Reaction of 4-Bromosydnones (3) with Potassium Thiocyanate and Selenocyanate. General Procedure. A stirred mixture of 4.1 mmol of **3** and 4.1 mmol of potassium thiocyanate or selenocyanate in 10 ml of anhydrous DMF was heated at 80—90 °C. After 1—1.5h (reaction with potassium thiocyanate) or 4—6h (reaction with selenocyanate) of heating, the reaction mixture was cooled and poured into ice-water. The precipitated solid was collected by filtration and recrystallized from ethanol-acetone (10:1) to provide pure **11** or **12** (Table 3).

Reaction of 4-Bromo-3-phenylsydnone (3a) with Potassium *O*-Ethyl Dithiocarbonate. To a stirred solution of 1.00 g (4.2 mmol) of **3a** in 15 ml of anhydrous DMF was added 0.67 g (4.2 mmol) of potassium *O*-ethyl dithiocarbonate and then the mixture was heated at 80—90 °C. After ca. 0.5h, potassium bromide began to precipitate. After 4h, the reaction mixture was cooled and was poured into ice-water and then the precipitates were collected by filtration; 0.32 g (44%); mp 156—150 °C. Recrystallization from ethanol provided 0.30 g (41%) of pure **11a** as a yellow solid.

We are grateful for valuable discussion with Dr. Haruo Matsuyama of Tokyo Metropolitan University.

Efficient Synthesis of a New Amino Acid, (2*S*,3*R*,4*R*)-4-Chloro-3-hydroxyproline

Sannamu Lee,* Yasushi Kodera,† Kosaku Noda,†† Haruhiko Aoyagi, Tetsuo Kato, and Nobuo Izumiya
Laboratory of Biochemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812

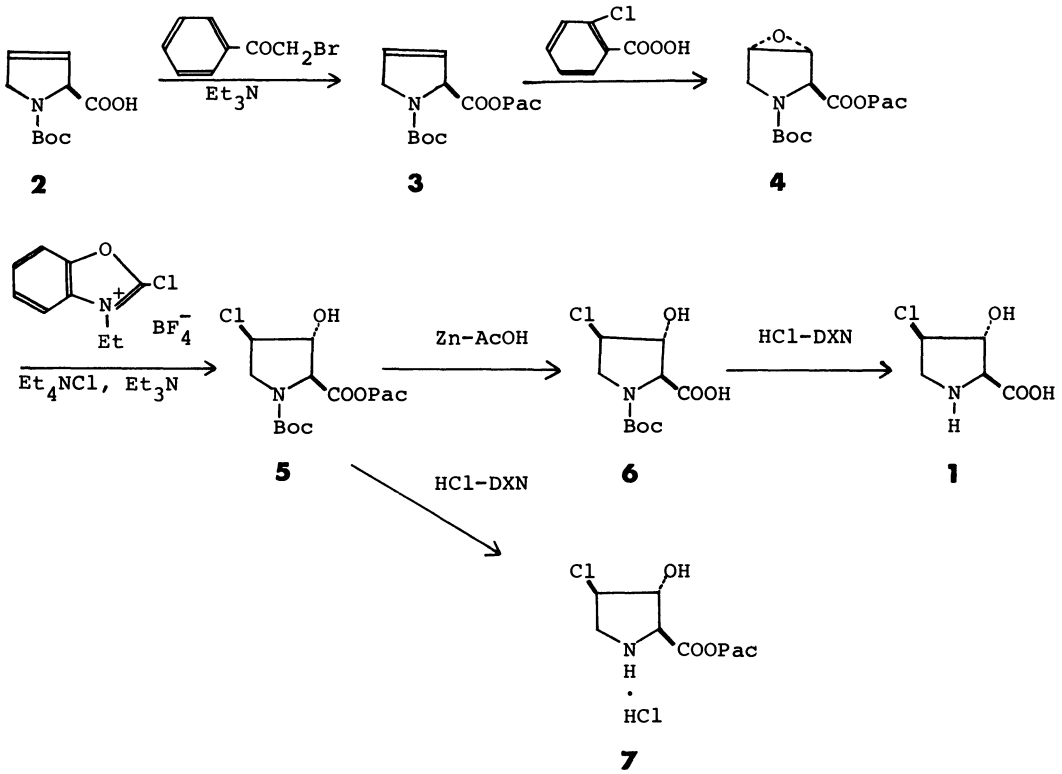
††Laboratory of Biochemistry, Fukuoka Women's University, Higashi-ku, Fukuoka 813
(Received September 12, 1985)

An unusual new amino acid, (2*S*,3*R*,4*R*)-4-chloro-3-hydroxyproline, was stereospecifically synthesized through a four-intermediate from Boc-3,4-dehydro-L-proline. The obtained product was stable in a mild alkaline solution.

The 3,4-disubstituted prolines occur in natural cyclic peptide toxins, e.g., virotoxin[1] and cyclochlorotine.[2] The two diastereomeric 3,4-dihydroxy-L-prolines in virotoxin were synthesized from *N*-tosyl-3,4-dehydro-L-proline methyl ester by Kahl and Wieland.[3] (2*S*,3*S*,4*R*)-Dichloroproline in cyclochlorotine has neither been isolated in a free state nor synthesized because of its instability under acid hydrolytic and mild basic conditions. In the course of studying the structure-activity relationship of cyclochlorotine, we found that both chlorine moieties in 3,4-dichloroproline are essential regarding toxic activity,[4] although attempts to synthesize 3,4-dichloroproline were unsuccesful.

Here, we report the synthesis of an interesting proline derivative, (2*S*,3*R*,4*R*)-4-chloro-3-hydroxyproline (**1**) through a stereoselective route (Scheme 1). The phenacyl group, which is deprotected by zinc powder in an aqueous acetic acid, was selected for the protection of the carboxyl group in order to avoid alkaline conditions.[5] Boc-3,4-dehydro-L-proline (**2**) was converted to its phenacyl ester (**3**) in high yield. Compound **3** was treated with *m*-chloroperbenzoic acid and an obtained crude product was purified by silica gel chromatography to give the corresponding epoxide (**4**). The stereochemistry in this epoxide was not directly clarified but a TLC of the reaction mixture showed only two main spots of the epoxide and the starting material, except for a few trace spots. This result suggests that the configuration of the obtained epoxide is a 2,3-*trans* form in consideration of the stereoselective epoxidation of *m*-chloroperbenzoic acid.[6] A treatment of **4** with 2-chloro-3-ethylbenzoxazolium tetrafluoroborate was expected to give Boc-3,4-dichloro-L-proline phenacyl ester,[7] but yielded Boc-3-hydroxy-4-chloro-L-proline phenacyl ester (**5**) instead. A deprotection of the phenacyl group using zinc powder in acetic acid gave Boc-3-hydroxy-4-chloro-L-proline (**6**), which was converted to 3-hydroxy-4-chloro-L-proline (**1**) with HCl in dioxane. Compound **5** was treated with HCl in dioxane to



Scheme 1.

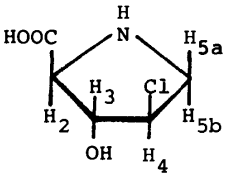
a) Protones of **1** were defined as described below.



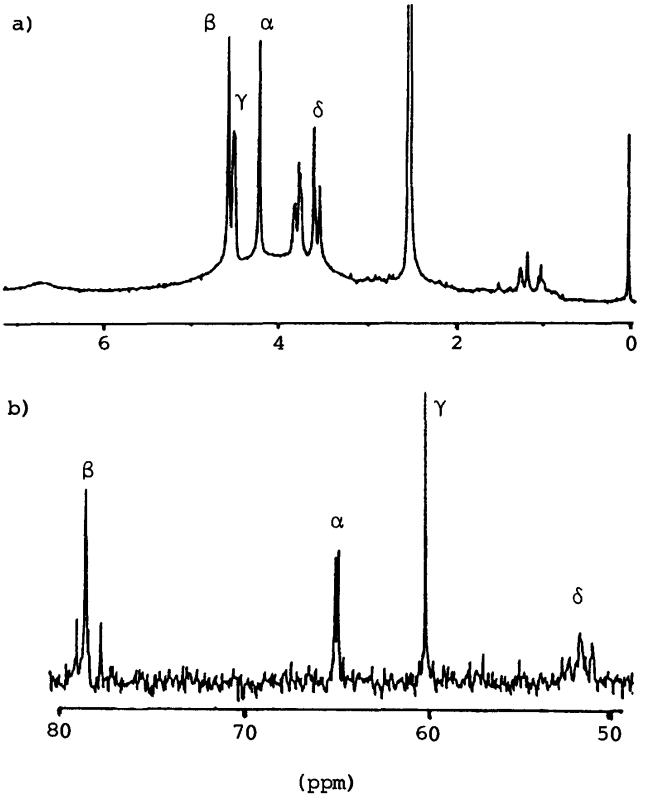


Fig. 1. ^{1}H-NMR spectrum of **1** (a) and ^{13}C-NMR spectrum of **1** resulting from selective irradiation of γH (b). The peak of δC showed a coupling with γH.

give 3-hydroxy-4-chloro-L-proline phenacyl ester (**7**). Compounds **6** and **7** can be used as acid and amine components, respectively, in a peptide synthesis.

The substituted positions of 3-hydroxy and 4-chloro groups in the proline was determined by a ^{13}C{^{1}H} selective decoupling technique of NMR (Fig. 1). The stereochemistry of 3-hydroxy and 4-chloro groups was determined to be 2,3-*trans* and 3,4-*trans*, respectively, compared to the coupling constants of 3,4-dihydroxy-L-proline diastereoisomer (Table 1). These results suggest that the ring opening of epoxide **3** arose from its trans side, attacking (exclusively) position 4.

This 3-hydroxy-4-chloro-L-proline was stable under ammoniacal alkaline conditions the same conditions under which dichloroproline in cyclochlorotine decomposes to a pyrrole derivative with the release of hydrogen chloride.[2)] This result means that 3-hydroxy-4-chloro-L-proline derivatives can be used for a conventional peptide synthesis. Proline analogs with a variety of functional groups have been developed for use in peptide and protein chemistry since proline often plays an important role for maintaining conformation and biological activities. This new amino acid may be useful for structure-activity studies as a proline analog having both hydrophobic and hydrophilic functional groups.

Experimental

All the melting points are uncorrected. TLC was carried out on silica gel G (Merck). Optical rotations were measured on a Union high-sensitivity polarimeter PM-71. ^{1}H and ^{13}C NMR spectra were recorded in a DMSO-d_6 solution on a JEOL FX-200 spectrometer at 29°C. Tetramethylsilane was used as an internal reference; sample concentration, 10—30 mg ml^{-1}. Amino acid analyses were performed using a Yanagimoto automatic analyzer LCA-8.

Boc-3,4-dehydro-L-proline Phenacyl Ester (3): To a solution of Boc-3,4-dehydro-L-proline (**2**)[8)] (6.39 g, 30 mmol) and Et_3N (4.06 ml) in EtOAc was added phenacyl bromide (5.77 g, 29 mmol) at room temperature. Stirring was continued for 6 h and the precipitate was filtered off. The filtrate was diluted with EtOAc (100 ml). The solution was washed with water, 4% $NaHCO_3$ and water, and dried over Na_2SO_4. The filtrate was evaporated in vacuo to give an yellow oil; yield, 9.47 g (98%); R_f=0.66 ($CHCl_3$–EtOH, 9:1).

***Trans*-Boc-3,4-epoxy-L-proline Phenacyl Ester (4):** To a solution of **3** (9.47 g, 28 mmol) and 2,6-di-*t*-butyl-*p*-cresol in $CHCl_3$ (100 ml), *m*-chloroperbenzoic acid (6.79 g, 28 mmol of 80% assay) dissolved in $CHCl_3$ (50 ml) was added dropwise over a period of 2 h with vigorous stirring. The mixture

was heated to reflux for 3 h. The content of the flask was cooled in an ice bath and the precipitate was removed by filtration. The filtrate was washed with 10% $NaHSO_3$, 4% $NaHCO_3$, and water, and dried over Na_2SO_4. The filtrate was then evaporated to give an oil (9.80 g). A solution of the oil in $CHCl_3$ was applied to a silica gel column (4×62 cm); cyclohexane–EtOAc (4:1) was used as an eluant and a 7.5 ml fraction was collected. Fractions 358—490 were collected and evaporated to produce an oil; yield, 2.12 g (22%); R_f=0.35 (cyclohexane–EtOAc, 4:1). A portion of starting material **3** (4.01 g) was recovered from fractions 235—335.

Boc-(2*S*,3*R*,4*R*)-4-chloro-3-hydroxyproline Phenacyl Ester (5): To a stirred suspension of **4** (335 mg, 1 mmol), tetraethylammonium chloride (165 mg, 1 mmol) and 2-chloro-3-ethylbenzoxazolium tetrafluoroborate (269 mg, 1 mmol) in CH_2Cl_2 (4 ml) was added (dropwise) a solution of Et_3N (0.17 ml) in CH_2Cl_2 (2 ml) at 0 °C under a nitrogen atmosphere.[7] The resulting mixture was stirred at room temperature for 48 h. After evaporation of the solvent, the residue was applied to a LiChroprep Si 60 (40—63 μm) column (1×20 cm); $CHCl_3$–EtOAc (9:1) was used as an eluant, 2 ml fraction. Fractions 10—13 were collected and evaporated to give an oil; yield 120 mg (32%); R_f=0.58 ($CHCl_3$–EtOAc, 9:1).

Boc-(2*S*,3*R*,4*R*)-4-chloro-3-hydroxyproline (6): To a stirred solution of **5** (250 mg, 0.67 mmol) in 90% acetic acid was added zinc powder (30 mg) at room temperature. After 2 h, the precipitate was filtered off, and the filtrate was evaporated in vacuo. The residue was acidified with 10% citric acid and extracted with EtOAc. The extract was dried over Na_2SO_4 and evaporated to give an oil; yield 150 mg (84%). R_f=0.17 ($CHCl_3$–MeOH, 5:1).

(2*S*,3*R*,4*R*)-4-Chloro-3-hydroxyproline Phenacyl Ester Hydrochloride (7): Compound **5** (690 mg, 1.8 mmol) was treated with 3.5 M HCl (1 M=1 mol dm^{-3}) in dioxane (5.1 ml) for 2 h and the solution was evaporated. The obtained product was collected with the aid of ether. Recrystallization from MeOH–ether gave 463 mg (80%); mp 168—169 °C; R_f=0.38 ($CHCl_3$–MeOH, 9:1).

Found: C, 48.73; H, 4.83; N, 4.29%. Calcd for $C_{13}H_{15}O_4NCl_2$: C, 48.76; H, 4.72; N, 4.37%.

(2*S*,3*R*,4*R*)-4-Chloro-3-hydroxyproline (1): Compound **6** (30 mg, 0.1 mmol) was treated with 4.7 M HCl in dioxane (2 ml) for 2 h at room temperature. The solution was evaporated. The residual oil was applied to a Dowex 50 (H^+ form); 10% pyridine was used as an eluant. The fraction containing the product was evaporated to give a solid; yield, 12 mg (68%); $[\alpha]_D^{20}$ −18.1° (*c* 0.25, MeOH); R_f=0.34 (1-butanol–AcOH–pyridine–H_2O, 4:1:1:2).

Found: C, 34.39; H, 5.15; N, 7.75%. Calcd for $C_5H_8O_3NCl \cdot 1/2H_2O$: C, 34.39; H, 5.19; N, 8.02%.

Stability of 1: To a solution of **1** (5.0 mg) in water (2 ml), Et_3N was added to adjust at pH 10.5. The solution was left to stand for 2 d at room temperature. An aliquot of the solution was applied on the amino acid analyzer (column size; 0.4×12.5 cm, pH of buffer solution; 3.25). Only a single peak of **1**, eluted for 6.0 min (cf Pro, at 12 min), was detected.

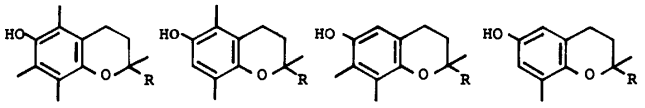
Oxidation of Lipids. XIII. Antioxidant Activities of α-, β-, γ-, and δ-Tocopherols

Etsuo NIKI,* Jyunichi TSUCHIYA, Yasuyuki YOSHIKAWA, Yorihiro YAMAMOTO, and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113
(Received September 18, 1985)

The antioxidant activities of α-, β-, γ-, and δ-tocopherols were studied. They were all effective as antioxidant in the oxidations of methyl linoleate in homogeneous solution. When one of the four tocopherols was used alone, they were consumed at the same rate and they suppressed the oxidation for the same period. However, the stabilities of chromanyloxyl radicals derived from the corresponding tocopherols varied considerably and decreased in the order α>β≅γ>δ -chromanyloxyl radicals. α-Tocopherol reacts quite rapidly with β-, γ-, and δ-chromanyloxyl radicals to give α-chromanyloxyl radical and β-, γ-, and δ-tocopherols respectively. Accordingly, when the four tocopherols were used together, α-tocopherol was consumed first, then β- and γ-tocopherols were consumed, and δ-tocopherol began to decrease after most of α-, β-, and γ-tocopherols were depleted.

The non-enzymatic, random peroxidations of biological molecules and foods by molecular oxygen have received much attention recently in connection with their pathological, toxicological, clinical, and nutritional effects.[1-12] Tocopherols (vitamin E) have been accepted to function as potent antioxidant by scavenging peroxyl radicals and interrupting free radical chain reactions. In a series of our study on the oxidation of lipids and its inhibition, we have studied in this work on the relative antioxidant activities of α-, β-, γ-, and δ-tocopherols.



R: $C_{16}H_{33}$-

α-Tocopherol β-Tocopherol γ-Tocopherol δ-Tocopherol

Experimental

Natural *d*-α-, *d*-β-, *d*-γ-, and *d*-δ-tocopherols provided by Eisai Co. Ltd. were used as received. Commercial methyl linoleate was purified by silica-gel column before use. Dimyristoyl phosphatidylcholine (PC) was used as received from Sigma Chemicals. 2,2'-Azobis(2,4-dimethylvaleronitrile) (AMVN) was used as a radical initiator in order to generate initiating free radicals at a constant and known rate. The rate of chain initiation was determined by the conventional method[13-15] as reported previously[16,17] using 2,6-di-*t*-butyl-4-methylphenol as an antioxidant. Commercial galvinoxyl and 2,2-diphenyl-1-picrylhydrazyl were used as received.

Liposome was prepared as reported previously[18,19] and subjected to sonication with a Branson Sonifier Model 185 to obtain a unilamellar vesicles. The oxidation was carried out at 37°C under air in a Pyrex glass ampoule immersed in a water bath. The reaction mixture was agitated with a magnetic stirrer. The rate of oxygen uptake was followed with a pressure transducer and the rate of consumption of tocopherols was followed with high performance liquid chromatography at 294 nm. Electron spin resonance (ESR) spectra were recorded on a X-band JEOL FE1X spectrometer at room temperature.

Results and Discussion

The rate of spontaneous oxidation of methyl linoleate was quite small, but the oxidation proceeded smoothly in the presence of AMVN without any noticeable induction period and a constant rate of oxygen uptake was observed. When tocopherol was added to the reaction mixture, the oxidation was suppressed markedly and a clear induction period was observed. Figures 1 and 2 show the results of oxidation of methyl linoleate initiated with AMVN in the presence of α-tocopherol and γ-tocopherol respectively. The dotted line in Fig. 1 shows the oxygen uptake in the absence of tocopherol. Figures 1 and 2 show that α-tocopherol and γ-tocopherol were consumed linearly with time and when all of tocopherols were depleted, the induction period was over and a fast oxidation took place. It is noteworthy that the rate of oxidation after the induction period is similar to that in the absence of tocopherol. Similar results

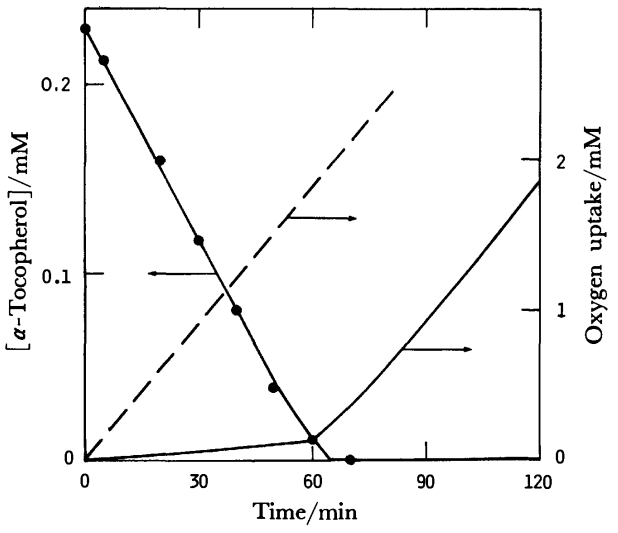


Fig. 1. Rates of oxygen uptake and α-tocopherol decay in the oxidation of 144 mM methyl linoleate in benzene under air at 37°C initiated with 30.0 mM AMVN. The dotted line show the oxygen uptake in the absence of α-tocopherol.

144	30.4	β 0.307	δ 0.307	10220	823	5.06×10^5	3.28

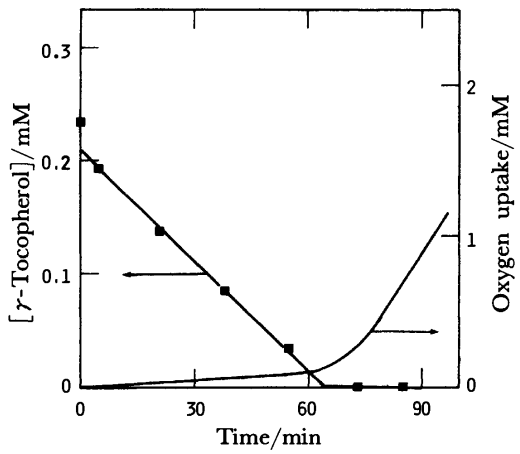

Fig. 2. Rates of oxygen uptake and γ-tocopherol disappearance in the oxidation of 137 mM methyl linoleate in benzene under air at 37°C initiated with 28.9 mM AMVN.

have been observed for β-and δ-tocopherols. The pertinent results are summarized in Table 1.

The oxidation of methyl linoleate (LH) initiated with AMVN (A-N=N-A) and inhibited by tocopherol (IH) proceeds by the following reaction mechanisms,[14,16-18,20]

$$\text{A-N=N-A} \longrightarrow [\text{A}\cdot\text{N}_2\cdot\text{A}] \longrightarrow (1-e)\text{A-A} \quad (1)$$
$$\searrow\ 2e\text{A}\cdot, \quad (2)$$

$$\text{A}\cdot + \text{O}_2 \longrightarrow \text{AO}_2\cdot, \quad (3)$$

$$\text{AO}_2\cdot + \text{LH} \xrightarrow{\text{O}_2} \text{AOOH} + \text{LO}_2\cdot, \quad (4)$$

Propagation:

$$\text{LO}_2\cdot + \text{LH} \xrightarrow{k_p} \text{LOOH} + \text{L}\cdot, \quad (5)$$

$$\text{L}\cdot + \text{O}_2 \longrightarrow \text{LO}_2\cdot \quad (6)$$

Termination;

$$\text{LO}_2\cdot + \text{IH} \xrightarrow{k_{inh}} \text{LOOH} + \text{I}\cdot, \quad (7)$$

$$(n-1)\text{LO}_2\cdot + \text{I}\cdot \longrightarrow \text{stable products}, \quad (8)$$

$$\text{LO}_2\cdot + \text{LO}_2\cdot \xrightarrow{k_t} \text{stable products}, \quad (9)$$

where e is the efficiency of free radical generation from AMVN, n is the stoichiometric number of peroxyl radicals trapped by each antioxidant, and k_p, k_{inh}, and k_t are the rate constants for reactions 5, 7, and 9 respectively.

The rate of chain initiation, R_i, is given by Eq. 10,

$$R_i = 2ek_d[\text{AMVN}], \quad (10)$$

where k_d is the rate constant for unimolecular decomposition of AMVN. The induction period, t_{inh}, is given by Eq. 11.

$$t_{inh} = n[\text{IH}]/R_i = n[\text{IH}]/2ek_d[\text{AMVN}] \quad (11)$$

Table 1 also shows the results of oxidation of methyl linoleate inhibited by the combination of two types of tocopherols. Figure 3 shows the plot of induction period as a function of $[IH]/R_i$. Table 1 and Fig. 3 show that the induction period is proportional to the total concentration of tocopherols independent of their types and inversrly proportional to the rate of chain initiation or the concentration of AMVN as expected from Eq. 11.[21]

The rate of oxidation in the absence of antioxidant or after the induction period is given by Eq. 12.

$$R_p = k_p[\text{LH}](R_i/2k_t)^{1/2} \quad (12)$$

The data in the last column of Table 1 show that Eq. 12 holds for all tocopherols.

Figure 4 shows the rates of disappearance of α-tocopherol and γ-tocopherol during the oxidation of methyl linoleate in benzene in the presence of both α- and γ-tocopherols. Figure 5 shows the similar results

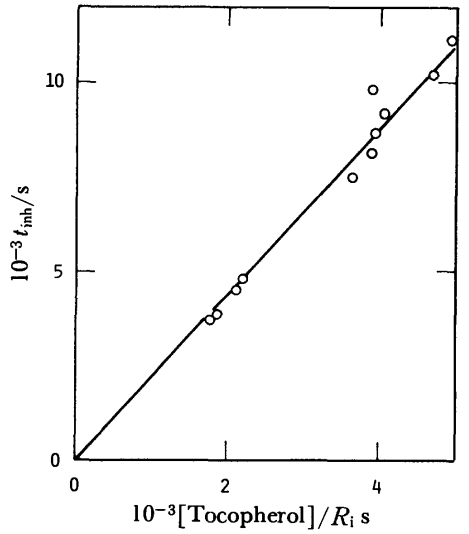

Fig. 3. Plot of induction period as a function of [tocopherol]/R_i for the oxidations of methyl linoleate in benzene under air at 37 °C initiated with AMVN.

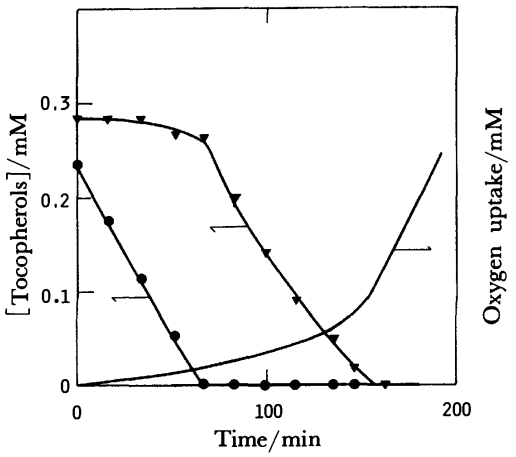

Fig. 5. Oxygen uptake and disappearance of α-(●) and δ-(▼) tocopherols during the oxidation of 144 mM methyl linoleate in benzene initiated with 30.5 mM AMVN inhibited by 0.230 mM α-tocopherol and 0.284 mM δ-tocopherol.

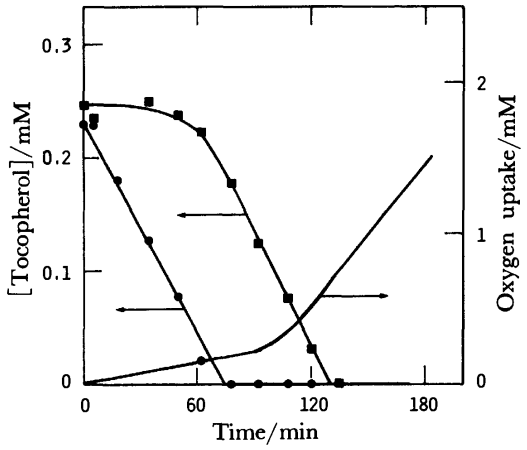

Fig. 4. Rates of oxygen uptake and disappearance of α-(●) and γ-(■) tocopherols in the oxidation of 144 mM methyl linoleate in benzene under air at 37 °C initiated with 30.4 mM AMVN.

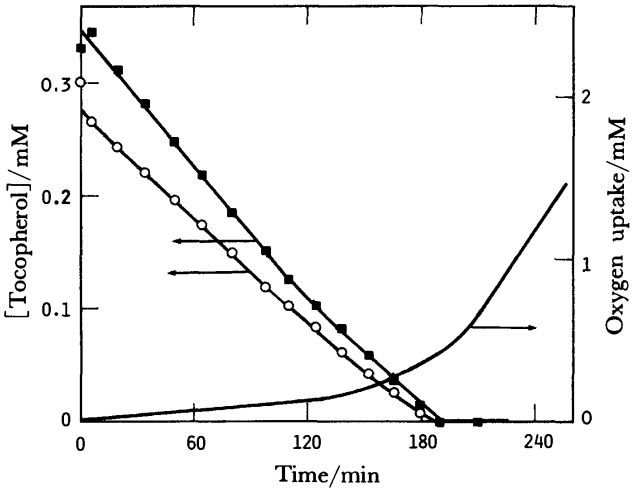

Fig. 6. Rates of oxygen uptake and β-(○) and γ-(■) tocopherols disappearance in the oxidation of 140 mM methyl linoleate in benzene under air at 37 °C initiated with 29.6 mM AMVN.

observed in the oxidation of methyl linoleate inhibited by both α- and δ-tocopherols. These results show that only α-tocopherol disappeared first linearly while γ- or δ-tocopherol remained almost unchanged at first and then they disappeared after α-tocopherol was depleted. When all tocopherols disappeared, the induction period was over and a fast oxidation took place. On the other hand, Fig. 6 shows that β- and γ-tocopherols disappeared at a similar rate when both of them were present together.

Figure 7 shows the rate of disappearance of four tocopherols during the oxidation of methyl linoleate in benzene. It can be seen that α-tocopherol disappeared first, then β- and γ-tocopherols disappeared at a similar rate, and finally δ-tocopherol followed. Interestingly, β- and γ-tocopherols were not consumed when appreciable amount of α-tocopherol was present, while most of δ-tocopherol remained until α-, β-, and γ-tocopherols were depleted.

The above results suggest that four tocopherols behave similarly as antioxidant when only one of them is present alone but also that the stabilities of tocopherols and/or chromanyloxyl radicals derived therefrom differ considerably.

The stabilities of chromanyloxyl radicals were studied by ESR. It has been observed that each tocopherol has its own specific ESR spectrum.[23-26] Chromanyloxyl radicals were generated as previously reported[26,27] by the interaction of tocopherol with galvinoxyl radical. The ESR spectrum of galvinoxyl radical disappeared instantaneously when it was reacted with α-tocopherol, and α-chromanyloxyl

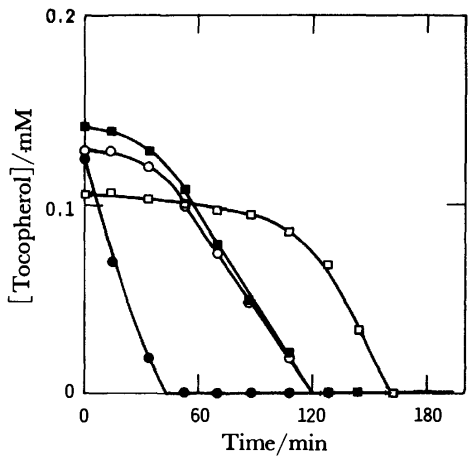

Fig. 7. Rates of disappearance of tocopherols during the oxidation of 144 mM methyl linoleate in benzene under air at 37°C initiated with 30.1 mM AMVN. Initial concentrations of tocopherols are: α(●)=0.124 mM, β(○)=0.130 mM, γ(■)=0.141 mM, γ(□)=0.105 mM.

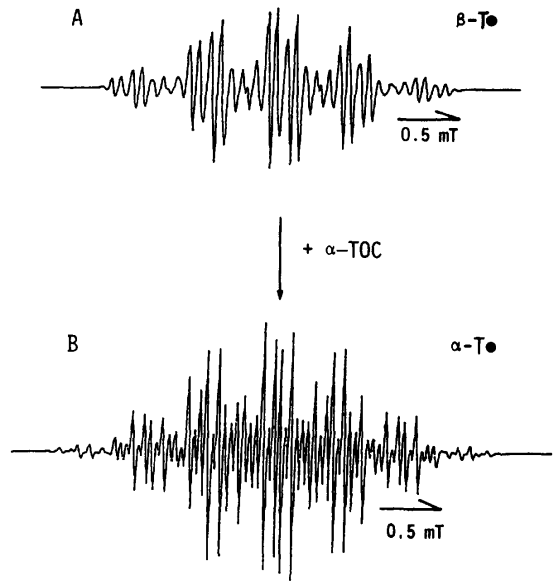
radical was observed. β-, γ-, and δ-Tocopherols also reacted with galvinoxyl similarly. The rates of interactions between galvinoxyl and tocopherols in homogeneous solution were too fast to follow by a conventional method.

The rate of interactions between galvinoxyl radical incorporated into dimyristoyl PC liposomes and tocopherol incorporated into different dimyristoyl PC liposomes was followed by ESR. Galvinoxyl radical disappeared much more slowly than in homogeneous system and the pseudo first order rate constant was obtained as 10.1×10^{-4}, 5.44×10^{-4}, 5.00×10^{-4}, and 4.76×10^{-4} s^{-1} at 30°C for α-, β-, γ-, and δ-tocopherols respectively. Burton and Ingold[14] measured the reactivities of four tocopherols toward polystyrenylperoxyl radical and observed that the reactivities decreased in the same order of $\alpha>\beta\cong\gamma>\delta$ -tocopherols.

The interactions of tocopherol with chromanyloxyl radicals were also studied. The chromanyloxyl radical was prepared by the interaction of the corresponding tocopherol with 2,2-dipheyl-1-picrylhydrazyl. When α-tocopherol was prepared at first and then β-, γ-, or δ-tocopherol was added, no change in ESR spectrum was observed. On the other hand, when β-chromanyloxyl radical was first prepared and then α-tocopherol was added to the solution, β-chromanyloxyl radical disappeared quite rapidly and it was replaced by α-chromanyloxyl radical as shown in Fig. 8. Similar results were observed for the interactions of γ- and δ-chromanyloxyl radicals with α-tocopherol.

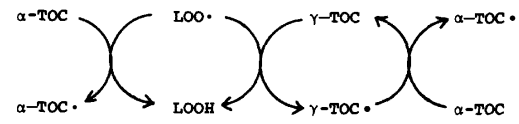
The above results suggest that both the reactivities of tocopherols toward peroxyl and phenoxyl radicals and stabilities of chromanyloxyl radicals decrease in the order of $\alpha>\beta\cong\gamma>\delta$. When, for example, both α- and γ-tocopherols are present, α-tocopherol scavenges the peroxyl radical predominantly, while γ-tocopherol scavenges peroxyl radicals more slowly but



β-T• + α-TOC ⟶ β-TOC + α-T•

Fig. 8. Change of ESR spectrum observed when β-chromanyloxyl radical was interacted with α-tocopherol.
A: ESR spectrum of β-chromanyloxyl radical, B: ESR spectrum observed when α-tocopherol was added to the solution containing β-chromanyloxyl radical.

γ-chromanyloxyl radical formed by the interaction of γ-tocopherol with peroxyl radical must react with α-tocopherol rapidly to give γ-tocopherol and α-chromanyloxyl radical. Accordingly, only α-tocopherol must be consumed at first, while γ-tocopherol remains almost unchanged.



This study was supported in part by Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

21) It may be noteworthy that the stoichiometric numbers n for the hindered phenols with alkyl substituents on both ortho positions are close to 2, whereas those for non-hindered phenols are smaller than 2.[22] The results of Table 1 and Fig. 3 suggest that the values of n for α-, β-, γ-, and δ-tocopherols are same within experimental error under the present reaction conditions. It has been found previously[17] that α-tocopherol and 2,6-di-*t*-butyl-4-methylphenol have same n values. These results may be attributed to the high concentration of peroxyl radicals in the present oxidation initiated with AMVN. If the concentration of peroxyl radical is smaller and the chromanoxyl radical has longer lifetime, the n values for β-, γ-, and δ-tocopherols may be smaller than that for α-tocopherol.

Synthesis of Selenoxides by Oxidation of Selenides with *t*-Butyl Hypochlorite, and Its Application for Synthesis of Optically Active Selenoxide

Michio KOBAYASHI,* Hiromi OHKUBO, and Toshio SHIMIZU
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received September 18, 1985)

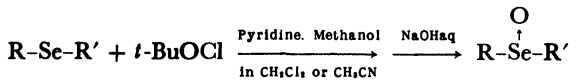
An effective synthesis of selenoxides by the oxidation of selenides with *t*-butyl hypochlorite in the presence of methanol and pyridine followed by hydrolysis is descrived. This oxidation method is particularly effective for the oxidation of selenides which possess electron-withdrawing groups. A synthesis of partially optically active selenoxide with bulky substituents can be achieved using a novel oxidation method.

The oxidation of organic selenides to selenoxides has been carried out using several oxidizing reagents, such as hydrogen peroxide,[1] ozone,[2] peracetic acid,[1] dinitrogen tetraoxide,[3] (dichloroiodo)benzene,[4] *N*-chlorosuccinimide,[5] *t*-butyl hypochlorite[5] and sodium periodate.[4] Among these, sodium periodate is most widely used in laboratories. However, the oxidation of diaryl selenides by this reagent is retarded or completely prevented by the presence of strong electron-withdrawing groups. Ozone is effective in this respect, but its oxidation tends to go beyond the stage of the selenoxides. Nothing is known regarding the oxidation of a selenide substituted with electron-withdrawing groups in the case of oxidation with positive halogenating species. We report here a new synthesis of various selenoxides with an electron-withdrawing substituent through a reaction of selenides and *t*-butyl hypochlorite in the presence of methanol and pyridine followed by hydrolysis.

There had been no example of an optically active selenoxide for a long time. The difficulty of an optical resolution of selenoxide is due to its facile racemization through achiral hydrates.[6] In 1970, optically active selenoxide was isolated for the first time using steroidal systems.[7] Recently, partially optically active selenoxides were synthesized by Davis et al.[8] We also report here on the synthesis of optically active selenoxide using a novel oxidation technique.

Results and Discussion

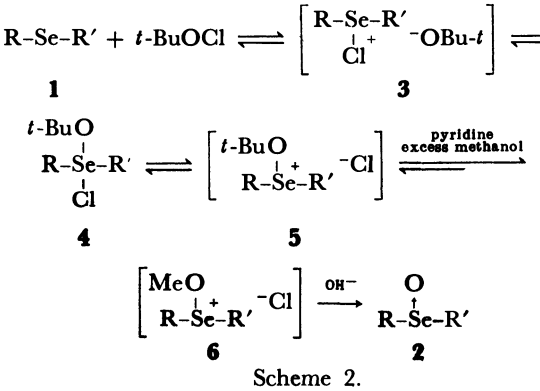
To a solution of selenide in dichloromethane or acetonitrile were added an equimolar pyridine and an excess amount of methanol. An equimolar *t*-butyl hypochlorite in the same solvent was added slowly



1 2

Scheme 1.

to a stirred solution of the selenide at −25 °C. Stirring continued for 40 min at −25 °C. The mixture was hydrolyzed by an addition of a sodium hydroxide solution. Results are shown in Table 1. By the present method, 4,4′-dinitrodiphenyl selenide (**1g**), which could not be oxidized by sodium periodate,[4] was oxidized to 4,4′-dinitrodiphenyl selenoxide (**2g**) in 90% yield. Nitro-substituted diaryl selenides (**1f** and **1h**) were also oxidized to the corresponding selenoxides (**2f** and **2h**) in good yields, respectively. Methyl *p*-(phenylseleno)benzoate (**1i**), which possesses an electron-withdrawing carboxyl group on an aromatic ring, was similarly oxidized to the corresponding selenoxide **2i** in good yields. By oxidation with sodium periodate, **1i** gave **2i** in only 22% yield. Even selenoxides (**2c** and **2d**) with bulky substituents were obtained in good yields. An undesired oxidation of selenoxide to selenone was not occur with the present method. Both methanol and pyridine play important roles to ensure good yields of selenoxides, since the yield of 4,4′-dinitrodiphenyl selenoxide (**2g**) decreases in the absence of pyridine (Table 2). Also, the yields of 4,4′-dinitrodiphenyl selenoxide (**2g**) and 2,4-dinitrodiphenyl selenoxide (**2h**) were greatly decreased in the absence of both methanol and pyridine. The present reaction is thought to proceed via an intermediary selenonium salt **5**. The formation of this type of



Scheme 2.

selenonium salt was reported in a reaction of diphenyl selenide with *t*-butyl hypochlorite.[10] An equilibrium seems to exist among the starting materials, **3**, selenurane **4** and **5**. The addition of excess methanol and pyridine may cause a shift the equilibrium toward the right, resulting in the formation of a selenonium salt

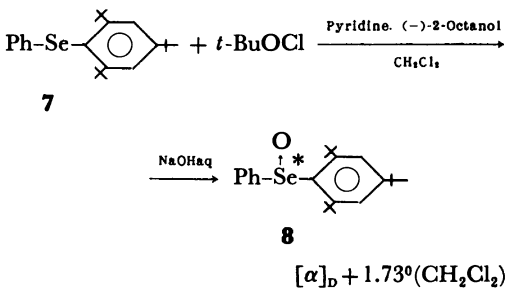
6, the hydrolysis of which gives selenoxide **2** in good yield.

Recently, Davis et al. reported the synthesis of partially optically active selenoxides by kinetic differentiation during the formation of selenimides.[8] We have attempted to synthesize the optically active selenoxide, the selenium moiety of which was flanged by two bulky substituents to prevent racemization, by an application of the present oxidation method. To a solution of 2,4,6-tri-*t*-butyldiphenyl selenide (**7**) in dry dichloromethane was added equimolar pyridine and excess amounts of (−)-2-octanol (twentyfold of the selenide). An equimolar *t*-butyl hypochlorite in dichloromethane was slowly added to the stirred solution at −40°C. Stirring continued for 2 h at −40°C. After hydrolysis and extraction, (−)-2-octanol was removed in vacuo (30°C/10^{-3}—10^{-4} mmHg (1 mmHg=133.322pa)) and the remaining selenoxide **8** was recrystallized from dichloromethane–hexane. Mp 133.5—134°C. $[\alpha]_D^{32}$ +1.73° (*c* 0.948, CH_2Cl_2). The CD spectrum shows the positive Cotton effect at 291 nm. An enantiomeric excess



Seheme 3.

of 1.0% was estimated by HPLC using an optically active column. This enantioselectivity suggests the presence of (−)-1-methylheptyloxyselenonium salt as an intermediate. When (+)-2-octanol was used, selenoxide with a negative optical rotation ($[\alpha]_D^{33}$ −0.428°) was obtained. The racemization of **8** was found to be very slow in neutral solvents at room temperature.

Experimental

All melting points were determined on a Yamato MP-21. IR spectra were recorded on a Hitachi 260-10 spectrometer, ^{1}H-NMR spectra with TMS as an internal standard on a JEOL JNM-PMX60$_{SI}$, CD spectrum on a JASCO J-40A, and Mass spectra on a JEOL JMS-DX300 mass spectrometer. The optical rotation was measured on a JASCO DIP-140 digital polarimeter. Silica-gel TLC and column chromatography were performed on a Merck Kieselgel 60F$_{254}$ and a Wako Wakogel C-200, respectively. Organic solvents were purified and dried by the usual procedures.

Materials. The starting materials (**1a**, **1b**, **1c**, **1f**, **1g**, and **1h**) are all well known compounds.[8,11-14]

***p*-Tolyl 2,4,6-Triisopropylphenyl Selenide (1d):** Compound **1d** was prepared from bis(2,4,6-triisopropylphenyl)-diselenide and *p*-tolylmagnesium bromide. Yield=68%. Mp 59.5—61 °C. IR (KBr) ν=800, 1015, 1560, 1590, 2800—3100 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=1.08 (12H, d, J=6.6 Hz, CH_3 of ortho isopropyl), 1.22 (6H, d, J=6.6 Hz, CH_3 of para isopropyl), 2.16 (3H, s, CH_3 of tolyl), 2.4—3.0 (1H, m, para methine), 3.66 (2H, hep., J=6.6 Hz, ortho methine), 6.90 (4H, s, aromatic protons of tolyl), 7.03 (2H, s, aromatic protons of triisopropylphenyl). Found: m/z 374.1512 (^{80}Se), Calcd for $C_{22}H_{30}{}^{80}Se$: 374.1512.

2-Methoxydiphenyl Selenide (1e): Compound **1e** was prepared from diphenyl diselenide and *o*-methoxyphenyl-magnesium bromide. Yield=59%. Bp 143—145 °C/2 mmHg. IR (liq. firm) ν=740, 1020, 1245, 1470, 1575, 2800—3100 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=3.78 (3H, s, CH_3), 6.6—7.7 (9H, m, aromatic protons). Found: m/z 264.0076 (^{80}Se), Calcd for $C_{13}H_{12}O^{80}Se$: 264.0053.

Methyl *p*-(Phenylseleno)benzoate (1i): Compound **1i** was prepared by the esterification of *p*-(phenylseleno)-benzoic acid which was obtained by a reaction of benzeneselenol, potassium hydroxide and *p*-iodobenzoic acid.[15] Yield=67%. Mp 78—79 °C. IR (KBr) ν=1700(C=O) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=3.85 (3H, s, OCH_3), 7.2—7.7 (5H, m, aromatic protons of phenyl), 7.32 and 7.83 (4H, ABq, J=8.2 Hz, aromatic protons of *p*-substituted benzene ring). Found: m/z 292.0002 (^{80}Se), Calcd for $C_{14}H_{12}O_2{}^{80}Se$: 292.0002.

2,4,6-Tri-*t*-butyldiphenyl Selenide (7): Compound **7** was prepared by a reaction of 2,4,6-tri-*t*-butylphenyllithium and benzeneselenenyl bromide in THF and purified by recrystallization from hexane-ethanol. Yield=28% (based on 2,4,6-tri-*t*-butyl-1-bromobenzene). Mp 127.5—128 °C. IR (KBr) ν=730, 1470, 2800—3000 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=1.35 (9H, s, para *t*-butyl), 1.48 (18H, s, ortho *t*-butyl), 6.4—7.1 (5H, m, aromatic protons of phenyl), 7.49 (2H, s, aromatic protons of tri-*t*-butylphenyl). Found: m/z 402.1812 (^{80}Se), Calcd for $C_{24}H_{34}{}^{80}Se$: 402.1825.

Typical Procedure for the Oxidation of Selenide. To a solution of selenide (1.0 mmol) in dichloromethane (30 ml) was added an equimolar pyridine and an excess amount of methanol (ca.5 mmol). The solution was cooled to −25 °C under dry nitrogen. An equimolar *t*-butyl hypochlorite in dichloromethane (5 ml) was slowly added to the stirred solution and stirring continued for 40 min at −25 °C. A sodium hydroxide solution (2 mmol in 5 ml of water) was added to the mixture at this temperature with stirring. Then, the resulting mixture was allowed to become room temperature and the organic layer was separated. The aqueous phase was extracted with dichloromethane. The combined organic extract was concentrated and the remaining product was purified either by silica-gel column chromatography or by recrystallization. When acetonitrile was used as a solvent, extraction was carried out after the evaporation of acetonitrile. Among the resulting selenoxides, **2a**, **2c**, and **2g** are known compounds.[5,8,9]

Methyl *p*-Tolyl Selenoxide (2b): Mp 106—107.5 °C. IR (KBr) ν=810 (Se=O), 1400, 1490, 2900—3100 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=2.34 (3H, s, CH_3 of tolyl), 2.51 (3H, s, CH_3-Se), 7.25 and 7.55 (4H, ABq, J=8.4 Hz, aromatic protons). Found: m/z 201.9892 (^{80}Se), Calcd for $C_8H_{10}O^{80}Se$: 201.9896.

***p*-Tolyl 2,4,6-Triisopropylphenyl Selenoxide (2d):** Mp 147—148.5 °C. IR (KBr) ν=810, 820(Se=O), 1460, 2850—3000 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=0.88, 1.18, 1.22 (18H, d, J=6.6 Hz, CH_3 of isopropyl), 2.30 (3H, s, CH_3 of tolyl), 2.5—3.1 (1H, m, para methine), 3.72 (2H, hep., J=6.6 Hz, ortho methine), 7.01 (2H, s, aromatic protons of triisopropyl-phenyl), 7.18 and 7.42 (4H, ABq, J=8.1 Hz, aromatic protons of tolyl). Found: m/z 390.1464 (^{80}Se), Calcd for $C_{22}H_{30}O^{80}Se$: 390.1461.

2-Methoxydiphenyl Selenoxide (2e): Mp 133.5—134.5 °C. IR (KBr) ν=770, 820(Se=O), 1020, 1040, 1230, 1270, 1310, 1470 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=3.81 (3H, s, CH_3), 6.8—8.0 (9H, m, aromatic protons). Found: m/z 279.9977 (^{80}Se), Calcd for $C_{13}H_{12}O_2{}^{80}Se$: 280.0002.

4-Nitrodiphenyl Selenoxide (2f): Mp 134.5—135.5 °C. IR (KBr) ν=744, 825(Se=O), 847, 1344(NO_2), 1516(NO_2)cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=7.3—7.8 (5H, m, aromatic protons of phenyl), 7.82 and 8.22 (4H, ABq, J=9.0 Hz, aromatic protons of nitrophenyl). Found: m/z 294.9753 (^{80}Se), Calcd for $C_{12}H_9NO_3{}^{80}Se$: 294.9747.

2,4-Dinitrodiphenyl Selenoxide (2h): Mp 134.5 °C(decomp). IR (KBr) ν=730, 830(Se=O), 915, 1079, 1340(NO_2), 1526(NO_2), 1602 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=7.3—7.9 (5H, m, aromatic protons of phenyl), 8.7—9.1 (3H, m, aromatic protons of dinitrophenyl). Found: m/z 339.9662 (^{80}Se), Calcd for $C_{12}H_8N_2O_5{}^{80}Se$: 339.9598.

Methyl *p*-(Phenylseleninyl)benzoate (2i): Mp 160—161 °C. IR (KBr) ν=739, 761, 825(Se=O), 1204, 1269, 1435, 1585, 1724(C=O) cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=3.92 (3H, s, OCH_3), 7.4—7.6 (5H, m, aromatic protons of phenyl), 7.81 and 8.15 (4H, ABq, J=7.6 Hz, aromatic protons of *p*-(methoxycarbonyl)phenyl). Found: m/z 307.9933 (^{80}Se), Calcd for $C_{14}H_{12}O_3{}^{80}Se$: 307.9951.

(+)-2,4,6-Tri-*t*-butyldiphenyl Selenoxide (8): To a solution of 2,4,6-tri-*t*-butyldiphenyl selenide (**7**) (0.75 mmol) in dry dichloromethane (13 ml), was added equimolar pyridine and an excess amount of (−)-2-octanol (15 mmol). The solution was cooled to −40 °C under dry nitrogen. An equimolar *t*-butyl hypochlorite (0.75 mmol) in dry dichloromethane (2 ml) was slowly added to the stirred solution and stirring was continued for 2 h at −40 °C. A sodium hydroxide solution (1.5 mmol in 5 ml of water) was added to the mixture at this temperature with stirring.

Then, the resulting mixture was allowed to become room temperature and the organic layer was separated. The aqueous phase was extracted with dichloromethane. The resulting selenoxide **8** was purified by recrystallization from dichloromethane–hexane after the removal of (−)-2-octanol in vacuo (30 °C/10^{-3}—10^{-4} mmHg). Chemical Yield=54%. Mp 133.5—134 °C. $[\alpha]_D^{32}$ +1.73 °(*c* 0.948, CH_2Cl_2). $[\theta]_{291}$ +236 (Methanol). IR (KBr) ν=745, 840(Se=O), 1360, 1585, 2800—3100 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=1.35 (9H, s, para *t*-butyl), 1.45 (18H, s, ortho *t*-butyl), 6.7—7.3 (5H, m, aromatic protons of phenyl), 7.46 (2H, s, aromatic protons of tri-*t*-butylphenyl). Found: *m/z* 418.1818 (^{80}Se), Calcd for $C_{24}H_{34}O^{80}Se$: 418.1774. The enantiomeric excess was determined by HPLC on an optically active column (Bakerbond chiral phase HPLC column DNBPG/Aminopropylsilica; 25 cm×4.6 mm; using hexane: 2-propanol=95:5 as eluent.

(Received September 21, 1985)

β-Cyclodextrin (β-CyD) was covalently immobilized on silica gel by chlorination of silica gel with thionyl chloride or silicon tetrachloride, followed by the reaction of the resulting chlorinated silica gel with β-CyD in pyridine. The amounts of the immobilized β-CyD were 8×10^{-5} to 1.4×10^{-4} mol per 1 g of the β-CyD–silica gel composites. On heating, the composites did not exhibit weight decrease up to 250 °C. The β-CyD in the composites formed 1 : 1 complex with phenol in aqueous solutions, and the equilibrium constant for the dissociation of the complex was 6×10^{-3} mol dm^{-3} at 25 °C. The immobilized β-CyD exhibited catalytic activity in the cleavage of 4-nitrophenyl acetate at 25 °C, pH 8.7.

Cyclodextrins (CyDs), cyclic oligomers of 6—8 glucose molecules, form inclusion complexes with various guest compounds. The magnitude of the complex formation is largely dependent on the structure of guest compound.[1,2] CyDs exhibit specific catalyses in the selective syntheses of various chemicals such as 4-chloroanisole,[3] vitamin K analogs,[4] 4-hydroxybenzaldehydes,[5] 4-hydroxybenzoic acids,[6] and 3-indolecarbaldehyde.[7]

Many works have been carried out on the immobilization of CyDs using organic materials either as cross-linking agents or as supports. Gels, prepared by the reactions of CyDs with epichlorohydrin or diisocyanates, were successfully used for column chromatography[8–13] and selective catalyses.[14–18] CyDs immobilized on polyacrylamide gels as supports were effective for column chromatography.[19] Water-soluble polymers containing CyDs were also prepared.[20]

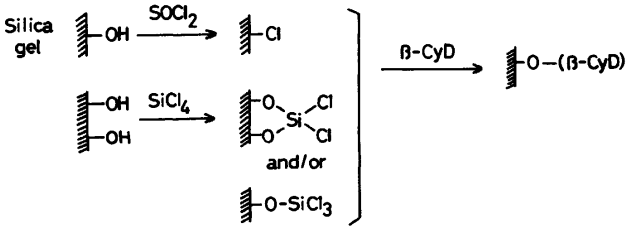
However, there have been a few reports on the immobilization of CyDs on inorganic supports. Fujimura et al.[21] immobilized CyDs to silica gel by the reaction of aminated silica gel with CyD tosylate. Kawaguchi et al.[22] also immobilized CyDs on silica gel by condensation of carboxylated silica gel with CyDs having amino groups by use of 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide. Both methods require synthesis of modified CyD prior to immobilization.

In this paper, a simpler immobilization of CyDs on silica gel, which does not involve synthesis of modified CyDs, is reported. Silica gel is first chlorinated with thionyl chloride or silicon tetrachloride, and then is reacted with intact β-CyD. Thermal stabilities and binding properties of the β-CyD-silica gel composites are shown. Furthermore, the catalytic activity of the immobilized β-CyD in the cleavage of 4-nitrophenyl acetate is described.

Experimental

Materials. β-CyD was recrystallized from water, and was dried at 110 °C in vacuo. Silica gel (average diameter, 60 μm; surface area, 370 m^2 g^{-1}; average pore diameter, 130 Å; total pore volume, 0.96 dm^3 g^{-1}) was obtained from Iatron Co. and was dried at 110 °C in vacuo. Pyridine was distilled over metallic magnesium ribbon after prolonged refluxing over the same. All other reagents were dried and purified in usual ways.

Immobilization of β-Cyclodextrin on Silica Gel. Immobilization of β-CyD on the silica gel was carried out as depicted in Scheme 1. First, silica gel was added to thionyl chloride or silicon tetrachloride with or without benzene as solvent, and the mixture was refluxed for 5—20 h. The resulting solids were washed with dry benzene, and were dried at 110 °C in vacuo. Then, the solids were reacted with β-CyD in pyridine at 80 °C for 10 h. After the reactions, the solids were repeatedly washed with water, soaked in water for a week, and then dried in vacuo at 110 °C. The contents of β-CyD in the β-CyD–silica gel composites were estimated either from the carbon contents on elemental analyses or from the decrease of weight on thermogravimetric analyses (see Results and Discussion Section). The values determined by these two methods were identical with each other within 1%.



Scheme 1.

Characterization of β-CyD–Silica Gel Composite. Thermogravimetric analyses were made on a Shimadzu Model DT-30 Thermal Analyzer. Surface area (by BET method), pore volume, and pore size (by the Inkley method) were obtained by the analyses of the nitrogen isotherms measured by using an Orr Surface-Area Pore-Volume Analyzer 2100 D (Micromeritics Co.).

Determination of Equilibrium Constant for Complex Formation between β-Cyclodextrin Immobilized on Silica Gel and Phenol. The β-CyD-silica gel composite (100 mg) was added to 3 cm^3 aqueous solution of phenol (the concentration p_o). The mixture was vigorously shaken, and then was incubated at 25 °C for 30 min. The equilibrium concentration (p) of phenol in aqueous medium in the presence of the β-CyD–silica gel composite was determined

**A part of this paper was preliminarily presented at the 26th International Congress of Pure and Applied Chemistry, Tokyo (1977). Abstracts, Session I, p. 260.

Table 1. Immobilization of β-CyD to Silica Gel

Code	Silica gel	β-CyD	Chlorination of silica gel		Amount of β-CyD in β-CyD-silica gel composite	
	g	g	Agent[a)]	Reaction time/h	wt% in composite	10^{-4} mol per 1 g composite
A-1	18	5	$SOCl_2$(60)	20	16.0	1.4
A-2	18	4	$SOCl_2$(60)	5	10.4	0.88
A-3	18	5	$SOCl_2$/benzene (40/40)	10	15.0	1.3
A-4	20	5	$SiCl_4$/benzene (10/50)	10	9.4	0.83

a) The numbers in parentheses refer to the amounts used (in cm^3).

spectroscopically at 270 nm.

The equilibrium constant K_d for the dissociation of the complex was determined by plotting p vs. $p/(p_0-p)$ according to Eq. 1,

$$p = c_0 \cdot p/(p_0-p) - K_d. \quad (1)$$

Here, c_0 is the amount of the immobilized β-CyD, which is charged per unit volume of specimen. Equation 1 is obtained from Eq. 2, which is based on the assumption that the immobilized β-CyD form 1:1 complex with phenol.

$$K_d = p \cdot [c_0 - (p_0-p)]/(p_0-p). \quad (2)$$

The equilibrium constant for the dissociation of the complex between unmodified β-CyD and phenol in homogeneous solution at 25 °C was determined spectroscopically at 280 nm, according to the method in the literature.[23)]

Kinetics. To a quartz cell, a required amount of β-CyD-silica gel composite and 3 cm^3 of pH 8.7 Tris buffer solution were added at 25 °C. After a thermoequilibrium was attained, 20×10^{-3} cm^3 or less of a stock solution of 4-nitrophenyl acetate in acetonitrile was charged, and the mixture was vigorously stirred. The cleavage was followed by the release of 4-nitrophenol at 400 nm. The rate constants were determined by using usual first-order equation.

Results and Discussion

Immobilization of β-Cyclodextrin on Silica Gel. As shown in Table 1, β-CyD was successfully immobilized on silica gel according to Scheme 1, using either thionyl chloride or silicon tetrachloride as chlorinating agent of silica gel. The amounts of the immobilized β-CyD were 8×10^{-5} to 1.4×10^{-4} mol per 1 g of the β-CyD-silica gel composites. The resulting composites were fine and white particles, as long as purities and dryness of the reagents used, especially of pyridine, were sufficiently high. Otherwise, the particles turned to tan to dark brown color on the treatments.

There were no substantial changes observed either in the scanning electron micrographs of the particles or in the surface area of the particles before and after the treatments.

Figure 1 (a) depicts a thermogravimetric curve for the β-CyD-silica gel composite (code A-1 in Table 1). The composite is stable even at elevated temperatures, and no decomposition is detected up to 250 °C.

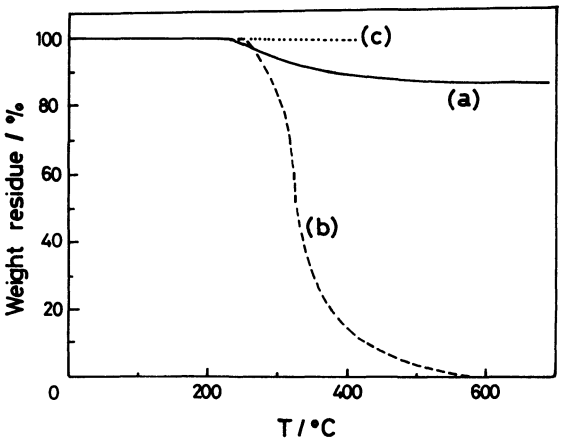


Fig. 1. Thermogravimetric analyses on (a) the β-CyD-silica gel composite (code A-1), (b) β-CyD, and (c) silica gel: the heating rate, 5 °C min^{-1} under air.

Neither color change of the composite nor its softening is observed here. A weight loss due to the oxidative degradation of the β-CyDs in the composites starts at 250 °C and almost ends up at 630 °C, when the heating rate is 5 °C min^{-1}. From the difference between the weight residue at 250 °C and the value at 630 °C, the amount of the β-CyD in the composite is estimated to be 16 wt%. This value satisfactorily agrees with that (15.0 wt%) calculated from the carbon content (6.65%) on elemental analysis.

β-CyD itself starts oxidative degradation at 260 °C, which completes at 580 °C (Fig. 1 (b)).

Virtually identical thermogravimetric curves were obtained for all the other composites A-2, A-3, and A-4, except for the difference in the magnitude of weight loss due to the difference in the amount of the β-CyD immobilized on the silica gel.

Covalent attachment of the β-CyD to silica gel was confirmed by the absence of loss of the β-CyD moieties on repeated washing of the composites with water or 0.002 M hydrochloric acid (1 M=1 mol dm^{-3}). The amount of the β-CyD was determined by thermogravimetric analyses on these specimens.

The largest value for the immobilization of β-CyD (1.4×10^{-4} mol per 1 g of the composite, code A-1) corresponds to occupation of 380 A^2 surface of the silica gel by one β-CyD molecule: the silica gel has surface

Table 2. Equilibrium Constant K_d for the Dissociation of the Complex between the β-CyD Immobilized to Silica Gel and Phenol in Aqueous Solution at 25°C

β-CyD-silica gel composite	K_d	Amount of β-CyD/10^{-6} mol[a)]	
	10^{-3} mol dm^{-3}	Charged	Kinetically determined
A-2	6.5±1.9	8.8	7.3±2.0
A-4	6.6±0.8	8.3	8.0±0.6
Intact β-CyD (Non-immobilized)	1.6±0.3	—	—

a) Amount of β-CyD in 3 cm^3 for specimen.

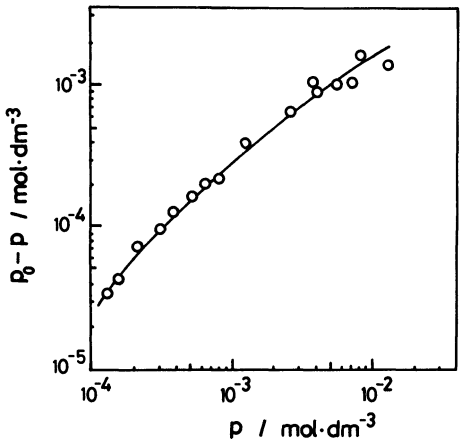

Fig. 2. Plot of (p_0-p) vs. p for the complex formation between the β-CyD immobilized on silica gel and phenol in aqueous solution at 25°C: 100 mg of the composite A-2, which contained 8.8×10^{-6} mol of β-CyD, was added to 3 cm^3 of phenol solution with the charged concentration p_0, and the equilibrium concentration p of phenol in aqueous medium was measured.

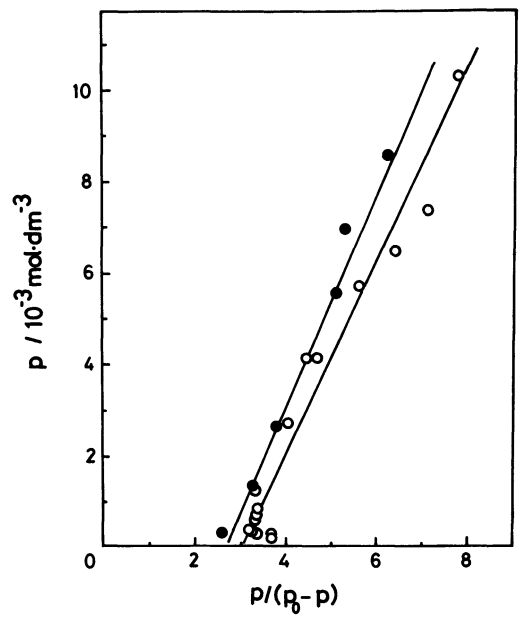

Fig. 3. Plots of p vs. $p/(p_0-p)$ for the complex formation between the β-CyD immobilized on silica gel and phenol in aqueous solution at 25°C: ○, composite A-2 (the charged amount of β-CyD, 8.8×10^{-6} mol); ●, the composite A-4 (the charged amount of β-CyD, 8.3×10^{-6} mol); Definition of p and p_0 as well as the experimental methods should be referred to the footnote in Fig. 2.

area of 370 m^2 per 1 g. This value is only 2.1 fold larger than the molecular cross-section area (184 A^2) of β-CyD, perpendicular to the longitudinal axis of the cavity. The outer diameter of β-CyD is 15.3 A.[2] Thus, the surface of the silica gel is largely covered by β-CyD molecules in the composites.

Complex Formation between the β-Cyclodextrin Immobilized on Silica Gel and Phenol. When the β-CyD-silica gel composite was mixed with aqueous phenol solution and the mixture was vigorously shaken, the concentration of phenol in the aqueous medium rapidly decreased. This shows that the β-CyD immobilized to silica gel forms complex with phenol and takes it out of the aqueous medium. Usually equilibrium was attained in less than 20 min.

Figure 2 depicts the plot of (p_0-p) vs. p. Here, 100 mg of the composite A-2, which contained 8.8×10^{-6} mol of β-CyD, was added to 3 cm^3 of aqueous phenol solution of the charged concentration p_0, and the equilibrium concentration p of phenol in the aqueous medium was measured. Logarithm of (p_0-p), which corresponds to the amount of phenol forming complex with the immobilized β-CyD, asymptotically increases with logarithm of p, the equilibrium concentration of phenol in the solution.

In Fig. 3, p is plotted against $p/(p_0-p)$ according to Eq. 1 for the complex formation of phenol with the immobilized β-CyDs in the composites A-2 and A-4. For both of the composites, linearities of the plots are satisfactorily fine. These results confirm that the β-CyDs immobilized on the silica gel form 1:1 complexes with phenol. Cooperativity of two immobilized β-CyD molecules or more in the complex formation is not detected.

Table 2 lists the equilibrium constants K_d for the dissociation of the complex between the β-CyD immobilized on silica gel and phenol in aqueous solution at 25°C. The K_d values for the immobilized β-CyDs in both of the composites A-2 and A-4, determined from the intercepts on the ordinate (see Eq. 1), are almost identical with each other. About 4 fold larger K_d values for these immobilized β-CyDs, compared with the value for intact β-CyD, are associated with larger steric hindrance on the complex formation.

Table 3. Catalytic Activity of the β-CyD Immobilized to Silica Gel in the Cleavage of 4-Nitrophenyl Acetate[a)]

Catalyst	Amount of β-CyD/10^{-6} mol	Pseudo-first order rate constant of cleavage/10^{-4} s^{-1}
β-CyD–silica gel composite		
A-2 (100 mg)	8.8	1.5
A-3 (60 mg)	7.8	1.9
A-4 (100 mg)	8.3	1.9
A-4 (300 mg)	24.9	2.4
Intact β-CyD (9.4 mg)	8.3	2.9
(Non-immobilized) (11.2 mg)	9.9	3.2
(Non-immobilized) (28.3 mg)	24.9	5.8
Silica gel (100 mg)	0.0	1.2
None	0.0	1.2

a) Catalysts were added to 3 cm^3 of pH 8.7 Tris buffer solution. The charged concentration of 4-nitrophenyl acetate was 3.3×10^{-5} mol dm^{-3}.

The amounts of the immobilized β-CyD in the specimens, determined from the slopes of the straight lines in Fig. 3 are in good agreements with the charged amounts, estimated from the compositions of the β-CyD–silica gel composites. This fact shows that β-CyDs were successfully immobilized on the silica gel in their intact forms and also confirms the validity of the procedures employed in the present study for the determination of K_d values.

Catalytic Activity of the β-Cyclodextrin Immobilized on Silica Gel. The cleavage of 4-nitrophenyl acetate in the presence of the β-CyD–silica gel composites obeyed first-order kinetics. This result rules out a possibility that diffusion of the substrate to the vicinity of the immobilized β-CyD is rate-determining.

As shown in Table 3, all the β-CyD–silica gel composites exhibit catalytic activities for the cleavage of 4-nitrophenyl acetate. The activity is definitely attributed to the functions of the immobilized β-CyD, since the silica gel alone has no catalytic activity at all.

The catalytic activities of the immobilized β-CyDs are 2—4 fold smaller than that of intact β-CyD. This is associated with smaller substrate-binding constant, as shown in Table 2. Kinetic determination of the catalytic rate constants and the substrate binding constants was not successful, due to small magnitude of acceleration.

Conclusion

β-Cyclodextrin was covalently immobilized on silica gel as support. The resulting composites were stable up to 250 °C, where most of organic supports or organic polymers were hard to be used due to decomposition or deformation. The immobilized β-cyclodextrins exhibited both binding and catalytic activities.

The authors are indebted to Mr. Tatsuro Tsuru, Institute of Industrial Science, The University of Tokyo, for the measurement of nitrogen isotherms and to Mr. Fumio Tsuji for his technical assistance.

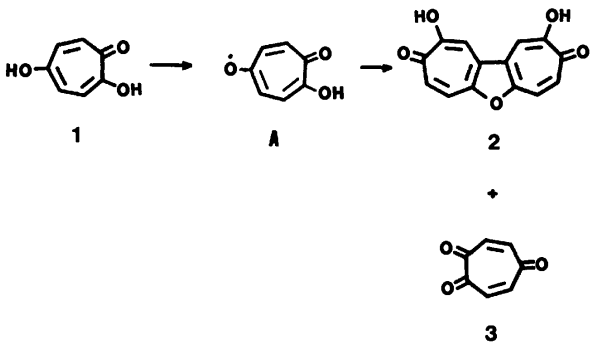
The Cerium(IV) Ammonium Nitrate Oxidation of 5-Hydroxy-2-methoxytropone to Bitropolonyl Derivatives and One-Step Synthesis of 3-Methoxy-*p*-tropoquinone

Akira MORI, Yasutoshi ISAYAMA,† and Hitoshi TAKESHITA*
Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
†Graduate School of Engineering Sciences, 39, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
(Received September 30, 1985)

Unlike the benzenoid equivalent, *p*-methoxyphenol, the cerium(IV) ammonium nitrate (CAN)-oxidation of 5-hydroxy-2-methoxytropone gave C-C coupling products. On the other hand, either by thallium(III) nitrate (TTN) or CAN at 50 °C, 5-hydroxytropolone, a free tropolone, gave 3-methoxy-*p*-tropoquinone together with *p*-tropoquinone and 8-oxabicyclo[3.2.1]octenone derivatives, but no dimeric product.

We have recently developed a practical method for preparing *p*-tropoquinone mono- and diacetals by thallium(III) nitrate (TTN) oxidation of 2-alkoxy-5-hydroxytropones,[1] useful intermediates for various functionalized troponoids. This one-pot type preparation of acetals from 2-alkoxy-5-hydroxytropones was favored since it takes advantage of a two-electron oxidation (type I) path. According to the path of a one-electron oxidation (type II), the different behaviors were considered regarding the oxidation of 5-hydroxytropolone (**1**). With a stoichiometric amount of silver acetate,[2] it yielded 2,10-dihydroxydicyclohepta[*b*,*d*]furan-3,9-dione (**2**) through a coupling of the semiquinone radical intermediate (**A**). However, with two moles of the agent, it afforded *p*-tropoquinone (**3**). Indeed, the yields of the tropoquinones were generally better than those produced through a reaction with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ).[3]



Scheme 1.

Accordingly, the oxidation of 2-alkoxy-5-hydroxytropones by a type-II agent, such as cerium(IV) ammonium nitrate (CAN),[4] should be worthwhile. Moreover, although it has already been noticed that the metal salt-induced oxidation of free tropolone derivatives at 0 °C is ineffective due to the formation of insoluble metal salts,[1] the reaction has been produced by heating at 50 °C in methanol. The results are described on the following pages.

Results and Discussion

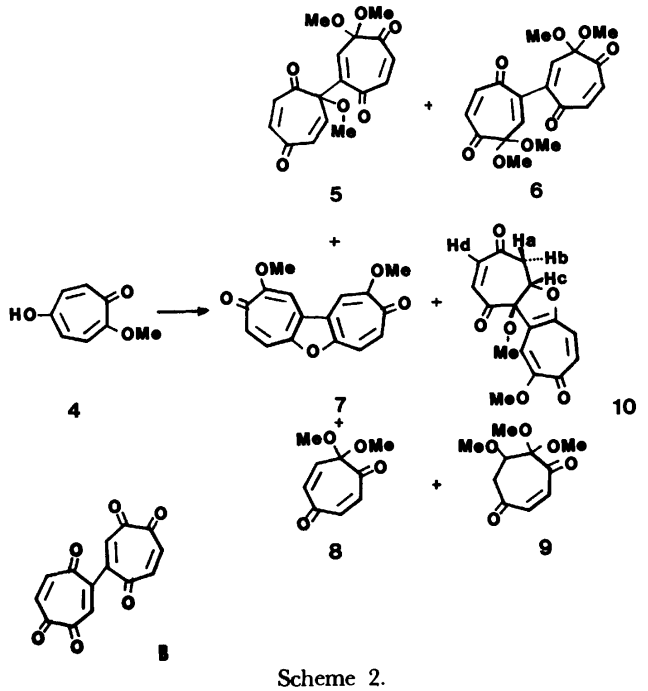
During the oxidation of 5-hydroxy-2-methoxytropone (**4**) with two equivalents of CAN in anhydrous methanol, an instantaneous oxidation occurred to give two crystalline dimeric condensates (**5** and **6**) along with 2,10-dimethoxydicyclohepta[*b*,*d*]furan-3,9-dione (**7**),[5] *p*-tropoquinone dimethyl acetal (**8**)[1,6] and its methanol adduct (**9**).[1]

The dimer (**5**) showed three methoxyl groups on the sp^3-carbons and seven olefinic protons in the ^1H NMR spectrum. Also there were four carbonyl signals in the ^{13}C NMR. All these factors are consistent with our formulation.

The other dimer, **6**, yellow needles, exhibited only eight signals in the ^{13}C NMR, indicating a symmetrical structure. In the ^1H NMR, there were overlapping signals for four methoxyl groups on the sp^3-carbons and six olefinic protons. Therefore, a newly formed C–C bond must be at C-4 and C-4′. Also, **6** was bi(3,3-dimethoxy-4,7-dioxo-1,5-cycloheptadienyl). This corresponds to the bis-monoacetal of hitherto unknown biquinone, bi(*p*-tropoquinonyl) (**B**).

Particularly, this oxidation was sensitive to water. When the CAN-oxidation of **4** was carried out in methanol containing a trace amount of water, a new dimeric product (**10**) was obtained together with **5**, **7**, **8**, and **9**. The ^1H NMR spectrum of **10** revealed signals due to two methoxyl groups, five olefinic protons, and three protons on the sp^3-carbons. The coupling parameters observed in the signals [3.09 (Ha, dd, J=15, 2.5 Hz), 3.42 (Hb, ddd, J=15, 7.5, 1 Hz), 5.06 (Hc, dd, J=7.5, 2.5 Hz), and 6.73 (Hd, dd, J=12.5, 1 Hz)] indicated an arrangement of these four protons as shown in the scheme. Other than **7**, **10** was the only fully-conjugated tropone derivative among the oxidation products. The seven-membered rings of all other products contained a sp^3-carbon, such as an acetal group or a tertiary ether. The formation of **10** under moistened conditions illustrates the important role of a proton in the following step of the reaction; e.g., a coupling of the intermediate, **C** (an analog of **A**) to **D** at C-2 and C-4 via the type II-process, can be readily aromatized to a 5-hydroxy-2-methoxytropone (**E**). The subsequent CAN-oxidation of **E** should give the dimethyl acetal, **5**. However, in the presence of water, **E** was intramolecularly cyclized to **10**. Therefore, a further oxidation of **10** (as well as **7**), having no free hydroxyl group, was slow under these conditions.

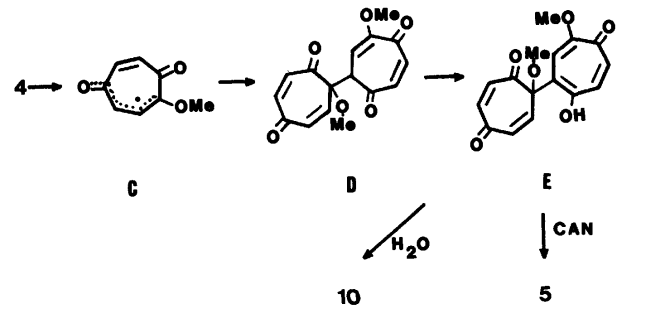
Also, CAN was preferentially co-ordinated with water to prevent the further oxidation.



Scheme 2.

It is possible to classify the products into three categories, i.e., i) monomeric products (**8** and **9**), ii) C-2–C-4′ condensates (**5** and **10**), and iii) C-4–C-4′ condensates (**6** and **7**). The relative yields of these products showed a dependence on several conditions. Under anhydrous conditions, they were 22% for i), 9% for ii), and 48% for iii). In the presence of water, they were 19% for i), 44% for ii), and 20% for iii). Thus, there was a predominance of iii) in an anhydrous media and ii) in the presence of water.

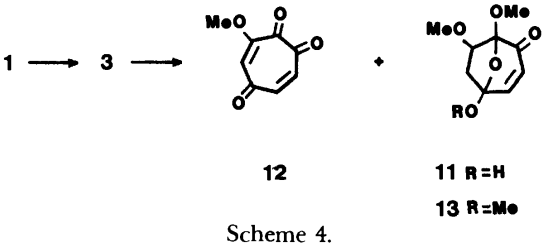
In order to obtain **B**, a hydrolysis of **6** under various conditions has been attempted, but none of the products have been identified. Presumably, **B** is too reactive under the reaction conditions to form complex mixtures. Other transformations attempted so far with these dimeric products were unsatisfactory; i.e., a Thiele reaction in a mixture of acetic anhydride and acetic acid, a zinc reduction in acetic acid, and hydrolysis with perchloric acid in aqueous acetone all gave intractable mixtures.



Scheme 3.

Next, a CAN oxidation of **1** was carried out at room temperature in methanol. A new product (**11**) was identified along with **3**. The ^{1}H NMR spectrum of **11** showed signals attributable to a methylene group, two methoxyl groups, two vicinal vinylic protons on the six-membered ring, and a proton on the sp^3-carbon bearing an oxygen function. Therefore, **11** should be an 8-oxabicyclo[3.2.1]octenone derivative.

For a comparison, the TTN-oxidation of **1** was also carried out in methanol at 50°C to obtain two new products (**12** and **13**). According to spectral evidence, the former, **12**, was 3-methoxy-*p*-tropoquinone. Although its yield was not very high, a one-step preparation should be useful from a practical point of view.[1] The structure of **13** was identified to be a methylated derivative of **11** from NMR spectral evidence; the ^{1}H NMR spectrum of **13** showed a close resemblance to that of **11** except for the presence of an additional methoxyl methyl singlet. Also, a comparison of the ^{13}C NMR chemical shifts led to the same conclusion (see Experimental). Interestingly, a TTN-oxidation of **3** in methanol gave **11** together with **13**. Thus, it is clear that **3** is a precursor of these oxidation products.



Scheme 4.

It should be mentioned that, unlike **4**, the TTN-oxidation of **1** formed no dimers. In other words, for the oxidation of **1**, there is no difference between the oxidizing agents (TTN and CAN) in this respect. This means that the transformations of an intermediate (**A**) to **3** by a one-electron oxidation process is rather easier than the C–C coupling process. This is parallel to the previous results regarding silver salt-oxidation, another one-electron oxidizing process of **1**.[2] With a stoichiometric amount of the reagent, it gave **3** in good yield; but, with a smaller amount, it also gave the C-4–C-4′ coupling product, **2** (Scheme 1).

In conclusion, the major products formed in the CAN-oxidation of **4** were the C–C coupling products. These differed remarkably to those formed in a TTN oxidation. This difference results from the nature of the oxidizing agent, as has been mentioned. It is noteworthy that, as has been reported, the CAN-oxidation of 4-methoxyphenol in methanol gave 4,4-dimethoxy-2,5-cyclohexadienone in 65% yield.[7] No other paper has described any accompanied C–C coupling product until a recent study by Maruyama

et al. They reported such a C-C coupling which gave a benzoquinonoid crown ether derivative.[8] In a contrast a facile C-C bond formation in the troponoids may be attributable to the presence of an adjacent carbonyl group which helps to delocalize an unpaired electron. Accordingly, the semiquinone radicals of tropoquinones would be more stable than those of benzoquinones to enable the intermolecular reaction. Otherwise, quinone acetals, e.g., **8**, should be formed by a reaction with CAN and the solvent-caged methanol. It would be interesting to investigate the electrochemical behaviors by the cyclic voltammetry of the tropoquinones. This would determine whether this is reflected to it or not. Such research will be published in due course.

Experimental

All the mps were measured by means of a Yanagimoto Micro-mp Apparatus and are uncorrected. Elemental analyses were performed by Miss S. Hirashima of the Research Institute of Industrial Science, Kyushu University. The NMR spectra were measured by means of a JEOL FX 100 Spectrometer in $CDCl_3$ solutions and the chemical shifts measured were expressed in δ units from the internal Me_4Si. The mass spectra were measured by means of a JEOL OISG-2 Spectrometer. The UV spectra were measured by means of a Hitachi 124 Spectro photometer in MeOH. The IR spectra were taken in either as KBr disks or as an inserted liquid film between NaCl plates using a Jasco IR-A 102 Spectrometer.

CAN-Oxidation of 4. a) To an anhydrous MeOH solution (6 cm^3) of **4** (100 mg), carefully desiccated CAN (721 mg) was added at 0°C. After 1 h, the mixture was warmed to 20—25°C and stirred for another 30 min. The mixture was then diluted with water, extracted with $CHCl_3$, and chromatographed on a silica-gel column with AcOEt-hexane (1:4) to give **5** [a yellow oil, 9.6 mg; 9%. Found: M.W., 332.0901 (M^+). Calcd for $C_{17}H_{16}O_7$: 332.0895. ^1H NMR δ=3.16 (3H, s), 3.28 (3H, s), 3.30 (3H, s), 6.40 (1H, d, J=12 Hz), 6.43 (2H, d, J=1.5 Hz), 6.44 (1H, s), and 6.74 (1H, d, J=12 Hz). ^{13}C NMR δ=50.7, 50.9, 53.7, 88.8, 103.0, 132.6, 133.5, 134.7, 135.6, 135.8, 137.8, 138.2, 144.1, 189.5, 191.5, 192.1, and 192.4, IR ν: 2950, 1710, 1660, 1620, and 1450 cm^{-1}], **8** (15.5 mg; 13%), and **9** (12.6 mg; 9%), which were identical with authentic samples,[1] together with **6** [yellow needles, mp 100°C (decomp), 12.0 mg; 10%. Found: C, 59.71; H, 5.09%. Calcd for $C_{18}H_{18}O_8$: C, 59.66; H, 5.01%. ^1H NMR δ= 3.28 (12H, s), 6.40 (2H, d, J=13 Hz), 6.43 (2H. s). and 6.58 (2H, d, J=13 Hz). ^{13}C NMR δ=50.8 (4C), 103.0 (2C), 132.3 (2C), 135.8 (2C), 138.2 (2C), 143.8 (2C), 191.4 (2C), and 191.6 (2C). IR ν: 1710, 1660, 1450, 1160, and 1050 cm^{-1}. UV λ_{max}^{MeOH}: 229 nm(ε=17800) and 380 (900)].

On the other hand, the aqueous washings were acidified with dil HCl, and extracted with 1-butanol; the solvent was evaporated in vacuo to leave **7** (colorless crystals, mp 226—228°C (lit,[5] mp 227—230°C), 35.5 mg; 38%.).

b) To an MeOH solution (3 cm^3) of **4** (80 mg), CAN (577 mg), fresh but not further purified, was added all at once at 0°C. After 1 h, the mixture was warmed to 20—25°C and stirred for an additional 30 min. The mixture was diluted with water, extracted with $CHCl_3$, washed with $NaHCO_3$, and chromatographed on a silica-gel column to give **8** (9.6 mg; 10%), **9** (9.1 mg; 8%), **5** (5.2 mg; 6%), and **10** [pale yellow needles, mp 150—150.5°C. 30.2 mg; 38%. Found: M. W., 302.0786 (M^+). Calcd for $C_{16}H_{14}O_6$: 302.0789. ^1H NMR δ=3.09 (1H, dd, J=15, 2.5 Hz), 3.35 (3H, s), 3.42 (1H, ddd, J=15, 7.5, 1 Hz), 3.85 (3H, s), 5.06 (1H, dd. J=7.5, 2.5 Hz), 6.31 (1H, s), 6.37 (1H, dd, J=12.5, 1 Hz), 6.74 (1H, d. J=12.5 Hz), 7.02 (1H, d, J=13 Hz), and 7.26 (1H, d, J=13 Hz). ^{13}C NMR δ=44.8. 52.0, 56.5, 78.8, 97.4, 107.2, 118.4, 125.2, 135.4, 139.8, 140.2, 158.9, 161.0, 178.9, 193.7, and 194.1. IR ν: 1710, 1670, 1560, 1510, 1450, 1320, 1240, and 1070 cm^{-1}. UV λ_{max}^{MeOH}: 234 nm (ε=22700), 336 (8700), 359 (7600), 377 (7950), and 395 (6900)].

From the aqueous washings, **7** (14.9 mg; 20%) was obtained by extraction with 1-butanol.

CAN-Oxidation of 1. To an MeOH solution (2 cm^3) of **1** (70 mg), CAN (280 mg) was added, and stirred at 20—25°C for 15 min. The mixture was then diluted with water, extracted with $CHCl_3$, and chromatographed on a silica-gel column with AcOEt-hexane (1:4) to give **3** (15.3 mg; 22%) and **11** [a colorless oil, 10.2 mg; 10%. Found: M. W., 200.0696 (M^+). Calcd for $C_9H_{12}O_5$: 200.0686. ^1H NMR δ=2.20 (1H, dd, J=13.5, 2.5 Hz), 2.53 (1H, dd, J=13.5, 10 Hz), 3.26 (3H, s), 3.45 (3H, s), 4.07 (1H, dd, J=10, 2.5 Hz), 6.28 (1H, d, J=9 Hz), and 7.26 (1H, d, J=9 Hz). ^{13}C NMR δ=39.6, 52.5, 58.8, 83.3, 104.2, 104.8, 128.4, 155.0, and 194.4. IR ν: 3400, 1703, and 1610 cm^{-1}].

TTN-Oxidation of 1. To an MeOH solution (5 cm^3) of **1** (200 mg), TTN (950 mg) was added. After 20 min, the reaction mixture was warmed at 50°C and stirred for 2 h. The mixture was then diluted with water, extracted with $CHCl_3$, and chromatographed on a silica-gel column with AcOEt-hexane (1:3) to give **12** [colorless crystals, mp 121—123°C, 43.5 mg; 18%. Found: m/z, 138.0310 (M^+—28). Calcd for $C_7H_6O_3$: 138.0315. ^1H NMR δ=3.80 (3H, s), 5.93 (1H, s), 6.61 (1H, d, J=13.5 Hz), and 6.79 (1H, d, J=13.5 Hz). ^{13}C NMR δ=56.2, 107.7, 134.4, 137.2, 158.6, 181.6, and 187.3 (2C). IR ν: 1680, 1640, and 1590 cm^{-1}. UV $\lambda_{max}^{CHCl_3}$: 255 nm (ε=14000), 286 (550), 356 (1100)], and **13** [a colorless oil, 18.6 mg; 6%. Found: M. W., 214.0836 (M^+). Calcd for $C_{10}H_{14}O_5$: 214.0840. ^1H NMR δ=1.97 (1H, dd, J=13.5, 2.5 Hz), 2.53 (1H, dd, J=13.5, 10 Hz), 3.26 (3H, s), 3.47 (3H, s), 3.50 (3H, s), 3.98 (1H, dd, J=10, 2.5 Hz), 6.22 (1H, d, J=10 Hz), and 7.22 (1H, d, J=10 Hz). ^{13}C NMR δ=40.2, 52.3, 53.7, 58.6, 82.9, 105.3, 109.0, 131.2, 153.0, and 192.1. IR ν: 1740, 1710, 1610, 1560, and 1450 cm^{-1}. UV λ_{max}^{MeOH}: 219 nm (ε=6050)].

TTN-Oxidation of 3. To an MeOH solution (2 cm^3) of **3** (178 mg), TTN (575 mg) was added and stirred at 20—25°C for 10 min. After stirring at 50°C for 1 h, the mixture was diluted with water and extracted with $CHCl_3$. Silica-gel column chromatography with AcOEt-hexane (2:3) yielded **12** (28.2 mg; 13%) and **11** (42 mg; 16%).

We would like to thank The Ministry of Education, Science, and Culture for a Grant-in-Aid for Scientific Research to A. M. (No. 60470025).

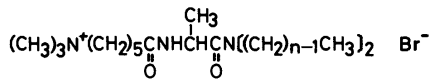
Transformation between Lamellar and Nonlamellar Aggregates Formed with Synthetic Peptide Lipids†

Yukito MURAKAMI,* Jun-ichi KIKUCHI, Toshihiko TAKAKI, and Katsuya UCHIMURA
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received September 30, 1985)

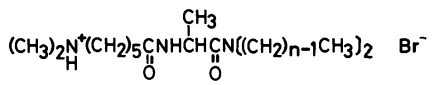
The morphological behavior of various combinations of the following synthetic lipids was investigated in the aqueous dispersion state by means of electron microscopy, differential scanning calorimetry, and fluorescence polarization spectroscopy as well as by turbidity and X-ray diffraction measurements: $N^+C_5Ala2C_n$ and $N^+(H)C_5Ala2C_n$ as cationic, $(SO_3^-)C_5Ala2C_n$ as anionic, and QC_5Ala2C_n as nonionic (n=14, 16). Aqueous dispersions of various combinations of cationic and anionic lipids at the equimolar ratio afforded nonlamellar aggregates, having highly ordered and three-dimensional network structure with repeating distances in the 70—130 Å range, above their phase transition temperatures (T_m). However, any slight loss of the fractional balance retained at the equimolar ratio led to the formation of bilayer aggregates. Under such conditions that allow the formation of nonlamellar aggregates, the high microscopic homogeneity of cationic and anionic lipid molecules was attained, originating from the intramembrane electrostatic interaction between cationic and anionic head moieties to form highly developed ion-pair clusters on the aggregate surface. Meanwhile, the nonlamellar phase appeared above T_m was spontaneously transformed into the normal bilayer phase below T_m as confirmed by electron microscopy and turbidity measurements. The nonlamellar phase was also characterized by the low-angle X-ray diffraction method and was consistent with the highly developed domain with the face-centered cubic lattice.

The polymorphic phase behavior has been found to arise by changing compositions and properties of membrane-forming lipids in the aqueous dispersion state.[1] In contrast with extensive studies on the bilayer phase, characterization of the nonbilayer ones, such as inverted hexagonal (H_{II}), lipidic particle (LIP), and inverted cubic (C_{II}) phases, has been limited to systems composed of naturally occurring lipids up to the present time.[2] In connection with dynamic functions of biomembranes, the correlations between lipid compositions and morphological transitions between bilayer and nonbilayer phases pose major unsolved subjects.[2,3] In this regard, simple model systems composed of synthetic lipids may make useful contributions toward general understanding of biological phenomena. Although various bilayer-forming lipids have been prepared,[4] synthetic lipids capable of forming nonbilayer aggregates under diluted conditions in aqueous media have been scarcely treated. Recently, we have found that a series of ionic peptide lipids involving an amino acid residue interposed between a polar head group and an aliphatic double-chain segment form bilayer membranes (vesicles and/or lamellae) in the aqueous dispersion state.[5] On the other hand, nonionic lipids having the quinoyl group as a polar head have been confirmed to form nonlamellar network aggregates when they were dispersed in aqueous media.[6] As described in our preliminary communication,[7] the similar morphology was also observed for equimolar mixtures of cationic and anionic peptide lipids.

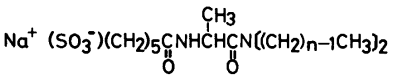
In order to understand the molecular basis for formation of nonlamellar aggregates, the morphological behavior of various combinations of the following synthetic lipids was investigated in the aqueous dispersion state: $N^+C_5Ala2C_n$ and $N^+(H)C_5Ala2C_n$ as cationic, $(SO_3^-)C_5Ala2C_n$ as anionic, and QC_5Ala2C_n as nonionic (n=14, 16).



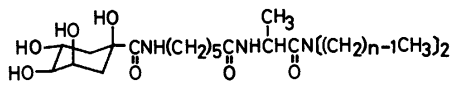
$N^+C_5Ala2C_n$ (n=14,16)



$N^+(H)C_5Ala2C_n$ (n=14,16)



$(SO_3^-)C_5Ala2C_n$ (n=14,16)



QC_5Ala2C_n (n=14,16)

Experimental

Materials. 1,6-Diphenyl-1,3,5-hexatriene (DPH) was obtained from Nakarai Chemicals as a guaranteed reagent and used without further purification. The preparation of the following lipids has been reported previously: *N,N*-ditetradecyl-N^α-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide ($N^+C_5Ala2C_{14}$),[5c] *N,N*-dihexadecyl-N^α-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide ($N^+C_5Ala2C_{16}$),[5c] sodium *N,N*-ditetradecyl-N^α-(6-sulfohexanoyl)-L-alaninamide [$(SO_3^-)C_5Ala2C_{14}$],[6b] sodium *N,N*-dihex-

adecyl-N^{α}-(6-sulfohexanoyl)-L-alaninamide [$(SO_3^-)C_5Ala2C_{16}$],[6b] *N,N*-ditetradecyl-N^{α}-[6-(quinoylamino)hexanoyl]-L-alaninamide (QC_5Ala2C_{14}),[6a)#] and *N,N*-dihexadecyl-N^{α}-[6-(quinoylamino)hexanoyl]-L-alaninamide (QC_5Ala2C_{16}).[6b)#]

***N,N*-Ditetradecyl-N^{α}-[6-(dimethylamino)hexanoyl]-L-alaninamide (NC_5Ala2C_{14}).** This material was prepared in a manner similar to that reported for the synthesis of *N,N*-didodecyl-N^{α}-[6-(dimethylamino)hexanoyl]-L-alaninamide,[5b] and isolated as the hydrobromide salt [$N^+(H)C_5Ala2C_{14}$]: a white glassy solid, final mp 123 °C; $[\alpha]_D^{25}$ −15.0° (*c* 1.01, ethanol); IR (KBr) 2920 and 2850 (CH), and 1640 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$, TMS) δ=0.88 [6H, br t, $(CH_2)_{13}C\underline{H}_3$], 1.0—2.0 [57H, m, $CH_2(C\underline{H}_2)_{12}CH_3$, $CH(C\underline{H}_3)$, and $CH_2(C\underline{H}_2)_3CH_2CO$], 2.28 [2H, br t, CH_2CO], 2.81 [6H, s, $(C\underline{H}_3)_2HN^+$], 2.9—3.8 [6H, m, N^+CH_2 and $NC\underline{H}_2(CH_2)_{12}CH_3$], 4.80 [1H, m, $C\underline{H}(CH_3)$], and 6.83 [1H, d, CONH].

Found: C, 66.40; H, 11.42; N, 5.75. Calcd for $C_{39}H_{79}N_3O_2\cdot$HBr: C, 66.63; H, 11.47; N, 5.98.

***N,N*-Dihexadecyl-N^{α}-[6-(dimethylamino)hexanoyl]-L-alaninamide (NC_5Ala2C_{16}).** This material was prepared in a manner as described above and isolated as the hydrobromide salt [$N^+(H)C_5Ala2C_{16}$]: a white glassy solid, final mp 126 °C; $[\alpha]_D^{25}$ −20.8° (*c* 1.01, ethanol); IR (KBr) 2920 and 2850 (CH), and 1640 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$, TMS) δ=0.87 [6H, br t, $(CH_2)_{15}C\underline{H}_3$], 1.0—2.0 [65H, m, $CH_2(C\underline{H}_2)_{14}CH_3$, $CH(C\underline{H}_3)$, and $CH_2(C\underline{H}_2)_3CH_2CO$], 2.25 [2H, br t, CH_2CO], 2.80 [6H, s, $(C\underline{H}_3)_2HN^+$], 2.9—3.7 [6H, m, N^+CH_2 and $NC\underline{H}_2(CH_2)_{14}CH_3$], 4.79 [1H, m, $C\underline{H}(CH_3)$], and 6.77 [1H, d, CONH].

Found: C, 68.16; H, 11.80; N, 5.55. Calcd for $C_{43}H_{87}N_3O_2\cdot$HBr: C, 68.03; H, 11.68; N, 5.54.

Preparation of Molecular Aggregates. As for mixed lipid systems, chloroform solutions of two different lipids were mixed at appropriate molar ratios and evaporated to dryness to give thin films. Each film placed in 2 mL of deionized and distilled water was subjected to vortex mixing with glass beads at room temperature (ca. 20 °C) for 1—10 min to afford an aqueous dispersion sample. Whenever necessary, the dispersion sample was subsequently sonicated with a probe-type (W-220F, Heat Systems-Ultrasonics) or a bath-type sonicator (Bransonic 12, Yamato Scientific Co.) and allowed to stand for 20 min at room temperature.

Analyses and Measurements. Elemental analyses were performed at the Microanalysis Center of Kyushu University. Melting points were measured with a Yanagimoto MP-S1 apparatus (hot-plate type). IR spectra were recorded on a JASCO IR-810 spectrophotometer. ^{1}H-NMR spectra were taken on a Hitachi R-24B or a Hitachi Perkin-Elmer R-20 spectrometer. Turbidity measurements were run at 400 nm on a Hitachi 340 or a Union Giken SM-401 high sensitivity spectrophotometer with a cell of 1.0-mm path length. A Daini Seikosha SSC-560U calorimeter was used for differential scanning calorimetry (DSC). The phase transition temperature (T_m, temperature at a peak maximum of DSC thermogram) and the enthalpy change for phase transition (ΔH) were determined in the same manner as reported previously.[6b] Electron micrographs were taken on a JEOL JEM-200B electron microscope installed at the Research Laboratory for High Voltage Electron Microscopy of Kyushu University. The negatively stained samples for the measurements were prepared in a manner as described previously.[6b]

The fluorescence polarization measurements were carried out on a Union Giken FS-501A fluorescence polarization spectrophotometer equipped with a Sord microcomputer M200 Mark II; the emission at 450 nm originated from DPH was monitored upon excitation at 366 nm with a slit width of 3.5 nm for both excitation and emission sides. The steady-state fluorescence anisotropy (r_s) was calculated by Eq. 1, where I is the fluorescence intensity, and the subscripts v and h refer to the orientations, vertical and horizontal, respectively, for the excitation and analyzer polarizers in this sequence. C_f is the grating correction factor, given by I_{hv}/I_{hh}.

$$r_s=(I_{vv}-C_fI_{vh})/(I_{vv}+2C_fI_{vh}) \quad (1)$$

The nickel-filtered Cu $K\alpha$ radiation (λ=1.5418 Å) from a Rigaku Rotaflex RU-200 X-ray generator was used for X-ray diffraction measurements. Each sample was sealed up in a specimen holder equipped with mica windows, and a low-angle diffraction pattern was recorded on a Fuji X-ray film 150; a sample—film distance being set at 200 mm.

Results

Electron Microscopy. We have previously reported aggregate morphology of the following individual lipids in aqueous media: $N^+C_5Ala2C_n$,[5c] $(SO_3^-)C_5Ala2C_n$,[6b] and QC_5Ala2C_n.[6] Additional lipids having the amino group, NC_5Ala2C_n (n=14, 16), were prepared in this work and found to behave as cationic lipids under acidic conditions (below pH 6) that allow the amino head moiety to be protonated, $N^+(H)C_5Ala2C_n$.[8] The cationic $N^+(H)C_5Ala2C_n$ was found to constitute multilayered aggregates, bent lamellae and vesicles (Fig. 1A), in the aqueous dispersion state and single-walled vesicles in the diameter range 200—1000 Å (Fig. 1B) after treated with a probe-type sonicator for 2 min at 30 W.

When equimolar amounts of a cationic lipid, $N^+(H)C_5Ala2C_{16}$, and an anionic one, $(SO_3^-)C_5Ala2C_{14}$, were dispersed in water at pH 4.0 and 20 °C, the formation of nonlamellar aggregates was detected by electron microscopy with the negative staining technique; highly ordered network structure with a repeating distance of 100 Å (Fig. 2A). Similar aggregates with repeating distances in the 70—130 Å range were observed in aqueous dispersions of the following combinations of cationic and anionic lipids at the equimolar ratio above their phase transition temperatures; $N^+C_5Ala2C_{14}$–$(SO_3^-)C_5Ala2C_{14}$,[7] $N^+C_5Ala2C_{16}$–$(SO_3^-)C_5Ala2C_{16}$, $N^+(H)C_5Ala2C_{14}$–$(SO_3^-)C_5Ala2C_{14}$, $N^+(H)C_5Ala2C_{14}$–$(SO_3^-)C_5Ala2C_{16}$ (Fig. 2B), and $N^+(H)C_5Ala2C_{16}$–$(SO_3^-)C_5Ala2C_{16}$. Such characteristic morphological behavior was also confirmed by the freeze-fracture electron microscopy as typically shown for the $N^+C_5Ala2C_{14}$–$(SO_3^-)C_5Ala2C_{14}$ system; close

Quinoyl is the conventional name for 1,3,4,5-tetrahydroxy-[1*R*-(1α, 3α, 4α, 5β)]cyclohexylcarbonyl.

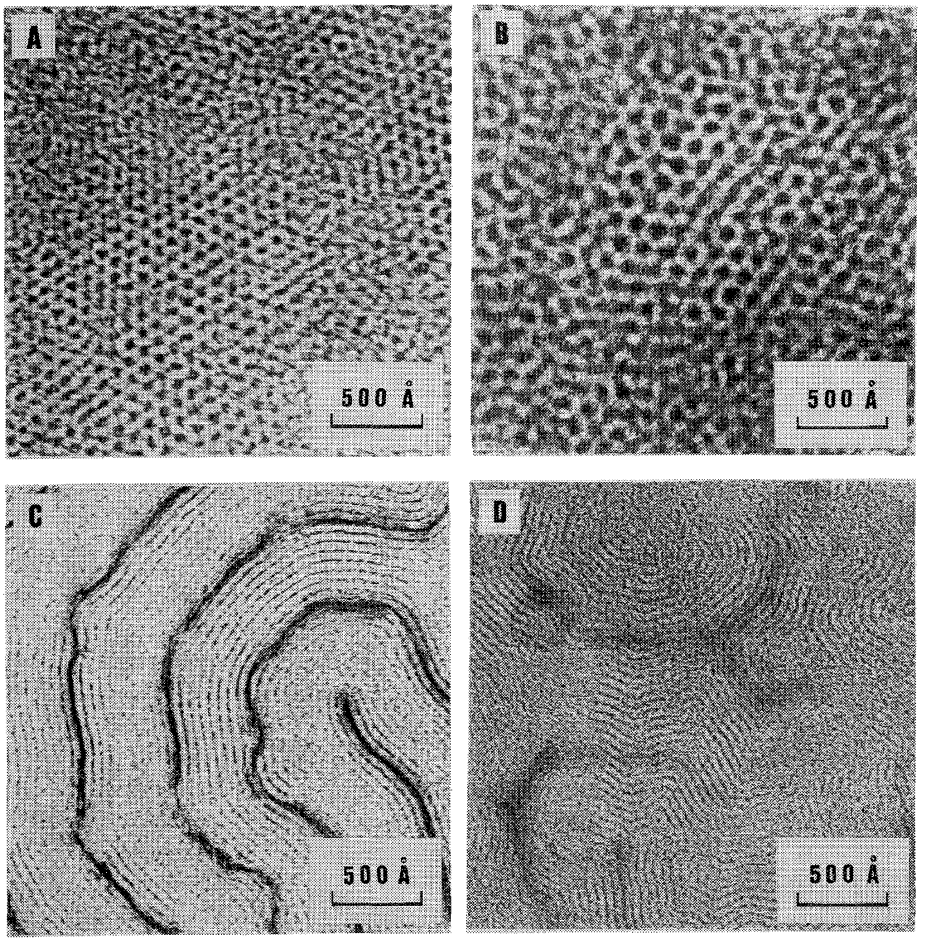

Fig. 2. Electron micrographs for equimolar mixtures (2.5 mmol dm^{-3} each) of two peptide lipids with the following combinations in the dispersion state, as negatively stained with uranyl acetate: A, $N^+(H)C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{14}$; B, $N^+(H)C_5Ala2C_{14}$ and $(SO_3^-)C_5Ala2C_{16}$; C, $N^+(H)C_5Ala2C_{14}$ and $N^+C_5Ala2C_{16}$; D, QC_5Ala2C_{14} and $(SO_3^-)C_5Ala2C_{16}$.

packing of globular aggregates.[7] On the other hand, other mixed lipid systems, containing two kinds of peptide lipids at the equimolar ratio, formed normal bilayer aggregates in the aqueous dispersion state; e.g., $N^+C_5Ala2C_n$-$N^+(H)C_5Ala2C_n$ (Fig. 2C), N^+-C_5Ala2C_n-QC_5Ala2C_n, $N^+(H)C_5Ala2C_n$-QC_5Ala2C_n,

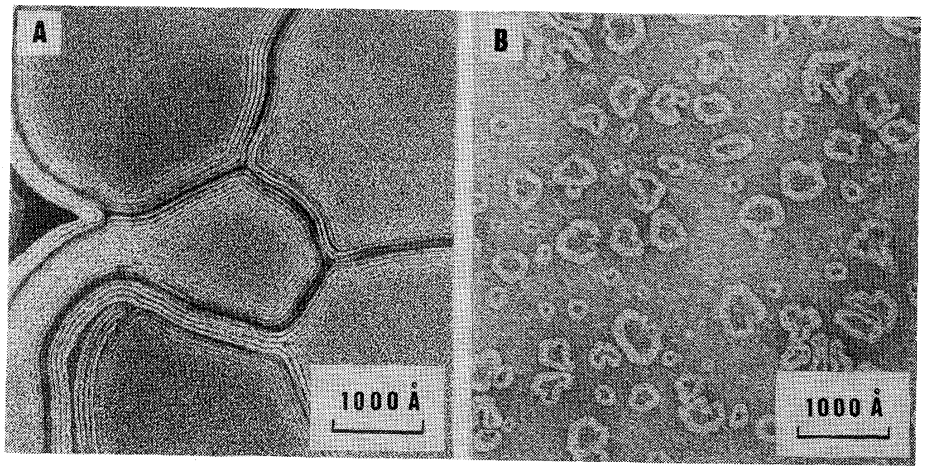

Fig. 3. Electron micrographs for a mixture of $N^+(H)C_5Ala2C_{14}$ (3.75 mmol dm^{-3}) and $(SO_3^-)C_5Ala2C_{14}$ (1.25 mmol dm^{-3}), as negatively stained with uranyl acetate: A, aqueous dispersion; B, aqueous solution sonicated for 60 min with a bath-type sonicator at 30 W.

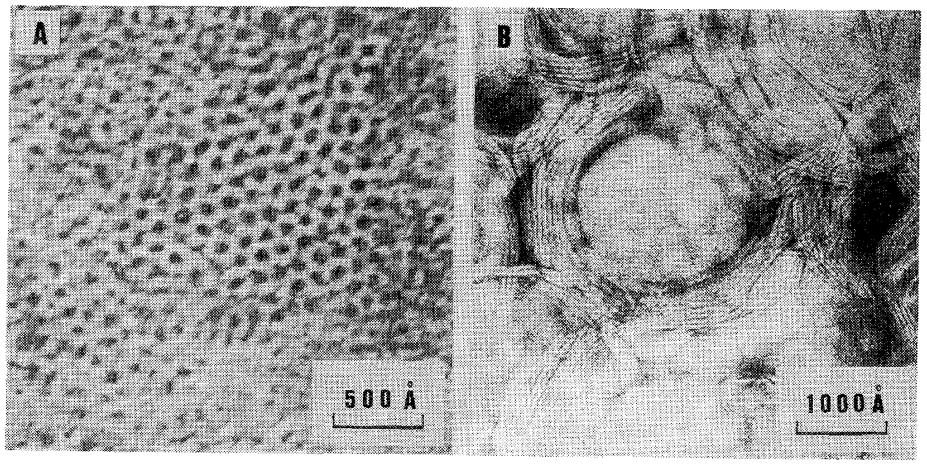

Fig. 4. Electron micrographs for an equimolar mixture (2.5 mmol dm^{-3} each) of $N^+C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{16}$ in the dispersion state, as negatively stained with uranyl acetate: A, prepared at 50°C; B, prepared at 5°C.

and QC_5Ala2C_n-$(SO_3^-)C_5Ala2C_n$ (Fig. 2D). As for the systems composed of cationic and anionic lipids, any slight loss of the fractional balance retained at the equimolar ratio leads to the formation of bilayer aggregates. For example, bent lamellae were observed in an aqueous dispersion of $N^+(H)C_5Ala2C_{14}$ and $(SO_3^-)C_5Ala2C_{14}$ at the 3:1 molar ratio (Fig. 3A) and converted into single-walled vesicles in the diameter range 200—600 Å upon sonication with a bath-type sonicator for 60 min at 30 W (Fig. 3B). It needs to be noted that the aggregate morphology is subjected to change by the temperature range adopted for investigation, even if both cationic and anionic lipids were mixed exactly at the equimolar ratio, and the nonlamellar network aggregates were observed above the gel-liquid crystalline phase transition temperature. For example, the $N^+C_5Ala2C_{16}$-(SO_3^-)-C_5Ala2C_{16} system, T_m at 27.0°C (vide infra), formed nonbilayer and bilayer aggregates at 50 and 5°C, respectively, in the dispersion state as shown in Fig. 4.

Differential Scanning Calorimetry (DSC). The phase transition parameters (maximum temperature, T_m; enthalpy change, ΔH) for the bilayer aggregates formed with individual ionic lipids in the aqueous dispersion state are linearly correlated with the size of double-chain segment,[5c] and the nature of the head group segments has little effect on the parameters.[6b] The T_m and ΔH values for the cationic bilayer aggregates composed of $N^+(H)C_5Ala2C_n$ at pH 6 are 1.3°C and 17.6 kJ mol^{-1} for n=14 and 24.8°C and 27.6 kJ mol^{-1} for n=16, respectively. These values are comparable to those observed for other ionic bilayer aggregates having the same double-chain segments.[6b]

The phase transition parameters for the mixed lipid systems are listed in Table 1. It is clear that the T_m value is primarily dependent on the size and combination of the double-chain segments. The aggregate composed of two different lipids having the same double-chain segment shows a T_m value comparable to those for the aggregates of individual lipids, whereas the aggregate

Table 1. Phase Transition Parameters for Homogeneous Lipid Mixtures in Aqueous Dispersion

Mixed lipid system[a]	T_m/°C (ΔH/kJ mol^{-1})[b]			
	$m=n=14$	$m=14$, $n=16$	$m=16$, $n=14$	$m=n=16$
$N^+(H)C_5Ala2C_m/N^+C_5Ala2C_n$	2.0 (18.4)		16.1	25.3 (31.4)
$N^+C_5Ala2C_m/QC_5Ala2C_n$		13.9	14.2 (26.8)	
$QC_5Ala2C_m/(SO_3^-)C_5Ala2C_n$	2.3 (12.6)	15.3 (17.6)	14.3 (20.1)	
$N^+C_5Ala2C_m/(SO_3^-)C_5Ala2C_n$	4.9 (13.0)		15.5 (25.5)	27.0 (25.9)
$N^+(H)C_5Ala2C_m/(SO_3^-)C_5Ala2C_n$	4.3 (13.4)	14.2 (18.0)		27.0 (27.2)

a) Concentration of each lipid, 2.5 mmol dm^{-3}. b) ΔH values are given in parentheses. Each system without ΔH showed a broad peak which makes it difficult to evaluate the accurate value.

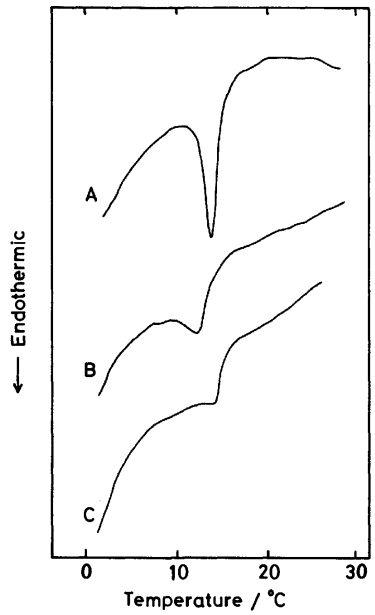

Fig. 5. DSC thermograms for equimolar mixtures (2.5 mmol dm^{-3} each) of two peptide lipids with the following combinations in the dispersion state: A, $N^+C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{14}$; B, $N^+(H)$-C_5Ala2C_{16} and $N^+C_5Ala2C_{14}$; C, $N^+C_5Ala2C_{14}$ and QC_5Ala2C_{16}.

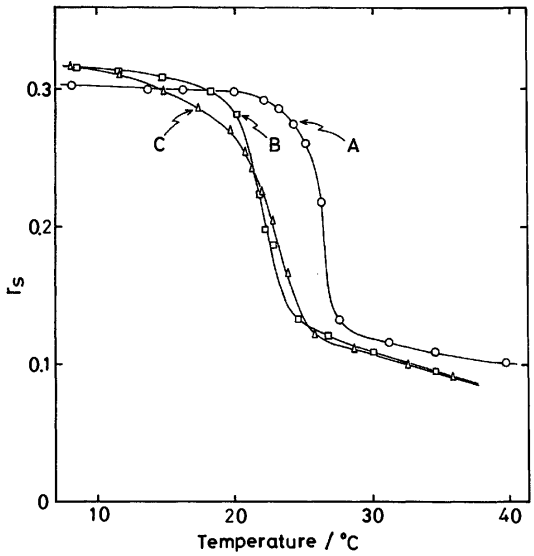

Fig. 6. Correlations of steady-state fluorescence anisotropy r_s with temperature for DPH (1.0×10^{-7} mol dm^{-3}) embedded in the following aggregates at pH 6.0: A, an equimolar mixture (2.5 mmol dm^{-3} each) of $N^+(H)C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{16}$; B, 5 mmol dm^{-3} $N^+(H)C_5Ala2C_{16}$; C, 5 mmol dm^{-3} $(SO_3^-)C_5Ala2C_{16}$.

formed with an equimolar mixture of two kinds of lipids having different double-chain segments provides a phase transition peak in an intermediate region between intrinsic peaks of the individual aggregates. The ΔH values for the mixed lipid systems, which involve single species of the double-chain segments, are nearly identical with those for the corresponding bilayer aggregates of individual lipids.

The electrostatic interaction mode effective in the polar aggregate domain is reflected on the DSC thermographic pattern when the aggregate is composed of two kinds of peptide lipids having different double-chain segments. As shown in Fig. 5, the 1:1 cationic-anionic lipid system exhibits a sharp phase transition peak as compared with those for other mixed lipid systems. This undoubtedly indicates that highly homogeneous mixing of the cationic and anionic lipids is attained and consequently the surface charge is effectively neutralized without phase separation through formation of tight ion-pairs.

Fluorescence Polarization Spectroscopy. The steady-state fluorescence anisotropy (r_s) of 1,6-diphenyl-1,3,5-hexatriene (DPH) embedded in various aggregates is shown in Fig. 6 for selected cases as a function of temperature. The T_m value for an equimolar mixture of $N^+(H)C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{16}$ was obtained from the inflection range (27 °C) and is in good agreement with that evaluated by DSC. The extent of variation of r_s for the mixed lipid system is comparable to those for the individual lipid systems over a whole temperature range studied.

Turbidity Measurements. The nonlamellar aggregates formed with both cationic and anionic lipids together provide largely developed domains (2000—20000 Å)[7] as reflected on the extent of turbidity which is appreciably larger than those observed for individual bilayer membranes in the dispersion state. Correlations of turbidity with temperature for aqueous dispersions of some mixed lipid systems are shown in Fig. 7. The bilayer aggregates, composed of $N^+C_5Ala2C_{16}$-$N^+(H)C_5Ala2C_{16}$ and (SO_3^-)-C_5Ala2C_{16}-QC_5Ala2C_{16}, do not undergo any turbidi-

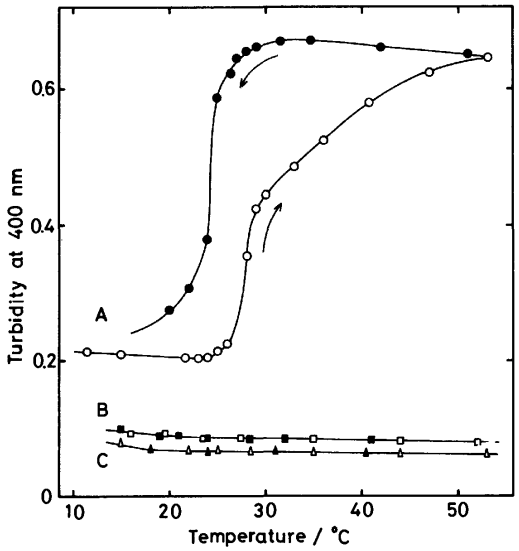

Fig. 7. Correlations of turbidity with temperature for equimolar mixtures (2.5 mmol dm^{-3} each) of two peptide lipids with the following combinations in the dispersion state: A, $N^+(H)C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{16}$; B, $N^+(H)C_5Ala2C_{16}$ and $N^+C_5Ala2C_{16}$; C, QC_5Ala2C_{16} and $(SO_3^-)C_5Ala2C_{16}$. The values observed in heating and cooling processes are indicated with open and closed circles, respectively, and the measurements were carried out after incubation for 30 min at respective temperatures.

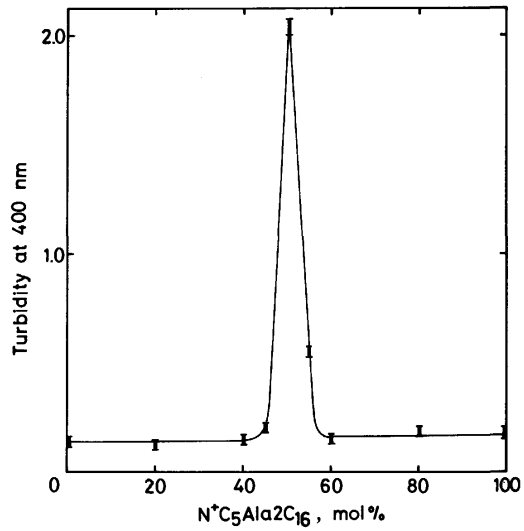

Fig. 8. Correlation of lipid composition with turbidity in the dispersion state for the homogeneously mixed system of $N^+C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{16}$ at 30°C; total lipid concentration, 5.0 mmol dm^{-3}.

ty change over the whole temperature range regardless of the phase transition. On the other hand, turbidity of the $N^+(H)C_5Ala2C_{16}$–$(SO_3^-)C_5Ala2C_{16}$ system is subjected to change in a sigmoidal manner with a hysteresis effect as shown in Fig. 7. The inflection range for turbidity change apparently corresponds to the phase transition temperature, and the turbidity observed below T_m is comparable to that for the bilayer aggregates. A similar correlation of turbidity with temperature was observed for the aqueous dispersion of $N^+C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{16}$, mixed at the equimolar ratio.

As for the mixed lipid system composed of $N^+C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{16}$, its turbidity at 30°C (above T_m) is much sensitive to the lipid composition; the normal bilayer aggregates were spontaneously formed when the composition loses the fractional balance, retained at the equimolar ratio of both lipids, to any slight extent (Fig. 8). The extent of turbidity of the same mixed lipid system was independent of the lipid composition below T_m and comparable to that observed for the bilayer aggregates. The identical correlation of turbidity with lipid composition was also observed for the $N^+C_5Ala2C_{14}$–$(SO_3^-)C_5Ala2C_{14}$ system at 21°C (above T_m).

X-Ray Diffraction Measurements. The low-angle X-ray diffraction technique was applied to the mixed lipid system composed of $N^+C_5Ala2C_{14}$ and $(SO_3^-)C_5Ala2C_{14}$ at room temperature (15±5°C). An equimolar mixture of the lipids in water (the weight fraction of the total lipid quantity, 0.40) showed four diffractions consistent with spacings of 88, 75, 53, and 43 Å (Fig. 9A). This spacing ratio ($1:\sqrt{3}/2:\sqrt{3}/\sqrt{8}:1/2$) rules out the occurrence of lamellar and hexagonal phases since these requires the ratios of 1:1/2:1/3:1/4 and $1:1/\sqrt{3}:1/\sqrt{4}:1/\sqrt{7}$, respectively.[9] The present spacing ratio is in conformity with diffractions from (111), (200), (220), and (222) planes of the face-centered cubic (fcc) lattice having a lattice constant (a), 152 Å. The (111) plane of the fcc lattice is the closest packed one, and the distance between the nearest neighbors in the plane ($a/\sqrt{2}$, 108 Å) is referred to the repeating distance of elements (internal aqueous compartments; see Fig. 10) and in good agreement with the values evaluated by electron microscopy.[7] When the weight fraction of the total lipid quantity in water was reduced to 0.20, the $a/\sqrt{2}$ value was slightly increased to give 111 Å. Meanwhile, a mixture of $N^+C_5Ala2C_{14}$ and $(SO_3^-)C_5Ala2C_{14}$ at a molar ratio of 45:55 in water (the weight fraction of the total lipid quantity, 0.17) afforded a single diffraction with spacing of 52 Å (Fig. 9B), which corresponds to the bilayer thickness evaluated from the CPK molecular models.

Discussion

In the course of our studies on model membranes composed of synthetic peptide lipids,[5,6] we have emphasized that the hydrogen-belt domain[10] constructed with amino acid residues in the intramembrane phase contributes much to the morphological stability of such aggregates. The tight intramembrane hydrogen-bonding interaction, which leads to the formation of the hydrogen-belt domain, was confirmed by various spectroscopic measurements.[6b,11] The cationic peptide lipids such as $N^+C_5Ala2C_n$ (n=12—18)

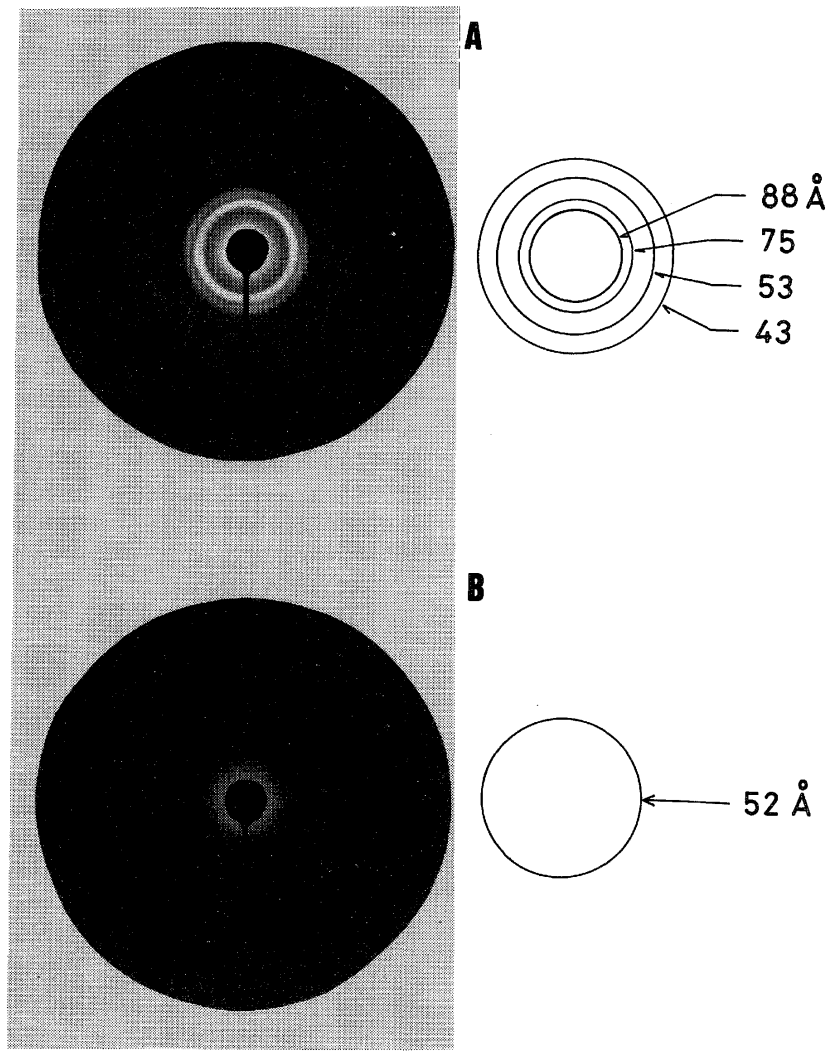

Fig. 9. X-Ray diffraction patterns for the following samples dispersed in water: A, an equimolar mixture of $N^+C_5Ala2C_{14}$ and $(SO_3^-)C_5Ala2C_{14}$ (weight fraction of the total lipid species, 0.40); B, a mixture of $N^+C_5Ala2C_{14}$ and $(SO_3^-)C_5Ala2C_{14}$ at the 45:55 molar ratio (weight fraction of the total lipid species, 0.17).

form multiwalled bilayer aggregates in the aqueous dispersion state, which are then transformed into single-walled vesicles upon sonication.[5c] Such single-walled vesicles are morphologically stable enough to inhibit fusion or aggregation under ordinary conditions.[5c] Regardless of the nature of amino acid residues and ionic head moieties placed in synthetic peptide lipids, the phase transition parameters for these aggregates in the aqueous dispersion state are primarily dependent on the length of the hydrophobic double-chain segment.[6b] On the other hand, nonionic peptide lipids having the quinoyl residue as a polar head moiety, QC_5Ala2C_n, form nonlamellar assemblies with the highly ordered and three-dimensional network arrangement of small aqueous compartments.[6a] Since the phase transition enthalpy (ΔH) and the fluorescence polarization parameter (r_s) obtained with DPH in the gel state for these aggregates are smaller than those for bilayer aggregates having the same double-

chain segments,[6b] the nonlamellar phase seems to be stable regardless of the phase transition.

As for the mixed peptide lipid systems, the bilayer phase is predominantly present under conditions that the total surface charge of the aggregate is not completely neutralized. On the other hand, the nonlamellar phase, schematically shown in Fig. 10, appears in the aqueous dispersions of cationic and anionic lipids mixed at the 1:1 molar ratio above T_m (Figs. 2 and 3). Under the latter conditions, the aggregates retain the high microscopic homogeneity of cationic and anionic lipid molecules (Fig. 5). The achievement of such microscopic homogeneity must be originated from the intramembrane electrostatic interaction between cationic and anionic head moieties to form highly developed ion-pair clusters on the membrane surface. Furthermore, the nonlamellar phase appeared above T_m in the mixed system of cationic and anionic lipids was spontaneously transformed into the normal bilayer phase below T_m as confirmed by the negative staining electron microscopy (Fig. 4). Since the nonlamellar domain is much more extensively developed than the bilayer one, the morphological transition between them was also reflected on turbidity change, accompanied with a hysteresis loop as shown in Fig. 7. In the light of the above observations, the gel to liquid-crystalline transition, which takes place in the hydrophobic domain, is thermodynamically required for transformation of the bilayer phase into the nonbilayer one. The liquid-crystalline bilayer phase, which would appear between the bilayer gel phase and the nonbilayer phase,[1a] was not detected by DSC, fluorescence polarization, and turbidity measurements under ordinary conditions.

It has been proposed that the aggregate morphology, which is favored thermodynamically in aqueous media, is theoretically rationalized in view of the dynamic packing mode of lipid molecules by introducing the critical packing parameter, $v/(a_0 l_c)$; where v, a_0, and l_c are the hydrocarbon volume, optimal surface area, and critical chain length of a lipid molecule, respectively.[12] According to this concept, the nonlamellar structure requires $v/(a_0 l_c)>1$, whereas the bilayer structure is favored under the conditions $1/2<v/(a_0 l_c)<1$. As we have previously discussed, the a_0 value is the primary factor which acts to develop the aggregate morphology observed for QC_5Ala2C_n.[6b] On the other hand, the 1:1 cationic-anionic lipid system develops the bilayer phase in the gel state. Therefore, the average a_0 value seems to be larger than that for QC_5Ala2C_n. However, the critical packing parameter must become larger than 1 in the temperature range above T_m by increasing the v value. This effect is plausibly brought about by defrosting the rotational motion of the hydrophobic double-chain segment.

The formation of *lipidic particles* or *lipidic intramembranous particles* has been detected in various aqueous lipid mixtures and in total lipid extracts under physiological conditions by means of electron microscopy.[2] Globular aggregates are arranged in three-dimensional quasi-crystalline manners and associated to afford various lipidic particles, showing large variation in shape, size, and packing behavior, as observed for the following mixed lipid systems: cardiolipin and egg phosphatidylcholine in the presence of calcium ions,[3a] monogalactosyldiacylglycerol and digalactosyldiacylglycerol,[3f] cardiolipin and chlorpromazine,[13] dioleoylphosphatidic acid and chlorpromazine,[13] and dilinoleoylphosphatidylethanolamine and egg phosphatidylcholine.[14] The lipidic particle phase has been suggested to consist of spherical aggregates of inverted micelles arranged in a closely packed organization[13] or to involve inverted micelles sandwiched in between lipid bilayers.[3f] These two concepts on morphological behavior have been subjected to some debate.[14,15] An aggregation mode for the system composed of dilinoleoylphosphatidylethanolamine and egg phosphatidylcholine at the 85:15 molar ratio in the quasi-crystalline state, in fact, was consistent with an isotropic cubic phase[14] in a manner as observed for systems composed of ordinary detergents such as potassium carboxylates and quaternary ammonium halides bearing a long alkyl chain[16] and of monoglycerides such as 1-monoolein and 1-monostearin,[17] all being based on the X-ray diffraction method. Such lipidic particles have been often observed in an intermediate step during the phase transition between lamellar and inverted hexagonal (H_{II}) phases.[14,18] The globular aggregates formed with an equimolar mixture of cationic and anionic lipids in the present study apparently constitute a highly developed quasi-crystalline phase with the face-centered cubic lattice. However, this phase remains stable in the aqueous dispersion state without being transformed into the H_{II} phase under the present conditions. The previous studies with mixed lipid systems, which allow the formation of lipidic particles, claimed that one of the mixed lipid species at least needs to prefer to constitute the H_{II} phase for each mixed system when it is dispersed in water alone.[2] However, this concept must be revised since lipidic particles are also formed with two kinds of lipids which constitute individually normal bilayer aggregates in the aqueous dispersion state. Thus, the formation of globular aggregates is primarily controlled by the critical packing parameter, which is subjected to change by the intramembrane interaction mode among the polar head moieties and/or the rotational freedom of the hydrophobic double-chain segment of lipid species. However, the molecular basis for the formation of various three-dimensional quasi-crystalline phases, such as inverted hexagonal and inverted cubic, needs to be clarified by employing appropriate synthetic lipids. Since it has been suggested that lipidic particles assume important roles in membrane fusion and trans-membrane transport,[2]

the present nonbilayer systems may provide useful means for clarifying those mechanisms.

We are grateful to professor Tisato Kajiyama of Kyushu University for the X-ray diffraction measurements. The present work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture (No. 58430016).

Stereoselective Preparation of Acyclic *syn*-β-Amino Alcohols from β-Hydroxy Ketones via the Corresponding *O*-Benzyl Oximes

Koichi NARASAKA,* Yutaka UKAJI, and Shigeru YAMAZAKI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received October 2, 1985)

Reduction of β-hydroxy ketone *O*-benzyl oximes with lithium aluminum hydride in the presence of sodium or potassium methoxide afforded the corresponding *syn*-β-amino alcohols in highly stereoselective manner. A lythraceae alkaloid, lasubine II, was synthesized stereoselectively by applying this method.

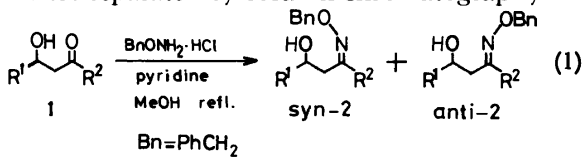
Over the years there have been a large number of efforts directed to control chiral induction in acyclic precursors, and various studies which demonstrate the synthetically useful level of stereocontrol have been published for diastereoselection between adjacent carbon atoms (1,2-relationships).[1] Only a limited number of method, however, have been published to regulate 1,3-chiral induction in acyclic systems,[1b,2,3] leaving this area still in a relatively primitive state of development.

Concerning 1,3-chiral induction of acyclic systems, we have studied and briefly reported the stereoselective preparation of β-amino alcohols from β-hydroxy ketones.[4] In this paper, the results of the stereoselective preparation of *syn*-β-amino alcohols via β-hydroxy ketone *O*-benzyl oximes are reported in detail with the revised mechanism.

Previously one of the authors found that β-hydroxy ketones are stereoselectively reduced with sodium borohydride via boron chelates giving *syn*-1,3-diols.[5] Then we turned our interest to the stereoselective preparation of β-amino alcohols from β-hydroxy imines, hydrazones, or oximes, by stereoselective reduction directed by the hydroxyl group.

Among β-hydroxy imines, hydrazones, and oximes, we chose to use β-hydroxy ketone *O*-benzyl oximes. *O*-Benzyl oximes **2** are readily prepared almost quantitatively from β-hydroxy ketones **1**. They are very stable and easily handled as compared with the corresponding imines. Also it was found that the reactivity of *O*-benzyl oximes toward the reduction with lithium aluminum hydride (LAH) exceeded that of the corresponding dimethylhydrazones.

Various β-hydroxy ketones **1** were prepared by aldol reactions between aldehydes and methyl ketones, and converted to the corresponding *O*-benzyl oximes by the treatment with *O*-benzylhydroxylamine hydrochloride and pyridine in refluxing methanol.[6] The resulting *O*-benzyl oximes **2** were equilibrium mixtures of *syn*- and *anti*-isomers *syn*-**2** and *anti*-**2**,[7] which were separated by column chromatography.



(1)

Then the stereoselectivity of the reduction with LAH was examined based on the following hypothesis. The reaction of **2** with LAH would generate the aluminum alcoholate **3**, and the intramolecular reduction would proceed through cyclic transition states T_1 or T_2 (Fig. 1). The steric interaction between R^1 and R^2 would destabilize the transition state T_2, hence the reduction might be expected to proceed through the transition state T_1 to result in the formation of a *syn*-β-amino alcohol **4**.[8]

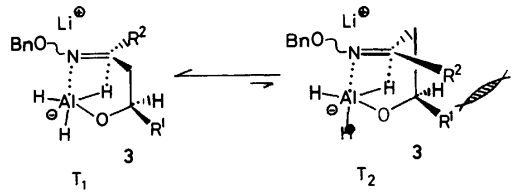


Fig. 1.

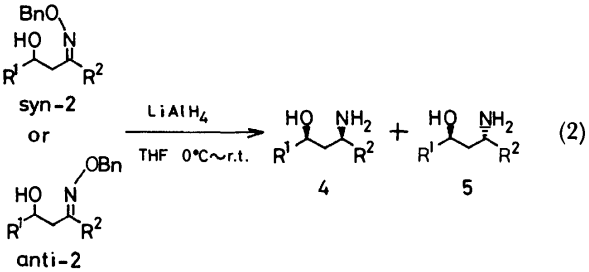
Each isomer *syn*-**2** or *anti*-**2** was reduced with an excess amount of LAH in THF between 0 °C and room temperature, and the results are listed in Table 1. From *syn*-*O*-benzyl oximes *syn*-**2**, *syn*-amino alcohols **4** were obtained in high stereoselectivity. In comparison with the high stereoselectivity in the reduction of *syn*-*O*-benzyl oximes *syn*-**2**, the reduction of *anti*-*O*-benzyl oximes *anti*-**2** proceeded only in moderate selectivity. When the reduction of *anti*-*O*-benzyl oxime *anti*-**2a** was tried at lower temperature (ca. −10 °C), the selectivity toward the *syn*-amino alcohol **4a** was found to increase to 89% from 77% but was still not sufficiently high. At the temperature below −10 °C, unfortunately the reduction hardly proceeded.



(2)

During this study, it was found that when sodium methoxide was added to the reaction mixture a significant effect on the stereoselectivity and the acceleration of the LAH reduction was observed. As

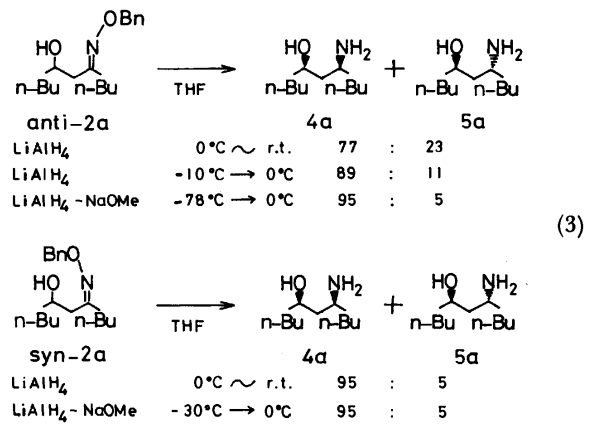
a) Isomeric ratio was determined by GLC (OV-101). b) Isomeric ratio was determined by the isolation of *syn*- and *anti*-amino alcohols. c) Isomeric ratio was determined by the conversion to the corresponding acetates.

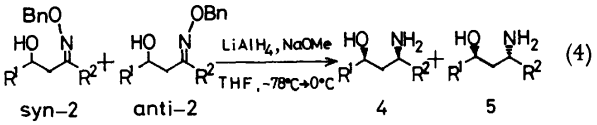
mentioned before, the reduction of *anti*-**2a** with LAH occurred at ca. −10°C and did not proceed at −78°C. On the other hand, in the presence of sodium methoxide the LAH reduction of the C=N bond in *anti*-**2a** occurred even at −78°C. After the reduction of C=N bond in *anti*-**2a** was completed, the reaction temperature was gradually raised to 0°C to completely convert the resulting half reduced intermediate, *O*-benzylhydroxylamine derivative, to β-amino alcohol and benzyl alcohol. Furthermore, it is important to note that *syn*-amino alcohol **4a** was obtained in excellent stereoselectivity (**4a**:**5a**=95:5) by this procedure (Eq. 3).

The reaction of *syn*-**2a** with LAH was also examined in the presence of sodium methoxide. Although *syn*-*O*-benzyl oxime *syn*-**2a** was scarcely reduced below 0°C by the treatment with LAH, the presence of sodium methoxide was so effective that the reduction of C=N bond proceeded at −30°C. And the *syn*-amino alcohol **4a** was also obtained in excellent selectivity (**4a**:**5a**=95:5).



(3)

These results prompted us to examine the prepatation of β-amino alcohol from a mixture of *syn*- and *anti*-*O*-benzyl oxime **2a** by the reduction with LAH-sodium methoxide. A mixture of *syn*- and *anti*-**2a** was treated with 15 molar amounts of LAH in the presence of 10 molar amounts of sodium methoxide at −78°C. After the consumption of *anti*-**2a** was evidenced by TLC, the reaction temperature was gradually raised to 0°C and stirred overnight. In excellent stereoselectivity (96%), *syn*-amino alcohol **4a** was obtained. When the reduction was performed employing 7.5 molar amounts of LAH and 5 molar amounts of sodium methoxide, the selectivity was slightly decreased (*syn*-**2a**:*anti*-**2a**=94:6). Further, the reduction did not proceed at −78°C with 5 molar amount of LAH and 2.5 molar amounts of sodium methoxide. Hence, the reduction of various *O*-benzyl oximes **2** were investigated using 15 molar amounts of LAH and 10 molar amounts of sodium methoxide, and the results are summarized in Table 2. Generally, the selectivity toward *syn*-amino alcohols **4** is quite excellent. Only in the cases that subsituent (R) is (or are) phenyl group(s), the selectivity is decreased but still high.



(4)

The stereochemistry of the products were confirmed by ^{13}C NMR spectra and the conversion of amino alcohols **4** and **5** to cyclic urethanes **8** and **9**. According to the empirical rule of ^{13}C NMR spectra of a β-amino alcohol, the chemical shift of the methine carbon adjacent to the hydroxyl group is observed at the lower field in the case of a *syn*-amino alcohol **4** as compared with an *anti*-isomer **5**.[9]

Furthermore, the relative reactivity in the cyclization of urethanes of each isomers **6** and **7** indicated the stereochemistry. Treatment of amino alcohols **4** and **5** with methyl chloroformate and triethylamine gave the corresponding urethanes **6** and **7**, respectively. The *syn*-urethanes **6** were easily converted to the cyclic urethanes **8** at room temperature by treatment with sodium hydride in benzene. On the other hand, the cyclization of *anti*-urethanes **7** did not occurred at room temperature but at the temperature of refluxing benzene. The inferior reactivity of the *anti*-isomers **7** is due to the disfavored transition state of the cyclization in which the R^2 group should orient to the pseudo-axial direction (Fig. 2). The relative stereochemistry of **4e** and **5e** determined by this way was agreed with the stereochemical assignment determined by ^{13}C NMR spectra.[9]

Instead of sodium methoxide, potassium methoxide was also found to be effective for the stereocontrol of

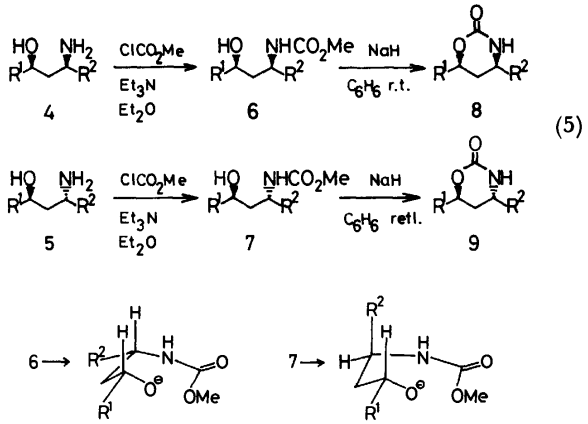
a) Potassium methoxide was used. b) Lithium methoxide was used.

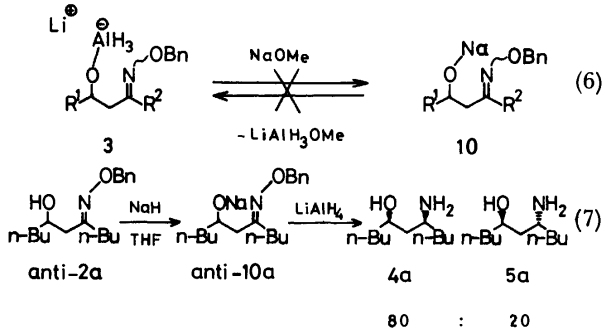


(5)

Fig. 2.

the LAH reduction. However, the slightly inferior selectivity was observed when lithium methoxide was employed (Table 2).

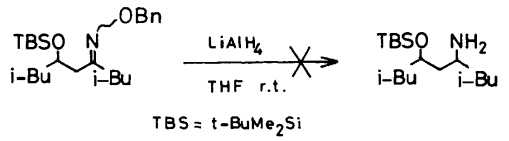
In the previous report,[4b] we supposed that the enhanced selectivity and reactivity by the addition of methoxide may be due to the formation of a sodium alcoholate **10** by an equilibrium between the aluminum alcoholate **3**. In order to ascertain this assumption, the sodium alcoholate *anti*-**10a** generated in situ by treatment of the *anti*-*O*-benzyl oxime *anti*-**2a** with sodium hydride in THF was reduced with LAH. But the reduction did not proceed at −78 °C but −20 to 0 °C, and the products ratio of *syn*- and *anti*-amino alcohols (**4a**:**5a**=80:20) was not so excellent as compared with the result in Table 2. Consequently, it was indicated that the sodium alcoholate **10** is not the actual intermediate in the reduction of *anti*-*O*-benzyl oxime *anti*-**2** in the presence of sodium methoxide.



(6)

(7)

Next, the confirmation of the intramolecular reduction via the intermediate aluminum alcoholate **3** was examined by the reduction of *syn*- and *anti*-*O*-benzyl oximes after the protection of the hydroxyl groups as silyl ethers. The *t*-butyldimethylsilyl ethers of *syn*-**2b** and *anti*-**2b** were treated with LAH, but the reduction did not occur even at room temperature.



(8)

These observations may indicate that the formation of the intermediate aluminum alcoholate **3** is indispensable for the reduction of the C=N bond and the reduction may proceed by the intramolecular fashion as shown in Fig. 1. Coordination of methoxide to the aluminum of this intermediate **3**[10] may increase the nucleophilicity of the hydride, and the reduction proceeds at the lower temperature resulting *syn*-β-amino alcohol **4** in excellent stereoselectivity.

As mentioned, it was noted that the reduction of *O*-benzyl oximes with LAH in the presence of sodium or potassium methoxide provides a highly stereoselective method for the preparation of *syn*-β-amino alcohols starting from β-hydroxy ketones. The present method has a wide applicability to prepare various *syn*-β-amino alcohols because β-hydroxy ketones are readily prepared by directed aldol reactions.[11]

In these years, much efforts have been concentrated in the stereoselective preparation of β-amino alcohols, and several selective methods have been developed by the reduction of isoxazolines[9,12] and enaminones[3a] the iodocyclocarbamation of a homoallylamine,[3b] the intramolecular Michael addition of *O*-carbamates,[3c] the sulfoxide-mediated intramolecular hydroxylation of a remote olefin,[13] and the Grignard reaction of β-alkoxy imines.[3d] The present method affords the alternative procedure for the preparation of unprotected *syn*-β-amino alcohols.

As an efficient and practical method for the preparation of acyclic *syn*-β-amino alcohols was established, a new synthetic route to a lythraceae alkaloid, lasubine

II,[14] was investigated by applying this method.[15] Lythraceae alkaloids have been generally synthesized by the condensation of isopelletierine with aromatic aldehydes[16] or the [2+3] cycloaddition of tetrahydropyridine *N*-oxide.[17] In our synthetic strategy an acyclic key intermediate, a *syn*-β-amino alcohol **16**, was prepared firstly, and the successive cyclization processes afforded a bicyclic lasubine II (**22**) in a stereoselective manner.

Veratraldehyde was converted to a 1,3-dithiane **11**,[18] which was alkylated with 2-bromo-1,1-dimethoxyethane and the product **12** was hydrolyzed with concd hydrochloric acid to an aldehyde **13**. The aldol reaction between the aldehyde **13** and the kinetic lithium enolate of 5-hexen-2-one afforded a β-hydroxy ketone **14** in 80% yield. At this stage, the whole carbon skeleton required for the synthesis of lasubine II was arranged.

The aldol product **14** was converted to a *O*-benzyl oxime **15** as a mixture of almost equal amount of *syn*- and *anti*-isomers. The *O*-benzyl oxime **15** was reduced with LAH in the presence of potassium methoxide. During this reaction, the reaction temperature should be carefully controlled. After the reduction mixture was stirred at −78 °C overnight, the temperature was gradually raised to −15 °C during 5 h and the mixture was stirred for 12 h at −15 °C. When the reaction temperature was raised above −15 °C, the cleavage of dithioacetal group was observed. After the hydrolysis, the *syn*-β-amino alcohol **16** was isolated in 65% yield.[19]

For the construction of a octahydroquinolizine skeleton, the hydrolysis of dithioacetal group of **16** was investigated but did not afford the fruitful result. Therefore, the amino group of **16** was protected as a *t*-butylcarbamate **17** and then the dithioacetal group was hydrolyzed with *N*-chlorosuccinimide and silver nitrate in aqueous acetonitrile to give a hydroxy ketone **18** in 73% yield. The deprotection of the amino group with trifluoroacetic acid in dichloromethane spontaneously yielded a labile cyclic imine **19**, which was submitted to the successive reduction without isolation. Treatment of **19** with LAH in the presence of sodium methoxide in THF afforded the *cis*-2,6-disubtituted piperidine **20** stereoselectively.[20–22]

Hydroboration of **20** with bis(1,2-dimethylpropyl)-borane and the successive oxidation with alkaline hydrogen peroxide afforded a diol **21**. The regioselective tosylation of the primary hydroxyl group in **21** was carried out employing *p*-toluenesulfonyl chloride and pyridine at −20 °C to give (±)-lasubine II (**22**).

Thus the stereoselective synthesis of lasubine II has been achieved via an acyclic intermediate, demonstrating a new and useful strategy for the preparation of lythraceae alkaloids.

Experimental

All the melting points are uncorrected. The IR spectra were determined on a Hitachi Model 260-30 spectrometer. The ^1H NMR spectra were recorded with a Hitachi R-24B, a Varian EM-390, and a JEOL GX-400 spectrometers, and ^{13}C NMR spectra were measured with a JEOL FX-90Q spectrometer in $CDCl_3$ with tetramethylsilane as an internal standard. The MS spectra were taken on a JEOL JMS-D300. Benzene was distilled and dried over sodium wire. Tetrahydrofuran (THF) and diethyl ether were freshly distilled from sodium benzophenone ketyl. Pyridine and dichloromethane were distilled from CaH_2 and stored over Molecular Sieve. Purification of products was performed by column chromatography on silica gel (Wakogel C-200 or Merck, Art. 9385 Kieselgel 60, 230—400 mesh), preparative TLC on silica gel (Wakogel B-5F) or on aluminum oxide (Merck, Art. 1103 Aluminiumoxid 60 PF_{254}, Typ E), and Chromatotron on aluminum oxide (Merck, Art. 1092 Aluminiumoxid GF_{254}, Typ E).

β-Hydroxy ketones **1a—f** were prepared by the aldol reaction of kinetic lithium enolates of the corresponding methyl ketones with aldehydes, and purified by column chromatography on silica gel. Further details of the reaction procedure are described in the preparation of **14**.

Preparation of 7-Benzyloxyimino-5-undecanol (2a). A solution of 7-hydroxy-5-undecanone (604 mg, 3.2 mmol) and *O*-benzylhydroxylamine hydrochloride (574 mg, 6.6 mmol) in pyridine (0.5 mL) and methanol (8 mL) was refluxed for 30 min.[6] After the most of methanol was removed in vacuo, water was added to the residue and was extracted with CH_2Cl_2. The separated organic layer was dried over Na_2SO_4 and was

condensed under reduced pressure. Purification by column chromatography on silica gel (hexane:ethyl acetate=15:1, v/v) gave the *syn*-*O*-benzyl oxime *syn*-**2a** (473 mg, 50%) and the *anti*-oxime *anti*-**2a** (431 mg, 46%).[23]

Stereoselective Reduction of a Mixture of the *O*-Benzyl Oximes *syn*-2a and *anti*-2a. To a THF (135 mL) solution of LAH (30 mmol) and sodium methoxide (1.08 g, 20 mmol) was added a 52:48 mixture of *syn*-**2a** and *anti*-**2a** (total 583 mg, 2 mmol) in THF (6 mL) at −78 °C under an argon atmosphere, and stirred for 6 h at −78 °C. After the complete consumption of *anti*-**2a** was indicated by TLC analysis, the reaction mixture was gradually warmed to 0 °C during 6 h and stirred for 18 h at 0 °C. The mixture was quenched with sat. aqueous sodium sulfate (8.8 mL) and the resulting precipitate was filtered off. The condensed filtrate was purified by preparative TLC on aluminum oxide (CH_2Cl_2: methanol=20:1, v/v) to give *syn*-7-amino-5-undecanol (**4a**) and the *anti*-isomer **5a** (total 343 mg, 92%) in the ratio of 96:4, respectively.

***syn*-7-Amino-5-undecanol (4a)**: IR (neat) 3370, 3300 cm^{-1}. ^{1}H NMR δ=0.60—1.75 (20H, m), 2.38—3.03 (1H, m), 2.93 (3H, br s), 3.47—3.97 (1H, m). ^{13}C NMR δ=73.00 (>CHOH).

***anti*-7-Amino-5-undecanol (5a)**: IR (neat) 3370, 3300 cm^{-1}. ^{1}H NMR δ=0.62—1.73 (20H, m), 2.57—3.22 (1H, m), 2.80 (3H, br s), 3.52—4.03 (1H, m). ^{13}C NMR δ=69.13 (>CHOH).

The stereoselective reduction of **2b—f** was carried out by the same procedure, and the elemental analyses were performed after the conversion to the corresponding cyclic urethanes **8** and **9**.

***syn*-6-Amino-2,8-dimethyl-4-nonanol (4b)**: IR (neat) 3370, 3290 cm^{-1}. ^{1}H NMR δ=0.85 (12H, d, *J*=6.0 Hz), 0.92—2.02 (8H, m), 2.52—3.02 (1H, m), 3.10 (3H, br s), 3.50—3.98 (1H, m). ^{13}C NMR δ=70.78 (>CHOH).

The amino alcohol **4d** and **5d** could not be separated by TLC on aluminum oxide. The ratio was determined by the transformation to the corresponding acetates.

General Procedure for Acetylation of Amino Alcohols. To a CH_2Cl_2 (5 mL) solution of a mixture of *syn*- and *anti*-amino alcohols (ca. 100 mg) were added acetic anhydride (0.2 mL), pyridine (0.5 mL) and a catalytic amount of 4-(dimethylamino)pyridine under an argon atmosphere, and the resulting mixture was stirred at room temperature overnight. After evaporation of the excess acetic anhydride, pyridine and CH_2Cl_2 in vacuo, the residue was purified by preparative TLC on silica gel to afford the corresponding acetates.

***syn*-5-Acetamido-3-acetoxy-1-phenylhexane**: IR (neat) 3300, 1735, 1645 cm^{-1}. ^{1}H NMR δ=1.03 (3H, d, *J*=6.7 Hz), 1.42—2.12 (4H, m), 1.80 (3H, s), 1.92 (3H, s), 2.30—2.73 (2H, m), 3.50—4.27 (1H, m), 4.53—5.00 (1H, m), 5.80—6.27 (1H, m), 7.08 (5H, s).

***anti*-5-Acetamido-3-acetoxy-1-phenylhexane**: IR (neat) 3290, 1735, 1640 cm^{-1}. ^{1}H NMR δ=1.05 (3H, d, *J*=6.8 Hz), 1.45—2.22 (4H, m), 1.88 (3H, s), 1.94 (3H, s), 2.32—2.77 (2H, m), 3.63—4.17 (1H, m), 4.57—5.12 (1H, m), 5.17—5.65 (1H, m), 7.07 (5H, s).

***syn*-3-Amino-1-phenyl-1-butanol (4e) and the *anti*-Isomer 5e**: IR, ^{1}H NMR, and ^{13}C NMR spectra were identical with

those of lit.[9] IR (neat) 3360, 3280 cm^{-1}. ^{1}H NMR δ=1.13 (3H, d, J=7.2 Hz), 1.50—1.78 (2H, m), 2.67—3.53 (1H, m), 3.17 (3H, br s), 4.91 (1H, dd, J=6.0, 9.6 Hz). ^{13}C NMR δ=71.74 (>CHOH, *anti*), 74.96 (>CHOH, *syn*). The isomer ratio was determined by the conversion to the acetates.

***syn*-3-Acetamido-1-acetoxy-1-phenylbutane**: IR (neat) 3300, 1720, 1645 cm^{-1}. ^{1}H NMR δ=1.08 (3H, d, J=6.6 Hz), 1.58—2.25 (2H, m), 1.85 (3H, s), 2.00 (3H, s), 3.52—3.98 (1H, m), 5.40—5.98 (1H, m), 5.72 (1H, t, J=7.0 Hz), 7.30 (5H, s).

***anti*-3-Acetamido-1-acetoxy-1-phenylbutane**: IR (neat) 3300, 1715, 1640 cm^{-1}. ^{1}H NMR δ=1.08 (3H, d, J=6.8 Hz), 1.70—2.40 (2H, m), 1.82 (3H, s), 2.00 (3H, s), 3.67—4.48 (1H, m), 5.43—5.75 (1H, m), 5.68 (1H, dd, J=8.4, 9.0 Hz), 7.22 (5H, s).

***syn*-3-Amino-1,3-diphenyl-1-propanol (4f) and the *anti*-Isomer 5f**: IR, ^{1}H NMR and ^{13}C NMR spectra were well agreed with those of lit.[9] IR (KBr) 3360, 3280 cm^{-1}. ^{1}H NMR δ=1.65—2.15 (2H, m), 3.12 (3H, br s), 3.82—4.17 (1H, m), 4.62—5.00 (1H, m), 7.12 (5H, s), 7.16 (5H, s). ^{13}C NMR δ=71.78 (>CHOH, *anti*), 74.95 (>CHOH, *syn*). The ratio of *syn* to *anti* was also determined by the transformation to the acetates.

***syn*-3-Acetamido-1-acetoxy-1,3-diphenylpropane**: IR (neat) 3290, 1735, 1645 cm^{-1}. ^{1}H NMR δ=1.62—2.72 (2H, m), 1.80 (3H, s), 1.90 (3H, s), 4.63—5.15 (1H, m), 5.48 (1H, t, J=6.8 Hz), 6.13—6.67 (1H, m), 7.12 (5H, s), 7.17 (5H, s).

***anti*-3-Acetamido-1-acetoxy-1,3-diphenylpropane**: IR (neat) 3320, 1735, 1650 cm^{-1}. ^{1}H NMR δ=1.82 (3H, s), 1.90 (3H, s), 2.03—2.47 (2H, m), 4.73—4.92 (1H, m), 5.55—5.97 (1H, m), 5.62 (1H, dd, J=6.0, 8.4 Hz), 7.17 (10H, s).

Transformation of 4a to *cis*-Cyclic Urethane 8a. To an ether (6 mL) solution of *syn*-amino alcohol **4a** (113 mg, 0.69 mmol) and triethylamine (96 mg, 0.95 mmol) was added dropwise a solution of methyl chloroformate (68 mg, 0.72 mmol) in ether (3 mL) under an argon atmosphere and then stirred for 90 min at room temperature. To the mixture was added ice and the resulting solution was extracted with CH_2Cl_2. The separated organic layer was dried over Na_2SO_4 and condensed under reduced pressure. Purification by preparative TLC on silica gel (hexane: ethyl acetate=1:1, v/v) gave *syn*-7-methoxycarboxylamino-5-undecanol **6a** (113 mg, 76%). Next, a benzene (3 mL) solution of **6a** was added to a suspension of sodium hydride (55% dispersion in mineral oil) (23 mg, 0.52 mmol) in benzene (3 mL) under an argon atmosphere, and the mixture was stirred at room temperature for 3 h. Sat. aqueous NH_4Cl was added and the mixture was extracted with CH_2Cl_2. After being dried over Na_2SO_4, the CH_2Cl_2 solution was condensed in vacuo. The residue was purified by preparative TLC on silica gel (hexane: ethyl acetate=1:1, v/v) to give the cyclic urethane **8a** (90 mg, 70% from **4a**).

***cis*-4,6-Dibutyltetrahydro-2*H*-1,3-oxazin-2-one (8a)**: Mp 73.5—74.5 °C (H_2O-methanol). IR (KBr) 3250, 3130, 1680 cm^{-1}. ^{1}H NMR δ=0.57—2.12 (20H, m), 3.02—3.62 (1H, m), 3.85—4.03 (1H, m), 6.06—6.93 (1H, m). Found: C, 67.85; H, 10.87; N, 6.58%. Calcd for $C_{12}H_{23}NO_2$: C, 67.56; H, 10.87; N, 6.57%.

Transformation of 5a to *trans*-Cyclic Urethane 9a. *anti*-Urethane **7a** was obtained by the same procedure for **6a** (quant.). To a suspension of sodium hydride (55% dispersion in mineral oil) (4 mg, 0.08 mmol) in benzene (3 mL) was added a benzene (3 mL) solution of **6a** (18 mg, 0.07 mmol) under an argon atmosphere, and the mixture was refluxed for 30 min. After cooling to room temperature, sat. aqueous NH_4Cl was added and the solution was extracted with CH_2Cl_2. The extracts were dried over Na_2SO_4 and condensed in vacuo. Purification by preparative TLC on silica gel (hexane:ethyl acetate=1:1, v/v) afforded the cyclic urethane **9a** (12 mg, 72% from **5a**).

***trans*-4,6-Dibutyltetrahydro-2*H*-1,3-oxazin-2-one (9a)**: IR (neat) 3260, 3130, 1710 cm^{-1}. ^{1}H NMR δ=0.62—2.27 (20H, m), 3.08—3.60 (1H, m), 3.97—4.47 (1H, m), 5.83—6.17 (1H, m). Found: m/z 213.1689. Calcd for $C_{12}H_{23}NO_2$: M, 213.1727.

Transformation of other amino alcohols **4b—e**, **5b—e** to cyclic urethanes was carried by the same method described above. By the treatment with methyl chloroformate and triethylamine, a mixture of *syn*- and *anti*-β-amino alcohols **4d** and **5d**, **4e**, and **5e** were converted *syn*- and *anti*-urethane **6d** and **7d**, **6e** and **7e**, respectively, which were separated by preparative TLC.

***cis*-4,6-Bis(2-methylpropyl)tetrahydro-2*H*-1,3-oxazin-2-one (8b)**: Mp 94.5—95.0 °C. Total Synthesis of Lasubine II. **2-(2,2-Dimethoxy-**

ethyl)-2-(3,4-dimethoxyphenyl)-1,3-dithiane (12). To a solution of 2-(3,4-dimethoxyphenyl)-1,3-dithiane (**11**)[18] (2.00 g, 7.80 mmol) in THF (40 mL) was added *n*-BuLi (7.15 mmol) in hexane (6.3 mL) at −42 °C under an argon atmosphere was stirred for 2.5 h at −15 °C.[23] At −78 °C a THF (6 mL) solution of 2-bromo-1,1-dimethyoxyethane (1.17 g, 6.50 mmol) was added, and then gradually warmed to 0 °C. After stirred for 24 h at 0 °C, the reaction mixture was quenched with sat. aqueous NH_4Cl and the organic layer was extracted with ether. The separated organic layer was dried over Na_2SO_4 and was condensed under reduced pressure. Purification by column chromatography (hexane:ethyl acetate=5:1, v/v) gave the dimethyl acetal **12** (1.88 g, 84%). ^1H NMR δ=1.69—2.09 (2H, m), 2.12—2.40 (2H, m), 2.50—2.80 (4H, m), 3.13 (6H, s), 3.77 (6H, s), 4.08—4.39 (1H, m), 6.50—6.92 (1H, m), 7.08—7.50 (2H, m).

2-Formylmethyl-2-(3,4-dimethoxyphenyl)-1,3-dithiane (13). To a THF (80 mL) solution of **12** was slowly added concd HCl (20 mL). In a few minutes, the solution was turned to yellow and hydrolysis was completed. The reaction mixture was extracted with ether and the organic layer was washed with 4% aqueous $NaHCO_3$ and brine, dried over Na_2SO_4, and concentrated in vacuo to leave an oily residue. The residue was chromatographed on silica gel with hexane–ethyl acetate (8:1, v/v) as an eluting solvent to yield the aldehyde **13** (1.39 g, 76%). IR (neat) 1720 cm^{-1}. ^1H NMR δ=1.65—2.04 (2H, m), 2.54—2.83 (4H, m), 2.89 (2H, d, *J*=3.6 Hz), 3.76 (6H, s), 6.58—6.80 (1H, m), 7.09—7.40 (2H, m), 9.52 (1H, d, *J*=3.6 Hz). Found: *m/z* 298.0678. Calcd for $C_{14}H_{18}O_3S_2$: M, 298.0695.

2-(2-Hydroxy-4-oxo-7-octenyl)-2-(3,4-dimethoxyphenyl)-1,3-dithiane (14). To a solution of lithium diisopropylamide (5.7 mmol) in THF (50 mL) was added a solution of 5-hexen-2-one (0.50 g, 5.2 mmol) in THF (5 mL) at −78 °C under an argon atmosphere, and the mixture was stirred for 1 min at −78 °C. A THF (5 mL) solution of the aldehyde **13** (1.39 g, 4.5 mmol) was added. Immediately, the reaction mixture was quenched with sat. aqueous NH_4Cl and was extracted with ether. The combined ether extracts were washed with brine, dried over Na_2SO_4, and condensed under reduced pressure. Purification by column chromatography (hexane : ethyl acetate=3:1—1:1, v/v) gave the β-hydroxy ketone **14** (1.45 g, 80%). IR (neat) 3530, 1710, 1640 cm^{-1}. ^1H NMR δ=1.48—2.83 (15H, m), 3.77 (6H, s), 3.90—4.37 (1H, m), 4.58—5.05 (2H, m), 5.23—5.94 (1H, m), 6.56—6.83 (1H, m), 7.10—7.44 (2H, m). Found: *m/z* 396.1375. Calcd for $C_{20}H_{28}O_4S_2$: M, 396.1427.

***O*-Benzyl Oxime of β-Hydroxy Ketone 14.** A solution of β-hydroxy ketone **14** (1.31 g, 3.3 mmol) and *O*-benzylhydroxylamine hydrochloride (0.63 g, 3.9 mmol) in pyridine (0.6 mL) and methanol (45 mL) was refluxed for 5 h. After removal of the solvents in vacuo, water was added to the residue and was extracted with CH_2Cl_2. The separated organic layer was dried over Na_2SO_4 and was condensed under reduced pressure. Purification by column chromatography on silica gel (hexane: ethyl acetate=2:1, v/v) gave the ca. 1:1 mixture of *syn*- and *anti*-*O*-benzyl oxime **15** (1.66 g, quant.). IR (neat) 3530, 1640 cm^{-1}. ^1H NMR δ=1.57—2.80 (15H, m), 3.70 (6H, s), 3.85—4.25 (1H, m), 4.42—5.00 (2H, m), 4.86 (2H, s), 5.15—5.92 (1H, m), 6.50—6.78 (1H, m), 7.07 (5H, s), 7.10—7.37 (2H, m). Found: *m/z* 501.1961. Calcd for $C_{27}H_{35}NO_4S_2$: M, 501.2006.

***syn*-β-Amino Alcohol 16.** To a suspension of potassium methoxide (5.21 g, 74 mmol) in THF (400 mL) was added a THF (82 mL) solution of LAH (111 mmol) under an argon atmosphere and the mixture was stirred for 15 min at −78 °C. To that solution was added the *O*-benzyl oxime **15** (3.71 g, 7.4 mmol) in THF (100 mL) dropwise and the reaction mixture stirred overnight at −78 °C, then gradually warmed to −15 °C for 5 h, and stirred for 12 h at −15 °C. The reaction was carefully quenched with sat. aqueous Na_2SO_4 (32 mL) and the resulting precipitate was filtered off. The condensed filtrate was purified by Chromatron on aluminum oxide (CH_2Cl_2: methanol=25:1, v/v) to give *syn*-β-amino alcohol **16** (2.94 g, 65%). IR (neat) 3380, 3300, 1640 cm^{-1}. ^1H NMR δ=0.77—1.42 (4H, m), 1.48—2.25 (6H, m), 2.38—2.90 (5H, m), 2.72 (3H, br s), 3.58—4.09 (1H, m), 3.75 (6H, s), 4.57—5.07 (2H, m), 5.29—6.00 (1H, m), 6.60—6.83 (1H, m), 7.12—7.50 (2H, m). ^{13}C NMR δ=24.84, 27.57, 27.74, 29.90, 39.14, 43.53, 51.49, 53.25, 55.80, 55.96, 57.50, 69.15 (>CHOH), 110.81, 112.00, 114.82, 121.27, 134.35, 137.98, 147.87, 148.84. Found: *m/z* 397.1708. Calcd for $C_{20}H_{31}NO_3S_2$: M, 397.1744.

Protection of Amino Alcohol 16 with *t*-Butoxycarbonyl Group. To a CH_2Cl_2 (20 mL) solution of amino alcohol **16** (1.43 g, 3.6 mmol) was added *O*-*t*-butyl *S*-(4,6-dimethyl-2-pyrimidinyl) thiocarbonate (1.74 g, 7.2 mmol) and stirred overnight.[25] The reaction mixture was quenched with water and extracted with CH_2Cl_2. The combined extracts were washed with brine and dried over Na_2SO_4. After the solvent was removed in vacuo, the residue was chromatographed on silica gel by using hexane–ethyl acetate (1:1, v/v) to give *t*-butoxycarbonylamino alcohol **17** (1.38 g, 77%). IR (neat) 3370, 1700, 1640 cm^{-1}. ^1H NMR δ=1.12—1.73 (4H, m), 1.42 (9H, s), 1.73—2.95 (11H, m), 3.18—4.13 (2H, m), 3.83 (6H, s), 4.40—5.13 (3H, m), 5.37—6.10 (1H, m), 6.68—6.95 (1H, m), 7.28—7.52 (2H, m). Found: *m/z* 497.2244. Calcd for $C_{25}H_{39}NO_5S_2$: M, 497.2269.

Hydroxy Ketone 18. To an acetonitrile (15 mL)–water (1.5 mL) solution of *N*-chlorosuccinimide (178 mg, 1.34 mmol) and silver nitrate (225 mg, 1.50 mmol) was added an acetonitrile (5 mL) solution of **17** (166 mg, 0.33 mmol) at −42 °C and stirred for 1 h at that temperature.[26] To the mixtrure was added sat. aqueous Na_2SO_3 (1 mL) and stirred for 1 min. After addition of sat. aqueous Na_2CO_3 (1 mL), the reaction mixture was stirred for 1 min and brine (1 mL) was added. The resulting precipitate was filtered off and the filtrate was extracted with ether. The combined extracts were washed with brine and dried over $MgSO_4$. Concentration in vacuo and purification by preparative layer chromatography on silica gel (hexane: ethyl acetate=1:1, v/v) gave the hydroxy ketone **18** (99 mg, 73%). IR (neat) 3370, 1690 cm^{-1}. ^1H NMR δ=1.02—2.29 (6H, m), 1.30 (9H, s), 2.85—3.13 (2H, m), 3.57 (1H, br s), 3.77—4.23 (2H, m), 3.76 (6H, s), 4.38—5.04 (3H, m), 5.29—6.00 (1H, m), 6.68 (1H, d, *J*=8.6 Hz), 7.08—7.52 (2H, m). Found: *m/z* 407.2216. Calcd for $C_{22}H_{33}NO_6$: M, 407.2306.

(2S*,4S*,6S*)-6-(3-Butenyl)-2-(3,4-dimethoxyphenyl)-4-piperidinol (20). To a 1:1 mixture of trifluoroacetic acid and CH_2Cl_2 (1 mL) was added the hydroxy ketone **18** (104 mg, 0.23 mmol) at 0 °C. After being stirred for 10 min, the reaction mixture was quenched with 28% aqueous ammonia and extracted with CH_2Cl_2. The extracts were washed with water then brine and immediately condensed in vacuo under 20 °C. The residue, dissolved in THF (5 mL), was added to the suspension of sodium methoxide (175 mg, 3.2 mmol) and LAH (THF soln 1.2 mL, 1.6 mmol) in THF (5 mL) at −78 °C under an argon atmosphere.

The reaction mixture was stirred at −78°C for 1 h, at −42°C for 1 h, at −18°C for 1 h, and at 0°C overnight.[21] The reaction mixture was quenched with sat. aqueous Na_2SO_4 (0.5 mL) and the resulting precipitate was filtered off. After dried over Na_2SO_4, the filtrate was condensed under reduced pressure and the oily residue was purified by preparative TLC on aluminum oxide (CH_2Cl_2: methanol=40:1 v/v) to furnish *cis*-2,6-disubstituted piperidine **20** (40 mg, 60%). IR (neat) 3400, 1640 cm^{-1}. ^1H NMR δ=1.05—1.90 (6H, m), 1.79 (2H, br s), 1.90—2.34 (2H, m), 2.91—3.42 (1H, m), 3.86 (3H, s), 3.88 (3H, s), 4.01 (1H, dd, J=3.9, 10.2 Hz), 4.18—4.38 (1H, m), 4.75—5.13 (2H, m), 5.52—6.10 (1H, m), 6.71—7.00 (3H, m). ^{13}C NMR δ=30.12, 36.03, 39.03, 41.52, 50.98, 55.55, 55.99, 65.58, 11.57, 111.49, 114.66, 118.91, 137.76, 138.41, 148.25, 149.08. Found: m/z 291.1784. Calcd for $C_{17}H_{25}NO_3$: M, 291.1832.

(2S*,4S*,6S*)-6-(4-Hydroxybutyl)-2-(3,4-dimethoxyphenyl)-4-piperidinol (21). To a THF (0.7 mL) solution of B_2H_6 (1.28 mmol) was added 2-methyl-2-butene (180 mg, 2.56 mmol) in THF (5 mL) at −15°C and stirred for 2 h at 0°C under an argon atmosphere.[27] To the mixture was added a THF (6 mL) solution of **20** (93 mg, 0.32 mmol) and stirred for 45 min at that temperature. To the solution were added a few drops of water, then 3 M aqueous NaOH (1 mL (1 M=1 mol dm^{-3})), and 30% hydrogen peroxide (2 mL). After stirred for 1 h the mixture was extracted with chloroform, then washed with 1% aqueous Na_2CO_3, sat. aqueous Na_2SO_3, and brine. The organic layer was dried over Na_2SO_4 and condensed in vacuo. The residue was purified by preparative TLC on aluminum oxide (CH_2Cl_2: methanol=20:1, v/v) to give the diol **21** (86 mg, 87%). IR (neat) 3350 cm^{-1}. ^1H NMR δ=1.03—1.90 (10H, m), 2.18 (3H, br s), 2.68—3.20 (1H, m), 3.26—3.60 (2H, m), 3.70 (3H, s), 3.73 (3H, s), 3.80—4.28 (2H, m), 6.64—6.85 (3H, m). Found: m/z 309.1913. Calcd for $C_{17}H_{27}NO_4$: M, 309.1938.

(±)-Lasubine II (22). To a solution of the diol **21** (86 mg, 0.28 mmol) in pyridine (2 mL) was added *p*-toluenesulfonyl chloride (167 mg, 0.88 mmol) at −20°C under an argon atmosphere and stirred for 1.5 h at −20°C. After stirred overnight at 0°C, the reaction was quenched with ice and extracted with ethyl acetate. The extracts were washed 0.1 M aqueous NaOH, dried over Na_2SO_4, and condensed in vacuo. The residue was purified by preparative TLC on aluminum oxide (CH_2Cl_2 : methanol=20:1) to afford (±)-lasubine II (57 mg, 70%). IR ($CHCl_3$) 3610, 2930 cm^{-1}. ^1H NMR δ=1.26—1.91 (12H, m), 2.39—2.42 (1H, m), 2.69 (1H, d, J=11.60 Hz), 3.31 (1H, dd, J=3.36, 11.60 Hz), 3.86 (3H, s), 3.88 (3H, s), 4.00—4.21 (1H, m), 6.78—6.91 (3H, m). MS, m/z (relative intensity) 291(M^+, 472), 164 (332), 154 (434). Found: m/z 291.1878. Calcd for $C_{17}H_{25}NO_3$: M, 291.1833. ^1H NMR (400 MHz) and IR spectra of the synthetic (±)-lasubine II (**22**) was identical with those of the natural lasubine II. Mass spectrum also completely agreed with those values reported by C. Kibayashi.[17]

The authors are grateful to Professor Teruaki Mukaiyama for valuable discussion during this work. We are indebted to Professor Kaoru Fuji for his kind gift of ^1H NMR (400 MHz) and IR spectra of natural lasubine I and II, and also thank Dr. Tatsushi Murae for performing high-resolution mass spectra.

Studies on β-Turn of Peptides. XII.[1] Synthetic Confirmation of Weak Activity of [D-Pro$^{5,5'}$]-Gramicidin S Predicted from β-Turn Preference of Its Partial Sequence

Kazuki SATO, Rika KATO, and Ukon NAGAI*
Mitsubishi-Kasei Institute of Life Sciences, 11 Minamiooya, Machida, Tokyo 194
(Received October 5, 1985)

[D-Pro$^{5,5'}$]-Gramicidin S was synthesized to confirm a prediction that D-D sequence at the corner position had low preference for β-turn. The analog showed much weaker activity than gramicidin S and also showed different CD spectra from those of gramicidin S. The results indicate that the analog can not take stable, gramicidin S-like, β-sheet conformation.

In the previous papers, we reported that the CD spectra of *N*-(2,4-dinitrophenyl)tetrapeptide *p*-nitroanilides reflected well the β-turn preference of the tetrapeptide sequences.[2-4] β-Turn preferences of the tetrapeptides related to the β-turn part sequences of gramicidin S (GS), *cyclo*(-Val$^{1,1'}$-Orn$^{2,2'}$-Leu$^{3,3'}$-D-Phe$^{4,4'}$-Pro$^{5,5'}$-)$_2$, [5] which was well known to take β-sheet conformation with two β-turns (Fig. 1),[6-8] had good correlation with antibiotic activities of the GS analogs having similar tetrapeptides sequences at their β-turn parts.[1,3] The GS analogs having D-D sequences at 4—5 and 4′—5′ positions were predicted not to take GS-like β-sheet conformation from the result that Dnp-Leu-D-Ala-D-Leu-Val-pNA showed much weaker CD bands than Dnp-Leu-D-Ala-Leu-Val-pNA did.[3] To confirm this prediction, we synthesized [D-Pro$^{5,5'}$]-GS which had D-Phe-D-Pro sequences at 4—5 and 4′—5′ positions.

Results and Discussion

Synthesis of [D-Pro$^{5,5'}$]-GS (8). [D-Pro$^{5,5'}$]-GS was synthesized according to a scheme shown in Fig. 2. In a cyclization reaction, a pentapeptide with D-Pro at the C-terminus was chosen as a precursor, because many GS analogs had been synthesized in satisfactory results by a similar strategy.[9,10] Boc-Val-Orn(Z)-Leu-D-Phe-D-Pro-OH (**4**) was prepared by azide coupling of Boc-Val-Orn(Z)-Leu-N_2H_3[11] and H-D-Phe-D-Pro-OH (**3**), and converted to its active ester (**5**). Cyclization of H-Val-Orn(Z)-Leu-D-Phe-D-Pro-OSu (**6**) derived from **5** by acid treatment was carried out in anhydrous pyridine at the final concentration of 3 mM (1 M=1 mol dm^{-3}). After usual work-up,[12] a mixture of the crude cyclized peptides was applied to a column of Sephadex LH-20 (Fig. 3). The product obtained from the major peak (peak A) was determined to be cyclic dimer by FAB-MS measurement (M$^+$, 1141) after hydrogenolysis. Peak-B fractions afforded cyclic trimer (M$^+$, 1711) after hydrogenolysis. It is interesting that cyclization of pentapeptide active ester af-

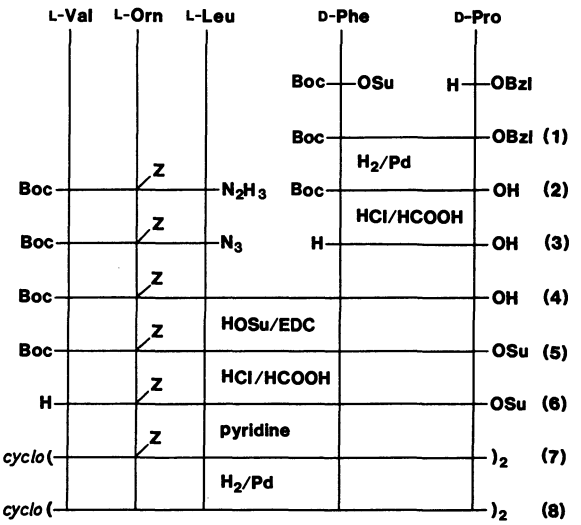

Fig. 2. Synthetic scheme of [D-Pro$^{5,5'}$]-GS (**8**).

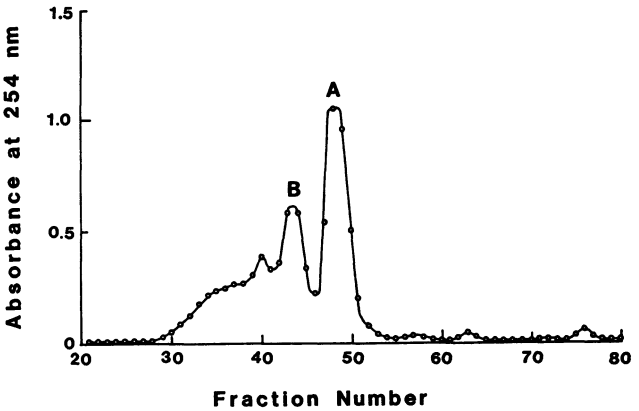

Fig. 3. Elution profile of crude cyclized peptides. For detail, see experimental section.

Table 1. Antibiotic Activity of GS and Its Analog (Minimum Inhibitory Concentration, μg/ml)

Strain	GS	[D-Pro$^{5,5'}$]-GS
Staphylococcus aureus MCI-1380	3.13	100
Bacillus subtilis marfurg 168	1.56	25
Escherichia coli C-600	>100	>100

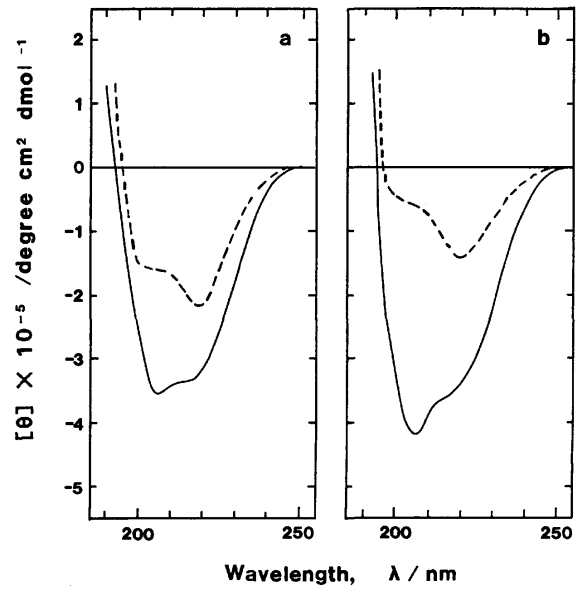

Fig. 4. CD spectra of GS and its analog measured at 25°C in (a) H_2O and in (b) MeOH solutions.
——: GS, ----: [D-Pro$^{5,5'}$]-GS.

forded much polymeric products and almost no cyclic monomer, since there are few papers which reported the absence of cyclic monomerization of pentapeptides.[10,13]. The results suggest that the sequence of [D-Pro$^{5,5'}$]-GS is unsuitable for compact, folded conformation.

Biological Activity. The antibiotic activity of the synthesized analog was compared with that of GS. The minimum concentration of the compound necessary for the complete inhibition of growth of several microorganisms was determined by a dilution method using a nutrient agar (Table 1). The analog showed much weaker activity than GS indicating that Pro at 5, 5′ position could not be replaced with D-Pro without affecting on its activity.

CD Spectra. In many GS analogs, good correlation was observed between their CD spectra and activities.[11,14] CD spectra of [D-Pro$^{5,5'}$]-GS and GS were measured in H_2O and in MeOH solutions (Fig. 4). The analog showed different CD patterns from those of GS in both solutions and also showed larger solvent dependence of CD intensities than GS did. These results suggested that the analog did not take stable,

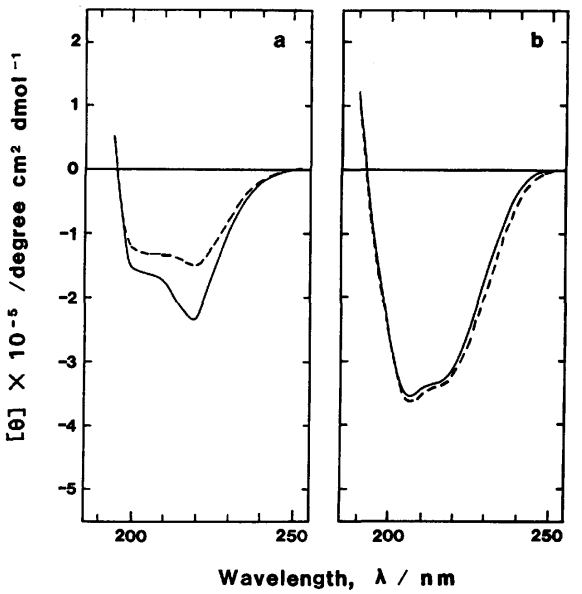

Fig. 5. Temperature dependence of CD spectra of (a) [D-Pro$^{5,5'}$]-GS and (b) GS in H_2O solution.
——: 10°C, ----: 85°C.

GS-like, β-sheet conformation. The large temperature dependence of CD spectra of the analog also suggested that the analog had flexible conformation (Fig. 5).

Structure-Activity Relationship. The decreased activity of the analog is considered to be caused by the conformational change as described above. And it is quite reasonable to consider that the conformational change is caused by the reluctance of D-Phe-D-Pro sequence to take stable, GS-like, β-turn conformation.

Present study proves that CD spectra of the chromophoric derivatives of tetrapeptides are useful for predicting the conformation and activity of bioactive peptides such as GS in which β-turn conformation plays an important role for its activity.

Experimental

All the melting points were uncorrected. Thin-layer chromatographies were carried out on Merck silica gel 60 F_{254} plates with the following solvent systems, the ratio in parentheses after the solvent system being indicated by vol: R_f^1, $CHCl_3$-MeOH (5:1); R_f^2, $CHCl_3$-MeOH-AcOH (95:5:1); R_f^3, *n*-BuOH-AcOH-pyridine-H_2O (4:1:1:2); R_f^4, *n*-BuOH-AcOH-H_2O (4:1:5, organic). Optical rotations were measured on a JASCO DIP-360 digital polarimeter. FAB-MS spectra were measured on a JEOL HX-100 mass spectrometer.

Boc-D-Phe-D-Pro-OBzl (1). To a chilled solution of H-D-Pro-OBzl·HCl (1.21 g, 5 mmol) in $CHCl_3$ (20 ml) were added TEA (0.7 ml, 5 mmol) and Boc-D-Phe-OSu (1.81 g, 5 mmol). After being stirred overnight at room temperature, the solution was evaporated under reduced pressure. The residue was dissolved in EtOAc and washed succesively with 10% citric acid, 4% $NaHCO_3$, and H_2O, and the solution was dried over anhydrous Na_2SO_4. After evaporation of the

solvent, the residue was crystallized by addition of ether and recrystallized from EtOAc-ether; yield, 1.76 g (78%); mp 104—108 °C; $[\alpha]_D^{24}$ 50.2° (*c* 0.7, MeOH); R_f^1=0.83, R_f^2=0.73, R_f^3=0.86, R_f^4=0.87.

Found: C, 68.97; H, 7.11; N, 6.37%. Calcd for $C_{26}H_{32}O_5N_2$: C, 69.01; H, 7.13; N, 6.19%.

Boc-D-Phe-D-Pro-OH (2). Compound **1** (769 mg, 1.7 mmol) dissolved in MeOH (20 ml) was hydrogenated in the presence of Pd-black (ca. 200 mg) for 5 h at room temperature. After filtration of catalyst, the filtrate was evaporated to leave an colorless oil which was used for the next reaction without further treatment; yield was quantitative; R_f^1=0.36, R_f^2=0.21, R_f^3=0.58, R_f^4=0.65.

H-D-Phe-D-Pro-OH·HCl (3·HCl). Compound **2** (616 mg, 1.7 mmol) was dissolved in 0.1 M hydrogen chloride in formic acid (26 ml). The solution was allowed to stand at room temperature for 30 min and evaporated. The desired product was collected by filtration with the aid of ether and used for the next reaction without further treatment; yield was quantitative; R_f^3=0.48, R_f^4=0.38.

Boc-Val-Orn(Z)-Leu-D-Phe-D-Pro-OH (4). To a solution of Boc-Val-Orn(Z)-Leu-N_2H_3[11] (541 mg, 0.91 mmol) in DMF (5 ml) were added 2 M hydrogen chloride in EtOAc (1.4 ml) and isopentyl nitrite (0.14 ml, 1.0 mmol) at −60 °C. After being left to stand at −20 °C for 10 min, the solution was cooled again to −60 °C and neutralized with TEA (0.38 ml, 2.73 mmol). To the mixture was added a chilled solution of **3**·HCl (508 mg, 1.7 mmol) and TEA (0.48 ml, 3.4 mmol) in DMF (3 ml). The reaction mixture was stirred at 5 °C for 2 d and then evaporated. Addition of 10% citric acid to the residue gave a white precipitate. The crude product (794 mg, >100%) dissolved in MeOH (2 ml) was applied to a column (3×170 cm) of Sephadex LH-20 and eluted with MeOH, each 12 ml fraction being collected. The fractions (No. 49—55) containing the desired product detected by UV absorption and TLC were collected and evaporated, and the residue was recrystallized from MeOH-ether; yield, 518 mg (69%); mp 116—120 °C; $[\alpha]_D^{24}$ −15.6° (*c* 0.6, MeOH); R_f^1=0.30, R_f^2=0.66, R_f^3=0.70, R_f^4=0.77.

Found: C, 62.11; H, 7.67; N, 9.98%. Calcd for $C_{43}H_{62}O_{10}N_6 \cdot 0.5H_2O$: C, 62.08; H, 7.63; N, 10.10%.

Boc-Val-Orn(Z)-Leu-D-Phe-D-Pro-OSu (5). To a chilled solution of **4** (411 mg, 0.5 mmol) and HOSu (115 mg, 1 mmol) in DMF (4 ml) was added a solution of EDC·HCl (192 mg, 1 mmol) in $CHCl_3$ (1 ml). After being stirred at 5 °C overnight, the solution was evaporated under reduced pressure. The precipitate fromed by the addedion of chilled H_2O was collected by filtration and dried in vacuo over P_2O_5. The product was used for next reaction without further treatment; yield 441 mg (96%); R_f^1=0.79, R_f^2=0.21.

H-Val-Orn(Z)-Leu-D-Phe-D-Pro-OSu·HCl (6·HCl). Compound **5** (441 mg, 0.48 mmol) was dissolved in 0.1 M hydrogen chloride in formic acid (7.2 ml). The solution was allowed to stand at room temperature for 30 min and evaporated to leave an oil which was crystallized by addition of ether. The product was used for the next reaction without further treatment; yield 390 mg (90%); R_f^1=0.25.

***Cyclo*[-Val-Orn(Z)-Leu-D-Phe-D-Pro-]$_2$ (7).** A solution of **6**·HCl (390 mg, 0.46 mmol) in DMF (5 ml) was added dropwise into pyridine (148 ml) at room temperature. The final concentration was 3 mM. The reaction mixture was stirred overnight and evaporated. The residue was dissolved in mixture (36 ml) of MeOH-H_2O (5:1, by vol.), and applied to columns (1.6×10 cm each) of Dowex 50 (H^+ form) and Dowex 1 (OH^- form). The columns were washed with the same solvent (100 ml) and the combined effluent was evaporated to leave a white solid, which was collected with the aid of H_2O. The crude product (198 mg, 61%) dissolved in MeOH (2 ml) was applied to a column (3×170 cm) of Sephadex LH-20 and eluted with MeOH, each 12 ml fraction being colleted (Fig. 3). The fractions (No. 47—51) containing the desired product were collected and evaporated. The product was recrystallized from MeOH-EtOAc-ether; yield 65 mg (20%); mp 148—153 °C; $[\alpha]_D^{24}$ −42.6° (*c* 0.2, MeOH); R_f^1=0.76, R_f^2=0.12, R_f^3=0.95, R_f^4=0.92.

Found: C, 63.30; H, 7.34; N, 11.59%. Calcd for $C_{76}H_{104}O_{14}N_{12} \cdot H_2O$: C, 63.14; H, 7.53; N, 11.63%.

***Cyclo*(-Val-Orn-Leu-D-Phe-D-Pro-)$_2$·2HCl ([D-Pro$^{5,5'}$]-GS·2HCl) (8·2HCl).** Compound **7** (48 mg, 0.03 mmol) dissolved in 0.02 M hydrogen chloride in MeOH (3 ml) was hydrogenated in the presence of Pd-black (ca. 100 mg) for 3 h at room temperature. After filtration of catalyst, the filtrate was evaporated and the residue was recrystallized from MeOH-ether; yield, 30 mg (83%); mp 251—255 °C; $[\alpha]_D^{24}$ −40.9° (*c* 0.7, MeOH); R_f^3=0.62, R_f^4=0.15; MS (FAB), *m/z* 1141 ($C_{60}H_{92}O_{10}N_{12}$, M^+).

Found: C, 55.78; H, 7.71; N, 12.95%. Calcd for $C_{60}H_{92}O_{10}N_{12} \cdot 2HCl \cdot 4H_2O$: C, 56.02; H, 7.99; N, 13.07%

Paper Electrophoresis. Electrophoresis was carried out with Whatman No. 1 paper and a solvent system of formic acid-AcOH-MeOH-H_2O (1:3:6:10, by vol., pH 1.8) for 2 h at 500 V/30cm. [D-Pro$^{5,5'}$]-GS showed single spot and the mobility was as follows: [D-Pro$^{5,5'}$]-GS, 7.3 cm; GS, 7.5 cm.

CD Measurements. CD spectra were recorded on a JASCO J-40 spectropolarimeter in 0.1 mM solution using a cell of 1 mm pass length.

Microbiological Assays. The minimum concentration of the compounds necessary for the complete inhibition of growth of several microorganisms was determined by a dilution method using a nutrient agar "Eiken" Sensitivity Test Agar E-MC10.

We thank Miss Manami Oku of our institute for measurement of FAB-MS spectra and the members of Analysis Center of Mitsubishi Chemical Industries Ltd. for elemental analysis.

Rearrangement Approaches to Cyclic Skeletons. III. Practical Route to *cis*-Bicyclo[4.3.0]non-4-en-7-ones Based on Photochemical [1,3] Acyl Migration of Bicyclo[3.2.2]non-6-en-2-ones[1]

Tadao UYEHARA,* Yasuhiro KABASAWA, Toshiaki FURUTA, and Tadahiro KATO
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-Aoba, Sendai 980
(Received October 7, 1985)

1-Methoxybicyclo[3.2.2]non-6-en-2-ones and the related compounds were derived I) from the Diels-Alder type 1,4-addition products of tropones with ethylene by selective reduction of the α,β-unsaturated carbonyl part (hydrosilylation followed by hydrolysis) and/or II) from bicyclo[2.2.2]oct-5-en-2-ones a) by the ring-enlargement utilizing Tieffeneau-Demjanov type conditions (1, TMS-CN; 2, $LiAlH_4$; 3, $NaNO_2$-AcOH) and/or b) by the related ring-expansion using trimethylsilyldiazomethane and boron trifluoride etherate. These bridged compounds were transformed into the respective [1,3] acyl migration products, *cis*-bicyclo[4.3.0]non-4-en-7-ones, in practical yields by direct irradiation through a Pyrex filter.

The photochemical behavior of tricyclo[2.2.2]oct-5-en-2-ones (**1**) has been investigated extensively.[3] The triplet-sensitized oxa-di-π-methane rearrangement of them into tricyclo[3.3.0.$0^{2,8}$]octan-3-ones (**3**) is particularly noticeable as a key reaction of syntheses of bi- and tricyclopentanoid natural products. On the other hand, there are only a few studies on the photochemical reaction of the higher homologs, bicyclo[3.2.2]non-6-en-2-ones (**4**).[4] As a part of our program to develop methods for stereoselective syntheses of [*m*–*n*] fused-ring natural products from bicyclic systems, we were interested in photochemical reactions of **4**.

As is analogized from those reactions of **1**, the expected products from ketones **4** are the [5—6] fused-ring compounds (**5**) and/or the related tricyclic ketones (**6**). The C_2–C_9 bond of **6** will be cleaved to give the [5—6] fused-ring compounds which are different from **5**. Thus, whichever photochemical rearrangement is predominant we can get [5—6] fused-ring compounds.

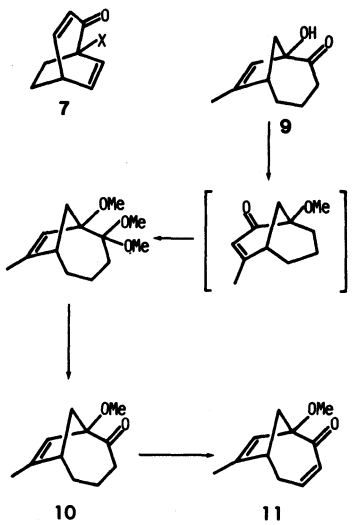
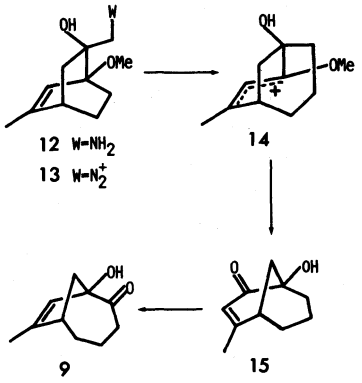
Results and Discussion

Syntheses of Bicyclo[3.2.2]non-6-en-2-ones. Already, we have reported that photochemical transformation of bicyclo[3.2.2]nona-3,6-dien-2-ones (**7**) into the C_7-disubstituted bicyclo[4.1.0]hept-2-enes is a practical synthetic method for [3—6] fused-ring sesquiterpenes such as sesquicarene[5] and isosesquicarene.[2] Bicyclononadienones **7a** and **7c** are the products of Diels-Alder reaction of tropones and ethylene.[6] Hydrosilylation of **7a** and **7c** with triethylsilane in the presence of Wilkinson's complex followed by hydrolysis[7] gave bicyclo[3.2.2]non-6-en-2-ones **4a** and **4c** in 47 and 84% yields, respectively. Another route to **4c** is sequential treatment of bicyclo[2.2.2]oct-5-en-2-one **1c**[8] with 1) cyanotrimethylsilane in the presence of a catalytic amount of zinc iodide, 2) lithium aluminium hydride, and 3) sodium nitrite in aqueous acetic acid (method A in Table 1). This Tieffeneau-Demjanov ring expansion[9] is useful to prepare the C_5-bridgehead methyl derivative (**4d**) from **1d**.[8] When 1-methylbicyclo[2.2.2]octenone **1b**[10] was treated similarly, the desired ketone (**4b**) was obtained along with a small amount of the regioisomer, 1-methylbicyclo-[3.2.2]non-6-en-3-one (**8**).[11]



However, a similar treatment of **1e**[12] gave the unexpected compound, 1-hydroxybicyclo[4.2.1]non-7-en-2-one (**9**), instead of **4e**. Treatment of **9** with trimethyl orthoformate in the presence of TsOH gave the trimethoxy derivative. Acetal exchange of the product with acetone yielded **10**. The enone was transformed into the α,β-unsaturated ketone (**11**) by palladium-catalyzed oxidation[13] of the enol trimethylsilyl ether of **10**. Proton-NMR spectra of **11** suggest this compound consists of the four-, two-, and one- carbon bridges.

Hydroxy ketone **9** is derived presumably from the hydroxylamine **12** which should give diazonium ion **13**. The 1,3-shift of the ethano bridge of **13** is not extravagant because of the additional stabilization of the resulting carbonium ion (**14**) with its methyl group. It is reasonable that ketone **9** is thermodynamically more stable than the valence isomer (**15**) since we can convert the former into **10**.



Ring enlargement of **1e** was accomplished by utilizing of trimethylsilyldiazomethane and BF_3-etherate (below −72 °C) to give **4e** on desilylation with potassium carbonate in methanol[14] (method B in table 1). Table 1 shows this Tiffeneau-Demjanov type homologation is a general method to obtain bicyclo[3.2.2]non-6-en-2-ones from respective bicyclo[2.2.2]oct-5-en-2-ones. As observed in monocyclic systems,[14] the methylene carbon migrates in preference to the other in this bridged bicyclic system.

Photochemical Reactions of Bicyclo[3.2.2]non-6-en-2-ones. Table 2 shows the conditions and the results of these photoreactions. As reported previously,[4] direct irradiation of **4a** through a Pyrex filter gave mainly the [1,3] acyl migration product (**5a**). The minor products of the reaction were undefined aldehydes. Formation of these is presumably due to the hydrogen abstraction process of the diradical which mainly turns into **5a**. When acetone was used as the solvent, the product (**6a**) via the oxa-di-π-methane rearrangement was obtained competitively with **5a**. The tricyclic structure of **6a** is supported by its spectral characteristics which clearly show the presence of the six-membered ring ketone conjugated with a three-membered ring: IR (CCl_4) 1690 (C=O) cm^{-1}.

The photochemical behavior of the bridgehead methyl derivative (**4b**) is very similar to that of **4a**.

Table 1. Tieffeneau-Demjanov Ring Enlargements of Bicyclo[2.2.2]oct-6-en-2-ones

Substrate	Method[a]	Product	Yield/%
1b	A	**4b**[b]	49
1c	A	**4c**	64
1c	B	**4c**	73
1d	A	**4d**	64
1d	B	**4d**	80
1e	A	**9**	40
1e	B	**4e**	73
1f	B	**4f**	71

a) Described in the text. b) With 4.5% of **8**.

Table 2. Photochemical Rearrangement of Bicyclo[3.2.2]non-6-en-2-ones

Substrate	Solvent	Concentration	Time	Products
		mol dm^{-3}	h	%
4a	Hexane	0.012	2	**5a** (53)
4a	Acetone	0.039	5.5	**5a** (18), **6a** (18)[a]
4b	Hexane	0.025	3.5	**5b** (55)
4b	Acetone	0.020	3.5	**5b** (28), **6b** (23)[b]
4c	THF	0.010	4	**5c** (55)
4c	Acetone	0.031	4	**16** (64)
4d	Hexane	0.018	6	**5d** (56)
4d	THF	0.010	4	**5d** (56)
4d	Acetone	0.023	6.5	**5d** (41)

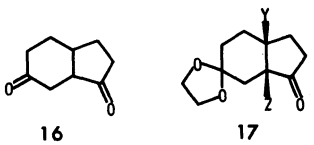
4f	THF	0.010	4	**5f** (50)

a) Ketone **4a**, 37%, was recovered. b) With 18% of recovery of **4b**.

In contrast with these, only the respective [1,3] acyl migration products (**5d—f**) were obtained from the substrates (**4d—f**) possessing a methoxyl group at the bridgehead position by irradiation in acetone. When the reaction of **4c** was carried out in acetone, a mixture of the isomeric diketones (**16**) was obtained. However, the HPLC analysis of the irradiated acetone solutions indicated that the primary product derived from **4c** is the [1,3] acyl migration product (**5c**).

The respective [1,3] acyl migration products (**5c—f**) are obtained in practical yields by direct irradiation of the bridged ketones (**4c—f**) in hexane or THF. As is analogized from the reactivity of **4c** in acetone, these enol methyl ethers are less stable compounds. However, the ethylene acetals (**17e—f**) derived selectively by acetal exchange are remarkably stable compounds.



Thus, the most useful process among the photochemical conversions of bicyclo[3.2.2]non-6-en-2-ones is the [1,3] acyl rearrangement to give bicyclo[4.3.0]non-4-en-7-ones. The products derived from the substrates having a methoxyl group at the bridgehead

position are synthetically versatile compounds because that they have a masked ketone in the six-membered ring and a carbonyl group itself in the five-membered ring. An application of this [1,3] acyl migration to a natural product synthesis has already been reported.[1]

In contrast with the cases of bicyclo[2.2.2]oct-5-en-2-ones,[3] the oxa-di-π-methane rearrangement dose not predominate over the [1,3] acyl migration when acetone was used as the solvent. The [1,2] migration process disappears when the irradiation of the substrate having a methoxyl group at the bridgehead was carried out in acetone.

In order to understand the photochemistry of these homoconjugated systems generally, the chemistry of an additional bridged system, bicyclo[3.2.1]oct-6-en-2-ones, is under investigation. Preliminary results indicate that 1) the processes via S_1 (n-π^*), T (π-π^*), and T (n-π^*) give the products due to hydrogen abstraction, oxa-di-π-methane rearrangement, and [1,3] acyl migration, respectively, and 2) the energy difference between T (π-π^*) and T (n-π^*) is not large.[15] These results and the mechanistic studies of the reactions described in this paper will be reported in due course.

Experimental

General. Melting and boiling points are uncorrected. UV (in cyclohexane) and IR spectra (in CCl_4, unless otherwise mentioned) were recorded on Hitachi Model 323 and 215 spectrometers, respectively. ^1H NMR spectra (in CCl_4, unless otherwise noted) were obtained on JEOL JNM-PMX60, Varian EM-390 90 MHz, or Varian XL-200 NMR spectrometers, using tetramethylsilane as an internal standared. ^{13}C NMR spectra (in $CDCl_3$) were recorded on a JEOL FX 90Q NMR spectrometer. The mass spectral studies were conducted using a Hitachi M-52 spectrometer. Tetrahydrofuran and ether were distilled from benzophenone ketyl under argon, immediately prior to use. Dichloromethane was distilled from P_2O_5 and stored on 4A molecular sieves. Wilkinson's complex[16] and *N*-nitroso-*N*-trimethylsilylmethylurea[17] were prepared by using literature procedures. All reactions were monitored by analytical TLC using E. Merck precoated silica gel $60F_{254}$ plates. Column chromatography was carried out with E. Merck silica gel 60 (70—230 mesh ASTM). Analytical HPLC was performed on a Warters Associates Model R-401 liquid chromatograph using a 25 cm×4 mm stainless-steel column packed with Lichrosorb SI 100. Analytical VPC was carried out using a Hitachi 663-50 gas chromatograph, outfitted with a 3 m×3 mm stainless-steel column packed with 10% FFAP on 60/80 Uniport B.

Preparation of Bicyclo[3.2.2]non-6-en-2-one (4a). A flask containing of a mixture of 2.65 g (19.8 mmol) of bicyclo-[3.2.2]nona-3,6-dien-2-one (**7a**), ca. 10 mg of Wilkinson's complex, and 3.47 ml (21.7 mmol) of triethylsilane, was heated at 60 °C under argon for 4 d with stirring. The mixture was diluted with 20 ml of pentane, and filtered through a Celite layer. After removal of the solvent, the remaining oil (5.38 g) was treated with 0.6 g of K_2CO_3 in a mixture of 15 ml each of acetone, methanol, and water for 1 h. The solution was diluted with water, and extracted with ether. The extracts were combined, washed with two portions of water and with saturated brine, and then dried over $MgSO_4$. Removal of the volatiles by Kugelrohr distillation (100 °C/23—30 Torr (1 Torr=133.322 Pa)) gave 1.25 g (47%) of **4a** as colorless oil. **4a**: UV 289 (sh, ε 82), 298 (88), and 308 nm (72); IR 1700 (s) cm^{-1}. The 2,4-DNP derivative of **4a**: mp 149.5—150.5 °C (decomp). Found: C, 57.19; H, 5.08; N, 17.89%. Cacld for $C_{15}H_{16}N_4O_4$: C, 56.91; H, 5.10; N, 17.71%.

Preparation of 1-Methoxybicyclo[3.2.2]non-6-en-2-one (4c). a) Reduction of 1-Methoxybicyclo[3.2.2]nona-3,6-dien-2-one (7c). A mixture of 2.08 g (12.69 mmol) of **7c**, ca. 10 mg of [Rh(PPh_3]Cl, and 3.04 ml (19.0 mmol) of triethylsilane was heated at 60 °C overnight under argon. A similar workup to that employed for the synthesis of **4a** gave 3.37 g of a colorless oil. Chromatography (70 g of silica gel, 10:1—5:1 hexane, ethyl acetate) of the oil gave 1.78 g (84%) of **4c**: Colorless oil; UV 302 nm (ε103); IR 1715 (s) cm^{-1}. ^1H NMR δ=6.20 (H_6, dd, J=9.3, and 7.2 Hz), 5.87 (H_7, broad d, J=9.3 Hz), 3.22 (3H, s), 2.68 (H_5, m), 2.5—2.0 (2H, m), and 2.0—1.5 (6H, m); ^{13}C NMR δ=205.0 (s), 135.7 (d), 131.1 (d), 83.7 (s), 51.6 (q), 39.1 (t), 31.9 (t), 30.8 (d), 28.9 (t), and 22.7 (t); MS (13.5 eV) *m/z* (rel intensity) 166 (M^+, 55) and 110 (100). Found: C, 71.97; H, 8.65%. Calcd for $C_{10}H_{14}O_2$: C, 72.25; H, 8.49%.

b) Ring Enlargement of 1-Methoxybicyclo[2.2.2]oct-5-en-2-one (1c). (As a General Procedure for Method A). To a mixture of 2.40 g (15.77 mmol) of **1c** and ca. 10 mg of zinc iodide was added 2.3 ml (16.56 mmol)of cyanotrimethylsilane (TMSCN) at 0 °C, under argon, and the mixture was allowed to stand overnight at room temperature. After recognition of the end of the reaction from the disappearance of **1c**, the reaction mixture was diluted with 10 ml of dry ether, and the solution was added via a canula into a suspension of 0.9 g (23.66 mmol) of $LiAlH_4$ in 40 ml of dry ether at 0 °C. After stirring overnight at room tempetrature, this reaction mixture was treated successively with 0.9 ml of water, 0.9 ml of 15% aqueous NaOH, and 2.7 ml of water. A granular precipitate was filtered with K_2CO_3, and the filtrate was concentrated in vacuo to give 3.34 g of a pale yellow oil. To a solution of this oil in aqueous acetic acid, prepared from 4.7 ml of AcOH and 24 ml water, was added a solution of 1.63 g (23.64 mmol) of sodium nitrite in 7.9 ml of water over a period of 3 h using an Eyela Model MP-101 micro tube pump. After stirring overnight, the reaction mixture was diluted with water and extracted with three portions of ether. The extracts were combined, washed successively with saturated aqueous Na_2CO_3 and NaCl solutions, and dried over $MgSO_4$. Evaporation of the solvent gave 1.98 g of a yellow oil. Chromatography of the oil using 80 g of silica gel (10:1 hexane, ethyl acetate) gave 1.67 g (64%) of pure **4c**.

c) Ring Enlargement of 1-Methoxybicyclo[2.2.2]oct-5-en-2-one (1c) Using $TMSCHN_2$ and BF_3 Etherate. (As General Procedure for Method B). In a flask equipped with a Dry Ice condenser and a efficient magnetic stirrer were placed 4.59g (25.67 mmol) of *N*-nitroso-*N*-trimethylsilylmethylurea and 20 ml of pentane. To the mixture was added 8.8 ml of 20% aqueous potassium hydroxide solution at 0 °C. After 1.5 h stirring at 0 °C, the organic layer was diluted with pentane, separated, washed with water, and dried over Na_2SO_4. This solution was concentrated carefully to ca. 15 ml, and diluted with 30 ml of dichloromethane. To a solution of 1.56 g (10.3 mmol) of **1c** in 38 ml dichloromethane

was added 1.96 ml (15.34 mmol) of BF_3-etherate at −78 °C under argon and the mixture was stirred for 5 min. To this reaction mixture was added that $TMSCHN_2$ solution over a period of 1.5 h below −73 °C. After 30 min stirring, to the solution was added 40 ml of saturated aqueous $NaHCO_3$ solution. The mixture was allowed to warm to room temperature with stirring, and the organic layer was separated, washed with saturated brine, dried over $MgSO_4$, and concentrated in vacuo. Chromatography (40 g of silica gel, 8:1 hexane, ethyl acetate) of the remaining oil (2.2 g) gave 1.24 g (73%) of pure **4c**.

1-Methylbicyclo[3.2.2]non-6-en-2-one (4b): Colorless oil; UV 240 (sh, ε 62), 288 (sh, 91), 297 (102), and 303 nm (sh, 91); IR 1710 (s) cm^{-1}. ^1H NMR δ=6.21 (H_6, dd, J=8.9 and 7.5 Hz), 5.64 (H_7, d, J=8.9 Hz), 2.8—2.3 (3H, m), 2.0—1.2 (6H, m), and 1.11 (3H, s); MS (25 eV) m/z (rel intensity) 150 (M^+, 81) and 106 (100). The 2,4-DNP derivative of **4b**: Mp 138—139 °C. Found: C, 58.13; H, 5.46; N, 16.87%. Calcd for $C_{16}H_{18}N_4O_4$: C, 58 17; H, 5.49; N, 16.96%.

1-Methoxy-6-methylbicyclo[3.2.2]non-6-en-2-one (4d): Colorless oil; UV 293 (sh, ε 100), 301.5 (177), 311 (100), and 322 nm (sh, 65); IR 1715 (s) cm^{-1}. ^1H NMR δ=5.84 (1H, d, J=9.0 Hz), 5.76 (1H, dd, J=9.0 and<1.0 Hz), 3.18 (3H, s), 2.6—2.1 (3H, m), 2.0—1.3 (5H, m), and 1.16 (3H, s): ^{13}C NMR δ=204.6 (s), 140.7 (d), 130.2 (d), 83.5 (s), 51.6 (q), 39.7 (t), 39.3 (t), 34.9 (s), 30.9 (t), 29.0 (t), and 29.0 (q); MS (25 eV) m/z (rel intensity) 180(M^+, 14) and 124 (100). The 2,4-DNP derivative of **4d**: Mp 156—156.5 °C. Found: C, 56.82; H, 5.74; N, 15.50%. Calcd for $C_{17}H_{20}N_4O_5$: C, 56.66; H, 5.59; N, 15.55%.

1-Methoxy-5-methylbicyclo[3.2.2]non-6-en-2-one (4e): Mp 38.5—39.5 °C; UV 292 (sh, ε 141), 320 (174), 311 (169), and 323 nm (sh, 98); IR 1715 (s) cm^{-1}; ^1H NMR δ=5.45 (1H, s), 3.19 (3H, s), 2.6—2.1 (4H, m), 1.83 (3H, d, J=1.5 Hz), and 2.0—1.5 (5H, m); ^{13}C NMR δ=205.5 (s), 145.1 (s), 123.7 (d), 83.8 (s), 51.5 (q); MS (25 eV) m/z (rel intensity) 194 (M^+, 4) and 138 (100). DNP derivative of **4e**: Mp 131.5—132.5 °C. Found: C, 56.63; H, 5.65; N, 15.52%. Calcd for $C_{17}H_{20}N_4O_5$: C, 56.66; H, 5.59; N, 15.55%.

1-Methoxy-5,6-dimethylbicyclo[3.2.2]non-6-en-2-one (4f): Colorless oil; UV 292 (sh, ε 141), 302 (179), 312 (174), and 323 nm (sh, 102); IR 1710 (s) cm^{-1}; ^1H NMR δ=5.49 (1H, broad s), 3.18 (3H, s), 1.79 (3H, d, J=1.5 Hz), 2.5—1.3 (8H, m), and 1.12 (3H, s); ^{13}C NMR δ=205.4 (s), 146.5 (s), 124.7 (d), 83.8 (s), 51.4 (q), 39.1 (t), 39.0 (t), 37.3 (s), 31.7 (t), 26.3 (q), and 19.1 (q); MS (25 eV) m/z (rel intensity) 194 (M^+, 4) and 138 (100). Found: C, 74.10; H, 9.46%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

1-Methylbicyclo[3.2.2]non-6-en-3-one (8): Colorless oil; IR 1695 (s) cm^{-1}; ^1H NMR δ=6.14 (1H, dd, J=9.0 and 7.1 Hz), 5.95 (1H, d, J=9.0 Hz), 2.57 (1H, m), 2.4—2.25 (4H, m), 1.9—1.6 (4H, m), and 1.13 (3H, m); MS (13.5 eV) m/z (rel intensity) 150 (M^+, 81), 108 (100), and 93 (71). The 2,4-DNP derivative of **8**: Mp 140—141 °C. Found: C, 58.36; H, 5.68; N, 16.95%. Calcd for $C_{16}H_{18}N_4O_4$: C, 58.17; H, 5.49; N, 16.96%.

1-Hydroxy-7-methylbicyclo[4.2.1]non-7-en-2-one (9): Mp 71—72 °C; IR 1695 (s) cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.14 (1H, broad s), 4.07 (1H, broad s), 1.74 (3H, d, J=1.5 Hz), 3.3—1.3 (9H, m); ^{13}C NMR δ=212.7 (s), 147.9 (s), 127.9 (d), 88.8 (d), 46.9 (d), 44.3 (t), 40.5 (t), 30.6 (t), 20.6 (t), and 15.1 (q); MS (25 eV) m/z (rel intensity) 116 (M^+, 34) and 109 (100). Found: C, 42.56; H, 8.64%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

Preparation of 1-Methoxy-7-methylbicyclo[4.2.1]non-7-en-2-one (10): To a solution of 280.4 mg (1.68 mmol) of **9** and 1.8 ml (16.4 mmol) of trimethyl orthoformate in dry dichloromethane was added a catalytic amount of TsOH at room temperature under argon. The resulting deep blue solution was allowed to stand overnight, and diluted with 20 ml of ether. The solution was successively washed with saturated aqueous $NaHCO_3$ solution, water, and saturated brine, and dried over $MgSO_4$. Evaporation of the solvents gave 373.6 mg of a yellow oil. To a solution of this oil in 5 ml of acetone was added a catalytic amount of TsOH, and the resulting deep blue solution was allowed to stand for 40 min. A similar workup to that used previously gave 291.5 mg of a yellow oil. Purification by chromatography (12 g of silica gel, 5:1 hexane, ethyl acetate) gave 232.5 mg (77%) of **10**: Colorless oil; IR 1710 (s) cm^{-1}. ^1H NMR δ=5.15 (1H, m), 3.11 (3H, s), 2.98 (1H, m), 2.5—2.2 (2H, m), 2.2—2.0 (2H, m), 1.70 (3H, d, J=1.5 Hz), 2.0—1.2 (4H, m); ^{13}C NMR δ=209.8 (s), 148.4 (s), 126.3 (d), 95.0 (s), 51.9 (q), 47.2 (d), 42.8 (t), 40.5 (t), 31.0 (t), 21.2 (t), and 15.1 (q). The 2,4-DNP derivatve of **10**: Mp 172—172.5 °C. Found: C, 56.38; H, 5.75; N, 15.43%. Calcd for $C_{17}H_{20}N_4O_5$: C, 56.66; H, 5.59; N, 11.55%.

Preparation of 1-Methoxy-7-methylbicyclo[4.2.1]nona-3,7-dien-2-one (11). The enol trimethylsilyl ether of **10** was prepared by treating with LDA and then with TMSCl at −78 °C. To a mixture of 87.9 mg of palladium acetate (0.39 mmol), 43 mg (0.39 mmol) of p-benzoquinone, and 1 ml of acetonitrile, prepared under argon, was added a solution of 195.2 mg (0.78 mmol) of the enol ether in 2 ml of acetonitrile at room temperature. After stirring overnight, the reaction mixture was poured in 0.5 M hydrochloric acid (1 M=1 mol dm^{-3}) and extracted with ether. The combined extracts were washed successively with saturated aqueous $NaHCO_3$ solution, water, and saturated brine, and dried over $MgSO_4$. Concentration followed by chromatography (8 g of silica gel, 5:1 hexane, ethyl acetate) gave 55.8 mg (40%) of **11**: Colorless oil; IR 1680 (s) cm^{-1}. ^1H NMR δ=5.87 (H_4, dtd, $J_{4,3}$=13.5, $J_{4,5}$=3.0, and $J_{4,6}$=0.7 Hz), 5.62 (H_3, ddd, $J_{3,4}$=13.5, $J_{3,5}$=2.3, and 1.5 Hz), 5.34 (H_8, q, J=1.5 Hz), 3.21 (OCH_3, s), 3.00 (H_6, m), 2.58 (H_5, 2H, m), 2.21 (H_9, 1H, d, $J_{9,6}$=1.5 Hz), 2.17 (H_9, 1H, s), and 1.73 (CH_3, dd, $J_{,8}$=1.5 and $J_{,6}$=0.75 Hz); MS (25 eV) m/z (rel intensity) 178 (M^+, 14) and 110 (100).

Photoreaction of 4a (General Procedure). A solution of 156.9 mg (1.15 mmol) of **4a** in 100 ml of hexane was placed in an immersion well equipped with a Pyrex filter and degassed by sonication. Irradiation of the solution under nitrogen using a 100-W Rikou high pressure Hg lamp for 2 h resulted in more than 95% conversion. From the crude photolysate (126.9 mg), 83.0 mg (53%) of **5a** was isolated by column chromatography (4 g of SiO_2, 15:1 hexane, ether).

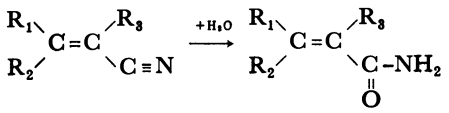
Catalytic Hydration of Unsaturated Nitriles to Unsaturated Amides Using Colloidal Copper Dispersions

Hidefumi HIRAI,* Hidehiko WAKABAYASHI, and Makoto KOMIYAMA
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received October 25, 1985)

Homogeneous hydrations of unsaturated nitriles such as acrylonitrile, methacrylonitrile, and crotononitrile to the corresponding unsaturated amides have been carried out in water at 80°C by use of colloidal copper dispersions as catalysts. The dispersions are prepared by reduction of copper(II) sulfate, copper(II) chloride, and copper(II) acetate with sodium tetrahydroborate in the presence of various polymers. The dispersions with poly(*N*-vinyl-2-pyrrolidone), poly(vinyl alcohol), methylamylopectin, methylcellulose, ethylcellulose, and (2-hydroxyethyl)-cellulose exhibit much larger catalytic activities than the copper precipitates prepared by reduction of the copper salts with sodium tetrahydroborate in the absence of the polymers. For all the catalytic reactions with the colloidal dispersions, selectivity for the unsaturated amides is 100% and formation of any by-products is not detected at all. Electron microscopy shows that no significant structural change occurs in the dispersions during the catalytic hydration. The catalytic activity monotonously increases with increasing amount of poly(*N*-vinyl-2-pyrrolidone) up to the charged ratio 20 of the monomeric residue to copper(II) ion, showing saturation at the ratio larger than 20. When the degree of the polymerization of poly(*N*-vinyl-2-pyrrolidone) is varied at a fixed residual molar ratio 40, the activity shows a maximum at the degree of polymerization 1440. The results are interpreted both by the change in the size of the colloidal copper particles and by the difference in the magnitude of the interactions between the polymers and the copper particles.

Hydration of unsaturated nitriles such as acrylonitrile and methacrylonitrile to the unsaturated amides such as acrylamide and methacrylamide (Eq. 1) is important in



(1)

industry.[1,2] Many heterogeneous catalysts, most of which contain transition metals or their salts, have been reported.[1-6] Copper metal supported on silica,[3] magnesia,[3] or γ-alumina[4] showed high activity and high selectivity in the hydration of acrylonitrile to acrylamide. However, there have been few reports on homogeneous catalysts for selective hydrations of unsaturated nitriles to unsaturated amides.

Previously,[7] the authors showed that stable colloidal dispersions of copper metal could be prepared by the reduction of copper(II) sulfate with sodium tetrahydroborate in the presence of various polymers. The resulting colloidal dispersions were highly active and selective homogeneous catalysts for the hydration of acrylonitrile to acrylamide, as reported in a preliminary communication.[8]

This paper reports the catalytic activities of the colloidal copper dispersions, prepared by the reduction of copper salts in the presence of various polymers, for the hydration of acrylonitrile, methacrylonitrile, and crotononitrile to the corresponding unsaturated amides. Effects of the amounts of the protective polymers and their degrees of polymerization on the catalytic activities of the dispersions are described. Furthermore, dependence of the catalytic activity on the size of the colloidal copper particles is shown.

Experimental

Materials. Poly(*N*-vinyl-2-pyrrolidone)s, amylopectin, methylcellulose (degree of methylation 2.0), (2-hydroxyethyl)cellulose (degree of hydroxyethylation 1.6) (from Tokyo Kasei Kogyo Co.), poly(vinyl alcohol)s (from Junsei Pure Chemicals Co.), ethylcellulose (degree of ethylation 1.0) (from Nakarai Chemicals), and dextrin (from Kanto Chemicals) were repeatedly (2—5 times) reprecipitated from aqueous solutions with acetone. Methylamylopectin was prepared according to the literature,[9] and had a degree of methylation 1.1, as determined by ^{1}H-NMR spectroscopy.

Copper(II) sulfate from Yoneyama Chemical Co. was recrystallized from water twice. Copper(II) chloride, copper(II) acetate, copper(II) nitrate, and sodium tetrahydroborate were obtained from Koso Chemical Co.

Acrylonitrile was distilled after being washed successively with aqueous sodium hydroxide solution, aqueous phosphoric acid solution, and pure water. Methacrylonitrile and crotononitrile were purified by distillation.

Water was doubly distilled and then was degassed by boiling under a reduced pressure.

Nitrogen gas, which had a purity higher than 99.9995%, was purchased from Nippon Sanso Co.

Preparation of Colloidal Copper Dispersions.[7] Typical procedure for the preparation of colloidal copper dispersions is as follows. Copper(II) sulfate or the other copper salts (0.15 mmol) and various amounts of protective polymers were stirred in 22 cm^3 of water at 80°C under nitrogen for 1 h. Then sodium tetrahydroborate (0.30 mmol) in 3 cm^3 of water was added at 25°C. The color of the solution changed immediately, and colloidal copper dispersions were obtained as black or reddish dark brown homogeneous solutions.

Catalytic Hydration of Unsaturated Nitriles Using Colloidal Copper Dispersions. The hydrations of acrylonitrile, methacrylonitrile, and crotononitrile were carried out at 80°C under nitrogen by adding the corresponding nitrile (9.1 mmol) to the colloidal copper dispersions. Product analyses were made with gas chromatography (Tenax GC

column, 2 m×3 mm glass column, 170°C).

Electron Microscopy. Electron micrographs of the colloids were obtained by a Hitachi Model HU-12A electron microscopy operated at 100 kV. Sample films were prepared from the colloidal dispersions on collodion films coated with a carbon layer by evaporating the solvent to dryness.

Results

Catalytic Hydrations of Unsaturated Nitriles Using Colloidal Copper Dispersions. Table 1 shows the catalytic activities of the colloidal copper dispersions, prepared by the reduction of copper(II) sulfate with sodium tetrahydroborate in the presence of various polymers, for the hydration of acrylonitrile in water at 80°C. The dispersions with poly(*N*-vinyl-2-pyrrolidone) (PVP), poly(vinyl alcohol), poly(potassium vinyl sulfate), methylamylopectin, methylcellulose, ethylcellulose, and (2-hydroxyethyl)cellulose exhibit much larger catalytic activities than the copper precipitates obtained by the reduction of copper(II) sulfate with sodium tetrahydroborate in the absence of the polymers. For example, the yield (27.3 mol%) of acrylamide for the colloidal copper dispersion with PVP of viscosity-averaged degree of polymerization (DP) 1440 is about 90 fold larger than that (0.3 mol%) for the copper precipitates.

The catalytic activity of the dispersion with methylamylopectin is 40 times as large as that with amylopectin. The dispersions with methylcellulose, ethylcellulose, and (2-hydroxyethyl)cellulose show 40 fold larger catalytic activities than the dispersion with dextrin. Measurement of the catalytic activity of the dispersion with cellulose has not been successful yet due to poor solubility of cellulose in water.

In the catalytic hydration of acrylonitrile using all the colloidal copper dispersions, except for the one with poly(potassium vinyl sulfate), the product was acrylamide alone. Either the formation of ethylene cyanohydrin due to hydration of the C-C double bond in place of the C-N triple bond, or the formation of acrylic acid, due to hydrolysis of acrylonitirle or acrylamide, was not detected at all. In contrast, the reaction using the copper precipitates, prepared by the reduction of copper(II) sulfate in the absence of the polymers, yielded considerable amount of ethylene cyanohydrin, resulting in the selectivity 97% for acrylamide.

When the colloidal copper dispersion with poly(potassium vinyl sulfate) was used as catalyst, ethylene cyanohydrin was produced as by-product together with an unidentified by-product.

The open circles in Fig. 1 show the time-conversion curve for the catalytic hydration of acrylonitrile using the colloidal copper dispersion with PVP (DP=1440). The yield of acrylamide monotonously increases with reaction time, attaining 68 mol% at 15 h. Up to this yield, the reaction satisfactorily follows first-order equation, and the selectivity for acrylamide is 100%.

The catalytic rate for the colloidal copper dispersion is more than 50 fold larger than that for the copper precipitates-PVP suspension system (the closed circles in Fig. 1). In the suspension system, the copper precipitates were first prepared by reducing copper(II) sulfate with sodium tetrahydroborate in the absence

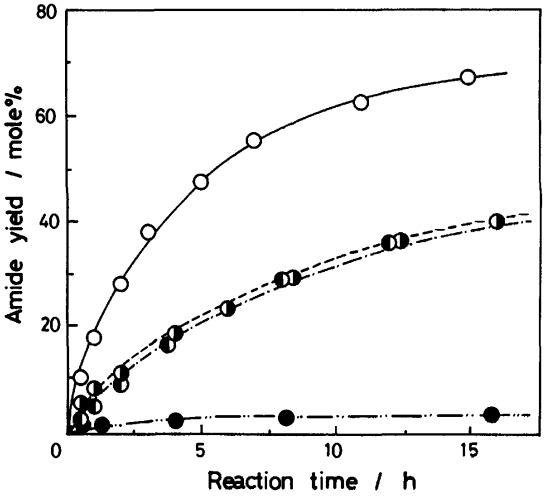

Fig. 1. Time course for the selective hydration of acrylonitrile (○), methacrylonitrile (◑), and crotononitrile (◐) catalyzed by the colloidal copper dispersion with PVP (DP=1440): 80 °C; $[Cu]_0=5.0\times10^{-3}$, [unsaturated nitrile]$_0=3.0\times10^{-1}$, and [monomeric residue of PVP]$_0=2.0\times10^{-1}$ mol dm^{-3}; the closed circles refer to the catalysis by the suspension composed of copper precipitates and PVP (details are described in the text.).

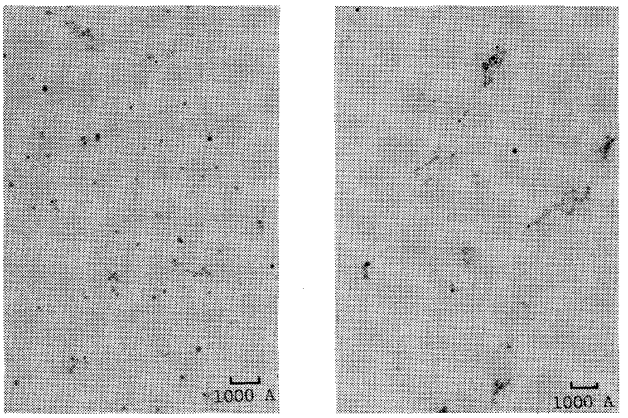

Fig. 2. Electron micrographs of the colloidal copper dispersions prepared by use of PVP (DP=1440) at the charged ratio 20 of the monomeric residue with respect to copper(II) sulfate; (a) before the catalytic hydration; (b) after the catalytic hydration of acrylonitrile at 80 °C for 2 h.

of PVP, and then they were charged to the reaction mixture together with PVP. The amount of PVP added was exactly identical with that used for the preparation of the colloidal dispersion. With the catalysis by the copper precipitates-PVP suspension system, considerable amount of ethylene cyanohydrin was formed as by-product, and the selectivity for acrylamide was 97%. This is significantly in contrast with 100% selectivity achieved by the colloidal copper dispersions.

The colloidal copper dispersions also catalyzed the hydrations of methacrylonitrile and crotononitrile to the corresponding unsaturated amides (◑ and ◐ in Fig. 1). The selectivities are 100% for both of the reactions. The rates for these methyl-substituted acrylonitriles are about 1/2 of the value for acrylonitrile itself.

Stability of Colloidal Copper Dispersion in the Catalytic Hydration. Catalytic hydration of acrylonitrile using the colloidal copper dispersion, prepared with the use of PVP, proceeded homogeneously throughout the reaction time. Neither precipitation nor change in color of the dispersion was perceived. Figure 2 shows the electron micrographs of the dispersion with PVP (DP=1440), before and after the hydration. In both of the electron micrographs, dispersion of colloidal copper particles is fine, In addition, the average diameter (100 A) of the particles after the hydration is exactly identical with that (100 A) before it. Thus, no significant structural change in the colloidal dispersion occurs during the catalytic reaction.

The colloidal copper dispersions with poly(potassium vinyl sulfate), dextrin, amylopectin, methylamylopectin, methylcellulose, ethylcellulose, and (2-hydroxyethyl)cellulose were also stable during the catalytic hydration. In the reaction using the dispersion with poly(vinyl alcohol), however, considerable amounts of black precipitates were formed during the reaction.

Effect of Copper Species on the Catalytic Activity of Colloidal Copper Dispersion. Table 2 lists the catalytic activities of the colloidal copper dispersions prepared by the reduction of various copper salts with sodium tetrahydroborate in the presence of PVP (DP=1440). The dispersions prepared from copper(II) sulfate and copper(II) chloride show high catalytic activities and 100% selectivity for acrylamide. No precipitation and color change are found during the catalytic reactions here.

The dispersion from copper(II) acetate exhibits also 100% selectivity, although the catalytic activity is slightly smaller. This dispersion is less stable than the ones from copper(II) sulfate and copper(II) chloride, and black precipitates are formed in the course of the catalytic reaction.

In the case of the colloidal copper dispersion prepared from copper(II) nitrate, the color of the dispersion gradually changed from dark brown to yellowish green. Ethylene cyanohydrin is formed as by-product, and both the yield and the selectivity for acrylamide are low.

Dependence of the Catalytic Activity of the Colloidal Copper Dispersion on the Amount and the Degree of Polymerization of Protective Polymer. Figure 3 shows the plot of the catalytic activity of the colloidal copper dispersions for the hydration of acrylonitrile vs. the amount of PVP (DP=1440) used for the preparation of the dispersion. The activity gradually increases with increase in the charged ratio of the monomeric residue of PVP to copper(II) sulfate, up to the ratio 20. At the ratio larger than 20, however, the activity is almost independent of the amount of PVP.

Table 2. Catalytic Activities of Colloidal Copper Dispersions Prepared by the Reduction of Various Copper Salts in the Presence of PVP (DP=1440)[a)]

Copper salt	Color of colloidal dispersion	Acrylamide formation	
		Yield/mole%[b)]	Selectivity/%
$CuSO_4 \cdot 5H_2O$	Reddish dark brown	28.1	100
$CuCl_2 \cdot 2H_2O$	Reddish dark brown	26.8	100
$Cu(OCOCH_3)_2$	Dark brown	17.2	100
$Cu(NO_3)_2$	Dark brown[c)]	0.4	81[d)]

a) Reaction conditions: 80°C, 2h; $[Cu]_0=5.0\times10^{-3}$, $[acrylonitrile]_0=3.0\times10^{-1}$, and [monomeric residue of PVP]$_0=1.0\times10^{-1}$ mol dm^{-3}. b) Value with respect to the charged acrylonitrile. c) The color gradually changed to yellowish green during the catalytic reaction. d) By-product was ethylene cyanohydrin.

