In recent years there has been a considerable interest in binuclear metal complexes because of their unique properties arising from the two metal ions in close proximity. As a face-to-face binucleating ligand, Ōkawa et al. have prepared 1,2,3,4-tetrakis(salicylideneamino)-2,3-dimethylbutane (abbreviated as H_4sata) which contains two "salpn" moieties (H_2salpn=*N,N'*-disalicylidene-1,2-propanediamine) combined at the 2-carbon atom of the diamine chain (Fig. 1).[2)] This ligand forms binuclear complexes M_2(sata) (M=Cu, Ni, Fe, Mn) which take two possible configurations, (i.e., stacking and nonstacking), caused by the rotation about the bridging C–C bond. The electronic and ESR spectra and electrochemical data suggested that the two MN_2O_2 planes are stacked in a face-to-face manner and interact with each other in solution.[3)] The structures of these complexes have not yet been confirmed by X-ray analysis, since we have obtained no crystal suitable for the analysis. In this study, however, another batch of crystals have proved to have better quality, thus we have carried out the X-ray structure analysis of Cu_2(sata).

Experimental

The Cu_2(sata) complex was prepared by the method previously reported.[2)] Crystals suitable for X-ray study were obtained as dark brown plates by crystallization from a dilute ethanol solution after standing one year. Anal. Found: C, 56.03; H, 4.83; N, 7.21%. Calcd for $C_{36}H_{40}Cu_2N_4O_7$=Cu_2(sata)·C_2H_5OH·$2H_2O$: C, 56.31; H, 5.25; N, 7.30%. A crystal with dimensions of 0.11×0.36×0.40 mm^3 was used for the X-ray analysis. The unit-cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer with graphite-monochromated Mo Kα radiation (λ=0.71073 Å) at 24±1 °C.

Crystal Data: $C_{36}H_{40}Cu_2N_4O_7$, F.W.=767.83; triclinic; $P\bar{1}$; a=16.691(1), b=17.106(1), c=15.641(1) Å; α=117.25(1), β=117.95(1), γ=88.83(1)°; D_m=1.50; D_c=1.50 g cm^{-3}; Z=4.

The intensity data were collected by the 2θ-ω scan technique with a scan rate of 3° min^{-1} in ω. A total of 8144 reflections with 2θ<43° were collected. The intensity data were corrected for the Lorentz and the polarization effects, but not for absorption. 4829 Independent reflections with $|F_o|>3\sigma(|F_o|)$ were considered as "observed" and were used for the structure analysis. The structure was solved by the direct method and refined by the block-diagonal least-squares method. The ethyl groups of ethanol molecules could not be located probably due to the disorder in the solvent molecules. Hydrogen atoms are not included in the calculation. In the least-squares refinement a weighting scheme, $w=(6.81+|F_o|+0.005|F_o|^2)^{-1}$ was employed. The final discrepancy factors were $R_1=\sum||F_o|-|F_c||/\sum|F_o|=0.080$ and $R_2=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.119$.

The atomic scattering factors and the anomalous dispersion corrections were taken from International Tables for X-Ray Crystallography.[4)] All the calculations were carried out on the FACOM M-200 computer in the Computer Center of Kyushu University by the use of a local version of the UNICS-III programs.[5)] The final positional and thermal parameters are given in Table 1. The anisotropic thermal parameters and the F_o—F_c tables have been deposited as a Document No. 8643 at the Office of the Editor.

Results and Discussion

The crystal contains two crystallographically independent binuclear molecules; they are represented as A and B. There are no significant differences in bond lengths and angles between A and B. The molecular structure of A is shown in Fig. 2, the "en-chelated structure" (Fig. 1) which was supposed from the electronic spectrum[2)] has been confirmed. The molecule consists of two "Cu(salpn)" moieties linked by the C(8)–C(8)′ bond. All the coordination geometries are nearly square planar, four donor atoms around a copper atom being coplanar with the deviations within ±0.14 Å. Each "Cu(salpn)" moiety does not form a rigorous plane, and may be described as "umbrella-shape."[6)] The five-membered chelate rings (Cu–N(1)–C(8)–C(9)–N(2), Cu′–N(1)′–C(8)′–C(9)′–N(2)′) assume a gauche conformation similar to that observed in the Cu(salpn)[7)] and Cu(salen)[8)] complexes (H_2salen=*N,N'*-disalicylidene-1,2-ethanediamine). Bond lengths and angles of the "Cu(salpn)"

moieties fall in the range of the values reported for a series of Cu(salen)-type complexes.[6–8]

It was pointed out that the ligand was diastereomeric (dl and meso) with respect to the 2- and 3-carbon atoms of the 2,3-dimethyl-1,2,3,4-butanetetramine moiety, and its configuration was inferred as the dl-form from the configurational study for the related complexes.[9] The present structural data have confirmed that the configuration of the tetramine moiety is the dl-form.

The Cu_2(sata) molecule in the crystal takes a nonstacked form though the discussions based on the

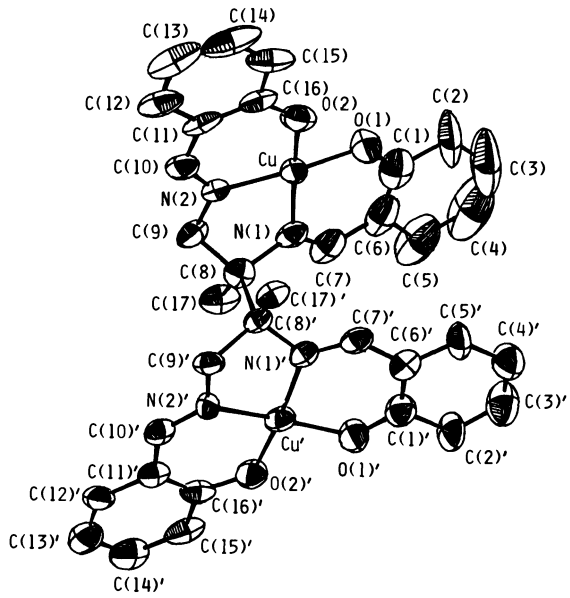

Fig. 2. Molecular structure of the Cu_2(sata) complex with thermal ellipsoids (35% probability level). Distances (l/Å): Cu–O(1) 1.879(12), 1.876(20); Cu–O(2) 1.879(12), 1.876(11); Cu–N(1) 1.921(13), 1.936(12); Cu–N(2) 1.936(11), 1.949(17); Cu′–O(1)′ 1.887(12), 1.888(16); Cu′–O(2)′ 1.888(12), 1.875(13); Cu′–N(1)′ 1.932(12), 1.950(13); Cu′–N(2)′ 1.921(11), 1.944(15). Angles (ϕ/°): O(1)–Cu–O(2) 87.2(5), 88.7(7); O(1)–Cu–N(1) 94.8(5), 95.2(6); N(1)–Cu–N(2) 84.9(5), 84.0(6); O(2)–Cu–N(2) 94.2(5), 93.1(6); O(1)′–Cu′–O(2)′ 88.1(6), 87.7(7); O(1)′–Cu′–N(1)′ 94.7(6), 94.7(6); N(1)′–Cu′–N(2)′ 84.3(5), 84.1(6); O(2)′–Cu′–N(2)′ 93.8(5), 94.6(6). Dihedral angles (τ/°) between the coordination planes, O(1)–N(1)–N(2)–O(2) and O(1)′–N(1)′–N(2)′–O(2)′: 11.2, 10.4 for molecules A and B, respectively.

electronic and ESR spectra and electrochemical properties in solution all pointed a stacked form. The intramolecular copper-copper distance is 6.118(3) Å. There is neither axial coordination nor intermolecular association, the closest atom, N(2), of neighboring molecule being separated from the copper atom by 3.447(14) Å. The present results do not contradict the conclusions derived from the solution studies, since the rotation about the C(8)–C(8)′ bond is feasible in solution so that the two coordination planes stack.

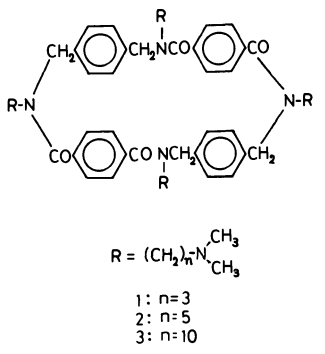
Tetraoxotetraazaparacyclophanes with Various Alkyl Chains as Hosts for Hydrophobic Compounds

Masato KODAKA* and Toshio FUKAYA
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received March 29, 1986)

Synopsis. Tetraoxotetraazaparacyclophanes with short or long alkyl chains and tertiary amino groups were synthesized. It was shown that *NN'N''N'''*-tetrakis-(3-dimethylaminopropyl)-3,10,21,28-tetraoxo-2,11,20,29-tetraaza[3.3.3.3]paracyclophane and *NN'N''N'''*-tetrakis-(5-dimethylaminopentyl)-3,10,21,28-tetraoxo-2,11,20,29-tetra-aza-[3.3.3.3]paracyclophane as well as *NN'N''N'''*-tetrakis-(10-dimethylaminodecyl)-3,10,21,28-tetraoxo-2,11,20,29-tetra-aza-[3.3.3.3]paracyclophane could undergo a complex formation with picrate and 8-anilino-1-naphthalenesulfonic acid, while the dissociation constants for the former cyclophanes were larger than those for the latter cyclophane. The hydrolysis of *p*-nitrophenyl hexanoate was also studied in the presence of the cyclophanes and azide ion (N_3^-), but the reaction was not significantly activated.

Chemical reactions in vivo are catalyzed by enzymes, where host-guest complexes are formed between substrates and enzymes before reactions take place. Another typical example of host-guest complexes can be seen in antigen-antibody reactions. Murakami et al. designed several tetraoxotetraazaparacyclophanes possessing four or eight long alkyl chains (octopus azaparacyclophanes) and characterized the complex formation with hydrophobic compounds.[1-3] Other types of water-soluble cyclophanes were synthesized by Tabushi et al.[4,5] and Odashima et al.,[6] which could undergo complex formations with some hydrophobic anionic compounds.

In the present work, we have studied the former type of cyclophanes, which have shorter alkyl chains than those characterized by Murakami et al.[1-3] and have tertiary amino groups. The substrate-binding ability of such tetraoxotetraazaparacyclophanes with shorter alkyl chains has not been studied so far.



Experimental

Tetraoxotetraazaparacyclophanes (**1**, **2**, **3**) were synthesized in a similar manner as reported.[1,2] Potassium picrate (Kanto Chemical Co.), 8-anilino-1-naphthalenesulfonic acid magnesium salt (ANS) (Nakarai Chemicals) and *p*-nitrophenyl hexanoate (*p*-NPH) (Tokyo Kasei Kogyo Co.) were used as supplied. Other reagents used were of the purest grade available.

Electronic absorption and fluorescence spectra were taken on a Beckman Model 34 spectrophotometer and a JASCO FP-4 fluorescence spectrophotometer, respectively, at pH 6.3 (0.1 mol dm^{-3} Na_2HPO_4–0.1 mol dm^{-3} NaH_2PO_4 buffer) and 25 °C. The hydrolysis of *p*-NPH was investigated under the conditions: pH 8.1 (0.05 mol dm^{-3} NaH_2PO_4–0.025 mol dm^{-3} $Na_2B_4O_7$ buffer), μ=0.1 (KCl) and 32 °C. The reaction rate was determined by measuring the absorbance at 400 nm, originating from the liberated *p*-nitrophenol, with a Beckman Model 34 spectrophotometer.

Results and Discussion

The absorption spectrum of potassium picrate changed upon the addition of **1**, **2**, or **3**. Typical spectral changes caused by **3** are shown in Fig. 1. By assuming the formation of a 1:1 complex between picrate and the cyclophane, the dissociation constants (K_d) were evaluated by the Benesi-Hildebrand plot[1] and are summarized in Table 1. In Fig. 2 is shown a typical plot for **1**. It should be noted that **1** and **2** form relatively stable complexes with picrate but their dissociation constants are larger than that with **3**.

It is generally known that the fluorescence intensity of ANS is significantly increased when it is situated in hydrophobic environments.[7] Thus, the dissociation constants for the complexes formed with ANS and the cyclophanes were obtained from the fluorescence measurements. Figure 3 shows the typical Benesi-

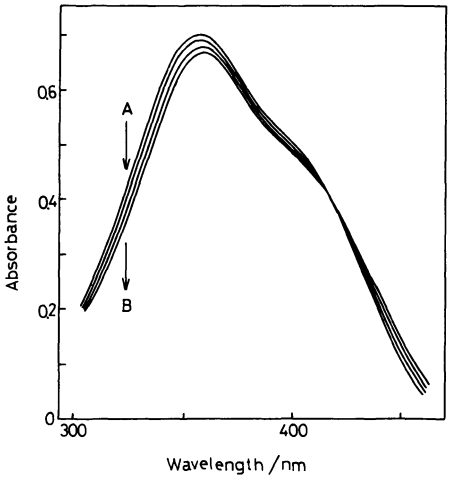


Fig. 1. Absorption spectra of potassium picrate at various concentrations of **3**: pH 6.3(0.1 mol dm^{-3} Na_2HPO_4–0.1 mol dm^{-3} NaH_2PO_4 buffer); 25 °C. The concentrations(mol dm^{-3}) of **3** are 0, 5×10^{-6}, 5×10^{-5} and 1×10^{-4}; read from A to B. The concentration of potassium picrate is 5×10^{-5} mol dm^{-3}.

1(1×10^{-3} mol dm^{-3})	1	1.7	1
2(1×10^{-3} mol dm^{-3})	1	1.7	1
3(5×10^{-5} mol dm^{-3})	1	1.8	40
3(1×10^{-4} mol dm^{-3})	1	2.1	50

a) pH 8.1 (0.05 mol dm^{-3} NaH_2PO_4–0.025 mol dm^{-3} $Na_2B_4O_7$ buffer), μ=0.1(KCl), 32 °C. b) Increase in the k value per mol dm^{-3} cyclophane.

Hildebrand plot for **1**. The determined K_d values are summarized in Table 1. Here, as in the case of picrate, **1** and **2** form relatively stable complexes with ANS, although **3** forms a much more stable complex with ANS than **1** and **2**. The relative deficiency of the stability for the complexes with **1** and **2** seems to be ascribed to the inefficient hydrophobicity provided by the shorter alkyl chains. The hydrophobicity of the cyclophane-skeleton seems to give an important effect on the complex formation in the case of **1** and **2** in comparison with the case of **3**.

The hydrolyses of active esters have been widely studied as catalyzed by enzyme-mimetic compounds or systems. Various cyclophanes have been used as enzyme models in the hydrolyses of active esters.[1,2,5,8] In the present study, the hydrolysis of *p*-nitrophenyl hexanoate (*p*-NPH) in the presence of the cyclophanes (**1**, **2**, and **3**) and azide ion(N_3^-) was investigated. Under the present experimental conditions, the cyclophanes may attract *p*-NPH by a hydrophobic interaction and N_3^- by an electrostatic force. The reaction followed the pseudo-first-order kinetics until the conversion of ca. 70%, although the rate enhancement was not so large. The pseudo-first-order rate constants (k) are shown in Table 2. In the presence of N_3^- (1×10^{-2} mol dm^{-3}) and **1** or **2** (1×10^{-3} mol dm^{-3}), k was increased by ca. 6% as compared with that in the presence of only N_3^-. In the case of **3**, the increase in the k value per mol dm^{-3} cyclophane ($\Delta k/C$) was much larger than in the cases of **1** and **2**. The strong binding ability of **3** toward *p*-NPH may be responsible for the larger rate acceleration. The enhancement was, however, not so significant as a whole, probably owing to the poor ability of **3** to bind N_3^-.

In the present study, tetraoxotetraazaparacyclophanes with shorter alkyl chains (**1** and **2**) and the one with relatively long alkyl chains (**3**) have been characterized. As a result, **1** and **2** have been found to include the hydrophobic anionic compounds (picrate and ANS), whereas the binding ability of **1** and **2** is not so large as that of **3**. These cyclophanes enhanced the hydrolysis of *p*-NPH to a minor extent.

Selective 2′-*O*-Methylation of Pyrimidine-Ribonucleosides by Trimethylsulfonium Hydroxide in the Presence of Mg^{2+} and Ca^{2+} Ions[1)]

Kiyoshi YAMAUCHI,* Toru NAKAGIMA, and Masayoshi KINOSHITA

Synopsis. Reactions of various ribonucleosides with trimethylsulfonium hydroxide were investigated in the presence of Mg^{2+} and Ca^{2+} ions. The 2′-OH groups of pyrimidine-ribonucleosides were methylated selectively.

The 2′-OH group of a ribonucleoside is assumed to be similar in reactivity toward various acylating and alkylating reagents to the 2′-OH groups of other ribonucleosides.[2)] In this paper we wish to report that (a) the 2′-OH groups of pyrimidine-ribonucleosides were methylated selectively by trimethylsulfonium hydroxide [$(CH_3)_3S^+$ OH^-, abbreviated as Me_3SOH hereafter] in the presence of Mg^{2+} and Ca^{2+} ions and (b) the selectivity was much higher than that observed in purine-ribonucleosides.

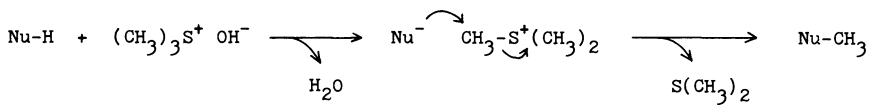
Methylation reactions were carried out by stirring a mixture of ribonucleosides and 1.5—2 equivalents of Me_3SOH in the presence and absence of 0.25—1 equivalent of $Mg(acac)_2$ or $Ca(acac)_2$ (acac=acetylacetonato) in DMF at 70 °C for 1 h. The metal salts were soluble in the solvent and allowed the reactions to occur in homogeneous solutions. Me_3SOH is a SN2-type reagent which reacts with nucleophiles according to the general scheme of Eq. 1.[3)] Methylation of the acetylacetone ligand by Me_3SOH was negligible under the conditions used. Typical results are listed in Table 1. One may draw the following conclusions.

(i) In the absence of $Mg(acac)_2$ and $Ca(acac)_2$, methylation occurred rather randomly on the ribose and the purine or pyrimidine moieties of the starting nucleosides (Entries 1, 4, 6, and 8).

(ii) In the presence of $Mg(acac)_2$ and $Ca(acac)_2$, Ado gave chiefly a mixture of 2′-MeAdo and 3′-MeAdo in a ratio of ca. 2.5:1 (entries 2 and 3).[1)] The combined extents of 2′-*O*-methylation and 3′-*O*-methylation[4)], however, showed only slight increases to 39 and 19% from 31 and 11%, respectively, which were observed in the absence of the metal salts. The use of the metal salts did not offer any merits of 2′-*O*- and 3′-*O*-methylations of other purine-ribonucleosides such as Guo, N^6-MeAdo and 1-MeGuo, either (the results are omitted in the Table).

(iii) By contrast, $Mg(acac)_2$ and $Ca(acac)_2$ allowed Me_3SOH to attack selectively and efficiently the 2′-OH groups of the pyrimidine-ribonucleosides such as Cyd, 3-MeUrd and 3-BenzylUrd (Entries 5 and 9—11). The yields of the 2′-*O*-methyl derivatives were better than those of the previous procedures.[5-8)] Urd gave 3,2′-Me_2Urd in a modest yield perhaps through 2′-*O*-methylation of the primary product, 3-MeUrd (Entry 7). The ratio of the 2′-*O*-methylation to the 3′-*O*-methylations were more than 10.

Many transition metal ions including Sn^{2+} and Cu^{2+} ions have been known to promote 2′-*O*- and 3′-*O*-methylations of both purine- and pyrimidine-nucleosides, affording the corresponding 2′-*O*-methyl and 3′-*O*-methyl derivatives with ratios of 2—5:1,[5-8)] and the effects have been attributed to the increased nucleophilicity of the 2′(3′)-*O*-atom upon their chelation with the metal ions.[9,10)] The same concept



(1)

may be applied to an efficient 2′-*O*- and 3′-*O*-methylations of 2′,3′-*O*-(dibutylstannylene)uridine with methyl iodide.[11)] Although it has been unsettled why a combination of Me_3SOH and $Mg(acac)_2$ or $Ca(acac)_2$ permitted the pyrimidine-nucleosides to undergo selective 2′-*O*-methylation, yet the results would be ascribed most likely to the chelating property of the metal ions (to the nucleosides) which might be different from the transition metal ions. The mechanism of the 2′-*O*-methylation is now under investigation.

Experimental

Ado, Cyd, and Urd were the highest purities obtainable commercially. 3-MeUrd and authentic samples (2′-MeAdo, 3′-MeAdo, N^6,2′-Me_2Ado, N^6,3′-Me_2Ado, 2′-MeCyd, 3′-MeCyd, N^4-MeCyd, 2′-MeUrd, 3,2′-Me_2Urd, and 3-MeUrd) were prepared previously.[8,13)] 3-BenzylUrd was synthesized by treating Urd (2.0 g, 8.2 mmol) in DMF (10 ml) with sodium hydride (60% in oil, 0.33 g, 8.2 mmol) followed by addition of benzyl bromide (1.7 g, 10 mmol) and refluxing the turbid mixture for 3 h. The reaction mixture was concentrated and applied to a silica-gel column. Elution with a mixture of chloroform and methanol (10–1 v/v) afforded 3-BenzylUrd, which was recrystallized from water; 2.4 g (88%), mp 179—181 °C, UV λ_{max} (H_2O) 261 nm (ε 7500) at pH 1 and 6, 261 nm (ε 7500) at pH 11.

Similarly, 2′-MeUrd was benzylated a the *N*-3 position to give 3-Benzyl, 2′-MeUrd in a 75% yield: Mp 156—158 °C; UV λ_{max} (H_2O) 260.5 nm (ε 10700) at pH 1 and 6, 262 nm (ε 10400) at pH 11; NMR ($CDCl_3$–CD_3OD, 2–1 v/v) δ=7.95 (d, 1, $J_{5,6}$=8.2 Hz), 7.35 (m, 5, C_6H_5), 5.88 (d, 2, $J_{1',2'}$=3.0 Hz), 5.77 (d, 2, $J_{5,6}$=8.2 Hz), 5.11 (s, 2, $CH_2C_6H_5$), 3.8—4.3 (m, 5, $C_{2'}H$, $C_{4'}H$, and $C_{5'}2H$), and 3.56 (s, 3, CH_3). Found: C,

a) Reaction conditions: nucleoside-Me_3SOH-$Mg(acac)_2$ or $Ca(acac)_2$-DMF=2 mmol-3.4 mmol-1 mmol-8 ml; reaction temperature and time: 70 °C and 1 h, respectively. b) The TLC-UV yields of the products in the reaction mixtures were determined in a manner similar to that mentioned previously (Ref. 13). The major products were isolated in the yields shown in the brackets. The isolated compounds had the following physical constants. 2′-MeAdo, mp 202—203 °C (from ethanol)(lit,[7] 202—203.5 °C); UV λ_{max} (H_2O) 259 nm (ε 14000) at pH 6. 3′-MeAdo, mp 176—177 °C (from ethanol)(lit,[7] 174—176 °C); UV λ_{max} (H_2O) 259 nm (ε 24500) at pH 6. N^6,2′-Me_2Ado, mp 104—105 °C (from acetone-hexane)(lit,[8] 103—105 °C); UV λ_{max} (H_2O) 265 nm (ε 14200) at pH 6. N^6,3′-Me_2Urd, mp 189—190 °C (from acetone-hexane)(lit,[8] 189—191 °C); UV λ_{max} (H_2O) 265 nm (ε 16500) at pH 6. 2′-MeCyd, mp 252—254 °C (from ethanol)(lit,[7] 251—254 °C); UV λ_{max} (H_2O) 271 nm (ε 8900) at pH 6. 3′-MeCyd, mp 209—210 °C (from ethanol)(lit,[7] 210—211 °C); UV λ_{max} (H_2O) 271 nm (ε 9000) at pH 6. 3,2′-MeUrd, mp 138—140 °C (from hexane)(lit,[14] 140—141 °C); UV λ_{max} (H_2O) 261 nm (ε 9800) at pH 6. 3-Benzyl,2′-MeUrd, mp as well as UV and NMR spectra were identical with those of the authentic sample (see the experimental section). c) The reaction of the Entry 11 gave 3-Benzyl,2′-MeUrd exclusively.

58.40; H, 6.05; N, 7.84%. Calcd for $C_{17}H_{20}N_2O_6$: C, 58.61; H, 5.78; N, 8.04%.

General Mathylation Procedure. A mixture of nucleoside (2.0 mmol) and 1.7 equivalents of a 0.7 M methanol solution (1 M=1 mol dm^{-3}) of Me_3SOH[3] was concentrated in the absence and presence of one equivalent of $Mg(acac)_2$ or $Ca(acac)_2$ below 20 °C. DMF (8 ml) was added to the resulting residue, and the mixture was stirred magnetically at 70 °C for 0.5—1 h. A product-distribution in the methylation reaction using authentic samples and isolation of major products were conducted in a manner similar to that mentioned previously.[8,13] A ratio, 2′-*O*-methyl nucleoside/3′-*O*-methyl isomer, was determined from the area ratio of the corresponding methoxyl groups in the NMR spectrum of the mixture which was separated from the reaction mixture by silica gel chromatography.

Optimal amounts of Me_3SOH and the $M(acac)_2$s were about 1.5—2 equivalents and 0.5 equivalent, respectively, to the starting nucleosides. The use of the excess $M(acac)_2$s did not improve overall yields of methylation. The optimal reaction temperature was 60—80 °C. At higher temperature, Me_3SOH underwent significantly decomposition to methanol and dimethyl sulfide.

10) Cu^{2+} and other transition metal ions were less selective than Mg^{2+} and Ca^{2+} ions in methylating the 2′-OH

groups of ribonucleosides. For instance, when Ado and Cyd were subjected to methylation reactions using 0.5 equivalent of $Cu(acac)_2$ under the conditions similar to those of Entry 2 and 5 of Table 1, the former provided 2′-MeAdo and 3′-MeAdo in 41 and 37%, respectively, and the latter furnished 2′-MeCyd and 3′-MeCyd in 60 and 22%, respectively.[8] A combination of diazomethane and tin(II) chloride converted Ado into 2′-MeAdo and 3′-MeAdo in 44 and 56%, respectively.[6,7] No detectable methylation of Ado was observed with the systems of diazomethane and Mg^{2+} and Ca^{2+} ions.[6]

Synthesis of 2,3-Dihydro-2-alkyl-3-(substituted amino)-1*H*-isoindol-1-ones. 2-Alkylation of 2,3-Dihydro-3-(substituted amino)-1*H*-isoindol-1-ones in a Phase-Transfer Catalyst System

Ryu SATO,* Toshihide SENZAKI, Takehiko GOTO, and Minoru SAITO
Department of Resource Chemistry, Faculty of Engineering, Iwate University, Morioka 020
(Received April 17, 1986)

Synopsis. A variety of 2,3-dihydro-2-alkyl-3-(substituted amino)-1*H*-isoindol-1-ones were conveniently synthesized by selective 2-alkylation of 2,3-dihydro-3-(substituted amino)-1*H*-isoindol-1-ones, which were derived from 2-cyanobenzaldehyde, with some alkyl halides in a phase-transfer catalyst system.

We recently reported the formation of γ-lactams, 2,3-dihydro-3-(substituted amino)-1*H*-isoindol-1-ones, from the reaction of 2-cyanobenzaldehyde with primary and secondary alkylamines at room temperature in excellent yields, and also revealed that the amines used were introduced regioselectively into the 3-position, not into the 2-position, of the 2,3-dihydro-3-(substituted amino)-1*H*-isoindol-1-ones.[1] Since 2-alkylated isoindol-1-ones could not be obtained directly by the method, our interests focused on the selective alkylation at the 2-position of 2,3-dihydro-3-(substituted amino)-1*H*-isoindol-1-ones. Although, to our knowledge, there have been no reports on the direct 2-alkylation of the isoindol-1-ones, the selective *N*-alkylation of amides in the presence of a phase-transfer catalyst have recently appeared.[2] We also reported the one-pot synthesis of alkyl aryl trithiocarbonates from benzenethiols and carbon disulfide with alkyl halides in the presence of a phase-transfer catalyst in good yields.[3] Thus, because of the experimetal simplicity, superior regioselectivity and high yields of the products, the phase-transfer catalyst(PTC) has been used widely for alkylations of some nitrogen or sulfur organic compounds which are difficult to be alkylated regioselectively.[4] This elegant technique encouraged us to explore the regioselective 2-alkylation of 2,3-dihydro-3-(substituted amino)-1*H*-isoindol-1-ones with alkyl halides. In this paper, we wish to report a first example for the 2-alkylation of 2,3-dihydro-3-(substituted amino)-1*H*-isoindol-1-ones(**2**), which are derived from 2-cyanobenzaldehyde(**1**),[1] in the phase-transfer catalyst(PTC) system to give 2,3-dihydro-2-alkyl-3-(substituted amino)-1*H*-isoindol-1-ones(**3**) in high yields (Scheme 1).

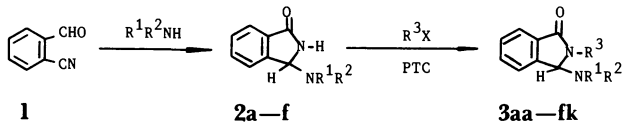
a) Tetrabutylammonium iodide was used as phase-transfer catalyst. b) Isolated yields based on the substrates.



1 2a—f 3aa—fk

Scheme 1.

Many 2,3-dihydro-2-alkyl-3-(substituted amino)-1*H*-isoindol-1-ones(**3**) were obatained in high yields as shown in Table 1. It should be noted that the synthesis of many functionalized isoindol-1-ones(**3**) containing cyano, chloro and unsaturated alkyl groups in the molecules as shown in the table was carried out successfully, of which antiflammatory activity has been observed.[5] In the absence of the phase-transfer catalyst, the substrate, isoindol-1-one(**2**), was not alkylated at all. Various quarternary ammonium salts, for example, methyltrioctylammonium chloride(TOMAC) and tetrabutylammonium bromide and iodide could be used, and little difference by the catalyst was observed in the present reaction. On the other hand, a considerable increase of the yield of 2-alkylated isoindol-1-ones(**3**) could be confirmed when the concentration of sodium hydroxide aqueous solution was changed to 50% from 20%. It is noteworthy that a high selectivity was observed in this reaction. Thus, 2-alkylated isoindol-1-ones(**3aa-cg**) were obtained by treating 3-amino(**2a**), 3-methylamino(**2b**), and 3-(*t*-butylamino)-2,3-dihydro-1*H*-isoindol-1-one(**2c**) with alkyl halide in the presence of tetrabutylammonium iodide in high yields without any 3-(alkylated amino)-2,3-dihydro-1*H*-isoindol-1-one (Runs 1—7). These reactions proceeded smoothly at 20 °C to 60 °C.

Consequently, a novel route to 2-alkyl-3-(substituted amino)-2,3-dihydro-1*H*-isoindol-1-ones(**3**) from 2-cyanobenzaldehyde(**1**) was confirmed.

Experimental

Measurements. All the melting points were uncorrected. NMR, IR and Mass spectra were recorded with a HITACHI R-22, HITACHI 295 and HITACHI RMU-6M, respectively. Elemental analysis were determined with YANAGIMOTO MT-3.

Materials. 2,3-Dihydro-3-(substituted amino)-1*H*-isoindol-1-ones(**2**) were obtained from reactions of 2-cyanobenzaldehyde(**1**) with the corresponding amines.[1]

General Procedure for the Preparation of 2,3-Dihydro-2-alkyl-3-(substituted amino)-1*H*-isoindol-1-ones(3) from 2,3-Dihydro-3-(substituted amino)-1*H*-isoindol-1-ones(2). An alkyl halide (1.1 mmol) was added dropwise to a mixture of 1.0 mmol of 2,3-dihydro-3-(substituted amino)-1*H*-isoindol-1-ones(**2**), 0.2 mmol of tetrabutylammonium iodide, 5 ml of benzene and 5 ml of 50% aqueous sodium hydroxide. The order of addition of the materials did not affect the results. After the completion of the addition, stirring was continued at 20 °C until the substrate disappeared (monitoring by TLC). Water (5 ml) was added to the reaction mixture and then the benzene layer was separated. The aqueous layer was extracted with benzene three times (5 ml each), and the organic layers were combined. Evaporation of the solvent from the combined benzene solution after drying with magnesium sulfate gives a yellow oil. Desired 2,3-dihydro-2-alkyl-3-(substituted amino)-1*H*-isoindol-1-ones(**3**) were obtained as clear colorless crystals by column chromatgraphy of the oil on silica gel (Wako gel C-300) using chloroform as eluent, followed by repeated recrytallization from chloroform-hexane. All products were new compounds, being assigned by physical, spectral and analytical data as follows.

3aa. Colorless crystals, mp 106 °C; IR (KBr) 3370, 3000, 2900, and 1685 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.80 (s, 2H, NH_2), 2.31 (s, 3H, CH_3), 4.37 and 5.10 (d, 2H, J=15.0 Hz, CH_2), 5.90 (s, 1H, CH) and 7.00—7.90 (m, 8H, arom); MS (70 eV) *m/z* 252 (M^+); Found: C, 76.14; H, 6.39; N, 11.10%. Calcd for $C_{16}H_{16}N_2O$: C, 76.16; H, 6.39; N, 11.10%.

3ab. Colorless crystals, mp 77 °C; IR (KBr) 3390, 3300, 2960, 1760, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.27 (t, 3H, 6.5 Hz, CH_3), 1.84 (s, 2H, NH_2), 4.14 and 4.52 (d, 2H, 17.0 Hz, CH_2), 4.18 (d, 2H, 6.5 Hz, CH_2), 5.42 (s, 1H, CH) and 7.45—7.85 (m, 4H, arom); MS (70 eV) *m/z* 234 (M^+); Found: C, 61.32; H, 6.02; N, 11.67%. Calcd for $C_{12}H_{14}N_2O_3$; C, 61.53; H, 6.02; N, 11.96%.

3bc. Colorless crystals, mp 107 °C; IR (KBr) 3340, 2925, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.94 (s, 3H, CH_3), 2.08 (bs, 1H, NH), 4.50 and 5.16 (d, 2H, 15.0 Hz, CH_2), 5.27 (s, 1H, CH) and 7.10—7.90 (m, 8H, arom); MS (70 eV) *m/z* 287 (M^+); Found: C, 66.88; H, 5.18; N, 9.76%. Calcd for $C_{16}H_{15}N_2OCl$: C, 67.02; H, 5.27; N, 9.77%.

3bd. Colorless crystals, mp 108 °C; IR (KBr) 3320, 2900, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.00 (s, 3H, CH_3), 4.28 and 5.09 (d, 2H, 15.0 Hz, CH_2), 5.22 (s, 1H, CH), 7.08—7.92 (m, 7H, arom); MS (70 eV) *m/z* 321 (M^+); Found: C, 59.65; H, 4.32; N, 8.72%. Calcd for $C_{16}H_{14}N_2OCl_2$: C, 59.83; H, 4.39; N, 8.72%.

3ce. Colorless crystals, mp 171 °C; IR (KBr) 3325, 2955, and 1670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.33 (s, 9H, CH_3), 3.07 (s, 3H, CH_3), 5.20 (s, 1H, CH) and 7.35—7.83 (m, 4H, arom); MS (70 eV) *m/z* 218 (M^+); Found: C, 71.12; H, 8.43; N, 12.87%. Calcd for $C_{13}H_{18}N_2O$: C, 71.53; H, 8.31; N, 12.83%.

3cf. Colorless crystals, mp 137 °C; IR (KBr) 3320, 2960, 2900, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (s, 9H, CH_3), 1.40 (b, 1H, NH), 4.07 (dd, 1H, 16.0,6.5 Hz, CH_2), 4.64 (dd, 1H, 16.0, 3.5 Hz, CH_2), 5.35 (s, 1H, CH), 6.00—6.60 (m, 2H, CH=CH) and 7.10—7.88 (m, 9H, arom); MS (70 eV) *m/z* 320 (M^+); Found: C, 78.67; H, 7.64; N, 8.84%. Calcd for $C_{21}H_{24}N_2O$: C, 78.71; H, 7.55; N, 8.74%.

