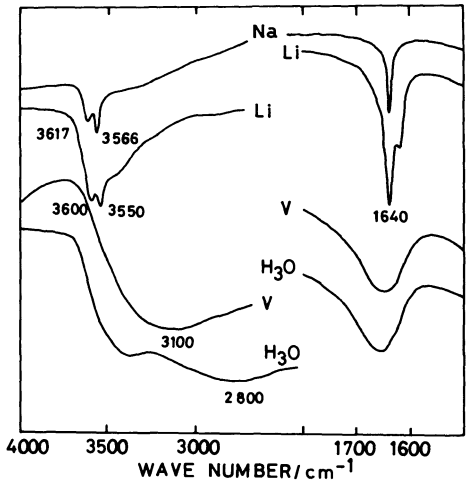

Fig. 3. IR spectra of hydrated cubic phases. Na, Li, V and H_3O are cations located in the interstitial sites of the framework. Here, V stands for a vacancy.

volumes of NH_4ZP and LiZP is 1.1 cm^3 for the cubic phases and 7.2 cm^3 for the rhombohedral phases.[8] The small difference in the cubic phases may be due to the presence of rigid and large ellipsoidal cages which various monovalent ions occupy without considerable changes in the configuration.

Hydrous LiZP and NaZP showed narrow absorption bands in the frequency range 1500 to 4000 cm^{-1} as illustrated in Fig. 3. The wave number of the sharp bands depends on the nature of the monovalent cation. These narrow bands are attributed to OH absorption bands of water molecules whose oxygen atoms interact with adjacent Li or Na ions (ion-dipole interaction). Similar narrow absorption bands of water are common for zeolites.[10]

Cubic H_3OZP showed a broad absorption band near 2800 cm^{-1} which was absent for hydrated VZP. The latter phase exhibited a broad band near 3100 cm^{-1} which could be attributed to a hydrogen-bonded OH stretching vibration.

The d_{310} values of cubic NaZP were approximately constant up to 520 °C. The lattice constant at 520 °C is 10.186 Å which is similar to the value (10.173 Å) at room temperature. The coefficient of linear thermal expansion is 1.6×10^{-6} K^{-1}.

The existence of large vacant sites in a skeleton structure is a necessary condition for the materials of low thermal expansion. Nasicon-type compounds fulfil this requirement and $Ca_{0.5}Zr_2(PO_4)_3$, $ZrNb(PO_4)_3$, and $KTi_2(PO_4)_3$ were demonstrated to be of low thermal expansion.[11–14] Structural analysis of a single crystal of Nasicon has revealed that configurations of polyhedra exhibited little temperature dependence.[6] Therefore, the thermal expansion of Nasicon was mainly caused by changes of bond angles between the adjacent polyhedra.

Cubic AZP has also a three dimensional skeleton structure. Moreover, half of the interstitial cation sites are vacant. These structural features satisfy the requirement for low thermal expansion. Therefore, cubic AZP may have low thermal expansion.

Lattice constants of cubic AZP do not increase considerably when the monovalent cations were completely replaced by the other larger ions as mentioned earlier. This suggests that an increase in size of a monovalent ion caused by a rise in temperature has little effect on the lattice constant of cubic AZP. In fact, cubic NaZP was proved to be of low thermal expansion by high temperature X-ray diffraction.

Splitting Parameters in Ligand Field Absorption Bands of Cobalt(III) Ammine Complexes with Chloro or Aqua Ligands

Yoshihiro MITSUTSUKA,* Ichiji KONDO, and Masayoshi NAKAHARA†
Department of Chemistry, Faculty of Science and Engineering, Meisei University, Hodokubo, Hino 191

(Received January 28, 1986)

The splitting parameters of ligand field absorption bands for cobalt(III) ammine complexes containing aqua or chloro ligands were investigated by microspectrophotometry. The polarized absorption spectra were measured for these crystals. The spectra obtained were separated into Gaussian components according to a nonlinear least-squares method. The splitting parameters were determined from the locations of the components for the first absorption band.

The splitting pattern of the ligand field absorption band for cobalt(III) complexes with different ligands was predicted according to a semiempirical procedure proposed by Yamatera,[1] the so-called Yamatera's rule. Further, the rule was applied to the ligand field bands of cobalt(III) chelate complexes by Matsuoka et al.[2]; it is well-known that the rule does hold in the splitting pattern of the band.

The present work was carried out in order to establish the splitting parameters of some ligands in cobalt(III) complexes. In an aqueous solution it should be possible to determine the parameters of shifting and splitting in spectral patterns, but some complexes are more or less subject to hydrolysis in an aqueous solution and an exact spectrum cannot be obtained. Therefore, a spectral measurement in a crystalline solid is preferable.

In this study, polarized spectra were measured for a single crystal in order to intensify particular components of the absorption band of the complex and to increase the reliability of the spectral analyses. The microspectrophotometric technique was used for the spectral measurement since it is very difficult to grow a single crystal large enough to measure the absorption spectra by a common technique.

Experimental

Microspectrophotometer. The electronic spectra were recorded on a Shimadzu D40R-w spectrophotometer. A part of the optical construction in the microphotometer is illustrated in Fig. 1. Two photomultipliers (R928, Hamamatsu TV) were used for the measurement. Polarized light was obtained by using a Glan Thompson prism in front of a mirror chopper. A sample beam was focused on a crystal of the complex salt with a reflecting objective (MO30X, Olympus) and collected on a photomultiplier with another objective. Since the intensity of the sample beam decreased by approximately 60%, the reference beam was balanced by adjusting an attenuator. The size of the focused beam was 0.03 mm in width and 0.06 mm in length; the width could be reduced by narrowing the slit of the spectrophotometer.

Sample. A large single crystal of the complex salt was required for this experiment. Cobalt(III) ammine complexes, containing chloro and aqua as ligands, were used because these complexes form large single crystals. Since these ligands differ regarding ligand field strength from each other, the components of the absorption band could be distinctly observed. As a result it was easy to analyze the spectrum. The complexes prepared by conventional means were identified by chemical analyses as well as IR and UV spectrophotometry. When the absorbance of the crystal was too high, the crystal was sliced[3] in the desired direction and was then polished smooth and flat.

Measurement. To ensure the best alignment of the electric vector of the incident beam with the axis of maximum absorbance, a Glan Thompson prism was turned until the absorbance reached a maximum. The spectrum of a single crystal was then recorded. After the optical axis of the prism was rotated 90°, another polarized spectrum was also measured. After the crystal was removed from the light beam, a base line was recorded. A net spectrum was obtained by subtracting the base-line absorbance from the observed spectrum.

Curve Analysis. It was proposed by Mead[4] that the absorption curve of the complex was empirically represented by the sum of Gaussian error functions. The absorption

curve obtained was statistically separated into its band components by using the nonlinear least-squares method (SSVM method[5]).

Results and Discussion

Figure 2 shows the electronic spectra of the complexes studied and the calculated curves. The peak positions of the calculated Gaussian components are summarized in Table 1. The splitting components can be clearly distinguished for the so-called first absorption band ($^1T_{1g} \leftarrow {}^1A_{1g}$ in O_h complexes and the corresponding transitions in the complexes of lower symmetries). In this case, no explicit splitting was observed in the so-called second absorption band, ($^1T_{2g} \leftarrow {}^1A_{1g}$ in O_h complexes and the corresponding transitions in the complexes of lower symmetries); the rule of average environment was followed. Furthermore, the second band in some cases somewhat overlapped the charge-transfer band. Thus, the average position of the band is listed in Table 1.

The splitting pattern of the absorption band for octahedral and pseudooctahedral complexes having various ligands has been qualitatively explained according to Yamatera's rule. The rule was applied to

the spectra of the complete series of $[Co(ox)_x(gly)_y(en)_z]$ chelate complexes as reported by Matsuoka et al.[2] They suggested that the rule describes the band location and shape for these chelate complexes. In the present work, complexes including only unidentate ligands were employed in order to eliminate the chelate effect.

According to Yamatera's rule, the first band of octahedral and pseudooctahedral complexes consists of three components corresponding to the transitions $d_{xy} \rightarrow d_{x^2-y^2}$, $d_{yz} \rightarrow d_{y^2-z^2}$, and $d_{zx} \rightarrow d_{z^2-x^2}$. When a complex has the same six ligands, the three transition energies should be the same; therefore, it appears that the first absorption band shows no splitting. However, the presence of two or more kinds of ligands in a complex gives rise to band splitting. In this study Yamatera's parameter was somewhat modified and used as follows. For example, when a $d_{xy} \rightarrow d_{x^2-y^2}$ transition takes place in a plane including the four ligands of L1, L2, L3, and L4 (located on the X and Y axes), the

Table 3. δ Values of Amminecobalt(III) Complexes

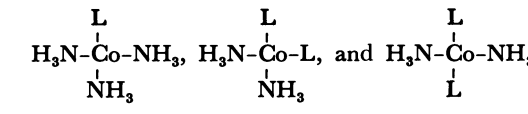
Complex	$\delta(NH_3)$ $\times 10^3$ cm^{-1}	δ(L) $\times 10^3$ cm^{-1}	
$[Co(NH_3)_6](ClO_4)_3$	21.30[6]	—	
$[CoCl(NH_3)_5]SO_4\cdot 2H_2O$	21.27	$\delta(Cl^-)$	9.30
cis-$[CoCl_2(NH_3)_4]_2S_2O_6$	20.91	$\delta(Cl^-)$	11.91
trans-$[CoCl_2(NH_3)_4]Cl$	21.05	$\delta(Cl^-)$	10.69
$[Co(NH_3)_5(H_2O)]_2(C_2O_4)_3\cdot 4H_2O$	21.61	$\delta(H_2O)$	12.53
cis-$[Co(NH_3)_4(H_2O)_2]_2(SO_4)_3\cdot 3H_2O$	21.95	$\delta(H_2O)$	15.43

energy of the transition can be represented by the sum of the $(1/4)\delta$(L) contributions to the ligand field strength from individual ligands:

$$\frac{1}{4}[\delta(L1)+\delta(L2)+\delta(L3)+\delta(L4)].$$

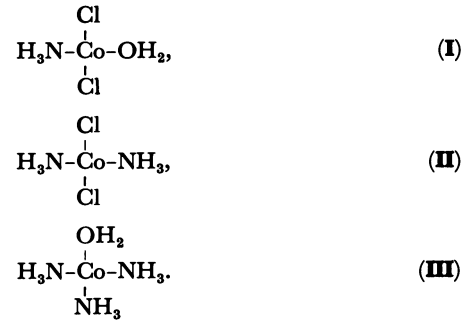
Expressions corresponding to the other transitions can be similarly represented. The skeletons and expressions of their band positions are shown in Table 2. The δ(L) for each ligand in an individual complex is readily calculated from their expressions in the respective complex. Yamatera's parameters δ(L), thus obtained, are also listed in Table 3.

It is known[6] that the positions of the absorption maxima of various complexes in a crystal vary with the kind of counter ion; for example, the maximal degree in band shifts due to counter ions is about 300 cm^{-1} in $[Co(NH_3)_6]X_3$ crystals, except for the occurrence of strong association absorption bands or charge-transfer bands. Therefore, the $\delta(NH_3)$ values of these complexes are in fair agreement with each other (Table 3). Then, it can be assumed that the usable value of $\delta(NH_3)$ is 21.3×10^3 cm^{-1}. However, the treatment of a δ(L) other than $\delta(NH_3)$ is not so simple. The order of δ(L) (L=H_2O, Cl^-) obtained from $[CoL(NH_3)_5]$ and also from *cis*-$[CoL_2(NH_3)_4]$ agrees with that of the spectrochemical series.[7,8] The values of $\delta(Cl^-)$ obtained from $[CoCl(NH_3)_5]$, *cis*-$[CoCl_2(NH_3)_4]$, and *trans*-$[CoCl_2(NH_3)_4]$ are 9.31, 11.91, and 10.69×10^3 cm^{-1}, respectively. These values differ from one another depending on their coordination states. The difference of (1/4) δ(L) values is considered here for the following skeletons:



The δ value of ligand L is variable, depending on the other ligands at the cis or trans position. Therefore, particular consideration is necessary for these results. Since the ligand field splitting, 10 Dq, essentially corresponds to the energy difference between $e_g^*(\sigma)$ and $t_{2g}^*(\pi)$, or between σ and π antibonding levels, the difference stated above in the δ(L)'s in chloro and aquacomplexes also arises from the differences in their splitting effects. NH_3 is a fairly strong σ donor but a poor π donor. On the other hand, H_2O and Cl^- with one or two π donor electron pairs will have a much larger ligand-to-metal π interaction than that of NH_3. While the values of $\delta(NH_3)$, 21.30×10^3 cm^{-1}, are nearly the same for any complex, the values of $\delta(Cl^-)$ and $\delta(H_2O)$ vary according to their coordination structure, as described above. Thus δ(L) values of such ligands should be adopted according to the respective coordination structure.

Here, the δ values determined above are applied to a complex whose structure is known. The first absorption band in *trans*(Cl)-$[CoCl_2(NH_3)_3(H_2O)]Cl$, dichro salt,[10] should split into three components corresponding to the skeletons of



(I)

(II)

and

(III)

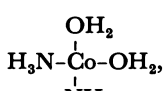
Since the $\delta(H_2O)$ for the skeleton (I) was not obtained, the δ value is taken to be the same as that for (III); then, the calculated positions corresponding to three skeletons are:

$$\frac{1}{2}\delta(Cl^-)+\frac{1}{4}\delta(H_2O)+\frac{1}{4}\delta(NH_3)=13.80, \quad (1)$$

$$\frac{1}{2}\delta(Cl^-)+\frac{1}{2}\delta(NH_3)=15.99, \quad (2)$$

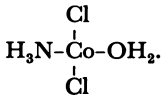
$$\frac{1}{4}\delta(H_2O)+\frac{3}{4}\delta(NH_3)=19.11. \quad (3)$$

The values of (2) and (3) agree well with the observed band positions, 15.75 and 19.21×10^3 cm^{-1} (Table 1). In spite of careful experiments extending as far as ca. 1100 nm (9000 cm^{-1}), the band corresponding to (I) could not be found. The question arises as to why the band splits into only two components. A possible explanation is that the predicted $\delta(H_2O)$ value for (I) is different from that for (III). The presence of two Cl^- ligands at the cis positions for H_2O would increase the $\delta(H_2O)$ value for (I). To make this more clear, the spectra of $[CoCl_2(NH_3)_2(H_2O)_2]HSO_4$ were measured (Table 1). Although the crystal structure of this complex has not been clarified, Kyuno[11] has given a coordination structure which was presumed from its UV and IR spectra; two chloro ligands coordinate in the trans positions, as well as two ammine and two aqua ligands in the cis positions. Therefore, the first band should consist of two components corresponding to



(IV)

and



(V)

The position corresponding to skeleton (**IV**) can then be calculated from the values in Table 3:

$$\frac{1}{2}\delta(H_2O) + \frac{1}{2}\delta(NH_3) = 18.37 \quad (4)$$

The value is in good agreement with the observed value, 18.48×10^3 cm^{-1} (Table 1). Therefore, skeleton (**V**) should correspond to the value observed at 15.63×10^3 cm^{-1}; thus

$$\frac{1}{2}\delta(Cl^-) + \frac{1}{4}\delta(H_2O) + \frac{1}{4}\delta(NH_3) = 15.63. \quad (5)$$

From the resuls described above, the component corresponding to (1) should appear at about 15.63×10^3 cm^{-1}. Thus, it is considered that in a dichro salt, the band which could not been found overlaps with the component (2) in the band at 15.75×10^3 cm^{-1}.

It has been shown for a series of aqua and chloro amminecobalt(III) complexes that the positions of components of the first absorption band qualitatively follow Yamatera's rule and also that an excellent quantitative agreement between the rule and experiments can be obtained by using parameter values which are derived by taking into account the effect of coexisting ligands.

The authors are greatly indebted to Dr. Masahiro Morita of the Science University of Tokyo for making programming and computer time available for this study. They also thank Dr. Haruo Yamamoto of Meisei University for the technical service regarding the apparatus. One of authors (Y. M.) thanks Dr. Hisao Hidaka of Meisei University for his encouragement.

Synthesis and Electrical Conductivity of a New Family of Pt Mixed Valence Complexes: $Pt_6(NH_3)_{14}Cl_{10}X_4$ (X=ClO_4, BF_4, and PF_6)

Masako TANAKA* and Ikuji TSUJIKAWA
Department of Chemistry, Faculty of Science, Kyoto University,
Kitashirakawaoiwake-cho, Sakyo-ku, Kyoto 606
(Received February 10, 1986)

A new family of Pt mixed valence complexes: $Pt_6(NH_3)_{14}Cl_{10}X_4$ (X=ClO_4, BF_4, and PF_6) was synthesized from the Magnus green salt (MGS) by the partial oxidation using an oxidant of H_2O_2 or by electrochemical method. On partial oxidation, the 1/6 of Cl^- ligands in MGS are randomly replaced by NH_3 ligands and simultaneously counter ions X are introduced. These complexes comprise of one-dimensional chains with direct contact between Pt atoms and consequently a quasi-one-dimensional band made up of $5d_{z^2}$ orbital of Pt is formed. The average valence of Pt is +2.33 and the distance between Pt atoms along a chain is shorter than or comparable to that of $K_2[Pt(CN)_4]Br_{0.3}\cdot xH_2O$ (KCP). The electrical conductivity σ of these complexes was measured from 80 K to r.t. The σ(r.t.) is rather high in spite of the measurement on the powder pressed pellets. This suggests that σ along a chain direction may be as high as that of KCP if single crystals can be obtained. The conductivity data were fitted using a gap energy with various temperature dependence. In the complex with X=PF_6, there may be a phase transition caused by ordering of PF_6^- ions at about 110 K.

In the last decade, many quasi-one-dimensional compounds have been synthesized and intensively studied.[1] They comprise both organic and inorganic substances. Among organic charge transfer complexes, tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ) was most intensively studied in 1970's. TTF-TCNQ shows very high and anisotropic conductivity and shows metallic behavior down to 57 K at which it shows sharp metal-insulator(MI) transition, that is, the three-dimensional Peierls transition.[2] Since then, many analogues of TTF-TCNQ have been synthesized to suppress the Peierls transition and to obtain metallic state or superconductivity at low temperature.[3] Consequently, the first organic superconductor $(TMTSF)_2PF_6$ (TMTSF: tetramethyltetraselenafulvalene) was obtained, which has T_c of about 1 K under a pressure of 1.2 GPa.[4] Subsequently, $(TMTSF)_2ClO_4$, a superconductor below 1.4 K at an ambient pressure, was synthesized.[5] Recently a new class of sulfur-based organic conductors $(BEDT\text{-}TTF)_2X$ (X=ReO_4, I_3, IBr_2)(BEDT-TTF: bis(ethylenedithio)tetrathiafulvalene) have been synthesized and studied intensively.[6] At present it arrives at the stage of seeking a superconductor with higher transition temperature in organic compounds. On the other hand, in transition metal mixed valence complexes, KCP, one of Krogmann salts,[7] was the most studied substance in 1970's.[2,8] It shows a high and anisotropic conductivity at room temperature and shows a giant Kohn anomaly characteristic of one-dimensional compounds. But it does not show distinct transition of three-dimensional ordering to the Peierls state, because of the randomness caused by Br^- which occupies 60% of the crystallographic sites and partially oxidizes Pt atoms. And it has been found that the metal dithiolates such as $Li_{0.8}[Pt(mnt)_2](H_3O)_{0.3}\cdot 1.7H_2O$[9] (mnt: maleonitriledithiolate) and the metallomacrocycle complexes such as Ni(Pc)I[10] (Pc: phthalocyanine) have rather high conductivity, though their conductivity is due to π electrons. Recently, the transition metal trichalcogenide MX_3 and the blue bronze attract much attention from the fact that the theoretically expected Peierls–Fröhlich state is realized in these compounds.[8] In any way, since 1980, none of transition metal complexes with conductivity due to d electrons has attracted interests. Only the third model of excitonic superconductor by KCP-like complex was proposed by W. A. Little.[11]

As mentioned above, though KCP is a good model as the quasi-one-dimensional conductor, which comprises the quasi-one-dimensional band made up of $5d_{z^2}$ orbital of transition metal, the elucidation of its physical properties has not yet been achieved. Therefore, it will be worthwhile that the transition metal complexes with more excellent properties than KCP will be found, that is, with higher conductivity, with free of randomness and with lower temperature of the Peierls transition.

We intended to elucidate the mechanism of the MI transition in the one-dimensional conductor with $5d_{z^2}$ band, so that we planned to synthesize new substances which are free from randomness and do not contain water of crystallization which drastically changes physical properties. For the preparation of such compounds, we choose the Magnus green salt $[Pt(NH_3)_4][PtCl_4]$ (abbreviated as MGS hereafter) as a starting material, which has the columnar structure and the filled band made up of $5d_{z^2}$ orbitals of Pt atoms. Then, MGS is partially oxidized by replacing a ligand NH_3 or Cl^- with another ligand with a different charge. Once Pt^{2+} is oxidized to Pt^{4+}, the position vertical to the coordination plane is labile and readily coordinated by donor ligands, such as Cl, Br, I, H_2O, etc. Therefore, the oxidation reaction must take place in a strong acid solution without any other ligands to coordinate in order to retain the one-dimensional chain structure.[12] Hence, the oxidation was proceeded in a $HClO_4$, HBF_4 or HPF_6 acid solution. As the result, we could obtain new mixed valence complexes of Pt; $Pt_6(NH_3)_{14}Cl_{10}X_4$ (X=ClO_4, BF_4, and PF_6)(hereafter abbreviated as POC, POB, and POP respectively). The synthesis, crystal structure

and electrical conductivity of the complexes are reported in this paper.

Experimental

Preparation. Powder of MGS is suspended in 10% $HClO_4$, HBF_4, or HPF_6 solution at room temperature and is oxidized for a few weeks by oxidant of H_2O_2 or by electrochemical method. Consequently, green MGS is changed to the partially oxidized salt POC, POB, or POP. They are brown with metallic luster. Partially oxidized salts thus obtained are in powder form, however, fibrous small needles crystallize from the filtrate. The acids, HPF_6, and HBF_4 are decomposed on heating so POB and POP cannot be recrystallized from these acids, while recrystallization of POC can be made from 2—40% $HClO_4$ solution. The crystals are dichroic with dark brown and colorless for polarized light parallel and perpendicular to the needle axis, respectively.

Structure. Though complete analysis of structure has not been achieved because of the smallness of single crystals of these three compounds, the lattice constants are determined from powder patterns of X-ray diffraction and from X-ray oscillation photographs about the needle axis as well for POC and POB. For POB, lattice constants could be determined on a four-circle diffractometer. IR spectra of POC are observed with KBr pellets.

Electrical Conductivity. The d.c. conductivities of pressed pellets of POC, POB, and POP prepared under pressure of 2.7—3.6×10⁸ Pa were measured between r.t. and 80 K by the two probe method using silver paste for electrodes' contact.

In addition, thermal properties were examined using a DSC between 100 K and r.t.

Results

Elemental analyses were carried out mainly for POC, because POC could be prepared with high purity by the recrystallization, as mentioned above. Found: H, 2.10; N, 8.77; Cl, 22.97; O, 12.06%. Calcd for $Pt_3N_7H_{21}Cl_7O_8$: H, 1.96; N, 9.07; Cl, 22.96; O, 11.84%. POC and POB were determined to be isomorphous from X-ray powder patterns. For POP, Found: H, 1.94; N, 8.41%. Calcd for $Pt_3N_7H_{21}Cl_{10}P_2F_{12}$: H, 1.81; N, 8.37%.

Table 1. Lattice Constants of POC, POB, and POP (Å)

	POC	POB	POP
a	15.07	14.917	6.93
c	5.62	5.696	5.78

POC, POB, and POP belong to tetragonal system and their lattice constants are listed in Table 1. There were no diffuse lines in oscillation photographs of POC and POB. IR spectra for POC which are consistent with the T_d symmetry of ClO_4 suggest that ClO_4 is introduced not as ligand but as a counter ion. The data are listed in Table 2 together with the data from literature.[13]

The experimental results of the electrical conductivity σ measured on heating from liquid N_2 temperature to room temperature are shown in Fig. 1. Conductivity maxima σ_{max} appear at about 287 K(T_{max}) and 273 K

for POC and POP, respectively and below T_{max}, POC and POP are semiconductive. POB is semiconductive in all temperature region observed, though a slight shoulder is observed at 276 K. If σ in the semiconductive region is expressed as $\sigma=\sigma_0\exp(-E_a/k_BT)$, the activation energy E_a becomes considerably small. They are listed in Table 3 together with the values of the conductivity at room temperature. Above T_{max}, they are metallic in the sense of $d\sigma/dT<0$. The MI transition mentioned above takes place in temperature region rather broad as in KCP or NMP-TCNQ (NMP: *n*-methylphenazine). Above 313 K(T_{min}) for POC, σ is again semiconductive with a rather large E_a of an order of 1 eV. While, their starting material MGS is semiconductive over all temperature region with $E_a\simeq0.19$ eV.

No anomalies can be detected in thermal analyses by the DSC for MGS and its partially oxidized complexes unlike a ligand substituting mixed valence complex $Pt_6(NH_3)_{10}Cl_{10}(HSO_4)_4$ (POS) where a glass transition caused by freezing of internal rotation of substituted ligand of HSO_4^- and a structural transition were observed.[14]

Discussion

In MGS, the Pt atoms coordinated in plane by NH_3 and by Cl are stacked alternately and form one-dimensional chains with direct contact of Pt. In the present partially oxidized complexes, the repeating distance in the chain direction is twice of the distance between Pt atoms, retaining the periodicity of the starting material MGS. On the other hand, the averaged valence of Pt, +2.33 evaluated from the formula, suggests that the repeating distance in the chain direction is six times of the distance between Pt atoms. This implies that two of twelve Cl ligands of three molecules of MGS -[$Pt(NH_3)_4$]-[$PtCl_4$]-[$Pt(NH_3)_4$]-[$PtCl_4$]-[$Pt(NH_3)_4$]-[$PtCl_4$]- are randomly replaced by NH_3 ligands in such a way that NH_3 ligands locate in positions trans to Cl^- ligands, which results from a stronger trans-effect of Cl^- than that of NH_3. Then introduced counter ions are assumed to locate between the chains and to form the hydrogen bonding with NH_3. The ligand substitution and the introduction of counter ions result in the partial oxidation, as the result of which 1/6 of Pt atoms changes their valence from +2 to +4 to provide a mixed valence state. The averaged valence of Pt becomes +2.33. This value itself is commensurate with the lattice unlike in KCP. Because of this partial oxidation, the distances between Pt atoms along a chain become shorter from 3.25 Å for MGS[15] to 2.81, 2.85, and 2.89 Å for POC, POB, and POP, respectively. They are comparable to or shorter than that of KCP (2.89 Å)[8] and closer to the value for Pt metal of 2.77 Å. This shrinkage of the distance between Pt atoms comes from the smallness of the substituted ligand of NH_3, which excludes the steric hindrance, and reflects the bare effect of the partial oxidation.

Proposed structure viewed along the chains is given in Fig. 2. The lattice parameter a for POB is smaller than that of POC. This can be explained by the difference in the bond lengths in the counter anions of 1.43 Å[16] and 1.44 Å[16] for B-F (in BF_4^-) and Cl-O (in ClO_4^-), respectively. The parameter a is twice the distance between the nearest neighbour chains. This must come from the lack of the inversion center in a tetrahedral counter anion. The disorder in a chain could not bring about such doubled periodicity. A counter anion with a T_d symmetry can have two probable orientation. The difference in the orientation causes the doubled periodicity. On the other hand, for POP, in which there are octahedral PF_6^- ions, the lattice constant a is the distance between the nearest neighbour chains. The bond length of P-F (1.58 Å (in PF_6^-))[17] is longer than those of Cl-O and B-F, but the lattice constant a is shorter than a half of those of POC and POB. POP may have a different form of packing of counter anions from that in POC and POB.

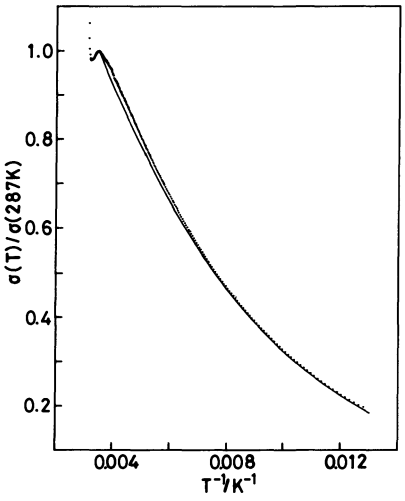

Fig. 3. Electrical conductivity of POC. Dots are the experimental data. Solid line is calculated using $\sigma=\sigma_0 \ln(1+\exp(-E_g/2k_BT))$ with $E_g=390$K (34 meV).

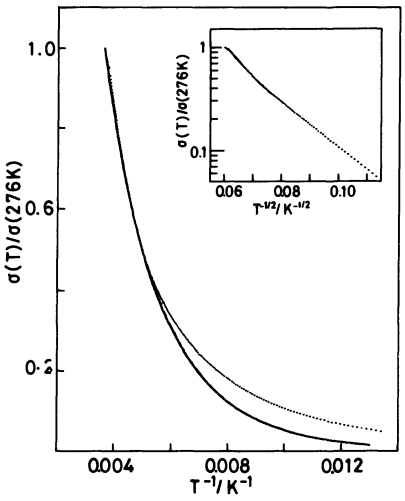

Fig. 4. Electrical conductivity of POB. Dots are the experimental data. Solid line is calculated using the gap energy with temperature dependence of $E_g(T)=E_g(0)(1-T^2/T_c^2)$, where $E_g(0)=760$K (65 meV) and $T_c=276$K. The plot of $\sigma(T)/\sigma(276\text{K})$ against $T^{-1/2}$ is shown in the inset.

Next, we will discuss the temperature dependence of the d.c. conductivity of these new mixed valence complexes of Pt. The conductivity values of the partially oxidized complexes are alike each other and rather high in spite of the measurements on the powder compressed pellets. It is surprising when we notice that the densities of electrons in conductivity of the present complexes comes from the fact that Pt atoms are partially oxidized and the distance between Pt atoms becomes shorter. The values of σ are almost the same as that of KCP. This suggests the conductivity along the chain axis will be as high as that of KCP ($\sigma_{//}=3.5\times10^2$ S cm^{-1} at r.t.),[18] if single crystals can be obtained. We obtained the conductivity only for compressed pellets as mentioned above, so we cannot analyse it quantitatively but may discuss its temperature dependence. The temperature dependence of these complexes differs each other. POC and POP show gradual MI transition at 287 and 273 K, respectively, and for POB at about 276 K a slight shoulder is observed in the conductivity. The MI transition mentioned above is probably the Peierls transition as in KCP. The transition temperature is higher and the activation energy is smaller than those of KCP. Though the temperature dependence of the conductivity above the transition temperature is also of interest in elucidating the nature of this transition, our data are not yet sufficient to make extensive analysis. Therefore, we will only discuss the temperature dependence below the transition temperature. Since the gap energy $E_g(=2E_a)$ is rather small and comparable to k_BT, we must use an explicit form of the Fermi distribution function $f(E)=1/(1+\exp(\beta(E-\zeta)))$ on calculating the number of electrons n in a conduction band, where ζ is the chemical potential and $\beta=1/k_BT$. As n is thought to be small, the temperature dependence in ζ is neglected. Assuming the energy independent constant density of state $N(0)$ at the conduction band, n is derived to be $n=N(0)k_BT\ln(1+e^{\beta\zeta})$. When the origin of energy is taken to the bottom of a conduction band, $\zeta=-E_g/2$, where E_g is the gap energy open up due to the Peierls transition. Since the conductivity σ is expressed using relaxation time τ and effective mass m^* as $\sigma=ne^2\tau/m^*$, $\sigma=\sigma_0\ln(1+\exp(-E_g/2k_BT))$ when we take $\tau\propto T^{-1}$ as in a metal. Even though there will remain the probability that random potential due to ligand substitution do randomly localize electrons in a chain. In this case $\zeta=-E_g$ is taken in the above formulation. The electrical conductivity data are usually fitted empirically using a gap energy with a various temperature dependence[14,19]; BCS-type $E_g(T)=E_g(0)(1-T/T_c)^{1/2}$, $E_g(T)=E_g(0)(1-T^2/T_c^2)$, and $E_g(T)=E_g(0)/(1+\exp(T-T_c)/T)$ and temperature dependent mobility[20] $\mu\propto T^{-\alpha}$. Then, the temperature dependent gap energy is taken as the order parameter. When there exists structural disorder in one-dimensional system, all electrons are localized at $T=0$K. Therefore, electrical conductivity can occur mainly by phonon assisted hopping. Then the conductivity can be expressed[21] as $\ln(\sigma/\sigma_0)=-(T_0/T)^{1/2}$.

For POC, $\sigma=\sigma_0\ln(1+\exp(-E_g/2k_BT))$ with temperature independent gap energy $E_g=390$ K(34 meV) gives a good agreement with experimental values as shown in Fig. 3. If the temperature dependence is introduced in the gap energy, the deviation becomes appreciable especially in higher temperature region. This temperature independence of the gap energy indicates

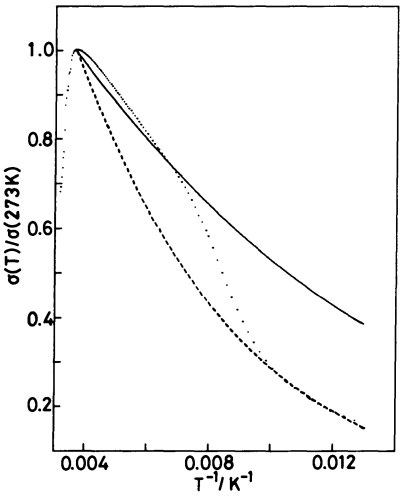

Fig. 5. Electrical conductivity of POP. Dots are the experimental data. Solid line and broken line are calculated using $\sigma=\sigma_0 \ln(1+\exp(-E_g/2k_BT))$ with E_g=240K (21 meV) and E_g=440K (38 meV) respectively.

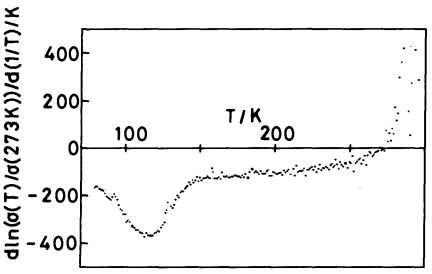

Fig. 6. Logarithmic derivation of the conductivity dln $(\sigma(T)/\sigma(273\text{K}))/\text{d}(1/T)$ plotted as a function of the temperature for POP.

that none of the previous forms of the gap function is applicable. Hence, the MI transition might be induced by structural phase transition, though anomaly cannot be detected in the DSC measurement. Conductivity of POB cannot be expressed in a single formula of σ. Above about 200 K, the gap energy with a temperature dependence of $E_g(T)=E_g(0)(1-T^2/T_c^2)$ gives best fit to the data, where $E_g(0)$=760 K(65 meV) and T_c=276 K. In the region from 77 K to 150 K, the plot of $\log\sigma$ against $T^{-1/2}$ gives linear relation as shown in Fig. 4. This suggests defects or imperfections in a chain and that conductivity due to hopping is dominant at lower temperature as observed in KCP. Conductivity of POP differs considerably from those of POC and POB. There is a change in the temperature dependence at about 110 K. The temperature independent gap energy about 240 K(21 meV) above 110 K and that about 440 K(38 meV) below 140 K give best fit to the experimental results as shown in Fig. 5. A plot of $\text{d}(\ln(\sigma/\sigma_{298\text{K}}))/\text{d}(1/T)$ against T shows minimum at about 110 K as shown in Fig. 6. There is a possibility that the structural phase transition takes place at 110 K. Above 110 K, counter ions PF_6^- freely rotate or librate between two statistically equivalent positions, and below 110 K PF_6^- ions takes a kind of ordering. Such behavior of octahedral anions is observed for $(TMTTF)_2SbF_6$ (TMTTF: tetramethyltetrathiafulvalene) at 154 K where MI transition takes place.[22]

We could synthesize a new family of transition metal complexes $Pt_6(NH_3)_{14}Cl_{10}X_4$. The conductivity is very high, though randomness cannot be excluded. Various kinds of temperature dependent conductivity are observed in these complexes. The behavior depends on the counter anions. Counter anions both tetrahedral and octahedral can be introduced by altering the acid on synthesis. The syntheses of complexes with other anions such as ReO_4^- and AsF_6^- are in progress. We are also trying to grow single crystals in order to make clear the crystal structure and physical properties. Furthermore, conductivity measurements with four-probe and under a high pressure are in progress in order to elucidate the gradual MI transition.

The authors wish to express their sincere thanks to Professor Tsuyoshi Murao and Dr. Yoshitami Ajiro of Kyoto University for their helpful discussions. We also would like to thank to Dr. Koshiro Toriumi of I.M.S. and Professor Tasuku Ito of Tohoku University for obtaining the lattice constants of POB on a four-circle diffractometer.

The Solvent-Extraction Equilibrium of Vanadium(III, IV, V) with Acetylacetone in Nonpolar Solvents

Hisanori IMURA and Nobuo SUZUKI*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received April 9, 1986)

The extraction of vanadium(III, IV, V) with 0.01—0.1 mol dm^{-3} acetylacetone in such nonpolar organic solvents as heptane, benzene, and chloroform has been investigated at pH 1—7 under a nitrogen atmosphere. The extraction constant, the partition coefficient, and the stability constant for the vanadium(III) and vanadium(IV) chelate were determined. Vanadium(V) was found to have been extracted as the vanadium(IV) chelate with reduction.

Vanadium is present in aqueous solutions in +2, +3, +4, and +5 oxidation states. In the presence of air, the quadrivalent and quinquevalent states are stable. Recently, the extraction equilibrium of vanadium has been investigated by using some chelating agents such as 8-quinolinol for vanadium(V)[1] and dithizone for vanadium(IV, V).[2] On the other hand, the spectrophotometric determination of vanadium using the extraction of vanadium(III) with 50% acetylacetone in chloroform has been previously reported.[3] However, little is known about the extraction equilibrium of vanadium in lower oxidation states, especially of vanadium(III).

In the present paper, the extraction chemistry of vanadium (III, IV, V), which are expected to occur in nature, is systematically studied in acetylacetone-nonpolar organic solvent systems.

Experimental

Reagents. A radioisotope, ^{48}V, was produced from high-purity titanium foils by a (p,n) reaction with 18 MeV protons using a cyclotron of Tohoku University. The titanium targets were dissolved in diluted sulfuric acid, and an excess amount of hydrogen peroxide was added to oxdize the titanium carrier to the quadrivalent state. After the excess of hydrogen peroxide has been removed by heating, carrier-free ^{48}V was extracted with 0.02 M(1 M=1 mol dm^{-3}) diethylammonium diethyldithiocarbamate in carbon tetrachloride at pH 4.5—5, washed with an aqueous solution at pH 4.5, and back-extracted with 10 M nitric acid. This solution was evaporated to dryness and dissolved in concentrated hydrochloric acid. Then the solution was fed into an anion-exchange column (Dowex 1X8, 0.8 cm inner diameter ×10 cm height) and eluted with concentrated hydrochloric acid. The ^{48}V fraction was collected and evaporated to dryness. To the residue, concentrated nitric acid was added, and the mixture was heated to completely decompose organic impurities and then evaporated to dryness. Finally, ^{48}V was dissolved in 0.01 M perchloric acid or sulfuric acid.

A carrier solution of vanadium(V) (ca. 0.02 M) was prepared by dissolving high-purity vanadium(V) oxide (Specpure; Johnson Matthey Chem., Ltd.) in perchloric acid or sulfuric acid. The radioactive vanadium(V) solution (10^{-4}—10^{-2} M) was prepared by mixing an appropriate amount of the vanadium(V) carrier and carrier-free ^{48}V, evaporating the mixture to dryness, dissolving it in 0.5 M perchloric acid, and heating it for about 1 h. To confirm the isotopic equilibrium of vanadium, the radioactive vanadium(V) in a 0.1 M sodium hydroxide solution was also prepared and used for the extraction of vanadium(V). The radioactive vanadium(IV) solution was prepared by reducing the vanadium(V) with sodium hydrogensulfite: to the radioactive vanadium(V) in a sulfuric acid solution, sodium hydrogensulfite (ca. 1 M) was added, and the excess of sulfite was removed by heating.

The 2,4-pentanedione(acetylacetone, Hacac) was washed with a diluted ammonia solution and water and then doubly-distilled through a fractionating column after drying. The tris(acetylacetonato)vanadium(III)[V(acac)$_3$] was prepared by the method of Dilli and Patsalides[4] and used to examine its stability in solutions for air oxidation. The oxobis(acetylacetonato)vanadium(IV)[VO(acac)$_2$] was obtained from Dojindo Laboratories. The chloroform was of a spectroscopic grade and was washed with redistilled water several times before use. The other organic solvents were purified by the usual methods. Unless otherwise stated, the reagents used were of a guaranteed reagent grade.

The ionic strength of an aqueous phase was kept at 0.10 M by the use of perchloric acid and sodium hydroxide. The pH of the aqueous phase was adjusted with 0.01—0.10 M perchloric acid, 0.01 M acetic acid, and 0.01 M sodium hydroxide. All the reagent solutions used for the extraction of vanadium(III) and vanadium(IV) were purged for 30 min with nitrogen which had been purified through a pyrogallol-potassium hydroxide solution just before use.

Apparatus. The γ-activity of ^{48}V was measured with an NaI(Tl) well-type scintillation counter. The electronic spectrum of the vanadium chelate was measured with a doublebeam spectrophotometer. The pH value of the equilibrated aqueous phase was measured with a glass electrode.

Extraction Procedure of Vanadium(III). When vanadium(III) was prepared by the reduction of vanadium(V), the purification of the vanadium(III) formed was found to be inevitable if reliable extraction data were to be obtained. Hence, an organic vanadium(III) solution was prepared and purified as follows, and the distribution ratio of vanadium(III) was determined by the back-extraction technique. A stream of purified nitrogen was passed through an 80-cm^3 extraction vessel with three necks in order to displace the air. An aqueous solution (pH 3—5) containing radioactive vanadium(V) (ca. 1×10^{-4} M) and an organic solvent containing 0.01—0.1 M Hacac were then placed in the vessel, and the mixture was stirred. A small amount of 2 M

sodium dithionite as a reducing agent was added to the contents to make up about a 0.05 M concentration of dithionite. Then the contents were vigorously stirred for 1—3 h. After the mixture had been left to stand, the organic phase was taken out and stirred again with a perchloric acid solution in an appropriate concentraion (0.01—0.1 M) to remove a small amount of the vanadium(IV) complexes from the organic phase. To the purified organic phase containing $V(acac)_3$ we then added an appropriate amount of Hacac, after which the solution was diluted with the organic solvent to adjust it to the desired concentrations of Hacac (0.01—0.1 M) and $V(acac)_3$ (10^{-6}—10^{-5} M). This organic solution (5 cm^3) was shaken with an aqueous solution (5 cm^3) for 1—24 h at pH 1—7 in a stoppered centrifuge tube in which the air had been displaced with nitrogen. After centrifugation, an aliquot was pipetted out from each phase, and the γ-activity was measured. The distribution ratio(D) of vanadium(III) was calculated by the counting rates. The equilibrium pH value was measured immediately after shaking. To confirm the extraction equilibrium, the forward extraction was also performed, and the distribution ratio was measured. Vanadium(III) was back-extracted with 1.0 M perchloric acid from the organic phase. A 0.5-cm^3 portion of the aqueous vanadium(III) solution was added to the centrifuge tube containing the organic (5 cm^3) and the aqueous phase (4.5 cm^3), and the contents were shaken. All the extraction procedures were performed under a nitrogen atmosphere at 25 °C.

Extraction Procedure of Vanadium(IV). An aqueous solution (5 cm^3) containing 1×10^{-5} M radioactive vanadium(IV) was shaken with an organic solution (5 cm^3) containing 0.1 M Hacac for 1—6 h in a centrifuge tube. After centrifugation, an aliquot was pipetted out from each phase, and the γ-activity was measured. In the back-extraction, the organic phase obtained by the forward-extraction was shaken with a fresh aqueous phase. All the extraction procedures were performed under a nitrogen atmosphere at 25 °C.

Extraction Procedure of Vanadium(V). An aqueous solution (5 cm^3) containing 10^{-6}—10^{-4} M radioactive vanadium(V) was shaken with an organic solution (5 cm^3) containing 0.01—0.1 M Hacac for 24 h at 25 °C. The distribution ratio was determined in the same manner as that in vanadium(III, IV). Only the back-extraction was performed under a nitrogen atmosphere.

Theoretical

The extraction equilibrium of a metal ion, M^{n+}, with a chelating agent, HA, can be expressed as follows:

$$M^{n+} + nHA_{org} \rightleftharpoons MA_{n,org} + n\,H^+ \quad (1)$$

$$K_{ex} = \frac{[MA_n]_{org}[H^+]^n}{[M^{n+}][HA]^n_{org}}, \quad (2)$$

where the subscript "org" denotes the organic phase, and K_{ex}, the extraction constant. The distribution ratio of the metal can be written as:

$$D = \frac{[MA_n]_{org}}{[M^{n+}] + \sum_{m=1}^{n} [MA_m{}^{(n-m)+}]}. \quad (3)$$

Equation 3 can be rewritten by using the partition coefficient of the neutral chelate(MA_n), P_M, and the overall stability constant of $MA_m{}^{(n-m)+}$ in the aqueous phase, β_m:

$$D = \frac{P_M\beta_n[A^-]^n}{1 + \sum_{m=1}^{n} \beta_m[A^-]^m} \quad (4)$$

$$= K_{ex}\left(\frac{P_{HA}}{K_{HA}}\right)^n \frac{[A^-]^n}{1 + \sum_{m=1}^{n} \beta_m[A^-]^m}, \quad (5)$$

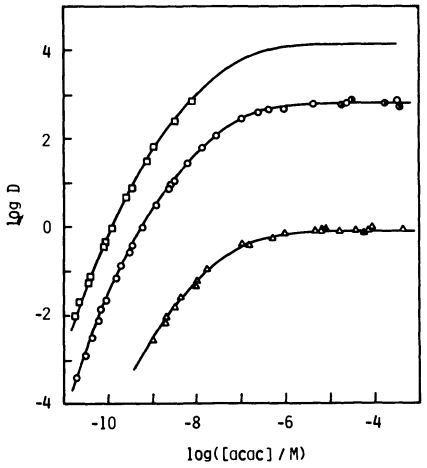

Fig. 3. Distribution ratio of vanadium(III) as a function of acac concentration in the aqueous phase. The solid lines indicate the computed values.

Results and Discussion

Extraction of Vanadium(III). Since vanadium(III) is unstable in the presence of oxygen, the stability of $V(acac)_3$ solutions was examined by using the chelate synthesized in an inert gas atmosphere. Figure 1 shows the absorbance of the chelate in heptane solutions as a function of the standing time. It gradually decomposes in a heptane solution saturated with air until it has completely decomposed after standing for four days. In that solution, the formation of $VO(acac)_2$ due to the oxidation of $V(acac)_3$ was observed from the absorption spectrum. However, the addition of Hacac significantly prevents the oxidation decomposition, even in the presence of air. In addition, the vanadium(III) chelate is quite stable in a heptane solution saturated with nitrogen.

Under a nitrogen atmosphere, the extraction of vanadium(III) with Hacac in an organic solvent was first attempted using an aqueous vanadium(V) solution and a strong reducing agent, such as sodium dithionite or sodium borohydride. However, it was found that the complete conversion of vanadium(V) to vanadium(III) was difficult. Hence, in order to obtain accurate distribution data on vanadium(III), we adopted the back-extraction technique described above. Figure 2 shows the extraction curves of vanadium(III) with 0.10 M Hacac in heptane, benzene, and chloroform. The distribution ratio obtained from the forward extraction is in good agreement with that obtained from the back extraction. This fact means that the extraction equilibrium was completely

achieved within the agitation time given in each solvent system; 1—120 min for the heptane system, 2—6 h for the benzene system, and 18—24 h for the chloroform system, at pH 1—2. The solid lines indicate the values calculated using the equilibrium constants determined as below.

Moreover, the detailed extraction of vanadium(III) was performed with a different amount of Hacac in the organic solvent (0.01—0.10 M) at pH 1—7. Figure 3 shows the plots of log D against the logarithm of the equilibrium concentration of the acac anion in the aqueous phase. The equilibrium concentration of acac was calculated by using the following equation:

$$[A^-] = \frac{C_{HA}}{(P_{HA}+1)[H^+]/K_{HA}+1}, \quad (6)$$

where C_{HA} denotes the initial concentration of Hacac. The literature values of K_{HA} and P_{HA} were used; i.e., log K_{HA} was -8.82,[5] and log P_{HA} was -0.052 for heptane,[6] 0.736 for benzene,[7] and 1.367 for chloroform.[7] In the low-concentration region of acac, the slope for the plots of log D vs. log [acac] is 3, as is to be expected from the extraction of $V(acac)_3$. The equilibrium constants, P_M and β_m, can be determined according to Eq. 4: the P_M values in the heptane and benzene system were directly determined as the limiting value of the distribution ratio in the high-concentration region of acac. The stability constants, β_1, β_2, and β_3, were determined by the least-square fitting (SALS program, University of Tokyo) on the basis of Eq. 4, using the distribution data in the benzene system. The P_M value in the chloroform system was determined by the least-square fitting using the β_1, β_2, and β_3 values obtained above. The K_{ex} value was calculated as $K_{ex}=P_M\beta_3K_{HA}^3P_{HA}^{-3}$. The equilibrium constants are listed in Table 1. The solid lines in Fig. 3 indicate the values computed using these equilibrium constants, they are in good agreement with the experimental plots.

Extraction of Vanadium(IV). Figure 4 shows the extraction curves of vanadium(IV) with 0.10 M Hacac in heptane, benzene, and chloroform. The distribution ratio of vanadium(IV) did not vary at various agitation times from 1 to 6 h. The distribution ratio obtained from the back-extraction is in good agreement with that obtained from the forward extraction, and the extraction equilibrium is completely achieved. Figure 5 shows the plots of log D against log[acac]. In the low-concentration region of acac, the slope for the plots is 2, as is to be expected from the extraction of $VO(acac)_2$. The P_M value in each solvent system was directly determined as the limiting value of the distribution ratio in the high-concentration region of acac. The stability constants, β_1 and β_2, were determined by the least-square fitting on the basis of Eq. 4, using the distribution data in the benzene system. The K_{ex} value was calculated as $K_{ex}=P_M\beta_2K_{HA}^2P_{HA}^{-2}$. These values are listed in Table 1. The solid lines in Figs. 4 and 5 indicate the values computed using these equilibrium constants; they are in good agreement with the experimental plots.

Extraction of Vanadium(V). The extractability of vanadium(V) was much lower than those of vanadium(III) and vanadium(IV) and the extraction equilibrium could not be achieved. Figure 6 shows that the distribution ratio of vanadium(V) very gradually increases with an increase in the shaking time in both the benzene and chloroform systems. This phenomenon was also observed even at lower vanadium(V) concentrations such as 8.2×10^{-7} M. In such a low-concentration region, polynuclear species of vanadium(V), especially of metavanadates, which are relatively slow equilibrium species, are not formed.[8] Figure 7 shows the plots of log D against the pH at several shaking intervals. The gradual increase in log D is seen at pH 2—5 in the forward-extraction. On the other hand, the distribution ratios in the back-extraction are in agreement with those of vanadium(IV). This result was also obtained in the benzene system under similar extraction and back-extraction conditions. These facts suggest that vanadium(V) is reduced to vanadium(IV) and extracted as stable $VO(acac)_2$. This conclusion is consistent with the previous observation that the vanadium(V)-acetylacetone complex cannot be isolated because of its ready reduction to the quadrivalent state.[3]

Equilibrium Constants of Vanadium(III, IV). The equilibrium constants are summarized in Table 1. No data for vanadium(III) have been reported thus far. It was revealed that not only P_M, β_1, β_2, and β_3 for

Table 1. Equilibrium Constants in the Extraction of V(III) and V(IV) at 25 °C

Chelate	Solvent	$\log K_{ex}$	$\log P_M$	$\log \beta_1$	$\log \beta_2$	$\log \beta_3$
$V(acac)_3$	Heptane	−0.31	−0.112			
	Benzene	0.23	2.793	10.19	19.18	26.10
	Chloroform	−0.32	4.141			
$VO(acac)_2$	Heptane	−3.42	−1.979			
	Benzene	−3.08	−0.066	8.59	16.10	
	Chloroform	−3.12	1.157			

vanadium(III) are all almost the same as those for iron(III) in a series of first-transition metal(III)–acetylacetone chelates,[9] i.e., the equilibrium constants of iron(III) in the benzene system, log P_M=2.785, log β_1=10.63, log β_2=19.26, and log β_3=26.22. Such similarities are supported by the fact that the ionic radius of vanadium(III), 0.640×10^{-8} cm,[10] is quite close to that of iron(III), 0.645×10^{-8} cm[10]; additionally, the metal-oxygen-bond length in $V(acac)_3$ obtained by the X-ray crystallography, 1.982×10^{-8} cm,[11] is close to that in $Fe(acac)_3$, 1.992×10^{-8} cm.[11] These results suggest that the nature of the coordination bonds in the vanadium(III) chelate is hardly different from that in the iron(III) chelate. Consequently, the agreement of the partition coefficient between the vanadium(III) and the iron(III) chelate may be attributed to the similarity in the polarity of their bonds and in the solute-solvent interactions between the chelate and the organic solvent or water.

The equilibrium constants of $VO(acac)_2$ was compared with those of bis(acetylacetonato) chelates of the first-transition metals(II). It was found that the stability constant of the vanadium(IV) chelate is larger than that of the copper(II) chelate, *i.e.*, log β_1=7.93 and log β_2=14.56,[12] which are largest values among the first-transition metal(II) chelates. On the other hand, the partition coefficient of the vanadium(IV) chelate was considerably smaller than that of the copper(II) chelate; i.e., the log P_M in the benzene system is 0.897.[12] These facts may be attributed to the higher charge of the central metal as +4 as well as to the polarity of the oxo group in the vanadium(IV) chelate.

(Received April 25, 1986)

A voltammetric detection system for measuring the concentration of chloride ions in fresh concrete has been developed. A comparative determination using the Volhard titration method showed that the voltammetric system works as well in slushy concrete as in an aqueous chloride solution. No interference from the admixture was observed.

There is a growing trend to use sea sand instead of river sand for making concrete. However, sea sand is likely to contain a lot of chloride which can assist in the corrosion of reinforcing steel.[1,2] It is important, therefore, to determine the on-the-spot chloride content in fresh concrete in order to avoid exceeding the maximum limit. At present, various photoelectric, conductometric, and ion-selective detectors are available for measuring chloride ions in solution.[3] These detectors, however, present considerable technical difficulties when chloride-ion detection is attempted in fresh concrete.[3,4]

Preliminary studies[5,6] of a voltammetric method have shown that a voltammetric sensor has an excellent response to chloride in sea sand and fresh concrete samples. This paper reports the results of a study designed to develop a voltammetric system that seems to work as well in slushy concrete as in an aqueous solution.

Experimental

Instrumentation. A schematic diagram of the voltammetric detection system is shown in Fig. 1 together with the voltammetric sensor which consists of a small silver electrode (working electrode), a lead(II) sulfate/sodium sulfate electrode (reference electrode), and a stainless-steel electrode (counter electrode). Details regarding the voltammetric sensor have been previously described.[5]

The sensor was connected to a computer-controlled potentiostat consisting of an adder, a current-voltage converter(I/V), a sample-and-hold circuit(S/H), an analog-to-digital converter(A/D), display devices (LED, digital printer and x-y polotter), and a microcomputer. Bias and pulse voltages are applied to the adder through a summing resistor (omitted in Fig. 1), respectively. The pulse width of the pulse voltage is established by a pulse-time switch (digital). The start signal, initiated by depressing the start switch in the digital timing and control section, gates the pulse from the analog waveform generator to the potential

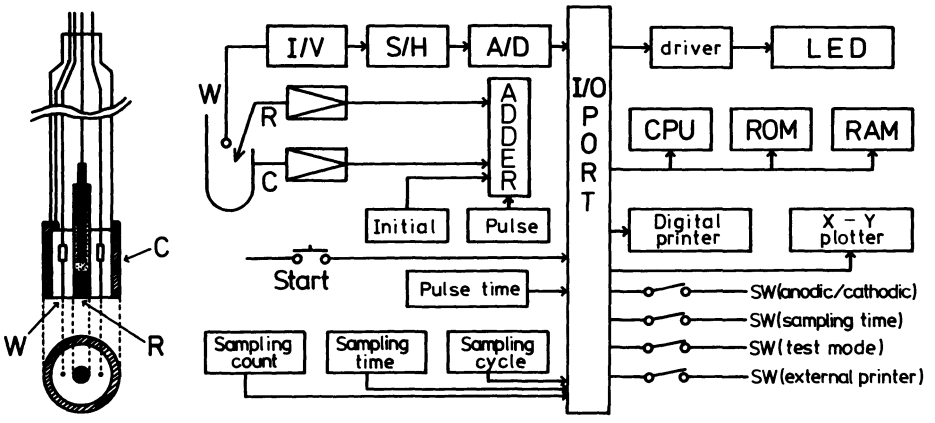

Fig. 1. Schematic diagram of the voltammetric sensor and the voltammetric detection system used for the determination of chloride ions in fresh concrete.
W: Working electrode, C: counter electrode, R: reference electrode, I/V: current-voltage converter, S/H: sample-and-hold, A/D: analog-to-digital converter, CPU: microcomputer, ROM: read-only memory, RAM: random-access memory.

control circuit and the cell. This also initiates a timing routine which controls the read signals to the analog-to-digital converter.

The current-monitoring sequence is accomplished by selecting three digital switches on a patchboard which controls the sampling count, sampling time and sampling cycle. The number of measurements and the interval of each run are controlled by a sampling-count switch and a sampling-cycle switch. A sample-and-hold circuit operates after the elapsed sampling time and the instantaneous current on chlonoamperogram is obtained. The analog-to-digital converter measures and converts the analog voltages from the current-measuring circuit. The digital information is stored in a random-access-memory unit. Upon completion of the measurements, the stored information can be recalled, then printed or plotted on an x-y plotter by operating a manual switch in the control section.

For a chloride determination, the electrolysis current is monitored only after the double-layer charging current has decayed. The working curve is stored in a read-only-memory unit and a fast determination of the chloride content is accomplished after comparing the current due to the chloride with a standard sample.

Procedure. During operation, the sensor is immersed in a concrete paste or paste filtrate with the working electrode held at 0.1 volt; at this potential silver chloride is reduced. Then, a 0.6-volt square-wave potential is applied to the working electrode and both the oxidation and reduction currents are monitored as a function of time. The electrode reaction is given by

$$Ag + Cl^- \longrightarrow AgCl + e \quad \text{(anodic)} \qquad (1)$$

and

$$AgCl + e \longrightarrow Ag + Cl^- \quad \text{(cathodic)}. \qquad (2)$$

The results of the oxidation currents are mainly described in this paper. Usually, the following values are used for measurements: 10—15 for sampling count, 30—50 ms for sampling time, and 1 s for a sampling cycle. The current data correspond to the sampling count; an average of these data are printed out by a digital printer. Current-time curves can be plotted on an x-y plotter if necessary.

Materials. Fresh concrete was prepared by mixing ordinary portland cement (Asano, Onoda, Denka, and Kaihatsu), mineral aggregate, and water. It also contained some air and sometime air-entraining agents (Pozzolith No. 70, obtained from Pozorisu Bussan Co.). Reagent-grade sodium chloride was added to the mixing water to make a solution of the desired chloride concentration.

Reagent-grade silver nitrate, ammonium thiocyanate, ammonium iron(III) sulfate and nitrobenzene were used in Mohr[7] or Volhard[8] titration.

Results and Discussion

When portland cement is mixed with water, the cement particles become dispersed in the water. This suspension changes from the liquid state (slurry) to a plastic or a stiff paste with time. At the same time, a series of reactions occur between the two materials. These reactions are aggregately called the hydration of the cement and are frequently discussed in the literature:[9,10]

$$2(3CaO\cdot SiO_2) + 6H_2O \longrightarrow 3CaO\cdot 2SiO_2\cdot 3H_2O + 3Ca(OH)_2 \qquad (3)$$

$$2(2CaO\cdot SiO_2) + 4H_2O \longrightarrow 3CaO\cdot 2SiO_2\cdot 3H_2O + Ca(OH)_2 \qquad (4)$$

$$3CaO\cdot Al_2O_3 + 6H_2O \longrightarrow 3CaO\cdot Al_2O_3\cdot 6H_2O \qquad (5)$$

$$4CaO\cdot Al_2O_3\cdot Fe_2O_3 + 2Ca(OH)_2 + 10H_2O \longrightarrow 3CaO\cdot Al_2O_3\cdot 6H_2O + 3CaO\cdot Fe_2O_3\cdot 6H_2O \qquad (6)$$

Rapid hydration occurs primarily between the tricalcium aluminate of the cement and water. Simultaneously, the water becomes saturated mainly with calcium hydroxide, calcium aluminate, and gypsum; slurry-cement solutions exhibit remarkably strong alkaline nature.

It has been known that a number of insoluble complex salts such as $3CaO\cdot Al_2O_3\cdot CaCl_2\cdot 10H_2O$ (Friedel salt), $3CaO\cdot Fe_2O_3\cdot CaCl_2\cdot 10H_2O$, and $3CaO\cdot Al_2O_3\cdot CaCl_2\cdot 32H_2O$ are formed with chloride ions if chloride is present in the solution.[11] In fresh concrete, however, a major portion of the chloride is present as free chloride ions. The chloride determination was tested under various analytical conditions.

Working Curve in Chloride Solutions. The current-concentration characteristics of the voltammetric sensor were tested in chloride solutions with varying sodium chloride concentrations. The anodic current was measured at 50 ms after the beginning of electrolysis. Typical examples of the results are plotted in Fig. 2; a well-defined working curve was obtained in the range 0—1% NaCl (by weight).

The analyst usually wishes to measure the concentration of the chloride ions rather than their currents; thus concentration standards are necessary. When a sodium chloride solution is used for calibrating the electrode, the linearity in the standard seems to be excellent (Fig. 2). Thus, the working curve in the computer's memory was standardized before use.

Working Curve of Chloride in Cement Paste. A working curve for a cement paste which was prepared from different (Onoda, Denka, and Kaihatsu) commercially available cements was tested. Also 50 g of

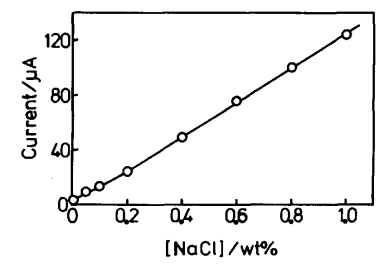

Fig. 2. Current-concentration characteristics of voltammetric sensor obtained in sodium chloride solutions (20 °C). sampling time=50 ms; sampling cycle=1 s.

portland cement was dissolved into 28 g of water containing various concentrations of sodium chloride. This cement paste was vigorously agitated in the thermostat(25 °C) for 20—30 min. Then, the sensor was immersed in a slushy paste and the current was measured fifteen times for a sampling time of 20 ms and a sampling cycle of 1 s. The average current for fifteen measurements was plotted against the chloride concentration after subtracting the background current.

The results are shown in Fig. 3. Although the background current due to the chloride-free-cement paste was somewhat different for each sample, a linear relation was found among those working curves: the slopes of the working curves were consistent with each other.

Reproducibility of Currents. The reproducibility of currents in a series of measurements was tested for a sodium chloride solution, a cement paste and fresh concrete. The composition of a cement paste is only cement and water, while fresh concrete contains water, cement, sand, gravel, and an air-entraining agent.

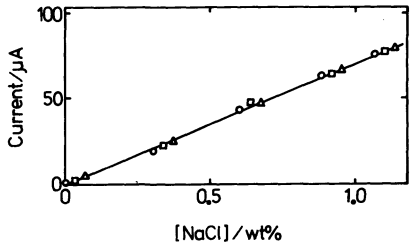

Fig. 3. Current-concentration characteristics of the voltammetric sensor obtained in cement pastes containing sodium chloride (25 °C).
Water/cement ratio=56%; sampling time=20 ms; sampling cycle=1 s.
○: Onoda cement, △: Denka cement, □: Kaihatsu cement.

The sensor was directly immerced in the solution, cement paste or mortar, and the current was measured every second with an appropriate sampling time (20—50 ms).

Examples of raw-current data for ten runs are given in Table 1. Though the voltammetric sensor used in these measurements was not the same, a good reproducibility was seen for different media. The precision between runs varied from 1.5 to 5% over a range of 0.05 to 0.5% chloride. The last two columns are the currents for ten determinations, which involve ten runs in each measurement.

In general, the currents obtained in fresh concrete and cement paste were found to be smaller than those of a sodium chloride solution; this might be caused by a higher viscosity of the cement and by a bleeding phenomenon. When a concrete, after consolidation but still plastic, is allowed to stand unagitated, water usually appears at the surface. This autogeneous flow of mixing water within (or its emergence from freshly placed concrete, mortar or paste) is called bleeding, or water gain.[12]

Determination of Chloride in Fresh Concrete. Many different concretes are now being produced under different technical and economical conditions for a wide variety of purposes. Selections of concrete ingredients should be based on the construction conditions, the type of concrete structure, and the price and properies of the ingredients. In experiments, two types of fresh concretes with different consistencies were prepared; one was the normal concrete (slump=12 cm) and the other was hard concrete (slump=3 cm).

Fresh-concrete types were produced, according to JIS A 1138,[13] by mixing ordinary portland cement, natural sand, crushed stone, an air-entraining agent, and water. A proper amount of sodium chloride was

a) Weight percent of NaCl for the weight of dry sand used. b) Difference between the voltammetric method and Volhard method.

added to the mixing water. The water/cement ratio was 48—55% and the sand/aggregate ratio was 42—44%. Table 2 summarizes the mix proportion used for the production of test concrete. The chloride concentration is usually expressed as the weight of sodium chloride divided by the weight of the small aggregate in a unit volume of concrete; this is the sodium chloride-sand ratio by weight.

The fresh-concrete types were filtered by an aspirator and the chloride content was measured by the voltammetric system. The chloride content was also determined by the Volhard method. Table 3 summarizes the results of the chloride content, slump and air content. The results show that the slump and air content agree with their target values; an adjustment of the batch weights for the test concrete was carried out satisfactory. Sample 1 (corresponding to no chloride content) showed a slight presence of chloride. This may have been caused by chloride contamination from the cement, air-entraining agent or water. However, it can be seen that the mutual relation between the voltammetric and Volhard methods was sufficiently estimated from the result of the measurements given in Table 3 (sample 1 through 4). The result of sample 5 shows that the voltammetric determination worked well for lower-water-content concrete; this method is applicable for concrete produced in general construction.

In conclusion, the convenience of this voltammetric system suggests that it could find on-the-spot applications in concrete manufacturing, in the construction industry, or for other consumers of concrete for a quality control of concrete.

The authors express their sincere thanks to Dr. Yoshikiyo Kato of Yamagata University for his continuous encouragements.

Mössbauer and DTA Studies of K_2SO_4-$ZnSO_4$-$Fe_2(SO_4)_3$ Glasses

Tetsuaki NISHIDA* and Yoshimasa TAKASHIMA

(Received April 30, 1986)

A structural study of ternary sulfate glasses has been performed to elucidate the nature of the chemical bond and the local structure of these glasses. Mössbauer parameters (isomer shift and quadrupole splitting) show drastic decrease with an increase in the K_2SO_4 content. This is ascribed to the gradual change in the coordination number of iron (Fe^{3+}) from six (Oh) to four (Td) when the K_2SO_4 content is higher than about 60 mol%. Lattice dynamic information obtained from low-temperature Mössbauer measurements suggests that the chemical bond between the iron and the neighboring oxygen is essentially ionic. All the Mössbauer results for the ternary sulfate glasses suggest that the Fe^{3+} ions are present at the vacant sites (voids) of the pseudospherical SO_4^{2-} ions which are considered to be randomly packed to constitute the ionic glasses. Glass transition temperature (T_g) of these sulfate glasses, obtained from DTA measurements, also shows a gradual decrease with increasing K_2SO_4 content. This result is very similar to the composition dependency of the Mössbauer parameters described above, and suggests that the ionic field strength of the sulfate glasses decreases with increasing K_2SO_4 content. These experimental results are ascribed to the increased intermolecular bond length between the pseudospherical SO_4^{2-} units.

Zinc sulfate-based glasses are considered to be constituted of randomly packed SO_4^{2-} ions which have essentially spherical geometry.[1-5] The feature of these glasses will lie in the essentially ionic nature of the chemical bond between the SO_4^{2-} ions and in the lack of so-called network structure. This is quite distinguishable from the case of ordinary oxide glasses such as silicate and borate glasses, in which each network-forming atom (Si and B) is covalently bonded with each other by oxygen atoms. As for the ionic salt glasses other than the $ZnSO_4$-based glasses, nitrate, nitrite, carbonate, formate, and acetate glasses are known to be present.[1] These ionic salt glasses seem to be very interesting and important materials from the scientific point of view, because their glass structure is quite different from the structure of ordinary oxide glasses, as described above. Coulombic interaction between cation (e.g., K^+ and Zn^{2+}) and anion (e.g., SO_4^{2-}) and a packing effect of them are therefore considered to be predominant factors for the preparation of the ionic salt glasses. Physical properties of some $ZnSO_4$-based glasses, such as density, refractive index, glass transition temperature, and heat capacity, have been studied by Rao et al.[2,3] They reported that the increase in the $ZnSO_4$ content results in gradual increases in density and refractive index of these glasses. A structural model for the K_2SO_4-$ZnSO_4$ glasses was proposed on the basis of the composition dependency of these physical properties.[2] A few structural studies of $ZnSO_4$-based glasses have been performed by means of X-ray diffraction[4] and ESR.[5,6] Coordination numbers of K^+, Na^+, and Zn^{2+} in the $ZnSO_4$-based glasses are known to be twelve, eight, and six, respectively.[2-4] An ESR study of binary K_2SO_4-$ZnSO_4$ glasses doped with Cu^{2+} or Mn^{2+} suggests that these transition metal ions occupy the octahedral sites, just as in the case of the Zn^{2+} ions surrounded by six oxygen atoms given by six SO_4^{2-} tetrahedra.[2]

The present Mössbauer and DTA (Differential Thermal Analysis) studies of the ternary K_2SO_4-$ZnSO_4$-$Fe_2(SO_4)_3$ glasses were carried out in order to obtain the structural information such as the coordination number and the symmetry of metal ions and the nature of the chemical bond between the metal ions and the SO_4^{2-} ions. Mössbauer spectroscopy is well utilized for the structural study of several inorganic glasses[7-18] by the authors. Mössbauer study of some halide glasses, i.e., KCl-$ZnCl_2$[17] and BaF_2-ZrF_4,[18] revealed that these glasses are constituted of three-dimensional network of $ZnCl_4$ tetrahedra and of the one- or two-dimensional chain-like polymer of ZrF_6 octahedra, respectively. DTA measurements also give us some useful information on the structure of glasses. In general, the increase in the coordination number of network-forming atom is known to result in a gradual increase in the glass transition temperature (T_g).[15,19-23] For example, step-by-step structural changes of network formers from BO_3 to BO_4 units and from GeO_4 to GeO_6 units are well reflected in T_g in borate and germanate glasses, respectively. This is probably due to the increased degree of bridging in the glass skeleton. On the other hand, a decreased degree of bridging in the glass skeleton, brought about by the formation of nonbridging oxygen atom, is observed as a gradual decrease in T_g.[15,22,23] As for the T_g of the $ZnSO_4$-based glasses, a composition dependency has so far been observed only in a ternary K_2SO_4-Na_2SO_4-$ZnSO_4$ glass system,[3] in which an increase in T_g is ascribed to the increased coordination number of alkali metal ion caused by the substitution of K_2SO_4 for Na_2SO_4.

Experimental

A series of K_2SO_4-$ZnSO_4$-$Fe_2(SO_4)_3$ glasses, in which $Fe_2(SO_4)_3$ content is lower than 12 mol%, were prepared by

fusing the individual mixtures (1 g) of K_2SO_4, $ZnSO_4 \cdot 7H_2O$, and $Fe_2(SO_4)_3$, of a guaranteed reagent grade, at 640—740 °C for 2—40 min using an electric muffle furnace. The anhydrous $Fe_2(SO_4)_3$ was prepared by heating the commercially available $Fe_2(SO_4)_3 \cdot nH_2O$ at 235 °C for 6 h, because the simultaneous DTA and TG (Thermal Gravity) measurements of the hydrous iron(III) sulfate proved to be almost completely dehydrated when heated at 235 °C. Each melt in a platinum crucible was quenched with ice-cold water after the fusion. All the glass samples prepared in this way show transparent and brown color. Mössbauer measurements were performed by a constant acceleration method at various temperatures with a proportional counter and a 1024 channel-multichannel scaler. Cobalt-57 (10 mCi) diffused into a palladium foil was used as the Mössbauer source. As for the reference material of isomer shift, a metallic iron foil enriched with iron-57 was used. Calibration of the Mössbauer spectrometer was also performed using the iron foil. Every Mössbauer spectrum obtained from room-temperature measurement was analyzed into a quadrupole doublet, having the same width and intensity with each other, due to Fe^{3+} ions. On the other hand, each Mössbauer spectrum obtained at temperatures lower than room temperature was analyzed into two kinds of quadrupole doublets due to Fe^{3+} and Fe^{2+} ions. Mössbauer measurements were performed in such a condition that the thickness of the glass sample should be as thin as possible. Simultaneous DTA and TG measurements were performed for each glass sample of 20 mg with a heating rate of 5 °C min^{-1}. The DTA and TG measurements were performed over the range from room temperature to 700 °C, using Al_2O_3 powder as a standard material for the DTA measurement.

Results and Discussion

The glass-forming region for the ternary K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses prepared in the present study is shown with a solid line in Fig. 1, in which open circles indicate the formation of glass samples. Closed and half-closed circles in Fig. 1 indicate the formations of ceramics (devitrified) and glass-ceramics (partially devitrified), respectively. It is seen from Fig. 1 that the glass-forming region for the binary K_2SO_4–$ZnSO_4$ system is in the range of 35—65 mol%, which is approximately consistent with the already published results.[2-4,24-26] At the early stage of the present study, ternary glass system K_2SO_4–$ZnSO_4$–$FeSO_4$ was also tried to prepare with $FeSO_4 \cdot 7H_2O$ or $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$. As the result, the latter reagent proved to be useful for the preparation. The ternary $ZnSO_4$-based glasses prepared with $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$, however, showed the absorption only due to Fe^{3+} ions in the Mössbauer spectra. This will be due to the oxidation reaction of Fe^{2+} to Fe^{3+} during the sample preparation, because all of the sample preparations was performed in the atmosphere. The glass-forming region for the ternary $ZnSO_4$-based glasses prepared with $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ is shown by a dotted line in Fig. 1. Sample preparation for the ternary K_2SO_4–$ZnSO_4$–Fe_2O_3 system was also attempted in the present study, but no vitreous sample could be obtained.

A typical Mössbauer spectrum of the ternary K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glass system is shown in Fig. 2a. The spectrum indicates that the iron is present as a paramagnetic Fe^{3+} ion in these glasses. It is speculated from Fig. 2a that only a small amount of Fe^{2+} ions is also present in these glasses. (Note that a weak peak around 2 mm s^{-1} is a part of the quadrupole doublet due to Fe^{2+} ions and that the relative absorption intensity of the Fe^{2+} peak is comparable to the amplitude of the scattering of the points around the base line.) Each Mössbauer spectrum measured at room temperature is therefore analyzed into a quadrupole doublet only due to Fe^{3+} ions, as is shown by a solid line in Fig. 2a.

Mössbauer parameters for the ternary $ZnSO_4$-based glasses are summarized in Table 1, in which the Mössbauer parameters for the anhydrous $Fe_2(SO_4)_3$ used for the preparation of the glass samples are also

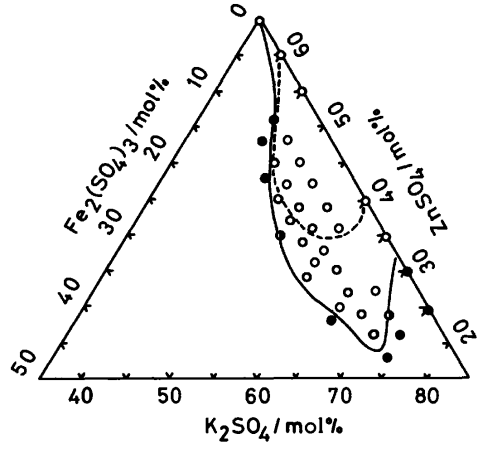

Fig. 1. Glass-forming region for the K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ system.

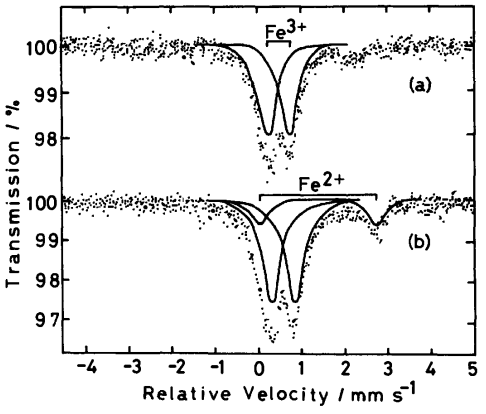

Fig. 2. Mössbauer spectra of $47K_2SO_4 \cdot 45ZnSO_4 \cdot 8Fe_2(SO_4)_3$ glass. (a): At room temperature (296 K), (b): at 78 K.

shown for comparison. Table 1 demonstrates that the isomer shift and the quadrupole splitting show drastic and gradual decreases when the K_2SO_4 content increases. On the other hand, linewidth shows a gradual increase with the increase in the K_2SO_4 content. The magnitude of the linewidth is larger than that of the ordinary crystalline compounds, which is usually smaller than ca. 0.4 mm s^{-1} in the case of ^{57}Fe-Mössbauer spectroscopy. (Compare to the linewidth of the anhydrous $Fe_2(SO_4)_3$ shown in Table 1.) The absorption peak with large linewidth is ascribed to the increased irregularities in the interatomic bond length and bond angle. Figure 3 shows the drastic decrease in the isomer shift with an increase in the K_2SO_4 content. The drastic change in the isomer shift corresponds to a gradual change in the coordination number of Fe^{3+} from six to four. The isomer shifts of Fe^{3+} with octahedral symmetry are known to be larger than ca. 0.4 mm s^{-1}.[7-14] On the other hand, the isomer shifts are usually smaller than ca. 0.4 mm s^{-1} in the case of tetrahedral Fe^{3+} ions.[7-14] In the several Mössbauer studies of oxide and halide glasses[7-18] performed until now by the authors, the coordination number of iron or tin has shown single values even if the composition changes. The change in the coordination number of iron from six to four shown in Fig. 3 is, therefore, considered to be a very rare case. It is speculated from Fig. 3 that the coordination number of iron is essentially six when the K_2SO_4 content is lower than about 60 mol% in the case of K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses containing 8 mol% $Fe_2(SO_4)_3$. In such glasses, Fe^{3+} ions are considered to be present at the substitutional sites of Zn^{2+} ions which are reported to be octahedrally surrounded by six oxygen atoms originating from six SO_4^{2-} tetrahedra.[2-6] On the other hand, the Fe^{3+} ions in the ternary K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses are speculated to occupy tetrahedral sites surrounded by four oxygen atoms when the K_2SO_4 content is higher than 60 mol%. The four oxygen atoms in these glasses will be provided by four SO_4^{2-} ions. Within the authors' knowledge, the four-fold coordinated metal ions are not observed in the $ZnSO_4$-based glasses until now, and most of the transition metal ions have been considered to occupy the octahedral sites at the substitutional sites of Zn^{2+} ions.[5,6] In the binary or ternary K_2SO_4–$ZnSO_4$ glasses, by the way, the increase in the K_2SO_4 content is known to result in decreases in density and ionic field strength of the glasses.[2-4] A decrease in the density seems to suggest the prolonged intermolecular distance between SO_4^{2-} ions. In such a condition, the interatomic distance between iron and the neighboring oxygen atom will also be prolonged, because every Fe^{3+} ion is considered to be present at the vacant sites (voids) surrounded by six or four SO_4^{2-} ions. The gradual increase in the interatomic distance between the iron and the oxygen will reduce the crystal field strength, and the coordination number of iron will gradually decrease from six to four with increasing K_2SO_4 content. The isomer shift of anhydrous $Fe_2(SO_4)_3$ used for the sample preparation (Table 1) is typical of the octahedral Fe^{3+} ion with high ionicity, and is in good agreement with the published data for the ionic crystals containing iron.[27,28]

The gradual change in the coordination number of iron from six to four seems to be correlated with the

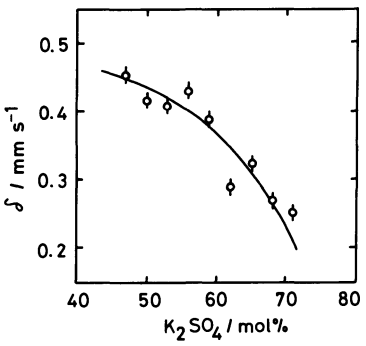

Fig. 3. Change in the isomer shift of Fe^{3+} with K_2SO_4 content of the K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses.