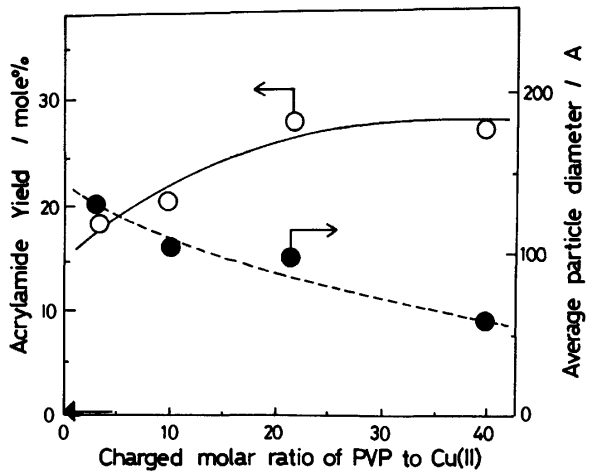

Fig. 3. Plots of the catalytic activity (○) of the colloidal copper dispersion in the hydration of acrylonitrile and the average diameter (●) of the colloidal copper particles as functions of the amount of PVP (DP=1440) used for the preparation of the dispersion: reaction conditions, 80°C, 2h; $[Cu]_0=5.0\times10^{-3}$ and $[acrylonitrile]_0=3.0\times10^{-1}$ mol dm^{-3}, the arrow refers to the result for the catalysis by the copper precipitates prepared in the absence of PVP.

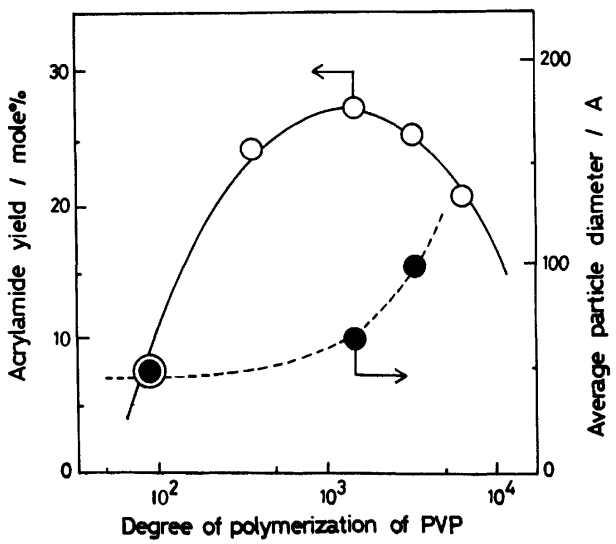

Fig. 4. Plots of the catalytic activity (○) of the colloidal copper dispersion in the hydration of acrylonitrile and the average diameter (●) of the colloidal copper particles as functions of the degree of polymerization of PVP: the charged ratio of the monomeric residue of PVP to copper(II) sulfate was kept constant at 40; reaction conditions, 80°C, 2h; $[Cu]_0=5.0\times10^{-3}$ and $[acrylonitrile]_0=3.0\times10^{-1}$ mol dm^{-3}.

Even at the ratio 3 of monomeric residue of PVP to copper(II) sulfate, the dispersion is stable throughout the reaction time. The activity of this dispersion is about 50 times as large as that, shown by the arrow in Fig. 3, of the copper precipitates prepared without PVP.

In Fig. 4, the catalytic activity of the colloidal copper dispersion is plotted against the degree of polymerization (DP) of PVP. Here, the ratio of monomeric residue of PVP to copper(II) sulfate is kept constant at 40. The activity increases with increasing degree of polymerization below DP 1440. Above DP 1440, however, the activity decreases with increasing degree of polymerization.

The closed circles in Figs. 3 and 4 show the average diameters of colloidal copper particles, determined by electron microscopy, for the corresponding dispersions. The average particle diameter decreases with increasing amount of PVP (Fig. 3) and with decreasing degree of polymerization of PVP (Fig. 4). Relationship between the catalytic activity and the average particle diameter will be discussed in the Discussion Section.

Discussion

Catalytic Activities of the Colloidal Copper Dispersions for the Hydration of Unsaturated Nitriles to Unsaturated Amides. The higher catalytic activities of the colloidal copper dispersions than the copper precipitates (Table 1) is mainly attributable to the fact that the effective surface area of copper metal is larger due to smaller particle diameter. The diameter of all the particles in the colloidal copper dispersion with PVP (DP=1440), exhibiting the largest catalytic activity, for example, are between 20 to 190 A, as described previously.[7] However, the particle diameter in the copper precipitates, prepared in the absence of polymer, ranges from 40 to 3500 A. Here, dominant part of the charged copper atoms is used for the

Table 3. Comparison of the Catalytic Activity for Colloidal Copper Dispersion Using PVP (DP=3240) with the Value for Copper on Silica-Magnesia in the Hydration of Acrylonitrile[a)]

a) Reaction conditions: 80°C, 30 min; $[\text{acrylonitrile}]_0=1.8\times10^{-1}$ mol dm^{-3}. b) [monomeric residue of PVP]$_0$/[Cu]$_0$=20. c) Date from Ref. 3.

formation of large particles, resulting in small value of the total surface area. The catalytic activity of the precipitates is small even in the suspension system formed by the addition of PVP (● in Fig.1).

In addition, the colloidal copper catalysts are more active than the copper precipitates, since the reactions proceed homogeneously and thus the contacts between the copper metal particles and the unsaturated nitriles are much more efficient. The catalytic activity of the dispersion prepared from copper(II) acetate, which shows precipitation of copper particles during the reaction, is about 2/3 of the values of the dispersions from copper(II) sulfate and copper(II) chloride, which are homogeneous throughout the reactions (Table 2).

Table 3 shows the comparison of the catalytic activity of the homogeneous colloidal copper catalyst with the value of a heterogeneous catalyst, copper supported on silica-magnesia.[3)] Reaction conditions are identical with each other except for the fact that the amount of copper used in the colloidal copper catalyst is about 34 fold smaller than that used in the heterogeneous catalyst. The rate of formation of acrylamide per the charged copper atom for the colloidal copper catalyst is 11 fold larger than the value for the heterogeneous catalyst. The selectivity for acrylamide is 100% for the colloidal catalyst, whereas the selectivity is 97% for the heterogeneous catalyst. Thus, the colloidal copper catalyst is superior to the heterogeneous catalyst, at least with respect to the catalytic activity and selectivity.

Selective catalyses by the colloidal copper dispersion are probably associated with absence or minimal amount of lattice defects, suppressing undesired side reactions. As shown by the previous electron diffraction experiments,[7)] the copper atoms in the colloidal copper particles are arranged in an ordered way, which is almost identical with that in the crystal of bulk copper metal. Selective catalyses by the colloidal dispersions of noble metals such as rhodium and palladium in the hydrogenation of olefins and dienes have been known.[10,11)]

Factors Governing the Catalytic Activity of Colloidal Copper Dispersion. The increase of the catalytic activity of the colloidal copper dispersion with increasing amount of PVP at the charged ratio 20 or smaller of monomeric residue of PVP to copper(II) sulfate (Fig. 3) is ascribed to increase in the surface area of copper particles due to decrease in the particle size. The increase of the activity with decreasing degree of polymerization of PVP at the DP 1440 or larger (Fig. 4) is also attributed to increasing surface area. The protective polymers protect fine colloidal copper particles from mutual coaggregation both in the preparation of the colloidal dispersion and in the catalytic hydration, providing effective contacts between the copper particles and the substrates unsaturated nitriles.

The catalytic activities of the colloidal copper dispersions are also dependent on the magnitude of the interactions between the polymers and the colloidal copper particles.[12)] The stronger interactions reduce the catalytic activities by competitive suppression of the interactions of the substrates unsaturated nitriles with the copper particles. The 4 fold decrease in the catalytic activity with decreasing degree of polymerization from 1140 to 90, in spite of decreasing average particle diameter from 60 to 50 A (Fig. 4), is attributable to this effect. The magnitude of the interactions of PVP with colloidal metal particles increases with decreasing degree of polymerization.[13)] Increase of the residual molar ratio of PVP with respect to copper(II) sulfate from 20 to 40 shows virtually no increase in the catalytic activity (Fig. 3), since enhancement of the competitive suppression by PVP on the interactions of the nitriles with the copper particles compensates the acceleration due to decrease in the average particle diameter from 100 to 60 A.

Large catalytic activities of the dispersions with methylamylopectin, methylcellulose, ethylcellulose, and (2-hydroxyethyl)cellulose than the values for the dispersions with dextrin and amylopectin (Table 1) are also consistent with the arguments. Alkylation of the hydroxyl groups prevents hydrogen bondings between the monomeric residues in the polysaccharides, resulting in more flexible and stretching conformations of the polymers. Thus, the surface of the copper metal particles in the dispersions protected by these alkylated polysaccharides is more favorable for the unsaturated nitriles to make interactions than the surface in the dispersions protected by the polymers with rigid and compact conformations.

With the use of the polymers such as poly(ethylene oxide) and β-cyclodextrin, which interact with the colloidal copper particles too weakly, no colloidal copper dispersions are obtained. Only copper precipitates are formed on the reduction of copper(II) sulfate with sodium tetrahydroborate in the presence of these polymers.[7]

The authors would like to thank Koichi Adachi for his valuable assistance in electron microscopy measurements.

Electrolytic Recovery of Silver from Photographic Fixing Solutions with a Fluidized Bed Electrode

Isao SEKINE* and Hiroyuki ISHII
Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda, Chiba 278
(Received January 17, 1985)

For an effective electrolytic recovery of silver from photographic fixing solutions, polarization measurements and potentiostatic electrolysis were carried out using active carbon as a fluidized bed electrode. The optimum conditions, determined by the electrolytic recovery, required a static bed height was 4 mm, a bed expansion rate 14%, and an initial set potential −0.84 V vs. SCE. The current efficiency in this case was about 75%, and the limiting concentration for recovery of silver was about 5 ppm. The electrolytic duration for recovery of the silver was reduced to about half by enlarging the electrolytic cell. Other products formed during the electrolysis were hydrogen sulfide (H_2S) and silver sulfide (Ag_2S). When silver deposited under the optimum conditions was dissolved in 5M-HNO_3 (1M=1mol dm^{-3}) of 100 ml, the recovery efficiency of the silver was about 75%.

Electrolytic recovery of metals with a fluidized bed electrode is favorable in dilute solutions. It is also known to be more effective than a fixed bed electrode.[1-4] Active carbon, which has an ability for physical adsorption and a better conductivity, has rarely been used in electrolytic recovery as material for a bed electrode.

In the present work, the effective electrolytic recovery of silver in the photographic fixing solution was investigated using active carbon. The various kinds of photographic fixing solutions contain relatively large amount of silver ion. Therefore, the recovery of silver is important from the viewpoint of saving natural resources. Moreover, the optimum conditions for carrying out effective potentiostatic electrolysis were determined by measuring the cathodic polarization curve and by electrolysis. Factors are the static bed height, the bed expansion rate, and the initial set potential. The effect of scale up of the electrolytic cell and the recovery efficiency of silver were also investigated. The product deposited on the cathode was identified by X-ray diffraction.

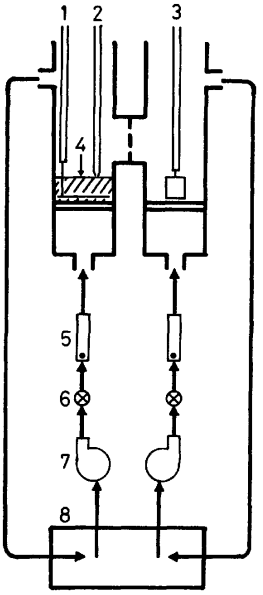

Fig. 1. Apparatus for electrolytic recovery of Ag. 1: Working electrode (Pt wire), 2: Reference electrode (SCE), 3: Counter electrode (Pt plate), 4: Fluidized bed electrode (active carbon), 5: Flow meter, 6: Valve, 7: Pump, 8: Tank in water bath.

Experimental

Cell and Electrode. The cell for the electrolytic recovery is shown in Fig. 1. The cell is made of acrylic resin. It has an H-type structure with an inside diameter of 26 mm or 18 mm. The diameter of both the inlet and the outlet for the solution was 7 mm. Anolyte and catholyte were divided by a diaphragm to prevent the electrolyte from mixing by natural convection. The electrolyte was filtered through a porous acrylic resin plate interposed at a point 35 mm up from the inlet through which the solution flows into the cell. The average particle diameter of the active carbon used as a fluidized bed electrode was 1.53 mm. The active carbon was used after immersion in distilled water for more than one day. The cathode was a spiral platinum wire of 0.5 mm diameter used as a feeder electrode on the porous acrylic resin plate, and the active carbon was placed on the feeder electrode. The anode was a platinum plate of 15×10 mm. Both anode and cathode were subsequently washed with ethanol, 1M-HNO_3 and 1M-HCl. The reference electrode was a saturated calomel electrode (SCE).

Electrolyte. The electrolyte was prepared by diluting tenfold a photographic fixing solution with distilled water. The electrolyte with a volume of 1 dm^3 was pumped to the cell from a tank maintained at 30 °C; the flow rate was controlled by a Teflon valve and was determined through a flow meter. Moreover, the electrolyte was circulated from the outlet of the cell to the tank, after it had fluidized the active carbon.

Polarization Measurement and Electrolysis. The measurements of the polarization curves were carried out by the potentiostatic method. The potential was changed stepwise from a natural electrode potential (NEP) to a less noble potential at a scan rate of 50 mV min^{-1}. The electrolytic recovery of silver was also carried out for 6 h by the potentiostatic method.

Concentration Determination of Silver Ion. The concentration of silver ion in the solution was determined by atomic absorption analysis. In this analysis, air-acetylene was used as a flame, and the wavelength of irradiation was 3281 Å for Ag. The concentration of silver ion was determined from

the calibration curve.

Analysis of Silver Sulfide. Silver sulfide as another product was deposited like a halo on the surface of the granular active carbon. This product was identified by X-ray diffraction. The wavelength of the irradiating X-ray was 1.9373 Å (Fe $K\alpha$).

Recovery Efficiency of Silver. To obtain the recovery efficiency of silver, the electrolysis was carried out under optimum conditions with a static bed height of 4 mm, a bed expansion rate of 14%, a set potential of −0.84 V vs. SCE and an electrolytic duration of 3 h. The amount of silver recovered from the photographic fixing solutions by electrolysis was about 0.5 g. In this case, the recovery of silver was stopped before the concentration of silver ion reached the lower limited value of about 5 ppm, because a large amount of silver sulfide was formed. The silver deposited on the active carbon was dissolved in 5M-HNO_3 of 100 ml for 2 h with stirring. The recovery efficiency of silver was obtained by the ratio of the dissolved silver (g) to the deposited silver (g).

Results and Discussion

Polarization Measurements. (I) Effect of Concentration: In the cell having an inside diameter of 26 mm, the polarization curves for the photographic fixing solutions diluted 2, 5, 10, and 20 times with water are shown in Fig. 2. These data were obtained by measurement under the following conditions: The static bed height of fluidized bed electrode was 4 mm, the bed expansion rate 14%, and the solution temperature 30±0.5 °C. In the case of the feeder electrode only, the flow rate of solution was 0.3 dm^3 min^{-1}. The current density on both the fluidized bed and the feeder electrode increases only with increasing concentration of silver. This can be explained by the fact that the bulk concentration of silver ion is directly proportional to the current. When the concentration of silver ion in the photographic fixing solution increases from 285 ppm in 20 times dilution to 2850 ppm in twofold dilution, the specific conductivity increases from 7500 to 53900 $\mu S\,cm^{-1}$, so that the current increases. Throughout the potential range, the current on the fluidized bed electrode is greater than that on the feeder electrode. Consequently, the

fluidized bed would act as an effective electrode. However, the fluidized bed electrode was found to work effectively when the photographic fixing solution was diluted with water more than 10 times and the static bed height was 12 mm. This can be explained by the fact that the shape of the polarization curves obtained under these conditions resembled that in Fig. 2.

(II) Effect of the Static Bed Height: In a cell having an inside diameter of 26 mm, the polarization curves for static bed heights of 4, 8, and 12 mm, and for a feeder electrode only are shown in Fig. 3. These data were obtained at an expansion rate of the bed of 14% and a solution temperature of 30±0.5 °C. The current density decreases with increasing static bed height. As the ohmic drop in the fluidized bed electrode increases with increasing amount of active carbon, the decrease of the current density would be ascribed to the spread of potential distribution in the bed. When the static bed height was 4 mm, a fluidized bed electrode was more effective than a feeder electrode over all potential ranges. This current density was approximately the same as that with a small cell of 18 mm inside diameter. The optimum static bed height of the cells having inside diameters of 18 and 26 mm was 4 mm.

(III) Effect of Bed Expansion: In the cell having an inside diameter of 26 mm, the polarization curves for bed expansion rates of 10, 14, 17, 20, and 30% at a static bed height of 4 mm and a solution temperature of 30±0.5 °C are shown in Fig. 4. In all cases, a small difference in the current density was observed at less noble potentials than −0.8 V vs. SCE. However, the current density in the noble potential range less than −0.9 V increased steeply. These phenomena can be attributed to the evolution of H_2S and H_2.[5] In the less noble potential range below −0.8 V, the current density shows the highest value at a bed expansion rate of 14%. The current value is approximately the same at 17 and 20%, and lowest at 10 and 30%. In the case of a bed expansion rate smaller than 14%, the current density was small because the effective surface area of electrode was not spread sufficiently. In the range of 14—20%, the transfer to the cathode surface of the Ag^+ ion is promoted by the rotatory motion of the active carbon particles themselves, and the collision numbers among the particles as well as between the particles and the feeder are considerably increased. The charge transfer reaction is believed to proceed smoothly. Also, the thickness of the diffusion layer became smaller because of the flow of electrolyte; hence the current density increased.[6] Above 20%, the conductivity of the fluidized bed electrode deteriorates because the space rate of active carbon particles is increased. The amount of active carbon serving as an electrode was gradually diminished. As the resistance of the bed became progressively greater with increasing bed expansion rate, the current density is inferred to become smaller.[7] The current density with the cell of inside diameter of 26 mm did not differ significantly

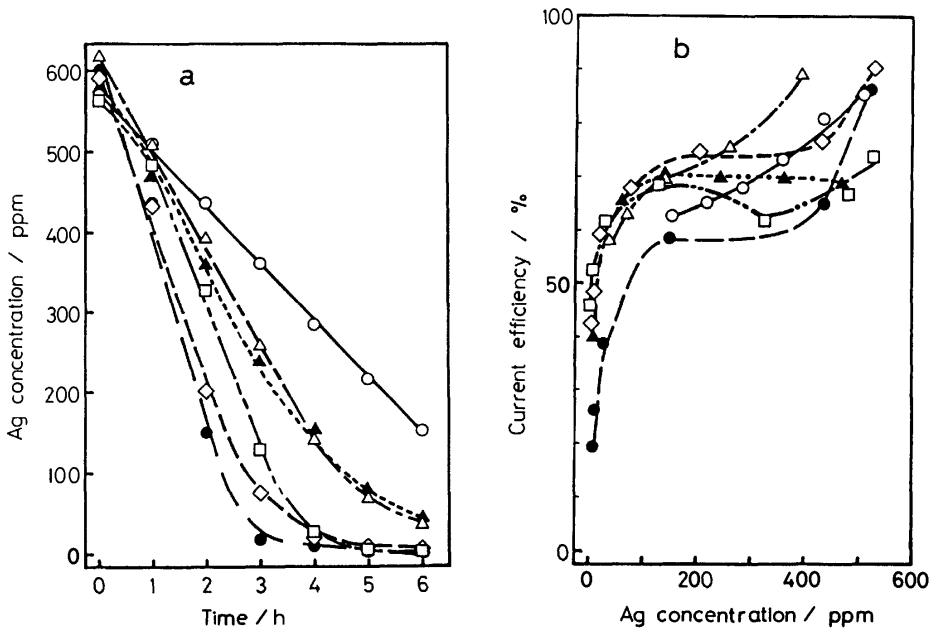

Fig. 5. (a) Change of concentration of silver ion as a function of time, and (b) current efficiency vs. concentration curves for various initial set potentials at bed bed height of 4 mm and expansion of 14%.

from that for the cell of 18 mm inside diameter.

Macroelectrolysis. (1) Effect of Initial Set Potential: The relationship between the concentration of silver ion and the electrolytic duration at various set potentials is shown in Fig. 5(a), and the current efficiency in this case is shown in Fig. 5(b). These data were obtained for a static bed height of 4 mm, bed expansion rate of 14%, and solution temperature of 30±0.5 °C with the cell of inside diameter of 26 mm. The electrolytic duration for recovery of silver became much shorter as the set potential shifts to a less noble potential. The concentration of silver ion decreased linearly from about 600 ppm to about 100 ppm by electrolysis. At a concentration below about 100 ppm, the electrolytic duration for recovery of silver gradually increased. On enlarging the inside diameter of cell, the electrolytic duration for recovery of silver ion up to 50 ppm took about 5.8 h at the inside diameter of 18 mm, but it could be reduced to about 3.5 h in a cell of 26 mm diameter. On the other hand, at concentrations of silver ion up to about 100 ppm the current efficiency increased steeply with increasing concentration. At a concentration of silver ion above about 100 ppm, it was independent of the concentration and reached a value of about 60—75%. The low current efficiency in the concentration range up to about 100 ppm can be ascribed to the diffusion of silver ion in the dilute solution.[8] Such a tendency was similar to that described by Walker et al. for the electrolytic recovery of copper.[9] Moreover, the low current efficiency was due to the formation of other products such as H_2S and Ag_2S. The evolution of H_2S was observed at concentrations below about 100 ppm of silver ion, and at a negative set potential lower than −0.8 V vs. SCE. The H_2S evolution reaction[5] is considered to occur by

$$S_2O_3^{2-} + 2H_2O + 2e^- \longrightarrow H_2S + SO_3^{2-} + 2OH^- \quad (1)$$

Furthermore, a black powder was deposited on the cathode at all set potentials as the concentration of the silver ion decreased. The black powder was shown to be Ag_2S by X-ray diffraction analysis. The deposition reaction of silver from photographic fixing solutions is given as

$$Ag^+ + 2S_2O_3^{2-} \rightleftharpoons [Ag(S_2O_3)_2]^{3-} \quad (2)$$

$$Ag(S_2O_3)_2^{3-} + e^- \longrightarrow 2S_2O_3^{2-} + Ag \quad (3)$$

Then, this reaction competes further with the formation of silver sulfide as follows:[10]

$$H_2S \rightleftharpoons H^+ + HS^- \quad (4)$$

$$H_2S + 2[Ag(S_2O_3)_2]^{3-} \longrightarrow Ag_2S + 2H^+ + 4S_2O_3^{2-} \quad (5a)$$

or

$$HS^- + 2[Ag(S_2O_3)_2]^{3-} \longrightarrow Ag_2S + H^+ + 4S_2O_3^{2-} \quad (5b)$$

From both the recovery time and the current efficiency, it is concluded that the optimum set potential was −0.84 V vs. SCE, and that the limiting concentration of recovery was about 5 ppm. Further, when the inside

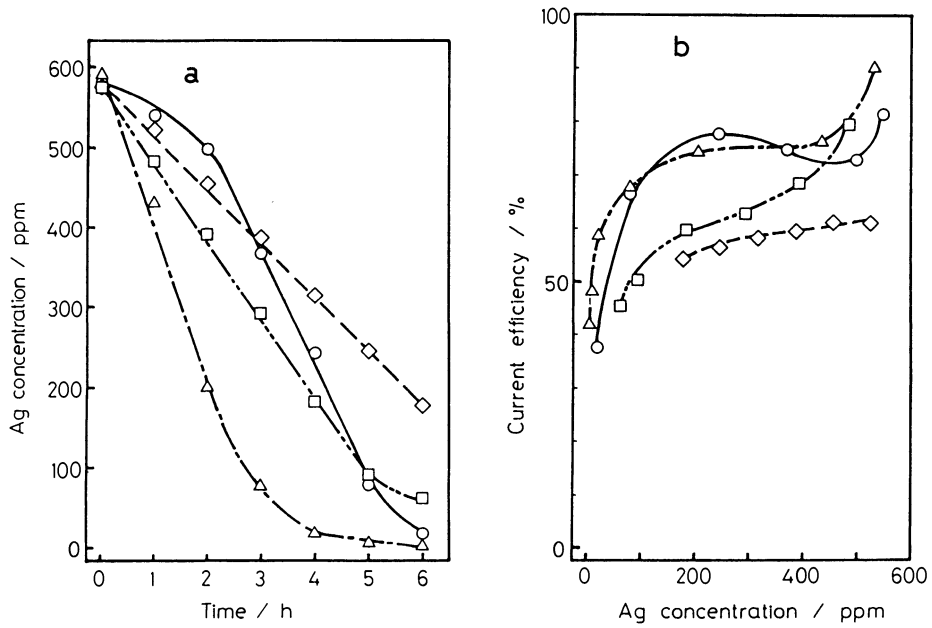

Fig. 6. (a) Change of concentration of silver ion as a function of time, and (b) current efficiency vs. concentration curves for various static bed heights at set potential of −0.84 V vs. SCE and expansion of 14%.
—○—: feeder only, —△—: 4 mm, —□—: 8 mm, —◇—: 12 mm.

diameter of the cell is enlarged from 18 mm to 26 mm, the electrolytic duration for recovery of silver became fairly short. However, the current efficiency for 26 mm was similar to that for 18 mm. In actual electrolysis, the electrolytic duration for recovery was found to be shorter as the electrode surface area is larger in the experimental range.

(II) Effect of Static Bed Height: In the cell having an inside diameter of 26 mm, the relationship between the concentration of silver ion and the electrolytic duration in various static bed heights is shown in Fig. 6(a). The current efficiency in such a run is shown in Fig. 6(b). The bed expansion rate was 14%, the initial set potential −0.84 V vs. SCE, and the solution temperature 30 °C. The electrolytic duration for recovery became shorter as the static bed height decreased. As shown in Fig. 3, the current density at less noble potential than −0.7 V vs. SCE became smaller in the order of 4, 8, and 12 mm of the bed height. Hence, the electrolytic duration for recovery was found to correspond to the result of the polarization measurement. The dependence of the electrolytic duration for recovery on the static bed height would be ascribed to the IR-drop as described previously. The electrolytic duration for recovery with the feeder electrode only was longer than that for the others with in about three hours. As seen in Fig. 3, the current density with the feeder electrode only was much smaller than that with the fluidized bed electrode. These results show that the electrolytic duration for recovery was long at the beginning of electrolysis. The value of the current efficiency decreased in the order of 4, 8, and 12 mm. However, silver sulfide was observed to produce in any bed height. Consequently, the optimum static bed height was 4 mm. The electrolytic duration for recovery of silver with the cell of inside diameter of 26 mm became shorter with decreasing static bed height resembling that obtained with the cell of inside diameter of 18 mm. Hence, the electrolytic duration for recovery was reduced as the inside diameter of the cell increased.

(III) Effect of Bed Expansion Rate: In the cell having an inside diameter of 26 mm, the relationship between the concentration of silver ion and the electrolytic duration in various bed expansion rates is shown in Fig. 7(a). The current efficiency in electrolysis with static bed height of 4 mm, set potential of −0.84 V vs. SCE, and solution temperature of 30± 0.5 °C is shown in Fig. 7(b). The electrolytic duration for recovery of silver was found to be almost independent of the bed expansion rate over the range of the experiment. Such a result would follow from the polarization curve in Fig. 4, because the current density did not change remarkably at various bed expansion rates. However, the current efficiency was optimal in a bed expansion rate of 14%. This may be ascribed to the increase of the effective surface area of the electrode, the decrease of the thickness of the diffusion layer, and the decrease of the bed resistance, as discussed above. At all bed expansion rates, H_2S and Ag_2S were observed to form as the concentration of silver ion decreased. From these results, it is concluded that the optimum bed expansion rate is 14%.

Yield of Silver. When silver deposited on active

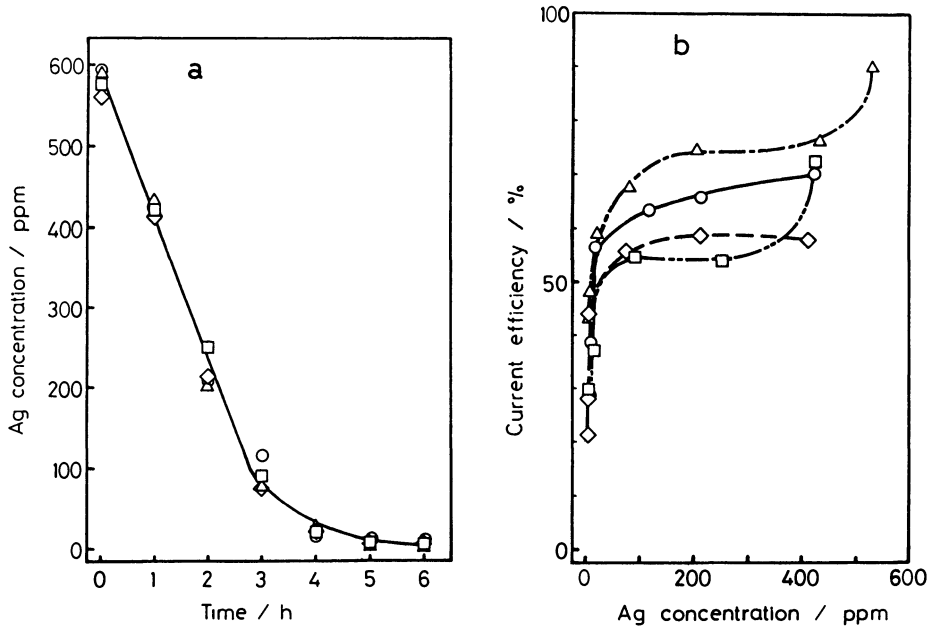

Fig. 7. (a) Change of concentration of silver ion as a function of time, and (b) current efficiency vs. concentration curves for various bed expansion rates at set potential of −0.84 V vs. SCE and bed height of 4 mm.

carbon was dissolved in 100 ml of 5M-HNO_3, the yield was about 75%. Silver of 25% could not be recovered, this may be attributed to the silver deposited inside of active carbon not being completely dissolved, and to silver isolated from the surface of the electrode as powdery Ag_2S being deposited on the inside of the pump, valve, and flowmeter.

The authors wish to thank Mr. Takashi Sugiyama for carrying out some of the experiments.

Phase Transition of *N*-Acyl Amino Acids with Different Acyl Group

Shigeyoshi MIYAGISHI,* Seiichi MATSUMURA, Tsuyoshi ASAKAWA, and Morie NISHIDA
Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kanazawa 920
(Received May 13, 1985)

The solid-liquid phase transitions of *N*-acyl amino acids with different acyl groups were investigated using a differential scanning calorimeter and an infrared spectrophotometer. The enthalpy and entropy changes of the transition increased by 3—5 kJ mol^{-1} and 8—10 J K^{-1}mol^{-1}, respectively, for an additional methylene group in *N*-acylglycine, and 7 kJ mol^{-1} and 18 J K^{-1}mol^{-1}, respectively, in the *N*-acyl-L-alanine series. The same thermodynamic quantities of *N*-acylvalines were only slightly dependend on the acyl chain length, while they varied irregularly for the *N*-acylleucine series. Both the enthalpy and entropy were smaller for the L-form than for its racemic isomer in the *N*-acylleucines (C_{12} and above) and *N*-acylvalines. The differences of the thermodynamic quantities between the L- and DL-forms seems to result mainly from the difference of the molecular packing in the solid state.

Chirality of molecules is one of the most important factors in determining the molecular packing in the solid state. For compounds with the long hydrocarbon chain, it is known that both the packing of the chains[1] and the degree of hydrogenbonding[1,2] depend on the chirality. Tachibana and his coworkers[1,3-5] found that 12-hydroxyoctadecanoic acid exhibited a chirality effect in a monolayer state, as well as in the solid state. Such chiral aggregation phenomena have often been found in monolayers,[6-10] ion aggregations,[11] micelles,[12,13] and liquid crystals.[14-16] It has also been reported that the liquid state of racemic 2-octanol differs considerably from that of the enantiomers in its physical properties.[17] Our previous paper[18] concerning the phase transition of *N*-acyl amino acids indicated that the chirality effect depended on the amino acid residue.

In the present work, the dependence of the chirality effect on an acyl group was examined with a differential scanning calorimeter and an infrared spectrophotometer.

Experimental

N-Acyl amino acids were prepared and purified according to a procedure described previously.[13,18,19] *N*-acylglycines were recrystallized from a mixture of ethanol and petroleum ether, and the other *N*-acyl amino acids were recrystallized from a mixed solvent of diethylether and petroleum ether. A differential scanning calorimeter (Daini Seikosha DSC,

model SSC/560S) was used for measurements of the transition temperatures and their enthalpies under the same conditions as described previously.[18] Infrared(IR) spectra were recorded on a JASCO A202 spectrophotometer.

Results and Discussion

Thermal Analysis. The phase-transition temperatures, enthalpies, and entropies of the *N*-acyl amino acids are given in Table 1. The table shows that several *N*-acyl amino acids undergo a transition below the melting point. No distinct correlation existed between the thermodynamic quantities of the transition and the structure of the compound. If this transition is considered as a partial melting, the total enthalpy corresponding to a change from the solid to the liquid state should be the sum of the enthalpy of fusion and the transition enthalpy. Such summation should be true also for the entropy. The total enthalpy and entropy are plotted in Figs.1—4.

The total enthalpy(ΔH) and total entropy(ΔS) increased with the length of an acyl group in the *N*-acylglycine and *N*-acyl-L-alanine series. The increment

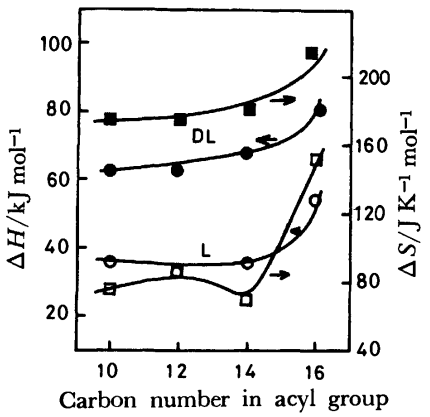

Fig. 3. Enthalpies and entropies of fusion of *N*-acylvalines.

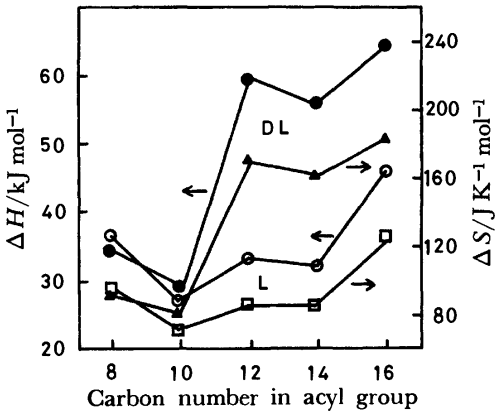

Fig. 4. Enthalpies and entropies of fusion of *N*-acylleucines.

per methylene group in ΔH and ΔS was 3—5 kJ mol^{-1} and 8—10 J K^{-1} mol^{-1}, respectively for the glycine derivatives. These figures are compatible with the corresponding values (4 kJ mol^{-1} and 9 J K^{-1} mol^{-1}) for normal paraffins,[20] monoglycerides,[21] and the racemic *N*-acylalanines.[18] The acyl groups in the monoglycerides and the racemic *N*-acylalanines were concluded to behave in the same manner as a normal alkane when they melted. Therefore, the acyl groups of the *N*-acylglycines seem to behave in the same manner as normal paraffins in regard to the phase transition.

For the L-alanine series, ΔH and ΔS increased by 7 kJ mol^{-1} and 18 J K^{-1} mol^{-1} respectively for each additional methylene group, as seen in Fig. 2. These values were abnormally large as compared with those of the racemic isomer.[18] This result implies a possibility for the acyl groups of the L-isomers to interact attractively with each other in the solid state or to do so repulsively in the liquid state.

In the *N*-acylvaline series, ΔH and ΔS increased slightly with the chain length of the acyl group (Fig. 3). The magnitude of their increments were small suggesting that the methylene chains were fusible or melted in the solid state. The change occuring in the amino acid part of the molecule may contribute to most

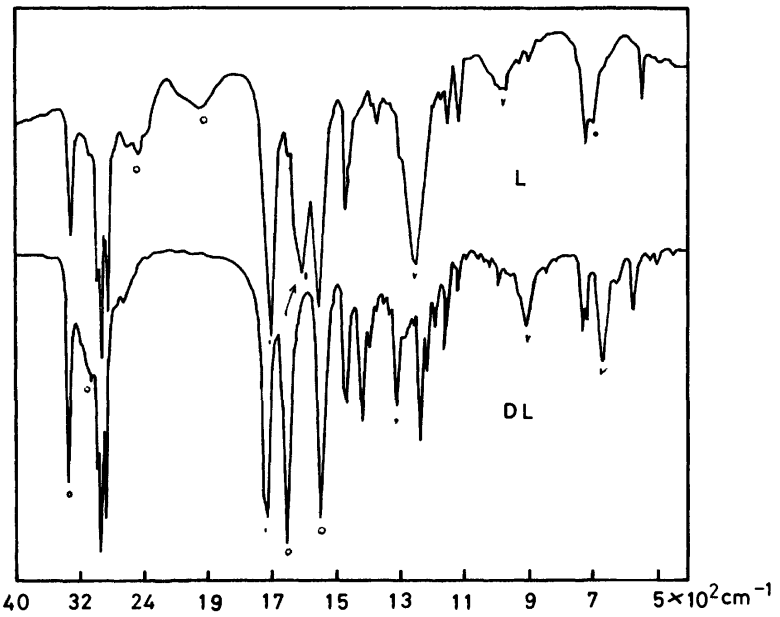

Fig. 5. IR spectra of *N*-tetradecanoyl-L-valine and -DL-valine.

of ΔH and ΔS, when the *N*-acylvalines undergo a transition from solid to liquid. The relation of the thermodynamic quantities with the acyl group was more complicated in the *N*-acylleucines. The enthalpy and the entropy varied in a zigzag form with the length of the acyl group (Fig. 4). Therefore we must consider that the acyl group and the amino acid part in the molecule interact strongly with each other when the phase transition occurs and the influence becomes larger as the molecular structure becomes more complicated.

Next we shall consider the chirality effect. In the alanine series, ΔH and ΔS increased linearly with the chain length of the acyl group, however, a difference was observed in the slope between the chiral and racemic series. For the compounds with the acyl chain shorter than a tetradecanoyl group, the racemic compounds gave larger ΔH and ΔS than the corresponding L-isomers, while *N*-hexadecanoyl-L-alanine had large values compared with its racemic isomer (Fig. 2). The differences between the values of the L- and DL-forms were smaller in the alanine series than in the valine and leucine series (as seen in Figs. 2—4).

Every racemic *N*-acylvalines gave larger ΔH and ΔS than the optically active isomers (as be seen in Fig. 3). In the *N*-acylleucine series, octanoyl and decanoyl derivatives respectively gave nearly identical values for both the chiral and racemic isomers, while the racemic derivatives with a longer acyl chain had large ΔH and ΔS compared with the chiral isomer. The experimental results indicate that if the liquid state is taken as the standard, the racemic form is thermally more stable and more ordered in the solid state than the chiral form, in the case of the *N*-acylvalines and the *N*-acylleucines (except for C_8 and C_{10}). Therefore the chirality effect depends not only on the structure of the amino acid residue but also on the chain length of the acyl group.

The specific heat of fatty acid (C_6—C_{25}) is 2.13—2.42 $J\,g^{-1}\,K^{-1}$ in the liquid state and 1.88—2.09 $J\,g^{-1}\,K^{-1}$ in the solid state,[22a] although the values of the specific heat of the *N*-acyl amino acids are not known. If the values for the *N*-acyl amino acids can be assumed to be similar to those of the fatty acids, the difference of the specific heat between the liquid and solid states is about 0.3 $J\,g^{-1}\,K^{-1}$. For the *N*-decanoyl valines (the melting point is 380.5 and 355 K for the L- and DL-forms), we get the value of 2 $kJ\,mol^{-1}$ (=0.3×(380—355)×271.4) as the enthalpy change due to the temperature difference. This value is negligibly small compared with the difference found in Fig. 3. This fact reveals that the differences between the thermodynamic quantities of the L- and DL-forms have some other origin.

IR Spectra. Information about the solid state is available from the measurement of its IR spectrum, because the spectrum is known to depend on its crystal structure. The IR spectra of the *N*-acyl amino acids were measured in KBr pellets in order to examine a difference of the solid state between the L- and DL-forms. Both the optically active and racemic *N*-acylalanines gave almost identical absorption characteristics except for the region from 600 to 700 cm^{-1}. The band at 690 cm^{-1} is ascribed to O-C=O angle deformation and the band at 640 cm^{-1} may be the C=O bending mode of the CONH group.[23] These two bands were replaced by a single band at 650 cm^{-1} in the racemic form.

Figure 5 shows that there is a significant difference between the spectra of the *N*-acyl-L-valine and -DL-valine. The strong bands at 1710, 1310, 900, and 660 cm^{-1} in the racemic form are associated with a carboxyl group.[24] The C=O stretching band at

1710 cm^{-1} and the C-OH stretching band at 1310 cm^{-1} in the racemic form shifted to 1700 and 1250 cm^{-1}, respectively, in the chiral form. The OH bending band at 900 cm^{-1} and the O-C=O angle deformation band at 680 cm^{-1} shifted to 980 and 695 cm^{-1}, respectively. On the other hand, the bands at 3310, 3100, 1650, and 1550 cm^{-1} in the DL-form are ascribed to amide A, B, I, and II bands respectively.[25] The amide A, B, and II bands are mainly associated with the N-H vibration, while the amide I band is largely a C=O stretching vibration. The amide I band at 1650 cm^{-1} in the DL-form shifted to 1600 cm^{-1} in the L-form, but the amide A, B, and II bands scarcely changed. The broad band near 3100 cm^{-1} in the racemic form was ascribed to hydrogenbonded OH vibration. The corresponding band in the L-form overlapped with the methyl and methylene stretching bands. In addition, two broad bands were observed at 1900 and 2500 cm^{-1} in the L-form.

It is well known that the hydrogenbonded OH band shifts to a lower frequency when the hydroxyl groups form multiple hydrogenbonding.[25] Furthermore the amide A and I bands shift to the low frequency direction and the amide II band to a higher frequency side when the strength of the hydrogenbonds increase owing to intermolecular association.[25] Chen and Parthasarathy[26] found from X-ray studies that short intermolecular hydrogenbonds between the carboxyl OH group and the *N*-acyl oxygen atom are an important feature for *N*-acyl amino acids and link the molecules in a head-to-tail fashion in an infinite chain. These facts suggest the following two possibilities. The small shift of the amide A, B, and II bands suggests that there is little difference in the contribution of the NH group to the hydrogenbonding between the L- and DL-forms. Some of the differences between the L- and DL-forms may result from a difference in the hydrogenbonding between the carboxyl OH group and the oxygen atom of the *N*-acyl group. However, the difference between the IR spectra seen in Fig. 5 is too large to be due to only the difference in the hydrogenbonding force. It is well known that the frequency of the amide I bands depends on the molecular conformation.[23,27,28] The authors reported in the previous paper[18] that the DL-derivatives of the *N*-acyl amino acids form racemic compounds in the solid state. Usually the IR spetrum and the crystal structure of the racemic compound differ significantly from those of the racemic mixture and the optically active isomers. We should also take into account the difference in the molecular packing between the L- and DL-forms. The optically active *N*-acyl amino acids gave different X-ray diffraction patterns from those of the racemic isomers.[29,30] The fatty acids usaully have an anti-parallel packing of the molecules in their solid states.

Therefore we assume two possibilities about the molecular packing in the L-form. The first case is the formation of a dimer or a molecular packing relatively similar to it. This dimer may be formed due to hydrogen bonding between the carboxyl OH group in one molecule and the *N*-acyl oxygen atom in the other molecule, and these molecules may be linked in an anti-parallel fashion to each other. In addition, such molecular packing can make the skeletal plane of the hydrocarbon chain parallel with its neighbors and enables us to explain a single peak at 720 cm^{-1} (see later). The second possibility is the formation of a similar bilayer structure as that found in the long chain fatty acids except for the hydrogen bonding. The hydrogenbonds in the latter case are formed between the carboxyl groups, but those in the *N*-acyl-L-valine may be formed between the carboxyl OH group and the *N*-acyl oxygen atom. In addition the bilayer structure may be linked to each other by the hydrogenbonds. In the racemic form the molecule has a different chirality from its neighbors. The valine residue group in the *N*-acylvaline may take up a trans position with respect to its NH group and thereby may prevent strong interaction between its *N*-acyl oxygen atom and the carboxyl group in its neighboring molecule compared with that in the L-from.

The IR spectrum of *N*-hexadecanoyl-L-valine was different from those of the other chiral *N*-acylvalines. Its spectrum was similar to those of the racemic derivatives in the region above 1500 cm^{-1} and was different in the regions of the methylene rocking and wagging bands. Furthermore the bands associated with the carboxyl group and the amide group had the same frequency and shape as those of the racemic isomer. *N*-Hexadecanoyl-L-valine seems to be different from the other *N*-acyl-L-valines in the solid state and to give larger thermodynamic quantities than the other (see Fig. 3). The spectra of the racemic *N*-acylvalines were almost the same as each other. This probably suggests that the racemic derivatives have closely similar crystal forms.

In the racemic *N*-acylvaline series, the methylene rocking vibration gives rise to split components at 715 and 725 cm^{-1}. In the L-forms a single rocking band which overlapped the carboxyl angle deformation band, was observed (Fig. 5). The *N*-acylglycines and *N*-acylleucines also exhibited a splitting of the methylene rocking band. On the other hand, the alanine derivatives gave a sharp single band at 720 cm^{-1} (Fig. 6). Such splitting of the methylene rocking band has been found in fatty acids,[24] normal paraffins,[31,32] 12-hydroxyoctadecanoic acid,[1] polyethylene,[33] and lithium *n*-hexadecanoate,[34] and is related to a hydrocarbon chain packing in the crystal. In the powder X-ray diffraction pattern of *N*-dodecanoyl-DL-valine,[30] the peaks at 4.11 and 3.72 A are in good agreement with those in the B- and C-forms of octadecanoic acid and the C-form dodecanoic acid, in which the methylene chain skeletal plane is nearly perpendicular to its neighbors in the orthorhombic subcell.[35]

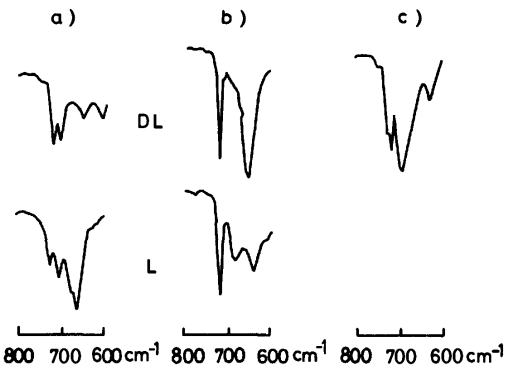

Fig. 6. Comparison of IR spectrum between L- and DL-isomers.
a) *N*-Tetradecanoylleucines, b) *N*-Tetradecanoylalanines, and c) *N*-Tetradecanoylglycine.

This agreement supports the nearly perpendicular packing of the methylene chains in *N*-dodecanoyl-DL-valine. Therefore the splitting in the methylene rocking band can be explained by such packing of the methylene chains. In its L-form, the peak corresponding to the hexagonal subcell packing of the methylene chains was not detected in the powder X-ray diffraction pattern.[30] Thus the parallel packing of the skeletal plane of the methylene chain may give the single peak at 720 cm^{-1}.

N-Octanoyl- and *N*-decanoyl-DL-leucines gave the same spectrum as those of the *N*-acyl-L-leucines. The spectra of the other racemic *N*-acylleucines differed from those of the chiral isomers. In the region above 1500 cm^{-1}, the consideration of the comparison of the L- and DL-forms in the valine derivatives was also applicable to the leucine series. In other regions, a band at 660 cm^{-1} in the L-form was replaced by two bands at 650 and 610 cm^{-1} in the DL-form, and the OH bending band at 920 and 970 cm^{-1} were replaced by a single band at 940 cm^{-1}.

The above results indicate that the *N*-acyl amino acids with large difference between the L- and DL-forms in the thermodynamic quantities also exhibit big differences in their IR spectra. The differences found in the IR spectra reflects that of the solid state, because the measurement of the spectra was done at room temperature. Analogy between the results of the thermal analysis and the spectral data indicates that the differences of the thermodynamic quantities between the L- and DL-forms result mainly from the difference of the molecular packing in the solid state.

In Situ X-Ray Observation on the Intercalation of Weak Interaction Molecules into Perovskite-Type Layered Crystals $(C_9H_{19}NH_3)_2PbI_4$ and $(C_{10}H_{21}NH_3)_2CdCl_4$

Yuri I. Dolzhenko,† Tamotsu Inabe, and Yusei Maruyama*

(Received August 5, 1985)

The intercalation-deintercalation process of weak interaction organic molecules such as 1-chloronaphthalene and *o*-dichlorobenzene into highly oriented polycrystalline $(C_{10}H_{21}NH_3)_2CdCl_4$ films and hexane into $(C_9H_{19}NH_3)_2PbI_4$ single crystals has been observed in situ by using X-ray technique. The process is highly reversible. Increasing of interlayer spacing is in reasonable agreement with the size of the intercalated molecules and corresponds to the parallel orientation of aromatic ring planes or hexane chains in between two paraffin layers of the host crystals.

Intercalation phenomena of layered compounds have been known for a long time, and a considerable variety of host lattices that can incorporate atomic or molecular guest species have been investigated, e.g. graphite, clay minerals, layered cyanides, layered dichalcogenides and so on.[1] The attention paid to these compounds began to grow significantly about fifteen years ago, when it was found that some physical properties of layered materials, for example such as superconductivity or cooperative lattice distortions, etc., can be modified significantly by intercalation.[2] On the other hand, intercalated phases show potential technological significance. Their application as reversible electrodes for high-energy-density batteries,[3] and their efficiency as heterogeneous catalysts[4] are well known.

Both academic and technological aspects of intercalation chemistry stimulate an effort to understand the structure, bonding and formation of these compounds in more detail and attempts to synthesize new layered materials and intercalation compounds with interesting structures and properties. During the past few years the range of layered compounds which can be intercalated has been extended to such materials as the almost insulating semiconductor, PbI_2,[5,6] metallic and electron donor type lattice, Ag_2F,[7] black phosphorus (which has both electron-donating and accepting potentiality),[8] and others.[1]

Possible new candidates for intercalation process studies are perovskite-type layered structures of the general formula, $(C_nH_{2n+1}NH_3)_2MCl_4$, where $M=Cu^{2+}$, Mn^{2+}, Cd^{2+}, Fe^{2+}, Pd^{2+}, Co^{2+}, or Zn^{2+}. Great interest has been shown in these compounds during the past decade since they exhibit a large variety of structural and magnetic phase transitions.[9-11] Some of these compounds, for example $(C_{10}H_{21}NH_3)_2CdCl_4$, are considered as crystalline models of lipid bilayer membranes.

In this communication, we wish to report the first brief results of organic molecules intercalation into $(C_nH_{2n+1}NH_3)_2MX_4$(X: halogen) layered materials, namely 1-chloronaphthalene (hereafter $C_{10}H_7Cl$) and *o*-dichlorobenzene ($C_6H_4Cl_2$) into $(C_{10}H_{21}NH_3)_2CdCl_4$ (C_{10}-$CdCl_4$) and hexane into $(C_9H_{19}NH_3)_2PbI_4$ (C_9-PbI_4), recently obtained by us.

Experimental

A highly oriented polycrystalline film of C_{10}-$CdCl_4$ in 0.05 mm thickness was obtained by slow cooling on the surface of a hot aqueous solution, which contains $C_{10}H_{21}NH_3$ and $CdCl_2$ in the amounts of reaction stoichiometry, acidized with a few drops of aqueous HCl solution. The film was scooped onto a glass plate and dried. The film so obtained has the same c-parameter of the lattice as that already reported for a single crystal.[10] The phase transition temperatures also correspond to the reported ones.

C_9-PbI_4 single crystals were recently synthesized in our laboratory using a silica-gel technique.[12] We believe this is the first example of $(C_nH_{2n+1}NH_3)_2MX_4$ family with M=Pb and X=I. The crystal has a dark orange square-like shape of $3\times3\times0.1$ mm^3. The details of the synthesis and complete characterization of this compound will be published elswhere soon. Here we only want to note that the C,H-chemical analysis corresponds to the assigned formula within an error of 0.05%.

By TGA it is established that in the region of 290—310 °C C_9-PbI_4 decomposes by a few steps involving melting and loses about 50% of its weight, this is in reasonable agreement with the reaction, $(C_9H_{19}NH_3)_2PbI_4 \rightarrow 2C_9H_{19}NH_3I + PbI_2$. X-Ray diffraction patterns of the remainder correspond to pure PbI_2. By optical reflectance and DSC measurements it was found that C_9-PbI_4 undergoes two phase transitions at 315 and 240 K. Under a polarizing microscope it seems that the higher temperature transition is an order-disorder one as in C_{10}-$CdCl_4$ and similar compounds. At this transition temperature the interlayer spacing changed discontinuously from 19.88 Å to 21.83 Å. The full structure determination of C_9-PbI_4 crystals is currently in progress and will be published elsewhere.

In situ X-ray analysis was carried out with the use of a Rigaku Geiger-flex Model 2027 X-ray diffractometer (with copper target). A C_9-PbI_4 single crystal of about 4 mm^2 or C_{10}-$CdCl_4$ film of approximately 5 mm^2 was mounted on a glass plate. The c-axis direction of the crystals was perpendicular to the glass surface. In the case of $C_{10}H_7Cl$, the intercalation-deintercalation process was easily observed by X-ray diffraction in the following procedure. One or two

drops of $C_{10}H_7Cl$ were dropped on the C_{10}-$CdCl_4$ film and it was kept under these conditions for about 5 min. Then, excess liquid was removed by absorbing with filter paper and the glass plate was set in the diffractometer for observation. At this stage of the procedure, $C_{10}H_7Cl$ was still continuing to intercalate into C_{10}-$CdCl_4$, but that amount of $C_{10}H_7Cl$ was enough to observe all the phases of the intercalation-deintercalation process. Deintercalation proceeded after a short time of heating.

In the case of hexane and $C_6H_4Cl_2$ in situ intercalation was carried out by vapor evaporation of the liquid impregnated in cotton mounted on the back side of the glass plate. The scanning was limited only to the region of strong reflections, i.e. $2\theta=5°$—$25°$ for C_{10}-$CdCl_4$ and $2\theta=15°$—$33°$ for C_9-PbI_4. Because of the high vapor pressure of hexane, we had to use rapid scanning and a short time-constant. In spite of that, the recorded diffractograms were highly reproducible and clear. All measurements were carried out at room temperature.

Results and Discussion

1) Intercalation into C_{10}-$CdCl_4$. According to Ref. 10, C_{10}-$CdCl_4$ consists of $[CdCl_4]^{2-}$ layers sandwiched between alkylammonium chains as is shown in a simplified form in Fig. 1 (a). The ammonium end of each chain is linked to the layer by weak hydrogen bonding, N-H····Cl.

Successive changes of X-ray diffraction patterns by exposing to $C_{10}H_7Cl$ are shown in Fig. 2. As one can easily see in Fig. 2 (a), after a 5 min exposure the intensities of the host crystal diffractions decrease remarkably and a well defined series of new (001) lines appear (marked with arrows). During the intercalation process (Fig. 2 (b), (c)), the intensities of the original lines are continuously decreasing while new ones are increasing in the same manner until full intercalation is achieved (Fig. 2 (d)). During deintercalation the diffraction patterns change inversely. The diffraction patterns for the completely $C_{10}H_7Cl$ deintercalated C_{10}-$CdCl_4$ polycrystalline film is shown in Fig. 2 (f). $C_6H_4Cl_2$ intercalation-deintercalation process for

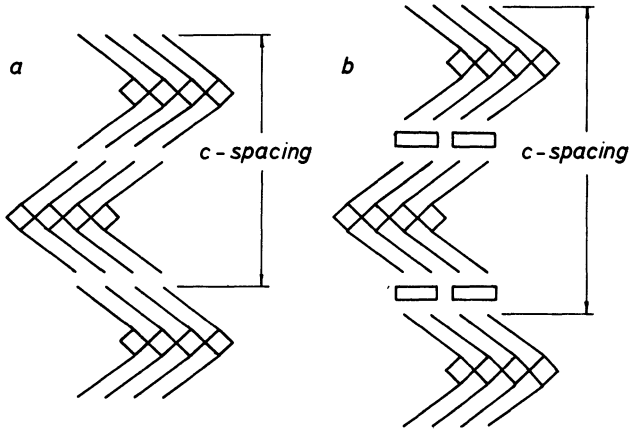

Fig. 1. Simplified schematic representation of nonintercalated (a) and intercalated (b) structures of C_{10}-$CdCl_4$.

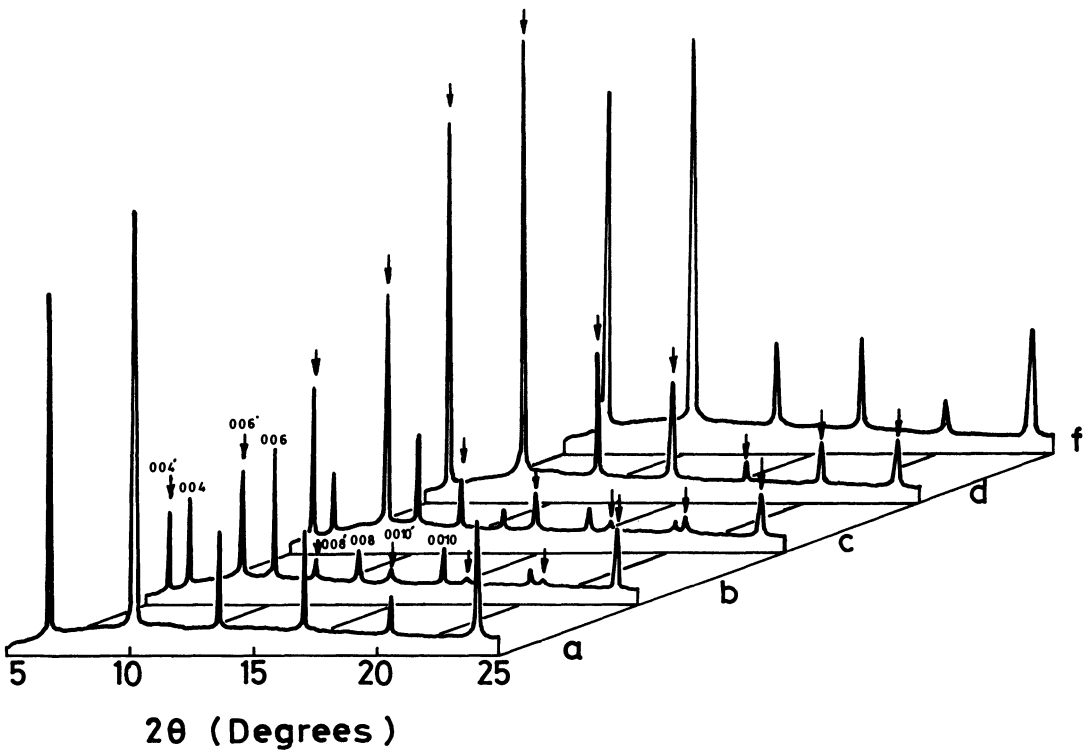

Fig. 2. X-Ray diffraction patterns of C_{10}-$CdCl_4$ during defferent phases of intercalation-deintercalation process with $C_{10}H_7Cl$. Pure C_{10}-$CdCl_4$ (a), successive phases of partially intercalated situation (b, c), fully intercalated (d), and completely deintercalated sample (f). The lines corresponding to the intercalated phases are marked with arrows. All diffraction patterns are recorded at the same sensitivity which equals to 20 kcps for the full scale.

C_{10}–$CdCl_4$ is observed in a same manner. By intercalation C_{10}–$CdCl_4$ c-spacings increased from 51.62 Å to 59.1 Å for $C_{10}H_7Cl$ and to 58.9 Å for $C_6H_4Cl_2$. In order to understand these differences and to know the exact positions of the intercalated molecules further investigations are required. The first brief results of interlayer increasing, i.e. 3.75 Å for $C_{10}H_7Cl$ and 3.65 Å for $C_6H_4Cl_2$ per one C_{10}–$CdCl_4$ layer, are in reasonable aqreement with the thickness of the aromatic rings and suggest the parallel orientation of the aromatic rings of guest molecules with the layer planes of the host crystal (Fig. 1 (b)).

The process was highly reversible. After three cycles of this procedure for the same C_{10}–$CdCl_4$ film, there was no significant change in the diffraction patterns and, surprisingly, even sharper lines were observed. For the first cycle of $C_{10}H_7Cl$ intercalation-deintercalation into C_{10}–$CdCl_4$, it took about 6 h and for the next two cycles only about 2 h. $C_6H_4Cl_2$ intercalation into C_{10}–$CdCl_4$ is remarkably faster and even for the first full cycle it required only about one hour and a half.

2) Intercalation into C_9–PbI_4. Although the full structural analysis of C_9–PbI_4 has not yet been solved, all observations of this compound suggest that C_9–PbI_4 has a similar structure to the C_{10}–$CdCl_4$ crystalline matrix in which the organic bilayers are embedded. The size of the I_6 octahedra the center of which is occupied by the Pb^{2+} ion is assumed to be the same as in PbI_2.[13] Further we suppose that for the best orientation of the N–H····I bonding, the N-atoms of the alkylammonium chains are occupying the A sites of a perovskite-type layer and lie in approximately the same plane with unshared I atoms of I_6 octahedra similarly to C_{10}–$CdCl_4$. On these assumptions the thickness of the $[PbI_4]^{2-}$ layer is estimated to be 6.45 Å and the $C_9H_{19}NH_3^+$ chain length which is rising above and below the $[PbI_4]^{2-}$ layer is calculated to be as long as 13.33 Å, based on the same assumptions as in Ref. 14. For this arrangement and taking into account that the C_9–PbI_4 interplanar spacing is as long as 19.88 Å at room temperature, we can conclude that the direction of the alkylammonium chain is tilted about 60° with respect to the normal to the octahedra layer. The following calculations are all made on these assumptions.

In the case of C_9–PbI_4 single crystals it was easy to observe the intercalation-deintercalation process. On dropping the C_9–PbI_4 crystal into hexane the color immediately changed from dark orange to yellow, and it turned back to original color after removing the crystal from the hexane. Deintercalated crystals have a slightly deformed shape, but do not lose their integrity even after keeping for one week in hexane, and they do not lose their weight during prolonged washing on a filter with hexane.

By watching with the naked eye or a polarizing microscope it is possible to observe the introduction of such solvents as hexane, benzene, dichloromethane, dichlorobenzene, chloronaphthalene or any other soft enough solvents from the view point of intermolecular interactions. In the case of more polar and/or potentially H-bonding solvents such as tetrahydrofuran, ethanol, acetone, we observed solvation but not molecular inclusion. In the case of the introduction of $C_{10}H_7Cl$ or $C_6H_4Cl_2$, we could observe only a decrease in the intensities of the host crystal diffraction lines and disordered pattern. No lines corresponding to a new interlayer spacing appeared. Only with such a weak solvent as hexane and with fresh C_9–PbI_4 single crystals could we observe new interlayer spacings clearly and unambiguously. These results are represented in Fig. 3. The first X-ray scanning started at about 10 s after exposing the crystal to hexane vapor (Fig. 3 (b)). The

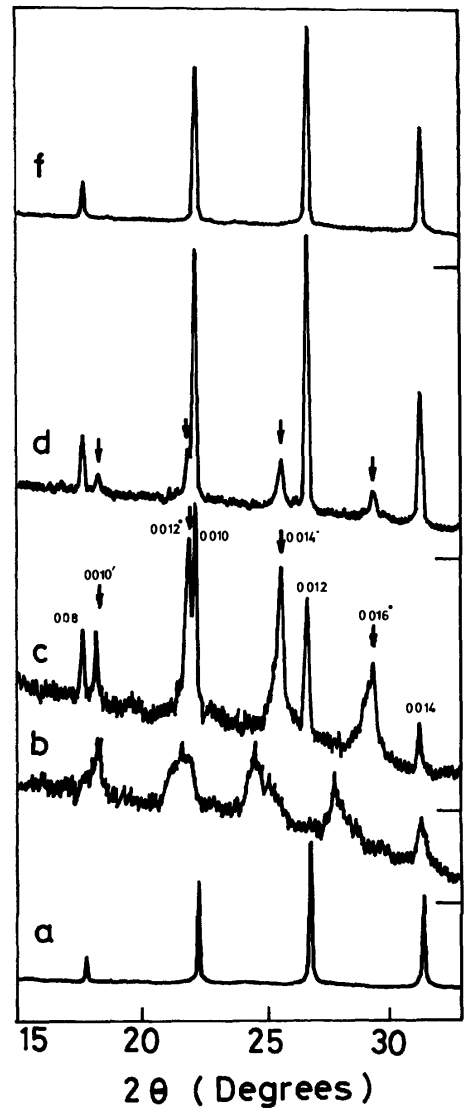

Fig. 3. X-Ray diffraction patterns of C_9–PbI_4 during different phases of hexane intercalation-deintercalation process. The lines corresponding to the intercalated phases are marked with arrows. X-Ray diffractometer full scale sensitivities correspond to 40 kcps for (a), 4 kcps for (b, c), 10 kcps for (d), and 20 kcps for (f).

diffracted patterns consist of a group of diffuse lines. We did not try to index these lines because of the nonequilibrium situation and the co-existence of multistates in this scanning. From this result we can presume only one conclusion, that the hexane intercalation into C_9-PbI_4 crystal passes through rather highly disordered states with some average interlayer spacings. On the contrary, for the next scanning (Fig. 3 (c)) the starting point was ≈5 min after the process had begun and it is clearly to be seen that these are two series of diffraction lines. One series corresponds to the host C_9-PbI_4 interlayer spacing pattern with decreased intensities, while other lines (marked with arrows) correspond to an interlayer spacing as long as 24.27 Å, or in other words a 4.36 Å increase per one C_9-PbI_4 layer. This value is reasonably close to the paraffinic chain diameter and suggests the parallel orientation of hexane chains with respect to the host crystal layers.

For the next scanning (Fig. 3 (d)), the intensities of the host crystal lines are increassing while the intensities of the new series of lines are decreasing and a completely deintercalated picture occurs after one hour (Fig. 3 (f)).

It is not impossible to observe the second cycle of hexane intercalation-deintercalation into C_9-PbI_4, but the recorded diffraction patterns become diffuse and not so clear due to the much more rapid rate of the process and a tendency to disordering.

3) General Discussion. The process we observed seems similar to the already reported results of organic molecules inclusion into paraffin layers of nickel cyanide-normal alkylamine layered systems.[15,16] However, there is a clearly distinguishable difference between these cases. In the reported case, no sharp dependence of the interlayer spacing on the amount or size of the excessively introduced amines was observed. Matsunaga clearly observed new interlayer spacings, but they did not correspond to the size of the excessively introduced molecules.[16] In our investigation all observed interlayer spacings are very clearly defined and in reasonable agreement with the size of the intercalated molecules.

As we interpret it, the main reason for such a difference between the observed processes lies in our host material structures. In their case only one layer of normal alkylamine molecules exists in between two crystalline nickel cyanide layers. Accordingly excessively introduced organic molecules penetrate inside the paraffin layer with changing of the packing coefficient of the amine molecules.[16] This pocess seems like a two-dimensional solvation with respect to the paraffin layers, or solvated intercalation with respect to the nickel cyanide layers.[17] In our cases of C_{10}-$CdCl_4$ and C_9-PbI_4 the crystals consist of organic bilayers in between two $[MX_4]^{2-}$ layers. In this case organic molecules presumably penetrate not inside but in between the alkylammonium layers retaining the full structure of C_{10}-$CdCl_4$ or C_9-PbI_4 layers perfectly unchanged. This behavior as well as reversibility are the main requirements for the exact definition of intercalation (see, for example, Ref. 17).

We believe that the existence of organic bilayers and the softness or weakness in view of intermolecular interaction forces of introduced organic molecules are the main reasons for the existence of the observed intercalation without breaking the host crystal framework structure. To our knowledge this type of introduction of molecules is reported here for the first time.

If we combine the results obtained here and reported before,[15,16] it is possible to imagine three steps of interaction processes for such layered materials and organic solvents. (i) For strong host matrixes and weak interaction guest molecules—intercalation with clearly defined new interlayer spacings corresponding to the size of the guest molecules. (ii) An intermediate situation with molecular inclusion inside paraffin layers. (iii) For weak matrixes and strong solvents-solvation leading to homogeneous solutions, for example, C_9-PbI_4 solvation in tetrahydrofuran and so on.

We belive that each member of the $(C_nH_{2n+1}NH_3)_2MX_4$ family can be intercalated with appropriate organic solvents. Moreover, we cannot exclude the possibility for similar process as secondary intercalation of long amine intercalated transition metal dichalcogenides in which an amine bilayer structure is present.

Finally, we want to note that it is difficult to imagine any charge transfer especially in the case of hexane intercalation. Thus, we believe that we really observe pure van der Waals intercalation.

We want to thank Prof. M. Sato for useful discussion. This work was done during a stay of Y. I. Dolzhenko at the Institute for Molecular Science. He would like to express his thanks to the Authorities of IMS of Okazaki National Institutes and special thanks to his host scientist Prof. Y. Maruyama for the possibility to pursue this work.

Nanosecond Laser Photolysis of *N*-Methylindole in Acetonitrile

Nobuaki KANAMARU and Jiro TANAKA
Department of Chemistry, Faculty of Science, Nagoya University, Furo-cho, Chikusa-ku, Nagoya, Aichi 464
(Received August 19, 1985)

Nanosecond laser photolysis (nslp) of *N*-methylindole (NMI) was investigated using XeCl laser (308 nm) so that excitation is performed at the red edge of the first absorption band. At least three transient absorptions were observed i.e. those to be ascribed to $S_n \leftarrow S_1$, $T_n \leftarrow T_1$ transitions and ion-pair like species with peaks at ≈ 700 nm, ≈ 460 nm, and ≈ 380 nm, respectively. The transient absorptions were found to be produced by monophotonic processes. The lifetimes of the triplet state and the ion pair were determined to be ≈ 3.1 μs and ≈ 29 μs, respectively, in degassed solutions. Transient photoconductivity (tpc) measured on the same system indicated that there are both rise and decay components. Its fastest decay component of ≈26 μs is close to that of the transient absorption ascribed to the ion pair. This result provides another example of monophotonic electron ejection through fluorescent states of aromatic amines in polar solvents, such as, acetonitrile.

Potophysics and photochemistry (especially photoionization) of indole and its derivatives including tryptophan have been the subjects of intensive research. As for photophysics, the nature of fluorescent states in polar solvents has been discussed by many people and recent consensus on assignment is to an ^1L_a/CT state,[1] where a CTTS (charge transfer to solvent) state[2-4] seems to be involved. This seems to be related to a red edge excitation effect[5] in photophysical behaviors which indicates a strong interaction of a solute molecule with solvent molecules in the excited states. Although phenomena of this kind are usually interpreted by a solvent cage effect,[5,6] possible contribution of the CTTS state[2] cannot be neglected. As for photochemistry, photoionization i.e., electron ejection from indoles to the solvent, was of a great concern. This phenomenon has partly been connected with biological interests.[7]

In this labolatory, photoionization mechanisms of aromatic amines in polar solvents such as acetonitrile (AN) have been studied for years.[8] In the case of 8-anilino-1-naphthalenesulfonate (1,8-ANS), a biphotonic ionization mechanism was elucidated where the CTTS state is suggested to be an intermediate state.[9] In case of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) in acetonitrile (AN), a monophotonic ionization through a fluorescent level was confirmed where a major product is an ion pair between $TMPD^+$ and AN^-.[10] The latter conclusion is made on the basis of the following three kinds of experiments: fluorescence lifetime measurements (including solvent and temperature effects), ns and ps laser photolysis (nslp and pslp), and the transient photoconductivity measurements.

Recently, there are several publications concerning the monophotonic ionization of aromatic amines in polar solvents. Nogami et al.[11] have studied monophotonic ionization of *N,N,N′,N′*-tetramethyl-1,6-pyrenediamine (TM-1,6-PDA) in acetonitrile by nslp and tpc measurements, and therefrom, proposed the existence of a long-lived ion pair based on the slow rise time (several μs) of photocurrent, in spite of the rapid (≲50 ns) appearence of a cation-like absorption. Hirata et al.[12] did more detailed experiments on the acetonitrile solution of bis(dimethylamino)tetrahydropyrene (BDATP) by using a ps laser. In this case, the rise time of cation-like absorption was found to be ≈2 ns in agreement with the lifetime of fluorescence, while the rise time of photocurrent was found to be ≈9 ns. Thus, monophotonic ionization from fluorescent level through an ion-pair state was proposed. Experiments on *N,N,N′,N′*-tetramethylbenzidine (TMB) were also performed by Hirata et al.[13] In this case, the lifetime of the ion pair was ≈ 4.5 μs. The same group[14] also published the results on TMPD in acetonitrile which gave almost the same data as ours[10] but with some different interpretations.

The photophysical and photochemical schemes proposed in the studies mentioned in the above two paragraphs were not conclusive, e.g., as regards to the mechanism of the ion-pair formation. For instance, in comparing the time dependence of photocurrents with that of transient absorptions, the heterogeneity of the electrode reactions had to be taken into account, i.e., the mobilities of the charge carriers and also the electrode potential working on the ion pair.[10] As for the transient photoconductivity in polar solvents, no established theory is available in contrast to the case of nonpolar solvents.[15]

The aim of the present study is to add more data on this subject so that a clearer identification of the ion pair could be made. A new aspect is that the molecules are excited at the red edge of the 0, 0 band of NMI. Since a fluorescent level is directly excited, a possible mechanism of direct monophotonic ionization before vibrational relaxation may be eliminated.

Experimental

Apparatus and Procedure. The experimental methods of nslp are practically the same as those described in the previous paper[10] except for the fact that a XeCl laser (Lumonics TE 430-2, λ=308 nm and τ=≈ 8 ns, used at ≈ 20 mJ output) replaced a N_2 laser. In case of tpc the size of electrodes was 5×5 mm^2, the separation between them being 2 mm, so that a wider area was illuminated to avoid a biphotonic ionization due to a strong laser light. A 5.1 kΩ

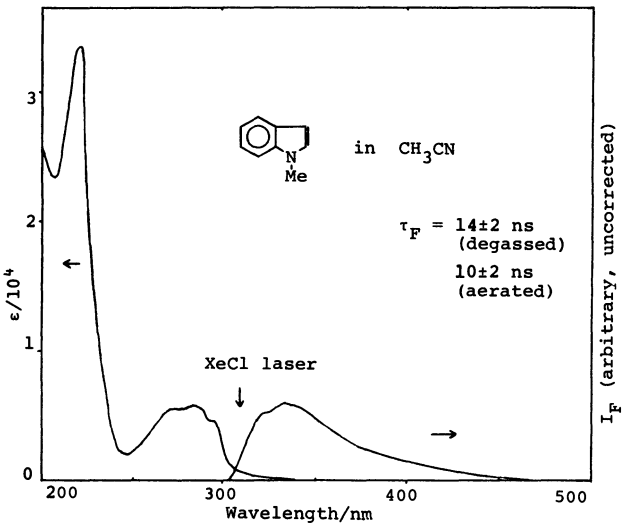

Fig. 1. Absorption and fluorescence spectra of *N*-methylindole in acetonitrile.

termination had to be used because of a small current yield. This caused ≈ 0.5 μs rise time of the system. All the experiments were done at ≈ 25 °C.

Materials. NMI purchased from Tokyo Kasei was vacuum distilled. Spectrograde acetonitrile from Nakarai Chem. was used without further purification.

Results and Discussion

Absorption and Fluorescence. Figure 1 shows the absorption and fluorescence spectra of NMI in acetonitrile. The first peak at ≈ 295 nm is ascribed to the 0, 0 band of the S_1 (^1L_b)←S_0 transition,[1] while the fluorescence is ascribed to the S_1'(^1L_a/CT)→S_0 transition.[1] Also shown in the figure is the location of excitation by the laser which is exactly at the red edge of the first absorption band. Namely, only molecules which are in the solvent cages similar to those of the emitting levels S_1'(^1L_a/CT) are selected by the laser light. Therefore, practically no vibrational relaxation, and little solute-solvent relaxation is required for the optically prepared excited state to reach the fluorescent state. The fluorescence lifetimes in the degassed and aerated solutions were determined to be τ_F°=14±2 ns and τ_F=10±2 ns, respectively. The difference is ascribed to the diffusion-controlled quenching of the fluorescing S_1' state by oxygen: $k_q \approx 10^{10}M^{-1}s^{-1}$ by $k_q[O_2]$=$(k_F+k_{nr}+k_q[O_2])-(k_F+k_{nr})=1/\tau_F-1/\tau_F^\circ=1/(10\times10^{-9})-1/(14\times10^{-9}) \approx 3\times10^7$ (s^{-1}) with [O_2] assumed to be $\approx10^{-3}$ M[1] (The solubility data is not available for the AN solution.). Here, k_F and k_{nr}, respectively, are the radiative and nonradiative decay rates of the S_1' state.

Nanosecond Laser Photolysis. Typical result of nslp on the degassed solution of NMI (6.5×10^{-3}M) is shown in Fig. 2. Time-resolved spectra at t=0, 50 ns and 0.1, 0.5, 4, 16 μs after laser excitation are given by dashed lines in the figure. The shorter-wavelength portions (≤610 and ≤410 nm) of the spectra at t=0 and 50 ns are not available due to interference by the scattered light mainly of fluorescence. The decay curve at each wavelength was represented by the sum of three exponential curves from which "component" spectra i.e., pre-exponential factors, A_s, A_m, and A_ℓ as functions of wavelengths were obtained as shown by the solid lines in the figure with lifetimes τ_s, τ_m, and τ_ℓ, respectively. The component spectra A_m and A_ℓ are similar to those of T_n←T_1 absorptions and of the cation radicals of indole derivatives, respectively, given in the literatures.[3,7,16] Therefore, the former is safely ascribed to the T_1 state of NMI, while the latter is ascribed to the ion pair between NMI^+ and AN^- rather than a free NMI^+, because its decay is described almost by a single-exponential curve. Oxygen effects are also explained by these assignments. The lifetime of the short-lived component has a wide distribution around the mean value of 40 ns compared to the other two, with the minimum value corresponding to the fluorescence lifetime. This fact indicates the existence of species other than S_1' state of NMI. A possible candidate for this species might be (free) AN^-[17] as in the case of TMPD.[10] However, the spectral shapes of the short-lived components could not be determined uniquely, so that any decisive assignment is not presented. Therefore, the spectra at 0 ns may be regarded as the sum of $S_n^{(\prime)}$←S_1' absorption and that of the other species, and the A_s spectra should be taken as a difference spectrum between those of before and after decay of the short-lived species.

The transient absorption intensity depends upon the intensity of the laser (I_{exc}): The plots at the wavelengths and times where the absorbance (A) exceeds 0.01, showed that A is proportional to I_{exc} in the region of $0.2\times I_{max} \leq I_{exc} \leq 0.7\times I_{max}$($I_{max}$≈20 mJ), while for $I_{exc}>0.7\times I_{max}$, a saturation effect was observed. However, the spectral shapes and the shapes of the decay curves did not depend on I_{exc}. Therefore, all the species observed can be safely regarded to be produced monophotonically. Generally speaking, even if $A \propto I_{exc}$, under the condition that the molar absorption coefficient (ε) at the exciting wavelength of the sample is very small (in this case $\varepsilon<10^3$ at 308 nm) we can not completely deny the possibility of a biphotonic process if ε of a possible intermediate for the process is very large. However, assignment to the ion pair instead of NMI^+ would rule out this possibility, because no report is available which indicates the biphotonic formation of an ion pair through the S_1 state.

The effect of aeration on the same solution was observed as that shown in Fig. 3. The presentation is practically the same as that in Fig. 2. Comparison of the components between Figs. 2 and 3 indicate that apparently the yields of the major species (S_1' and T_1 states and the ion pair) are not influenced by the introduction of air (oxygen) and only lifetimes are shortened by O_2. Small changes in the yields may not be

[1] 1 M=1 mol dm^{-3}.

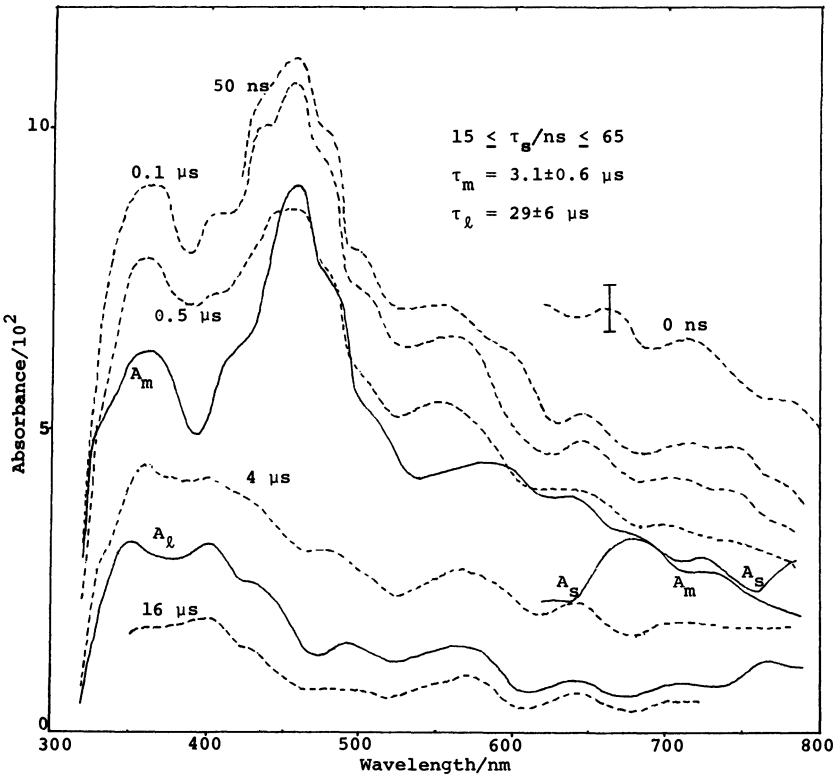

Fig. 2. Nanosecond laser photolysis of a degassed acetonitrile solution (6.5×10^{-3} M) of *N*-methylindole: Time-resolved and decomposed spectra.

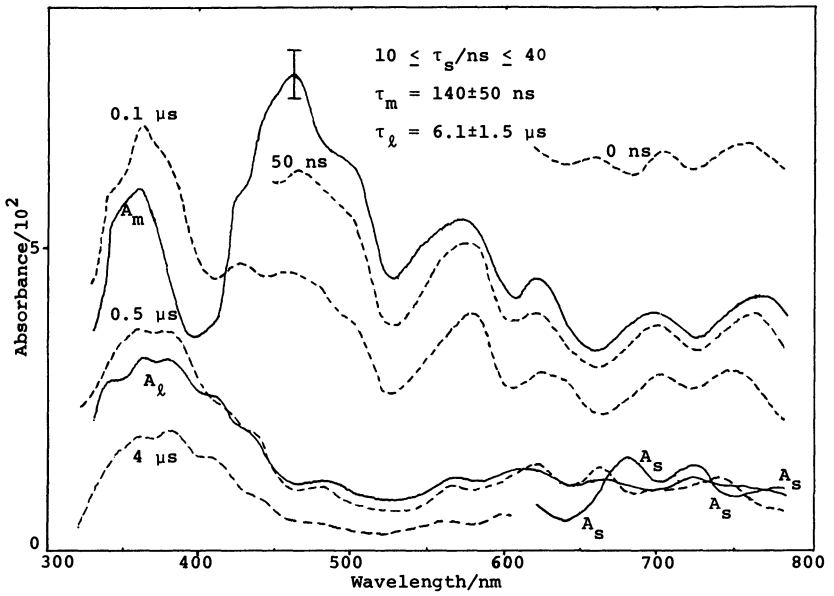

Fig. 3. Nanosecond laser photolysis of an aerated acetonitrile solution (6.5×10^{-3} M) of *N*-methylindole: Time-resolved and decomposed spectra.

consistent with fluorescence-lifetime shortening by oxygen. This fact, however, is rationalized if we assume that both intersystem-crossing and electron-ejection rates increased to the same extent (≈40%). Namely, the ion pair formed in the aerated solution might be due to the ion pair between NMI^+ and O_2^- possibly formed through an exciplex, $NMI^+\cdots O_2^-$ rather than that between NMI^+ and AN^-. There are some discrepancies between the two figures in the wavelength region of $\lambda>500$ nm. These may be interpreted by assuming another component with a lifetime of ≈ 100 ns in the case of the aerated solution. However, a spectral shape for this component is difficult to be determined uniquely because its lifetime is very close to that of the triplet state. The decreased lifetime of the short-lived component is interpreted as (diffusion-controlled)

Table 1. Time Behavior of Photoconductivity of 2×10^{-3} M NMI in N_2 Bubbled and Aerated(in Parenthesis) Acetonitrile Solutions, Respectively

	r	d_1	d_2	d_3
τ_j/μs	1.6±0.3	26±5	400±100	$>10^3$
	(1.3±0.3)	(8±2)	(180±40)	($>10^3$)
$i_j^\circ/\sum_k i_{d_k}^\circ$	−1.00±0.10	0.60±0.10	0.12±0.02	0.28±0.06
	(−0.95±0.10)	(0.60±0.10)	(0.15±0.03)	(0.25±0.05)

quenching of the S_1' state (vide supra) and another species like AN^- by oxygen. The quenching rate of the T_1 state, $k_q'[O_2]=(k_{nr}'+k_q'[O_2])-k_{nr}'=1/\tau_m-1/\tau_m^\circ=1/(140\times10^{-9})-1/(3.1\times10^{-6})=7\times10^6$ (s^{-1}) is just reasonable. Here $\tau_m^\circ=1/k_{nr}'$ is an intrinsic lifetime of the T_1 state. The decay rate of the long-lived component can be interpreted by two alternative schemes or their compromises (e.g. by assuming an equilibrium between them); (1) as the decay rate $k_d=1/\tau_\ell\approx1.6\times10^5$ (s^{-1}) of the ion pair, $NMI^+\cdots O_2^-$, or (2) by the quenching rate, k_q'' of $NMI^+\cdots AN^-$ by oxygen with $k_q''[O_2]=1/\tau_\ell-1/\tau_\ell^\circ=1/(6.1\times10^{-6})-1/(29\times10^{-6})\approx1.3\times10^5$ (s^{-1}). Both these numbers are not unusual for these processes. Although quenching (lifetime shortening) of the ion pairs by oxygen was not clearly demonstrated for the other systems,[11-14] nslp experiments on aminonaphthalenes (naphthalenamines and naphthalenediamines)[18] and *N,N,N',N'*-tetramethyl-2,7-pyrenediamine[19] done in this laboratory presented similar results.

Transient Photoconductivity. In order to obtain more and complementary informations on the scheme, transient photoconductivity was measured for the nitrogen-bubbled and air-saturated acetonitrile solutions of NMI. Its time profile was analyzed as a sum of one or two exponential rise and three exponential decay curves:

$$i_p(t)=\sum_j i_j^\circ e^{-t/\tau_j};\ \{j\}=(c, r, d_1, d_2, d_3).$$

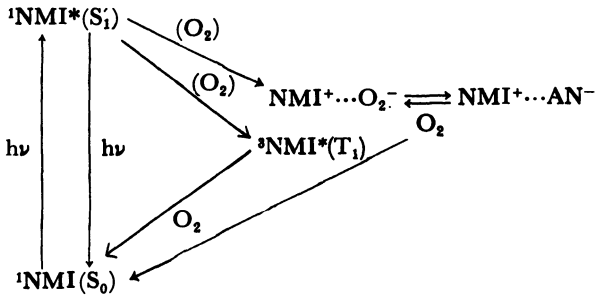
Here, τ_c corresponds to the time constant of the detection system ($\approx$ 0.5 μs). i_p values were proportional to I_{exc} in the region $0.2\times I_{max}\lesssim I_{exc}\lesssim I_{max}$ indicating that the chemical species responsible for the photoconductivity is ascribed to that formed by a monophotonic process. The yield of photocurrent i.e., that of the radicals was estimated to be $\Phi_i\approx0.05$ which is more than one order of magnitude lower than that of TMPD ($\Phi_i\approx0.8$), but comparison was not easy due to large difference and a possible contribution of the biphotonic process in the latter case. The photocurrent yields were almost the same for the nitrogen-bubbled and air-saturated solutions. i_j°, normalized for $i_{d_1}^\circ+i_{d_2}^\circ+i_{d_3}^\circ\equiv1$, and τ_j values for $j=r$, d_1, d_2, and d_3 are given in Table 1, while $i_c^\circ=1-i_r^\circ$ with $\tau_c=0.5$ μs. Since the analysis was made by assuming the sum of five (or four) exponential functions (no deconvolution was made), the actual τ_r values are expected to be slightly less than those given in the table but definitely more than τ_c. This kind of facts have been usually taken as evidences of the ion pairs formed by photo-irradiation and then dissociated with time constants τ_r's (The process with τ_r was not found in nslp experiments and it has been explained by a resemblance of the spectra of the cation and the ion pair.).[11-13] If we apply the above judgement to the present system, the decay portion of the photoconductivity has to be ascribed to the decay behaviors of free ionic species such as NMI^+, AN^-, and some scavengers' anions (X_i^-). However, we regard the process with τ_r rather as the evidence of the formation of the ion pair which dissociates at electrode surfaces by the applied field: The major decay portion of the photoconductivity is governed by the decay of the ion pair existing in the liquid phase which is the origin of the transient absorption in the nslp experiment. This assessment is supported by the following facts: (1) Long-lived (with O_2 effect) transient species (identified to the ion pair) were observed in both nslp (nearly single exponential τ_ℓ component) and tpc (non-exponential but $\tau_{d_1}\sim\tau_\ell$) experiments. (2) Rises (τ_r) were observed in the case of tpc [correspondent to the dissociation rate(s) of the ion pair at the electrode(s) ($1/\tau_r$) which is larger than the intrinsic decay rate of the ion pair ($1/\tau_\ell$)]. (3) The yield of the ion pair $\Phi_{i.p.}$ is estimated to be $\approx$0.1 by this assessment from $\Phi_i\approx0.05$ which is consistent with $\Phi_{i.p.}\approx0.2$ as is estimated from nslp data assuming $\varepsilon_{TT}\approx\varepsilon_{i.p.}$ and $\Phi_F\approx0.1$. (4) Therefore, the longer-lived portion of tpc (τ_{d_2} and τ_{d_3}) has to be ascribed to the heterogeneity of the tpc experiment, i.e., differences in the diffusion rates of the ionic species (freed at the electrodes) and so on.

The above judgement underscores the need of careful examinations of the complementary experimental data of nslp and tpc experiments for elucidating the photoionization mechanisms including ion pairs.

Since presence of the ion pair as a unique chemical species is well established, some comments will be added on the results of TMPD photolysis in acetonitrile solutions[10] which have some differences from those of the present system: (1) The 0.7 μs decay component in the transient photoconductivity ascribed to free $TMPD^+$ is absent in the transient absorption. This fact can be interpreted by assuming that the charge of AN^- taken at the anode is compensated by the $TMPD^+$ arrived at the cathode with the time constant of 0.7 μs. (2) The decrease in the photocurrent corresponding to the ion pair by aeration can be easily explained if we assume that an ion pair with O_2 is formed which

may be less dissociative at the electrodes. This kind of O_2 effect was not observed for NMI solutions because dissociation of $NMI^+\cdots AN^-$ is less feasible ($\tau_r \lesssim 1.6\,\mu s$) than that of $TMPD^+\cdots AN^-$ ($\tau_r < 10$ ns).

In concluding this paper, one candidate for the scheme of the aerated system is given below:



The scheme for the oxygen-free system is almost obvious.

(Received August 24, 1985)

X-Ray absorption spectra of the sulfur K-edges of SO_4^{2-}, SO_3^{2-}, $S_2O_3^{2-}$, and $S_2O_x^{2-}$ (x=5—8) were measured with synchrotron radiation. The spectra show similarly strong absorption bands which originate in bound-state transitions to antibonding 3p-type orbitals and in shape resonances related to 3d-type orbitals. The K-edge spectrum for the terminal sulfur atom in $S_2O_3^{2-}$, however, shows only a bound-state transition. Differences in chemical environments and bonding around the X-ray absorbing atoms are discussed to interpret the spectra.

K- and L-shell X-ray absorption spectra for molecules such as SO_4^{2-},[1] SF_6,[1,2] and SiF_4,[3] where electronegative ligand atoms surround a central atom, show resonance-like bands below and above the ionization threshold and quite weak Rydberg series. Nefedov[4] and Dehmer[5] first introduced the concept of effective potential barrier in interpreting X-ray absorption spectra of molecules in which a B, S, or Si atom is bonded with two or more electronegative atoms. When an excited electron is within the cage of electronegative atoms near an electropositive atom, the electron experiences net attraction due to the partially screened nucleus of the central atom; when an excited electron is at a long distance, the electron undergoes only the Coulomb attraction by the molecular ion. At intermediate distances the potential constitutes a barrier due to electronegative atoms located there. The barrier in this case is primarily a pseudopotential barrier rather than the centrifugal barrier which is known in context with high angular momentum states of atoms[6] and molecules.[7] The effective potential barrier separates excited states into outer- and inner-well states. In the inner-well region, there exist bound and quasi-bound states below and above the ionization threshold, respectively. Transitions to inner-well states are of strong tendency to occur because of the large overlap between the wavefunctions of the initial and final states. On the other hand, Rydberg transitions are considerably or completely suppressed because Rydberg orbitals are in the outer-well region.

The effective potential barrier is only a qualitative concept and is not a rigorously physical model. Recently, the orgin of the resonance-like absorption near the inner-shell ionization threshold is interpreted in terms of shape resonance[7] or multiple-scattering resonance[8] within the framework of a rigorous theory of potential scattering. The molecular orbital theory is also powerful for predicting the energy position and transition probability of quasibound-state resonances as well as bound-state resonances.[3,9] In all cases, the chemical environment and bonding around an X-ray absorbing atom contribute dominantly to the origin of resonances.

Ion SO_4^{2-} is a typical cage-like molecule and its inner shell absorption spectra have been studied both experimentally[1] and theoretically.[5,10] There exist various kinds of stable sulfur-containing oxyanions. It is thus interesting to measure X-ray absorption spectra of several derivatives of SO_4^{2-} and to investigate how the deformation of the cage-like structure with T_d symmetry can be reflected on absorption spectra. Relative to SO_4^{2-}, SO_3^{2-} can be regarded as a one-ligand-free ion and $S_2O_3^{2-}$ as a one-ligand-exchange ion.

In the present work, we measured sulfur K-edge absorption spectra for SO_4^{2-}, SO_3^{2-}, and $S_2O_3^{2-}$ as well as their S 2p XPS spectra and interpret the ligand effect on resonance-like bands; i.e., transitions to bound and quasi-bound states. Furthermore, we measured absorption spectra for $S_2O_x^{2-}$ (x=5—8) and analyse them by comparison with spectra for SO_4^{2-}, SO_3^{2-}, and $S_2O_3^{2-}$.

Experimental

All samples for measurements were polycrystalline powders of sodium salts: Na_2SO_3, Na_2SO_4, $Na_2S_2O_3$, $Na_2S_2O_5$, $Na_2S_2O_6\cdot 2H_2O$, $Na_2S_2O_7$, and $Na_2S_2O_8$. They were obtained from Wako Pure Chemical Industry Co. and were not purified any further. The sample of $Na_2S_2O_7$ contained ≈10% $NaHSO_4$.

Sulfur K-edge absorption spectra were measured with a UHV compatible double crystal monochromator[11] at the Soft X-Ray Station (BL-11B) of the Photon Factory in the National Laboratory for High Energy Physics. Ge(111) was used as a monochromatizing crystal and its energy resolution was about 1 eV around the sulfur K-edge (≈2.5 KeV). Absorption spectra were obtained by collecting total electrons from the samples, which had been coated on oxidized aluminium plates. The photon energy was calibrated with the first intense peak (2469.8 eV) in the sulfur K-edge absorption spectrum of NiS powder.[12]

Sulfur 2p XPS spectra were measured with a laboratory ESCA spectrometer VG ESCALAB. Mg $K\alpha$ line (1253.6 eV) was used as an excitation source. Samples coated on scotch tape were used. Binding energies of spectra were calibrated with the Au $4f_{7/2}$ peak (83.8 eV) from gold evaporated on samples.

Results and Discussion

SO_4^{2-} and SO_3^{2-}. In the absorption spectrum for Na_2SO_4 shown in Fig. 1, there exist an intense peak (indicated as A) and two broad bands (indicated as B and C). Nefedov and Fomichev[1] also measured the sulfur K- and $L_{2,3}$-edge absorption spectra for Na_2SO_4. But the K-edge spectrum for SO_4^{2-} obtained in the present work shows a much better resolution than that by Nefedov and Fomichev.[1] Ion SO_4^{2-} belongs to the T_d point group, and there are two unoccupied valence (antibonding) orbitals, a_1^* of 3s character and t_2^* of 3p character; the intense peak A is assigned not to S 1s-a_1^* (dipole forbidden) but to S 1s-t_2^* dipole allowed transition. Following previous investigations,[1,2,5] the K- and $L_{2,3}$-shell absorption spectra can be placed on a common relative energy scale referenced to the location of respective inner-shell ionization potentials. Based on Dehmer's interpretation of the $L_{2,3}$ spectrum for ion SO_4^{2-} [5] and on the theoretical interpretation of the Si K-edge absorption spectrum for the isoelectronic molecule SiF_4 (cited in Ref. 3), the peaks B and C in the K spectrum for SO_4^{2-} shown in Fig. 1 are transitions to 3d-like e* and t_2^* orbitals, respectively. In the T_d symmetry, however, the e* orbital does not have a p component and peak B cannot be assigned only to a 1s-e* transition. We should appreciate a contribution from a 1s-t_2^* transition to peak B. Thus, it is necessary to reinterpret the origin of peak C as well as peak B.

The spectrum for Na_2SO_3 is also shown in Fig. 1. Ion SO_3^{2-} has a trigonal-pyramidal C_{3v} structure with a sulfur atom at the apex. There are two valence-type unoccupied orbitals: e* of $3p\pi$ character and a_1^* of 3s and $3p\sigma$ character. Transitions from S 1s to these orbitals are both dipole-allowed; the most intense peak indicated as A can be assigned to a transition to the e* valence orbital and the second peak B to a transition to the a_1^* orbital. Furthermore, there are one a_1^* and two e* orbitals of 3d character. The a_1^* orbital of 3d character with a large contribution from 3p is directed toward the region where there is no ligand or no potential barrier; the transition to a_1^* becomes lower in energy and stronger in intensity. The third peak C can be assigned to the transition to the d-like a_1^* orbital. Other d-type (e*) shape resonance are observed in the higher energy region similarly to the case of SO_4^{2-}.

$S_2O_3^{2-}$ and $S_2O_5^{2-}$. In the absorption spectrum for $Na_2S_2O_3$ shown in Fig. 2, several bound-state transitions are observed. Ion $S_2O_3^{2-}$, belonging to the C_{3v} point group, is considered as SO_3^{2-} coordinated with one more sulfur atom. There are inequivalent sulfur atoms (central and terminal); the terminal sulfur atom is negative (formal oxidation number −2) and the central sulfur atom highly positive (formal oxidation number +6). This explains well the S 2p XPS spectrum

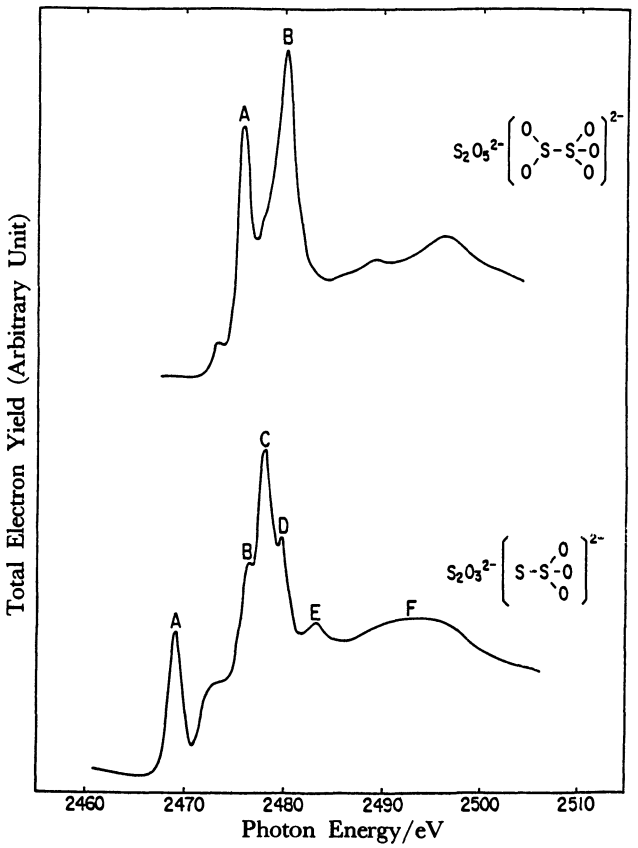

Fig. 2. Sulfur K-edge absorption spectra of $Na_2S_2O_3$ and $Na_2S_2O_5$.

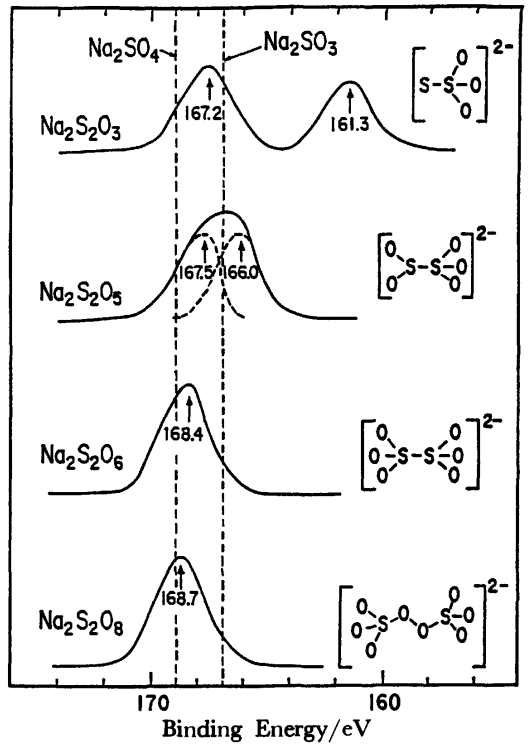

Fig. 3. Sulfur 2p XPS spectra of Na_2SO_4, Na_2SO_3, $Na_2S_2O_3$, and $Na_2S_2O_x$ (x=5—8).

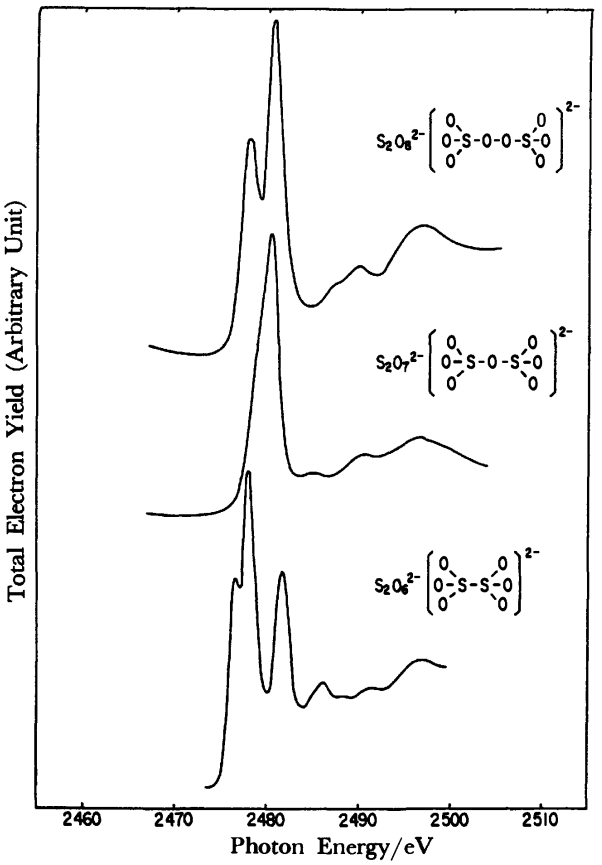

Fig. 4. Sulfur K-edge absorption spectra of $Na_2S_2O_6$, $Na_2S_2O_7$, and $Na_2S_2O_8$.

shown in Fig. 3, where the lower energy peak at 161.3 eV corresponds to the terminal S 2p peak and the peak at 167.2 eV to the central S 2p. Siegbahn et al.[13] reported the S 1s XPS spectrum for $Na_2S_2O_3$, where the difference between the binding energies of the two sulfur atoms is 7.0 eV, larger than the S 2p chemical shift (5.9 eV). The energy difference between peaks A and B in the S K-edge absorption spectrum is 7.2 eV as shown in Fig. 2; therefore, peaks A and B correspond to the transitions to the same lowest unoccupied orbital from the terminal and the central S 1s orbitals, respectively. Based on a simple molecular orbital calculation, there are three antibonding orbitals, $13a_1$* (terminal $3p\sigma$ and central $3p\sigma$), 9e* (central $3p\pi$), and $14a_1$* (central 3s and $3p\sigma$); the peaks A and B are associated with the transitions to the $13a_1$* orbital. The broad band at about 2475 eV between A and B is considered as an onset of the terminal S 1s ionization. It should be noted that the spectrum of the terminal S K-edge shows no shape resonances because the terminal sulfur atom is not affected by the potential barrier. Peaks C and D are assigned to the transitions from central S 1s to 9e* and $14a_1$*, respectively. They may correspond to the peaks A and B observed in the spectrum for Na_2SO_3 (Fig. 1); the energy separation of C and D for $S_2O_3^{2-}$ is the same as that of A and B for SO_3^{2-}. But C and D for $S_2O_3^{2-}$ shift to the higher energy by about 2.5 eV than A and B for SO_3^{2-}, probably due to the electrostatic effect by the terminal sulfur. Peak E observed for $S_2O_3^{2-}$ is attributed to a d-type shape resonance, which may correspond to peak C for SO_3^{2-}; it is noted that the resonance E of $S_2O_3^{2-}$ is weaker in intensity and higher in energy than the resonance C of SO_3^{2-}, probably due to the chemical bonding with the negative sulfur atom. These results indicate that the peak position and intensity of the d-type shape resonances are very sensitive to the surroundings of the X-ray absorbing atom.

The S K-edge spectrum for $Na_2S_2O_5$ is also shown in Fig. 2. In the XPS spectrum shown in Fig. 3, a broad 2p band is observed. This band has two components associated with $-SO_2$ and $-SO_3$ as indicated by the broken lines, as was previously investigated by Siegbahn et al.[13] In the S K-edge spectrum, the two intense peaks A and B correspond to transitions associated with $-SO_2$ species and $-SO_3$ species, respectively. The energy separation between peaks A and B is 4.4 eV and is larger than the S 1s chemical shift, ≈2 eV, which is estimated from the formal oxidation numbers of $-S(III)O_2$ and $-S(V)O_3$.[13] These two peaks may be attributed to transitions to different final orbitals.

$S_2O_6^{2-}$, $S_2O_7^{2-}$, and $S_2O_8^{2-}$. The absorption spectra of S K-edge of $Na_2S_2O_6$, $Na_2S_2O_7$ and $Na_2S_2O_8$ are shown in Fig. 4. Ions $S_2O_x^{2-}$ (x=6—8) have equivalent sulfur atoms.

The chemical environment of the sulfur atoms in $S_2O_6^{2-}$ is similar to that of the central sulfur atom in

Table 1. Assignments of the Absorption Spectra of S K-Edge of Na_2SO_4, Na_2SO_3, and $Na_2S_2O_3$

SO_4^{2-} energy/eV		Transition
2479.9	A	S 1s→t_2*
2488.7	B	d-type shape resonance
2495.6	C	d-type shape resonance

SO_3^{2-} energy/eV		Transition
2475.5	A	S 1s→e*
2477.5	B	→a_1*
2478.9	C	d-type shape resonance
2487.6	D	d-type shape resonance
2494.6	E	d-type shape resonance

$S_2O_3^{2-}$ energy/eV		Transition
2469.2	A	Terminal S 1s→a_1* (Terminal, central S 3pσ)
2476.4	B	Central S 1s→a_1* (Terminal, central S 3pσ)
2478.0	C	→e_1* (Central S 3pπ)
2479.8	D	→a_1* (Central S 3s and 3pσ)
2483.2	E	d-type shape resonance
2493.2	F	d-type shape resonance

Table 2. Assignments of the Absorption Spectra of S K-Edge of $Na_2S_2O_5$, $Na_2S_2O_6$, $Na_2S_2O_7$, and $Na_2S_2O_8$

$S_2O_5^{2-}$ energy/eV		Transition
2475.8	A	S1s→3p (−SO_2)
2480.2	B	→3p (−SO_3)
2489.2		d-type shape resonance
2495.9		d-type shape resonance

$S_2O_6^{2-}$ energy/eV	Transition
2476.5	S 1s→3pσ (S-S)
2477.8	→3pπ (S-O)
2481.7	→3pσ (S-O)
2486.0	d-type shape resonance
2491.2	d-type shape resonance
2496.7	d-type shape resonance

$S_2O_7^{2-}$ energy/eV	Transition
2480.5	S 1s→3p
2490.5	d-type shape resonance
2496.5	d-type shape resonance

$S_2O_8^{2-}$ energy/eV	Transition
2478.2	S 1s→3pσ
2480.7	→3pπ
2486.9	d-type shape resonance
2489.8	d-type shape resonance
2496.7	d-type shape resonance

$S_2O_3^{2-}$. Therefore, in the spectrum for $S_2O_6^{2-}$ shown in Fig. 4, three intense peaks arising from 1s→3p bound-state transitions can be interpreted as corresponding to peaks B, C, and D of the spectrum for $S_2O_3^{2-}$ shown in Fig. 2.

The spectrum for $S_2O_7^{2-}$ closely resembles that for SO_4^{2-}, because each sulfur atom in $S_2O_7^{2-}$ is surrounded by four oxygen atoms. The most intense peak can be considered as a transition from S 1s to t_2*-like (local symmetry) orbital of S 3p character. However, the peak has a shoulder structure at the lower energy side, which may come from ≈10% impurity of $NaHSO_4$ or from a nearly forbidden transition to a_1*-like (local symmetry) orbital of 3s character.

It is expected that the spectrum for $S_2O_8^{2-}$ should resemble that for SO_4^{2-} because of similar chemical environment and bonding to each other. However, two intense peaks are observed, which should be 1s→3p bound-state transitions. It may be reasonable to understand that the higher energy peak is a transition to a t_2*-like (local symmetry) orbital and that the lower one is a transition to an a_1*-like (local symmetry) orbital with a large mixing with t_2* (local symmetry) due to considerable symmetry-lowering in comparison with SO_4^{2-} and $S_2O_7^{2-}$.

Conclusion

Tables 1 and 2 summarize the present results of absorption spectra of S K-edge of Na_2SO_4, Na_2SO_3, $Na_2S_2O_3$, and $Na_2S_2O_x$ (x=5—8) together with the present interpretations. In the spectra for SO_4^{2-}, SO_3^{2-}, and $S_2O_3^{2-}$, there are remarkable differences in 1s→3p bound-state transitions and d-type shape resonances. Especially, the peak position and intensity of the d-type shape resonances are very sensitive to the surroundings of the X-ray absorbing atom. The spectra for $S_2O_x^{2-}$ (x=5—8) can be interpreted on the analogy of those for SO_4^{2-}, SO_3^{2-}, and $S_2O_3^{2-}$.

The authors wish to thank Dr. Mitsuyuki Soma in the National Institute for Environmental Studies for his help in the measurement of the XPS spectra, and Mr. Yoshinori Kitajima in the University of Tokyo for valuable discussion.

Crystal Structures of Trimethylammonium Hexaiodotellurate(IV) and Heptaiodotellurate(IV)

Hideko KIRIYAMA,* Yukiko MIZUHASHI, and Junji OOTANI
Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657
(Received August 30, 1985)

Crystal structures of the title compounds were determined by X-ray diffraction method. The crystal data and the final R values are: $[(CH_3)_3NH]_2TeI_6$, cubic, $Pa3$, a=13.210(2) Å, V=2305.2(9) Å^3, Z=4, R=0.057 for 263 observed unique reflections and $[(CH_3)_3NH]_2TeI_7$, tetragonal, $P4/nmm$, a=13.921(3), c=6.224(2) Å, V=1206.4(8) Å^3, Z=2, R=0.051 for 553 reflections. The structure of hexaiodo complex is a modified K_2PtCl_6 type. The discrete $[TeI_6]^{2-}$ octahedra are practically regular with a Te-I distance of 2.952(2) Å. The trimethylammonium cations lie on the unit cell triad axes and form trifurcated, weak hydrogen bonds of NH···3I. In contrast, the Te^{IV} coordination in the heptaiodo complex is an elongated octahedron with Te-I(1)=2.934(1) and Te-I(2)=3.124(4), 3.100(4) Å. These TeI_6 octahedra form linear trans TeI_5 chains running along c by sharing each pair of opposite vertices. Extra iodine atoms also stack along c with nearly equidistant I-I separations of 3.091(6) and 3.133(6) Å. The trimethylammonium cation is distributed randomly over four configurations in a cavity formed by two $[TeI_5]_n^{n-}$ and two $[I]_{2n}^{n-}$ columns. Thus, the chemical constitution of the heptaiodo complex can be expressed as di-trimethylammonium *catena*-μ-iodo-tetraiodo tellurate(1-) *catena*-diiodide(1-), $[(CH_3)_3NH]_{2n}^{2n+}[TeI_5]_n^{n-}[I]_{2n}^{n-}$.

A series of methylammonium hexahalometallate(IV), $[(CH_3)_nNH_{4-n}]_2MX_6$ where M=Pd, Pt, Sn, Te, X=Cl, Br, I and n=1, 2, 3, 4 has been widely studied so far by means of X-ray diffraction, NMR, NQR, dielectric and thermal analyses in view of structural chemistry focussed on their phase transitions and molecular dynamics.[1-5] Our preliminary report on $(CH_3NH_3)_2TeCl_6$ suggested that tellurate complexes of the series, especially their iodo analogs would be somewhat different from other hexahalometallates in nature.[6] In order to ascertain this suggestion the system of methylammonium hexaiodotellurate(IV), $[(CH_3)_nNH_{4-n}]_2TeI_6$ has been studied by X-ray diffraction and ^{1}H NMR measurements. In this paper, the X-ray results obtained for n=3 are described.

The X-ray powder patterns showed that trimetylammonium (abbreviated as Me_3NH hereinafter) hexaiodotellurate is isostructural with the corresponding hexachlorotellurate complex.[7] Thus, it was found that the structure is an antifluorite type in principle, but the crystal symmetry is lowered from $Fm3m$ to $Pa3$ owing to the presence of Me_3NH^+ cations. At the beginning of the work it was desired to determine the geometry of $[TeI_6]^{2-}$ ion more accurately than those in the literature.[8] Because the Me_3NH complex evidently contains discrete $[TeI_6]^{2-}$ anions, its crystal structure was analyzed by X-ray diffraction.

During preliminary attempts to grow single crystals of $(Me_3NH)_2TeI_6$ suitable for structure determination, a novel complex of formula $(Me_3NH)_2TeI_7$ was obtained by chance. Therefore, the heptaiodo complex was also subjected to an X-ray analysis in order to elucidate such a unique chemical constitution as well as the role of extra iodine atoms.

Experimental

Preparation. A saturated aqueous solution of trimethylammonium iodide added dropwise to a hydrogen iodide solution of tellurium dioxide in a stoichiometric molar ratio yielded black precipitates. The product was cubic from its X-ray powder patterns and was a hexaiodotellurate complex of $(Me_3NH)_2TeI_6$ from elemental analyses. The precipitate was dissolved into a hot, dilute HI solution and then brown-black prismatic crystals were grown from the solution held at ca. 50 °C for several days. These crystals were not identical to the source material of $(Me_3NH)_2TeI_6$, as evidenced by the X-ray powder pattern, and confirmed to correspond to $(Me_3NH)_2TeI_7$ by careful, chemical analyses.

Found: C, 6.62; H, 1.84; N, 2.55; I, 79.14%. Calcd for $C_6H_{20}N_2TeI_7$: C, 6.34; H, 1.77; N, 2.47; I, 78.19%.

To avoid such a change in composition, solvents and temperatures were varied upon recrystallization, and the pure hexaiodo complex was successfully recrystallized only from absolute ethanol solution not including HI acid at an optimum temperature near 50 °C. Thus obtained single crystals of $(Me_3NH)_2TeI_6$ were black, octahedral and less than 70 μm, these being used for the present study.

X-Ray Structure Determination. As the X-ray analytical methods used were almost the same for both complexes, the following description is made mainly for $(Me_3NH)_2TeI_7$ and briefly for $(Me_3NH)_2TeI_6$.

$(Me_3NH)_2TeI_7$: The density was measured by pycnometry with petroleum at 20 °C; the lattice parameters and the space group ($P4/nmm$ from systematic absences: $hk0$, $h+k=2n+1$) were previously determined with a Weissenberg camera; crystal 0.12×0.12×0.20 mm^3 in size was mounted with c coincident with the goniostat axis; Rigaku AFC-4 diffractometer, graphite-monochromatized Mo$K\alpha$ radiation, 40 kV-200 mA; unit cell parameters were refined by least-squares methods on the basis of 25 2θ values ($18° < 2\theta < 28°$, λ=0.71069 Å); intensity measurement was performed up to 2θ=55° ($0 \le h \le 12$, $0 \le k \le 18$, $-8 \le l \le 8$), ω—2θ scan technique, scan rate 4° min^{-1} (ω); all intensities were corrected for some X-ray damage (8.2% decay) by a factor of $a\exp(bN)$, where a=1.0043 and b=0.00011 obtained by least-squares on the basis of the intensity variation of three standard reflections (502, 060, and 004) every 50 reflections through experiments and N the ordinal number of measurements; 1523 reflections including 722 equivalent ones were measured, $R_{int}=\sum||F_o|-\langle|F_o|\rangle|/\sum|F_o|$=0.031, 248 weak reflections classified as unobserved [$|F_o| < 3\,\sigma(F_o)$], 553 observed unique reflections used for the structure determination;

Lorentz-polarization factors and absorption were corrected, empirical absorption correction factors on F 0.9986—1.0595; [9] the positions of Te and I were deduced from a Patterson map, starting with these positions the other non-H atoms were determined from electron density maps and refined by full-matrix least-squares on F with anisotropic thermal parameters for Te and I, and isotropic ones for N and C; the H atoms were not found from difference maps, and omitted in the refinement, $\sum w(|F_o|-|F_c|)^2$ minimized for 31 parameters, $w=[\sigma^2(F_o)]^{-1}$; final R=0.051, R_w=0.044, and goodness of fit $S=[\sum w(|F_o|-|F_c|)^2/(m-n)]^{1/2}$=1.74, where m is the number of unique reflections and n the number of refined parameters, ratio of maximum least-squares shift to error, $(\Delta/\sigma)_{max}$, was 0.3 for C(1) and $(\Delta/\sigma)_{mean}$=0.07, maximum positive and maximum negative electron densities in final difference Fourier synthesis, $(\Delta\rho)_{max}$ and $(\Delta\rho)_{min}$, were 1.24 and −1.46e/Å^3, respectively.

$(Me_3NH)_2TeI_6$: Black, octahedral crystal used was 0.07×0.07×0.07 mm^3 in size; lattice parameters were refined by least-squares methods based on 12 2θ values (17°<2θ<22°, λ=0.71069 Å); ω scan technique, $2\theta_{max}$=55° ($0\leq h\leq 17$, $0\leq k\leq 17$, $0\leq l\leq 17$), 2800 measured reflections, 891 unique reflections, 628 unobserved [$|F_o|<7\sigma(F_o)$], 263 observed unique reflections used for the structure determination; R_{int}(based on F)=0.097, standard reflections 400, 040, 004, intensity variation less than 3.0%, absorption correction neglected because of small size of crystal; structure was solved by heavy atom method and refined by full-matrix least-squares on F with anisotropic thermal parameters for non-H atoms, $\sum w(|F_o|-|F_c|)^2$ minimized for 24 parameters, $w=[\sigma^2(F_o)]^{-1}$; R=0.057, R_w=0.040, S=2.04, $(\Delta/\sigma)_{max}$=0.01, $(\Delta\rho)_{max}$ and $(\Delta\rho)_{min}$ in final difference Fourier synthesis were 1.20 and −1.62 e/Å^3, respectively.

In both cases, neutral atom scattering factors and anomalous dispersion terms were taken from Internationl Tables for X-ray Crystallography[10] and *UNICS* Program System,[11] Finger Computing System[12] and their modifications used for calculations at the Computation Center of Osaka University and later at the Information Processing Center of Kobe University.

The crystal date are summarized in Table 1. The positional and thermal parameters of hexaiodo and heptaiodo complexes are listed in Tables 2 and 3, respectively.[13]

Results and Discussion

The Structure of Hexaiodo Complex, $(Me_3NH)_2TeI_6$. The crystal of hexaiodo complex consists of octahedral anions $[TeI_6]^{2-}$ and group cations $[(CH_3)_3NH]^+$ in an arrangement of the K_2PtCl_6 structure, as shown in Fig. 1. The length of six equivalent Te–I bonds is 2.952(2) Å, and the two I–Te–I bond angles are 89.90(7)° and 90.10(7)°, indicating that the coordination octahedra of Te^{IV} atoms are practically regular. The obtained value of 2.952 Å is more reliable than 2.93 Å found in K_2TeI_6[8] and can be compared to 2.947(2) Å corrected for thermal motion in Rb_2TeI_6.[14] The Me_3NH^+ cations occupy the eight tetrahedral holes at 1/4, 1/4, 1/4 etc. The C–N bond length 1.51(5) Å and the C–N–C bond angle 110(2)° are reasonable in comparison with those in the literature, cf. 1.466—1.487 Å, 110.2—112.1° for $(CH_3)_3NHCl$[15] and 1.478 Å and 111.6° for $(Me_3NH)_2SnCl_6$[16]. The threefold axis of each cation is aligned with the unit cell triad axis and its N–H bond approaches to one iodine triangle of the nearest octahedron with three symmetrical N···I distances of 3.87(3) Å. Then the H···I distance and the N–H–I angle were calculated to be 3.14 Å and 130°, respectively, by assuming the hydrogen position at a distance of 1.02 Å from its attached

nitrogen with sp^3 hybridization. The scheme of trifurcated hydrogen bonds, N-H···3I, is quite similar to that found in $(Me_3NH)_2TeCl_6$,[7] although H···I distance is only a little shorter than the normal van der Waals approach, 3.4 Å.[17] On the other hand, the CH_3 group is surrounded by five I(1) atoms with distances of 3.84—4.27 Å, less than or near the van der Waals distance 4.2 Å.

The Structure of Heptaiodo Complex, $(Me_3NH)_2TeI_7$. A projetion of the crystal structure along ***a*** with the numbering of atoms and a stereo pair of structure viewed along ***c*** are shown in Figs. 2 and 3, respectively. Selected interatomic distances and angles are listed in Table 4.

The Te atom is coordinated by six iodine atoms, 4I(1) and 2I(2), in an elongated octahedral arrangement. These octahedra are connected to each other by sharing two opposite vertices of each octahedron to form a linear trans chain running along ***c***. The bond length of Te to terminal I(1), 2.934(1) Å, is shorter than 2.952(2) Å found in cubic $(Me_3NH)_2TeI_6$ and agrees with 2.930(2) Å in Rb_2TeI_6, which is uncorrected for librational motion of $[TeI_6]^{2-}$ ion.[14] The central Te atom is at 0.026(3) Å below or above the coordination plane formed by 4I(1). The Te–I(2) bridging distances of 3.124(4) and 3.100(4) Å are longer than that for the terminal I(1) by 0.18 Å. The lengthening of a bond to a bridging halide ion is quite common: In $[MeAlCl_2]_2$ the Al–Cl distances are 2.25 and 2.05 Å for bridging and terminal chlorine atoms, respectively.[18] Another example is found in $BaFeF_5$, where the mean Fe–F distances are 1.90 Å for bridging atoms and 1.82 Å for terminal fluorine atoms within the linear trans $[FeF_5]_n^{2n-}$ chain.[19] Thus the formed polymeric chain is a previously unknown, newly found chemical species for halotellurate anions and can be described as $[TeI_5]_n^{n-}$.

Another striking feature of the structure is that extra

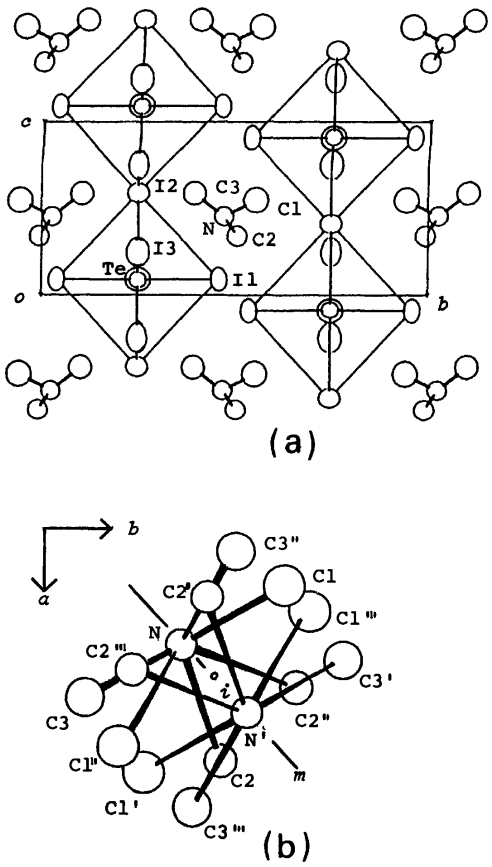

Fig. 2. Crystal structure of $(Me_3NH)_2TeI_7$. (a) The projection along [100], and (b) disordered configurations of the Me_3NH^+ cation. Symbols are: none, (x, y, z); $(')$, $(\bar{x}, \bar{y}, \bar{z})$; $('')$, (y, x, z); $(''')$, $(\bar{y}, \bar{x}, \bar{z})$.

iodine atoms, I(3)'s, are also stacked along ***c*** to form a linear polyiodide chain within the crystal lattice. More remarkable is the appearance of nearly equal I–I bond lengths with successive values of 3.091(6) and 3.133(6) Å. Both separations are larger than the I–I bond lengths of 2.715(6) Å in crystalline iodine and also of the mean 2.92(1) Å for seventeen compounds including linear, symmetric triiodide ions.[20,21] Such an approximately linear array of equally spaced iodine atoms was first proposed for some polyiodide compounds of starch and cyclodextrin, but later works proved that these results probably correspond to disordered structure.[22,23] On the other hand, recent studies on some metal complexes of α-cyclodextrin polyiodide and also on various stacked organometallic iodide compounds have shown that long polyiodide chains exclusively consist of I_2 and/or $[I_n]^-$ (n=1, 3, and 5) moieties.[24] Consequently, a linear and nearly equidistant array of iodine atoms was first realized in the heptaiodo complex, although its presence had been speculated so far only as an extreme model case or interpreted in terms of a statistical structure or disordered arrangements. In contrast with many other polyiodide compounds, no indication of diffuse scattering or superstructure appearance was disclosed on

Weissenberg photographs of the heptaiodo complex. The thermal parameters of I(3) are, in fact, relatively large to those of I(1) and I(2) and more anisotropic with root-mean-square amplitudes of 0.34 Å (at most) parallel to the polyiodide chain and of 0.25 Å perpendicular to it, but there is no sufficient evidence for establishing disordered structure. The appearence of unique iodine array in the present complex may be associated with the fact that the length of repeating unit in $[I]^{n-}_{2n}$ chain is almost the same as that in $[TeI_5]^{n-}_n$ chain, which corresponds to the *c* spacing of the unit cell, 6.2 Å.[25]

The Me_3NH^+ cation is inserted between two $[TeI_5]^{n-}_n$ and two $[I]^{n-}_{2n}$ columns. The electron density map revealed a statistical arrangement of Me_3NH^+ ions. Four equivalent N atoms in the unit cell are distributed on the special position **8j** of the space group *P4/nmm* with a statistical weight of 0.5, while the methyl carbon atoms, C(1), C(2), and C(3), are located on each individual **16k** positions with a statistical weight of 0.25. Each Me_3NH^+ cation is therefore distributed over four configurations with the equal probability; any two of which are related by either the center of symmetry or the mirror plane as illustrated in Fig. 2(b). The mean C-N bond length of 1.50 Å and the mean C-N-C bond angle of 110° for the disordered Me_3NH^+ cations are comparable to those for the ordered one in the hexaiodide described earlier.

The NH hydrogen positions of cations were calculated on the basis of sp^3 N atoms with N-H distances of 1.02 Å as in hexaiodide. Weak, but significant hydrogen bonds are formed between NH and I atoms with distances of 3.84(2) Å for N···I and 2.90 Å for H···I, and with the angle N-H···I of 154°. The statistical distribution of Me_3NH^+ cation is probably associated with the formation of hydrogen bonds and packing restriction of molecular ions. Some intermolecular CH_3···I distances are less than the sum of the van der Waals radii of 4.2 Å, suggesting weak interaction due to C-H···I hydrogen bonds; their minimum distances are 3.85(7) Å for C(1)-I(3), 3.74(5) Å for C(2)-I(1) and 3.77(7) Å for C(3)-I(1).

In conclusion, the present X-ray analysis together with the neutralization principle of electric charges revealed that the chemical constitution of the newly prepared catena heptaiodo complex is $[(CH_3)_3NH]^{2n+}_{2n}[TeI_5]^{n-}_n[I]^{n-}_{2n}$. The presence of such a peculier polyiodide ion of $[I]^{n-}_{2n}$ is interesting in view of the chemical bond.

The authors wish to express their thanks to Lecturer Kichiro Koto of Osaka University for his guidance in part and to Dr. Yuriko Yamagata for her help during this work. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 593700350 from the Ministry of Education, Science and Culture.

Effects of Bivalent Metal Cations on the Conformation and Aggregation of Poly(L-glutamic acid)

Hiroshi MAEDA,* Tsuyoshi HIRAMATSU, and Shoichi IKEDA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received September 25, 1985)

In the solution of fully neutralized poly(L-glutamic acid) in the absence of supporting electrolytes, the α-helix was induced by the addition of five transition metal chlorides in the following order: $CuCl_2 \geq CdCl_2 > ZnCl_2 > NiCl_2 > CoCl_2$. The induction did not occur by the addition of $BaCl_2$, $CaCl_2$, or $MgCl_2$. The induction by transition metal cations was inhibited in the presence of a supporting electrolyte (NaCl). Distortion of circular dichroism (CD) spectra occurred as the induction of the α-helix proceeded, which was shown to be recognizable when apparent aggregation number m exceeded about 100. Conformation of the polypeptide in these aggregates was expected to be the α-helix based on the conformation in the precipitates obtained at these mixing ratios which gave distorted CD spectra, which was determined by infrared absorption spectra.

Induction of the secondary structures of fully neutralized anionic polypeptides was studied on poly(L-glutamic acid)(PGA)[1] and poly (*S*-carboxymethyl-L-cysteine)(poly[Cys(CH_2COOH)][2] by the addition of cationic surfactants of different head groups but of a common hydrocarbon tail. Different behaviors were observed between these two polypeptides. The induction of the α-helix of PGA occurred for three surfactants with small differences among their inducing powers,[1] while the induction of the β-structure of poly[Cys(CH_2COOH)] depended on the kind of head groups.[2] Furthermore, in the presence of 0.1 M NaCl, the induction of the α-helix of PGA was completely inhibited,[1] while that of the β-structure of poly[Cys(CH_2COOH)] was scarcely perturbed.[2]

It is interesting to examine whether such a definite difference exists between the inductions of the α-helix and the β-structure caused by the addition of bivalent metal cations. Effects of bivalent metal cations on the conformation of poly[Cys(CH_2COOH)][3] and its side chain homolog[4] were already examined. Interactions of bivalent metal cations with PGA has been extensively studied,[5–15] including the induction of the α-helix by Cu^{2+} and Cd^{2+} ions. Nevertheless, available data for the present purpose of comparison are not sufficient for PGA. Therefore, previous studies[3,4] are extended to the induction of the α-helix of PGA in the present study.

Another purpose of the present study is clarifying the origin of the distortion of the circular dichroism (CD) spectra of PGA. The distortion of CD has been attributed to the aggregation of α-helices,[16,17] or to the β-structure[15] without providing evidence for both aggregation and conformation. In the present study both the aggregation number and the conformation of the polypeptide in the aggregates are examined.

Experimental

Weight average molecular weight and the degree of polymerization of the used PGA sample were 6.3×10^4 and 480, respectively, as determined from light scattering. Reagent grade $CuCl_2\cdot2H_2O$, $CdCl_2\cdot(1/2)H_2O$, $NiCl_2\cdot6H_2O$, and $BaCl_2\cdot2H_2O$ were purchased from Nakarai Chemicals Ltd. (Kyoto). Reagent grade $ZnCl_2$ was from Wako Pure Chemicals or prepared by the reaction of Zn with HCl. $CaCl_2\cdot4H_2O$ (suprapur) and $CoCl_2\cdot6H_2O$ were from Merck. $MgCl_2\cdot6H_2O$ was from Baker.

Circular dichroism (CD) was measured with a Jasco J-40 A circular dichrograph using a cell of 1 mm light path at 25±0.1 °C. Light scattering was mesured on a Chromatix KMX-6 low-angle light-scattering photometer at ambient temperature (24±2°C). A 6—7° annulus was chosen to observe the scattered light which collected the light of about 4—5° scattering angle for aqueous solutions. A 0.2 mm field stop was selected which defined the scattering volume. Millipore membrane filters of 0.1, 0.22, and 0.30 μm pore size were used to filter the solutions containing aggregates of aggregation number smaller than 12, about 53 to 170, and greater than 250, respectively. Measurements of pH were carried out with an Iwaki M-225 pH meter. Infrared absorption spectra of precipitates in KBr pellets were taken with a Jasco IRA-2 spectrophotometer at 24±2°C. Precipitates of PGA-metal ion complexes were collected by centrifugation(ca. 1500 g), dried in a desicator over P_2O_5 for one or 2 d, and then mixed with dry KBr powder. The mixture was ground finely and kept in a desicator over P_2O_5 for several days. The mixture was pressed (6—7 t/cm^2) to a pellet for 3 min in vacuo. The pH of the solutions prior to the addition of a metal chloride was adjusted to be 6.7±0.2 by the addition of NaOH, if necessary. Then, various amounts of a metal chloride were added and the mixtures were incubated for 12—24 h at 24±2°C before the measurements. Concentrations of the polymer C_P and metals C_M are expressed in residue molarity and molarity M ($mol\,dm^{-3}$), respectively.

Results

Induction of the α-Helix. In Fig. 1 are shown the CD spectra of the solutions containing 1 mM PGA and various amounts of $NiCl_2$. On addition of $NiCl_2$, the α-helix was induced as indicated by a change of CD spectra. The helical content was about 75% at the mixing ratio C_M/C_P of 2.0. Further addition of $NiCl_2$ did not enhance the α-helix formation but distorted the CD spectra (curve f) and eventually led to the precipitation. No isodichroic point is seen in Fig. 1. The same behavior was observed on the addition of $CoCl_2$. On the contrary, an isodichroic point was found

around 203—204 nm in the α-helix induction by $CuCl_2$ or $CdCl_2$. This behavior is consistent with the reported one.[11] Change of the CD spectra on the addition of $ZnCl_2$ was an intermediate one between these two types. Since a distortion of the CD spectra at high mixing ratios occurred around 210 nm, the residue ellipticity at 222 nm ($[\theta]_{222}$) was used as a measure of the helical content.

In Fig. 2, the residue ellipticities at 222 nm are plotted against the mixing ratio C_M/C_P for eight bivalent metal

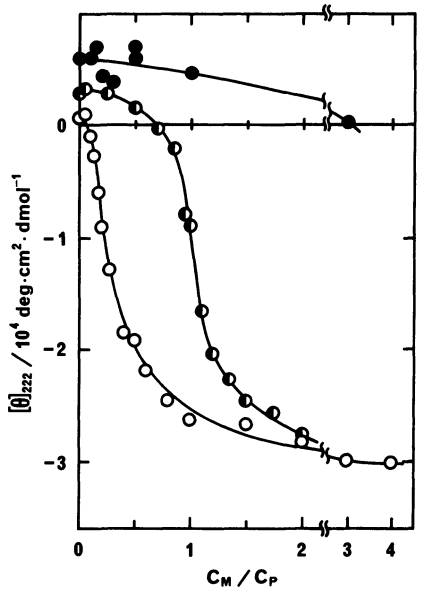

Fig. 3. Effects of NaCl on the induction of the α-helix by the addition of $NiCl_2$. C_P=1.0 mM. NaCl concentration (M). (○): 0, (◐): 0.010, and (●): 0.10.

chlorides. Induction of the α-helix occurred completely on the addition of $CuCl_2$ or $ZnCl_2$, while precipitation occurred before the induction was completed in the case of $CdCl_2$, $NiCl_2$, or $CoCl_2$. Contrary to these five transition metals, $BaCl_2$, $CaCl_2$, or $MgCl_2$ did not induce the α-helix. In the range of C_M/C_P below about 5, $[\theta]_{222}$ varied from nealy zero (or small positive) to −3000-−8000 for these three alkaline earth metals. No further change occurred, however, in the range of C_M/C_P greater than about 5. Consequently, the change of CD spectra can be ascribed to a kind of the reported effect of ionic strength[18] rather than to a partial conversion to the α-helix.

Precipitation of the polypeptide occurred in the range of C_M/C_P greater than about 30 in the case of $BaCl_2$ or $CaCl_2$, while precipitation did not occur at C_M/C_P=200 in the case of $MgCl_2$. The change of $[\theta]_{222}$ occurred in one step for every bivalent cation, although apparently two-step changes are seen in Figure 2 for Ni^{2+}, Co^{2+}, and Mg^{2+} simply because abscissa scales are changed.

Effect of Supporting Electrolyte. The effect of $NiCl_2$ on the conformation of PGA was also examined in 0.01 M and 0.1 M NaCl solutions. The result is shown in Fig. 3, together with the result in the absence of NaCl for the sake of comparison. In 0.01 M NaCl, the induction of the α-helix was hampered when C_M/C_P was smaller than about unity but became comparable with that in the absence of NaCl in the range of C_M/C_P between 1.5 and 2. Precipitation occurred when C_M/C_P was greater than about 2. In 0.1 M NaCl, the induction did not occur up to C_M/C_P=3 and precipitation occurred on further addition of $NiCl_2$. The inductive effect of $NiCl_2$ was thus largely suppressed in the

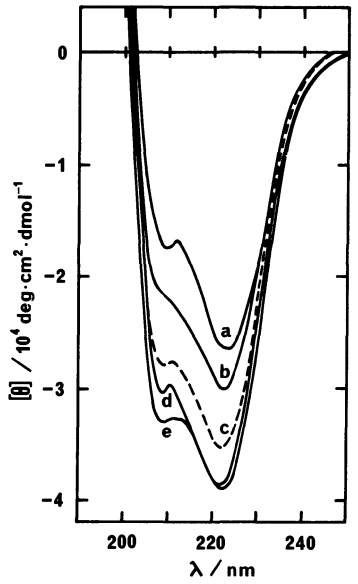

Fig. 4. CD spectra at the mixing ratios slightly smaller than those caused precipitation. Mixing ratios (C_M/C_P). (a): $CoCl_2$ 5.0, (b): $NiCl_2$ 6.0, (c): $CdCl_2$ 0.275, (d): $ZnCl_2$ 0.82, and (e): $CuCl_2$ 0.30. The CD curve (c) was obtained on turbid solutions.

presence of 0.1 M NaCl. This inhibitory action of ionic strength is similar to that found on the interaction of PGA with surfactants,[1] or other polyion-bivalent metal interactions.[19,20] This behavior is in contrary to the effect of ionic strength on the induction of β-structure of poly(*S*-carboxymethyl-L-cysteine) by bivalent metal cations.[3] Also, it is reported that interaction of $Cu(NO_3)_2$ with poly(methacrylic acid) was not affected by the presence of 0.1 M $NaNO_3$.[21]

Distortion of the CD Spectra. When a transition metal chloride was added to such an amount more than required to the maximum induction for that species, the CD spectra began to be distorted in a way that $[\theta]_{208}$ decreased in magnitude. The CD spectra obtained at the mixing ratio near but slightly smaller than that caused precipitation are shown in Fig. 4 for five transition metal chlorides. Distortion occurred only slightly in the case of $CuCl_2$. In the case of $CdCl_2$, the spectra were obtained on a turbid solution and hence represented by a dashed curve c. These spectra shown in Fig. 4 might be associated with the presence of the β-structure.

The distortion of the CD spectra can be clearly discriminated when the correlation between $[\theta]_{208}$ and $[\theta]_{222}$ is examined (Fig. 5) as proposed previously.[1] A straight line in Fig. 5 represents the induction of the α-helix, probably including the effect of ionic strength on the CD spectra. The data of $CdCl_2$ located in the range $-[\theta]_{222}>2\times10^4$ were taken on turbid solutions. Deviation from the straight line occurs at different helical contents for different species; the following order of the helical content is seen, $CoCl_2<NiCl_2<CdCl_2<ZnCl_2$. The deviation is not clear for $CuCl_2$.

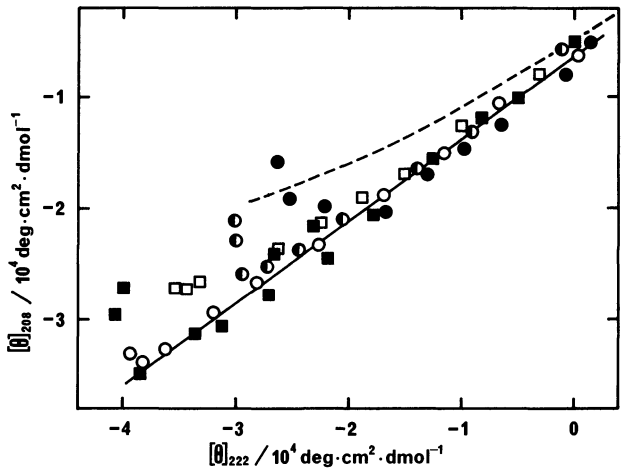

Fig. 5. Correlation between $[\theta]_{222}$ and $[\theta]_{208}$ in the presence of various amounts of a given metal chloride. The same symbols are used as in Figure 2 to represent different metal species. A dashed curve represents the result of the addition of $NiCl_2$ in 0.01 M NaCl.

A dashed line in Fig. 5 represents the result on the addition of $NiCl_2$ in 0.01 M NaCl. Distortion of the CD spectra also occurred in 0.01 M NaCl as shown by a non-zero curvature of the dashed line.

Aggregation of PGA in 0.01 M NaCl. Light scattering was measured on the 0.01 M NaCl solutions containing 1 mM PGA and various amounts of $NiCl_2$. Apparent aggregation number m was evaluated by Eq. 1.

$$m = \Delta R_\theta(C_M)/\Delta R_\theta(C_M=0) \quad (1)$$

In Eq. 1, ΔR_θ represents a difference of light intensities between a solution and a solvent at a scattering angle θ, which is very close to zero in the present study. Underlying assumptions leading to Eq. 1 are: (1) refractive index increment does not vary appreciably on addition of $NiCl_2$ and (2) the second virial coefficient can be ignored for any aggregates. (In the absence of $NiCl_2$, the contribution from the second virial coefficient did not exceed 5%) In spite of these approximations, the apparent aggregation number m is expected to be a useful measure for the extent of aggregation. When the dependence of m on the mixing ratio given in Fig. 6 is compared with that of $[\theta]_{222}$ given in Fig. 3, it is seen that aggregation occurs at small mixing ratios corresponding to low helical contents. For example, at $C_M/C_P=1.0$, $-[\theta]_{222}$ is smaller than 10^4, yet aggregation number already reaches 167. If every two carboxylate groups are assumed to bind to a Ni^{2+} ion, then m should be corrected to 136 instead of 167. This provides a rough estimate of the consequence of assumption (1).

As a measure of the extent of distortion of CD spectra, the slope of the dashed curve given in Fig. 5 was

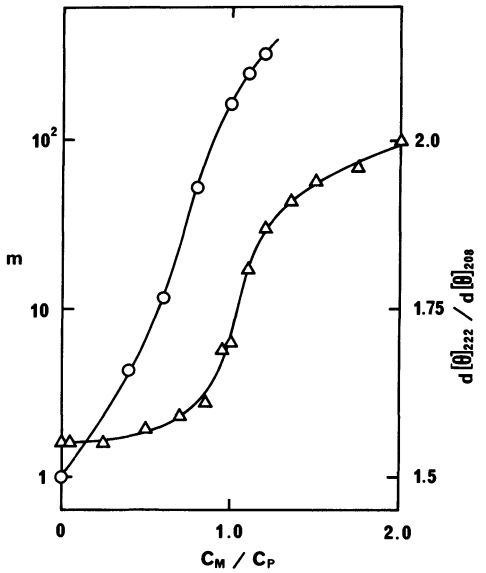

Fig. 6. Apparent aggregation number m and a measure of the distortion of the CD spectra, $d[\theta]_{222}/d[\theta]_{208}$, as functions of the mixing ratio (C_M/C_P) of $NiCl_2$ in 0.01 M NaCl. (○) m and (△) $d[\theta]_{222}/d[\theta]_{208}$ refer to the left and right ordinate scales, respectively.

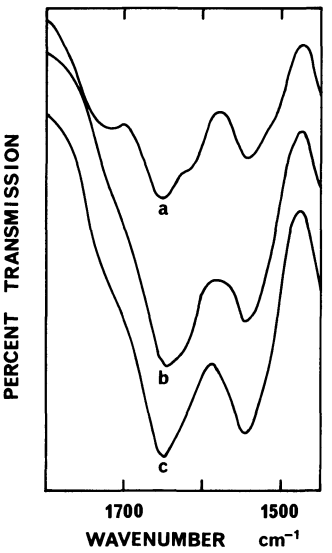

Fig. 7 Infrared absorption spectra of the precipitates in KBr disks consisting of PGA and (a): $CuCl_2$, (b): $NiCl_2$, or (c): $CoCl_2$.

tentatively employed which is represented by Eq. 2.

$$[\theta]_{208}/10^4 = 0.473([\theta]_{222}/10^4)^2 + 0.631([\theta]_{222}/10^4) - 0.050 \quad (2)$$

Equation 2 was obtained from the exeprimental points by the least square method. The slope, $d[\theta]_{222}/d[\theta]_{208}$ was evaluated by differentiating Eq. 2. The slope is 1.55—1.60 in the range well approximated by a straight line. When $C_M/C_P>1.0$, the slope increases sharply to 1.80 or greater. Consequently, it is concluded that the distortion of the CD spectra becomes first recognizable when m is larger than about 100.

Infrared (IR) Absorption Spectra of Precipitates. At the mixing ratio where the distorted CD spectra shown in Fig. 4 were obtained, precipitation occurred when the polypeptide concentration exceeded 1 mM. Consequently, conformation of the polypeptide in the precipitates rather than in solution was examined by infrared absorption spectra. The IR spectra of the precipitates are shown in Fig. 7 obtained from the solution of C_P=10 mM by the addition of $CuCl_2$, $NiCl_2$, or $CoCl_2$. Amide I, II, and V bands were found at 1650—1655 cm^{-1}, 1550 cm^{-1}, and 630 cm^{-1}, respectively, for these three complexes. These band positions indicated that the conformation of PGA was the α-helix.[22-24]

A band around 1620 cm^{-1} was observed in the complex with $CuCl_2$, which can be assigned to antisymmetric stretching of side chain carboxylato group covalently bound to a copper atom,[25,26] rather than to the amide I band in the β-structure. There is no room to expect the presence of the β-structure in the case of $CuCl_2$, since distortion of the CD spectra did not occur appreciably. Corresponding bands could not be resolved in the case of $NiCl_2$ or $CoCl_2$.

The β-structure is one of stable conformations of PGA in the solid state.[27-31] The presence of the β-structure of PGA in solution has not been confirmed until now. Furthermore, dissolution of the β-precipitates of PGA was reported to be very difficult.[30] Based on all these findings, it is quite unlikely that the conformation of the polypeptide changed from the β-structure to the α-helix during the precipitation in the present study. We can, therefore, conclude that the conformation of PGA in soluble aggregates is the α-helix.

Discussion

Induction of the α-Helix as Compared with That of the β-Structure. Induction of the α-helix of PGA in the media of no added salt occurred in the present study by the addition of transition metal chlorides in the order of $Cu^{2+} \gtrsim Cd^{2+} > Zn^{2+} > Ni^{2+} > Co^{2+}$. On the other hand, alkaline earth metals ($BaCl_2$, $CaCl_2$, $MgCl_2$) did not induce the α-helix. This result is in good agreement with that found on the induction of the β-structure of poly[Cys(CH_2COOH)].[3] Furthermore, the order of the inducing power of transition metal cations is also in good agreement with the interaction of poly(methacrylic acid) with these metal cations.[21] Contrary to the induction by cationic surfactants, where clearly different behaviors were found between the inductions of the α-helix[1] and the β-structure,[2] the induction of the secondary structures by bivalent metal cations is similar for both the α-helix. and the β-structure.[3]

The interaction of transition metal cations with these

two polypeptides, PGA and poly[Cys(CH_2COOH)], is much stronger than that of cationic surfactants. Difference of the stabilities between the α-helix and the β-structure escapes detection in the strong interaction with transition metal cations, while it is sensitively detected by the weak interaction with cationic surfactants.

However, clear difference between the interactions operating in the induction of the α-helix and the β-structure shows up when the effect of ionic strength is examined. The induction of the β-structure requires greater stabilization than that required for the α-helix induction. Hence the β-induction is scarcely affected by ionic strength of the environment, while the α-induction is effectively inhibited as the ionic strength increases.

Distortion of the CD Spectra. Distortion of CD spectra of the α-helix just as found in the present study has been often observed before.[1,16,17,32,33] Theoretical calculations show that the distortion occurs as a result of the aggregation of α-helices.[16,33,34] Comparison of the distorted CD spectra found in the present study with the calculated spectra[34] provides an estimate of the radius of assumed spherical aggregates to lie between 0.03 and 0.1 μm. On the other hand, the solution of C_M/C_P=1.0 could be filtered without trouble with a membrane of 0.22 μm pore size but not with a membrane with 0.1 μm pore size. Consequently, it is expected that the largest dimension of the aggregates in the solution exceeds 0.1 μm and that the aggregates have rather asymmetric shape but their optical properties are well approximated by spheres having a radius lying between 0.03 and 0.1 μm.

(Received September 30, 1985)

The pulse radiolysis of a Freon mixture (FM), an equivolume mixture of $CFCl_3$ and CF_2BrCF_2Br, at 77 K gave transient absorption bands with peaks at 360, 490, and 530 nm, whose decay was enhanced by cation scavengers: propylamine, triethylamine, *N,N'*-diethylaniline, and biphenyl. The degree of the enhancement was independent of the difference in the ionization potential between the matrix and the solute molecules. In the FM matrix, positive-charge transfer from biphenyl cations to some other solute molecules showed energy dependence similar to that observed in the *s*-butyl chloride matrix. The rate of inter-solute positive-charge transfer was faster in the FM matrix than in the *s*-butyl chloride matrix. These results were discussed in relation to current electron transfer theories.

An equivolume mixture of Freon 11 ($CFCl_3$) and Freon 114B2 (CF_2BrCF_2Br), which will be referred to as the Freon mixture or FM, provides an optically transparent glass at 77 K, which is used as an excellent matrix for preparation of radical cations by irradiation with ionizing rays.[1] The optical absorption spectra of (radical) cations of aromatic hydrocarbons and other compounds have been measured in the γ-irradiated FM matrix.[2-4] The formation of cations probably results from positive-charge (PC) transfer from trapped holes in the FM matrix produced by irradiation, as in the *s*-butyl chloride (*s*-BuCl) matrix;[5-8] however, no kinetic studies have been carried out concerning PC transfer in the FM matrix.

From the theoretical point of view, the vibrational mode of both matrix and solute molecules can affect the rate of electron or hole transfer.[9] The FM matrix which consists of carbon-halogen bonds differs in the vibrational mode from the *s*-BuCl matrix dominated by the carbon-hydrogen bond. Thus, the PC-transfer rate in FM may differ from that in *s*-BuCl, and comparative measurement of the same donor-acceptor pair in FM and in *s*-BuCl seemed to be the best feasible experiment to examine the effect of matrix vibrations.

This paper deals with a pulse radiolysis study on PC transfer in FM matrices at 77 K. Two types of PC transfer, matrix-to-solute and solute-to-solute, were studied. This study also revealed the presence of two or three types of holes or radiation-induced cationic entities in the FM matrix, although their nature is not yet elucidated. The compounds used as solutes and their ionization potentials in the gas phase are: biphenyl, 8.27 eV; pyrene, 7.55 eV; propylamine (PrA), 8.78 eV; triethylamine (TEA), 7.50 eV; *N,N*-dimethylaniline (DMA), 7.10 eV.

Experimental

A pulse radiolysis apparatus at Nuclear Engineering Research Laboratory, University of Tokyo, was used.[10] A 10-ns pulse of 35-MeV/1-A electron beam focused to a diameter of 2 mm was irradiated to a sample placed in a Dewer vessel filled with liquid nitrogen. The monitoring light passes through the sample to the opposite direction to the electron beam on the identical axis and is detected with a Hamamatsu-TV R-928 photomultiplier after monochromatized with a Ritsu MC-10 monochromator. The photoelectric signal was fed to a Riken-Denshi TCH-4000 transient digitizer whose time base was operated by a logarithmic time clock.[5] The shortest accessible time of this detection system was 1 μs, but measurememt was also made in the nanosecond region by the use of conventional detection devices.[10] The dosimetry was carried out by using hydrated electrons in water at room temperature on the basis of a value of 3.5 for *G*-value (molecules/100 eV) at 10 ns and 1.3×10^4 $M^{-1}cm^{-1}$ (1 M=1 mol dm^{-3}) for the molar absorption coefficient (ε) at 600 nm.[11]

Daifron S1 and 114B2 ($CFCl_3$ and CF_2BrCF_2Br, respectively) purchased from Daikin Ind. Co. were dried on Drierite. Other chemicals (Tokyo Kasei) were used as received. Samples were deaerated by the freezing-pumping method in early experiments but were aerated later, since aeration was found to cause no practical effects.

Results

Transient absorption spectra in the FM glass containing no solutes are exhibited in Fig. 1 and some decay curves are shown in Fig. 2. Although the shortest time indicated in Figs. 1 and 2 is 3 μs, no other transient bands were found before this time in the nanosecond measurement. As shown in Fig. 2, the transient absorptions at peaks of 360 and 490 nm decay with the logarithm of time but the absorption at 600 nm scarcely decays initially. This apparent constancy in the 600-nm absorption is probably ascribed to cancellation of the decrease in the 600-nm absorbing species by the increase due to its production from a transient with the 360-nm and/or the 490-nm band. In the spectrum at 10 ms, the 360-nm band is still alive but the 490-nm band has already been replaced by a broad band with a peak near 530 nm which will be called tentatively the 530-nm band, although this band can really be a composition of the 490-nm band and another band which may be a long-lived one with a peak near 560

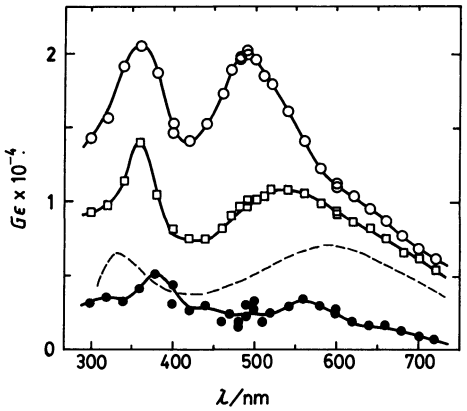

Fig. 1. Transient absorption spectra in an FM glass at 77 K at 3 μs ○, 10 ms □, and 3.7 s ● after the pulse. Thin dashed curve: the spectra taken after γ irradiation (Ref. 1).

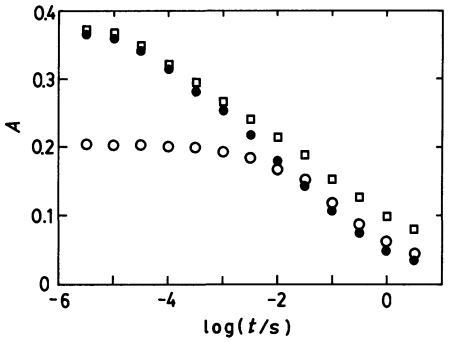

Fig. 2. The decay in the absorbances at 360 nm □, 490 nm ●, and 600 nm ○ in an FM glass plotted as a function of the logarithm of time.

nm.

The spectrum at 3.7 s differs from the one observed in steady-state measurement as shown in Fig. 1. Discrepancy between pulse and steady-state experiments also occurs in the absorption intensity: The $G\varepsilon$ at the 560-nm peak at the 3.7-s spectrum of the pulse radiolysis is 3.3×10^3 $M^{-1}cm^{-1}$, which is smaller than the values for a 585-nm peak in the γ-irradiated FM glass: $4.5\times10^3 M^{-1}cm^{-1}$ in measurement by Grimison and Simpson[1] and 7.1×10^3 $M^{-1}cm^{-1}$ in our re-measurement.[12] In the rather soft FM matrix, the rise in local temperature caused by the strongly focused electron beam in the pulse radiolysis may enhance charge recombination which removes these matrix transients. In fact, the fast decay of the matrix transients in FM glass as shown in Fig. 2 contrasts with the very slow decay of trapped electrons in the alkaline-ice[13] and the 2-methyltetrahydrofuran[14] matrices as well as of trapped holes in the *s*-BuCl matrix.[5-8] However, it should be remarked that the decay of the biphenyl cation in the FM matrix is as slow as its decay in the *s*-BuCl matrix, as will be shown later.

As shown in Figs. 3 and 4, the decay of these matrix transients was enhanced by addition of a solute like

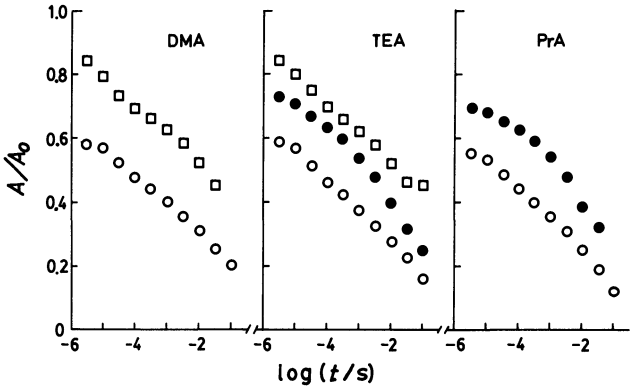

Fig. 3. Survival curves of trapped holes measured at 360 nm □, 490 nm ●, and 600 nm ○ in the presence of DMF, TEA, and PrA, each at 0.1 M.

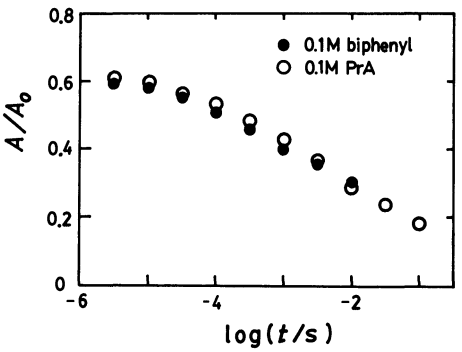

Fig. 4. Survival curves of the 490-nm hole band in the presence of biphenyl and PrA, each at 0.1 M.

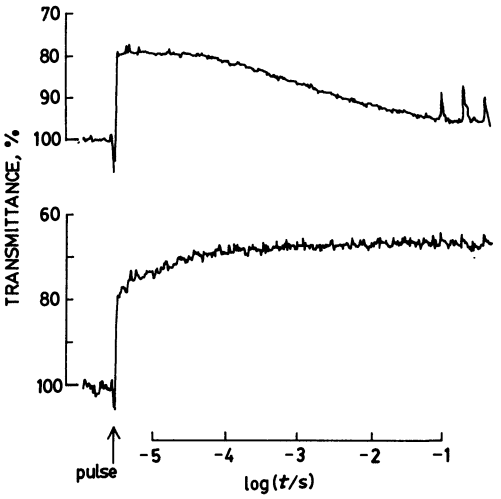

Fig. 5. The decay of the hole absorption at 490 nm and the corresponding growth of the biphenyl-cation absorption at 700 nm in an FM glass containing 0.03 M biphenyl.

triethylamine, propylamine, *N*,*N*-dimentylaniline, and biphenyl; the first three are typical cation scavengers that do not act on anionic species, and biphenyl scavenges both cationic and anionic species. Furthermore, the 490-nm absorption band of the DMA cation[4] and the 390- and 690-nm bands of the biphenyl

cation were oserved in these experiments (see also Fig. 5); cations of TEA and PrA were not detected simply because of their weak absorptions.[4] Thus, these matrix transients which are probably composed of a few entities can be regarded as cationic species originating in the matrix, and will be referred to the (trapped) holes in this paper, although some of them may not really be the hole but cationic fragment radicals of a solvent component or certain ion pairs.

In steady-state γ radiolysis at 77 K, absorption maxima appear at 330 and 585 nm in the FM matrix, at 310 and 535 nm in the $CFCl_3$ matrix, and at 360 nm in the CF_2BrCF_2Br matrix;[1] the last two matrices are opaque. Comparison of the wavelengths of these maxima suggests that the 360-nm transient band observed in the pulse radiolysis may be assigned to a cationic species originating in CF_2BrCF_2Br and the 530-nm transient to a cationic species from $CFCl_3$. Decisive assignment of these bands seems difficult; such assignment has been unsuccesful for transient bands of carbon tetrachloride on which extensive studies have been made.[15]

In Figs. 3 and 4, survival ratios, A/A_0, where A and A_0 denote the absorbances in the presence and in the absence of a solute, respectively, are plotted against the logarithm of time; the decay that proceeds with the logarithm of time is common to reactions in rigid matrices.[5-7] This type of plot is usually used for presentation of the kinetic data in rigid matrices, and is called a survival curve. No corrections in the absorbance were made for possible overlap of the bands, since the spectrum of each component could not be isolated. The absorbance for the broad 530-nm band was measured at 600 nm in order to avoid the influence of the tail of the 490-nm band. Cations of biphenyl and DMA possess intense absorption bands in the visible region as mentioned above; therefore, the change in the net hole absorption at such wavelengths could not be measured in systems containing these solutes. A survival curve for a single species is given by[16]

$$A/A_0 = \exp\left[-C\int_0^\infty \{1-\exp(-kt)\}4\pi R^2 dR\right] \quad (1)$$

where C is the solute (PC acceptor) concentration and k is the first-oder rate constant of PC transfer which depends on the donor-acceptor distance, R. Thus, if two survival curves measured for the same concentration of different solutes agree with each other, the rate constants of the PC transfer to these solutes are identical. Note that the parallel survival curves do not indicate the same rate constant.

In Fig. 3 the survival curves of the holes measured at different bands do not agree. This disagreement means that these bands should be assigned to different species, i.e., there are three kinds of holes or cationic species. The disagreement of these survival curves, however, may be due to an experimental reason that the absorbance could not be corrected for the overlap of other bands. The survival curves of the hole measured at the same wavelength agree with one another among glassy solutions containing different solutes, as shown in Fig. 3. This coincidence can be interpreted as that the rate is independent of the energy gap which is measured as the difference in the ionization potential between the matrix and the solute molecules. This independence contrasts with the previous result that the survival curve of trapped holes in the *s*-BuCl matrix shifts downward as the ionization potential of the solute compound decreases.[5]

A time profile of the absorption signal for the biphenyl-cation band at 700 nm is depicted in Fig. 5 in comparison with that of the 490 nm band of the hole. Monitoring of the holes at 360 and 600 nm was unable because of masking by the strong biphenyl-cation bands. The absorption at 700 nm already formed at the initial time can be attributed to the tail of the 530-nm band and also to a band of biphenyl cations produced within 1 μs. The growth of the biphenyl-cation band in parallel with the decay of the trapped hole absorbing at 490 nm suggests that the biphenyl cation is formed by PC transfer from this hole, although other holes may also contribute to the formation of biphenyl cations. The rather slow decay of biphenyl cations contrasts with the rapid decay of the holes in the neat FM glass. This contrast in decay suggests that the FM matrix is softer than the *s*-BuCl matrix so that small trapped holes can move to attain certain rearrangement but larger biphenyl cations cannot.

Positive-charge transfers from biphenyl cations to TEA, DMA, and pyrene molecules were also studied in FM matrices containing both 0.14 M biphenyl and 0.03 M of each of the acceptor solutes, where the positive charge is first trapped by excess biphenyl and then trasferred from biphenyl cations to acceptor molecules. The survival curves of these donor-acceptor pairs in FM are shown in Fig. 6. The curve shifts downward, i.e. the rate increases, with decreasing ionization potential of a PC acceptor. The similar dependence has also been observed in *s*-BuCl[5,6] and poly(methyl methacrylate) matrices[17] at 77 K. Thus such a dependence is normal, although it contrasts with the energy-gap-independent rate observed in PC transfer from the solvent holes. In Fig. 6 the curves in *s*-BuCl[5b] are also depicted for comparison. In each donor-acceptor pair, the curve for the FM matrix lies lower than that for the *s*-BuCl matrix. It should be noted, however, that this comparison is made under the conditions of different biphenyl concentrations: 0.2 M for *s*-BuCl and 0.14 M for FM, the latter being limited by solubility. As the biphenyl concentration decreases, the biphenyl cation yield may decrease owing to the competition with the acceptor which can also scavenge the hole. A decrease in the biphenyl cation yield was estimated at 5% for a biphenyl-pyrene system on the basis of previous results of steady-state experiments.[18] The magnitude of the observed shift is more than 15%; thus there seems to

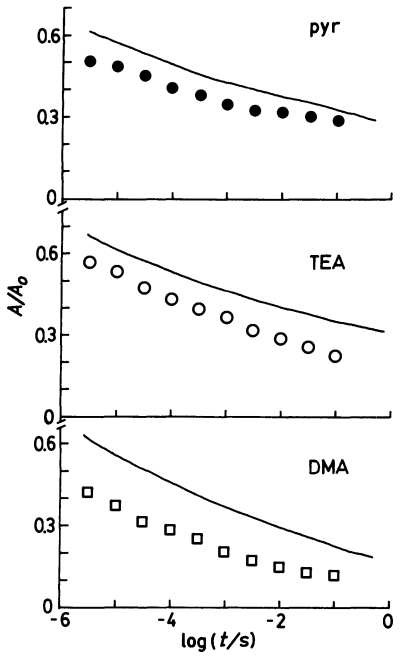

Fig. 6. Survival curves of biphenyl cations in the presence of PC acceptors at 0.03 M: pyrene, TEA, and DMA in FM (points) and in *s*-BuCl (lines) (Ref. 3).

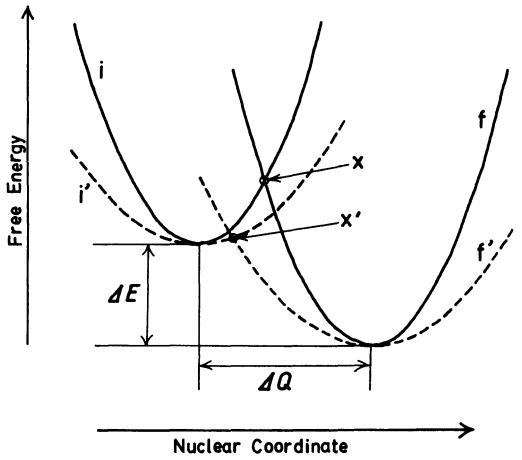

Fig. 7. Possible energy-surface diagrms of a donor-acceptor system in *s*-BuCl (solid curves) matrix and in FM matrix (dashed curves); *i* and *i'* indicate the initial states and *f* and *f'*, the final states.

be the shift of the survival curve with the change of matrix from *s*-BuCl to FM.

Discussion

Electron and hole transfers are explained on the basis of the Fermi golden rule, and the first-order rate constant is expressed as the product of a term associated with electronic interactions, ν, and the thermally-avaraged Franck-Condon factor, F:[5,6,9]

$$k = \nu F \qquad (2)$$

Early theories[19] predict that the (thermally-averaged) Franck-Condon factor first increases with the energy gap and then decreases. The regions where the Franck-Condon factor increases and decreases are called the normal and the inverted region, respectively. On the other hand, some experimental results[20] indicate that the rate reaches a plateau above a certain value of the energy gap in contrast to the theories. A new theoretical explanation has recently been presented for this plateau.[21]

Equation 2 indicates that the Franck-Condon factor can be estimated from the rate constant if the value of the electronic interaction term is known. However, its reliable evaluation is very difficult both experimentally and theoretically. In most data analyses, the electronic interaction has been regarded implicitly as being identical regardless of donors and acceptors. A modified assumption that it is identical for the same donor has also been adopted in analysis of long-range electron transfer.[5-7] In this paper, we assume that for donor-acceptor pairs containing a common PC donor electronic interactions are identical. i.e. the relative Franck-Condon factor is proportional to the observed rate.

A feature of PC transfer from the hole in the FM matrix is the lack of the energy dependence over a rather wide ΔE-range of 1.28 eV. The energy independent rate is known to occur actually if the energy gap of a systems is very large.[20] In other words, if a hole has such a high energy that the ΔE against a solute molecule becomes large enough, the rate will be almost constant irrespective of solute. In *s*-BuCl the rate of PC transfer from the hole to the same solute as that used in the present experiments increases with increasing energy gap. This fact indicates that the energy gap of the hole-acceptor pair in *s*-BuCl is as low as to correspond to the normal region. The ionization potential of FM is probably higher than that of *s*-BuCl (10.65 eV), since the ionization potentials of CF_2BrCF_2Br and $CFCl_3$ are 11.4[22] and 11.7 eV,[23] respectively. Thus, for PC transfer from a trapped hole, the energy difference of a system with the same solute will be larger in the FM matrix than in the *s*-BuCl matrix.

The results of the studies on carbon tetrachloride[15] suggest that the matrix transients in the FM glass may not be assigned to cations of solvent molecules but to other complicated species such as ion pairs similar to $CCl_3^+Cl^-$ proposed for carbon tetrachloride. If ion pairs are involved, the energetics of the system will be complicated, and the above simple consideration may not immediately apply.

The normal energy-gap dependence was observed for the positive-charge transfer from the biphenyl cation where energy gaps are not so large. The point of interest with this reaction is acceleration caused by change of a matrix from *s*-BuCl to FM. Freons and

their mixtures are characterized by poorer solvation abilities than *s*-BuCl. Major molecular vibrations in Freon are carbon-halogen vibrations whose frequency is lower than carbon-hydrogen vibrations dominating *s*-BuCl. These comparisons indicate that an energy surface for a donor-acceptor pair in the FM matrix is represented by a weaker function (or broader curve) than that for the same pair in the *s*-BuCl matrix. The energy diagram as illustrated in Fig. 7 can explain the faster rate in FM matrix in the normal energy-gap dependence region on the assumption that both energy gap (ΔE) and shift in nuclear coordinate (ΔQ) are unchanged. This diagram indicate that broadning of the energy surface lowers the crossing point from x to x' and reduces the activation energy to accelerate the reaction.

(Received September 30, 1985)

The electrochemical behaviors of van der Waals face of p-InSe single crystal electrodes in 0.5M H_2SO_4 and 1M NaOH (1M=1 mol dm^{-3}) with and without illumination have been thoroughly investigated. In 0.5M H_2SO_4, relatively large cathodic dark current was observed and the onset potentials for the current in dark and under illumination were ca. −0.8 V (vs. Ag/AgCl) and ca. −0.5 V, respectively, at as-prepared electrode. The current seemed to be mainly due to hydrogen evolution reaction. The dark current decreased significantly and the photocurrent increased by removing surface steps. These results and impedance analyses show that the surface steps create surface states which act as recombination centers and mediators for charge transfer. Both the dark- and photocurrent onset potentials in 1M NaOH were more negative than those in 0.5M H_2SO_4 by ca. 0.5 V. The dark current was quite large and the photocurrent was small in 1M NaOH even after removing surface steps. By depositing Pt on p-InSe, the photocurrent onset potential shifted towards positive by several hundred mV. The reaction mechanism of photoelectrochemical hydrogen evolution was discussed by considering the above results.

One of the major difficulties in the photoelectrochemical energy conversion is the lack of stability of the semiconductor electrodes under illumination.[1] Many attempts were made to stabilize the electrodes[2] and to seek new electrode materials.[3]

Layered compound semiconductors are expected to have high stability as photoelectrodes.[4] Also, because there is no dangling bond, which creates surface states, at cleaved surface of these materials,[5] the surface recombination probability should be low that leads to high conversion efficiency. Although the photoelectrochemical characteristics of transition metal chalcogenides have been studied very extensively,[6] those of III—VI compound semiconductors are not well known. Indium selenide (InSe) has an ideal energy gap (1.1—1.3 eV[7]) for solar energy conversion devices[8] but only a few reports are available for this application.[9] The photoelectrochemical behavior of InSe was first reported by McCann very briefly.[10] Recently, Levy-Clement et al. reported basic electrochemical characteristics of InSe relatively in detail.[11]

In this paper, we report the thorough study of (photo)electrochemical hydrogen evolution reaction at van der Waals face of p-InSe single crystal.

Experimental

InSe single crystals used in this study were grown by the Bridgman method.[12] p-InSe was doped with Zn by 0.1%. Cleaved surface was always used as an electrode. An ohmic contact was obtained by an In-Zn alloy. Because of weak mechanical strength of the material, Ti plate was used as a support. After the ohmic contact was insured, silver conducting paste (Fujikura Kasei Co. Ltd., Dotite D-550) was used to fix the back side of the electrode to a Ti plate to which Cu wire was connected by using the conducting paste. Except the front face, all other parts were covered with epoxy resin and the electrode was then placed in a glass tubing.

Electrolyte solutions were prepared by using reagnt grade chemicals and water purified by Milli-Q water purification system (Millipore Corp.).

An ordinary three compartment cell with a Pyrex window was used for the measurements. A counter and a reference electrode were a Pt wire and a Ag/AgCl electrode, respectively. The electrode potential was controlled by using a potentiostat (Hokuto Denko, HA-501).

A 500W Xe lamp (Ushio Electric Co. Ltd., UXL-500D-0) with an IR absorbing filter (Toshiba, IRA-20) or a monochromator (Ritsu Oyo Kogaku, MC-25NP) was used as a light source for photocurrent-potential and photocurrent-wavelength relation measurements. The photocurrent-wavelength measurements were carried out with a constant light intensity. A 20 mW He-Ne laser (NEC Corp., GLG5700) with ND filters was used as a light source for the light intensity-photocurrent relation measurements. The intensity of the light was monitored by means of a light power meter (Anritsu Electric Co. Ltd., ML-94A with an MA-97A detector).

Impedance measurements were carried out in dark by using the potentiostat and a frequency response analyzer (NF Electronic Co. Ltd., S-5720B) which was controlled by a personal computer (NEC Corp., PC-8801) via GP-IB interface. In these measurements, a large Pt foil was used as a counter electrode to minimize the impedance due to the counter electrode.

Platinization of the electrode was performed either by dipping the electrode in a H_2PtCl_6 solution (20 mM, pH=4) for 1 min or by the electodeposition in the same solution at 0 V (vs. Ag/AgCl). In the latter case, the amount of Pt deposited was estimated from the charge passed during the deposition.

XPS spectra and visible and near-IR absorption spectra were obtained by using an ESCA-3 (VG Scienticific Ltd.) and a photospectrometer (Shimadzu Ltd., UV-365), respectively.

All the electrochemical measurements were carried out at room temperature after the electrolyte solution was deaerated by passing a purified He gas for at least 20 min.

Results

Spectroscopic Characterization. Layers of InSe were removed by adhesive tape and visible and near-IR spectra of this sample were taken against the adhesive tape without InSe layers as a reference. Figure 1 shows

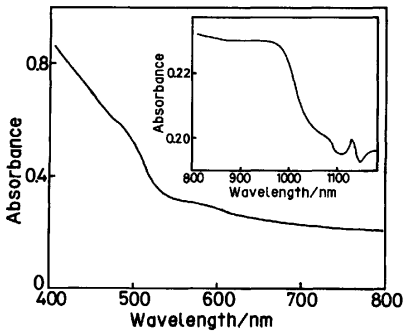

Fig. 1. Absorption spectra of InSe in visible region and in near IR region (inset).

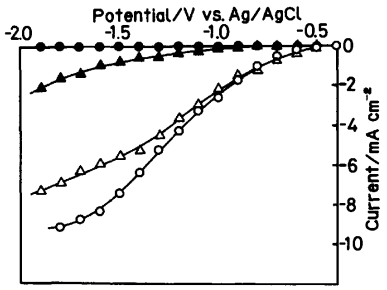

Fig. 2. The dark current (▲,●)- and photocurrent (△,○)-potential relations in 0.5 M H_2SO_4. ▲,△: As-prepared electrode. ●,○: Same electrode after removal of surface steps.

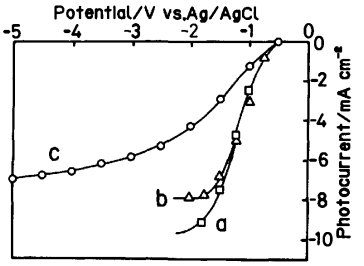

Fig. 3. The photocurrent-potential relations of three p-InSe samples in 0.5 M H_2SO_4. (a): Sample 1, (b): Sample 2, (c): Sample 3.

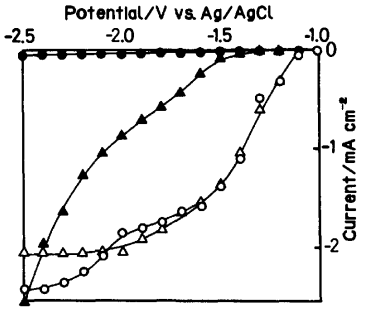

Fig. 4. The dark current (▲,●)- and photocurrent (△,○)-potential relations in 1 M NaOH. ▲,△: As-prepared electrode. ●,○: Same electrode after removal of surface steps.

the visible and near IR absorption spectra. The results were essentially in good agreement with those of Piccioli et al.[7b] with indirect absorption edge at ca. 1000 nm and direct absorption edge at ca. 500 nm. The peak around 1130 nm is considered to be due to exitons.[7b]

Peak energies of the XPS spectra of InSe surface due to In 3d peaks obtained without sputtering agree with those of In metal due to In 3d peaks with Ar^+ sputtering within experimental error, suggesting that indium exists as In(0) state and there is no noticeable indium oxide layer at InSe surface.

Current-Potential Relations with and without Illumination. Figure 2 shows typical current-potential relations of an as-prepared p-InSe electrode in 0.5M H_2SO_4 with and without illumination of light. Relatively large cathodic dark current was observed and while the dark current onset potential was ca. −0.8 V, the cathodic photocurrent was observed at potentials more negative than ca. −0.5 V. The current seemed to be mainly due to hydrogen evolution, since bubbles were observed at the electrode surface and no surface change was noticed after the measurements.

It has been known that the existence of steps at semiconductor electode surface, the van der Waals face of layered compounds in particular, affects the electrochemical behavior of the electrode both with and without illumination.[13] Although the electrode surface was prepared by removing steps with adhesive tape, there were still many steps on the as-prepared InSe clectrode. When the as-prepared electrode was anodically polarized, the dark anodic current due to the oxidation of the electrode was observed. The anodic dark current flowed preferentially through steps as regions near steps became red due to Se deposition.[14] After the Se deposition, the position of steps became more apparent and the removal of steps became easier. Thus, the most of the experiments reported in this work were carried out after the electrode was anodically polarized at 0.5 V (vs. Ag/AgCl) and the surface steps were removed as much as possible. Figure 2 also shows the current-potential relations of the same electrode but after the removal of steps. It is very clear from this figure that the dark current reduced significantly while the photocurrent increased by removing steps. The results reported by Levy-Clement et al. showed relatively large dark current, suggesting the existence of many surface steps.[11]

During the experiments, we noticed the electrochemical behavior differed from sample to sample quite significantly. Figure 3 shows the photocurrent-potential relations of three samples[15] used for the experiments. Although the photocurrents were observed at potentials more negative than ca. −0.5 V and saturated with the value of 8—10 mA cm^{-2} at all samples, the potentials at which the photocurrent showed saturation were different from sample to sample.

Figure 4 shows the current-potential relations in 1M

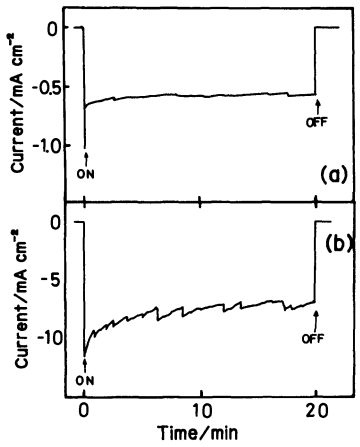

Fig. 5. Current-time relations of p-InSe in 0.5 M H_2SO_4 at (a) −1.0 V and (b) −2.0 V vs. Ag/AgCl. Current before illumination are taken as zero.

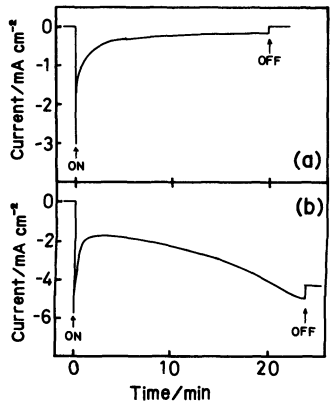

Fig. 6. Current-time relations of p-InSe in 1.0 M NaOH at (a) −1.5 V and (b) −2.5 V vs. Ag/AgCl. Current before illumination are taken as zero.

NaOH of the sample used in Fig. 2 with more and less surface steps. Both the dark and the photocurrent onset potential were more negative than those in 0.5M H_2SO_4 by ca. 0.5 V. These results contrast to the results of GaSe at which no pH dependence was observed.[16] In 1M NaOH, the dark current was quite large even with less surface steps and the photocurrent was small compared to the current in 0.5M H_2SO_4. After the measurements in 1M NaOH, white film was observed on the surface and the electrode swelled and was very easily broken.

Stability. The photocurrent was relatively constant and no significant change of the dark current was observed in 0.5M H_2SO_4 as shown in Fig. 5(a) and (b). The fluctuation of the current was mainly caused by hydrogen bubble which stack on and suddenly left from the electrode surface. On the other hand, in 1M NaOH the photocurrent decreased very quickly (Fig. 6(a) and (b)) and the dark current increased at strong negative bias (Fig. 6(b)). As was the case in the current-potential relation measurements, white film was formed and the electrode became mechanically very weak after the stability measurements in 1M NaOH.

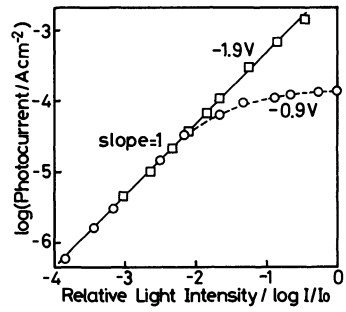

Fig. 7. Light intensity dependence of the photocurrent of p-InSe in 0.5 M H_2SO_4 at −0.9 V (○) and −1.9 V (□) vs. Ag/AgCl (I_o=1.41 mW cm^{-2}).

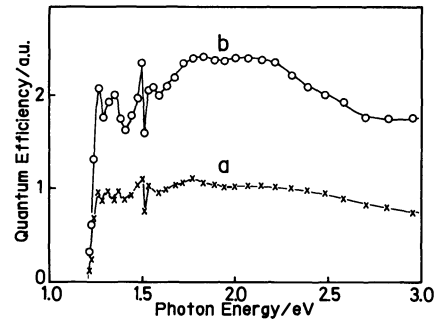

Fig. 8. The photocurrent action spectra of p-InSe in 0.5 M H_2SO_4. At −0.9 V (curve a) and −1.9 V (curve b) vs. Ag/AgCl.

Effect of Light Intensity on Photocurrent. Figure 7 shows the photocurrent-light intensity relations in 0.5M H_2SO_4 at −0.9 V and at −1.9 V. At −0.9 V at which the potential dependence of the photocurrent was large, the photocurrent increased linearly with light intensity as far as the intensity was not too strong but it tended to saturate at higher light intensity. On the other hand, at −1.9 V at which the photocurrent was almost independent of potential, the photocurrent increased lineary with the light intensity even at highest intensity employed in this study . Light intensity independent photocurent has been reported at various semiconductor electrodes.[17]

Quantum Efficiency Action Spectra. Since, as reported above, the quantum efficiency may be affected by light intensity, the quantum efficiency action spectra were obtained with constant light intensity for all measurements. Figure 8 shows the action spectra at −0.9 V and at −1.9 V. No significant shape difference between two spectra was observed. The bandgap energy obtained from these spectra (≈1.2 eV) is in good agreement with the absorption edge (cf Fig. 1).

Impedance Measurements. Figures 9 and 10 are the Cole-Cole plots of the impedance of p-InSe with many steps and with less steps, respectively, in 0.5M H_2SO_4. Although the real component increased with the decrease of the frequency in both cases, the frequency dependence of the imaginary component was

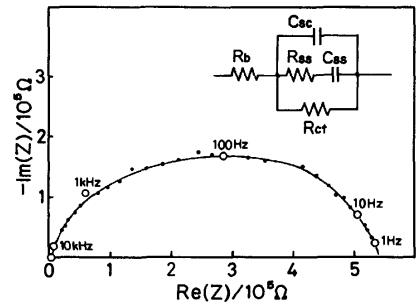

Fig. 9. Cole-Cole plot and the equivalent circuit of p-InSe electrode with many steps in 0.5 M H_2SO_4 without illumination of light. R_b and C_{sc} represent a bulk resistance and a space charge layer capacitance, respectively.

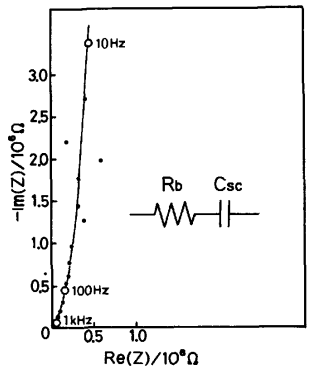

Fig. 10. Cole-Cole plot and the equivalent circuit of p-InSe electrode with many steps in 0.5 M H_2SO_4 without illumination of light. R_{ss} and C_{ss} are the resistance and capacitance of surface state, respectively, and R_{ct} is a charge transfer resistance.

quite different. While the absolute value of the imaginary component of p-InSe with many steps increased with the decrease of the frequency, reached the maximum at ca. 100 Hz and decreased with the decrease of the frequency, that of p-InSe with less steps increased monotonically with the decrease of the frequency.

The equivalent circuits for the former and the latter are also shown in Figs. 9 and 10, respectively.[18] Because of large dark current which leads to the sticking of hydrogen bubble on the electrode surface, the reproducibility of the impedance measurements was low and the potential dependence of the impedance was not determined at the electrode with many steps. The values of the space charge capacitance determined by analyzing the impedance results at various potentials in 0.5M H_2SO_4 with the equivalent circuit shown in Fig. 10 were used to obtain the Mott-Schottky plot of the electrode with less steps (Fig. 11). The flat band potential determined from the plot is +0.2 V (vs. Ag/AgCl). No reliable results were obtained in 1M NaOH due to continuous change of the electrode state.

Effect of Platinum Treatment. The photocurrent-potential relations in 0.5 M H_2SO_4 of p-InSe dip-treated in the H_2PtCl_6 solution and of p-InSe on which Pt was electrodeposited are shown in Fig. 12. In both cases, the photocurrent onset potential shifted towards positive by several hundred mV by Pt treatments. The saturated photocurrent was not affected by the treatments.

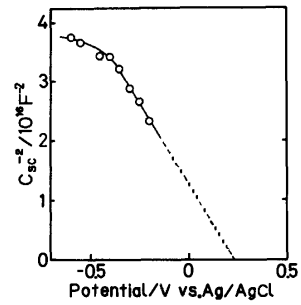

Fig. 11. The Mott-Schottky plot of p-InSe electrode with less steps in 0.5 M H_2SO_4.

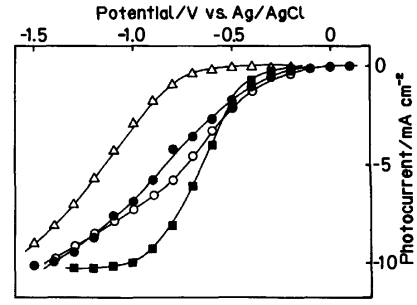

Fig. 12. The photocurrent-potential relations of p-InSe in 0.5 M H_2SO_4. △: Bare, ○: Dip-treated in 20 mM H_2PtCl_6 (pH=4) for 60 sec. ● and ■: Pt electrodeposited. Platinum was electrodeposited in 20 mM H_2PtCl_6 (pH=4) at 0 V vs. Ag/AgCl and the average thickness of Pt was estimated to be 2 Å (●) and 20 Å (■), respectively.

Discussion

pH-Potential Diagram (Pourbaix Diagram) and Stability. To examine the thermodynamic stability of InSe, the pH-potential diagram was constructed (Fig. 13). In Fig. 13, lines (1)—(10) represent the equilibrium reactions of the same numbers shown in Table 1. From the figure, it is confirmed that the red material deposited after the anodic polarization is Se. The white film observed on InSe surface after the (photo)-electrochcmical measurements in 1M NaOH solution must be indium, according to the figure. Although the stable region is wider in acidic solutions than in alkaline solutions, the big difference of the stability observed between these solutions experimentally cannot be explained simply by the thermodynamic data. Reaction (8) should be kinetically more favorable than reaction (6). There is also a possibility of intercalating reaction[22]

$$InSe + Na^+ + e^- \longrightarrow InSe(Na) \qquad (I)$$

Table 1. Equilibrium Reactions of InSe and the Corresponding Electrode Potentials

Reaction	Electrode Potential/V vs. NHE
(1) $In^{3+}+3/2H_2O=1/2In_2O_3+3H^+$	(pK=7.73)
(2) $In_2O_3+H_2O=2InO_2^-+2H^+$	(pK=−17.05)
(3) $In^{3+}+Se+3e^-=InSe$	E=0.233+0.0197 log[In^{3+}]
(4) $1/2In_2O_3+Se+3H^++3e^-=InSe+3/2H_2O$	E=0.386−0.0591 pH
(5) $InO_2^-+Se+4H^++3e^-=InSe+2H_2O$	E=0.721−0.0197 log[InO_2^-]−0.782pH
(6) $InSe+2H^++2e^-=In+H_2Se$	E=−0.987−0.0295 p_{H_2Se}−0.0591 pH
(7) $InSe+H^++2e^-=In+HSe^-$	E=−1.129−0.0295 log[HSe^-]−0.0295 pH
(8) $InSe+2e^-=In+Se^{2-}$	E=−1.546−0.0295 log[Se^{2-}]
(9) $H_2Se=H^++HSe^-$	(pK=4.77)
(10) $HSe^-=H^++Se^{2-}$	(pK=14.01)

The thermodynamic values used for calculation are all taken from Ref. 19 for indium compounds and from Ref. 20 for selenium compounds except for $\Delta G_f^\circ(InSe)$=129.26 kJ·mol^{-1} which is taken from Ref. 21.

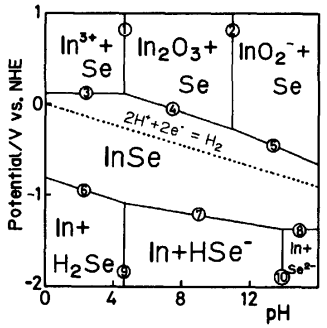

Fig. 13. The pH-potential diagram for the InSe-water system at 25 °C. Each line represents the equilibrium reaction of the same number shown in Table 1 with the following activity. For lines (1) and (3), [In^{3+}]=10^{-6}; for lines (2) and (5), [InO_2^-]=10^{-6}; for lines (6) and (9), p_{H_2Se}=10^{-6}; for lines (7), (9), and (10), [HSe^-]=10^{-6}; for lines (8) and (10), [Se^{2-}]=10^{-6}.

in 1M NaOH, as the mechanical strength of the electrode became very weak after the measurements.

The Reason for Irreproducible Current-Potential Relations. As shown in Fig. 3, the electrochemical behaviors were different from sample to sample. Particularly, the potentials at which the photocurrent showed saturation were different by as large as ≈3 V. In all cases, the photocurrent linearly increased with the potential at medium bias conditions and the resistances calculated from the linear portion by using ohmic law were 0.12 kΩ (sample 1), 0.13 kΩ (sample 2), and 0.50 kΩ (sample 3). The larger the resistance was, the more negative the potential at which the photocurrent saturated. The conductivity of InSe shows anisotropy and that perpendicular to the van der Waals face is relatively low.[23] Thus, the relatively large bulk resistance ⊥ the electrode surface causes large ohmic drop and the actual potential drop at the semiconductor/electrolyte interface (including within space charge layer) becomes low. The resistance difference among samples seemed to be due to the thickness difference.

Effect of Steps on the Electrochemical Behavior. As shown in Fig. 3, the dark current decreased significantly and the photocurrent increased by removing surface steps. The surface steps at which dangling bonds exist[24] certainly create surface states.[25] The results of current-potential relations can be explained by considering the existence of surface states at the electrode with many steps. Thus, the surface states act as recombination centers[26] and mediators for charge transfer,[27] resulting in smaller photocurrent and larger dark current at the electrode with many steps. The impedance analyses (Figs. 9 and 10) also support the above arguments. While the equivalent circuit for the electrode of less steps is simply a series combination of a bulk resistance, R_b, and a space charge capacitance, C_{sc}, the contribution of a surface state resistance, R_{ss}, a surface state capacitance, C_{ss}, and a charge transfer resistance, R_{ct}, should be taken into account in the case of the equivalent circuit for the electrode of many steps. Small R_{ct} is equivalent to a large dark current. By removing steps, the concentration of surface states becomes low and, therefore, C_{ss} becomes small and R_{ss} and R_{ct} become large, giving the equivalent circuit of the electrode of less steps.

The Mechanism for Photoelectrochemical Hydrogen Generation and Effect of Pt Modification. The photocurrent-potential and the photocurrent-light intensity relations at p-InSe in 0.5M H_2SO_4 provide information for the photoelectrochemical hydrogen generation mechanism. The hydrogen evolution reaction at p-type semiconductor under illumination proceeds by the following processes.[28]

(a) Bulk processes:

$$h\nu \longrightarrow p_v^+ + e_c^-, \quad (II)$$

$$e_c^- \longrightarrow (e_c^-)_s, \quad (III)$$

$$e_c^- + p_v^+ \longrightarrow \text{recombination}, \quad (IV)$$

where p_v^+ is the hole in the valence band and $(e_c^-)_s$ and e_c^- are the electrons in the conduction band at the surface and at other places, respectively.

(b) Surface processes:

$$(e_c^-)_s + H_3O^+ \longrightarrow H(a) + H_2O, \quad (V)$$

$$H(a) + (e_c^-)_s + H_3O^+ \longrightarrow H_2 + H_2O, \quad (VI)$$

$$H(a) + H(a) \longrightarrow H_2, \quad (VII)$$

$$(p_v^+)_s + H(a) + H_2O \longrightarrow H_3O^+, \quad (VIII)$$

$$(e_c^-)_s + (p_v^+)_s \longrightarrow \text{Surface recombination}, \quad (IX)$$

$$(e_c^-)_s + \square_{ss} \longrightarrow \boxed{e^-}_{ss}, \quad \boxed{e^-}_{ss} + (p_v^+) \longrightarrow \square_{ss}, \quad (X)$$

where H(a) represents hydrogen atom adsorbed on the semiconductor, $(p_v^+)_s$ is the hole in the valence band at the surface, $\boxed{e^-}_{ss}$ is the occupied surface state, and $\square_{ss}$ is the unoccupied surface state. The step expressed in Eq. (X) is the surface recombination via surface state. The combination of step (V) and step (VIII) could be called the surface recombination via adsorbed hydrogen state. The rate determining step for the hydrogen evolution reaction must be different at potentials more positive than ca. −1.8 V where the photocurrent incrcased with the increase of cathodic bias but became independent of light intensity at relatively high intensity from that at potentials more negative than ca. −1.8 V where the photocurrent was almost independent of the potential but increased linearly with light intensity. In the latter case, the generation of electron-hole pair (step (IV)) is the rate determining srep.[29] This was verified by the fact that the platinization did not affect the saturation photocurrent. On the other hand, in the former case, the rate seems to be controlled by the surface processes. The disagreement of the flat band potential (≈0.2 V) and the photocurrent onset potential (≈−0.5 V) is due to the fact that the reactions (V)—(VII) are slow compared to reactions (VIII)—(X). The significant increase of the photocurrent in this potential region and the positive shift of the photocurrent onset potential by the surface modification with Pt which is known to accelerate the hydrogen evolution reaction in dark[30] (steps (V)—(VII)) again support this mechanism. Although the photoelectrochemical characteristics of p-InSe is improved much by Pt modification, the photocurrent onset potential is still relatively negative and, thus, the efficiency is small. Further improvement is required to reach the efficiency level of other metal modified semiconductor electrodes, e.g. p-InP.[31]

Prof. T. Yokokawa is acknowledged for the encouragement during the course of this work.

Preparation and Coercivity of Cobalt Ultrafine Particles by Reduction of Multilayered CoO-SiO Films

Yoshichika BANDO and Takahito TERASHIMA*
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received April 27, 1985)

Films containing Co ultrafine particles were prepared by hydrogen reduction of periodically multilayered CoO–SiO films which were formed by alternating deposition of CoO and SiO. The films containing Co particles maintained the periodicity similar to the original films. Using samples of CoO single layer sandwiched between SiO layers, highly dispersed Co particles in the reduced sample were observed by transmission electron microscopy. The average size of the Co particles was almost as large as the thickness of CoO layer. The coercivities of the multilayered films containing Co particles were measured at room temperature and 77 K; they decreased with decreasing particle size from 20 nm to 3nm. Superparamagnetism was observed for the Co particles with average sizes below 4nm at room temperature. The formation and the magnetic property of the Co ultrafine particles in the Co–SiO system is dicussed.

Periodically multilayered films composed of two substances have been investigated as a means of producing materials having unusual properties.[1-4] Studies of multilayered films have been limited to their structure and physical properties such as their magnetic, electric and mechanical behavior. The present paper deals with chemical change of multilayered films of CoO–SiO. Silicon oxide ($SiO \sim SiO_2$) has been used as a coating for passivation of semiconductor devices and for coating ultrafine particles.

It has been reported that the coating of precursor particles, such as hydroxides and oxides with silicon compounds frequently has a great effect on the shape and size of metallic or oxide particles prepared by reduction or decomposition of the precursor.[5,6] The role of the silicon oxide in the reduction or decomposition process has not been made clear.

In multilayered CoO–SiO films, a CoO layer is coated with SiO layers. The reduction of the CoO layers in the multilayered film may therefore be similar to that of oxide precursor particles coated with silicon compounds which change into silicon oxide. Investigations of the reduction of multilayered CoO–SiO films contribute to the elucidation of the role of silicon oxide in the preparation of ultrafine particles.

SiO is readily evaporated and the deposited SiO is amorphous. SiO films have strong adhesion to various substrates, environmental stability, and superior mechanical properties. These properties improve the quality of the the multilayered films. Silicon oxide is oxidized during deposition process and its composition (SiO_{1+x}) depends on deposition parameters such as the evaporation rate, the substrate temperature and the degree of vacuum. Hereafter, SiO_{1+x} will be expressed as SiO. Since the thickness of the silicon oxide coating on the oxide or metal particles is considered to be below 2 nm, it is desirable that the SiO layer used in the present experiment be as thin as possible within the limits of a continuous films. We chose 1.5 nm as a suitable layer thickness of SiO.

Fine particles of Co are readily prepared by hydrogen reduction of CoO at a low temperature. Furthermore, Co ultrafine particles have many interesting properties as magnetic materials and catalysts. Therefore, CoO is the most suitable as a constituent of multilayered films for our purpose.

CoO ultrathin films can be prepared by reactive evaporation.[7] Periodically multilayered films may be prepared by alternating deposition of CoO and SiO.

Experimentals

SiO was deposited by evaporation of SiO in a vacuum of 10^{-4}Pa and CoO was reactively deposited by evaporation of Co metal in oxygen at a pressure of 5×10^{-2}Pa. The thickness and deposition rate of each layer were monitored by an oscillating quartz sensor. The deposition rates of both CoO and SiO were 0.1 nm s^{-1}. The thickness of the SiO layers was chosen to be at 1.5 nm and those of CoO layers were designed to be 1.5 to 20 nm. Glass plates and polyimide films were used as substrates (glass for X-ray diffraction and polyimide films for magnetic measurements). During deposition, the substrate was kept at room temperature by water cooling. Reduction of the multilayered films was achieved by heating them in a hydrogen atmosphere at 200°C for 1 h. The CoO–SiO films and the reduced films were examined by X-ray diffraction (RIGAKU ROTAFLEX RU-200) using Cu $K\alpha$ radiation and transmission electron microscopy (JEOL JEM-100CX and JEM-200CX). The magnetic properties of the reduced films were measured by a vibrating-sample magnetometer (TOEI VSM-3).

Results

Reduction of the Multilayered CoO–SiO Films.

The cobalt oxide layers in the as-deposited film were identified to be CoO by X-ray diffraction, as shown in Fig. 1(a). As-reduced films were black and lustrous. X-ray diffraction showed that there was mainly hcp Co metal in the reduced films as shown in Fig. 1(b). However, the existence of the fcc phase was confirmed by electron diffraction of the reduced film as shown in Fig. 1(c); this includes the (200) ring of fcc Co. These results of X-ray and electron diffractions thus showed that both hcp and fcc Co exist in the reduced films, but the amount of the fcc phase is small.

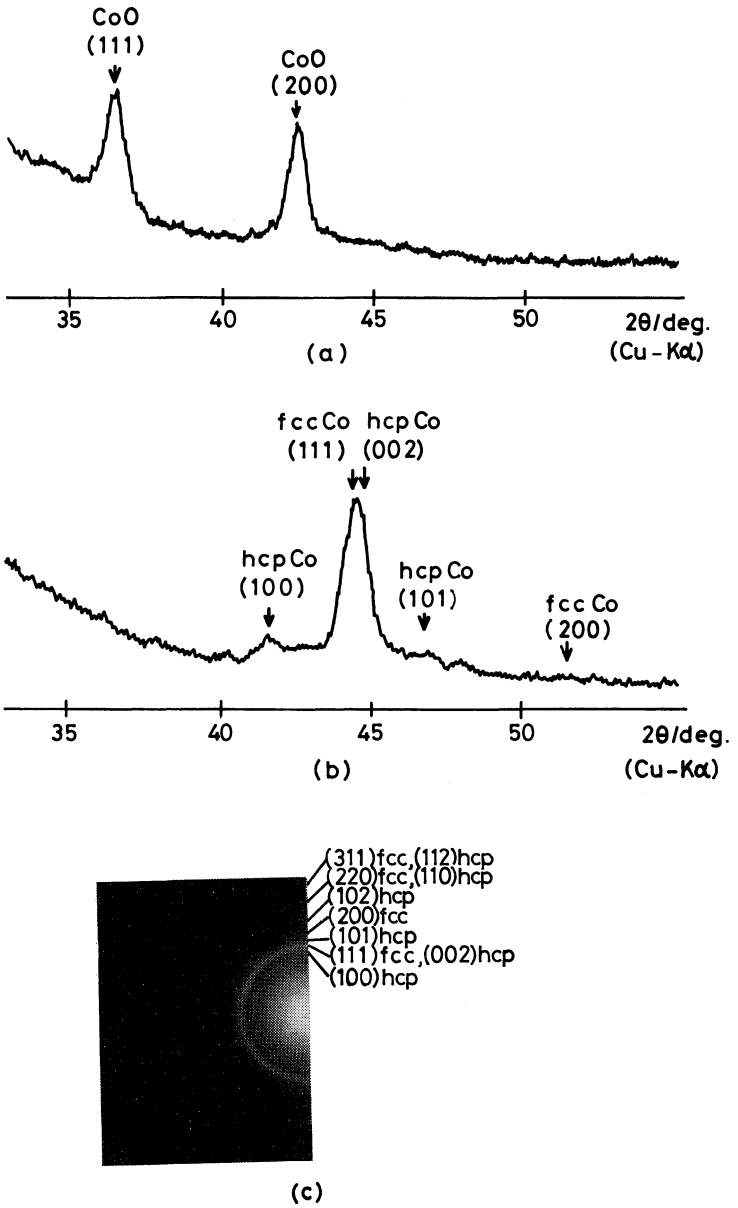

Fig. 1. (a) X-Ray diffraction pattern of the as-deposited [CoO-(13.5 nm)-SiO(1.5 nm)]×10. (b) X-Ray diffraction pattern of the reduced [CoO(13.5 nm)-SiO(1.5 nm)]×10. (c) Transmission electron diffraction pattern of the reduced [SiO(10 nm)-CoO(15 nm)-SiO(3 nm)].

Periodicity of the Multilayered Films Before and after Reduction. The periods of composition modulation in the multilayered films were determined by low angle X-ray diffraction. The 2nd and 3rd Bragg diffraction peaks for the as-deposited film were observed as shown in Fig. 2(a), and the period calculated from diffraction angles was in good agreement with the designed period.

As shown in Fig. 2(b), the value of period of the reduced film is almost the same as that of the as-deposited films. This means that the periodicity persists during reduction and the thickness of the Co layers is similar to that of CoO layers, as the thickness of SiO layer should be invariable.

Reduction of Single CoO Layer Sandwiched in between SiO Layers. The samples of single CoO layer sandwiched in between SiO were prepared as follows. The CoO layer was deposited on SiO support film on a mesh for electron microscopic observation and was coated by a SiO film. The single CoO layer was directly examined by TEM, as shown in Fig. 5. The electron diffraction pattern shows CoO and the micrograph shows a continuous film consisting of microcrystallites. Results of TEM examination for the sample after heated in H_2 at 200 °C are shown in Fig. 6. The diffraction pattern indicated metallic Co with the hcp and fcc structures; this is consistent with the pattern in Fig. 1(c). Co ultrafine particles with

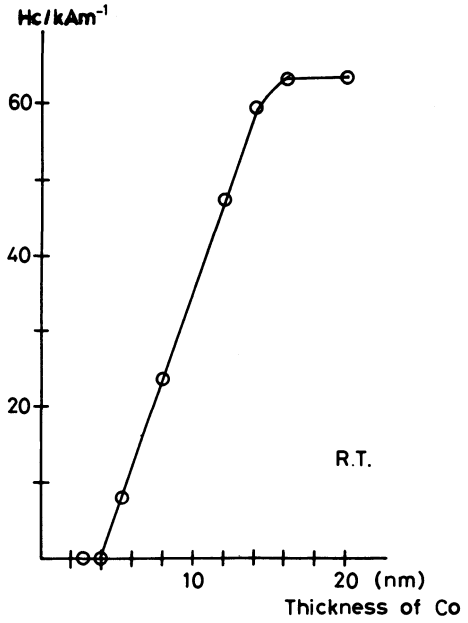

Fig. 3. Coercive force *Hc* measured at room temperature as a function of thickness of Co layer. Total thickness of Co layers in each film was fitted to be about 100 nm.

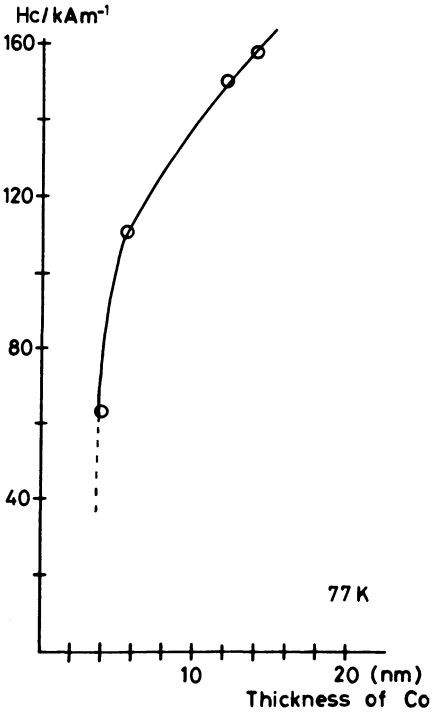

Fig. 4. Coercive force *Hc* measured at 77 K as a function of thickness of Co layer.

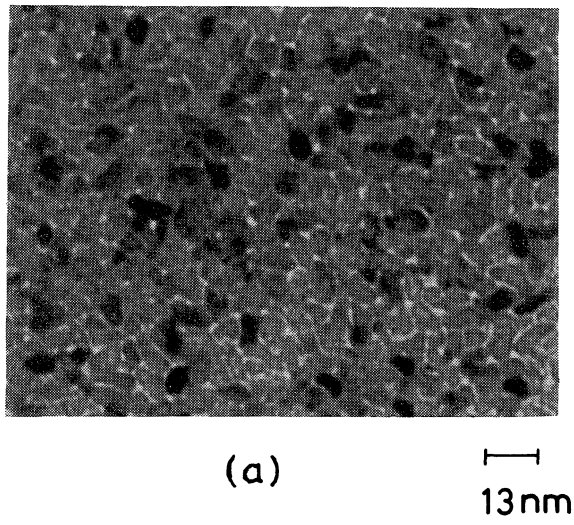
sizes ranging from 4 to 20 nm were clearly observed in microphotograph of a sample prepared by reducing the 9 nm thick CoO layer. For the 5 nm thick CoO layer, the size of the Co particles in the reduced sample ranged from 2.5 nm to 8 nm, as shown in Fig. 7(a). The average size of the Co particles is close to the value for the thickness of the original CoO layer. The lattice image of a Co particle shown in Fig. 7(b) indicates that the particle is a single crystal.

Magnetic Measurement of the Reduced Films. The reduced films showed ferromagnetism with typical hysteresis loops. Figure 3 shows the coercive force *Hc* measured at room temperature as a function of the thickness of Co layer. *Hc* decreased with decreasing Co layer thickness and became zero below 4 nm thick. The magnetic curves of films with 4 nm or less thick Co layers were superparamagnetic. When the magnetic curves were measured at 77 K, *Hc* for the film containing 4 nm thick Co layers was as high as 63 kA/m, as shown in Fig. 4. These magnetic data for the reduced films show that they contain metallic Co which is highly dispersed in ultrafine particles.

Discussion

It is clear from the experimental results that ultrafine Co particles are prepared by reducing the CoO–SiO multilayered film in H_2. Furthermore, it is surprising that the reduced films containing Co particles have the periodicity of composition modulation. This means that SiO layer as thin as 1.5 nm supports the multilayered structure during reduction, as shown in Fig. 8. The reduction of CoO to Co would not occur at once. When a CoO layer sandwiched between SiO



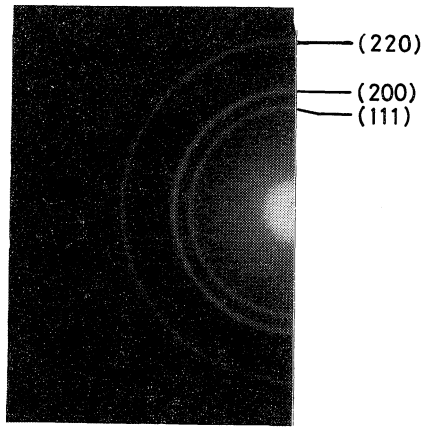


Fig. 5. (a) TEM image of the as-deposited [SiO(10 nm)–CoO(10 nm)–SiO(3 nm)]. (b) Transmission electron diffraction pattern of the same sample.

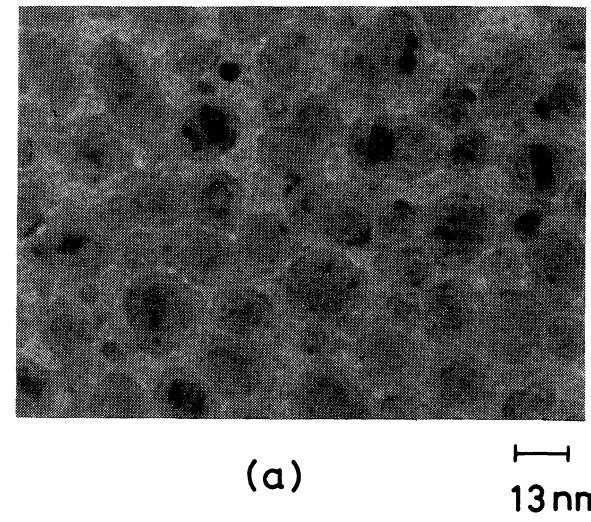

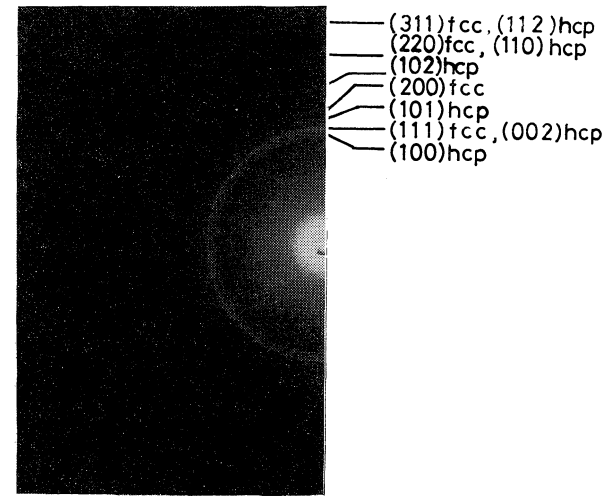

Fig. 6. (a) TEM image of [SiO(10 nm)–Co(10 nm)–SiO(3 nm)]. (b) Transmission electron diffraction pattern of the same sample.

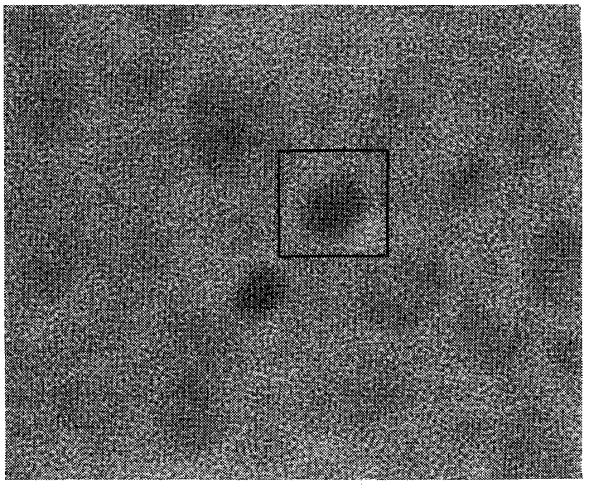
films is reduced, some portions of the layer would remain as CoO and maintain the original SiO-SiO interlayer distance. When the remaining CoO is successively reduced, the Co particles already formed would maintain the interlayer distance. When CoO changes into Co, the volume reduces to about a half; this comes from the release of oxygen and an increase of the density from 6.3×10^3 kg m^{-3} for CoO to 8.9×10^3 kg m^{-3} for Co.

The formation of the highly dispersed ultrafine particles is caused by both of the constant SiO-SiO interlayer distance before and after reduction and of the volume decrease from CoO to Co. If the Co particles have the shape of columns with a diameter and a height equal to CoO layer thickness d and arrayed in a regular triangular lattice, as shown in Fig. 9, the distance between the nearest neighbor columns is calculated to be 1.35 d, showing formation of isolated particles.

The Co ultrafine particles less than 20 nm constitute a single magnetic domain. For an assembly of single domain particles with the easy axes oriented at random, in a non-ferromagnetic matrix, the value of Hc is expressed as follows:[8]

$$Hc = 0.48 \times 2K/Is \qquad (1)$$

where K is the magnetic anisotropy energy constant and Is is the saturation magnetization. Using Is=1.79 T[9] and $K=4.6\times10^5$ Jm^{-3}[10] for hcp Co, Hc would be about 247 kAm^{-1}. In Fig. 3, maximum coercivity of 63 kAm^{-1} is considerably lower compared with the calculated value. K value for fcc Co is considered to be as large as 2×10^4 Jm^{-3},[11] and Hc would be about 11 kAm^{-1}.



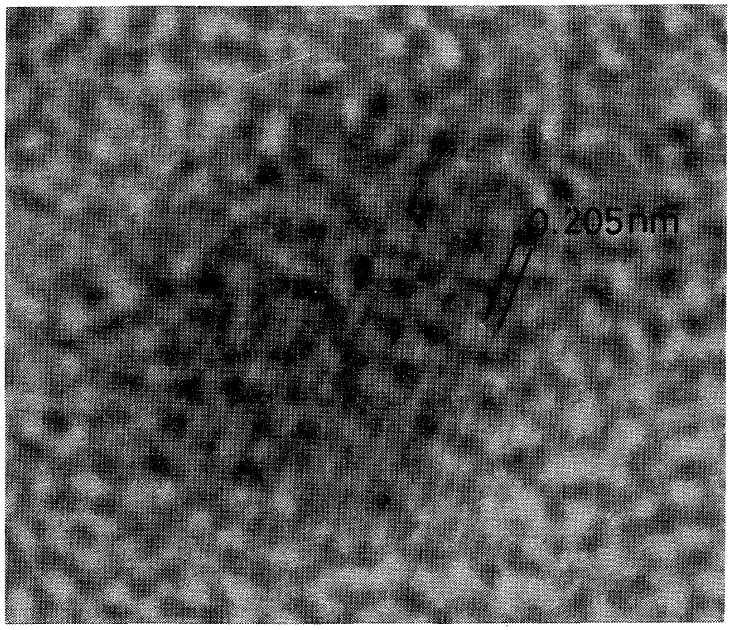


Fig. 7. (a) TEM image ot [SiO(10 nm)-Co(5 nm)-SiO(3 nm)].
(b) The lattice image of the particle indicated in (a).

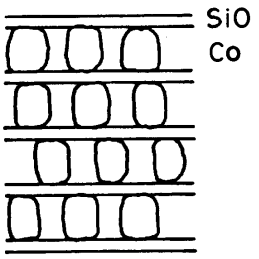

Fig. 8. Schematical illustration of the multilayered structure containing Co particles supported by continuous SiO layers.

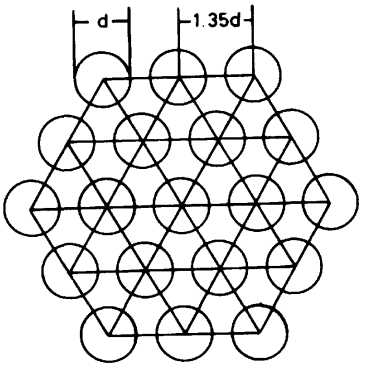

Fig. 9. Schematical illustration of the location and size of the reduced Co particles in film plane.

If the assembly of Co particles consists of both the fcc and the hcp particles, the low value of Hc obtained suggests that the amount of the fcc phase particles should be more than that of the hcp particles. However, the results of X-ray and electron diffraction measurements indicated only a small amount of the fcc phase. As the difference between the free energies of fcc and hcp in Co metal is small, a particle may frequently contain both phases; the fcc stacking may be regarded as stacking faults in the hcp phase.

Therefore, individual particles obtained may contain both phases. The existence of the fcc phase in the hcp Co may decrease the large uniaxial magnetic anisotropy energy due to hexagonal symmetry.

Using Is=1.79 T and Hc=63 kAm^{-1} of the experimental value, K would be 1.2×10^5 Jm^{-3}. Using this K value, we can calculate the critical size for superparamagnetism at room temperature by the expression,[11]

$$\tau = \tau_0 \times \exp(KV/kT) \quad (2)$$

where τ is the superparamagnetic relaxation time, τ_0 is the frequency factor, V is the magnetic volume of the particles, k is Boltzman's constant and T is the temperature. When the coercivity is zero for a static magnetic measurement, τ is of the order of 10^2 s. The blocking temperature T_B is defined as the temperature below which the particles show ferromagnetism, i.e., the temperature at which τ is of the order of 10^2 s. The critical size for superparamagnetism at room temperature is calculated by the relation KV/kT=25, assuming $\tau_0=10^{-9}$ s and $\tau=10^2$ s. The diameter calculated for column particles is 10.3 nm. In Fig. 6, the average size is 9 nm, but the sizes are distributed from 20 nm to 4 nm. The decrease in Hc for particle diameters below 1.6 nm in Fig. 3 is attributed to the presence of the superparamagnetic particles. With decreasing thickness, the ratio of the superparamagnetic particles increases and the value of Hc drops abruptly. It is reasonable that the particles with an average size of 9 nm have half the value of the maximum coercivity. At 77 K, the value of the anisotropy would be estimated to be 3.0×10^5 Jm^{-3} from maximum Hc=160 kAm^{-1}. The critical size for superparamagnetism is 4.8 nm; this is reasonable in consideration of the value of the coercivity of the Co particles with an average size of 5 nm.

So far, we have discussed the K value and the critical size for superparamagnetism on the assumption that the fcc phase exists within the hcp Co particles. The calculated values are in good agreement with the observed ones, which indicates that our assumption is reasonable.

The values of Is and Hc in the reduced films persisted over 1 year or longer. Therefore, SiO is a good protector to oxidation of Co ultrafine particles. On the other hand, SiO-coated CoO is readily reduced to Co at 200°C; accordingly oxygen atoms should be able to pass through SiO layer. Furthermore, it is clear that SiO has a function to support the original shape of the starting material such as the multilayered structure during reduction. It is concluded that these characteristics of SiO as a coating make it suitable for use in the preparation of metallic or oxide ultrafine particles for magnetic recording media and catalyst.

The authors thank Professors T. Takada and M. Takano of the Institute for Chemical Research, Kyoto University, and Prof. T. Shigematsu of Konan University for fruitful discussions. Thanks also due to Dr. N. Nakayama of the same Institute for the suggestion for the observation of TEM. This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Kinetics and Mechanism of Replacement of Glycinate in Bis(glycinato)oxovanadium(IV) by Oxalate

Jung-Sung KIM,† Woo-Sik JUNG, Hiroshi TOMIYASU, and Hiroshi FUKUTOMI*
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received July 25, 1985)

The kinetics of formation of bis(oxalato)oxovanadate(IV) $[VO(ox)_2(H_2O)]^{2-}$ (hereafter water molecule will be omitted) from the reaction of bis(glycinato)oxovanadium(IV) $[VO(gly)_2]$ with oxalate has been studied by the stopped-flow method. The reaction was found to consist of two consecutive steps, a relatively slow step (k_1) and a fast one (k_2). The values of rate constants k_1 and k_2 were independent of the concentration of free oxalate and of the pH of solution ranging from 4.2 to 6.5. Similar behavior was also observed in the acid decomposition of $[VO(gly)_2]$. A mechanism passing through an intermediate, $[VO(ox)(gly)]^-$, was proposed.

The kinetics of ligand-substitution reactions for a variety of oxovanadium(IV) complexes has been studied extensively.[1-12] The study of ^{17}O NMR in $[VO(H_2O)_5]^{2+}$[2,3] revealed that the rate of water exchange at the axial position was extremely fast, but relatively slow at the basal positions, in which the rate constant was determined by the conventional NMR line-broadening method. Since then, much interest has been centered in the kinetic study of ligand substitutions in oxovanadium(IV) complexes to compare the rate constants of various ligand substitutions with those of water exchange.

The kinetic behavior of oxovanadium(IV) complexes appears to be quite interesting, for the rates of ligand substitutions differ as much as some hundreds according to substituting ligands and structures of complexes. In the case of formation of chelate complex, $[VO(gly)]^+$, from $[VO\text{-}gly]^+$, glycinate of which coordinates as a unidentate ligand, the rate constant was about 1/10 of that of water exchange at the basal positions.[6] Much slower rate was reported for the anation reaction in [VO(pmida)](pmida=*N*-(2-pyridylmethyl)iminodiacetate) by NCS^- and N_3^-.[9]

In this paper we report the kinetics of the replacement of glycinate in $[VO(gly)_2]$ by oxalate

$$[VO(gly)_2] + 2ox^{2-} \longrightarrow [VO(ox)_2]^{2-} + 2gly^- \qquad (1)$$

for a further understanding of substitution mechanisms in oxovanadium(IV) complexes.

Experimental

The preparation and analysis of the oxovanadium(IV) stock solution were described in a previous paper.[4] Analytical grade (Wako Pure Chemical Ind., Ltd.) perchloric acid, sodium oxalate and sodium perchlorate which was recrystallized twice from aqueous solution were used. The ionic strength was adjusted at 1.0 M (1 M=1 mol dm^{-3}) by using sodium perchlorate. A Union Giken RA-401 stopped-flow spectrophotometer was used for accumulated stopped-flow measurements, where accumulations were carried out at least ten times. Absorption spectra were measured by using a Shimadzu UV-365 spectrophotometer with 20 mm quartz cells.

Results and Discussion

The absorption spectra of $[VO(gly)_2]$ and $[VO(ox)_2]^{2-}$, whose assignment was reported in the earlier papers,[7,14] are shown in Fig. 1. It was found that the spectra of final products of the reaction between $[VO(gly)_2]$ and oxalate were consistent with that of $[VO(ox)_2]^{2-}$ indicating that the stoichiometry can be written by Eq. 1 under the conditions studied. The rate of the reaction was measured from the change in absorbance at 555 nm. A typical stopped-flow trace is shown in Fig. 2 together with a pseudo-first-order plot ($\log(A_t - A_f)$ vs. time), where A_t and A_f refer to the relative absorbances at times t and infinity, respectively. As is seen in Fig. 2, the pseudo-first-order plot deviates from a straight line in spite of excess sodium oxalate suggesting that the reaction consists of two consecutive steps. The results lead to the following reaction mechanism passing through an intermediate complex, (Int),

$$[VO(gly)_2] \xrightarrow{k_1} (Int) \xrightarrow{k_2} [VO(ox)_2]^{2-}, \qquad (2)$$

where k_1 and k_2 represent the first-order rate constants for each step. Based on the above reaction mechanism, the stopped-flow traces were analyzed by means of the nonlinear-least-squares method using k_1, k_2, and ε_{Int} (molar extinction coefficient of (Int)) as unknown parameters. The calculated values of absorbance with time agree remarkably with the observed data (Fig. 2), where ε_{Int} is taken to be 9.9 M^{-1}cm^{-1} at 555 nm. Since the consecutive first-order reaction similar to the present reaction admits of two mathematical solutions which are a set of alternative parameters, it is necessary to determine which is the correct set of parameters.[15] The alternative molar extinction coefficient, ε'_{Int}, is give by

$$\varepsilon'_{Int} = \varepsilon_{VO(gly)_2} + \frac{k_1(\varepsilon_{Int} - \varepsilon_{VO(gly)_2})}{k_2} \qquad (3)$$

and the value of ε'_{Int} is calculated at 13.2 M^{-1}cm^{-1} by using the values of $\varepsilon_{VO(gly)_2}$=16.0 M^{-1}cm^{-1} and ε_{Int}=

†Present address: Department of Chemistry, Taegu University, Taegu, Korea.

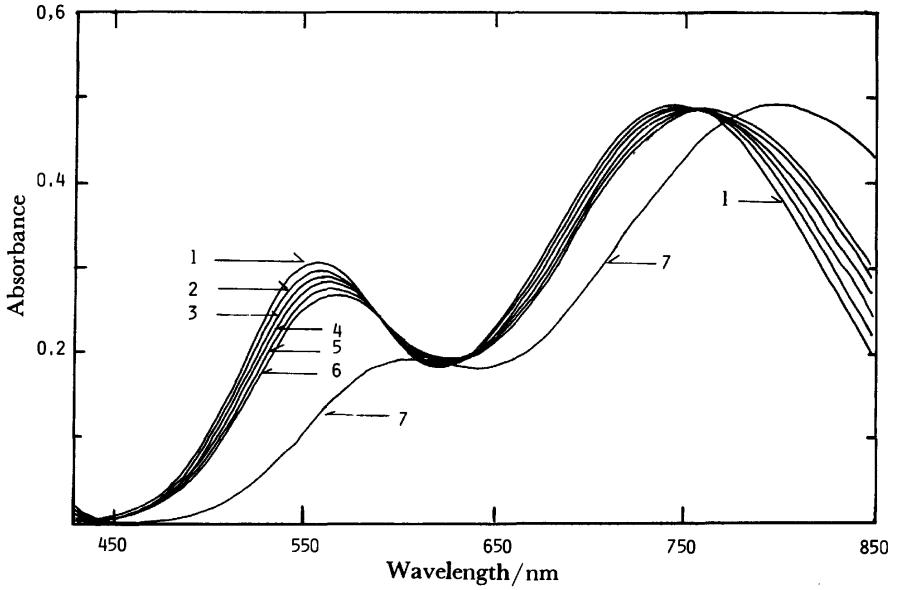

Fig. 1. Absorption spectra of $[VO(gly)_2]$ (1) and $[VO(ox)_2]^{2-}$ (7). Spectra (2—6) were obtained by the addition of small amounts of Na_2ox to the $[VO(gly)_2]$ solution. The conditions are as follow: [VO(IV)]=9.38×10^{-3} M, [glycine]= 2.00 M, pH=6.5 at 20°C. [Na_2ox]=0 (1), 1.24×10^{-3} (2), 2.49×10^{-3} (3), 4.98×10^{-3} (4), 7.46×10^{-3} (5), 9.95×10^{-3} M (6), and excess Na_2ox (7).

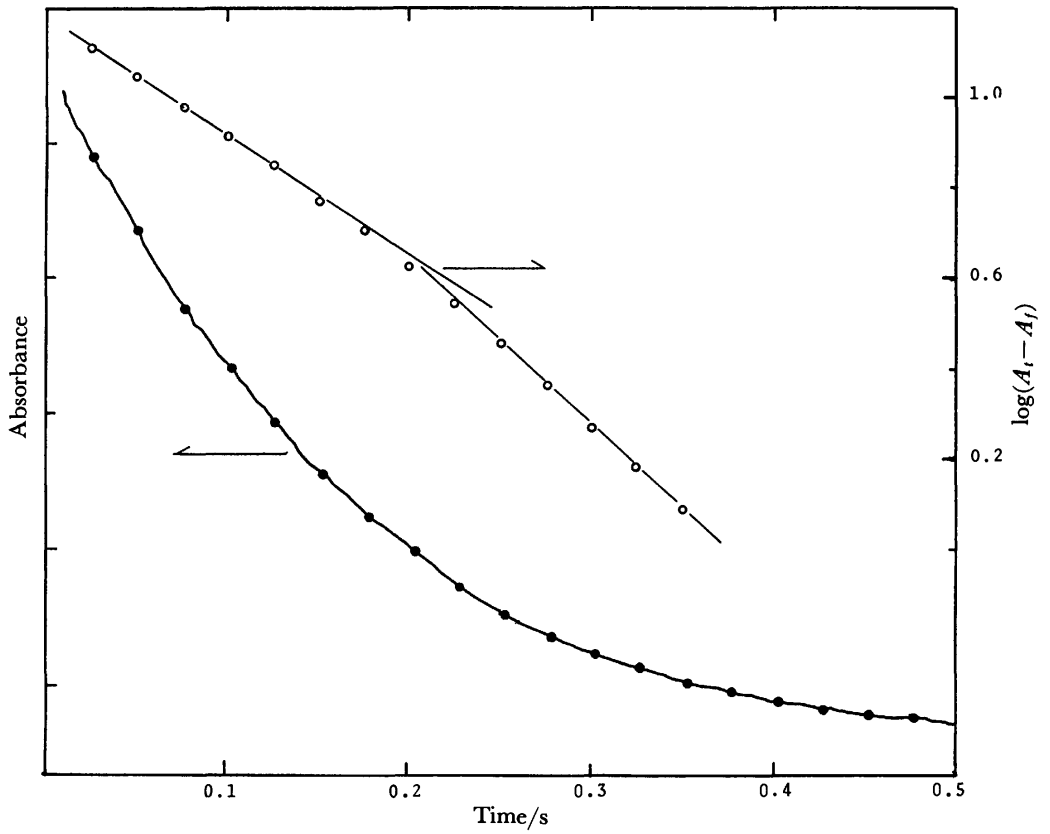

Fig. 2. Typical stopped-flow trace. $[VO(gly)_2]_o$=0.0116 M, $[Na_2ox]_o$=0.125 M, ionic strength= 1.0 M, pH=4.64 at 20°C.
○: Pseudo-first-order plot, ●: nonlinear-least-squares fits based on reaction mechansim (2).

Table 1. Values of k_1 and k_2 at 20 °C under Various Conditions

pH	$[Na_2ox]$ / M		k_1 / s^{-1}	k_2 / s^{-1}
4.64	0.125		6.95	17.5
4.93	0.100		7.76	14.8
5.74	0.075		7.96	16.1
6.57	0.050		8.81	17.8
4.67	0.075		7.45	14.5
4.23	0.050		7.07	19.3
		Average	7.67	16.7

$9.9\,M^{-1}cm^{-1}$ at 555 nm, $k_1=7.67\,s^{-1}$ and $k_2=16.7\,M^{-1}cm^{-1}$ at 20 °C in Table 1. Additional experiments were carried out to estimate the approximate value of molar extinction coefficient of (Int) and to choose between ε_{Int} and ε'_{Int}. A small amount of sodium oxalate was weighed and added to an aqueous solution at pH=6.5 containing $[VO(gly)_2]$ (9.38×10^{-3} M) and glycine (2.0 M), where a volume change due to the addition of Na_2ox was negligible. In Fig. 1, the absorbance at 555 nm decreases as the concentration of Na_2ox increases and the spectra have three isosbestic points at 585, 635, and 735 nm. Addition of excess Na_2ox gives the spectrum of $[VO(ox)_2]^{2-}$, which passes through neither of the above isosbestic points. It is clear that the addition of small amounts of Na_2ox results in the formation of an intermediate complex and it seems most likely that the intermediate is a mixed-ligand complex, $[VO(ox)(gly)]^-$. The value of ε_{Int} at 555 nm was determined to be $10.4\,M^{-1}cm^{-1}$ assuming that the absorbance change in Fig. 1 is based on the following equilibrium.

$$[VO(gly)_2] + ox^{2-} = [VO(ox)(gly)]^- + gly^- \qquad (4)$$

In conclusion, these results support the former solution for k_1 and k_2 with $\varepsilon_{Int}=9.9\,M^{-1}cm^{-1}$.

It can be seen in Table 1 that both k_1 and k_2 are independent of the initial concentrations of sodium oxalate and pH's within experimental errors. These results are particularly surprising in view of the fact that the substitution rates in oxovanadium(IV) complexes are usually affected by the species of substituting ligands and their concentrations.[4,5,9]

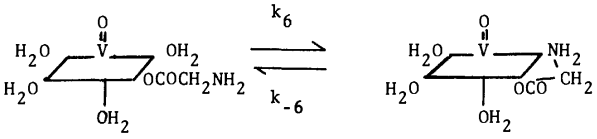
The rate of dissociation of glycinate from $[VO(gly)_2]$ by the addition of perchloric acid has been also measured by the stopped-flow method. Since the pH of the solution after mixing $[VO(gly)_2]$ and perchloric acid solutions was 3.0 and the major species in such a pH region of oxovanadium(IV)-glycine system was known to be $[VO(H_2O)_5]^{2+}$ and $[VO(Hgly)]^{2+}$ where glycine coordinated as a unidentate ligand,[14] the reaction can be written by

$$[VO(gly)_2] \xrightarrow{+H^+} [VO(H_2O)_5]^{2+} + [VO(Hgly)]^{2+}. \qquad (5)$$

The stopped-flow trace was very similar to that in Fig. 2 and showed again two components. Rate constants $k_{d(1)}$ and $k_{d(2)}$ for the initial and latter steps respectively were also determined by the nonlinear-least-squares method. The values of $k_{d(1)}$ and $k_{d(2)}$ in Table 2 were determined with the molar extinction coefficient of an intermediate, $\varepsilon_{d(Int)}=8.8\,M^{-1}cm^{-1}$, which was about the mean of those of $[VO(gly)_2]$ and $[VO(H_2O)_5]^{2+}$ at 555 nm, 16.0 and $2.2\,M^{-1}cm^{-1}$, respectively. In analogy with reaction (1), some uncertainty remains as to the reasonable sets of values of $k_{d(1)}$ and $k_{d(2)}$ in reaction (5). Since the molar extinction coefficient of $[VO(Hgly)]^{2+}$ has not been determined accurately, it is even more difficult to evaluate the molar extinction coefficient of the intermediate in reaction (5) than in reaction (1). Although the complete solution was not obtained at present, the fact that the reaction (5) proceeds via two steps might suggest a similarlity of mechanisms in both reactions. As the difference in rate constants $k_{d(1)}$ and $k_{d(2)}$ is not significant, the above suggestion as to the mechanistic similarity seems to be acceptable even when $k_{d(1)}$ and $k_{d(2)}$ are interchanged.