3cg. Colorless crystals, mp 157 °C; IR (KBr) 3350, 2970, and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (s, 9H, CH_3), 1,47 (b, 1H, NH), 4.85 (d, 2H, 6.0 Hz, CH_2), 5.28 (s, 1H, CH) and 6.89—7.90 (m, 7H, arom); MS (70 eV) *m/z* 363 (M^+); Found: C, 62.76; H, 5.49; N, 7.69%. Calcd for $C_{19}H_{20}N_2OCl_2$: C, 62.82; H, 5.55; N, 7.71%.

3de. Colorless crystals, mp 53 °C; IR (KBr) 2960, 2825, and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.06 (t, 6H, 7.5 Hz, CH_3), 2.62 (q, 4H, 7.5 Hz, CH_2), 3.08 (s, 3H, CH_3), 5.22 (s, 1H, CH) and 7.30—7.86 (m, 4H, arom); MS (70 eV) *m/z* 218 (M^+); Found: C, 71.29; H, 8.23; N, 12.60%. Calcd for $C_{13}H_{18}N_2O$: C, 71.53; H, 8.31; N, 12.83%.

3dh. Colorless crystals, mp 69 °C; IR (KBr) 2975, 2840, 2250, and 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (t, 6H, 7.5 Hz, CH_3), 2.64 (q, 4H, 7.5 Hz, CH_2), 4.22 and 4.75 (d, 2H, 17.5 Hz, CH_2), 5.48 (s, 1H, CH) and 7.35—7.93 (m, 4H, arom); MS (70 eV) *m/z* 243 (M^+); Found: C, 69.00; H, 7.09; N, 16.98%. Calcd for $C_{14}H_{17}N_3O$: C, 69.11; H, 7.04; N, 17.27%.

3di. Colorless crystals, mp 79 °C; IR (KBr) 2950, 2820, and 1680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (t, 6H, 7.3 Hz, CH_3), 2.54 (q, 4H, 7.3 Hz, CH_2), 4.24 and 5.23 (d, 2H, 15.0 Hz, CH_2), 5.15 (s, 1H, CH) and 7.20—7.95 (m, 9H, arom); MS (70 eV) *m/z* 294 (M^+); Found: C, 77.22; H, 7.54; N, 9.31%. Calcd for $C_{19}H_{22}N_2O$: C, 77.52; H, 7.53; N, 9.52%.

3da. Colorless crystals, mp 64 °C; IR (KBr) 2960, 2825, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (t, 6H, 7.5 Hz, CH_3), 2.30 (s, 3H, CH_3), 2.54 (q, 4H, 7.5 Hz, CH_2), 4.19 and 5.20 (d, 2H, 15.0 Hz, CH_2), 5.14 (s, 1H, CH) and 6.98—7.88 (m, 8H, arom); MS (70 eV) *m/z* 308 (M^+); Found: C, 77.78; H, 7.97; N, 8.93%. Calcd for $C_{20}H_{24}N_2O$: C, 77.89; H, 7.84; N, 9.08%.

3dj. Colorless crystals, mp 87 °C; IR (KBr) 2960, 2840, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (t, 6H, 7.3 Hz, CH_3), 2.37 (s, 3H, CH_3), 2.53 (q, 4H, 7.3 Hz, CH_2), 4.30 and 5.20 (d, 2H, 15.0 Hz, CH_2), 5.10 (s, 1H, CH) and 7.08-7.95 (m, 8H, arom); MS (70 eV) *m/z* 308 (M^+); Found: C, 77.85; H, 7.93; N, 9.00%. Calcd for $C_{20}H_{24}N_2O$: C, 77.89; H, 7.84; N, 9.08%.

3dk. Colorless crystals, mp 69 °C; IR (KBr) 2950, 2820, and 1680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (t, 6H, 7.5 Hz, CH_3), 2.54 (q, 4H, 7.5 Hz, CH_2), 4.26 and 5.13 (d, 2H, 15.0 Hz, CH_2), 5.14 (s, 1H, CH), 7.25 (s, 4H, arom) and 7.35—7.93 (m, 4H, arom); MS (70 eV) *m/z* 329 (M^+); Found: C, 69.01; H, 6.39; N, 8.54%. Calcd for $C_{19}H_{21}N_2OCl$: C, 69.40; H, 6.44; N, 8.51%.

3dc. Colorless crystals, mp 88 °C; IR (KBr) 2960, 2830, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (t, 6H, 7.5 Hz, CH_3), 2.53 (q, 4H, 7,5 Hz, CH_2), 4.63 and 5.13 (d, 2H, 15.5 Hz, CH_2), 5.24 (s, 1H, CH) and 7.10—7.96 (m, 8H, arom); MS (70 eV) *m/z* 329 (M^+); Found: C, 69.17; H, 6.44; N, 8.47%. Calcd for $C_{19}H_{21}N_2OCl$: C, 69.40; H, 6.44; N, 8.51%.

3dg. Colorless crystals, mp 126 °C; IR (KBr) 2960, 2825, and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (t, 6H, 7.4 Hz, CH_3), 2.52 (q, 4H, 7.4 Hz, CH_2), 4.60 and 5.04 (d, 2H, 15.5 Hz, CH_2), 5.20 (s, 1H, CH) and 7.10—7.93 (m, 7H, arom); MS (70 eV) *m/z* 363 (M^+); Found: C, 62.58; H, 5.41; N, 7.64%. The Absolute Configuration of Isoprelaurefucin[1)]

Minoru SUZUKI,* Kazuya KURATA,† Teruaki SUZUKI, and Etsuro KUROSAWA*

(Received April 2, 1986)

Synopsis. (3*Z*)-Isoprelaurefucin has been isolated as a major metabolite from the red alga *Laurencia nipponica* Yamada, and its structure was confirmed by chemical correlation with isoprelaurefucin. Furthermore, the absolute configuration of isoprelaurefucin was established on the basis of chemical evidence.

During our continuing studies on the constituents of the red marine alga *Laurencia nipponica* Yamada, one of the Japanese species of the genus *Laurencia* (Rhodomelaceae; Rhodophyta), we have newly collected at Asari and Hariusu, near Otaru, Hokkaido, and isolated (3*Z*)-isoprelaurefucin (**1**) in 20 and 23% yields of the extracts, respectively. (3*Z*)-Isoprelaurefucin has previously been obtained as the minor metabolite from *L. subopposita*[2)] and *L. nipponica*.[3)] In this note we describe the structural confirmation of (3*Z*)-isoprelaurefucin (**1**) and the absolute configuration of isoprelaurefucin (**2**).[4)]

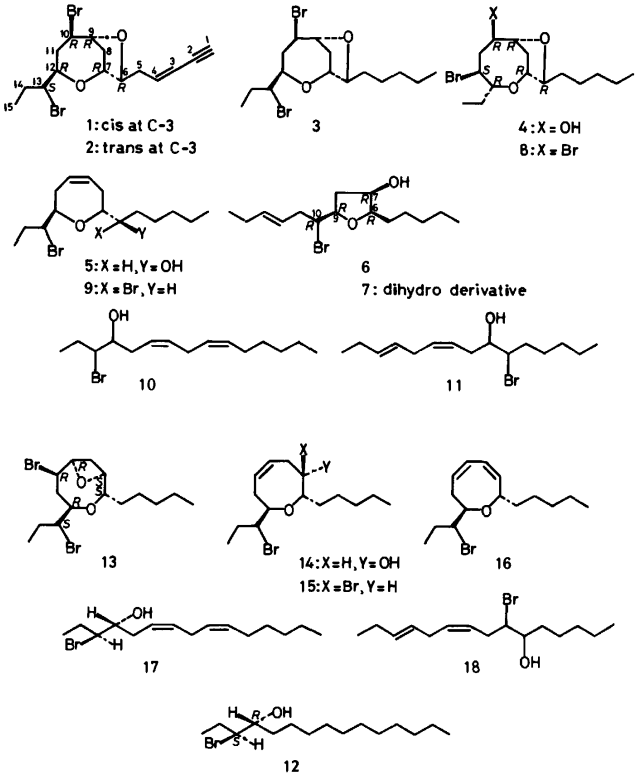
(3*Z*)-Isoprelaurefucin (**1**), $C_{15}H_{20}O_2Br_2$ (*m/z* 394, 392, and 390; M^+), colorless oil, $[\alpha]_D^{21}$ −75.5° (*c* 1.41; $CHCl_3$), indicated in its IR, UV, ^1H NMR, and MS spectra the presence of a *cis*-2-penten-4-ynyl grouping [ν_{max} 3300, 2120, and 760 cm^{-1}; λ_{max} 222 nm (ε 14600); δ=3.11 (1H, d, *J*=2 Hz), 5.59 (1H, br d, *J*=11 Hz), and 6.08 (1H, ddd, *J*=11, 7, 7 Hz); *m/z* 329, 327, and 325; $M^+-C_5H_5$]. The spectral data of **1** were very similar to those of isoprelaurefucin (**2**),[4)] which has previously been isolated as a minor component from *L. nipponica* collected at Moheji, near Hakodate, Hokkaido, suggesting that **1** is the geometric isomer of the double bond at C-3 of **2**. Hydrogenation of **1** over PtO_2 in ethanol gave the hexahydro derivative, $C_{15}H_{26}O_2Br_2$, which was identical with the hydrogenated product **3**[4)] of isoprelaurefucin (**2**) in all respects.

Of the six chiral centers at C-6, C-7, C-9, C-10, C-12, and C-13 in isoprelaurefucin (**2**), the absolute configurations at C-6, C-7, and C-9 were unambiguously established as 6*R*, 7*R*, and 9*R*, respectively,[4)] on the basis of the chemical correlation with the known compound, hexahydrolaurefucin (**4**).[5)] The remaining configurations at C-10, C-12, and C-13, however, were inferred from the biogenetical viewpoint and the chemical observation that the elimination reaction of the hexahydro derivative (**3**) with zinc and acetic acid generated 9-*cis*-12-*trans*-pentadeca-9,12-diene-6,7-diol.[4)] Therefore, in order to confirm the absolute stereochemistries at C-10, C-12, and C-13, we carried out the following chemical correlation with the known compounds.

Treatment of hexahydroisoprelaurefucin (**3**) with zinc and acetic acid in methanol yielded two unsaturated alcohols, **5** and **6**, which have the same molecular formula $C_{15}H_{27}O_2Br$. One of the unsaturated alcohols, compound **6** was hydrogenated in ethanol over PtO_2 to give a saturated compound which was identical with compound **7**,[6)] which has been derived from compound **8**,[6,7)] kumausallene,[6)] and kumausynes.[8)] Hence the absolute configuration at C-10 in **1** was established as *R*.

Another unsaturated alcohol, compound **5** showed in its mass spectrum the relatively intense fragments at *m/z* 219 and 217 ($M^+-C_6H_{13}O$) and 197 ($M^+-C_3H_6Br$), thus indicating that compound **5** was generated from **3** by the oxolane ring cleavage to contain an oxepane ring with 1-bromopropyl and 1-hydroxyhexyl side chains. Furthermore, compound **5** was brominated with carbon tetrabromide and triphenylphosphine[9)] in benzene to give a dibromo ether **9**, $C_{15}H_{26}OBr_2$, whose IR spectrum indicated no hydroxyl absorption. Compound **9**, on treatment with zinc and acetic acid in methanol, afforded two unsaturated bromohydrins **10** and **11**, $C_{15}H_{27}OBr$. Hydrogenation of **10** over PtO_2 in ethyl acetate yielded the saturated bromohydrin **12**, $C_{15}H_{31}OBr$, $[\alpha]_D^{18}$ −3.14°. The fragment ions at *m/z* 185 ($M^+-C_3H_6Br$) and 153 and 151 ($M^+-C_{11}H_{23}$) in the mass spectrum of **12** showed that the bromohydrin **12** is 3-bromo-4-pentadecanol.

On the other hand, treatment of hexahydrolaureatin (**13**)[10)] with zinc and acetic acid in methanol resulted in the cleavage of oxetane ring in **13** to give an unsaturated alcohol **14**, $C_{15}H_{27}O_2Br$, which was further brominated with carbon tetrabromide and triphenylphosphine to yield a dibromo ether **15**, $C_{15}H_{26}OBr_2$, with the concomitant formation of a dehydrobromination product **16**, $C_{15}H_{25}OBr$. Moreover, treatment of **15** with zinc and acetic acid in methanol yielded two unsaturated bromohydrins **17** and **18**, $C_{15}H_{27}OBr$. One of the bromohydrins, compound **17** showed almost identical spectral data with those of **10** derived from isoprelaurefucin. In the ^1H NMR spectra of **10** and **17**, the shape of the signals of the C_8–H_2, flanked by two double bonds, at δ 2.7—2.9 and the olefinic protons at δ 5.1—5.8 is slightly different, indicating that the double bond at C-6 in **10** and **17** cosisted of a mixture of *cis* and *trans* double bonds whose ratio were different. Hydrogenation of **17** over PtO_2 in ethyl acetate gave the saturated bromohydrin, (3*S*,4*R*)-3-bromo-4-pentadecanol (**12**), $[\alpha]_D^{17}$ −2.88°, which was completely identical with the bromohydrin **12** derived from isoprelaurefucin. Thus, the absolute configurations of the remaining chiral centers at C-12 and C-13 were established as *R* and *S*, respectively. Consequently, the structures, including the absolute configuration, of (3*Z*)-isoprelaurefucin and isoprelaurefucin are represented by formulae **1** and **2**, respectively.



Experimental

The IR spectra were measured on a Hitachi EPI-G2 or a JASCO A-102 spectrophotometers. The UV spectra were obtained on a Shimadzu UV-240 spectrophotomer. The ^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 or a JEOL JNM-FX 270 spectrometers, using tetramethylsilane as an internal reference in $CDCl_3$. The low and high resolution mass spectra were taken with a JEOL JMS-D300 or a JEOL JMS-DX300 spectrometers. Optical rotations were determined on a JASCO DIP-140 or a Atago Polax polarimeters in $CHCl_3$. Silica gel (Merck, Kieselgel 60, 70—230 mesh) was used for column chromatography. High-performance liquid chromatography was performed on a JASCO TRI ROTAR-III with a Megapak SIL CN column.

Collection. Algae were collected at Asari and Hariusu, near Otaru, Hokkaido, in June 18, 1982.

Isolation of (3Z)-Isoprelaurefucin (1). Half-dried alga (60 g), collected at Asari, was extracted with MeOH, and the resulting MeOH extract was treated with 0.5 mol dm^{-3} aqueous KOH in the usual manner to give a neutral oil (0.77 g) which was chromatographed on a silica-gel column. The earlier benzene fraction was further subjected to repeated silica-gel column chromatography to yield pure (3Z)-isoprelaurefucin (**1**) (150 mg); oil; $[\alpha]_D^{21}$ −75.5° (*c* 1.41); UV (EtOH), λ_{max} 222 (ε 14600) and λ_{inf} 214 (ε 12800) and 231 (ε 10900) nm; IR (film), ν_{max} 3300, 2120, 1293, 1245, 1200, 1140, 1105, 1088, 1075, 1055, 1020, 975, 863, and 760 cm^{-1}; ^1H NMR and ^{13}C NMR, Table 1; MS (70 eV), *m/z* (rel intensity) 394, 392, 390 (0.3:0.6:0.3; M^+), 329, 327, 325 (5:11:6; $M^+-C_5H_5$), 313, 311 (12:11; M^+—Br), 271, 269 (7:4; $M^+-C_3H_6Br$), 231 (22; M^+—Br-HBr), 137 (24), 123 (26), 121 (54), 119 (21), 109 (45), 107 (27), 95 (59), 93 (66), 91 (23), 81 (43), 79 (38), 71 (35), and 69 (31). Found: *m/z* 311.0648. Calcd for $C_{15}H_{20}O_2$ ^{79}Br: M–Br, 311.0647.

Hydrogenation of (3Z)-Isoprelaurefucin (1). (3Z)-Isoprelaurefucin (**1**) (296 mg) was hydrogenated in EtOH over PtO_2-catalyst. After removal of the catalyst and the solvent, the residual oil was chromatographed on silica-gel column to yield **3** (287 mg); oil; $[\alpha]_D^{22}$ −48.6° (*c* 1.20); IR (film), ν_{max} 1197, 1180, 1140, 1108, 870, 835, 792, 759, and 691 cm^{-1}; ^1H NMR, δ=0.89 (3H, br t, *J*=6 Hz), 1.06 (3H, dd, *J*=7, 7 Hz), 3.6—3.9 (2H, m), 4.1—4.4 (3H, m), and 4.61 (1H, br d, *J*=7 Hz); MS (75 eV), *m/z* 319, 317 (12:12; M^+—Br), 318, 316 (20:19; M^+—HBr), 277, 275 (2:2; $M^+-C_3H_6Br$), 238 (14; M^+—Br-Br), 237 (74; M^+—Br-HBr), 167 (12), 137 (39), 123 (100), 122 (57), 109 (34), 99 (35), 95 (26), 93 (50), 71 (28), 67 (43), 55 (32), 43 (26), and 41 (34). These spectral data were consistent with those of hexahydroisoprelaurefucin (**3**).[4]

Table 1. ^{13}C and ^1H NMR Data for (3Z)-Isoprelaurefucin (**1**)

a) Spectrum was measured at 25.0 MHz in $CDCl_3$ (TMS as int. standard). b) Spectrum was recorded at 270 MHz in $CDCl_3$ (TMS as int. standard). Assignments were made with the aid of 2D-COSY and spin decoupling (in part) experiments. c) Assignments may be reversed.

Treatment of 3 with Zn-AcOH. To a solution of **3** (230 mg) in MeOH (5 ml) was added zinc dust (500 mg) and acetic acid (0.25 ml). The mixture was stirred for 15 h at room temperature and then filtered to remove the zinc dust. The filtrate was extracted with ether. The ethereal solution was successively washed with water, 5% aqueous $NaHCO_3$, and water, dried over Na_2SO_4, and then evaporated to leave a residual oil, which was chromatographed on silica-gel column to give **5** (97 mg) and **6** (15 mg): **5**; oil; $[\alpha]_D^{22}$ −5.23° (*c* 2.86); IR (film), ν_{max} 3440, 3020, 1657, 1218, 1195, 1132, 1100, 1020, 1000, 929, 905, and 795 cm^{-1}; ^1H NMR, δ=0.89 (3H, br t, *J*=6 Hz), 1.08 (3H, dd, *J*=7, 7 Hz), 3.48 (1H, m), 3.9—4.4 (3H, m), and 5.70 (2H, m); MS (75 eV), *m/z* 320, 318 (1:1; M^+), 302, 300 (0.6:0.6; M^+-H_2O), 239 (9; M^+—Br), 238 (15; M^+—HBr), 219, 217 (47:43; $M^+-C_6H_{13}O$), 197 (61; $M^+-C_3H_6Br$), 139 (33), 137 (100), 121 (53), 119 (24), 114 (24), 109 (98), 99 (52), 97 (33), 95 (49), 93 (73), 83 (40), 81 (31), 79 (43), 71 (33), 67 (82), 55 (51), and 41 (44).

Hydrogenation of 6. Compound **6** (12 mg) was hydrogenated in EtOH over PtO_2-catalyst in the usual manner to give **7** (12 mg); oil; $[\alpha]_D^{22}$ +3.46° (*c* 0.867); whose spectral

properties were compatible with those of compound **7**,[6] which was derived from compound 8,[7] kumausallene,[6] and kumausynes.[8]

Conversion of 5 into 9. A solution of **5** (54 mg) in dry benzene (3.5 ml) was refluxed with triphenylphosphine (110 mg) and carbon tetrabromide (140 mg) for 1 h in N_2 atmosphere. The subsequent removal of the solvent gave a residual substance, which was purified by silica-gel column chromatography to afford **9** (64 mg); oil; $[\alpha]_D^{22}$ −5.36° (*c* 0.933); IR (film), ν_{max} 3010, 1217, 1168, 1092, 1022, 799, and 670 cm^{-1}; ^1H NMR, δ=0.90 (3H, br t, *J*=6 Hz), 1.07 (3H, dd, *J*=7 Hz), 3.9—4.3 (4H, m), and 5.70 (2H, m); MS (75 eV), *m/z* 384, 382, 380 (0.9:1.7:1.1; M^+), 261, 259 (41:40; $M^+-C_3H_6Br$), 232, 230 (10:10; $M^+-Br-C_5H_{11}$), 219, 217 (60:61; $M^+-C_6H_{12}Br$), 151 (38), 137 (40), 109 (100), 95 (39), 93 (30), 81 (30), 79 (40), 67 (69), 55 (28), and 41 (39).

Treatment of 9 with Zn-AcOH. To a solution of **9** (60 mg) in MeOH (1.2 ml) was added zinc dust (150 mg) and acetic acid (0.06 ml). The mixture was stirred for 22 h at room temperature and then worked up in a manner similar to the case of **3**. The resulting oily substance was subjected to HPLC eluted with hexane-isopropyl alcohol (100:0.25) to yield **10** (13 mg) and **11** (8 mg): **10**; oil; $[\alpha]_D^{17}$ +5.21° (*c* 1.30); IR (film), ν_{max} 3420, 3020, 1285, 1050, 1037, 1027, 970, and 803 cm^{-1}; ^1H NMR, δ=0.88 (3H, br t, *J*=6 Hz), 1.08 (3H, dd, *J*=7, 7 Hz), 2.41 (2H, t, *J*=5.5 Hz), 2.7—2.9 (2H, m), 3.76 (1H, br ddd, *J*=5.5, 5.5, 5.5 Hz), 4.07 (1H, ddd, *J*=8, 5.5, 5 Hz), and 5.1—5.8 (4H, m); MS (70 eV), *m/z* 223 (11; M^+-Br), 205 (20; M^+-Br-H_2O), 95 (44), 93 (30), 81 (58), 79 (53), 71 (100), 69 (58), 67 (81), 55 (66), 43 (92), and 41 (73); **11**; oil; ^1H NMR, δ=0.90 (3H, br t, *J*=6 Hz), 0.97 (3H, dd, *J*=7, 7 Hz), 2.40 (2H, t, *J*=6 Hz), 2.7—2.9 (2H, m), 3.74 (1H, m), 4.19 (1H, m), and 5.1—5.8 (4H, m).

Hydrogenation of 10. Compound **10** (13 mg) was hydrogenated in EtOAc over PtO_2-catalyst in the usual manner to yield **12** (12 mg); oil; $[\alpha]_D^{18}$ −3.14° (*c* 1.21); IR (film), ν_{max} 3400, 1285, 1125, 1075, 1055, 1040, 1020, 920, and 803 cm^{-1}; ^1H NMR, δ=0.88 (3H, br t, *J*=6 Hz), 1.08 (H, dd, *J*=7, 7 Hz), 3.69 (1H, m), and 4.09 (1H, ddd, *J*=7.5, 6, 3.5 Hz); MS (70 eV), *m/z* 291, 289 (0.3:0.3; M^+-H_2O+H), 227 (2; M^+-Br), 185 (85; $M^+-C_3H_6Br$), 153, 151 (4:4; $M^+-C_{11}H_{23}$), 111 (69), 97 (97), 83 (94), 69 (100), 57 (59), 55 (89), 43 (89), and 41 (92).

Treatment of Hexahydrolaureatin (13) with Zn-AcOH. To a solution of hexahydrolaureatin (**13**)[10] (500 mg) in MeOH (12.5 ml) was added zinc dust (1.25 g) and acetic acid (0.63 ml). The mixture was stirred for 110 min at room temperature and then worked up in a manner similar to the case of **3**. The resulting oil was chromatographed on silica-gel column to give **14** (183 mg); oil; $[\alpha]_D^{22}$ +93.7° (*c* 1.33); IR (film), ν_{max} 3450, 3010, 1655, 1280, 1195, 1120, 1060, 1045, 797, and 692 cm^{-1}; ^1H NMR, δ=0.89 (3H, br t, *J*=6 Hz), 1.09 (3H, dd, *J*=7, 7 Hz), 3.5—4.1 (4H, m), and 5.6—6.0 (2H, m); MS (70 eV), *m/z* 320, 318 (0.5:0.5; M^+), 239 (5; M^+-Br), 220, 218 (6:6; $M^+-C_5H_{11}-C_2H_5$), 197 (28; $M^+-C_3H_6Br$), 121 (37), 114 (79), 113 (83), 109 (67), 95 (75), 67 (100), 55 (97), 43 (77), and 41 (69).

Bromination of 14. A solution of **14** (150 mg) in dry benzene (6 ml) was refluxed with triphenylphosphine (280 mg) and carbon tetrabromide (350 mg) for 70 min in N_2 atmosphere. After removal of the solvent, the residual oil was chromatographed over silica-gel column to yield **15** (23 mg) and **16** (30 mg): **15**; oil; $[\alpha]_D^{22}$ −34.1° (*c* 1.40); IR (film), ν_{max} 3020, 1660, 1285, 1219, 1198, 1070, 1089, 1071, 1050, and 695 cm^{-1}; ^1H NMR, δ=0.90 (3H, br t, *J*=6 Hz), 1.07 (3H, dd, *J*=7, 7 Hz), 3.8—4.2 (4H, m), and 5.5—5.9 (2H, m); MS (70 eV), *m/z* 384, 382, 380 (0.3:0.6:0.3; M^+), 303, 301 (25:25; M^+-Br), 261, 259 (30:32; $M^+-C_3H_6Br$), 220, 218 (44:45), 203, 201 (99:100; $M^+-C_5H_{11}-C_2H_5$), 192, 190 (45:45), 179 (39), 151 (35), 95 (40), 79 (39), 67 (55), 55 (37), 43 (28), and 41 (35); **16**; oil; $[\alpha]_D^{17}$ +151° (*c* 1.40); UV (EtOH), λ_{max} 225 nm (ε 4930); IR (film), ν_{max} 3010, 1080, 1060, 1020, 805, and 792 cm^{-1}; ^1H NMR, δ=0.88 (3H, br t, *J*=6 Hz), 1.06 (3H, dd, *J*=7, 7 Hz), 3.5—4.3 (3H, m), 5.27 (1H, dd, *J*=10.5, 8 Hz), and 5.2—6.2 (3H, m); MS (75 eV), *m/z* 302, 300 (4:4; M^+), 231, 229 (4:4; $M^+-C_5H_{11}$), 221 (68; M^+-Br), and 79 (100).

Treatment of 15 with Zn-AcOH. To a solution of **15** (23 mg) in MeOH (0.5 ml) was added zinc dust (50 mg) and acetic acid (0.03 ml). The mixture was stirred for 3 h at room temperature and then worked up in a manner similar to the case of **3**. The resulting oil was subjected to HPLC eluted with hexane-isopropyl alcohol (100:0.20) to give **17** (12 mg) and **18** (5 mg): **17**; oil; $[\alpha]_D^{18}$ +6.33° (*c* 1.29); whose spectral data were almost identical with those of **10** derived from isoprelaurefucin; **18**; oil; ^1H NMR, δ=0.90 (3H, br t, *J*=6 Hz), 0.97 (3H, dd, *J*=7, 7 Hz), 2.5—2.9 (4H, m), 4.16 (1H, m), and 5.3—5.7 (4H, m).

Hydrogenation of 17. Compound **17** (12 mg) was hydrogenated in EtOAc over PtO_2-catalyst in the usual manner to give **12** (10 mg); oil; $[\alpha]_D^{17}$ −2.88° (*c* 1.14); whose spectral properties were identical with those of **12** derived from isoprelaurefucin.

Pseudo-Sugars. XVI. Facile Synthesis of Pseudo-α-D and L-Glucopyranoses[1]

Seiichiro OGAWA,* Kazufumi NAKAMURA, and Tohei TAKAGAKI
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Yokohama 223
(Received March 19, 1986)

Synopsis. Optically active pseudo-α-glucopyranoses have been synthesized from enantiomeric (1,3,5/2,4)-2,3-diacetoxy-4,5-dibromo-1-cyclohexanecarboxylic acids, obtained by optical resolution of the racemic modification using (+)- and (−)-α-methylbenzylamines.

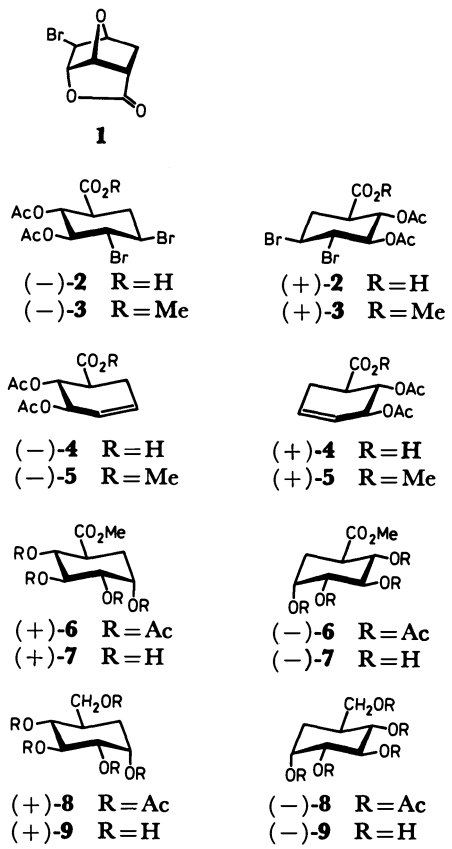
Recently, pseudo-α-DL-glucopyranose[2] has been shown to inhibit glucokinase activity and glucose-stimulated insulin release.[3] Accordingly, it has become necessary to provide quantities of the pseudo-sugars, as optically active forms, for a further biological and biochemical studies. We now describe a facile synthesis of pseudo-α-D and L-glucopyranoses, starting from (−) and (+)-enantiomers of (1,3,5/2,4)-2,3-diacetoxy-4,5-dibromo-1-cyclohexanecarboxylic acid (**2**), respectively, obtained by an optical resolution[4] of the racemic modification.[5]

Pseudo-α-D-glucopyranose has already been synthesized from D-glucose by two research groups.[6,7] The sequence of the present synthesis could readily be conducted with a high selectivity and a high overall yield, and has an advantage to furnish both D- and L-enantiomers with ease.

The racemic acid (±)-**2** was successfully resolved by use of commercially available (+)- and (−)-α-methylbenzylamines. Thus, a mixture of (*R*)-(+)-amine salts of (−)-**2** and (+)-**2** was fractionally crystallized from ethanol to give, in 54% yield, the pure (*R*)-(+)-amine salt of (−)-**2**, from which the free acid (−)-**2** ($[\alpha]_D$ −5.1°) was obtained by treatment with sodium carbonate followed by hydrochloric acid. Similarly, the acid (+)-**2** ($[\alpha]_D$ +5.2°) was obtained by use of the (*S*)-(−)-amine. The absolute configuration of (−)-**2** could be estabilised as shown in Scheme by identification with the authetic sample derived from (3*S*)-(+)-2-*exo*-bromo-4,8-dioxatricyclo[4.2.1.0^{3,7}]nonan-5-one[8] (**1**) by treatment with hydrogen bromide in acetic acid.

The present synthesis of **9** was carried out in the following sequence,[5] previously used for the preparation of the racemic modification.

Treatment of the acid (−)-**2** with methanol and acetyl chloride gave the methyl ester (−)-**3** in 91% yield. Compound (−)-**2** was debrominated with zinc dust in acetic acid to give 96% yield of the olefin (−)-**4**. Similarly, (−)-**3** was converted into the olefin (−)-**5** in 92% yield. Oxidation of (−)-**5** with osmium tetraoxide and hydrogen peroxide in *t*-butyl alcohol, followed by acetylation, afforded selectively the tetraacetate (+)-**6** in 85% yield.[9] *O*-Deacetylation of (+)-**6** with methanolic sodium methoxide gave the methyl ester (+)-**7** ($[\alpha]_D$ +48°) quantitatively. Reduction of (+)-**6** with lithium aluminum hydride in tetrahydrofuran, followed by acetylation, gave the pentaacetate (+)-**8** ($[\alpha]_D$ +57°) in 98% yield. *O*-Deacetylation of (+)-**8** gave pseudo-α-D-glucopyranose (+)-**9** ($[\alpha]_D$ +67°)[10] quantitatively. The overall yield of (+)-**9** from (−)-**2** was about 70%.



Likewise, pseudo-α-L-glucopyranose (−)-**9** ($[\alpha]_D$ −67°) was obtained from (+)-**2**.

The structures of **8** and **9** were established on the basis of the ^{1}H NMR spectra.[2,11]

Experimental

Melting points were determined on a MEL-TEMP capillary melting-point apparatus and are uncorrected. Optical rotations were measured on a Jasco DIP-4 polarimeter. The ^{1}H NMR spectra were recorded on a Varian EM-390 (90 MHz) spectrometer for solution of chloroform-*d* or deuterium oxide. The silica gel used for column chromatography was Wakogel C-300 (Wako Co., Osaka). The structures of the optically active compounds synthesized were confirmed by comparison of the ^{1}H NMR spectra with those of the corresponding racemic modifications.[2,5,11]

Optical Resolution of DL-(1,3,5/2,4)-2,3-Diacetoxy-4,5-dibromo-1-cyclohexanecarboxylic Acid[2] [(±)-2]. To a solution of the acid (±)-**2** (20 g, 50 mmol) in ethanol (200 ml) was

added (*R*)-(+)-α-methylbenzylamine[12] (7.7 ml, 60 mmol), and the mixture was kept in a refrigerator (0—5 °C) overnight. The precipitates, a mixture of the salts, were collected by filtration and washed with 2-propanol. The salts were fractionally crystallized from ethanol to give the pure (*R*)-(+)-amine salt of (−)-**2** (6.8 g, 52%) as white needles: Mp 187—190 °C; $[\alpha]_D^{20}$ +8.7° (*c* 1.0, MeOH).

Found: C, 43.68; H, 4.74; N, 2.67%. Calcd for $C_{19}H_{25}Br_2NO_6$: C, 43.62; H, 4.82; N, 2.67%.

Similarly, by use of (*S*)-(−)-α-methylbenzylamine, the (*S*)-(−)-amine salt of (+)-**2** was obtained in 47% yield, needles (from EtOH): Mp 187—190 °C; $[\alpha]_D^{21}$ −8.6° (*c* 0.90, MeOH).

Found: C, 43.58; H, 4.75; N, 2.55%.

A portion (1.46 g, 3.13 mmol) of (*R*)-(+)-amine salt of (−)-**2** was treated with 2 M aqueous sodium carbonate (40 ml) (1 M=1 mmol dm^{-3}) at room temperature for 2 h, and then the solution was extracted with ether (20 ml×3). The solvent was removed to leave recovered (*R*)-(+)-amine (0.36 g 92%). The aqueous layer was acidified with 1 M hydrochloric acid and extracted with ether (100 ml×3). The extracts were dried over anhydrous sodium sulfate and concentrated to give a crystalline residue. Recrystallization from 2-propanol gave the acid (−)-**2** (1.19 g, 95%) as prisms: Mp 180—181 °C; $[\alpha]_D^{19}$ −5.1° (*c* 0.90, EtOH).

Found: C, 33.10; H, 3.69; Br, 39.45%. Calcd for $C_{11}H_{14}Br_2O_6$: C, 32.86; H, 3.51; Br, 39.75%.

From (*S*)-(−)-amine salt of (+)-**2**, the acid (+)-**2** was obtained in 93% yield, prisms (from *i*-PrOH): Mp 180—181 °C; $[\alpha]_D^{21}$ +5.2° (*c* 1.8, EtOH).

Found: C, 31.99; H, 3.21%. Calcd for $C_{11}H_{14}Br_2O_6 \cdot 0.5\,H_2O$: C, 32.14: H, 3.68%.

Preparation of (−)-2 from (3*S*)-(+)-2-*exo*-Bromo-4,8-dioxatricyclo[4.2.1.0^{3,7}]nonan-5-one[7] (1). The bromolactone **1** (1.0 g, 4.6 mmol) was heated with 20% hydrogen bromide–acetic acid (6 ml) in a sealed tube at 85 °C for 42 h. The reaction mixture was poured into ice–water (70 ml) containing sodium hydrogencarbonate (2 g) and the precipitates, after standing overnight in a refrigerator, were collected by filtration. Recrystallization from ethanol gave (−)-**2** (0.86 g, 44%) as prisms: Mp 182—183 °C; $[\alpha]_D^{23}$ −4.7° (*c* 0.72, EtOH).