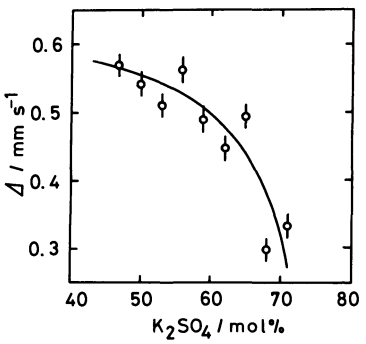

Fig. 4. Change in the quadrupole splitting of Fe^{3+} with K_2SO_4 content of the K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses.

composition dependency of the quadrupole splitting. This is shown in Fig. 4, from which it is seen that the quadrupole splitting decreases drastically with increasing K_2SO_4 content. Very small quadrupole splittings (0.30 and 0.33 mm s^{-1}) are observed when the K_2SO_4 content is close to 70 mol%; the quadrupole splittings are smaller than the linewidths of the corresponding absorptions, i.e., 0.56 and 0.53 mm s^{-1} in the cases of the glasses with the K_2SO_4 contents of 68 and 71 mol%, respectively. From the distinct decrease in the quadrupole splitting for the higher K_2SO_4-content glasses (Fig. 4), it is concluded that the symmetry around the Fe^{3+} ion increases with increasing K_2SO_4 content. (Each Fe^{3+} ion has a symmetric electron configuration of $3d^5$ in the outer-most orbital, and therefore only the electric field gradient caused by the neighboring atoms or ions, i.e., oxygen atoms in the present study, will be the primary origin of the quadrupole splitting.) The gradual decrease in the quadrupole splitting with increasing K_2SO_4 content therefore suggests that the symmetry around the Fe^{3+} ion is higher when surrounded by four SO_4^{2-} ions than when surrounded by six SO_4^{2-} ions. It is seen from Table 1 that the quadrupole splitting for the anhydrous $Fe_2(SO_4)_3$ is smaller than those for the ternary K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses. The very small quadrupole splitting for the Fe^{3+} ion is in agreement with the published data,[27,28] and reflects the nearly cubic symmetry. All the Mössbauer parameters for the anhydrous $Fe_2(SO_4)_3$ shown in Table 1 therefore suggest that the local environment of iron in the ternary K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses is quite different from that of iron in the anhydrous $Fe_2(SO_4)_3$ used for the preparation.

The composition dependency of the glass transition temperature (T_g), obtained from DTA measurements of the ternary K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses, is shown in Fig. 5. It is obvious from Fig. 5 that the T_g shows a distinct composition dependency similar to that of the isomer shift shown in Fig. 3. The gradual decrease in the T_g with an increase in the K_2SO_4 content suggests that the strength of the chemical bond between metal ions (K^+, Zn^{2+}, and Fe^{3+}) and

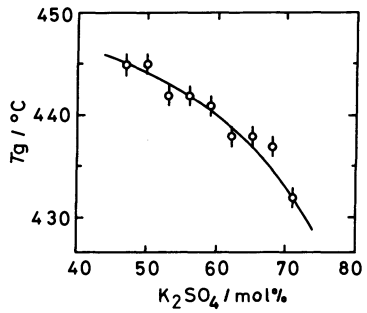

Fig. 5. Change in the glass transition temperature (T_g) with K_2SO_4 content of the K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses.

SO_4^{2-} ions becomes weakened when the fraction of the K_2SO_4 content increases. This is ascribed to the increased intermolecular distance between SO_4^{2-} ions and to the increased interatomic distance between the metal ions and the SO_4^{2-} ions, as described above. The increased intermolecular and interatomic distances are assumed from the decrease in the density observed in the binary K_2SO_4–$ZnSO_4$ or ternary K_2SO_4–Na_2SO_4–$ZnSO_4$ glasses when the K_2SO_4 content increases.[2-4] (The interatomic distance between the sulfur atom and the four oxygen atoms constituting a pseudospherical SO_4^{2-} ion is considered not to be changed even if the composition is changed.)

Mössbauer measurements of a ternary K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glass, at various temperatures lower than room temperature, were also performed to know the nature of the chemical bonds between metal ions and SO_4^{2-} ions and between two SO_4^{2-} ions. Measurements of Mössbauer spectra at low temperatures have already been performed on germanate[15,16] and BaF_2–ZrF_4–FeF_2[18] glasses, and some useful information on the intermolecular force constant has been obtained by the authors. The intermolecular force constant (θ^2M) is expressed by

$$\theta^2M = 3E^2/kc^2(-\mathrm{d}\ln f/\mathrm{d}T)^{-1}, \quad (1)$$

where E and f are transition energy (14.4 keV in the case of ^{57}Fe-Mössbauer spectroscopy) and recoil-free fraction in the Mössbauer spectrum, respectively. In the Eq. 1, k and c are Boltzmann constant and the velocity of light, respectively. It is easily understood from Eq. 1 that the value of θ^2M, in which θ is so-called Debye temperature and M is the mass of Mössbauer nucleus, can be obtained by dividing $3E^2/kc^2$, i.e., 7.76×10^3 in the present study, with the slope of the straight line obtained in the $\ln f$ vs. temperature (T) plot. In the present study, an absorption area (A) is plotted instead of the recoil-free fraction f, because $\mathrm{d}\ln f/\mathrm{d}T$ can be approximated by $\mathrm{d}\ln A/\mathrm{d}T$ when a very thin sample is used.

Mössbauer spectrum of $47K_2SO_4\cdot45ZnSO_4\cdot8Fe_2(SO_4)_3$ glass at lower temperatures consists of two quadrupole doublets, as is also shown in Fig. 2b, due to Fe^{3+} and Fe^{2+} ions. At lower temperatures, the relative absorption area of the Fe^{2+} peak proved to be somewhat higher than that at room temperature. For example, the absorption area amounts to 17.5% at 78 K (Fig. 2b), showing a gradual decrease with increasing temperature. The formation of Fe^{2+} species is probably due to an electron transfer from a part of SO_4^{2-} ions, which are considered to be thermally decomposed into SO_2 and O_2 during the fusion, to the Fe^{3+} ions. All the Mössbauer parameters for the $47K_2SO_4\cdot45ZnSO_4\cdot8Fe_2(SO_4)_3$ glass, obtained at lower temperatures, are summarized in Table 2. It is obvious from Table 2 that the isomer shift and the quadrupole splitting of the Fe^{3+} absorptions show

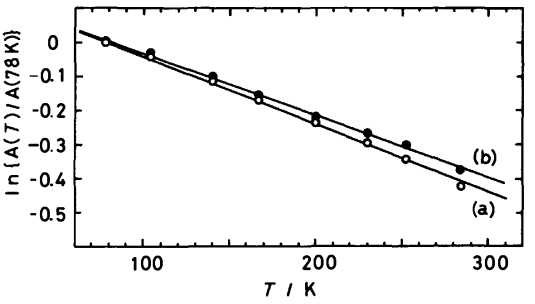

Fig. 7. Changes in the absorption area for the $47K_2SO_4 \cdot 45ZnSO_4 \cdot 8Fe_2(SO_4)_3$ glass with temperature. (a): Fe^{3+} plus Fe^{2+}, (b): only Fe^{3+}.

distinct decreases when the temperature increases. This is illustrated graphically in Fig. 6, from which it is seen that both Mössbauer parameters show linear relationships with temperature. These results indicate that no structural change, such as a phase transition observed in a BaF_2–ZrF_4–FeF_2 glass,[18] occurs in the ternary K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glass within the temperature region ranging from 78 to 284 K. In the case of the BaF_2–ZrF_4–FeF_2 glass,[18] the corresponding plots of isomer shift and quadrupole splitting vs. temperature were found to be individually composed of two straight lines crossed with each other at the phase transition temperature of 225 K. Changes in the isomer shift and the quadrupole splitting of the Fe^{2+} absorptions are not graphically shown in the present study because they have large experimental errors. However, they also have a tendency to decrease almost linearly with increasing temperature.

Change in the absorption area with temperature is shown in Fig. 7, where the absorption area of Fe^{3+} plus Fe^{2+} (Fig. 7a) and that of only Fe^{3+} (Fig. 7b) are plotted separately. It is obvious from Fig. 7a and b that the absorption area shows a linear relationship with temperature. The linear correlationship between $\ln A$ and T suggests that a Debye model can be applied to the so-called lattice dynamic study of the K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glass, and that no structural change occurs within the temperature range of 78 to 284 K. This is consistent with the results for the isomer shift and the quadrupole splitting described above. In Fig. 7, each absorption area is normalized by the absorption area at 78 K. From the slope of the straight line shown in Fig. 7a, θ^2M value proved to be 3.9×10^6. This is almost the same as the θ^2M value of 4.3×10^6 obtained from the corresponding plot of the absorption area of only Fe^{3+} ions (Fig. 7b). Anyhow, these values are larger than the representative values ($1-3\times10^6$) reported for the monomer or polymer compounds[29] of which chemical bond is known to be essentially covalent. The θ^2M value is known to reflect the degrees of bridging and packing as well as the nature of the chemical bonds of several crystalline and non-crystalline compounds.[15,16,18,29] Considering the experimental results together with the structural model proposed for binary K_2SO_4–$ZnSO_4$ or ternary K_2SO_4–Na_2SO_4–$ZnSO_4$ glasses, that the glasses consist of random close packing of pseudospherical SO_4^{2-} ions,[2-4] the θ^2M values obtained in the present study seem to reflect the essentially ionic nature of the chemical bonds between metal ions and SO_4^{2-} ions and between two SO_4^{2-} ions. It seems that the θ^2M values obtained for the $47K_2SO_4 \cdot 45ZnSO_4 \cdot 8Fe_2(SO_4)_3$ glass in the present study are a little smaller than those for the representative ionic compounds such as $BaSnO_3$ and SnO_2, of which θ^2M values are estimated to be 22.4×10^6 and 8.9×10^6, respectively.[15] This is probably due to the difference in the degree of packing effect. ($BaSnO_3$ and SnO_2 are known to be rigid ionic crystals of perovskite- and rutile-type structures, respectively.) Mössbauer studies of several germanate glasses[15,16] containing 2 mol% SnO_2 revealed that the θ^2M value has a close correlationship with the composition of glass, ranging from 6.2×10^6 to 8.7×10^6. In the germanate glasses,[15,16] tin (IV) proved to be ionically present at the interstitial sites of the three-dimensional network composed of GeO_4 and GeO_6 units. In the case of $25BaF_2 \cdot 65ZrF_4 \cdot 10FeF_2$ glass,[18] the θ^2M value showed a drastic change from

6.9×10^6 to 1.9×10^6 at the phase transition temperature described above. In the ZrF_4 -based glass,[18] iron(III) proved to be ionically present at the interstitial sites of one- or two-dimensional zigzag chains composed of ZrF_6 octahedra. Judging from all the experimental results discussed in the present paper, the chemical bonds between metal ions (K^+, Zn^{2+}, and Fe^{3+}) and SO_4^{2-} ions and between two SO_4^{2-} ions are concluded to be essentially ionic. The K_2SO_4–$ZnSO_4$–$Fe_2(SO_4)_3$ glasses are therefore concluded to be composed of random close packing of pseudospherical SO_4^{2-} ions. Potassium, zinc, and iron ions are considered to be ionically present at the vacant sites (voids) made by the pseudospherical SO_4^{2-} ions.

The authors are grateful to Misses Setsuko Saruwatari and Maori Horiuchi for their kind help in the experiments. One of the authors (TN) is grateful to the Itoh Science Foundation for the financial support.

Binuclear Metal Complexes. 58.[1] Synthesis and Properties of Mixed-Valence Diiron(III,IV) Complexes of Salen Analogs with Pendant Thioether Group

Hisashi Ōkawa,* Kaoru Horiuchi, Wakako Kanda, Hiroki Oshio,† and Sigeo Kida†

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka 812

(Received May 6, 1986)

Iron complexes of the composition $[Fe_2(L)_2O]PF_6$ have been obtained with *N,N'*-disalicylidene-2-methyl-4-(1-methylethylthio)-1,2-butanediamine (H_2L^1) and *N,N'*-disalicylidene-2-methyl-4-ethylthio-1,2-butanediamine (H_2L^2). They were characterized as mixed-valence diiron(III,IV) complexes composed of high-spin iron(III) and low-spin iron(IV). Cryomagnetic measurements demonstrated the operation of an antiferromangetic spin-exchange interaction ($J=-12.3--13.9\,cm^{-1}$) between the Fe^{III} and Fe^{IV} ions. ESR signals at liquid nitrogen temperature ($g=4.03$ and 2.00) were reasonably attributed to the ground spin state ($S_T=3/2$) in the spin-coupled dimer. In the Mössbauer spectra two quadrupole splitting doublets due to iron(III) and iron(IV) were observed. The complexes were discussed in comparison with mixed-valence complexes of *N,N'*-disalicylideneethylenediamine (H_2salen), $[Fe_2(salen)_2O]X$, composed of high-spin iron(III) and high-spin iron(IV).

It is worthwhile to design pentadentate ligands consisting of a planar unsaturated tetradentate system and an axial base, because such a pentacoordinate environment is often seen at the active site of metalloenzymes such as hemoglobin[2] and myoglobin.[3] For this purpose there have been synthesized some pentadentate salen analogs (H_2salen=*N,N'*-disalicylideneethylenediamine) possessing a pyridyl,[4] hydroxyphenyl,[5] methoxyphenyl,[5] or alkylthio group[6,7] as the pendant group. Salen analogs with thioether pendant group were recently synthesized in our laboratory.[6] These ligands formed pentacoordinate cobalt(II) complexes with the thioether sulfur at the axial site under nitrogen atmosphere while hexacoordinate O_2-adducts in the presence of molecular oxygen. In this study we have synthesized iron complexes of salen analogs, *N,N'*-disalicylidene-2-methyl-4-(1-methylethylthio)-1,2-butanediamine (H_2L^1) and *N,N'*-disalicylidene-2-methyl-4-ethylthio-1,2-butanediamine (H_2L^2) (see Fig. 1). The objects of this study are to characterize the complexes and to elucidate the sulfur coordination effect on the property of the complexes. A similar ligand, (*S*)-*N,N'*-disalicylidene-4-methylthio-1,2-butanediamine, was prepared by Amundsen et al.[7] However, they found no evidence of thioether coordination in its iron(III) complex.

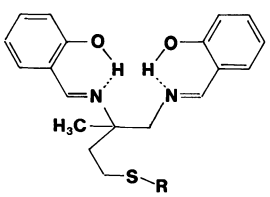

Fig. 1. Chemical structure of ligands: R=*i*-C_3H_7, H_2L^1; R=C_2H_5, H_2L^2.

Experimental

Preparation. The synthesis of H_2L^1 is described in the previous paper.[6] H_2L^2 was prepared in this study in nearly the same way as that of H_2L^1 except for the use of 4-ethylthio-2-butanone instead of 4-(1-methylethylthio)-2-butanone as the starting material.

Iron complexes were obtained as follows. Iron(II) sulfate heptahydrate (1×10^{-3} mole) and the ligand (1×10^{-3} mole) were dissolved in ethanol (50 cm^3), and the mixture was heated at 80 °C for 30 min. To this was added NH_4PF_6 (2×10^{-3} mole), and the mixture was heated for 3 h with stirring. Insoluble materials were separated by filtration, and the solvent was evaporated to dryness. The residue was dissolved in dichloromethane, and the solution was allowed to stand for one week. The crude product thus obtained was dissolved in dichloromethane and reprecipitated by adding ether to this solution. This operation was repeated five times to give brown microcrystals.

$[Fe_2(L^1)_2O]PF_6$, yield ca. 90 mg. Found: C, 50.81; H, 5.04; N, 5.40%. Calcd for $C_{44}F_6Fe_2H_{52}N_4O_5PS_2$; C, 50.92; H, 5.05; N, 5.40%.

$[Fe_2(L^2)_2O]PF_6$, yield ca. 70 mg. Found: C, 49.98; H, 4.91; N, 5.66%. Calcd for $C_{42}F_6Fe_2H_{48}N_4O_5PS_2$: C, 49.96; H, 4.79; N, 5.55%.

Physical Measurements. Infrared spectra were obtained on a Hitachi-Parkin-Elmer 225 grating IR spectrometer on KBr disks. Electronic spectra were recorded on a Shimadzu MPS-5000 spectrometer. Magnetic susceptibilities were measured by the Faraday method in the range 80—300 K. The apparatus was calibrated using $Hg[Co(NCS)_4]$.[8] Diamagnetic corrections were carried out using Pascal's constants.[9] Cyclic voltammograms and differential pulse polarograms were recorded on a Yanagimoto P-1000 voltammetric analyzer in freshly distilled dichloromethane. The measurements were carried out with a three-electrode

† Present address: Coordination Chemistry Laboratories, Institute for Molecular Science, Okazaki National Research Instiutes, Myodaiji, Okazaki 444.

cell equipped with a glassy-carbon working electrode, a platinum-coil auxiliary electrode, and a calomel electrode as the reference electrode. Tetrabutylammonium perchlorate (0.1 mol dm^{-3}) was added as the supporting electrolyte. All the potentials were normalized by the use of ferrocene as an internal standard.[10] ESR spectra (X-band) were recorded on a JEOL JES-FE-3X instrument on powder samples at room temperature and liquid nitrogen temperature. Mössbauer spectra were measured with a constant-acceleration spectrometer (Ausin Science Associates) using a cobalt 57 source diffused into palladium foil. All the spectra were fitted to the Lorentzian line shape using the least-squares method. The velocity scale was normalized with respect to the center of the spectrum of metallic iron at 297 K.

Results and Discussion

Analytical results satisfactorily coincided with the formula $[Fe_2(L)_2O]PF_6$, which suggested the formation of oxo-bridged mixed-valence diiron(III,IV) complexes.

The effective magnetic moments (μ_{eff} per metal ion) for the L^1- and L^2-complexes were 4.28 and 4.36 BM, respectively. As the temperature was lowered to the liquid nitrogen temperature, the moments decreased to 3.45 and 3.58 BM, respectively. The temperature-dependence of the magnetic moments is presumably due to an antiferromagnetic spin-exchange interaction through the oxo-bridge but not due to other effects such as spin-crossover phenomenon.

For analyzing the magnetism of the complexes, a spin Hamiltonian for an isotropic exchange interaction for a dimer ($\mathcal{H}=-2J\hat{S}_1\cdot\hat{S}_2$) was adopted, where J is the exchange integral and $\hat{S}_1$ and $\hat{S}_2$ are the spin operators for metals 1 and 2, respectively. Magnetic susceptibility equation for the case $Fe^{III}(S=5/2)$-$Fe^{IV}(S=2)$ have been derived by Wojciechowski as follows:[11]

$$\chi_M = \frac{Ng^2\beta^2}{4kT} \times \frac{165\exp(-24J/kT)+84\exp(-15J/kT)+35\exp(-8J/kT)+10\exp(-3J/kT)+1}{5\exp(-24J/kT)+4\exp(-15J/kT)+3\exp(-8J/kT)+2\exp(-3J/kT)+1} + N\alpha$$

With this equation Wollmann and Hendrickson well explained the magnetisms of their mixed-valence diiron(III,IV) complexes, $[Fe_2(salen)_2O]X$, which is structurally similar to the present complexes. When this equation was applied to the present complexes, however, very poor fits to the experimental data were obtained.

It is noted that the magnetic moments for the L^1- and L^2-complexes are considerably lower than that of $[Fe_2(salen)_2O]PF_6$ at room temperature (≈4.7 BM at 300 K), but are higher than that of $[Fe_2(salen)_2O]PF_6$ at liquid nitrogen temperature (≈3.0 BM at 78 K). This suggests that for the present complexes the highest total-spin quantum number is smaller than that ($S_T=9/2$) for $Fe^{III}(S=5/2)$-$Fe^{IV}(S=2)$ and the lowest total-spin quantum number is larger than that ($S_T=1/2$) for $Fe^{III}(S=5/2)$-$Fe^{IV}(S=2)$. Such a situation occurs only when either of the iron(III) or iron(IV) is in low-spin state. Therefore, magnetic simulations were attempted with the susceptibility equations for $Fe^{III}(S=5/2)$-$Fe^{IV}(S=1)$ and $Fe^{III}(S=1/2)$-$Fe^{IV}(S=2)$, together with those for $Fe^{III}(S=3/2)$-$Fe^{IV}(S=2)$, $Fe^{III}(S=3/2)$-$Fe^{IV}(S=1)$, $Fe^{III}(S=1/2)$-$Fe^{IV}(S=2)$, and $Fe^{III}(S=1/2)$-$Fe^{IV}(S=1)$. As the result, only the equation for the $Fe^{III}(S=5/2)$-$Fe^{IV}(S=1)$ case,

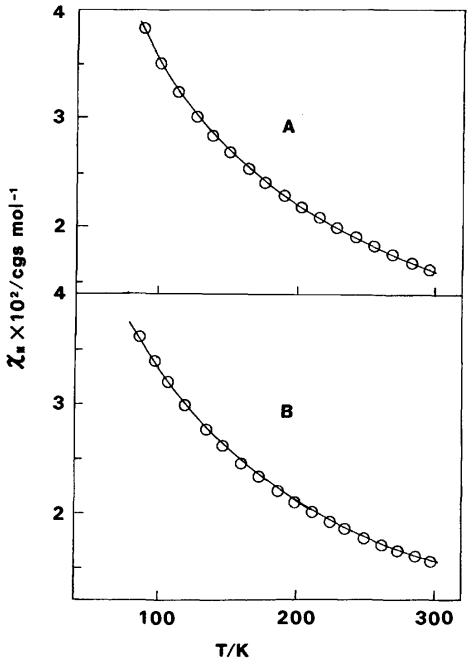

Fig. 2. Temperature-variations of magnetic susceptibility of $[Fe_2(L^1)_2O]PF_6$ (A) and $[Fe_2(L^2)_2O]PF_6$ (B). Solid curves are drawn based on the equation for the spin-coupled (S=5/2)-(S=1) system (see text), with the paramenters $J=-12.3$ cm^{-1} and $g=2.01$ for A and $J=-13.9$ cm^{-1} and $g=2.00$ for B.

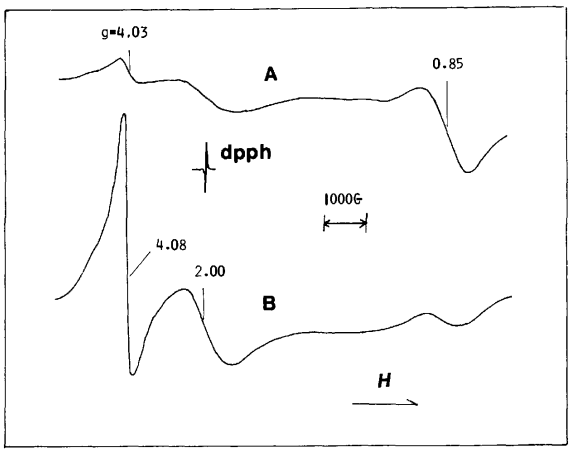

Fig. 3. X-band ESR spectra of $[Fe_2(L^1)_2O]PF_6$ at room temperature (trace A) and at liquid nitrogen temperature (trace B).

$$\chi_M = \frac{Ng^2\beta^2}{4kT} \times \frac{84\exp(-12J/kT)+35\exp(-5J/kT)+10}{4\exp(-12J/kT)+3\exp(-5J/kT)+2} + N\alpha,$$

could reasonably explain the temperature variation of magnetic susceptibilities for the L^1- and L^2-complexes as shown in Fig. 2. The magnetic parameters obtained by best-fit technique are $J=-12.3\,cm^{-1}$ and $g=2.01$ for the L^1-complex and $J=-13.9\,cm^{-1}$ and $g=2.00$ for the L^2-complex; the temperature-independent paramagnetism $N\alpha$ being assumed to be zero in this simulation.

Thus, magnetic investigations demonstrate the presence of low-spin iron(IV) in the present complexes. It must be emphasized that the complexes $[Fe_2(salen)_2O]X$ involve high-spin iron(IV).[12] The low-spin state of the iron(IV) in $[Fe_2(L)_2O]PF_6$ presumably results from the coordination of the pendant thioether sulfur to the metal ion. On the other hand, it is unclear at present whether the sulfur coordination to the iron(III) occurs or not in these complexes.

X-band ESR spectra of the L^1-complex were obtained on powder sample at room temperature and liquid nitrogen temperature (Fig. 3). The spectrum at room temperature (trace A) exhibits three signals at $g=4.03$, 2.00, and 0.85. At liquid nitrogen temperature (trace B) the $g=0.85$ signal practically disappeared, whereas the $g\approx4.0$ and 2.0 signals increased their intensities. It is likely that the $g=4.08$ and 2.00 signals in trace B are due to the ground spin state and the $g=0.85$ signal in trace A is due to one of the excited spin states of the mixed-valence diiron(III,IV) complex. The low temperature spectrum (trace B) can be reasonably interpreted in terms of the total-spin ground state ($S_T=3/2$) of the spin-coupled $Fe^{III}(S=5/2)$-$Fe^{IV}(S=1)$ dmer; the $g=2.00$ and 4.08 signals being attributed to the $g_{//}$ and $g_{\perp}$ components of the $(+1/2\leftrightarrow-1/2)$ transition, respectively. The signal due to the $(+3/2\leftrightarrow+1/2)$ and $(-1/2\leftrightarrow-3/2)$ transitions are not observed probably because of a large zero-field splitting owing to the low molecular symmetry and the spin-orbit coupling interaction. Therefore, the ESR spectral result also strongly supports the presence of low-spin iron(IV) in $[Fe_2(L)_2O]PF_6$. In contrast to this, for $[Fe_2(salen)_2O]X$ only a broad signal with a line width of $\approx$650 G has been observed near $g=2.0$.[12]

Cyclic voltammogram (CV) and differential pulse polarogram (DPP) for the L^1-complex are shown in Fig. 4. The CV and DPP both showed two reduction waves at -0.40 and -1.58 V. The L^2-complex also showed two reduction waves at -0.56 and -1.52 V. For analyzing the electrochemical behaviors of the present complexes, the electrochemical data for $[Fe(salen)]_2O$[13] seemed helpful. In our measurements, this complex showed one reduction wave at -1.55 V, attributable to the process $Fe^{III}Fe^{III}/Fe^{II}Fe^{III}$.[13] Notably this potential well corresponds to the second reduction potential for $[Fe_2(L)_2O]PF_6$. Thus, we may assign the second wave to the $Fe^{III}Fe^{III}/Fe^{II}Fe^{III}$ process and the first wave to the $Fe^{III}Fe^{IV}/Fe^{III}Fe^{III}$ process. Electrochemical results, therefore, support the fact that $[Fe_2(L)_2O]PF_6$ are mixed-valence diiron(III,IV) complexes.

The ^{57}Fe Mössbauer spectra of the L^1-complex were obtained at 296, 80, and 15 K. The spectra were practically independent of temperature. The spectrum at 80 K is shown in Fig. 5. The spectrum consists of two doublets of closely similar isomer shifts and quadrupole splittings, implying the presence of two kinds of iron, i.e., Fe^{III} and Fe^{IV}. The spectrum was analyzed by computer technique into four peaks with nearly equal intensity and half-band width (Fig. 5). We tentatively assigned the peaks 1 and 3 to the iron(IV) and the peaks 2 and 4 to the iron(III). Another pairing (1 and 4; 2 and 3) is also possible, but our assignment is based on the general concept that

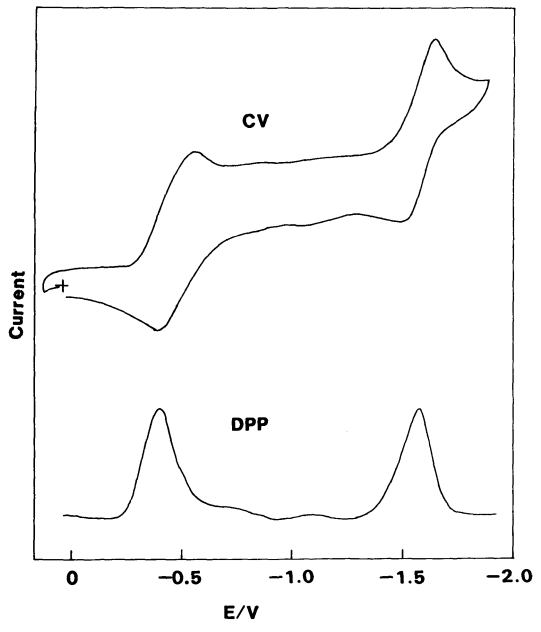

Fig. 4. Cyclic voltammogram and differential pulse polarogram of $[Fe_2(L^1)_2)]PF_6$: concd $=1.02\times10^{-3}$ M (1 mol dm^{-3}); scan rate $=0.01$ V s^{-1} for both CV and DPP; in CH_2Cl_2.

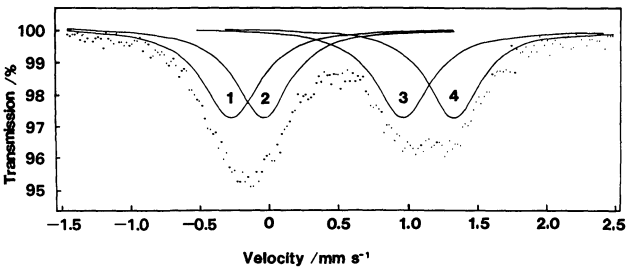

Fig. 5. Mössbauer spectrum of $[Fe_2(L^1)_2O]PF_6$ at 80K.

Table 1. Mössbauer Parameters for $[Fe_2(L^1)_2O]PF_6$

T/K	Fe^{III}		Fe^{IV}	
	δ	Δ	δ	Δ
295	0.463	1.478	0.310	1.054
80	0.647	1.399	0.343	1.256
15	0.673	1.368	0.344	1.296

δ, isomer shift/mm s^{-1}; Δ, quadrupole splitting/mm s^{-1}.

the isomer shift for iron(IV) is smaller than that for iron(III). The results are given in Table 1. The isomer shift and quadrupole splitting assigned to the high-spin iron(III) are quite reasonable. On the other hand, Mössbauer spectral data for low-spin iron(IV) are very limited.[14-16] Of these complexes, tris(disubstituted dithiocarbamato)iron(IV) tetrafluoroborates show isomer shift falling in the range 0.45—0.57 mm s^{-1} relative to sodium pentacyanonitrosylferrate(III).[16] Thus the isomer shift assigned to the iron(IV) of the L^1-complex does not seem unreasonable.

From the above results, it is concluded that the $[Fe_2(L)_2O]PF_6$ complexes are mixed-valence diiron(III,IV) complexes, probably bridged by oxo group. Oxo-bridged diiron(III,III) complexes have been characterized by an intense IR band in the 800—900 cm^{-1} region, which is assigned to the asymmetric Fe–O–Fe stretching mode.[17] The present complexes do not show such a band in the 800—900 cm^{-1} region. We also examined far IR spectra of the complexes, in comparison with the spectra of the nickel(II) complexes of H_2L^1 and H_2L^2. However, any characteristic IR band was seen for the diiron complexes. It should be noted that $[Fe_2(salen)_2O]X$[12] also showed no IR band attributable to the Fe–O–Fe stretch. As suggested by Wollmann and Hendrickson,[12] it is probable that the Fe–O–Fe band of $[Fe_2(L)_2O]PF_6$ is weakened in intensity, shifted in position, and obscured by ligand vibrations.

Mixed-valence complexes generally show intervalence transfer bands in visible or near IR region.[18-20] The electronic spectra of $[Fe_2(L)_2O]PF_6$ in dichloromethane showed absorption bands at 260, 320, 420, and 500 nm. The spectrum of the L^1-complex is given in Fig. 6. No absorption was found in the near IR region. Despite the different spin state of iron(IV), $[Fe_2(L)_2O]PF_6$ showed an absorption spectrum very similar to that of $[Fe_2(salen)_2O]PF_6$.[12] By the inspection of the spectra of $[Fe(salen)]_2O$ and $[Fe_2(salen)_2O]X$, Wollmann and Hendrickson tentatively assigned the ≈500 nm band of the latter complex to the intervalence transfer band.[12] According to Hush,[20] the energy of an intervalence transfer band should vary with $(1/n^2)$-$(1/D)$ of solvent, where n is the refractive index and D the dielectric constant of solvent. The electronic spectra of $[Fe_2(L)_2O]PF_6$ were

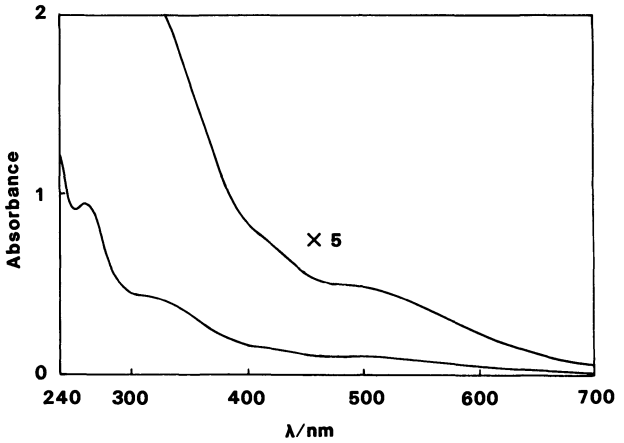

Fig. 6. Electronic spectra of $[Fe_2(L^1)_2O]PF_6$: concd= 2.377×10^{-5} M; in CH_2Cl_2.

measured in various solvents (CH_2Cl_2, $CHCl_3$, CH_3CN, CH_3OH, dioxane), and it was found that the frequency of the ≈500 nm band was practically independent of the solvents. Probably this band is not intervalence transfer band but a charge transfer band from the phenolic oxygen to the iron(III) or iron(IV). Since intramolecular electron transfer from high-spin iron(III) to low-spin iron(IV) should produce the mixed-valence state composed of intermediate-spin iron(III) and high-spin iron(IV), the intervalence transfer band for $[Fe_2(L)_2O]PF_6$ must be located at a higher energy region than 500 nm and concealed by more intense absorptions.

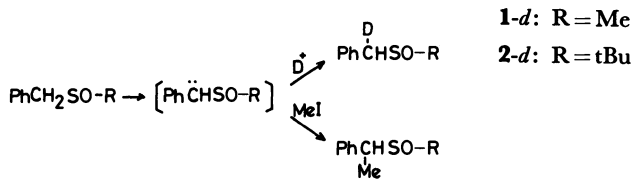
(Received December 10, 1985)

X-Ray analysis of a stereoselectively monodeuterated benzyl *t*-butyl sulfoxide, PhCHDSO-tBu, revealed that the *t*-butyl and phenyl groups are oriented anti to each other in this molecule. Integrated intensities for ten reflections were measured on a two-circle neutron diffractometer and the relative intensity distribution was compared with the calculated neutron structure factors, assuming the atomic parameters obtained by the X-ray analysis. It is concluded that the benzylic hydrogen which is flanked by S-O and *t*-Bu was replaced by deuterium. The results require that the earlier assignment for the relative configuration of PhCHDSO-tBu, should be revised; an important conclusion in view of current discussions of sulfur stereochemistry.

It has been reported that the isotopic exchange and the alkylation of benzyl alkyl sulfoxides, $PhCH_2SO$-Me (**1**) and $PhCH_2SO$-tBu (**2**), proceed via different stereochemical pathways;[1] retention of the configuration for the H-D exchange, and inversion of the configuration for the methylation (Fig. 1). The configuration assignments of the partially deuterated sulfoxides, **1**-*d*[2] and **2**-*d*,[1b] were made by correlating them chemically to optically active benzyl-α-*d* alcohols, the configuration of which has been believed to be established; [(+)-(*S*) and (−)-(*R*)].[3]

The opposite stereochemical outcome for the H-D exchange and the methylation (Fig. 1) is unusual in the current understanding of carbanion chemistry, since electrophilic substitution reactions are more reasonably expected to occur with retention of the intermediate carbanion configuration. In order to examine this point, we prepared crystals of a stereoselectively deuterium-labelled benzyl *t*-butyl sulfoxide (**2**-*d*), and determined the relative disposition of the deuterium atom with respect to the S-O bond by X-ray and neutron diffraction study.

The problem is to know which hydrogen atom (H_{7A} or H_{7B} in Fig. 2) was exchanged by D; it is possible to distinguish the H and D atoms at the benzyl methylene by calculating the structure factors of neutron diffraction which is based on the result of X-ray analysis. Analyses of the crystallographic data revealed that the relative configuration of **2**-*d*, which has been believed to date,[1b,4] should be reversed. This is an important conclusion in view of current discussions of the stereochemistry of sulfoxides.[1,4,5]



1-*d*: R=Me
2-*d*: R=tBu

Fig. 1.

Experimental

Materials. A solution of benzyl *t*-butyl sulfoxide (**2**, 10 mmol) in dry tetrahydrofuran (100 ml) was treated, under nitrogen at −70°, with a hexane solution of butyllithium (12 mmol). After standing for 5 min, the reaction mixture was treated with deuterium oxide (10 ml), and then diluted with water (50 ml). This was neutralized and extracted with ether (200 ml). The ether layer was washed 3 times with water, dried over $MgSO_4$, and then concentrated to give a crude solid of the monodeuterated product. The solid was crystallized from ligroin. This was again crystallized from ligroin solution by slow cooling. A large crystal of approximate dimensions 4×2.5×0.2 mm was chosen for

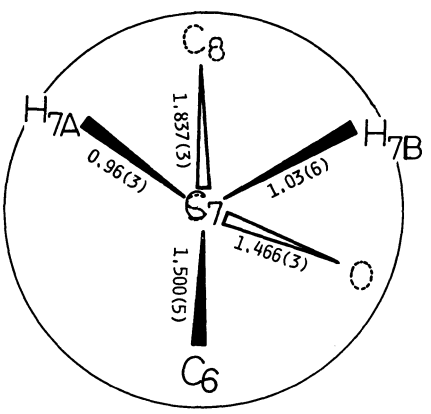


Fig. 2. Newman projection of the compound **2**, viewing along C_7–S axes.

neutron diffraction study. NMR (CCl_4, ppm): 3.64 (1H, s, CHD), 1.25 (9H, s, *t*-Bu), 7.26 (5H, s, Ar).

Crystal Data. Benzyl *t*-butyl sulfoxide, $C_{11}H_{16}OS$, M.W.= 196, Partially-deuterated compound, $C_{11}H_{15}DOS$. Monoclinic, Space group $P2_1/n$, Z=4. For full hydrogen compound, a=14.284(7), b=13.185(7), c=6.015(4) Å, β= 93.83(5)°, U=1130 Å^3, D_{calcd}=1.1508 g cm^{-3}, μ for Cu $K\alpha$ radiation 21.8 cm^{-1}.

X-Ray measurement was carried out using a small crystal of the deuterated compound of approximate dimensions 0.2×0.3×0.1 mm. Intensities were measured on a Philips PW1100 diffractometer using graphite monochromated Cu $K\alpha$ radiation. 2543 Reflections were measured within the 2θ range of 6° through 156°. 466 Reflections were below the 2σ(I) level and regarded as unobserved. A total of 2077 reflections were then used for the structure determination.

The structure was determined by the direct method using MULTAN[6] and refined by the block-diagonal least-squares method to an R value of 0.072. All the 16 hydrogen atoms were found on the difference electron-density map and they were included in the refinement process with isotropic temperature factors.

Results and Discussions

The final atomic parameters are listed in Table 1. The bond lengths and angles are listed in Tables 2 and 3.[7] The values observed in the present molecule are typical of the related compounds. Some relevant torsional angles are listed in Table 4.

Figure 2 illustrates the orientation of the phenyl group (represented by C_6) to the S–O bond and to the *t*-butyl group (represented by C_8). A stereoview of the molecule is shown in Fig. 3. It is clear that the *t*-butyl group is flanked by the two hydrogen atoms and that the *t*-butyl and the phenyl groups are oriented anti to each other.

It is interesting to compare this conformation with those found in the diastereoisomeric pair of 1-phenylethyl *t*-butyl sulfoxides, [(α *R*, *SS*/*SS*, *SR*)- and (α *R*, *SR*/α *S*, *SS*)-**3**], determined by X-ray methods[8] (Fig. 4). In both of these compounds, the *t*-butyl group has been shown to be gauche to the phenyl group and anti to the methyl group (Fig. 4d, e). The conformation of **3** has been shown to be maintained in solutions by NMR (LIS),[9] ORD[8b] and dipole moment measurements[10]; the conclusion was supported by molecular force-field calculations[11].

The conformation of **2** in solution was also studied by various methods. Although the force-field calculations[11] favored a gauche conformation of *t*-butyl and phenyl groups (Fig. 4c), the energy difference between the anti conformer (Fig. 4a) is small. A dipole moment[10] study favored the anti conformation. NMR

and mechanistic considerations[4b] suggested that this compound takes a folded conformation (Fig. 4b); this conclusion rests, however, on the configuration assignments of the monodeuterated benzyl *t*-butyl sulfoxides (αR, $SS/\alpha S$, SR)- and (αR, $SR/\alpha S$, SS)-**2**-*d*,[1b,4] which is correlated chemically to the optically active benzyl-α-*d* alcohol.[3]

To identify which benzyl hydrogen atom (H_{7A} or H_{7B}) is replaced by deuterium atom, two sets of neutron structure factors were calculated assuming the atomic parameters listed in Table 1; $F_A(hkl)$ based on the model A, in which only H_{7A} is exchanged by D, and $F_B(hkl)$ for model B in which only H_{7B} is exchanged by D. Since the crystal is flattened on (010) plane and it is easier to measure the $h0l$ reflection intensities, ten $h0l$ reflections were chosen having the largest $|F_A|$or$|F_B|$ and the largest $||F_A|-|F_B||$ values. The values are listed in Table 5. Neutron scattering lengths b were taken from the International Tables for X-ray Crystallography III.[12] They were S 0.310, C 0.661, N 0.935, O 0.578, H −0.378, D 0.650 (10^{-12} cm). Integrated intensities for the ten $h0l$ reflections were measured on a two-circle neutron diffractometer at the Japan Atomic Energy Research Institute in Tokai (JAERI). The primary beam was monochromated by a crystal monochromator giving radiation of wavelength 2.338 Å. The observed $|F(h0l)|$ values are normalized to $|F(101)|$ and are listed in Table 5. Inspection of the Table shows that the H–D exchange took place on H_{7B}; the hydrogen atom flanked by S–O and the *t*-butyl groups.

From the above results, we conclude that the configuration assignment of the stereoselectively deuterated sulfoxide (**2**-*d*), reported by Durst et al.,[1b] is in error.

In view of the revised assignment, the paradoxes in the sulfoxide stereochemistry may well be understood. Thus, as expected, the stereochemical pathways for the H–D exchange and the methylation of **2** are the same. A gauche conformation was suggested for **2** (Fig. 4b) by LIS measurements and mechanistic con-

siderations.[4b] With the revised assignment, the solution conformation of **2** is concluded as *t*-Bu/Ph anti (Fig. 4a); this is the conformation found in crystals and is compatible with the results obtained by dipole moment measurements.[10] The alcoholic analogue of **2**, ($PhCH_2CHOH$-tBu),[14] has been shown to have the *t*-Bu/Ph anti conformation in solutions. This, again, is consistent with the above conclusion regarding the solution conformation of **2**.

A question remains, however, as to the origin of the erroneous configuration assignment of **2**-*d*. At present, we do not know whether this arose from the chemical correlation process,[1b] or originated from the absolute configuration assignment of optically active benzyl alcohol.[3]

We wish to thank Professors Shigeru Oae (Okayama College of Science), Atsuyoshi Ohno (Kyoto Univ.), and Ukon Nagai (Mitsubishi Institute of Life Sciences) for useful discussions.

Photochemical Reactions of Aryltriethylgermanes and Diethyldiphenylgermane

Michio KOBAYASHI* and Masanori KOBAYASHI
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
(Received January 16, 1986)

Aryltriethylgermanes and diethyldiphenylgermane were found to split easily to generate germyl radicals by irradiation with a medium-pressure mercury lamp in hexane or cyclohexane. The germyl free radicals produced reacted with hydrocarbon radicals generated from the solvent by hydrogen abstraction either by recombination or by disproportionation.

There have been only a few studies[1] of the photochemical reaction of organogermanium compounds. We have investigated the photochemical behavior of several alkylarylgermanes and found that germanium–carbon bonds are cleaved readily by irradiation to generate germyl free radicals and the results will be described in this paper.

Results and Discussion

Photochemical reactions of three aryltriethylgermanes, Et_3GeAr (**1a**, Ar=Ph; **1b**, Ar=*p*-$CH_3C_6H_4$; **1c**, Ar=*p*-$NO_2C_6H_4$) and diethyldiphenylgermane Et_2GePh_2 (**1d**) were examined.

When a solution of **1a** (or **1b**) in hexane was irradiated under an argon atmosphere with a 450 W medium-pressure mercury lamp through a Vycor filter for 20—30 min, about 40% of the substrate was photolyzed. Hexyltriethylgermanes, Et_3GeR (**2a**, R=*n*-C_6H_{13}; **2b**, R=$CH(CH_3)C_4H_9$; **2c**, R=$CH(C_2H_5)$-C_3H_7(*n*-), hexaethyldigermane (**3**), benzene (or toluene in the case of **1b**) and dodecanes (**5**) were identified as products. Structure assignment was performed by GC–MS, IR, ^1H NMR, and ^{13}C NMR. The yields were estimated by GLC and HPLC. The results are summarized in Table 1.

$$\underset{\mathbf{1}}{Et_3GeAr} \xrightarrow[\text{hexane}]{250\text{ nm}} \underset{\mathbf{2}}{Et_3GeR} + \underset{\mathbf{3}}{(Et_3Ge)_2} + \underset{\mathbf{4}}{ArH} + \underset{\mathbf{5}}{C_{12}H_{26}}$$

a: Ar=Ph
b: Ar=*p*-Tol

In the case of **1a**, some polymers were also formed. The relative yields of **2b** and **2c** could not be determined, since these two products have almost the same GLC retention time.

Formation of hexaethyldigermane (**3**), hexyltriethylgermanes (**2a—c**) and large amounts of benzene (or toluene) indicates that the aryl–germanium bond, not the alkyl–germanium bond, splits in the photolysis as is shown in the following reaction sequences.

$$Et_3GeAr \longrightarrow Et_3Ge\cdot + Ar\cdot$$
$$RH + Ar\cdot \longrightarrow R\cdot + ArH$$
$$Et_3Ge\cdot + R\cdot \longrightarrow Et_3GeR$$
$$2Et_3Ge\cdot \longrightarrow (Et_3Ge)_2$$
RH=hexane

In the first step, the aryl–Ge bond is cleaved. Since the germyl free radical is known[1,2] to possess little ability to abstract hydrogen atom from alkanes, the aryl radical must play a major role to abstract a hydrogen atom from the solvent (hexane or cyclohexane). Hexyl radicals may recombine with a germyl radical to give triethylhexylgermanes or with other hexyl radicals to form a dodecane mixture. The germyl radical can also dimerize to hexaethyldigermane.

The ratio **2a**/(**2b**+**2c**) after statistical correction (10/18 with **1a**; 4/15 with **1b**) evaluates the relative reactivity for primary to secondary C–H toward hydrogen abstraction from a hexane by a phenyl radical. Relative selectivities of hydrogen abstraction from primary, secondary, and tertiary C–H by a phenyl radical generated thermally from phenylazotriphenylmethane was reported as 1 : 9.3 : 44 at 60 °C.[3] Compared with the latter figures, the selectivities of the aryl radical from **1a** or **1b** are about 1/2 to 1/4.

The reason for the preferential cleavage of the aryl–Ge bond instead of the alkyl–Ge bond may be explained as follows. The UV absorption maximum of aryltriethylgermane (**1a**, **1b**) lies near the 257 nm region, which corresponds to a ^1L_a transition of the

Table 1. Photolysis of Aryltriethylgermanes

Ar	Irr. time / min	Products (yield/%)[a]					Recovered **1**/%
		2a	**2b** **2c**	**3**	**4**	**5**	
Ph (**1a**)	20	5	6	13	78	Trace	49
p-$CH_3C_6H_4$ (**1b**)	30	12	30	57	97	Trace	65

a) Yields were based on the starting materials consumed.

benzene pi orbital. Since in the present photochemical experiments, a medium pressure mercury lamp was used as the light source, 253.7 nm radiation with highest intensity is considered to excite the aryl pi electron of the arylgermanes, accompanied by a weakening of the aryl–Ge bond, thus subsequently resulting in its splitting before the energy transfer to an ethyl–Ge bond occurred effectively.

The effects of the triplet sensitizer was examined using acetophenone. When **1b** was irradiated in hexane for 30 min in the presence of acetophenone (0.1 mol/mol of **1b**), the extent of the photolysis of **1b** was found to be about 7%, much lower than that in the absence of acetophenone. This finding suggests that the photolysis proceeds via a singlet excited state. The decrease of the extent of the photolysis may be attributed to the quenching effects of acetophenone.

The photochemical behavior of *p*-nitrophenyltriethylgermane (**1c**) was different from those of **1a** and **1b**. Irradiation of **1c** in cyclohexane for 15 min (or in benzene for 5 h) with a 450 W medium-pressure mercury lamp through a Vycor filter under an argon atmosphere resulted in the formation of a complex mixture. Small amounts of phenyltriethylgermane (**1a**) (3%), *p*-hydroxyphenyltriethylgermane (14%) and cyclohexanone (11%) were detected among the products. (the yields in parenthesis are conversion yields. 78% of **1c** was recovered). No cyclohexyltriethylgermane was detected. These findings suggest that the nitro group of **1c** suffers photolysis more readily than the carbon–germanium bond.

When diethyldiphenylgermane (**1d**) was irradiated in hexane for 30 min under argon with radiation of wavelength >250 nm, the main products were diethylphenylgermane (**6a**), diethylphenylgermylhexanes (**7a—c**), benzene, and dodecanes (**5**).

$$\underset{\textbf{1d}}{Et_2GePh_2} \xrightarrow[\text{hexane}]{} \underset{\textbf{6a}\ 23\%}{Et_2GeH(Ph)} + \underset{\textbf{7a};\ R=\text{hexyl}\ 12\%;\ \textbf{7b};\ R=\text{1-methylpentyl}\ 26\%;\ \textbf{7c};\ R=\text{1-ethylbutyl}\ 5\%}{Et_2GeR(Ph)} + \underset{133\%}{PhH}$$

$$+ \underset{\text{trace}}{C_{12}H_{26}} + \underset{77\%}{\text{recovered } \textbf{1d}}$$

(yields are conversion yields)

The remarkable difference of the photochemical behavior of **1d** from those of **1a** or **1b** is the production of hydrogermane (**6a**) and no formation of digermane $(Et_2GePh)_2$. In order to confirm that the hydrogen atom of hydrogermane **6a** originated from the solvent hexane, **1d** was irradiated in cyclohexane-d_{12}. Formation of deuteriogermane, Et_2GePhD (**6b**) was confirmed by GC-MS. As mentioned before, the germyl free radical is believed to lack ability to abstract a hydrogen atom from alkanes.[1,2] The only known examples of hydrogen abstraction by a germyl radical are the cases of the reaction in toluene or 2-propanol as solvent.[2] Formation of **6a** may be explained by a disproportionation reaction between a diethylphenylgermyl radical and hexyl radicals (hexyl, 1-methylpentyl and 1-ethylbutyl radical), as shown in the following equation:

$$Et_2\dot{G}ePh + \cdot C_6H_{13} \longrightarrow \underset{\textbf{6a}}{Et_2GeH(Ph)} + C_6H_{12}$$

Formation of a saturated and an unsaturated compound by a disproportionation reaction between two free radicals is well known among aliphatic hydrocarbon radicals. To confirm the formation of hexenes required in the disproportionation, bromine was added to the solvent recovered by distillation. After being kept for a few h in the dark, the mixture was concentrated and the residue subjected to GC–MS analysis. Formation of 6% of a dibromohexane mixture (1,2-, 2,3-, and 3,4-) was observed, thus verifying the formation of hexenes in the photoreaction of diethyldiphenylgermane in hexane. When the photolysis of **1d** was carried out in cyclohexane, formation of hydrogermane **6a** (23%) and cyclohexene (10% as dibromocyclohexane) was detected. The absence of digermane among the products in the photolysis of **1d** may be attributed to the steric hindrance toward recombination of the diethylphenylgermyl radical.

The possibility of the photochemical generation of germylene (**9**) from **1d** was also examined. If two geminal phenyl groups of **1d** split off from germanium atom simultaneously, diethylgermylene and biphenyl would be formed. When **1d** was photolyzed in the presence of 2,3-dimethyl-1,3-butadiene, (which is known as a good scavenger for germylene,[4]) in cyclohexane as solvent, only a trace of 1,1-diethyl-3,4-dimethyl-3-germacyclopentene and 0.5—1.0% of biphenyl were detected by GC–MS. This finding indicates that the Ph–Ge bond splitting occurs stepwise in the photolysis of **1d**.

$$Et_2GePh_2 \begin{cases} \longrightarrow Et_2\dot{G}ePh + Ph\cdot \\ \not\longrightarrow Et_2Ge: + Ph\text{-}Ph \end{cases}$$

9

In this reaction, no products which should arise from the addition of diethylphenylgermyl radical to diene were detected by GC-MS. The main products in this experiment were those from the recombination of a cyclohexyl radical and a germyl radical as in the absence of 2,3-dimethyl-1,3-butadiene.

Experimental

GLC and HPLC were performed on a Hitachi 163 Gas Chromatograph with SE-30 10% coated column (2 m) and a Hitachi 655 Liquid Chromatograph with Hitachi 638-

41 UV monitor. IR and UV spectra were recorded on a Hitachi 260-10 IR spectrophotometer and Hitachi 220 A UV spectrophotometer respectively. The proton NMR spectra were recorded at 60 MHz using a JNM-PMX-60 spectrometer with TMS as an internal standard in $CDCl_3$ or C_6D_6. Mass spectra were measured with a JMS-DX300 high resolution mass spectrometer.

Materials. *p*-Tolyltriethylgermane (**1b**),[5] *p*-nitrophenyltriethylgermane (**1c**),[6] diethyldiphenylgermane (**1d**)[7] and hexaethyldigermane (**3**)[8] were prepared according to the literature.

Phenyltriethylgermane (1a): Bromotriethylgermane (5.00 g; 20.9 mmol) in benzene (20 cm^3) was added to the phenylmagnesium bromide prepared from bromobenzene (4.00 g; 25.0 mmol) and magnesium (0.60 g ; 25.0 m gatom) in ether (30 cm^3). The mixture was refluxed for 3.5 h, then hydrolyzed with ice and dilute hydrochloric acid. After the usual work-up and purification by silica-gel column chromatography with hexane as an eluent and fractional distillation, **1a** was obtained in 94% yield. Bp 77—78 °C/1 mmHg (1 mmHg=133.322 Pa)(lit,[5] 117—118 °C/13.5 mmHg). UV; λ_{max}=257 nm, ε=230. ^{1}H NMR δ=0.97—1.03 (m, 15H), 7.34—7.37 (m, 5H). MS; *m/z* 238 (M^+).

Hexyltriethylgermane (2a): Bromotriethylgermane (2.00 g; 8.34 mmol) in tetrahydrofuran (50 cm^3) was added to hexylmagnesium bromide prepared from 1-bromohexane (2.75 g; 16.7 mmol) and magnesium (0.41 g; 16.7 m gatom) in THF (50 cm^3). The reaction mixture was refluxed for 17 h. After the usual work-up, the product was purified by silica-gel column chromatography and fractional distillation. Yield 97%. Bp 60 °C/0.7 mmHg (lit, [9] 117 °C/20 mmHg). ^{1}H NMR δ=0.45—1.53 (m, 28H). MS; *m/z* 246 (M^+).

1-Methylpentyltriethylgermane (2b): This compound was synthesized from bromotriethylgermane (4.00 g; 16.7 mmol) and 1-methylpentylmagnesium bromide, prepared from 2-bromohexane (5.15 g; 33.4 mmol), in a similar way as **2a**. Yield 43%. Bp 56—57 °C/0.5 mmHg. MS; *m/z* 246 (M^+): Exact MS; Found, 217.0995, Calcd for $C_{10}H_{23}Ge$ ($M^+-C_2H_5$) 217.1011. ^{1}H NMR; δ=0.40—1.67 (m, 28H).

1-Ethylbutyltriethylgermane (2c) was synthesized from bromotriethylgermane and 3-bromohexane in a similar way as **2b**. Yield 59%. Bp 62—64 °C/1.05 mmHg. MS; *m/z* 246 (M^+): Exact MS; Found, 217.1004, Calcd for $C_{10}H_{23}Ge$ ($M^+-C_2H_5$) 217.1011. ^{1}H NMR; δ=0.43—1.67 (m, 28H).

Bromodiethylphenylgermane (8): Bromine (5.61 g; 35.1 mmol) in 1,2-dibromoethane (10 cm^3) was added to diethyldiphenylgermane (10.0 g; 35.1 mmol) in 1,2-dibromoethane (100 cm^3) at 80—85 °C. The mixture was refluxed for 2 h, then the solvent was distilled off under reduced pressure. The residue was purified by fractional distillation. Yield 80%. Bp 110—112 °C/4 mmHg (lit,[10] 141 °C/18 mmHg). MS; *m/z* 288 (M^+). ^{1}H NMR; δ=0.85—1.90 (m, 10H), 7.17—7.70 (m, 5H).

Diethylphenylgermane (6a): **8** (2.00 g; 6.95 mmol) in dry ether (10 cm^3) was slowly added to lithium aluminum hydride (0.26 g; 6.95 mmol) in ether (20 cm^3) with stirring and refluxing. The reaction mixture was refluxed for 2 h. The reaction was quenched by slow addition of water with cooling and followed by 3 M sulfuric acid. The organic layer was separated within 10 min and dried over sodium sulfate. After expelling the solvent, the residue was purified by fractional distillation. Yield 83%. Bp 100—102 °C/21 mmHg. MS; *m/z* 210 (M^+). ^{1}H NMR; δ=0.75—1.28 (m, 10H), 4.40—4.63 (m, 1H), 7.03—7.60 (m, 5H). IR (neat); 2007 cm^{-1} (ν_{Ge-H}). Exact MS; *m/z* Found, 210.0548, Calcd for $C_{10}H_{16}{}^{74}Ge$ 210.0462.

1-(Diethylphenylgermyl)hexane (7a): **8** (3.01 g; 10.5 mmol) in THF (50 cm^3) was added to hexylmagnesium bromide prepared from 1-bromohexane (3.44 g; 20.9 mmol) and magnesium (0.51 g; 20.9 m gatom) in THF (100 cm^3). The reaction mixture was refluxed for one night and hydrolyzed with ice and water. The THF layer was separated and the aqueous layer extracted with ether. After the solvent was evaporated, the residue was purified by silica-gel column chromatography and fractional distillation. Yield 48%. Bp 100 °C/0.6 mmHg. MS; *m/z* 265 ($M^+-C_2H_5$): Exact MS; Found, 265.1043, Calcd for $C_{14}H_{23}Ge$ ($M^+-C_2H_5$) 265.1011. ^{1}H NMR; δ=0.63—1.70 (m, 23H), 7.07—7.57 (m, 5H).

2-(Diethylphenylgermyl)hexane (7b): This compound was synthesized from **8** (2.94 g; 10.2 mmol) and 1-methylpentylmagnesium bromide prepared from 2-bromohexane (3.44 g; 20.9 mmol) in a similar way to **7a**. Yield 45%. Bp 95—96 °C/0.55 mmHg. MS; *m/z* 294 (M^+): Exact MS; Found, 265.0978, Calcd for $C_{14}H_{23}Ge$ ($M^+-C_2H_5$) 265.1011. ^{1}H NMR δ=0.67—1.63 (m, 23H), 7.07—7.55 (m, 5H).

3-(Diethylphenylgermyl)hexane (7c) was prepared from **8** (1.60 g; 5.56 mmol) and 1-ethylbutylmagnesium bromide in a similar way to **7a**. Yield 43%. Bp 101 °C/0.85 mmHg. MS; *m/z* 294 (M^+): Exact MS; Found, 265.0964, Calcd for $C_{14}H_{23}Ge$ ($M^+-C_2H_5$), 265.1011. ^{1}H NMR; δ=0.60—1.77 (m, 23H), 7.07—7.57 (m, 5H).

Photolysis: A typical example of the photolysis is described in the case of **1a**. A solution containing 210.7 mg (0.89 mmol) of **1a** in 230 cm^3 hexane was irradiated under an argon atmosphere with a 450 W medium-pressure mercury lamp (Hanovia) through a Vycor filter for 20 min. After the removal of the solvent by distillation, the products were analyzed by GC-MS. Products **2**, **3**, and **5** were identified by comparison of their GLC retention time and mass fragment pattern with those of authentic samples.

Photolysis of 1d in cyclohexane-d_{12}: A solution containing 4.14 mg of **1d** in 0.7 cm^3 of cyclohexane-d_{12} was externally irradiated with a 450 W medium-pressure mercury lamp through a Vycor filter for 30 min. The photolysate was analyzed by GC-MS. Although a parent peak of deuterated germane (**6b**) was not observed, its fragment peaks, *m/z* 182 (**6b**$-C_2H_5$) and 153 (**6b**$-2C_2H_5$) (base peak) were observed with high intensity.

Thanks are due to The Asai Germanium Research Institute for donation of tetrachlorogermane.

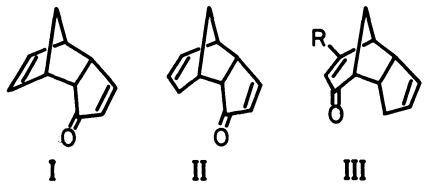
Synthesis and Photolysis of Tricyclo[5.3.1.$0^{2,6}$]undeca-3,9-dien-8-ones and -4,9-dien-8-ones. Formation of Novel Trishomocubanones[1)]

Toshio Ogino* and Kazuyuki Awano*,†
Department of Chemistry, Faculty of Education, Niigata University,
Ikarashi, Niigata 950-21
†Department of Industrial Chemistry, Nagaoka Technical College,
Nishikatagai, Nagaoka 940
(Received February 14, 1986)

A series of 10-substituted tricyclo[5.3.1.$0^{2,6}$]undeca-3,9-dien-8-ones (**6**) and the 4,9-dien-8-one isomers (**7**) were synthesized and photolyzed. Upon irradation, whereas most of the derivatives underwent [2+2] photocyclization to give the corresponding novel trishomocubanones, the methyl and phenyl derivatives of **7** afforded products attributable to intramolecular hydrogen abstraction by the β-carbon of the α,β-unsaturated ketone along with the photocyclization products.

Because of the efficient construction of strained polycyclic molecules and the storage of solar energy, intramolecular photochemical [2+2] cyclizations of bridged dienes or dienones have attracted considerable attention in recent years. In particular, the conversion of dicyclopentadienone (**I**) to bishomocubanone is the best known example of such a reaction.[2)] However, there have been no systematic studies on the photochemistry of the homologous dienones such as **II** or **III**, whose structural feature is very unique from the point of view that they have an allylic system facing to the conjugated enone moiety in the rigid molecule. These compounds are expected to undergo not only [2+2] photocyclization to give novel trishomocubane frameworks but also competitive intramolecular allylic hydrogen abstraction by the excited enones. Only a few examples are known for the photochemical reactions in which intramolecular hydrogen abstraction occurs competitively along with [2+2] photocyclization.[3,4)]



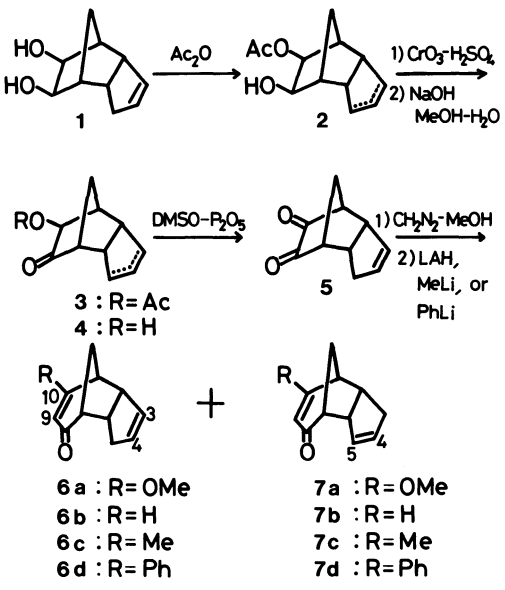
I II III

It seems to us of interest to synthesize the derivatives of **III** (**6a—d**) variously substituted at the β-carbon of the α,β-unsaturated enone and their isomers **7a—d** and to study their photochemical behavior. Details of such a study are reported herewith.

Results and Discussion

Syntheses of 10-Substituted Tricyclo[5.3.1.$0^{2,6}$]undecadienones. Scheme 1 shows the outline of the syntheses for **6a—d** and **7a—d**. The key compounds **6a** and **7a** were first synthesized starting from the diol **1**, which had been prepared by phase-transfer-assisted permanganate oxidation of *endo*-dicyclopentadiene in dichloromethane followed by treatment with an aqueous base.[5)] Since it was difficult to oxidize **1** directly into the α-diketone **5**, the conversion was accomplished in the following manner. The diol (**1**) was partially acetylated with acetic anhydride at room temperature to give an isomeric mixture of the monoacetates **2**. Chromium trioxide oxidation of **2** followed by alkaline hydrolysis of the resulting keto acetates **3** afforded the α-ketol **4** as an isomeric mixture in 60% overall yield from **1**. The conversion of **4** into **5** with conventional oxidizing agents ($FeCl_3$–HCl, $Cu(OAc)_2$–AcOH, and $CuSO_4$–pyridine) failed. However, treatment of **4** with DMSO at 80—90 °C in the presence of P_2O_5[6)] afforded **5** as a single product in 56% yield. The structure of **5** was supported by the spectral characteristics [IR 1770 and 1750 cm^{-1}; UV 475 nm (ε 24)], which are quite similar to those reported for camphorquinone.[7)]

Treatment of **5** with diazomethane in diethyl ether in the presence of a small amount of methanol[8)] gave an isomeric mixture of **6a** and **7a** in a 6 : 4 ratio via ring expansion and subsequent methylation of the resulting β-diketone. The mixture was separated by



Scheme 1.

preparative GLC or column chromatography on silica gel-$AgNO_3$. The IR (1640 and 1600 cm^{-1} for both **6a** and **7a**) and UV spectra [254 nm (ε 9300) for **6a**; 254 nm (ε 12900) for **7a**] exhibited the characteristic absorptions of α,β-unsaturated β-methoxycyclohexenone.

The assignments of the double-bond position in the cyclopentene rings of **6a** and **7a** were established by NMR studies using $Eu(dpm)_3$ as the shift reagent. The induced shifts determined for the olefinic proton signals are summarized in Table 1. Since the extremely large shift ($\Delta\delta$=5.56 ppm) observed for an olefinic proton of **7a** could be attributed to proximity of this hydrogen to the carbonyl group, **7a** were assigned to the structure having the double bond at C_4–C_5, and hence **6a** to the one having the double bond at C_3–C_4. This was further supported by the structures of the photoproducts of these compounds (vide infra).

The compound **6a** was then converted to **7b** (R=H), **7c** (R=Me), and **7d** (R=Ph) by reactions with LAH, MeLi, and PhLi, respectively, followed by acid treatment. In a similar fashion, **7a** was converted to **6b** (R=H), **6c** (R=Me), and **6d** (R=Ph). The structures of all the new compounds were evidenced by spectroscopic data (see Experimental), and the assignments of the double bond position were also compatible with the results of photolysis as described below.

Photolyses of the Tricyclo[5.3.1.$0^{2,6}$]undecadienones (6a—d and 7a—d). Irradiation of a benzene solution of **6a** in a Pyrex tube gave the [2+2] photocycloaddition product **8a** exclusively. The structure of the product was supported by the IR absorption at 1700 cm^{-1}, which indicated the presence of a six-membered cyclic ketone as expected from the structure of **6a** (but not **7a**), and also by the ^1H NMR spectrum, which was devoid of signals attributable to olefinic protons downfield from the methoxyl signal at δ 3.20.

Table 1. Induced Shifts of the Vinyl Proton Signals by $Eu(dpm)_3$

Compound	Hydrogen	$\Delta\delta^{a)}$ ppm
6a	C_3-H	1.52
	C_4-H	1.52
7a	C_4-H	2.45
	C_5-H	5.56

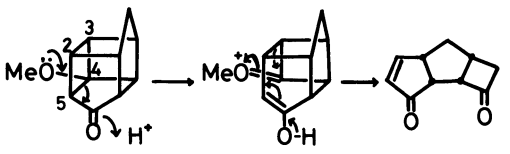
a) Changes in chemical shift at the molar ratio $Eu(dpm)_3$/substrate = 1 extrapolated from the data observed at the ratio 0—0.18.

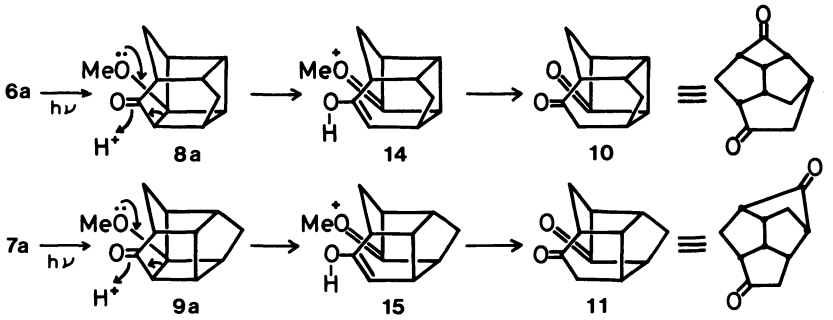
Treatment of **8a** with an acid in methanol gave **10**, a novel tetracyclic diketone, whose structure was deduced from the IR bands at 1765 (cyclobutanone) and 1700 cm^{-1} (cyclohexanone), and from the ^1H NMR spectrum (devoid of methoxyl signals).

In a similar fashion, irradiation of **7a** gave an unstable cylization product **9a**, which was more easily transformed into the tetracyclic diketone **11** upon treatment with an acid, or even on standing in a refrigerator overnight, possively due to acidic impurities on the glass wall or in the solvent. The structure of **11** was also deduced from the spectroscopic data [IR absorption at 1735 cm^{-1} (cyclopentanone) and NMR spectrum devoid of methoxyl signal].

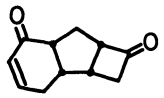
The formation of **10** and **11** can be rationalized by the retro-aldol type β-scission of the photoproducts (de Mayo reaction)[9] induced by protonation of the carbonyl groups and subsequent hydrolysis of the oxonium ions (**14** and **15**) as depicted in Scheme 2.

Recently, Zwanenburg, and co-workers[10] have reported a similar acid-catalyzed ring opening of methoxy-substituted bishomocubanone **16**. In this case, however, the initial scission of the C_4–C_5 bond is followed by subsequent C_2–C_3 bond cleavage, thus giving the tricyclic enedione **18**. The absence of signals due to olefinic protons in the ^1H NMR spectra of **10** and **11** can exclude the analogous enedione structures (**19** and **20**) for the ring opening products from **8a** and **9a**.

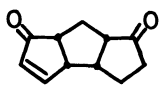




Scheme 2.



19

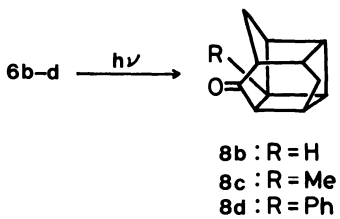


20

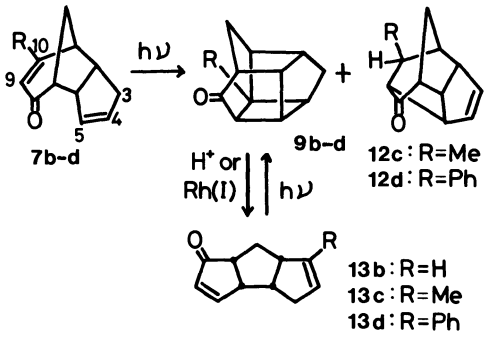
Irradiation of **6b—d** in benzene all resulted in the exclusive formation of trishomocubanones **8b—d** via [2+2] photocycloaddition (Scheme 3). The structures of the products were assigned by the IR absorptions (**8b**: 1695 cm^{-1}, **8c**: 1685 cm^{-1}, and **8d**: 1700 cm^{-1}) which are compatible with cyclohexanones in polycyclic rigid systems[11] and by the ^{13}C NMR spectra which displayed no resonances for sp^2-hybridized carbon other than those assigned to the carbonyl carbon and the aromatic ring. Further evidence was given by the mass spectra which are almost superimposable on those of the corresponding starting dienones.

Irradiation of **7b** gave **9b** exclusively, whereas irradiation of **7c** and **7d** produced not only the photocyclization products **9c** and **9d**, but also additional photoproducts **12c**[12] and **12d**, respectively. The product ratios estimated by ^1H NMR were 5 : 1 for **9c**/**12c**, and 4 : 1 for **9d**/**12d**. Since any attempts to separate the products by chromatography failed in both cases, **9c** and **9d** were converted to the tricyclic dienones **13c** and **13d** by treatment with acids,[13] and then regenerated by irradiation after the chromatographic separation from unchanged **12c** and **12d**, respectively (Scheme 4).

Again, the structures of **9b—d** were supported by the IR spectra (**9b**: 1720 cm^{-1}, **9c**: 1710 cm^{-1}, and **9d**: 1725 cm^{-1}), the ^1H NMR spectra (devoid of all low-field signals), and the ^{13}C NMR spectra (no resonances for sp^2-hybridized carbon other than those assigned to the carbonyl carbon and the aromatic ring). In addition, the mass-fragmentation patterns of this series of compounds (**9b—d**) were found to be quite similar to those of the dienones **13b—d**, respectively. The latter compounds have been obtained by acid or Rh(I)-catalyzed cycloreversion of **9b—d** and shown to reproduce the trishomocubanones (**9b—d**) upon irradiation (Scheme 4).[13,14] Recently, Mehta and coworkers have also established the similar interconversion between the pentacyclic diones **21** and the bis(enone)s **22**.[15]



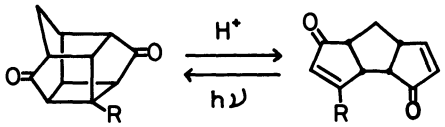
Scheme 3.



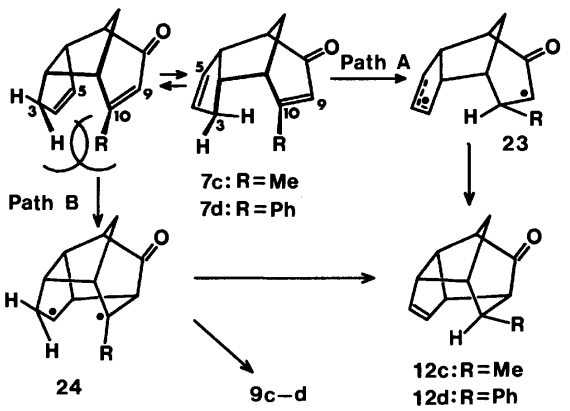
Scheme 4.

On the other hand, the ^1H NMR spectra of **12c** and **12d**, particularly the two olefinic proton signals at δ 5.79 (dd, J=6 and 3 Hz) and 6.10 (dd, J=6 and 3 Hz) for **12c**, and at δ 5.90 (dd, J=6 and 2.5 Hz) and 6.33 (dd, J=6 and 2.5 Hz) for **12d**, indicated that the double bond in the cyclopentene ring is retained in these compounds. This observation, coupled with the empirical formulae, $C_{12}H_{14}O$ for **12c** and $C_{17}H_{16}O$ for **12d**, determined by high-resolution mass spectra and elemental analysis suggested that these products have tetracyclic structures which are expected by intramolecular hydrogen abstraction. This was supported by the off-resonance ^1H decoupled ^{13}C NMR spectra. Namely, of the eleven skeletal carbons in each compound, one was accounted for by a signal for a carbonyl carbon [δ=219.2 (s) for **12c** and δ=218.5 (s) for **12d**], two were by signals for olefinic carbons [δ=133.6 (d) and 129.0 (d) for **12c**, and δ=134.8 (d) and 128.9 (d) for **12d**], seven were by signals for methine carbons [δ=54.5, 53.2, 52.7, 46.9, 45.8, 38.9, and 35.9 (all d) for **12c**, and δ=54.3, 52.9, 48.8, 46.5, 46.2, 45.8, and 40.6 (all d) for **12d**], and the remaining one was by a signal for a methylene carbon [δ=43.5 (t) for **12c**, and δ=42.4 (t) for **12d**]. These data, coupled with the appearance of the methyl signal as a doublet at δ 0.95 in ^1H NMR of **12c**, indicated that the hydrogen abstraction occurred at the β-carbon of the conjugated enone. Furthermore, of all the possible structures expected by hydrogen abstraction, only those depicted as **12c** and **12d** satisfied the IR spectra (1735 cm^{-1} for both **12c** and **12d**) which indicated the presence of the cyclopentanone rings.

Although a fair number of examples of the photoreactions which involve intramolecular allylic or benzylic hydrogen abstraction by the β-carbon of a conjugated enone have been reported,[16] a few examples of the reactions in which hydrogen abstrac-



21 22

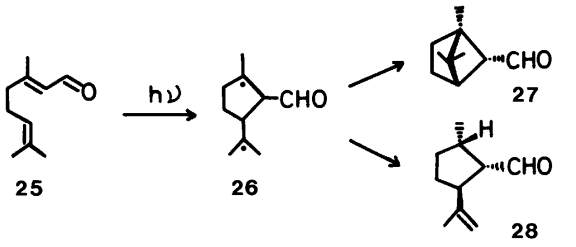


Scheme 5.

tion by the β-carbon occured along with intramolecular [2+2] photocyclization are known mainly with citral and related compounds.[4a] The mechanistic possibilities (which cannot presently be distinguished) include the following.

Initial abstraction of the C_3-hydrogen atom by the β-carbon of a triplet enone (possively common to [2+2] cyclization) gives biradical **23** (path A in Scheme 5), which in turn collapses to **12**. Dreiding model examination of **7c—d** indicated that the β-carbon-to-C_3-hydrogen distance is 1.9—2.5 Å, which is within the limit for the sum of the van der Waals radii of 2.90 Å suggested for hydrogen abstraction by carbon.[17] Furthermore, this inspection of the model disclosed that the substitution at C_{10} causes changes of the conformation so that the β-carbon-to-hydrogen distance becomes shorter and the hydrogen atom to be transferred becomes axial owing to the steric repulsion between the substituent and C_3-hydrogen. In this conformation, on the contrary, the spatial relationship of the two carbon-carbon double bonds comes to be unfavorable for the [2+2] cycloaddition reaction.

An alternative mechanism involves the initial bond formation between C_5 and C_9 to give the biradical **24** which may be a common intermediate for both **9c—d** and **12c—d** (path B in Scheme 5). A similar mechanism has been proposed for the photoreaction of citral (**25**) in which the biradical intermediate **26** derived from a triplet precursor led to both the [2+2] photocyclization product **27** and the hydrogen



abstraction product **28**.[4a] In addition, a same mechanism has been also proposed for the intermolecular photoreaction between 2-cyclohexenone and 2-methylpropene on the basis of the formation of 2-(2-methylallyl)cyclohexanone together with the corresponding cycloaddition product.[18]

Although we prefer path A because this provides the explanation for the production of the hydrogen transfer products from the reaction of **7c** and **7d**, the present results do not define the detailed mechanism of the photoreaction.