Considering the results in Tables 1 and 2, we propose a mechanism, in which the ring opening, i.e. the rupture of V-N bonds in $[VO(gly)_2]$, is the initiation step of the reaction as shown in Fig. 3. The bond rupture results in the formation of complex II, where one glycinate coordinates as a unidentate ligand. Complex II is attacked by ox^{2-} (Hox^-) and forms complex III, and then more stable complex IV. Complex IV corresponds to the (Int) in Eq. 2. If the initial ring opening is assumed to be rate determining, the oxalate specics, ox^{2-} and Hox^-, and their concentrations give no effect on the substitution rate, and k_1 should be the rate constant of the ring opening in $[VO(gly)_2]$. Similarly the k_2 step corresponds to the over-all process from IV to VI and k_2 refers to the rate constant of the ring opening in complex IV. Similar mechanism passing through an intermediate unis(glycinato)complex, $[VO(gly)]^+$, is proposed for the acid decomposition of $[VO(gly)_2]$. In the earlier study[7] dealing with the formation of $[VO(ox)_2]^{2-}$ from the aqua complex, the rate was dependent on the concentrations of ox^{2-} and Hox^-, and the second-order rate constants were determined to be 1.29×10^4 and $7.0\times10^2\,M^{-1}s^{-1}$ at 15 °C for ox^{2-} and Hox^-, respectively. These results clearly indicate that the rate of the over-all process from II to IV in Fig. 3 is at least hundred times faster than that of the initial ring opening under the present conditions.

It is interesting to compare the present reactions with the following reaction in unis(glycinato)oxovanadium(IV).[6]



(6)

Table 2. Rate Constants and Activation Parameters in Ligand-Substitution Reactions in Oxovanadium(IV) Glycine Complexes

Reaction	Rate constant/s^{-1}		ΔH^*	ΔS^*
	20 °C	25 °C	kJ mol^{-1}	JK^{-1} mol^{-1}
$[VO(gly)_2]+ox^2 \longrightarrow [VO(ox)_2]^{2-}$				
k_1	7.67	11.3	51.2	−55
k_2	16.7	29.7	—	—
Acid decomposition of $[VO(gly)_2]$				
$k_{d(1)}$	7.47	—	—	—
$k_{d(2)}$	14.3	—	—	—
Ring closure of $[VO\text{-}gly]^+$	—	35	57.1	−24
Ring opening of $[VO(gly)]^+$	—	19	—	—

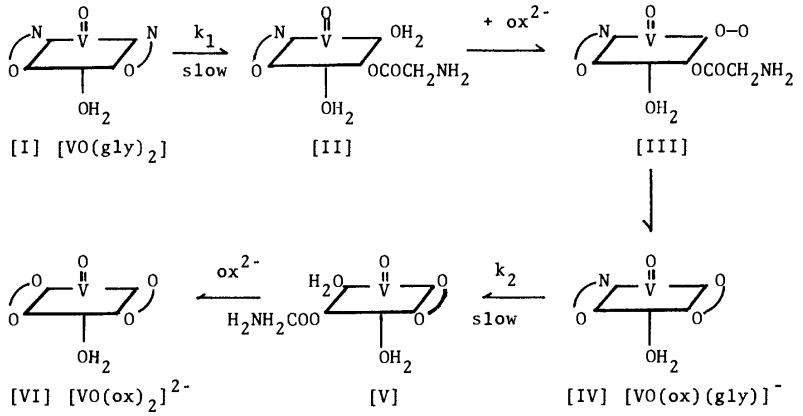


Fig. 3. Proposed reaction mechanism.

The values of rate constants k_6 and k_{-6} for the closing and opening of glycinate chelate ring, respectively, are listed with those of activation parameters in Table 2. The fact that the k_{-6} value (19 s^{-1} at 25 °C) is comparable to k_1 and k_2 values may support the proposed mechanism in Fig. 3.

In Table 1, the values of k_2 are nearly double the k_1 values under various conditions indicating that the amino group of glycine is more labile in $[VO(gly)(ox)]^-$ than in $[VO(gly)_2]$. This result can be accounted for by assuming that the oxalate at the basal positions in $[VO(gly)(ox)]^-$ has much stronger affinity for VO^{2+} than does glycinate and contributes to weakening the V-gly bond on the opposite side.

A mechanism in which the reaction is initiated by the rupture of V-N bonds at the basal positions can be ruled out because only $[VO\text{-}OCOCH_2NH_2]^+$ and $[VO\text{-}OCOCH_2NH_3]^{2+}$ complex ions have been known to be stable when glycine coordinates to the oxovanadium(IV) ion as a unidentate ligand.[13,14]

It may be concluded that there is little doubt of the mechanism in Fig. 3. However, it should be noted that this conclusion does not necessarily mean the dissociative mechanism. In oxovanadium(IV) ions water is a good ligand and said to be quite labile at the basal positions. The rate constant of water exchange was, in fact, reported to be 500 s^{-1} in $[VO(H_2O)_5]^{2+}$,[1,2] which is ten times larger in comparison with the time scale of the present study, and accordingly a water molecule might assist to initiate the ring opening.

Paramagnetic Cobalt(III) Complexes with Organic Ligands. IX.[1] The Preparation and Properties of Paramagnetic Tetraammine(5-nitrosalicylideneaminato)cobalt(III) Complexes

Yoshihisa YAMAMOTO* and Eiko TOYOTA
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
(Received August 9, 1985)

The title paramagnetic cobalt(III) complexes, [Co()$(NH_3)_4$]X_3,(X_3: $Cl_2 \cdot NO_3$, $(NO_3)_3$), both green color, have been isolated and characterized by analytical, spectroscopic and magnetic methods. The effective magnetic moments are 1.7 BM, suggesting an unpaired spin. The ^1H NMR spectra indicate that the unpaired spin on the complexes is localized over the π-orbitals of the chelated ligand. In the XPS, the high binding energy area at 286—289 eV of the C 1s peak of both the complexe is larger than that for the corresponding diamagnetic cobalt(III) complex. The cobalt 2p peaks do not have satellites in the same manner as the usual diamagnetic cobalt(III) complexes. It can be concluded that an unpaired spin on complexes is not located on the cobalt atom, but is located over the π-orbitals of the chelated ligand of complexes.

Previously, we have been concerned with the preparation and properties of several green paramagnetic amine(5-nitrosalicylato)cobalt(III) complexes, [Co(5-NO_2sal)L]$^{2+}$ (L: $(NH_3)_4$,[2] en_2,[3] $(bpy)_2$,[4] quadridentate amine[4,5]). Their effective magnetic moments are 1.7—1.9 BM, suggesting an unpaired spin. Until now, the organic ligand in paramagnetic cobalt(III) complexes has been a 5-nitrosalicylato ligand. Therefore, very little is known regarding the isolation and physical properties of paramagnetic cobalt(III) complexes, in contrast to the information on diamagnetic cobalt(III) complexes with various organic ligands.[6—17] The isolation of a new paramagnetic cobalt(III) complex was tried with another organic ligand. As a result, a new paramagnetic cobalt(III) complex has been isolated with a 5-nitrosalicylideneaminato ligand, [Co()$(NH_3)_4$]$Cl_2 \cdot NO_3$. This paper deals with the preparation and properties of the paramagnetic cobalt(III) complex and with the electronic state of the unpaired spin.

Experimental

Measurements. The NMR spectra were recorded with an FX-60 apparatus (JEOL) for ^{13}C NMR and with an R-40 apparatus (Hitachi) or Varian XL-200 NMR spectrometer for ^1H NMR. The IR spectra were recorded on potassium bromide disks with an IR-27G apparatus (Shimadzu). The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The magnetic susceptibilities were measured by the Faraday's method using a magnetic balance (Shimadzu) between liq. N_2 and room temperature. The electric conductivities of aqueous solutions were determined by the use of a Shimadzu CM-30 conductometer at room temperature. For the XPS measurements, samples were placed on a gold mesh holder and dispersed with acetone. After evacuating to a vacuum better than 7×10^{-7} Pa(5×10^{-9} Torr), samples were cooled to 200 K and irradiated with Mg $K\alpha$ X rays (120 W). The instrument used was a VG ESCA 3-electron spectrometer. Analyzer energy was set so as to give the half width at half maximum [FWHM] of an Au $4f_{7/2}$ peak of 1.18 eV. The peak separation of N 1s or C 1s spectra was achieved using the Gauss-Newton least-squares method, where a mixed Gaussian-Lorentzian curve shape having a fixed FWHM was utilized. The binding energies of the electrons were calibrated by assigning 285.0 eV to the C 1s peak of the normal benzene-ring carbon.

Preparation of Complexes. Pramagnetic Tetraammine(5-nitrosalicylideneaminato)cobalt(III) Dichloride Nitrate (1a): Three cm^3 of 60% nitric acid were added to tetraammine(salicylideneaminato)cobalt(III) chloride hydrate (**2a**)[16] (2.0 g, 5.95 mmol) of russet color. The color of the complex changed to green. Further, 3 cm^3 of 60% nitric acid was added to the solution and stirred. The solution was filtered using a glass filter (G-4) and the filtrate was added to acetone. The precipitated green complex was filtered, washed with acetone, and dried. The obtained complex was dissolved in 3 cm^3 of 60% nitric acid, the solution was filtrated and the filtrate was added to acetone. A precipitated green complex was filtered, washed with acetone and dried. This process was repeated again. From an orange colored filtrate, the corresponding orange diamagnetic complexes **3** and **5** (see below) were isolated. Yield: 0.85 g (33.6%). Found: C, 19.55; H, 4.24; N, 22.62; Cl, 16.68%. Calcd for $CoC_7H_{17}N_7O_6Cl_2$ (MW 425.10) C, 19.78; H, 4.03; N, 23.06; Cl, 16.68%. Absorption spectrum: 363 nm (ε=5050), 450 nm (ε=2830), and 663 nm (ε=10060) in 60% nitric acid. IR spectrum: 1630 cm^{-1} ($C{=}N_{str.}$) and 830 cm^{-1} ($\rho_r(NH_3)_r$). Λ=371 S cm^2 $equiv^{-1}$ in water.

Paramagnetic Tetraammine(5-nitrosalicylideneaminato)cobalt(III) Trinitrate (1b): This complex was prepared from a reaction mixture of 60% nitric acid (6 cm^3) and tetraammine(salicylideneaminato)cobalt(III) nitrate (**2b**)[16] (2.0 g, 5.39 mmol) with the preparation method of **1a**. Yield: 0.93 g (36.1%). Found: C, 17.13; H, 3.85; N, 25.84%. Calcd for $CoC_7H_{17}N_9O_{12}$ (MW 478.21) C, 17.58; H, 3.58; N, 26.36%. Absorption spectrum: 360 nm (ε=4960), 455 nm (ε=3330) and 667 nm (ε=11000) in 60% nitric acid. IR spectrum: 1630 cm^{-1} ($C{=}N_{str.}$) and 830 cm^{-1} ($\rho_r(NH_3)_r$). Λ=363 S cm^2 $equiv^{-1}$ in water.

Tetraammine(5-nitrosalicylideneaminato)cobalt(III) Dinitrate (3): The orange colored acetone filtrate of **1a** or **1b** was concentrated. After 10 h, a precipitated orange complex was filtered and recrystallized from water. Yield: 0.32 g (12.9%).

Found: C, 19.80; H, 3.76; N, 26.70%. Calcd for $CoC_7H_{17}N_8O_9$ (MW 416.20) C, 20.20; H, 4.12; N, 26.92%. Absorption spectrum: 363 nm (ε=12600) and 480 nm (ε=210) in water. IR spectrum: 1635 cm^{-1} ($C{=}N_{str.}$) and 830 cm^{-1} ($\rho_r(NH_3)_r$). Λ= 226 S cm^2 $equiv^{-1}$ in water.

Tetraammine(3,5-dinitrosalicylideneaminato)cobalt(III) Dinitrate (5): The orange colored acetone filtrate of **1a** or **1b** was permitted to stand for at least 3 d, then, the solution was concentrated. Thus, precipitated complex **5** was filtered and recrystallized from water. Yield: 0.44 g (16.0%). Found: C, 18.59; H, 3.94; N, 26.78%. Calcd for $CoC_7H_{16}N_9O_{11}$ (MW 461.20) C, 18.23; H, 3.50; N, 27.33%. Absorption spectrum: 357 nm (ε=11900) and 480 nm (ε=210) in water. IR spectrum: 1635 cm^{-1} ($C{=}N_{str.}$) and 830 cm^{-1} ($\rho_r(NH_3)_r$). Λ=250 S cm^2 $equiv^{-1}$ in water. ^1H NMR spectrum δ=3.04 (s, 3H), 3.19 (s, 3H), 3.32 (s, 3H), 3.98 (s, 3H) for NH_3; δ=8.29 (d, 1H) for H_4, δ=8.44 (t, 1H) for H_6, δ=8.82 (dd, 1H) for CH=N and δ=10.58 (d, 1H) for C=NH in 1.8 mol dm^{-3} D_2SO_4 solution. The H_3 and H_5 proton signals disappeared by nitration at room temperature.

Solubility. Complexes **1a—b** are soluble in water, 60% nitric acid, DMSO, DMF, and 35% hydrochloric acid, and slightly soluble in methanol but insoluble in the common organic solvents. Complexes **3** and **5** are soluble in water, DMSO, DMF, and insoluble in the common organic solvents. Complex **3** is soluble in 60% nitric acid and 35% hydrochloric acid, but **5** is slightly soluble in 60% nitric acid and 35% hydrochloric aicd.

Results and Discussion

Paramagnetic tetraammine(5-nitrosalicylideneaminato)cobalt(III) complexes, $[Co(HN{=}HC\text{-}C_6H_3(NO_2)\text{-}O)(NH_3)_4]X_3$ (X_3:$Cl_2\cdot NO_3$ (**1a**) and $(NO_3)_3$ (**1b**)), have been isolated from reaction mixtures of diamagnetic tetraammine(salicylideneaminato)cobalt(III) complexes, $[Co(HN{=}HC\text{-}C_6H_4\text{-}O)(NH_3)_4]X_2\cdot nH_2O$ (X=Cl, n=1 (**2a**); X=NO_3, n=0 (**2b**)), 60% nitric acid and acetone. The electric conductivity in an aqueous solution was ca. 360 S cm^2 $equiv^{-1}$. The elemental analysis are in agreement with the theoretical values. The magnetic susceptibility obeyed the Curie-Weiss law with effective magnetic moments of 1.7 BM, suggesting the presence of one unpaired spin. The formula conforms to the quadrivalence of cobalt. The rocking frequency of ligand ammonia, however, was observed at 830 cm^{-1} in the IR spectra. This is the range for Co(III) ammine complexes.[18-20] The absorption spectra showed a characteristic strong peak at about 660 nm. In the XPS (Table 1), the nitrogen 1s peaks were separated into four peaks at ca. 399.6 for NH=, at 400.6 for NH_3, at 405.8 for NO_2, and at 407.4 eV for NO_3. The C 1s peaks were separated into four peaks at ca. 285.0, 286.1, 287.1, and 288.5 eV as is shown in Fig. 1. The peak at 285.0 eV is assigned to normal benzene-ring carbon atoms[21] and hydrocarbon contamination. Three peaks in the 286—289 eV region with high binding energies have been assigned to electron-poor carbon atoms, relative to normal ring carbon atoms. The spin orbit separation of Co 2p was 15.0 eV. The ^1H NMR spectra were measured in a 1.8 mol dm^{-3} D_2SO_4 solu-

a): Ref. 2 and 21. The values of XPS are slightly different from those reported previously,[21] as the data analysis has been carried out more precisely by using a computer and a different reference peak (cf. Experimental section).

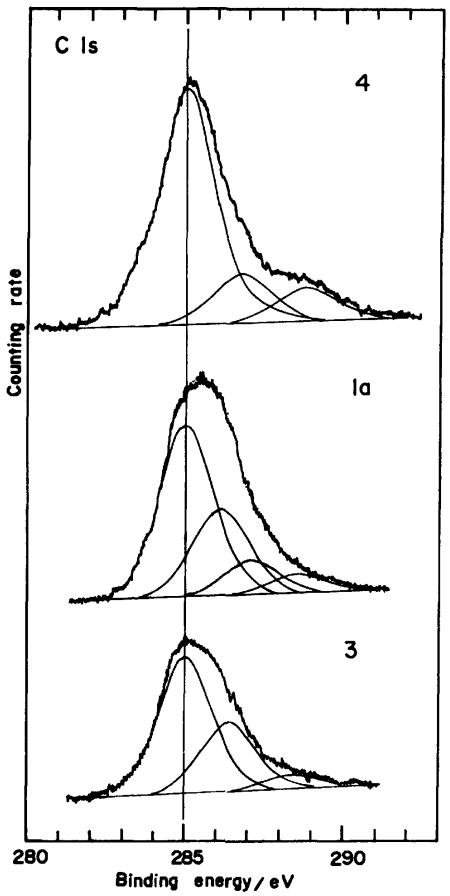

Fig. 1. The XPS in the C 1s region at 220 K of **1a**, **3**, and **4** complexes.

4 : $[Co(^{OOC}_{O}\langle\rangle\text{-}NO_2)(NH_3)_4]Cl\cdot NO_3\cdot H_2O$

1a : $[Co(^{HN=HC}_{O}\langle\rangle\text{-}NO_2)(NH_3)_4]Cl_2\cdot NO_3$

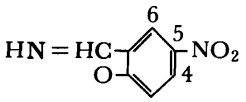
3 : $[Co(^{HN=HC}_{O}\langle\rangle\text{-}NO_2)(NH_3)_4](NO_3)_2$

tion but the ^{13}CNMR spectra did not show the expected signals due to of paramagnetism.

In the XPS results for **1a**, the peak of the high binding energy area of C 1s is larger than that of the corresponding orange diamagnetic cobalt(III) complex, $[Co(^{HN=HC}_{O}\langle\rangle\text{-}NO_2)(NH_3)_4](NO_3)_2$ (**3**) as is shown in Fig. 1. The peak area of the high binding energy region for **1a** is larger than that for the green paramagnetic tetraammine(5-nitrosalicylato)cobalt(III) complex,[21] $[Co(5\text{-}NO_2sal)(NH_3)_4]X_2$ (**4**). The total intensity ratio (carbon/nitrogen) between seven carbons and five nitrogens (NH_3+NH) is 1.47 for **1a** and 1.31 for **3**, and experimental scattering due to the contamination is about ±15%. The difference in the proportion between **1a** and **3**, however, is always clearly observed. Thus, the electronic state of the chelated ligand of **1a** is different from that of **3**. On the other hand, the Co $2p_{3/2}$ peak at 782.2 eV does not have satellites at 200 K. It is similar to that of diamagnetic cobalt(III) complexes[22,23] and paramagnetic cobalt(III) complexes, e.g., μ-amido-μ-hyperoxobis(ethylenediamine)cobalt(III) tetranitrate,[21] however, shows satellites at 200 K. Then, the unpaired spin on **1a** can be localized over the chelated ligand, but it can not be located on the cobalt atom.

In the ^{1}H NMR spectrum of **1a**, complex **1a** changed to **3** in 1.8 mol dm^{-3} D_2SO_4 solution at −20 °C,[1] the spectrum showing signals of both **1a** and **3**. An H_5 ring proton signal disappeared due to nitration. The signals at δ=7.28 (d), 7.90 (d), 8.20—8.46 (m) and 11.14 (d) were assigned to the H_3, H_4, H_6 and CH=N and C=NH protons, respectively. Their chemical shifts and coupling constants are very similar to those of **3** (Table 2). Thus, the σ-bonds which are formed from protons and carbon atoms (sp^2 configuration) of a chelated ligand resemble the σ-bond of **3**. The unpaired spin can not be located over the hydrogen of the chelated ligand.[1] Thus, an unpaired spin on **1a**

Table 2. ^{1}H NMR Spectra of Complexs **1a**, **2a**, and **3**

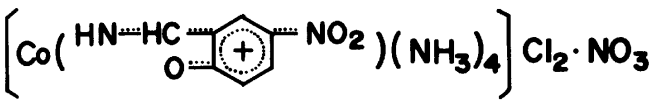


δ

Complex No.	H_3	H_4		H_5	H_6	CH=N	C=NH	NH_3 δ			Temp
	($^3J_{HCCH}$) Hz	($^3J_{HCCH}$) Hz	($^4J_{HCCCH}$) Hz	($^3J_{HCCH}$) Hz	($^4J_{HCCCH}$) Hz	($^3J_{HNCH}$) Hz					°C
1a	7.28 d (9.5)	7.90 d (9.5)	—	—	8.2—8.5 m	8.2—8.5 m	11.14 d	3.26(s)	3.50(s)	4.18(s)	−20
3	6.98 d (9.3)	7.94 dd (9.3)	(3.0)	—	8.30 d (3.0)	8.18 d (11.5)	10.47[a]	3.03(s, 3H)	3.15(s, 6H)	3.93(s, 3H)	+25
2a	7.00 d (8.5)	7.2—7.4 m		6.70 t (7.6)	7.2—7.4 m	8.05 d (11.5)	9.91[a]	3.01(s, 9H)		3.83(s, 3H)	+25

Solvent: 1.8 mol dm^{-3} D_2SO_4; Standard: internal DSS (δ=0). a): broad signal.

has been identified over the π-orbitals of the chelated ligand. Therefore, **1a** is a radical cobalt(III) complex;



A clear distinction between **1a** and **4** was found regarding stability, the Curie-Weiss constant and the XPS of Co 2p. Complex **1a** is more unstable than **4** for ^{1}H NMR measurements. This might be due to a difference in the electronic state of the cobalt atom. The Curie-Weiss constant of **1a** indicates ferromagnetism and the Co 2p peak does not have any satellites.

The absorption spectra of **1a** and **4**[2] have characteristic strong peaks at about 660 nm ($\varepsilon \fallingdotseq 10000$). This strong peak was not observed for **2a** and **3**, the usual diamagnetic cobalt(III) complexes and paramagnetic μ-amido-μ-hyperoxo cobalt(III) complexes[24-26] ($\varepsilon \fallingdotseq 417$ at 687 nm) and the related complexes. Thus, the strong peak is due to the unpaired spin on the complex.

The results for **1b** are listed in Table 1. The results of orange diamagnetic tetraammine(3,5-dinitrosalicylideneaminato)cobalt(III) dinitrate,  (**5**), are given in the experimental section.

The authors wish to express their gratitute to Dr. Hidetaka Konno of Hokkaido University for his discussion and XPS measurements.

Solvent Effect on the Liquid-Liquid Partition Coefficients of Dimethyldithiocarbamic Acid and Its Copper(II) Chelate

Hisanori IMURA, Satoru MATSUMORA, and Nobuo SUZUKI*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received August 16, 1985)

Partition coefficients of dimethyldithiocarbamic acid and its copper(II) chelate have been determined in various organic solvents –0.10 mol dm^{-3} aqueous perchlorate solution systems at 25 °C. The effects of inert organic solvents are explained with the aid of the regular solution theory. Also, a linear free-energy relationship between the partition coefficient of the copper(II) chelate and that of the reagent is demonstrated. The partition coefficient of the copper(II) chelate is compared with that of bis(2,4-pentanedionato)copper(II) and various factors governing the partition coefficients of these chelates are discussed with the aid of the scaled particle theory.

Dithiocarbamate derivatives are highly versatile chelating agents for the separation and determination of metals by solvent extraction, liquid chromatography, etc. In chelate extraction, the extractability of metal ions can be expressed by the partition coefficients of the reagent and the neutral metal chelate, the acid-dissociation constant of the reagent, and the stability constant of the chelate. The partition coefficients are strongly dependent on organic solvents and are the most important factors affecting the extractability of a metal ion. However, the partition for dithiocarbamate-group reagents and their metal chelates even for a diethyldithiocarbamate reagent which is most frequently used in extraction separation has been scarcely investigated. The effect of organic solvents has not been investigated at all.

In this research, the partition coefficients of dimethyldithiocarbamic acid(Hdmdtc), the most simple compound in the dithiocarbamate group, and its copper(II) chelate ($Cu(dmdtc)_2$) were determined in various organic solvent systems. Here, the relationship between the partition coefficient of the chelate and that of the reagent is theoretically explained. Such a relationship has been thoroughly studied regarding various β-diketone systems in this laboratory.[1-4] The solvent effect has been elucidated with the aid of the regular solution theory and the scaled particle theory. Some factors governing the partition coefficient of the metal chelate are discussed by comparing the partition coefficient of $Cu(dmdtc)_2$ with that of bis(2,4-pentanedionato)copper(II)($Cu(acac)_2$).[3]

Experimental

Reagents and Apparatus. Sodium dimethyldithiocarbamate dihydrate ($Nadmdtc \cdot 2H_2O$) was obtained from Tokyo Kasei Co., Ltd. and was purified by recrystallization from acetone-absolute ether. Bis(dimethyldithiocarbamato)copper(II) ($Cu(dmdtc)_2$) was obtained from Tokyo Kasei Co., Ltd. and purified by vacuum sublimation.

A carrier-free radioisotope, ^{67}Cu, was produced by a photonuclear reaction of $^{68}Zn(\gamma,p)^{67}Cu$. Radioactive copper(II) perchlorate solutions of the desired concentration were prepared as described in a previous paper.[3]

Organic solvents were purified by the usual chemical treatment and distillation. The ionic strength in the aqueous phase was adjusted to 0.10 M (1 M=1 mol dm^{-3}) by the use of sodium perchlorate. Other reagents and equipment were the same as those used previously.[3]

Measurements of Partition Coefficient (P_A) of Hdmdtc by a Kinetic Method. Dithiocarbamate group reagents have a strong tendency to decompose in acidic aqueous solutions. The partition coefficient of dimethyldithiocarbamic acid was determined by utilizing its decomposition reaction in the aqueous phase. The partition coefficient of Hdmdtc between carbon tetrachloride and 0.10—0.03 M perchloric acid solutions with an ionic strength of 0.10 was determined by measuring both the stripping rate of Hdmdtc from the organic to the aqueous phase and the decomposition rate in the aqueous phase. The organic solution of Hdmdtc was prepared by an extraction, as follows: A 1 cm^3 portion of a 0.06 M Nadmdtc aqueous solution was added to 9 cm^3 of 0.03 M perchloric acid and 10 cm^3 of carbon tetrachloride in a centrifuge tube with a ground-glass stopper. Immediately, the contents were shaken for 15 s and centrifuged for 30 s at 4000 rpm. The organic phase was taken out and diluted to about a 5×10^{-4} M Hdmdtc solution with carbon tetrachloride. This working solution of Hdmdtc was prepared just before the following kinetic stripping experiment. This Hdmdtc solution (5 cm^3) was vigorously shaken for various times between 10 and 150 s with an equal volume of 0.10 M or 0.03 M perchloric acid solution. The shaking speed was as high as 430 strokes per min in order to attain a rapid mass transfer of the organic-aqueous interface. Immediately after centrifuging for 30 s, the absorbance of Hdmdtc in the carbon tetrachloride phase was measured at 285 nm. The decomposition of Hdmdtc in the organic phase during the shaking within 150 s could be neglected. The stripping-rate constant of Hdmdtc was calculated from the absorbance measurement at various shaking time intervals.

The decomposition rate of Hdmdtc in an aqueous phase was separately measured by spectrophotometry. The decrease in absorbance at 270 nm was measured as a function of time after an injection of 0.01 cm^3 of a 0.06 M Nadmdtc aqueous solution into an optical cell containing 4 cm^3 of a 0.10 M or 0.03 M perchloric acid solution saturated with carbon tetrachloride. All experiments were carried out in a thermostated room at 25±1 °C.

Measurements of Distribution Ratio (D_A) of Hdmdtc. A 0.1 cm^3 portion of 0.1—0.4 M Nadmdtc in water was added to a centrifuge tube containig 5 cm^3 of an organic solvent, 1 cm^3 of 0.50 M sodium perchlorate, and 3.9 cm^3 of a 0.01

M phosphate buffer solution of pH 5.5—7.0. The contents were shaken for 30 s and centrifuged for 30 s. An aliquot of each phase was pipetted out. The aqueous phase was diluted with 0.1 M sodium hydroxide to about 100-fold and the absorbance was measured at 280 nm. In the alkali solution, dimethyldithiocarbamate was very stable and its molar absorption coefficient was 13800 $M^{-1}cm^{-1}$ at an absorption maximum of 280 nm due to the $dmdtc^-$ anion. To determine the Hdmdtc concentration distributed in the organic phase, the organic phase was shaken with an appropriate volume of a 0.1 M sodium hydroxide solution for 3 min. Dimethyldithiocarbamic acid was back-extracted into the alkaline aqueous solution and determined by measuring the absorbance at 280 nm. The distribution ratio of the dimethyldithiocarbamate was calculated from the concentration of each phase. The equilibrium pH value was measured with a glass electrode just after shaking.

Measurements of Partition Coefficient (P_M) of Cu(dmdtc)$_2$. A small portion (0.01 cm^3) of a 5×10^{-5}—5×10^{-2} M radioactive copper(II) solution was added to a 30 cm^3 centrifuge tube containing 5 cm^3 of an organic solvent and 5 cm^3 of a 1×10^{-4}—1×10^{-2} M Nadmdtc aqueous solution (pH 7—8). The contents were shaken for 15—60 min. After centrifuging, an aliquot (0.1—3 cm^3) was very carefully taken from each phase. The γ-activities of each phase were measured with a well-type NaI(Tl) scintillation counter and the partition coefficient of the copper(II) chelate was calculated. The equilibrium pH value was measured with a glass electrode.

A back extraction was performed as follows. An organic phase containing the radioactive copper(II) chelate which was prepared in the forward extraction (as just mentioned above) was shaken with the aqueous phase containing Nadmdtc at pH 7—8. The P_M value was determined by the same manner as that for the forward extraction.

Results

Partition Coefficient of Hdmdtc. Since dimethyldithiocarbamic acid very rapidly decomposes in an acidic aqueous solution, the partition coefficient was determined using the decomposition reation (decomposition rate) of Hdmdtc. When different organic solutions containing Hdmdtc were shaken with the aqueous solutions at pH 1—2, their concentrations in the organic phase decreased with an increase in the shaking time. This decrease was faster in accordance to the following order for organic solvents; benzene< carbon tetrachloride<heptane. This phenomenon seems to be due to the following reactions,

$$Hdmdtc_{org} \rightleftharpoons Hdmdtc \quad (1)$$

$$Hdmdtc \longrightarrow (CH_3)_2NH + CS_2, \quad (2)$$

where the subscript org denotes the species in the organic phase. The equilibrium constant for Eq. 1 corresponds to the partition coefficient of Hdmdtc and the rate constant for Eq. 2 is the decomposition-rate constant (k_d) in the aqueous phase. The decomposition rate of the aqueous phase in a sufficiently low pH region can be written as follows:[5,6]

$$-\frac{d[Hdmdtc]}{dt} = k_d[Hdmdtc]. \quad (3)$$

On the other hand, the decrease in the Hdmdtc concentration in the organic phase upon shaking is given by

$$-\frac{d[Hdmdtc]_{org}}{dt} = k_{st}[Hdmdtc]_{org}, \quad (4)$$

where k_{st} is the stripping-rate constant. From Eqs. 3 and 4, the following relation is obtained,

$$P_A = \frac{k_d}{k_{st}} - 1. \quad (5)$$

Respective first-order plots of Eqs. 3 and 4 gave good linear relationships from which the rate constants, k_d and k_{st}, were determined. The results for the carbon tetrachloride-perchloric acid system are shown in Table 1. The P_A values obtained at different perchloric acid concentrations are consistent within experimental error.

Table 1. Rate Constants for Stripping (k_{st}) and Decomposition (k_d) and Partition Coefficient (P_A) of Dimethyldithiocarbamic Acid in the Carbon Tetrachloride System at 25 °C

$[H^+]$	k_{st}	k_d [b]	P_A [c]
M	$10^{-3}s^{-1}$	$10^{-2}s^{-1}$	
0.10	4.62	6.42±0.22	12.9±0.5
0.030 [a]	3.85	5.49±0.14	13.3±0.4
0.030 [a]	3.78	5.49±0.14	13.5±0.4

Average value of P_A: 13.2±0.4.
a) I=0.10 by $NaClO_4$. b) Result for three measurements. c) Calculated from $P_A=k_d/k_{st}-1$.

The distribution ratio of dimethyldithiocarbamate is expressed by

$$D_A = \frac{[Hdmdtc]_{org}}{[Hdmdtc] + [dmdtc^-]}. \quad (6)$$

This can be written using P_A and the acid-dissociation constant, K_a,

$$D_A = \frac{P_A}{1 + K_a/[H^+]}. \quad (7)$$

If $[H^+]$ is much smaller than K_a,

$$D_A = \frac{P_A[H^+]}{K_a}. \quad (8)$$

Figure 1 shows plots of log D_A vs. pH for various organic solvent systems. Each plot is close to a straight line with a slope of −1; thus, Eq. 8 was found to hold in the pH regions as expected from the pK_a value of

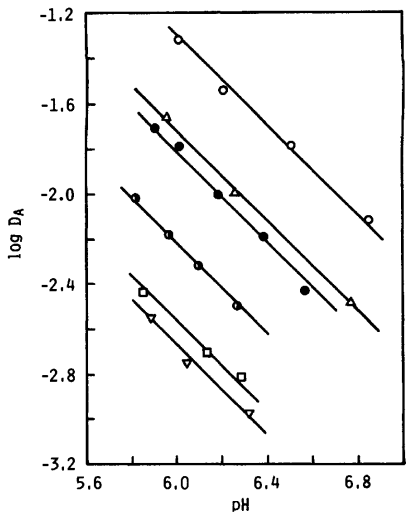

Fig. 1. Distribution ratio of dimethyldithiocarbamate as a function of pH in various organic solvent systems.
○: Benzene, △: isopropylbenzene, ●: carbon tetrachloride, ◑: dibutyl ether, □: heptane, ▽: hexane.

Hdmdtc shown below. The pK_a value of Hdmdtc can be obtained using the P_A value determined for the carbon tetrachloride system (Table 1). The value was determined to be 3.05±0.06 (the activity of hydrogen ions was used in place of the concentration in Eq. 8). This is in agreement with a value of 3.21 for an ionic strength of 0.01.[6] The partition coefficients of Hdmdtc in organic solvent systems other than carbon tetrachloride can be readily determined from Eq. 8 using the K_a value. These date are listed in Table 4.

Partition Coefficient of Cu(dmdtc)$_2$. The distribution ratio of copper(II) is expressed by

$$D_M = \frac{[Cu(dmdtc)_2]_{org}}{[Cu^{2+}] + [Cu(dmdtc)^+] + [Cu(dmdtc)_2] + \cdots} \quad (9)$$

and can be written using the partition coefficient of Cu(dmdtc)$_2$ and the overall stability constant (β_n) in the aqueous phase,

$$D_M = \frac{P_M\beta_2[dmdtc^-]^2}{1 + \beta_1[dmdtc^-] + \beta_2[dmdtc^-]^2 + \cdots}. \quad (10)$$

If the dimethyldithiocarbamate concentration in the aqueous phase is sufficiently high and the formation of such anionic complexes as $Cu(dmdtc)_3^-$ is negligible, the D_M values become independent of the ligand concentration and are consistent with P_M. To confirm this, P_M was determined at different ligand concentrations (Table 2). The obtained P_M values are thought to be constant within the experimental error when the ligand concentrations are altered by two orders of magnitude. The values obtained by forward extraction of copper(II) are in good agreement with those obtained by back extraction. This result demonstrates the complete attainment of the partition equilibrium of the copper(II) chelate.

Table 2. Partition Coefficient of Cu(dmdtc)$_2$ at Different Dimethyldithiocarbamate Concentration in the Heptane System at 25 °C

[dmdtc$^-$]/M	pH	log P_M

1.2×10^{-5}	3.781[a]
1.2×10^{-5}	3.788[a]

Concentration of dmdtc$^-$: 1.0×10^{-2} M.
a) Obtained from back extraction.

The P_M value was measured at different copper(II) concentrations to ascertain the absence of a polymerized species of the chelate in the organic and aqueous phases. The results for the carbon tetrachloride system are shown in Table 3. A constant P_M was obtained within the experimental error when the copper(II) concentration was altered by more than an order of magnitude. The P_M values of Cu(dmdtc)$_2$ in various organic solvent systems are summarized in Table 4.

The partition coefficients of Cu(dmdtc)$_2$ were larger than those of Hdmdtc in all the solvents and the order of the solvents for each solute was the same, i.e., benzene>isopropylbenzene>carbon tetrachloride>dibutyl ether>heptane≈hexane.

Discussion

The partition coefficient of a molar fraction scale can be written using a modified equation based on the regular solution theory,[3]

$$\ln P_2^\circ = \frac{V_2}{RT}[C_{ww} - C_{oo} + 2(C_{o2} - C_{w2}')], \quad (11)$$

where V and C are the molar volume and the cohesive energy density, respectively. The subscripts (2, w, and o) denote the solute, water, and organic solvent, respectively. The parameter C_{w2}' expresses the interac-

a) Average of two measurements. b) Solubility parameter calculated from heat of vaporization at 25 °C.[18] c) Dipole moment (1D=3.333×10^{-30} Cm).

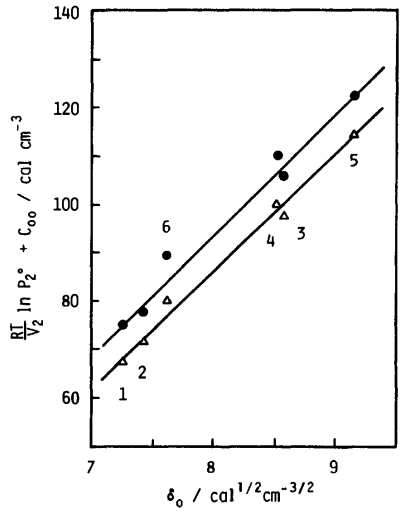

Fig. 2. Evaluation of the partition coefficients based on the regular solution theory. The numbers correspond to those in Table 4.
△: Hdmdtc, ●: Cu(dmdtc)$_2$.

tion between the solute and water involving a specific interaction such as hydrogen and coordination bonding. If a geometric mean approximation for C_{o2} with the solubility parameters, δ, is valid, Eq. 11 can be rewritten as follows,

$$\frac{RT}{V_2}\ln P_2^\circ + C_{oo} = 2\delta_2\delta_o + C_{ww} - 2C_{w2}'. \quad (12)$$

A linear relationship between the left hand side of Eq. 12 and δ_o is expected. An apparent solubility parameter of the solute(δ_2) and the interaction term with water ($C_{ww}-2C_{w2}'$) can be obtained from the slope and the intercept, respectively. Figure 2 shows plots for Hdmdtc and its copper(II) chelate, where their molar volumes were estimated as follows. The van der Waals volume[7] of Hdmdtc can be calculated to be 62.81 cm^3 mol^{-1} and is very close to that of enol of 2,4-pentanedione(acetylacetone, Hacac), 60.14 cm^3 mol^{-1}. Assuming that the ratio of the van der Waals volume to the molar volume of each chelating agent is the same in Hacac (the molar volume; 101.59 cm^3 mol^{-1}[18]) and Hdmdtc, the molar volume of Hdmdtc (106 cm^3 mol^{-1}) is obtained. The molar volume of Cu(dmdtc)$_2$ was estimated to be 190 cm^3 mol^{-1} using the relation between the molar volume of acetylacetone and that of its copper(II) chelate.[2] In the plots of Hdmdtc and its copper(II) chelate, good linear relationships are found for non-polar organic solvents, except for dibutyl ether (Fig. 2). It seems that the organic solutions of these solutes can be taken as apparently regular solutions and that the solvent effects can be interpreted according to Eq. 12. The apparent solubility parameters of Hdmdtc and Cu(dmdtc)$_2$ were calculated to be 12.2 and 12.7 cal$^{1/2}$cm$^{-3/2}$ (conversion factor: 1 cal$^{1/2}$cm$^{-3/2}$=2.0455 J$^{1/2}$cm$^{-3/2}$) respectively from the slope of the plots as described above. Since these values were obtained using a limited number of solvents (i.e., hexane and heptane in alkanes, carbon tetrachloride of haloalkanes and benzene and isopropylbenzene of phenyl compounds), it is difficult to precisely determine their magnitudes. However, the value for Cu(dmdtc)$_2$ is larger than those for copper(II) β-diketonates such as acetylacetonate (11.6 cal$^{1/2}$cm$^{-3/2}$), 1,1,1-trifluoro-2,4-pentanedionate (11.2 cal$^{1/2}$cm$^{-3/2}$), and 1-(2-thienyl)-4,4,4-trifluoro-1,3-butanedionate (11.0 cal$^{1/2}$cm$^{-3/2}$), which were determined by means of a similar technique.[4] This suggests a somewhat high polarity of the former. Metal dithiocarbamate chelates have lone-pair electrons at nitrogen atoms which are readily released from nitrogen to sulfur atoms.[9-12] This seems to be responsible for the polarity of the dimethyldithiocarbamate molecule and may cause interactions with a solvent having a large dipole moment, such as dibutyl ether. Hence, it follows that a positive deviation for dibutyl ether for Eq. 12 can be observed from Fig. 2.

The parameter, $C_{ww}-2C_{w2}'$, of Cu(dmdtc)$_2$, which indicates the interaction between the solute and water, is the same as that of the reagent, i.e., −110 cal cm^{-3} (convergion factor: 1 cal cm^{-3}=4.184 J cm^{-3}) was obtained from the plots for Eq. 12 (Fig. 2). This result means that Cu(dmdtc)$_2$ has no specific interaction with water (such as coordination bonding to the central metal) and is remarkably different from that in the acetylacetonate system.[3] In fact, the absorption spectrum of the dimethyldithiocarbamate chelate in donor solvents such as dibutyl ether and acetone was almost the same as that in carbon tetrachloride and benzene (the absorption peak was at 435 nm in

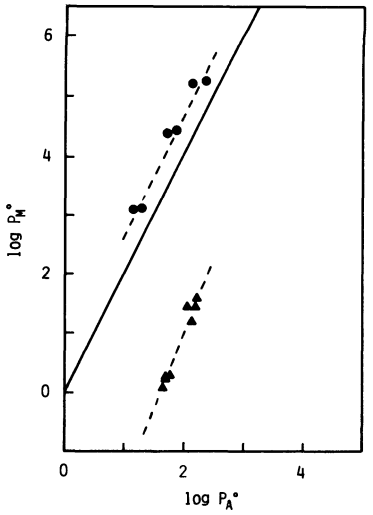

Fig. 3. Relationship between the partition coefficients of the copper(II) chelate and the reagent. ●: $Cu(dmdtc)_2$, ▲: $Cu(acac)_2$.[3]

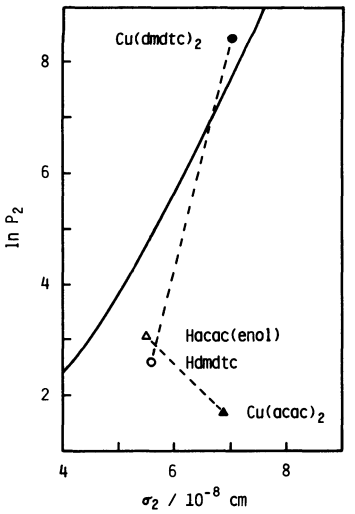

Fig. 4. Comparison of the partition coefficients of dimethyldithiocarbamates and acetylacetonates[3] with those of cavity calculated by the scaled particle theory in the carbon tetrachloride system. Solid line shows the calculated value of $(\bar{G}_{c,w}-\bar{G}_{c,o})/RT$.

these solvents) and the change in the absorption spectrum of the acetylacetonate chelate in dibutyl ether and water was observed.[3]

Since Eq. 12 holds for a chelate and a reagent, the following relation can be derived,

$$\log P_M^\circ = \frac{V_M}{V_A}\log P_A^\circ + \frac{2V_M}{2.30RT}(\delta_M-\delta_A)\delta_o + \frac{2V_M}{2.30RT}(C_{wA}'-C_{wM}'). \quad (13)$$

If the difference between δ_M and δ_A as well as between C_{wM}' and C_{wA}' is small, that is, solute-solvent interactions for the chelate are similar to those for the reagent, a plot of log P_M° vs. log P_A° is expected to be a straight line with a slope of two (V_M/V_A is approximately equal two) passing through the origin. Figure 3 shows plots for $Cu(dmdtc)_2$ together with those for $Cu(acac)_2$.[3,4] The plots of $Cu(dmdtc)_2$ are close to a straight line as expected from the preceding discussion; however, those of $Cu(acac)_2$ are in a much lower region. This suggests that the specific solute-water interactions are weak for the dimethyldithiocarbamate chelate but remarkably strong for the acetylacetonate chelate.

As described in a previous paper,[4] it is difficult to discuss the strict physical meaning of the solute-water interaction parameter based on the simple regular-solution concept, but it is worth evaluating a solute-water interaction with the aid of the scaled particle theory(SPT), which is applicable to an aqueous solution without any adjustable parameters.

The partition coefficient can be written using the Gibbs free energy for the cavity formation($\bar{G}_c$) and for an interaction ($\bar{G}_i$) in the organic and aqueous phases,[2,13]

$$\ln P_2 = \frac{\bar{G}_{c,w}-\bar{G}_{c,o}}{RT} + \frac{\bar{G}_{i,w}-\bar{G}_{i,o}}{RT}. \quad (14)$$

The cavity-formation energy can be calculated using the SPT;[14]

$$\bar{G}_c = -RT\ln(1-y) + RT\frac{3y}{1-y}\left(\frac{\sigma_2}{\sigma_1}\right) + RT\left[\frac{3y}{1-y}+\frac{9}{2}\left(\frac{y}{1-y}\right)^2\right]\left(\frac{\sigma_2}{\sigma_1}\right)^2 + \frac{N_A yp}{\rho}\left(\frac{\sigma_2}{\sigma_1}\right)^3 \quad (15)$$

where σ_1 and σ_2 are the molecular diameters of the solvent and solute, N_A is Avogadro's number, p is the pressure, ρ is the number density of the solvent and y is the packing fraction ($y=\pi\rho\sigma_1^3/6$). The molecular diameter of the solute was estimated using an empirical correlation[4] between the molecular diameter of various compounds determined by the SPT[14,15] and their molar volumes. The values for Hdmdtc and $Cu(dmdtc)_2$ are 5.59×10^{-8} and 6.98×10^{-8} cm, respectively. Figure 4 shows the partition coefficients of Hdmdtc, Hacac(enol) and respective copper(II) chelates as a function of the molecular diameter. The solid line indicates the hypothetical partition coefficient of the cavity, which may be considered to be of a solute where $\bar{G}_{i,w}=\bar{G}_{i,o}$. The plots for Hdmdtc and Hacac are similar, but those of both the copper(II) chelates are significantly different. The partition coefficients of Hdmdtc and $Cu(dmdtc)_2$ lie close to a solid line calculated according to the SPT, compared with that of $Cu(acac)_2$. This means that the difference in the interaction energies for solute-carbon tetrachloride and solute-water is not so great for $Cu(dmdtc)_2$ and Hdmdtc. Consequently, the partition coefficient in this system is mainly governed by the difference between the cavity-formation energy in the organic and aqueous phases. On the other hand, the partition coefficient of

$Cu(acac)_2$ is remarkably lower than that of $Cu(dmdtc)_2$ as well as the cavity. This suggests that interactions of $Cu(acac)_2$ with water molecules are much stronger than that with organic solvent molecules.

Such differences regarding dimethyldithiocarbamate and the acetylacetonate chelate in solute-solvent interactions may be ascribed to the nature of their coordination bonds. The dimethyldithiocarbamate chelate involving sulfur donor atoms has a larger effect on ligand field stabilization than the acetylacetonate chelate involving oxygen donor atoms. Hence, the copper(II)-sulfur bonding is more covalent.[16,17] This results in a greater electron transfer from the ligand to the metal. Consequently, in the dimethyldithiocarbamate chelate the ability of the further coordination to the central metal with donor solvents and of the hydrogen bonding to the donor atoms of the ligand is much lower than that in the acetylacetonate chelate.

In conclusion, the partition coefficient of $Cu(dmdtc)_2$ was close to that calculated from the difference of the cavity-formation energy between the organic and the aqueous phase. The partition coefficients of the chelating agents, Hdmdtc and Hacac(enol), did not deviate much from that calculated from the cavity-formation energy. This suggests that specific interactions with water are weak for those solutes, especially for $Cu(dmdtc)_2$. On the other hand, the partition coefficient of $Cu(acac)_2$ was remarkably lower than that calculated from the cavity-formation energy. This suggests that the specific interactions between $Cu(acac)_2$ and water, such as coordination and hydrogen bonding,[3] are strong.

(Received September 2, 1985)

New multi-sulfur 1,2-dithiolene complexes in which the 1,2-dithiolene moiety is extended by incorporating heterorings have been prepared and characterized by IR spectroscopy, X-ray diffraction method, and cyclic voltammetry. Partial oxidation of these complexes are expected to provide the multi-dimensional molecular conductors. Electrochemical properties of these complexes are compared with those of the dmit-complexes (dmit=2-thioxo-1,3-dithiole-4,5-dithiolate).

Extensive works have been carried out to synthesize and study a large range of inorganic one-dimensional metals based on the partially oxidized platinum-atom chain (for example, KCP; $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$).[1] Recent discoveries of the molecular conductors containing partially oxidized metal 1,2-dithiolene complexes have extended the range of materials for study.[2] In these compounds, the conduction pathway is formed by overlapping of ligand-centered π-system (predominantly the sulfur orbitals) and not principally of the metal orbitals. The dmit-complex (dmit=2-thioxo-1,3-dithiole-4,5-dithiolate), among others, has shown a special property, the multi-dimensional intermolecular S···S interaction, which originates from the 1,3-dithiole-2-thione rings incorporated to the 1,2-dithiolene moiety.[2] The dimensionality of the electronic structure is closely related to the stabilization of the metallic state. Although 1,2-dithiolene complexes extended by incorporating heterorings containing chalcogen atoms should be of special interest in view of the multi-dimensional molecular conductor, there was no well-characterized example except the dmit-complex and its isomer, the dmt-complex (dmt=3-thioxo-3*H*-1,2-dithiole-4,5-dithiolate).[3] In this paper, the preparation of new multi-sulfur 1,2-dithiolene ligands and their complex formation with nickel and platinum are reported.

Results and Discussion

Synthetic process is shown in the Scheme. For the preparation of the ligands, hydrolysis of 1,3-dithiole-2-thiones with base was used.[4] Hydrolysis of the 1,3-dithiole-2-thiones **1a—c** by hot ethanolic potassium hydroxide under argon provided air-sensitive dipotassium salts which were subsequently treated with $NiCl_2$ in methanol or K_2PtCl_4 in water at room temperature. After air-oxidation, addition of *n*-Bu_4NBr resulted in the precipitation of monoanionic species **2a—e**.

Infrared spectra (KBr disk, Table 1) of these complexes show the absorptions characteristic of the bis(1,2-dithiolene) metal complexes.[5]

The structure of the $Ni(C_4H_4S_5)_2^-$ anion is shown in Fig. 1. The Ni–S distances are comparable with those found in other monoanionic nickel dithiolene complexes.[5,6] The C–S bond distances in the dithiolene group vary from 1.707 to 1.728 Å and are thus close

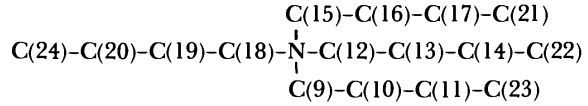
C(9)-C(24) are carbon atoms in tetrabutylammonium cation:



to the value 1.71 Å reported for C-S double bonds.[7] The "ethylenic" bond distances 1.360 and 1.377 Å are intermediate between double and single bond values. The external seven-membered heterorings take chair conformation, and C(5)-C(8), S(9), and S(10) largely deviate from the plane containing the rest of the anion. The C-S bond distances between the dithiolene ring and the external heteroring are slightly shorter than S(sp2)-C(sp2) distance 1.77 Å, and the remaining C-S bonds are single bonds since the usual value for a single bond is 1.81 Å.[7]

Electrochemical data of five new complexes **2a—e** and $(n\text{-Bu})_4N[M(dmit)_2]$ (M=Ni, Pt) are shown in Table 2. These complexes are reduced in one-electron step. This step is electrochemically reversible for all complexes. The reduction potential (E_2) values of the new complexes **2a—e** are comparable to those of alkyl-substituted arene-1,2-dithiolene complexes.[5] Fairly negative E_2 values explain the susceptibility to air-oxidation. The E_2 values of the dmit-complexes are less negative than those of **2a—e**, comparable to that of $Ni(S_2C_2(CF_3)_2)_2^-$.[5] In the 1,2-dithiolene complexes, the E_2 value is less negative when the substituted group is an electron-withdrawing group.[5] The above results suggest the electron-withdrawing property of the thioxo group in the dmit-complex. In all cases, the effect of the metal ion on the E_2 value is rather small.

In oxidation the cyclic voltammograms of **2b, c,** and **d** show a reversible oxidation to the neutral species at potentials (E_1) in the range of 0.06—0.28 V. At slow sweep rates (50 mV s^{-1}) the oxidation of **2a** is irreversible, at faster sweep rates becomes reversible (Fig. 2). At all sweep rates (50—200 mV s^{-1}), the oxidation of **2e** and $M(dmit)_2^-$ is irreversible (Fig. 2).

The $\Delta E(=E_1-E_2)$ values of the dmit-complex are ca. 0.3 V, while those for other 1,2-dithiolene complexes including **2a—e** are larger than 0.7 V.[5] This suggests that in the case of the dmit-complex the intermolecular Coulomb repulsion energy in the conducting state is smaller than that in other 1,2-dithiolene complexes.[8]

The ability of **2a—e** to form the conducting partially oxidized salt is suggested by the fact that the E_1 and E_2 values of **2a—e** are close to those of the unsubstituted 1,2-dithiolene complex $Ni(C_2H_2S_2)_2$ (E_1=0.09, E_2=−0.95 V vs. SCE) which provides the conducting compounds with the organic donors (TTF; Tetrathiafulvalene and TTT; Tetrathiotetracene(5, 6: 11,12-bis(epithio)naphthacene)).[9]

Experimental

1,3-Dithiole-2-thiones **1a—c** were synthesized from 4,5-bis(benzoylthio)-1,3-dithiole-2-thione and corresponding dibromoalkanes or bis(chloromethyl) sulfide.[10]

Preparation of Complexes. **n-$Bu_4N[Ni(C_4H_4S_4)_2]$ 2a:** A mixture of 20 ml of ethanol, 2.0 g (36 mmol) of potassium hydroxide, and 1.0 g (4.5 mmol) of 2,5,7,9-tetrathia-

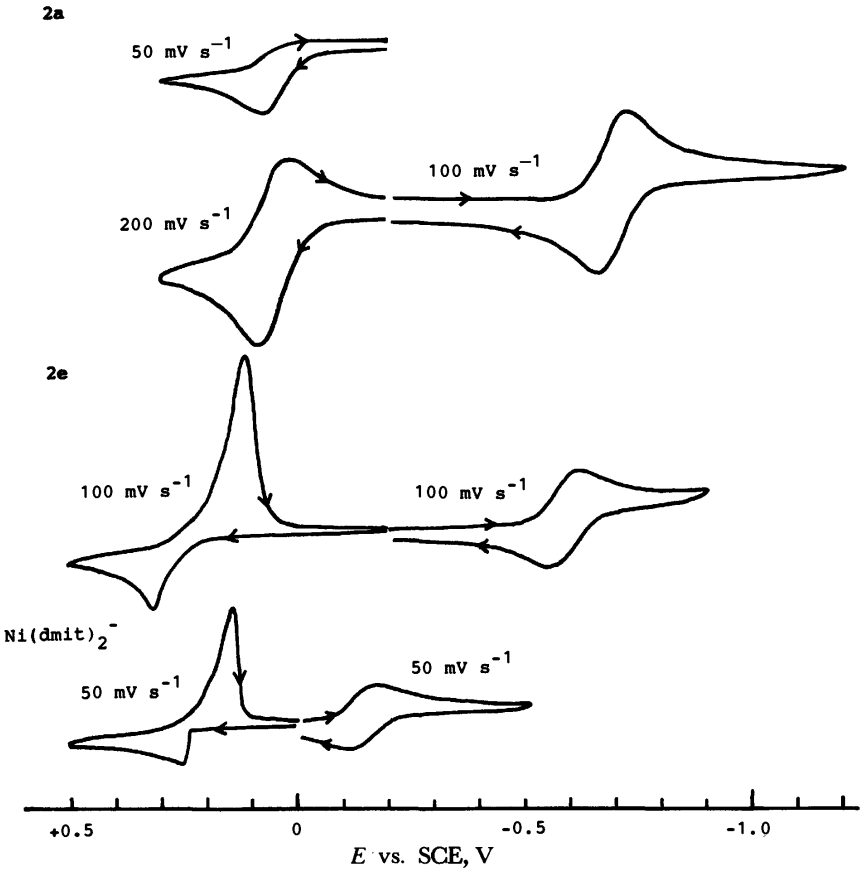


Fig. 2. Cyclic voltammograms of **2a**, **2e**, and $Ni(dmit)_2^-$.

bicyclo[4.3.0]non-1(6)-ene-8-thione **1a** was stirred for 1.5 h at 40—45 °C (water bath temperature) under argon. The resulting pale yellow micro crystals of the dipotassium salt were isolated by filtration, washed with a 4 ml portion of ethanol twice under argon, and dried in vacuo. The salt was dissolved in 20 ml of methanol and treated with 0.3 g (1.3 mmol) of $NiCl_2 \cdot 6H_2O$ in 20 ml of methanol. Stirring was continued overnight at room temperature under argon. Air was bubbled through the reaction mixture for 15 min. After filtration (yellow residue), to the dark green filtrate was added 2.0 g of tetrabutylammonium bromide. The dark green precipitate was isolated by filtration with suction, washed with methanol, and air-dried at room temperature. The crude complex was dissolved in 65 ml of acetone. After filtration, to the filtrate was added 65 ml of 2-propanol. Concentration of the solution with a rotary evaporator gave dark green crystals of **2a**, which were isolated by filtration, washed with methanol and ether, and dried in vacuo. Yield 0.45 g (54% based on Ni). Found: C, 43.39; H,7.13; N,2.00; S, 37.36%. Calcd for $C_{24}H_{44}NS_8Ni$: C, 43.55; H,6.70; N, 2.12; S, 38.76%.

Other complexes (**2b**, **2c**, **2d** and **2e**) were prepared analogously.

***n*-Bu_4N[Pt($C_4H_4S_4$)$_2$] 2b:** Yield 26% based on Pt. Found: C, 35.88; H, 5.83; N, 1.67; S, 31.91%. Calcd for $C_{24}H_{44}NS_8Pt$: C, 36.11; H, 5.56; N, 1.67; S, 31.91%.

***n*-Bu_4N[Ni($C_5H_6S_4$)$_2$] 2c:** Yield 34% based on Ni. Found: C, 44.98; H, 7.60; N, 1.90; S, 36.37%. Calcd for $C_{26}H_{48}NS_8Ni$: C, 45.27; H, 7.01; N, 2.03; S, 37.18%.

***n*-Bu_4N[Pt($C_5H_6S_4$)$_2$] 2d:** Yield 4% based on Pt. Found: C, 37.57; H, 6.23; N, 1.62; S, 31.07%. Calcd for $C_{25}H_{48}NS_8Pt$: C, 37.79; H, 5.85; N, 1.70; S, 31.04%.

***n*-Bu_4N[Ni($C_4H_4S_5$)$_2$] 2e:** Yield 46% based on Ni. Found: C, 39.72; H, 6.28; N, 1.69; S, 42.76%. Calcd for $C_{24}H_{44}NS_{10}Ni$: C, 39.71; H, 6.11; N, 1.93; S, 44.16%. To date, attempts to prepare *n*-Bu_4N[Pt($C_4H_4S_5$)$_2$] have been unsuccessful.

Infrared Spectra. Spectra of compounds pressed in KBr disks were recorded on a model 260-30 Hitachi infrared spectrophotometer over the range 400—4000 cm^{-1}.

Structural Study. The crystal of **2e** has been investigated by X-ray diffraction. The crystal data are: monoclinic, space group $P2_1/c$, a=12.374(3), b=15.748(4), c=20.127(5) Å, β=119.54(2)°, V=3412.2 Å^3, Z=4. A total of 4501 independent reflections ($2\theta \leq 60°$, $|F_o| > 3\sigma(|F_o|)$) were recorded on a Rigaku automatic four-circle diffractometer using Mo $K\alpha$ radiation. The intensity data were corrected for the Lorentz and the polarization effects, but not for absorption. The structure was solved by the direct method and refined by the block-diagonal least-squares method on a PANAFACOM U-1300 computer by the use of a local version of the UNICS-III programs.[11] Scattering factors were taken from Ref. 12. The weighting scheme, $w=1/(\sigma(F_o)^2+0.0001|F_o|^2)$ was employed. The final discrepancy factors were $R_1=\sum||F_o|-|F_c||/\sum|F_o|=0.067$ and $R_2=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.074$. The final atomic coordinates are listed in Table 3. A list of the final F_o-F_c table, and anisotropic temperature factors are deposited as Document No.8618 at the office of Bull. Chem. Soc. Jpn.

Electrochemical Study. Electrochemical measurements were performed with a YANACO polarographic analyzer P-1100 at 18 °C. Tetrabutylammonium perchlorate was used as a supporting electrolyte. A glassy carbon was employed as a working electrode. The counter electrode was a platinum wire which was immersed directly in the electrolysis solution. An aqueous saturated calomel electrode (SCE) was separated from the test solution by a fine-porosity glass frit and a salt bridge filled with the solution under study. All potentials are reported vs. an aqueous SCE.

Aftereffects of Nuclear Decay in $^{57}CoCl_2 \cdot nH_2O$ (n=2 and 6) Investigated by γ-X Ray Coincidence Mössbauer Spectroscopy

Takayuki KOBAYASHI*,† and Jean M. FRIEDT
Centre de Recherches Nucléaires, 67037 Strasbourg Cedex, France
(Received September 11, 1985)

The anomalous states produced by electron capture decay of ^{57}Co in $CoCl_2 \cdot 2H_2O$ and $CoCl_2 \cdot 6H_2O$ are investigated using conventional Mössbauer emission spectroscopy and a γ-X ray coincidence method which allows to isolate events with a reduced influence of the Auger electron self-irradiation. The formation of the anomalous electronic and structural configuration is assigned to the self-radiolysis of the water ligands. The mechanism involves both the nearest and the next nearest H_2O coordination shell according to the densities of these ligand molecules in the respective shells.

In insulating materials, doped or labelled with radioactive nuclei, anomalous valence or structural configurations of the decaying atoms are sometimes formed besides the normal state. This is called the aftereffect of nuclear decay which can be investigated very uniquely (in situ analysis on a time scale of the order of 100 ns after the decay) using Mössbauer emission spectroscopy.[1-6] One often invoked mechanism for these aftereffects considers that the chemical bonds in the immediate vicinity of the decaying atom are ruptured by the emitted photons and particles, e.g. the X-rays and Auger electrons emitted after the electron capture (EC) decay of ^{57}Co.[7] The resulting radicals hence formed around the atoms would play a determinant role in stabilizing the anomalous states. In the case of inorganic divalent compounds surrounded by water ligands it is considered that the formation of the anomalous trivalent Fe^{3+} arises mainly from free OH radicals produced by internal radiolysis of the H_2O ligands. This mechanism is simulated by γ-irradiation experiments of the Fe salt hydrates which for instance in the case of $FeSO_4 \cdot nH_2O$ (n=0,1,4,7) conclusively demonstrated the oxidation of Fe^{2+} by OH radicals:[8]

$$Fe^{2+} + OH \rightleftharpoons Fe^{3+} + OH^-. \quad (1)$$

However, the mechanisms of the aftereffects of nuclear decay are certainly more complicated than those of an external irradiation because of the superposition of primary excitations (direct ionization and excitation) and because of distribution in the particle flux and energy etc. In order to improve the understanding of those phenomena, it is desirable to modulate the conditions of the internal irradiation, i.e., to change the energy, intensity or the time involved in the processes. One possible approach relies on a γ-X ray coincidence technique, which allows to measure Mössbauer emission spectra corresponding to a reduced flux of Auger electrons after the EC decay of ^{57}Co. In this work we report a study, by using the γ-X ray coincidence technique, of the aftereffects in the hydrated compounds with water ligands; $CoCl_2 \cdot 2H_2O$ and $CoCl_2 \cdot 6H_2O$ labelled with ^{57}Co.

Experimental

Principle of the Experiment. After the EC decay of ^{57}Co, a K-X ray or K-Auger electron is emitted with the probability of approximately 30 or 60%, respectively.[9] The K-X ray emission causes one vacancy in the L or M shell, while two vacancies are produced in the L and/or M shells owing to the K-Auger effect. Each vacancy brings about the Auger cascade in the outer shells. Therefore, more (factor of $\approx$2) low-energy electrons are emitted during the Auger cascade after the K-Auger process than after the K-X ray emission. If a Mössbauer spectrum is observed, by the coincidence technique, i.e. only when K-X rays are emitted, the flux of the low-energy Auger electrons is reduced compared with that in the conventional Mössbauer emission method. By comparing the coincidence spectrum with the conventional one, it is expected to obtain new insights into the mechanisms of the aftereffects. This is the idea of the γ-X ray coincidence Mössbauer method, which is described elsewhere in more detail.[10,11]

Preparation of Samples. In order to avoid decomposition of the sample material during the measurements, very thin and little chemical compound ($CoCl_2 \cdot 2H_2O$ or $CoCl_2 \cdot 6H_2O$) labelled with ^{57}Co was surrounded with a large quantity of the same and unlabelled compound, and sealed between thin Mylar films. The intensity and specific activity of the sample source were approximately 10 μCi and 40 Ci mole^{-1}, respectively.

Measurements. The slow coincidence technique was used for the measurements, and the coincidence and conventional Mössbauer spectra were observed simultaneously at room temperature. The block diagram of the measuring system is shown in Fig. 1. The detectors used for 6.5 keV X-rays and 14.4 keV γ-rays were NaI(Tl) crystals with 1-inch diameter and 0.2-mm thickness. Since the resolving time of X-ray signals was approximately 4 μs, the universal coincidence unit was opened, for γ-rays, for sufficiently long time compared with the lifetime of the Mössbauer level and therefore the line-broadening due to the time effects[12,13] was considered to be negligible. In order to get a large geometrical efficiency, the sample source was placed just in front of the X-ray detector. The contribution of random coincidences was subtracted from the observed coincidence spectrum. The random coincidence counting rate was less than 20% of the total coincidence counting rate.

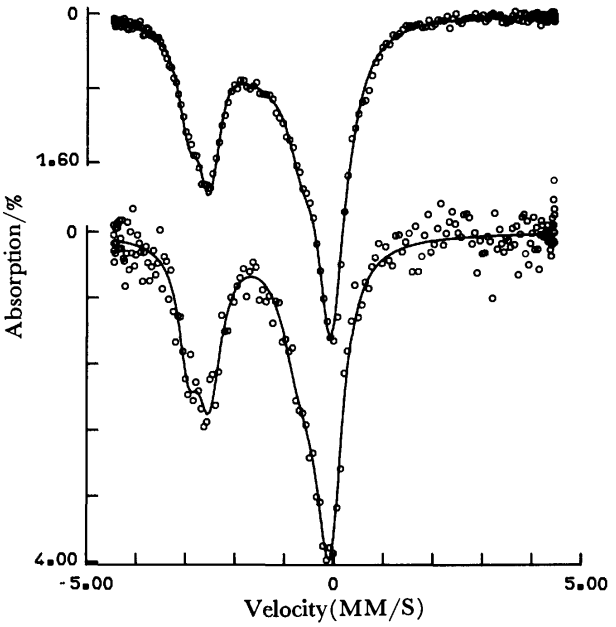

Fig. 2. Observed spectra of $CoCl_2 \cdot 2H_2O$. Upper and lower figures are the conventional and coincidence spectra with base-line counts of approximately 7.1×10^6 and 2.6×10^5, respectively.

Results

The observed spectra shown in Figs. 2 and 3 are composed of a large main peak and a small side peak, and were analyzed as a superposition of several Lorentzian lines. Rather good fits are obtained by assuming three symmetrical quadrupole doublets when the spectra are analyzed individually. However, in order to reach a consistent analysis of both the conventional and the coincidence data it appeared

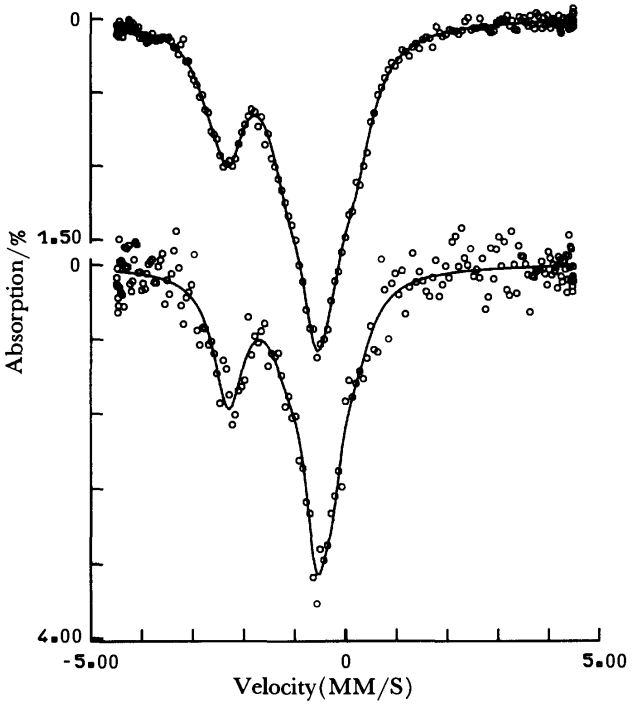

Fig. 3. Observed spectra of $CoCl_2 \cdot 6H_2O$. Upper and lower figures are the conventional and coincidence spectra with base-line counts of approximately 6.6×10^6 and 2.1×10^5, respectively.

necessary to introduce a number of conditions:

1) The hyperfine parameters of the several sites are equal in the coincidence and in the conventional spectra.

2) All the components in the coincidence spectrum must be found in the conventional spectrum, since the resonance absorption after X-ray emission contributes to the conventional spectrum as well as to the coincidence spectrum.

3) The line-width in the coincidence spectrum is equivalent to or less than the corresponding width in the conventional spectrum, because the defects of surroundings of ^{57}Fe after the decay of ^{57}Co under the coincidence conditions are expected to be reduced in comparison with the conventional measurements.

The good and simultaneous fits of the conventional and coincidence spectra are realized with the parameters in Table 1 which satisfy the above conditions.

In reference to the isomer shift (I.S.) and quadrupole splitting (Q.S.) of $FeCl_2 \cdot 2H_2O$[14] and $CoCl_2 \cdot 6H_2O$ doped with a small amount of Fe, the components Fe^{2+} (1) in Table 1 are attributed to the normal states in the lattice.

Discussion

The relative intensities of the components in the spectra are shown graphically in Fig. 4. The Fe^{2+}(1) contribution is greater in the coincidence spectrum than in the conventional one, reflecting the reduced influence of the low-energy electrons in the coincidence

Table 1. Mössbauer Parameters of the Conventional and Coincidence Spectra

State	I.S.	Q.S.	Conventional width	Conventional intensity	Coincidence width	Coincidence intensity
	mm s^{-1}	mm s^{-1}	mm s^{-1}	%	mm s^{-1}	%

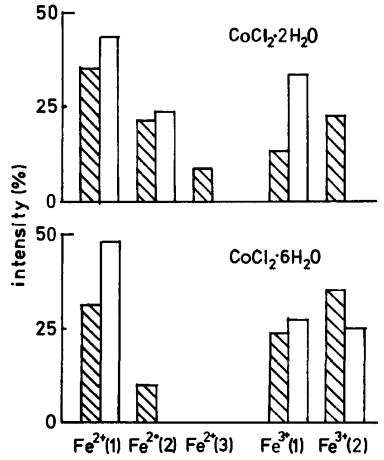

Fig. 4. Relative intensities of the components in the spectra. The slash marked and blank bars denote the results from the conventional and the coincidence spectra, respectively.

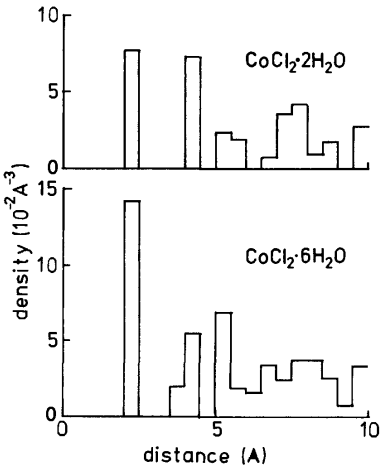

Fig. 5. Densities of H_2O molecules as a function of distance from a Co atom in $CoCl_2 \cdot 2H_2O$ and $CoCl_2 \cdot 6H_2O$.

spectrum. A mechanism for the appearance of the states other than $Fe^{2+}(1)$ is searched from consideration of the densities of H_2O molecules as a function of distance from a Co atom in the source materials (Fig. 5).

Many nearest neighbouring H_2O molecules exist in the hexahydrate. However, in the dihydrate the density of the second nearest neighbouring H_2O is equivalent to that of the nearest H_2O. Therefore, it is expected that the role of the second nearest H_2O in the aftereffects is relatively more important in the dihydrate than in the hexahydrate. The variety of the states in the dihydrate (Fig. 4) is assigned to the effect of these further H_2O molecules. Since the hypothesis that Fe^{3+} states are formed through oxidation of Fe^{2+} by OH radicals produced by radiolysis of H_2O in hydrated compounds (reaction (1)) is accepted widely, it is reasonably conjectured that one of $Fe^{3+}(1)$ and $Fe^{3+}(2)$ states corresponds to the effect of the nearest H_2O whereas the other is connected with the second nearest H_2O.

The nearest neighbouring H_2O exerts a greater influence on the electric field gradient (EFG) than the further H_2O. Therefore, the greater Q.S. of $Fe^{3+}(2)$ suggests the formation of $Fe^{3+}(2)$ due to radiolysis of the nearest H_2O and the $Fe^{3+}(1)$ states are the effect of the further H_2O. Some of the low-energy Auger electrons which have escaped from the nearest H_2O layer break a second nearest or further H_2O into H and OH radicals. However, contrary to the case of Fe^{2+}, an electron can hardly transfer to this OH radical from the Co^{2+} ion situated close to the OH through the reaction $Co^{2+}+OH \rightarrow Co^{3+}+OH^-$. Therefore, this OH radical oxidize the Fe^{2+} ion, which has emitted the Auger electrons, to form the $Fe^{3+}(1)$ state, or recombines with H after a while.

The energy of the Auger electrons determining the aftereffects is very low (less than a few hundred electron volts), and their range in the lattice is expected very short. Moreover, some of the electrons collide elastically with the H_2O molecules or Cl^- ions in the nearest H_2O layer (without breaking these molecules) and hence loose more energy. Therefore, it is expected

that the stopping power of the electrons is greater on the average in the second nearest or further layer than that in the nearest H_2O layer. Under the coincidence conditions, the number of the emitted Auger electrons is reduced to approximately a half,[10] and therefore the nearest H_2O in the dihydrate sustains hardly radiolysis. This might be the main reason why the $Fe^{3+}(2)$ component is not found in the coincidence spectrum of the dihydrate although the contribution of $Fe^{3+}(1)$ is rather great. In the hexahydrate, owing to the great density of the nearest H_2O, the probability of radiolysis in the nearest H_2O layer is fairly great even under the coincidence conditions. Consequently, both of the Fe^{3+} components appear in the conventional and coincidence spectra.

The appearence of the $Fe^{2+}(2)$ states can actually also be attributed to the effect of the second nearest H_2O. When a OH radical originated outside of the nearest H_2O layer oxidizes Fe^{2+}, it brings about the $Fe^{3+}(1)$ states as mentioned before. On the other hand, when the Fe^{2+} ion does not suffer oxidation by the OH radical in the second nearest H_2O layer, the $Fe^{2+}(2)$ state may appear. In the case that OH survives without recombination with H, the local symmetry around the Fe ion becomes lower and this results in an increase Q.S. value. In the other case that the OH recombines with H, the position of the produced H_2O may differ from its regular crystal site hence may increase the Q.S., as observed for $Fe^{2+}(2)$. Since the second nearest H_2O is less important in the hexahydrate than in the dihydrate, the relative intensity of $Fe^{2+}(2)$ is limited in the conventional spectrum of the hexahydrate. This state is not found in the coincidence spectrum due to the reduced number of the Auger electrons.

The $Fe^{2+}(3)$ state may appear by the effect of the further than second nearest H_2O. The absence of $Fe^{2+}(3)$ in the spectra of the hexahydrate supports this assumption. The unusually small Q.S. can arise from a fortuitous compensation between the lattice and orbital contributions to the EFG. Alternatively, thermal vibration of the localized lattice after the decay of ^{57}Co can conceivably reduce the EFG around Fe^{2+}.

In conclusion, the difference of the emission spectra observed in conventional and in γ-X ray coincidence Mössbauer spectroscopy confirms unambiguously the effectiveness of the Auger and conversion electron self-irradiation in determining the mechanism of stabilization of the anomalous configurations of the decayed atoms. A comparative analysis of the coincidence and regular data in the hydrates $CoCl_2 \cdot 6H_2O$ and $CoCl_2 \cdot 2H_2O$ suggests that the radical reactions involve mostly the nearest neighbour coordination shell in the hexahydrate. In the presence of a lower density of radiosensitive H_2O ligands, as found in the dihydrate, the second nearest coordination shell is also involved in the mechanism of stabilization of the anomalous configurations.

The authors wish to express their thanks to Richard Poinsot for his helpful cooperation.

The Crystal and Molecular Structure of Δ-(8-Methyl-1,3,6,10,13,16,19-heptaazabicyclo[6.6.6]icosane)cobalt(III) Perchlorate Monohydrate

Ushio SAKAGUCHI* and Tasuku ITO†
Kumamoto University of Commerce, Ooe, 2-5-1, Kumamoto 862
†Institute for Molecular Science, Myodaiji, Okazaki 444
(Received October 2, 1985)

The structure of Δ-(8-methyl-1,3,6,10,13,16,19-heptaazabicyclo[6.6.6]icosane)cobalt(III) perchlorate monohydrate, Δ-[Co($C_{14}H_{33}N_7$)](ClO_4)$_3$·H_2O, has been determined by single crystal X-ray diffraction techniques. Crystal data are the following: space group $P2_12_12_1$, a=16.379(2) Å, b=16.388(2) Å, c=9.753(1) Å, V=2617.9(5) Å^3, Z=4, 3983 nonzero structure factors ($|F_o|>3\sigma(|F_o|)$), R=0.0447, and R_w=0.0491. The geometry of the cation can be approximated very closely by a composite of [Co(sen)]$^{3+}$ and [Co(sep)]$^{3+}$, where sen=1,1,1-tris(4-amino-2-azabutyl)ethane and sep=1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]icosane.

The macrotricyclic hexaamine cage complexes of cobalt(III), with a commom basic structure **I** in Fig. 1, have several interesting properties. We have recently reported that these complexes are 3 to 6 orders of magnitude more acidic than ordinary cobalt(III) amine complexes and exploited this property to show the dominance of double hydrogen bonding in the ion association of these complexes.[1] It was implicitly assumed there that for favorable double hydrogen bonding, the complexes all take the $(lel)_3$ conformation, where $(lel)_3$ refers to the C–C vectors of "ethylenediamine" (en) moieties parallel to the cap-to-cap axis of the molecule. In contrast to this, the [Co(diNOsar-H)]$^{2+}$ (I with X=Y=C–NO_2) ion has been reported[2] to have the $(ob)_3$ conformation, where diNOsar-H is the deprotonated form of 1,8-dinitro-3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane and $(ob)_3$ refers to the C–C vectors of "en" rings oblique to the cap-to-cap axis of the compound. Thus, it seemed to be interesting to investigate the conformation of [Co(azamesar)]$^{3+}$ (**I** with X=C–CH_3, Y=N), where azamesar=8-methyl-1,3,6,10,13,16,19-heptaazabicyclo[6.6.6]icosane. Further, we found that under some conditions, [Co(azamesar)]$^{3+}$ undergoes fragmentation reaction, which might result from steric strain.[3] Though the nature of this reaction is not clear as yet, steric strain has been shown to play an important role in determining spectroscopic[4] and chemical properties[5] as well as electron self-exchange rates in hexaamine cobalt(III) complexes. For example, complexes of type **I** exchange electron some 10^5-fold faster than the parent [Co(en)$_3$]$^{3+}$ ion[6] and Geselowitz[7] proposed a ligand strain as a mojor factor for this difference. Therefore, examination of ligand strain might be considered to contribute to the elucidation of these problems.

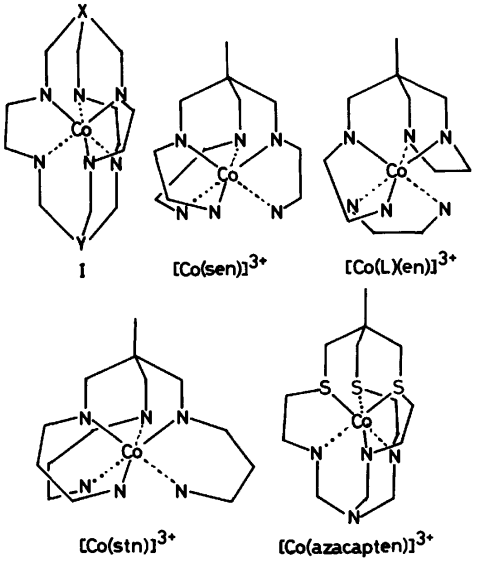

Fig. 1. Schematic illustration of complexes.

Experimental

Material. The compound was synthesized, according to the method of Creaser et al.,[8] by the reaction of aqueous ammonia and formaldehyde with Δ-[Co(sen)]$^{3+}$, which had been prepared[4] and optically resolved[9,10] by the methods reported previously, where sen=1,1,1-tris(4-amino-2-azabutyl)ethane. The crystals were grown by slow evaporation of an aqueous solution into orthorhombic blocks elongated along the c axis.

Crystal Data. A yellow crystal of [Co($C_{14}H_{33}N_7$)](ClO_4)$_3$·H_2O with dimensions of 0.32×0.24×0.20 mm was used for the data collection. The determination of cell constants and the collection of the intensity data were carried out at about 25 °C on a Rigaku AFC-5 automated four-circle diffractometer with Mo$K\alpha$ radiation made monochromatic by a graphite plate (λ=0.71073 Å). The cell constants, determined by a least-squares method using 50 independent reflections (25°<2θ<30°), were a=16.379(2) Å, b=16.388(2) Å, c=9.753(1) Å, and V=2617.9(5) Å^3. The space group was determined to be $P2_12_12_1$ (D_2^4, No. 19) from the systematic absences for $h00$ ($h=2n+1$), $0k0$ ($k=2n+1$), and $00l$ ($l=2n+1$). The measured density of 1.73 g cm^{-3} obtained by a flotation method agrees well with the calculated value of 1.712 g cm^{-3} for Z=4. The intensity data were collected for $+h$, $+k$, $+l$ and $-h$, $-k$, $-l$ by the θ—2θ scan technique to a maximum 2θ value of 60° at a scan rate of 3° min^{-1} (40 kV, 25 mA). Scan widths ($\Delta\theta$) were calculated from the formula $\Delta\theta=(1.1+0.5\tan\theta)°$. The intensity measurements were automatically repeated until $\sigma_c(|F_o|)/|F_o|$ became less than 0.05, where $\sigma_c(|F_o|)$ is a standard deviation calculated from counting statistics. The maximum

†Present address: Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980.

number of repetition was 3. Three reference reflections monitored after every cycle of 100 measurements showed no significant variation in intensity during the data collection. Out of 5632 independent reflections measured, 3983 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination. They were corrected for Lorentz-polarization effects, but no absorption correction was applied since the linear absorption coefficient of $\mu(\mathrm{Mo}K\alpha)=10.65\,\mathrm{cm}^{-1}$ was low.

Structure Determination and Refinement. The structure was solved by standard heavy-atom techniques. The position of Co atom was determined from the three-dimensional Patterson map. The remaining atoms except hydrogen atoms were all revealed in subsequent Fourier syntheses. After all the non-hydrogen atoms were refined isotropically, a series of refinements using anisotropic thermal parameters for all non-hydrogen atoms reduced an R value, $\sum||F_o|-|F_c||/\sum|F_o|$, to 0.0614 and an R_w value, $[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}$, to 0.0724, where F_o and F_c are the observed and calculated structure factors, respectively. The weighting scheme used was $w=[\sigma_c^2+(0.015|F_o|)^2]^{-1}$. All the hydrogen atoms were located from subsequent difference Fourier maps. Further refinements, using anisotropic thermal parameters for all non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms, reduced R to 0.0447 and R_w to 0.0491.

The absolute configuration was checked by reversing the signs of the $\Delta f''$ terms and repeating the final refinement sequence, to give significantly larger R of 0.0528 and R_w of 0.0597. In Table 1 are compared the observed and calculated intensity ratios of 12 Bijvoet pairs for which the observed reflection $|F(hkl)|$ and counter-reflection $|F(\bar{h}\bar{k}\bar{l})|$ differed by more than 14%.

The final difference Fourier map showed no peaks higher than 0.83 e/Å^3.

The atomic scattering factors for non-hydrogen atoms were taken from International Tables for X-ray Crystallography[11] and those for hydrogen atoms from Stewart, Davidson, and Simpson.[12] The anomalous dispersion coefficients[11] were used for non-hydrogen atoms in structure factor calculations. The final atomic coordinates for non-hydrogen atoms are given in Table 2,[13] according to the atom labels of Fig. 2. All the computations, including ORTEP[14] drawings were carried out by a HITAC M-200H computer at the Computer Center of the Institute for Molecular Science. The Universal Crystallographic Computation Program System, UNICS III,[15] was used.

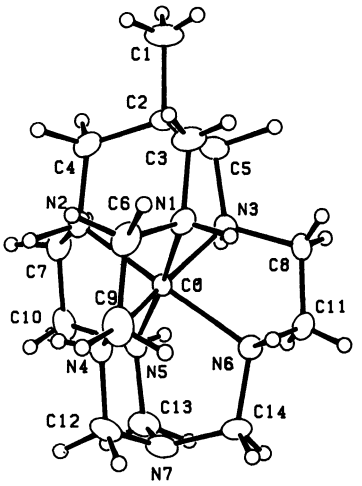

Fig. 2. Structure of the cation with atom labels. Thermal ellipsoids are drawn to include 30% of probability distribution.

Results and Discussion

The crystal structure as viewed down the c axis is shown in Fig. 3. The crystal may be considered to be made up of alternate layers of complex cations and anions, both extending in the bc plane. The cation hydrogen-bonds, via N-H groups, to water oxygens (N2···Ow=2.913(6) Å and N4···Ow=3.240(7) Å) and to perchlorate oxygens (N1···O(10)=3.038(6) Å, N1···O(11)=3.399(7) Å, N6···O(10)=3.057(6) Å, and N6···O(12)=3.317(10) Å). Interatomic distances and angles are given in Table 3.

The structure of Δ-[Co(azamesar)]$^{3+}$ cation, given in Fig. 2, has a pseudo-threefold axis of rotation and may be viewed as a composite of [Co(sen)]$^{3+}$ (Fig. 1) and [Co(sep)]$^{3+}$ (**I** with X=Y=N), where sep= 1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]icosane.[16] The absolute configuration of the cation that shows a positive circular dichroism peak in the first absorp-

The coordination geometry around Co(III) appears to be typical for this type of complexes. The Co-N bond length and N-Co-N bond angle averaged over C_3 equivalents are 1.977(12)Å and 86.0(3)°. The corresponding values in [Co(sen)]$^{3+}$ are 1.971(6) Å and 86.1(2)°, respectively.[10] Further, other bond lengths and angles of the "[Co(sen)]$^{3+}$" moiety of [Co(azamesar)]$^{3+}$ are slso very similar to those of [Co(sen)]$^{3+}$. Thus, it may be concluded that the N(CH$_2$-)$_3$ capping takes place without affecting significantly the geometry of [Co(sen)]$^{3+}$.

The C1-C2 bond length (1.562(7)Å) appears to be

somewhat longer than normal. However, this may not be physically significant, because no such trend was observed in our previous structural studies on cobalt(III) complexes with ligands containing the $CH_3C(CH_2-)_3$ capping group, such as *Λ*-[Co(sen)]Cl·*d*-tart·$6H_2O$,[10] [Co(L)(en)]$(ClO_4)_3$,[4] and [Co(stn)]-$Cl_3\cdot 3.5H_2O$,[5] where tart=tartrate ion, L=6-methyl-6-(4-amino-2-azabutyl)-1,4-diazacycloheptane, and stn=1,1,1-tris(5-amino-2-azapentyl)ethane (see Fig. 1).

The C-N bond lengths alternate along the ligand strand from the capping nitrogen N7 to the first carbon atom of the "en" moiety; for example, the C-N bond lengths vary from 1.457(7) Å to 1.510(6) Å to 1.473(6) Å along the chain N7-C14-N6-C11, in this order. Concomitantly with the bond length alternation of this type, C(cap)-N(cap)-C(cap) angles open (the cap flattens) up to an average value of 114.1(6)°. Both of these tendencies are observed in other aza-capped complexes like $[Co(sep)]^{3+}$ and [Co(azacapten)]$^{3+}$ (azacapten=8-methyl-6,10,19-trithia-1,3,13,16-tetraazabicyclo[6.6.6]icosane; see Fig. 1),[16,17] and considered to be responsible for very reduced proton affinity of the capping nitrogens.[8]

The "en" rings of the cation adopt the $(lel)_3$ conformation. This is most clearly seen in Fig. 4. This $(lel)_3$ conformation has also been reported for *Λ*-[Co(sen)]Cl·*d*-tart·$6H_2O$[10] and *Λ*-[Co(sep)]$Cl_3\cdot H_2O$.[16] In this conformation, all the N-H hydrogens point approximately to the C_3 equatorial direction and therefore are more suitable for double hydrogen bonding proposed previously (between two N-H hydrogens of the cation and oxygen atoms of the associating anion) than in the $(ob)_3$ one. The energy difference between the $(lel)_3$ and $(ob)_3$ conformations in the cage complexes of cobalt(III) is estimated to be rather small.[2] Thus, it is probable that the $(lel)_3$ conformation may be stabilized by such double hydrogen bonding in aqueous solution; multiple hydrogen bonding is known to be capable of stabilizing one conformation selectively over the other.[18]

Deviations from the tetrahedral value are observed in C-C-N, C-N-C, and Co-N-C angles, as well as the previously noted C(cap)-N(cap)-C(cap) angles. The angles averaged over C_3 equivalents are, along the ligand strand from C2, C2-C(cap)-N(en)=113.9(1)°, C(cap)-N(en)-C(en)=112.4(8)°, C(en)-N(en)-C(cap)=113.0(6)°, and N(en)-C(cap)-N(cap)=112.8(7)°. The Co-N(en)-C(cap) angles similarly averaged are 115.9(22)° near the $CH_3C(CH_2-)_3$ cap and 116.0(1)° near the $N(CH_2-)_3$ cap. The torsional angles averaged similarly are, along the ligand strand from Cl to C2 to C(cap) and so on, Cl-C2-C(cap)-N(en)=173.7(12)°, C2-C(cap)-N(en)-C(en)=116.0(5)°, C(cap)-N(en)-C(en)-C(en)=171.8(8)°, N(en)-C(en)-C(en)-N(en)=53.4(5)°, C(en)-C(en)-N(en)-C(cap)=169.8(5)°, and C(en)-N(en)-C(cap)-N7=117.8(7)°. All these angles do not differ significantly from the corresponding angles of $[Co(sen)]^{2+}$ and $[Co(sep)]^{3+}$, suggesting that the ligand strain does not differ significantly.

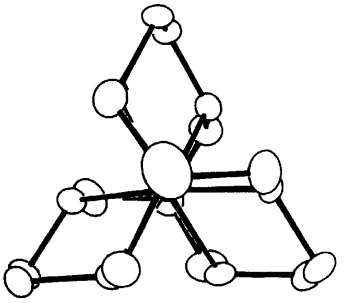

Fig. 4. Projection down the pseudo-threefold axis of rotation of the cation. Ellipsoids enclose 30% probabilities.

Parity Rule. Algorithmic Method for the Assignment of Chiral Centers

Mitsuharu KOTERA*
U. A. 464 Laboratoire de Chimie Organique, Faculté des Sciences et des Techniques de Rouen,
76130 Mont Saint Aignan, France
(Received July 30, 1985)

Synopsis. A simple new algorithm is presented for the assignment of *R/S* configuration of chiral centers described in any projection form.

The configuration *R* and *S* of a chiral center (such as carbon with four ligands) is generally determined by the sequence rule procedure:[1,2] This procedure involves, in the last step, a mental transfer of the molecule described in a two dimensional surface. Such a mental transfer can become more and more difficult with increasing molecular complexity and even experienced chemists may make mistakes in this step.

Here we wish to present a simple algorithm for the assignment of chiral center configuration. This method requires no transformation of the first projection described and is, furthermore, applicable to complex molecules.

The method is outlined as follows:

(1) Assign the priority numbers for each group surrounding the chiral center.

(2) Take the number of the group which is clearly directed forward, and then the three others in a clockwise manner. Thus a sequence of four numbers is obtained.[3]

(3) Then take each of the first three numbers in the sequence, and count *how many* smaller numbers follow each one from left to right. Take the sum of these counts.

(4) In the case of an *R*-configuration, the resulting sum will be even. For an *S*-configuration, the operation will yield an odd sum.[4]

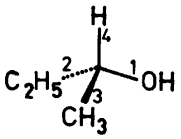

Fig. 1.

For example, consider the configuration of 2-butanol (Fig. 1). The number of the methyl group (No. 3) directed forward is taken first. Then the three other groups (No. 4, No. 1, No. 2) are taken in a clockwise manner. Thus the sequence 3-4-1-2 is obtained. After No. 3, TWO smaller numbers (No. 1 and No. 2) follow. After No. 4, TWO smaller numbers (No. 1 and No. 2) follow. After No. 1, NO smaller number follows. TWO+TWO+ZERO=FOUR, an even sum is obtained. This indicates that the configuration is *R*.

The Figs. 2—5 show the flexibility of this method for many different projection forms.

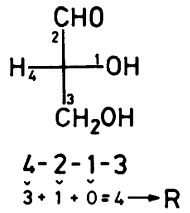

Fig. 2.

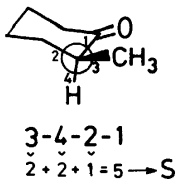

Fig. 3.

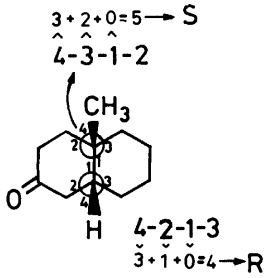

Fig. 4.

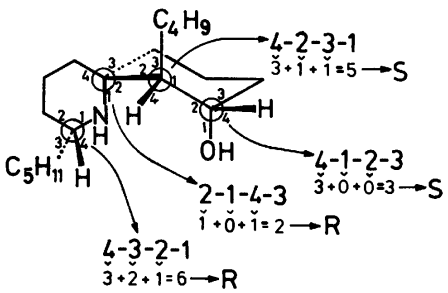

Fig. 5.

The rule will always give the correct answer provided the diagram is clearly drawn.[5] This method has advantages over the others,[6-10] in which many numbers or tables must be memorized. Here, the sequence to be remembered is simply "forward directed group first," "the three others in a clockwise manner," "how many smaller numbers follow" and "even=*R*." The rule will be particularly useful when there are many chiral centers to be assigned and verified.

The author thanks Dr. G. P. Moss for his helpful suggestion about the examples 7—10.

2) V. Prelog and G. Helmchen, *Angew. Chem. Int. Ed.*, **21**, 567 (1982).

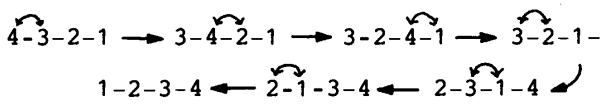
3) Regardless of which number is taken in second place, the result is the same as long as the clockwise manner is respected.

4) This algorithm is based on the following facts.

1° The sequence 1-2-3-4 corresponds to the *R*-configuration.

2° When two numbers of a sequence are interchanged, the related configuration is inversed.

3° The sums of the number of smaller numbers following in the sequence correspond to the number of changes necessary to afford the series 1-2-3-4. For example, from the sequence 4-3-2-1, one can arrive at the sequence 1-2-3-4 with the six following exchanges:



5) It must be noted that in some representations, it becomes difficult (Figs. 6—8) or even impossible (Figs. 9—10) to choose a forward directed group. In Fig. 6, only the backward directed group is indicated. In such cases, one must choose, as the forward directed group, one of the two neighbouring groups on either side of the backward directed group. In the case of Figs. 7—10, the problems are due to the representations themselves. The configuration of a chiral center represented as in Fig. 11 (a planar carbon) cannot be known without some further information. The true configuration of Fig. 11 must be either 12 or 14, and in each case, it is different. This ambiguous representation can be found in Figs. 7—10. In Figs. 7—8, we know what are intended here. But in the case of Fig. 9, we are not sure of the configuration of the carbon in question. The starred carbon in Fig. 10 which appeared in IUPAC E rule[11] is almost planar and it will be impossible to determine its configuration.

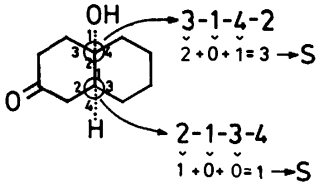


Fig. 6.

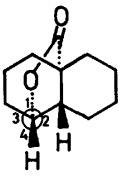

Fig. 7.

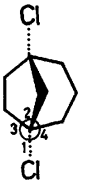

Fig. 8.

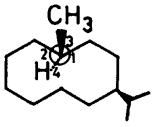

Fig. 9.

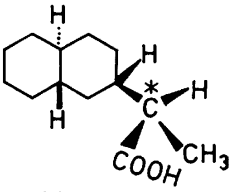

Fig. 10.

Fig. 11. Fig. 12. Fig. 13. Fig. 14. Fig. 15.

We wish to insist that the figures must be clearly drawn.

1° Generally, it is sufficient to indicate only one well chosen group directed forward or backward for each chiral center as in Fig. 13 and Fig. 15, and its configuration will be clear. (It is assumed that the Fisher type representation Fig. 12 or Fig. 14 is implicated in them)

2° If there are two groups directed respectively forward and backward on the opposite sides of one chiral center as in Fig. 11, its configuration is locally ambiguous.

Thus the configuration of encircled carbons in Fig. 7 and Fig. 8 will be clearer in Fig. 16 and Fig. 17. Figure 9 may be drawn as in Fig. 18, and Fig. 10 as in Fig. 19 or Fig. 20.

^{35}Cl NQR and Ionicities of a Few *N*-Chloroimides

Yoshitaka NAGAO* and Shigeyoshi KATAGIRI
Department of Chemistry, Faculty of Science, Hirosaki University, Bunkyo-cho, Hirosaki 036
(Received July 26, 1985)

Synopsis. ^{35}Cl NQR frequencies were measured for *N*-chlorosuccinimide (NCS), *N*-chlorophthalimide (NCP), *N,N'*-dichlorobarbital (NDCB), sodium *N,N'*-dichloroisocyanurate dihydrate (Na-NDCI·2H$_2$O) and *N,N',N''*-trichloroisocyanuric acid (NTCI). The ionicities estimated by a ^{35}Cl NQR study increased in the following order; NCS<NCP <NDCB<Na-NDCI·2H$_2$O<NTCI. A linear relationship between the ionicities of chlorine atoms and the polarographic reduction potentials of N-Cl bonds was found. The ionicity was related to the reactivity.

Since the first report on a ^{35}Cl NQR study of the N-Cl bond by Segel et al.,[1] several papers about ^{35}Cl NQR studies of molecules with this bond have been published.[2-6] The ^{35}Cl NQR frequency is higher for a N-Cl bond than for a C-Cl bond because the electronegativity of chlorine is practically the same as that of nitrogen.

N-halogenoimides are effective reagents for the halogenation and the oxidation of olefins, alcohols and carbonyl compounds. In this paper, we report on the ^{35}Cl NQR frequencies for a few *N*-chloroimides and the reactivities of these compounds.

Experimental

The materials, except for *N,N'*-dichlorobarbital, were purified several times by the recrystallization of commercial products. *N,N'*-dichlorobarbital was prepared by a method described in the literrature[7] and purified by recrystallization. It was identified by its IR spectrum.

An NQR spectrometer of the type described by Dean[8] was used. The signals were either observed on a CRO or recorded on a chart. The resonance frequencies were measured on a CRO screen with the help of an RF-signal generator (Trio, Model SG-2) and a frequency counter (Anritsu, MF-55D).

Sample tubes of about 22-mm diameter were used. All measurements were made at liquid-nitrogen temperature.

Results and Discussion

The ^{35}Cl NQR frequencies of the *N*-chloroimides at liquid-nitrogen temperature are given in Table 1. For *N*-chlorosuccinimide (NCS) and *N*-chlorophthalimide (NCP), the observed frequencies agree with those found in the literature.[3] *N,N',N''*-trichloroisocyanuric acid† (NTCI) showed two resonance lines ν_1=58.902 MHz and ν_2=46.423 MHz. The latter agrees with the result of Fitzky et al.[4] The frequency ratio, ν_1/ν_2=1.2688, agrees with the isotope frequency ratio, $\nu(^{35}Cl)/\nu(^{37}Cl)$. Therefore, it was found that the result of Fitzky et al. corresponds to the ^{37}Cl NQR frequency of NTCI. According to Hart et al.,[3] all the nitrogen atoms of the compounds cited in Table 1 have $tr^1tr^1tr^1\pi^2$ hybridization states and their structures are either planar or near planar.[9] This conclusion is consistent with the IR and Raman spectra.[10,11]

Table 1. ^{35}Cl NQR Parameters of *N*-Chloroimides at Liquid Nitrogen Temperature

Compound	ν/MNz	e^2Qq/h / MHz	i
N-Chlorosuccinimide	54.095	108.2	−0.01
N-Chlorophthalimide	55.402	110.8	0.01
N,N'-Dichlorobarbital	57.036	114.1	0.03
Sodium *N,N'*-dichloroisocyanurate dihydrate	58.208	116.4	0.05
N,N',N''-Trichloroisocyanuric acid	ν_1=58.902 ν_2=46.423	117.8	0.06

The asymmetry of the field gradient in this case originates from the π-bond character of the N-Cl bond. From the possible resonance structures, the π character can be excluded. Therefore, the asymmetry parameter, η, must be negligibly small and the quadrupole coupling constant, e^2Qq/h, is twice the resonance frequency. We have calculated the quadrupole coupling constant (Table 1). The coupling constant of NCS is smaller and the values for other compounds are larger than that of the chlorine atom (109.74 MHz for ^{35}Cl[12]). This indicates that the chlorine atom of NCS has a negative charge and others are posivively charged. According to Townes and Dailey,[12] the coupling constant is given by

$$e^2Qq = (1+\alpha i)(e^2Qq)_{atom}$$

where i stands for the bond ionicity and $(e^2Qq)_{atom}$ denotes e^2Qq of the atomic chlorine. For a negative ionicty, α=−1 is used and for a positive ionicity α= 1.28. Here, the s and d characters of chlorine are neglected because the electronegativity of chlorine is practically the same as that of nitrogen and the d character is always less than 5% for the chlorine atom.[12] By the use of this relation, the ionic character of the N-Cl bonds were evaluated (Table 1). Sodium *N,N'*-dichloroisocyanurate†† dihydrate (Na-NDCI·2H$_2$O) has a lower ionicity than that of NTCI since the sodium ion decreases the inductive effect of the carbonyl group to the N-Cl bond. The ionicity increases in the following orde; NCS<NCP <NDCB<Na-NDCI·2H$_2$O<NTCI.

Figure 1 shows the relationship between the ionicity, i, and the polarographic reduction potential,[13] $E_{1/2}$, of *N*-chloroimides. The reduction of the N-Cl bond becomes easier when the polarity of the N-Cl bond increases. The result of a polarographic study shows

† Systematic name: 1,3,5-trichloro-1,3,5-triazine-2,4,6-(1*H*,3*H*,5*H*)-trione.

†† Systematic name: 1,3-trichloro-1,3,5-triazine-2,4,6-(1*H*,3*H*,5*H*)-trione sodium salt.

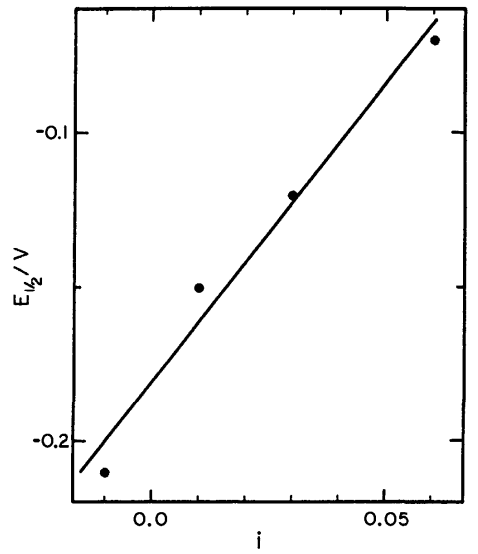

Fig. 1. The relationship between the ionic character, i, and reduction potential, $E_{1/2}$ of *N*-chloroimide.

that the polarity of *N*-chloroimide increases in the following order; NCS<NPC<NDCB<NTCI. This is in agreement with the results of our ^{35}Cl NQR study.

Reactions of NTCI and NCS with some metal alkyls and metal chlorides were studied by Leimeister et al.[14] Substitution reactions occur with NTCI, whereas NCS reacts only with $SnCl_5$, forming hexachloroantimonate. This fact shows that the chlorine atom of NTCI is more positive than that of NCS. Otsuji et al.[13] sudied the reactions of cyclohexanone with NTCI and NDCB. The results show that the N-Cl bond is more polar in NTCI than in NDCB. They also studied the chlorination of cyclohexene with NDCB and NCS and concluded that the polarity of the N-Cl bond increases from NCS to NDCB. These three facts explain why the polarity of the N-Cl bond increases in the following order; NCS<NDCB<NTCI. This agrees with the order of the ionicity evaluated in the present study. Thus, we conclude that the ionicity of *N*-chloroimides (as estimated by the ^{35}Cl NQR study) provides a good measure of the reactivities of the *N*-chloroimides.

Activity Coefficients of Dimethyl-β-cyclodextrin in Aqueous Solutions

Koichiro MIYAJIMA,* Takayo MUKAI, Masayuki NAKAGAKI, Masaki OTAGIRI,† and Kaneto UEKAMA†
Faculty of Pharmaceutical Sciences, Kyoto University Yoshida-shimoadachi-cho, Sakyo-ku, Kyoto 606
†Faculty of Pharmaceutical Sciences, Kumamoto University 5-1, Oe-honmachi, Kumamoto 862
(Received August 1, 1985)

Synopsis. The activity coefficients of aqueous solutions of dimethyl-β-cyclodextrin were measured by vapor pressure osmometry at 25, 35, and 45±0.1 °C. The activity coefficient decreased with increase of concentration at each temperature. Both the excess enthalpy and the excess entropy were positive. The negative excess free energy originates from the large excess entropy term, indicating that dimethyl-β-cyclodextrin is a hydrophobic solute.

In a previous paper,[1] we determined the activity coefficients of α- and γ-cyclodextrins in aqueous solutions at 25 °C. In contrast with the concentration dependence of activity coefficients of aqueous solutions of D-glucose,[2] the activity coefficients of these cyclodextrins decreased with increase of concentration, implying that these solutes either associate or break the water structure.

Dimethyl-β-cyclodextrin(DM-β-CD) is heptakis(2,6-di-*O*-methyl)-β-cyclodextrin. The solubility of DM-β-CD in water is about ten times larger than that of β-CD and is soluble in organic solvents.[3] The complex formation and the properties of complexes are now being extensively studied.

From these points of view, we determined the temperature dependence of the activity coefficients of DM-β-CD in aqueous solutions to elucidate the solution property.

Experimental

Materials. DM-β-CD supplied from Toshin Chemicals was recrystallized from water. The purity was confirmed by HPLC and ^{1}H NMR. The compound was dried in vacuo at room temperature for several days before use. The melting point was 96 °C. Reagent grade sodium chloride obtained from Nakarai Chemical Co. Ltd. was used after drying in vacuo at 100 °C for 2 d. Aqueous solutions of these compounds were prepared with water purified by distillation and deionization.

Method. Vapor pressure over aqueous solution was measured at 25, 35, and 45±0.1 °C with an osmometer model 117 manufactured by Corona Electric Co. Ltd. To obtain the accurate results, osmotic pressures of DM-β-CD solution and NaCl solution (reference) of corresponding concentration were measured consecutively in every set of measurement. The experimental determination of osmotic coefficient was precise to ±0.02.

Results

The relations between the osmotic coefficients ϕ and the concentration m in $mol^{-1}kg$ at 25, 35, and 45 °C are shown in Fig. 1. The values of ϕ decrease with increase of concentration at each temperature. By the least-square fitting, the values of ϕ at the respective temperatures are expressed in terms of m as

$$\phi_{25} = 1 - 6.73\,m + 37.4\,m^2,$$

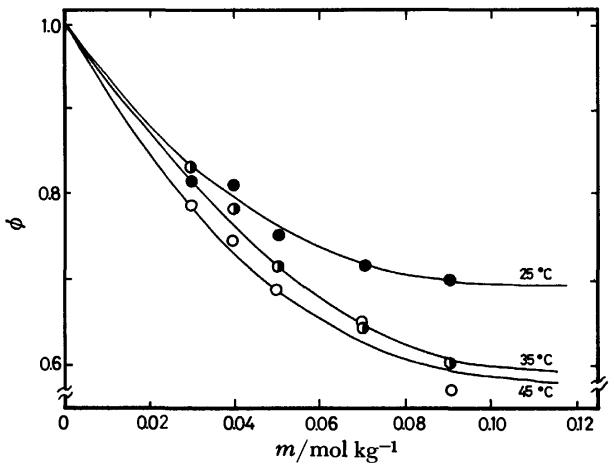

Fig. 1. Relation between osmotic coefficient and concentration for DM-β-CD at various temperatures.
●: 25 °C, ◑: 35 °C, ○: 45 °C.

$$\phi_{35} = 1 - 7.07\,m + 28.0\,m^2, \quad (1)$$

and

$$\phi_{45} = 1 - 8.49\,m + 44.4\,m^2.$$

The activity coefficient is calculated from Eq. 2.

$$\ln\gamma = (\phi - 1) + \int_0^m \frac{\phi - 1}{m}\,dm \quad (2)$$

Introducing Eq.1 into Eq. 2 and integrating, we obtain

$$\ln\gamma_{25} = -13.5\,m + 56.6\,m^2,$$

$$\ln\gamma_{35} = -14.1\,m + 42.0\,m^2, \quad (3)$$

and

$$\ln\gamma_{45} = -17.0\,m + 66.6\,m^2.$$

The activity coefficient vs. m curves are shown in Fig. 2.

The excess thermodynamic quantities are calculated from Eqs. 4, 5, and 6

$$G^{ex} = mRT(1 - \phi + \ln\gamma), \quad (4)$$

$$S^{ex} = -\left(\frac{\partial G^{ex}}{\partial T}\right)_p \quad (5)$$

and

$$H^{ex} = G^{ex} + TS^{ex}, \quad (6)$$

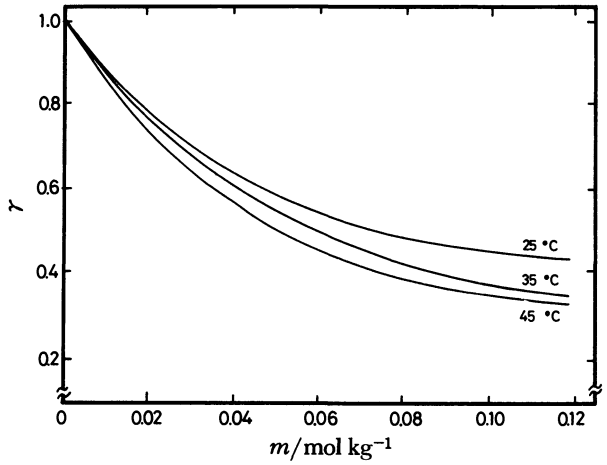

Fig. 2. Relation between activity coefficient and concentration at various temperatures.

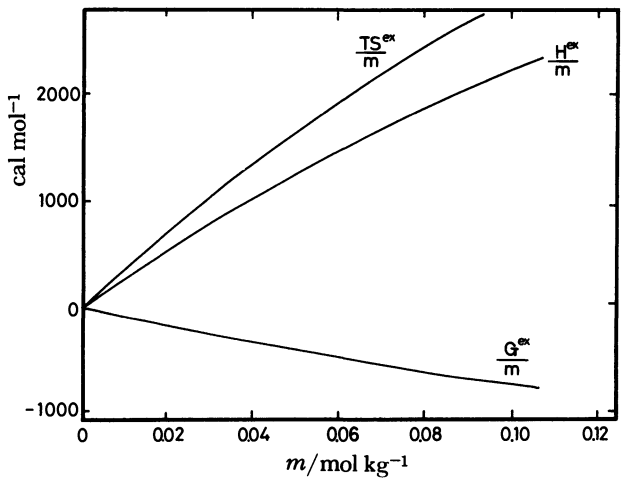

Fig. 3. Molar excess thermodynamic quantities vs. concentration curves at 35 °C. (1 cal=4.184 J)

where R and T are of usual meanings. The molar excess thermodynamic quantities are shown in Fig. 3 as a function of m.

Discussion

As shown in Figs. 1 and 2, the values of ϕ and γ decrease with increase of m. Similar trends were observed in aqueous solutions of α- and γ-CDs. But the decreasing tendency of activity coefficient with increase of m for DM-β-CD is more significant than those of α- and γ-CDs. In general, the decrease in activity coefficient with increase of m is interpreted in terms of two different effects, i.e. structure breaking effect and the association of the solutes. However, such a large decrease of activity coefficient in low concentration is more likely to take place as a results of the solute-solute interaction rather than the solute–solvent interaction. In contrast with the case of aqueous α-CD solution, the negative excess free

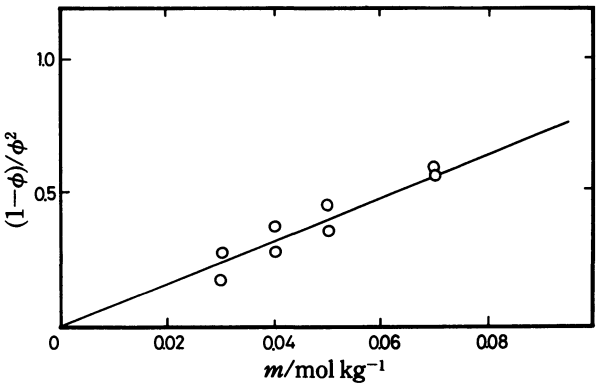

Fig. 4. $(1-\phi)/\phi^2$ vs. concentration curve at 25 °C.

energy of aqueous DM-β-CD solution originates from the predominance of positive entropy term over positive enthalpy as seen in Fig. 3, indicating that DM-β-CD is a hydrophobic solute like tetrabutylammonium salts.[5] The self salting-in effect based on the hydrophobic interaction among DM-β-CD molecules increase with concentration, resulting in the increase of excess entropy by the destruction of iceberg around DM-β-CD molecules. Positive enthalpy also increases with concentration because of the melting of iceberg. But the values of TS^{ex} is larger than that of H^{ex} for the hydrophobic solute. The hydrophobic nature of DM-β-CD should be attributed to the methyl groups which locate on the outer surface of the molecule.

By assuming that the large decrease of activity coefficient with increase of m is based on the dimer formation through hydrophobic interaction, we calculated the formation constant(K) at each temperature with Eq. 7.[6]

$$K = (1-\phi)/m\phi^2 \tag{7}$$

The relation between $(1-\phi)/\phi^2$ and m at 25 °C is shown in Fig. 4. From the slope of curve, 8.1, 11.4, and 12.5 $mol^{-1}kg$ were obtained as the K values at 25, 35, and 45 °C. The increase of K with temperature is consistent with the theoretical results of hydrophobic interaction between leucine and isoleucine in water.[7]

In conclusion, DM-β-CD is a hydrophobic solute in contrast with α- and γ-CDs which are hydrophilic.[1]

Thermal Diffusion of Prototropic Ions in Water

Naokata TAKEYAMA* and Kimie NAKASHIMA
Department of Industrial Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received August 5, 1985)

Synopsis. Regarding the Soret effect of prototropic ions of H^+ and OH^- in dilute aqueous solutions, it has been mentioned that heat-of-transport values for ions are in good agreement with those of the activation energies for ionic diffusion in the Arrhenius expression. The physicochemical significance of these facts is discussed in relation to the inclusion of thermal diffusion terms in Kramers' formula for ordinary diffusion flux.

The Soret effect regarding an aqueous ionic solution can be described with the Nernst-Hartley approximation in very dilute conditions by

$$J = -D^\circ \operatorname{grad} m - D'm \operatorname{grad} T \quad (1)$$

for ions under the Kohlrausch law which concerns the independent mobility of ions. J is the ionic diffusion flux, m the ionic molal concentration, D° the limiting ionic diffusion coefficient, D' the ionic thermal diffusion coefficient, and T the temperature which is dependent on the position coordinate.[1] At a Soret steady state of $J=0$, the Soret coefficient s° and the heat-of-transport Q^* are expressed[2] as

$$s^\circ = -d\ln m/dT = D'/D^\circ = Q^*/RT^2, \quad (2)$$

where R is the gas constant. The heats of transport for various ions are subject to the additivity rule for electrolytes in sufficiently dilute aqueous solutions.[2] Reversely, Q^* for ions should be derived from the observed heats of transport for various electrolytes. At present, there is no good method for dividing the heat of transport of an electrolyte into the heats of transport for constituent ions, except for a conventional method proposed by Snowdon and Turner[2] on the scale of $Q^*=0$ for Cl^- at 298 K and 0.01 mol kg^{-1}. It is obvious that the conventional values are not suitable for a physicochemical discussion. In this regard, the present authors have proposed a rational method for dividing the heats of transport for electrolytes into those for ions after the introduction of a reduction rule with reference to thermal diffusion coefficients of 1-1 electrolytes in aqueous solutions at 298 K and 0.01 mol kg^{-1}.[3] Although this method is quite different from the conventional method of Snowdon and Turner, the values of Q^* for H^+ and OH^- obtained from both methods are in good agreement.

On the other hand, as is well known, the Arrhenius expression for ionic diffusion coefficients shows a narrower applicability than for the reaction-rate constants.[4] An apparent activation energy E_a can still be introduced:

$$\partial \ln D^\circ/\partial T = E_a/RT^2 \quad (3)$$

for a certain temperature. However, E_a continues to be temperature dependent.[5,6]

Table 1. Ionic Quantities of Diffusion and Thermal Diffusion for H^+ and OH^- in Water at 298 K

Ion	D°	D'	Q^*	E_a
	$10^{-5}cm^2s^{-1}$	$10^{-8}cm^2s^{-1}K^{-1}$	kJ mol^{-1}	kJ mol^{-1}
H^+	9.31	161.1	12.8	12.8
OH^-	5.32	119.9	16.7	16.8

Here, we wish to discuss various relations between Q^* and E_a for H^+ and OH^- in water.

Table 1 summarizes the values of D°, D', Q^*, and E_a that were estimated for H^+ and OH^- at 298 K. The values of D° were obtained by the Nernst-Einstein relation from the limiting molar conductivities of H^+ and OH^-, of which the temperature dependences have been used to estimate the values of E_a according to Eq. 3.[6] The values of D' have been calculated from the values of Q^* using Eq. 2 with D° at 298 K.

It has been found that Q^* is equal to E_a for H^+ and OH^-, respectively. This relation is never valid for ions other than H^+ and OH^-. For example, referring to Li^+, there is a much larger difference between $Q^*=-0.01$ kJ mol^{-1} [3] and $E_a=18.9$ kJ mol^{-1}. These are obtained in a quite similar manner to the cases of H^+ and OH^-.

In order to understand this fact most simply for H^+ and OH^- in water, we use Kramers' formula for an isothermal diffusion flux[7]

$$J = -\exp(-U/RT) \operatorname{grad} D^\circ m \exp(U/RT). \quad (4)$$

The notation is the same as that mentioned above and U is an external potential which is dependent on the positions of the diffusing ions. For the present, we assume that D° is indirectly dependent on position through the position dependence of T, even in non-isothermal conditions. Thus, Eq. 4 can be expanded into

$$J = -D^\circ \operatorname{grad} m - (\partial D^\circ/\partial T)m \operatorname{grad} T + D^\circ m(U/RT^2) \operatorname{grad} T - (D^\circ m/RT) \operatorname{grad} U. \quad (4\cdot a)$$

The last term on the right side of Eq. 4.a is a drift term due to an external force. The second and third terms can be reduced to a thermal-diffusion term by taking the thermal-diffusion coefficient

$$D' = D^\circ(\partial \ln D^\circ/\partial T - U/RT^2). \quad (4\cdot b)$$

In the presence of U, using Eqs. 2 and 3, the heat of transport is

$$Q^* = E_a - U. \quad (4\cdot c)$$

In the absence of U, Eqs. 4.b and 4.c are simply

$$D' = \partial D^\circ/\partial T \quad (4\cdot d)$$

and

$$Q^* = E_a. \tag{4.e}$$

From Eqs. 2 and 3 it is easily seen that Eq. 4.d is equivalent to Eq. 4.e, and vice versa. Equation 4.e, which is independent of U, corresponds to cases of the thermal diffusion of H^+ and OH^- in water. Moreover, it can be mentioned that Eq. 4.d agrees with an earlier proposition by Wirtz.[8]

As an important consequence of Eq. 4.e and in harmony with the empirical fact that Q^* equals E_a for H^+ and OH^-, we can consider that the values of the heat of transport of H^+ and OH^- which we used are reasonable.

In this regard, it is a well known fact that in the case of superionic solid conductors the activation energies of ionic conduction are equal to the heats of transport derived from ionic thermoelectric power.[9] These conductors are composed of mobile superions and rigid lattice ions. These are dealt with theoretically by using a lattice gas model.[10] In comparison with these superionic conductors, it can be proposed that H^+ and OH^- behave like a superion in an immobile hydrogen bonded quasi-lattice in water due to the Grotthuss' mechanism.

5) In Ref. 4 the following equation is shown as the temperature dependence with rather more success:

$$D^\circ = AT^n \exp(-E/RT)$$

with constant A, n, and E within applicable temperature ranges.

For H^+, n and E are -13.7 and 46.9 kJ mol^{-1} from 273 to 329 K, and -3.31 and 18.5 kJ mol^{-1} from 329 to 373 K. For OH^- these are -27.7 and 85.4 kJ mol^{-1} from 273 to 308 K, and -5.41 and 27.5 kJ mol^{-1} from 308 to 373 K. As a reference, for Li^+ these are -17.2 and 61.6 kJ mol^{-1} from 273 to 310 K, and -8.12 and 38.1 kJ mol^{-1} from 310 to 373 K. The relationship to E_a is $E_a=E+nRT$ at a temperature T.

EXAFS Studies of the Behavior of $Rh_6(CO)_{16}$ Supported on γ-Al_2O_3 Surface

Kiyotaka ASAKURA, Yasuhiro IWASAWA,* and Haruo KURODA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received August 13, 1985)

Synopsis. The structural change of $Rh_6(CO)_{16}$ supported on γ-Al_2O_3 surface during a decarbonylation-recarbonylation cycle was studied by means of EXAFS (extended X-ray absorption fine structure) spectroscopy. $Rh_6(CO)_{16}$ cluster framework was found to be decomposed into $Rh(CO)_2(OAl\lesssim)_2$ after the reaction with a mixture of O_2 and H_2O, and reversely regenerated by the subsequent treatment with a mixture of CO and H_2O.

Metal carbonyl clusters supported on inorganic oxides have been demonstrated to provide a new way of preparation of noble solid catalysts as well as new chemistry in the research boundary between homogeneous and heterogeneous catalytic systems. Smith et al. and Watters et al. suggested that $Rh_6(CO)_{16}$ physisorbed on Al_2O_3 surface was transformed to twin carbonyl Rh species by the treatment with a mixture of O_2 and H_2O, and reversely, the twin carbonyl Rh species was recarbonylated again to the original $Rh_6(CO)_{16}$ cluster by the subsequent treatment with a mixture of CO and H_2O from the results of IR spectroscopy.[1-3] Since the carbonyl stretching modes of Rh species give no direct information on the feature of Rh–Rh bonding, the details of the structural change of the metal framework of $Rh_6(CO)_{16}$ supported on Al_2O_3 surface still remaind to be solved.

In the present paper we report the EXAFS and XANES studies on a $Rh_6(CO)_{16}/\gamma$-Al_2O_3 system to obtain the information on structural changes of the Rh_6 framework.

Experimental

Supporting $Rh_6(CO)_{16}$ onto γ-Al_2O_3 was carried out by an impregnation method using a hexane or chloroform solution of $Rh_6(CO)_{16}$ under high purity Ar (99.9995%) atmosphere, followed by evacuation to remove the solvent. γ-Al_2O_3 was pretreated at 773 K for 2 h in a dry air in situ before use as a support. Hereinafter, the Al_2O_3 supported $Rh_6(CO)_{16}$ thus obtained is denoted as Sample 1. The sample was treated with a mixture of O_2 (26.6 kPa) and H_2O(2 kPa) at room temperature for 30 h in a closed-circulating system to which the cells for EXAFS measurements were connected. The treated sample is denoted as Sample 2. Sample 2 was further treated with a mixture of CO(26.6 kPa) and H_2O(2 kPa) at 323 k for 15 h, Sample 3 being thus obtained. After each treatment, the samples were transferred to EXAFS cells without contacting air. EXAFS measurements were conducted by use of synchrotron radiation at Photon Factory in National Laboratory for High Energy Physics (KEK-PF).[4] The analysis of EXAFS spectra was performed by a curve fitting technique employing theoretically derived phase shift and amplitude function.[5-7]

Results and Discussion

Figure 1 shows the EXAFS oscillations and Fourier transforms of the Rh K-edge EXAFS of $Rh_6(CO)_{16}$ powder, Samples 1, and 3, respectively. The Fourier

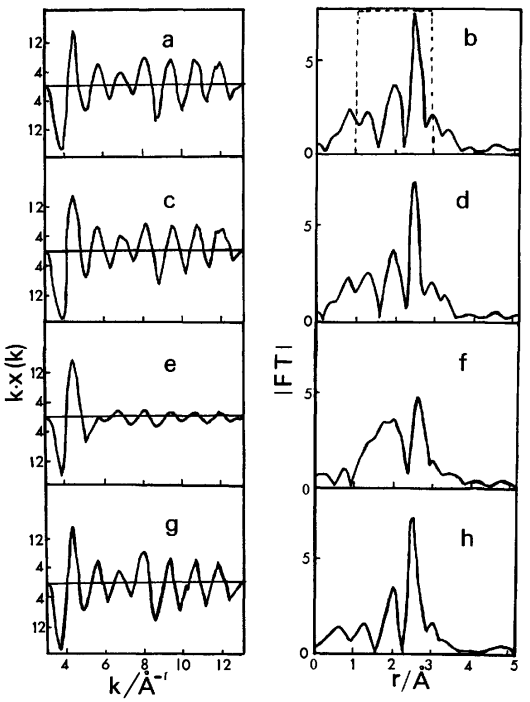

Fig. 1. k-Weighted EXAFS oscillations and Fourier transforms.
(a), (c), (e), and (g) are the k-weighted EXAFS oscillations of $Rh_6(CO)_{16}$ powder, Sample 1, Sample 2, and Sample 3, respectively. (b), (d), (f), and (h) are the Fourier transforms of $Rh_6(CO)_{16}$ powder, Sample 1, Sample 2, and Sample 3, respectively. The broken line in the Fig. 1b is the Fourier filtering window.

transform of $Rh_6(CO)_{16}$ showed a strong peak at 2.75 Å referred to the Rh–Rh bond in Fig. 1b. The contribution of back-scattering by Rh atoms to the Rh K-edge EXAFS oscillation was observed over a wide range of the wave number of ejected photoelectron(k) as shown in Fig. 1a. Thus the information obtained from the EXAFS analysis largely reflects the structure of Rh metal framework. The main peak in Fig. 1b was back-Fourier transformed in the range of 1—3 Å as shown in the Figure and four-shell curve fitting analyses were carried out considering Rh–C(terminal carbonyl group), Rh–C(triply bridged carbonyl group), Rh–O and Rh–Rh and the results were obtained to be given in Table 1. The Rh–Rh bond length (2.76Å) was in good agreement with the crystallographic data of $Rh_6(CO)_{16}$[8] (Rh–Rh=2.78 Å).

The EXAFS oscillation (Fig. 1c) and the Fourier transform (Fig. 1d) of Sample 1 were similar to those of $Rh_6(CO)_{16}$ cluster itself. The bond length and coordination number of each coordination shell around a Rh atom were found by the curve-fitting analysis to be about the same as those of $Rh_6(CO)_{16}$ as shown in Table 1. Thus, $Rh_6(CO)_{16}$ is concluded to be

Table 1. The Curve Fitting Results

a), b) C(term) and C(bridge) mean the carbon atoms of terminal and μ_3-bridged carbonyl ligands, respectively. c) Rh-O means the interaction between Rh and O in carbonyl ligand. d) 1-term curve fitting analysis of Rh-Rh. e) 4-term curve fitting analysis of Rh-C(term)+Rh-C(bridge)+Rh-O+Rh-Rh

supported on γ-Al_2O_3 retaining its cluster framework.

The EXAFS oscillation and Fourier transform of Sample 2 shown in Figs. 1e and 1f were much different from those of Sample 1. The decrease in the intensity of the main peak in the Fourier transform indicates the partial breaking of Rh–Rh bond of the cluster. Smith et al.[2] suggested by IR studies that $Rh_6(CO)_{16}$ supported on Al_2O_3 is decomposed to mononuclear $Rh^I(CO)_2$ species by O_2 treatments(more easily in the presence of moisture). The present EXAFS analysis also indicates the Rh–Rh bond breaking. However, in contrast to the almost complete decomposition of the Rh_6 framework by the IR studies,[2] the Rh–Rh bond was still observed at a distance of 2.75 Å similar to that found in $Rh_6(CO)_{16}$. The EXAFS data suggested that part of $Rh_6(CO)_{16}$ remained almost unchanged after O_2+H_2O treatment. The discrepancy between the IR observation[2] and the present EXAFS analysis is not clear at the present, but the generally known surface heterogeneity of Al_2O_3 employed may give an effect to the behaviors of Rh clusters.

The EXAFS oscillation and the Fourier transform of Sample 3 in Figs. 1g and 1h were identical to those of $Rh_6(CO)_{16}$ as well as Sample 1. The EXAFS analysis in Table 1 clearly reveals that the $Rh_6(CO)_{16}$ framework was completely regenerated on the γ-Al_2O_3 surface by the CO+H_2O treatment for 15 h.

The XANES spectra of Rh K-edge of Samples 1 and 3 given in Fig. 2b and Fig. 2d, respectively were similar to that of $Rh_6(CO)_{16}$ as shown in Fig. 2a, which is compatible with the EXAFS data. The relative intensity of peak A to peak B in the XANES region of Sample 2 changed as shown in Fig. 2c. In the EXAFS studies of a $Ru_3(CO)_{12}/Al_2O_3$ system, peak A near the Ru K-edge becomes stronger than peak B when the Ru_3 cluster was converted to a mononuclear $Ru(CO)_2(OAl\lesssim)_2$ species forming the chemical bonds between Ru atoms and surface oxygens.[9] The XANES spectra suggest the formation of the γ-Al_2O_3-attached species $Rh(CO)_2(OAl\lesssim)_2$ as previously proposed.

In summary, $Rh_6(CO)_{16}$ was physisorbed on the γ-Al_2O_3 surface without any structural change of the Rh_6 framework. $Rh_6(CO)_{16}$ was mostly decomposed into the mononuclear species $Rh(CO)_2(OAl\lesssim)_2$ by a mixture of O_2+H_2O treatment, but some of the cluster remain

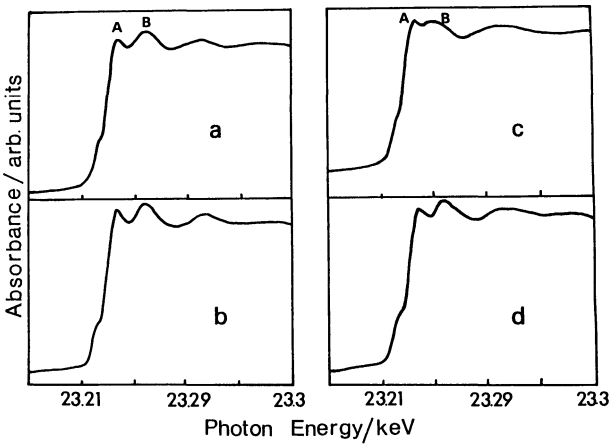

Fig. 2. XANES spectra of unsupported $Rh_6(CO)_{16}$ cluster (a), Sample 1 (b), Sample 2 (c), and Sample 3 (d).

ed in the form of $Rh_6(CO)_{16}$. After the subsequent treatment of the $Rh(CO)_2(OAl\lesssim)_2$ with a mixture of CO+H_2O, $Rh_6(CO)_{16}$ was found to be completely regenerated on the basis of the EXAFS and XANES spectra.

Crystal and Molecular Structure of a Potentially Five-Coordinate Palladium(II) Complex Containing 1,10-Phenanthroline. Chlorobis(triphenylphosphine)-(1,10-phenanthroline)palladium(II) Tetrafluoroborate

Zenei TAIRA† and Shinsaku YAMAZAKI*

(Received July 15, 1985)

Synopsis. The X-ray crystal structure of a potentially five-coordinate palladium(II) complex containing 1,10-phenanthroline, $[PdCl(PPh_3)_2(phen)][BF_4]\cdot(CH_3)_2CO$ has been determined. The structure was solved by the heavy-atom method and refined to R=0.051.

Concerning intermediates in the rearrangement of square planar d^8 complexes, many five-coordinate platinum(II) complexes have hitherto been isolated.[1-9] The crystal structures of the platinum(II) complexes containing 1,10-phenanthroline[2,3] thus far studied are mostly distorted square pyramids. They do not display any dissociation processes in a solution, since ^{195}Pt satellites have been observed in the ^1H, ^{13}C NMR spectra.

On the other hand, palladium(II) analogues stabilized by potentially bidentate 1,10-phenanthroline are relatively rare, and their solution behaviour is still umbiguous.

The preparation and characterizations of potentially five-coordinate complexes of palladium(II) containing phen and its 2,9-dimethyl derivative have been described elsewhere by the present author.[10,11] Among them, $[PdCl(PPh_3)_2(phen)][BF_4]$ is especially interesting because, judging from some spectral evidence, the solution structure of this potentially five-coordinate complex seems to be rather close to a four-coordinate geometry with an unidentate phen.

This note will deal with the X-ray crystal and molecular structure of $[PdCl(PPh_3)_2(phen)][BF_4]\cdot(CH_3)_2CO$.

Structure Determination and Refinement

Large deep orange crystals of $[PdCl(PPh_3)_2(phen)][BF_4]\cdot(CH_3)_2CO$ were grown from an ethanol-acetone(1:1) mixed solution under natural vaporization at room temperature. A crystal with dimensions of 0.3×0.3×0.2 mm was mounted on a Rigaku AFC-6B four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The crystal data are: space group *Pnma* with Z=4, a=19.915(5), b=14.833(2), and c=15.917(3) Å. V=4701.9 Å^3. μ(Mo $K\alpha$) 5.75 cm^{-1}. D_m= 1.406 g cm^{-3}(by flotation), D_x=1.401 g cm^{-3}. Within the range of $2\theta<50°$, 4139 independent reflections with $|F_o|>6\sigma_F$ were collected for background, Lorenz, and polarization factors, but absorption correction was not applied.

The position of the Pd atom was determined from a three-dimension Patterson map. The remaining non-hydrogen atoms were located by successive difference Fourier syntheses. The structure, in which Pd and Cl atoms and the phenanthroline occupy a mirror plane with y=1/4, was refined by the block-diagonal least-squares method with the anisotropic thermal parameters.

The hydrogen atoms included on the structure factor calculations were located from the difference map. The function minimized was $\sum w\Delta F^2$, where w=1.0.

The final R value was 0.051(R_w=0.056). The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[12] Lists of the anisotropic thermal parameters and the final positional parameters, tables of the bond distances and angles, and a table of the observed and calculated structure factors are preserved by the Chemical Society of Japan (Document No. 8609). The structure-analysis calculations were performed with a Rasa program (Rigaku) and X-STANP (Taira) using a PANAFACOM U-1400 computer system.

Results and Discussion

The crystal-structure view of the $[PdCl(PPh_3)_2(phen)][BF_4]\cdot(CH_3)_2CO$ is shown in Fig. 1. The inter-atomic distances and angles are shown in Table 1. The distances of the two nitrogen atoms of the phen from the palladium are unequal in that one nitrogen atom with a long Pd-N distance(2.68 Å) is at the apex of a distorted square pyramidal structure. The elonga-

Table 1. Bond Distances(l/Å) and Angles(ϕ/°) in the Coordination Sphere of $[PdCl(PPh_3)_2(phen)]^+$

Distances			
Pd-Cl	2.31(2)	Pd-P	2.34(2)
Pd-N(01)	2.09(5)	Pd-N(12)	2.68(4)
Angles			
Cl-Pd-P	88.0(3)	Cl-Pd-N(01)	166.5(1)
Cl-Pd-N(12)	123.3(1)	P-Pd-N(01)	92.3(4)
P-Pd-N(12)	90.0(6)	N(01)-Pd-N(12)	70.2(2)

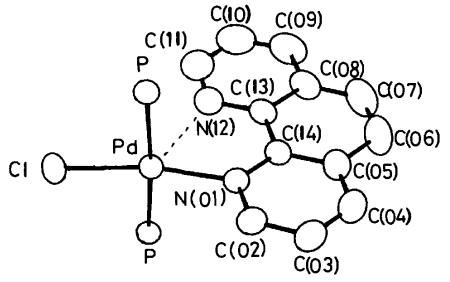

Fig. 1. Structural view of $[PdCl(PPh_3)_2(phen)]^+$. For the sake of clarity, phenyl rings of PPh_3 are omitted.

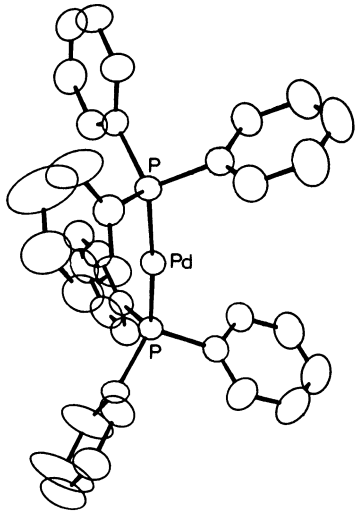

Fig. 2. Structural view of PPh_3 in $[PdCl(PPh_3)_2(phen)]^+$. For the sake of clarity, Cl atom and phenanthroline molecule are omitted.

tion of the apical M-N distance is in accordance with the observations previously reported for d^8 square pyramidal complexes.[2-4,8,9] It should be noticed that $[PdCl(PPh_3)_2(phen)]^+$ is so distorted as to approach a quasi-trigonal bipyramid. The phen plane, including the palladium and chlorine atoms, exactly coincides with a crystallographical mirror plane. The two angles of P-Pd-N(12) are both 90.03°, and those of P-Pd-N(01) are equivalent as well (92.3°). The bond lengths of P-Pd are 2.34Å, a value of which is comparable with those found in $[PdCl_2(PMe_2Ph)_3]$ (2.326 and 2.344Å for the basal bond lengths).[4]

Two phosphorous atoms in $[PdCl(PPh_3)_2(phen)]^+$ are displaced towards Cl and N(12), away from N(01) (P-Pd-P, 175.5°). The distortion is probably due to a steric crowding of the bulky phosphines,[4,8] and *N*-heterocyclic rings.

The distance of the non-bonding N···N bite of the phen molecule is 2.787 Å in $[PdCl(PPh_3)_2(phen)]^+$, slightly longer than the range (2.63—2.73 Å) cited in the bidentate phen.[13] The N(01)-Pd-N(12) angle, 70.2°, is, however, much smaller than that found in $[Pd(NO_3)_2(phen)]$ (83°).[13] In the five-coordinate platinum(II) complexes previously found, the corresponding N···N bite of the phen and the N-Pt-N angle are 2.81 Å, and 69.7° in $[PtCl(PEt_3)_2(phen)]^+$ (the two phosphines are mutually cis)[2] and 2.85 Å, and 68.2° in $[Pt(CN)(phen)_2]^+$[3] respectively. This preliminary information about the corresponding platinum(II) complexes may indicate that the bite of the phen in $[PdCl(PPh_3)_2(phen)]^+$ is more strengthened than those in $[Pt(CN)(phen)_2]^+$ and $[PtCl(PEt_3)_2(phen)]^+$. This effect may be seen in the C(07)-C(08)-C(09) angle whose deviation from 120° is 4.2°, while the deviations of the corresponding angle in $[PtCl(PEt_3)_2(phen)]^+$ and $[Pt(CN)(phen)_2]^+$ are within the range of 2.2—2.3°.[2,3]

The other bond distances and angles in the phen rings of $[PdCl(PPh_3)_2(phen)]^+$(Table preserved by the Chemical Society of Japan) do not differ significantly from those in the two platinum(II) complexes described above.

The cavities between cations are occupied by the

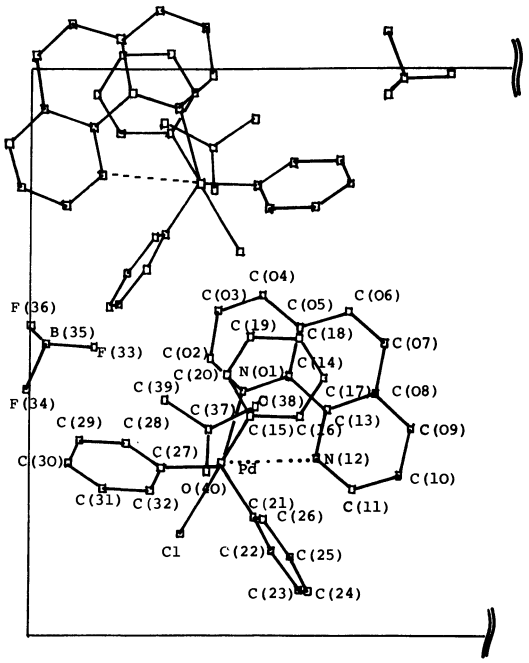

Fig. 3. The crystal structure of $[PdCl(PPh_3)_2(phen)][BF_4]\cdot(CH_3)_2CO$ viewed along b axis. For the sake of clarity, a half of the unit cell along b axis is omitted.

comparatively small solvation acetone, as is shown in Fig. 3. The BF_4^- anion is not bonded to the palladium, since the closest Pd-F distance is 4.83 Å.

Thus, the crystal structure of $[PdCl(PPh_3)_2(phen)]^+$ should be viewed either as a distorted square pyramidal complex in which there is a very weak apical metal-nitrogen interaction, or as a square planar complex involving a unidentate phen ligand, the second nitrogen being outside the coordination sphere of the metal.

High-Resolution ^{13}C NMR Spectra of *trans*-[Co^{III}(2,3-Alkanedione dioximato)$_2$(pyridine)$_2$]I Complexes in the Solid State

Setsuko KINOSHITA,* Hisanobu WAKITA, and Isao MASUDA
Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01
(Received July 30, 1985)

Synopsis. High-resolution ^{13}C NMR spectra of the title complexes showed two type signals based on the "packing effect" and the long-chain alkyl group of the dioximato ligand was found to be fixed near the axial pyridine ligand in the solid state.

To determine molecular structures in the solid state, X-ray crystal structure analyses are preferable. However, they are time consuming and are sometimes impossible because of the difficulty of making single crystals. Recently, high-resolution ^{13}C NMR techniques in the solid state (CP/MAS) have been developed, and attempts to apply these techniques are now being made.[1] The CP/MAS measurement can readily give some information about the molecular conformations and the molecular packings even for such compounds in the solid state.

In the previous paper, we reported that the pyridine liberation-anation reaction of the series of *trans*-[Co(R,CH_3-dioxH)$_2$(py)$_2$]I (R,CH_3-dioxH$_2$: CH_3-C(=NOH)-C(=NOH)-R; R=CH_3, C_2H_5, *n*-C_3H_7 and *n*-C_4H_9, py: pyridine) fitted well to the Taft's plot, indicating that the Co(III)-py bond is weakened not only by the electron-donating inductive effect of R but also by the steric effect of R.[2] Therefore, the long-chain alkyl group, R, was expected to be fixed near the axial pyridine ligand in the solid state. On the other hand, ^1H and ^{13}C NMR Spectra and T_1 measurements of the complexes indicated that the R group was moving segmentally in dimethyl-d_6 sulfoxide (DMSO-d_6) solution.[3]

In this paper, CP/MAS is applied to these complexes and the molecular structure and the molecular packing of the complexes are estimated in the solid state.

Experimental

A JEOL NM-SH 200 spectrometer (50 MHz for ^{13}C) was used for the CP/MAS measurement. The complexes used were fine needle crystals obtained by slow evaporation of a saturated solution in methanol. The spectral assignments were made using Opella's method[4] and in comparison with the spectra in DMSO-d_6 solution.[3]

Results and Discussion

As is shown in Fig. 1, the C^1 and C^2 resonances of the [Co(CH_3,CH_3-dioxH)$_2$(py)$_2$]I complex were separated into two peaks, respectively, though they appeared as a single peak in DMSO-d_6 solution. The [Co(C_2H_5,CH_3-dioxH)$_2$(py)$_2$]I complex showed a spectrum similar to that in DMSO-d_6 solution, but the [Co(*n*-C_3H_7,CH_3-dioxH)$_2$(py)$_2$]I showed a spectrum different from that in solution; the C^1 resonance was separated into two peaks, while the C^2 and C^3 resonances overlapped. The spectrum of [Co(*n*-C_4H_9, CH_3-dioxH)$_2$(py)$_2$]I complex was similar to that in solution. The numerical data for these spectra are summarized in Table 1.

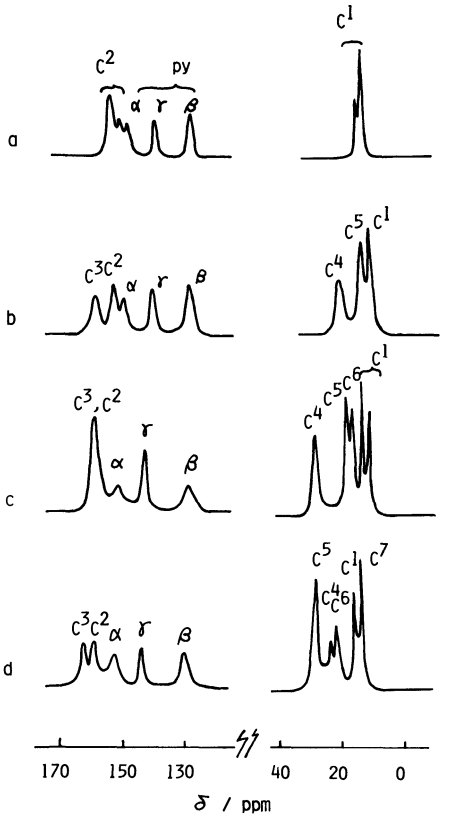

Fig. 1. High-resolution ^{13}CNMR spectra of [Co(R, CH_3-dioxH)$_2$(py)$_2$]I in the solid state.
a: R=CH_3, b: R=C_2H_5, c: R=*n*-C_3H_7, d: R=*n*-C_4H_9. Each carbon atom of the ligands is noted as a following example; C^1H_3-C^2(=NOH)-C^3(=NOH)-C^4H_2-C^5H_2-C^6H_2-C^7H_3.

The results obtained here are understandable if each carbon resonance of the complexes can show two type NMR signals, i.e., A type and B type, based on a "packing effect".[1] The observed signals were assigned as follows: C^1, 14.9 ppm (A type), 17.1 ppm (B type); C^2, 155.2 ppm (A type), 158.5 ppm (B type); C^3, 161.6 ppm (A type), 162.5 ppm (B type). The C^4, C^5, C^6, C^7, resonances showed no observable splittings between A type and B type. The [Co(C_2H_5,CH_3-dioxH)$_2$ (py)$_2$] I and [Co(*n*-C_4H_9,CH_3-dioxH)$_2$(py)$_2$]I complexes showed only A type or B type signal, respectively. While, [Co(CH_3,CH_3-dioxH)$_2$(py)$_2$]I and [Co(*n*-C_3H_7,CH_3-dioxH)$_2$(py)$_2$]I complexes showed both A type and B type signals. As for the [Co(*n*-C_3H_7,CH_3-dioxH)$_2$-(py)$_2$]I complex, four signals, i.e., C^2(A), C^2(B), C^3(A),

Table 1. High-Resolution ^{13}C NMR Data of $[Co(R,CH_3\text{-dioxH})_2(py)_2]I$ Complexes in the Solid State

R	δ/ppm									
	C^1		C^2		C^3		C^4	C^5	C^6	C^7
CH_3	15.6	17.5	155.0	158.0	—	—	—	—	—	—
C_2H_5	14.9	—	155.3	—	161.6	—	21.4	12.9	—	—
n-C_3H_7	14.2	17.0		159.6			29.1	19.4	12.2	—
n-C_4H_9	—	16.9	—	159.0	—	162.5	25.1	28.9	23.2	14.6

Each carbon atom of the ligands is noted as a following example;
C^1H_3-C^2(=NOH)-C^3(=NOH)-C^4H_2-C^5H_2-C^6H_2-C^7H_3.

C^3(B), were mixed up and appeared as a single peak at 159.6 ppm.

The splitting of an NMR signal based on a "packing effect" was also observed for $[Co(CH_3,CH_3\text{-dioxH})_2(NH_3)_2]NO_3$ complex: In D_2O solution, C^1 and C^2 appeared at 15.3 and 159.7 ppm, respectively, as a single peak, but, in the solid state, they appeared as a double peak, respectively. The X-ray structural analysis of the complex showed that two NH_3 ligands coordinate to Co(III) at trans positions and the space group is $P2_1/c$ with two molecules in the unit cell.[5] According to this X-ray structural analysis, there are two non-equivalent positions for the C^1 and C^2 carbons, respectively, which can cause the splitting of the NMR signals.

In DMSO solution, higher-field shifts were observed for both ^1H and ^{13}C resonances of the C^5, C^6, and C^7 groups on complex formation and the higher-field shifts of ^{13}C resonances were mainly attributable to the ring-current shielding of the axial pyridine ligand for these complexes.[3] In the solid state, the C^6 resonance of $[Co(n\text{-}C_3H_7,CH_3\text{-dioxH})_2(py)_2]I$ complex appears at 12.2 ppm, which is 4.0 ppm higher-field in comparison with that of free n-C_3H_7,CH_3-dioxH$_2$ ligand in the solid state. In DMSO solution, the corresponding peak shift was 1.3 ppm.[3] The amount of the shift caused by the above ring-current effect was the largest for C^6 carbon of $[Co(n\text{-}C_3H_7,CH_3\text{-dioxH})_2(py)_2]I$ complex of all the carbons in the series of the complexes. Judging from these facts, the long-chain alkyl group in the equatorial plane may be assumed to be fixed near the axial pyridine ligand in the solid state. Such a location of the R group is susceptible to ring-current shielding of the pyridine ligand and the chain length is most advantageous for the complex including R=n-C_3H_7 to experience the largest shielding effect. This location is also in accord with the expectation, based on the kinetic study, that the R group is fixed so as to weaken the Co(III)-py bonding.[2] In solution, the long-chain alkyl group is moving freely and the effect of the ring-current shielding is smaller than that in the solid state.

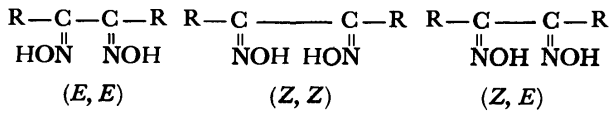
Estimation of Isomer Ratio of 2,3-Alkanedione Dioxime Using High-Resolution ^{13}C NMR in the Solid State

Setsuko KINOSHITA,* Hisanobu WAKITA, and Isao MASUDA
Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01
(Received August 15, 1985)

Synopsis. High-resolution ^{13}C NMR spectra were measured for the CH_3-C(=NOH)-C(=NOH)-R (R=CH_3, C_2H_5, n-C_3H_7, and n-C_4H_9) series in the solid state. A commercially available powder, dimethylglyoxime (R=CH_3), produced two C^2 signals, indicating two isomers: i.e., *s-trans-(E,E)* and *s-cis-(E,E)*. The ratio of *trans*: *cis* was estimated to be 3:1.

Tanaka et al. reported that there are three possible structural isomers for dioximes.[1] Each isomer gave



a different ^1H NMR signal for the NOH proton in DMSO-d_6 solution, and the ratio of the isomers was estimated from the ratio of the peak areas.[1]

On the other hand, a newly developed high-resolution ^{13}CNMR technique (CP/MAS) was applied for coal and oil shale and the aromatic-olefinic fraction was determined by an integration of the solid-state spectra.[2]

In this paper, CP/MAS spectra were measured for the 2,3-alkanedione dioxime (CH_3-C(=NOH)-C(=NOH)-R: R=CH_3, C_2H_5, n-C_3H_7, and n-C_4H_9) series in the solid state. The existence of *trans* and *cis* isomers was identified for a commercially available powder dimethylglyoxime (R=CH_3), and the ratio of the isomers was estimated from the ratio of the peak areas.

Experimental

A commercially available guaranteed reagent, dimethylglyoxime (Wako Pure Chemical Industries, LTD), was used for the measurement. Other 2,3-alkanedione dioximes were prepared as previously described[3] and recrystallized from methanol-chloroform (1:1). A JEOL NM-SH200 spectrometer (50 MHz for ^{13}C) was used for the measurements. All spectra were obtained using magic-angle spinning at room temperature. The spectra were generated from ca. 1000 scans at a rate of one scan per ten seconds. The methylen carbon of adamantane (29.5 ppm from TMS) was used as an external standard.

Results and Discussion

The high-resolution ^{13}CNMR (CP/MAS) spectra of 2,3-alkanedione dioximes are shown in Fig. 1. Also, numerical data are summerized in Table 1. Opella's method was used for the assignment of signals.[4] According to this method, only quarternary and methyl carbons appear as is exemplified for R=n-C_3H_7 dioxime in Fig. 2-a. In the case of R=C_2H_5, n-C_3H_7, n-C_4H_9 dioximes, the ^{13}CNMR spectra in the solid state were similar to those obtained in DMSO-d_6 solution

Table 1. High-Resolution ^{13}C NMR Data of CH_3-C(=NOH)-C(=NOH)-R

R	δ/ppm						
	C^1	C^2	C^3	C^4	C^5	C^6	C^7
CH_3	9.5	155.9 153.6	—	—	—	—	—
C_2H_5	9.3	154.2	159.5	17.6	11.6	—	—
n-C_3H_7	9.6	155.1	159.0	27.5	20.2	16.2	—
n-C_4H_9	9.1	154.5	158.6	23.7	28.3	23.7	14.0

(Fig. 2-b, c). However, as for R=CH_3 dioxime, the C^2 resonance separated into two peaks in the solid state, though it appeared as a single peak in DMSO-d_6 solution (Fig. 3-b, c).

It was reported that carbons directly bonded to nitrogen atoms sometimes showed doublet patterns in CP/MAS spectra.[5] If this is also the case for the dioximes, the C^2 and C^3 resonances of R=C_2H_5, n-C_3H_7, and n-C_4H_9 dioximes should show similar splittings. However, such a phenomenon was not observed (Fig. 1).

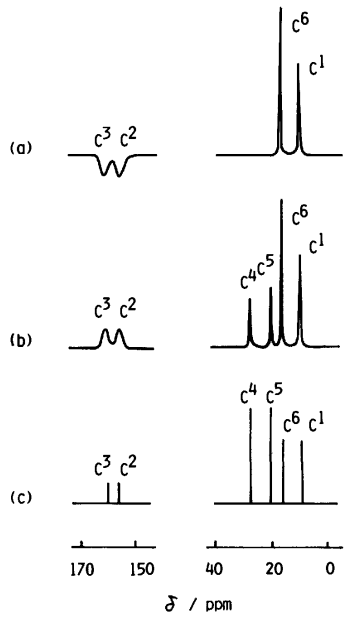

Fig. 2. ^{13}C NMR spectra of CH_3-C(=NOH)-C(=NOH)-CH_2-CH_2-CH_3.
(a): CP/MAS spectrum using Opella's method (in the solid state), (b): CP/MAS spectrum (in the solid state), (c): in DMSO-d_6 solution.

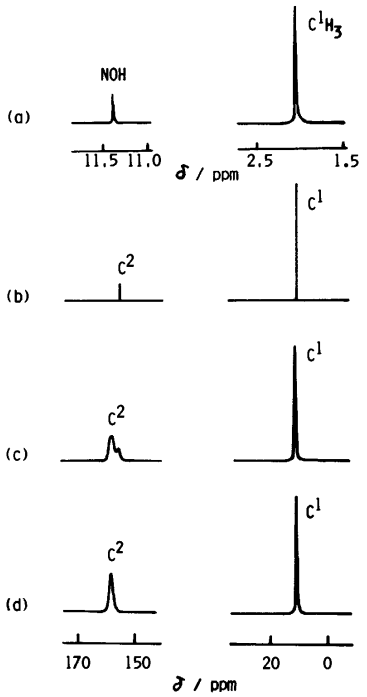

Fig. 3. ^1H and ^{13}C NMR spectra of CH_3-C(=NOH)-C(=NOH)-CH_3.
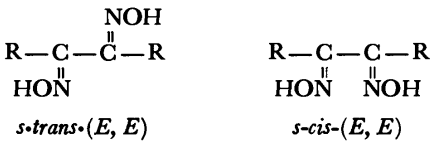
(a): ^1H NMR spectrum in DMSO-d_6 solution, (b): ^{13}C NMR spectrum in DMSO-d_6 solution, (c): CP/MAS spectrum of commercial powder compound, (d): CP/MAS spectrum of recrystallized crystal.

The ^1H NMR spectrum of the R=CH_3 dioxime showed only one NOH signal in DMSO-d_6 solution (Fig. 3-a), indicating that there are no isomers, such as the previously described *(E,E)*, *(Z,Z)*, and *(Z,E)*.[1] Since the rotation of a C=NOH double bond is inhibited, it is hardly expected that there are such isomers only in the solid state.

The CP/MAS resonance sometimes splits into two peaks based on the "packing effect."[6] According to an X-ray single crystal analysis of R=CH_3 dioxime (obtained by a slow evaporation of the solvent ethanol), the R=CH_3 dioxime has a *s-trans-(E,E)* conformation and the space group is $P\bar{1}$-C_i^1 with one molecule in the unit cell.[7] Therefore, the peak splitting based on the "packing effect" cannot be expected for the R=CH_3 dioxime. When commercially available dimethylglyoxime (R=CH_3) was recrystallized by a slow evaporation of solvent ethanol or methanol-chloroform (1:1), the splitting of the C^2 resonance was not observed, though the C^1 resonance showed a similar signal as that of the commercial powder compound (Fig. 3-d).

Considering these facts, it is concluded that there were two isomers, i.e., *s-trans-(E,E)* and *s-cis-(E,E)*, in the commercial powder dimethylglyoxime. In solution, these two isomers were indistinguishable since the (HON=)C-C(=NOH) single bond can rotate freely.



The molar fraction of the two isomers was estimated by an integration of the spectra. For a quantitative analysis, the contact time (CT) and the repetition time (RT) must be appropriately chosen.[2] In this study, the CP/MAS spectra were taken while choosing CT=2 ms and RT=10 s. Under these conditions, the dioximes (R=C_2H_5, n-C_3H_7 and n-C_4H_9) gave a peak ratio C^2:C^3=1:1 (Fig. 1), indicating the probability of the quantitative analysis. In the case of the commercial powder dimethylglyoxime (R=CH_3), it was estimated from an integration of the corresponding C^2 signals that the ratio *s-trans-(E,E)*: *s-cis-(E,E)* is 3:1. As for R=C_2H_5, n-C_3H_7 and n-C_4H_9 dioximes, these molecules are considered to exist only in *s-trans* or *s-cis* forms in the crystals.

Total Synthesis of (±)-Zeylena

Seiichiro OGAWA* and Tohei TAKAGAKI
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Yokohama 223
(Received July 30, 1985)

Synopsis. Zeylena, isolated from the roots of *Uvaria zeylanica* L. (Annonaceae), has been synthesized as a racemic modification by an intramolecular cyclo-addition reaction of DL-*trans*-2,3-dihydroxy-1-(benzoyloxymethyl)cyclohexa-4,6-diene 3-(*E*)-cinnamate or its acetate.

Zeylena (**7**) was isolated from the methanol extract of the roots of *Uvaria zeylanica* L. (Annonaceae).[1] Although it was found to lack tumor inhibitory activity, its biogenetic relationship to other biologically active *Uvaria* constituents has stimulated much interest.[2]

In continuation to our study for highly-oxygenated cyclohexane compounds,[3] we now describe a synthesis of racemic zeylena starting from DL-*trans*-2,3-diacetoxy-1-(benzoyloxymethyl)-4,6-cyclohexadiene (**1**).[4]

Selective *O*-deacetylation of **1** with *p*-toluenesulfonic acid in methanol gave the 2-acetate (**2**) and the dihydroxy compound (**3**) in 29 and 51% yeild, respectively. The structures were assigned on the basis of the ^{1}H NMR spectra.[3]

The monoacetate **2** was treated with (*E*)-cinnamoyl chloride in dichloromethane and pyridine to give the 3-(*E*)-cinnamate (**4**) in 62% yield. Intramolecular Diels-Alder reaction of **4** was carried out in toluene in a sealed tube at 70 °C for 4 d to afford a 91% yield of crystalline (±)-zeylena acetate (**6**),[1] which was readily convertible into racemic **7** in 40% yield[5] by treatment with *p*-toluenesulfonic acid in methanol–dichloromethane. The ^{1}H NMR spectra data of **7** were shown to be superposable on those of an authentic sample.[1,6]

Alternatively, selective esterification of **3** with the acid chloride was attempted in dichloromethane and pyridine at −60 °C. A mixture of the products was separated on a silica-gel column to afford the desired 3-(*E*)-cinnmate (**5**) in 27% yield, the structure of which was confirmed by the ^{1}H NMR spectrum. The ester **5** was then subjected to similar cyclo-addition reaction conditions to afford racemic **7** in 98% yield.

Experimental

Melting points were determined in a capillary in a MELTEMP melting point apparatus and are uncorrected. ^{1}H NMR spectra were recorded with a Varian EM-390 (90 MHz) spectrometer in chloroform-*d* solution with tetramethylsilane as an internal standard. Mass spectra were measured with a Hitachi M 80B spectrometer. The silica gel used for column chromatography was Wakogel C-300 (Wako Co., 300 mesh).

Selective *O*-Deacetylation of DL-*trans*-2,3-Diacetoxy-1-(benzoyloxymethyl)-4,6-cyclohexadiene (1).[4] Compound **1** (100 mg, 0.30 mmol) was treated with *p*-toluenesulfonic acid (25 mg) in methanol (5 ml) as described in the reaction of the optically active **1**.[3] The products were separated on a silica-gel column to give 25 mg (29%) of DL-*trans*-2-acetoxy-1-benzoyloxymethyl-4,6-cyclohexadien-3-ol (**2**) as a syrup and 38 mg (51%) of DL-*trans*-1-benzoyloxymethyl-4,6-cyclohexadiene-2,3-diol (**3**) as a syrup. Both compounds were assigned by comparison of their ^{1}H NMR spectra with those of the corresponding optically active compounds.[3] MS (70 eV) *m/z* (rel intensity), data for **2**, 288 (M^+; 2.8), 228 (12), 124 (8), and 105 (100); data for **3**, 246 (M^+; 2.7), 228 (11), 124 (86), and 105 (100).

DL-*trans*-2-Acetoxy-1-benzoyloxymethyl-3-[(*E*)-cinnamoyloxy]-4,6-cyclohexadiene (4). To a solution of **2** (67 mg, 0.23 mmol), dichloromethane (1.0 ml), and pyridine (0.2 ml) was added a solution of (*E*)-cinnamoyl chloride (83 mg, 0.50 mmol) in dichloromethane (0.5 ml) dropwise at −50 °C, and then the mixture was stirred at the same temperature for 10 min. The mixture was diluted with ethyl acetate (10 ml) and washed with 1 M† hydrochloric acid, saturated aqueous sodium hydrogencarbonate, and saturated aqueous sodium chloride, and then dried over anhydrous sodium sulfate. Removal of the solvent gave a syrup, which was chromatographed on a silica-gel column (8 g) with ethyl acetate–hexane (1:4) as an eluant to give mainly 60 mg (62%) of **4** as a syrup. ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.02 (3H, s, OAc), 4.93 (2H, s, CH_2OBz), 5.63 (1H, dd, $J_{2,3}$=6.2 Hz, $J_{3,4}$=3.3 Hz, H-3), 5.93 (1H, d, H-2), 6.00—6.33 (3H, m, H-4, 5, and 6), 6.37 (1H, d, J=15.5 Hz, COCH=CHPh), 7.33—7.57 (8H, m) and 7.80—8.03 (2H, m) (OBz and COCH=CHPh), 7.68 (1H, d, COCH=CHPh); MS (70 eV) *m/z* (rel intensity) 418 (M^+; 4.4), 376 (2.6), 228 (19), 131 (100), and 105 (60).

(±)-Zeylena Acetate (6). A solution of **4** (23 mg, 0.05 mmol) and toluene (1.0 ml) was heated in a sealed tube at 70 °C for 4 d. The mixture was concentrated and the residue was eluted from a column of silica gel (1 g) with ethyl acetate–hexane (2:5) to give 21 mg (91%) of **6** as plates; mp 150 °C (recrystallized from methanol–dichloromethane). ^{1}H NMR data ($CDCl_3$, 90 MHz) was identical with those reported for an optically active compound.[1]

Found: C, 71.60; H, 5.48%. Calcd for $C_{25}H_{22}O_6$: C, 71.77; H, 5.26%.

(±)-Zeylena (7). To a solution of **6** (39 mg, 0.09 mmol) in dichloromethane–methanol (1:6) (7 ml) was added *p*-toluenesulfonic acid (80 mg, 0.42 mmol) and the mixture was stirred at room temperature for 3 d. The mixture was then neutralized with sodium hydrogencarbonate and an insoluble material was removed by filtration. The filtrate was concentrated and the residue was chromatographed on a silica-gel column (2 g) with ethyl acetate–hexane (1:2) to give 14 mg (40%) of **7**; mp 173—174 °C (recrystallized from

† 1 M = 1 mol dm^{-3}.

dichloromethane–methanol). The ^{1}H NMR spectrum was superposable on that of an authentic sample.[1]

Found: C, 73.22; H, 5.51%. Calcd for $C_{23}H_{20}O_5$: C, 73.40; H, 5.32%.

DL-*trans*-1-Benzoyloxymethyl-3-[(*E*)-cinnamoyloxy]-4,6-cyclohexadien-2-ol (5). To a solution of **3** (193 mg, 0.78 mmol) in dichloromethane (2.0 ml) and pyridine (0.8 ml) was added at −60 °C a solution of (*E*)-cinnamoyl chloride (133 mg, 0.80 mmol) in dichloromethane (0.8 ml), and the mixture was stirred at 0 °C for 0.5 h. TLC [ethyl acetate–hexane (1:2)] showed three componets (R_f=0.53, 0.34, and 0.26) and a trace of **3**. The mixture was diluted with ethanol and the solution was concentrated. The residual products were processed as described in the preparation of **4**. Fractionation of the products on a silica-gel column with ethyl acetate–hexane (1:3) gave mainly 81 mg (27%) of **5**; mp 87—88 °C (recrystallized from ether). TLC, R_f=0.34. ^{1}H NMR ($CDCl_3$, 90 MHz) δ=3.09 (1H, br s, OH), 4.45 (1H, d, $J_{2,3}$=7 Hz, H-2), 5.04 (2H, narrow m, CH_2OBz), 5.67 (1H, dd, $J_{3,4}$=3 Hz, H-3), 5.82—6.14 (3H, m, H-4, 5, and 6), 6.41 (1H, d, J=15.5 Hz, CHCH=CHPh), 7.31—7.54 (8H, m) and 8.01—8.12 (2H, m) (OBz and COCH=CHPh), 7.70 (1H, d, COCH=CHPh).

Found: C, 73.54; H, 5.54%. Calcd for $C_{23}H_{20}O_5$: C, 73.40; H, 5.32%.

Intramolecular Diels-Alder Reaction of 5. A solution of **5** (60 mg, 0.16 mmol) and toluene (2.0 ml) was heated in a sealed tube at 70 °C for 4 d. The mixture was concentrated and the residue was purified on a silica-gel column to give 59 mg (98%) of **7**, mp 173—174 °C, identical with the compound obtained from **6** in all respects.

The authors wish to thank Mr. Saburo Nakada for his elemental analyses.

5) The reaction is not optimized. A considerable amount of the methyl ester has been shown to be formed under these conditions.

6) Comparison of the ^{1}H NMR spectrum with that of an authentic sample was kindly carried out by Professor Robert B. Bates (University of Arizona), to whom our thanks are due.

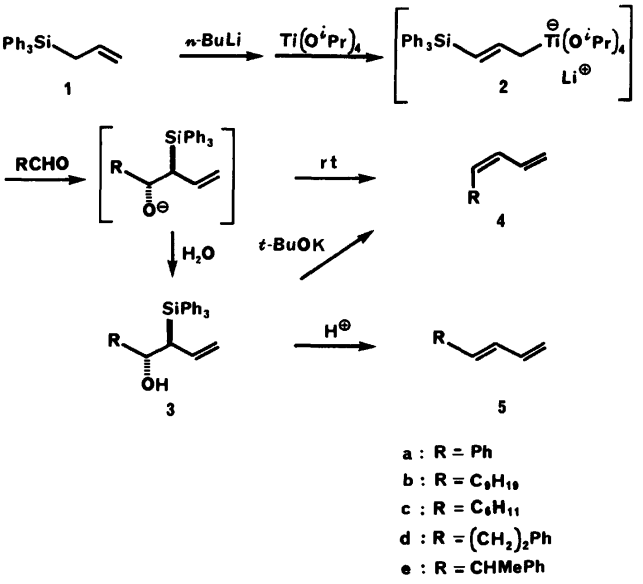
A Practical Synthesis of 1,3-Diene Using Allyltriphenylsilane and Titanium Tetraisopropoxide

Yoshihiko IKEDA and Hisashi YAMAMOTO*
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received September 12, 1985)

Synopsis. A practical method for the stereoselective preparation of 1,3-dienes by the use of allyltriphenylsilane as a key reagent is described.

A Peterson reaction involves the addition of a stoichiometric quantity of an α-silyl carbanion to a carbonyl group.[1] Recently, the scope of this process has been extended significantly.[2] One problem which had not been resolved was the control of regio- and stereoselectivity in the reaction of α-silylallyl carbanions with aldehydes and ketones.[3] This problem has now been solved by converting carbanions into the corresponding organotitanium compounds. Thus, Reetz and Sato recently reported independently the regio- and stereochemistry in reactions of trimethylsilylallyl anions with aldehydes as being highly controlled via the corresponding titanium reagent.[4] We also described a similar synthesis of 1,3-dienes using phenyl 1-(trimethylsilyl)-2-propenyl sulfide and titanium tetraisopropoxide.[5] During the course of our work, we found that the triphenylsilyl group has excellent potential as a control element in Peterson olefination since the three phenyl groups provide strong steric screening, not only for the silicon to which they are attached but to the next atom and even beyond. Furthermore, and much more importantly, it was found to be that, because of the inductive effect of three phenyl groups, the proton-metal exchange reaction of triphenylsilyl derivatives using butyllithium is much easier compared to the more common trimethylsilyl derivatives.[6] In this note we illustrate the utility of allyltriphenylsilane[7] for the synthesis of 1,3-dienes.

Alylltriphenylsilane (**1**), mp 92—94°C, was readily prepared in 86% yield from allylmagnesium bromide and 1 equiv of chlorotriphenylsilane in ether at 0°C.[7] It undergoes clean metallation with butyllithium in tetrahydrofuran (THF) (0°C for 30 min) to form lithio derivative of **1**. In contrast to the metallation of allyltrimethylsilane, the reaction proceeded smoothly in the absence of *N,N,N',N'*-tetramethylethylenediamine (TMEDA) or hexamethylphosphoric triamide (HMPA).[6] The addition of titanium tetraisopropoxide to this solution at −78°C generated a solution of the titanium reagent **2** which is a highly useful reagent for the synthesis of either (*Z*)- or (*E*)-1,3-dienes. Thus, a reaction of **2** with an equivalent of aldehyde was completed in 1 h at −78°C. After the usual work-up, β-triphenylsilyl alcohols (**4**) were obtained. A treatment of **3** with potassium *t*-butoxide at room temperature for 10 min yielded (*Z*)-1,3-diene **4**, *E*/*Z*=<1:50. With sulfuric acid in THF for 16 h, followed by a similar work-up, **3** yielded (*E*)-1,3-diene **5**, *E*/*Z*=>50:1. The geometry was verified by a spectral comparison and/or gc analyses with alternatively prepared samples of 1,3-dienes using the conventional Wittig reactions.



Experimental

The IR spectra were determined on a Hitachi 260-10 spectrometer in a CCl_4 solution unless otherwise stated. The NMR spectra were recorded on a JNM-PMX 60 spectrometer, using TMS (tetramethylsilane) as an internal standard. The analyses were performed at the Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University. Tetrahydrofuran was distilled from benzophenone ketyl. All the experiments were carried out under an argon atmosphere. Purification of the product was carried out by column chromatography on silica gel Fuji BW-820.

1-Phenyl-2-triphenylsilyl-3-buten-1-ol (3a): To a solution of allyltriphenylsilane (901 mg, 3.0 mmol) in dry THF (6 ml) was added butyllithium (1.6 mol cm^{-3} hexane solution, 1.57 ml, 2.5 mmol) at 0°C. The resulting pale-yellow solution was stirred at 0°C for 1 h, turning redish brown, and cooled to −78°C. Titanium tetraisopropoxide (0.80 ml, 2.7 mmol) was added at −78°C and the mixture was stirred for 30 min at this temperature, during which period the color changed to bright yellow. Finally, a solution of benzaldehyde (211 mg, 2.0 mmol) in dry THF (2 ml) was added at −78°C, and the reaction mixture was then stirred for 1 h. The reaction was quenched by an addition of ice-cold aqueous hydrochloric acid. The product was extracted twice with hexane, dried over $MgSO_4$, concentrated in vacuo, and purified by column chromatography on silica gel to give the alcohol **3a** as colorless crystals (732 mg, 90% yield): Mp 135—137°C; IR (neat) 3550, 3030, 1425, 1100, 1040, 910, 735, and 695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.87 (br, 1H, OH), 2.84 (dd, *J*=3 and 10 Hz, 1H), 4.68 (dd, *J*=2 and 17 Hz, 1H), 4.90 (dd, *J*=2 and 11 Hz, 1H), 5.13 (br, 1H), 6.05 (ddd, *J*=11, 17, and 10 Hz, 1H), 6.74—8.08 (m, 5H). Anal. ($C_{28}H_{26}OSi$) C, H.

3-Triphenylsilyl-1-tridecen-4-ol (3b) was obtained in 83%

yield as a colorless liquid: IR (CCl_4) 2880, 1410, and 990 cm^{-1}; ^1H NMR (CCl_4) δ=0.53—2.17 (br, 20H), 2.59 (dd, J=11 and 3 Hz, 1H), 3.85 (br, 1H), 4.70—5.20 (m, 2H), 5.95 (ddd, J=16, 11, and 11 Hz, 1H). Anal. ($C_{31}H_{40}OSi$) C, H.

(*Z*)-1-Phenyl-1,3-butadiene (4a): To a solution of the alcohol **3a** (296 mg, 0.73 mmol) in dry THF (3 ml) was added potassium *t*-butoxide (92 mg, 0.80 mmol) at room temperature. The mixture was stirred at room temperature for 10 min. TLC analyses showed the complete consumption of the starting alcohol. After the usual work-up, the crude product was purified by column chromatography on silica gel using pentane as an eluant to afford the diene **4a** as a clear liquid (95 mg, 100%): IR (neat) 3100, 3040, 2980, 2950, 1820, 1640, 1610, 1500, 1455, 1440, 1085, 1040, 1010, 955, 915, 870, 820, 790, 760, 700 cm^{-1}; ^1H NMR (CCl_4) δ=4.96—5.49 (br m, 2H), 5.93—7.49 (m, 8H). Anal. ($C_{10}H_{10}$) C, H.

A gc analysis of the product revealed an *E*/*Z* ratio of 1:50. An authentic mixture of the diene was prepared independently via allyl Wittig reagent and benzaldehyde.

Direct preparation of the (*Z*)-diene **4a**: After the addition of decanal, the reaction mixture was stirred at −78 °C for 1 h and at 30 °C for 3 h. After the usual work-up, (*Z*)-1,3-tridecadiene was obtained in 70% yield.

(*Z*)-1,3-Tridecadiene (4b) was similarly prepared in a quantitative yield as a colorless oil: IR (neat) 3100—2750, 1805, 1640, 1590, 1460, 1380, 970, 900, 780, 720 cm^{-1}; ^1H NMR (CCl_4) δ=0.67—2.50 (br, 19H), 4.86—5.60 (m, 3H), 5.88 (dd, J=11 and 11 Hz, 1H), 6.53 (ddd, J=11, 11, and 16 Hz); Anal. ($C_{13}H_{24}$) C, H.

(*Z*)-1-Cyclohexyl-1,3-butadiene (4c) was prepared in 69% yield as a colorless oil: IR (CCl_4) 3074, 2990, 1645, 1600, 1002, 967, 910 cm^{-1}; ^1H NMR (CCl_4) δ=0.66—2.35 (br. m, 10H), 2.41 (br. m, 1H), 4.85—5.44 (m, 3H), 5.79 (dd, J=11 and 11 Hz, 1H), 6.57 (ddd, J=11, 11 and 17 Hz, 1H); Anal. ($C_{10}H_{16}$) C, H.

(*Z*)-6-Phenyl-1,3-hexadiene (4d) was prepared in quantitative yield as a colorless oil:[8] IR (CCl_4) 3020, 2920, 1595, 1490, 1450, 1430, 990, 900 cm^{-1}; ^1H NMR (CCl_4) δ=2.20—2.90 (br. m, 4H), 4.83—5.62 (m, 3H), 5.91 (dd, J=11 and 11 Hz, 1H), 6.51 (ddd, J=11, 11 and 16 Hz, 1H), 7.07 (5H). Anal. ($C_{12}H_{14}$) C, H.

(*Z*)-5-Phenyl-1,3-hexadiene (4e) was prepared in 82% yield as a colorless oil: IR (CCl_4) 2970, 2930, 1600, 1490, 1450, 995, 905 cm^{-1}; ^1H NMR (CCl_4) δ=1.31 (d, J=7 Hz, 3H), 3.90 (dq, J=7 and 9 Hz, 1H), 4.94—5.58 (m, 3H), 5.87 (dd, J=10 and 10 Hz, 1H), 6.61 (ddd, J=10, 10, and 16 Hz, 1H), 7.06 (5H). Anal. ($C_{12}H_{14}$) C, H.

(*E*)-1-Phenyl-1,3-butadiene (5a): A mixture of the alcohol **3a** (217 mg, 0.53 mmol) and a catalytic amount of sulfuric acid (2 drops) in dry THF (10 ml) was stirred at room temperature for 16 h. The mixture was poured into water and the product was extracted with hexane, dried, and purified by column chromatography on silica gel to give the diene **5a** as an oil (57 mg, 82%): IR (CCl_4) 3070, 3005, 1795, 1625, 1593, 1480, 1440, 1155, 1065, 950, 890, 850 cm^{-1}; ^1H NMR (CCl_4) δ=4.92—5.49 (m, 2H), 6.07—6.89 (m, 3H), 6.89—7.59 (m, 5H). Anal. ($C_{10}H_{10}$) C, H.

(*E*)-1,3-Tridecadiene (5b): A mixture of the alcohol **3b** (220 mg, 0.48 mmol) and a catalytic amount of sulfuric acid (2 drops) in dry THF (6 ml) was stirred at reflux for 4 h. The mixture was poured into water and the product was extracted with hexane, dried, and purified by column chromatography on silica gel to give the diene **5b** as an oil (65 mg, 75%). IR (CCl_4) 3150—2800, 1870, 1660, 1610, 1560, 1480, 1390, 1265, 1130, 1050, 960, 905, 870 cm^{-1}; ^1H NMR (CCl_4) δ=0.63—2.47 (br, 19H), 4.70—6.53 (m, 5H). Anal. ($C_{10}H_{10}$) C, H.

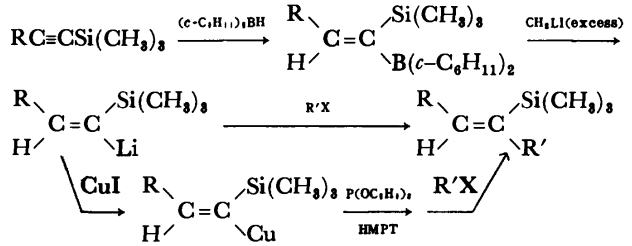
Stereoselective Synthesis of Allyl- or Alkynyl-Substituted (Z)-Vinylsilanes via Organoboranes

Masayuki HOSHI,* Yuzuru MASUDA, and Akira ARASE
Department of Industrial Chemistry, Kitami Institute of Technology, Kitami 090
(Received September 17, 1985)

Synopsis. Copper(I) iodide-catalyzed cross-coupling reactions of (Z)-(1-trimethylsilyl-1-alkenyl)dicyclohexylboranes with allyl bromide or 1-bromo-1-hexyne gave stereoselectively (Z)-1,4-dienes or conjugated (Z)-enynes having a trimethylsilyl group on the internal carbon atom of the double bond.

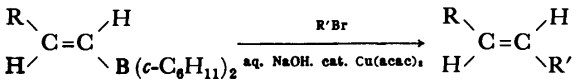
Vinylsilanes are versatile intermediate in organic synthesis.[1] There have been several approaches to the synthesis of these useful compounds. Uchida et al. reported a stereoselective synthesis of (Z)-vinylsilanes via (Z)-(1-trimethylsilyl-1-alkenyl)dicyclohexylboranes (**1**) starting from 1-trimethylsilyl-1-alkynes.[2] As depicted in Scheme 1, **1** were once transformed to the corresponding vinyllithium or vinylcopper(I) compounds before the cross-coupling reactions with organic halides while the reactions were carried out in situ. In the vinyllithium route, an excess amount of methyllithium, and in the vinylcopper(I) route, an excess amount of methyllithium and a small excess amount of copper(I) iodide were employed.



Scheme 1.

A similar cross-coupling reaction of (Z)-(1-trimethylsilyl-1-nonenyl)dicyclohexylborane with allyl bromide was performed by using stoichiometric amount of copper(I) bromide–methyl sulfide.[3]

On the other hand, the authors have found that a catalytic amount of bis(acetylacetonato)copper(II) catalyzed a stereoselective cross-coupling reactions of alkenyldialkylboranes with organic bromides including allyl bromide and 1-alkynyl bromides (Scheme 2).[4–6]

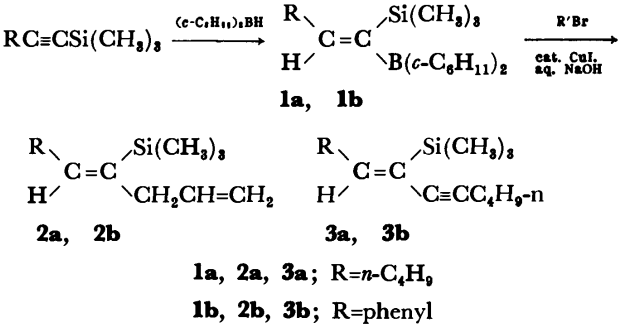


Scheme 2.

Above facts suggested that it was probable to transform 1-trimethylsilyl-1-alkenyldicyclohexylboranes (**1a**) directly to (Z)-vinylsilanes by using catalytic amount of bis(acetylacetonato)copper(II).

As was suggested, (Z)-4-(trimethylsilyl)-1,4-nonadiene (**2a**) was obtained in 84% yield, uncontaminated by *E* isomer, in the reaction of **1a** with allyl bromide in the presence of 5 molar% of bis(acetylacetonato)copper(II).

In further studies to increase the yield of **2a**, copper(I) iodide was found to be far more effective catalyst. Thus, **1a** was transformed to **2a** quantitatively in the presence of 10 molar% of copper(I) iodide (Scheme 3). The use of far less amount of copper(I) compound than in the reaction reported earlier seemed synthetically interesting.



Scheme 3.

Copper(I) chloride and copper(I) bromide showed little catalytic effect and the yields of **2a** could not exceed 76 and 78% respectively even in the presence of stoichiometric amount of these copper compounds.[2,3]

Similarly, (Z)-1-phenyl-2-(trimethylsilyl)-1,4-pentadiene (**2b**) was afforded in 92% yield from (Z)-(1-trimethylsilyl-2-phenylvinyl)dicyclohexylborane (**1b**) and allyl bromide.

The present reaction could be applied also to the synthesis of trimethylsilyl-substituted conjugated enynes which were expected to be interesting intermediates because of the unique position of the trimethylsilyl group in the molecule. Thus, similar reactions of **1a** and **1b** with 1-bromo-1-hexyne afforded (Z)-6-(trimethylsilyl)-5-dodecen-7-yne (**3a**) and (Z)-1-phenyl-2-(trimethylsilyl)-1-octen-3-yne (**3b**) in moderate yields respectively.

Z-Configuration was assigned to these compounds by direct comparisons of IR and ^{1}H NMR spectra of 1,4-dienes and conjugated enynes, obtained by stereospecific desilylation of vinylsilanes[7] with those obtained by our previous work.[4]

These results are shown in Table 1.

All vinylsilanes obtained in the reactions were found to be isomerically pure by GLC using a glass capillary column and by ^{1}H NMR spectra.

Reactions of **1a** and **1b** with alkyl bromides failed to give satisfactory results under the present reaction conditions.

Experimental

Instruments. IR spectra (film) were recorded with a Hitachi 285 spectrometer. ^{1}H NMR (60 MHz) spectra (CCl_4,

TMS) were run on a Hitachi R-20A spectrometer. Mass spectra were recorded with a Hitachi M-52 mass spectrometer.

Reagents. Cyclohexene and tetrahydrofuran (THF) were dried over lithium aluminium hydride and distilled under argon stream before use. 1-Trimethylsilyl-1-hexyne,[8] 1-phenyl-2-(trimethylsilyl)acetylene[8] and 1-bromo-1-hexyne[9] were prepared as described in the literatures. Allyl bromide was dried over molecular sieves-4A. Commercial copper(I) iodide was used without any purification. THF solution of BH_3 was prepared by the method described in the literature.[10]

Reaction Procedure. A 50-ml round bottomed flask, equipped with a gas inlet for argon, a sample inlet with a serum cap and a magnetic stirring bar, was flushed with argon. In the flask, 1-trimethylsilyl-1-alkyne (10 mmol) was added at 0 °C to the suspension of dicyclohexylborane (10 mmol) in THF, prepared by hydroboration of cyclohexene (20 mmol) with the THF solution of BH_3 (10 mmol) at 0 °C for 2 h, and then the reaction mixture was stirred at 0 °C for 1 h and then additional 1 h at room temperature in order to complete the reaction. Copper(I) iodide (1 mmol) and allyl bromide or 1-bromo-1-hexyne (10 mmol) were successively added to the solution at 0 °C and the solution was treated with 10 mmol of 3M[†]-NaOH at this temperature for 1 h. The residual boron compound was decomposed by oxidation with hydrogen peroxide. The reaction mixture was extracted three times with diethyl ether. The combined extracts were washed twice with NaCl-saturated water and dried over anhydrous sodium sulfate. After evaporation of the solvent, the residue was put on a column packed with silica gel (Wako-gel Q-50).

Spectral data of the products are as follows.

(*Z*)-4-Trimethylsilyl-1,4-nonadiene (2a). ^{1}H NMR δ=0.12 (s, 9H), 0.89 (m, 3H) 1.07—1.50 (m, 4H), 1.86—2.37 (m, 2H), 2.63—2.85 (m, 2H), 4.68—5.07 (m, 2H), and 5.40—6.07 (m, 2H). IR: 3075, 1640, 1615, 1250, 995, 910, 835, 760, and 685 cm^{-1}. MS: *m/z* 196 (M^+).

(Received September 26, 1985)

Synopsis. The structures of amijitrienol and 14-deoxyisoamijiol, two new diterpenoids isolated from the brown seaweed *Dictyota linearis*, have been established as **1** and **2** on the basis of spectral and chemical evidence.

In previous papers, we have described the isolation of four diterpenoids of the dolastane class[1,2] and a unique member of the secodolastane class[3] from the brown seaweed *Dictyota linearis*. Our continuing search for the biologically active constituents of this alga has led to the isolation of two additional congeners, designated amijitrienol and 14-deoxyisoamijiol. In this note, a structural elucidation of these new compounds is presented. They were found to have a moderate antimicrobial activity against *Staphylococcus aureus* and *Mucor mucedo*.[4]

Amijitrienol (**1**), $C_{20}H_{30}O$, mp 129.0—129.5 °C, $[\alpha]_D^{18}$ +15.1° (*c* 0.09, EtOH), was isolated as fine needles in 0.0015% yield of fresh alga by conventional silica-gel column chromatography and preparative high-performance liquid chromatography. The IR, UV, and ^{1}H NMR spectra of **1** indicated the presence of one hydroxyl group [3440 cm^{-1}; δ=3.38 (1H, dd, *J*=3.0 and 3.0 Hz)], one conjugated diene [3080, 1640, and 890 cm^{-1}; 230 nm (ε=17000)], two tertiary methyl groups [δ=0.88 and 1.30 (3H each, s)], one isopropyl group [δ=0.93, 0.94 (3H each, d, *J*=6.8 Hz), and 2.64 (1H, qq, *J*=6.8 and 6.8 Hz)], and three olefinic protons [δ= 4.63 (1H, dd, *J*=2.6 and 2.6 Hz), 4.75 (1H, dd, *J*=2.6 and 2.1 Hz), and 5.81 (1H, s)]. In addition, the ^{13}C NMR data for **1** showed the presence of one fully-substituted double bond (δ=139.7 and 142.6), one tri-substituted double bond [δ=136.9 (s) and 138.8 (d)], and one exocyclic methylene group [δ=110.9 (t) and 150.5 (s)], together with two quaternary carbon atoms, one oxygen-bearing methine group, and six methylene groups. These facts suggested that **1** has a structure analogous to that of amijiol (**3**),[1] in which the allylic alcohol functionality in **3** is replaced by a C_{13}—C_{15} conjugated diene. This was confirmed by the chemical correlation of **1** with **3**. Thus, the acetylation of **1** with acetic anhydride and pyridine gave an acetate (**4**), which was found to be identical with the compound derived from **3** via the acetate (**5**)[1] by dehydration with phosphoryl chloride and pyridine.

14-Deoxyisoamijiol (**2**), $C_{20}H_{32}O$, mp 89.0—90.0 °C, $[\alpha]_D^{18}$—2.6° (*c* 0.09, EtOH), was obtained as fine needles in 0.0056% yield and displayed spectral data quite similar to that of 14-deoxyamijiol (**6**).[1] The 400 MHz ^{1}H NMR spectra of **2** and **6**, which were completely assigned by an extensive decoupling study and NOE measurements, were distinct from one another essentially only in the chemical shift of the methine proton on the oxygenated carbon atom [δ(**2**)—δ(**6**)=0.76 ppm]. This fact and the pertinent ^{13}C NMR data revealed that the hydroxyl group of **2** is attached to $C_{2\alpha}$ instead of $C_{4\alpha}$ in **6** and that the relationship of **6** to **2** corresponds to that of amijiol (**3**) to isoamijiol (**7**).[1] Consequently, 14-deoxyisoamijiol must be represented by structure **2**.

Experimental

All the mps were determined on a Mitamura micromelting-point apparatus and are uncorrected. The IR and UV spectra were recorded on a JASCO model A-202 spectrophotometer and a Hitachi 340 spectrophotometer, respectively. The ^{1}H (400 MHz) and ^{13}C (100 MHz) NMR spectra were taken on a Bruker WH-400 instrument in $CDCl_3$ solutions, with TMS as the internal standard. Mass spectra were recorded at 70 eV on a Finnigan MAT 312. A Union Gikken apparatus, model PM-101, was used for a measurement of the rotations. High-performance liquid chromatographic separation was performed on a Waters Associates HPLC model 6000A, with a TSK-GEL LS-410KG (ODS) column.

Isolation. Fresh alga (3.9 kg), collected in the Bay of Tosa in July 1982, was chopped up and extracted with methanol (10 l) for one week. The methanol solution was concentrated up to about 1.5 l and extracted with dichloromethane (0.5 l×3). The dichloromethane layer was washed with water, dried over Na_2SO_4, and evaporated to dryness. Then, the residue (42 g) was subjected to chromatography over silicic acid (800 g), eluting with hexane–ethyl acetate mixtures, ethyl acetate increasing from 10 to 50%. Elution with 20% ethyl acetate in hexane gave a fraction (506 mg) which was further purified by high-performance liquid chromatography (TSK-GEL LS-410KG, 80% MeOH in water) to obtain amijitrienol (**1**) and 14-deoxyisoamijiol (**2**).

Amijitrienol (1). The crude material was recrystallized from hexane to give white needles (59 mg); mp 129.0—129.5 °C, $[\alpha]_D^{18}$ 15.1° (*c* 0.09, EtOH); IR (nujol) 3440, 3080, 1640, and 890 cm^{-1}; UV (EtOH) 230 nm (ε=17000); ^{1}H NMR ($CDCl_3$) δ=0.88 and 1.30 (3H each, s, 20- and 16-H_3), 0.93 and 0.94 (3H each, d, *J*=6.8 Hz, 18- and 19-H_3), 2.64 (1H, qq, *J*=6.8 and 6.8 Hz, 17-H), 3.38 (1H, dd, *J*=3.0and 3.0 Hz, 4-H), 4.63

(1H, dd, J=2.6 and 2.6 Hz, 15-Ha), 4.75 (1H, dd, J=2.6 and 2.1 Hz, 15-Hb), and 5.81 (1H, s, 13-H); ^{13}C NMR ($CDCl_3$) δ=150.5 (C_1), 142.6 (C_8), 139.7 (C_9), 138.8 (C_{13}), 136.9 (C_{14}), 110.9 (C_{15}), 78.3 (C_4), 52.3 (C_{12}), 44.8 (C_5), 42.5 (C_{11}), 33.4 (C_2), 29.2 (C_3), 28.6 (C_6), 27.3 (C_{10}), 27.1 (C_{17}), 27.0 (C_{16}), 21.9 (C_7), 21.3 (C_{18}), 20.9 (C_{19}), and 20.5 (C_{20}); MS (70 eV) m/z 286 (M^+), 271 (M^+-CH_3), 253 ($M^+-CH_3-H_2O$), 243 ($M^+-C_3H_7$), and 225 ($M^+-C_3H_7-H_2O$). Found: m/z 286.2326. Calcd for $C_{20}H_{30}O$: M, 286.2297.

14-Deoxyisoamijiol (2). The crude substance was recrystallized from hexane to yield white needles (217 mg); mp 89.0—90.0 °C, $[\alpha]_D^{18}$ −2.6° (c 0.09, EtOH); IR (nujol) 3260, 3080, 1640, and 890 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.64 and 1.11 (3H each, s, 20- and 16-H_3), 0.93 and 0.94 (3H each, d, J=7.0 Hz, 18- and 19-H_3), 1.08 (1H, ddd, J=13.1, 3.2, and 3.2 Hz, 4β-H), 1.33 (1H, ddd, J=14.6, 4.9, and 4.0 Hz, 6β-H), 1.45 (1H, dd, J=13.9 and 2.8 Hz, 13α-H), 1.54 (1H, dd, J=13.9 and 11.5 Hz, 13β-H), 1.58 (2H, m, 11-H_2), 1.75 (2H, m, 3-H_2), 1.86 (1H, ddd, J=14.6, 11.8, and 4.9 Hz, 6α-H), 1.91 (1H, ddd, J=13.1, 8.3, and 5.3 Hz, 4α-H), 2.13 (1H, ddddd, J=16.6, 4.9, 4.0, 1.5, and 1.5 Hz, 7α-H), 2.17 (2H, m, 10-H_2), 2.40 (1H, dddd, J=16.6, 11.8, 4.9, and 1.3 Hz, 7β-H), 2.61 (1H, qq, J=7.0 and 7.0 Hz, 17-H), 2.69 (1H, dddd, J=11.5, 2.8, 1.5, and 1.3 Hz, 14α-H), 4.28 (1H, dd, J=2.8 and 2.8 Hz, 2β-H), 4.67 (1H, dd, J=1.5 and 1.3 Hz, 15-Ha), and 4.97 (1H, dd, J=1.3 and 1.3 Hz, 15-Hb); ^{13}C NMR ($CDCl_3$) δ=153.8 (C_1), 140.2 (C_8), 139.0 (C_9), 109.8 (C_{15}), 74.3 (C_2), 50.1 (C_{12}), 42.1 (C_{13}), 41.2 (C_{11}), 41.1 (C_4), 40.5 (C_{14}), 39.4 (C_5), 36.6 (C_3), 30.2 (C_6), 27.4 (C_{10}), 26.8 (C_{17}), 24.1 (C_{16}), 21.9 (C_7), 21.1 (C_{18}), 20.9 (C_{19}), and 15.3 (C_{20}); MS (70 eV) m/z 288 (M^+), 273 (M^+-CH_3), 255 ($M^+-CH_3-H_2O$), 245 ($M^+-C_3H_7$), and 227 ($M^+-C_3H_7-H_2O$). Found: m/z 288.2459. Calcd for $C_{20}H_{32}O$: M, 288.2453.

Acetylation of 1. A solution of **1** (49 mg) in acetic anhydride (0.2 ml) and pyridine (0.8 ml) was allowed to stand at room temperature overnight and then worked up in the usual way. The product was subjected to chromatography using a Robar column (Merck, LiChroprep Si 60, size B) and 10% ether in hexane as the eluent to give an acetate (**4**) as a viscous oil (30 mg); IR ($CHCl_3$) 1738 and 1260 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.92 and 1.29 (3H each, s, 20- and 16-H_3), 0.92 and 0.94 (3H each, d, J=6.8 Hz, 18- and 19-H_3), 2.08 (3H, s, $COCH_3$), 2.63 (1H, qq, J=6.8 and 6.8 Hz, 17-H), 4.64 (1H, m, 15-Ha), 4.66 (1H, m, 15-Hb), 4.77 (1H, dd, J=3.0 and 2.0 Hz, 4-H), and 5.74 (1H, s, 13-H); ^{13}C NMR ($CDCl_3$) δ=170.9 ($\underline{C}OCH_3$), 150.3 (C_1), 142.7 (C_8), 139.7 (C_9), 137.1 (C_{13}), 136.7 (C_{14}), 111.0 (C_{15}), 80.1 (C_4), 52.2 (C_{12}), 43.3 (C_5), 42.5 (C_{11}), 32.8 (C_2), 29.8 (C_3), 29.4 (C_6), 27.2 (C_{10}), 27.0 (C_{17}), 26.9 (C_{16}), 21.8 (C_7), 21.4 ($CO\underline{C}H_3$ and C_{18}), 20.9 (C_{19}), and 20.5 (C_{20}); MS (70 eV) m/z 328 (M^+), 313 (M^+-CH_3), 285 ($M^+-C_3H_7$), 268 (M^+−AcOH), 253 (M^+-CH_3-AcOH), and 225 ($M^+-C_3H_7$-AcOH). Found: m/z 328.2404. Calcd for $C_{22}H_{32}O_2$: M, 328.2402.

Dehydration of 5. A mixture of **5** (80 mg) and $POCl_3$ (0.12 ml) in pyridine (0.6 ml) was stirred at room temperature for three days. The reaction mixture was worked up in the usual manner and the resulting product was chromatographed using a Robar column (LiChroprep Si 60, size B) and 10% ether in hexane as the solvent to yield a diene (30 mg) which was identified by TLC, IR, and ^{1}H NMR comparisons with **4**.

The present work was partially supported by a Grant-in-Aid for Co-operative Research from the Ministry of Education (No. 58340030).

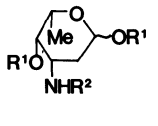
An Improved Synthesis of *N*-Trifluoroacetyl-L-daunosamine

Yoshikazu KIMURA, Teruyo MATSUMOTO, Michiyo SUZUKI, and Shiro TERASHIMA*
Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229
(Received July 18, 1985)

Synopsis. A process which can afford a large quantity of the title compound was explored by modifying the Horton's original route. The developed process features highly stereoselective reduction of the oxime with sodium dihydrobis(2-methoxyethanolato)aluminate(1-) and efficient dehydrobromination with 1,8-diazabicyclo[5.4.0]undec-7-ene.

L-Daunosamine (3-amino-2,3,6-trideoxy-L-*lyxo*-hexopyranose) (**1**) attracts much attention in recent years as an aminosugar component of natural and unnatural anthracycline antibiotics which show prominent anticancer properties.[1,2]

In connection with synthetic studies on optically active anthracyclines,[3] we required a large quantity of *N*-trifluoroacetyl-L-daunosamine (**2**) from which the substrate for glycosidation reaction, 1,4-bis(*O*-*p*-nitrobenzoyl)-3-*N*-trifluoroacetyl-L-daunosamine (**3**), can be readily prepared. It is well known that a trifluoroacetyl group is well suited for protecting the amino group of **1** during glycosidation reaction since it can be readily removed under mild alkaline conditions without cleavage of the formed glycoside linkage.[1-3] However, while **2** can be usually prepared from *N*-



1: R^1= R^2= H
2: R^1= H, R^2= CF_3CO
3: R^1= p-$NO_2C_6H_4CO$, R^2= CF_3CO

acetyl- or *N*-benzoyl-L-daunosamine through **1**-hydrochloride by protective group exchange,[1,2,5] direct preparation method of **2** has never been explored.

In this note, we wish to describe a new synthesis of **2** which is developed by modifying the Horton's original synthetic scheme for *N-acetyl*-L-daunosamine.[4] The developed method includes the following advantages over the Horton's procedure. (1) Trifluoroacetyl group is introduced at the early stage of the synthetic process. This can exclude the above-mentioned tedious protective group exchange. (2) Highly stereoselective reduction of the oxime **5** can be accomplished with sodium dihydrobis(2-methoxyethanolato)aluminate(1-) (Vitride or Red-Al) in toluene in place of lithium aluminum hydride (LAH) in ether. The latter reported reduction which should be carried out using a Soxhlet extraction apparatus is clealy not applicable to a large scale synthesis. (3) Cheap 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) can effect clean dehydrobromination in a similar manner to expensive silver fluoride. By employing these improved synthetic methods, we have succeeded in readily obtaining a large quantity of **2** from methyl α-D-mannopyranoside (**4**).

Thus, according to the reported method,[4] **5** was prepared in 52% overall yield starting from **4**. The reduction of **5** with Vitride in toluene was found to proceed more stereoselectively than with LAH, giving the trifluoroacetamide **6a** in 59% overall yield as a sole product after trifluoroacetylation. NMR analysis of **6a** definitely disclosed that the formation ratio of the desired *ribo*-isomer **6a** to the undesired *arabino*-isomer **6b** is more than 99:1. This result is clearly superior to the reported reduction of **3** with LAH in ether,[4] in which a mixture of the *ribo*- and *arabino*-isomers could be produced in a ratio of 88:12 by our hands. The highly stereoselective reduction observed for Vitride may be due to steric bulkiness of the reducing agent which carries two 2-methoxyethoxy groups.

Similarly to the original route,[4] treatment of **6a** with *N*-bromosuccinimide (NBS) gave the bromide **7** in 85% yield. Dehydrobromination of **7** with inexpensive DBU in benzene afforded **8** in 75% yield in a similar manner to that reported with silver fluoride. The unsaturated sugar **8** was elaborated to methyl *N*-trifluoroacetyl-L-daunosamine (**9**) in 53% yield, mp 155.5—156.5 °C, $[\alpha]_D^{20}$ −46.7° (methanol), by sequential transesterification with methanol and catalytic hydrogenation over palladium on carbon. Further hydrolysis of the methyl glycoside **9** with 20% acetic acid quantitatively produced **2**, mp 146—147 °C, $[\alpha]_D^{20}$ −127.2° (methanol).

Taking into account several novel aspects including high stereoselectivity, operational simplicity, and use of less expensive reagents, the explored synthetic scheme is expected to hold promise in a large scale preparation of **2**.

Scheme 1.

Experimental

Methyl 4,6-*O*-Benzylidene-2,3-dideoxy-3-trifluoroacetamido-α-D-ribo-hexopyranoside (6a). A 70% toluene solution of Vitride (95 mL, 333 mmol) was added to a solution of **5**[4] (mp 202 °C, $[\alpha]_D^{23}$ +203° (*c* 1.21, $CHCl_3$)) (lit,[4] mp 203 °C, $[\alpha]_D^{23}$ +202° (*c* 1.2, $CHCl_3$)) (20.0 g, 71.6 mmol) in toluene (350 mL) with stirring at −40 °C. After stirring at −40 °C for 0.5 h and at 25 °C for 4 h, the reduction was quenched by successively adding H_2O (7 mL), 15% NaOH (7 mL), and H_2O (21 mL) to the reaction mixture. The upper toluene layer was separated, dried over anhyd K_2CO_3, filtrated through a pad of Celite, then concentrated in vacuo, to afford crude methyl 3-amino-4,6-*O*-benzylidene-2,3-dideoxy-α-D-hexopyranoside as a pale yellow viscous oil.

Pyridine (24.1 g, 305 mmol) and trifluoroacetic anhydride (44.0 g, 210 mmol) were successively added to an ethereal solution (200 mL) of the oily amine with stirring at −40 °C. After stirring at 0 °C for 3 h, the ethereal mixture was filtered to remove insoluble materials and the solid collected was washed with ether. The ethereal filtrates and washings were combined, washed successively with satd $NaHCO_3$ and satd NaCl, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo, gave an oily residue, which was purified by column chromatography (benzene/EtOAc=10/1) to give pure **6a** as a colorless oil (15.1 g, 59%), $[\alpha]_D^{21}$ +8.6° (*c* 1.47, $CHCl_3$). IR (neat): 3410, 1735, 1540 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.93—2.10 (m, 2H, 2-H_2), 3.41 (s, 3H, OCH_3), 3.60—4.80 (m, 6H, 1-, 3-, 4-, 5-H_4+6-H_2), 5.57 (s, 1H, PhC<u>H</u>), 7.15—7.43 (m, 5H, Ph), 7.67 (d, *J*=9 Hz, 1H, NH). MS *m/z*: 361 (M^+).

Methyl 4-*O*-Benzoyl-6-bromo-2,3,6-trideoxy-3-trifluoroacetamido-α-D-ribo-hexopyranoside (7). Following to the reported method,[4] a suspension of **6a** ($[\alpha]_D^{21}$ +8.6° (*c* 1.47, $CHCl_3$)) (15.1 g, 41.9 mmol), NBS (9.03 g, 50.7 mmol), and $BaCO_3$ (12.0 g, 60.8 mmol) in anhyd CCl_4 (350 mL) was heated at reflux with stirring under irradiation with a 60W tungsten lamp. After 1.5 h reaction, the whole mixture was cooled and filtered to remove insoluble materials. The solid collected was washed with CH_2Cl_2 (10 mL×3). The organic phases were combined, washed successively with 5% $NaHSO_3$ and satd $NaHCO_3$, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo gave a residue, which was purified by column chromatography (benzene/EtOAc=20/1) to afford **7** as a pale yellow solid (16.3 g, 88%), mp 100—102 °C. This was recrystallized from a mixture of benzene and hexane to give an analytical sample of **7**, mp 111.5—112 °C, $[\alpha]_D^{20}$ +39.3° (*c* 1.07, $CHCl_3$). IR (KBr): 3400, 1730, 1545 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.83—2.40 (m, 2H, 2-H_2), 3.33—3.77 (m, 2H, 6-H_2), 3.35 (s, 3H, OCH_3), 4.02—4.30 (m, 1H, 5-H), 4.67—5.00 (m, 2H, 1-H+3-H). 5.10 (dd, *J*=10 and 5 Hz, 1H, 4-H). 7.23—8.07 (m, 6H, NH+Ph). MS *m/z*: 439 (M^+), 441 ($[M+2]^+$). Found: C, 43.83; H, 3.69; N, 3.14%. Calcd for $C_{16}H_{17}BrF_3NO_5$: C, 43.66; H, 3.89; N, 3.18%.

Methyl 4-*O*-Benzoyl-2,3,6-trideoxy-3-trifluoroacetamido-α-D-erythro-hex-5-enopyranoside (8). A mixture of **7** (mp 100—102 °C) (8.26 g, 18.8 mmol) and DBU (3.76 g, 24.7 mmol) in benzene (10.5 mL) was heated at reflux for 2.5 h with stirring. After cooling, the mixture was filtered and the solid collected was washed with benzene. The combined filtrates were concentrated in vacuo to give a dark brown oil, which was purified by column chromatography (benzene/EtOAc=20/1) to give pure **8** as a pale yellow oil (5.07 g, 75%), $[\alpha]_D^{20}$ +17.6° (*c* 0.67, $CHCl_3$). IR (neat): 3400, 1735, 1670, 1540, 1000 cm^{-1}. ^1H NMR ($CDCl_3$): δ=1.90—2.46 (m, 2H, 2-H_2), 3.47 (s, 3H, OCH_3), 4.61—4.98 (m, 4H, 1,3-H_2+6-H_2), 5.57—5.73 (m, 1H, 4-H), 7.20—8.10 (m, 6H, NH+Ph). MS *m/z*: 359 (M^+).

Methyl *N*-Trifluoroacetyl-L-daunosamine (9). A 1.0 M† solution of sodium methoxide in MeOH (0.7 mL, 0.7 mmol) was added to a solution of **8** ($[\alpha]_D^{20}$ +17.6° (*c* 0.67, $CHCl_3$)) (5.07 g, 14.1 mmol) in MeOH (15 mL), and the mixture was stirred at room temperature for 15 h. After acetic acid (0.05 mL) was added to the mixture, the methanolic solution was concentrated in vacuo. The residue was purified by filtration through a short silica-gel column (ether) to give crude methyl 3-trifluoroacetamido-2,3,6-trideoxy-α-D-*erythro*-hex-5-enopyranoside as a yellow oil (4.9 g, quantitative yield).

A mixture of the oily unsaturated sugar derivatives (4.9 g) and 5% Pd-C (505 mg) in MeOH (100 mL) was stirred under a hydrogen atmosphere at atmospheric pressure for 4 h. Filtration and concentration in vacuo gave a pale yellow solid, which was purified by column chromatography (benzene/EtOAc=4/1) to afford pure **9** as a colorless crystals (1.94 g, 53%), mp 143—145 °C. A part of this sample was recrystallized from a mixture of EtOAc and hexane to give an analytical sample of **9**, mp 155.5—156.5 °C, $[\alpha]_D^{20}$ −46.7° (*c* 0.10, CH_3OH). IR (KBr): 3475, 3300, 1750, 1588 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.30 (d, *J*=6.5 Hz, 3H, CH_3), 1.58 (dd, *J*=12 and 9 Hz, 1H, 2-*ax*-H), 2.05 (ddd, *J*=12, 4.5, and 2 Hz, 1H, 2-*eq*-H), 2.15 (d, *J*=10 Hz, 1H, OH), 3.48 (s, 3H, OCH_3), 3.38—3.70 (m, 2H, 4-, 5-H_2), 3.80—4.25 (m, 1H, 3-H), 4.35 (dd, *J*=9 and 2 Hz, 1H, 1-H), 6.75 (brs, 1H, NH). Found: C, 41.98; H, 5.64; N, 5.42%. Calcd for $C_9H_{14}F_3NO_4$: C, 42.03; H, 5.49; N, 5.45%.

***N*-Trifluoroacetyl-L-daunosamine (2).** A 20% acetic acid (10 ml) was added to **9** (mp 143—145 °C) (200 mg, 0.78 mmol) and the mixture was stirred at 100 °C for 2 h. After cooling, the mixture was concentrated in vacuo below 30 °C, and the residue was purified by filtration through a short silica-gel column (EtOAc) to give pure **2** as a pale yellow solid (187 mg, 100%), mp 140—141.5 °C. A part of this sample was recrystallized from EtOAc to give an analytical sample of **2**, mp 146—147 °C, $[\alpha]_D^{20}$ −127° (*c* 0.10, MeOH, *equil.*) (lit,[5] mp 146—147 °C). IR (KBr): 3460, 3350, 1710, 1550, 1170 cm^{-1}. ^1H NMR ($(CD_3)_2SO$) δ=1.08 (d, *J*=6 Hz, 3H, CH_3), 1.40—2.30 (m, 2H, 2-H_2), 3.30—4.50 (m, 3H, 3-, 4-, 5-H_3), 4.83 (d, *J*=5 Hz, 1H, OH), 5.00—5.27 (m, 1H, 1-H). 6.08 (d, *J*=3 Hz, 1H, OH), 9.00 (brd, *J*=9 Hz, 1H, NH). Reactions of Sodium Hydrogentelluride with α-Azido Ketones and α-Azido Bromides

Hitomi SUZUKI,* Takashi KAWAGUCHI, and Koji TAKAOKA
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790
(Received August 15, 1985)

Synopsis. When treated with sodium hydrogentelluride in ethanol at room temperature, α-azido ketones are easily converted to pyrazines via the self-condensation of initially formed α-amino ketones followed by aerobic oxidation during work-up. On a similar treatment, activated α-azido bromide such as 1,2-diphenyl-1-azido-2-bromoethane suffers E2-type β-elimination to give the corresponding olefin as the sole product, while ordinary α-azido bromides afford complicated mixtures containing amino and olefinic compounds among other products.

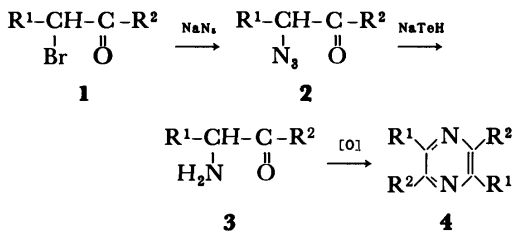
On heating with an excess of sodium borohydride in ethanol under nitrogen, elemental tellurium is reduced to form sodium hydrogentelluride as a wine-colored

$$Te + NaBH_4 + 3C_2H_5OH \xrightarrow[N_2,\,\Delta]{} NaHTe + B(OC_2H_5)_3 + 3H_2$$

solution. This reagent was first introduced by Barton in 1975,[1] but, in spite of its versatility as a selective reagent for reduction of a variety of organic compounds,[2] it has received little attention until recently. In a recent paper,[3] we have reported that sodium hydrogentelluride has an excellent ability to reduce alkyl and aryl azides to the corresponding amines under mild conditions. The reaction proceeds rapidly to completion and products are usually obtained in high state of purity. As an extension of this work, we have examined the reactions of sodium hydrogentelluride with polyfunctional azides, α-azido ketones and α-azido bromides, with an intent to see if the reaction can be used as a means to construct some nitrogen-containing heterocycles under mild conditions.

α-Azido ketones (**2**), readily prepared from α-bromo ketones (**1**) by standard procedure, was reacted with sodium hydrogentelluride in ethanol under nitrogen. The reaction occurred with immediate liberation of nitrogen and precipitation of free tellurium. After a while, the reaction mixture was exposed to air, freed from insoluble matter by filtration over a thin layer of Celite, and evaporated under reduced pressure to afford pyrazines (**4**). Several substituted pyrazines prepared by utilizing this procedure are summarized in Table 1, together with spectral data of the products. Yields shown do not represent optimized values.

Although the present method worked quite well with ordinary secondary azido ketones, it is not of a general nature. Thus, treatment of some primary azido ketones



such as α-azidoacetophenone and azidoacetone with sodium hydrogentelluride led to complicated mixtures of unidentified products. Azido ketone activated by adjacent electron-withdrawing group also failed to yield pyrazine; ethyl α-azidoacetoacetate gave only polymeric materials.

Reported procedures for converting carbonyl compounds into pyrazines include the reaction of 1,2-diketones with 1,2-diamines[4,5] or α-amino amides,[6] ammonolysis of α-halo ketones,[7,8] oxidation of ketones with alkaline hexacyanoferrate(III),[9] reduction of α-azido ketones with hydrogen over catalyst[10] or triphenylphosphine,[11] and reaction of ketones with iodine azide.[12]

Conversion of azide to amine may be explained to occur via a pathway which involves the attachment of hydrogentelluride anion to the terminal nitrogen atom of the azido group, followed by the fragmentation of the resulting triazene-type adduct in a way as

Table 1. Preparation of Pyrazines **4** from α-Azido Ketones **2**

	Pyrazine **4**		Mp	Yield/%	IR (KBr)	^{1}H NMR ($CDCl_3$)

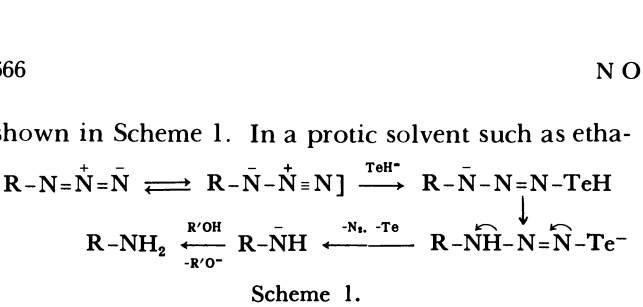
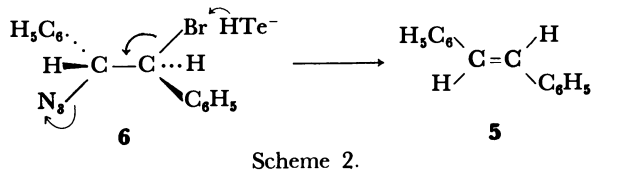
shown in Scheme 1. In a protic solvent such as ethanol, amide anion is protonated to give amine. It was therefore of interest for us to see if the amide anion generated from α-azido bromide might undergo an intramolecular nucleophilic displacement of bromine atom by adjacent negative nitrogen, leading to the nitrogen-containing cyclic system, i.e. aziridine. Thus, *erythro*-1-azido-2-bromo-1,2-diphenylethane (**6**) was prepared from *trans*-stilbene (**5**) and added to an ethanolic solution of sodium hydrogentelluride at room temperature. Tellurium immediately precipitated with effervescence and the original olefinic hydrocarbon **5** was obtained in nearly quantitative yield. The absence of amino compound in the product mixture and preservation of the original stereochemistry at carbon-carbon double bond suggest that this conversion involves the E2-type β-elimination as shown in Scheme 2.



Scheme 1.



Scheme 2.

On a similar treatment, 3-azido-2-bromo-2-methylbutane and 1-azido-2-bromocyclohexane afforded complicated mixtures containing amino and olefinic compounds among other products, but the expected azacyclic compounds could not be detected.

Experimental

Melting points were determined on a hot stage apparatus and are not corrected. ^{1}H NMR spectra were obtained at 60 MHz on a JEOL model JMN-60 spectrometer for solutions in carbon tetrachloride. IR spectra were recorded as potassium bromide disks on a Hitachi EPI-3G spectrophotometer.

Powdered tellurium was a commercial product of 99.99% purity and used as received. Azido ketones were prepared from the corresponding bromo ketones by treatment with an excess of sodium azide in acetone. Bromo azides were obtained by treating olefins with bromine azide, generated in situ from bromine and sodium azide in dichloromethane/30% hydrochloric acid.[14] Products were identified by ^{1}H NMR, IR and mass spectra as well as by comparison with authentic specimens. All compounds obtained are known.

Conversion of α-Azido Ketones (2) to Pyrazines (4); Typical Procedure: Sodium hydrogentelluride was prepared by heating powdered tellurium (0.65 g, 5.1 mmol) and sodium borohydride (0.45 g, 11.9 mmol) in ethanol (20 ml) for 1 h under a nitrogen atmosphere. To the resulting dark red solution, 2-azidocyclohexanone (**2a**; 0.278 g, 2.0 mmol) in ethanol (5 ml) was added with stirring. The color instantly turned black and was followed by evolution of nitrogen. After stirring for a while, the mixture was left open to air to destroy excess reagent and oxidize a dihydropyrazine formed via self-condensation of α-amino ketone (**3a**). Removal of metallic tellurium by filtration over Celite followed by evaporation of solvent afforded crude 1,2,3,4,6,7,8,9-octahydrophenazine (**4a**) as a solid residue, which was purified by chromatography over silica gel or recrystallization from methanol. Yield, 0.164 g (87%). Mp 105—106 °C (lit,[15] 106—108 °C).

Reaction of *erythro*-1-Azido-2-bromo-1,2-diphenylethane (6) with Sodium Hydrogentelluride. To a solution of sodium hydrogentelluride, prepared from tellurium (0.26 g, 2.0 mmol), sodium borohydride (0.19 g, 5.0 mmol) and ethanol (20 ml), was added α-azido bromide **6** (0.60 g, 2.0 mmol) in ether (2 ml) under nitrogen and the resulting black mixture was stirred for 2 h at room temperature. Addition of water (20 ml) followed by extraction of the product with dichloromethane afforded *trans*-stilbene (0.35 g, 98%). Mp 122—124 °C (lit,[16] 123—124 °C).

CD Spectra of Bis(2,4-dinitrophenyl) Derivatives of Acyclic Diamino Compounds Having Two Asymmetric Centers

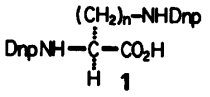
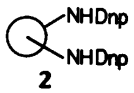
Synopsis. Chiroptical properties of bis(2,4-dinitrophenyl) derivatives of acyclic diamino compounds were discussed. The derivatives of diamines in which the two NH_2-bearing carbons are asymmetric having the same chirality exhibited Cotton effects of much larger intensity than the corresponding diamine derivatives having only one asymmetric carbon atom. Relation between sign and magnitude of Cotton effect at the longest wavelength of bis(2,4-dinitrophenyl) derivatives and structure and stereochemistry of parent diamino compounds was summarized in a tabulated form.

Bis(2,4-dinitrophenyl) (di-Dnp) derivatives of α,ω-diamino acids exhibit characteristic pattern of CD spectra above 300 nm and sign of the Cotton effect at the longest wavelength was found to be negative for the diamino acid derivatives with L-configuration (**1**, n=1—4). The Cotton effect was assumed to be due to exciton coupling of the electric transition moments of 400 nm band of the two DnpNH chromophores. Direction of the transition moment was calculated to be oriented approximately parallel to the C-NHDnp



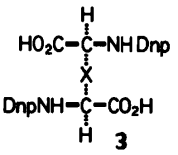
1



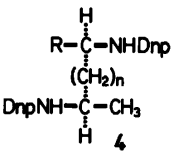
2

bond. Thus, conformers **2** having negative chirality of the two C-NHDnp bonds were assumed to be responsible for the characteristic negative Cotton effect at the longest wavelength, and a rule named di-Dnp chirality rule was proposed, which correlates sign of the Cotton effect around 400 nm with chirality of the two C-N bonds of the di-Dnp derivatives.[1]

CD spectrum of di-Dnp derivative of L-cystine (**3**, X=CH_2SSCH_2) was very similar to those of L-α,ω-diamino acid derivatives **1** exhibiting negative Cotton effect around 400 nm. Magnitude of the Cotton effect of the L-cystine derivative ($[\theta]_{412}$ −21100), however, was much larger than that of L-lysine derivative (**1**, n=4; $[\theta]_{427}$ −6400),[1] in spite of apparent larger separation of the two DnpNH chromophores by intervening six atoms in the former compound than in the latter which contains five intervening carbon atoms. Larger intensity of Cotton effects of the cystine derivative was assumed to be due to presence of additional chiral center, which restricts relative steric arrangement of the two chromophoric groups more effectively to interact with each other to give characteristic Cotton effects. Since the Cotton effects in concern are generated by electronic interaction of the two DnpNH chromophores, effect of presence and/or introduction of non-aromatic groups such as CO_2H upon the spectra can be considered essentially steric in nature.



3



4

In order to ascertain the assumption di-Dnp derivatives of (2*S*,5*S*)-diaminoadipic and (2*S*,6*S*)-diaminopimelic acids [**3**, X=$(CH_2)_n$, n=2 and 3] were prepared, which correspond to derivatives of L-ornithine and L-lysine (**1**, n=3 and 4),[1] respectively, having an extra carboxyl group creating additional asymmetric center. As expected the di-Dnp derivatives **3** [X=$(CH_2)_n$, n=2 and 3] showed a similar pattern of CD spectra with the intensity two to three times as large as the corresponding **1** (n=3 and 4), respectively (Table 1).

Di-Dnp derivatives of alkanediamines (**4**, R=CH_3, n=0 and 1) were also synthesized and their CD spectra were recorded as summarized in Table 1. The (2*R*,3*R*)-butanediamine derivative (**4**, R=CH_3, n=0)[2] can be considered as an analog of (*R*)-1,2-propanediamine derivative (**4**, R=H, n=0)[1], whose methylene group is substituted by a methyl group generating an additional chiral center of the same chirality. Cotton effects of the butanediamine derivative were much larger than those of the propanediamine derivative, which also demonstrated the effect of introducing another chiral center. (2*R*,4*R*)-Pentanediamine derivative (**4**, R=CH_3, n=1) is an analog of the propanediamine derivative having an additional methyl group as well as an intervening methylene group between the two chromophore-bearing carbon atoms. While the additional chiral center is considered to restrict the two DnpNH groups in favorable conformation to give characteristic CD spectrum, the extra methylene group has an effect of spatially separating two chromophores and also giving more conformational freedom than the case of the propanediamine derivative. The two opposing effects seem to cancell each other to result in observed Cotton effects of comparable intensity.

From the results described above the sign and magnitude of Cotton effect around 400 nm of di-Dnp derivatives of chiral acyclic diamines can be summarized as given in Table 2. Positive and negative Cotton effects, respectively, are observed if absolute configuration of the asymmetric center corresponds to that of D- and L-α,ω-diamino acid derivatives. If the compound possesses two chiral centers of the same chirality larger Cotton effect is expected than that having only one chiral center, while chiral centers of different chirality evidently afford achiral meso compounds designated as 0 in Table 2 (entry c).

Table 1. CD Spectral Data of di-Dnp Derivatives of Acyclic Chiral Diamines[a)]

Compound	Molecular ellipticity ($[\theta]/10^2$) and wavelength (λ/nm) in parentheses

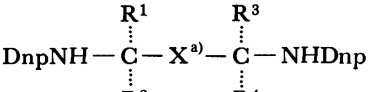
a) Recorded in methanol solution unless otherwise noted. b) Ref 1. c) Recorded in methanol–tetrahydrofuran (**1** : 1 v/v).

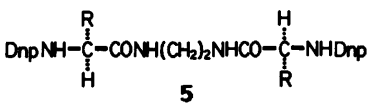
Table 2. Relation between Absolute Configuration and Sign of Cotton Effect at the Longest Wavelength of di-Dnp Derivatives of Acyclic Diamino Compounds



Entry	R^1	R^2	R^3	R^4	$[\theta]^{max}_{\approx 400}$
a	R[b)]	H	H	R	++[c)]
b	R	H	H	H	+
c	R	H	R	H	0[d)]
d	H	R	H	H	−
e	H	R	R	H	−−

a) X implies an achiral chain. b) R implies a non-aromatic group. c) ++ and −− mean that larger Coton effect is expected than + and − if comparisons are made among the compounds with the same or similar intervening group X. d) 0 means no chirality.

It is interesting that bis(Dnp-L-α-aminoacyl) derivatives **5** of ethanediamine correspond to general formula of entry a in Table 2 for which positive Cotton effect



5

around 400 nm is expected in spite of L-configuration of the constituent amino acids. As expected the L-alanine derivative (**5**, R=CH_3) exhibited positive Cotton effect ($[\theta]_{398}$+11100) and a similar CD spectrum is observed also for the L-valine derivative (**5**, R=$CH(CH_3)_2$; $[\theta]_{398}$+14400).

Experimental

Melting points were measured on a Yanagimoto micro melting point apparatus and uncorrected. All the derivatives synthesized exhibited reasonable ^{1}H NMR spectra with a Varian XL-200 or a HITACHI R-24A spectrometer and gave satisfactory elemental analysis for C, H, and N (<±0.4%). CD spectra were recorded on a JASCO J-40C spectropolarimeter as summarized in Table 1.

(2*S*,5*S*)-Bis(2,4-dinitroanilino)hexanedioic Acid [3, X=$(CH_2)_2$]. (2*S*,5*S*)-Diaminoadipic acid[3] was 2,4-dinitrophenylated according to Sanger.[4] Yellow needles from ethyl acetate–benzene; mp 220—223 °C.

(2*S*,6*S*)-Bis(2,4-dinitroanilino)heptanedioic Acid [3, X=$(CH_2)_3$]. This compound was prepared similarly from (2*S*,6*S*)-diaminopimelic acid.[3,5] Yellow prisms from methanol; mp 114—118 °C.[6]

(2*R*,4*R*)-N^2,N^4-Bis(2,4-dinitrophenyl)-2,4-pentanediamine (4, R=CH_3, n=1). (2*R*,4*R*)-Pentanediamine (*R*,*R*)-di-*O*-benzoyltartrate[7] was dinitrophenylated with 1-fluoro-2,4-dinitrobenzene–$NaHCO_3$ in acetone–H_2O. Yellow prisms from acetone; mp 218—219 °C.

(2*S*,3*S*)-N^2,N^3-Bis(2,4-dinitrophenyl)-2,3-butanediamine (enantiomer of 4, R=CH_3, n=0). This compound was prepared from (2*S*,3*S*)-butanediamine *R*,*R*-tartrate.[8] Yellow prisms from acetone; mp 217—218 °C.

***N*,*N*'-Bis[*N*-(2,4-dinitrophenyl)-L-alanyl]ethanediamine 5 (R=CH_3).** This compound was synthesized by coupling of Dnp-L-alanine (153 mg, 0.6 mmol) and ethanediamine (15 mg, 0.25 mmol) in *N*,*N*-dimethylformamide(DMF)–tetrahydrofunan (2:1) using dicyclohexylcarbodiimide (124 mg, 0.6 mmol). Yellow powder (107 mg, 80%) from DMF–methanol; mp 277—280 °C.

***N*,*N*'-Bis[*N*-(2,4-dinitrophenyl)-L-valyl]ethanediamine 5 [R=$(CH_3)_2$CH].** This compound was synthesized from Dnp-L-valine similarly as above. Yellow powder; mp>300 °C.

We wish to thank Dr. Ukon Nagai of Mitsubishi-Kasei Institute of Life Sciences for helpful discussions.

The Structure of Bis(dibenzyl sulfoxide)tris(*O,O'*-diethyl dithiophosphato)-lanthanum(III), $La\{(C_2H_5O)_2PS_2\}_3\{(C_6H_5CH_2)_2SO\}_2$

Takashi IMAI, Mamoru SHIMOI, and Akira OUCHI*
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received August 21, 1985)

Synopsis. The crystal and molecular structure of the title complex has been determined by the use of the single-crystal X-ray diffraction method. The crystal of $LaC_{40}H_{58}O_8P_3S_8$, F.W.=1155.20, is triclinic; space group $P\bar{1}$, a=13.300(5), b=19.816(8), c=11.257(4) Å, α=92.79(4), β=114.92(3), γ=75.40(4)°, U=2598(2) Å^3, Z=2, D_m=1.48(3), D_x=1.48 g cm^{-3}, and μ(Mo $K\alpha$)=1.29 mm^{-1}. Each lanthanum(III) atom is octa-coordinated and is in a dodecahedral geometry. The oxygen atoms of dibenzyl sulfoxide molecules are ligated at both ends of the base of a trapezia, and the chelating *O,O'*-diethyl dithiophosphates span two m edges and one a edge.

Some stable *O,O'*-dialkyl dithiophosphate (R_2dtp)-Lewis base mixed complexes of lanthanoids(III), where the former ligands are ligated to the hard-metal atom through the soft sulfur atoms, have already been synthesized, and some of their structures have been elucidated.[1-6] In such mixed complexes, the same kind of the ligated atoms are apt to take contiguous positions;[3,7] the M(iPr_2dtp)$_3L_2$ complexes in the octa-coordinated dodecahedral geometry, where M=lanthanoid(III) metal, iPr=$(CH_3)_2CH$-, and L= dimethyl sulfoxide (dmso)[4] or *N,N*-dimethylacetamide (dma),[2] have the Lewis-base oxygen atoms at both ends of one m-edge; tentatively we have named these complexes the "mmm-type" after their chelating positions. However, even in the same type of complexes, when the Lewis-base ligands are relatively large in size, for example, in the cases of the triphenylphosphine oxide (Ph_3PO) and benzamide (bza) adducts, the base oxygen atoms ligate at both ends of the base of a trapezia; [1,3] tentatively we name these complexes the "mma-type." Although the steric hindrance of the ligands may be the main cause of this structure, the polarity of the Lewis base may affect the ligating position, too. Consequently, it is interesting to study the structures of some dialkyl sulfoxide adduct, where the base is more polar than acid amide, but is large. Therefore, we have investigated the structure of the title complex by means of the single-crystal X-ray diffraction method.

Experimental

Preparation of Bis(dibenzyl sulfoxide)tris(*O,O'*-diethyl dithiophosphato)lanthanum(III), and the Neodymium(III) Complex. Lanthanum(III) chloride heptahydrate (1.00 g, 2.7 mmol), Na(Et$_2$dtp) (Et=C_2H_5-) (2.24 g, 10.8 mmol), and dibenzyl sulfoxide (bzso) (1.36 g, 5.9 mmol) were dissolved in about 10 cm^3 of warm ethanol. After the residue has been filtered off, the solution was evaporated using a rotary vacuum evaporator at about 80 °C, and the resinous residue thus obtained was redissolved into warm benzene (about 10 cm^3). After the residue has then been cooled, it was allowed to stand in contact with the vapor of petroleum ether at the ambient temperature for several days. Crystals came out (about 2.2 g; 1.90 mmol; yield= 90%). The isomorphous neodymium(III) complex was obtained by almost the same process. Anal. ($MC_{40}H_{58}O_8P_3S_8$) M=La or Nd, C, H. Neither mmm-type complexes, such as [Nd(iPr_2dtp)$_3$(dmso)$_2$],[4] nor ionic ones, such as [Nd(iPr_2dtp)$_2$(dbso)$_3$][Nd(iPr_2dtp)$_4$] (where dbso=dibutyl sulfoxide),[6] were obtained by this process.

Single-Crystal X-Ray Analysis. A crystal with dimensions of 0.35×0.32×0.30 mm^3 was used for the measurement. All edges were ground off. The reflections within the range of $3°<2\theta<56°$ were collected on a Rigaku AFC-6A four-circle automated X-ray diffractometer with Mo $K\alpha$ radiation, employing the ω—2θ scan technique. Of the 12632 independent reflections, 9764 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the refinement. The intensities were corrected for the Lorentz and polarization factors, but no correction was made for the absorption and extinction. All the calculations were carried out on a HITAC M-280H computer at the Computer Center of The University of Tokyo, using the local version of UNICS.[8] The scattering factors were taken from the tables.[9]

Structure Determination. The structure was solved by the heavy-atom method. All non-hydrogen atoms were found, and the positions of the phenyl hydrogen atoms were calculated from those of the neighboring carbon atoms, assuming that C-H=1.08 Å and that their B_{iso}=10.0. The final R value was 0.044,[10] applying anisotropic temperature factors for all non-hydrogen atoms.