Methyl (1*S*)-(−) [(−)-3] and (1*R*)-(+)-(1,3,5/2,4)-2,3-Diacetoxy-4,5-dibromo-1-cyclohexanecarboxylate [(+)-3]. A mixture of (−)-**2** (0.91 g, 2.3 mmol), acetyl chloride (0.1 ml), and methanol (10 ml) was heated at reflux for 2 h, and then neutralized with sodium hydrogencarbonate. The reaction mixture was concentrated and the residue was acetylated with acetic anhydride (5 ml) and pyridine (5 ml) overnight at room temperature. The mixture was concentrated, the residue was taken up in ethyl acetate (30 ml), and the solution was washed with 1 M hydrochloric acid, saturated aqueous sodium hydrogencarbonate, and water, dried, and concentrated. Recrystallization of the residue from ethanol gave (−)-**3** (0.85 g, 91%) as needles: Mp 140—141 °C; $[\alpha]_D^{20}$ −15.5° (*c* 1.4, $CHCl_3$).

Found: C, 34.48; H, 3.88; Br, 38.53%. Calcd for $C_{12}H_{16}Br_2O_6$: C, 34.64; H, 3.88; Br, 38.41%.

Similarly, (+)-**2** was converted into the ester (+)-**3**; needles (from EtOH): Mp 140—141 °C; $[\alpha]_D^{20}$ +15.4° (*c* 0.85, $CHCl_3$).

Found: C, 34.97; H, 3.89%.

(1*S*)-(−) [(−)-4] and (1*R*)-(+)-(1,3/2)-2,3-Diacetoxy-4-cyclohexene-1-carboxylic Acid [(+)-4]. To a solution of (−)-**2** (0.93 g, 2.3 mmol) in acetic acid (20 ml) was added zinc dust (1.5 g, 23 matom) in portions at 70 °C for 0.5 h. The insoluble material was filtered and the filtrate was concentrated. The residue was taken up in ethyl acetate (20 ml) and the solution was washed with saturated aqueous sodium hydrogencarbonate and water, dried, and concentrated. Recrystallization of the residue from carbon tetrachloride gave (−)-**4** (0.54 g, 96%) as prisms: Mp 113—115 °C; $[\alpha]_D^{17}$ −2.5° (*c* 1.9, EtOH).

Found: C, 54.32; H, 5.70%. Calcd for $C_{11}H_{14}O_6$: C, 54.54; H, 5.83%.

Similarly, (+)-**4** was obtained from (+)-**2**; prisms (from CCl_4): Mp 113—115 °C; $[\alpha]_D^{17}$ +2.7° (*c* 2.7, EtOH).

Found: C, 54.38; H, 5.73%.

Methyl (1*S*)-(−) [(−)-5] and (1*R*)-(+)-(1,3/2)-2,3-Diacetoxy-4-cyclohexene-1-carboxylate [(+)-5]. The ester (−)-**3** (0.50 g, 1.2 mmol) was treated with zinc dust in acetic acid as described for the preparation of (−)-**4** to give (−)-**5** (0.28 g, 92%) as needles (from ether): Mp 45—47 °C; $[\alpha]_D^{18}$ −22° (*c* 1.6, $CHCl_3$).

Found: C, 55.87; H, 5.96%. Calcd for $C_{12}H_{16}O_6$: C, 56.25; H, 6.29%.

Similarly, the ester (+)-**3** was converted into (+)-**5**; needles (from ether): Mp 45—47 °C; $[\alpha]_D^{17}$ +21° (*c* 0.96, $CHCl_3$).

Found: C, 55.98; H, 6.07%.

Methyl (1*S*)-(+) [(+)-6] and (1*R*)-(−)-(1,3/2,4,5)-2,3,4,5-Tetraacetoxy-1-cyclohexanecarboxylate [(−)-6]. A mixture of (−)-**5** (0.51 g, 2.0 mmol), *t*-butyl alcohol (11 ml) containing 30% hydrogen peroxide (2 ml), and *t*-butyl alcohol (3.8 ml) containing osmium tetraoxide (19 mg) was stirred at room temperature for 24 h. Excess peroxide was decomposed by addition of sodium sulfite and the mixture was concentrated. The residue was acetylated in a usual way and the product was eluted from a column of silica gel (30 g) with 2-butanone–toluene (1:8) to give (+)-**6** (0.63 g, 85%) as prisms (from EtOH): Mp 79—80 °C; $[\alpha]_D^{23}$ +56° (*c* 1.1, $CHCl_3$).

Found: C, 51.30; H, 5.87%. Calcd for $C_{16}H_{22}O_{10}$: C, 51.34; H, 5.92%.

Similarly, (−)-**6** was obtained from (+)-**5**; prisms (from EtOH): Mp 79—80 °C; $[\alpha]_D^{22}$ −58° (*c* 1.1, $CHCl_3$).

Found: C, 51.08; H, 5.77%.

Methyl (1*S*)-(+) [(+)-7] and (1*R*)-(−)-(1,3/2,4,5)-2,3,4,5-Tetrahydroxy-1-cyclohexanecarboxylate [(−)-7]. Compound (+)-**6** (45 mg, 0.12 mmol) was treated with 0.1 M methanolic sodium methoxide (2 ml) at room temperature for 2 h, and then the mixture was neutralized by passage through a short column of Amberlite IR 120B (H^+) resin. The eluate was concentrated to give (+)-**7** (25 mg, 100%) as a syrup: $[\alpha]_D^{20}$ +48° (*c* 0.71, MeOH).

Found: C, 45.59; H, 6.66%. Calcd for $C_8H_{14}O_6 \cdot 0.25H_2O$: C, 45.60; H, 6.94%.

Similarly, (−)-**7** was obtained from (−)-**6**; syrup: $[\alpha]_D^{20}$ −48° (*c* 0.98, MeOH).

Found; C, 46.61; H, 6.58%. Calcd for $C_8H_{14}O_6$: C, 46.60; H, 6.84%.

(1*S*)-(+) [(+)-8] and (1*R*)-(−)-(1,3/2,4,5)-2,3,4,5-Tetraacetoxycyclohexanmethanol [(−)-8]. The ester (+)-**6** (100 mg, 0.27 mmol)was treated with lithium aluminum hydride (55 mg, 1.4 mmol) in tetrahydrofuran (2 ml) at room temperature for 8 h. The mixture was processed in a usual way to give a hydroxy compound, which was acetylated with acetic anhydride in pyridine. The product was purified by passage through a short column of alumina with chloroform to give (+)-**8** (103 mg, 98%) as a syrup: $[\alpha]_D^{21}$ +57° (*c* 0.90, $CHCl_3$) [lit,[6] $[\alpha]_D^{22}$ +37° ($CHCl_3$)] (Found: C, 52.44; H, 6.01%).

Similarly, (−)-**8** was obtained from (−)-**6**; syrup: $[\alpha]_D^{20}$ −56° (*c* 1.1, $CHCl_3$).

(1*S*)-(+) [(+)-9] and (1*R*)-(−)-(1,3/2,4,5)-2,3,4,5-Tetrahydroxycyclohexanemethanol [(−)-9]. Compound (+)-**8** (56 mg, 0.14 mmol) was treated with 0.1 M methanolic sodium methoxide (2 ml) at room temperature for 3 h. The mixture was neutralized with Amberlite IR 120B (H^+) resin to give (+)-**9** (27 mg, 100%) as a syrup: $[\alpha]_D^{21}$ +67° (*c* 0.50, MeOH) [lit,[6] $[\alpha]_D^{25}$ +30° (MeOH)].

Similarly, the pentol (−)-**9** was obtained from (−)-**8**:

syrup: $[\alpha]_D^{21}$ −67° (*c* 1.5, MeOH).

Found: C, 47.32; H, 7.66%. Calcd for $C_7H_{14}O_5$: C, 47.18; H, 7.92%.

The authors are grateful to Prof. Tetsuo Suami for a kind advice, and to Mr. Saburo Nakada and Mr. Akio Takahashi for elementary analyses. The present work was partially supported by a grand of the Asahi Glass Foundation for the contribution to industrial technology.

Synopsis. In the presence of some metal ions and sodium iodate, 1,2-naphthoquinone (**1**) readily reacted with methanol to give 4-methoxy-1,2-naphthoquinone (**2a**). The activity of the metal ions increased in the following order: Co(II)<Ni(II) ≪ Cu(II)<La(III) ≪ Ce(III). The reaction was remarkably affected by the reaction temperature, reaction time, and molar ratio of the chelating agent. By the use of 1 equivalent of cerium salt to **1**, the yield of **2a** increased to 81% at 20 °C for 30 min. In higher alcohols, the addition reaction proceeded under similar conditions to give 4-alkoxy-1,2-naphthoquinones (**2b**—f) in 46—75% yields.

The quinone moiety plays an extremely important role in biological systems. A large number of methods have been applied for preparations of *o*- and *p*-quinones.[1] In these methods, two main approaches have been frequently used to synthesize 1,2-naphthoquinones, either by the oxidation of 1-amino-2-naphthols or a suitably substituted naphthol, or by the Michael addition of a nucleophile to the parent quinone.[1] In the addition reaction of a nucleophile, alcohols do not normally add to the quinones and, therefore, methyl or ethyl alcohol has been used as a recrystallizing solvent for some 1,2-naphthoquinone derivatives.[2]

Recently, M. Matsuoka et al.[3] and M. Hida et al.[4] independently reported an excellent direct amination of aminoanthraquinone or anthraquinone in the presence of metal salts or a metal complex. Moreover, hypervalent iodine oxides have been found to oxidize various dihydroxy aromatics to the corresponding quinones in high yields under very mild conditions.[5]

In this paper, we wish to report a novel and simple method for the preparation of 4-alkoxy-1,2-naphthoquinones (**2**) from the addition reaction of 1,2-naphthoquinone (**1**) with aliphatic alcohols in the presence of metal halides and sodium iodate as the oxidizing agent. The quinones, except for 4-methoxy-1,2-naphthoquinone, are unknown.

Results and Discussion

No reaction of **1** with methanol occurred in the absence of metal chlorides; however, in the presence of metal chlorides, methanol was added to **1** at room temperature to afford **2a**. The activities of metal chlorides in this methoxylation are shown in Table 1. Metal chlorides were arranged in the order of reactivities as follows: Ce(III) ≫ La(III)>Cu(II) ≫ Ni(II)> Co(II). The activity of the cerium(III) ion was particularly superior to those of other metal ions examined in this work. The water of crystallization was slightly effective regarding the activities of cobalt(II) and copper(II) salts (Runs 3 and 6).[6]

The effect of the reaction time and temperature on the reaction of **1** with methanol in the presence of cerium(III) chloride heptahydrate is shown in Table 2. The yield of **2a** increased up to 30 min at 20 °C and gradually decreased with a prolonged reaction time. Suprisingly, an unexpected product, i.e., 2-methoxy-1,4-naphthoquinone (**3**), began to be produced after 1 h; it became the exclusive product after 10 h (Runs 11—13). The reaction was also considerably affected by the reaction temperature. Within 30 min, only **2a** was obtained at temperatures below 20 °C; at higher temperatures, the yield of **3** increased and it was the sole product under reflux for 30 min (Run 18). These results indicate that **2a** is converted into **3** under these conditions.[7]

Next, we examined the effect of the molar ratio of

Table 1. Effect of Metal Chloride on the Reaction of **1** with Methanol[a]

cerium salt to **1** on the yield of **2a**; the results are shown in Table 3. The yield of **2a** increased with an increase in the molar ratio of cerium salt up to 1.0. The additional amounts of the cerium ion slightly depressed the yield to 70% (Runs 22—24). Therefore, the optimum reaction conditions for the preparation of **2a** were as follows: 20 °C for the temperature, 30 min for the reaction time, and one equivalent mol of cerium(III) chloride heptahydrate to 1.

On the bases of our experimental results, a tentative reaction mechanism is proposed as shown in Scheme 1. The formation of a chelate complex (**4**), in which 1- and 2-carbonyl oxygens of **1** are coordinated to the metal ion,[8] enhances the electrophilic character of the C_4-carbon in **1**, and facilitates a nucleophilic attack of methanol on that carbon. A similar role of the cerium ion has been observed during the addition of aromatic amines to 5,8-quinolinedione.[9] The 2,5-cyclohexadienone intermediate (**5**) may be enolized to afford 4-methoxy-1,2-naphthalenediol (**6**), and **6** is oxidized into **2a**. For a prolonged reaction time, the metal ion presumably recoodinates to **2a** and the methanol adds to the chelated quinone to give a hemiacetal. It finally results in the formation of **3**.[7] The details of the reaction mechanism for each step are still not clear, however, and are under investigation.

Other aliphatic alcohols also reacted with **1** in the presence of $CeCl_3 \cdot 7H_2O$ under similar conditions to afford **2b—f** in good yields (Table 4). Since cerium salt and **1** were slightly soluble in higher alcohols, a minimum amount of water and acetonitrile were necessarily added to dissolve both components (Runs 27—30). In addition, a prolonged reaction time was required for some alcohols in order to improve the yields of **2d—f**. Thus, the direct alkoxylation of 1,2-naphthoquinone in the presence of $CeCl_3 \cdot 7H_2O$ is synthetically useful method for the preparation of 4-alkoxy-1,2-naphthoquinones.

Experimental

1,2-Naphthoquinone was prepared according to a method described in the literature.[10] All metal chlorides and sodium iodate were reagent-grade and were used without further purification. Alcohols were purified by distillation. Column chromatography was performed on silica gel (Merck Kisel gel 60, Art. 7734), using chloroform as an eluent. Authentic samples of **2a**[11] and **3**[12] were prepared by the methods described in the literatures. All the yields were based on **1** that was used.

General Procedure. (a) A mixture of **1**, metal salt, sodium iodate, and methanol was stirred in a flask (see Tables 1, 2, and 3). The mixture was then poured into a 10%

aqueous solution of ammonium chloride, and extracted with chloroform. The organic layer was thoroughly washed with water, dried (Na_2SO_4), and concentrated in vacuo. The yields of **2a** and **3** were determined by ^1H NMR integrations of methoxyl and quinonoid protons. The products were isolated by TLC (ether:hexane=4:1) (R_f 0.28 for **2a**; 0.43 for **3**). The physical properties of **2a** and **3** were identical with those of authentic samples. The reaction with ethanol was carried out by the same procedure, and **2b** was separated by column chromatography. (Table 4).

(b) As cerium salt and **1** were slightly soluble in higher alcohols, the reactions were modified as follows: An alcohol (11 ml) was added to acetonitrile (3 ml) solution of **1** (0.8 mmol), and then cerium salt dissolved in 0.4 ml of water and sodium iodate (0.8 mmol) were added to the solution. The mixture was stirred for the time indicated in Table 4 at 20 °C. After a workup as described above, the product was separated by column chromatography. The yields of the products are summarized in Table 4.

Identification of the Products. 4-Ethoxy-1,2-naphthoquinone (2b): Orange needles (benzene-hexane); mp 121—123 °C; IR (KBr) 1705 (m) and 1657 (s) cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.55 (t, 3H, J=7.0 Hz), 4.23 (q, 2H, J=7.0 Hz), 5.90 (s, 1H), and 7.52—8.11 (m, 4H). Found: C, 71.01; H, 4.82%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.98%.

4-Propoxy-1,2-naphthoquinone (2c): Yellow needles (benzene-hexane); mp 115.5—116.5 °C; IR (KBr) 1700 (m) and 1650 (s) cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.11, (t, 3H, J=7.0 Hz), 1.95 (sex, 2H, J=7.0 Hz), 4.12 (t, 2H, J=7.0 Hz), 5.95 (s, 1H), and 7.52—8.18 (m, 4H). Found: 72.49; H, 5.49%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%.

4-Isopropoxy-1,2-naphthoquinone (2d): Orange yellow needles (benzene-hexane); mp 124—125 °C; IR (KBr) 1700 (m) and 1645 (s) cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.48 (d, 6H, J=7.0 Hz), 4.72 (sev, 1H, J=7.0 Hz), 5.90 (s, 1H), and 7.50—8.10 (m, 4H). Found: C, 71.19; H, 5.67%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%.

4-Butoxy-1,2-naphthoquinone (2e): Yellow needles (benzene-hexane); mp 95.5—96.5 °C; IR (KBr) 1690 (m) and 1640 (s) cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.02 (t, 3H, J=7.0 Hz), 1.36—1.72 (m, 2H), 1.90 (quint, 2H, J=7.0 Hz), 4.13 (t, 2H, J=7.0 Hz), 5.91 (s, 1H), and 7.48—8.12 (m, 4H). Found: C, 78.55; H, 6.77%. Calcd for $C_{14}H_{14}O_3$: C, 78.48; H, 6.59%.

4-Allyloxy-1,2-naphthoquinone (2f): Yellowish brown needles (benzene-hexane); mp 121.5—123.5 °C; IR (KBr) 1700 (m) and 1650 (s) cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=4.65 (m, 2H, OCH_2), 5.35—5.57 (m, 2H, $C=CH_2$), 5.91 (s, 1H), 5.96—6.44 (m, 1H, CH=C), and 7.49—8.11 (m, 4H). Found: C, 72.61; H, 4.55%. Calcd for $C_{13}H_{10}O_3$: C, 72.89; H, 4.71%.

The authors wish to thank Mr. Kazutoshi Yamasaki and Miss. Keiko Kurahashi for their assistance in carring out some of the experiments.

Studies on Special Type Surfactants. XVI. Preparation of Telomer-Type Surfactants Containing 4-Vinylpyridine and Oxidative Polymerization of 2,6-Xylenol Using Their Copper Complexes

Yoshifumi KOIDE,* Yasuyuki EDA, and Kimiho YAMADA
Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860
(Received January 13, 1986)

The polymerization of 2,6-xylenol (XOH) was catalyzed by using a copper complex of a telomer-type surfactant containing 4-vinylpyridine, 1-benzyl-4-vinylpyridinium chloride, and methyl acrylate or styrene (L-VP-Q, L-VP-Q-MA, L-VP-St, and L-VP-Q-St). A copper complex of L2.5VP3.9Q2.2MA catalyzed an emulsion polymerization of XOH more than that of L-VP-Q, 4-vinylpyridine polymer (VP-Q), or pyridine. Furthermore, the oxidative polymerization of XOH in several organic solvents was more effective than emulsion polymerization. The copper complexes formed reversed-micelles in water (3—10 vol%)-DMSO, and the catalytic actions were in the following order: L-VP-Q>VP-Q>pyridine. The acceleration by the L-VP-Q complex was considered to be due to the adsorption of XOH on reversed micelles.

Telomer-type surfactants have been characterized by the terminal alkyl group and polyfunctional groups.[1] Telomer-type surfactants bearing 4-vinylpyridine and 1-benzyl-4-vinylpyridinium chloride (L-VP-Q), oriented at the interface of water and an immisible organic solution, emulsify these solutions.[2] The emulsion polymerization of XOH using the L-VP-Q–copper complex was more catalytically active than that using the corresponding polymer (VP-Q) complex or a pyridine(py) complex in a water–benzene solvent.[2]

The oxidative polymerization of XOH was studied in detail by Tsuchida et al. using a VP-Q polymer complex and several solvents.[3,4] The catalytic activity was accelerated by a nonpolar field in the polymer ligand[3] and the nonpolar solvent.[4] Therefore, a telomer-type surfactant is expected to be an excellent catalyst since the surfactant forms a nonpolar field consisting dodecyl groups; a highly condensed catalytic active site consists of pyridyl groups above the critical micelle concentration (cmc). However, the oxidative polymerization of XOH using a catalyst of a surfactant-copper complex has not yet been seen. In this study, cotelomer-type surfactants bearing 4-vinylpyridine, 1-benzyl-4-vinylpyridinium chloride, and methyl acrylate or styrene were prepared and the oxidative polymerization of XOH using their copper complexes were examined in comparison with the VP-Q polymer or the py ligand for obtaining information regarding the catalytic character of a telomer-type surfacant.

Experimental

Syntheses of Cotelomer-Type Surfactants. The L-VP-Q telomer-type surfactants and the VP-Q polymer were obtained as described in a previous paper.[2] The cotelomer-type surfactants bearing 4-vinylpyridine, 1-benzyl-4-vinylpyridinium chloride, and methyl acrylate (L-VP-Q-MA) or styrene (L-VP-Q-St) were derived from the corresponding 4-vinylpyridine cotelomers (L-VP-MA, L-VP-St).

The preparation of L-VP-Q-MA was as follows: 4-Vinylpyridine (26.3—27.3 g), methyl acrylate (15.5—54.2 g), and 0.5 wt% of 2,2′-azobisisobutyronitrile (per weight of the mixed monomers) were added to 1-dodecanethiol (30.3—44.4 g); then, the reaction mixture was stirred at 70 °C for 6 h. After cooling to room temperature, the light-brown L-VP-MA was precipitated by adding hexane to the solution mixture. The crude L-VP-MA was reprecipitated twice with hexane after dissolving in chloroform. Then, benzyl chloride (1.0—1.2 g) was added dropwise to 100 cm^3 of a 2% L-VP-MA methanolic solution and the mixture was refluxed for 24 h. After cooling to room temperature, the reaction mixture was poured into 200 cm^3 of ether. The resulting precipitate, L-VP-Q-MA, was filtered and rinsed with ether. The cotelomer-type surfactant-bearing 4-vinylpyridine, 1-benzyl-4-vinylpyridinium chloride, and styrene, L-VP-Q-St, was obtained with styrene instead of methyl acrylate by the same procedure as the preparation of L-VP-Q-MA.

The compositions of the cotelomers (L-VP-MA, L-VP-Q-MA, L-VP-St, and L-VP-Q-St) were determined by means of molecular-weight (Corona 114 vapor-pressure osmometer) and the analytical data of nitrogen from elementary analyses. Detailed descriptions for preparing L-VP-MA and L-VP-St were reported in a preceding paper.[5] Then, the L-VP-Q-MA and L-VP-Q-St that quaternized with benzyl chloride were confirmed by the pyridinium absorption at 1640 cm^{-1} in the IR spectrum and the benzyl peak of 7.2 ppm in the NMR spectrum. The quaternized percent was calculated from the absorption ratio of the IR spectrum[2] or the integrated values of the NMR spectrum. The benzyl chloride reacted with the pyridyl groups of L-VP-MA in 90—95% yields. The chemical formulas and the elementary analyses of the cotelomers are shown in Table 1. The calculated values of C, H, and N based on the chemical formulas agreed with the analytical data.

Polymerization of XOH. The polymerization rate was measured in terms of the oxygen consumption.[2] The polymerization of XOH in an organic solution was as follows: The copper ($CuCl_2$ or CuCl) complex of telomer-type surfactant and the equimolar sodium hydroxide dissolved in a 10 cm^3 of organic solution was added to a 10 cm^3 of organic solution containing the known amount of XOH in a 100 cm^3 flask. The mixed solution was thermostated at 30 °C and shaken until a termination of oxygen absorption. Then, the solution was first added to 450 cm^3 of methanol and the resulting diphenoquinone (DQ) was filtered out. Then, 50 cm^3 of 35%-hydrochloric acid was added to the methanol. The resulting polyphenylene oxide (PPO) was

centrifuged, reprecipitated twice with a 35%-hydrochloric acid (10 vol%)-methanol (90) mixture after dissolving in chloroform, and dried.

Results and Discussion

Emulsion Polymerization of XOH. It is known that a plot of the volume of oxygen consumption against the amount of resulting PPO gives a straight line for a large excess of XOH.[6] Therefore, the polymerization rate can be determined by a measurement of the oxygen-consumption rate, with an error of about 2 $mm^3 min^{-1}$.

The emulsion polymerization of XOH using the L-VP-Q-copper complex was more catalytically active than that using the VP-Q polymer complex in a water–benzene solvent.[2] Moreover, the polymerization rate (66 $mm^3 min^{-1}$) using a L2.5VP3.9Q2.2MA complex which contains methoxycarbonyl groups was 1.4-times faster than that (47 $mm^3 min^{-1}$) using the L3.0VP5.0Q complex at pH 7.5. The acceleration was considered to be due to a slight increase in the nonpolarity formed by the methoxycarbonyl groups[3] in addition to the emulsification.[2] However, the resulting PPO were 3100—5100 of molecular weight and the by-product, DQ, yielded more than 10%. Consequently, the following polymerizations were carried out in a DMSO or a methanol–*o*-dichlorobenzene (DCB) mixture.

Oxidative Polymerization in DMSO. The high molecular weight of PPO and a small amount of DQ were obtained for the above-mentioned solvents by Tsuchida et al. using a VP-Q polymer complex.[7] The polymerization rate was accelerated under alkaline

conditions because of the low oxidation potential of XOH; however, a higher pH made the copper complex hydrolysis.[6] Therefore, equimolar sodium hydroxide was added to a copper complex.

The polymerization of XOH in a water (10 vol%)–DMSO(90) mixture was examined using the L5.1VP8.7Q or pyridine complex. The effects of the reaction time are indicated in Fig. 1. The yield of PPO increased with the passage of time, while the molecular weight of PPO increased steeply near the conclusion of the reaction (the oxygen consumption ceased). Therefore, the reaction was allowed to continue twice as long as

a) XOH: 0.5 mol dm^{-3}; $CuCl_2$: 0.01 mol dm^{-3}; [VP unit]/[Cu]=1.5. Solvent: 20 cm^3 of water-DMSO mixture; pH: 13.5; Temp: 30 °C; Oxidation: under aerobic conditions. a) PPO did not precipitate from methanol, which molecular weight seemed low.

the time necessary for a consumption of oxygen (the polymerization rate reduced nearly to zero). PPO was yielded in 75% with the L5.1VP8.7Q complex and 58% with the pyridine complex, and DQ yielded in 6% with the L5.1VP8.7Q complex and 8% with the pyridine complex.

Then, the effect of the water content in a DMSO solution was examined (Table 2). On the whole, the polymerization rates were not so fast at pH 13.5 when the VP-unit ratio to copper was 1.5 (the Cu complex is not hydrolyzed). However, the polymerization rate using the surfactant-copper complex was highly affected by the water content: L0.8VP3.2Q1.6MA 25.5 mm^3 min^{-1} at 3 vol% water in DMSO, 26.0 $mm^3 min^{-1}$ at 5 vol%, 22.0 $mm^3 min^{-1}$ at 7 vol%, 8.0 $mm^3 min^{-1}$ at 10 vol%, and 4.5 mm^3 min^{-1} at 50 vol%. On the other hand, the polymerization rates using the 62VP26Q polymer complex were nearly constant in 3—50 vol% of water contents (9.0 $mm^3 min^{-1}$ at 3 vol%, 7.5 mm^3 min^{-1} at 5 vol%, 7.0 $mm^3 min^{-1}$ at 7 vol%, 6.8 mm^3 min^{-1} at 10 vol%, and 6.6 $mm^3 min^{-1}$ at 50 vol%). Similar results had been obtained by Tsuchida et al.[7] Usually, a surfactant in a nonaqueous solution tends to aggregate or to form reversed micelles, and the structure varies with the water content.[8] The cmc of L5.1VP8.7Q-copper complex was actually confirmed in a water (5vol%)-DMSO(95) mixture by conductometric titration (cmc 4.8×10^{-4} mol dm^{-3}); however, that of the L5.1VP8.7Q complex in a water (50 vol%)-DMSO (50) mixture and those of 34VP51Q complex in a water (5 vol%)-DMSO(95) and a water (50 vol%)-DMSO(50) mixture were not found. The XOH anion would adsorb on the cationic reversed micelles or the cationic aggregated-surfactants in 3—10 vol% of water contents. The K_1 (the reciprocal of the Michaelis constant K_m) calculated from the Lineweaver-Burk plots were py-Cu 22 $dm^3 mol^{-1}$,[7] VP-Q-Cu 190,[7] and L-VP-Q-Cu 800—900, which means the affinity of the catalyst for the substrate.[9] Therefore, the rate using the telomer-type surfactants would become fast in the 3—10 vol% of water contents because the XOH was more condensed to the reversed micelles (about 40-times that of py) in addition to the nonpolar effect of the dodecyl group. The catalytic action of L5.1VP6.2Q9.4MA was more active than that of L0.8VP3.2Q1.6MA in the water (3 vol%)-DMSO(97) mixture. This difference is probably due to the extent of nonpolarity based on the methoxycarbonyl groups.

Then, the repeated use of telomer-type surfactants was examined. L0.8VP3.2Q1.6MA, the less active catalyst, was used repeatedly for the oxidative polymerization of XOH in a half scale of the abovementioned concentration (Table 2). Then, 60 cm^3 of 0.25 M (M=mol dm^{-3}) XOH in water (3 vol%)-DMSO (97) mixture was polymerized by 5×10^{-3} M $CuCl_2$ and 6.3×10^{-2} M L0.8VP3.2Q1.6MA at 30 °C under aerobic conditions. After the oxidative polymerization, the reaction mixture was divided in two parts; 10-cm^3 of the reaction mixture was used for a determination of PPO and 50 cm^3 of the remainder was subjected for further polymerization: 10 cm^3 of 0.5-M XOH in water (3 vol%)-DMSO mixture was added to 50 cm^3 of the reaction mixture. The resulting PPO were first 4800 of molecular weight in 64% yield, second 4800 in 69%, and third 4200 in 62%. In spite of the half-scale concentration, and the L0.8VP3.2Q1.6MA-copper solution was then diluted in series, the three findings were similar. Furthermore, the other telomer-type surfactants were confirmed their repeating use in similar reactivities.

Solvent Effects. The catalytic action of the VP-Q polymer complex was much affected by the solvent polarity.[4] Therefore, the effects of solvent polarity were examined on the assumption that the dielectric constant of mixed solvent D is equal to the sum of the individual products of the dielectric constant of the mixing species and its volume ratio.[10] The polarity was expressed as a dielectric parameter E; $E=(D-1)(2D+1)^{-1}$,[11] The E values for the 3—50 vol% water in DMSO were 0.485—0.488 (Table 2). The tendency that the catalytic action increased with a decrease in the solvent polarity could be recognized, but the

XOH: 0.5 mol dm^{-3}; $CuCl_2$: 0.01 mol dm^{-3}; [VP unit]/[Cu]=2. Volume: 20 cm^3; Dielectric parameter $E\{=(D-1)(2D+1)^{-1}\}$: 0.441, 0.449; Temp: 30°C; Oxidation: under aerobic conditions. a) PPO did not precipitate from methanol.

range of the E values was too narrow to discuss. The polymerization using the L-VP-St complex was examined in a py(20 vol%)-organic solvent (80) mixture; E value: py-benzene (Bz) 0.342, py-chlorobenzene (CB) 0.399, py-DCB 0.431, and py-nitrobenzene (NB) 0.476. The polymerization rate decreased with an increase in the solvent polarity, while the reduced viscosity of PPO was independent of the solvent polarity in the E range 0.342—0.476.

Then, the catalytic actions in a water (10 vol%)-DMSO (90) mixture (E 0.486) and in a MeOH (10 vol%)-DCB (90) mixture (E 0.441) were examined (Table 3). The polymerization rates of XOH in an MeOH-DCB mixture were higher than that in a water-DMSO mixture. Moreover, the catalytic actions in an MeOH (10 vol%)-DMSO (90) mixture (E 0.484) and in an MeOH (10 vol%)-Bz (90) mixture (E 0.371) were evaluated by using the L5.1VP8.7Q complex. The polymerization rates were as follows: In MeOH-Bz > MeOH-DCB > water-DMSO > MeOH-DMSO. The order of these rates was according to the order of solvent polarities, except for the water-DMSO mixture. It was proven by Tsuchida et al. that the rate-determining step for the oxidative polymerization of XOH using the VP-Q polymer complex was the reoxidation step in a polar solvent and was the electron-transfer step in a nonpolar solvent. Also, the total polymerization rate was fast in a nonpolar solvent.[4] However, the rate using the L5.1VP8.7Q complex in a polar water-DMSO mixture was higher than that in a less polar MeOH-DMSO mixture. The cmc of L5.1VP8.2Q complex in 3—10 vol% water in DMSO was found but that in an MeOH-DMSO mixture was not. Therefore, the higher rate in the water-DMSO mixture was presumably due to the concentration of XOH to the reversed-micelles. In these solvents the polymerization rate using the L5.1VP8.7Q, L0.8VP3.2Q1.6MA or L-VP-Q-St complex was faster than that using the 34VP51Q or pyridine complex because of the large aggregation.

Effect of Pyridine. The oxidative polymerization of XOH was considerably affected by adding pyridine.[4] The catalytic actions in MeOH-DCB-py solutions are shown in Table 4. Although the E values of these solutions are nearly equal to 0.44 (0.441—0.449), the polymerization rate and the reduced viscosity of PPO

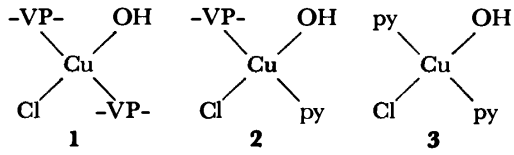
XOH: 0.2 mol dm^{-3}; CuCl: 5×10^{-3} mol dm^{-3}; [VP unit]/[Cu]=2. Volume: 40 cm^3; Temp: 30 °C; Oxidation: under oxygen atmosphere.

using the L5.1VP8.7Q complex increased at 3 vol% of the pyridine content. A similar result was also obtained upon using the L-VP-St complex. On the other hand, the catalytic actions without the telomer-type surfactants were, on the whole, less. Catalysts for the oxidative polymerization of XOH are known to possess the following structures:[4,12]



Presumably, the **2** that formed upon adding pyridine (3 vol%) was easier to use for forming complexes with XOH than **1** with a rigid structure; also, oxygen was more easy of access to the resulting **2**-XOH complex because of less steric hindrance.[12] Consequently, the addition of pyridine would accelerate the polymerization rate. However, in a large excess of the pyridine content (80 vol%) the polymerization rate using the L5.1VP8.7Q complex was slow and the reduced viscosity of PPO was low. By a further addition of pyridine, the structure of **2** could be converted to the inactive structure VP-$CuCl(py)_2$ etc. Similarly, the polymerization rate became slow when the VP-unit ratio in the L0.8VP3.2Q1.6MA to the copper was increased, i.e., 31.9 $mm^3 min^{-1}$ at ratio 5, 4.6 mm^3 min^{-1} at ratio 7, and 1.8 $mm^3 min^{-1}$ at ratio 10. On the other hand, the rate without the L5.1VP8.7Q in the 3 vol% of pyridine content was very slow and the rate in the 80 vol% of pyridine content was fast but the reduced viscosity was very low. The structures would be CuCl(OH)py and **3** or $CuCl(py)_3$.

Polymerization under Oxygen Atmospere. The polymerization of XOH was examined by using a Cu(I) complex under an oxygen atmosphere instead of the Cu(II) complex under aerobic conditions (Table 5). The polymerization rates using the 34VP51Q polymer and the pyridine monomer complexes were very fast in comparison with that using the L5.1VP8.7Q telomer complexes. Their catalytic actions in MeOH-DCB-py solutions became more active at a lower MeOH content and the order of the catalytic actions was in MeOH-Bz-py>MeOH-CB-py>MeOH-DCB-py. The polymerization-rate ratio (using L5.1VP8.7Q to the rate using the pyridine complex in the MeOH-DCB-py (10 vol%) mixture) was larger than the ratio in the MeOH-CB-py or the ratio in the MeOH-Bz-py mixture. The Cu(I) complex of a telomer-type surfactant would aggregate or form reversed-micelles in these solutions. The approach of oxygen to the surfactant complex would be more difficult than the pyridine complex because of a steric hindrance, even if the oxygen pressure increased. Then, the rate-determining step in a polar solvent was the reoxidation step and that in a nonpolar solvent was the electron-transfer step.[4] Therefore, the dependence of the polymerization rate on the catalyst in the more polar solvent (MeOH-DCB-py) would be larger than that in the more nonpolar solvent (MeOH-Bz-py). Nevertheless, the reduced viscosity of PPO using the L5.1VP8.7Q complex was the highest in the MeOH-DCB-py mixture. Furthermore, the increase of pyridine made the polymerization rate slow, but made the reduced viscosity high. The structure of the complex would become **3**. Naturally, the polymerization rate

XOH: 0.2 mol dm^{-3}; CuCl: 5×10^{-3} mol dm^{-3}; [VP unit]/[Cu]=2. HTAB: hexadecyltrimethylammonium bromide; Solvent: 40 cm^3 of MeOH(20 vol%)-DCB(70)-py(10) mixture; E: 0.451; Temp: 30°C; Oxidation: under oxygen atmosphere.

increased under an oxygen atmosphere, and the rate when using the telomer-type surfactant was relatively disadvantageous in comparison with the rate when using pyridine. However, the characters of the telomer-type surfactants for the polymerization of XOH were substantially similar to that under aerobic conditions.