Experimental

General. Melting points are uncorrected. IR spectra (in $CHCl_3$, unless otherwise noted) were recorded on JASCO A-102 and A-3 spectrometers. UV spectra were obtained on Hitachi 200-10 and JASCO UVIDEC-505 spectrometers. ^1H NMR spectra (in $CDCl_3$, unless otherwise noted) were determined on JEOL JNM-PMX 60 and Hitachi R-600 spectrometers with tetramethylsilane as the internal standard. ^{13}C NMR spectra (in $CDCl_3$) were obtained with a JEOL JNM-GX 270 spectrometer. GLC was performed on a Hitachi 063 gas chromatograph using PEG 20 M, DEGS, or Silicone SE-30. Mass spectra were taken on a Hitachi M-60 mass spectrometer at an ionization potential of 70 eV. High-resolution mass measurements were carried out on JEOL JMS-D-300 and Hitachi RMU-7MG mass spectrometers. Photochemical reactions were carried out in Pyrex tubes using 300 and 500 W high pressure mercury lamps, with running water cooling under a nitrogen atmosphere.

Preparation of Monoacetate 2. A solution of 3.05 g (18.3 mmol) of **1**[5] in 50 cm^3 of freshly distilled Ac_2O was stirred at 30 °C for 19 h. The mixture was then poured into water (170 cm^3), stirred at room temperature for 2.5 h, and extracted with four 40 cm^3 portions of $CHCl_3$. The extracts were combined, washed with saturated aqueous $NaHCO_3$ and saturated brine, and dried ($MgSO_4$). Removal of the solvent under reduced pressure gave an oily residue which was purified on a silica-gel column (benzene–Et_2O) to afford pure **2** (3.12 g, 85%) as colorless crystals: Mp 68—70 °C. ^1H NMR (CCl_4) δ=2.00 (3H, s), 3.79 (1H, br. t, J=4 Hz), 4.50 (1H, t, J=6 Hz), and 5.62 (2H, br. s). IR 3600, 1720, and 1090 cm^{-1}. Found: C, 69.23; H, 7.67%. Calcd for $C_{12}H_{16}O$: C, 69.21; H, 7.74%.

Jones' Oxidation of 2 to Keto Acetate 3. To a well stirred solution of **2** (3.01 g, 14.5 mmol) in acetone (60 cm^3) was added Jones' reagent (12 cm^3) dropwise over a period of 1.5 h at 0 °C. After continued stirring for 30 min, the mixture was treated with 25% aqueous $NaHSO_3$ (20 cm^3), and concentrated to one-third of its original volume. The residue was poured into water, and extracted with $CHCl_3$ (60 cm^3×5). The combined extracts were washed with saturated aqueous $NaHCO_3$ and saturated brine, and dried over $MgSO_4$. Evaporation of the solvent in vacuo gave **3** (2.32 g, 78%) as pale yellow crystals. An analytical sample was prepared by recrystallization from Et_2O–pet. ether: Mp 62—64 °C. ^1H NMR (CCl_4) δ=2.00 (3H, s), 4.59 (1H, dd, J=14 and 3 Hz), and 5.67 (2H, m). IR 1755 and 1735 cm^{-1}. Found: C, 69.29; H, 6.84%. Calcd for $C_{12}H_{14}O_3$: C, 69.05; H, 6.94%.

Hydrolysis of 3 to α-Ketol 4. To a stirred solution of **3** (2.20 g, 10.7 mmol) in methanol (30 cm^3) was added a methanolic solution (10 cm^3) of NaOH (0.6 g, 15.0 mmol) dropwise over a period of 10 min at room temperature under

a nitrogen atmosphere, and stirring was continued for 5 min. After evaporation of most part of the solvent, the residue was poured into water, and extracted with $CHCl_3$ (40 cm^3×5). The extracts were washed with saturated brine, dried over $MgSO_4$, and evaporated in vacuo to give **4** (1.59 g, 91%) as pale yellow crystals. An analytical sample was prepared by recrystallization from Et_2O–pet. ether: Mp 64—69 °C. ^1H NMR (CCl_4) δ=3.30 (1H, m), 3.54 (1H, m), and 5.60 (2H, br. s). IR 3600, 1750, and 1055 cm^{-1}. Found: C, 72.54; H, 7.80%. Calcd for $C_{10}H_{12}O_2$: C, 73.14; H, 7.37%.

DMSO Oxidation of 4 to α-Diketone (5). To a solution of **4** (6.18 g, 37.6 mmol) in dimethyl sulfoxide (110 cm^3) was added a solution of phosphorus pentoxide (16 g, 113 mmol) in DMSO (60 cm^3) at 90 °C over a period of 5 min. After standing for 30 min at 90 °C, the mixture was cooled, poured into water, and extracted with $CHCl_3$ (100 cm^3×5). The extracts were washed with water, saturated aqueous $NaHCO_3$, and saturated brine and dried over $MgSO_4$. After removal of the solvent at reduced pressure, the residue was purified on a silica-gel column (benzene–Et_2O) to afford 3.42 g (56%) of **5** as yellow crystals. An analytical sample was prepared by recrystallization from Et_2O–pet. ether: Mp 58—60 °C. ^1H NMR δ=1.85—3.85 (8H, m) and 5.53 (2H, br s). IR 1770 and 1750 cm^{-1}. UV (EtOH) 263 (ε 141) and 475 nm (ε 24). MS *m/z* 162 (M^+). Found: C, 73.17; H, 6.05%. Calcd for $C_{10}H_{10}O_2$: C, 74.06; H, 6.21%.

Preparation of 10-Methoxytricyclo[5.3.1.$0^{2,6}$]undeca-3,9-dien-8-one (6a) and 10-Methoxytricyclo[5.3.1.$0^{2,6}$]undeca-4,9-dien-8-one (7a) from 5. To a stirred solution of **5** (1.91 g, 11.8 mmol) in Et_2O (10 cm^3) were added an ethereal solution (100 cm^3) of diazomethane and MeOH (5 cm^3) in small portions at 0 °C, and the mixture was stirred overnight at room temperature. After evaporation of the solvent, separation of the residual oil (1.97 g) by preparative GLC (20% PEG 20 M on Chromosorb W-AW-DMCS, 230 °C) gave **6a** (0.89 g, 40%) as colorless crystals and **7a** (0.54 g, 24%) as a colorless oil. **6a**: Mp 67.5—69 °C. ^1H NMR δ=1.50—2.35 (4H, m), 2.50—3.50 (4H, m), 3.53 (3H, s), 4.93 (1H, s), and 5.50 (2H, m). IR 1640 and 1600 cm^{-1}. UV (EtOH) 254 nm (ε 9300). MS *m/z* (rel intensity) 190 (M^+, 100), 175 (4), 125 (89), 124 (98), 109 (29), 106 (15), 96 (9), 92 (10), 91 (9). Found: C, 75.73; H, 7.26%; *m/z* 190.0983. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%; M, 190.0993. **7a**: ^1H NMR δ=1.50—2.35 (4H, m), 2.50—3.50 (4H, m), 3.64 (3H, s), 4.91 (1H, s), and 5.48 (2H, s, $W_{1/2}$=4 Hz). IR 1640 and 1600 cm^{-1}. UV (EtOH) 254 nm (ε 12900). MS *m/z* (rel intensity) 190 (M^+, 100), 175 (3), 162 (10), 147 (20), 130 (11), 129 (11), 125 (61), 124 (100), 109 (60), 106 (91), 98 (21). Found: C, 75.20; H, 7.67%; *m/z* 190.0997. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%; M, 190.0993.

Preparation of Tricyclo[5.3.1.$0^{2,6}$]undeca-3,9-dien-8-one (6b) from 7a. To a refluxing mixture of $LiAlH_4$ (108 mg, 2.84 mmol) and dry Et_2O (20 cm^3) was added an anhydrous ethereal solution (5 cm^3) of **7a** (120 mg, 0.64 mmol). After refluxing for 2 h the mixture was cooled, treated with AcOEt (4 cm^3), and stirred with 25% H_2SO_4 (25 cm^3) at room temperature for 18 h. The organic solvent was evaporated in vacuo, and the aqueous solution was extracted with CH_2Cl_2 (15 cm^3×4). The extracts were washed with saturated aqueous $NaHCO_3$ and saturated brine, dried over $MgSO_4$, and evaporated in vacuo. Purification of the residue by silica-gel chromatography (benzene–Et_2O) gave pure **6b** (55 mg, 55%); Mp 49—53 °C. ^1H NMR δ=1.54—2.45 (4H, m), 2.65—3.30 (3H, m), 3.35—3.90 (1H, m), 5.56 (2H, br s, $W_{1/2}$=6 Hz), 5.90 (1H, d, *J*=10 Hz), and 6.93 (1H, dd, *J*=10 and 2 Hz). IR 1665 cm^{-1}. UV (EtOH) 230 nm (ε 4860). MS *m/z* (rel intensity) 160 (M^+, 26), 132 (5), 95 (100), 94 (30), 91 (13), 77 (25), 66 (38), 65 (13). Found: C, 81.99; H, 7.65%; *m/z* 160.0875. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%; M, 160.0888.

Preparation of Tricyclo[5.3.1.$0^{2,6}$]undeca-4,9-dien-8-one (7b) from 6a. To a suspension of lithium aluminum hydride (120 mg, 3.1 mmol) in dry Et_2O (45 cm^3) was added a solution of **6a** (121 mg, 0.64 mmol) in dry Et_2O (5 cm^3) under reflux and the mixture was heated for 1.5 h. Working up and purification similar to those employed for the synthesis of **6b** gave pure **7b** (52 mg, 51%) as colorless crystals: Mp 40—45 °C. ^1H NMR δ=1.50—2.46 (4H, m), 2.53—3.25 (3H, m), 3.35—3.80 (1H, m), 5.55 (2H, s), 5.83 (1H, dd, *J*=10 and 2 Hz), and 7.10 (1H, br t, *J*=8 Hz). IR 1665 cm^{-1}. UV (EtOH) 236 nm (ε 5800). MS *m/z* (rel intensity) 160 (M^+, 41), 132 (53), 131 (20), 117 (86), 104 (27), 95 (37), 94 (18), 91 (57), 79 (32), 78 (61), 77 (45), 67 (29), 66 (100), 65 (36). Found: C, 82.16; H, 7.60%; *m/z* 160.0957. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%; M, 160.0888.

Preparation of 10-Methyltricyclo[5.3.1.$0^{2,6}$]undeca-3,9-dien-8-one (6c) from 7a. To a stirred solution of **7a** (118 mg, 0.62 mmol) in dry Et_2O (20 cm^3) at room temperature under nitrogen atmosphere was added a solution of methyllithium in Et_2O (1.85 mol dm^{-3}, 2.7 cm^3) over a period of 45 min. The reaction mixture was refluxed for 2 h, cooled to 0 °C, and treated with H_2SO_4 (3 mol dm^{-3}, 15 cm^3) for 50 min with vigorous stirring. Most of the organic solvent was evaporated, and the aqueous solution was extracted with $CHCl_3$ (30 cm^3×3). The extracts were washed with saturated aqueous $NaHCO_3$, 3% aqueous Na_2SO_3 (20 cm^3) and saturated brine, dried ($MgSO_4$), and evaporated. Bulb-to-bulb (Kugelrohr) distillation of the residue [123—124 °C (1333 Pa)] gave pure **6c** (75 mg, 69%): Mp 42—45 °C. ^1H NMR δ=1.70—2.36 (4H, m), 1.83 (3H, s), 2.40—3.26 (3H, m), 3.40—3.83 (1H, m), 5.53 (2H, br s, $W_{1/2}$=3 Hz), and 5.66 (1H, br s, $W_{1/2}$=5 Hz). IR 1655 and 1620 cm^{-1}. UV (EtOH) 238 nm (ε 7950). MS *m/z* (rel intensity) 174 (M^+, 32), 159 (4), 109 (100), 108 (31), 91 (18), 79 (12), 77 (14), 66 (13), 65 (12). Found: C, 82.35; H,8.25%; *m/z* 174.1028. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%; M, 174.1045.

Preparation of 10-Methyltricyclo[5.3.1.$0^{2,6}$]undeca-4,9-dien-8-one (7c) from 6a. To a stirred solution of **6a** (121 mg, 0.64 mmol) in dry Et_2O (20 cm^3) was added an ethereal solution of methyllithium (1.85 mol dm^{-3}, 2 cm^3) under nitrogen atmosphere at room temperature over a period of 50 min. The reaction mixture was worked up and purified by a method similar to that employed for the synthesis of **6c** to give **7c** (73 mg, 66%) as a colorless oil: ^1H NMR δ=1.70—2.43 (4H, m), 2.02 (3H, s), 2.60—3.30 (3H, m), 3.30—3.80 (1H, m), 5.55 (2H, br s, $W_{1/2}$=2 Hz), and 5.65 (1H, br s, $W_{1/2}$=5 Hz). IR 1655 and 1620 cm^{-1}. UV (EtOH) 237 nm (ε 7300). MS *m/z* (rel intensity) 174 (M^+, 68), 159 (4), 146 (50), 131 (100), 117 (27), 106 (40), 105 (27), 93 (33), 92 (96), 91 (51), 80 (48). Found: C, 82.52; H, 8.13%; *m/z* 174.1025. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%; M, 174.1045.

Preparation of 10-Phenyltricyclo[5.3.1.$0^{2,6}$]undeca-3,9-dien-8-one (6d) from 7a. To a stirred solution of **7a**

(275 mg, 1.45 mmol) in dry Et_2O (30 cm^3) was added an ethereal solution of phenyllithium (1.66 mol dm^{-3}, 5.5 cm^3) at 0 °C over a period of 40 min under nitrogen atmosphere. The reaction mixture was refluxed for 3 h, poured into ice-cold 25% H_2SO_4 (20 cm^3), and stirred for 1 h. Most of the organic solvent was evaporatd, and the aqueous solution was extracted with $CHCl_3$ (50 cm^3×3). The extracts were washed with saturated aqueous $NaHCO_3$ and saturated brine, dried ($MgSO_4$), and evaporated. The residue was chromatographed on silica-gel (benzene–Et_2O) to give **6d** (214 mg, 62%) as colorless crystals: Mp 98—100 °C. ^1H NMR δ=1.70—2.43 (4H, m), 2.83—3.33 (2H, m), 3.35—3.93 (2H, m), 5.43 (2H, m), 6.22 (1H, s), and 7.42 (5H, br s). IR 1655 and 1600 cm^{-1}. UV (EtOH) 222 (ε 7530) and 290 nm (ε 13800). MS *m/z* (rel intensity) 236 (M^+, 57), 171 (100), 170 (71), 153 (56), 152 (22), 142 (20), 141 (21), 128 (21), 115 (36), 77 (23). Found: C, 86.28; H, 6.90%; *m/z* 236.1263. Calcd for $C_{17}H_{16}O$: C, 86.41; H, 6.82%; M, 236.1202.

Preparation of 10-Phenyltricyclo[5.3.1.$0^{2,6}$]undeca-4,9-dien-8-one (7d). To a stirred solution of **6a** (406 mg, 2.13 mmol) in dry Et_2O (45 cm^3) was added an ethereal solution of phenyllithium (1.66 mol dm^{-3}, 6.5 cm^3) at 0 °C under nitrogen atmosphere over a period of 1 h, and refluxed for another 40 min. The reaction mixture was poured into ice-cold 25% H_2SO_4 (40 cm^3), stirred vigorously for 100 min, and then worked up and purified by a method similar to that employed for the synthesis of **6d** to give **7d** (368 mg, 73%) as pale yellow crystals: Mp 68—71 °C. ^1H NMR δ=1.80—2.50 (4H, m), 3.00—3.36 (2H, m), 3.40—3.90 (2H, m), 5.57 (2H, br s), 6.20 (1H, s), and 7.43 (5H, br s). IR 1655 and 1600 cm^{-1}. UV (EtOH) 222 (ε 9540) and 290 nm (ε 15800). MS *m/z* (rel intensity) 236 (M^+, 77), 208 (34), 194 (29), 171 (56), 170 (57), 167 (31), 166 (29), 155 (100), 154 (43), 153 (21), 142 (93), 141 (54), 129 (26), 128 (38), 117 (24), 115 (72), 106 (99). Found: C, 86.15; H, 6.85%; *m/z* 236.1179. Calcd for $C_{17}H_{16}O$: C, 86.41; H, 6.82%; M, 236.1202.

Photochemical Transformation of 6a into 7-Methoxypentacyclo[5.4.0.$0^{2,6}$.$0^{3,10}$.$0^{5,8}$]undecan-9-one (8a). A solution of **6a** (10 mg) in benzene (3 cm^3) was irradiated for 6 h. Evaporation of the solvent in vacuo gave **8a** (10 mg) as a colorless oil, which was analyzed without purification because of its instability: ^1H NMR δ=1.50—1.83 (2H, m), 1.85—2.16 (2H, m), 2.50—3.83 (7H, m), and 3.20 (3H, s). IR 1700 cm^{-1}.

Acid Treatment of 8a. To a solution of **8a** (33 mg) in methanol (3 cm^3) was added ten drops of hydrochloric acid (1 mol dm^{-3}) at 50 °C. The mixture was stirred for 1.5 h, poured into saturated aqueous $NaHCO_3$ (10 cm^3), and extracted with $CHCl_3$ (10 cm^3×3). The extracts were washed with saturated brine, dried ($MgSO_4$), and evaporated to give the diketone **10** (25 mg, 82%) as colorless crystals: Mp 154—156 °C. IR 1765 and 1700 cm^{-1}. MS *m/z* (rel intensity) 176 (M^+ 4), 148 (72), 133 (14), 110 (18), 106 (11), 105 (34), 83 (12), 82 (100), 80 (12), 79 (34), 78 (29). Found: *m/z* 176.0838. Calcd for $C_{11}H_{12}O_2$: M, 176.0837.

Photochemical Transformation of 7a into 7-Methoxypentacyclo[5.4.0.$0^{2,6}$.$0^{3,10}$. $0^{4,8}$]undecan-11-one (9a). Irradiation of a solution of **7a** (10 mg) in benzene (3 cm^3) for 2.5 h and evaporation of the solvent gave **9a** (10 mg) as an unstable colorless oil. ^1H NMR δ=1.50—2.50 (6H, m), 2.50—3.30 (5H, m), 3.50 (3H, s). IR 1730—1700 cm^{-1}.

Acid Treatment of 9a. To a solution of **9a** (12 mg) in methanol (2 cm^3) was added five drops of hydrochloric acid (1 mol dm^{-3}) at 75 °C. The mixture was stirred for 2 h, and worked up by a method similar to that described in the reaction of **8a** to give **11** (7 mg, 63%) as colorless crystals: Mp 118—120 °C. ^1H NMR δ=1.20—3.40 (12H, m). IR 1735 cm^{-1}. MS *m/z* (rel intensity) 176 (M^+, 100), 147 (65), 133 (16), 131 (25), 130 (12), 106 (13), 94 (22). Found: *m/z* 176.0868. Calcd for $C_{11}H_{12}O_2$: M, 176.0837.

Photochemical Transformation of 6b into Pentacyclo[5.4.0.$0^{2,6}$.$0^{3,10}$.$0^{5,8}$]undecan-9-one (8b). Irradiation of a solution of **6b** (28 mg) in benzene (5 cm^3) for 2 h and purification of the product by column chromatography (benzene–Et_2O) gave **8b** (26 mg, 94 %) as a colorless oil. ^1H NMR δ=1.50—2.16 (4H, m) and 2.20—3.43 (8H, m). ^{13}C NMR δ=217.3 (s), 58.1 (d), 47.0 (d), 46.9 (d), 46.8 (d), 41.1 (d), 40.2 (d), 40.0 (d), 39.9 (t), 37.7 (d), and 34.6 (t). IR 1695 cm^{-1}. MS *m/z* (rel intensity) 160 (M^+, 31), 132 (15), 117 (27), 95 (100), 94 (35), 91 (27), 79 (15), 78 (21), and 77 (24). Found: C, 82.21; H, 7.60%; *m/z* 160.0876. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%; M, 160.0888.

Photochemical Transformation of 6c into 7-Methylpentacyclo[5.4.0.$0^{2,6}$.$0^{3,10}$.$0^{5,8}$]undecan-9-one (8d). Irradiation of a solution of **6c** (87 mg) in benzene (7 cm^3) for 3 h and purification of the product by chromatography (benzene–Et_2O) gave **8c** (70 mg, 81%) as a colorless oil. ^1H NMR δ=1.17 (3H,s), 1.47—2.10 (4H, m), and 2.15-3.30 (7H, m). ^{13}C NMR δ=217.1 (s), 57.1 (d), 54.0 (d), 46.4 (d), 46.1 (d), 45.1 (s), 44.0 (d), 43.7 (d), 38.0 (d), 38.0 (t), 34.8 (t), and 23.4 (q). IR 1685 cm^{-1}. MS *m/z* (rel intensity) 174 (M^+, 24), 159 (3), 146 (9), 131 (17), 109 (100), 108 (40), 93 (10), 92 (17), and 91 (29). Found: C, 82.45; H, 8.15%; *m/z* 174.0994. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%; M, 174.1045.

Photochemical Transformation of 6d into 7-Phenylpentacyclo[5.4.0.$0^{2,6}$.$0^{3,10}$.$0^{5,8}$]undecan-9-one (8d). Irradiation of a solution of **6d** (75 mg) in benzene (56 cm^3) for 10 h and purification of the product by chromatography (benzene–Et_2O) gave **8d** (30 mg, 40%): Mp 61—65.5 °C. ^1H NMR δ=1.60—1.90 (2H, m), 2.13 (2H, br s), 3.07 (5H, br s), 3.41 (2H, m), and 7.25 (5H, m). ^{13}C NMR δ=216.1 (s), 145.4 (s), 128.5 (d, 2C), 126.1 (d), 124.8 (d, 2C), 57.1 (d), 54.4 (d), 50.9 (s), 47.8 (d), 46.3 (d), 44.3 (d), 43.7 (d), 38.8 (t), 38.7 (d), and 34.82 (t). IR 1700 cm^{-1}. MS *m/z* (rel intensity) 236 (M^+, 25), 172 (11), 171 (100), 170 (61), 165 (15), 155 (16), 154 (16), 153 (40), 152 (20), 141 (21), 128 (16), 115 (34), and 102 (14). Found: C, 86.35; H, 6.85%; *m/z* 236.1206. Calcd for $C_{17}H_{16}O$: C, 86.41; H, 6.82%; M, 236.1202.

Photochemical Transformation of 7b into Pentacyclo[5.4.0.$0^{2,6}$.$0^{3,10}$.$0^{4,8}$]undecan-11-one (9b). Irradiation of a solution of **7b** (30 mg) in benzene (5 cm^3) for 2 h and purification by chromatography (benzene–Et_2O) gave **9b** (26 mg, 89%) as colorless crystals: Mp 116—118 °C. ^1H NMR δ=1.35—3.35 (12H, m). ^{13}C NMR δ=218.8 (s), 52.5 (d), 51.4 (d), 50.5 (d), 45.8 (d), 45.1 (d, 2C), 42.2 (t), 41.7 (d), 39.6 (d), and 35.6 (t). IR 1720 cm^{-1}. MS *m/z* (rel intensity) 160 (M^+, 43), 132 (56), 131 (25), 117 (100), 104 (30), 95 (28), 91 (60), 79 (64), 78 (81), 77 (38), 67 (23), and 66 (63). Found: C, 82.25; H, 7.62%; *m/z* 160.0909. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%; M, 160.0888.

Photochemical Transformation of 7c into 7-Methylpentacyclo[5.4.0.$0^{2,6}$.$0^{3,10}$.$0^{4,8}$]undecan-11-one (9c) and 10-Methyltetracyclo[5.3.1.$0^{2,6}$.$0^{5,9}$]undec-3-en-8-one (12c). Irradiation of a solution of **7c** (92 mg) in benzene (7 cm^3) for 2 h gave an

inseparable mixture of **9c** and **12c** as a colorless solid. The ratio of **9c** to **12c** (5 : 1) was determined by the relative intensities of methyl proton signals in ^{1}H NMR. The mixture was treated with p-TsOH (50 mg) in benzene (10 cm^3) for 10 h at room temperature, washed with aqueous $NaHCO_3$ and brine, dried ($MgSO_4$). After evaporation of the solvent, the residue (79 mg) was chromatographed on silica gel to give **12c** (17 mg) and **13c**[13] (48 mg). **12c**: Mp 42—43 °C. ^{1}H NMR δ=0.95 (3H, d, J=7 Hz), 1.40—2.75 (7H, m), 2.80—3.40 (2H, m), 5.79 (1H, dd, J=6 and 3 Hz), and 6.10 (1H, dd, J=6 and 3 Hz). ^{13}C NMR δ=219.2 (s), 133.6 (d), 129.0 (d), 54.5 (d), 53.2 (d), 52.7 (d), 46.9 (d), 45.8 (d), 43.5 (t), 38.9 (d), 35.9 (d), and 16.5 (q). IR 1735 cm^{-1}. MS m/z (rel intensity) 174 (M$^+$, 56), 159 (14), 146 (54), 145 (31), 132 (26), 131 (82), 130 (24), 129 (31), 128 (29), 118 (37), 117 (69), 115 (51), 109 (72), 93 (76), 92 (87), and 91 (100). Found: C, 82.53; H, 8.12%; m/z 174.1017. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%; M, 174.1044.

Regeneration of 9c from 13c: Irradiation of a solution of **13c** (37 mg) in benzene (5 cm^3) for 3 h and purification of the product by chromatography (benzene–Et_2O) gave **9c** (34 mg, 94%) as colorless crystals: Mp 82—84 °C. ^{1}H NMR δ=1.10 (3H, s), 1.45—2.05 (4H, m), and 2.10—3.10 (7H, m). ^{13}C NMR δ=218.5 (s), 57.4 (d), 53.6 (s), 52.7 (d), 52.6 (d), 50.6 (d), 46.7 (d), 44.4 (d), 40.4 (d), 36.2 (d), 34.3 (t), and 23.1 (q). IR 1710 cm^{-1}. MS m/z (rel intensity) 174 (M$^+$, 69), 159 (6), 146 (56), 131 (100), 117 (31), 115 (21), 109 (80), 108 (35), 106 (34), 105 (30), 93 (77), 92 (99), and 91 (72). Found: C, 82.62; H, 8.11%; m/z 174.1017. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%; M, 174.1045.

Photochemical Transformation of 7d into 7-Phenylpentacyclo[5.4.0.0^{2,6}.0^{3,10}.0^{4,8}]undecan-11-one (9d) and 10-Phenyltetracyclo[5.3.1.0^{2,6}.0^{5,9}]undec-3-en-8-one (12d). Irradiation of a solution of **7d** (64 mg) in benzene (6 cm^3) for 1.5 h gave a mixture of **9d** and **12d**. The ratio of **9d** to **12d** (4 : 1) was determined by the relative intensities of phenyl proton signals of **9d** and olefinic proton signals of **12d** in the ^{1}H NMR. The mixture was stirred with **3** drops of BF_3 etherate in benzene (10 cm^3) for 40 min at room temperature, washed with aqueos $NaHCO_3$ and brine, dried ($MgSO_4$), and the solvent was evaporated. Chromatography of the products (55.3 mg) gave **12d** (16 mg) and **13d**[13] (35.2 mg). **12d**: Mp 102—104 °C. ^{1}H NMR δ=1.9—3.5 (9H, m), 5.90 (1H, dd, J=6 and 2.5 Hz), 6.33 (1H, dd, J=6 and 2.5 Hz), and 7.28 (5H, m). ^{13}H NMR δ=218.2 (s), 142.7 (s), 134.8 (d), 128.9 (d), 128.4 (d, 2C), 127.6 (d, 2C), 126.1 (d), 54.3 (d), 52.9 (d), 48.8 (d), 46.5 (d), 46.2 (d), 45.8 (d), 42.4 (t), and 40.6 (d). IR 1735 cm^{-1}. MS m/z (rel intensity) 236 (M$^+$, 42), 208 (13), 171 (16), 170 (27), 166 (24), 155 (48), 154 (28), 143 (20), 142 (100), 141 (21), 129 (34), 128 (40), 117 (53), 116 (28), 115 (83), and 106 (66). Found: C, 86.26; H, 6.98%; m/z 236.1201. Calcd for $C_{17}H_{16}O$: C, 86.41; H, 6.82%; M, 236.1202.

Regeneration of 9d from 13d: Irradiation of a solution of **13d** (38 mg) in benzene (7 cm^3) for 90 min and purification of the product by column chromatography gave **9d** (31 mg, 82%) as colorless crystals: Mp 36.5—38 °C. ^{1}H NMR δ=1.50—2.40 (5H, m), 2.45—3.25 (6H, m), and 6.90—7.50 (5H, m). ^{13}C NMR δ=218.5 (s), 146.0 (s), 128.5 (d, 2C), 126.16 (d), 124.9 (d, 2C), 60.1 (s), 56.0 (d), 55.9 (d), 52.3 (d), 50.9 (d), 47.6 (d), 44.8 (d), 40.9 (t), 36.5 (d), and 35.7 (t). IR 1725 cm^{-1}. MS m/z (rel intensity) 236 (M$^+$, 40), 208 (16), 171 (35), 170 (29), 165 (15), 156 (14), 155 (100), 154 (26), 153 (16), 142 (41), 141 (29), and 115 (40). Found: C, 86.05; H, 7.01%; m/z 236.1221. Calcd for $C_{17}H_{16}O$: C, 86.41; H, 6.82%; M, 236.1202.

The authors wish to thank to Professors Hajime Katayama and Akira Kato of Niigata College of Pharmacy for the measurements of high-resolution mass spectra, and Professor Teruo Fujimoto and Mr. Takeo Kazama of Technological University of Nagaoka for the NMR measurements at 270 MHz. We also wish to express our thanks to Professor Koji Isogai and Mr. Jun-ichi Sakai of Niigata University for the measurements of mass spectra and their helpful discussions. This work was partially supported by Grant-in-Aids for Scientific Research (No. 56540295 and No. 58740240) from the Ministry of Education, Science and Culture.

Reaction of Carbocations Derived from Alkanes with Carbon Monoxide in HF-SbF_5 Superacid

Norihiko YONEDA,* Yukio TAKAHASHI,† Tsuyoshi FUKUHARA, and Akira SUZUKI
Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received February 15, 1986)

Alkanes readily react with CO and H_2O in HF-SbF_5 at 30 °C under atmospheric pressure and give considerably different product distributions from those in the usual Koch-Haaf reaction. When using C_5- or C_6-alkanes with tertiary C-H bonds, a considerable amount of secondary carboxylic acids are produced by the reaction of CO with secondary alkyl cations. Such cations may appear as transient intermediates in the course of the carbon skeletal isomerization of initially formed tertiary cations. For the straight-chain alkanes, the protonolysis at C-C bonds initiated the reaction to give fragment alkyl cations. This resulted in the formation of carboxylic acids with a lower number of carbon atoms than the starting alkanes. Intermolecular hydride shift between the fragment cations and the starting alkanes occurred at the same time to form a large amount of carboxylic acids with the alkyl group of the same number of carbon atoms as the starting alkane. On the other hand, for alkanes with more than seven carbon atoms, β-scission occurs exclusively to produce C_4-, C_5-, and C_6-carboxylic acids.

Ionization of alkanes to the corresponding alkyl cations in superacid media such as FSO_3H-SbF_5 and HF-SbF_5 has been well investigated.[1] The reaction of alkyl cations thus obtained with nucleophiles such as benzene[2] and carbon monoxide[3] has also been described. Paatz and Weisgerber reported that the reactions of isopentane, methylcyclopentane or cyclohexane with carbon monoxide in the presence of HF-SbF_5 at room temperature under atmospheric pressure gave C_6- or C_7-acids along with some ketones.[4] The reaction is highly interesting, especially because of the mild reaction conditions.[5,6] However, no extensive studies of the reaction have been reported to date. We have therefore undertaken a detailed study, using alkanes with various skeletal structures in order to clarify the reaction of alkyl cations derived from the alkanes with carbon monoxide in superacidic media.[7]

In this report, we shall discuss the reaction, initiated by the ionization of σ-bonds in alkanes, followed by trapping with carbon monoxide and quenching with water to give carboxylic acids. Our discussion will be based on the detailed analysis of the composition and isomer distribution of the products.

Experimental

Materials. Pure alkanes and carbon monoxide were of commercially available and were used without further purification. SbF_5 and anhydrous hydrogen fluoride were distilled, twice and once, respectively.

General Procedure of Carboxylation. A solution of HF-SbF_5 (5:1 molar ratio, ca. 20 ml) was placed in a 100-ml Kel-F three-necked reaction vessel under vigorous stirring at an appropriate temperature. The substrate (5—20 mmol) was added dropwise during 15 min to the acid solution, while carbon monoxide was introduced at a constant flow rate of 20 ml min^{-1} at 30 °C. After the reaction was completed, the resulting solution was hydrolyzed with ice-water, and the product obtained after usual work-up[8] were identified by means of GLC, GC-mass, IR, NMR spectrometry, and by comparison with authentic samples.

Carboxylic Acids as Authentic Samples. Propanoic acid (**1**), 2-methylpropanoic acid (**2**), 2,2-dimethylpropanoic acid (**3**), 2-methylbutanoic acid (**4**) and 2,2-dimethylbutanoic acid (**8**) are commercially available. 2-Methylpentanoic acid (**5**),[21] 2-ethylbutanoic acid (**6**),[21] 2,3-dimethylbutanoic acid (**7**),[22] 2,2-dimetylbutanoic acid (**8**),[23] 2,2,3-trimethylbutanoic acid (**9**),[24] 2-ethyl-2-methylbutanoic acid (**10**),[15] 2,2-dimethylpentanoic acid (**11**),[15] 2-ethyl-3-methylbutanoic acid (**12**),[25] 2,3-dimethylpentanoic acid (**13**),[26] 2-methylhexanoic acid (**14**),[27] 2-ethylpentanoic acid (**15**),[28] 2,3,3-trimethylbutanoic acid (**16**),[29] 2,4-dimethylpentanoic acid (**17**)[30] and 2,2,3,3-tetramethylbutanoic acid (**18**),[31] were prepared according to Hussey's[9] or/and Creper's[10] methods and identified with the aid of IR, NMR, and MS. All products were liquid except for **18** (mp 198—199 °C, lit,[30] 198.5—199.5 °C) and exhibited reasonable spectra. These were esterified with diazomethane.[8] The retention times and volumes of GLC (Hitachi FID-063, Column: Silicon DC-550. 45 m, 150 °C) of these methyl esters were appropriate as a means of qualitative and quantitative identification for the products.

Results and Discussion

The results of the reaction of C_5- and C_6-alkanes with carbon monoxide are shown in Tables 1 and 2. Tables 1 and 2 indicate that the isomer distribution of the major products (C_6-acids and C_7-acids) are independent of the individual skeletal structures of the starting alkanes under the same conditions. A considerably high yield of secondary carboxylic acids are found in the products. In a marked contrast, it was reported that tertiary carboxylic acids were exclusively produced from nonbranched alkenes or alcohols in the Koch-Haaf carboxylation using usual strong acids such as H_2SO_4.[11] It is likely that the reaction of branched C_5- and C_6-alkanes is readily initiated by

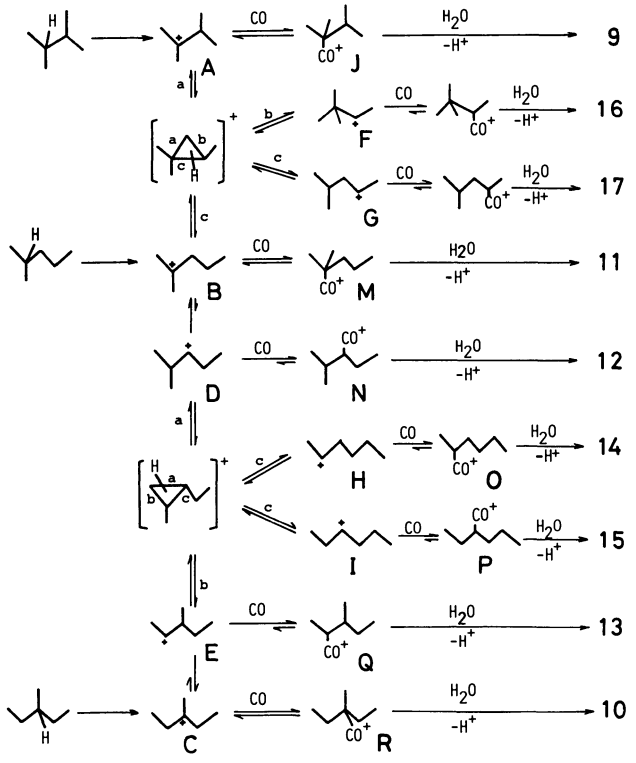
a) Reaction conditions: See footnote in Table 1. b) 3-Methylpentane. 2-Methylpentane and 2,3-dimethylbutane gave almost the same results.

protonolysis[12)] at their tertiary C–H bonds to give the corresponding tertiary alkyl cations which in turn undergo skeletal isomerization via secondary alkyl cations.[13)] The alkyl cations under the present conditions seem more electrophilic[14)] than those expected in the reaction of alkenes, alcohols or alkyl halides under the Koch–Haaf conditions. The Koch–Haaf conditions usually require either high temperature and pressure or a high concentration of carbon monoxide achieved by use of copper(I) carbonyl catalyst under highly acidic conditions.[15,16)] These alkyl cations can react with carbon monoxide to form acyl cations which give the corresponding carboxylic acids by quenching with water as shown in Scheme 1. When the reaction time is longer, as is the case with the reaction of hexanes as shown in Table 2, the ratio of secondary carboxylic acids **12—17** to tertiary ones **9—11** is increased and the isomer distributions in the product seem to attain an equilibrated state after 3 h. Tertiary alkyl cations, **A–C** in Scheme 1, derived from starting alkanes (2-methylpentane, 3-methylpentane and 2,3-dimethylbutane) rearrange rapidly to reach an equilibrium with each other which can be observed by NMR as demonstrated by Brouwer.[13)] Secondary alkyl cations **D–I** may form as transient intermediates in the course of the re-

arrangement of initially formed tertiary alkyl cations to other tertiary skeletal ones. Although spectroscopic attempts to observe the formation of such secondary cations in superacids were unsuccessful.[17] These alkyl cations may be in a high concentration and/or have a sufficiently long life time in a HF-SbF_5 solution to bring about the reaction with carbon monoxide. Thus, isomer distributions of carboxylic acids found in the initial stage of reaction depend largely on the equilibrium mixtures of these isomeric alkyl cations

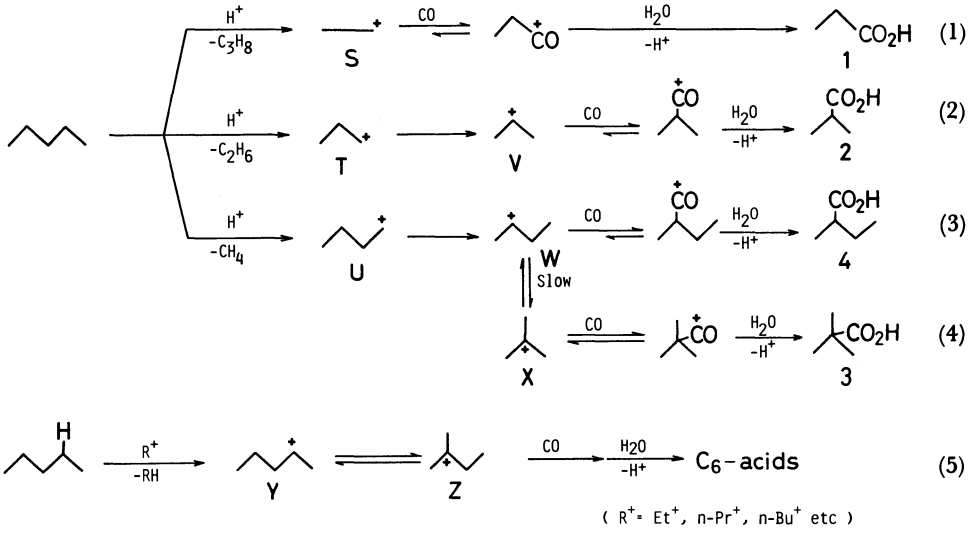


Scheme 1.

A–I including the secondary ones. On the other hand, when the reaction time is longer, an actual increase in the ratio of the secondary carboxylic acids **12—17** to tertiary ones **9—11** occurs. This seems unreasonable because of the rearrangement from more stable tertiary carbocations to less stable secondary ones is unlikely. This would probably result from the equilibration of alkanoyl cations **J–R**.[18,19]

For straight chain C_5- or C_6-alkanes, on the other hand, the protonolysis at carbon-carbon bonds takes place to give fragment alkyl cations **S–T** and C_1- — C_4-alkanes where the protonolysis at secondary C–H bonds in the substrate is preferred as shown in Scheme 2. The fragment alkyl cations **S–U** thus formed are responsible for the preferred formation of carboxylic acids **1—4** with the alkyl group of a lower number of carbon atoms than the starting alkanes (Eqs. 1—4). They are also responsible for the ionizaton of starting alkanes by the abstraction of hydride ion at secondary C–H bonds which in turn produced carboxylic acids with the alkyl group with the same number of carbon atoms as in the starting alkanes (Eq. 5). Thus, compared with the reaction of branched C_5- and C_6-alkanes, a considerably large amount of gaseous hydrocarbons, i.e., methane, ethane, propane and butanes were observed in these reactions.

The isomer distribution of C_6- and C_7-carboxylic acids are the same as that in the reaction of branched alkanes. As shown in Table 1, however, there is a distinction among the isomer distributions of C_5-carboxylic acids produced in the reactions of C_5- and C_6-alkanes. This can be explained by the slow occurrence of the skeletal isomerization of butyl cations arising from suitable protonolysis at carbon-carbon bonds in the substrates compared to those of pentyl, **Y** and **Z**, or higher alkyl cations as demonstrated by Brouwer.[13]



Scheme 2.

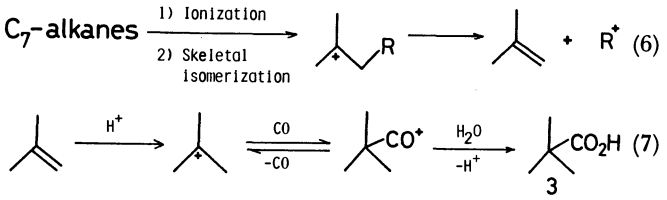
Reaction conditions: See footnote in Table 1.



Scheme 3.

In contrast to C_5- or C_6-alkanes, the reactions of such substrates having seven or eight carbon atoms gave C_4- and/or C_5-carboxylic acids almost exclusively, as shown in Table 3. In other words, these alkanes can give a small amount of C_8-, C_9- or C_{10}-carboxylic acids with an alkyl group of the same number of carbon atoms of starting alkanes. From the product distribution, these alkanes, as shown in Eqs. 6 and 7 in Scheme 3, were ionized in the same fashion as those in the case of C_5- or C_6-alkanes. They gave alkyl cations which easily undergo exclusive β-scission and produce fragment alkyl cations R^+ and 2-methylpropene resulting from the preferential formation of **3** under the present reaction conditions. Interestingly, the product distribution obtained in the reaction of C_7-alkanes is quite different from those found in the reaction of alcohols or halides having the same carbon skeletal structure as alkanes under the same reaction conditions. 2,4-Dimethyl-2-pentanol, for example, reacted with carbon monoxide and water to give a considerable amount of C_6- and C_7-carboxylic acids together with C_4- and C_5-carboxylic acids. This is in contrast with the product distribution in the reaction of 2,4-dimethylpentane which yielded 79% of **2** and 21% of **3** without any other products under the same conditions as shown in Scheme 4. C_7-alkyl cations, which were formed in the reaction of the alcohols in a HF–SbF_5 solution, may be abundant and may give rise to oligocondensation to produce such alkyl cations which have fourteen or more carbon atoms. These oligocondensed alkyl cations undergo β-scission to give *t*-butyl cation and C_6-cations which in turn gave C_5- and C_7-carboxylic acids, respectively. C_6-acids may arise from C_5-alkyl cations derived from another β-scission process of these or other oligocondensed alkyl cations. 2,4-Dimethylpentane, on the other hand, may be ionized slowly to yield the alkyl cation, because mass transfer between acid and the hydrocarbon phase is a rate-determining step. Such an alkyl cation may take place in a limited oligocondensation with each other. Thus, β-scission of the alkyl cation may take place predominantly to produce 2-methylpropene and isopropyl cation which in turn gave C_4- and C_5-carboxylic acids.

Another characteristic feature in the reaction of C_7-alkanes is the product compositions which differ from each other as shown in Table 4. The exact reaction pathway giving these product distributions is not clear, but fragment alkyl cation R^+ (*t*-butyl or isopropyl cation), produced by β-scission of parent alkyl cations, may play an important role in the formation of C_5- and C_4-carboxylic acids and also in the ionization of the starting alkanes. This resulted in

Table 4. Products Found in Gaseous Phase in the Carboxylation of Tertiary C_7 Alkanes

Substrate	Products found in the gaseous phase/%				
	Isobutane	Butane	Propane	Ethane	Methane
3-Methylhexane	Some	1	90	8	Some
2,4-Dimethylpentane	82	Some	17	Some	—

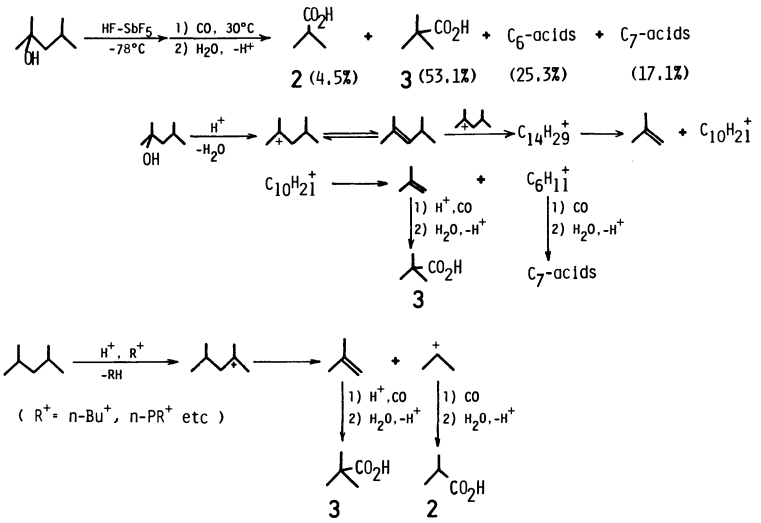
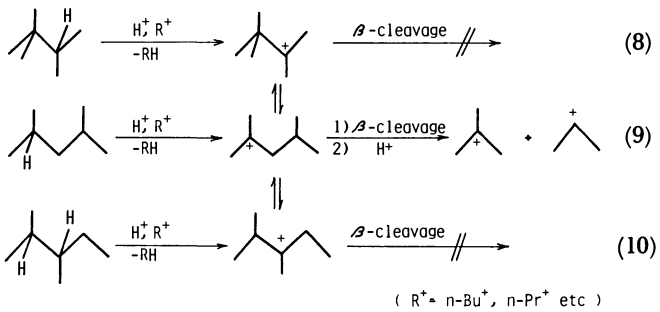
2,2,3-Trimethylbutane	60	—	39	Some	Some

Reaction conditions: See footnote in Table 1.

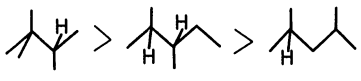


Scheme 4.

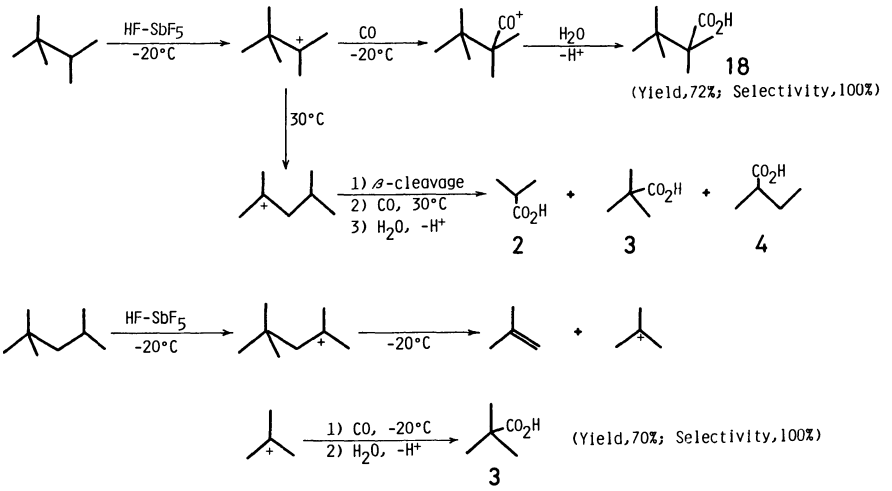
the formatiom of C_7-alkyl cations, and then propane and isobutane are produced by the intermolecular hydride ion transfer reaction as shown in Scheme 5. For C_7-alkanes, other than 2,4-dimethylpentane, initially formed C_7-alkyl cations must be rearranged in such an alkyl cation to give isopropyl and *t*-butyl cations by β-scission, since initially formed C_7-alkyl cations have unfavorable skeletal structures for β-scission reaction (Eqs. 8 and 10). The preferential formation of **2** prior to **3** and isobutane prior to propane in the reactions of 2,4-dimethylpentane, 2,3-dimethylpentane, and 2,2,3-trimethylbutane (Tables 3 and 4) are observed. *t*-Butyl cation, formed in Eq. 9, seems to play a much more important role to undergo intermolecular hydride abstraction from the starting C_7-alkanes in preference to that undergone by isopropyl cation in Eq. 9. Such a predominant occurrence of hydride abstraction with *t*-butyl cation may be attributed to the equilibrations in the reaction of these alkyl cations and carbon monoxide. Namely, the equilibrium of the reaction of isopropyl cation and carbon monoxide to produce isobutyryl cation leans far toward the isobutyryl cation compared to the reaction of *t*-butyl cation and carbon monoxide to produce pivaloyl cation[18] as seen in Eqs. 2 and 4 in Scheme 2. By these equilibrations, *t*-butyl cation may always exist in a higher concentration than isopropyl cation in the reaction mixture. The hydride abstraction of the substrate with the *t*-butyl cation (R^+) may proceed in Eqs. 8—10. On the other hand, in the case of C_7-alkanes, there is a much higher steric hindrance against the intermolecular hydride abstraction with *t*-butyl cation, than with the isopropyl cation. Such a steric hindrance may be expected in the following C_7-alkanes order.



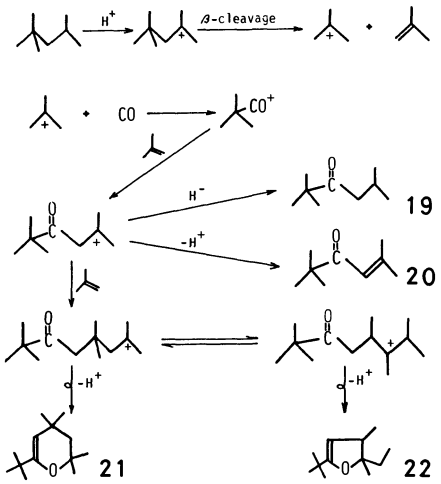
Scheme 5.



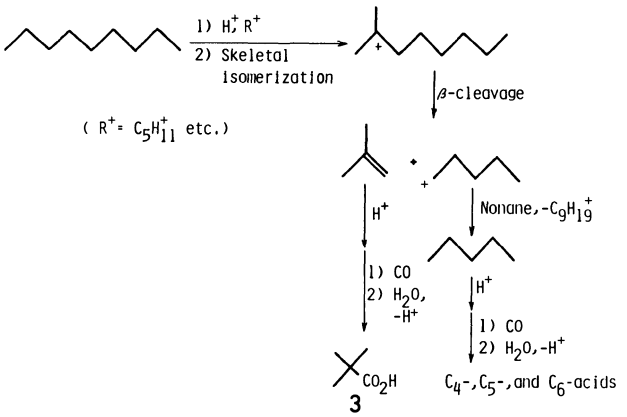
Thus, this steric factor renders the ratio of the products, i.e., between **2** and **3** or between isobutane and propane in these reactions variable as shown in



Scheme 6.



Scheme 7.



Scheme 8.

Tables 3 and 4. The preferred formation of **3** in the reaction of 2- or 3-methylhexane is still unclarified. However, judging from the preferred formation of propane in this case, it seems that the β-scission of the alkyl cations derived from these alkanes can afford *s*-propyl cation which is a highly reactive electrophile and can readily attack the tertiary C–H bond in the starting alkane.

In general, the lower the reaction temperature, the β-scission of alkyl cations is more difficult. The exclusive formation of **18** was observed in the reaction of 2,2,3-trimethylbutane in good yield at −20 °C as shown in Scheme 6. However, in the reaction of 2,2,4-trimethylpentane, initially formed 1,1,3,3-tetramethylbutyl cation undergoes the reaction involving the β-scission remarkably even at −20 °C to give *t*-butyl cation and 2-methylpropene which in turn reacts with carbon monoxide to yield **3** exclusively.

As shown in Scheme 7, when 2,2,3-trimethylpentane is in excess relative to SbF_5 (alkane/SbF_5 molar ratio 2, HF/SbF_5 molar ratio 10), ketones (**19**/(20%), **20**/(31%)) and cyclic ethers (**21**+**22**/29%) were produced together with **3** and 2-methylpropane.[20] A large amount of 2-methylpropene was formed from the β-scission of initially formed 1,1,3,3-tetramethylbutyl cation may react directly with pivaloyl cation resulting in the formation of these ketones and cyclic ethers.

In the reaction of nonane, a large amount of C_6-carboxylic acids together with C_4- and C_5-carboxylic acids were formed as shown in Table 3. The principal reaction path accompanied with β-scission of initially formed alkyl cation may be again well accounted for in the product composition as shown in Scheme 8. The intermolecular hydride ion shift between the substrate and primary pentyl cation produced by the β-scission of the initially formed alkyl cation will give rise to pentane and C_9-alkyl cations. Pentane, thus formed, could react with carbon monoxide and water to yield C_4-, C_5-, and

C_6-carboxylic acids. Hence, the product composition in the reaction of nonane exhibited an almost similar product composition that was observed in the reaction of pentane itself as shown in Table 1. The only difference in the composition is that it has a relatively high distribution of **3** which may have arisen mostly from the reaction of 2-methylpropene formed by the β-scission of C_9-alkyl cations.

A Convenient Preparative Method of Nitrile Oxides by the Dehydration of Primary Nitro Compounds with Ethyl Chloroformate or Benzenesulfonyl Chloride in the Presence of Triethylamine

Tomio SHIMIZU,* Yoshiyuki HAYASHI, Hiroshi SHIBAFUCHI, and Kazuhiro TERAMURA
Department of Color Chemistry and Technology, Faculty of Industrial Arts,
Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received February 17, 1986)

Three nitrile oxides (MeOCOC≡N→O, PhC≡N→O, and EtC≡N→O) were effectively generated in situ by dehydration of the corresponding primary nitro compounds (RCH_2NO_2) with $PhSO_2Cl$ or ClCOOEt in the presence of triethylamine. Various cycloadducts were prepared by the reaction of them with dipolarophiles. Some advantages of these methods are described in comparison with other known methods.

1,3-Dipolar cycloaddition reaction using nitrile oxides is one of the versatile methods for the preparation of five-membered heterocycles.[1] Preparation of nitrile oxides by the dehydration of primary nitro compounds has been known so far.[2-8] Following combinations of reagents have been known to be effective for the dehydration; (a) PhNCO and Et_3N,[3] (b) Ac_2O and AcONa,[4] (c) AcCl and MeONa,[5] (d) *p*-TsOH,[6] (e) $POCl_3$,[3d] (f) Diketene and Na,[7] and (g) H_2SO_4.[8] The most widely used one among these methods is (a). Though the method has been known to be sufficiently effective for the preparation of a variety of heterocycles, an equimolar amount of *N,N'*-diphenylurea is formed as a by-product during the reaction. In many cases, separation of the by-product from the reaction mixture can be accompilshed easily by filtration because diphenylurea shows very low solubilities towards many organic solvents. But, in some cases, the desired heterocyclic compounds also show solubilities similar to that of diphenylurea towards organic solvents, thus, the separation is often tedious. Recently, we reported the cycloaddition reactions of dipolarophiles with nitrile oxides prepared by the action of a catalytic amount of *p*-TsOH on primary nitro compounds [method (d)].[6a] Though this reaction gave no such by-products and the yields of the desired heterocycles are also comparable to those by the method (a), good results could not be attained in some cases where the primary nitro compounds bear thermally labile functional groups because of the necessity of the high reaction temperature (>140 °C).

Hydrolysis of ethyl chloroformate or benzenesulfonyl chloride gives water soluble products, (EtOH+HCl+CO_2) or ($PhSO_3H$+HCl). The use of these reagents for the dehydration of primary nitro compounds has the advantage that the by-products can be removed easily by washing the reaction mixture with water. We report here the usefulnes of the combination of reagents such as ClCOOEt/Et_3N and $PhSO_2Cl$/Et_3N for the dehydration of primary nitro compounds.

Results and Discussion

The reaction of methyl nitroacetate (**1**) with allyl *p*-nitrophenyl ether in the presence of various amounts of ClCOOEt and Et_3N in several kinds of solvents was examined in order to search the optimum reaction conditions. Table 1 summarizes the results along with yields of the cycloadduct, methyl 5-(*p*-nitrophenoxymethyl)-2-isoxazoline-3-carboxylate (**2f**). Table 1 suggests that the maximum yield of the cyclo-

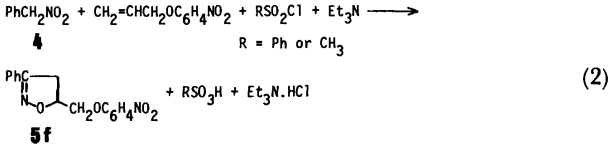
(1)

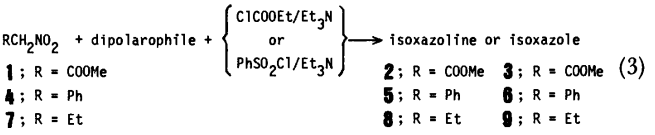
adduct was obtained by the treatment of the substrates with two molar amount of the dehydrating agents in benzene at the refluxing temperature (Method A). As expected, evolution of CO_2 gas and formation of ethanol were observed.

We also examined the reactions of (nitromethyl)benzene (**4**) with allyl *p*-nitrophenyl ether in the presence of benzenesulfonyl chloride (or methanesulfonyl chloride) and Et_3N under various conditions (Table 2). In



(2)

this case, the optimum conditions for the cycloadduct, 3-phenyl-5-(*p*-nitrophenoxymethyl)-2-isoxazoline (**5f**), were as follows; the use of two molar amounts of benzenesulfonyl chloride and Et_3N, and chloroform as a solvent at room temperature (Method B). Reactions of some primary nitro compounds (**1**, **4**, and **7**) with a number of dipolarophiles were carried out under these conditions (Method A and B). Table 3 summarized the results. The yields obtained in the reaction by use of another dehydrating agents are also shown for convenience of comparison.



(3)

The structure of the cycloadducts, 2-isoxazolines (**2**, **5**, and **8**) and isoxazoles (**3**, **6**, and **9**), were established by the comparison of the spectral and physical proper-

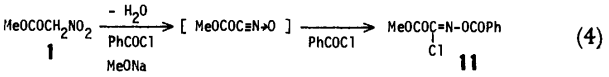
ties of the cycloadducts with those of anthentic specimens (see Experimental Section).

Almost cycloadducts can be easily isolated from the reaction mixtures after washing the reaction mixtures with water followed by usual work-up. However, in some cases by Method A, formation of an unexpected product made the isolation of desired cycloadducts difficult. The structre of the unexpected product was found to be R-C(Cl)=NOCO$_2$Et (**10a**: R=COOMe, **10b**: R=Ph, **10c**: R=Et) on the basis of elemental and spectral analyses, In fact, a considerable amount of **10** was obtained along with furazan 2-oxide, dimer of the nitrile oxide, in the rections of primary nitro compounds with ClCOOEt/Et$_3$N in the absence of dipolarophile. The formation of methyl 2-chloro-2-(benzoyloxyimino)acetate (**11**), MeOCOC(Cl)=NOCOPh, which has a structure similar to **10a**, has been reported in the dehydration reaction of **1** with benzoyl chloride and MeONa, and explained on the basis of 1,3-addition of benzoyl chloride to nitrile



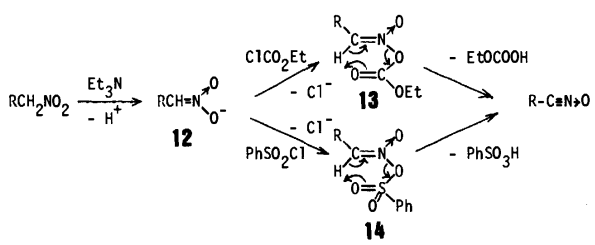
(4)

oxide.[5a] The formation of **10** in the present reaction may also be explained by a similar mechanism. The mechanism for the formation of nitrile oxide from primary nitro compounds by both Method A and B can be explained as shown in Scheme 1; i) abstraction of α-hydrogen of the primary nitro compounds by triethylamine gives its nitronate anion (**12**), ii) substitution reaction of ClCOOEt or PhSO$_2$Cl with the nitronate anion gives ethoxycarbonyl or benzenesulfonyl nitronate (**13** or **14**), respectively, and iii) elimination of EtOCO$_2$H or PhSO$_3$H from the nitronates via a cyclic transition state gives the nitrile oxides.

The present two methods for generation of nitrile oxides were found to be usefull ones for the preparation of 2-isoxazolines and isoxazoles because of the easiness of the operation and of the use of low-priced dehydrating agents.

Experimental

Measurements. All melting and boiling points are uncorrected. The ^{1}H NMR spectra were measured on a Varian T-60A instrument with Me$_4$Si as an internal standard; chemical shifts are given in δ units and coupling constants (J) are in herz units: s=singlet; d=doublet; t=triplet; q=quartet; m=multiplet br=broad singlet. The IR spectra were recorded on a Hitachi 215 Infrared Spectrophotometer. All new products gave satisfactory elemental analyses (±0.3% for C, H, and N).



Scheme 1.

Materials. Methyl nitroacetate (**1**)[9] and (nitromethyl) benzene (**4**)[10] were prepared according to the method described in the literatures. Chloroform was used after passing through column chromatography on almina for the purpose of removal of contaminant ethanol which exists in the solvent as a stabilizer. The other chemicals were of commercial origin and were used without further purification.

Reation of Primary Nitro Compounds with Dipolarophiles in the Presence of Ethyl Chloroformate and Triethylamine (Method A). General Procedure. To a stirred benzene solution (50 ml) of primary nitro compound (0.01 mol), dipolarophile (0.01 mol), and ethyl chloroformate (2.17 g, 0.02 mol) was added a benzene solution (10 ml) of triethylamine (2.02 g, 0.02 mol) at room temperature. Gradual evolution of CO_2 (trapped as $CaCO_3$) and ethanol was observed in the course of the reaction. (Sometimes evolution of a small amount of ethyl chloride was also observed). After refluxing the benzene solution for 6 h, the reaction mixture was cooled and washed with water several times. The benzene solution was dried over sodium sulfate and evaporated in a rotary evaporator to give crude products. Crystalline crude products were recrystallized from the solvents and oily crude products were purified by the fractional distillation. In some cases, a small amount of R-C(Cl)=NOCOEt (R=CO$_2$Me, Ph, and Et) or Et$_2$NCO$_2$Et was also isolated by the fractional distillation. Yields of the cycloadducts are shown in Table 3. Similar yields of the cycloadducts were attained from the reaction using ClCOOMe instead of ClCOOEt.

Reaction of Primary Nitro Compounds with Dipolarophiles in the Presence of Benzenesulfonyl Chloride and Triethylamine (Method B). General Procedure. To a stirred chloroform solution (50 ml) of primary nitro compound (0.01 mol), dipolarophile (0.01 mol), and benzenesulfonyl chloride (3.53 g, 0.02 mol) was added triethylamine (2.02 g, 0.02 mol) below 10 °C. The mixture was stirred for 15 h at room temperature and then washed with water several times. The chloroform solution was dried over sodium sulfate and evaporated in a rotary evaporator. Distillation of PhSO$_2$Cl in vacuo from the residue gave crude products. Crystalline or oily products were purified according to the Method A. Complete elimination of PhSO$_2$Cl from the crude products can be easily attained by stirring them with aqueous 2-aminoethanol, though this operation can not be used for the compounds bearing ester functional group. Yields of the cycloadducts are shown in Table 3. Similar yields of the cycloadducts were obtained from the reaction using p-toluenesulfonyl chloride instead of PhSO$_2$Cl. Compounds (**2d—f**,[6a] **2g**,[12] **2l**,[6a] **3a**,[12] **3b**,[5a] **5a**,[11] **5c**,[3b] **5d—f**,[6a] **5g**,[13] **5h**,[14] **5i—j**,[15] **5k**,[5a] **5l**,[6a] **6a**,[5a] **6b**,[4a] **8b—c**,[3a] **8g—h**,[3a] **8i**,[3d] **8k—l**,[6a] **9a**,[3c] and **9b**[4a]) obtained by the Methods (A and/or B) were identified on the basis of the melting (or boilig) points and the spectral data. Melting (or boiling) points, NMR spectral data, and analytical data of the other cycloadducts were as follows; **2a**: Bp 115 °C/1.1 mmHg(1 mmHg=133.322 Pa); ^{1}H NMR (CDCl$_3$)

An Equimolar Reaction of Primary Nitro Compounds with ClCOOEt in the Presence of Triethylamine. An equimolar (0.02 mol) mixture of primary nitro compound (**1**, **4**, or **7**), ClCOOEt, and triethylamine in benzene (50 ml) was refluxed for 6 h. The reaction mixture was washed with water several times, and then evaporated in a rotary evaporator. In the case of $PhCH_2NO_2$ (**4**), residual crystals were recrystallized from ethanol to give pure 3,4-diphenylfurazan 2-oxide in 60% yield; mp 112—114 °C (lit,[16] 114 °C). In the case of $MeOCOCH_2NO_2$ (**1**), residual oil was distilled in vacuo to give pure dimethyl 3,4-furazan-dicarboxylate 2-oxide in 25% yield; bp 115 °C/2 mmHg (lit,[16] 151 °C/10 mmHg). In the case of 1-nitropropane, distillation of residual oil gave recovered nitropropane (30%) and ethyl diethylcarbamate (20%) [bp 73 °C/25 mmHg (lit,[17] bp 165 °C)].

Reaction of Primary Nitro Compounds with Double the Molar Quantity of ClCOOEt and Triethylamine. To a benzene solution (50 ml) of primary nitro compound (0.02 mol) and ClCOOEt (0.04 mol) was added triethylamine (0.04 mol) and then the mixture was refluxed for 6 h. After filtration of triethylamine hydrochloride the filtrate was evaporated to give oily residue, which was distilled in vacuo to give esters of chloroximes; **methyl 2-chloro-2-(ethoxycarbonyldioxyimino)acetate (10a)**: 25% Yield, bp 100 °C/1 mmHg; ^{1}H NMR (δ) in $CDCl_3$; 1.4 (t, 3H, J=7), 4.0 (s, 3H), and 4.2 (q, 2H, J=7). Found: C, 34.64; H, 3.96; N, 6.69; Cl, 16.72%. Calcd for $C_6H_8NO_3Cl$: C, 34.37; H, 3.82; N, 6.68; Cl, 16.95%.

α-Chloro-α-(ethoxycarbonyloxyimino)toluene (10b): 70% Yield, bp 110—115 °C/0.3 mmHg, mp 32—34 °C (from hexane), ^{1}H NMR (δ) in $CDCl_3$: 1.4 (t, 3H, J=7), 4.3 (q, 2H, J=7), 7.3—7.6 (m, 3H), and 7.8—8.1 (m, 2H). IR (nujol): 1780 cm^{-1} (-OCOO-). Found: C, 52.96; H, 4.38; N, 6.27; Cl, 15.50%. Calcd for $C_{10}H_{10}NO_3Cl$; C, 52.75; H, 4.40; N, 6.15; Cl, 15.57%.

1-Chloro-1-(ethoxycarbonyldioxyimino)propane (10c): 3% Yield, bp 70—74 °C/1.3 mmHg, ^{1}H NMR (δ) in $CDCl_3$: 1.25 (t, 3H, J=7), 1.37 (t, 3H, J=7), 2.7 (q, 2 H, J=7), and 4.33 (q, 2H, J=7).

(Received March 13, 1986)

The reaction of (methylthio)diphenyl- and methyl(methylthio)phenylcyclopropenium salts with Grignard reagents (methyl, 1-methylethyl, and phenyl) yielded 1-(methylthio)cyclopropenes as major products together with isomeric 3-methylthio-1-cyclopropenes in moderate total yields. Phenyllithium also reacted similarly with the salt to afford cyclopropenes in lower yields. Thermal ring opening of 1-(methylthio)cyclopropenes took place readily at room temperature or on heating at around 80 °C to give indene and/or butadiene derivatives in good yields. Product analysis of the reaction in methanol as well as kinetic studies of one of 1-(methylthio)cyclopropenes gave strong evidence for the intermediacy of vinylcarbene in the ring opening of cyclopropene.

Cyclopropenes have long intrigued chemists because of their strained structure. Indeed, extensive as well as intensive studies on preparation of new cyclopropenes,[2-5] photochemical and thermal ring opening,[6-14] and synthetic utilization of cyclopropenes[15-19] have been of continuing interest.

In continuation of our studies on the reactions of mono(alkylthio)cyclopropenium salts,[20] we found an easy route for the preparation and facile ring-opening reaction of 1-(alkylthio)cyclopropenes (**2**). In this paper we report full details of the results.

The reaction of tris(alkylthio)cyclopropenium salts with nucleophiles have been reported to yield substitution products (cyclopropenes or ring-opened products) proceeding through an addition-elimination mechanism.[19]

1-Sulfinyl- and 1-sulfonylcyclopropenes are obtained by the photolysis of the corresponding 3*H*-pyrazoles at −30 °C.[21,22] In contrast, there is no report describing any 1-alkylthiocyclopropene as a stable compound.[23,24]

Table 1. The Reaction of **1a** with PhMgBr or PhLi

Reactant /mol[a]	Reaction conditions[b]		Products(Yield/%)	
	Solvent	Additive[c]	**2a**	**3a**
PhMgBr (3)	Ether		64	23
(5)	Ether		72	5
(5)	Ether	c	69	4
(5)	THF		64	5
(5)	THF	c	55	14
PhLi (5)	Ether		39	15
(5)	Ether	c	26	11
(5)	THF		14	9
(5)	THF	c	17	0
(5)	THF[d]		0	0

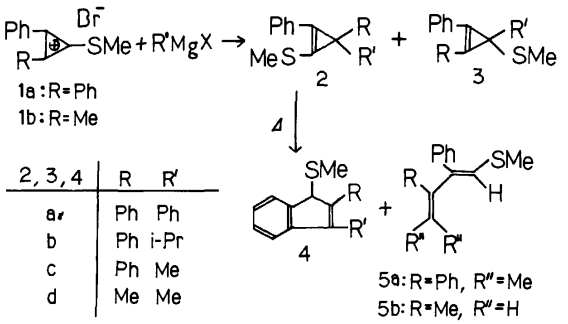
a) Moles of the reactant to one mole of **1a**. b) Reaction at room temperature otherwise noted. c) *N,N,N',N'*-Tetramethylethylenediamine (TMED, 5 mol) was added. d) At −50°C.

To a suspension of 1-methylthio-2,3-diphenylcyclopropenium bromide (**1a**)[20] in dry benzene was added phenylmagnesium bromide (3 times excess) in one portion, and the mixture was stirred giving a clean solution. After 5 min the resulting solution was quenched with ice water and the organic layer was separated. ^{1}H NMR spectroscopic analyses revealed that the crude product was a mixture of two isomeric cyclopropenes **2a** and **3a**. The major component was separated by column chromatography and confirmed to be 1-methylthio-2,3,3-triphenylcyclopropene (**2a**) on the basis of IR, ^{1}H and ^{13}C NMR, and mass spectral data. The other isomer **3a** decomposed upon attempted chromatographic separation. All attempts to improve yields or to change product ratios of **2a** and **3a** were unsuccessful as shown in Table 1. The use of phenyllithium gave large amounts of unidentified by-products. The reaction of trisubstituted cyclopropenium salts with Grignard reagents provides a general route for the preparation of cyclopropenes.[6,9,12,14] This is indeed the case for **1a**. The reaction of **1a** with Grignard reagent in ether or THF produced 1-(alkylthio)cyclopropenes, though no change in product ratio was observed on addition of tetramethylethylenediamine (TMED).[25]

Similar treatment of **1a** and **1b** with other Grignard reagents, R'MgX, gave the corresponding cyclopropenes **2** in good yields together with isomeric cyclopropenes **3** (Table 2). Cyclopropene **3a**, which

Table 2. The Reaction of **1a** and **1b** with Grignard Reagents

1	Reactants R'MgX	Products(Yield/%)	
1a	PhMgBr	**2a**(64)	**3a**(23)
1a	*i*-PrMgBr	**2b**(90)	**3b**(0)
1a	MeMgI	**2c**(83)	**3c**(12)
1b	MeMgI	**2d**(96)	**3d**(0)
1b	PhMgBr	**2a**(82)	



Scheme 1.

could not be purified by chromatography, was independently prepared from triphenylcyclopropenium perchlorate and methanethiol in the presence of triethylamine.

An examination of the distribution of the products **2** and **3** suggests that Grignard reagents preferentially attack the carbon atom unsubstituted by sulfur, this regioselectivity being attributed to the strong electron-releasing properties of methylthio group and steric repulsion between the substituents (MeS and/or Ph) of **1** and Grignard reagents.

Tetraphenylcyclopropene rearranges at temperatures as high as 235—240 °C to give triphenylindene,[26] whereas the ring opening reaction of 1-(methylthio)-cyclopropenes **2a—d** took place easily at room temperature or on heating at 80 °C, producing indene **4** and/or butadiene derivatives **5** in good yields as shown in Table 3, although 3-(methylthio)-1,2,3-triphenylcycloprop-1-ene (**3a**) was stable even at 200 °C. The structures of the products **4a—c** and **5a,b** was confirmed on the basis of their spectroscopic studies.

Theoretical calculations suggest that the ring opening of cyclopropene proceeds directly to a diradical planar intermediate.[27,28] To explain the photolysis products of cyclopropene, a diradical and/or vinylcarbene has been postulated.[6,9,10–14,29] Few studies have been performed as to the mechanistic aspects of thermal ring opening of cyclopropenes.[30]

The relatively stable cyclopropene **2b** was subjected to precise studies for the ring-opening reaction. Thermolysis of **2b** in benzene gave indene **4b** and butadiene **5a** in a 1:1 ratio (Table 3), whereas thermolysis of **2b** in boiling methanol afforded methyl ether **6E** and **6Z** in 51% yield along with **4b** and **5a** in 43% yield. Addition of triethylamine or sodium hydroxide to the methanol solution increased the total yield of **6E** and **6Z** to a maximum of 82%. The structure of **6E** and **6Z** was confirmed by ^{1}H NMR data as well as by conversion to aldehydes **7E** and **7Z** on treatment with mercury(II) acetate in acetic acid. The stereochemistry of **6** and **7** was assigned on the assumption that the protons of a group R cis to the phenyl are shielded and appear at higher field than

Table 3. Thermolysis of **2a—d** and **3a** in Benzene

Reactant	Reaction conditions		Product(Yield/%)
	Temp/°C	Time/h	
2a	25	3	**4a**(95)
2b	80	30	**4b**(46), **5a**(44)
2c	80	2	**4c**(87)
2d	80	4	**5b**(82)
3c	200	100	Recovery

Table 4. Rate Constants for the Thermolysis of **2b**

Solvent (ε)	Temp/°C	$10^5 k_1$ s^{-1}
PhCl (5.61)	65.3	3.45±0.15
Pyridine (12.3)	65.3	2.66±0.16
PhCN (25.2)	65.3	2.77±0.13
CD_3OD (32.6)	60.2	2.69±0.10
	65.3	4.57±0.19, 4.41±0.23[a] 4.60±0.25[b]
	69.8	7.37±0.43
	75.0	11.8 ±0.43
$PhNO_2$ (34.6)	65.3	2.67±0.17
$MeNO_2$ (38.6)	65.3	3.01±0.17

To a solution of **2b** (0.09—0.13 mol dm^{-3}) NaOD was added at a) 0.07 and b) 0.14 mol dm^{-3}.

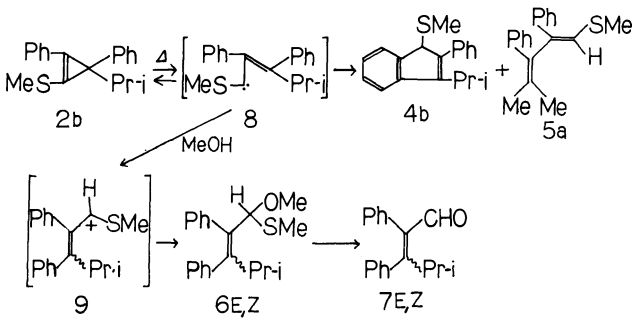
those of the group R trans to the phenyl.[31] The ratios of **6E** and **6Z**, and **7E** and **7Z** were determined to be 7:3 and 2:1, respectively, by ^{1}H NMR analysis, though separation of mixtures of E and Z by chromatography was unsuccessful.

We have performed a kinetic experiment in order to help clarify a reasonable mechanism for the ring opening of **2**. The rate was followed at suitable time intervals by analyzing the ^{1}H NMR spectra of the methylthio group of **2b** by using methyl phenyl sulfide or dimethyl sulfone internal standard. The disappearance of **2b** gave a good first-order rate constant k_1. The change of the solvent from chlorobenzene to nitromethane (ε 5.6—38.6) did not affect significantly the reaction rate (Table 4).

With regard to formation of the methyl ether, the kinetic experiment ruled out a mechanism involving a nucleophilic attack of alkoxide onto the cyclopropene ring of **2b** to give **6E** and **6Z**, since addition of sodium hydroxide to the methanol solution had no effect on the rate constants.

Tetraphenylcyclopropene has been reported to rearrange to indene with the activation energy of 167 kJ mol^{-1},[26] while the rearrangement of **2b** requires 98.6 kJ mol^{-1}.

These results indicate a sequence involving ring opening of **2b** to give a more stable vinylcarbene, stabilized by the adjacent alkylthio group,[32] followed by intramolecular hydrogen abstraction to afford **4b**



Scheme 2.

and/or **5a**. In contrast to tetraphenylcyclopropene[26] and **3a**, the introduction of alkylthio groups on carbon-1 of the cyclopropene ring made the ring opening easier. The fact that the addtion of a base to the methanolic solution of **2b** increased the yields of methyl ethers **6E** and **6Z** might be attributable to the high reactivity of methoxide with the protonated vinylcarbene (the alkylthiocarbonium ion **9**).

Laser flash photolysis technique has provided insight on the chemistry of the carbene intermediate.[33-35] Carbene reacts with alcohols to give either C–H or O–H insertion products depending on its multiplicity.[33-35] Singlet ground state carbenes yield ethers by the reaction with alcohols.[33,34a,b,36]

It has been clarified that protonation and ylide formation mechanisms are possible for the ether generation depending on the structure of carbene.[37]

Products analyses of photochemical ring opening of 5-(alkylthio)pyrazoline[23,24] and thermal ring opening of 1-sulfinyl- and 1-sulfonylcyclopropenes[21,22] have revealed the intermediacy of thio-, sulfinyl-, and sulfonylvinylcarbenes. Furthermore, an alkoxcarbene intermediate, e.g., an oxygen analogue of **8**, has been postulated and trapped by methanol or ethanol in the photochemical reaction of nortricyclanone and related compounds.[38]

Sulfur-substituted carbenes are known to serve either as a nucleophle or an electrophile, depending on the substituent and reaction conditions.[37] We feel, though not well-founded, that **8** is protonated prior to nucleophilic attack by methanol or methoxide ion since the electron-releasing property of the methylthio group would stabilize a carbonium ion intermediate **9** as revealed in the facile ring-opening reaction of **1a** with cyclic and acyclic 1,3-diketones.[20]

In summary, an appropriate substitution of cyclopropenes with an alkylthio group permits thermally facile ring opening leading to indene and/or butadiene derivatives in good yields.