Results and Discussion

Some selected bond lengths and angles are shown in Table 1.[11] A perspective drawing of the complex, with the numbering scheme, is shown in Fig. 1; the crystal packing diagram, in Fig. 2, and a schematic presentation of the bonding mode of the ligating atoms around the metal atom, in Fig. 3.

As is shown in the figures, the central metal atom is octa-coordinated and is in a dodecahedral geometry. Three Et$_2$dtp ligands are chelated through two corresponding sulfur atoms; two of them span m-edges, while the other one spans a-edge. Two bzso oxygen atoms ligate at both ends of the base of a trapezia. Therefore, this complex is of the mma-type; it was found that, even in the case of the adduct of polar dialkyl sulfoxides, the mma-type structure is more stable than the mmm-type structure when the steric effect is dominant.

The bond lengths of La-S are 2.992—3.091 Å (3.024 Å on the average); they are about the same as the sum of their ionic radii as presented by Shannon (3.00 Å).[12] On the other hand, the La-O bond lengths are 2.415 and 2.413 Å, shorter than the sum of the Shannon radii (2.51 Å); the phenomenon has previously been found in the other [La(R_2dtp)$_3L_2$]-type complexes, too.[1-4]

Respective complex molecules are independent in the crystal; no bridgings by the coordinated ligands or

The Nernst-Planck Type Equation in Nonequilibrium Thermodynamics

Hideo KIMIZUKA
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812
(Received September 27, 1985)

Synopsis. A single-term expression of the Nernst-Planck type equation conformable with nonequilibrium thermodynamics has been presented. The equation may be applicable to treat the electric properties of the multi-ionic system, although the individual ion flux is unobservable.

It is well known that the Nernst-Planck equation is a single-term expression and has been regarded as applicable to multi-ionic systems in classical transport theory.

On the other hand, in nonequilibrium thermodynamics, an isothermal ion flux in a multi-ionic system is expressed by a linear combination of the negative electrochemical potential gradients with the phenomenological coefficients, or the sum of Nernst-Planck type equations.[1] However, it is formidable to treat a multi-ionic system due to many phenomenological coefficients which must be experimentally determined, although nonequilibrium thermodynamics is known to be theoretically rigorous.

Thus, it is advantageous to determine the conditions for utilizing Nernst-Planck type equations in a way so as not to contradict nonequilibrium thermodynamics. This will greatly simplify the treatment of the transport process.

It has been shown in a preceding paper[2] that a Nernst-Planck type equation with a diffusion coefficient can express only ionic movements without an electric current in a binary electrolyte solution. It will be shown in the present paper that a Nernst-Planck type equation with a conductive absolute mobility is applicable to the transport process of a multi-ionic system, although the ion flux is unobservable.

Theory

The isothermal flux of an ion α, j_α, in a multi-ionic electrolyte solution may be written on the basis of nonequilibrium thermodynamics[1]

$$j_\alpha = -\sum_\beta l_{\alpha\beta}\nabla\bar{\mu}_\beta \tag{1}$$

where the subscript β refers to ion β; $l_{\alpha\beta}$ denotes the phenomenological coefficient, and $\nabla\bar{\mu}_\beta$ is the gradient of the electrochemical potential of ion β, $\bar{\mu}_\beta$.

For the sake of simplicity, it is assumed that the system is in a steady-state condition in which the fluxes, the concentration and the potential profiles are functions only of the coordinate and are independent of time.

Equation 1 leads to an equation for the electric current I as follows;

$$I = \sum_\alpha Z_\alpha F j_\alpha = -\sum_\alpha Z_\alpha F u_\alpha C_\alpha \nabla\bar{\mu}_\alpha \tag{2}$$

where Z_α denotes the charge, F the Faraday constant and C_α the concentration. u_α, the conductive absolute mobility, is related to $l_{\alpha\beta}$ by[1]

$$u_\alpha = \sum_\beta Z_\beta l_{\beta\alpha}/Z_\alpha C_\alpha . \tag{3}$$

Putting

$$j_\alpha^* = -u_\alpha C_\alpha \nabla\bar{\mu}_\alpha \tag{4}$$

and comparing Eq. 2 with Eqs. 1, 3 and 4, we find

$$I = \sum_\alpha Z_\alpha F j_\alpha = \sum_\alpha Z_\alpha F j_\alpha^*. \tag{5}$$

In Eq. 5, $Z_\alpha F j_\alpha^*$ denotes the part of the electrical ion current that is driven by the electrochemical potential gradient of ion α. Equation 4 is the same form as the Nernst-Planck equation with an absolute mobility. However, it should be noted that j_α^* is an unobservable flux and differs from the observable flux j_α as can be seen by comparing Eq. 1 with Eqs. 3 and 4. Nevertheless, Eq. 4 can be used to obtain an equation for the electric current, as can be seen from Eq. 5. When the system is in a steady state, j_α^* may also be regarded as a constant.

Equation 1 may also be written as[3]

$$j_\alpha = -\sum_\beta Z_\beta F l_{\alpha\beta}\nabla(\psi-\psi_\beta) \tag{6}$$

where ψ denotes the electric potential and ψ_β the equilibrium potential for ion β. Similarly, Eq. 4 leads to

$$j_\alpha^* = -Z_\alpha F C_\alpha u_\alpha \nabla(\psi-\psi_\alpha). \tag{7}$$

Equations 6 and 7 hold even in the absence of an electric current, where j_α, j_α^*, and ψ become j_α^0, j_α^{*0}, and ψ^0, respectively. When the electric current is small, it may be assumed that changes in the concentration profiles and phenomenological coefficients caused by an electric current can be ignored. This corresponds to an assumption of constant ψ_α's. In this case, we have from Eqs. 3, 6, and 7

$$j_\alpha - j_\alpha^0 = j_\alpha^* - j_\alpha^{*0} = -Z_\alpha F C_\alpha u_\alpha \nabla(\psi-\psi^0), \tag{8}$$

which is conformable with Eq. 5. It is evident from Eq. 8 that

$$j_\alpha = j_\alpha^* = -Z_\alpha F C_\alpha u_\alpha \nabla\psi, \tag{9}$$

when there is no concentration gradient.

For a membrane-aqueous electrolyte system with an isotropic membrane, the equations for isothermal fluxes relative to the membrane can be expressed by[4]

$$j_\alpha = -\sum_\beta l_{\alpha\beta}\nabla\tilde{\mu}_\beta - l_{\alpha w}\nabla\tilde{\mu}_w, \tag{10}$$

$$j_w = -\sum_\beta l_{w\beta}\nabla\tilde{\mu}_\beta - l_{ww}\nabla\tilde{\mu}_w, \tag{11}$$

where α and β refer to ions α and β, respectively, and w, water. The hydrodynamic electrochemical potential is given by

$$\tilde{\mu}_\gamma = \bar{\mu}_\gamma + P\bar{v}_\gamma, \quad (\gamma=\alpha, \beta, w) \tag{12}$$

where P denotes the pressure and $\bar{v}_\gamma$ the partial molar volume of species γ. For this system, the membrane current is given by

$$I = \sum_\alpha Z_\alpha F j_\alpha = \sum_\alpha Z_\alpha F j_\alpha^* + F j_w^*, \tag{13}$$

where

$$j_\gamma^* = -u_\gamma C_\gamma \nabla \tilde{\mu}_\gamma, \quad (\gamma = \alpha, \beta, w). \tag{14}$$

The conductive absolute mobility u_α for ion α is given by Eq. 3. Similarly, the equation for the electroosmotic water mobility is expressed by

$$u_w = \sum_\alpha Z_\alpha l_{\alpha w}/C_w. \tag{15}$$

Regarding flux, Eq. 8 also holds for all ionic species. For the observable flux of water, the equation for the electroosmotic water flow is

$$j_w - j_w^0 = -FC_w u_w \nabla(\psi - \psi^0). \tag{16}$$

For an unobservable flux,

$$j_w^* = j_w^{*0} \tag{17}$$

since there is no potential term in $\tilde{\mu}_w$.

Discussion

According to Eqs. 8 and 16, $C_\gamma u_\gamma$ ($\gamma = \alpha, \beta, w$) can be determined by measuring the fluxes and the potentials; hence, the electrical properties of the system, such as ion and electroosmotic conductances, the membrane conductance and the transport number can be evaluated from the $C_\gamma u_\gamma$'s. In addition, the unobservable fluxes (j_γ^* and j_γ^{*0}) can also be evaluated using Eq. 14. Thus, j_α can be calculated according to Eq. 8, provided j_α^0 is known. However, all the phenomenological coefficients should be determined in order to predict the diffusional flux j_α^0. Unfortunately, it seems to be hopeless to predict j_α^0 in a multi-ionic system having more than three kinds of ionic species. This is because there are too many phenomenological coefficients which must be experimentally determined.

For a binary electrolyte solution, the diffusional ion flux at zero electric current j_α^0 is given by a single-term expression[2]

$$j_\alpha^0 = -D_\alpha C_\alpha \nabla \bar{\mu}_\alpha / RT = -\omega_\alpha C_\alpha \nabla \tilde{\mu}_\alpha, \tag{18}$$

where D_α denotes the diffusion coefficient, ω_α ($=D_\alpha/RT$) the diffusional absolute mobility, R the gas constant, and T the absolute temperature. D_α and ω_α are related to the phenomenological coefficients as follows[2];

$$D_\alpha C_\alpha / RT = \omega_\alpha C_\alpha = Z_\beta (l_{\alpha\alpha} l_{\beta\beta} - l_{\alpha\beta}^2)/(Z_\alpha l_{\alpha\beta} + Z_\beta l_{\beta\beta}). \tag{19}$$

Comparing Eq. 18 with Eq. 4,

$$\frac{j_\alpha^0}{j_\alpha^{*0}} = \frac{\omega_\alpha}{u_\alpha} = 1 - \lambda_{\alpha\beta}\left(\frac{1}{\lambda_\alpha} + \frac{1}{\lambda_\beta}\right) = F(\lambda_{\alpha\beta}), \tag{20}$$

where λ_α and λ_β are the equivalent conductances of ions α and β, respectively. $\lambda_{\alpha\beta}$ is an element of the equivalent ion conductance matrix, given by the relation[2]

$$\lambda_{\alpha\beta} = Z_\alpha Z_\beta F^2 l_{\alpha\beta}/|Z_\alpha| C_\alpha. \tag{21}$$

Since the phenomenological coefficients or the elements of the conductance matrix for a binary electrolyte solution can be determined experimentally[1], j_α^0 can be evaluated according to Eq. 18. Hence, from Eqs. 8 and 20,

$$j_\alpha = j_\alpha^* - j_\alpha^{*0} + j_\alpha^0 = j_\alpha^* - j_\alpha^{*0}[1 - F(\lambda_{\alpha\beta})] \tag{22}$$

enabling us to evaluate j_α from j_α^*, j_α^{*0}, and $F(\lambda_{\alpha\beta})$.

Concerning $F(\lambda_{\alpha\beta})$, it has been shown in the preceding paper[2]

$$F(\lambda_{\alpha\beta}) = |Z_\alpha| F^2 D_\alpha / RT\lambda_\alpha \tag{23}$$

$$F(\lambda_{\alpha\beta}) = \nu_\alpha |Z_\alpha| D_s/(\nu_\alpha + \nu_\beta)\lambda t_\alpha t_\beta (1 + d \ln \gamma_s / d \ln C_s), \tag{24}$$

where the subscript s refers to salt. ν_α and ν_β denote the stoichiometric coefficients, D_s the diffusion coefficient, λ the equivalent conductance of salt, t_α and t_β the transport numbers, γ_s the activity coefficient and C_s, the salt concentration. The value of $F(\lambda_{\alpha\beta})$ decreases with a decrease in the electrolyte concentration and tends to unity as the concentration approaches zero[2] where $u_\alpha = \omega_\alpha$. This indicates that interionic interactions vanish at an infinite dilution and there is no distinction between Eqs. 1 and 4. When $F(\lambda_{\alpha\beta})$ is unity, Eqs. 23 and 24 lead to the Nernst–Einstein and Nernst–Hartley equations, respectively. These are derived on the basis of the Nernst–Planck equation. Thus, it may be said that the original Nernst–Planck equation is valid only at an infinite dilution where Eqs. 4 and 18 are identical.

Eqations 4 and 18 differ from each other at finite electrolyte concentrations (where $F(\lambda_{\alpha\beta})$ differs from unity) and should be used with the precautions described in the present paper. From this point of view, u_α and ω_α should be distinguished from each other and can be called the conductive absolute mobility and the diffusional absolute mobility, respectively. This is due to the process by which they are defined. Nevertheless, these equations are still being used in current papers without distinction. However, the Nernst–Planck type equations (4, 14, and 18) are single-term expressions and enable us to use the results from classical membrane theories based on the Nernst–Planck equation if those theories were formulated under reasonable assumptions and the proposed precautions are taken into account.

Thus, the use of single-term expressions is advantageous for an easier treatment of the transport process using nonequilibrium thermodynamics. Hence, these equations can be regarded as revised Nernst–Planck equations. A determination of all phenomenological coefficients is required in order to completely describe and characterize the transport process in a multi-ionic system. At present this process seems to be hopeless in systems having more than four

components. Further study is required in order to solve this problem.

(Received August 26, 1985)

Synopsis. New bis(crown ether)s **3** consisting of a benzocrown unit and a monoazacrown unit connected by an oxyethylene linkage were synthesized. Their complexation behavior proved to be analogous to that of lariat monoazacrown ethers rather than that of bis(benzocrown ether)s.

In our previous paper,[1] it was shown that the selectivity of bis(benzocrown ether)s in the complexation with alkali metal cations could be changed by varied combinations of two benzocrown units(ring size; 15, 18, 21), and the behavior was understood by the formation of an intramolecular sandwich complex. The results led us to investigate the complexation characteristics of a new type of bis(crown ether)s consisting of a benzocrown unit and a monoazacrown unit connected by an oxyethylene linkage. This paper describes their synthesis and relative contribution of the linking group and another crown unit in the complexation with alkali metal cations.

Experimental

Material. Benzocrown ethers, 4′-hydroxybenzocrown ethers **5**, monoazacrown ethers, *N*-[2-[2-(tosyloxy)ethoxy]-ethyl]substituted monoazacrown ethers **4** were prepared according to the published methods.[1-3] The guaranteed reagent of alkali metal chlorides, alkali metal hydroxide and picric acid were used without further purification except for drying.

Synthesis of Bis(crown ether)s 3. The tosylate **4** (3 mmol) in dioxane (15 cm³) was added dropwise to a mixture of 4′-hydroxybenzocrown ether **5** (3 mmol) and sodium hydroxide (10 mmol) in DMSO–dioxane (9:1, 15 cm³) under nitrogen over a period of 1 h at 80 °C, and then the solution was refluxed for 20 h. After cooling, the mixture was filtered and the filtrate was concentrated under reduced pressure. The residual oily product was chromatographed over an alumina column ($CHCl_3$ eluent) and then purified by a medium pressure liquid chromatography (Silica-gel/MeOH–$CHCl_3$, 2:98(v/v)). The lariat ethers **2** were prepared by a similar method and purified by Kugelrohr distillation.

Solvent Extraction. The extraction experiment was carried out in a CH_2Cl_2-H_2O system at 25 °C, according to the Pedersen's procedure.[4] Extraction equilibria were measured under the same conditions, and four measurements were carried out at varied ligand concentrations in one system. The constants are defined as:

$$M^+_{aq} + A^-_{aq} + Cr_{org} \overset{K_e}{\rightleftharpoons} MCrA_{org}, \quad (1)$$

$$MCrA_{org} \overset{K_d}{\rightleftharpoons} MCr^+_{org} + A^-_{org}, \quad (2)$$

$$Cr_{org} \overset{P_e}{\rightleftharpoons} Cr_{aq}, \quad (3)$$

$$K_e = [MCrA]_{org}/[M^+]_{aq}[A^-]_{aq}[Cr]_{org}, \quad (4)$$

$$K_d = ([MCr^+]_{org}[A^-]_{org})/[MCrA]_{org}, \quad (5)$$

$$P_e = [Cr]_{aq}/[Cr]_{org}. \quad (6)$$

From Eqs. 4—6 we can get:[5]

$$K_e = \frac{(1+P_e)(2[A]+K_d-(K_d^2+4K_d[A])^{1/2})}{2f([M]_0-[A])([A]_0-[A])([Cr]_0-[A])} \quad (7)$$

where f is the single-ion activity coefficient of alkali metal cation in aqueous phase, [A] is the total concentration of the picrate anion in organic phase and $[M]_0$, $[A]_0$, and $[Cr]_0$ is the initial concentration of the cation, picrate anion and crown unit, respectively. Equation 8 is used for intermolecular sandwich complex, while Eq. 9 for intramolecular one.[6]

$$K_e = \frac{(1+P_e)^2(2[A]+K_d-(K_d^2+4K_d[A])^{1/2})}{2f([M]_0-[A])([A]_0-[A])([Cr]_0-2[A])^2} \quad (8)$$

$$K_e = \frac{(1+P_e)(2[A]+K_d-(K_d^2+4K_d[A])^{1/2})}{2f([M]_0-[A])([A]_0-[A])([Cr]_0-2[A])} \quad (9)$$

P_e can be obtained from the extraction in the absence of picrates. K_e was evaluated by a regression analysis with varied K_d to minimize the deviation among the calculated values for the measurements over the range of the concentration of crown unit (8.9×10^{-6}—1.4×10^{-3} mol dm^{-3}).

Stability Constants. The complex stability constants were determined on a mixture of ligand (0.30—0.60 mmol dm^{-3}) and MCl (0.4—2.0 mmol dm^{-3}) in 90% (w/w) aqueous MeOH at 25 °C. Emf was measured with the ion selective electrode (Na^+-ISE(TOA NA-15B) for Na^+ and monovalent cation electrode (Corning cat. No. 476220) for K^+, Cs^+ against a Ag/AgCl reference electrode by use of an Orion Research Model 701A digital "Ionalyzer." The details of the method of the measurement and calculation were described by H. K. Frensdorff[7a] and G. W. Gokel, et al.[7b] The results are shown in Table 3. The following equations were used in the calculation, Eqs. 10 and 11 for monocrown ethers and 12—16 for bis(crown ether)s.[1]

$$M^+ + Cr \overset{K_{m1}}{\rightleftharpoons} M^+Cr$$

$$K_{m1} = K_{obsd1} = [M^+Cr]/([M^+][Cr]) \quad (10)$$

$$M^+Cr + Cr \overset{K_{m2}}{\rightleftharpoons} CrM^+Cr$$

$$K_{m2} = K_{obsd2} = [CrM^+Cr]/([M^+Cr][Cr]) \quad (11)$$

$$\overset{\frown}{Cr}\ \overset{\frown}{Cr'} + M^+ \overset{K_{b1}}{\rightleftharpoons} \overset{\frown}{Cr}\ \overset{\frown}{Cr'}M^+$$

$$K_{b1} = [\overset{\frown}{Cr}\ \overset{\frown}{Cr'}M^+]/([\overset{\frown}{Cr}\ \overset{\frown}{Cr'}][M^+]) \quad (12)$$

$$\overset{\frown}{Cr}\ \overset{\frown}{Cr'}M^+ \overset{K_{b2}}{\rightleftharpoons} Cr\overset{\frown}{M^+}Cr'$$

$$K_{b2} = [Cr\overset{\frown}{M^+}Cr']/[\overset{\frown}{Cr}\ \overset{\frown}{Cr'}M^+] \quad (13)$$

$$\overset{\frown}{Cr}\ \overset{\frown}{Cr'}M^+ + M^+ \overset{K'_{b1}}{\rightleftharpoons} M^+\overset{\frown}{Cr}\ \overset{\frown}{Cr'}M^+$$

$$K'_{b1} = [M^+\overset{\frown}{Cr}\ \overset{\frown}{Cr'}M^+]/([\overset{\frown}{Cr}\ \overset{\frown}{Cr'}M^+][M^+]) \quad (14)$$

$$K_{obsd1} = K_{b1}(1+K_{b2}) \quad (15)$$

$$K_{obsd2} = K'_{b1}/(1+K_{b2}) \quad (16)$$

Results and Discussion

Presence of the lariat group markedly increased the extractability of monoazacrown ethers **2—3**, as described by M. Okahara, et al.[3,8] and the effect is in marked contrast to that of the similar group in benzocrown ethers as shown in Table 1.[1] The monoazacrown ethers bearing a lariat group showed a similar extractability with small cations. Li^+ and Na^+. For K^+, Rb^+, and Cs^+ the extraction behavior of the four bis(crown ether)s **3a—d** seems to be divided into two groups depending on the azacrown unit involved; i.e., **3a** and **3b** of lower extractability and **3c** and **3d** of higher one, which may be compared with **2a** and **2b**, respectively. The comparison between **2a** and **3a** (or between **2b** and **3c**) shows that the introduction of a terminal B15C5 group in place of a phenyl group does not exert any marked increase in the extractability, and the values in the parentheses obtained with the same concentration of the azacrown unit may be explained by a concomitant increase in concentration of B15C5 group. Considerable enhancement of the extractability of **3b** over **3a** and of **3d** over **3c** could be understood by the larger complexability of B18C6 than B15C5. It should be emphasized that none of these bis(crown

* No regression analysis was done for K_{obsd2}, since the standard deviation of K_{obsd1} was less than 10%.

ether)s **3a—d** shows any marked increase in extractability for cations larger than their hole size as is known in bis(benzo-15-crown-5)-K^+ or bis(benzo-18-crown-6)-Cs^+ system. These considerations lead us to the reasoning that the complexation behavior of the present bis(crown ether)s is principally governed by the effect of the lariat group and the benzocrown unit plays a minor role. The extraction equilibrium constants (Table 2) are almost consistent in tendency with the results in Table 1. The similarity in K_e of **2a** and **3a**, and of **2b** and **3d** again supports the absence of any extra effect of another crown unit in **3a—d** since the formation of the intramolecular sandwich complex is known to give rise to a definitive enhancement in K_e for bis(benzocrown ether)s.[1,9] In the cases of **2b**-K^+ and **3d**-K^+ the calculation with Eq. 7 or Eq. 9 gave larger deviation (>60%), while the recalculation with Eq. 8 gave a good result. The result suggests that the bis(crown ether) **3d**, as well as the lariat ether **2b**, can form an intermolecular sandwich complex in some cases.

Although the stability constants in a homogeneous system are not always parallel with the results from a two-phase equilibrium we can still get the following information from Table 3. The monoazacrown ether **1b** and the lariat ethers **2a**, **2b** can form 2:1 complex with K^+. If the bis(crown ether) **3a** or **3d** forms an intramolecular sandwich complex there must be an increase in K_{obsd1} due to the contribution of K_{b2} in Eq. 15, but **3a** and **3d** show K_{obsd1} comparable with the lariat ether **2a** and **2b**, respectively. The appearance of K_{obsd2} in **3d** means that there exists the complex in which both crown units hold two cations independently (Eq. 14).

The unique behavior of the bis(crown ether)s **3** should come from their special structures. For lariat ethers, e.g. *N*-(methoxyethyl)monoaza-18-crown-6, the X-ray analysis showed that the ring donor atoms take a chair conformation. A cation larger than the hole size is disposed above the ring plane, and the lariat group in the side arm is not cradling the cation between it and the macroring but rather is pushing the cation out.[10] This fact may explain why the lariat ether **2b** and the bis(crown ether)s **3c**, **3d** can hold K^+ as an intermolecular sandwich complex in the solvent extraction.

Synopsis. Imidoyl chlorides were good substrates which can react with a variety of organotin compounds to give ketimines in the presence of a catalytic amount of palladium complex. Under similar conditions, *C*-tributylstannyl imines did not give the products except with 2-(tributylstannyl)benzothiazole, -benzoxazole, and 1-methyl-2-(tributylstannyl)imidazole. And *N*-tributylstannyl imines could not be utilized.

The cross-coupling of organotin compounds with organic halides catalyzed by palladium complex is an important and versatile method of stereo- and regiospecific carbon–carbon bond formation.[1] Thus aryl and vinyl bromides are good substrates, and aryl- and vinyl-tin compounds are good reagents. From the structural analogy, imidoyl chlorides and stannyl imines are expected to be good substrates and reagents, respectively. This is further suggested by that imidoyl chloride undergoes the oxidative addition to the low valent palladium complex,[2] since such oxidative adducts are considered to be intermediates in the palladium-catalyzed coupling between organotins and halides. In this note, we report about possible utility of the following three types of reactions.

$$R^1CCl=NR^2 + n\text{-}Bu_3SnR^3 \xrightarrow{[Pd]} R^1R^3C=NR^2 + n\text{-}Bu_3SnCl$$

$$R^3X + n\text{-}Bu_3SnR^1C=NR^2 \xrightarrow{[Pd]} R^1R^3C=NR^2 + n\text{-}Bu_3SnX$$

$$R^3X + n\text{-}Bu_3SnN=CR^1R^2 \xrightarrow{[Pd]} R^3N=CR^1R^2 + n\text{-}Bu_3SnX$$

As for heterocycles containing C=N bonds, palladium-catalyzed couplings of 2-halobenzothiazole with organozinc compound are known.[3,4] We also applied the cross-coupling of tin compounds with halides to these heterocycle systems.

I. Palladium-Catalyzed Reaction of Imidoyl Chloride and Related Compound with Organotin Compounds. As is shown in Table 1, imidoyl chlorides were good substrates to give ketimines when treated with a variety of organotin compounds in the presence of a catalytic amount of palladium complex. Quite recently, we have found similar trials published.[5] The best yields were obtained when the reaction was carried out using a slightly excess amount of tin reagents and 1 mol% of dichlorobis(triphenylphosphine)-palladium at 120 °C for 20 h in xylene. Prolonged reaction time decreased the yield of the product. The reaction with acetonyltributyltin gave two products, that is, the acetonylated product (isomerized to conjugated enone) and the iso-propenylated one, though in relatively low yields.

In the reaction with tin enolate (α-stannyl ketone or enol stannyl ether), dichlorobis(tri-*o*-tolylphosphine)palladium was a better catalyst than dichlorobis(triphenylphosphine)palladium, as in the case of cross-coupling of tin enolate with other organic halides.[6]

In allylation of *N*-(α-chlorobenzylidene)aniline, the product was isomerized to the conjugated imine which was identical to the product derived from the reaction with 1-propenyltributyltin. Although the stereochemistry of the product was not fully characterized, GLC analysis showed the mixture of *E*- and *Z*-isomer being produced.

II. Palladium-Catalyzed Reaction of Bromobenzene with Tributylstannyl Imines. There are two types of stannyl imines, *C*-stannyl imine and *N*-stannyl imine. The results of trials for the cross-coupling reaction of these stannyl imines with bromobenzene were summarized in Table 2.

C-Stannyl heterocycles, such as 2-(tributylstannyl)benzothiazole, -benzoxazole, and 1-methyl-2-(tributylstannyl)imidazole were found to be good reagents, while acyclic *C*-stannyl imine, *N*-[α-(tributylstannyl)-benzylidene]aniline and *N*-[1-(tributylstannyl)pentylidene]-*t*-butylamine did not react.

On the other hand, *N*-tributylstannyl imines could hardly be utilized in this type of reaction.

Experimental

^1H NMR spectra were taken on a Varian EM-360 spectrometer. IR spectra were obtained on Jasco A-100 spectrometer. MS spectra were taken by using JMS-07. GLC analyses were carried out with Ohkura 802 instrument, using columns (1.5 m) packed with 10% Silicone SE-30 and SF-96 on Celite 545. Bp and mp are uncorrected values. (1 mmHg=133.322Pa).

Materials. *N*-(α-Chlorobenzylidene)aniline (bp 110—115 °C/0.3 mmHg, mp 41 °C; lit,[7] bp 174—176 °C/12 mmHg, mp 41 °C) and 2-chlorobenzothiazole (bp 83.5 °C/1.4 mmHg; lit,[8] bp 135—136 °C) were prepared by the treatment of benzophenone oxime and benzothiazole with phosphorus pentachloride, respectively. $Bu_3SnCH_2CH=CH_2$,[9] $Bu_3SnCH=CH_2$,[10] $Bu_3SnCH=CHCH_3$,[11] Bu_3SnPh,[12] $Bu_3SnCH_2COCH_3$,[13] 1-cyclohexenoxytributyltin,[13] $Bu_3SnN=C(CCl_3)(OMe)$,[14] $Bu_3SnN=CPh(NEt_2)$,[15] and $Bu_3SnN=C=NSnBu_3$[16] were prepared according to the methods described in the literatures. 1-Methyl-2-(tributylstannyl)imidazole (bp 123—130 °C/0.3 mmHg), 2-(tributylstannyl)benzoxazole (bp 135—140 °C/0.15 mmHg), and 2-(tributylstannyl)benzothiazole (bp 144—146 °C/0.15 mmHg) were prepared by the treatment of 1-methylimidazole, benzoxazole, and benzothiazole with butyl lithium, followed by the addi-

tion of tributyltin chloride, respectively. *N*-[1-(tributylstannyl)pentylidene]-*t*-butylamine (bp 120—122 °C/0.3 mmHg) was prepared by the insertion of butyl lithium into *t*-butyl isocyanide, then the addition of tributyltin chloride.[17] *N*-[α-(tributylstannyl)benzylidene]aniline (bp 148—155 °C/0.3 mmHg) was prepared by the reaction of *N*-(α-chlorobenzylidene)aniline with lithium tributylstannate(II). ^{1}H NMR spectra of these tin compounds showed reasonable structures of them which were used without further characterizations. Palladium complexes were already reported.[6]

Reaction Procedure. A mixture of halide (3.0 mmol), tin compound (3.6 mmol), and palladium complex (0.03 mmol) in xylene (6 ml) was heated under argon at 120 °C for 20 h. After washed with aqueous potassium fluoride to remove the tributyltin halide produced, organic layer was extracted with ether and dried over sodium sulfate. Then after evaporation of ether, the product was isolated by distillation or recrystallization.

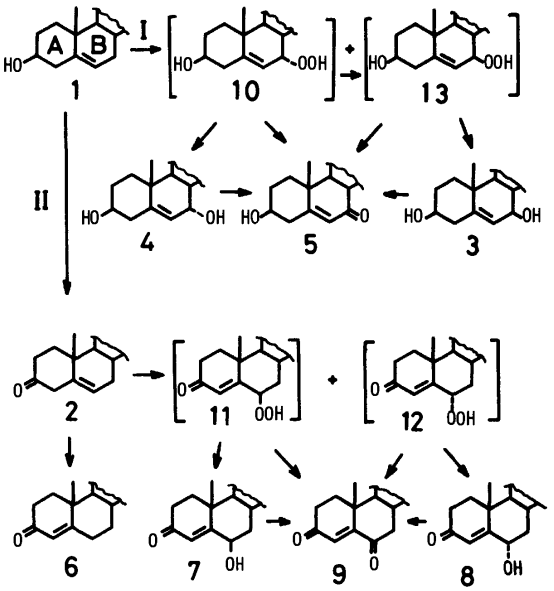
(Received September 24, 1985)

Synopsis. Cholesterol was oxidized (12% conversion) with platinum and oxygen to give several 7-oxygenated products, cholest-5-en-3-one, and cholest-4-en-3-one accompanied with its further oxygenation products at C-6. The pathways and mechanisms of the catalytic oxidation are discussed.

Platinum-catalyzed oxidation[1] has been used successfully for the oxidation of saturated sterols including 5α-cholestan-3β-ol and its 3α-epimer by Sneeden and Turner.[2] The attempts at the oxidation of cholesterol (cholest-5-en-3β-ol, **1**) have, however, met with failure.[2] This paper describes our reinvestigation of the oxidation of **1** with platinum and oxygen, which demonstrated that **1** undergoes catalytic oxidation.

The oxidation of **1** was performed by oxygen over prereduced platinum in ethyl acetate at the ambient pressure and temperature to yield Δ^5- (**2**, **3**, **4**, and **5**) and Δ^4- (**6**, **7**, **8**, and **9**) oxidation products as summarized in Table 1, most of which are known to be autoxidation products of **1**.[3-6] The oxidation of the Δ^5-3-one **2** under the same conditions yielded the Δ^4-3-one **6** and the 6-oxygenated products, **7**, **8**, and **9**, whereas the oxidation of **6** yielded only the unaltered substrate. The controlled oxidation of **1** and **2** in the absence of the catalyst afforded only the unchanged starting material. From the above, it can be assumed that there are two pathways (**I** and **II**) for the catalytic oxidation of **1**, as is illustrated in Scheme 1.

The first, minor, one (**I**) is to form the allylic oxygenation products: **3**, **4**, and **5**. These 7-oxygenated products are well-known radical autoxidation products of **1** and have been established to be formed via the initial formation of the 7-hydroperoxides (**10** and **13**), followed by thermal decomposition.[3-5] Although these hydroperoxides were not detected in the present oxidation of **1**, we suppose that the initial formation of **10** and **13** is also involved in the catalytic oxidation



Scheme 1. Proposed pathways for the platinum-catalyzed oxidation of cholesterol (**1**).

of **1**, which might be, in situ, decomposed over the catalyst to afford the 7-ols **3** and **4** and the 7-ketone **5**. The attempted catalytic oxidation of the 7α-hydroperoxide **10** yielded **3**, **4**, and **5**, with no substrate being recovered, while **10** remained mostly unaltered upon controlled oxidation in the absence of the catalyst, thus suggesting the lability of hydroperoxide over the platinum catalyst. The 7β-ol **3** might arise from **10** through epimerization to the 7β-hydroperoxide **13**, followed by decomposition, the epimerization of which was previously observed in a solution of ethyl acetate and some other solvents.[3]

The second, major pathway (**II**) of the catalytic oxidation of **1** is that proceeding via the dehydrogena-

a) The RRTs of **2**, **6**, and **9** corresponded to the ketones, and those of the other steroids corresponded to the TMSE derivatives. The RRTs of **10**, **11**, and **12** were for GLC decomposition products. b) Gvien as δ values. Figures in parentheses denote *J* values (Hz) for doublet signals, whereas $W_{1/2}$ values (Hz) for multiplet signals. The signals at δ 0.87 (6H, *d*, *J*~6 Hz, 26-H_3, 27-H_3) and 0.92 (3H, *d*, *J*~5 Hz, 21-H_3) also were observed for all of the steroids. s: singlet, d: doublet, m: multiplet.

tion to afford the ketone **2** as the primary product. Upon isomerization, this yields conjugated ketone **6**, not further oxidized, and upon a second oxidation it yields the epimeric 6-hydroxy ketones **7** and **8**. These 6-ols are known to be formed from the ketone **2**, accompanied by the 6-hydroperoxides **11** and **12** and other products, by irradiation in air using ^{60}Co gamma radiation,[6] and by autoxidation in acetic acid.[7] Although we did not detect the 6-hydroperoxides **11** and **12** in the present oxidation of **1**, we consider the involvement of the 6-hydroperoxides in the catalytic oxidation to be as likely as in the autoxidation of **1**;[6] they may be involved as intermediates which might be decomposed, in situ, to form the epimeric 6-ols **7** and **8** and diketone **9**. The attempted oxidation of **11** and **12** in the presence of platinum yielded the 6-ols **7** and **8** respectively in addition to **9**, while no starting material was recovered. The formation of the ketones **6** and **9** is also known in the oxidation of **1** promoted by the Ni-Cr-O catalyst in xylene under reflux.[8]

Thus, **1** has undergone catalytic oxidation with platinum and oxygen under ambient pressure and temperature to yield several dehydrogenated and oxygenated products. The oxygenation of **1** in the catalytic oxidation is considered to proceed by means of a free-radical-type reaction promoted by platinum catalyst. Although saturated sterols have been oxidized successfully by the catalytic oxidation,[2] the reactivity of **1** in the catalytic oxidation was found to be extremely low (12% conversion) in this study. Such a low reactivity of **1** might be attributed to its 3β-hydroxy-Δ^5 structure since the other 3β-hydroxy-Δ^5-sterols **3** and **4**, which possess an additional hydroxyl group at C-7, also remained mostly unaltered by the catalytic oxidation. The oxidation has been found to proceed preferentially on the axial hydroxyl group rather than on the equatorial one as for the epimeric 6-hydroxy steroids **7** and **8** although the selectivity was not so clear cut as that of carbohydrates.[1] Table 2 showed the melting points, and chromatographic and ^{1}H NMR spectroscopic data of twelve steroids (**1**—**12**). The ^{1}H NMR spectroscopy has distinguished unequevocally between each of the double bond- and stereo-isomers of steroids. The ketone **2** was indistinguishable from conjugated ketone **6** in GLC which suggested the formation of **6** from **2** by thermal isomerization during GLC. The GLC peaks of the hydroperoxides **10**, **11**, and **12** were considered to be corresponded to the thermal decomposition products.[9]

Experimental

General Methods and Materials. The melting points are uncorrected. The HPLC was carried out on a Partisil 5 ODS-2 column (25 cm×10 mm i.d., two columns in series) using a UV detector (monitored at 212 nm) or a RI detector with MeOH as mobile phase. The GLC was performed with a SCOT OV-17 glass capillary column (30 m×0.3 mm i.d.) at 260 °C. The RRTs (relative retention times) in the HPLC and GLC were expressed relative to **1** and the trimethylsilyl ether (TMSE) derivative of **1**, respectively. The EI-MS spectra (70 eV) were taken by means of a probe injection. The ^{1}H NMR spectra (100 MHz) were obtained in a $CDCl_3$ solution, with Me_4Si as the internal standard. The thin-layer chromatography (TLC) was performed on plates of precoated silica gel. A commercial sample of **1** was purified through the dibromide by the method of Shoenheimer.[10,11] The other steroids were prepared from **1** as has previously been described.[12] All the steroid samples for the oxidation, which were identified on the basis of the mp, and the chromatographic and spectroscopic data, were recrystallized from MeOH or from MeOH-H_2O mixture several times and did not contain any detectable levels of autoxidation products.

Oxidation of Steroids and Analysis of the Oxidation Products. The oxidation was performed in a way similar to that described by Sneeden and Turner.[2] A suspension of PtO_2 (50 mg) in EtOAc (15 ml) was first reduced to Pt in an atmosphere of H_2, after which the H_2 was carefully replaced with air by repeated evacuation. The system was then filled with O_2, and the catalyst suspension was stirred until the uptake of O_2 ceased. The sample (50 mg) was added, the system was filled again with O_2, and the reaction was continued for 24 h at ambient pressure and temperature. The product was then passed through a short Florisil column in

order to remove the catalyst. A portion of the product was analyzed and fractionated by HPLC, while the other portion was analyzed by GLC as the TMSE derivatives. Steroid hydroperoxides were detected on TLC by spraying with *N,N*-dimethyl-*p*-phenylenediamine.[6] The oxidation products were identified on the basis of mp, and the chromatographic and spectroscopic data after isolation.

We wish to thank Kazuhisa Honma for his technical assistance.

Preparation of Solid Catalysts for Vapor-Phase Decomposition of Carbonyl Sulfide

Masamichi AKIMOTO,* Hirotoshi SUTO, and Hiroo NIIYAMA
Department of Chemical Engineering, Tokyo Institute of Technology,
Ookayama, Meguro-ku, Tokyo 152
(Received May 31, 1985)

The vapor-phase catalytic decomposition of COS (COS→CO+1/xS$_x$ and 2COS→CO$_2$+CS$_2$) has been mechanistically investigated so as to prepare solid catalysts which are active and selective for the first reaction. The comparison of the catalytic activity and selectivity of a series of Al_2O_3 catalysts with their acid-base properties and the different behavior of these two catalytic decomposition reactions in the poisoning of an Al_2O_3 catalyst with SO_2 demonstrate that electron-donating sites catalyze the first reaction whereas Lewis acidic sites do so the second reaction. CaO catalysts are prepared by thermal decomposition of $CaCO_3$ at elevated temperatures and their catalytic activity is compared with their amount of electron-donating sites. The greatest catalytic activity and selectivity for the first reaction(yield of CO+S$_x$=21.4%, selectivity=80.2% at 873 K) are obtained over CaO catalyst prepared at 1123 K which has the greatest electron-donating ability. These values of the yield and selectivity to CO+S$_x$ are much greater than those obtained over Al_2O_3 catalysts.

The catalytic decomposition of COS to CO and elemental sulfur is of industrial importance in view of the recovery of hydrogen from H_2S and the oxidative dehydrogenation of hydrocarbons.

Fukuda and co-workers[1] proposed the following two-step closed cycle for the decomposition of H_2S.

$$H_2S + CO \longrightarrow H_2 + COS \quad (1)$$
$$COS \longrightarrow CO + 1/xS_x \quad (x=2,4,6,\cdots) \quad (2)$$

They reported that almost an equilibrium conversion of H_2 could be produced in the first reaction at 493—573 K with a cobalt sulfide catalyst.[2] In the second reaction, however, both CO_2 and CS_2 were always produced by the side reaction (Reaction 3) and in the

$$2COS \longrightarrow CO_2 + CS_2 \quad (3)$$

case of homogeneous decomposition reaction such an elevated temperature as 1103 K had to be used for the decomposition of COS to CO and elemental sulfur (S_x) with a selectivity of 95%.[2]

On the other hand, COS has been employed as a source of atomic sulfur in the catalytic oxidative dehydrogenation of lower paraffinic hydrocarbons and arylalkyl compounds.[3-6] In this oxidative dehydrogenation, COS is catalytically decomposed to CO and atomic sulfur which then abstracts hydrogen atoms from these hydrocarbons to give unsaturated hydrocarbons and H_2S. The most striking feature of this dehydrogenation is the ability to produce unsaturated hydrocarbons with high selectivity even over such catalysts SiO_2, Al_2O_3, MgO, and TiO_2 as have conventionally been used as carriers.

Although the catalytic decomposition of COS is thus industrially important, only a few papers have been published on the mechanism of the catalytic reaction and the preparation of active and selective catalysts.[5,7] In the present work, we have elucidated the nature of surface active sites responsible for the second and third reactions and have then tried to prepare active and selective catalysts for the second reaction by thermal decomposition of $CaCO_3$.

Experimental

Reaction and Catalyst. Vapor-phase catalytic decomposition of COS was carried out using a conventional flow fixed-bed reactor at atmospheric pressure (1 Torr=133.322 Pa). The reactor system comprised a 15-mm-i.d. quartz tube, 400 mm long, and a concentric thermowell. The reactor was heated with a cylindrical electric furnace. The catalysts employed are the referenced Al_2O_3 catalysts of the Catalysis Society of Japan (JRC-ALO-1, -2, -4, and -5) and CaO. CaO catalysts were prepared by thermal decomposition of $CaCO_3$ (Mallincrodt Inc., 99.95% purity) at elevated temperatures. Raschig rings (2×2 mm) were added above and below the catalyst bed. Purchased COS of greater than 97.5 vol% purity (Matheson Co., CO_2 1.4 vol%, N_2+CO 0.6 vol%, CS_2 0.19 vol%, O_2 0.10 vol%, and H_2O 0.01 vol%) was used without further purification. For convenience, helium (purity>99.99 vol%) was used as the diluent in the catalytic studies, and the total feed rate was always held at 200(NTP) cm^3 min^{-1}: the standard feed composition of COS was 5.0 vol%.

Analysis. The reaction products (COS, CO, CO_2, and CS_2) were analyzed by gas chromatography using Porapak R(0.8 m, 363 K) and Porapak S(0.6 m, 363 K) in series as the separating column and helium as the carrier gas. The ESR measurements were carried out with a JEOL JES-PE spectrometer operating in the X band, adopting a 100 kHz modulation frequency. The g values of paramagnetic species were determined by the use of Mn^{2+} dissolved in MgO, and radical concentrations were estimated by comparing with the standard solution of 2,2-diphenyl-1-picrylhydrazyl in benzene. Purchased SO_2 (Matheson Co., purity>99.98%) was used in the ESR studies after purification by freeze-pumping method.

Results

Nature of Active Sites. Table 1 summarizes the results of catalytic decomposition of COS at 873 K over the referenced Al_2O_3 catalysts of the Catalysis Society of Japan. Previous experiments indicated no effects of film and pore diffusions on the catalytic activity and selectivity in the decomposition of COS at 873 K (catalyst size=10—100 mesh, pore diameter=84—309 Å). Previous experiments also indicated the ratio of the yield of CO_2 to that of CS_2 to be unity in the catalytic decomposition of COS up to 923 K, and no significant change in the catalytic activity and selectivity with time was observed at 473—923 K.

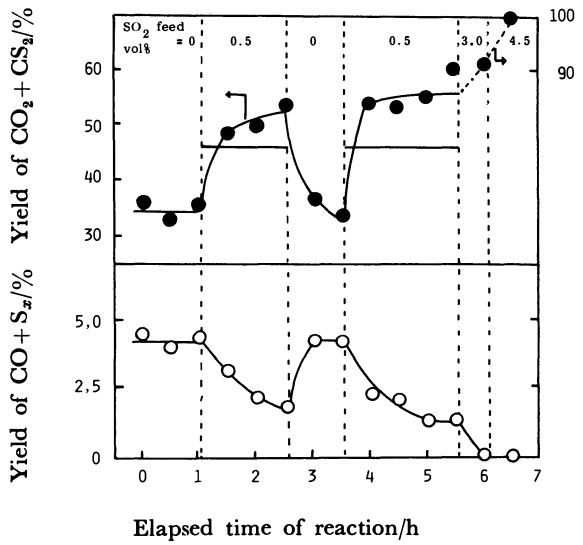

Fig. 1. Poisoning and promotional effects of SO_2 on the catalytic decomposition of COS at 763 K. Catalyst: JRC-ALO-4 Al_2O_3 1.0 g. COS+He: 200 (NTP)cm^3 min^{-1} (COS 10.0 vol%). The horizontal solid lines show the sum of the yield of CO_2+CS_2 in the absence of SO_2 (ca. 36%) and the yield of CO_2 calculated by assuming the complete consumption of introduced SO_2 due to Reaction 4(10.0%).

The yield of $CO+S_x$ was 14.3% over JRC-ALO-2 Al_2O_3, but it increased gradually with increasing the amount of basic sites and reached 16.9% over JRC-ALO-5 Al_2O_3. The selectivity to $CO+S_x$ also increased from 25.7% to 36.0% with such a change in the chemical properties of Al_2O_3 catalysts. In contrast, the yield of CO_2+CS_2 was the greatest, 41.3%, over the most acidic Al_2O_3 catalyst (JRC-ALO-2) and the selectivity to $CO+S_x$ was the lowest, 25.7%, over this catalyst.

The participation of electron-donating sites and acidic sites in the catalytic decomposition of COS was confirmed by the poisoning of JRC-ALO-4 Al_2O_3 catalyst with SO_2 at 763 K (Fig. 1). That is, the yield of $CO+S_x$ over JRC-ALO-4 Al_2O_3 decreased from 4.3% to 1.7% upon introduction of SO_2 into the reactant mixture (0.5 vol%) and the yield was nearly 0% when the concentration of SO_2 in the feed mixture was 3.0 and 4.5 vol%. When JRC-ALO-4 Al_2O_3 was degassed at 773 K for 1 h and then exposed to 20 Torr SO_2 at 673 K for 30 min, SO_2^- radicals with g values of $g_\perp$=2.002 and $g_{/\!/}$=2.008[9] were formed with an amount of ca. 10^{17} spins g^{-1}.

In contrast, the yield of CO_2+CS_2 increased upon introduction of SO_2 (Fig. 1). Here, a portion of SO_2 introduced reacted with COS to produce CO_2 and elemental sulfur according to Reaction 4.

$$SO_2 + 2COS \longrightarrow 2CO_2 + 3/xS_x \quad (4)$$

However, the yields of CO_2 observed in the presence of SO_2 were always greater than the sum (ca. 46%) of the yield of CO_2+CS_2 observed in the absence of SO_2 (ca. 36%) and that of CO_2 calculated by assuming the complete consumption of introduced SO_2 due to Reaction 4 (10.0%) (Fig. 1). This result is an evidence for the view that participation of acidic sites in the catalytic decomposition of COS to CO_2+CS_2 took place, as discussed later in this paper.

Preparation of CaO Catalysts. The results of Table 1 and Fig. 1 suggest that strongly basic and less acidic catalysts are superior for the catalytic decomposition of COS to $CO+S_x$. The preparation of

Table 1. Results of the Decomposition of COS over Al_2O_3 Catalysts at 873 K

Al_2O_3 catalysts	JRC-ALO-2	JRC-ALO-1	JRC-ALO-4	JRC-ALO-5
BET surface area/m^2 g^{-1}	298	176	174	253

Selectivity to $CO+S_x$/%	25.7	33.4	33.7	36.0

Catalyst: 1.0 g. COS+He:200(NTP) cm^3 min^{-1} (COS 5.0 vol%).
Data for the physicochemical properties of Al_2O_3 catalysts: Ref. 8.

strongly basic metal oxides by thermal decomposition of alkaline earth metal carbonates has been reported.[10] We have prepared CaO catalysts by thermal decomposition of $CaCO_3$ and then compared their catalytic activity and selectivity with their amount of electron-donating sites. Here, the amount of electron-donating sites was determined by the amount of SO_2^- radicals formed upon adsorption of SO_2 on CaO. Figure 2 shows the ESR spectrum of SO_2^- radicals formed on CaO. Figure 3 shows the variation of the amount of SO_2^- radicals formed on CaO prepared at different decomposition temperatures. $CaCO_3$ (0.178 g=CaO 0.10 g) was decomposed at various elevated temperatures for 5 h under 10^{-5} Torr. The obtained CaO was exposed to SO_2 at the pressure of 10 Torr at room temperature and was then heated at 473 K for 30 min in the presence of SO_2. The g values of SO_2^- radicals formed, g_1=2.008 and 2.009, g_2=2.004, and g_3=2.002 (Fig. 2), agree well with those reported.[10] The amount of SO_2^- radicals was negligibly small over CaO prepared at 873 K, but it increased with rising decomposition temperature to reach the maximum value (ca. 2×10^{17} spins g CaO^{-1}) at 1073—1123 K and then decreased with further rise (Fig. 3).

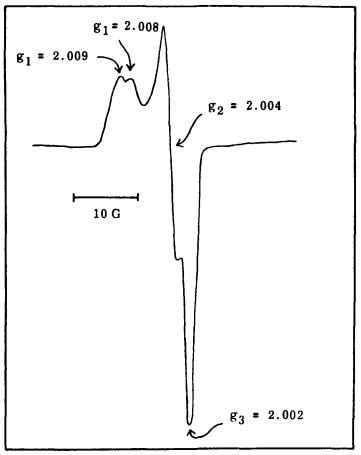

Fig. 2. ESR spectrum of SO_2^- radicals formed on CaO.
$CaCO_3$: 0.178 g (=CaO 0.10 g), decomposed at 1053 K for 5 h under 10^{-5} Torr. SO_2: 10 Torr, adsorbed at room temperature and then heated at 473 K for 30 min.

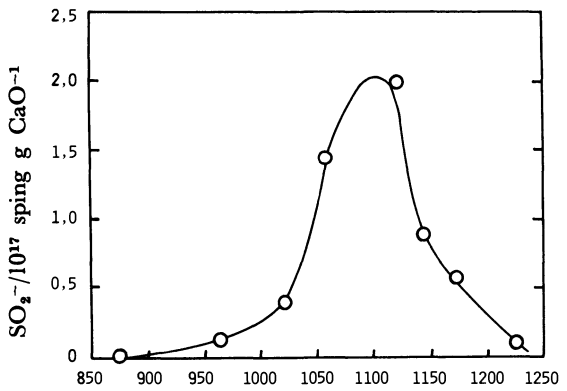

Fig. 3. Variation of the amount of SO_2^- radicals formed on CaO with rising decomposition temperature for thermal decomposition of $CaCO_3$.
$CaCO_3$: 0.178 g (=CaO 0.10 g), decomposed for 5 h under 10^{-5} Torr. The obtained CaO was exposed to SO_2 at the pressure of 10 Torr at room temperature and was then heated at 473 K for 30 min.

The rapid decrease in the amount of SO_2^- radicals above 1123 K is caused by the crystallization of CaO formed.[10] CaO catalyst prepared at a decomposition temperature of 1123 K had the greatest amount of electron-donating sites (Fig. 3).

Catalytic Decomposition of COS over CaO. Figure 4 shows the variation of the catalytic activity of CaO with rising decomposition temperature for $CaCO_3$. Here, $CaCO_3$ (0.89 g=CaO 0.50 g) was weighed into the catalytic reactor and was then decomposed for 5 h at various temperatures in flowing He(100(NTP) cm^3 min^{-1}). The obtained CaO was employed for catalytic studies without any exposure to air. These CaO catalysts also showed no significant change in the catalytic activity and selectivity with time during the decomposition of COS. The yield of $CO+S_x$ over CaO prepared at 923 K was 19.7% at 873 K, but it increased gradually with rising decomposition temperature to reach the

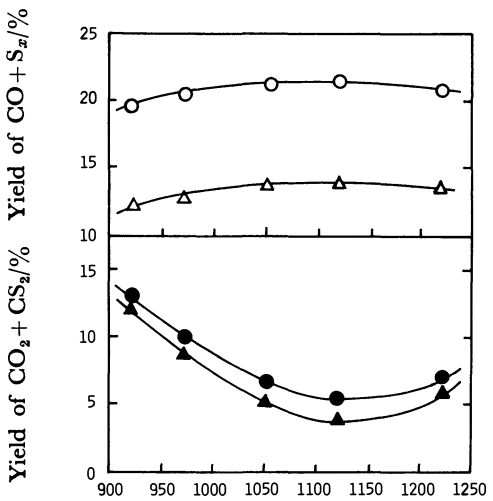

Fig. 4. Variation of the catalytic activity of CaO with rising decomposition temperature for $CaCO_3$.
$CaCO_3$: 0.89 g (=CaO 0.50 g), decomposed for 5 h in flowing helium (100(NTP)cm^3 min^{-1}) in the catalytic reactor. COS+He: 200 (NTP)cm^3 min^{-1} (COS 5.0 vol%). Reaction temperature: △,▲ —823 K, ○,● —873 K.

maximum value (21.4%) at a decomposition temperature of 1123 K and then decreased with further rise in decomposition temperature (Fig. 4). On the other hand, the yield of CO_2+CS_2 over CaO prepared at 923 K was 12.9% at 873 K, but it decreased with rising decomposition temperature to reach the minimum value (5.3%) at 1123 K and then increased with further rise. The selectivity to $CO+S_x$ at 873 K thus increased from 60.4% to 80.2% with rising decomposition temperature from 923 K to 1123 K and then decreased to 76.4% at 1223 K. A similar behavior of the catalytic activity and selectivity is seen at a reaction temperature of 823 K (Fig. 4). X-Ray diffraction analysis revealed no formation of calcium sulfide and calcium carbonate in these CaO catalysts during the catalytic decomposition of COS at 823 and 873 K. Thus, CaO catalyst prepared by thermal decomposition of $CaCO_3$ at 1123 K was the most active and selective one in the CaO prepared in the present work.

Effect of the Volume of Reactor. The observed relation of the yield of $CO+S_x$ with the temperature for thermal decomposition of $CaCO_3$ is fairly flat and the catalytic activity of CaO for the second reaction does not change so sharply as the amount of SO_2^- radicals formed (Figs. 3 and 4). A similar behavior can be seen between the yield of $CO+S_x$ over the referenced Al_2O_3 catalysts and their amount of basic sites (Table 1). These results suggest one possibility that a heterogeneously initiated homogeneous decomposition of COS to $CO+S_x$ also took place in the catalytic decomposition of COS at 823—873 K. This additional decomposition reaction must be of chain-reaction type. We have also studied the effect of volume of the reactor below catalyst bed on the catalytic activity and selectivity of JRC-ALO-4 Al_2O_3 at 873 K. As summarized in Table 2, the yields of $CO+S_x$ and CO_2+CS_2 and the selectivity to $CO+S_x$ were 16.9, 32.4, and 34.2%, respectively, when the volume of reactor below catalyst bed was 10 cm^3. Nearly the same values were obtained for the volume of 35 cm^3 (Table 2). Thus, no effect of the volume on the catalytic activity and selectivity was found.

Table 2. Effect of the Volume of Reactor below Catalyst Bed on the Catalytic Decomposition of COS at 873 K

Volume/cm^3	10	35
Conversion of COS/%	49.3	49.5
Yield of $CO+S_x$/%	16.9	16.5
Yield of CO_2+CS_2/%	32.4	33.0
Selectivity to $CO+S_x$/%	34.2	33.3

Catalyst: JRC-ALO-4 Al_2O_3 1.0 g. COS+He:200 (NTP) $cm^3\,min^{-1}$ (COS 5.0 vol%).

Discussion

The mechanism of the vapor-phase catalytic decomposition of COS was first investigated by Haas and Khalafala.[7] Since the degree of decomposition at a given temperature was approximately the same for such diverse catalysts as α-Al_2O_3, χ-Al_2O_3, Ti/χ-Al_2O_3, and silica gel regardless of their BET surface area and chemical composition, the catalytic decomposition of COS was believed to take place thermocatalytically.[7] In our previous studies on the catalytic oxidative dehydrogenation of hydrocarbons with COS over SiO_2, Al_2O_3, MgO, and TiO_2, however, it was demonstrated that the catalytic activity of these metal oxides for the decomposition of COS to $CO+S_x$ was great when the amount of electron-donating sites at the surface of these metal oxides was great.[6]

In the present work, the observed increase in the yield and selectivity to $CO+S_x$ with increasing the basicity of Al_2O_3 catalysts (Table 1) suggests that the participation of electron-donating sites in the catalytic decomposition of COS to $CO+S_x$ took place, as suggested previously.[6] On the other hand, the observation of the greatest yield of CO_2+CS_2 over the most acidic Al_2O_3 catalyst (JRC-ALO-2, Table 1) suggests the role of acidic sites (maybe Lewis acidic sites) in the catalytic decomposition of COS to CO_2+CS_2. These views are further supported by the results of poisoning of JRC-ALO-4 Al_2O_3 catalyst with SO_2 during the decomposition of COS, which resulted in the remarkable decrease in the yield of $CO+S_x$ (Fig. 1). Since COS^- radicals formed on the surface of MgO were readily decomposed to $CO+S_x$ even at low temperatures,[11] we believe that the catalytic decomposition of COS to $CO+S_x$ took place through the donation of electrons from the catalyst surface to adsorbed COS molecules.

$$\mathrm{COS} + * \rightarrow \overset{\mathrm{COS}^{\delta-}}{\underset{*}{\uparrow}}\mathrm{e} \rightarrow \mathrm{CO} + \mathrm{S} \rightarrow \mathrm{CO} + 1/x\mathrm{S}_x, \qquad (5)$$

where * is an electron-donating site at the surface of catalyst.

In contrast to the yield of $CO+S_x$, the yield of CO_2+CS_2 rather increased upon introduction of SO_2 (Fig. 1). It was reported that the catalytic activity of CaO–SiO_2 for the dehydrogenation of 1-butanol increased upon introduction of pyridine into the reactant mixture.[12] This promotional effect of pyridine was explained in terms of the high electron-donating ability of pyridine: The surface sites adjacent to adsorbed pyridines become rich in electron density and these sites act as basic sites.[12] In the present work, an acidic gas SO_2 was fed into the catalytic reactor and was adsorbed as SO_2^- at the

surface of Al_2O_3 catalyst. Hence it is probable that upon introduction of SO_2 the strength of Lewis acidic sites adjacent to adsorbed SO_2^- was greatly enhanced or that the surface sites adjacent to adsorbed SO_2^- became acidic sites. We believe that this inductive effect of SO_2 gave rise to increase in the catalytic activity of Al_2O_3 for the decomposition of COS to CO_2+CS_2. A concerted mechanism involving the participation of Lewis acidic sites and electron-donating sites is rejected for the reaction of COS to CO_2+CS_2 since the latter sites were poisoned by SO_2 (Fig. 1). We now believe that a COS molecule adsorbed on a Lewis acidic site reacts with a gaseous COS molecule to form a surface intermediate which then decomposes into CO_2+CS_2.

$$\begin{array}{l} \mathrm{COS} + * \rightarrow \underset{*}{\overset{\mathrm{COS}^{\delta+}}{\downarrow \mathrm{e}}} \quad + \mathrm{COS(g)} \\ \qquad\qquad\qquad\qquad \rightarrow \quad (\mathrm{intermediate})_{\mathrm{ads}} \\ \qquad\qquad\qquad\qquad\qquad \rightarrow \mathrm{CO_2} + \mathrm{CS_2} \end{array} \qquad (6)$$

where * is a Lewis acidic site.

Haag and Miale[5] proposed that the catalytic decomposition of COS to CO_2+CS_2 takes place through participation of surface sulfur atoms evolved by the decomposition of COS to CO+S. In the present work, however, the catalytic decomposition of COS to CO_2+CS_2 took place even at such low reaction temperatures as 473—573 K at which the catalytic decomposition of COS to CO+S_x did not take place (e.g., JRC-ALO-2 Al_2O_3, yield of CO_2+CS_2= 17.8% at 473 K and 23.4% at 573 K). This finding does not support the mechanism of CO_2+CS_2 formation proposed by Haag and Miale. Thus, in addition to the thermocatalytic mechanism proposed by Haas and Khalafala,[7] we propose the mechanism for the decomposition of COS involving the participation of surface electron-donating sites and Lewis acidic sites.

The above mechanistic finding made in the present work indicates that strongly basic catalysts are superior for the selective decomposition of COS to CO+S_x. CaO catalysts prepared by thermal decomposition of $CaCO_3$ have been well known as strongly basic catalysts. In the present work, CaO catalysts thus prepared showed very low catalytic activities for the decomposition of COS to CO_2+CS_2 compared with Al_2O_3 catalysts and the selectivity to CO+S_x was as high as 60—80% at 873 K (Table 1, Fig. 4). Particularly CaO catalyst prepared at 1123 K, which had the greatest electron-donating ability, showed the greatest values of the yield and selectivity to CO+S_x (21.4 and 80.2%) and at the same time the lowest yield of CO_2+CS_2 (5.3%) at 873 K (Figs. 3 and 4). This superiority of CaO catalyst prepared at 1123 K can be understood by comparing with the equilibrium conversion of COS at 873 K. That is, in the reaction conditions empolyed in Table 1 and Fig. 4 elemental sulfurs at equilibrium are of S_2 type[13] and the equilibrium conversions of COS to CO+S_2 and CO_2+CS_2 are 27.3 and 35.3%, respectively, the selectivity to CO+S_2 being 43.6%.[14] Although the surface acidity was not determined for these CaO catalysts, the observation of the greatest values of the yield and selectivity to CO+S_x and the lowest value of the yield of CO_2+CS_2 over CaO catalyst prepared at 1123 K (Fig. 4) is as expected.

On the other hand, the absenece of the effect of volume of the reactor below catalyst bed on the catalytic activity and selectivity of JRC-ALO-4 Al_2O_3 (Table 2) does not indicate the presence of a heterogeneously initiated chain reaction-type homogeneous decomposition of COS to CO+S_x in the catalytic decomposition of COS. At present, the reason for the lack of a close relation between the yield of CO+S_x and the amount of SO_2^- radicals (Figs. 3 and 4) is not known. At any rate, the above findings made in the present work suggest the possibility that we can further enhance the catalytic activity and selectivity for the decomposition of COS to CO+S_x by preparing much more strongly basic catalysts.

Catalysis by Transition-Metal Carbides. VII. Kinetic and XPS Studies of the Decomposition of Methanol on TiC, TaC, Mo_2C, WC, and W_2C

Masahiro ORITA, Isao KOJIMA, and Eizo MIYAZAKI*
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received July 5, 1985)

The catalytic decomposition of methanol was investigated on a series of powdered transition-metal carbides, such as TiC, TaC, Mo_2C, WC, and W_2C, which had been catalytically activated by evacuation at high temperatures. WC was found to produce methyl formate ($HCOOCH_3$) with a high selectivity (above 80%), whereas CO and H_2 were mainly produced on clean TaC, Mo_2C, and W_2C surfaces. XPS measurements combined with an analysis of the peak intensities revealed that the catalytic activation of WC and TaC was attributable to the removal of surface oxygen and the subsequent formation of monocarbide surfaces. On the other hand, the minor activities leading to the formation of methyl formate on W_2C and Mo_2C were concluded to be due to the formation of oxycarbide surfaces. The deuterium distributions in the products during the reaction of CH_3OD suggest that the methyl formate is produced via the dimerization of the intermediate adspecies, CH_2O.

The transition metal carbides have been well investigated because of their unique physical properties, such as extremely high melting points, metal-like thermal and electronic conductivities, paramagnetism, and superconductivity.[1] In addition, they have recently been shown to form an interesting new group of catalysts;[2-7] the ordered incorporation of carbon atoms into a metal lattice makes chemisorptive and catalytic properties different from those of the parent metals. In order to characterize carbide catalysts, we have investigated the catalytic activities of the carbides of TaC, TiC, WC, and Mo_2C and have found that they exhibit high activities for the hydrogenation of benzene,[8] ethylene,[9,10] and carbon monoxide.[11] Further, detailed kinetic studies of the hydrogenation of carbon monoxide on powdered WC, W_2C, and W showed that the catalytic behavior of WC was in contrast with that of W_2C and W, that is, the activity depended on the carbon/metal ratio and on the lattice structure.[12]

On the other hand, the dehydrogenation of methanol to produce methyl formate with a high selectivity is currently an important problem in heterogeneous catalysis in relation to C_1 chemistry, and a great deal of research has been conducted into the catalysis of this reaction by metal and metal-oxide surfaces. In a previous paper,[13] it was found that WC was an excellent catalyst for producing methyl formate from the decomposition of methanol. In the present paper, we wish to report the detailed kinetic and XPS results for TiC, TaC, WC, W_2C, and Mo_2C.

Experimental

Two reaction systems were employed. One was a recirculation reactor, 520 ml in volume, which was directly connected with a gas chromatograph system equipped with two separation columns containing Porapak Q and Molecular sieve 5X. This system also had a U-tube connected to the gas circulation system to remove the condensable products from the reaction system during the course of the reaction by cooling them to a lower temperature. The other was a UHV batch reactor made of metal and glass. The analysis of the gas-phase composition was done by means of a quadrupole mass analyzer (ANELVA AGA 100). Most of the kinetic measurements were carried out using the former reactor. The distribution of D atoms contained in the products was, however, analyzed by the use of the latter batch reactor.

The reactants, CH_3OH(obtained from the Nakarai Kagaku Co., 99.6% pure) and CH_3OD(Merck, 98%), were subjected to vacuum distillation to remove any dissolved air prior to use for the reaction measurements. The powdered catalysts, TiC(99% purity), TaC(99%), WC(99%), W_2C(99%), and Mo_2C(99%), were obtained from Furu-uchi Kagaku or M. R. C., and they were catalytically activated as has been described previously[9,10] by heating in a vacuum at various high temperatures.

The surface analysis of the catalysts was performed on a Hewlett-Packard 5950A ESCA spectrometer, using monochromatic Al $K\alpha$ excited radiation. The samples, pressed into disks, were transferred into the preparation chamber of the spectrometer and subjected to in situ heat-treatment in a vacuum.

Results

Product Distributions. Table 1 shows the kinetic results and the product distributions at a 20% conversion of methanol on various carbide catalysts which had been pretreated at high temperatures in a vacuum. As has been reported previously on the hydrogenation of benzene[8] and ethylene,[9,10] the catalytic activities for methanol decomposition on TaC and WC were generated by evacuation at 1000 °C for TaC and 700 °C for WC and were almost unchanged up to 1200 °C. TaC produced mainly CO and H_2, plus a small amount of CO_2, and the product distribution did not depend on the temperature for the activation of the catalyst, whereas the activity gradually decreased with repeated use. WC produced methyl formate with a high selectivity (above 80%). On the other hand, the catalytic activities of Mo_2C were found to increase gradually

Table 1. The Kinetic Results and the Product Distributions on Various Carbides

Catalysts	Evacuation temperature / °C	Reaction temperature / °C	Initial rate[a] of CH_3OH consumption/(molecule s^{-1} g^{-1})	Distribution of carbon-containing products / %
TiC	1000	300	0	—
Tac	1100	190	3.1×10^{17}	CO(91), CO_2(9)
WC	900	200	1.5×10^{17}	HCO_2CH_3(81), CO(19)
W_2C	1200	220	3.5×10^{17}	CO(83), HCO_2CH_3(17)
Mo_2C	500	300	2.2×10^{17}	CH_4(84), CO(16)
	800	200	2.5×10^{17}	CO(59), HCO_2CH_3(41)
	1000	200	5.0×10^{17}	CO(100)

a) The initial pressure of methanol is 23 Torr (1 Torr=133.322 Pa).

with an increase in the evacuation temperature, and the distribution of products also varied with it; following the evacuation at 500 °C, the main products were CH_4, H_2O, H_2, CO_2, and CO, but at 800 °C they were CO, H_2, and methyl formate, and at 1000 °C they were only CO, and H_2. The activities of W_2C also increased with the increase in the evacuation temperatures, while the product distribution was unchanged. In the table, results at the highest activity are given for W_2C; the main products were CO, H_2, and methyl formate, while the selectivity for methyl formate was much lower than that of WC. The activity of TiC was negligible below 300 °C, whereas above 400 °C small amounts of CH_4 and H_2O were formed.

Kinetic Measurements. It is to be noted that, among the metal-carbide catalysts, only WC produced methyl formate with a high selectivity. The detailed kinetic measurements of WC were performed in order to compare the reaction mechanism with the previous results on the transition-metal and oxide catalysts on which the kinetics had already been established. Figure 1 shows the changes in the gas-phase components with the reaction time for the methanol decomposition at 200 °C. It may be seen that in the initial stage of the reaction, methyl formate appeared more rapidly than CO and reached almost a constant concentration after 30 min, while the CO concentration monotonously increased with the time. After 45 min, the U-tube connected to the reactor was cooled to −42 °C to reduce the methanol concentration and to allow the methyl formate to remain in the gas phase. However, the concentration of methyl formate gradually decreased, accompanied by almost twice as large an increase in CO, indicating that the methyl formate decomposed into CO. The selectivity for methyl formate on WC is plotted against the conversion at diferent reaction temperatures in Fig. 2. With the increase in the reaction temperature the selectivity apparently decreased, however it reaches nearly 100% when the line is extrapolated to zero conversion in each case.

The pressure and temperature dependences were

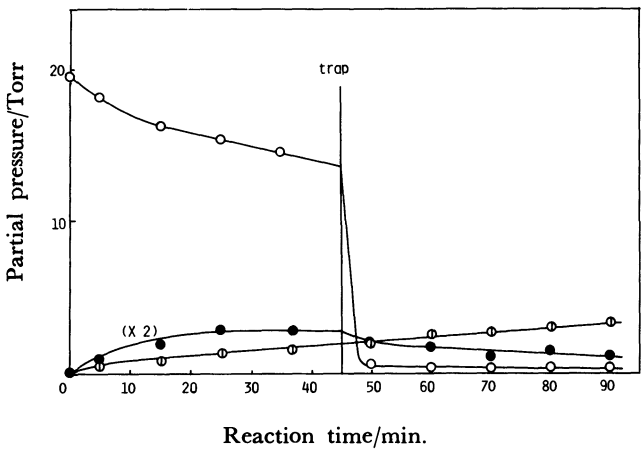

Fig. 1. The change in the gas phase components with the reaction time. After 45 min reaction, the U-tube was cooled down to −42°C. ○: Methanol, ⓘ: carbon monoxide, ●: methyl formate.

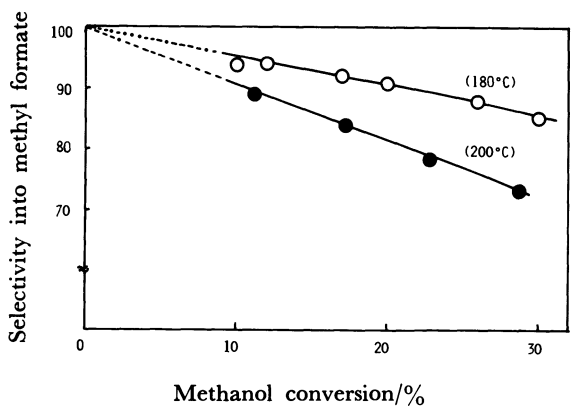

Fig. 2. The selectivity into methyl formate on WC as a function of the methanol conversion. The initial methanol pressure is 21.4 Torr. Reaction temperatures are 180 and 200 °C.

measured by changing the initial pressure of methanol and the reaction temperature respectively. It was found that the plots of the reciprocal of the reaction rate($1/r_0$) against the reciprocal of the initial pressure($1/p_0$) gave straight lines for a constant reaction temperatures, as is shown in Fig. 3. The

apparent activation energy was then estimated to be 6.2 kcal† mol^{-1}. The reaction of CH_3OD was also investigated using the batch-type reactor. Figure 4 shows the changes in the concentrations of deuterated methyl formate in the gas phase. The line was drawn using the mass peaks of m/z=59—64 and fragment patterns with a least-square approximation; d_0-methyl formate was predominantly formed in the initial stage of the reaction. The amount of d_1-species became appreciable with the passage of the time, but the d_2- to d_5-species produced by successive exchange reactions were negligible. Furthermore, among the molecules of H_2, HD, and D_2 produced during the decomposition, HD was predominant at the initial stage of the reaction.

The kinetic measurements were also carried out on Mo_2C, where the main products were CO and H_2. A linear relationship similar to that of WC was also obtained between $1/r_0$ and $1/p_0$. The reaction order and the apparent activation energy were found to be about 1.0 at 160 °C and 5.4 kcal mol^{-1} respectively.

XPS Measurements. The XPS spectra were measured for all the catalysts employed. A part of the results have been published previously.[9,10] In Table 2 are summarized the atomic ratios of the surface concentration of the C or O atom to that of metal atoms of the catalysts which had been evacuated under conditions similar to those employed in the kinetic measurements. The ratios of the concentrations of the constituent atoms were estimated from the integrated peak area, upon taking into consideration the photoelectron cross section, the mean free path of electrons, and the apparatus function which is dependent on the kinetic energy of photoelectrons.[14] For the activated WC and TaC surfaces the ratio of C atoms to metals came out to be nearly unity. WC showed no traces of any contaminant oxygen, but TaC was slightly covered with oxygen. The values of the carbon/metal ratio for TiC and W_2C were lower than in the bulk composition, and their surfaces was found to be covered with oxygen. XPS measurements of Mo_2C were done for samples evacuated at room temperature, 550, 800, and 1050 °C since the catalytic behavior of Mo_2C changed with the evacuation temperature. Figure 5 shows the spectra of the Mo 3d, and the O ls regions for Mo_2C. Without any heat-treatment, the catalyst surface was mostly covered with oxygen and the Mo 3d states mainly consisted with highly oxidized states, as may be seen in Fig. 5(a) and (e). Following the evacuation at 550 °C, the peaks corresponding to Mo 3d shifted to the lower-binding-energy side, with a mixing of several states. Following the evacuation at 800 °C, two peaks due to the spin-orbit coupling of Mo 3d appeared, along with small shoulders on the higher-binding-energy side. At 1000 °C, they turned into two sharper peaks, and the peak due to O ls

Table 2. The Atomic Ratio of the Surface Concentration of C or O Atom to that of Total Metallic Species in the Catalysis

	Treatment temperature	Atomic ratio C/M	O/M
TiC	1100 °C	0.8	0.3
TaC	1130	1.1	0.1
WC	1080	0.94	0.0
W_2C	700[a]	0.33	0.3
Mo_2C	20	0.12	2.9[b]
	550	0.15	1.3
	800	0.13	0.8
	1050	0.18	0.1

a) The sample was reduced in the H_2 atmosphere at the temperature. b) Ratio of O to Mo(1) species.

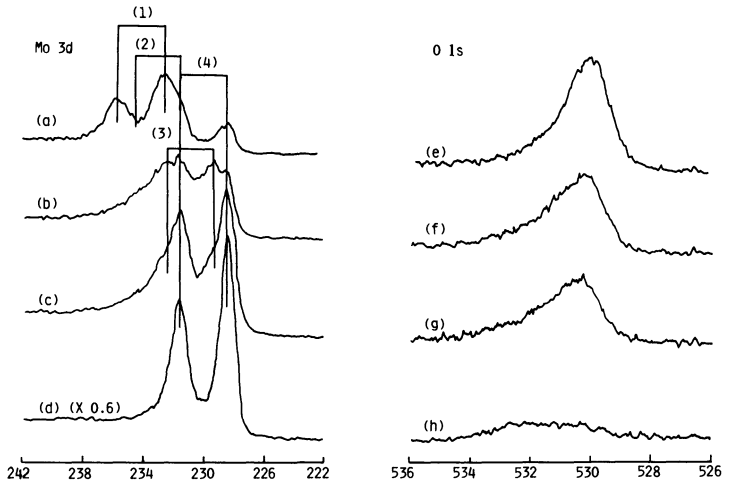

Fig. 5. The change of XPS spectra of Mo 3d and O 1 s regions for Mo_2C with pretreated temperatures. (a), (e); 20°C, (b), (f); 550°C, (c), (g); 800°C and (d), (h); 1050 °C.

almost disappeared. The various peaks in the Mo 3d regions described above can be classified into 4 different states, labeled from (1) to (4) in Fig. 5 (a—d). State 1, with the highest binding energy (232.6, 235.6 eV) observed mainly for the untreated surface, can be attributed to the Mo^{6+}-oxidized state, since the binding energies are almost identical to the values[15] reported for MoO_3 and the observed O/Mo ratio is also close to the ratio of the composition. State 2 (231.5, 234.6 eV) may be assigned to Mo^{5+} from the XPS results on the Mo/Al_2O_3 catalyst reported by Patterson et al.[15] Above the evacuation temperature of 800 °C, State 4 (228.3, 231.5 eV) becomes predominant, and the binding energies are larger than those of Mo metal, suggesting the formation of the carbide.[16] However, it is noteworthy that the C/Mo ratio is much smaller than that expected from the initial bulk composition. The sample evacuated at 800 °C is also interesting in the sense that it contains a slightly oxidized State 3 (229.4, 232.6 eV); this sample exhibited a special catalytic activity of producing methyl formate.

The XPS spectra of the valence regions are given in Fig. 6. The densities of states below E_f, which arise mainly from C 2p and metal d-electrons, are distinctive for the carbide catalysts: TiC and TaC have rock salt structure in which the electronic structures can be explained essentially in terms of a simple rigid-band model. The minimum of the density of states occurs at E_f for TiC; and thus, the extra electrons in Ta are induced to fill the higher-energy antibonding bands to increase the destabilization of TaC. This destabilization effect is compensated for by the lowering of the d-bands relative to the C 2p state for TaC. However, the additional filling of electrons which might occur for VIa-metal

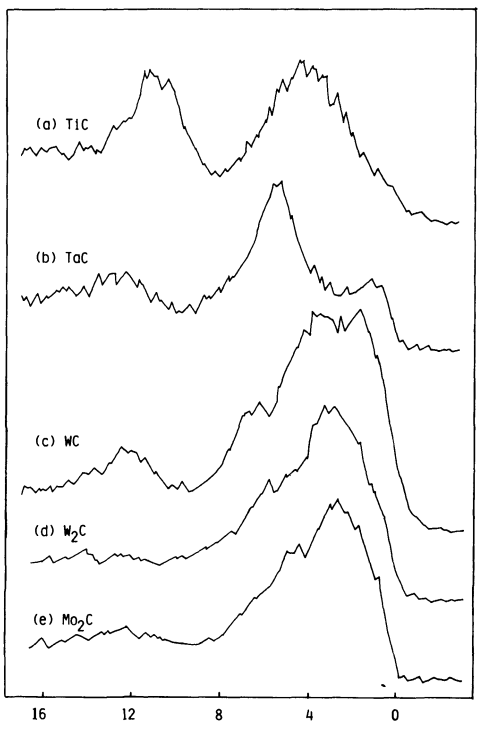

Fig. 6. The XPS valence band spectra of TiC, TaC, WC, W_2C, and Mo_2C.

elements, like W and Mo, change the crystal structure of their carbides into hcp; this results in a more extensive mixing of C 2p with metal d-electrons than in the rock salt structure. The peaks around 12 eV below the E_f correspond to C 2s bands. The difference in the intensities of the C 2s peaks relative to the density of the states near E_f is due to the difference in the photoelectron cross-section of d-

electrons in metal, which increase with an increase in the atomic number.[17] The present XPS spectra of WC and W_2C are generally consistent with those reported previously;[18] it is worth mentioning that the densities of the states of WC near E_f are higher than those of W_2C and Mo_2C. The lower intensities of the C 2s peaks of W_2C and Mo_2C, which are about one-half that of WC, suggest the accumulation of metallic species near the surface.

Discussion

Reaction Mechanism. So far, kinetic studies of the decomposition of methanol have been extensively carried out on various transition metals and their oxides.[19–22] Miyazaki et al. made detailed investigations of Cu[23] and Ni[24] catalysts and proposed two different reaction pathways for the decomposition of methanol. A recent review by Joyner also proposed two kinds of reaction mechanisms on the metallic catalysts;[25] one was a process to form methyl formate as given by Scheme 1, while the other was a process to decompose into CO and H_2 as is given by Scheme 2. The reaction mechanism by Scheme 1 is well known to occur on Cu and Ag catalysts, whereas Scheme 2 is for Pd, Rh, and Ni.

$$CH_3OH(g) \rightleftarrows CH_3OH(a) \quad (1a)$$
$$CH_3OH(a) \rightleftarrows CH_2O(a) + H_2(g) \quad (2a)$$
$$2CH_2O(a) \rightleftarrows HCOOCH_3(g) \quad (3a)$$

Scheme 1.

$$CH_3OH(g) \rightleftarrows CH_3O(a) + H(a) \quad (1b)$$
$$CH_3O(a) \rightleftarrows CH_2O(a) + H(a) \quad (2b)$$
$$CH_2O(a) \rightleftarrows CHO(a) + H(a) \quad (3b)$$
$$CHO(a) \rightleftarrows CO(a) + H(a) \quad (4b)$$
$$2H(a) \rightleftarrows H_2(g) \quad (5b)$$
$$CO(a) \rightleftarrows CO(g) \quad (6b)$$

Scheme 2.

The present results of methanol decomposition on the transition metal carbide catalysts may be interpreted within a similar framework; WC was found to produce methyl formate with a high selectivity, whereas the other carbides produced mainly CO and H_2. The one slight exception is on TiC and Mo_2C, where CH_4 and H_2O were produced. Since these products were generally formed on metal oxide catalysts[26] and since the XPS spectra showed presence of considerable oxygen on the catalysts, this distribution may safely be attributed to the oxide formation on the surfaces. The high selectivity for methyl formate on WC makes it easy to investigate the reaction mechanism. The linear relationship in Fig. 3 leads to the following rate equation in the initial stage of the reaction on WC

$$r_0 = a\,p_0/(1 + b\,p_0), \quad (1)$$

where a and b are constants. This rate Eq. 1 suggests that the decomposition of the adsorbed methanol into an intermediate adsorbate is the rate-determining step. As is shown in Fig. 4, the selective formation of d_0-methyl formate and HD from CH_3OD in the initial stage of the reaction strongly suggests that the reaction given by Step (2a) proceeds on the surface. These findings are quite similar to those observed on the Cu surface.[23]

Scheme 2 shows, on the other hand, that the decomposition into CO and H_2 is initiated by the dissociative adsorption of methanol into methoxide and H species. As no methyl formate was detected, the intermediate methoxide is considered to decompose directly via Steps (2b)—(4b) into CO. Further, the UPS results of NbC(111)[27] revealed the formation of methoxide after the admission of methanol, suggesting the involvement of a surface reaction like Step (2b) on W_2C, TaC, and clean Mo_2C, where the main products are carbon monoxide and hydrogen. The similar pressure dependence of the rate on Mo_2C to the rate equation (I) suggests that Step (2b) in Scheme 2 is the rate-determining step. Thus, the reaction Schemes (1 and 2) given above are also effective for the metal-carbide catalysts; the different product distributions among the carbide catalysts seem to result from the different stabilizations of intermediate species, $CH_3O(a)$ and $CH_2O(a)$.

Characteristics of Transition-Metal Carbides. (i) In the previous studies, the surface oxygen was found to play a dominant role in the catalytic activation of transition-metal carbides; the presence of oxygen strongly reduced the activity of the hydrogenation of benzene[8] and ethylene[9,10] on TaC. The present kinetic and XPS measurements also indicate that the removal of surface oxygen is necessary for the generation of the activity of methanol decomposition on TaC and WC. On the other hand, Mo_2C pretreated in vacuo at 800 °C yielded activities comparable to those of TaC and WC, even though its XPS spectra revealed the presence of a large amount of oxygen on the surface. Interestingly, on such a surface with oxygen, an appreciable amount of methyl formate is formed, whereas clean Mo_2C evacuated at 1100 °C, produced merely CO and H_2. This shows that the surface oxygen on Mo_2C forms an oxycarbide[3] like MoO_xC_y and that its electronic states are varied to be suitable for stabilizing the $CH_2O(a)$ adsorbate. The minor selectivity into methyl formate observed on W_2C may also be ascribed to the partial formation of oxycarbide. Thus, such oxycarbide-oxygen in dimetallic carbides of Mo_2C, and W_2C apperantly

behaves as "carbon" in the corresponding monocarbides, though MoC has not been obtained as a stable substance.

(ii) It is generally accepted that the electronic states near E_f have great importance for the chemical activity of a surface. Information about these states is available from the measurements using photoelectron spectroscopy. The few studies[18,28,29] which have been done following the first suggestion by Levy and Boudart[30] that the catalytic activity of WC is to be attributed to the density of states similar to Pt conflict as to the point whether or not the chemical activity can be directly related to the state densities of the valence regions. As is shown in Fig. 6, it seems to be sure that the onset of sharp peaks at E_f of TaC is responsible for the appearance of larger catalytic activity as compared with TiC and that the catalytic properties of WC can be related to the higher state density at E_f than at W_2C, although it is not clear in all cases that the higher density at E_f is related to the higher catalytic activity.

(iii) In the present work, the distinctive selectivity between WC and W_2C for methyl formate was shown. The improvement of selectivity for methyl formate by alloying into carbides was also reported by Ko et al.,[4,5] TPRS studies on Mo and W single crystals have shown that methyl formate is not formed from formaldehyde on the pure metal surfaces, but is apparently formed after the carburization of these crystals. Similar results were also obtained on powdered Ni catalysts at the reaction temperature of 30—80 °C.[31] The formation of carbide may result in the reduction of the chemical activity of the adsorbing gases and in suppression of the complete decomposition into C, O, and H atoms which occurs on the original pure metals.

(iv) It is likely that, for alloy systems with rigid crystal structures, like metal carbides, the surface arrangement of the constituent atoms plays a dominant role in the catalytic activity. According to recent calculations of the band structures of the bulk and surface of WC[32] by Mattheiss and Hamann, the metal-terminated W(1×1) surface of WC(0001) exhibits a distinctive surface-state density due to d-electrons at E_f. The work function of the metal-terminated surface is also much smaller than that of the carbon-terminated surface. Recently, surface spectroscopic studies of transition-metal carbides have been performed under uhv conditions using such single-crystal surfaces as TiC(100), TiC(111),[33,34] NbC(100), and NbC(111).[27] An important finding of these studies is that their cleaned (111) surfaces consist of metals on the topmost layer; thus they are chemically more active than the (100) surfaces which consist of a regular array of coexisting metal and carbon atoms. The previous comparative investigation of WC, W_2C, and W powdered catalysts for the hydrogenation of CO also showed that the catalytic behavior of WC is quite in contrast with those of W_2C and W; the metal-terminated surfaces are responsible for the catalysis, since the electronic states of the topmost metal layer of WC(0001) would preferably be modified by the second carbon underlayer to produce an active site for the hydrogenation of carbon monoxide, while, on the other hand, the influence of the third carbon layer on the topmost tungsten layer of W_2C would be small. These effects may contribute to the distinctive selectivity between WC and W_2C presently observed for the formation of methyl formate. Therefore, the complete carburization of W to form WC seems necessary for the appearance of a new catalytic feature to produce methyl formate on WC.

Flocculation of Iron(III) Oxide Hydrate Sols Induced by α,ω-Type Surfactants

Kunio Esumi,* Kazuki Yamada, Toshie Sugawara, and Kenjiro Meguro
Department of Applied Chemistry, Institute of Colloid and Interface Science,
Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received July 23, 1985)

The interactions of disodium salt of bis(3-sulfopropyl) α,ω-alkanedicarboxylate(C10-α,ω and C12-α,ω) with monodispersed spherical particles of iron(III) oxide hydrate sols were studied by measuring the mean particle size, the zeta-potential and the amounts of adsorption. The sols were flocculated by the addition of small amounts of C10-α,ω and C12-α,ω. The flocks thus formed were redispersed by the further addition of these surfactants. The flocculation of sols upon the addition of α,ω-type surfactants occurred over a wider concentration range than upon the addition of an ordinary surfactant, such as sodium dodecyl sulfate(SDS). Furthermore, the mechanism of redispersion upon the addition of α,ω-type surfactants is different with the two-fold adsorption layer in SDS.

Studies of the interactions between surfactants and solid particles in an aqueous solution are very important from the point view of the dispersion stability of solids.[1-4] For this reason, the mechanism of the flocculation and redispersion of sol particles in the presence of surfactants[5,6] has been reported. However, the surfactants used in these works were ordinary ones which have a hydrophilic group at one end of the hydrophobic chain.

Recently, some reports on α,ω-type surfactants, which have a hydrophilic group at each end of a long hydrocarbon chain, have been published.[7-9] It seemed that it would be interesting to study the interactions of solid particles with α,ω-type surfactants, because α,ω-type surfactants could be expected to interact with solid particles differently from ordinary ones because of their structure.

In this work, the interactions between α,ω-type surfactants and monodispersed spherical particles of iron(III) oxide hydrate sols were investigated by measuring the mean particle size, the zeta-potential, and the amounts of adsorption. The results obtained were compared with those of an ordinary surfactant.

Experimental

Materials. (a) Surfactant: Disodium salt of bis(3-sulfopropyl)-α,ω-alkanedicarboxylate[7-9] was prepared from the corresponding dimethyl α,ω-alkanedicarboxylate, sodium hydroxide, and 1,3-propanesulfone, which had all been purified by vacuum distillation. The crude product was recrystallized three times from methanol and then further extracted for 100 h with acetone by means of a Soxhlets extractor.

The chemical formulae of the α,ω-type surfactants were as follows:

$$NaO_3S(CH_2)_3OOC(CH_2)_nCOO(CH_2)_3SO_3Na \quad (n=10,\ 12)$$

(b) Monodispersed Spherical Particles of Iron(III) Oxide Hydrate Sol: Hydro-sols consisting of spherical hematite particles with a narrow size distribution were prepared by essentially the same procedure as Matijevic et al.[10,11] described. 6.66 cm^3 of a 2.97 M† $FeCl_3$ solution was diluted to 1000 cm^3 with HCl(pH 3.1). Approximately 200 cm^3 of this solution was then passed through a 0.22 μm Nuclepore filter in order to equilibrate the membrane, after which the filtrate was discarded. The rest of the solution was filtered and distributed in 10 cm^3 screw-capped test-tubes, which were then aged for 24 h at 100 °C in an air-convection oven controlled at a constant temperature (Model DN-61, Yamato Science Co.). After cooling to room temperature, the collected particles were diluted with $HClO_4$ (pH 3.1) and then centrifuged at 8000 rpm for 30 min. The supernatant solution was discarded, and the particles were again diluted with the same $HClO_4$ solution and centrifuged. This procedure was repeated eight times. Upon the completion of the washing, the particles were redispersed in ion-exchanged water to be used as a stock sol. The washing process was repeated until no chloride or iron(III) ions could be detected in the supernatant solution. The final stock sol had a concentration of 1.31 mg cm^{-3}, as determined directly by dry-weight measurement, and was kept at pH 5.8.

The mean particle size was determined by the use of a particle analyzer(Autosizer Model 700, Malvern Co., Ltd.). The average diameter was 130 nm. X-ray diffraction measurements showed that the nearly spherical particles of α-Fe_2O_3 were paracrystalline; they consisted of very uniform globular crystallites.

Methods. The pH and the ionic strength of mixtures containing given amounts of ferric oxide sol and a surfactant were adjusted to make then suitable; then the mixture was agitated at a constant temperature(25 °C) for 2.5 h. In order to keep the ionic strength constant, all the measurements were carried out in 1×10^{-2} M sodium chloride: hydrochloric acid and sodium hydroxide were used to adjust the pH of these mixtures.

Measurements. (1) Zeta-Potential: The zeta-potential of the sols was measured at 20 °C by means of an electrophoresis apparatus, Laser-Zee meter Model-500(Pen Kem, Inc.). The zeta-potential values were calculated by using the Helmholtz-Smoluchowski

† 1 M=1 mol dm^{-3}.

equation:

$$\zeta = K\eta V/\varepsilon E,$$

where ζ is the zeta potential, K is a constant, η is the viscosity of the medium, V is the mobility, ε is the dielectric constant of the medium, and E is the electric field.

(2) Amount of Adsorption: Sixty cm^3 of the sol dispersion was mixed with the solution of the α,ω-type surfactant solutions of various concentrations, and the mixture was stirred for 2.5 h at 25 °C. After the adsorption was reached an equilibrium, the dispersion was separated by centrifugation at 10000 rpm for 30 min. A Methylene Blue acidic solution was added to the supernatant solution, and then the anionic surfactant–Methylene Blue complex thus formed was extracted in the chloroform phase.[12,13] The absorbance of the extract was measured at 652 nm by means of a double-beam spectrophotometer (220A, Hitachi Co.). The amount of adsorption was calculated from the difference in the absorbance before and after the adsorption.

(3) Stability Ratio: As soon as the sols had been mixed with the surfactant solution, the turbidity of the mixture was recorded and the initial slope of the optical density vs. time curve was obtained. The measurements were carried out at 25 °C and at a wavelength of 540 nm. The stability ratio(W) was calculated from the ratio of the rapid-coagulation rate(k_0) to the slow-coagulation rate(k) of sols:[14]

$$W = k_0/k$$

(4) Flushing: The sols flocculated by the addition of the surfactant solution were added to organic solvents, and then the mixture was shaken. The behavior of flushing for sols was observed with the naked eye.

Results and Discussion

In order to characterize the iron(III) oxide hydrate sol, the zeta-potential and the mean particle size of single sol were measured as a function of the pH. The isoelectric point of sol was estimated to be pH 7, which agreed fairly well with the literature value.[10]

On studying the interactions between iron(III) oxide hydrate sol and each surfactant, the values of the zeta-potential and the mean particle size of sols at various pH values were measured as a function of the concentration of each surfactant. Further, the amounts of surfactant adsorbed on sols were determined at two different pH values, i.e., pH 3.5 and pH 5.8. As it is considered that the interactions between the sol and anionic surfactant in an alkaline solution seem less significant because the surface of sol is negatively charged in alkaline solution, the pH values described above were employed.

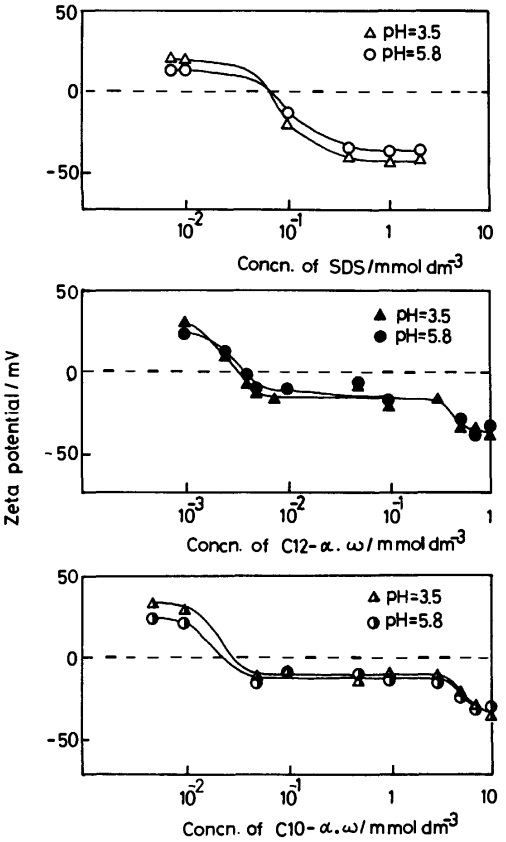

Fig. 1. The change in zeta-potential of sols as a function of concentration of surfactant.

Figure 1 shows the change in the zeta-potential of sols as a function of the concentration of the surfactant at pH 3.5 and pH 5.8. In the case of SDS, the surface of the sol charged positively at the initial stage became negative with an increase in the concentration of SDS, and the value of zeta-potential reached at a constant value, −40 mV. The results obtained for α,ω-type surfactants were similar to those of SDS. However, in the case of an α,ω-type surfactant, the zeta-potential was kept constant over a wide range of concentration at about −10 mV and then, with the further addition of an α,ω-type surfactant, decreased to about −40 mV for both α,ω-type surfactants.

Figure 2 shows the change in the mean particle size of the sols as a function of the concentration of the surfactant at pH 3.5 and pH 5.8. The particle size of the sols increased suddenly upon the addition of the surfactant, indicating that the sols were flocculated. Upon the further addition of the surfactant, the particle size of sols decreased again. Thus, the change in the mean particle size of the sols indicates that the dispersion-flocculation-redispersion of sols occurs by means of the surfactant. It is noteworthy that the flocculation of the sols upon the addition of

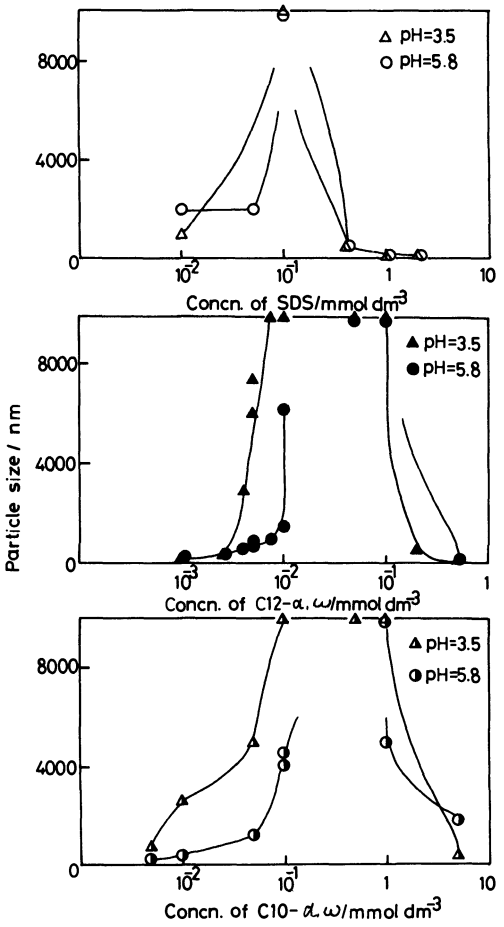

Fig. 2. The change in mean particle size of sols as a function of concentration of surfactant.

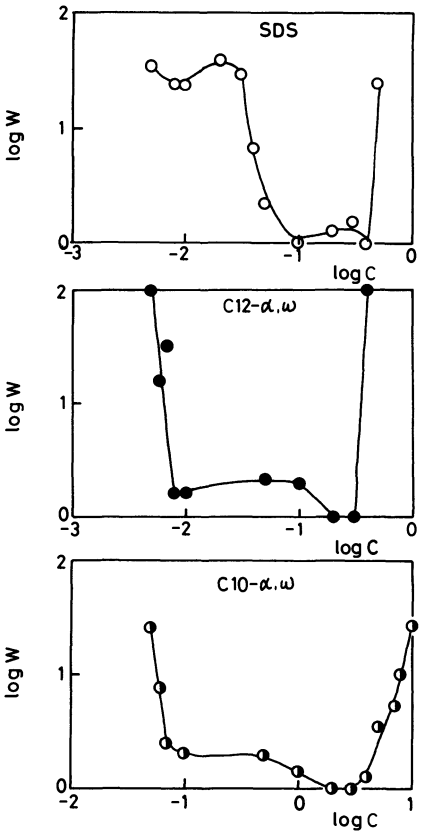

Fig. 3. Relationship between stability ratio of sols and concentration of surfactant at pH 5.8.

α,ω-type surfactants occurs over a wider range of surfactant concentrations than that in SDS.

To examine the flocculation region in detail, the stability ratio of the sols was measured. The change in the stability ratio of the sols as a function of the logarithm of the concentration of the surfactant at pH 5.8 is presented in Fig. 3. In the region of rapid coagulation, log W is nearly zero. From Fig. 3, it can be seen that the region of the flocculation of the sols upon the addition of SDS ranges from 0.1 mM to 0.4 mM. On the other hand, the region of the flocculation of the sols upon the addition of C12-α,ω ranges from 0.008 mM to 0.3 mM, and that of C10-α,ω, from 0.07 mM to 4 mM. Accordingly, it was found that the flocculation region upon the addition of an α,ω-type surfactant was much wider than that by SDS. The difference between the concentrations corresponding to the flocculation regions of C10-α,ω and C12-α,ω is mainly attributing to the difference in their surface activity: The surface activity of C12-α,ω is much higher than that of C10-α,ω.[7]

Figure 4 presents the adsorption isotherms at pH 3.5 and pH 5.8 where the adsorption density(mol m^{-2}) is given as a function of the equilibrium concentration of the surfactant. The adsorption density of SDS increased gradually and then became constant. A slight inflection point appeared at about 0.1 mM of SDS. The adsorption isotherms of the α,ω-type surfactants had a plateau over a wide range and then increased suddenly. Finally, the saturated amount of adsorption was obtained. It should be noted that the concentration ranges of these plateaus are in fairly good agreement with the flocculation region of the sols caused by the surfactants. From these results on the mean particle size, the zeta-potential, and the adsorption measurements, the interactions between the sols and the α,ω-type surfactant were found to be slightly stronger at pH 3.5 than at pH 5.8, probably because of the difference in the electric interactions between them.

The properties of the sol flocks formed by the addition of the α,ω-type surfactants and SDS were characterized by the flushing process. When the flocks of the sols formed by SDS were shaken with toluene, the flocks were transferred to the toluene phase; well-dispersed sols were obtained in the toluene phase. The reason for this transfer can be explained by the mechanism of forming a hydro-

phobic adsorption layer on the surface of the sol particles.[5] However, the flocks formed by the addition of the α,ω-type surfactants were dispersed in neither the water phase nor the toluene phase, but moved to the water/toluene interface.

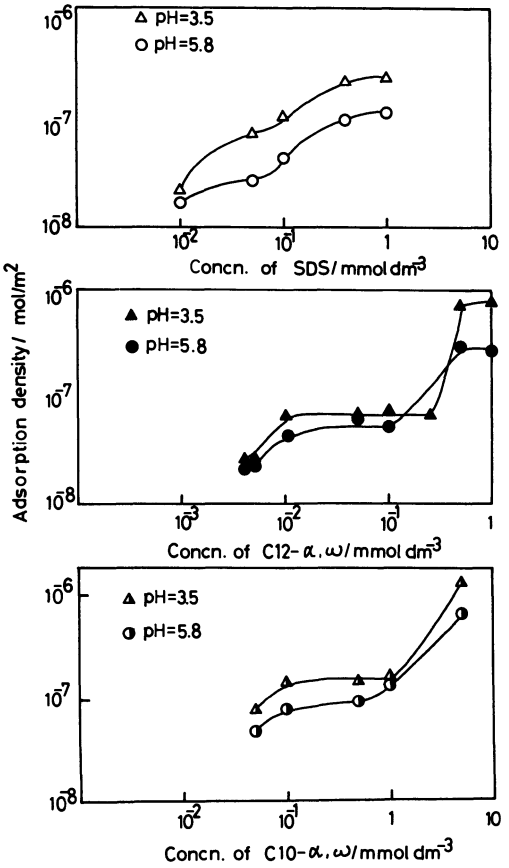

Fig. 4. Adsorption density of surfactant on sols as a function of concentration of surfactant.

Based on all the results obtained, the mechanisms of the flocculation and redispersion of sols occurring upon the addition of α,ω-type surfactants were discussed, and the results shown schematically in Fig. 5 were obtained. When low concentrations of α,ω-type surfactants are added to the sols, the surface charge of the sols is neutralized, resulting in the flocculation of the sols, much as in the case of SDS.[15] Two flocculation models by α,ω-type surfactants are proposed. The flocculation model of the left side seems unreasonable, however, because the surface of sols treated with α,ω-type surfactants does not exhibit the hydrophobic character usually obtained by flushing. On the other hand, the flocculation model of the right side indicates that α,ω-type surfactants act as bridging agents among the sols. The mechanism of bridge-forming among sols is a bimolecular process: the flocculation rate must be proportional to the product, $\theta(1-\theta)$, of the fractions covered(θ) and notcovered($1-\theta$) with the adsorbed α,ω-type surfactant. As can be seen in Fig. 3, the experimental points lie almost on a parabola, corroborating the bimolecular flocculation.[16] This bridging action renders the sols less hydrophobic than the surface of the sols flocculated by the addition of SDS. The flocculated sols thus obtained moved at the toluene/water interface and behaved like a film upon the flushing. This film-like behavior might be due to the penetration of toluene into the hydrocarbon chain of the α,ω-type surfactant, thus forming a bridge. On the further addition of an α,ω-type surfactant, the mean particle size of the sols decreased, as is shown in Fig. 2, since the redispersion of the sols was achieved. The mechanism of redispersion, which is schematically shown in Fig. 5, can be explained in terms of the monolayer

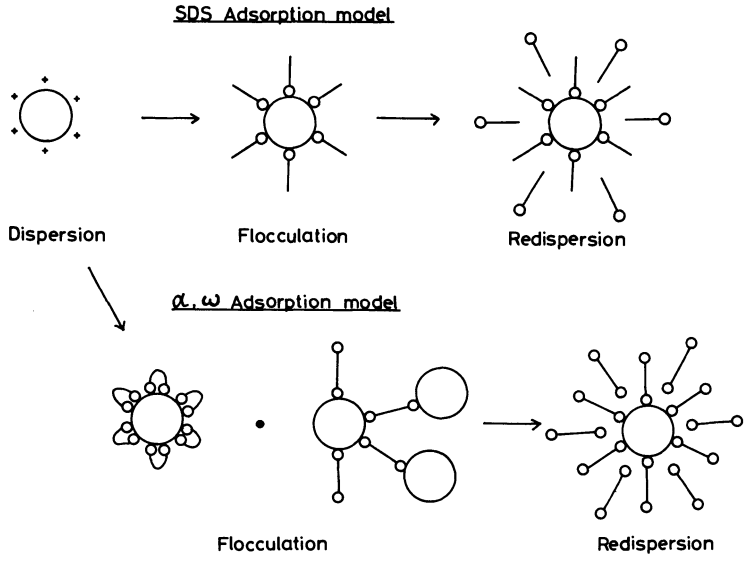

Fig. 5. A model for mechanism of flocculation and redispersion of sols by surfactant.

adsorption from the data of the zeta-potential and the amount of adsorption. Accordingly, the redispersion state of sols by α,w-type surfactants is different from the two-fold adsorption layer caused by SDS.

The Electrical Properties of $La_{2-x}Sr_xNiO_4$ ($0 \leqq x \leqq 1$)

Kenji ISHIKAWA,* Shin-ichi KONDO, Yuichi SUZUKI, Shin-ichi TAKAYAMA, Kazuhiko SHIMADA, and Yasuo SUZUKI
Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Higashi-mita, Tama-ku, Kawasaki 214
(Received July 27, 1985)

The electrical resistivities and Seebeck coefficients of mixed oxides, $La_{2-x}Sr_xNiO_4$, have been determined under an He atmosphere at 77.4—673.2 K. It has been shown that the temperature dependences of the Seebeck coefficients of the oxides were fairly well approximated by this equation: $S=AT+B+C/T$, where T is the thermodynamic temperature. The coefficients of the equation, A, B, and C, were given by the least-squares method. The metal-semiconductor ratios $\{\alpha \equiv (C/T)/(AT+C/T)\}$ were given to characterize the thermoelectrical properties of $La_{2-x}Sr_xNiO_4$. The maximal activation energies (E_a(resis.) and E_a(Seebeck)) and the maximal metal-semiconductor ratio (α) were obtained with the strontium concentration of $La_{2-x}Sr_xNiO_4$ at $x=0.5$. The lattice distortion of the oxides is responsible for the maxima of the activation energies and of the metal-semiconductor ratio at $x=0.5$.

The K_2NiF_4-type oxides are of great interest because of their unusual electrical properties. For example, La_2NiO_4 exhibits a gradual metal-semiconductor transition,[1-7] while $LaSrNiO_4$ is a metallic conductor[1,3,4] in the a axis direction of the tetragonal cell. The mixed oxides, La_2NiO_4 and $LaSrNiO_4$, form a continuous series of solid solutions,[3,4,8,9] $La_{2-x}Sr_xNiO_4$, which are also (tetragonal) K_2NiF_4-type oxides at $x=0$—1. Kononyuk et al.[3,4] have provided the resistivity and the thermoelectromotive force data of $La_{2-x}Sr_xNiO_4$. The measurements of the previous paper,[3,4] however, have been restricted to above room temperature; the data at temperatures below 300 K are not given.

In this paper, the electrical and transport properties of $La_{2-x}Sr_xNiO_4$ are reported in the range of 77.4—673 K, and the effects of lattice distortion on the electrical and transport properties are discussed.

Experimental

The mixed oxides, $La_{2-x}Sr_xNiO_4$, were prepared by heating a mixture of La_2O_3 (Shin-etsu Chem. Ind. Co., 99.9%), $SrCO_3$ (prepared from reagent grade $Sr(NO_3)_2$), and NiO (Koujundo Kagaku Co., 99.99%) in air at 1423 K for 20 h with intermittent grinding. The X-ray powder-diffraction method was employed for their identification.

Sintered specimens about 3 mm^2 in cross section and 10 mm long, which had been cut from pelletized samples 13 mm in diameter and 1 mm thick, were used for the electrical-resistivity and Seebeck-coefficient measurements.

Both four- and two-probe methods were employed for the resistivity measurements.

The Seebeck coefficients were determined by measuring the electric fields which were produced across a sintered bar of the specimen by the presence of temperature gradients. Two small copper blocks were employed for the potential leads. The temperature differences between the two potential leads were maintained within 15 K during the measurements.

The absolute Seebeck coefficients of the samples, S(abs.), were obtained by means of this equation:[10]

$$S(\text{abs.}) = S(\text{Cu}) - \Delta V/\Delta T, \quad (1)$$

where S(Cu) was the absolute Seebeck coefficient of copper[11] and where ΔV and ΔT were the potential and temperature differences between the two copper blocks respectively. All the resistivity and the Seebeck coefficient measurements were carried out under an He atmosphere.

Results and Discussion

The X-ray studies revealed that $La_{2-x}Sr_xNiO_4$ were tetragonal K_2NiF_4-type oxides over the entire range of x.[8]

The electrical resistivity measurements showed that all the sintered polycrystalline samples were semiconductors at room temperature (Fig. 1). In the series

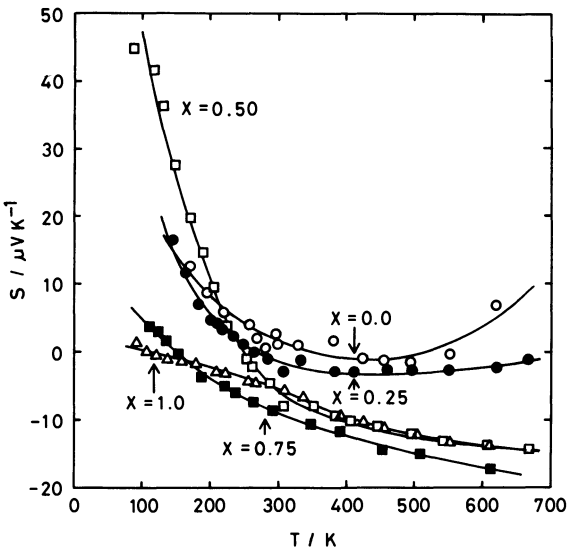

Fig. 2. Absolute Seebeck coefficients of $La_{2-x}Sr_xNiO_4$.

of $La_{2-x}Sr_xNiO_4$, a maximum value of the activation energy,

$$\rho=\rho_0\exp(E_a/kT), \quad (2)$$

was obtained from the slope of the resistivity curve of $La_{1.5}Sr_{0.5}NiO_4$[3,4] (Table 1). A gradual metal-semiconductor transition was found in the resistivity curves of La_2NiO_4 and $La_{1.75}Sr_{0.25}NiO_4$ around 500 K.[1-7,9]

The thermo-electromotive force data (Fig. 2) suggested that $LaSrNiO_4$ was a metallic conductor,[1,3,4] but the resistivity data (Fig. 1) indicated that $LaSrNiO_4$ was a semiconductor with small activation energy. Charge transport among the grains across the boundary is probably responsible for the semiconduction of the polycrystalline $LaSrNiO_4$.

Goodenough[5,6] has proposed a band model of La_2NiO_4 in which the conduction band, a narrow $\sigma^*_{x^2-y^2}$ band, is split into two bands by either electron correlations or a charge-density wave; the lower band of the two is fully occupied by electrons, whereas the higher one is empty. It is safe to assume that $La_{2-x}Sr_xNiO_4$ have essentially the same energy-band structure as that of La_2NiO_4, since the crystal structures of La_2NiO_4 and $La_{2-x}Sr_xNiO_4$ are identical.

The $La_{2-x}Sr_xNiO_4$ oxides contain x Ni^{3+} cations per formula. If $La_{2-x}Sr_xNiO_4$ have the same energy band as La_2NiO_4, $La_{2-x}Sr_xNiO_4$ must be metallic conductors at any x except at x=1, even at low temperatures, since x holes do exist in $La_{2-x}Sr_xNiO_4$. Metallic conduction, however, was not observed in the series of $La_{2-x}Sr_xNiO_4$ except for $LaSrNiO_4$ in either Kononyuk's[3,4] and the present work at room temperature. This phenomenon can be understood if the nickel 3d holes are trapped around Sr^{2+} and are in the collective state, because Sr^{2+} is more negative than La^{3+}. In $La_{2-x}Sr_xNiO_4$, many donors, that is, acceptors of holes, should exist in the lower band of La_2NiO_4, and the conduction band of La_2NiO_4 must be deformed by Sr^{2+}.

So many Sr^{2+} and Ni^{3+} should also influence the transport properties of $La_{2-x}Sr_xNiO_4$. Thermo-electromotive force measurements showed that the Seebeck coefficients of $La_{2-x}Sr_xNiO_4$, except for La_2NiO_4 and $La_{1.75}Sr_{0.25}NiO_4$, decreased with an increase in the temperature over the entire range of measurements (Fig. 2). The Seebeck coefficient curves of La_2NiO_4 and $La_{1.75}Sr_{0.25}NiO_4$, however, had minima at around 500 K, where metal-semiconductor transitions were observed. All oxides were p-type conductors at low temperatures, but they were n-type above moderate temperatures.

In general, the Seebeck coefficient of a metallic conductor can be represented by this relation:

$$S=AT+B, \quad (3)$$

where A and B are constants and where T is the thermodynamic temperature. On the other hand, the Seebeck coefficient of a semiconductor is expressed as:

$$S=C/T, \quad (4)$$

where C is a constant. In the case of an intrinsic semiconductor, Eq. 4 can be altered as:

$$S=(k/e)(E_a/kT), \tag{5}$$

where k is the Boltzmann constant, e is the electronic charge, and E_a is the activation energy.

The Seebeck coefficient curves of the sintered samples of $La_{2-x}Sr_xNiO_4$ (Fig. 2) were complicated and could not be expressed simply by either Eqs. 3 or 4. Since the oxides were electrically anisotropic and both La_2NiO_4 and $La_{1.75}Sr_{0.25}NiO_4$ exhibit a "gradual" metal-semiconductor transition (Fig. 1), we hypothetically assumed that the metallic conduction and the semiconduction parts of the thermo-electromotive force, viz., $AT+B$ and C/T, coexist in the polycrystalline samples of $La_{2-x}Sr_xNiO_4$ and that their Seebeck coefficient consists of the sum of the two parts. The Seebeck coefficient of $La_{2-x}Sr_xNiO_4$ can, then, be written as:

$$S=AT+B+C/T. \tag{6}$$

This equation can also be written in this form:

$$ST=AT^2+BT+C. \tag{7}$$

The coefficients A, B, and C were evaluated by fitting the experimental measurements to Eq. 7 with a digital computer, using the least-squares method.

In Fig. 3 the observed and calculated products, ST, are plotted as a function of the temperature. The solid lines represent the calculated values (ST(calcd)= AT^2+BT+C). The calculations by the least-squares method were employed to obtain the thermo-electromotive force data at high temperatures (Table 1). The calculated values were in fair agreement with the values found for most of the temperature region. However, large deviation of the observed ST values from the calculated lines, which were greater than the limits of experimental error (±2 mV), were found in the low-temperature p-type regions of La_2NiO_4, $La_{1.75}Sr_{0.25}NiO_4$, and $La_{1.5}Sr_{0.5}NiO_4$. Unfortunately, it was not elucidated from our experimental data why the ST values of the samples ($x\leqq0.5$) deviated from the calculated ST curves at low temperatures.

In Fig. 4 the A and C coefficients are plotted as a function of the strontium concentration, x. The A coefficient was positive at $x\leqq0.6$ and negative at $x>0.6$. On the other hand, the C coefficient was positive over the whole range of x and increased with an increase in x. Figure 4 shows that both holes ($A\geqq0$ at $x<0.6$) and electrons ($A<0$ at $x>0.6$) were involved in the metallic conduction and that the holes were responsible for the semiconduction ($C\geqq0$ at $x=0$—1).

We attempted to seek a parameter (or a function) which contained the thermo-electromotive force data,

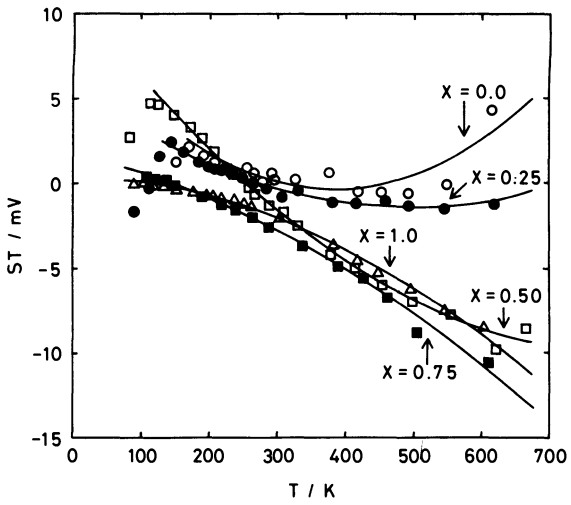

Fig. 3. ST vs. T plots of $La_{2-x}Sr_xNiO_4$. The solid lines indicate the calculated values.

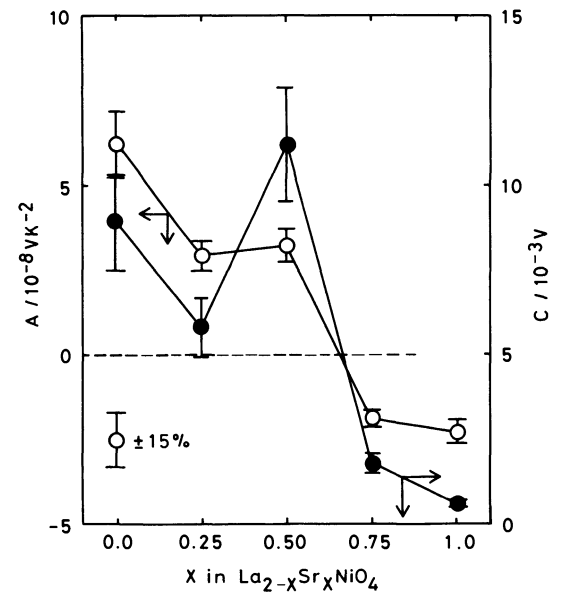

Fig. 4. The A and C values of $La_{2-x}Sr_xNiO_4$. $S=AT+B+C/T$

i.e., A, B, and C, and which was related to the resistivity data. As has been described previously, the A and B coefficients were correlated with the metallic conduction, while the C parameter was correlated with the semiconduction. The thermo-electromotive force, AT, and C/T were temperature-dependent, and their values were determined by the sign, the density, and the mobility of the charge carriers in the energy band, while the residual power, B, was temperature-independent and it was usually difficult to predict its value. It seemed inappropriate to compare the values of A and/or C with B, since the value of B was unpredictable. Therefore, the B coefficient was ignored in evaluating the parameter (or the fucncton) in this paper.

The paprameter (or the function) was conveniently

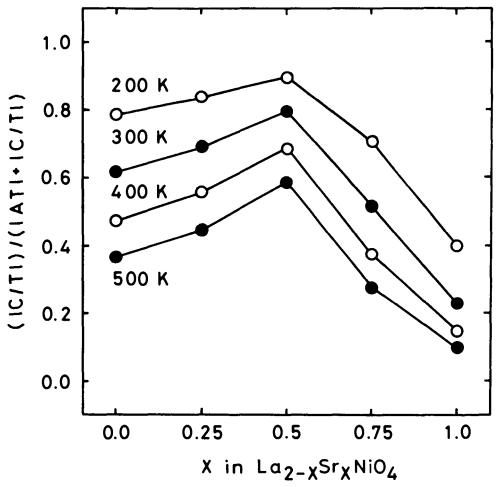

Fig. 5. The $(C/T)/(AT+C/T)$ values of $La_{2-x}Sr_xNiO_4$. $S=AT+B+C/T$

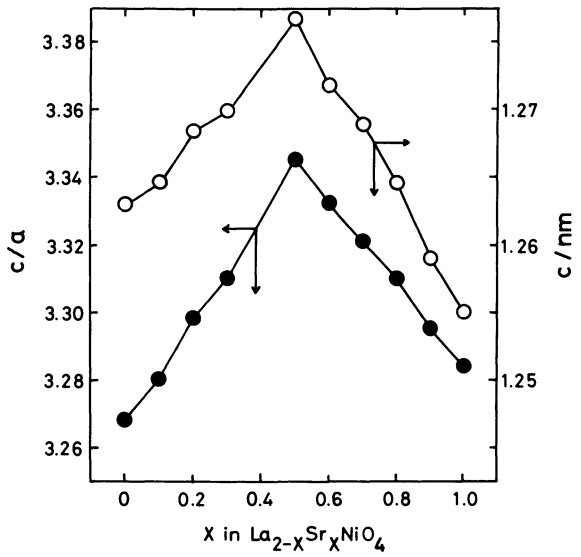

Fig. 6. Strontium concentration dependence of the c value and the c/a ratio of $La_{2-x}Sr_xNiO_4$ at 300 K. The lattice constants a and c were obtained from Gopalakrishnan et al.[8]

defined as the ratio of AT (metallic conductor) and C/T (semiconductor) as:

$$\alpha=\frac{C/T}{AT+C/T}\ . \tag{8}$$

The α parameter was named the metal-semiconductor ratio of the thermo-electromotive force.

In Fig. 5 the metal-semiconductor ratio of the oxides is plotted as a function of the strontium concentration. The metal-semiconductor ratio of the oxides decreased with an increase in the temperature. The ratio increased with x at $x<0.5$, but it decreased with x at $x\geqq 0.5$ at any temperature. Ganguly and Rao[1] and Kononyuk et al.[4] have reported that La_2NiO_4 showed a metal-semiconductor transition at 500 K and that $LaSrNiO_4$ was a metallic conductor. The metal-semiconductor ratio of La_2NiO_4 was 0.4 at 500 K, while that of $LaSrNiO_4$ was 0.2 at room temperature (Fig. 5). The metal-semiconductor transition seemed to occur at a critical value of $\alpha=0.3\pm0.1$. The $La_{1.5}Sr_{0.5}NiO_4$ oxide exhibited no metal-semiconductor transition because the metal-semiconductor ratio of the oxide was appreciably larger than the critical value in the temperature range measured.

In Fig. 6 the c/a and c values at room temperature of $La_{2-x}Sr_xNiO_4$, where a and c are the lattice constants of the tetragonal cell obtained from Gopalakrishnan et al.,[8] are plotted as a function of the strontium concentration. The shape of the metal-semiconductor ratio against the strontium-concentration curve in Fig. 5 very much more closely resembles the c vs. x curve than the c/a vs. x one.

In Table 1 the activation energies obtained from the resistivity data (E_a (resis.))(Eq. 2) and the activation energies calculated from the thermo-electromotive force data (E_a(Seebeck))(Eq. 5) are tabulated. The activation energies, E_a(Seebeck), are given merely as references, because the E_a(Seebeck) energies have some ambiguity which result from assuming that $La_{2-x}Sr_xNiO_4$ are intrinsic semiconductors. The activation energy (E_a(resis.)) and E_a(Seebeck) both had maxima at $x=0.5$. The activation energies must also be responsible for the crystal distortion.[5,6] The results in Figs. 5 and 6 and Table 1 indicate that the activation energy, as well as metal-semiconductor ratio of $La_{2-x}Sr_xNiO_4$, is correlated to the lattice distortion of the crystal.

(Received August 3, 1985)

A cylindrical resonator for the measurement of ultrasonic absorption has been designed. It was found that a newly designed resonator can determine the absolute value of the ultrasonic absorption coefficient of water at frequencies above 0.7 MHz. For aqueous solutions it has a sufficient resolution power down to 0.2 MHz by means of a reference measurement. Precise measurements of ultrasonic absorption were carried out for aqueous solutions of dodecyltrimethylammonium bromide using a newly designed resonator and two other previously reported resonators. The ultrasonic relaxation spectra show a single relaxation process within the investigated frequency range. The relaxation process can be ascribed to a "fast" relaxation related to the exchange of a surfactant between micelles and bulk solution. The kinetic parameters for the exchange process were estimated on the basis of Teubner's theory.

Precise measurements of the ultrasonic absorption below 10 MHz are very important for a variety of ultrasonic relaxation studies, such as the kinetics of micellar solutions,[1-5] the dynamics of segmental motions of polymer chains in a solution[6,7] and the dynamics of simple molecules.[8,9] For a kinetic study of micellar solutions, a precise measurement within this frequency range is inevitably required since it is well known that most micellar solutions show an ultrasonic relaxation phenomena within the frequency range 0.1 to 10 MHz.

For frequencies below 1 MHz, however, few measurements have been carried out and only an ultrasonic study has been reported for the typical micellar solutions of sodium dodecyl sulfate by Yasunaga et al.[4] using an ultrasonic reverberation method. Although the reverberation method has been an available technique for measuring ultrasonic absorption within this frequency range, it usually requires a great volume of a sample (several to ten liters).[10] Also, its accuracy is sometimes insufficient. Therefore, applications of this technique have been limited to the micellar solutions with high ultrasonic absorption coefficients.

On the other hand, a cylindrical resonator method which was originally developed by Eggers,[11] has proved to be a powerful technique for measuring the ultrasonic absorption coefficient of liquids and solutions at frequencies below 10 MHz. However, it is still difficult to make precise measurements using this method on samples with low ultrasonic absorption coefficients, such as water and dilute aqueous solutions at frequencies below 2.5 MHz. The main reason for the difficulty is that the mechanical loss of the cylindrical resonator sharply increases with a decreasing frequency. In order to reduce the mechanical loss, a few improvements have been made; for example, Eggers et al.[12,13] developed a pressure concave resonator and Choi et al.[14,15] proposed a plano-concave resonator and an optical detector using Raman-Nath light diffraction.

Recently, we have succeeded in reducing the mechanical loss of a cylindrical resonator without using a pressure concave resonator and without using an optical detector. Our improvement was simply in using a pair of X-cut quartz transducers with large diameters. It was found that a newly designed resonator can determine the absolute value of the ultrasonic absorption coefficient of water at frequencies above 0.7 MHz. For aqueous solutions it has a sufficient resolution down to 0.2 MHz, by means of a reference measurement.

In this paper we present a detailed description of the resonator and results regarding precise measurements of the ultrasonic absorption on aqueous solutions of a cationic surfactant, dodecyltrimethylammonium bromide, at frequencies from 0.2 to 10 MHz. The experimental results are discussed on the basis of a theory developed by Teubner.[16]

Experimental

Principle of the Resonator Method. Prior to a description of the resonator cell, the principle of the resonator method will be briefly presented. With this method, a resonator cell consists of a liquid column sealed by two X-cut quartz transducers. A frequency-variable oscillator drives the input transducer and produces a series of standing waves in the liquid column at resonance frequencies; then, sharp resonance peaks are detected by an output detector. At the n-th resonance frequency, f_n, the quality factor, Q, of the cell is given by

$$Q^{-1} = \Delta f_n / f_n, \quad (1)$$

where Δf_n is the half-power bandwidth (hereafter abbrevi-

†† Permanent Address; Academy of Economics, Department of General and Analytical Chemistry, Institute of Commodity Sciences, 60-957 Poznań, Poland.

ated as HPB) of the n-th resonance peak. For an ideal cylindrical resonator containing a liquid sample, the Q factor is given by

$$Q^{-1} = \alpha\lambda/\pi, \tag{2}$$

where α is the ultrasonic absorption coefficient of the sample and λ the ultrasound wavelength. In practice, Eq. 2 does not hold since there are several inherent factors called "mechanical" loss in the design of the cell. Therefore, Eq. 2 should be modified as follows:

$$Q^{-1} = \Delta f_n/f_n = \frac{\alpha\lambda}{\pi} + Q^{-1}_{mechanical}, \tag{3}$$

where $Q^{-1}_{mechanical}$ represents the mechanical loss of the cell. For a determination of the ultrasonic absorption coefficient of a sample, $Q^{-1}_{mechanical}$ should be eliminated by a reference measurement in the same cell at the same frequencies using a suitable liquid. Then, the excess absorption per wavelength $(\alpha\lambda)_{excess}$ in the liquid is obtained from Eq. 4.

$$(\alpha\lambda)_{excess} = \pi[(\Delta f_s - \Delta f_r)/f_n] \tag{4}$$

In Eq. 4, Δf_s and Δf_r represent the corresponding HPB values of the n-th resonance peak in the sample and the reference liquid, respectively.

Design of Resonator. The absolute value of the ultrasonic absorption coefficient can be determined using a resonator having a negligible mechanical loss compared with $\alpha\lambda/\pi$ of the liquid sample. Then, an accurate measurement can be easily performed. Therefore, a reduction of the mechanical loss is an essential point for the design of a resonator.

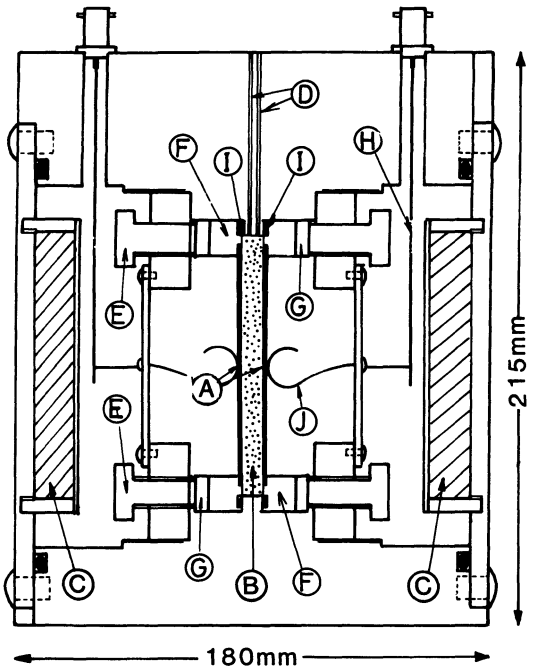

Fig. 1. Sectional view of the ultrasonic resonator, (A): X-cut quartz transducers, (B): cavity (sample room), (C): desiccant, (D): filling hole, (E): screw for parallelism adjustment, (F): supporter for transducer, (G): spacer, (H): lead, (I): O-ring, (J): electrode.

Figure 1 shows the resonator cell designed for this study. The dimensions of the cell are ca. 180 mm in width, 240 mm in length, and 215 mm in height, respectively. The acoustical path length is ca. 7 mm, and the liquid column has a total volume of ca. 50 ml, together with the dead space. The following improvements were carried out to reduce the mechanical loss as much as possible.

For the cell: (1) In order to separate the resonance frequency of the cavity from that of the total cell system, a sufficiently heavy cell (ca. 60 kg) was made of stainless steel (SUS 27). (2) Parallelism between transducers also contributes to the mechanical loss at the lower frequency region; thus, it was coarsely adjusted by measuring the distance between two transducers (with a precision of $\pm 1/100$ mm) using a dial indicator and was finally tuned by inspecting the pulse echo pattern on a synchroscope in a way similar to the usual pulse method. (3) Each transducer was supported only at its back surface with a holder to minimize the mechanical load on its surface. This makes the transducer vibrate better in thickness mode. (4) Two thin filling holes (1 mm in diam.) were drilled to minimize the disturbance of the resonance condition. (5) Desiccant (silica gel) was sealed within a cage attached to the wall of the cell since the mechanical loss of the resonator greatly depends on the humidity in the chamber behind the transducer.

For transducers: (1) In the frequency range below 2 MHz, the diffraction of sound makes a major contribution to the mechanical loss. The diffraction was suppressed by using a pair of quartz transducers with large diameters(90 mm). (2) A high quality factor of the transducers is also required in order to reduce the mechanical loss. For this purpose, the fundamental frequencies of the two transducers were matched within 0.05% (2.001 and 2.002 MHz, respectively) and their surfaces were polished to within optical grade. These transducers were purchased from Valpay-Fisher Co. Inc., U.S.A.

Measurement System and Temperature Control. Our apparatus for the resonator method consists simply of two frequency synthesizers (Rockland Model 5100, 0—2 MHz, John-Fluke Model 6039 A, above 2 MHz), a resonator cell and two detectors (Yokogawa Hewlett Packard Model 3400 RMS voltmeters). A detailed description of the apparatus has been published elsewhere.[17] Any temperature drift in a sample makes it difficult to obtain an accurate HPB reading since the resonance frequency is very sensitive to drift due to temperature fluctuations. The temperature of a water bath was controlled with an accuracy of $\pm 10^{-3}$ °C by means of a digital temperature-control system. The temperature drift in the sample could also be minimized using the sufficiently large heat capacity of the cell (due to its large size and weight).

Materials. Dodecyltrimethylammonium bromide (hereafter abbreviated as DTAB) and the other chemicals used in this study were purchased from Nakarai Chemicals Co. Ltd. and used without further purification. A chemical analysis of the DTAB was carried out at Prof. Tsuge's laboratory at our university and the purity of the sample was confirmed to be: C_{12}=99.9%, C_{10}=0.0%, and C_{14}=0.1%.

Ultrasonic Absorption and Sound Velocity Measurements. Three cylindrical resonators were used to measure the ultrasonic absorption in the frequency range

0.2—10 MHz: the resonator designed here (0.2—2 MHz); the other two reported previously,[17] one with 50 mm diameter crystals with a fundamental frequency of 2 MHz (0.8—3.2 MHz), and the other with a 30 mm diameter, 5 MHz crystals for the frequency range above 2.2 MHz. The ultrasonic absorption coefficients of aqueous solutions of DTAB were determined by the reference measurement on the basis of Eq. 4 using distilled, degased water as a reference liquid. The sound velocity was measured mostly with the cylindrical resonators and occasionally with an ultrasonic interferometer working at a fixed frequency 4.000 MHz.

Results and Discussion

Characteristic Properties of Resonator. Figure 2 shows the HPB values for water measured at 25 °C (using the designed resonator). For a comparison, the results using the other two resonators are also plotted. The HPB values of a resonator without a mechanical loss can be calculated using a modified form of Eq. 2:

$$\Delta f_n = \frac{\alpha}{f_n^2} \cdot \frac{u}{\pi} \cdot f_n^2, \tag{5}$$

where u is the sound velocity in the sample. Equation 5 shows that Δf_n should vary linearly with the square of the resonance frequency, f_n^2, in non-relaxing liquids. The solid line in the figure represents the HPB values of water calculated from Eq. 5. In that calculation, the ultrasonic absorption and sound velocity values for water at 25 °C were taken as $\alpha/f^2=22.6\times10^{-17}$ s^2 cm^{-1} and $u=1.497\times10^5$ cm s^{-1}, respectively. The deviation of the HPB data from a straight line represents the mechanical loss of the resonator at that frequency. If the obtained HPB values fall directly on a straight line, an absolute measurement of the ultrasonic absorption is possible using this resonator. It is readily seen from Fig. 2 that an absolute measurement for water is possible at frequencies above 0.7 MHz using a combination of these three resonators.

Figure 3 shows the resolution power of the designed resonator for measuring the ultrasonic absorption coefficient. Three lines represent the HPB values of water calculated from Eq. 5 at 15, 20, and 25 °C, respectively. The resonator can detect small differences (ca. 2.6×10^{-17} s^2 cm^{-1}) in α/f^2 of water at these temperatures. In the case of benzene having a higher ultrasonic absorption coefficient (860×10^{-17} s^2 cm^{-1} at 20 °C), the low-frequency limit of an absolute measurement goes down to ca. 0.5 MHz.

If the observed HPB values deviate from those

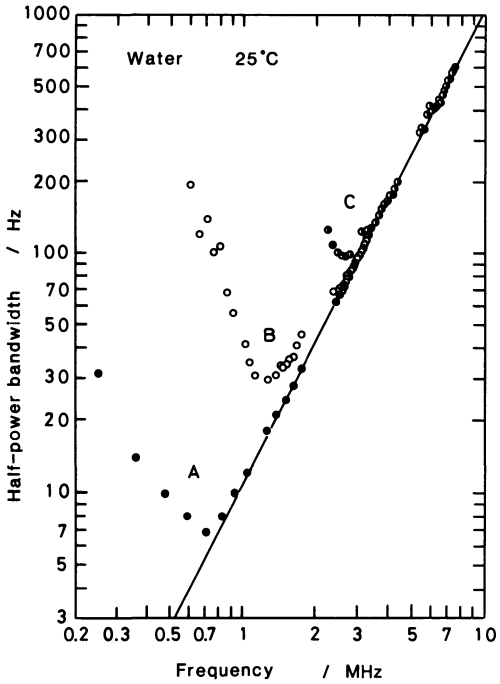

Fig. 2. The HPB values of resonance peaks for water at 25°C. A solid line represents the calculated HPB values of water from Eq. 5. For comparison, HPB values for the other two resonators used in this study are also plotted, (●): Resonator A (this work, 0.2—2 MHz), (○): resonator B (0.8–3.2 MHz), (◑): resonator C (2.2—8 MHz).

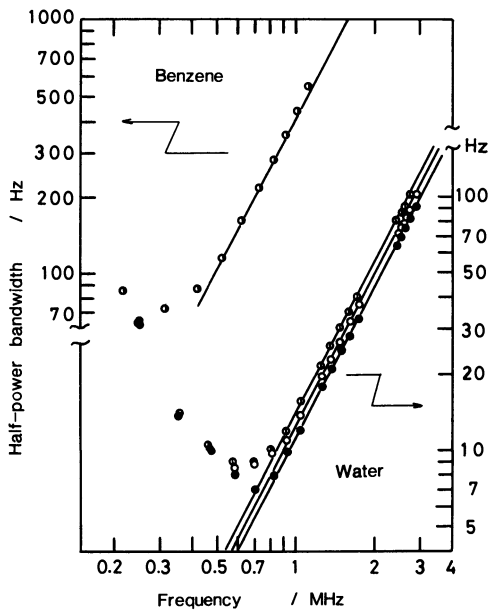

Fig. 3. The HPB values of resonance peaks observed in water at 15 (◫), 20 (○), and 25 °C (●) and in benzene (◑) at 20 °C. Solid lines represent the HPB values calculated from Eq. 5. Following data (except α/f^2 of benzene) are taken from literature[31] in the calculation, $\alpha/f^2=28.7\times10^{-17}$ s^2 cm^{-1}, $u=1.466\times10^5$ cm s^{-1} (water at 15°C), $\alpha/f^2=25.2\times10^{-17}$ s^2 cm^{-1}, $u=1.483\times10^5$ cm s^{-1} (water at 20°C), $\alpha/f^2=860\times10^{-17}$ s^2 cm^{-1}, $u=1.324\times10^5$ cm s^{-1} (benzene at 20°C).

calculated from Eq. 5, as is shown in Fig. 3 (for benzene at frequencies below 0.5 MHz and also for water below 0.7 MHz), the ultrasonic absorption coefficient can be determined by a reference measurement on the basis of the Eq. 4. Figure 4 shows the result of a reference measurement of the ultrasonic absorption of benzene at 20 °C. *o*-Xylene was used as a reference liquid because it has a similar acoustical impedance to that of benzene; also, no relaxation process in *o*-xylene was reported by Ohsawa[18] at the frequencies above 10 KHz. The ultrasonic absorption coefficient determined by the reference measurement is in good agreement with that determined by an absolute measurement using a pulse technique. This indicates that the designed resonator detects the reliable ultrasonic absorption coefficient at frequencies above 0.2 MHz.

Ultrasonic Absorption in Aqueous Solutions of DTAB. Figure 5 shows the result of ultrasonic absorption measurements for aqueous solutions of DTAB. The data are expressed as a plot of the absorption coefficient vs. the logarithmic frequency. An ultrasonic relaxation process can be observed within the frequency range investigated for all DTAB solutions. It is expressed well by the equation for a single relaxation

$$\frac{\alpha}{f^2} = \frac{A}{1+(f/f_r)^2} + B, \tag{6}$$

where f represents the measured frequency, f_r is the relaxation frequency, A the relaxation amplitude, and B the contribution to sound absorption from any other processes that may be occurring at higher frequencies beyond our frequency range. A linearlized least-square method was used to fit Eq. 6 to the ultrasonic absorption data and the relaxation parameters, A, B, and f_r, were determined. The solid lines in Fig. 5 represent the calculated ultrasonic relaxa-

tion spectra from Eq. 6 and the arrows indicate the location of the relaxation frequency. Table 1 summarizes the determined values of the relaxation parameters for aqueous solutions of DTAB. As can be seen in Fig. 5 and Table 1, the designed resonator can detect an ultrasonic relaxation process having a small relaxation amplitude. The relaxation amplitude observed here is about two orders smaller in magnitude than those of aqueous solutions of sodium dodecyl sulfate investigated by using the reverberation method.[4]

The reciprocal relaxation times can be calculated from the relaxation frequency as $1/\tau=2\pi f_r$ and are plotted as a function of the total concentration of DTAB in Fig. 6. For a comparison, the results of P-jump[1,19] and ultrasonic relaxation[2,4,20] studies on aqueous solutions of a series of sodium alkyl sulfates and those of alkyltrimethylammonium bromides are also plotted. The present results are consistent with those reported in the literature. Our data sufficiently completes the range from 10^5 to 10^7 s^{-1}, which has been a vacant zone since there are few available methods for ultrasonic absorption and P-jump measurements. It can also be seen from Fig. 6 that the reciprocal relaxation time of solutions that are a series of alkyltrimethylammonium bromides is always located at the higher frequency side in comparison with those solutions of sodium alkyl sulfates.

Estimation of Kinetic Parameters for Micellar Formation. Judging from the investigated frequency range and other information from the literature,[1-3] the relaxation process observed here should be ascribed to a "fast" relaxation process, due to an exchange process of a surfactant between micelles and a bulk solution. The kinetic parameters for this process can be estimated by applying some of the important relations derived from a general model of the micellar formation proposed recently.

Teubner[16] has derived the following expression for the relaxation time of the ultrasonic relaxation due to a surfactant exchange process between micelles and a bulk solution, using the approximations introduced by Aniansson and Wall.[21]

$$\frac{1}{\tau}=2\pi f_r=\frac{k_{-1}}{\sigma^2}+\frac{k_{-1}}{\bar{m}}\left(\frac{C}{C_1}-1\right), \tag{7}$$

where C and C_1 represent the total and monomer concentrations of surfactant, respectively, and usually C_1 is assumed to be equal to the critical micelle concentration. Notations $\bar{m}$ and σ represent the mean aggregation number and the variance of the size distribution on proper micelles, respectively, and k_{-1} is the mean of the dissociative rate constant. He has further derived an expression for absorption maxima per wavelength, μ_{max}, as follows[22]:

$$\mu_{max}=\frac{\pi\rho u^2(\Delta V_s)^2C_1\frac{\sigma^2}{\bar{m}}\left(\frac{C}{C_1}-1\right)}{2RT\left\{1+\frac{\sigma^2}{\bar{m}}\left(\frac{C}{C_1}-1\right)\right\}}, \tag{8}$$

where μ_{max} is defined as $\mu_{max}=A f_r u/2$. Here ΔV_s[23] represents the change in the molar volume due to the exchange process, ρ is the density of the solution, R is the gas constant and T is the temperature.

An examination of Eq. 7 indicates that a graph of $1/\tau$ vs. (C/C_1-1) should give a linear correlation with the intercept and slope of the line providing values for k_{-1}/σ^2 and $k_{-1}/\bar{m}$, respectively (Fig. 7 shows that a linear correlation).

If values of the critical micelle concentration and the micelle aggregation number are available, kinetic parameters k_{-1} and σ^2 can be estimated from the values of k_{-1}/σ^2 and $k_{-1}/\bar{m}$. The value of the associative rate constant k_1 is further estimated on the basis of the assumption, $k_1=k_{-1}/C_1$. Table 2 lists the values of the estimated kinetic parameters. Here, the following data were used: $C_1=1.46\times10^{-2}$ M (from experiment[24]); aggregation number $\bar{m}=49$ (average value in the literature[25-28]).

ΔV_s is estimated from an analysis of the relaxation amplitude. Figure 7 also shows the results of a relaxation amplitude analysis. As is seen in the figure, there is a small disagreement[29] between

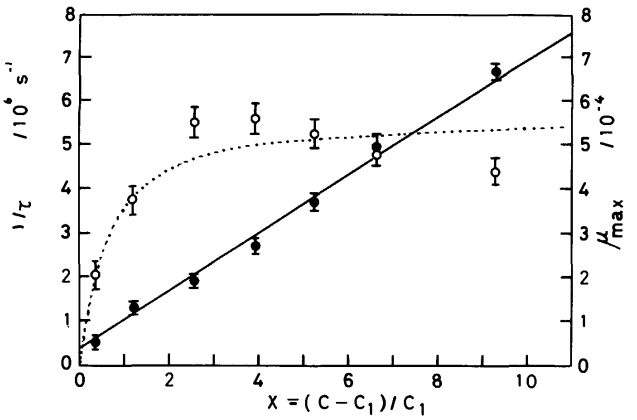

Fig. 7. Reciprocal relaxation times, $1/\tau$ (●), and absorption maxima per wavelength, μ_{max} (○), as a function of the ratio of micellar to monomer concentrations normalized with cmc, $X=(C-C_1)/C_1$. Solid and dotted lines represent values calculated from Eqs. 7 and 8, respectively.

Table 2. Kinetic Parameters for Aqueous Solutions of DTAB at 25 °C

k_1	k_{-1}	σ	$\sigma^2/\bar{m}$	ΔV_s
$M^{-1}s^{-1}$	s^{-1}	—	—	$cm^3\,mol^{-1}$
2.2×10^9	3.2×10^7	8.8	1.6	5.3

experiment and theory. The measured absorption maxima per wavelength, μ_{max}, at first, increases and reaches its maximum value, and then decreases with increasing concentration. On the other hand, a mathematical examination of Eq. 8 indicates that it should increase monotonically and never decrease with increasing concentration if $\sigma^2/\bar{m}$ and ΔV_s remain constant. A similar disagreement has been already reported by some investigators. Teubner[16] has pointed out that the disagreement may be due to a neglect of the activity coefficients and/or the monomer concentration decreasing with an increasing surfactant concentration above the critical micelle concentration. On the other hand, Gettins et al.[30] have pointed out that it may arise from a thermodynamical treatment in Teubner's theory. Though it is difficult, at this stage, to clarify the sources of the disagreement, the values of ΔV_s and kinetic parameters estimated here are quite reasonable if they are compared with those that have been reported in the literature.[1,16]

The authors would like to express their appreciation to Prof. Shin Tsuge of Nagoya University for chemical analysis of DTAB used in this study. The present work was supported in part by a Grant-in-Aid for Scientific Research (Special Research Project on Ultrasonic Spectroscopy and Its Application to Materials Science, No. 59220014) from the Ministry of Education, Science and Culture.

22) It should be noted that the numerical factor of 2 is inserted in the denominator of Eq. 8 in order to make it compatible with the more practical definition of μ_{max} as previously defined in Ref. 32 and used in this study.
23) Note that ΔV in Teubner's theory represents the volume change of reaction per unit change of ordering parameter, ξ, at constant entropy and temperature (in our paper ΔV is expressed as ΔV_s). The ΔV is related to the volume change at constant pressure and temperature, $(\Delta V)_{P,T}$ as follows:

$$\Delta V = (\Delta V)_{P,T} - \frac{vT\theta^{\infty}}{C_p^{\infty}}\Delta S_P,$$

where ΔS_P represents the entropy change of reaction per unit change of ξ, and C_p, v, and θ are molar heat capacity at

constant pressure, molar volume, and expansivity, respectively. Superscript ∞ represents the instantaneous or "frozen" properties measured at fixed ξ.

29) Of course much better agreement will be obtained if we make the relaxation amplitude analysis, independently of the relaxation time analysis, as a few investigators[30] have done. However, ultrasonic relaxation spectra should be analysed in a selfconsistent way for both relaxation time and relaxation amplitude because the ultrasonic relaxation study does not provide a couple of information, relaxation time and amplitude, independently.

Studies of Collectors. VII.[1] Flotation of Heavy Metal Ions by Using Colored Surfactant

Yoshifumi KOIDE,* Shigekazu SATO, and Kimiho YAMADA
Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860
(Received August 14, 1985)

Colored surfactants containing complex radicals(R-Bc, R-Bs, R-Sh, R-S, R-C, R-Ha, and R-Hb) were applied as ion-flotation collectors and foam-fractionation collectors. The extent of floatabilities for the colored complexing surfactants and metal ions was easily recognized by the degree of discoloration. R-Bc, R-Bs, and R-Sh with low HLB values formed floatable complexes in pH 6—9 with Cu^{2+}, Cd^{2+}, Hg^{2+}, Pb^{2+}, and Sr^{2+}. The residual concentrations of R-Sh, R-Bc, and R-Bs were below 0.1 ppm; however, these concentrations gradually increased after obtaining a minimum concentration of metal ions. Since R-C, R-Ha, and R-Hb had high HLB values, they easily floated Cu^{2+}, Pb^{2+}, and Cd^{2+} by foam fractionation. The concentrations of R-C, R-Ha, and R-Hb in foams or aqueous solutions were correlated to their foaming abilities.

Ion flotation is a method for separating trace amounts of metal ions from an aqueous solution.[2] The collector should be designed so as to effectively float specific metal ions, and the collector should not remain in the residual solution. In order to develop such a collector, the characteristics of surfactants containing complex radicals have been studied. In a previous paper, it was proved that complexing surfactants within an HLB range of 4—14 could very effectively remove metal ions during ion flotation. If their aqueous solutions produce a stable foam by bubbling air, such a complexing surfactant can be expected to be an excellent foam-fractionation collector. Therefore, such a complexing surfactant should be examined regarding applications both as an ion-flotation collector and a foam-fractionation collector. Thus far, its behavior in an aqueous solution and its characteristics during foam fractionation have not been sufficiently elucidated, e.g., as a residual collector, a mechanism of foam fractionation, etc.. In such studies, a simultaneous determination of metal ions and collectors is preferable. A colored surfactant can be easily detected by colorimetry. Moreover, the floatability of metal ions can also be estimated from the fading of a colored surfactant solution. In this study, seven easily prepared colored surfactants were applied as an ion-flotation collector and as a foam-fractionation collector. There have been some reports related to the removal of metal or dye ions using an ionic surfactant and a complexing agent.[2,4,5] However, no papers have been published on a comparative study of the metal-floating mechanism regarding ion flotation and foam fractionation using a colored complexing surfactant.

Experimental

Synthesis of Colored Surfactants. Diazotized *o*-aminobenzoic acid reacted at a pH of 4 with ethyl acetoacetate to form hydrazone. The hydrazone coupled at 0—3 °C with diazotized *p*-toluidine in an alkaline solution to form a 1,5-diphenyl-formazan compound(F).[6] Dyes containing carboxylic or sulfonic acid (R-Bc, M-Bc, R-Bs, and M-Bs, see Fig. 1) were obtained by the coupling of diazotized *p*-aminobenzoic acid and diazotized sulfanilic acid with *N*-dodecylaniline or with *N*-methylaniline, respectively,[7] The crude F, R-Bc, M-Bc, R-Bs, and M-Bs were purified by recrystallization from ethanol. Then, *p*-dodecylaniline was prepared by heating 1-dodecanol with aniline at 250 °C in the presence of zinc chloride (bp 185—191 °C/5 mmHg†).[8] The diazotized *p*-dodecylaniline coupled at pH 4 with 4,5-dihydroxy-1-naphthalene-sulfonic

acid to form R-Sh, at pH 9 with 8-amino-1-naphthol,5-sulfonic acid to form R-S, at pH 5 with 4,5-dihydroxy-2,7-naphthalene-disulfonic acid to form R-C, or at pH 5 with 8-amino-1-naphthol-3,6-disulfonic acid to form R-Ha and at pH 9 to form R-Hb. The five crude dyes(disodium salts) were precipitated by salting techniques. The dyes were washed with acetone and then with small amount of cold water. The formulas and abbreviations are shown in Fig. 1.

Apparatus and Procedures. The flotation apparatus and procedures were the same as those previously reported.[3] The floatability(%) of a metal ion was calculated using:

$$f = \frac{a_0 - a_1}{a_0} \times 100,$$

where a_0 and a_1 denote the initial and the final metal concentrations. The metal ions were determined with an atomic absorption spectrophotometer (Hitachi 170—30) and the minimum values were determined by the decrease of the colored surfactant. The floatability of a colored surfactant was calculated using the same formula as that for metal ions. Its amount in an aqueous solution was determined by spectrophotometry (Hitachi model 101).

Results and Discussion

Colored Surfactant. The structures of colored surfactants were confirmed by means of their IR spectra (Shimadzu IR-408), chromatograms, elementary analyses (Yanaco CHN Corder MT-3), and a determination of an azo group using a titanium trichloride solution.[9] F: Mp 182.0—185.0 °C; IR (KBr) 1700 (carboxyl group $\nu_{C=O}$), 1600 ($\nu_{C=O}$), and 850 (phenylene δ_{C-H}) cm^{-1}; Found: C, 62.6; H, 4.8; N, 17.8%; Calcd for $C_{17}H_{16}N_4O_3$: C, 62.95; H, 4.97; N, 17.27%. R-Bc: Mp 199—202 °C; Found: C, 73.3; H, 8.4; N, 9.9%; Calcd for $C_{25}H_{35}N_3O_2$: C, 73.31; H, 8.61; N, 10.26%. R-Bs: Mp 225—228 °C; Found; C, 64.0; H, 8.0; N, 9.3%; Calcd for $C_{24}H_{35}N_3O_3S$: C, 64.68; H, 7.90; N, 9.43%. R-Sh: Yield 23%; Found: N, 4.96%; Calcd for $C_{28}H_{35}N_2O_5SNa$: N, 5.24%. R-S: Yield 37%; Found: N, 7.36%; Calcd for $C_{28}H_{36}N_3O_4SNa$: N, 7.87%. R-C: Yield 51%; Found: N, 4.28%; Calcd for $C_{28}H_{34}N_2O_8S_2Na_2$: N, 4.40%. R-Ha: Yield 44%; Found: N, 6.52%; Calcd for $C_{28}H_{35}N_3O_7S_2Na_2$: N, 6.61%. R-Hb: Yield 38%; Found: N, 6.57%; Calcd for $C_{28}H_{35}N_3O_7S_2Na_2$: N, 6.61%. The colors of these surfactants were orange or red. Table 1 shows their absorption spectra and surface activities. Their molar absorptivities were of the order 10^4, the same as that of a commercial dye. The absorption spectrum changed with pH. At pH 3, R-Sh and R-C showed a deep color (purple) and the others showed a slight color (R-Bc red, R-Bs red, R-Ha violet, and R-Hb red). The concentrations could be determined by absorbance measurements.

Surface tensions were measured on a Du Noüy surface-tension balance. The colored surfactants lowered the surface tension to 40—47 dyn cm^{-1} {above their critical micelle concentrations (cmc)}. However, M-Bc and M-Bs (having no long alkyl group) scarcely lowered the surface tension. The surface tension of an F solution was 53 dyn cm^{-1}. The cmc of colored surfactants were low, and that of R-S couldn't be measured because of a lower solubility. Their low solubility and low cmc might be caused by a hydrophobic property based on the naphthalene ring and on the hydrogen bridge between both hydroxyl groups or between hydroxyl and amino groups.

Table 1. Absorption Spectra and Surface Activities

Ion Flotation. The determination method was at first examined using a colored precipitation reagent. An organic precipitation reagent usually has a slight ability to float metal ions[1] since its solution shows a weak surface activity. Cd^{2+} flotation using F was effective at pH 7, even from a solution of the Cd^{2+}–Ca^{2+} mixture (Fig. 2-left). The final concentration of Cd^{2+} was 2.2±0.1 ppm (initial: 10 ppm). The concentration was lowered a little by adding an excess of F. Dissolved metal and collector concentrations depend on their solubility product if the resulting complex is floatable. However, an excess additive is not effective. In order to easily detect final concentrations, reversed additives were examined, i.e., a small amount of Cd^{2+} was successively added to a colored F solution. Initially, the color scarcely changed. Then, it faded after Cd^{2+} was added (greater than 2.3±0.2 ppm) since the F formed a floatable Cd^{2+} complex. Figure 2-right shows the absorbance change of an F solution when metal ions (Cu^{2+}, Ni^{2+}, Cd^{2+}, Zn^{2+}, and Ca^{2+}) were successively added. The inflection point in the F concentration curve indicated the minimum metal concentration in the solution. The minimum concentration of Cd^{2+} (according to the inflection-

△: Cu^{2+}, ○: Cd^{2+}, ▲: Zn^{2+}, ●: Pb^{2+}, ■: Ca^{2+}.

point method) agreed with the final concentration of Cd^{2+} by the usual determination (Fig. 2-left). The minimum values from the F-concentration curve were Cu^{2+} 0.8 ppm<Ni^{2+} 1.5 ppm<Cd^{2+} 2.3 ppm<Zn^{2+} 9.3 ppm<Ca^{2+} 12 ppm. A selective removal of Cd^{2+} from the Ca^{2+} mixture can be seen by the inflection point in the F-concentration curve.

Then, the colored surfactants containing long alkyl groups (R-Bc, R-Bs, R-Sh, and R-S) were examined below their cmc as ion-flotation collectors. The floatabilities of these surfactants were easily determined by the discolored solution and the colored scum. The floatabilities of Cu^{2+}, Cd^{2+}, Zn^{2}, Pb^{2+}, and Ca^{2+} using R-Bc or R-Bs were high at pH 6—9. The minimum metal concentrations (from the inflection points of the R-Bc concentration curve) were Cu^{2+} below 0.5 ppm, Cd^{2+} 0.5 ppm, Zn^{2+} 1 ppm, Pb^{2+} 1.5 ppm (indistinct), Ca^{2+} 8 ppm (indistinct),

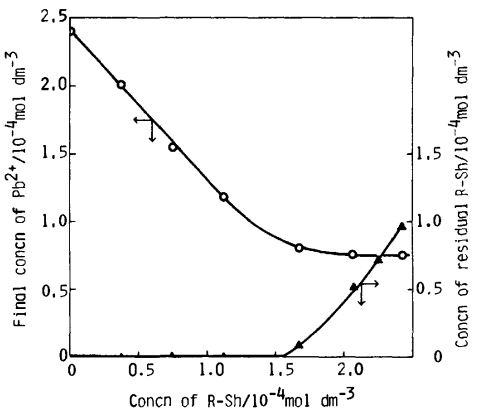

Fig. 4. Final concn of Pb^{2+} and concn of residual R-Sh.
Initial Pb^{2+} concn: 2.4×10^{-4} mol dm^{-3}; pH 6.0.
○: Pb^{2+}, ▲: R-Sh.

as shown in Fig. 3. Similarly, the values from an R-Bs concentration curve were all below 0.5 ppm. However, the inflection point of an M-Bc or M-Bs concentration curve was not observed in the metal-concentration range of 0—15 ppm (Cu^{2+}, Cd^{2+}, Zn^{2+}, Pb^{2+}, Ca^{2+}). Therefore, a long alkyl group is necessary to serve as an effective collector. Each minimum metal concentration according to R-Bc or R-Bs concentration curves (except Ca^{2+}) had similar values compared with that in F. The similar values suggest less selectivity. Their smaller selectivities were presumably caused by similar attractive electrostatic forces between the anionic collectors and the cationic metal ions. The removal of metal ions by ion flotation using sodium dodecanoate(SD) or sodium dodecyl sulfate(SDS) was also less selective,[10] but the minimum values were lower than those according to R-Bc or R-Bs concentration curves. The difference might be based on their HLB. The Cu^{2+} and Pb^{2+} floatabilities using the dihydroxy-type R-Sh were high at pH 4—8, and those using the hydroxy amino-type R-S were high at pH 7—10. The structures of floatable complexes were considered to be R-Sh$\langle_{O}^{O}\rangle$M(metal) and R-S$\langle_{NH_2}^{O}\rangle$MOH at an optimum pH, and those of unfloatable complexes would be cationic metal complexes at a lower pH and anion complexes with OH^- in higher pH. Thus, the flotation efficiency is affected by the HLB of a complex.[3] Figure 4 shows the relation between the additive, R-Sh, and its residual concentration in Pb^{2+} flotation. The Pb^{2+} concentration in an aqueous solution gradually decreased with an increase of R-Sh; then, it became constant (minimum value of Pb^{2+} concentration). The concentration of the residual R-Sh stayed close to zero (below 0.1 ppm) during while Pb^{2+} was decreasing. However, the R-Sh concentration gradually increased after an attainment of a minimum Pb^{2+} concentration. Similar

results were obtained using R-Bc and R-Bs. The increase in the collector concentration showed that the minimum concentration of a metal ion depended on their solubility product, and that the added collector was unfloatable. Therefore, an ion-flotation collector should be added carefully. Any addition must be stopped after an attainment of the minimum metal concentration. The removal slope of Pb^{2+} indicated that the molar ratio of the R-Sh–Pb complex was 1:1. The same ratio was obtained by an analysis of the scum and by a titration-curve measurement of 4,5-dihydroxy-2,7-naphthalene-disulfonic acid with Cu^{2+}, a similar chelate complex.[11] Furthermore, the potentiometric titration curves of R-Sh (with and without metal ions) were measured. The order of the stability constants was $Cu^{2+}>Pb^{2+}>Cd^{2+}>Ca^{2+}$. Therefore, Pb^{2+} could be selectively floated from a Pb^{2+}–Ca^{2+} mixture. The bonding forms of R-Sh, R-S, and F with metal ions differ from those of R-Bc and R-Bs. The minimum value using R-Sh, R-S, or F was inferior to that using R-Bc or R-Bs, since the solubilities of the complex salts (R-Bc and R-Bs) were lower than those of the chelate complexes (R-Sh, R-S, and F). However, the selectivities of the chelate complexes were superior to those of the complex salts.

Foam Fractionation. Disulfo-type R-C, R-Ha, and R-Hb with a large hydrophilic property were used below their cmc as foam-fractionation collectors after they showed a foaming ability. A separation was recognized by a discoloration of a solution and the appearance of a colored foam. Figure 5 shows a simple determination of the minimum metal concentration using R-Ha. The inflection point for the foam fractionation was not very clear since a colored surfactant also floated without the metal ions. However, the inflection points could be read from Fig. 5. The order of the selectivity was $Cd^{2+}>Ca^{2+}>Pb^{2+}>Cu^{2+}$, whereas the stability constants of R-Ha complexes were $Cu^{2+}>Hg^{2+}>Pb^{2+}>Cd^{2+}>Ca^{2+}$. These differences are probably caused by their foaming power, as described in the following section. Furthermore, 10^{-4} mol dm^{-3} of radioactive $^{90}Sr^{2+}$ was removed (80—87% in pH 4—11) using 2×10^{-4} mol dm^{-3} of R-Hb; the floatability was twice as high as that using SDS.

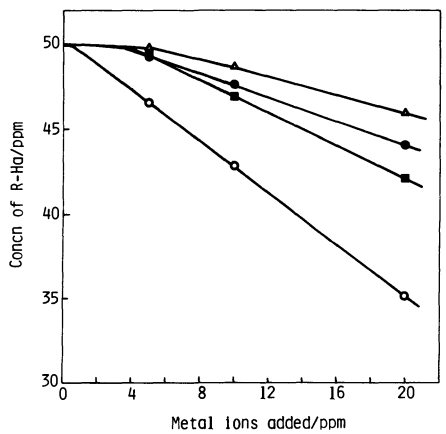

Fig. 5. Determination of min metal concn according to inflection point for foam fractionation.
○: Cd^{2+}, ■: Ca^{2+}, ●: Pb^{2+}, △: Cu^{2+}.

The foam fractionation for the floatabilities of four metal ions and these surfactants are shown in Table 2. The floatabilities using R-C were Cd^{2+} 97%, Cu^{2+} 68%, Pb^{2+} 65%, and Hg^{2+} 24%. The ratio of the metal-ion floatability to the R-C floatability was about 1(0.9—1.1) and the ratio to the R-Ha or R-Hb floatability was 0.7—1.0, except for that of Hg^{2+}. The order of the stability constants was $Cu^{2+}>Hg^{2+}>Pb^{2+}>Cd^{2+}>Ca^{2+}$. The stability constant of the 1,8-dihydroxylnaphthalene-3,6-disulfonic acid complex was log K_{CuL} 13.45,[11] while that of the metal hydroxide was log K_{HgOH} 11.51, log $K_{Hg(OH)_2}$ 11.15, and log K_{CuOH} 6.03.[12] Therefore, Hg^{2+} could be hydrolyzed at pH 7 and a ratio of the Hg^{2+} floatability to the colored surfactant of less than 0.6. Furthermore, the floatability was also affected by the foaming power. The relation between the foaming power and the concentration of the colored surfactant in a foam was measured at pH 3, 7, and 12 (Fig. 6). Such a foaming power (to rise to the top of a vessel) is required of a foam-fractionation collector. However, the formation of a rich foam lowered the surfactant concentration in the foam but not in an aqueous solution. A similar relation was observed in the presence of metal ions. The low foaming power was, consequently, excellent for the separation of the

complex. However, R-Bc, R-Bs, and R-Sh can't be used as a foam-fractionation collector because of the instability of the foam. The residual concentration of a colored surfactant in the presence of metal ions was higher than that in their absence; i.e., R-Ha 12 ppm (with Cu^{2+}), 11 ppm (with Hg^{2+}), 16 ppm (with Pb^{2+}), 14 ppm (with Cd^{2+}), 6 ppm (without). Contrary to ion flotation, an excess surfactant is necessary to float metal complexes by foam. Furthermore, the residual surfactant concentration is expected to become lower by increasing the bubbling rate.[2] However, its effect on foam fractionation was not examined.

HLB Character in Foam Fractionation. The minimum concentration for ion flotation depended on the solubility product when the resulting complex was floatable. The floatability was affected by the HLB. However, the minimum concentration and floatability in a foam fractionation depended on their complex formation and on their foaming abilities. Foaming ability was correlated to the residual concentration of a surfactant. The concentration became low when the solubility product of the complex was small. Then, the HLB values were also low. Therefore, the foaming power can be associated with their HLB value. The calculated HLB values of complexes, based on the Oda equation,[13] are shown in Table 3. The floatable species were thought to be surfactant-hydroxo-metal complexes (Sur-MOH). The suitable HLB value for ion flotation was considered to be 5—12 and the value for foam fractionation was considered to be 21. These HLB ion-flotation values are almost the same as the value (4—14) reported in a previous paper.[1] Also, the HLB values for a foam fractionation were found to be larger than those for ion flotation.

a) Calcd HLB based on the Oda equation.[13] b) Sur=M.

The results presented in this work provide an explanation for the character of a complexing surfactant during ion flotation and foam fractionation. A colored surfactant was well suited for a simultaneous determination of the collector and metal ions. The complexing surfactant remained slightly in an aqueous solution, but its ion-flotation concentration increased upon adding a collector after an attainment of the minimum metal concentration. The metal-floating mechanism in foam fractionation was explained using the HLB value. Thus, the characteristics of a complexing surfactant have become more apparent. In this experiment, the complex radicals which were used were less selective for specific metal ions. An excellent colored complexing collector can be obtained by a selection of a complex radical and the regulation of its HLB.

Pulse Radiolysis Study of Reaction of OH Radicals with Triose Reductone

Hideo Horii,* Yasuo Abe, and Setsuo Taniguchi
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai 593
(Received August 19, 1985)

The reaction between the hydroxyl radical (OH) and triose reductone (2,3-dihydroxy-2-propenal) in an aqueous solution has been studied by spectrophotometric pulse radiolysis. The OH radical adds to triose reductone (TRH_2) to form the transient OH adduct ($TRH(OH)^{-\cdot}$) with an absorption maximum at 398 nm, ε= 3150 $M^{-1}cm^{-1}$ (1 M=1 mol dm^{-3}) in a neutral solution. The OH adduct decays by second-order kinetics in the pH range 2—12. The rate constants for the reactions of the OH radical with dissociated and undissociated triose reductone are 1.4×10^{10} $M^{-1}s^{-1}$ and 9.9×10^{9} $M^{-1}s^{-1}$, respectively. The dependence of the transient absorption on the pH shows that the OH adduct has a pK_a value of 4.7.

The structure of triose reductone (2,3-dihydroxy-2-propenal) was determined to be CH(OH)=C(OH)-CHO by H. von Euler and C. Martius.[1] A very important characteristic of "reductone" is a strong reducing ability due to its enediol group, -C(OH)=C-(OH)-.[2] Well-known reductones, L-ascorbic acid,[3-5] adrenaline,[6] and dopamine[7] which play significant roles in biological systems, have been studied by pulse radiolysis. These reductones react with OH radicals to form OH adducts or one-electron oxidized radicals. The OH adducts can be converted to one-electron oxidized radicals by dehydration. Thus, the oxidation of the reductones has been shown to proceed through the intermediate radicals. Triose reductone is yielded in biological systems[1,8-10] and in the process of the browning reaction of milk.[11] In addition, it reacts with amino compounds to yield anil compounds[2] or causes a DNA-breaking action in the presence of Cu^{2+}.[12] The enzymatic oxidation of triose reductone has also been reported to produce a free radical in an ESR study.[13,14] It is useful to study the oxidation mechanism of triose reductone, as it is an important compound in biological systems[2] and is one of the simplest reductones. We have kinetically studied the oxidations of triose reductone using oxygen and hydrogen peroxide,[15] a peroxodisulfate ion,[16] and a hexacyanoferrate(III) ion,[17]. In our previous paper[18,19] it was found that triose reductone is oxidized by $X_2^{-\cdot}$ (X=SCN, Cl, Br, I) and $N_3\cdot$ to yield a one-electron oxidized radical. In the present research we studied the reaction of the OH radical with triose reductone kinetically and found a different transient species from the one-electron oxidized radical ($TR^{-\cdot}$).

Experimental

Pulse irradiation was accomplished using the 18 MeV linac (High Voltage Engineering Co.) of the Radiation Center of Osaka Prefecture at room temperature (about 20 °C). Details of the detection systems, dosimetry, and solution handling techniques were previously described.[19] All solutions were prepared from triply distilled water. Dinitrogen monoxide (Showa Denko Co., High Purity, upper limit of O_2 content: 10 ppm) was used after the deaeration of solutions by argon (Osaka Sanso Co., For Instrument Grade). The solutions were bubbled before irradiation for ≈60 min with Ar and N_2O. This procedure converts hydrated electrons into OH radicals. Triose reductone was prepared and purified by the method of Euler and Martius.[1] All other chemicals used were of analytical reagent grade. The pH of solutions was generally adjusted by an addition of the appropriate amounts of $HClO_4$ or NaOH.

Results and Discussion

Absorption Spectra of the Transient Intermediates Yielded by OH Radicals. A N_2O-saturated solution containing 300 μM of triose reductone at pH 7.8 was pulse-irradiated at a dose of about 500 rad per pulse. The spectrum of the transient intermediate immediately after a pulse at pH 7.8 is shown in Fig. 1. The transient absorption almost disappears upon the addition of 0.2 M *t*-BuOH, which scavenges OH

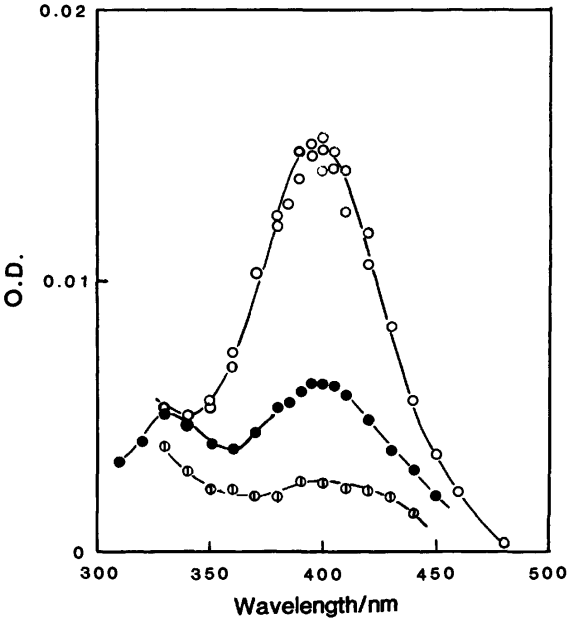

Fig. 1. Transient absorption spectra produced by pulse irradiation of N_2O saturated 3×10^{-4} M triose reductone solution. Normalized dose, 500 rad; pH 7.8 (○), pH 4.63 (●), pH 3.03 (Ⓓ).

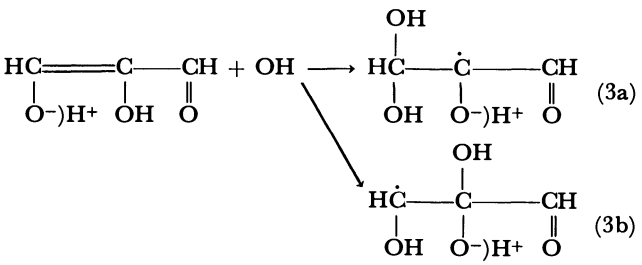
radicals. The result indicates that a transient absorption is produced by a reaction of triose reductone with the OH radical. The absorption spectrum shows an almost symmetrical (Gaussian-type) band with a maximum at 398 nm and a width at half-maximum of 71 nm. The shape of this spectrum is similar to that[19] of the triose reductone radical ($TR^{-}\cdot$, λ_{max}=398 nm) yielded through the oxidation of triose reductone by the inorganic radicals ($N_3\cdot$, $(SCN)_2^{-}\cdot$, $Br_2^{-}\cdot$, etc). The absorption coefficient around a neutral pH was obtained to be 3150 $M^{-1}cm^{-1}$ at 398 nm from the linear slope of absorbance vs. pulse dose. This value is about half of that of the triose reductone radical (5500 $M^{-1}cm^{-1}$).[19] Analogous facts have been found through a pulse radiolysis of ascorbic acid.[3] The absorption coefficients of the spectra become smaller with a decrease in the pH. The spectra of the transients at pH 4.63 and 3.03 are also shown in Fig. 1. The absorption at 398 nm almost disappears at pH 3. The triose reductone radical ($TR^{-}\cdot$) has a pK_a of 1.4.[19] If this intermediate is the triose reductone radical, the absorbance around 400 nm should remain unchanged at a pH >3. From these facts, it is seen that this transient species is not the triose reductone radical. It should be the OH adduct of triose reductone, since the OH radical is easy to add to an unsaturated bond. Triose reductone has two dissociation constants[15] (pK_1=5.0, pK_2=13.0). Therefore, the reaction scheme can be described by the following equations.

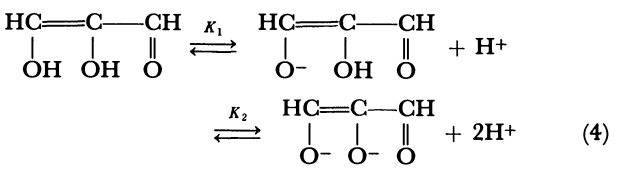
$$H_2O \rightsquigarrow e_{aq}^{-},\ H,\ OH,\ H_2O_2,\ H_2 \qquad (1)$$

$$N_2O + e_{aq}^{-} \longrightarrow OH + OH^{-} + N_2 \qquad (2)$$



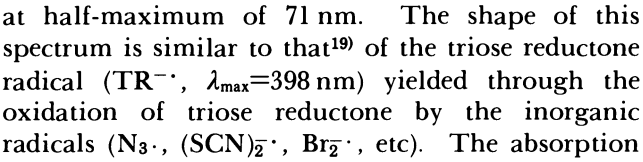
(3a)

(3b)



(4)

The electron density is greater on C2 than C3 from the results of ab initio MO calculations of triose reductone.[20] It is also presumed by electronic effects. Hence, an electrophilic attack of the OH radical is more likely to occur through reaction 3b than 3a. Ascorbic acid reacts with the OH radical to yield the OH adduct and the adduct loses H_2O (or OH^{-}) to form the ascorbic acid radical.[3] However, the conversion of the OH adduct of triose reductone into the $TR^{-}\cdot$ radical was not observed. This OH adduct should be rather stable and can not be converted into the $TR^{-}\cdot$ radical by dehydration as in the following reaction (5).



(5)

Rate Constants for the Reactions of Dissociated and Undissociated Triose Reductone with OH Radicals. The rate constant for the reaction of dissociated triose reductone with the OH radical was measured by the competition between TRH^{-} and *t*-BuOH with OH (Eqs. 3 and 6).

$$t\text{-BuOH} + OH \longrightarrow t\text{-BuOH radical} + H_2O \qquad (6)$$

From this competition it follows that

$$\frac{D_0}{D_s} = 1 + \frac{k_6[t\text{-BuOH}]}{k_3[TRH^{-}]}, \qquad (I)$$

where D_0 and D_s are the optical densities at 400 nm in the absence and presence of *t*-BuOH, respectively. *t*-Butyl alcohol is a well-known scavenger of OH redicals. A plot of D_0/D_s versus [*t*-BuOH]/[TRH^{-}] gives a straight line (Fig. 2a). From the slope, k_3 was determined to be 1.4×10^{10} $M^{-1}s^{-1}$, taking $k_6=5.2\times10^{8}$ $M^{-1}s^{-1}$.[21] Below a pH of 3.5, the transient absorption is very small above a wavelength of 310 nm. Therefore, the rate constant for a reaction of undissociated triose reductone with OH radicals was measured by the competition between TRH_2 and SCN^{-} with OH radicals. (Eqs. 3 and 7)

$$SCN^{-} + OH \longrightarrow \cdot SCN + OH^{-} \qquad (7)$$

The $\cdot SCN$ radical reacts with SCN^{-} to form $(SCN)_2^{-}\cdot$ which has an absorption maximum at 472 nm, according to the following reaction.

$$SCN^{-} + \cdot SCN \longrightarrow (SCN)_2^{-}\cdot \qquad (8)$$

From this competition it follows that

$$\frac{D_0}{D_s} = 1 + \frac{k_3[TRH_2]}{k_7[SCN^{-}]}, \qquad (II)$$

where D_0 and D_s are the optical densities at 472 nm, in the absence and presence of TRH_2, respectively. A plot of D_0/D_s versus [TRH_2]/[SCN^{-}] gives a straight line (Fig. 2b). From the slope, k_3 was determined to be 9.9×10^{9} $M^{-1}s^{-1}$, taking $k_7=1.1\times10^{10}$ $M^{-1}s^{-1}$,[22] which is most reliable in the competition method of thiocyanate. The rate constants of both the dissociated and the undissociated forms are summarized in Table 1. For the sake of a comparison, the data for L-ascorbic acid[3] (where 6×10^{9} $M^{-1}s^{-1}$ is used for k_7 and the recalculated data using $k_7=1.1\times10^{10}$

b: Ref. 3.

$M^{-1}s^{-1}$) are also listed in Table 1. The rate constants for an addition of OH radicals with both reductones are almost diffusion controlled, but a little larger in dissociated forms than undissociated ones, respectively.

pK_a of the OH Adduct of Triose Reductone. The molar extinction coefficients (ε) of the OH adduct of triose reductone (determined at 400 nm as a function of pH) are shown in Fig. 3. The numerical values of ε were corrected for the transient species ($\varepsilon_{400\,nm}=300$ $M^{-1}cm^{-1}$)[19] produced by a reaction of triose reductone with the H radical. The smooth line in Fig. 3 was computed by assuming that the pH dependence of the extinction coefficient results from an acid-dissociation process, using $\varepsilon_{400\,nm}^{TRH_2(OH)\cdot}=250$ $M^{-1}cm^{-1}$, $\varepsilon_{400\,nm}^{TRH(OH)^{-}\cdot}=3150$ $M^{-1}cm^{-1}$. The acid-dissociation constant giving the best fit to the data was pK_a=4.7. The acid-base equilibrium is given as follows.

$$TRH_2(OH)\cdot \overset{pK_a=4.7}{\rightleftharpoons} TRH(OH)^{-}\cdot + H^+ \qquad (9)$$

The pK_a value of the OH adduct transient species is a little smaller than that of triose reductone (pK_1=5.0). This fact shows that the OH adduct radical is a little more acidic than triose reductone.

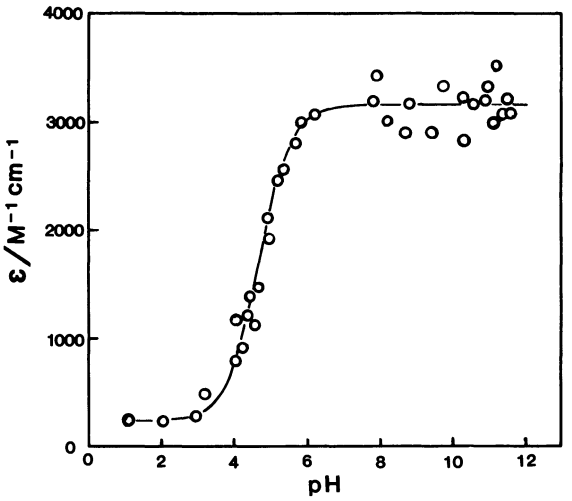

Fig. 3. Dependence of molar extinction coefficient(ε) at 400 nm, of the OH adduct of triose reductone on pH. N_2O saturated solutions of 1—5×10^{-4} M triose reductone.

Radical Decay Rate. The transient species yielded by a reaction of triose reductone with OH radicals decay by second-order kinetics over a wide pH range (pH 2—12). The reaction rate for two ions is dependent on the ionic strength (μ), as approximately given[23] by

$$\log k/k_0 = Z_AZ_B(1.02\mu^{1/2})/(1+\mu^{1/2}) = Z_AZ_Bm, \qquad (III)$$

where k_0 is the value of k at zero ionic strength, Z_A and Z_B are the charges of the two ions, and μ is the total ionic strength. The effect of the ionic strength on the decay rate of the OH adduct of triose reductone was studied at pH 9.4, where the radical was presumed to be dissociated from the value of pK_a (4.7), using sodium sulfate to vary μ. A plot of log $k_{obsd}/\varepsilon_{400}$ vs. m gave a straight line with a slope of

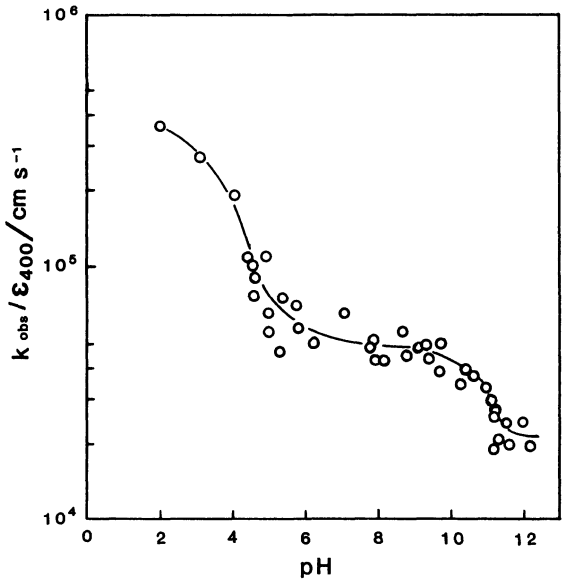

Fig. 4. Dependence of decay rate ($k_{obsd}/\varepsilon_{400}$) of the OH adduct of triose reductone radical corrected for ionic strength on pH.
N_2O saturated solutions of $1-5\times10^{-4}$ M triose reductone.

0.77. Hence, this intermediate probably has a unit negative charge and can be assigned to the one-dissociated OH adduct radical ($TRH(OH)^{-}\cdot$) in the pH range 5—10. Figure 4 shows the pH dependence of $k_{obsd}/\varepsilon_{400}$, where k_{obsd} is the observed second-order rate constants of the transients at 400 nm in triose reductone solutions saturated with N_2O. The rate constants were corrected for ionic strength. The values of k_{obsd} are almost constant in the pH range 5.5—9.5 ($k_{obsd}=1.5\times10^8$ M^{-1} s^{-1}). However, in the pH range 3—5.5, complex reactions as a result of the acid-base equilibrium of the intermediate occur according to the following equations.

$$TRH(OH)^{-}\cdot + TRH(OH)^{-}\cdot \longrightarrow \text{Products} \quad (10)$$

$$TRH_2(OH)\cdot + TRH(OH)^{-}\cdot \longrightarrow \text{Products} \quad (11)$$

$$TRH_2(OH)\cdot + TRH_2(OH)\cdot \longrightarrow \text{Products} \quad (12)$$

The effect of the H adduct of triose reductone seems to become greater around pH 2. The rate constant of k_{obsd} at pH 11.5 is 7×10^7 M^{-1} s^{-1}. The change of the rate constant around pH 11 is not yet well understood. This result might suggest the effect of a second dissociation of the OH adduct. However, since the data vary to a considerable extent, it is difficult to give a clean explanation.

The authors wish to thank the members of the linac group for operating the linac.

Electrocatalysis in Metal Hydride Electrode. I. Hydrogen Electrode Reaction on Group-IB and VIII Metals Deposited on Palladium Substrates

Ken-ichi MACHIDA and Michio ENYO*
Research Institute for Catalysis, Hokkaido University, Sapporo 060
(Received September 2, 1985)

Hydrogen electrode reactions (HER) on thin-layer electrodes of group-IB and VIII metals (Cu, Ag, Au, Ni, and Pt) prepared by electro-deposition on Pd foil substrates were studied (together with the Pd foil itself) in 0.5 M H_2SO_4 and 1.0 M NaOH (M=mol dm^{-3}) at 303 K by a transient technique. The reactions on these metals were concluded to proceed via a Volmer-Tafel reaction route and the exchange current densities of the elementary steps, i_{oV} and i_{oT}, were then evaluated. The electrocatalytic activities towards the Volmer step were observed to be in the order Pt>Pd>Au>Ag>Cu in an acidic solution and Pt>Pd>Ni≧Ag≧Au≧Cu in an alkaline solution. The activities towards the Tafel step were Pt≧Pd>Au>Cu>Ag in an acidic solution and Pd>Pt>Au>Cu=Ag>Ni in an alkaline solution. The results were summarized in terms of the parameter m_o ($=i_{oV}/i_{oT}$). This parameter was used to describe the electrochemistry of the energy efficiency of a hydride-type hydrogen-storage electrode, when the metals were employed for the purpose of modifying the electrode surface. Pt and Ag (among the group-IB metals) in both acidic and alkaline solutions were revealed to be suitable electrocatalysts.

The entry of hydrogen into metal or alloy electrodes during the electrochemical evolution of hydrogen has been studied for a long time, mainly in connection with the problem of the hydrogen embrittlement of substrate metals.[1,2] On the other hand, the potential of hydrogen-absorbing metals or alloys as a means of energy storage has been noted during the last ten years.[3] Secondary batteries using hydrogen-storage matrices, such as alloys based on alkaline earth metals or lanthanoid metals, possess (in principle) larger capacitance per unit weight than lead-acid batteries. According to Videm,[4b] their theoretical energy densities are as follows: MgH_2/air; 1900, CaH_2/air; 680, and $LaNi_5H_6$/air; 458 Wh kg^{-1}, whereas the conventional lead-acid battery is 161 Wh kg^{-1}.

The construction of hydride cells using aqueous[4-7] electrolytes may be divided into two types: The direct type in which hydrogen-storage materials (metal hydrides) are directly immersed in the electrolyte,[4a,b,d] and the indirect type in which a hydrogen-permeable membrane (such as Pd foils) is employed as a hydrogen electrode at the same time as a container of metal hydrides.[4b,4c,5-7] The latter may also include a type in which hydrogen is stored outside the cell by means of, e.g. metal hydrides. While alkaline media might only be practical for the former type, both acid and alkaline solutions might be used in the latter.

The present discussion is not concerned with the latter indirect type since it is essentially a H_2/air fuel cell (with a combined operation as a water electrolyzer) equipped with a suitable device of H_2 storage. This type is probably suitable for a large-scale energy storage device. On the other hand, a more detailed analysis would be required regarding the former type. This is the topic of the present work.

Basic Concepts. In the direct-type electrochemical hydrogen energy storage system, hydrogen produced on the cathode is dissolved into the electrode material and then ionized during its use as a current generator. The efficiency of the energy conversion through charging and discharging processes may be lowered by various factors, such as hydrogen diffusion in the metal hydride. However, the most important factor concerning its electrochemistry is the overpotentials involved in those processes. In this respect, for a given metal-hydride system chosen for hydrogen storage, a surface modification with other (metallic) materials might be required in order to improve the efficiency.

Further, it is well known that many of the metal hydrides tend to pulverize during hydrogen charging/discharging cycles and, thus, introduce difficulties concerning practical devices. To prevent this, a microcapsulation technique involving the coating of a metal hydride powder with a ductile metal has been proposed.[8] This may completely change the electrocatalytic property of the hydride electrode; hence, one should know the surface modification effects of each candidate metal.

The majority of hydrogen-absorbing metals or alloys have a plateau region in the absorption isotherm, e.g. the α-β phase transition region in the Pd-H system. This provides the basic character of that hydrogen-storage system. Naturally, one should cover this region during operation in order to maximize the storage capacity.

The extent of hydrogen absorption into metals or alloys which are polarized in aqueous or other protonic environments is intimately related to the HER mechanism. If HER proceeds through the Volmer-Tafel reaction route:

Volmer step,

$$H^+B + e \rightleftharpoons H(a) + B \quad (B=H_2O, OH^-)$$

Tafel step,

$$2\,H(a) \rightleftharpoons H_2,$$

the overpotential components for these elementary steps (η_V and η_T) under steady-state polarization are given, respectively, by,[9]

$$\eta_V = \eta + \frac{RT}{F} \ln \gamma_H, \quad (1)$$

$$\eta_T = -\frac{RT}{F} \ln \gamma_H, \quad (2)$$

where $\gamma_H = a_H/a_{H,o}$, a_H is activity of the hydrogen adatom, H(a), established during the steady-state polarization. The subscript o indicates the equilibrium of the overall reaction. The overall overpotential, η, is related to the component overpotentials by $\eta = \eta_V + \eta_T$.[9]

If an electrode material with an extensive and rapid hydrogen absorption is used, a plateau region (in the time window of 10^{-3}—10^{0} seconds in the case of thin Pd foil) usually appears on the galvanostatic overpotential rise transient curves or on the overpotential decay transients after current interruption. The plateau overpotential value on the rise transient curve may be explained[9] as the overpotential component required for the Volmer step to proceed with the rate predetermined by the applied current. No overpotential component for the Tafel step should be required at the very beginning of the transient, provided that a_H is effectively equal to $a_{H,o}$, owing to high rate of dissolution of H(a) into the electrode and, hence, the insignificant growth of a_H during this very short period of time. Only after a prolonged polarization time does a growth of a_H take place and, hence, of η beyond this level. Accordingly, an extrapolation of the plateau to time zero yields the overpotential component, η_1. An analysis of η_1 readily provides the kinetic parameters of the Volmer step, e.g. i_{oV} and the symmetry factor, β, being separated from those of the Tafel step (see below, Fig. 3, etc.).

Likewise, an extrapolation of the plateau on the overpotential decay transient to time zero after a current interruption should divide η into two overpotential components: η_1' for the short time process and η_2' for the long time process, where $\eta = \eta_1' + \eta_2'$. As discussed elsewhere,[9] η_2' is related to γ_H, the activity level reached during a steady-state polarization as,

$$\frac{RT}{F} \ln \gamma_H = -\eta_2'. \quad (3)$$

Hence, we find, referring to Eq. 2,

$$\eta_2' = \eta_T. \quad (4)$$

Similarly,

$$\eta_1' = \eta - \eta_2' = \eta - \eta_T = \eta_V. \quad (5)$$

Equation 3 may be related to the equivalent hydrogen pressure/fugacity $\bar{P}_{H_2}$ of the plateau region of the metal hydride electrode, given as the ratio over the reference pressure $\bar{P}_{H_2,o}$ (usually the atmospheric pressure), by combining it with the Nernst equation for a concentration cell,

$$E = -\frac{RT}{2F} \ln (\bar{P}_{H_2}/\bar{P}_{H_2,o}) \quad (6)$$

and to the relation (in terms of chemical potentials concerning the hypothetical hydrogen adsorption equilibrium) $\mu_{H_2} = 2\mu_{H(a)}$. Thus, we find,[10]

$$\eta_2' = -\frac{RT}{2F} \ln (\bar{P}_{H_2}/\bar{P}_{H_2,o}). \quad (7)$$

This indicates that the value of η required to charge up an electrode with hydrogen should be such that it contains a magnitude of η_2' that at least satisfies Eq. 7. Since $\bar{P}_{H_2}$ should, in principle, be larger than the reference hydrogen pressure in the same system, η_2' must always be finite. Its magnitude is determined by the type of the hydride used and the operating conditions chosen.

On the other hand, η_1' is the overpotential component, or additional amount of energy which is required to produce hydrogen from water. Accordingly, the smaller the magnitude, the smaller will be the energy consumption during the charging (also discharging). Hence, the higher will be the efficiency of the energy storage. It may be said, therefore, that the surface modification electrocatalysts that have small η_1' values compared with η_2' should be employed in order to minimize the energy loss.

The ratio η_1'/η_2' (or η_V/η_T) is determined by the specific rates of the elementary reaction steps. A series of studies[11] on HER (by means of a deuterium tracer technique) have already revealed the rates of the Volmer and Tafel steps on several electrocatalysts (Rh, Ir, Ni, Pt, Ag, and Au). Also, in our recent studies,[12,13] details regarding HER characteristics on Pd, Cu, Ag, and Ni have been investigated by means of a galvanostatic overpotential transient analysis.

In the present work, the HER characteristics of group-IB and VIII metal catalysts, particularly the ratio of the rates of the Volmer and Tafel elementary steps, are reported and the use of these metals as surface modification electrocatalysts in metal-hydride type secondary batteries is discussed.

Experimental

Preparation of Electrodes. Pd foils (a rectangular form of 5×5 mm, 12.5 μm in thickness) were used as substrates of the electrodes, which provided the hydrogen storage characteristics needed to carry out the transient polarization analysis mentioned above. Pd foil electrodes coated with

one of the group-IB metals or with Pt were prepared by electro-deposition from 0.5 M H_2SO_4 solutions containing $CuSO_4 \cdot 5H_2O$, $AgNO_3$, $HAuCl_4 \cdot 4H_2O$, or $H_2PtCl_6 \cdot 6H_2O$, respectively. This was done up to a thickness corresponding to $2-5\times10^{-7}$ mol cm^{-2} (apparent) or of the order of 10^{-6} cm in thickness (as judged from the amount of electricity applied, assuming 100% current efficiency). A series of preliminary experiments indicated that these coatings were sufficient to give rise to their own electrodic characteristics and yet retain an acceptable level of hydrogen permeability into the Pd foil substrates. This is required for the present type of transient analysis.

Electrochemical Measurements. The galvanostatic and potentiostatic polarization experiments were carried out in 0.5 M H_2SO_4 and 1.0 M NaOH at 303 K by using a previously described technique.[14] The electrolytic solution was prepared from a special grade H_2SO_4 (Wako, Tokyo) and pro analysi grade NaOH (Merck Japan, Ltd.) with water obtained from a Millipore pure water system. The real surface areas of the test electrodes were evaluated from double-layer capacitance data obtained by a pulse technique, assuming a value of 18 μF cm^{-2} (true).

The amount of hydrogen stored in the electrode was determined by measuring the quantities of electricity needed for its potentiostatic anodic ionization at 400 mV (RHE). The measurements were carried out after a steady-state polarization for several hours which was set at a desired overpotential between $\eta=-20$ and 200 mV. The overpotential component η_2' was evaluated from short time decay transients taken during the steady-state polarization.

Results and Discussion

Overpotential Transients. For all the electrodes prepared in this work, the overpotential plateau in a short-time transient curve (several seconds) has been easily recognized. Thus, the electrodes are considered to have good hydrogen permeabilities. Typical long-time rise and decay transient curves observed on a Pd foil and Au- or Pt-coated Pd foils in acidic and alkaline solutions are shown in Figs. 1 and 2, respectively. Similar behaviors were also observed on the other electrodes. The ratio η_1'/η_2' was generally observed to be larger in an acidic than in an alkaline solution.

Palladium. This element has a high hydrogen permeability, allowing a detailed study of the HER characteristics by a previously reported transient technique.[9,10,12,14]

Typical "Tafel" plots of η_1 on a bare Pd foil electrode in both acidic and alkaline solutions are shown in Fig. 3. The polarization characteristics in these solutions were very similar to each other. The slope of the linear portions in their Tafel plots was usually close to 120 mV decade^{-1} (both in the anodic and cathodic sides). Thus, they are practically symmetric on the abscissa. This form well substantiates the view that η_1 originates from the Volmer step. The i_{oV} values were estimated from linear plots of η_1 vs. i near the reversible potential (the inset figures) by the relation[9] $i_{oV}=(RT/F)/(di/d\eta_1)_o$. These were in good agreement with those

anticipated from the Tafel plots, being about 5×10^{-3} and 2×10^{-5} A cm^{-2} (true) in the acidic and alkaline solutions, respectively.

The total overpotential, η, and the slowly decaying overpotential component, η_2', are shown in Fig. 4. Tafel plots of η and η_2' are seen to possess a linear portion with a slope of about 120—140 or 30—40 mV decade^{-1}, respectively. The latter value indicates that η_2' can be attributed to the Tafel step.[9] This again confirms the former conclusion that the HER on Pd proceeds via the Volmer-Tafel reaction route. The exchange current density of the Tafel step was evaluated by the relation[9] $i_{0T}=(RT/2F)/(\mathrm{d}i/\mathrm{d}\eta_2')_0$ to be about 5×10^{-4} and 1×10^{-4} A cm^{-2} (true) in the acidic and alkaline electrolyte, respectively.

In an alkaline solution, the rate of the overall HER was slower than in the acidic solution. In this case, the decrease in the rate was particularly significant for the Volmer step as compared with the Tafel step. As a consequence, the value of i_0 in the alkaline solution evaluated from the linear η vs. i plot (the reaction resistance) at low η by the relation[9] $i_0=(RT/F)/(\mathrm{d}i/\mathrm{d}\eta)_0$ (approximately valid when $i_{0V} \ll i_{0T}$) became fairly close to i_{0V} and smaller than i_{0T}. Thus, the HER kinetics were mostly dominated by the Volmer step. Correspondingly, the m_0 value became as small as 0.2. This is very small compared with that in an acidic solution (m_0=10). Accordingly, Pd in acidic solutions should yield a high energy storage efficiency if used by itself or to modify the surfaces of other hydrogen-storage electrode materials. However, that would not be the case in an alkaline solution.

Group-IB Metals. As is well known, the HER on these elements does not proceed as rapidly as on group-VIII metals. The i_0 values have been reported to be 10^{-5}—10^{-7} A cm^{-2} (true) both in acidic and alkaline solutions,[15,16] except that Au after anodic activation occasionally shows a very high activity.

The cathodic and anodic polarization behaviors of η_1 on an Au/Pd foil electrode are shown in Fig. 5. Like Pd, the polarization characteristics are quite acceptable as that of the Volmer step. The i_{0V} values were, however, scattered between 3×10^{-3} and 3×10^{-6} A cm^{-2} (true). Among them, the Volmer step on Au

0.5 M H_2SO_4 and 1.0 M NaOH, 303 K.

in an acidic solution only was very fast. On the other hand, the Tafel plots on η and η_2' (Fig. 6) had a slope of about 120 and 30 mV decade^{-1}, respectively. This was the same as for the previously observed values on Pd. The overpotential component η_2' was, hence, attributed to the Tafel step, yielding the i_{oT} values in the range 10^{-4} to 10^{-6} A cm^{-2} (true). These results on Cu and Ag in 0.5 M H_2SO_4 were in good agreement with those reported earlier.[12] The value of m_o was in the order Ag>Au>Cu in an acidic solution or Ag>Cu>Au in an alkaline solution (see Table 1 below). Among the group-IB metals, Ag was, thus, found to be an acceptable electrocatalyst in metal hydride secondary batteries in acidic (or alkaline) solutions.

Nickel. Details of HER on $LaNi_5$ film, Ni–Ti alloy films, amorphous Ni–Ti alloy ribbons, and Ni–V alloy ingots (all having a high hydrogen permeability) in 1.0 M NaOH were reported in previous papers.[13] The electrocatalytic characteristics on those alloys could essentially be attributed to the nickel on their surfaces. This idea was supported by SEM observations and XPS surface analyses.[13] The HER on these metals was also concluded to proceed via the Volmer-Tafel reaction mechanism with mixed rate-determining characteristics. Both the i_{ov} and i_{oT} values were estimated to be around 10^{-6} A cm^{-2} (true). Among these alloys in an alkaline solution, the m_o value on a $LaNi_5$ film was considerably larger (m_o=4) than the others (m_o=1—2.5). The scatter of the data among the alloys is not well understood. It may be due to an effect related to the different ways of preparation or to a synergistic effect due to the alloying component. The reasonably high values of m_o on Ni indicate that Ni may be an acceptable electrocatalyst in metal-hydride secondary batteries, or that a surface modification may not be required if Ni-based hydrogen storage materials are used without microcapsulation, etc.

Platinum. The exchange current density of HER on Pt is around 10^{-3} and 10^{-4} A cm^{-2} (true) in acidic and alkaline solutions, respectively.[15,16] However, in the latter media, the electrocatalytic activity of Pt is occasionally unstable and becomes considerably lower with time.

Figure 7 shows Tafel plots of η_1 in 0.5 M H_2SO_4 and 1.0 M NaOH. The polarization characteristics clearly show that η_1 originates from the Volmer step. As seen from the figure, the discharge process on Pt in an acidic solution was very rapid and i_{ov} was 6×10^{-2} A cm^{-2} (true). On the other hand, the activity in an alkaline solution was rather unstable and, after one day of standing, it became lower by nearly two orders of magnitude compared with the level immediately after the cell was set up. The i_{ov} values were 3.3×10^{-3} and 5.4×10^{-5} A cm^{-2} (true) for the former and the latter cases, respectively.

The cathodic and anodic polarization behaviors of η and η_2' are presented in Fig. 8. The slope of the Tafel plots of η_2' was about 30 mV decade^{-1}, indicating that this overpotential component was caused by the Tafel step (plus possibly a minor degree of contribution from the H_2 diffusion in the case of the acidic solution). The i_{oT} values on Pt (after one day of standing) were 5×10^{-4} and 1.3×10^{-5} A cm^{-2} (true) in acidic and alkaline solutions, respectively. Consequently, the m_o values were

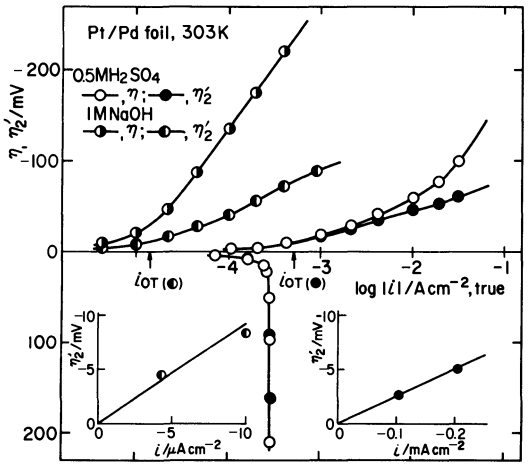

Fig. 8. Cathodic and anodic polarization behaviors of the total overpotential η and the slowly decaying overpotential component η_2' on Pt-deposited Pd foils. The arrows indicate i_{oT} and i_o obtained at low overpotentials (the inset figure.)
0.5 M H_2SO_4 and 1.0 M NaOH, 303 K.

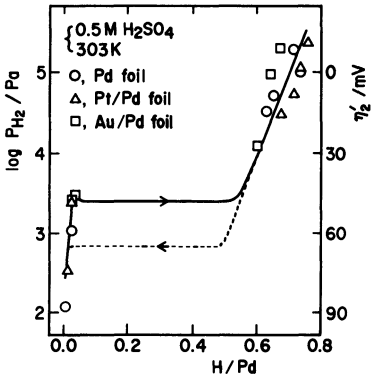

Fig. 9. Typical desorption isotherm (η_2' or $\log P_{H_2}$ vs. H/Pd) obtained on Pd and Au- or Pt-deposited Pd foil electrodes after polarizations between $\eta = -20$ and 200 mV at 303 K for several hours. The absorption/desorption isotherm[17] at ca. 300 K is shown for comparison.

evaluated to be 120 and 4 in the acidic and alkaline solutions, respectively. The value for an acidic solution is particulary large and, thus, Pt is an excellent electrocatalyst for a surface modification regarding this type of battery.

Amount of the Electrochemical Hydrogen Storage. The hydrogen absorbed into electrodes covered with Cu, Ag, Au, and Pt during hydrogen evolution is expected to obey Eq. 7, as the HER is concluded to proceed via the Volmer-Tafel reaction route, just as for the Pd or Ni electrodes.[12,13] In Fig. 9, the relationship between the hydrogen content and the overpotential component η_2' (and not η) observed on a bare Pd foil and a Pt- or Au-coated Pd foil electrodes are shown together with a typical absorption/desorption isotherm for Pd.[17] It can be seen that the experimental data are reasonably close to the isotherm curve in spite of the fact that the data were obtained on different metals with only the substrate being common (Pd). None of the data were found on the plateau region, presumably due to the sharp variation of the isotherm in this region. These observations substantiate the above analysis that the effective pressure of the electrochemically evolved hydrogen is determined by η_2' (Eq. 7) regardless of the type of electrode material as long as the HER obeys the Volmer-Tafel mechanism.

Comparison of Metals as Electrocatalysts. The obtained kinetic parameters are summarized in Table 1. In 0.5 M H_2SO_4, the Volmer step was generally more rapid than the Tafel step, or m_o was for the most part larger than unity. The order of the elementary step rates was Pt>Pd>Au>Ag>Cu for the Volmer step and Pt≧Pd>Au>Cu>Ag for the Tafel step, respectively. Consequently, that for m_o was Pt>Pd>Ag>Au>Cu. Hence, Pt was concluded to be the most suitable material for an electrode surface modification in the present context.

In 1.0 M NaOH, the rates of the Volmer step were considerably decreased (as a whole) compared with the Tafel step. Hence, the efficiency in question should be lowered. Their electrocatalytic activity was in the order Pt>Pd>Ni≧Ag≧Au≧Cu for the Volmer step and Pd>Pt>Au>Cu=Ag>Ni for the Tafel step. A relatively high m_o value was observed on Pt or Ni ($LaNi_5$ film), although the value for Ni was somewhat dispersed if Ti, Zr, or V was used instead of La as the alloying element. These are considered suitable for alkaline systems.

Conclusion

The HER on the electrodes of Cu, Ag, Pd, and Pt, was concluded to proceed via the Volmer-Tafel reaction route in both acidic and alkaline solutions, as well as on Ni in alkaline media. The relationship between the amount of hydrogen absorbed in the electrodes during a hydrogen evolution reaction and the overpotential component η_2' for the Tafel step, shows that this overpotential component is the quantity which determines the absorption conditions. On the other hand, η_1' represents the reaction affinity necessary for producing hydrogen from water. Thus, it entirely gives rise to a corresponding amount of energy consumption. The energy efficiency in the charge/discharge cycles of metal-hydride secondary batteries, therefore, dependes on the fraction of η_2' which shares in the overall

Table 1. Kinetic Parameters[a] of the Hydrogen Electrode Reaction on Group-IB and VIII Metals

	Electrode	0.5 M H_2SO_4			1.0 M NaOH		
		$\log i_{oV}$	$\log i_{oT}$	m_o	$\log i_{oV}$	$\log i_{oT}$	m_o
Cu	(Cu/Pd foil)	−5.15[b]	−4.5[b]	0.23[b]	−5.8	−5.2	0.25

Thermodynamic Study on Solvent Extraction of Alkali Metal Picrates with 18-Crown-6 into $CHCl_3$

Yasuyuki TAKEDA* and Akio TANAKA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260
(Received October 11, 1985)

Enthalpy (ΔHex) and entropy changes (ΔSex) for overall extractions of alkali metal (Na, K, Rb, and Cs) picrates with 18-crown-6 (18C6), and those ($\Delta H_{D,L}$ and $\Delta S_{D,L}$) for distribution of 18C6 itself were determined between $CHCl_3$ and water, all the extracted complexes being 1:1:1 complexes. The ΔHex and ΔSex values of 18C6 for all the alkali metals are negative. The $\Delta H_{D,L}$ and $\Delta S_{D,L}$ values of 18C6 are both positive. Enthalpy (ΔHex′) and entropy changes (ΔSex′) for ion-pair extractions of 18C6-alkali metal ion complexes with picrate anions were calculated. All the ΔHex′ and ΔSex′ values are negative except for ΔSex′ value of Na (positive). The ion-pair extractions were discussed from the thermodynamic point of view.

In order to evaluate complexing power and selectivity of newly-synthesized crown compounds for metal ions, solvent extraction has been widely used. Numerous data have been reported for their extraction ability and selectivity toward metal ions. However, only a few thermodynamic parameters regarding solvent extraction with crown compounds have been presented.[1] Thermodynamic quantities provide very valuable information on extraction mechanisms on molecular grounds. Further investigation of extraction processes from the thermodynamic point of view is important for understanding in detail solute-solvent interactions of crown compounds and their complexes and for designing crown compounds with high extractability and selectivity.

In the present study, enthalpy and entropy changes for the overall extraction of alkali metal picrates with 18-crown-6 (18C6), and those for distribution of 18C6 have been determined between $CHCl_3$ and water. Extraction processes of alkali metal picrates with 18C6 were discussed from the standpoint of thermodynamics.

Experimental

18-Crown-6 (Nisso Co., Ltd.) was recrystallized from acetonitrile and, prior to use, dried at 80 °C in a vacuum. Chloroform, picric acid, NaOH, and KOH were analytical grade reagents. Rubidium and caesium hydroxides were reagent-grade. Chloroform was washed three times with distilled water. The other reagents were used without further purification.

The experimental procedures were almost the same as those described in previous papers.[2,3] Extractions were conducted at 15, 20, 25, 30, and 32±0.3 °C. Concentrations of 18C6, alkali metal hydroxides, and picric acid were 9.5×10^{-6}—6.3×10^{-3} M (1 M=1 mol dm^{-3}), 4.2×10^{-3}—1.8×10^{-2} M, and 2.1×10^{-4}—4.0×10^{-4} M, respectively. Extractions were carried out at pH 10.0—11.3.

The Distribution Coefficient of 18C6. Experimental procedures were similar to those in the previous paper.[2] The concentration range of 18C6 was from 2.0×10^{-3} M to 7.5×10^{-2} M. Experiments were carried out at 15, 20, 25, 30, and 32±0.3 °C. Each distribution coefficient value of 18C6 is the average of about ten measurements.

Results

In an equilibrium between a chloroform solution of a crown ether (L) and an aqueous solution of an alkali metal ion (M^+) and a picrate ion (A^-), the equilibrium constants are defined as

$$K\text{ex} = [MLA]_o/[M^+][L]_o[A^-], \quad (1)$$

$$K_{D,L} = [L]_o/[L], \quad (2)$$

$$K_{ML} = [ML^+]/[M^+][L], \quad (3)$$

$$K\text{ex}' = [MLA]_o/[ML^+][A^-], \quad (4)$$

where the subscript "o" and the lack of subscript denote the organic and aqueous phases, respectively. The overall extraction equilibrium constant (Kex) can be written as

$$K\text{ex} = K_{ML}K\text{ex}'K_{D,L}^{-1}. \quad (5)$$

The distribution ratio of the alkali metal is represented by

$$D = [MLA]_o/[M^+]. \quad (6)$$

Combination of Eqs. 1 and 6 leads to

$$D = K\text{ex}[L]_o[A^-]. \quad (7)$$

A plot of log ($D/[A^-]$) against log $[L]_o$ shows a straight line with a slope of 1 in every case, indicating that Kex can be described by Eq. 1. The values of $[L]_o$ and $[A^-]$ in Eq. 7 were calculated by

Na	−26.0	−4.6[5]	0.6
K	−41.8	−13.22[6]	−6.6
Rb	−46.9	−7.1[5]	−17.8
Cs	−50.1	−10[5]	−18.1

a) $\Delta Hex = -\Delta H_{D,L} + \Delta H_{ML} + \Delta Hex'$, b) $\Delta Sex = -\Delta S_{D,L} + \Delta S_{ML} + \Delta Sex'$, where subscripts "ex, D,L, ML, and ex'" refer to reactions represented by Eqs. 1—4, respectively.

From Figs. 1 and 2, $R \ln K_{D,L}$ vs. T^{-1} and $R \ln Kex$ vs. T^{-1} plots are found to be linear. Enthalpy change (ΔH) and entropy change (ΔS) for Eqs. 1 and 2 were calculated from these data. The thermodynamic parameters are listed in Table 3.

Discussion

Values of $\log K_{D,L}$ at 25 °C of 15-crown-5 (15C5) and benzo-15-crown-5 (B15C5) for $CHCl_3$/water system are 0.91[7] and 2.4[8a], respectively. The contribution of an ether oxygen atom to $\log K_{D,L}$ (π_0) at 25 °C for $CHCl_3$/water system can be calculated from $\log K_{D,L}$ values of 15C5 and 18C6 by using the contribution of a methylene group to extraction constants of ion-pairs (π_{CH_2}), π_{CH_2} being 0.47.[9] Values of π_0 are −0.76 for 15C5 and −0.81 for 18C6 (15C5: (0.91−0.47×10)÷5, 18C6: (0.786−0.47×12)÷6). The values are nearly identical. The π_0 value is −0.79 on the average. The contribution of a benzo group to $\log K_{D,L}$ ($\pi_{C_6H_4}$) can also be calculated from $\log K_{D,L}$ values of B15C5 and dibenzo-18-crown-6 (DB18C6) ($\log K_{D,L}$=3.9[8b] at 25 °C) by means of the values of π_{CH_2} and π_0. Values of $\pi_{C_6H_4}$ are 2.5$_9$ for B15C5 and 2.4$_4$ for DB18C6 (B15C5: 2.4−{0.47×8+(−0.79×5)},

DB18C6: [3.9−{0.47×8+(−0.79×6)}]÷2). They are nearly equal. The $\pi_{C_6H_4}$ value is 2.5[1] on the average. From these empirical parameters, log $K_{D,L}$ values at 25 °C between $CHCl_3$ and H_2O for several crown ethers can be estimated.

In the case of 18C6, the orders of log *K*ex and log *K*ex′ for $CHCl_3$ system and that of log K_{ML} are K>Rb>Cs>Na, Rb≧K>Cs>Na, and K>Rb>Cs>Na, respectively (Table 2). The extraction selectivity of 18C6 for alkali metal ions shows the size-fit correlation and is completely consistent with the selectivity in water, whereas it is not always in agreement with the ion-pair-extraction selectivity.

For 18C6, log *K*ex′ value sequences of a given alkali metal are CH_2Cl_2>$CHCl_3$>C_6H_6 (Table 2). This indicates that the extractability of the ion-pair, MLA, decreases with a decrease in dielectric constant (CH_2Cl_2 8.93,[10] $CHCl_3$ 4.9,[11] C_6H_6 2.3[11] at 25 °C).

It is interesting to compare the ion-pair extractability of K(18C6)A into $CHCl_3$ with that of tetrabutylammonium picrate (Bu_4NA). The log *K*ex′ value of K(18C6)A at 25 °C is about one order of magnitude smaller than the ion-pair extraction constant ($K_{ex,ip}$=$[Bu_4NA]_o/[Bu_4N^+][A^-]$=5.75[9] at 25 °C) of Bu_4NA, although the size of K(18C6)A is nearly identical with that of Bu_4NA.[12] From shapes and sizes of K(18C6)A and Bu_4NA, it seems that the difference in ion-association constants in water between them is not so large. Thus, the data indicate that solute-water interaction of $K(18C6)^+$ is much stronger than that of Bu_4N^+.

It is seen from Table 3 that $\Delta H_{D,L}$ and $\Delta S_{D,L}$ values of 18C6 are both positive and the $T\Delta S_{D,L}$ value at 25 °C is larger than the $\Delta H_{D,L}$ value. Consequently, the fact that 18C6 is more soluble in $CHCl_3$ than in water is completely due to entropy contribution. The explanation for the positive values of $\Delta H_{D,L}$ and $\Delta S_{D,L}$ of 18C6 is the same as that provided in the previous paper.[3]

The ΔHex and ΔSex values of 18C6 for all the alkali metals are negative. Tables 2 and 3 show that the second largest $-\Delta H$ex value of K is canceled by the second smallest $-T\Delta S$ex value, resulting in the greatest log *K*ex, and that the smallest $-\Delta H$ex and $-T\Delta S$ex values of Na balance each other, leading to the smallest log *K*ex. The ΔHex′ value plays a major role in determining the magnitude of ΔHex, whereas the $\Delta S_{D,L}$ value plays a major role in determining the magnitude of ΔSex.

The *K*ex′ value of 18C6 for the $CHCl_3$ system (at 25 °C) decreases in the order, Rb≈K>Cs>Na (Table 2). The largest ΔHex′ and ΔSex′ values of Na cancel each other, resulting in the lowest ion-pair extractability; the second greatest ΔHex′ and ΔSex′ values of K balance each other, leading to the highest ion-pair extractability (Table 3).

All the ΔHex′ and ΔSex′ values are negative except for the ΔSex′ value of Na. Although sizes of these 18C6-alkali metal ion complexes are much the same,[12] both ΔHex′ and ΔSex′ values vary with the alkali metal ion trapped in the 18C6 cavity. This reflects differences in chemical nature of the alkali metal ions in the cavity. The ΔHex′ and ΔSex′ values of Na are much larger than those of the other alkali metals. A possible explanation for the very large ΔHex′ and ΔSex′ values of Na is as follows. The 18C6-Na^+ complex may be most strongly hydrated in an aqueous phase due to the highest charge density of Na^+ and much smaller size of Na^+ compared to that of the 18C6 cavity. The strong interaction between Na^+ in cavities of 18C6 and its analog and solvent molecules was observed in the previous works.[12,13] When the Na^+ complex is extracted into $CHCl_3$ phase, a large amount of water molecules attached to the complex have to be released. This may be responsible for the very large ΔHex′ and ΔSex′ values fo Na.

(Received April 12, 1985)

In an investigation on the behavior of a cadmium ion-selective electrode in methanol-water and ethanol-water mixtures, potential measurements were carried out with a digital pH/mV meter, a cadmium ion-selective indicator electrode and a silver-silver chloride reference electrode. The calibration curves, slopes of the response, response times, effects of temperature, relation between the potential and the pH-meter reading and selectivity of the electrode were discussed. The response of cadmium ions (electromotive force) was linear between 10^{-7}—10^{-2} mol dm^{-3} in water. However, the linear range became narrower with an increase in the alcohol content. The slopes in alcohol-water mixtures (27—33 mV/decade in methanol-water mixtures, 21—29 mV/decade in ethanol-water mixtures) were nearly equal to the Nernstian slope (29.6 mV/decade). The response times of the cadmium ion-selective electrode in 99 v/v% methanol and in 99 v/v% ethanol were somewhat long, but were still within 5 min for all solutions consisting of 10^{-5}—10^{-1} mol dm^{-3} of cadmium ions. The selectivity of the cadmium ion-selective electrode in various media was examined by the mixed-solution method using potassium, sodium, calcium and magnesium ions as the interfering ions. It was found that a cadmium ion-selective electrode could be used to determine cadmium ions in an alcohol-water solution, although the response time became longer and the linear range of the response became narrower with an increase in the alcohol content.

Ion-selective electrodes are used mainly for the determination of inorganic ions in aqueous solutions.[1,2] The behavior of ion-selective electrodes (halide ion-selective electrode,[3-6] copper ion-selective electrode,[7] lead ion-selective electrode[8] and so on) in nonaqueous solvents has already been reported. However, no study has been reported regarding the properties of a cadmium ion-selective electrode in organic solvents. When ion-selective electrodes are to be used in organic solvents, their properties (such as sensitivity, selectivity, and response time) might be expected to be strongly dependent on the solvents.[9] The effects of alcohol on the potentiometric chelatometric titration of cadmium ions with a cadmium ion-selective electrode was examined by the authors.[10]

This paper is concerned with the detailed behavior of a cadmium ion-selective electrode in methanol, ethanol, and their mixtures with water.

Experimental

Apparatus. A cadmium ion-selective electrode (Orion, Model 94-48A) was used in conjunction with a reference electrode (TOA, Model HS-205C) that was appropriate for the particular solvent used. In 99 v/v% methanol and ethanol solutions, a saturated aqueous potassium chloride solution in the reference electrode was replaced by a saturated solution of potassium chloride in methanol or ethanol.[11]

Reagent. Stock solutions (0.1 mol dm^{-3}) of cadmium chloride in water, in 25, 50, 75, and 99 v/v% methanol and in 25, 50, 75, and 99 v/v% ethanol were prepared and diluted as needed. Calcium nitrate tetrahydrate and magnesium sulfate heptahydrate were dehydrated by heating. All other reagents were analytical-reagent grade from Wako Pure Chemicals.

Procedure. All potentiometric measurements were carried out under constant stirring with a Teflon-covered stirring bar and a magnetic stirrer. The cell consisted of a 50-cm^3 glass beaker fitted with a rubber stopper, bored out for the insertion of electrodes and a thermometer. Successive runs were made by the immersion method in a series of cadmium-ion solutions (10^{-8}—10^{-1} mol dm^{-3}) in decade steps of increasing concentrations.

Results and Discussion

Calibration Curves. Calibration curves for the cadmium ion-selective electrode in water and in 25, 50, 75, and 99 v/v% methanol are shown in Fig. 1.

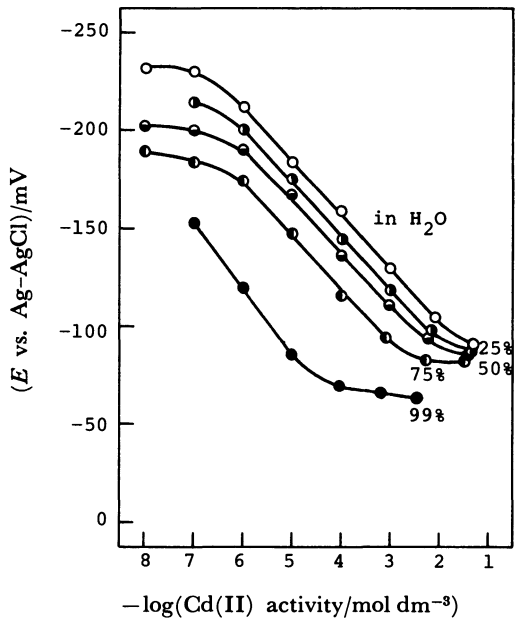

Fig. 1. Responses of the cadmium ion-selective electrode in methanol-water mixtures.

Cadmium-ion solutions of 10^{-8}—10^{-1} mol dm^{-3} are discussed. The logarithm of the cadmium ion activity, calculated by the Debye-Hückel approximation[12] (Eq. 1), was plotted along the X-axis.

$$\log \gamma_{\pm} = -\frac{A|Z_+Z_-|I^{1/2}}{1+BaI^{1/2}} \quad (1)$$

$\gamma_{\pm}$; Mean activity coefficient, Z; Electric charge, I; Ionic strength, A and B; Constants of the Debye-Hückel theory,[13] and a; Ion-size parameter.

The permittivities of alcohol-water mixed solutions (ε_{AW}) were obtained using the following equation;

$$\varepsilon_{AW} = \varepsilon_W - (\varepsilon_W - \varepsilon_A)X_A \quad (2)$$

ε_W; Permittivity of water, ε_A; Permittivity of alcohol, and X_A; Molar fraction of alcohol.

Curves shifted to more positive values with an increase in the alcohol content. The response was linear between 10^{-7}—10^{-2} mol dm^{-3} in water, but the range became narrower with an increase in alcohol content. Linearity was lost at higher cadmium-ion concentrations, presumably because ion pairs were formed by association in 50—99 v/v% methanol.

Figure 2 shows the calibration curves of the cadmium ion-selective electrode in water and in 25, 50, 75, and 99 v/v% ethanol. The results obtained in ethanolic solutions were similar to those in methanolic solutions.

The activity coefficients in alcohol-water mixed solutions were influenced by several factors compared with those in water. It was known that Eq. 1 could be used for aqueous solutions at ionic strengths of less than 0.1. However, in this work it was found that the activity coefficients could be calculated by the Debye-Hückel approximation within the following ranges; less than 10^{-2} mol dm^{-3} of cadmium ions in a 25 v/v% alcohol-water mixed solution, less than 10^{-3} mol dm^{-3} of cadmium ions in 50 and 75 v/v% alcohol-water mixed solutions and less than 10^{-5} mol dm^{-3} of cadmium ions in a 99 v/v% alcohol-water mixed solution.

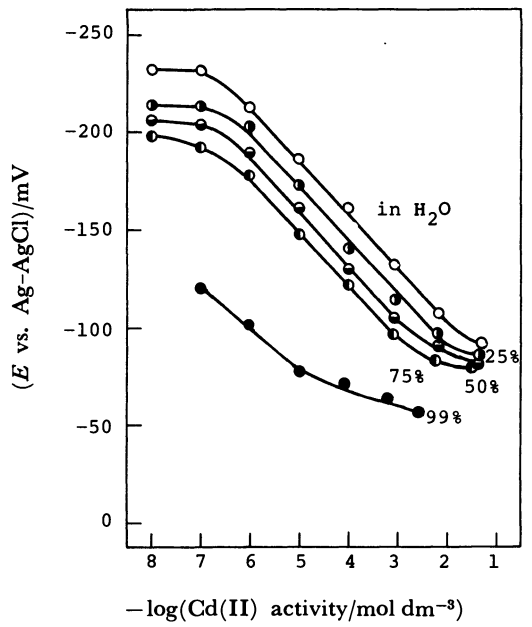

Fig. 2. Responses of the cadmium ion-selective electrode in ethanol-water mixtures.

Slopes of the Response. The slopes of the responses of the cadmium ion-selective electrode in various media are shown in Table 1. The slopes in alcohol-water mixtures (27—33 mV/decade in methanol-water mixtures and 21—29 mV/decade in ethanol-water mixtures) were similar to the Nernstian slope (29.6 mV/decade) and the correlation coefficient was nearly equal to 1. Good correlations were obtained between cadmium-ion activities and the observed potentials.

Response Time. The response times of the cadmium ion-selective electrode obtained in various media are shown in Table 2. The response time tended to decrease with an increase in the cadmium-ion concentration for all the solutions. The response times of the electrode in 99 v/v% methanol and in 99 v/v% ethanol were especially long, but the response times were less than 5 min in all solutions of 10^{-5}—10^{-1} mol dm^{-3} of cadmium ions.

Effects of Temperature. The effects of temperature on the slopes of the responses are shown in Table 3. Electrode potentials were measured between 0—50 °C. In all the solutions, the electrode potentials shifted to more positive values almost linearly with an increase in temperature. The theoretical slope calculated using the Nernst equation increased by ca. 1 mV per 10 °C rise in temperature. A similar tendency was observed in alcohol-water mixtures.

The Relation between the Potential and ΔpH. The relation between the electrode potential and the change in the reading of pH meter, ΔpH, upon an

addition of acid was examined (Fig. 3). The pH meter was calibrated with a glass electrode, a saturated calomel electrode and a pH standard aqueous solution. The ΔpH values of samples were adjusted with acetic acid. The electrode potentials were constant at a ΔpH of 3.5—5.0 in alcohol-water mixtures. The deviation increased for a ΔpH below 3.5.

Selectivity of the Cadmium Ion-Selective Electrode. The selectivity of the cadmium ion-selective electrode in various media was examined using the mixed-solution method (Table 4). Interferences by potassium, sodium, calcium and magnesium were investigated. The selectivity coefficients for potassium ions in 25—99 v/v% methanol (7.2×10^{-3}—5.0×10^{-2}) and in ethanol (3.6×10^{-3}—4.2×10^{-3}) were greater than those reported in the literature for an aqueous solution (6.7×10^{-8}).[14] Similarly, those for sodium ions in 25—99 v/v% methanol (3.9×10^{-3}—8.4×10^{-2}) and in ethanol (2.4×10^{-3}—1.4×10^{-1}) were greater than those reported in the literature (3.2×10^{-8}).[14] The selectivity coefficients for calcium ions in 25—99 v/v% methanol (2.0×10^{-4}—3.6×10^{-4}) and in 25—99 v/v% ethanol (3.3×10^{-5}—2.1×10^{-4}), for magnesium ions in 25—75 v/v% methanol (5.2×10^{-4}—1.1×10^{-3}) and in 25—50 v/v% ethanol (1.9×10^{-4}—5.6×10^{-4}) were in fair agreement with those reported in the literature (2.2×10^{-4} and 1.6×10^{-4}),[14] respectively.

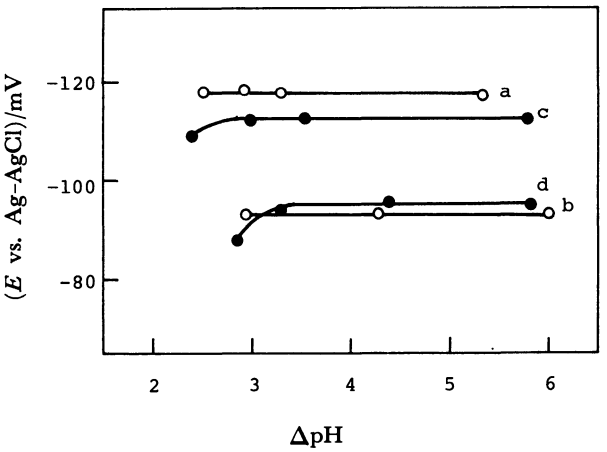

Fig. 3. The relation between the potential and ΔpH in methanol-water mixtures and ethanol-water mixtures: 10^{-3} mol dm^{-3} cadmium ion in (a) 25, (b) 75 v/v% methanol and in (c) 25, (d) 75 v/v% ethanol.

The cadmium ion-selective electrode could be used

Spectrophotometric Determination of Micro Amounts of Thiocyanate via Permanganate Reaction

Yasuyuki MIURA* and Tomozo KOH
Department of Chemistry, Faculty of Science, Tokai University, 1117, Kitakaname, Hiratsuka, Kanagawa 259-12
(Received September 5, 1985)

A method has been developed for the determination of micro amounts of thiocyanate. It is based on the reaction of thiocyanate with a given amount of permanganate as an oxidizing agent in a dilute sulfuric acid medium and on the spectrophotometric measurement of iodine as triiodide, which is formed by the oxidation of iodide with an excess of permanganate for its reaction with thiocyanate. The conditions for the thiocyanate to be quantitatively oxidized were established by varying the temperature, reaction time, and amounts of sulfuric acid and permanganate. The present method can be successfully applied to the determination of thiocyanate in the range from 7×10^{-7} to 4×10^{-5} mol dm^{-3} (0.4—23.2 μg SCN^- in 10 cm^3). In eleven determinations for 10-cm^3 sample solutions containing 0.250 μmol of thiocyanate, the present method gave a mean value of 0.251 μmol, with a standard deviation of 0.0022 μmol and a relative standard deviation of 0.88%. Chloride, bromide, iodide, and cyanide did not interfere with the determination of 14.5 μg of thiocyanate in the presence of 1000 μg, 500 μg, 100 μg, and 50 μg, respectively.

Iron(III) reacts easily with thiocyanate to give a red iron(III)-thiocyanate complex in an acid medium. Therefore, iron(III)[1] is widely used for the photometric determination of small amounts of thiocyanate. However, in measuring thiocyanate at concentrations as low as the 10^{-5} mol dm^{-3} level, the iron(III) method is not considered useful because of its low sensitivity. For the sensitive spectrophotometric determination of thiocyanate, the pyridine-pyrazolone,[2,3] the pyridine–benzidine,[4,5] and the pyridine–barbituric acid[6] methods have been devised. Moreover, extraction methods using copper–pyridine,[7] tris(1,10-phenanthroline)iron(II),[8] Neutral Red,[9] mercury(II) Methylthymol Blue-zephiramine,[10] and mercury(II)–quinoline[11] reagents have been proposed. These methods[2-11] have, however, some disadvantages: pyridine is unpleasant and noxious, benzidine has a carcinogenic property, and solvent extraction is generally troublesome. Koh and Iwasaki[12] have previously reported a very sensitive method of determining thiocyanate (3×10^{-7}—1×10^{-5} mol dm^{-3}) based on the extraction of thiocyanate with Methylene Blue into 1,2-dichloroethane and the spectrophotometric measurement of the organic phase.

The purpose of this work, using the reaction of thiocyanate with permanganate, is to develop a method for the sensitive determination of thiocyanate without any solvent extractions or poisonous reagents. The optimal conditions under which thiocyanate can be oxidized by permanganate were established. The proposed method is based on the reaction of thiocyanate with a given amount of permanganate in an acidic medium[13] according to following Eq. 1, and then on the spectrophotometric measurement of the iodine thus formed, after converting the permanganate in excess for its reaction with thiocyanate into iodine[14] according to Eq. 2:

$$5SCN^- + 6MnO_4^- + 8H^+ \longrightarrow 6Mn^{2+} + 5SO_4^{2-} + 5CN^- + 4H_2O \quad (1)$$

$$2MnO_4^- + 10I^- + 16H^+ \longrightarrow 2Mn^{2+} + 5I_2 + 8H_2O \quad (2)$$

Experimental

Apparatus. All spectrophotometric measurements were made at 350 nm with a Shimadzu Model UV-240 recording spectrophotometer with 10-mm quartz cells. Desired temperatures were controlled by a Taiyo Coolnit Model CL-15 thermoregulator. Redistilled water used was freed from any permanganate-consuming impurities with a Nippon Millipore, Ltd., Model Milli-QII apparatus.

Reagents. All chemicals were of an analytical grade and were used without further purification.

Standard Thiocyanate Solution. A 0.1 mol dm^{-3} thiocyanate solution was prepared by dissolving potassium thiocyanate in redistilled water. The solution was standardized by Volhard's method. The working solutions were prepared by suitable dilution.

Standard Permanganate Solution.[15] A 0.02 mol dm^{-3} permanganage solution was prepared by heating the solution in which potassium permanganate had been dissolved to boiling, keeping it at a temperature slightly below the boiling point for 1 h, and then allowing it to stand for 3 d at room temperature. After the manganese dioxide thus obtained had been filtered off by suction with a sintered glass filter(3SG4), the filtrate was standardized by oxidation-reduction titration using standard sodium oxalate. The stock solution of 0.02 mol dm^{-3} standard permanganate proved to be stable; even after six months, no measurable change was found by the present method when it was stored at room temperature in dark. A working solution of the 2×10^{-4} mol dm^{-3} permanganate solution obtained by the appropriate dilution of the stock solution could be used for 2 d.