Then, the effects of hexadecyltrimethylammonium bromide (HTAB) on the oxidation polymerization of XOH were examined (Table 6). By the addition of HTAB, the reduced viscosity of PPO became high. However, the yields of PPO and DQ were nearly constant, and all the polymerization rates became slow (about 30 mm^3 min^{-1} while the reaction time became long). These results suggested that the HTAB interfered with the formation of catalyst–XOH complex because the HTAB attracted the XOH anions, and that the HTAB kept the growing PPO highly dispersed.

The Enantioselective Hydrogenation of Methyl Levulinate on the Interactive and Noninteractive Sites of Nickel Surfaces with Preadsorbed Asymmetric Compounds

Michio Yokozeki, Kazuo Shimokoshi, and Eizo Miyazaki*
Department of Chemistry, Tokyo Institute of Technology, 2-12-1, Ohokayama, Meguro-ku, Tokyo 152
(Received February 2, 1986)

The gaseous hydrogenation of methyl levulinate on the Ni surface modified with the optically active tartaric, malic and lactic acids was studied. It was found that γ-valerolactone is formed on an unmodified surface, while optically active methyl 4-hydroxypentanoate [MHP] and γ-valelolactone [VL] are formed consecutively on modified surfaces. Using these results and the temperature dependency of the reaction rates, along with previous theoretical results [*J. Phys. Chem.*, **89**, 2397 (1985)], it was concluded that, on an Ni surface modified with preadsorbed optically active acids, there are two different and independently operative sites, i.e., noninteractive (nonselective) and interactive (selective) sites which give the enantioselectivity. Further, the fractions of the noninteractive sites in the total amount of active sites were estimated to be about 18 and 13% for TA- and MA-modified surfaces respectively. A similar character of the active sites was found for the enantioselective hydrogenation of methyl acetoacetate [MAA] to methyl 3-hydroxybutyrate [MHB] on TA-modified Ni, where the fraction of noninteractive sites was evaluated to be about 15%.

It is known that such transition metal catalysts as Ni, when an optically active molecule such as tartaric acid is preadsorbed on their catalyst surfaces, become enantioselective for the hydrogenation of methyl acetoacetate.[1-3] Two different mechanisms for this selectivite reaction have been proposed as important processes on the surface:[3,5,6] (1) The complex formation with the substrate and modifiers,[4,5] and (2) the control of the orientations of the reactants by rather strong interaction between reactants and modifiers. In the previous theoretical studies based on the molecular orbital calculations with the MNDO method,[7] it was predicted that the hydrogen-bond-like interactions between reactants and preadsorbed hydroxy acids can control the form of the reactants on the surface.

On the other hand, as has been reported by Harada et al. in their study of liquid phase reactions,[8] the enantioselectivity of these systems is dependent upon the nature of the surface sites on which the reaction occurs; i.e., the high enantioselectivity is expected only from the reactions on the appropriately modified surface sites. In fact, the low-pressure gaseous hydrogenation of methyl acetoacetate (MAA) on the modified Ni surface provided an optical yield of, at most about 50%.[3] Therefore, in order to clarify the enantio-face-differentiating activity of the catalysts, it is desirable to obtain detailed knowledge of the processes occurring on both modified and unmodified surface-active sites. Harada et al. have clarified, using KBr as the site selective preadsorber in the modifier solution, that the Raney-Ni surface has two kinds of sites, i.e., effective and noneffective sites for the enantioselectivity.[8]

In the present work we investigated the hydrogenation of methyl levulinate (ML) on a nickel catalyst with and without the modification of optically active hydroxy acids, and found that the products formed on modified surfaces were different from those on an unmodified nickel surface. Using this reactant, we could obtain an insight into the processes on the modified surface. Further, this information on the surface sites of the modified Ni could be made use of in giving reasonable interpretations to the enantioselective hydrogenation of MAA in the gas phase, because the hydrogenation of MAA produced only methyl 3-hydroxybutylate (MHB) on both surfaces of Ni.

In the present paper, first we will describe the results of the enantioselective hydrogenation of methyl levulinate on nickel surfaces modified with various optically active hydroxy acids, and then the results obtained by applying a similar method to the analyses of the enantioselective hydrogenation of MAA to MHB.

Experimental

The apparatus used for the preparation of the catalysts and the reaction was the same as that reported previously.[3a] The modifiers used were (*R,R*)-tartaric acid (TA), (*S*)-malic acid (MA), (*S*)-3-hydroxybutyric acid (HBA), and (*S*)-lactic acid (LA). The modification was made by introducing 0.1 mol l^{-1} solutions of hydroxy acids at room temperature into a reaction cell which contained the nickel previously reduced by hydrogen. The pH of the modifier solutions was controlled at 5.0 by the use of sodium hydroxide. After 1.5 h of contact, the catalyst was washed by deaired methanol in a storage area attached to the cell. These processes were performed in the vacuum system.

Hydrogen of 2.66×10^4 Pa was circulated through the liquid ML (or MAA) storage, and a gaseous mixture of H_2 and the reactants was introduced into the reaction cell. The partial pressure of the ML vapour was 90 Pa. The reaction rates of hydrogenation were monitored by the change in the total pressure. The products were collected by means of liquid-nitrogen trap and analyzed by the use of a gas chromatograph (Yanagimoto G2800-F) using a 200 cm glass column packed with polyethylene glycol 20M (20%) on Celite 545 at 110 C. The optical rotation of the products was measured by means of a Yanagimoto OR-50 polarimeter.

Two different products, methyl 4-hydroxypentanoate (MHP) and γ-valerolactone (VL), were obtained by the hydrogenation of ML on TA-modified Ni. The optical yield

of the products was calculated based on the value of $[\alpha]_D^{22}=-35.1$ (neat) for (*S*)-γ-valerolactone.[9] In the present experiments, in order to obtain the optical rotation accurately, the mixture was heated with Amberlyt 15 to convert all the MHP to VL. The enantioselectivities, ES, were defined as the percentage of enantiomer excess in the products.

Results and Discussion

In the hydrogenation of ML on TA-modified Ni catalysts at 323 to 353 K, two kinds of products, methyl 4-hydroxypentanoate (MHP) and γ-valerolactone (VL), were obtained, whereas on an unmodified Ni surface nearly 100% of the ML was converted to VL. The following consecutive mechanism, consisting of two steps, I and II, has been reported for this reaction on the surface.[10]

$$\underset{\text{ML}}{CH_3\overset{\overset{O}{\|}}{C}CH_2CH_2COOCH_3} + H_2 \xrightarrow{\text{I}}$$

$$\underset{\text{MHP}}{CH_3\underset{\underset{OH}{|}}{CH}CH_2CH_2COOCH_3} \xrightarrow{\text{II}} \underset{\text{VL}}{CH_3\overset{\overset{O}{\diagup\diagdown}}{CH}\underset{\underset{CH_2-CH_2}{|\quad|}}{CO}} + CH_3OH$$

The ratio of MHP to the total products (VL+MHP) was about 60—70% in the former case, it decreased gradually with the increase in the reaction temperature. The hydrogenation character on Ni modified with other hydroxy acids, such as MA, LA, and HBA, was similar to that on TA-modified Ni; the ratios of MHP at 323 K were 69 (TA), 64 (ML), 62 (LA), and 60% (HBA). However, the enantioselectivity observed on ML modified Ni was less than that on TA-modified Ni, and on LA- and HBA-modified Ni the enantioselectivities were too low to be detected. The observed reaction rates at various temperatures on the unmodified (R_1) and modified (R_2) catalysts and also the % MHP in the products on Ni modified with TA and MA are compared in Table 1.

Unfortunately, the quantity of MHP in the gas-phase-reaction products was not large enough to measure the rotation of MHP and VL separately, and the optical rotation of MHP has not been reported. The optical rotations of the products were, therefore, measured before and after all the MHP, obtained initially, had been converted thermally into VL. Table 2 lists the optical rotations, the proportions, and the optical yield of the products. As may be seen in the table, the optical rotation was opposite in direction for the samples before and after the conversion. Since the rotating directions of VL and MHP in the same configuration are opposite to the reported value, $[\alpha]_D^{24}=+10.5$, for the related acid [(*S*)-4-pentanoxiacid] of MHP, the observed change indicates that (*R*)-MHP was formed on the modified surface and converted to (*R*)-VL by thermal treatment. The effect of the preadsorbed optically active hydroxy acids on the enantioselectivity is, therefore, apparent, even though their optical yields are not very high.

Figure 1 shows the variations in the rates of the product formation on the unmodified and TA- or MA-modified Ni surfaces with the reaction temperature. It may be seen that the apparent activation energy (33 kcal†mol^{-1}) obtained for VL formation on the unmodified Ni was very close to those on the TA- and MA-modified Ni, i.e., 33 and 31 kcal mol^{-1} respectively, while the energies for MHP on the two

† 1 cal=4.184 J.

Table 3. Rates, Enantioselectivities and r Values for MAA Hydrogenation to MHB on TA-modified Ni

Reaction temperature	Unmodified Ni Rate	TA-modified Ni Rate	ES	r

surfaces modified with TA (18 kcal mol^{-1}) and MA (28 kcal mol^{-1}) were quite different. These results, therefore, strongly suggest that the nature of the reaction for the formation of VL is similar on both unmodified and modified surfaces. Further, in order to estimate the fraction of the surface sites for VL formation in the total amount of active sites for the hydrogenation, the value $\%r=(100-\%MHP)R_1/R_2$ was calculated at each temperature. The values, shown in Table 1, were found to be independent of the reaction temperature, but dependent on the modifiers used, i.e., about 18 and 13% for TA- and MA-modified surfaces respectively.

These results suggest that MHP and VL are formed on different surface sites. On the nickel surfaces modified with the preadsorbed hydroxy acids, there might be two different and independently operative sites, (a) the "interactive" (selective) and (b) "noninteractive" (nonselective) sites. In the hydrogenation of ML on the interactive sites, the reaction may cease at Step I to form MHP, while the reaction proceeds further to Step II on such noninteractive sites as the bare nickel surfaces.

On the other hand, Table 3 summarizes the rates and enantioselectivities obtained for the hydrogenation of methyl acetoacetate (MAA) to methyl 3-hydroxybutyrate (MHB) on TA-modified Ni. It can reasonably be assumed that, in the enantioselective hydrogenation of MAA on modified nickel surfaces, the reaction proceeds on the interactive sites, where the reactants are controlled by neighboring preadsorbed hydroxy acid molecules to form an optically active product preferentially.[7] Therefore, the fraction of the noninteractive sites of a modified surface can be estimated in a manner similar to that described above; i.e., by dividing the rate of the nonstereospecific reaction on TA-modified catalyst by that on the corresponding unmodified catalyst at each temperature. The calculated results are listed in Table 3. The values ($\%r$), as expected, were found to hold almost constant (15%) throughout the reaction temperatures.

In conclusion, Ni surfaces modified with optically active acids are divided into interactive and noninteractive parts. The fraction of the noninteractive sites in the total amount of active sites is in the range of 10 to 20%, depending on the modifiers used. These sites seem to exist independently; thereby, it may be suggested that one can suppress the reaction rate on noninteractive sites using some appropriate reagents which cover the noninteractive sites preferentially.

Solubilities and Free Energies of Transfer for Lanthanoid Iodates in Dimethyl Sulfoxide-Water Mixtures

Hiroshi Miyamoto,* Hiroko Iijima, and Masako Sugawara
Department of Chemistry, Faculty of Education, Niigata University, Ikarashi-2, Niigata 950-21
(Received February 14, 1986)

The solubilities of lanthanoid iodates in dimethyl sulfoxide (DMSO)-water mixtures at 25 °C were measured. Thirteen lanthanoid iodate dihydrates $Ln(IO_3)_3 \cdot 2H_2O$ (Ln=Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lu) were used. From the measured solubilities, the Gibbs free energies of the transfer of the iodates from water into aqueous DMSO solutions were calculated. The tetrad effect behavior reported by Peppard et al. was observed in both the variation with the lanthanoid atomic number of the solubility data and that with the atomic number of the free energies of transfer. The tetrad effect behavior seems to depend on a change in the solvation of the lanthanoid ions in variation with the crystal radii of the trivalent lanthanoid ions. In each system the logarithm of the solubility of the iodates decreases almost linearly with the reciprocal of the dielectric constant of the mixtures, as is expected from the Born equation or its modification when dealing with mixtures with narrow dielectric constant, ranging between 78.5 and 78.0.

As is well-known, variations in the thermodynamic data regarding lanthanoid(III) ions in aqueous solutions show no simple correlation with the crystal radii of the trivalent cations. A plot of the thermodynamic data as a function of the radius often exhibits a break somewhere in the middle of the lanthanoid series. For example, a plot of the stability constants of many lanthanoid complex systems against the lanthanoid atomic number shows a gadolinium break.[1,2] Peppard et al.[3] have reported that in certain liquid-liquid extraction systems the behavior of lanthanoid(III) ions has been interpreted in terms of four tetrads, rather than in terms of two octads. The tetrad effect proposed by Peppard et al. has been theoretically studied by Nugent.[4] He stated that the effect originates mainly from the quantum mechanical interelectronic repulsion energy of the q electrons in a $4f^q$ electron configuration.

Siekierski and Salomon[5,6] have studied the thermodynamic behavior of the solubility phenomena using recently published critically evaluated solubility and activity data of lanthanoid nitrates. They stated that the variations of the thermodynamic and congruent melting points as a function of atomic number can be interpreted mainly in terms of changes in the inner-sphere coordination number for both solid hexahydrates and aquo ions. Bertha and Choppin[7] have measured the heats of solution and the solubilities of the lanthanoid iodates in water at 25 °C and from these data the thermodynamic parameters of hydration were calculated. They proposed that the variations of the entropies of hydration across the lanthanoid series support the suggestion of a change in the hydration number of the lanthanoid ions somewhere in the middle of the series.

The lanthanoid iodates were chosen for this study of the solubility phenomena for several reasons. For all of the lanthanoid iodates except lanthanum and promethium salts their dihydrates could be prepared. Their relative insolubility allowed an easy determination of the solubility product values. They exhibited desirable precipitation characteristics with no evidence of colloidal suspension.

The solubility data of lanthanoid iodates in water at 25 °C except those of cerium, promethium and lutetium iodates have been reported by Firsching and Paul.[8] Bertha and Choppin[7] have also measured the solubilities of the iodates in water at 25 °C except that of promethium iodate. However, the solubilities of lanthanoid iodates in a variety of binary solvent mixtures have not yet been studied systematically. Monk[9,10] measured the solubilities of lanthanum iodate only in various solvent mixtures, and discussed the relation between the solubility of the iodates and the dielectric constant of aqueous solvent mixtures. Miyamoto, Shimura, and Sasaki[11] have reported the solubilities of lanthanoid iodates except lanthanum and promethium iodates in aqueous methanol media and in aqueous ethanol media. They also pointed out that the neodymium and erbium breaks appeared in addition to the gadolinium break in these systems.

In this study, the solubilities of thirteen iodates of the lanthanoid series in dimethyl sulfoxide (DMSO)-water mixed solvents were measured. From the solubility data, the Gibbs free energies of transfer from water into aqueous DMSO solutions were calculated. The dependence of the solubility of the lanthanoid iodates in aqueous aprotic solvent mixtures on the crystal radii of trivalent lanthanoid ions and on the lanthanoid atomic number was studied, and the dependence of the free energies of transfer on those was also considered.

Experimental

Preparation of Lanthanoid Iodates. The lanthanoid iodates were prepared by a dropwise addition of both the acidic solutions of lanthanoid nitrates and the aqueous potassium iodate solution. The agreement between the chemically found and the theoretically calculated values for dihydrate salts was within ±0.5 %. The results of chemical analyses of the prepared iodates were supported by thermal analyses.

Preparation details and analytical methods of the iodates

Table 1. Solubility of Lanthanoid Iodates in Dimethyl Sulfoxide-Water Mixtures at 25 °C

a) Data for pure water and for DMSO-water mixture from Ref. 12. b) Data for pure water from Ref. 13.

were previously reported.[11]

Preparation of Binary Aqueous Solvent Mixtures. Guaranteed grade DMSO was purchased from Wako Chemicals Co., and was distilled under reduced pressure three times. Redistilled water with a specific conductivity of 0.98±0.05 μS cm^{-1} was used. The binary solvent mixtures by weight were made from the purified DMSO and the redistilled water.

Solubility Measurements. The supersaturation method was used. The purified lanthanoid iodates and DMSO-water mixtures were placed into glass-stoppered bottles, which were slowly rotated in a thermostat at 27 °C for about 12 h. The temperature was lowered to 25.00±0.05 °C and the bottles were continuously rotated for 48 h, after which no further change was observed within the relative average deviation of 0.3%. The solubilities of the iodates were determined in water and in 40 mass percent DMSO solvent mixtures.

After settling in a thermostat at 25 °C for about one hour, the solutions were filtered through a vaccum-jacketed sintered-glass filter. The filtrates were kept in the thermostat at 25 °C for about one hour. Aliquots were diluted with redistilled water for adjusting to a suitable concentration for titration. Aqueous potassium iodide and hydrochloric acid were added and the liberated iodine was titrated with a sodium thiosulfate solution that had been standardized with potassium iodate using a starch indicator. In cases where the solubility was small, aliquots of the saturated solution were added to a known amount of potassium iodate and the mixtures were back-titrated with a standardized thiosulfate solution. All solubility measurements were performed in duplicate.

Results and Discussion

Solubilities of Lanthanoid Iodates in DMSO–Water Solvent Mixtures. The observed solubilities of lanthanoid iodate dihydrates $Ln(IO_3)_3 \cdot 2H_2O$ (Ln=Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lu) in DMSO-water mixtures at 25 °C are given in Table 1 along with the standard deviations of each solubility determination. The dielectric constants of DMSO-water mixtures[12] and of water[13] are also listed in Table 1.

The solubility determination of lanthanum iodate in the mixtures was not performed since the iodate dihydrate crystals could not be prepared. The solubility of promethium iodate is also missing from the table since a starting material such as promethium oxide or nitrate for the preparation of promethium iodate could not be purchased.

The solubilities of lanthanoid iodates in water at 25 °C have been reported by Firsching and Paul,[8] and Bertha and Choppin.[7] Miyamoto, Shimura, and Sasaki[11] measured the solubilities of the iodates in water at 25 °C and have reported the recommended values of the iodate solubilities in water at 25 °C by applying the evaluation guidelines[14] of the IUPAC Solubility Data Project. Our results regarding the solubility determination of the iodates are in good agreement with the recommended values.

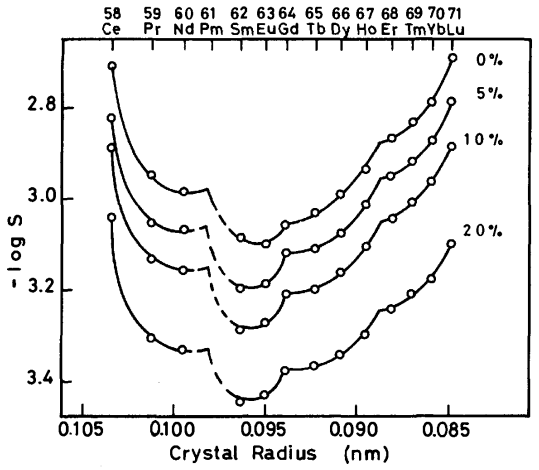

Fig. 1. Dependence of the logarithm of the solubility on the crystal radii (nm) of lanthanoid ions(III).

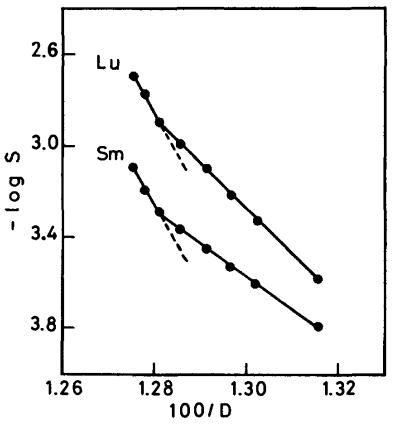

Fig. 2. Dependence of the logarithm of the solubility of samarium and lutetium iodates on the reciprocal of the dielectric constant of DMSO-water mixtures.

In this study, the DMSO concentrations of the solvent mixtures were in the range from 0 to 40 mass percent. At concentrations above 40 mass percent, the solubility could not be determined by an iodometric titration because the end point of the titration was not clear.

The relation between the logarithm of the solubility of lanthanoid iodates in DMSO-water mixtures and the lanthanoid atomic number is shown in Fig. 1., which also shows the dependence of the solubility of the iodates on the crystal radii of the trivalent lanthanoid ions. Recently, the ionic radii of many cations in aqueous solutions containing trivalent lanthanoid ions were theoretically determined by Marcus,[15] but the data of some cations in a series of trivalent lanthanoid ions are lacking. Therefore, the crystal radii of trivalent lanthanoid ions reported by Templeton and Dauben[16] were adopted.

In Fig. 1, although the points corresponding to lanthanum and promethium are lacking, it can be seen that the solubility curves pass through a minimum at atomic number 62 (samarium). By analyzing the solubility curves in further detail, the points on a plot of the logarithm of the solubility of lanthanoid iodates in DMSO-water mixtures vs. atomic number may be grouped, through the use of four smooth curves without inflections, into four tetrads with the gadolinium point being common to the second and third tetrads and the extended smooth curves intersecting, additionally, in the 60—61 and 67—68 atomic number regions.

As is well known, a plot of the stability constants of many lanthanoid complex systems[1,2] against the lanthanoid atomic number shows a gadolinium break. Peppard et al.[3] have reported that in certain liquid-liquid extraction systems the behavior of trivalent lanthanoid ions can be interpreted in terms of four tetrads, rather than in terms of two octads. The present solubility study also reveals the three break points, and the tetrad effect reported Peppard et al.[3] was observed.

The solubility of sparingly soluble salts as a function of the static dielectric constant of mixtures has been related to the Born equation[17] or its modification.[18-20] An example of the relation between the logarithm of the solubility and the reciprocal of the dielectric constant of the mixtures is shown in Fig. 2 for samarium iodate-DMSO-water and lutetium iodate-DMSO-water systems. In addition to the solvent mixtures having DMSO concentrations of 5, 10, 20, and 40 mass percent, solvents of DMSO with concentrations of 15, 25, and 30 mass percent were also used to determine the solubilities of the two systems. The circles indicate the observed solubilities of the iodates and dash lines are from a modified Born equation.

In each system the logarithm of the solubility of the iodates decreases almost linearly with the reciprocal of the dielectric constant of the mixtures, as is expected from the Born equation[17] or its modification[18-20] when dealing with mixtures of the narrow dielectric constant range of 78.5—78.0, but when dealing with mixtures of the dielectric constant range of 78.0—76.0 deviation from the Born equation was found. The dielectric constant range of 78.5—78.0 where a plot of the logarithm of the solubility vs. the reciprocal of the dielectric constant of the binary aqueous solvent mixtures follows the modified Born equation is narrower than that of methanol-water[11] and ethanol-water[11] systems.

For example, the relation between the logarithm of the solubility of the sparingly soluble salts and the reciprocal of the dielectric constant of mixed solvents is given by Davis, Ricci and Sauter[18] as

$$\ln (S_w/S_x) = (Z_+Z_-e^2/2rkT)/(1/D_x - 1/D_w), \quad (1)$$

where S and D represent the solubility of the iodates based on the molar scale and the dielectric constant of the mixtures, respectively, and the subscripts w and x

Table 2. The $2r$ Values of Lanthanoid Iodates Systems Calculated from Eq. 1 (10^9 units)

refer to the water system and the mixed solvent systems, respectively. Equation 1 corresponds to the first term of Koizumi's equation,[20] and the r value (solvation radius) was defined as Eq. 2:

$$1/r = (1/2)(1/r_+ + 1/r_-) \quad (2)$$

The $2r$ values calculated from Eq. 1 are given in Table 2. In "Index" column of Table 2, S_w and S_x (x=5, 10, 20, and 40) represent the solubility of iodates in water and that in the mixed solvent of the DMSO concentration x based on the mass percent scale, respectively, which were used to calculated the $2r$ values.

The physical properties of a DMSO–water system have been extensively studied.[13,21,22] These data point to strong interactions between water and DMSO in mixtures, which may be attributed to hydrogen bonding. Fox and Whittingham[21] have reported that the maximum interaction occurs in the region of about 0.3 mole fraction, enhancement of water structure expects perhaps at very low concentration (<0.01 mole fraction). The extensive literature[23] dealing with the DMSO–water interaction indicates that the solution properties of aqueous DMSO are dominated by 2:1 H_2O–DMSO complex, and only one result reported by Glasel[24] has been given 3:1 H_2O:DMSO complex.

When the electrolytes were added to DMSO–water solvent mixtures, the maximum interaction of DMSO and water changed distinctly. Indeed, Mastroianni, Pikal and Lindenbaum[25] have reported that the heats of dilution for lithium bromide in aqueous DMSO solutions exhibit a maximum around 20 mol% DMSO.

In a solubility study involving silver halides in DMSO–water mixtures,[26] the variation in the solubility data shows no simple correlation with the DMSO concentration in the mixtures. The solubility of silver chloride increases with an increase in the DMSO concentration, but those of silver bromide and iodide are reversed. From these results, the solubility phenomena of electrolytes in DMSO–water mixtures are no simple behavior.

In this study, as are given in Table 2 and shown in Fig. 2, the $2r$ values are classified into two categories. In each iodate system, one group consists of the $2r$ values for the lower DMSO concentration range (<2.5 mol%), and the other is those for the DMSO concentration of 20 and 40 mass percent (>5.0 mol%). The change of the slope depends on that of the solvation of lanthanoid ions, and it may also reflect the change of the DMSO–water interaction effected by lanthanoid ions.

Gibbs Free Energies of Transfer of Lanthanoid Iodates from Water into Aqueous DMSO Media. The aim of this section is to explore the dependence of the free energy of transfer for lanthanoid iodates from water into aqueous DMSO solutions on the lanthanoid atomic number.

The free energy of transfer of lanthanoid iodates from water into binary aqueous solvent mixtures is given by

$$\Delta G_t^\circ[\mathrm{Ln(IO_3)_3}] = RT \ln [K_{sp}(w)/K_{sp}(x)], \quad (3)$$

and the solubility product K_{sp} can be calculated from

$$K_{sp} = 27S^4\gamma_\pm^4. \quad (4)$$

Here, S and $\gamma_\pm$ represent the solubility of the iodates based on the molar scale and the molar activity coefficient of the iodates, respectively.

The solubilities of the iodates in water S_w and in DMSO–water mixtures S_x are related to the free energy of transfer from water into binary aqueous solvent mixtures:

$$\Delta G_t^\circ[\mathrm{Ln(IO_3)_3}] = 4RT \ln [S_w\gamma_\pm(w)/S_x\gamma_\pm(x)]. \quad (5)$$

From the solubility data, Blandamer, Burgess, and Duffield[27] have calculated the free energies of transfer of potassium cyanide from water into binary aqueous solvent mixtures. In the study, three methods were adopted to calculate the free energy of transfer. One approach was by an estimation of molar mean activity coefficients using the Debye–Hückel limiting law;[28] the other was also by an estimation of activity coefficients using the Güntelberg equation;[28] the rest was by the calculation of the quantity ΔG_t° on the molar scale from the observed solubility assuming $\gamma_\pm(w)/\gamma_\pm(x) \simeq 1$ in Eq. 5. For example, in pure DMSO the free energies calculated by using the Debye–Hückel equation and that calculated by using the Güntelberg equation were 21.8 and 21.9 kJmol^{-1}, respectively, and that calculated from the solubility assuming $\gamma_\pm(w)/\gamma_\pm(x) \simeq 1$ was 23.2 kJmol^{-1}. The relative average deviation is 2.7%. A comparison of the three results of the free energy of transfer to a series of pure solvent has been shown that the assumption $\gamma_\pm(w)/\gamma_\pm(x) \simeq 1$ was reasonable.

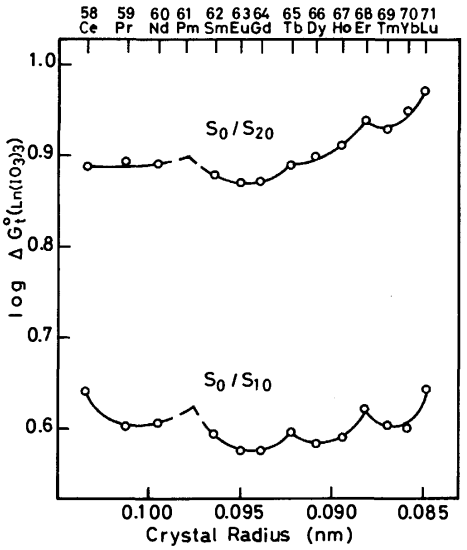

Fig. 3. Dependence of the logarithm of the free energy of transfer on the crystal radii (nm) of lanthanoid ions(III).

In this study, an estimation of molar activity coefficients used the Güntelberg equation[28] and the Davies equation.[28] Also, the free energies of transfer of the lanthanoid iodates from water into aqueous DMSO solutions were calculated from the observed solubility using Eq. 5. Further, Eq. 5 assuming $\gamma_{\pm}(w)/\gamma_{\pm}(x)\simeq 1$ was also used to calculate the free energies of transfer. From the results for samarium and lutetium iodate systems, the relative average deviation of the free energy of transfer calculated using the three methods was the range of 1.0—2.0%. The results are better than that of potassium cyanide in pure DMSO. Therefore, the free-energy values of the iodates calculated from the assumption $\gamma_{\pm}(w)/\gamma_{\pm}(x)\simeq 1$ were used in Fig. 3.

The dependence of free energy of transfer for lanthanoid iodates from water into aqueous DMSO solutions on the lanthanoid atomic number is shown in Fig. 3. The ratios S_0/S_{10} and S_0/S_{20} (Fig. 3) refer to the solubility ratio given explicitly in Eq. 5 and subscripts 0, 10, and 20 refer to the organic co-solvent concentrations of the mixtures. In Fig. 3, the points on a plot of the free energy of transfer against the lanthanoid atomic number can be divided into four curves with break points at atomic number 68 (erbium) and 65 (terbium) and in the 61—62 region. The behavior of trivalent lanthanoid ions is interpreted in terms of four tetrads, rather than in terms of two octads. Although the break points obtained in this free-energy study differ slightly from the behavior of the normal tetrad effect reported by Peppard et al.,[3] it can be seen that a tetrad-effect-like behavior is also observed in this free-energy study. However, Fujisawa and Suzuki[29] have reported that from a stability constant study the three break points were placed at 60 (neodymium), 64 (gadolinium) and 68 (erbium). Nugent[4] has stated that the variation in the interelectronic-repulsion-stabilization energy for the lanthanoid aqueous ions results in a tetrad effect at the 1/4, 1/2, and 3/4 filled shells of a 4f electronic configuration. However, a more detailed theoretical treatment as well as additional experimentation are necessary.

The figures referring to solubility ratios S_0/S_5 and S_0/S_{40} are not shown here, but the behavior of the curves is almost similar to that of S_0/S_{10} and S_0/S_{20}.

Effects of Cyclodextrins on the Fluorescence of Diphenyl Phosphate in Aqueous Solution

Sanyo HAMAI
Department of Physics, Miyazaki Medical College, Kiyotake, Miyazaki 889-16
(Received February 14, 1986)

The effects of α-, β-, and γ-cyclodextrin (CD) on intramolecular excimer formation between the two phenyl groups of diphenyl phosphate (DP) in aqueous solution were investigated by means of absorption and fluorescence spectra. It was found that DP forms 1 : 1 inclusion compounds with α-, β-, and γ-CDs. In the inclusion compound with α- or β-CD, only one phenyl group of a DP molecule is incorporated in the cavity of a CD molecule. In the case of γ-CD, however, the cavity can accommodate either one or two phenyl groups of a DP molecule. The pH dependence of the equilibrium constant for the formation of the inclusion compound between DP and β-CD has also been examined. Over the pH range from 3.46 to ≈10 the equilibrium constant does not change, whereas for pH values above ≈11 it decreases drastically.

Cyclodextrins (CDs) are cyclic oligosacharides consisting of more than five glucopyranose units. CDs containing 6, 7, and 8 glucose units are specified as α-CD, β-CD, and γ-CD, respectively. The effects of these CDs on the fluorescence properties of various aromatic compounds have been studied extensively.[1-8] The fluorescence intensity of a guest molecule is usually enhanced by the formation of an inclusion compound with CD.[1-5,7,8]

There have been several studies on the inclusion compounds of CDs with 1,3-bichromophoric substances which form an intramolecular excimer between two biphenyl groups or two naphthyl groups.[9-12] Bis(4-biphenylylmethyl)ammonium chloride (BBA) exhibits both a monomer and an excimer fluorescence in aqueous solution. The effects of CDs on the two emission bands have been reported by Emert et al.[9] The addition of α-CD to a BBA aqueous solution results in the reduction of the excimer fluorescence. No excimer peak is observed when β-CD is added. In contrast, excimer fluorescence is enhanced by the addition of γ-CD. The authors have suggested that the smaller cavity of α- and β-CDs which can accommodate only one aryl residue inhibits excimer formation, whereas the larger cavity of γ-CD, which can host two aryl moieties, enhances excimer formation considerably. For 1,3-bichromophoric substances possessing two naphthyl groups, it has also been shown that two naphthyl groups in the same molecule can be located inside the γ-CD cavity.[9-12]

Among the 1,3-bichromophoric compounds investigated up to now, dibenzylammonium chloride (DA) is the only compound that possesses two phenyl groups.[9] The addition of α-, β-, and γ-CDs have no effects on both the monomer and the excimer fluorescence of DA. This result has been explained as due to the prevention of a deep penetration of DA by both the second benzene moiety and the positively charged nitrogen.

Although the formation of an inclusion compound with CD is affected by other factors than the cavity size of CD and the molecular size and shape of a guest molecule, it appears that two phenyl groups, which are less bulky than two naphthyl groups, can be incorporated in the same γ-CD cavity. Thus, as a 1,3-bichromophoric compound having two phenyl groups, we selected diphenyl phosphate which was found to show both monomer and excimer fluorescence in aqueous solutions, and investigated the formation of inclusion compounds of diphenyl phosphate with α-, β-, and γ-CDs by means of absorption and fluorescence spectra.

Experimental

Diphenyl phosphate, purchased from Nakarai, was recrystallized twice from cyclohexane. β-Cyclodextrin (β-CD) from Nakarai was recrystallized three times from water. α- and γ-CDs obtained from Nakarai and Tokyo Kasei, res ectively, were used without further purification.

The absorption spectra were measured with a Shimadzu 260 spectrophotometer, and the fluorescence spectra were recorded on a Shimadzu RF-501 spectrofluorometer equipped with a cooled EMI 9789QA photomultiplier. Fluorescence was viewed at right angles to the direction of excitation, and the spectra were corrected for the spectral response of the detection system as previously described.[5] The absorption and fluorescence spectra were measured at 25±0.1 °C unless otherwise stated. Aerated sample solutions were used throughout this work.

Results and Discussion

Complex Formation of Diphenyl Phosphate (DP) with α- and β-Cyclodextrins (CDs). Since DP is a monoprotic acid, DP can take both anionic and neutral forms. By using a conventional titration method, the pK_a of DP was determined to be 2.4. At the DP concentration (5×10^{-4} mol dm^{-3}) used for this work, the pH of an aqueous DP solution was 3.46. Therefore, the DP at 5×10^{-4} mol dm^{-3} is predominantly in its anionic form in aqueous solution.