Experimental

1) General. Melting points were uncorrected. The ^{13}C FT NMR spectra were recorded either on a JEOL JNM FX-60 spectrometer (15.04 MHz) or JEOL JNM FX-90Q (22.49 MHz) and ^1H NMR spectra on a Hitachi-Perkin Elmer R-24 (60 MHz). The IR spectra were recorded on a JASCO A-3 spectrometer.

2) Preparation of (Methylthio)cyclopropenium Salts. (Methylthio)cyclopropenium salts **1** and triphenylcyclopropenium salt were prepared as previously described.[20]

3) The Reaction of Cyclopropenium Salts 1 with Grignard Reagents to Give Cyclopropenes 2 and 3. General Procedure. To a cooled suspension of **1** (3 mmol) in benzene (20 ml) was added a Grignard reagent (9 mmol or 15 mmol in ether or in THF 15 ml prepared before hand and TMED was added in some runs) for 5 min with stirring. The mixture was stirred for additional 5 min to give a clean solution. Crushed ice (30 g) was added to the solution portionwise, and the organic layer was separated and dried over sodium carbonate. The ^1H NMR and IR spectroscopic studies indicated that the crude product was a mixture of two isomeric cyclopropenes. The yields of the respective products were estimated by ^1H NMR integration using dimethyl sulfone as an inner standard and the results are shown in Table 1.

The reaction of **1a** with phenylmagnesium bromide yielded a mixture of cyclopropenes. The major product was isolated by chromatography over silica gel and identified to be 1-methylthio-1,2,3-triphenyl-1-cyclopropene (**2a**). Oil; IR(neat) 1790 cm^{-1}; ^1H NMR($CDCl_3$) δ=2.44 (3H, s, MeS) and 6.9—7.6 (15H, m, 3 Ph). **2a** was thermally unstable even at room temperature to yield **4a** (see the next section). The minor product was not isolated, but its IR and ^1H NMR spectrum indicated the presence of 3-methylthio-1,2,3-triphenylcycloprop-1-ene (**3a**) in the crude reaction product.

Independent preparation of **3a** was undertaken. A suspension of triphenylcyclopropenium perchlorate (1 mmol)in a mixture of methanethiol (3 mmol), triethylamine (2 mmol) and dry benzene (20 ml) was stirred at room temperature for 3 h. After the separation of the precipitate, the benzene solution was condensed and the residue was crystallized from hexane to yield colorless crystals of **3a** in a 67% yield. **3a**: Mp 121.5—122.5 °C; IR (KBr) 1820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.95 (3H, s, MeS) and 7.0—7.9 (15H, m, 3 Ph); MS (*m/z*) 314 (M^+). Found: C, 83.45; H, 5.77%. Calcd for $C_{22}H_{18}S$: 84.03; H, 5.77%.

The reaction of **1a** with 1-methylethylmagnesium bromide yielded 3-(1-methylethyl)-2-methylthio-1,3-diphenylcyclopropene (**2h**): Oil; IR (neat) 1780 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 and 0.92 (6H, d, *J*=7 Hz, 2Me), 2.48 (3H, s, MeS), 2.87 (1H, sept, *J*=7 Hz $Me_2C\underline{H}$), and 7.0—7.7 (10H, m, 2Ph); ^{13}C NMR ($CDCl_3$) δ=17.2 (q, MeS), 21.1 and 21.4 (q, $\underline{Me}_2CH$), 30.8 (d, $Me_2\underline{C}H$), 43.7 (s, C_3), 115.3 (s), 117.2 (s), 125.4 (d), 127.0 (d), 127.2 (d), 127.8 (d), 128.0 (d), 128.6 (d), 129.2 (s), and 145.8 (s); MS (*m/z*) 280 (M^+). Found: C, 80.54; H, 7.02%. Calcd for $C_{19}H_{20}S$: C, 81.38; H, 7.19%.

The reaction of **1a** with methylmagnesium iodide yielded two cyclopropenes. The major product was isolated over silica-gel chromatography and was found to be 3-methyl-2-methylthio-1,3-diphenylcyclopropene (**2c**): Oil; IR (neat) 1780 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.71 (3H, s, C_3-Me), 2.39 (3H, s, MeS), and 6.9—7.6 (10H, m, 2Ph); ^{13}C NMR ($CDCl_3$) δ=16.5 (q, C_3-$\underline{Me}$), 22.1 (q, MeS), 31.9 (s, C_3), 116.0 (s), 117.6 (s), 125.3 (d), 125.9 (s), 126.1 (d), 127.2 (d), 127.8 (d), 128.0 (d), and 146.8 (s); MS (*m/z*) 252 (M^+). Found: C, 80.62; H, 6.31%.

Calcd for $C_{17}H_{16}S$: C, 80.90; H, 6.38%.

The minor product was not isolated(decomposed during chromatography), but found to be 3-methyl-3-methylthio-1,2-diphenylcyclopropene (**3c**): IR (neat) 1810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.42 (3H, s, Me), 2.07 (3H, s, MeS).

The reaction of 1-methyl-2-methylthio-3-phenylcyclopropenium bromide (**1b**) with methylmagnesium iodide yielded 3,3-dimethyl-1-methylthio-2-phenylcyclopropene (**2d**) as a major product. **2d**: Oil; IR (neat) 1760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.39 (6H, s, 2Me), 2.54 (3H, s, MeS), and 7.1—7.5 (5H, m, Ph); MS (*m/z*) 190 (M^+). Found: C, 75.31; H, 7.42%. Calcd for $C_{12}H_{14}S$: C, 75.73; H, 7.41%.

4) Thermolysis of 2 and 3a. A solution of **2** or **3a** in benzene was heated at appropriate temperature. The reaction was checked by means of TLC (silica gel, $CHCl_3$–petroleum ether, 1:4) at suitable time intervals. After the reaction, the mixture was either chromatographed over silica gel or recrystallized from an appropriate solvent.

Upon heating at 80 °C or on standing at room temperature **2a** gave 1-methylthio-2,3-diphenylindede (**4a**): Mp 158 °C (2-propanol); ^1H NMR ($CDCl_3$) δ=1.41 (3H, s, MeS), 4.82 (1H, s, 1-CH), and 7.0—8.1 (14H, m, Arom); ^{13}C NMR ($CDCl_3$) δ=9.1 (q, MeS), 52.0 (d, C_1) , 120.3 (d), 124.1 (d), 126.0 (d), 127.2 (d), 127.5 (d), 127.6 (d), 127.9 (d), 128.6 (d), 129.4 (d), 134.6 (s), 134.9 (s), 140.7 (s), 142.0 (s), 144.1 (s), and 144.7 (s); MS (*m/z*) 314 (M^+). Found: C, 84.14; H, 5.84%. Calcd for $C_{22}H_{18}S$: C, 84.03; H, 5.77%.

Upon heating **2b** yielded 3-(1-methylethyl)-1-methylthio-2-phenylindede **4b** and 4-methyl-1-methylthio-2,3-diphenyl-1,3-pentadiene (**5a**). **4b**: Mp 108—109 °C (2-propanol); ^1H NMR ($CDCl_3$) δ=1.30 (3H, d, *J*=7 Hz, Me CH), 1.39 (3H, s, MeS), 1.46 (3H, d, *J*=7 Hz, MeCH), 3.32 (1H, m, Me_2CH), 4.69 (1H, s, C_1H), and 7.2—7.9 (10H, m, 2 Ph); MS (*m/z*) 280 (M^+). Found: C, 81.11; H, 7.16%. Calcd for $C_{19}H_{20}S$: C, 81.38; H, 7.19%.

5a: Mp 103—104 °C (2-propanol); ^1H NMR ($CDCl_3$) δ=1.71 (3H, s, CH_3), 1.84 (3H, s, CH_3), 2.25 (3H, s, MeS), 6.06 (1H, s, C_1–H), and 7.0—7.5 (10H, m, 2 Ph); MS (*m/z*) 280 (M^+). Found: C, 80.86; 7.09%. Calcd for $C_{19}H_{20}S$: C, 81.38; H, 7.19%.

Upon heating at 80 °C for 2 h **2c** yielded **4c** in 87% yield. 3-Methyl-1-methylthio-2-phenylindene (**4c**): Mp 89—91 °C (MeOH); ^1H NMR ($CDCl_3$) δ=1.30 (3H, s, MeS), 2.23 (3H, d, *J*=2 Hz. 3-Me), 4.72 (1H, q, *J*=2 Hz, 1-CH), and 6.9—7.8 (9H, m, Arom); ^{13}C NMR ($CDCl_3$) δ=9.2 (q, MeS), 11.8 (q, 3-Me), 52.0 (d, 1-CH), 119.0 (d), 123.7 (d), 125.8 (d), 127.1 (d), 127.5 (d), 128.2 (d), 129.1 (d), 135.5 (s), 135.9 (s), 141.4 (s), 143.9 (s), and 145.6 (s); MS (*m/z*) 252 (M^+). Found: C, 80.73; 6.43%. Calcd for $C_{17}H_{16}S$: C, 80.90; H, 6.38%.

On heating **2d** gave 3-methyl-1-methylthio-2-phenyl-1,3-butadiene (**5b**): Mp 41 °C (hexane); ^1H NMR ($CDCl_3$) δ=1.93 (3H, bs, CH_3), 2.16 (3H, s, MeS), 4.43 (1H, bs, CH), 4.80 (1H, bs, CH), 6.20 (1H, bs, CH), and 6.9—7.6 (5H, m, Ph); MS (*m/z*) 190 (M^+). Found: C, 75.51; H, 7.43%. Calcd for $C_{12}H_{14}S$: C, 75.73; H, 7.41%.

5) Thermolysis of 2b in Methanol. A solution of **2b** (200 mg) in methanol (10 ml) was heated at reflux and the reaction was monitored by means of TLC (silica gel, chloroform–petroleum ether, 1:4). After the reaction (24 h) the mixture was condensed and chromatographed over silica gel to give two mixtures. The former elution was a mixture of **4b** and **5a** in 43% yield, products from thermolysis of **2b**, and the latter was a mixture of (*E*)- and (*Z*)-1-methoxy-4-methyl-1-methylthio-2,3-diphenyl-2-pentenes (**6E**) and (**6Z**). Although the separation of the two methyl ethers by chromatography was unsuccessful, ^1H NMR spectra of the mixture showed two groups of signals corresponding to **6E** and **6Z** in a ratio of 3:7. **6E**: ^1H NMR ($CDCl_3$) δ=0.98 and 1.00 (6H, d, *J*=7 Hz, Me_2CH), 2.13 (3H, s, MeS), 2.5—3.2 (1H, m, Me_2CH), 3.46 (3H, s, MeO), 5.29 (1H, s, CH), and 6.6—7.6 (10H, m, 2Ph). **6Z**: δ=0.78 (6H, d, *J*=7 Hz, Me_2), 1.75 (3H, s, MeS), 2.5—3.2 (1H, m, Me_2CH), 3.16 (3H, s, MeO), 4.56 (1H, s, CH), and 6.6—7.6 (10H, m, 2 Ph). MS (*m/z*) 312 (M^+). Found: C, 76.75; H, 7.78%. Calcd for $C_{20}H_{24}OS$: C, 76.88; H, 7.74%.

Desulfurization of a mixture of **6E** and **6Z** with mercury(II) acetate in aqueous chloroform (bilayers reaction) gave a mixture of two aldehydes (*E*)- and (*Z*)-4-methyl-2,3-diphenyl-2-pentenal (**7E** and **7Z**) in a 58% yield. ^1H NMR spectrum of the mixture ($CDCl_3$) showed two sets of signals: δ=1.05 (6H, d, *J*=7 Hz, Me_2), 3.83 (1H, sept, *J*=7 Hz, Me_2CH), and 10.18 (1H, s, CHO), and 0.85 (6H, d, *J*=7 Hz, Me_2), 2.72 (1H, sept, *J*=7 Hz, Me_2CH), and 9.13 (1H, s, CHO) corresponding to **7E** and **7Z** (2:1) together with 6.4—7.5 (m, Ph); MS (*m/z*) 222 (M^+). Found: C, 86.94; H, 7.28%. Calcd for $C_{18}H_{18}O$: C, 86.36; H, 7.25.

Addition of triethylamine (1 ml) or sodium hydroxide (0.3 g) to a solution of **2b** (0.2 g) in methanol (10 ml) increased the yield of the methyl ether **6** to 82% and no **4b** and **5a** were isolated.

5) Kinetic Experiment of Thermolysis of 2b. A solution of **2b** (0.09—0.13 M (1 mol dm^{-3})) and methyl phenyl sulfide or dimethyl sulfone as an inner standard in an appropriate solvent was sealed in an NMR sample tube and was kept stand in a thermostated bath (±0.1 °C); the rate was followed at suitable time intervals (at least 10 times) by analyzing the ^1H NMR spectra of the methyl groups of **2b** and the internal standard by the peak-height method averaging 5 measurements. The results are summarized in Table 4.

Regioselectivity in the Catalytic Hydrogenolysis of 1-Amino-1-cyclopropanecarboxylic Acid and Its Methyl Ester

Koji ISOGAI,* Jun-ichi SAKAI, Keiji YAMAUCHI, and Katsuya WATANABE
Department of Applied Chemistry, Faculty of Engineering, Niigata University, Ikarashi, Niigata 950-21
(Received March 17, 1986)

The title compounds were hydrogenolyzed over Pd-C. The ring-bond cleavage in the hydrogenolysis of the acid in water or methanol occurred at both the C_1–C_2 bond and the C_2–C_3 bond in nearly equal proportion, whereas the C_1–C_2 bond was cleaved mainly in the presence of ammonia and the C_2–C_3 bond was cleaved mainly in acetic acid. Selective hydrogenolysis of the C_1–C_2 bond of ester occurred in hexane or methanol, whereas the C_2–C_3 bond was hydrogenolyzed mainly in acetic acid. The role of the amino group is discussed.

Although many studies on the regioselectivity in the catalytic hydrogenolysis of substituted cyclopropanes have been reported,[1] little attention has been given to the catalytic hydrogenolysis of aminocyclopropanes. Recently, Musso[2] reported that 1-amino-1-cyclopropanecarboxylic acid was hydrogenolyzed selectively at the opposite bond of the amino group in methanol in the absence or in the presence of ammonia by the use of a palladium catalyst. On the contrary, we found previously that *exo*-7-aminobicyclo[4.1.0]heptane and *exo*-6-aminobicyclo[3.1.0]hexane were hydrogenolyzed exclusively at the adjacent bond of the amino group in hexane using both palladium and nickel catalysts.[3] In order to make clear the role of the amino group which might cause these conflicting results, we have investigated the hydrogenolysis of methyl 1-amino-1-cyclopropanecarboxylate (**1**) and 1-amino-1-cyclopropanecarboxylic acid (**2**) in neutral, basic or acidic solution.

Table 1. Hydrogenolysis of Methyl 1-Amino-1-cyclopropanecarboxylate (**1**)

Run No.	Solvent	Conversion %	Composition of products/%		
			C_2–C_3 Fission		C_1–C_2 Fission
			3	**4**	**5**
1[a]	Hexane	0	—	—	—
2[b]	Hexane	64	—	2	98
3[a]	CH_3OH	0	—	—	—
4[b]	CH_3OH	28	17	—	83
5[a]	CH_3COOH	28	84	12	4

Substrate: 58 mg, 0.5 mmol. Catalyst: Pd-C, 50 mg. Reaction time: 24 h. a) Room temperature, atmospheric pressure. b) 80°C, 50 kg cm^{-2}.

The hydrogenolysis of **1** and **2** was carried out by the use of palladium-charcoal (Pd-C) catalyst and the results are shown in Tables 1 and 2.

The hydrogenolysis of **1** was made easy by increasing the reaction temperature and the hydrogen pressure. The hydrogenolysis of **1** in hexane gave selectively methyl 2-aminobutanoate (**5**) as the C_1–C_2 bond cleaved product, accompanied by a slight amount of methyl 2-amino-2-methylpropanoate (**4**) as the C_2–C_3 bond cleaved product. The hydrogenolysis of **1** in methanol also gave mainly **5**, accompanied by a small amount of methy 2-methylpropanoate (**3**) as the C_2–C_3 bond cleaved product. On the other hand, when acetic acid was used as a solvent, selective hydrogenolysis of the C_2–C_3 bond of **1** occurred at

Table 2. Hydrogenolysis of 1-Amino-1-cyclopropanecarboxylic Acid (**2**)

Substrate: 100 mg (1 mmol). Catalyst: Pd-C, 200 mg. Solvent: 10 ml. Reaction time: 24 h. a) 100 °C, 80 kg cm^{-2}. b) Room temperature, atmospheric pressure. c) NH_3 is contained in amounts eight times the molar quantity of **2**. d) CH_3COOH is contained in amounts ten times the molar quantity of **2**. e) NH_3 is contained in amounts five times the molar quantity of **2**. f) PtO_2 (50 mg) is used instead of Pd-C. g) Products were determined as methyl esters.

room temperature under atmospheric pressure to give **3** and **4**, accompanied by a slight amount of **5**.

The hydrogenolysis of **2** was carried out in water and the reaction products were converted into methyl esters to submit to vapor-phase chromatography (VPC). The ring-bond cleavage of **2** in water occurred at both the C_1–C_2 bond and the C_2–C_3 bond in nearly equal proportion, whereas the C_1–C_2 bond was cleaved mainly in the presence of aqueous ammonia and the C_2–C_3 bond was cleaved mainly in the presence of acetic acid. The results (Run No. 9, 10, and 11) obtained by the reinvestigation under the conditions reported by Musso[2] were analogous to that described above.

According to Musso's report,[2] the ratios of 2-amino-2-methylpropanoic acid and 2-aminobutanoic acid obtained in the hydrogenolysis of **2** using Pd–C in methanol, Pd–C in methanol–ammonia and Pt in acetic acid were reported, respectively, as follows: 90%, 10%; 98.5%, 1.5%; 23%, 77%. He explained the results on the basis of his proposal,[4] concerning the regioselective effect of substituents in the hydrogenolysis of cyclopropanes, in the following manner. The amino group plays as an electron-donating group in the neutral or the basic solvent and the hydrogenolysis occurs at the weakened C_2–C_3 bond preferentially, whereas the amino group plays as an electron withdrawing group in the acidic solvent and causes the C_1–C_2 bond cleavage mainly.

Contrary to his explanation, however, our finding suggests strongly that the amino group of **2** contributes mainly to the cleavage of the C_1–C_2 bond when the hydrogenolysis is carried out under the condition in which the amino group behaves as a free amine, whereas the C_2–C_3 bond cleavage is prefered under the condition in which the amino group forms an ammonium ion. Additionally, the C_2–C_3 bond cleavage was accompanied by the elimination of the amino group.

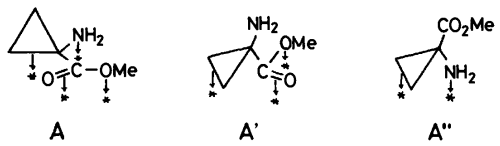

Fig. 1. Adsorbed states of **1** in neutral solvents.

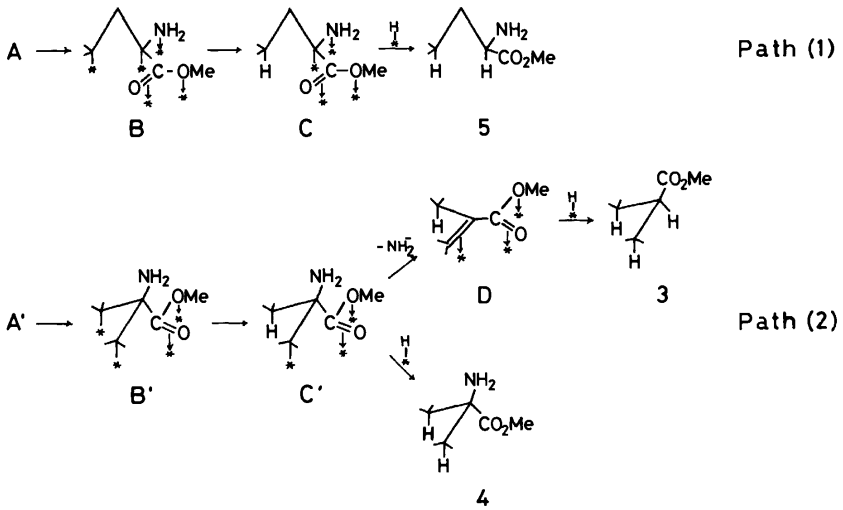
The obtained results may be explained by considering the adsorbed states of **1** and **2** on the catalyst. The probable adsorbed states of **1** are shown in Fig. 1. The adsorbed state A which is adsorbed with the amino group, the methoxycarbonyl group and the C_1–C_2 bond of the cyclopropane ring seems to be preferable to A′ which is adsorbed with the methoxycarbonyl group and the C_2–C_3 bond or A″ which is adsorbed with the amino group and the C_2–C_3 bond. Therefore, it is expected that the predominant product is the C_1–C_2 bond cleaved product in the hydrogenolysis of **1** in the neutral solvent as shown in Path (1) in Scheme 1. The obtained results support this consideration.

A pathway of the formation of the minor products **3** and **4** is shown in Path (2) in Scheme 1. The C_2–C_3 bond cleavage of the adsorbed state A′ occurs more easily than that of the adsorbed state A″ because the unadsorbed amino group behaves as an electron-donating group and contributes to weakening the C_2–C_3 bond. The elimination of the amino group can be explained as an example of the elimination in the half-hydrogenated state.[5–8] In the half-hydrogenated state C′ formed from A′ via B′, the combination with the chemisorbed hydrogen competes with the elimination of the amino group caused by the donation of the electron of the carbon–metal bond to the C_1–C_2 bond. The tendency toward the elimination seems to be enhanced by the solvation of the leaving group with protic solvents such as methanol and water.

In the acidic solvent, the amino group of **1** is converted to ammonium ion and loses the ability of



Scheme 1.

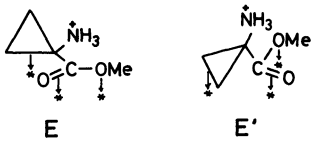


Fig. 2. Adsorbed states of **1** in acidic solvents.

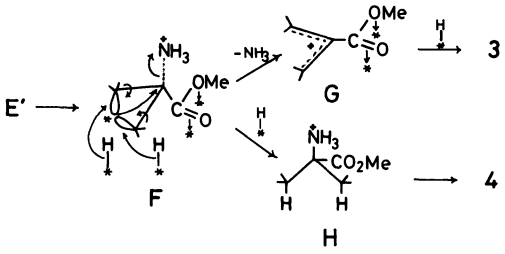
adsorption to the catalyst. Therefore, two forms of the adsorbed states E and E′, adsorbing with the methoxycarbonyl group and the C_1–C_2 bond or the C_2–C_3 bond, can be considered as shown in Fig. 2.

Although the hydrogenolysis of methyl cyclopropanecarboxylate has not been reported, it is expected that the C_1–C_2 bond is cleaved selectively because cyclopropyl methyl ketone is hydrognolyzed at the C_1–C_2 bond selectively.[9] If the ammonio group in **1** behaves as an electron withdrawing group and contributes to cleaving the adjacent C_1–C_2 bond as mentioned in Musso's proposal, it is expected that the combined influences of the ammonio and the methoxycarbonyl groups would cause the exclusive C_1–C_2 bond cleavage of **1**. On the contrary, the selective cleavage of the opposite C_2–C_3 bond and the elimination of the ammonio group were observed in our experiment. These results suggest that **1** is adsorbed mainly in the adsorbed state E′ and the hydrogenolysis proceeds according to the similar pathway shown in Path (2) in Scheme 1.

However, the hydrogenolysis of **1** in acetic acid proceeded more easily than in hexane or methanol and was accompanied by considerable elimination of the ammonio group. Therefore, it seems to be necessary to consider the relationship between the accelaration of the C_2–C_3 bond cleavage and the easy elimination of the ammonio group.

It is well-known that the accelerating effect in the solvolysis of cyclopropyl tosylates[10] or halides[11] is explained by the concept of σ-participation. In the adsorbed state E′, π-adsorption of the C_2–C_3 bond to the catalyst surface and the C–NH_3^+ bond are opposite in direction. Because the relationship in direction is preferable stereoelectronically, the acceleration of the hydrogenolysis in acidic solvent may be explained somewhat more clearly by the concept of the σ-participation. An increase of the polarization in C–NH_3^+ bond caused by the solvation makes the C_2–C_3 bond cleavage easy and the elimination of the ammonio group proceeds predominantly, competing with the combination of chemisorbed hydrogen as shown in Scheme 2.

Since the details of experimental conditions were not described in Musso's report, it is difficult to point out the cauces of discrepancies observed in the hydrogenolysis of **2**. However, the obtained results can be explained reasonably in the following manner. In aqueous solution, equilibrium is established among the dipolar ion of **2** and the anion and the



Scheme 2.

cation forms of **2**, whereas it is largely in the anion form in basic solution and largely in the cation form in acidic solution. Therefore, the composition of products in the hydrogenolysis of **2** in water is dependent on the equilibrium of the three forms of **2**. The anion form is adsorbed mainly with the C_1–C_2 bond, the amino group and the carboxyl group to give the C_1–C_2 bond cleaved product, whereas the dipolar ion and the cation form are adsorbed mainly with the C_2–C_3 bond and the carboxyl group to give the C_2–C_3 bond cleaved products being accompanied by the elimination of the ammonio group. The behavior of **2** in the hydrogenolysis in methanol, methanol–ammonia or acetic acid may be explained in a similar manner as above.

Experimental

Infrared spectra were recorded on a Hitachi 270-30 spetrometer. ^{1}H NMR spectra were recorded on a JEOL JNM-PMX 60 spectrometer. Chemical shifts (δ) are recorded in ppm downfield Me_4Si.

1-Amino-1-cyclopropanecarboxylic Acid (2). **2** was prepared according to the method described in the literature.[12] To a solution of 1-[(diphenylmethylene)amino]-1-cyclopropanecarbonitrile, mp 77—80 °C, lit,[12] mp 77—80 °C, (7.5 g, 30.5 mmol) in ether (75 ml) was added 1 mol dm^{-3} hydrochloric acid (150 ml) and the mixture was stirred for 12 h at room temperature. The layers were separated and the aqueous layer was refluxed with concentrated hydrochloric acid (150 ml) for 4 h. After removal of the water, the residue was taken up in a small volume of water and passed through a column packed with weakly basic anion-exchange resin Bio-Rad AG3-X4A) to give 2.8 g of **2**: Mp 229—231 °C, lit,[12] mp 229—231 °C; ^{1}H NMR (D_2O)[12] δ=1.5 (2H, m, C$\underline{H}_2$), 1.2 (2H, m, C$\underline{H}_2$); IR(KBr) 1626 (ν_{COO^-}), 1538 ($\delta_{NH_3^+}$); Found: C, 47.36; H, 6.79; N, 13.97%. Calcd for $C_4H_7NO_2$: C, 47.52; H, 6.98; N, 13.85%.

Methyl 1-Amino-1-cyclopropanecarboxylate (1). To a solution of **2** (2.5 g, 24.8 mmol) in methanol (10 ml) was passed dried hydrogen chloride and refluxed for 12 h. After removal of the methanol the residue was made basic with diluted sodium carbonate solution and extracted with chloroform. The fractional distillation gave 0.6 g of **1**: Bp 45—47 °C/27 mmHg (1 mmHg=133.322 Pa); ^{1}H NMR (CCl_4) δ=3.60 (3H, s, OC$\underline{H}_3$), 1.77 (2H, s, N$\underline{H}_2$), 1.15 (2H, m, C$\underline{H}_2$), 0.92 (2H, m, C$\underline{H}_2$); IR (CCl_4) 3396 (ν_{NH}), 1724 ($\nu_{C=O}$), 1622 (δ_{NH}), 1192 (ν_{CO}); Found: C, 52.08; H, 7.92; N, 12.21%. Calcd for $C_5H_9NO_2$: C, 52.16; H, 7.88; N, 12.16%.

Hydrogenolysis of 1. A solution of **1** (58 mg, 0.5 mmol) in hexane, methanol or acetic acid (5 ml) was stirred with Pd-C (50 mg, Kawaken Fine Chemical Co.: Pd-C(M)) at room temperature under hydrogen at atmospheric pressure or at 80 °C under hydrogen pressure of 50 kg cm^{-2} for 24 h. When hexane was used as a solvent, the reaction mixture was submitted directly to VPC to determine the composition of products. When methanol or acetic acid was used as a solvent, hexane (15 ml) was added to the reaction mixture and washed with water to remove the methanol or the acetic acid and submitted to VPC.

Hydrogenolysis of 2. A solution of **2** (100 mg, 1 mmol) in water (10 ml) in the absence or in the presence of aqueous ammonia (8 mmol) or acetic acid (10 mmol) was stirred with Pd-C (200 mg) at 100 °C under hydrogen pressure of 80 kg cm^{-2} for 24 h. After the catalyst and the water were removed from the reaction mixture, the residue was esterified with methanol in the presence of hydrogen chloride and submitted to VPC.

A solution of **2** (100 mg, 1 mmol) in methanol (10 ml) in the absence or in the presence of ammonia (5 mmol) was stirred with Pd-C (200 mg) at 100 °C under hydrogen pressure of 80 kg cm^{-2} for 24 h. The reaction mixture was esterified in a similar manner as above and submitted to VPC.

A solution of **2** (100 mg, 1 mmol) in acetic acid (10 ml) was stirred with Pd-C (200 mg) or PtO_2 (50 mg) at room temperature under hydrogen at atmospheric pressure for 24 h. The reaction mixture was esterified with methanol and submitted to VPC.

Identification of Products. The products were identified by comparison with ^{1}H NMR, IR spectra and the values of T_R in VPC of authentic samples prepared by the esterification of the corresponding carboxylic acids in the usual way.

Methyl 2-Methylpropanoate (3): Bp 92—93 °C, lit,[13] bp 91.5 °C/742 mmHg; ^{1}H NMR (CCl_4) δ=3.16 (3H, s, $OC\underline{H}_3$), 2.73—2.27 (1H, m, J=7.0 Hz, C$\underline{H}$), 1.14 (6H, d, J=7.0 Hz, $C\underline{H}_3$×2); IR (CCl_4) 1736 ($\nu_{C=O}$), 1200 (ν_{CO}), 1156 (ν_{CO}).

Methyl 2-Amino-2-methylpropanoate (4): Bp 132—134 °C, lit,[14] bp 133—134 °C; HCl salt: Mp 182—183 °C, lit,[14] mp 182—183 °C; ^{1}H NMR(CCl_4) δ=3.62 (3H, s, $OC\underline{H}_3$), 1.41 (2H, s, $N\underline{H}_2$), 1.25 (6H, s, $C\underline{H}_3$×2); IR (CCl_4) 3396 (ν_{NH}), 1730 ($\nu_{C=O}$), 1192 (ν_{CO}), 1142 (ν_{CO}).

Methyl 2-Aminobutanoate (5): Bp 68—70 °C; HCl salt: mp 149—150 °C, lit,[15] mp 150—151 °C; ^{1}H NMR (CCl_4) δ=3.60 (3H, s, $OC\underline{H}_3$), 3.23 (1H, t, J=7.0 Hz, C$\underline{H}$), 1.92—1.23 (2H, m, $C\underline{H}_2$), 1.30 (2H, s, $N\underline{H}_2$), 0.92 (3H, t, J=7.0 Hz, $C\underline{H}_3$); IR (CCl_4) 3404 (ν_{NH}), 1738 ($\nu_{C=O}$), 1174 (ν_{CO}), 1140 (ν_{CO}).

(Received April 7, 1986)

The salt effect of $(n\text{-Bu})_4NClO_4$ and NaOPh on the polarimetric and titrimetric rate constants (k_p and k_t, respectively) has been examined for the S_N1 solvolyses of optically active 2,2-dimethyl-1-(*p*-methoxyphenyl)-propyl (**1**) and 2,2-dimethyl-1-phenylpropyl *p*-nitrobenzoates (**2**) in pure phenol solvent. Four patterns, A, B, C, and D of the k_p–k_t profile against the added salt concentration have been observed for the phenolyses of **1**, **2**, and 2,2-dimethyl-1-(*p*-nitrophenyl)propyl *p*-nitrobenzoate (**3**). The patterns can specify the number of the sequential ion-pair intermediates (i.e., one or two), the product-forming stage (i.e., the 1st or the 2nd intermediate), and the species of reactant at the product-forming step (i.e., solvent phenol molecule, the phenoxide, or the perchlorate). The feature of the pattern of the k_p–k_t profile is predominantly controlled by two factors, (i) the stability of the carbocation intermediate derived from the substrates **1**—**3** and (ii) the nucleophilicity of the added salt. The patterns of salt effect on the product distribution (% of ROPh, *o*- and *p*-RC_6H_4OH) are also compatible with such rationalization of the four patterns.

In view of the recent recognition of multiple intermediates in S_N1 solvolysis,[2] we need to know how many ion-pair intermediates exist in each solvolysis, before we consider about the structure of the ion pair as the intermediate. However, the example which actually presents experimental evidence for the presence of multiple intermediates has not so often been reported except by Winstein's[3,4] and our groups.[5–8]

As a result of such dearth of examples in the literature, there has been seen diversity of suggested structures on the ion-pair intermediates, especially for the second stage.[9] By the same token, there has been little direct proof[10] to a view that, as the reactivity of substrate is varied, the relative proportions of simultaneous nucleophilic attack at the different intermediate stages will change.[10,11]

It was previously reported that retentive phenolyses of optically active aralkyl systems can apparently be classified into two groups in which the products derived from either the first or the second ion-pair intermediate, on the basis of four patterns of the salt effect of sodium phenoxide on k_p (polarimetric rate constant) and k_t (titrimetric rate constant) profile.[5,6] However, the examples were so insufficient to correlate explicitly the ion-pair stage (the first or the second) of the product formation with the ion-pair stability (or the reactivity).

Recently, we have further investigated on the salt effect of two salts with different nucleophilicity (i.e., sodium phenoxide and tetrabutylammonium perchlorate) on the k_p and k_t and also on the product distribution (% of ROPh, *o*-, and *p*-RC_6H_4OH) for the phenolyses of 2,2-dimethyl-1-(*p*-methoxyphenyl)propyl (**1**) and 2,2-dimethyl-1-phenylpropyl *p*-nitrobenzoates (**2**). Thus, it has led us to recognize that products come from "the second ion-pair intermediate" alone in the phenolysis of **1**, whereas only "the first ion-pair intermediate" is the source of the products in that of **2**, reflecting the stability sequence of the carbocation intermediate derived from **1** and **2**.

In addition, it has been disclosed in the phenolysis of **2** that the added salts, i.e., sodium phenoxide and tetrabutylammonium perchlorate, can change the k_p–k_t pattern from the pattern B to the pattern C depending on their nucleophilicity, and hence the virtual reactant toward the ion-pair intermediate can be specified as the phenoxide in the presence of sodium phenoxide and as the phenol molecule in the presence of tetrabutylammonium perchlorate.

Results and Discussion

Phenolysis Rates and Stability of the Ion-Pair Intermediates. The titrimetric rate constants for the phenolyses in phenol at 125 °C in the presence of sodium phenoxide (0.1 M (1 M=1 mol dm^{-3})) have previously been reported for **1**—**3**.[6] The $k_{t,rel.}$ and the k_p values, which were not cited in the previous paper,[6]

† Presented in part by K. O. at the 7th IUPAC Conference on Physical Organic Chemistry, in Auckland, New Zealand, August, 1984.

Table 1. Phenolysis Rates of *p*-Substituted 2,2-Dimethyl-1-phenylpropyl *p*-Nitrobenzoates **1**—**3** in the Presence of Sodium Phenoxide at 125 °C

Substrate[a]	$[NaOPh]_o$/M	k_t/s^{-1} [b,c]	$k_{t,rel.}$	k_p/s^{-1} [d]

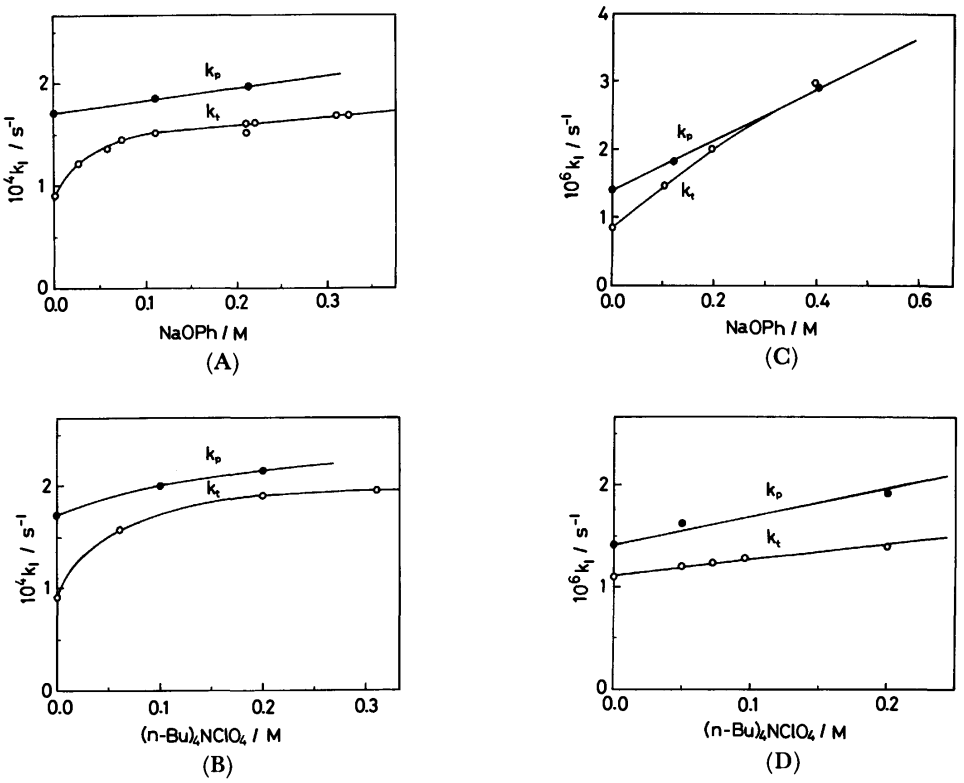

Fig. 1. Effect of added salt concentration on the first-order rate constants (k_p and k_t) in the phenolyses.
(A): (1) in the presence of NaOPh at 75 °C.
(B): (1) in the presence of $(n\text{-Bu})_4NClO_4$ at 75 °C.
(C): (2) in the presence of NaOPh at 125 °C.
(D): (2) in the presence of $(n\text{-Bu})_4NClO_4$ at 125 °C.

are shown along with the k_t values in Table 1.

The k_t decreases in the sequence **1**>**2**>**3** (relative rate; 178000:64.9:1.00). The k_p ($k_p/k_t<1.4$) decreases in the same sequence **1**>**2**. Thus, each of the phenolysis intermediate should become less stable in the order of rate sequence.

Salt Effect on Phenolysis Rates. The measurement of k_p and k_t values were carried out at variable concentrations of added sodium phenoxide or tetrabutylammonium perchlorate for the optically active substrates **1** at 75 °C and **2** at 125 °C. Subsequently, the k_p and k_t were plotted against the salt concentration (Fig. 1).

Such k_p-k_t diagrams can in general be classified into four patterns, A–D (Fig. 2), provided that there is no normal salt effect.[6]

A common feature of patterns A and B is seen in "the special salt effect" on k_t, which has first been recognized in acetolyses of many substrates by Winstein and his coworkers.[3,4,9,15] The special salt effect indicates that the added salt reacts with an ion-pair intermediate making the rate of ion-pair return negligibly low as compared with the rate of the product formation.

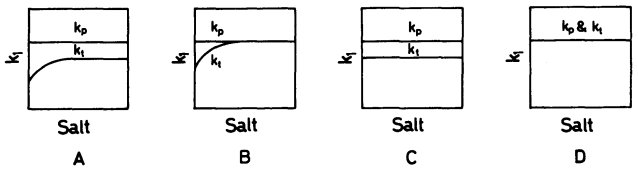

Fig. 2. Four patterns of salt effect on k_p and k_t in S_N1 solvolysis (in the absence of normal salt effect; cited from Ref. 6).

In pattern A, the k_p exceeds the k_t over the whole range of the added salt concentration and the k_p/k_t ratio is constant at higher concentrations of the salt. This indicates the existence of two kinetically-distinguishable intermediates in the solvolysis system as pointed out by Winstein and his coworkers.[3,4]

By contrast, in pattern B the discrepancy between k_p and k_t virtually disappears with increase in the salt concentration. The coincidence in the k_p and k_t values at higher salt concentrations suggests that the consumption rate of the ion-pair intermediate becomes far greater than the return rate and consequently that the solvolysis proceeds via a single ion-pair intermediate alone.

The k_t values in patterns C and D are invariant despite of increase in concentration of the added salt. Thus, the patterns C and D indicate that not the salt but a solvent molecule alone participates in the formation of the product. They clearly indicate that the intermediate is so reactive as to react with the solvent molecule before it does with the added salt. Consequently, we can see from the patterns C and D the existence of a single ion-pair intermediate alone in the reaction system.

In the pattern C, in addition, the intermediate partially returns to the substrate, partially reacts with the solvent molecule, and partially racemizes in itself. In the pattern D, however, all of the intermediate is scavenged by the solvent molecule alone.*

We can characterize such salt effect on k_p and k_t, using the parameters proposed by Winstein and his coworkers,[13] i.e., $k_{t,ext}^{\circ}/k_t^{\circ}$ ($k_{t,ext}^{\circ}$: k_t value extrapolated at [salt]=0 from its linear part at higher salt concentrations, k_t°: k_t value at [salt]=0) and $[salt]_{1/2}$ (salt concentration corresponding to $0.5(k_{t,ext}^{\circ}+k_t^{\circ})$) for special salt effect, and also using Winstein's equations[13] $k_p=k_p^{\circ}(1+b_p[salt])$ (k_p°: k_p value at [salt]=0) and $k_t=k_{t,ext}^{\circ}(1+k_t[salt])$ for normal salt effect on k_p and k_t, respectively. Such parameters for phenolyses of **1**—**3**, which include some previously-reported,[6] are tabulated in Table 2.

The phenolysis of **1** in the presence of NaOPh or $(n\text{-Bu})_4NClO_4$, follows pattern A (Fig. 1 and Table 2; $k_{t,ext}^{\circ}/k_t^{\circ}>1$, $[salt]_{1/2}>0$, and $k_p/k_t>1$) which suggests that both NaOPh and $(n\text{-Bu})_4NClO_4$ attack the second intermediate (I_2).

The other examples of pattern A have been observed in the phenolysis of 1-(*p*-methoxyphenyl)ethyl *p*-nitrobenzoate in the presence of NaOPh[5] and also in the acetolyses of *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl brosylate and tosylate in the presence of $LiClO_4$.[3]

The k_p-k_t profile for **2** against the added NaOPh concentration, which belongs to pattern B (Fig. 1 and Table 2; $k_{t,ext}^{\circ}/k_t^{\circ}>1$, $[salt]_{1/2}>0$, and $k_p/k_t=1$), indicates that the phenoxide ion attacks the first ion-pair intermediate to result in neither ion-pair return nor racemization of the intermediate itself at higher NaOPh concentrations. The other examples of pattern B have been found in the phenolyses of 2,2-dimethyl-1-(*p*-methoxyphenyl)propyl trifluoroacetate,[6] 1-ethyl-1,5-dimethylhexyl chloride and *p*-nitrobenzoate,[7] and 1-methylheptyl tosylate,[7] the acetolysis of

* The intermediate may return without racemization and also without isotope scrambling of two oxygen atoms in the *p*-nitrobenzoyloxy group of leaving one.

2-(*p*-methoxyphenyl)propyl tosylate,[4] and the trifluoroacetolysis of 1-methylpropyl tosylate.[14]

In this context, it deserves to mention that Winstein and his coworkers measured the sum ("k_1"$=k_t+k_r$) of the k_t for 2-(*p*-methoxyphenyl)propyl tosylate and the rearrangement rate (k_r) to 1-(*p*-methoxyphenyl)-1-methylethyl tosylate as the ionization rate constant instead of the k_p and they regarded the "k_1"$-k_t$ (instead of k_p-k_t) profile for the acetolysis of 2-(*p*-methoxyphenyl)propyl tosylate as pattern A in the presence of $LiClO_4$.[4] However, the ratios of "k_1"$/k_t$ for this system are calculated to be 1.24, 1.14, and 1.03 at $LiClO_4$ concentrations 0.0300, 0.0600, and 0.100 M, respectively, by the use of their rate data.[4] Thus, it certainly decreases to 1.00 at higher $LiClO_4$ concentrations. In other words, the "k_1" and k_t lines must coincide with each other at the higher salt concentration than 0.1 M. Consequently, the profile should not belong to pattern A, but to pattern B, and hence the nucleophile should attack the first, not the second, ion-pair intermediate in the acetolysis.

The phenolysis of **2** in the presence of $(n\text{-Bu})_4NClO_4$† exhibits pattern C (Fig. 1 and Table 2; $k^\circ_{t,ext}/k^\circ_t=1$, $[salt]_{1/2}=0$, and $k_p/k_t>1$) instead of B. The added perchlorate is less nucleophilic than NaOPh and the intermediate is scavenged by the solvent phenol instead of the perchlorate. Thus, this is reflected in the changeover of the pattern from B to C (Table 2).

The same pattern C has been observed in the other phenolyses of 1-phenylethyl,[5] 1-phenylpropyl,[6] 2-methyl-1-phenylpropyl,[6] 1-methyl-1-phenylpropyl,[6] *p*-chlorobenzhydryl *p*-nitrobenzoates[6] in the presence of NaOPh), and 1-phenylethyl chloride (in the presence of $PhNH_2$††). The same pattern C has been also found in the acetolysis of *exo*-2-norbornyl brosylate in the presence of KOAc.†††,[16]

The *p*-nitrobenzoate (**3**) should give a relatively less stable and short-lived ion-pair intermediate, and the racemization was not observed in the reclaimed substrate at a half life. Hence, although the k_p was not measured for **3**, it is most probable that **3** follows pattern D (Table 2; $k^\circ_{t,ext}/k^\circ_t=1$, $[salt]_{1/2}=0$, and $k_p/k_t=1$). The phenolyses of 1-(*p*-nitrophenyl)ethyl *p*-nitrobenzoate[5] and 1-ethyl-1,5-dimethylhexyl trifluoroacetate in the presence of NaOPh[6] and the acetolysis of *endo*-2-norbornyl brosylate in the presence of KOAc†††,[16] offer the other examples of pattern D.

Among the phenolyses of the three substrates **1**—**3**, the reaction temperature (75 °C) for **1** in the presence of $(n\text{-Bu})_4NClO_4$ is lower than those for the others (see Table 2). However, the pattern A for **1** has been observed in the presence of NaOPh at both 125[6] and 75 °C (Table 2). Therefore, the k_p-k_t pattern for $(n\text{-Bu})_4NClO_4$ would most probably follow pattern A even at 125 °C.

Accordingly, under the exactly identical conditions the k_p-k_t profiles for phenolyses of **1**—**3** should exhibit pattern A for **1**, B in the presence of NaOPh for **2**, C in the presence of $(n\text{-Bu})_4NClO_4$ for **2**, and D for **3**.

The similar feature of the k_p-k_t profile has been observed for the phenolysis of 1-phenylethyl system, A for $p\text{-}CH_3O$, C for unsubstituted, and D for $p\text{-}NO_2$.[5]

These results, in turn, show that the k_p-k_t pattern should change in the order A→B→C→D as the stability of phenolysis intermediate decreases and also as the nucleophilicity of added salt decreases. For **1** which gives the most stable carbocation among the homologue, the second ion-pair intermediate (I_2) is attacked by both NaOPh and $(n\text{-Bu})_4NClO_4$. For **2** which generates relatively less stable carbocation, the phenoxide ion and a solvent molecule (in a solvation shell) attack the first ion-pair intermediate (I_1), but $(n\text{-Bu})_4NClO_4$ can not have the chance to react with I_1. For **3** which produces the most reactive carbocation among the homologue, I_1 reacts instantly with the solvent phenol molecule alone as it forms.

A similar tendency is seen in the comparison of acetolyses of *threo*-2-(*p*-methoxyphenyl)-1-methylpropyl and 2-(*p*-methoxyphenyl)propyl tosylates; their rates (k°_p) decrease in the sequence the former (2.70×10^{-5} s^{-1} at 25 °C[3]) > the latter (1.79×10^{-5} s^{-1} at 50 °C[4]) and follow the k_p-k_t patterns A and B, respectively (vide supra).

It has been claimed that in the S_N1 solvolysis the product may be produced via some or all of possible intermediates.[2] In addition, a view[10,11] has been presented that as the stability of the intermediates varies, the relative portions of nucleophilic attack stages will change. However, little direct evidence[10] has been given to the view. Our result shows that, conservatively speaking of the phenolysis, all of the products are substantially derived from a single ion-pair intermediate, either I_1 or I_2.

Thus, from the k_p-k_t patterns, we can determine the number of ion-pair intermediate, in the other words, the product-forming stage and the species of reactant (the solvent molecule or the added salt). Hence, the intermediate stage of nucleophilic attack is fundamen-

† 2,6-Di-*t*-butyl-4-methylpyridine was added to the phenolysis of **2** in the presence of $(n\text{-Bu})_4NClO_4$ in order to neutralize the liberated acid which might cause the rearrangement of the phenyl ether to the alkylphenols.[15]

†† Although the pattern A was previously reported for the phenolysis of 1-phenylethyl chloride in the presence of aniline,[8] reexamination of the salt effect for the system in our laboratory has now disclosed that it does not follow pattern A, but C.

††† For the acetolyses of *exo*-[16] and *endo*-2-norbornyl brosylates,[17] the rates were measured only at one or two concentrations of added KOAc. The k_p-k_t patterns, however, can be estimated to be C for the exo-isomer and D for the endo-isomer.

Table 3. Features of Four Patterns of the k_p-k_t Diagram against Concentration of Added salt in the Phenolyses of 2,2-Dimethyl-1-(*p*-substituted phenyl)propyl *p*-Nitrobenzoates **1**—**3**

X[a]	Pattern[b]	No. of intermediate	Added salt	Nucleophile[c]	Ion-pair return	Ion-pair intermediate		
						Life	Stability (Reactivity)	Racemization

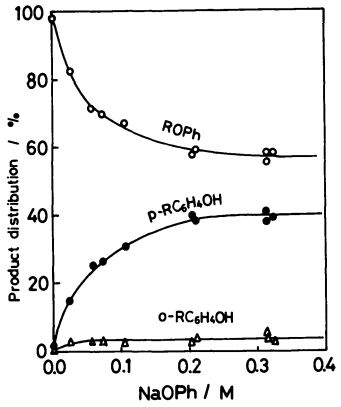

Fig. 3. Product distribution in the phenolysis of 2,2-dimethyl-1-(*p*-methoxyphenyl)propyl *p*-nirtobenzoate (**1**) in the presence of added sodium phenoxide in phenol at 75 °C.

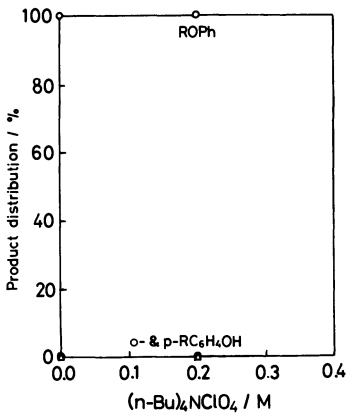

Fig. 4. Product distribution in the phenolysis of 2,2-dimethyl-1-(*p*-methoxyphenyl)propyl *p*-nitrobenzoate (**1**) in the presence of added tetrabutylammonium perchlorate in phenol at 75 °C (at 0% reaction extrapolated from product distributions at 5—70% reaction).

tally dependent on the stability (the reactivity or the life span) of S_N1 ion-pair intermediate and the nucleophilicity of the added salt or the solvent molecule. These are summarized in Table 3.

Salt Effect on Product Distribution. The product distribution (% of ROPh, *o*-, and *p*-RC_6H_4OH) was examined by the use of GLPC for the phenolyses of **1** with variable concentrations (0—0.3 M) of added NaOPh or $(n\text{-Bu})_4NClO_4$ at 75 °C under conditions identical with those employed in rate measurements. When the distribution was plotted against the concentration of added salt, patterns similar to the salt effect on k_t were observed in the diagrams; the results are shown in Figs. 3—5, along with that for **2** which was reported in the previous paper.

For **1** and **2** in the presence of NaOPh, the yield of *p*-alkylphenol increases and that of alkyl phenyl ether decreases in a pattern similar to the special salt effect on k_t (Figs. 2 and 4). The yield of *o*-alkylphenol is

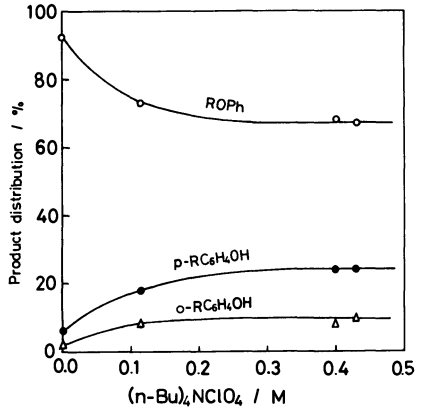

Fig. 5. Product distribution in the phenolysis of 2,2-dimethyl-1-phenylpropyl *p*-nitrobenzoate (**2**) in the presence of added sodium phenoxide in phenol at 125 °C (cited from Ref. 6).

almost invariable. From constancy of the product distribution at higher salt concentrations, it is concluded that almost all of the products at higher salt concentrations are derived from the reaction of the phenolysis intermediate with the added salt, not with the solvent phenol molecule.

For **1** in the presence of $(n\text{-Bu})_4NClO_4$, the product distribution is almost invariable inspite of increase in the added salt concentration and predominantly the phenyl ether alone (extrapolated at 0% reaction from product distribution curves at 5—70% reaction¶; Fig. 3).

Thus, the special salt effect by NaOPh appears on both the k_t value and the product distribution, whereas the special salt effect by $(n\text{-Bu})_4NClO_4$ does not appear on the product distribution but on the k_t value alone.

The perchlorate certainly reacts with the intermediate to give another intermediate, which is rapidly consumed by the solvent phenol molecule alone. On the role of $(n\text{-Bu})_4NClO_4$ at the product formation stage, further examination is in progress.

In conclusion, only after confirmation of the ion-pair stage of nucleophilic attack, we can deduce the detailed structure of the ion-pair intermediates from the stereochemical outcomes for both O- and C-alkylations in phenolyses. The ion-pair structure will be discussed in the following paper.

Experimental

^{13}C and ^1H NMR spectra were taken with a JEOL model JNM FX-100 25 MHz and a Hitachi model R-24 60 MHz instruments, respectively; IR spectra with a Hitachi model 215 spectrophotometer, and GLPC was performed with Hitachi model 163 and model 023-6003 instruments. Optical rotations were measured with a JASCO DIP-SL polarimeter.

Materials. Optically active **1** and **2** were synthesized in the previously-reported manner.[6] Sodium phenoxide was prepared by refluxing a toluene solution of phenol with sodium metal. Tetrabutylammonium perchlorate, an analytical reagent grade, was recrystallized from ethanol and dried in vacuo. 2,6-Di-*t*-butyl-4-methylpyridine was prepared by a known method.[18]

Titrimetric Rate Constants (k_t). The usual aliquot technique[5,6] was employed for measurement of k_t. The diminution in base concentration in the presence of NaOPh was followed by titration in acetone with standard hydrochloric acid; the increase in acid concentration in the presence of $(n\text{-Bu})_4NClO_4$ or in the absence of added salt was followed by titration with aqueous sodium hydroxide solution. Methyl Red was used as an indicator. The k_t values are tabulated in Table 2.

Polarimetric Rate Constants (k_p). The previously-reported procedure[5,6] was followed. The rate data against the added salt concentration are summarized in Table 2.

Product Distribution Analysis. Product distributions of phenolyses were analyzed by GLPC in a manner similar to that reported earlier.[19]

The authors thank the Ministry of Education, Science, and Culture for a Grant-in-Aid for Scientific Research.

¶ The extrapolation was carried out in order to eliminate the effect of the liberated acid which caused the rearrangement of the phenyl ether to the alkylphenols.[15]

(Received April 12, 1986)

Reaction of 1-diazo-3-trimethylsilylpropanone with olefins in the presence of cupric acetylacetonate ($Cu(acac)_2$) affords cyclopropyl trimethylsilylmethyl ketones. One-flask procedure for the formation of these silylated ketones and subsequent treatment with organometallics or with lithium diisopropylamide (LDA) and then carbonyl compounds gives a variety of vinylcyclopropanes or cyclopropyl vinyl ketones in good yields, respectively. Cycloaddition of 1-diazo-3-trimethylsilylpropanone with acetylenes and similar carbon–carbon bond formation at the side chain of the cycloadducts lead to 3-pyrazolyl vinyl ketones.

Rapidly growing importance of organosilanes in recent organic synthesis owes to their wide utility in carbanion chemistry. Silicon–carbon bond can be smoothly desilylated by action with a silylophile leading to the regioselective formation of carbanion, and deprotonation can be performed by action with a base at the carbon substituted by the silyl moiety generating silyl-stabilized carbanion.[1] The resulting carbanionic species can be utilized for carbon–carbon bond-forming reactions. Accordingly, addition of a silyl moiety to functionalized molecule produces a new reagent of multi-functionalized type.[2]

Silicon–carbon bond is relatively inert under normal conditions so that the compounds bearing this bond may be often isolated and the silyl moiety may survive on a chemoselective reaction at the preexisting functionality. Use of the both functionalities in separate steps, one by one in two different orders, adds new synthetic potentials to the parent molecule providing a new reagent.

The present report describes the synthetic utility of 1-diazo-3-trimethylsilylpropanone (**1**) which bears a diazo ketone and a silyl functionalities. Though this diazo compound **1** has been known for these seven years, there is no report available on its utilization to organic synthesis.[3] Here, the diazo ketone functionality is to be first used for the cyclopropanation of olefins or the cycloaddition reaction with acetylenes, and the silyl functionality on the resulting cyclopropanes or cycloadducts is to be utilized for the subsequent carbon–carbon bond formation.

Results and Discussion

1-Diazo-3-trimethylsilylpropanone (**1**) was previously synthesized by the reaction of diazomethane with trimethylsilylacetyl chloride,[3] which is available from commercially available chloromethyltrimethylsilane via trimethylsilylacetic acid.[4] We first investigated to open a more convenient route to **1** starting from readily available materials. For this purpose, acetic acid was converted into its dianion by treatment with LDA and the anion was silylated with two equivalent amounts of chlorotrimethylsilane to give 70% of trimethylsilylacetic acid after hydrolysis (Scheme 1). The carboxylic acid was then transformed into trimethylsilylacetyl chloride or isopropyl trimethylsilylacetyl carbonate in 83 or 89% yield, respectively. The diazo compound **1** was obtained by the subsequent treatment of the silylacetyl chloride or the silylacetyl carbonate with diazomethane in ether. This method makes possible to prepare large quantities of **1** from less expensive acetic acid and chlorotrimethylsilane.

a) Cyclopropyl silylmethyl ketones are first prepared from **1** and olefins according to the procedure shown in Table 1. Dry THF and then organometallics are added by syringe. All reactions are carried out under dry nitrogen. b) PhLi: In cyclohexane-diethyl ether (7 : 3); PhMgBr: In THF; *n*-BuLi: In hexane; *n*-HepMgBr: In THF; CH_2=CHLi: Prepared in situ from tetravinyltin and butyllithium in THF. These organometallics are used in a slight excess (1.2—1.3 equivalent to **1**). c) A: 1 h at 0 °C; B: 1 h at −78 °C and then 30 min at room temperature. After the reaction is completed, the mixture is treated with aqueous acetic acid. d) Isolated yield based on **1**. e) Isolated as a cycloadduct with dimethyl fumarate. f) Yield of the fumarate cycloadduct. g) Isolated as a cycloadduct with *N*-methylmaleimide. h) Yield of the maleimide cycloadduct.

Reactions of **1** with a variety of olefins proceeded rapidly and cleanly at 60 °C in the presence of a catalytic amount of $Cu(acac)_2$ to give cyclopropyl trimethylsilylmethyl ketones **2—11** (Scheme 2 and Table 1). As the carbene generated from **1** by the elimination of nitrogen tends to undergo ready coupling dimerization reaction giving 3-hexene-2,5-dione after spontaneous desilylation, this reactive species has to be captured as soon as it is generated.[5] Therefore, olefins were used as solvents if they are liquid, and were used in large excess in dry benzene if solid. When the diazo compound **1** was slowly added by syringe to the mixture of olefin and catalyst preheated at 60 °C, formation of the coupling product became negligible. This addition took at least 30 min when 1 mmol of **1** was employed. Copper powder could be used instead of $Cu(acac)_2$, but yields of the cyclopropanes were found less satisfactory.

Although they are able to be isolated, the cyclopropyl trimethylsilylmethyl ketones **2—11** thus obtained are quite sensitive to moisture in the air suffering from ready protodesilylation. As the separation or purification procedure through column chromatography on silica gel met with awful loss of the silylated products, the crude reaction mixture was directly subjected to vacuum distillation to give pure **2—11** in fairly good yields (Table 1). The yields of some high-boiling products were determined on the basis of GLC analysis.

Nucleophilic addition of organometallics onto the carbonyl group of trimethylsilylacetyl substituent of **2**, **5**, and **7—9** gave vinylcyclopropanes **12—16** after elimination of trimethylsilanol (Scheme 2). One-flask procedure was most conveniently applied to the sequence of cyclopropanation and nucleophilic addition. Thus, the reaction of **1** with an olefin was first carried out under the conditions shown in Table 1. The reaction mixture was diluted with dry tetrahydrofuran (THF) and an organometallic reagent previously prepared was added. After the completion of nucleophilic addition, the mixture was treated with acetic acid to give vinylcyclopropanes **12—16** (Table 2).

Use of Grignard reagents as organometallics at the

a) Cyclopropyl silylmethyl ketones are first prepared from **1** and olefins according to the procedure shown in Table 1 under argon. The resulting mixture is added slowly by syringe to a solution of LDA, previously prepared from butyllithium and diisopropylamine in THF, at −78 °C. After 45 min, carbonyl compounds are added and the mixture is allowed to stir at −78 °C for 1 h and then at room temperature for 1 h (under nitrogen). b) Isolated yield based on **1**.

second step in the above one-flask procedure resulted in extremely decreased yields of vinylcyclopropanes. Coupling reaction products of the Grignard reagents were far major products in these cases. When the Grignard reagents were slowly added at −78 °C, this undesired coupling reaction could be significantly suppressed. However, yields of the vinylcyclopropanes were not satisfactory yet. Employment of organolithiums instead of Grignard reagents afforded better yields of the vinylcyclopropanes **13**—**16** (Table 2).

The silyl-stabilized carbanions generated by the deprotonation of cyclopropyl silylmethyl ketones **2**—**7** and **9** with LDA smoothly reacted with a variety of carbonyl compounds to afford cyclopropyl vinyl ketones **17**—**23** (Scheme 2). One-flask procedure for the sequence of cyclopropanation, anion generation, carbonyl addition, and silanol elimination was again employed without any serious troubles (Table 3).

Thus, 1-diazo-3-trimethylsilylpropanone (**1**) was successfully utilized to the synthesis of a variety of vinylcyclopropanes **12**—**16** and cyclopropyl vinyl ketones **17**—**23** through a simple one-flask procedure.

We further continued to use **1** in the synthesis of heterocyclic compounds. Cycloaddition reaction of **1** with *N*-phenylmaleimide or dimethyl fumarate produced the corresponding cycloadducts **A**. However, these cycloadducts were found to undergo ready protodesilylation during their separation procedure through column chromatography over silica gel to give 3-acetyl-2-pyrazolines **24** and **25** (Scheme 3).

Similar reaction of **1** with an acetylenic dipolarophile such as dimethyl acetylenedicarboxylate or dibenzoylacetylene produced the corresponding cycloadduct **B**, which again suffered from ready desilylation to give 3-acetylpyrazole **26** or **27** in excellent yield. Treatment of the crude reaction mixture, which nearly consisted of silylated cycloadduct **B**, with more than two equivalents of LDA and the subsequent reaction with benzaldehyde gave 3-pyrazolyl vinyl ketone **28** or **29** (Scheme 4).

Although all the above one-flask reactions are successful examples of consecutive use of the diazo ketone functionality and then the silyl moiety of 1-diazo-3-trimethylsilylpropanone (**1**), use of these functional groups in the different order was found not fruitful. For example, **1** was treated with benzaldehyde in the presence of tetrabutylammonium fluoride (TBAF) to give 60% yield of 3-diazo-4-hydroxy-4-phenyl-2-butanone (**30**). This product was presumably formed by the initial generation of carbanion **C** through desilylation of **1**, a 1,3-proton migration leading to another carbanion **D**, and its addition with benzaldehyde (Scheme 5).

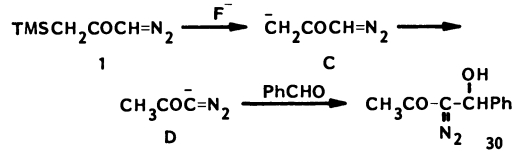

Scheme 5.

Experimental

General. Melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C NMR spectra on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as internal standard. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN micro analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or of aluminum oxide 60 F-254 type-E (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako), or Kieselgel 60 (Merck, 230—400 mesh) was used. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Gas liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatography (Yanagimoto) with a flame ionization detector using a glass column (SE-30, 3×

2000 mm). Micro vacuum distillation was carried out with a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Trimethylsilylacetic Acid. To a solution of diisopropylamine (3.0 g, 29.7 mmol) in dry THF (20 ml) was added dropwise butyllithium (18.7 ml, 29.7 mmol) at 0 °C under nitrogen. After 10 min, acetic acid (0.84 g, 14 mmol) in THF (1 ml) was added dropwise. After 1.5 h at 0 °C chlorotrimethylsilane (3.64 ml, 28 mmol) was added, the mixture was stirred for 2 h, poured into saturated sodium chloride solution, acidified to pH 3 with 1 M-HCl (1 M=1 mol dm^{-3}), and extracted with ether (20 ml). The ether was evaporated and the residue was treated with aqueous methanol overnight. This mixture was poured into ice water and extracted with ether (20 ml). The ether was dried and evaporated to give colorless solid of the acid (1.3 g, 70%): Mp 40 °C; ^{1}H NMR ($CDCl_3$) δ=0.23 (9H, s, TMS), 1.98 (2H, s, CH_2), and 10.20 (1H, br, OH).

This silylacetic acid was also obtained in 81% yield from chloromethyltrimethylsilane via its Grignard reagent according to the known method.[4]

Isopropyl Trimethylsilylacetyl Carbonate. To a mixture of trimethylsilylacetic acid (2.32 g, 17.6 mmol) and isopropyl chloroformate (2 ml, 17.6 mmol) in dry ether (20 ml) was added slowly triethylamine (2.44 ml, 17.6 mmol) at room temperature. The mixture was stirred for 12 h and colorless precipitate separated was removed by filteration. The filtrate was distilled under vacuum to give colorless liquid of the carbonate (3.4 g, 89%): Bp 101—103 °C/8398 Pa; IR (neat) 1790, 1250, and 850 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.18 (9H, s, TMS), 1.32 (6H, d, *i*-Pr), 2.00 (2H, s, CH_2), and 4.91 (1H, m, *i*-Pr); MS *m/z* (rel intensity, %) 117 (41), 75 (93), and 43 (base peak). Found: C, 49.65; H, 8.26%. Calcd for $C_9H_{18}O_4Si$: C, 49.52; H, 8.32%.

1-Diazo-3-trimethylsilylpropanone (1). To a solution of trimethylsilylacetic acid (5.2 g, 39 mmol) in dry petr. ether (10 ml) was added dropwise thionyl chloride (5.01 g, 42 mmol). The mixture was heated at 45—50 °C for 1 h and distilled under vacuum to give trimethylsilylacetyl chloride (bp 60—61 °C/4000 Pa, 4.88 g, 83%): IR (neat) 1805, 1715, 1250, 1095, and 845 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.22 (9H, s, TMS) and 2.51 (2H, s, CH_2).

The chloride (3 g, 19.9 mmol) was slowly added to the ether solution of diazomethane at 0 °C, which was previously prepared from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (21.5 g, 100 mmol) and distilled with ether. The mixture was stirred at 0 °C for 30 min and then at room temperature for 12 h. The ether and unreacted diazomethane were removed under vacuum below room temperature. The residue was distilled under vacuum to give **1** (bp 46 °C/107 Pa, 2.24 g, 72%): IR (neat) 2110, 1620, 1330, and 840 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.14 (9H, s, TMS), 2.03 (2H, s, CH_2), and 5.04 (1H, s, CH=N_2); MS *m/z* (rel intensity, %) 156 (M^+, 10), 116 (22), 84 (65), 75 (31), and 73 (base peak).

When isopropyl trimethylsilylacetyl carbonate was employed instead of trimethylsilylacetyl chloride in the above procedure, 62% yield of **1** was obtained.

General Procedure for the Cyclopropanation of Olefins with 1. A mixture of olefins (0.5 ml) and $Cu(acac)_2$ (13 mg, 0.05 mmol) was heated at 60 °C under nitrogen. When olefins are solid, they were dissolved in dry benzene (4 mmol in 1 ml). To this mixture, **1** (1 mmol) was slowly added by syringe in a period of 30 min. After the addition was completed, the mixture was subjected to vacuum distillation on a Kugelrohr micro distilling apparatus to give pure cyclopropyl trimethylsilylacetyl ketones **2**—**11**, except for **9** which could not be distilled. Results are summarized in Table 1.

2: Colorless liquid; bp 135 °C/53 Pa; IR (neat) 1675, 1250, and 850 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.08 (9H, s, TMS), 1.1—2.2 (4H, m, *c*-Pr), 2.32 (2H, s, CH_2), and 6.9—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=−1.06 (q, TMS), 18.71 (t, CH_2 of *c*-Pr), 28.65, 33.47 (each d, CH of *c*-Pr), 39.83 (t, CH_2), 126.07, 126.48, 128.60 (each d), 140.72 (s), and 206.90 (s, CO); MS *m/z* (rel intensity, %) 232 (M^+, 24), 142 (23), 141 (35), 115 (35), 75 (24), and 73 (base peak). HRMS Found: *m/z* 232.1287. Calcd for $C_{14}H_{20}OSi$: M, 232.1284.

3: Colorless liquid; bp 145 °C/67 Pa; IR (neat) 1675, 1410, 1255, and 855 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.03 (9H, s, TMS), 0.6—2.0 (17H, m, *n*-Hex and *c*-Pr), and 2.30 (2H, s, CH_2); MS *m/z* (rel intensity, %) 240 (M^+, 6), 115 (38), 75 (46), and 73 (base peak). HRMS Found: *m/z* 240.1898. Calcd for $C_{14}H_{28}OSi$: M, 240.1908.

4 (Mixture of two stereoisomers): Colorless liquid; bp 80 °C/67 Pa; IR (neat) 1670, 1255, and 855 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.12 (9H, s, TMS), 0.7—1.8 (10H, m, *n*-Pr and *c*-Pr), 1.10, 1.13 (3H, each s, Me), 2.30, and 2.35 (2H, each s, CH_2, 3:1); ^{13}C NMR ($CDCl_3$) δ=−0.94 (q, TMS), 14.24, 15.41, 20.06, 20.59 (each q, Me), 22.59, 23.30, 24.65 (each t), 30.24, 30.71 (each s, q-C), 33.36 (t), 35.65, 36.24 (each d), 40.71, 40.94, 43.71 (each t), and 207.31 (s, CO); MS *m/z* (rel intensity, %) 212 (M^+, 11), 115 (37), 93 (27), 75 (44), and 73 (base peak). HRMS Found: *m/z* 212.1515. Calcd for $C_{12}H_{24}OSi$: M, 212.1595.

5: Colorless liquid; bp 100 °C/27 Pa; IR (neat) 1680, 1660, 1405, 1245, and 840 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.12 (9H, s, TMS), 1.1—1.9 (11H, m, CH_2 and CH), and 2.29 (2H, s, CH_2); ^{13}C NMR ($CDCl_3$) δ=−1.00 (q, TMS), 21.12, 23.12 (each t), 25.06, 35.65 (each d), 39.71 (t), and 208.60 (s, CO); MS *m/z* (rel intensity, %) 210 (M^+, 35), 75 (55), and 73 (base peak). HRMS Found: *m/z* 210.1436. Calcd for $C_{12}H_{22}OSi$: M, 210.1439.

6: Colorless liquid; bp 110 °C/20 Pa; IR (neat) 1660, 1420, 1240, and 840 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.11 (9H, s, TMS), 0.8—2.4 (13H, m, CH_2 and CH), and 2.28 (2H, s, CH_2); ^{13}C NMR ($CDCl_3$) δ=−1.06 (q, TMS), 28.77, 29.71 (each t), 30.53 (d), 32.47 (t), 37.59 (d), 39.65 (t), and 208.02 (s, CO); MS *m/z* (rel intensity, %) 224 (M^+, 4), 75 (32), and 73 (base peak). HRMS Found: *m/z* 224.1573. Calcd for $C_{13}H_{24}OSi$: M, 224.1594.

7: Colorless liquid; bp 140 °C/53 Pa; IR (neat) 1670, 1430, 1250, and 850 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.12 (9H, s, TMS), 1.1—2.2 (15H, m, CH_2 and CH), and 2.29 (2H, s, CH_2); MS *m/z* (rel intensity, %) 238 (M^+, 9), 115 (25), 75 (36), and 73 (base peak). HRMS Found: *m/z* 238.1774. Calcd for $C_{14}H_{26}OSi$: M, 238.1752.

8: Colorless liquid; bp 150 °C/200 Pa; IR (neat) 1670, 1245, and 840 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.12 (9H, s, TMS), 0.6—1.9 (11H, m, CH_2 and CH), and 2.24 (2H, s, CH_2); ^{13}C NMR ($CDCl_3$) δ=1.17 (q, TMS), 25.41 (d), 28.47 (t), 28.71 (d), 28.94 (t), 36.00 (d), 40.12 (t), and 208.54 (s, CO); MS *m/z* (rel intensity, %) 222 (M^+, 34), 75 (25), and 73 (base peak). HRMS Found: *m/z* 222.1438. Calcd for $C_{13}H_{22}OSi$: M,

222.1439.

9: Colorless liquid; ^{1}H NMR ($CDCl_3$) δ=0.12 (9H, s, TMS), 1.91 (1H, t, J=2.5 Hz, CH), 2.33 (2H, s, CH_2), 3.49 (2H, t, J=2.5 Hz, CH), and 7.3—7.6 (6H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=0.99 (q, TMS), 30.65 (d), 39.98 (t), 49.50 (d), 120.41, 123.64, 127.46 (each d), 131.39, 142.90, 143.25 (each s), and 204.66 (s, CO). As pure **9** could not be obtained, its protodesilylated derivative was submitted for elemental analysis: Colorless prisms (hexane); mp 98—99 °C; IR (KBr) 1660 cm^{-1}; MS m/z (rel intensity, %) 208 (M^+, 10) and 165 (base peak). HRMS Found: m/z 208.0894. Calcd for $C_{15}H_{12}O$: M, 208.0888.

10: Colorless liquid; bp 90 °C/40 Pa; IR (neat) 1670, 1425, 1240, and 840 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.15 (9H, s, TMS), 1.0—1.3 (5H, m, Et and CH_2), 2.22 (2H, s, CH_2TMS), 2.2—2.4 (1H, m, CH), and 3.2—3.6 (3H, m, Et and CH); ^{13}C NMR ($CDCl_3$) δ=−1.06 (q, TMS), 15.00 (q), 17.71 (t), 30.18 (d), 39.53 (t), 62.77 (d), 66.65 (t), and 206.90 (s, CO); MS m/z (rel intensity, %) 200 (M^+, 3), 81 (42), 75 (28), and 73 (base peak). HRMS Found: m/z 200.1251. Calcd for $C_{10}H_{20}O_2Si$: M, 200.1231.

11: Colorless liquid; bp 95 °C/53 Pa; IR (neat) 1750, 1670, 1240, 1225, and 845 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.15 (9H, s, TMS), 1.1—1.5 (2H, m, c-Pr), 2.00 (3H, s, MeCO), 2.37 (2H, s, CH_2), and 4.25 (1H, m, c-Pr); ^{13}C NMR ($CDCl_3$) δ=−1.06 (q, TMS), 15.68 (t, CH_2), 20.72 (q, MeCO), 28.88 (d), 39.98 (t, CH_2TMS), 56.36 (d), 170.74 (s, COO), and 205.72 (s, CO); MS m/z (rel intensity, %) 154 (M^+−70, 16), 75 (40), 73 (93), 45 (23), and 43 (base peak). This compound showed no parent ion peak, the elemental analysis through HRMS being impossible.

General Procedure for the One-Pot Synthesis of Vinylcyclopropanes 12—16 from 1. Cyclopropyl silylmethyl ketones **2**, **5**, and **7—9** were prepared according to the method mentioned above. To the crude product was added dry THF (2 ml for 1 mmol of **1**), and then a solution of organometal previously prepared was added dropwise by syringe. When the reaction was over (the reaction conditions are shown in Table 2), aqueous acetic acid was added and the mixture was stirred at room temperature for 1 h. This acidic solution was neutralized with aqueous sodium hydrogencarbonate and extracted with diethyl ether (10 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (15:1) to give vinylcyclopropanes **12—16**. The results are listed in Table 2.

12a: Colorless liquid; IR (neat) 1640 and 1605 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.87 (3H, t, Me of n-Bu), 0.7—2.2 (10H, m, CH_2 and CH), 4.60 (2H, s, =CH_2), and 6.9—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.94 (q, Me), 15.50, 22.42 (each t, CH_2), 25.49, 28.56 (each d, CH), 30.26, 36.11 (each t, CH_2), 106.28 (t, =CH_2), 125.43, 125.63, 128.20 (each d), 142.88 (s), and 149.90 (s); MS m/z (rel intensity, %) 200 (M^+, 7), 143 (base peak), 141 (33), 129 (69), 128 (65), 116 (22), 115 (81), 104 (23), 103 (21), 91 (95), 80 (44), 79 (23), 78 (27), and 77 (46). HRMS Found: m/z 200.1552. Calcd for $C_{15}H_{20}$: M, 200.1564.

12b: Colorless liquid; IR (neat) 1640 and 1605 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, m, Me of n-Hep), 1.0—2.2 (16H, m, CH_2 and CH), 4.65 (2H, s, =CH_2), and 6.9—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.08 (q, Me), 15.50, 22.66 (each t, CH_2), 25.53 (d, CH), 28.12 (t, CH_2), 28.60 (d, CH), 29.19, 29.34, 31.87, 36.45 (each t, CH_2), 106.28 (t, =CH_2), 125.43, 125.67, 128.20 (each d), 142.92 (s), and 149.99 (s); MS m/z (rel intensity, %) 242 (M^+, 8), 143 (base peak), 129 (35), 128 (26), 115 (25), 91 (48), and 80 (31). HRMS Found: m/z 242.2037. Calcd for $C_{18}H_{26}$: M, 242.2033.

Diels-Alder Cycloadduct of 12c with Dimethyl Fumarate (Mixture of two stereoisomers): Colorless liquid; IR (neat) 1740 and 1610 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.9—2.9 (10H, m, CH_2 and CH), 3.60 (6H, s, COOMe), 5.37 (1H, m, 2-H), and 6.8—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.00, 14.65 (each t, CH_2), 23.12, 23.71 (each d, CH), 28.00 (t, CH_2), 29.12 (d, CH), 29.88, 30.06 (each t, CH_2), 41.35, 41.65 (each d, CH), 51.89 (q, COOMe), 118.13 (d, 2-C), 125.77, 125.89, 128.48 (each d), 135.83 (s), 142.83 (s, 1-C), and 175.36 (s, COOMe); MS m/z (rel intensity, %) 314 (M^+, 15), 255 (22), 254 (base peak), 195 (52), 194 (33), 117 (64), 115 (27), and 91 (87). Found: C, 72.62; H, 7.09%. Calcd for $C_{19}H_{22}O_4$: C, 72.59; H, 7.06%.