Standard Thiosulfate Solution. A 0.1 mol dm^{-3} thiosulfate solution was prepared by dissolving sodium

thiosulfate pentahydrate in freshly boiled and cooled redistilled water containing a small amount of sodium carbonate as a stabilizer. The thiosulfate solution was standardized by iodimetry a week after preparation. A 5×10^{-4} mol dm^{-3} thiosulfate solution was obtained by diluting the standardized thiosulfate exactly.

Iodide Solution. A 0.5 mol dm^{-3} iodide solution was prepared by dissolving 41.7 g of potassium iodide in redistilled water containing 200 mg of sodium carbonate as a stabilizer and by then diluting it to 500 cm^3.

Recommended Procedure. A 1.5 cm^3 of 0.8 mol dm^{-3} sulfuric acid and 4 cm^3 of a 2×10^{-4} mol dm^{-3} standard potassium permanganate solution were placed in a 25-cm^3 volumetric flask. To this mixture, 10-cm^3 of a sample solution containing thiocyanate up to 0.400 μmol were added. The mixture was then allowed to stand for 10 min in the temperature range from 15 to 40 °C to complete the oxidation of thiocyanate. Then, 1 cm^3 of 0.5 mol dm^{-3} potassium iodide was added to form iodine equivalent to the excess permanganate, and 3 cm^3 of 5×10^{-4} mol dm^{-3} sodium thiosulfate were added to decrease the absorbance of the iodine as triiodide to an appropriate value. The flask was filled to the mark with redistilled water. The absorbance of a solution of the triiodide complex thus formed was measured against distilled water at 350 nm in about 5 min after the dilution.

A permanganate-free reagent blank was prepared by placing 1.5 cm^3 of 0.8 mol dm^{-3} sulfuric acid, 14 cm^3 of redistilled water in place of both 4 cm^3 of 2×10^{-4} mol dm^{-3} permanganate and 10 cm^3 of a sample solution containing thiocyanate, and 1 cm^3 of 0.5 mol cm^{-3} iodide in a 25-cm^3 volumetric flask. After the flask had been filled to the mark with redistilled water, the absorbance was measured against distilled water at 350 nm in about 5 min. This absorbance value was subtracted from each of the absorbances for thiocyanate and the reagent blank, for iodide is susceptible to air-oxidation in an acid medium.

Results and Discussion

Calibration Plots. Figure 1 shows the calibration graphs obtained by treating a series of standard solutions of thiocyanate according to the recommended procedure and permanganate according to a procedure where 4 cm^3 of redistilled water were used instead of 4 cm^3 of 2×10^{-4} mol dm^{-3} permanganate. The graph for permanganate was prepared to confirm the stoichiometry and the completion of the reaction of thiocyanate with permanganate. According to Eq. 1, if 5 mol of thiocyanate react with 6 mol of permanganate completely and stoichiometrically, the graph for thiocyanate should coincide with that for permanganate (the expected graph) in excess amounts for the reaction with thiocyanate, when each of the molar concentration scales for thiocyanate and permanganate is drawn as in Fig. 1. Figure 1 proves that the reaction proceeded to stoichiometric completion under the conditions of Procedure.

The precision was estimated from 11 results for 10-cm^3 aliquots of a solution containing 0.250 μmol of thiocyanate. The present method gave a mean value of 0.251 μmol, with a standard deviation of 0.0022 μmol and a relative standard deviation of 0.88%. This method give a higher sensitivity than the copper(II) diethyldithiocarbamate-silver(I)[16] and the rhenium[17] methods without any need for solvent extractions or poisonous reagents.

30	0.052	0.055	0.053	0.057

a) Absorbances for 3.2×10^{-5} mol dm^{-3} permanganate (the expected values).

Rate of Reaction of Thiocyanate with Permanganate. The reaction rate was investigated at temperatures ranging from 10 to 40 °C. The amount of the reagents and the addition order were as in the above procedure. The results are given in Table 1. The reaction was gradually accelerated by an increase in the temperature. The absorbances for

4×10^{-5} mol dm^{-3} thiocyanate reached those for 3.2×10^{-5} mol dm^{-3} permanganate, which are the expected values, in 20 min at 10 °C, in 10 min at 15 °C, in 5 min at 25 °C, and in 3 min at 40 °C, and then kept constant until 30 min had passed. These facts confirm that the reaction proceeds to completion as long as it is carried out for 10 min at temperatures from 15 to 40 °C. On the other hand, when thiocyanate was allowed to react with permanganate in a solution of a low acidity using 1.5 cm^3 of 0.3 mol dm^{-3} sulfuric acid, the reaction did not proceed to completion according to Eq. 1. Therefore, the effect of acidity was investigated at 20 °C. The results are shown in Table 2. The absorbances for 4×10^{-5} mol dm^{-3} thiocyanate coincided with the expected value in 10 min with 1.5 cm^3 of 0.6 mol dm^{-3} sulfuric acid, in 5 min with 1.5 cm^3 of each 0.8 and 1.0 mol dm^{-3} sulfuric acid, and in 3 min with 1.5 cm^3 of 1.5 mol dm^{-3} sulfuric acid. Consequently, 1.5 cm^3 of 0.8 mol dm^{-3} sulfuric acid was employed in this experiment.

30	0.053	0.055	0.058	0.051

a) Absorbances for 3.2×10^{-5} mol dm^{-3} permanganate (the expected values). The volume of the sulfuric acids used was 1.5 cm^3.

Effect of Amounts of Permanganate. For measuring the effects of the amounts of permanganate, thiocyanate was allowed to react with various amounts of potassium permanganate for 10 min at 20 °C. In this experiment, the thiosulfate, which is used in order to reduce the absorbance, was not added. The absorbance, therefore, increased with the increase in the amounts of permanganate employed. The resulting graphs (given in Fig. 2) were normalized in such a way that each calibration graph for thiocyanate with various amounts of permanganate was permitted to shift in parallel fashion to cause each reagent blank to accord with that obtained under the conditions of Procedure. When 2.5 and 3.0 cm^3 of 2×10^{-4} mol dm^{-3} permanganate were used, the reaction did not go to completion because the amounts of permanganate were insufficient. However, when 3.5, 4.0, or 4.5 cm^3 of the permanganate solution were used, the graphs for thiocyanate formed a straight line and coincided completely with that obtained under the conditions

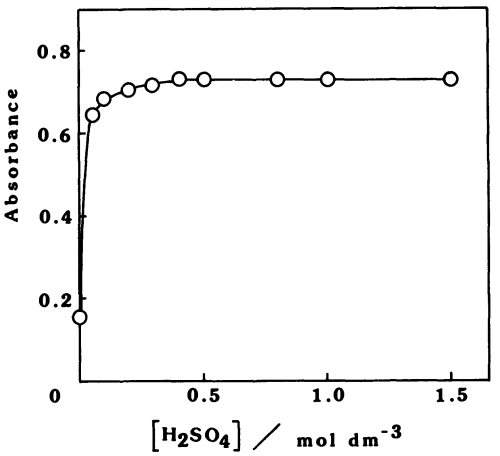

Fig. 3. Effect of amounts of sulfuric acid on liberation of iodine by oxidation with permanganate. A 10 cm^3 of 6×10^{-5} mol dm^{-3} permanganate was treated as in procedure, where 1.5 cm^3 sulfuric acid solution in various molar concentrations were used and 4 cm^3 of redistilled water were employed instead of 4 cm^3 of 2×10^{-4} mol dm^{-3} permanganate.

a) 3 cm^3 of 0.5 mol dm^{-3} NaF were added. b) 1 cm^3 of 0.05 mol dm^{-3} sulfamic acid was added.

of Procedure. Consequently, 4.0 cm^3 of 2×10^{-4} mol dm^{-3} permanganate were employed.

Effect of Amounts of Iodide. In order to estimate the optimal amount of iodide on the formation of iodine equivalent to excess amounts of permanganate for the reaction of Eq. 1, 1 cm^3 of 0.1, 0.3, 0.5, 0.7, or 1.0 mol dm^{-3} iodide solution was used in Procedure. In all cases, calibration graphs for thiocyanate gave straight lines with a good reproducibility, and the sensitivity increased with the increase in the amounts of iodide used. In the recommended procedure, 1 cm^3 of a 0.5 mol dm^{-3} iodide solution was used, for it gives the appropriate absorbance value for the reagent blank.

Effect of Amounts of Sulfuric Acid on Liberation of Iodine. For measuring the effects of the amounts of sulfuric acid on the oxidation of iodide by permanganate to iodine, 1.5 cm^3 of a sulfuric acid solution in various molar concentrations were employed in Procedure. As can be seen in Fig. 3, when 1.5 cm^3 of 0.4—1.5 mol dm^{-3} sulfuric acid were used, the absorbance reached the maximum value and subsequently remained constant. Therefore, 1.5 cm^3 of 0.8 mol dm^{-3} sulfuric acid were used in Procedure.

Stability of Triiodide Complex Solution. The absorbance of the triiodide complex solution increased progressively with time because iodine is formed by the air-oxidation of iodide in an acidic solution. The triiodide complex solution prepared according to Procedure was allowed to stand for various periods of time at room temperature. The results are given in Table 3. The absorbances for the reagent blank and 4×10^{-5} mol dm^{-3} thiocyanate gave nearly constant values over the range from 3 to 7 min. Therefore, all the absorbances were measured in about 5 min after the contents had been diluted to 25 cm^3 by the recommended procedure.

Effect of Diverse Ions. A 10-cm^3 portion of a solution containing 14.5 μg of thiocyanate and various amounts of diverse ions was treated exactly as in Procedure. Iron(II), nitrite, sulfide, and sulfite gave positive errors for the determination of thiocyanate, even when present in trace amounts, because they reduce permanganate. However, the interference of nitrite could be eliminated by decomposing it with sulfamic acid. Iron(III) gave a negative interference in the presence of 10 μg because it reacts with iodide to form iodine, but its interference was eliminated by masking with fluoride. For the determination of 14.5 μg of thiocyanate with an error of below 2.1% by the present method, foreign ions can be tolerated at the levels given in Table 4. Anions such as chloride, bromide, iodide, and cyanide, which interfere seriously in the conventional determination of thiocyanate are tolerated in amounts of 10000 μg, 500 μg, 100 μg, and 50 μg, respectively, in the present method.

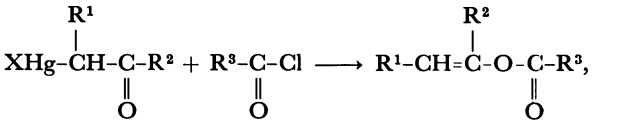
Stereoselectivity in the Synthesis of Enol Esters from Chloromercurio Aldehydes and Acyl Chlorides

Wakichi FUKUDA,* Hozumi SATO, and Hiroshi KAKIUCHI
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received September 9, 1985)

Reactions of chloromercurio aldehydes with acyl chlorides gave a variety of (*Z*)- and (*E*)-enol esters. The *Z*/*E* ratio of the enol esters is dependent on the structure of chloromercurio aldehydes but independent of that of acyl chlorides. *Z*-Rich enol esters were prepared by acylation of 2-chloromercurio aldehydes derived from propanal, butanal, and 2-phenylethanal, while *E*-rich 1-acyloxy-1,3-butadiene was obtained by acylation of (*E*)-4-chloromercurio-2-butenal. Reaction mechanisms for the stereoselective formation of these enol esters are discussed together with the isomer composition of starting enol acetates from which the chloromercurio aldehydes were prepared.

Various methods are available for synthesis of enol esters. The most practical technique involves treatment of aldehydes or ketones with appropriate acid anhydrides or acid chlorides under either acidic or basic conditions.[1—10] Other major methods for preparing enol esters involve addition of carboxylic acids to alkynes[11—16] and palladium-catalyzed acyloxylation of olefins.[17]

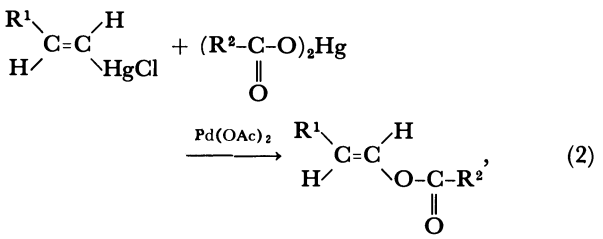
Although limited in scope, organomercurials are used for preparing enol esters.[18] Halomercurio aldehydes or ketones can be *O*-acylated with acyl chlorides:[19,20]



(1)

where R^1 and R^2 are each hydrogen, alkyl, or aryl, R^3 is alkyl or aryl, and X is halogen.

Reactions of vinylmercurials with mercury(II) carboxylates in the presence of a catalytic amount of palladium(II) acetate lead stereospecifically to formation of enol esters:[21]



(2)

where R^1 is hydrogen, alkyl, or aryl, and R^2 is alkyl or aryl.

An attempt was made to prepare enol acrylate from propanal and acrylic anhydride or acryloyl chloride in the presence of quinoline or potassium acetate, but it was unsuccessful since polymers were formed easily. Under mild conditions, enol acrylates and methacrylates were prepared by reaction of chloromercurio aldehydes with acryloyl chloride or methacryloyl chloride according to the procedure by Nesmeyanov et al.[20] It was found with this reaction that enol esters prepared were stereoselective depending on the structure of chloromercurio aldehydes.

In this article, the stereoselectivity in the synthesis of enol esters from chloromercurio aldehydes and acyl chlorides is described, together with the effect of the isomer composition (*Z*/*E*) of starting enol acetates from which chloromercurio aldehydes are prepared.

Results and Discussion

Compositions of Geometric Isomers of Starting Enol Acetates. Enol acetates can be prepared by reactions of aldehydes either with acetic anhydride in the presence of potassium acetate (method A) or with 2-acetoxy-1-propene in the presence of *p*-toluenesulfonic acid (method B). Their yields were in the range from 12 to 73% (1-acetoxy-1-propene (**1a**)<1-acetoxy-1-butene (**2a**)<1-acetoxy-1,3-butadiene (**4a**)<1-acetoxy-2-(phenyl)ethene (**3a**)). This order may be interpreted in terms of the stability of enol forms. The enol/keto ratio for ethanal was less than 10^{-7} under conditions where the enol content of acetone was measurable.[22] On the other hand, aryl-substituted ethanals gave stable enols.[23]

All of the enol esters prepared were mixtures of (*Z*)- and (*E*)-isomers. The 1-acetoxy-1-propene (**1a**) obtained by method A was a *Z*/*E* mixture with a ratio of 51/49, which is consistent with the literature.[5,6] The *Z*/*E* ratio of 1-acetoxy-1-butene (**2a**) was 47/53, while those of 2-phenyl-1-(acetoxy)ethene (**3a**) and 1-acetoxy-1,3-butadiene (**4a**) were 35/65 and 38/62, respectively.

Scheme 1 shows the reaction process for method A where an ambident enolate anion may be formed as an intermediate. The geometry of the enol esters will be determined in the addition step of acyl residue to the enolates. The results for **1a** and **2a** suggest that methyl and ethyl substituents (R^1=CH_3, C_2H_5)

contribute little to the difference in stability and/or reactivity between (*Z*)- and (*E*)-enolates. Therefore, the *Z*/*E* ratios of **1a** and **2a** are almost 1/1.

When 2-substituent in the enolate is phenyl or vinyl, the *Z*/*E* ratios are less than 2/3. Heiszwolf and Kloosterziel[24] have reported an *O*-alkylation of ambident enolate anion obtained from 2-phenylethanal. The *Z*/*E* ratios of the enol ethers prepared in dimethyl sulfoxide and in liquid ammonia were 9/10 and 3/2, respectively, while those of the intermediate enolate anions were 3/2 in both solvents. Although the enolates prepared by method A are not so stable as those prepared in dimethyl sulfoxide and in liquid ammonia, the product determining step will be the reaction of the enolate with acetic anhydride. The result for **3a** suggests that the (*E*)-enolate of 2-phenylethanal reacts with acetic anhydride more rapidly than the (*Z*)-enolate. This may be interpreted in terms of steric and electronic effects of phenyl residue on the enolate anion. The reaction of 2-butenal with acetic anhydride may proceed along the same process as that of 2-phenylethanal. But the vinyl substituent will give little effect on both stability and reactivity of the enolates. Alternatively, the *Z*/*E* ratio of **4a** may rather be controlled by the concentrations of (*Z*)- and (*E*)-enolates since (*E*)-2-butenal is present mainly in *s-trans*-conformation[25,26] which leads to the formation of (*E*)-enolate.

The *Z*/*E* ratios of **2a** and **4a** prepared by method B were 65/35 and 17/83, respectively. Scheme 2 involves an intermediate cation in the reaction of butanal with 2-acetoxy-1-propene. The intermediate cation for (*E*)-isomer will be more stable than that for (*Z*)-isomer because of the steric interaction between acetoxy and ethyl residues. Both *anti*- and *syn*-elimination of proton from the intermediates will give *E*-rich enol ester. By contrast, the result suggests that the product determining step is not the elimination of proton but the addition of acetyl cation to butanal. It suggests a formation of the intermediate for (*Z*)-isomer in preference to that for (*E*)-isomer and no interconversion between the intermediates which was shown by Skell and Hall[27] for the E1 reaction of 3-deuteriobutyl-2-tosylate. The reason for the preferential formation of the intermediate for (*Z*)-isomer remains open.

Scheme 3 shows the reaction process of 2-butenal and 2-acetoxy-1-propene. The *Z*/*E* ratio of **4a** will be determined by the addition of acetyl cation to the carbonyl oxygen of 2-butenal, since the elimination of terminal methyl proton in the intermediate is of no effect on the geometry of the products. As the *O*-acetylations of *s-cis*- and *s-trans*-2-butenal give the intermediate cations of (*Z*)- and (*E*)-enol acetates, respectively, the *Z*/*E* ratio of **4a** may be controlled by the s-cis/s-trans ratio of 2-butenal. The result, the *Z*/*E* ratio of 17/83, is in agreement with the s-cis/s-trans ratio of the literature.[25,26]

Stereoselectivity in the Reaction of Chloromercurio Aldehydes with Acyl Chlorides. Reactions of four chloromercurio aldehydes with acyl chlorides were conducted to give respective enol esters. Table 1 shows that the reactions of 2-(chloromercurio)butanal (**2x**) with three acyl chlorides give the correspond-

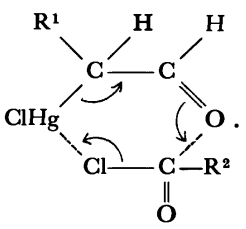
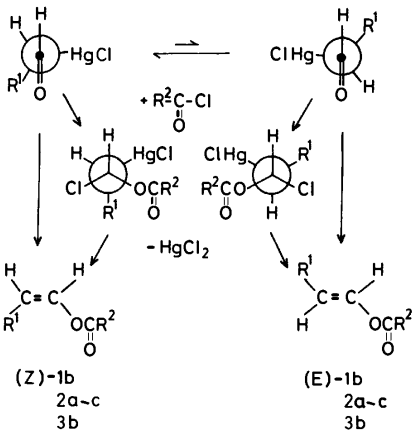
ing enol esters of which the *Z*/*E* ratios are about 85/15. These ratios for the enol esters (**2a—c**) are independent of the acyl chlorides. The reactions of 2-(chloromercurio)propanal (**1x**) and 2-phenyl-2-(chloromercurio)ethanal (**3x**) with acryloyl chloride give 1-acryloyloxy-1-propene (**1b**) and 2-phenyl-1-(acryloyloxy)ethene (**3b**) having the *Z*/*E* ratios of 84/16 and 76/24, respectively.

Scheme 4 shows the reaction pathways of 2-substituted 2-chloromercurio aldehydes with acyl chlorides. Two stable conformations of the 2-chloromercurio aldehydes are suggested on the basis of torsional angle (98°) of Hg-C-C=O which was given by Halfpenny and Small.[28] Of the two conformations suggested, *syn*-1,2-dihydrogen form may be more stable than *anti*-1,2-dihydrogen form because of the steric interaction of 1-hydrogen with 2-substituent (R^1). 2-Chloromercurio aldehydes in each conformation will give stereoselectively (*Z*)- and (*E*)-enol esters. There are two reaction routes to be considered in each case. One of them is a spontaneous 1,3-displacement reaction of acyl cation with chloromercurio residue. The stereoselectivity of this route can be interpreted in terms of the formation of a six-membered intermediate between acyl chloride and 2-chloromercurio aldehyde

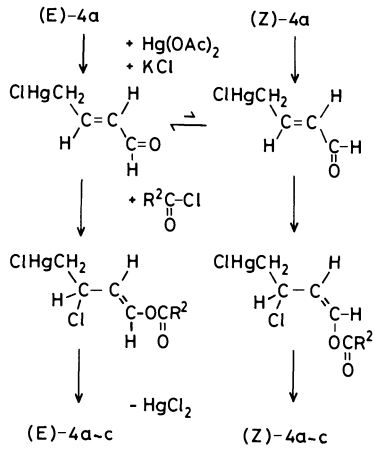




Scheme 4. Pathways for the formation of enol esters.

Compound	**1b**	**2a**	**2b**	**2c**	**3b**
R^1	CH_3	CH_3	C_2H_5	C_2H_5	C_6H_5
R^2	CH_2=CH	CH_3	CH_2=CH	C_6H_5	CH_2=CH

The other is an addition-elimination reaction between acyl chlorides and 2-chloromercurio aldehydes. The stereoselectivity will come from the *anti*-addition of chloride with respect to 2-chloromercurio residue and the *anti*-elimination of mercury(II) chloride from *threo*- and *erythro*-2-chloromercurio-1-acyloxy-1-chloro intermediates. Such compounds as 1-acyloxy-1-chloro derivatives were prepared by Kyburz et al.[29] through reaction of aldehydes or ketones with acyl chlorides in the presence of Lewis acid. The mechanism of *anti*-addition and *anti*-elimination was proposed by Larock and Bernhardt[30]



Scheme 5. Pathways for the formation of 1-acyloxy-1,3-butadienes.

Compound	4a	4b	4c
R^2	CH_3	CH_2=CH	CH_2=C(CH_3)

for the acylation of vinylmercurials.

In any cases the *syn*-1,2-dihydrogen conformation will lead to the formation of (*Z*)-enol ester. In conclusion, the stereoselectivity in the reactions of 2-chloromercurio aldehydes **1x—3x** with acyl chlorides may be controlled by the conformational structures of **1x—3x** when the reactions follow any one of the routes.

On the other hand, the reaction of 4-chloromercurio-2-butenal (**4x**) with acyl chlorides leads to the formation of *E*-rich 1-acyloxy-1,3-butadienes **4a—c** as shown in Table 1. Scheme 5 shows the reaction pathways for the stereoselective formations of *s-trans*- and *s-cis*-**4x** which react with acyl chlorides to give (*E*)- and (*Z*)-**4a—c**, respectively. The results suggest that conformational isomerization between *s-trans*- and *s-cis*-**4x** is difficult under reaction conditions where **4x** is slightly soluble and may associate together as verified on the basis of IR spectra. Another support for this suggestion is provided by the effect of reaction time on the *Z*/*E* ratio of product **4a** which was 5/95 at the beginning and 15/85 at the end for the reaction of **4x** with acetyl chloride. The *Z*/*E* ratio of the 1-acyloxy-1,3-butadiene prepared was almost equal to that of the starting enol acetate. The results also suggest that the product controlling step is the *O*-acylation of **4x**, since the elimination of a 4-chloromercurio residue from the *O*-acylated **4x** leads to the formation of a terminal vinylic double bond.

In conclusion, both the reaction of 1-acetoxy-1,3-butadiene with mercury(II) acetate and that with potassium chloride, as well as the reaction of the resultant (*E*)-4-chloromercurio-2-butenal with acyl chloride, can be carried out stereoselectively according to the structures of the substrates.

Experimental

General Method. Propanal, butanal, 2-phenylethanal, 2-butenal, 2-acetoxy-1-propene, acrylic acid, and methacrylic acid were commercial reagents and distilled before use. 2-Phenylethanal was supplied as a 50% solution in diethyl phthalate. Acryloyl chloride and methacryloyl chloride were prepared by the reaction of acrylic acid and methacrylic acid with benzoyl chloride, respectively. Solvents were purified in the usual way. The other reagents used were commercially available and used as they were.

Enol esters prepared were purified by distillation until their purities became higher than 99% as checked by GLC analyses on a 20% diethylene glycol succinate coated on Neopak 1A (Nishio Industry Co., Ltd.). They were identified by both IR and ^{1}H NMR spectra. GLC analyses were performed on a Shimadzu GC-4CPT gas chromatograph equipped with a thermal conductivity detector. ^{1}H NMR spectra were recorded on a JEOL-JNM C-60H spectrometer, and IR spectra were recorded on a Hitachi EPI-2 or a Shimadzu IR-400 spectrophotometer. The *Z*/*E* ratio of enol ester was determined by ^{1}H NMR spectrum and/or by GLC analysis. The peak of (*Z*)-olefinic proton in each ^{1}H NMR spectrum appeared at higher magnetic field than that of the (*E*)-olefinic proton. In the GLC analysis, the peak for the shorter retention time was assigned to the (*Z*)-isomer.

Preparation of Starting Enol Acetates. Method A: Enol acetylation with acetic anhydride in the presence of potassium acetate was conducted according to the procedure described in the literature.[2,3]

1-Acetoxy-1-propene (1a):[2] Propanal (1 mol), acetic anhydride (1.5 mol), and potassium acetate (0.125 mol) were refluxed for 8 h, the mixture was distilled, and the boiling fraction at 80—118 °C was washed with aqueous sodium carbonate and with distilled water and dried over sodium sulfate. Redistillation gave **1a**: Yield 12%; bp 103—106 °C; ^{1}H NMR δ=4.78 (0.51H, quintet, J=6.26 Hz, (*Z*)-2-H) and 5.30 (0.49H, quintet, J=6.24, 12.5 Hz, (*E*)-2-H); *Z*/*E* ratio 51/49 (lit,[5] 52.5/46.2; lit,[6] 48/52).

1-Acetoxy-1-butene (2a):[2] Similar treatment of butanal gave **2a**: Yield 37%; bp 122—124 °C; ^{1}H NMR δ=4.78 (0.47H, q, (*Z*)-2-H) and 5.36 (0.53H, sextet, (*E*)-2-H);[31,32] *Z*/*E* ratio 47/53.

1-Acetoxy-2-phenylethene (3a):[1] Similar treatment of 2-phenylethanal gave **3a**: Yield 73%; bp 73—74 °C/0.3 mmHg (1 mmHg=133.322 Pa); ^{1}H NMR δ=5.59 (0.35H, d, J=7.50 Hz, (*Z*)-2-H) and 6.32 (0.65H, d, J=13.05 Hz, (*E*)-2-H);[21,33] *Z*/*E* ratio 35/65.

1-Acetoxy-1,3-butadiene (4a):[3] 2-Butenal (1 mol) was added dropwise into a refluxing mixture of acetic anhydride (1.5 mol) and potassium acetate (1 mol). The mixture was refluxed further for half an hour. After cooling, it was washed successively with aqueous sodium carbonate, 20% sulfuric acid, and aqueous sodium carbonate and dried over sodium sulfate. Distillation under reduced pressure gave **4a**: Yield 57%; bp 56—58 °C/40 mmHg; ^{1}H NMR δ=7.05 (0.38H, d, (*Z*)-1-H) and 7.38 (0.62H, d, (*E*)-1-H); *Z*/*E* ratio 38/62.

Method B: Enol acetylation with 2-acetoxy-1-propene in the presence of *p*-toluenesulfonic acid and copper(II) acetate was carried out according to the literature.[4] Both **2a** and **4a** were prepared. **2a**: Yield 33%; bp 122—123 °C; *Z*/*E* ratio 65/35 by GLC. **4a**: Yield 70%; bp 51.0—52.5 °C/30 mmHg; *Z*/*E* ratio 17/83 by ^{1}H NMR.

Chloromercurio Aldehydes. 2-(Chloromercurio)propanal (1x): The preparative method for **1x** was a modification of that employed by Curtin and Hurwitz[2] as follows: Mercury(II) acetate (0.2 mole) was dissolved in 300 cm^3 of distilled water at ice-temperature. To this solution **1a** (0.2 mol) was added. When a homogeneous solution was obtained, 100 cm^3 of aqueous potassium chloride (0.2 mol) was added with vigorous stirring. It was agitated for several hours and allowed to stand overnight. The precipitate formed was separated on a suction funnel, washed with distilled water repeatedly, and dried in vacuo. **1x**: Yield 66%; mp 66—69 °C.

2-(Chloromercurio)butanal (2x):[2] Similarly, the reaction of **2a** with mercury(II) acetate and then with potassium chloride gave **2x**: Yield 83%; mp 90—94 °C; IR (benzene) 2700 (CO-H) and 1690 (C=O) and (Nujol mull) 2750 (CO-H) and 1630 cm^{-1} (C=O).

2-Chloromercurio-2-(phenyl)ethanal (3x): Similarly, the reaction of **3a** with mercury(II) acetate and then with potassium chloride gave **3x**: Yield 74%; mp 180 °C (decomp).

4-Chloromercurio-2-butenal (4x): The reaction of **4a** with mercury(II) acetate and then with potassium chloride gave **4x**: Yield 94%; mp 118—121 °C (decomp); IR (benzene) 1681 (C=O) and 1614 (C=C) and (Nujol mull) 1635 (C=O) and 1600 cm^{-1} (C=C). A comparison of the IR spectrum of **4x** with that of 2-butenal (1680 ((C=O) and 1640 cm^{-1} (C=C)) suggests that the chloromercurio group adds on 4-carbon rather than 2-carbon in **4x**. The lowering in wave number of the absorption band for the carbonyl stretching vibration has been observed by Susz[34] on a number of carbonyl compounds coordinated to Lewis acids; thus, coordination of mercury(II) chloride lowered 31 cm^{-1} the absorption band of the carbonyl in acetophenone.

The chloromercurio aldehydes (**1x**—**4x**) are slightly soluble in benzene, tetrahydrofuran, acetone, or tetrahydronaphthalene, and soluble in *N*,*N*-dimethylformamide.

Preparation of Enol Esters from Chloromercurio Aldehydes and Acyl Chlorides. The procedure employed was in general that employed by Nesmeyanov et al.[20]

1-Acryloyloxy-1-propene (1b): Acryloyl chloride (0.14 mol) was added to a tetrahydronaphthalene solution (150 cm^3) of **1x** (0.14 mol) and hydroquinone (0.5 g) at 40 °C under nitrogen stream. When the addition of acryloyl chloride was finished, the temperature was raised to 60 °C and the reaction was continued for 6 h. A few drops of quinoline were added to the reaction mixture. After the insoluble mercury(II) chloride was separated, the solution was distilled under reduced pressure. The low-boiling fraction was collected and redistillation gave **1b**: Yield 58%; bp 42.0—42.5/30 mmHg; n_D^{25} 1.4429; d_4^{25} 0.9409; IR (neat) 1730 (C=O), 1670 (enol C=C), and 1630 cm^{-1} (C=C); ^{1}H NMR δ=4.95 (0.84H, quintet, (*Z*)-2-H) and 5.33 (0.16H, sextet, (*E*)-2-H); *Z*/*E* ratio 84/16 and 88/12 by GLC.

1-Acryloyloxy-1-butene (2b): The reaction of **2x** with acryloyl chloride was carried out in benzene solution, the procedure employed being the same as that for **1b** except posttreatment: After removal of the insoluble mercury(II) salt, the benzene solution was evaporated off in a rotary evaporator. The residue was dissolved in diethyl ether, and the solution was washed with 10% aqueous sodium hydrogencarbonate and with distilled water, and then dried over sodium sulfate. Redistillation gave **2b**: Yield 38%; bp 47.5—48.0 °C/17 mmHg; n_D^{25} 1.4417; d_4^{25} 0.9260; IR (neat) 1730 (C=O), 1668 (enol C=C), and 1623 cm^{-1} (C=C); ^{1}H NMR δ=4.85 (0.87H, q, (*Z*)-2-H) and 5.45 (0.13H, sextet, (*E*)-2-H); *Z*/*E* ratio 87/13 and 83/17 by GLC.

1-Benzoyloxy-1-butene (2c): The reaction of **2x** with benzoyl chloride in a similar procedure with **2b** gave **2c**: Yield 70%; bp 66—70 °C/1.0 mmHg; IR (neat) 1724 (C=O) and 1663 cm^{-1} (enol C=C); ^{1}H NMR δ=4.91 (0.85H, q, (*Z*)-2-H) and 5.56 (0.15H, sextet, (*E*)-2-H); *Z*/*E* ratio 85/15 and 83/17 by GLC.

2-Phenyl-1-(acryloyloxy)ethene (3b): The reaction of **3x** with acryloyl chloride was carried out in a similar manner with **2b**. Redistillation gave **3b**: Yield 51%; bp 65—68 °C/0.15 mmHg; n_D^{25} 1.4480; d_4^{25} 1.0650; IR (neat) 1740 (C=O), 1660 (enol C=C), and 1630 cm^{-1} (C=C); ^{1}H NMR δ=7.96 (0.26H, d, (*E*)-1-H); *Z*/*E* ratio 74/26 and 76/24 by GLC.

1-Acryloyloxy-1,3-butadiene (4b): The reaction of **4x** with acryloyl chloride was carried out at 50 °C for 3 h because of a high polymerization tendency of **4b**. Redistillation gave **4b**: Yield 39%; bp 45.0—45.5 °C/5 mmHg; n_D^{25} 1.4956; d_4^{25} 0.9723; IR (neat) 1735 (C=O), 1660 (enol C=C), and 1631 cm^{-1} (C=C); ^{1}H NMR δ=7.10 (0.32H, d, (*Z*)-1-H) and 7.43 (0.68H, d, (*E*)-1-H); *Z*/*E* ratio 32/68 and 30/70 by GLC.

1-Methacryloyloxy-1,3-butadiene (4c): The reaction of **4x** with methacryloyl chloride was carried out in a similar manner to the preparation of **2b**. Redistillation gave **4c**: Yield 63%; bp 35.0—36.5 °C/1.5 mmHg; n_D^{25} 1.4897; d_4^{25} 0.9486; IR (neat) 1735 (C=O), 1660 (enol C=C), and 1637 cm^{-1} (C=C); ^{1}H NMR δ=7.14 (0.34H, d, (*Z*)-1-H) and 7.43 (0.66H, d, (*E*)-1-H); *Z*/*E* ratio 34/66.

(Received June 10, 1985)

It was confirmed that the cathodic crossed coupling of acetone with unsaturated compounds in aqueous sulfuric acid could proceed smoothly, when the compounds which had radical-acceptable double bonds and were adsorbed on a mercury cathode were used. From this fact, it was concluded that the coupling occurs via the addition of a radical intermediate formed by the one-electron reduction of acetone to the double bonds on the cathode surface. Possibility of the addition of an anionic intermediate derived from acetone was excluded by no occurrence of the coupling of acetone with a polar acetylenic triple bond compound adsorbed on the cathode.

A number of electrochemical bimolecular reactions, e. g. dimerization, have been known and some of them have been used for purposes of syntheses in laboratories and industries. In previous works,[1-3] one (T. N.) of the authors reported a new type of crossed hydrocoupling reaction: When mixtures of acetone and activated olefins such as acrylic acid derivatives and maleic acid were reduced at a mercury cathode in aqueous sulfuric acid, their crossed hydrodimers were formed in good yields and current efficiencies. This reaction was successfully extended by using other aliphatic carbonyl compounds and C–N unsaturated compounds such as pyridines and amino nitriles instead of acetone and activated olefins, respectively.[4-13]

It should be generally important to clarify reaction mechanisms in order to design and optimize the reactions to be useful in a viewpoint of synthesis. A tentative mechanism (Scheme 1, path A, C=X–Y: CH_2=CH–CN) for the crossed hydrocoupling of acetone with acrylonitrile was first proposed by one(T. N.) of the authors. Afterward, Brown and Lister[14] also proposed another mechanism(Scheme 1, path B) on the basis of cyclic voltammetry of a mixture of acetone and acrylonitrile in aqueous sulfuric acid. However their mechanism was confuted by other investigators.[15]

† Present adress: Chemistry Department, Faculty of Science, Cairo University, Giza, Arabic Republic of Egypt.

More recently, Shono et al.[16,17] have reported that the intramolecular electroreductive cyclization of carbonyl compounds having inactive olefinic parts can occur in good yields in neutral solutions. Although they have briefly mentioned a mechanism equivalent to path B as the most plausible one, they have not given any obvious evidence and not verified the path B in comparison with path A.

In this study, we wish to clarify the reaction mechanism of which the key step has been still ambiguous and to indicate more clearly the scope, e. g. the possible extension and limitation, of this remarkable reaction.

Results and Discussion

Mixtures of acetone and various types of compounds having unsaturated carbon–carbon or carbon–nitrogen bonds were reduced at a mercury cathode in

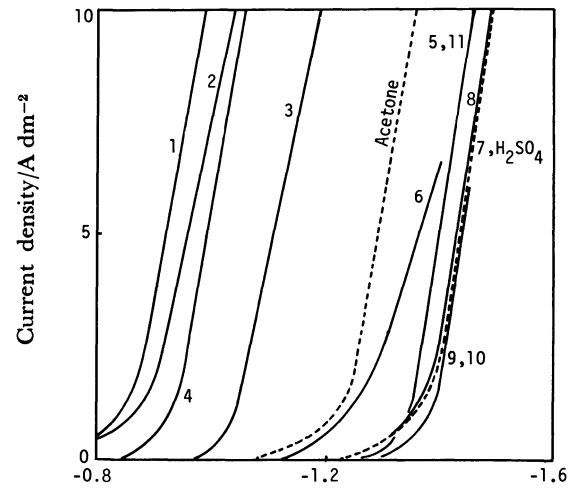

Fig. 1. Polarization curves of unsaturated compounds (**1**—**11**) and acetone at a mercury cathode in 20 wt% H_2SO_4. Concentration: **1**, **3**, and **8**, 0.1 mol dm^{-3}; **2**, **4**—**7**, and **9**—**10**, 0.4 mol dm^{-3}; **11**, saturated; acetone, 50 wt%.

aqueous sulfuric acid.

Polarization curves of acetone and the unsaturated compounds measured in aqueous sulfuric acid by a steady state method are shown in Fig. 1. By comparing the reduction potentials of the unsaturated compounds with that of acetone, the compounds were classified into two groups: One consists of the compounds which seem to be more easily reduced than acetone, while those in the other group are more difficultly or can not be reduced.

The compounds such as phenyl vinyl sulfoxide (**1**), methyl vinyl sulfone (**2**), *N*-vinylpyridinium bromide (**3**), and quinoline (**4**), which belong to the former group, were reduced at less negative potentials than acetone to give the corresponding non-crossed coupling products by their own reduction. When a mixture of **1** and acetone was electrolyzed by passing 2.0 F (1 F= 96480 C) mol^{-1} of charge, 1,2-bis(phenylthio)ethane was formed in 66% yield and 33% of the starting **1** were recovered. The reaction scheme of this reduction may be written down as in Scheme 2 on the basis of material and charge balances observed. According to this scheme, current efficiency for the reaction was estimated to be about 100%, though ethylene was not quantitatively analyzed. The reduction of **2** consumed coulometrically 2 F mol^{-1}, but any reduction products[18] were not separated. The reduction of **3** and **4** gave the corresponding dimeric hydropyridine and hydroquinoline, respectively, but their exact molecular structures could not be determined.

The unsaturated compounds having more negative reduction potentials than that of acetone could give the corresponding crossed coupling products with acetone as shown in Table 1. From a fact that considerable amounts of 2-propanol and 2,3-dimethyl-2,3-butanediol were formed as by-products in all the electrolyses, the occurrence of acetone reduction was confirmed.

It had been found that the addition of acetone to the 2-position of an *N*-unsubstituted pyridinium ring occurred exclusively.[4] However, though *N*-ethylpyridinium bromide (**5**) gave three crossed coupling products, their complete molecular structures (positions of 1-hydroxy-1-methylethyl groups and unsaturated bonds on the hydropyridine rings) could not be determined, as shown in Table 1. Isoquinoline (**6**) gave a sole crossed coupling product, though another isomeric one could be also expected to be formed as shown in Scheme 3. This result is rationalized as due to a more favorable limiting structure **6** than **6'** (in Scheme 3). Diethyl vinylphosphonate (**7**) behaved as a typical activated olefin to give the crossed coupling product with acetone as well as acrylonitrile.[2] The unsaturated bonds of **5**—**7** are highly polarized and they are so-called Michael acceptors[19] which should be able to accept a carbanion intermediate formed by the two-electron reduction of acetone. Therefore, the probability of path A in Scheme 1 can not be excluded.

Results described above are interesting but not very important to discuss the reaction mechanism in detail. The most important result for clarification of the mechanism was obtained in the reaction of trimethylvinylammonium bromide (**8**) with acetone.

Since a nitrogen atom has not d-orbital which can accept an electron, nitrogen ylids are generally very unstable and difficultly formed.[20] This is a reason for that vinylammoniums can not undergo Michael addition[21] which should proceed via nitrogen ylid intermediates, though their double bonds should be highly polarized. On the other hand, vinylsulfoniums and vinylphosphoniums can undergo the addition,[19,21] since both sulfur and phosphorus atoms have d-orbitals. As shown in Table 1, trimethylvinylammonium bromide (**8**) gave the corresponding crossed coupling product with acetone, though **8** is not a Michael acceptor but a polarized olefin. This fact should exclude path A and consequently supports path B.

A further evidence for path B was obtained by using inactive olefins such as allylamine (**9**) and allyl alcohol (**10**). The former and the latter gave the corresponding crossed coupling products in reasonable and much lower yields, respectively, in aqueous sulfuric acid. It was independently confirmed that the olefins themselves could not be reduced under electrolytic conditions. Since lifetimes of aliphatic radicals, except for allylic and benzylic ones, are generally very short, the addition of a radical intermediate derived from acetone to the olefins in

a) Based on the starting unsaturated compounds. b) Not estimated. c) Under galvanostatic conditions at 6 A dm^{-2} of current density. d) Isolated as a mixture of the corresponding cis and trans-lactones. e) Estimated from a result reported in previous work.[27]

path B should take place on surface or vicinity of cathode in competition with its own coupling to form 2,3-dimethyl-2,3-butanediol and its further reduction to form 2-propanol. On the basis of this consideration, the higher yield with **9** is rationalized as due to its higher concentration on the cathode surface. Such a higher concentration is achieved by adsorption of protonated **9** ($CH_2{=}CH{-}CH_2{-}NH_3^+$) which is electrostatically attracted to the negatively polarized cathode: It had been confirmed by electrode-interfacial capacity measurement and AC-polarography that acrylonitrile and pyridinium adsorb in aqueous sulfuric acid.[22] On the other hand, the protonation of **10** does not seem to be so sufficient that it can adsorb strongly and undergo easily the addition of the radical intermediate on the cathode surface.

In contrast, in the case of the intramolecular reductive cyclization of unsaturated carbonyl compounds,[16,17] high yields of the cyclized product should be reasonably expected, since the unsaturated part should exist in the vicinity of radical part formed: In this case, the high yields can be expected regardless of the adsorption. Recently, Little et al.[23] have reported that the intramolecular reductive cyclization of ketones having activated olefinic double bonds can proceed efficiently in not only acidic but also neutral media. More recently, Shono et al.[24] have reported an improved intermolecular reductive coupling of ketones with inactive olefins: They electrolyzed mixtures of aliphatic ketones and olefins in the presence of trimethylchlorosilane at a zinc cathode in DMF containing tetraethylammonium tetrafluoroborate to obtain the corresponding crossed coupling products in good yields but in low current efficiencies. They have shown a path B-like mechanism for this reaction. This method was also applicable to activated olefins and aldehydes.[25]

Regioselective addition of radicals in the intramolecular cyclization may be explained on the basis of ease and difficulty of formation of substituted ring systems in each case. However, regioselectivity observed in the intermolecular addition of radicals to polarized double bonds has not been rationalized yet. In this work, it was attempted to calculate reaction indexes for radical addition and collate with experimental results. The reaction indexes of acrylonitrile and pyridinium as typical sample molecules are given in Table 2. Table 2 shows that all the indexes indicate 3- and 2-positions in acrylonitrile and pyridinium, respectively, as the most favorable ones for the radical addition and in fact the addition took place at these positions. This coincidence may be one of evidences for path B.

It is generally known that acetylenes are less reactive than olefins towards free radicals while more reactive towards nucleophiles.[26] In fact, acetylenecarboxylic acid derivatives undergo Michael addition.[19] The reduction potential of methyl 2-butynoate (**11**) seemed more negative than that of acetone but it gave no crossed hydrocoupling product with acetone: The starting **11** was almost completely recovered. On the other hand, in a previous work[27] methyl crotonate (**12**) as an olefinic analogue of **11** had been found to give the corresponding crossed coupling product with acetone in a reasonable yield. In this work, it was also confirmed by the electrode-interfacial capacity measurement that the adsorption of **11** on a mercury cathode occurred similarly to that of **12**. These facts also exclude path A.

Path A might be also excluded to rationalize stereochemistry of the crossed hydrocoupling products of cyclohexenecarboxylic acid derivatives with acetone.[28]

It is known that the reduction of acetone in acidic solutions gives 2-propanol as a main product at a mercury cathode and propane as a sole product at other cathodes such as cadmium, aluminum, and zinc.[29] The formation of 2-propanol is obviously via the carbanion intermediate, while propane seems to be formed via the radical intermediate. In a previous work,[13] the cathodes other than mercury were also found to result in the formation of the crossed coupling product of acrylonitrile with acetone in considerable yields. This fact also may support path B.

Table 2. Reaction Indexes for Radical Addition to Acrylonitrile and Pyridinium

Reaction index	Positions				
	Acrylonitrile		Pyridinium		
	2	**3**[a]	**2**[a]	**3**	**4**
Free atomic valence	0.3678	0.8877	0.4094	0.3977	0.4051
Localization energy	2.5532	1.7136	2.5011	2.5413	2.5311
Frontier electron density	0.4061	0.7615	0.4094	0.2842	0.3052
Super delocalizability	0.8443	2.0210	0.8695	0.8336	0.8621

a) Position at which the addition occurred actually in electrolyses.

Conclusion

1) The crossed hydrocoupling of carbonyl compounds with unsaturated ones proceeds via the addition of radical intermediates genarated by the one-electrone reduction of the formers to the latters, as shown in path B, Scheme 1.

2) Radical-acceptable unsaturated bonds are available for the crossed coupling, regardless of their polarization.

3) Under conditions where concentration of the unsaturated compounds on the surface or vicinity of cathodes can be kept high by their adsorption, the crossed coupling can smoothly proceed: The composition of electrolytic solutions is not an essential factor, if they adsorb sufficiently.

4) In intramolecular coupling, so-called cyclization, the adsorption is not an important matter.

5) To obtain synthetically satisfactory results, it is required to use the unsaturated compounds reduced at more negative potentials than the carbonyl compounds.

Experimental

Materials. Methyl Vinyl Sulfone (2): To prepare **2**, methyl 2-hydroxyethyl sulfide was first synthesized from 2-chloroethanol and methanethiol by the modified method of Kirner and Richtery.[30] Yield 65%; bp 53—54 °C/8 Torr (1 Torr=133.322 Pa) (lit,[30] 68—70 °C/20 Torr). The sulfide obtained thus was converted into methyl 2-chloroethyl sulfide by treatment with thionyl chloride. Yield 67%; bp, 57—59 °C/12 Torr (lit,[31] 55—56 °C/30 Torr). This sulfide was oxidized to the corresponding sulfone with 30% hydrogen peroxide solution in acetic acid and then the reaction mixture was evaporated to dryness. The residual oily material was treated with triethylamine to convert it into the titled sulfone (**2**).[32] Yield 68%; bp 105—107 °C/17 Torr (lit,[32] 115—117 °C/19 Torr); IR (liquid film), 3030, 2950, 1300, 1140, and 960 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=2.90 (s, 3H, $C\underline{H}_3$) and 6.7—7.0 (m, 3H, $C\underline{H}=C\underline{H}_2$).

***N*-Vinylpyridinium Bromide (3):** A mixture of pyridine (5.1 cm^3, 0.063 mol) and 1,2-dibromoethane (6.5 cm^3, 0.076 mol) was allowed to stand for 14 d at room temperature and then *N*-(2-bromoethyl)pyridinium bromide crystallized out was collected.[33] Yield, 65%. A mixture of the bromide thus obtained and potassium hydroxide in ethanol was stirred for 1.5 h at room temperature. The potassium bromide precipitated was filtered off and the filtrate was treated with

charcoal. The decolored ethanol solution was poured into ether, and then the titled compound (**3**) was collected and recrystallized from a mixture of ethanol and ether. Yield, 62%; mp 154—155 °C; ^{1}H-NMR (D_2O) δ=5.8—6.3 (m, 2H, CH=C$\underline{H}_2$), 7.3—7.8 (m, 1H, C$\underline{H}$=CH$_2$), and 8.0—9.1 (m, 5H, pyridine-$\underline{H}$).

***N*-Ethylpyridinium Bromide (5):** Pyridine (10.0 g, 0.13 mol) was reacted with ethyl bromide (14.5 g, 0.13 mol) for 2 d at room temperature and then precipitated **5** was collected and recrystallized from a mixture of ethanol and ether. Yield 81%; mp 120—121 °C; ^{1}H-NMR (D_2O) δ=1.78 (t, 3H, C$\underline{H}_3$), 4.80 (q, 2H, C$\underline{H}_2$), and 8.1—9.0 (m, 5H, pyridine-$\underline{H}$).

Other chemicals used were commercially supplied.

Electrolysis. An H-type divided cell with a sintered glass diaphragm was used. The cathode and anode were a mercury pool (7.1 cm^2) and a platinum plate, respectively.

Before electrolysis, polarization curves were measured by a steady state method. The electrolysis was carried out by a controlled potential method at 30 °C. The electrolytic solution was a mixture of acetone (30 g) and aqueous sulfuric acid (20 wt%, 30 g) containing substrates (**1—11**, 5—20 mmol).

Product Analysis. A general procedure was as follows. After the cathodic solution was neutralized (pH 1) with sodium hydroxide solution (20 wt%), it was extracted with organic solvents (mainly ether). When basic products were expected, the resulting aqueous layer was made strongly alkaline by addition of excess sodium hydroxide and then extracted again. All the extracts were dried over anhydrous sodium sulfate and analyzed by gas chromatography (PEG 20 M, 2 m, 190 °C for diethyl 3-hydroxy-3-methylbutylphosphonate; PEG 6000, 2 m, 70—170 °C for 2-propanol, 2,3-dimethyl-2,3-butanediol, 4-methyl-1,4-pentanediol, and methyl 3-methyl-2-butenyl sulfone; Tritone X305, 2 m, 170—180 °C or PEG-5% KOH, 1—2 m, 150—180 °C for 1-ethyl-2-(1-hydroxy-1-methylethyl)tetrahydropyridine, 1-ethyl-2-(1-hydroxy-1-methylethyl)piperidine, 1-ethyl-2,5-bis(1-hydroxy-1-methylethyl)piperidine, 4-methyl-3-pentenylamine, 2,2′-bi(1,2,3,4-tetrahydroquinoline), and 1-(1-hydroxy-1-methylethyl)-1,2,3,4-tetrahydroisoquinoline).

Reduction Product of Phenyl Vinyl Sulfoxide (1): 1,2-Bis(phenylthio)ethane crystallized out from the cathodic solution, when the solution was allowed to stand overnight. Mp 68—69 °C; IR (KBr), 1580, 1480, 1440, 740, and 690 cm^{-1}; MS (*m/z*), 246 (M$^+$). Found: C, 68.02; H, 5.71; S, 25.93%. Calcd for $C_{14}H_{14}S_2$: C, 68.25; H, 5.73; S, 26.03%.

Reduction Products of Methyl Vinyl Sulfone (2): The ethereal extract was evaporated and then the residual oil was distilled. The main fraction was methyl ethyl sulfone and also few drops of a higher boiling point fraction were obtained at ca. 120 °C/Torr. The high resolution mass spectrum indicated that the latter fraction would be methyl 3-methyl-2-butenyl sulfone which might be formed by dehydration of the original crossed hydrocoupling product (methyl 3-methyl-3-hydroxybutyl sulfone) with acetone. Found: *m/z* 148.0502. Calcd for $C_6H_{12}O_2S$: M 148.0556.

Reduction Product of *N*-Vinylpyridinium Bromide (3): A strongly basic product was separated by preparative gas chromatography. From the mass spectrum, it seemed to be 1,1′-divinyl-2,2′-bipiperidine or 1,4-bis(1-tetrahydropyridyl)butane. MS (*m/z*), 220 (M$^+$).

Reduction Product of Quinoline (4): A solid crystallized out from the cathodic solution made alkaline seemed to be a 2,2′-bi(1,2,3,4-tetrahydroquinoline). Mp 112—114 °C; MS (*m/z*), 262 (M$^+$); IR (KBr), 3360, 2940, 1605, 1490, 1260, 1120, and 750 cm^{-1}.

Crossed Hydrocoupling Products of *N*-Ethylpyridinium Bromide (5) with Acetone: Three fractions, which seemed to be isomeric mixtures, were separated by preparative gas chromatography, but the complete structures of products could not be determined by NMR study. 1-Ethyl-?-(1-hydroxy-1-methylethyl)-?,?,?,?-tetrahydropyridine. MS (*m/z*), 169 (M$^+$). 1-Ethyl-?-(1-hydroxy-1-methylethyl)piperidine. MS (*m/z*), 171 (M$^+$). Picrate: Mp, 156—157 °C. Found: C, 47.62; H, 6.00; N, 13.83%. Calcd for $C_{16}H_{24}N_4O_8$: C, 47.99; H, 6.04; N, 13.99%. 1-Ethyl-?,?-di(1-hydroxy-1-methylethyl)-piperidine. MS (*m/z*), 227 (M$^+$).

Crossed Hydrocoupling Product of Isoquinoline (6) with Acetone: 1-(1-Hydroxy-1-methylethyl)-1,2,3,4-tetrahydroisoquinoline was separated by preparative gas chromatography. Mp 82—83 °C; MS (*m/z*), 191 (M$^+$); IR (KBr), 3310, 3200, 2990, 2940, 2910, 1490, 1370, 1260, 1210, 1160, 1110, 970, 860, and 750 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.04 (s, 3H, C$\underline{H}_3$), 1.32 (s, 3H, C$\underline{H}_3$), 2.6—3.4 (m combined, 6H, C$\underline{H}_2$C$\underline{H}_2$-N$\underline{H}$-C$\underline{H}$-C-O$\underline{H}$), 3.95 (s, 1H, C$\underline{H}$), and 7.1—7.3 ppm (m combined, 4H, benzo-$\underline{H}$). On adding D_2O, the total relative intensity of the complicatedly combined multiplets at δ 2.6—3.4 ppm decreased by one third and a singlet peak for HDO appeared. The IR and NMR spectra suggested an intermolecular hydrogen bonding between the hydroxyl and amino groups. Found: C, 75.23; H, 9.25; N, 7.32%. Calcd for $C_{12}H_{17}NO$: C, 75.12; H, 8.97; N, 7.32%.

Crossed Hydrocoupling Product of Diethyl Vinylphosphonate (7) with Acetone: Distillation of a chloroform extraction afforded diethyl 3-hydroxy-3-methylphosphonate. Bp 125 °C/6 Torr; IR (liquid film), 3370, 2990, 2950, 1220, 1030, and 960 cm^{-1}; MS (*m/z*), 224 (M$^+$); ^{1}H-NMR ($CDCl_3$) δ=1.2 (s, 6H, C$\underline{H}_3$-C-OH), 1.3 (t, 6H, C$\underline{H}_3$-CH$_2$-O), 1.7—2.2 (m, 4H, C$\underline{H}_2$-C$\underline{H}_2$), 3.0 (s, 1H, O$\underline{H}$), and 3.8—4.3 (overrapping m, 4H, C$\underline{H}_2$-O).

Crossed Hydrocoupling Product of Trimethylvinylammonium Bromide (8) with Acetone: The cathodic solution was neutralized (pH 6.0) and then extracted with ether. The aqueous layer was evaporated to dryness under reduced pressure and extracted with ethanol. The ethanolic extract was poured into ether, trimethyl(3-hydroxy-3-methylbutyl)ammonium bromide precipitated was collected, and recrystallized from a mixture of ethanol and ether. Mp 172—173 °C; MS (*m/z*), 94 and 96 (CH_3Br), 59 ($(CH_3)_2C$=OH$^+$), and 85 ($(CH_3)_2$N=CH$_2^+$); ^{1}H-NMR (CD_3OD) δ=1.30 (s, 6H, C$\underline{H}_3$), 1.8—2.1 (m, 2H, C$\underline{H}_2$-CH$_2$-N), 3.23 (s, 9H, (C$\underline{H}_3$)$_3$-N$^+$), and 3.4—3.7 (m, 2H, C$\underline{H}_2$-N). Found: C, 42.79; H, 9.35; N, 6.16%. Calcd for $C_8H_{20}NBrO$: C, 42.49; H, 8.91; N, 6.19%.

Crossed Hydrocoupling Product of Allyl Amine (9) with Acetone: 4-Methyl-3-pentenylamine, which corresponds to the dehydration product of 4-methyl-4-hydroxypentylamine, was separated by preparative gas chromatography. MS (*m/z*), 99 (M$^+$), 82 (M$^+$—NH$_3$), and 41 ($C_3H_5^+$).

Crossed Hydrocoupling Product of Allyl Alcohol (10) with Acetone: 4-Methyl-1,4-pentanediol was separated by distillation of the ethereal extract of the cathodic solution. Bp 100 °C/11 Torr. Identified with the authentic sample prepared from γ-butyrolactone and 2 equiv methylmagne-

sium iodide.

Electrode-Interfacial Capacity Measurement. The capacity was measured by an impedance-bridge method similar to that used in previous work.[22]

Calculation of Reaction Indexes. The indexes were calculated by a HMO method using a computing program given by Kikuchi.[34] Following HMO parameters concerning with nitrogen atom were used. Acrylonitrile: Coulomb integrations of N and C in the cyano group, 1.2 and 0.1, respectively; resonance integration of C≡N, 1.0. Pyridinium: Coulomb integrations of N^+ and C adjacent to the N^+, 0.6 and 0.3, respectively; resonance integration of $^+N{=}C$, 1.0.

We are grateful to the UNESCO and the Japanese Ministry of Education, Science, and Culture for making possible Dr. Kandeel's participation to this study.

Hydration of the Oxyethylene Chain. Hypersonic Velocities in Aqueous Solutions of α-Methyl-ω-methoxyoligo(oxyethylene)s and α-Methyl-ω-hydroxyoligo(oxyethylene)s as Studied by Brillouin Scattering

Hiroatsu MATSUURA* and Koichi FUKUHARA
Department of Chemistry, Faculty of Science, Hiroshima University,
Higashisenda-machi, Naka-ku, Hiroshima 730
(Received August 22, 1985)

Hydration of the oxyethylene chain was studied by a Brillouin-scattering method; hypersonic velocities in aqueous solutions of $CH_3(OCH_2CH_2)_mOCH_3$ with m=1—4 and $CH_3(OCH_2CH_2)_mOH$ with m=2 and 3 were measured. The concentration of the solution, at which the sound velocity gave a maximum value, led to the number of water molecules, at the highest hydration, per ether linkage in the oxyethylene chain. The experimental results showed that 1.8 water molecules take part in the hydration of each $-CH_2OCH_2-$ group and that the number of the water molecules is virtually constant independently of the oxyethylene-chain length as far as the number of the oxyethylene units is limited up to four. These findings indicate that a sort of hydration complex of approximately 1 $-OCH_2CH_2-$: 2 H_2O is formed in the aqueous solution. It is suggested that the stabilization of the *gauche* conformation for the OCH_2-CH_2O group in aqueous solution, as evidenced by Raman-spectroscopic observations, is promoted greatly by the hydrogen bond of water molecules which are bridged between the adjacent ether oxygens in the oxyethylene chain.

Properties and structures of nonionic surfactants having oxyethylene chain as a hydrophilic group have been studied extensively by various experimental methods.[1] One of the current interests in nonionic surfactant chemistry is the hydration of the oxyethylene chain,[2-9] since the hydration structure is closely related to the size and shape of the micelles[10,11] and the phase behavior.[12] In order to elucidate the hydration of the oxyethylene chain in the nonionic surfactants, investigation of hydration structure is first required for simple model compounds consisting of the oxyethylene units.

In the present work, we have studied hydration of the model compounds, α-methyl-ω-methoxyoligo(oxyethylene)s $CH_3(OCH_2CH_2)_mOCH_3$ (m=1—4) and α-methyl-ω-hydroxyoligo(oxyethylene)s $CH_3(OCH_2CH_2)_mOH$ (m=2 and 3), by measuring hypersonic velocities in aqueous solutions of these compounds by a Brillouin-scattering method. Brillouin scattering from liquid gives directly the velocity of sound propagating in the medium.[13] In the liquid medium, fluctuations of density arise from the presence of sound waves of various wavelengths associated with the thermal energy of the medium, and passing of a monochromatic light-beam through such a medium gives rise to a change of frequency in the scattered light owing to the density fluctuation, the frequency shift $\Delta\nu$ being given by[14]

$$\Delta\nu = \pm 2\nu_i(v/c)n\sin(\theta/2), \quad (1)$$

where ν_i is the frequency of the incident light, v is the velocity of sound in the medium, c is the velocity of light in vacuum, n is the refractive index of the medium, and θ is the angle of scattering. For usual Brillouin-scattering experiments, the sound velocities obtained are those in the hypersonic region with frequencies of 1—10 GHz.

The sound velocity is correlated with elasticity or, conversely, compressibility of the medium in which the sound propagates. Accordingly, knowledge of the sound velocity will provide useful information of the structure of liquid or solution. It is expected that, when some ordered close structure is formed in solution, the volume and the compressibility of the solution will in general change; this leads to a change in sound velocity in the medium. The composition of the solution, at which the sound velocity reaches the extreme, is often the stoichiometric composition of a complex formed between the components. We have, therefore, examined the variation of the sound velocity with concentration for the aqueous solutions of $CH_3(OCH_2CH_2)_mOCH_3$ (m=1—4) and $CH_3(OCH_2CH_2)_mOH$ (m=2 and 3). A similar procedure, by detecting the change in fluidity of solutions, has been used to investigate extent of hydration.[15]

Experimental

$CH_3(OCH_2CH_2)_mOCH_3$ (m=1—4) and $CH_3(OCH_2CH_2)_mOH$ (m=2 and 3) supplied by Tokyo Kasei Kogyo Co., Ltd. were purified by repeated distillation under reduced pressure. Water was carefully purified by distillation and filtration. Aqueous solutions of various mole fractions of these materials were prepared for the Brillouin-scattering measurements.

The experimental arrangement for the measurement of Brillouin scattering was essentially the same as that used in the previous studies.[16,17] The light source was a helium-neon gas laser (NEC GLG5800) operated in the fundamental transverse mode at 632.8 nm with an output of about 50 mW. The light scattered from the sample at 90°

away from the incident-beam direction (θ=90°) was analyzed by a pressure-scanned Fabry-Pérot interferometer of Mizojiri Kogaku Kogyo Co., Ltd. The spacer between the interferometer etalons had a thickness of 6.075 mm, which gave the free spectral range[18] of 24.674 GHz. The Brillouin-scattering measurements were made, at least five times for each of the solutions, at 298±0.5 K by using a thermostat apparatus.

Results and Discussion

Some typical Brillouin spectra measured in this work are shown in Fig. 1. For the determination of sound velocity from the frequency shift, refractive index is required for each of the solutions studied. The refractive indices of aqueous solutions of $CH_3OCH_2CH_2OCH_3$ and $CH_3(OCH_2CH_2)_2OCH_3$ at various concentrations are available in the literature.[19,20] Therefore, the refractive indices at desired concentrations for these compounds were obtained from these data. The sound velocity thus obtained as a function of mole fraction of the solute is shown in Fig. 2. Since precise refractive-index data are not available for aqueous solutions of $CH_3(OCH_2CH_2)_3OCH_3$, $CH_3(OCH_2CH_2)_4OCH_3$, $CH_3(OCH_2CH_2)_2OH$, and $CH_3(OCH_2CH_2)_3OH$, the refractive indices were assumed to be

$$n = x_1 n_1 + x_2 n_2, \tag{2}$$

where x_1 and x_2 are mole fractions of the solution components and n_1 and n_2 are the refractive indices for their neat liquids. The sound velocities thus derived for the four compounds given above are shown in Figs. 3 and 4. In order to ensure the assumption of Eq. 2, the sound velocities for $CH_3OCH_2CH_2OCH_3$ and $CH_3(OCH_2CH_2)_2OCH_3$ are plotted, as shown in Fig. 5, against the refractive indices evaluated through Eq. 2. The plots in Figs. 2 and 5 give in fact the same value, within experimental error, of the mole fraction x_m, at which the sound velocity gives a maximum value, for each of the two compounds.

Figures 2—4 show that the maximum value of the sound velocity is at the mole fractions of 0.100, 0.085, 0.074, and 0.065, respectively, for the aqueous solutions of the monomer, dimer, trimer, and tetramer of $CH_3(OCH_2CH_2)_mOCH_3$ and at the mole fractions of 0.126 and 0.103, respectively, for those of the dimer and trimer of $CH_3(OCH_2CH_2)_mOH$. At these mole fractions of x_m, the aqueous solutions of

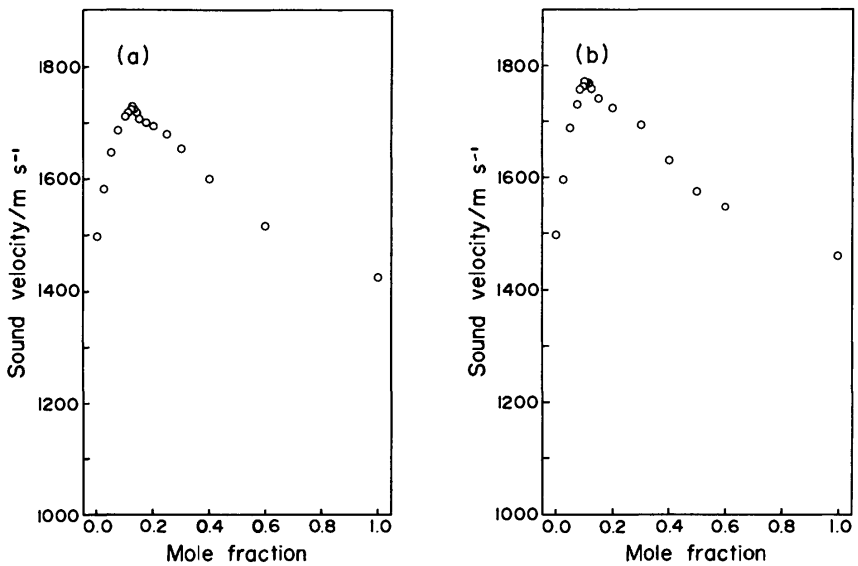

Fig. 4. Sound velocity vs. mole fraction of aqueous solutions of (a) $CH_3(OCH_2CH_2)_2OH$ and (b) $CH_3(OCH_2CH_2)_3OH$. A linear relation of refractive index with mole fraction is assumed.

the oligo(oxyethylene) compounds form the most compressed structure and all of the water molecules are expected to be involved in the hydration. For mole fractions of the solute larger than x_m, amount of water molecules is not enough to form the most close-packed solution structure; molecules of the oligo(oxyethylene) compounds themselves do not tend to form close structure as indicated by the fact that these molecules take rather disordered conformation in the neat liquid.[21] For mole fractions smaller than x_m, on the other hand, water molecules are more than enough for the highest hydration and the excess water molecules separate molecules of the oligo(oxyethylene) compounds from one another in solution, leading to less close solution structure.

The number of the water molecules, which are involved in the highest hydration, per each molecule of the oligo(oxyethylene) compounds is evaluated from their mole fractions x_m, at which the sound velocity is the maximum. The numbers obtained for

$CH_3(OCH_2CH_2)_mOCH_3$ with m=1, 2, 3, and 4 are 9.0_0, 10.7_6, 12.5_1, and 14.3_8, respectively, and those for $CH_3(OCH_2CH_2)_mOH$ with m=2 and 3 are 6.9_4 and 8.7_1, respectively. These results are summarized in Table 1.

The number of water molecules, at the highest hydration, per inner ether linkage $-CH_2OCH_2-$ in the molecular chain can be evaluated from the experimental results. If we assume that the corresponding number per terminal CH_3OCH_2- group is given by a half of the number of water molecules per molecule of $CH_3OCH_2CH_2OCH_3$. Thus, by using the number of 4.5 (=9.0/2) water molecules for the terminal CH_3OCH_2- part, the numbers of water molecules of hydration per $-CH_2OCH_2-$ group, $N_{CH_2OCH_2}$, are derived for the series of $CH_3(OCH_2CH_2)_mOCH_3$ compounds by the following equation:

$$N_{CH_2OCH_2} = (N_{mol} - 2\times 4.5)/n_{CH_2OCH_2}, \quad (3)$$

where N_{mol} is the number of water molecules, at the highest hydration, per molecule and $n_{CH_2OCH_2}$ is the number of the $-CH_2OCH_2-$ group in the molecule. The values obtained are 1.7_6, 1.7_6, and 1.7_9 for the compounds of m=2, 3, and 4, respectively, which contain one, two, and three $-CH_2OCH_2-$ groups in the molecule. For the series of $CH_3(OCH_2CH_2)_mOH$ compounds, the number of hydration water molecules per $-CH_2OCH_2-$, $N_{CH_2OCH_2}$, may be given as a difference between the numbers of water molecules per molecule of $CH_3(OCH_2CH_2)_3OH$ (8.7_1) and $CH_3(OCH_2CH_2)_2OH$ (6.9_4); the number derived is 1.7_7.

It is worthy to note that the number of water molecules per ether linkage in the inner part of the oxyethylene chain, when the highest hydration is attained, is essentially the same for all of the model compounds treated in the present work. This experimental finding indicates that extent of hydration of the oxyethylene chain is virtually constant independently of the chain length as far as the number of the oxyethylene unit is limited up to four. The composition of a maximum of 1.8 water molecules per inner ether linkage, or equivalently per inner oxyethylene group, determined in the present work indicates that a sort of hydration complex of

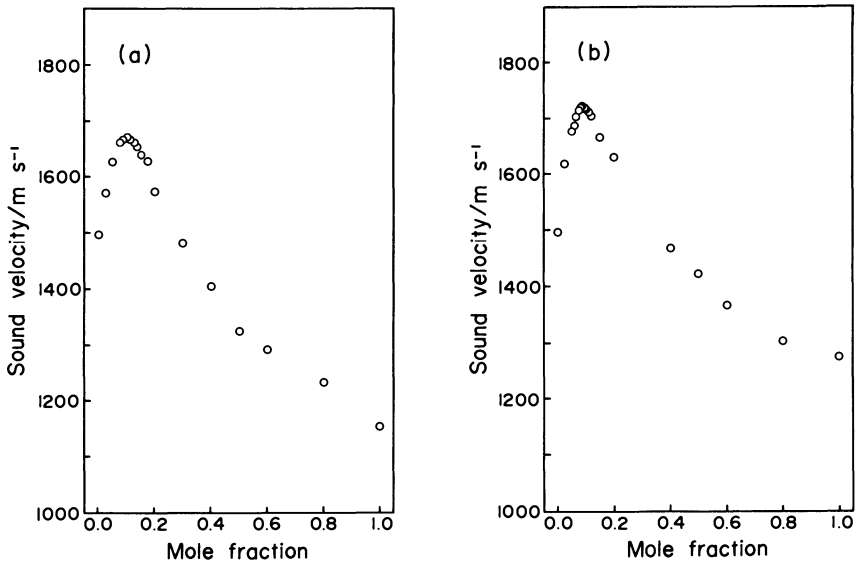

Fig. 5. Sound velocity vs. mole fraction of aqueous solutions of (a) $CH_3OCH_2CH_2OCH_3$ and (b) $CH_3(OCH_2CH_2)_2OCH_3$. A linear relation of refractive index with mole fraction is assumed.

approximately 1 $-OCH_2CH_2-$:2 H_2O is formed in the aqueous solution. The oxyethylene chain is incorporated with the water molecules in the formation of the structured hydration framework.

The present result of the extent of hydration appears to be consistent with the previous result, by means of the fluidity measurement, of 2.0 water molecules per ether linkage in $CH_3OCH_2CH_2OCH_3$ and $CH_3(OCH_2CH_2)_2OCH_3$.[15] The previous study[15] showed, however, that the extent of hydration was not different between the terminal CH_3OCH_2- group and the inner $-CH_2OCH_2-$ group. This inconsistency with the present result may be associated in part with the inherencies in the two different physical properties. It may be instructive to mention that the NMR measurements on α-hydro-ω-hydroxypoly(oxyethylene) with average molecular weight of 400, which corresponds to approximately nine oxyethylene units in the molecule, showed that three molecules of water were required for the hydration of each oxyethylene unit.[22]

The present observations show that more water molecules are involved in the hydration at the terminal CH_3OCH_2- group than at the inner $-CH_2OCH_2-$ group. This may be accounted for by possible existence of additional water molecules in the vicinity of the terminal methoxyl group. These water molecules will contribute, incorporated with the water molecules involved in the hydration at the inner ether linkages, to the formation of the structured hydration framework. This means that additional water molecules are necessary to close up an open end of the hydration framework at the CH_3O- terminal. For the compounds with the hydroxyl terminal, on the other hand, the $HOCH_2-$ group with hydrogen-bonding affinity can participate, in conjunction with the water molecules of hydration, in forming the hydration framework, and accordingly less water molecules of hydration will suffice for the terminal $HOCH_2-$ group. In fact, the results, shown in Table 1, on $CH_3(OCH_2CH_2)_mOH$ suggest that less than one water molecule is responsible for the hydration at the $HOCH_2-$ group.

The conformation of the oxyethylene chain in aqueous solution has been examined by a Raman-spectroscopic method[21,23,24]; further investigations are now in progress in our recent series of studies.[25,26] According to the analysis of Raman spectra,[21] the oxyethylene chain in aqueous solution becomes more ordered as the solution is diluted down to the mole fraction x_m, at which the hydration is completed. The dominant ordered structure is described by the *gauche* conformation of the OCH_2-OCH_2 group. On dilution with water, the *trans-gauche* conformation for the $O-CH_2-CH_2O$ group is most predominantly stabilized as compared with other possible conformations, and the *gauche-gauche* conformation follows the *trans-gauche*. The *gauche-trans* and *trans-trans* conformations are, however, much less stabilized than the above two, when the solution is diluted with water.[21]

These spectroscopic findings indicate that the stabilization of the *gauche* conformation for the OCH_2-CH_2O group is promoted greatly by the hydrogen bond formed between the ether oxygens and water molecules of hydration. Further speculation is possible that the water molecules are bridged between the immediately adjacent ether oxygens in the oxyethylene chain, in conformity with the stabilized *gauche* conformation of the OCH_2-CH_2O group. Various hydration models of the oxyethylene chain have been in fact proposed previously.[27–29] It seems, however, that further comprehensive experimental efforts are required for establishing more sophisticated hydration structures. The bridging hydrogen bonding mentioned above is nevertheless one of the most essential factors to maintain the *gauche* OCH_2-CH_2O structure in the oxyethylene chain.

It has been reported that the extent of hydration changes with increasing oxyethylene-chain length in α-n-alkyl-ω-hydroxypoly(oxyethylene)s, $CH_3(CH_2)_{n-1}(OCH_2CH_2)_mOH$, where the n-alkyl group is relatively long ($n>10$).[1] For these nonionic surfactant molecules, the effect of the alkyl chain seems to be significantly important in forming favorable hydration structures. The present result, obtained from the simpler model compounds, will be a basis for studying more complicated interactions between the hydrophilic moiety of the nonionic surfactants and water molecules.

The authors wish to express their thanks to Misses Noriko Soei and Tomoko Imabayashi for their assistance in the experimental work.

Interaction of Poly[*S*-(2-carboxyethyl)-L-cysteine] with Cationic Surfactants

Hiroshi MAEDA,* Yoriko TANAKA, and Shoichi IKEDA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received September 6, 1985)

The induction of the β-structure of fully ionized poly[*S*-(2-carboxyethyl)-L-cysteine] in solution markedly depended on the kind of head group of cationic surfactants; it occurred by the addition of dodecylammonium chloride (DAC) but not by the addition of dodecyldimethylammonium chloride (DDAC) or dodecyltrimethylammonium chloride (DTAC), as concluded based on circular dichroism spectra. The induction of the β-structure by DAC was not inhibited by raising ionic strength of the medium but was enhanced when the polypeptide concentration was increased. The polypeptide took the β-structure in the precipitates produced by the addition of any one of these three surfactants, as indicated by the infrared absorption (IR) spectra. Intensity of a characteristic absorption band of carboxylate group around 1570 cm^{-1} for the complex with DDAC was vanishingly weak, while those with DAC and DTAC were medium and strong, respectively. The precipitates were solubilized in the presence of excess amount of surfactants. In the solubilized solution, the β-structure was again found in the case of DAC, irrespective of the polypeptide concentration, but it was found only at high polypeptide concentrations in the case of DDAC.

Interaction of anionic polypeptides with cationic surfactants has been examined by monitoring the secondary structure of polypeptides.[1-3] Recently, we have examined the effect of different cationic surfactants on the induction of the secondary structures of anionic polypeptides.[4,5] Three surfactants used in these studies were dodecylammonium chloride (DAC), dodecyldimethylammonium chloride (DDAC), and dodecyltrimethylammonium chloride (DTAC). They have different ionic heads but a common hydrocarbon tail (dodecyl group).

Induction of the α-helix of poly(L-glutamic acid) (PGA) occurred by the addition of these three surfactants.[4] On the other hand, the β-structure of poly(*S*-carboxymethyl-L-cysteine) (poly[Cys(CH_2COOH)]) was induced by the addition of DAC but not by the addition of DDAC or DTAC.[5] PGA has been used as a standard model polypeptide for the α-helix.[6-10] Characterization of the β-structure of poly[Cys(CH_2COOH)] has been carried out recently.[11-13]

The observed marked difference between PGA and poly[Cys(CH_2COOH)] is expected to originate from different nature of the two secondary structures; α-helix and β-structure. Direct interaction sites in either polypeptide with surfactant ammonium groups are carboxylate groups. In the complexes of poly[Cys(CH_2COOH)] with DDAC or DAC, proton transfer to carboxylate groups from the ammonium head groups was indicated in the solid state.[5] The extent of proton transfer depends on the intrinsic dissociation constant K_0 of carboxyl group for a given surfactant head group. There is a great difference between the values of pK_0 of the two polypeptides; pK_0=4.4 for PGA[8] and pK_0=3.2 for poly[Cys(CH_2COOH)].[14] It is possible, therefore, that different nature of the interactions of these two polypeptides with the same surfactants partly originates from a consequence of the different values of pK_0. In the present study, the interaction of poly-[*S*-(2-carboxyethyl)-L-cysteine] (poly[Cys(CH_2CH_2COOH)]) with the three same cationic surfactants, DAC, DDAC, and DTAC, is examined by observing circular dichroism of solutions and infrared absorption spectra of precipitates. This polypeptide is a side-chain homolog of poly[Cys(CH_2COOH)] and carries carboxyl groups of pK_0=4.0.[14] Consequences of different values of pK_0 of carboxyl groups and different numbers of methylene groups are expected to show up in the interaction with the surfactants.

Experimental

Poly[*S*-(2-carboxyethyl)-L-cysteine] (poly[Cys(CH_2CH_2COOH)]) was synthesized as described previously[15] and its weight-average molecular weight and degree of polymerization were 3.5×10^4 and 200, respectively, as estimated from the viscosity-molecular weight relation on poly[Cys(CH_2COOH)].[16] Three surfactants used in the present study were the same lots as used in the previous studies.[4,5] Values of critical micelle concentration (cmc) in 0.01 M† NaCl are 1.23×10^{-2} M[17] and 1.14×10^{-2} M[18] for DAC and DDAC, respectively. Values of cmc for DTAC are 2.16×10^{-2} M (in water) and 1.59×10^{-2} M (in 0.02 M NaCl).[17] Concentrations of polypeptide C_P and surfactant C_D are expressed in residue molarity and molarity, mol dm^{-3} (M), respectively. Composition of the solutions is specified by C_P and the mixing ratio C_D/C_P. Circular dichroism (CD) spectra were taken on a Jasco J 40A circular dichrograph using cells of light paths of 1 and 10 mm. Four scans were averaged in most cases. Infrared absorption (IR) spectra of polypeptide-surfactant complexes in KBr discs were obtained on a Jasco IRA-2 spectrophotometer. Measurements of CD and IR were carried out at 24±2 °C.

Effects of different ways of preparing solutions were examined previously[5] and they were shown not to affect the obtained results significantly in so far as measurements were made on the solutions incubated more than 12 h. In

† 1 M=1 mol dm^{-3}.

the present study, solutions were prepared by adding small volumes of concentrated surfactant stock solutions to polypeptide solutions and incubated at 24±2 °C for 12 to 24 h.

Results

Interactions in 1×10^{-2} M Tris HCl (pH 7.4) in the absence of other supporting electrolytes were examined in the first place. In Fig. 1, CD spectra of solutions at a residue concentration C_P of 1×10^{-4} M are shown. In the absence of surfactants, the CD spectra (labeled a in Fig. 1A—C) of random coils are characterized by two negative bands, one around 200 nm and the other at 225 nm. On addition of DAC, the residue ellipticity, $[\theta]$, around 200 nm increased and became positive, while that at 225 nm became more negative. At the mixing ratio of 2.2, the spectrum (e) resembles that of typical β-structure (although incomplete) induced by protonation. On the other hand, no significant change occurred on addition of DDAC or DTAC. Effects of three surfactants can be compared clearly when values of residue ellipticities around band positions, $[\theta]_{205}$ and $[\theta]_{225}$, are plotted against the mixing ratio C_D/C_P (Fig. 2). The β-structure of poly[Cys(CH_2CH_2COOH)] was induced by the addition of DAC but not by DDAC or DTAC, similar to the previous result on poly[Cys(CH_2COOH)].[5] Further addition of the surfactants caused precipitation of the polypeptide. Precipitation occurred at the mixing ratios of about 3 for DAC, 15 for DDAC, and 20 for DTAC. When the mixing ratios exceeded 100, however, solubilization took place and the conformation of the polypeptide in the solubilized solutions was again the β structure in the case of DAC but random coils in the case of DDAC or DTAC.

The results at $C_P=1\times10^{-3}$ M are shown in Fig. 3. Induction of the β-structure by DAC was significantly enhanced when the polypeptide concentration was raised. Induction of the β-structure did not take place in the case of DDAC or DTAC even at this concentration. Precipitation occurred at the mixing ratios considerably smaller than those at $C_P=1\times10^{-4}$ M: about 0.8 for DAC, 1 for DDAC, and 3 for DTAC. Solubilization occurred for DAC when mixing ratios exceeded 100 and for DDAC ($C_D/C_P>400$) but not for DTAC up to $C_D/C_P=500$. In solubilized solutions, the β-structure was found for DAC and also for DDAC, although the extent of induction was not large for the latter.

Interaction in the presence of 0.1 M NaCl was examined at $C_P=1\times10^{-4}$ M (Fig. 4). As compared with the result on DAC in the absence of NaCl, increase in ionic strength slightly inhibited the induction of the β-structure by DAC. No induction by DDAC or DTAC was also found in the presence of 0.1 M NaCl. Solubility of the polypeptide decreased in 0.1 M NaCl, since precipitation of the polypeptide occurred at the mixing ratios (about 2, 6, and 12 for DAC, DDAC, and DTAC, respectively), which were smaller than those found in the absence of 0.1 M NaCl. Solubilization at high mixing ratios occurred only for DAC.

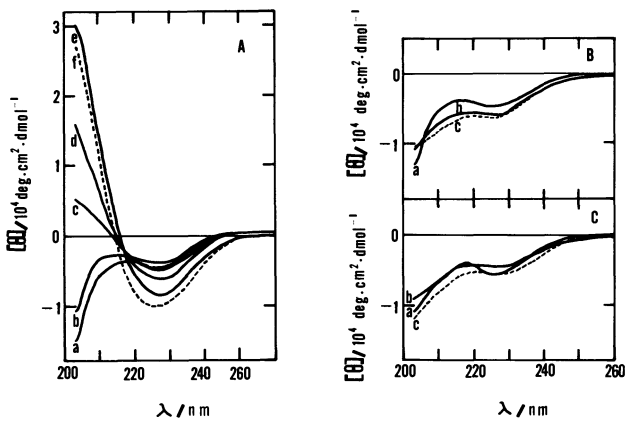

Fig. 1. CD spectra of poly[Cys(CH_2CH_2COOH)] in 1×10^{-2} M Tris HCl (pH 7.4) at $C_P=1\times10^{-4}$ M. (A) DAC. Mixing ratios (C_D/C_P): (a) 0, (b) 0.6, (c) 1.0, (d) 1.4, (e) 2.2, and (f) 100. (B) DDAC. Mixing ratios (C_D/C_P): (a) 0, (b) 6.2, and (c) 150. (C) DTAC. Mixing ratios (C_D/C_P): (a) 0, (b) 14, and (c) 100.

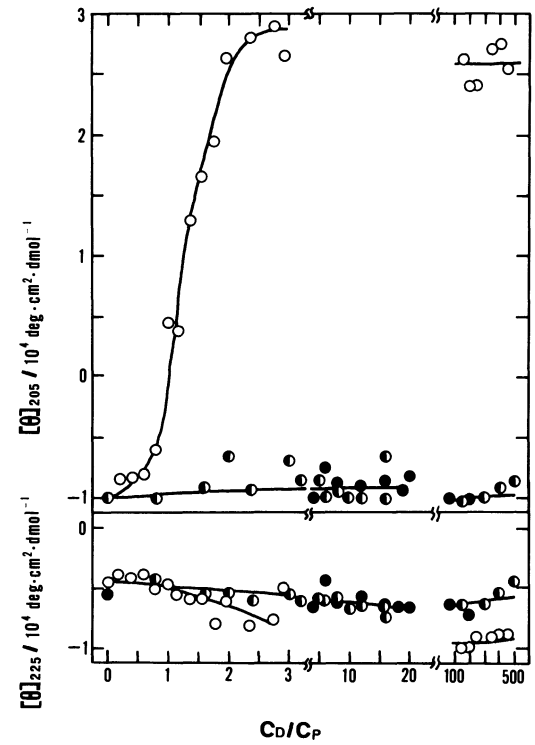

Fig. 2. Dependence of residue ellipticities $[\theta]_{205}$ and $[\theta]_{225}$ on the mixing ratio C_D/C_P in 1×10^{-2} M Tris HCl (pH 7.4) at $C_P=1\times10^{-4}$ M. (○) DAC, (◐) DDAC, and (●) DTAC.

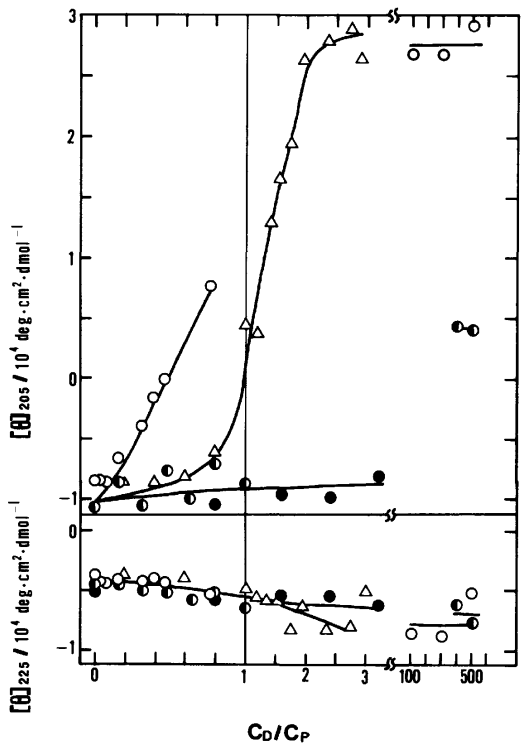

Fig. 3. Dependence of residue ellipticities $[\theta]_{205}$ and $[\theta]_{225}$ on the mixing ratio C_D/C_p in 1×10^{-2} M Tris HCl(pH 7.4) at $C_p=1\times10^{-3}$ M. (○) DAC, (◐) DDAC, and (●) DTAC. Data at $C_p=1\times10^{-4}$ M (△) in the case of DAC are also shown for comparison.

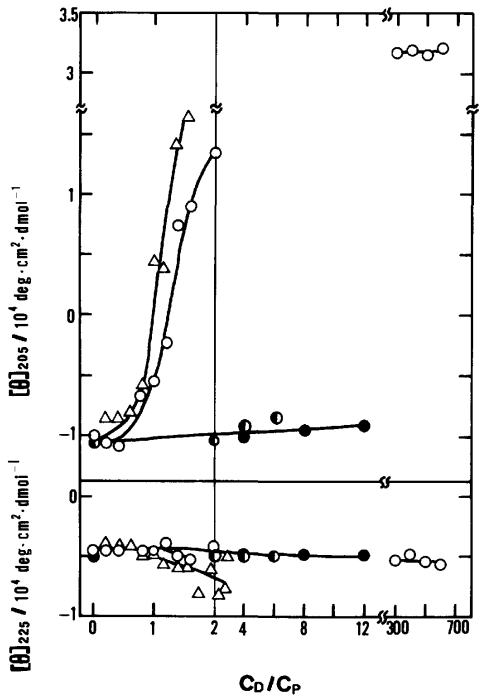

Fig. 4. Dependence of residue ellipticities $[\theta]_{205}$ and $[\theta]_{225}$ on the mixing ratio C_D/C_p in 1×10^{-2} M Tris HCl (pH 7.4) in 0.1 M NaCl at $C_p=1\times10^{-4}$ M. (○) DAC, (◐) DDAC, and (●) DTAC. Data for DAC in the absence of 0.1 M NaCl (△) are also shown for comparison.

In Fig. 5, correlation between two residue ellipticities of the polypeptide at 205 nm and 225 nm is shown. The data in the presence of DAC (open symbols) show two distinct regions; one corresponds to the induction of the β-structure at low mixing ratios and the other to solubilized solutions. The magnitude of the negative band around 225 nm, which is associated with n-π^* transition of the peptide chromophore, is greater in the solubilized solutions than in the solutions at low mixing ratios. This increased magnitude represents a decrease of the polarity around peptide chromophore in the solubilized state. This environmental effect on $[\theta]_{225}$ is very weak in solutions containing DTAC (filled symbols). In the presence of DDAC (half-filled symbols), however, the magnitude of $[\theta]_{225}$ increases considerably even for random coils at $C_p=1\times10^{-4}$ M, which is likely a preinduction stage of the β-structure at $C_p=1\times10^{-3}$ M in the solubilized solutions. Precipitation, solubilization and the conformation of the polypeptide in solution are summarized in Fig. 6. Three zones (A, B, C) for each surfactant represent, respectively, the results obtained at $C_p=1\times10^{-4}$ M, at $C_p=1\times10^{-3}$ M, and at $C_p=1\times10^{-4}$ M in 0.1 M NaCl. It is to be noted that 1×10^{-2} M Tris buffer (pH=7.4) was present in every case.

Infrared absorption (IR) spectra (Figure 7) of the complexes of poly[Cys(CH_2CH_2COOH)] with three surfactants were taken on the precipitates obtained at

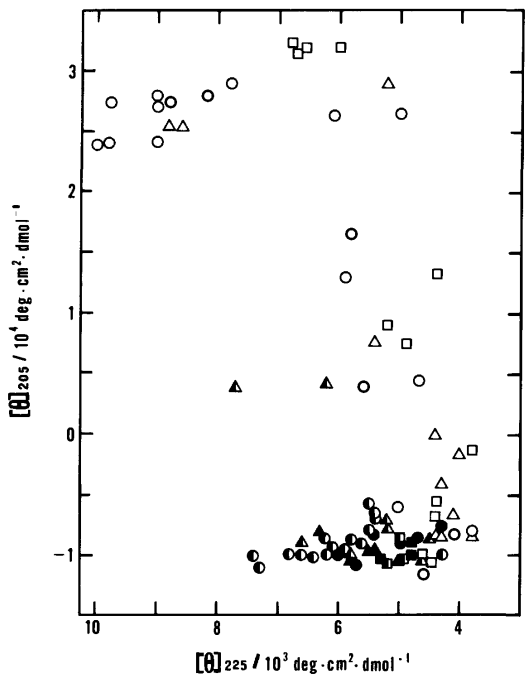

Fig. 5. Correlation between $[\theta]_{205}$ and $[\theta]_{225}$. Open, half-filled, and filled symbols represent the data on DAC, DDAC, and DTAC, respectively. Circles; $C_p=1\times10^{-4}$ M. Triangles; $C_p=1\times10^{-3}$ M. Squares; $C_p=1\times10^{-4}$ M in 0.1 M NaCl.

C_P=1×10^{-2} M and C_D/C_P=1. Amide I bands were observed at 1630 cm^{-1} [$\nu(\pi,0)$][19] and 1695 cm^{-1} [$\nu(0,\pi)$][19] and amide II bands were observed at 1525 cm^{-1} for three complexes, and hence antiparallel β-structure was confirmed as the conformation of the polypeptide. Proton transfer from ammonium head group to carboxylate was judged by measuring the intensity of antisymmetric streching mode of COO$^-$ groups found at 1570 cm^{-1}. The intensity was very weak, medium, and strong in the complexes with DDAC, DAC, and DTAC, respectively, if compared with the intensity of amide II band in each case. Thus, protonation of carboxylate groups was indicated in the complexes with DDAC and DAC.

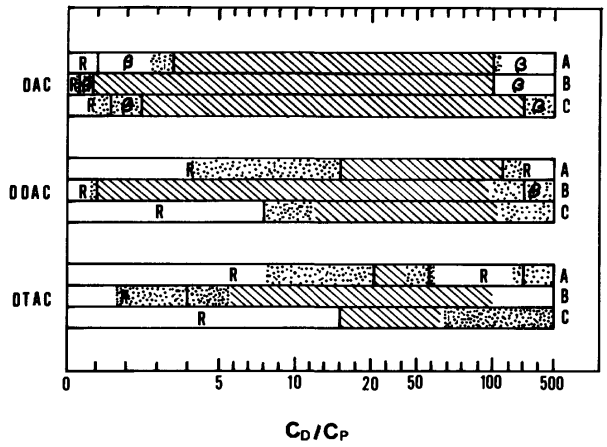

Fig. 6. Schematic phase diagram of a mixture of poly[Cys(CH_2CH_2COOH)] in the presence of a surfactant in 1×10^{-2} M Tris HCl (pH 7.4). Three zones A, B, and C correspond to the data at C_P=1×10^{-4} M, C_P=1×10^{-3} M, and C_P=1×10^{-4} M in 0.1 M NaCl, respectively. Blank region; solution. Dotted region; turbid solutions. Hatched region; precipitates. Conformations of the polypeptide in solutions are designated by R (random coils)or β(β-structure).

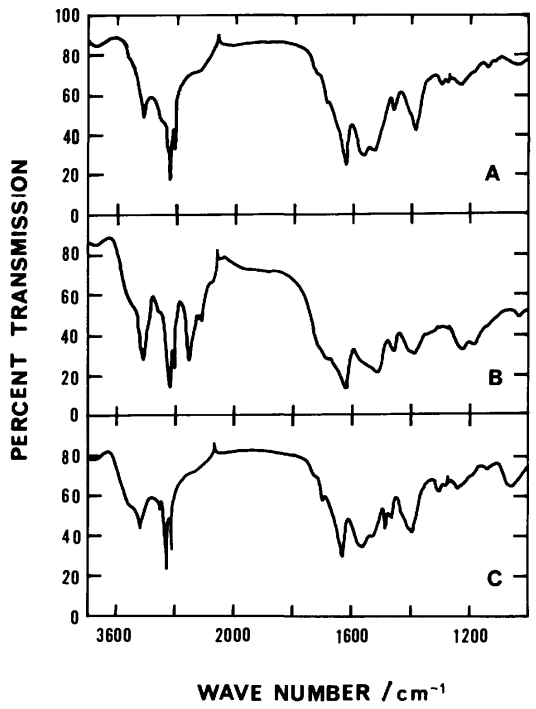

Fig. 7. Infrared absorption spectra of precipitates containing poly[Cys(CH_2CH_2COOH)] complexed with DAC (A), DDAC (B), and DTAC (C).

Discussion

Present results on poly[Cys(CH_2CH_2COOH)] and previous ones on poly[Cys(CH_2COOH)] are summarized in Table 1 and compared with each other. Very similar results are obtained between these two polypeptides with respect to the induction of the β-structure in solution as well as the effects of ionic strength and the polypeptide concentration on the induction. This comparison indicates that difference in acidities of the carboxyl groups between the two polypeptides scarcely affects their interaction with the cationic surfactants. It is concluded from this finding that the different interactions of the three surfactants with PGA[4] and poly[Cys(CH_2COOH)][5] essentially arise from different characters of the two secondary structures, α-helix and β-structure, and cannot be attributed much to different nature of the carboxyl groups of the two polypeptides. Therefore, present study confirms the validity of the previous discussion.[5]

On the other hand, there are several significant differences between the results on poly[Cys(CH_2COOH)] and poly[Cys(CH_2CH_2COOH)]. The addition of DDAC induced the β-structure of poly[Cys(CH_2CH_2COOH)] to some extent under a limited condition; solubilized solutions at high polypeptide concentrations. Induction of the β-structure of poly[Cys(CH_2COOH)] by the addition of DDAC did not occur under any condition examined. Conformations of the complexes with DTAC were random coil in the case of poly[Cys(CH_2COOH)] but the β-structure in the case of poly[Cys(CH_2CH_2COOH)]. Measurements of CD in solubilized solutions were hampered by the presence of (assumed) large aggregates in the case of the following combinations: DTAC-poly[Cys(CH_2CH_2-$COOH$)] and DDAC-poly[Cys(CH_2COOH)].

In addition to different values of pK_0 of side chain carboxyl groups, there is another important consequence of different side chains between these two polypeptides; different extents of hydrophobic nature of the side chains. Induction of the β-structure by DDAC in the solubilized solutions at C_P=1×10^{-3} M as well as the β-conformation of the complex with DTAC in the solid state can be ascribed to the enhanced stability of the β-structure of poly[Cys-(CH_2CH_2COOH)] due to increased nonpolar nature.[14,20]

Table 1. Comparison of Major Conformations of the Two Polypeptides in the Presence of Three Surfactants

	Solution		Precipitates		Solubilized solution	
Polypeptide[a)]	M	E	M	E	M	E
DAC	beta	beta	beta	beta	beta	beta
DDAC	coil	coil	beta	beta	x[b)]	beta (1 mM) coil (0.1 mM)
DTAC	coil	coil	coil	beta	coil	x[b)] (1 mM) coil (0.1 mM)

a) Poly[Cys(CH_2COOH)] and poly[Cys(CH_2CH_2COOH)] are abbreviated as M and E, respectively. b) Conformations could not be assessed from highly perturbed CD spectra.

Optical and Magnetic Properties of $(DBTTF)_2(Cu_2Cl_6)$ and $(DBTTF)_2(Cu_2Br_6)$ Complexes

Masashi TANAKA
Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464
(Received October 7, 1985)

Optical reflection and magnetic susceptibility measurements of $(DBTTF)_2(Cu_2Cl_6)$ and $(DBTTF)_2(Cu_2Br_6)$ complexes were carried out. The analysis of the reflection spectra of the single crystals of these complexes shows that the electronic structure of $DBTTF^+$ cation molecules is typical of the dimer type configuration. The magnetic susceptibilities of these complexes were measured over a temperature range of 2—300 K. The magnetic behavior conforms to a modified Bleaney-Bowers equation, indicating the existence of the spin coupling within the $Cu_2Cl_6^{2-}$ or $Cu_2Br_6^{2-}$ dimers and the antiferromagnetic spin interaction between $Cu_2Br_6^{2-}$ dimers.

There has been considerable interest recently in organic conductors which have highly anisotropic electrical, optical and magnetic properties. Tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ) is one of them which received the most detailed attention. After the discovery of the TTF-TCNQ complex, many compounds with fulvalene rings were synthesized to obtain the radical salts with highly electrical conductivity. Dibenzotetrathiafulvalene (DBTTF) is one of those compounds[1] and the direct oxidation of DBTTF by halogens and metal halides were reported to yield radical salts such as $(DBTTF)_2I_3$,[2] $(DBTTF)_8(SnCl_6)_3$,[3] and $(DBTTF)_3(SnBr_6)$.[3] Furthermore, we reported the crystal structure of $(DBTTF)_2(Cu_2Cl_6)$[4] and $(DBTTF)_2(Cu_2Br_6)$.[5] These complexes consist of the organic conducting stack and the inorganic magnetic stack and are supposed to have the interest properties of both the electrical conductivity and the magnetization. In the present paper, therefore, we report the optical and magnetic properties of $(DBTTF)_2(Cu_2Cl_6)$ and $(DBTTF)_2(Cu_2Br_6)$ complexes.

Experimental

The crystal of $(DBTTF)_2(Cu_2Cl_6)$ and $(DBTTF)_2(Cu_2Br_6)$ complexes was prepared by using the close system-evaporation crystallizer transfering DBTTF and $CuCl_2$ or $CuBr_2$ from solid sources to an acetonitrile solution.[6,7] The reflection spectra of the single crystal at the normal incidence were measured over the range of 5000—25000 cm^{-1} by means of a reflection spectrophotometer made in our laboratory and the temperature dependence of the magnetic susceptibility of the powder of the samples were recorded on a Oxford magnetic susceptibility instrument of the Instrument Center, Institute for Molecular Science, Okazaki. All calculations for the analysis of the experimental data were made on a FACOM M382 computer of Nagoya University.

Theoretical

For the dimer system of DBTTF cations, the Hamiltonian H can be written by the Hubbard approximation as follows,

$$H = -t\sum_{\sigma=\alpha,\beta}(a_{1,\sigma}^{+}a_{2,\sigma}+a_{2,\sigma}^{+}a_{1,\sigma}) + U\sum_{i=1,2}n_{i,\alpha}n_{i,\beta}, \quad (1)$$

where $a_{1,\sigma}$ and $a_{2,\sigma}$ are the annihilation operators of the π-electron occupying HOMO of the DBTTF molecule at the sites 1 and 2, σ represents the spin of π-electron, $n_{i,\sigma}=a_{i,\sigma}^{+}a_{i,\sigma}$, t is the electron transfer integral between the sites 1 and 2, and U is the intramolecular Coulomb integral. Then, the following ground and lower excited configuration functions are taken into account for the calculation of the electronic states of the dimer system.

$$\Phi_{T,1} = a_{1,\beta}a_{2,\beta}\Phi_{HF}, \quad (2)$$

$$\Phi_{T,0} = \frac{1}{\sqrt{2}}(a_{1,\beta}a_{2,\alpha}+a_{1,\alpha}a_{2,\beta})\Phi_{HF}, \quad (3)$$

$$\Phi_{T,-1} = a_{1,\alpha}a_{2,\alpha}\Phi_{HF}, \quad (4)$$

$$\Phi_{S,0} = \frac{1}{\sqrt{2}}(a_{1,\beta}a_{2,\alpha}-a_{1,\alpha}a_{2,\beta})\Phi_{HF}, \quad (5)$$

$$\Phi_{CT}(+) = \frac{1}{\sqrt{2}}(a_{1,\beta}a_{1,\alpha}+a_{2,\beta}a_{2,\alpha})\Phi_{HF}, \quad (6)$$

$$\Phi_{CT}(-) = \frac{1}{\sqrt{2}}(a_{1,\beta}a_{1,\alpha}-a_{2,\beta}a_{2,\alpha})\Phi_{HF}. \quad (7)$$

Here, Φ_{HF} means the Hartree-Fock wavefunction of the neutral dimer of DBTTF. Then, the secular equations are solved and the eigenfunctions and eigenvalues are obtained as follows, and the energy diagram of the cation dimer system is depicted in Fig. 1,

$$\left.\begin{aligned}\Psi_G &= c_1\Phi_{S,0}+c_2\Phi_{CT}(+),\\ E_G &= (U-\sqrt{U^2+16t^2})/2,\end{aligned}\right\} \quad (8)$$

$$\Psi_{T,i} = \Phi_{T,i}\ (i=-1,\ 0,\ 1), \quad E_{T,i} = 0, \quad (9)$$

$$\Psi_{CT}(-) = \Phi_{CT}(-), \quad E_{CT}(-) = U, \quad (10)$$

$$\left.\begin{aligned}\Psi_{CT}(+) &= c_2\Phi_{S,0}-c_1\Phi_{CT}(+),\\ E_{CT}(+) &= (U+\sqrt{U^2+16t^2})/2,\end{aligned}\right\} \quad (11)$$

where the parameters c_1 and c_2 are expressed by the next equations,

$$c_1 = \frac{2t}{\sqrt{E_G^2+4t^2}} \quad \text{and} \quad c_2 = \frac{-E_G}{\sqrt{E_G^2+4t^2}}. \tag{12}$$

The optically allowed transition from Ψ_G to $\Psi_{CT}(-)$ has the transition energy given by,

$$\Delta E_{CT} = E_{CT}(-) - E_G = (U+\sqrt{U^2+16t^2})/2, \tag{13}$$

and the oscillator strength of the CT band can be expressed as follows,

$$f = 3 \times 1.085 \times 10^{11}\Delta E_{CT}|\langle\Psi_G|r|\Psi_{CT}(-)\rangle|^2$$
$$= 3 \times 1.085 \times 10^{11}\frac{4t^2}{\sqrt{U^2+16t^2}}|R_{12}|^2, \tag{14}$$

where R_{12} is the distance between the DBTTF molecules.

The magnetic susceptibility X_{DBTTF} of the cation dimer system is given as follows,

$$X_{DBTTF} = \frac{N(g_1\beta)^2}{k_BT} \times \frac{1}{3+\exp(J_1/k_BT)}, \tag{15}$$

where $J_1=(\sqrt{U^2+16t^2}-U)/2$, g_1 is the magnetic field splitting factor, β the Bohr magneton, N the Avogadro number, k_B the Boltzman constant, and T the absolute temperature.

For the $Cu_2X_6^{2-}$ ion, the ground state of a free Cu^{2+} ion is $^2D_{5/2}$ corresponding to the electronic configuration of $(1s)^2(2s)^2(2p)^6(3s)^2(3p)^6(3d)^9$. The planar $Cu_2X_6^{2-}$ ion has D_{2h} symmetry and the symmetry orbitals can be obtained by group theoretical means from the 3d orbitals on the Cu^{2+} ion and the $np\sigma$ and $np\pi$ orbitals on the halogen ion X^-. For the 3d orbitals on the Cu^{2+} ion, the fivefold degeneracy of the d orbital is completely removed under the D_{2h} symmetry.[8] The d_{xy} level is the highest one occupied by an electron and the other levels (d_{z^2}, $d_{x^2-y^2}$, d_{xz}, d_{yz}) are occupied by two electrons. As the result, the d-d transitions are expected to be located in the 10000—15000 cm^{-1} region. The charge transfer bands from the ligand to the d orbital may occur over the higher wavenumber region. However, these transitions are very weak and can be neglected for the analysis of the reflection spectra of the complex. On the other hand, the pairs of Cu^{2+} ions interact through exchange forces and each pair forms a lower singlet and an upper triplet state as is shown in Fig. 1. The exchange energy J_2 corresponds to the magnitude of the splitting between the singlet and triplet states and the magnetic susceptibility $X_{Cu_2X_6}$ of the $Cu_2X_6^{2-}$ dimer system is given by the modified Bleaney-Bowers equation,[9]

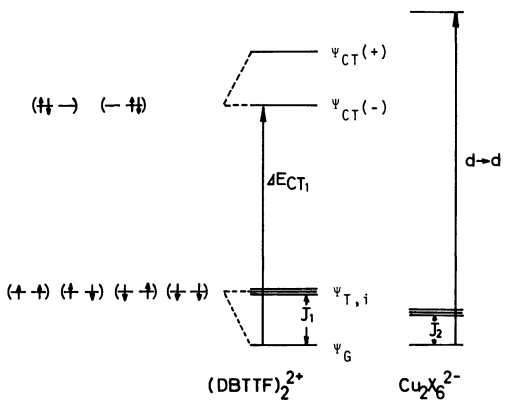

Fig. 1. Energy diagram of the complex $(DBTTF)_2$-(Cu_2X_6).

$$X_{Cu_2X_6} = \frac{N(g_2\beta)^2}{k_B(T-\Theta)} \times \frac{1}{3+\exp(J_2/k_BT)}, \tag{16}$$

where Θ is the Weiss constant that takes into account the spin interaction between the dimer ions.

The magnetic susceptibility $X(T)$ of the complex can be expressed by assuming that there is a separate contribution to the susceptibility from the DBTTF cation dimer, the $Cu_2X_6^{2-}$ anion dimer and the paramagnetic impurity,

$$X(T) = X_{DBTTF} + X_{Cu_2X_6} + \frac{N(g_3\beta)^2}{3k_BT}, \tag{17}$$

where the third term is the impurity term.

The optical reflectivity R can be expressed by the following equation,

$$R = \frac{1+|\varepsilon|-\sqrt{2(|\varepsilon|+\varepsilon_1)}}{1+|\varepsilon|+\sqrt{2(|\varepsilon|+\varepsilon_1)}}, \tag{18}$$

using the semiclassical Lorentz dielectric function,

$$\varepsilon(\omega) = \varepsilon_{core} + \sum_j \frac{\Omega_j^2}{\omega_j^2-\omega^2-i\omega\gamma_j}$$
$$= \varepsilon_1(\omega) + i\varepsilon_2(\omega), \tag{19}$$

where $\varepsilon_1(\omega)$ and $\varepsilon_2(\omega)$ are the real and imaginary parts of the dielectric function of the DBTTF cation dimers, and $|\varepsilon|=\sqrt{\varepsilon_1^2(\omega)+\varepsilon_2^2(\omega)}$. The oscillator strength f is determined by using the equation,

$$f = \frac{m_e}{4\pi N_0 e^2}\Omega_j^2. \tag{20}$$

Here, m_e is the electron mass, and N_0 is the number density of DBTTF molecule.

By fitting the above-mentioned equations of the reflectivity R and the magnetic susceptibility $X(T)$ to

the observed values, the optical and magnetic parameters of the complexes, $(DBTTF)_2(Cu_2X_6)$, can be obtained and their energy structure can be determined.

Results and Discussion

$(DBTTF)_2$-(Cu_2Cl_6) Complex. The crystal of $(DBTTF)_2$-(Cu_2Cl_6) complex crystallizes in the form of the dark reddish plates (0.35×0.008×0.60 mm) and has the natural developed plane of (010). The space group is monoclinic $C2/m$ and the unit cell dimensions are a=9.216, b=24.958, c=7.300 Å, and β=108.23°.[4,6] The projection of the complex onto the bc and ac planes are shown in Fig. 2. The stacking column of the cation molecules of DBTTF elongates along the c axis.

The reflection spectra were observed for the polarizations parallel and perpendicular to the c axis on the ac plane as is shown in Fig. 3. The 9000 cm^{-1} band in the c axis spectrum can be assigned to the CT_1 band of a dimer type system classified by Tanaka, et al.[10] and the dispersion around 20000 cm^{-1} in the $\perp$ c axis spectrum to the LE band of $DBTTF^+$ cation radical.[11] The best fit of Eq. 18 to the observed reflectivity is obtained and the calculated reflection spectra are depicted in Fig. 3 in order to compare with the observed ones. The obtained parameters (Ω_j, ω_j, γ_j, and ε_{core}) are shown in Table 1 together with the oscillator strength determined by Eq. 20. Then, the experimental data (ΔE_{CT_1}=8700 cm^{-1}, f=0.75, and R_{12}=3.65 Å) give U=6500 cm^{-1}, t=2200 cm^{-1}, and J_1=2200 cm^{-1} as the spectroscopic values. Accordingly, the crystal of the complex has the semiconductive property as the dielectric function can be well expressed by the Lorentz equation without the Drude equation.

The temperature dependence of the magnetic susceptibility of the powder of the complex were measured over a temperature range of 2—300 K as is shown in Fig. 4. The best fit of Eq. 17 to the observed one is obtained and the calculated susceptibility is depicted in Fig. 4. The obtained parameters are J_1>1000 cm^{-1}, J_2=95 cm^{-1}, g_2=2.65, Θ=0, g_3=0.89.

$(DBTTF)_2$-(Cu_2Br_6) Complex. The crystal of the $(DBTTF)_2$-(Cu_2Br_6) complex crystallizes in the form of the dark reddish plates (0.13×0.05×0.20 mm) and

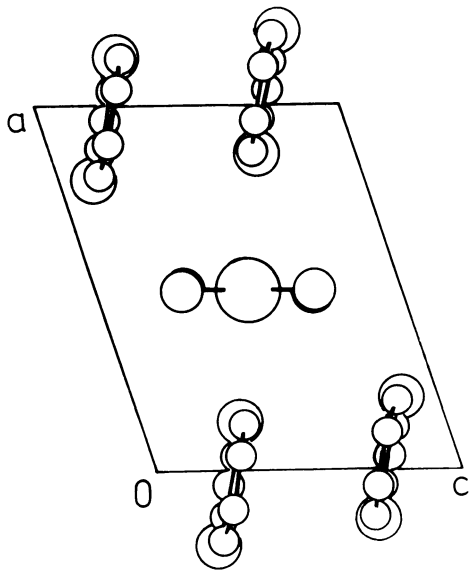

Fig. 2. The projection of the $(DBTTF)_2(Cu_2Cl_6)$ crystal onto the ac plane.

has the natural developed planes of (010) and (101). The space group is triclinic, $P\bar{1}$ and the unit cell are dimensions a=9.982, b=12.122, c=7.893 Å, α=83.70, β=112.80, and γ=104.97°.[5,7] The stacking of DBTTF molecules is illustrated in Fig. 5. The stacking column of the $DBTTF^+$ cations elongates along the c axis with an interplanar distance of about 3.5 Å and two DBTTF molecules form the dimer system in the unit cell.

Table 2. Dielectric Parameters of the Lorentz Fits of Reflectivity Data for $(DBTTF)_2(Cu_2Br_6)$

	// L on (010)	// b on (101)		⊥ b on (101)	
ε_{core}	1.702	2.203		2.200	
Ω_j/cm^{-1}	7600	14600	23300	4600	14000
ω_j/cm^{-1}	9900	16000	23700	18500	30000
γ_j/cm^{-1}	2550	2500	6600	2800	9000
f	0.27	1.0		0.1	

The reflection spectra were observed for the polarization parallel and perpendicular to the b axis on the developed plane (101) and parallel to the L direction on the (010) plane as is shown in Fig. 6. The 10000 cm^{-1} band in the L axis spectrum can be assigned to the CT_1 band[11] and the 16000 and 18000 cm^{-1} bands in the spectra on the (101) plane to the LE bands of $DBTTF^+$ cation radical.[10] The best fit of Eq. 20 to the observed reflectivity is obtained and the calculated reflection spectra are depicted in Fig. 6 in order to compare with the observed ones. The obtained parameters (Ω_j, ω_j, γ_j, and ε_{core}) are shown in Table 2 together with the oscillator strength determined by Eq. 20. Then, the observed oscillator strength f_{obsd} on the (010) plane equals to the next equation,

$$f_{obsd} = f\cos^2\varphi. \tag{21}$$

Here f is given by Eq. 14 and φ=52° is the angle between the L direction shown in Fig. 5 and the stacking axis (c axis) of DBTTF molecule. The experimental data (ΔE_{CT_1}=9900 cm^{-1}, f_{obsd}=0.27, and R_{12}=3.5 Å) give U=7700 cm^{-1}, t=2300 cm^{-1}, and J_1=2150 cm^{-1} as the spectroscopic values. Accordingly, the crystal of the complex has the semiconductive property like $(DBTTF)_2$-(Cu_2Cl_6).

The temperature dependence of the magnetic susceptibility of the powder of the complex were measured over a temperature range of 2—260 K as is shown in Fig. 7. The best fit of Eq. 17 to the observed one is obtained and the calculated susceptibility is depicted in Fig. 7. The obtained parameters are J_1>1000 cm^{-1}, J_2=150 cm^{-1}, g_2=1.88, Θ=−83 K, g_3=1.23. The negative value for Θ indicates the presence of antiferromagnetic spin interaction between the anion dimers. Our result for J_2 and g_2 values is consistent with the conclusion observed in the majority of copper(II) complexes that the spin-exchange interaction is stronger through bromine ions than through chlorine ions.[9]

On the Mechanism of Transfer of Sodium Ion across the Nitrobenzene/Water Interface Facilitated by Dibenzo-18-crown-6

(Received November 1, 1985)

The question of the site of ionophore–ion complex formation, whether it is in the organic phase (EC), in the aqueous phase (CE), or at the interface (E), in the transfer facilitated by dibenzo-18-crown-6 of sodium ion across the nitrobenzene/water interface was studied by kinetic analysis of the ion transfer using a.c. polarographic method. The results indicate that the interface reaction mechanism (E) is the most probable of the three.

The transfer of alkali metal and alkaline earth metal ions across the organic solvent or oil(O)/water(W) interface facilitated by the presence of natural or synthetic ionophores, such as valinomycin, nonactin, and crown ethers in the organic phase, has been intensively studied by Koryta[1] and his group,[2–9] Wang and Pang[10] and Yoshida and Freiser[11] using various electrochemical techniques. Despite the great effort devoted to elucidate the mechanism of the ionophore-mediated ion transport, the central question about the site of the complex formation and its dissociation, whether it is in the organic phase (EC mechanism), in the aqueous phase (CE mechanism) or at the interface (E mechanism), has not been settled yet. Koryta et al.[6] came to the conclusion that the valinomycin-facilitated transfer of potassium ion across the nitrobenzene/water interface takes place via two mechanisms, the EC and E mechanisms in parallel. Experimental results suggesting the interface reaction mechanism (E mechanism) have also been presented.[12] By contrast, Yoshida and Freiser[11] have presented experimental evidence which they interpret as meaning that potassium ion reacts in the aqueous phase with valinomycin that has transferred from the nitrobenzene phase (that is, CE mechanism). Quite recently, Lin and Freiser[24] have presented further experimental results suggesting that the mechanism of the potassium ion transfer facilitated by dibenzo-18-crown-6 across the 1,2-dichloroethane/water interface may depend on the concentration of potassium ion in the aqueous phase. The facilitated transfer of the alkali metal ions at the O/W interface is a very rapid process and is diffusion-controlled when observed using electrochemical methods such as cyclic voltammetry,[1–9,12] chronopotentiometry,[10] and current-scan polarography with an electrolyte dropping electrode.[11] In our opinion, the answer about the mechanism can be obtained only by kinetic study of the formation and dissociation of the ion-ionophore complex at and near the interface.

In previous papers,[13,14] we have shown that the a.c. polarographic method is useful in studying the kinetics and mechanism of ion transfer across the O/W interface. In this study[15] we have applied the a.c. polarographic method to study the facilitated transfer of sodium ion across the nitrobenzene/water interface in the presence of dibenzo-18-crown-6 (DB18C6) in the nitrobenzene phase and attempted to elucidate its mechanism on the basis of the analysis of kinetic parameters obtained by this method.

Experimental

Chemicals. Tetrapentylammonium chloride (TPACl) and tetramethylammonium chloride (TMACl) were obtained commercially. Triply distilled water was used to prepare the aqueous electrolyte solution. An aqueous solution of TPACl was stirred with silver chloride overnight and the filtrate was used. The concentrations of TPACl and TMACl were determined by potentiometric titration with a standard silver nitrate solution. Tetrapentylammonium tetraphenylborate (TPATPB) was prepared by the equimolar addition of an ethanol solution of tetrapentylammonium iodide to an ethanol solution of sodium tetraphenylborate. The resulting precipitate was repeatedly washed with twice-distilled water and recrystallized several times from an ethanol–acetone (3:2) mixture. Commercial DB18C6 was twice recrystallized from benzene and was dried at 80 °C under reduced pressure. Analytical-grade nitrobenzene was purified by a method previously described.[13] The nitrobenzene solution of TPATPB was prepared in the dark just before use. The other chemicals of commercial analytical grade were used as received.

Electrochemical Measurements. The electrolytic cell used here was essentially the same as that described elsewhere.[13] A flat test interface with an area of 0.241 cm^2 was formed at the end of a glass tube, which was treated in advance with dimethyldichlorosilane as described before.[16] The test interface was renewed for each measurement of a single voltammogram or a single chronoamperometric current-time curve.

The electrochemical cell was:

$$\begin{array}{l} \qquad\qquad\qquad\

application of the potential step E and being corrected for the base current. The plot of the current, $I_{t=10\,s}$, against E gave well-defined current-potential curves, as shown in Fig. 3. The limiting current, $(I_{t=10\,s})_l$, was proportional to $^*C_L^o$. A plot of E against $\log\{(I_{t=10\,s})/[(I_{t=10\,s})_l-(I_{t=10\,s})]\}$ yielded a straight line with the slope of 58±2 mV over the $^*C_L^o$ range studied. The half-wave potential, $E_{1/2}$, coincided with the E_m of the corresponding cyclic voltammogram.

A.c. Polarography. In Fig. 4, curves a and a′ show the real (Y_t') and imaginary (Y_t'') components of the admittance plotted against the linear sweep voltage, that is, the applied d.c. potential, $E_{d.c.}$, for the transfer of Na^+ ion across the interface between a 0.1 mol dm^{-3} NaCl aqueous solution and a 0.1 mol dm^{-3} TPATPB nitrobenzene solution containing 0.5×10^{-3} mol dm^{-3} DB18C6. After correction for the base admittance (curves b and b′), these admittances give the real (Y_F') and imaginary (Y_F'') components of the facilitated transfer of Na^+ ion at the nitrobenzene/water interface. The summit potentials of the Y_F' vs. $E_{d.c.}$ and Y_F'' vs. $E_{d.c.}$ curves agreed well within experimental error with each other and with the midpoint potential of the corresponding cyclic voltammogram (Fig. 1). The ion-transfer admittance can be expressed by a series combination of an equivalent resistance, r_s, and an equivalent capacitance, c_s.[13] Figure 5 shows the plots of r_s and $1/\omega c_s$ at $E_{d.c.}=E_{1/2}=0.275$ V against $\omega^{-1/2}$ ($\omega=2\pi f$, f being the a.c. frequency) of the ion transfer across the same interface as that in curves a and a′ in Fig. 4. Both plots gave straight lines with a common slope. Similar linear plots of r_s and $1/\omega c_s$, each set with a common slope, σ, were obtained at several other d.c.

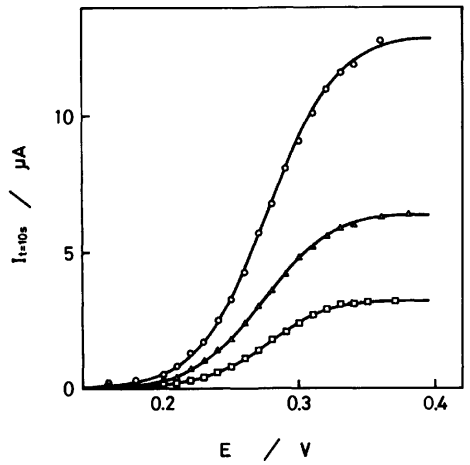

Fig. 3. Plot of $I_{t=10\,s}$, corrected for the base current, against E for the Na^+-ion transfer across the interface between a 0.1 mol dm^{-3} NaCl aqueous solution and a 0.1 mol dm^{-3} TPATPB nitrobenzene solution containing 0.5×10^{-3} (□), 1.0×10^{-3} (△), and 2.0×10^{-3} (○) mol dm^{-3} DB18C6.

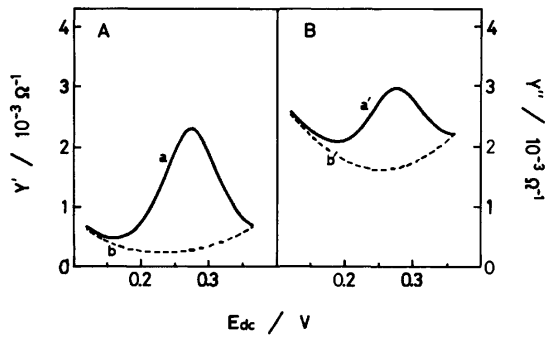

Fig. 4. Real (A) and imaginary (B) components of the admittance of the interface between a 0.1 mol dm^{-3} NaCl aqueous solution and a 0.1 mol dm^{-3} TPATPB nitrobenzene sotution, at $f=50$ Hz, in the presence (a and a′) and the absence (b and b′) of 0.5×10^{-3} mol dm^{-3} DB18C6 in the nitrobenzene phase.

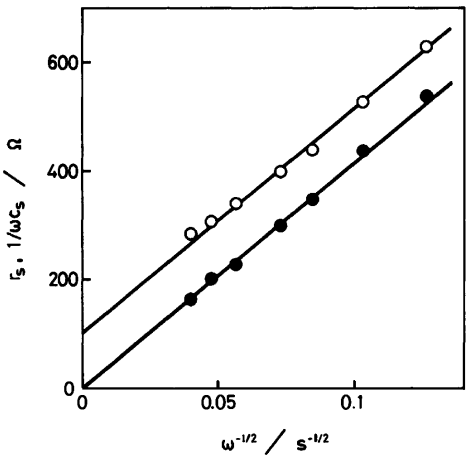

Fig. 5. Plots of the real (○) and imaginary (●) components of the ion transfer impedance at $E_{d.c.}=E_{1/2}^r=0.275$ V against $\omega^{-1/2}$, for the Na^+-ion transfer across the interface between a 0.1 mol dm^{-3} NaCl aqueous solution and a 0.1 mol dm^{-3} TPATPB nitrobenzene solution containing 0.5×10^{-3} mol dm^{-3} DB18C6.

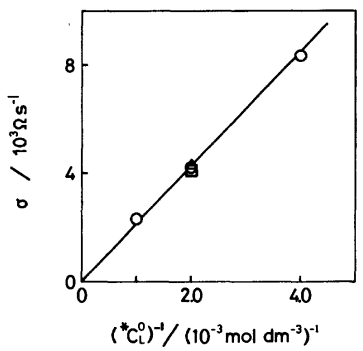

Fig. 6. Plot of σ at $E_{d.c.}=E_{1/2}^r$ against $(^*C_L^o)^{-1}$. $^*C_M^w$: (△) 0.05, (○) 0.1, and (□) 0.2 mol dm^{-3}.

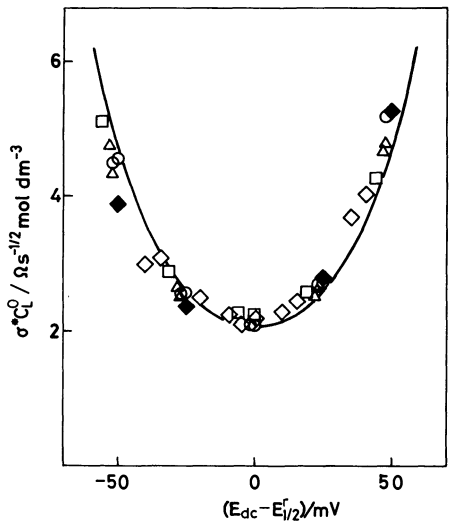

Fig. 7. Plot of $\sigma^*C_L^o$ against $(E_{d.c.}-E_{1/2}^r)$.
(○): $^*C_L^o=0.25\times10^{-3}$ and $^*C_M^w=0.1$ mol dm^{-3}, (△): $^*C_L^o=0.5\times10^{-3}$ mol dm^{-3} and $^*C_M^w=0.1$ mol dm^{-3}, (□): $^*C_L^o=1\times10^{-3}$ mol dm^{-3}, and $^*C_M^w=0.1$ mol dm^{-3}, (◇): $^*C_L^o=0.5\times10^{-3}$ mol dm^{-3} and $^*C_M^w=0.05$ mol dm^{-3}, (◆): $^*C_L^o=0.5\times10^{-3}$ mol dm^{-3} and $^*C_M^w=0.2$ mol dm^{-3}.
The solid line is the theoretical one drawn by Eq. 22 with $D_L^o=2.3\times10^{-6}$ cm^2 s^{-1}.

potentials in the range of $|E_{d.c.}-E_{1/2}|\leq0.05$ V for the interface between an aqueous solution of 0.05—0.2 mol dm^{-3} NaCl and a nitrobenzene solution of 2.5×10^{-4}—1×10^{-3} mol dm^{-3} DB18C6 containing 0.1 mol dm^{-3} TPATPB. Figure 6 shows a plot of σ obtained at $E_{d.c.}=E_{1/2}$ against $1/^*C_L^o$, indicating that σ was inversely proportional to $^*C_L^o$ but independent of $^*C_M^w$. The same dependence of σ on $^*C_L^o$ was observed at other $E_{d.c.}$'s at $|E_{d.c.}-E_{1/2}|\leq0.05$ V. Also, the σ values changed with $E_{d.c.}-E_{1/2}$ for a given set of $^*C_L^o$ and $^*C_M^w$ (see Fig. 7 below).

Discussion

When in the organic phase there is a lipophilic ligand, L, (usually belonging to the family of ionophores) that forms a lipophilic complex ML_n (n=1,2,...) with the transferring ion M^z (z=the number of charges), the transfer of M^z ion from the aqueous to the organic phase is facilitated; that is, it takes place at a less positive (if $z>0$) or at a less negative (if $z<0$) potential of the aqueous phase referred to that of the organic phase.[12] From a kinetic viewpoint, three kinds of the mechanisms of facilitated ion transfer may be postulated. In the following, we assume that the lipophilic ligand L is a neutral carrier.

(1) EC Mechanism. The ion M^z is transferred from the W to the O phase (Eq. 1a), followed by the formation of a complex ML_n with the ligand L (Eq. 1b) in the O phase:

$$M^z(W) \underset{\vec{k}_M(E)}{\overset{\vec{k}_M(E)}{\rightleftharpoons}} M^z(O), \tag{1a}$$

$$M^z(O) + nL(O) \underset{k_1^b}{\overset{k_1^f}{\rightleftharpoons}} ML_n^z(O) \quad K^o = k_1^f/k_1^b. \tag{1b}$$

(2) CE Mechanism. The ligand L is first transferred from the O to the W phase (Eq. 2a) and forms the complex ML_n with the ion M^z in the W phase (Eq. 2b); this is followed by the transfer of the complex from the W to the O phase (Eq. 2c):

$$L(O) \underset{k_L^b}{\overset{k_L^f}{\rightleftharpoons}} L(W) \qquad d_L = k_L^b/k_L^f, \tag{2a}$$

$$M^z(W) + nL(W) \underset{k_2^b}{\overset{k_2^f}{\rightleftharpoons}} ML_n^z(W) \quad K^w = k_2^f/k_2^b, \tag{2b}$$

$$ML_n^z(W) \underset{\vec{k}_{ML}(E)}{\overset{\vec{k}_{ML}(E)}{\rightleftharpoons}} ML_n^z(O). \tag{2c}$$

(3) E Mechanism. The complex ML_n is formed in a single step taking place at the O/W interface:

$$M^z(W) + nL(O) \underset{\vec{k}_{M/ML}(E)}{\overset{\vec{k}_{M/ML}(E)}{\rightleftharpoons}} ML_n^z(O). \tag{3}$$

Differential equations to express the diffusion coupled with complex formation of M, L, and ML_n in both organic and aqueous phases can easily be written and were solved, under appropriate conditions and assumptions, to give the theoretical equations of the polarographic (normal pulse polarographic) current-potential curves and also of the a.c. impedance of the ion transfer for each of these three mechanisms. Detailed results will be published elsewhere. Here only those important results relevant to discussion of the mechanism will be given.

Let us first assume (1) that the bulk concentration of M^z ion in the aqueous phase, $^*C_M^w$, is exceedingly large compared with that of L in the organic phase, $^*C_M^w \gg {}^*C_L^o$ (see Results), (2) that the partition coefficient of the carrier between the organic and aqueous phases, $d_L=C_L^o/C_L^w$, is so large ($d_L \gg 1$) that the presence of L in the bulk of the aqueous phase can be neglected, and (3) that the complex formation in the organic phase is largely shifted to the complex side ($K^oC_M^o \gg 1$) so that the presence of M^z ion in the organic phase can virtually be neglected. Then the reversible (*Nernstian*) normal pulse polarographic wave (I–E curve) of facilitated ion transfer can be expressed for the three mechanisms by the same equation:

$$E = E_M^\ddagger - (RT/zF)\ln K^o - (RT/zF)\ln {}^*C_M^w + (RT/zF)\ln[(\kappa_L^o)^n/\kappa_{ML}^o] + (RT/zF)\ln[I/(I_1-I)^n], \tag{4}$$

with

$$\kappa_L^\circ = (D_L^\circ/n^2\pi t)^{1/2} \quad \text{and} \quad \kappa_{ML}^\circ = (D_{ML}^\circ/\pi t)^{1/2} \tag{5}$$

where $E_M^\ominus$ is the standard ion transfer potential of Eq. 1a with respect to the reference electrode system (see Eq. 11 below) of Cell I and is related to the standard ion-transfer potentials of Eqs. 2c and 3, $E_{ML}^\ominus$ and $E_{M/ML}^\ominus$, respectively, both with respect to the same reference electrode system as above, by

$$E_M^\ominus - (RT/zF)\ln K^\circ = E_{ML}^\ominus - (RT/zF)\ln K^w + (RT/zF)\ln (d_L)^n \tag{6}$$

$$= E_{M/ML}^\ominus. \tag{7}$$

In these equations K° ($=k_1^f/k_1^b$) and K^w ($=k_2^f/k_2^b$) are the formation constants of Eqs. 1b and 2b, D_L° and D_{ML}° are the diffusion coefficients of L and ML_n in the organic phase, respectively, t is time measured from the voltage pulse rise, and I_l is the limiting diffusion current given by

$$I_l = zFA^*C_L^\circ(D_L^\circ/n^2\pi t)^{1/2}, \tag{8}$$

where A is the electrode surface area, and F, R, and T are used in their usual meanings.

Experimental results by cyclic voltammetry and potential-step chronoamperometry (normal pulse polarography) all indicate that the Na^+ ion transfer facilitated by DB18C6 at the nitrobenzene/water interface is d.c. reversible (*Nernstian*). That E_m and $E_{1/2}$ coincide with each other and are independent of $^*C_L^\circ$, and also that the log $[I/(I_l-I)]$ vs. E plot is linear with the reciprocal slope of 58±2 mV both indicate that n=1, that is, that there is formation of a 1:1 complex. Then Eq. 4 can be rewritten as Eq. 9 with the reversible half-wave potential $E_{1/2}^r$ defined by Eq. 10:

$$E = E_{1/2}^r + (RT/zF)\ln [I/(I_l-I)], \tag{9}$$

$$E_{1/2}^r = E_M^\ominus + (RT/2zF)\ln (D_L^\circ/D_{ML}^\circ) - (RT/zF)\ln K^\circ - (RT/zF)\ln {}^*C_M^w. \tag{10}$$

The observed dependence of $E_{1/2}(=E_m)$ on log $^*C_M^w$ (Fig. 2) was explained well by Eq. 10.

The potential E is usually expressed by

$$E = \Delta\phi + \Delta E_{ref}, \tag{11}$$

where $\Delta\phi$ is the potential difference between phases II and III in Cell I and ΔE_{ref} is the constant determined by the reference electrode system in Cell I, that is, RE1 and RE2 (see Experimental). In Cell I with 0.1 mol dm^{-3} TPATPB (NB, phase II)/0.1 mol dm^{-3} NaCl (W, phase III), ΔE_{ref} was determined to be 0.275 V from the reversible half-wave potential of tetramethylammonium (TMA^+) ion measured with the same reference electrode system as that used here and $\Delta\phi_{TMA}^\ominus$=0.035 V.[17] Then, $E_M^\ominus = E_{Na}^\ominus$ ($=\Delta\phi_{Na}^\ominus + \Delta E_{ref}$) was calculated to be 0.629 V using $\Delta\phi_{Na}^\ominus$=0.354 V.[17] Finally log K° was calculated to be 7.0 by Eq. 10 by assuming $D_L^\circ = D_{ML}^\circ$. Also, using the values from the literatures of d_L=2.3×10^4 [18] and K^w=14.6 mol^{-1} dm^3,[19] $E_{ML}^\ominus$ ($=\Delta\phi_{ML}^\ominus + \Delta E_{ref}$) was calculated by Eq. 6 (with n=1) to be 0.028 V, which gives $\Delta\phi_{ML}^\ominus$=−0.248 V. Similarly, $E_{M/ML}^\ominus$ was calculated by Eq. 7 to be 0.216 V, which gives $\Delta\phi_{M/ML}^\ominus$=−0.059 V.

In addition to the above assumptions (1)—(3), we further assume that the facilitated ion transfer processes are d.c. reversible. Then r_s and $1/\omega c_s$ of the facilitated ion transfer by 1:1 complex formation can be written[20] for each of the above three mechanisms, while assuming that $D_L^\circ = D_{ML}^\circ$, as follows.

(1) EC Mechanism:

$$r_s = \frac{RT}{z^2F^2A}\left[\frac{1}{\vec{k}_M(E_{d.c.})^*C_M^w} + \frac{K^\circ}{\rho_c}\cdot\left(\frac{1+\rho_c}{k_1^f D_L^\circ {}^*C_L^\circ}\right)^{1/2}\right] + \frac{RT}{z^2F^2A}\cdot\frac{1}{{}^*C_L^\circ\sqrt{2\omega D_L^\circ}}\cdot\frac{(1+\rho_c)^2}{\rho_c}, \tag{12}$$

$$1/\omega c_s = \frac{RT}{z^2F^2A}\cdot\frac{1}{{}^*C_L^\circ\sqrt{2\omega D_L^\circ}}\cdot\frac{(1+\rho_c)^2}{\rho_c}, \tag{13}$$

and

$$r_k \equiv (r_s - 1/\omega c_s) = \frac{RT}{z^2F^2A}\left[\frac{1}{\vec{k}_M(E_{d.c.})^*C_M^w} + \frac{K^\circ}{\rho_c}\left(\frac{1+\rho_c}{k_1^f D_L^\circ {}^*C_L^\circ}\right)^{1/2}\right] \tag{14}$$

with

$$\rho_c = \exp[zF(E_{d.c.} - E_{1/2}^r)/RT] \tag{15}$$

Here it is also assumed that the equilibrium and rate constants of the complex formation reaction in the organic plhase, K° and k_1^f, are so large that the conditions $K^\circ {}^*C_L^\circ \gg (\rho_c+1)^2$ and

$$\frac{k_1^f}{\omega}\left[\frac{K^\circ {}^*C_L^\circ + (1+\rho_c)^2}{K^\circ(1+\rho_c)}\right] \gg \left[\frac{K^\circ {}^*C_L^\circ}{\sqrt{2}(1+\rho_c)^2}\right]^{2/3}$$

are simultaneously satisfied.

(2) CE Mechanism:

$$r_s = \frac{RT}{z^2F^2A}\cdot\frac{(1+\rho_c)d_L}{K^w {}^*C_M^w {}^*C_L^\circ} \times\left[\frac{1}{\vec{k}_{ML}(E_{d.c.})} + \left(\frac{K^w(K^w {}^*C_M^w + 1)}{k_2^f D^w}\right)^{1/2}\right] + \frac{RT}{z^2F^2A}\cdot\frac{1}{{}^*C_L^\circ\sqrt{2\omega D_L^\circ}}\cdot\frac{(1+\rho_c)^2}{\rho_c} \tag{16}$$

$$1/\omega c_s = \frac{RT}{z^2F^2A}\cdot\frac{1}{{}^*C_L^\circ\sqrt{2\omega D_L^\circ}}\cdot\frac{(1+\rho_c)^2}{\rho_c} \tag{17}$$

and

$$r_k \equiv (r_s - 1/\omega c_s) = \frac{RT}{z^2F^2A}\cdot\frac{(1+\rho_c)d_L}{K^w {}^*C_M^w {}^*C_L^\circ} \times\left[\frac{1}{\vec{k}_{ML}(E_{d.c.})} + \left(\frac{K^w(K^w {}^*C_M^w + 1)}{k_2^f D^w}\right)^{1/2}\right]. \tag{18}$$

In Eqs. 16—18 the following three conditions are also assumed: (a) the rate constant of the transfer of L across the interface is large enough to satisfy $2k_L^f/\sqrt{2\omega D_L^\circ} \gg 1$, (b) the partition coefficient is large enough to satisfy both $d_L \gg (D^w/D_L^\circ)^{1/2}$ and $[(D^w/D_L^\circ)^{1/2}+d_L]/K^w{*}C_M^w \gg 1$ (where D^w is the common diffusion coefficient in the aqueous phase; $D^w=D_M^w=D_L^w=D_{ML}^w$), and (c) the rate constant of the complex formation in the aqueous phase is very large enough to satisfy $\xi=k_2^f(K^w{*}C_M^w+1)/\omega K^w \gg 1$ and $\xi \gg 2(K^w{*}C_M^w)^2$ simultaneously.

(3) E Mechanism:

$$r_s = \frac{RT}{z^2F^2A}\cdot\frac{(1+\rho_c)}{\vec{k}_{M/ML}(E_{d.c.}){*}C_M^w{*}C_L^\circ} + \frac{RT}{z^2F^2A}\cdot\frac{1}{{*}C_L^\circ\sqrt{2\omega D_L^\circ}}\cdot\frac{(1+\rho_c)^2}{\rho_c}, \quad (19)$$

$$1/\omega c_s = \frac{RT}{z^2F^2A}\cdot\frac{1}{{*}C_L^\circ\sqrt{2\omega D_L^\circ}}\cdot\frac{(1+\rho_c)^2}{\rho_c}, \quad (20)$$

and

$$r_k \equiv (r_s - 1/\omega c_s) = \frac{RT}{z^2F^2A}\cdot\frac{(1+\rho_c)}{\vec{k}_{M/ML}(E_{d.c.}){*}C_M^w{*}C_L^\circ}. \quad (21)$$

These theoretical equations predict that in either of the three mechanisms, the plot of r_s and $1/\omega c_s$ against $\omega^{-1/2}$ should yield straight lines with a common slope, σ, which is defined by

$$\sigma = \frac{RT}{z^2F^2A}\cdot\frac{1}{{*}C_L^\circ\sqrt{2D_L^\circ}}\cdot\frac{(1+\rho_c)^2}{\rho_c}. \quad (22)$$

The σ value should be inversely proportional to ${*}C_L^\circ$ but be independent of ${*}C_M^w$. These predictions agreed with the experimental results shown in Figs. 5 and 6. Figure 7 shows the plot of $\sigma{*}C_L^\circ$ against $E_{d.c.}$. The solid line in this figure is the theoretical line calculated by Eq. 22 using $D_L^\circ=2.3\times10^{-6}$ cm^2 s^{-1}. Thus the experimental dependence of r_s and $1/\omega c_s$ on $\omega^{-1/2}$ can be explained equally well by any of the mechanisms EC, CE, or E. On the other hand, the theoretical Eqs. 14, 18, and 21 predict that in the EC mechanism r_k ($\equiv(r_s-1/\omega c_s)$) should vary linearly with $({*}C_L^\circ)^{-1/2}$ (Eq. 14), whereas in the CE and E mechanisms r_k should be inversely proportional to ${*}C_L^\circ$ (Eqs. 18 and 21). In Figs. 8 and 9 r_k obtained at $E_{d.c.}=E_{1/2}^r$ for the case of ${*}C_M^w=0.1$ mol dm^{-3} is plotted against $({*}C_L^\circ)^{-1/2}$ or $({*}C_L^\circ)^{-1}$, respectively. The plot of r_k against $({*}C_L^\circ)^{-1/2}$ (Fig. 8) appears to be linear in the concentration range studied, but the intercept of the straight line at $({*}C_L^\circ)^{-1/2}=0$ was negative. This is inconsistent with the theoretical equation 14 (EC mechanism), which predicts a positive (or zero) intercept. Also, Eq. 14 predicts that the following inequality should hold in the EC mechanism:

$$(r_s - 1/\omega c_s) > \frac{RT}{z^2F^2A}\cdot\frac{K^\circ}{\rho_c}\left(\frac{1+\rho_c}{k_1^f D_L^\circ {*}C_L^\circ}\right)^{1/2}. \quad (23)$$

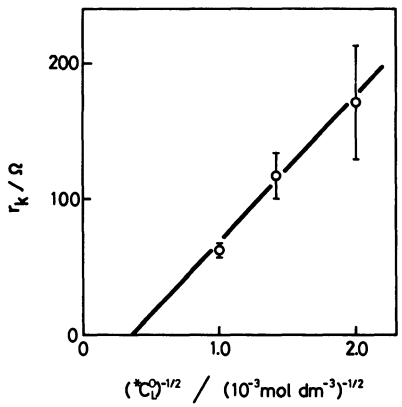

Fig. 8. Plot of $r_k(\equiv(r_s-1/\omega c))$ at $E_{d.c.}=E_{1/2}^r$ and ${*}C_M^w=0.1$ mol dm^{-3} against $({*}C_L^\circ)^{-1/2}$. The vertical bars indicate the standard deviations.

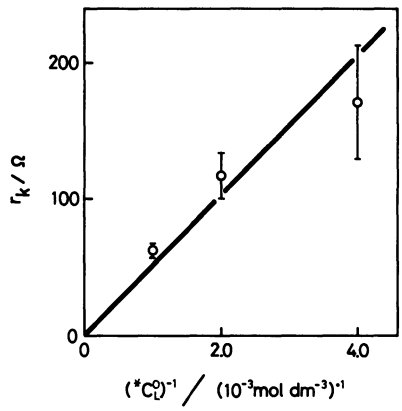

Fig. 9. Plot of $r_k(\equiv(r_s-1/\omega c_s))$ at $E_{d.c.}=E_{1/2}^r$ and ${*}C_M^w=0.1$ mol dm^{-3} against $({*}C_L^\circ)^{-1}$. The vertical bars indicate the standard deviations.

Application of this inequality to the result given in Fig. 5 with $K^\circ=9.8\times10^6$ mol^{-1} dm^3 and $D_L^\circ=2.3\times10^{-6}$ cm^2 s^{-1}, as determined in this paper, yielded the lowest limit of k_1^f to satisfy Eq. 14 as $k_1^f>1.5\times10^{13}$ mol^{-1} dm^3 s^{-1}. This value seems unreasonably high for a bimolecular reaction in solution. According to Debye,[21] the rate constant for a diffusion-controlled bimolecular reaction, k_D, is given by

$$k_D = 4\pi N_L(D_A+D_B)r_D, \quad (24)$$

where N_L is the Avogadro constant, D_A and D_B are the diffusion coefficients of the reactants A and B, and r_D is the reaction distance. Using $r_D=1.5\times10^{-7}$ cm and $(D_A+D_B)=10^{-5}$ cm^2 s^{-1}, we obtain $k_D=1.1\times10^{10}$ mol^{-1} dm^3 s^{-1}. These results indicate that the EC mechanism should be excluded from the present system. The plot shown in Fig. 9 indicates that r_k is inversely proportional to ${*}C_L^\circ$, suggesting that both the CE mechanism (Eq. 18) and the E mechanism (Eq. 21) are applicable to the present system. For the CE mechanism, the following inequality is predicted from Eq. 18:

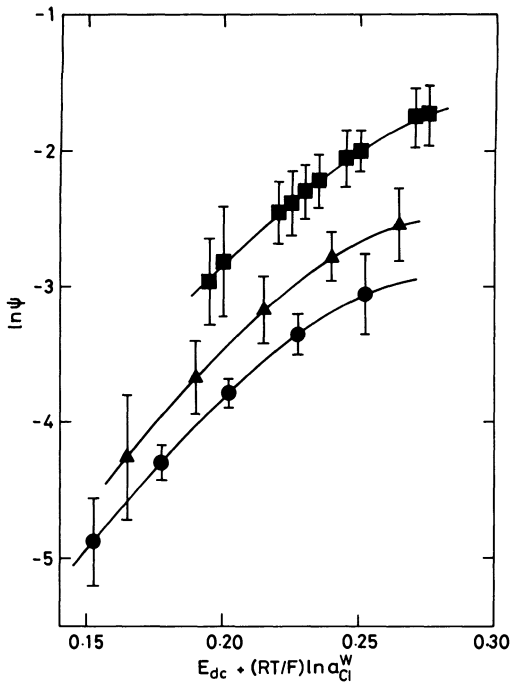

Fig. 10. Plot of $\ln\psi$ against $E_{d.c.}+(RT/F)\ln a^{W}_{Cl}$. $*C^{W}_{M}$: (■) 0.05; (▲) 0.1; (●) 0.2 mol dm^{-3}. The vertical bars indicate the standard deviations.

$$(r_s - 1/\omega c_s) > \frac{RT}{z^2F^2A}\cdot\frac{(1+\rho_c)d_L}{K^{W}*C^{W}_{M}*C^{\circ}_{L}}\left[\frac{K^{W}(K^{W}*C^{W}+1)}{k^{f}_{2}D^{W}}\right]^{1/2}. \quad (25)$$

Application of this inequality to the results shown in Fig. 5 with K^{w}=14.6 mol^{-1} dm^3,[19] d_L=2.3×10^4,[18] and D^{w}=10^{-5} cm^2 s^{-1} leads to the lowest limit of k^{f}_{2} to satisfy Eq. 18 as k^{f}_{2}>2.7×10^{12} mol^{-1} dm^3 s^{-1}. When another value of d_L=2×10^3, which is calculated from the solubility data of DB18C6 in water[22] and nitrobenzene,[23] is used, we obtain k^{f}_{2}>2×10^{10} mol^{-1} dm^3 s^{-1}. Either value suggests a very low probability of the CE mechanism, which leads us to the conclusion that the E mechanism is the most probable mechanism for the present system.

In Fig. 10 the logarithm of ψ defined by

$$\psi = \frac{RT}{z^2F^2A}\cdot\frac{(1+\rho_c)}{*C^{W}_{M}*C^{\circ}_{L}}\cdot\frac{1}{(r_s - 1/\omega C_s)} \quad (26)$$

is plotted against the corrected d.c. potential, $(E_{d.c.})_{corr}=E_{d.c.}+(RT/F)\ln a^{W}_{Cl}$ (see Results). In the E mechanism, ψ can be given from Eq. 21 by

$$\psi = \vec{k}_{M/ML}(E_{d.c.}). \quad (27)$$

Figure 10 shows that the rate constant of the interface reaction of the E mechanism (Eq. 3) $\vec{k}_{M/ML}(E_{d.c.})$ depends on the potential difference across the nitrobenzene/water interface, $\Delta\phi$, and that $\vec{k}_{M/ML}(E_{d.c.})$ increases with increasing positive $\Delta\phi$. This seems quite reasonable. Figure 10 also shows that the rate constant at a given potential difference increases with decreasing NaCl concentration in the aqueous phase. This result indicates that the rate constant of the interface reaction is highly dependent on the structure of the electric double layer at the interface.[13,14]

Equation 18 implies that, if the CE mechanism would be applicable to the present system, the dependence of the ψ values on the NaCl concentration ($*C^{W}_{M}$) could in part be explained by the second term in the square brackets on the right-hand side of Eq. 18. On the other hand, the dependence of ψ on $\Delta\phi$ in Fig. 10 implies that the first term in the square brackets is not negligible, which in turn implies that the value of the bimolecular-reaction rate constant k^{f}_{2} should be larger than a theoretically possible value of a bimolecular reaction in solution, as discussed above.

In conclusion, it can be stated that the a.c. polarographic behavior of the transfer of Na^+ ion facilitated by DB18C6 at the nitrobenzene/water interface is explained most reasonably by the interface reaction mechanism (E mechanism) of the three mechanisms that have been proposed.

Solvent Effects on Extraction of Aluminum(III), Gallium(III), and Indium(III) with Decanoic Acid

Hiromichi YAMADA,* Hisao HAYASHI, Yukio FUJII, and Masateru MIZUTA
Faculty of Engineering, Gifu University, 1-1 Yanagido, Gifu 501-11
(Received September 11, 1985)

Extraction of aluminum(III) and indium(III) with decanoic acid in 1-octanol was carried out at 25 °C and at an aqueous ionic strength of 0.1 mol dm^{-3} ($NaClO_4$). Monomeric and tetrameric aluminum(III) decanoates and monomeric indium(III) decanoate are responsible for the extraction. From a comparison of the present results with those obtained from the previous works,[1-4] the polymerization of the extracted species was found to be more extensive in benzene than in 1-octanol, and the metal decanoates were highly polymerized in the following order in both solvents: Al>Ga>In.

In the extraction of metal ions with carboxylic acids, polymerized metal carboxylates are sometimes found as an extracted species. In particular, trivalent aluminum, gallium, and indium are characterized to form up to hexameric decanoate in non-coordinating solvents such as benzene.[1-3] In the previous work which has described the results on the extraction of gallium(III) with decanoic acid in some inert solvents, it was noted that the more polar the solvent, the less polymerized were the extracted decanoates.[4] Subsequently, also in the extraction of copper(II) decanoate, the extracted species has been established to be only the dimeric copper(II) decanoate for the various inert solvents[5] but to be the monomeric and dimeric copper(II) decanoates for some alcohols[6,7] and ketones.[8]

The present paper deals with the extraction of aluminum(III) and indium(III) with decanoic acid in 1-octanol, and by comparison of the present results with those obtained from the previous papers,[1-4] it was found that the degree of polymerization of the metal decanoates decreased in the following order in both benzene and 1-octanol: Al>Ga>In, and the metal decanoates were more extensively polymerized in benzene than in 1-octanol.

Experimental

Reagents. Aluminum(III) perchlorate: Commercial aluminum(III) perchlorate nine hydrates (99.9%) was recrystallized from distilled water.

Indium(III) perchlorate was prepared in the same manner as presented previously.[3]

Sodium perchlorate, decanoic acid, and 1-octanol were purified by the method described previously.[6]

Reagent grade Xylenol Orange was used for the complexiметric titration of aluminum and indium as an indicator and for the spectrophotometric determination of lower concentration of aluminum.

All other reagents were of reagent grade and used without further purification.

Procedure. Partition was carried out in the same manner as was stated in the previous report.[4] Shaking for 17 h was found to be sufficient for complete equilibration in each extraction system. Total concentrations of metals and decanoic acid were 5×10^{-3} and 0.5—2.0 mol dm^{-3}, respectively. Ionic strength in the aqueous phase was adjusted to 0.1 mol dm^{-3} with sodium perchlorate. Hydrogen ion concentration in the aqueous phase was determined by the same method as presented previously.[4]

Apparatus. The apparatus were similar to those previously used.[4]

Results and Discussion

Extraction Equilibrium. When a j-merized metal decanoate of the composition $M_jA_aH_h(3j=a-h)$ is responsible for the extraction of a trivalent metal ion with decanoic acid, the extraction equilibrium is written as:

$$jM^{3+} + a(HA)_o \overset{K_{ex(jah)}}{\rightleftharpoons} (M_jA_aH_h)_o + 3jH^+$$

with $(HA)_o$ denoting the monomeric decanoic acid in the organic phase, and the extraction constant defined as

$$K_{ex(jah)} = \frac{[M_jA_aH_h]_o[H^+]^{3j}}{[M^{3+}]^j[HA]_o^a}, \quad (1)$$

where the subscript o refers to the organic phase and as described previously, the dimerization of decanoic acid does not occur to any appreciable extent in 1-octanol.[6] The total concentration of a metal in the organic phase, $C_{M,o}$ is represented by the following expression:

$$C_{M,o} = \sum_j\sum_a j[M_jA_aH_h]_o = \sum_j\sum_a jK_{ex(jah)}([M^{3+}][H^+]^{-3})^j[HA]_o^a. \quad (2)$$

When only $M_jA_aH_h$ is responsible for the extraction, the following equation is obtained under the conditions where any side reaction of a metal ion is not appreciable in the aqueous phase:

$$\log C_{M,o} = j(\log C_{M,w} - 3\log[H^+]) + a\log[HA]_o + \log j + \log K_{ex(jah)}. \quad (3)$$

According to Eq. 3, the degree of polymerization of the extracted species can be determined from the slope of the plot of log $C_{M,o}$ against (log $C_{M,w}$−3 log[H$^+$]) at constant [HA]$_o$. The results for aluminum(III) and indium(III) are shown in Figs. 1 and 2, respectively. From Fig. 1, it is expected that the monomeric and tetrameric aluminum(III) decanoates are preferentially extracted in 1-octanol. Then the following expression can be derived from Eq. 2:

$$\log C_{Al,o} - (\log C_{Al,w} - 3\log[H^+]) - a\log[HA]_o - \log K_{ex(1a,h)} = \log\left\{1 + \frac{4K_{ex(4a',h')}}{K_{ex(1a,h)}}[HA]_o^{(a'-a)}(C_{Al,w}[H^+]^{-3})^3\right\}, \quad (4)$$

where $K_{ex(1a,h)}$ and $K_{ex(4a',h')}$ denote the extraction constants of the monomeric and tetrameric aluminum(III) decanoates, respectively. It is expected that the plot of {log $C_{Al,o}$−(log $C_{Al,w}$−3 log[H$^+$])} against (log$C_{Al,w}$−3 log[H$^+$]) at constant [HA]$_o$ fits with the normalized curve, log(1+X^3) vs. log X. The results are depicted in Fig. 3. As shown in Fig. 3, it is confirmed that the monomeric and tetrameric species are responsible for the extraction. The plots deviate upward from the normalized curve at the middle region. This suggests that a small amount of the dimeric and/or trimeric species exists together with the main monomeric and tetrameric species.

As evident from Fig. 2, on the other hand, the monomeric indium(III) species is predominantly extracted. With decreasing concentration of decanoic acid in the organic phase and with increasing indium concentration in the organic phase, that is, with decreasing hydrogen ion concentration in the aqueous phase, the plots get to deviate from the straight line with a slope of 1.0. It seems most likely that these "deviations" are resulted from the hydrolysis of

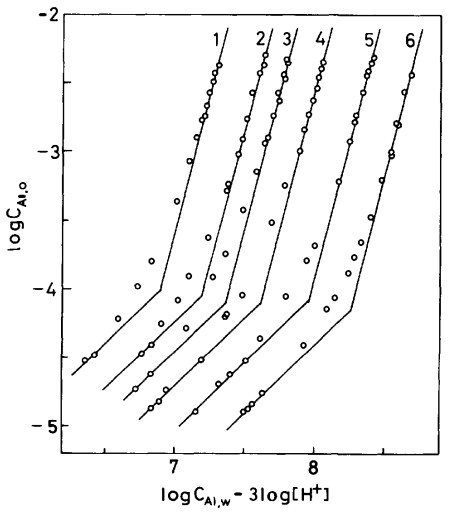

Fig. 1. Determination of the degree of polymerization of aluminum(III) decanoates.
C_{HA}; No. 1: 2.0, No. 2: 1.5, No. 3: 1.25, No. 4: 1.0, No. 5: 0.7, No. 6: 0.5 mol dm^{-3}. Solid lines are the straight lines with slopes of 1.0 and 4.0, respectively.

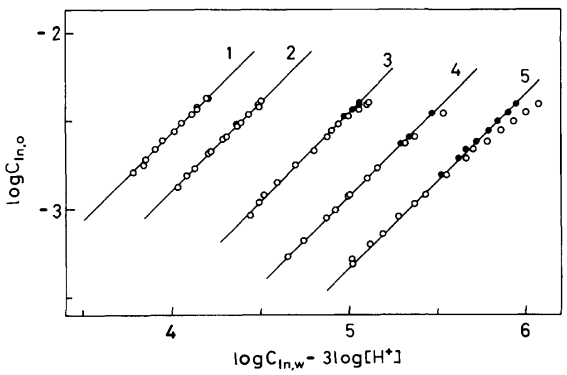

Fig. 2. Determination of the degree of polymerization of indium(III) decanoate.
C_{HA}; No. 1: 2.0, No. 2: 1.5, No. 3: 1.0, No. 4: 0.7, No. 5: 0.5 mol dm^{-3}. Solid lines are the straight lines with a slope of 1.0. Solid points are the corrected ones by considering the hydrolysis of indium(III) ion in the aqueous phase: log $C_{In,o}$, vs. log $C_{In,w}$ − 3 log [H$^+$] − log $\alpha_{In(OH)}$.

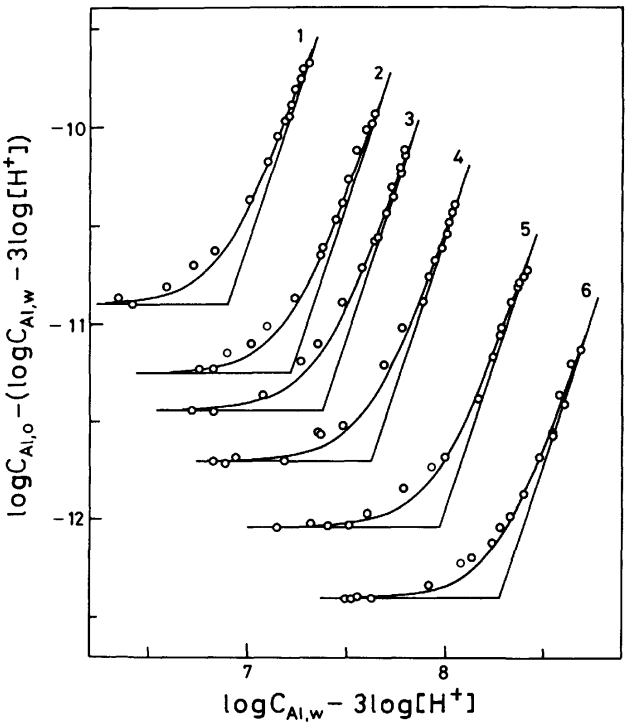

Fig. 3. The identification of the degree of polymerization of aluminum(III) decanoates.
Solid curves are the normalized curves, log(1+X^3) vs. log X. Solid lines are the asymptotes of the normalized curves. Numbers are the same as in Fig. 1.

indium(III) ion in the aqueous phase. Under the present experimental conditions, we can expect the following hydrolysis reactions of indium(III) ion in the aqueous phase:

$$In^{3+} + H_2O \rightleftharpoons In(OH)^{2+} + H_3O^+$$
$$In(OH)^{2+} + H_2O \rightleftharpoons In(OH)_2^+ + H_3O^+$$

with the hydrolysis constants,

$$K_1 = \frac{[In(OH)^{2+}][H_3O^+]}{[In^{3+}]}$$

and

$$K_2 = \frac{[In(OH)_2^+][H_3O^+]}{[In(OH)^{2+}]},$$

respectively. Taking into account these reactions, the following expression instead of Eq. 3 can be derived from Eq. 2:

$$\log C_{In,o} = \log C_{In,w} - 3\log[H^+] - \log \alpha_{In(OH^-)} + a\log[HA]_o + \log K_{ex(1ah)}, \quad (5)$$

where $\alpha_{In(OH^-)}$ denotes the side reaction coefficient of indium(III) ion in the aqueous phase:

$$\alpha_{In(OH^-)} = 1 + \frac{K_1}{[H_3O^+]} + \frac{K_1 \cdot K_2}{[H_3O^+]^2}. \quad (6)$$

Then in Fig. 2, the deviations of the observed points from the straight line with a slope of 1.0 refer to $\log \alpha_{In(OH^-)}$. According to Eq. 6, a plot of $(\alpha_{In(OH^-)}-1)[H^+]$ against $1/[H^+]$ for the markedly deviated points at C_{HA}=0.5 mol dm^{-3} (No. 5) in Fig. 2 is shown in Fig. 4. The plot is found to be linear and the following hydrolysis constants were calculated from the intercept and slope of the straight line by the least-squares method: $\log K_1$=−4.1 and $\log K_2$=−2.7. Various hydrolysis constants for indium(III) ion have been presented: $\log K_1$=−4.41 and $\log K_2$=−4.16 at 25 °C and at ionic strength of 3 mol dm^{-3} ($NaClO_4$),[9] $\log K_1$=−3.48, $\log K_2$=−4.19, and $\log K_3$=−5.08 at 25 °C and at ionic strength of 0.1 mol dm^{-3} ($NaClO_4$),[10] and $\log K_1$=−4.22 and $\log K_2$=−2.92 at 25 °C and at ionic strength of 3 mol dm^{-3} ($LiClO_4$).[11] As shown in Fig. 2, the solid points, which are corrected by considering the hydrolysis of indium(III) ion in the aqueous phase, fit well the straight line with a slope of 1.0 also at C_{HA}=1.0 and 0.7 mol dm^{-3}.

Subsequently, the number of decanoic acid molecules involved in the extracted species was determined in the following manner. In the region where the j-meric species prevails, the following expression is derived from Eq. 2:

$$\frac{1}{j}\log C_{M,o} - (\log C_{M,w} - 3\log[H^+]) = \frac{1}{j}\log \sum_a (K_{ex(jah)}[HA]_o^a) + \frac{1}{j}\log j. \quad (7)$$

According to Eq. 7, the total number of decanoic acid molecules involved in the j-mer can be determined from the slope of the plot of $\{\frac{1}{j}\log C_{M,o} - (\log C_{M,w} - 3\log[H^+])\}$ against $\log[HA]_o$. The results for both aluminum and indium are shown in Figs. 5 and 6, respectively. In the region where the monomeric aluminum decanoate prevails, the plot falls on the straight line with a slope of 3.0 at higher concentration of decanoic acid in the organic phase but deviates upward from the straight line at lower concentration of decanoic acid in the organic phase.

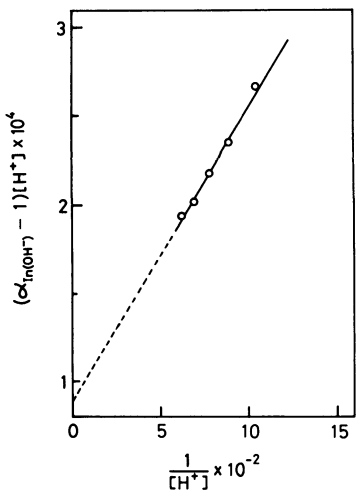

Fig. 4. Determination of the hydrolysis constants of indium(III) ion in the aqueous phase.
The intercept and slope of the straight line were calculated by the least-squares method.

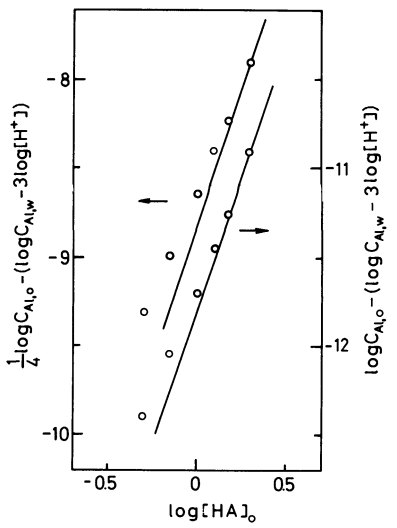

Fig. 5. Determination of the number of decanoic acid molecules involved in the monomeric and tetrameric aluminum(III) decanoates.
Solid lines are the straight lines with a slope of 3.0.

This result suggests that the two monomeric aluminum(III) decanoates are responsible for the extraction in the lower concentration of aluminum in 1-octanol: one of them is AlA_3 and the other $AlA_aH_h(a<3)$. Under these conditions the total concentration of aluminum in the organic phase can be written as:

$$\log C_{Al,o} - (\log C_{Al,w} - 3\log[H^+]) = 3\log[HA]_o + \log K_{ex(130)} + \log\left(1+\frac{K_{ex(1ah)}}{K_{ex(130)}}[HA]_o^{(a-3)}\right). \quad (8)$$

Comparing the plot of the left-hand side of Eq. 8 against $-\log[HA]_o$ with the normalized curves,

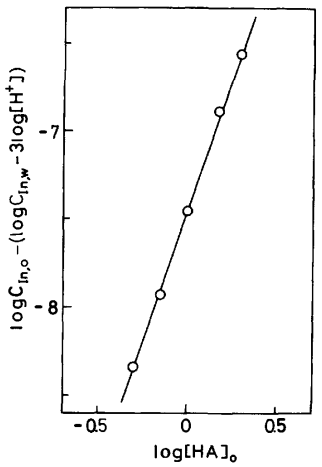

Fig. 6. Determination of the number of decanoic acid molecules involved in the monomeric indium(III) decanoate.
Solid line is the straight line with a slope of 3.0.

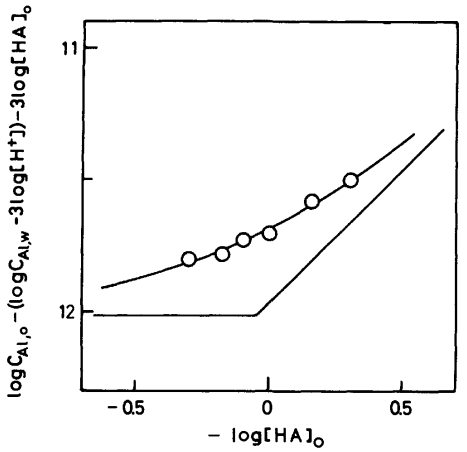

Fig. 7. Determination of the number of decanoic acid molecules involved in the monomeric aluminum(III) decanoates by the curve-fitting method.
Solid curve is the normalized curve, $\log(1+X)$ vs. $\log X$. Solid lines are the asymptotes of the normalized curve.

$\log(1+X^n)$ vs. $\log X$, we can determine another monomeric species. The result is shown in Fig. 7. The plot fits well the normalized curve: $\log(1+X)$ vs. $\log X$, that is, $n=3-a=1$ or $a=2$. From the electroneutrality of the extracted species, it can be noted that another monomeric species involves one hydroxyl group. From Fig. 7, we can also obtain the respective extraction constants, $K_{ex(130)}$ and $K_{ex(12-1)}$ by the curve-fitting method. The results obtained are summarized in Table 1 together with the other constants.

In the region where the tetrameric aluminum decanoate prevails, the slope of the plot of $\{\frac{1}{4}\log C_{Al,o} - (\log C_{Al,w} - 3\log[H^+])\}$ against $\log[HA]_o$ on the basis of Eq. 7 ($j=4$) gets steeper with the concentration of decanoic acid in the organic phase, and approaches 3.0. This result indicates the following species: Al_4A_{12} and $Al_4A_aH_h(a<12)$ as the tetrameric extracted species. Then the following relation can be derived:

$$\log C_{Al,o} - 4(\log C_{Al,w} - 3\log[H^+]) - 12\log[HA]_o = \log\left(1+\frac{K_{ex(4ah)}}{K_{ex(4120)}}[HA]_o^{(a-12)}\right) + \log 4 + \log K_{ex(4120)}. \quad (9)$$

The values of $\{\log C_{Al,o} - 4(\log C_{Al,w} - 3\log[H^+]) - 12\log[HA]_o\}$ are plotted against $-\log[HA]_o$ as depicted in Fig. 8. According to the curve-fitting method, in which the plot is compared with the normalized curves, $\log(1+X^n)$ vs. $\log X$, the number of decanoic acid molecules involved in another tetrameric species can be determined together with the extraction constants of the two tetrameric Al(III) decanoates. In Fig. 8, the plot fits the normalized curve, $\log(1+X^4)$ vs. $\log X$, that is, $n=12-a=4$, or $a=8$ and then h is equal to -4. In analogy with the monomer stated above, four hydroxide ions should

Solid and dotted curves correspond to benzene and 1-octanol, respectively.

be involved in another tetrameric aluminum(III) decanoate. The extraction constants $K_{ex(4120)}$ and $K_{ex(48-4)}$ determined by the curve-fitting method are given in Table 1. Consequently, AlA_3, $AlA_2(OH)$, Al_4A_{12}, and $Al_4A_8(OH)_4$ are responsible for the extraction with decanoic acid in 1-octanol.

In the case of indium(III), on the other hand, the plot of $\{\log C_{In,o}-(\log C_{In,w}-3\log[H^+])\}$ against $\log[HA]_o$ falls on the straight line with a slope of 3.0. Then only InA_3 is extracted with decanoic acid in 1-octanol. The extraction constant $K_{ex(130)}$ can be obtained from the intercept of the straight line in Fig. 6. The result is given in Table 1.

Consequently, the extraction equilibria for aluminum(III) and indium(III) are represented as follows:

Aluminum(III):

$$Al^{3+} + 3(HA)_o \overset{K_{ex(130)}}{\rightleftharpoons} (AlA_3)_o + 3H^+$$

$$Al^{3+} + 2(HA)_o + H_2O \overset{K_{ex(12-1)}}{\rightleftharpoons} (AlA_2(OH))_o + 3H^+$$

$$4Al^{3+} + 12(HA)_o \overset{K_{ex(4120)}}{\rightleftharpoons} (Al_4A_{12})_o + 12H^+$$

$$4Al^{3+} + 8(HA)_o + 4H_2O \overset{K_{ex(48-4)}}{\rightleftharpoons} (Al_4A_8(OH)_4)_o + 12H^+$$

Indium(III):

$$In^{3+} + 3(HA)_o \overset{K_{ex(130)}}{\rightleftharpoons} (InA_3)_o + 3H^+.$$

Solvent Effects. The previous results[1-4] are also listed in Table 1 for comparison. Table 1 suggests that the degree of polymerization of the extracted species for aluminum(III), gallium(III), and indium(III) is more extensive in benzene than in 1-octanol and increases in the following order in both solvents: Al>Ga>In. In 1-octanol the addition of a decanoic acid molecule to each metal decanoate did not occur to any appreciable extent. It is convenient to imagine that some octanol molecules are solvated to the extracted species. As shown in Table 1, the dimeric and tetrameric extracted species in benzene were not observed, while in 1-octanol the trimeric and hexameric ones were not detected. Then it can be expected that the polymerization of metal decanoates in benzene and 1-octanol proceeds through the different mechanism. Further, the difference in the composition of the monomeric indium(III) decanoates in benzene($InA_3(HA)_3$) and 1-octanol(InA_3) can be explained by a notion that in benzene decanoic acid behaves primarily as a dimer and, then a dimeric decanoate(HA_2^-) coordinates to indium ion as a bidentate ligand, whereas in 1-octanol decanoic acid exists only in a monomer form and, then a monomeric decanoate solvated by some octanol molecules binds to indium ion. As we have already reported, also in the extraction of copper(II) there was a remarkable difference in the extracted species between solvating[7,8] and nonsolvating[5] solvents.

The extraction curves calculated from the results given in Table 1 are illustrated in Fig. 9. As shown in Fig. 9, aluminum(III) and gallium(III) ions are extracted with decanoic acid in 1-octanol at the higher pH region than in benzene, while indium(III) decanoate is extracted in 1-octanol at the lower pH region than in benzene. Then it is expected that indium(III) is selectively extracted from a mixture of these three metal ions with decanoic acid by using 1-octanol as a diluent. Usually but not always, much

attention must be paid to the coextraction caused by the formation of mixed metal carboxylates in the extraction of polymerized metal carboxylates. Fortunately under the present experimental conditions, only the monomeric indium(III) decanoate is extracted with decanoic acid in 1-octanol. Therefore, there is scarcely a fear that aluminum(III) and gallium(III) are coextracted with indium(III) as a mixed metal decanoate.

Consequently, the selection of a solvent used in the extraction of metal carboxylates is one of the important considerations, and may occasionally results in the improvement of the selectivity.

Formation of the *N,N*-Bidentate Chelates of 2-(2-Pyridylazo)-phenolic Ligands with Nickel(II) in Nonaqueous Solvents

Yoshihiro KUDO, Noboru YOSHIDA, and Masatoshi FUJIMOTO*
Department of Chemistry II, Faculty of Science, Hokkaido University, Sapporo 060
(Received September 17, 1985)

The formation of *N,N*-bidentate 1:2 complexes of nickel(II) with various *N,N,O*-terdentate 2-(2-pyridylazo)-phenolic ligands was detected spectrophotometrically in ethyl acetate and was examined with respect to the influences of Brønsted bases, the counter anions in the nickel(II) salts employed, solvent basicity, and the steric requirements around the donor nitrogen atoms in the ligand in the 1:2 complex. It is concluded that the stability of the *N,N*-bidentate complex species in solutions predominantly depends on the basicity of the counter anions X in NiX_2 and of the solvent. In the case of 1-(2-pyridylazo)-2-naphthol, owing to a high steric hindrance of the naphthalene ring, the formation of the *N,N*-bidentate complex was not observed even in the solvent of low basicity such as dioxane.

It is well known that in aqueous solutions nickel(II) ions react with *N,N,O*-terdentate 2-(2-pyridylazo)phenolic ligands such as 4-(2-pyridylazo)-resorcinol (PAR) to form *N,N,O*-terdentate complexes.[1] Recently, we first reported the formation of an *N,N*-bidentate complex of an *N,N,O*-terdentate ligand, 4-(4-methyl-2-pyridylazo)resorcinol (4-MePAR), with nickel(II) perchlorate in an aprotic solvent, 1,4-dioxane.[2] The *N,N*-bidentate complex was isolated from neat dioxane solution and identified to be in a distorted planar configuration in which four nitrogen atoms of the two ligand molecules are coordinated to the nickel(II) atom (Fig. 1). Upon addition of a Brønsted base such as imidazole to the dioxane solution of the *N,N*-bidentate species, an *N,N,O*-terdentate complex was formed.[2] This fact indicates that weak Brønsted bases can promote the release of the intramolecularly hydrogen-bonded proton, N···H–O, in the *N,N*-bidentate complex.

In the present paper, we discuss the conditions required for the formation of the *N,N*-bidentate complexes of *N,N,O*-terdentate 2-(2-pyridylazo)phenolic ligands with a number of nickel(II) salts in various nonaqueous solvents.

Experimental

Materials. Ethyl acetate (Wako) was dried with anhydrous magnesium sulfate (Nakarai) or Molecular Sieves 4A (Wako) and distilled under argon atmosphere immediately before use. Ethanol and pyridine were dried with Molecular Sieves 3A or 4A and distilled under argon atmosphere. 1,4-Dioxane was purified as reported in the previous paper.[2] The purified solvents were stored under argon atmosphere. Other solvents used here were of specially-prepared reagent grade (Nakarai) or of guaranteed reagent grade (Wako).

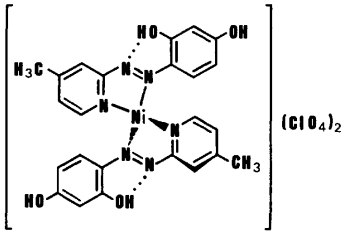

Fig. 1. Proposed configuration of the isolated *N,N*-bidentate chelate of nickel(II) perchlorate with 4-MePAR.[2]

Nickel(II) perchlorate dihydrate was prepared as described in the previous work.[2] Other nickel(II) salts were of reagent grade unless otherwise specified. The perchlorates of zinc(II), manganese(II), and lanthanum(III) were prepared by the same method as in the synthesis of nickel(II) perchlorate. The contents of water in the metal salts were determined by Karl-Fischer titration. Found: $Ni(ClO_4)_2 \cdot 2.4H_2O$ (dried by heating the hexahydrate in vacuo), $Ni(ClO_4)_2 \cdot 6.1H_2O$, $NiCl_2 \cdot 1.0H_2O$ (dried by heating the hexahydrate in vacuo), $NiCl_2 \cdot 5.7H_2O$ (Wako, $NiCl_2 \cdot 6H_2O$), $Zn(ClO_4)_2 \cdot 6.1H_2O$, $Mn(ClO_4)_2 \cdot 4.0H_2O$ (dried the hexahydrate in vacuo over P_2O_5 at room temperature).

The free ligands, 4-MePAR, 5-dimethylamino-2-(2-pyridylazo)phenol (DAPAP), and 4-(2-pyridylazo)phenol (*p*-PAP), were prepared as described in the previous paper.[2] Other ligands, PAR,[3] 4-(*x*-methyl-2-pyridylazo)-resorcinol (*x*-MePAR, *x*=3, 5, and 6),[4] 4-(2-pyridylazo)-orcinol (PAO),[5] and 2-(2-pyridylazo)-1-naphthol (α-PAN),[6] were prepared and purified according to the literature. 1-(2-Pyridylazo)-2-naphthol (β-PAN) was obtained from Dojindo Laboratories and used without further purification.

The *N,N,O*-terdentate complex of DAPAP employed here was synthesized as follows. The free ligand, DAPAP (172 mg, 0.71 mmol), was dissolved in 100 cm^3 of warm ethanol. Nickel(II) chloride (95 mg, 0.40 mmol) dissolved in 10 cm^3 of water was added to the deep red solution of DAPAP. A dark pink solution obtained was evaporated to ca. 2/3 volumes and allowed to stand for several days in the dark. The dark wine red crystals were filtered, washed with water, and dried overnight in vacuo over P_2O_5. Found: C, 57.64; H, 4.84; N, 20.74%. Calcd for $Ni(C_{13}H_{13}N_4O)_2$: C, 57.70; H, 4.84; N, 20.70%. The *N,N,O*-terdentate complexes of α- and β-PAN were obtained by the analogous method. Found: $[Ni(\alpha\text{-panH}_{-1})_2]^{0,\dagger}$: C, 64.67; H, 3.47; N, 13.47%.

† α-panH$_{-1}$ denotes the mono-deprotonated anionic form resulting from the dissociation of the *o*-hydroxyl proton of α-PAN.

$[Ni(\beta\text{-panH}_{-1})_2]^0$: C, 64.80; H, 3.73; N, 15.14%. Calcd for $Ni(C_{15}H_{10}N_3O)_2$: C, 64.90; H, 3.63; N, 15.14%.

Measurements. Electronic spectra and pH* (pH-meter readings) of the sample solutions at 25 °C were measured using the procedure reported previously.[2] Karl-Fischer titrations were performed with the 10—40 mg sample dissolved in 25 cm^3 of dried methanol (Dassui-Yozai ML, Mitsubishi) using a Mitsubishi Kasei Karl-Fischer titrator Model MS-2.

Results and Discussion

Formation of an *N,N*-Bidentate Complex of Nickel(II) Perchlorate with 4-MePAR in Ethyl Acetate. Figure 2 shows a spectral change for the complex formation of nickel(II) perchlorate dihydrate with 4-MePAR in ethyl acetate. The spectrum of the free ligand, 4-MePAR, possesses an absorption maximum at 381 nm ($\varepsilon_{max}=2.07\times10^4$ mol^{-1} dm^3 cm^{-1}) (Curve 1). In the low concentrations of nickel(II) perchlorate, an orange solution was formed (Curve 3). On further addition of nickel(II) perchlorate ($[Ni(II)]_t/[4\text{-MePAR}]_t>0.4$) to the orange solution, the absorbance around 450 nm decreased with the increase of that around 430 nm; the color of the solution was yellow. The spectrum of the yellow solution has a single absorption maximum at 428 nm ($\varepsilon_{max}=4.62\times10^4$ mol^{-1} dm^3 cm^{-1} at $[Ni(II)]_t/[4\text{-MePAR}]_t\simeq2$) (Curve 5). Two sets of isosbestic points were observed in the overall spectral change. Molar ratio method indicates that the metal to ligand ratio of the complex in the orange solution is 1:3. The metal to ligand ratio of the final complex in the yellow solution was found to be 1:2. The above reaction behavior in ethyl acetate was also reproduced by using a hexahydrate of nickel(II) perchlorate. This fact shows that the coordinated water in nickel(II) perchlorate specimen does not significantly affect the formation of the 1:2 complex of nickel(II) with 4-MePAR.[7]

Curve 1 in Fig. 3 shows a spectrum in ethyl acetate of an *N,N*-bidentate complex, $[Ni(4\text{-mepar})_2](ClO_4)_2$, which was isolated from dioxane solution.[2] The spectrum has a single absorption band at 431 nm ($\varepsilon_{max}=3.49\times10^4$ mol^{-1} dm^3 cm^{-1}).[8] The spectrum of the yellow ethyl acetate solution essentially coincides with that of the isolated bidentate complex. This fact indicates that the *N,N*-bidentate complex is also formed in ethyl acetate as in neat dioxane.

Reactions of the *N,N*-Bidentate Complex with Brønsted Bases in Ethyl Acetate. The color change from yellow to pink was observed upon addition of a Brønsted base such as *o*-chloroaniline, *m*-chloroaniline, 2,6-lutidine, and imidazole to the ethyl acetate solution of the isolated *N,N*-bidentate complex, $[Ni(4\text{-mepar})_2](ClO_4)_2$. The spectral change of the bidentate complex on addition of 2,6-lutidine is shown in Fig. 3. The spectral change shows two distinct isosbestic points at 481 nm for the first step and at 503 nm for the second step. This fact implies that the reaction proceeds in two steps. Molar ratio method indicates that the ratio of the bidentate complex to the base in the overall reaction is 1:2. The spectrum in ethyl acetate of the final complex with λ_{max}'s at 400 ($\varepsilon_{max}=3.5\times10^4$) and 546 nm ($\varepsilon_{max}=3.2\times10^4$ mol^{-1} dm^3 cm^{-1}) essentially coincides with that of an *N,N,O*-terdentate complex, $[Ni(4\text{-meparH}_{-1})_2]^0$, isolated from aqueous solution.[2] From these results, the spectral change of the reaction between the bidentate complex, $[Ni(4\text{-mepar})_2](ClO_4)_2$, and 2,6-lutidine is attributed to the formation of the *N,N,O*-terdentate complex, $[Ni(4\text{-meparH}_{-1})_2]^0$, indicating the deprotonation of the two *ortho*-hydroxyl groups of the ligands in the bidentate complex.

The behavior of the reactions in ethyl acetate of

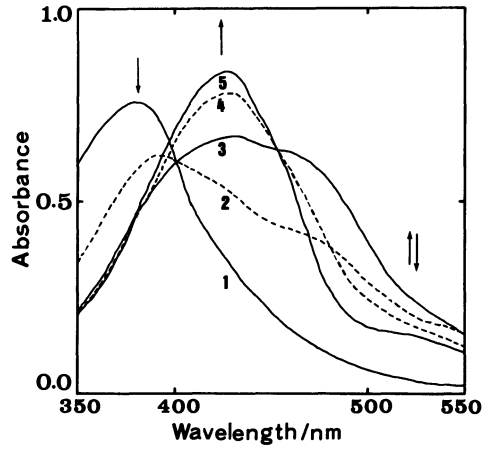

Fig. 2. Spectral change in the complex formation between nickel(II) perchlorate and 4-MePAR at 25 °C in ethyl acetate. $[4\text{-MePAR}]_t=3.57\times10^{-5}$ mol dm^{-3}. $[Ni(II)]_t=0.00$ (1), 0.75 (2), 1.31 (3), 3.00 (4), and 7.49×10^{-5} mol dm^{-3} (5).

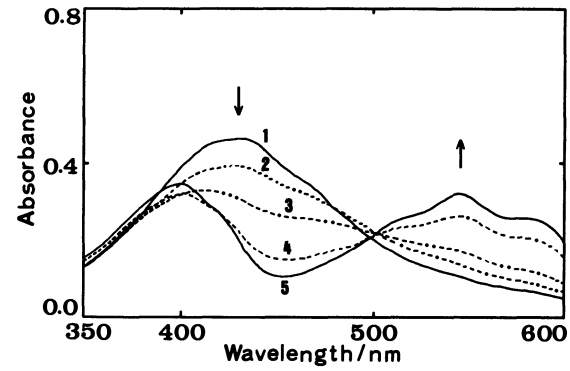

Fig. 3. Spectral change upon addition of 2,6-lutidine to the ethyl acetate solution of the isolated bidentate complex, $[Ni(4\text{-mepar})_2](ClO_4)_2$, at 25 °C. $[Ni\text{-}(4\text{-mepar})_2(ClO_4)_2]_t=9.89\times10^{-6}$ mol dm^{-3}. $[2,6\text{-Lutidine}]_t=0.00$ (1), 0.70 (2), 1.41 (3), 2.10 (4), and 4.66×10^{-5} mol dm^{-3} (5).

nickel(II) perchlorate with 4-MePAR and that of the bidentate complex with the base was identical with the behavior in neat dioxane.[2] This fact suggests that the effects of the solvation by ethyl acetate molecule on the reactions of $Ni(ClO_4)_2$ with 4-MePAR and of the Brønsted base with the bidentate complex are similar to the effects of the solvation by dioxane molecule.

Spectral Assignments of the Free Ligand 4-MePAR and Its Nickel(II) Complexes. In general, the bathochromic shift (red shift) of the absorption band in solution of azobenzene derivatives is caused by the following factors: Introduction of the auxochromic functional group such as OH and $N(CH_3)_2$ into the *para*-position of azo group, presence of the intramolecular hydrogen bond, N···H-O, bonding of cation such as proton to the azo nitrogens, and deprotonation of hydroxyl group.[9-13a,b] The absorption spectra of azobenzene derivatives with an auxochromic group have an absorption band in the range of 310—450 nm with relatively larger extinction coefficient ($\simeq 10^4$ mol^{-1} dm^3 cm^{-1}) in aqueous solutions and in organic solvents.[9-14] These bands are ascribed to the π-π^* (conjugation) transition of the azo chromophore.[9-12,15]

The absorption spectrum of 4-MePAR (Curve 1 in Fig. 2) is expected to show a large bathochromic shift compared with that of azobenzene, since 4-MePAR involves three functional groups, *p*-OH, *o*-OH, and CH_3, and the strong intramolecular hydrogen bonding. The main band of 4-MePAR shifted to longer wavelength (see below), owing to the interaction of transition dipole with highly polarizable solvents.[14] From the above results, the main band of the free ligand, 4-MePAR, could be assigned to that of π-π^* transition of the azo chromophore.

The *N,N*-bidentate chelate of nickel(II) with 4-MePAR has two five-membered chelate rings between nickel(II) and the two coordinated nitrogens in the ligand, namely, pyridyl and azo nitrogens (see Fig. 1). If the nickel(II) ions electrostatically act to the azo nitrogen in the same manner as proton, then the band of π-π^* transition of the free ligand should show a shift to longer wavelength by the formation of the Ni(II)-N(azo) bonds.[9,11] This assumption is consistent with the observed bathochromic shift of the *N,N*-bidentate complex. Thus, the main band at 431 nm of the *N,N*-bidentate chelate of nickel(II) (Curve 1 in Fig. 3) could probably be ascribed to a band of π-π^* transition. The absorption spectrum of the *N,N,O*-terdentate chelate of 4-MePAR in ethyl acetate (Curve 5 in Fig. 3) shows two characteristic bands at 400 and 546 nm with large molar extinction coefficients ($\simeq 3\times10^4$ mol^{-1} dm^3 cm^{-1}). The bands may be ascribed to those of π-π^* transition due to the deprotonation and/or the coordination of *o*-hydroxyl groups.[9]

The main bands of PAR, its methyl derivatives, and their nickel(II) complexes would also be assigned in a similar manner.

Spectral Features for Nickel(II) Complexes of 2-(2-Pyridylazo)phenolic Ligands. The absorption spectra of the free ligands generally show large red shifts by complex formation with metal ions in various solvent systems.[1,16,17] For example, Florence et al. have reported that in aqueous solution the *N,N,O*-terdentate complexes of M(II) ions with DAPAP derivatives have two absorption maxima in the range of 500 to 560 nm.[17] The similar spectral feature was observed in the complexes of other 2-(2-pyridylazo)-phenolic ligands.[1,16] Table 1 summarizes the value of the red shift, $\Delta\lambda_{max}=\lambda_{max}(\text{complex})-\lambda_{max}(\text{free ligand})$,[18] for the complexes of nickel(II) with 2-(2-pyridylazo)phenolic ligands in some nonaqueous solvents together with the color of the solution of the complexes. The complexes, $[Ni(pap)_2]^{2+}$,[19] and $[Ni(4\text{-mepar})_2]^{2+}$, have the *N,N*-bidentate structure both in dioxane[2] and in ethyl acetate. Other nickel(II) complexes, $[Ni(4\text{-meparH}_{-1})_2]^0$, $[Ni(\alpha\text{-panH}_{-1})_2]^0$, $[Ni(\beta\text{-panH}_{-1})_2]^0$, and $[Ni(\text{dapapH}_{-1})_2]^0$, which were isolated from aqueous solution, are in the *N,N,O*-terdentate structure.[1,2,17] The values of $\Delta\lambda_{max}$ for the *N,N*-bidentate and those for the *N,N,O*-terdentate complexes are remarkably different. The values of $\Delta\lambda_{max}$ for the *N,N*-bidentate complexes were in the range of 45 to 77 nm, while those for the *N,N,O*-terdentate complexes in the range of 102 to 165 nm regardless of the kind of solvent used here;

Table 1. The Values of Red Shift ($\Delta\lambda_{max}$) and the Color of the Solution of the *N,N*-Bidentate and the *N,N,O*-Terdentate Complexes of Nickel(II)

Species	$\Delta\lambda_{max}$[a]/nm	Color	Solvent[b]

a) $\Delta\lambda_{max}=\lambda_{max}(\text{complex})-\lambda_{max}(\text{free ligand})$. b) AcOEt denotes ethyl acetate. c) *N,N*-Bidentate structure. d) *N,N,O*-Terdentate structure. e) Synthesized complex. f) Ref. 2.

the values of the red shifts for the formations of the *N,N,O*-terdentate complexes are much larger than those of the *N,N*-bidentate complexes.

These results suggest that the coordination mode of the ligand in nickel(II) complexes can be distinguished by the magnitude of the red shifts of the absorption bands in the complex formation. The colors of the complexes of nickel(II) with 2-(2-pyridylazo)phenolic ligands are also quite different depending on the coordination mode, namely, yellowish color of the solutions is ascribed to the *N,N*-bidentate species and reddish color to the *N,N,O*-terdentate species (Table 1).

Effects of the Counter Anions in Nickel(II) Salts on the Formation of the *N,N*-Bidentate Complex. The spectral data of the 4-MePAR complexes of various nickel(II) salts in dioxane and in ethyl acetate are listed in Table 2 together with the pK_a values of the corresponding conjugate acids of the counter anions in the nickel(II) salts, metal to ligand ratio in the complex, and the colors of the solutions of the complexes. From the values of $\Delta\lambda_{max}$ and the color of the solution, the formation of the *N,N*-bidentate complex is confirmed also in the reaction of nickel(II) bromide with 4-MePAR (Curve B in Fig. 4). The spectra for the complexes of 4-MePAR with other nickel(II) salts such as chloride, nitrate, and acetate do not show the single band characteristic of the *N,N*-bidentate complexes but show that of the *N,N,O*-terdentate complexes as depicted by the two characteristic bands in the visible region (Curve C in Fig. 4). The spectrum of the 4-MePAR complex of a nickel(II) salt with counter anions of higher pK_a value shows a larger red shift, indicating the formation of an *N,N,O*-terdentate complex. These results reveal that the counter anions, Cl^-, NO_3^-, and CH_3COO^-, act as an acceptor on the *o*-hydroxyl protons of the *N,N*-bidentate complex.[2]

Effects of Solvents on the Formation of the Bidentate Complex of Nickel(II) Perchlorate with 4-MePAR. Table 3 shows the absorption spectral data, metal to ligand ratios in the overall reaction, the color of the solution of the Ni(II)-4-MePAR complexes in thirteen solvents together with their properties, donor number (DN) and dielectric constants. The donor number is generally used as an empirical parameter of the solvent basicity; a high value of DN corresponds to the high basicity of solvent molecules.[20] The larger red shifts ($\Delta\lambda_{max}\simeq130$ nm) were observed for the reactions in the solvents of high DN, indicating only the formation of the *N,N,O*-terdentate complexes. In the solvents of lower DN such as nitromethane, the smaller red shifts, $\Delta\lambda_{max}$, were observed in the complex formation, showing the formation of the *N,N*-bidentate complexes. The addition of imidazole to the final

Ni(II)-4-MePAR complex in nitromethane caused a further red shift of about 60 nm in the visible region. The color of the nitromethane solution was changed from orange to pink. These facts strongly support the conversion of the *N,N*-bidentate complex to the *N,N,O*-terdentate complex in nitromethane. The contribution of the dielectric effect of the solvents to the formation of the *N,N*-bidentate complex was not obvious (Table 3).

The above results indicate that the stability in the solution of the *N,N*-bidentate species is strongly influenced by the basicities of the solvents, the counter anions, and the bases, B, added.

The reaction behavior of the Ni(II)-4-MePAR system is summarized in Scheme 1, where the ligand 4-MePAR is represented by LHH*; H and H* denote the *ortho*- and the *para*-hydroxyl protons, respectively.

Reactions between Nickel(II) Perchlorate and Various 2-(2-Pyridylazo)phenolic Ligands in Dioxane and Ethyl Acetate. Table 4 shows the spectral data of various 2-(2-pyridylazo)phenolic ligands and their metal complexes in dioxane and in ethyl acetate. All ligands except for β-PAN reacted with nickel(II) perchlorate to form the *N,N*-bidentate complexes as deduced from the smaller values of the red shift, $\Delta\lambda_{max}$, and the color of the solution. Upon addition of a Brønsted base, the formation of the *N,N,O*-terdentate complexes was observed for all ligands except for *p*-PAP having no coordinating *o*-hydroxyl group.

The spectra of the yellow solutions of the Ni(II)-DAPAP complexes in dioxane and ethyl acetate showed negative $\Delta\lambda_{max}$. Upon addition of a Brønsted base to the yellow solution of the

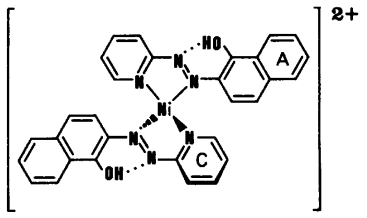
a) Color of the solution after the addition of a small excess of imidazole to the solution of the *N,N*-bidentate complex. b) In 1%(v/v) 2,6-lutidine-AcOEt. c) Ref. 2. d) In 30%(v/v) dioxane-water, pH*=4.59, and I=0.1 mol dm^{-3} ($NaClO_4$). e) Synthesized complex.

Ni(II)-DAPAP complexes, the color of the solution turned pink, showing the formation of the *N,N,O*-terdentate complex. The complex in the yellow solution has been isolated as $[Ni(dapap)_2](ClO_4)_2 \cdot H_2O$[21] from the dioxane solution.[2] The amount of proton liberated in the reaction, $[Ni(dapap)_2]^{2+} + 2H_2O \rightarrow [Ni(dapapH_{-1})_2]^0 + 2H_3O^+$, was found to be almost twice that of the complex dissolved in 30%(v/v) dioxane-water.[2] The spectral feature of the *N,N*-bidentate complex in ethyl acetate was similar to that in dioxane. From these results, the Ni(II)-DAPAP complex, yellow in ethyl acetate, was confirmed to be in the *N,N*-bidentate structure.

α-PAN, an isomer of β-PAN, reacted with nickel(II) perchlorate to form the *N,N*-bidentate complex (Curves 1 and 2 in Fig. 5). Upon addition of imidazole in neat dioxane the bidentate complex converted to the *N,N,O*-terdentate complex (Curve 3 in Fig. 5). β-PAN, however, did not form the *N,N*-bidentate complex. The difference in the reaction behavior between α-PAN and β-PAN with nickel(II) may be due to a steric hindrance of the bulky naphthalene ring in β-PAN. The configuration of the *N,N*-bidentate complex, $[Ni(4\text{-}mepar)_2](ClO_4)_2$, isolated from dioxane solution, has been reported to be a distorted planar around the nickel(II) atom (see Fig. 1).[2,22] If the *N,N*-bidentate 1:2 nickel(II) complex of α-PAN and β-PAN in dioxane solution



$[Ni(\alpha\text{-}pan)_2]^{2+}$

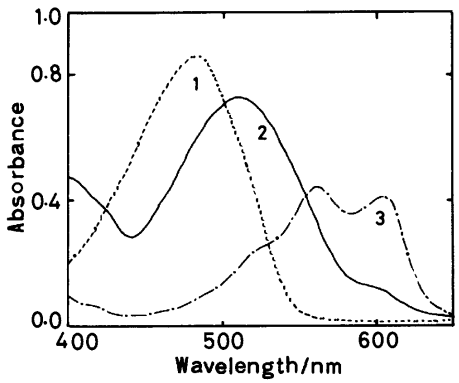


Fig. 5. Spectral features of the free ligand α-PAN and its nickel(II) complexes at 25 °C in neat dioxane. are in the same configuration as that of the isolated bidentate complex, $[Ni(4\text{-mepar})_2](ClO_4)_2$, then the *N,N*-bidentate 1:2 nickel(II) complex of *β*-PAN is

$[Ni(\beta\text{-pan})_2]^{2+}$

presumed to have a large steric hindrance caused by the pyridyl ring (Ring C) in one ligand molecule and the bulky naphthalene ring (Ring B) in another ligand molecule. The naphthalene ring in the isomer *α*-PAN is expected to show no steric hindrance on the coordination of the donor nitrogen atoms because the ring A in the bidentate complex of *α*-PAN should occupy an opposite position compared with the ring B in the possible *N,N*-bidentate complex of *β*-PAN. In the coordination of the donor nitrogens in the 1:2 complexes of nickel(II) with 6-MePAR or PAO, the steric hindrance of the *ortho*-methyl group in pyridine ring or benzene ring was not obviously observed, though the configuration of the *N,N*-bidentate 1:2 complexes of these ligands is considered to be highly strained.

Complex Formation of the Other Metal Ions with Methyl-PAR Derivatives. The reaction behavior of zinc(II) perchlorate with 4-MePAR or 6-MePAR in ethyl acetate suggests the formation of the similar *N,N*-bidentate complex to that of nickel(II) in ethyl acetate (Table 4). The same results were also obtained in the reactions of manganese(II) perchlorate or lanthanum(III) perchlorate with 6-MePAR in ethyl acetate (Table 4). The formation of the *N,N*-bidentate complex of cobalt(II) bromide with 4-MePAR was also detected spectrophotometrically in dioxane.

Enhanced Acidity of the *ortho*-Hydroxyl Group in the Ligand 4-MePAR as a Sequence of *N,N*-Coordination to Nickel(II). The pK_a values in aqueous solution of the conjugate acids of the Brønsted bases are increased in the orders of Br^-(−9)<ClO_4^-(−8)<Cl^-(−7)<NO_3^-(−1.64)<AcO^-(4.756) for the anionic bases[23b] and DMF(0.0)<*o*-chloroaniline(2.6)<*m*-chloroaniline(3.5)<aniline(4.6)<pyridine(5.2)<2,6-lutidine(6.75)<imidazole(7.4) for the neutral bases.[23c] In the solvents of lower basicity, the *N,N*-bidentate complex is formed in the reactions between 4-MePAR and nickel(II) salts, in which the counter anion of the nickel(II) is perchlorate or bromide. The other nickel(II) salts form only the *N,N,O*-terdentate complex. These facts indicate that the perchlorate and bromide ions behave as a weaker base than the other counter anions even in ethyl acetate and dioxane.

From the above results, an average pK_a value to be estimated in aqueous solution for the *ortho*-hydroxyl group of the ligand 4-MePAR in the *N,N*-bidentate nickel(II) complex may be evaluated to be ca. −7. The pK_a value of the *ortho*-hydroxyl group of the free ligand 4-MePAR in aqueous solution was reported to be ca. 11.[4] Namely, owing to the *N,N*-coordination to nickel(II), the *ortho*-hydroxyl group of the ligand 4-MePAR behaves as such a strong acid in aqueous media as HCl and $HClO_4$.

The authors are indebted to Dr. Taira Imamura for helpful discussion. They wish to thank Mr. Shoichi Kaihara for the syntheses and purifications of the free ligands, 3- and 5-MePAR.

18) We adopt the value of the longest λ_{max}, when two or more absorption bands are observed in the visible region. Though the physical meaning of $\Delta\lambda_{max}$ is not yet clear, this value is useful for the discrimination of the *N,N*-bidentate and the *N,N,O*-terdentate species in solution.

19) The ligand *p*-PAP reacts with metal ions to form only the *N,N*-bidentate complexes in solution, since *p*-PAP possesses no coordinating *o*-hydroxyl group. See, R. G. Anderson and G. Nickless, *Anal. Chim. Acta*, **39**, 469 (1967); Ref. 2.

20) V. Gutmann, "The Donor-Acceptor Approach to Molecular Interactions," Plenum Press, New York, N. Y. (1978), p. 17.

21) The *N,N*-bidentate 1:2 complex of nickel(II) with DAPAP was identified to be a monohydrate (Found: 0.93H_2O) by Karl-Fischer titration. Found: C, 39.78; H, 3.62; N, 14.36; Cl, 9.20%. Calcd for $Ni(C_{13}H_{14}N_4O)_2(ClO_4)_2 \cdot H_2O$: C, 41.08; H, 3.98; N, 14.74; Cl, 9.33%.

22) In ethyl acetate, nickel(II) perchlorate hexahydrate was found to be in a six-coordinated structure with λ_{max} (ε_{max})=725 (2.2), 1163 (2.4), 1213 (2.5), 1450 (2.0), and 1938 nm (6.9 $mol^{-1}\,dm^3\,cm^{-1}$). It has been reported that in aqueous solution the spectrum of the $[Ni(H_2O)_6](ClO_4)_2$ has absorption maxima at 396 (ε_{max}=4.9), 663 (1.8), 729 (2.1), and 1176 nm (2.1 $mol^{-1}\,dm^3\,cm^{-1}$) (see, H. Ito, *Nippon Kagaku Zasshi*, **77**, 1383 (1956)). Since the wavelength for the d-d transition of the divalent nickel did not remarkably change upon addition of the free ligand 4-MePAR to the light green solution of nickel(II) perchlorate, the configuration of the bidentate nickel(II) complex in ethyl acetate solution may be considered to be an octahedral involving the coordination of water and/or solvent molecules.

Condensations of 1,4-Cyclohexanediones and Secondary Aromatic Amines. II. *N*-Phenylation of Diarylamines

Kazuo HAGA,* Katsumasa IWAYA, and Ryohei KANEKO
Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishii-machi, Utsunomiya 321
(Received April 15, 1985)

The condensations of 1,4-cyclohexanedione with several diphenylamines were investigated in order to determine the limit of the utility of this reaction for the *N*-phenylation of aromatic secondary amines. 4-Methoxy-, 4,4′-dimethyl-, and 4,4′-dibromodiphenylamines produced their *N*-phenylated compounds in fairly good yields, but 4-hydroxy-, 3-methoxy-, and 4,4′-bis(dimethylamino)diphenylamines produced poor yields. Nitro-substituted diphenylamines gave *N*-phenyl derivatives in low yields along with *N*-4-hydroxyphenyl derivatives. *N,N′*-Diphenyl-*p*-phenylenediamine and *N,N′*-diphenylbenzidine gave corresponding tetra-*N*-phenyl diamines in good yields. The condensation of *N*-phenyl-1-naphthylamine, *N*-phenyl-2-naphthylamine, di-2-pyridylamine, phenothiazine, and carbazole with 1,4-cyclohexanedione were also examined.

In a previous paper[1] the authors showed that the condensation of secondary aromatic amines with 1,4-cyclohexanedione(**1**) in the presence of *p*-toluenesulfonic acid gave *N*-phenyl derivatives. In the case of *N*-ethylaniline, a *p*-chloro or *p*-nitro substituent facilitated the reaction. Diphenylamine also reacted with the 1,4-dione to afford triphenylamine in good yield in spite of a low nucleophilicity. It would be interesting to know to what extent the *N*-phenylation of very low-nucleophilic amines proceeds since condensation with the 1,4-dione is expected to be useful for the *N*-phenylation of diarylamines under mild conditions. In this paper the condensation of several diphenylamines and some analogous amines with 1,4-cyclohexanedione are investigated, and the limit of the utility of this method for *N*-phenylation and solvent effects are discussed.

Results and Discussion

Condensation of Diphenylamines. The condensation of diphenylamines with 1,4-cyclohexanedione was carried out in the presence of *p*-toluenesulfonic acid in a manner similar to that discussed in the previous paper.[1] The results are shown in Table 1. The diphenylamines can be divided into three groups according to their reactivities. Most of diphenylamines (except nitro derivatives) gave only *N*-phenylated compounds (**3a—i**) as isolable products (Eq. 1). 4,4′-Dimethyl- and 4,4′-dibromodiphenylamines (**2g** and **2i**) gave the corresponding triphenylamines (**3g** and **3i**) in good yields, as did diphenylamine (**2h**).

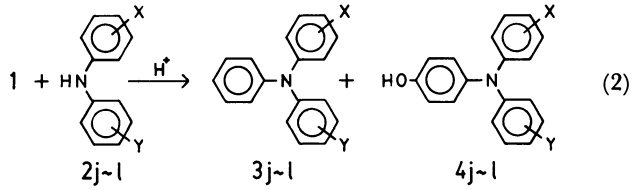
a) 1,4-Cyclohexanedione; 0.25 g (2.23 mmol). Diphenylamines; 2.23 mmol. *p*-Toluenesulfonic acid; 10 mg. b) The reaction was carried out in toluene (10 cm^3) at the refulux temperature. c) Resinous products were obtained.

On the other hand, strong electron-donating substituents seemed to be unfavorable for this type reaction, except for the *p*-ethoxyl group. 4-Hydroxy-, 3-ethoxy-, and 3,3′-diethoxydiphenylamines (**2b**, **2e**, and **2f**) produced triphenylamines in poor yields and 3,3′-dihydroxydiphenylamine (**2c**) gave no triphenylamine. The low yields of these *N*-phenyl derivatives may be similar to the results of the *N*-phenylation of *N*-ethylanilines. In the latter case, there was a tendency for electron-withdrawing substituents to facilitate the *N*-phenylation; *N*-ethylanilines substituted by electron-donating groups showed relatively low reactivity. These facts have been explained in terms of the acidity of the conjugate acids as the actual catalyst. However, 4-ethoxydiphenylamine

(**2d**) gave 4-ethoxytriphenylamine (**3d**) in good yield. This shows that the conjugate acid of **2d** is sufficiently acidic to catalyze the reaction. The basicity of diphenylamine, itself, is very weak. Therefore, the acidity of the conjugate acid of any diphenylamine must be strong even if it is substituted by an electron-donating group. Therefore, the low yields of the triphenylamines from **2b**, **2c**, **2e**, and **2f** must be due to side reactions. Actually, these diphenylamines produced some resinous by-products which could not be purified and remained unidentified. According to an infrared analysis, the by-products contained carbonyl groups. Also, the condensation of the secondary amines with the 1,4-dione seemed to occur at aromatic nuclei. In the case of the *p*-ethoxyl derivative (**2d**), the corresponding by-product was hardly produced. The difference between the reactivity of **2d** and that of **2e** is now under investigation. The condensation of 4,4′-bis(dimethylamino)diphenylamine (**2a**) with the 1,4-dione also gave triphenylamine **3a** in a low yield. In this case, 80% of the starting amine was recovered. The dimethylamino groups of **2a** are more basic than the inside diarylamino group; thus, protonation must occur on the dimethylamino group (the conjugate acid of **2a** is much more weak than that of diphenylamine). Therefore, the low reactivity of **2a** is due to the low activity of the conjugate acid.

The last group of diphenylamines (nitro-substituted diphenylamines) also showed a small reactivity and 4,4′-dinitrodiphenylamine (**2k**) could hardly give *N*-phenylated derivative. In these cases, by-products were isolated and identified to be 4-hydroxy-4′-nitrotriphenylamine (**4j**), 4-hydroxy-4′,4″-dinitrotriphenylamine (**4k**), and 4-hydroxy-3,3″-dinitrotriphenylamine (**4l**). The yields of these hydroxy



(2)

derivatives were also poor; therefore, the low yields of the triphenylamines must be due to the very low nucleophilicity of the amino groups. It is worth noting that the *p*-bromo substituent facilitated the reaction but the nitro substituent did not. That is to say, the effect of the bromo group on diphenylamines is parallel with that on *N*-ethylanilines, whereas the effect of the nitro group is opposite. This is because the decrease in the nucleophilicity of the nitro-substituted diphenylamines is more remarkable rather than an increase in the acidity of the conjugate acid.

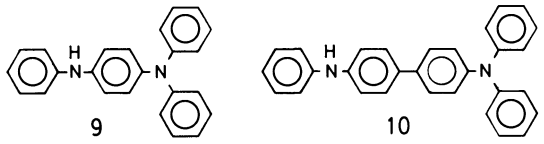
These results indicate that the reaction depends on both the necleophilicity of the amine and the acidity of the conjugate acid. Since both factors can be assumed to have a reverse tendency for many amines, they must compensate for each other in the *N*-phenylation of most aniline derivatives. If either of the two factors decreases very much, *N*-phenylation proceeds with difficulty, for example, as in the case of aliphatic amines or the dinitrodiphenylamines. Consequently, this *N*-phenylation is applicable for an aromatic secondary amine which is more nucleophilic than 4-nitrodiphenylamine; however, it is necessary to take into account the side reaction for several diphenylamines substituted by electron-donating groups. The condensation of other secondary amines analogous to diphenylamine were examined in order to determine any further utility of this reaction.

The *N*-Phenylation of Other Secondary Amines. As analogies of diphenylamine, two aromatic diamines, three cyclic amines, di-2-pyridylamine, and *N*-phenyl naphthylamines were examined for the reactivity of the *N*-phenylation. The results are shown in Table 2. *N,N′*-Diphenyl-*p*-phenylenediamine (**5**) and *N,N′*-diphenylbenzidine (**7**) gave *N,N,N′,N′*-tetrapheny-*p*-phenylenediamine (**6**) and *N,N,N′,N′*-tetraphenylbenzidine (**8**), respectively, in good yields. In these reactions, *N,N,N′*-triphenylphenylenediamine (**9**) and *N,N,N′*-triphenylbenzidine (**10**) should be formed

Table 2. Condensation of Diarylamine Other than Diphenylamines[a)]

Diarylamine	Time/h	Product (yield/%)
 (**5**)	20	*N,N,N′,N′*-Tetraphenyl-*p*-phenylenediamine (**6**) (80)
 (**7**)	20	*N,N,N′,N′*-Tetraphenylbenzidine (**8**) (78)
 (**11**)	24	No product
 (**12**)	24	No product
 (**13**)	12	*N*-Phenylcarbazole (**14**) (6.6) 1-Phenylcarbazole (**15**) (12)
 (**22**)	12	*N,N*-Diphenyl-1-naphthylamine (**23**) (19)
 (**24**)	12	*N,N*-Diphenyl-2-naphthylamine (**25**) (28)
 (**26**)	12	*N*-Phenylphenothiazine (**27**) (43)

a) The conditions were as same as that in Table 1.



9 10

as intermediates. These compounds could not be isolated, but the formation of **6** and **8** showed that the intermediates also reacted easily with one further molecule of the 1,4-dione. On the other hand, di-2-pyridylamine (**11**) gave no tertiary amine and most of the starting materials were recovered. The facility of the *N*-phenylation of **5**, **7**, **9**, and **10** indicates that the *N*-phenylation of a polyamino aromatic compound proceeds if amino groups other than a reaction point are not more basic than the reaction point. In the case of **11**, however, both factors (nucleophilicity and acidity) which govern the reaction are under unfavorable situations. It is well known that 2- or 4-aminopyridine is more basic than aniline and that protonation occurs on the ring nitrogen,[2] and pyridine, itself, is much more basic than diphenylamine. Then, the conjugate acid of **11** is also less acidic than that of diphenylamine, but the exocyclic amino group is less nucleophilic because of the electron-withdrawing property of the pyridine ring.

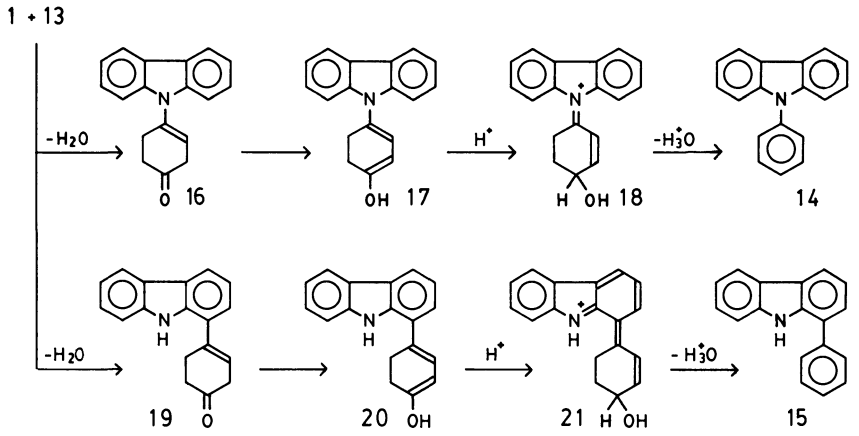
Also, 10,11-dihydro-5*H*-dibenzo[*b*,*f*]azepine (**12**) did not give any phenylated compound and the starting amine was recovered. The differences between **12** and diphenylamine or carbazole must be due to a steric hindrance; that is, the ethylene linkage must inhibit the nitrogen from attacking the carbonyl of the 1,4-dione.

Carbazole (**13**) had been estimated to have a very low reactivity. Actually, about 80% of **13** was recovered upon condensation with the 1,4-dione. *N*-Phenylcarbazole (**14**), however, was obtained in low yield together with 1-phenylcarbazole (**15**). The fact that *C*-phenylation is easier than *N*-phenylation in carbazole can be explained by the mechanisms shown in Scheme 1. The formation of monoenamine **16** (an intermediate of *N*-phenylation) is a reversible reaction; but the formation of **19** is irreversible and **19** easily changes to **15** under the influence of a strong acid. Comparing the stability of **18** with that of **21**, the protonation of **20** is seen to be easier than that of **17**. *C*-Phenylation could not be observed for diphenylamines. Carbazole is a much weaker base than diphenylamine.[3] This suggests that the lone-pair electrons of the nitrogen atom of carbazole are more delocalized than those of diphenylamine. Therefore, the carbocyclic rings should be more active toward an electrophilic attack than the phenyl groups of diphenylamine. In the case of diphenylamines substituted with electron-donating groups, the substituents increase the activity of the phenyl group but also increase the nucleophilicity of the nitrogen. These reactions of carbazole are very interesting, but the low reactivity of the nitrogen of carbazole also shows the limit of the utility of this method for *N*-phenylation.

N-Phenyl-1-naphthylamine (**22**) and *N*-phenyl-2-naphthylamine (**24**) gave the corresponding *N*,*N*-diphenylnaphthylamines (**23** and **25**), respectively, but in low yields. Phenothiazine (**26**) produced *N*-phenylphenothiazine (**27**) in moderate yield. These results are less satisfactory, but still show that this *N*-phenylation method is applicable to secondary amines beyond aniline derivatives.

Solvent Effect. *N*-Phenylation reactions in several polar solvents were much slower than that in aromatic hydrocarbons. In the condensation of diphenylamine (**2h**) in dimethyl sulfoxide, triphenylamine was scarcely produced. The condensation of phenothiazine (**26**) in dioxane for 24h resulted in only a 13% yield of the *N*-phenyl derivative. Carbazole (**13**) in a mixture of xylene and nitrobenzene scarcely gave *N*-phenylcarbazole.

Diphenylamines substituted with nitro groups have poor reactivities, as described above. While the



Scheme 1.

Table 3. Solvent Effect on the Condensation of 4,4′-Dinitrodiphenylamine with 1,4-Cyclohexanedione[a)]

Solvent	Catalyst /mg	Time /h	Product **3k**	(Yield/%) **4k**
Toluene	10	18	0.2	4.2
	40	18	0.6	4.6
	40	36	1.1	7.8
Toluene/DMSO	10	18	0.6	trace
(80/20)	40	18	1.9	trace
Dioxane	40	18	0.6	—
Xylene/Nitrobenzene (80/20)	40	18	—	13

a) The conditions were virtually identical with those shown in Table 1 except for the solvent and the amount of *p*-toluenesulfonic acid as the catalyst.

reactivity of **2k** is especially low, such a reaction of **2k** in high concentration could not be performed in toluene because of the poor solubility. Further, the formation of the 4-hydroxyphenyl derivatives suggests that the dehydrogenation of the monoenamines of the 1,4-dione is accompanied by their dehydration. The relative rates of these simultaneous reactions were expected to be affected by the polarity of solvent. The results of the condensation of **2k** carried out for several conditions are shown in Table 3. In toluene, an increase in the amount of the catalyst or the reaction period leads to an increase in the yields of both **3k** and **4k**; yet, their yields are very poor. In a mixture of toluene and dimethyl sulfoxide or in dioxane, **4k** was scarcely produced. In every solvent, the total yield of the two products was smaller than that in toluene. In a mixture of xylene and nitrobenzene, **3k** was not produced; however, the yield of **4k** increased. It can be said that nitrobenzene accelerated the dehydrogenation to afford **4k**, which resulted in inhibiting the formation of **3k**. This shows that an oxidizing action of a nitro group can occur in the reaction system. Therefore, dehydrogenation in the absence of nitrobenzene must be catalyzed by the nitro groups of 4,4′-dinitrodiphenylamine.

These results show that polar solvents are unfavorable and only the aromatic hydrocarbons are favorable as solvents for the condensation process.

Experimental

General. Melting points were uncorrected. ^{1}H-NMR spectra were recorded on a JNM-C-60HL spectrometer with $(CH_3)_4Si$ as an internal standard. IR spectra were taken on a JASCO Model IR-G spectrophotometer. Mass spectra were measured on a Hitachi M-80 mass spectrometer.

Materials. 4-Ethoxy-, 3-ethoxy-, and 3,3′-diethoxydiphenylamines were prepared from 4-hydroxy-, 3-hydroxy-, and 3,3′-dihydroxydiphenylamines, respectively. Ethylation was carried out using ethyl iodide in a 10% ethanolic potassium hydroxide solution. This was a modification of Houston's method[4)] for the preparation of 4-propoxydiphenylamine. 4-Ethoxydiphenylamine (**2d**) was prepared in 52% yield: Mp 71 °C. 3-Ethoxydiphenylamine (**2e**) was obtained in 80% yield: Bp 162 °C/1.5 Torr (1 Torr=133.322 Pa). 3,3′-Diethoxydiphenylamine (**2f**) was isolated by distillation and following column chromatography on silica gel: yield, 22%; bp 189 °C/1 Torr. *N*-Benzoyldiphenylamine was obtained by the usual method from diphenylamine and benzoyl chloride: Mp 175.5—176.5 °C (from ethanol). 4,4′-Dibromodiphenylamine (**2i**) was prepared by bromination of *N*-benzoyldiphenylamine in chloroform and following hydration in 3% ethanolic potassium hydroxide solution: Yield, 56%; mp 100—102 °C (lit,[5)] 105.5—107 °C). 3,3′-Dinitrodiphenylamine (**2l**) was prepared according to the method of Hodgson and Dodgson[6)]: Mp 186—187.5 °C (lit, 188 °C). 4-Nitrodiphenylamine (**2j**) was prepared from 4-bromonitrobenzene and acetanilide. The procedure was virtually identical with that of Hodgson and Dodgson for **2l** but the intermediate, *N*-acetyl-4-nitrodiphenylamine was hydrated in a 0.2% ethanolic potassium hydroxide solution since hydration in an acidic solution was difficult. Compound **2j** was obtained in 50% yield: Mp 131—132.5 °C; IR (KBr disk) 3320, 1595, 1475, 1295, 1105, 745, and 640 cm^{-1}. 4,4-Dinitrodiphenylamine (**2k**) was obtained from diphenylamine in a manner similar to that used by Chen et al.[5)]: Mp 216—218 °C (lit, 217—218 °C). All other diphenylamines and secondary amines in Table 2 were commercially available and were used after purification (if necessary).

Condensation of the Secondary Amines with 1,4-Cyclohexanedione (1). General Method: The procedure was virtually identical to that described in the previous paper.[1)] A two-necked flask was fitted with a reflux condenser and an inlet tube. In the flask, a filter paper thimble packed with $CaCl_2$ was hung under the condenser in order to dehydrate the refluxed solvent. A mixture of 0.25 g (2.23 mmol) of 1,4-cyclohexanedione, the amine (2.23 mmol) and 10 mg of *p*-toluenesulfonic acid in 10 cm^3 of toluene was refluxed. After 12 h, the solution was freed of solvent in vacuo and then the residue was separated by column chromatography on silica gel. The product was eluted with hexane-benzene.

Condensation of Diphenylamines (2a—i). The isolated products and the yields are shown in Table 1, and their properties are presented below.

4,4′-Bis(dimethylamino)triphenylamine (3a): Mp 151—152 °C (lit,[7)] 157 °C; ^{1}H NMR ($CDCl_3$) δ=2.88 (12H, broad s) and 7.30—6.52 (13H, m); IR (KBr disk) 1600, 1590, 1510, and 1490 cm^{-1}; MS (70 eV), *m/z* (rel intensity), 331 (M^+, 100), 316 (14), and 166 (11); High-resolution mass spectra (HR-MS), *m/z* 331.2105; Calcd for $C_{22}H_{25}N_3$: M, 331.2050.

4-Hydroxytriphenylamine (3b): Mp 125.5—126.5 °C; IR (KBr disk) 3550, 1580, 1510, and 1490 cm^{-1}; MS (70 eV), *m/z* (rel intensity), 262 (20), 261 (M^+, 100), 260 (17), 167 (6), and 77 (8); HR-MS, *m/z* 261.1117, Calcd for $C_{18}H_{15}NO$: M, 261.1154.

4-Ethoxytriphenylamine (3d): Mp 76—78 °C; NMR ($CDCl_3$), δ=1.46 (3H, t), 4.07 (2H, q), and 6.79—7.45 (14H, m); IR (KBr disk) 1580, 1485, and 1235 cm^{-1}; MS (70 eV), *m/z* (rel intensity), 289 (M^+, 94), 260 (100), and 77 (14); HR-MS, *m/z* 289.1511; Calcd for $C_{20}H_{17}NO_2$: M,

289.1466.

3-Ethoxytriphenylamine (3e): Colorless liquid; ^{1}H NMR ($CDCl_3$) δ=1.29 (3H, t), 3.89 (2H, q) and 6.38—7.38 (14H, m); IR (neat) 1580, 1490, and 1215 cm^{-1}; MS (70 eV), *m/z* (rel intensity), 289 (M^+, 100), 260 (35), 244 (18) and 77 (21); HR-MS, *m/z* 289.1513; Calcd for $C_{20}H_{17}NO_2$: M, 289.1466.

3,3′-Diethoxytriphenylamine (3f): Light blue liquid ^{1}H NMR ($CDCl_3$) δ=1.35 (6H, t), 3.91 (4H, q) and 6.42—7.33 (13H, m); IR (neat) 1580, 1480 and 1195 cm^{-1}; MS (70 eV), *m/z* (rel intensity), 333 (M^+, 100), 304 (6), and 276 (7); HR-MS, *m/z* 333.1634; Calcd for $C_{22}H_{23}NO_2$: M, 333.1727.

4,4′-Dimethyltriphenylamine (3g): Mp 107—108 °C; ^{1}H NMR ($CDCl_3$) δ=2.28 (6H, s) and 6.75—7.52 (13H, m); IR (KBr disk) 1593, 1507, 1490, 1320, 1290, and 1280 cm^{-1}; MS (70 eV), *m/z* (rel intensity), 273 (M^+, 100), 257 (6), and 180 (5); HR-MS, *m/z* 273.1539; Calcd for $C_{20}H_{19}N$: M, 273.1518.

4,4′-Dibromotriphenylamine (3i): Colorless viscous liquid; IR (neat) 1575, 1480, 1310, 820, and 505 cm^{-1}; MS (70 eV), *m/z* (rel intensity) 405 (51), 403 (100), and 401 (52); relative intensity of isotopic cluster calculated from $C_{18}H_{13}NBr_2$, 50.4:100:50.5 (M+4:M+2:M).

Condensation of Nitro Substituted Diphenylamines (2j, 2k, and 2l). The procedure was virtually identical with that described above. After **3j—l** were separated by column chromatography on silica gel eluted with hexane-benzene, hydroxy derivatives **4j—l** were eluted with benzene-ether. The latter compounds were further purified by chromatography on alumina. They were eluted with ethanol after elution with ether.

4-Nitrotriphenylamine (3j): Mp 138—139 °C; IR (KBr disk) 1575, 1490, 1320, and 1110 cm^{-1}; MS, *m/z* (rel intensity), 290 (M^+, 100), 244 (35), 243 (28), 242 (21), 167 (20), 166 (19), and 77 (19); HR-MS, *m/z* 290.1089; Calcd for $C_{18}H_{14}N_2O_2$: M, 290.1056.

4-Hydroxy-4′-nitrotriphenylamine (4j): Decomposed above 250 °C; IR (KBr disk) 3400, 1575, 1480, 1300, and 1110 cm^{-1}, MS, *m/z* (rel intensity), 306 (M^+, 100), 260 (23), 251 (26), and 83 (15); HR-MS, *m/z* 306.0988; Calcd for $C_{18}H_{14}N_2O_3$: M, 306.1002.

4,4′-Dinitrotriphenylamine (3k): Mp 206—207 °C; IR (KBr disk) 1585, 1575, 1500, and 1335 cm^{-1}; MS, *m/z* (rel intensity), 335 (M^+, 34), 259 (100), 223 (14), 167 (42), 166 (28), and 69 (51); HR-MS, *m/z* 335.0932, Calcd for $C_{18}H_{13}N_3O_4$: M, 335.0907.

4-Hydroxy-4′,4″-dinitrotriphenylamine (4k): Mp 243—245 °C; IR (KBr disk) 3500, 1575, 1490, 1305, and 1110 cm^{-1}; MS, *m/z* (rel intensity), 351 (M^+, 100), 259 (29), and 258 (16); HR-MS, *m/z* 351.0759; Calcd for $C_{18}H_{13}N_3O_5$: M, 351.0853.

3,3′-Dinitrotriphenylamine (3l): Mp 144.5—145.5 °C; IR (KBr disk) 1520, 1510, 1340, and 1270 cm^{-1}: MS, *m/z* (rel intensity), 335 (M^+, 100), 243 (39), 242 (39), and 241 (24); HR-MS, *m/z* 335.0929; Calcd for $C_{18}H_{13}N_3O_3$: M, 335.0907.

4-Hydroxy-3′,3″-dinitrotriphenylamine (4l): Mp 175—178.5 °C; IR (KBr disk) 3400, 1525, 1510, and 1345 cm^{-1}; MS, *m/z* (rel intensity), 351 (M^+, 100), 259 (39), 258 (26), and 257 (10); HR-MS, *m/z* 351.0915; Calcd for $C_{18}H_{13}N_3O_5$: M, 351.0854.

Condensation of Diamine 5 and 7. The procedure was virtually identical with the general method, but 1,4-cyclohexanedione was used by double molar quantity to 1 mol of the diamine.

***N,N,N′,N′*-Tetraphenyl-*p*-phenylenediamine (6):** Mp 197—198 °C; IR (KBr disk) 1590, 1505, 1493, and 1270 cm^{-1}; MS, *m/z* 412 (M^+).

***N,N,N′N′*-Tetraphenylbenzidine (8):** Mp 224—225 °C; IR (KBr disk) 1585, 1490, 1480, and 1275 cm^{-1}; MS, *m/z* 488 (M^+).

Condensation of Carbazole. The procedure was virtually identical with the general method but the column chromatograpy on silica gel with hexane was repeated several times to isolate products **14** and **15**.

***N*-Phenylcarbazole (14):** Mp 90—92 °C; Picrate, mp 127—128 °C; IR (KBr disk) 1590, 1500, 1445, and 1230 cm^{-1}; MS, *m/z* 243 (M^+).

1-Phenylcarbazole (15): Mp 129—130 °C (lit,[7] 133 °C); picrate, mp 150—151 °C (lit,[8] 151 °C); IR (KBr disk) 3320, 1620, 1590, 1500, 1410, 1320, and 1230 cm^{-1}; MS, *m/z* 243 (M^+).

Condensation of *N*-Phenyl-1-naphthylamine (22), *N*-Phenyl-2-naphthylamine (24) and Phenothiazine (26). These condensations were carried out by the general method.

***N,N*-Diphenyl-1-naphthylamine (23):** Mp, 137.5—138.5 °C; IR (KBr disk) 1590, 1490, 1390, 1290, and 1275 cm^{-1}; MS, *m/z* 295 (M^+).

***N,N*-Diphenyl-2-naphthylamine (24):** Mp, 120—121 °C; IR (KBr disk) 1620, 1590, 1490, 1275, and 755 cm^{-1}; MS, MS, *m/z* 295 (M^+).

***N*-Phenylphenothiazine (15):** Mp 93—94 °C; IR (KBr disk) 1580, 1485, 1455, and 1300 cm^{-1}; MS, *m/z* 243 (M^+).

The authors wish to thank Mr. Makoto Roppongi for his technical assistance in preparing some of amines.

The potential-current relationships of DMF solutions of a series of iron-sulfur compounds have revealed that in the presence of clusters $[Fe_4S_4(SR)_4]^{2-}$ (R=$PhCH_2$ or Bu^t) and $[M_2Fe_6S_8(SEt)_9]^{3-}$ (M=Mo or W) the electroreduction of CO_2 proceeds at the potential shifted by about 0.7 and 0.5 V, respectively, to the positive direction compared to the potential at which CO_2 is reduced without any catalyst. When controlled potential electrolysis of a DMF solution containing $[Fe_4S_4(SCH_2Ph)_4]^{2-}$ was carried out under CO_2 at −2.0 V vs. SCE, phenylacetate and formate were formed as the products resulting from CO_2 reduction. The cubane structure of this cluster collapsed rapidly under these conditions. However, when excess amount of $PhCH_2SH$ was added to the catholyte, the cluster structure was preserved during a relatively long period of electrolysis, and the yield of phenylacetate increased but that of formate decreased compared with the reaction in the absence of free $PhCH_2SH$.

Utilization of carbon dioxide has evoked much interest in relevance to the development of alternative carbon sources of fuels and chemicals. However, the fixation of CO_2, the stable carbon end product, inevitably necessitates considerable energy input. The electrochemical reduction of CO_2 is presumably one of the most potential methods for converting CO_2 into organic substances but the direct reduction requires the large overpotential.[1-4] Recently several transition metal complexes were reported as the catalysts to diminish the overvoltage. Among these are Co and Ni tetraazamacrocycles,[5-9] [Re(bipyridine)$(CO)_3Cl$][10] and [Rh(diphosphine)$_2$Cl].[11] From the former two catalytic systems, CO is produced in high current efficiencies, whereas the Rh complex catalyzes the formation of formate. In a previous communication, we reported that the iron-sulfur clusters $[Fe_4S_4(SR)_4]^{2-}$([2−]), first prepared by Holm and his coworkers as the ferredoxin model compounds,[12] remarkably diminish the overvoltage of CO_2 electroreduction.[13] From this reaction system, a substantial amount of formate is obtained together with a little CO. Here we wish to describe the detail of this reaction.

Results and Discussion

Current-Potential Relationships of DMF Solutions Containing Iron-Sulfur Clusters under CO_2. The direct electroreduction of CO_2 in nonaqueous media has been reported by several authors.[3,14] In every case the reduction proceeds only at extremely negative potentials. In fact, investigation of the reduction of CO_2 in a solution of 0.1 M $[Bu^n_4N][BF_4]$ (M= mol dm^{-3}) in DMF on mercury electrode has revealed that potentials more negative than −2.4 V vs. SCE are required for the reduction. However, addition of 2 mM $[Fe_4S_4(SR)_4]^{2-}$ (R=CH_2Ph or Bu^t) to the solution lowers the effective reduction potential by about 0.7 V. Figure 1 shows the current (I)-potential (E) relationship of a solution of $[Fe_4S_4(SCH_2Ph)_4]^{2-}$ (**1**) in DMF recorded on mercury pool cathode with 13.5 cm^2 surface area. Cluster **1** exhibits two succesive reduction waves corresponding to two redox processes [2−]/[3−] and [3−]/[4−] under N_2 (Fig. 1 c). When CO_2 gas was bubbled

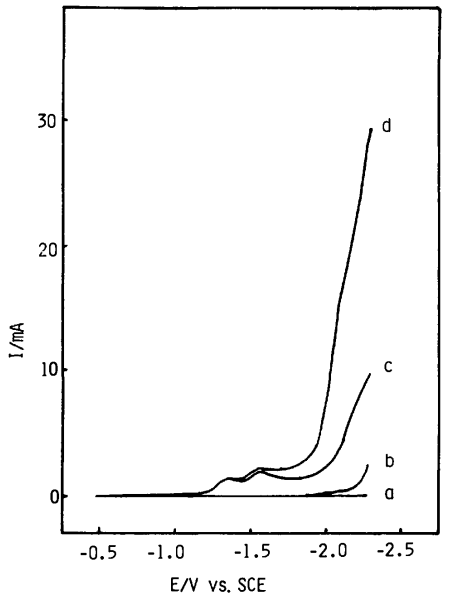

Fig. 3. *I–E* relationships of a solution of 0.1 M $[Bu^n_4N][BF_4]$ in DMF. (a): Without cluster under N_2, (b): Without cluster under CO_2, (c): In the presence of 2 mM cluster **4** under N_2, (d): In the presence of 2 mM cluster **4** under CO_2.

through the solution for several minutes, the reduction current of CO_2 increased remarkably at potentials more negative than −1.7 V (Fig. 1 d). The same trend is also observed in the case of $[Fe_4S_4(SBu^t)_4]^{2-}$ (**2**). In contrast with these compounds, the cluster $[Fe_4S_4(SPh)_4]^{2-}$ (**3**) does not have any effect on the electroreduction of CO_2 as shown in Fig. 2. Although cluster **3** is reduced to [3−] and then [4−] in the same manner as clusters **1** and **2**, the electron transfer from the reduced **3** to CO_2 does not occur substantially. When cluster **1** was reduced to [4−] under CO_2, it decomposed rapidly to generate in situ the other species which enhanced the electroreduction of CO_2 (vide infra). On the other hand, degradation of cluster **3** also proceeded substantially under the same conditions but the similar enhancement for reduction of CO_2 was not observed. It is interesting that the rate of the electroreduction of CO_2 depends very much upon the kind of thiolate ligands of cluster [2−].