Figure 1 shows the absorption spectra of 5×10^{-4} mol dm^{-3} DP in aqueous solutions containing varying concentrations of β-CD. The absorption band of DP is red-shifted with isosbestic points at 228 and 254 nm as the concentration of β-CD is increased. This finding indicates a simple equilibrium involving a 1:1

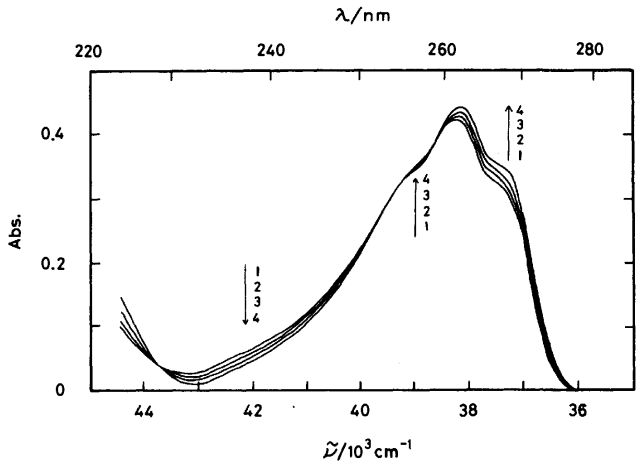

Fig. 1. Absorption spectra of DP (5×10^{-4} mol dm^{-3}) in aqueous solution in the presence of β-CD. Concentration of β-CD: (1) 0 mol dm^{-3}; (2) 10^{-3} mol dm^{-3}; (3) 2×10^{-3} mol dm^{-3}; (4) 5×10^{-3} mol dm^{-3}; (5) 10^{-2} mol dm^{-3}.

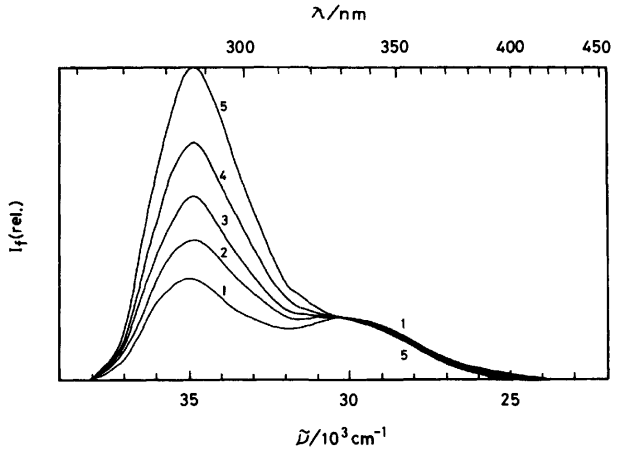

Fig. 2. Fluorescence spectra of DP (5×10^{-4} mol dm^{-3}) in aqueous solution in the presence of β-CD. Concentration of β-CD: (1) 0 mol dm^{-3}; (2) 10^{-3} mol dm^{-3}; (3) 2×10^{-3} mol dm^{-3}; (4) 4×10^{-3} mol dm^{-3}; (5) 10^{-2} mol dm^{-3}.

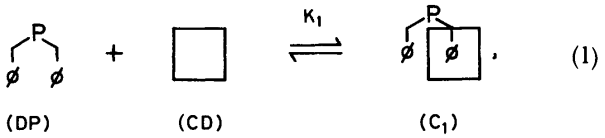
inclusion compound of DP formed with β-CD. The equilibrium between DP and a 1:1 inclusion compound of DP with β-CD can be represented by the following scheme:



(1)

where C_1 is a 1:1 inclusion compound of DP with CD in which only one phenyl group of a DP molecule is incorporated in the cavity of a CD molecule, and K_1 is an equilibrium constant for the formation of C_1. Because of a very small variation in the absorbance, we could not reliably determine the value of the equilibrium constant from the absorption data.

Figure 2 illustrates the fluorescence spectra of DP (5×10^{-4} mol dm^{-3}) in aqueous solutions with varying concentrations of β-CD. The fluorescence spectrum of DP alone exhibits two bands whose maxima are at 286 and 330 nm, respectively. The 286-nm band can be assigned to a monomer fluorescence since phenyl dihydrogenphosphate shows only one fluorescence band with a maximum at 288 nm in aqueous solution. The 330-nm band can be assigned to the intramolecular excimer fluorescence of DP from the following. (1) Even at a DP concentration as low as 5×10^{-5} mol dm^{-3}, the fluorescence spectrum was identical to that for a 5×10^{-4} mol dm^{-3} DP solution. (2) The excitation spectrum for the 330-nm band was the same as that for the 286-nm band. (3) The maxima of the excimer emissions of benzene and 1,3-diphenylpropane are reported to be 320 and 333 nm, respectively.[13,14] Corresponding to the C–C–C carbon-atom skeleton in the cases of 1,3-bichromophoric propanes, the three-atom molecular chain, O–P–O, in a DP molecule is responsible for the formation of the intramolecular excimer.

The addition of β-CD results in a remarkable enhancement of the DP monomer band without a shift in the maximum position of the monomer band. In contrast to the dibenzylammonium chloride studied by Emert et al., the effect of β-CD on the DP fluorescence is evident. To evaluate the intensity of excimer emission, the fluorescence spectrum of phenyl dihydrogenphosphate was assumed to be the same as that of the DP monomer, and the tail of its emission, which extends to ≈380 nm, was subtracted from the excimer portion of the spectrum. The true intensity of the excimer band decreased upon increasing the β-CD concentration.

In the cases of benzene and naphthalene derivatives, the equilibrium constants for the formation of inclusion compounds, obtained from the absorption and fluorescence spectrophotometric methods, almost coincide with each other.[5,16] The rate constants of the association and dissociation reactions for the systems of a naphthalene derivative and β-CD are of the order of 10^7 mol^{-1} s^{-1} and 10^4 s^{-1}, respectively.[15] Although the corresponding rate constants for DP are not available, the above values are small compared with the expected decay rate constant (the order of 10^8 s^{-1}) of the singlet excited state of DP. Therefore, it is likely that an equilibrium between excited DP and β-CD cannot be established within the lifetime of excited DP. Thus, K_1 was evaluated to be 200 mol^{-1} dm^3 from the intensity change in the monomer fluorescence of DP, according to the method previously described.[5] This value is in good agreement with the equilibrium constants reported for the 1:1 inclusion compound formed between benzene and β-CD (196±10 (28 °C) and 169±1 (25 °C) mol^{-1} dm^3).[16,17]

When α-CD was added to a DP aqueous solution, similar changes were observed both in the absorption

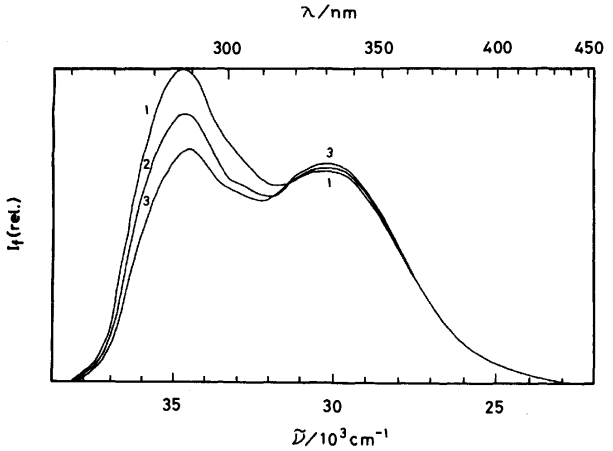


Fig. 3. Fluorescence spectra of an aqueous DP (5×10^{-4} mol dm^{-3}) solution in the presence of γ-CD at 43°C. Concentration of γ-CD: (1) 0 mol dm^{-3}; (2) 10^{-2} mol dm^{-3}; (3) 2×10^{-2} mol dm^{-3}.

and fluorescence of DP except that these changes were much smaller than those for β-CD, indicating the formation of the C_1 inclusion compound between DP and α-CD to a smaller extent. For α-CD, K_1 was determined to be 0.85 mol^{-1} dm^3 from measurements of the DP monomer fluorescence. The equilibrium constant for the formation of the 1:1 inclusion compound between benzene and α-CD has been reported to be 31.6±0.1 mol^{-1} dm^3 at 25°C.[17] A marked disparity between the equilibrium constant of α-CD with DP and that with benzene suggests a strong obstruction against complex formation by the substituent group (-O-P(-O$^-$)(=O)-O-Ph) in the DP molecule.

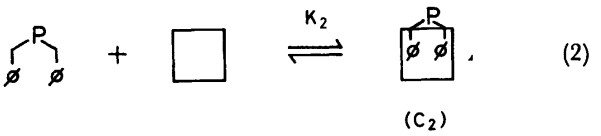
Complex Formation of DP with γ-CD. Below a γ-CD concentration of $\approx3\times10^{-2}$ mol dm^{-3}, the spectral change in the DP absorption was similar to that for β-CD. However, above a γ-CD concentration of $\approx3\times10^{-2}$ mol dm^{-3}, no isosbestic points were observed in the absorption spectra. This finding indicates the coexistence of at least two different equilibria between DP and γ-CD at a high γ-CD concentration. In this work, therefore, we restricted the γ-CD concentration up to 3×10^{-2} mol dm^{-3}. We found that a spectral change of the DP fluorescence caused by the addition of γ-CD varied significantly with temperature. In the lower-temperature range (below ≈10°C), the DP monomer fluorescence was enhanced with a decrease in the excimer fluorescence by the addition of γ-CD. As in the cases of α- and β-CDs, the enhancement of the monomer fluorescence is due to the formation of the 1:1 inclusion compound, C_1, of DP with γ-CD. From the fluorescence measurements, K_1 was evaluated to be 1.5 mol^{-1} dm^3 at 3°C. Figure 3 shows the DP fluorescence spectra at 43°C in the absence and presence of γ-CD. A decrease in the DP monomer fluorescence was observed in the higher-temperature range (above ≈25°C), accompanied by an enhancement of the DP excimer

Table 1. ΔH and ΔS for the Formation of the 1:1 Inclusion Compounds (C_1) of DP with α- and β-CDs

	DP		Benzene[a]	
	α-CD	β-CD	α-CD	β-CD
ΔH/kJ mol^{-1}	−37	−8.0	−13.1	−1.9
ΔS/J K^{-1} mol^{-1}	130	15	−15.5[b]	36.1[b]

a) From Ref. 17. b) Calculated from the equilibrium constant and the corresponding enthalpy change shown in Table 1 of Ref. 17.

fluorescence. The result in the higher-temperature range is similar to that for 1,3-bichromophoric compounds possessing two naphthyl or two biphenyl groups, indicating that two phenyl groups in a DP molecule are inserted into the same cavity of a γ-CD molecule.[9-12] The change in the DP fluorescence spectra in the higher-temperature range can be interpreted by the following equilibrium:



(2)

where C_2 is an inclusion compound in which two phenyl groups in a DP molecule are incorporated in the same cavity and K_2 is an equilibrium constant for the formation of C_2. In the case of C_2, it is likely that excited DP changes its geometrical conformation inside the γ-CD cavity within its lifetime and emits both a monomer and an excimer fluorescence. Even at a high temperature, C_1 in Eq. 1 can exist in a DP solution containing γ-CD. Since C_1, if it exists, contributes to both an increase in the monomer band and a decrease in the excimer band, the reverse intensity changes, a decrease in the monomer band and an increase in the excimer band (Fig. 3), is due mainly to the existence of C_2. By assuming that the presence of C_1 was negligible, K_2 at 43°C was determined to be 30 mol^{-1} dm^3 from the intensity change in the monomer fluorescence. At such a high temperature as 43°C, the increase in the DP excimer fluorescence at the expense of the DP monomer fluorescence may suggest that the enthalpy change (ΔH) for the C_2 formation is close to zero and, on the other hand, the entropy change (ΔS) for that is a positive value. Unfortunately, the thermodynamic parameters for K_1 and K_2 in the DP-γ-CD system could not be estimated because neither C_1 nor C_2 could be ignored over the fairly wide temperature range examined.

Temperature Dependence of K_1 for α- and β-CDs. From the temperature dependence of K_1 for α- and β-CDs, ΔH, and ΔS for the formation of C_1 could be obtained. The results are listed in Table 1 together with the data of benzene reported by Tucker and Christian.[16] For the inclusion compound of β-CD, positive values of

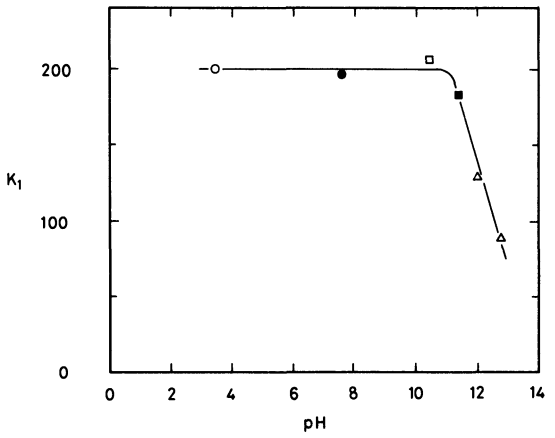


Fig. 4. pH dependence of K_1 for β-CD: (○) without buffer; (●) KH_2PO_4–NaOH buffer; (□) $NaHCO_3$–NaOH buffer; (■) Na_2HPO_4–NaOH buffer; (△) KCl–NaOH buffer.

ΔS were obtained for both DP and benzene. The larger $-\Delta H$ value for DP than that for benzene suggests that the substituted benzene ring fits more tightly the size of the β-CD cavity than the unsubstituted benzene nucleus. In the case of α-CD, ΔS for benzene is negative, whereas that for DP is positive. This result may show that a benzene molecule is more rigidly incorporated in the α-CD cavity than a DP molecule is. The larger $-\Delta H$ of α-CD both for DP and benzene than those of β-CD reveal that the cavity size of α-CD is more appropriate to the complexation with the benzene ring than that of β-CD.

pH Dependence of K_1 for β-CD. In order to further study the inclusion processes of DP, we examined the pH dependence of K_1 for β-CD. In Fig. 4, the values of K_1 are plotted as a function of pH. K_1 is constant at pH values between 3.46 and ≈10. However, K_1 abruptly decreases as the pH is increased above ≈11. The pK_a value for α-CD is known to be 11.8.[18] Since both α- and β-CDs are constituted from the identical glucopyranose units, nealy the same value of pK_a is expected for β-CD. As already mentioned, DP exists as an anionic form over the whole pH range studied. Therefore, the sharp drop of K_1 in Fig. 4 indicates an electrostatic repulsion between an anionic DP and an anionic β-CD molecule. In addition, if the deprotonation of β-CD at pH≈11 causes a conformation change in β-CD, this change can play an important role in the reduction of K_1.

The author wishes to thank Professor Fumio Hirayama for his valuable discussion.

Heterogeneous Hydration of Acrylonitrile over the Metal Oxide Catalysts in Liquid Phase

Kazuo SUGIYAMA,* Hiroshi MIURA, Yasushi NAKANO, Hideyuki SEKIWA, and Tsuneo MATSUDA
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-okubo, Urawa 338
(Received February 15, 1986)

The liquid-phase hydration of acrylonitrile has been examined over various single metal oxide catalysts at 65 °C. Numerous metal oxides have proved to be active for hydration and have been used to produce three products: acrylamide, ethylene cyanohydrin, and bis(2-cyanoethyl) ether. These oxide catalysts could be divided into two groups with respect to the acrylamide selectivity with 100% or not. A good relationship between the catalytic abilities (activity and selectivity) and the solid acid-base properties of each metal oxide group examined in benzene or in water was observed. Differences in the hydration selectivity to either a C≡N or a C=C bond of acrylonitrile over the catalysts could be explained on the basis of the IR spectra of two adsorbed states of acrylonitrile on the metal oxide surface. It was proved that the liquid-phase hydration of acrylonitrile over the insoluble metal oxide catalysts was an acid-base-catalyzed reaction proceeding on the acidic or basic surface hydroxyl groups.

Acrylonitrile (AN) is a reactive organic molecule owing to two kinds of reactive unsaturated bonds: a C≡N triple bond and a C=C double bond. Many derivatives were produced by an addition reaction to the AN.[1] For example, a water molecule could easily be added to the two functional groups in either acidic or basic media.[2,3] Using sulfuric acid, the acrylamide sulfate was produced during the initial stage of a stoichiometoric reaction as follows:

$$\underset{\text{acrylonitrile (AN)}}{CH_2{=}CH{-}C{\equiv}N} + H_2SO_4 + H_2O \longrightarrow CH_2{=}CHCONH_2{-}H_2SO_4 \quad (1)$$

Acrylamide (AA) could be obtained by the neutralization of the sulfate with an alkali solution such as aqueous ammonia.

$$CH_2{=}CHCONH_2{-}H_2SO_4 + 2NH_3 \longrightarrow \underset{\text{acrylamide (AA)}}{CH_2{=}CHCONH_2} + (NH_4)_2SO_4 \quad (2)$$

On the other hand, in a basic medium using an aqueous sodium hydroxide,[4] the hydration of AN catalytically proceeded to produce ethylene cyanohydrin (ECH), bis(2-cyanoethyl) ether (BCE), and AA as follows:

$$CH_2{=}CH{-}C{\equiv}N + H_2O \longrightarrow \underset{\text{ethylene cyanohydrin (ECH)}}{HOCH_2CH_2C{\equiv}N} \quad (3)$$

$$CH_2{=}CH{-}C{\equiv}N + HOCH_2CH_2C{\equiv}N \longrightarrow \underset{\text{bis(2-cyanoethyl) ether (BCE)}}{O(CH_2CH_2C{\equiv}N)_2} \quad (4)$$

$$CH_2{=}CH{-}C{\equiv}N + H_2O \longrightarrow CH_2{=}CHCONH_2 \quad (5)$$

In the case of metal oxides, the heterogeneous catalytic hydration of AN could also be observed,[5-10] and produced the same products as those in the case of the homogeneous hydration. The product distributions on the catalysts were similar to those in homogeneous acid-bese hydration of AN. Consequently, it is considered that the catalytic abilities (hydration activity and selectivity) are correlated with the solid acid-base properties of the metal oxide catalysts.

In this study the relationship between the catalytic behaviors of various metal oxides and their solid acid-base properties was examined in order to confirm whether the mechanism in the liquid-phase hydration of AN could be applied to a heterogeneous acid-base catalytic reaction.

Experimental

Catalyst Preparation: Metal oxides as catalyst were generally prepared by the decomposition of the hydroxides or carbonates of metals-to-metal oxides at 110 °C for 12 h or at >200 °C for 3 h. The surface areas of the catalysts were determined by the B.E.T. method. The catalysts used in this study are listed in Table 1. The detailed preparation methods are as follows;

(1) MnO_2: Commercially available electrolytic manganese dioxide (type FM-H, Toyo Soda Manuf. Co.) was used without further purification.

Samples 2 to 5 were chemically prepared in accordance with a method described by Kanungo[11] as below:

(2) α-MnO_2: $MnSO_4$ was dissolved in 0.5-M (1 M=1 mol dm^{-3}) hot sulfuric acid at 80 °C, precipitated with ammonium peroxodisulfate until the pink color of the solution disappeared. The precipitate was thoroughly washed with deionized water and then dried.

(3) β-MnO_2: $Mn(NO_3)_2$ was thermally decomposed in a stream of air.

(4) γ-MnO_2: An aqueous $Mn(NO_3)_2$ was oxidized with a dilute $KMnO_4$ solution.

(5) δ-MnO_2: An aqueous (0.38 M) $KMnO_4$ was reduced with 6-M aqueous HCl at 80 °C.

Other samples were prepared as follows;

(6) Co_3O_4: Cobalt hydroxide was precipitated from an aqueous $Co(NO_3)_2$ with aqueous NaOH, followed by a thorough washing of the precipitate and drying.

(7) Co_3O_4: Cobalt carbonate was thermally decomposed in a stream of air.

(8) Co_3O_4: Cobalt hydroxide was precipitated from a

$Co(NO_3)_2$ solution with aqueous ammonia.

(9) Co_3O_4: Cobalt hydroxide was precipitated from a $CoCl_2$ solution with aqueous NaOH.

(10) NiO(A): Nickel hydroxide was precipitated from a $Ni(NO_3)_2$ solution with aqueous NaOH, as reported in a previous paper.[10]

(11) CuO(A): Copper hydroxide was precipitated from a $Cu(NO_3)_2$ solution with aqueous NaOH.

(12) Fe_2O_3: Iron hydroxide was precipitated from an $Fe(NO_3)_3$ solution with aqueous ammonia.

(13) PbO_2: Lead nitrate was thermally decomposed in a stream of air.

(14) WO_3: Ammonium parawolframate was thermally decomposed in a stream of air.

(15) SiO_2: Commercially available silica sol (Catalloid H-20, Catalysts & Chemicals Ind. Co.) was dried in air and then calcined.

(16) TiO_2: Titanium hydroxide was precipitated from a $Ti(SO_4)_2$ solution with aqueous ammonia.

(17) Al_2O_3(A): Commercially available alumina (Neobead GB, Mizusawa Chem. Co.) was used.

(18) MnO: Manganese carbonate was thermally decomposed in a stream of nitrogen.

(19) MgO: Basic magnesium carbonate was thermally decomposed in air.

(20) ZnO: Zinc carbonate was thermally decomposed in air.

(21) Cu_2O: Copper(II) oxide was partially reduced in a stream of 2 vol% of propylene diluted by nitrogen, in accordance with the manner described by Mikhal'chenko et al.[12]

(22) NiO(B): Basic nickel carbonate was thermally decomposed in a stream of air, as reported in the previous paper.[10]

(23) CuO(B): Basic copper carbonate was thermally decomposed in a stream of air.

(24) Ag_2O: The precipitate was obtained from an $AgNO_3$ solution with aqueous NaOH.

(25) La_2O_3: Lanthanum hydroxide was precipitated from a $La(NO_3)_3$ solution with aqueous ammonia.

(26) Al_2O_3(B): Aluminum tri-isopropoxide was hydrolyzed, followed by washing of the precipitate and then dried.

(27) PbO: Lead hydroxide was precipitated from a $Pb(NO_3)_2$ solution with aqueous KOH.

Activity Measurement: The hydration of AN was carried out by the use of a four-necked flask equipped with a mechanical stirrer, a reflux condenser, a thermometer and a screw cap for sampling. Pure water (100 ml) and AN (8.5 ml) purified by distillation were introduced into the reactor and kept at 65 °C. The catalyst (2.5±0.1 g) was transferred from the calcination glass-tube to the reactor, followed by stirring. The rotation speed was 2000 rpm. The reaction products were analyzed by an FID gas chromatograph. Column packing used were both a Porapak QS (4 mmϕ×1 m, 170 °C) for analysis of AN, AA, and ECH and a PS 400 on Chromosorb W (4 mmϕ×2 m, 170 °C) for BCE.

Acid-Base Strength Distribution of Dark-Colored Solid Oxides: As the active catalysts for the hydration of AN to AA were dark-colored metal oxides, the acid-base strength distribution on these colored samples was determined by the modified indicator method that we developed. A characteristics of this method is that a commercially available separate ground-glass Gooch crucible for measuring the acidic or basic properties of the samples can be used, and the dark-colored sample and a white standard probe with a known acidity or basicity is situated in the upper and lower parts separated by a glass filter with a pore size of 20—30 μ. The detailed procedure was described in a previous paper.[13]

Equi-Acid-Base Point (EABP) of Metal Oxides: The value of EABP of metal oxide represents the acid-base properties of the solid catalysts dispersed in water.[14,15] The EABP of metal oxide catalysts was determined by a pH shift method in accordance with the manner described by Tari et al.[16] The metal oxide sample (2.5±0.1 g) and pure water (100 ml) were introduced into an Erlenmeyer flask equipped with a glass stopper in a decarbonated nitrogen atmosphere and then permitted to stand for one week. The pH value of the supernatant solution in the flask was measured with a pH meter.

IR Measurements: Infrared spectroscopic measurements of the AN adsorbed on both SiO_2 and MgO catalysts were made using a JEOL JIR-100 FTIR spectrometer. Sample treatment and adsorption of AN gas were carried out with a glass gas-handling system capable of achieving a 10^{-6} Torr vacuum. The quartz IR cell used was a conventional T-shaped cell with separate zones for heating and for taking spectra. CaF_2 windows were used. Spectra were collected by co-adding 100 scans at a resolution of 4 cm^{-1}. SiO_2 or MgO sample wafers were prepared by pressing 20 mg of a sample under a pressure of 200 kg cm^{-2} to form a disk about 20 mm in diameter. After SiO_2 and MgO wafers were, respectively, heated at 500 °C for 2 h in a cell, AN vapor (45 Torr (1 Torr=133.322 Pa)) was adsorbed to the sample at room temperature for 15 min and then evacuated for 3 min. All spectra were recorded at room temperature.

Amount of AN Adsorbed: Preheated MnO_2 (at 110 °C) or MgO (at 700 °C) sample (2.5 g) was, respectively, put into an Erlenmeyer flask with glass stopper, and then 100 ml of a 2.5 wt% AN aqueous solution was poured into the flask. After stirring for 6 h, the sample was allowed to stand for 40 h at room temperature and then kept at 40 °C for 4 h. The amount of adsorbed AN was determined from the difference of the concentration of AN before and after adsorption. The concentration of AN was measured by gas chromatographically.

Results and Discussion

Catalytic Activity and Selectivity: The catalytic activity (conversion of AN) and selectivity of the liquid-phase hydration of AN over various insoluble metal oxides were examined at 65 °C for 6 h in a batch reactor. The reaction results are summarized in Table 1. Many metal oxides had shown the catalytic activity of the AN hydration, and gave three products: AA, ECH, and BCE. The catalysts used in the AN hydration could be classified into two groups with respect to AA selectivity. One group, defined as "Group A," represents the metal oxides with a 100% AA selectivity and another, defined as "Group B," represents other metal oxides with a low AA selectivity.

The order of the catalytic activity of the oxides in Group A resulted as follows:

$MnO_2 > Co_3O_4 > NiO(A) > CuO(A) > Fe_2O_3 > PbO_2$, $WO_3 > SiO_2$, TiO_2, Al_2O_3(A).

Table 1. Catalytic Activity and Selectivity on Various Single Metal Oxides

Catalyst	Raw materials	Calcination temp/°C	Surface area/$m^2 g^{-1}$	Conversion of AN/%	Selectivity/%

Especially, MnO_2, Co_3O_4, NiO(A), and CuO(A) were effective catalysts for AA formation with 100% selectivity. The catalytic activity of both MnO_2 and Co_3O_4 strongly depended on both the catalytic preparation method and the pretreatment temperature.

The order of the catalytic activity of the oxides in Group B was as follows:

$$MnO > MgO > ZnO > Cu_2O > NiO(B) > CuO(B) > Ag_2O > La_2O_3 > Al_2O_3(B), PbO.$$

MnO was the most active catalyst for AN hydration in all the metal oxide catalysts examined. The more active catalysts in Group B showed the lower selectivity to AA.

It should be noted that the NiO, CuO, and Al_2O_3 prepared with two kinds of methods had different AA selectivities, regardless of their same crystal structure, which was determined by an X-ray diffraction method. Also, both carbonates and hydroxides of the manganese, cobalt, nickel and copper were inactive for liquid-phase AN hydration. When their salts were decomposed to the corresponding oxides, a hydration activity just appeared.

From the results of solid acid-base properties summarized by Tanabe[17] it could be proved that almost all the catalysts of Group A possessed a solid acidity, while the catalysts of Group B were rich in basic properties. It seems that the solid acid-base properties of the metal oxide catalysts are closely related to the catalytic activity and selectivity of AN hydration. This correlation is clarified in the next section.

Electronegativity of the Metal Ion and Selectivity to AA: A qualitative acid-base property of metal oxides can be explained by the electronegativity of the metal ion of an oxide.[18] The relationship between the selectivity to AA and the electronegativity of the metal ion of metal oxide catalysts is illustrated in Fig. 1. A good relation was obtained. The value of the electronegativity of Co_3O_4 could be expressed using the value of arithmetic mean of Co^{2+} and Co^{3+} ion. All the metal oxides for which the electronegativity was 11 or greater showed 100% selectivity to AA. The selectivity to AA of the catalysts decreased with decreasing electronegativity of the metal ion. Differences of the selectivity to AA on the NiO, CuO, and Al_2O_3 catalysts could not be

explained from the electronegativity since it is a qualitative measure of the solid acidity or basicity of metal oxide catalysts.

Acid-Base Property on the Metal Oxides: A quantitative measurements of the acidity and basicity on the metal oxide catalysts can be generally made using the indicator titration method. However, the properties of dark-colored solid samples are difficult to measure by this method. Accordingly, our modified titration method[13] was adapted during the course of this. The acid-base properties of some metal oxide catalysts for AN hydration in Group A or B were obtained as shown in Table 2, although not all the catalysts shown in Table 1 were examined.

The Group A catalysts with 100% AA selectivity showed acidic strength between pK_a 3.3 and 6.8; that is, a rather weak acidic site is related to AA formation. On the other hand, Group B catalysts with a low AA selectivity exhibited a pK_a value of 9.3 or greater. The acidic and basic sites on the NiO(B) and CuO(B) catalyst surfaces showed a pK_a of 4.8 or less and a pK_a of 15.0 or greater, respectively. Consequently, the acidic sites on the metal oxide surface participate with the hydration of the C≡N bond in an AN molecule and the basic sites do the same with C=C bond.

As shown in Fig. 2, a good relationship between the catalytic activity of the metal oxides and the amount of acid at p$K_a\leqq+4.8$ or of base at p$K_a\geqq+9.3$ was obtained. Thus, rather weak acid-base properties on metal oxides are closely related to AN hydration. The pK_a value of the oxonium (H_3O^+) or hydroxide (OH^-) ion was −1.7 or +15.7, respectively.[19] Consequently, it is considered that the acidic or basic site of metal oxides ranging in a pK_a range between −1.7 and +15.7 effectively act for AN hydration. One can conclude that a metal oxide catalysts having moderate acid-base properties is suitable for the liquid-phase hydration of AN.

Equi-Acid-Base Point (EABP) of the Metal Oxides: The acid-base property of an insoluble metal oxide dispersed in water can be represented by the EABP; the pH value is used as a measure of acidity or basicity on the oxides.[15] The EABP values of the metal oxide catalysts used were obtained in the pH range of 3.6—11.2; in this pH range a homogeneous AN hydration in acidic or basic liquid phase did not progress.[20] The EABP value of the metal oxides in Group A was below 7, i.e., rather acidic, while that of the oxides in the Group B was above 7, i.e., rather basic. These results

indicate that each of the metal oxides in Group A or B has both acidic or basic properties, even in water. A typical solid acid catalyst, SiO_2–Al_2O_3 showed an EABP value of 7, showing that it is inactive for AN hydration.

Figure 3 illustrates the relationship between the AA selectivity and the EABP value of the catalysts. The metal oxide catalysts which have an acidic property in water showed 100% selectivity to AA. While in the case of the metal oxides which had basic properties in water, the AA selectivity of the catalysts decreased upon increasing their basicity. Figure 4 shows the logarithm of the catalytic activity against the EABP values of the metal oxides, indicating the pattern of a character of

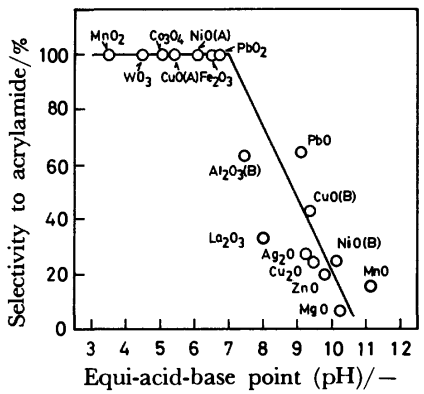

Fig. 3. Relationship between the selectivity to acrylamide and the value of equi-acid-base point of metal oxide catalysts.

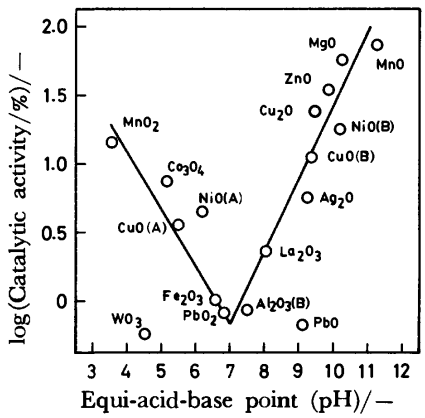

Fig. 4. Relationship between the catalytic activity and the value of equi-acid-base point of metal oxide catalysts.

"V." The EABP value of the bottom of the "V" was just 7. These results suggested that the hydration activity of the metal oxides are proportional to the amount of acidic or basic sites on the oxide surface.

Effect of Poisoning: As shown in Table 3, the catalytic activity of MnO_2 was depressed by the addition of such basic materials as sodium hydroxide, whereas the activity of an MgO catalyst was inhibited by the addition of such acidic materials as phosphoric acid. Furthermore, by the addition of a buffer solution of pH=7 (such as a tetrachlorozincate anion complex ($ZnCl_4^{2-}$)[20]) the catalytic activity of both MnO_2 and MgO was entirely lost. These results also indicate that the acidic site on MnO_2 and the basic site on MgO act as the active sites of the catalysts for AN hydration.

Effectiveness of the Metal Oxide Surface: The effectiveness of the metal oxide surface on the active sites for the heterogeneous liquid-phase hydration of AN was determined by a comparison of the homogeneous AN hydration in an aqueous acidic or basic solution. As shown in Table 4, heterogeneous AN hydration did not progress in an aqueous H_2SO_4 solution adjusted to pH 3.6, which was the same pH value of EABP of MnO_2 catalyst. AA was not observed until the pH value in the solution became to 2.1. In the case of a basic AN solution, a small amount of products was formed in an aqueous NaOH solution adjusted to pH 10.3. Only when the supernatant solution of MgO catalyst was used, a slight conversion of AN was observed. In conclusion, the AN conversion of homogeneous catalysts was extremely small compared with that of metal oxide catalysts with the same pH value.

In addition, the lower apparent activation energy of MnO_2 and MgO catalysts than that of H_2SO_4 and NaOH could be calculated, and the AN adsorption to

the MnO_2 and MgO surface was actually observed in the liquid phase. Consequently, it can be concluded that the acidic or basic site on metal oxide surface acts as the active site for the liquid-phase hydration of AN.

IR Spectra of Adsorbed AN: The IR spectra of the AN adsorbed on the metal oxides were examined in order to obtain more detailed information with respect to the hydration selectivity to either a C≡N triple bond or a C=C double bond in an AN molecule. The IR spectra of AN adsorbed on SiO_2 and MgO are shown in Fig. 5. The IR spectrum of liquid-state AN shows three characteristic absorption bands; C≡N stretching vibration at 2230 cm^{-1}. C=C stretching vibration at 1609 cm^{-1} and CH_2 deformation vibration at 1415 cm^{-1}, respectively.[21,22] When AN was adsorbed on the SiO_2 C≡N band shifted to higher band (2241 cm^{-1}) and a new broad absorption band of surface OH group at ca. 3650 cm^{-1} appeared. This result suggests that the covalent coordination through an N(2s) lone pair of electrons of the AN[23] takes place on the surface OH group of a SiO_2 catalyst. On the other hand, when AN was adsorbed on the MgO surface, two new bands appeared at 1453 and 2939 cm^{-1} and the C≡N band shifted to a higher frequency. These new absorption bands (1453, 2939 cm^{-1}) instead of indicating the disappearance of the vinyl-group absorption bands could be, respectively, assigned to the C–H bending and stretching vibrations of a chain $-CH_2-$ in the ECH molecule. The broad absorption band of the OH stretching vibration from 3400 to 3700 cm^{-1} appears to indicate the formation of an alcoholic bond between the surface OH group and the terminal carbon atom in the AN molecule. These results suggest that σ- or π-component coordination through the C=C double bond of the AN[24] arises on the surface OH groups of an MgO catalyst.

It is known that an acidic or a basic OH group is formed on a metal oxide surface when a water molecule adsorbs to the surface as shown in Fig. 6.[25,26] The EABP value of the metal oxide mentioned before is the difference of the surface concentration between acidic and basic OH groups.[14] The difference of selectivity to the hydration products of the metal oxide catalysts could be explained according to the EABP values of the catalysts. Therefore, the adsorbed state of AN on the acidic or basic OH groups on the metal oxide surface can be schematically depicted as shown in Fig. 7, based on the IR data. It is considered that the selectivity of AN hydration is controlled by acidic or basic OH groups on the metal oxide surface, and that the catalytic activity is also proportional to the amount of surface OH groups on the catalyst.