13a: Colorless liquid; IR (neat) 1625 and 1450 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.1—2.2 (11H, m, CH_2 and CH), 4.73, 5.08 (each 1H, d, J=1.5 Hz, =CH_2), and 7.1—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=20.37 (d, CH), 22.13, 24.19 (each t, CH_2), 29.06 (d, CH), 108.20 (t, =CH_2), 126.70, 127.87, 128.75, 129.34 (each d), 142.72 (s), and 150.71 (s); MS m/z (rel intensity, %) 198 (M^+, 14), 155 (30), 142 (31), 141 (67), 129 (33), 128 (64), 115 (84), 103 (24), 102 (32), 91 (52), 89 (21), 79 (20), 78 (27), 77 (79), and 38 (base peak). HRMS Found: m/z 198.1390. Calcd for $C_{15}H_{18}$: M, 198.1408.

13b: Colorless liquid; IR (neat) 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.8—2.1 (20H, m, Me, CH_2, and CH), 4.43, and 4.48 (each 1H, br s, =CH_2); ^{13}C NMR ($CDCl_3$) δ=14.03 (q, Me), 19.54 (d, CH), 21.49, 22.52, 23.59 (each t, CH_2), 29.04 (d, CH), 30.46, 36.60 (each t, CH_2), 103.84 (t, =CH_2), and 152.09 (s); MS m/z (rel intensity, %) 178 (M^+, 18), 136 (58), 135 (26), 121 (84), 107 (32), 95 (23), 94 (34), 93 (73), 81 (62), 80 (25), 79 (84), 77 (42), and 42 (base peak). HRMS Found: m/z 178.1697. Calcd for $C_{13}H_{22}$: M, 178.1698.

13c: Colorless liquid; IR (neat) 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.87 (3H, m, Me of n-Hep), 1.1—2.1 (23H, m, CH_2 and CH), 4.39, and 4.43 (each 1H, br s, =CH_2); ^{13}C NMR ($CDCl_3$) δ=14.08 (q, Me), 19.49 (d, CH), 21.49, 22.71, 23.63 (each t, CH_2), 28.26 (d, CH), 29.04, 29.38, 29.73, 31.92, 36.94 (each t, CH_2), 103.89 (t, =CH_2), and 151.98 (s); MS m/z (rel intensity, %) 220 (M^+, 7), 136 (20), 121 (22), 93 (26), 91 (24), 81 (27), 79 (39), 77 (22), and 40 (base peak). HRMS Found: m/z 220.2203. Calcd for $C_{16}H_{28}$: M, 220.2190.

Diels-Alder Cycloadduct of 13d with Dimethyl Fumarate (Mixtures of two stereoisomers): Colorless liquid; IR (neat) 1730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.7—2.9 (17H, m, CH_2 and CH), 3.65 (6H, s, COOMe), and 5.28 (1H, m, 2-H); ^{13}C NMR ($CDCl_3$) δ=16.94, 17.59 (each d, CH), 21.47, 23.53, 28.18 (each t, CH_2), 29.77 (d, CH), 30.18 (t, CH_2), 41.59, 41.89 (each d, CH), 51.83 (q, COOMe), 115.95 (d, 2-C), 137.43 (s, 1-C), 175.48, and 175.60 (each s, COOMe); MS m/z (rel intensity, %) 292 (M^+, 13), 232 (base peak), 173 (49), 172 (20), 105 (25), and 91 (66). Found: C, 69.88; H, 7.99%. Calcd for $C_{17}H_{24}O_4$: C, 69.84; H, 8.27%.

14a: Colorless liquid; IR (neat) 1620, 1485, 1460, and 1440 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.7—2.3 (15H, m, CH_2 and CH), 4.80, 5.10 (each 1H, d, J=1.5 Hz, =CH_2), and 7.0—7.6 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.47 (d, CH_2), 26.71, 26.88 (each t, CH_2), 28.77 (d, CH), 29.71 (t, CH_2), 108.13 (t,

=CH_2), 126.24, 127.42, 128.31 (each d), 142.25, and 149.89 (s); MS *m/z* (rel intensity, %) 226 (M^+, base peak), 169 (27), 156 (38), 155 (67), 143 (48), 142 (24), 141 (40), 130 (30), 129 (45), 128 (32), 115 (29), and 91 (36). HRMS Found: *m/z* 226.1717. Calcd for $C_{17}H_{22}$: M, 226.1720.

14b: Colorless liquid; IR (neat) 1630, 1460, and 1440 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.8—2.1 (24H, m, Me, CH_2, and CH), 4.39, and 4.44 (each 1H, br s, =CH_2); ^{13}C NMR ($CDCl_3$) δ=14.06 (q, Me), 22.53 (t, CH_2), 25.18 (d, CH), 26.71, 26.94 (each t, CH_2), 29.36 (d, CH), 29.71, 30.48, 36.71 (each t, CH_2), 104.54 (t, =CH_2), and 151.89 (s); MS *m/z* (rel intensity, %) 206 (M^+, 8), 149 (25), 107 (22), 95 (24), 93 (39), 91 (35), 81 (47), 79 (59), 77 (36), and 42 (base peak). HRMS Found: *m/z* 206.2039. Calcd for $C_{15}H_{26}$: M, 206.2033.

Diels-Alder Cycloadduct of 14c with Dimethyl Fumarate (Mixture of two stereoisomers): Colorless liquid; IR (neat) 1730, 1460, and 1430 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.6—2.9 (21H, m, CH_2 and CH), 3.60 (6H, s, COOMe), and 5.25 (1H, m, 2-H); ^{13}C NMR ($CDCl_3$) δ=22.77, 23.41, 26.64, 26.88, 28.18, 29.71, 30.06, 30.24, 41.59 (d), 41.89 (d), 51.89 (q, COOMe), 116.30 (d, 2-C), 137.13 (s, 1-C) and 175.66 (s, COOMe); MS *m/z* (rel intensity, %) 320 (M^+, 3), 91 (23), and 59 (base peak). Found: C, 70.75; H, 9.01%. Calcd for $C_{19}H_{28}O_4$: C, 71.22; H, 8.81%.

15a (Mixture of two stereoisomers): Colorless liquid; IR (neat) 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.7—1.6 (10H, m, CH_2 and CH), 2.47 (1H, br s, CH), 4.78, 5.12 (each 1H br s, =CH_2), and 7.1—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.16, 18.36 (each d, CH), 22.75 (t, CH_2), 25.49 (d, CH), 28.95, 29.54, 31.69 (each t, CH_2), 36.23 (d, CH), 109.13 (t, =CH_2), 126.27, 127.54, 128.32 (each d), 142.48 (s), and 148.63 (s); MS *m/z* (rel intensity, %) 210 (M^+, 97), 195 (22), 182 (30), 181 (21), 168 (25), 167 (58), 165 (31), 156 (67), 155 (48), 154 (22), 153 (27), 152 (24), 143 (30), 142 (50), 141 (69), 130 (30), 129 (51), 128 (66), 115 (83), 103 (42), 91 (94), and 77 (base peak). HRMS Found: *m/z* 210.1411. Calcd for $C_{16}H_{18}$: M, 210.1408.

15b (Mixture of two stereoisomers): Colorless liquid; IR (neat) 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.5—2.1 (19H, m, Me, CH_2, and CH), 2.23 (1H, br s, CH), 4.40, and 4.45 (each 1H, br s, =CH_2); ^{13}C NMR ($CDCl_3$) δ=14.11 (q, Me), 18.69 (d, CH), 22.66 (t, CH_2), 24.95, 28.90, 29.64 (each t, CH_2), 30.37, 30.66 (t, CH_2), 35.28, 36.72 (d, CH), 36.91, 37.21 (t, CH_2), 105.61 (t, =CH_2), and 150.59 (s); MS *m/z* (rel intensity, %) 190 (M^+, 24), 148 (36), 133 (41), 120 (25), 105 (24), 94 (37), 92 (21), 91 (57), 82 (24), 81 (88), 80 (base peak), 79 (26), and 78 (62). HRMS Found: *m/z* 190.1677. Calcd for $C_{14}H_{22}$: M, 190.1720.

Diels-Alder Cycloadduct of 15c with *N*-Methylmaleimide (Mixture of stereoisomers): Colorless liquid; IR (neat) 1775, 1710, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.5—2.7 (16H, m, CH_2 and CH), 2.90 (3H, s, NMe), 3.00 (1H, m, CH), and 5.42 (1H, m, 6-H); ^{13}C NMR ($CDCl_3$) δ=19.30, 22.47, 22.83 (each d, CH), 24.24 (t, CH_2), 24.94 (d, CH), 25.83, 28.53, 29.47 (each t, CH_2), 35.88, 39.53, 39.77 (each d, CH), 118.42 (d, 6-C), 140.54 (s), 180.25, and 180.54 (each s, CON); MS *m/z* (rel intensity, %) 271 (M^+, 23), 216 (24), 192 (35), 129 (24), 128 (22), 117 (32), 116 (37), 93 (21), 92 (25), 91 (base peak), 80 (52), 79 (50), 78 (40), and 77 (57). Found: C, 75.01; H, 7.99; N, 5.11%. Calcd for $C_{17}H_{21}NO_2$: C, 75.25 H, 7.80; N, 5.16.

16a: Pale yellow liquid; IR (neat) 1610, 1605, and 1490 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.82 (1H, t, *J*=3.0 Hz, CH), 3.16 (2H, d, *J*=3.0 Hz, CH_2), 5.00, 5.27 (each 1H, s, =CH_2), and 7.1—7.5 (11H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=33.24, 44.12 (each d, CH), 109.66 (t, =CH_2), 119.66, 123.19, 126.13, 127.66, 127.89, 128.13, 128.48, 128.90 (each d), 132.13, 137.60, 140.96, 145.42, and 147.42 (each s); MS *m/z* (rel intensity, %) 268 (M^+, 44) and 165 (base peak). HRMS Found: *m/z* 268.1248. Calcd for $C_{21}H_{16}$: M, 268.1251.

16b: Pale yellow liquid; IR (neat) 1625, 1605, and 1460 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.8—2.2 (9H, m, Me, CH_2, and CH), 2.90, 3.04, 3.32 (each 1H, m, CH), 4.65, 4.72 (each 1H, br s, =CH_2), and 6.8—7.7 (6H, m, Ar); MS *m/z* (rel intensity, %) 248 (M^+, 8), 166 (58), 165 (base peak), 153 (39), and 152 (29). HRMS Found: *m/z* 248.1563. Calcd for $C_{19}H_{20}$: M, 258.1564.

Diels-Alder Cycloadduct of 16c with Dimethyl Fumarate (Mixture of stereoisomers): Pale yellow liquid; IR (neat) 1738 and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.41 (1H, t, *J*=3.0 Hz, CH), 2.25 (4H, m, CH_2), 2.82 (2H, m, CH), 3.01 (2H, d, *J*=3.0 Hz, CH), 5.34 (1H, m, 2-H), and 7.1—7.5 (6H, (m, Ar); ^{13}C NMR ($CDCl_3$) δ=27.88, 29.41 (each t, CH_2), 30.36, 30.94, 41.24, 41.53, 45.65 (each d, CH), 51.95 (q, NMe), 118.95, 119.48, 122.95, 127.54, 128.48 (each d), 132.01, 135.01, 137.36, 145.48 (each s), 175.19, and 175.36 (each s, COOMe); MS *m/z* (rel intensity, %) 362 (M^+, 5), 165 (62), 152 (23), 91 (29), and 59 (base peak). HRMS Found: *m/z* 362.1627. Calcd for $C_{23}H_{22}O_4$: M, 362.1517.

General Procedure for the One-Pot Synthesis of Cyclopropyl Vinyl Ketones 17—23 from 1. Cyclopropyl silylmethyl ketones **2—7** and **9** were prepared under argon according to the procedure described above. The resulting mixture was slowly added at −78 °C by syringe to a solution of lithium diisopropylamide (1.1 equivalent) which had been previously prepared from butyllithium (in hexane) and diisopropylamine in THF at −78 °C. After 45 min, a carbonyl compound (1 equivalent) in dry THF (1 ml/1 mmol) was added, the mixture was stirred at −78 °C for 1 h, and then at room temperature for 1 h. All these procedures were carried out under nitrogen. The resulting mixture was poured into aqueous ammonium chloride, extracted with diethyl ether (20 ml×2), the combined extracts were dried over magnesium sulfate, and finally evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (20—50:1) to give cyclopropyl vinyl ketones **17—23**. The results are listed in Table 3.

17a: Colorless prisms (ethyl acetate-hexane); mp 80—81 °C; IR (KBr) 1655 and 1595 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—1.4, 1.6—1.8 (each 1H, m, CH_2 of *c*-Pr), 2.2—2.6 (2H, m, CH of *c*-Pr), 6.63, 7.38 (each 1H, d, *J*=16.5 Hz, -CH=CHPh), and 6.8—7.4 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=19.26 (t, CH_2 of *c*-Pr), 29.65, 31.70 (each d, CH of *c*-Pr), 126.05, 126.46, 128.28, 128.46, 128.87, 130.34 (each d), 134.50, 140.49 (each s), 142.31 (d, =CHPh), and 197.74 (s, CO); MS *m/z* (rel intensity, %) 248 (M^+, 24), 131 (59), 117 (21), 116 (48), 115 (94), 104 (30), 103 (83), 102 (33), 91 (54), 89 (22), 78 (26), and 77 (base peak). HRMS Found: *m/z* 248.1175. Calcd for $C_{18}H_{16}O$: M, 248.1200.

17b: Colorless prisms (ethyl acetate-hexane); mp 128.5—129.5 °C; IR (KBr) 1650 and 1575 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—1.5, 1.6—1.9 (each 1H, m, CH_2 of *c*-Pr), 2.2—2.7 (2H, m, CH of *c*-Pr), 6.23 (1H, d, *J*=15.0 Hz, -COCH=), and 6.6—7.4 (13H, m, Ph and =CHPh); ^{13}C NMR ($CDCl_3$) δ=19.18 (t, CH_2 of *c*-Pr), 29.47, 31.59 (each d, CH of *c*-Pr), 126.24, 126.60, 126.83, 127.36, 128.65, 128.95, 130.01 (each d), 136.18, 140.83 (each s), 141.66, 142.60 (each d, COCH=CHCH=

CHPh), and 198.01 (s, CO); MS *m/z* (rel intensity, %) 274 (M^+, base peak), 183 (39), 170 (28), 157 (67), 129 (37), 128 (71), 127 (30), 117 (31), 115 (38), 104 (21), and 91 (38). Found: C, 87.56; H, 6.61%. Calcd for $C_{20}H_{17}O$: C, 87.88; H, 6.66%.

17c: Colorless liquid; IR (neat) 1670, 1650, and 1615 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.05 (3H, t, Me of Et), 0.8—1.8 (3H, m, CH_2 and CH of *c*-Pr), 2.23 (2H, m, CH_2 of Et), 2.2—2.7 (1H, m, CH of *c*-Pr), 6.12 (1H, br d, *J*=15.5 Hz, -COCH=), 6.84 (1H, dt, *J*=15.5, 6.6, and 6.6 Hz, EtCH=), and 6.9—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=12.24 (q, Me of Et), 18.88 (t, CH_2 of *c*-Pr), 25.53 (t), 29.12, 30.59 (each d), 126.18, 126.54, 128.60, 129.83 (each d), 140.83 (s), 148.83 (d, =CHEt), and 198.25 (s, CO); MS *m/z* (rel intensity, %) 200 (M^+, 4), 117 (28), 116 (35), 115 (base peak), 91 (70), 89 (24), 83 (57), 78 (22), and 77 (25). HRMS Found: *m/z* 200.1198. Calcd for $C_{14}H_{16}O$: M, 200.1196.

17d: Colorless liquid; IR (neat) 1675, 1650, and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.02, 1.09 (each 3H, d, *J*=7.3 Hz, Me of *i*-Pr), 1.2—1.8 (3H, m, CH_2 and CH of *c*-Pr), 2.2—2.7 (2H, m, CH of *c*-Pr and CH of *i*-Pr), 6.04 (1H, br d, *J*=15.9 Hz, -COCH=), 6.78 (1H, dd, *J*=15.9 and 6.9 Hz, *i*-PrCH=), and 6.2—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=19.14 (t, CH_2 of *c*-Pr), 21.31 (q, Me of *i*-Pr), 29.24, 30.76, 31.18 (each d), 126.05, 126.35, 127.75, 128.40 (each d), 140.61 (s), 153.41 (d, *i*-PrCH=), and 198.32 (s, CO); MS *m/z* (rel intensity, %) 214 (M^+, 23), 171 (21), 117 (29), 116 (30), 115 (70), 97 (55), 91 (56), and 41 (base peak). HRMS Found: *m/z* 214.1355. Calcd for $C_{15}H_{18}O$: M, 214.1355.

17e: Colorless liquid; IR (neat) 1670 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—1.8 (3H, CH_2 and CH of *c*-Pr), 1.85, 2.13 (each 3H, s, Me), 2.3—2.6 (1H, m, CH of *c*-Pr), 6.12 (1H, br s, -COCH=), and 6.9—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=18.88 (t, CH_2 of *c*-Pr), 20.82, 27.65 (each q, Me), 29.06, 34.24 (each d, CH of *c*-Pr), 124.72, 126.24, 126.48, 128.60 (each d), 141.13 (s), 155.13 (s, $=C(Me)_2$), and 198.60 (s, CO); MS *m/z* (rel intensity, %) 200 (M^+, 44), 115 (37), 91 (26), 83 (base peak), and 55 (53). HRMS Found: *m/z* 200.2794. Calcd for $C_{14}H_{16}O$: M, 200.2794.

18a: Colorless liquid; IR (neat) 1675, 1645, and 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.86 (3H, m, Me of *n*-Hex), 1.1—2.1 (14H, CH_2 and CH), 6.72 (1H, d, *J*=16.5 Hz, -COCH=), 7.2—7.5 (5H, m, Ph), and 7.47 (1H, d, *J*=16.5 Hz, PhCH=); ^{13}C NMR ($CDCl_3$) δ=14.12 (q, Me of *n*-Hex), 18.71 (t, CH_2 of *c*-Pr), 22.71, 26.88, 27.94, 29.06, 29.24, 31.88, 33.53 (CH_2 and CH), 126.77, 128.88, 129.13, 130.42 (each d), 135.01 (s), 141.89 (d, =CHPh), and 199.78 (s, CO); MS *m/z* (rel intensity, %) 256 (M^+, 8), 147 (27), 131 (base peak), 103 (79), 91 (26), and 77 (50). HRMS Found: *m/z* 256.1826. Calcd for $C_{18}H_{24}O$: M, 256.1826.

18b: Pale yellow liquid; IR (neat) 1670, 1635, and 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.87 (3H, t, Me of *n*-Hex), 1.1—1.5 (11H, m, CH_2 and CH), 1.90 (1H, m, CH of *c*-Pr), 6.46 (1H, dd, *J*=3.5 and 2.0 Hz, 4-H of furyl), 6.63 (1H, d, *J*=3.5 Hz, 3-H of furyl), 6.75 (1H, d, *J*=15.8 Hz, -COCH=), 7.34 (1H, d, *J*=15.8 Hz, furylCH=), and 7.46 (1H, d, *J*=2.0 Hz, 5-H of furyl); ^{13}C NMR ($CDCl_3$) δ=14.12 (q, Me of *n*-Hex), 18.59 (t, CH_2 of *c*-Pr), 22.71 (t), 26.83, 28.47 (each d, CH of *c*-Pr), 29.06, 29.30, 31.88, 33.54 (each t, CH_2), 112.65, 115.59 (each d, 3- and 4-C of furyl), 123.89 (d, -COCH=), 128.07 (d, furylCH=), 144.89 (d, 5-C of furyl), 151.66 (s, 2-C of furyl), and 199.31 (s, CO); MS *m/z* (rel intensity, %) 246 (M^+, 11), 121 (65), 65 (82), and 41 (base peak). HRMS Found: *m/z* 246.1628. Calcd for $C_{16}H_{22}O_2$: M, 246.1619.

18c (Mixture of two stereoisomers): Colorless liquid; IR (neat) 1680, 1660, and 1625 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.85, 1.06 (each 3H, t, Me of *n*-Hex and Et), 1.2—2.4 (16H, m, CH_2 and CH), 6.59 (1H, br d, *J*=16.0 Hz, -COCH=), and 6.81 (1H, dt, *J*=16.0, 5.7, and 5.7 Hz, *n*-HexCH=); ^{13}C NMR ($CDCl_3$) δ=12.41, 13.82, 14.11 (each q, Me of *n*-Hex and Et), 18.24 (CH_2 of *c*-Pr), 22.71, 24.47, 25.59, 26.35, 26.53, 26.93, 29.06, 29.30, 29.83, 31.88, 33.53 (CH_2 and CH), 129.95, 131.19 (each d, -COCH=), 147.54, 148.01 (each d, EtCH=), 198.72, and 200.07 (each s, CO); MS *m/z* (rel intensity, %) 208 (M^+, 9), 98 (28), 95 (21), 83 (base peak), and 55 (69). HRMS Found: *m/z* 208.1829. Calcd for $C_{14}H_{24}O$: M, 208.1821.

18d (Mixture of two stereoisomers): Colorless liquid; IR (neat) 1675, 1650, and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (3H, m, Me of *n*-Hex), 1.09 (6H, d, Me of *i*-Pr), 1.2—2.7 (15H, CH_2 and CH), 6.12 (1H, br d, *J*=16.2 Hz, -COCH=), and 6.79 (1H, dd, *J*=16.2, 6.3, and 6.3 Hz, *i*-PrCH=); ^{13}C NMR ($CDCl_3$) δ=14.06 (q, Me of *n*-Hex), 18.24 (t, CH_2 of *c*-Pr), 21.43, 22.65, 24.47, 25.65, 26.35, 26.47, 26.94, 29.00, 29.24, 29.77, 31.18, 31.88, 33.43 (CH_2 and CH), 128.01, 129.24 (each d, -COCH=), 152.30, 152.72 (each d, *i*-PrCH=), 198.96, and 200.25 (each s, CO); MS *m/z* (rel intensity, %) 222 (M^+, 6), 97 (49), 69 (25), and 40 (base peak). HRMS Found: *m/z* 222.1978. Calcd for $C_{15}H_{26}O$: M, 222.1982.

19a (Mixture of two stereoisomers): Colorless liquid; IR (neat) 1675, 1650, and 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.9—1.6 (9H, m, Me, CH_2, and CH), 1.20 (3H, s, Me), 2.24 (1H, m, CH of *c*-Pr), 6.97 (1H, br d, *J*=16.0 Hz, -COCH=), 7.4—7.7 (5H, m, Ph), and 7.68 (1H, d, *J*=16.0 Hz, PhCH=); ^{13}C NMR ($CDCl_3$) δ=14.24, 15.53 (each q, Me of *n*-Pr and Me), 20.12, 20.47, 22.18, 22.94, 24.41, 31.18, 31.77, 33.77, 34.12, 34.65, 43.47 (CH_2 and CH), 128.18, 128.36, 129.07, 130.30 (each d), 135.01 (s), 141.42 (d, PhCH=), and 198.01 (s, CO); MS *m/z* (rel intensity, %) 228 (M^+, 49), 146 (28), 131 (base peak), 129 (20), 128 (21), 115 (26), 103 (74), 102 (27), 91 (34), and 77 (68). HRMS Found: *m/z* 228.1504. Calcd for $C_{16}H_{20}O$: M, 228.1513.

19b (Mixture of two stereoisomers): Colorless liquid; IR (neat) 1680, 1655, and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.6—2.3 (18H, m, Me, CH_2, and CH), 6.00 (1H, br d, *J*=15.5 Hz, -COCH=), and 6.66 (1H, dt, *J*=15.5, 6.0, and 6.0 Hz, EtCH=); ^{13}C NMR ($CDCl_3$) δ=12.41, 14.24, 15.47 (each q, Me of *n*-Pr, Me of Et, and Me), 20.06, 20.41, 21,65, 22.34, 24.35, 25.47, 30.30, 30.88, 33.06, 33.59, 33.77, 43.53 (CH_2 and CH), 131.30 (d, -COCH=), 147.31, 147.42 (each d, EtCH=), and 198.13 (s, CO); MS *m/z* (rel intensity %) 180 (M^+, 16), 83 (76), 81 (21), 67 (22), and 55 (base peak). HRMS Found: *m/z* 180.1619. Calcd for $C_{12}H_{20}O$: M, 180.1513.

19c (Mixture of two stereoisomers): Colorless liquid; IR (neat) 1675, 1650, and 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.7—2.6 (14H, Me, CH_2, and CH), 1.06 (6H, d, Me of *i*-Pr), 6.11 (1H, br d, *J*=16.5 Hz, *i*-PrCH=), and 6.73 (1H, dd, *J*=16.5 and 6.3 Hz, -COCH=); ^{13}C NMR ($CDCl_3$) δ=14.30, 15.47 (each q, Me of *n*-Pr and Me), 19.30, 20.06, 20.41, 21.53, 21.77, 22.47, 24.41, 30.36, 30.93, 31.12, 33.18, 33.77, 43.59 (Me, CH_2, and CH), 129.42 (d, -COCH=), 152.19, 152.30 (each d, *i*-PrCH=), and 198.48 (s, CO); MS *m/z* (rel intensity, %) 194 (M^+, 7), 97 (34), 69 (24), and 40 (base peak). HRMS Found: *m/z* 194.1670. Calcd for $C_{13}H_{22}O$: M, 194.1670.

20a: Colorless liquid; IR (neat) 1670, 1645, and 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.7—2.0 (11H, m, CH_2 and CH), 6.64

(1H, d, J=16.2 Hz, -COCH=), 7.1—7.4 (5H, m, Ph), and 7.35 (1H, d, J=16.2 Hz, PhCH=); ^{13}C NMR ($CDCl_3$) δ=21.14 23.45 (each t, CH_2), 26.36, 34.30 (each d, CH), 126.70, 128.16, 128.81, 130.10 (each d), 134.86 (s), 141.08 (d, PhCH=), and 199.32 (s, CO); MS m/z (rel intensity, %) 226 (M^+, 82), 225 (23), 183 (base peak), 145 (37), 134 (21), 131 (28), 129 (35), 105 (22), 103 (56), 102 (34), 91 (49), and 75 (35). HRMS Found: m/z 226.1349. Calcd for $C_{16}H_{18}O$: M, 226.1357.

20b: Colorless liquid; IR (neat) 1680, 1655, and 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.09 (3H, t, Et), 1.2—2.0 (11H, m, CH_2 and CH), 2.25 (2H, q, Et), 6.15 (1H, d, J=16.2 Hz, -COCH=), and 6.87 (1H, dt, J=16.2, 6.3, and 6.3 Hz, EtCH=); ^{13}C NMR ($CDCl_3$) δ=12.29 (q, Me of Et), 21.12, 23.18, 25.47 (each t, CH_2), 25.71, 33.12 (each d, CH), 129.95 (d, -COCH=), 147.36 (d, EtCH=), and 199.95 (s, CO); MS m/z (rel intensity, %) 178 (M^+, 12), 107 (28), 91 (21), 83 (37), 79 (32), 77 (30), 67 (31), and 40 (base peak). HRMS Found: m/z 178.1357. Calcd for $C_{12}H_{18}O$: M, 178.1357.

20c: Colorless liquid; IR (neat) 1675, 1655, and 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.06 (6H, d, Me of i-Pr), 1.1—2.0 (10H, CH_2 and CH), 2.44 (1H, m, CH of i-Pr), 6.05 (1H, br d, J=16.0 Hz, -COCH=), and 6.70 (1H, dd, J=16.0 and 6.3 Hz, i-PrCH=); ^{13}C NMR ($CDCl_3$) δ=21.14, 21.43, 23.25, 25.95, 31.12, 33.35 (Me, CH_2, and CH), 127.87 (d, -COCH=), 152.00 (d, i-PrCH=), and 200.09 (s, CO); MS m/z (rel intensity, %) 192 (M^+, 14), 149 (39), 107 (43), 97 (25), 91 (26), 81 (24), 79 (35), 77 (33), 69 (23), and 41 (base peak). HRMS Found: m/z 192.1511. Calcd for $C_{13}H_{20}O$: M, 192.1513.

20d: Colorless liquid; IR (neat) 1660 and 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.1—1.8 (11H, m, CH_2 and CH), 1,83, 2.10 (each 3H, br s, Me), and 6.16 (1H, br s, -COCH=); ^{13}C NMR ($CDCl_3$) δ=20.24 (q, Me), 20.65, 21.18 (each t, CH_2), 23.30 (d, CH), 25.53 (q, Me), 36.59 (d, CH), 125.07 (d, -COCH=), 153.13 (s, $(Me)_2C$=), and 200.72 (s, CO); MS m/z (rel intensity, %) 178 (M^+, 46), 163 (22), 135 (base peak), 122 (22), 121 (38), 109 (70), 96 (26), 83 (97), 79 (23), 67 (21), and 55 (75). HRMS Found: m/z 178.1331. Calcd for $C_{12}H_{18}O$: M, 178.1357.

21: Colorless needles (ethyl acetate–hexane); mp 85—86 °C; IR (KBr) 1655, 1640, and 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.8—2.1 (13H, m, CH_2 and CH), 6.66 (1H, d, J=16.5 Hz, -COCH=), 7.1—7.5 (5H, m, Ph), and 7.41 (1H, d, J=16.5 Hz, PhCH=) ^{13}C NMR ($CDCl_3$) δ=28.71, 29.83 (each t, CH_2), 31.65 (d, CH), 32.41 (t, CH_2), 38.36 (d, CH), 126.78, 128.36, 129.01, 130.30, each d), 135.01 (s), 141.48 (d, PhCH=), and 198.90 (s, CO); MS m/z (rel intensity, %) 240 (M^+, base peak), 183 (91), 131 (46), 103 (40), 91 (25), and 77 (40). Found: C, 84.77; H, 8.37%. Calcd for $C_{17}H_{20}O$: C, 84.96; H, 8.39%.

22a: Colorless needles (ethyl acetate–hexane); mp 94—95 °C; IR (KBr) 1650, 1625, and 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.8—2.2 (15H, m, CH_2 and CH), 6.70 (1H, d, J=16.5 Hz, -COCH=), 7.1—7.6 (5H, m, Ph), and 7.42 (1H, d, J=16.5 Hz, PhCH=); ^{13}C NMR ($CDCl_3$) δ=26.35, 29.24 (CH_2), 31.41, 34.41 (each d, CH), 127.07, 128.42, 129.07, 130.36 (each d), 135.13 (s), 141.54 (d, PhCH=), and 199.60 (s, CO); MS m/z (rel intensity, %) 254 (M^+, 15), 183 (53), 146 (45), 131 (97), 128 (20), 103 (base peak), 102 (23), 91 (33), and 77 (93). Found: C, 85.12; H, 8.85%. Calcd for $C_{22}H_{16}O$: C, 84.99; H, 8.72%.

22b: Colorless prisms (ethyl acetate–hexane); mp 74—75 °C; IR (KBr) 1650 and 1595 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ= 1.1—2.2 Z(15H, m, CH_2 and CH), 6.36 (1H, dd, J=3.3 and 2.0 Hz, 4-H of furyl), 6.52 (1H, d, J=3.3 Hz, 3-H of furyl), 6.59 (1H, d, J=16.2 Hz, -COCH=), 7.20 (1H, d, J=16.2 Hz, furylCH=), and 7.37 (1H, d, J=2.0 Hz, 5-H of furyl); ^{13}C NMR ($CDCl_3$) δ=26.35, 26.47, 29.24 (each t, CH_2), 31.36, 34.93 (each d, CH), 112.60, 115.36, 124.18, 127.77 (each d), 144.77 (d, 5-C of furyl), 151.66 (s, 2-C of furyl), and 199.24 (s, CO); MS m/z (rel intensity, %) 244 (M^+, 12), 173 (20), 121 (80), 94 (22), 91 (23), 81 (28), 79 (24), 77 (22), and 65 (base peak). Found: C, 78.65; H, 8.25%. Calcd for $C_{16}H_{20}O_2$: C, 78.87; H, 8.33%.

22c: Colorless needles (ethyl acetate–hexane); mp 28—29 °C; IR (KBr) 1670, 1650, and 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.06 (3H, t, Et), 1.2—2.1 (15H, m, CH_2 and CH), 2.19 (2H, m, Et), 6.12 (br d, J=15.9 Hz, -COCH=), and 6.83 (1H, dt, J=15.9, 6.0, and 6.0 Hz, EtCH=); ^{13}C NMR ($CDCl_3$) δ=12.35 (q, Me of Et), 25.51, 26.30, 26.47, 29.23 (each t, CH_2), 30.77, 33.30 (each d, CH), 130.07 (d, -COCH=), 147.60 (d, EtCH=), and 199.84 (s, CO); MS m/z (rel intensity, %) 206 (M^+, 1), 83 (49), 81 (21), 79 (30), 77 (23), 67 (27), and 56 (base peak). HRMS Found: m/z 206.1682. Calcd for $C_{14}H_{22}O$: M, 206.1670.

22d: Colorless plates (ethyl acetate–hexane); mp 52.5—54 °C; IR (KBr) 1650 and 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.07 (6H, d, Me of i-Pr), 0.8—2.1 (15H, m, CH_2 and CH), 2.45 (1H, m, CH of i-Pr), 6.07 (1H, br d, J=15.6 Hz, -COCH=), and 6.73 (1H, dd, J=15.6 and 6.0 Hz, i-PrCH=); ^{13}C NMR ($CDCl_3$) δ=21.41 (q, Me), 26.30, 26.47, 29.18 (each t, CH_2), 30.94, 31.12, 33.47 (each d, CH), 128.13 (d, -COCH=), 152.42 (d, i-PrCH=), and 200.25 (s, CO); MS m/z (rel intensity, %) 220 (M^+, 4), 177 (20), 149 (23), 107 (28), 97 (base peak), 95 (26), 93 (28), 91 (38), 81 (55), 79 (58), 77 (31), and 69 (39). HRMS Found: m/z 220.1835. Calcd for $C_{15}H_{24}O$: M, 220.1826.

23: Colorless needles (ethyl acetate–hexane); mp 154.5—155.5 °C; IR (KBr) 1660 and 1605 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.30 (1H, t, J=2.8 Hz, CH of c-Pr), 3.59 (1H, d, J=2.8 Hz, CH of c-Pr), 6.64 (1H, d, J=15.5 Hz, -COCH=), 7.1—7.5 (11H, m, Ar), and 7.38 (1H, d, J=15.5 Hz, PhCH=); ^{13}C NMR ($CDCl_3$) δ=35.30, 46.53 (each d, CH), 120.95, 124.01, 126.36, 127.71, 128.48, 129.07, 130.65, 131.67, 134.66, 143.01 (d), 143.54 (s), and 195.89 (s, CO); MS m/z (rel intensity, %) 296 (M^+, 13), 165 (base peak), 164 (28), 163 (32), 131 (65), 103 (32), and 77 (27). Found: C, 89.24; H, 5.60%. Calcd for $C_{22}H_{16}O$: C, 89.16; H, 5.44%.

Reaction of 1 with *N*-Phenylmaleimide Leading to 24. A mixture of **1** (312 mg, 2 mmol) and *N*-phenylmaleimide (346 mg, 2 mmol) in dry benzene (5 ml) was stirred under nitrogen at room temperature for 10 h. The solvent was evaporated in vacuo and the residue was chromatographed over silica gel with hexane–ethyl acetate (1:1) to tive **24** (262 mg, 51%): Pale yellow prisms (ethyl acetate–hexane); mp 160.5—161.5 °C; IR (KBr) 3400, 1720, and 1670 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.41 (3H, s, COMe), 4.72, 5.06 (each 1H, d, J=10.5 Hz, 3a- and 6a-H), and 7.1—7.6 (6H, m, Ph and NH); ^{13}C NMR ($CDCl_3$) δ=25.92 (q, COMe), 50.34 (d, 3a-C), 64.42 (d, 6a-C), 126.21, 128.94, 129.13 (each d), 131.12 (s), 143.70 (s, 3-C), 170.85, 173.18 (each s, CON), and 192.09 (s, CO); MS m/z (rel intensity %) 257 (M^+, 75), 228 (46), 119 (base peak), 95 (78), 93 (29), 91 (20), and 55 (54). HRMS Found: m/z 257.0800. Calcd for $C_{13}H_{11}N_3O_3$: M, 257.0800.

Reaction of 1 with Dimethyl Fumarate Leading to 25. The reaction of **1** (156 mg, 1 mmol) with dimethyl fumarate (144 mg, 1 mmol) under the same conditions gave

25 (139 mg, 62%): Pale yellow liquid; IR (neat) 3350, 1740, and 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.26 (3H, s, COMe), 3.60, 3.64 (each 3H, s, COOMe), 4.21, 4.60 (each 1H, d, J=5.4 Hz, 4- and 5-H), and 7.07 (1H, br, NH); ^{13}C NMR ($CDCl_3$) δ=25.58 (q, COMe), 50.92 (d, 4-C), 53.02, 53.16 (each q, COOMe), 66.42 (d, 5-C), 146.87 (s, 3-C), 169.87, 170.21 (each s, COOMe), and 192.87 (s, CO); MS m/z (rel intensity, %) 228 (M^+, 9), 195 (24), 169 (83), 137 (48), 125 (33), 95 (33), 93 (base peak), 83 (29), and 59 (32). HRMS Found: m/z 228.0745. Calcd for $C_9H_{12}N_2O_5$: M, 228.0756.

Reaction of 1 with Dimethyl Acetylenedicarboxylate Leading to 26. A mixture of **1** (312 mg, 2 mmol) and dimethyl acetylenedicarboxylate (284 mg, 2 mmol) in dry benzene (4 ml) was heated under reflux for 3.5 h under nitrogen. The solvent was evaporated in vacuo. ^1H NMR of the residue showed a quantitative formation of the cycloadduct **B** (E=COOMe). The residue was chromatographed over silica gel with hexane–ethyl acetate (3:1) to give **26** (431 mg, 95%): pale yellow plates (ethyl ether); mp 55—56 °C; IR (KBr) 3200, 1730, and 1680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.58 (3H, s, COMe), 3.87, 3.95 (each 3H, s, COOMe), and 7.29 (1H, br, NH); ^{13}C NMR ($CDCl_3$) δ=26.77 (q, COMe), 52.90, 53.13 (each q, COOMe), 117.54, 135.03, 146.89 (each s), 158.99, 164.45 (each s, COOMe), and 191.98 (s, CO); MS m/z (rel intensity, %) 226 (M^+, 4), 195 (13), 93 (33), 79 (14), 67 (17), 66 (13), 65 (19), and 43 (base peak). HRMS Found: m/z 226.0591. Calcd for $C_9H_{10}N_2O_5$: M, 226.0589.

Reaction of 1 with Dibenzoylacetylene Leading to 27. The reaction of **1** (134 mg, 0.86 mmol) with dibenzoylacetylene (218 mg, 0.86 mmol) under reflux in dry THF (2 ml) for 3 h and the followed chromatographic separation gave **27** (198 mg, 73%): Colorless prisms; mp 154—155 °C; IR (KBr) 3220, 1660, and 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.36 (3H, s, COMe), 7.1—8.0 (10H, m, Ph), and 11.70 (1H, br, NH); ^{13}C NMR ($CDCl_3$) δ=27.94 (q, COMe), 116.89, 125.42 (each s), 128.54, 128.89, 129.36, 130.30 (each d), 133.66, 134.07, 136.13, 137.42 (each s), 186.13, 190.01, and 191.84 (each s, CO); MS m/z (rel intensity, %) 318 (M^+, 44), 241 (45), 223 (22), 105 (66), and 77 (base peak). Found: C, 71.43; H, 4.39; N, 9.01%. Calcd for $C_{19}H_{14}N_2O_3$: C, 71.64; H, 4.43; N, 8.80%.

General Procedure for the One-Pot Synthesis of 3-Pyrazolyl Vinyl Ketones 28 and 20. 3-Silylacetylpyrazoles **B** (E=COOMe or COPh) were prepared in dry THF (1 mmol in 2 ml) according to the method shown above. This mixture was added to LDA (2 mmol in THF) at −78 °C. After 30 min at −78 °C, benzaldehyde (1 mmol) in THF (1 ml) was added dropwise, the mixture was stirred at 0 °C for 2 h, poured into aqueous ammonium chloride, and extracted with diethyl ether (20 ml). The ether was dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with chloroform-ethyl acetate (12:1) to give **28** or **29**.

28: Yield 53%; Colorless plates (ethyl ether); mp 145—146 °C; IR (KBr) 3200, 1720, 1650, and 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.86, 3.92 (each 3H, s, COOMe), 7.2—7.5 (6H, m, Ph and NH), 7.51, and 7.81 (each 1H, d, J=15.6 Hz, CH=CH); ^{13}C NMR ($CDCl_3$) δ=53.12, 53.32 (each q, COOMe), 118.41 (s), 121.39, 129.05, 131.20 (each d), 134.62, 135.16 (each s), 146.04 (d), 148.09 (s), 159.37, 164.50 (each s, COOMe), and 182.56 (s, CO); MS m/z (rel intensity, %) 314 (M^+, 28), 283 (27), 282 (80), 224 (20), 131 (26), 103 (base peak), 102 (38), 93 (24), and 77 (65); Found: C, 61.34; H, 4.63; N, 8.96%. Calcd for $C_{16}H_{14}N_2O_5$: C, 61.14; H, 4.49; N, 8.91%.

29: Yield 41%; Pale yellow prisms (ethyl ether); mp 180—181 °C; IR (KBr) 3170, 1640, and 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.9—7.6 (12H, m, Ar), 7.44, 7.77 (each 1H, d, J=15.8 Hz, CH=CH), and 7.7—8.0 (4H, m, Ar); MS m/z (rel intensity, %) 406 (M^+, 12), 105 (56), 103 (30), and 77 (base peak). Found: C, 76.71; H, 4.40; N, 6.95%. Calcd for $C_{26}H_{18}N_2O_3$: C, 76.83; H, 4.46; N, 6.89%.

Reaction of 1 with Benzaldehyde in the presence of TBAF Leading to 30. To a mixture of **1** (232 mg, 1.5 mmol) and benzaldehyde (160 mg 1.5 mmol) in dry THF (2 ml) was added TBAF (2.25 ml, 2.25 mmol) at room temperature. The mixture was stirred under nitrogen at room temperature for 30 min and poured into water (30 ml). Organic layer was extracted with dichloromethane (20 ml×2), the combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane–ethyl acetate (1:1) to give **30** (170 mg, 60%): Colorless liquid; IR (neat) 3400, 2050, and 1625 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.22 (3H, s, COMe), 3.40 (1H, br s, OH), 5.94 (1H, s, CH), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.54 (q, COMe), 67.11 (d, CH), 125.41, 127.93, 128.52 (each d), 139.32 (s), and 190.80 (s, CO); MS m/z (rel intensity, %) 190 (M^+, 13), 162 (27), 161 (50), 148 (62), 143 (65), 119 (48), 107 (31), 105 (43), 102 (22), 91 (65), 80 (39), 78 (77), and 43 (base peak). Found: C, 61.30; H, 4.57; N, 8.65%. Calcd for $C_{16}H_{14}O_5$: C, 61.14; H, 4.49; N, 8.91%.

(Received April 14, 1986)

Effect of the structure of insoluble pyridinium-type polymer on its ability to capture bacteria in water was investigated. Strong ability of the polymer was further confirmed by an equilibrium capture experiment. The ability was quantitatively evaluated by the removal coefficient reported previously based on initial rate of decrease of viable cell counts caused by the presence of the polymer. The coefficient uniformly increased with the content of pyridinium group, and considerably increased when the content of divinylbenzene became smaller. The coefficient also increased with the content of 4-vinylpyridine in the polymer matrix. Based on these observations, presence of pyridinium group was concluded to be essentially important in the affinity of the polymer for bacterial cells. Hydrophilicity and high degree of swelling in water of the polymer matrix appeared to enhance the ability to capture bacteria.

A recent publication from this laboratory described a novel and remarkable ability of cross-linked poly(4-vinylpyridinium halide) to remove bacteria from water.[1] This insoluble pyridinium-type polymer captured many bacteria alive by contact with them. The polymer was found to capture virus in water strongly with keeping the viral activity.[2] This nature of the polymer appears to be of wide application in microbiology and biotechnology.

We are now attempting to immobilize microbial cells on this polymer in order to apply the new technology to the production of useful materials by biochemical reactions. Although various methods are known for the immobilization of enzymes and microbial cells, continuous efforts are being made to pursue new materials and techniques for the immobilization.[3] Immobilization of these biocatalysts to solid materials by chemical reaction is apt to result in damage to the enzyme activity. Entrapment of them in the gel of polymeric substances is apt to result in a decrease of the contact of substrates with enzymes and microbial cells. Adsorption onto ion-exchange resin is not strong and is reversible. However, immobilization on the insoluble pyridinium-type polymer can be realized without chemical reaction and entrapment. Surface-immobilized, live bacteria entities on this polymer are expected to show useful properties.

Prior to this research work, it is necessary to obtain information about basic properties of the insoluble pyridinium-type polymer. As was reported previously,[1] the capturing ability of the polymer is not limited to viable cells. The difference in the ability for viable and killed bacteria was insignificant, and physicochemical interaction appeared to be much more important than physiological action in the phenomenon. In this work, we have investigated effect of the structure of the polymer on its ability to capture bacteria.

Experimental

Materials. 4-Vinylpyridine provided by Koei Chemical Co. Ltd., Osaka, and commercial products of divinylbenzene,[5] styrene, ethanol and toluene were purified by distillation before polymerization. Commercial products of 2,2′-azobisisobutyronitrile, benzyl bromide, and other chemicals were used without further purification.

Insoluble Pyridinium-Type Polymer. Cross-linked poly(*N*-benzyl-4-vinylpyridinium bromide) was used as the insoluble pyridinium-type polymer. Procedure for the preparation of the polymer is given below. Polymerizations were carried out in a 2-l round-bottomed three-necked flask under a nitrogen atmosphere. Copolymerization of 4-vinylpyridine with divinylbenzene, and that of 4-vinylpyridine with styrene and divinylbenzene were carried out using 2,2′-azobisisobutyronitrile as initiator at 75 °C for 5 to 6 h according to the procedure of Katchalsky et al.[4] with minor modifications.[5]

The copolymer was converted to the insoluble pyridinium-type polymer as follows. The copolymer was added to methanol, and the mixture was kept at room temperature for about 20 h. Methanol was separated by filtration. The swollen copolymer was added to toluene in a three-necked flask connected with a mechanical stirrer and a reflux condenser. The mixture was stirred gently, and the prescribed amount of benzyl bromide was added: The solution was allowed to react at 60 to 80 °C for 3 h under stirring. After the reaction, the polymer was separated by filtration, and was washed by benzene, methanol and water followed by drying in vacuo to constant weight. In order to determine content of pyridinium group, the polymer in the bromide form was transferred into the polymer in the nitrate form by treatment with excess 1 M† potassium nitrate in a column method. Titration of the eluted solution with standard 0.1 M silver nitrate using eosin as indicator showed the content of pyridinium group in the polymer.

For comparison with the insoluble pyridinium-type polymer, four commercial resins were used in this work. Amberlite IRA-900 and IRA-400 supplied by Rohm & Haas Co., Philadelphia, Pa., were used as strong base anion-exchange resins, which had a styrene-divinylbenzene matrix with quaternary ammonium group. The resins were preconditioned according to a usual method,[5] and were

† 1M=1 mol dm^{-3}.

used in the chloride form. Amberlite IRA-45 supplied by Rohm & Haas Co. was used as a weak base anion-exchange resin, which had a styrene-divinylbenzene matrix with primary, secondary, and tertiary amino groups. The resin was preconditioned to the free base form in a similar manner. Amberlite XAD-4 supplied by Rohm & Haas Co. was used as porous styrene-divinylbenzene resin with no ion-exchange functional group. This nonionic resin was preconditioned by washing with methanol followed by washing with water.

Bacteria. *Escherichia coli* was incubated and treated as was reported previously.[1]

Procedure. All procedures of the removal experiments were carried out under aseptic conditions as was reported previously.[1]

Serial dilutions of cell suspensions were done of the medium prepared by dissolving KH_2PO_4 (4.5 g), Na_2HPO_4 (6.0 g), L-cystin·HCl (0.5 g), and tween 80 (0.5 g) in 1000 ml of water. The diluted cell suspensions were transferred to plates of Eosin-Methylene Blue-agar (BBL). The measurements of viable cell counts were done after incubation at 37 °C for 24 h.

Results and Discussion

Ability of the insoluble pyridinium-type polymer to capture bacteria was evaluated by the removal coefficient defined as:[1]

$$\text{Removal coefficient} = \frac{V}{Wt}\log\,[N(0)/N(t)]$$

Here, $N(0)$ is the initial viable cell count, $N(t)$ is the viable cell count at contact time t, V is the volume of viable cell suspension, W is the dry weight of the polymer, and t is the contact time. The coefficient was shown to be independent on initial cell count $N(0)$ and concentration of insoluble polymer W/V.[1] Although the difference in the content of pyridinium group should be taken into consideration, cross-linked poly(*N*-benzyl-4-vinylpyridinium bromide and chloride) were most effective among the polymers examined. Although commercial resins also showed the ability to some extent, that of the insoluble pyridinium-type polymer was outstanding.

The removal coefficient is a dynamic index of the ability of polymers to capture bacteria, and is based on initial rate of decrease of viable cell counts. On the other hand, equilibrium capture experiment would also be important for the evaluation of the basic and definitive ability of the polymer to capture bacteria.[6] Thus we have performed the equilibrium capture experiment at 37 °C. After the mixture of polymer and *E. coli* in sterilized physiological saline reached equilibrium, viable cell counts were determined. The experimental isotherm for *E. coli* on the insoluble pyridinium-type polymer is shown in Fig. 1 (graph A). The isotherm on cross-linked poly(4-vinylpyridine), i.e., the polymer without pyridinium group is shown in Fig. 1 (graph D). The isotherms on various other polymers are also shown in Fig. 1 (graphs B, C, and E). As can be seen in Fig. 1, the insoluble pyridinium-type polymer was confirmed to have a much stronger ability to capture bacteria when compared with that of other types of polymers examined.

The ability of the insoluble pyridinium-type polymer to capture bacteria appeared to depend on the content of pyridinium group.[1] We have examined the effect using cross-linked poly(*N*-benzyl-4-vinylpyridinium bromide) containing various amount of the pyridinium group. In Fig. 2 is shown the result. The coefficient uniformly increased with the content of pyridinium group. This result indicates the importance of the presence of pyridinium group in the ability of the polymer to capture bacteria on its surface. Electrostatic interaction between the positive charge on the surface of the polymer and the negative charge of the microbial cell surface appears to be

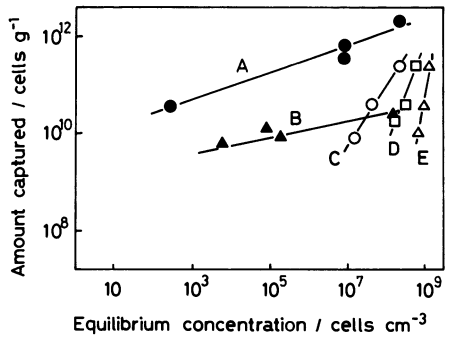

Fig. 1. Experimental isotherms of the capture of *E. coli* by insoluble polymers. important, although the strong effect of the benzyl group is not clear.

Cross-linked poly(*N*-benzyl-4-vinylpyridinium bromide) was prepared under various conditions in order to examine the effect of higher structure of the polymer upon its ability to capture bacteria. Results are given in Table 1.

Runs 1 to 4 were performed to examine the effect of the degree of cross-linking of the polymer. Here, content of 4-vinylpyridine and that of the pyridinium group were kept nearly constant, and part of divinylbenzene was replaced by styrene. As is obvious in Table 1, the removal coefficient increased with the decrease of the content of divinylbenzene. The result shows that decrease of the degree of cross-linking caused the increase of the ability of the polymer to capture bacteria. In this case, the polymer swells very well in water. The effective surface area in water is much larger, which enhances the ability of the polymer to capture bacterial cells.

Runs 5 to 7 were carried out to examine effect of composition of the matrix of the polymer. In these cases, content of pyridinium group was kept nearly constant at 2.1 mmol g^{-1}, and that of divinylbenzene was also fixed around 28%. As can be seen in Table 1, the removal coefficient increased with the content of 4-vinylpyridine. This result shows that hydrophilicity of the polymer matrix enhanced the affinity of the polymer for bacterial cells.

It would be noteworthy to remind that cross-linked poly(*N*-alkly-4-vinylpyridinium bromides) were much less effective than cross-linked poly(*N*-benzyl-4-vinylpyridinium bromide) for the capture of bacterial cells.[1] Hydrophobicity of the long alkyl group of the polymer did not strengthen the ability to capture bacteria. The *N*-dodecyl polymer and the *N*-hexadecyl polymer showed smaller values of the removal coefficient than that of the polymer with no pyridinium group, i.e., cross-linked poly(4-vinylpyridine). Hydrophobicity of the polymer seems to diminish its ability to capture bacteria.

The ability of the insoluble pyridinium-type polymer to capture bacteria is much higher than that of tetraalkylammonium-type anion-exchange resins. With respect to the strength of positive charge, tetraalkylammonium-type resin would not be inferior to the insolube pyridinium-type polymer. The difference between the two types of polymers in the ability to capture bacteria seems to be ascribable mainly to the difference in hydrophilicity. The pyridinium group is highly hydrophilic. For example, linear polymer of poly(*N*-benzyl-4-vinylpyridinium bromide) is hygroscopic.

The Stereochemistry of the Reduction of Carbon-Carbon Double Bond with the Cultured Cells of *Nicotiana tabacum*

Takayuki SUGA,* Toshifumi HIRATA, and Hiroki HAMADA†
Department of Chemistry, Faculty of Science, Hiroshima University,
Higashisenda-machi, Naka-ku, Hiroshima 730
(Received April 19, 1986)

The stereochemistry in the reduction of the C–C double bond adjacent to the carbonyl group with the cultured cells of *Nicotiana tabacum* was investigated by feeding (4*R*)-[6-^{2}H]-(−)-carvone to the cultured cells. It was found that the hydrogen attack to the C–C double bond takes place stereospecifically from the *si*-face at C-1 and the *re*-face at C-6, being trans-addition.

A general mechanism for the biological reduction of a C–C double bond is briefly reviewed.[1] On the other hand, the reduction of a C–C double bond in living cells has been described for the biotransformation of steroids with plant cultured cells,[2–4] but little is reported on the stereochemical aspect of the reduction in the plant tissue cultures. We recently found that the cultured cells of *Nicotiana tabacum* reduce the C–C double bond adjacent to the carbonyl group of carvone (**1**) and then the carbonyl group, whereas the cells do not attack the C–C double bond in the 1-methylethenyl group.[5] It was found that the hydrogen attack to the conjugated C–C double bond takes place stereospecifically from the *si*-face at C-1.[5] However, the stereochemistry of the hydrogen attack at C-6 of **1** has not been elucidated yet. To complete the stereochemical studies on the reduction of the conjugated C–C double bond with the cultured cells of *N. tabacum*, we have now investigated the stereochemistry of the hydrogen addition to the 6-position of carvone by examining the orientation of deuterium in a resultant product in the biotransformation of ^{2}H-labeled carvone with the cultured cells.

Results and Discussion

Incubation of (4*R*)-[6-^{2}H]-(−)-carvone (**2**) (deuterated by 97.6 atom %) with the cultured cells of *N. tabacum* was carried out in a manner similar to that described in our previous paper[5] to yield neodihydrocarveol (**3**) as a main product. The mass spectrum of **3** showed a molecular ion peak at *m/z* 155 and $[M-H_2O]^+$ ion peak at *m/z* 137. The relative intensities of the peaks indicated that 97% of the molecules of **3** were labeled with deuterium. The proton noise decoupled ^{13}C NMR spectrum of the product **3** closely resembled to the spectrum of the nonlabeled neodihydrocarveol (**4**), except that the C-6 signal of **3** at δ_c 27.8 was a somewhat weak triplet ($J_{^{13}C-^2H}$=20 Hz), whereas the corresponding signal of the nonlabeled compound **4** was a singlet. This indicates that one of the hydrogen atoms at C-6 is deuterated.

The orientation of deuterium in the product **3** was determined by comparison of its ^{1}H NMR spectrum with that of the nonlabeled compound **4**, as given in Fig. 1. Complete assignments of the ^{1}H NMR signals of **3** and **4** were made on a 500 MHz NMR spectrum and are shown in Table 1. The assignments were confirmed by a two-dimensional H/H shift correlation NMR spectrum of the nonlabeled compound **4**; all correlations expected were found in the spectrum. The disappearance of the 6α-H signal in the ^{1}H NMR spectrum of **3** indicates the 6α-atom to be deuterium. Thus, it was demonstrated that the *R* hydrogen atom at the 6-position of **3** was added when the carbocyclic double bond of carvone (**2**) was reduced in the cultured cells of *N. tabacum*.

As has been described in our previous paper,[5] the cultured cells of *N. tabacum* have the ability to reduce (4*R*)- and (4*S*)-carvones; (4*R*)-carvone was transformed to (1*R*,2*S*,4*R*)-neodihydrocarveol and (4*S*)-carvone to (1*R*,4*S*)-isodihydrocarvone and (1*R*,2*S*,4*S*)-neoisodihydrocarveol. The formation of these compounds indicates that carvone is stereospecifically reduced to the compound with the chirality of *R* at the C-1 and that of *S* at the C-2 in its biotransformation with the cultured cells. Putting the previous and present results together, thus, the mode of the hydrogen

a) Measured at 500 MHz in $CDCl_3$.

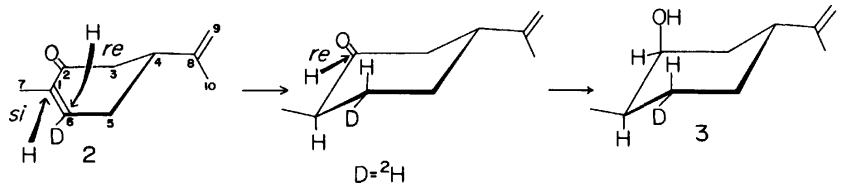

Fig. 2. Stereospecific hydrogen attack in the reduction of the C–C double bond and the carbonyl group of (−)-carvone (**2**) by the suspension cells of *N. tabacum*.

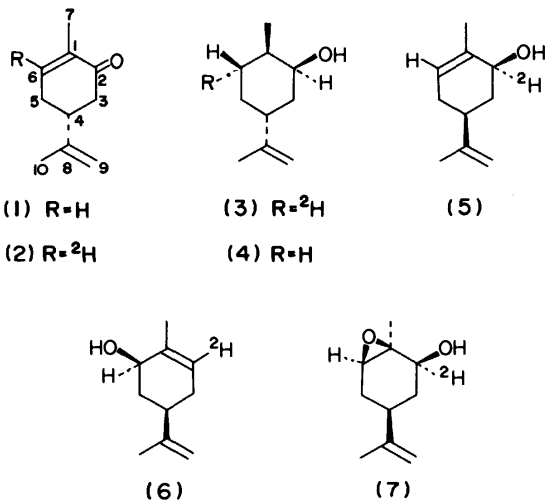
addition in the reduction of carvone with the cultured cells of *N. tabacum* was perfectly established as shown in Fig. 2; at first, the hydrogen attack to the carbocyclic double bond takes place stereospecifically from the *si*-face at C-1 and the *re*-face at C-6. Accordingly, the mode of the hydrogen addition to the C–C double bond conjugated with the carbonyl group is trans. After occurrence of this C–C double bond reduction, the hydrogen attack to the carbonyl group at the 2-position takes place stereospecifically from the *re*-face.



Experimental

Analytical and preparative TLC were carried out on 0.25-mm and 0.5-mm thick silica-gel plates (Merck silica gel 60, GF_{254}). GLC analyses were performed on an instrument equipped with FID and a glass column (3 mm×2 m) packed with 15% DEGS, 15% PEG-20M, and 2% OV-17 on Chromosorb W (AW-DMCS; 80—100 mesh) at 100, 120, and 90—200 °C (3 °C min^{-1}), respectively. ^{1}H NMR spectra were obtained at 90 and 500 MHz in $CDCl_3$ with TMS as an internal standard. GC–MS spectra were recorded on a mass spectrometer equipped with a gas chromatograph with 15% DEGS column (3 mm×2 m) by EI mode at 70 eV.

Substrate. (4*R*)-[6-^{2}H]-(−)-Carvone (**2**) was prepared by reduction of (+)-carvone with NaB^2H_4, isomerization of the resultant (+)-*cis*-carveol (**5**) to (−)-enantiomer **6**,[6] and then oxidation of the enantiomer **6**, as described below.

(i) (4*S*)-[2-^{2}H]-(+)-*cis*-Carveol (5). To a soln of (+)-carvone (3.8 g) ($[\alpha]_D^{25}$ +59.0° (neat); n_D^{25} 1.4990) in MeOH (20 cm^3), NaB^2H_4 (3.0 g) was added by portions at 0 °C. After standing for 30 min at room temp, the reaction mixture was extracted with ether and then subjected to preparative TLC with hexane-EtOAc (7:3, v/v) to give (4*S*)-[2-^{2}H]-(+)-*cis*-carveol (**5**) (3.0 g): *m/z* (rel intensity) 153 (M^+, 2), 135 (M^+-H_2O, 38), 120 (23), and 85 (100).

(ii) 1,3-Transposition of 5. According to the reported procedure,[6] the ^{2}H-labeled (+)-*cis*-carveol (**5**) (3.0 g) was oxidized with *t*-butyl hydroperoxide and oxobis(2,4-pentanedionato-*O*,*O*′)vanadium(IV) to give a ^{2}H-labeled epoxy-alcohol **7** (1.3 g). This epoxy-alcohol **7** was converted to the mesylate derivative (1.8 g) with mesyl chloride-triethylamine. Treatment of the mesylate (1.8 g) with a

sodium-naphthalene reagent[6] dissolved in THF afforded (4*R*)-[6-^{2}H]-(−)-*cis*-carveol (**6**) (0.48 g): ^{1}H NMR (90 MHz) δ=1.64 (s, 6H, 1- and 8-Me), 4.09 (m, 1H, 2-H), and 4.60 (m, 2H, 9-H_2); *m/z* (rel intensity) 153 (M^+, 1), 135 (M^+-H_2O, 35), 120 (23), and 85 (100).

(iii) Oxidation of 6. To a soln of the ^{2}H-labeled (−)-*cis*-carveol (**6**) (0.41 g) in CH_2Cl_2 (50 cm^3), pyridinium-chromium trioxide[7] (2.2 g) was added drop by drop at 5 °C. The mixture was stirred for 1 h at room temp. After filtration, the product was extracted with ether, dried (Na_2SO_4), and freed of the solvent. The residue was subjected to preparative TLC with hexane-EtOAc (95:5, v/v) to give (4*R*)-[6-^{2}H]-(−)-carvone (**2**) (0.28 g): $[\alpha]_D^{25}$ −59.3° (*c* 1.5, EtOH); n_D^{25} 1.4997 (lit,[5] $[\alpha]_D^{25}$ −60.4°, n_D^{25} 1.5000); >99% pure on GLC; *m/z* (rel intensity) 151 (M^+, 6), 136 (M^+-CH_3, 3), and 83 (100); ^{1}H NMR (90 MHz) δ=1.76 (bs, 6H, 1- and 8-Me) and 4.78 (bs, 2H, 9-H_2). The signal at δ 6.78 for C(6)-H, which is observed in the ^{1}H NMR spectrum of nonlabeled carvone, disappeared in the NMR spectrum of **2**. The relative intensities of the molecular ion peaks in the mass spectra of **2** and nonlabeled carvone indicated that 97.6% of the molecules of carvone were labeled with deuterium.

Incubation of (4*R*)-[6-^{2}H]-(−)-Carvone (2) with the Tobacco Suspension Cells. The suspension cells of *N. tabacum* "Bright Yellow" were prepared as described in Ref. 5; the cells were cultured in a 300-ml conical flask containing 100 ml of Murashige and Skoog's medium.[8] To the flask containing the suspension cells (about 50—70 g fresh wt/flask), the ^{2}H-labeled carvone (**2**) (10 mg/flask; total 500 mg) was administered, and then the cultures were incubated at 25 °C for 10 d on a rotary shaker (70 rpm) in the dark.

Isolation and Identification of the Product. The cultured mixture was worked up in a manner similar to that described in Ref. 5; a product was extracted with ether and subjected to preparative TLC on silica gel with hexane-EtOAc (1:4, v/v). The product was identified by direct comparison of TLC, GLC, and spectral data with those of an authentic sample. The physical constants and spectral data of the product were as shown below.

(1*R*,2*S*,4*R*)-[6-^{2}H]-(+)-neodihydrocarveol (3): $[\alpha]_D^{25}$ +30.0° (*c* 0.15, EtOH); IR ν_{max} (film) 3435 (OH) and 1645 (C=C) cm^{-1}; ^{1}H NMR (90 MHz) δ=0.98 (3H, d, *J*=6 Hz, 1-Me), 1.71 (3H, s, 8-Me), 3.88 (1H, bs, >CH-OH), 4.68 (2H, bs, >C=CH_2), (500 MHz) see Table 1; ^{13}C NMR (22.6 MHz, in $CDCl_3$) δ_c=150.2 (s, C-8), 108.7 (t, C-9), 71.0 (d, C-2), 38.8 (t, C-3), 37.8 (d, C-4), 36.1 (d, C-1), 31.4 (t, C-5), 27.8 (bm, C-6), 21.0 (q, C-7), 18.3 (q, C-10); *m/z* (rel intensity) 155 (M^+, 4), 137 (M^+-H_2O, 77), 122 (79), 108 (100), 94 (66), and 79 (62).

Preparation of Authentic Neodihydrocarveol (4). Following the procedure described in the Ref. 9, (+)-neodihydrocarveol (**4**) was prepared from (−)-carvone by the reduction with zinc powder: $[\alpha]_D^{25}$ +29.9° (*c* 0.30, EtOH) (lit,[5] $[\alpha]_D^{25}$ +29.1°), IR ν_{max} (film) 3442 (OH) and 1645 (C=C) cm^{-1}; ^{1}H NMR (90 MHz) δ=0.98 (3H, d, *J*=6 Hz, 1-Me), 1.70 (3H, s, 8-Me), 3.90 (1H, br, >CH-OH), 4.71 (2H, bs, >C=CH_2), (500 MHz) see Table 1; *m/z* (rel intensity) 154 (M^+, 5), 136 ($M-H_2O$, 55), 121 (67), 79 (57), and 41 (100).

The authors thank Takasago Perfumery Co. Ltd. for a gift of the sample of (−)-carvone, Drs. Akio Yasui and Shigetoshi Amiya of Central Research Laboratories of Kuraray Co. Ltd. for the measurement of the 500 MHz ^{1}H NMR, and the JEOL Co. Ltd. for the measurement of the two-dimensional H/H shift correlation NMR. The present work was in part supported by Grant-in-Aids for Developmental Scientific Research No. 57840030 (1982) and 59840013 (1984) from the Ministry of Education, Science and Culture.

Phenolic Solvent-Assisted Hydrogenolysis of *trans*-Stilbene

Tatsuro MIZUKI, Shigeru FUTAMURA,* and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo,
Hongo, Bunkyo-ku, Tokyo 113
(Received April 21, 1986)

Phenolic solvents such as phenol, 3,4-xylenol, 2-naphthol, and 5,6,7,8-tetrahydro-2-naphthol greatly promote toluene formation in the hydrogenolysis of *trans*-stilbene, compared with hydroaromatic hydrocarbon solvents. Toluene is afforded in the thermal decomposition of the phenolic solvent adduct to *trans*-stilbene, not via bibenzyl.

It is well-known that mixed solvents composed of phenols and tetralin greatly promote coal liquefaction.[1-7]

Considerable amounts of phenolic compounds are produced inherently in coal liquefaction[3] and their ambident character is quite interesting as acid catalyst[4] and polar media penetrating into the micropores of coal and dissolving polar and high molecular weight components of coal liquids formed during coal liquefaction.[3,6]

Mechanisms for the action of phenols have already been investigated by some groups, using model compounds such as di-2-naphthyl ether,[4] *p*-hydroxyphenyl phenyl ether,[8] benzyl phenyl ether, and dibenzylamines.[9] In these systems, however, unified interpretations have not been made on the source of donatable hydrogen and hydrogen transfer mechanism (homolytic[4,9] or heterolytic[8] cleavage of the O-H bond).

Quite recently, we have shown that phenolic solvents are greatly effective in the hydrogenolysis of *trans*-stilbene, compared with hydroaromatic hydrocarbon solvents.[10] Since olefinic structures can be formed transiently during coal liquefaction, it is significant to clarify the reactivity of phenols toward aromatic olefins in their hydrogenolysis and solvent addition.

In this paper, we present that phenolic solvents can act as hydrogen-donor solvent under coal liquefaction conditions and that they promote hydrogenolysis of aromatic olefins such as *trans*-stilbene via solvent addition.

Experimental

Materials. The following substrates and solvents were commercially purchased and further purified if needed by the conventional method: *trans*-stilbene, bibenzyl, phenol, 3,4-xylenol, 2-naphthol, 5,6,7,8-tetrahydro-2-naphthol(THN), tetralin, 9,10-dihydroanthracene(DHA), and naphthalene.

Instrumental. The GC analyses were carried out on a Shimadzu GC-9A-TCD apparatus equipped with a stainless steel column of 5% OV 17 on Chromosorb W(DMCS). The ^{1}H NMR spectra of the products were obtained on a Varian EM 360A NMR Spectrometer (60 MHz), using Me_4Si as an internal standard.

Batch Experiments. 10 mmol of *trans*-stilbene or bibenzyl and a 10-fold molar excess of a solvent were put into a 90 ml SUS 316 magnetically stirred autoclave. After being pressurized up to 2.0 MPa, the autoclave was heated up to the prescribed temperature within 30 min and maintained at the temperature for 30 min. After the reaction, the autoclave was cooled by an electric fan to room temperature. The products were recovered with tetrahydrofuran and subjected to GC analysis using chlorobenzene as an internal standard.

Product Analyses. The yields of toluene, bibenzyl, *o*- and *p*-benzylphenols were analyzed by GC. (1,2-Diphenylethyl)-phenols[11] were isolated by silica-gel column chromatography and identified by means of ^{1}H NMR and GC-MS. Their ^{1}H NMR and GC-MS data are as follows: δ=3.17 (d, 2H, J=7.2 Hz), 4.33 (t, 1H, J=7.2 Hz), 5.14 (s, 1H, exchangeable with D_2O), 6.62—7.06 (m, 14H). m/z=274 (2.5 (M^+)), 183 (100), 165 (46), 91 (17).

Results and Discussion

As Table 1 shows, phenolic solvents such as 3,4-xylenol, 2-naphthol, and THN show higher hydrogen-

donatabilities than tetralin in the hydrogenolysis of *trans*-stilbene at 400 °C. It is noteworthy that toluene formation is greatly promoted by these solvents, contrasting with hydroaromatic hydrocarbon solvents.

Table 2 shows a solvent effect on molar ratio of toluene/bibenzyl in the hydrogenolyses of *trans*-stilbene and bibenzyl. If toluene is afforded exclusively via the thermal cracking of bibenzyl, ratio A/B in Table 2 is expected to fall around unity. In fact, this ratio is given as 2 for tetralin as solvent. On the other hand, 30- to 40-fold increase in ratio A/B is observed for the phenolic solvents. These facts suggest that in the phenolic solvents, toluene could be given in the common mechanism other than the thermal cracking of bibenzyl.

A good linearity was observed in the first-order plot for *trans*-stilbene conversion in the temperature range of 380—435 °C. Figure 1 shows the plot of ln k_{obsd} versus $1/T$ depicted on the basis of the above data. As Table 3 shows, almost no difference is observed in the activation energies for 2-naphthol, THN, and tetralin as solvent.

On the other hand, 10 to 100 times larger values of frequency factor are obtained for the phenolic solvents compared with tetralin. Such difference still has to be unravelled, but it may indicate that some ionic interaction between phenols as weak acids and *trans*-stilbene as π-base is effective in formation of the encounter complex.

Thus, hydrogenolysis of *trans*-stilbene in phenol was carried out in order to understand the reaction profile. As Fig. 2 shows, 71% of *trans*-stilbene was converted in this reaction, and bibenzyl, toluene, benzylphenol, and (1,2-diphenylethyl)phenol(DPEP) were afforded in 27, 19, 24, and 19% selectivities, respectively. Neither benzene nor ethylbenzene was obtained in this reaction. According to GC analysis, benzylphenol was a 2.7:1.0 mixture of *o*- and *p*-forms. Phenol adduct to *trans*-stilbene, DPEP is considered to be formed in the coupling of 1,2-diphenylethyl radical and phenoxyl radical or in the addition of 1,2-diphenylethyl radical to phenol followed by loss of a hydrogen atom. Since 1,2-diphenylethyl radical is detected by ESR[12] and is known to be produced in the pyrolysis of bibenzyl,[13] it can be also produced in the monohydrogen transfer from phenol to *trans*-stilbene.

1,2-Diphenyl-1-phenoxyethane(DPPE), one of the solvent adducts was not obtained in this reaction. Thermal instability of benzyl phenyl ether at 340 °C[14] suggests that all of DPPE decompose thermally at 400 °C.

The larger value for ratio toluene/bibenzyl from *trans*-stilbene in phenol (1.38) in Table 2 may reflect less steric hindrance of phenol or phenoxyl radical toward the approach of 1,2-diphenylethyl radical.

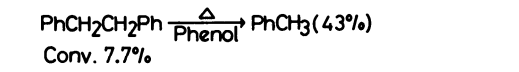

Fig. 3. Hydrogenolysis of bibenzyl in phenol. Parenthesis denotes selectivity.

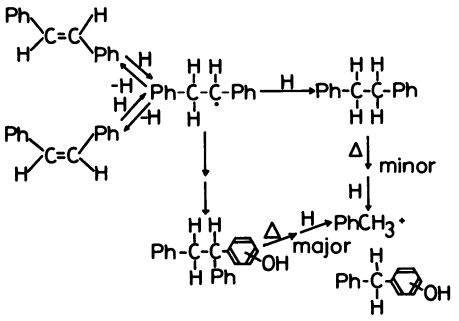

Fig. 4. Possible mechanism for the hydrogenolysis of *trans*-stilbene in phenol.

In these systems, isomerization of stilbene from trans to cis is observed during the course of the reaction. Although no *cis*-stilbene can be detected, using DHA as solvent, about 5% of stilbene is recovered as a cis-form in the phenolic solvents at 380 °C. This value is a little larger than that obtained in the isomerization of *trans*-stilbene to *cis*-stilbene in naphthalene. Such solvent effect on the distribution of the stilbene isomers also supports the homolytic monohydrogen transfer mechanism from phenolic solvents to *trans*-stilbene, and the concerted mechanism can be precluded.

Under these reaction conditions, only 7.7% of bibenzyl was converted to give toluene in 43% selectivity. No benzylphenol was detected by GC in this reaction(see Fig. 3). Therefore, it is unlikely that toluene and benzylphenol were derived from the benzyl radical produced in the thermal cracking of bibenzyl under the reaction conditions. 68% of DPEP decomposed to afford benzylphenol and toluene in 66 and 61% selectivities, respectively, under the same conditions. Since the carbon to carbon single bond in DPEP is more labile than that of bibenzyl, toluene and benzylphenol could be produced in the thermal cracking of DPEP as Fig. 4 shows.

Proton transfer from phenol to *trans*-stilbene is another possibility,[5] but bibenzyl formation from 1,2-diphenylethyl cation cannot be explained by this mechanism.

Here remains the question as to the transferable hydrogen in the phenolic solvents. Comparison of the hydrogen donatabilities of 2-naphthol and naphthalene in Table 1 suggests the involvement of phenolic hydrogens in the hydrogen-transfer process. Thus, hydrogenation of *trans*-stilbene was carried out using a 7:3 mixture of 2-NpOD and 2-NpOH. GC–MS analysis shows that deuterated bibenzyls are formed as

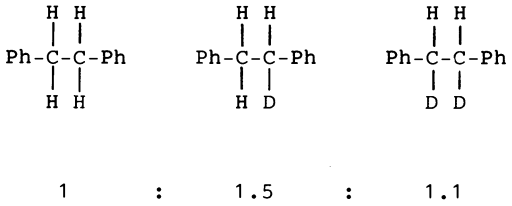

Fig. 5. Deuterium distribution in bibenzyl.

shown in Fig. 5. According to GC analysis, the conversion of 2-naphthol(2-NpOD+2-NpOH) was lower than that of 2-NpOH by 10%. ^{1}H NMR spectroscopy showed that scrambling between phenolic hydrogens and aromatic ring hydrogens was negligible under the reaction conditions. All these facts suggest that phenolic hydrogens are really used in the hydrogenolysis of *trans*-stilbene.

In conclusion, it has been shown that hydrogenolysis of *trans*-stilbene is promoted by the phenolic solvents such as phenol, 3,4-xylenol, 2-naphthol, and 5,6,7,8-tetrahydro-2-naphthol via the phenolic solvent adduct to *trans*-stilbene. Hydrogen-transfer from these phenolic solvents is considered to proceed by radical mechanism.

The authors are very grateful to Dr. Akio Nishijima and Mr. Hiromichi Shimada at the National Research Institute for Industry for the measurement of the GC–MS spectra.

(Received May 1, 1986)

Cathodic methods for the esterification of carboxylic acids and the etherification of phenol and benzenethiol under mild conditions were developed. The esterification was successfully carried out at room temperature by the reaction of alkylating reagents with cathodically-generated quaternary ammonium carboxylates. The etherification was similarly achieved using electrogenerated quaternary ammonium phenolate and halonitrobenzenes. A hindered phenolate anion cathodically-generated from 2,6-di-*t*-butyl-*p*-cresol remarkably promoted aldol condensation of aromatic ketones and aldehydes, and allowed subsequent Michael reaction to provide efficiently symmetrical 1,5-diketones.

Recently, there has been an increasing interest in the utilization of anionic species with onium counter cations in organic synthesis, since their reactivities are sometimes quite different from those of the anions with metal counter cations.[1] However, the preparation of the anionic species with onium counter cations from the corresponding ones with alkali metal cations is often troublesome and not practical since the use of expensive crown ethers and onium fluorides is required. Phase transfer catalysts (PTC's) enhance the nucleophilicity of anionic moieties, however, they are not always applicable owing to their instability under heating[2] and the impossibility of realizing completely dry reaction media.

Cathodic reduction of organic compounds generates anionic species with onium counter cations such as R_4N^+[3,4] and R_3S^+[4] when onium salts ($R_4N^+X^-$ and $R_3S^+X^-$) are used as supporting electrolytes. Therefore, cathodic reduction seems to be a convenient and versatile method for the generation of such active anionic species.

Therefore, as part of a broad program of the application of electrogenerated active species to organic synthesis,[3-6] cathodic esterification of carboxylic acids and etherification of phenols through S_NAr reaction were at first successfully achieved.[7]

Negatively charged species behave not only as nucleophiles but also as bases. Iversen and Lund[8] first demonstrated that an anionic species electrogenerated from azobenzene allows ylide formation from a phosphonium salt and the subsequent Wittig reaction. One (M.M.B.) of the authors named such anionic species and their precursors "electrogenerated bases (EGB's)" and "pro-bases (PB's)", respectively, and studied intensively and systematically synthetic utilization of some types of EGB's derived from azobenzene derivatives,[9,10] active olefins,[11] oxygen,[5,12-15] and carbon tetrachloride.[16] Most recently, we have found novel EGB-catalyzed polymerization of *N*-carboxy anhydrides of amino acids.[6]

Shono and Kashimura[17] have also explored the application of EGB's to organic synthesis and found that a base electrogenerated from 2-pyrrolidone possesses intriguing reactivity to promote various reactions with high selectivity. Although EGB's seem to be promising bases for organic synthesis, only a limited number of types of PB's have been reported so far.[8-17]

In a continuation of study on the utilization of EGB's, we have explored new ones and found that a certain type of phenolate anion also can be a useful base, that is, a hindered phenolate anion derived from 2,6-di-*t*-butyl-*p*-cresol remarkably promoted aldol condensation and allowed subsequent Michael reactions to provide efficiently symmetrical 1,5-diketones.