We have also examined the potential-current relationships of DMF solutions of a series of other iron-sulfur compounds under N_2 and CO_2. The molybdenum-iron-sulfur cluster $[Mo_2Fe_6S_8(SEt)_9]^{3-}$ (**4**) is effective for the reduction of CO_2 (Fig. 3). The positive shift of the reduction potential amounts to about 0.5 V. The tungsten analogue $[W_2Fe_6S_8(SEt)_9]^{3-}$ also gives essentially the same results. However, the analogous clusters containing SPh ligands cannot facilitate the electroreduction of CO_2, as is also observed for cluster **3** (Fig. 4). The mononuclear

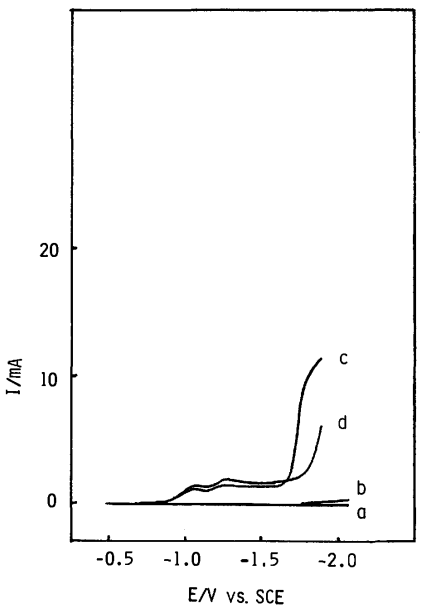

Fig. 4. *I–E* relationships of a solution of 0.1 M $[Bu^n_4N][BF_4]$ in DMF. (a): Without cluster under N_2, (b): Without cluster under CO_2, (c): In the presence of 2 mM cluster **5** under N_2, (d): In the presence of 2 mM cluster **5** under CO_2.

compound $[Fe(SEt)_4]^{2-}$ decomposed immediately in DMF to give an insoluble solid, when CO_2 was bubbled through the solution, and the *I–E* curve of this mixture under CO_2 is just the same as that of the direct noncatalyzed reduction. On the other hand,

the dinuclear compound $[Fe_2S_2(SEt)_4]^{2-}$ was rapidly converted to the cubane cluster with Fe_4S_4 core under the electrolytic condition.[15] Therefore, the *I–E* curve of a solution of this cluster in DMF becomes very close to that of cluster [2−].

Controlled Potential Electrolysis of a Solution of $[Fe_4S_4(SCH_2Ph)_4]^{2-}$ (1) or $[Mo_2Fe_6S_8(SEt)_9]^{3-}$ (4) in DMF Saturated with CO_2. Since a DMF solution of cluster **1** has demonstrated an excellent CO_2 fixing ability under the electroreductive conditions, the preparative controlled potential electrolysis was performed at the potential of −2.0 V vs. SCE by using $[Bu^n_4N][BF_4]$ as suporting electrolyte. Since CO was produced only with 1—2% current efficiency from the present system as reported already,[13] the analysis of the gaseous phase was omitted hereafter and CO_2 was bubbled through the catholyte during electrolysis to enhance the reaction rate.

To determine the lifetime of cluster **1** as catalyst, time-dependence of the concentration of cluster **1** during the electrolysis has been followed by measuring the cyclic voltammograms and the absorption spectra of the reaction solution, which are shown in Fig. 5. In the cyclic voltammograms, the reduction wave at the peak potential of about −1.4 V corresponding to the [2−]→[3−] process is observed clearly at the early stage of the electrolysis but it disappears when the electrolysis is furthermore continued. The absorption spectra of the catholyte also show a rapid decrease of the absorption band at 420 nm characteristic of cluster **1**. These findings indicate that the cubane structure of cluster **1** is preserved only for an initial period and CO_2 fixation catalyzed by cluster **1** occurs only at the early stage. However, it should be noted that the reduction current observed at potentials more negative than −1.5 V increases remarkably after the degradation of the cubane structure. This implies that other type(s) of catalysts may be generated in situ. Analogous rapid decomposition of the cubane structure is also observed when a DMF solution containing molybdenum-iron-sulfur cluster **4** is electrolyzed at −2.0 V under CO_2.

The products in the catholyte were analyzed by HPLC after removing the solid deposited by the addition of water to the electrolyte. A typical liquid chromatogram of the catholyte obtained from the electrolysis of the system containing cluster **1** is given in Fig. 6, which indicates the formation of six products (A—F). None of these peaks appeared in the chromatogram of the catholyte if the reduction was carried out at −2.0 V in the absence of cluster **1**. Formate corresponds to peak B. No oxalate was produced in this catalytic electrolysis. This is in sharp contrast to the predominant formation of oxalate in the electrolysis of CO_2 at −2.4 V in DMF without any catalyst. The product A isolated by preparative HPLC was identified as phenylacetate by its IR and NMR spectra. Isolation of the other products C, D, and E was also attempted. Since the IR spectra of these products in crude forms do not show C=O stretching bands, these compounds are

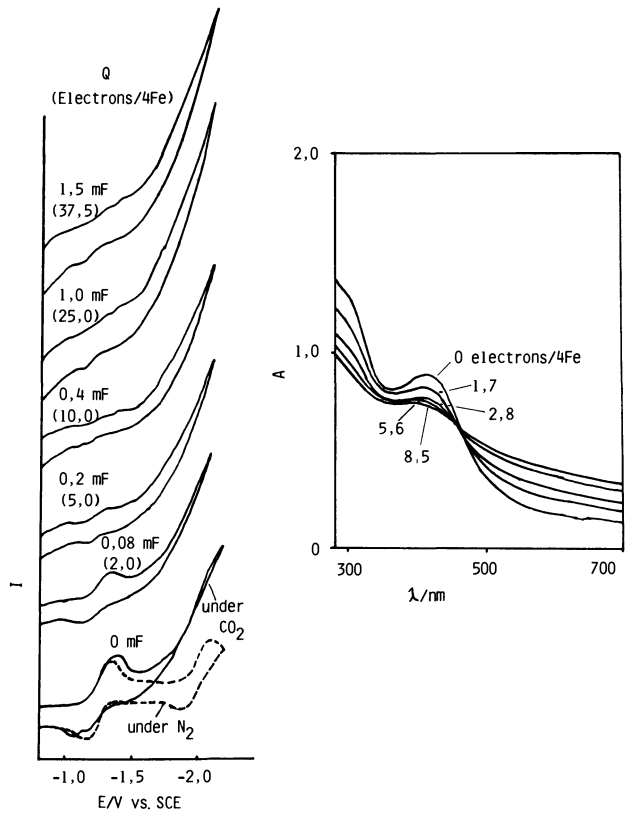

Fig. 5. Dependence of cyclic voltammograms (left) and absorption spectra (right) of a solution of 2 mM cluster 1 in DMF on the electricities passed.

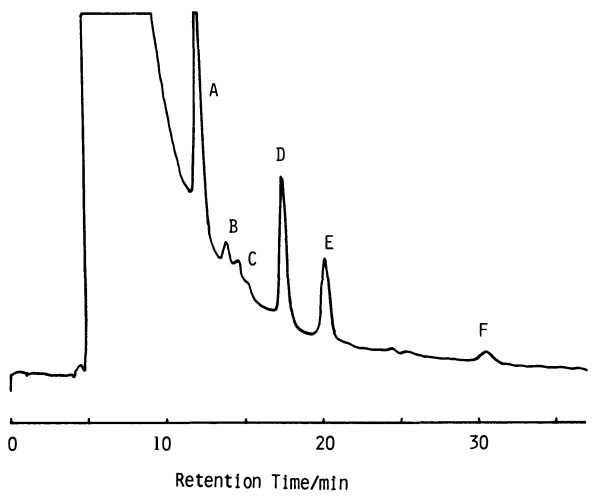

Fig. 6. Liquid chromatogram of the products after the electrolysis in the presence of 2 mM cluster **1** until 1.5 mF of electricities passed.

probably not derived from the electroreduction of CO_2. Thus, more effort to characterize these compounds was abandoned.

When the electrolysis of a DMF solution containing cluster **4** was performed at −2.0 V vs. SCE under CO_2, three products were detected by the HPLC analysis of the catholyte. One of them could be assigned to formate but the yield was quite low. The IR spectra of the other two components in crude forms indicate that these products may not be derived from CO_2. Neither propionate, which may be expected on the analogy of the formation of phenylacetate from the system containing **1**, nor oxalate was produced.

Table 1. Yields of Phenylacetate and Formate Formed by the Controlled Potential Electrolysis Using Cluster **1** as Catalyst Precursor[a)]

Q/mF	Phenylacetate Yield mol/4Fe atoms	Phenylacetate η %	Formate Yield mol/4Fe atoms	Formate η %
0.5	0.40	6.4	0.85	14
1.0	0.50	4.2	2.4	19
1.5	0.58	2.8	3.3	17
2.0	0.68	2.7	5.5	22
3.0	0.75	2.0	10	27
4.0	0.88	1.8	10	20
5.0	0.88	1.4	11	17

a) Cluster **1**: 2 mM; $[Bu^n_4N][BF_4]$: 0.1 M; At −2.0 V vs. SCE.

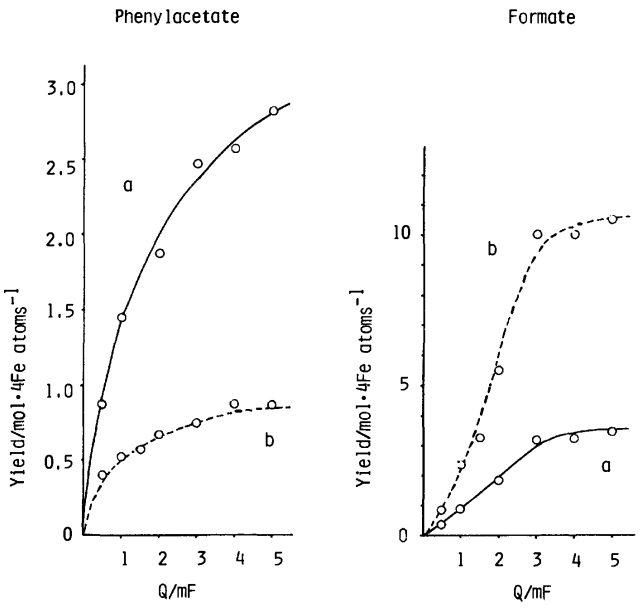

Fig. 7. Yields of phenylacetate and formate formed by the electrolysis of a solution of 2 mM cluster **1** in the presence (full line) or absence (broken line) of excess $PhCH_2SH$.

Formation of Phenylacetate and Formate by Controlled Potential Electrolysis Catalyzed by Cluster 1. In Table 1 are summarized the yields of phenylacetate and formate when the electroreduction of CO_2 in the presence of cluster **1** was continued until the prescribed electricities passed. Current efficiencies (η) are calculated by assuming that two electrons are required in the formations of each product ($H^+ + CO_2 + 2e^- \rightarrow HCOO^-$, $PhCH_2S^- + CO_2 + 2e^- \rightarrow PhCH_2COO^- + S^{2-}$).

The yields of these products are visuallized in Fig. 7 by broken lines. Production of both compounds nearly finished when about 3 mF of electricities passed. The ultimate yield of phenylacetate is close to 1 mol per mol of cluster **1** initially added to the catholyte before the electrolysis. This suggests that phenylacetate is produced from one thiolate ligand of each cubane. Degradation of the cubane structure, which is monitored by the change of cyclic voltammograms and absorption spectra of the reaction mixture, is probably initiated by the conversion of one $PhCH_2S$ ligand into phenylacetate. The final yield of formate amounts to about 10 mol per mol of cluster **1** in the catholyte for the electrolysis continued until 3 mF or more electricities have passed. The optimum current efficiency of 27% for production of formate is observed when 3.0 mF of electricities have passed. The hydrogen atom in formate, at least in part, seems to be derived from tetraalkylammonium ion of the supporting electrolyte or the cation of cluster **1**, since in the gas analysis after the electrolysis were detected considerable amounts of hydrocarbons, which were undetectable in such cases where oxalate was formed predominantly.

Since the conversion of $PhCH_2S$ ligands of cluster **1** into phenylacetate proceeds under this electrolytic conditions concurrent with the collapse of the cubane core, excess $PhCH_2SH$ was added to the catholyte to retain the cubane structure. Table 2 and the full line

Table 2. Yields of Phenylacetate and Formate Formed by the Electrolysis in the Presence of Excess $PhCH_2SH$[a)]

Q/mF	Phenylacetate Yield mol/4Fe atoms	Phenylacetate η %	Formate Yield mol/4Fe atoms	Formate η %
0.5	0.88	14	0.35	5.6
1.0	1.5	12	0.85	6.8
2.0	1.9	7.5	1.8	7.3
3.0	2.5	6.6	3.2	8.5
4.0	2.6	5.2	3.3	6.5
5.0	2.8	4.5	3.5	5.6

a) Cluster **1**: 2 mM; $[Bu^n_4N][BF_4]$: 0.1 M; $PhCH_2SH$: 21 mol/4Fe atoms; At −2.0 V vs. SCE.

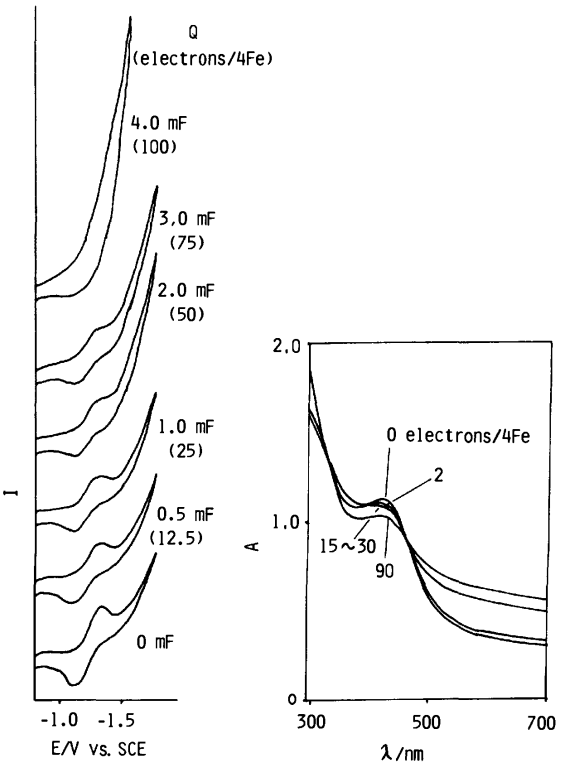

Fig. 8. Dependence of cyclic voltammograms (left) and absorption spectra (right) of a solution of 2 mM cluster **1** in DMF on the electricities passed in the presence of excess $PhCH_2SH$.

in Fig. 7 show the yields of phenylacetate and formate when the electrolysis was carried out in the presence of excess $PhCH_2SH$ (21 mol/mol of cluster **1**). The yield of phenylacetate is approximately tripled compared to that from the original system, whereas the formation of formate is remarkably supressed. Figure 8 illustrates time dependence of cyclic voltammograms and absorption spectra taken during the electrolysis, which definitely shows the retention of the redox wave and the absorption band characteristic of cluster **1**. This indicates that addition of excess $PhCH_2SH$ to the catholyte can prevent degradation of the cluster structure. Since the yield of formate decreases while the cluster structure is maintained, the species that catalyze the formation of formate are not the reduced cluster **1** but the other stuff generated in situ from cluster **1**.

Experimental

Materials. Iron-sulfur compounds, $[Et_4N]_2[Fe_4S_4(SCH_2Ph)_4]$(**1**),[12] $[Me_4N]_2[Fe_4S_4(SBu^t)_4]$(**2**),[12,16] $[Bu^n{}_4N]_2[Fe_4S_4(SPh)_4]$ (**3**),[12] $[Et_4N]_3[Mo_2Fe_6S_8(SEt)_9]$(**4**),[17,18] $[Bu^n{}_4N]_3[Mo_2Fe_6S_8(SPh)_9]$(**5**),[17] $[Et_4N]_3[W_2Fe_6S_8(SEt)_9]$,[17] $[Me_3NCH_2Ph]_2[Fe(SEt)_4]$,[19] and $[Me_3NCH_2Ph]_2[Fe_2S_2(SEt)_4]$[19] were prepared according to the published methods and handled under a nitrogen atmosphere. DMF was dried over CaH_2 and distilled under reduced pressure of N_2 before use.

Electrochemical Apparatus. A cylindrical cell with an anode compartment separated from a cathode by a glass frit and Hokuto Denko instrumentation (HA-501 Potentiostat, HF-201 Coulombmeter and HB-105 Function Generator) were used for the controlled potential electrolysis as well as the recording of current-potential curves and cyclic voltammograms of the catholyte. The mercury pool with 13.5 cm^2 surface area and a platinum plate were employed as working and counter electrodes, respectively, and the potential of the cathode was referred to SCE. The supporting electrolyte was 0.1 M $[Bu^n{}_4N][BF_4]$. Current-potential curves and cyclic voltammograms were recorded under N_2 or CO_2 with the scan rate of 2 and 200 mV s^{-1}, respectively.

Controlled Potential Electrolysis. A DMF solution containing 2 mM cluster **1** or **4** and 0.1 M $[Bu^n{}_4N][BF_4]$ was electrolyzed under CO_2 until the appropriate electricities passed, using the apparatus described above. CO_2 was continually bubbled through the catholyte (20 ml) during the electrolysis. Change in the cluster concentration with time was followed by recording the cyclic voltammograms of the catholyte directly and by measuring the absorption spectra of small portions of the catholyte diluted 4 times with DMF. Absorption spectra were recorded on a Shimadzu UV-240 spectrometer using a quartz cell with 1.0 mm path length connected to a Schlenk tube.

Analysis of the Product by HPLC. To the electrolyte was added water and then the solid precipitated was removed by filtration, which contains the supporting electrolyte and the compounds originated from clusters. The colorless filtrate was adjusted to 100 ml in volume with water and analyzed directly by Toyo Soda HLC-803 equipped with the column packed with a weakly basic anion exchange resin (Toyo Soda DEAE-2SW). The products were eluted at the flow rate of 0.7 ml min^{-1} by the phosphate buffer solution (pH 5.0) prepared by dissolving KH_2PO_4 (9.87 g) in distilled water/acetonitrile (725 ml/275 ml). To analyze oxalate pH of the eluant had to be neutralized up to 6.6. Chromatograms were recorded on a Toyo Soda UV-8 model II detector by monitoring the absorbance at 200 nm. A typical chromatogram is shown in Fig. 6. The amounts of formate and phenylacetate were determined from the calibration curve plotted separately.

Isolation and Characterization of the Products. As for the products formed by the electrolysis using cluster **1** and cluster **4**, an assignment by HPLC was not successful except for formate. Thus, isolation of four products from the former system (peaks A, C, D, and E in Fig. 6) and two from the latter was carried out. After the addition of water (about 200 ml) to the combined catholyte (about 350 ml) of the repeated electrolyses, the mixture was filtered. The filtrate was evaporated to nearly dryness in vacuo and the residue was extracted with water (100 ml×3). The extracts were combined, concentrated to about 50 ml and then fractionated by preparative HPLC. Since the phosphate buffer solution was used as the eluant, all fractions dried up contained KH_2PO_4 as the main component. So the residues were extracted with appropriate solvent by using Soxhlet extractor and the extracts were dried up carefully. The resulting solid or oil was characterized by recording its

IR and NMR spectra on Shimadzu IR-400 and JEOL GX-400 spectrometers, respectively.

The financial support of this research by the Ministry of Education, Science and Culture of Japan (Grant-in-Aid for Scientific Research 60119001) is greatly appreciated.

(*Z*)- and (*E*)-4,4-Dimethyl-5-oxo-2-pentenoic Acids and Their Derivatives

Kunio Ito and Shingo Miyajima*
Department of Applied Chemistry, Faculty of Engineering, Toyo University,
Kawagoe, Saitama 350
(Received October 21, 1985)

(*Z*)-4,4-Dimethyl-5-oxo-2-pentenoic acid (**1**) exists almost exclusively in the hydroxy lactone form, the tautomeric equilibrium constant (K=[Ring]/[Chain]) being 2.8×10^3 in water as estimated by the pK_a method. Several examples are described of preference for ring forms of derivatives of **1**, which are capable of exhibiting ring-chain tautomerism. (*E*)-4,4-Dimethyl-5-oxo-2-pentenoic acid (**7**) reacts with thionyl chloride to afford a trimeric chloro lactone, which on treatment with water or aniline gives the corresponding hydroxy or anilino lactone. Compound **1** or **7** reacts with a variety of phenylhydrazines to yield dihydropyrazole derivatives, except for 2,4-dinitrophenylhydrazine which on reaction with **1** gives a 2,4-dinitrophenylhydrazino lactone.

Recently (*Z*)-4,4-dimethyl-5-oxo-2-pentenoic acid (**1**) has been concluded to exist predominantly in the hydroxy lactone form (**1r**) on the basis of its IR and ^{1}H NMR spectra.[1,2] It seems of interest to examine this compound in more detail since six-membered hydroxy lactones have rarely been reported[1-3] and little is known about their ring-chain tautomerism or derivatives; five-membered ones have been extensively studied.[4] We report in this paper an investigation of the tautomerism and derivatives of **1**. We also report on the cyclic trimers of (*E*)-4,4-dimethyl-5-oxo-2-pentenoic acid (**7**) and its chloride and anilide.

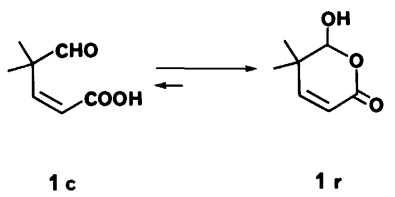

Fig. 1.

Although **1r** is the virtually sole detectable form, a rapid interconversion between **1r** and **1c** on the NMR time scale at ordinary temperature could be verified;[5] when less than one equivalent of *t*-butylamine as a base was added to **1** in water, the averaged resonances of **1r** and the *t*-butylammonium salt of **1c** appeared instead of the superposition of the individual ones.

The equilibrium constant, K, in water at 25 °C was estimated by the pK_a method. The observed pK_a value of **1** (7.63) can be related to p$K_{a,0}$ by Eq. 2[6]

$$K = [\mathbf{1r}]/[\mathbf{1c}], \quad (1)$$

$$pK_{a,0} = pK_a - \log(K+1), \quad (2)$$

where p$K_{a,0}$ denotes the hypothetical pK_a of **1c**. The p$K_{a,0}$ was estimated to be 4.18 from the pK_a of **7** (4.45) and the Hammett relations of the K_a values in (*Z*)- and (*E*)-3-substituted acrylic acids.[7] By applying Eq. 2 K was calculated to be 2.8×10^3. This strong preference of **1** for cyclization exhibits a marked contrast to the case of 5-oxoalkanoic acids which show no sign of cyclization.[4]

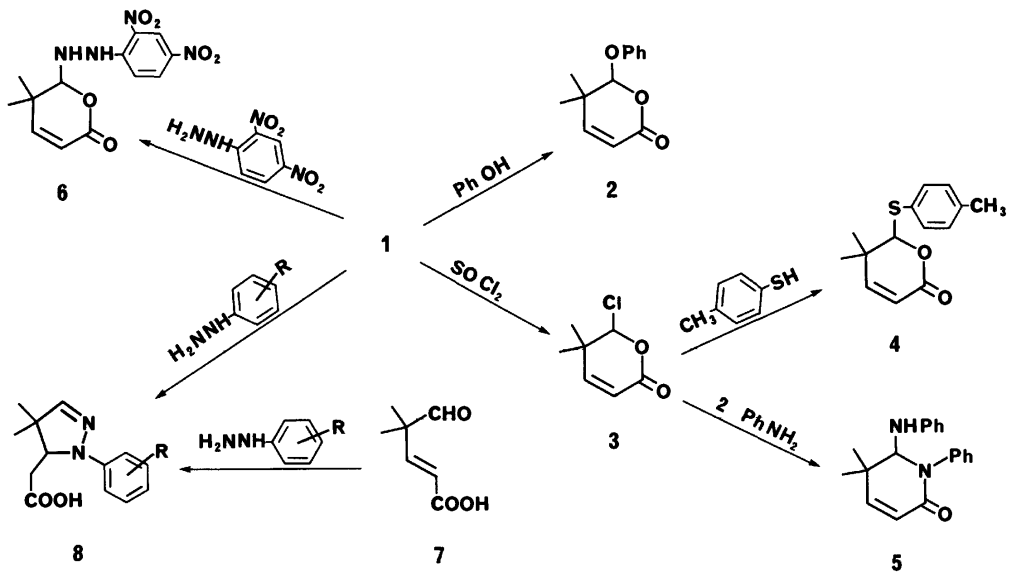

Fig. 2.

As described in our preceding paper,[2] methyl (*Z*)-4,4-dimethyl-5-oxo-2-pentenoate in methanol containing H_2SO_4 or sodium methoxide as a catalyst isomerizes almost completely to 6-methoxy-5,5-dimethyl-5,6-dihydro-2*H*-pyran-2-one. Further examples of preference for ring forms of the derivatives of **1**, which are capable of exhibiting ring-chain tautomerism, are described below. Compound **1** reacted with phenol in the presence of H_2SO_4–H_3BO_3 as a catalyst[8] to give the phenoxy lactone **2**. Treatment of **1** with thionyl chloride yielded the chloro lactone **3**. Compound **3** on reaction with *p*-toluenethiol or two equivalents of aniline afforded the *p*-tolylthio lactone **4** or the anilino lactam **5**.

Compound **1** or the (*E*)-isomer **7**, prepared by hydrolysis of methyl (*E*)-5-(*t*-butylimino)-4,4-dimethyl-2-pentenoate,[2] reacted with a variety of phenylhydrazines to afford the dihydropyrazoles **8** (Tables 1 and 2). Structural assignment was based primarily on their ^1H NMR spectra. The methylene protons in **8** are rendered non-equivalent by the adjacent chiral center and form part AB of pattern ABX. 2,4-Dinitrophenylhydrazine, on the other hand, on reaction with **1** gave the hydrazino lactone **6**. Presumably, the nucleophilicity of the –NH– nitrogen of the initially formed hydrazone is insufficient for addition to moiety –CH=CH–CO_2H.

It is interesting to note that, when **7** was allowed to react with thionyl chloride, the trimeric chloro lactone **9** was obtained in 48% yield. The trimeric

a) Aromatic protons are omitted. In the case of **8** (R=*p*-NO_2), $(CD_3)_2SO$ was used as a solvent.

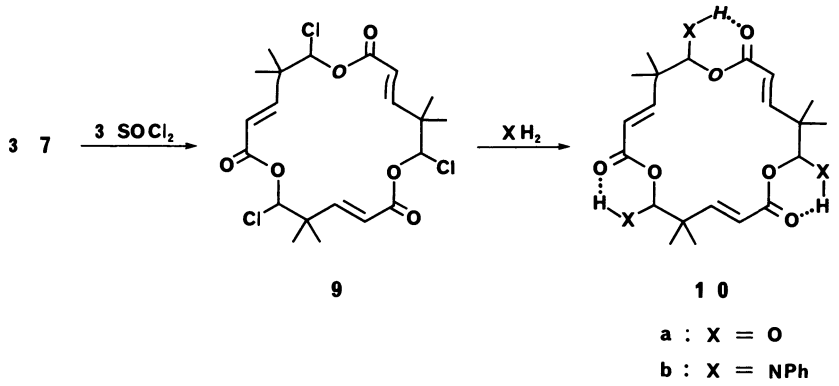

Fig. 3.

structure was confirmed by a relevant mass spectrum showing peaks at m/z 447 and 445 due to $(M-Cl)^+$ and further by vapor phase osmometry. With water or aniline **9** yielded the corresponding hydroxy (**10a**) [MS (CI) m/z 427 $(M+H)^+$] or anilino lactone (**10b**) [MS m/z 651 (M^+)]. In each of these crown-type compounds, the three methine protons occur as a single absorption in the ^1H NMR spectrum (δ 4.49—4.61). This suggests that these protons may have the cis configuration.

Experimental

All melting points and boiling points are uncorrected. IR spectra were recorded on a Hitachi 285 spectrometer. ^1H NMR data were obtained with a Hitachi R-24B spectrometer by using TMS or DSS as an internal standard. Mass spectra were measured with a Shimadzu GCMS-QP1000 spectrometer at 70 eV of ionization energy by use of a direct-inlet system. Microanalyses were performed at the Microanalysis Laboratory, Department of Chemistry, Faculty of Science, the University of Tokyo.

Observation of Progress of the Neutralization of 1 by ^1H NMR Spectroscopy. To a solution of **1** (30.0 mg, 0.211 mmol) in D_2O (0.50 ml) was added *t*-butylamine (15.6 mg, 0.213 mmol) in six portions. A typical signal of **1r** at δ 5.43 due to the methine proton shifted, on addition of the base, toward 9.34 due to an aldehyde proton proportionally to the amount of the base added.

pK_a Measurements. pK_a values were determined at 25±0.1 °C in N_2 by titration of acids in water (0.05 M, 1 M=1 mol dm^{-3}) with aq NaOH (0.05 M) under control by a pH meter with glass and calomel electrodes. The instrument was calibrated by using 0.05 M potassium hydrogen phthalate (pH 4.01 at 25 °C) and 0.01 M sodium tetraborate (pH 9.18 at 25 °C).

5,5-Dimethyl-6-phenoxy-5,6-dihydro-2*H*-pyran-2-one (2). A mixture of **1** (1.50 g, 10.6 mmol), phenol (15.0 g, 159 mmol), H_2SO_4 (20 mg, 0.20 mmol), H_3BO_3 (5 mg, 0.08 mmol), and toluene (25 ml) was refluxed under a water separator for 1 h. Water (60 ml) was added, and the aq layer was separated and extracted with ether (2×30 ml). The combined organic layers were dried (Na_2SO_4), concentrated, and distilled, giving 1.89 g of a fraction, bp 130.0—132.0 °C/0.35 mmHg (1 mmHg=133.322 Pa), which on standing crystallized (mp 65.0—74.0 °C). Recrystallization from ethyl acetate afforded 1.42 g (62%) of **2**: Mp 74.0—76.8 °C; mp 76.5—77.5 °C after further recrystallization; IR (KBr) 1727 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.22 (s, 6H, $C(CH_3)_2$), 5.49 (d, J=1 Hz, 1H, CH), 5.86 (d, J=9.5 Hz, 1H, CH=C<u>H</u>CO), 6.58 (dd, J=9.5, 1 Hz, 1H, C<u>H</u>=CHCO), and 6.9—7.4 (m, 5H, ArH). Found: C, 71.69; H, 6.47%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%.

6-Chloro-5,5-dimethyl-5,6-dihydro-2*H*-pyran-2-one (3). Thionyl chloride (7.00 g, 58.8 mmol) was added with stirring to **1** (7.11 g, 50.0 mmol) during 10 min. The mixture was allowed to stand at room temperature for 20 min and then heated at 65 °C for 20 min. Removal of the excess of thionyl chloride in vacuo and distillation gave 5.18 g (65%) of **3**: Bp 77.0—78.5 °C/0.55 mmHg; IR (neat) 1747 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.27 (s, 3H, CH_3), 1.32 (s, 3H, CH_3), 5.88 (d, J=9.5 Hz, 1H, CH=C<u>H</u>CO), 5.96 (d, J=1.5 Hz, 1H, CH), and 6.66 (dd, J=9.5, 1.5 Hz, 1H, C<u>H</u>=CHCO). Found: C, 52.17; H, 5.85%. Calcd for $C_7H_9ClO_2$: C, 52.35; H, 5.65%.

5,5-Dimethyl-6-(*p*-tolylthio)-5,6-dihydro-2*H*-pyran-2-one (4). A solution of **3** (1.50 g, 9.34 mmol) and *p*-toluenethiol (1.67 g, 13.4 mmol) in pyridine (8.0 ml) was refluxed for 5 h. Water (40 ml) was added and the mixture was extracted with ether (3×30 ml). The ethereal extract was dried (Na_2SO_4), concentrated, and distilled to give 1.93 g (83%) of **4**: Bp 141.0—143.0 °C/0.25 mmHg; mp 71.5—75.0 °C; mp 75.0—75.6 °C after recrystallization from cyclohexane; IR (KBr) 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.22 (s, 3H, CH_3), 1.28 (s, 3H, CH_3), 2.26 (s, 3H, $ArCH_3$), 5.20 (s, 1H, CH), 5.74 (d, J=9.5 Hz, 1H, CH=C<u>H</u>CO), 6.51 (d, J=9.5 Hz, 1H, C<u>H</u>=CHCO), and 6.9—7.4 (m, 4H, ArH). Found: C, 67.74; H, 6.53%. Calcd for $C_{14}H_{16}O_2S$: C, 67.71; H, 6.49%.

6-Anilino-5,5-dimethyl-1-phenyl-5,6-dihydro-2(1*H*)-pyridinone (5). A mixture of **3** (0.287 g, 1.79 mmol) and aniline (1.01 g, 10.8 mmol) was heated at 100 °C for 2 h. Water (5 ml) was added, and the mixture was extracted with ether (3×5 ml). The ethereal extract was dried (Na_2SO_4) and concentrated. After removal of the excess of aniline in vacuo, the residual solid was recrystallized from benzene-hexane, giving 0.326 g (62%) of **5**: Mp 135.5—139.0 °C; mp 141.0—141.7 °C after further recrystallization; IR (KBr) 3305 (NH), 1655 (C=O), and 1610 cm^{-1} (sh, C=C); ^1H NMR ($CDCl_3$) δ=1.20 (s, 3H, CH_3), 1.42 (s, 3H, CH_3), 4.42 (br d, J=11 Hz, 1H, NH), 4.92 (br dd, J=11, 1.5 Hz, 1H, CH), 6.00 (d, J=10 Hz, 1H, CH=C<u>H</u>CO), 6.32 (dd, J=10, 1.5 Hz, 1H, C<u>H</u>=CHCO), and 6.2—7.4 (m, 10H, ArH). Addition of

D_2O resulted in loss of the signal at 4.42 and collapse of the signal at 4.92 to a doublet (J=1.5 Hz). Found: C, 78.35; H, 6.91; N, 9.29%. Calcd for $C_{19}H_{20}N_2O$: C, 78.05; H, 6.89; N, 9.58%.

6-(2,4-Dinitrophenylhydrazino)-5,5-dimethyl-5,6-dihydro-2*H*-pyran-2-one (6). To a hot solution of 2,4-dinitrophenylhydrazine (0.204 g, 1.03 mmol) in 0.1 M HCl (60 ml) was added **1** (0.141 g, 0.992 mmol) in water (2.0 ml). The mixture was heated under reflux for 8 h. The crude solid was collected, washed with water, dried, and recrystallized from ethyl acetate to afford 0.163 g (51%) of **6**: Mp 173.5—176.0 °C; mp 176.0—176.5 °C after an additional recrystallization from benzene; IR (KBr) 3370, 3348 (NH), 1670 (C=O), and 1614 cm^{-1} (C=C); ^1H NMR [$(CD_3)_2SO$] δ=1.19 (s, 3H, CH_3), 1.28 (s, 3H, CH_3), 4.81 (dd, J=5, 1 Hz, 1H, CH), 5.82 (d, J=9.5 Hz, 1H, CH=C<u>H</u>CO), 6.58 (dd, J=9.5, 1 Hz, 1H, C<u>H</u>=CHCO), 6.79 (br d, J=5 Hz, 1H, N<u>H</u>NHAr), 7.26—8.82 (m, 3H, ArH), and 9.97 (br s, 1H, NHN<u>H</u>Ar). Addition of D_2O resulted in loss of the signals at 6.79 and 9.97 and collapse of the signal at 4.81 to a doublet (J=1 Hz). Found: C, 48.25; H, 4.19; N, 17.24%. Calcd for $C_{13}H_{14}N_4O_6$: C, 48.45; H, 4.38; N, 17.38%.

(*E*)-4,4-Dimethyl-5-oxo-2-pentenoic Acid (7). A mixture of methyl (*E*)-5-(*t*-butylimino)-4,4-dimethyl-2-pentenoate[2] (21.2 g, 0.100 mol) and 4 M HCl (150 ml) was refluxed for 5 h. The reaction mixture was extracted with ether (3×50 ml). The ethereal extract was washed with water, dried (Na_2SO_4), concentrated, and distilled to give 10.6 g (75%) of **7**: Bp 115.0—117.0 °C/0.20 mmHg; mp 55.5—56.1 °C; IR (KBr) 3000 (OH), 2815, 2700 (CHO), 1720, 1682 (C=O), 1635 (C=C), and 988 cm^{-1} (H>C=C<H); ^1H NMR (CCl_4) δ=1.28 (s, 6H, $C(CH_3)_2$), 5.81 (d, J=16 Hz, 1H, CH=C<u>H</u>COOH), 7.00 (d, J=16 Hz, 1H, C<u>H</u>=CHCOOH), 9.37 (s, 1H, CHO), and 11.98 (br s, 1H, COOH). Found: C, 58.85; H, 7.16%. Calcd for $C_7H_{10}O_3$: C, 59.14; H, 7.09%.

1-Aryl-4,4-dimethyl-4,5-dihydro-1*H*-pyrazole-5-acetic Acids (8). Typical examples are as follows:

A: A solution of *p*-nitrophenylhydrazine (0.161 g, 1.05 mmol) in acetic acid-water (1:1, w/w) (3.0 ml) was refluxed with **1** (0.144 g, 1.01 mmol) for 3 h. Water (5.0 ml) was added and the mixture was cooled. The crystalline product was collected, washed with water, and dried, giving 0.234 g (83%) of **8** (R=*p*-NO_2), mp 195.3—196.3 °C. An analytical sample was prepared by recrystallization from ethanol-cyclohexane.

B: A solution of *p*-chlorophenylhydrazine hydrochloride (0.186 g, 1.04 mmol) and anhydrous sodium acetate (0.085 g, 1.04 mmol) in acetic acid-water (1:1, w/w) (3.0 ml) was refluxed with **7** (0.142 g, 1.00 mmol) for 3 h. Working up as described above gave 0.219 g (82%) of **8** (R=*p*-Cl), mp 128.0—130.0 °C. An analytical sample was prepared by recrystallization from ethanol-cyclohexane.

(3*E*,9*E*,15*E*)-6,12,18-Trichloro-5,5,11,11,17,17-hexamethyl-1,7,13-trioxacyclooctadeca-3,9,15-triene-2,8,14-trione (9). Thionyl chloride (8.85 g, 74.4 mmol) was added dropwise to **7** (10.0 g, 70.3 mmol) during 10 min. The mixture was allowed to stand overnight at room temperature. The resulting solid was recrystallized from chloroform to give 3.59 g of **9**, mp 153.5—156.7 °C. Further recrystallization from the mother liquor afforded an additional 1.87 g, mp 150.5—155.0 °C; overall yield 48%. The pure sample after additional recrystallizations had mp 156.8—157.5 °C: IR (KBr) 1754 (C=O), 1628 (C=C), and 987 cm^{-1} (H>C=C<H); ^1H NMR ($CDCl_3$) δ=1.15 (s, 18H, $6CH_3$), 4.61 (s, 3H, 3CH), 6.01 (d, J=15.5 Hz, 3H, 3CH=C<u>H</u>CO), and 7.18 (d, J=15.5 Hz, 3H, 3C<u>H</u>=CHCO); MS *m/z* (rel intensity) 447 (6), 446 (2), 445 (9), and 125 (100). Found: C, 52.48; H, 5.46; Cl, 22.04%; M, 480 (measured with a Corona 117 vapor pressure osmometer). Calcd for $C_{21}H_{27}Cl_3O_6$: C, 52.35; H, 5.65; Cl, 22.08%; M, 481.8.

Compound 10a. A solution of 0.483 g (1.00 mmol) of **9** in 50 ml of tetrahydrofuran containing 1.0 ml of water was kept at room temperature for 15 h. The solution was concentrated in vacuo to ca. 2 ml. Water (10 ml) was added and the mixture was extracted with chloroform (3×20 ml). The chloroform extract was dried (Na_2SO_4) and evaporated in vacuo. The residual solid was dried at 110 °C in vacuo for 3 h and recrystallized from chloroform to afford 0.378 g (88%) of **10a**: Mp 200.3—201.8 °C; IR (KBr) 3000 (OH), 1692 (C=O), 1649 (C=C), and 983 cm^{-1} (H>C=C<H); ^1H NMR ($CDCl_3$) δ=1.10 (s, 18H, $6CH_3$), 4.51 (s, 3H,3CH), 5.82 (d, J=16 Hz, 3H, 3CH=C<u>H</u>CO), 7.02 (d, J=16 Hz, 3H, 3C<u>H</u>=CHCO), and 11.8 (br s, 3H, 3OH); MS (CI) *m/z* 427 $(M+H)^+$. Found: C, 59.14; H, 6.99%. Calcd for $C_{21}H_{30}O_9$: C, 59.14; H, 7.09%.

Compound 10b. To a stirred solution of **9** (0.482 g, 1.00 mmol) in chloroform (20 ml) was added a solution of aniline (0.281 g, 3.02 mmol) and triethylamine (0.304 g, 3.00 mmol) in chloroform (5 ml) during 15 min. Stirring was continued for an additional 3 h. The mixture was washed with water (3×25 ml) and dried (Na_2SO_4). The solvent was removed in vacuo and the residual solid was recrystallized from chloroform, giving 0.546 g (84%) of **10b**: Mp 138.5—140.5 °C; mp 141.0—142.0 °C after further recrystallization; IR (KBr) 3270 (NH), 1663 (C=O), and 977 cm^{-1} (H>C=C<H); ^1H NMR ($CDCl_3$) δ=1.01 (br s, 18H, $6CH_3$), 4.49 (s, 3H, 3CH), 6.01 (d, J=15 Hz, 3H, 3CH=C<u>H</u>CO), 6.92 (d, J=15 Hz, 3H, 3C<u>H</u>=CHCO), 6.9—7.7 (m, 15H, ArH), and 8.45 (br s, 3H, 3NH); MS *m/z* 651 (M^+). Found: C, 71.59; H, 6.84; N, 6.39%. Calcd for $C_{39}H_{45}N_3O_6$: C, 71.87; H, 6.96; N, 6.45%.

Pseudo-Sugars. XIV. Synthesis of Sweet-Tasting Pseudo-β-DL-fructopyranose

Tetsuo SUAMI,* Seiichiro OGAWA, Makoto TAKATA, Kuninobu YASUDA, Kiyoshi TAKEI, and Atsuo SUGA
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Yokohama 223
(Received November 16, 1985)

Pseudo-β-DL-fructopyranose was synthesized from DL-1,2-di-*O*-acetyl-(1,3/2)-3-bromomethyl-5-cyclohexene-1,2-diol by a six steps reaction: Dehydrobromination, epoxidation, acetolysis, reduction, and deacetylation, in overall yield of 4.8%. Pseudo-β-DL-fructopyranose was found to be nearly as sweet as D-fructose which is the most sweet sugar known in naturally occurring carbohydrates.

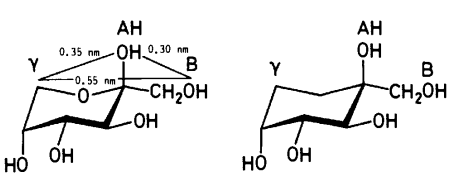
In the preceding paper,[1] it was described that pseudo-β-DL-glucopyranose was equally as sweet as D-glucose. Therefore, a ring-oxygen in a pyranoid sugar plays no important role in an appearance of sweetness and a replacement of the ring-oxygen by a methylene group gives no detrimental effect on an intensity of its sweetness. This is not surprising, since a conformational feature of sweetness eliciting units, an AH (proton donor), a B (proton acceptor)[2-5] and a third hydrophobic component (γ),[6] of the pyranoid sugar with a distance of 0.30 (AH–B), 0.35 (AH–γ) and 0.55 nm (B–γ) is almost the same as those of the pseudo-hexopyranose.

While D-fructose is the most sweet sugar known in naturally occurring carbohydrates and its intense sweetness (1.8 times more sweet than sucrose) is attributable only to a β-D-fructopyranose form.[2,7,8] And it is anticipated that pseudo-β-D-fructopyranose must be fairly sweet. This expectation prompted us to synthesize pseudo-β-DL-fructopyranose (**1**) for an evaluation of its sweetness. A starting material used in the present synthesis is known DL-1,2-di-*O*-acetyl-(1,3/2)-3-bromomethyl-5-cyclohexene-1,2-diol[9] (**3**).

Results and Discussion

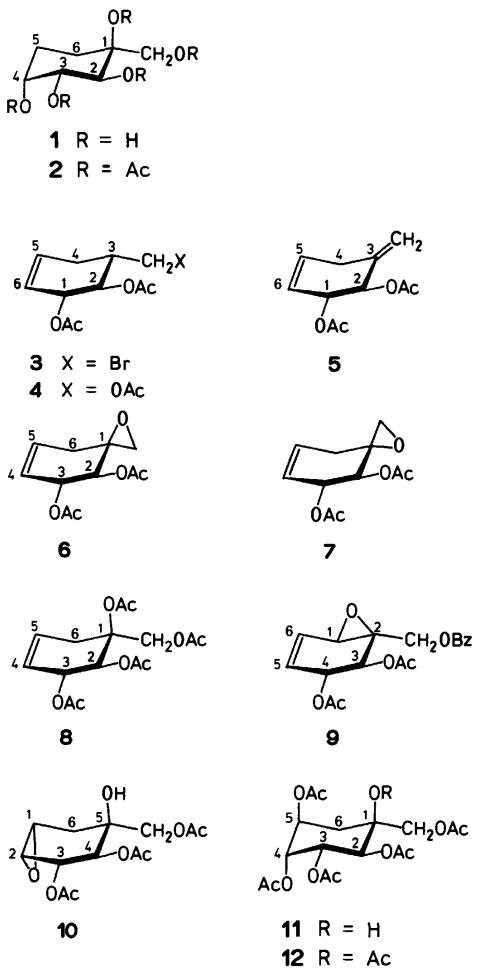
Dehydrobromination of **3** with 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) in toluene afforded the aimed diene diacetate (**5**) as a major product in 56% yield, and the triacetate (**4**) as a minor by-product in 12% yield. The structure of **5** was elucidated by the ^{1}H NMR spectrum that exhibited the two broad singlets due to the methylene protons of the cyclic and exocyclic double bond at δ 3.00 (2H) and 5.05 (3H), respectively. Compound **4** is considered to be formed by a substitution of the bromo group in **3** with an acetate ion generated in situ by a partial deacetylation of **3**.

Preferential epoxidation of the exocyclic double bond in **5** with *m*-chloroperbenzoic acid (*m*CPBA) in the presence of phosphate buffered solution (pH 8) gave the epoxide (**6**) in 52% yield (based on **5** consumed) and a complex mixture which consisted



β-D-Fructopyranose Pseudo-β-D-fructopyranose

Scheme 1.



Formulas depict only one of the respective enantiomers.

Scheme 2.

mainly of another epoxide (**7**).[10] The structure of **6** was deduced from the following successive reactions.

Nucleophilic opening of the oxirane ring of **6** with an acetate ion, followed by acetylation with acetic anhydride and 4-dimethylaminopyridine (DMAP) gave the crystalline tetraacetate (**8**) as a sole product in 81% yield. The structure of **8** was elucidated by the fact that **8** was also obtained from known DL-3,4-di-*O*-acetyl-1,2-anhydro-(1,2,3/4)-2-*C*-benzoyloxymethyl-5-cyclohexene-1,2,3,4-tetrol[11] (**9**) by $LiAlH_4$ reduction, hydrolysis and subsequent acetylation.

Deacetylation of **8** in methanolic sodium methoxide and successive epoxidation with *m*CPBA in acetic acid for 6 d, followed by acetylation afforded the epoxide triacetate (**10**) in 59% yield, as well as the pentaacetate (**11**) in 12% yield. The structure of **10** was established by the ^1H NMR spectrum that showed a doublet of doublets at δ 3.50 (J=4.2 and 2.3 Hz), a doublet of doublets at δ 5.58 (J=9 and 2.3 Hz), and another doublet at δ 5.18 (J=9 Hz). These signals were attributable to H-2, H-3, and H-4, respectively. The structure of **11** was also assigned by the ^1H NMR spectrum that revealed four sharp singlets due to the five acetoxyl groups at δ 1.98 (3H), 2.07 (3H), 2.09 (6H), and 2.11 (3H). Furthermore, an exhaustive acetylation of **11** with acetic anhydride in the presence of DMAP gave the crystalline hexaacetate (**12**), which showed four sharp singlets ascribed to the six acetoxyl groups at δ 1.96 (3H), 2.04 (9H), 2.06 (3H), and 2.10 (3H) in its ^1H NMR spectrum.

Epoxidation of the double bond of the deacetylated **8** with *m*CPBA in acetic acid seemed to proceed stereoselectively with a cis-directing effect of the vicinal hydroxyl group on C-3[12] and **10** was obtained as a primary product, and a part of **10** was converted to **11** by hydrolysis during the prolonged reaction period of 6 d.

Reduction of **10** with $LiAlH_4$ in THF, followed by acetylation afforded the pentaacetate (**2**), mp 147—148 °C in 34% yield. The ^1H NMR spectrum of **2** revealed a doublet of doublets at δ 5.17 (J=10.5 and 3.3 Hz) which was due to an axial proton on C-3 coupled with an equatorial proton on C-4. The reaction seemed to proceed regioselectively through a reductive opening of the oxirane ring which was conducted by an existence of an axial tertiary hydroxyl group on C-5.[13]

Deacetylation of **2** in methanolic sodium methoxide gave pseudo-β-DL-fructopyranose **1** as a syrup in a quantitative yield. An evaluation of an intensity of its sweetness was carried out with six college personnel by a comparison with D-fructose, and **1** was found to be nearly as sweet as D-fructose.

Experimental

General. Melting points were determined on a Büchi 510 capillary melting point apparatus and are uncorrected. ^1H NMR spectra were taken on a Varian EM-390 (90 MHz) in chloroform-*d* with a reference to tetramethylsilane as an internal standard. TLC was performed on a plate coated with silica gel 60 F-254 (Merck, Darmstadt). The silica gel used for a column chromatography was Wakogel C-300 (Wako Co., Osaka). Organic solutions were dried over anhydrous sodium sulfate and concentrated below 45 °C under reduced pressure.

DL-(1,3/2)-1,2-Diacetoxy-3-acetoxymethyl-5-cyclohexene (4) and DL-*trans*-1,2-diacetoxy-3-methylene-5-cyclohexene (5). A mixture of DL-(1,3/2)-1,2-diacetoxy-3-bromomethyl-5-cyclohexene[9] (**3**) (22.3 g, 77 mmol), DBU (25 ml, 160 mmol) and toluene (250 ml) was stirred at 120 °C for 2.5 h. The cooled mixture was washed successively with 1 M hydrochloric acid(1 M=1 mol dm^{-3}), aqueous sodium hydrogencarbonate and water, dried, and concentrated, giving 15.8 g of a crude mixture of products. Chromatography on a silica-gel column (390 g) with ethyl acetate-toluene (1:20, v/v) as an eluant gave 9.1 g (56%) of **5** as a syrup: TLC, R_f=0.44 (ethyl acetate-toluene, 1:8); ^1H NMR ($CDCl_3$, 90 MHz) δ=2.04 (3H, s) and 2.10 (3H, s) (2 OAc), 2.87—3.03 (2H, m, H-4 and 4'), 5.00—5.10 (3H, m, H-1, 7, and 7'), 5.44 (1H, narrow m, H-2), 5.60 (1H, dq, $J_{5,6}$=10,5 Hz, $J_{1,5}$=$J_{4,5}$=$J_{4',5}$=2 Hz, H-5), 5.89 (1H, dt, $J_{1,6}$=$J_{4,6}$=3.4 Hz, H-6).

Found: C, 62.85; H, 6.71%. Calcd for $C_{11}H_{14}O_4$: C, 62.61; H, 6.67.

Another fraction gave 2.6 g (12%) of **4** as a syrup: TLC, R_f=0.20 (ethyl acetate-toluene, 1:8). ^1H NMR ($CDCl_3$, 90 MHz) δ=2.00 (6H, s) and 2.03 (3H, s) (3 OAc), 3.92 (1H, dd, $J_{3,7}$=5 Hz, J_{7gem}=11.3 Hz, H-7), 4.20 (1H, dd, $J_{3,7'}$=3.5 Hz, H-7'), 5.13 (1H, dd, $J_{1,2}$=7.5 Hz, $J_{2,3}$=11.5 Hz, H-2).

Found: C, 58.08; H, 6.72%. Calcd for $C_{13}H_{18}O_6$: C, 57.77; H, 6.71%.

DL-2,3-Di-*O*-acetyl-1,7-anhydro-(1,2/3)-1-*C*-hydroxymethyl-4-cyclohexene-1,2,3-triol (6). A mixture of **5** (2.1 g, 10 mmol), *m*CPBA (1.73 g, 10 mmol), 1,2-dichloroethane (60 ml), and 0.1 M phosphate buffer solution (pH 8) (30 ml) was stirred vigorously at 0—5 °C for 20 h. The mixture was washed with 10% aqueous sodium thiosulfate (10 ml), and the organic layer was dried and concentrated, giving 2.3 g of a syrup. Chromatography on silica-gel column (200 g) with 2-butanone-toluene (1:2, v/v) gave 0.75 g (52% yield based on **5** consumed) of **6** and 0.27 g of a mixture which consisted mainly of the isomeric epoxide (**7**), together with 0.92 g of **2** (recovered yield 44%). ^1H NMR ($CDCl_3$, 90 MHz) for **6**, δ=2.05 (3H, s) and 2.08 (3H, s) (2 OAc), 2.40 (2H, br s, H-6 and 6'), 2.70 (1H, d) and 2.08 (1H, d) ($J_{4,5}$=4.5 Hz, H-4 and 5), 5.06 (1H, d, $J_{2,3}$=6 Hz, H-2), 5.40—5.60 (1H, br d, H-3), 5.72 (1H, br dq, $J_{4,5}$=10.5 Hz, H-5), 5.95 (1H, dt, $J_{3,4}$=$J_{4,6}$=3.4 Hz, H-4), and for **7**, δ=2.56 (2H, d, J=6 Hz, H-6 and 6'), 2.82 (2H, br s, H-7 and 7'), 5.62 (1H, br d) and 5.91 (1H, br d) (J=12 Hz, H-4 and 5).

Found for **6**: C, 58.14; H, 6.26%. Calcd for $C_{11}H_{14}O_5$: C, 58.40; H, 6.24%.

DL-1,2,3-Tri-*O*-acetyl-(1,2/3)-1-*C*-acetoxymethyl-4-cyclohexene-1,2,3-triol (8). A mixture of **6** (0.44 g, 1.9 mmol), anhydrous sodium acetate (0.47 g, 5.7 mmol), and 90% aqueous 2-methoxyethanol (10 ml) was stirred at 75 °C for 2 h. The mixture was concentrated and the residue was treated with acetic anhydride (5 ml) and pyridine (5 ml) in the presence of DMAP (40 mg) at 75 °C for 14 h. The

product was purified by a silica-gel column with 2-butanone–toluene (1:10, v/v) as an eluant, giving crystals which were recrystallized from a small amount of water to yield 0.52 g (81%) of **8** as prisms; mp 76—77 °C. ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.00 (6H, s), 2.04 (3H, s), and 2.06 (3H, s) (4 OAc), 2.56 (1H, br dd, $J_{5,6}$=2.3 Hz, J_{6gem}=18.5 Hz, H-6), 3.19 (1H, dd, $J_{5,6'}$=3.5 Hz, H-6'), 4.52 (2H, s, C$\underline{H}_2$OAc), 5.36 (1H, d, $J_{2,3}$=7.5 Hz, H-2), 5.50—5.77 (3H, m, H-3, 4, and 5).

Found: C, 54.91; H, 6.03%. Calcd for $C_{15}H_{20}O_8$: C, 54.87; H, 6.03%.

Preparation of 8 from DL-3,4-Di-*O*-acetyl-1,2-anhydro-(1,2,3/4)-2-*C*-benzoyloxymethyl-5-cyclohexene-1,2,3,4-tetrol[11] (9). A mixture of **9** (0.10 g), $LiAlH_4$ (33 mg, 3 molar equiv), and THF (3 ml) was stirred at room temperature for 2 h. Excess reagent was decomposed by addition of ethyl acetate, the precipitates were filtered and the filtrate was concentrated. The residue was acetylated with acetic anhydride and pyridine at 60 °C for 28 h, and the product was purified by a silica-gel column, giving 23 mg (24%) of **8** as a syrup, the ^{1}H NMR spectrum of which was superposable on that of the compound obtained before.

DL-3,4-Di-*O*-acetyl-1,2-anhydro-(1,2,3/4,5)-5-*C*-acetoxymethyl-1,2,3,4,5-cyclohexanepentol (10) and DL-2,3,4,5-Tetra-*O*-acetyl-(1,2,5/3,4)-1-*C*-acetoxymethyl-1,2,3,4,5-cyclohexanepentol (11). To a solution of **8** (0.28 g, 0.85 mmol) in methanol (2 ml) was added 1 M methanolic sodium methoxide (0.15 ml), and the mixture was stirred at room temperature for 20 min. After neutrallization with Amberlite IR-120 (H^+) resin, the solution was concentrated. The residue was dissolved in acetic acid (2 ml) and treated with *m*CPBA (0.29 g, 1.7 mmol) at room temperature for 6 d. The mixture was processed in the usual way and the products were acetylated with acetic anhydride and pyridine. Fractionation of the crude products on a silica-gel column with ethyl acetate–hexane (2:3, v/v) as an eluant gave first 0.15 g (59%) of **10** as a syrup: ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.05 (3H, s), 2.07 (3H, s), and 2.10 (3H, s) (3 OAc), 2.65 (1H, br s, OH), 3.33 (1H, td, $J_{1,2}$=4.2 Hz, $J_{1,6}$=4 Hz, $J_{1,6'}$=ca. 1 Hz, H-1), 3.50 (1H, dd, $J_{2,3}$=2.3 Hz, H-2), 3.74 (1H, d) and 4.03 (1H, d) (J_{7gem}=11 Hz, C$\underline{H}_2$OAc), 5.18 (1H, d, $J_{3,4}$=9 Hz, H-4), 5.58 (1H, dd, H-3).

Found: C, 51.65; H, 5.84%. Calcd for $C_{13}H_{18}O_8$: C, 51.65; H, 6.00%.

The second fraction gave 0.04 g (12%) of **11** as a syrup: ^{1}H NMR ($CDCl_3$, 90 MHz) δ=1.98 (3H, s), 2.07 (3H, s), 2.09 (6H, s), and 2.11 (3H, s) (5 OAc), 3.87 (1H, d) and 4.07 (1H, d) (J_{7gem}=11.3 Hz, C$\underline{H}_2$OAc), 5.02 (1H, q, $J_{4,5}$=$J_{5,6}$=$J_{5,6'}$=*ca.* 4 Hz, H-5), 5.36 (1H, dd, $J_{3,4}$=3 Hz, H-4), 5.51 (1H, dd, $J_{2,3}$=9.8 Hz. H-3).

Compound **11** (22 mg, 0.05 mmol) was acetylated in the presence of DMPA, and the product was purified by a silica-gel column with 2-butanone–toluene (1:4, v/v) as an eluant to give the hexaacetate (**12**) (25 mg, 100%) as prisms; mp 135.5—136 °C. ^{1}H NMR ($CDCl_3$, 90 MHz) δ=1.96 (3H, s), 2.04 (9H, s), 2.06 (3H, s), and 2.10 (3H, s) (6 OAc), 4.40 (2H, s, C$\underline{H}_2$OAc), 5.09 (1H, q, $J_{4,5}$=$J_{5,6}$=$J_{5,6'}$=3 Hz, H-5), 5.29—5.59 (3H, m, H-2, 3, and 4).

Found: C, 50.88; H, 5.72%. Calcd for $C_{19}H_{26}O_{12}$: C, 51.12; H, 5.87%.

DL-1,2,3,4-Tetra-*O*-acetyl-(1,2/3,4)-1-*C*-acetoxymethyl-1,2,3,4-cyclohexanetetrol (2). To a solution of **10** (81 mg) in THF (10 ml) was added $LiAlH_4$ (52 mg, 5 molar equiv) and the mixture was refluxed for 0.5 h. After water had been added, an insoluble material was removed by filtration. The filtrate was concentrated and the residue was acetylated in the presence of DMAP. The product was purified by a silica-gel column with 2-butanone–toluene (1:10, v/v) as an eluant, giving 35 mg (34%) of **2** as prisms; mp 147—148 °C. ^{1}H NMR ($CDCl_3$, 90 MHz) δ=1.96 (3H, s), 2.05 (6H, s), and 2.13 (6H, s) (5 OAc), 4.48 (2H, s, C$\underline{H}_2$OAc), 5.17 (1H, dd, $J_{2,3}$=10.5 Hz, $J_{3,4}$=3.3 Hz, H-3), 5.45 (1H, d, H-2), 5.30—5.52 (2H, m, H-4 and 5).

Found: C, 52.58; H, 6.23%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.81; H, 6.21%.

DL-(1,2/3,4)-1-*C*-Hydroxymethyl-1,2,3,4-cyclohexanetetrol (Pseudo-β-DL-fructopyranose) (1). A mixture of **2** (56 mg) and methanol (0.5 ml) containing 1 M methanolic sodium methoxide (15 μl) was stirred at room temperature for 2.5 h. The mixture was then passed through a short column of Amberlite IR-120 (H^+) resin and concentrated, giving 26 mg (100%) of **1** as a syrup.

Found: C, 47.43; H, 7.78%. Calcd for $C_7H_{14}O_5$: C, 47.19; H, 7.92%.

The authors wish to thank Mr. Saburo Nakada for his elementary analyses, and to Mr. Tohei Takagaki and Mr. Yasushi Shibata for their assistance in the preparative experiments.

The Hydrogenation of Benzil Catalyzed by Cobalt(II) Dimethylglyoxime Complex

Keisuke MITA
Osaka Municipal Technical Research Institute, Morinomiya, Joto-ku, Osaka 536
(Received May 21, 1985)

Kinetic studies on the catalytic hydrogenation of benzil to benzoin by bis(dimethylglyoximato)cobalt(II), $Co(Hdmg)_2$, were carried out by varying the concentration of $Co(Hdmg)_2$ and pyridine. The initial rate of the hydrogenation reaction was first order with respect to the overall cobalt concentration at a constant overall pyridine concentration. On the other hand, the rate passed through a peak as the overall pyridine concentration was increased at a constant overall cobalt concentration. The peak was observed at $[py]_T = 130\ mmol\ dm^{-3}$, where the square bracket denotes the concentration in the liquid phase. These results show that the initial reaction rate, V_{in}, can be expressed by the following rate equation,

$$V_{in} = k[Co(Hdmg)_2]\frac{58[py]_T}{1+58[py]_T},$$

where, $k=1.1\ min^{-1}$.

It has been known that bis(dimethylglyoximato)-cobalt(II), $Co(Hdmg)_2$, referred to as cobaloxime, shows a catalytic activity for the hydrogenation of certain unsaturated organic compounds in the presence of bases such as pyridine.[1] The influence of the concentration of cobalt and pyridine on the rate of hydrogenation has been studied by various researchers. Simandi and coworkers studied the hydrogenation of free dimethylglyoxime added in excess of the amount required for cobaloxime formation at a constant pyridine concentration.[2] Due to the influence of the cobalt concentration, they observed that the initial rate of the hydrogenation was second order with respect to the overall cobalt concentration. Yamakawa and coworkers studied the hydrogenation of benzil in the presence of 4,4′-trimethylenebis(pyridine) as a base at a constant ratio of the cobalt and the base.[3] They also found that the initial rate of hydrogenation was second order with respect to the overall cobalt concentration. In a previous paper, we reported that a plot of the reaction rate vs. the overall cobalt concentration gave a sigmoidal curve for benzil hydrogenation at a constant cobalt-pyridine ratio.[4]

Due to the influence of base concentrations, Yamakawa and coworkers reported that the initial reaction rate increased and remained constant as the concentration of base was increased.[3] Tylrik and coworkers studied the asymmetric hydrogenation of benzil in the presence of quinine or morpholine.[5] They also reported that the initial reaction rate increased and remained constant as the concentration of the base was increased.

The second-order dependence of the reaction rate on the cobalt concentration implies that two molecules of cobaloxime(II) are required to activate one molecule of H_2.[2] Although, due to the influence of the concentration of base, a mechanism in which excess base act as a proton acceptor and accelerate the H–H bond cleavage has been proposed,[2,6,8] no kinetic model that can quantitatively explain the dependency of the reaction rate on the base concentration has ever been proposed for catalytic hydrogenation by $Co(Hdmg)_2$.

In this work, kinetic studies on the catalytic hydrogenation of benzil to benzoin by $Co(Hdmg)_2$ were carried out. From the rate data obtained for various concentrations of $Co(Hdmg)_2$ and pyridine, it was found that the initial reaction rate was first order with respect to the overall cobalt concentration at a constant pyridine concentration and that the initial reaction rate passed through a peak as the pyridine concentration was increased at a constant overall cobalt concentration. These results could be successfully interpreted by a rate law which shows a first-order dependence on the concentration of $Co(Hdmg)_2py$ at a constant pyridine concentration. A kinetic model that can quantitatively explain the dependency of the reaction rate on the concentration of pyridine was also proposed.

Experimental

A 27 cm^3 methanol solution of $Co(Hdmg)_2$ was prepared by mixing $Co(NO_3)_2 \cdot 6H_2O$, dimethylglyoxime (H_2dmg), and NaOH in a ratio of 1:2:2 under a hydrogen atmosphere. The preliminary hydrogen uptake (H_2 uptake) was initiated by the injection of an appropriate amount of pyridine and a 1.5 cm^3 deoxygenated toluene solution of benzil to the reaction vessel under vigorous stirring. Just before the preliminary H_2 uptake was completed, 1.5 cm^3 of the methanol solution of benzil was again injected. The hydrogenation was carried out under an atmospheric pressure of hydrogen at 20 °C and was followed by measuring the volume of the H_2 uptake using a gas burette.

The H_2 uptake rate was almost constant at the first ca. 1—5 min and then droped. Therefore, the average volume of the H_2 uptake during the 2nd and 3rd minute was taken

as the initial reaction rate, V_{in}. This rate was found to increase and to saturate with increased stirring. The rate measurement was performed under conditions where the rate was independent of stirring. The reproducibility for measurements of the H_2 uptake rate was good. An analysis by gas chromatography showed that benzoin was the only product of the reaction.

Results

During this experiment, the same methanol solution of $Co(Hdmg)_2$ and pyridine was repeatedly used four times for the hydrogenation of 1.5, 1.5, 3.0, and 1.5 mmol benzil according to the method described in the Experimental section. After each incremental addition of benzil, the initial H_2 uptake rate was measured. As a typical example, Fig.1 shows that the initial rate increased after the first run and then became almost constant over the 2nd—4th runs. The results show that the initial rate of H_2 uptake was independent of the concentration of benzil, in agreement with results from the literature.[2,4] It can also be seen from Fig. 1 that the decomposition of $Co(Hdmg)_2$ or its pyridine adducts is negligible under the present experimental conditions. However, it is not clear why the rate of the lst run is lower compared with those of the other runs. Therefore, in all the experiments described here, the initial H_2 uptake rate of the 2nd run was taken as a measure of the catalytic activity in order to obtain a reproducible hydrogenation activity.

Figure 2 shows the dependence of the initial rate of H_2 uptake on $[Co]_T$ for the hydrogenation of benzil at a constant $[py]_T$, where $[Co]_T$ is the initial overall $Co(Hdmg)_2$ concentration and $[py]_T$ is the initial overall pyridine concentration. It can be seen from Fig. 2 that the initial rate of H_2 uptake (V_{in}) is first order with respect to $[Co]_T$,

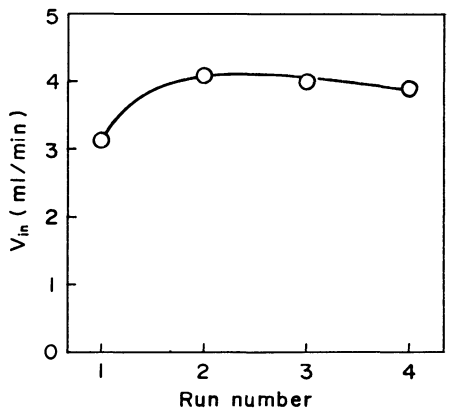

Fig. 1. Activity change of $Co(Hdmg)_2$–pyridine system for the hydrogenation of benzil.
$[Co]_T$: 13 mmol dm^{-3}, $[py]_T$: 330 mmol dm^{-3}, volume of catalytic solution: 30 cm^3, Temp: 20 °C, H_2 pressure: 1 atm, [benzil]: 25 mmol dm^{-3}.

$$V_{in} = k[Co]_T. \quad (1)$$

It can also be seen from Fig. 2 that the initial rate of H_2 uptake increases and then passes a peak as $[py]_T$ increases at a constant$[Co]_T$. The peak was observed at $[py]_T$=130 mmol dm^{-3}. As a typical example, the initial H_2 uptake rate at $[Co]_T$=13 mmol dm^{-3} was ploted against $[py]_T$ using the data in Fig. 2. This plot was indicated in Fig. 3 by a open circle.

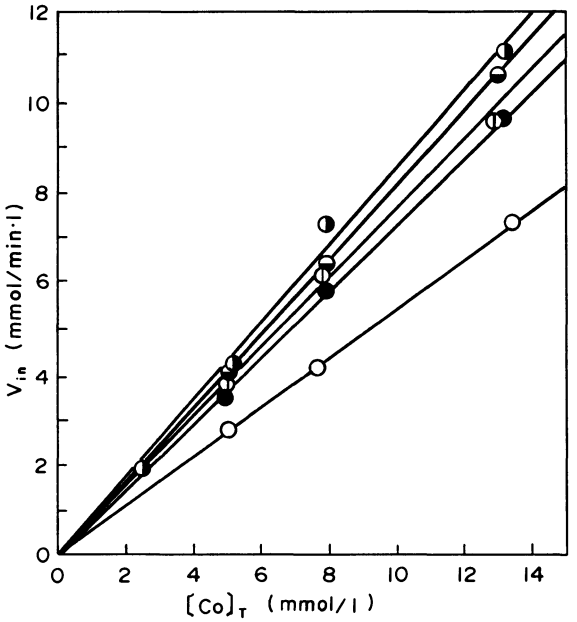

Fig. 2. Dependence of the initial rate of H_2 uptake (V_{in}) on $[Co]_T$.
$[py]_T$=33 (○), 66 (◑), 130 (◑), 330 (◒), and 530 mmol dm^{-3} (●).

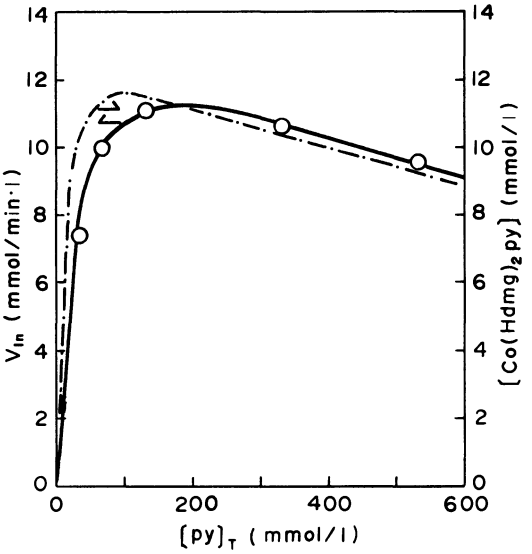

Fig. 3. Plots of V_{in} vs. $[py]_T$ (○: experimental, ——: calculated from Eq. 9) and plots of $[Co(Hdmg)_2py]$ vs. $[py]_T$ (----: calculated by using K_1=186 and K_2=0.75 dm^3 mol^{-1}). $[Co]_T$=13 mmol dm^{-3}.

Discussion

In a solution containing $Co(Hdmg)_2$ and pyridine, the following successive coordination equilibria are readily achieved.

$$Co(Hdmg)_2 + py \overset{K_1}{\rightleftharpoons} Co(Hdmg)_2py \quad (2)$$

$$Co(Hdmg)_2py + py \overset{K_2}{\rightleftharpoons} Co(Hdmg)_2py_2 \quad (3)$$

The stepwise stability constants (K_1 and K_2) were determined using the visible absorption spectra.[2] The calculated values are: K_1=186 and K_2=0.75 $dm^3\,mol^{-1}$.

According to the literature,[2,5,7] $Co(Hdmg)_2py_2$ dose not interact with molecular H_2. In the present experiment, the hydrogenation of benzil by $Co(Hdmg)_2$ did not occur in the absence of pyridine, indicating that $Co(Hdmg)_2$ shows no catalytic activity. Therefore, only $Co(Hdmg)_2py$ can be considered to be active for the hydrogenation of benzil.

The concentration of $Co(Hdmg)_2py$ can be calculated from $[Co]_T$ and $[py]_T$ by using the stepwise stability constants in Eqs. 2 and 3. Introducing the relation between $[Co]_T$ and $[Co(Hdmg)_2py]$, the plots of V_{in} vs. $[Co]_T$ in Fig. 2 were re-formed to the plots of V_{in} vs. $[Co(Hdmg)_2py]$. The plots are shown in Fig. 4. It can be seen from Fig. 4 that at a fixed pyridine concentration the initial H_2 uptake rate is linearly proportional to the concentration of $Co(Hdmg)_2py$ as is given by the following rate equation.

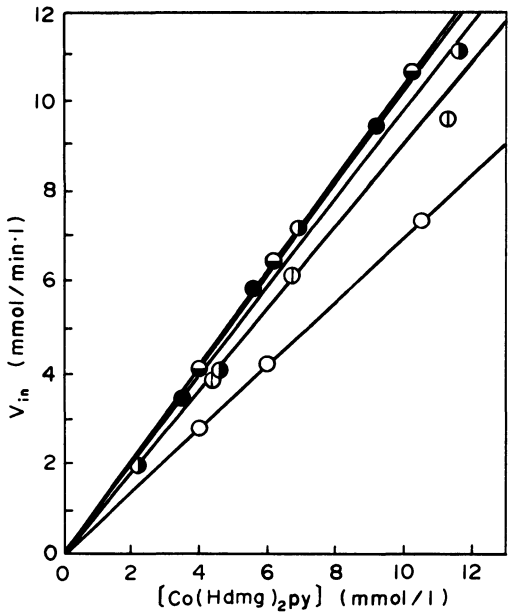

Fig. 4. Plot of V_{in} vs. $[Co(Hdmg)_2py]$.
$[py]_T$ (mmol dm^{-3})=33 (○), 66 (◑), 130 (◑), 330 (◒), and 530 (●).

$$V_{in} = k[Co(Hdmg)_2py] \quad (4)$$

The value of k, that is $V_{in}/[Co(Hdmg)_2py]$, was determined by the slope of the plot in Fig. 4 at each pyridine concentration and Fig. 5 shows the plot of $V_{in}/[Co(Hdmg)_2py]$ vs. $[py]_T$. As is shown in Fig. 5, the value of $V_{in}/[Co(Hdmg)_2py]$ increases and saturates upon increasing the pyridine concentration.

It has been proposed that excess pyridine acts as a proton acceptor and accelerates the H–H bond cleavage in the following manner.[5–7]

$$H_2 + Co(Hdmg)_2py + py \longrightarrow py\cdots H\cdots H\cdots Co(Hdmg)_2py \quad (5)$$

The plot in Fig. 5 also indicate that excess pyridine acts as catalysts together with $Co(Hdmg)_2py$ (in agreement with the literature). The simplest rate law which could be expected for the plot in Fig. 5 is given in Eq. 6.

$$k = k_1\frac{K[py]_T}{1+K[py]_T} \quad (6)$$

By uing Eq. 6, Eq. 4 leads to Eq. 7.

$$V_{in} = k_1[Co(Hdmg)_2py]\frac{K[py]_T}{1+K[py]_T} \quad (7)$$

Thus, the result shown in Fig. 5 was for an analysis according to Eq. 7. It is convenient to transform Eq. 7 into one that gives a straight-line plot. This can be done by taking the reciprocal of both side of Eq. 7 to give Eq. 8,

$$\frac{[Co(Hdmg)_2py]}{V_{in}} = \left(\frac{1}{k_1K}\right)\frac{1}{[py]_T} + \left(\frac{1}{k_1}\right), \quad (8)$$

where the quantities within the parentheses are constant. The plot of $V_{in}/[Co(Hdmg)_2py]$ vs. $[py]_T$ in Fig. 5 was transformed to a plot of $[Co(Hdmg)_2py]/V_{in}$ vs. $1/[py]_T$. As can be seen in Fig. 6, $[Co(Hdmg)_2py]/$

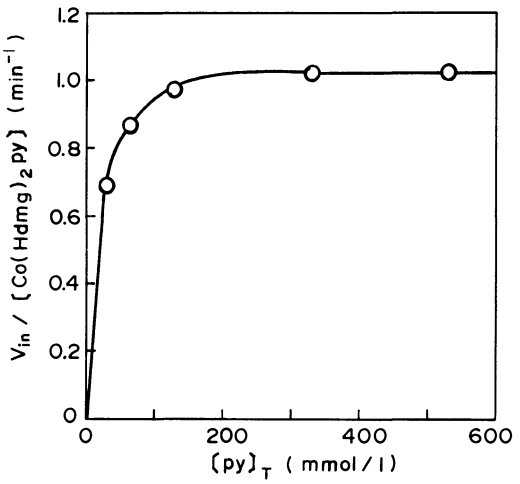

Fig. 5. Plot of $V_{in}/[Co(Hdmg)_2py]$ vs. $[py]_T$.

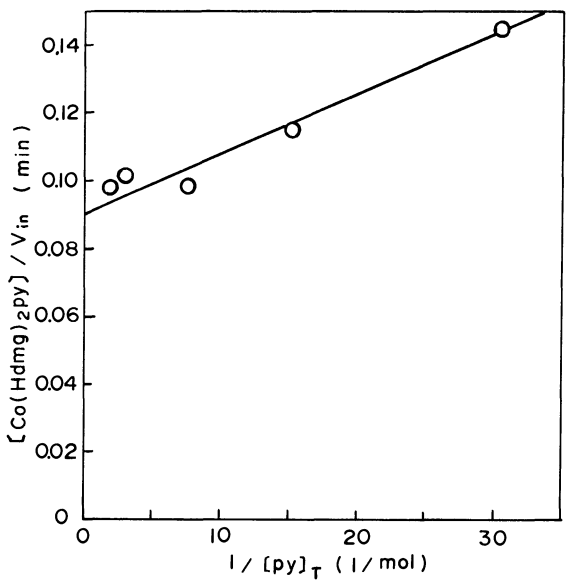

Fig. 6. Plot of $[Co(Hdmg)_2py]/V_{in}$ vs. $1/[py]_T$.

V_{in} is almost linearly proportional to $1/[py]_T$. This confirms the validity of the rate law.

The values of k_1 and K in Eq. 8 can be calculated from the slope and the intercept of the plot in Fig. 6. Finnally, the rate law was expressed as

$$V_{in} = 1.1(min^{-1})[Co(Hdmg)_2py]\frac{58[py]_T}{1+58[py]_T}. \quad (9)$$

The plot of $[Co(Hdmg)_2py]$ vs. $[py]_T$ at a constant $[Co]_T$ was calculated from $[Co]_T$ and $[py]_T$ using the stepwise stability constants in Eqs. 2—3. As a typical example, a plot at $[Co]_T=13$ mmol dm^{-3} is shown in Fig. 3 by a broken line. It can be seen from the plots that the concentration of $Co(Hdmg)_2py$ increased and passes a peak as the pyridine concentration increases. As is shown in Fig. 3, the concentration of pyridine at which the plot of $Co(Hdmg)_2py$ vs. $[py]_T$ shows a peak clearly deviates from that at which the plot of V_{in} vs. $[py]_T$ shows a peak. On the other hand, the V_{in} value which was calculated from Eq. 9 was ploted against $[py]_T$. This plot is shown in Fig. 3 by a real line. An excellent fit was observed between the calculated plot of V_{in} vs. $[py]_T$ and the experimental plot of V_{in} vs. $[py]_T$. This also suggest the validity of Eq. 9.

The value of V_{in} was calculated from Eq. 9 at a constant ratio of $[py]_T/[Co]_T$, and the values were ploted against $[Co]_T$. The plot showed a sigmoidal curves. This is the reason why the reaction rate is reported to be second order with respect to $[Co]_T$[3] or why the plot of V_{in} vs. $[Co]_T$ showed a sigmoidal curve[4] for the hydrogenation of benzil at a constant ratio of $[py]_T/[Co]_T$. However, the second-order dependence on $[Co]_T$ for the hydrogenation of dimethylglyoxime at a constant pyridine concentration[2] could not be interpreted by Eq. 9. The hydrogenation rate of dimethylglyoxime is much lower than that of benzil. Therefore, the mechanism of the hydrogenation of dimethylglyoxime may be different from that of benzil.

Dynamic Investigation of Aqueous Solutions of 2-*t*-Butoxyethanol and 3-Methoxy-3-methyl-1-butanol by Ultrasonic Methods

Sadakatsu NISHIKAWA,* Ryutaro SHINOHARA, and Goro TANAKA
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received September 17, 1985)

Ultrasonic absorption in the frequency range of 6.5 to 220 MHz has been measured in aqueous solutions of 3-methoxy-3-methyl-1-butanol and 2-*t*-butoxyethanol as a function of the concentration along with the measurement of sound velocity at 1.92 and 2.5 MHz at 25 °C. A single relaxational ultrasonic absorption has been found in both solutions and it is interpreted by a reaction kinetics associated with the interaction between solute and solvent, AB $\rightleftharpoons$ A+B where AB is the complex, A the solute and B the solvent. The forward and backward rate constants for the interaction have been determined from the concentration dependence of the relaxation frequencies to be $k_f=1.4\times10^8$ s^{-1} and $k_b=1.1\times10^8$ mol^{-1} dm^3 s^{-1} for 3-methoxy-3-methyl-1-butanol solution and $k_f=9.0\times10^7$ s^{-1} and $k_b=1.3\times10^8$ mol^{-1} dm^3 s^{-1} for 2-*t*-butoxyethanol solution. The water structure has also been estimated from the absorption data and it has been clarified for the water structure promoted by additions of such solutes. Correlations between the structures of the solutes and the ultrasonic properties of the solutions are discussed in terms of the hydrophobicity of the solutes.

The molecular structure of a self-associating liquid solvent is well known to be changed by the addition of solutes.[1] It is interesting and important to examine experimentally how much the change would be induced in relatively concentrated solutions. Ultrasonic techniques are very suitable to investigate such questions and they have been used extensively. They also give the dynamic information about the solutions and liquids. Rao and Verrall[2] have reported that in an aqueous micellar solution of 2-butoxyethanol (Butyl Cellosolve) the relaxation observed in the MHz frequency range is associated with the exchange reaction of the alcohol between the mixed micelles and the surrounding bulk solution. This has considerable interest in relation to microemulsions. However, clear relaxational absorptions are observed at concentrations below 1 mol dm^{-3} even if surfactant are not added.[3,4] Without some clarification of the mechanism, it is difficult to discuss such ternary systems. By means of ultrasonic absorption and velocity measurements, we have been studying the effects on water structure when non-electrolytes, e.g. alcohols or ethers, are added.[3-7] It has been found, so far, that the ultrasonic relaxations observed in the MHz frequency range are closely related to the balance of the hydrophobicity and hydrophilicity of the solute molecules.

To clarify the relation between the solute structures and the ultrasonic properties, we have chosen two isomeric solutes viz. 3-methoxy-3-methyl-1-butanol and 2-*t*-butoxyethanol. We consider that the structural effect of the solutes on the solvent water may shed light on the ultrasonic properties when they are examined in the solutions with isomeric solutes.

Experimental

The chemicals used were commercial samples obtained from Tokyo Kasei Co., Ltd. and distilled once under reduced pressure. Solvent water was doubly distilled. The desired concentrations of the solutions were made by weighing the solutes.

The ultrasonic absorption coefficient, α, was measured by the improved pulse apparatus in the frequency range from 6.5 MHz to 220 MHz; the principle and the detailed procedure of the measurement are described elsewhere.[4] The sound velocity was measured by an interferometer opperated at 2.5 MHz and a sing around meter at 1.92 MHz. The accuracy of both apparatuses is less than 1 m s^{-1}. The cells for the absorption and velocity measurements were immersed in a water bath which was controlled within ±0.005 °C and the measurements were performed at 25 °C.

The densities were measured at various temperatures by a standard pycnometer the volume of which was about 4.8 cm^3 and the thermal expansibility at 25 °C was determined. The viscosity coefficients of the solutions were measured by a Ubbelohde type viscometer at 25.0±0.1 °C.

Results and Interpretation

The quantity α/f^2 where f is the frequency has been found to be frequency dependent for aqueous solutions of 3-methoxy-3-methyl-1-butanol (from 2.2 mol dm^{-3} to 5.5 mol dm^{-3}) and 2-*t*-butoxyethanol (from 1.3 mol dm^{-3} to 5.0 mol dm^{-3}). The experimental values of α/f^2 for the 2-*t*-butoxyethanol solution are shown in Fig. 1 at various frequencies as a function of the analytical concentration, C_e. A peak sound absorption concentration has been observed though it is dependent on the measurement frequency. A similar dependence has also been observed for the 3-methoxy-3-methyl-1-butanol solution. No frequency dependence of α/f^2 is found in either liquid solutes.

In general, the frequency dependence of the sound absorption coefficient can be well described by the next equation if it is due to a single relaxation process.

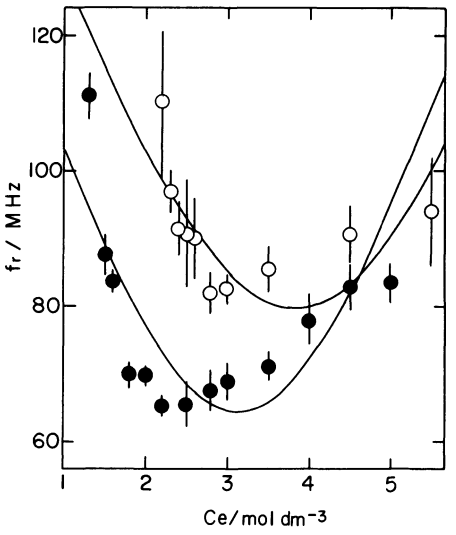

Fig. 4. The concentration dependence of the relaxation frequency for aqueous solutions of 3-methoxy-3-methyl-1-butanol(—○—) and 2-*t*-butoxyethanol (—●—) at 25 °C. The solid curves are the calculated ones.

that is, with Eq. 1 and Eq. 1′. The ultrasonic parameters, A, B, and f_r have been determined by a nonlinear least mean square method using microcomputer. The spectrum which is represented by both Eqs. 1 and 1′ can be seen on a computer display in order to check how the experimental data fit the theoretical curves. The ultrasonic results are listed in Table 1 along with some thermodynamic quantities. The solid curves in Figs. 2 and 3 are those calculated using these parameters. It is seen that a clear single relaxation process has been observed in both solutions. Figure 4 represents the concentration dependences of the relaxation frequencies and they

The concentration dependences of the amplitude of the excess absorption. the background absorption and the classical absorption for aqueous solutions of 3-methoxy-3-methyl-1-butanol and 2-t-butoxyethanol. —◐—: A, —◑—: B and —ⓘ—: $(\alpha/f^2)_{class}$ for 3-methoxy-3-methyl-1-butanol, —○—: A, —●—: B and —⊖—: $(\alpha/f^2)_{class}$ for 2-t-butoxyethanol.

show a minimum. Figure 5 shows the dependence of the amplitude of the excess absorption and the back ground absorption. The classical absorption which is mainly due to shear viscosity is obtained by the next equation.[8]

$$(\alpha/f^2)_{class} = 8\pi^2\eta/3c^3\rho, \quad (2)$$

where η is the viscosity coefficient and ρ the solution density. The results for both solutions are also shown in Fig. 5 and are smaller than those of the back ground absorptions. This means that the observed relaxational absorptions are not due to the shear viscosity and another relaxation may be predicted at more than 200 MHz in both solutions which we will not consider further.

The sound velocity shows a maximum as is seen in Table 1. The adiabatic compressibility, κ_s, of the solution is obtained with the help of the next equation.

$$\kappa_s = (\rho c^2)^{-1} \quad (3)$$

The concentration dependences of the compressibility are shown in Fig. 6 along with some other solutions in order to compare where the concentra-

tion is converted to the molar fraction, n_e.

These concentration dependences of the ultrasonic properties, e.g. peak sound absorption concentration and peak sound velocity concentration are characteristic of aqueous solutions of nonelectrolytes with hydroxyl groups. In order to analyze such dependences, various models have been proposed.[9,10] The present authors have also been studying such phenomena on the bases of the experimental facts and only one reasonable mechanism is possible.[3-7] This is expressed by the following reaction.

$$AB \underset{k_b}{\overset{k_f}{\rightleftharpoons}} A + B, \qquad (4)$$

where A is the solute, B the solvent and AB a solute solvent complex; k_f and k_b are the forward and backward rate constant respectively. In our model, it is assumed that the solvent water exists in hydrogen bonded and non-hydrogen bonded states, and the latter can participate in the above reaction. The model is similar to that proposed by Andreae et al. (model IV in Ref. 9). Under this assumption, the relation between the analytical concentrations and the relaxation frequency is derived as follows.[5]

$$2\pi f_r = k_b[(C_e - \beta C_w + K_{12})^2 + 4\beta C_w K_{12}]^{1/2}, \qquad (5)$$

where C_w the analytical concentration of the solvent, K_{12} the equilibrium constant defined as $K_{12}=k_f/k_b$ and β the molar fraction of the non-hydrogen bonded water. It is a good assumption that the parameters, k_b, K_{12}, and β are concentration independent and they are determined so as to obtain the best fit of the experimental relaxation frequencies to Eq. 5. The solid curves in Fig. 4 are those calculated using these parameters and they seem to fit reasonably for both solutions. The β parameter is a good measure to estimate the effect of the solute on water structure. These calculated rate and thermodynamic constants are tabulated in Table 2.

The excess absorption amplitude A is related to the volume and enthalpy change of the reaction by the next equation.[11]

$$\mu_{max} = Af_r c/2 = \pi(\rho c^2 \Gamma/2RT)(\Delta V - \alpha_p^\infty \Delta H/\rho C_p^\infty)^2 (C_p^\infty/C_p^\circ) \qquad (6)$$

where μ_{max} is the maximum excess absorption perwave length, R the gas constant, T the absolute temperature, ΔH the standard enthalpy change of the reaction, ΔV the standard volume change of the reaction, α_p^∞ the thermal expansibility at high frequency limit, C_p° the specific heat at low frequency, C_p^∞ that at high frequency limit and Γ the concentration term which is given by $\Gamma=(1/[AB]+1/[A]+1/[B]-1/[AB]+[A]+[B]))^{-1}$. The most effective terms to control the concentration dependence of the maximum excess absorption per wavelength may be $\rho c^2\Gamma$. Once the equilibrium constant, K_{12}, and the β value are determined, it is possible to calculate the concentration of the reactants and then the term is obtainable. In Fig. 7, the calculated values of $\rho c^2\Gamma$ for aqueous solution of 3-methoxy-3-methyl-1-butanol are plotted against the concentration along with the experimental results of the maximum excess absorption per wavelength. A similar dependence has also been observed in the solution of 2-*t*-butoxy-

Discussion

The observed ultrasonic absorption in aqueous solutions of 3-methoxy-3-methyl-1-butanol and 2-*t*-butoxyethanol are characteristic of a single relaxation in the frequency range from 6.5 to 220 MHz. However, in solutions of 2-butoxyethanol[3,4] and 2-isobutoxyethanol[6] which are also isomers, another relaxation has been observed at less than 10 MHz in addition to that observed from the range of 30 to 100 NHz. Such a process has also been predicted by Fanning and Kruus.[12] The slower relaxation has been attributed to the perturbation of the equilibrium associated with the molecular aggregates or microemulsions. Depending upon the structure of the solute or the property, which may be mainly due to the hydrophobicity, a single or double relaxations appear. This is the experimental fact obtained from the frequency dependence of the ultrasonic absorption.

It has been found that the β values which are introduced to interpret the observed relaxation process increase with decreasing hydrophobicity of the solute molecules.[13] The β values obtained increase in the series 2-butoxyethanol, 2-isobutoxyethanol, 2-*t*-butoxyethanol and 3-methoxy-3-methyl-1-butanol as is seen in Table 2. Therefore, this series is expected to indicate the order of the hydrophobicity of the solute. The β value indicates the fraction of water which can interact with solute molecules or the fraction of the less structured water. The lower this value, the higher the water structure is promoted. Comparing with the β value in liquid water,[14] the values obtained are still lower than that in liquid water. This means that the solutes used in this investigation act as the structure promoter to water within the seriese, 2-butyoxyethanol, 2-isobutoxyethanol, 2-*t*-butoxyethanol, 3-methyl-3-methoxy-1-butanol. This fact is also obtained from the analysis of the concentration dependence of the relaxation frequency.

The hydrophobicity of the solute may also influence the concentration dependence of the compressibility. As is seen in Fig. 6, κ_s goes through a minimum. The minimum occurs at the lower concentration and the curve is sharper the more hydrophobic the solute. This kind behavior is also seen in the concentration dependence of an apparent molar volume.[15] The series of the concentration where the compressibility shows a minimum or the series of the sharpness of the curve seems to be the same as that of the β values. This is the experimental fact obtained from the concentration dependences of the density and the sound velocity.

It is interesting to examine the correlation between these two independent results, that is, the value which is obtained from the absorption data and the behavior of the compressibility which is obtained from the velocity and density data. Figure 8 shows the plots of the β values vs. the molar fraction at which the compressibility of the solution indicates a minimum ($n_{e\,\min}$). A linear relationship seems to hold. Comparing the results of the 2-*t*-butoxyethanol

solution with that of 3-methoxy-3-methyl-1-butanol, it is seen that the position of the oxygen atom in the molecule may influence the hydrophobicity of the molecules because both the vertical and the horizontal values of the latter solution in Fig. 8 are lower than that of the former. This might be because the *t*-butyl group is bulky when the hydrophobic group of 3-methoxy-3-methyl-1-butanol is compared with that of 2-*t*-butoxyethanol. Murty and Subrahmanyan[16] have reported the structure enhancing efficiency of the isomeric butyl alcohols in the order, *t*-butyl>butyl alcohol from sound velocity studies. However, the present study indicated that 2-butoxyethanol has a more enhancing effect on water structure than 2-*t*-butoxyethanol. Lara and Desnoyers[17] have also investigated the solution properties of 2-butoxyethanol from the solution compressibility and they have found that microemulsions exist in the solution. Their result is consistent with ours which has been estimated from the ultrasonic absorption and velocity results. No previous reports of such a clear correlation between the results of the absorption and the compressibilities in the aqueous solutions are known to the authors.

It has been reported[4,7,13] that the standard volume and enthalpy changes of the reaction may be calculated using Eq. 6 on the assumption that $C_p^\infty/C_p^\circ \cong 1$ and $\alpha_p^\infty/\alpha_p^\circ \cong 1$. In order to estimate the reaction parameters, we have measured the thermal expansibility of both solutions and it is listed in Table 1. If such assumptions for the specific heat and the expansibility were satisfied, the plots of $(\mu_{max}/\rho c^2\Gamma)^{1/2}$ vs. $\alpha_p^\circ/\rho C_p^\circ$ might give a straight line. However, a linear plot has been obtained in a limited concentration range. We considered that the contribution of the relaxational specific heat, $\delta C_p = C_p^\circ - C_p^\infty$, may be important when the reaction parameters, ΔV and ΔH are determined simultaneously over such wide concentration ranges. However, it may be concluded that the dominant term which controls the concentration dependence of the maximum excess absorption is clearly $\rho c^2\Gamma$ as is seen in Fig. 6. In order to obtain the quantitative analysis of the concentration dependence of the maximum excess absorption per wavelength in the present two solutions, the experimental specific heat at a constant pressure is required but it is not available in our laboratory.

The effect of the second component, such as salts or surfactants, on the ultrasonic properties in aqueous solutions of nonelectrolytes are interesting in relation to the microemulsion in the solutions. They are now under investigation and the results will be reported in due course.

This work was partly supported by the Saneyoshi Fundation.

Hydrates of Organic Compounds. X. The Formation of Clathrate Hydrates of Tetrabutylammonium Alkanesulfonates

Haruo NAKAYAMA* and Hideyuki USUI
Department of Chemistry, Faculty of Engineering, Yokohama National University,
Tokiwadai, Hodogaya-ku, Yokohama 240
(Received September 25, 1985)

The solid–liquid phase diagrams of binary mixtures of water with tetrabutylammonium alkanesulfonate $(n\text{-}C_4H_9)_4NO_3SR$(R=$CH_3$–$C_5H_{11}$) and with tetrabutylammonium benzenesulfonate were examined in order to confirm the formation of clathrate-like hydrates. It has been found that (1) all the sulfonates examined can form clathrate-like hydrates with hydration numbers either around 30 or around 39; (2) these hydrates can be classified into three groups I, II, and III on the basis of the hydration numbers and melting points just as in the case of a series of tetrabutylammonium carboxylate hydrates; and (3) generally, the melting points of these sulfonate hydrates are lower than those of tetrabutylammonium carboxylate hydrates. The formation of clathrate-like hydrates of tetrabutylammonium hydrogensulfite and of tetrabutylammonium sulfite has also been reported and is discussed in an appendix.

In previous papers[1,2] the formation of a clathrate-like hydrate by a series of tetrabutylammonium carboxylates ($(n\text{-}C_4H_9)_4NOOCR$; R=H–$C_{10}H_{21}$ and unsaturated alkyl groups ranging from C_2H_3 to C_9H_{17}) was confirmed from the solid-liquid phase diagrams. These hydrates were classified into three groups, I, II, and III, on the basis of the melting points and hydration numbers.

The group I hydrates include the hydrates formed by salts with short alkyl groups such as R=H, CH_3, C_2H_5, $n\text{-}C_3H_7$, $i\text{-}C_3H_7$, $t\text{-}C_4H_9$, C_2H_3(acrylate), and C_3H_5(methacrylate, crotonate, and 3-butenoate). Two characteristic features of the group I hydrates are (a) the hydration number is around 30 and (b) most of the melting points are in the range 10—18 °C, i.e., they are very stable as compared with the group II and III hydrates mentioned below. From the fact that the hydration number is around 30, the crystal structure of the group I hydrates seem to be iso-structural with that of a well-known tetrabutylammonium fluoride hydrate.[3] However, high stability of the group I hydrates cannot be explained by a simple distortion effect of the anion on the hydrogen-bonded water framework within the hydrate.[4] Thus, it has been concluded that the alkyl group of the carboxylate anion is located in a pentagonal dodecahedron, which exists in a gap between the arrangement of large polyhedra (tetrakaidecahedron and/or pentakaidecahedron filled by one of the butyl groups of the tetrabutylammonium cation) and is believed to be either vacant or partially filled by a small molecule such as free water, oxygen, and nitrogen.

The group II hydrates are formed exclusively by all the carboxylates with R=C_4H_9, C_5H_{11}, C_4H_7, and C_5H_9 except for $t\text{-}C_4H_9$, and have hydration numbers around 39. The fact that the hydration number is around 39 indicates that the crystal structure of the group II hydrates are essentially similar to those of tetrabutylammonium benzoate hydrate, which has an ideal composition of $(n\text{-}C_4H_9)_4NOOCC_6H_5\cdot 39.5H_2O$,[5] in which the benzoate anion is surrounded by one more large cage of water. The melting points of these hydrates are not so high as those of the group I hydrates; they are at most about 12 °C.

The group III hydrates are formed by tetrabutylammonium carboxylates with long alkyl chains ranging from C_6 to C_{10} including unsaturated chains of C_7 and C_9. Although the hydration number of these hydrates is around 30 as in the case of the group I hydrate, the melting points are appreciably lower than those of the group I hydrates. From the fact that the hydration number is around 30 and such long alkyl chain cannot be accommodated within a single pentagonal dodecahedron, the possible crystal structure of these hydrates will be iso-structural with $(n\text{-}C_4H_9)_4NF$ hydrate but with the long alkyl chain of the carboxylate anion penetrating into two pentagonal dodecahedra which are facesharing with each other. The low stability of these hydrates, i.e., low melting point (around 5 °C or below), can be explained by a large distortion effect caused by the long alkyl chain of the carboxylate anion.

In this paper, from the solid–liquid phase diagrams for eight binary mixtures of tetrabutylammonium alkanesulfonate–water, the effect of the shape and/or length of the alkyl group of a sulfonate anion on the stability and the hydration numbers of their clathrate-like hydrates has been examined from a similar point of view. The formation of clathrate-like hydrates of tetrabutylammonium alkanesulfonates has not been reported previously.

In addition, the formation of clathrate-like hydrates of tetrabutylammonium salts containing either HSO_3^- ion or SO_3^{2-} ion, tetrabutylammonium hydrogensulfite and tetrabutylammonium sulfite, has also been reported and discussed.

Experimental

An aqueous solution of tetrabutylammonium alkanesulfonates, $(n\text{-}C_4H_9)_4NO_3SR$ (R=CH_3, C_2H_5, $n\text{-}C_3H_7$, i-

C_3H_7, n-C_4H_9, i-C_4H_9, and n-C_5H_{11}), and of tetrabutylammonium benzenesulfonate was prepared by neutralization of aqueous tetrabutylammonium hydroxide solution with an aqueous solution of either the corresponding alkanesulfonic acid or benzenesulfonic acid. The tetrabutylammonium hydroxide solution was obtained by treating tetrabutylammonium iodide with freshly prepared silver hydroxide in water followed by filtration of the AgI precipitate. Tetrabutylammonium iodide was prepared by precipitation from an aqueous solution of tetrabutylammonium bromide, which was purchased from Tokyo Kasei Kogyo Co. Ltd., with addition of potassium iodide, followed by washing with water and air-drying in a desiccator. The iodide was purified by repeated recrystallization from ethyl acetate–acetone mixture. Methanesulfonic acid and benzenesulfonic acid were purchased from Tokyo Kasei Kogyo Co. Ltd. and ethanesulfonic acid from Aldrich Chemical Co.. These acids were used without further purification. Aqueous solutions of n-$C_3H_7SO_3H$, i-$C_3H_7SO_3H$, n-$C_4H_9SO_3H$, i-$C_4H_9SO_3H$, and n-$C_5H_{11}SO_3H$ were obtained by passing each sodium salt solution through a column of cation exchange resin (Amberlite IR-120B) converted, in advance, into the acid form by about 2 M† hydrochloric acid solution. The sodium salts, except for n-$C_5H_{11}SO_3Na$ which was purchased from Tokyo Kasei Kogyo Co. Ltd., were synthesized by the Strecker reaction:[6] The corresponding alkyl iodide was refluxed for a few days with an aqueous sodium sulfite solution containing about twice the molar quantity of the iodide. After the water had been evaporated under reduced pressure, the reaction product was extracted with ethanol. The sodium salt was purified by repeated recrystallization from ethanol and was confirmed by its NMR spectra. Differential thermal analyses showed that melting points of all the sodium alkanesulfonates synthesized were higher than 350 °C.

The solid-liquid phase diagrams for the binary systems of water–tetrabutylammonium alkanesulfonate (or tetrabutylammonium benzensulfonate) were determined in the same manner as described in previous papers.[1,4] The concentration of each mother solution of tetrabutylammonium alkanesulfonate was determined by measuring the amount of tetrabutylammonium cation by titration with a sodium tetraphenylborate solution standardized by pure $(n\text{-}C_4H_9)_4NI$ solid.

Results and Discussion

The solid–liquid phase diagrams for tetrabutylammonium alkanesulfonate–water binary systems are shown in Figs. 1 and 2, as well as for a tetrabutylammonium benzenesulfonate–water system. In these figures the logarithm of the concentration of the tetrabutylammonium salt expressed as mole fraction (X) is plotted against the reciprocal of the absolute temperature. The temperature expressed in ordinary Celsius units is shown on the upper side of the figure.

In these figures the existence of the congruent melting points at $X\simeq0.033$ (Figs. 1 and 2) and at $X\simeq0.024$ (Fig. 2) clearly indicates that these sulfonates can form a clathrate-like hydrate. The former hydrate corresponds to the one with hydration numbers around 30 and the latter around 39. The presence of all the hydrates is confirmed in this study. As is seen in Fig. 2, phase diagrams of tetrabutylammonium 1-propanesulfonate–water and of tetrabutylammonium 1-butanesulfonate–water systems show

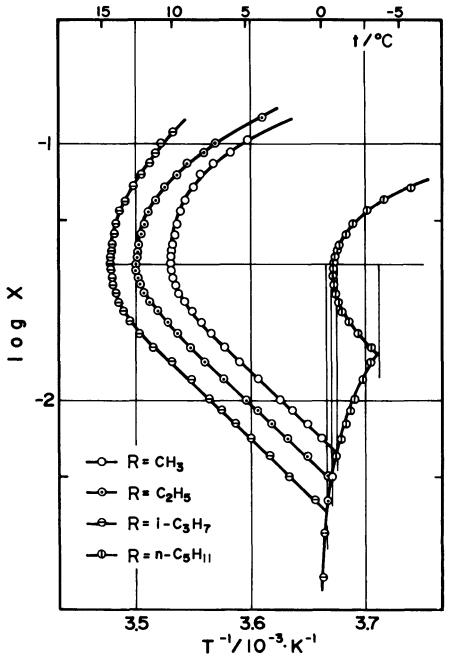

Fig. 1. Solid–liquid phase diagrams for the water–$(n\text{-}C_4H_9)_4NO_3SR$ systems.

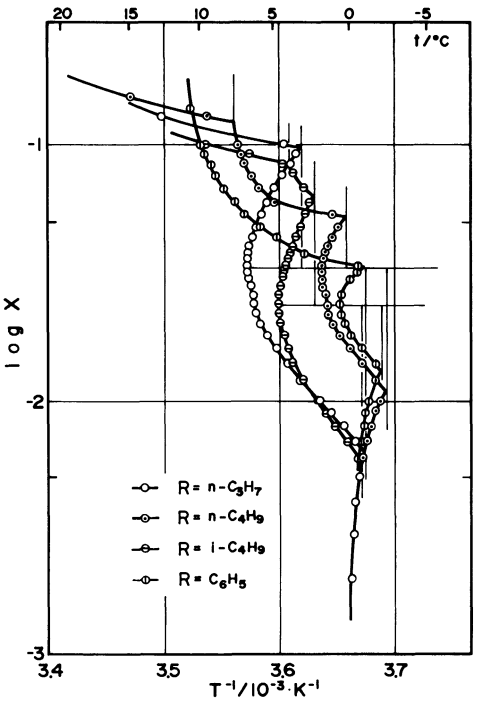

Fig. 2. Solid–liquid phase diagrams for the water–$(n\text{-}C_4H_9)_4NO_3SR$ systems.

† 1 M=1 mol dm^{-3}.

incongruent melting points at $X \simeq 0.025$. However, this temperature is almost the same as the dissolution temperature of the solution whose concentration is $X=0.024$; i.e., the $\log X$ vs. $1/T$ curve is virtually vertical around $X \simeq 0.024$. For this reason, and also for the other reason mentioned below, it can be concluded that in these systems two kinds of clathrate-like hydrates (with hydration numbers around 30 and 39) are formed simultaneously.

The other reason is the fact that in these two systems the slope $-\partial \log X/\partial(1/T)$ in dilute region, in the vicinity of $X \simeq 0.015$ for example, is about 1.20 times that of the hydrate having hydration numbers around 30 (Fig. 1) and is about 0.9 times that of the tetrabutylammonium 2-methyl-1-propanesulfonate system (Fig. 2) in which only one type of hydrate with hydration number around 39 is formed. It has been concluded in a previous paper[7] that a large portion of the molal heat of solution of a clathrate-like hydrate in water is the molal heat of fusion of the hydrate, which is approximately equal to the molal heat of fusion of ice I multiplied by the hydration number of the hydrate: i.e., the value of the slope $-\partial \log X/\partial(1/T)$ is roughly proportional to the hydration number of the hydrate. Thus, in the two systems noted above the mean hydration number is larger than 30 but smaller than 39. Since the possible structure of the hydrate is either the one with hydration number of around 30 or the one with around 39, this indicates that two types of the hydrates are present simultaneously.

All the melting points and the hydration numbers, determined from each congruent melting point and congruent composition, are summarized in Table 1. Although the curve shown in Figs. 1 and 2 has a fairly flat peak around a congruent composition, the hydration number of each hydrate can be determined within the limits of error indicated in Table 1 since, when the ampoules containing solutions of slightly different composition are warmed gradually, the ampoule which finally dissolves can easily be determined. In Fig. 3, the melting point of the hydrate is plotted against the number of carbon atoms in the main alkyl-chain of each sulfonate anion. The number attached to each point stands for the same sulfonate as the one listed in Table 1. The points corresponding to the hydrates of a series of normal alkanesulfonates are connected by a solid line. A filled circle indicates the hydrate with hydration number around 30 and an open circle indicates the one with a hydration number around 39. Similar to the carboxylate hydrates mentioned above, these hydrates can be classified into three groups; I, II, and III. They are also shown in Fig. 3.

The group I hydrates include the hydrates formed by sulfonates with R=CH_3, C_2H_5, and i-C_3H_7 (hydrates 1, 2, and 5 in Table 1) and have hydration numbers around 30. As mentioned in the introduction section, it can be concluded that these hydrates are iso-structural with $(n\text{-}C_4H_9)_4NF \cdot 30H_2O$ hydrate and that such alkyl chains as CH_3, C_2H_5, and i-C_3H_7 are accommodated within a vacant pentagonal dodecahedron. These hydrates are fairly stable as compared with the group II and III hydrates mentioned below. The most stable hydrate is that of tetrabutylammonium 3-methyl-1-butanesulfonate (14.4 °C, Table 1), indicating that the group i-C_3H_7 is most suitably fitted to a pentagonal dodecahedron. However, this melting point is relatively lower than that of the most stable carboxylate hydrates of group I: 18.0 °C for $(n\text{-}C_4H_9)_4NOOCC_2H_5$ hydrate.[1]

The group II hydrates which have hydration numbers around 39 are formed by sulfonates with

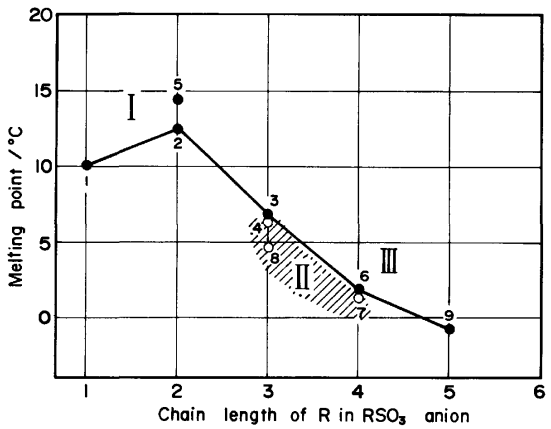

Fig. 3. Relationship between the melting points of the tetrabutylammonium alkanesulfonate, $(n\text{-}C_4H_9)_4NO_3SR$, hydrates and the chain length of R in the sulfonate anion. The number attached to each point indicates the same hydrate as the one listed in Table 1. Three groups shown by I, II, and III are explained in the text.

R=*n*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, and C_6H_5 (hydrates 4, 7, 8, and 10 in Table 1). Among them the most stable hydrate is the one with R=*n*-C_3H_7 (6.3 °C). As mentioned above, in these hydrates such alkyl groups as R=*n*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, and C_6H_5 seem to be surrounded by either a tetrakaidecahedron or a pentakaidecahedron as in the well-known (*n*-$C_4H_9)_4NOOCC_6H_5 \cdot 39.5H_2O$[5] hydrate.

Group III hydrates which have hydration numbers around 30, as in the case of the group I hydrates, are fairly unstable and are formed by sulfonates with R=*n*-C_3H_7, *n*-C_4H_9, and *n*-C_5H_{11} (hydrates 3, 6, and 9 in Table 1). These hydrates seem to be iso-structural with the (*n*-$C_4H_9)_4NF \cdot 30H_2O$ hydrate and such alkyl chains as *n*-C_3H_7, *n*-C_4H_9, and *n*-C_5H_{11} are supposed to be accommodated in a space where two face-sharing pentagonal dodecahedra are present. The hydrates 3 and 6, which have the same anion as the hydrate 4 and 7, respectively, are classified as group III hydrates instead of group I hydrates from the fact that their melting points are relatively low as compared with those of the hydrates 1, 2, and 5. Furthermore such anions as *n*-$C_3H_7SO_3^-$ and *n*-$C_4H_9SO_3^-$ are too large to form stable hydrates of group I as is mentioned below (Fig. 4). Although the reason why the sulfonates with R=*n*-C_3H_7 and *n*-C_4H_9 can form two kinds of hydrates is not clear; it is obvious that the stability of the two types of hydrates is almost the same since the difference in the melting points between hydrate 3 and 4, and between hydrate 6 and 7, is small as is shown in Table 1.

In Fig. 4 the melting points of a series of tetrabutylammonium alkanesulfonate hydrates are plotted against the conventional partial molal volume ($\overline{V}°_{conv}$) of the sulfonate anion at 25 °C. This figure includes similar plots for a series of tetrabutylammonium carboxylate hydrates reported earlier.[1] The conventional partial molal anionic volume is defined as a partial molal volume at infinite dilution on the assumption that partial molal volume of H^+ ion at infinite dilution is equal to zero.[14] These are used as an indication of the effective volume of the anion within a hydrate solid since the state in which an anion is surrounded by a hydrogen-bonded water cage will not be so different from the state in which the anion is surrounded by water molecules in an aqueous solution at infinite dilution. The conventional partial molal volume of each carboxylate and alkanesulfonate anion was obtained from the partial molal volume of each sodium salt[8-13] at infinite dilution using the relation that $\overline{V}°_{conv}$ for Na^+ ion is equal to $-1.21\ cm^3\ mol^{-1}$ at 25 °C.[14] Since the sulfonate anion is bulky as compared with carboxylate anion, the conventional partial molal volume of $C_nH_{2n+1}SO_3^-$ ion is nearly equal to that of $C_{n+1}H_{2n+3}COO^-$ ion. In Fig. 4, the domains of the group I, II, and III hydrates are also indicated. It is interesting to note that both the stability of the hydrate (i.e., the melting point) and the tendency toward which group of the hydrate can be formed are closely related to the anionic size in the two series of hydrates. However, for the same value of abscissa in Fig. 4 the melting points of a series tetrabutylammonium alkanesulfonate hydrates are lower than those of tetrabutylammonium carboxylate hydrates, indicating that the stability of the hydrates is dependent not only upon the anionic volume but also upon the chemical constitution of the anion. The distortion of the hydrogen-bonded water cage seems to be greater when it surrounds a SO_3 portion than when it surrounds a COO portion, due to the increased number of oxygen atoms in the former structure. The melting point of the tetrabutylammonium benzenesulfonate hydrate, 0.6 °C (Table 1), is also lower than that of tetrabutylammonium benzoate hydrate, which is reported to be about 6.0 °C.[5]

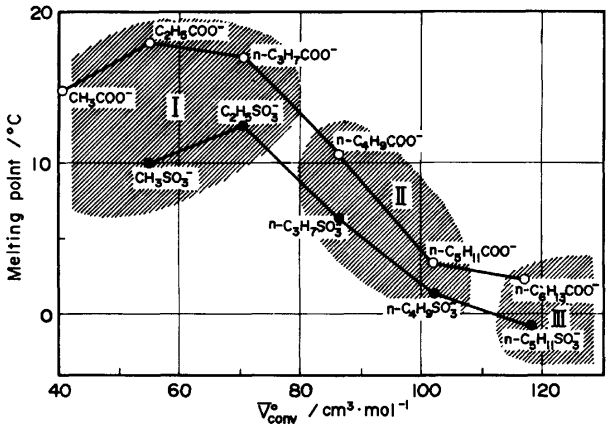

Fig. 4. Relationship between the melting points of the hydrates of either tetrabutylammonium alkanesulfonates or tetrabutylammonium carboxylates and the conventional partial molal anionic volumes. Anions are shown to each point. Three groups shown by I, II, and III are explained in the text.

Appendix

The formation of clathrate-like hydrates of two tetrabutylammonium salts whose anion is either HSO_3^- or SO_3^{2-}, tetrabutylammonium hydrogensulfite ((*n*-$C_4H_9)_4NHSO_3$) and tetrabutylammonium sulfite ([(*n*-$C_4H_9)_4N]_2SO_3$), has also been examined, although the electronic structure around the sulfur atom in these inorganic ions is different from that in an alkanesulfonate ion. The solid-liquid phase diagrams of two binary mixtures, (*n*-$C_4H_9)_4NHSO_3$-H_2O and [(*n*-$C_4H_9)_4N]_2SO_3$-H_2O, are shown in Fig. 5 in the same manner as in Figs. 1 and 2. Aqueous solutions of these two salts were obtained by neutralization of aqueous (*n*-$C_4H_9)_4NOH$ solution with an appropriate amount of sulfurous acid solution whose concentration was determined by iodometry.[15] Figure 5 clearly indicates that these

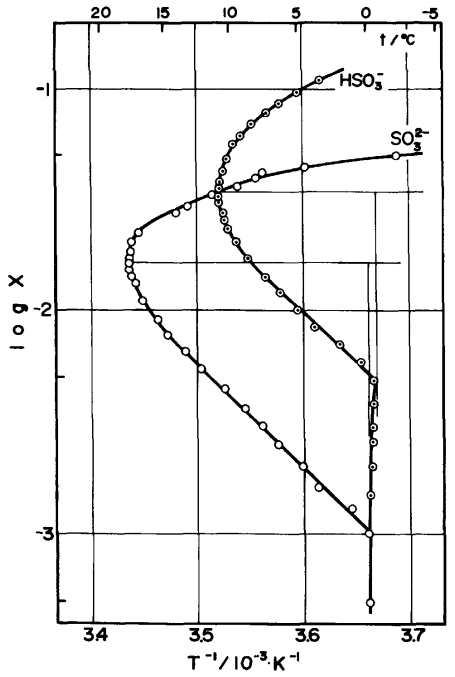

Fig. 5. Solid–liquid phase diagrams for the water–(n-$C_4H_9)_4NHSO_3$ and water–$[(n\text{-}C_4H_9)_4N]_2SO_3$ systems.

two salts can also form clathrate-like hydrates. This is confirmed in this experiment. The melting point and hydration number are 10.9 °C, 30±2 for the (n-$C_4H_9)_4NHSO_3$ hydrate and 17.8 °C, 62±4 for the $[(n\text{-}C_4H_9)_4N]_2SO_3$ hydrate, respectively. Like many other clathrate-like hydrates formed by tetrabutylammonium inorganic salts,[4] the crystal structure of both hydrates seems to be isostructural with the well-known (n-$C_4H_9)_4NF\cdot 30H_2O$ hydrate since the number of moles of water molecule per (n-$C_4H_9)_4N^+$ ion is about 30 in both hydrates.

The melting point of the $[(n\text{-}C_4H_9)_4N]_2SO_3$ hydrate is fairly high as has generally been found[4] in other hydrates of tetrabutylammonium salts having di-valent anions like CO_3^{2-} and WO_4^{2-}; 18.3 °C for the carbonate hydrate and 15.0 °C for the tungstate hydrate. The melting point of the (n-$C_4H_9)_4NHSO_3$ hydrate (10.9 °C) is somewhat higher (about 2 °C) than that expected from a linear relationship between the melting point of the hydrates and $\bar{V}°_{conv}$ of anions for a series of hydrates of tetrabutylammonium salts having mono-valent inorganic anions.[4] The value of $\bar{V}°_{conv}$ for HSO_3^- ion was estimated to be 25.68 $cm^3\ mol^{-1}$ at 25 °C from a density measurement for an aqueous solution of $NaHSO_3$ in the usual way.[13,16] The slightly elevated melting point of the (n-$C_4H_9)_4NHSO_3$ hydrate can be ascribed at least partly to the fact that a part of (n-$C_4H_9)_4NHSO_3$ is converted into $[(n\text{-}C_4H_9)_4N]_2SO_3$, which gives a more stable hydrate than (n-$C_4H_9)_4NHSO_3$, in aqueous solution since evolution of SO_2 gas is detected when concentrating a dilute solution of (n-$C_4H_9)_4NHSO_3$ by evaporation of water at reduced pressure. Thus, the aqueous solution of (n-$C_4H_9)_4NHSO_3$ is somewhat unstable especially in concentrated solution and the hydrate formed from this aqueous solution seems to be a mixed clathrate-like hydrate of (n-$C_4H_9)_4NHSO_3$ and $[(n\text{-}C_4H_9)_4N]_2SO_3$. Since both hydrates can be considered to be iso-structural with each other as mentioned above, the formation of a mixed clathrate hydrate of both salts is in principle possible. However, the amount of the $[(n\text{-}C_4H_9)_4N]_2SO_3$ salt within the mixed hydrate seems to be small because the observed melting point (10.9 °C) of the hydrate is about 7 °C as low as that of the $[(n\text{-}C_4H_9)_4N]_2SO_3$ hydrate (17.8 °C).

Formation of NH($A^3\Pi$) by Electron-Impact Dissociation of Isothiocyanic Acid

Ikuo TOKUE and Yoshio ITO
Department of Chemistry, Faculty of Science, Niigata University, Niigata 950-21
(Received October 7, 1985)

Emission spectra of the fragments of Isothiocyanic acid (HNCS) produced by electron impact were studied. The onset for formation of NH($A^3\Pi$) is 9.2±0.5 eV. On the basis of the excitation function of the NH(A–X) band, NH(A) is shown to be formed via a spinforbidden process HNCS→NH($A^3\Pi$)+CS($X^3\Sigma^+$) near the onset. At higher energies, a spin-allowed process HNCS→NH(A)+CS($a^3\Pi$) seems to be predominant. The ratio of the formation rate of NH(c) to that of NH(A) is 0.18±0.03.

Isothiocyanic acid (HNCS) has 16 valence electrons and is isoelectronic with isocyanic acid (HNCO). The ground state of both molecules is known to have trans bent structure (C_s symmetry).[1,2] Emission spectra of the fragments from isocyanic acid (HNCO) and their formation mechanisms have been extensively investigated by photolysis[3–6] and electron-impact dissociation.[7,8] It was shown in a previous paper[8] that NH(A) near its onset is produced via a spin-forbidden excitation and that NH(A) at higher energies, NH(c), NCO(A), and NCO(B) are produced via a spin-allowed excitation. On the other hand, there has been only a little amount of information[9] about the dissociation mechanism of HNCS.

In the present study, the emission spectra of the fragments produced by electron-impact on HNCS have been analyzed for the first time. Dissociation processes for formation of NH(A) are assigned on the basis of the emission spectra and the excitation function. To sssist with the assignment, we have derived the excitation energy to the singlet and triplet states of HNCS by a semiempirical calculation (CNDO/S). In addition, the vibrational and rotational distributions of the NH(A) and NH(c) states are estimated on comparing the observed spectrum of the NH emission with synthetic envelopes.

Experimental

The apparatus and the experimental conditions have been described previously.[10] The pressure of the sample vapor in the collision region during the emission measurement was controlled to 2.7—6.7 mPa by a variable leak valve.

The HNCS was prepared by heating the mixture of dry, powdered samples of KSCN and $KHSO_4$ to 70 °C under vacuum.[11] The vapor generated was dried over P_2O_5 and trapped at liquid N_2 temperature. After being pumped several times at about −30 °C to remove volatile impurities, it was stored just before use in a gas reservoir at a pressure less than 3 Torr† measured by Pirani gauge to avoid deposition on the Pyrex wall.

A spectral band pass of 0.32 nm fwhm was used for the measurement of the excitation function. The energy scale for the impinging electron was calibrated by using the onset and the peak of the excitation function[12] for the (1,0) band of the $N_2(C^3\Pi_u–B^3\Pi_g)$ emission from N_2 mixed together in the sample gas.

Results and Discussion

Emission Spectra. Figure 1 shows the emission spectra in the region 250—500 nm obtained by electron impact on HNCS. These specta belong to the hydrogen Balmer lines, the CN($B^2\Sigma^+–X^2\Sigma^+$),

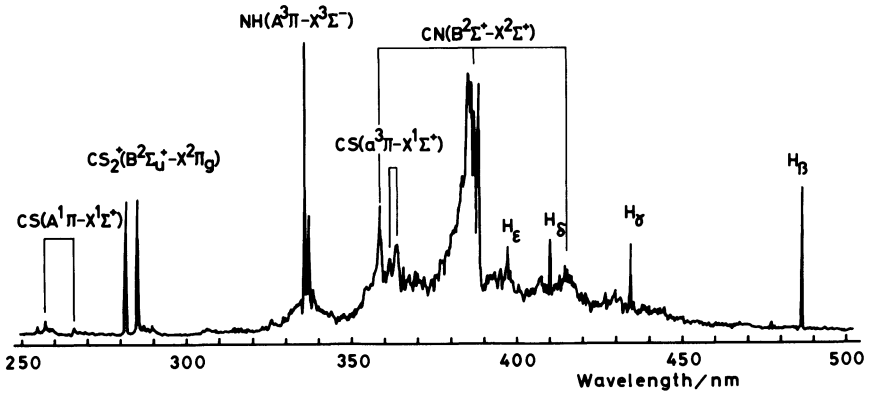

Fig. 1. Emission spectra produced by electron impact (150 V, 45 μA) on HNCS at 5.7 mPa.

† 1 Torr=133.322 Pa.

$CS(a^3\Pi-X^1\Sigma^+)$, $NH(A^3\Pi-X^3\Sigma^-)$, $CS(A^1\Pi-X^1\Sigma^+)$ bands.[13] The sharp emission near 280 nm is assigned to the $CS_2^+(B^2\Sigma_u^+-X^2\Pi_g)$ band from CS_2 impurity.[14] In addition, broad emission is observed between 340 and 470 nm. This is attributed to the NCS radical since the peaks observed near 370, 394, 396, 408, 430, 443 nm agree with those found in the literature.[15]

Although the CS_2^+(B–X) and $CS_2^+(A^2\Pi_u-X^2\Pi_g)$ band produced by electron impact on CS_2 are very strong,[16] the CS_2^+(A–X) band is not found between 450 and 530 nm as shown in Fig. 1. In a supplementary measurement, the CS(a–X) band is not observed by electron impact on CS_2 under the same conditions as for HNCS. It follows that the CS(a–X) band is produced from HNCS and that the CS(A–X) band includes a minor contribution from CS_2 impurity. On comparison with the emission produced from CS_2 under the same conditions, we concluded that the influence of CS_2 impurity in the emission spectrum is negligible except for the CS(A–X) band.

The ratio of the emission intensity of the NH(A–X) band to that of the CN(B–X) band was not reproducible. This indicates that the sample vapor includes HCN impurity since the CN(B–X) emission from HCN is generally known to be very strong. HCN is considered to be formed secondarily in the gas reservoir by the reaction[10] $3HNCS \rightarrow HCN + H_2C_2N_2S_3$. The influence of HCN impurity upon the CN(B–X) band is difficult to be estimated. In addition, the CS(a–X) band overlapped the CN(B–X) band. Hence, we did not measure the excitation function of the CS(a–X) band and did not attempt the population analysis about the CN(B–X) band. Neverthless, it is noteworthy that the appearance voltage of the CS(a–X) band is higher than the NH(A–X) band. This will be discussed in a later section.

Population Analysis of NH(A). The emission spectrum which covers the region 324—344 nm consists of two heavily overlapping bands corresponding to the (0,0) band of the NH(c–a) system and the (0,0) and (1,1) bands of the NH(a–X) system. The rotational structure can be resolved only partly due to the limited resolution. The observed spectrum is therefore compared with band envelopes simulated by a microcomputer. The procedure of the band-envelope analysis has been reported in detail.[17]

This analysis of the intensities of the NH emission bands provides information about the ratio of the formation rate of $NH(c^1\Pi)$ to that of $NH(A^3\Pi)$, P(c)/P(A), in the dissociative excitation. In addition, it provides the rotational distribution and the relative vibrational population, $N_v/N_{v=0}$, of the NH radical. In this analysis, the rotational distribution of the v level of the NH(A) or the NH(c) state is assumed to be represented by a Boltzmann temperature (T_v).

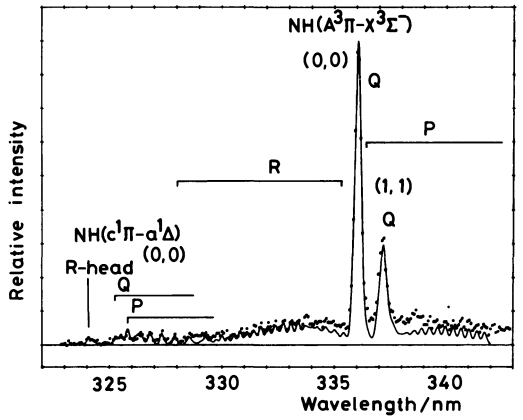

Fig. 2. The observed spectrum of NH (dots) at an impact energy of 30 eV with 0.17 nm fwhm resolution. The trace is the best-fit synthetic spectrum.

The observed spectrum at an impact energy of 30 eV is compared in Fig. 2 with synthetic envelopes. T_0 of NH(c) is fixed to be 1000 K. $P(c)/P(A)$ is derived to be 0.18±0.03 and is independent of the impact energy from the onset up to 80 eV. T_0 and N_1/N_0 of NH(A) are estimated to be ≃3000 K and 0.42±0.05, respectively. T_0 of NH(A) is nearly equal to that for HNCO, while N_1/N_0 of NH(A) is considerably larger than that for HNCO (0.24—0.30).

The disagreement between the observed spectra and the synthetic envelopes near 337 nm in Fig. 2 is attributable to the (2,2) band of the NH(A–X) transition which is not included in band envelopes. In addition, there is a tendency of synthetic envelopes to deviate from the observed spectrum at the wavelengths longer than 333 nm. This is probably caused by overlapping of the $NCS(A^2\Pi-X^2\Pi)$ and $NCS(B^2\Sigma^+-X^2\Pi)$ bands, since the NCS emission has been observed between 330 and 500 nm.[15]

Excitation Function of the NH(A–X) Band. Figure 3 shows the excitation function of the NH(A–X) band from HNCS. This is very similar in shape to that from HNCO.[8] The excitation function of the NH(c–a) band cannot be measured because of its weak intensity. The onset for formation of NH(A) is found to be 9.2±0.5 eV. In addition, the second rise in the plot appears near 20 eV.

The main dissociation processes leading to the formation of NH(A) and NH(c) from HNCS at low energy are as follows:

$$HNCS \rightarrow NH(A^3\Pi) + CS(X^1\Sigma^+), \quad \Delta H = 8.44\ \text{eV}, \quad (1)$$
$$HNCS \rightarrow NH(A^3\Pi) + CS(a^3\Pi), \quad \Delta H = 11.87\ \text{eV}, \quad (2)$$
$$HNCS \rightarrow NH(c^1\Pi) + CS(X^1\Sigma^+), \quad \Delta H = 10.17\ \text{eV}. \quad (3)$$

The ΔH values derived by using the electronic energy[13] and the enthalpy of formation[18] of HNCS and of the fragments, represent the enthalpy of

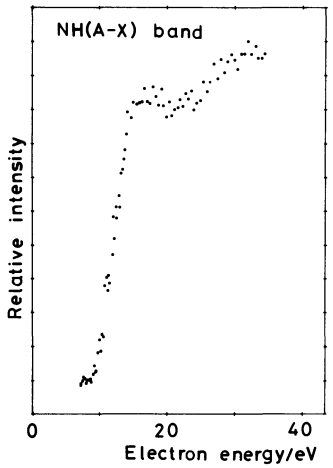

Fig. 3. NH(A-X) emission intensity at the head of the (0, 0) band versus electron energy.

dissociation. Process 1 is a spin-forbidden reaction, while Processes 2 and 3 are spin-allowed reactions. On comparing the observed onset with ΔH, it becomes evident that Process 1 is the main dissociation process leading to the formation of NH(A) near its onset. Process 2 seems to be the main dissociation process at higher energies on the following grounds. First, the excitation function of the NH(A-X) band rising linearly with the electron energy near the onset deviates from the straight line at 12 eV. This value is nearly equal to the ΔH for Process 2. Second, the excitation function above 20 eV increases monotonously with the electron energy. This implies that NH(A) is mainly produced via a spin-allowed excitation at higher energies. Third, the appearance voltage of the CS(a-X) band is higher than that of the NH(A-X) band. This indicates that CS(a) is not produced by the reaction HNCS→NH(X)+CS(a) with ΔH=8.45 eV.

In order to support the foregoing conclusion, we have carried out a semiempirical calculation (CNDO/S).[19] The excitation to the singlet and triplet HNCS states is estimated on the assumption that the Franck-Condon principle is valid. The structural parameters for the ground state of HNCS (trans bend) reported by Yamada et al.[1] are used for the calculation. The electronic configuration in the ground state of HNCS is $(1—4)a'^2 1a''^2 (5,6)a'^2 2a''^2$. This configuration agrees with the result by the HF/STO-3G calculation by using the GAUSSIAN 80 system.

Considering the accuracy of CNDO/S calculation, we can attempt only qualitative discussion. By resolving the species of NH($A^3\Pi$) and CS($X^1\Sigma^+$) into that of point group C_s, we obtain $^3A'+^3A''$ and $^1A'$, respectively. The product between these species yields the $^3A'$ and $^3A''$ states for non-linear HNCS. The observed onset for formation of NH(A) indicates that the precursor for the NH(A)+CS(X) products lies in the region 8.7—9.7 eV. Moreover, the NC bond of the precursor is expected to be weakened due to the promotion of an electron from the bonding orbital. Thus, the 6-$^3A'$ (at 8.0 eV) and 6-$^3A''$ (at 8.7 eV) states are considered to be most probable as the precursor. The former corresponds to the excitation out of the 5a′ MO into the 7a′ MO (in plane π_{NC}→in plane π_{NCS}*) and the latter corresponds to the excitation out of the 5a′ MO into the 3a″ MO (in plane π_{NC}→out-of-plane π_{NCS}*). The fact that the 6-$^3A'$ and 6-$^3A''$ states lie considerably lower than the next NH($a^1\Delta$)+CS($a^3\Pi$) state (9.74 eV) which can only correlate with the triplet HNCS states gives another ground for the above inference.

The authors thank the Computer Center, Institute for Molecular Science, for the use of the HITAC M-200H computer and the Library Program GAUSSIAN 80.

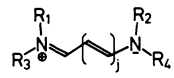
Electronic Spectra of Two Polymorphs of (5-Dimethylamino-2,4-pentadienylidene)dimethylammonium Perchlorate

Norimichi SANO and Jiro TANAKA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received October 28, 1985)

Reflection spectra were measured on two polymorphs of (5-dimethylamino-2,4-pentadienylidene)dimethylammonium perchlorate in order to determine the origin of the J band. One polymorph exhibited two bands with different polarization characteristics; one of them is explained by the molecular-exciton (MX) band of a $\pi\pi^*$ transition character and the other is an intermolecular charge-resonance (CR) band, the polarization being along the direction connecting the nitrogen atoms of the adjacent molecules. The other polymorph exhibited a quasi-metallic reflection due to the overlapping of the CR and MX bands.

Cyanine dyes have a characteristic structure with an odd polymethine chain and two terminal nitrogen



atoms. It has been well known that the aggregate of the cyanine dye exhibits peculiar spectral characteristics in the visible region. Especially, the aggregation behavior and the spectral sensitization of photographic silver halide emulsions have been investigated.[1-3]

From investigations of the spectra of some aggregates and those of crystals of cyanine dyes,[4-6] it has been shown that a J band appeared in the crystals when the molecular overlap was significant in laterally shifted dye stacks. In such a condition, the charge-resonance (CR) configuration strongly interacted with the molecular-exciton (MX) configuration, where the interaction was assisted by a strong π-electron overlap. In contrast with the case of the crystals of electron donor-acceptor complexes, the intermolecular CR absorption band of pure molecular crystals have eluded direct observation for years, especialy that of cyanine dyes, although electric field modulated spectra indicated the existence of intermolecular CR transition in 9,10-dichloroanthracene,[7] for which the anomalous absorption polarization had been reported.[8] The CR bands of anthracene,[9] naphthacene and pentacene[10] were also recently found.

In this paper, the reflection spectra and Kramers-Kronig (K-K) absorption spectra are presented on two polymorphs with space groups *Cc* (the yellow form)[11] and $P2_1/a$ (the orange form),[12] of (5-dimethylamino-2,4-pentadienylidene)dimethylammonium perchlorate (5-DMP, abbreviated to BDP in the literature).

Anex and Simpson[13] reported a quasi-metallic reflectivity in the spectra of the yellow form, and its origin has been investigated theoretically by Philpott[14] and Rimbey.[15] On the other hand, Dähne and his coworkers[16] have found the existence of an orange-colored crystal having the same constituent, and have noticed a difference in the reflection spectra. Although Sieber et al. had reported the molecular and crystal structures of the orange form,[17] a more precise X-ray analysis was performed by our group,[12] and the molecular geometry with a bond-alternated character on the conjugated system and the charge-density distribution were determined.

In this paper, we present evidence of an intermolecular CR band between cation molecules in crystals of the orange form. Investigations regarding two modifications of a crystal of 5-DMP and a comparison with the previous study for 3-DMP ((3-dimethylamino-2-propenylidene)dimethylammonium perchlorate)[18] are very illuminating for an assignment of the electronic transitions of the J-type band.

Experimental

Materials. 5-DMP was synthesized by the method of Malhotra and Whiting.[19] The product was purified with active charcoal and recrystallized several times from ethanol. Single crystals of the orange form were grown from methanol and those of the yellow form from ethanol. These were used for reflection measurements. Crystalline forms and faces were confirmed by taking X-ray photographs using the Weissenberg camera.[11,12,17]

Crystal Structures. The Orange Form:[12,17] Crystals of the orange form were prismatic (Fig. 1(a)) and were elongated along the *c* axis, showing the {100}, {110}, and {010} zone axes. Lattice parameters are given in Table 1. The molecular packing in the orange form is shown in Fig.

Table 1. Lattice Parameters for Polymorphs of 5-DMP

	Orange form	Yellow form

2 as a projection onto the (010) face (for clarity, only half of the molecules in a unit cell are illustrated). The nearest-neighbor molecules are related by a translational symmetry. Since the space group of the orange form is $P2_1/a$ (C_{2h}^5), the exciton wavefunction of the B_u symmetry is allowed for light polarized parallel with the *ac* plane and that of the A_u symmetry is active along the *b* axis.

The Yellow Form:[11] Crystals of the yellow form were transparent laths and elongated along the *c* axis. The prominent zone axes were {010} and {110} (Fig. 1(b)).

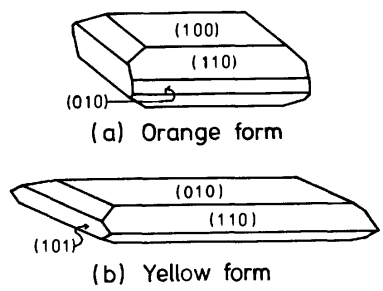

Fig. 1. Crystal morphology for (a) the orange form and (b) the yellow form.

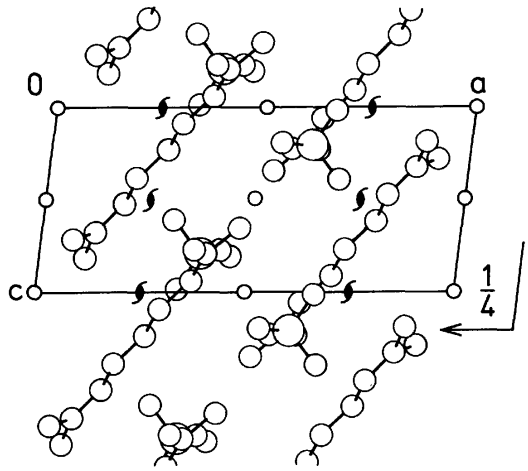

Fig. 2. Crystal structure of the orange form with symmetry symbols.

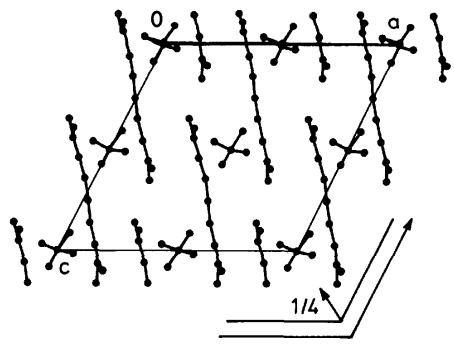

Fig. 3. Crystal structure of the yellow form with symmetry symbols.

Lattice parameters are shown in Table 1. The arrangement of the molecules in a crystal is shown in Fig. 3, where the molecules are stacked along the *c* axis. Since the space group of the yellow form is *Cc* (C_s^4), the exciton wavefunctions which have an *ac* component and a *b* component have A′ and A″ symmetries, respectively.

Measurements. Reflection spectra were measured on a microscopic spectrophotometer as reported previously.[5] The reflectivities were converted to molar absorption coefficients by a K-K transformation on a FACOM M-382 computer of the Nagoya University Computation Center. The computation program was based on the method of Ahrenkiel.[20] The absorption spectra of the monomer in solution were measured on a Hitachi 330 spectrophotometer.

Results

Solution Spectrum. The spectrum of a methanol solution at room temperature is shown in Fig. 4. Measurements of aqueous and chloroform solutions gave almost the same results. Although the absorption band has an asymmetric shape, vibrational structures are not clear. The oscillator strength is 1.08, and the transition-dipole length is estimated to be 2.02 Å.

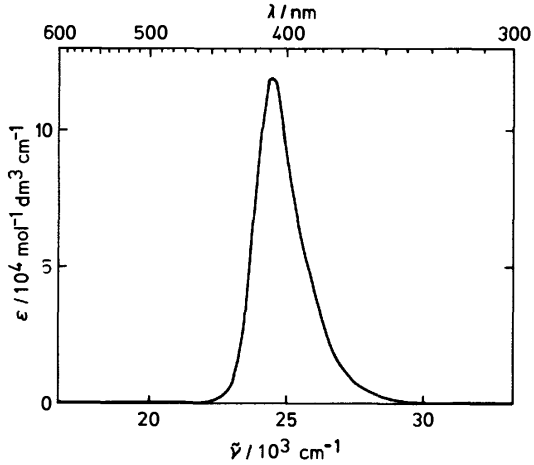

Fig. 4. Solution spectrum of 5-DMP at room temperature in methanol ($c=2\times10^{-5}$ mol dm^{-3}).

Crystalline Reflection Spectra. The Orange Form: Figure 5 shows the reflection spectra obtained for several polarization directions on the (010) face. Spectra **1** and **3**, respectively, are for parallel and perpendicular polarizations to the long axis of a cation molecule. It should be pointed out that a single reflection peak at 21500 cm^{-1} is found in the spectrum **3**. For the other polarization directions, there are at least two reflection peaks. One of them is apparently due to the $\pi\pi^*$ transition of the cation molecule, and the other in the 21500 cm^{-1} region is clearly due to an extra transition which appears only in a crystal through an intermolecular interaction.

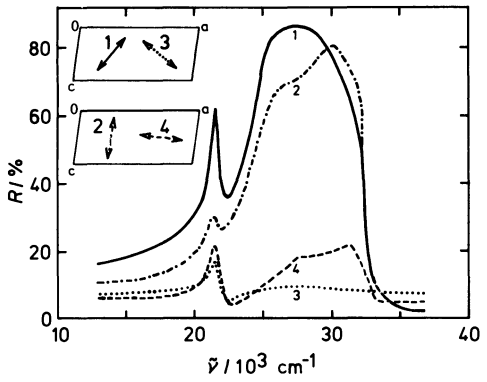

Fig. 5. Reflection spectra from the (010) face of the orange form.

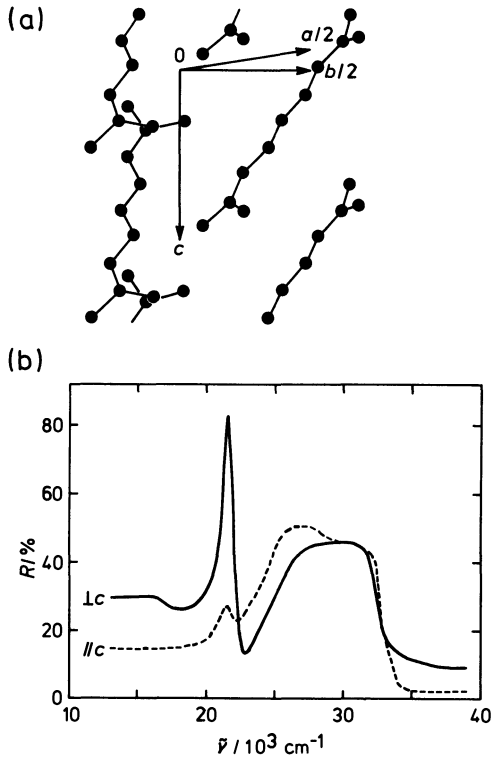

Fig. 6. (a) Projection onto the (1$\bar{1}$0) face of the orange form and (b) the reflection spectra from the (1$\bar{1}$0) face.

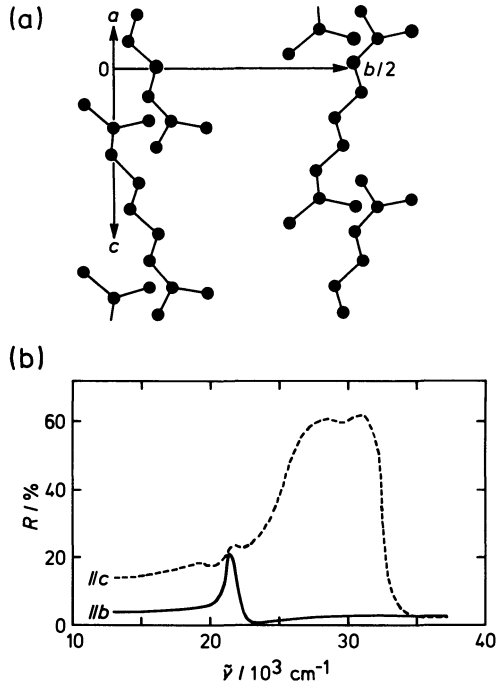

Fig. 7. (a) Projection onto the (100) face of the orange form and (b) the reflection spectra from the (100) face.

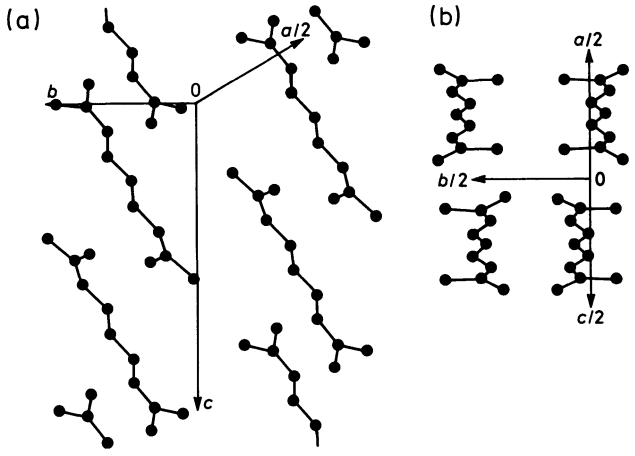

Fig. 8. (a) Projection onto the (110) and (101) faces of the yellow form.

The direction of the transition moment for the latter one is distinct from that of the $\pi\pi^*$ transition.

Figure 6(a) shows a projection onto the (1$\bar{1}$0) face. In this projection, two kinds of molecular orientations are shown, where the direction connecting the nitrogen atoms of the adjacent cation molecules is almost perpendicular to the c axis. The reflection spectra from the (1$\bar{1}$0) face is shown in Fig. 6(b). On this face, the intensity of the 21500 cm^{-1} band is maximum for the direction perpendicular to the c axis, and the B_u symmetry state of the $\pi\pi^*$ transition is greatly blue shifted in this direction. The apparent shift may be partly due to an interference effect by the 21500 cm^{-1} transition, since a sharp dip at 23000 cm^{-1} might influence the reflectance of the $\pi\pi^*$ transition at the lower edge.

In a projection onto the (100) face (Fig. 7(a)), the N···N direction is almost vertical to the developed face. Figure 7(b) shows the reflection spectra from the (100) face. In the c-axis spectrum, the 21500 cm^{-1} peak is observed very weakly and the $\pi\pi^*$ transition is largely blue shifted. In the b-axis spectrum, only a single band is found at 21500 cm^{-1}.

The Yellow Form: Figures 8(a) and (b) show projections onto the (110) and (101) faces. Figure 9 shows the reflection spectra from the (010), (110), and

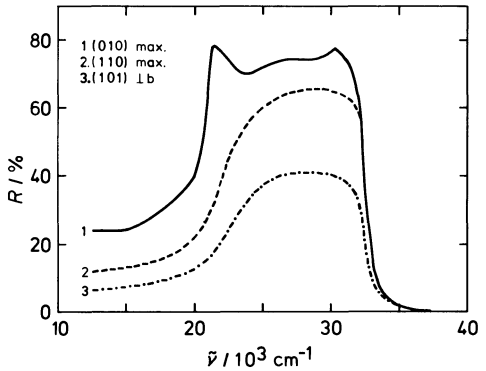

Fig. 9. Reflection spectra from the (010), (110), and (101) faces of the yellow form.

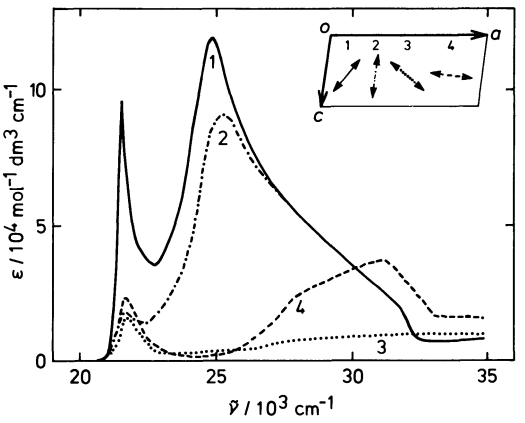

Fig. 10. Absorption spectra for the (010) face of the orange form.

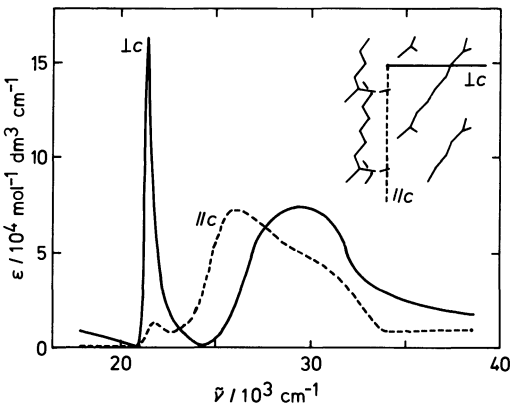

Fig. 11. Absorption spectra for the (1$\bar{1}$0) face of the orange form.

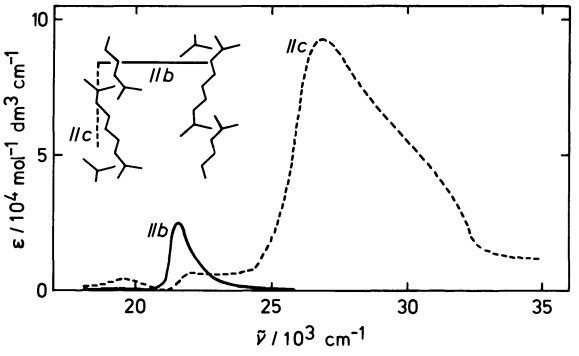

Fig. 12. Absorption spectra for the (100) face of the orange form.

(101) faces. The polarizations of light which gives the maximum reflectivities are almost parallel to the projections of the long axis of the cation molecules. This direction deviates by 5° from the long axis on the (010) face. On each face, the reflectivities with the polarization perpendicular to the maximum direction are less than 5%. Broad reflection bands are attributed mostly to the $\pi\pi^*$ transition on each face. On the (010) face, a high reflectance for a wide energy range of 1.5 eV ($\approx$12000 cm^{-1}) is shown; it exhibits a peak at the lower edge of 21200 cm^{-1}. This reflection band has been noticed as a typical quasi-metallic reflection band.[13,21,22]

K-K Transforms to Absorption Spectra. The Orange Form: The absorption spectra were obtained by a K-K transformation of the reflection spectra from the (010), (1$\bar{1}$0), and (100) faces (Figs. 10, 11, and 12). A remarkable feature of the absorption spectra is that the 21500 cm^{-1} peak shows a quite anomalous polarization behavior. As previously mentioned, the direction of the transition moment is different from that of the $\pi\pi^*$ transition on the (010) face, and the intensity is particularly strong on the (1$\bar{1}$0) face. Considering the dichroic ratio on these crystalline faces, the direction of the transition moment of the 21500 cm^{-1} band is deduced to be on the line connecting the N···N atoms; therefore, the character of this transition is assigned to the charge-resonance (CR) band between adjacent stacked molecules.

Another conspicuous characteristic of the spectra is that the peak positions of the $\pi\pi^*$ transition (MX band) are shifted to blue in many directions, presumably because the higher tail of the 21500 cm^{-1} band interferes with the rise of the reflection spectra due to the $\pi\pi^*$ transition. In the consideration of the energy levels of the MX band, this effect must be taken into account by assuming that the center of the MX band is blue shifted.

The absorption spectra of the (100) face along the *c* axis show weak peaks in the 21500 cm^{-1} region and a very strong band in the region 27000—32000 cm^{-1}. Along the *b* axis, the $\pi\pi^*$ transition shifts to red and overlaps with the CR band at 21500 cm^{-1}. These tendencies of the band shift and the splitting will be discussed in the next section.

The Yellow Form: The transformed absorption

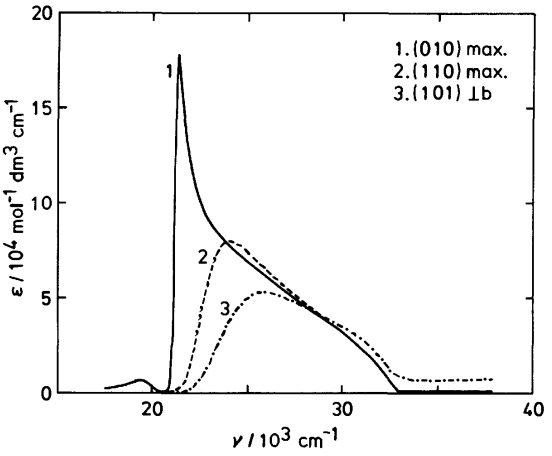

Fig. 13. Absorption spectra for the (010), (110), and (101) faces of the yellow form.

spectra for the yellow form are shown in Fig. 13. A very sharp peak at 21300 cm^{-1} and a broader peak near the 23000 cm^{-1} region were obtained on the (010) face. This is a characteristic feature of a strong metallic reflection band. The presence of two peaks was recognized in the earlier work of Fanconi et al.[21] The band feature may be due to the overlapping and mixing of the CR and MX configurations. Such a sharp peak is not found for the other faces, (110) and (101), although weak reflectivity humps are found in the 21500 cm^{-1} region. In this crystal, the effect of the CR interaction seems to appear only when the energy level of the MX configuration is close to that of the CR configuration.

Comparison with 3-DMP. In a previous study regarding the reflection spectra of 3-DMP,[18] we observed only an MX-type excited state; any token of the CR band was not detected. This is reasonable since the intermolecular overlap between cation molecules is not large and no specific interaction exists between nitrogen atoms of the adjacent molecules. In 5-DMP crystals, an additional transition is found which is due to an intermolecular electron exchange interaction due to a significant molecular overlap. The cause of such a contrast may be that 5-DMP has a longer conjugated system than 3-DMP; therefore, both the donor and the acceptor properties are enhanced in 5-DMP and the CR interaction is increased. The length of the conjugated chain in pentamethine may be optimum because a chain that is too long may reduce the charge density of the HOMO and the LUMO at the terminal nitrogen atoms.

Discussion

A criterion of the J band is a sharp and red-shifted absorption band, a characteristic of the aggregate; then, the 21500 cm^{-1} band of the orange form is a typical J band. Although the condition for the appearance of a J band is not yet clear, the present experimental result may provide a key for resolving this long-standing problem.

The 21500 cm^{-1} band is ascribed to a transition which is different from the $\pi\pi^*$ transition because the reflection spectra from the (010) face of the orange form (Fig. 5) show two strong peaks in the 21500 cm^{-1} and 27000 cm^{-1} regions. These are difficult to explain by an exciton-type band splitting of a single $\pi\pi^*$ transition. In the spectra on the (010) face, only the B_u state is observable using normally incident light. Also, a single transition should produce a single peak. Such a theoretical prediction has been confirmed from many experiments on various crystals. The direction of the transition moment of the 21500 cm^{-1} band should be determined from polarization measurements for all possible faces. However, the actual spectra are rather complicated because of the intensity borrowing or the mixing with the $\pi\pi^*$ transition.

In our previous studies on the spectra of cyanine dye crystals,[4,5] we have shown that the charge-resonance (CR) type band is strongly mixed with the molecular-exciton (MX) type band. Although the polarization of the charge-transfer (CT) band of the electron donor-acceptor complex is believed to lie along the direction connecting the centers of the HOMO of the donor and the LUMO of the acceptor molecules, the present CR band gives a different result. It shows that the transition moment is directed along the line connecting the N···N atoms of the adjacent dye molecules. This means that the nitrogen atoms of the cyanine dye may take on a canonical polar structure at the moment of a transition in which CR takes place between the $N\cdots N^+$ atoms. This argument is based on the fact that the intensity of the CR band arises from two sources; one is a genuine CR transition moment directed along the N···N direction, and the other comes from a mixing with the MX configuration.

By this assignment, the characteristic sharp band shape of the J band can be ascribed to the nitrogen π orbital since a sharp band feature is often found in the photoelectron spectra of the nonbonding orbital.[23] A sharp band shape is considered as an evidence of a small coupling with a molecular vibration; in other words, a nonbonding character of the nitrogen π orbital may give a small coupling with a molecular vibration in the CR spectra.

The present dye in solution exhibited a broad single absorption (Fig. 4). However, Gerhold observed two overlapping peaks in low temperature glass and estimated the vibrational interval at 1150 cm^{-1}.[14] The blue-shifted $\pi\pi^*$ bands are much

broader in the crystalline spectra than in the solution, but the 21500 cm^{-1} band is sharp without any vibrational progression.

Theoretical Consideration on the Electronic States in the Crystals. In order to discuss the interaction of the CR configuration with the MX configuration in the crystal, the effect of the intermolecular overlap interaction is considered here in detail. As previously mentioned, the interactions of the nearest-neighbor molecules extend along the c axis for both orange and yellow crystals. Therefore, we can restrict our treatment to a one-dimensional array of the molecules along the c axis.

An intense electronic absorption is found for the electronic transition between the HOMO (φ) and the LUMO (θ), and a charge transfer also occurs between the HOMO and the neighbor's LUMO. From the previous discussion regarding the direction of the CR band, an interaction between nitrogen atoms may be more important. However, in the following argument we consider interactions between molecular orbitals. The ground configuration of the system is given by

$$\Phi_G = |\cdots\varphi_{i-1}\bar{\varphi}_{i-1}\varphi_i\bar{\varphi}_i\varphi_{i+1}\bar{\varphi}_{i+1}\cdots|, \tag{1}$$

and the CR configuration is described by

$$\Phi^{\pm}_{CR} = \frac{1}{\sqrt{2N}}\sum_{i=1}^{N}(\Phi_{i\to i+1}\pm\Phi_{i+1\to i}), \tag{2}$$

where

$$\Phi_{i\to i+1} = \frac{1}{\sqrt{2}}(|\cdots\varphi_{i-1}\bar{\varphi}_{i-1}\theta_{i+1}\bar{\varphi}_i\varphi_{i+1}\bar{\varphi}_{i+1}\cdots| + |\cdots\varphi_{i-1}\bar{\varphi}_{i-1}\varphi_i\bar{\theta}_{i+1}\varphi_{i+1}\bar{\varphi}_{i+1}\cdots|) \tag{3a}$$

and

$$\Phi_{i+1\to i} = \frac{1}{\sqrt{2}}(|\cdots\varphi_{i-1}\bar{\varphi}_{i-1}\varphi_i\bar{\varphi}_i\theta_i\bar{\varphi}_{i+1}\cdots| + |\cdots\varphi_{i-1}\bar{\varphi}_{i-1}\varphi_i\bar{\varphi}_i\varphi_{i+1}\bar{\theta}_i\cdots|). \tag{3b}$$

The MX configuration can be represented for the translationally equivalent molecules by

$$\Phi_{MX} = \frac{1}{\sqrt{N}}\sum_{i=1}^{N}\Phi_i \tag{4}$$

where

$$\Phi_i = \frac{1}{\sqrt{2}}(|\cdots\varphi_{i-1}\bar{\varphi}_{i-1}\theta_i\bar{\varphi}_i\varphi_{i+1}\bar{\varphi}_{i+1}\cdots| + |\cdots\varphi_{i-1}\bar{\varphi}_{i-1}\varphi_i\bar{\theta}_i\varphi_{i+1}\bar{\varphi}_{i+1}\cdots|). \tag{5}$$

Now let us consider the matrix elements between these configurations by calculating the transfer integrals which are approximated as being propotional to the overlap integrals between the relevant molecular orbitals. The abbreviated formulae for the overlap integrals are given by

$$S_{11} = \langle\varphi_i|\varphi_{i+1}\rangle, \quad S_{12} = \langle\varphi_i|\theta_{i+1}\rangle, \quad S_{21} = \langle\theta_i|\varphi_{i+1}\rangle, \text{ and } S_{22} = \langle\theta_i|\theta_{i+1}\rangle. \tag{6}$$

An approximate formula for estimating the transfer integral is given by

$$t_{mn} = kS_{mn} \quad (m, n=1, 2). \tag{7}$$

The symmetries of the φ and θ orbitals in this system give a relation $S_{12}=-S_{21}$; hence, the matrix element between the Φ_G and the Φ^-_{CR} configurations is given by

$$\langle\Phi_G|\mathscr{H}|\Phi^-_{CR}\rangle = \frac{1}{\sqrt{N}}\sum_{i=1}^{N}(\langle\varphi_i|\mathscr{H}|\theta_{i+1}\rangle-\langle\theta_i|\mathscr{H}|\varphi_{i+1}\rangle) = \sqrt{N}k(S_{12}-S_{21}) = 2\sqrt{N}kS_{12}. \tag{8}$$

The Φ^+_{CR} configuration interacts with the Φ_{MX} configuration and the matrix element is calculated as

$$\langle\Phi^+_{CR}|\mathscr{H}|\Phi_{MX}\rangle = \frac{1}{\sqrt{2}}\cdot\frac{1}{N}\sum_{i=1}^{N}(\langle\Phi_{i\to i+1}|\mathscr{H}|\Phi_i\rangle + \langle\Phi_{i-1\to i}|\mathscr{H}|\Phi_i\rangle + \langle\Phi_{i+1\to i}|\mathscr{H}|\Phi_i\rangle + \langle\Phi_{i\to i-1}|\mathscr{H}|\Phi_i\rangle) = \sqrt{2}k(S_{22}-S_{11}). \tag{9}$$

The matrix element given in Eq. 8 is renormalized to evaluate the contribution of the Φ^-_{CR} configuration to the ground state per molecule. Then, the secular equation (including the Φ_G and the Φ^-_{CR} configurations) is given by

$$\begin{vmatrix} -E & 2kS_{12} \\ 2kS_{12} & E^-_{CR}-E \end{vmatrix} = 0. \tag{10}$$

The mixing of the Φ_{MX} and the Φ^+_{CR} configurations is calculated by solving the secular equation

$$\begin{vmatrix} E^+_{CR}-E & \sqrt{2}k(S_{22}-S_{11}) \\ \sqrt{2}k(S_{22}-S_{11}) & E_{MX}-E \end{vmatrix} = 0. \tag{11}$$

The calculation of the overlap integrals is performed by a previously reported method,[24] and obtained values are as shown in Table 2. The magnitudes of these integrals are fairly large for an intermolecular interaction and the transfer integrals are estimated by setting k=—15 eV in Eq. 7. This choice of k is reasonable in view of the Mulliken-

Table 2. Molecular Integrals between the MO's of Stacked Dye Molecules

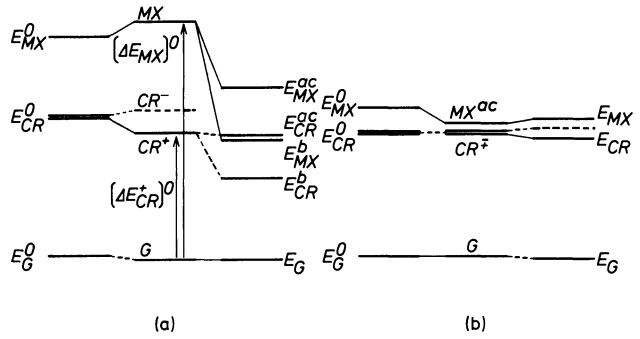

Fig. 14. Calculation procedures of the electronic states in the crystals; (a) for the orange form and (b) for the yellow form.

Wolfsberg-Helmholtz formula. It states that $k=KW$, since if we take the orbital energy of HOMO at $W=-10$ eV then $K=1.5$.[24]

The Orange Form: The calculation procedure is shown in Fig. 14(a), where the interaction of the Φ_{CR}^+ and the Φ_{MX} configurations is first considered; then, the exciton band splittings in the CR+ and the MX states are evaluated.

The initial diagonal energies for the orange form are set at $E_{CR}^0=22800\,cm^{-1}$ and $E_{MX}^0=29300\,cm^{-1}$, respectively. The blue shift of the MX state, compared to a solution spectra, is assumed to harmonize the calculated energy levels with the observed spectra. The transfer integrals of the orange form are apparently larger than those of the yellow form (Table 2). Accordingly, the mixing of the Φ_{CR}^+ configuration with the Φ_{MX} configuration is more impotant in the orange form than in the yellow form. After solving the secular equations, 10 and 11, the energy levels of the CR+ and the MX states were found at $(\Delta E_{CR}^+)^0=21900\,cm^{-1}$ and $(\Delta E_{EX})^0=30800\,cm^{-1}$, respectively, where the stabilization of the ground state was taken into account. These energy levels correspond to the center of the Davydov components. The transition moments were obtained as being a vector sum of the CR- and the MX-type moments multiplied by coefficients which were obtained by solving the secular equations. In this treatment, the CR-type moment was taken as the vector connecting the two nitrogen atoms of adjacent dye molecules. The transition length of the MX-type moment was set at 2.2 Å, larger by 10% than the solution's value. Such a bathochromism of the MX transition might exist due to the effect of the CR interaction.

In order to explain the splitting of the crystalline MX states, the exciton energy shifts were calculated for the measured faces by a dipole-dipole approximation.[5] The dipole sum was extended for molecules in a disc with a radius of 200 Å and a depth of 20 Å, placed in the crystalline surface. The wavefunctions for a MX state having A_u and B_u symmetries are given by

$$A_u : \Psi_b = \frac{1}{\sqrt{N}} \sum_{i=1}^{N} (\Psi_{1i} - \Psi_{2i} + \Psi_{3i} - \Psi_{4i}) e^{i\boldsymbol{k}\cdot\boldsymbol{R}_i} \quad (12a)$$

and

$$B_u : \Psi_{ac} = \frac{1}{\sqrt{N}} \sum_{i=1}^{N} (\Psi_{1i} - \Psi_{2i} - \Psi_{3i} + \Psi_{4i}) e^{i\boldsymbol{k}\cdot\boldsymbol{R}_i} \quad (12b)$$

where i is the numbering of the unit cell, and 1, 2, 3, and 4 designate the molecular sites. Ψ_{1i} means that the original site of the i-th cell is excited and others are in the ground state. Ψ_{2i}, Ψ_{3i}, and Ψ_{4i} are wavefunctions in which excitation occurs at sites related to the original site by the space group operators: center of symmetry, screw axis and glide plane, respectively.

The results of the calculation for the energy levels and intensities are shown in Table 3. Agreement between the observed and the calculated results is quite reasonable in spite of the complicated patterns of the spectra for the respective faces.

On the (010) face, only the B_u component is expected to appear and the observed band positions and intensities are well explained by the mixing of the Φ_{CR}^+ configuration with the Φ_{MX} configuration. The MX band for the $\perp c$ polarization was found at 28000—31000 cm^{-1} region, and such an unusual blue shift might be appeared by a decrease of the reflectivity at 26000 cm^{-1} region which is caused by the interference effect of the dip at 22500 cm^{-1}.

With the $(1\bar{1}0)$ face, the calculated spectrum for the $\|c$ direction is in good agreement with the observed spectrum. However the $\perp c$ component shows two discrepancies. First, the band intensity at the 21500 cm^{-1} region is much smaller than the observed

value in spite of the fact that the CR$^+$- and the MX-A_u states were calculated to be in this region. The sum of these intensities were not sufficient to account for the prominent strong peak. Secondly, the MX level for the $\perp c$ direction was calculated at 25400 cm^{-1} while the observed value was 29000 cm^{-1}. This blue shift may have occurred due to an interference of the sharp peak at 21500 cm^{-1}.

On the (100) face, the spectrum for the *b*-axis polarization gives a single peak and the calculated energies for the CR and the MX states are close together in agreement with the experiment. The peak position for the *c* axis is well explained by the calculation. However, the calculated intensity for the 21500 cm^{-1} band is larger than the observed one. This may depend on the calculation method.

An alternative approach to the calculation of the energy level is that the splitting of the Φ_{MX} level is first calculated for each face; then, the interaction with the Φ^+_{CR} configuration is considered on each face (Fig. 14(b)). By this method, the mixing coefficient is varried on each face and an overly enhanced intensity for the CR band of the (100) face may be reduced.

The Yellow Form: The calculation of the yellow form follows the latter method, and the shift of the Φ_{MX} configuration is evaluated at first by taking E^0_{MX} at 23800 cm^{-1} with the transition dipole length of 2.2 Å. The dye molecule in the yellow form lies along its long axis perfectly perpendicular to the *b* axis; therefore, the A″ component is not expected. In fact, the observed spectra did not show any intensity of the A″ component.

Following the present calculation, the A′ level of the Φ_{MX} configuration was calculated at 21700 cm^{-1} for the (010) face; it was very close to the assumed CR level, E^0_{CR}=21900cm^{-1}. The coupling between these two configurations is very significant; therefore, the resultant states are regarded as completely mixed states of the Φ_{MX} and Φ^+_{CR} configurations. The observed intensity is much larger than the calculated one. This may be due to the effect of the CR interaction. The sharp pattern of the 21300 cm^{-1} band may be regarded as an example of the J band; this is reasonable because it has about 50% of the CR characteristics. However, it should also be mentioned that a metallic reflection band always gives a sharp peak at the lower edge.

On the (110) face, the MX band is predicted to be slightly red shifted, and the observed peak is so shifted. The calculated CR band was not found, presumably because it was burried under the tail of the strong peak situated at the higher-energy side.

The MX band for the (101) face is calculated to

shift to blue; this is in agreement with the observed tendency. The CR band is predicted to be very weak because of a small mixing with the Φ_{MX} configuration. No reflection peak was detected at the lower-energy side.

Concluding Remarks. The spectral features of the excited states of the orange and the yellow forms of 5-DMP crystals are well explained by a consideration of the CR excited configuration in the 22000 cm^{-1} region. The transition moment of this transition is directed along the N···N atoms of the adjacent dye molecules, suggesting that the CR occurs between molecules represented by a canonical structure of Me_2N-C=C-C=C-C=N^+Me_2. A large contribution of this structure to the molecular structure of the orange form is geometrically supported by a precise X-ray analysis.[12] The sharp envelope of the CR band may be associated with the mechanism of the appearance of the J band; a charge-transfer excitation in the nonbonding orbital of a nitrogen atom occurs in a rigid molecule. Although the J band has been considered to appear due to a red shift of the molecular $\pi\pi^*$ transition in the aggregates of laterally stacked dyes, the present analysis shows that the genuine origin of the J band is the existence of a new kind of excited configuration which appears in the N···N atoms at a short distance with a favorable molecular overlap in the stacking. A single and strong J-type band may appear when the CR configuration coexists and mixes with the MX configuration of a large transition moment in the same energy region. A separate and sharp J band is found when the CR configuration is situated away from the MX configuration. The spectrum of the (010) face of the yellow form corresponds to the former case, while the spectra of the orange form represent the latter situation. Thus, the spectral features of the aggregates and crystals of cyanine dye are characterized by a CR interaction between the moieties including the nitrogen atoms of the conjugated system of the cyanine dye; the interaction occurs in a specifically favorable molecular stacking. The appearance of the J band is thus explained to be a result of a peculiar intermolecular interaction between the cyanine dye molecules.

This reseach was supported by a grant in aid of the special research project on the properties of molecular assemblies (No. 60104002) from the Minitry of Education, Science and Culture.

Vibrational Correction for Methylamine and Determination of the Zero-Point Average Structure

Takao IIJIMA
Faculty of Science, Gakushuin University, Mejiro, Toshimaku, Tokyo 171
(Received November 2, 1985)

The method of vibrational corrections for a molecule which has a large amplitude intramolecular motion has been revised and applied to the determination of the zero-point average structure of methylamine. Necessity of torsional correction for this type of molecules has been pointed out and the method has been presented. A recent result of electron diffraction was jointly used with the effective moments of inertia obtained by microwave spectroscopy by Takagi and Kojima. The structural parameters in r_z and φ_z with the estimated limits of error in parentheses are: r(C–N)=1.471(3) Å, r(C–H)=1.101(3) Å, r(N–H)=1.019(6) Å, ∠HCH=108.4(5)°, ∠HNH=106.0(6)°, and ∠CNH=111.5(7)°. Deuterium isotope effects in the structural parameters were also determined.

Rotational constants obtained by molecular spectroscopy usually suffer complicated vibrational effects. Corrections for the effects have been successfully applied to the determination of molecular structures, especially in a joint analysis by means of a combined use of spectroscopic and diffraction data. The method is established in the small amplitude approximation for intramolecular motions.[1,2] The present author and coworker extended the method for the molecules which have a large amplitude torsional motion.[3,4] However, in an attempt to determine the structure of methylamine, it became apparent that the formulation given in the previous work[3] was not adequate for this molecule.

In Ref. 3 the formulation was based on the rigid top-rigid frame theory by Kilb, Lin, and Wilson,[5] in which the principal axes fixed to the frame were the reference axes of overall rotation of the molecule. This means that counter motion of the molecule to the internal rotation was neglected. This is an appropriate approximation for a molecule with a relatively heavy frame as compared with the top.

For CH_3NH_2, the frame NH_2 is lighter than the top CH_3, and the counter motion can not be neglected. The theory of rotation-torsion Hamiltonian of this molecule has been derived by many workers in the approximation of rigid semiasymmetric internal rotors.[6–9] Based on these works, especially on the one by Itoh[8], a revised method of vibrational corrections has been formulated in the present paper.

A correction has also been made to the expression of the n-matrix given in the appendix of Ref. 3. A transformation which projects the top-fixed coordinates onto the frame-fixed axes appears in the formulation. G and F matrices[10] are practically invariant under this transformation as assumed in Ref. 3, though it does not hold rigorously unless both the top and the frame have a common C_3 axis. However, the invariance of L matrix assumed at the same time is unacceptable.

Because of the near degeneracy of the E-type coordinates any L matrix obtained by an arbitrary rotation around the C_3 axis can be a set of eigenvectors of the vibrational equation. The assumed invariance of L means a choice among many equally valid sets.

In the calculation of n-matrix elements, evaluation of the derivative of l-matrix elements[11] with respect to the torsional angle is necessary. For this purpose the L matrix must be given as a function of the torsional angle. From the invariance of G and F alone, i.e. that of the vibrational secular equation, no answer to this question comes out. A more intuitive assumption has been introduced, and the formulation for calculating the n-matrix elements has been revised and described in the Appendix.

As a result, the method of the vibrational calculation employed in Ref. 3, in which the top and the frame were regarded as two independent molecules, has no special advantage. Therefore it has been abandoned and ordinary vibrational calculations of the GF matrix method has been employed.

The n-matrix has no effect on the vibrational corrections for the principal moments of inertia,[4] although the moments of inertia of the top around its axis are affected to a considerable extent. Most of the previously reported results of structure analyses are little affected by the present revision, because they have been obtained mainly from the principal moments of inertia.

Kinetic Energy and Vibrational Corrections

The motion of a methylamine-type molecule undergoing rotation and torsion is described by three angular velocities as discussed by Itoh.[8] The reference axes rotate by the angular velocity $\boldsymbol{\omega}$; the top, i.e. the methyl group, rotates around its C_3 axis by the angular velocity $\dot{\gamma}$, and the molecule as a whole rotates by the angular velocity $\boldsymbol{\omega}_1$ so that the angular momentum associated with $\dot{\gamma}$ may be canceled by the momentum of the counter motion which is associated with $\boldsymbol{\omega}_1$. The rotation of the reference axes is a constant of motion, and the

corresponding total angular momenta give a set of good quantum numbers. These axes may be called the molecule-fixed axes, but do not coincide with the principal axes of the moments of inertia which are fixed to the frame, i.e., the amino group, and rotate by the angular velocity $\boldsymbol{\omega}+\boldsymbol{\omega}_1$. Several of the notations in the present paper are different from those of Ref. 8. The comparisons are given in Table 1.

By considering vibrational motions as well, the velocity vector of each atom is now expressed as

$$\boldsymbol{V}_i = (\boldsymbol{\omega}\times\boldsymbol{r}_i) + (\boldsymbol{\omega}_1\times\boldsymbol{r}_i) + (\dot{\boldsymbol{\gamma}}\times\boldsymbol{\sigma}_i) + \boldsymbol{v}_i, \tag{1}$$

where

$$\boldsymbol{v}_i = \dot{\boldsymbol{\rho}} - (\boldsymbol{\omega}_1\times\boldsymbol{\rho}_i) - (\dot{\boldsymbol{\gamma}}\times\boldsymbol{\varepsilon}_i), \tag{2}$$

for the i-th atom of the top, and

$$\boldsymbol{V}_j = (\boldsymbol{\omega}\times\boldsymbol{r}_j) + (\boldsymbol{\omega}_1\times\boldsymbol{r}_j) + \boldsymbol{v}_j, \tag{3}$$

where

$$\boldsymbol{v}_j = \dot{\boldsymbol{\rho}}_j - (\boldsymbol{\omega}_1\times\boldsymbol{\rho}_j), \tag{4}$$

for the j-th atom of the frame. Equations 1 and 3 are the revised expression for Eqs. 4 and 6 of Ref. 3. In the present work, however, the term for the translation of the center of gravity of the molecule is omitted from the beginning. The definitions of various symbols are summarized in Table 2.

The requirement that the angular momentum associated with $\dot{\boldsymbol{\gamma}}$ is canceled by the momentum associated with $\boldsymbol{\omega}_1$ is expressed as

$$C_2^0\dot{\boldsymbol{\gamma}} = -\boldsymbol{I}^0\boldsymbol{\omega}_1, \tag{5}$$

and therefore,

$$\boldsymbol{\omega}_1 = -(\boldsymbol{I}^0)^{-1}C_2^0\dot{\boldsymbol{\gamma}}. \tag{6}$$

where C_2 is the moment of inertia of the top around its axis and $\boldsymbol{I}$ is the tensor of the moments of inertia of the whole molecule. The superscript 0 indicates the values at the equilibrium configuration. By introducing a unit vector $\boldsymbol{\lambda}$ along $\dot{\boldsymbol{\gamma}}$, we have

Table 1. Comparison of the Notations

	This work	Ref. 8
Angular velocity of the reference axes	$\boldsymbol{\omega}$	$\boldsymbol{\omega}_2$
Angular velocity of the frame-fixed axes	$\boldsymbol{\omega}+\boldsymbol{\omega}_1$	$\boldsymbol{\omega}$
Angular velocity of the top relative to the frame: scalar representation	$\dot{\gamma}$	$\dot{x}$
vector representation	$\dot{\boldsymbol{\gamma}}$	
Angular velocity of the counter motion of the whole molecule	$\boldsymbol{\omega}_1$	$\boldsymbol{\omega}_1$
Vector relating $\dot{\boldsymbol{\gamma}}$ to $\boldsymbol{\omega}_1$ (Eq. 7)	$\boldsymbol{\nu}$	$\boldsymbol{\lambda}$
Unit vector along the top axis	$\boldsymbol{\lambda}$	$\boldsymbol{c}/C_2$

$$\boldsymbol{\omega}_1 = -(\boldsymbol{I}^0)^{-1}C_2^0\boldsymbol{\lambda}\dot{\gamma} = \boldsymbol{\nu}\dot{\gamma}. \tag{7}$$

The mass-adjusted displacement vector can be expanded in terms of the vibrational normal coordinates Q_s by the use of the l-matrix[11] as

$$\sqrt{m_i}\boldsymbol{\rho}_i = \boldsymbol{l}_{is}Q_s, \tag{8}$$

where $\boldsymbol{l}_{is}$ is a vector with the components $(l_{is}^{(x)}, l_{is}^{(y)}, l_{is}^{(z)})$. The summation symbol over s is omitted by the convention that if a subscript appears only on one side of an equation twice or more in a term, the summation over it must be taken. Because of the possible dependence of $\boldsymbol{l}_{is}$ on Ω_1 and γ, the first term of Eq. 2 multiplied by $\sqrt{m_i}$, that is, the time derivative of Eq. 8 with respect to the reference axes, becomes

$$\sqrt{m_i}\dot{\boldsymbol{\rho}}_i = \boldsymbol{l}_{is}\dot{Q}_s + \frac{\mathrm{d}\boldsymbol{l}_{is}}{\mathrm{d}\Omega_1}\omega_1 Q_s + \frac{\mathrm{d}\boldsymbol{l}_{is}}{\mathrm{d}\gamma}\dot{\gamma}Q_s, \tag{9}$$

where Ω_1 is the virtual angle-variable corresponding to $\boldsymbol{\omega}_1$. It is easily conceived that

$$\frac{\mathrm{d}\boldsymbol{l}_{is}}{\mathrm{d}\Omega_1}\omega_1 = \boldsymbol{\omega}_1\times\boldsymbol{l}_{is}, \tag{10}$$

since the $\boldsymbol{l}_{is}$ vector changes only its direction when the whole molecule rotates by $\boldsymbol{\omega}_1$. From Eqs. 8 and 10 we have

$$\frac{\mathrm{d}\boldsymbol{l}_{is}}{\mathrm{d}\Omega_1}\omega_1 Q_s = \sqrt{m_i}(\boldsymbol{\omega}_1\times\boldsymbol{\rho}_i), \tag{11}$$

and this term divided by $\sqrt{m_i}$ is canceled by the second term of Eq. 2. For $(\mathrm{d}\boldsymbol{l}_{is}/\mathrm{d}\gamma)$, however, the situation is not so simple since the configuration of the molecule changes by the torsional motion.

The third term of Eq. 2 can be rewritten as

$$\dot{\boldsymbol{\gamma}}\times\boldsymbol{\varepsilon}_i = \dot{\boldsymbol{\gamma}}\times\boldsymbol{\rho}_i - \dot{\boldsymbol{\gamma}}\times\Delta\boldsymbol{g}, \tag{12}$$

where $\Delta\boldsymbol{g}$ is the displacement vector of the center of gravity of the top and is given in terms of the normal coordinates as

$$\Delta\boldsymbol{g} = M_T^{-1}\boldsymbol{L}_{Ts}Q_s, \tag{13}$$

Table 2. Definitions of Symbols

$\boldsymbol{r}_i$, $\boldsymbol{r}_j$	Instantaneous position vector of an atom; the origin is the center of gravity of the molecule.
$\boldsymbol{\rho}_i$, $\boldsymbol{\rho}_j$	Displacement vector: $\boldsymbol{r}_i-\boldsymbol{r}_i^0$, $\boldsymbol{r}_j-\boldsymbol{r}_j^0$ a)
$\boldsymbol{\sigma}_i$	Instantaneous position vector of an atom of the top; the origin is the center of gravity of the top.
$\boldsymbol{\varepsilon}_i$	Displacement vector: $\boldsymbol{\sigma}_i-\boldsymbol{\sigma}_i^0$ a)

a) The superscript 0 indicates the equilibrium values.

with M_T, the mass of the top, and

$$\boldsymbol{L}_{Ts} = \sqrt{m_i}\boldsymbol{l}_{is}. \tag{14}$$

By means of Eqs. 1, 2 and Equations derived so far, we have

$$\begin{aligned}\sqrt{m_i}\boldsymbol{V}_i &= \sqrt{m_i}(\boldsymbol{\omega}\times\boldsymbol{r}_i) + \sqrt{m_i}(\boldsymbol{\omega}_1\times\boldsymbol{r}_i) + \sqrt{m_i}(\dot{\gamma}\times\boldsymbol{\sigma}_i)\\ &\quad + \boldsymbol{l}_{is}\dot{Q}_s + \frac{d\boldsymbol{l}_{is}}{d\gamma}\dot{\gamma}Q_s - \dot{\gamma}\times\boldsymbol{l}_{is}Q_s\\ &\quad + \dot{\gamma}\times\boldsymbol{L}_{Ts}Q_s\sqrt{m_i}M_T^{-1}\\ &= \sqrt{m_i}(\boldsymbol{\omega}\times\boldsymbol{r}_i) + \sqrt{m_i}(\boldsymbol{\nu}\times\boldsymbol{r}_i)\dot{\gamma}\\ &\quad + \sqrt{m_i}(\boldsymbol{\lambda}\times\boldsymbol{\sigma}_i)\dot{\gamma} + \boldsymbol{l}_{is}\dot{Q}_s + \boldsymbol{n}_{is}\dot{\gamma}Q_s,\end{aligned} \tag{15}$$

for the i-th atom of the top, where

$$\boldsymbol{n}_{is} = \frac{d\boldsymbol{l}_{is}}{d\gamma} - \boldsymbol{\lambda}\times\boldsymbol{l}_{is} + \sqrt{m_i}M_T^{-1}\boldsymbol{\lambda}\times\boldsymbol{L}_{Ts}. \tag{16}$$

Similarly, Eq. 3 for the j-th atom of the frame is transformed to

$$\sqrt{m_j}\boldsymbol{V}_j = \sqrt{m_j}(\boldsymbol{\omega}\times\boldsymbol{r}_j) + \sqrt{m_j}(\boldsymbol{\nu}\times\boldsymbol{r}_j)\dot{\gamma} + \boldsymbol{l}_{js}\dot{Q}_s + \boldsymbol{n}_{js}Q_s\dot{\gamma}, \tag{17}$$

where

$$\boldsymbol{n}_{js} = \frac{d\boldsymbol{l}_{js}}{d\gamma}. \tag{18}$$

The expression for the kinetic energy T can now be obtained from Eqs. 15 and 17, and after simplification by Eckart's and Sayvetz's conditions,[12-14] as

$$\begin{aligned}2T &= (\sqrt{m_i}\boldsymbol{V}_i)^2 + (\sqrt{m_j}\boldsymbol{V}_j)^2\\ &= \boldsymbol{\omega}\boldsymbol{M}\boldsymbol{\omega} + 2\boldsymbol{\omega}\boldsymbol{\zeta}_{ss'}Q_s\dot{Q}_{s'} + \dot{Q}_s\dot{Q}_s.\end{aligned} \tag{19}$$

In Eq. 19 the vectors $\boldsymbol{\omega}$ and $\boldsymbol{\zeta}$ are extended to include $\dot{\gamma}$ and $\zeta_{ss'}^{(\gamma)}$ as the fourth component, i.e., $\boldsymbol{\omega}=(\omega_x, \omega_y, \omega_z, \dot{\gamma})$ and $\boldsymbol{\zeta}_{ss'}=(\zeta_{ss'}^{(x)}, \zeta_{ss'}^{(y)}, \zeta_{ss'}^{(z)}, \zeta_{ss'}^{(\gamma)})$. The expression is formally the same as that for the well known vibration-rotation energy of ordinary molecules,[10] except that the ordinary three-dimensional expression is extended to the four-dimensional one.

Among the components of the $\boldsymbol{M}$-tensor, $M_{\alpha\beta}(\alpha,\beta=x,y,z)$ are the ordinary instantaneous moments of inertia $\boldsymbol{I}$ with respect to the reference axes. The other components are,

$$\begin{aligned}M_{\gamma\gamma}(=U) &= \boldsymbol{\nu}\boldsymbol{I}\boldsymbol{\nu} + m_i\{\boldsymbol{\sigma}_i^2 - (\boldsymbol{\lambda}\cdot\boldsymbol{\sigma}_i)^2\}\\ &\quad + 2m_i\{(\boldsymbol{\lambda}\cdot\boldsymbol{\nu})\boldsymbol{\sigma}_i^2 - (\boldsymbol{\lambda}\cdot\boldsymbol{\sigma}_i)(\boldsymbol{\nu}\cdot\boldsymbol{\sigma}_i)\}\\ &\quad + 2\boldsymbol{\lambda}\cdot(\boldsymbol{\Lambda}_{is}\times\boldsymbol{n}_{is})Q_s^2 + 2\boldsymbol{\nu}\cdot(\boldsymbol{l}_{is}\times\boldsymbol{n}_{is})Q_s^2\\ &\quad + 2\boldsymbol{\nu}\cdot(\boldsymbol{l}_{js}\times\boldsymbol{n}_{js})Q_s^2 + \boldsymbol{n}_{is}^2Q_s^2\\ &\quad + \boldsymbol{n}_{js}^2Q_s^2 - 2\boldsymbol{\nu}\cdot(\boldsymbol{\lambda}\times\boldsymbol{L}_{Rs})Q_s,\end{aligned} \tag{20}$$

where

$$\boldsymbol{\Lambda}_{is} = \boldsymbol{l}_{is} - \sqrt{m_i}M_T^{-1}\boldsymbol{L}_{Ts}, \tag{21}$$

and

$$\boldsymbol{L}_{Rs} = \sqrt{m_i}(\boldsymbol{\sigma}_i^0\times\boldsymbol{\Lambda}_{is}). \tag{22}$$

And the cross terms are

$$\begin{aligned}M_{\alpha\gamma} &= m_i\{\nu_\alpha r_i^2 - (\boldsymbol{r}_i)_\alpha(\boldsymbol{\nu}\cdot\boldsymbol{r}_i)\} + m_i\{\lambda_\alpha\sigma_i^2 - (\boldsymbol{\sigma}_i)_\alpha(\boldsymbol{\lambda}\cdot\boldsymbol{\sigma}_i)\}\\ &\quad + m_j\{\nu_\alpha r_j^2 - (\boldsymbol{r}_j)_\alpha(\boldsymbol{\nu}\cdot\boldsymbol{r}_j)\}\\ &\quad + (\boldsymbol{l}_{is}\times\boldsymbol{n}_{is})_\alpha Q_s^2 + (\boldsymbol{l}_{js}\times\boldsymbol{n}_{js})_\alpha Q_s^2 - (\boldsymbol{\lambda}\times\boldsymbol{L}_{Rs})_\alpha Q_s.\end{aligned} \tag{23}$$

$(\alpha=x, y, z)$

In Eqs. 20 and 23 the terms of $Q_sQ_{s'}$ are omitted because they will vanish when the averaging over the vibrational state is performed. Note that for a vibrationless state (Q_s=0), Eq. 20 reduces to $C_2-\boldsymbol{\nu}\dot{\boldsymbol{I}}\boldsymbol{\nu}$ and Eq. 23 to 0, to become identical with the expression given by Eq. 7 of Ref. 8, $\boldsymbol{\omega}-\boldsymbol{\lambda}\dot{x}$ in Ref. 8 being replaced by the $\boldsymbol{\omega}$ in the present work.

The expression for $\zeta_{ss'}$ are,

$$\zeta_{ss'}^{(\alpha)} = (\boldsymbol{l}_{is}\times\boldsymbol{l}_{is'})_\alpha + (\boldsymbol{l}_{js}\times\boldsymbol{l}_{js'})_\alpha, \quad (\alpha=x, y, z) \tag{24}$$

and

$$\begin{aligned}\zeta_{ss'}^{(\gamma)} &= \boldsymbol{\lambda}\cdot(\boldsymbol{\Lambda}_{is}\times\boldsymbol{l}_{is'}) + \frac{1}{2}(\boldsymbol{n}_{is}\boldsymbol{l}_{is'} + \boldsymbol{n}_{is'}\boldsymbol{l}_{is})\\ &\quad + \frac{1}{2}(\boldsymbol{n}_{js}\boldsymbol{l}_{js'} + \boldsymbol{n}_{js'}\boldsymbol{l}_{js})\\ &\quad + \boldsymbol{\nu}\cdot(\boldsymbol{l}_{is}\times\boldsymbol{l}_{is'} + \boldsymbol{l}_{js}\times\boldsymbol{l}_{js'}).\end{aligned} \tag{25}$$

The procedure of transforming Eq. 19 to the quantum mechanical Hamiltonian and the method of numerical calculation to obtain vibrational corrections for $\boldsymbol{I}$ and U, are formally the same as given in Ref. 3, and are not reproduced here. Numerical values of the vibrational corrections for the configuration of γ=0 are listed in Table 3 as ΔI_{vib}. The force constants determined by Hamada et al.[15] were used in the numerical calculations.

Table 3. Vibrational and Torsional Corrections for the Moments of Inertia of CH_3NH_2 (in uÅ² units)

	$I^{(eff)}$ a)	ΔI_{tor}	ΔI_{vib}	$I^{(z)}$
A	22.331_6	-0.011_4	0.084_8	22.405_0

a) Effective values by Takagi and Kojima.[17] Conversion factor 505376 MHz·uÅ² was used. b) Obtained by solving Eq. 31.

Torsional Average

It seems that Itoh[8] did not pay much attention to the difference among the reference axes and the frame-fixed axes. His Hamiltonian (Eq. 11 of Ref. 8) is actually expressed in terms of the angular momentum conjugate to the angular velocity of the frame-fixed axes. In fact his expression for kinetic energy, the unnumbered equation before the Eq. 11, is easily shown to be equivalent to Eq. 3 by Hecht and Dennison.[6]

Itoh's skillful presentation succeeded in introducing the coupling between the torsional motion and the rotational quantum number K without a discussion on the boundary conditions for the wave function.[16] However his formulation did not include the additional rotation of the newly chosen axes around the axis in the direction of ω_1. This rotation would bring about the dependence of the rotational constants on the torsional angle γ, as is fully described by Hecht and Dennison.[6]

Because of the γ-dependence of the rotational constants, the effective values of the rotational constants determined by the analysis of microwave spectra, e.g. those by Takagi and Kojima[17], become slightly different from those values at $\gamma=0$. In the case of a methylamine-type molecule, this effect must be also corrected for in addition to the vibrational corrections.

The rotational constants tensor can be expressed as

$$\begin{pmatrix} b & 0 & 0 \\ 0 & c & d \\ 0 & d & a \end{pmatrix}, \tag{26}$$

with respect to the reference axes and for $\gamma=0$. The γ-dependence is derived by Hecht and Dennison[6] as

$$\begin{pmatrix} b\cos^2 \nu\gamma + c\sin^2 \nu\gamma & (b-c)\sin \nu\gamma \cos \nu\gamma & -d\sin \nu\gamma \\ (b-c)\sin \nu\gamma \cos \nu\gamma & b\sin^2 \nu\gamma + c\cos^2 \nu\gamma & d\cos \nu\gamma \\ -d\sin \nu\gamma & d\cos \nu\gamma & a \end{pmatrix}. \tag{27}$$

By expanding each element by γ to the order of γ^2 and taking average over γ, we find

$$\begin{aligned} b^{\mathrm{eff}} &= b - \Delta, \\ c^{\mathrm{eff}} &= c + \Delta, \end{aligned} \tag{28}$$

where

$$\Delta = (b-c)\nu^2\langle\gamma^2\rangle. \tag{29}$$

Corrections to other terms are minor.

The relation between b^{eff} and b (also c^{eff} and c) can be transferred to the relation between the moment of inertia A^{eff} and A (B^{eff} and B) with respect to the initially chosen conventional axes as

$$A = A^{\mathrm{eff}}\left(1-\frac{\Delta}{b}\right), \quad B = B^{\mathrm{eff}}\left(1+\frac{\Delta}{c}\right). \tag{30}$$

Numerical values for these torsional corrections are shown in Table 3 as ΔI_{tor}. The value of $\langle\gamma^2\rangle$ was estimated from the torsional frequency in the harmonic approximation.

The symbols A, B, C, etc. are usually used for rotational constants. However in the case of methylamine they are customarily used for the moments of inertia with respect to the conventional x, y, z axes; z axis is chosen parallel to the top axis and z-y plane is the symmetry plane of the molecule at $\gamma=0$. The components of the inertia tensor of this coordinate system are denoted as $I_{xx}=A$, $I_{yy}=B$, $I_{zz}=C$ and $I_{yz}=-D$. The rotational constants a, b, c, etc. are related to A, B, C, etc. as in Eq. 27 of Ref. 8 or in Table XII of Ref. 17.

Since the results of analysis of microwave spectra are reported in terms of A, B, C, etc., the vibrational and torsional corrections evaluated in the present work are reported in terms of the values applicable to A, B, C, etc. The observed effective values were first corrected for the torsional effect to yield the effective values for the configuration of $\gamma=0$. Then the vibrational corrections evaluated for $\gamma=0$ were applied, and the values of A, B, C, etc. corresponding to the zero-point average structure were obtained, as summarized in Table 3.

Zero-Point Average Structure

The moments of inertia for methylamine and its deuterated species CD_3ND_2 and CH_3ND_2 were reported by Takagi and Kojima.[17] The torsional and vibrational corrections as discussed in the preceding sections were applied to the reported values and the moments of inertia $I^{(z)}$ for the zero-point average structure were obtained as shown in Table 3 and 4. The zero-point moments of the methyl top around its axis, $C_2^{(z)}$ or $I_\gamma^{(z)}$, were also obtained from $U^{(z)}$ by solving the equation,

$$U^{(z)} = \frac{C_2^{(z)}[B^{(z)}(C^{(z)}-C_2^{(z)})-(D^{(z)})^2]}{B^{(z)}C^{(z)}-(D^{(z)})^2}. \tag{31}$$

The zero-point average structure, i.e. a set of structural parameters which give a best fit to $I^{(z)}$, was determined. The structural parameters are the

Table 4. Zero-Point Moments of Inertia for CD_3ND_2 and CH_3ND_2 (in uÅ^2 units)

	CD_3ND_2	CH_3ND_2
A	30.594_7	24.984_3
B	32.536_1	26.967_4
C	9.740_8	6.582_5
D	1.000	0.959_3
U	2.187_9	1.635_7
C_2	6.380_4	3.18—3.37

distances C–N, C–H, N–H, and the angles ∠HCH, ∠HNH, ∠CNH and the tilt of the methyl top. For the deuterated species, the parameters may be slightly different from those of the parent species. The difference (deuterated–parent) is called the isotope effect. The isotope effects in the C–N and C–H distances were fixed at the calculated values by assuming the Morse parameter a to be 2.0 Å^{-1}.[1,2] The isotope effects in N–D and ∠DND of CH_3ND_2 were assumed to be equal to those of CD_3ND_2. The isotope effects in ∠HCH and the tilt of CH_3ND_2 were assumed to be zero.

For the C–N distance, the result of electron diffraction[18] was transferred. Otherwise a rather wide range of structural parameters would have been permissible. The $r_g - r_z$ correction for the C–N distance was evaluated to be 0.0010 Å which includes the centrifugal distortion 0.0005 Å, by assuming the Morse parameter a to be 2.0 Å^{-1}.

The results are summarized in Table 5. The uncertainties in parentheses correspond to the uncertainty of the C–N distance, ±0.003 Å and the assumed uncertainties of $I^{(2)}$, ±0.01 uA^2. The C_2 of CH_3ND_2 was not used, because in this case the two solutions of the parabolic equation (Eq. 31) become very close and the uncertainties of B, C, and U are amplified and lead to a very uncertain value of C_2. It was attempted to adjust also the isotope effects in ∠DND and the tilt of CH_3ND_2. A better fit was obtained but the results were physically unacceptable because the values of the isotope effects were in contradiction to the naturally expected trend that the isotope effects for this species must be in between those of CD_3ND_2 and zero.

The determined N–H distance and its isotope effect are in agreement with those of ammonia by Morino et al.[19]; r_z 1.024(1) Å and δ(N–D) −0.002(2) Å. The HNH angle is smaller than that of ammonia 107.3(1)°. This result is examined as follows.

By considering the wagging-inversion potential determined by Tsuboi et al.[20] the zero-point average of the wagging-inversion normal coordinate Q_6 was estimated. From the L^{-1}-matrix elements it was found that major contribution to Q_6 came from the symmetry coordinates S_4, the C–N stretching, and S_6, the amino-wagging given by

$$S_6 = \frac{1}{\sqrt{3}}(\Delta\beta_1 + \Delta\beta_2 + \Delta\alpha), \tag{32}$$

where β_1 and β_2 are the two CNH angles and α is the HNH angle. The zero-point average of S_4 was estimated by the use of the mean square amplitude and the Morse parameter, and $\langle S_6\rangle_0$ was obtained from $\langle Q_6\rangle_0$. Then the zero-point average of $\Delta\beta_1+\Delta\beta_2+\Delta\alpha$ was evaluated to be 2.0°. The isotope effect for this sum of angles was then estimated to be −0.7°. The corresponding quantity from Table 5 becomes −1.2±0.8°, which is comparable to the estimated value from the wagging-inversion potential.

Table 5. Zero-Point Average Structure of Methylamine

	r_z, φ_z[a]	$\delta_{CD_3ND_2}$[b]	$\delta_{CH_3ND_2}$[b]
C–N	1.471(3)[c]	[−0.000$_4$][d]	[−0.000$_2$][d]
C–H	1.101(3)	[−0.002][d]	[0.0][e]
N–H	1.019(6)	−0.003(3)	[−0.003][e]
∠HCH	108.4(5)	−0.2(1)	[0.0][e]
∠HNH	106.0(6)	0.4(2)	[0.4][e]
∠CNH	111.5(7)	−0.8(3)	−0.6(3)
θ[f]	2.97(4)	0.00(3)	[0.00][e]

a) Distance in Å and angles in degrees units. 1Å=100 pm. Uncertainties in parentheses are the estimated limits of error. b) Isotope effects: deuterated−parent. c) The result of electron diffraction.[18] d) Calculated. e) Assumed. f) Tilt angle of the methyl group away from the hydrogen atoms of the amino group.

It is noted that the isotope effect for ∠CNH is negative while that for ∠HNH is positive. This suggests that the initial stage of the wagging-inversion motion is composed of a decrease in ∠HNH and an increase of ∠CNH, showing a repulsive effect of the methyl group. A slightly smaller value for the HNH angle of methylamine as compared with that for ammonia is consistent with this view of the repulsive interaction.

Appendix

n-Matrix Elements. In methylamine molecule each normal mode is well localized to the corresponding symmetry coordinate. Thus an assumption was made that the E-type symmetry coordinates change direction as the methyl group rotates relative to the frame, and the other types of symmetry coordinates are invariant. Then we have for the displacement vector of the i-th atom of the top,

$$\boldsymbol{\rho}_i = \begin{pmatrix} \mathcal{R}(\gamma) \\ & 1 \end{pmatrix} \{\boldsymbol{A}_{ir}L_{rs}Q_s + \boldsymbol{A}_{it}L_{ts}Q_s\} + \boldsymbol{A}_{iq}L_{qs}Q_s, \tag{A. 1}$$

where the notation follows Ref. 3. The γ-dependence of l_{is} is explicitly given by Eq. A.1, and the n-matrix elements are obtained by the definition given by Eq. 16 simply as

$$\boldsymbol{n}_{is} = -\sqrt{m_i}\boldsymbol{\lambda} \times \boldsymbol{A}_{iq}L_{qs} + \sqrt{m_i}M_T^{-1}\boldsymbol{\lambda} \times \boldsymbol{L}_{Ts}. \tag{A. 2}$$

Note that the γ-dependent terms in the first and the second term of Eq. 16 cancel each other.

Similarly for the j-th atom of the frame,

$$\boldsymbol{\rho}_j = \boldsymbol{A}_{jr}L_{rs}Q_s + \boldsymbol{A}_{jt}\mathcal{R}(\gamma)L_{ts}Q_s + \boldsymbol{A}_{jq}L_{qs}Q_s, \tag{A. 3}$$

and by Eq. 18 we have

$$\boldsymbol{n}_{js} = \sqrt{m_j}\boldsymbol{A}_{jt}\frac{d\mathcal{R}(\gamma)}{d\gamma}L_{ts}. \tag{A. 4}$$

The derivative is given as

$$\frac{d\mathcal{R}(\gamma)}{d\gamma} = \begin{pmatrix} -\sin\gamma & -\cos\gamma \\ \cos\gamma & -\sin\gamma \end{pmatrix}, \quad \text{(A. 5)}$$

and for the configuration at $\gamma=0$,

$$\left(\frac{d\mathcal{R}(\gamma)}{d\gamma}\right)_{\gamma=0} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}. \quad \text{(A. 6)}$$

Absorption Spectra of Tetrahedral Co(II) in Single Crystals of $[N(CH_3)_4]_2[CoX_4]$ (X=Cl,Br)

Kazuo KOJIMA and Jiro MATSUDA*
Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603
(Received July 18, 1985)

The optical absorption spectra of single crystals of $[N(CH_3)_4]_2[CoCl_4]$ and $[N(CH_3)_4]_2[CoBr_4]$ have been measured over the range of 4000—33000 cm^{-1} at the temperature of liquid nitrogen and at room temperature. The spectra have been analyzed using the crystal-field theory which includes spin-orbit coupling. Some discussion of the Racah parameter B and of the $^4T_1(^4F)$ and $^4T_1(^4P)$ states is presented.

The electronic spectra of tetrahalocobaltate(II) have been extensively studied[1-17] in two types of compounds, R_2CoX_4 and R_3CoX_5, but most reports have covered either the spin-allowed or the spin-forbidden transition regions. For example, Cotton et al.[4] have studied the spin-allowed transitions of R_2CoX_4, while Harada et al.[10,12,13] and Bird et al.[11] have analyzed in detail the spin-forbidden transitions in single crystals of Cs_3CoCl_5 and Cs_3CoBr_5. Exceptionally, Ferguson[5] has investigated the spectra of both the spin-allowed and spin-forbidden transitions in the mixed crystals of $R_2[Co_xZn_{1-x}Cl_4]$ at low temperatures.

In the present paper, the absorption spectra of $[CoX_4]^{2-}$ in single crystals of tetramethylammonium salts $[N(CH_3)_4]_2[CoX_4]$, where X is Cl or Br, are reported over the range of 4000—33000 cm^{-1}; this study was undertaken in order to investigate both the spin-allowed and the spin-forbidden d-d transitions in $[CoX_4]^{2-}$ and to compare the electronic transitions in the chloro complex with those in the bromo complex. Tetramethylammonium salts are chosen for the present study because the $[CoCl_4]^{2-}$ complex ion in this salt is known to show only a little deviation from regular tetrahedral symmetry, T_d, at room temperature.[16,18,19]

The spectra of $[N(CH_3)_4]_2[CoCl_4]$ have been studied in the infrared region by Quinn and Smith[9] and from the visible to the near-ultraviolet region by Hosoya et al.[17] as well as Ferguson.[5] The spectra of $[N(CH_3)_4]_2[CoBr_4]$ have never been reported in any region.

Other interesting studies have also been presented concerned with magnetic properties,[2,4,6,20-22] theoretical calculations[23,24] of energy levels, and the electron-spin density[25-28] of $[CoX_4]^{2-}$ complexes.

Experimental

Single crystals of $[N(CH_3)_4]_2[CoX_4]$ were obtained by the slow evaporation, at room temperature, of aqueous solutions containing a stoichiometric composition of $N(CH_3)_4X$ and CoX_2. Crystals of $[N(CH_3)_4]_2[CoCl_4]$ and $[N(CH_3)_4]_2[CoBr_4]$ are blue and greenish-blue prisms respectively. Mixed crystals of $[N(CH_3)_4]_2[Co_xZn_{1-x}X_4]$ were prepared from aqueous solutions of $N(CH_3)_4X$, CoX_2, and ZnX_2.

The spectra were recorded on a Shimadzu MPS-50L spectrophotometer at 77 K and on a Hitachi 340 instrument at room temperature. For measurements at 77 K, cut and polished specimens about 2×2 mm^2 and 0.2—1.0 mm thick were either immersed (visible and near-infrared regions) or not immersed (ultraviolet region) in liquid nitrogen in a glass Dewar apparatus. Filters of POLAROID HN-42T (visible region) and HR-INFRARED (near-infrared region) were used to measure the polarized spectra of $[N(CH_3)_4]_2[CoCl_4]$. The crystarographic c axis was determined by the X-ray oscillation method. For measurements in the spin-allowed bands at room temperature, small specimens about 1×1 mm^2 and 0.1—0.2 mm thick were used.

Results and Discussion

The unpolarized spectra are shown in Figs. 1 and 2, while their numerical data are summarized in Table 1. The overall features of the spectra are similar to the previous data.[1,5,11,16,17] Considerable differences can be found between the spectra of $[N(CH_3)_4]_2[CoCl_4]$ and $[N(CH_3)_4]_2[CoBr_4]$ in the III and IV bands in Fig. 2; the spectra in both these bands are, however, remarkably sharpened by the cooling of the crystals to 77 K. The low-energy absorption in the $^4T_1(^4F)$ band (near-infrared region) in $[N(CH_3)_4]_2[CoCl_4]$ is resolved at 77 K. A shoulder observed in the spectra of $[N(CH_3)_4]_2[CoBr_4]$ at room temperature appears as a peak of 30960 cm^{-1} at 77 K. Bird et al.[11] have reported the corresponding peak in Cs_3CoBr_5 at 4.2 K.

Since the spectra of the $^4T_1(^4P)$ bands are too intense to be resolved even at 77 K, those of the mixed crystals at room temperature are shown in Fig. 3. There are four structures in these bands, and their patterns are almost unchanged at 77 K.

The polarized spectra of $[N(CH_3)_4]_2[CoCl_4]$ are shown in Figs. 4 and 5. No significant difference between the polarized spectra for $\boldsymbol{E}//c$ and $\boldsymbol{E}\perp c$ can be found, and these results are similar to Ferguson's observations.[5]

The spectra of tetraethylammonium salt $[N(C_2H_5)_4]_2[CoCl_4]$ are also observed (not shown) and are similar to those of the tetramethylammonium salt

a) Observed at 77 K. b) Γ_6(*), Γ_7(**), and the others are Γ_8. c) Shoulder. d) Observed for mixed crystals. e) Observed at room temperature. f) Vibrational bands.

$[N(CH_3)_4]_2[CoCl_4]$, except that the spectra in the region of 17000—25000 cm^{-1} in the tetraethylammonium salt are shifted to wavenumbers lower by 150-300 cm^{-1} compared with the tetramethylammonium salt.

For $[N(CH_3)_4]_2[CoCl_4]$, the very weak peak of 8610 cm^{-1} observed distinctly at room temperature (Fig. 1) and the four peaks of 4410, 4280, 4170, and 4080 cm^{-1} may all be due to the vibrational transitions in $[CoCl_4]^{2-}$, accompanied by the $^4A_2 \rightarrow {}^4T_1(^4F)$ electronic transition. The spectra of these vibrations can not be assigned, although some

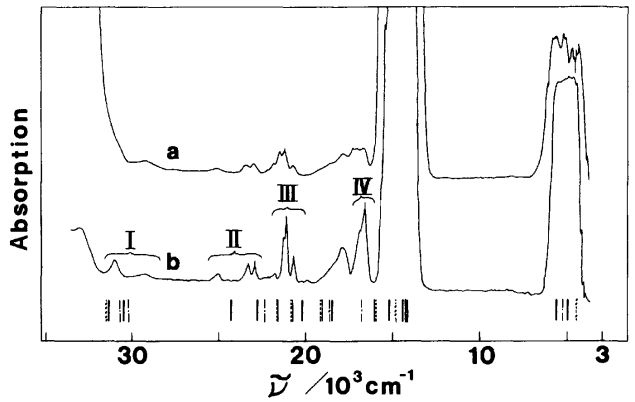

Fig. 2. Absorption spectra of $[N(CH_3)_4]_2[CoBr_4]$ at room temperature (a) and 77 K (b). Calculated energy levels are shown by vertical lines; Γ_8(——), Γ_7(– – –), and Γ_6(- - - -).

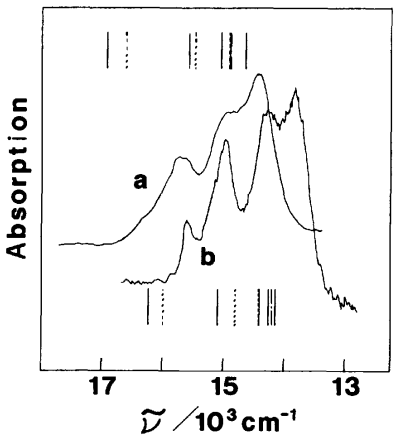

Fig. 3. The $^4A_2 \rightarrow {}^4T_1(^4P)$ absorption bands of mixed crystals $[N(CH_3)_4]_2[Co_xZn_{1-x}Cl_4]$ (a) and $[N(CH_3)_4]_2[Co_xZn_{1-x}Br_4]$ (b) at room temperature. Note that the scale of the ordinate for b is enlarged than that of a. Calculated energy levels are shown by vertical lines; Γ_8(——), Γ_7(– – –), Γ_6(- - - -).

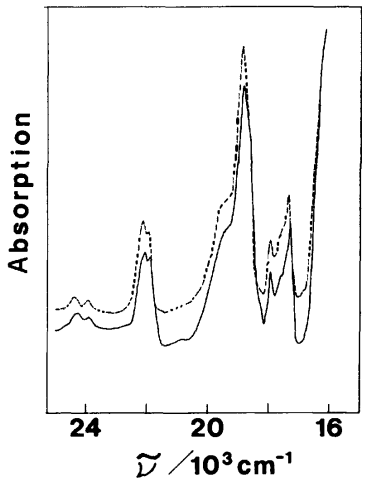

Fig. 4. The polarized spectra of the spin-forbidden bands in $[N(CH_3)_4]_2[CoCl_4]$ at 77 K; $\boldsymbol{E}_{\perp c}$ (——) and $\boldsymbol{E}_{//c}$ (- - - -).

vibrational bands in the $[CoCl_4]^{2-}$ complex have been reported.[13,16,29,30] For $[N(CH_3)_4]_2[CoBr_4]$, the corresponding bands are at 4200, 4080, and 3950 cm^{-1}, but those intensities are low relative to the bands of $[N(CH_3)_4]_2[CoCl_4]$.

In order to calculate the energy levels on the basis of the strong crystal-field theory, the symmetry of the $[CoX_4]^{2-}$ ion is assumed to be T_d, for little anisotropy is observed in the polarized spectra at 77 K (Figs. 4 and 5). Tanabe-Sugano energy matrices,[31] including spin-orbit ones,[32] are diagonalized, using a HITAC M-160H computer, for various values of the D_q, B, C, and ζ parameters, where D_q is the crystal-field strength, B and C are Racah parameters, and ζ is the spin-orbit coupling constant. The calculated energy levels are shown as vertical lines in Figs. 1—3 and in Table 1. Those levels are calculated with D_q=310 cm^{-1}, B=740 cm^{-1}, C=4.6B, and ζ=490 cm^{-1} for $[N(CH_3)_4]_2[CoCl_4]$ and D_q=280 cm^{-1}, B=720 cm^{-1}, C=4.6B, and ζ=500 cm^{-1} for $[N(CH_3)_4]_2[CoBr_4]$. From these calculations, it is shown that the bands of the regions of I and II are mainly due to the transitions of $^4A_2 \rightarrow {}^2T_1(^2F)$, $^2T_2(^2F)$, $^2A_2(^2F)$, and $^4A_2 \rightarrow {}^2E(^2D)$, $^2T_2(^2D)$ respectively. The other absorption bands in the regions of III and IV can be ascribed to the transitions to some components of the ^2P, ^2H, and ^2G terms.

The values calculated for the two complexes do not agree precisely with the observed data in the regions of II and III. If the higher energy states arising from the ^2D, ^2P, and ^2H terms were estimated with B over

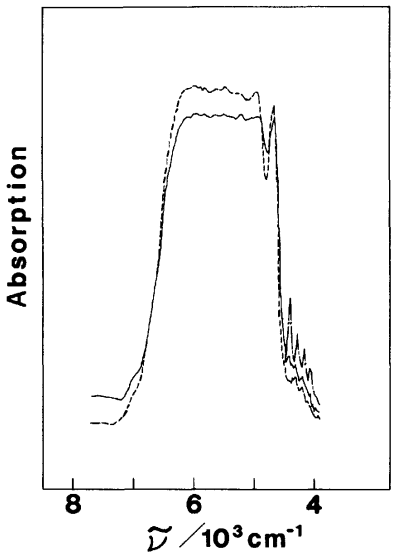

Fig. 5. The polarized spectra of the $^4T_1(^4F)$ band in $[N(CH_3)_4]_2[CoCl_4]$ at 77 K; $E \perp c$ (——), $E // c$ (– – –), and unpolarized (— — —).

740 cm^{-1}, the results of calculation should be in good agreement with the spectral regions of II and III. Hosoya et al.[17] have successfully estimated the energies only for the spin-forbidden transitions in $[N(CH_3)_4]_2[CoCl_4]$ with the large B value of 780 cm^{-1}. On the other hand, Ferguson[5] has obtained the small B value of 720 cm^{-1}. This may result from the disregard for the ≈26500 cm^{-1} band due to the ^2D term. Harada and Tsujikawa[12] have estimated the various values of B viz 740—840 cm^{-1} for Cs_3CoCl_5 and 710—798 cm^{-1} for Cs_3CoBr_5 in the regions of II and III. This can be explained by the fact that a different B value is necessary for each energy level, as in Ferguson's suggestion[5] that e orbitals differ from t_2 orbitals in the extent of expansion. There is a marked tendency for small B values and large B values to be obtained from the spectra for the spin-allowed and for the spin-forbidden transitions respectively.

Horrocks and Burlone[24] have obtained e_σ=2300 cm^{-1} and B=740 cm^{-1} for $[CoCl_4]^{2-}$ in both Cs_3CoCl_5 and Cs_2CoCl_4 by using the angular-overlap model for the spin-allowed transitions. This e_σ value corresponds to the D_q value of 307 cm^{-1}, which agrees with the D_q value in this study. The angular-overlap model is useful for the study of low-symmetry complexes and is a realistic model for metal-ligand covalent bonding, but the formalism is in the ligand-field theory. An analysis of the spectra due to the spin-forbidden transitions by the angular-overlap model is to be hoped for.

Hiller et al.[23] have obtained much valuable information on the cobalt-ligand bonding in $[CoCl_4]^{2-}$ by using the ab initio MO calculations only for the

$^4A_2$, $^4T_2$, and $^4T_1$, states. The calculated energies of 3450 cm^{-1} ($^4A_2 \rightarrow {}^4T_2(^4F)$), 6100 cm^{-1} ($^4A_2 \rightarrow {}^4T_1(^4F)$), and 21600 cm^{-1} ($^4A_2 \rightarrow {}^4T_1(^4P)$) do not seem to account successfully for the experimental data of 3000, 5500, and 15000 cm^{-1} respectively. Results for the spin-forbidden transitions are also desirable. Hiller et al. have described that the $^4T_1(^4P)$ and $^4T_1(^4F)$ states are composed mainly (≈60%) of the $e^3t_2^4$ and $e^2t_2^5$ configurations respectively and that these results disagree with the results of the simple crystal-field theory. This configuration has already been reported for CoO_4 complexes by Pappalardo et al.[33] Our results for the $^4T_1$ states for $[N(CH_3)_4]_2[CoCl_4]$ are shown in Table 2. A similar relation can be found in this study between the states of electronic configuration. The low-energy state of $^4T_1(^4F)$ is composed of the 64—68% $e^2t_2^5$ configuration, while the high-energy $^4T_1(^4P)$ state is composed of the 53—68% $e^3t_2^4$ configuration, where the e orbital has lower energies than the t_2 orbital in the T_d symmetry. On the contrary, Ferguson[5] has reported that $^4T_1(^4F)$ has the configurations of 66% $e^3t_2^4$ and 33% $e^2t_2^5$ and that $^4T_1(^4P)$ has 31% $e^3t_2^4$ and 69% $e^2t_2^5$. The reason for these inverse results can not be found in his report.

For $[N(CH_3)_4]_2[CoBr_4]$, the results are similar to those in Table 2 (not shown).

In the bands of I and $^4T_1(^4P)$, the computed energies agree less with the observed spectra in $[N(CH_3)_4]_2[CoBr_4]$ than with those of $[N(CH_3)_4]_2[CoCl_4]$; this may be due to the difference in the covalency of the Co-X bond between the two complexes.

The $^4A_2 \rightarrow {}^4T_2(^4F)$ transition may be expected to be in the infrared region, outside the spectral region in the present study. The computed energies of this transition for both the complexes are listed in Table 1. For $[N(CH_3)_4]_2[CoCl_4]$, those energies are predicted to be at 3410, 3330, 3070, and 2920 cm^{-1}; hence, the split width is 490 cm^{-1}. For the corresponding

transition, Quinn and Smith[9] have observed relatively sharp absorptions in the region of 3340—3540 cm^{-1} which lie at higher energies than our calculated ones. On the other hand, Stapele et al.[6] have reported this corresponding absorption band in the range of 2800—3500 cm^{-1} for $Cs_3Zn_{0.9}Co_{0.1}Cl_5$.

The present authors wish to thank Professor Naotake Nakamura of Ritsumeikan University for his kind help in the X-ray measurements.

The Separation and Concentration of Gallium(III) and/or Indium(III) Using Polystyrene Resins Functionalized with Complexane-Type Ligands

Toshishige M. SUZUKI,* Toshiro YOKOYAMA, Hideyuki MATSUNAGA, and Tetsuo KIMURA
Government Industrial Research Institute, Tohoku. 4-2-1 Nigatake, Sendai 983
(Received November 13, 1985)

Macroreticular styrene-divinylbenzene copolymers functionalized with iminodiacetic acid and diethylenetriamine-*N,N,N'',N''*-tetraacetic acid have been examined in order to apply them to the selective recovery of gallium(III) and/or indium(III) from acidic solutions. The equilibrium adsorption capacities, distribution coefficients, and metal-adsorption rates of the polymer resins for Group IIIb ions and other common metal ions have been studied. The selectivity sequence of the present resins are as follows: Fe(III)> In(III)>Ga(III)≈Cu(II)>Zn(II)>Al(III). The selective recovery of In(III) and/or Ga(III) from acidic solutions has been demonstrated using a column of the present resins.

In spite of the increasing requirement for gallium and indium in the electronic and semiconductor industries, the natural abundance of these metals is extremely small. Therefore, it is urgent to establish a process to recover gallium and indium selectively from low-grade ores or industrial scraps. For the recovery of less-common metals, there is a growing interest in the use of hydrometallurgical techniques which involve a leaching stage to dissolve the metals, followed by further stages to separate the metal ions of interest from other impurities. In 1976 a process based on solvent extraction was proposed to recover gallium from a sodium aluminate solution.[1] Chelating polymer resins containing a highly selective complexing group are one of the attractive candidates to apply to the metal separation procedure because of their operational flexibility and practical convenience.[2] Among the multidentate ligands, iminodiacetic acid (IDA) and ethylenediamine-*N,N,N',N'*-tetraacetic acid (EDTA) are known to form extremely stable complexes with Ga(III)[3] and In(III)[4], hence, the chelating resins with these types of functional groups seem promising for the recovery of the metal ions from the leaching solutions.

We have prepared cross-linked polystyrene resins with complexane-type ligands structurally analogous to IDA or EDTA (Fig. 1). It was found that these chelating resins can adsorb Ga(III) and In(III) selectively from an acidic solution; the preliminary results have previously been reported briefly.[5] This paper presents full, detailed description dealing with the adsorption characteristics of the chelating resins and their use in the column separation of Ga(III) and/or In(III) from other common-metal ions.

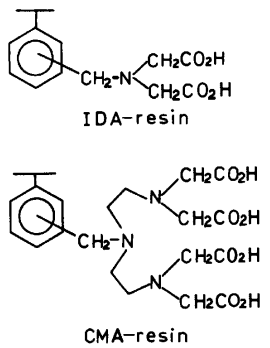

Fig. 1. Cross-linked polystyrene resins containing multidentate functional group.

Experimental

Materials. Reagent-grade $In(NO_3)_3 3H_2O$, $Ga(NO_3)_3 \cdot 3H_2O$, and metallic gallium (99.99% grade) were used for the preparation of the stock solution. Metallic gallium was dissolved with *aqua regia*, and this solution was used for the column feed. Chloromethylated polystyrene beads (Cl, 17.1%, 60—100 mesh) were kindly donated by the Mitsubishi Chemical Co., Ltd. The resin matrix was macroreticular (MR) type styrene-10%-divinylbenzene copolymer with a surface area and mean pore diameter of 7.3 $m^2 g^{-1}$ and 720 Å, respectively.

IDA Resin. A suspension of chloromethylated polystyrene beads (45 g) and diethyl iminodiacetate[6] (85.6 g) in 450 cm^3 of dioxane was refluxed for 72 h with continuous stirring. The solid beads were then transfered to a Soxhlet extractor, extracted with ethanol, and then dried in vacuo. Yield, 76 g. To the dry beads (75 g) we then added a sodium hydroxide solution (20 g in 500 cm^3 of ethanol); the mixture was refluxed for 24 h under stirring. The beads were filtered off and washed successively with water, 2 M HCl (M=mol dm^{-3}), water, and then ethanol. Following a final washing with ether, the beads were dried at 50 °C in vacuo. Yield, 54.4 g. The nitrogen content of the IDA resin thus obtained was 3.7%, which corresponds to a ligand content of 2.6 mmol per gram resin.

CMA Resin. Polystyrene beads were functionalized with bis[2-(salicylideneamino)ethyl]amine[7] by the reaction of chloromethylated polystyrene and the Schiff base.[8] The resulting resin was hydrolyzed by treating it with 6 M HCl, yielding the diethylenetriamine-bound resin.[8] The carboxymethylation of the diethylenetriamine resin using the following procedures afforded the CMA resin.

To a solution of bromoacetic acid (213.6 g in 600 cm^3 of water) we added a sodium hydroxide solution (133 g in 600 cm^3 of water) drop by drop keeping the temperature of the reaction solution below 5 °C. To this solution we then

added the diethylenetriamine resin (50 g), after which the mixture was gently shaken for 7 d at room temperature. The resin beads were collected, washed with water, and then treated with 2 M HCl. After having been washed successively with water, ethanol, and ether, the resin beads were dried in vacuo. Yield, 69.7 g. The nitrogen analysis of the resin (6.92%) indicates that the resin formally contains 1.65 mmol of the functional group per gram resin.

Determination of Adsorption Capacity. A batchwise technique was employed to determine the equilibrium adsorption capacity (amount of metal ion adsorbed on one gram of dry resin), with the metal ion always being in an excess over the ligand content. Typically, 500 mg of dry resin (H^+ form) was added to ca. 80 cm^3 of metal ion solution (0.02 M) of a certain pH, and the suspension was stirred at room temperature overnight. Then the mixture was transferred to a volumetric flask (100 cm^3) and finally diluted to the mark with water. The amount of the metal ion was determined with an atomic-absorption spectrometer. The capacity of the resins was calculated from the change in the metal concentration observed. The resin beads were placed in a glass column and washed thoroughly with water. The adsorbed metal ion was liberated from the resin beads by elution with 20 cm^3 of 2 M HCl, and the metal ion in the eluent was analyzed as has been described above. In most cases, a satisfactory material balance was observed between the metal ion liberated from the resin and that remaining in the solution.

Distribution Coefficients. The equilibrium distribution coefficients of the metal ions were determined by a batchwise procedure. A 500 mg portions of dry resin was immersed in 100 cm^3 of a metal ion solution (1 mM). The pH values from 3.0 to 5.0 were adjusted with an acetate buffer, while those below 3.0 were adjusted with perchloric acid. After shaking had continued for 5 d, the equilibrium pH and the amount of metal ion remain in the supernatant were determined. The results are expressed as the distribution coefficients, K_d=amount of metal adsorbed on one gram of the resin/amount of metal remaining in 1 cm^3 of the solution.

Adsorption Rate. The time-course of metal adsorption was monitored by measuring the change in the metal concentration in the solution. To a 1000 cm^3 portion of 1 mM metal solution (I=0.01, NaCl) at the given pH, we added 5 g of the chelating resin, which had been swollen with water in advance. While stirring, small portions of the metal solution were withdrawn at appropriate intervals and the change in the metal ion concentration was determined.

Column Separation of Metal Ion Mixture. A typical procedure is as follows: A 5-g sample of the CMA resin was swollen with water and poured onto a glass column (ϕ 1.2×10.2 cm). The metal ion solution containing Ga(III) (2.5 mM) and Al(III) (120 mM) was continuously passed through the column at a constant rate of 1.5 $cm^3\,min^{-1}$. The effluent was fractionated into 17 cm^3 portions, and the amount of the metal ion was determined. The Ga(III) in the feed solution was adsorbed quantitatively on the column up to 1600 cm^3, while Al(III) was leaked out of the column. The adsorbed Ga(III) was liberated from the column by elution with 2 M HCl. The resin was regenerated by this procedure and can be used in the successive column operations. In a similar manner, Ga(III) and/or In(III) was selectively adsorbed from the solution containing excess amounts of Al(III), Ca(II), and Zn(II).

For the actual leaching solution, which often contains Fe(III) and Cu(II), H_2S was bubbled in at pH 1.0 and the precipitate was removed prior to column operation.

Measurements. The metal-ion concentration was determined with a Shimadzu atomic absorption/flame photometer, Model AA-610S.

Results and Discussion

Chelating Resins. The IDA resin was prepared by the treatment of the chloromethylated polystyrene with diethyl iminodiacetate, followed by the hydrolysis of the ester with a sodium hydroxide solution. The CMA resin was obtained by the *N*-carboxymethylation of the diethylenetriamine-bound resin, in which the amine is linked to polystyrene uniquely through the secondary nitrogen.[8] The IDA resin contains tridentate iminodiacetic acid, whereas the functional group of the CMA resin formally involves two sets of IDA groups, by analogy with EDTA. The IDA and CMA resins contain approximately 2.6 and 1.7 mmol, respectively of the functional group per 1

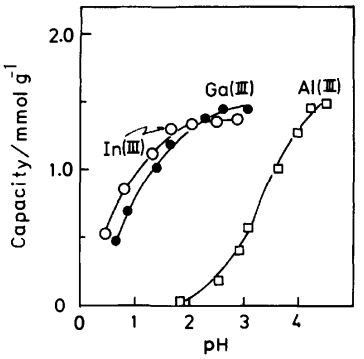

Fig. 2. Equilibrium adsorption capacity of the CMA resin for Al(III) (□), Ga(III) (●), and In(III) (○) as a function of pH.

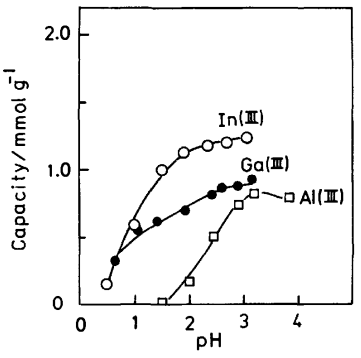

Fig. 3. Equilibrium adsorption capacity of the IDA resin for Al(III) (□), Ga(III) (●), and In(III) (○) as a function of pH.

Table 1. Maximum Adsorption Capacity of the Resins

Metal ion	Adsorption capacity/mmol metal g^{-1} (pH)	
	IDA resin	CMA resin
Al(III)	0.8 (4.0)	1.5 (4.2)
Ga(III)	0.9 (2.8)	1.5 (2.0)
In (III)	1.2 (2.0)	1.4 (1.8)
Fe(III)	0.7 (2.0)	1.5 (1.9)
Cu(II)	2.7 (4.0)	2.4 (4.0)
Zn(II)	2.3 (4.5)	2.2 (5.0)

gram of the resin.

Equilibrium Adsorption Capacity. The present resins readily adsorb various kinds of metal ions from an acidic solution. The profiles of the adsorption capacities as a function of the pH for Al(III), Ga(III), and In(III) are given in Figs 2 and 3. The maximum adsorption capacities, including other common metal ions, are listed in Table 1, along with the equilibrium pH. The capacities of the CMA resin for most of the trivalent metal ions are around 1.5 mmol g^{-1} resin; this value is comparable to the estimated ligand content, while those for the IDA resin are much lower than its ligand content. These results can be attributed to the difference in the dentate number of the functional groups. Each functional group in the CMA resin is expected to form 1:1 octahedral complexes in a fashion similar to those of EDTA complexes, whereas two sets of the IDA units are required for the IDA resin to form stable octahedral complexes. In contrast to homogeneous systems, such an opportunity must be considerably restricted when the IDA groups are fixed on a rigid polymer. For bivalent ions, such as Cu(II) and Zn(II), on the other hand, the adsorption capacities of the IDA resin are nearly equal to the ligand content, presumably because each IDA unit can form 1:1 complexes with these metal ions.

Distribution Coefficients. The distribution coefficients of the CMA resin for In(III), Ga(III), Fe(III), Cu(II), and Zn(II) were examined as a function of the pH; the results are given in Fig. 4. The slopes in the linear plots are approximately 3.0 for the adsorption of trivalent ions, whereas for Cu(II) and Zn(II) the slopes are close to 2.0. These results indicate that the adsorption of trivalent metal ions is accompanied by the release of three protons, while for bivalent ions two protons are liberated from the CMA resin. These observations are consistent with the expectation that each functional group in the CMA resin forms a 1:1 complex with trivalent metal ions.

Although the log K_d vs. pH profiles of the CMA and the IDA resins resemble each other, those of the CMA resin appear in a relatively lower pH region

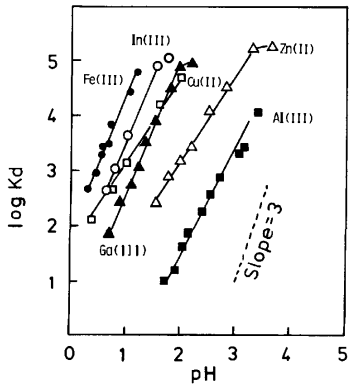

Fig. 4. Log K_d of the CMA resin for some metal ions as a function of pH.

Table 2. Adsorption Rate of the Resins for Al(III), Ga(III), and In(III) ($t_{1/2}$, min)[a)]

Metal ion	pH	IDA Resin	CMA Resin
Al(III)	4.2	5	7
Ga(III)	2.0	30	25
In(III)	2.0	10	8

a) The time required to quench a half of the metal ion adsorbed at equilibrium. Metal ion concentration: 1 mM (1000 cm^3), I=0.01 (NaCl) Resin; 5 g.

than those of the IDA resin, irrespective of the metal ions examined. This demonstrates that the CMA resin can form much more stable complexes than the IDA resin due to the chelating effect of the functional group.