Conclusions

On the basis of the results described above, we conclude that the liquid-phase hydration of AN on a metal oxide is an acid-base-catalyzed reaction and that the active sites are probably the acidic or basic OH groups on the metal oxide surface.

1) The metal oxide catalysts on liquid-phase hydration of AN could divided into two groups with respect to AA selectivity. Group A is the oxide which gives the AA selectivity with 100% and Group B is the oxide which forms three kinds of products, ECH, BCE, and AA.

2) A good relationship between the hydration abilities (activity and selectivity) of AN on a metal oxide catalysts and the acid-base properties on metal oxides determined by the indicator titration method was observed. The catalytic activity of catalysts of Group A or B is proportional to the number of acid sites at $pK_a \leqq +4.8$ or basic sites at $pK_a \geqq +9.3$, respectively. A

moderate strength of an acid or base ($3.3<pK_a\leqq9.3$) is effective for the liquid-phase hydration of AN.

3) The equi-acid-base point (EABP) values of the metal oxide catalysts of Group A were below 7, and the catalytic conversion increased upon decreasing the EABP value. The EABP value of Group B metal oxides was above 7, and the catalytic activity increased with increasing the EABP value.

4) Two types of the adsorption states assigned to either cyano or vinyl group of AN were observed on the metal oxides.

ESR Study of Glass-Like Carbons

Kazuro KAWAMURA* and Shiushichi KIMURA†
Department of Chemistry, National Defense Academy, 1-10-20, Hashirimizu, Yokosuka 239
†Research Laboratory of Engineering Materials, Tokyo Institute of Technology,
Nagatsuta, Midori-ku, Yokohama 227
(Received March 26, 1986)

ESR studies were carried out on a variety of glass-like carbons made from different precursors heat-treated in the range 300—2500 °C. It was found that the behaviors of unpaired electrons were nearly identical. The temperature dependence of ESR spectrum showed that the behavior of localized unpaired electrons in the glass-like carbons changed to that of delocalized ones at HTT about 2500 °C. The ESR spectrum of the glass-like carbons heat-treated at 800 °C consisted of a single line under a pressure of above 10^{-4} Torr but split into two components when air was admitted. This strong interaction with unpaired electrons and air (oxygen molecules) is caused by the active structure related to micropores in the glass-like carbons. We suppose that the polyene type radicals are the most suitable as the active structure to interpret the behavior of unpaired electrons in glass-like carbons heat-treated at 800 °C. As another major point in this study, it was found that there is a correlation between unpaired electron concentration and the g value.

In general carbonized organic materials contain high concentrations of unpaired electrons produced by bond breaking during the pyrolysis. The unpaired electrons are usually stable at room temperature or below, and their behavior is easily observed by ESR absorption measurements. There are many reports of ESR studies on carbonized materials and excellent reviews have been made by Singer,[1] Mizushima,[2] and Mrozowski.[3] ESR studies of glass-like carbons made from cure resins have also been reported.[4–6] There have been few studies on ESR absorption measurements for glass-like carbons made from different precursors which have been heat-treated in a temperature range as wide as 300—2500 °C. Heat treatments in this temperature range cover the process of carbon precursor formation and those of carbonization and graphitization, and are required for ESR study of glass-like carbon to get informations on the behavior of the localized and delocalized unpaired electrons through the microstructural change in the course of heat treatment.

In the present paper, ESR absorption measurements are reported for glass-like carbons prepared from three kinds of cure resins heat-treated between 300 and 2500 °C. The effect of adsorbed air on the ESR absorption spectrum is investigated for glass-like carbons obtained at 800 °C in the temperature range −170—200 °C.

Experimental

Three kinds of cure resins, epoxy resin cured with 2,4,6-trinitrophenol (Epikote 828/TNP =90/10), furfuryl alcohol resin and phenol-formaldehyde resin were heat-treated at temperatures between 300 and 2500 °C under the same conditions as those described previously.[7] ESR absorption spectra were measured for the samples by a JEOL X-band spectrometer, model JES-PE-lX, using 100 KHz magnetic field modulation with the microwave power of 8 mW and crystal current of 0.2 mA. No saturation on the spectrum could be seen under this condition. Temperature was measured by a standard copper-constantan thermocouple put close to the sample in the microwave cavity. The temperature in the cavity was controlled within ±1 °C in the temperature range −170—200 °C by flowing cold gas from liquid nitrogen or hot air through the inside of the cavity by a JES-VT-3A variable temperature controller. Samples were powdered and contained in quartz tubes of 6 mm o.d. To study the effect on adsorbed air for the samples, two vacuum conditions were employed: (1) a low vacuum, the sample was sealed in the quartz tube with a pressure of about 10^{-2} Torr (1 Torr=133.322 Pa), (2) a high vacuum, the sample was sealed in the quartz tube after evacuating to a pressure of above 10^{-4} Torr with heating at 150 °C for 1 h.

The g values of the samples were determined by comparison with that of Mn^{2+} in MgO placed in the cavity close to the sample. The g value for Mn^{2+} was predetermined by comparison with that of DPPH (g=2.0036).[8] The g value of the sample was calculated by the equation $g=g_s H/(H-\Delta H_{diff})$, where g_s and H are the g value and the field at resonance of the standard samples, and ΔH_{diff} is the difference between the field at resonance for the test sample and that for the standard sample. The accuracy of the measurement of the g value was ± 0.0002. The line shapes of the ESR spectra for all samples investigated were almost Lorentzian shape. The area S, which is proportional to the absorption intensity was estimated by the equation, $S=(\pi/3)(\Delta H)^2 \cdot h$,[9] where ΔH is the line width of the first derivative spectrum and h is the peak-to-peak height. The unpaired electron concentration was determined by comparing the area on the spectrum of the sample with that of DPPH.

Results

1. Examination in High Vacuum. The ESR absorption spectra of glass-like carbons made from the three kinds of resins heat-treated at the temperatures in the range 300—2500 °C were nearly identical. Figure 1 shows an example of the typical change of the ESR absorption spectrum of glass-like carbons with heat treatment temperature (HTT). The results in Fig. 1 were measured for the glass-like carbon from epoxy resin cured with TNP. The spectra for HTT up to 2000 °C consist of a narrow single line, while the spectrum for HTT of 2500 °C contains two com-

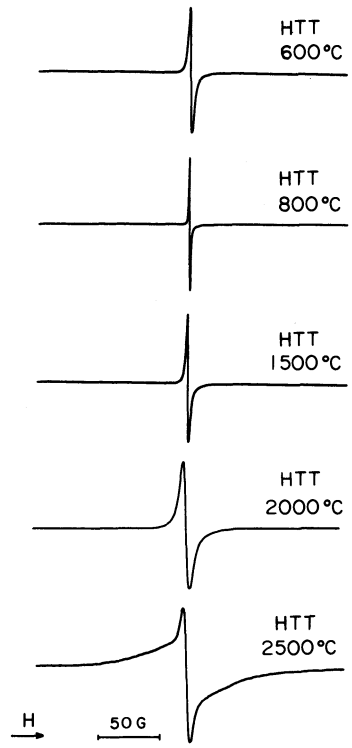

Fig. 1. Change of ESR absorption spectrum of glass-like carbon made from epoxy resin cured with 10 wt% of TNP at different HTT in a high vacuum.

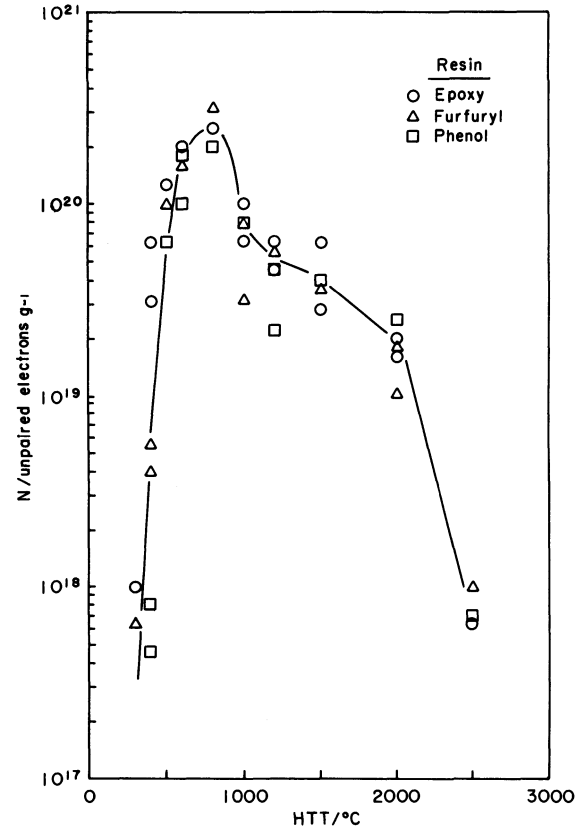

Fig. 2. Changes of unpaired electron concentrations (N) in glass-like carbons with HTT in a high vacuum.

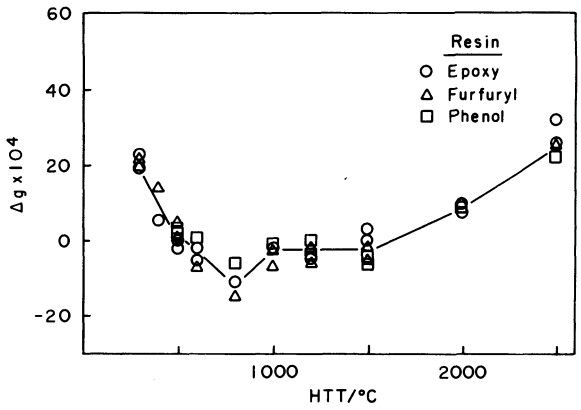

Fig. 3. Changes of Δg on ESR absorption spectra of glass-like carbons with HTT in a high vacuum.

ponents, narrow- and broad-line components. The line widths for narrow-line components are 5—9 G and that for broad one is about 30 G. Broad-line component is not clear to detect quantitatively.

The unpaired electron concentration (N) and the g value of the three kinds of glass-like carbons are shown in Figs. 2 and 3 plotted as a function of HTT. It should be noted that a maximum occurs in N vs. HTT curve at HTT of about 800 °C and a shoulder in the HTT range 1200—1500 °C as shown in Fig. 2. Similar data have been reported by Mrozowski[10] and Toyoda et al.[5] The g values of the glass-like carbons are very close to that of the free spin, g=2.0023, but small change in g with HTT can be seen. As shown in Fig. 3, as with increasing HTT the g shift Δg(Δg= g_s−2.0023, g_s: g value of each sample), decreases steeply to a minimum at HTT of 800 °C at first, increases a little bit to a value at 1000 °C, keeps the value up to HTT of 1500 °C, and then increases gradually. If we combine the results in Figs. 2 and 3, it is seen that an inverse relation exists between N and Δg.

Figure 4 shows the typical temperature dependence of the line width, ΔH, and the peak-to-peak height, h of the spectra at HTT's 800 and 2500 °C. At HTT of 800 °C ΔH decreases gradually and h increases monotonically, as the temperature is decreased. This behavior is similar to that of DPPH, which is characteristic of localized unpaired electrons.[11] At HTT of 2500 °C, little change in ΔH or h against temperature is observed.

In Fig. 5 the S_t/S_{20} is plotted as a function of inverse temperature for glass-like carbons heat-treated at various temperatures, where S_t and S_{20} are the areas of ESR absorption spectra of t °C and 20 °C, respectively. A good linear relationship is resulted at each HTT. The slopes of the straight lines are positive for HTT lower than 2000 °C, and that is slightly negative at HTT of 2500 °C.

2. Examination in Low Vacuum. Figure 6 shows the temperature dependence of the ESR absorption spectrum of glass-like carbon made from epoxy resin

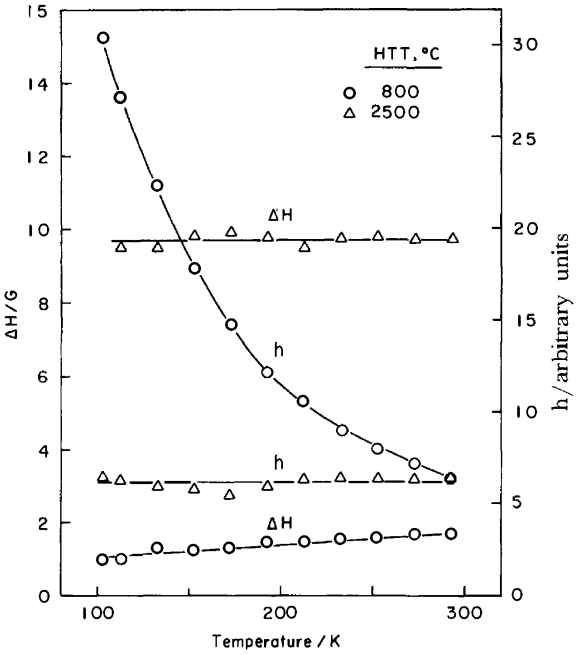

Fig. 4. Temperature dependence of line width (ΔH) and intensity of peak-to-peak height (h) of ESR absorption spectrum of glass-like carbon made from epoxy resin cured with 10 wt% of TNP in a high vacuum.

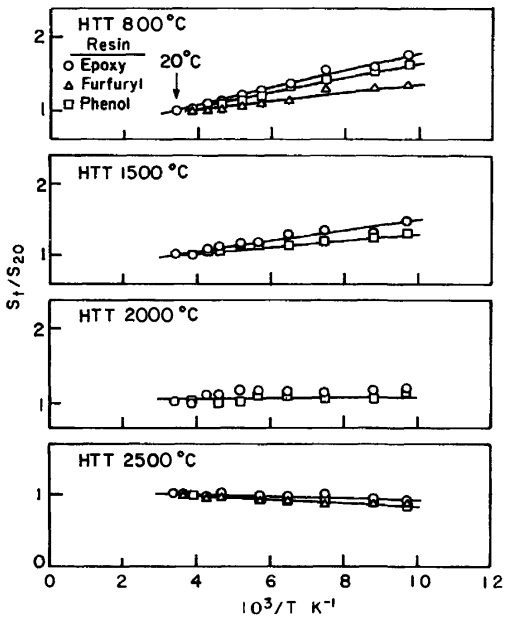

Fig. 5. Relation between relative absorption intensity (S_t/S_{20}) and $1/T$ of glass-like carbons in a high vacuum.

cured with TNP heat-treated at 800°C. In contrast with the spectrum in high vacuum the ESR absorption spectra measured for HTT of 800°C in a low vacuum at room temperature consist of two components, narrow- and broad-line components. The spectrum is common for all three cure resins heat-treated at

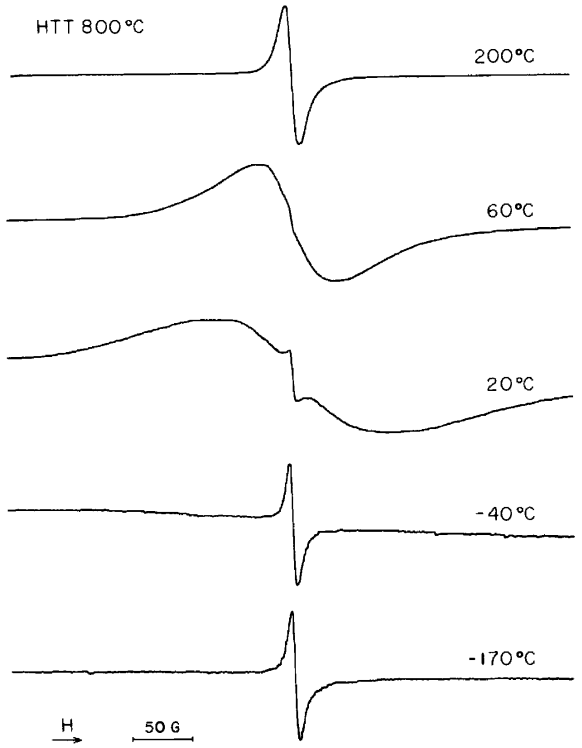

Fig. 6. Change in ESR absorption spectrum of glass-like carbon made from epoxy resin cured with 10 wt% of TNP in a low vacuum.

800°C. The line width of the broad-line component ranges 100 to 500 G and the width of the narrow one 2 to 5 G. The vacuum condition and the measurement temperature affect the line width and the intensity of the broad-line component strongly. The broad-line spectrum observed under a low vacuum changed back to the narrow-line spectrum in high vacuum as shown in Fig. 1 (HTT 800°C), and the line broadening appears immediately when air is admitted. The line-broadening seen in the glass-like carbons heat-treated at 800°C was also observed in the glass-like carbon made from furfuryl alcohol resin heat-treated at 1000°C, but not observed in glass-like carbons prepared at other HTT in the range 300—2500°C.

The broad-line component in the spectrum observed at 20°C shown in Fig. 6 becomes broader and weaker as the temperature is decreased, and the line width increases to the width broaden than 1000 G at −60°C. At a temperature below −70°C the broad-line component is too wide to be detected. When the temperature is increased above room temperature, the broad-line component is narrowed, and the narrow-line component can be seen as a slight shoulder on the broad-line component at 60°C as shown in Fig. 6. The narrow-line component is imperceptible on the broad one at 70°C by narrowing of the broad-line component, and the line width of the broad one at 200°C ranges 10—20 G. Therefore, the line width of the broad-line component increases, and the intensity

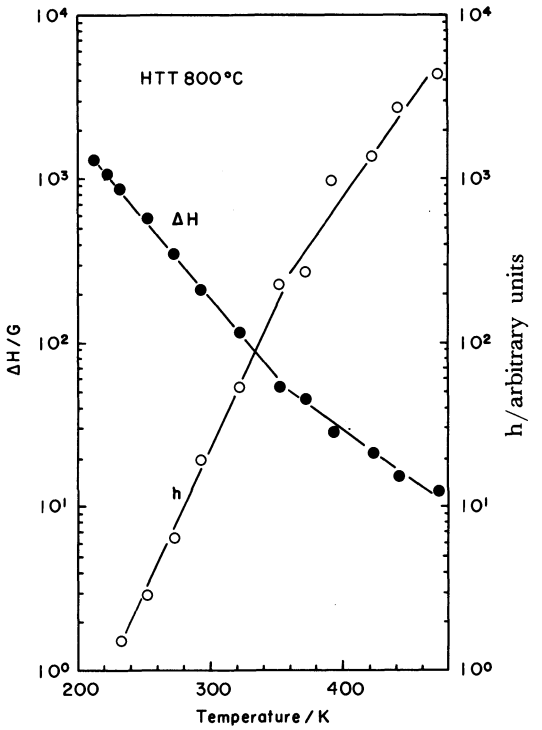

Fig. 7. Temperature dependence of line width (ΔH) and intensity of peak-to-peak height (h) of broad-line component of ESR spectrum of glass-like carbon made from epoxy resin cured with 10 wt% of TNP in a low vacuum.

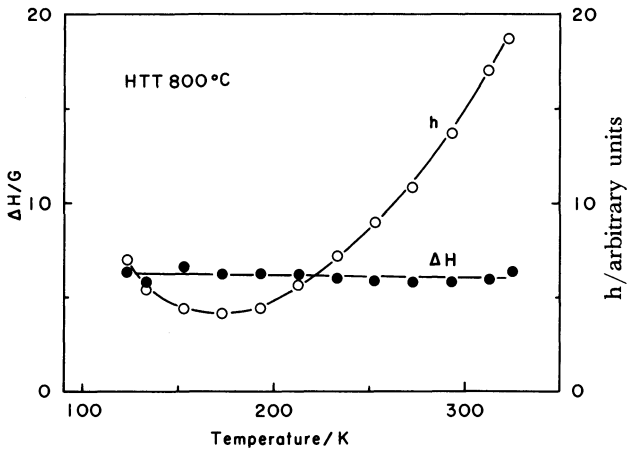

Fig. 8. Temperature dependence of line width (ΔH) and intensity of peak-to-peak height (h) of narrow-line component of ESR spectrum of glass-like carbon made from epoxy resin cured with 10 wt% of TNP in a low vacuum.

decreases markedly, as the temperature is decreased. The trend is shown in Fig. 7. On the other hand, as shown in Fig. 8, the line width of the narrow-line component is almost constant, and with decreasing temperature the peak-to-peak height decreases to a minimum at around 173 K (−100°C) and then increases. The ratio S_t/S_{20} is plotted as a function of inverse temperature for narrow- and broad-line components for HTT of 800°C in Fig. 9. A minimum

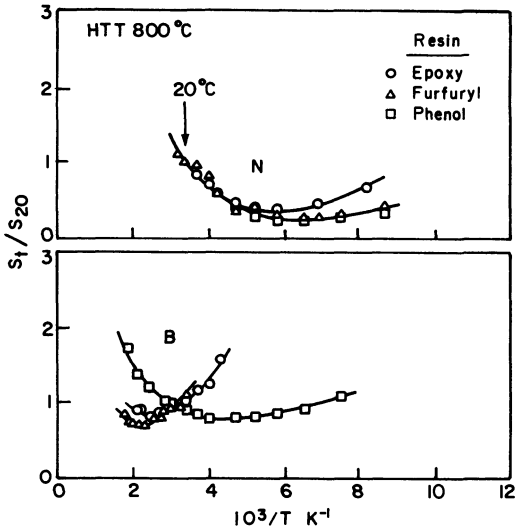

Fig. 9. Relation between relative absorption intensity (S_t/S_{20}) and $1/T$ of glass-like carbons in a low vacuum, N for narrow-line component and B for broad-line component.

of the narrow-line component appeares in the range 153—183 K. On the other hand, a minimum is also observed for broad-line component, but the minimum appears at higher temperature than that for the narrow-line component.

Discussion

1. Examination in High Vacuum. The unpaired electrons at HTT 800°C are mainly localized because of the positive slope of the S_t/S_{20} vs. $1/T$ plots (Fig. 5). The decrease of the slope with increasing HTT indicates that there is a gradual decrease in the localized spin centers and increase in the delocalized spin centers, and the decrease is probably due to the growth of the carbon layer planes. The behavior of the localized unpaired electrons observed in these carbonized resins changes to delocalized one at HTT around 2500°C, because of the slight negative slope as shown in Fig. 5.[12]

The change of g value with HTT is very small in each sample in the HTT range 300—2500°C, but this change is strongly correlated to the unpaired electron concentration as mentioned in Results (Figs. 2 and 3). Logarithm of the value of the unpaired electron concentration shows a good linear relationship against Δg as shown in Fig. 10. The relationship can be fitted to $\log N = A + B \cdot \Delta g \times 10^4$, by a linear least-squares analysis, where $A = 19.7 \pm 0.4$, $B = -0.068 \pm 0.025$. The interaction of unpaired electrons becomes stronger as the unpaired electron concentration is increased, and the strong interaction makes the g value to decrease.

2. Examination in Low Vacuum. Singer et al. studied the effect of paramagnetic gases on the ESR absorption of carbon material[13] and found that O_2 and NO affects strongly on broadening the ESR ab-

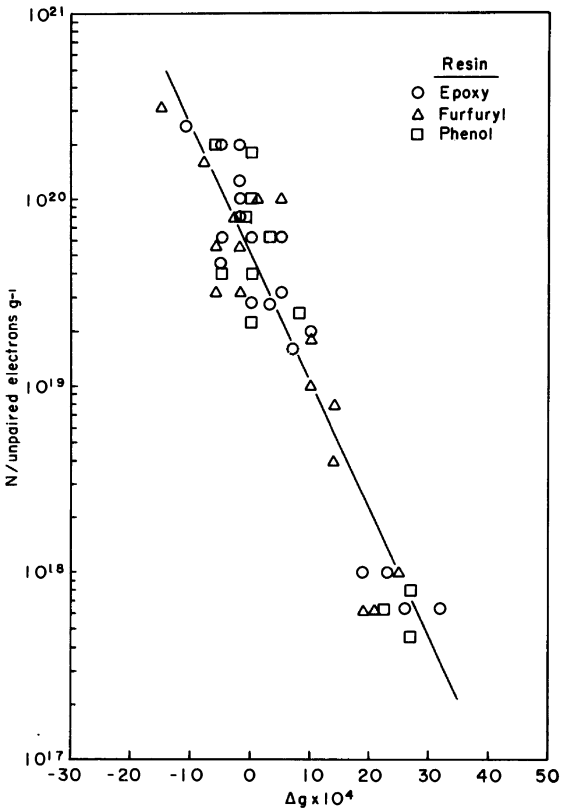

Fig. 10. Unpaired electron concentration as a function of Δg for glass-like carbons made from cure resins.

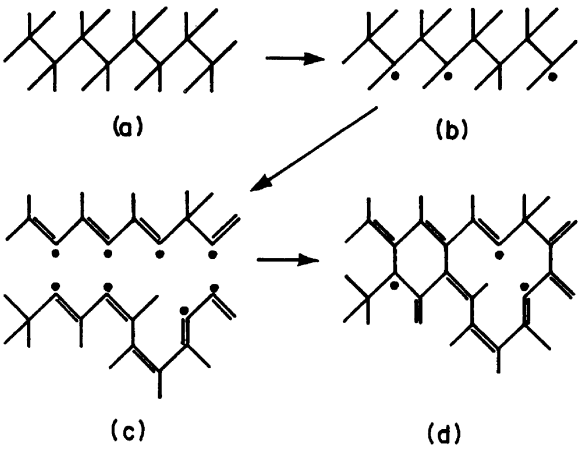
sorption spectrum, while N_2 no influence. Therefore, line broadening seen in the spectrum for HTT of 800°C is caused by the strong interaction between unpaired electrons in glass-like carbons and adsorbed oxygen molecules. The broadening phenomenon was also observed by Fielder et al. in the ESR study of pyrolysis of acrylonitrile homopolymer fibers (PAN).[14] They found that the ESR spectrum of char made from PAN pyrolysis at 700—850°C showed a single narrow line in vacuum. When the sample was exposed to air, the spectrum separated into two components with a narrow line of about 2 G width and a broad line of about 40 G width, and only a broad line was observed after a long exposure to air. Analysis of the volatile products produced from PAN during pyrolysis at 800°C showed that the major constituent was HCN, and most likely nitrogen came from heteroaromatics, thus leaving highly reactive fragments. They assumed that this effect of air on the spectrum is the formation of the highly reactive fragments produced by the rupture of heteroaromatics. Our finding of the broadening of the ESR absorption spectrum of glass-like carbons in low vacuum at HTT 800°C is basically the same phenomenon. In addition, we believe that the strong physical adsorption of air on the surface of glass-like carbons at HTT 800°C is caused by micro-pores developed during pyrolysis. Noda et al.[15] and Fitzer et al.[16] reported that the surface area attained in the glass-like carbons showed a maximum at HTT near 800°C, indicating development of an open micropores. As shown in Fig. 9, changes in narrow-line components of three glass-like carbons are almost the same as those in broad-line components except a little difference in temperature for the minimum point. These trends indicate that the narrow-line component is also influenced by the adsorption of air indirectly. Since for localized unpaired electrons S_t/S_{20} increases with increasing inverse temperature and for delocalized unpaired electrons S_t/S_{20} decreases, the variations in Fig. 9 are due to a mixed behavior for the localized and the delocalized unpaired electrons. Unpaired electrons in glass-like carbon heat-treated at 800°C are very much influenced by oxygen molecules adsorbed on the surface.

The formation of unpaired electrons through the pyrolysis of cure resins can be explained as follows;



Here, the Structure (a) indicates the hydrocarbon chain in the original cure resin. The unpaired electrons appear by the dehydrogenation reaction and chain breaking during pyrolysis as shown in Structure (b). The unpaired electrons in radical structures increase at near HTT of 800°C as shown in Structure (c) and decrease gradually by the recombination of unpaired electrons as shown in Structure (d) as HTT is increased. A strong interaction of unpaired electrons caused by the exchange of the position is expected in the polyene type radicals (Structure (c)). And also the behavior of this type of radicals can be easily affected by oxygen molecules adsorbed on the active surface on which micropores are developed well. A strong exchange interaction between unpaired electrons of glass-like carbons and oxygen molecules makes the spin-spin relaxation time T_2 shorter, T_2 is given by $T_2=\hbar/\sqrt{3}g\beta\Delta H$, where $\hbar$ is the Plank constant devided by 2π and β is the Bohr magneton,[17] and as the result broadening of the ESR absorption spectrum is observed.

Summary

ESR studies were carried out for glass-like carbons

prepared from the cure resins (epoxy resin, phenol-formaldehyde resin and furfuryl alcohol resin) in the HTT range 300—2500°C. The measurements were made at temperatures in the range −170—200°C under conditions of a high and a low vacuum. The ESR absorption spectra of the glass-like carbons obtained from these resins were almost identical. The unpaired electron concentration shows a maximum at HTT near 800°C. When air is admitted to the glass-like carbons obtained at HTT 800°C, the ESR absorption spectra split into two components. This splitting is caused by the exchange interaction of unpaired electrons in the glass-like carbons and oxygen molecules absorbed on the surface. From the ESR data in a high vacuum, for the glass-like carbons made from the cure resins heat-treated at the temperature around 2500°C unpaired electrons are delocalized ones. The value of the unpaired electron concentration (N) and the g-shift, $\Delta g(\Delta g=g_s-2.0023)$ can be fitted to $\log N = A+B\cdot\Delta g$, independent of the particular carbon.

(Received March 28, 1986)

The polarized Raman and infrared spectra of [$^1H_4$]- and [$^2H_4$]pyridazines were studied. Assignments of the normal vibrations made by previous workers were reexamined on the basis of polarization behavior of the Raman and infrared bands and also through the normal coordinate calculation, and reasonable assignments are presented.

Although the vibrational spectra of aromatic azines such as pyridine, pyrimidine, and pyrazine have been studied by many workers, few informations are available for the normal vibrations of pyridazine. Vibrational analyses of the Raman and infrared spectra of pyridazine were made by Ito et al.[1] and Lord et al.[2] on the basis of intercomparison with the normal vibrations of benzene, pyridine, and diazines, and by Stidham and Tucci[3] on the basis of the isotopic effect on the vibrational frequencies. Their vibrational assignments, however, are not consistent with each other. Especially for the assignments of the non-totally symmetric vibrations, there are many discrepancies in the vibrational modes and frequencies. Therefore, definite experimental evidences are needed for the reasonable assignments of the normal vibrations.

In this work, vibrational assignments for [$^1H_4$]- and [$^2H_4$]pyridazines are reexamined through measurements of the polarization behavior of the Raman and infrared spectra and also through the normal coordinate calculation and reliable assignments of the normal vibrations are given.

Experimental

Material. [$^2H_4$]Pyridazine was synthesized by the exchange reaction of [$^1H_4$]pyridazine, which was obtained from Aldrich Chemical Company, with D_2O and NaOD. Isotopic purity of the product was determined by the nuclear magnetic resonance measurement. The samples used for the experiment were purified by repeated distillation under reduced pressure.

Optical Measurements. Polarization measurement of the Raman spectrum was made in liquid and single crystal phases with a JEOL 400 T Laser Raman Spectrophotometer. The sample was excited with the 514.5 nm line from an Ar^+ ion laser. [$^1H_4$]- and [$^2H_4$]Pyridazines crystalize at −8 °C. Although single crystals of the sample could be easily obtained by the Bridgman method, samples with rectangular shape needed for the quantitative observation of the polarized Raman spectrum could not be prepared because pyridazine is quite volatile and hygroscopic and the crystal surface became opaque and deliquesced immediately after the crystal was cut off with a razor blade. Thus the polarized Raman spectrum was observed in the following way. Single crystals were grown in capillary glass tubes of 3 mm in diameter having a sharp conical end by the Bridgman method and a well grown single crystal was selected. The extinction directions of the crystal were determined under the polarized light. The direction of crystal growth which was along the capillary tube was found to be one of the extinction directions. Determination of another extinction direction was made by rotating the capillary tube, which was supported horizontally, around the crystal growth direction under the light polarized perpendicular to the capillary tube. The extinction direction thus detected was more clearly confirmed by tilting the capillary tube from the horizontal orientation. These two extinction directions will be referred to as u and v axes, respectively. The w axis is taken to be perpendicular to both the u and v axes. These procedures were carried out in a box where the temperature was kept at −12 °C. The crystal specimen was held in a Raman sample cell kept at −12 °C in such a way that the u axis of the crystal was directed parallel to the polarization direction of the excitation laser beam and the Raman scattering was observed at right angles with the laser beam. The observation was made with two crystal orientations. In the first orientation the v axis and in the second the w axis were directed parallel to the propagation direction of the laser beam, respectively. Thus the uu, uv, and uw polarized Raman spectra were obtained, where the first letter refers to the direction of polarization of the excitation laser beam and the latter to that of the scattering light.

The infrared spectrum was observed in vapor and single crystal phases with a Hitachi Infrared Spectrophotometer Model 345. Preparation of the single crystal sample and the method of measurement of the polarized infrared spectrum are exactly the same as those described previously.[4]

Normal Coordinate Calculation

The normal coordinate calculations for [$^1H_4$]- and [$^2H_4$]pyridazines were performed through the standard GF matrix method with a FACOM M-200 computer at the Computer Center of Fukuoka University. The molecular structure of [$^1H_4$]pyridazine was taken from the data determined by Almenningen et al.[5] The F matrix elements for the in-plane and out-of-plane vibrations were evaluated with the potential fields of an improved modification of the Urey–Bradley and valence force fields, respectively, as described previously.[4,6,7] Values of the force constants for the in-plane and out-of-plane vibrations are given in Tables 1 and 2, respectively. The notations of the force constants are the same as those described previously.[4,6,7] Calculated vibrational frequencies and modes are listed in Tables 3 and 4, respectively.

Table 1. Force Constants for In-Plane Vibrations

$K_{N\text{-}N}$	5.5	$F_{N\cdots C}$	0.6
$K_{N\text{-}C}$	5.3	$F_{C\cdots C}$	0.8
$K_{C\text{-}C}$	4.5	$F_{N\cdots H}$	0.55
$K_{C\text{-}H}$	4.6	$F_{C\cdots H}$	0.45
H_{CNN}	0.5	k_{rr}^{o}	0.05
H_{NCC}	0.35	k_{rr}^{m}	−0.05
H_{CCC}	0.4	k_{RR}^{m}	−0.1
H_{NCH}	0.2	$f_{\beta\beta}^{o}$	0.12
H_{CCH}	0.27	ρ	0.37

Force consatants denoted by K, H, F, ρ, and k are given in hN m^{-1} (=mdyn/Å) and f in aNmrad^{-2} (=mdynÅ/rad^2) units. R refers to the N-N, C-N and C-C bonds, r to the C-H bond and β to the ∠NCH and ∠CCH. Superscripts o and m refer to ortho and meta, respectively.

Table 2. Force Constants for Out-of-Plane Vibrations

$Q_{N\text{-}N}$	0.17	q^{m}	0.01
$Q_{N\text{-}C}$	0.19	p^{o}	0.06
$Q_{C\text{-}C}$	0.21	p^{m}	−0.06
P_{H}	0.33	t_{N}^{o} [a]	−0.03
q_{N}^{o} [a]	−0.04	t_{C}^{o} [a]	−0.02
q_{C}^{o} [a]	−0.03	t^{m}	−0.01

Force constants are given in aNmrad^{-2} (=mdynÅ/rad^2) units. a) Subscript N indicates that the force constants are concerned with the torsional coordinates involving the C-N and N-N bonds and subscript C the C-C bond. Superscripts o and m refer to ortho and meta, respectively.

Results and Discussion

The relative intensities of the Raman bands in the polarized Raman spectrum are governed by the orientation of the molecules in crystal, that is, the relative intensities depend on the direction cosines between the molecular and crystal axes in the oriented gas model approximation. Therefore, the molecular vibrations belonging to the same symmetry species should show the same polarization behavior in the polarized Raman spectrum observed with a certain crystal orientation with respect to the polarization directions of the excitation and scattering lights. If the crystal structure is known, the relative intensities of the bands can be calculated from the direction cosines between the crystal and molecular axes and thus, the observed polarization behavior of the Raman bands gives a quantitative justification for the assignments of the normal vibrations. Even if the crystal structure is unknown, the polarized Raman spectrum can be observed along the extinction directions. The extinction axes of the crystal coincide with the crystal axes in general and thus the observed polarization behavior of the Raman bands gives a qualitative information for the classification of the observed Raman bands into a certain symmetry species. We applied this experimental procedure for the assignments of the normal vibrations of halosubstituted pyrimidines[8] and pyridine[9] and obtained satisfactory results.