Results and Discussion

Cathodic Esterification of Carboxylic Acids. The esterification of carboxylic acids is an important and well-established reaction in organic synthesis. Reasonably, simple methods for the esterification under mild conditions should be required in many cases. One of the "simple methods" may be to react metal salts of carboxylic acids with alkylating reagents but this is generally "not mild" because of the high temperatures required.[18] In a previous paper,[19] one (M.M.B.) of the authors reported that quaternary ammonium salts of carboxylic acids reacted with alkyl halides to give the corresponding esters in high yields. In this method, the esterification reaction itself could proceed smoothly at room temperature, in other word, under "mild" conditions, but the preparation of either quaternary ammonium hydroxides or their carboxylates (**2**) was not very "simple". Afterword, some other methods which seemed to be mild were proposed but they were not simple because of the use of special and expensive reagents such as 1,8-diazabicyclo[5.4.0]-undec-7-ene,[20,21] 1-ethyl-2-fluoropyridinium tetrafluoroborate,[22] and alkyl chloroformates.[23]

With this in mind, a convenient method for

Scheme 2.

preparing quaternary ammonium salts of carboxylic acids (**2**) by cathodic reaction and the successive one-pot esterification in a cathode chamber was developed as shown in Scheme 1.

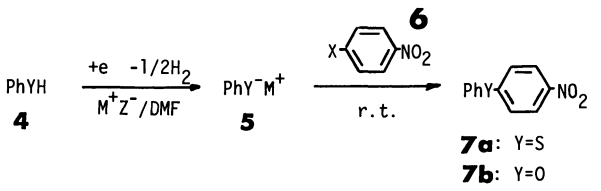
Two procedures for the esterification were employed as follows: In the presence of alkylating reagents, electrolytic reduction of carboxylic acids was carried out in DMF containing Et_4NOTs (Method A). In other method (Method B), the alkylating reagents were added to the catholyte after the electrolysis.

At first, we examined the esterification of acetic acid with butyl bromide by controlled-potential electrolysis. As shown in Scheme 2, the esterification proceeded at room temperature in both procedures to give butyl acetate. Since the amounts of electricity passed were smaller than the theoretical amount for the formation of the acetate anion because of decrease of the current during electrolysis, the yields were low although the current efficiencies were satisfactory.

Constant current electrolysis was found to improve the yield remarkably regardless of the procedures as shown in Table 1.

The yield of butyl acetate formed in Method A was greatly affected by kind of butyl halides used as alkylating reagents. The less electrophilic chloride gave a lower yield than the bromide. Although the iodide should be more electrophilic than the bromide, the former gave a lower yield. This fact is rationalized as due to a less negative reduction potential of the iodide than the bromide: It was confirmed that considerable amounts of the iodide were simultaneously reduced to the corresponding hydrocarbon. Butyl tosylate was also used in the esterification, but it did not give a higher yield than the bromide.

In order to prevent the simultaneous reduction of alkylating reagents, they were added to the catholyte after completion of the electrolysis (Method B). In the esterification of acetic acid with butyl halides by this method, the most electrophilic iodide and the least electrophilic chloride gave the highest and lowest



Scheme 3.

yields, respectively. Method B also resulted in high or reasonable yields in the esterification of other simple acids such as propionic and benzoic acids.

The esterification was successfully extended to somewhat complicated acids. It is noticeable that adipic acid gave the diester, though only 1.0 F mol^{-1} of charge was passed. When stoichiometric amounts of charge and methyl iodide for the formation of the diester were used, the yield of the diester reached to 80%. An α-hydroxy acid (mandelic acid) was also esterified in a high yield. Acids with electroreducible groups such as chloro, 1-propenyl, ethynyl, and 3-pyridyl groups could be esterified without the simultaneous reduction of their electroreducible groups.

Although Method A was inferior to Method B in yield, the former is much simpler than the latter and therefore the former may be more useful for esterification in some cases.

Shono and Kashimura have reported another excellent cathodic esterification using a base electrogenerated from 2-pyrrolidone.[17c] However, our method is simpler and does not require the use of any electrogenerated bases.

Cathodic Etherification. Preparation of Diarylethers Using Electrogenerated Phenolate Anions. Nucleophilic aromatic substitution with phenolate anions to give diaryl ethers is also one of important reactions in organic synthesis. Recently, diarylether derivatives have found to be effective as pesticides, particulary as herbicides and certain types of such ethers are now commercially produced.[24] However, substituents of the aromatic rings often eliminate and thus provide undesired by-products because of the high temperatures required in their synthesis. Because of this, most recently, many efforts have been made to solve such problems using PTC's.[25] However, there are limitations to their utilization because the usual type of PTC's are sometimes consumed due to their reaction with phenolate anions under heating; therefore special thermally-stable PTC's must be employed in these cases.[2]

These problems prompted us to attempt nucleophilic aromatic substitution using electrogenerated phenolate anion. At first, the reaction of benzenethiolate anion, an analogue of the phenolate, with halonitrobenzenes was examined. Benzenethiolate anion (**5a**) was cathodically generated from benzenethiol; subsequent reaction of the resulting **5a** with various *p*-halonitrobenzenes (**6**) was carried out in DMF at room temperature, as shown in Scheme 3.

Table 2. Preparation of Diaryl Ethers **7** from Halonitrobenzenes and Electrogenerated Benzenethiolate and Phenolate Anions

Run	4 Y	6 X	Supporting electrolyte[a]	Reaction time/h	Yield of 7[b] /%

12	O	*o*-Cl	A	5.0	31[c]

a) A=Et_4NOTs, B=$NaClO_4$. b) Isolated yield. c) *o*-Nitrophenyl phenyl ether (**7c**).

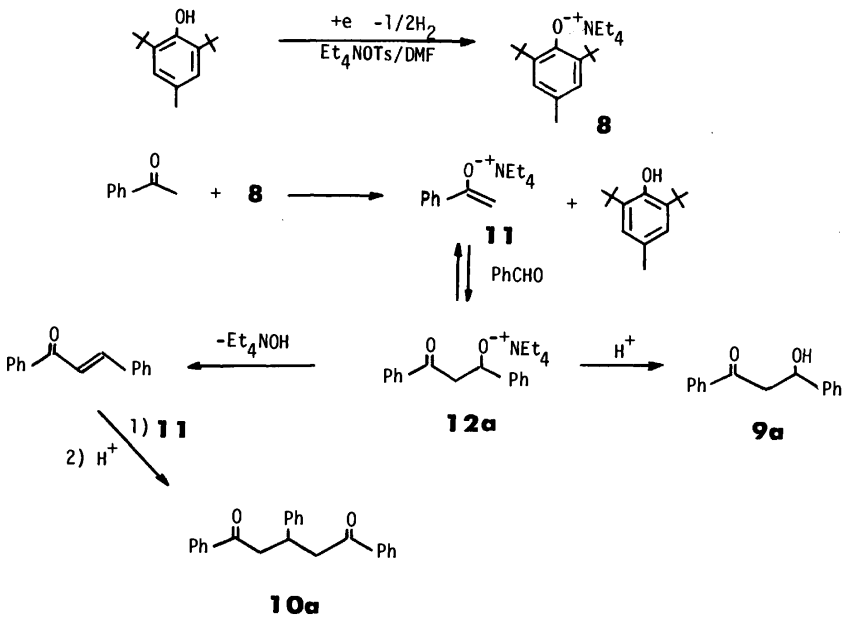
The results are summarized in Table 2.

The reaction proceeded almost quantitatively to give *p*-nitrophenyl phenyl sulfide (**7a**). This cathodic thioetherification was not affected by the kind of halogen atoms of **6** and the supporting electrolytes (M^+Z^-) probably because the benzenethiolate anion is inherently so reactive.

Next, the reaction was similarly carried out using phenol instead of benzenethiol to give *p*-nitrophenyl phenyl ether (**7b**) in good to excellent yields. In this case, the yield of **7b** depended on the kind of halogen atoms of **6**. *p*-Fluoronitrobenzene gave the best result since fluorine atom is known to be an excellent leaving group in such S_NAr reaction (Run 6). *p*-Iodonitrobenzene usually gives a poor yield in such a reaction; however, a satisfactory yield could be achieved by this cathodic method (Run 11).

Although *o*-chloronitrobenzene is sterically hindered to S_NAr reaction, the etherification proceeded to provide **7c**, though its yield was rather low (Run 12).

Furthermore, it is noticeable that the reaction was greatly affected by the cation of the supporting electrolyte as follows: The etherification did not proceed when sodium perchlorate was employed instead of Et_4NOTs as a supporting electrolyte (Run 10). This fact suggests that the nucleophilicity of quaternary ammonium salt of phenolate anion cathodically generated is much higher than that of the corresponding sodium salt.[26] In order to comfirm the effect of a counter cation, the reaction of *p*-bromonitrobenzene with sodium phenolate prepared by the treatment of phenol with sodium hydride was



Scheme 4.

Table 3. Hindered Phenolate Anion-Promoted Aldol Condensation of Acetophenone with Benzaldehyde

a) Isolated yield. b) The sodium salt of **8** was prepared using sodium hydride. c) Large amounts of inseparable by-products were formed. d) A catalytic amount of **8** (0.05 equivalent) was used.

also examined under the same conditions as in the electrolysis. Expectedly, the reaction scarcely proceeded and provided only trace amounts of the desired product **7b**.

Thus, the cathodic method has an advantage as follows: The reactivity of anions can be controlled by the selection of supporting electrolytes, particularly their counter cations. It was demmonstrated here that quaternary ammonium phenolate cathodically prepared has a potential utility for the facile synthesis of *p*-nitrophenyl aryl ethers under mild conditions.

Aldol Condensation Promoted by Electrogenerated Hindered Phenolate Anion. Just like LDA, hindered phenolate anions seem to possess much lower nucleophilicity compared to ordinary phenolates. In fact, the reaction of *p*-bromonitrobenzene with the anion **8** cathodically derived from 2,6-di-*t*-butyl-*p*-cresol was found not to proceed at all. Therefore, this hindered phenolate anion seems to be one of promising candidates for EGB's.

Brown[27] and Corey[28] have successfully employed lithium and potassium salts of **8** for the generation of enolate anions from ketones and α-halo ketones; this allowed successive carboxylation and homologation, respectively.

These facts prompted us to investigate aldol condensations using hindered phenolate anion **8** since the reaction sought here is a typical base-promoted one.[29] Aldol condensation of acetophenone and benzaldehyde was at first attempted under various conditions as follows: 2,6-di-*t*-butyl-*p*-cresol was reduced cathodically in DMF containing Et_4NOTs and then the catholyte was added to a mixed solution of acetophenone and benzaldehyde.

The results are summarized in Table 3.

Aldol product **9a** was found to be formed only at temperatures below 0 °C (Runs 1 and 2). When the reaction time was longer even at 0 °C, 1,5-diketone **10a** was obtained solely in a high yield (Run 3). At ambient temperature, **10a** was obtained in good yields regardless of the reaction time (Runs 4 and 5). On the other hand, the sodium salt of the phenolate anion **8** gave large amounts of various by-products together with 1,5-diketone **10** (up to 42% yield), regardless of both the reaction temperature and reaction time (Run 6). The reaction giving **10a** seems to proceed stepwise as shown in Scheme 4.

Although the aldol condensation is an efficient method for forming new carbon–carbon bonds, the product selectivity is not always satisfactory under equilibrium conditions.[30] It is known that the intermediate keto alkoxide **12** is stabilized by six-

a) Isolated yield. b) Reaction temp = 50 °C. c) Large amounts of various by-products were formed. d) Propiophenone was used. e) The product **9b** (: threo/erythro ≈ 1, ^{1}H NMR) was formed.

membered cyclic metal chelate formation (Fig. 1) in the presence of a divalent metal cation thus providing a single aldol product.[31] On the contrary, the intermediate **12** lacking such stabilization often leads to various side reactions such as retrograde aldol, poly-condensations, and enone formation followed by Michael addition; therefore inseparable mixtures of aldol products are obtained. Although a quaternary ammonium salt of the intermediate **12a** belongs to the latter case, the aldol condensation followed by dehydration and Michael addition proceeded highly selectively to provide 1,5-diketone in excellent yields in contrast to the case of the corresponding sodium salt (Run 6).

The same aldol condensation was examined by using quaternary ammonium phenolate (**5b**) instead of **8**, however the reaction became so complicated that no products could be separated probably because simultaneous nucleophilic attack of the phenolate anion to the starting compounds and/or products took place. It was also comfirmed that the reaction did not proceed smoothly with catalytic amount of **8** (Run 7).

Since the quaternary ammonium salt of hindered phenolate anion **8** was found to be an effective base for the formation of symmetrical 1,5-diketone **10**, this reaction was similarly carried out using various ketones and aldehydes (Scheme 5).

As shown in Table 4, 1,5-diketones **10** were prepared in moderate to good yields from aromatic ketones and aromatic aldehydes, whereas no products were obtained from aliphatic analogues (Runs 7 and 8). Moreover, the aldol product, keto alcohol **9b**, was obatined solely instead of 1,5-diketone from propiophenone and benzaldehyde although the yield was rather low (Run 12). This may be due to the difficulty of dehydrating the intermediate keto alkoxide **12b** (Scheme 6). It was also found that the yield of **10** was greatly affected by the substituents on the benzene rings of both ketones and aldehydes. Since the initial step of the aldol condensation reaction is abstraction of a proton from α-carbon of the ketones, the observed substituent effect was easily understood, as shown in Scheme 4.

Since the products thus obtained are known to be easily converted into pyrylium salts which possess wide utility for various organic synthesis,[32] this base-promoted reaction seems to be highly useful.

Experimental

^{1}H NMR spectra were recorded at 60 MHz on a Varian EM 360 NMR spectrometer using $CDCl_3$ and Me_4Si as solvent and internal standard, respectively. IR spectra were obtained with a Hitachi 295 infrared spectrometer. Mass spectra were obtained with a JEOL JMS-D100 mass spectrometer.

Electrolytic Procedure. An H-type electrolytic cell divided with a glass filter diaphragm was used. Platinum plates (2×3 cm) were used as cathode and anode. The catholyte was 40 cm^3 of 0.5 mol dm^{-3} Et_4NOTs or $NaClO_4$/

anhydrous DMF containing 6—10 mmol of substrates (**1**, **4**, **8**). Constant current (1.6A dm^{-2}) electrolysis was mainly carried out by passing 1.0—1.2F (1F=96480C) mol^{-1} of charge under a nitrogen atmosphere at room temperature.

Cathodic Esterification of Carboxylic Acids. Method A: Alkylating reagents (11 mmol of alkyl halides or tosylates) had been added to the catholyte containing carboxylic acids (10 mmol) before the current was turned on. After the electrolysis, the catholyte was allowed to stand for 1 h at room temperature.

Method B: Similar to Method A except that the alkylating reagents were added to the catholyte after the current had been turned off. In both methods, the catholyte was poured into water and then extracted with dichloromethane. The extract was analyzed by gas chromatography using a 2 m PEG 20M column at 100—200 °C.

Preparation of Diaryl Ethers (7) Using Electrogenerated Phenolate Anions. After the electrolysis of 6 mml of benzenethiol or phenol had been carried out by passing 1.0F mol^{-1}, the catholyte was added to a stirred solution of 5 mmol of *o*- or *p*-halonitrobenzene in 10 cm^3 of DMF. The reaction mixture was stirred at room temperature, and then the mixture was poured into water. After extraction with ether, the extracts were dried over anhydrous sodium sulfate. After removal of the solvent, the remaining residue was chromatographed on silica gel. Elution with a mixed solvent of hexane and ethyl acetate (50:1) provided pure products **7**. The products, *p*-nitrophenyl phenyl sulfide (**7a**)[33] and *p*-nitrophenyl phenyl ether (**7b**)[34] were identified by spectroscopic comparison with authentic samples.

***o*-Nitrophenyl Phenyl Ether (7c):** Yellow oil. IR (KBr): 1520 cm^{-1} (ν_{NO_2}). ^1H NMR δ=6.85—7.75 (m, 8H, Ar-H) and 7.80—8.05 (m, 1H, Ar-H). MS *m/z* 215 (M^+). Found: C, 66.71; H, 4.22; N, 6.18%. Calcd for $C_{12}H_9O_3N$: C, 66.97; H, 4.21; N, 6.51%.

Aldol Condensation Promoted by Electrogenerated Hindered Phenolate Anion (8). After the electrolysis had been carried out in 40 cm^3 of DMF containg 10 mmol of 2,6-di-*t*-butyl-*p*-cresol, 13.3 cm^3 of the catholyte was added to a stirred solution of 3 mmol of ketone and 3 mmol of aldehyde in 7 cm^3 of DMF under a nitrogen atmosphere. After stirring (TLC control), the reaction mixture was poured into an aqueous solution of NaCl and then extracted with ether. After drying and concentrating, the remaining residue was chromatographed on silica gel. Elution with a mixed solvent of hexane and diethyl ether (4:1) provided keto alcohol (**9**) or 1,5-pentanedione (**10**).

The products, 3-hydroxy-1,3-diphenyl-1-propanone (**9a**),[31] 1,3,5-triphenyl-1,5-pentanedione (**10a**),[31] 3-(4-methoxyphenyl)-1,5-diphenyl-1,5-pentanedione,[35] 3-(3,4-dimethoxyphenyl)-1,5-diphenyl-1,5-pentanedione,[35] 3-(4-chlorophenyl)-1,5-diphenyl-1,5-pentanedione,[35] 3-phenyl-1,5-di-*p*-tolyl-1,5-pentanedione,[36] 1,5-bis(4-methoxyphenyl)-3-phenyl-1,5-pentanedione[37] were identified by spectroscopic comparison with authentic samples.

3-(3-Methoxyphenyl)-1,5-diphenyl-1,5-pentanedione: Mp 88—90 °C. IR (KBr): 1680 cm^{-1} ($\nu_{C=O}$). ^1H NMR δ=3.15—3.50 (m, 2H, CH_2), 3.65—4.35 (s, 3H, CH_3O and m, 1H, CH), and 6.55—8.10 (m, 14H, Ar-H). MS *m/z* 358 (M^+). Found: C, 80.29; H, 5.97%. Calcd for $C_{24}H_{22}O_3$: C, 80.42; H, 6.19%.

1,5-Bis(4-chlorophenyl)-3-phenyl-1,5-pentanedione: Mp 125—127 °C. IR (KBr): 1690 cm^{-1} ($\nu_{C=O}$). ^1H NMR δ=3.30—3.65 (m, 4H, CH_2), 3.90—4.35 (m, 1H, CH), and 7.20—8.10 (m, 13H, Ar-H). MS *m/z* 400 (M^++4), 398 (M^++2), and 396 (M^+). Found: C, 69.83; H, 4.83; Cl, 18.17%. Calcd for $C_{23}H_{18}O_2Cl_2$: C, 69.53; H, 4.57; Cl, 17.85%.

3-Hydroxy-2-methyl-1,3-diphenyl-1-propanone (9b): Colorless oil. IR (liquid film): 3500 (ν_{OH}) and 1670 cm^{-1} ($\nu_{C=O}$). ^1H NMR δ=0.85—1.30 (d, 3H, CH_3), 3.20—3.90 (m, 2H, OH and MeCH), 4.77—5.13 (d, 1H, CHOH), and 7.05—8.10 (m, 10H, ArH). MS *m/z* 240 (M^+). Found: C, 79.67; H, 6.66%. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

(Received January 24, 1986)

Methylbenzenes and naphthalenes were oxidized to quinones with aqueous(60%) H_2O_2 in acetic acid in the presence of a 0.24 wt% Pd(II)-sulfonated polystyrene type resin. The selectivities to quinones were higher in naphthalenes than in methylbenzenes. Among the naphthalenes used, 2-methylnaphthalene, 2,3-dimethylnaphthalene, and 2,6-dimethylnaphthalene gave 1,4-quinones in good yields(50—64%). The increase in the reaction temperature increased the selectivity to quinones from 40% at 20 °C to 70% at 70 °C.

The oxidation of 2-methylnaphthalene with chromium trioxide to 2-methyl-1,4-naphthoquinone (vitamin K_3) is known to be a practical process.[1] Recently, various quinones have been prepared from aromatic hydrocarbons with chromium trioxide by the addition of 18-crown-6 ether.[2] However, catalytic oxidation is valuable since the use of a large amount of chromium trioxide gives rise to problems in the treatment of waste water. Along this line, the oxidation of aromatic hydrocarbons to quinones with H_2O_2 in the presence of acid catalysts has been claimed.[3] As for metal-ion catalysts, naphthalenes and anthracenes have been oxidized with ammonium peroxodisulfate under the coexistence of ammonium cerium(IV) sulfate and silver(I) nitrate[4] in an emulsified solution. From a practical standpoint, a solid catalyst is useful in the separation of the catalyst from the reaction products.

In the oxidation of 2-methylnaphthalene to 2-methyl-1,4-naphthoquinone, we have found a palladium catalyst supported on sulfonated polystyrene type resins.[5] In this work palladium catalysts were applied to the oxidation of methylbenzenes and naphthalenes since several quinone compounds showed antitumor or antibiotic activities.

The reaction rates and selectivities to the quinones differed widely with the substituents on methylbenzenes and naphthalenes.

Experimental

Reagents and Preparation of the Catalyst. Methyl benzenes, naphthalenes, 1,2-naphthoquinone, 1,4-naphthoquinone, 2-methyl-1-naphthol, 2,3,5-trimethylhydroquinone, 2-methyl-1,4-naphthoquinone, 2,5-dimethyl-p-benzoquinone, and 2,3,5,6-tetramethyl-*p*-benzoquinone, were purchased commercially. Aqueous (60%) H_2O_2 was obtained from Mitsubishi Gas Chemical Co. The conditioning of sulfonated polystyrene type(SP) resin (DOWEX 50w-x8, 200-400 mesh, H-form, 1 g, water content 50%) was carried out by allowing it to stand for 1 h in 30 ml of acetic acid. The solvent was removed and the SP resin was washed with acetic acid; then, a 0.24 wt% Pd(II)-SP resin catalyst was prepared from 5 mg of $Pd(AcO)_2$ and the SP resin (1 g) by stirring in 20 ml of acetic acid for 5 h at 50 °C. The catalyst was separated and washed three times with acetic acid. Melting points were determined with a Yanagimoto micro melting-point apparatus and were uncorrected.

2,3-Dimethyl-1,4-naphthoquinone. 2,3-Dimethyl-naphthalene (385 mg, 2.5 mmol) was oxidized with 60% H_2O_2 (0.7 ml, 15.6 mmol) at 50 °C for 8 h in 10 ml of acetic acid in the presence of the 0.24 wt% Pd(II)-SP resin catalyst (1 g). After the catalyst had been separated, the reaction mixture was diluted with water to 40 ml and poured into the separating funnel with hexane to extract the quinone from the reaction mixture. The hexane layer was washed with water, dried, and evaporated. The quinone was crystallized from methanol; mp 126—127 °C. Lit,[6] mp 127 °C. Found: C, 77.68; H, 5.46%. Calcd for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

2,6-Dimethyl-1,4-naphthoquinone. 2,6-Dimethylnaphthalene (768 mg, 5.0 mmol) was oxidized with 60% H_2O_2 (1.05 ml, 23.4 mmol) at 50 °C for 8 h in 20 ml of acetic acid in the presence of the 0.24 wt% Pd(II)-SP resin catalyst (2 g). The quinone was obtained from the reaction mixture in the same way as 2,3-dimethyl-1,4-naphthoquinone; mp 137—138 °C. Lit,[7] mp 136—137 °C. Found: C, 77.30; H, 5.41%. Calcd for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

2,3,5-Trimethyl-*p*-benzoquinone. 2,3,5-Trimethyl-*p*-benzoquinone was prepared from 2,3,5-trimethyl-*p*-hydroquinone with chromium trioxide in dichloromethane/diethyl ether according to a method described in the literature[2]; mp 30 °C. Lit,[2] mp 32 °C. Found: C, 71.41; H, 6.92%. Calcd for $C_9H_{10}O_2$: C, 71.98; H, 6.71%.

2-Methyl-1,4-naphthalenediol. 2-Methyl-1,4-naphthalenediol was prepared by reducing 2-methyl-1,4-naphthoquinone with sodium dithionite according to a method from the literature[1]. Mp 150—160 °C. Found: C, 75.94; H, 5.57%. Calcd for $C_{11}H_{10}O_2$: C, 75.84; H, 5.79%.

General Procedure for the Oxidation of Methylbenzenes and Naphthalenes. Naphthalenes (2.5 mmol), acetic acid (10 ml), and the 0.24 wt% Pd(II)-SP resin catalyst (1 g) were added to a 50 ml flask. Oxidation was initiated by the addition of 60% H_2O_2 (0.35 ml, 7.8 mmol) under magnetic stirring. After 4 h, an additional 0.35 ml of 60% H_2O_2 was added and the solution was heated until the oxidation was almost completed. The products were analyzed by high-performance liquid chromatography (HPLC) (M & S pack C-18, 4.6×150 mm column, Gilson Co. model 302) using MeOH–H_2O (100:15) as the eluent (flow rate, 0.5 ml min^{-1}; detector, UV at 285 nm). 2,6-Dimethylnaphthalene or 2-methylnaphthalene was used as an internal standard. Retention times were 1,2-naphthoquinone 3.9 min, 1,4-naphthoquinone 4.6 min, 2-methyl-1,4-naphthoquinone 5.5 min, 2,3-dimethyl-1,4-naphthoquinone 7.0 min, 2,6-dimethyl-1,4-naphthoquinone 6.6 min, 2,5-dimethyl-*p*-benzo-

quinone 4.4 min, 2,3,6-trimethyl-*p*-benzoquinone 5.2 min, 2,3,5,6-tetramethyl-*p*-benzoquinone 6.8 min, naphthalene 7.2 min, 2-methylnaphthalene 9.6 min, 2,3-dimethylnaphthalene 12.9 min, 2,6-dimethylnaphthalene 13.8 min, *p*-xylene 7.8 min, 1,2,4-trimethylbenzene 10.7 min, and 1,2,4,5-tetramethylbenzene 14.0 min, respectively.

Results and Discussion

Oxidation of Methylbenzenes and Naphthalenes. In the oxidation of 2-methylnaphthalene to 2-methyl-1,4-naphthoquinone, the composition of the catalysts and the reaction conditions such as metal ions, anions, the supports of palladium, and solvents have been studied previously.[5] The best catalyst was prepared from palladium salts and sulfonated polystyrene-type resins in acetic acid by an ion-exchanging procedure at 50 °C for a 5-h heating. When a 0.24 wt% palladium-sulfonated polystyrene type resin (SP resin) was used, the conversion of 97% and the selectivity of 55% were attained at 50 °C for 8 h. Though the SP resin itself catalyzed the oxidation, the activity was poor; a conversion of 54% and a selectivity of 37% were obtained under the same reaction conditions. Acetic acid was an effective solvent for the oxidation. In our oxidation system 2-methyl-1,4-naphthoquinone was sufficiently stable in separated experiments; a quinone of 9.9% was decomposed after 8 h at 50 °C.

In this report, the oxidation of methylbenzenes and naphthalenes was carried out with aqueous 60% H_2O_2 by using palladium catalysts. Results are shown in

Table 1. Oxidation of Methylbenzenes and Naphthalenes to Quinones

Substrate	Quinone	Temp °C	Time h	Conv %	Yield %
Naphthalene		50	8	67.9	12.6
2-Methylnaphthalene		60	8	92.9	59.9
2,3-Dimethylnaphthalene		50	6	95.1	51.2
2,6-Dimethylnaphthalene		50	8	97.9	64.7
p-Xylene		70	8	37.2	6.6
1,2,4-Trimethylbenzene		70	10[a]	77.6	3.3
1,2,4,5-Tetramethylbenzene		70	8	74.8	8.4

Substrate (2.5 mmol), 60% H_2O_2 (0.7 ml, 15.6 mmol), 0.24 wt% Pd(II)-SP resin (DOWEX 50 w-x8, 200—400 mesh) 1 g, and AcOH 10 ml were used. a) H_2O_2 of one equivalent to 1,2,4-trimethylbenzene was added each at 0 h, 4 h, and 7 h.

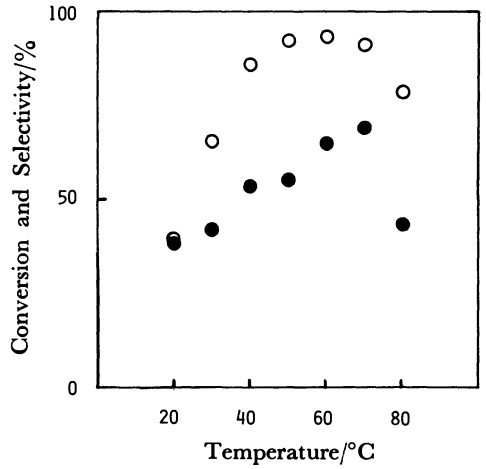

Fig. 1. Effect of the temperature on the conversion and the selectivity of the oxidation of 2-methylnaphthalene to 2-methyl-1,4-naphthoquinone with H_2O_2. 2-Methylnaphthalene 0.35 g(2.5 mmol), 60% H_2O_2 0.7 ml(15.6 mmol), 0.24 wt% Pd(II)-SP resin (DOWEX 50w-x8, 200—400 mesh) 1 g, and AcOH 10 ml were used. The oxidation was carried out for 8 h. ○: Conversion, ●: Selectivity.

Table 1. Methylbenzenes such as *p*-xylene, 1,2,4-trimethylbenzene, and 1,2,4,5-tetramethylbenzene were oxidized to give 2,5-dimethyl-*p*-benzoquinone, 2,3,5-trimethyl-*p*-benzoquinone, and 2,3,5,6-tetramethyl-*p*-benzoquinone, respectively, with poor yields of 3—8% at 70 °C. On the other hand, naphthalenes were oxidized easily to give methylnaphthoquinones; 2-methyl-, 2,3-dimethyl-, and 2,6-dimethylnaphthalene gave corresponding 1,4-quinones from naphthalenes with selectivities of 54, 53, and 66%, respectively. The only quinone from naphthalene was 1,4-naphthoquinone, since the decomposition of 1,2-naphthoquinone occurred vigorously.

Figure 1 shows the effect of the reaction temperature on the conversion and the selectivity in the oxidation of 2-methylnaphthalene. The conversion increased upon increasing the reaction temperature up to 50 °C and a constant value of around 90% was attained. However, a further increase in the reaction temperature (80 °C) collapsed the catalyst and the activity decreased drastically.

The selectivity also increased linearly upon increasing the reaction temperature to 70 °C. Therefore, we carried out the oxidation at temperatures between 50 and 70 °C. Usually, a higher selectivity is expected when mild reaction conditions are employed. Our results were contrary to the general tendency. For this complicated result, the presence of two different types of active species working under different temperature ranges are considered, i.e., hydroxyl cations[8] worked mainly at higher temperatures to give quinones and hydroxyl radicals at lower temperatures to afford polymerized compounds as by-products.[9]

Table 2. Oxidation Rates of 2-Methylnaphthalene, 2-Methyl-1-naphthol, and 2-Methyl-1,4-naphthalenediol

Substrate	Initial rate[a] $\times 10^{-4}$ mol dm^{-3} min^{-1}	Select.[b] %
2-Methylnaphthalene	5.9	55
2-Methyl-1-naphthol	72.2	61
2-Methyl-1,4-naphthalenediol	1500	100

Substrate (5.0 mmol), 60% H_2O_2 (one equivalent to the substrates), 0.24 wt% Pd(II)-SP resin (DOWEX 50w-x8, 200—400 mesh) 2 g, and AcOH 20 ml were used. The oxidation was carried out at 50 °C. a) The rate of formation of 2-Methyl-1,4-naphthoquinone. b) The selectivity to 2-methyl-1,4-naphthoquinone.

The Oxidation of Various Substituted Benzenes and Naphthalenes. The yields of quinones varied with the position and the number of the methyl groups attached to benzenes and naphthalenes (Table 1). As a tendency, electron-donating substituents, such as methyl and methoxyl groups at carbon-2, accelerated the oxidation. On the other hand, nitro groups greatly retarded the oxidation; the ratios for the initial oxidation rates were MeO:Me:H:Cl:NO_2=11.1:3.4:1.0:0.6:0.1. The large substituent effect and an ionic media of our reaction system suggested that an electrophilic attack of peroxigenated palladium at the 1-position of naphthalenes to give 1-naphthols is a key step for the quinone formation followed by the hydroxylation to carbon-4. 2-Methyl-1-naphthol and 2-methyl-1,4-naphthalenediol, the supposed intermediates, were easily oxidized to give quinones as shown in Table 2.

The nature of the palladium catalysts in the oxidation with peroxides is still ambiguous. Recently, a peroxidized palladium complex has been prepared from *t*-BuOOH and $Pd(AcO)_2$ and used for the oxidation of olefins to ketones.[10] In our catalyst, *t*-BuOOH was inactive to the oxidation of 2-methylnaphthalene.

The oxidations of methoxybenzenes with chromium trioxide have afforded benzoquinones selectively.[11] Also, 1,2,3-trimethoxybenzene has been oxidized to give dimethoxy-*p*-benzoquinones with H_2O_2 in acetic acid in the presence of hexacyanoferrate.[12] On the other hand, the palladium-SP resin catalyst easily oxidized *o*-, *m*-, and *p*-dimethoxybenzenes with H_2O_2 to give polymerized tars.

Effect of Pore-Size Distribution on the Catalytic Performance for Coal Liquefaction. II. Carbonaceous and Metallic Deposition on the Catalyst

Hiromichi SHIMADA,* Minoru KURITA, Toshio SATO, Yuji YOSHIMURA, Yoshinori KOBAYASHI, and Akio NISHIJIMA
National Chemical Laboratory for Industry, Yatabe, Ibaraki 305
(Received February 18, 1986)

The behavior of carbonaceous and metallic depositions on catalysts during hydroliquefaction of coal was investigated by using several kinds of catalyst supports with different pore-size distribution values in order to obtain the fundamental data for designing long-life catalysts. Higher concentration of carbonaceous deposition was observed on large-pore and bimodal catalysts than was observed on the comparative small-pore and unimodal catalysts, respectively. However, the carbonaceous deposit was distributed more evenly inside large pores than it was inside small pores. The micropores of the bimodal catalysts were more effectively used than were those of the unimodal catalysts. Thus, the unimodal catalysts with small pores suffered more severe pore-mouth poisoning than the bimodal or the large-pore catalysts. The penetration behavior of the metallic components was found to be different for each metal. Discrete minerals such as clay could not penetrate into the catalyst pores and were deposited on the external surface of the catalyst particle. While, the metallic components coordinated with organic compounds such as phenolates or chelates deposited inside the macro- and mesopores. Easy access of the large asphaltenic molecules to the active sites resulted in high coal-liquefaction activity for the catalyst. This was accompanied by large amounts of both carbonaceous and metallic depositions. It is concluded that large-pore or bimodal pore structure is required for both high liquefaction activity and suppression of pore-mouth poisoning.

In the previous paper,[1] the authors reported that the pore-size distribution of the catalyst support have a great effect on the catalytic activity and selectivity for direct liquefaction of coal. The results are summarized as follows;

1. Catalysts with large pores are more advantageous in the production of asphaltenes (toluene-solubles) from coal than those with small pores.
2. Small pores tend to produce light products such as oils (hexane-solubles).
3. Bimodal catalysts with macroporosity ($r>300$ nm) and microporosity ($r<10$ nm) performed excellently in terms of both total liquefaction and oil production.

Another important catalytic performance required for hydrotreating catalysts, besides activity and selectivity, is long life time, which depends strongly upon carbonaceous deposition and metallic foulants on the catalyst. The recent development of catalysts for hydrotreating petroleum fractions has shown that it is necessary to clarify the behavior of the poisoning materials on the catalyst in order to design a new type of catalyst with longer life.[2-7]

Several investigations have been undertaken on the effects of the pore structure of the catalyst support on its aging behavior during hydroliquefaction of coal[8,9] or hydrotreating of coal-derived liquids.[10,11] They have demonstrated the beneficial effects of increasing pore radius or bimodal pore-size distribution of the catalyst support. As for the behavior of the carbonaceous and metallic foulants on the catalyst, it was found that there was a higher rate of deposition of the foulants during coal liquefaction as compared with petroleum hydroprocessing.

Bertolacini et al.[8] reported that the slowest decline of activity for hydroliquefaction of coal was found for bimodal catalyst with large micropores ($r\approx10$ nm). They indicated that the surface area and pore volume decreased more rapidly for catalysts with small micropores than those with large pores. They also found that carbonaceous deposition caused a shift in micropore-size distribution with time on stream to lower pore diameter. Stiegel et al.[11] reported slower deactivation for catalysts with bimodal pore-size distribution than those with unimodal pores during hydrotreating of coal-derived liquids. They found that the former accumulates larger amounts of metallic foulants than the latter in spite of similar coke concentrations on all of the catalysts. Several researchers have applied electron microprobe (EPMA) analysis to the profiling of metallic components in catalyst particles and have reported different penetrations by the elements.[12-14]

In spite of these efforts, there still remain several questions unresolved concerning the aging behavior of catalysts because of the lack of information about the behavior of the poisoning materials on the catalyst. For example, it is still inclear why bimodal catalysts are much better than unimodal catalysts in terms of aging, although the superiority of the bimodal catalysts in the initial activity could be attributed to the high effective diffusivity.[1,15,16] It is not clear how each metallic foulant behaves on the catalyst and decreases the activity.

In the present paper, the authors aimed to clarify the behavior of foulants on catalysts in order to obtain the fundamental data needed for understanding the

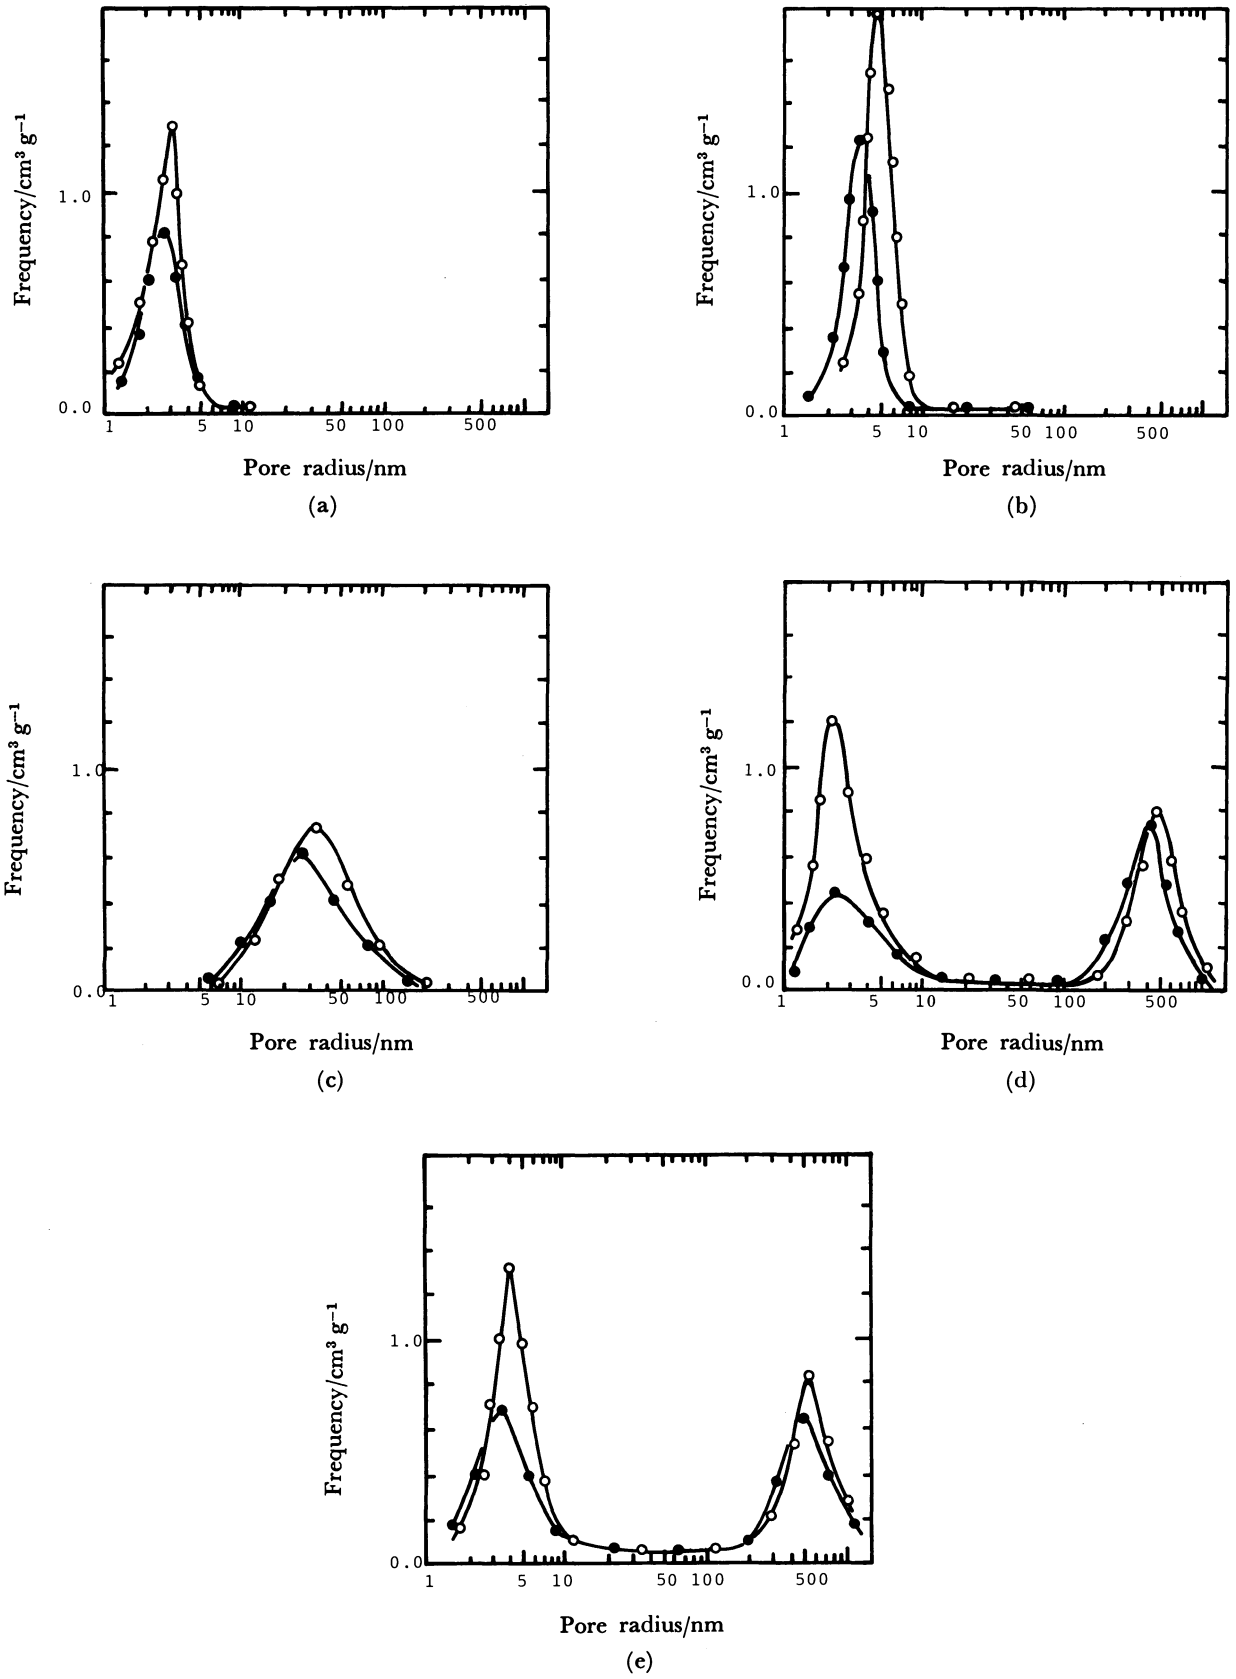

Fig. 1. Changes in pore-size distributions of the catalysts A (a), B (b), C (c), D (d), and E (e).
○: Fresh catalyst, ●: Used catalyst.

aging behavior of catalysts. Emphasis was placed on the effect of the pore structure on the deposition behavior. For this purpose, detailed analysis was carried out on five used catalysts with micro- ($r<10$ nm), meso- ($10<r<100$ nm) and macroporosity ($r>100$ nm) employing new surface analytical techniques such as X-ray photoelectron spectroscopy (XPS) and secondary ion mass spectrometry (SIMS) to investigate the metallic deposit.

Experimental

Catalysts. The molybdenum based catalysts were prepared by impregnation of Al_2O_3 supports (sphere with a diameter of 1.5 mm). The details of the procedures used are described in a previous paper.[3] The physical properties and chemical composition of the freshly prepared catalysts are summarized in Table 1. Pore-size distribution curves for the catalysts are shown in Fig. 1.

Reaction Procedure. The coal used was a subbituminous Taiheiyo coal containing 16.1% ash (dry base). All the reactions were carried out in a 500-cm^3 autoclave with a magnetically-driven stirrer. The reaction conditions are as follows: hydrogen initial pressure (at 27 °C), 9.8 MPa; temperature, 400 °C; time, 2 h. Other details for procedures used are described in the previous paper.[1]

Characterization of the Catalyst. The catalyst used was Soxhlet extracted with tetrahydrofuran for 16 h and dried in vacuo at 300 °C before analysis. Analytical techniques employed in this study of the fresh and used catalysts were as follows.

The carbonaceous deposit on the catalyst was determined by using a CHN analyzer (Yanagimoto, MT-3). A mercury porosimeter (AMINCO, 60000 psi) was used for the determination of the specific surface area, pore volume, and pore-size distribution of the catalyst. The amounts of Fe, Ca, and Ti deposited on the catalysts were measured by an X-ray fluorescence analyzer. An atomic absorption spectrometer was used in the determination of Na and Mg. An X-ray photoelectron spectrometer (XPS, Shimadzu ASIX-1000) with Mg anode (270 w) was used for evaluating the concentration of carbon and metallic elements on the surface of the catalyst particles.

A secondary ion mass spectrometer (SIMS, Hitachi IMA-2) was employed for the depth profiling of each metallic element around the external surface of the used catalyst. All the samples were bomberded by 10-keV O_2^+ ions at a current of about 2×10^{-6} A. A beam of electrons was applied to the sample's surface during analysis to prevent charge build-up.

Results and Discussion

Carbonaceous Materials. Table 1 shows the amount of carbon contained in the carbonaceous materials deposited on the catalyst during coal liquefaction. For unimodal catalysts, the carbon concentration on the surface of the catalyst increased with the pore radius of the catalyst support. This is in agreement with the trend observed for the catalysts used in hydrotreating petroleum residue.[2,4] This trend is attributed to the severe pore-diffusion limitation of the large molecules which cause carbonaceous deposition. It is also shown in Table 1 that carbonaceous materials were deposited in higher concentration on the bimodal catalysts (catalysts D and E) than they were on the unimodal catalysts (catalysts A and B). On the contrary, Stiegel et al.[11] reported that similar concentrations of carbon were deposited on both unimodal and bimodal catalysts during hydrotreating of coal-derived liquids. This discrepancy may be attributed to the difference in pore diffusion between coal and coal-derived liquids.

The changes in physical properties of the catalyst after coal liquefaction are also shown in Table 1. The r(S.A.) values (the ratio of the surface area of the used catalyst to that of the fresh one) increased with the pore radius, showing that the loss in the surface area was greater for small-pore catalysts than for large-pore catalysts. The bimodal catalysts (catalysts D and E) gave smaller r(S.A.) values than did the unimodal catalysts (catalysts A and B), again contrary to the results by Stiegel et al.[11], who reported similar concentration of carbon on both the catalysts. This discrepancy can be partly attributed to the fact that they chose bimodal catalysts with large micropores and unimodal catalysts with small micropores.

Figure 1 clearly shows the changes in pore-size distribution. Small micropores (Fig. 1 (a) and (d))

suffered severe pore plugging, while meso- and macroporosity did not change appreciably. More accumulated carbonaceous deposit was observed on the micropores of the bimodal catalysts than on those of the unimodal catalysts, which is consistent with Table 1.

It is clear that carbonaceous deposition is caused by large asphaltenic molecules, especially those containing heteroatoms such as nitrogen or oxygen.[17] Due to diffusion limitation of the large molecules, an increase in the concentration of the deposit was observed with increasing pore size. On the contrary, the smaller decrease in surface area and pore volume for the former than the latter indicated that the deposits were evenly distributed on the inner surface of large pores, while they localized around the mouth of the small pores (Fig. 2).

In the case of bimodal catalysts, the macroporosity enhanced the diffusion of large molecules into the micropores which are the branches between the macropores. The small pores of unimodal catalysts are narrow and long, while those of bimodal catalysts are connected to macropores, and are shallower (Fig. 2). Thus, the macroporosity caused a higher concentration of carbonaceous deposition on the inner surface of the micropores for the bimodal catalysts.

It has already been shown that most of the carbonaceous deposition on catalysts during the initial stage of a run is by reversibly adsorbed molecules.[2,18] Therefore, high concentrations of reversibly adsorbed carbonaceous deposits on bimodal or large-pore catalysts during the initial stage of a run occurs on the inner surface of the catalyst and does not necessarily result in rapid deactivation of the catalyst. In fact, high total conversion was given over the large-pore catalyst, C, and the bimodal catalysts, D and E, (Table 1). It is apparent that the unimodal catalysts with microporosity suffered the most severe pore-mouth poisoning. It is important to prevent the production of inactive coke on the catalyst in order to reduce the deactivation rate of the catalyst. High pore diffusion may play an important role in the suppression of this production.

Metallic Foulants. Table 2 shows the amount of metallic foulants on the catalyst during coal liquefaction. In the table, the total amount deposited on each catalyst (5 g) is given. For each metallic component, the amount deposited increased with the pore radius of the catalyst support. The tendency was quite evident for Ca and Ti, but not as clear for Na.

Comparison of the amount of metal deposited on the catalyst with the total amount in coal showed that Ti and Mg were deposited on the large-pore catalysts preferentially. Little Si was deposited on the catalyst, although it was the most abundant metallic element in coal.

Table 3 shows the concentration, by XPS, of each metallic component on the external surface of the

TiO_2/mg	1	4	7	11	17	83
Fe_2O_3/mg	5	7	13	16	17	500

a) The total amount deposited on all the catalyst (5 g). b) The total amount contained in the coal (60 g). Other major components are SiO_2 (6300 mg), Al_2O_3 (2000 mg), and K_2O (61 mg). The amount of SiO_2 and Al_2O_3 on the used catalyst could not be determined because they are the components of the fresh catalysts. The amount of K_2O was too little to be determined. c) Most probable pore radius.

catalyst. For all of the catalysts the XPS analysis gave a much higher concentration for each of the metallic foulants than was obtained by chemical analysis. It should be emphasized that very high concentrations of Ca, Ti, and Si were observed on the external surface layer, even for the small-pore catalysts (catalysts A and B), in spite of there being relatively little deposition through the entire catalyst particle.

The authors utilized a secondary ion mass spectrometer (SIMS) to investigate the penetration behavior of metallic foulants into the inner part of catalyst particles.[19,20] SIMS analysis gave more detailed information on the profiling around the external surface of the particle as compared with EPMA. Figure 3 shows the depth-profile curves measured by SIMS. The ordinate, $I_{M\,cor}$ (corrected intensity for element M), is given by :

$$I_{M\,cor}(t) = \frac{I_M(t)/I_{Al}(t)}{I_M(0)/I_{Al}(0)},$$

Where $I_M(t)$ is the observed intensity for element M at sputtering time, t. The abscissa, sputtering time, is proportional to the depth from the external surface layer of the catalyst particle.

Figure 3 clearly displays the difference in the behavior between the metallic elements. In the case of the small-pore catalyst A, Na showed much greater penetration than other elements. On the other hand, in the catalyst E with micro- and macropores, Ca, Mg, Ti, and Fe penetrated more deeply into the inner part of the catalyst particle than Na. For both catalysts, the profiles of Si and K decreased rapidly. Na could even penetrate into the catalyst particles having no large pores, while Ca, Ti, Fe, and Mg could not enter small pores. Si and K could not intrude even into large pores.

Table 3. Deposited Metals on the External Surface of the Catalyst Sphere[a)]

Catalyst	A	B	C	D	E
Na_2O/wt%	3.7	3.0	3.9	3.0	3.9
CaO/wt%	1.8	1.7	1.9	1.4	1.9

Fe_2O_3/wt%	4.5	3.3	4.9	3.0	2.1
SiO_2/wt%	23.	39.	18.	15.	34.

a) The determination was carried out by using XPS. And calculated basing on the measured area of the spectra and cross section given by Scofield.[21]

The above data, Tables 2, 3, and Fig. 3, clearly indicated that the metallic deposition behavior is quite different for each metal. The behavior of each metallic component is dependent upon its coordination which affects its effective particle size and its interaction with the catalyst. The metallic components can be classified into two categories.[22] The first is as mineral matter present as discrete particles such as pyrite, quartz, and other clay minerals. The second is as organic matter which can be classified into two subcategories. One consists of inorganic salts of organic acids and the other as organic chelates.

The results indicate that most of the silicon in the coal occurs in the minerals, such as quartz, calcite, or kaolinite which could be observed as crystalline materials by X-ray diffraction. The particle size of the minerals is larger than the pore mouth of the macropores. High concentrations of Si on the external surface of the catalyst particles (Table 3) indicate the "filtration" of the minerals by the surface of the catalyst. It is inferred that most of the potassium occurs in the minerals also. This is in agreement with the results obtained by Gorin[22] which indicated that K is an exception among alkali and alkaline earth metals.

Other elements, at least in part, will be associated with the organic matter. The major portion of the

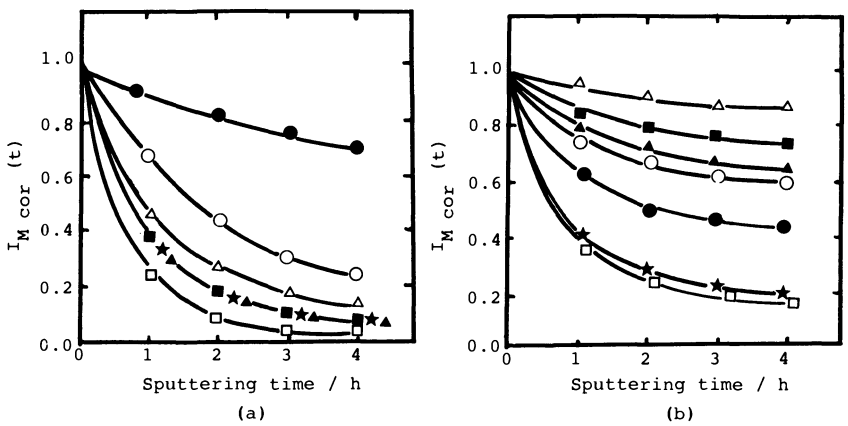

Fig. 3. Depth profiles of metal elements for the catalyst A (a) and the catalyst E (b).
●: Na, ○: Fe, △: Ca, ■: Mg, ★: Si, ▲: Ti, □: K.

alkali and alkaline earth metals in coal are present as inorganic salts of organic acids. The low pore-diffusion limitation seen for Na suggests that it is present as inorganic salts of low molecular weight organic acids such as phenols. Na from these phenolates was probably exchanged for protons from the acidic sites of the catalyst during deposition.

The next deepest penetration into the small-pore catalysts was observed for Fe (Fig. 3), which is consistent with the results in Table 2 that showed Fe was the second most abundant metallic foulant on small-pore catalysts. While, the ratio of the deposited amount to the total amount in coal was very low (Table 2). These results suggest that most of the iron is in the form of inorganic minerals, but that some of the iron is present in a small molecular weight component which can penetrate into catalyst pores. It cannot be excluded that a part of the iron is present as fine particles of minerals such as pyrite.

The low pore diffusion found for Mg and Ca indicated that these metals are present in large asphaltenic molecules, such as humates. Ca was deposited in a lower amount on the catalyst relative to the total amount in coal as compared with Mg (Table 2). This indicates that some of the Ca is present in minerals. The deposition behavior of Ti resembled that of Mg, indicating the presence of organotitanium chelate compounds.[22-24]

Inorganic minerals are deposited on the external surface of the catalyst, which causes pore-mouth poisoning. More rapid deactivation of small particle size catalysts[9] can be attributed to this poisoning. Macroporosity of bimodal catalysts enhances the diffusion of large asphaltenic molecules into micropores, while it prevents the access of the minerals to the inner surface of the catalyst particle. The deposition of metals coordinated with organic compounds was caused by the decomposition of the organic matter. In fact, higher rate of metal deposition in the large-pore (catalyst C) or the bimodal (catalysts D and E) catalysts was accompanied by high coal-liquefaction activity of the catalyst (Table 1). As a consequence, it may be impossible to suppress the deposition without decreasing coal liquefaction activity. Therefore, high resistance against metallic deposition is required for catalysts with high activity and long life time.

As has been described above, the pore-size distribution greatly affects the deposition behavior of carbonaceous and metallic materials. On the large-pore and the bimodal catalysts, higher rates of deposition were observed than that found for the small-pore and the unimodal catalysts, respectively. However, deposition (except that due to inorganic minerals) results from the effective use of the inner surface of the catalyst which leads to high coal liquefaction activity. It was also found that large-pore or bimodal catalysts are more advantageous than microporous unimodal catalysts from the view point of pore-mouth poisoning.

A ^{14}N NMR Relaxation Study of Aqueous Alkyltrimethylammonium Salt Solutions

Yuhei Uzu,* Jiro Nakagawa, and Masatoki Yokoi
Department of Chemistry, Faculty of Science, Shinshu University,
Asahi, Matsumoto 390
(Received March 13, 1986)

Synopsis. ^{14}N spin-lattice and spin-spin relaxation times were measured in a series of alkyltrimethylammonium salts at higher concentrations above the critical micell concentration. Octyltrimethylammonium bromide and dodecyltrimethylammonium chloride form spherical micelles at all concentrations, while decyl- and dodecyltrimethylammonium bromides form larger and rodlike micelles such as the hexadecyltrimethylammonium bromide suggested previously.

The transition of the shape of micelles in aqueous solutions is known to occur for various surfactants. In connection with this phenomenon, a change from spherical to rodlike micelles at higher concentrations has, also, been observed by macroscopic techniques, such as light scattering, viscosity and electron microscopic observation etc.[1-3] The significance of the spectroscopic work is evident for the dynamical study of the micellar phenomenon at the molecular level. Here, nuclear magnetic resonance (NMR) is a very powerful tool; thus, that many ^{1}H, $^{2}H(D)$, and ^{13}C studies have been reported in this field.[4-6] It has been shown that the longitudinal relaxation time, T_1, and the transverse relaxation time, T_2, can give information about the intensity of molecular motions. The time scale of the molecular motions is usually characterized by the parameter τ_c, the rotational correlation time. Recently, a study of ^{14}N relaxation times, T_1 and T_2, of hexadecyltrimethylammonium bromide (CTAB) and chloride (CTAC) micellar solutions has been reported by Henriksson et al.,[7] suggesting a change from spherical to rodlike form for the CTAB micellar shape.

With the aim of further documenting changes in the micellar shape, we have undertaken a systematic study of a series of alkyltrimethylammonium systems using the applicability of ^{14}N NMH.

The surfactants used in this study were alkyltrimethylammonium bromides with 8, 10, and 12 carbon atoms in the aliphatic chain, and dodecyltrimethylammonium chloride (DTAC). Dodecyltrimethylammonium bromide (DTAB), decyltrimethylammonium bromide (DeTAB) and DTAC were supplied from Kanto Chemical Inc. and purified through several recrystallizations from an ethanol-ether mixture. Octyltrimethylammonium bromide (OTAB) was synthesized by reacting equimolar quantities of trimethylamine and octyl bromide in ethanol at −3 °C for 5 d. As a check of the purity of the surfactants, cmc determinations were performed by means of a surface-tension method; the cmc's agreed closely with those values from the literature.[8] Deuterium oxide was used without further purification. ^{14}N relaxation times were measured at 6.42 MHz by a JEOL-FX90QFT NMR. The experimental temperature was 27 °C. Its reliability was monitored by the alternative insertion of a thermister into the sample position; the temperature was found to be ±0.5 °C. Spectra were recorded in the FT mode and T_1 was obtained by the 180°—τ—90° pulse sequence. T_2 was calculated from the half-width of the absorption signal in the fourier transform spectrum using the relation $(\pi\ T_2)^{-1}=\Delta\nu-\Delta\nu_{inhom}$, where $\Delta\nu$ is the experimental line width and $\Delta\nu_{inhom}$ is the contribution to the line width from magnetic field inhomogeneities. $\Delta\nu_{inhom}$ was determined from the spectrum of an aqueous solution of ammonium nitrate, which has a negligible contribution to the line width from relaxation.

The observed ^{14}N relaxation times, T_1 and T_2, for several alkyltrimethylammonium bromides are plotted in Fig. 1 as functions of the surfactant concentration. For a comparison, the result at 28.5 °C for CTAB reported by Henriksson et al.[7] is also given in the Fig. 1. All measurements obtained here have been performed at concentrations well above the cmc. When the concentration is increased, there is a gradual decrease in the relaxation times, and both T_1 and T_2 values initially have the same values, as are those for normal micellar solutions which extreme narrowing condition is fulfilled. At higher concentrations, T_2 still continues to decrease with increasing concentration, while T_1 becomes rather larger compared with T_2; consequently, T_1 differs from T_2, except for OTAB. For DTAB, a broader minimum in T_1 was

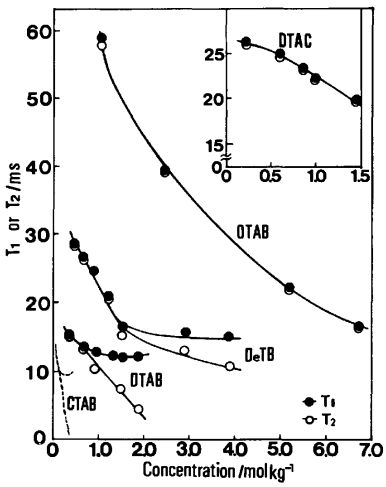

Fig. 1. ^{14}N relaxation times T_1 and T_2 vs. concentration at 27 °C for various surfactants. For comparison, the result for CTAB at 28.5 °C by Henriksson et al.[7] is included as the dashed curve.

also observed at $c \approx 1.5$ mol kg^{-1}, just as that for CTAB.[7] In such a case, it was suggested that the rotational motion about the principal axis of the electric field gradient at the nitrogen nucleus, the N-C$_\alpha$ bond, would not be described by a single correlation time based upon the rotational motion of isotropically reorienting molecule. Henriksson et al.[7] explained this observation by assuming that two kinds of molecular motions are effective for the relaxation. One is a local fast anisotropic motion of the molecule and the other is a slower motion over a distance of the order of micellar dimensions. For the fast motion which makes approximately constant contribution to the relaxation, the correlation time is $\tau_c^f = 4.5 \times 10^{-10}$ s at 27 °C in DTAB micelles.[9] On the other hand, the correlation time for the slow motion, τ_c^s, increases rapidly with the concentration.[7] This can be regarded as the slow motion that is tied to the distribution of aggregation numbers of the micelles, implying that the overall motion becomes more important for the relaxation. The calculation with τ_c^s value in DTAB micelles gives approximately 1.53×10^{-8} s[9] at $c = 1.5$ mol kg^{-1}, which is obviously much larger than τ_c^f. These values are of similar magnitude to those calculated for CTAB micelles by Henriksson et al., indicating that the same types of larger micelles are present in both systems. As the alkyl chain length is shortened, the discontinuous change tends to be shifted to the higher-concentration region and the relaxation times become larger. At the same time, it is suggested that T_1 gradually approaches T_2.

On the other hand, the relaxation behavior for OTAB seems to be different from the other surfactants and $T_1 = T_2$ holds throughout the concentration range examined. The differences in micellar size and shape would bring about a different relaxation behavior. This result is certainly expected since the concentrated solution of OTAB consists of spherical micelles.[2] Also, the behavior in aqueous solutions of DTAB and DTAC in Fig. 1 is found to be quite different and the relaxation times are about twice as long for the DTAC as for the DTAB solutions. The most likely explanation is that bromide ions can lower the electrostatic repulsion between the cationic head groups in the DTAB micelles and make a closer packing and tighter binding of the surfactant molecules on the micellar surface.[7] This seems to be caused by a phase change in the molecular packing accompanied by a phenomenon similar to that of the transition from spherical to rod-shaped micelles at high concentrations. In analogy with the above discussion, no change in the micellar shape occurs with DTAC and the micelles tend to remain spherical over all the concentration range, as already noted by Ozeki and Ikeda.[11] Accordingly, these results can be best explained by the occurrence of both rodlike (in which $T_2 < T_1$) and spherical (in which $T_1 = T_2$) micelles.

The Magnetic Properties of the Copper(II) Compounds with 3- and 4-Piperidinecarboxylic Acids

Shuji EMORI,* Nobuhide MORISHITA, and Yoneichiro MUTO
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received March 20, 1986)

Synopsis. Compounds of formula $[CuX_2(C_5H_{11}NCOO)_2]\cdot 3H_2O$ (X=NO_3, Cl, Br), $[Cu(NO_3)_2(C_5H_{11}NCOO)_2]\cdot 2(NH_2)_2CO$, and $Cu[(CH_3)_2CHCOO]_2\cdot(NH_2)_2$ CO have been prepared. The correlation of their magnetic properties with the pK_a values of their parent carboxylic acids is discussed.

A recent X-ray study[1] of a compound formed by the reaction of copper(II) nitrate with β-alanine has shown that four 3-ammoniopropionates bridge two copper(II) ions, forming a dimeric structure similar to that of copper(II) acetate monohydrate.[2,3] Previously, we also found that dinuclear copper(II) ω-ammonio carboxylates were obtained during a treatment of ω-amino carboxylic acids with copper(II) halides.[4] Since there still remain unclear points about the influence of a carboxylato substituent on the magnetic properties of dinuclear copper(II) carboxylates,[5] these ammonio carboxylates seem to be appropriate for studying the substitution effects. Then, as a continuation of our studies, we have prepared several new copper(II) compounds with 3- and 4-piperidinecarboxylic acids (nipecotic and isonipecotic acids) and examined the relation between their magnetic properties and the pK_a values of their parent acids. For the sake of discussion, the urea adduct of copper(II) isobutyrate was also prepared.

Compounds with a stoichiometry of $[CuX_2(C_5H_{11}NCOO)_2]\cdot 3H_2O$ (X=NO_3, Cl, Br) were prepared by a previously described method for copper(II) ω-amino carboxylates.[4] The urea adducts, $[Cu(NO_3)_2(C_5H_{11}NCOO)_2]\cdot 2(NH_2)_2CO$ and $Cu[(CH_3)_2CHCOO]_2\cdot(NH_2)_2CO$, were prepared according to the reported general procedure.[6]

The IR spectra of the copper(II) piperidinecarboxylate show bands near 1585—1593 cm^{-1} connected with NH_2^+ deformations[7] in addition to the characteristic bands in the ranges of 1430—1450 and 1600—1660 cm^{-1} connected with symmetric and unsymmetric COO stretching vibrations of the carboxyl groups.[8]

The effective magnetic moments (Table 1) were evaluated from the room-temperature magnetic susceptibilities, which were corrected for the diamagnetic contribution of constituent atoms using Pascal constants[9] and $N\alpha=60\times10^{-6}$ emu mol^{-1} (1 emu=$4\pi\times10^{-6}$ m^3). The temperature dependence of the magnetic susceptibilities (80—300 K) of $[Cu(NO_3)_2(3\text{-}C_5H_{11}NCOO)_2]\cdot 3H_2O$, $[Cu(NO_3)_2(4\text{-}C_5H_{11}NCOO)_2]\cdot 3H_2O$, and $Cu[(CH_3)_2CHCOO]_2\cdot(NH_2)_2CO$ were measured. The results agreed well with the Bleaney-Bowers equation,[10] using the following parameters: $g=2.13$ and $2J=-314$ cm^{-1}, $g=2.14$ and $2J=-330$ cm^{-1}, and $g=2.18$ and $2J=-342$ cm^{-1} for the compounds with 3- and 4-piperidinecarboxylic acids and isobutyric acid, respectively, indicating the presence of a dinuclear unit, which contains four zwitterionic (piperidinio)formate ($C_5H_9NH_2^+$–COO^-) bridges between the copper(II) ions similarly to copper(II) acetate monohydrate.

For dimers with this type of structure, it has been pointed out that the magnitude of a superexchange interaction through carboxylato bridging groups is inversely related to the basicity of the bridging group, as measured by the pK_a value of its parent acid.[11] In a previous study of copper(II) (substituted propionate)s, we found that this trend was maintained for a series of copper(II) ω-ammonio carboxylates.[4] In the present study, the bridging groups were substituted isobutyrate ligands and the pK_a values of the parent acids

Table 1. Analytical Data and Effective Magnetic Moments at 20 °C

Compound	Found(Calcd)/%					μ_{eff}/BM
	Cu	X	H	C	N	
$[Cu(NO_3)_2(3\text{-}C_5H_{11}NCOO)_2]\cdot 3H_2O$	12.78		5.63	29.06	11.29	1.37
	(12.71)		(5.65)	(28.83)	(11.21)	
$[CuCl_2(3\text{-}C_5H_{11}NCOO)_2]\cdot 3H_2O$	14.15	16.18	5.97	32.47	6.25	1.32
	(14.22)	(15.87)	(6.32)	(32.26)	(6.27)	
$[Cu(NO_3)_2(4\text{-}C_5H_{11}NCOO)_2]\cdot 3H_2O$	12.82		5.59	28.94	11.24	1.34
	(12.71)		(5.65)	(28.83)	(11.21)	
$[Cu(NO_3)_2(4\text{-}C_5H_{11}NCOO)_2]\cdot 2(NH_2)_2CO$	11.31		5.36	29.61	19.66	1.37
	(11.23)		(5.34)	(29.71)	(19.80)	
$[CuBr_2(4\text{-}C_5H_{11}NCOO)_2]\cdot 3H_2O$	11.82	29.51	5.12	26.90	5.19	1.31
	(11.86)	(29.83)	(5.27)	(26.90)	(5.23)	
$Cu[(CH_3)_2CHCOO]_2\cdot(NH_2)_2CO$	21.11		6.08	35.77	10.22	1.33
	(21.34)		(6.09)	(36.30)	(9.41)	

varied from 3.53 and 4.03 (estimated from the Branch–Calvin equation[12]) for 3- and 4-piperidinecarboxylic acids to 4.63 for isobutyric acid. The singlet-triplet separation value ($-2J$) of $[Cu(NO_3)_2(4\text{-}C_5H_{11}NCOO)_2]\cdot 3H_2O$ ($330cm^{-1}$) is larger than that of $[Cu(NO_3)_2(3\text{-}C_5H_{11}NCOO)_2]\cdot 3H_2O$ ($314\,cm^{-1}$), and also the magnetic moment of $[Cu(NO_3)_2(4\text{-}C_5H_{11}NCOO)_2]\cdot 2(NH_2)_2CO$ (1.37 BM) is larger than that of $Cu[(CH_3)_2CHCOO]_2\cdot(NH_2)_2CO$ (1.33 BM). Therefore, the order for the extent of an antiferromagnetic interaction between the two copper(II) ions is isobutyrate>4-piperidinecarboxylate>3-piperidinecarboxylate, indicating that the magnetic interaction in the series of copper(II) dialkylacetates also tends to decrease as the acid strength of the parent acid becomes stronger.

(Received March 26, 1986)

Synopsis. Oxygen content of SnO_2 and Zn_2SnO_4 crystals grown by the vapor phase method was determined by 14 MeV neutron activation analysis. The oxygen contents in the crystals were a little smaller than the theoretical values. The oxygen deficiency in the crystals was found to be related to their inherent semiconductive properties and density.

Many oxides show a semiconductive property originating in the deviation of oxygen from stoichiometry. The authors have already reported on the growth of SnO_2,[1-3] ZnO,[4] and Zn_2SnO_4[5] crystals by the vapor phase method. There is a possible of oxygen deficiency in these crystals because they grew with high growth rate. Therefore, informations on the deviation of oxygen from stoichiometry is important to understand their properties.

Activation analysis has been applied to the determination of the oxygen contents in many organic or inorganic compounds.[6-10] However, its application of oxygen analysis to oxide single crystals is quite a few.

In the present paper, the determination of oxygen contents in SnO_2 and Zn_2SnO_4 crystals was carried out by activation analysis.

Experimental

Samples used in this study were SnO_2 (with/without additives), and Zn_2SnO_4 crystals grown at 1300 °C for 2 hours in porcelain crucible by the vapor phase method. The SnO_2 crystals were obtained from the mixture of SnO_2 and Sn powders, and the Zn_2SnO_4 were also from ZnO and Sn powders. SnO_2 powder (chemical reagent) and ZnO_2 powder (special reagent) were used as reference sample. Sample (ca. 0.1 g) and graphite powder (reagent for spectroscopy, ca. 2.7 g) were mixed sufficiently. The pellets (1.25 cm×1 cm) of the mixed sample were sealed in cylindrical polyethylene containers of 1.5 cm×2 cm. The containers containing samples were transferred from the position of the sample charger to the target area with a pneumatic tube. Samples in the containers were bombarded with 14 MeV neutron with 5×10^9 n s^{-1} of neutron intensity for 30 second at target area. After being bombarded, the containers were transferred to a 4.44 cm×5 cm sodium iodide well-type detector with a pneumatic tube to measure the 6.13 MeV γ-ray from 7.35 sec-halflife ^{16}N produced by the reaction of $^{16}O(n,p)^{16}N$. A neutron generator (by Toshiba Co. Ltd) accelerates deuterium ion to generate 14 MeV neutron by the $^3T(d,n)^4He$ reaction: $^3_1T+^2_1d\rightarrow^4_2He+^1_0n+17.59$ (MeV). As a standard sample for calibration, sucrose (guaranteed reagent) was used. The calibration curve on the basis of sucrose-graphite standard sample shows a good linearity in the range of 0 mg to 26.0 mg of oxygen.

Results and Discussion

Table 1 shows the average values on measurements of 3 to 4 times. The values of SnO_2 powder and ZrO_2 powder as reference samples show close agreement with their theoretical values. The values of undoped, antimony-doped and chromium-doped SnO_2 crystals were of the same value, 20.9%. There are no significant differences between the theoretical and the measured values within experimental errors. The oxygen contents is nearly theoretical value. On the other hand, that of vanadium-doped SnO_2 crystals showed clearly a smaller value, 19.9%, than the three others. The density of V-doped crystals was between 5.4 and 5.8. The values were smaller than 6.15 for undoped SnO_2 crystals and 6.12—6.29 for Sb-doped crystals grown at the same vapor phase method. The electrical resistivitiy of the crystals along the growth direction of an a-axis showed semiconductivity at temperatures from 150° to 400 °C. Accordingly, the semiconductive property of V-doped SnO_2 crystals will be due to oxygen defect.[2]

In regards to Zn_2SnO_4 crystals grown under the same conditions, dendrite crystals grown in the initial stage of reaction contain somewhat lower oxygen (19.3%) than that (19.6%) of needle crystals grown in the latter stage of reaction. Both Zn_2SnO_4 crystals showed a lower oxygen content than the theoretical value (20.4%). The electrical resistivity of the needle crystals along growth direction was about 10^3—10^4 ohm cm at room temperature.

On a survey of analytical results, the values of oxygen contents in the vanadium-doped SnO_2 and Zn_2SnO_4 crystals were somewhat smaller than the theoretical values, though antimony-doped and

Table 1. Oxygen Content in SnO_2 and Zn_2SnO_4 Crystals by 14 MeV Newtron Activation Analysis

Crystals	Radiated sample Irradiated /mg	Oxygen content %	Theoretical value/%
SnO_2 powder	80.7	21.0	21.2
ZrO_2 powder	82.6	26.1	26.0
SnO_2	83.7	20.9	21.2
Sb-doped SnO_2	93.9	20.9	21.2
V-doped SnO_2	95.7	19.9	21.2
Cr-doped SnO_2	87.4	20.9	21.2
Zn_2SnO_4(needle)	87.1	19.6	20.4
Zn_2SnO_4(dendrite)	89.8	19.3	20.4

chromium-doped ones had nearly theoretical value. Accordingly, the crystals with low oxygen contents used in the present experiments will have an oxygen deficiency leading to semiconductivity.

Tautomeric Equilibrium of Salicylidene Schiff Base. UV-Visible Absorption and Raman Spectroscopic Studies

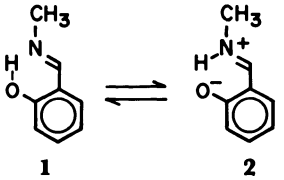
Ho-hi LEE and Teizo KITAGAWA*
Institute for Molecular Science, Okazaki National Research Institutes, Okazaki 444
(Received February 24, 1986)

Synopsis. The solvent effect and temperature dependence on the Raman and absorption spectra demonstrated the existence of a tautomeric equilibrium for the title compound between the enol form and the protonated Schiff base form in methanol; the latter form is more stable by ca. 850 cal mol^{-1}(1 cal=4.184 J) than the former. Characteristic Raman bands for the two tautomers have been identified.

An intramolecular proton transfer has been considered to be a major factor for controlling the activity of some biological molecules.[1] Aspartate aminotransferase, having a pyridoxal Schiff base as a cofactor, is an example for which the enzymic activity has been associated with the protonation state of the cofactor,[2] although the detailed mechanism has not yet been established. Salicylidene Schiff bases are expected to serve as a good model for the active site of the pyridoxal enzyme. Previous IR and UV-visible absorption studies[3-5] suggested that the Schiff base exists as a tautomeric mixture in a polar solvent; however there has been no firm spectroscopic evidence for this idea. Accordingly, in this study, the UV-visible and Raman spectra were investigated for the simplest Schiff base of this class, namely, *N*-salicylidene methylamine (SAL-MA) and *N*-(*o*-methoxybenzylidene)methylamine (ANIS-MA) (Fig. 1), in which the vibrational contribution from the amine moiety is minimized. SAL-MA has a proton that can be transferred whereas ANIS-MA does not. Thus, ANIS-MA can serve as a model of tautomer **1** in Fig. 1.

Experimental

SAL-MA and ANIS-MA were synthesized by a direct condensation of salicylaldehyde or *o*-anisaldehyde with methylamine in alkaline methanol (MeOH), respectively. The absorption spectra were recorded on a Hitachi 220S spectrometer. For Raman measurements, the off-resonance condition was chosen so that Raman signals from both tautomers could be observed simultaneously. The 514.5 nm line of an Ar^+ ion laser (NEC GLG3200) was used for the excitation. Excitation at shorter wavelengths brought about an intense fluorescence which hindered us from measuring the resonance Raman spectrum of each tautomer. Raman spectra were recorded on a JEOL-400D Raman spectrometer equipped with a cooled RCA-31034a photomultiplier. Low-temperature measurements for absorption and Raman spectra were carried out in a specially designed glass Dewar. A quartz cell with a 1-mm path length was placed inside the Dewar and cooled with cold ethanol. The temperature of the sample was monitored by a thermocouple attached to the sample cell.



1 2

Fig. 1. Tautomeric structures of SAL-MA. For ANIS-MA the OH group is replaced by the OCH_3 group in **1**.

Results and Discussion

The UV-visible absorption spectrum of SAL-MA in pure MeOH is shown in the inset of Fig. 2. Two bands were observed around 300 and 400 nm. For convenience, the bands at 300 and 400 nm are designated as Band A and B, respectively. When the solvent was changed from pure MeOH to pure $CHCl_3$, the 400-nm band disappeared and in a mixed solvent of MeOH/$CHCl_3$ SAL-MA gave an intermediate spectrum (not shown). On the other hand, ANIS-MA gave a single peak near 300 nm both in MeOH and $CHCl_3$. As the temperature was lowered, the relative intensity of Band B to Band A for SAL-MA increased. Isosbestic points were obtained at 283, 338, and 435 nm. The solvent effect and the temperature dependence suggest that there are two species in a MeOH solution of SAL-MA; one absorbs light at 300 nm and the other at 400 nm. The latter species should have a more polar structure than the former. In Fig. 2 the logarithm of the ratio of the peak intensities are plotted against the reciprocal absolute temperature. A fairly good straight line was obtained; its slope indicates that the species giving rise to Band B is more stable than the other by ca. 850 cal mol^{-1}. This is comparable to the value for *N*-(2-hydroxy-1-naphthylmethylene) aniline reported by Dudek.[6]

Figure 3 shows the temperature dependence and solvent effect on the Raman spectra of SAL-MA,

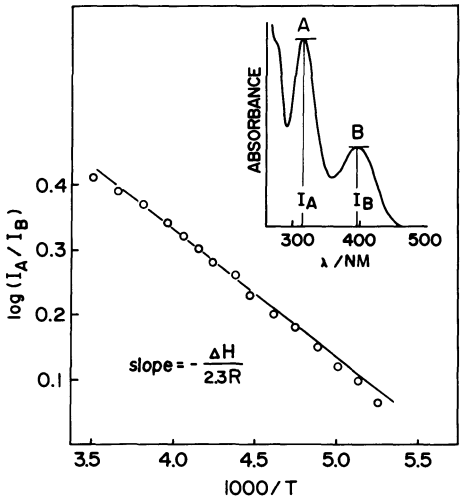


Fig. 2. Plot of the logarithm of the ratio of peak intensities versus the reciprocal absolute temperature. The inset is UV-visible absorption spectrum of SAL-MA in MeOH at 295 K.