The selectivity sequence of the CMA resin is; Fe(III)>In(III)>Ga(III)≈Cu(II)>Zn(III)>Al(III), which coincides with the order of the formation constants of the EDTA complexes.[9] The apparent selectivity suggests the possibility of the column separation of Ga(III) and In(III) from the solution containing Zn(II) and Al(III). The K_d profile also suggests that Fe(III) and Cu(II) would greatly interfere with the adsorption of Ga(III) and In(III).

Adsorption Rate. Although the equilibrium capacity and the K_d values are of fundamental importance in characterizing the chelating resin, the rate of adsorption is extremely important from a practical point of view. The time-course of the adsorption of Al(III), Ga(III), and In(III) was examined at their optimal pH region by monitoring the metal ion concentration in the batch systems. The time required to adsorb a half of the metal ion adsorbed at the equilibrium ($t_{1/2}$) is listed in Table 2. The adsorption rates for these metal ions are, in any case, sufficiently rapid to allow a continuous column

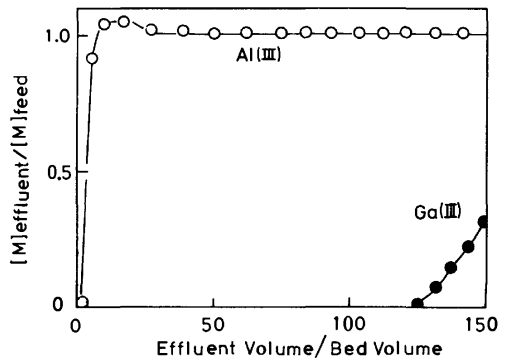

Fig. 5. Column breakthrough profile for the separation of Ga(III) and Al(III). Bed resin: CMA resin (5 g, 13 cm^3). pH: 1.8. $[M]_{feed}$: Al(III) (120 mM), Ga (III) (2.5 mM).

operation. The rate sequence is; Al(III)≳In(III)> Ga(III) under the present experimental conditions. The rate of adsorption has been claimed to be determined by the diffusion process inside the matrix in most of the ion-exchange systems.[10] On the basis of the electrophoresis experiments for the CMA resin, it was found that the resin beads are negatively charged at pH values higher than 2.0, where the carboxyl protons in the functional group may begin to dissociate.[11] The local charge density must be enriched inside the polymer beads with the sequential dissociation of protons; hence, the migration of positivily charged species into the polymer must be facilitated. The higher adsorption rate observed for Al(III) at pH 4.0 can be interpreted by this hypothesis. An opposed trend has been observed when the oxometalate anion (MoO_4^{2-}) was fed to the CMA resin and has been attributed to the charge repulsion between the resin and the incoming anion.[2e]

The observed rate sequence is almost independent of the nature of the anions present in the solution. Hence, provided that the chemical forms of Ga(III) and In(III) are not much different from each other under the given experimental conditions, the apparent difference in adsorption rate between them cannot be explained simply by the charge interaction mechanism. Although we have no clear explanation for the much slower rate for Ga(III) as compared to In(III), it should be noted that the rate sequence coincides with the order of lability of the metal ions.[12]

Column Separation. The apparent selectivity of the CMA resin suggests the possibility of the column separation of Ga(III) and In(III) from the solution of Al(III) or Zn(II). When a model solution (pH, 1.8) containing 2.5 mM of Ga(III) and 120 mM of Al(III) was passed through the column of the CMA resin, Ga(III) was quantitatively adsorbed on the resin, while Al(III) was found in the eluate, as is shown in Fig. 5. The amount of Ga(III) adsorbed on one gram of the resin at the breakthrough point (breakthrough capacity) was 0.95 mmol g^{-1}, approximately 65% of the equilibrium capacity. In a similar column operation using 1.7 mM of In(III) and 110 mM of Al(III), the breakthrough capacity for In(III) was found to be 0.8 mmol g^{-1}. The adsorbed Ga(III) or In(III) was liberated from the resin in a concentrated form on elution with 2 M HCl. Although a similar quantitative separation was achieved by using the IDA resin, the breakthrough capacity was much lower than in the case of the CMA resin, as is to be expected from the difference in their equilibrium capacities.

Among the metal ions commonly encountered in an acid-leaching solution of natural ores and industrial scraps, Fe(III) and Cu(II) compete most strongly in the adsorption of Ga(III) and In(III), as is to be expected from the K_d profiles. Therefore, it is preferable to remove these ions prior to the column operation. Interference from Cu(II) and Fe(III) can be considerably avoided by the treatment of the leaching solution with H_2S gas. By this procedure, Cu(II) can be eliminated from the solution as precipitate of CuS; at the same time, Fe(III) can be reduced to Fe(II), which has a much lower affinity for the present chelating resins than do In(III) and Ga(III).

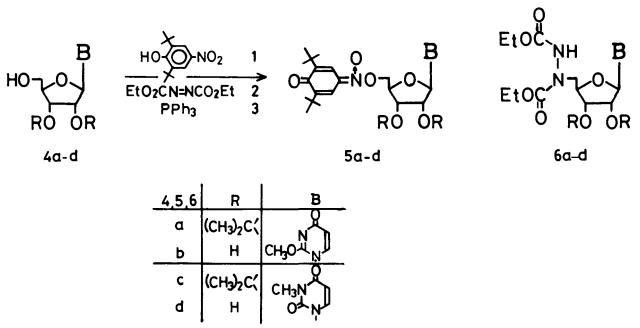
2,6-Di-*t*-butyl-4-nitrophenol reacted with O^2-methyluridine, N^3-methyluridine or 4-triazolyl-1-(β-D-ribofuranosyl)-2(1*H*)-pyrimidinone in the presence of diethyl azodicarboxylate and triphenylphosphine selectively at the 5′-position to give the corresponding 4-(nucleosid-5′-yl-*aci*-nitro)-2,6-di-*t*-butylcyclohexa-2,5-dienone (*aci*-nitro ester of nucleoside) in 39—72% yields along with varied amounts of 5′-deoxy-5′-[*N*,*N*′-bis(ethoxycarbonyl)-hydrazino]nucleosides. By comparison of the reactions of pyrimidine nucleosides having free 2′- and 3′-hydroxyl groups with those of their 2′,3′-*O*-isopropylidene derivatives, the ratio of *aci*-nitro ester to 5′-deoxy-5′-hydrazinonucleoside was affected by the protecting groups as well as the time required for the addition of diethyl azodicarboxylate to a solution of other reactants. Similarly, N^1,N^6,2′,3′-*O*-tetrabenzoyladenosine afforded the expected *aci*-nitro ester in 83% yield. The *aci*-nitro esters prepared were successfully reacted with stabilized phosphoranes such as (ethoxycarbonylmethylene)triphenylphosphorane or (acetylmethylene)triphenylphosphorane giving 1-[(*E*)-β-D-ribo-hept-5-enofuranosyl]- or 1-[(*E*)-β-D-ribo-oct-5-enofuranosyl]-pyrimidines and -purines. When the two stage reactions were carried out by one-pot procedure without isolation of *aci*-nitro esters, overall yields of alkenofuranosylpyrimidines were markedly improved.

Nucleoside antibiotics such as ezomycins, octosyl acids, and sinefungin have a common structural unit comprising higher-carbon sugars and pyrimidine or purine bases. For the synthesis of these antibiotics and their analogues from ribonucleosides, the creation of C–C bond at the 5′-position is required and nucleoside 5′-aldehyde has been generally chosen as a key intermediate. Thus, protection of 2′- and 3′-hydroxyl groups of a nucleoside, oxidation of 5′-hydroxyl group, and subsequent treatment of the resulting aldehyde with anionic species such as Wittig reagents affords the corresponding homologated nucleoside.[2,3] Because of instability of nucleoside 5′-aldehydes, however, only a limited number of oxidation process have been utilized.[2] Therefore, there are ongoing needs to develop a convenient procedure for carbon-chain extension of nucleosides.

Recently, we have reported the synthesis of *aci*-nitro esters by the reaction of alcohols with 2,6-di-*t*-butyl-4-nitrophenol (**1**), diethyl azodicarboxylate (**2**), and triphenylphosphine (**3**).[4] As a masked aldehyde, the *aci*-nitro ester prepared reacted with Wittig reagents giving the corresponding olefins.[5] The reaction would involve intermediacy of aldehyde or ketone which successively reacts with Wittig reagents. An advantage would thereby accrue to the preparation of olefins via unstable aldehydes. Further, it was found that improved yields were obtained when the sequence of reactions were carried out by one-pot procedure without isolation of *aci*-nitro ester. Application of this methodology to the synthesis of 1-[(*E*)-5-enofuranosyl]-uracils from uridine has also been shortly reported.[6]

In this paper, we wish to report the synthesis of 1-[(*E*)-5-enofuranosyl]-pyrimidine and -purine derivatives via *aci*-nitro esters.

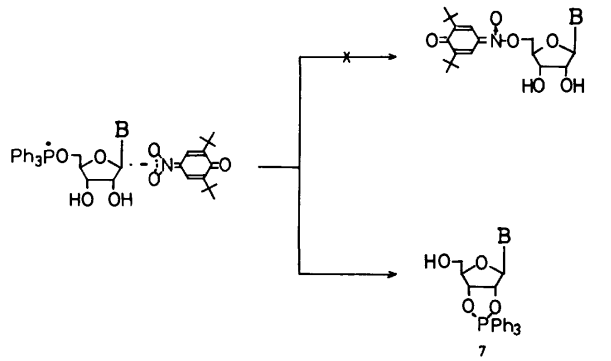
Reactions of Uridine Derivatives. When 2′,3′-*O*-isopropylideneuridine was allowed to react with **1**, **2**, and **3**, intramolecular dehydration occurred giving 2′,3′-*O*-isopropylidene-O^2,5′-cyclouridine rather than expected *aci*-nitro ester. In order to prevent the cyclouridine formation, the uracil moiety was protected by methyl group. O^2-Methyl- or N^3-methyl-2′,3′-*O*-isopropylideneuridine (**4a**, **4c**) reacted smoothly with **1** in the presence of 1.5 molar amounts of **2** and **3** at room temperature overnight to give the corresponding *aci*-nitro ester (**5a** or **5c**) in 84 or 83% yield, respectively. We did not attempt to isolate 5′-deoxy-5′-hydrazinouridine derivative (**6a**, **6c**)(vide infra).



In view of the fact that the condensation of unprotected nucleosides with carboxylic acids using **2** and **3** selectively affords 5′-*O*-acylnucleosides,[7] high regioselectivity could also be expected in the formation of *aci*-nitro esters. Thus, O^2-methyluridine (**4b**) and N^3-methyluridine (**4d**) were used as nucleoside components. When **2** (3 equiv) was added dropwise over a period of 2 h to a solution of **1** (1.5 equiv), **3** (3 equiv), and **4b**, followed by being stirred overnight, *aci*-nitro ester (**5b**) was obtained in

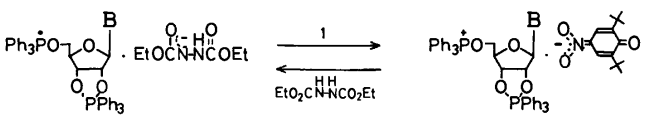
72% yield accompanying a trace of 5′-deoxy-5′-hydrazinouridine derivative (**6b**). Under the same conditions, **4d** afforded *aci*-nitro ester (**5d**) and 5′-deoxy-5′-hydrazinouridine derivative (**6d**) in 39 and 41% yields, respectively. In both cases, the products derived from the reaction at 2′- and/or 3′-hydroxyl group could not be obtained.

In contrast to the preparation of *aci*-nitro esters of fully protected uridines (**4a**, **4c**),[8] more than two equivalents of **2** and **3** were required for the conversion of uridines having free 2′- and 3′-hydroxyl groups. In fact, when **4b** was treated with 1 molar amount each of **1**, **2**, and **3**, the corresponding *aci*-nitro ester (**5b**) was hardly formed as monitored by TLC of the reaction mixture. These results suggest that one-equivalents of **2** and **3** were consumed by the formation of 2′,3′-*O*-(triphenylphosphoranediyl) ring.[9] The data concerning to the reaction of uridine with **2**, **3**, and an acidic component support the initial formation of 5′-*O*-(triphenylphosphonio)uridine. Thus, when carboxylic acid or phosphoric diester was used as an acidic component the corresponding 5′-*O*-substituted uridine was exclusively formed. On the other hand, with weak nucleophile such as phthalimide, intramolecular process is favorable to give O^2,5′-cyclouridine.[9b] Since uracil moiety was protected in the present reactions, it would be rational to assume that phosphonio group migration predominated over the intermolecular displacement by *aci*-nitronate anion and 2′,3′-*O*-(triphenylphosphoranediyl)-O^2-methyl- or -N^3-methyluridine (**7**) was formed.[9]



7

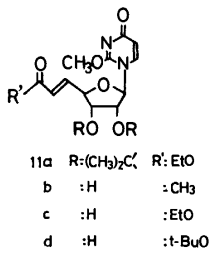
The formation of **6d** suggests that reaction mixture contains nucleoside phosphonium salts **8** and **9** in equilibrium. The reaction courses would therefore depend on the equilibrium constant and nucleophilicity of the counter anions comprising in **8** and **9**.



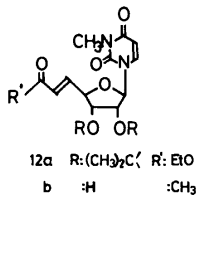
8 **9**

Although no kinetic data are available, the conversion of **9** to uridine 5′-*O*-*aci*-nitro ester would be rate-determining step because of low nucleophilicity of *aci*-nitronate anion. In order to suppress the formation of **6b** and **6d**, the concentration of diethyl hydrazinedicarboxylate must be minimized. This requirement could be satisfied at least at an early stage of the reaction by slow addition of **2** to a solution of other reactants.[10] In fact, when **2** was added dropwise within 0.5 h to a solution of **1**, **3**, and **4b**; **5b** and **6b** were obtained in 47 and 30% yields, respectively. When **4d** was used, the yield of **6d** was increased to 76%.

Next, the reaction of uridine 5′-*aci*-nitronates with Wittig reagents was examined. When *aci*-nitro ester (**5a** or **5c**) was treated with 2 molar amounts of (ethoxycarbonylmethylene)triphenylphosphorane (**10**) in benzene under reflux for 8 h, 1-[(*E*)-5,6-dideoxy-7-ethoxy-2,3-*O*-isopropylidene-β-D-ribo-hept-5-eno-1,4-furanosid-7-ulosyl]-O^2-methyl- or -3-methyluracil (**11a** or **12a**) was obtained in 81 or 70% yield, respectively. Under similar conditions, the reaction of *aci*-nitro ester (**5b** or **5d**) with (acetylmethylene)triphenylphosphorane (**13**) completed within 2 h to give 1-[(*E*)-5,6,8-trideoxy-β-D-ribo-oct-5-eno-1,4-furanosid-7-ulosyl]-O^2-methyl or -3-methyluracil (**11b** or **12b**) in 66 or



11a R:$(CH_3)_2C$, R′: EtO
b :H :CH_3
c :H :EtO
d :H :t-BuO



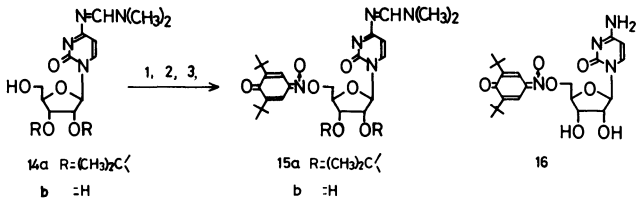
12a R:$(CH_3)_2C$, R′: EtO
b :H :CH_3

50% yield, respectively. ^{1}H-NMR spectroscopy showed that **11a** was pure *E*-isomer, $C_{5'}$H and $C_{6'}$H appearing as sharp double doublets at 7.06 and 6.03 ppm with $J_{5',6'}$=16.7 Hz, $J_{4',5'}$=5.5 Hz, and $J_{4',6'}$= 1.5 Hz. Similarly, the ^{1}H-NMR spectrum of **11b**, **12a**, and **12b** showed similar pattern of signals as shown in experimental section.

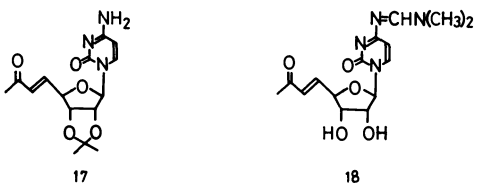
It was found that overall yields of enofuranosyluracils were improved by one-pot procedure without isolation of *aci*-nitro ester. Thus, to a solution of **4b**, **1**, and **3** in THF was added **2** in THF at room temperature for 2 h. The reaction mixture was stirred overnight and **13** in benzene was added. The resulting solution was successively refluxed for 2 h giving **11b** in 73% yield. By the same procedure, **4d** afforded **12b** in 43% yield. When **4b** was allowed to react with **1**, **2**, and **3**, followed by **10** or (*t*-butoxycarbonylmethylene)triphenylphosphorane by one-pot procedure, the second step completed in 3 h giving the expected 1-[(*E*)-β-D-ribo-hept-5-enofuranos-

yl]-uracils (**11c**, **11d**) in 70% yield.

Reactions of Cytidine Derivatives. Similar to the case of 2′,3′-*O*-isopropylideneuridine, the reaction of N^4-benzoyl-2′,3′-*O*-isopropylidenecytidine with **1**, **2**, and **3** quantitatively gave N^4-benzoyl-2′,3′-*O*-isopropylidene-O^2,5′-cyclocytidine. This result suggests that both hydrogen atoms of the amino group should be substituted to prevent undesirable cyclization. Thus, the cytosine moiety was protected by dimethylaminomethylene group. When N^4-dimethylaminomethylene-2′,3′-*O*-isopropylidenecytidine (**14a**) reacted with **1** by the use of 1.5 molar amounts of **2** and **3**, the corresponding *aci*-nitro ester (**15a**) was obtained in 54% yield. The reaction of N^4-dimethylaminomethylenecytidine (**14b**) with **1** (1.5 equiv), **2** (3 equiv), and **3** (3 equiv) afforded *aci*-nitroester (**15b**) in 32% yield accompanying with deprotected product (**16**; 14%).

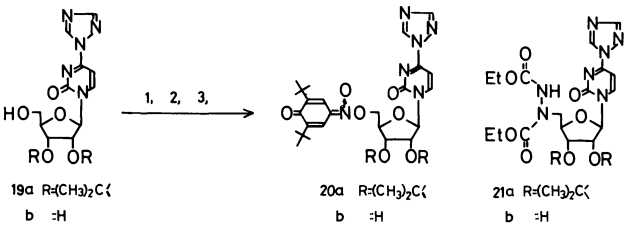


When **15a** was treated with **13** in THF under reflux for 6.5 h, no N^4-dimethylaminomethylene-1-[(*E*)-5,6,8-trideoxy-2,3-*O*-isopropylidene-β-D-ribo-oct-5-eno-1,4-furanosid-7-ulosyl]-2(1*H*)-pyrimidinone could be isolated but N^4-amino-1-[(*E*)-5,6,8-trideoxy-2,3-*O*-isopropylidene-β-D-ribo-oct-5-eno-1,4-furanosid-7-ulosyl]-2(1*H*)-pyrimidinone (**17**) was obtained in 18% yield. On the other hand, the reaction of **15b** with **13** gave N^4-dimethylaminomethylene-1-[(*E*)-5,6,8-trideoxy-β-D-ribo-oct-5-eno-1,4-furanosid-7-ulosyl]-2(1*H*)-pyrimidinone (**18**) in 31% yield. No deprotected product could be isolated.



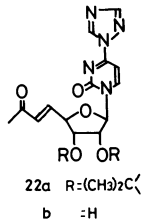
17 18

As the dimethylaminomethylene group was obviously inadequate for the present purpose because of instability, 4-triazolyl-1-(2,3-*O*-isopropylidene-β-D-ribofuranosyl)-2(1*H*)-pyrimidinone (**19a**) was used. Compound **19a** was readily prepared from 2′,3′-*O*-isopropylideneuridine by the modification of Reese's procedure.[11] The transformation of the triazolyl group into various functional groups involving amino group has been demonstrated.[12] Therefore, carbon-chain extension of **19a** is synthetically useful because a variety of pyrimidinenucleosides would be prepared from a single precursor. The reaction of **19a** with two equivalents of **1**, **2**, and **3** resulted in the formation of the corresponding *aci*-nitro ester (**20a**) and 5′-deoxy-5′-hydrazino derivative (**21a**) in 61 and 20% yields, respectively, while the reaction of 4-triazolyl-1-(β-D-ribofuranosyl)-2(1*H*)-pyrimidinone (**19b**) with two equivalents of **1**, **2**, and **3** exclusively gave *aci*-nitro ester (**20b**) in 71% yield without detectable formation of hydrazino derivative (**21b**).



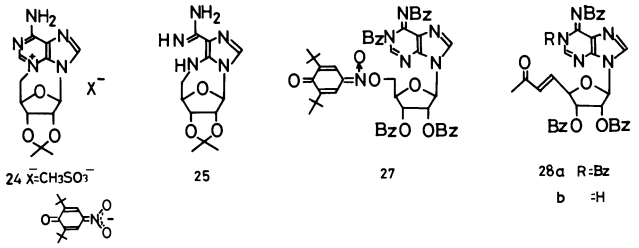
Similar to the case of uridine derivatives, the *aci*-nitro ester derived from the reaction at 2′- and/or 3′-hydroxyl group could not be detected.

The reaction of **13** with **20a** or **20b** afforded the corresponding (*E*)-olefins (**22a** or **22b**) in 61 or 77% yield, respectively. By a one-pot reaction, **19b** afforded **22b** in 68% yield.



Reactions of Adenosine Derivatives. When N^6-dimethylaminomethylene-2′,3′-*O*-isopropylideneadenosine (**23**) was allowed to react with two equivalents of **1**, **2**, and **3**, expected *aci*-nitro ester could not be obtained. Examination of the crude reaction mixture by paper chromatography revealed the formation of a compound having UV_{max} (MeOH) 292 nm. Anzai has demonstrated that, by treatment with aqueous sodium hydroxide, 2′,3′-*O*-isopropylidene-N^3,5′-cycloadenosine (**24**; $X^- = CH_3SO_3^-$) converted into N^5,5′-anhydro-5-amino-4-amidino-1-(2,3-*O*-isopropylidene-β-D-ribofuranosyl)imidazole (**25**) which exhibits UV_{max} (MeOH) 290 nm.[13] Thus, the results obtained could be explained by assuming the initial formation of **24** (X^-=2,6-di-*t*-butyl-4-nitrophenoxide anion) which decomposed into **25** during manipuration. In order to prevent the undesirable cyclization, N^1,N^6,2′,3′-*O*-tetrabenzoyladenosine (**26**) was used where nucleophilicity of N^3-position was decreased by the electron-withdrawing group. When **26** was allowed to react with **1** in the presence of **2** and **3**, the corresponding *aci*-nitro ester (**27**) was obtained in 83% yield. When **27** was treated with **13** in THF

under reflux for 8 h, N^1,N^6-dibenzoyl-9-[(*E*)-2,3-di-*O*-benzoyl-β-D-ribo-oct-5-eno-1,4-furanosid-7-ulosyl]-adenine (**28a**) and N^6-benzoyl-9-[(*E*)-2,3-di-*O*-benzoyl-β-D-ribo-oct-5-eno-1,4-furanosid-7-ulosyl]-adenine (**28b**) were obtained in 19 and 36% yields, respectively.



Conclusion. The reaction of nucleosides with **1**, **2**, and **3** resulted in the formation of the corresponding *aci*-nitro esters. The condensation selectively took place at 5′-hydroxyl group, no protection at 2′- and 3′-hydroxyl groups being required. A serious side reaction is the competitive formation of 5′-deoxy-5′-hydrazino nucleosides. However the formation of the side products could be partly suppressed by a slow addition of **2**. Although no explanation can be offered at the present stage of investigation, a comparison of reactions of nucleosides having free 2′- and 3′-hydroxyl groups with those of 2′,3′-*O*-isopropylidene nucleosides revealed that the protecting group might influence the reactivity of the intermediary phosphonium salts. Thus, the isopropylidene group of uridine derivatives (**4a**, **4c**) facilitated the *aci*-nitro ester formation, while the reverse was found for **19a**. The yield of 5′-deoxy-5′-hydrazinouridines was also affected by manner of protection of uracil moiety. Since *aci*-nitro esters can be utilized as masked aldehydes, the conversion of uridine, cytidine, and adenosine derivatives into *aci*-nitro esters and subsequent reaction with stabilized phosphoranes provides a convenient procedure for the preparation of the corresponding carbon-chain extended nucleosides.

Experimental

Methods. Preparative layer chromatography (PLC) was carried on 20 cm×30 cm glass coated with Merck silica gel PF_{254}. Kiesel-gel 60 (Merck, mesh 70—220) was used for column chromatography (5 cm×30 cm). ^{1}H-Nuclear magnetic resonance (NMR) spectra were measured on Hitachi R-20 (60 MHz) or JEOL GX-270 (270 MHz) spectrometer using tetramethylsilane as internal standard. Ultraviolet absorption spectra were obtained with a Hitachi EPS-3T recording spectrometer. Elemental analyses were obtained from Institute of Physical and Chemical Research, Wako, Saitama.

The nucleosidic starting materials, O^2-methyl-2′,3′-*O*-isopropylideneuridine (**4a**),[14] N^3-methyl-2′,3′-*O*-isopropylideneuridine (**4c**),[3b] O^2-methyluridine (**4b**),[8] N^3-methyluridine (**4d**),[3b] N^4-dimethylaminomethylene-2′,3′-*O*-isopropylidenecytidine (**14a**),[15] N^4-dimethylaminomethylenecytidine (**14b**),[15] 4-triazolyl-1-(2,3-*O*-isopropylidene-β-D-ribofuranosyl)-2(1*H*)-pyrimidinone (**19a**),[11] 4-triazolyl-1-(β-D-ribofuranosyl)-2(1*H*)-pyrimidinone (**19b**),[11] N^6-dimethylaminomethylene-2′,3′-*O*-isopropylideneadenosine (**23**),[15] and N^1,N^6,2′,3′-*O*-tetrabenzoyladenosine (**26**)[16] were prepared by known procedures or their modifications.

Preparations of *aci*-Nitro Ester. Preparations of 5a and 5c. A solution of **2** (261 mg, 1.5 mmol) in THF (1 ml) was added dropwise over a period of 1 h to a mixture of uridine derivative (**4a** or **4c**, 298 mg, 1 mmol), **1** (375 mg, 1.5 mmol), and **3** (393 mg, 1.5 mmol) in THF (3 ml). The solution gradually colored red-orange on addition of **2** and kept stirring at room temperature overnight. The **5a** was separated by PLC ($CHCl_3$:EtOAc: MeOH=10:5:1) in 84% yield: red-orange oily semisolid; ^{1}H-NMR ($CDCl_3$)[17] δ=1.29 and 1.30 (18H, s, *t*-Bu), 1.38 and 1.60 (6H, s, isopropylidene CH_3), 4.06 (3H, s, OCH_3), 4.37 (1H, dd, 4′-H), 4.58 and 4.67 (2H, dd, $J_{5'a,4'}$=4.3 Hz, $J_{5'b,4'}$=5.9 Hz, $J_{5'a,5'b}$=12.0 Hz, 5′-H), 4.82 (1H, dd, $J_{2',3'}$=6.6 Hz, $J_{3',4'}$=3.3 Hz, 3′-H), 4.89 (1H, dd, $J_{1',2'}$=2.3 Hz, 2′-H), 5.85 (1H, d, 1′-H), 5.99 (1H, d, $J_{5,6}$=7.6 Hz, 5-H), 7.41 (1H, d, 6-H), and 7.36 and 7.54 (2H, d, quinone H).

5c was isolated by PLC (benzene:EtOAc=10:1) in 83% yield: red-orange oil; ^{1}H-NMR ($CDCl_3$) δ=1.29 (18H, s, *t*-Bu), 1.36 and 1.56 (6H, s, isopropylidene CH_3), 3.31 (3H, s, NCH_3), 4.37 (1H, m, 4′-H), 4.62 and 4.63 (2H, d, $J_{4',5'}$=6.3 Hz, 5′-H), 4.95 (1H, dd, $J_{3',4'}$=4.0 Hz, $J_{2',3'}$=6.4 Hz, 3′-H), 5.12 (1H, dd, $J_{1',2'}$=1.6 Hz, 2′-H), 5.53 (1H, d, 1′-H), 5.77 (1H, d, $J_{5,6}$=7.9 Hz, 5-H), 7.20 (1H, d, 6-H), and 7.35 and 7.59 (2H, d, quinone H).

Preparations of 5b and 5d. A mixture of **1** (375 mg, 1.5 mmol), **3** (786 mg, 3 mmol), and uridine derivative (**4b** or **4d**, 256 mg, 1 mmol) in THF (3 ml) was stirred and a solution of **2** (261 mg, 1.5 mmol) in THF (1 ml) was added over a period of 1 h at room temperature. After 3 h, **2** (1.5 mmol) in THF (1 ml) was further added for 1 h. The nucleoside (**4b** or **4d**) dissolved on addition of **2** and the solution gradually colored red-orange. After the solution kept stirring overnight, the residue was evaporated under reduced pressure. The residue was purified by column chromatography ($CHCl_3$:MeOH=10:1) to afford **5b** or **5d** in 72 or 39% yield. **5b**: red-orange semisolid; ^{1}H-NMR (60 MHz, DMSO-d_6) δ=1.22 and 1.27 (18H, s, *t*-Bu), 3.91 (3H, s, OCH_3), 5.41 and 5.63 (2H, d, 2′-, 3′-OH), 5.79 (1H, d, $J_{1',2'}$=5.2 Hz, 1′-H), 5.90 (1H, d, $J_{5,6}$=8.4 Hz, 5-H), 7.30 and 7.58 (2H, d, quinone H), and 7.73 (1H, d, 6-H). **5d**: red-orange semisolid; ^{1}H-NMR (60 MHz, $CDCl_3$) δ=1.31 (18H, s, *t*-Bu), 3.31 (3H, s, NCH_3), 5.72 (1H, s, 1′-H), 5.80 (1H, d, $J_{5,6}$=7.6 Hz, 5-H), 7.45 (1H, d, 6-H), and 7.36 and 7.55 (2H, d, quinone H).

In the case of the preparation of **5d**, a side product (**6d**) was obtained in 41% yield (oil; UV_{max} (MeOH) 265 nm, UV_{min} 235 nm; ^{1}H-NMR (60 MHz, $CDCl_3$) δ=1.24 (6H, t, $-CH_2\underline{CH_3}$), 3.27 (3H, s, OCH_3), 5.70 (1H, d, 1′-H), 5.80 (1H, d, $J_{5,6}$=8.5 Hz, 5-H), 7.45 (1H, d, 6-H), and 7.63 (1H, br s, NH).

In a similar reaction, when **2** (3 mmol) was added to the THF solution of **1**, **3**, and **4b** or **4d** within 0.5 h, the undesirable products, 5′-deoxy-5′-hydrazino derivatives (**6b** or **6d**) was obtained in 30 or 76% yield, respectively. The **6b** was recrystallized from CH_3CN and melted at 147—149 °C (UV_{max} (MeOH) 235, 250 (sh) nm, UV_{min} 215 nm; ^{1}H-NMR (60 MHz, DMSO-d_6) δ=1.17 (6H, t, $-CH_2\underline{CH_3}$), 5.24 and

5.56 (2H, d, 2'-, 3'-OH), 5.70 (1H, d, $J_{1',2'}$=4.4 Hz, 1'-H), 5.88 (1H, d, $J_{5,6}$=7.8 Hz, 5-H), 7.75 (1H, d, 6-H), and 9.58 (1H, br s, NH)).

Preparation of 15a. By a similar procedure described in the preparation of **5a** and **5c**, **14a** (389 mg, 1.24 mmol) reacted with 1.5 equivalents of **1**, **2**, and **3**. The **15a** was isolated by the use of column chromatography ($CHCl_3$:EtOAc:MeOH=12:5:1) in 54% yield (orange oil; ^{1}H-NMR ($CDCl_3$) δ=1.27 and 1.29 (18H, s, *t*-Bu), 1.36 and 1.55 (6H, s, isopropylidene CH_3), 3.15 and 3.18 (6H, s, $-N(CH_3)_2$), 4.43 (1H, m, 4'-H), 4.68 and 4.79 (2H, dd, $J_{5'a,4'}$=7.2 Hz, $J_{5'b,4'}$=4.9 Hz, $J_{5'a,5'b}$=12.0 Hz, 5'-H), 5.06 (1H, dd, $J_{3',4'}$=3.3 Hz, $J_{2',3'}$=6.3 Hz, 3'-H), 5.27 (1H, d, 2'-H), 5.50 (1H, s, 1'-H), 6.04 (1H, d, $J_{5,6}$=7.3 Hz, 5-H), 7.39 (1H, d, 6-H), 7.36 and 7.59 (2H, d, quinone H), and 8.81 (1H, s, =CH-).

Preparations of 15b and 16. For the reaction of **14b** (420 mg, 1.53 mmol), 1.5 equivalents of **1** and 3 equivalents of **2** and **3** were used. **15b** and **16** were isolated by column chromatography ($CHCl_3$:MeOH=12:1) in 36 and 14% yields, respectively. **15b**: orange oil; ^{1}H-NMR ($CDCl_3$) δ=1.26 and 1.30 (18H, s, *t*-Bu), 3.13 and 3.20 (6H, s, $-N(CH_3)_2$), 4.1—4.3 (3H, m, 4'-H, 5'-H), 4.4—4.6 (2H, m, 2'-H, 3'-H), 4.74 and 4.79 (2H, d, 2'-, 3'-OH), 5.82 (1H, d, $J_{1',2'}$=3.3 Hz, 1'-H), 6.07 (1H, d, $J_{5,6}$=7.3 Hz, 5-H), 7.35 and 7.53 (2H, d, quinone H), 7.70 (1H, d, 6-H), and 8.73 (1H, s, =CH-).

Preparations of 20a and 20b. When **19a** (282 mg, 0.84 mmol) reacted with 2 equivalents of **1**, **2**, and **3**, **20a** and 5'-deoxy-5'-hydrazino derivative (**21a**) were isolated by the use of column chromatography ($CHCl_3$:MeOH=15:1) in 61 and 20% yields, respectively. **20a**: orange oil; ^{1}H-NMR (60 MHz, $CDCl_3$) 1.26 (18H, s, *t*-Bu), 1.36 and 1.60 (6H, s, isopropylidene CH_3), 5.68 (1H, s, 1'-H), 7.02 (1H, d, $J_{5,6}$=8.0 Hz, 5-H), 7.26 and 7.48 (2H, d, quinone H), 8.00 (1H, d, 6-H), and 8.06 and 9.15 (2H, s, triazole H). **21a**; oil; ^{1}H-NMR (60 MHz, CD_3OD) δ=1.23 (6H, t, $-CH_2\underline{CH_3}$), 1.32 and 1.52 (6H, s, isopropylidene CH_3), 5.83 (1H, s, 1'-H), 7.02 (1H, d, $J_{5,6}$=7.6 Hz, 5-H), 8.36 (1H, d, 6-H), and 8.26 and 9.30 (2H, s, triazole H).

Compound **19b** (210 mg, 0.71 mmol) was allowed to react with 2 equivalents of **1**, **2**, and **3** by the same procedure described in the preparation of **5b** and **5d**. The reaction mixture being stirred for 2 d, the residue obtained by the removal of THF was applied to a silica-gel column and eluted with a mixture of $CHCl_3$–EtOAc–MeOH (10:5:1) giving 71% yield of **20b**; orange oil; ^{1}H-NMR (60 MHz, $CDCl_3$) δ=1.33 (18H, s, *t*-Bu), 5.90 (1H, s, 1'-H), 7.05 (1H, d, $J_{5,6}$=7.0 Hz, 5-H), 7.30 and 7.58 (2H, d, quinone H), 8.30 (1H, d, 6-H), and 8.06 and 9.20 (2H, s, triazole H). A 20% of the starting material **19b** was recovered.

Preparation of 27. A solution of **2** (94 mg, 0.64 mmol) in THF (2 ml) was added dropwise over a period of 1 h to a mixture of **26** (203 mg, 0.3 mmol), **1** (149 mg, 0.6 mmol), and **3** (156 mg, 0.6 mmol) in THF (3 ml). The reaction mixture was kept stirring at room temperature for 2 d. After being evaporated, the residue was purified by PLC (benzene:EtOAc=10:1) giving **27** in 83% yield: orange oil; ^{1}H-NMR ($CDCl_3$) δ=1.24 and 1.27 (18H, s, *t*-Bu), 4.7—4.8 (2H, m, 5'-H), 4.94 (1H, m, 4'-H), 6.17—6.26 (2H, m, 2'-H, 3'-H), 6.39 (1H, d, $J_{1',2'}$=4.3 Hz, 1'-H), 7.2—8.0 (22H, m, aromatic and quinone H), and 8.25 and 8.67 (2H, s, purine H).

Reaction of *aci*-Nitro Esters with Wittig Reagents. Preparations of 11a and 12a. One mmol of **5a** or **5c** in benzene (10 ml) was treated with 2 molar amounts of **10** under reflux for 8 h and then evaporated. The **11a** and **12a** were isolated by the column chromatography using $CHCl_3$–MeOH (10:1) in 81 and 70% yields, respectively. **11a**: oil; ^{1}H-NMR (60 MHz, $CDCl_3$) δ=1.29 (3H, t, $-CH_2\underline{CH_3}$), 1.38 and 1.60 (6H, s, isopropylidene CH_3), 4.01 (3H, s, OCH_3), 6.00 (1H, d, $J_{5,6}$=8.0 Hz, 5-H), 6.05 (1H, d, 6'-H), 6.98 (1H, dd, $J_{5',6'}$=15.0 Hz, $J_{4',5'}$=4.8 Hz, 5'-H), and 7.36 (1H, d, 6-H). **12a**: oil; ^{1}H-NMR (60 MHz, $CDCl_3$) δ=1.29 (3H, t, $-CH_2\underline{CH_3}$), 1.38 and 1.59 (6H, s, isopropylidene CH_3), 3.31 (3H, s, NCH_3), 4.23 (2H, q, $-CH_2-$), 5.70 (1H, d, $J_{1',2'}$=1.5 Hz, 1'-H), 5.81 (1H, d, $J_{5,6}$=8.1 Hz, 5-H), 6.03 (1H, dd, $J_{4',6'}$=1.2 Hz, 6'-H), 7.06 (1H, dd, $J_{5',6'}$=16.7 Hz, $J_{4',5'}$=5.5 Hz, 5'-H), and 7.33 (1H, d, 6-H).

The **11a** was treated with 80% acetic acid under reflux for 2 h and then evaporated. The residue was purified by column chromatography (EtOAc) to quantitatively give 1-[(*E*)-5,6-dideoxy-7-ethoxy-β-D-ribo-hept-5-eno-1,4-furanosid-7-ulosyl]uracil; mp 163—165 °C; UV_{max} (MeOH) 263 nm, UV_{min} 241 nm; ^{1}H-NMR (60 MHz, CD_3OD) δ=1.28 (3H, t, $-CH_2\underline{CH_3}$), 5.75 (1H, d, $J_{5,6}$=7.6 Hz, 5-H), 5.83 (1H, d, $J_{1',2'}$=3.0 Hz, 1'-H), 6.10 (1H, dd, $J_{4',6'}$=1.2 Hz, 6'-H), 7.07 (1H, dd, $J_{5',6'}$=15.5 Hz, $J_{4',5'}$=5.2 Hz, 5'-H), and 7.58 (1H, d, 6-H); Found: C, 50.00; H, 5.16; N, 8.97%. Calcd for $C_{13}H_{16}N_2O_7$: C, 50.00; H, 5.16; N, 8.97%.[18]

Preparations of 11b and 12b. Similar to the case of preparations of **11a** and **12a**, **11b** and **12b** were obtained in 66 and 50% yields, respectively. The **11b** was recrystallized from EtOH, mp 189—190 °C; UV_{max} (H_2O) 228, 250 (sh) nm; ^{1}H-NMR (60 MHz, DMSO-d_6) δ=2.28 (3H, s, $COCH_3$), 3.92 (3H, s, OCH_3), 5.92 (1H, d, $J_{5,6}$=7.6 Hz, 5-H), 6.20 (1H, d, 6'-H), 7.00 (1H, dd, $J_{5',6'}$=16.0 Hz, $J_{4',5'}$=5.6 Hz, 5'-H), and 7.73 (1H, d, 6-H); Found: C, 52.28; H, 5.71%. Calcd for $C_{13}H_{16}N_2O_6$: C, 52.70; H, 5.44%. The **12b** was recrystallized from EtOH, mp 128—130 °C; UV_{max} (H_2O) 219, 260 nm, UV_{min} 250 nm; ^{1}H-NMR (60 MHz, $CDCl_3$) δ=2.30 (3H, s, $COCH_3$), 3.30 (3H, s, NCH_3), 5.83 (1H, d, $J_{5,6}$=8.0 Hz, 5-H), 6.35 (1H, d, 6'-H), 6.91 (1H, dd, $J_{5',6'}$=16.0 Hz, $J_{4',5'}$=4.5 Hz, 5'-H), and 7.38 (1H, d, 6-H); Found: C, 52.20; H, 5.44; N, 9.50%. Calcd for $C_{13}H_{16}N_2O_6$: C, 52.70; H, 5.44; N, 9.46%.

Preparation of 11b by One-Pot Reaction. To a solution of **4b** (256 mg, 1 mmol), **1** (377 mg, 1.5 mmol), and **3** (786 mg, 3 mmol) in THF (3 ml) was added **2** (261 mg, 1.5 mmol) in THF (1 ml) at room temperature for 1 h. The reaction mixture being stirred for 3 h, **2** (1.5 mmol) in THF (1 ml) was further added for 1 h. To the solution kept stirring overnight, **13** (636 mg, 2 mmol) in benzene (10 ml) was added. The resulting solution was refluxed for 3 h and evaporated under reduced pressure. The residue was purified by column chromatography ($CHCl_3$:MeOH=7:1) to give **11b** in 73% yield.

Preparations of 17 and 18. A THF solution of **15a** (437 mg, 0.80 mmol) and **13** (234 mg, 0.80 mmol) was refluxed for 7.5 h and then evaporated under reduced pressure. The residue was purified by PLC ($CHCl_3$:MeOH=9:1) to give **17** in 18% yield: oil; UV_{max} (MeOH) 271 nm; ^{1}H-NMR ($CDCl_3$) δ=1.35 and 1.57 (6H, s, isopropylidene CH_3), 2.26 (3H, s, $COCH_3$), 4.66 (1H, m, 4'-H), 4.98 (1H, m, 3'-H), 5.21 (1H, d, $J_{2',3'}$=6.0 Hz, 2'-H), 5.49 (1H, s, 1'-H), 5.88 (1H, d, $J_{5,6}$=7.3 Hz, 5-H), 6.24 (1H, d, 6'-H), 6.95 (1H, dd, $J_{5',6'}$=16.1 Hz, $J_{4',5'}$=6.4 Hz, 5'-H), and 7.30 (1H, d, 6-H).

The **15b** (209 mg, 0.38 mmol) in THF (8 ml) was treated with **13** (239 mg, 0.81 mmol) under reflux for 5 h and then evapotated. The **18** was isolated by column chromatography using $CHCl_3$–MeOH (8:1) in 31% yield; oil; UV_{max} (MeOH) 319 nm, UV_{min} 261 nm; ^{1}H-NMR ($CDCl_3$–CD_3OD) δ=2.35 (3H, s, $COCH_3$), 3.17 and 3.22 (6H, s, $N(CH_3)_2$), 3.94 (1H, m, 3′-H), 4.18 (1H, d, $J_{2',3'}$=5.4 Hz, 2′-H), 4.66 (1H, m, 4′-H), 5.82 (1H, s, 1′-H), 6.44 (1H, dd, $J_{4',6'}$=1.4 Hz, 6′-H), 6.18 (1H, d, $J_{5,6}$=7.2 Hz, 5-H), 6.95 (1H, dd, $J_{5',6'}$=16.3 Hz, $J_{4',5'}$=5.0 Hz, 5′-H), 7.71 (1H, d, 6-H), and 8.87 (1H, s, =CHN–).

Preparations of 22a and 22b. A solution of *aci*-nitro ester [**20a** (76 mg, 0.13 mmol) or **20b** (230 mg, 0.43 mmol)] and **13** (2 equiv) in THF (7 ml) was refluxed for 7 h. After the solvent was removed, the residue was purified by column chromatography. For the reaction of **20a**, elution with $CHCl_3$–MeOH (15:1) gave **22a** as an oil in 61% yield; UV_{max} (MeOH) 313 nm, UV_{min} 282 nm; ^{1}H-NMR ($CDCl_3$) δ=1.38 and 1.67 (6H, s, isopropylidene CH_3), 2.30 (3H, s, $COCH_3$), 4.78 (1H, m, 4′-H), 5.02 (1H, m, 3′-H), 5.23 (1H, d, $J_{2',3'}$=6.3 Hz, 2′-H), 5.74 (1H, s, 1′-H), 6.25 (1H, dd, $J_{4',6'}$=1.0 Hz, 6′-H), 6.94 (1H, dd, $J_{5',6'}$=16.2 Hz, $J_{4',5'}$=6.6 Hz, 5′-H), 7.09 (1H, d, $J_{5,6}$=7.3 Hz, 5-H), 7.96 (1H, d, 6-H), and 8.15 and 9.26 (2H, s, triazole H).

For the reaction of **20b**, elution with EtOAc–MeOH (8:1) afforded a 77% yield of **22b** which was recrystallized from $CHCl_3$–MeOH: mp 208—209 °C; UV_{max} (MeOH) 217, 251, 316 nm, UV_{min} 233, 280 nm; ^{1}H-NMR ($CDCl_3$) δ=2.32 (3H, s, $COCH_3$), 3.93 (1H, dd, $J_{3',4'}$=4.8 Hz, $J_{4',5'}$=7.7 Hz, 4′-H), 4.18 (1H, dd, $J_{2',3'}$=3.4 Hz, 2′-H), 4.57 (1H, dd, 3′-H), 5.85 (1H, d, $J_{1',2'}$=0.6 Hz, 1′-H), 7.03 (1H, d, $J_{5,6}$=7.7 Hz, 5-H), 6.29 (1H, d, 6′-H), 7.07 (1H, dd, $J_{5',6'}$=16.1 Hz, 5′-H), 8.41 (1H, d, 6-H), and 8.43 and 9.46 (2H, s, triazole H); Found; C, 49.90; H, 4.52; N, 20.73%. Calcd for $C_{14}H_{15}N_5O_5$: C, 50.45; H, 4.54; N, 21.01%.

Preparations of 28a and 28b. A THF (7 ml) solution of **27** (228 mg, 0.25 mmol) and **13** (148 mg, 0.5 mmol) was refluxed for 7.5 h and then evaporated. The residue was purified by PLC (benzene:EtOAc=5:1 and $CHCl_3$:MeOH=20:1) to give **28a** and **28b** in 19 and 36% yields, respectively. **28a**: mp 112—115 °C; UV_{max} (MeOH) 232, 277 nm, UV_{min} 219, 267 nm; ^{1}H-NMR ($CDCl_3$) δ=2.29 (3H, s, $COCH_3$), 5.03 (1H, dd, $J_{3',4'}$=5.9 Hz, $J_{4',5'}$=5.6 Hz, 4′-H), 6.04 (1H, dd, $J_{2',3'}$=5.6 Hz, 3′-H), 6.4—6.5 (2H, m, 1′-H, 2′-H), 6.38 (1H, d, 6′-H), 7.02 (1H, dd, $J_{5',6'}$=16.2 Hz, 5′-H), and 8.25 and 8.68 (2H, s, purine H). **28b**: oil; UV_{max} (MeOH) 232, 282 nm, UV_{min} 257 nm; ^{1}H-NMR ($CDCl_3$) δ=2.32 (3H, s, $COCH_3$), 5.08 (1H, dd, $J_{3',4'}$=5.3 Hz, $J_{4',5'}$=5.6 Hz, 4′-H), 6.09 (1H, dd, $J_{2',3'}$=5.6 Hz, 3′-H), 6.5—6.6 (2H, m, 1′-H, 2′-H), 6.57 (1H, d, 6′-H), 7.06 (1H, dd, $J_{5',6'}$=16.2 Hz, 5′-H), 8.31 and 8.84 (2H, s, purine H), and 9.29 (1H, br s, NH).

Syntheses of Some 6-Oxa- and 2,8-Dioxabicyclo[3.2.1]octanes in Connection with the Daphniphyllum Alkaloids

Shigeru NISHIYAMA, Yoichi IKEDA, and Shosuke YAMAMURA*
Department of Chemistry, Faculty of Science and Technology, Keio University,
Hiyoshi, Kohoku-ku, Yokohama 223
(Received October 16, 1985)

In connection with the daphniphyllum alkaloids, some 6-oxa- and 2,8-dioxabicyclo[3.2.1]octanes, which are included as a partial structure of daphmacrine and codaphniphylline, have been synthesized starting from geraniol.

Previously, we could isolate a number of novel alkaloids from the plant *Daphniphyllaceae.*[1] From a structural point of view, these alkaloids, which are biosynthesized from six mevalonate via squalene, are classified into six types of nitrogen heterocyclic skeletons. Among them, remarkable variations in the remaining partial structure except for the main nitrogen heterocyclic skeleton are found in the group of daphniphylline-type alkaloids, in which codaphniphylline (**1**) and daphmacrine (**2**) are included. As a part of our synthetic study on these alkaloids, we wish to describe the syntheses of some 6-oxa- and 2,8-dioxabicyclo[3.2.1]octanes starting from geraniol.

The known monoacetate (**3**)[2] derived from geraniol in three steps was treated with PhCOCl–pyridine in dichloromethane (room temp, 3 h) in order to differentiate the two original allylic hydroxyl groups, giving rise to the corresponding benzoate (**4**), in quantitative yield, which was further converted into a desired cyclization product (**5**) in four steps, as follows.

The benzoate (**4**) was treated with $Hg(OCOCF_3)_2$ (1.5 equiv) in nitromethane under argon (−15 °C, 3 h) and then stirred with aqueous sodium chloride (room temp, 20 h) to give the corresponding organomercury chloride (**6**),[3] which was directly subjected to reductive demercuration with $NaBH_4$ in *N,N*-dimethylformamide with oxygen bubbling (0 °C, 30 min)[4] and then oxidized with pyridinium chlorochromate (PCC) in dichloromethane (room temp, 4 h) to afford the cyclohexanone derivative (**5**) in 60% overall yield from **4**. The ketone (**5**) was hydrolyzed with saturated methanolic ammonia (0 °C, 5 h) to afford a diol (**7**) in 89% yield, which was further oxidized with pyridinium dichromate (PDC) in *N,N*-dimethylformamide (0 °C, 1 h) to give an aldehyde (**8**) in 85% yield. The resulting aldehyde was treated with 1,2-ethanedithiol–BF_3 etherate to afford the corresponding thioacetal (**9**), which was hydrolyzed with K_2CO_3 in methanol (0 °C, 2 h) to give a dihydroxy compound (**10**), in 84% overall yield. Furthermore, the compound (**10**) was oxidized with PDC in *N,N*-dimethylformamide (room temp, 1 h) to give rise to a desired lactone (**11**) [mp 162—164 °C, IR (film) 1780 and 1715 cm^{-1}] in 54% yield. On $NaBH_4$ reduction in ethanol–dioxane (1:1) (0 °C, 2 h) followed by acetylation with Ac_2O–pyridine, the resulting lactone (**11**) was readily converted into an acetate (**12**), mp 146.5—147.5 °C, in 78% overall yield, in which the newly formed acetoxyl group must be in an axial configuration, as judged from its ^1H NMR spectrum [δ=4.91(1H, br s)].

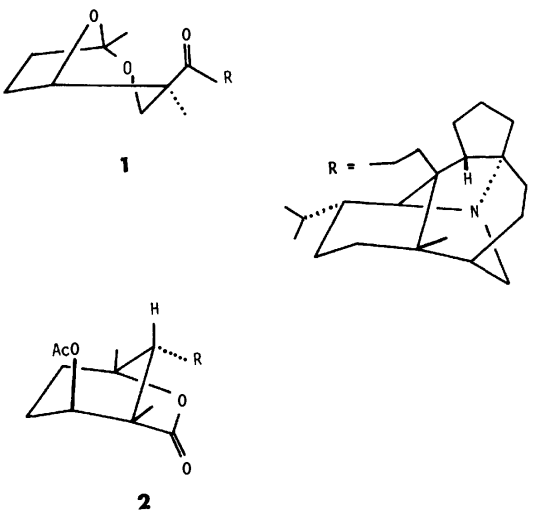

Fig. 1. Structures of codaphniphylline (**1**) and daphmacrine (**2**).

In the next step, the lactone (**12**) was successively treated with thallium trinitrate (TTN) (2.2 equiv) in chloroform–methanol (1:1) (room temp, 1 h),[5] trifluoroacetic acid (TFA) in chloroform containing a small amount of water (0 °C, 1 h), and SiO_2 (room temp, overnight) to afford an acid (**13**) which on methylation with MeI–K_2CO_3 in *N,N*-dimethylformamide (0 °C, 4 h) was converted into the corresponding ester (**14**) [IR (film) 1665 and 1625 cm^{-1}] in 48% overall yield from **12**. In the above procedure, the desired aldehyde (**15**) is too unstable to be separable and seems to be simultaneously converted into the α,β-unsaturated aldehyde (**13**), which has been also produced on exposure to K_2CO_3 in methanol. Finally, this ester (**14**) was successfully converted into the desired 2,8-dioxabicyclo[3.2.1]octane derivative (**16**) which has the same oxygen heterocyclic skeleton

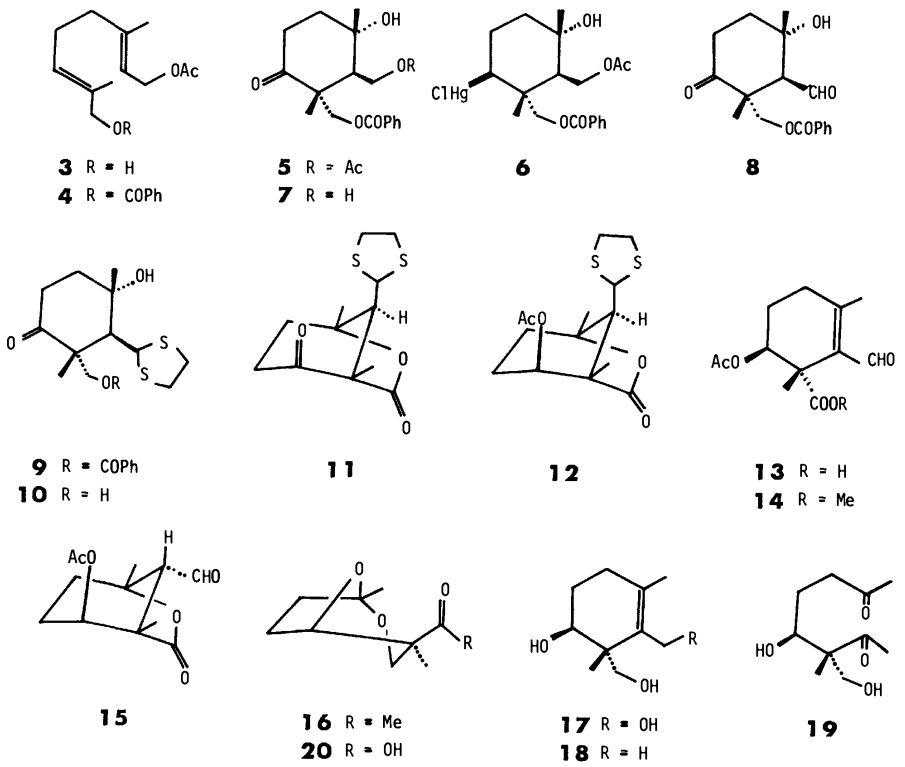

Fig. 2.

as that of codaphniphylline (**1**), as follows.

The ester (**14**) was reduced with excess $NaBH_4$ in ethanol (room temp, overnight) to afford a triol (**17**) and the acetate which on ammonolysis at 0 °C for 2 d afforded **17** in almost quantitative yield. Thus, the total yield of **17** from **14** was 69%. The triol so far obtained was subjected to hydrogenolysis using Pd-C in methanol (room temp, 1.5 h) to give a diol (**18**), mp 104—104.5 °C, in 87% yield. In the last step, on ozonization of **18** in methanol (−60 °C, 30 min) followed by reduction with excess Me_2S, the resulting diketone (**19**) was spontaneously cyclized to the desired acetal (**16**), in 72% yield, having the same oxygen heterocyclic skeleton as that of codaphniphylline (**1**), as judged from its ^1H NMR spectrum [δ=3.49 (1H, d, J=12 Hz), 4.27 (1H, dd, J=12, 2 Hz), and 4.68 (1H, m)], which was similar to that of the degradation product (**20**) of daphniphylline [δ=3.63 (1H, d, J=12 Hz), 4.30 (1H, dd, J=12, 2 Hz), and 4.77 (1H, m)].[6]

On the basis of biogenetic consideration of these daphniphyllum alkaloids, which are biosynthesized from squalene,[1] these two 6-oxa- and 2,8-dioxabicyclo-[3.2.1]octanes have been synthesized. Further synthetic study on the nitrogen heterocyclic moiety of these alkaloids are in progress.

Experimental

All the melting points were obtained on a Mitamura Riken melting point apparatus and uncorrected. IR spectra were recorded on a JASCO Model A-202 spectrophotometer. ^1H NMR spectra were obtained on a Varian EM-390 NMR spectrometer (90 MHz) using tetramethylsilane as an internal standard. Coupling constants are given in Hz (s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet). High resolution mass spectra were obtained on a Hitachi M-80 GC-MS spectrometer operating with an ionization energy (70 eV). Preparative and analytical TLC were carried out on silica-gel plates (Kieselgel 60 F_{254}, E. Merck A. G. Germany) using UV light and/or 5% molbdophosphoric acid in ethanol for detection, unless otherwise stated.

Benzoylation of 3. A solution of **3** (3.0 g) and benzoyl chloride (3.5 ml) in CH_2Cl_2 (30 ml) containing pyridine (2.3 ml) was stirred at room temperature for 3 h. The resulted mixture was partitioned between EtOAc and water, and the organic layer was washed successively with 2M HCl (1 M=1 mol dm^{-3}) and aqueous $NaHCO_3$, and then dried over anhydrous Na_2SO_4. After evaporation of the solvent, the residue was chromatographed on silica gel (200 g) using hexane–EtOAc (5:1) as eluent to give the benzoyl derivative (**4**) as an oil (4.5 g): IR (film) 1730, 1720, 1600, and 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.75 (6H, s), 2.07 (3H, s), 2.14 (4H, complex), 4.57 (2H, d, J=7 Hz), 4.71 (2H, s), 5.2—5.6 (2H, complex), 7.3—7.6 (3H, complex), and 7.95—8.15 (2H, complex); Found: m/z 316.1677. Calcd for $C_{19}H_{24}O_4$: M, 316.1673.

Cyclization of the Benzoate (4) to the Cyclohexanone Derivative (5). To a solution of $Hg(OCOCF_3)_2$ (4.0 g) in CH_3NO_2 (50 ml) at −20 °C under argon was added a solution of **4** (2.0 g) in CH_3NO_2 (10 ml). The mixture was stirred at approximate −15 °C for 3 h, and then excess

aqueous NaCl was added. After stirring at room temperature for 20 h, the reaction mixture was extracted with $CHCl_3$. The organic extract was dried over anhydrous Na_2SO_4, and concentrated under reduced pressure to leave an oil (3.9 g), which was dissolved in DMF (16 ml), and a 4 ml portion of the solution was gradually added to a solution of $NaBH_4$ (112 mg) in DMF (15 ml) with oxygen bubbling. After being reacted at 0 °C for 30 min, precipitated mercury was filtered off using Celite. The filtrate was partitioned between EtOAc and 2M HCl. The organic layer was washed with aqueous $NaHCO_3$ and dried over anhydrous Na_2SO_4, and then concentrated under reduced pressure. The remaining DMF solution was submitted to the same procedure as above. The combined product was dissloved in CH_2Cl_2 (50 ml), and oxidized with PCC (3.5 g) at room temperature for 4 h. The reaction mixture was filtered and the filtrate was concentrated under reduced pressure to give a brownish residue, which was chromatographed on silica gel (150 g) using $CHCl_3$-EtOAc (4:1) as eluent to afford **5** as an oil (1.3 g): IR (film) 3450, 1710br., 1595, and 1575 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.21 (3H, s), 1.42 (3H, s), 1.99 (3H, s), 2.0—3.0 (5H, complex), 4.16 (1H, dd, J=12, 5 Hz), 4.45 (1H, dd, J=12, 5 Hz), 4.50 (1H, d, J=11 Hz), 4.72 (1H, J=11 Hz), 7.3—7.6 (3H, complex), and 7.9—8.1 (2H, complex); Found: m/z 349.1627. Calcd for $C_{19}H_{25}O_6$: M+1, m/z 349.1649.

Hydrolysis of 5 to the Diol (7). The ketone (**5**) (0.17 g) was treated with saturated methanolic ammonia (10 ml) at 0 °C for 5 h, and then this mixture was concentrated under reduced pressure to leave an oil, which was purified by preparative TLC [hexane-EtOAc (1:1)] to give the desired diol (**7**) (0.11 g) and the starting material (**5**) (0.03 g). **7** as an oil: IR (film) 3450, 1705, 1595, and 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (3H, s), 1.52 (3H, s), 1.9—2.1 (2H, complex), 2.2—2.7 (3H, complex), 3.9—4.05 (2H, complex), 4.45 (2H, s), 7.3—7.6 (3H, complex), and 7.85—8.05 (2H, complex); Found: m/z 307.1534. Calcd for $C_{17}H_{23}O_5$: M+1, m/z 307.1543.

Oxidation of the Diol (7) with PDC. A mixture of **7** (36 mg) and PDC (89 mg) in DMF (1 ml) was stirred at 0 °C for 1 h. The reaction mixture was directly submitted to preparative TLC [hexane-EtOAc (1:1)] to yield the aldehyde (**8**) (11 mg) in addition to the starting material (**7**) (23 mg). **8** as an oil: IR (film) 3450, 1715, 1625, 1600, 1580, and 1550 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (3H, s), 1.40 (3H, s), 2.0—2.7 (3H, complex), 2.8—3.2 (3H, complex), 4.53 (1H, d, J=11 Hz), 5.01 (1H, d, J=11 Hz), 7.3—7.6 (3H, complex), 7.9—8.1 (2H, complex), and 9.67 (1H, d, J=4 Hz); Found: m/z 305.1387. Calcd for $C_{17}H_{21}O_5$: M+1, m/z 305.1387.

Protection of the Aldehyde (8) with 1,2-Ethanedithiol. To a solution of **8** (41 mg) in CH_2Cl_2 (2 ml) were added 1,2-ethanedithiol (34 µl) and $BF_3 \cdot OEt_2$ (14 µl), and the mixture was stirred at 0 °C for 5.5 h. The resulting mixture was washed with aqueous $NaHCO_3$, and then dried over anhydrous Na_2SO_4, and concentrated under reduced pressure. The residue was purified by preparative TLC [hexane-EtOAc (1:1)] to give the thioacetal (**9**) (44 mg): Mp 125—127.5 °C (from hexane-EtOAc); IR (film) 3400, 1710, 1600, and 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (3H, s), 1.53 (3H, s), 1.5—2.2 (5H, complex), 3.0—3.4 (4H, complex), 4.25 (1H, d, J=12 Hz), 4.41 (1H, d, J=12 Hz), 4.52 (1H, d, J=12 Hz), 7.3—7.65 (3H, complex), and 8.0—8.15 (2H, complex); Found: m/z 381.1219. Calcd for $C_{19}H_{25}O_4S_2$: M+1, m/z 381.1193.

Hydrolysis of the Thioacetal (9). A solution of **9** (0.15 g) and K_2CO_3 (64 mg) in MeOH (7 ml) was stirred at 0 °C for 2 h. The reaction mixture was quenched with H_2O and worked up as usual to give a crude product, which was purified by preparative TLC using hexane-EtOAc (1:1) to give a diol (**10**) (0.1 g) as a crystalline solid: ca. 123 °C; IR (film) 3350 and 1695 cm^{-1}; ^1H NMR ($CDCl_3$+D_2O) δ=1.26 (3H, s), 1.56 (3H, s), 1.5—2.2 (5H, complex), 3.0—3.4 (4H, complex), 3.45 (1H, d, J=11 Hz), 3.91 (1H, d, J=11 Hz), and 4.41 (1H, d, J=12 Hz); Found: m/z 246.0734. Calcd for $C_{11}H_{18}O_2S_2$: M−CH_2O, m/z 246.0747.

Oxidation of the Diol (10) with PDC. A mixture of **10** (22 mg) and PDC (0.15 g) in DMF (1 ml) was stirred at room temperature for 1 h. The resulting brown solution was passed through a short silica-gel column [hexane-EtOAc (1:2)] and purified by preparative TLC [hexane-EtOAc (1:2)] to afford the lactone (**11**) (7.1 mg) and the starting diol (**10**) (8.7 mg). **11**: Mp 162—164 °C (from hexane-EtOAc); IR (film) 1780 and 1715 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.48 (3H, s), 1.77 (3H, s), 2.1—2.4 (2H, complex), 2.5—2.65 (2H, complex), 2.73 (1H, d, J=10 Hz), 3.0—3.4 (4H, complex), and 4.24 (1H, d, J=10 Hz); Found: m/z 272.0513. Calcd for $C_{12}H_{16}O_3S_2$: M, m/z 272.0539.

Reduction of the Lactone (11) Followed by Acetylation. A mixture of **11** (45 mg) and $NaBH_4$ (7 mg) in EtOH (1 ml) and dioxane (1 ml) was stirred at 0 °C for 1 h and then worked up as usual to give a hydroxy compound (38 mg): Mp 125.5—127 °C (from hexane); IR (film) 3450 and 1755 br. cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.48 (3H, s), 1.63 (3H, s), 1.7—2.1 (4H, complex), 2.27 (1H, d, J=10 Hz), 3.0—3.3 (4H, complex), 3.37 (1H, br.s), and 5.23 (1H, d, J=10 Hz); Found: m/z 274.0694. Calcd for $C_{12}H_{18}O_3S_2$: M, m/z 274.0695.

This compound (28 mg) was dissolved in excess Ac_2O-pyridine and allowed to stand at room temperature overnight, and then worked up as usual to afford the acetate (**12**) (30 mg): Mp 146.5—147.5 °C (from hexane); IR (film) 1770 and 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 (3H, s), 1.65 (3H, s), 1.6—2.1 (4H, complex), 2.14 (3H, s), 2.26 (1H, br.d, J=12 Hz), 3.1—3.4 (4H, complex), 4.94 (1H, br.s), and 5.02 (1H, d, J=12 Hz); Found: m/z 316.0813. Calcd for $C_{14}H_{20}O_4S_2$: M, m/z 316.0802.

Formation of the α,β-Unsaturated Aldehyde (14). A mixture of **12** (19 mg) and TTN (58 mg) in $CHCl_3$ (0.5 ml) and MeOH (0.5 ml) was stirred at room temperature for 1 h. After filtration of salt precipitated, the filtrate was partitioned between $CHCl_3$ and H_2O, and the organic layer was dried over anhydrous Na_2SO_4 and then concentrated under reduced pressure. The residue was treated with TFA (0.5 ml) in $CHCl_3$ (0.5 ml) containing small amount of H_2O at 0 °C for 1 h. The mixture was diluted with $CHCl_3$ and neutralized with aqueous $NaHCO_3$. The organic layer was dried over anhydrous Na_2SO_4 and then concentrated under reduced pressure to leave a syrup, which was charged on silica-gel plates and kept at room temperature overnight. Development of the plate using $CHCl_3$-MeOH (4:1) afforded a crude product, which on methylation with MeI (6 µl)-K_2CO_3 (11 mg) in DMF (0 °C, 4 h) led to the ester (**14**) (7.1 mg) as an oil: IR (film) 1730, 1665, and 1625 cm^{-1};

^{1}H NMR ($CDCl_3$) δ=1.35 (3H, s), 1.55—2.65 (4H, complex), 2.04 (3H, s), 2.18 (3H, S), 3.60 (3H, s), 5.19 (1H, m), and 10.00 (1H, s); Found: *m/z* 254.1114. Calcd for $C_{13}H_{18}O_5$: M, *m/z* 254.1152.

Formation of the Triol (17). To a solution of **14** (15 mg) in EtOH (1 ml) was added $NaBH_4$ (13 mg) at 0 °C, and then the reaction temperature was gradually elevated to room temperature. After being stirred at room temperature overnight, the mixture was neutralized with AcOH and then concentrated under reduced pressure to leave a syrup, which was passed through a short silica-gel column [hexane–acetone (3:1)] to give the triol (**17**) (4.4 mg) and the acetate (4.4 mg). The latter was directly treated with mathanolic ammonia at 0 °C for 2 d to afford **17** (3.3 mg) as a syrup: IR (film) 3380 cm^{-1}; ^{1}H NMR ($CDCl_3$+D_2O) δ=0.85 (3H, s), 1.77 (3H, s), 1.4—2.3 (4H, complex), 3.67 (2H, d, *J*=1.5 Hz), 4.02 (1H, d, *J*=12 Hz), ca. 4.0 (1H, overlapped with the doublet), and 4.29 (1H, d, *J*=12 Hz); Found: *m/z* 186.1261. Calcd for $C_{10}H_{18}O_3$: M, *m/z* 186.1255.

Hydrogenolysis of the Triol (17). The triol (**17**) (5.3 mg) in MeOH (1 ml) was hydrogenated over catalyst 10% Pd-C at room temperature for 1.5 h. After filtration of the catalyst, the filtrate was concentrated under reduced pressure and then directly separated by a short silica-gel column using hexane–acetone (5:1) to afford **18** (2.6 mg) and the unreacted **17** (2.0 mg). **18**: Mp 104–104.5 °C (from hexane–EtOAc); IR (film) 3400 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ= 1.02 (3H, s), 1.61 (6H, s), 1.7—2.2 (4H, complex), 3.52 (1H, d, *J*=11 Hz), 3.74 (1H, d, *J*=11 Hz), and ca. 3.75 (1H, overlapped with the doublet); Found: *m/z* 170.1286. Calcd for $C_{10}H_{18}O_2$: M, *m/z* 170.1305.

Ozonization of the Diol (18). Ozone was passed through a solution of **18** (20 mg) in MeOH (5 ml) at −60 °C for 30 min. After excess ozone was purged with N_2, the reaction solution was treated with excess Me_2S as usual, and then concentrated under reduced pressure. The residue was purified by preparative TLC [hexane–EtOAc (1:1)] to give the acetal (**16**) (14 mg), and the starting material (2 mg) was recovered. **16** as an oil: IR (film) 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.85 (3H, s), 1.48 (3H, s), 1.8—2.1 (4H, complex), 2.39 (3H, s), 3.49 (1H, *d*, *J*=12 Hz), 4.27 (1H, dd, *J*=2, 12 Hz), and 4.68 (1H, m); Found: *m/z* 184.1087. Calcd for $C_{10}H_{16}O_3$: M, *m/z* 184.1097.

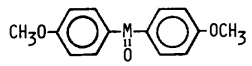
Polymer-Supported Diaryl Selenoxide and Telluroxide as Mild and Selective Oxidizing Agents

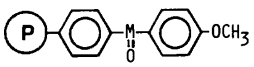
Nan Xing Hu, Yoshio Aso, Tetsuo Otsubo, and Fumio Ogura*
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University,
Saijo, Higashi-Hiroshima 724
(Received October 18, 1985)

Polystyrene-bound diaryl selenoxide and telluroxide have been prepared, which behaved as mild oxidizing agents for thiols to disulfides, phosphines to phosphine oxides, hydroquinone and catechol to *p*- and *o*-benzoquinones, and thioketones to oxo compounds. The telluroxide completed these reactions in shorter periods or under milder conditions than the selenoxide. In addition, they effected novel solvent-dependent reactions of thioamides involving thioureas to 1,2,4-thiadiazoles or to nitriles. In nonacidic solvents, the dehydrosulfurization to nitriles occurred in preference to the oxidative dimerization to 1,2,4-thiadiazoles, but an acidic solvent such as acetic acid promoted the latter reaction.

Although organoseleniums[1] and telluriums[2] have recently received much attention as new synthetic reagents, most of their low-molecular species are extremely stinking and toxic. The immobilization of such reagents on polymer-resins would not only avoid the difficulties arising from volatility, but also provide some additional advantages including simplification of product work-up and recycle of the used reagents. There have been nevertheless known few examples of polymer-supported seleniums[3,4] and none of polymer-supported telluriums. Selenoxides[5–7] and telluroxides[8] have been recently recognized to have effective oxidizing abilities due to their weak chalcogen–oxygen bonds relative to sulfoxides. In particular, we and Barton et al. reported bis(*p*-methoxyphenyl) selenoxide **1a**[7] and telluroxide **1b**,[8] respectively, as new and versatile



1a M=Se
1b M=Te



2a M=Se
2b M=Te

oxidizing agents. From the viewpoint of the practical use, we have designed the immobilization of these reagents on polymer-resins. Michels et al. already reported polymer-supported diphenyl selenoxide, but its reactivity has been revealed only for oxidation of 2-methylnaphthalene to 2-naphthaldehyde.[3] Here we report on the facile syntheses of polystyrene-bound diaryl selenoxide **2a** and telluroxide **2b** and on their reactivities toward various compounds as compared to monomeric counterparts **1a** and **1b**.[9]

Results and Discussion

Polystyrene-bound diaryl selenoxide **2a** and telluroxide **2b** were conveniently prepared as shown in Scheme 1. Poly(*p*-lithiostyrene) **3** was readily accessible from partial bromination of 1% cross-linked polystyrene resin, followed by halogen-metal exchange with butyllithium according to the method reported by Farrall and Fréchet.[10] Treatment of **3** with *p*-methoxyphenyl selenocyanate **4a**[11] gave a polymeric selenide **5a**, which was then converted via selenium dibromide **6a** into a light brown polymer of selenoxide **2a**. The infrared spectrum of **2a** closely resembled that of **5a**, but indicated a strong Se=O absorption at 820 cm^{-1}.[3] A polymeric telluroxide **2b** was similarly synthesized, starting from reaction of poly(*p*-lithiostyrene) **3** and *p*-methoxyphenyl tellurocyanate **4b**.[12] In contrast to well-defined Se=O absorptions, Te=O absorptions were obscure in the infrared spectrum of **2b**.

Both of the polymeric reagents **2a** and **2b**, like monomeric counterparts **1a** and **1b**, were inert to simple amines, amides, alcohols, and phenols, but readily oxidized thiols to disulfides, phosphine to phosphine oxides, and hydroquinone and catechol to *p*- and *o*-benzoquinones in dichloromethane, chloroform, or acetic acid as a swelling solvent at room temperature. In addition, **2a** converted sulfides into sulfoxides in acetic acid, while **2b** did not behave similarly.[13] These results are summarized in Table 1. The spent reagents could be recovered as the reduced species **5a** or **5b** by simple filtration and reused after

oxidation. The appreciable decrease of their activities was not observed even over ten recycles. Table 1 indicates that telluroxide **2b** completed reactions in shorter periods than selenoxide **2a**, reflecting the weaker Te=O bond relative to Se=O bond. The difference in reactivity between the two reagents became marked in the reactions toward thioketones. As shown in Table 2, telluroxide **2b** could smoothly convert thioketones and thioesters into the corresponding oxo compounds. As an exceptional case, thiocamphor was preferentially converted into a divinyl disulfide, being induced via enethiolization (Run 3). On the other hand, the selenoxide **2a** was less reactive toward most of the thioketones and failed to react with 4,5-bis(methylthio)-1,3-dithiole-2-thione (Run 5) and methyl thiobenzoate (Run 6) even under forced conditions.

It has become apparent that monomeric selenoxide

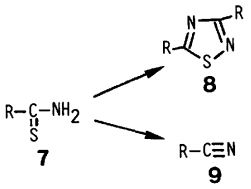
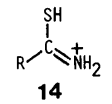
a) p-Chlorobenzonitrile was obtained in 47% yield as an acompanying product. b) Reaction at 75 °C resulted in dehydrosulfurization to give $(C_6H_5)_2NCN$ in 93% yield.



Scheme 2.

1a and telluroxide **1b** undergo different types of reactions toward thioamides involving thioureas as shown in Scheme 2. For example, reaction of thiobenzamide **7** (R=Ph) with **1a** in ethanol at room temperature gave 3,5-diphenyl-1,2,4-thiadiazole **8** (R=Ph) in 86% yield.[7] On the other hand, a similar treatment with **1b** gave benzonitrile **9** (R=Ph) in 78% yield. Polymeric selenoxide **2a**, unlike monomeric counterpart **1a**, hardly effected such oxidative dimerization, and permitted the formation of thiadiazole **8** in acetic acid at 75 °C. Some results are shown in Table 3. Treatments in usual solvents such as ethanol, acetonitrile, benzene, ethyl acetate, and 1,2-dichloroethane favored dehydrosulfurization to nitriles **9**. The best yield (84%) of benzonitrile from thiobenzamide was realized in refluxing ethanol. A wide variety of primary thioamides and thioureas were thus convertible into the corresponding nitriles in high yields as shown in Table 4. *N,N'*-Diphenylthiourea (Run 11) and tetramethylthiourea (Run 12), structurally incapable of forming nitriles, were smoothly oxidized to the corresponding ureas. The polymeric telluroxide **2b**, as a whole, behaved like the polymeric selenoxide **2a**, though the reaction conditions were much milder. Tables 3 and 4 also demonstrate the results of the oxidative dimerization and dehydrosulfurization, respectively, at room temperature. Table 3 shows that the oxidative dimerization with **2b** is not so effective and specific as that with **2a**. For example, treatment of p-chlorothiobenzamide with **2b** in acetic acid (Run 2) gave 3,5-bis(p-chlorophenyl)-1,2,4-thiadiazole (31%), together with p-chlorobenzonitrile (47%). Furthermore, *N,N*-diphenylthiourea did not undergo any oxidative dimerization on treatment with **2b** in acetic acid and rather favored dehydrosulfurization at an elevated temperature (Run 3).

Two mechanisms A and B, which can explain the formation of thiadiazole **8** and nitrile **9**, respectively, are proposed in Scheme 3.[14] Both mechanisms are initiated by addition of the reagent **2** to thioamide **7**, leading to an adduct **10**. A definite difference arises from whether the adduct **10** can react with another thioamide **7** to give a termolecular intermediate **11**, leading via a few steps to thiadiazole **8**, or degrade spontaneously to nitrile **9**. Monomeric selenoxide **1a** favors pathway A, while monomeric telluroxide **1b** favors pathway B. The difference is presumably related to their oxidizing abilities. On the other hand, both polymeric reagents **2a** and **2b** take pathway B in usual solvents, regardless of their oxidizing abilities and degree of swelling. The steric hindrance of the polymer lattice presumably prevents access of the reaction site of adduct **10** to another thioamide **7**, resulting in spontaneous degradation to nitrile **9**. The different reaction type in acetic acid is attributable to its acidity. The protonation of thioamide **7** to iminium **14** is expected to facilitate



pathway A, because **14** is much more susceptible to nucleophilic attack of adduct **10** than **7**. This was supported by an additional experimental result that the dehydrosulfurization of thiobenzamide **7** (R=Ph) with polymeric selenoxide **2a** to benzonitrile **9** (R=Ph) in ethanol was depressed by addition of a

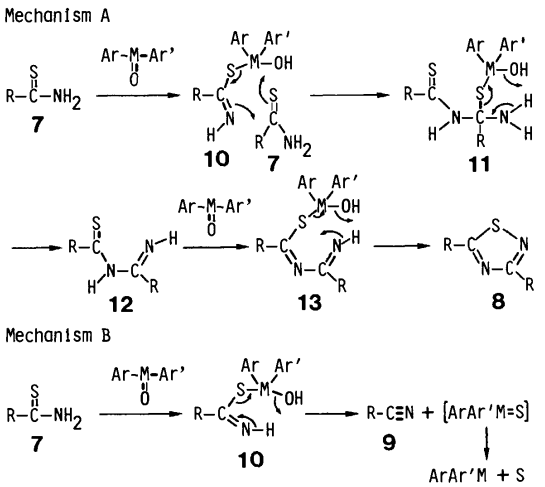
a) Yield contained that (42%) of 2,4,6-triimino-1,3,5-triphenyl-hexahydro-1,3,5-triazine which was formed by ready trimerization of phenylcyanamide; Ref. 22.



Scheme 3.

small amount of hydrochloric acid, forming instead 3,5-diphenyl-1,2,4-thiadiazole **8** (R=Ph) in 78% yield. In contrast, some of oxidative dimerizations with polymeric telluroxide **2b** in acetic acid competed with dehydrosulfurizations because of its relatively stronger oxidizing ability, indicating that the selectivity of either pathway A or B depends on a subtle balance of steric and electronic effects.

It has been thus understood that polymer-supported diaryl selenoxide **2a** and telluroxide **2b** like monomeric counterparts **1a** and **1b** behave as mild and selective oxidizing agents and complement each other owing to their different reactivities. In addition, they have turned out to effect novel solvent-dependent reactions of thioamides involving thioureas to 1,2,4-thiadiazoles or to nitriles. Although several methods for the oxidative dimerization of thioamides to 1,2,4-thiadiazoles[15] and for the dehydrosulfurization of thioamides to nitriles,[16] have so far been developed, they require relatively severe reaction conditions or highly reactive reagents which may affect other functional groups. The present methods using polymer-supported reagents **2a** and **2b** conveniently complement the preceding procedures, because of their wide applicability, high selectivity, and operational simplicity.

Experimental

Material. Polystyrene resin used in this research was 1% divinylbenzene-styrene copolymer, Bio-Beads S-Xl, purchased from Bio-Rad Laboratories. It was converted into poly(*p*-lithiostyrene) **3** according to the procedure of Farrall and Fréchet.[10] Most of the substrates examined in the oxidations with polymeric reagents **2a** and **2b** were commercially available. Thiobenzophenone, thiofenchone, thiocamphor, and methyl thiobenzoate (Runs **1**—3,6 of Table 2) were obtained from reactions of the corresponding ketones[17] and ester[18] with Lawesson's reagent, 2,4-bis(4-methoxyphenyl)-**1**,3-dithia-2,4-diphosphetane-2,4-disulfide. 4,5-Bis(methylthio)-**1**,3-dithiole-2-thione (Run 5 of Table 2) was accessible from reaction of carbon disulfide with sodium, followed by methyl iodide.[19] Substituted thiobenzamides, phenylethanethioamide, and octadecanethioamide (Runs 2—7 of Table 4) were obtained from reactions of the corresponding amides with phosphorus pentasulfide in dioxane.[16]

Preparation of Polymeric Selenide 5a. Poly(*p*-lithiostyrene) resin **3**, in situ prepared from 5.0 g of partially brominated polystyrene containing 3.0 mequiv of bromine per gram,[10] was swollen in 50 ml of dry THF in a nitrogen atmosphere. After a solution of *p*-methoxyphenyl selenocyanate **4a**[11] (5.1 g, 24 mmol) in 10 ml of dry THF was added, the slurry was stirred at room temperature for 30 min and then at 60 °C overnight. The resin was collected by filtration, and washed successively with THF, 1:1 THF-water, water, again THF, and finally MeOH. After dryness under reduced pressure at 60 °C, a light brown resin of selenide **5a** (5.69 g) was obtained. Elemental analysis for selenium revealed that the resin contained 1.5 mequiv of Se per gram.

Preparation of Polymeric Selenoxide 2a. A solution of bromine (1.92 g, 12 mmol) in 10 ml of CCl_4 was dropwise added into a suspension of the resin **5a** (5.0 g) swollen in 30 ml of CCl_4. The slurry was stirred at room temperature for 4.5 h. The resulting selenium dibromide **6a** was collected by filtration, and washed successively with CCl_4 and THF. It was then mixed with 50 ml of THF and 10 ml of 15% NaOH aq, and refluxed overnight. The resin was collected by filtration, and washed once with THF, repeatedly with 1:10 THF-water until the washings turned neutral, and finally with MeOH. After dryness under reduced pressure at 60 °C, a light brown resin of selenoxide **2a** (4.9 g) was obtained. IR (KBr disk); 820 cm^{-1} (Se=O).

Preparation of Polymeric Telluride 5b. In a similar manner as described for polymeric selenide **5b**, a reddish yellow resin of telluride **5b** (8.05 g) was obtained from reaction of poly(*p*-lithiostyrene) **3**, in situ generated from 8.0 g brominated polystyrene (3.0 mequiv of bromine per gram), and *p*-methoxyphenyl tellurocyanate **4b**[12] (8.0 g, 31 mmol). Elemental analysis for C (75.50%) and H (6.11%) indicated that the resin contained the degree of 1.3 mequiv functionalization per gram.

Preparation of Polymeric Telluroxide 2b. In the quite same way as described for the preparation of polymeric selenoxide **2a**, a brown resin of telluroxide **2b** (8.1 g) was obtained via tellurium dibromide **6b** from telluride **5b** (8.0 g).

General Procedure for Oxidations with Polymeric Selenoxide 2a or Telluroxide 2b. An oxidizable substrate (0.5 mmol) was mixed with 20% excess of polymeric reagent **2a** or **2b** swollen in 10 ml of a solvent specified for each reaction. The mixture was treated under such conditions as described in Tables 1, 2, 3, or 4. After the reaction was completed, the spent reagent was removed by suction filtration, and washed throughly with the same solvent as used in the reaction. The filtrate and washings were combined and concentrated in vacuo. The residue was subjected to short column chromatography on silica gel or gel permeation liquid chromatography to give the corresponding pure product. All the products were characterized by comparison of their melting points and spectral data with those of the authentic samples, which were commercially available except divinyl disulfide (Run 3 of Table 2),[8] 1,3-dithiolan-2-one (Run 4 of Table 2),[20] 4,5-bis(methylthio)-1,3-dithiol-2-one (Run 5 of Table 2),[21] 3,5-diphenyl-1,2,4-thiadiazole (Run **1** of Table 3),[7] 3,5-bis(*p*-chlorophenyl)-**1**,2,4-thiadiazole (Run 2 of Table 3),[21] 3,5-bis(diphenylamino)-**1**,2,4-thiadiazole (Run 3 of Table 3),[7] 5-imino-4-phenyl-3-phenylamino-4,5-dihydro-1,2,4-thiadiazole (Run 4 of Table 3),[7] phenylcyanamide (Run 9 of Table 4),[22] and diphenylcyanamide (Run 10 of Table 4).[23]

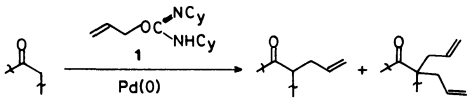
2-Allylisourea as an Effective Agent for Direct α-Allylation of Ketone and Aldehyde Assisted by Palladium(0) under Neutral Conditions

Yoshio INOUE,* Masanori TOYOFUKU, Masaaki TAGUCHI, Shin-ichi OKADA, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980
(Received October 23, 1985)

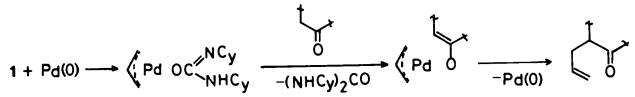
Direct α-allylation of a variety of ketones and aldehydes with 2-allylisourea took place in the presence of a catalytic amount of a palladium(0) complex under neutral and mild conditions. Scope and limitations of this novel method have been investigated.

The palladium-assisted allylation of active hydrogen compounds of pK_a's 10—17 is known to take place smoothly with a variety of allylic compounds,[1a] i.e., esters,[1b] ethers,[1b] alcohols,[1b] amines,[1b] sulfones,[1c] ammonium halides,[1d] sulfonium halides,[1d] nitro derivatives,[1e] and phosphates.[1f] The reaction pathway via π-allylpalladium intermediates is widely accepted.[1a] Usually the reaction is carried out under basic conditions to convert the active hydrogen compounds into their conjugate bases. However alkali metal enolates derived from ketones tend not to readily undergo this allylation.[2] Several improvement have been made including the change of the palladium catalyst[3] and metal enolates used.[4] Recently decarboxylative α-allylation of ketones under neutral conditions using allyl keto carboxylates and allyl enol carbonates have also been exploited.[5]

2-Alkylisourea can be used as the alkylating agent[6] for active hydrogen compounds such as hydrogen chloride, carboxylic acids, phenols, and imides. 2-Allylisourea is employed as an agent for the palladium-catalyzed allylation of imides[6f] and amides.[6g] Previously, we reported briefly that 2-allyl-1,3-dicyclohexylisourea (**1**) was an effective agent for



α-allylation of simple ketones.[7] That is the first example of the direct α-allylation of ketone assisted by palladium(0) under neutral conditions. A likely mechanism is as follows. The isourea **1** oxidatively adds to palladium(0) to afford a π-allylpalladium complex and the isourea anion. The anion thus formed is basic enough to abstract an α-proton of a ketone to produce the ketone enolate. Then the enolate attacks the π-allyl group on the palladium to afford the observed product.



In this paper, we report the extension of this method to a variety of ketones and aldehydes and also describe the related reactions.

Results and Discussion

2-Allylic-substituted isoureas were prepared from allylic alcohols and dicyclohexylcarbodiimide (DCC) in the presence of a catalytic amount of copper(I) chloride.[8] The allylation reaction was carried out simply by mixing a substrate (1.0 equiv) and an allylic-substituted isourea (1.0 equiv) in the presence of a palladium(0) complex combined with PPh_3 or $Ph_2PCH_2CH_2PPh_2$ (dppe) as the catalyst.

α-Allylation of Ketone. Initially, several reaction parameters were examined using cyclohexanone as a probe for α-allylation with **1**. The results are shown in Table 1. Allylation occurred selectively toward monoallylation in tetrahydrofuran (THF), 1,4-dioxane, diethylene glycol dimethyl ether (diglyme), benzene, and acetonitrile, but the yields were modest. The reaction proceeded efficiently in dipolar, aprotic solvents, i.e., dimethyl sulfoxide (DMSO), hexamethylphosphoric triamide (HMPT), and *N*,*N*-dimethylformamide (DMF). Although monoallylation was main in these solvents, considerable diallylation also took place. This effect of solvent was similar to that observed usually in the alkylation of the metal enolate of a ketone.[9]

The effect of ligand was examined in DMF solvent. Tributylphosphine completely suppressed the reaction. A moderate yield toward monoallylation resulted with triphenylphosphine as ligand. The allylation took place efficiently by the use of ditertiary phosphines [$R_2P(CH_2)_nPR_2$; R=Ph (n= 2, 3, 4), R=Me (n=2)]. Substantial diallylation occurred at the same time. The diarsine ligand $Ph_2As(CH_2)_2AsPh_2$ afforded a catalytically less active species. The effectiveness of the bidentate phosphine ligand has been demonstrated in the palladium-catalyzed allylation.[5c,10] The effect is ascribed to its tendency to generate a cationic (π-allyl)palladium intermediate which is more active than the neutral

one toward nucleophilic reactions.[5c,11)]

Noteworthy is the inclination of THF as a solvent to afford a monoallylation product although the yield is unsatisfactory in general. In order to increase monoallylation, the effects of added inorganic salts, i.e., lithium acetate, sodium acetate, and lithium bromide, were examined with a [$Pd(PPh_3)_3$] catalyst. Addition of lithium acetate (0.16 equiv) afforded the monoallyl ketone in a significantly increasing yield. The formation of the diallyl ketone was only modest. In contrast, sodium acetate and lithium bromide did not gave influence respectably.

Enol trimethylsilyl ether from cyclohexanone also participated in the reaction involving 2-allylisourea. Somewhat slower reaction was observed compared to that of the original ketone with a slight increase in the mono/di ratio.

Table 2 shows the results of α-allylation of various ketones with **1** in DMF at ambient temperature in the presence of a palladium(0)-dppe catalyst. α,α-Diallylation predominated for acetone. Ethyl methyl ketone was allylated exclusively at the methylene carbon. These observations indicate that this allylation reaction involving **1** and ketone is controlled thermodynamically. Diethyl ketone afforded α-mono- and α,α'-diallylated products. Exclusive diallylation occurred for acetophenone. Propiophenone was selectively converted to the monoallylated product, whereas α-tetralone gave mainly the diallylation product. As a rule the allylation of simple ketones with **1** in DMF solvent by a palladium(0)-dppe catalyst afforded mainly or exclusively di- and trialkylated derivatives.

α,β-Unsaturated ketones, e.g., mesityl oxide and 2-cyclohexenone, reacted with **1** to produce α-allyl-β,γ-unsaturated ketones. Abstraction of the γ-hydrogen followed by allylation at the α-position will afford the observed products.

Usually α-alkylation of ketone with alkyl halide or sulfonate has been carried out using a strong base. Normally there are a number of obstacles; a) self-condensation; b) polyalkylation; c) non-regioselective alkylation for unsymmetrical ketones. The obstacle a) was completely eliminated by this neutral allylation means. Although palladium(0)-dppe was an effective catalyst in DMF solvent, polyallylation was usually accompanied. Effective monoallylation was accomplished only for propiophenone. A considerable improvement toward monoallylation of cyclohexanone was attained by the addition of

lithium acetate with [Pd(PPh$_3$)$_3$] as the catalyst in THF solvent. Addition of lithium acetate was also effective to the other ketones. Thus, the monoallylation of diethyl ketone, acetophenone, and mesityl oxide increased from 5, 22, and 9% into 6, 34, and 20%, respectively (LiOAc, 0.2 equiv; [Pd(PPh$_3$)$_3$], THF, reflux, 2 h). As for the obstacle c), the regioselectivity of allylation is left to thermodynamic control.

Extension of this method was attempted intramolecularly to make a ring. The allylic isourea derived from 8-hydroxy-6-octen-2-one was submitted to the reaction at 100 °C for 2 h in DMF with a palladium(0)-dppe catalyst. However the only product isolated was 5,7-octadien-2-one (62% yield). Exclusive 1,4-elimination took place.

As propiophenone was selectively converted to the monoallylation product with 2-allylisourea, the regiochemistry with respect to the allylic group and the stereochemistry around the double bond were investigated with this ketone employing several 2-allylic-substituted isoureas. The results are summarized in Table 3. The less substituted site of the allylic system in the isourea reacted preferentially. The composition of the products from 2-(1-methyl-2-propenyl)isourea was analogous to that from (*E*)-2-butenylisourea. This indicates that the intermediate from each should be same. Initial (*E*)-geometry around the double bond was retained during the reaction except for the partial loss observed in the (*E*)-2-butenylisourea case. These results support the intermediacy of a π-allylpalladium species having the *syn*-configuration predoninantly.[12]

Unfortunately, the allylation involving γ,γ-disubstituted allylic system, i.e., prenyl and geranyl, did not occur by a palladium(0)-dppe catalyst. Instead 1,4-elimination of the isoureas proceeded exclusively to afford isoprene and myrcene/ocimene, respectively. Several papers dealt with 1,4-elimination of allylic compounds to dienes by palladium catalysts.[13] For comparison, we studied the 1,4-elimination of geranyl- and nerylisourea in the absence of ketone in some detail. Geranylisourea was converted to myrcene, (*E*)-, and (*Z*)-ocimene in the ratio 24:58:18 (DMF, 120 °C, 5 h; total yield 67%). Another experiment in THF afforded the same products in the ratio 67:21:12 (r.t., 48 h; total yield 99%). Nerylisourea gave the trienes in the ratio 77:16:7 (DMF, 120 °C, 5 h; total yield 58%). Thus the selectivity of the 1,4-elmination reaction involving allylic isourea was comparable to that involving allylic acetate,[13a] but was not to be compared with that involving allylic acetate and organozinc compounds.[13c]

Allylation of Aldehyde. Results are shown in Table 4. Generally direct alkylation of aldehydes with alkyl halide is not possible, because base treatment of aldehydes normally gives rapid aldol condensations. Only those aldehydes bearing one α-hydrogen have been alkylated in moderate yield by the use of a phase-transfer catalyst.[14] The present method enabled the effective allylation of cyclohexanecarbaldehyde having one α-hydrogen. Diallylation was predominant for butanal with a [$Pd(PPh_3)_3$] catalyst in DMF as solvent. The results obtained here were remarkable because aldol condensation was not observed. The reaction of butanal in THF solvent was very sluggish to afford monoallylation product in a low yield (<7%). With dppe as ligand, both α,α-diallylation and aldol-type condensation of butanal took place in DMF solvent. α,β-Unsaturated aldehyde, i.e., (*E*)-2-hexenal, was also α,α-diallylated giving a β,γ-unsaturated aldehyde.

In order to get the scope and the limitations of this neutral allylation method, various types of compounds were subjected to the reaction. Simple esters, nitriles, and 1-alkynes did not participate in this allylation under the standard reaction conditions (Pd(0)-dppe, DMF, r.t., 3 h), the pK_a values for which are higher than 24. In contrast, methyl phenylacetate and phenylacetonitrile were reactive to afford 2-phenyl-4-pentenoate (91%) and 2-phenyl-4-pentenenitrile (27%)/ 2-allyl-2-phenyl-4-pentenenitrile (34%)/ *N*-allylphenylethenimine (29%), respectively. Thus the introduction of a phenyl group facilitated the reaction. Indene (pK_a 20) and fluorene (pK_a 23) were reactive to yield 3-allyl-1*H*-indene (61%, monoallylation followed by the double bond isomerization)/ 1,1-diallyl-1*H*-indene (14%, diallylation) and 9-allyl-9*H*-fluorene (43%)/ 9,9-diallyl-9*H*-fluorene (51%), respectively. In the suggested scheme described earlier, the isourea anion generated in situ functions as a base to abstract a proton from the nucleophile. Although the exact pK_a value for the conjugate acid of the isourea anion is not available from current literatures, it seems probable that the generation of the conjugate anion is not sufficient for the compound of pK_a value higher than 24.

Experimental

General. IR spectra were recorded on a Shimadzu IR 430 spectrometer. ^1H and ^{13}C NMR spectra were measured on a JEOL JNM-FX60Q and/or a Hitachi R-24A instrument using $CDCl_3$ as the solvent. The chemical shifts are expressed in parts per million downfield from the internal tetramethylsilane, and signal patterns are indicated as s, singlet; d, doublet; t, triplet; q, quartet; qu, quintet; m, multiplet. Mass spectra were recorded on a JEOL D-300 instrument. GLC analyses were performed on either Shimadzu GC-3AH, Shimadzu GC-6AM, or Hitachi 164 instrument, using the following columns: Column A, 20% Silicone DC-550, 3 m; Column B, 10% FFAP, 3 m; Column C, 20% Silicone GE SE-52, 2 m; Column D, 3% Silicone OV-1, 2 m.

Materials. 2-Allylic-substituted isoureas were prepared according to the published method.[8] An allylic alcohol (0.1 mol) and DCC (0.1 mol) were heated at 60—80 °C in the presence of a catalytic amount of copper(I) chloride (70 mg) till the absorptions of DCC disappeared in the IR spectrum. The reaction mixture was diluted with dicloromethane and filtered. The filtrate was washed with aqueous ammonia solution to remove the catalyst. The organic layer was washed with water, and dried over sodium sulfate. Although the isoureas thus obtained could be distilled under high vacuum (~10^{-4} mmHg*), they were sufficiently pure for the present allylation reactions.

General Procedure A for Allylation of Cyclohexanone with 1 (Table 1). Cyclohexanone (491 mg, 5 mmol) and **1** (1.32 g, 5 mmol) were reacted in a given solvent (10 cm^3) in the presence of a palladium catalyst under the conditions described in Table 1 under nitrogen. The palladium catalyst employed was $[Pd(PPh_3)_3]$[15] (89 mg, 0.1 mmol) or $[Pd(dba)_2]$[16] (58 mg, 0.1 mmol)-ligand (ligand/Pd=3 for the monodentate ones; ligand/Pd=1 for the bidentate ones). The reaction was analyzed by GLC (column A, 150 °C). Analytical samples were obtained by preparative GLC (column C, 140 °C).

2-Allyl-1-cyclohexanone (2): ^{1}H NMR δ=1.00—2.80 (m, 11H), 4.80—5.30 (m, 2H), 5.35—6.30 (m, 1H). ^{13}C NMR δ=212.17, 136.44, 116.11, 50.28, 42.02, 37.77, 33.37, 27.90, 24.94. IR (neat) 3080, 1710, 1640, 990, 910 cm^{-1}.

A Mixture of 2,2- and 2,6-Diallyl-1-cyclohexanone (3): ^{1}H NMR δ=1.08—2.65 (m, ca. 8H), 2.21—2.43 (m, ca. 4H), 4.70—5.18 (m, 4H), 5.36—6.18 (m, 2H). IR (neat) 3080, 1700, 1640, 990, 910 cm^{-1}.

Allylation of Cyclohexanone with 1 with Addition of Lithium Acetate. A mixture of the isourea **1** (5 mmol), cyclohexanone (5 mmol), $[Pd(PPh_3)_3]$ (0.1 mmol), and lithium acetate (53 mg, 0.8 mmol) was stirred for 2 h in refluxing THF (10 cm^3). GLC analysis (column A, 150 °C) showed that the yields of mono- and diallylcyclohexanone were 56 and 5%, respectively.

General Procedure B for Allylation of Ketones with 1 (Table 2). A DMF solution (10 cm^3) of a ketone (5 mmol) and **1** (1.32 g, 5 mmol) was stirred for 1—24 h at an ambient temperature in the presence of $[Pd(dba)_2]$ (58 mg, 0.1 mmol)-dppe (40 mg, 0.1 mmol) under nitrogen. The reaction was analyzed by GLC. Analytical samples were obtained by either preparative GLC (G) or column chromatography (C) on silica gel according to general procedure C. The products **4**,[17] **11**,[18] and **13**[18] were identified by the comparison of their ^{1}H NMR and IR spectra with those reported earlier.

3-Allyl-5-hexen-2-one (5): G (column A, 160 °C). ^{1}H NMR δ=2.18 (s, 3H), 2.20—2.40 (m, 4H), 2.40—2.92 (m, 1H), 4.80—5.18 (m, 4H), 5.38—6.02 (m, 2H). IR (neat) 1718, 1640, 990, 918 cm^{-1}.

3-Methyl-5-hexen-2-one (6): G (column A, 160 °C). ^{1}H NMR δ=1.07 (d, 3H), 2.09 (s, 3H), 1.93—3.00 (m, 3H), 4.80—5.45 (m, 2H), 5.39—6.09 (m, 1H). IR (neat) 3090, 1708, 1640, 985, 910 cm^{-1}.

3-Allyl-3-methyl-5-hexen-2-one (7): G (column A, 160 °C). ^{1}H NMR δ=1.08 (s, 3H), 2.06 (s, 3H), 2.20—2.35 (m, 4H), 4.80—5.18 (m, 4H), 5.36—6.07 (m, 2H). IR (neat) 3090, 1708, 1640, 990, 910 cm^{-1}.

4-Methyl-1,8-nonadien-5-one (8): G (column A, 160 °C). ^{1}H NMR δ=0.99 (d, 3H), 1.80—2.86 (m, 7H), 4.78—5.20 (m, 4H), 5.34—6.10 (m, 2H). IR (neat) 3080, 1708, 1640, 990, 910 cm^{-1}. MS (70 eV) *m/z* 152 (M^+), 109, 83, 69, 67, 55.

4-Methyl-6-hepten-3-one (9): G (column A, 150 °C). ^{1}H NMR δ=1.08 (d, 3H), 1.10 (t, 3H), 2.54 (q, 2H), 2.05—2.96 (m, 3H), 4.81—5.20 (m, 2H), 5.40—6.25 (m, 1H). ^{13}C NMR δ=214.17, 135.76, 116.56, 47.74, 34.45, 32.24, 16.17, 7.69. IR (neat) 3080, 1710, 1640, 990, 910 cm^{-1}.

4,6-Dimethyl-1,8-nonadien-5-one (10): G (column A, 150 °C). ^{1}H NMR δ=1.03 (dd, 6H), 1.56—2.58 (m, 6H), 4.80—5.16 (m, 4H), 5.32—6.03 (m, 2H). IR (neat) 3070, 1708, 1640, 990, 910 cm^{-1}.

1-Phenyl-2-allyl-4-penten-1-one (12): C (benzene). ^{1}H NMR δ=2.05—2.85 (m, 4H), 3.75 (qu, 1H), 4.77—5.20 (m, 4H), 5.30—6.07 (m, 2H), 7.19—8.00 (m, 5H). IR (neat) 3080, 1680, 1640, 1580, 1445, 990, 910 cm^{-1}.

2-Allyl-3,4-dihydro-1(2*H*)-naphthalenone (14): C (hexane/ethyl acetate=20). ^{1}H NMR δ=1.76—2.84 (m, 5H), 2.88—3.25 (dd, 2H), 4.89—5.41 (m, 2H), 5.49—6.20 (m, 1H), 7.10—8.23 (m, 4H). IR (neat) 3070, 1680, 1640, 990, 910 cm^{-1}.

2,2-Diallyl-1(2*H*, 3*H*, 4*H*)-naphthalenone (15): C (hexane/ethyl acetate=20). ^{1}H NMR δ=2.13 (t, 2H), 2.50 (t, 4H), 3.09 (t, 2H), 4.86—5.51 (m, 4H), 5.55—6.29 (m, 2H), 7.08—8.29 (m, 4H). IR (neat) 3070, 1675, 1640, 990, 910 cm^{-1}.

3-Isopropenyl-5-hexen-2-one (16): G (column C, 140 °C). ^{1}H NMR δ=1.64 (m, 3H), 2.10 (s, 3H), 2.40 (t, 2H), 3.18 (t, 1H), 4.76—5.18 (m, 4H), 5.36—6.08 (m, 1H). IR (neat) 3070, 1710, 1640, 990, 890 cm^{-1}. MS (70 eV) *m/z* 138 (M^+), 97, 95, 81, 67.

3-Allyl-3-isopropenyl-5-hexen-2-one (17): G (column C, 140 °C). ^{1}H NMR δ=1.64 (m, 3H), 2.02 (s, 3H), 2.43 (d, 4H), 4.74—5.40 (m, 6H), 5.44—6.08 (m, 2H). IR (neat) 1710, 1640, 990, 890 cm^{-1}. MS (70 eV) *m/z* 178 (M^+), 136, 93, 83, 81, 55.

2-Allyl-3-cyclohexen-1-one (18): G (column C, 140 °C). ^{1}H NMR δ=1.80—2.75 (m, 7H), 4.75—5.20 (m, 2H), 5.21—6.21 (m, 3H). IR (neat) 3090, 1710, 1640, 990, 912 cm^{-1}. MS (70 eV) *m/z* 136 (M^+), 108, 80, 79, 68.

General Procedure C for Allylation of Propiophenone with Allylic-Substituted Isourea (Table 3). A DMF solution (10 cm^3) of propiophenone (671 mg, 5 mmol) and an allylic-substituted isourea (5 mmol) was stirred for 1 h in the presence of $[Pd(dba)_2]$ (58 mg, 0.1 mmol)-dppe (40 mg, 0.1 mmol) at a given temperature under nitrogen. After being cooled to room temperature, the reaction mixture was diluted with diethyl ether and the *N,N'*-dicyclohexylurea that was formed was filtered off. The filtrate was washed with saturated NaCl solution. The organic layer was dried on $MgSO_4$ and the solvent was removed in vacuo. The products were isolated by column chromatography on silica gel (hexane/ethyl acetete=20). The isomer ratio was determined by GLC.

Reaction of Propiophenone with (*E*)-2-Butenylisourea: A Typical Procedure. Propiophenone (671 mg, 5 mmol) and (*E*)-2-butenylisourea (1.39 g, 5 mmol) were stirred in DMF (10 cm^3) at 60 °C for 1 h under nitrogen in the presence of

* 1 mmHg=133.322 Pa.

[Pd(dba)$_2$] (58 mg, 0.1 mmol)-dppe (40 mg, 0.1 mmol). The products were obtained according to the general procedure C after purification by column chromatography on silica gel eluting with hexane–ethyl acetate (20:1). Yield 818 mg (87%). Samples for spectroscopic analysis of the isomers **19**, **20**, and **21** were obtained by preparative GLC (column B, 160 °C).

(*E*)-2-Methyl-1-phenyl-4-hexen-1-one (19): G. ^{1}H NMR δ=1.16 (d, 3H), 1.60 (d, 3H), 1.90—2.70 (m, 2H), 3.10—3.80 (m, 1H), 5.20—5.60 (m, 2H), 7.26—8.00 (m, 5H). IR (neat) 1680, 965 cm^{-1}. MS *m/z* (70 eV) 188 (M$^+$), 173, 145, 134, 106, 105, 77.

(*Z*)-Isomer (20): G. This was isolated in an impure state, being contaminated by the (*E*)-isomer. ^{1}H NMR δ=1.20 (d, 3H), 1.60 (d, 3H), 2.12—2.56 (m, 2H), 3.20—3.72 (m, 1H), 5.24—5.56 (m, 2H), 7.17—8.04 (m, 5H). IR (neat) 1680 cm^{-1}. MS *m/z* (70 eV) 188 (M$^+$), 105, 77.

2,3-Dimethyl-1-phenyl-4-penten-1-one (21): G. ^{1}H NMR δ=1.00 (d, 3H), 1.12 (d, 3H), 2.28—2.96 (m, 1H), 3.04—3.80 (m, 1H), 4.76—5.16 (m, 2H), 5.40—6.12 (m, 1H), 7.18—8.05 (m, 5H). IR (neat) 1680, 990, 910 cm^{-1}. MS (70 eV) *m/z* 188 (M$^+$), 134, 106, 105, 77.

2,4-Dimethyl-1-phenyl-4-penten-1-one (22): C (hexane/ethyl acetate=20). ^{1}H NMR δ=1.16 (d, 3H), 1.72 (s, 3H), 2.03—2.80 (m, 2H), 3.17 (q, 1H), 4.71 (m, 2H), 7.25—8.03 (m, 5H). IR (neat) 1685, 1655, 890 cm^{-1}. MS (70 eV) *m/z* 188 (M$^+$), 106, 105, 83, 77.

(*E*)-2-Methyl-1,5-diphenyl-4-penten-1-one (23): G (column D, 200 °C). ^{1}H NMR δ=1.16 (d, 3H), 1.96—2.92 (m, 2H), 3.16—3.80 (m, 1H), 6.08 (dt, 1H), 6.36 (d, 1H), 6.92—8.04 (m, 10H). IR (neat) 1680, 960 cm^{-1}. MS *m/z* (70 eV) 250 (M$^+$), 235, 117, 115, 105.

2-Methyl-1,3-diphenyl-4-penten-1-one (24): G (column D, 200 °C). ^{1}H NMR δ=1.24 (d, 3H), 3.60—3.96 (m, 2H), 4.68—5.28 (m, 2H), 5.60—6.18 (m, 1H), 6.88—8.08 (m, 10H). IR (neat) 1680, 990, 910 cm^{-1}. MS (70 eV) *m/z* 250 (M$^+$), 235, 117, 105, 77.

(*E*)-2-Methyl-1-phenyl-4-octen-1-one (25): G (column D, 160 °C). ^{1}H NMR δ=0.84 (t, 3H), 1.20 (d, 3H), 1.10—1.60 (m, 2H), 1.68—2.76 (m, 4H), 3.16—3.80 (m, 1H), 5.20—5.55 (m, 2H), 7.25—8.08 (m, 5H). IR (neat) 1680, 965 cm^{-1}. MS *m/z* (70 eV) 216 (M$^+$), 173, 134, 106, 105, 77.

2-Methyl-1-phenyl-3-vinylhexan-1-one (26): G (column D, 160 °C). ^{1}H NMR δ=0.80 (t, 3H), 1.10 and 1.14 (d, 1.5H and d, 1.5H; due to the asymmetric carbon), 1.04—1.60 (m, 4H), 2.16—2.72 (m, 1H), 3.10—3.90 (m, 1H), 4.60—5.20 (m, 2H), 5.24—5.96 (m, 1H), 7.36—8.08 (m, 5H). IR (neat) 1680, 995, 910 cm^{-1}. MS (70 eV) *m/z* 216 (M$^+$), 173, 134, 105, 77.

General Procedure D for Allylation of Aldehydes with 1 (Table 4). A DMF solution (10 cm^3) of an aldehyde (5 mmol) and **1** (1.32 g, 5 mmol) was stirred for 1—20 h at an ambient temperature in the presence of [Pd(PPh$_3$)$_3$] (89 mg, 0.1 mmol) or [Pd(dba)$_2$] (58 mg, 0.1 mmol)-dppe (40 mg, 0.1 mmol) under nitrogen. The reaction was analyzed by GLC. Analytical samples were obtained by preparative GLC.

1-Allylcyclohexanecarbaldehyde (27): G (column C, 140 °C). ^{1}H NMR δ=1.10—2.01 (m, 8H), 2.15 (d, 2H), 4.80—5.22 (m, 2H), 5.26—6.07 (m, 1H), 9.44 (s, 1H). IR (neat) 3070, 1725, 1640, 990, 910 cm^{-1}.

2-Allyl-2-ethyl-4-pentenal (28): G (column C, 140 °C). ^{1}H NMR δ=0.85 (t, 3H), 1.58 (q, 2H), 2.27 (d, 4H), 4.85—5.33 (m, 4H), 5.35—6.14 (m, 2H), 9.42 (s, 1H). IR (neat) 3080, 1725, 1640, 990, 910 cm^{-1}.

(*E*)-2-Allyl-2-ethyl-3-hexenal (29): G (column C, 140 °C). ^{1}H NMR δ=0.82 (t, 3H), 0.98 (t, 3H), 1.65 (q, 2H), 1.81—2.31 (m, 2H), 2.37 (d, 2H), 4.81—5.26 (m, 2H), 5.30—6.07 (m, 3H), 9.30 (s, 1H). ^{13}C NMR δ=202.83, 135.70, 127.95, 118.38, 117.88, 36.79, 36.16, 26.19, 25.51, 13.72, 7.97. IR (neat) 3080, 1725, 1645, 990, 970, 910 cm^{-1}.

Reaction of (*E*)-2-Hexenal with 1: A Typical Procedure. (*E*)-2-Hexenal (491 mg, 5 mmol) and **1** (1.32 g, 5 mmol) were stirred for 2 h in DMF (10 cm^3) at an ambient temperature under nitrogen in the presence of [Pd(dba)$_2$] (58 mg, 0.1 mmol)-dppe (40 mg, 0.1 mmol). A mixture of the starting aldehyde, **30**, and **31** was obtained according to the general procedure C after chromatographic work-up on silica gel eluting with hexane–ethyl acetate (20:1). Samples for spectroscopic analysis of the product **30** and **31** were obtained by GLC (column C, 170 °C). Quantitative analyses were performed on GLC (column C, 170 °C).

(*E*)-2-Allyl-2-hexenal (30): ^{1}H NMR δ=0.95 (t, 3H), 1.22—1.87 (m, 2H), 2.45 (q, 2H), 3.00 (d, 2H), 4.73—5.21 (m, 2H), 5.32—6.19 (m, 1H), 6.53 (t, 1H), 9.36 (s, 1H). The chemical shift (δ=9.36) of the formyl proton indicated the presence of an (*E*)-double bond.[19] IR (neat) 3080, 1685, 1640, 990, 910 cm^{-1}. MS (70 eV) *m/z* 138 (M$^+$), 95, 81, 79, 67, 53.

(*E*)-2,2-Diallyl-3-hexenal (31): ^{1}H NMR δ=0.99 (t, 3H), 1.80—2.40 (m, 2H), 2.38 (d, 4H), 4.83—5.26 (m, 4H), 5.36—6.12 (m, 4H), 9.37 (s, 1H). IR (neat) 3080, 1725, 1640, 995, 975, 915 cm^{-1}. MS (70 eV) *m/z* 178 (M$^+$), 137, 93, 79, 67.

Asymmetric Addition of Hydrogen Cyanide to Substituted Benzaldehydes Catalyzed by a Synthetic Cyclic Peptide, *Cyclo*((*S*)-phenylalanyl-(*S*)-histidyl)

Yoshiyuki KOBAYASHI, Shoichi ASADA, Ichigen WATANABE, Hiroaki HAYASHI, Yoshiyuki MOTOO, and Shohei INOUE*

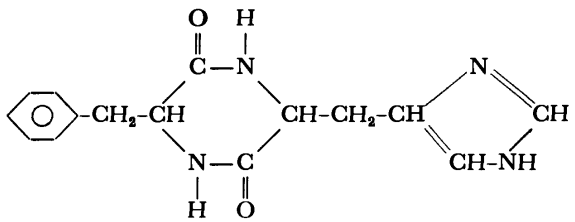
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 8, 1985)

Using *cyclo*((*S*)-phenylalanyl-(*S*)-histidyl) as catalyst, optically active cyanohydrins from substituted benzaldehydes with *p*-methyl, *m*-methyl, *o*-methyl, *m*-methoxyl, or *m*-phenoxyl group were obtained with optical yield of 82—33%. For the asymmetric cyanohydrin synthesis, nonpolar solvent such as benzene or carbon tetrachloride was advantageous, while no asymmetric synthesis took place in methanol or dimethyl sulfoxide.

Enzymatic reactions are characterized by the high degree of specificity and high efficiency under mild conditions. In the application of natural enzyme as catalyst for synthetic reactions, possible shortcomings are the facts that natural enzymes are usually stable under rather limited conditions and that the product obtained is limited only to one of the possible optical isomers. In the asymmetric synthesis catalyzed by synthetic peptides, on the other hand, preferred configuration of the product of the catalyzed reaction can be selected as desired, by the selection of (*R*)- or (*S*)-amino acid in the synthesis of the catalytically active peptides. Therefore, the studies of asymmetric synthesis catalyzed by synthetic peptides are of much interest.

We have studied asymmetric cyanohydrin synthesis catalyzed by synthetic peptides.[1-4] Optically active cyanohydrin is a useful synthetic intermediate which can be readily transformed into optically active α-hydroxy carboxylic acid. More specifically, (*S*)-cyanohydrin of *m*-phenoxybenzaldehyde, for example, is an essential building block for the synthesis of a particularly effective insecticide.[5]



1

Since it is known that cyanohydrin synthesis is catalyzed by a base, we have used cyclic or linear dipeptides containing (*S*)-histidine as a base catalyst. Among the peptides we examined, *cyclo*((*S*)-phenylalanyl-(*S*)-histidyl) (**1**, *cyclo*(-(*S*)-Phe-(*S*)-His-)) was found to be an effective catalyst for the asymmetric cyanohydrin synthesis from benzaldehyde to give the highest optical yield ever reported (90%) under appropriate conditions.[2,3] This catalyst is applicable also to the asymmetric cyanohydrin synthesis from aliphatic aldehydes with optical yield of 30—40%.[4] In the present study, attempts were made to extend the application of *cyclo*(-(*S*)-Phe-(*S*)-His-) to asymmetric cyanohydrin synthesis from substituted benzaldehydes.

In the asymmetric cyanohydrin synthesis from benzaldehyde with *cyclo*(-(*S*)-Phe-(*S*)-His-) in benzene, the reaction mixture was heterogeneous at first but became homogeneous with the progress of the reaction, and the optical yield of the product was the highest in the early stage but decreased in prolonged reaction.[2,3] Since these phenomena are considered to be due, at least partly, to the change in the polarity of the system with the progress of the reaction by the formation of the product, the effect of the solvent on the reaction was investigated using benzaldehyde as substrate.

Results and Discussion

Addition Reaction to Substituted Benzaldehyde. The results obtained in the addition of hydrogen cyanide to substituted benzaldehydes catalyzed by *cyclo*(-(*S*)-Phe-(*S*)-His-) are summarized in Table 1. The reaction conditions employed were the same as those that gave the highest optical yield for benzaldehyde; in benzene at 35 °C for 30 min. All the products obtained from the substituted benzaldehydes examined were of fairly high optical yields. These

a) Benzaldehyde: 25 mmol, hydrogen cyanide: 25 mmol, *cyclo*(-(*S*)-Phe-(*S*)-His-): 0.5 mmol, solvent: 10 cm^3, reaction temperature: 35 °C. b) Preferred configuration is *R*. c) Ref. 2), 3).

optical yields were higher than those reported for D-oxynitrilase, which is a specific enzyme for the addition of hydrogen cyanide to benzaldehyde, although the reaction conditions are not indentical.[6] Using cinnamaldehyde as substrate under the same conditions, the optical yield of the product was 31% at 24% conversion. Thus, *cyclo*(-(*S*)-Phe-(*S*)-His-) is a better catalyst than natural enzyme for asymmetric cyanohydrin synthesis from some aldehydes.

Effect of Solvent on the Reaction of Benzaldehyde. As reported previously,[2] the reaction mixture in the addition of hydrogen cyanide to benzaldehyde in benzene catalyzed by *cyclo*(-(*S*)-Phe-(*S*)-His-) was heterogeneous in the early stage, and became homogeneous after about 30 min. This change from heterogeneity to homogeneity of the reaction mixture is considered to be due to the formation of the product, mandelonitrile. In fact, *cyclo*(-(*S*)-Phe-(*S*)-His-) (0.5 mmol) is soluble in a mixture of racemic mandelonitrile (25 mmol) and benzene (10 cm^3). We attempted to examine the influence of the product on the reaction by adding phenylacetonitrile or benzyl alcohol as the analog of the product to the reaction system. However, the addition of 5 cm^3 of the analog to the reaction mixture, consisting of benzaldehyde (50 mmol), hydrogen cyanide (50 mmol), *cyclo*(-(*S*)-Phe-(*S*)-His-) (1.0 mmol) and benzene (15 cm^3), did not dissolve the peptide, and the optical yield of the product in the asymmetric addition was not much affected. For example, upon addition of phenylacetonitrile the optical yield of the product was 72.5% after 30 min (conv. 60%) and 24.5% after 12 h (conv. 85%), respectively.

† 1 M=1 mol dm^{-3}.

The asymmetric benzaldehyde cyanohydrin synthesis catalyzed by *cyclo*(-(*S*)-Phe-(*S*)-His-) was examined in various solvents, as summarized in Table 2. The reaction in carbon tetrachloride was heterogeneous at first and then became homogeneous similarly to the reaction in benzene. The reaction in other solvents such as chloroform, diethyl ether, acetonitrile, and methanol was heterogeneous. On the other hand, dimethyl sulfoxide dissolved *cyclo*(-(*S*)-Phe-(*S*)-His-), and the reaction proceeded homogeneously and very rapidly to complete within a few minutes.

The reaction in nonpolar solvent such as benzene or carbon tetrachloride, or in solvent with lower polarity such as diethyl ether or chloroform, gave fairly high optical yield of the product. In the reaction using acetonitrile as solvent, the product had a moderate optical activity, while in methanol with almost the same dielectric constant the product exhibited no optical activity. No asymmetric reaction took place in strongly polar solvent such as dimethyl sulfoxide, although the reaction was stopped in a very short time in order to avoid possible decrease in the optical yield with reaction time.

Thus, nonpolar solvent is advantageous for this asymmetric cyanohydrin synthesis, while strongly polar solvent or protic solvent which is considered to weaken the interaction between catalyst and substrates is disadvantageous.

Experimental

Materials. Hydrogen cyanide was prepared from sodium cyanide and sulfuric acid as described previously.[4] All the aldehydes were distilled in nitrogen under reduced pressure. Carbon tetrachloride, diethyl ether, chloroform, and acetonitrile were distilled over calcium hydride in nitrogen. Methanol was distilled over magnesium in nitrogen. Dimethyl sulfoxide was distilled over calcium hydride in nitrogen under reduced pressure. Phenylacetonitrile and benzyl alcohol were distilled in nitrogen under reduced pressure. Commercially available racemic mandelonitrile was dried over Drierite. Other reagents and solvents were commercially purchased and used without futher purification.

Catalyst. *N*-Benzyloxycarbonyl-(*S*)-phenylalanyl-(*S*)-histidine methyl ester [Z-(*S*)-Phe-(*S*)-His-OMe] was prepared by the reaction of benzyloxycarbonyl-(*S*)-phenylalanine with (*S*)-histidine methyl ester as described previously.[4]

Cyclo[(*S*)-phenylalanyl-(*S*)-histidyl][*cyclo*(-(*S*)-Phe-(*S*)-His-)] was prepared from Z-(*S*)-Phe-(*S*)-His-OMe by the removal of benzyloxycarbonyl group by hydrogenation with palladium-black followed by cyclization in refluxing methanol according to the reported procedure.[2] The crude product was recrystallized from water and dried at room temperature under reduced pressure. This product was dissolved in hot ethanol and reprecipitated by adding the ethanol solution to five-fold amount of petroleum ether; mp 251—256 °C; $[\alpha]_D^{t.t.}=-62.1°$ (C=1.95 g/100 cm^3; acetic acid) (lit,[7] mp 267—268 °C; $[\alpha]_D^{20}=-72°$ (C=2.00 g/100 cm^3; acetic acid)).

Addition Reaction. *Cyclo*(-(*S*)-Phe-(*S*)-His-) (0.5 mmol) was placed in a 50 cm^3 round-bottomed flask equipped with a three-way cock, and the atmosphere of the flask was replaced with nitrogen. To this were added the solvent (10 cm^3) and aldehyde (25 mmol) with magnetic stirring, then 1 cm^3 of hydrogen cyanide was added with a chilled syringe. The conversion of aldehyde was determined by infrared spectrum of the reaction mixture using the absorption band due to ν_{C-H} of aldehydic hydrogen at 2735 cm^{-1}. The reaction was stopped by adding 0.5 cm^3 of 2 mol dm^{-3} HCl-CH_3OH. Unreacted hydrogen cyanide and solvent were removed from the reaction mixture through a trap containing aqueous alkali under reduced pressure. Ether was added to the residue, and the supernatant solution containing the product was separated. After washing the residue several times with ether, the combined ether solution and washings were filtered to remove the residual catalyst, then ether was removed under reduced pressure to leave a viscous liquid, which was confirmed to be a mixture of cyanohydrin and unreacted aldehyde by ^{1}H-NMR spectrum in $CDCl_3$. The mole fraction of cyanohydrin in this mixture was determined on the basis of ^{1}H-NMR signals due to C<u>H</u>(O<u>H</u>) (δ=5.5 and 4.5—5.0, respectively) of cyanohydrin and due to the aldehydic hydrogen (δ=9.9).

Determination of Optical Yield. For the determination of the optical purity of the product from *p*-tolualdehyde (**1a**), the product was reacted with (+)-perfluoro-2-propoxypropionyl chloride to give the corresponding ester quantitatively. ^{19}F-NMR spectrum of the ester was measured and the diastereomeric ratio of the ester was calculated from the signals of the trifluoromethyl group bonded to the chiral center.[8] As for *m*-phenoxybenzaldehyde and cinnamaldehyde, the optical purity of the product was calculated from the reported optical rotation of the product; for (*S*)-*m*-phenoxybenzaldehyde cyanohydrin ((*S*)-α-cyano-3-phenoxybenzyl alcohol), $[\alpha]_D^{25}=-24.8°$ (C=1.2 g/100 cm^3; $CHCl_3$)[9]; for (*R*)-cinnamaldehyde cyanohydrin, ((*R*)-α-cyanocinnamyl alcohol), $[\alpha]_D=+77°$ (C=8.4 g/100 cm^3; $CHCl_3$).[10] For the product from other aldehydes, the optical purity was determined by the high-pressure liquid chromatgraph using a chiral column Chiralcel OB (Daicel Chem. Ind., Ltd.); eluent, hexane/isopropyl alcohol (9/1); detecting wavelength, 254 nm.

Measurement. IR spectra were recorded on a Hitachi 260-30 spectrophotometer. NMR spectra were recorded on a Hitachi R-40 spectrometer. The optical rotations of the products at 589 nm were measured using Perkin-Elmer Polarimeter 241 or JASCO DIP-360 Digital Polarimeter. High pressure liquid chromatogram was recorded using Hitachi 638-30 High Pressure Liquid Chromatograph. Melting points were taken on a Yanagimoto Mel-Temp apparatus.

Electron-Transfer-Initiated Photoreactions of 1-Methyl-2-phenyl-1-pyrrolinium Perchlorate with α-Heteroatom-Substituted Alkanoate Anions

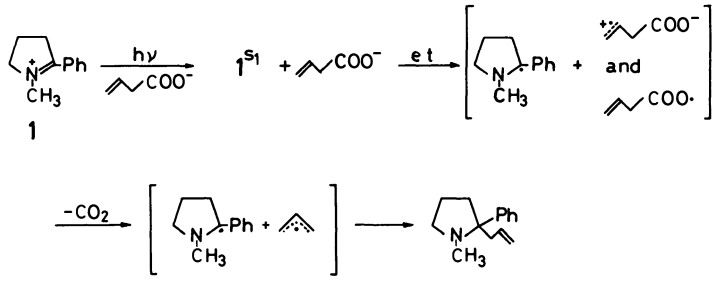
Yoshiaki KURAUCHI, Hideo NOBUHARA, and Kazuya OHGA*
Department of Environmental Chemistry and Engineering, Faculty of Engineering, Oita University, Dannoharu, Oita 870-11
(Received September 20, 1985)

The irradiation of aqueous solutions of 1-methyl-2-phenyl-1-pyrrolinium perchlorate (**1**) in the presence of α-hydroxyalkanoate anions led to the formation of 2-(hydroxyalkyl)pyrrolidine adducts and a reduction product, 1-methyl-2-phenylpyrrolidine. Mechanistic studies demonstrated that photoaddition reactions were induced by one-electron transfers from the carboxylato groups of alkanoates to the excited singlet state of **1** ($\mathbf{1}^{S_1}$), followed by an efficient decarboxylation. Furthermore, the photoreaction of **1** with ethoxyacetate was found to give a 2-(ethoxymethyl)pyrrolidine adduct in preference to the reduction product. For photoreactions with 2-mercaptopropionate and α-amino acids, the reduction product was detected. *N*-Acetylglycinate gave a 2-(acetylaminomethyl)pyrrolidine adduct in fairly high yield (80%). The features of these photoreactions with α-heteroatom-substituted alkanoates are discussed in terms of fluorescence-quenching efficiencies and the properties of radicals formed through electron transfers to $\mathbf{1}^{S_1}$.

Carboxylic acids are known to undergo electron-transfer-initiated photodecarboxylations in the presence of such electron acceptors as heterocyclic[1] and carbonyl[2] compounds and 1-cyanonaphthalene.[3] The reactions are facile in the case of acetic acid derivatives of the type $RXCH_2CO_2H$(R=aryl, X=O, S, and NH). When aliphatic analogues (R=H or alkyl), except for the S compound, are employed as electron donors, however, electron transfers to the excited states of the acceptors were either not observed[2] or took place with a lower efficiency[1d] due to their higher ionization potentials. Consequently, few details are known about an electron-transfer-initiated photoreaction in which the α-heteroatom-substituted alkanoic acids participate.

On the other hand, various types of photoaddition reactions involving iminium cations have been systematically investigated by Mariano and his co-workers from mechanistic[4] and synthetic[5] points of view. A proposed mechanism involves one-electron transfers from a variety of donors to the excited singlet states of the cations as important primary steps. For example, 2-phenyl-1-pyrrolinium perchlorate and its *N*-methyl derivative (**1**) were converted into 2-pyrrolidinyl radicals by electron transfers. Then, cation radical intermediates derived from π- and *n*-electron donors (such as olefins, allylsilanes, alcohols, and ethers) were transformed into neutral radicals by nucleophilic capture, deprotonation, and desilylation. The coupling of resulting radical pairs afforded 2-substituted 2-phenylpyrrolidines.

Previously, we reported[6] on the decarboxylative photoaddition of a 3-butenoate anion to the pyrrolinium cation **1** in an aqueous solution. The photoaddition follows, on the whole, the above-mentioned mechanism. Moreover, fluorescence-quenching experiments and an estimation of the free-energy change have suggested that a mechamism which rationalizes this photoaddition involves electron-transfer processes from both the vinyl and carboxylato groups (Scheme 1). This implies that the carboxylato group possesses a reducing ability comparable to those of mono-substituted olefins and that the excited singlet state of the cation **1** ($\mathbf{1}^{S_1}$) behaves as an effective electron acceptor for the carboxylato group. In the present research, we employed this aqueous pyrrolinium-cation system in order to elucidate the chemical behavior of α-heteroatom-substituted alkanoic acids in an electron-transfer-initiated photoreaction.



Scheme 1.

Results and Discussion

Fluorescence Quenching. The fluorescence of **1** was quenched by various aliphatic carboxylate anions (Table 1). All measurements were made on aqueous solutions with a pH of 6; thus, all the acids existed exclusively in carboxylate anionic forms. The solutions contained 0.5 M (1 M=1 mol dm^{-3}) $NaClO_4$ in order to minimize a salt effect (described later). Also, solutions containing **1** and the acids were stable while standing in the dark. The fluorescence and absorption spectra of **1** revealed an absence of the excited- or ground-state complex formation. Stern-Volmer plots yielded straight lines with intercepts equal to 1. The quenching constants ($k_q\tau$) obtained from the least-squares slopes of the plots are given in Table 1.

α-Hydroxyalkanoate anions, which can be seen in the first three rows, had quenching efficiencies similar to each other. On the other hand, no effective quenching was observed at a lower pH where the acids exist in undissociated forms. The oxidation potentials of aliphatic carboxylate anions in acetonitrile are normally lower (ca. 1.6 V vs. SCE)[7] than those of alcohols (ca. 2.5—3.8 V vs. SCE)[8] which are known to serve as quenchers for the fluorescence of the pyrrolinium cation **1**.[8] This leads us to infer that the fluorescence quenching by the hydroxyalkanoate anions is induced by electron transfers from the carboxylato groups to $\mathbf{1}^{S_1}$, although the Stern-Volmer quenching-rate constants (k_q, estimated to be ca. 6—8×10^8 M^{-1} s^{-1} using the singlet lifetime (τ=1 ns)[8] of **1** in 10% aqueous acetonitrile) are slightly less than a diffusion-controlled rate constant (6.64×10^9 M^{-1} s^{-1}).[9]

A more precise evaluation of the energetics of this electron transfer with the aid of Eq. 1 proposed by

$$\Delta G_{et}(\text{eV}) = E(D/D^+) - E(A^-/A) - e^2/\varepsilon\alpha - E_{0,0} \quad (1)$$

Rehm and Weller[10] requires knowledge of the electrochemical and spectroscopic data of **1** and the anions in an aqueous solution. The reduction potential, $E(A^-/A)$, and the singlet energy, $E_{0,0}$, of **1** were found to be −0.95 V (vs. SCE) and 3.9 eV, respectively. The oxidation potentials ($E(D/D^+)$) of the α-hydroxyalkanoates could not be obtained since discrete oxidation waves were difficult to observe in aqueous solutions;[11] thus, the critical potential of acetate (1.9 V vs. SCE)[12] was employed as the oxidation potential. The coulombic attraction term ($e^2/\varepsilon\alpha$) may be neglected since the two radical species generated by the one-electron transfer are neutral in the present systems. The free-energy change, ΔG_{et}, obtained in this way is −1.1 eV, and supports the idea that a one-electron transfer is energetically feasible. Furthermore, the $k_q\tau$ values for the anions were almost the same as those for acetate (0.57±0.03 M^{-1}) and propionate (0.62±0.02 M^{-1}) anions and the fluorescence of **1** was little quenched by 2-propanol ($k_q\tau$<0.04). These findings agree with the suggestion that electron transfers from the hydroxyl groups are not appreciably responsible for the quenching.

In the case of sulfur-substituted alkanoic acids, a more efficient quenching can be predicted by the high HOMO energies of analogous S compounds.[13] The quenching efficiency of 2-mercaptopropionate was high as shown in Table 1; the estimated k_q value

a) Obtained from Stern-Volmer plots at pH 6.0. b) ϕ_{dis}, ϕ_a, and ϕ_r are quantum yields for the **1** disappearance, the adduct formation, and the reduction product formation, respectively, and were obtained using aqueous solutions (pH 6.0) containing **1** of 1.00×10^{-3} M, carboxylate of 0.5 M, and $NaClO_4$ of 0.5 M. The quantum yields in blank spaces were not determined. c) Total yields of two diastereomers. d) It was difficult to purify this carboxylic acid up to a grade acceptable for quenching experiments. e) No major products other than the reduction product **7** were detected by means of GLC. f) Isolated yield. Other yields were determined by GLC analyses.

using the singlet lifetime of **1** was $4.8\times10^9\ M^{-1}\ s^{-1}$ and near the diffusion-controlled limit. Moreover, this efficiency was nearly equal to that of the free mercaptopropionic acid ($k_q\tau=4.33\pm0.09\ M^{-1}$), indicating a predominant electron transfer from the mercapto group. In conformity with these findings, the free acid and the carboxylate anion were found to have almost the same and much lower oxidation potentials: 0.79 V (vs. SCE) for the free acid, 0.66 V (vs. SCE) for the anion.

Glycine and α-aminoisobutyric acid exhibited less quenching-efficiencies than those of the α-hydroxyalkanoates and acetate since the α-amino acids exist as *N*-protonated forms at pH 6 and probably since the strongly electron-withdrawing NH_3^+ groups diminish an electron transfer from the carboxylato groups. Increasing the pH of the solution increased the efficiencies: e.g., a $k_q\tau$ value with glycine was $5.9\pm0.1\ M^{-1}$ at pH 12. This demonstrates an efficient electron transfer from the unprotonated amino group, as predicted by the generally recognized low ionization potentials of alkylamines.[14]

A *N*-acetylglycinate anion, not subject to *N*-protonation, afforded a somewhat large $k_q\tau$ value ($1.03\ M^{-1}$). Its free carboxylic acid also had a quenching ability, though the efficiency was fairly low ($k_q\tau=0.19\pm0.02\ M^{-1}$). This appears to imply that an electron transfer from the acetylamino group can take place to some extent in competition with that from the carboxylato.

Photoreactions of 1 in the Presence of Alkanoate Anions. The pyrrolinium cation **1** was irradiated in aqueous solutions adjusted to pH 6.0 with NaOH and contained carboxylic acids (0.08—0.69 M (listed in Table 1)) to give photoadducts **2—6** and a reduction product **7**. 2-Mercaptopropionic acid and two α-amino acids showed no formation of major

6, R = -CH_2NHCCH_3 (O)

products other than **7** in GLC analyses of the photolysates. The irradiations were carried out through a Pyrex glass permitting light absorption exclusively by **1** ($\lambda_{max}=258$ nm, $\varepsilon=12050$). The progress of a reaction was followed by the UV spectra. The irradiations were allowed to continue until ca. 90% of **1** disappeared. The products were isolated after being extracted with chloroform followed by either preparative TLC or preparative GLC.

The identification of the photoadduct **2** obtained from irradiation in the presence of glycolate was made by a direct comparison of the ^1H NMR and IR spectra with those of an authentic sample.[8] The other photoadducts were identified on the basis of comparisons of the characteristic spectroscopic properties of structurally related substances[4] and elemental analyses of 2,4,6-trinitroresorcinolate (styphnate) derivatives. The photoadduct **3** from lactate was a mixture (1 : 1.2) of two diastereomers, separable by silica-gel TLC. The structure of the reduction product **7** was verified by a direct spectroscopic comparison with an authentic sample.[15] The yields of the reduction product and photoadducts are summarized in Table 1 together with the quantum yields obtained for [carboxylates] of 0.5 M.

Mechanistic Studies. In order to unravel the mechanistic features of these photoreactions, the glycolic acid system was investigated in greater detail. Figure 1 shows that the quantum yields for the disappearance of **1** (ϕ_{dis}), for the formation of **2** (ϕ_a), and for the formation of **7** (ϕ_r) depend significantly on the concentration of $NaClO_4$. The quantum yields were reduced by an addition of $NaClO_4$, but exhibited no further decrease at $NaClO_4$ concentrations above ca. 0.4 M. A similar salt effect was observed regarding the fluorescence quenching. Thus, the fluorescence intensity of **1** in the presence of the quencher (glycolate) increased (namely, the quenching efficiency decreased) upon increasing the concentration of $NaClO_4$. The intensity remained unchanged in the $NaClO_4$ concentration range of 0.4 to 0.5 M, as shown in Fig. 2. Accordingly, the

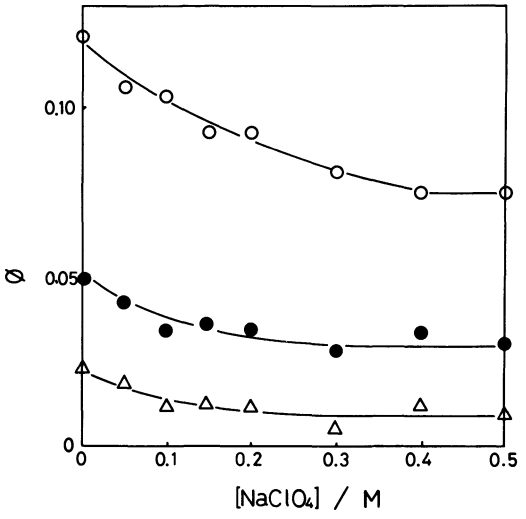

Fig. 1. Dependence of quantum yields, ϕ_{dis}(○), ϕ_a (●), and ϕ_r(△), on the concentration of $NaClO_4$ in a glycolate system (pH 6.0, [**1**]$=1.00\times10^{-3}$ M, [glycolate]$=0.2$ M).

mechanistic studies described in the present paper were made regarding aqueous solutions containing 0.5 M $NaClO_4$ (unless otherwise noted).

Figure 3 shows changes in the quantum yields as a function of the solution pH. ϕ_{dis} and ϕ_a increased steeply around pH 3.5 and remained, substantially, unchanged above pH 4.5. The pK_a of glycolic acid is 3.83; thus, Fig. 3 demonstrates that the disappearance of **1** and the formation of **2** took place more efficiently in the presence of the glycolate anion than in the presence of the free glycolic acid. This corresponds to the above-mentioned fact that the effective quenching of the fluorescence of **1** was observed with the anion, but not with the free acid. This suggests that the photoaddition reaction proceeds mainly via $\mathbf{1}^{S_1}$ by an electron transfer from the anion. Similar pH dependencies of the quantum yields were also observed in the case of an α-hydroxyisobutyric acid system (Fig. 4).

A plausible mechanism for the formation of the photoadduct **2** from the glycolate anion analogous to that for the 3-butenoate system[6] (as depicted in Scheme 2) involves the radical-pair intermediates **9** and **10**. **9** is formed by an electron transfer from the glycolate donor to $\mathbf{1}^{S_1}$ presumably through the intervention of an encounter complex **8** and is returned to the ground state of **1** and glycolate by a back electron transfer. The intermediate **10** is formed by the decarboxylation of **9** and is transformed into **2** by a radical coupling within the solvent cage. In addition, the formation processes of the reduction product **7** and other products, as yet unidentified, from **9** and **10** should be taken into consideration. The rate constants of these processes are appended in Scheme 2.

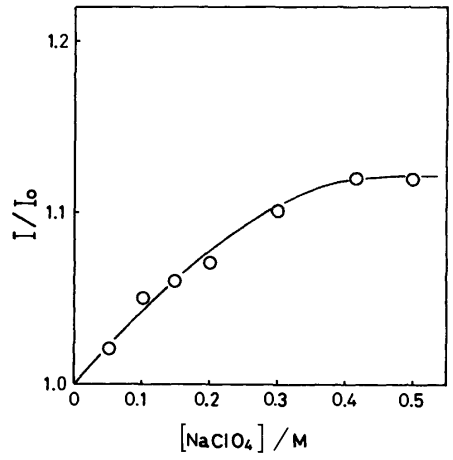

Fig. 2. Dependence of the fluorescence intensity of **1** (I) on the concentration of $NaClO_4$ in the presence of glycolate of 0.2 M. I_0 is the intensity in the absence of $NaClO_4$. The solution pH was 6.0 and [**1**] 1.00×10^{-3} M.

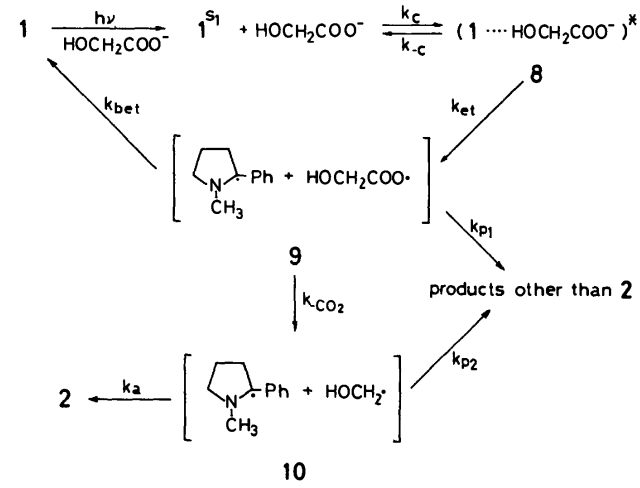

Scheme 2.

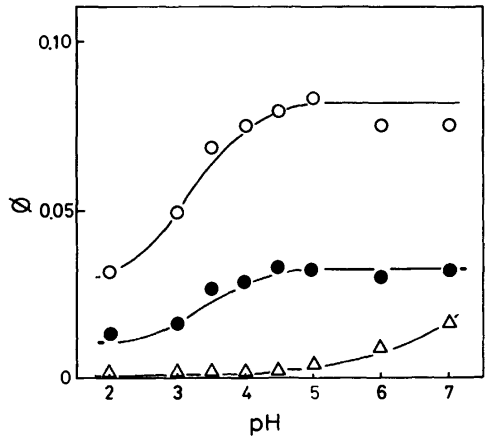

Fig. 3. Dependence of quantum yields, ϕ_{dis}(○), ϕ_a (●), and ϕ_r(△), on pH in a glycolic acid system([**1**]= 1.00×10^{-3} M, [glycolic acid]=0.2 M, [$NaClO_4$]= 0.5 M).

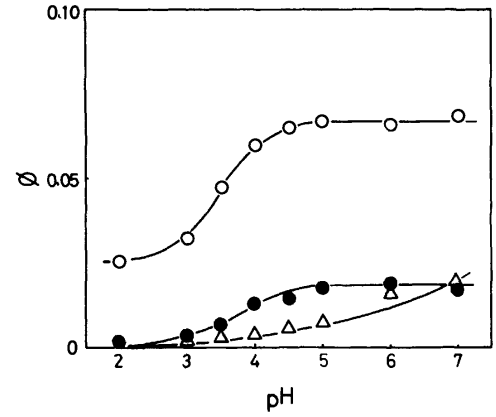

Fig. 4. Dependence of quantum yields, ϕ_{dis}(○), ϕ_a (●), and ϕ_r(△), on pH in an α-hydroxyisobutyric acid system([**1**]= 1.00×10^{-3} M, [$NaClO_4$]=0.5 M). In this case, ϕ_a represents a quantum yield for the formation of **4**.

A steady-state analysis of the sequence gives

$$\phi_a = \alpha_a k_q \tau[HA]/(1 + k_q\tau[HA]) \quad (2)$$

or

$$\phi_a^{-1} = \alpha_a^{-1} + (\alpha_a k_q \tau[HA])^{-1} \quad (3)$$

where [HA] and α_a represent the concentration of the glycolate anion and the limiting quantum yield (ϕ_a at [HA]$\rightarrow\infty$), $\{k_{-CO_2}/(k_{-CO_2}+k_{bet}+k_{p1})\}\{k_a/(k_a+k_{p2})\}$, respectively. k_q is mathematically equivalent to $k_c k_{et}/(k_{et}+k_{-c})$. The ratio ($k_q\tau$) of the intercept to the slope of a linear plot of ϕ_a^{-1} vs. $[HA]^{-1}$ (Fig. 5) was 0.66±0.27 M^{-1}. This value agreed with the $k_q\tau$ value (Table 1, 0.61 M^{-1}) obtained from the fluorescence quenching. This result also supports the idea that the photoaddition is an excited singlet-state process of **1**.

If, in this manner, both the reaction and the fluorescence-quenching processes can be considered together under a unified mechanism, the limiting quantum yield α_a can be estimated to be 0.27 (from Eq. 2) using $k_q\tau$ from the fluorescence quenching and the ϕ_a obtained at [HA] of 0.5 M. The limiting quantum yield α_{dis} ($=(k_{-CO_2}+k_{p1})/(k_{-CO_2}+k_{bet}+k_{p1})$) for the disappearance of **1** can also be calculated using the ϕ_{dis} denoted in Eq. 4 and is given in Table 2

$$\phi_{dis} = \alpha_{dis} k_q \tau[HA]/(1 + k_q\tau[HA]) \quad (4)$$

together with the limiting quantum yields estimated in a similar manner for the α-hydroxyisobutyrate system. The α_{dis} (0.64) for the glycolate system indicates that the fraction of the back electron transfer in the total disappearance pathways of **9** was 36%. Furthermore, the ratio ($=\{k_a/(k_a+k_{p2})\}\{k_{-CO_2}/(k_{-CO_2}+k_{p1})\}$) of α_a to α_{dis} implies that $k_{-CO_2}/(k_{-CO_2}+k_{p1})>0.42$. Thus, the decarboxylation of **9** takes place in a proportion of over 27% and the decarboxylation of the hydroxyacetoxyl radical partner in **9** is a sufficiently rapid pathway to compete with the back electron transfer.[16] This reflects the fact that the α_a and α_{dis} were fairly large; namely, the photoreaction of **1** in the presence of the glycolate anion was appreciably efficient.

Likewise, the fraction of decarboxylation for the α-hydroxyisobutyrate system can be estimated to be greater than 15%. However, it should be pointed out that a smaller α_a/α_{dis} value for this system, probably due to the formation of the reduction product **7** via the intermediate **10** in a higher quantum yield than that for the glycolate system (see Table 1), allowed us to underestimate k_{-CO_2}.

All the quantum yields, ϕ_{dis}, ϕ_a, and ϕ_r for the glycolate system were decreased by an addition of $NaClO_4$ (Fig. 1). Moreover, the degrees of the decreases were almost the same when considering at least two cases of ϕ_{dis} and ϕ_a: for example, ϕ_{dis} exhibited a 38% decrease at [$NaClO_4$] of 0.5 M; ϕ_a a 39% decrease. In addition, a decrease of the fluorescence-quenching efficiency upon an addition of the salt was also observed (Fig. 2). It is important to note that in the absence of the glycolate quencher, the salt did not affect the intensity of the fluorescence of **1**. This signifies that the singlet lifetime was not affected by the salt. Thus, it seems likely that the term k_q[HA], which is common to the two quantum yields (Eq. 2 and 4), and the fluorescence quantum

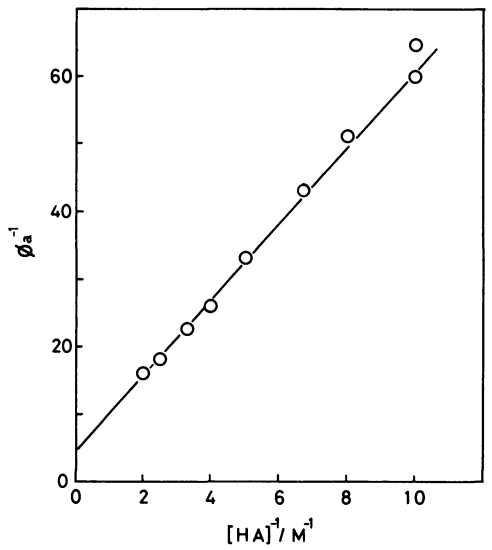

Fig. 5. Double reciprocal plot of the quantum yield for the formation of **2**(ϕ_a) vs. the concentration of glycolate([HA]).

Table 2. Limiting Quantum Yields for the **1** Disappearance(α_{dis}) and for the Photoadduct Formation(α_a) and Fractions of Pathways from the Intermediate **9**

Carboxylate anion (R-COO⁻) R-	α_{dis}	α_a	α_a/α_{dis}	Fractions of pathways		
				Back electron transfer	Decarboxylation	Formation of other products

a) Determined from the intercept(α_a^{-1}) of a linear plot shown in Fig. 5.

yield (ϕ_f) denoted in Eq. 5, was reduced by an addition of $NaClO_4$.

$$\phi_f = k_f\tau/(1 + k_q\tau[HA]), \quad (5)$$

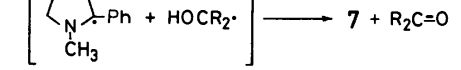
where k_f is a rate constant for the fluorescence of **1**. Hence, the relationships between the increased rates of the quantum yields ($\phi/\phi^\circ - 1$) and the decreased rate of the fluorescence intensity in the presence of the quencher ($1 - I/I^\circ$), based on the quantum yields (ϕ°) and the intensity (I°) at [$NaClO_4$] of 0.5 M, can be expressed as

$$1 - I/I^\circ = k_q^\circ\tau[HA](\phi/\phi^\circ - 1). \quad (6)$$

Here, k_q° is the quenching-rate constant at a [$NaClO_4$] of 0.5 M.

Linear plots of $1 - I/I^\circ$ vs. $\phi_{dis}/\phi_{dis}^\circ - 1$ and $\phi_a/\phi_a^\circ - 1$ having slopes of $k_q^\circ\tau[HA]$ (Fig. 6) gave $k_q^\circ\tau = 0.87 \pm 0.07\ M^{-1}$ from a plot against $\phi_{dis}/\phi_{dis}^\circ - 1$ and $0.77 \pm 0.15\ M^{-1}$ from that against $\phi_a/\phi_a^\circ - 1$, respectively. These $k_q^\circ\tau$ values are in satisfactory agreement with the $k_q\tau$ ($0.61\ M^{-1}$) obtained from fluorescence-quenching experiments at a [$NaClO_4$] of 0.5 M, within the experimental limits of error. They verify the salt effect on the $k_q[HA]$ term. The addition of $NaClO_4$ probably causes an instability in the postulated encounter complex **8**, which is formed from a cation and an anion; thus, it is reasonable to assume that the salt effect involves (in part) a decrease in the k_q value.

It is again worth noting that a higher quantum yield for the formation of **7** was observed in the case of α-hydroxyisobutyrate compared to the case of glycolate (Table 1). This suggests that the α-hydrogen of the α-hydroxyalkanoate anions did not serve as a hydrogen source for the formation of **7**. On the other hand, ketyl radicals are known to be active reducing agents;[17] e.g., the radicals can transfer hydrogen atoms to aryl ketones.[17b] It thus seems reasonable to propose that a major pathway for the formation of **7** involves a disproportionation of the radical pairs formed after the decarboxylation (for the glycolate system, **10**), even though a mechanism for



the formation was not investigated as thoroughly as that for the adduct formation. In particular, the reason why the yields of **7** increased with an increase in pH (Figs. 3 and 4) remains obscure. Formaldehyde (15%), acetaldehyde (18%), and acetone (32%) were formed in reasonable yields in the glycolate, lactate, and α-hydroxyisobutyrate systems, respectively. **7** was formed in a very low yield (<3%) for the case of an ethoxyacetate having no hydroxyl group. These findings support the idea of this disproportionation pathway. Furthermore, the results that a successive substitution of a methyl group at the α position induced a decrease in ϕ_a and, on the contrary, induced an increase in ϕ_r (Table 1) could be interpreted in terms of a simple steric hindrance of the methyl group during the radical pair combination which produced the photoadducts.

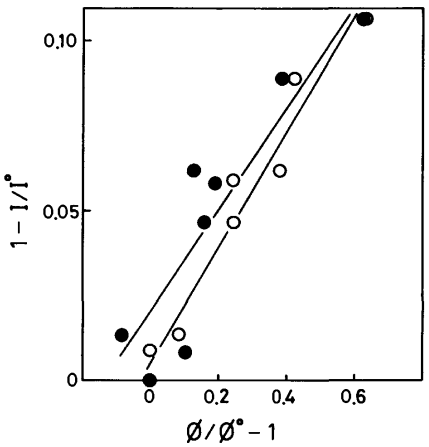


Fig. 6. Relationships between dependencies of the **1** fluorescence intensity(I) and the quantum yields, ϕ_{dis}(○) and ϕ_a(●), on the concentration of $NaClO_4$ in the presence of glycolate of 0.2 M. ϕ° and I° represent the quantum yields and the fluorescence intensity at [$NaClO_4$] of 0.5 M.

Photoreactions of 1 with Sulfur- and Nitrogen-Substituted Alkanoates. In the case of 2-mercaptopropionate, only the reduction product **7** was detected as a major product (Table 1). As described above, an electron transfer from 2-mercaptopropionate (predominantly from the mercapto group) to $\mathbf{1}^{S_1}$ takes place more efficiently than those from α-hydroxyalkanoates. Accordingly, a primary event for this photoreaction can be reasonably assumed to be an electron transfer leading to the formation of a 1-methyl-2-phenylpyrrolidinyl radical and the ensuing, predominant formation of a radical $H\overset{+}{S}\dot{C}H(CH_3)$-$COO^-$. On the other hand, S-H bonds possess relatively low dissociation energies and are, consequently, subject to a hydrogen-atom abstraction. Thus, **7** is quite likely to be formed through a hydrogen-atom abstraction of pyrrolidinyl radical within a solvent cage from $H\overset{+}{S}CH(CH_3)COO^-$ or a mercaptoalkyl radical $HS\dot{C}HCH_3$ resulting after decarboxylation, or through an out-of-cage hydrogen-atom abstraction from the mercaptopropionate anion, in preference to the formation of an adduct analogous to the photoadducts from the α-hydroxyalkanoates.

In cases of glycine and α-aminoisobutyric acid, **7** was also detected as a very low-yield product (Table 1). This is apparently due to a quite inefficient electron transfer at pH 6 (vide supra). A photolysis at

a higher pH (where the NH_3^+ groups of the α-amino acids are deprotonated) was impossible to perform since the higher pH brought about a thermal instability of **1**.[18]

On the other hand, *N*-acetylglycinate gave an adduct **6** in fairly high yield (80%, Table 1). A reasonably efficient electron transfer from the glycinate (vide supra) can induce the formation of an acetylaminoacetoxyl radical $CH_3CONHCH_2COO\cdot$ via an electron transfer from the carboxylato group and of a radical zwitterion $CH_3\overset{+}{C}\overset{\cdot}{N}HCH_2COO^-$ via an electron transfer from the acetylamino group. Both these radicals could be transformed into an acetylaminomethyl radical **11** via decarboxylation.

$$CH_3-\overset{O}{\overset{\|}{C}}-NHCH_2\cdot$$

11

This is rather efficiently induced since the methyl radical **11** is stabilized by a conjugation with the acetylamino group. Thus, the formation of **6** in high yield is understandable in terms of the formation of this stable radical as well as in terms of the efficient primary electron-transfer pathway.

Experimental

General. Melting points were determined with a Yanagimoto micro melting-point apparatus and are uncorrected. UV spectra were obtained with a Shimadzu UV-202 or JASCO UVIDEC-610A spectrophotometer. Fluorescence emission and IR spectra were recorded on a Shimadzu RF-510 spectrometer and a Hitachi 285 spectrophotometer, respectively. Mass spectra were taken with a JEOL JMS-01SG-2 spectrometer. ^1H NMR spectra were recorded on a Hitachi R-24B spectrometer with TMS as the internal standard. GLC (PEG-20M) was performed using a Shimadzu GC-3BF or a Hitachi 263-30 chromatograph with a flame-ionization detector. Preparative TLC was performed on silica-gel plates (Merck Kieselgel 60 PF_{254}).

Materials. **1** was prepared and purified according to a method from the literature:[8] mp 117.5—119.0 °C. *N*-Acetylglycine (Aldrich, 99%) was treated with an activated carbon, then recrystallized four times from methanol. The other reagents were all purchased from commercial sources and purified by recrystallization or vacuum distillation just before use.

Fluorescence Quenching Experiments. The relative intensities of the fluorescence at 380 nm of **1** (1.00×10^{-3} M) were measured at 25±1 °C. The excitation wavelength (at which the quenchers do not absorb light) was 305 nm. Aqueous solutions were adjusted to pH 6.0 with 4 M NaOH when carboxylate anions were used as quenchers. The slopes of Stern-Volmer plots were determined by a least-squares analysis of the obtained data for solutions containing 0.5 M $NaClO_4$. Concentrations of the quenchers were in the 0.05—0.5 M ranges.

Preparative Irradiations. Preparative irradiations were carried out using a 400 W high-pressure mercury lamp (Riko-Sha UVL-400HA) equipped with a Pyrex water jacket under an argon atmosphere. The lamp was immerged in the reaction solutions (200 cm^3, pH 6.0) and photolysates were acidified (pH 1) with HCl and then concentrated to 20 cm^3 in vacuo, unless otherwise noted. The acidic solutions were made basic (pH 10) with NaOH, saturated with NaCl, and extracted with three 40-cm^3 portions of chloroform. The extracts were dried over anhydrous Na_2SO_4 and then concentrated in vacuo to give oily residues. These were subjected to GLC analyses. Photoproducts were isolated by preparative GLC or TLC. Styphnate derivatives of the photoadducts and of reduction product **7** were separated out from equimolar solutions of the photoproducts and 2,4,6-trinitroresorcinol in ethanol, and recrystallized from ethanol.

The yields of the photoproducts were determined by GLC analyses (except for the *N*-acetylglycine photosystem) and are summarized in Table 1. The internal standards used were 9,10-dihydroanthracene for **2**, acenaphthene for **3**, **4**, and **5**, and naphthalene for **7**.

Photolysis of 1 with Glycolic Acid: An aqueous solution containing **1** (400 mg, 7.7 mM) and glycolic acid (10.5 g, 0.69 M) was irradiated for 120 min. Then, the photolysate was worked up by the above-mentioned method to give a crude oil (435 mg). A GLC analysis of the oil showed the formation of two major products: 1-methyl-2-hydroxymethyl-2-phenylpyrrolidine **2** and 1-methyl-2-phenylpyrrolidine **7**. These were isolated by preparative GLC. Spectral data for **2** and **7** were as follows and were identical with those of authentic samples.[8,15] **2**: ^1H NMR ($CDCl_3$) δ=1.65—3.4 (6H, m, ring methylenes), 2.11 (3H, s, N-CH_3), 2.85 (1H, s, OH), 3.77, 3.93 (2H, d and d, *J*=11 Hz, $C\underline{H}_2OH$), 7.1—7.6 (5H, m, ArH); IR (liquid film) 3390 (broad), 2940, 1600, 1445, 1060, 760, and 700 cm^{-1}. **7**: ^1H NMR ($CDCl_3$) δ=1.6—3.5 (7H, m, ring protons), 2.17 (3H, s, N-CH_3), 7.1—7.5 (5H, m, ArH).

The identification of **7** was confirmed by a direct comparison of the IR spectrum of a styphnate derivative from **7** with that from the authentic sample and by a melting-point value (184.5—185 °C) for a mixture of the derivatives. IR (KBr disk) of the styphnate derivative: 3425 (broad), 3030, 2760, 1650, 1590, 1540, 1460, 1380, 1345, 1300, 1200, 1090, 760, and 710 cm^{-1}.

Photolysis of 1 with Lactic Acid: The irradiation (190 min) of an aqueous solution of **1** (600 mg, 11.6 mM) containing lactic acid (5.41 g, 0.3 M) gave 760 mg of a crude oil. A GLC analysis of the oil showed the formation of three major products, **7** and two diastereomeric 1-methyl-2-(1-hydroxyethyl)-2-phenylpyrrolidines **3**. The diastereomers were separated by preparative TLC (hexane:diethyl ether=3:7, R_f=0.23 and 0.14).

3(R_f=0.23): ^1H NMR ($CDCl_3$) δ=1.05 (3H, d, *J*=6.4 Hz, CH($C\underline{H}_3$)OH), 1.90 (3H, s, N-CH_3), 1.0—3.2 (6H, m, ring methylenes), 3.84 (1H, s, OH), 4.42 (1H, q, *J*=6.4 Hz, $C\underline{H}$(CH_3)OH), 7.0—7.5 (5H, m, ArH); IR (liquid film) 3400 (broad), 2980, 1600, 1450, 1120, 765, and 705 cm^{-1}; MS (75 eV) *m/z* (rel intensity) 205 (M^+; 13), 204 (82), 160 (100).

This compound was further characterized as its styphnate derivative (mp 127.3—129.5 °C). Found: C, 50.76; H, 4.97; N, 12.72%. Calcd for $C_{19}H_{22}N_4O_9$: C, 50.67; H, 4.92; H, 12.44%.

3(R_f=0.14): ^1H NMR ($CDCl_3$) δ=0.92 (3H, d, *J*=6.4 Hz, CH($C\underline{H}_3$)OH), 2.14 (3H, s, N-CH_3), 0.85—3.3 (6H, m, ring methylenes), 3.45 (1H, s, OH), 4.06 (1H, q, *J*=6.4 Hz,

C<u>H</u>(CH$_3$)OH), 7.1—7.6 (5H, m, ArH); IR (liquid film) 3400 (broad), 2975, 1600, 1450, 1120, 765, and 705 cm^{-1}; MS (75 eV) *m/z* (rel intensity) 205 (M$^+$; 8.6), 204 (60), 160 (100).

The formation ratio of the isomers (R_f=0.23: R_f=0.14) was 1:1.2.

Photolysis of 1 with α-Hydroxyisobutyric Acid: The irradiation (180 min) of **1** (400 mg, 7.7 mM) in the presence of α-hydroxyisobutyric acid (4.16 g, 0.2 M) gave 374 mg of a crude oil. A GLC analysis of the oil showed the formation of **7** and 1-methyl-2-(1-methyl-1-hydroxyethyl)-2-phenylpyrrolidine **4**. The photoadduct **4** was isolated by preparative TLC (hexane:diethyl ether=3:7).

4: ^{1}H NMR ($CDCl_3$) δ=1.32, 1.44 (6H, s and s, C(C<u>H</u>$_3$)$_2$OH), 2.53 (3H, s, N-CH$_3$), 1.1—3.4 (6H, m, ring methylenes), 3.45 (1H, s, OH), 7.1—7.6 (5H, m, ArH); IR(liquid film) 3440 (broad), 2975, 1600, 1445, 1155, 760, and 705 cm^{-1}; MS (CI) *m/z* (rel intensity) 220 (M+H; 42), 160 (100).

An elemental analysis of the styphnate derivative of **4** (mp 130.8—133.5 °C) was as follows: Found: C, 51.79; H, 5.17; N, 12.23%. Calcd for $C_{20}H_{24}N_4O_9$: C, 51.72; H, 5.21; N, 12.06%.

Photolysis of 1 with Ethoxyacetic Acid: A GLC analysis of a crude oil (416 mg) obtained after the irradiation (120 min) of **1** (7.7 mM) in the presence of ethoxyacetic acid (0.2 M) showed the formation of 1-methyl-2-ethoxymethyl-2-phenylpyrrolidine **5** and a very small amount of **7** (<3%). The photoadduct **5** was isolated by preparative TLC (hexane:diethyl ether=3:7).

5: ^{1}H NMR ($CDCl_3$) δ=1.20 (3H, t, *J*=6.6 Hz, OCH$_2$C<u>H</u>$_3$), 1.7—2.6 (4H, m, methylenes at C-3 and C-4 of ring), 2.28 (3H, s, N-CH$_3$), 2.8—3.3 (2H, m, N-C<u>H</u>$_2$), 3.52 (2H, q, *J*=6.6 Hz, OC<u>H</u>$_2$CH$_3$), 3.6, 3.8 (2H, d and d, *J*=9.0 Hz, C<u>H</u>$_2$OCH$_2$CH$_3$), 7.1—7.7 (5H, m, ArH); IR (liquid film) 2975, 2865, 1600, 1445, 1115, 765, and 705 cm^{-1}; MS (75 eV) *m/z* (rel intensity) 219 (M$^+$, 3), 160 (100).

An elemental analysis of the styphnate derivative of **5** (mp 137.2—138.5 °C) was as follows: Found: C, 51.63; H, 5.16; N, 12.29%. Calcd for $C_{20}H_{24}N_4O_9$: C, 51.72; H, 5.21; N, 12.06%.

Photolysis of 1 with *N*-Acetylglycine: **1** (400 mg, 7.7 mM) was irradiated in the presence of *N*-acetylglycine (4.68 g, 0.2 M) for 240 min. The GLC analysis of an obtained oil (303 mg) revealed no distinct peak. 1-Methyl-2-(acetylaminomethyl)-2-phenylpyrrolidine **6** was isolated by preparative TLC (acetone) in a high yield (286 mg, 80%).

6: ^{1}H NMR ($CDCl_3$) δ=1.96 (3H, s, CH$_3$CO), 2.10 (3H, s, N-CH$_3$), 1.7—2.4 (4H, m, methylenes at C-3 and C-4 of ring), 2.6—3.2 (2H, m, methylene at C-5 of ring), 3.45, 3.93 (2H, dd and dd, *J*=13.4, 6.8, 3.4 Hz, C<u>H</u>$_2$NH), 6.05 (1H, broad s, NH), 7.1—7.5 (5H, m, ArH); IR (liquid film) 3300 (broad), 2960, 1650, 1540, 1440, 760, and 700 cm^{-1}; MS (75 eV) *m/z* (rel intensity) 232 (M$^+$; 0.16), 231 (100), 160 (63).

An elemental analysis of the styphnate derivative of **6** (mp 164.2—166.3 °C) was as follows: Found: C, 50.11; H, 5.00; N, 14.59%. Calcd for $C_{20}H_{23}N_5O_9$: C, 50.32; H, 4.86; N, 14.67%.

Photolysis of 1 with α-Amino Acids: A GLC analysis of a crude oil (250 mg), obtained after the irradiation (300 min) of **1** (400 mg, 7.7 mM) in the presence of α-aminoisobutyric acid (4.12 g, 0.2 M), showed the formation of **7**; other products were not identified.

When glycine was used as a carboxylic acid, **7** was also detected as a product.

Photolysis of 1 with 2-Mercaptopropionic Acid: An argon-purged aqueous solution (20 cm^3) containing **1** (40.0 mg, 7.7 mM) and 2-mercaptopropionic acid (0.425 g, 0.2 M) in a Pyrex glass tube was irradiated using a merry-go-round apparatus (described below) for 300 min. The photolysate was acidified (pH 1) with HCl and concentrated to ca. 2 cm^3 in vacuo. The concentrate was made basic (pH 10) with NaOH and then extracted with 6 cm^3 of chloroform. In this extract, only the reduction product **7** was detected as a major product by means of a GLC analysis.

Identification and Determination of Carbonyl Compounds: Aldehydes and acetone formed during photoreactions of the hydroxyalkanoate systems were isolated as their 2,4-dinitrophenylhydrazone derivatives which were identified by a direct comparison of the IR spectra and melting points with those of authentic samples. These derivatives were determined by means of HPLC (JASCO Familic-100, SC-01, 80% methanol).

Determination of Quantum Yields. The qantum yield for the formation of **2** was measured using a linear optical-bench system equipped with a 500 W super-high-pressure mercury lamp (Ushio USH-500D) at 25±1 °C. The beam of the 280 nm band was isolated with a monochromator (Jarrel Ash JE-25E) and was divided into two portions using a beam splitter tilted at 45° with respect to the beam. The transmitted light was used to irradiate an argon-purged aqueous solution (pH 6.0, [**1**]=1.00×10^{-3} M, [glycolate]=0.5 M, [$NaClO_4$]=0.5 M) in a cyclindrical cell (20×10 mm). It absorbed >96% of the light during photolysis runs. The diverted light (perpendicular to the transmitted light) was received by a UV radiometer (TOPCON UVR-254) in order to monitor the light output. The amount of transmitted light (1.54×10^{14} quanta s^{-1}) absorbed by the sample solution was determined by a calibration of the radiometer against the trioxalatoferrate-(III) actinometry (0.006 M potassium trioxalatoferrate-(III)).[19]

Product analyses were performed by GLC for the reaction mixtures. These were worked up in the same way as the preparative run using 9,10-dihydroanthracene as an internal standard: ϕ_a=0.057, 0.060, and 0.068 at 1.11, 1.08, and 0.878×10^{18} quanta of absorbed photons.

The quantum yields for the formation of the other photoadducts (**3**, **4**, and **5**), for the formation of reduction product, **7**, and for the disappearance of **1** were determined at 25±1 °C using a merry-go-round apparatus equipped with the same 400 W high-pressure mercury lamp that was employed for the preparative run. Aqueous solutions (20 cm^3) in Pyrex glass tubes containing **1** of 1.00×10^{-3} M, carboxylic acids of 0.5 M and $NaClO_4$ of 0.5 M were adjusted to pH 6.0. The glycolic acid solution employed for the determination of the quantum yield for the formation of **2** was used as an actinometer solution. Photolysates were subjected to a GLC analysis in the same manner as for the determination of the quantum yield of **2**. Internal standards were the same as those used for the determination of chemical yields in the preparative runs. The degrees (<10%) of the disappearance of **1** were obtained from the decrease of the absorbance at λ_{max} of 258 nm.

The relative quantum yields at different concentrations of glycolate and at different concentrations of $NaClO_4$ and

the pH dependencies of the quantum yields were also determined using the merry-go-round apparatus as described above.

Cyclic Voltammetry. The CV measurements were carried out using a Yanaco P8-ES unit and a Yanaco P8-PT potentiostat. The working electrode in a three-electrode cell was a platinum disk (3 mm diameter) sealed into a teflon tube and the counter electrode was a pool of mercury. SCE was used as a reference electrode. Current-voltage curves were recorded on a Yokogawa 3078 X-Y recorder. The reduction current of **1** was observed as a discernible shoulder on the large reduction wave of water when an aqueous solution containing **1** of 5.0×10^{-3} M and $NaClO_4$ of 0.1 M was used. The measured value (−0.95 V) was almost the same in magnitude as the value obtained in acetonitrile.[4] For a determination of the oxidation potentials of 2-mercaptopropionic acid and its carboxylate anion, aqueous solutions containing the acid of 4.0×10^{-3} M and $NaClO_4$ of 0.5 M were used. With the carboxylate anion, the pH of the aqueous solution was adjusted to 6.0 with NaOH.

The authors wish to express their thanks to Professor Patrick S. Mariano of the University of Maryland for his stimulating suggestions. We also would like to thank Professor Masashi Tashiro, the Research Institute of Industrial Science of Kyushu University, for elemental analyses and mass spectral measurements, and the staff of Oita Works of Sumitomo Chemical Co., Ltd. for CI-Mass measurements.

Photoionization Threshold Energies of Amine Solutions Studied by Photoelectron Emission by Solution

Iwao WATANABE,* Keiichi MAYA, Yoshiki YABUHARA, and Shigero IKEDA
Department of Chemistry, Faculty of Science, Osaka University,
Toyonaka, Osaka 560
(Received June 28, 1985)

The threshold energies E_t of photoelectron emission by solutions (PEES) were determined for several butylamines in acetonitrile and water. The correlations between E_t and gas-phase ionization potential I_P and oxidation potential E_{ox} were found to be linear. The difference between E_t and I_P originates from the electronic polarization energy of solvent molecules and the polarization energy was found to be inversely proportional to the solvation radius in accordance with the Born solvation free energy model. The E_t values were also compared with E_{ox} to discuss the reorientation relaxation of solvent molecules in the electron transfer process. The selective coverage of aqueous solution surface with amine molecule was indicated by the PEES technique.

The reactivity of an electron donor in solution is often estimated from its gas-phase ionization potential I_P or from the electrochemical oxidation potential E_{ox}. There are, however, many molecules which do not allow the measurement of I_P or E_{ox}. Low vapor pressure molecules of high molecular weight or ionic species present only in solvated state are almost out of the reach of the gas-phase UPS technique, while some molecules do not give clear oxidation wave owing to the limitations of availability of electrode material or supporting electrolytes, or to irreversible chemical reaction involved in the electron transfer reaction. The most controversial point on the use of I_P may be the complete neglect of solvation effects.

Although the UPS of solution samples have been measured for inorganic anions[1] and organic molecules,[2] the solvents used have been limited to the organic materials of the lowest vapor pressures.

The photoelectron emission by solution (PEES) experiment[3] is a new technique which has been used to determine the external ionization potential I_P(ext) of solvated organic[4] and inorganic anions[5] and metal cations[6] in aqueous solutions and it should be able to treat almost any solvent and any solvated species. The I_P(ext) can be obtained as the photoionization threshold energy E_t by using the PEES technique. The E_t for a molecule X corresponds to the energy change of the following reaction,

$$X(solv) \rightarrow X^+(solv) + e^-(vac). \qquad E_t \qquad (1)$$

The E_t is different from the internal ionization potential I_P(int) by the amount of V_0, the conduction band energy of the solvent referred to vacuum, and therefore, the reference level of the I_P(int) depends on the solvent while that of the E_t does not.

The I_P(int) corresponding to the following reaction,

$$X(solv) \rightarrow X^+(solv) + e^-(solv), \qquad I_P(int) \qquad (2)$$

has been determined either by measuring photoconductance[7] or by detecting solvated electron.[8] The photoconductance measurement can be performed only with low conductance organic solvents and the detection of solvated electron involves rather complicated experiments. On the other hand, the E_t measurement by PEES can treat not only low conductance organic solvent but also high conductance ionic aqueous solution and the concept of the experiment is rather simple.

This work reports the E_t values for primary, secondary, and tertiary butylamines in acetonitrile and water to be compared with gas-phase I_P and E_{ox} in solution. Both I_P and E_{ox} are available for these amines and the character of their HOMO is well understood.[9] The differences between E_t, I_P and E_{ox} will be interpreted in terms of their solvation radii and the reorientation of solvent molecules after the photoionization.

Experimental

The photoelectron emission spectra were obtained with a new instrument which is similar to the reported.[3a] In this paper, only the modification from the original will be described.

1. The VUV monochromater used is Model 302-VM (λ-Minuteman Lab., Acton, Mass., USA), focal length; 20 cm, grating; 1200 lines/mm. The slit width was 1 mm.

2. Photoelectron current was detected by using a charge integrator instead of a lock-in amplifier. The charge integrator is an Electrometer Operational Amplifier (Keithley Model 301) having a feedback capacitor of 100 pF and a mercury relay switch to discharge the capacitor. The integration and the discharge were synchronized to the rotation of a glass wheel covered with sample solution. The integration time was normally 1 s during which the wheel rotated exactly 4 times.

3. In order to monitor the photon intensity a part of the photon beam just after the exit slit was accepted by a sodium salicylate film on the end (cut at 45° and polished) of a quartz optical fiber (1 mm dia.) which guided the converted UV light to a photomultiplier (Hamamatsu,

R647). The current from the photomultiplier was fed to another integrator which worked exactly in the same manner as the one for the photoelectron current.

4. A beam shutter driven magnetically from outside the lamp housing was placed between the hydrogen lamp and the entrance slit of the monochromater. The shutter was open for 1 s to measure photoelectron current and close for the same period to measure "dark current."

In order to get high photon flux relatively wide slit width was used. Therefore, all the E_t values were corrected according to the resolution of the monochromater.

The spectra were taken at −30 °C for acetonitrile solutions and at 1 °C for aqueous solutions. In order to discriminate the photoionization of gaseous molecules from that of solution, the spectra at several different temperatures were also obtained for the acetonitrile solutions.

This technique is rather insensitive to impurity and needs a relatively high concentration solution, 0.1—1 mol dm^{-3}. However, the aqueous solution was extremely sensitive to the contamination from surface active species. Therefore, the spectrum for aqueous solution was always obtained after a run with pure water to evaluate the contribution from contaminations.

The water content in acetonitrile used was determined by Karl Fischer titration method. Though the content varied from 12 to 54 mmol dm^{-3}, it did not cause any change in the PEE spectra of amines.

The gas-phase He(I)-UPS had also been carried out in this laboratory.[10]

Results

In Fig. 1 are shown the PEE spectra of 0.1 mol dm^{-3} butylamine in acetonitrile at different temperatures. The PEE spectra show the quantum yield Y of photoelectron emission per incident exciting photon at the energy of the photon $h\nu$. The spectrum of acetonitrile (curve D) is included to show that the photoionization of the solvent was not detected. As the solution is cooled down, the yield at high energy region decreases, but that between 8 and 8.5 eV increases. The yield current at higher photon energy (>8.6 eV) is concluded to be originated from the photoionization of gaseous amine molecules present in the space between the exit window of the monochromater and the solution, since the rising point of the curve A is very close to the adiabatic I_P for butylamine (8.62 eV). At the lower temperature, viz. in the lower gas pressures of the amine and acetonitrile, the photoelectron from the solution increases. This is the result of the reduction of photoelectron collision with the gaseous molecules. The PEE spectra were taken at the lowest possible temperature, i.e. −30 °C for acetonitrile solutions, and only low energy region of the spectrum (lower than gas I_P) was used to determine the threshold energy.

The threshold energy E_t is determined by using the extrapolation method based on the following equation by Brodsky-Tsarevsky,[11]

$$Y = (h\nu - E_t)^n, \tag{3}$$

where $h\nu$ is the exciting photon energy. The PEES study on aqueous solutions has been done successfully by plotting $Y^{1/n}$ against photon energy with n value of 2 or 2.5 to determine E_t as follows,[3b,3c]

$$Y^{1/n} = h\nu - E_t. \tag{4}$$

In the present study on amines, n value of 2.5 gave better linear plot than 2 for all of the PEE spectra obtained. An example of the $Y^{0.4}$ plot to determine E_t is shown in Fig. 2 for the curve A, the same spectrum as C in Fig. 1.

Although it has recently been reported that the shape of the photoelectron emission yield against photon energy should be affected by dielectric dispersion of the solvent,[12] the difference on E_t resulted from the use of 2 or 2.5 for n value amounted 0.1 eV normally and the difference, therefore, does not affect the present discussion.

The quantum yield from butylamine in acetoni-

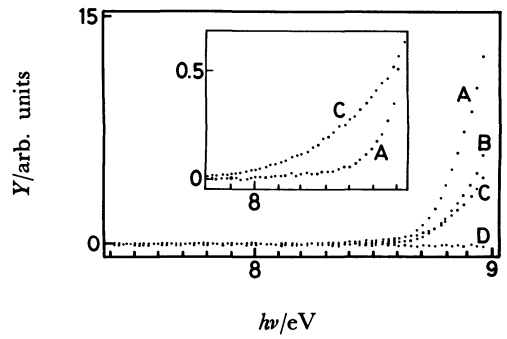

Fig. 1. PEE spectra of 0.1 mol dm^{-3} butylamine in acetonitrile taken at different temperatures. A: 1 °C, B: −10 °C, C: −30 °C, D: acetonitrile only at −30 °C.

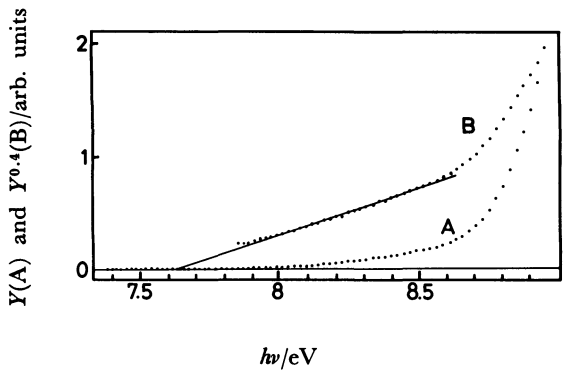

Fig. 2. PEE spectrum of 0.1 mol dm^{-3} butylamine in acetonitrile at −30 °C (A) and its $Y^{0.4}$ plot (B) to determine E_t.

trile solution is proportional to the concentration as shown in Figs. 3 and 4. In Fig. 3 are shown the yields at different photon energies, while the relation between the slope of the $Y^{0.4}$ plot and the concentration is shown in Fig. 4 by taking $(dY^{0.4}/dE)^{2.5}$ vs. concentration. In the figure are also included the E_t values determined at different concentrations. The yields for all the amines studied in acetonitrile were proportional to their concentrations, although the low solubility of tributylamine limited the highest yield at around 0.05 mol dm^{-3}.

Another example of PEE spectrum is shown in Fig. 5 for butylamine in water containing 10 mmol dm^{-3} KOH to suppress the protonation of the amine. It seems that the $Y^{0.4}$ plot is composed of two lines. One of them is drawn in the figure, which gives the E_t value of around 7.6 eV for the amine in water. The other corresponds to the ionization either of 10 mmol dm^{-3} OH^- ion whose E_t has been reported to be 8.45 eV,[13] or of gaseous amine. The yield from butylamine in aqueous solution is not proportional to the concentration as shown in Fig. 6. The 1 mmol dm^{-3} solution gave almost the same spectrum as the 0.1 mol dm^{-3} solution. This fact indicates that the surface of aqueous solution is covered with butylamine molecule and that this spectroscopic technique is sensitive only to the surface of the solution. The E_t obtained for butylamine in water (7.7 eV) is the same as that in acetonitrile. The PEE spectra of secondary and tertiary butylamines in water gave E_t values similar to the I_P values for the corresponding gas molecules, therefore, they will not be reported here.

The E_t values determined were corrected for the resolution of the monochromater and are collected in Table 1 together with I_P and E_{ox} values, by He(I)-UPS[9,10] and cyclic voltammetry,[14] respectively.

Benzene	9.25	9.25	7.80	1.44	0.26[a] 0.26[b]			

a) Calculated from P_+. b) Calculated from densities at −30 °C. If the data are not available, they are estimated by extrapolating known values, Ref. 19. c) Calculated from E_t and E_{ox} ($-R=E_t-E_{ox}-4.5$). The 4.5 is to convert the value (vs. NHE) to the one referred to vacuum level.[26]

between E_t measured in acetonitrile and I_P in gas-phase was found to be linear,

$$E_t = 0.73 \times I_{Pa} + 1.40 \quad (5)$$

or

$$E_t = 0.74 \times I_{Pv} + 0.81, \quad (6)$$

where I_{Pa} and I_{Pv} are adiabatic or threshold and vertical ionization potentials for gaseous molecule, respectively. Therefore, the *photochemical* reactivity of the amine as an electron donor in acetonitrile can well be estimated from the gas-phase I_P values. The term *photochemical* is used here to distinguish vertical transition from adiabatic reaction process. Since I_P corresponds to the energy change of the following reaction,

$$X(vac) \rightarrow X^+(vac) + e^-(vac), \qquad I_P \quad (7)$$

the difference ($I_P - E_t$) comes from the difference between solvation energies $\Delta G(solv)$ of X and X^+,

$$X(vac) \rightarrow X(solv), \qquad \Delta G(solv) \quad (8)$$

$$X^+(vac) \rightarrow X^+(solv). \qquad \Delta G^+(solv) \quad (9)$$

$$I_P - E_t = \Delta G(solv) - \Delta G^+(solv). \quad (10)$$

It has been known that there exists the surface potential at a gas/solution interface (0.08±0.06 V for water[15] and −0.10±0.06 V for acetonitrile[16]). Though the values of E_t and $\Delta G^+(solv)$ include the surface potential, the effect of the potential is cancelled in Eq. 10, because the potential which accelerates the escaping photoelectron from solution to gas phase also accelerates the incoming cation from gas phase into solution by the same amount. In any case, the surface potential is considered to be small and will be neglected in the present study.

Note that the species $X^+(solv)$ which appears in Eqs. 1 and 9 is not completely solvated, because the photoionization leaves X^+ ion having the same solvation geometry as the neutral molecule X. Only the electronic polarization of the solvent molecules is induced by the photoionization of X. One, therefore, divides $\Delta G^+(solv)$ into $\Delta G(solv)$ and the polarization energy P_+,

$$\Delta G^+(solv) = \Delta G(solv) + P_+. \quad (11)$$

From Eqs. 10 and 11,

$$I_P - E_t = -P_+. \quad (12)$$

The polarization energy is frequently estimated by modifying the Born equation[17] for the electrostatic solvation energy of ion as follows,

$$P_+ = -(e^2/2r)(1 - \varepsilon_{op}^{-1}), \quad (13)$$

where r is the radius of the central ion, ε_{op} the optical dielectric constant of the solvent. Since, as already mentioned, the geometry of $X^+(solv)$ is quite the same as X(solv), r could be called the *radius of solvation sphere of the neutral molecule* X. Now we can obtain the r by using Eq. 13.

The problem one must answer for the use of Eq. 12 to obtain P_+ is whether the E_t value determined by the present method corresponds to adiabatic or vertical ionization process of the species in the solvent, or to somewhere else. We have obtained[18] a theoretical yield spectrum by use of Eq. 3 with an assumption that the density of states for amine molecules in solution is the same as that in gaseous phase, i.e. the Y was obtained by a convolution calculation of the gas-UPS band with Eq. 3. The UPS first band of butylamine pertaines to the ionization of nitrogen lone pair electron and is broad (0.83 eV in the half width). If the extrapolation to $Y^{0.4}=0$ on the theoretical yield curve is performed near to the threshold region, the E_t value comes close to I_{Pa}, while the extrapolation gives the value of I_{Pv} if the theoretical curve at far high energy region from I_{Pv} is used. In the higher energy region of the real PEE spectra there are other photoionization processes, e.g. the photoionizations of other species in the solution and the gaseous amine molecule. On the other hand, lower energy region is obscured by noise current. Therefore, the usable region for the extrapolation is limited to about 0.5 eV in the present study on amines. Our simulation calculation indicates that the extrapolation in the present study gives the E_t value corresponding to the midpoint of I_{Pa} and I_{Pv}. In the PEE studies by Delahay, the lenghth of the region for extrapolation used to determine E_t is almost 1 eV or even longer.[5] He considered the E_t obtained by his extrapolation method as the vertical ionization potential of the solute. In the present study we take the average of I_{Pa} and I_{Pv} as the I_P for gaseous amine to compare with E_t. Thus,

$$-P_+ = (I_{Pa} + I_{Pv})/2 - E_t. \quad (14)$$

The values of P_+ and r calculated by using Eq. 13 are included in Table 1. The ε_{op} in Eq. 13 is estimated to be 1.89[19] for acetonitrile at −30 °C.

The values of r should be used only to estimate the degree of solvation because of the following reason. Neither the geometrical shape nor the charge distribution on the amine cation is spherical. The density of the positive charge on the cation must be localized on the nitrogen atom, since the photoionization removes the nitrogen lone pair electron. The polarization energy is the function of the distance between charge center and solvent molecules, and the number of solvent molecules around the cation. We call the r most appropriately *effective* solvation radius.

The r of 0.25 nm is obtained for butylamine in water and is smaller than that in acetonitrile. The decrease of r in water could be interpreted in terms of the hydrogen bonds between the amine and water molecules. However, the fact that the amine molecule is deposited on the aqueous solution surface implies that such molecule must have smaller number of solvent molecules and thus larger effective solvation radius. We certainly need more knowledge of the solution structure of alkylamine to interpret the value of r.

Correlation between E_t and E_{ox}. Most of the butylamines studied in the present study can be oxidized electrochemically on a platinum electrode in acetonitrile. The oxidation potentials E_{ox} determined with cyclic voltammetry by Mann[14] are also included in Table 1. Since the cyclic voltammetry gives completely irreversible waves for the alkylamines, the E_{ox} values read at the peak position in the voltammograms are by no means equilibrium potentials thermodynamically meaningful and the values must depend on sweep rate and other experimental conditions.[25] In view of the present study, the E_{ox} values are considered to be the potentials at which the following one-electron oxidation reaction can take place at a rate comparable to that of diffusion process.

$$X(solv) \rightarrow X^+(solv) + e^-(electrode). \quad E_{ox} \quad (15)$$

If the E_{ox} were of an equilibrium oxidation potential, the difference between E_t and the E_{ox} both referred to the common vacuum level[26] should be the reorganization energy for the electron transfer reaction 15.[3c] That is because E_t is the energy difference between solvated molecule X and the cation X^+ with the same molecular and solvation structures as the neutral molecule X, while E_{ox} is the energy difference between the X and the X^+ with the most stable molecular and solvation structures. Therefore the energy states for the cations X^+ in Eqs. 1 and 15 are not the same.

Due to the irreversibility in the alkylamine case, however, the interpretation of the difference $(E_t - E_{ox})$ is not straightforward, but should be as follows. The difference is the relaxation energy from the photoionized state which corresponds to the ion having the same molecular and solvation geometries as the neutral molecule, to the partially relaxed ionic state as for the molecular (inner) and solvation (outer) geometries which corresponds to the transition state of the electron transfer. The plot of E_{ox} vs. E_t gives a line with a slope of 0.58 as shown in Fig. 7. The difference $(E_t - E_{ox})$, containing the relaxation energy R to the transition state, is greater for the smaller amine. Since the molecular relaxation energies R_{in} estimated from $(I_{Pa} - I_{Pv})$ are almost the same (0.60—0.68 eV) for the amines studied, the difference reflects the outer relaxation R_{out}. Therefore, the reorientation energy of acetonitrile molecules around the smaller amine cation is greater.

The R_{out} for metal complex has been calculated for the studies on the PEE of aqueous solutions[5,20,21] by

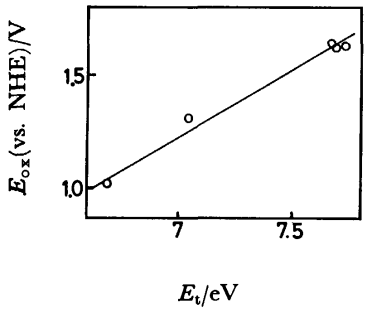

Fig. 7. Correlation between oxidation potential E_{ox} and threshold energy E_t of butylamines in acetonitrile. The data for E_{ox} are taken from Ref. 14.

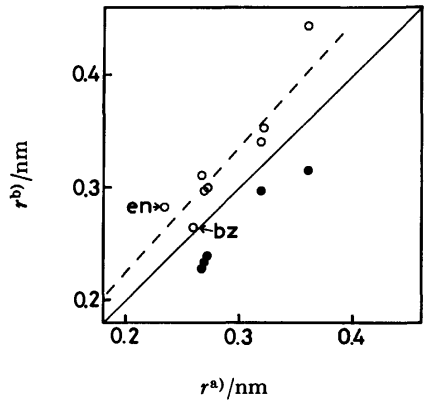

Fig. 8. Correlation between solvation radii determined from the densities of pure liquid $r^{a)}$ and PEE experiments $r^{b)}$; from polarization energy (○) and reorganization energy (●). The densities at −30 °C are estimated by extrapolating known values, Ref. 19. Solid line: slope=1, corresponding to k=0.5, broken line: the line corresponding to k=0.558, see the text. en: ethylenediamine, bz: benzene.

using the following equation,

$$R_{out} = -(e^2/2r)(\varepsilon_{op}^{-1} - \varepsilon_s^{-1}), \quad (16)$$

where ε_s is the static dielectric constant of solvent. The same equation has been used to calculate outer-sphere activation energy for electron exchange reactions.[22]

Since we already know the r value from polarization energy, the values of R_{out} can be calculated by using Eq. 16 and are listed in Table 1. The calculation concludes that most part of R comes from R_{out}.

Estimation of r. There are several different ways to estimate the value of r. Delahay[3c] calculated the r using the molecular density δ of pure material as follows,

$$r = k(m/\delta)^{1/3}, \quad (17)$$

where m is the molecular weight and k is $(3/4\pi)^{1/3}$ (=0.62). Inokuchi et al. have calculated the polarization energies for aromatic[23] and aliphatic[24] hydrocarbons using Eqs. 13 and 17 with k=0.5, and they obtained good agreement with experimental polarization energies for solid hydrocarbons. They also tried other r values but the agreement was poorer.

The r values determined from polarization energies and calculated by using Eq. 17 with k=0.5 are compared in Fig. 8. The result of Fig. 8 shows that the best linear relation between the r values is obtained at k=0.558. It was also found that the polarization energy obtained by taking I_P in Eq. 12 from I_{Pa} instead of $(I_{Pa}+I_{Pv})/2$ gave unreasonably large r values and, on the other hand, from I_{Pv} too small r. This fact is considered supporting our simulation calculation which indicates that the E_t values for amines are average ionization potentials for vertical and adiabatic processes.

Since the experimental value of $(E_t - E_{ox})$ seems to be almost equal to the outer relaxation energy, the estimation of r is attempted by taking $R_{out} = -(E_t - E_{ox})$ and by using Eq. 16 and the r values so obtained are plotted in Fig. 8. The agreement of the r values from the polarization and relaxation energies and from the densities implies that the Born approximation should be useful for a rough estimate of energetics of PEE process.

In the figure are added other experimental results for benzene and ethylenediamine. The added points lie on the same line as for amines. We have expected that these two molecules might behave in different way, because the butylamine cation has the electronic charge localized on the nitrogen atom, while the charge on benzene ion must be delocalized and two equivalent nitrogen atoms in ethylenediamine may contribute to the delocalization of cationic charge on the molecule. However, the experimental results show that the Born approximation could be applied to either of linear, plane or unsymmetrical molecule equally well. At the present stage, therefore, the PEES experiment can not predict how the charge produced by photoionization is distributed on the cation.

^{1}H NMR Studies on the Reorientational Motions of Cations in Four Solid Phases of Methylammonium Iodide and the Self-Diffusion of Ions in Its Highest-Temperature Solid Phase

Hiroyuki Ishida, Ryuichi Ikeda, and Daiyu Nakamura*
Department of Chemistry, Faculty of Science, Nagoya University,
Chikusa-ku, Nagoya 464
(Received September 20, 1985)

Four solid phases of CH_3NH_3I named as α', β', δ, and ε were studied by the temperature dependence of ^{1}H spin-lattice relaxation time T_1 and ^{1}H spin-spin relaxation time T_2 (for ε) at several NMR frequencies, and of ^{1}H NMR second moment. Phase transitions were studied by means of differential thermal analysis and ^{1}H T_1. The X-ray powder patterns of the highest-temperature ε phase taken at ca. 440 K revealed that the crystal forms a CsCl-type cubic lattice. The measurements of differential scanning calorimetry gave unusually small entropy of melting indicating that the cations of the ε phase are in a state having the most part of their motional freedom. From ^{1}H NMR T_1 experiments, it was found that the transformation of the room-temperature α' phase to the low-temperature stable β' phase needed longer time than three months at Dry Ice temperature for samples carefully purified and dried for a long time under vacuum whereas it was completed within two weeks for roughly dried samples. The NMR results indicated that the cations are bound tightly in the β' phase whereas they are fairly free to reorient in the low-temperature substable δ phase. In the α' phase, the cations perform C_3 reorientations very rapidly about their C–N bond axis. The cations of the ε phase undergo overall rotation as well as self-diffusion which was confirmed by electrical conductivity measurements. The mechanism of the self-diffusion of the cations is discussed.

Methylammonium iodide (MAI) had been known for a long time to form two solid phases below room temperature from the temperature dependence study of infrared spectra.[1,2] The α' phase stable at room temperature has a tetragonal structure belonging to the space group $P4/nmm$, and is isomorphous with the room-temperature α' phase of CH_3NH_3Br.[3] The low-temperature δ phase of MAI has been thought to have the same crystal structure as the substable δ phase of the bromide, because the two phases showed very similar IR spectra.[1,2] Recently, the transition temperature T_{tr} between the α' and δ phases of MAI was determined to be 167 K from the ^{127}I NQR study.[4]

^{1}H NMR studies on the molecular motion of the cation[5,6] were reported for MAI and its partially deuterated analog CH_3ND_3I. Recently, we found the existence of a new high-temperature ε phase stable above 414 K for MAI and reported as a letter.[5] The new phase has a marked feature that the cations undergo self-diffusion as well as overall reorientation in the crystal. In view of the dynamical behavior of ions, this phase is thought to be analogous to the high-temperature phase of $CH_3NH_3NO_3$ ($MANO_3$), which is very close to the plastic phase found in various molecular crystals.[7,8]

Very recently, Yamamuro et al.[9] found the stable low-temperature phase named as β' from the calorimetric study of MAI crystals. This phase was obtained by annealing the sample at 205 K for ca. 5 d.

In the present investigation, we have carried out measurements on the 2nd moment M_2 of ^{1}H NMR absorptions, ^{1}H spin-lattice and spin-spin relaxation times T_1 and T_2, respectively, differential thermal analysis (DTA), differential scanning calorimetry (DSC), and X-ray powder diffraction of MAI, to obtain information about the nature of the liquid-like ε phase and also to compare the dynamical properties of the cation in the stable low-temperature β' phase with those in the α' and δ phases.

Experimental

Methylammonium iodide was synthesized by mixing an aqueous solution of methylamine with a nearly stoichiometrical amount of hydroiodic acid. The resulting solution was left to stand over phosphorus pentaoxide in a vacuum desiccator to evaporate water slowly. Pale yellow crystals separated were purified by recrystallizations three times from a mixed solvent of ethanol and chloroform. Colorless tabular crystals obtained were dried in a vacuum desiccator. The partially deuterated analog, CH_3ND_3I was prepared from purified MAI by performing successive crystallizations from heavy water. All the manipulations were carried out in a dry bag because the samples were hygroscopic. After the samples were ground and put in glass ampoules, they were again dried under vacuum at ca. 80 °C.

Temperature dependence measurements of wide-line ^{1}H NMR spectra were performed at a Larmor frequency of 40 MHz by means of JEOL-MW-40S spectrometer equipped with a temperature controller. ^{1}H T_1 observed at 11.5, 20, 31.5, and 42.5 MHz was measured by the inversion recovery method using two spectrometers described elsewhere.[10,11] ^{1}H T_2 was determined at 31.5 and 42.5 MHz by applying Hahn's spin-echo method.[12] Electrical conductivity and DTA measurements were carried out by use of homemade apparatus already reported.[8,13] A Perkin-Elmer DSC-1B apparatus was used to determine enthalpy changes at the solid-solid phase transition and melting temperatures abbreviated as T_{tr} and T_m, respectively. Observed transition enthalpies were calibrated by the melting enthalpy of

metallic indium[14] (purity: 99.99%). X-Ray powder diffraction photographs were taken for the ε phase with the sample sealed in a glass capillary, using a Weisenberg camera from Rigaku Denki Co.

Results

Structural information about the ε phase was obtained by taking X-ray powder photographs at ca. 440 K. The observed patterns were well explained with a CsCl-type cubic lattice having the lattice constant a=4.86 Å and Z=1. Table 1 shows the adequacy of the present analysis.

The DTA curves recorded in a temperature range of 80-520 K were shown in Fig. 1. When the sample was heated and cooled, a small heat anomaly accompanying a long tail on the low-temperature side was observed at the same peak-temperature of 167 K. As already reported for the phase transitions

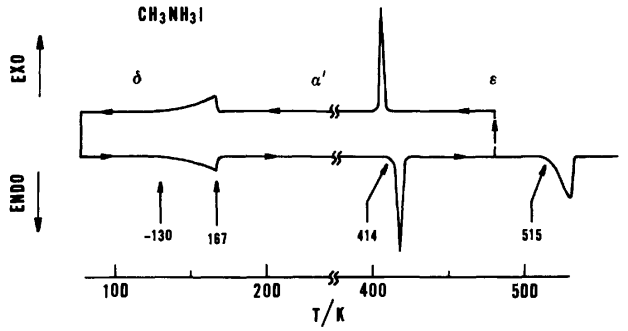

Fig. 1. Differential thermal analysis (DTA) curves of CH_3NH_3I crystals. Endothermic anomalies due to solid-solid phase transitions from the low-temperature substable δ to the room-temperature α' phase and from α' to the highest-temperature solid phase ε appear at 167 and 414 K, respectively. Heat anomaly due to phase transition between the low-temperature stable β' phase and α' is missing.

310	60.0	60.2

taking place in some methylammonium salts[13,15,16] which showed small heat anomalies similar to the above one, the temperature of the DTA peak could be attributed to T_{tr} (167 K). This agrees well with T_{tr} determined for this salt from the temperature dependence study of ^{127}I NQR[4] and that (166.1 K) from the heat capacity study.[9]

When the sample was heated above room temperature, a large heat-absorption anomaly was recorded at 414 K. The enthalpy change at this phase transition was determined from DSC measurements as 6.1 kJ mol^{-1}. With increasing temperature furthermore, melting of the sample started at ca. 515 K together with gradual decomposition which was confirmed by observing the color change to yellow. The enthalpy of melting was roughly estimated to be ca. 7 kJ mol^{-1}.

In CH_3ND_3I, a heat anomaly was observed at the same temperature of 167 K as that of MAI, having almost the same shape as that of MAI recorded on the DTA measurements of both heating and cooling runs. On the other hand, the phase transition to the ε phase took place at 419 K which is higher by 5 K than that of MAI.

The samples used in the foregoing DTA experiments were dried by keeping the glass tubes at 80 °C for ca. 8 h under a high vacuum in order to remove an extremely small amount of water and other volatile impurities possibly included in them. These samples were only partly transformed in our experiments from α' into the low-temperature stable β' phase found by Yamamuro et al[9] although they were left to stand (annealed) for three months at the Dry Ice temperature (196 K). The existence ratio of β' to α' phase was determined at ca. 196 K by separating free induction decay signals of these phases which gave greatly different T_1 of 10 ms and 10 s, respectively. For the above samples repeatedly prepared several times, the β'-phase content was observed to be in a range of ca. 70—0% after the foregoing annealing treatment. These variations of the content values may be due to impurities included in the sample and/or the difference of the grain size of the pulverized crystals. On the other hand, the samples dried at room temperature for ca. 20 min under a high vacuum were transformed into the β' phase almost completely, even when they were annealed at the same temperature only for two weeks. Accordingly, the samples dried by the former method were employed for the ^1H NMR measurements of the α', δ, and ε phases and also for the DTA and DSC experiments, while those dried by the latter method were employed for the study of ^1H NMR only for the β' phase.

The temperature variation of M_2 observed for MAI between 77 and 430 K is shown in Fig. 2. An almost temperature independent M_2 of ca. 8.5 G^2 was

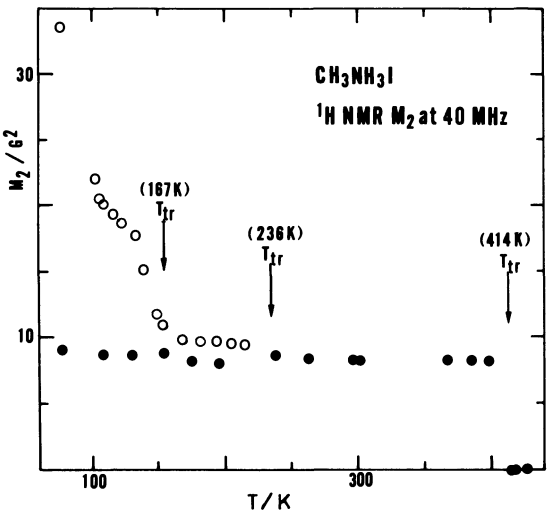

Fig. 2. Proton NMR second moment, M_2 observed at a Larmor frequency of 40 MHz for CH_3NH_3I crystals (○ for β': ● for α', δ, and ε). The transition temperature, T_{tr} from β' to α' was determined from ^1H T_1 experiments as 236 K while other T_{tr} values from DTA.

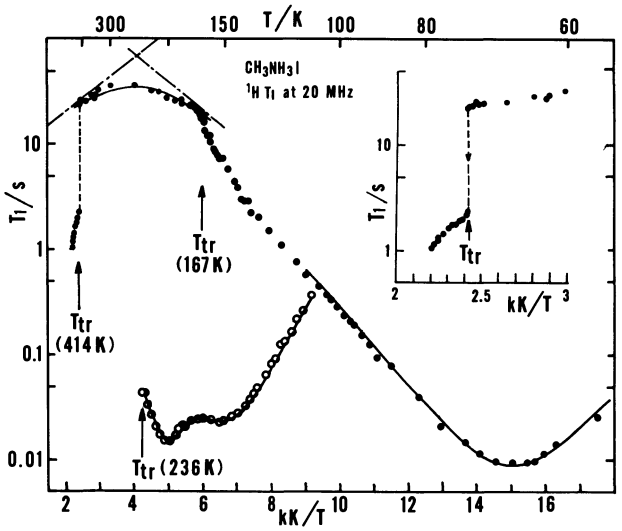

Fig. 3. Temperature dependences of ^1H T_1 observed at 20 MHz for CH_3NH_3I. T_1 data obtained for the α', δ, and ε phases are shown by dots while those of β' phase are plotted by open circles. The enlarged plots near T_{tr} from α' to ε are inserted. Solid curves indicate best fitted curves calculated by the least-squares method. Solid lines broken by dots given in the α' phase are the calculated log T_{1MA} and log T_{1SR} lines defined in the text.

obtained for the α' phase below ca. 410 K and also for the δ phase above 77 K. The M_2 values of 8.8 and 7.5 G^2 determined at 77 and 300 K, respectively, by Tsau and Gilson[17] are consistent with the present results. The large M_2 value of 34±3 G^2 was obtained at 77 K for the β' phase. With increasing temperature, M_2 of this phase decreased gradually and an almost constant value of 9.5±0.3 G^2 was observed between 170 and 220 K, above which temperature we could not definitely discriminate between the β' and α' phases because of the coexistence of both phases. When the sample was heated from room temperature, M_2 decreased discontinuously at T_{tr} to the ε phase and extraordinarily small M_2 values less than 0.01 G^2 were obtained for this phase.

The temperature dependences of ^1H T_1 in MAI and CH_3ND_3I determined in a temperature range of 57—455 K at 20 MHz are shown in Figs. 3 and 4, respectively.

The δ phase of MAI and CH_3ND_3I exhibited a single T_1 minimum the value of which was 9 and 12 ms, respectively, at approximately the same temperature of 67 K. With increasing temperature in this phase up to ca. 130 K, the log T_1 versus T^{-1} plot increased linearly. Above 130 K, the log T_1 value increased more steeply and deviated from a line obtained by extrapolation from the low-temperature side. Moreover, a small jump in the log T_1 curve could be found at 167 K. This temperature agrees well with T_{tr} determined by DTA. By referring to the anomalous DTA curve observed around T_{tr}, this transition is attributable to a second-order one.

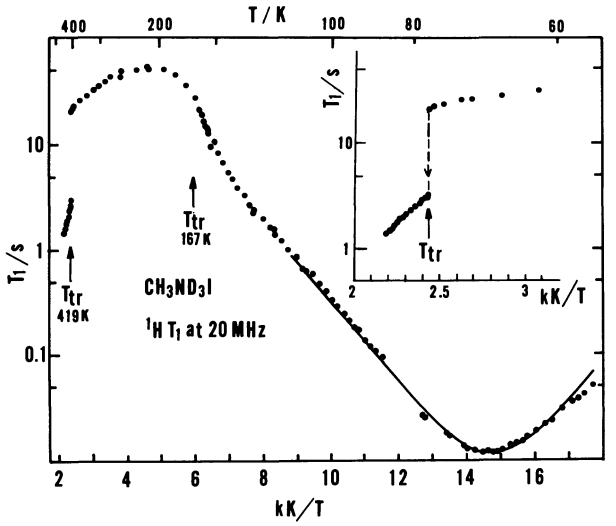

Fig. 4. Temperature dependences of ^1H T_1 observed at 20 MHz for CH_3ND_3I. Near T_{tr} from the α' to ε phase, the axis of abscissa is enlarged and an enlarged plot is inserted in the figure. The solid curve is the best-fitted theoretical curve.

However, a slight discontinuity in T_1 was observed at T_{tr} suggesting the presence of some first-order nature in this phase transition.

In the β' phase of MAI, two T_1 minima of 22 and 15 ms were located at 154 and 202 K, respectively. At 236 K, T_1 increased discontinuously by about two

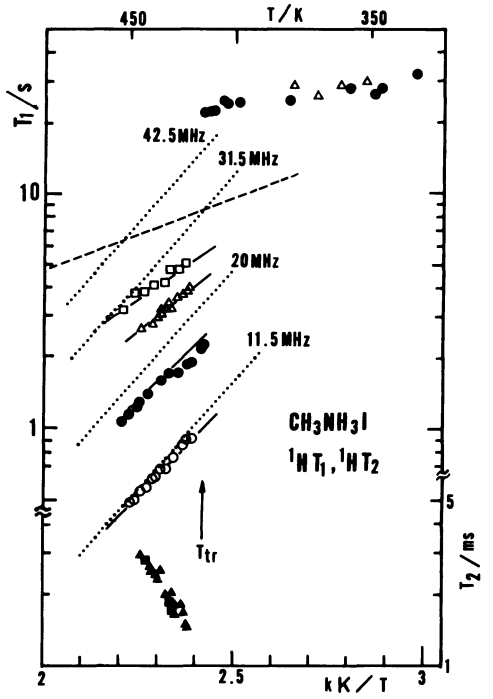

Fig. 5. Temperature dependences of ^1H T_1 observed at 11.5 (○) 20 (●), 31.5 (△), and 42.5 (□) MHz; and ^1H T_2 observed at 31.5 (▲) and 42.5 (■) MHz mainly for the ε phase of CH_3NH_3I. The frequency independent $\log T_{1I}$ estimated for the ε phase is shown by a broken line and frequency dependent $\log T_{1d}$ derived from each observed frequency is shown by dotted lines. Solid lines indicate the best fitted one to the observed values at each frequency.

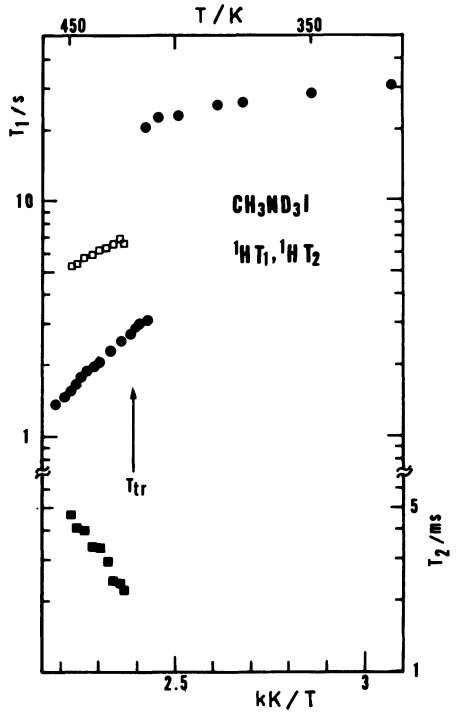

Fig. 6. Temperature dependences of ^1H T_1 observed at 20 (●) and 42.5 MHz (□); and ^1H T_2 observed at 42.5 MHz (■) mainly for the ε phase of CH_3ND_3I.

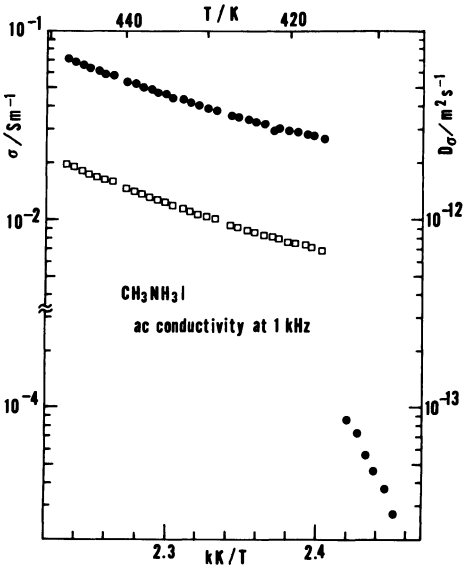

Fig. 7. Temperature dependences of electrical conductivity σ (●) values observed at 1 kHz and the diffusion constants D_σ (□) evaluated for CH_3NH_3I.

orders of magnitude, above which temperature the same T_1 values as those of the α' phase were observed. Accordingly, this discontinuity observed in T_1 can be assigned to the phase transformation from β' to α'. The transformation was completed with a reasonably fast rate at this temperature which is higher than T_{tr} of 220 K determined from the calorimetric study,[9] where superheating of β' by ca. 10 K was reported.

In the α' phase of MAI, a broad T_1 maximum (ca. 35 s) was observed at ca. 270 K. A similar maximum of ca. 40 s was also obtained at ca. 240 K for the α' phase of CH_3ND_3I. With increasing temperature, a sudden T_1 decrease was observed for the α' phase of MAI and CH_3ND_3I at 414 and 419 K, respectively. These temperatures agree well with T_{tr} to the ε phase already determined by DTA.

The temperature dependences of ^1H NMR relaxation times (T_1, T_2) determined for each ε phase of MAI and CH_3ND_3I are given in Figs. 5 and 6, respectively.

In each ε phase, plots of $\log T_1$ decreased linearly with decreasing T^{-1}, whereas those of $\log T_2$ increased linearly against T^{-1}.

Electrical conductivity measurements were performed for pulverized MAI crystals by use of 1 kHz ac electric field in a temperature range of 408—443 K and the results are shown in Fig. 7. When the sample was heated in the α' phase, the electrical conductivity σ increased steeply but continuously. However, it jumped at T_{tr} to the value of 2.7×10^{-2} S m^{-1}, which is larger by about three orders of magnitude than those obtained for the α' phase.

Discussion

Calculated Second Moments. Theoretical values of M_2 for a MA^+ ion in the following three motional states were evaluated by assuming the same geometry of the cation as that employed in our previous report on solid CH_3NH_3Br.[16] The M_2 values calculated for the cation, in the rigid lattice, performing the reorientation as a whole about the cationic C_3 axis, and undergoing the overall rotation about its center of gravity. They are 38, 11, and 1.1 G^2, respectively. ^1H-^1H and ^1H-^{127}I interionic contributions to M_2 were estimated by use of the crystal structure of the α' phase[3] for the calculations of the first two cationic motional states. For the ε phase revealed in the present investigation, M_2 was calculated for the last motional state because the cation should behave as an isotropic ion in the cubic ε phase.

Low-Temperature Substable δ Phase. The M_2 value of 8.5 G^2 observed for the δ phase is close to the value calculated for the cation in which both CH_3 and NH_3^+ groups perform C_3 reorientation about their symmetry axis. From this value, the averaged reorientational rates of both groups can be estimated to be faster than 10^5 Hz in the δ phase above 77 K.

The random C_3 reorientation of either CH_3 or NH_3^+ group gives rise to ^1H T_1 expressed by,[18]

$$T_1^{-1} = C\{\tau_R/(1+\omega_H^2\tau_R^2) + 4\tau_R/(1+4\omega_H^2\tau_R^2)\}, \quad (1)$$

where

$$C = (9/20)\gamma_H^4\hbar^2 r^{-6}. \quad (2)$$

In these equations, γ_H, r, ω_H, and τ_R are the gyromagnetic ratio of a proton, the interprotonic distance, the ^1H angular Larmor frequency, and the correlation time of either CH_3 or NH_3^+ C_3 reorientation, respectively. Taking into account only for each intragroup contribution to the relaxation, the spin-lattice relaxation rate, T_{1MA}^{-1} of the cations can be written as,

$$T_{1MA}^{-1} = (1/2)(T_{1CH_3}^{-1} + T_{1NH_3}^{-1}), \quad (3)$$

where T_{1CH_3} and T_{1NH_3} are given by Eq. 1.

The T_1 minima of 9 and 12 ms observed for the δ phase of MAI and CH_3ND_3I, respectively, agree well with the theoretical values of 9.9 and 11 ms in the same order. These values were calculated by use of Eqs. 1—3 for the C_3 reorientations of CH_3 and NH_3^+ groups in MAI crystals and for the C_3 reorientation of CH_3 groups in CH_3ND_3I crystals. In this calculation, we employed the same geometry of the cation as that used in the calculation of M_2.

Assuming an Arrhenius-type relationship between the activation energy, E_a for the C_3 reorientation and τ_R, we have

$$\tau_R = \tau_{RO}\exp(E_a/RT), \quad (4)$$

where τ_{RO} has the usual meaning. Fitting calculation of the ^1H T_1 data of MAI and CH_3ND_3I determined in the δ phase to Eqs. 1—4 was performed by the least-squares method using a program SALS[19] in the Computation Center of Nagoya University. The best fitted T_1 curves obtained are shown in Figs. 3 and 4 by solid lines. The optimum values of E_a, τ_{RO}, and C obtained through the calculation are given in Table 2.

The motional mode of the cation in the δ phase of MAI and CH_3ND_3I can be considered from the following discussion as the C_3 reorientation of the cation as a whole with keeping its rigid structure. This motional mode (correlated C_3 reorientation) of the cation has already been observed in some hexahalo metal complexes.[20,21] The presence of the correlated C_3 reorientation of the cation in the δ phase is explained by the facts that MAI gives a single T_1 minimum attributable to the C_3 reorientation of both CH_3 and NH_3^+ groups, and the E_a value of ca. 7 kJ mol^{-1} obtained for both salts is smaller than that of ca. 8 kJ mol^{-1} evaluated for the barrier to internal rotation of the cation.[20,21] The appearance of this motional mode indicates that the cations are considerably free to reorient about their C–N bond axes and, therefore, the δ phase forms loosely packed crystals.

Above 133 K, ^1H T_1 observed for MAI deviated gradually from the calculated curve. The deviation of T_1 from the normal BPP curve far below T_{tr} and the anomalous DTA curve recorded in the same temperature region have been also observed below T_{tr} from the δ to α' phase of CH_3NH_3Br crystals.[16] This T_1 deviation can be regarded as a significant feature of the second-order-like phase transition from the substable δ phase to the room-temperature α' phase. Therefore, it is expected that the correlation time of the C_3 reorientation of the cation in these crystals is shortened rapidly near T_{tr} with increasing temperature.

Low-Temperature Stable β' Phase. By comparing M_2 of 34±3 G^2 observed at 77 K in the β' phase with the theoretical value of 38 G^2 for the rigid lattice, the cations can be expected to be almost rigid in the crystal. This is in a marked contrast to the motional state of the cation in the δ phase described above and indicates that the cations in the β' phase are strongly hindered to reorient. Accordingly, one can conclude that the ions in the β' phase are more compactly packed in crystals than those of δ in accordance with the fact that the former phase rather than the latter is the stable one at low temperatures.[9]

The ^1H T_1 data of these phases are capable of a similar interpretation. A shallow T_1 minimum of

Table 2. Activation Energies (E_a), Pre-Exponential Factors (τ_{RO}), Motional Constants (C), and Motional Modes of Methylammonium Ions in Four Phases of Solid Methylammonium Iodide

	Phase	E_a/kJ mol^{-1}	$\tau_{RO}/10^{-14}$ s	$C/10^9$ s^{-2}	Motional Mode
CH_3NH_3I	δ	6.6±0.1	2.7	9.8	Correlated C_3 reorient.
	β'	11.2±0.1	73	7.3	C_3 reorient. of CH_3

*Evaluated from T_2.

22 ms appearing at the lower temperature of 154 K in the β' phase of MAI can be assigned to the CH_3 C_3 reorientation, while the deep one (15 ms) at 202 K is attributable to the NH_3^+ C_3 reorientation in agreement with the temperature dependence of M_2 observed in this phase. These assignments of ^1H T_1 minima are acceptable because ^1H T_1 minima calculated for CH_3 and NH_3^+ groups performing the C_3 reorientation in the cation are 23 and 17 ms, respectively, at a Larmor frequency of 20 MHz.[20] The motional parameters and activation energies for the C_3 reorientation of both groups were evaluated in the same way as that described in the foregoing δ phase. The results are given in Table 2 and the calculated curve is shown in Fig. 3 by solid line. The E_a values obtained for the C_3 reorientation of both groups are larger in β' than in δ clearly indicating that the cations in the former phase are more tightly bound in the crystalline lattice in agreement with the foregoing discussion.

It is noteworthy that the β' crystal of MAI yields two ^1H T_1 minima while the δ only a single minimum. This indicates that the correlated C_3 reorientation of the cation is the easiest reorientational mode of the cation in the latter crystal, whereas the barrier of the CH_3 groups to reorient in the former, which is considerably higher than that of the internal rotation, is distinguishably lower enough than that of the NH_3^+ groups. The large E_a value derived for the NH_3^+ C_3 reorientation in β' suggests that this phase has a crystal structure efficiently to be formed by N–H···I type hydrogen bonds.

Room-Temperature α' Phase. In this phase, a ^1H T_1 maximum was observed for both MAI and CH_3ND_3I crystals, and it should be noted that no frequency dependence was observed in the hot side of the maximum. These experimental facts indicate that a new relaxation process other than the usual magnetic dipolar relaxation contributes to ^1H T_1 observed in this phase. The most feasible mechanism for the new motional process is spin-rotation relaxation originating from the uniaxial rotation of the CH_3 and NH_3^+ groups around each C–N bond axis of the cations. For the crystals of several ammonium salts,[22–24] where NH_4^+ ions are thought to be almost free to perform overall rotation, it is reported that ^1H T_1 can be interpreted in terms of this mechanism. Although the present cation performs uniaxial reorientation in the crystal, this process is still valid provided that the reorientation is rapid enough.

When both spin-rotation and magnetic dipolar interactions due to the uniaxial rotation of the cations contribute to ^1H T_1, the observed T_1 can be written by

$$T_1^{-1} = T_{1MA}^{-1} + T_{1SR}^{-1}, \tag{5}$$

where T_{1SR} indicates ^1H T_1 originating from the spin-rotation mechanism. Since the condition, $\omega_H\tau_R \ll 1$ is fulfilled for both CH_3 and NH_3^+ reorientations in the α' phase, T_{1MA} can be connected with the averaged C_3 reorientational correlation time $\bar{\tau}_R$ of these groups by,

$$T_{1MA}^{-1} = (5/2)(C_{CH_3} + C_{NH_3^+})\bar{\tau}_R, \tag{6}$$

where C_{CH_3} and $C_{NH_3^+}$ denote the motional constants for the CH_3 and NH_3^+ C_3 reorientations, respectively, as given in Eq. 2. Therefore, log T_{1MA} is expected to increase linearly with decreasing T^{-1} in this phase because $\bar{\tau}_R$ can be expressed by Eq. 4.

For T_{1SR}, a temperature dependence can be derived from a theoretical consideration that T_{1SR} is propor-

tional to $\bar{\tau}_R$ in the present system.[25] Under a condition that both $\log T_{1MA}$ and $\log T_{1SR}$ change linearly against T^{-1}, the T_1 data observed can be divided into two components by the least-squares method. The best fitted T_{1MA} and T_{1SR} straight lines thus obtained are shown in Fig. 3 using solid lines broken by dots. The gradient of the two lines having opposite signs yielded the same E_a of 5±1 kJ mol^{-1}. This result is compatible with our present assumptions that both T_{1MA}^{-1} and T_{1SR} are proportional to $\bar{\tau}_R$.

Since the present E_a obtained for the C_3 reorientation of the cation is comparable to the thermal energy at 300 K ($RT \approx 2.5$ kJ mol^{-1}), we can say that the cations perform the C_3 reorientation quite freely in this phase. This provides a strong support for the presence of the spin-rotation relaxation. Substituting the value of $(C_{CH_3}+C_{NH_3^+})$ calculated using Eq. 2 into Eq. 6, one obtains $\bar{\tau}_R$ to be 1.5×10^{-13} s at 300 K. This is extraordinarily short for usual solids and nearly the same order of magnitude as those usually observed for nonviscous liquids. For example, $\bar{\tau}_R$ for the C_3 rotation of CH_3 groups in liquid toluene is reported to be ca. 1×10^{-13} s at ca. 250 K,[26] and that for the overall rotation of molecules in liquid ammonia is ca. 2×10^{-13} s at 347 K.[27] ^{1}H T_1 observed for these compounds in their liquid state is reported to clearly involve the spin-rotation mechanism. Therefore, it may be concluded that the spin-rotation relaxation due to highly free uniaxial-rotation of the present cations plays an important role in ^{1}H T_1 observed at elevated temperatures.

High-Temperature ε Phase. The extremely small M_2 and unusually long T_2 values observed for this phase imply that the isotropic rotation of the cation about its center of gravity and also self-diffusion of the cations in the crystal take place rapidly. As reported previously for the highest-temperature solid phase of $CH_3NH_3NO_3$[7,8] the most effective relaxation mechanism in the ε phase of the present salt is expected to be the cationic self-diffusion.

In the present ε phase, MA^+ cations perform isotropic reorientations which are assumed to occur much more frequently than the translational jump of the cation through the lattice sites. This means that we can calculate average distances between protons belonging to different cations by simply regarding as that the all protons in a cation are fictitiously located at the center of gravity of the cation.

In our previous study,[8] we employed the monovacancy mechanism for the explanation of the cationic self-diffusion in crystals as a simple mechanism and could well explain the observed NMR data. According to Torrey and Sholl,[28,29] the ^{1}H spin-lattice relaxation rate, T_{1HH}^{-1} and the ^{1}H spin-spin relaxation rate, T_{2HH}^{-1} due to interionic ^{1}H dipolar interactions which are randomly modulated by self-diffusion can be written by,

$$T_{1HH}^{-1} = 2\alpha y[g(y) + 4g(2y)], \tag{7}$$

$$T_{2HH}^{-1} = \alpha y[3g(0) + 5g(y) + 2g(2y)], \tag{8}$$

where

$$\alpha = (3/20)\gamma_H^4\hbar^2 p a^{-6}\omega_H^{-1}, \tag{9}$$

$$y = (1/2)\omega_H\tau_H. \tag{10}$$

In the above equation, a, p, and τ_H are the lattice constant, the ratio of the number of the resonant protons to the number of the lattice sites in a unit sublattice, and the correlation time of the self-diffusion of the cations respectively. The detailed expression of $g(y)$ is given in Sholl's paper.[29]

Besides magnetic dipolar interactions operative between protons, interactions between protons and iodine nuclei also provide another relaxation process, because iodine nuclei having a large quadrupole moment are expected to have a shorter relaxation time than T_{1HH} due to appreciably fast quadrupolar relaxation even if the crystal has high symmetry such as cubic. In fact, the iodine nuclei in the crystals of the high-temperature phases of NH_4I having CsCl and NaCl type cubic structures are known to have the temperature independent T_1 of ca. 3.2 ms.[30] Under the assumption of shorter ^{127}I T_1, the relaxation times T_{1HI} and T_{2HI} can be expressed by,[18,29]

$$T_{1HI}^{-1} = 2\beta\tau_H[g'\{(\omega_H-\omega_I)\tau_H\} + 3g'(\omega_H\tau_H) + 6g'\{(\omega_H+\omega_I)\tau_H\}], \tag{11}$$

$$T_{2HI}^{-1} = \beta\tau_H[2g'(0) + g'\{(\omega_H-\omega_I)\tau_H\} + 3g'(\omega_H\tau_H) + 6g'(\omega_I\tau_H) + 6g'\{(\omega_H+\omega_I)\tau_H\}], \tag{12}$$

where

$$\beta = (7/12)\gamma_H^2\gamma_I^2\hbar^2 a^{-6}. \tag{13}$$

In these equations, γ_I and ω_I denote the gyromagnetic ratio and the angular resonance frequency of ^{127}I nuclei, respectively. The functional form of $g'(y)$ is the same as that of $g(y)$, where the positional vectors connecting protons are replaced by those connecting ^{1}H and ^{127}I nuclei for the former function.

As another relaxation mechanism between ^{1}H and ^{127}I nuclei, the dipolar relaxation of the second kind proposed by Norris et al.[31] is expected to contribute to ^{1}H T_1 because T_1 of the quadrupolar ^{127}I nuclei is considered to become very short as in the case reported for NH_4I.[30] Since no data of the relaxation times of ^{127}I in any phase of solid MAI are available, we roughly estimated the T_1 value of MAI due to this mechanism. The calculation was performed by use of the equation reported by Norris et al.[31]

assuming the same ^{127}I T_1 value as that of NH_4I described above. The T_1 value evaluated is longer by ca. 10^4 times than the values observed in this phase. This suggests that the contribution of ^{127}I T_1 to the observed T_1 through this mechanism can be neglected in the present discussion.

In Eqs. 11 and 12, the self-diffusion of iodide ions expected to be possibly excited was assumed to be much slower than that of the cations, namely, $\tau_H \ll \tau_I$ by considering their large mass. Here, τ_I indicates the diffusion correlation time of the anion. Eqs. 11 and 12 were proved to be still valid by substituting $(\tau_H^{-1}+\tau_I^{-1})$ for τ_H^{-1}, even if τ_I becomes comparable to τ_H. Since the observed T_1 of the ε phase decreased with increasing temperature, the condition of $\omega_H\tau_H \gg 1$ is reasonably assumed to be fulfilled over the whole temperature range of this phase. Therefore, Eqs. 7, 8, 11, and 12 can be rewritten as,

$$T_{1HH}^{-1} = 4\alpha(S_0 - S_1/\bar{Z})/y, \tag{14}$$

$$T_{2HH}^{-1} = 3\alpha y g(0), \tag{15}$$

$$T_{1HI}^{-1} = \beta[(S_0' - S_1'/\bar{Z})/(\omega_H - \omega_I)^2 + (S_0' - S_1'/\bar{Z})/\omega_H^2 + 2(S_0' - S_1'/\bar{Z})/(\omega_H + \omega_I)^2]1/2\tau_H, \tag{16}$$

$$T_{2HI}^{-1} = 2\beta\tau_H g'(0), \tag{17}$$

where $\bar{Z}$ denotes the number of the nearest neighbors of the simple cubic sublattice. S_i and S_i' are defined in Sholl's paper.[29] Accordingly, the total relaxation rates, $T_{1\varepsilon}^{-1}$ and $T_{2\varepsilon}^{-1}$ determined for the protons of this phase are given by $(T_{1HH}^{-1}+T_{1HI}^{-1})$ and $(T_{2HH}^{-1}+T_{2HI}^{-1})$, respectively.

In Eqs. 14 and 15, S_0, S_1, and $g(0)$ can be calculated by regarding as that the protonic system assumed to be concentrated at the center of gravity of the cation forms a simple cubic sublattice, because the crystal has the CsCl type bcc structure. According to the Sholl paper,[29] he obtained S_0=8.4019, S_1= 11.5739, and $g(0)$=18.21. Using the numerical values evaluated by Sholl[29] for the simple cubic and bcc lattices, S_0', S_1', and $g'(0)$ in Eqs. 16 and 17 applicable to the system involving ^1H-^{127}I interactions were calculated to be 20.644, −3.470, and 32.7, respectively. Employing the following values, a=4.86×10^{-10} m and $\bar{Z}$=6, the total relaxation rates can be obtained as,

$$T_{1\varepsilon}^{-1} = \tau_H^{-1}[20.1\omega_H^{-2} + 0.43(\omega_H - \omega_I)^{-2} + 1.28\omega_H^{-2} + 2.56(\omega_H + \omega_I)^{-2}] \times 10^8, \tag{18}$$

$$T_{2\varepsilon}^{-1} = 1.09 \times 10^9\tau_H. \tag{19}$$

Since ω_H/ω_I is approximately constant for the present case, it is evident from Eq. 18 that $T_{1\varepsilon}$ should be proportional to ω_H^2 at a constant temperature, and also the gradient of the log T_1 versus T^{-1} plot should be constant and independent of ω_H. However, the observed gradients of the log T_1 curves depend on ω_H employed and become gentle with increasing ω_H. Moreover, the ratio of ^1H T_1 observed at 20 and 42.5 MHz is T_1(20 MHz)/T_1(42.5 MHz)=0.36 in disagreement with the theoretical value of 0.22 derived from Eq. 18. These facts suggest that ^1H T_1 observed for the ε phase of MAI cannot be explained by the single relaxation mechanism of self-diffusion as dominantly concerned with.

Here, we introduce another assumption that two relaxation mechanisms appreciably contribute to ^1H T_1 of this phase and one of them involves ω_H whereas the other does not. For this case, the observed T_1 can be expressed by

$$T_1^{-1} = T_{1d}^{-1} + T_{1i}^{-1}, \tag{20}$$

where T_{1d} and T_{1i} represent ^1H T_1, which are proportional to ω_H^2 and independent of ω_H, respectively. Using Eq. 20, two components, T_{1d} and T_{1i}, were obtained from the observed T_1 values. The results are shown in Fig. 5. ^1H spin-rotation interaction already discussed in the α' phase can be proposed as the most probable relaxation mechanism for T_{1i} which decreases with increasing temperature. Because isotropic rotation of the cations is thought to be very rapid in this liquid-like ε phase, it will be the main origin of this mechanism.

The frequency dependent part T_{1d}, on the other hand, can be unequivocally assigned to the self-diffusion of the cations. The E_a value of 35 kJ mol^{-1} was obtained for this motional mode from the slope of the log T_{1d} curves of different ω_H. From the slope of the log T_2 versus T^{-1} curve, the same E_a value should be obtained as that derived above. However, a much larger E_a of ca. 48 kJ mol^{-1} was obtained from the log T_2 curve. Also for CH_3ND_3I, E_a derived from the log T_2 curve (45 kJ mol^{-1}) is much larger than that roughly evaluated from the log T_1 curve observed at 20 MHz (≈30 kJ mol^{-1}), although no accurate value could be determined because the T_1 data of CH_3ND_3I were obtained at only two ω_H.