The polarized Raman and infrared spectra of [$^1H_4$]-

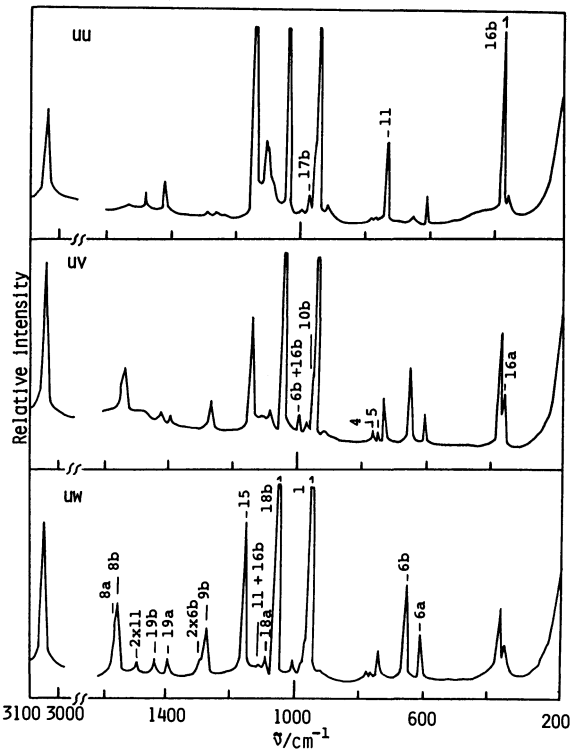

Fig. 1. Polarized Raman spectrum of [$^1H_4$]pyridazine single crystal.

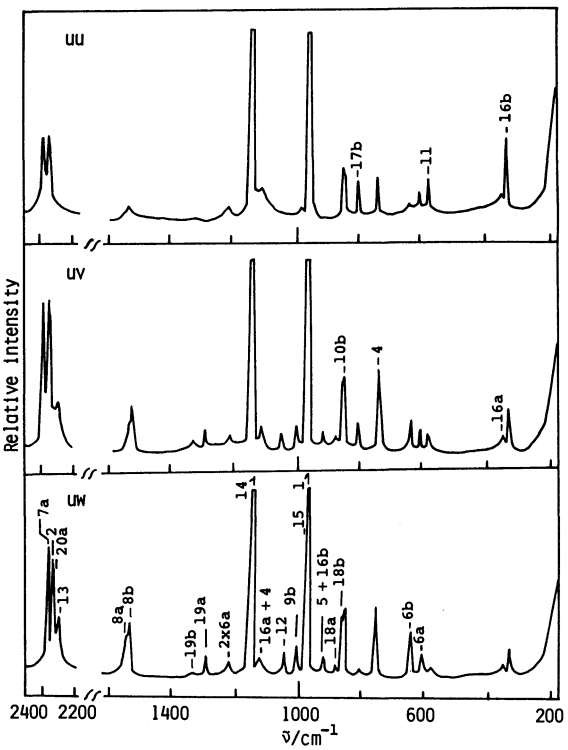

Fig. 2. Polarized Raman spectrum of [$^2H_4$]pyridazine single crystal.

and [$^2H_4$]pyridazines observed in single crystals are shown in Figs. 1, 2, 3, and 4, respectively. The nontotally symmetric vibrational bands in the polarized Raman spectrum of a single crystal can be classified

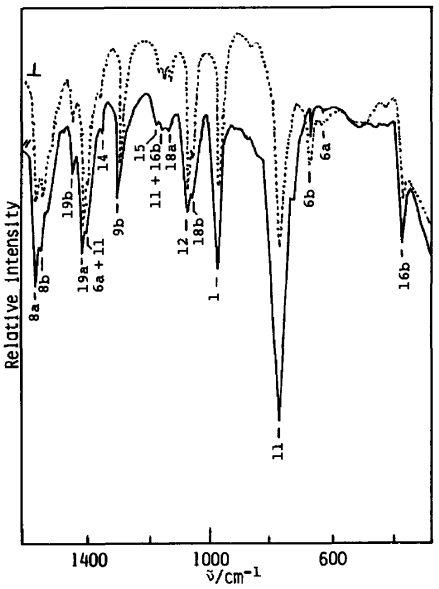

Fig. 3. Polarized infrared spectrum of [$^1H_4$]pyridazine single crystal.

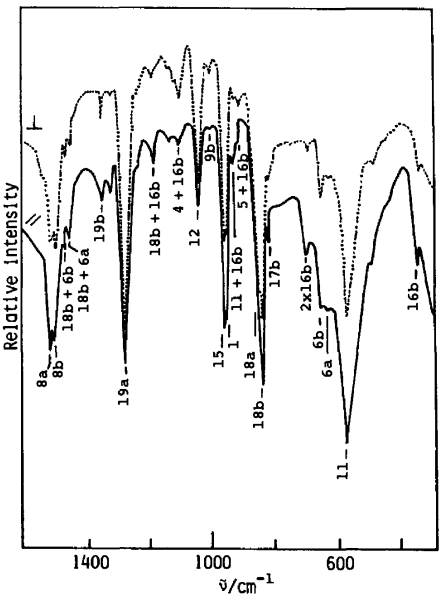

Fig. 4. Polarized infrared spectrum of [$^2H_4$]pyridazine single crystal.

into three types of polarization behavior as can be seen in Figs. 1 and 2. The intensity relationship of the polarized Raman bands belonging to the first type is $I_{uw} > I_{uv} \gg I_{uu}$, the second type $I_{uu} > I_{uv} > I_{uw}$ and the third type $I_{uv} > I_{uw} > I_{uu}$. These three types of polarization behavior are referred to as types α, β, and γ, respectively. The polarized infrared spectra measured with the incident lights polarized parallel and perpendicular to the crystal growth direction are referred to as // and $\perp$ spectra and drawn with the solid and dotted lines, respectively. The infrared bands in crystal can be classified into three types I, II, and III based on their polarization behavior. The intensity relationship of the bands belonging to the first type is $I_{//} \simeq I_{\perp}$, the second and third types $I_{//} > I_{\perp}$ and $I_{//} < I_{\perp}$, respectively.

The moments of inertia calculated from the molecular structure suggest that the infrared bands belonging to a_1, b_2, and b_1 symmetry species show A, B, and C band contour in [$^1H_4$]pyridazine and B, A, and C contour in [$^2H_4$]pyridazine, respectively. Therefore, each Raman and infrared bands can be experimentally classified into a certain symmetric species based on the polarization behavior observed in crystal phase together with the band contour in vapor phase. The determination of the vibrational modes can be made based on the normal coordinate calculation.

[$^1H_4$]Pyridazine. a_1 Species: Strongly polarized Raman bands observed at 3070, 3053, 1441, 1352, 1150, 1063, and 963 cm^{-1} in liquid phase can be straightforwardly assigned to the totally symmetric ν_{7a}, ν_2, ν_{19b}, ν_{14}, ν_{15}, ν_{18b}, and ν_1 vibrations, respectively, by referring the normal coordinate calculation. The infrared band corresponding to the ν_1 vibration shows A band contour in vapor and the type I polarization in crystal. Infrared bands at 1555 and 632 cm^{-1} show the type I polarization in crystal and therefore these bands were assigned to the ν_{8a} and ν_{6a} vibrations, respectively, although the corresponding Raman band at 1570 cm^{-1} seems to be depolarized in liquid due to overlapping of a band assigned to the ν_{8b} vibration and the corresponding Raman band at 622 cm^{-1} is very slightly polarized in liquid.

b_2 Species: Infrared bands observed at 1408, 1283, 1058, and 663 cm^{-1} show B band contour in vapor and therefore can be assigned to the b_2 vibrations. Thus these bands were assigned to the ν_{19a}, ν_{9b}, ν_{12}, and ν_{6b} vibrations, respectively. The corresponding infrared and Raman bands observed in crystal show the type III and type α polarization, respectively. Raman bands at 3080, 3041, 1564, and 1113 cm^{-1} show also the type α polarization in crystal and the corresponding infrared bands show the type III polarization in crystal. Therefore, these bands were assigned to the ν_{20a}, ν_{13}, ν_{8b}, and ν_{18a} vibrations, respectively.

b_1 Species: Infrared bands at 760 and 372 cm^{-1} show C band contour in vapor and hence these bands were assigned to the ν_{11} and ν_{16b} vibrations of b_1 species, respectively. The corresponding infrared and Raman bands observed in crystal show the type II and type β polarization, respectively. A Raman band at 986 cm^{-1} shows the type β polarization in crystal and thus this band was assigned to the ν_{17b} vibration.

a_2 Species: Depolarized Raman bands at 786, 775, and 363 cm^{-1} in liquid show the type γ polarization in crystal and therefore these bands were assigned to the ν_4, ν_5, and ν_{16a} vibrations of a_2 species, respectively, because the Raman bands showing the types α and β polarization in crystal were already assigned to the bands belonging to the b_2 and b_1 vibrations, respectively. A Raman band at 970 cm^{-1} which was not clearly

resolved in liquid shows the type γ polarization in crystal and thus this band was assigned to the ν_{10b} vibration.

The normal vibrations thus assigned are summarized in Table 3 together with those given by Stidham and Tucci.[3] Stidham and Tucci assigned the infrared band observed at 1417 cm^{-1} to the a_1 vibration but this band shows B band contour in vapor and the type III polarization in crystal. Thus this band should be assigned to the b_2 vibration. They also assigned the Raman bands observed at 1450, 1129, and 1032 cm^{-1} to the b_2 vibrations but the first two bands are polarized in liquid and the last shows a_2 polarization behavior in crystal. Therefore, the bands observed at 1417, 1450, 1129, and 1032 cm^{-1} by them were assigned to the ν_{19a}, ν_{19b}, $\nu_{11}+\nu_{16b}$, and $\nu_{6b}+\nu_{16b}$ vibrations, respectively. They observed a weak Raman band at 938 cm^{-1} and assigned to the a_2 vibration. This band, however, shows neither b_2, b_1, nor a_2 polarization behavior in crystal and thus we assigned it to the $\nu_{8a}-\nu_{6a}$ vibration. Stidham and Tucci observed very weak Raman bands at 753, 861, 842, and 410 cm^{-1} and assigned those to the out-of-plane vibrations but these bands could not be clearly observed in this work.

[$^2H_4$]Pyridazine. a_1 Species: Strongly polarized Raman bands observed at 2295, 2276, 1318, 1130, 965, 946, 835, and 600 cm^{-1} can be assigned to the ν_{7a}, ν_2, ν_{19b}, ν_{14}, ν_{15}, ν_1, ν_{18b}, and ν_{6a} vibrations, respectively. The corresponding infrared bands show the type I polarization in crystal. An infrared band at 1515 cm^{-1} shows the type I polarization in crystal and hence this band was assigned to the ν_{8a} vibration, although the corresponding Raman band at 1532 cm^{-1} seems to be depolarized in liquid due to overlapping of a band assigned to the ν_{8b} vibration.

b_2 Species: Infrared bands observed at 1268 and 1035 cm^{-1} show A band contour in vapor and the type III polarization in crystal, and the corresponding Raman bands show the type α polarization in crystal. Therefore, these bands were assigned to the ν_{19a} and ν_{12} vibrations, respectively. Raman bands observed at 2272, 2247, 1525, 980, 865, and 639 cm^{-1} show the type α polarization in crystal and the corresponding infrared bands show the type III polarization in crystal. Therefore these bands were assigned to the ν_{20a}, ν_{13}, ν_{8b}, ν_{9b}, ν_{18a}, and ν_{6b} vibrations, respectively.

b_1 Species: Infrared bands observed at 562 and 321 cm^{-1} show C band contour in vapor and the type II polarization in crystal. The corresponding Raman bands show the type β polarization in crystal. Hence these bands were assigned to the ν_{11} and ν_{16b} vibrations, respectively. A Raman band observed at 802 cm^{-1} shows the type β polarization in crystal and the corresponding infrared band shows the type II polarization

a) H. D. Stidham and J. V. Tucci, *Spectrochim. Acta*, **23A**, 2233 (1967).

in crystal. Therefore this band was assigned to the ν_{17b} vibration.

a_2 Species: Depolarized Raman bands at 820, 738, and 347 cm^{-1} show the type γ polarization in crystal and therefore these bands were assigned to ν_{10b}, ν_4, and ν_{16a} vibrations, respectively. The ν_5 vibrational band could not be resolved in the polarized Raman spectrum.

The normal vibrations of [$^2H_4$]pyridazine thus assigned are summarized in Table 4 together with those given by Stidham and Tucci.[3] Stidham and Tucci assigned the Raman bands at 1270 and 1318 cm^{-1} to the a_1 and b_2 vibrations, respectively. However the former shows b_2 and the latter a_1 polarization behavior, and thus we assigned these bands to the ν_{19a} and ν_{19b} vibrations, respectively. A polarized Raman band at 1203 cm^{-1} in liquid was assigned the $2\nu_{6a}$ vibration although Stidham and Tucci assigned it to the ν_{14} vibration. A strong and polarized Raman band at 1130 cm^{-1}, which was assigned to the $2\nu_{11}$ vibration by them, was assigned to the ν_{14} vibration in this work. Stidham and Tucci assigned a very weak Raman band at 710 cm^{-1} to the b_1 vibration, but this band shows neither b_2, b_1, nor a_2 polarization behavior in single crystal, and therefore, this band was assigned to the $\nu_{19b}-\nu_{6a}$ vibration. They also assigned very weak Raman bands at 686 and 766 cm^{-1} to the a_2 vibrations, but these bands could not be observed in this work.

Agreements between observed and calculated vibrational frequencies for both [$^1H_4$]- and [$^2H_4$]pyridazines are satisfactory. We believe that the polarization behavior of the Raman and infrared bands gives clear and definite experimental justification for the assignments, and the normal vibrations determined in this work are quite reliable.

Synergistic Extraction of Copper(II) and Zinc(II) with Tributyl Phosphate and Crown Ether

Yuko HASEGAWA,* Hirofumi MIYATA, and Satoshi YOSHIDA
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received March 29, 1986)

The solvent extraction of copper(II) and zinc(II) with 12-crown-4 (12C4) or 15-crown-5 (15C5) as picrates into chloroform containing tributyl phosphate (TBP) has been studied. The following conclusions have been reached. i) Even in the presence of TBP which is more basic than crown ether, either copper(II) or zinc(II) is extracted in association with 2 moles of 12C4 or 15C5. ii) The crown ether complex of either copper(II) or zinc(II) forms 1 : 1 : 1 (metal(II) : crown ether : TBP) stoichiometric adducts in chloroform. iii) The 12C4 complex of either copper(II) or zinc(II) forms more stable adducts with TBP than the 15C5 complex. iv) The extraction of the metal (II) with 15C5 and TBP is better than that of 12C4 and TBP. v) The copper(II) complex with 12C4 or 15C5 forms more stable TBP adducts than those from zinc(II) complex.

It has been previously reported[1] that the extraction of zinc(II) with crown ether and picrate ion is not very different from that of copper(II), while the extraction of zinc(II) with β-diketones such as acetylacetone is remarkably poorer than that of copper(II).[2] The different behavior of the ion pair extraction of zinc(II) from the chelate extraction has been explained in terms of the difference in coordination structure of the extracted metal(II) species. This leads to the idea that the adduct formation or the solvation of zinc(II) complexes in organic phase may be different between the ion pair and the chelate.

In the present work, the adduct formation constants between the crown ether–picrate ion pair of zinc(II) or copper(II) and tributylphosphate (TBP) in chloroform have been determined by the solvent extraction method to compare with those of the chelates.

Experimental

All reagents employed were of analytical grade. Tributylphosphate ex. Tokyo Kasei Inc. was purified by washing with water, 0.1 M (M=mol dm^{-3}) sodium hydroxide solution, and 0.1 M perchloric acid.

Copper(II) or zinc(II) nitrate (2.5×10^{-2}M), lithium picrate, and a crown ether were agitated in a stoppered glass tube by a mechanical shaker for an hour with same volume of chloroform containing TBP of various concentrations. The metal(II) in organic phase was then back-extracted with 0.1 M perchloric acid and its concentration was measured by means of atomic absorption spectrometer. Detailed procedures have been described previously.[1]

The distribution ratio D was defined as

$$D=\frac{[M(II)]_{o,total}}{[M(II)]_{a,total}},$$

where the subscripts "o" and "a" denote the organic and aqueous phases, respectively.

Results and Discussion

When zinc(II) and copper(II) were extracted from lithium picrate solution containing a given amount of 12C4 or 15C5 into chloroform in the presence of 0.1 M TBP, the distribution ratio increased in proportion to the square of the anion concentration. This result indicates that one mole of the metal ions are extracted with two moles of picrate ions, in the similar manner to the extraction of the metal(II)–crown ether–picrate into chloroform reported earlier.[1]

The distribution ratio of the metal(II) between lithium picrate solution and TBP–chloroform is plotted against the concentration of TBP in Fig. 1 (symbols are triangles). The log–log plots give straight lines with inclination of 2, although the plots deviate from the straight line in a higher concentration region. It indicates that the ion pair between the metal(II) and picrate ion is accompanied by 2 moles of TBP. From the slope analysis, the extraction constants ($Kex_{02}=D[A^-]_a^{-2}[TBP]_o^{-2}$) of copper(II) and zinc(II) from lithium picrate solution into TBP–chloroform were determined to be 1.3 and 0.4 as log Kex_{02}, respectively.

In the higher concentration region these metal ions seem to be extracted with more than 2 moles of TBP. Hence, the data obtained in the TBP region lower than 0.3M were employed to the data analysis in the present study.

It has been reported[1] that the ion pair between the metal(II) and picrate ion is accompanied by 1 or 2 moles of crown ethers when extracted. Therefore, when the ion pair including a crown ether forms adducts with TBP, the distribution ratio can be represented as

$$D=\frac{\sum[ME_lA_2]_o+[MT_2A_2]_o+\sum[ME_mT_nA_2]_o}{[M^{2+}]_a}, \quad (1)$$

where M, E, A, and T denote the metal(II), crown ether, picrate ion, and TBP, successively, l, m, and n being the integer 1 or 2.

Equation 1 can be rewritten by introducing the extraction constants as follows:

$$D=\{(Kex_{10}[E]_a+Kex_{20}[E]_a^2)+Kex_{02}[T]_o^2+\sum Kex_{mn}[E]_a^m[T]_o^n\}[A^-]_a^2 \quad (2)$$

Figure 1 also shows the relationship between distribution ratio and TBP concentration in the case of metal(II) extraction from an aqueous solution contain-

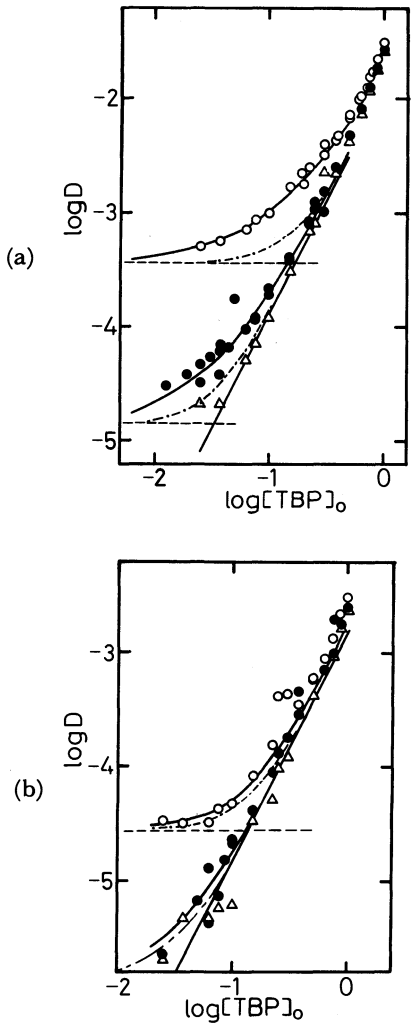

Fig. 1 Extraction of Cu(II)(a) and Zn(II)(b) from 2.5×10^{-2} M lithium picrate solution containing 2.5×10^{-2} M 15C5(○), 12C4(●) or no crown ether(△) into TBP-chloroform.
Solid lines are calculated by the following equation using the constants listed in Table 1.

$$D=\left(\frac{K_{ex10}}{1+K_D}E_T+\frac{K_{ex20}}{(1+K_D)^2}E_T^2+K_{ex02}[T]_o^2+\frac{K_{ex11}}{1+K_D}E_T[T]_o\right)[A^-]^2$$

Chain lines are calculated using only the first three terms in the equation, i.e. ignoring adduct formation.

ing lithium picrate and crown ether into TBP–chloroform. The chain curves in Fig. 1 are obtained by combining the extraction with crown ether $\{(K_{ex10}[E]_a+K_{ex20}[E]_a^2)[A^-]^2\}$ with the extraction with TBP $(K_{ex02}[T]_o^2[A^-]^2)$. The observed distribution ratio is higher than the calculated value given by the chain line. The difference will be ascribed to the adduct formation represented by the third term of the numerator in Eq. 1. Then the extraction constants of the mixed complex or the complex solvated with TBP can be determined as

Table 1. Summary of Equilibrium Constants When the Metal(II) is Extracted as Picrates with Crown Ethers and/or TBP into Chloroform

	Cu(II)		Zn(II)	
	12C4	15C5	12C4	15C5
$\log K_{ex10}$[1)]	0.64	2.09	−0.15	1.01
$\log K_{ex20}$[1)]	3.07	4.44	1.80	3.28
$\log K_{ex11}$	2.54	3.49	1.25	1.69
$\log K_{ex02}$	1.30		0.36	
$\log\bar{\beta}_{11}$	1.90	1.40	1.40	0.68

$$K_{ex_{mn}}=\frac{[ME_mT_nA_2]_o}{[M^{2+}]_a[E]_a^m[T]_o^n[A^-]_a^2}$$

m and n = 0, 1, or 2

$$\bar{\beta}_{11}=\frac{[MEA_2T]_o}{[MEA_2]_o[T]_o}$$

$$D/[A^-]_a^2-K_{ex02}[T]_o^2=K_{ex10}[E]_a+K_{ex20}[E]_a^2+(K_{ex11}[E]_a+K_{ex21}[E]_a^2)[T]_o+(K_{ex12}[E]_a+K_{ex22}[E]_a^2)[T]_o^2+\cdots \quad (3)$$

When the left side of Eq. 3 was plotted against $[T]_o$, straight lines were obtained for the data in Fig. 1. It indicates that the dominant species extracted is accompanied by one mole of TBP in these systems. The slope is $(K_{ex11}[E]_a+K_{ex21}[E]_a^2)$. Since the data in Fig. 1 were obtained at a constant crown ether concentration, $K_{ex11}[E]_a$ and $K_{ex21}[E]_a^2$ can not be calculated separately. As the first approximation, K_{ex21} was ignored and only K_{ex11} was determined. The constants obtained are listed in Table 1.

To check the validity of K_{ex11}, the distribution ratio of the metal(II) between an aqueous solution containing crown ether and lithium picrate (2.5×10^{-2} M) and 0.1 M TBP–chloroform has been measured. Figure 2 shows the plot of the distribution ratio against the total concentration of crown ether. The chain curves were obtained by combining the metal(II) extraction from an aqueous solution containing lithium picrate of constant concentration without crown ether into chloroform containing 0.1 M TBP (flat lines given by broken lines in Fig. 2) with the extraction from lithium picrate solution with crown ethers into chloroform containing no TBP (another broken line in Fig. 2). The observed distribution ratio is higher than the calculated one due to the adduct formation. The situation is thus similar to that in Fig. 1.

The solid curves in Figs. 1 and 2 calculated using the constants fit well with the observed distribution ratios.

The validity of K_{ex11} was also confirmed by measuring the distribution ratio at a higher concentration, 0.1 M, of crown ether, because the relationship between the distribution ratio and concentrations of crown ether and TBP in Eq. 3 applies to all concentrations. Figure 3 gives the plot of the distribution ratio against TBP concentration in the logarithmic units.

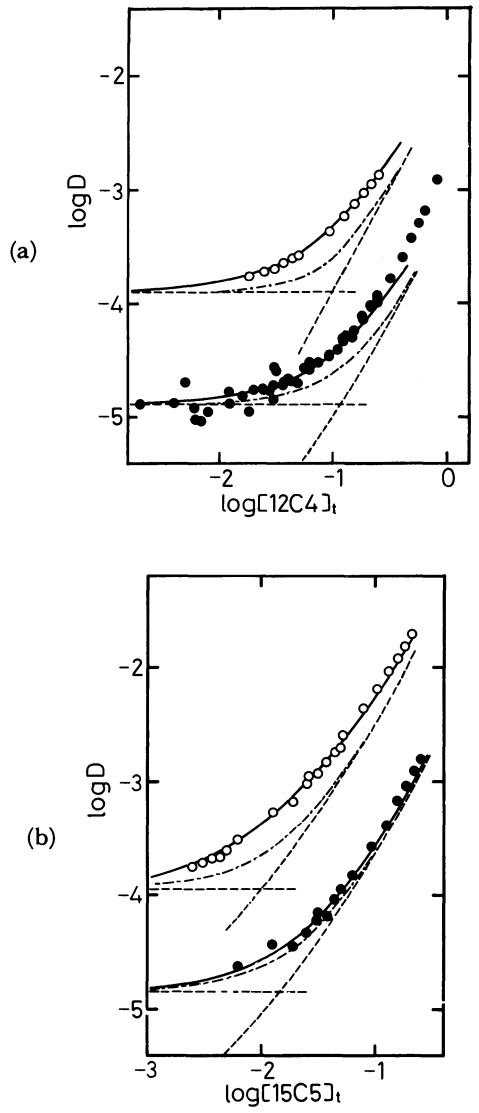

Fig. 2. Distribution ratio of Cu(II)(O) and Zn(II)(●) between 2.5×10^{-2} M lithium picrate solution contaning 12C4(a) and 15C5(b) and 0.1M TBP chloroform as a function of crown ether concentration.
Broken lines shows the extraction with TBP (flat lines) or a crown ether as picrates. Chain lines are obtained by combining the two lines above mentioned.
Solid lines are calculated by the equations denoted in Fig. 1 using the constants in Table 1.

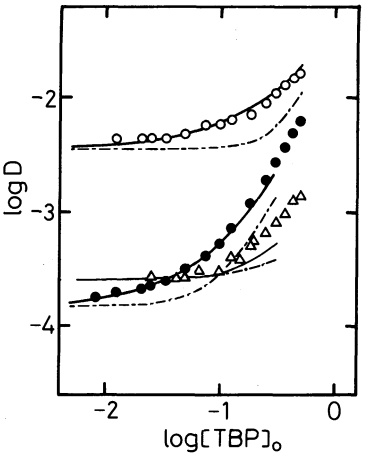

Fig. 3. Extraction of copper(II) with 0.1M 15C5(O) and 12C4(●) or of zinc(II) with 15C5(△) from 2.5×10^{-2} M lithium picrate solution into TBP-chloroform.
Solid lines are calculated by the equation in Fig. 1 using the constants in Table 1.
Chain lines are calculated on assuming no adduct formation.

The calculated values by using the constants in Table 1 are shown by solid line in Fig. 3. The calculated values fit well the experimental data for copper(II). However, the fitness does not appear for zinc(II) in the higher TBP concentration range, although the constants explain well the data in Figs. 1 and 2. The result may suggest that in the extraction with such a high concentration of crown ether, TBP could form adducts with bis-crown ether complex, ZnE_2A_2 as well as the mono-complex, $ZnEA_2$.

The present study reveals that the crown ether complex of either copper(II) or zinc(II) forms 1:1:1 (metal(II): crown ether: TBP) stoichiometric adducts similar to those formed between neutral ligands and metal(I)-crown ether complexes.[3,4] Since TBP seems to be more basic than crown ether, crown ether in the complexes could be replaced by TBP, although the metal(II) can be extracted in association with two moles of crown ether in the absence of TBP. However, Fig. 2 shows that the limiting slope of the plot between crown ether concentration and the distribution ratio is two, indicating that the complex with 2 moles of crown ether may be extracted even in the presence of TBP.

The formation constant of the adducts can be represented as

$$MEA_{2(o)} + T_{(o)} \rightleftharpoons MEA_2T_{(o)}$$

$$\bar{\beta}_{11} = \frac{[MEA_2T]_o}{[MEA_2]_o[T]_o} \quad (4)$$

and $\bar{\beta}_{11}$ can be obtained from the relation

$$\bar{\beta}_{11} = Kex_{11}/Kex_{10}. \quad (5)$$

The formation constants of the adducts are listed in Table 1. As seen in Table 1, the complex of either copper(II) or zinc(II) with 12C4 will form more stable adducts with TBP than the metal complex with 15C5, of which cavity size being larger than 12C4. However, the increase of the extraction with the adduct formation is more remarkable in 15C5 complexes than in 12C4 complexes as seen in Fig. 1. The larger enhancement in the extraction with 15C5 in spite of smaller formation constant of the adduct can be explained as follows: the extractability of the adduct (Kex_{11}) depends on the extractability of the parent crown ether complex as

well as on the property of adduct formed in the organic solvent ($\bar{\beta}_{11}$), i.e., the 12C4 complex forms more stable adducts than the 15C5 complex, while the 15C5 complex as picrate is extracted better than the 12C4 complex. Consequently, the enhancement in the extraction is more remarkable with 15C5–TBP than with 12C4–TBP.

Table 1 also shows that the adducts from copper(II) complexes with crown ether are more stable than those from zinc(II) complexes. The tendency seems to be opposite to the chelate extraction system. For example, Sekine and Ihara reported[2] that the first formation constant of the adduct between TBP and (trifluoroacetylacetonato)copper(II) is 2.16 in logarithmic unit, whereas that of the zinc(II) chelates is 4.29, that is, zinc(II) chelate forms more stable adduct with TBP than copper(II) chelate. They further suggested,[2] as a general tendency of adduct formation of metal chelates, that the chelate easily extractable forms less stable adducts. For example, the extraction of tfa–zinc(II) (tfa means trifluoroacetylacetonato) was much poorer than that of tfa–copper(II) under the same conditions. They explained the difference between the extractability of copper(II) and zinc(II) with chelating agents and the difference of adduct stability between copper(II) and zinc(II) in terms of the different coordination structures; when zinc(II) is extracted with β-diketones, zinc(II) takes the coordination number of 6, so that the zinc(II) chelate with β-diketone may hydrate with water molecules. Therefore, the extraction of (β-diketonato)zinc(II) is poorer than that of (β-diketonato)copper(II). Furthermore, since the hydrated water molecules may be replaced with neutral ligands such as TBP, the adduct from zinc(II) chelate is more stable than that from copper(II) chelate. On the other hand, since zinc(II) takes the coordination number of four when the metal(II) is extracted as the ion pair,[1,5] zinc(II) does hardly have a room to accept extra ligand. The different electronic structure of zinc(II) and copper(II) will be one of the reasons why the adduct formation is different between their chelates and their ion pairs.

When the adduct formation of the crown ether complex in the present study is compared with the adduct formation in chelates, the behavior of adduct formation of ion pair or cationic complex in organic phase seems to be very different from that of metal chelates.

Effects of EDTA Derivatives on the Photoreduction of Methyl Viologen by a Thiacarbocyanine Sensitizer in a Micellar Solution

Masayuki NAKAGAKI, Hiroaki KOMATSU,* Hiromi TANAKA, and Tetsurou HANDA†
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-shimoadachi-cho, Sakyo-ku, Kyoto 606
†Gifu Pharmaceutical University, Mitahorahigashi, Gifu 502
(Received April 1, 1986)

The photoinduced reduction of Methyl Viologen (MV^{2+}) by ethylenediaminetetraacetate (EDTA), 1,2-propanediamine-*N,N,N′,N′*-tetraacetate (MeEDTA), and *trans*-1,2-cyclohexanediamine-*N,N,N′,N′*-tetraacetate (CyDTA) was investigated by using 3,3′-dioctadecylthiacarbocyanine (C^{+}_{18-18}) as a sensitizer in a micellar solution of a nonionic surfactant, heptaethylene glycol monododecyl ether. The production rate of reduced Methyl Viologen ($MV^{+\cdot}$) decreased with the light-irradiation time, while the deceleration increased in the order of: CyDTA<MeEDTA<EDTA. The concentration of the EDTA derivatives at the micellar surface was estimated to be in the order of EDTA<MeEDTA<CyDTA, this difference in the concentration being attributed to such hydrophobic groups as methyl group and cyclohexane ring in the EDTA-derivative molecules. The high concentration of the EDTA derivatives at the surface accelerated the reaction of the sensitizer divalent cation radical ($C^{2+\cdot}_{18-18}$) with the EDTA derivatives, prevented the consumption of $MV^{+\cdot}$ through the back reaction of $C^{2+\cdot}_{18-18}$ with $MV^{+\cdot}$, and facilitated the efficient photoproduction of $MV^{+\cdot}$. It was demonstrated that the hydrophobic interaction between the EDTA-derivative molecules and the micellar surface is an important factor in determining the efficiency of the photoinduced $MV^{+\cdot}$ production.

The phtotoreduction of an electron acceptor (A) by a photoexcited sensitizer (S*) has received much attention in recent years (Reaction 1).[1-4] One common feauture of such a reaction is the high efficiency of the dark reaction of recombination (Reaction 2), which is facilitated by the energetics and the initial proximity of the reactants:

$$S^* + A \longrightarrow S^+ + A^- \quad (1)$$

$$S^+ + A^- \longrightarrow S + A \quad (2)$$

It is often desirable to maximize the yield of photoreduction, and techniques to minimize the recombination have been much studied. Such techniques have generally involved physically separating the products of the photoreaction and then removing one of them by means of an added substance. In order to separate the products, charged micellar,[5] charged vesicular[6] or colloidal SiO_2 surfaces[7] and vesicular bilayers[8,9] have been used. The additives used to remove S^+ from the systems are generally good reducing agents or electron donors (D).[10] Thus,

$$D + S^+ \longrightarrow D^+ + S. \quad (3)$$

The overall reaction in such a three-component system is given as follows:

$$D + S^* + A \longrightarrow D^+ + S + A^-. \quad (4)$$

In the system involving S in the micellar phase and D and A in the bulk aqueous phase, the high concentration of D at the micellar surface prevents the recombination (Reaction 2) and leads to the high efficiency of the photoreduction. Accordingly, the efficient photoreduction can be expected to be realized by the use of a substance as D, which can be strongly bound to the micellar surface. To demonstrate the above concept, we investigated the photoinduced reduction of Methyl Viologen by means of three kinds of ethylenediaminetetraacetate derivatives as a reducing agent in an aqueous phase sensitized by 3,3′-dioctadecylthiacarbocyanine incorporated in a nonionic micelle, composed of heptaethylene glycol monododecyl ether. The difference in the reaction rate between the ethylenediaminetetraacetate derivatives is examined. The results obtained are discussed in terms of the binding between the ethylenediaminetetraacetate derivatives and the micellar surface.

Experimental

The 3,3′-dioctadecyl-2,2′-thiacarbocyanine (C^{+}_{18-18}) bromide (the structure is shown in Fig. 1a) and 3,3′-diethyl-2,2′-thiacarbocyanine (C^{+}_{2-2}) bromide were purchased from the Japan Research Institute for Photosensitizing Dye Co., Ltd., and were used without further purification. The disodium ethylenediaminetetraacetate (EDTA), 1,2-propanediamine-*N,N,N′,N′*-tetraacetate (MeEDTA), and *trans*-1,2-cyclohexanediamine-*N,N,N′,N′*-tetraacetate (CyDTA) (the structures of these EDTA derivatives are shown in Fig. 1) were obtained from Dojindo Laboratories. The Methyl Viologen (1,1′-dimethyl-4,4′-bipyridinium, MV^{2+}) dichloride was received from the Sigma Chemical Company. The nonionic surfactant, heptaethylene glycol monododecyl ether (HED), was obtained from the Nikko Chemicals Co., Ltd.; the reported value of the critical micelle concentration is 8×10^{-5} M (1 M=1 mol dm^{-3}).[11] The monoethylene glycol monohexyl ether (MEH) was purchased from the Tokyo Chemical Industry Co., Ltd. The water was doubly distilled from a quartz still.