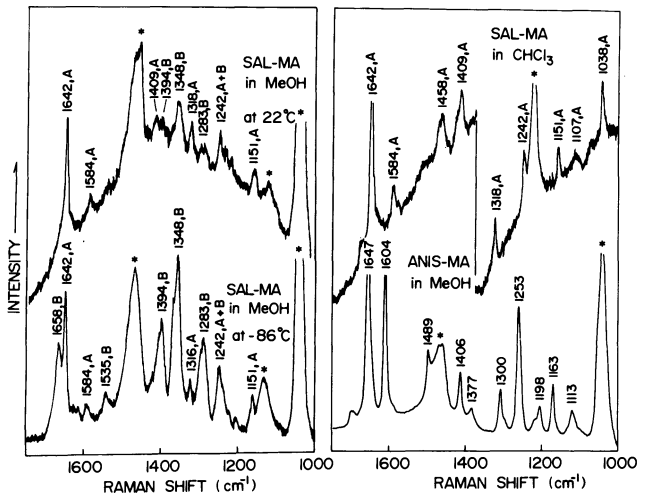

Fig. 3. Raman spectra of SAL-MA and ANIS-MA. left panel; Raman spectra of SAL-MA in MeOH at 22 °C (top) and at −86 °C (bottom), right panel; Raman spectra of SAL-MA in $CHCl_3$ (top) and ANIS-MA in MeOH (bottom) at room temperature. Excitation 514.5 nm, 150 mW, spectral slit-width 5 cm^{-1}. Solvent peaks are denoted by asterisks.

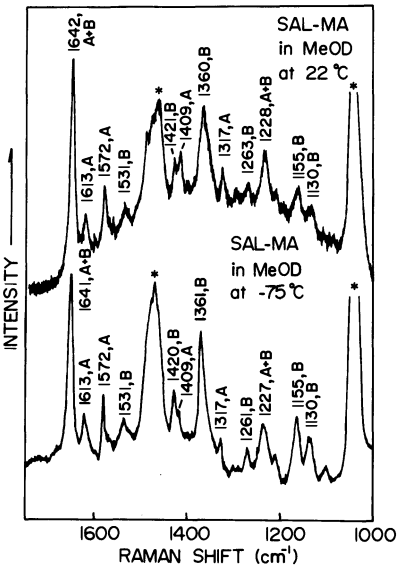

Fig. 4. Temperature dependence of Raman spectra of SAL-MA in MeOD. Excitation 514.5 nm, 100 mW, spectral slit-width 5 cm^{-1}.
Solvent peaks are denoted by asterisks.
The 1228 cm^{-1} and 1155 cm^{-1} bands contain marginal intensity contributions from the solvent.

together with the spectrum of ANIS-MA in MeOH. As the temperature of the MeOH solution of SAL-MA is lowered, the intensities of the Raman bands marked by B increase at the expense of intensities of the Raman bands marked by A. Most noticeable are the doublet features around 1650 cm^{-1} which fall in the C=N stretching region. This temperature dependence for Raman bands A and B is comparable with that observed for Bands A and B in the UV-visible absorption spectrum. In $CHCl_3$ SAL-MA shows only Raman bands marked by A. Consequently, it follows that the species yielding Bands A and B in the UV-visible spectra give rise to Raman bands A and B, respectively. It is noteworthy that the Raman spectrum of ANIS-MA is much closer to the Raman spectrum of A than to that of B.

The A bands of SAL-MA at 1642 and 1242 cm^{-1} correspond to the bands of ANIS-MA at 1647 and 1253 cm^{-1}, respectively. In MeOD the 1642 cm^{-1} band remained unshifted but the 1242 cm^{-1} band was shifted to lower frequency by 14 cm^{-1} (as shown in Fig. 4). The spectrum of O-deuterated SAL-MA in $CHCl_3$, which gives exclusively A peaks, showed the unshifted 1642 cm^{-1} band but lacked the 1242 cm^{-1} band, although the lower-frequency side of the 1242 cm^{-1} band was masked by the solvent band. The C-OH stretching mode of phenol shifts from 1252 to 1241 cm^{-1} upon O-deuteration.[7] Therefore, the 1642 and the 1242 cm^{-1} bands can be assigned to the -C=N- and C-OH stretching modes, respectively. The bands of SAL-MA at 1584, 1151, and 1038 cm^{-1} are assigned to the benzene ring modes (ν_{8a}, ν_{9a}, and ν_{18a}, respectively). These results suggest that species A corresponds to the enol form (**1** in Fig. 1). With regard to the Raman spectrum of species B, on the other hand, a comparison of Fig. 3 with Fig. 4 suggests that the 1658 cm^{-1} band undergoes a low-frequency shift by 15 cm^{-1} and the 1283 cm^{-1} band seems to disappear when the solvent is changed from MeOH to MeOD. The former can be assigned to the -C=NH^+-stretching mode because the higher frequency for the -C=NH^+- stretch compared to the -C=N- stretch and the proximity of the -C=ND^+- stretching frequency to the -C=N- one are consistent with the results for retinal Schiff base derivatives.[8] The latter is a candidate for the NH bending mode of the -C=NH^+- group, although the frequency seems to be too low for this mode. The effects of *N*-deuteration on the other B peaks are rather complicated; this prevents us from giving consistent band assignments. However, the data shown here strongly suggest that the B species takes a protonated Schiff base, structure **2**.

In conclusion, clear evidence for the tautomerism of a salicylidene Schiff base between **1** and **2** in Fig. 1 was obtained for the first time from the Raman spectrum; this will help in an interpretation of the resonance Raman spectrum of the pyridoxal enzyme.

The authors are grateful to Mr. Shinji Hashimoto for help with the low-temperature experimental arrangement.

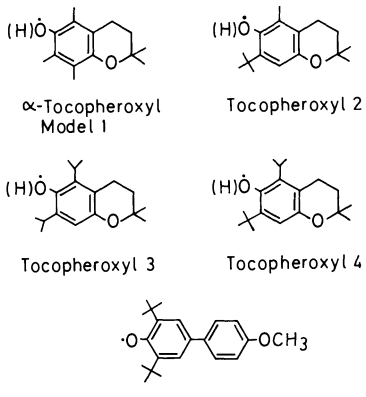
Optical Spectra of Tocopheroxyl Model Radicals

Kazuo MUKAI,* Yoshiko WATANABE, and Kazuhiko ISHIZU
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
(Received March 17, 1986)

Synopsis. Tocopheroxyl model radicals have been prepared by the reaction between tocopherol models and stable phenoxyl radical in ethanol under nitrogen atmosphere. Optical spectra were recorded, and wavelength of absorption peaks (λ_{max}) and molar extinction coefficients (ε) were correctly determined.

The role of vitamin E (α-, β-, γ-, and δ-tocopherols) as an important biological antioxidant has been well recognized in recent years.[1] The antioxidant properties of the tocopherols have been ascribed to the initial oxidation of the phenolic hydroxyl group, producing tocopheroxyl radicals. Therefore, recently, several investigators including present authors have studied the ESR spectra of tocopheroxyl radicals, and determined the proton hyperfine splittings exactly.[2-4] By using pulse radiolysis technique, Packer et al. reported direct evidence for a free radical interaction between vitamin E (α-tocopherol) and vitamin C in vitro.[5] In the work, they observed the transient absorption spectrum of α-tocopheroxyl radical, showing an absorption peak (λ_{max}) at 425 nm. However, the value of molar extinction coefficient (ε) has not been reported, because of a rapid decrease in absorption at 425 nm.

Structure



Recently, we have prepared the tocopherol model compounds **1**, **2**, **3**, and **4** having large alkyl substituents at both ortho positions (C-5 and C-7).[6] The tocopheroxyl radicals produced by the oxidation of the above tocopherols are fairly stable. Therefore, in the present work, we have succeeded in measuring the absorption spectra of the tocopheroxyls **2**, **3**, and **4**, and determined the values of λ_{max} and ε for these tocopheroxyls. However, in the case of α-tocopheroxyl model **1**, the radical is unstable, and thus we could only determine the wavelengths of absorption peaks.

Experimental

The preparation of tocopherol model compounds was reported in a previous paper.[6]

The 2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl (abbreviated to phenoxyl **5** hereafter) was prepared according to the method of Müller et al.[7] Radical concentration of **5** was obtained from the results of the paramagnetic susceptibility measurements at 20 °C, after correcting for the diamagnetic contribution ($\chi_{dia}=-0.220\times10^{-3}$ emu mol^{-1}) calculated by the Pascal's method. The value was 100% for **5** assuming the Curie law.

Tocopheroxyl radicals **1**, **2**, **3**, and **4** have been prepared by the reaction between stable phenoxyl radical **5** and corresponding tocopherols in ethanol at 23 °C under nitrogen atmosphere.

The visible spectra were recorded with a Hitachi EPS-3T spectrophotometer.

Results and Discussion

The phenoxyl radical **5** is very stable in the absence of tocopherol, and shows absorption peaks at λ_{max}=376 nm (ε=17600) and 580 nm (ε=4280). Phenol precursor of **5** and tocopherol model **4** show absorption peaks at λ_{max}=267 nm (ε=19500) and λ_{max}=295 nm (ε=3610), respectively, in ethanol: no absorptions were observed in the visible absorption region. By adding the ethanol solution of tocopherol **4** (6.0×10^{-4} M) to the solution of phenoxyl **5** (4.0×10^{-4}M)(1:1 in volume) at 23 °C, the absorption spectrum of phenoxyl **5** immediately changed to that of tocopheroxyl **4** (see Fig. 1). Here, new absorptions at visible region (λ_{max}=341, 400, and 419 nm) are due to tocopheroxyl **4**, and the weak absorption at 580 nm is due to remaining phenoxyl **5** (5.0%). The tocopheroxyl **4** is considerably stable at 23 °C, and the absorption intensity only gradually decreases with time. There-

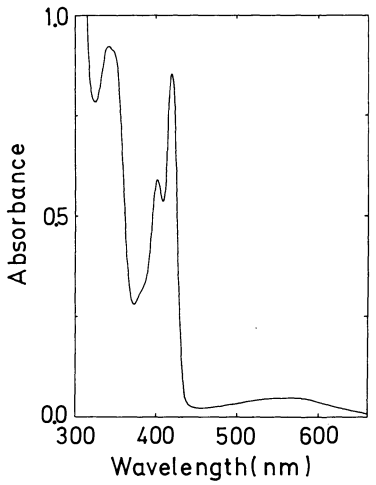


Fig. 1. Absorption spectrum of tocopheroxyl **4** in ethanol.
The weak absorption at 580 nm and the shoulder at 376 nm are due to remaining phenoxyl **5** (5.0%).

Table 1. Absorption Peaks (λ_{max}) and Molar Extinction Coefficients (ε) of Tocopheroxyl Radicals **1**, **2**, **3**, and **4** in Ethanol

1	λ_{max} (nm)	340	405	427
	ε (M^{-1} cm^{-1})	—	—	—
2	λ_{max}	338	398	419
	ε	3720	2390	3910
3	λ_{max}	338	401	420
	ε	4100	2490	4010
4	λ_{max}	341	400	419
	ε	3990	2510	3990

fore, the molar extinction coefficients are calculated to be ε=3990 M^{-1} cm^{-1} at 341 nm, ε=2510 M^{-1} cm^{-1} at 400 nm, and ε=3990 M^{-1} cm^{-1} at 419 nm for tocopheroxyl **4**, after correcting for the remaining phenoxyl **5** (5.0%). Similarly, tocopherols **1**, **2**, and **3** were reacted with phenoxyl **5**, and the optical spectra of tocopheroxyls **1**, **2**, and **3** were observed. The remaining phenoxyl radical **5** was 4.4% for **1**, 9.5% for **2**, and 11.9% for 3. The values of λ_{max} and ε obtained are listed in Table 1. However, in the case of α-tocopherol model **1**, the tocopheroxyl radical **1** produced is unstable, and absorption decreases rapidly with time.[6] Therefore, the value of ε cannot be determined.

As it is clear from the results listed in Table 1, the values of λ_{max} in tocopheroxyls **1**, **2**, **3**, and **4** are similar to each other as expected. Further, the values of ε obtained for tocopheroxyls **2**, **3**, and **4** are very similar to each other at three absorption peaks, where the difference in the ε value is 9% at most. The result suggests that the ε value of α-tocopheroxyl model is also similar to those of tocopheroxyls **2**, **3**, and **4**. As described in a previous section, Packer et al. have observed the absorption peak at 425 nm in water-2-propanol-acetone mixtures. In the present work, we have observed three absorption peaks (340, 405, and 427 nm) at visible region for α-tocopherol model **1**. The value of λ_{max} at the longest wavelength (427 nm) in α-tocopheroxyl model shows good accordance with that (425 nm) of α-tocopheroxyl reported by Packer et al.

We are very grateful to Miss Kimiko Takamatsu, Miss Ayako Ono, and Mr. Yuichi Uemoto for their help in the preparation of tocopherols.

Selective Allylation of Sodium Naphtholate

Shigetoshi YAMADA,* Toru TAKESHITA,† and Juntaro TANAKA
Department of Industrial Chemistry, Junior College of Technology, Shizuoka University, Hamamatsu 432
†Teijin Institute for Biomedical Reserch, Hino, Tokyo 191
(Received March 19, 1986)

Synopsis. The reaction of 1- or 2-naphthol with allylic halides (1-chloro-3-methyl-2-butene, 1-chloro-3,7-dimethyl-2,6-octadiene, *trans*-1-chloro-2-butene and *trans*-1-chloro-2-hexene) in the presence of metallic sodium gave naphthols having the corresponding allylic group selectively.

1,4-Naphthoquinones and 1,4-naphthalenediols which have polyprenyl units as side chains are widely distributed from bacteria to higher plants and animals, and many of these compounds are known as biological active compounds.[1]

In previous papers,[2-4] we described that the reaction of phenols with allylic halides in the presence of alkali metals gave ortho-allylated phenols in high yields. This procedure was considered to be applicable to the synthesis of the naturally occurring compounds. Therefore, we now wish to report the allylation of 1- or 2-naphtholate which gives 2- or 1-allylic naphthol selectively.

Table 1. The Effects of Alkali Metals

Metals	Convn. %	Product/%			Unknown
		3	**5**	**6**	
Li	73	63	12	4	21
Na	96	82	3	2	13
K	88	77	6	4	13

In regard to C-allylation of naphthols, Sharma et al.[5] have reported that the naphthols were treated with isoprene and iodotrimethylsilane in acetonitrile to give C-allylated naphthols. Whiting et al.[6] also have reported that 1-(3-methyl-2-butenyl)-2-naphthol was prepared from the (phenylthio)naphtho[2,1-*b*]pyran derivative. However, the yields of allylic naphthols in each cases were quite poor.

By contrast, when this reaction actually was attempted with our method, C-allylated compounds were obtained in good yields. In the reaction of 1-(**1**) or 2-naphthol (**2**) with 1-chloro-3-methyl-2-butene in the presence of metallic sodium, 2-(3-methyl-2-butenyl)-1-naphthol (**3**) or 1-(3-methyl-2-butenyl)-2-naphthol (**4**) was obtained in a yield of 82% or 86%, respectively. As the minor products, 1-naphthyl 3-methyl-2-butenyl ether (**5**), 2,2-dimethyl-3,4-dihydro-2*H*-naphtho[1,2-*b*]pyran (**6**), 2-naphthyl 3-methyl-2-butenyl ether (**7**) and 3,3-dimethyl-1,2-dihydro-3*H*-naphtho[2,1-*b*]pyran (**8**) were found in very poor yields, respectively.

The effect of the alkali metals in this reaction is shown in Table 1.[7] From this result, it was found that the metallic sodium was useful for obtaining selectively naphthols having 3-methyl-2-butenyl group.

In a same manner as above, the reaction of

Experimental

The following procedure is the typical experimental conditions used in the reaction of naphthols with allylic halides in the presence of metallic sodium.

The reaction of 1-naphthol with 1-chloro-3-methyl-2-butene. To an ethereal solution (15 ml) of 1-naphthol (2.88 g, 0.02 mol), metallic sodium (0.46 g, 0.02 g atom) was added. After the mixture was stirred for 1 h, 1-chloro-3-methyl-2-butene (2.09 g, 0.02 mol) was added slowly and the mixture was refluxed for 30 min. Then, the solution was acidified with 0.1 mol dm^{-3} aq HCl and extracted with ether. The ethereal solution was treated with 10% aq NaOH to remove the unreacted naphthol, and washed with Claisen's alkali. The Claisen's alkali phase was acidified with 1 mol dm^{-3} aq HCl and extracted with ether, and the ether layer was washed with water and dried over anhydrous sodium sulfate. After the removal of the solvent by distillation under reduced pressure, 2-(3-methyl-2-butenyl)-1-naphthol (**3**) was obtained in the yield of 82%. In order to identify the minor products, the ether layer, which was washed with Claisen's alkali as described above, was chromatographed over alumina. The alumina column was eluted with hexane and 1-naphthyl 3-methyl-2-butenyl ether (**5**) and 2,2-dimethyl-3,4-dihydro-2*H*-naphtho[1,2-*b*]pyran (**6**) were obtained in 3 and 2% yields, respectively. The structures of these products were identified by means of the IR, ^1H NMR and elemental analysis (Table 2).

7) The reaction was carried out under conditions described below: (**1**) (0.02 mol), 1-chloro-3-methyl-2-butene (0.02 mol), alkali metal (0.02 g atom), ether (15 ml), reflux, reaction time 30 min.

8) It was found that these compounds (**9**—**13**) are composed of approximately 90—93% of E-type configuration by means of HPLC. HPLC was performed with a JASCO BIP-I instrument equipped with a UV detector (250 nm) using a Finepak SIL reversed-phase column (4.6 mm×25 cm) and methanol/H_2O (17/4) as an eluent at a flow speed of 1.0 ml min^{-1}.

Thermal Isomerization Equilibrium between 2′-Hydroxychalcones and Flavanones

Yukio HOSHINO* and Noboru TAKENO†
Department of Natural Science, Muroran Institute of Technology, Mizumoto-cho, Muroran 050
†Department of Industrial Chemistry, Muroran Institute of Technology, Mizumoto-cho, Muroran 050
(Received March 19, 1986)

Synopsis. Nine substituted 2′-hydroxychalcones and the corresponding flavanones were heated separately at 230±0.2 °C in nitrogen atmosphere. Both materials were mutually isomerized under these reaction conditions and the equilibrium constants of this isomerization were measured by means of HPLC analyses. The substituent effect on the equilibrium is discussed and thermodynamic functions (ΔG, ΔH, and ΔS) are calculated.

2′-Hydroxychalcones (**1**) and flavanones (**2**) constitute an important class of naturally occuring pharmacological compounds[1] and are intermediates in the biosynthesis of flavonoids.[2] Both materials are the structual isomers of each other; the isomerization of 2′-hydroxychalcones results in the corresponding flavanones and is usually effected under the influence of mineral acids and enzymes.[3] Kinetic studies on the isomerization equilibrium between **1** and **2** in an aqueous alkali and in an alkaline methanolic medium have also been reported.[4]

In the related work on flavonoids, we discovered the fact that **1** and **2** are mutually isomerized (partially) in a column (TENAX-GC) of gas chromatography at 285 °C. We now report on experimental results concerning the thermal isomerization equilibrium between **1** and **2** in a none-solvent environment at temperatures above those melting points.

Table 1. Equilibrium Constants of the Thermal Isomerization between 2′-Hydroxychalcones and Flavanones

Compd 1, 2	K[a]	Temp °C

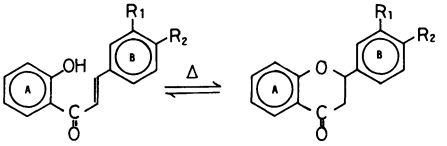
d	0.943	
e	1.05	
f	1.47	
g	1.40	
h	1.55	
i	1.69	

a) $K=C_f/C_c$, where C_c and C_f are the concentrations of 2′-hydroxychalcones and flavanones, respectively.



a $R_1=R_2=H$ **b** $R_1=H$, $R_2=OCH_3$ **c** $R_1=H$, $R_2=CH_3$ **d** $R_1=H$, $R_2=CH(CH_3)_2$ **e** $R_1=CH_3$, $R_2=H$ **f** $R_1=H$, $R_2=Cl$ **g** $R_1=H$, $R_2=Br$ **h** $R_1=Cl$, $R_2=H$ **i** $R_1=Br$, $R_2=H$

When 2′-hydroxychalcone (**1a**) and flavanone (**2a**) were heated separately at 230±0.2 °C, both materials mutually isomerized. These equilibria were attained in about 5 h. The equilibrium constants were measured as the concentration ratio of **2a** to **1a** by means of an HPLC analysis using the calibration method of the peak area ratio vs. the concentration ratio. The attainment of equilibrium was confirmed by an agreement of both equilibrium constants within the experimental error.

Under the same reaction conditions and using the same analytical procedures, 3 or 4-substituted chalcones (**1b—i**) and the corresponding flavanones (**2b—i**) were examined. The results are summarized in Table 1. In all cases, no material was detected outside of the chalcones and the flavanones. Nitro derivatives of **1** and **2** could not be correctly examined because of considerable resinification or the carbonization.

Although extreme equilibrium shifts due to the introduction of substituents were not observed, Table 1 shows that the equilibrium constant decreased due to the electron-donating group on the B-ring; this increased as a result of the electron-withdrawing group. These results gave an excellent Hammett-type linear free energy relationship using Brawn-

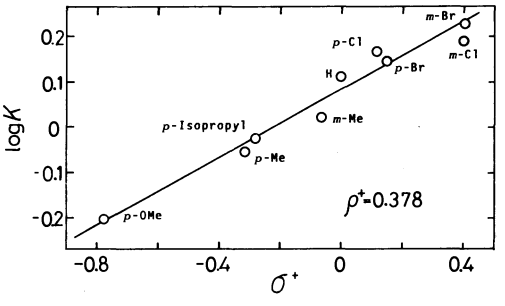


Fig. 1. Hammett plots for the thermal isomerization equilibrium between 2′-hydroxychalcones and flavanones.

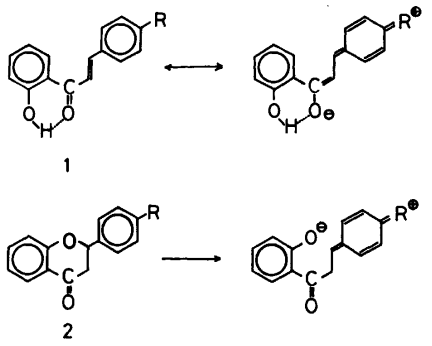

Scheme 1.

Okamoto's σ^+ constant (r=0.996, Fig. 1). In the liquid state, **1** seem to have a strong intramolecular hydrogen bond and the electron-donating groups on the para-position in the B-ring tend to strengthen it further by resonance (Scheme 1). Thus those groups can prevent the cyclization of **1** into **2**; this can result in a decrease in the equilibrium constant, i.e., the advantage of **1**. On the other hand, the above-mentioned substituents can facilitate a bond cleavage between the oxygen atom of heterocycle and C_2-carbon atom in the case of the conversion of **2** into **1** as shown in Scheme 1, and also bring about a similar effect regarding equilibrium.

In order to obtain the thermodynamic parameters, the equilibrium constants at several temperatures were measured regarding the interconversion of **1a** and **2a**. The obtained results are also shown in Table 1. These results show that the equilibrium shifts to **1a** as the temperature rises. **1a** might be more stable than **2a** at high temperatures. According to Eq. 1, the thermodynamic parameters (ΔG, ΔH, and ΔS) for this equilibrium condition were calculated on the basis of a plot

$$RT \ln K = -\Delta G = -\Delta H + T\Delta S \quad (1)$$

of $\ln K$ vs. $1/T$ (Fig. 2). The following values were obtained: $\Delta G^{503}=-1.07$ (kJ mol^{-1}), $\Delta H=-8.78$ (kJ mol^{-1}) and $\Delta S=-15.5\pm0.2$ (J mol^{-1} K^{-1}). The negative value of ΔS might be due to a decrease in the degree of freedom owing to cyclization. From the value of ΔH, it is clear that the conversion of **1a** into **2a** is an exothermic reaction.

Experimental

Materials. Chalcones and flavanones were prepared according to the known procedures;[5] related physical data have already been reported,[6] except for the following derivatives. Melting points are uncorrected.

4-Methyl-2′-hydroxychalcone (1c): Mp 120.0—121.5 °C; ^{1}H NMR (CCl_4) δ=2.36 (3H, s, 4-CH_3), 6.70—7.88 (10H, m, Olefin and Aromatic), 12.66 (1H, s, 2′-OH). Found: C, 80.73; H, 5.75%. Calcd for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92%.

4-Isopropyl-2′-hydroxychalcone (1d): Mp 74—75 °C; ^{1}H NMR (CCl_4) δ=1.26 (6H, d, $CH(\underline{CH_3})_2$, J=6.5 Hz), 2.91 (1H, septet, $\underline{CH}(CH_3)_2$, J=6.5 Hz), 6.72—7.92 (10H, m, Olefin and Aromatic), 12.65 (1H, s, 2′-OH). Found: C, 81.11; H, 6.71%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

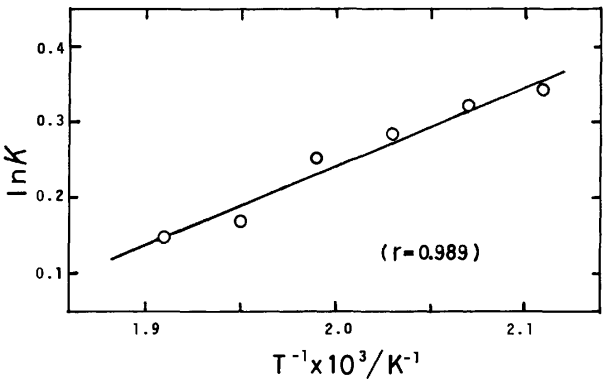

Fig. 2. Temperature dependence of the equilibrium constants of the thermal isomerization.

4-Bromo-2′-hydroxychalcone (1g): Mp 146—147 °C; ^{1}H NMR ($CDCl_3$) δ=6.82—7.92 (10H, m, Olefin and Aromatic), 12.68, (1H, s, 2′-OH). Found: C, 59.42, H, 3.64, Br, 26.30%. Calcd for $C_{15}H_{11}O_2Br$: C, 59.43, H, 3.66, Br, 26.36%.

3-Chloro-2′-hydroxychalcone (1h): Mp 104—105 °C; ^{1}H NMR (CCl_4) δ=6.75—7.86 (10H, m, Olefin and Aromatic), 12.49 (1H, s, 2′-OH). Found: C, 69.46, H, 4.15, Cl, 13.65%. Calcd for $C_{15}H_{11}O_2Cl$: C, 69.64, H, 4.29, Cl, 13.70%.

3-Bromo-2′-hydroxychalcone (1i): Mp 104—106 °C; ^{1}H NMR (CCl_4) δ=6.73—7.86 (10H, m, Olefin and Aromatic), 12.46 (1H, s, 2′-OH). Found: C, 59.20, H, 3.59, Br, 26.25%. Calcd for $C_{15}H_{11}O_2Br$: C, 59.43, H, 3.66, Br, 26.36%.

4′-Isopropylflavanone (2d): Mp 76—77 °C; ^{1}H NMR (CCl_4) δ=1.27 (6H, d, $CH(\underline{CH_3})_2$, J=9.0 Hz), 2.64—3.14 (3H, m, $\underline{CH}(CH_3)_2$ and C_3-H_{ax}, H_{eq}), 5.37 (1H, d·d, C_2-H_{ax}, $J_{ax\cdot ax}$=12.5 Hz, $J_{ax\cdot eq}$=5.0 Hz), 6.88—7.49 (7H, m, Aromatic), 7.85 (1H, d·d, C_5-H, J_{ortho}=8.5 Hz, J_{meta}=2.0 Hz). Found: C, 81.10, H, 6.70%. Calcd for $C_{18}H_{18}O_2$: C, 81.17, H, 6.81%.

General Procedure. In two test tubes (15 mmϕ×105 mm), ca. 0.1 g of **1a** and **2a** were placed separately, and the air in the tubes was displaced with nitrogen to avoid any resinification or carbonization. Then, these tubes were tightly sealded with Uni-stoppers and were dipped in a silicone oil bath adjusted to 230±0.2 °C. After about 5 h, the reaction mixtures were rapidly cooled at room temperature and solved in chloroform (50 ml). Then, the equilibrium constants were determined by an HPLC analysis using instruments by Yanagimoto High Speed Liquid Chromatograph L-2000.

NAD(P)$^+$-NAD(P)H Models. 59. 1,2- Versus 1,4-Reduction of β,γ-Unsaturated α-Keto Ester

Atsuyoshi OHNO,* Tsuneo YASUMA, Kaoru NAKAMURA, and Shinzaburo OKA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received March 29, 1986)

Synopsis. Depending on the reactivity of the reducing agent, β,γ-unsaturated α-keto ester is reduced into either β,γ-unsaturated α-hydroxy ester or saturated α-keto ester as the result of 1,2- or 1,4-reduction.

It has been reported that the asymmetric reduction by a chiral NAD(P)H model, *N*-(α-methylbenzyl)-1-propyl-2,4-dimethyl-1,4-dihydronicotinamide (Me_2-PNPH), is a useful tool in obtaining a chiral alcohol as a building block of natural products and many other bio-active compounds.[1] Namely, the reduction of α-keto esters results in excellent enantio-specificity. In order to extend the scope of this interesting asymmetric reduction, we further studied the reduction of α-keto esters that have various functional groups.

Table 1. Reduction of β,γ-Unsaturated and Other α-Keto Esters with 4*R*, 9*R*-Me_2PNPH

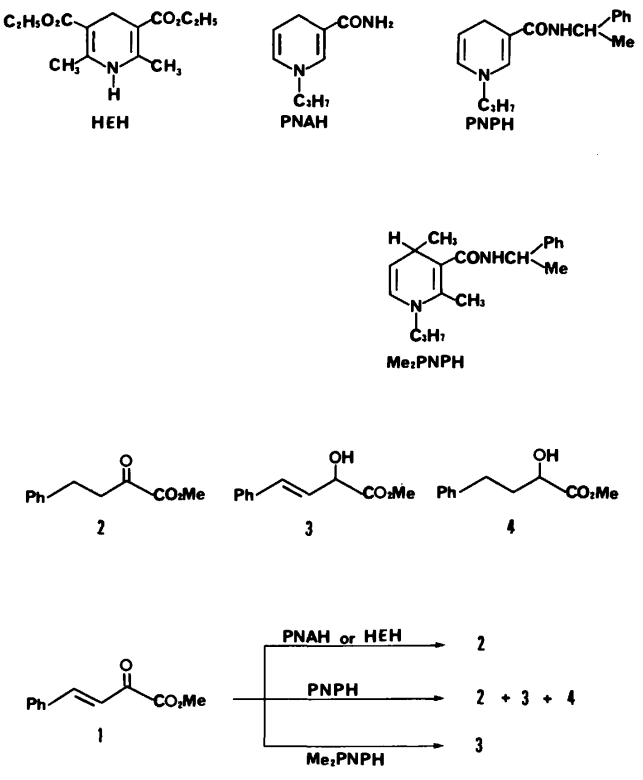
When the absolute configurations of the products are known, they are indicated on the structures. c) Not observed. d) Isolation yield. e) Yield measured on VPC.

Results and Discussion

The results are summarized in Table 1, which apparently shows that the presence of various functional groups in the substrate does not interfere the reduction both in chemical yield and in enantio-specificity.

Among these, the reduction of methyl (*E*)-2-oxo-4-phenyl-3-butenoate (**1**) is especially interesting. The reduction of this keto ester with 1-propyl-1,4-dihydronicotinamide (PNAH) or with the Hantzsch ester (HEH) was recently studied by Meijer and Pandit[2] and it was reported that the sole product was the corresponding saturated α-keto ester (**2**) as a result of the 1,4-reduction. Since Me_2PNPH is more reactive reducing agent than PNAH due to electron-releasing substituents, two methyl groups on the 1,4-dihydropyridine ring and an α-methylbenzyl group on the amide nitrogen, the difference in the product seems to stem from the difference in reactivity of these reagents. Therefore, we also studied the reduction with *N*-(α-methylbenzyl)-1-propyl-1,4-dihydronicotinamide (PNPH), which is expected to have medium reactivity and found that the reaction affords **2**, methyl (*E*)-2-hydroxy-4-phenyl-3-butenoate (**3**) and methyl 2-



Scheme 1.

hydroxy-4-phenylbutanoate (**4**) in 14, 14, and 7% yields, respectively (Scheme 1). Since it is known that PNPH has no ability to reduce an α-hydroxy olefin, there remains no doubt that **4** is the reduction product from **2**.

The origin of the reactivity-selectivity relationship is not known at present. However, the present result seems to support our prvious proposal that the reduction is composed of succesive transfers of an electron, a proton, and an electron: The reactivity of the reducing agent is defined by its ability for the initial electron transfer. When the activation energy for this process becomes small, the activation energy for the proton-transfer process overwhelms the former and the reaction becomes to appear as if it proceeded with the transfer of a hydrogen atom or a hydride.[3,4] Since the transfer of an electron is the orbital-controlled process, the reaction takes place at the soft reaction center, the olefinic carbon, to result in the 1,4-reduction, whereas the hydride-like species prefers to attack harder reaction center, the carbonyl-carbon, through the charge-density-controlled reaction to result in the 1,2-reduction.

Experimental

Materials. General procedures for the preparation of the 1,4-dihydronicotinamide derivatives were described in the previous papers.[1,3]

Methyl 2-oxo-4-phenyl-3-butenoate[2,5] and methyl 2-oxo-3,5,7-nonatrienoate[6] were respectively prepared according to the literature procedures. Methyl 2-oxo-4-phenylbutanoate, methyl 2-oxo-2-(2-thienyl)acetate, and methyl 2-oxo-4-(1,3-dioxolan-2-yl)butanoate were synthesized by the reaction of the corresponding Grignard reagents and dimethyl oxalate in tetrahydrofuran according to the general procedure.[7]

Methyl 2-oxo-4-(methylthio)butanoate was obtained by methylation of 2-oxo-4-(methylthio)butanoic acid, which was prepared from D,L-methionine by oxidation with D-amino acid oxidase.[8] Dimethyl 2-oxoglutalate was obtained by methylation of 2-oxoglutalic acid. *S*-Methyl 2-oxo-2-phenylethane-thioate is a kind gift from Prof. K. Ogura of Chiba University.

Procedure. The reaction was run with 1.1 equivalent amount of PNAH, PNPH, or Me_2PNPH in the presence of 1 equivalent amount of magnesium perchlorate in acetonitrile for appropriate period (about a day) under an argon atmosphere in the dark at room temperature.

Isolation of the reaction products and the method to determine the enantiomer excess by ^{1}H NMR spectroscopy and on VPC were described in the previous papers.[1,3]

Insertion of Benzyne and Substituted Benzynes into the S-S Bond of Diphenyl and Di-*p*-tolyl Disulfides Yielding the Corresponding *o*-Bis(arylthio)benzenes

Juzo NAKAYAMA,* Takayuki TAJIRI, and Masamatsu HOSHINO
Department of Chemistry, Faculty of Science, Saitama University,
Urawa, Saitama 338
(Received April 10, 1986)

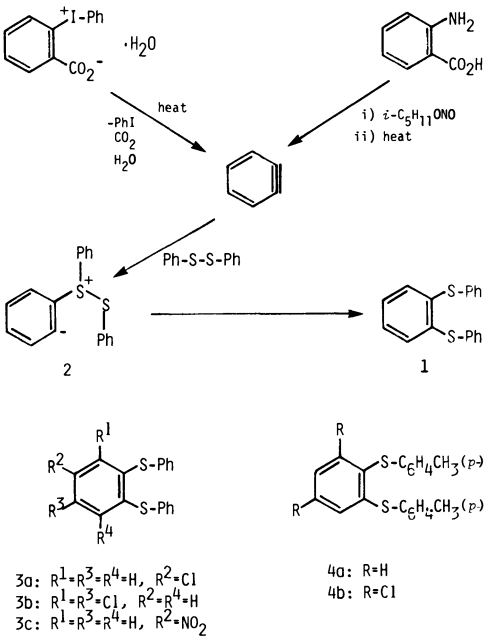
Synopsis. Benzyne and substituted benzynes undergo insertion into the S-S bond of diphenyl and di-*p*-tolyl disulfides to afford the corresponding *o*-bis(arylthio)benzenes in low but reproducible yields.

Petragnani and Toscano reported that benzyne, generated by thermolysis of diphenyliodonium-2-carboxylate monohydrate,[1] inserts into the Se–Se and Te–Te bonds of diphenyl diselenide and bis(*p*-ethoxyphenyl) ditelluride to afford *o*-bis(phenylseleno)- and *o*-bis(*p*-ethoxyphenyltelluro)benzenes, respectively, but it fails to insert into the S–S bond of diphenyl disulfide, the latter being recovered quantitatively.[2] In connection with our continuing study on reactions of benzyne with sulfur compounds, we reexamined the reaction of benzyne with diphenyl disulfide and found that benzyne reacts with diphenyl disulfide to give *o*-bis(phenylthio)benzene in a low but reproducible yield. Herein we report the insertion of benzyne and substituted benzynes into the S–S bond of diphenyl and di-*p*-tolyl disulfides yielding the corresponding *o*-bis(arylthio)benzenes.

First the reaction of benzyne with diphenyl disulfide was reinvestigated under the conditions that were reported by Petragnani and Toscano.[2] Thus 2 equivalents of diphenyliodonium-2-carboxylate monohydrate was heated with diphenyl disulfide in boiling *o*-dichlorobenzene for 0.5 h. The resulting brown mixture was evaporated and the residue was chromatographed on a column of silica gel. Elution with hexane afforded *o*-bis(phenylthio)benzene (**1**) in 8% yield with quantitative recovery of the unreacted diphenyl disulfide. The structure of **1** was established by comparison with the authentic sample prepared by an alternative systhesis.[3]

Next benzyne, generated by aprotic diazotization of anthranilic acid,[4] was allowed to react with diphenyl disulfide. Thus a solution of anthranilic acid in dioxane was added to a gently refluxing solution of isopentyl nitrite and diphenyl disulfide in 1,2-dichloroethane (anthranilic acid:isopentyl nitrite:diphenyl disulfide=2:2.1:1). Workup of the mixture with silica-gel column chromatography afforded the sulfide **1** in 14% yield with quantitative recovery of the unreacted disulfide.

Thus it is clear that, contrary to the previous report,[2] benzyne is able to insert into the S–S bond of diphenyl disulfde. The reaction probably proceeds via the intitial formation of the betaine intermediate (**2**) as depicted below. The initial formation of betaine intermediates by reaction of benzyne with organic sulfides is well-documented.[5]



In order to know more about the generality and chracteristics of the present reaction, reactivities of substituted benzynes toward diphenyl and di-*p*-tolyl disulfides were examined. 4-Chloro-, 3,5-dichloro, and 4-nitrobenzynes were generated by aprotic diazotization of 4-chloro-, 3,5-dichloro-, and 4-nitroanthranilic acids, respectively. These benzynes, produced from 2 equivalents of anthranilic acids, reacted with diphenyl disulfide to afford the sulfides **3a**, **3b**, and **3c** in 25, 19, and 30% yields, respectively. Benzyne and 3,5-dichlorobenzyne reacted with di-*p*-tolyl disulfide to give the sulfides **4a** and **4b** in 17 and 14% yields, respectively.

The present reaction involves the initial electrophilic attack of benzynes on the sulfur atom of the disulfides, and therefore more electrophilic benzynes would be expected to give higher yields of the insertion products. However, the above results do not show such a tendency markedly. This is due to the fact that a competitive side reaction, addition of isopentyl alcohol (produced from isopentyl nitrite) to benzynes yielding isopentyl aryl ethers, occurs to consume benzynes, especially when benzynes are strongly eletrophilic.

In conclusion insertion of benzyne and substituted benzynes into diaryl disulfides generally occurs to yield *o*-bis(arylthio)benzenes in low but reproducible yields.[6]

Experimental

Diphenyliodonium-2-carboxylate monohydrate was purchased from Lancaster Synthesis Ltd. Anthranilic acid and 4-chloro- and 3,5-dichloroanthranilic acids were obtained from Tokyo Kasei Kogyo and 4-nitroanthranilic acid from Aldrich. Column chromatography was carried out on 70—230 mesh Merck silica gel. Isopentyl nitrite was prepared by the literature method.[7]

Reaction of Diphenyl Disulfide with Benzyne Generated from Diphenyliodonium-2-carboxylate Monohydrate. A mixture of 549 mg (2.5 mmol) of diphenyl disulfide and 1.717 g (5 mmol) of diphenyliodonium-2-carboxylate monohydrate in 10 ml of *o*-dichlorobenzene was refluxed for 0.5 h. The resulting brown mixture was evaporated under reduced pressure and the residue was chromatographed on a column of silica gel. Elution with hexane afforded 505 mg (92%) of diphenyl disulfide and then 56 mg (8%) of *o*-bis(phenylthio)benzene (**1**). ^{1}H NMR and IR spectra of **1** agreed with those of the authentic sample prepared by an alternative synthesis.[3]

Reaction of Diphenyl Disulfide with Benzyne Generated by Aprotic Diazotization of Anthranilic Acid. To a gently refluxing mixture of 2.18 g (10 mmol) of diphenyl disulfide and 2.46 g (21 mmol) of isopentyl nitrite in 100 ml of 1,2-dichloroethane was added dropwise a solution of 2.74 g (20 mmol) of anthranilic acid in 10 ml of dioxane over a period of 0.5 h. After the completion of the addition, the mixture was refluxed for 0.5 h and evaporated. The resulting residue was chromatographed on a column of silica gel. Elution with hexane gave 1.86 g (86%) of diphenyl disulfide and then 0.42 g (14%) of *o*-bis(phenylthio)benzene (**1**).

Reaction of Diphenyl Disulfide with 4-Chloro-, 3,5-Dichloro-, and 4-Nitrobenzynes. 4-Chloro-, 3,5-dichloro-, and 4-nitrobenzynes were generated by aprotic diazotization of two equivalents of 4-chloro-, 3,5-dichloro-, and 4-nitroanthranilic acids, respectively, and allowed to react with an equivalent of diphenyl disulfide in a similar manner described above. Chromatographic purification afforded the following new *o*-bis(phenylthio)benzenes.

1,2-Bis(phenylthio)-4-chlorobenzene (3a): Yield, 25%; viscous oil; ^{1}H NMR (CCl_4) δ=6.8—7.0 (3H, m), 7.23 (5H, s), and 7.30 (5H, s). Found: C, 65.73; H, 3.94; Cl, 10.80; S, 19.28%. Calcd for $C_{18}H_{13}ClS_2$: C, 65.74; H, 3.98; Cl, 10.78; S, 19.50%.

1,2-Bis(phenylthio)-3,5-dichlorobenzene (3b): Yield, 19%; mp 87—88 °C; ^{1}H NMR (CCl_4) δ=6.43 (1H, d, J=1.6 Hz), 6.9—7.3 (6H, m), and 7.36 (5H, s). Found: C, 59.37; H, 3.29; Cl, 19.72; S, 17.50%. Calcd for $C_{18}H_{12}Cl_2S_2$: C, 59.51; H, 3.33; Cl, 19.52; S, 17,65%.

1,2-Bis(phenylthio)-4-nitrobenzene (3c): Yield, 30%; yellow viscous oil; ^{1}H NMR (CCl_4) δ=6.70 (1H, d, J=9.0 Hz), 7.23 (5H, s), 7.30 (5H, s), and 7.6—7.9 (2H, m). Found: C, 63.56; H, 3.86; N, 4.22; S, 18.53%. Calcd for $C_{18}H_{13}NO_2S_2$: C, 63.69; H, 3.86; N, 4.13; S, 18.89%.

Reaction of Di-*p*-tolyl Disulfide with Benzyne and 3,5-Dichlorobenzyne. Di-*p*-tolyl disulfide was allowed to react with benzyne and 3,5-dichlorobenzyne generated from 2 equivalents of the corresponding anthranilic acids in a manner described above to give *o*-bis(*p*-tolylthio)benzene (**4a**) and 1,2-bis(*p*-tolylthio)-3,5-dichlorobenzene (**4b**).

4a: Yield, 17%; mp 75.5 °C; ^{1}H NMR (CCl_4) δ=2.32 (6H, s), 6.97 (4H, s), and 7.0—7.5 (8H, m). Found: C, 74.52; H, 5.63; S, 19.88%. Calcd for $C_{20}H_{18}S_2$: C, 74.49; H, 5.63; S, 19.88%.

4b: Yield, 14%; mp 70—72 °C; ^{1}H NMR (CCl_4) δ=2.23 (3H, s), 2.37 (3H, s), 6.43 (1H, d, J=2.0 Hz), and 6.8—7.5 (9H, m). Found: C, 61.42; H, 4.09; Cl, 18.25; S, 16.40%. Calcd for $C_{20}H_{16}Cl_2S_2$: C, 61.38; H, 4.12 Cl, 18.12; S, 16.38%.

Preparation of Some 1,3-Selenazin-4-ones

Masataka YOKOYAMA,* Katsushi KUMATA, Hidekatsu HATANAKA, and Tadashi SHIRAISHI
Department of Chemistry, Faculty of Science, Chiba University,
Yayoi-cho, Chiba 260
(Received April 12, 1986)

Synopsis. 2-Cyano-3-hydroseleno-3-(methylthio)acrylamide reacts with carbonyl compounds in the presence of sulfuric acid and aroyl chlorides in the presence of pyridine to give the corresponding 2,3-dihydro-4*H*-1,3-selenazin-4-ones and 4*H*-1,3-selenazin-4-ones in moderate yields, respectively.

In the chemistry of heterocycles containing selenium and nitrogen atoms, many literatures concerning 1,3-selenazoles have appeared and their features have been well documented.[1] However, only some reports have been published on the synthesis of 4*H*-1,3-selenazines perhaps because of the synthetic difficulty.[2] During the course of studies on heteroatom rearrangements[3] we have fond a convenient preparative procedure for *S*,*S*-dimethyl dithioselenocarbonate (**1**).[4] As is synthetic application it was found that

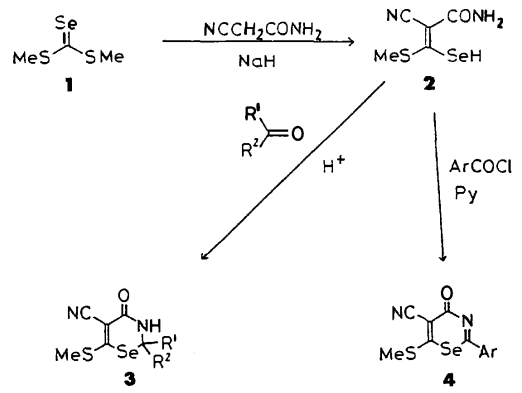
Scheme



3a $R^1=R^2=CH_3$ **4a** Ar=Phenyl
3b $R^1,R^2=-(CH_2)_5-$ **4b** Ar=2-Naphthyl
3c $R^1=n\text{-}C_3H_7$, $R^2=H$ **4c** Ar=*p*-Methoxyphenyl
3d $R^1=C_6H_5$, $R^2=H$ **4d** Ar=*p*-Chlorophenyl
3e $R^1=$Furyl, $R^2=H$ **4e** Ar=3-Pyridyl

several 4*H*-1,3-selenazin-4-ones could be easily synthesized starting from **1**. Herein we wish to report their preparations.

Compound **1** reacted with cyanoacetamide in the presence of sodium hydride under the oxygen-free conditions to give 2-cyano-3-hydroseleno-3-(methylthio)-acrylamide (**2**) (77% yield), which could be kept for two or three weeks in a refrigerator without decomposition. Compound **2** was allowed to react with various carbonyl compounds in the presence of sufuric acid and some aroyl chlorides in the presence of pyridine to afford the corresponding 2,3-dihydro-4*H*-1,3-selenazin-4-ones (**3**) and 4*H*-1,3-selenazin-4-ones (**4**) in moderate yields, respectively (see Table). In this reaction the use of acetophenone, benzophenone, and acyl chlorides did not give a satisfactory result.

Experimental

Microanalyses were performed with a Perkin-Elmer 240 elemental analyser at the Analytical Center of Chiba University. IR spectra were recorded on a Hitachi 215 spectrometer. ^1H NMR spectra were determined with Japan Electron Optics Lab. (JEOL) JNM-FX-270 and MH-100. The chemical shifts are given in ppm with $(CH_3)_4Si$ as an internal standard. Mass spectra were measured on a Hitachi M-60 spectrometer at an ionizing energy at 70 eV. Chloroform and pyridine were purified by standard procedure, and tetrahydrofuran (THF) was distilled from benzophenone ketyl.

2-Cyano-3-hydroxyseleno-3-(methylthio)acrylamide (2): A 100 ml two-necked round flask equipped with a reflux condenser and a Teflon-coated magnetic bar, is dried in vacuo and then flushed with argon. In this flask are placed sodium hydride (60% dispersion, 1.6 g, 40 mmol) and THF (40 ml). To the resulting slurry solution is added cyanoacetamide (0.84 g, 10 mmol). After stirring at room temperature for 20 min, *S,S*-dimethyl dithioselenocarbonate (2.2 g, 12 mmol) solution in THF (10 ml) is added and the mixture is refluxed with stirring for 2.5 h until orange coloration is produced. The reaction is quenched with dropping of a degassed water under ice cooling, and a mixture of benzene (40 ml) and degassed water (40 ml) is added to the resulting solution. After shaking in a separatory funnel flushed with argon, an aqueous layer is transfered to a 100 ml Erlenmeyer flask containing hexane (20 ml). The aqueous solution is acidified with 6M-HCl (1 M=1 mol dm^{-3}) under ice cooling. The obtained material is collected, washed with degassed water (20 ml×2), and dried in a vacuum desiccator; yellow powder of mp 102—104 °C; 1.7 g, yield 77% ; IR (KBr) 3380, 3280, 3200 (s), 2200 (vs), and 1650 cm^{-1} (vs); ^1H NMR ($CDCl_3$) 2.72 (s, 3H, SCH_3), 7.26 (br, 2H, NH_2), and 16.38 (s, 1H, SeH).

Compound **2** thus obtained is used for the following procedures without purification because **2** decomposes to some extent on recrystallization.

5-Cyano-6-methylthio-2-propyl-2,3-dihydro-4*H*-1,3-selenazin-4-one (3c). Typical Procedure: A mixture of **2** (0.44 g, 2 mmol), *n*-butyraldehyde (0.2 g, 3 mmol)[3], 6M-H_2SO_4 (2 ml), and methanol (8 ml) is stirred for 4 h at room temperature. The reaction is quenched with water, thus obtained crystals are collected, and recrystallized from isopropyl alcohol to give **3c** as pale yellow needles; 0.22 g, yield 41%.

5-Cyano-2-(*p*-chlorophenyl)-6-methylthio-4*H*-1,3-selenazin-4-one (4d). Typical Procedure: A mixture of **2** (0.66 g, 3 mmol, *p*-chlorobenzoyl chloride (1.2 g, 7.6 mmol), pyridine (1.6 ml), and chloroform (10 ml) is shaken for 3 h at room temperature. The reaction is quenched with water and then ethanol, the obtained material is collected, dried in a vacuum desiccator; cream-colored powder (recry. from chloroform–hexane); 0.66 g, yield 66%.

Nicotinoyl chloride is prepared according to the literature.[5] The others are prepared from the reaction of the corresponding carboxylic acids with thionyl chloride in the usual way.

The Microwave Spectrum of (*Z*)-(Propionaldehyde Oxime)

Makoto KATAYAMA, Takeshi SAKAIZUMI, Ichiro YAMAGUCHI, and Osamu OHASHI*
Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102
(Received March 28, 1986)

Synopsis. The microwave spectrum of (*Z*)-(propionaldehyde oxime) was observed in the frequency region of 10 to 30 GHz. The rotational constants (MHz) for the ground vibrational state were determined to be A=15453.95±0.20, B=2733.60±0.03, and C=2394.85±0.02. The conformation has been plausibly deduced to be the *ap*, *Z*-form from the rotational constants. The dipole moments were determined by the Stark effect: μ_a=0.889±0.010 and μ_b=0.364±0.025 *D*.

From its rotational spectrum propionic acid has been shown to exist predominantly in *sp*-conformation in which the methyl group eclipses the carbonyl bond and the hydroxyl hydrogen is located between the two oxygen atoms.[1] Nuclear magnetic resonance spectroscopic study[2] of propionaldehyde oxime has suggested that this molecule exists in two stereoisomeric forms, termed *E* and *Z* forms with respect to the C=N bond. Each of the conformers has four possible rotational conformations with respect to the C_2–C_3 single bond if the OH bond is assumed to be at the trans position to the C=N bond just as in acetaldehyde oxime[3,4] and acrylaldehyde oxime,[5,6] as shown in Fig. 1. The microwave spectroscopic study[7] has revealed that (*E*)-(propionaldehyde oxime) exists in an *ac*, *E*-conformation (See Fig. 1).

	sp	sc	ac	ap

Fig. 1. Four possible rotatonal conformers, their calculated rotational constants, and the numbering of carbon atoms of an *ap*, (*Z*) -(propionaldehyde oxime)

Experimental

Propionaldehyde oxime was prepared by the method described elsewhere.[7]

The microwave spectrometer employed was the same one as described elsewhere.[7] The spectrum was observed at room temperature.

Results and Discussion

A survey of the spectrum was made in the frequency region of 19 to 22 GHz in which the J=4—3 transition lines were expected to be observed from the molecular model calculation of the rotational constants.

The six absorption line frequencies of the J=4—3 transtions led to the preliminary rotational constants which were employed to predict the other transition lines. The assignments of the transition lines were made on the basis of their characteristic Stark effects. The frequencies of the transitions assigned to the

	$\mu_c=0$(assumed)		
	$\mu_t=0.961\pm0.019$		

ground vibrational state of (*Z*)-(propionaldehyde oxime) are listed in Table 1.

From comparison between the observed and calculated rotational constants and values of $\Delta I(=I_c-I_a-I_b)$ listed in Table 3 and Fig. 1, it has been reasonably concluded that the conformation of (*Z*)-(propionaldehyde oxime) with respect to the C_2–C_3 bond is an *ap* form in contrast to the *ac* form for (*E*)-(propionaldehyde oxime).[7] Table 4 shows the structural parameters of this molecule used for a model calculation of the rotational constants.

Two satellite lines which could be attributable to vibrationally excited states were observed in the vicinity of the ground state lines. The results of the least squares analysis of data are given in Tables 2 and 3. From the trends of changes in the rotational constants and values of ΔI given in Table 3, these two satellites should be ascribed to one vibrational mode that may be the torsional motion around the C_2–C_3 bond.

The dipole moments were determined by the measurements of the Stark effects of the 3_{13}—2_{12} and 3_{12}—2_{11} transition lines. The electric field in the absorption cell was calibrated with OCS[8] as a standard. The observed and calculated Stark coefficients are given in Table 5 together with the dipole moments experimentally determined.

Table 5 shows that the observed Stark coefficients are in good agreement with the ones calculated from the dipole moments determined by the least squares analysis assuming $\mu_c=0$. The above fact is consistent with that the conformation of (*Z*)-(propionaldehyde oxime) is an *ap*, *Z*-form.

Tris(tellurato)cobaltate(III) and Tris(ethylenediamine)tris(tellurato)-tetracobaltate(III) Complexes[1)]

Yoichi SHIMURA* and Yutaka HOSOKAWA
Department of Chemistry, Faculty of Science, Osaka University,
Toyonaka, Osaka 560
(Received April 24, 1986)

Synopsis. Alkali metal salts of two new telluratocobaltate(III) complexes, $[Co(TeO_6H_4)_3]^{3-}$ and $[Co_4Te_3O_{18}(en)_3]^{6-}$, have been prepared. The latter heteropoly type complex and the related periodate analogue $[Co_4I_3O_{18}(en)_3]^{3-}$ have been optically resolved.

Only a limited number of telluratocobalt(III) complexes have been known such as $[Co(TeO_6H_4)(en)_2]Cl\cdot 3H_2O$[2)] and $K_3[Co(TeO_6H_4)_2(OH)_2]$.[3,4)] We report here two new entries, $K_3[Co(TeO_6H_4)_3]\cdot 2H_2O$ and $Na_3H_3[Co_4Te_3O_{18}(en)_3]\cdot 6H_2O$, of which the former belongs to a trischelate type and the latter to a hexol-like heteropoly type[5)] as seen in Fig. 1.

Experimental

$K_3[Co(TeO_6H_4)_3]\cdot 4H_2O$. To a solution of 0.84 g (3.1 mmol) of *cis*-$K[Co(CO_3)_2(NH_3)_2]\cdot H_2O$[6)] in 20 cm³ of water was added a solution of 2.5 g (11 mmol) of $Te(OH)_6$ in 20 cm³ of water with mechanical stirring. After the evolution of carbon dioxide ceased, a solution of 1.12 g (20 mmol) of potassium hydroxide in 20 cm³ of water was added gradually, and the mixture was stirred for a few hours at about 75 °C. The resulting solution was kept in a refrigerator overnight and filtered to remove a pale green precipitate of unknown nature. The filtrate was kept in a refrigerator for week. Then the dark green product was washed with methanol, ethanol, and acetone, and dried in a desiccator over silica gel. Found: H, 1.80; Co, 6.0; K, 12.4; Te, 40.8%. Calcd for $H_{20}O_{22}CoK_3Te_3$: H, 2.16; Co, 6.3; K, 12.6; Te, 41.1%.

$Na_3H_3[Co_4Te_3O_{18}(en)_3]\cdot 6H_2O$. A solution of 2.3 g (10 mmol) of $Te(OH)_6$ in 15 cm³ of water was added to a mixed solution of 2.6 g (9.4 mmol) of *trans*-$[CoCl_2(NH_3)_2(en)]Cl\cdot H_2O$[7)] and 1.0 g (3.0 mmol) of *cis*-$[Co(NH_3)_4(H_2O)_2](SO_4)_{1.5}\cdot 1.5H_2O$ in 30 cm³ of water. A solution of 2.4 g (60 mmol) of sodium hydroxide in 20 cm³ of water was added gradually to the mixture with mechanical stirring, and the stirring was continued at about 60 °C until the evolution of ammonia ceased. After cooling to room temperature an appropriate amount of ethanol was added gradually and the resulting solution was kept in a refrigerator overnight. The greenish brown product deposited was separated by a centrifuge, recrystallized twice from a 0.001 mol dm⁻³ sodium hydroxide solution by adding a small amount of ethanol, and washed with methanol and acetone several times. Found: C, 5.76; H, 3.54; N, 6.60; Co, 17.6; Te, 29.0%. Calcd for $C_6H_{39}N_6O_{24}Co_4Na_3Te_3$: C, 5.69; H, 3.10; N, 6.63; Co, 18.6; Te, 30.2%.

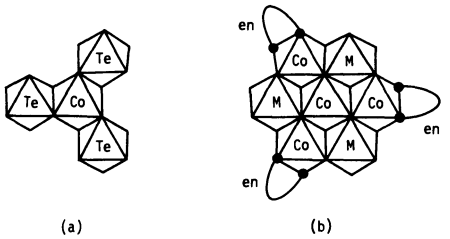

Fig. 1. Schematic structure of (a) Δ-$[Co(TeO_6H_4)_3]^{3-}$ and (b) $\Delta\Lambda'(\Lambda'')_3$-$[Co_4M^{(x)}{}_3O_{18}(en)_3]^{(24-3x)-}$ ($M^{(x)}$= Te^{VI} or I^{VII}). For the notation of absolute configuration, see the text.

$Na_3[Co_4I_3O_{18}(en)_3]\cdot 11H_2O$. This periodate complex was prepared in the same way as for the corresponding tellurate one by using H_5IO_6 instead of $Te(OH)_6$ at 80 °C. Found: C, 5.11; H, 3.26; N, 6.27%. Calcd for $C_6H_{46}N_6O_{29}Co_4I_3Na_3$: C, 5.33; H, 3.43; N, 6.22%. The visible-UV absorption spectrum was identical to that of the known free acid $H_3[Co_4I_3O_{18}(en)_3]\cdot 5H_2O$[8)] which was prepared from $H_3[Co_4I_3O_{18}(H_2O)_6]\cdot 8H_2O$.[8,9)]

Optical Resolution of $[Co_4M^{(x)}{}_3O_{18}(en)_3]^{(24-3x)-}$ ($M^{(x)}$=Te^{VI} and I^{VII}). A solution of 0.02 g of the resolving agent Λ-$(+)_{589}$-$[Co(en)_3]Br_3\cdot H_2O$ in 30 cm³ of water was added by portions with vigorous stirring to a solution of 0.1 g of $Na_3H_3[Co_4Te_3O_{18}(en)_3]\cdot 6H_2O$ dissolved in 100 cm³ of a 0.001 mol dm⁻³ sodium hydroxide solution. The mixture was concentrated to about 40 cm³ at 5—15 °C in air. The greenish brown less-soluble diastereomer deposited was separated by a centrifuge and washed with water–methanol (1:3). The diastereomer was stirred in a 0.001 mol dm⁻³ sodium hydroxide solution with a cation exchanger SP-Sephadex C-25 (Na^+ form) while being cooled in an ice-bath. The solution was filtered to remove the Sephadex, and CD (circular dichroism) of the filtrate was measured. $\Delta\varepsilon_{589}$=+0.31 cm⁻¹ mol⁻¹ dm³.

The corresponding periodate complex was resolved similarly using a solution of 0.12 g of $H_3[Co_4I_3O_{18}(en)_3]\cdot 5H_2O$ in 150 cm³ of a sodium hydroxide solution (pH 12) and a solution of 0.012 g of Λ-$(+)_{589}$-$[Co(en)_3]Br_3\cdot H_2O$ in 25 cm³ of water. The enantiomer obtained from the less-soluble diastereomer has $\Delta\varepsilon_{589}$=−0.68 cm⁻¹ mol⁻¹ dm³. An attempt was made to resolve the $[Co(TeO_6H_4)_3]^{3-}$ complex by a similar way, but only slight CD intensity was observed in the visible region.

Measurements. A Shimadzu UV-200 spectrophotometer and a JASCO MOE-1 spectropolarimeter were used for the absorption and CD measurements, respectively, of aqueous solutions at room temperature.

Results and Discussion

The absorption spectrum of $[Co(TeO_6H_4)_3]^{3-}$ ion was measured in a cooled 0.1 mol dm⁻³ potassium hydroxide solution (Fig. 2). The first spin-allowed d-d absorption band is located at 16500 cm⁻¹ and the position of tellurate ligand $TeO_6H_4^{2-}$ is determined in the spectrochemical series of oxygen chelate ligands: acetylacetonate(1−) 16900>oxalate(2−) 16570>tellurate(2−) 16500>malonate(2−) 16460>nitrate(1−) 16400>carbonate(2−) 15500 (values in the series mean the wavenumbers of the first d-d absorption bands of trischelate complexes). The strong absorption band at 27500 cm⁻¹ [log (ε/cm⁻¹ mol⁻¹ dm³)=3.18] is assigned to a ligand-to-metal charge transfer transition

Table 1. CD and Absorption Data[a] in the First d-d Transition Region

Complex	$\sigma_{ext}(\Delta\varepsilon)$	$\sigma_{max}(\log\varepsilon)$	Chromophore
$[Co(TeO_6H_4)_3]^{3-}$		16.5(1.82)	CoO_6

	17.8(−1.12)	18.2(2.61)	CoO_4N_2

a) Energies of CD extrema, σ_{ext}, and absorption maxima, σ_{max}, are given in 10^3 cm^{-1}, and the intensities $\Delta\varepsilon$ and ε in cm^{-1} mol^{-1} dm^3.

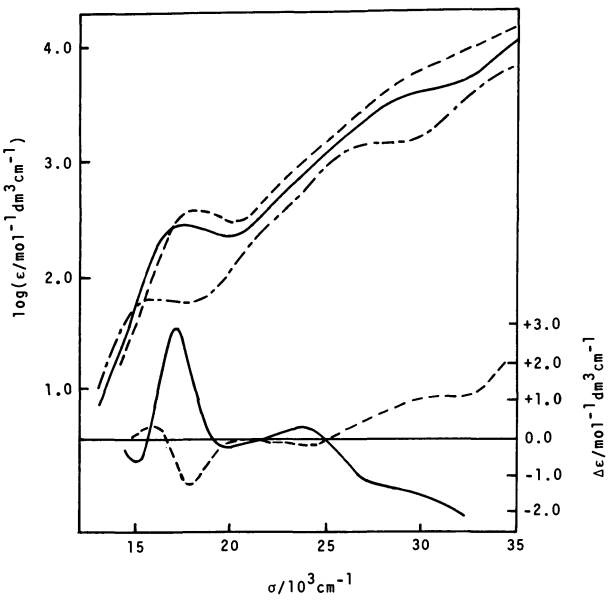

Fig. 2. Absorption and CD spectra of $(+)^{CD}_{589}$-$[Co_4Te_3O_{18}(en)_3]^{6-}$ (——) and $(-)^{CD}_{589}$-$[Co_4I_3O_{18}(en)_3]^{3-}$ (----), absorption spectrum of $[Co(TeO_6H_4)_3]^{3-}$ being also shown (——).

$e_g(Co)\leftarrow p_\pi(O)$ concerning the bridging oxo ligands.[10]

The tris(ethylenediamine)tris(tellurato)tetracobaltate(III) complex has a composition quite similar to that of the known periodate complex[8] $[Co_4I_3O_{18}(en)_3]^{3-}$. The parent aqua ion $[Co_4I_3O_{18}(H_2O)_6]^{3-}$ had been established in full detail from X-ray crystallography by two independent groups of workers.[11,12] A less characterized aqua derivative of the tellurato heteropoly compound had also been reported briefly.[3,4] For the present preparation of the heteropoly type tris(ethylenediamine) complexes, it was essential to use a mixed solution of two kinds of cobalt(III) complexes, one containing ethylenediamine and the other not.

$$3[CoCl_2(NH_3)_2(en)]Cl + [Co(NH_3)_4(H_2O)_2](SO_4)_{1.5} + 3Te(OH)_6 + 15NaOH \longrightarrow Na_3H_3[Co_4Te_3O_{18}(en)_3] + 9NaCl + 1.5Na_2SO_4 + 10NH_3 + 17H_2O$$

When only one kind of complex $[CoCl_2(NH_3)_2(en)]Cl$ was used, the main products containing tellurate ligands were a brown hexanuclear and a blue pentanuclear condensate of chain structure.[10] On the other hand, by using another kind of cobalt(III) complex $[Co(NH_3)_4(H_2O)_2](SO_4)_{1.5}$, the tris(tellurato)-cobalt(III) complex was obtained.

The $(+)^{CD}_{589}$-tellurato and $(-)^{CD}_{589}$-periodato heteropoly complexes show the similar CD patterns, the signs of the corresponding CD bands being opposite (Fig. 2 and Table 1). The enantiomer shown in Fig. 1 has the absolute configuration Δ concerning the $Co(MO_6)_3$ moiety, while Λ' the $Co(CoO_4en)_3$ moiety. In addition, the same enantiomer has three Λ'' peripheral chromophores $Co(en)(MO_6)_2$ (M=Te or I). Thus the total absolute configuration of this isomer should be represented by $\Delta\Lambda'(\Lambda'')_3$. From the well-known criterion that the Λ isomer of a trischelate cobalt(III) complex has a sign (+) for the main CD band in the first d-d absorption region,[13] the $(+)^{CD}_{589}$-$[Co_4Te_3O_{18}(en)_3]^{6-}$ isomer with a main positive CD band in the CoO_4N_2 chromophore region (Table 1) is assigned to be $\Delta\Lambda'(\Lambda'')_3$ configuration and the $(-)^{CD}_{589}$-$[Co_4I_3O_{18}(en)_3]^{3-}$ isomer to the $\Lambda\Delta'(\Lambda'')_3$ configuration. Unfortunately, the optical resolution of trischelate type complex $[Co(TeO_6H_4)_3]^{3-}$ was achieved only partially, and the quantitative CD curve was not obtained.

(Received April 10, 1986)

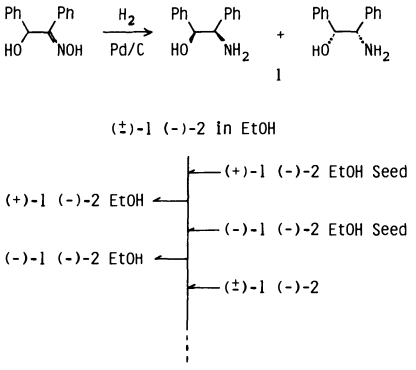
Synopsis. *erythro*-2-Amino-1,2-diphenylethanol was efficiently resolved into a pair of enantiomers by reciprocal crystallization of the diastereomeric salts with (−)-mandelic acid on alternate seeding.

Racemic *erythro*-2-amino-1,2-diphenylethanol (**1**), which can be easily prepared from commercially available benzoin oxime, has a similar fundamental structure to ephedrine. Therefore, optically active **1** is considered to be useful as an artificial chiral source. From this viewpoint optically active **1** has been applied in our laboratory as a chiral auxiliary in optical resolutions[1] and asymmetric syntheses.[1,2] Optically active **1** can be obtained by the fractional crystallization of the diastereomeric salts of racemic **1** with D-glutamic acid[3] or with (+)-10-camphorsulfonic acid,[4] by the preferential crystallization of the enantiomeric salts of racemic **1** with cinnamic acid,[1] and by chromatographic separation of diastereomeric 2-oxazolidinone derivative of racemic **1**.[5] The fractional crystallization, however, requires several recrystallization to get (+)- and (−)-**1** in high optical purities. The resolution efficiency of the preferential crystallization is not so high as observed in usual one although (+)- and (−)-**1** are obtained in high optical purities by simple operation. Moreover, the chromatographic separation includes multiple step and has a limitation in a quantity per one operation. We therefore examined another method to prepare optically active **1** more efficiently and easily.

Treatment of (+)- and (−)-**1**, which was prepared by preferential crystallization,[1] with an equimolar amount of (−)-mandelic acid (**2**) gave a pair of diastereomeric salts. Between the solubilities of these two salts in methanol and ethanol, there was little difference, meaning that it is impossible to resolve simply these diastereomeric salts by fractional crystallization. Actually a mixture of both diastereomeric salts with ethanol of crystallization deposited on cooling a hot clear ethanol solution of the mixture. By contrast, (+)-**1**·(−)-**2**·EtOH salt deposited preferentially when the supersaturated solution was cooled to about 40 °C by standing at room temperature and seeded with a small amount of diastereomerically pure (+)-**1**·(−)-**2**·EtOH salt. Moreover, seeding of (−)-**1**·(−)-**2**·EtOH salt to the filtrate gave (−)-**1**·(−)-**2**·EtOH salt preferentially. On the basis of specific rotations, these salts were found to be highly diastereomerically pure. This result means that racemic **1** can be resolved by "reciprocal crystallization of diastereomeric salts on alternate seeding," which is very rare in the optical resolution of diastereomers.

By repeating alternate seeding of (+)-**1**·(−)-**2**·EtOH and (−)-**1**·(−)-**2**·EtOH salts in this order to the mother liquor, which was supersaturated in a similar magnitude on addition of (±)-**1**·(−)-**2**·salt, both diastereomeric salts were reciprocally obtained in high diastereomeric purities. The result is shown in the Table. This procedure could be carried out in 0.10—0.05 mol scale to give both of diastereomeric salts in large quantities with high diastereomeric purities.

The recrystallized diastereomeric salts were dissolved in hot water and treated with aqueous ammonia to give white precipitates, respectively. Recrystallization of them from ethanol gave optically pure (+)- and (−)-**1**.



Experimental

All melting points were measured by a Laboratory Devices MEL-TEMP apparatus and are uncorrected. Optical rotations were recorded on a JASCO DIP-360 Digital Polarimeter.

Table 1. Reciprocal Crystallization of (±)-**1**·(−)-**2** Salt on Alternate Seeding

Run[a]	(±)-**1**·(−)-**2** Salt Supplied (g)	Signs of Seed **1**·**2**·EtOH	Yield g	Diastereomeric Purity/%
1	—	(+) (−)	1.37	94
	—	(−) (−)	1.37	99
2	2.32	(+) (−)	1.33	96
	—	(−) (−)	0.99	97
3	2.13	(+) (−)	1.09	96
	—	(−) (−)	1.37	99

a) The initial composition of the mother liquor: (±)-**1**·(−)-**2** salt (3.65 g) in ethanol (60 ml).

(±)-*erythro*-2-Amino-1,2-diphenylethanol (**1**) was synthesized by hydrogenation of commercially available benzoin oxime.[1,3] A pair of optically active **1** was prepared by the preferential crystallization of enantiomeric salts of racemic **1** with cinnamic acid salt.[1] (−)-Mandelic acid (**2**) is of commercial origin and was used without any purification.

Preparation of (+)-1·(−)-2·EtOH and (−)-1·(−)-2·EtOH Salts for Seeds. The reaction of (+)- or (−)-**1** with (−)-**2** in ethanol, followed by recrystallization from ethanol, gave the corresponding diastereomeric salts in pure state, respectively. The salts, dried at room temperature for 12 h over P_2O_5 in vacuo, contained an equimolar amount of ethanol of crystallization. They were used as seeds for the reciprocal crystallization of diastereomeric salts on alternate seeding.

(+)-**1**·(−)-**2**·EtOH salt: Mp 167—168.5 °; $[\alpha]_{435}^{17}$ +93.9° (*c* 1.00, MeOH). (−)-**1**·(−)-**2**·EtOH salt: Mp 162—163.5 °; $[\alpha]_{435}^{15}$ −259.7° (*c* 1.00, MeOH).

Drying at 80 °C for 24 h over P_2O_5 in vacuo gave the dastereomeric salts without ethanol of crystallization.

(+)-**1**·(−)-**2** salt: Mp 165—167 °C; $[\alpha]_{435}^{17}$ +105.7 ° $[\alpha]_{D}^{17}$ +49.0° (*c* 1.00, MeOH).

Found: C, 72.49; H, 6.08; N, 3.96%. Calcd for $C_{22}H_{23}NO_4$: C, 72.31 H, 6.34; N, 3.83%.

(−)-**1**·(−)-**2** salt: Mp 156—158 °C; $[\alpha]_{435}^{15}$ −292.5°, $[\alpha]_{D}^{15}$ −134.4° (*c* 1.00, MeOH).

Found: C, 72.39; H, 6.20; N, 3.62%. Calcd for $C_{22}H_{23}NO_4$: C, 72.31; H, 6.34; N, 3.83%.

The diastereomeric purities of the deposited precipitates by reciprocal crystallization on alternate seeding and the recrystallized diastereomeric salts were calculated on the basis of the specific rotations of the salts with or without ethanol of crystallization, respectively.

Optical Resolution by Reciprocal Crystallization of Diastereomeric Salts on Alternate Seeding. A solution of (±)-**1** (2.13 g, 10 mmol) and (−)-**2** (1.52 g. 10 mmol) in 99% ethanol (60 ml) was refluxed until the solution became clear. The solution was cooled to about 40 °C by standing at room temperature and then seeded with (+)-**1**·(−)-**2**·EtOH salt (10 mg), followed by standing overnight at room temperature. The white precipitate deposited was collected by filtration and dried over P_2O_5 at room temperature in vacuo to give (+)-**1**·(−)-**2**·EtOH salt (1.37 g, 67%): $[\alpha]_{435}^{13}$ +83.8° (*c* 1.00, MeOH); 94% diastereomeric purity.

The filtrate was again refluxed, cooled, and seeded with (−)-**1**·(−)-**2**·EtOH salt. On standing the solution overnight at room temperature, white precipitate deposited. The precipitate was collected by filtration and dried at room temperature for 12 h in vacuo to give (−)-**1**·(−)-**2**·EtOH salt (1.37 g, 67%): $[\alpha]_{435}^{16}$ −257.9° (*c* 1.00, MeOH); 99% diastereomeric purity.

To the mother liquor was added (±)-**1**·(−)-**2** salt (2.32 g) and the solution was similarly refluxed, cooled, and seeded with (+)-**1**·(−)-**2**·EtOH and (−)-**1**·(−)-**2**·EtOH salts, successively. The process was repeated in a similar manner supplying 2.1—2.3 g of (±)-**1**·(−)-**2** salt in each run to give (+)-**1**·(−)-**2**·EtOH and (−)-**1**·(−)-**2**·EtOH salts in high diastereomeric purities. The initial three runs are shown in the Table.

The crystals of the same diastereomer were combined, recrystallized from ethanol, and dried at about 80 °C for 24 h in vacuo to give optically pure (+)-**1**·(−)-**2** and (−)-**1**·(−)-**2** salts.

(+)-**1**·(−)-**2** salt: 84% recrystallization yield; mp 165—167 °C; $[\alpha]_{435}^{15}$ +105.6 ° (*c* 1.00, MeOH); 100% diastereomeric purity.

(−)-**1**·(−)-**2** salt: 84% recrystallization yield; mp 156—157 °C; $[\alpha]_{435}^{15}$ −292.5 °C (*c* 1.00, MeOH); 100% diastereomeric purity.

Decomposition of the Diastereomeric Salts. In 530 ml of water (+)-**1**·(−)-**2** salt (28.61 g) was dissolved at 70 °C and then treated with aqueous ammonia (28 ml). Recrystallization of the resulting precipitate from ethanol gave (+)-**1** (11.57 g, 86%): Mp 142.5—144 °C; $[\alpha]_{D}^{19}$ +7.7° (*c* 0.60, EtOH); 100% optical purity (lit,[1] mp 143—144 °; $[\alpha]_{D}^{24}$ +7.7° (*c* 0.63, EtOH)).

Similar treatment of (−)-**1**·(−)-**2** salt (22.40 g), followed by recrystallization, gave (−)-1 (10.16 g, 80%): Mp 143—144.5 °C; $[\alpha]_{D}^{16}$ −7.5° (*c* 0.60, EtOH); over 99% optical purity (lit,[1] mp 143—144 °C; $[\alpha]_{D}^{32}$ −7.6° (*c* 0.60, EtOH).

Photoreaction of *N*-Alkylamides Containing Iron(III) Chloride by Monochromatic Light

Yasushi YOKOYAMA, Takahiro SUZUKI, and Yukio KURITA*
Department of Materials Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received January 8, 1986)

Synopsis. The photolysis of *N*-alkylamides containing $FeCl_3$ using monochromatic light corresponding to the absorption maxima were examined by ESR. Irradiation by 313-nm light resulted mainly in a hydrogen abstraction from the aliphatic carbon adjacent to either CO or NH, whereas 366-nm light produced an acyl radical in larger amounts.

The photoreduction of coordinated metal ions, accompanied by an oxidation of their ligands, is an interesting problem.[1] Recently, we have reported on an ESR study of the photolysis of some *N*-alkylamides containing $FeCl_3$ by UV light irradiation (300—400 nm).[2] We showed that: 1) Some amides gave a mixture of radicals consisting of **a** and **b** or **c** at liquid-nitrogen temperature and 2) amide–$FeCl_3$ complexes gave two absorption maxima in a $CHCl_3$ solution at 312 and 350 nm. Here, we report that the irradiation of amide–$FeCl_3$ complexes with 313-nm light, corresponding to one of the absorption maxima, gave mainly a hydrogen-abstracted radical (**b** or **c**). However, irradiation with 366-nm light, corresponding to another absorption maxima, gave an increased relative molar ratio of the acyl radical **a**.