In the preceding analysis of the relaxation times, we simply assumed that both T_{1d} and T_2 are determined through the same relaxation process. Referring to our T_1 and T_2 data observed in a fairly narrow temperature range without the location of T_1 minimum, the above assumption is not necessarily valid, because the origin of observed ^1H T_1 and T_2 cannot be definitely identified without the data in the temperature range where the condition $\omega_H\tau_H \leq 1$ is satisfied. The fact that the different E_a values were derived from T_{1d} and T_2 suggests the existence of at least two different relaxation processes of self-diffusion.

As one of the relaxation models involving two kinds of self-diffusion processes, it is conceivable for the present ε phase that both cations and anions perform self-diffusion with different correlation times. For this model, τ_H and τ_I can be calculated from the above T_{1d} and T_2 expressions by replacing τ_H^{-1} with $(\tau_H^{-1}+\tau_I^{-1})$. The τ_I values calculated in the whole temperature range observed were negative. This is unreasonable result and, therefore, the above model is unacceptable for the present case.

As another possible model, it is considered that the cations diffuse through the activation of two kinds of self-diffusion mechanisms, i.e., local translational jumps among the adjacent small number of vacancy sites and a long-range self-diffusion mode where the cations migrate to a long distance through many vacancies as already considered for simple ionic conductors.[32] It is expected that the former process gives a shorter τ_H and a smaller E_a than the corresponding values in the latter. By applying this model to the present ^1H relaxation data, we can derive a conclusion that the relaxation process of T_{1d} is thought to be caused by the short-range self-diffusion whereas that of ^1H T_2 is governed by the long-range process.

The observed values of σ shown in Fig. 7 increase discontinuously by three orders of magnitude at T_{tr} to the ε phase. The large value of σ in this phase is attributable to ionic conduction of the diffusible cations, the existence of which is verified by the present NMR study. From σ values observed, we can evaluate the diffusion constant D_σ of the cations using the Nernst-Einstein equation written by

$$D_\sigma = kT\lambda\sigma/(Ze)^2N, \tag{21}$$

where Ze, N, and λ are the charge of diffusing ions, their number in a unit volume, and the spacial correlation factor calculated to be λ=0.65331 for the simple cubic lattice,[33] respectively.

The conductivity measurements in the ε phase gave E_a of 51±3 kJ mol^{-1} which is larger than that derived from T_{1d}(31 kJ mol^{-1}) but close to that from ^1H T_2(48 kJ mol^{-1}). The fact that roughly the same value of E_a was obtained from σ and ^1H T_2 measurements suggests that the two different physical quantities are dominantly determined due to the same diffusion mechanism. In the present study, σ was measured by applying an ac electric field of 1 kHz. Since the transport distance, $\bar{r}_\sigma$ averaged in a time τ can be expressed by[34]

$$\bar{r}_\sigma = \sqrt{6D_0\tau}, \tag{22}$$

it can be shown that the long-range diffusion mainly contributes to σ, where ions migrate for longer distances than the order of 10^2 Å in a half cycle of 1 kHz. This gives a strong support for our previous conclusion about the process determing ^1H T_2.

The entropy changes at T_{tr}(414 K) and T_m of MAI crystals observed by DSC measurements were ΔS_{tr}=15 J K^{-1} mol^{-1} and $\Delta S_m \approx$14 J K^{-1}mol^{-1}, respectively. These values can be compared with ΔS_{tr}=28 J K^{-1} mol^{-1} and ΔS_m=12 J K^{-1} mol^{-1} obtained for $CH_3NH_3NO_3$ crystals,[8] because the highest-temperature solid phase of both crystals is the liquid-like solid one. The fact MAI has ΔS_{tr} smaller than $CH_3NH_3NO_3$ crystal is understandable by considering that spherical iodide ions have no orientational freedom. Although ΔS_{tr} and ΔS_m values in MAI are comparable, the latter is unusually small as compared with that of usual ionic crystals such as NaSCN, KSCN, and KN_3. These salts[35] have ΔS_m of 30—40 J K^{-1} mol^{-1}. Usual molecular plastic crystals[36] are known to have ΔS_m less than ca. 20 J K^{-1} mol^{-1}. Accordingly, it is concluded that the cations in the ε phase are in a state having the most part of their motional freedom in good agreement with the foregoing conclusion derived from the present NMR and X-ray studies, and the ε phase can be considered as a plastic phase. A similar state of molecule-like cations can be found in the highest-temperature solid phase of NH_4NO_3,[37] $CH_3NH_3NO_3$,[7,8] $CH_3NH_3ClO_4$,[7] $(CH_3NH_3)_2SO_4$,[38] and $[C(NH_2)_3]ClO_4$.[39]

The authors are grateful to Prof. S. Kawai and Dr. K. Kitahama of Osaka University and Dr. Y. Furukawa for their help in carrying out the measurements of X-ray diffraction. We also wish to thank Mr. K. Kawase and Dr. K. Toriyama in the Government Industrial Research Institute of Nagoya for help in the experiments of DSC.

(Received September 2, 1985)

Synopsis. Hydrogen storage type electrodes were fabricated from $LaNi_5$ powder after coating with group-IB metals by an electroless plating method, followed by press moulding. The hydrogen electrode reaction (HER) characteristics and mechanical stability during hydrogen charge/discharge cycles were then studied in 1.0 M (M= mol dm^{-3}) NaOH.

Storage type hydrogen/oxidant fuel cells using metal hydrides have been noted for their high energy storage capacities per unit weight.[1] There are, however, various problems to be solved before their realization, e.g. proper choice of systems with suitable pressure of the hydrogen charge/discharge cycles, prevention of pulverization of the hydrogen absorbing metals or alloys (metal hydrides) during use, etc. Ishikawa et al.[2] have reported recently that some hydrogen absorbing alloys can be "microcapsulated" with copper deposited by electroless plating so as to prevent the pulverization during repeated hydrogen charge/discharge cycles and that their hydrogen storage ability after the plating was maintained at the level comparable with those of the untreated alloys. We have reported elsewhere[3] that the electrocatalyst such as Pt or Ag, which possesses the greater rate of the Volmer over that of the Tafel step, namely the greater m_o ($=i_{ov}/i_{oT}$) value, is desirable as a surface modifier in the metal hydride electrode from the viewpoint of the energy efficiency in the charge/discharge cycles.

In this work, $LaNi_5$ powder was microcapsulated with a group-IB metal, and the electrochemical property in alkaline solution was investigated, together with their mechanical stability.

Experimental

Preparation of the Electrodes. $LaNi_5$ powder (particle size about 100 μm and the BET surface area 0.5 $m^2 g^{-1}$) was subjected to electroless plating of Cu or Ag from conventional solutions,[4] or of Au by immersion of the powder in 2.5×10^{-3} M tetrachloroauric (III) acid solution. Amount of the deposition in weight (mol) % was 12.5 (48.6) for Cu, 12.5 (36.4) or 25 (57.2) for Ag, and 25 (42.3) for Au, respectively.

The microcapsulated $LaNi_5$ powder was pelletized into discs (13 mm diameter×1 mm thickness) with use of Ni nets (200 mesh) as electric leads under a static pressure of 400 Kg cm^{-2} and then heated at 770 K in vacuo (5×10^{-4} Pa) for several hours. The $LaNi_5$ samples bound with PTFE [poly(tetrafluoroethylene)] emulsion were prepared according to the method described in the literature.[5] In some occasions, a small amount of Pt was further deposited electrochemically. The nickel nets were spot-welded to Ta wires which were in turn sealed into Pyrex glass tubings.

Electrochemical Measurements. Galvanostatic polarization studies[3] were carried out in 1.0 M NaOH at 303 K. Real surface area of the test electrode was evaluated from the double layer capacitance data assuming a value of 18 μF cm^{-2} (true).

Results and Discussion

HER Characteristics. A series of microcapsulated $LaNi_5$ electrodes showed stable electrochemical behaviors in a similar manner as bare $LaNi_5$ electrodes. Thus, a typical plateau region was clearly observed on their short time (a few seconds) galvanostatic overpotential rise or decay transient curves respectively before the attainment of the steady-state polarization or of equilibrium potential. Through these observations, the electrodes are judged to possess a good hydrogen absorbability. Hence, as discussed previously,[6-8] we could estimate two overpotential components, η_1 and η_2', for the water discharge step and the hydrogen adatom recombination step, respectively.

The Tafel plots of η_1 on these microcapsulated electrodes showed a basic symmetry between the anodic and cathodic branches and the slope of the linear portion was reasonably close to 120 mV $decade^{-1}$. This indicates that η_1 represents the component overpotential for an one electron transfer reaction, namely the Volmer step. Its exchange current density (i_{ov}) estimated from the linear plots of η_1 vs. i, the applied current, near the reversible HER potentials was as follows: Cu/$LaNi_5$ 5.9, Ag/$LaNi_5$; 9.8, and Au/$LaNi_5$; 3.7×10^{-6} A cm^{-2} (true).

On the other hand, the "Tafel lines" of η_2' in the cathodic region gave a slope of ca. 30 mV $decade^{-1}$, except in the region of very high current density where the slope became lower, and indicated that η_2' should be attributed to the Tafel step. The linear η_2' vs. i plots in the low overpotential region resulted in the following i_{oT} values: Cu/$LaNi_5$; 0.7, Ag/$LaNi_5$; 0.8, and Au/$LaNi_5$; 0.6×10^{-6} A cm^{-2} (true), which were roughly one order of magnitude smaller than the corresponding i_{ov} values. The values of i_{ov}, i_{oT}, and m_o ($=i_{ov}/i_{oT}$) estimated of the microcapsulated $LaNi_5$ electrodes are schematically summarized in Fig. 1, together with those observed on some Ni-based alloys[6-8] and PTFE-bound or Pt-modified $LaNi_5$ electrodes.

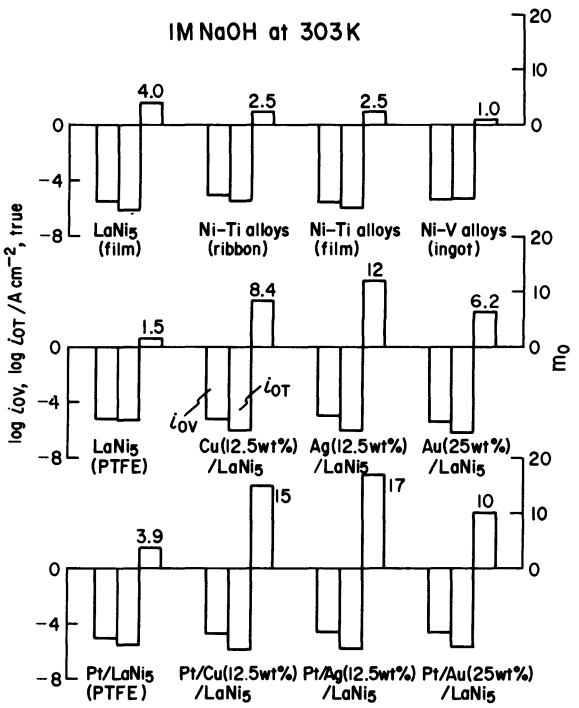

Fig. 1. Schematic diagram of the kinetic data obtained on Ni-based alloy ribbon or film electrodes, $LaNi_5$ electrodes coated with a series of group-IB metals, those further with Pt, and $LaNi_5$ electrodes bound with PTFE. 1.0 M NaOH, 303 K.

Table 1. Activation Energies for the Volmer and Tafel Steps and the Overall Reaction on Ni-Based Electrodes

Electrode	ΔE/kcal mol^{-1}		
	i_{ov}	i_{oT}	i_o
$Cu/LaNi_5$	9.0	4.5	4.6
$Ag/LaNi_5$	8.9	4.4	4.8
$Au/LaNi_5$	8.8	5.1	5.9

It was found that the microcapsulated $LaNi_5$ electrodes possessed much larger m_o values (6—12) than those (1—4) of the bare Ni-based alloys. Furthermore, they were considerably larger than those[3] observed on the group-IB metal electrocatalysts themselves. The larger m_o values were mainly caused by increased rates of the Volmer step and might indicate the existence of a synergistic effect between $LaNi_5$ and group-IB metals. A further increase up to m_o=17 was observed after a deposition of Pt on their surface. The PTFE-bound $LaNi_5$ electrode was mechanically very stable but the m_o value was relatively small (m_o=1.5): No polarization behaviors for HER could be studied with acceptable reliability, however, as hydrogen bubbles tightly adhered to the PTFE surface.

Mechanical Stability. The microcapsulated $LaNi_5$ electrodes prepared in this work were found to be stable even under polarizations up to η=−300 mV for a few ten hours. This was in agreement with the results reported on the hydrogen absorption/desorption cycles in gas phase[2] or in electrochemical system[9] of Cu-coated $LaNi_5$ specimens prepared in a similar manner as in this work. The electrodes were, however, damaged during polarizations over much longer durations even at potentials less than −300 mV.

Temperature Dependence. The activation heats evaluated from the Arrhenius plots of i_{ov}, i_{oT}, and i_o observed on the microcapsulated $LaNi_5$ electrodes are summarized in Table 1. The values were around 9 and 5 kcal† mol^{-1} for the Volmer and the Tafel step, respectively, and were in rough agreement with those observed on other Ni-based alloy electrodes.[6-8] Since the difference between the activation heats of two elementary reaction steps is appreciable (about 4 kcal mol^{-1}), m_o should significantly be increased at higher temperatures. This means that the energy efficiency may be improved if the hydrogen storage cells are operated at higher temperatures, but probably with the cost of decrease of the storage capacity.

Synthesis of 3-Substituted Indoles by a Palladium-Assisted Reaction

Akira KASAHARA,* Taeko IZUMI, Satoshi MURAKAMI, Hiroshi YANAI, and Masayuki TAKATORI†
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received October 3, 1985)

Synopsis. In the presence of palladium(II) chloride, 2-bromoanilines readily react with the methyl vinyl ketone and the ethyl acrylate to produce vinylogous arylamino ketones and esters. A palladium(0)-assisted cyclization of the arylamino ketones and the esters leads to a formation of 3-substituted indoles.

Beginning with the classical Fisher and Reissert methods, many reports on the synthesis of indoles have appeared from practical and theoretical points of view. Specifically, many 3-substituted indoles were well known to have a biological function, either as biochemical intermediates (aurin, tryptophan, tryptamine, serotonin) or as natural drugs (gramine, bufotenine, psilocine).

A variety of heterocyclic compounds can be synthesized using a palladium-catalyzed intramolecular functionalization of olefins as the ring-forming step.[1] Hegedus et al. have recently reported the synthesis of indoles from 2-allylanilines,[2] 2-vinylanilines,[2] and *N*-(3-bromo-2-vinylphenyl)-*p*-toluenesulfoamides[3] by a palladium-assisted cyclization reaction. Independent of their work, we present a new and efficient method for synthesizing 3-substituted indoles in two steps from 2-bromoanilines, based on a palladium-catalyzed reaction.

Bozell and Hegedus[4] reported previously that palladium(II) chloride catalyzed the reaction of anilines with methyl vinyl ketone and methyl acrylate to produce vinylogous arylamino ketones and esters. According to the method, 2-bromoaniline (**1a**), 2-bromo-5-methoxyaniline (**1b**), 2-bromo-3-methoxycarbonylaniline (**1c**), 2-bromo-4-methoxycarbonylaniline (**1d**), and 2-bromo-5-methoxycarbonylaniline (**1e**) reacted with conjugated olefins such as methyl vinyl ketone (**2a**) and ethyl acrylate (**2b**) to vinylogous arylamino ketones and esters (**3**) in good yield (Table 1). Nonconjugated olefins such as 1-hexene, styrene, and ethyl 2-acetamino-4-pentenoate, however, fail to undergo the amination. The structures of the products were determined on the basis of IR, ^{1}H-NMR, and mass spectral measurements and elemental analyses.

Table 1. The Reaction of 2-Bromoanilines and Olefins

2-Bromoaniline	Olefin	Product	Yield/%	Mp(θ_m/°C)
1a	**2a**	**3a**	76	46—47
1a	**2b**	**3b**	79	oil
1b	**2a**	**3c**	85	79—81
1b	**2b**	**3d**	78	67—68
1c	**2a**	**3e**	72	83—84
1c	**2b**	**3f**	74	80—81
1d	**2a**	**3g**	84	82—84
1d	**2b**	**3h**	68	113—114
1e	**2a**	**3i**	83	146—147
1e	**2b**	**3j**	85	112—113

A possible reaction course of **1** to **3** is shown in Eq 1. The catalytic palladium(II) species coordinates an olefin **2** which undergoes a nucleophilic attack by the amine to generate the σ-alkylpalladium complex. The σ-complex then decomposes by β-elimination to give an unstable palladium hydride complex and the observed product **3**. The palladium hydride complex ultimately forms palladium(0), which is reoxidized to palladium(II) by benzoquinone to complete the catalytic cycle.

In acetonitrile, the arylaminated olefins **3** were

warmed with a catalytic amount of palladium(II) acetate and tri-*o*-tolylphosphine to afford the expected 3-substituted indoles (**4**) in high yield (Table 2). The reaction **3** to **4** is thought to proceed by an oxidative addition of an aromatic halide **3** to the palladium(0) complex, followed by an intramolecular olefin insertion and a β-hydride elimination (Eq 2).

Experimental

All melting points are uncorrected. The IR spectra were measured on KBr disks with a Hitachi 260-10 spectrometer and ^{1}H-NMR spectra were obtained using a Hitachi R-22 spectrometer in $CDCl_3$. TMS was used as internal standard. The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer, using a direct-insertion probe at an ionization energy of 70 eV.

General Procedure for the Palladium-Catalyzed Reaction of 2-Bromoanilines (1) with Olefins (2). Dichlorobis-(acetonitrile)palladium(II) (778 mg, 3 mmol), benzoquinone (3.24 g, 30 mmol), lithium chloride (12.70 g, 300 mmol), and olefin 2 (30 mmol) were mixed in THF (100 cm^3) at room temperature. After stirring for 15 min, **1** (30 mmol) in THF (20 cm^3) was added. The resulting mixture was stirred for 24 h at room temperature and the solvent was removed under a reduced pressure. The residue was stirred with ether and filtered; the ether solution was repeatedly washed with 1 M sodium hydroxide(1 M=1 mol dm^{-3}) solution and water. The organic layer was dried over $MgSO_4$ and filtered and the solvent was removed to give the crude product which was purified by column chromatography using silica gel and hexane-benzene (2:1). The results are presented in Table 1.

General Procedure for the Palladium-Assisted Cyclization Reaction Vinylogous Arylamino Compounds (3) to Indoles (4). A mixture of **3** (14.9 mmol), palladium(II) acetate (0.167 g, 0.745 mmol), tri-*o*-tolylphosphine (0.906 g, 2.98 mmol), and triethylamine (1.88 g, 18.6 mmol) in acetonitrile (20 cm^3) was heated in a sealed tube flushed with nitrogen at 100 °C for 20 h. The cooled reaction mixture was diluted with ether and water. The ether layer was separated, washed with water, dried, and concentrated. The remaining residue was chromatographed on silica gel with benzene to give product **4**. The results are presented in Table 2.

The structures of the products were verified by elemental analyses, mass spectrometry, and by their ^{1}H-NMR and IR spectra. The complete ^{1}H-NMR, IR, and elemental analyses data are deposited at the Office of the Editor of the Bulletin of the Chemical Society of Japan (Document No. 8616).

Generation of the Selenonium Ylide by the Carbenic Reaction. Formation of Cyclopropane Derivatives via Selenonium Ylide

Toshikazu IBATA* and Makoto KASHIUCHI
Institute of Chemistry, College of General Education, Osaka University,
Toyonaka, Osaka 560
(Received October 28, 1985)

Synopsis. The $Cu(acac)_2$-catalyzed decomposition of α-diazoacetophenones in the presence of bis(*p*-methoxyphenyl) selenide (**3**) did not give the corresponding selenonium ylide but gave *r*-1,*c*-2,*t*-3-tribenzoylcyclopropanes through the successive reaction of the intermediary selenonium ylide. On the other hand, the reaction of diazodimedone with **3** gave bis(*p*-methoxyphenyl)selenonium 4,4-dimethyl-2,6-dioxocyclohexylide.

The chemistry of the sulfonium ylide has extensively been studied in last two decades from the structural and synthetic interests.[1] Since the early work of Diekmann,[2] thermal and photolytic decomposition of diazo compounds in the presence of sulfides has been recognized as one of the general synthetic method of stable sulfonium ylide.[3] On the other hand, synthesis of the selenonium ylides have not so widely been studied.[4] As a continuation of our work on sulfonium ylide,[5] formation of selenonium ylide by the carbenic reaction was studied.

Results and Discussion

For the stabilization of selenonium ylide, decrease of positive charge induced on selenium atom seems to be effective. Therefore, diphenyl selenide attached by electron-releasing methoxyl groups on the para positions was used as a substrate of the reaction. The $Cu(acac)_2$-catalyzed decomposition of *p*-methoxy-α-diazoacetophenone (**1a**) in benzene solution at 80 °C in the presence of 3 molar amount of bis(*p*-methoxyphenyl) selenide (**3**) gave colorless crystals, mp 161 °C, besides the recovered selenide (**3**). The results of elemental analysis indicated that the product did not contain selenide moiety. The analytical values agreed with the calculated ones for the dimer or trimer of the corresponding carbene (**2**) generated from the diazoacetophenone (**1a**). The spectroscopic data showed that the product is *r*-1,*c*-2,*t*-3-tris(*p*-methoxybenzoyl)cyclopropane (**7a**). In its NMR spectrum the coupling pattern of methine proton signals, δ=3.62 (d, 2H) and 4.14 (t, 1H), revealed that the cyclopropane had trans configuration. Other substituted diazoacetophenones gave the corresponding cyclopropane derivatives in similar reactions in reasonable yields as is shown in Table 1.[6] In order to confirm the catalytic action of the selenide (**3**), the reactions were carried out using different amounts of **3**. When the amount of **3** was reduced to 1/3 of the amount to **1**, the yield of **7** decreased a little. However, 1/20 amount of **1** was still shown to be effective for promotion of the reaction (Table 2). Detailed inspection of these reaction mixtures by column chromatography indicated that neither *r*-1,*c*-2,*c*-3-triaroylcyclopropane nor 1,2-diaroylethylene (**8**) was detected, despite the 1,2-diaroylethylenes were obtained by the copper-catalyzed decomposition of **1** in the absence of sulfide or selenide (**3**).[7]

The reaction seems to be explained in the following Scheme. At the first stage of the reaction, the ketocarbene[8] generated by the $Cu(acac)_2$-catalyzed decomposition of diazoacetophenone reacts with selenide (**3**) to give bis(*p*-methoxyphenyl)selenonium aroylmethylide (**4**). Failure of the isolation of selenonium ylide (**4**) may be attributed to the high reactivity of **4** to give 1:2-betaine (**5**) by the further reaction with **1**. The betaine **5** reacts with another molecule of diazoacetophenone under the liberation of nitrogen affording 1:3-betaine (**6**) which gave the cyclopropane **7** by the cyclization via elimination of selenide (**3**). The elimination process of **3** from the betaine (**5**) to give 1,2-diaroylethylene (**8**) could be neglected because of absence even a trace amount of **8** in the reaction mixture. If the dimer (**8**) was formed,

Table 1. Yields and NMR Chemical Shift of *r*-1, *c*-2, *t*-3-Tribenzoylcyclopropanes

Run	Ar	Yield/%	Chemical shift of methine/δ

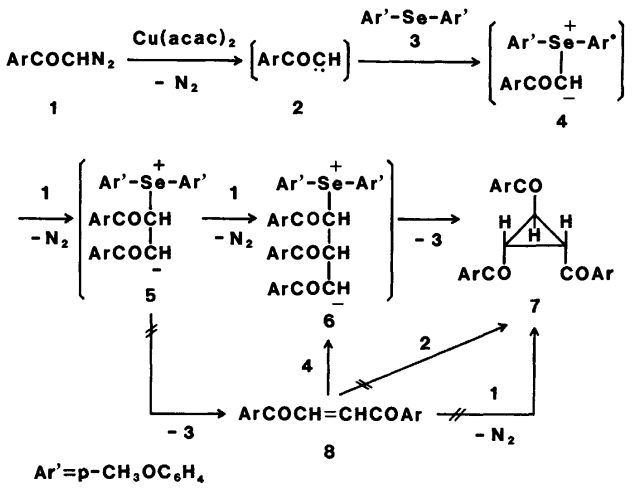
Table 2. The Effect of the Amount of **3** on the Yield of *r*-1, *c*-2, *t*-3-Tritoluoylcyclopropane (**7b**)[a]

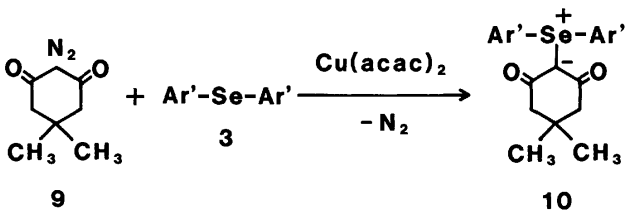
Amount of **3**/g	Yield of **7b**/%
1.00	68
0.50	69
0.30 (1 mmol)	61
0.15	54
0.05	44

a) The reaction was carried out in benzene solution using 3 mmol of *p*-methyldiazoacetophenone and 0.050 g of $Cu(acac)_2$ at 80 °C.



Scheme

the next steps to give cyclopropane (**7**) are: (a) reaction with **1** affording **7** and N_2 directly; (b) reaction with **1** to give **7** and N_2 via corresponding 1,3-dipolar cycloadduct; (c) reaction with the carbene (**2**) to give **7**; (d) reaction with **4** to give the 1:3-betaine (**6**).[10] The processes (a) and (b) are shown not to occur under the reaction conditions (1 atm., 70 °C), and the process (c) can be neglected from the previous observation.[7] The process (d) is possible deducing from the case of sulfonium ylide.[10] The preferential formation of the *trans*-isomer may be explained by the steric factor on the cyclization process.[6]



Another method to attain the stability of ylides is to attach electron-attracting groups on anionic carbon of the ylide. Therefore, the diazodimedone (**9**) was used as an example of diazodiacyl compound instead of diazoacetophenones. Decomposition of **9** in a similar manner in the presence of selenide (**3**) gave 40% yield of expected selenonium ylide (**10**), which was confirmed by the spectroscopic data showing singlet ^{1}H NMR signals of two methoxyl, two methyl, and two methylene groups at δ 1.10, 3.82, and 2.37 ppm, respectively together with those of aromatic protons. This indicates that the product includes both selenide and carbene components. The C=O absorption of the selenonium ylide (**10**) at 1580 cm^{-1} also supported the ylide structure **10** in comparison to that of dimethylsulfonium diacetylide at 1565 and 1595 cm^{-1}.[9]

Experimental

The IR spectra were recorded on Perkin-Elmer model 983 and the ^{1}H NMR spectra were measured in $CDCl_3$ solution at 90 MHz on a Varian Spectrometer model EM390 using TMS as an internal standard.

Materials. Substituted α-diazoacetophenones were synthesized by the reaction of corresponding acid chlorides with excess diazomethane according to the method of Newman.[11] Diazodimedone was prepared from dimedone via diazo group transfer reaction using tosyl azide and triethylamine.[12] Bis(*p*-methoxyphenyl) selenide was prepared by the reaction of *p*-methoxyphenyldiazonium chloride with potassium selenide.[13]

General Procedure of the Cu(acac)$_2$-Catalyzed Decomposition of α-Diazoacetophenones in the Presence of 3. A benzene solution of α-diazoacetophenone (3 mmol) and **3** (1.00 g, 3.4 mmol) was heated at 70 °C in the presence of 10 mg (0.04 mmol) of Cu(acac)$_2$ until the evolution of N_2 ceased. The reaction mixture was separated by silica-gel column chromatography.[14]

Decomposition of Diazodimedone in the Presence of 3. A benzene solution of diazodimedone (0.50 g, 3 mmol) and **3** (1.00 g, 3.4 mmol) was refluxed for 10 h in the presence of catalytic amount of Cu(acac)$_2$. Separation of the reaction mixture through silica-gel column chromatography gave white crystals; mp 194-6 °C, 0.52 g (40%). Found: C, 61.04; H, 5.72%. Calcd for $C_{22}H_{24}O_4Se$: C, 61.25; H, 5.61%.

Improved Optical Resolution of (±)-1,2-Diphenylethylenediamine

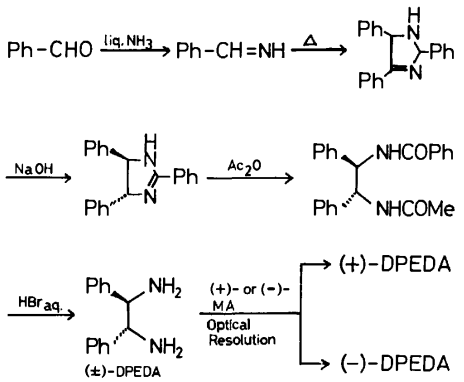
Kazuhiko SAIGO,* Naomi KUBOTA, Shoko TAKEBAYASHI, and Masaki HASEGAWA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received November 11, 1985)

Synopsis. (±)-1,2-Diphenylethylenediamine (DPEDA) was efficiently resolved by the fractional crystallization of its diastereomeric salts with optically active mandelic acid. ^{1}H-NMR spectrum of *N*-monoacylated DPEDA with an optically active derivatizing agent showed that DPEDA thus obtained was optically pure.

(±)-Diphenylethylenediamine (DPEDA) having an interesing structure of C_2 symmetry has been frequently used as a unique ligand of several metal complexes.[1] Moreover, it can be an auxiliary in asymmetric induction and an optically active component for the synthesis of optically active polyamides. From the viewpoint of synthetic utilization of optically active DPEDA, it is very important to develop a highly efficient method for the optical resolution of (±)-DPEDA. For its optical resolution there has been reported only one method using optically active tartaric acid as a resolving agent.[2] However, this seems to have some operational problems since it is very hard to recrystallize the diastereomeric salt deposited from the reaction mixture of (±)-DPEDA with optically active tartaric acid. Additionally, (+)-DPEDA is difficult to obtain in pure state because nonnatural type (−)-tartaric acid is too expensive to obtain in a large quantity.

In the present paper, we describe an efficient optical resolution of (±)-DPEDA by fractional crystallization using optically active mandelic acid (MA) as a resolving agent, of which both enantiomers are industrially available. We also confirmed the specific rotation of optically pure DPEDA, for which various values have been reported previously.[2]

(±)-DPEDA was prepared from benzaldehyde via isoamarine according to the methods in the literatures,[1a,3] as shown in the following scheme. The



reaction of (±)-DPEDA with two molar amounts of (+)-MA gave a mixture of diastereomeric salts. Recrystallization of the mixture for two times from ethanol yielded (+)-DPEDA·(+)-MA (1:2) salt in 82% yield. (−)-Enriched DPEDA, recovered from the mother solution and the filtrates, was allowed to react with two molar amounts of (−)-MA, and the resulting salt was similarly recrystallized twice from ethanol to give (−)-DPEDA·(−)-MA (1:2) salt in 82% yield. Decomposition of each salt with aqueous sodium hydroxide solution gave (+)- and (−)-DPEDA in 72 and 79% total yields, respectively.

To determine the optical purity, (+)-DPEDA ($[\alpha]_D^{22}$ +106.5° (*c* 1.07, MeOH)) was acylated with (−)-(benzylmethylphenylsilyl)acetic acid (BMPSA),[4] giving monoacylated (+)-DPEDA. Its ^{1}H-NMR spectrum was compared with that of *N*-monoacylated (±)-DPEDA. On the basis of the area ratio of methyl protons of the (−)-BMPSA resudue in two diastereomeric monoamides, the optical purity of (+)-DPEDA was found to be 99.6%. Consequently, the specific rotations of optically pure DPEDA were determined as follows.

Table 1. The Specific Rotations of Optically Pure DPEDA

Solvent	[α] 589	577	546	435	405
MeOH[a]	106.9	109.8	126.3	243.7	290.5
Et_2O[b]	82.6	85.4	99.8	191.3	243.0

a) *c* 1.07 at 22 °C. b) *c* 0.97 at 18 °C.

Experimental

Melting points were measured by a laboratory devices MEL-TEMP apparatus and are uncorrected. IR spectra were recorded on a JASCO IR-810 Spectrophotometer. Optical rotations were masured by a JASCO DIP-360 Digital Polarimeter. ^{1}H-NMR spectra were recorded on a JEOL JMR GX 400 Spectrometer.

(±)-DPEDA was prepared by the methods reported in the literature,[1a,3] mp 76—77 °C (lit,[3] 83 °C).

Optical Resolution of (±)-DPEDA. (±)-DPEDA (1.70 g, 8 mmol) and (+)-MA (2.43 g, 16 mmol) were dissolved in ethanol (20 ml) on heating. After cooling to room temperature, the crystals deposited were collected by filtration and washed with two portions of ethanol (1.5 ml each). Recrystallization of the mixture of the diastereomeric salts for two times from ethanol (25 ml then 20 ml), followed by drying over P_2O_5 under reduced pressure, gave almost pure (+)-DPEDA·(+)-MA (1:2) salt (1.69 g, 82% based on the half amount of DPEDA used): Mp 164—165 °C; IR (KBr) 3450 (-OH), 3100 ($-\overset{+}{N}H_3$), and 1530 ($-CO_2^-$) cm^{-1}; $[\alpha]_{435}^{16}$ +278.8°, $[\alpha]_D^{16}$ +126.9° (*c* 1.51, MeOH).

Calcd for $C_{30}H_{32}N_2O_6$: C, 69.75; H, 6.24; N, 5.42%. Found: C, 69.49; H, 6.11; N, 5.30%.

The minus enriched DPEDA (0.96 g, 4.5 mmol), recovered from the mother liquor and the filtrates by treating with aqueous sodium hydroxide, was similarly reacted with (−)-MA (1.37 g, 9 mmol) in ethanol (20 ml) on heating.

Cooling the solution at room temperature gave almost pure (−)-DPEDA·(−)-MA (1:2) salt (1.70 g, 82% based on the half amount of DPEDA used) without any recrystallization: Mp 163—164 °C; IR (KBr) 3450 (-OH), 3100 ($-\overset{+}{N}H_3$), and 1530 ($-CO_2^-$) cm^{-1}; $[\alpha]_{435}^{20}$ −277.9°, $[\alpha]_D^{20}$ −126.5° (*c* 1.40, MeOH).

Calcd for $C_{30}H_{32}N_2O_6$: C, 69.75; H, 6.24; N, 5.42%. Found: C, 69.78, H, 6.31; N, 5.36%.

(+)-DPEDA·(+)-MA (1:2) salt (1.68 g, 3.3 mmol) was treated with 4 mol dm^{-3} sodium hydroxide solution (36 ml) and extacted with ether (3×40 ml). The extracts were combined, dried over sodium hydroxide pellets, and concentrated under reduced pressure. Recystallization of the remaining residue from hexane gave (+)-DPEDA (0.61 g, 72% based on the half amount of DPEDA used): Mp 85—86.5 °C (lit,[2c] 80 °C); IR (KBr) 3380 ($-NH_2$), 3360 ($-NH_2$), and 705 (-Ar) cm^{-1}; $[\alpha]_D^{22}$ +106.5° (*c* 1.09, MeOH).

Calcd for $C_{14}H_{16}N_2$: C, 79.21, H, 7.60, N, 13.20%. Found: C, 79.26; H, 7.40; N, 13.00%.

The enantiomeric excess of (+)-DPEDA thus obtained was determined as follows: The ^1H-spectrum of the diastereomeric N-monoacylated mixture, prepared from (±)-DPEDA and (−)-BMPSA according to the procedure in the literature,[4] showed two methyl proton signals at δ 0.216 and 0.247 ppm, which correspond to methyl proton signal of the (−)-BMPSA residue in each diastereomeric N-monoacylated DPEDA. The integral ratio of these signals was 1:1. The ^1H-NMR spectrum also showed two methyl proton signals, of which integral ratio was 249:1. Based on this integral ratio, the enantiomeric excess of (+)-DPEDA was established to be 99.6%.

Using the values of the specific rotation and the enantiomeric excess of (+)-DPEDA, the specific rotation of optically pure DPEDA was calculated as shown in the Table.

A similar alkaline treatment of (−)-DPEDA·(−)-MA (1:2) salt (1.70 g, 3.3 mmol) gave (−)-DPEDA (0.67 g, 79% based on the half amount of DPEDA used): mp 85.5—86 °C (lit,[2c] 85—90 °C); $[\alpha]_D^{16}$ −105.2° (*c*, 1.06, MeOH); 97.5% optical purity.

Calcd for $C_{14}H_{16}N_2$: C, 79.21; H, 7.60; N, 13.20%. Found: C, 79.25; H, 7.30; N, 13.16%.

Similar satisfactory results were obtained when the optical resolution was carried out in 0.1—0.05 mol scales.

The authors wish to express their thanks to Dr. Daiyo Terunuma of Saitama University for a gift of optically active BMPSA.

Application of Electron Spectroscopy for Chemical Analysis to Studies of the Composition of Icosanoic Acid Monolayer

Koichi KOBAYASHI* and Kyo TAKAOKA
Laboratory of Chemistry, Musashi Institute of Technology, Setagaya-ku, Tokyo 158
(Received July 30, 1985)

Synopsis. Electron spectroscopy for chemical analysis (ESCA) was used to determine the composition of icosanoic acid (n-$C_{19}H_{39}COOH$) monolayer deposited on the microscope glass slide from the water surface containing Cd^{2+} at varying pH. It was found that the monolayers deposited from substrate at pH<4.6, pH>6.6, and pH=4.6—6.6 consist of icosanoic acid, cadmium icosanoate, and mixture of both substances, respectively.

A knowledge of the composition of a Langmuir-Blodgett film (L-B film) is important for understanding of its properties and structures. The compositions of L-B films have been studied by means of IR spectroscopy,[1,2] neutron activation analysis,[3] and photomeric measurements.[4]

Electron spectroscopy for chemical analysis (ESCA) has been attracting attention as a powerful method for determining structure and composition on the surface layer of materials. Few ESCA studies of Langmuir-Blodgett films, however, have been reported.[5,6]

In the present investigation, the attempt was made to determine the composition of icosanoic acid monolayer deposited on a microscope glass slide from cadmium substrate at various pHs by ESCA.

Experimental

Materials. Icosanoic acid (purity of 99%), cadmium chloride and potassium hydrogencarbonate were obtained from Sigma Chemical Co., Wako Pure Chemical Ind., and Kanto Kagaku Co., respectively and were used without further purification. Other chemicals used were of analytical reagent grade. Icosanoic acid was dissolved in purified chloroform to make a spreading solution of 3×10^{-4} mol dm^{-3}. The pH of the solution in the trough was adjusted by the addition of aqueous solutions of NaOH and HCl.

The water used was distilled three times after refluxing ordinary distilled water with acid permanganate, and then distilling it from an alkaline permanganate solution.

Apparatus. The substrates for film deposition were commercially available microscope glass slides (24 mm×50 mm×0.5 mm). The surfaces of the microscope slides were cleaned in the following manner: they were first sonicated with distilled water, subsequently soaked in a cleaning solution of concentrated acid permanganate overnight, rinsed repeatedly with distilled water, and then dried in a desiccator. The monolayer was prepared in a Langmuir trough (40 mm×385 mm×7 mm) with a well of a water depth of 37 mm and was deposited on the microscope glass slide by lifting the previously immersed glass slide at a velocity of 7 mm min^{-1} at constant surface pressure of 29.5 mN m^{-1}, which was given by the use of piston oil (*cis*-9-octadecenoic acid).

The solution in the trough was 3×10^{-4} mol dm^{-3} $CdCl_2$ and 5×10^{-4} mol dm^{-3} $KHCO_3$ with varying pH. Under these conditions, no visible drops of water occurred on the microscope slides. The deposition ratio was monitored by comparing the geometric area of the microscope slide to the change in the monolayer area during the deposition process at constant surface pressure. Only monolayer films whose deposition ratio was maintained within 100±1% were used in this experiment.

ESCA measurements were made with a JEOL JESCA-4 spectrometer using Mg $K\alpha$ X-ray source (1253.6 eV). The samples were mounted to give a take-off angle of 45°. The peak areas of the C_{1s} and Cd_{3d} bands of the samples were measured to calculate the composition of the cadmium icosanoate monolayer.

All the experiments were carried out at about 20 °C.

Results and Discussion

It is important to know the escape depth of photoelectrons in the case of quantitative analysis using ESCA. Brundle et al.[7] reported that the escape depth of photoelectrons from gold, silver, and indium substrates through cadmium icosanoate (2.68 nm thick) was 3.6—4.1 nm. In our study, the escape depth for photoelectrons emitted from Cd through the icosanoate moiety is generally expected to be larger than that determined for cadmium icosanoate. In addition, recent studies[8-10] on the structure of L-B film indicate that the orientation of molecules to the substrate surface is perpendicular in the first layer of the deposited monolayers either of long chain fatty acids or their salts. Therefore, the peak areas of the Cd_{3d} and C_{1s} bands observed are assumed to be proportional to the amount of Cd and C in the monolayer films, respectively.

The vacuum stability of the monolayer film deposited at pH 7.4 were studied. Figure 1 shows the effect of time on the peak areas of C_{1s} and Cd_{3d} bands under a pressure of about $(2—4)\times10^{-8}$ mmHg (1 mmHg=133.322 Pa). As can be seen in Fig. 1, the peak areas of C_{1s} bands decrease linearly with increasing time, while the peak areas of Cd_{3d} bands are almost invariable within experimental error. The investigations of the vacuum stability of deposited films of cobalt octadecanoate[11] and cadmium icosanoate[12] show that the salts of these fatty acids are stable even under high vacuum. Thus, the decrease in peak area of C_{1s} band is considered to be caused by the breaking of the hydrocarbon chain in cadmium icosanoate under the X-ray radiation. Accordingly, all subsequent ESCA experiments were performed over a time period during which the damage to the hydrocarbon chain was negligible.

Figure 2 shows typical C_{1s} and Cd_{3d} photoelectron spectra obtained from the deposited monolayer at pHs' 4.7, 5.8, and 7.6. In Fig. 2, we can see the photoelectron signals for C_{1s} at 288.0 eV, which correspond to the carbon (284.3 eV) of the ordinary hydrocarbon chain. The shift in the C_{1s} peak occurs by the electrical insulating properties of the monolayer and glass. In addition, it is evident from Fig. 2,

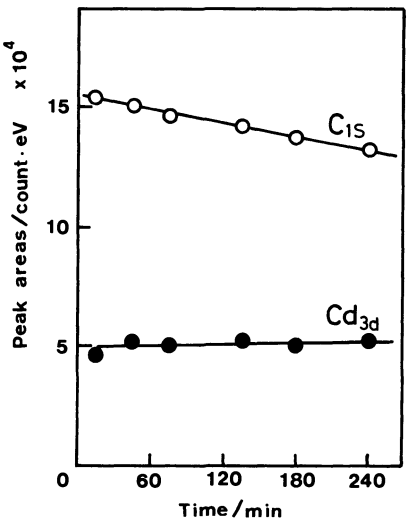

Fig. 1. Vacuum stability of cadmium icosanoate monolayer. The monolayers were deposited from cadmium substrate with pH=7.4.

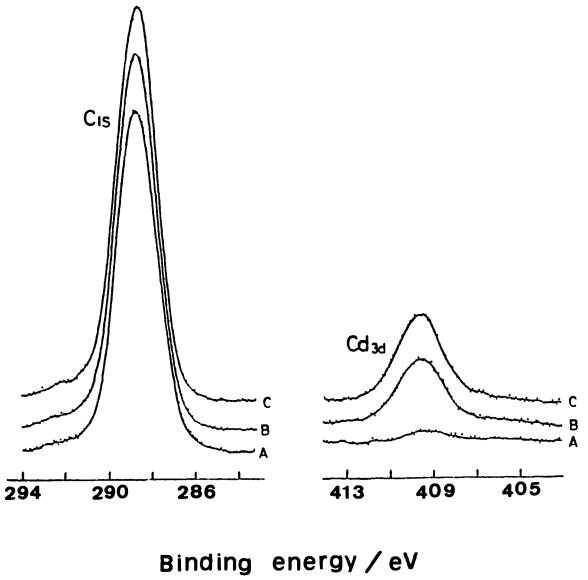

Fig. 2. C_{1s} and Cd_{3d} peaks for monolayer deposited from cadmium substrate with varying pH.
A: pH 4.7, B: pH 5.8, C: pH 7.6

that the carboxylic carbon band appears as a shoulder on the high energy side.[13] Also, we observed that the peak area of Cd_{3d} band was nearer to 0 in the lower pH region than about 4.6 and showed a constant value in the higher pH region than about 6.6. The near zero value at lower pH indicates no formation of cadmium icosanoate([Cd/RCOOH]=0), while the constant value at higher pH indicates the formation of cadmium icosanoate([Cd/RCOOH]=0.5), considering the pK_s value of 5.6. In order to calculate the [Cd/RCOOH] ratio at various pH, we assumed a linear relationship between the peak area of the Cd_{3d} band and the pH. The Cd_{3d}/C_{1s} peak area ratio calculated from the peak area of Fig. 2 and the [Cd/RCOOH] ratio were plotted against pH. The results are shown in Fig. 3. In this figure, the Cd_{3d}/C_{1s} peak area ratio or the [Cd/RCOOH] ratio

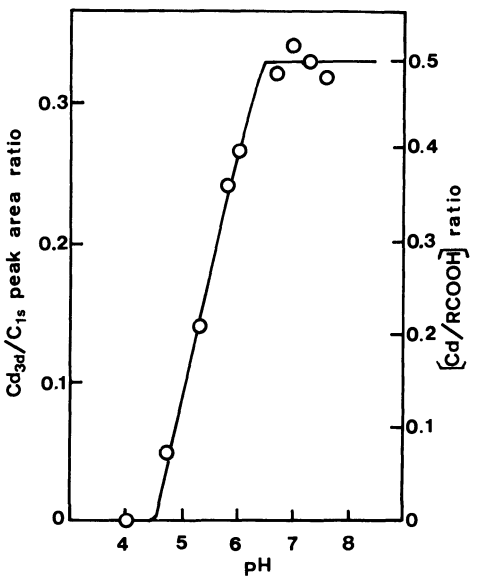

Fig. 3. Dependence of Cd_{3d}/C_{1s} peak area ratio or [Cd/RCOOH] ratio on pH.

increases from about pH 4.6 and reaches a plateau above about pH 6.6. In the lower pH region, the value of [Cd/RCOOH] is 0 which means the absence of cadmium ions. In the higher pH region, the value of [Cd/RCOOH] is about 0.5 which corresponds to the equivalent proportion of one bivalent cation to two fatty acids. Therefore, the monolayer deposited from solutions with pH<4.6 and pH>6.6 consist of icosanoic acid and cadmium icosanoate, respectively, and the monolayer deposited from solutions with pH=4.6—6.6 consist of the mixture of free acid and cadmium salt. Our experimental results are in good agreement with the observations of Petrov et al.,[3] using a combination of Langmuir-Blodgett technique and neutron activation analysis.

Influence of Higher Alcohols on Acid-Catalyzed Hydrolysis of Sodium Dodecyl Sulfate. Effect of Complex Formation

Masayuki NAKAGAKI and Shoko YOKOYAMA*
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-Shimoadachi-cho, Sakyo-ku, Kyoto 606
(Received September 20, 1985)

Synopsis. The order of effectiveness of 1-alkanols for increasing the rate of acid-catalyzed hydrolysis of sodium dodecyl sulfate is 1-dodecanol>1-tetradecanol ≫ 1-decanol. The effect of 1-alkanols on this hydrolysis is discussed from the viewpoint of formation of complexes composed of SDS and 1-alkanol.

In our preceding paper,[1] we reported the influence of 1-dodecanol ($C_{12}OH$) on the acid-catalyzed hydrolysis of sodium dodecyl sulfate (SDS) at concentrations above and below the critical micelle concentration (cmc). The hydrolysis of SDS at a concentration below the cmc is accelerated by addition of $C_{12}OH$ due to formation of a complex (SDS:$C_{12}OH$=2:1), and at concentrations above the cmc is initially suppressed by addition of $C_{12}OH$ due to reduction in surface charge density of the SDS micelle.

On the other hand, it has been known that complexes are formed not only between $C_{12}OH$[2-6] and SDS but also between other 1-alkanols[7,8] and SDS.

In this paper, therefore, we will deal with the influence of higher alcohols on the acid-catalyzed hydrolysis of SDS at concentrations below the cmc from the viewpoint of complex formation.

Experimental

Normal higher alcohols, 1-octanol (C_8OH), 1-decanol ($C_{10}OH$), 1-dodecanol ($C_{12}OH$), and 1-tetradecanol ($C_{14}OH$) obtained from Nakarai Chemicals Co. were of guaranteed reagent grade and used without further purification. Sodium dodecyl sulfate (SDS) was the same as that specified in our preceding paper.[1] Solutions were prepared by adding 1-alkanol to an aqueous 0.5 mmol dm^{-3} solution of SDS, followed by stirring for 20 h at 25 °C. The hydrolysis of SDS was carried out at pH 3.22±0.01 and 25±0.2 °C, and second-order rate constants were estimated as previously described.[1]

Results and Discussion

Effects of C_8OH, $C_{10}OH$, $C_{12}OH$, and $C_{14}OH$ on the Hydrolysis of SDS. Figure 1 shows rate constants for the hydrolysis of SDS against concentrations of 1-alkanols (or mole ratios of 1-alkanol to SDS). The relationship between $C_{12}OH$ and SDS which has been given in the preceding paper[1] is also included in Fig. 1. When the solution contains only premicellar SDS, the rate constant for the hydrolysis is very small but is increased markedly by addition of $C_{12}OH$ or $C_{14}OH$. Above mole ratio 0.5 of 1-alkanol to SDS, the rate constant is independent of the 1-alkanol concentration, which suggests formation of a complex of SDS with $C_{12}OH$[5,6] or $C_{14}OH$.[7]

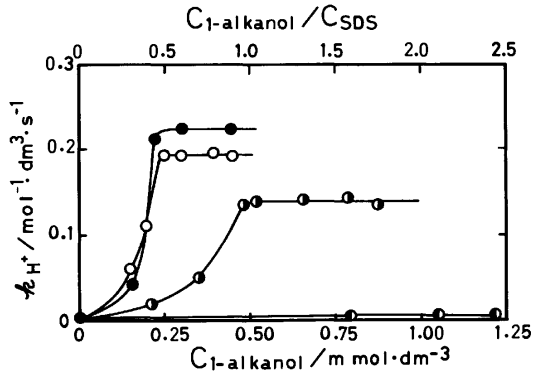

Fig. 1. Effect of 1-alkanols on the rate constant for hydrolysis of SDS at a concentration below the cmc
1-alkanol: ◐ C_8OH, ◑ $C_{10}OH$, ● $C_{12}OH$, ○ $C_{14}OH$
C_{SDS}: 0.50 mmol dm^{-3}
pH: 3.22

In the case of $C_{10}OH$, the rate constant increases with increasing concentration of $C_{10}OH$ and assumes a constant value at mole ratios of $C_{10}OH$ to SDS above 1.0. This tendency is consistent with formation of a 1:1 complex of SDS with $C_{10}OH$.[8]

The rate constants in the presence and absence of C_8OH do not so much differ from each other, even if C_8OH is added above mole ratio 2.0 to SDS. This suggest that there is no characteristic interaction between SDS and C_8OH. It has been reported[9] that a liquid crystal is formed in the C_8OH–SDS–water ternary system at a SDS concentration of 40 w/v%. We used too low a concentration of SDS for the formation of micelle (cmc values of SDS in the presence of 1-alkanols have been reported[8]). Therefore, it may be concluded that neither liquid crystal nor surfactant-alcohol complex is formed in this C_8OH system.

Regarding the relationship between the formation of liquid crystal and the rate constant for the hydrolysis of SDS, Barry and Schotten[10] reported that the rate constant was increased by an addition of 1-hexadecanol ($C_{16}OH$) due to formation of a liquid crystal in the $C_{16}OH$–SDS–water ternary system.

Effect of Complex Formation on Rate Constant. It has been suggested[4,6,7] that these complexes are formed by hydrogen bonding between the oxygen atom of sulfate and the OH group of alcohols. Therefore, the faster hydrolysis of SDS in the complexed state than in the noncomplexed state may be considered due to a proton being supplied by hydrogen bonding from $C_{12}OH$ to SDS in the first step of the hydrolysis mechanism:[11,12]

First step

$$C_{12}H_{25}OSO_3^- + H^+ \longrightarrow C_{12}H_{25}OSO_3H,$$

Second step

$$C_{12}H_{25}OSO_3H + H_2O \longrightarrow C_{12}H_{25}OH + HSO_4^- + H^+.$$

Moroi et al.[6] suggested that alkyl alcohol is more strongly bound to alkyl sulfate in a complex with alcohol to sulfate mole ratio 0.5 than in one with mole ratio 1.0. It is, therefore, considered that the complex with mole ratio 0.5 is more easily supplied with a proton in the first step of the hydrolysis than the one with mole ratio 1.0, which facility leads to the order of rate constants of hydrolysis: $k_c(C_{10}OH) < k_c(C_{12}OH)$, $k_c(C_{14}OH)$. In addition, the smaller k_c of the $C_{14}OH$-SDS complex than that of the $C_{12}OH$-SDS complex is considered due mainly to the steric effect. It is further considered that the aggregation of $C_{14}OH$ with SDS is more difficult than that of $C_{12}OH$ with SDS, because the two carbon atoms of $C_{14}OH$ protrude from the alkyl chain of SDS. This is consistent with the fact[4] that the complex between alkyl sulfate and 2-alkanol cannot be formed because of a difficulty of the aggregation.

Conclusion

The rate constant for the hydrolysis of SDS is increased by addition of $C_{10}OH$, $C_{12}OH$, or $C_{14}OH$ due to formation of complex (SDS:$C_{10}OH$=1:1), (SDS:$C_{12}OH$=2:1), or (SDS:$C_{14}OH$=2:1), respectively. Furthermore, the order of effectiveness of 1-alkanols for increasing the rate constant is $C_{12}OH > C_{14}OH > C_{10}OH$. This is due to the strength of hydrogen bonding between SDS and 1-alkanols and the steric effect of the complex.

In conclusion, we call attention to the difference in the effects of 1-alkanols on the hydrolysis of SDS (with respect to the formation of complex between SDS and 1-alkanols, and the rate constant for the complexed state), in contrast to the suggestion of Barry and Schotten[10] that $C_{16}OH$ and $C_{12}OH$ have a similar effect on the hydrolysis.

Effective Rotational Temperatures of N_2^+ (X) Produced by Electron-Impact Ionization on N_2

Hirofumi KAWAZUMI, Tuneaki UCHIDA, and Teiichiro OGAWA*
Department of Molecular Science and Technology, Kyushu University, Kasuga, Fukuoka 816
(Received September 21, 1985)

Synopsis. The laser-induced fluorescence of molecular ions, N_2^+ (X, $^2\Sigma_g^+$), was measured under the controlled electron-impact ionization of N_2 in the thermal gas jet. The effective rotational temperature of N_2^+ (X) increased from 320±5 K to 367±15 K for the incident electron energy from 750 eV to 17 eV.

The rotational distribution of ions should be a valuable probe of the dynamics of the ionization process. Nitrogen molecule is suitable for this purpose. The ionization process to the B state of N_2^+ has been studied upon the electron-impact ionization-excitation.[1,2] At high electron energies, $\Delta|J|=1$ is obeyed; at low electron energies (<100 eV), however, $\Delta|J|\geq 3$ transitions occur through multipole transitions.[2]

The rotational distribution has been measured on the X state of N_2^+ produced by controlled electron impact in the thermal gas flow[3,4] and the supersonic beam[5,6] using laser-induced fluorescence (LIF) technique. The incident electron energies previously used, however, were only 60[3] and 100[3,4] eV in the former and 50,[5] 80,[5] and 300[6] eV in the latter.

In this study, we measured the rotational distribution of N_2^+ (X) in the thermal gas jet at the wide electron energy range of 17—750 eV, and determined the effective rotational temperature (T_R) of N_2^+(X) in order to discuss the ionization process.

Experimental

The apparatus has been described in detail previously.[4] In brief, the sample gas was jetted into a collision chamber through a multicapillary array and was crossed perpendicularly with an electron beam. The excitation light was produced by a N_2 laser pumped tunable dye laser (Molectron UV24+DL14). The signal was accumulated using gated detection electronics with a boxcar integrator or a 100 MHz photoncounter. We calculated the number density of ions to be about 10^8 ions cm^{-3} from the electron-beam current (500 μA), the sample gas pressure (0.13 Pa), the ionization cross section (1.0×10^{-16} cm^{-2}),[7] and the fly-out rate coefficient from the laser-irradiation region (1.4×10^6 s^{-1}). There are comparable number of ions in the ion trap techniques.[8,9] About 0.2 counts of the LIF signal per laser pulse were necessary to obtain a good spectrum with a signal to noise ratio of 15 in several hours of accumulation; the typical intensity of scattering light from the laser was 0.04 counts.

Results and Discussion

A typical excitation spectrum of the B($v'=0$)—X($v''=0$) of N_2^+ (X) produced by controlled electron impact on N_2 at the incident electron energy of 28 eV is shown in Fig. 1. The relative rotational line intensities, $\ln\{I_{N',N''}/(N'+N''+1)\}$, were plotted versus

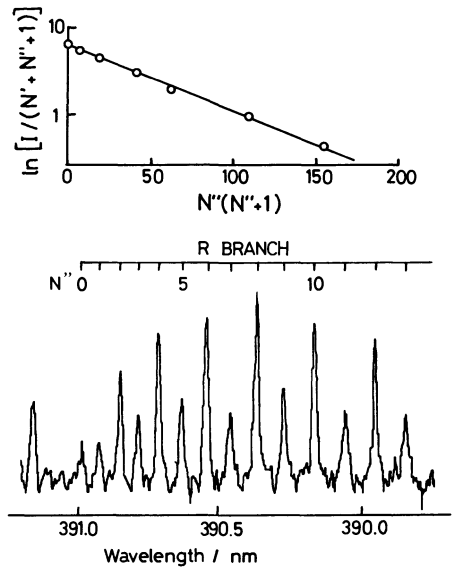

Fig. 1. Excitation spectrum of N_2^+ (X) (lower) and the rotational line intensity plot of even N'' lines of R branch (upper). Electron energy was 28 eV and N_2 pressure was 0.13 Pa.

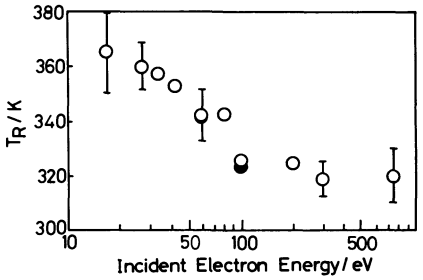

Fig. 2. The electron energy dependence of the effective rotational temperature (T_R) of N_2^+(X) produced by electron-impact ionization on N_2.
●: Allison et al., ○: this work.

$N''(N''+1)$, where N' and N'' are the upper and lower rotational quantum numbers of the transition, as also shown in Fig. 1. The plots were linear at all incident electron energies and gave the effective rotational temperature (T_R) of N_2^+ (X).

The electron energy dependence (17—750 eV) of T_R is shown in Fig. 2. The results obtained at 60 and 100 eV agree with the previous values[3] within experimental uncertainties. T_R was constant above 100 eV, and increased below 100 eV up to 367±15 K at 17 eV; T_R at 17 eV was higher by about 50 K than T_R at 750 eV.

In order to estimate effects of collisional relaxation, fly-out rate of the ions from the laser-irradiation

region has been measured through the intensity changes of the LIF signal at various delay times (0—2 μs) of the laser after the end of the pulsed electron beam. The LIF signal decayed exponentilly. The first-order decay analysis leads to a fly-out rate coefficient of 1.4×10^6 s^{-1} and a characteristic fly-out time of 0.71 μs. These values agree with the free diffusion rate estimated from the gas dynamics; a nitrogen molecular ion with the root-mean-square velocity of 511 m/s at 20 °C flies across the laser beam with the radius of 0.5 mm in about 1 μs. The characteristic collisional time at a pressure of 0.13 Pa is about 100 μs. These findings indicate that the observed spectrum was not disturbed by collisional relaxation. Cascade contributions are unimportant as the radiative lifetime of the A state (10 μs) is longer than the characteristic fly-out time and the ionization-excitation cross section to the B state is small[7]

In the ionization process for a homonuclear diatomic molecule such as H_2 and N_2, the selection rule of a rotational transition indicates ΔN to be an even number, e.g., $N''=N$, $N''=N\pm2$, and $N''=N\pm4$, where N and N'' are the rotational quantum number of N_2 and N_2^+ (X).[10,11] Change of the rotational quantum numbers between neutral and ionic molecules balances the angular momentum of the ejected electron, since the total angular momentum is conserved. In the photoionization of H_2, $\Delta N=0$ and $\Delta N=2$ transitions were observed with rotationally resolved photoelectron spectroscopy and $\Delta N=2$ transition was accounted for coupling between the p and f photoelectron waves.[11] The electron-impact ionization may be accompanied by an ejected electron with the large angular momentum through the multipole transition.[12] Therefore, the increase of T_R at lower electron energies is due to the increase of larger N transitions. At higher electron energies, $\Delta N=0$ transition is predominant and T_R of N_2^+ (X) do not change from that of N_2.

The electron energy dependence of T_R of N_2^+ (X) in this paper is considerably different from that of N_2^+ (B) previously reported.[13] This may be caused by the fact that the molecular orbital of the ejected electron for N_2^+ (X) is σ_g 2p, while that for N_2^+ (B) is σ_u 2s. The detailed analysis requires an experimental determination of the partial cross-section for each ΔN transition from a single rotational level.

The authors thank Professor Tamotsu Kondow of the University of Tokyo for his comments. The present study was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (56470014).

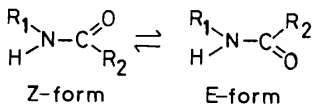
Kinetic Studies of Fast Equilibrium by Means of High-Performance Liquid Chromatography. XIII.[1] Separation of Rotamers of *N*-Alkyl-Substituted Amides

Masataka MORIYASU,* Atsushi KATO, and Yohei HASHIMOTO
Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658
(Received September 26, 1985)

Synopsis. Rotamers of *N*-alkyl-substituted amides have been separated by means of high-performance liquid chromatography(HPLC) at low column temperatures. The ratios of the *E*-rotamers have been found to increase in the following order: propionamides<acetamides<formamides.

We have already reported[1-3] the separation of rotamers of anilides by means of HPLC at low column temperatures. A similar separation seems to be possible for aliphatic amides. This report deals with the separation of rotamers of *N*-alkyl-substituted amides. The separation is found to be rather



Chart

difficult for the following reasons, although the energy barriers of the bond rotation about the carbonyl-nitrogen bonds for aliphatic amides are higher than those for anilides.[4] (1) Since aliphatic amides usally have only weak UV absorption in the range shorter than 230 nm, their detection is not easy when the amount is low. Furthermore, the solvent systems usable in HPLC is seriously restricted. (2) Aliphatic amides, especially their low molecular weight analogues such as *N*-methylformamide and *N*-methylacetamide, are adsorbed strongly on the surface of silica gel, and therefore broad and tailing peaks appear on the chromatograms.

Experimental

N-Methylformamide, *N*-methylacetamide, *N*-ethylacetamide, *N*-benzylformamide, and *N*-benzylacetamide were obtained commercially. *N*-Ethylformamide, *N*-propylformamide, and *N*-isopropylformamide were prepared from trichloroacetaldehyde (chloral) and the corresponding aliphatic amines.[5] *N*-Propylacetamide, *N*-isopropylacetamide, *N*-methylpropionamide, *N*-ethylpropionamide, and *N*-propylpropionamide were prepared by the reaction of acetamide (or propionamide) with hydrochlorides of aliphatic amines.[6] These synthesized amides were all purified by distillation. Several silica gel packings with different adsorptive activity (LiChrosorb SI 60, LiChrosorb SI 100, LiChrosphere SI 1000, and LiChrosphere SI 4000) were tried, and the least active among them (LiChrosphere SI 4000) gave the best results. Other experimental conditions were detailed elswhere.[1-3]

Results and Discussion

We first attempted the separation of rotamers of *N*-benzylformamide because this aliphatic amide has relatively strong absorption in the UV by dint of the benzyl substituent and the presence of both *E*-and *Z*-rotamers had been confirmed by NMR study.[7] The solvent system of hexane and 1-propanol containing a small amount of acetic acid, which had been successfully applied for the separation of rotamers of acetanilides,[3] did not give the separation of rotamers at different column temperatures (25 to −50 °C). The replacement of 1-propanol by other alcohols also did not give satisfactory results. The addition of acetic acid to the eluent had a significant effect on the peak shape and very broad and tailing peaks were obtained in the complete absence of acid. The increase of the acetic acid content suppressed tailing, but the two rotamers were still not separated. Addition of too much acetic acid is not suitable for UV detection due to the UV absorption of acetic acid. The activity of silica gel packings also had significant effects on the peak shape and the less active packings gave the better results. Other various solvent systems were tested for the separation of the rotamers of *N*-benzylformamide. The solvent system of hexane and ethyl acetate containing a small amount of acetic acid[2] achieved the separation of the rotamers at 0 °C, but this solvent system could not be used for other aliphatic amides due to the UV absorption of ethyl acetate. The use of other various common solvents including esters, ketones, and alkyl halides, was also impossible. The only solvent system which separated the rotamers was a mixture of hexane and diethyl ether containing a very small amount of acetic acid. Under this solvent system rotamers of *N*-alkyl-substituted amides including *N*-benzylformamide were separated as is exemplified in Fig. 1. The separation of formamides was achieved near 0 °C, while for the separation of acetamides a lower column temperature (−20 °C) was required. With the increase of the column temperature the two peaks

coalesced gradually and at room temperature only one peak appeared. As shown in Fig. 1 the HPLC conditions are far from ideal due to tailing. Further addition of acetic acid would alleviate tailing, but this was impossible for the UV detection. Contrary to formamides and acetamides, *E*-rotamers of propionamides were not detected even at very low column temperatures (−60 °C), which suggests that either the content of the *E*-rotamers is very low (<0.5%) or retention times of the two rotamers are close to each other. We consider that the former explanation is more probable. Table 1 indicates the percentages of *E*-rotamers in chloroform. The identification of the peak was carried out by comparing the HPLC results with the data obtained by ^{1}H-NMR for formamides.[8] The presence of *E*-rotamers of acetamides had not hitherto been reported by NMR studies,[4] but the presence of a few percent of *E*-rotamers was confirmed by HPLC. The following sequence of increasing percentages of *E*-rotamers (propionamides<acetamides<formamides) is explained in terms of the difference in steric hindrance between R_1 and R_2 in the *E*-forms.

The ratios of rotamers should also be affected by various conditions such as concentration, temperature, and solvent composition in which the amides are dissolved. *N*-Methylformamide was dissolved in several solvents (0.2 mol dm^{-3}, 25 °C) and the percentages of *E*-rotamers were determined which were as follows; 11% (carbon tetrachloride), 11% (chloroform), 10% (benzene), 9.0% (tetrahydrofuran), 8.2% (ethyl acetate), 8.2% (acetonitrile), 7.0% (diethyl ether), 6.3% (ethanol), and 5.8% (methanol). The effect of the concentration was also examined for *N*-methylformamide in chloroform, and the percentages of the *E*-rotamer were as follows; 13% (0.13 mol dm^{-3}), 11% (0.67 mol dm^{-3}), and 7.8% (6.7 mol dm^{-3}). The population ratios were relatively insensitive to the solvent composition and concentration, although some tendency was observed for the content of the *E*-rotamer to be slightly higher in nonpolar solvents and in dilute solutions. Similar behavior was also observed for other formamides such as *N*-ethylformamide and *N*-benzylformamide. This behavior is different from that of formanilides because the population ratios of formanilides are sensitive to the solvent composition as well as to the concentration[2] due to ring dimer formation.[9] The population ratios of formamides have more resemblance to those of *o*-substituted acetanilides.[3] These results suggest that ring dimer formation does not play an important role in the case of formamides. The population ratios of acetamides, on the other hand, resemble those of *o*-unsubstituted acetanilides.

The attempt to determine the rotational energy barriers by means of HPLC[1] was not carried out due to tailing. It can however, be safely concluded that the energy barriers for aliphatic amides are larger than those for anilides, because the separation of the rotamers of aliphatic amides was possible at relatively higher column temperatures. It can also be concluded that the energy barriers to the bond rotation of formamides are higher than those of acetamides.

Spectrophotometric Determination of Nickel with Sarcosinexylenol Blue

Joichi UEDA,* Yukiko FUKAZAWA, and Yuu KOIZUMI
Department of Chemistry, Faculty of Education, Kanazawa University,
Marunouchi, Kanazawa 920
(Received October 11, 1985)

Synopsis. Sarcosinexylenol Blue (SXB) was synthesized and the possibility of using SXB as a spectrophotometric reagent was examined. The fundamental conditions for the photometric determination of nickel which gave relatively strong coloration with SXB were studied. The simultaneous determination of nickel and zinc was also studied.

In a series of sulfophthalein derivatives, there are many useful compounds utilized as the spectrophotometric reagents for various metal ions.[1,2] The authors have newly synthesized Sarcosinexylenol Blue, 3,3′-bis[*N*-(carboxymethyl)methylaminomethyl]-*p*-xylenolsulfophthalein, as sulfophthalein derivative and examined its color reactions with metal ions. It was found that this reagent generally does not react as sensitively as Xylenol Oragne[1] which is a representative sulfophthalein reagent. However it gives relatively strong colors with some metal ions such as nickel, cobalt, cadmium, and iron(III), and there is a possibility to use this reagent as the photometric reagent for those ions. Nickel gave the strongest color, and we have studied in detail the best conditions for its use for the photometric determination of this ion and for the simultaneous determination of nickel and zinc. The usefulness of SXB in comparison with Glycinethymol Blue, Glycinecresol Red, and Methylthymol Blue[3] has been established, these have a similar structure to that of SXB, but SXB is more sensitive than those reagents. It also has relatively good selectivity for the diverse ions. The results obtained are shown below.

Experimental

Reagents. Standard Metal Solutions: A solution containing about 1 mg cm^{-3} of nickel or zinc was prepared by dissolving guaranteed reagent grade metal nitrate in a small amount of nitric acid and diluted with distilled water. The solutions were standardized by complexometric titration.

SXB Solution: A 0.05% SXB solution was prepared by dissolving in distilled water a weighed amount of SXB. The SXB was synthesized from Paraxylenol Blue, sarcosine, and formaldehyde by the Mannich condensation,[1] and separated from the reaction mixture on a cellulose column by 1-butanol saturated with 10% acetic acid. Then, the SXB was passed through a column of cation-exchange resins to convert it to the free acid form. The SXB, obtained as on orange compound has mp 137—140 °C. The result of the elemental analysis was as follows. Found: C, 56.52; H, 6.33; N, 4.12; S, 5.15%. Calcd for $C_{31}H_{36}O_9N_2S \cdot 2H_2O$: C, 57.41; H, 6.17; N, 4.32; S, 4.94%.

Buffer Solution: The pH was adjusted with 0.1 mol dm^{-3} borax-0.1 mol dm^{-3} hydrochloric acid and 0.1 mol dm^{-3} borax-0.1 mol dm^{-3} sodium hydroxide.

All the other reagents used were of guaranteed reagent grade.

Results and Discussion

Absorption Curves of SXB. The absorption spectra of 6.2×10^{-5} mol dm^{-3} SXB solution at various pH are shown in Fig. 1. The SXB solution colors reddish-orange in 4 mol dm^{-3} nitric acid. The color of the solution changes to yellow with increasing pH, but, over the pH range from 1.8 to 5.0, there is no color change and the solutions show almost the same absorption curves having an absorption maximum at 439—443 nm. On increase of the pH, however, the color of the solution changes again, and it becomes yellow-green at pH 6.0, blue-violet at pH 10.8, violet at pH 11.7, and blue at 13.4. With these color changes, the absorption maximum at 439—443 nm decreases, accompanied by an increase of that at 599—602 nm. At pH 13.4, the absorption maximum of the solution shifts to 611—614 nm.

Complexes of SXB and Metal Ions. The color reactions between SXB and metal ions were investigated. The results are summarized in Table 1, nickel, cobalt, cadmium, and iron(III) gave relatively strong colors whose molar absorptivities are $1—2\times10^4$. The chemical formula of the nickel complex obtained by mole ratio method is $Ni(SXB)_2$. In the case of zinc, there are two complexes, $Zn(SXB)_2$ at 650 nm and $Zn(SXB)_3$ at 580 nm. Cobalt forms $Co(SXB)_2$. Concerning the compositions of the cadmium and iron(III) complexes, no clear results could be obtained.

Determination of Nickel. Standard Procedure: A sample solution containing up to 60 μg of nickel is

Fe^{3+}	5.3	Reddish violet	524—529	1.4×10^4	
Co^{2+}	9.8	Blue	649—650	1.6×10^4	1:2
Ni^{2+}	10.1	Blue	640—642	2.2×10^4	1:2

Alkali metals, alkaline earth metals, bismuth(III), scandium, yttrium, thorium, zirconium, molybdenum(VI), and tungsten(VI) did not react with SXB. * Weak color.

placed in a 25 cm^3 volumetric flask. Then, 10 cm^3 of buffer solution and 5 cm^3 of 0.05% SXB solution are added. After making up the volume to 25 cm^3 (the final pH: 10.1), the absorbance is measured at 641 nm against a reagent blank.

Absorption Curves of Nickel Complex: The colored solution of the nickel complex has an absorption maximum at 640—642 nm which is nearly constant at pH 10.0—10.5.

The Effect of the Amount of SXB: The maximum and almost constant absorbance was obtained by adding from 3 to 7 cm^3 of 0.05% SXB solution for 20 μg of nickel.

Calibration Curves: Beer's law is observed up to 2.4 μg cm^{-3} of nickel. The relative standard deviation for five determinations was 0.91%.

Simultaneous Determination of Nickel and Zinc: The colored solution of the zinc complex has two absorption maxima at 579—582 and 649—651 nm. On the other hand, that of the nickel complex has only one absorption maximum at 640—642 nm. As a result, the absorbance at 649—651 nm of the zinc complex is affected by the absorbance of the nickel complex, but the absorbance at 579—582 nm of the zinc complex is not affected by that of nickel complex. Utilizing these facts, the simultaneous determination of these two elements has been investigated. Satisfactory results were obtained for a solution containing 5—25 μg of nickel and 20—50 μg of zinc. The procedure is as follows. The sample solution containing nickel and zinc is placed in a 50 cm^3 Erlenmeyer's flask. Then, 10 cm^3 buffer solution and 6 cm^3 of 0.05% SXB solution are added. After being kept for a few minutes in about 50 °C water bath, the solution is cooled with running water, transferred to a 25 cm^3 volumetric flask, and diluted to the mark with distilled water (the final pH: 10.1). The absorbance is measured at 580 and 650 nm within 15 min against a reagent blank. Zinc is determined from the absorbance at 580 nm, then, nickel is determined by subtracting the absorbance due to zinc from the total absorbance at 650 nm.

The Effect of Diverse Ions: The effect of thirty-seven diverse ions on the determination of 20 μg of nickel and 50 μg of zinc has been examined. Concerning anions, the presence of 10 mg each of oxalate, citrate, tartrate, phosphate, and sulfate, and 1 mg of fluoride does not interfere with either the nickel or the zinc determinations. For cations, nickel can be determined within 5% error in the presence of 500 μg each of alkali metals, alkaline earth metals, aluminium, gallium, gold, scandium, yttrium, lanthanoids, thorium, molybdenum(VI), and tungsten(VI), 100 μg each of indium, antimony(III), and manganese(II), and 20 μg each of bismuth(III), mercury(II), and palladium. But beryllium, tin(IV), lead, copper, zinc, cadmium, chromium(III), iron(III), and cobalt interfere with the determination. For the zinc determination, the presence of 500 μg each of alkali metals, alkaline earth metals, aluminium, gallium, bismuth(III), gold, scandium, yttrium, lanthanoids, thorium, molybdenum(VI), tungsten(VI), and palladium, 100 μg each of indium, antimony(III), and manganese(II), and 50 μg of mercury(II) does not interfere with the determination. Beryllium, tin(IV), lead, copper, cadmium, chromium(III), iron(III), cobalt, and nickel interfere when the measurements are carried out at 650 nm, but the interference from cobalt and nickel can be eliminated by the measurements at 580 nm.

A Molecular Orbital Approach to the Effect of Acid and Base on Mutarotation of D-Glucose

Akira IMAMURA,* Toshiya OKAJIMA, and Katsuya KANDA
Department of Chemistry, Faculty of Science, Hiroshima University,
Higashisenda-machi 1-1-89, Naka-ku Hiroshima 730
(Received November 15, 1985)

Synopsis. Molecular orbital calculations were performed for the study of the mechanism of the mutarotation of D-glucose (in Fig. 1) by the CNDO/2 method. The calculated results for a proposed mechanism are in good agreement with the experimental results in relation to the effect of the acid and the base, suggesting the validity of the proposed mechanism of mutarotation.

The mutarotation of D-glucose in solution is caused by the interconversion between α- and β-anomers. The mutarotation has been reported to be accelerated by acid or base, but this reaction is accelerated by the combination of both acid and base.[1,2] The proposed mechanisms of the acid, the base or the acid-base catalysis are shown in Fig. 1. All the three mechanisms include the formation of a chain intermediate by the cutting of the C_1–O_α bond. If we assume that the formation of this chain intermediate is the rate-determining step, it follows that if the acid or the base accelerates the breaking of the C_1–O_α bond, the reaction rate of the mutarotation should become faster on the whole. To investigate the validity of this interpretation, we performed a molecular orbital calculation by the CNDO/2 approximation,[3] and tried to inquire into the effect of the acid or the base.

Results and Discussion

The molecular structures of α- and β-D-glucose were determined by the energy gradient method in the CNDO/2 approximation using the program package GEOMIN.[4] The molecular structures thus obtained reproduced fairly well those obtained by the X-ray diffraction method.[5] In order to examine the effect of the acid and the base, we built models for the three mechanisms shown in Fig. 1. We chose H_3O^+ for the acid and H_2O, NH_3, OH^- for the base. The structures of the acid and the bases were optimized fully by the energy gradient method. H_3O^+ was set on the equatrial position of the ether oxygen(O_α) and the distance between the ether oxygen and the proton of H_3O^+ is 1.5 Å. The distance between the central atom of the bases and the proton of the anomeric OH group is also 1.5 Å. The central atom of the bases and this OH group were on a straight line. The conformation of the bases are as follows; the dihedral angle of C_1–O_β–O(base)–H′ equals to 90 degrees for H_2O and that of C_1–O_β–N(base)–H′ 180 degrees for NH_3. H′ stands for a proton of the bases. For OH^-, the proton of OH^- ion was set linearly. The position of the proton of the bases was determined so as to reduce the steric hindrance. We selected the arrangement of all atoms of the bases in this manner.

Furthermore, we define the symbols for special species; isolated glucose molecule is glucose^0, glucose interacting with H_3O^+ at the ether oxygen is glucose$^+$ and glucose^0 and glucose$^+$ interacting with the bases at the anomeric OH group are glucose^0-"base" and glucose$^+$-"base", respectively.

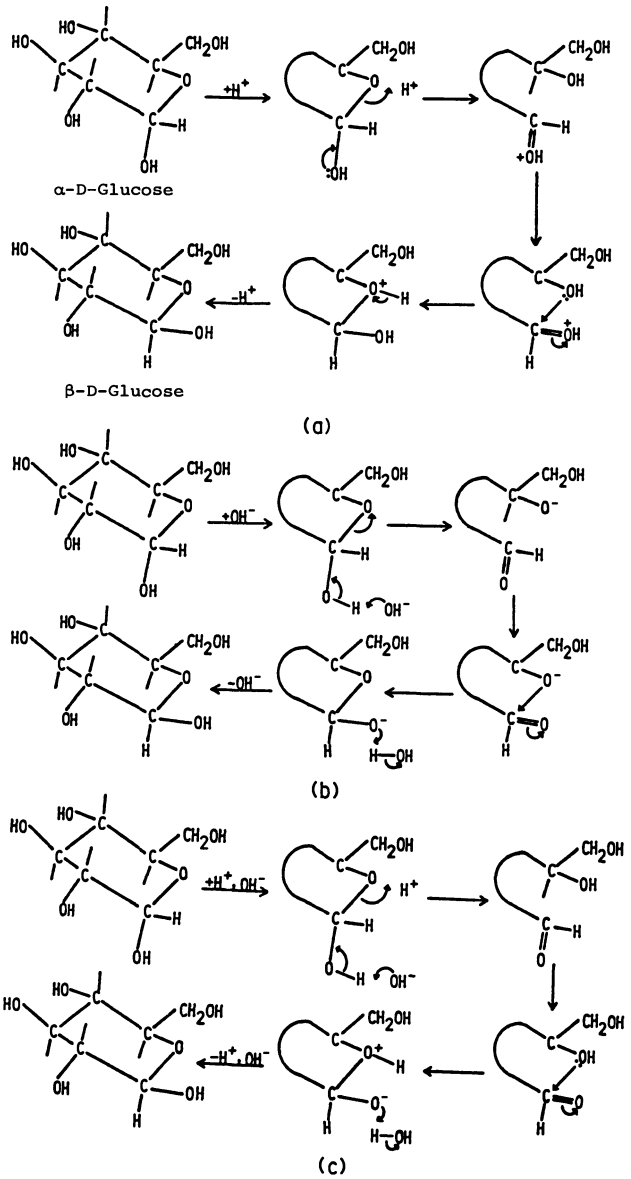

Fig. 1. (a) Acid catalyzed mechanism of mutarotation. (b) Base catalyzed mechanism of mutarotation. (c) Acid and base catalyzed mechanism of mutarotation.

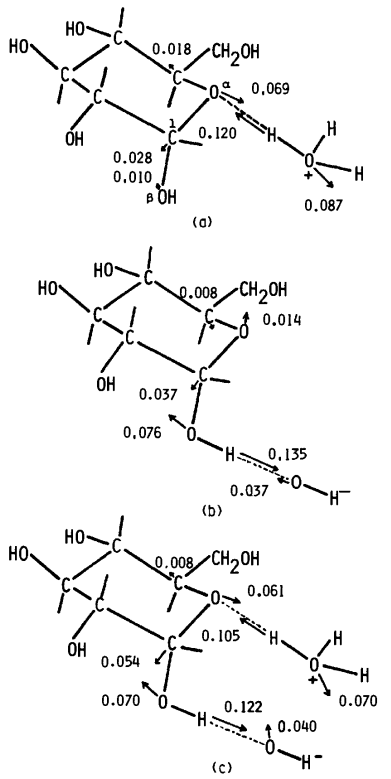

Fig. 2. Force on each atom for glucose$^+$ (a), glucose -OH$^-$ (b), and glucose$^+$ -OH$^-$ (c). Arrows in the figure represent the directions of forces, and numbers represent the magnitude of the forces in hartree/bohr.

For these models, the forces acting on the atoms were calculated by the energy gradient method. The results are shown in Fig. 2 for α-D-glucose. The common feature for the acid catalysis (a)(c) is that the force on the proton of H_3O^+ and that on the ether oxygen acts so as to attract each other and form a new O-H bond. As for the base catalysis (b)(c), the force on the proton of the anomeric OH group acts to elongate this O-H bond. Moreover it is noteworthy that the force to lengthen the C_1-O_α bond acts on both atoms and the C_1-O_β bond tends to shorten for all systems. These results are common to H_2O and NH_3. Needless to say glucose^0 has no component of force on each atom since its molecular structure was determined to be the equilibrium one by the energy gradient method.

In all model systems, the C_1-O_α bond was weakened by the interaction between glucose^0 and the acid or the base. The effects of the acid and the base were quantitatively evaluated by using the energy partition technique in the CNDO/2 method. The total energy (E) in the CNDO/2 method is represented in following form,

$$E = \sum_A E_A + \sum_{A<B}\sum E_{AB}$$

where E_A denotes the monoatomic contribution to the total energy of atom A, and E_{AB} the diatomic contribution of atoms A and B. The terms involved in E_A and E_{AB} were already evaluated in the literature[6] and hence are omitted here. The effects of the acid and the base were quantitatively evaluated by using the value of $E_{C_1\text{-}O_\alpha}$. That is, E_{AB} was regarded as a measure for the bond energy. In Table 1, the values of $E_{C_1\text{-}O_\alpha}$ are listed for α-D-glucose. This indicates that the C_1-O_α bond energy decreases in both glucose$^+$ and glucose^0-"base", and decreases much more in glucose$^+$-"base". These are in good agreement with the magnitude and the directions of the forces shown in Fig. 2. From these results, it is expected that the acid and the base increase the reaction rate for the mutarotation and the combination of the acid and the base increases the rate much more.

Next, on the supposition that the base abstracts the anomeric hydroxyl proton, $E_{C_1\text{-}O_\alpha}$ was calculated at

$r_e+0.2$	4.80	6.88	14.94
$r_e+0.3$	5.53	8.23	17.77

a) $\Delta E_{AB} = E_{AB}(\text{Glucose}^0\text{-"base"}) - E_{AB}(\text{Glucose}^0)$. b) $\Delta E_{AB} = E_{AB}(\text{Glucose}^+\text{-"base"}) - E_{AB}(\text{Glucose}^+)$. c) Optimized anomeric O_β-H bond length (r_e) is 1.032(Å).

three bond lengths of the O–H group. The differences in $E_{C_1\text{-}O_\alpha}$ between glucose^0 and glucose^0-"base" or between glucose$^+$ and glucose$^+$-"base" are respectively listed in Table 2 for α-D-glucose, indicating that the C_1–O_α bond energy decreases as the bond length of the O–H group increases. Moreover, the extent of the weakening of the C_1–O_α bond has relation to the strength of the base; OH^- remarkably decreases $E_{C_1\text{-}O_\alpha}$ followed by NH_3 and H_2O. The same results were obtained in β-D-glucose. That is, when the acid and the base interact with β-D-glucose, the forces on the atoms and the changes of the C_1–O_α bond energy have the same tendency as α-D-glucose.

Conclusion

We studied the effect of the acid or the base for the formation of a chain intermediate by analysis of both force and the C_1–O_α bond energy. From the results, we propose that the acid or the base facilitates the cleavage of the C_1–O_α bond and therefore speeds up the mutarotation as the whole. We also conclude that the acid-base catalysis increases the reaction rate more than the acid or the base catalysis alone and that the stronger the base the greater is the effect. Consequently, we can explain the experimental result by the present calculation and therefore suggest that the mechanism of the acid and the base catalysis in Fig. 1 is valid.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education. We are also grateful to the Information Processing Center of Hiroshima University for generous permission to use HITAC M-200H.

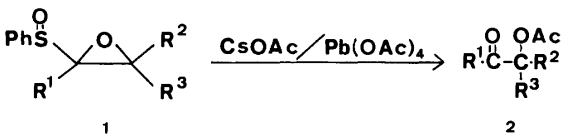
α,β-Epoxy Sulfoxides as Useful Intermediates in Organic Synthesis. IV.[1] A Novel Synthesis of α-Acetoxy Ketones from α,β-Epoxy Sulfoxides

Tsuyoshi SATOH, Shigeyasu MOTOHASHI, and Koji YAMAKAWA*
Faculty of Pharmaceutical Sciences, Science University of Tokyo,
Ichigaya-funagawara-machi, Shinjuku-ku, Tokyo 162
(Received September 21, 1985)

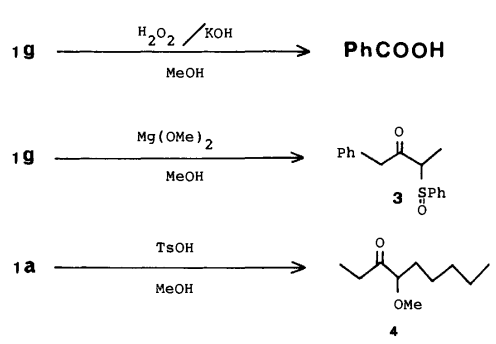
Synopsis. The treatment of α,β-epoxy sulfoxides, prepared from 1-chloroalkyl phenyl sulfoxides with ketones or aldehydes, with cesium acetate in dimethyl sulfoxide in the presence of lead tetraacetate afforded α-acetoxy ketones in moderate to good yields.

α-Oxygenated ketones are useful intermediates in synthetic organic chemistry. Recent years have seen a dramatic development in the synthetic procedures for α-hydroxy ketones and their derivatives. Among them, the acyloin condensation method[2] is one of the most well-known. The addition of acyl anion equivalents, such as lithium aldimines,[3] α-methoxyvinyllithium,[4] or carbanion of dithioacetal[5] to carbonyl compounds is a convenient procedure for constructing α-hydroxy ketones. The reaction of enol silyl ethers or enol acetates with *m*-chloroperbenzoic acid followed by hydrolysis,[6] acetoxylation of ketones with lead tetraacetate,[7] or direct oxidation of enolates with oxidants[8] are other good methods for the preparation of α-hydroxy ketones and their derivatives.

Recently, we reported[9] a new and versatile procedure for synthesizing α-substituted carbonyl compounds from α,β-epoxy sulfoxides (**1**). In the course of studies on the synthesis of α-substituted carbonyl compounds from α,β-epoxy sulfoxides (**1**), a new and efficient procedure was found which has a very different methodology from those mentioned above for the synthesis of α-acetoxy ketones (**2**). Such a procedure is given in Scheme 1.



Scheme 1.



Scheme 2.

It has already been reported[9] that the β-carbon of α,β-epoxy sulfoxides is highly reactive with various kinds of nucleophiles (including selenolates, thiolates, and amines) to afford carbonyl, α-sulfenylated carbonyl, and α-amino carbonyl compounds, respectively, in good yields. On the other hand, oxygen nucleophiles are known to have fewer nucleophilic properties than those of sulfur and nitrogen. In fact, alcoholates and potassium acetate were found to show almost no reactivity toward α,β-epoxy sulfoxides (**1**) in alcohol or in dimethyl sulfoxide (DMSO) at a temperature below 50 °C (within 30 min). On the other hand, a treatment of **1g** with alkaline hydrogen peroxide in methanol gave benzoic acid in 58% yield. A treatment of **1g** with magnesium methoxide in refluxing methanol yielded a rearranged product, 1-phenyl-3-phenylsulfinyl-2-butanone (**3**), in 63% yield. An acidic opening of the epoxy group of **1a** with *p*-toluenesulfonic acid in methanol gave the desired 4-methoxy-3-nonanone (**4**); however the yield was not sufficient. After much work, we at last found that the treatment of **1** with cesium acetate[10] in DMSO (in the presence of lead tetraacetate) afforded the desired α-acetoxy ketones in good yield. The results are summarized in Table 1.

In reactions in the absence of lead tetraacetate, the yields of the α-acetoxy ketones (**2**) were always less than 50% and α-phenylthio ketones[9a,11] were observed. To prevent the formation of this by-product, some oxidants were added to the reaction mixture and it was found that two equivalents of lead tetraacetate[12] worked well. Further, lead tetraacetate was found to show no reactivity toward α,β-epoxy sulfoxides in DMSO, namely the treatment of the sulfoxide (**1g**) with lead tetraacetate (2 equiv) in DMSO at 70 °C for 30 min afforded only the starting material in almost quantitative yield.

In entries 1—4, and 6—8 the α,β-epoxy sulfoxides have two diastereomers, expressed as L and P.[9b] These isomers show almost the same reactivity toward cesium acetate to afford the desired α-acetoxy ketones (**2**). It is worthwhile noting that regeioselectively acetoxylated products without their isomers are afforded in moderate to good yields (entries 1, 2, 4, and 5). Entry 5 shows that the α,β-epoxy sulfoxide having two alkyl groups on β-carbon exhibits much less reactivity than those having one alkyl group. The epoxy sulfoxide having a benzyl group in R^1 gave low yields of α-acetoxy ketones. This may be interpreted that lead tetraacetate oxidized benzyl group of the product **2g** (entry 7).[13] Entry 8 shows that an α-acetoxy ketone having

Table 1. α-Acetoxy Ketones from α,β-Epoxy Sulfoxides with Cesium Acetate

highly acidic hydrogens (**2h**) afforded **2i** through acyl migration.

Experimental

General. Infrared (IR) spectra were measured directly on a NaCl plate with a Hitachi 215 spectrometer. ^{1}H NMR spectra were measured in a $CDCl_3$ solution with a JEOL-FX-100 pulse Fourier-transform spectrometer using Me_4Si as an internal standard. All α,β-epoxy sulfoxides (**1**) used in this study are given in Refs. 9b and 11.

Treatment of 1g with Alkaline Hydrogen Peroxide. To a solution of **1g** (54 mg) in MeOH (3 ml) was added 10% KOH (1 ml) and 40% H_2O_2 (0.2 ml) and the solution was stirred at room temperature for 4 d. The MeOH was evaporated and the residue was extracted with benzene. The water layer was acidified and extracted with benzene. The usual work-up gave 14.2 mg (58%) of benzoic acid as colorless crystals.

1-Phenyl-3-phenylsulfinyl-2-butanone (3). A solution of $Mg(OMe)_2$ was prepared from dry MeOH (2 ml) and Mg (24.3 mg; 1 mmol) in a dry flask. To this was added a solution of **1g** (54.4 mg; 0.2 mmol) in MeOH; then the reaction mixture was refluxed under N_2 for 2 h. After the usual work-up, the product was purified by silica-gel column chromatography to afford 34 mg (63%) of **3** (diastereomeric mixture) as colorless oil. IR (neat): 1710 (CO), 1045 (SO) cm^{-1}; ^{1}H NMR δ=1.20, 1.34 (each d, J=7 Hz), 3.68—4.20 (m), 7.00—7.74 (m); MS m/z (%): 272 (M^+, trace), 147 (75), 125 (30), 91 (100); Found: m/z 272.0881. Calcd for $C_{16}H_{16}O_2S$: M, 272.0870.

4-Methoxy-3-nonanone (4). A solution of **1a** (53 mg; 0.2 mmol) in MeOH (1 ml) was added to a solution of $TsOH \cdot H_2O$ (190 mg; 1 mmol) in MeOH (1 ml) and the reaction mixture was refluxed under N_2 for 20 h. The MeOH was evaporated and the residue was extracted with benzene. After the usual work-up, the product was purified by silica-gel chromatography to give 9.4 mg (27%) of **4** as colorless oil. IR (neat): 1720 (CO) cm^{-1}; ^{1}H NMR δ=0.88 (3H, t, J=7 Hz), 1.07 (3H, t, J=7 Hz), 1.16—1.78 (8H, m), 2.56 (2H, q, J=7 Hz), 3.38 (3H, s), 3.62 (1H, t, J=6 Hz); MS m/z (%): 172 (M^+, 8), 115 (100).

General Procedure for the Preparation of α-Acetoxy Ketones (2) from α,β-Epoxy Sulfoxides (1). A typical procedure is described for the synthesis of 4-acetoxy-3-nonanone (**2a**). A solution of 3,4-epoxy-3-phenylsulfinylnonane (**1a**; 270 mg; 1 mmol) in DMSO (2.5 ml) was added to a mixture of CeOAc (1.92 g; 10 mmol) and $Pb(OAc)_4$ (985 mg; 2 mmol) in DMSO (2.5 ml). The reaction mixture was stirred at 100 °C under N_2 for 45 min. To the reaction mixture was added 10 ml of 10%-HCl and the whole was extracted with ether. Then the ether layer was washed with sat. aq $NaHCO_3$ followed by brine. The product was purified by silica-gel column chromatography to afford 170.7 mg (84%) of **2a** as a colorless oil. IR (neat): 1745, 1730 (CO) cm^{-1}; ^{1}H NMR δ=0.90 (3H, t, J=7 Hz), 1.08 (3H, t, J=7 Hz), 1.18—1.92 (8H, m), 2.18 (3H, s), 2.50 (2H, m), 5.04

(1H, dd, J=5, 6 Hz); MS m/z (%): 200 (M^+, trace), 157 (3), 130 (5), 83 (6), 43 (100).

2-Acetoxy-3-nonanone (2b). Colorless oil; IR (neat): 1745, 1730 (CO) cm^{-1}; ^1H NMR δ=0.89 (3H, t, J=7 Hz), 1.00—1.72 (8H, m), 1.40 (3H, d, J=7 Hz), 2.15 (3H, s), 2.50 (2H, m), 5.11 (1H, q, J=7 Hz); MS m/z (%): 200 (M^+, trace), 113 (80), 87 (17), 43 (100).

6-Acetoxy-7-tridecanone (2c). Colorless oil; IR (neat): 1745, 1730 (CO) cm^{-1}; ^1H NMR δ=0.89 (6H, t, J=6 Hz), 1.08—1.90 (16H, m), 2.16 (3H, s), 2.46 (2H, m), 5.05 (1H, dd, J=5, 7 Hz); MS m/z (%): 256 (M^+, trace), 113 (78), 85 (10), 43 (100); Found: m/z 256.2033. Calcd for $C_{15}H_{28}O_3$: M, 256.2036.

4-Acetoxy-2-methyl-3-nonanone (2d). Colorless oil; IR (neat): 1745, 1730 (CO) cm^{-1}; ^1H NMR δ=0.90 (3H, t, J=7 Hz), 1.00—1.90 (8H, m), 1.10, 1.16 (each 3H, d, J=8 Hz), 2.15 (3H, s), 2.60—3.00 (1H, m), 5.15 (1H, dd, J=5, 7 Hz); MS m/z (%): 214 (M^+, 1), 171 (4), 71 (45), 43 (100).

2-Acetoxy-2-methyl-3-nonanone (2e). Colorless oil; IR (neat): 1735, 1720 (CO) cm^{-1}; ^1H NMR δ=0.89 (3H t, J=6 Hz), 1.08—1.76 (8H, m), 1.48 (6H, s), 2.09 (3H, s), 2.46 (2H, t, J=7 Hz); MS m/z (%): 214 (M^+, 1), 171 (11), 113 (65), 85 (11), 43 (100).

2-Acetoxy-1-cyclohexyl-1-heptanone (2f). Colorless oil; IR (neat): 1750, 1730 (CO) cm^{-1}; ^1H NMR δ=0.90 (3H, t, J=6 Hz), 1.00—2.08 (18H, m), 2.15 (3H, s), 2.20—2.72 (1H, m), 5.14 (1H, dd, J=5, 7 Hz); MS m/z (%): 254 (M^+, 1), 184 (5), 111 (60), 83 (100), 43 (70); Found: m/z 254.1872. Calcd for $C_{15}H_{26}O_3$: M, 254.1880.

3-Acetoxy-1-phenyl-2-butanone (2g). Colorless oil; IR (neat): 1740, 1725 (CO) cm^{-1}; ^1H NMR δ=1.28 (3H, d, J=7 Hz), 2.14 (3H, s), 3.84 (2H, s), 5.20 (1H, q, J=7 Hz), 7.08—7.52 (5H, m); MS m/z (%): 206 (M^+, 3), 91 (48), 87 (18), 43 (100).

A Mixture of 1-Acetoxy-1-phenyl-2-octanone (2h) and 2-Acetoxy-1-phenyl-1-octanone (2i). Colorless oil; IR (neat): 1745, 1730 (CO) cm^{-1}; ^1H NMR δ=0.84 (t, J=7 Hz), 0.88 (t, J=6 Hz), 1.00—2.00 (m), 2.18, 2.20 (each s), 2.24—2.56 (m), 5.90 (dd, J=6, 7 Hz), 6.00 (s), 7.12—7.72 (m); MS m/z (%): 262 (M^+, 1), 149 (40), 113 (35), 107 (61), 105 (92), 43 (100).

X-Ray Crystal Structures of 2,4-Dimethyl-4,4a-dihydro-1*H*-[1,3,5]-triazino[1,2-*a*]quinoline-1,3,6(2*H*,5*H*)-trione and Its Dehydrogenated Derivative. Bond Length and EI Mass Fragmentation

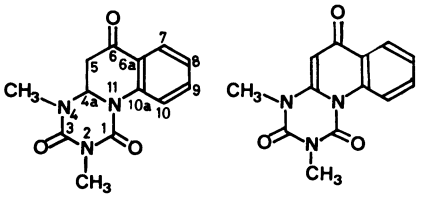
(Received October 5, 1985)

Synopsis. The crystal structures of the cyclic adduct **1** of 4-quinolinone with methyl isocyanate and its dehydrogenated derivative **2** have been determined by X-ray crystal structure analysis. Both crystal structure data of the C–N bond lengths in the triazinedione-ring skeleton suggest which bonds are broken in the initial EI mass fragmentation followed by the subsequent loss of a neutral MeNCO moiety.

Reactions and reactivities of pyridine derivatives have received continuous interest from organic chemists.[1] We recently reported on the preparation of some fused ring 1,3-dialkyl-1,3,5-triazine-2,4-(1*H*,3*H*)-dione derivatives and their mechanisms for the reactions of 4-pyridinone or 4-pyrimidinone with various alkyl isocyanates.[2] Here, we describe the X-ray structures of the parent cyclic adduct, 2,4-dimethyl-4,4a-dihydro-1*H*-[1,3,5]triazino[1,2-*a*]quinoline-1,3,6(2*H*,5*H*)-trione (**1**) and the corresponding dehydrogenated compound (**2**). The crystal structure data may allow to estimate the C–N bond which is broken in the initial EI mass fragmentation followed by the subsequent loss of a neutral molecule.[3]



1 **2**

Experimental

Colorless crystals of **1** and **2** were obtained by ordinary recrystallization procedures from a hexane/$CHCl_3$ solution and an acetonitrile solution, respectively.[2,3] A single crystal was selected or cut to an appropriate size for each X-ray study. Crystal data and experimental conditions for both **1** and **2** are summarized in Table 1. For the measurements of the unit-cell dimensions and integrated intensities at room temperature, a Rigaku computer-controlled four-circle diffractometer was employed with graphite-monochromatized Mo $K\alpha$ radiation (a rotating anode type, 60 KV, 200 mA; AFC 5FOS). The cell constants were determined by the least squares method from 10—12 reflections. Three standard reflections were checked every 55 reflections during the course of the intensity-data collection and no intensity decrease was observed. The intensities were corrected for the usual Lorentz and polarization effects.

The crystal structures were solved by the direct method with the MULTAN 78 program.[4] The refinements of the structures were performed by the block-diagonal least squares method using the HBLS-V program.[5] Several cycles of refinement, including anisotropic temperature factors and all the hydrogen atoms, reduced the R values for both cases (Table 1): the hydrogen atoms of the molecules were found from the difference Fourier maps and

they were refined with isotropic thermal parameters. The function minimized was $\sum w(|F_o|-|F_c|)^2$ with the following weighting scheme: $\omega=1/(\sigma^2(F_o)+a|F_o|+b|F_o|^2)$ for $|F_o|>0$ and $w=0$ for $|F_o|=0$. All the atomic scattering factors of C, N, O were taken from the "International Tables for X-Ray Crystallography".[6] The computations

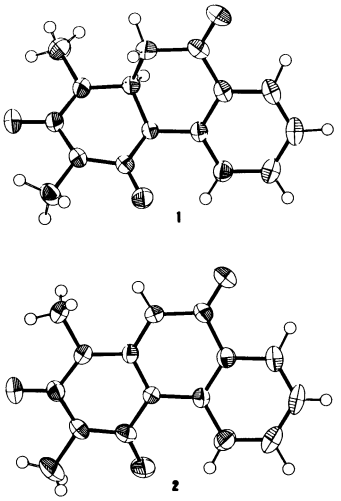

Fig. 1. ORTEP views of the compound **1** and **2**. The nonhydrogen atoms were drawn at the 50% probability level and the hydrogen atoms at an arbitrary diameter.

were carried out on an ACOS-850 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University. The final atomic positional and thermal parameters of **1** and **2** are listed in Tables 2 and 3, respectively. The tables of F_o and F_c, and anisotropic thermal parameters of the non-hydrogen atoms are deposited at the Chemical Society of Japan (Document No. 8620).

Results and Discussion

Figure 1 is a computer generated perspective (ORTEP)[7] view of these structures. The structures which had been previously determined by NMR and other spectral correlations[2] were confirmed. The bond lengths and the bond angles are given in Fig. 2 and Fig. 3, respectively, together with the atomic numberings. Neither abnormal bond lengths nor bond angles were found in these structures.

EI mass fragmentations of the compound **1** and **2** are reported,[3] where it is considered that the initial fragmentation of **1** mainly proceeds to the loss of a neutral MeNCO dimer via C(4A)–N(4) bond cleavage, yielding the *M/Z* 145 ion, and that of **2** proceeds to the loss of a neutral MeNCO monomer via C(1)–N(11) cleavage, yielding the *M/Z* 200 ion (Fig. 4).

In the present triazinedione ring, there are five C–N bonds directly concerned with the possible cleavage which is followed by the subsequent loss of the neutral molecule: i.e., C(4A)–N(4)–C(3)–N(2)–C(1)–N(11). The crystal data of the bond lengths in Fig. 2 show that the C(1)–N(11) bond for **2** is the longest among the five C(sp^2)–N bonds: on the other hand, the C(4A)–N(4) bond for **1** is the longest because of the C(sp^3)–N constituent. Therefore, although the comparison is restricted, the longest C–N bond among the five bonds seems to identify the C–N bond to be broken in the initial EI mass fragmentation giving the subsequent loss of the neutral *n*MeNCO moiety (*n*=1 or 2). A similar

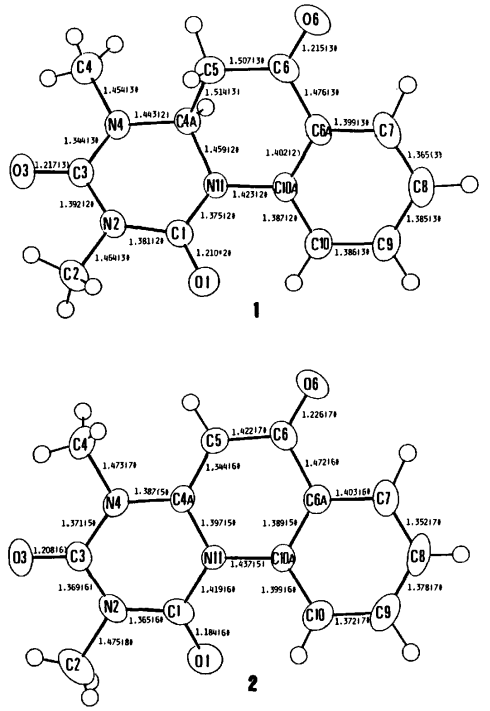

Fig. 2. Bond lengths (l/Å) of the compound **1** and **2**. Standard deviations in parentheses refer to the least significant digit.

situation is also observed between the C(sp^2)–N bond length and the initial EI mass fragmentation in the related structure of caffein.[8,9] This feature suggests that detailed information about bond lengths in crystals is important for mechanistic studies of reactions,[10] including initial EI mass fragmentation in a gas phase.

Preparation of Arylimidobis(sulfates)[1]

Fujio KANETANI
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University,
Saijo, Higashi-Hiroshima 724
(Received October 18, 1985)

Synopsis. Seven arylimidobis(sulfates), six of which are new compounds, have been prepared by the *N*-sulfonation of the corresponding primary aromatic amines with 2-methylpyridine-sulfur trioxide in 60—92% yields.

In our previous work[1] we isolated (2,4,6-trimethylphenylimido)bis(sulfate) from the thermal reaction of 2,4,6-trimethylanilinium butylamidosulfate. Mechanistic consideration of this reaction led us to the successful preparation of this imidobis(sulfate) by fusion of an equimolar mixture of butylamidosulfuric acid and butylammonium (2,4,6-trimethylphenylamido)sulfate. Recently, considerable attention has been given to the mechanism of the sulfonation of aniline with excess concentrated and fuming sulfuric acid,[2,3] and the intermediacy of phenylimidobis(sulfuric) acid[4] as well as (2- and 4-sulfophenylamido)sulfuric acid,[2,5] has been suggested. In this context, we have become interested in the chemistry of arylimidobis(sulfuric) acids and their salts. In this paper we report the preparation of arylimidobis(sulfates).

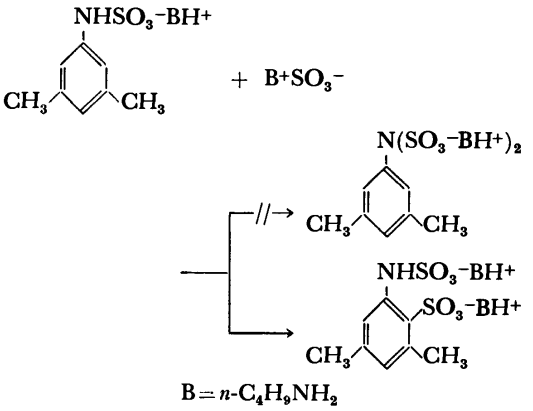
Results and Discussion

The standard method for the preparation of unsubstituted imidobis(sulfate) on a laboratory scale involves the fusion of ammonium amidosulfate itself[6] or the fusion of an equimolar mixture of ammonium amidosulfate and amidosulfuric acid.[7]

$$2\,NH_2SO_3NH_4 \xrightarrow[290-305\,^\circ C]{\Delta} HN(SO_3NH_4)_2 + NH_3$$

$$NH_2SO_3NH_4 + NH_3{}^+SO_3{}^- \xrightarrow[145-150\,^\circ C]{\Delta} HN(SO_3NH_4)_2$$

This method, however, cannot be applied to the synthesis of arylimidobis(sulfates) except (2,4,6-trimethylphenylimido)bis(sulfate), because their *N*-sulfonate group tends to thermally migrate to position(s) ortho and/or para relative to the amino group. In fact, the fusion of an intimate mixture of butylammonium (3,5-dimethylphenylamido)sulfate and butylamidosulfuric acid gave, in a 69% yield, (3,5-dimethyl-2-sulfonatophenylamido)sulfate instead of the desired (3,5-dimethylphenylimido)bis(sulfate) (see Experimental section).



Previously,[8] we reported a one-step method for the preparation of *N*-substituted imidobis(sulfates). This method involving the *N*-sulfonation of an appropriate amine with triethylamine-sulfur trioxide works well with aliphatic and alicyclic amines, but with aromatic amines gives only poor yields (see Ref. 8 and Table 1).

Vrba and Allan[9] have prepared disodium phenylimidobis(sulfate) by the *N*-sulfonation of aniline with 2-methylpyridine-sulfur trioxide. Unfortunately, this work was limited to the preparation of phenylimidobis(sulfate) itself and published only in a short communication. In addition, the yield of the isolated product was not given (presumably much less than 50%). Accordingly, we examined this reaction in some detail and found optimal conditions giving arylimidobis(sulfates) in good yields (Table 1).

Table 1. Preparation of Phenylimidobis(sulfate)[a]
$C_6H_5NH_2 + 2B\cdot SO_3 \longrightarrow C_6H_5N(SO_3{}^-BH^+)_2$

B	Mr[b]	Solv.	Reaction temp/°C	Reaction time/h	Yield/%[c]
$(C_2H_5)_3N$	2.19	2-MePy	25—30	71	17[e]

2-MePy[d]	2.42	2-MePy	17—18	71	84
2-MePy	2.34	2-MePy	88—92	1	78[f]

a) The imidobis(sulfate) was isolated as a sodium salt. b) Molar ratio of $B\cdot SO_3$ to aniline. c) Yields refer to the yield of isolated product based on aniline. d) 2-Methylpyridine. e) Data cited from: F. Kanetani and H. Yamaguchi, *Bull. Chem. Soc. Jpn.*, **47**, 2713 (1974). f) Isolated as the potassium salt.

Thus the *N*-sulfonation of aniline with a slight excess of 2-methylpyridine-sulfur trioxide at room temperature for 71 h gave phenylimidobis(sulfate) in a 84% yield, together with a small amount of phenylamidosulfate. The use of higher temperature accelerated the reaction without significant lowering of the yield; i.e., the reaction at 88—91 °C for 1 h produced the imidobis(sulfate) in a 77% yield. TLC analysis of the reaction mixture revealed the formation of (4-sulfonatophenylamido)sulfate[1] as a by-product. This compound may arise either from the para sulfonation of the phenylamidosulfate or from the thermal rearrangement of phenylimidobis(sulfate) formed.

Table 2. Preparation of Arylimidobis(sulfates)[a]
$ArNH_2 + 2(2\text{-}MePy \cdot SO_3$[b]$) \longrightarrow ArN(SO_3^- \ 2\text{-}MePyH^+)_2$

$ArNH_2$	Mr[c]	Reaction temp/°C	Reaction time/h	Yield/%[d]
2-Methyl-aniline	2.14	89—91	2	67
3-Methyl-aniline	2.09	20—21	71	71
		88—92	2	trace[e]
4-Methyl-aniline	2.16	89—91	2	63
2-Chloro-aniline	1.99	22—23	142	60
3-Chloro-aniline	2.08	21—22	71	70
4-Chloro-aniline	2.05	22—23	120	92

a) All imidobis(sulfates) were isolated as potassium salts and characterized by IR spectroscopy and elemental analysis. b) 2-Methylpyridine-sulfur trioxide addition compound. c) Molar ratio of 2-MePy·SO_3 to substrate amine. d) Yields refer to the yield of isolated product based on amine. e) TLC analysis revealed the formation of (3-methylphenylimido)bis(sulfate) but in a trace; the chief product was (3-methyl-4-sulfonatophenylamido)sulfate.

Table 2 summarizes the results of the *N*-sulfonation of some other primary aromatic amines with 2-methylpyridine-sulfur trioxide. As can be seen from the table, the reaction at room temperature for 2—6 d or at 90 °C for 1—2 h gives arylimidobis(sulfates) in yields of 60—92%. 3-Methylaniline provided an exception; thus the reaction at 88—92 °C for 2 h failed to yield (3-methylphenylimido)bis(sulfate) and resulted in the formation of a new compound, which is identified as (3-methyl-4-sulfonatophenylamido)sulfate.[10] On the contrary, at room temperature the reaction proceeded in an expected manner to afford (3-methylphenylimido)bis(sulfate) in a 71% yield. Our results suggest that the use of the reaction conditions of Vrba and Allan (0 °C, 1 h) would lead to much lower yields of arylimidobis(sulfates).

The IR spectra of all the arylimidobis(sulfates) prepared, as well as alkylimidobis(sulfates),[11] showed two to four strong absorption peaks in the range of 1220—1298 cm^{-1}, and two strong peaks at 1029±3 and 1080±4 cm^{-1}. The former peaks are attributable to antisymmetric and the latter to symmetric vibrations of the SO_3^- groups. The imidobis(sulfates) were soluble in water, sparingly soluble in methanol, and insoluble in other ordinary organic solvents. All the arylimidobis(sulfates) are very liable to acid hydrolysis, which leads to the formation of sulfate ion by way of the corresponding arylamidosulfate ions.

$$ArN(SO_3^-)_2 \longrightarrow ArNHSO_3^- + HSO_4^-$$
$$\longrightarrow ArNH_3^+ + 2HSO_4^-$$

over KOH pellets, distilled, and stored over molecular sieves 4A. 1,2-Dichloroethane was dried over $CaCl_2$, distilled and stored over molecular sieves 4A. Sulfur trioxide was obtained by distillation of 60% fuming sulfuric acid. IR spectra were recorded on a JASCO IR-S spectrophotometer. Thin-layer chromatography was performed on 0.25 mm-thick cellulose plates (Cellulose Mikrokristallin, E. Merck). Compounds were visualized by UV fluorescence or by placing the plates in a container filled with nitrous gases, followed by spraying with sodium 1-naphthol-4-sulfonate and subsequent exposure to ammonia gas. All the reactions were carried out under anhydrous conditions.

General Procedure for the Preparation of Arylimidobis(sulfates). Sulfur trioxide was distilled into 10 ml of cooled (5—10 °C) 1,2-dichloroethane. To this solution was added 30 ml of 2-methylpyridine drop by drop. After stirring for 10 min at 10 °C, a substrate amine in 10 ml of 2-methylpyridine was added and the mixture was then stirred at room temperature or at 90 °C. After the reaction had been complete, the solvent was removed in vacuo at a bath temperature below 30 °C. The residue was dissolved in aqueous potassium hydroxide. The solution was warmed for 30 min at 50 °C while its pH being kept at 8—9. The mixture was then treated with a 5% barium acetate solution until no more precipitate was formed. The filtered solution was concentrated to about 5 ml. To this solution was added a few drops of 10% aqueous KOH and 100 ml of hot ethanol. The mixture was allowed to stand overnight. The crystals were collected by filtration, washed with 90% ethanol, and dried in a vacuum desiccator.

Reaction of Butylammonium (3,5-Dimethylphenylamido)sulfate with Butylamidosulfuric Acid. An intimate mixture of butylammonium (3,5-dimethylphenylamido)sulfate (0.548 g, 2.00 mmol) and butylamidosulfuric acid (0.303 g, 1.98 mmol) was heated at 120 °C for 4 h. After cooling to room temperature, the glass-like product was dissolved in 10% aqueous KOH and the solution was evaporated to dryness. The residual solid was dissolved in a little hot water. This solution was then added, with vigorous stirring, to hot ethanol (90 ml) containing a few drops of 10% aqueous KOH. The mixture was allowed to cool to room temperature to give colorless crystals (0.491 g). Recrystallization gave the pure dipotassium N, 2-disulfonate; IR (KBr) 3280 (NH), 1201 (SO_3^-), 1149, 1086, 1050 (SO_3^-), 1015, 874, 856 (1H), and 755 cm^{-1}. This disulfonate furnished 2-amino-4,6-dimethylbenzenesulfonic acid when heated with dil. HCl.[10]

The author thanks Professor Richard N. Butler and Dr. William J. Spillane for the laboratory facilities during his stay at University College, Galway (Republic of Ireland) on sabbatical leave.

Color Reaction among Pyrogallol Red, Thorium(IV) and Samarium(III), and Its Application to the Determination of These Metals

Itsuo MORI,* Yoshikazu FUJITA, Kinuko FUJITA, Shoko KITANO, Itsuko OGAWA, Hiroshi KAWABE, Yozo KOSHIYAMA, and Takeshi TANAKA

Osaka College of Pharmaceutical Sciences, 2-10-65, Kawai, Matsubara, Osaka 580

(Received July 1, 1985)

Synopsis. The color reactions between Pyrogallol Red(PR) and thorium(IV), and also those among PR, thorium(IV) and samarium(III) were studied. Simple and sensitive spectrophotometric determinations of these ions were newly carried out in the range for 1—22 μg/10 cm³ of thorium (IV) and 0.5—10 μg/10 cm³ of samarium(III) at 635 nm by using the PR-Th-Sm ternary complex.

Although Pyrogallol Red(PR) has already been used for chelatometric titration and spectrophotometric determination of various metal ions,[1-5] the studies on the color reactions between PR and thorium(IV) or PR and rare earth elements such as samarium(III), lanthanum(III), etc. were comparatively few. We have found that the color reaction between PR and thorium(IV) or PR and samarium(III) was catalyzed by the coexistence of small amounts of samarium(III) or thorium(IV), respectively, and that the color was caused by a ternary complex system.

In this paper, the color reaction among PR, thorium(IV) and samarium(III) in the presence of a nonionic surfactant was studied, and the spectrophotometric determination of these ions using the PR-Th-Sm ternary complex was proposed.

Experimental

Apparatus and Reagents. Spectrophotometric determination was done on Shimadzu model UV-240 and 260 recording spectrophotometers with 1.0-cm fused quartz cells. The Hitachi-Horiba M-5 and F-7AD glass electrode pH meters were used for the pH measurements.

A 1.0×10^{-3} mol dm^{-3} solution of PR was prepared by dissolving PR (Tokyo Kasei Kogyo Co., Ltd.) in methanol. A stock solution (1.0×10^{-2} mol dm^{-3}) of thorium(IV) was prepared by dissolving of thorium nitrate in water. A stock solution (1.0×10^{-2} mol dm^{-3}) of samarium(III) was prepared by dissolving 360 mg of Sm_2O_3 in 3 cm³ of concd. hydrochloric acid, and it was diluted to 100 cm³ with water. The concentrations of the stock solutions of thorium(IV) and samarium(III) were determined by chelatometric titration,[4] and then the working solutions (5.0×10^{-4} mol dm^{-3}) were prepared by dilution of these stock solutions. A 1.0% of poly(vinyl alcohol) (PVA) solution was prepared by dissolving PVA (n=2000) in water. A 2.0×10^{-1} mol dm^{-3} sodium acetate-acetic acid buffer solution (Walpole buffer) was used for the pH adjustment. All the other reagents and materials were of analytical grade. Doubly-distilled water was used.

Determination of Thorium(IV): To a solution containing 1—22 μg thorium(IV) in a 10 cm³ volumetric flask were added 2.0 cm³ of a Walpole buffer solution (pH 4.5), 2.0 cm³ of a 1.0% PVA solution, 1.0 cm³ of a 1.0×10^{-4} mol dm^{-3} samarium(III) solution, and 1.5 cm³ of 1.0×10^{-3} mol dm^{-3} PR solution. The mixture was diluted to 10 cm³ with water, and the solution was kept at 60 °C for 30 min. After the mixture was cooled in water for 10 min, the absorbance of the PR-Sm-Th solution (Solution D) was measured at 635 nm against the PR-Sm solution (Solution C).

Determination of Samarium(III): A solution containing 0.5—10 μg samarium(III) was placed in a 10 cm³ volumetric flask. To this solution 2.0 cm³ of 1.0% PVA and buffer solutions, 1.0 cm³ of a 5.0×10^{-4} mol dm^{-3} thorium(IV) solution, and 1.5 cm³ of 1.0×10^{-3} mol dm^{-3} PR solution were added. The mixture was diluted to the mark with water, and heated at 60 °C for 30 min. After the mixture was cooled in water for 10 min, the absorbance of Solution D was measured at 635 nm against the PR-Th solution (Solution B).

Results and Discussion

Figure 1 shows the absorption spectra of PR solution (Solution A), PR-Th solution (Solution B), PR-Sm solution (Solution C) and PR-Th-Sm complex solution (Solution D) in the presence of PVA, respectively. Solution D gave a larger absorbance

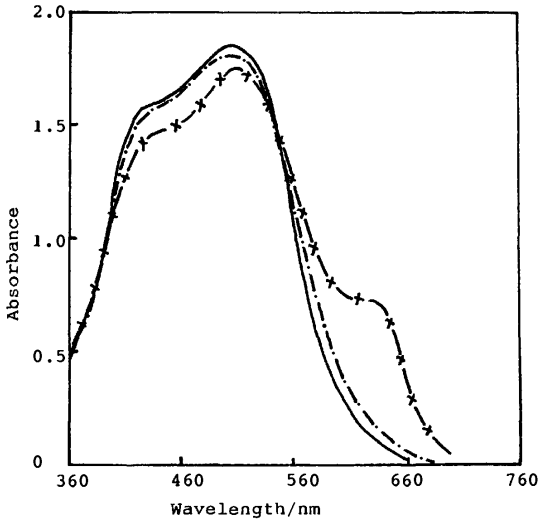

Fig. 1. Absorption spectra of PR-Th-Sm solution, PR-Th solution, PR-Sm solution and PR solution at pH 4.5 in the presence of PVA.

PR, 1.5×10^{-4} mol dm^{-3}; Thorium(IV), 5.0×10^{-6} mol dm^{-3}; Samarium(III), 1.0×10^{-5} mol dm^{-3}; Surfactant, 2.0 cm^3 of 1.0% surfactant/10 cm^3; pH 4.5; Reference, PR-Sm solution=Solution C

and was more stable than Solution B or C, and its absorbance was proportional to the concentration of thorium(IV) or samarium(III). The similar phenomena were observed in this reaction system, when rare earth elements such as lanthanum(III) were used instead of samarium(III), and hafnium(IV) or zirconium(IV) instead of thorium(IV).

The effect of pH on the reaction systems was examined. The maximum and constant absorbance was obtained in the pH range of 4.2 to 5.2 with 2.0 cm^3 of 2.0×10^{-1} mol dm^{-3} buffer solution. The reproducibilities of color development of Solutions B, C, and D without a surfactant were poor. As a dispersion agent, PVA was the most effective one among nonionic surfactants and these solutions gave the stable and the highest sensitivity as shown in Table 1.

The use of samarium(III) among the various rare earth elements tested-lanthanum(III), cerium(III), praseodymium(III), gadolinium(III), dysprosium(III), etc. was the most effective in terms of sensitivity.

The maximum and almost constant absorbance was obtained by using of $0.8—1.4\times10^{-5}$ mol dm^{-3} samarium(III) for the determination of thorium(IV), and $3.75—7.5\times10^{-5}$ mol dm^{-3} thorium(IV) solution for the determination of samarium(III) in the final concentration, respectively. The recommended volume of PR was 1.5 cm^3 of a 1.0×10^{-3} mol dm^{-3} solution in the final 10 cm^3.

Consequently, all further work was carried out with 1.0×10^{-5} mol dm^{-3} samarium(III) and 1.5×10^{-4} mol dm^{-3} PR solution for thorium(IV), and 1.5×10^{-4} mol dm^{-3} PR and 5.0×10^{-5} mol dm^{-3} thorium(IV) in the final concentration for the determination of samarium(III), respectively. A nearly constant absorbance of Solution D against Solution B or C was obtained after aging for 5 h at room temperature, or after 30 min at 60 °C. The absorbance was almost constant for at least 32 h at room temperature.

The calibration curves covered the range of 1—22 μg/10 cm^3 thorium(IV) and 0.5—10 μg/10 cm^3 samarium(III). The sensitivities of Sandell's scale were 0.0028 μg cm^{-2} for thorium(IV) and 0.0015 μg cm^{-2} for samarium(III), and the apparent molar absorption coefficients were 8.2×10^4 dm^3 mol^{-1} cm^{-1} for thorium(IV) and 1.0×10^5 dm^3 mol^{-1} cm^{-1} for samarium(III), respectively. The reproducibilities for thorium(IV)(11.6 μg) and samarium(III)(5 μg) were 1.4% and 1.5% (8 experiments).

Table 2. Effects of Foreign Ions for the Determination of Thorium(IV)

* foreign ion/thorium(IV)

The effects of foreign ions on the determination of thorium(IV) and samarium(III) were examined. The coexistence of sulfate, chloride, nitrate, nitrite, nickel(II), magnesium(II), calcium(II), etc. did not interfere in 100—200 fold mole excess over thorium-(IV) or samarium(III), and thiosulfate, sulfite, triethanolamine(TEA), L-ascorbic acid, copper(II), iron(III), zinc(II), cadmium(II), etc. in 2—10 fold mole excess over thorium(IV) or samarium(III). The tolerance limits were taken as the amount causing 2% error in the absorbance. Meanwhile, the coexistence of bismuth(III), tin(IV), etc. seriously interfered, and these interfering ions must be separated by suitable procedures. Interference by copper(II), iron(III) or zinc(II) can be prevented by addition of a sodium thiosulfate, TEA or L-ascorbic acid solution. The results for the determination of thorium(IV) are shown in Table 2.

The molar ratios of thorium(IV) to PR in the presence of large amounts of samarium(III), and those of samarium(III) to PR in the presence of thorium(IV) were estimated by the molar-ratio and continuous-variation methods, and these molar ratios

were found to be 1:2. On the other hand, the molar ratio of thorium(IV) to PR in the absence of samarium(III) was 2:3. Although further investigation is necessary, the coloring formed among PR, thorium(IV) and samarium(III) in the presence of PVA as a nonionic surfactant may be regarded as the ternary complex system.

In conclusion, the color reactions among PR, thorium(IV) and samarium(III) in the presence of PVA as a nonionic surfactant were discussed. The ternary complex system, PR-Th-rare earth elements such as samarium(III), was more stable and gave higher absorbance than the PR-Th system or PR-Sm system (Slution C)(=PR solution). Thus, simple, rapid and sensitive spectrophotometric determinations for thorium(IV) and samarium(III) by using the ternary complex (thorium(IV) 1:samarium(III) 1:PR 2) were established. The present method was 2—10 fold more sensitive than other methods[1-9] utilizing xanthene dyes (for example, Xylenol Orange(XO), Methylthymol Blue(MTB), PR) alone, and it was simple and rapid.

Although further investigation is necessary, the color reaction among various xanthene dyes (for example, gallein, XO, MTB, etc.), thorium(IV) and rare earth elements such as samarium(III) may be used as a new color reaction system in analytical chemistry like the reactions reported previously[10].

Presented at the 45th Symposium of the Society of the Analytical Chemistry of Japan, in Muroran, July, 1984.

Synopsis. Color reaction between indium(III) and *o*-hydroxyhyroquinonephthalein(Qnph) in the presence of a cationic surfactant was studied, and its application for the spectrophotometry and photometric titration of indium(III) was discussed. The color reaction between Qnph and indium(III) in the presence of hexadecyltrimethylammonium chloride(HTAC) was stable in weakly acidic media. The calibration curve was rectilinear in the range of 0—10 μg/10 cm³ of indium(III) at 560 nm, and the apparent molar absorption coefficient was 1.3×10^5 dm³ mol^{-1} cm^{-1}. The Sandell sensitivity was 0.0008 μg/cm² for indium(III).

For the detection and determination of indium(III) various methods using oxine, dithizone, Xylenol Orange(XO), Methylthymol Blue(MTB), Pyrocatechol Violet(PV), etc. have been reported.[1-11] However, most of these methods are complicated and/or not sufficiently sensitive. The color formation between *o*-hydroxyhydroquinonephthalein(Qnph) and indium(III) in the presence of hexadecyltrimethylammonium chloride(HTAC) as a cationic surfactant was sharp, stable and gave a larger absorbance than the color reaction without surfactant.

In this paper, the color reaction between Qnph and indium(III) was discussed, and then a simple, rapid and sensitive spectrophotometric method for the determination of indium(III) was established.

Experimental

Apparatus and Reagents. Spectrophotometric measurements were carried out on Shimadzu Model UV—200, UV-240 and Hitachi Model 150-20 recording spectrophotometers with 1.0-cm fused silica cells. A Shimadzu Model QV-50 spectrophotometer and its attachments were used for photometric titration of indium(III). Hitachi-Horiba Model F-7AD and M-5 glass electrode pH meters were used for the pH measurements.

A 1.0×10^{-3} mol dm^{-3} solution of Qnph was prepared according to the previous report.[12] The working solutions (5.0×10^{-4} mol dm^{-3}) of indium(III) and a 1.0×10^{-2} mol dm^{-3} EDTA solutions were prepared according to the previous reports,[9] respectively. A 2.0×10^{-2} mol dm^{-3} HTAC solution was prepared by dissolving HTAC in water, and a 2.0×10^{-1} mol dm^{-3} sodium acetate–acetic acid buffer solution was used for the pH adjustments. All the other reagents and materials were of analytical grade and were used without further purification. Doubly distilled water was used.

Standard Procedure. Spectrophotometric determination of indium(III): To a solution containing up to 10 μg indium(III) in a 10 cm³ volumetric flask were added 1.0 cm³ of a 2.0×10^{-2} mol dm^{-3} HTAC solution, 1.5 cm³ of a 1.0×10^{-3} mol dm^{-3} Qnph solution, and 2.0 cm³ of a 2.0×10^{-1} mol dm^{-3} acetate buffer solution(pH 5.4). The mixture was diluted to 10 cm³ with water(Solution B), and the solution was mixed well, and kept at room temperature for 10 min. The absorbance of Solution B was measured at 560 nm against the reagent blank(Solution A).

Photometric titration of indium(III): A solution containing less than 900 μg of indium(III) was placed in a tall beaker (40×90 mm); to this solution 5.0 cm³ of a 2.0×10^{-3} mol dm^{-3} HTAC solution and 1.5 cm³ of a 1.0×10^{-3} mol dm^{-3} Qnph solution were added. The pH of the solution was adjusted to about 3.5 with a 2.0×10^{-1} mol dm^{-3} sodium acetate-hydrochloric acid solution, was diluted to 30 cm³ with water, and was heated at 60—70 °C for 10 min. Then the mixed solution was titrated by a 1.0×10^{-2} mol dm^{-3} EDTA solution by measuring the absorbance at 560 nm or 520 nm. The concentrations of indium(III) were calculated from the relationship between the absorbance at 560 nm or 520 nm and the amounts used of a 1.0×10^{-2} mol dm^{-3} EDTA solution.

Results and Discussion

Color Reaction and Absorption Spectra. The color reaction between Qnph and indium(III) was studied in weakly acidic media with or without various kinds of surfactants——poly(oxyethylene)-sorbitan monolaurate (Tween 20) as a nonionic, HTAC as a cationic or sodium dodecyl sulfate(SDS) as an anionic surfactant. The Qnph–indium(III) complex solution in the presence of HTAC showed a considerable bathochromic shift with two times larger and more stable absorbance than the complex in the presence of Tween 20 or SDS.

Effects of pH and Surfactants. The maximum and constant absorbance was obtained in the pH range from 5.2 to 6.2 for indium(III) by addition of 2.0 cm³ of a 2.0×10^{-1} mol dm^{-3} Walpole acetate buffer solution in the final volume of 10 cm³. Among various surfactants, HTAC, hexadecylpyridinium chloride(HPC), zephiramine, HTAC, a cationic surfactant, was found to be the best as a dispersion agent. The maximum and constant absorbance could be obtained over the range of 0.5 to 2.0 cm³ of a 2.0×10^{-2} mol dm^{-3} HTAC solution to the final volume of 10 cm³. Subsequent measurement was carried out by addition of 2.0 cm³ of the buffer solution(pH 5.4) and 1.0 cm³ of a 2.0×10^{-2} mol dm^{-3} HTAC solution in the final volume of 10 cm³.

Effects of Qnph Concentration and Stability. The recommended concentration of Qnph was 1.5×10^{-4} mol dm^{-3} in the final solution. Under the conditions of the standard procedure, the maximum and almost constant absorbance was obtained by keeping the Qnph–indium(III) solution at room temperature for

Indium(III) taken: 7.2 μg/10 cm^3; Qnph: 1.5×10^{-4} mol dm^{-3}; pH: 5.4; HTAC: 2.0×10^{-3} mol dm^{-3}: Reference: Reagent blank.

longer than 10 min. The absorbance was almost constant at least for 90 min.

Calibration Curve and Repeatability. The calibration curve for indium(III) was constracted according to the standard procedure. Beer's law held in the concentration range of 0—10 μg of indium(III) in the final volume of 10 cm^3. The apparent molar absorption coefficient was estimated to be 1.3×10^5 dm^3 mol^{-1} cm^{-1} at 560 nm, and the Sandell sensitivity was calculated to be 0.0008 μg cm^{-2} for indium(III). The coefficient of variation(n=5) for 7.2 μg indium(III) was 1.5%.

Effects of Foreign Ions. The tolerance limits were taken as the amount causing 2% error in the absorbance. The coexistence of small amounts of copper(II), iron(III), aluminum(III), bismuth(III), etc. showed positive errors because of the formation of a colored complex with Qnph. In 2—30 fold molar excess of indium(III), the interference of copper(II), aluminum(III), and iron(III) could be overcome to some extent by addition of sodium thiosulfate, nitrilotriacetic acid(NTA) or sodium fluoride and potassium cyanide or sodium fluoride solutions, respectively. Also, the interference of bismuth(III) could be overcome by addition of NTA in a 50-fold excess. Although the coexistence of large amounts of tartrate, citrate and oxalate ions, etc. interfered, the presence of most anions scarcely interfered in the 100—200 fold molar excess of indium(III). The results are summarized in Table 1.

The Composition of the Complex. The molar ratio of Qnph to indium(III) in the presence of HTAC was estimated to be 2:1 by the molar-ratio and the continuous-variation methods. On the other hand, the molar ratio of Qnph to indium(III) in the coexistence of Tween 20 without HTAC was 3:2 by the molar-ratio method. The molar ratio of HTAC to the indium(III)-Qnph solution was found to be 2:1 in the presence of nonionic surfactants.

Photometric Titration. At the end point of the photometric titration of indium(III) by using Qnph as a metal indicator at around pH 3—5 in the coexistence of HTAC the color changed from orange red to yellow. In the photometric titration of indium(III), the difference of absorbance at 560 or 520 nm of the Qnph-indium(III) solution and that of the Qnph solution was measured. The proposed method was well suitable for differential titration of the mixed metal ion solution (for example, indium(III)-bismuth(III), indium(III)-thorium(IV), indium(III)-aluminum(III)-cobalt(II), etc.).

The recovery of indium(III) added to a waste water involving of copper(II), cadmium(II), lead(II), zinc(II), aluminum(III), iron(III), bismuth(III), etc. was examined, and the results were satisfactory (98.5—103.0%).

In conclusion, the color reactions between indium(III) and Qnph in the presence of various surfactants were studied, and a simple, rapid and sensitive spectrophotometric determination of indium(III) was established by using the color reaction between Qnph and indium(III) in the presence of HTAC in weakly acidic media. The calibration curve was linear in the concentration range of 0—10 μg/10 cm^3 for indium(III). The apparent molar absorption coefficient was estimated to be 1.3×10^5 dm^3 mol^{-1} cm^{-1}. The sensi-

tivity of this method was about 9 times greater than the oxine or MTB method,[3] and 3—4 fold greater than 1-(2-pyridylazo)-2-naphthol(PAN)[2] or previously reported method.[9] The effects of foreign ions were relatively smaller than the previous method.[9]

Though further investigation is necessary, the proposed method may be useful for the determination of indium(III) in alloys, iron ores, semiconductors, etc.

Presented at the 45th Symposium Society of the Analytical Chemistry of Japan, in Muroran, July, 1984.

Excited-State Reactions of Coumarins in Aqueous Solutions. III. The Fluorescence Quenching of 7-Ethoxycoumarins by the Chloride Ion in Acidic Solutions

Tetsuo MORIYA
Electrotechnical Laboratory, 1-1-4 Umezono, Sakura-mura, Niihari-gun, Ibaraki 305
(Received July 31, 1985)

The fluorescence yield of 7-ethoxycoumarins in acidic aqueous solutions becomes reduced with an increase in the chloride-ion concentration. In acidic solutions, two types of excited molecules, a neutral molecule and a protonated molecule with a positive charge, are generated by a UV light illumination. Only the excited state of a protonated molecule is quenched by a chloride ion; the quenching reaction proceeds via both a diffusional and a static process. The rate constant for the diffusional process is $(3.7—5.8)\times10^9$ mol^{-1} dm^3 s^{-1}. The static quenching component can be approximately described by the $V[Q]$ expression and the static quenching constant, V, is 1.2—1.7 mol^{-1} dm^3. One possible physical interpretation of the quenching mechanism is discussed in relation to the charge of colliding species and the electron transfers between them.

In a previous paper[1] interactions between 7-ethoxycoumarins and halide ions in a neutral aqueous solution were discussed. It has been revealed that bromide and iodide ions cause a very pronounced quenching effect on the fluorescence of 7-ethoxycoumarins. On the other hand, chloride ions show no indication of quenching, even at considerably high quencher concentrations. This has been explained in terms of the oder of the quenching ability of the halide ions, i.e., $I^- > Br^- \gg Cl^-$.

When a solution is changed from neutral to acidic, 7-ethoxycoumarins can take two forms of the photo-excited state, neutral and protonated. It was recently found that in an acidic solution, even chloride ions have a remarkable quenching effect on the fluorescence of the two molecular species.

To quantitatively analyze this phenomena, chloride ions were chosen as the quencher. Then, the fluorescence intensities of 7-ethoxycoumarin (**1**) and 7-ethoxy-4-methylcoumarin (**2**) in acidic aqueous solutions were measured in detail as a function of the quencher concentration. In this paper a reasonable scheme for the reaction kinetics is proposed and several reaction-rate constants are derived by means of the obtained data. The quenching mechanism is discussed while taking account of the ionic nature of the interacting species.

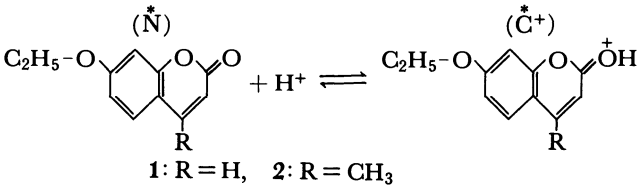
Experimental

Material. High-purity grade reagents of 7-ethoxycoumarin (**1**) and 7-ethoxy-4-methylcoumarin (**2**) were obtained from Molecular Probes Inc. and used as purchased. Their melting points were determined by means of DTA:[2] **1**, mp 84.8°; **2**, mp 115.5°. Sodium chloride, hydrochloric acid, and perchloric acid were of pure-quality from Wako Pure Chemical Ind. Water was permeated and distilled.

Methods. The UV absorption spectra were obtained on a Hitachi 323 spectrophotometer and fluorescence intensity measurements were made on a Hitachi MPF 4 spectrofluorometer with an S-5 type photomultiplier tube. Spectral measurements were performed at 20°C unless otherwise mentioned. For fluorescence measurements, the wavelengths of the excitation light were chosen to be 324 nm for **1** and 321 nm for **2**, corresponding to the absorption maximum of the respective compounds. The concentrations of the fluorescent molecules in a solution were $\approx5\times10^{-5}$ mol dm^{-3} for **1** and $\approx4\times10^{-5}$ mol dm^{-3} for **2**. These provided for the most reliable recordings of the fluorescence intensity using the spectrofluorometer.[3] The pH or H_0 value[4] of the solution was controlled with $HClO_4$ and HCl. In the quenching experiment, the fluorescence of a series of samples containing a constant amount of a fluorescent compound and a graduated amount of quencher was measured. Fluorescence lifetime measurements were performed by means of a time-correlated single-photon-counting fluorometer, similar to the one described in Ref. 5. When the lifetime was close to the decay time of repetitive short-pulsed light at 337 nm from an air-flash lamp, the deconvolution procedure was performed assuming the exponential decay of the fluorescence intensity. The resulting accuracy was within ±0.05 ns.

Results and Discussion

pH Dependence of Absorption and Fluorescence Spectra. In the electronically ground state of 7-ethoxycoumarins, only one molecular species was spectroscopically detectable in an aqueous solution of neutral and acidic regions (pH 7 to H_0 −3) where fluorescence-quenching measurements have been carried out. In the excited state, a neutral molecule, $\overset{*}{N}$ and a protonated molecule, $\overset{*}{C}^+$ appear.[6] The interconversion of these species can be described by the reaction:



1: R = H, **2**: R = CH_3

Figure 1 shows the UV absorption spectrum and the visible fluorescence spectra of 7-ethoxycoumarin (**1**). The absorption maxima of **1** and **2** in the neutral solution were 324 and 321 nm respectively. These absorption spectra did not vary over the wide pH range

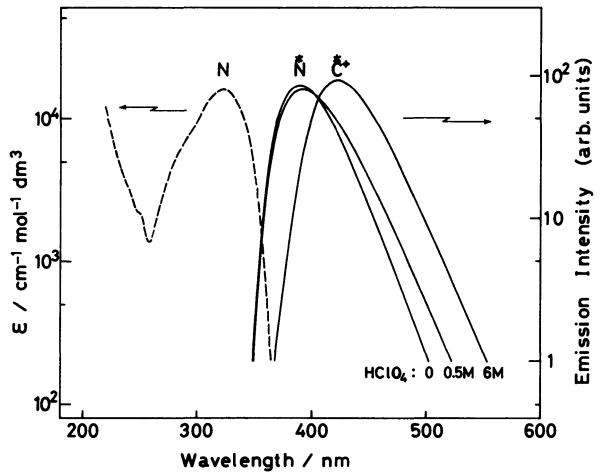


Fig. 1. Absorption and fluorescence spectra of 7-ethoxycoumarin (**1**) in aqueous solutions. N indicates the absorption spectrum of the neutral molecule. $\overset{*}{N}$ and $\overset{*}{C}^{+}$ are the fluorescence spectra from the excited state of the neutral and the protonated molecules respectively; the typical fluorescence spectra for the neutral solution and for the solution with 0.5 and 6 mol dm^{-3} $HClO_4$ added are shown.

of interest (H_0>−3). The new absorption band of a protonated molecule barely appeared in a solution of concentrated sulfric acid (H_0<−6) at longer wavelengths. Such absorption bands have been observed by others for similar coumarin derivatives;[18,19] the peaks are at 362 and 353 nm for **1** and **2**, respectively. In contrast, the fluorescence spectra began to change in shape and wavelength position for moderately acidic solutions. The fluorescence peak at 390 nm of Compound **1** in a neutral solution shifted to at last 423 nm at H_0≈−3; in the case of Compound **2**, these peaks were at 382 and 412 nm, respectively. The fluorescence peaks of these compounds at shorter wavelengths correspond to a neutral molecule in an excited state. The peaks at longer wavelengths correspond to a protonated molecule in an excited state.[6]

In moderately acidic solutions, these two types of fluorescence bands overlapped each other; therefore, it is necessary to separate the spectral bands in order to obtain a quantitative value for the relative fluorescence intensities of the two molecular species. For this procedure, it is very convenient to plot the emission intensity of the fluorescence spectrum with a logarithmic scale (Fig. 1). This is done because the contribution from each molecular species is readily recognized by adding the respective spectral bands and reconstructing the data in the graph at a given pH.

Fluorescence Quenching by Halide Ions. The fluorescence quenching by halide ions in a neutral aqueous solution was fully investigated in a previous paper and the quenching process was clarified.[1] From the experimentally obtained results, it has been concluded that chloride ions have no effect on the fluorescence intensity of a neutral molecule. Figure 2 shows plots of I_0/I vs. [Cl^-], where I_0 and I are the fluorescence intensities in the absence and in the presence of chloride ions. At pH≈7, a neutral molecule is the only species both in ground and excited states and Cl^- has no effect on the fluorescence intensity for [Cl^-]≲0.5 mol dm^{-3}.

Fluorescence Quenching by Chloride Ions in a Strongly Acidc Solution. When 6 mol dm^{-3} of $HClO_4$ was added beforehand to the solution (H_0=−2.84), protonated molecules became the unique species in the excited state and fluorescence was considerably quenched by the Cl^- (contained as a controlled amount of NaCl up to 0.25 mol dm^{-3}). In Fig. 2 data are shown for an aqueous solution with 6 mol dm^{-3} $HClO_4$ added; it can be seen from the figure that I_0/I depends linearly on [Cl^-]. In such case, the Stern-Volmer relationship derived under steady state conditions is apllicable:[7]

$$\frac{I_0}{I} = 1 + K_{sv}[Q]. \quad (1)$$

K_{sv} is the collisional quenching constant and [Q] is the quencher concentration. The data in Fig. 2 show the linear dependence of I_0/I on the concentration of chloride ions; the quenching constant, K_{sv}, of a protonated molecule (due to Cl^-) is estimated to be 6.80 mol^{-1} dm^3 for **1** and 4.21 mol^{-1} dm^3 for **2**. Using the rate constant, k_q, and the lifetime of the excited state of a protonated molecule, τ', the quenching constant is given by $K_{sv}=k_q\tau'$. The k_q values were estimated to be 1.39×10^9 mol^{-1} dm^3 s^{-1} for **1** and 8.77×10^8 mol^{-1} dm^3 s^{-1} for **2**, respectively, with the lifetimes shown in Table 2. The occurrence of this quenching effect is attributable to an increase in the interaction between positively charged molecules and negatively charged chloride ions through an attractive electrostatic force in comparison with the interaction between a neutral molecule and an ion.

Fluorescence Quenching by Chloride Ions in a Moderately Acidic Solution. When the same quenching experiment was performed in a moderately acidic solution, the dependence of I_0/I (for neutral and protonated molecules) on the Cl^- concentration did not obey the usual Stern-Volmer relationship, as can be clearly seen in Fig. 2 (a plot of I_0/I vs. [Cl^-]). The curve for the fluorescence of the neutral molecule curved downward away from a linear dependence; the curve for the protonated molecule curved upward. Since the sum of the concentrations of $HClO_4$ and HCl was made to be constant at 0.5 mol dm^{-3}, the ionic concentration,[8] Γ, and the acidity strength,[4] H_0, did not change for various concentrations of [Cl^-] (Γ=1 mol dm^{-3} and H_0=0.20). $\Gamma=\sum_i c_i z_i^2$, where c_i and z_i are the molar concentration and the valence of the ions in a solution. Thus, the unexpected behavior (mentioned above) cannot be related to a change in these values.

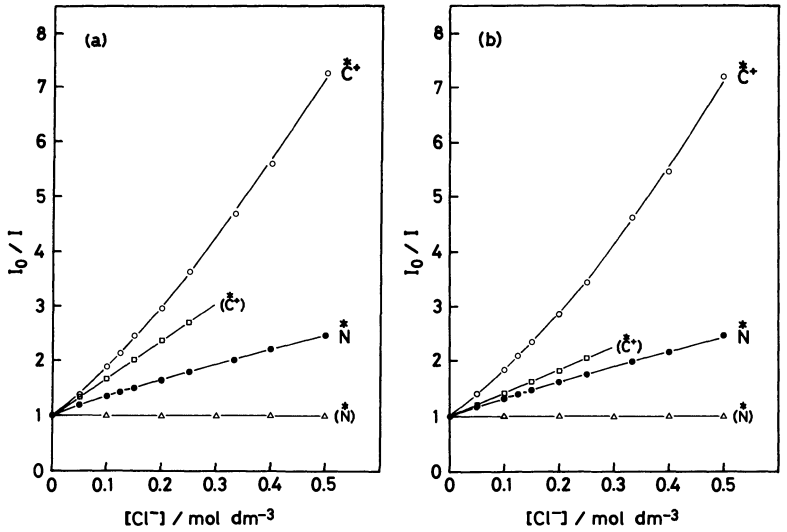

Fig. 2. Dependence of I_0/I on the concentration of the chloride ion in the neutral (△), the moderately acidic (○; ●), and the strongly acidic (□) solutions. (a), 7-ethoxycoumarin (**1**); (b), 7-ethoxy-4-methylcoumarin (**2**).

In order to analyze such phenomena from a general point of view, the following scheme for the chemical reaction and the fluorescence-quenching process is given:

$$N + h\nu_A \xrightarrow{G_{abs}} \overset{*}{N}, \tag{2}$$

$$\begin{array}{ccc} \overset{*}{N} + H^+ & \underset{k_2}{\overset{k_1}{\rightleftharpoons}} & \overset{*}{C}^+ \\ {\scriptstyle n_1}\swarrow\ \searrow{\scriptstyle n_2} & & {\scriptstyle n_1'}\swarrow\ \searrow{\scriptstyle n_2'} \\ N + h\nu_F \quad N & & C^+ + h\nu_F' \quad C^+ \end{array}, \tag{3}$$

$$W: \overset{*}{C}^+ + Q \underset{k_2'}{\overset{k_1'}{\rightleftharpoons}} (C^+Q)^* \xrightarrow{k_3'} C^+ + Q, \tag{4}$$

$$1 - W: \overset{*}{C}^+ + Q \longrightarrow C^+ + Q. \tag{5}$$

Here, N and C^+ represent neutral and protonated molecules, respectively. $\overset{*}{N}$ and $\overset{*}{C}^+$ are their excited states and Q and $h\nu$ represent the quencher and the light quantum. $(C^+Q)^*$ is the excited state of the encounter complex between $\overset{*}{C}^+$ and the quencher. G_{abs} is the generation rate of $\overset{*}{N}$; the k's and n's are the reaction-rate constants and the transition probabilities, respectively. Equation 3 describes an excited-state reaction of neutral molecules with protons which generates a protonated molecule. n_1 and n_1' are the radiative-transition probabilities that cause the fluorescence; n_2 and n_2' are the nonradiative-transition probabilities toward the electronic ground state. Equation 4 shows that the fraction, W, of $\overset{*}{C}^+$ obeys a collisional quenching process in which the encounter complex, $(C^+Q)^*$, decays nonradiatively to C^+ and Q with a rate of k_3'; Equation 5 shows that a fraction, $1-W$, of $\overset{*}{C}^+$ obeys the instantaneous deactivation process discussed in Ref. 1.

It is an essential idea for the explanation of experimental data that only a certain fraction, W, of the excited states is actually quenched by the collisional mechanism. The remaining fraction, $1-W$, is deactivated almost instantaneously after being formed since a quencher is accidentally positioned in the proximity of the molecule at the time of light-absorption and interacts very strongly with the molecule. Generally, this additional factor, W (a function of the quencher concentration, [Q]), can be approximated by $\exp(-V[Q])$, where V is the static quenching constant. If the model of Frank and Vavilov[9] is adopted for the instantaneous or "static" quenching process, an instantaneous quenching results when a quencher happens to reside within a "sphere of action" having a volume of V/N', where N' is the Avogadro's number per millimole.[10]

Since illuminating light is absorbed solely by neutral molecules under experimental conditions and the fraction, $1-W$, of the protonated molecule in the excited state is immediately quenched, the effective generation rate of neutral molecules in the excited state, $\tilde{G}(Q)$, is as a first approximation:

$$\begin{aligned} \tilde{G}(Q) &= G_{abs} - \{1 - W(Q)\} G_{abs} \frac{k_1[H^+]}{n_1 + n_2 + k_1[H^+]} \\ &= G_{abs} \frac{n_1 + n_2 + W(Q) k_1[H^+]}{n_1 + n_2 + k_1[H^+]}, \end{aligned} \tag{6}$$

where

$$W(Q) = \exp(-V[Q]) \text{ and } W(0) = 1. \tag{7}$$

The rate equations for each molecular species, therefore, become:

$$\frac{d[\overset{*}{N}]}{dt} = \tilde{G} - (n_1 + n_2 + k_1[H^+])[\overset{*}{N}] + k_2[\overset{*}{C}^+], \tag{8}$$

$$\frac{d[\overset{*}{C}^+]}{dt} = k_1[H^+][\overset{*}{N}] - (n_1'+n_2'+k_1'[Q]+k_2)[\overset{*}{C}^+] + k_2'[(C^+Q)^*], \quad (9)$$

$$\frac{d[(C^+Q)^*]}{dt} = k_1'[Q][\overset{*}{C}^+] - (k_2'+k_3')[(C^+Q)^*]. \quad (10)$$

If the steady-state condition is satisfied, we may obtain the densities of the excited molecules by letting the left-hand side of Eqs. 8—10 be zero. Then, the densities of $\overset{*}{N}$ and $\overset{*}{C}^+$ are:

$$[\overset{*}{N}] = \tilde{G}\tau / \left(1+\frac{1+k_q\tau'[Q]}{1+k_2\tau'+k_q\tau'[Q]}k_1\tau[H^+]\right), \quad (11)$$

$$[\overset{*}{C}^+] = \left(\tilde{G}\tau'\frac{k_1\tau[H^+]}{1+k_2\tau'+k_q\tau'[Q]}\right) \Big/ \left(1+\frac{1+k_q\tau'[Q]}{1+k_2\tau'+k_q\tau'[Q]}k_1\tau[H^+]\right), \quad (12)$$

where

$$\tau = \frac{1}{n_1+n_2} \text{ and } \tau' = \frac{1}{n_1'+n_2'}, \quad (13)$$

$$k_q = \gamma k_1' = \frac{k_3'}{k_2'+k_3'}k_1'. \quad (14)$$

τ and τ' correspond to the lifetimes of neutral and protonated molecules. k_q and γ are the apparent rate constant for the collisional quenching process and the efficiency of the quenching reaction, respectively. The total fluorescence intensities from $\overset{*}{N}$ and $\overset{*}{C}^+$ are defined by:

$$I^N = n_1[\overset{*}{N}] \text{ and } I^C = n_1'[\overset{*}{C}^+]. \quad (15)$$

Since the value of $\tilde{G}$ at [Q]=0 is G_{abs}, the fluorescence intensities at [Q]=0 for $\overset{*}{N}$ and $\overset{*}{C}^+$, i.e., I_0^N and I_0^C, are written as:

$$I_0^N = G_{abs}n_1\tau / \left(1+\frac{k_1\tau[H^+]}{1+k_2\tau'}\right) \text{ and} \quad (16)$$

$$I_0^C = \left(G_{abs}n_1'\tau'\frac{k_1\tau[H^+]}{1+k_2\tau'}\right) \Big/ \left(1+\frac{k_1\tau[H^+]}{1+k_2\tau'}\right). \quad (17)$$

Then, the relative fluorescence intensities, in comparison with the intensity at [Q]=0, of each excited molecule are given by:

$$\frac{I_0^N}{I^N} = \left\{\left(1+\frac{1+k_q\tau'[Q]}{1+k_2\tau'+k_q\tau'[Q]}k_1\tau[H^+]\right) \Big/ \left(1+\frac{k_1\tau[H^+]}{1+k_2\tau'}\right)\right\}\frac{1+k_1\tau[H^+]}{1+W(Q)k_1\tau[H^+]}, \quad (18)$$

$$\frac{I_0^C}{I^C} = \frac{I_0^N}{I^N}\frac{1+k_2\tau'+k_q\tau'[Q]}{1+k_2\tau'}. \quad (19)$$

From Eqs. 18 and 19, it is easily shown that $I_0^N/I^N \to 1$ and $I_0^C/I^C \to 1$ if $[Q] \to 0$, and $I_0^C/I^C > I_0^N/I^N > 1$ for $[Q] > 0$. These results can reasonably explain, in principle, the dependence of I_0/I on the concentration of the quencher. The experimental data in Fig. 2 show that I_0^C/I^C is always larger than I_0^N/I^N.

Tabel 1. Typical Values of I_0^N/I^N Shown in Fig. 2

Reaction-Rate Constants for the Quenching Process. To quantitatively analyze the quenching process in an acidic solution, we can derive from Eq. 19:

$$\frac{I_0^C/I^C}{I_0^N/I^N}=1+\frac{k_q\tau'}{1+k_2\tau'}[Q]. \tag{20}$$

This relationship predicts the linear dependence of $(I_0^C/I^C)/(I_0^N/I^N)$ on the concentration of the quencher; its slope gives the value of $k_q\tau'/(1+k_2\tau')$. The experimental data of $(I_0^C/I^C)/(I_0^N/I^N)$ vs. $[Cl^-]$ are plotted in Fig. 3. The dependence is a linear function of $[Cl^-]$ and the values of $k_q\tau'/(1+k_2\tau')$ are 4.00 mol^{-1}dm^3 for **1** and 3.92 mol^{-1}dm^3 for **2**, respectively.

It is helpful, at this stage, to define the fluorescence intensity of excited molecules at both $[Q]=0$ and $k_1\tau[H^+]\ll1$ by $\bar{I}_0^N$. From Eq. 16 we obtain $\bar{I}_0^N=G_{abs}n_1\tau$, and

$$\frac{\bar{I}_0^N}{I_0^N}=1+\frac{k_1\tau[H^+]}{1+k_2\tau'}. \tag{21}$$

The values of $\bar{I}_0^N/I_0^N$ and, of course, $k_1\tau[H^+]/(1+k_2\tau')$ are obtainable from the fluorescence data of a neutral solution and an acidic solution with $[H^+]=0.5$ mol dm^{-3}. The resulting values of $k_1\tau[H^+]/(1+k_2\tau')$ at $[H^+]=0.5$ mol dm^{-3} are 0.176 for **1** and 0.261 for **2**, respectively. Since the original form of $W(Q)$ as an exponential function of $[Q]$ is not tractable for an analytical calculation, the same approximation as was adopted in the former work[1] may be used again for a relatively low quencher concentration:

$$W(Q)\approx1-V[Q]. \tag{22}$$

Here, V is the static quenching constant. It is noted that this approximation has meaning only for $V[Q]<0.15$ when estimating the unknown parameter. Thus, the numerical values of I_0^N/I^N for the low concentration region of $[Cl^-]$ are cited in Table 1.

By using Tables 1 and 2 as well as the approximation given by Eq. 22, values of $k_q\tau'(=K_{sv})$ and V can be obtained from a best-fit analysis of the data points and the theoretical prediction. Then, K_{sv}, V, k_1, k_2, and k_q are given as cited in Table 3. Incidentally, the radius of the sphere-of-action for the quenching process, r, is estimated and cited in the same table, with the relation, $V/N'=4\pi r^3/3$, where N' is Avogadro's number per millimole. Qualitatively speaking, it is shown with the theoretical prediction that both I_0^N/I^N and I_0^C/I^C increase monotonically with an increase in the quencher concentration. The increase in I_0^N/I^N saturates at the higher concentration range and the value of I_0^N/I^N reaches asymptotically to $(1+k_2\tau')(1+k_1\tau[H^+])^2/(1+k_2\tau'+k_1\tau[H^+])$. The increase in I_0^C/I^C becomes linear with a slope of $(1+k_1\tau[H^+])^2k_q\tau'/(1+k_2\tau'+k_1\tau[H^+])$ in the higher concentration range. In general, I_0^N/I^N and I_0^C/I^C change in a complicated manner; thus, an analytical treatment has been possible only in the low concentration range where Eq. 22 is valid.

Equilibrium Constants in the Excited State. Since we know the values of k_1 and k_2, the reaction kinetics of Eq. 3 can be dealt with quantitatively. If equilibrium is reached in the excited state, analogous to the case in the ground state, the equilibrium constant for the conjugate acid of the neutral molecule, $\overset{*}{C}{}^+$, is described by $\overset{*}{K}_{C^+}=\overset{*}{a}_N a_{H^+}/\overset{*}{a}_{C^+}$. $\overset{*}{a}_N$ and $\overset{*}{a}_{C^+}$ are the activities of the neutral and protonated molecules in excited states, and a_{H^+} is the activity of a hydrogen ion. By using the difinition of the acidity function,[4] $H_0=-\log(a_{H^+}\overset{*}{f}_N/\overset{*}{f}_{C^+})$, where $\overset{*}{f}_N$ and $\overset{*}{f}_{C^+}$ are the activity coefficients of $\overset{*}{N}$ and $\overset{*}{C}{}^+$, and by assuming the relation, $k_1[\overset{*}{N}][H^+]=k_2[\overset{*}{C}{}^+]$, the following relation is obtainable for the $p\overset{*}{K}$ value:

$$p\overset{*}{K}_{C^+}=-\log\overset{*}{K}_{C^+}=-\log\frac{k_2}{k_1[H^+]}+H_0. \tag{23}$$

With the aid of Eq. 23, the $p\overset{*}{K}_{C^+}$ values were determined to be -0.10 for **1** and 0.06 for **2**, respectively.

Table 4. Comparison between the Collisional Quenching-Rate Constants and the Static Quenching Constants under Various Conditions

Substance	Quencher-Species	Condition	$k_q \times 10^{-9}$ / $mol^{-1}\,dm^3\,s^{-1}$	V / $mol^{-1}\,dm^3$
1	I^-–$\overset{*}{N}$	Neutral	10.2	1.6_2
	Br^-–$\overset{*}{N}$	Neutral	4.3_0	0.0_8
	Cl^-–$\overset{*}{C}^+$	$HClO_4$+HCl, 0.5M[a)]	5.8_0	1.2
	Cl^-–$\overset{*}{C}^+$	$HClO_4$, 6M	1.3_9	0
2	I^-–$\overset{*}{N}$	Neutral	9.6_5	1.8_1
	Br^-–$\overset{*}{N}$	Neutral	3.7_6	0.0_4
	Cl^-–$\overset{*}{C}^+$	$HClO_4$–HCl, 0.5M	3.6_5	1.7
	Cl^-–$\overset{*}{C}^+$	$HClO_4$, 6M	0.87_7	0

a) 1 M=1 mol dm^{-3}.

This shows that the forward and backward reactions described by Eq. 3 become competitive when the acidity function of a solution is in the proximity of zero.

Efficiency of the Collisional Quenching Process and Static Quenching Constant. The rate constant for the generation of the encounter complex, $(C^+Q)^*$, in Eq. 4 can be roughly estimated by the relation, $k_1' \approx 4\pi N' RD$. Here, R is the encounter distance between the reactants and D is the sum of the individual diffusion coefficients of the reactants.[11,12] If the values of R and D are reasonably assigned as 7 Å and 1.5×10^{-5} $cm^2\,s^{-1}$ (based on molecular and ionic volumes and the Stokes-Einstein relation[7]), the diffusion-limited value of the quenching-rate constant, k_1', is estimated to be about 8×10^9 $mol^{-1}\,dm^3\,s^{-1}$. The apparent rate constants for the collisional quenching, k_q, under various conditions are given in Table 4, together with the static quenching constants, V. k_q and k_1' are related by Eq. 14 and different by a factor, γ, representing the efficiency of the collisional quenching process.

Since k_q with $\overset{*}{N}$ quenched by iodide ions are comparable or slightly greater than 8×10^9 $mol^{-1}\,dm^3\,s^{-1}$, the efficiency of collisional quenching is supposed to be nearly unity, as has been concluded in previous work.[1] Such an effective collisional quenching has been attributed to a charge-transfer interaction between $\overset{*}{N}$ and I^- since the lower ionization energy of I^- (compared to other halide ions) increases the probability of a transfer of an electron from I^- to $\overset{*}{N}$.[13,14] However, the external heavy-atom effect through a spin-orbit coupling in the encounter complex between $\overset{*}{N}$ and I^- might also play a role in the collisional quenching process.[15] From the static quenching constant, V, for an interaction between $\overset{*}{N}$ and I^-, the radius of the sphere-of-action was calculated to be 8—9 Å. This is slightly larger than the value (6—7 Å) estimated as the sum of the radii of the coumarin and an iodide ion. Excited molecules generated very near to or in contact with iodide ions are subjected to an instantaneous deactivation toward the ground state due to the very strong interaction among the reactants.

When Br^- is used as a quencher, the efficiency of the collisional quenching process in a neutral solution becomes lower and, consequently, k_q decreases. This phenomenon is attributable to an increased ionization energy of Br^-, compared with I^-. This leads to a decrease in the strength of the charge-transfer interaction. Of course, a decrease in the heavy-atom effect of bromide ions might explain a part of this phenomenon. In parallel with this tendency, the static quenching constant, V in Table 4, decreases drastically and the encounter distance, R, for the collisional process is effectively shortened to γR. Thus, the radius of the sphere-of-action, being a measure of the interaction strength, is also considered to be shortened by the same order of magnitude as represented by the small value of V. Incidentally, Cl^- has no effect on fluorescence quenching for an excited neutral molecule, $\overset{*}{N}$, over the examined range of the quencher concentration.

In addition to the above-mentioned usual type of fluorescence quenching, we have recently found that $\overset{*}{C}^+$ is also quenched, even by the chloride ions in a moderately acidic solution, where $[H^+]=0.5$ mol dm^{-3}, while $\overset{*}{N}$ does not suffer quenching to any extent; k_q becomes $3.7—5.8\times10^9$ $mol^{-1}\,dm^3\,s^{-1}$, comparable in magnitude to the value for Br^- in a neutral solution. Since the heavy-atom effect of chloride ions is negligibly small compared to that from iodide and bromide ions, the occurrence of such intermediate quenching of $\overset{*}{C}^+$ by Cl^- (examined here) can be attributed to the existence of an attractive coulomb interaction between the reactants. Since $\overset{*}{N}$ does not have any charge on it, the interaction between $\overset{*}{N}$ and halide ions will be a contact interaction (a hard-core type interaction) in nature. Interactions between $\overset{*}{C}^+$ and Cl^-, on the other hand, are based on a long-ranged coulomb force, as long as the ionic concentration is low. However, the high concentration of dissolved ions tends to screen the interaction force. This attractive coulomb interaction will increase the probability of an electron being transferred from Cl^- to $\overset{*}{C}^+$ in the encounter complex, and, consequently, deactivating the complex to C^+ and Cl^- (Eq. 4). k_q is less than 8×10^9 $mol^{-1}\,dm^3\,s^{-1}$. One reason for

this may be that the efficiency of the collisional-quenching process becomes less than unity; then, every encounter event with Cl^- does not lead to a nonradiative decay of the excited protonated molecule. The other one is that k_i' may be affected by the ionic concentration, Γ, the effect of which would not be negligible under the experimental conditions. It is well known that the rate constant of a chemical reaction between particles with opposite charges becomes smaller if the ionic concentration of the solution would increase.[16] It has been very difficult to decide from only the data obtained here which factor for the collisional quenching process is essential to cause a smaller k_q value compared with the diffusion-limited value.

The static quenching constants, V (Table 4), for the quenching of $\overset{*}{C}^+$ by Cl^- in a moderately acidic solution is close to that for the quenching of $\overset{*}{N}$ by I^- in a neutral solution. The accuracy of V is not as high as that of k_q because of the approximation used here. However, it is sufficient for a qualitative discussion of the static quenching process. The estimated radius of the sphere-of-action for static quenching by Cl^- is 8—9 Å. This is, again, slightly larger than 6—7 Å that was estimated as the sum of the radii of the coumarin and a chloride ion. It may be considered strange that the interaction between $\overset{*}{N}$ and Br^- and the interaction between $\overset{*}{C}^+$ and Cl^- have similar k_q values but very different V values. The interaction between $\overset{*}{C}^+$ and Cl^- originates from an attractive coulomb force and extends rather widely over the solvent media; that between $\overset{*}{N}$ and Br^- is a contact interaction. This situation determines the great difference in V for the two cases.

Moreover, solvation effects and ion-pair generation[17] are considered to be important in a static-quenching event. The drastic decrease in V from I^- to Br^- (mentioned above) might be partly due to the strength of solvation ordering: $I^- < Br^- < Cl^-$. The solvation by water molecules will intervenes with the contact interaction and the static quenching of Br^- decreases in consequence. This point could not be checked for Cl^- since it shows no sign of a quenching effect in a neutral solution. Ion-pair generation is expected in the case of an interaction between $\overset{*}{C}^+$ and Cl^- if the both ionic species reside accidentally very near each other at the time the excited state of the protonated molecule is generated. There are, in general, two types of ion-pairs: the solvent-separated ion-pair and the contact-type ion-pair. The former is so loosely coupled that the electronic character of the species is almost the same as that of free ions. Considering the unchanged shape of the fluorescence spectrum of $\overset{*}{C}^+$ for a high concentration of Cl^- and the estimated sphere-of-action value, a solvent-separated ion-pair may be formed. This leads to the occurrence of an effective static quenching. In conclusion, static quenching may be effectively initiated in an atmosphere where reactants are caged by surrounding solvated water molecules. Ion-pair formation will strongly increase the probability of a deactivation of excited molecules.

Effect of the Ionic Concentration on the Rate Constant. When the ionic concentration, Γ, is 1 mol dm^{-3}, the Debye's screening length[8] is 4.3 Å. This is comparable to the mean radius of a molecule. The coulomb force between $\overset{*}{C}^+$ and Cl^-, being extended over the molecular dimension, is effective for static quenching. In the case of a solution with 6 mol dm^{-3} $HClO_4$ added, the Γ is almost determined by the amount of $HClO_4$ and $\Gamma \approx 12$ mol dm^{-3}. In this case, Debye's screening length becomes 1.2 Å and the electrostatic attraction is strongly screened by the ionic atomosphere. Thus, the interaction is limited to a region near the surface of the ionic species and the static quenching constant, V, becomes effectively zero, being inferred by the fact that the usual Stern-Volmer relation is apllicable to a plot of I_0/I vs. $[Cl^-]$.

As can be seen from Table 4, k_q for an interaction between $\overset{*}{C}^+$ and Cl^- in a solution of $[H^+]=0.5$ mol dm^{-3} is about four times larger than for a solution with an added 6 mol dm^{-3} $HClO_4$. As mentioned earlier, the reaction rate between particles with opposite charges becomes smaller if the ionic concentration is increased. Because of the very high value of the ionic concentration, the Debye-Hückel theory does not hold in its fundamental form, while the tendency of the change in the rate constant in ionic solutions is qualitatively correct from the point of view of a more detailed analysis.[16] The qenching effect of I^- and Br^- for $\overset{*}{C}^+$ in a solution containing 6 mol dm^{-3} $HClO_4$ was very large and the fluorescence was almost completely quenched in spite of the high ionic concentration. A quantitative experiment could not be performed in these cases.

The author wishes to thank Dr. Hiroyuki Anzai of this laboratory for his helpful advice and stimulating discussions during the course of this work.

The Solvent-Mode Effect on the Resonance Raman Excitation Profiles of Lycopene

Mineo SAITO and Yasushi MIKAMI*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received August 6, 1985)

The solvent-induced broadening mechanisms are considered in the calculation of resonance Raman excitation profiles (RREP) for the ν_1 and ν_2 vibrational modes of lycopene. The broadening mechanisms are classified into two groups: Inhomogeneous broadening due to a distribution of the 0-0 transition energies and solvent-induced homogeneous broadening due to coupling with low-frequency solvent-solute interactions. The conventional sum-over-states formula for RREP is transformed to a formally equivalent expression in the time domain. The results show that the homogeneous broadening dominates the RREP of lycopene.

Recently, Cotting et al.[1] have analyzed the Raman lines of lycopene by using a model including both homogeneous and inhomogeneous broadening mechanisms as well as the multi-mode theory. They have assumed that each broadening is characterized by a Lorentzian distribution with a line width, either Γ (homogeneous) or Γ_{inh} (inhomogeneous). They have calculated the resonance Raman excitation profiles (RREP) for the ν_1, ν_2, and ν_3 Raman lines using various values of Γ and Γ_{inh}, holding the total width Γ_{tot} ($=\Gamma+\Gamma_{\text{inh}}$) constant at a value determined from the absorption spectra. At the values of Γ_{tot} ranging from 450 cm^{-1} to 500 cm^{-1}, with about a 75% (350 cm^{-1}) contribution from Γ, the theoretical excitation profiles are in good agreement with the experimental data measured in ethyl alcohol, toluene, and carbon disulfide solvents. These results are more informative than those calculated by Hokins[2] with only homogeneous broadening. Cotting et al.[1] do not explicitly refer to the origin of homogeneous broadening. However, 350 cm^{-1} seems to be too large for a realistic damping constant.

In this context, it is worthwhile to see how the interpretations of the damping constant in the RREP for β-carotene analogous to lycopene have changed in the last several years. Since Inagaki et al.[3] reported the experimental RREP of β-carotene, their broad band shapes have been questioned by many investigators. In earlier work, the phenomenological damping constant was used in explaining the broadness of the RREP. Siebrand et al.[4] took a value larger than 200 cm^{-1} as a damping constant to reproduce the experimental data. However, Kodama et al.[5] have pointed out that the large value is due not to the damping effect but mainly to the solvent (-solute) low-frequency modes, which are not Raman active. Ho et al.[6] have found the pure damping constant to be of the order of 50 cm^{-1}, considering both the damping and the low-frequency-mode effects. Further, Chan et al.[7] emphasized that low-frequency modes provide a Gaussian type of broadening.

We can expect that the damping constant in lycopene is similar to that of β-carotene. Thus, the low-frequency-mode effect should be included in analyzing the RREP of lycopene. In this article, we will investigate the RREP of lycopene by considering the low-frequency-mode effect as well as the homogeneous broadening with a rather small damping constant. Inhomogeneous broadening is also taken into account. This broadening is static in nature, reflecting the spread in molecular transition frequencies. Thus, the statistical distribution provides a Gaussian-type broadening, in contrast with the Lorentzian shape taken by Cotting et al.[1]

Theory

In order to analyze the band shapes of the absorption spectra and the RREP of lycopene, we make the following assumptions:

(a) The Condon approximation is used, since the π-π^* transition is strongly allowed.

(b) Only one component of the electronic-transition moments is nonzero.

(c) The displaced harmonic oscillator model is used for both intramolecular modes and solvent (-solute) low-frequency modes.

(d) The Einstein model is assumed for the solvent modes. Thus, these modes are reduced to one collective mode, whose frequency and displacement are given by $\omega_s=N^{-1}\sum\omega_k$ and $\Delta_s^2=N^{-1}\sum\Delta_k^2$ respectively, were N is the total number of the solvent modes and where k refers to an individual solvent mode.

(e) The distribution of 0-0 transition frequencies is responsible for the inhomogeneous broadening and has a Gaussian form, i.e.:

$$\rho_{\text{inh}}(\omega)=(\sqrt{\ln 2})/\sqrt{\pi\Gamma_{\text{inh}}^2}\,\exp\left[-(\omega-\omega_{0'0})^2\ln 2/\Gamma_{\text{inh}}^2\right], \quad (1)$$

where $\omega_{0'0}$ is the mean value of the 0-0 transition frequencies and where Γ_{inh} is the inhomogeneous width.

The band-shape function of the absorption spectra of the system with inhomogeneous broadening is given by:

$$I(\omega_I)=\int d\omega\rho_{\text{inh}}(\omega+\omega_I)I_h(\omega), \quad (2)$$

where ω_I is the frequency of the incident light and where $I_h(\omega)$ is the band-shape function without inhomogeneous broadening. Within the Condon approximation, we can separate $I_h(\omega)$ into the high-frequency part, $I_0(\omega)$, and the low-frequency part, $\rho_{\text{low}}(\omega)$. Thus,

$$I_h(\omega)=|M_{ge}|^2\int d\omega' \rho_{low}(\omega')I_0(\omega'+\omega), \quad (3)$$

where M_{ge} is the electronic transition moment between the ground state (g) and the excited state (e). The high-frequency part, $I_0(\omega)$, represents the contribution from the optical modes which determine the intensity of the vibronic band. We can assume that the thermal excitation of the high-frequency modes can be neglected. Thus, the high-frequency part, $I_0(\omega)$, is given by:

$$\begin{aligned} I_0(\Omega) &= \frac{1}{\pi}\mathrm{Re}\sum_{v_1'=0}^{\infty}\cdots\sum_{v_n'=0}^{\infty}\prod_{j=1}^{n}|\langle 0|v_j'\rangle|^2\int_0^{\infty}dt\exp \\ &\quad [i(\Omega+\sum_{j=1}^{n}v_j'\omega_j)t-\Gamma t] \\ &= \frac{1}{\pi}\mathrm{Re}\int_0^{\infty}dt\prod_{j=1}^{n}\exp\left(-\frac{\Delta_j^2}{2}(1-e^{i\omega_j t})\right)\exp(i\Omega t-\Gamma t), \end{aligned} \quad (4)$$

where ω_j and v_j' are the vibrational frequency and the vibrational quantum number of the j-th mode in the excited state, and where Γ is the damping constant whose depenence on a vibrational level is neglected. The low-frequency part, $\rho_{low}(\omega')$, forms the band-shape function for the optical modes and is given by:

$$\rho_{low}(\omega')=\sum_{v_s=0}^{\infty}\sum_{v_s'=0}^{\infty}P_{v_s}|\langle v_s|v_s'\rangle|^2(v_s\omega_s-v_s'\omega_s-\omega') \quad (5)$$

where ω_s is a common vibrational frequency in the ground state and the excited state and where P_{v_s} the Boltzmann-distribution function of the v_s-th vibrational level in the ground state. $\rho_{low}(\omega')$ is also given by the following time integration:

$$\begin{aligned} \rho_{low}(\omega') &= \frac{1}{2\pi}\int_{-\infty}^{\infty}dt\exp\left(\frac{1}{2}\Delta_s^2(\langle n_s\rangle+1)e^{i\omega_s t}\right. \\ &\quad \left.+\frac{1}{2}\Delta_s^2\langle n_s\rangle e^{-i\omega_s t}-\frac{1}{2}\Delta_s^2(2\langle n_s\rangle+1)-i\omega' t\right) \end{aligned} \quad (6)$$

where $\langle n_s\rangle=(e^{h\omega_S/kT}-1)^{-1}$ is the thermal-average quantum number. We are concerned with the strong coupling case, i.e., $(1/2)\Delta_s^2(2\langle n_s\rangle+1)\gg 1$, in which the short time approximation used by Chan et al.[7] is valid. Thus, we can approximate $\rho_{low}(\omega')$ in this form:

$$\begin{aligned} \rho_{low}(\omega') &= \frac{1}{2\pi}\int_{-\infty}^{\infty}dt\exp\left(-it\left(-\frac{1}{2}\Delta_s^2\omega_s+\omega'\right)\right. \\ &\quad \left.-\frac{1}{4}\Delta_s^2(2\langle n_s\rangle+1)\omega_s^2 t^2\right) \\ &= (\sqrt{\ln 2}/\sqrt{\pi\Gamma_{low}^2})\exp[-(\omega'-\omega_{low})^2\ln 2/\Gamma_{low}^2], \end{aligned} \quad (7)$$

where $\omega_{low}=(1/2)\Delta_s^2\omega_s$ and where

$$\Gamma_{low}=\sqrt{\ln 2}\Delta_s\omega_s(2\langle n_s\rangle+1)^{1/2}. \quad (8)$$

Equation 7 indicates that the low-frequency mode induces a homogeneous broadening with a Gaussian shape with the width Γ_{low} and that the bodies of the absorption spectra are blue-shifted by ω_{low}. We call this broadening a "solvent-induced broadening."

By inserting Eq. 3 into Eq. 1, we obtain:

$$I(\omega_I)=|M_{ge}|^2\int d\omega\int d\omega'\rho_{inh}(\omega+\omega_I)\rho_{low}(\omega')I_0(\omega+\omega'). \quad (9)$$

Since both $\rho_{inh}(\omega+\omega_I)$, and $\rho_{low}(\omega')$ are Gaussian functions, their convolution is given by a Gaussian function:

$$I(\omega_I)=|M_{ge}|^2\int d\omega_a\rho_{tot}(\omega_a+\omega_I)I_0(\omega_a), \quad (10)$$

where:

$$\rho_{tot}(\Omega)=(\sqrt{\ln 2}/\sqrt{\pi\Gamma_{tot}^2})\exp[-(\Omega-\omega_{0'0}-\omega_{low})^2\ln 2/\Gamma_{tot}^2]$$

with $\Gamma_{tot}=\sqrt{\Gamma_{inh}^2+\Gamma_{low}^2}$. Only the total width, Γ_{tot}, can be obtained from the band shapes of the absorption spectra, so we cannot distinguish between inhomogeneous and solvent-induced homogeneous broadening. On the other hand, each broadening mechanism has a different influence on the band shapes of the RREP, as will be shown below.

The resonance Raman intensity of a fundamental line is given by:

$$S(\omega_I)\propto\omega_p^3\omega_I\int d\omega_a\rho_{inh}(\omega_a+\omega_I)\sum_{v_s=0}^{\infty}P_{v_s}|\alpha_{v_s}(\omega_a)|^2, \quad (11)$$

where ω_p is the frequency of the scattered light and where $\alpha_{v_s}(\omega_a)$ is the Raman tensor:

$$\begin{aligned} \alpha_{v_s}(\omega_a) &= -i(M_{ge})^2\sum_{v_1'=0}^{\infty}\cdots\sum_{v_1'=0}^{\infty}\int_0^{\infty}dt\langle 0|v_1'\rangle\langle v_1'|1\rangle e^{iv_1'\omega_1 t} \\ &\quad \times\prod_{j=2}^{n}|\langle 0|v_j\rangle|^2 e^{iv_j'\omega_j t}|\langle v_s|v_s'\rangle|^2 e^{i(v_s'-v_s)\omega_s t}e^{i\omega_a t-\Gamma t}. \end{aligned} \quad (12)$$

We can convert Eq. 12 into the analytic form, using the following relations:

$$\langle 0|v_j'\rangle\langle v_j'|1\rangle=\frac{\Delta_1}{\sqrt{2}}(1-e^{i\omega_1 t})\exp\left[-\frac{\Delta_1^2}{2}(1-e^{i\omega_1 t})\right], \quad (13)$$

$$|\langle 0|v_j'\rangle|^2 e^{iv_j'\omega_j t}=\exp\left[-\frac{\Delta_1^2}{2}(1-e^{i\omega_j t})\right] \quad (14)$$

and:

$$\begin{aligned} |\langle v_s|v_s'\rangle|^2 e^{i(v_s'-v_s)\omega_s t} &= \exp\left[-\frac{\Delta_s^2}{2}(1-e^{i\omega_s t})\right] \\ &\quad \times\sum_{p=0}^{v_s}\frac{v_s!\,e^{i(p-v_s)\omega_s t}}{p![(v_s-p)!]^2}\left(\frac{\Delta_s}{\sqrt{2}}(1-e^{i\omega_s t}-1)\right)^{2(v_s-p)}, \end{aligned} \quad (15)$$

where Δ_α (α=1, j, s) is the displacement of the α-th mode.

The lower-frequency part, Eq. 15, in Eq. 12 cannot be separated from the others, as in the case of absorption spectra, because the Boltzmann distribution factor, P_{v_s}, operates after $\alpha_{v_s}(\omega)$ is squared. The solvent-induced line-width, Γ_{low}, is related to the displacement, Δ_s, and the frequency, ω_s, of the low-frequency mode through Eq. 8. Thus, the solvent-induced line-broadening indirectly affects the RREP, though Γ_{low} does not explicitly appear in the formula. Fur-

ther, the RREP calculation clearly differentiates between the inhomogeneous broadening and the homogeneous broadening effects.

The time integrations in Eq. 4 and Eq. 12 can now be evaluated by the use of the time-dependent method proposed by Tannor and Heller.[9] In this article, the actual numerical integration is performed with the normalizing frequency, which has already been used in the calculation of radiationless transition rates in large molecules.[10,11] We now introduce the normalizing frequency, ω_N, which defines the integers:

$$\tilde{\omega}_j = \omega_j/\omega_N \text{ and } \tilde{\omega}_a = \omega_a/\omega_N.$$

Furthermore, the following quantities are defined:

$$\gamma = \Gamma/\omega_N \text{ and } x = \omega_N t.$$

Thus, we can write $I_0(\omega_a)$ in Eq. 9 as follows (see Eq. 4):

$$I_0(\omega_a) = \frac{1}{\pi\omega_N}\mathrm{Re}\sum_{v_1'=0}^{\infty}\cdots\sum_{v_n'=0}^{\infty}\prod_{j=1}^{n}|\langle 0|v_j'\rangle|^2 \times\int_0^{\infty}dx\exp(i\tilde{\omega}_a x+\sum_{j=1}^{n}iv_j'\tilde{\omega}_j x-\gamma x) \quad (16)$$

The time-integration in Eq. 16 leads to:

$$\int_0^{\infty}dx\exp(i\tilde{\omega}_a x+\sum_{j=1}^{n}iv_j'\tilde{\omega}_j x-\gamma x)=\frac{i}{\tilde{\omega}_a+\sum_{j=1}^{n}v_j'\tilde{\omega}_j+i\gamma} \quad (17)$$

On the other hand, we can easily obtain this relation:

$$\int_0^{2\pi}dx\exp\left(i\tilde{\omega}_a x+\sum_{j=1}^{n}v_j'\tilde{\omega}_j x-\gamma x\right)=\frac{i(1-e^{-2\pi\gamma})}{\tilde{\omega}_a+\sum_{j=1}^{n}v_j'\tilde{\omega}_j+i\gamma}. \quad (18)$$

because ω_j and ω_a are integers. Thus, we obtain:

$$I_0(\omega_a)=\frac{1}{\pi\omega_N(1-e^{-2\pi\gamma})}\sum_{v_1'=0}^{\infty}\cdots\sum_{v_n'=0}^{\infty}\prod_{j=1}^{n}|\langle 0|v_j\rangle|^2 \times\int_0^{2\pi}dx\exp(i\tilde{\omega}_a x+\sum_{j=1}^{n}iv_j'\omega_j x-\gamma x) =\frac{1}{\pi\omega_N(1-e^{-2\pi\gamma})}\int_0^{2\pi}dx\prod_{j=1}^{n}\exp\left[-\frac{\Delta_j^2}{2}(1-e^{i\tilde{\omega}_j x})\right]e^{i\tilde{\omega}_a x-\gamma x}. \quad (19)$$

Furthermore, we can replace the integration over the frequency in Eq. 10 by the following sum:

$$I(\omega_I)=\sum_{m=-\infty}^{\infty}\int_{m\omega_N}^{(m+1)\omega_N}d\omega_a\rho_{tot}(\omega_a+\omega_I)I_0(\omega_a) =\omega_N\sum_{m=-\infty}^{\infty}\rho_{tot}(m\omega_N+\omega_I)I_0(m\omega_N), \quad (20)$$

where we neglect the variation of the integrand in the $m\omega_N<\omega_a<(m+1)\omega_N$ region. A similar procedure leads to the following expressions for the resonance Raman intensity:

$$\alpha_{v_s}(\omega_a)=\frac{i}{\pi\omega(1-e^{-2\pi\gamma})}\int_0^{2\pi}dx\frac{1}{\sqrt{2}}(1-e^{i\omega_1 x}) \times\exp\left[-\frac{\Delta_1^2}{2}(1-e^{i\omega_1 x})\right] \times\prod_{j=2}^{n}\exp\left[-\frac{\Delta_1^2}{2}(1-e^{i\omega_j x})\right]\exp\left[-\frac{\Delta_s^2}{2}(1-e^{i\omega_s x})\right] \times\sum_{p=0}^{v_s}\frac{v_s!\,e^{i(p-v_s)\omega_s x}}{p![(v-p)!]^2}\left[\frac{\Delta_s^2}{2}(e^{i\omega_s x}-1)\right]^{2(v_s-p)} \quad (21)$$

and:

$$S(\omega_I)\propto\omega_p^3\omega_I\omega_N\sum_{m=-\infty}^{\infty}\rho_{inh}(m\omega_N+\omega_I)\sum_{v_s=0}^{\infty}P_{v_s}|\alpha_{v_s}(m\omega_N)|^2. \quad (22)$$

Results and Discussion

We will now analyze the band-shapes of the absorption spectrum and the RREP of lycopene in toluene solvents. The damping constant, Γ, is assumed to be $50\,cm^{-1}$ according to the case of β-carotene[6]; this corresponds to a picosecond relaxation process and seems to be realistic. This value has only a minor effect on the band-shapes of the absorption spectrum and the RREP, in the presense of inhomogeneous and solvent-induced homogeneous broadening mechanisms due to low-frequency modes.

The frequencies of the three Franck-Condon active modes, ν_1, ν_2, and ν_3, of lycopene are taken to be $\omega_1=1516\,cm^{-1}$, $\omega_2=1154\,cm^{-1}$, and $\omega_3=1005\,cm^{-1}$ respectively. The frequency, ω_s, and the displacement, Δ_s, of the solvent mode are related to the homogeneous line-width, Γ_{low}, through Eq. 8. In the following calculations, we first estimate the homogeneous line-width, Γ_{low}, from the absorption spectra. Thus, we do not need to provide ω_s and Δ_s independently. We prefer to give ω_s. Further, ω_s and Δ_s are somewhat arbitrary because only their combined quantity, i.e., Γ_{low}, is determined. Therefore, we can assume a round value of $50\,cm^{-1}$ as ω_s; this seems to be reasonable for an approximate frequency of the solvent mode. Let us now refer to the normalizing frequency, ω_N. For a given set of ω_j, a large number of ω_N values may give a value identical to those in Eqs. 19 and 21 because of the periodicity of the integrands. It is sufficient, however, to consider only their maximum- the largest common integer divider in the set. The value of ω_N should be, at most, $1\,cm^{-1}$ for our three ω_j values. However, even if some larger ω_N is used, the relative values of $\tilde{\omega}_j$ are not very largely altered, provided that each $\tilde{\omega}_j$ is redefined as the integer nearest to ω_j/ω_N. Therefore, we are allowed to adopt a larger ω_N than the largest common integer divider, disregarding a small rounding error. Thus, we take $25\,cm^{-1}$ as a value of ω_N. This value also satisfies the condition under which we can replace the integration into the sum in Eqs. 20 or 22, because the linewidth of lycopene is very large.

We adopt the same displacements of the three Franck-Condon active modes as those Cotting et al.[1] have used. Thus, we have $\Delta_1=1.1$, $\Delta_2=1.0$, and $\Delta_3=0.5$. Using these values of the displacements and varying the total width, Γ_{tot}, we calculate the absorp-

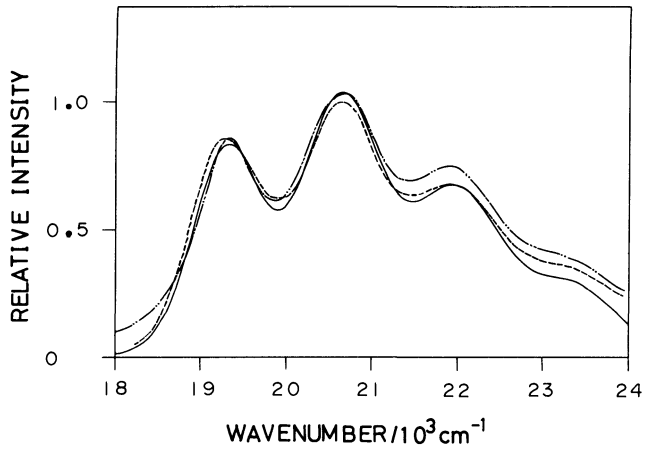

Fig. 1. Optical absorption line shapes for lycopene in toluene at 300 K. The measured absorption line shape (dashed line) is that of Ref. 1. The best fitted theoretical line shape (solid line) was obtained using Γ=50 cm^{-1} and Γ_{tot}=450 cm^{-1}, together with A_1=1.1, A_2=1.0, A_3=0.5 and $\omega_{0'0}+\omega_{low}$=19310 cm^{-1}. The (---) line is the another theoretical line shape with Γ=450 cm^{-1} and Γ_{tot}=0 cm^{-1}.

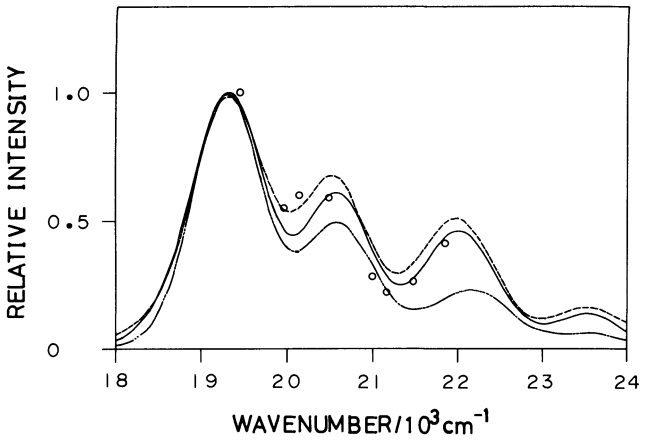

Fig. 2. Resonance Raman excitation profile line shapes of the ν_1 mode for lycopene in toluene at 300 K. The circles give a measured profile line shape of Ref. 1. The three theoretical curves are shown. The solid line is for Γ_{inh}=300 cm^{-1} and Γ_{low}=335 cm^{-1} the dashed line for Γ_{inh}=0 cm^{-1}, and Γ_{low}=450 cm^{-1} and the (---) line for Γ_{inh}=450 cm^{-1} and Γ_{low}=0 cm^{-1}. The other parameters used are the same as those in Fig. 1.

tion spectra and seek the curve best-fitting the experimental value. Figure 1 shows that the best fit is obtained at Γ_{tot}=450 cm^{-1} and $\omega_{0'0}+\omega_{low}$=19310 cm^{-1}. We also stress the good agreement in the lower-frequency region of the 0-0 band; this is in contrast to the result of Cotting et al. The disagreement may be due to a Lorentzian shape of the broadening. This fact is suggested by the following hypothetical calculations. We assume that only a pure damping effect contributes to the absorption band-width. That is to say, we take 450 cm^{-1} as the damping constant, Γ, and reduce Γ_{tot} to zero. The calculated absorbance comes to be higher than the one observed in the tail of the 0-0 band and resembles the result of Cotting et al. These results suggest that the main broadening mechanism is not related to the damping constant, Γ, giving a Lorentzian-type broadening, but to the width of inhomogeneous broadening, Γ_{inh}, and/or the width of the solvent-mode-induced broadening, Γ_{low}, both of which provide a Gaussian-type broadening.

In our model, Γ_{inh} and Γ_{low} cannot be distinguished in the analysis of the absorption spectra. On the other hand, the RREP calculation clearly differentiates between these effects, as has been shown in the previous section. First, we calculate the RREP for the two extreme cases. Figure 2 shows the RREP for the ν_1 vibrational mode of lycopene when only an inhomogeneous broadening exists and another extreme case in which only a homogeneous broadening mechanism is operative. The agreement between the theory and the experiment is better for the full homogeneous case than for the full inhomogeneous one. This fact suggests that the presence of low-frequency modes essentially determine the observed features of the RREP, in the case of the realistic damping constant, Γ, of 50 cm^{-1}. Further, a fairly large value (300 cm^{-1}) of inhomogeneous broadening Γ_{inh} only partly improves the RREP. This is intimately related to the Gaussian shape of homogeneous and inhomogeneous broadening. The total line-width for our Gaussian broadening is the same as that Cotting et al.[1] obtained by using the Lorentzian broadening mechanism. In the Lorentzian case, the total line-width, Γ_{tot}, is a sum of the inhomogeneous broadening, Γ_{inh}, and a damping constant, Γ. Since Γ_{tot} is determined to be constant from the absorption spectra, a large value of Γ_{inh} considerably reduces Γ. Cotting et al.[1] have already suggested that values of Γ_{inh} larger than 300 cm^{-1} may cause the major effect in the RREP. In our Gaussian case, however, the total line-width, Γ_{tot}, equals $\sqrt{\Gamma_{inh}^2+\Gamma_{low}^2}$. This relation leads to a still larger Γ_{low} (335 cm^{-1}), even at the large Γ_{inh} (300 cm^{-1}). The features of the RREP calculated with this Γ_{low} are similar to that of the full homogeneous case (Γ_{low}=450 cm^{-1}). In the presence of a large homogeneous broadening, an inhomogeneous broadening itself may little affect the RREP. A similar tendency is also shown for the ν_2 vibrational mode, as we can see in Fig. 3.

In conclusion, a reasonable damping constant, which is also similar to that of β-carotene, can be assumed for the case of lycopene if we take into account the solvent-induced broadening mechanisms. The full inhomogeneous broadening mechanism provides a rather large discrepancy between theory and experiment for the RREP. The experimental data are roughly consistent with the full homogeneous broadening mechanism. The effect of inhomogeneous

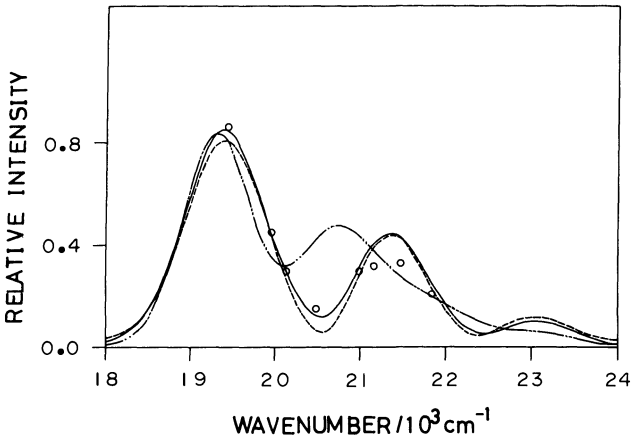

Fig. 3. Resonance Raman excitation profile line shapes of the ν_2 mode for lycopene in toluene at 300 K. The circles give a measured profile line shape of Ref. 1. The three theoretical curves are shown: The solid line is for $\Gamma_{inh}=300\,cm^{-1}$ and $\Gamma_{low}=335\,cm^{-1}$, the dashed line for $\Gamma_{inh}=0\,cm^{-1}$, and $\Gamma_{low}=450\,cm^{-1}$, and the (---) line for $\Gamma_{inh}=450\,cm^{-1}$ and $\Gamma_{low}=0\,cm^{-1}$. The other parameters used are the same as those in Fig. 1.

broadening partly improve the results, though the RREP values for the ν_1 and ν_2 vibrational modes of lycopene are insensitive to the large variation in Γ_{inh}.

The authors would like to thank Professor Takeshi Nakajima for his guidance and encouragement.

The Independent Electrochemical Detection of H_2O_2 and O_2 in Aqueous Alkaline Solutions on an Alkylsilanized Gold Electrode

Masamichi FUJIHIRA,* Hiroji MURAKI, and Shigeru AOYAGUI
Department of Chemical Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received August 27, 1985)

The cyclic voltammetric studies of H_2O_2 and O_2 in aqueous alkaline solutions were carried out on stationary gold electrodes unmodified and modified chemically with dodecyltriethoxysilane. Although two cathodic waves were observed for both H_2O_2 and O_2 on the unmodified electrode, only the second wave was observed for H_2O_2 on the modified electrode. Since the first cathodic wave of H_2O_2 overlaps that of O_2 on the unmodified electrode, the disappearance of the first wave of H_2O_2 makes it possible to distinguish O_2 from H_2O_2 on the modified electrode. The effect of alkylsilanization on the diminution and evolution of H_2O_2 or O_2 on gold electrodes was also confirmed by employing rotating ring-disk gold electrodes unmodified and modified similarly with dodecyltriethoxysilane. Furthermore, the reduction mechanism of H_2O_2 and the application of the independent electrochemical detection of H_2O_2 and O_2 are discussed.

In the last decade, the chemical modification of electrode surfaces has been intensively investigated as a means of making various functional electrodes.[1] In relation to the electrocatalysis of the modified electrodes for fuel cells, most researchers have been involved in the pursuit of a novel molecular design to accelerate electrochemical reactions.[2-4] However, for analytical purposes or mechanistic studies, we very often require the suppression of some undesirable electrode reactions to avoid the overlapping of a wave of interest with these unwanted ones. In the present paper, we demonstrate a novel electrode with a chemically modified surface for the independent detection of H_2O_2 and O_2 in aqueous alkaline solutions.

The analysis of H_2O_2 and O_2 in solutions is of great importance in the studies of fuel cells,[5-13] photocatalytic water splitting,[14-18] bioelectrochemistry,[19,20] etc. It has been difficult so far, however, to detect H_2O_2 and O_2 independently in their mixed system by electrochemical methods or by the conventional methods employed in the fields mentioned above, such as mass spectrometry and gas chromatography, since the waves of H_2O_2 and O_2 overlap each other on the electrodes and H_2O_2 is easily decomposed into O_2 and H_2O in the mass spectrometric and chromatographic apparatuses. The experimental findings described in the present paper show that the surface catalytic reduction of H_2O_2 on a polycrystalline gold electrode in aqueous alkaline solutions can be greatly suppressed by the chemical modification of the electrode surface with dodecyltriethoxysilane, while neither the reduction of O_2 nor the oxidation of H_2O_2 is affected appreciably. Namely, it is possible to detect H_2O_2 and O_2 on the electrode at different potentials without the overlapping of their waves. Recently we succeeded in finding evidence for the photolytic formation of H_2O_2 in TiO_2[21] and in $[Ru(bpy)_3]^{2+}$-modified TiO_2 aqueous suspensions by applying the present method. The present paper will describe the basis of the method in detail. The reduction mechanism of H_2O_2 will also be discussed on the basis of the new insight given by such a chemical modification.

Experimental

A gold plate and a gold ring-disk electrode were chemically modified with dodecyltriethoxysilane.[22] The chemical modification was carried out as follows. An unmodified gold plate, which had been thoroughly washed as has been described previously,[23] was immersed in a 10% silane coupling reagent solution, after which the solution was refluxed for 24 h. The reagent solution was prepared by the addition of dodecyltriethoxysilane to dry toluene. After silanization, the electrode was washed thoroughly with dry toluene. A gold ring-disk electrode was also chemically modified by the same procedure except that the ring-disk electrode was dipped in the coupling reagent solution in a desiccator at room temperature without reflux for 3 d. A gold plate or a chemically modified gold plate was used as a stationary working electrode. Electrochemical measurements with a homemade potentiostat were performed in a glass cell using, in addition, a gold plate and a saturated calomel electrode as a counter electrode and a reference electrode, respectively. Voltammetry with a gold ring-disk electrode or a chemically modified one was carried out with a Nikko Keisoku rotating ring-disk electrode system consisting of an RRDE-1 rotating ring-disk electrode drive with an SC-5 speed controller and a DPGS-1 dual potentiogalvanostat. A deaerated 0.3 mM H_2O_2 or an air-saturated aqueous solution, both containing 10 mM NaOH and 0.1 M KCl, was employed as the sample solution (1 M=1 mol dm^{-3}). All the solutions were prepared with doubly distilled water and G. R. -grade reagents. All the electrochemical measurements were performed at 25 °C.

Results and Discussion

Reduction and Oxidation of H_2O_2 on Unmodified and Chemically Modified Gold Electrodes. Figure 1A shows the cyclic voltammogram of the deaerated H_2O_2 solution on the unmodified gold electrode. On the negative sweep, starting at the rest potential of −0.13 V, two cathodic waves were observed with peak potentials of −0.2 and −0.8 V, respectively. Three mechanistic

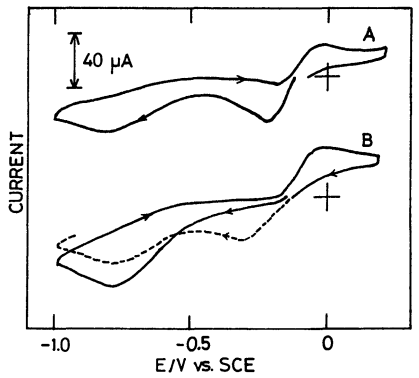

Fig. 1. Cyclic voltammograms of deaerated H_2O_2 aqueous solution on (A) an unmodified Au electrode and (B) a chemically modified Au electrode. NaOH (10 mM); KCl (0.1 M); H_2O_2 (ca. 0.3 mM); N_2 purged; sweep rate (40 mV s^{-1}); electrode area (0.79 cm^2).

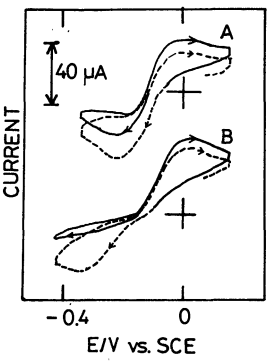

Fig. 2. Cyclic voltammograms of deaerated H_2O_2 aqueous solution on (A) an unmodified Au electrode and (B) a chemically modified Au electrode in the narrower potential range. Experimental conditions are the same as in Fig. 1.

interpretations of the first cathodic wave, with the peak potential of −0.2 V, have been presented. The first one is the surface catalytic reduction of H_2O_2, which proceeds via the adsorption of H_2O_2 on the surface of gold in the form of OH:[6,8]

$$HO_2^- + H_2O \longrightarrow 2OH(ads) + OH^- \quad (1)$$

$$2OH(ads) + 2e^- \longrightarrow 2OH^- \quad (2)$$

The second one is the surface catalytic reduction of H_2O_2, which proceeds via the adsorption of H_2O_2 on the surface in the form of O:[9]

$$HO_2^- \longrightarrow O(ads) + OH^- \quad (3)$$

$$O(ads) + e^- + H_2O \longrightarrow OH(ads) + OH^- \quad (4)$$

$$OH(ads) + e^- \longrightarrow OH^- \quad (5)$$

The third one is the reduction of O_2 generated by the chemical decomposition of H_2O_2 on the surface:[6,10]

$$2HO_2^- \longrightarrow O_2 + 2OH^- \quad (6)$$

$$O_2 + 2e^- + H_2O \longrightarrow HO_2^- + OH^- \quad (7)$$

However, the third mechanism can be ruled out because the peak potential of the first cathodic wave of H_2O_2 reduction is ca. 100 mV more positive than that of the O_2 reduction, as will be shown below. The second wave, with a peak potential of −0.8 V, may be due to the direct reduction of H_2O_2 on the gold surface:

$$HO_2^- + 2e^- + H_2O \longrightarrow 3OH^- \quad (8)$$

On the reverse scan, the cathodic current increased again in the potential region between −0.4 and −0.2 V. This indicates that the reduction shown by the first cathodic wave is limited within the narrow potential region.[6] Following the increase in the cathodic current, an anodic wave started at −0.15 V. This wave can be assigned to the oxidation of H_2O_2:[6,8]

$$HO_2^- + OH^- \longrightarrow O_2 + H_2O + 2e^- \quad (9)$$

Figure 1B shows the cyclic voltammogram of the deaerated H_2O_2 solution on the chemically modified gold electrode. In contrast with the current observed on the unmodified electrode, only one cathodic wave, with a peak potential of ca. −0.8 V, was observed. This wave can be ascribed to the direct reduction of H_2O_2 described above. The pronounced suppression of the first wave on the modified surface may result from the blocking of the catalytic sites which bind H_2O_2 in the form of OH or O. On the reverse scan, an anodic wave with an onset potential of −0.15 V was observed. This indicates that neither the oxidation of H_2O_2 to O_2 nor the direct reduction of H_2O_2 to H_2O is appreciably affected by alkylsilanization. On the second negative scan, a new wave starting at −0.1 V appeared. The peak potential of this new wave was −0.3 V which coincided with the peak potential of the first wave of the O_2 reduction, as will be shown below. This wave, therefore, can reasonably be assigned to the reduction of the O_2 which was generated on the preceding positive sweep.

Figure 2A shows the cyclic voltammogram of the deaerated H_2O_2 solution on the unmodified gold electrode recorded in a narrower potential region than that shown in Fig. 1A. All the waves can be assigned in the same way as those in Fig. 1A.

Figure 2B shows the cyclic voltammogram of the deaerated H_2O_2 solution on the chemically modified gold electrode, also recorded in a narrower potential region than that shown in Fig. 1B. On the first negative sweep, very little current flowed. On the reverse scan, consequently, a higher anodic current for the oxidation of H_2O_2 (Eq. 9) than that in Fig. 2A appeared because the irreversible transformation of H_2O_2 to H_2O was suppressed. On the second negative scan, a cathodic wave with a peak potential of −0.3 V was observed. This peak potential coincided with that of the first wave of O_2 reduction, as will be shown below. On the second

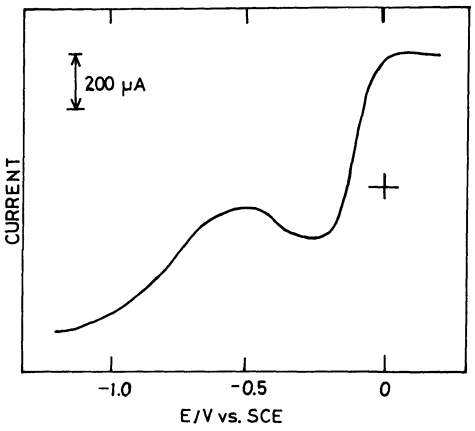

Fig. 3. Voltammetric curve of deaerated H_2O_2 aqueous solution on a rotating unmodified Au disk electrode. Sweep rate (20 mV s^{-1}); rotation speed (3600 rpm). Solution conditions are the same as in Fig. 1.

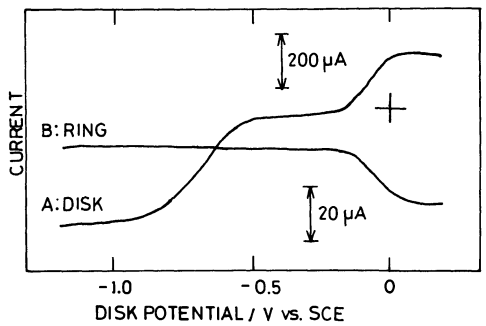

Fig. 4. (A) Current on a rotating chemically modified Au disk electrode and (B) current on a rotating chemically modified Au ring electrode for deaerated H_2O_2 aqueous solution as a function of the disk potential. positive sweep, the anodic wave height decreased a little, but the height was still much higher than that in Fig. 2A.

Figure 3 shows the current-potential curve for the deaerated H_2O_2 solution on an unmodified rotating disk electrode. This curve indicates that the oxidation wave height at anodic potentials is equal to the cathodic one at the potentials more negative than −1.0 V. This result is reasonable because both reactions, i.e., oxidation to O_2 and reduction to H_2O, are two-electron processes from H_2O_2. The dependence of these currents on the rotational speed confirmed that both currents are mass-transfer-limited. A maximal value of catalytic current was observed around −0.25 V. This also indicates that the surface catalytic reduction of H_2O_2 is limited within this potential region.

Figure 4A shows the current-potential curve for the deaerated H_2O_2 solution on a chemically modified rotating disk electrode. It is remarkable that the increase in the cathodic current between −0.15 and

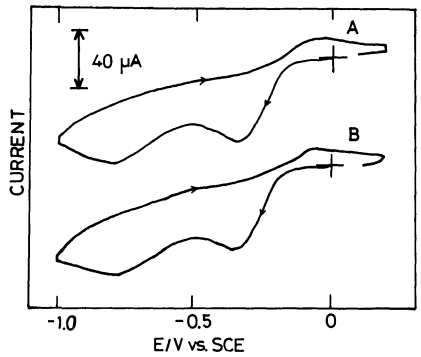

Fig. 5. Cyclic voltammograms of air-saturated aqueous solution on (A) an unmodified Au electrode and (B) a chemically modified Au electrode. Air-saturated. Other experimental conditions are the same as in Fig. 1.

−0.4 V shown in Fig. 3 was completely suppressed and that very little current flowed in the potential region. This suppression of the cathodic current corresponds to that observed on the stationary chemically modified gold electrode shown in Figs. 1B and 2B. The suppresion of the wave indicates that the chemical modification of the surface may block the catalytic sites of the gold surface. It is also seen in Fig. 4A that the magnitude of the H_2O_2 oxidation current at the potentials more positive than 0 V was smaller than that of H_2O_2 reduction current at the potentials more negative than −1.0 V. This may come from the contamination of the gold surface with impurities in the solution, which inhibits the oxidation of H_2O_2 more than the reduction of H_2O_2, since the cleaning of the gold surface by applying a more positive potential than +0.5 V, that was used for the unmodified electrode, had to be avoided for the maintenance of the modified surface.

Reduction of O_2 on Unmodified and Chemically Modified Gold Electrodes. Figure 5A shows the cyclic voltammogram of the air-saturated solution on the unmodified gold electrode. Two cathodic waves, with peak potentials of −0.3 and −0.8 V, respectively, were observed. The first wave corresponds to the reduction of O_2:[6,8-11]

$$O_2 + 2e^- + H_2O \longrightarrow HO_2^- + OH^- \qquad (10)$$

By comparing the results shown in Figs. 1—4 and 5A, we assigned the second wave to the direct reduction of H_2O_2 (Eq. 8) which had been generated by the O_2 reduction at the first cathodic wave (Eq. 10). On the reverse scan, an anodic wave starting at −0.15 V was observed. This was not observed when the sweep started first in the positive direction. The comparison of Figs. 1—4 and 5A also reveals that this anodic wave corresponds to the oxidation of H_2O_2.

Figure 5B shows the cyclic voltammogram of the air-saturated solution on the chemically modified gold electrode. The voltammogram is similar to that

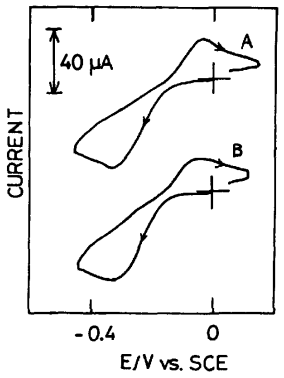

Fig. 6. Cyclic voltammograms of air-saturated aqueous solution on (A) an unmodified Au electrode and (B) a chemically modified Au electrode in the narrower potential range. Experimental conditions are the same as in Fig. 1.

recorded on the unmodified gold electrode shown in Fig. 5A. However, the ratio of the peak current of the first cathodic wave to that of the second cathodic wave, i_{p1}/i_{p2}, was slightly smaller on the chemically modified electrode shown in Fig. 5B than the ratio obtained on the unmodified one shown in Fig. 5A. On the unmodified gold electrode, the H_2O_2 generated by the O_2 reduction in the first cathodic wave (Eq. 10) was partially reduced further to H_2O by the succeeding reactions shown by the first cathodic wave in Fig. 1A (Eqs. 1, 2 or 3—5). On the other hand, since the further reactions were suppressed on the chemically modified electrode, the value of i_{p1}/i_{p2} became smaller than that on the unmodified one.

Figures 6A and 6B show the cyclic voltammograms of the air-saturated solution on the unmodified and chemically modified gold electrodes, respectively, recorded in a narrower potential region than those in Figs. 5A and 5B. The cathodic waves with a peak potential of −0.3 V indicate the reduction of O_2 to H_2O_2. On the reverse scan, the anodic waves with larger peak current than those shown in Figs. 5A and 5B were observed, since the H_2O_2 generated by the O_2 reduction at the cathodic waves (Eq. 10) was not consumed in the succeeding irreversible cathodic reaction, as is shown in Figs. 5A and 5B (Eq. 8). When the sweep started first in the positive direction, though not shown in the figures, these anodic waves were not observed on either electrode.

Figure 7 shows the disk and ring currents as a function of the disk potential for the air-saturated solution on an unmodified rotating gold ring-disk electrode. The ring potential was set at +0.16 V, where the H_2O_2 oxidation had been shown to be diffusion controlled by prior CV measurements. The current-potential curves clearly indicate that O_2 is reduced to H_2O_2 between −0.4 and −0.7 V and that O_2 is further reduced to H_2O under totally mass-transfer-limited conditions at potentials more negative than −1.0 V. A comparison of Figs. 3 and 7

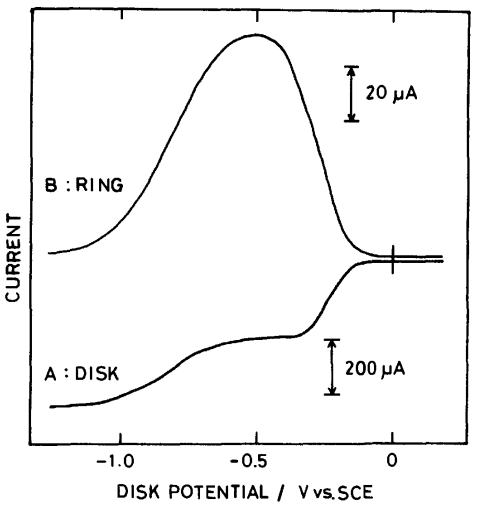

Fig. 7. (A) Current on a rotating unmodified Au disk electrode and (B) current on a rotating unmodified Au ring electrode for air-saturated aqueous solution as a function of the disk potential. Sweep rate (20 mV s^{-1}); rotation speed (3600 rpm); ring potential (0.16 V vs. SCE). Solution conditions are the same as in Fig. 1.

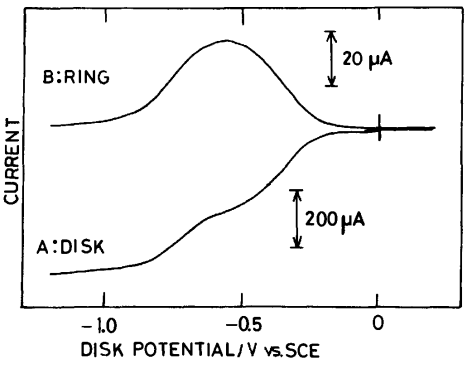

Fig. 8. (A) Current on a rotating chemically modified Au disk electrode and (B) current on a rotating chemically modified Au ring electrode for air-saturated aqueous solution as a function of the disk potential. Sweep rate (20 mV s^{-1}); rotation speed (3600 rpm); ring potential (0.10 V vs. SCE). Solution conditions are the same as in Fig. 1.

clearly shows that the potential where the H_2O_2 reduction starts is more positive than the potential where the O_2 reduction starts. This also supports the above interpretation that the intermediate of the H_2O_2 reduction between −0.2 and −0.4 V is not O_2, but adsorbed OH or O.

Figure 8 shows the disk and ring currents as a function of the disk potential for the air-saturated solution on a rotating electrode whose disk and ring electrodes had both been chemically modified. The ring potential was set at +0.1 V where the ring current reaches a plateau. In a qualitative sense, however, there was no significant difference from the result obtained on an unmodified rotating ring-disk electrode (shown in Fig. 7).

Independent Detection of H_2O_2 and O_2 on the Chemically Modified Gold Electrode. The experimental findings presented above lead to the conclusion that, on an alkylsilanized gold electrode, only oxygen can be reduced at around −0.3 V; therefore, the independent electrochemical detection of H_2O_2 and O_2 in their mixture is possible. More specifically, the concentration of H_2O_2 can be determined by its anodic or cathodic currents, and that of O_2 by its cathodic currents. Frumkin and his co-workers obtained two separate two-electron reduction waves for O_2 and H_2O_2 on an amalgamated gold electrode,[24] just as on mercury.[25] However, the use of amalgamated and other foreign-metal-adatom-modified electrodes[26] in positive potentials is limited by the dissolution of the foreign metals. In addition, the amalgamation is not suitable for modifying an optically transparent gold electrode for photoelectrochemical studies, for the stability of gold films decreases upon the amalgamation.

Figure 4B shows the ring current as a function of the disk potential for the deaerated H_2O_2 solution on a chemically modified rotating ring-disk electrode. The ring potential is set at −0.45 V, where O_2 can, but H_2O_2 cannot be reduced on the chemically modified gold electrode, as has been described above. The abrupt increase in the ring current from the residual current indicates that H_2O_2 is oxidized to O_2 at potentials more positive than −0.15 V. It should be noted that this observation is possible only on the chemically modified electrode, since, on the unmodified one, O_2 and also H_2O_2 are reduced at the potential of −0.45 V. This independent detection of O_2 is one of the most effective applications of the chemically modified electrode. In the experimental procedure of the chemical modification of the ring-disk electrode, however, the coupling solution could not be refluxed to avoid the contamination of the gold surface. The lack of refluxing sometimes causes an incomplete coverage of the electrode surface with the modifying molecules. The residual current observed at the potentials more negative than −0.15 V in Fig. 4B results from such an incompleteness, which permits the partial reduction of H_2O_2.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60040051 from the Ministry of Education, Science, and Culture.

^{129}I Mössbauer Spectroscopic Study of Several n-σ Charge-Transfer Complexes of Iodine with Thioethers

Hiroshi SAKAI,* Tomochika MATSUYAMA, and Yutaka MAEDA
Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka 590-04
(Received September 24, 1985)

^{129}I Mössbauer studies have been made of n-σ charge-transfer complexes of iodine with thioethers, such as thiane, 1,4-oxathiane, and 1,4-dithiane. The spectra of these complexes consist of two sets of quadrupole octets, corresponding to the bridging and terminal iodine atoms. The transferred charges from the thioethers are localized on the terminal iodine atoms, and the bridging iodine atoms have slightly positive charges. This result can be well explained in terms of a covalent bond between the sulfur and bridging iodine atoms or the MO treatment of a delocalized three-center four-electron bonding. The contributions of the dative structure to the ground state are estimated to be 36, 28, and 24% for thiane-iodine, 1,4-oxathiane-iodine, and 1,4-dithiane-iodine respectively. The nature of the charge-transfer bond is discussed in comparison with amine-iodine complexes.

The Mössbauer spectroscopy of ^{129}I is a powerful tool for the study of charge-transfer (CT) complexes containing iodine as an electron acceptor. The electronic structure of iodine is directly derived from the Mössbauer spectroscopy parameters, such as the quadrupole coupling constant (e^2Qq) and its sign, the asymmetry parameter (η), and the isomer shift (δ). Actually, many investigations of CT complexes of iodine have been reported to date using ^{129}I Mössbauer spectroscopy.[1-10] However, these investigations have been mostly concerned with nitrogen-containing compounds (amines) and with aromatic compounds as the electron donors.

Sulfur-containing compounds (thioethers) also act as electron donors and form n-σ type CT complexes with iodine in the same way as do amines. The crystal and molecular structures for some of these complexes (1,4-dithiane–iodine,[11] dibenzyl sulfide–iodine,[12] and 1,5-dithiocane–iodine[13]) have been determined by the X-ray diffraction method. In these complexes, the iodine molecule is bonded to the sulfur atom to give a linear S···I–I arrangement. The intramolecular I–I bond distance is longer than that of the free iodine molecule, whereas the intermolecular S···I bond distance is shorter than the sum of the respective van der Waals radii. Hendra and Sadasivan[14] measured the far-infrared spectrum of the 1,4-dithiane-iodine complex and found the I–I stretching frequency at 158 cm^{-1}, lower than that of free iodine molecules at 213 cm^{-1}.[15]

The properties of the CT complexes have been interpreted on the basis of the CT theory developed by Mulliken.[16] As is well known, the CT interaction between an electron donor (D) and an electron acceptor (A) is to be described in terms of the electronic-wave function of the ground state in this form;

$$\Psi_g = a\phi_0(\mathrm{D,A}) + b\phi_1(\mathrm{D^+-A^-}), \quad (1)$$

where ϕ_0 represents the wave function for a non-bond structure and ϕ_1, that for a dative structure in which one electron has been completely transferred from the donor to the acceptor molecule. The ground state, Ψ_g, stabilized by a resonance between the non-bond and dative structures. When A is the iodine molecule, the transferred electron may occupy the antibonding molecular orbital (σ_u*) of the iodine molecule. Therefore, the contribution of ϕ_1 to Ψ_g gives rise to an increase in the I–I bond distance and a decrease in the stretching frequency of the I–I bond. It is, therefore, important and interesting to estimate the contribution of the dative structure in order to understand the properties of the CT complexes in the electronic ground state.

In this paper we wish to report an ^{129}I Mössbauer spectroscopic study of the crystalline n-σ CT complexes between iodine and thioethers, such as thiane (tetrahydrothiopyrane)–iodine (1:1), 1,4-oxathiane–iodine (1:1), and 1,4-dithiane–iodine (1:2). The charge density and the charge distribution on each iodine atom are determined for these complexes, and the nature of the CT bond is discussed in comparison with amine–iodine complexes.

Experimental

Materials. The ^{129}I-labeled complexes were prepared on a small scale by mixing approximately stoichiometric amounts of the components in appropriate solvents. The radioisotope ^{129}I was purchased from the New England Nuclear Corporation in the standard form of Na^{129}I in a Na_2SO_3 solution. Molecular iodine ($^{129}I_2$), obtained by oxidizing Na^{129}I with 3 mol dm^{-3} H_2SO_4 and 10% H_2O_2, was extracted with chloroform, hexane, or carbon tetrachloride. Each iodine solution was thoroughly washed with water and passed through a Teflon filter to eliminate any slight amount of water.

The thiane–iodine complex was prepared by adding a stoichiometric amount of thiane to the iodine solution of chloroform. A dark-brown crystalline product was obtained by the subsequent concentration and cooling of the solution. The orange-red 1,4-oxathiane–iodine complex was prepared in hexane in the same manner as the thiane–iodine complex. The purple crystalline complex of 1,4-dithiane–iodine was obtained by adding a saturated iodine solution of carbon tetrachloride to a dithiane solution of the same solvent. Since those complexes slowly decompose in air, the samples obtained were immediately mounted in Teflon sample holders and kept in liq. N_2 until ready for the Mössbauer

measurements. The mole ratio of each component for these complexes was checked on nonradioactive (natural iodine) preparation samples by means of iodometry and elemental analysis. The thioether: I_2 ratios determined for the thiane-iodine, 1,4-oxathiane-iodine, and 1,4-dithiane-iodine complexes were 1:1, 1:1, and 1:2 respectively. The thichnesses of the absorbers were in the range of 20 to 30 mg $^{129}I/cm^2$.

^{129}I Mössbauer Effect Measurement. The $^{66}Zn^{129}Te$ source ($t_{1/2}$=70 min) was prepared by the irradiation of 150 mg $^{66}Zn^{128}Te$ at a thermal neutron flux of 2×10^{13} n cm^{-2} s^{-1} for 1 h in the Kyoto University Reactor (KUR). The source activity produced was initially about 10 mCi, which was sufficient to obtain a reasonable spectrum in 3—4 h of data collection. The 27.8 keV Mössbauer γ-ray was detected with a 1 mm-thick NaI(Tl) scintillation counter, and a 100 μm In foil was inserted between the absorber and the detector in order to selectively absorb 29.8 keV X-ray, resulting in the conversion of 39.6 keV Xe γ-ray. The Mössbauer measurement was performed in the transmission geometry by cooling the source and the absorber to 16 K with a closed-cycle helium refrigerator, "Cryodyne 1020." The Mössbauer spectrometer was calibrated using an iron spectrum.

Results and Discussion

In Figs. 1 and 2 the ^{129}I Mössbauer spectra at 16 K of the thiane-iodine, 1,4-oxathiane-iodine, and 1,4-dithiane-iodine complexes are presented. These spectra consist of a superposition of two quadrupole octets, as is to be expected from the molecular structure of the 1,4-dithiane-iodine complex. The spectra were analyzed by the least-squares method using a double set of the fitting parameters, e^2Qq, η, δ, full-width at half-maximum (2Γ), each peak intensity, and a single base line. The solid lines and the stick diagrams in the figures represent the best-fitted Lorentzian curves and the peak positions respectively. The Mössbauer parameters computed are given in Table 1, together with the results for some amine-iodine complexes published elsewhere. The e^2Qq value was converted to that of the ^{127}I nucleus by using the ground-state quadrupole moment ratio, $^{129}Q/^{127}Q=+0.70121$.[17]

The crystallographic data for the 1,4-dithiane-iodine complex suggest that only one atom of the iodine molecule is bonded to the sulfur atom, resulting in a linear S···I–I arrangement (Fig. 3).[11] The Mössbauer spectra shown in Figs. 1 and 2 are similar to each other. The similarity of these spectra suggests that iodine molecules are also bonded equatorially to the sulfur atoms of thiane and 1,4-oxathiane in the thiane-iodine and 1,4-oxathiane-iodine complexes. Since the values of e^2Qq, η, and δ for the 1,4-oxathiane-iodine complex are close to those for the other complexes, the iodine molecule may not interact with the oxygen atom of the 1,4-oxathiane molecule. In the 1,4-oxaselenane-iodine complex, the oxygen atom is also not involved in the intermolecular bonding.[18] These spectra are similar to those of the amine-iodine complexes. By analogy with the pyridine-iodine complex,[3,8] it is appropriate to assign the iodine with the larger quadrupole splitting (I_A) to the iodine atom coordinated to the sulfur atom (the bridging iodine atom), whereas the I_B should be assigned to the terminal iodine atom.

The values of e^2Qq, η, and δ are closely related to the charge distribution and the charge density on the iodine atom. As is shown in Table 1, these values for the I_A atoms are very close to each other in these complexes, suggesting that they are also similar in S···I_A bond

character. The small η values for I_A are consistent with the axially symmetric linear S···I_A–I_B orientation. On the other hand, the values of e^2Qq and δ for the I_B atoms increase in the order: thiane<1,4-oxathiane<1,4-dithiane. Since an increase in e^2Qq and δ corresponds to a decrease in the p-electrons charge density on the iodine atom, the extent of CT, i.e., the contribution of the dative structure to the ground state, increases in the order of : thiane>1,4-oxathiane>1,4-dithiane in these complexes.

The quantitative treatment of e^2Qq, η, and δ has been developed by Townes and Dailey[19] and Hafemeister et al.,[20] and an additional discussion of the ^{129}I Mössbauer parameters has been given in reviews.[21,22] According to those reviews, the observed e^2Qq, η, and δ values are related to the population of the 5p-electrons and the number of 5p-electron holes in the iodine atom as follows:

$$U_p = -e^2Qq_{obs}/e^2Qq_{atom} = -N_z + (N_x+N_y)/2 \quad (2)$$

$$\eta = 3(N_x-N_y)/2U_p \quad (3)$$

$$\delta = 1.5h_p - 0.54 \quad \text{(mm/s, for ZnTe source)} \quad (4)$$

where U_p is the number of unbalanced p-electrons and e^2Qq_{atom}, the atomic iodine quadrupole coupling constant, is equal to 2292.7 MHz for ^{127}I. N_x, N_y, and N_z are the populations of the 5p-electrons in the x, y, and z orbitals respectively, and $h_p=6-(N_x+N_y+N_z)$ is the number of p-electron holes in the $5p^6$ shell.

The U_p and h_p values obtained for the I_A and I_B atoms of the thioether-iodine complexes are presented in Table 1, together with those for some amine-iodine complexes. It can be observed that all the h_p values are larger than the U_p values for the I_A atoms. The same tendency is found in the I_A atoms of the amine-iodine complexes. This phenomenon has been successfully interpreted in terms of the contribution of $4d_\sigma$-electrons to the CT-bond formation.[8] That is, the S···I–I or N···I–I bonding can be described as a mixture of two extreme bonding schemes, i.e., a delocalized three-center four-electron bond using only the valence p-electrons and covalent σ bonds of two $d_\sigma p_\sigma$ hybrid orbitals of the center atom (I_A) with the two terminal atoms (S or N and I_B), as was first pointed out by Lucken.[23] The effect of the $4d_\sigma$ hybridization leads to an increase in the effective s-electron density and therefore markedly increases the δ value because of the large shielding coefficient, 0.85, for 4d-electrons compared to the value 0.35 for 5p-electrons.[8] On the contrary, if 5s-electrons take part in the CT-bond

formation ($sp\sigma$ hybridization), the δ value decreases greatly. Using Eqs. 4 and 5 in Ref. 8, the number of the $4d\sigma$-electron promotion to the 5p orbital can be easily estimated from the δ and e^2Qq values. The average values of δ and e^2Qq for the I_A atoms lead to 0.19 for h_d (the number of 4d-electron defects) and 0.88 for h_p. The contribution of the $d\sigma p\sigma$ hybridization to the S···I–I bond formation is estimated to be 19%, which is close to the value for the triethylamine–iodine complex. The promotion energy of the $4d\sigma$-electron may be compensated for by the stabilization of the CT-bond formation. Consequently, the bridging iodine atom is positively charged by 0.07(=0.19+0.88−1) in the present complexes.

On the other hand, Table 1 shows that the h_p values are in good agreement with the U_p values for the terminal iodine atoms (I_B). In the amine–iodine complexes, the h_p values are also close to U_p for the I_B atoms. This agreement implies that the bonding of the I_B atom is mainly due to $5p\sigma$-electrons. Therefore, the charge density of the I_B atom can be described with $1-h_p$. From the h_p values in Table 1, the I_B atoms for the thiane–iodine, 1,4-oxathiane–iodine, and 1,4-dithiane–iodine complexes are evaluated to be negatively charged by 0.43, 0.35, and 0.31 respectively.

The experimental fact that the transferred electron is not equally distributed on both I_A and I_B, but is strongly localized on I_B in the electronic ground state, can be qualitatively explained in terms of a covalent bond between the sulfur and I_A atoms. The distance of the intermolecular S···I_A bond is only 2.867 A for the 1,4-dithiane–iodine complex,[11] compared with the sum of the van der Waals radii of the sulfur and iodine atoms (4.0 A) or the sum of each covalent bond radius (2.37 A). This bond distance strongly suggests that a relatively strong covalent bond exists between the S and I_A atoms. For such strong CT complexes, Eq. 1, used for the weak interaction between a donor and an acceptor, is no longer applicable. Equation 1 may, then, be rewritten as follows:

$$\Psi_g = a\psi_0(>S,I_2) + b\psi_1(>S,I_A^+I_B^-) + c\psi_2(>S^+-I_AI_B^-), \quad (5)$$

where the first and second terms refer to the non-bond structures, and the third term, to the dative structure.. The fact that the I_A atom has slightly positive charges introduces the second term to the ground-state wave function. Fleming and Hanna[24] pointed out the importance of the second term because the electric field from lone pairs would give rise to an induced dipole in I_2 and would polarize partly to I^+I^-. Although the dative structure is usually described in terms of $\psi(>S^+-I_2^-)$, in which the two iodine atoms are equivalent, it is reasonable, in the case of strong complexes, to rewrite the dative structure as the third term because of the strong covalent bond between S^+ and I_A. The positive charge on the thioether is likely to be largely localized on the sulfur atom. Since S^+ presumably has a greater electron affinity than I_A in the intermolecular S^+–I_A bond, some positive charges may also be localized on I_A, resulting in the structure of $>S\ I_A^+\ I_B^-$. This structure is the same as that of the second term. Therefore, we include the effect of the ionic character on the second term, which is called "the ionic structure." The contribution of each structure to the ground-state wave function can be evaluated by means of the charge densities on the I_A and I_B atoms obtained from the Mössbauer spectrum, neglecting the overlap between ψ_0 and ψ_1, or between ψ_0 and ψ_2, as follows. Since the I_A atom is positively charged by 0.07, the contribution of the second term, in which I_A is a monocation, is found to be 7%. In both the second and third terms, the I_B atom exists as a monoanion. Therefore, the −0.43 charge localized on the I_B of the thiane complex leads to 43% for the contributions of the second and third terms. We obtain 36% for the contribution of the third term alone. The results for the thioether–iodine complexes are given in Table 2, together with those for some amine–iodine complexes.

Table 2. Contributions of the Non-Bond (a^2), Ionic (b^2), and Dative Structures (c^2) to the Ground-State Wave Function for the Thioether–Iodine and Amine–Iodine Complexes