$RCH_2\dot{C}O$ $RCH_2CONH\dot{C}HR'$ $R\dot{C}HCONHCH_2R'$
a **b** **c**

Photoreaction experiments were carried out on eight amides. Here, a typical example is given. The irradiation of the *N*-ethyl-acetamide (**2**)–$FeCl_3$ mixture at 77 K by 313-nm light for 20 min gave the ESR spectrum shown in Fig. 1a. It was analyzed and shown to be a 72/28 mixture of a 1:4:6:4:1 quintet

Table 1. Radicals Generated from Photoirradiated Amide–$FeCl_3$ Mixture and Their Relative Molar Ratio Observed by ESR at 77 K

Amides	313 nm[a] *g*-Value, A_H/mT	(**b** or **c**)/**a**	366 nm[b] *g*-Value, W_{msl}/mT	(**b** or **c**)/**a**

a) Irradiation by 313 nm light always generated a small to medium amount of acyl radical together with hydrogen-abstracted radical. Values at the right side of this column are the relative molar ratio of hydrogen-abstracted radical/acyl radical. In the cases of **2**, **5**, and **6**, the numerators contain the contribution from the alkyl radical generated from the acyl radical. "NH-side" refers to the radical -CONHĊH-(**b**), and "CO-side" refers to the radical -ĊHCONH-(**c**). Because A_H^{α} is indistinguishable from A_H^{β} in every case, both of them are represented by A_H. b) Irradiation by 366 nm light always generated a hydrogen-abstracted radical and an acyl radical. Values at the right side of this column are the relative molar ratios of the hydrogen-abstracted radical/acyl radical. c) Yield of the radicals was very low. d) Also containing the alkyl radical decarbonylated from the acyl radical **a**. e) Also containing $\cdot N{=}CH_2$ (g=2.002, A_H=8.9 mT) generated from $HN{=}CH_2$.[2,10] f) Undetermined.[11] g) On irradiation by 313 nm light, amides **5**, **6**, and **7** produced the 1 : 4 : 6 : 4 : 1 radicals which we assigned to $-X\dot{C}HCH_3$, not $-X\dot{C}HCH_2-$ (X=NH or CO) which occasionally shows a 1 : 2 : 2 : 2 : 1 quintet,[12] because **5**-d_2 ($CH_3CH_2CONHCD_2CH_2CH_3$) gave a quintet (g=2.002, A_H=2.43 mT) similar to that of **5**. h) Small amount of $-CH_2\dot{C}HCH_2-$ type radical was also existing.[9]

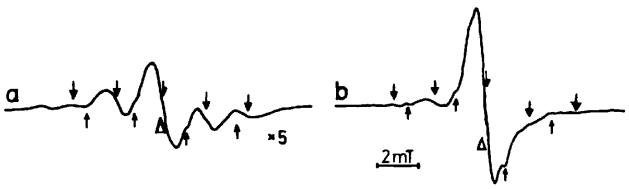

Fig. 1. (a) ESR spectrum of 313nm-irradiated **2**-$FeCl_3$ mixture. (b) ESR spectrum of 366nm-irradiated **2**-$FeCl_3$ mixture. Methyl radical is denoted by an upward arrow, **2a** by a delta, and **2b** by a downward arrow.

(g=2.002, A_H=2.1 mT, **2b**[3]) and a singlet (g=2.001, W_{msl}=1.5 mT, **2a**[5]),[6] together with a small amount of the methyl radical generated by decarbonylation from the acetyl radical.[2]

When the amide (**2**)-$FeCl_3$ mixture was irradiated by 366-nm light, the spectrum shown in Fig. 1b was obtained. This time, it was analyzed and shown to be a 48/52 mixture of **2b** and **2a**, along with (again) a small amount of the methyl radical.

The results obtained in a similar manner are summarized in Table 1.

In all cases, 313-nm light gave rise to the predominant formation of the hydrogen-abstracted radical **b** or **c**, except the amide **1** which produced a little amount of the radical; 366-nm light gave rise to the formation of a larger relative amount of the acyl radical **a** in most cases. This shows a difference in the natures of the two absorption bands in the UV spectra.[7]

The hydrogen-abstracted radicals generated by 313-nm light were classified into two groups. Group-one amides (**2** and **7**) generated a radical having an unpaired electron on the carbon atom adjacent to the NH group (**b**), whereas for group-two (**1**, **3**, **5**, **6**, and **8**), the electron appeared on the carbon atom adjacent to the CO group (**c**).[8]

In the case of amide **6**, a small amount of $-CH_2\dot{C}HCH_2-$ radical[9] was also observed upon irradiation with 313-nm light. Because amide **6** has an ethyl group on the carbonyl and the main hydrogen abstraction occurred on this side, the inner radical must be on the hexyl moiety on the NH group. This was confirmed by a GC–MS measurement (see below). From this experiment, the formation of three reaction products (*N*-(3-hexenyl)propanamide (**9**), *N*-hexyl-2-chloropropanamide (**10**), and *N*-(4-chlorohexyl)propanamide (**11**) was confirmed. Chloride **10** corresponds to a product from **6a**, and **9** and **11** are from the inner radical.

In some cases, the ESR spectrum after 313 or 365 nm irradiation showed the presence of alkyl radicals generated by a decarbonylation of the corresponding mother acyl radicals (**2**, **5**, and **6**).[2]

Experimental

Amides used in this study were prepared by a condensation of the corresponding monoalkylamine and acid chloride in benzene in the presence of pyridine, and purified by several distillations under a reduced pressure. Their purities were examined by gas chromatography (column SP-1000, 100—220 °C).

ESR Measurement. A sample for ESR measurement was prepared by dissolving $FeCl_3$ (Wako Pure Chem., chemical grade) in amide ($3—5\times10^{-3}$ mol dm^{-3}) under a nitrogen atmosphere and then degassed by a freeze-pump-thaw technique (three times) in a quartz sample tube.

Photoirradiation was carried out using a USH-500D 500W ultra-high-pressure mercury lamp (Ushio Co.).

Filters for 313-nm light irradiation[13] (9% transmittance at 313 nm) were water (cell length 50 mm), aqueous potassium hydrogen phthalate (5 g dm^{-3}, cell length 10 mm), potassium chromate in 0.1% aqueous sodium hydroxide (0.2 g dm^{-3}, cell length 10 mm), aqueous nickel(II) sulfate hexahydrate (100 g dm^{-3}, cell length 50 mm), and UV-D35 glass filter (Toshiba Glass Co., 3 mm thick). Filters for 366 nm light[13] (25% transmittance at 366 nm) were water (cell length 50 mm), Pyrex glass (2.5 mm thick), UV-35 and UV-D36A glass filters (both Toshiba Glass Co., 3 mm thick).

ESR spectra were recorded by a JEOL JES-ME-3X ESR spectrometer at liquid-nitrogen temperature immediately after irradiation for an adequate period (ca. 1—20 min) at that temperature.

GC-MS Measurement of Photoirradiation Product of 6-$FeCl_3$. Amide **6** containing $FeCl_3$ was irradiated by >300-nm light for about 6 h under a nitrogen atmosphere at room temperature. The resulting mixture was extracted with hexane, followed by an examination with GC–MS (JEOL D-300 Mass Spectrometer, column PG-20E, 80—160 °C. The oven temperature was increased at a rate of 8 °C per minute). **9**: Retention time 4′35″; m/z 155 (M^+; 15), 98 ($(M-CH_3CH_2CO)^+$; 29), 70 (29), 69 ($(CH_3CH_2CH{=}CHCH_2)^+$, allylic cleavage; 100), and 57 ($CH_3CH_2CO^+$; 35). **10**: Retention time 6′25″; m/z 191 (M^+; 7), 156 ($(M-Cl)^+$; 28), 128 ($M-CH_3CHCl)^+$; 64), 123 (7), 122 (8), 121 (24), 120 (23), 85 ($(M-CH_3CHClCONH)^+$; 100), 65 (CH_3CHCl^+; 7), and 63 (CH_3CHCl^+; 20). **11**: Retention time 8′05″; m/z 193 (M^+; 3), 191 (M^+; 10), 156 ($(M-Cl)^+$; 39), 155 ($(M-HCl)^+$; 20), 114 ($(M-CH_3CH_2CHCl)^+$; 55), 100 ($(M-CH_3CH_2CHClCH_2)^+$; 25), 87 (63), 86 ($CH_3CH_2CONHCH_2^+$; 89), 74 (35), 73 ($CH_3CH_2CONH^+$; 80), 58 (64), and 57 ($CH_3CH_2CO^+$; 100).

5) S. Noda, K. Fueki, and Z. Kuri, *J. Chem. Phys.*, **49**, 3287 (1968).

6) Relative molar ratio of the radicals was determined by simulation.

7) It seems to be quite reasonable to assign the 312-nm absorption band as the CT band from Cl^- to Fe(III) and the 350-nm band as the CT band from amide to Fe(III). The former caused the generation of Cl, which might abstract hydrogen from an amide molecule. The latter generated an amide cation radical which decomposed into an acyl radical, an imine, and a proton[2] when irradiated on the absorption maxima.

8) We could not clarify what nature of amides would determine the course of the hydrogen abstraction. However,

there is an apparent tendency that an $-X\dot{C}HCH_3$ type radical (X=NH or CO) is apt to be generated.

9) g-Value=2.001, $A_H^{\alpha}=A_H^{\beta}=3.23$ mT. see; A. Lund, *J. Phys. Chem.*, **76**, 1411 (1972).

Structure Model for Liquid Neopentane

Keiko NISHIKAWA
Department of Chemistry, Faculty of Science, Gakushuin University,
Mejiro, Toshima-ku, Tokyo 171
(Received October 21, 1985)

Synopsis. Structure simulation studies for liquid neopentane have been carried out by the use of real space expansion and reciprocal space expansion based on the local lattice structure model. A body centered cubic (bcc) model has reproduced Narten's experimental data very well.

X-Ray diffraction studies for liquid neopentane were carried out by Narten.[1] He measured the diffraction intensities from the liquid at eight different temperatures under high pressure from −17° (melting point) to 150 °C (cf. the critical point, 161 °C and 32 bar). He also attempted structure analysis, constructing an intermolecular correlation function from Percus-Yevick theory using the analytical solution for hard spheres. He reported that the calculated correlation function was in very good agreement with the experimental curves for values of $s \leq 1.5$ Å^{-1} but the deviation from the experimental intensity became large with increase of s ($s=4\pi\sin\theta/\lambda$).

In order to understand orientational correlation of molecular liquids, it is useful to construct a model in which we visualize a structure model which is to be tested against the experimental intensity. Such modeling for liquid structure, such as the "local lattice structure model" is usually formulated in the form of "real space expansion."[2-4] Recently a new method named "reciprocal space expansion" has been introduced by the present author and her coworker.[5,6] The real space expansion and reciprocal space expansion are complementary to each other; with good convergence in larger s-values for the former and the good convergence in the smaller s-region for the latter. The two methods were successfully applied to liquid carbon tetrachloride[4-6] based on the local lattice model of a bcc arrangement with head-tail head-tail packing.

In the present work the two methods have been applied to the structure simulation for liquid neopentane using the same bcc model. The diffraction intensities of liquid neopentane observed by Narten[1] are used.

First, the real space expansion was tried, and the weighted structure function $si(s)$ was used for the comparison of the simulated scattering intensities with the experimental ones. The least-squares refinement was carried out with four parameters; the lattice constant of the bcc cell a, the Prins parameter D,[7] the radius of the discrete structure region R_c and its temperature factor l_c. Because of the large values of l_{ij}, the more rigorous expression $\sin s(r_{ij}-l_{ij}^2/r_{ij})$[8] was used in the calculation instead of $\sin sr_{ij}$ of Eq. 4 in Ref. 4. For the values of the intramolecular distances r_{C-Me} and r_{Me-Me} and their root mean-square amplitudes l_{C-Me} and l_{Me-Me}, those obtained by the gas electron diffraction[9] were used. The group scattering factor for CH_3 group introduced by Narten[1] was used.

The number of molecules first contained in the discrete structure region was nine (a central molecule and the first nearest neighbors) at the initial trial, which was increased during the least-square refinements up to 51. That is the number of molecules included in the fourth nearest neighbors around the central molecule. Further increase of the number of molecules in the structure region no longer changed the feature of the calculated $si(s)$ curve. Scattering intensities ranging from 1 to 6 Å^{-1} have been used, because for the s-region smaller than 1 Å^{-1} spurious peaks inevitably appear whereas for the s-region larger than 6 Å^{-1} the calculated $si(s)$ is approximately equal to that of a free neopentane molecule and is considered hardly affected by the intermolecular interference. The results of the least-squares refinements for the

a) a: the lattice constant of the bcc lattice, d: the nearest neighbor distance calculated from a, D: the Prins parameter, R_c: the radius of the structure region, l_c: temperature factor for R_c. The values in parentheses are the standard deviations in the last significant digit. b) The reliability factor R is defined by

$$R = \left[\frac{\sum \{si(s)_{exp} - si(s)_{calc}\}^2}{\sum (si(s)_{exp})^2} \right]^{1/2}$$

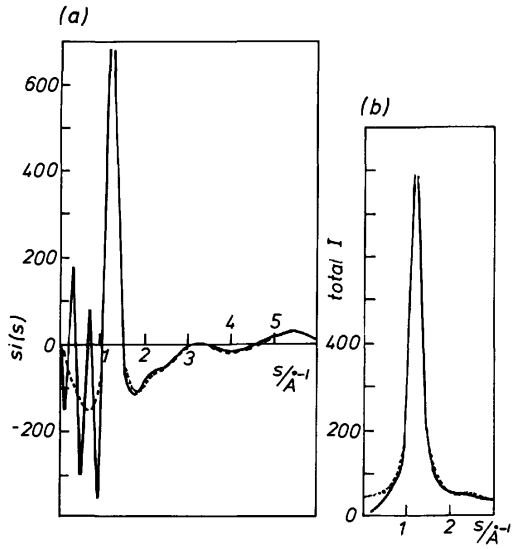

Fig. 1. The scattering intensities of liquid neopentane at −17 °C. The solid curves are the calculated intensities and the broken curves are Narten's experimental values. (a) Reduced intensity $si(s)$. The calculated one is obtained by the real space expansion based on the bcc model. (b) Total coherent intensity $I(s)$. The calculated one is obtained by the reciprocal space expansion.

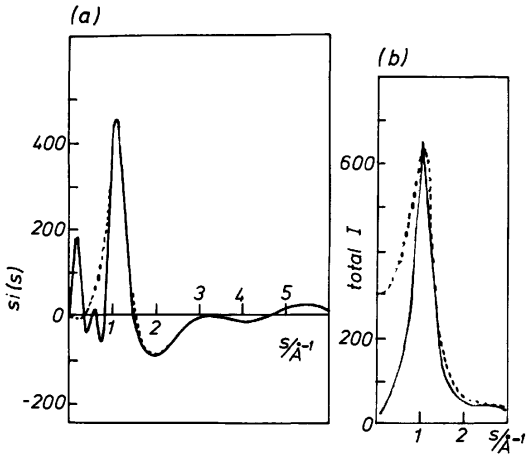

Fig. 2. The scattering intensities of liquid neopentane at 150 °C. See the caption of Fig. 1 for other details.

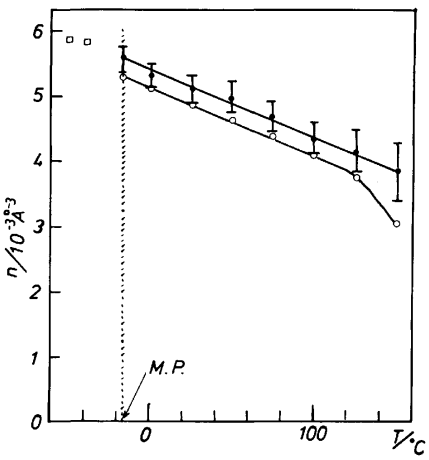

Fig. 3. Number densities n of neopentane. Dots show the values obtained by the bcc model, open circles those from Refs. 11 and 12 cited in Ref. 1 and squares for the plastic crystal phase.[13,14]

eight temperatures are shown in Table 1. The values of the nearest neighbor distance d are also given. The calculated $si(s)$ curves at −17° and 150 °C are respectively compared in Figs. 1(a) and 2(a) with Narten's experimental data.

Next, the reciprocal space expansion was carried out using the same a and D parameters. In this calculation reciprocal lattice points up to 600 are included. For the 600 the magnitude of the reciprocal lattice point vector is 5.32 Å^{-1} in the case of the data at −17 °C. The total coherent intensity is adopted, because it distinguishes the discrepancy between the experimental and simulated intensities in the small s-region. The results at −17° and 150 °C are shown in Figs. 1(b) and 2(b).

As seen in Figs. 1 and 2, X-ray scattering intensities from liquid neopentane could be well simulated by the bcc model, in the range of $s \geq 1$ Å^{-1} by the use of the real space expansion and in the range of $0.5 \leq s \leq 3$ Å^{-1} by the use of the reciprocal space expansion. Two peaks on the calculated curves at an s-region smaller than 1 Å^{-1} in Figs. 1(a) and 2(a) are all spurious due to the sudden onset of the continuum region to the discrete region, which do not appear in the total coherent intensity curves calculated by the reciprocal space expansion. A difference between the experimental and calculated intensities by the use of the reciprocal spece expansion is seen in the region of $s \leq 0.5$ Å^{-1}. The experimental scattering intensity near $s \approx 0$ Å^{-1} has a finite value because of the density fluctuation of the liquids.[10] With increase of temperature the density fluctuation increased and especially near the critical point this became significantly large. The density fluctuation was not included in the present formulation by the local lattice structure model.

From the variation of the lattice constants a's determined for the bcc model at different temperatures, the number densities of the liquid were calculated, these are shown in Fig. 3. The number densities decreased almost linearly with the increase of temperature. For comparison, the values tabulated in Narten's paper[1] are also given in Fig. 3. He obtained them by interpolating the values from the measurements of Gonzales and Lee[11] and from the values listed in the book by Timmermans.[12] The number density obtained from the present bcc model is approximately 5% larger than these values. The difference of these number densities may be explained by the possibility that the volatile neopentane contains many voids in its structure. The number densities for the plastic crystal at −40° and −50 °C calculated from values of the mass density determined by means of powder diffraction[13,14] are also shown in Fig. 3.

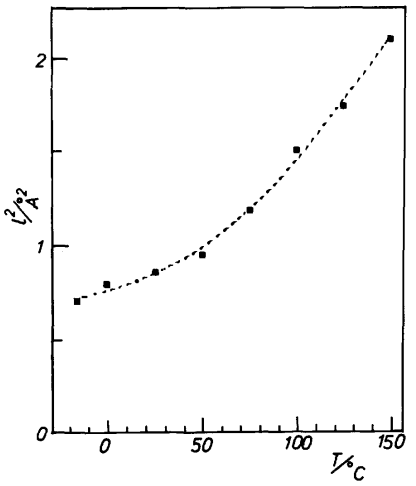

Fig. 4. Temperature dependence of the mean square deviation, l^2, of the neighboring neopentane molecules.

The mean square deviations of liquids increased as the distance between the central molecule and surrounding ones increased, and the deviations in the case of liquid neopentane were described well by the Prins relation $l_{ij}^2=2Dr_{ij}$.[7]

For harmonic oscillators at high temperature or low frequencies the mean square deviation of l^2 becomes[15]

$$l^2 = \frac{kT}{4\pi^2\mu\nu^2},$$

where ν is the frequency of the ocillator, T absolute temperature, and μ the reduced mass. Then l^2 is proportional to T. For several acceptable potentials with anharmonicity, the mean square deviation l^2 was calculated and found to be approximately proportional to T in this temperature range.[16] The observed l^2 was therefore expected to be nearly proportional to T. This however was not true in the present case, as is shown in Fig. 4. It exhibits a nearly parabolic increase with increase of temperature. This temperature dependence of the mean square deviations can be considered as the direct reflection of the effective potential that a molecule in the liquid feels. More detailed investigation on the mean square deviations will give information concerning the dynamical properties of the liquid but this is left for future studies.

The author wishes to express her thanks to Professor Takao Iijima, Gakushuin University, for his helpful suggestions and discussion.

Mössbauer Spectroscopic Study on the Mixed-Valence States of 1′,1‴-Bis(*o*-methylbenzyl)-, 1′,1‴-Bis(*m*-methylbenzyl)-, and 1′,1‴-Bis(*p*-methylbenzyl)biferrocenium Triiodide

Satoru NAKASHIMA, Motomi KATADA, Izumi MOTOYAMA, and Hirotoshi SANO*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received April 19, 1986)

Synopsis. 1′,1‴-Bis(*o*-methylbenzyl)-, 1′,1‴-bis(*m*-methylbenzyl)-, and 1′,1‴-bis(*p*-methylbenzyl)biferrocene were synthesized and Mössbauer spectroscopic measurements of their monocation salts were carried out at various temperatures in order to study the effect of the substituents on the mixed-valence states.

Biferrocene derivatives are easily monooxidized to give the corresponding monocations, which show a mixed-valence state. It is known that those compounds can be classified into two types of valence states of iron atoms, a trapped-valence type and an averaged-valence type, by means of Mössbauer spectroscopy.[1] The former type has different states of iron atoms corresponding to ferrocene-like bivalent and ferricenium-like tervalent iron atoms, while the latter has an equivalent state averaged over ferrocene-like bivalent and ferricenium-like tervalent iron atoms.

It has been reported that the triiodide salt of biferrocene itself is of the trapped-valence type from a low temperature to room temperature.[2] However, Iijima et al. observed the interesting temperature-dependence of the mixed-valence states for 1′,1‴-diethyl- and 1′,1‴-dipropylbiferrocenium triiodide which show an averaged-valence type near room temperature but a trapped-valence type at low temperatures.[3]

Recently, it was reported that the triiodide salts of monocationic 1′,1‴-di-*n*-butyl- and 1′,1‴-dibenzylbiferrocenium show a temperature-dependence similar to those observed in 1′,1‴-diethyl- and 1′,1‴-dipropylbiferrocenium triiodide, suggesting that the environment surrounding each cation in the solids should determine whether or not an intramolecular electron transfer occurs.[4]

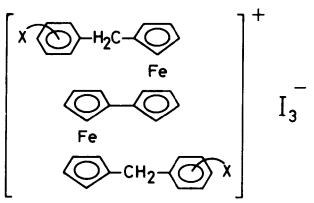

Fig. 1. Compounds.
(1) 1′,1‴-Bis(*o*-methylbenzyl)biferrocenium triiodide (X=*o*-CH_3)
(2) 1′,1‴-Bis(*m*-methylbenzyl)biferrocenium triiodide (X=*m*-CH_3)
(3) 1′,1‴-Bis(*p*-methylbenzyl)biferrocenium triiodide (X=*p*-CH_3)

The introduction of a methyl group to the benzyl substituent in 1′,1‴-dibenzylbiferrocene is expected to influence the packing of those cations in the solids. In the present paper, the triiodide salts of 1′,1‴-bis(*o*-methylbenzyl)-, 1′,1‴-bis(*m*-methylbenzyl)-, and 1′,1‴-bis(*p*-methylbenzyl)biferrocene (Fig. 1) were synthesized and investigated by means of Mössbauer spectroscopy in order to study the effects of the substituents on the valence states of iron atoms.

Experimental

Materials. 1′,1‴-Bis(*o*-, *m*-, and *p*-methylbenzyl)biferrocene were prepared by Ullmann coupling at 100—110 °C for 18 h of 1-bromo-1′-(*o*-, *m*-, and *p*-methylbenzyl)ferrocene, respectively. The products were checked by using ^{1}H NMR and elemental analysis. The data of elemental analysis for 1′,1‴-bis(*o*-, *m*-, and *p*-methylbenzyl)biferrocene are shown below, respectively: Found: C, 74.51; H, 4.64%, Found: C, 73.24; H, 6.57%, and Found: C, 75.18; H, 6.74%. Calcd for $C_{36}H_{34}Fe_2$: C, 74.76; H, 5.93%

The triiodide salts were prepared by partial oxidation of the corresponding 1′,1‴-bis(*o*-, *m*-, and *p*-methylbenzyl)-biferrocene in benzene with a stoichiometric amount of I_2. All the analytical data of 1′,1‴-bis(*o*-, *m*-, and *p*-methylbenzyl)biferrocenium triiodide salt are shown below, respectively: Found: C, 45.01; H, 4.17%, Found: C, 44.61; H, 4.19%, and Found: C, 42.99; H, 3.98%. Calcd for $C_{36}H_{34}Fe_2I_3$: C, 45.08; H, 3.57%.

Mössbauer Spectroscopic Measurements. ^{57}Co(Rh) moving in a constant-acceleration mode was used as the radioactive source for Mössbauer spectroscopic measurements. Mössbauer spectra were obtained by using an Austin Science Associates Mössbauer spectrometer and a proportional counter. The isomer shifts were referred to a metallic iron foil. The Mössbauer parameters were obtained by least-squares fitting to Lorentzian peaks.

Results and Discussion

Mössbauer spectroscopic measurements of 1′,1‴-bis(methylbenzyl)biferrocenes were carried out at 78 and 298 K. The Mössbauer spectroscopic data are shown in Table 1 together with those of 1′,1‴-dibenzylbiferrocene. It can be seen from Table 1 that all the spectral data show ferrocene-type bivalent iron, although the value of quadrupole splitting (ΔE_q) for 1′,1‴-bis(*o*-methylbenzyl)biferrocene is a little smaller than those of 1′,1‴-bis(*m*-methylbenzyl)- and 1′,1‴-bis(*p*-methylbenzyl)biferrocene.

Mössbauer spectroscopic measurements of 1′,1‴-bis(methylbenzyl)biferrocenium triiodides were carried out at 78 and 298 K. The Mössbauer spectra of 1′,1‴-bis(*o*-methylbenzyl)-, 1′,1‴-bis(*m*-methylbenzyl)-, and 1′,1‴-bis(*p*-methylbenzyl)biferrocenium tri-

iodide are shown in Figs. 2, 3, and 4, respectively. These Mössbauer spectroscopic data are summarized in Table 2 together with those of 1′,1‴-dibenzylbiferrocenium triiodide.

a) Isomer-shift data are reported with respect to metallic iron foil.

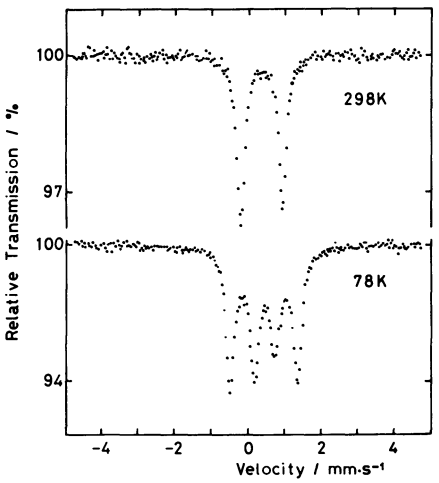

Fig. 2. Mössbauer spectra of 1′,1‴-bis (*o*-methylbenzyl) biferrocenium triiodide at 78 and 298K.

1′,1‴-Dibenzylbiferrocenium triiodide shows the remarkable temperature-dependence in its Mössbauer spectra; i.e., the spectra are of the trapped-valence type at low temperatures and of the averaged-valence type at high temperatures near room temperature.

Mixed-valence states observed in the present study depend on the position of methyl group in the benzyl

1′,1‴-Dibenzylbiferrocenium$^+$ I_3^-	298	0.44	1.11	100
	78	0.53	2.00	43
		0.51	1.21	14
		0.53	0.44	43
1′,1‴-Bis(*o*-methylbenzyl)-	298	0.44	1.14	100
biferrocenium$^+$ I_3^-	78	0.53	1.85	50
		0.54	0.57	50
1′,1‴-Bis(*m*-methylbenzyl)-	298	0.44	2.14	45
biferrocenium$^+$ I_3^-		0.45	0.26	55
	78	0.53	2.15	42
		0.58	ca. 0	58
1′,1‴-Bis(*p*-methylbenzyl)-	298	0.46	1.13	100
biferrocenium$^+$ I_3^-	78	0.53	1.87	35
		0.54	1.24	28
		0.54	0.59	37

a) Isomer-shift data are reported with respect to metallic iron foil.

substituent. In 1′,1‴-bis(*o*-methylbenzyl)biferrocenium triiodide, the spectrum at 78 K consists of an inner and an outer doublet with nearly 1:1 ratio in areal intensity, which are ascribable to ferricenium-like tervalent and ferrocene-like bivalent iron, respectively, while the spectrum consists of only one doublet at room temperature. The Mössbauer spectroscopic data for the doublet at 298 K show a close resemblance to those for 1′,1‴-dibenzylbiferrocenium triiodide at 298 K.

On the other hand, the Mössbauer spectra obtained in 1′,1‴-bis(*m*-methylbenzyl)biferrocenium triiodide show a trapped-valence state both at 78 and 298 K. Although the Mössbauer spectrum of 1′,1‴-bis(*p*-methylbenzyl)biferrocenium triiodide at 298 K shows an averaged-valence state as in the case of 1′,1‴-bis(*o*-methylbenzyl)biferrocenium triiodide at 298 K, the spectrum at 78 K seems to have both a trapped-valence state and an averaged-valence state.

The values of ΔE_q of outer ferrocene-like doublet found in *o*- and *p*-methylbenzyl derivatives at 78 K are a little smaller than that found in *m*-methylbenzyl derivative at 78 K, while the values of ΔE_q of inner ferricenium-like doublet found in *o*- and *p*-methylbenzyl derivatives at 78 K are a little larger than that found in *m*-methylbenzyl derivative at 78 K. This suggests that the interaction between Fe(II) and Fe(III) in *o*- and *p*-methylbenzyl derivatives is stronger than that in *m*-methylbenzyl derivative even at 78 K.

These results suggest that the position of methyl group in the benzyl substituent has important effects on the mixed-valence states of 1′,1‴-bis(methylbenzyl)-biferrocenium triiodides. In 1′,1‴-bis(*m*-methylbenzyl)biferrocenium triiodide, one of the terminal iodine atoms of the I_3^- anion is supposed to be situated closer to the Fe(III) atom of a cation(both at 78 and at 298 K) based on the assumption made on the studies of 1′,1‴-di-*n*-butyl- and 1′,1‴-dibenzylbiferrocenium triiodide[4] and the ^{129}I-Mössbauer spectroscopic studies of ferricenium, biferrocenium and 1′,1‴-dihalobiferrocenium iodide salts,[5] although further structual information on the compounds used is needed to verify the assumption.

Study of Packing State in Lipid Bilayers with the Aid of Ultraviolet Spectroscopy

Yoshio INOUE,* Yuji SEIYA, Minoru SAKURAI, and Riichiro CHÛJÔ
Department of Polymer Chemistry, Tokyo Institute of Technology,
O-okayama 2, Meguro-ku, Tokyo 152
(Received April 3, 1986)

Synopsis. The packing states of lipid bilayers of three phosphocholines were investigated based on the density dependent UV shifts of probes incorporated into bilayers. As UV probes, two retinal Schiff bases were used. It was confirmed that the packing state of the fatty acyl chain region is well probed by UV spectroscopy.

Lipids are prerequisite for an activation of membrane enzymes.[1] Lipid bilayers would contribute the stabilization of enzyme conformation required for an activation. In many cases, fluidity of lipid is also necessary for the enzyme activity.[2-4] For these reasons, many spectroscopic methods have been applied, for example, NMR,[5-11] ESR,[12-15] fluorescence,[16-19] IR,[20-22] etc. Up to now, an investigation of the state of lipid bilayers using an UV spectroscopy notwithstanding its high sensitivity has not been reported. In this note, we will show that the UV shifts could provide the information on packing states of lipid bilayers.

Experimental

Three types of phosphocholine(PC) were used; egg yolk phosphocholine(EPC), 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine(DMPC), and 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine(DPPC). As UV probes, retinal Schiff bases, i.e., *N*-retinylidene-butylamine(NRB) and α-(*t*-Butyloxycarbonyl)-ε-*N*-retinylidene-L-lysyl-L-phenylalanyl-L-tyrosine methyl ester(PEP) were used (Fig. 1). Methods of syntheses and characterization of these compounds were described elsewhere.[23,24] The molar ratio of probe to lipid was almost 1/10. Homogeneous vesicle dispersion in distilled water containing 100 mM NaCl (1 M=1 mol dm^{-3}) is prepared by sonication with TOMY model UR-200P sonicator at frequency 20 kHz and output power 200 W under cooling by ice/water until translucence (about 20 min). It has confirmed that the incorporation of retinal less than 20 mol% causes the slight expansion of EPC vesicle size but dose not induce the obvious disruption.[25] UV spectra were observed on a Beckman model 25 spectrometer with a probe concentration of ca. 5×10^{-2} mol dm^{-3}.

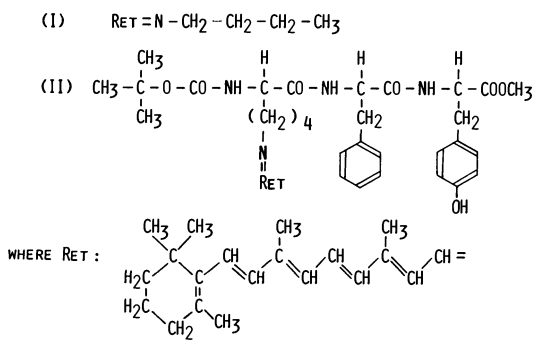

Fig. 1. Chemical structure of UV probes. (I) NRB and (II) PEP(peptide probe).

Results and Discussion

Retinal moiety of the peptide probe PEP is located in the region of fatty acyl chains in the bilayers.[24] NRB is also seemed to locate in the same region, but not near the polar head group, because of its higher hydrophobicity. PEP in EPC vesicle shows UV absorption maximum λ_{max} of retinal moiety at 380 nm, which is more bathochromic than in EPC inverted micell (in hexane, λ_{max}=360 nm).[24] This shift is mainly due to the van der Waals effect which depends on the density of medium. Similar shift has been observed in normal hydrocarbons as solvents, where the λ_{max} value of retinal Schiff base shifts to more bathochromic as the density of the solvent becomes larger.[26] Fatty acyl chains of EPC in inverted micell are not so densely packed compared with those in EPC bilayer vesicle. The λ_{max} value in vesicle is, therefore, in longer wavelength region than that in inverted micell. It suggests that by using the λ_{max} shift we can study the packing state of fatty acyl chain region of lipid bilayers.

Figure 2 shows the temperature dependence of the λ_{max} values of two probes in three different PC vesicles. At 5—10 °C, the λ_{max} values of probes in DPPC are larger than those in DMPC and EPC. This result suggests that DPPC bilayers are more densely packed than the other two PC bilayers. The bilayers of pure DPPC, DMPC, and EPC show phase transition at

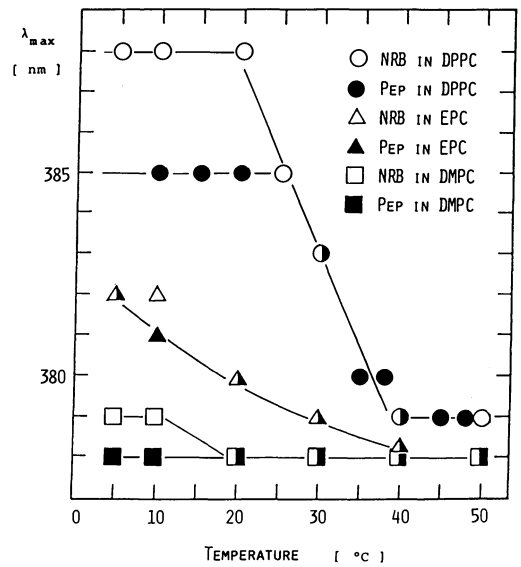

Fig. 2. Temperature dependence of λ_{max} values of UV probes in phosphocholine(PC) bilayers. Errors in temperature and λ_{max} are ±2.0 °C and ±1 nm, respectively.

temperatures (T_c) of 41.3,[27] 23.8, and −15.0 °C,[28] respectively. At the temperature range 5—10 °C, DMPC and DPPC would be in the gel state, while EPC in the fluid state. When the fatty acyl chains consist of saturated carbon-carbon bonds and the bilayers are in the gel state, the packing effect depends on the length of the acyl chains. Raman studies in the gel state showed that DMPC is more perturbed and its fatty acyl chains are more rich in gauche conformers than the case of DPPC.[27,29,30] The packing strength is influenced by the perturbation which becomes larger with a decreasing of the chain length.[30] Our UV result in the gel state parallel that from Raman study. Almost all acyl chains of EPC are longer than those of DPPC, but they contain a lot of unsaturated bonds,[28] loosening the packing of the bilayers. In DPPC bilayers, the λ_{max} value of NRB is larger than that of peptide probe PEP, indicating that the packing of DPPC acyl chains is affected by the nature of the probes. The smaller perturbation of NRB compared with PEP reflects the better compatibility of the former with the lipid bilayers.

On the other hand, the differences between the λ_{max} values of NRB and PEP are very small in DMPC and EPC bilayers. The packing of these bilayers may be not so dense by nature to be affected significantly by NRB and PEP.

At 40—50 °C, the bilayers of three PC types containing the UV probes would have almost the same packing density, since the λ_{max} values are almost the same and constant. The probes in EPC bilayers show small blue shift with an increase of temperature. EPC bilayers are in the fluid state in this temperature range and their packing becomes looser as temperature rises.

The λ_{max} values of both UV probes in the DPPC bilayers show large blue shifts with an increase in temperature from about 25 to 35 °C, indicating a large change in the packing state of bilayers. IR studies have showed that the acyl chain packing of DPPC changes from an orthorhombic to a hexagonal subcell between 36—38 °C (pretransition), which is lower than a main phase transition temperature T_c.[31,32] The UV λ_{max} shifts may correspond to this change in packing state. Thus this change would accompany the density change. For PC with saturated acyl chains, more gauche isomers exist in the fluid state than in the gel state.[30,31] The structural disorder of the fatty acyl chains would cause the loosening of the packing.

On the other hand, λ_{max} value in DMPC bilayers is almost constant both below and above T_c. For DMPC, consisting of shorter acyl chains, the alignment of acyl chains in the gel state are originally much disturbed[30] and the density would not change so much with phase transition. In this case, the packing would not be so strong even in the gel state.

From these UV results, it is confirmed that the packing strength of acyl chain region of bilayers is affected mainly by the length and the chemical structure of the fatty acyl chains when the polar head group is identical, and it also depends on the order or fluidity of bilayers. Further it is confirmed that UV spectroscopy is one of the best methods for the study of the packing state of lipid bilayers. Although the probe is used in this work at a relatively high concentration, it is easy to lower its concentration because of its high UV sensitivity. By using an UV probe bound to a protein, such as retinal which can bind to a protein through a lysine side chain by forming a Schiff base linkage as found in rhodopsin[33] and bacteriorhodopsin,[34] it would be possible to obtain the information on the state of lipid surrounding the protein and on the lipid-protein interaction.

Resonance Raman Spectra of Red-Shifted Retinal Schiff's Base

Toshiharu SUGIHARA and Teizo KITAGAWA*,†

†Institute for Molecular Science, Okazaki National Research Institutes, Myodaiji, Okazaki 444
(Received January 7, 1986)

Synopsis. We have found that the visible absorption maximum (λ_{max}) of retinal Schiff's base in fluoro alcohols is considerably red-shifted. The C=N stretching Raman line exhibits a frequency shift in deuterated fluoro alcohols, indicating that the Schiff's base is protonated. Frequencies of the in-phase C=C stretching Raman lines ($\nu_{C=C}$) changed linearly with λ_{max}, and the $\nu_{C=C}$ vs. λ_{max} correlation coincides with that observed for retinoid proteins.

In attempts to elucidate the structure-function relationship of retinoid proteins, resonance Raman (RR) spectroscopy has been extensively used to explore the molecular events which befall the chromophore of visual pigments[1-7] and bacteriorhodopsin[8-13] upon light irradiation. One of the remaining problems to be clarified is the origin of the opsin shift, that is, the large red shift of the absorption maximum of a retinal Schiff's base (RSB) in proteins compared with that in organic solvents. Recently we found that RSB in fluoro alcohols such as 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP) and 2,2,2-trifluoroethanol (TFE) (Abbreviations for the chemical substances are summarized in the footnote of Table 1) gives an absorption band which is strongly red-shifted at the expense of the ordinary band in the blue region.[14] The amount of the red shift is larger than that usually observed for protonation of a Schiff's base by a strong acid, and the relative intensity of the red-shifted band to the ordinary band depends on the solvent composition and temperature; dilution of the fluoro alcohol solution with an inert solvent such as chloroform or rise of temperature decreases the relative intensity of the red-shifted band to the blue band. We are curious to know what occurs on the chromophore which exhibits such a large red shift of λ_{max}. In this note we report on RR spectra of all-*trans*-RSB of Ile-Ala-Phe-OBzl (RetIAF) and of butylamine (RetBu) in the fluoro alcohols, pointing out that the interaction between the Schiff's base nitrogen and alcoholic hydroxyl group alters the π delocalization of retinal and changes $\nu_{C=C}$ in linear correlation with λ_{max}.

Experimental

RetIAF was synthesized by mixing all-*trans*-retinal with Ile-Ala-Phe-OBzl[15] in ethyl acetate. 40 mg of HCl Ile-Ala-Phe-OBzl was dissolved in 5 ml of water and the solution was adjusted to pH 9 by 5% $NaHCO_3$. The solution became a gel. After extraction with 15 ml of ethyl acetate the organic layer was dried over Na_2SO_4 and filtered. Molecular sieve (3A) was added to the filtrate and then 100 mg of all-*trans*-retinal was incorporated into the solution, which was left to stand at 0 °C for 24 h. After removal of the molecular sieve, the solution was evaporated to give a yellow oil. The slightly yellow precipitate, which was formed on addition of hexane, was collected, washed with hexane, and dried in vacuum; the yield was 24 mg. The purity of the compound was confirmed by ^1H and ^{13}C NMR. RetBu was prepared according to the literature.[16] Deuterated HFIP or TFE was obtained by distillation of a mixture of D_2O and the fluoro alcohol (4:1). Other solvents were distilled immediately before use. The Schiff's base solution at a concentration of ca. 0.1 mM (1 M=1 mol dm^{-3}) was used for the Raman measurements. Raman spectra were measured with a JEOL-400D Raman spectrometer and an Ar laser (Spectra Physics, model 164) or a He/Cd laser (Kinmon Electrics, CDR80SG). The laser power at the sample point was 2—24 mW. About 50 µl of the sample solution in a cylindrical cell kept at 4 °C was used for the measurement.

Results and Discussion

The RR spectra of RetIAF and RetBu in the 1400—1700 cm^{-1} region are shown in Figs. 1(A) and (B), respectively. It is seen that the frequencies of the Raman lines are sensitive to the solvent and this solvent effect is most pronounced for the C=C and C=N stretching modes. The in-phase C=C stretching modes ($\nu_{C=C}$) of RetIAF and RetBu appear at 1576 and

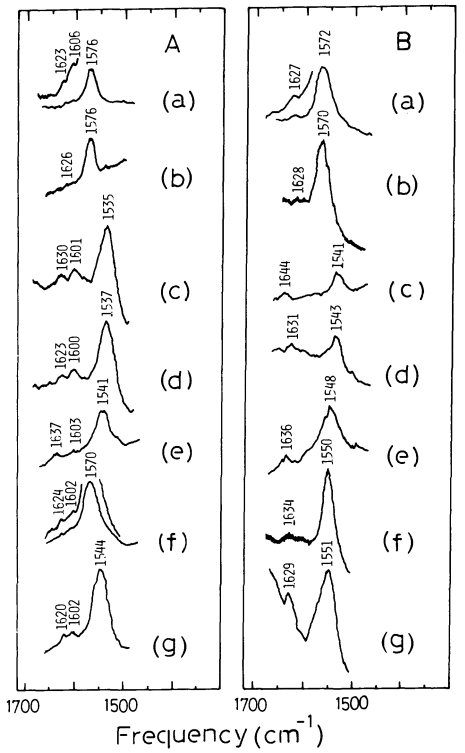

Fig. 1. The resonance Raman spectra of RetIAF (A) and RetBu (B) in the 1400—1700 cm^{-1} region. Excitation wavelengths and solvents are as follows: a): 441.6 nm, chloroform, b): 514.5 nm, chloroform, c): 514.5 nm, HFIP, d): 514.5 nm, HFIP (deuterated), e): 514.5 nm, TFE, f): 441.6 nm, TFE, g): 514.5 nm, TFE (deuterated).

1572 cm^{-1}, respectively, in chloroform (a) but they are shifted to 1535 and 1541 cm^{-1} in HFIP (c) and to 1541 and 1548 cm^{-1} in TFE (e). The Schiff's base C=N stretching modes ($\nu_{C=N}$) of RetIAF and RetBu appear at 1623 and 1627 cm^{-1}, respectively, in chloroform (a) but they are shifted to 1630 and 1644 cm^{-1} in HFIP (c) and to 1637 and 1636 cm^{-1} in TFE (e). Thus, the C=C and C=N stretching modes shift in opposite directions and their magnitudes are not correlated.

The visible absorption spectrum of RetIAF in TFE exhibits two absorption maxima at 368 and 494 nm, and the RR spectrum excited at 441.6 nm (f) is distinctly different from that excited at 514.5 nm (e). Therefore, it is deduced that there exist two molecular species in equilibrium in the TFE solution, each giving rise to an absorption band at either 368 or 494 nm. These are tentatively called the U and P species, respectively, in this paper. The bands in the 514.5 nm- and 441.6 nm-excited RR spectra are considered to arise predominantly from the P and U species, respectively. The U species gives the $\nu_{C=C}$ and $\nu_{C=N}$ lines at 1570 and 1624 cm^{-1} (f), respectively, while the P species gives the lines at 1541 and 1637 cm^{-1} (e). The RR spectrum of the TFE solution excited at 441.6 nm (f) is very close to that of the chloroform solution (a). The $\nu_{C=N}$ line of the P species exhibits frequency shift in deuterated fluoro alcohols [(d) and (g) in Figs. 1A and B], but that of the U species does not. Therefore, the P and U species are inferred to have protonated and unprotonated Schiff's bases, respectively.

On the other hand, protonation of RetIAF and RetBu in chloroform by a strong acid such as CF_3COOH caused frequency shifts of the $\nu_{C=C}$ mode by -32 and -15 cm^{-1}, respectively, and the $\nu_{C=N}$ mode by $+17$ and $+23$ cm^{-1}, respectively. The magnitude of the shift is smaller than the frequency difference between the chloroform and fluoro alcohol solutions for $\nu_{C=C}$, but it is larger for $\nu_{C=N}$. Table 1 summarizes the values of λ_{max}, $\nu_{C=C}$, and $\nu_{C=N}$ of RetIAF and RetBu in various solvents. When the values of λ_{max} are plotted against the values of $\nu_{C=C}$, it gives a straight line as displayed in Fig. 2. The linear correlation between λ_{max} and $\nu_{C=C}$ was previously reported for retinoid proteins,[5,9] but it is noteworthy here that the values of λ_{max} and $\nu_{C=C}$ of the present compounds in various solvents fall on the identical line with that of the retinoid proteins. This means that the solvent effect on the chromophore found in the present study is qualitatively the same as the role of surrounding proteins regarding the spectral property. Since the strength of the C=C bond in the conjugated linear molecules generally becomes weaker and thus the $\nu_{C=C}$ frequency becomes lower as delocalization of π electrons increases, the linear correlation between λ_{max} and $\nu_{C=C}$ suggests that the red-shift of λ_{max} of RetIAF and RetBu in fluoro alcohols as well as of retinylidene chromophore in proteins can be attributed to increas-

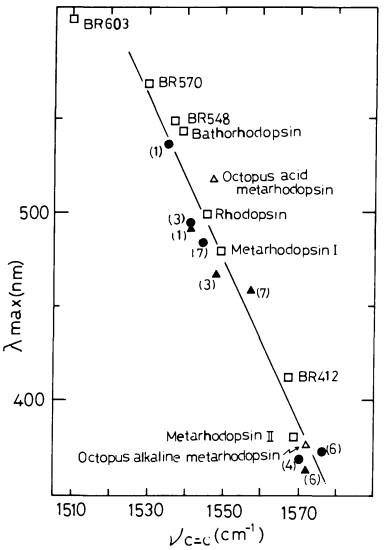

Fig. 2. Correlation between λ_{max} and $\nu_{C=C}$ for the present compounds and retinoid proteins. Data are obtained from rhodopsin,[3] bathorhodopsin,[1] metarhodopsin I and II,[5] bacteriorhodopsin,[12] octopus metarhodopsin,[7] and Table 1 (●: RetIAF and ▲: RetBu). Numbers besides the points represent the compounds specified in Table 1.

a) Abbreviations used are; RSB, retinal Schiff's base; RetIAF, RSB with Ile-Ala-Phe-OBzl; RetBu, RSB with butylamine; HFIP, 1,1,1,3,3,3-hexafluoro-2-propanol; TFE, 2,2,2-trifluoroethanol. b) Raman frequencies are obtained from the spectrum excited at 514.5 nm. c) Raman frequencies are obtained from the spectrum excited at 441.6 nm.

ed π delocalization. It is important to note that such π delocalization is controlled by the interaction at the Schiff's base.

An interesting feature of this study is that the $\nu_{C=N}$ modes of the red-shifted RetIAF and RetBu shift to lower frequencies in deuterated fluoro alcohols. Upon deuteration of HFIP, the $\nu_{C=N}$ modes of RetIAF (1630 cm^{-1}) and RetBu (1644 cm^{-1}) exhibit the frequency shift of −7 and −13 cm^{-1}, respectively, while the deuteration of TFE gives corresponding shifts of −17 and −7 cm^{-1}, respectively. This type of frequency shift is usually seen upon deuteration of proteins having protonated RSB.[3] Accordingly, it is likely that the alcoholic hydroxyl group acts as a Lewis acid and a proton is shared between the Schiff's base nitrogen and the alcoholic oxygen. If this were simply a hydrogen-bonding interaction in which the Schiff base nitrogen serves as a proton acceptor, the $\nu_{C=N}$ line would not exhibit such a large frequency shift upon deuteration of the alcohols. Therefore, the interaction between the N and H atoms is rather of a weak covalent type but it would not be categorized as a hydrogen bond. Thus, RetIAF and RetBu in fluoro alcohols behave as if they were protonated RSB. The solvent-dependent difference in frequency shifts upon deuteration reflects that the degree of coupling between the C=N stretching and the N–H in-plane bending modes varies depending on the strength of the quasi-covalent N–H bond. It is due to this vibrational coupling that the frequency of $\nu_{C=N}$ is not correlated with the frequency of $\nu_{C=C}$ or the values of λ_{max} despite the fact that the C=N bond is also affected by the π delocalization. We would stress finally that fluoro alcohol is more effective than a strong acid in shifting λ_{max} to red and on lowering $\nu_{C=C}$.

We wish to thank Prof. E. R. Blout of Harvard Medical School for his valuable suggestions and discussions.

Cubic Relation between Thermodynamic Functions and Natural Variables for Chemical Thermodynamic Systems

Makoto ISIHARA
Department of General Education, Shotoku-Gakuen Women's Junior College,
Nakauzura 1-38, Gifu 500
(Received January 16, 1986)

Synopsis. The relation between thermodynamic functions and natural variables for chemical thermodynamic systems is represented in terms of the geometry of a cube. Besides being helpful in understanding the abstractive nature of thermodynamic relation, this leads to a useful mnemonic as well.

It is well known that thermodynamic functions are characterized by natural variables and that they are related to one another through the Legendre transformation.[1] What we intend to show in this note is that the relation between thermodynamic functions and natural variables for chemical thermodynamic systems can be represented in terms of the geometry of a cube. Being simple, this does not seem to be trifling. Although it is quite probable that someone has noticed the fact already, no description of it can be seen in thermodynamic and chemical thermodynamic literature, as far as the author knows.[2] Only two kinds of thermodynamic squares,[3-5] which are mnemonic diagrams, have some relation with it, as mentioned later. The author is very afraid that his finding might be really a small rediscovery, but yet he believes that the fact is worth communicating here. It gives both conceptual and practical profits to workers studying and making use of chemical thermodynamics.

In general the thermodynamic function has the Pfaffian form consisting of several constituents, each of which is specified by the conjugate pair of extensive and intensive quantities. Let us denote the extensive and the intensive quantities for the i-th constituent, respectively, by $[1]_i$ and $[-1]_i$, which are rewritten as $[\sigma_i]_i$ with the parameter σ_i taking 1 or -1. We write $-\sigma_i$ as $\bar{\sigma}_i$ and -1 as $\bar{1}$ in the following. Denoting the thermodynamic function of natural variables $[\sigma_1]_1, \cdots, [\sigma_m]_m$ by $[\sigma_1 \cdots \sigma_m]$, we can put its Pfaffian form as

$$\mathrm{d}[\sigma_1 \cdots \sigma_m] = \sum_{i=1}^{m} \sigma_i [\bar{\sigma}_i]_i \mathrm{d}[\sigma_i]_i, \tag{1}$$

from which it follows immediately that

$$\left(\frac{\partial[\sigma_1 \cdots \sigma_m]}{\partial[\sigma_k]_k}\right)_{[\sigma_i]_i (i \neq k)} = \sigma_k [\bar{\sigma}_k]_k. \tag{2}$$

For the Legendre transformation changing one of natural variables from $[\sigma_k]_k$ into $[\bar{\sigma}_k]_k$ it is relevant to define the operator L_k as

$$L_k[\cdots \sigma_k \cdots] = [\cdots \sigma_k \cdots] - \sigma_k [\bar{\sigma}_k]_k [\sigma_k]_k. \tag{3}$$

This definition naturally gives

$$\mathrm{d}L_k[\cdots \sigma_k \cdots] = \mathrm{d}[\cdots \bar{\sigma}_k \cdots], \tag{4}$$

which allows us to put

$$L_k[\cdots \sigma_k \cdots] = [\cdots \bar{\sigma}_k \cdots]. \tag{5}$$

Substituting Eqs. 2 and 5 into Eq. 3, replacing σ_k with $\bar{\sigma}_k$, we have a generalized expression for the Gibbs–Helmholtz type equations

$$[\cdots \sigma_k \cdots] = [\cdots \bar{\sigma}_k \cdots] - [\bar{\sigma}_k]_k \left(\frac{\partial[\cdots \bar{\sigma}_k \cdots]}{\partial[\bar{\sigma}_k]_k}\right)_{[\sigma_i]_i (i \neq k)}. \tag{6}$$

On the other hand, From Eq. 2 the Maxwell relations are summarized in the form

$$\sigma_j \left(\frac{\partial[\bar{\sigma}_j]_j}{\partial[\sigma_k]_k}\right)_{[\sigma_j]_j} = \sigma_k \left(\frac{\partial[\bar{\sigma}_k]_k}{\partial[\sigma_j]_j}\right)_{[\sigma_k]_k} \quad (j \neq k), \tag{7}$$

the fixed variables other than $[\sigma_j]_j$ and $[\sigma_k]_k$ being suppressed for brevity. The abstractive nature of thermodynamic relation is succinctly expressed with the above notation.[6]

Now we confine ourselves to the three-constituent case. Surely this is a restriction, but it yields no serious loss of applicability. Putting $m=3$, we immediately see that our notation is ready to fit the geometry of a cube: Assign $[1]_i$'s and $[\bar{1}]_i$'s to six faces, $[\bar{1}]_i$ being opposite to $[1]_i$, assign $[\sigma_1\sigma_2\sigma_3]$ to the vertex formed by the three faces $[\sigma_1]_1$, $[\sigma_2]_2$, and $[\sigma_3]_3$, and assign L_i to the four edges connecting the vertices around $[1]_i$ with the vertices around $[\bar{1}]_i$. The scheme of the assignment is illustrated in Fig. 1 with a cubist-like manner. It is easy to find the geometrical counterparts of the equations mentioned in the preceding paragraph (vide infra). The cube tells us concisely the cyclic character of thermodynamic relation. Such geometrical emblematization seems to be impossible for general multi-constituent cases within usual "visible" polyhedrons.

The Pfaffian form of the internal energy U of the ν-component chemical thermodynamic system is written as

$$\mathrm{d}U = T\mathrm{d}S - p\mathrm{d}V + \sum_{\kappa=1}^{\nu} \mu_\kappa \mathrm{d}n_\kappa, \tag{8}$$

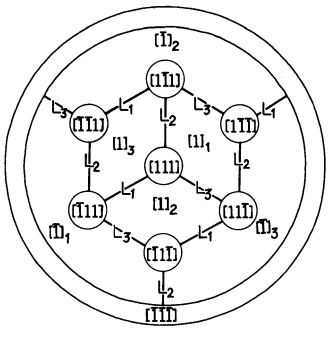

Fig. 1. Cubic relation.
The surrounding double circle stands for a vertex as well as small circles.

where T, S, p, V, μ_κ, and n_κ are the temperature of the system, the entropy, the pressure, the volume, the chemical potential and the amount of substance for the κ-th component, respectively. We have to treat more than three constituents except for the single-component case. It is never unpractical, however, to exclude the thermodynamic function of which natural variables are the chemical potential for some component(s) and the amount of substance for the other component(s). Using μ and n as representatives of μ_κ's and n_κ's, we can work actually within three constituents for chemical thermodynamic systems.[7] Thus the most typical and important choice is: $[1]_1=S$, $[\bar{1}]_1=T$, $[1]_2=-V$, $[\bar{1}]_2=p$, $[1]_3=n$, $[\bar{1}]_3=\mu$, and $[111]=U$. We have $[\bar{1}11]$ as the Helmholtz function A, $[1\bar{1}1]$ as the enthalpy H, and $[\bar{1}\bar{1}1]$ as the Gibbs function G. The grand (canonical) function, well-known in statistical mechanics and often denoted by Ω, corresponds to $[\bar{1}1\bar{1}]$. The others, $[11\bar{1}]$, $[1\bar{1}\bar{1}]$, and $[\bar{1}\bar{1}\bar{1}]$ have neither prevalent symbols nor names. We refer to this cube as U-cube.

Another choice to be mentioned comes from a famous rearrangement in Eq. 8

$$dS = \frac{1}{T}dU + \frac{p}{T}dV - \sum_{\kappa=1}^{\nu}\frac{\mu_\kappa}{T}dn_\kappa. \tag{9}$$

We set: $[1]_1=U$, $[\bar{1}]_1=1/T$, $[1]_2=V$, $[\bar{1}]_2=p/T$, $[1]_3=n$, $[\bar{1}]_3=-\mu/T$, and $[111]=S$. The three generalized Massieu functions[8] correspond to $[\bar{1}11]$, $[1\bar{1}1]$, and $[\bar{1}\bar{1}1]$; the first one and the third are the Massieu function J and the Planck function Y, respectively. We have $[\bar{1}1\bar{1}]$ as the Kramers function.[9] The others are nameless. This is S-cube. We can obtain various "thermodynamic cubes" likewise.

Next we show that thermodynamic cubes are useful and powerful as a mnemonic tool for thermodynamic relation. For this purpose it is appropriate to exemplify how to have the information from thermodynamic cubes. Let us take U-cube as an example. The view around the vertex G is shown in Fig. 2. We see that G has T, p, and n as natural variables, or reversely, that the thermodynamic function having T, p, and n as natural variables is G. We have the Pfaffian form

$$dG = -SdT + Vdp + \mu dn, \tag{10}$$

noting the faces behind and an extra negative sign for an intensive natural variable. A few views around edges are presented in Figs. 3 and 4 with some pliancy. In Fig. 3 we see that G is related to A through the Legendre transformation

$$G = A + pV \tag{11}$$

and that T and n are common natural variables in G and A. Figure 4 illustrates the way of obtaining the Gibbs–Helmholtz equations;

$$U = A - T\left(\frac{\partial A}{\partial T}\right)_{Vn}, \tag{12}$$

$$H = G - T\left(\frac{\partial G}{\partial T}\right)_{pn}. \tag{13}$$

The view around the face n is shown in Fig. 5. This indicates the four thermodynamic functions of which natural variables include n. Their partial derivatives with respect to n are μ (behind). This view is also adaptable for the two-constituent case of no chemical variable. Figure 6 concerns the following two Maxwell relations.

$$\left(\frac{\partial S}{\partial p}\right)_{Tn} = -\left(\frac{\partial V}{\partial T}\right)_{pn}, \tag{14}$$

$$\left(\frac{\partial p}{\partial T}\right)_{Vn} = \left(\frac{\partial S}{\partial V}\right)_{Tn}. \tag{15}$$

Note that an extra negative sign is supposed for every differentiation with respect to an intensive variable. The way of obtaining the Maxwell relations is completely analogous with that of thermodynamic squares. It should be emphasized that thermodynamic cubes have the neat sign convention throughout.

For mnemonics in thermodynamics,[10] we already have two kinds of thermodynamic squares, the Born

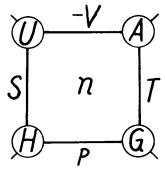

Fig. 5. Thermodynamic functions of a common natural variable.

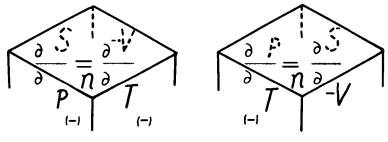

Fig. 6. The Maxwell relations.

diagram[3,4,11] and the Christie diagram,[5,12] which are suited to the Maxwell relations. Sign convention aside, a square in a thermodynamic cube gives the Christie diagram, which corresponds essentially to the Born diagram. The latter has thermodynamic functions and natural variables at sides and vertices, respectively, contrarily to the former. They work equivalently, as far as one square is concerned. Anyhow, no mnemonic is seriously necessary in the case of the two constituents (S,T) and (p,V). It is other cases that need a mnemonic tool.[13] It is undoubtful that a thermodynamic cube is far more excellent and general, even as a mnemonic, than a set of several thermodynamic squares with individual assignment of thermodynamic functions and natural variables.[3]

2) The author has checked a lot of descriptions related to the subject. There exist, however, so many books and articles on thermodynamics and chemical thermodynamics that he remains far away from the exhaustive inquiry.

3) H. B. Callen, "Thermodynamics," John Wiley & Sons, New York (1960), Section 7.2.

4) E. O. Koenig, *J. Chem. Phys.*, **3**, 29 (1935).

5) D. E. Christie, *Am. J. Phys.*, **25**, 486 (1957).

6) Thermodynamics itself is abstractive in the sense that it concerns no concrete form of thermodynamic functions.

7) As the case may be, we have additional terms $Xdx+\cdots$, say, due to an external field in Eq. 8. Even in such cases, if we choose three constituents relevantly with the rest of the Pfaffian form fixed, the cubic relation is valid within a defined family of thermodynamic functions. The relevant choice will be almost exclusively the original three.

8) H. B. Callen, "Thermodynamics," John Wiley & Sons, New York (1960), Section 5.4.

9) No symbol seems to prevail for this function.

10) As tabulation of its own value, we should cite Shaw's Jacobian table as well as Bridgman's table, which are more than mnemonics: A. N. Shaw, *Phil. Trans. Roy. Soc. London A*, **234**, 299 (1935); P. W. Bridgman, "Condensed Collection of Thermodynamic Formulas," Harvard University Press, Cambridge, Massachusetts (1926); J. C. Slater, "Introduction to Chemical Physics," McGraw-Hill, New York (1939), p. 27.

11) Not a few books contain description of such a thermodynamic square as quoted in Callen's book (Ref. 3). This kind of thermodynamic squares was initiated by M. Born in his lecture in 1929 according to L. Tisza, who named it the Born diagram: L. Tisza, "Generalized Thermodynamics," MIT Press, Cambridge, Massachusetts (1966), p. 64.

12) The Christie diagram originates from a mnemonic of natural variables for the $(S,T)-(p,V)$ case; see the references cited in Christie's note (Ref. 5). U-cube may be regarded as an improved generalization of the Christie diagram.

13) As a "real" mnemonic tool we recommend a truncated cube with symbols of thermodynamic functions on triangular faces, the edges around which are, of course, spurious.

Diode Laser Spectrum of the ν_8 Band of CH_3SH

Synopsis. The Stark effect was used to assign four series of the transitions in the heavily perturbed spectrum of methanethiol in the 14 μm region: K=0 and two K=1 series of A torsional symmetry and K=0 series of E symmetry. Effective parameters were determined for each series. The K=0 levels of A symmetry in the ν_8 state were found to be perturbed by a Fermi-type resonance.

Studies on the torsion-rotation energy levels in the excited states of the vibrations other than the torsion provide detailed information on hindered internal rotation. Most of the studies reported so far[1-4] are on methanol in the 9—10 μm region. In the present work, the torsion-rotation levels in the first excited ν_8 state of methanethiol (C-S stretching, 710 cm^{-1})[5] are studied.

The diode laser spectrometer described previously[6] was used in the present work. The frequency-modulated laser beam was passed through a cell of 55 cm in length equipped with parallel Stark plates separated by about 3 mm. A commercially available sample of methanethiol was used without further purification. The sample pressure was in the region of 0.3—2 Torr (1 Torr=133.322 Pa). About one thousand absorption lines were observed with four laser diodes in the range of 703.3—718.2 cm^{-1}. The absorption line frequencies were measured by interpolating the CO_2 ν_2 band lines[7,8] using etalon fringes. The absolute accuracy in the frequencies is estimated to be better than 0.003 cm^{-1} for unoverlapped lines.

At a medium resolution, the ν_8 band looked like a parallel band of a symmetric top, but once the P- and R-branches were resolved at a high resolution, their structures were much more complicated than those expected for a parallel band. Several series of lines were found in the complicated structures with the help of a Loomis-Wood diagram. Each of the series is composed of transitions with different J, the total angular momentum quantum number, and with the same quantum numbers, n, σ, and K,[9] where n is the torsional quantum number, σ specifies the torsional symmetry (σ=0 for A- and 1 for E-species), and K is the quantum number of the component of the total angular momentum along the internal rotation axis.[10] It was found, however, impossible to explain the spectrum on the basis of the conventional internal axis method (IAM)[10,11] by choosing appropriate torsional and rotational parameters for the excited vibrational state, because the ν_8 state was seriously perturbed by the torsionally excited states in the ground vibrational state. Accordingly, no assignment could readily be made for any of the series without further information, except that a pair of the $A(\sigma=0)$, K=1 series were identified unambiguously by their characteristic K-doubling pattern. The pair series are listed in the latter half of Table 1.

The Stark effect of the spectral lines provided another clue. The observed Stark-modulated spectrum was congested with Stark components and was very complicated. In contrast, a source-modulated spectrum with a DC field was found to be much simpler and readily gave a rough estimate of the magnitude of the Stark effect of each line. As the DC field was increased, most of the absorption lines were broadened and their peak intensities were decreased. Only the lines with a small Stark effect were left relatively unaffected in the spectrum even by a field as strong as 670 V/cm. An example is shown in Fig. 1. Since the transitions involving the K=0 levels do not show the first-order effect, they must be assigned to

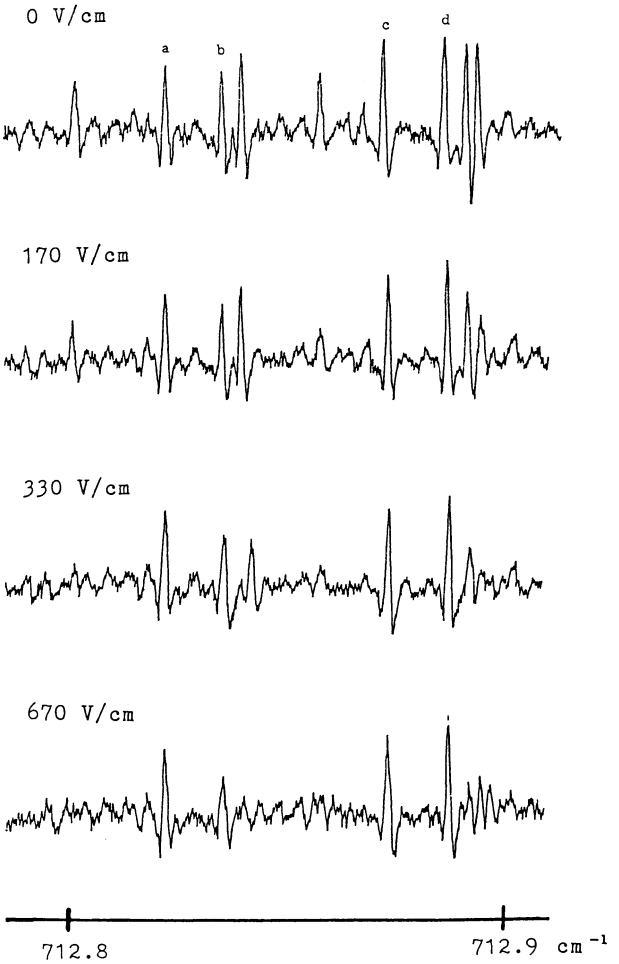

Fig. 1. Source modulated spectra of the CH_3SH ν_8 R(2) transitions with various DC Stark fields applied. At the Stark field of 670 V/cm, four lines, a—d, with relatively small Stark effect remain. a) 712.821, A, K=1, b) 712.835, unassigned, c) 712.874, A, K=1, d) 712.887 cm^{-1}, E, K=0.

a) All values in cm^{-1}. b) Values in parentheses are estimated errors in units of 10^{-3} cm^{-1}. c) Energy level notation for A species follows that for asymmetric rotors, $J_{Ka,\,Kc}$. d) Energy is given relative to the $J=K=0$ level of each species in the ground state. The energies without an asterisk are obtained from the observed infrared frequencies in the left column and the observed microwave frequencies.[12,13] For the asterisked levels, the ground state energy levels were calculated from the constants[12] and their estimated errors include the uncertainties in the calculation. e) Calculated by Eq. 1 from the parameters given below. f) Parameters in Eq. 1 determined by weighted least-squares. The numbers in parentheses are standard errors in units of the last digit of the parameter.

some of these lines least affected by Stark effects. Two series involving the $K=0$ levels were thus identified. The one at higher-frequency was assigned to the A-species and the other one at lower frequency to the E-species, as shown in the former half of Table 1, on the basis of the following consideration. In the Loomis-Wood diagram, the lower series is in a cluster of several series, whereas the higher one is separated from the cluster by about 0.5 cm^{-1}. The shift can be explained by a resonance of the $n=0$, A, $K=0$ stack of the ν_8 state with the $n=4$, A, $K=0$ stack in the ground vibrational state, which is located at about 40 cm^{-1} below the former stack. On the other hand, there are no nearby perturbing levels around the ν_8, $n=0$, E, $K=0$ stack.

The assigned transitions are combined with the ground state torsion-rotation energy levels[12,13] to give the vibration-torsion-rotation levels in the ν_8 state. The levels in the ν_8 state are fitted to

$$E(\sigma,\ J,\ K) = w_{\sigma K} + b_{\sigma K}J(J+1) - d_{\sigma K}\{J(J+1)\}^2, \quad (1)$$

by the weighted least-squares method; the results are shwon in Table 1. The fact that the values of b_{A0} and d_{A0} are close to those of b_{E0} and d_{E0} suggests that the resonance is of the Fermi type. The further analysis requires information on the perturbing $n=3$ and 4 levels in the ground vibrational state.

One of the authors, Kuniaki Nakagawa, would like to thank the late Professor Tsunetake Fujiyama for his encouragement in the early stage of the work. He is also grateful to Dr. Chikashi Yamada for his technical assistance. The authors are indebted to Professors Kozo Kuchitsu and Kojiro Takagi for critical reading of the manuscript. The medium resolution spectrum which served as a guide to the present measurement was kindly provided by Professor Fujiyama and Dr. Shi-aki Hyodo. This work was partly supported by the Joint Studies Program (1981—82 and 84—85) of the Institute for Molecular Science and by a Grant-in-Aid for Scientific Research No. 60740256 from the Ministry of Education, Science and Culture.

A Consideration on the Mechanism of the Wacker Reaction from the Viewpoint of the Trans Influence of Ligands ($OH^->Cl^->H_2O$)

Sumio SHINODA, Yasuyuki KOIE, and Yasukazu SAITO*
Institute of Industrial Science, The University of Tokyo,
22-1, Roppongi 7 Chome, Minato-ku, Tokyo 106
(Received February 22, 1986)

Synopsis. The trans influence of three ligands (OH^-, Cl^-, and H_2O) was compared for the first time according to the same experimental standard ($^1J(PtP_{trans})$). Based on the extremely high trans influence of the OH^- ligand, a mechanism was proposed for the palladium(II) oxidation of ethylene, which includes the rate-determining external attack of H_2O on a possible intermediate, *trans*-$[PdCl_2(OH)(C_2H_4)]^-$.

Although the palladium(II) oxidation of ethylene (the Wacker reaction) has been studied extensively, its mechanistic details (the stereochemistry of the hydroxypalladation and the nature of the rate-determining step) are still the subject of some debate.[1,2] While the mechanism proposed by Henry (rate-determining *syn*-hydroxypalladation) is consistent with the kinetics,[1] Bäckvall et al.[3] proposed a mechanism of the Wacker reaction which reconciles the anti stereochemistry of the hydroxpalladation step with the kinetics. The important point is that the hydroxylation occurs in a *reversible* reaction by the external attack of water on $[PdCl_2(OH_2)(C_2H_4)]$ (Eq. 1), followed by a rate-determining step in which the loss of chloride ion from $[HOCH_2CH_2PdCl_2(OH_2)]^-$ (Eq. 2) takes place.

$$[PdCl_2(OH_2)(C_2H_4)] + H_2O \rightleftharpoons [HOCH_2CH_2PdCl_2(OH_2)]^- + H^+ \quad (1)$$

$$[HOCH_2CH_2PdCl_2(OH_2)]^- \rightleftharpoons [HOCH_2CH_2PdCl(OH_2)] + Cl^- \quad (2)$$

However, the reversibility of Eq. 1 was seriously questioned on the basis of the deuterium isotope effect for ethylene-1,1-d_2,[4] and later on the basis of the relative rate of isomerization vs. oxidation with allyl-1,1-d_2 alcohol adopted as a substrate (very slow isomerization via hydroxypalladation-deoxypalladation processes, despite the rate expression for oxidation being the same as that for ethylene oxidation).[5,6] Thus, if anti stereochemistry is assumed for the hydroxypalladation step, the most likely mechanism which is consistent with the kinetics would be a rate-determining attack of H_2O on a $[PdCl_2(OH)(C_2H_4)]^-$ species.[7] In the present paper, we would like to discuss the possibility of this mechanism from the points of view of (i) the activation of coordinated ethylene toward the external attack of an H_2O molecule, (ii) the nature of the ethylene–palladium(II) bond, and (iii) the trans influence of the OH^- ligand. Some of the experimental data are our own and are presented here for the first time.

In a previous paper,[4] we suggested that the displacement of the coordinated ethylene to an unsymmetrical position was important in the Wacker reaction; its transition-state structure contrasts with that of ethylene methoxy-mercuration, which is accompanied by considerable C–O bond formation.[10] Actually, Eisenstein and Hoffmann[11] showed that a symmetrically η^2-coordinated olefin was deactivated toward attack by an external nucleophile, and that olefin slipping, a deformation to η^1 coordinantion, played a crucial role in activating the olefin, with an increase in the overlap population between the π^* orbital of the olefin and the electron pair of the nucleophiles. This idea was supported by recent experimental findings.[12]

The bonding nature of metal-ethylene π-complexes $[MCl_3(C_2H_4)]^-$ (M=Pd, Pt) was investigated by means of ab initio calculations on an extended basis,[13] where the creditability of the calculations was ensured by the agreement between the calculated and observed values for both the geometry and the barrier to rotaion in $[PtCl_3(C_2H_4)]^-$. For this complex, the amounts of σ-donation and π-back-donation were evaluated as 0.24 and 0.22 electrons respectively. As for $[PdCl_3(C_2H_4)]^-$ the corresponding values are 0.12 (σ-donation) and 0.07 (π-back-donation) electrons, indicating the weakness of the Pd-ethylene bond relative to the Pt-ethylene bond. By comparing these two values (0.12>0.07), it was also concluded that σ-donation is more important than π-back-donation in the case of $[PdCl_3(C_2H_4)]^-$. In fact, many kinds of experiments support these trends.[14–16]

Previously, an unexpectedly high trans influence of the OH^- ligand in comparison with the Cl^- ligand was pointed out[4] on the ground of the $^1J_{PtP}$ values for the Pt(II) complexes $[PtX(CH_3)(Ph_2PCH_2CH_2PPh_2)]$.[17] We determined here the corresponding value for the aqua complex, together with the acetone complex (Table 1), to complete the comparison of the trans influence among OH^-, Cl^-, and H_2O ligands. Table 1 unequivocally confirms that the trans influence of

		Rh	Ir	Rh	Ir	
OH^-	−1.55	1961	1949	−2.45	−2.68	−0.0941
Cl^-	−1.19	1980	1965	−2.05	−2.22	
H_2O						−0.7121

a) $P_L=E_{1/2}^{ox}[Cr(CO)_5L]-E_{1/2}^{ox}[Cr(CO)_6]$. From Ref. 29. b) From Ref. 30. c) Standard: Ag/Ag^+ 0.1 mol dm^{-3} CH_3CN solution. From Ref. 31. d) From Ref. 20.

OH^- is far stronger than not only Cl^- but also H_2O. Since the $^1J_{PtP}$ value reflects well the σ-bond strength between the platinum and phosphorus atoms, [18] it can be said that the Pt–P(trans) σ bond is most weakened in the case of the hydroxo complex because of the strongest σ bonding between the platinum(II) and the OH^- ligand.[19]

As far as we know, there are no other data available for comparing these three ligands on the same experimental standard. However, some relevant data are collected in Table 2. It is obvious from Table 2 that OH^- is the most electron-donating among the three. With respect to theoretical studies, the CNDO/2 calculations of pentaammine complexes $[M(NH_3)_5X]$ ($M=Co^{2+}$, Co^{3+}, Fe^{2+}, and Fe^{3+}; X=FH, OH_2, CO, NH_3, pyridine, OH^-, F^-, and CN^-) showed that the M-NH_3 bond was weakened when the trans ligand was changed from H_2O to OH^-.[20] Recently, on the basis of the equilibrium geometry obtained by ab initio calculations with energy-gradient methods, the trans influene order of $OH^->Cl^->NH_3>H_2O$ was concluded.[21]

According to the analysis of the palladium(II)–ethylene bond (vide supra), σ-donation (from the ethylene π orbital to the Pd d_σ orbital) is important. Taking into consideration the strong trans influence of the OH^- ligand (relative to Cl^- and H_2O), it is quite conceivable that the η^2-coordinated ethylene slips most easily when its trans position is occupied by this ligand.[22] If this process occurs exclusively for the hydroxo complex, the observed kinetics is compatible with the anti stereochemistry of hydroxy-palladation.

7) Bäckvall et al.[3] and Henry et al.[5] noted that the nucleophilic attack on a negatively charged π-olefin-metal complex is unlikely. However, even if this reaction is supposed to be driven by a cationic charge on the coordinating carbon atom, its charge density would not necessarily be determined by the formal charge of the complexed ion as a whole. Rather, the trans influence of ligands,[8] either ionic or neutral, seems more important. For instance, the ^1H chemilcal shifts and ν(Ir-H) of a series of hydridoiridium(III) complexes *trans*-[H(L)Ir(CO)(Cl)$(PPh_3)_2$] were shown to be understandable in terms of the σ-donor strength of the trans ligand L,[9] quite independent of the formal charge of the complex.

22) Due to the strong trans influence of ethylene, the formation of *trans*-$[PdCl_2(H_2O)(C_2H_4)]$ is substantial.[1] It is well known that the proton-dissociating ability of H_2O is enhanced by coordination with metal ions.[23] Further, this effect is emphasized when there is an olefin ligand at its trans position.[24] Leden and Chatt estimated the acid-dissociation constant of $[PtCl_2(H_2O)(C_2H_4)]$ to be of the order 10^{-5},[25] while Henry assumed 10^{-6} as the corresponding value of $[PdCl_2(H_2O)(C_2H_4)]$.[26] Although he claimed the presence of kinetically significant amounts of the intermediate *cis*-$[PdCl_2(OH)(C_2H_4)]^-$ on this standard (also assuming about 10% *cis*-form in the total), the acid-dissociation constant may be much higher in view of the extremely high affinity of Pd(II) to OH^- in comparison with Pt(II) (Eqs. 3 and 4).[27]

Synopsis. The crystal structure of a binuclear copper(II) complex with 1,2,3,4-tetrakis(salicylideneamino)-2,3-dimethylbutane (abbreviated as H_4sata), Cu_2(sata), was determined by the single-crystal X-ray diffraction method. The complex molecule has two coordination units formed by a planar 6-5-6 fused chelate ring and takes a nonstacked form.