The preparation of HED micellar solutions containing a sensitizer has been described elsewhere.[12] C^{+}_{18-18} is insoluble in water[13] and may be considered to be incorporated in the micellar phase. The sample solution (5×10^{-7} M C^{+}_{18-18}, 2×10^{-3} M MV^{2+}, 2×10^{-2} M HED in a buffered solution with 2×10^{-3} M EDTA derivatives and 2×10^{-3} M tris(hydroxymethyl)aminomethane, Tris, at pH 7.0) was placed in a quartz cell

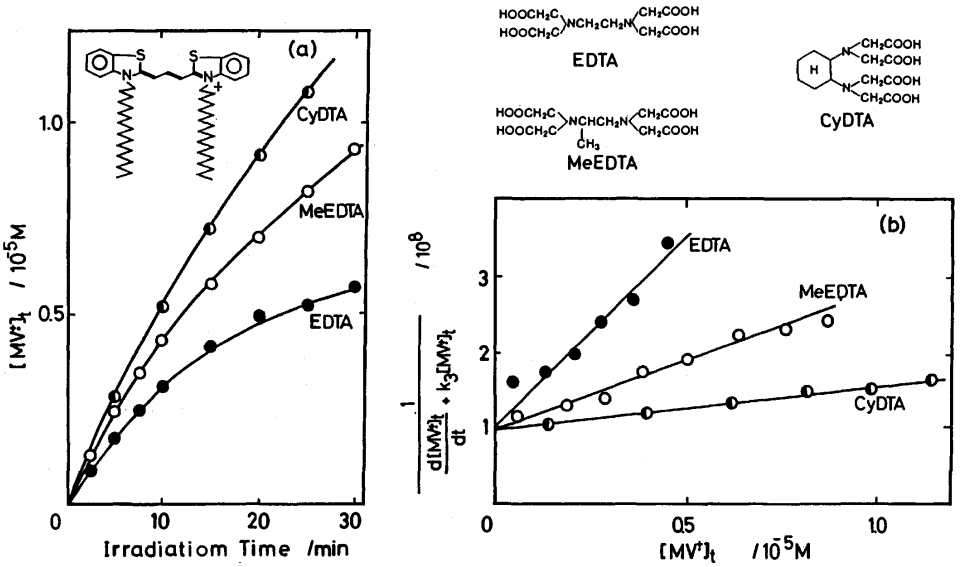

Fig. 1. (a) Built-up of $MV^{+\cdot}$ as a function of irradiation time at 25 °C. 5×10^{-7} M of C^{+}_{18-18} is solubilized in 2×10^{-2} M HED micellar solution (2×10^{-3} M EDTA derivatives, 2×10^{-3} M MV^{2+} and 2×10^{-3} M Tris at pH 7.0). Chemical structure of a sensitizer (C^{+}_{18-18}) is shown in the margin. (b) Variation of $1/(d[MV^{+\cdot}]_t/dt+k_3[MV^{+\cdot}]_t)$ as a function of $[MV^{+\cdot}]_t$ according to Eq. 8, and chemical structures of EDTA derivatives.

(1×1×4 cm) fitted with a stopcock was freed of oxygen by bubbling a nitrogen gas for 15 min, and was then degassed by aspiration at 2700 Pa (20 mmHg) prior to irradiation.

Irradiations were carried out using a Kondo-Sylvania 1 kW tungsten halogen lamp. A Toshiba KL-56 interference filter was used to obtain monochromic light, λ=560±5 nm (the absorption maximum of C^{+}_{18-18} in the HED micellar phase was about 560 nm). The intensity of light incident upon the cell was 3.26×10^{15} quanta s^{-1} as determined by trisoxalateferrate(III) actinometry.[14]

The production of reduced Methyl Viologen ($MV^{+\cdot}$) after intervals of irradiation was monitored by means of the absorption spectra on a Shimadzu UV-180 spectrophotometer. The concentration of $MV^{+\cdot}$ was calculated from the absorbance of the solution at 395 nm by taking $\varepsilon_{395nm}=3.8\times10^{4}$ M^{-1} cm.[15]

The measurements of the partition coefficient of EDTA derivatives from aqueous to water-saturated MEH phases were performed by the following procedure. The mixture of MEH solution, previously saturated with water, and a 2×10^{-3} M EDTA-derivative buffer solution was stirred well. After the centrifugation of the mixture, the aqueous phase was collected. Then, the decrease in the concentration of the EDTA derivatives in the aqueous phase was measured by chelatometry using magnesium chloride.

All the measurements were carried out at 25 °C.

Results

Photoreduction of MV^{2+}. A deoxygenated solution containing C^{+}_{18-18} in the HED micellar phase and MV^{2+} in the aqueous phase was irradiated with green light. As a result, the solution turned dark blue; a development of absorption maxima at about 395- and 603-nm was observed in the presence of EDTA derivatives. The development of the absorption maxima is characteristic of the formation of $MV^{+\cdot}$.[15] The subsequent introduction of air into the cuvette resulted in the prompt reoxidation of $MV^{+\cdot}$ to MV^{2+}, as manifested by decolorization.[16] In the dark or in the absence of the EDTA derivatives, no $MV^{+\cdot}$ was produced.

In Fig. 1a, the concentrations of $MV^{+\cdot}$ formed by irradiation with light are plotted against the irradiation time. In all the EDTA derivatives, the production rate of $MV^{+\cdot}$ decreased with the increase in the irradiation time. The degree of the deceleration increased in this order: CyDTA<MeEDTA<EDTA.

After the removal of the light, the concentration of $MV^{+\cdot}$ gradually decreased with the increase in the time as a result of the reoxidation of $MV^{+\cdot}$ to MV^{2+} by the small amount of oxygen dissolved in the solution.[17] In a previous study,[12] it was found that this reoxidation in the dark followed pseudo first-order kinetics and that the rate constant (k_3) was 5.4×10^{-5} s^{-1} under our conditions. Such a reoxidation of $MV^{+\cdot}$ to MV^{2+} may be considered to proceed not only after the removal of light, but also during irradiation with light.

The mechanism of the reaction which was proposed in a previous report[12] is depicted in Fig. 2. Assuming that the concentration of the sensitizer cation radical ($C^{2+\cdot}_{18-18}$) is constant in a stationary state and that the moles of MV^{2+}, $MV^{+\cdot}$, and EDTA derivatives in the HED micellar phase are much smaller than the total moles of the respective components in the solution, the measureable production rate of $MV^{+\cdot}$ during irradiation with light may be described by:

$$\frac{d[MV^{+\cdot}]_t}{dt}=\frac{k_1k_2[{}^3C^{+*}_{18-18}]_m[MV^{2+}]_m[EDTAd^{3-}]_m^{1/2}}{k_{-1}(P_{MV^+}[MV^{+\cdot}]_t)+k_2[EDTAd^{3-}]_m^{1/2}}-(k_3'P_{MV^+}[O_2]_m+k_3''[O_2]_a)[MV^{+\cdot}]_t, \quad (5)$$

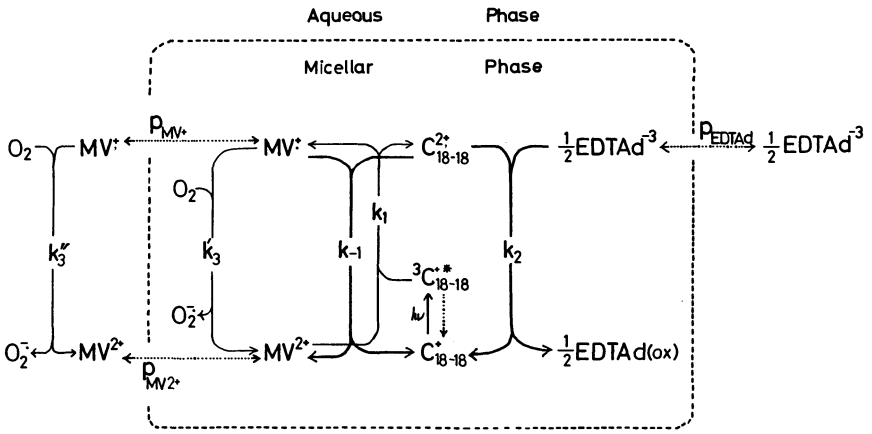

Fig. 2. The proposed mechanism of the photoreduction of MV^{2+} by EDTA derivatives. C^{+}_{18-18} and $^3C^{+*}_{18-18}$, sensitizers in the ground and the triplet excited states in the micellar phase; $C^{2+\cdot}_{18-18}$, sensitizer cation radical; EDTAd and EDTAd(ox), EDTA derivatives and the oxidated form of EDTAd; P_{MV2+}, P_{MV+}, and P_{EDTAd}, partition coefficients of MV^{2+}, $MV^{+\cdot}$, and $EDTAd^{3-}$ from the aqueous phase to the micellar pseudophase; k_1, k_{-1}, k_2, k_3' and k_3'', the rate constants of each reaction.

where $^3C^{+*}_{18-18}$ and $EDTAd^{3-}$ represent the sensitizer in the triplet excited state and the EDTA derivatives respectively. P_{MV+} stands for the partition coefficient of $MV^{+\cdot}$ from the bulk aqueous phase to the micellar pseudophase, defined as $P_{MV+}=[MV^{+\cdot}]_m/[MV^{+\cdot}]_a$. The subscripts a and m denote the concentration at the aqueous phase and at the micellar pseudophase, while the subscript t denotes the total concentration in the micellar solution. The initial rate of $MV^{+\cdot}$ production (V_{init}), which can be obtained from Eq. 5 at $[MV^{+\cdot}]_t \to 0$, is given as follows:

$$V_{init} = k_1[^3C^{+*}_{18-18}]_m[MV^{2+}]^0_m. \tag{6}$$

Here, $[MV^{2+}]^0_m$ is the initial value of $[MV^{2+}]_m$. Since, in this experiment, $[MV^{2+}]_t \gg [MV^{+\cdot}]_t$, and $[MV^{2+}]_m$ in Eq. 5 is nearly equal to $[MV^{2+}]^0_m$ and is a constant, Eq. 5 becomes:

$$\frac{d[MV^{+\cdot}]_t}{dt} = \frac{V_{init}k_2[EDTAd^{3-}]_m^{1/2}}{k_{-1}(P_{MV+}[MV^{+\cdot}]_t) + k_2[EDTAd^{3-}]_m^{1/2}} - k_3[MV^{+\cdot}]_t, \tag{7}$$

where $k_3=k_3'P_{MV+}[O_2]_m+k_3''[O_2]_a$. The second term on the right-hand side of Eq. 7 corresponds to the reoxidation rate of $MV^{+\cdot}$ to MV^{2+} in the dark after the removal of the light. Equation 7 indicates that the deceleration in the production rate of $MV^{+\cdot}$ with the increase in the time arises from the decrease in the first and the second terms on the right-hand side of the equation with the increase in $[MV^{+\cdot}]_t$.

Equation 7 may be transformed to:

$$\frac{1}{\frac{d[MV^{+\cdot}]_t}{dt} + k_3[MV^{+\cdot}]_t} = \frac{k_{-1}P_{MV+}}{V_{init}k_2[EDTAd^{3-}]_m^{1/2}}[MV^{+\cdot}]_t + \frac{1}{V_{init}}. \tag{8}$$

Plots of $1/(d[MV^{+\cdot}]_t/dt+k_3[MV^{+\cdot}]_t)$ vs. $[MV^{+\cdot}]_t$ according to Eq. 8 are shown in Fig. 1b. Here, the observed values evaluated from Eqs. 9 and 10 were substituted for the values of $d[MV^{+\cdot}]_t/dt$ and $[MV^{+\cdot}]_t$ respectively:

$$\frac{d[MV^{+\cdot}]_t}{dt} = \frac{[MV^{+\cdot}]_{t(n+1)} - [MV^{+\cdot}]_{t(n)}}{t(n+1) - t(n)} \tag{9}$$

and

$$[MV^{+\cdot}]_t = \frac{[MV^{+\cdot}]_{t(n+1)} + [MV^{+\cdot}]_{t(n)}}{2}. \tag{10}$$

Here, $[MV^{+\cdot}]_{t(n)}$ and $[MV^{+\cdot}]_{t(n+1)}$ are $[MV^{+\cdot}]_t$ at the measuring time $t=t(n)$ and at $t=t(n+1)$ respectively. These plots give straight lines, and the slope and the intercept lead to values for V_{init} and $(k_2[EDTAd^{3-}]_m^{1/2})/(k_{-1}P_{MV+})$ respectively, as is shown in Table 1.

The values of V_{init} in all the EDTA derivatives are the same, but the values of $(k_2[EDTAd^{3-}]_m^{1/2})/(k_{-1}P_{MV+})$ increase in this order; EDTA<MeEDTA<CyDTA. In the case of EDTA, the value of V_{init} with monochromic light (λ=560±5 nm, percent transmission of the filter at 560 nm, T_{560nm}=25%) is smaller than that with visible light (λ>460 nm, using Y-46 cut-off filter, T_{560nm}=90%). The values of $(k_2[EDTAd^{3-}]_m^{1/2})/(k_{-1}P_{MV+})$ are, however, the same in both irradiation intensities. These results correspond to the expectation that V_{init} is dependent on the intensity of the incident light, which is propotional to $[^3C^{+*}_{18-18}]$, but is independent of the kind of EDTA derivatives, as may be seen from Eq. 6, and that $(k_2[EDTAd^{3-}]_m^{1/2})/(k_{-1}P_{MV+})$ is affected by the kind of EDTA derivatives, but not by the light intensity.

Absorption Maxima of Sensitizer Dye in Various Solvents. Previously,[18] it was demonstrated that C^{+}_{2-2} and C^{+}_{18-18} showed considerably large shifts in their absorption maxima in various aliphatic alcohols used as solvents; the wave numbers at their absorption

Table 1. Experimental Values on Photoreduction of MV^{2+}

EDTAd	V_{init} / $M\,s^{-1}$	$\frac{k_2[EDTAd^{3-}]_m^{1/2}}{k_{-1}P_{MV+}}$ / $M^{1/2}$	P^*_{EDTAd}	Irradiation light
EDTA	1.00×10^{-8}	0.20×10^{-5}	1.2×10^{-2}	Monochromic[a]
	12.71×10^{-8}	0.19×10^{-5}		Visible[b]

maxima ($\tilde{\nu}_{max}$) increase with the dielectric constant (D) of alcohols. The value of D in the vicinity of the chromophore of C^+_{18-18} in the HED micellar phase, which has been defined as the effective dielectric constant (D_{eff}), was estimated as D_{eff}=20.0 using the values of $\tilde{\nu}_{max}$ and D for alcohols.[18] Similar procedures led to the D_{eff} value of 19.4 for C^+_{2-2} in a water-saturated MEH solution. These D_{eff} values correspond to the polarity of 1-propanol or 1-butanol, and indicate that the chromophore of C^+_{2-2} in the water-saturated MEH solution is dissolved in an environment with a micropolarity similar to that of C^+_{18-18} in the HED micellar phase.

Partition of EDTA Derivatives from Aqueous to Water-Saturated MEH Phases. The time course of the partition of EDTA derivatives between aqueous and water-saturated MEH phases was investigated; the results are shown in Fig. 3a. The partition equilibrium was established after about 3 h under our conditions. The partition coefficient of the EDTA derivatives from the aqueous to the water-saturated MEH phases (P^*_{EDTAd}) is given by:

$$P^*_{EDTAd} = \frac{C_m}{C_a} = \frac{V_a}{V_m}\left(\frac{C^0_a}{C_a} - 1\right), \qquad (11)$$

where C_a, C_m, and C^0_a are the concentration of the EDTA derivatives in the aqueous and water-saturated MEH phases, and the initial concentration of the EDTA derivatives in the aqueous phase respectively. Here, V_a and V_m are the volumes of the aqueous and water-saturated MEH phases respectively. Equation 11 may be rewritten as:

$$\frac{1}{C_a} = \frac{P^*_{EDTAd}}{C^0_a V_a} V_m + \frac{1}{C^0_a}. \qquad (12)$$

Plots of $1/C_a$ versus V_m according to Eq. 12 are shown in Fig. 3b in the case of V_a=10 ml. These plots give straight lines, and their slopes and intercept lead to the values for P^*_{EDTAd} shown in Table 1. These results indicate that the concentrations of the EDTA derivatives in the water-saturated MEH phase increase in the order of EDTA<MeEDTA<CyDTA at the partition equilibrium.

Discussion

The photoinduced reduction of MV^{2+} by EDTA has been carried out with various sensitizer dyes such as tris(2,2'-bipyridine)ruthenium,[1-6,8] porphyrins,[1-7,9,10,19]

and phatalocyanines[20] by numerous workers, and every effort has been made to maximize the efficiency of the photoinduced production of $MV^{+\cdot}$, for $MV^{+\cdot}$ is capable of generating hydrogen from water when platinum dioxide is used as a catalyst.[21] In our studies, 3,3'-dioctadecylthiacarbocyanine in a nonionic micelle has been adopted as a sensitizer.[12,13] This dye has been known as a probe for investigating the membrane potentials of erythrocyte membranes[22] and cell membranes of bacteria[23] and as a strong inhibitor of the endogeneous respiration of Ehrlich ascites tumor cells.[24]

In this study, in order to minimize the recombination of photoproducts (Eq. 13, corresponding to Eq. 2), EDTA derivatives are used as reducing agents, resulting in the removal of $C_{18\text{-}18}^{2+\cdot}$ from the system (Eq. 14, corresponding to Eq. 3) and in the prevention of the recombination of $C_{18\text{-}18}^{2+\cdot}$ with $MV^{+\cdot}$ (Eq. 9):

$$(C_{18\cdot18}^{2+\cdot})_m + (MV^{+\cdot})_m \xrightarrow{k_{-1}} (C_{18\text{-}18}^{+})_m + (MV^{2+})_m, \quad (13)$$

$$(C_{18\text{-}18}^{2+\cdot})_m + (EDTAd^{3-})_m \xrightarrow{k_2} (C_{18\cdot18}^{+})_m + (EDTAd(ox))_m. \quad (14)$$

It can be expected that the faster the process shown as Eq. 14 is, that is, the higher $[EDTAd^{3-}]_m$ and/or the rate constant (k_2) of this process is, the larger is the efficiency of the $MV^{+\cdot}$ production. As may be seen from Fig. 1, the production rates of $MV^{+\cdot}$ decrease with the increase in the time, and the deceleration is the smallest in CyDTA and the largest in EDTA. Equation 7, showing the production rate of $MV^{+\cdot}$, indicates that the deceleration of the $MV^{+\cdot}$ production arises from the decrease in the first and second terms on the right-hand side of Eq. 7 with the increase in $[MV^{+\cdot}]_t$. Furthermore, since V_{init}, k_3, k_{-1}, and P_{MV+} are independent of the kind of the EDTA derivatives and constant, Eq. 3 indicates that the larger $[EDTAd^{3-}]_m$ and/or k_2 is, the smaller is the deceleration of the $MV^{+\cdot}$ production.

As may be seen from the proposed mechanism, $MV^{+\cdot}$ is produced through the following process:

$$(^3C_{18\cdot18}^{+*})_m + (MV^{2+})_m \xrightarrow{k_1} (C_{18\text{-}18}^{2+\cdot})_m + (MV^{+\cdot})_m. \quad (15)$$

On the other hand, $MV^{+\cdot}$ disappears through the processes shown by Eqs. 13, 16, and 17:

$$(MV^{+\cdot})_m + (O_2)_m \xrightarrow{k_3'} (MV^{2+})_m + (O_2^{-\cdot})_m \quad (16)$$

$$(MV^{+\cdot})_a + (O_2)_a \xrightarrow{k_3''} (MV^{2+})_a + (O_2^{-\cdot})_a \quad (17)$$

Therefore, by using the reaction rate of these processes, the efficiency of $MV^{+\cdot}$ production (E) is introduced as follows:

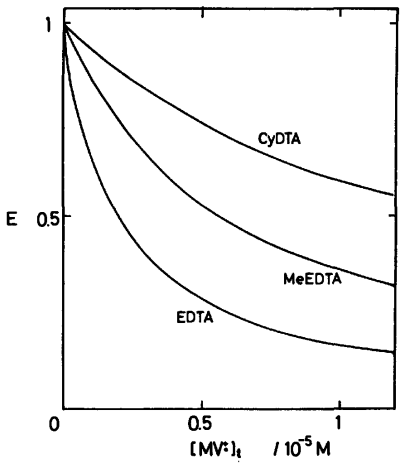

Fig. 4. Comparison of the efficiency of $MV^{+\cdot}$ production (E) between the three $EDTAd^{3-}$ as a function of $[MV^{+\cdot}]_t$. The values of E were evaluated using Eq. 19 and the values in Table 1.

$$E = \frac{k_1[^3C_{18\cdot18}^{+*}]_m[MV^{2+}]_m - k_{-1}[C_{18\text{-}18}^{2+\cdot}]_m[MV^{+\cdot}]_m - k_3[MV^{+\cdot}]_t}{k_1[^3C_{18\cdot18}^{+*}]_m[MV^{2+}]_m}$$

$$= 1 - \frac{k_3}{V_{Init}}[MV^{+\cdot}]_t - \frac{1}{1+\left(\frac{k_2[EDTAd^{3-}]_m^{1/2}}{k_{-1}P_{MV+}}\right)\frac{1}{[MV^{+\cdot}]_t}} \quad (18)$$

Here, $[C_{18\text{-}18}^{2+\cdot}]_m$ is constant and is equal to $V_{init}/(k_{-1}P_{MV+}[MV^{+\cdot}]_t + k_2[EDTAd^{3-}]_m^{1/2})$ in a stationary state (see Fig. 2). Since the value of k_3 is 10^{-5}-order and since the values of V_{init} are 10^{-8}-order, it may be considered that $k_3[MV^{+\cdot}]_t/V_{init} \ll 1$ at $[MV^{+\cdot}]_t$ below about 1×10^{-5} M. Therefore, Eq. 18 may reduce to:

$$E = \frac{1}{1+[MV^{+\cdot}]_t/\left(\frac{k_2[EDTAd^{3-}]_m^{1/2}}{k_{-1}P_{MV+}}\right)}. \quad (19)$$

Figure 4 compares the E values between the three EDTA derivatives as a function of $[MV^{+\cdot}]_t$. The values of E were calculated using the values of $(k_2[EDTAd^{3-}]_m^{1/2})/(k_{-1}P_{MV+})$ in Table 1. As may be seen from Fig. 4, the value of E for CyDTA decreases gradually with the increase in $[MV^{+\cdot}]_t$. On the other hand, the value of E for EDTA decreases rapidly in the region of small values of $[MV^{+\cdot}]_t$. Equation 19 indicates that the slower decrease of E for CyDTA with the increase in the $[MV^{+\cdot}]_t$ may be ascribed to the relatively high value of $[EDTAd^{3-}]_m$, i.e. $[CyDTA^{3-}]_m$ and/or k_2.

The binding between the EDTA derivatives and the HED micelle (P_{EDTAd}) was measured with the ultrafiltration method. However, the binding was slight and was not clearly detected. As has been mentioned before, the D_{eff} for $C_{18\text{-}18}^{+}$ in the HED micellar phase is 20.0 and corresponds to the polarity of 1-propanol or 1-butanol. This indicates that the chromophore of $C_{18\text{-}18}^{+}$ accommodated in the HED micellar phase is pro-

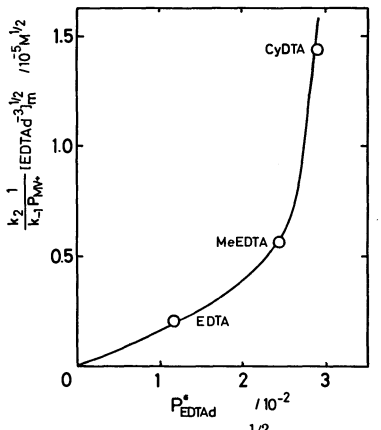

Fig. 5. Plots of $(k_2[EDTAd^{3-}]_m^{1/2})/(k_{-1}P_{MV+})$ versus P^*_{EDTAd}.

vided with a remarkably less polar environment than that in the aqueous phase, but it seems to be in a more polar environment than in a liquid hydrocarbon. These results indicate that the chromophore is located in the surface region of the HED micelle,[12] probably in its ethylene glycol mantle. The D_{eff} value for C^+_{2-2}, which has the same chromophore as C^+_{18-18}, in a water-saturated MEH solution is 19.4; this indicates that C^+_{2-2} is dissolved in a micropolarity similar to that of C^+_{18-18} in the HED micellar phase. Therefore, the concentration of the EDTA derivatives at the HED micellar surface (the binding between the EDTA derivatives and the HED micelle) was estimated from the partition coefficient (P^*_{EDTAd}) of the EDTA derivatives from the aqueous to the water-saturated MEH phases. As a result, the concentration of CyDTA in the water-saturated MEH phase is the highest,while that of EDTA is the lowest, in the three EDTA derivatives. These differences in the concentration of the EDTA derivatives in the water-saturated MEH phase may be attributed to the hydrophobic groups, such as the methyl group and cyclohexane ring in the EDTA-derivative molecules. The order of the concentration of EDTA derivatives in the water-saturated MEH phase coincides with that of the efficiency of $MV^{+\cdot}$ production (E), indicating that the local concentration of the EDTA derivatives at the HED micellar surface ($[EDTAd^{3-}]_m$) is an important factor in determining E.

Figure 5 shows the plots of the values of $(k_2[EDTAd^{3-}]_m^{1/2})/(k_{-1}P_{MV+})$ versus P^*_{EDTAd}. These plots suggest the close correlation between E and P^*_{EDTAd}. The difference in the value of k_2 in the three EDTA derivatives is probably a result of difference in the oxidation potential of the EDTA derivatives, their proximity to $C^{2+\cdot}_{18-18}$ in the micellar surface, which are also associated with their partition coefficient (P_{EDTAd}). Thus, though the k_2 values are somewhat different in the three EDTA derivatives, the agreement in the order in the EDTA derivatives between the ease of the partition to the MEH phase and the efficiency of $MV^{+\cdot}$ production indicates that the local concentration of the EDTA derivatives at the HED micellar surface is an important factor in determining the efficiency of $MV^{+\cdot}$ production.

In conclusion, it seems that the high concentration of EDTA derivatives at the micellar surface is essential for the efficient photoproduction of $MV^{+\cdot}$. It is also suggested that not only the electrostatic interaction, demonstrated by many workers, but also the hydrophobic interaction between EDTA derivatives and the micellar surface is important for the achievement of a high concentration of EDTA derivatives at the micellar surface and for the effective production of $MV^{+\cdot}$.

o-Quinodimethane Generation from α,α′-Dihalo-o-xylenes by Use of Sodium Benzenetellurolate

Nobuaki KAMBE, Takashi TSUKAMOTO, Noritaka MIYOSHI, Shinji MURAI, and Noboru SONODA*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received April 2, 1986)

Treatment of α,α′-dihalo-o-xylenes with sodium benzenetellurolate gave o-quinodimethane which readily reacted with dienophiles leading to Diels–Alder adducts. The best yields were obtained when the reaction was carried out in refluxing ethanol using two molar equivalents of the benzenetellurolate to α,α′-dihalo-o-xylenes. This reaction competes with substitution of the halogen atoms with the benzenetellurolate anion to afford α,α′-bis(phenyltelluro)-o-xylene, which did not give o-quinodimethane under identical conditions. It is likely that the reaction proceeds through nucleophilic attack of benzenetellurolate anion at the tellurium atom of α-halo-α′-phenyltelluro-o-xylene which is formed in situ by the substitution of one of the halogen atoms of the starting α,α′-dihalo-o-xylene with the benzenetellurolate anion. When sodium benzeneselenolate was employed, no evidence of o-quinodimethane formation was observed under similar conditions.

Since Cava and his co-worker first recognized the intermediacy of α,α′-dibromo-o-quinodimethane in the reaction of α,α,α′,α′-tetrabromo-o-xylene with sodium iodide,[1] a variety of methods for the generation of o-quinodimethane intermediates have been developed and used for organic synthesis.[2–10] Recent advances in this methodology have enabled the facile generation of o-quinodimethanes under mild conditions[4m–r] with stereocontrol of the subsequent Diels–Alder reaction with a dienophile (intermolecularly or intramolecularly), leading to the successful preparation of polycyclic compounds such as steroids, alkaloids, terpenoids and some antibiotics.

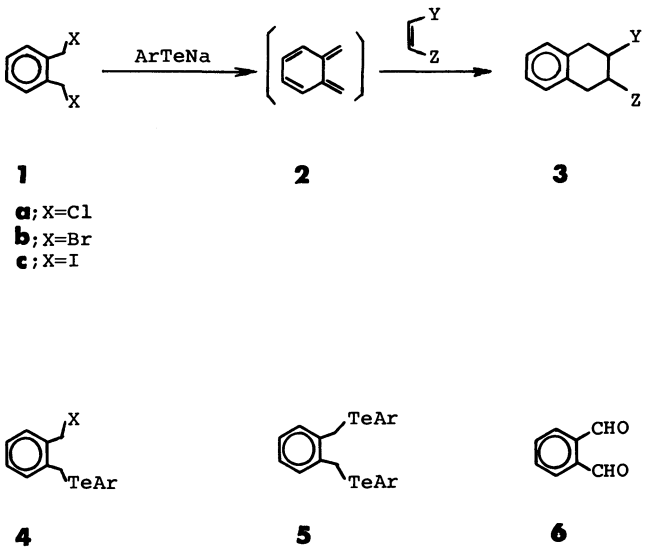
For the syntheses of relatively simple compounds via Diels–Alder reaction of the unsubstituted o-quinodimethane, α,α′-dihalo-o-xylenes may be the first choice because of their ready availability as starting materials. The heterogeneous 1,4-dehalogenation of α,α′-dihalo-o-xylenes proceeds through reductions with Zn,[4d,e] Fe,[4f] or Cu[4g] metals. Only one homogeneous reduction[9] was reported using iodide anion.[4a–c] Dehalogenation of vic-dihalides[11] or α-halo carbonyls[12] with iodide ion is a well-known and versatile reaction, but dehalogenation of α,α′-dihalo-o-xylenes to o-quinodimethanes with iodide anion was restricted to activated systems having alkoxyl substituents on the aryl rings[4b,c] or halogens in the benzylic positions.[4a]

In this paper we report a new o-quinodimethane generation from nonactivated α,α′-dihalo-o-xylenes (**1**) promoted by sodium benzenetellurolate giving rise to Diels–Alder adducts in the presence of dienophiles (Scheme 1).

Dehalogenation with tellurolate anions has been successfully achieved in the cases of α-halo carbonyls,[13] vic-dihalides,[14] 1,4-dibromo-2-enes,[15] and 3,7-dibromo-5-cyclooctadiene,[16] but no precedence has been reported for the generation of o-quinodimethanes from α,α′-dihalo-o-xylenes.

Results and Discussion

Dehalogenation of *vic*-dihalides[14] was reported using sodium hydrogen telluride (NaTeH), prepared from tellurium and sodium borohydride.[17] These successful results prompted us to investigate the dehalogenation of α,α′-dihalo-o-xylenes with NaTeH to generate o-quinodimethanes. The reaction in refluxing ethanol for 5 h in the presence of excess diethyl maleate gave diethyl 2,3-tetralindicarboxylate in 24% yield. In the cases of ethyl acrylate and other dienophiles, reduction of the C–C double bond of the dienophiles with NaTeH predominated, resulting in very poor yields of the desired adducts. In order to preclude this side reaction, we investigated the use of sodium benzenetellurolate (PhTeNa), as the nucleophile.



Scheme 1.

The reaction of α,α′-dihalo-o-xylenes with PhTeNa prepared from diphenyl ditelluride and sodium borohydride[18] was carried out in refluxing ethanol in the presence of an excess of a dienophile. Several dienophiles were examined using different arenetellurolate anions. The results are summarized in Table 1. Ethyl acrylate, methyl vinyl ketone, and acrylonitrile gave the corresponding Diels–Alder adducts in moderate yields. It should be noted that a similar reaction using sodium

a) Reaction conditions: Ar_2Te_2 (5 mmol), α,α'-dihalo-*o*-xylene (5 mmol), dienophile (50 mmol), $NaBH_4$ (10.5 mmol, 400 mg), EtOH (30 mL), reflux, 2 h. b) GLC yield.

benzeneselenolate, PhSeNa, gave α,α'-bis(phenylseleno)-*o*-xylene in 75% yield together with the Michael adduct of benzeneselenolate to ethyl acrylate instead of the desired Diels–Alder adduct (see Experimental section).

When the reaction was carried out at room temperature, no apparent change was observed and no adduct was detected. After reaching reflux, the reaction mixture turned red, which may be due to the color of diaryl ditelluride, suggesting that reduction with arenetellurolate had occurred. Monitoring of the reaction by GLC showed that the reaction was complete within 1 h. When $\alpha,\alpha,\alpha',\alpha'$-tetrabromo-*o*-xylene was employed, the expected adduct,[19] ethyl 2-naphthoate, was formed in very poor yield. This is in marked contrast[20] to the iodide ion induced quinodimethane formation in which the corresponding adduct was formed in 65% yield from $\alpha,\alpha,\alpha',\alpha'$-tetrabromo-*o*-xylene by the treatment with sodium iodide in the presence of *N*-phenylmaleimide.[4a)]

In all reactions in Table 1, the dialdehyde **6** was obtained as a by-product in about 30% yield based on the dihalide used. It is known that benzyl tellurolate is oxidized in air at room temperature to give benzaldehyde.[21] So the aldehyde is assumed to be formed by the oxidation of α,α'-bis(phenyltelluro)-*o*-xylene. In order to ensure this hypothesis, a control experiment was carried out. When a ethanol solution of PhTeNa and α,α'-dibromo-*o*-xylene was refluxed for 2 h, a new NMR singlet at δ 4.17 appeared, which was assigned to the methylene protons of α,α'-bis(phenyltelluro)-*o*-xylene (**5**). The mixture was then exposed to air and stirred at r.t. overnight, and the dialdehyde **6** was isolated in 60% yield. In a similar manner, α,α'-bis(phenyltelluro)-*o*-xylene (**5**) was isolated and conversion of **5** to **6** was monitored by NMR (see Experimental section).

The reaction of the α,α'-dibromo-*o*-xylene with sodium benzenetellurolate at room temperature or below resulted in substitution of bromide with $PhTe^-$ and no Diels–Alder adduct was detected by GLC. The reaction proceeds only when refluxed.

Another important factor was the molar ratio of PhTeNa to α,α'-dihalo-*o*-xylene. The yields of the desired adduct and the dialdehyde were plotted against the molar ratio of PhTeNa to α,α'-dibromo-*o*-xylene as shown in Fig. 1. The best yield of the adduct was obtained when the ratio was 2.0. As the ratio was increased the substitution predominated resulting in an increase of dialdehyde formation. An explanation for these results is that the excess of $PhTe^-$ displaces both halogen atoms of the dihalides before the reaction mixture reached reflux, and gave α,α'-bis(phenyltelluro)-*o*-xylene (**5**) which is not converted to the quinodimethane under these reaction conditions.

α,α'-Dichloro-*o*-xylene did not give the corresponding Diels–Alder adduct. When NaI was added to the reaction mixture of the α,α'-dichloro-*o*-xylene, the Diels–Alder adduct was obtained in a moderate yield,

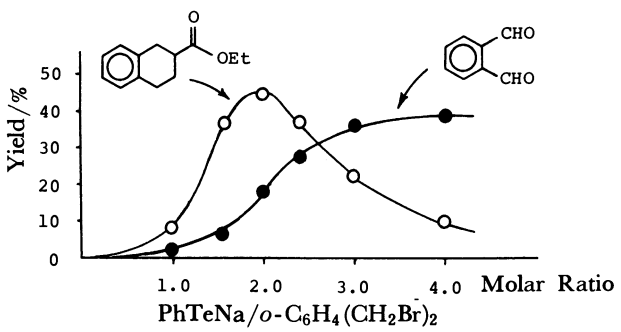

Fig. 1. Yields of the adducts at the different ratios of PhTeNa/*o*-$C_6H_4(CH_2Br)_2$.

probably due to the substitution of the chlorine atom with the iodine atom.

In order to elucidate the reaction path, some NMR studies were performed. When α,α'-dibromo-*o*-xylene was treated with two equivalents of PhTeNa in the presence of methyl acrylate at −20 °C in a mixed solvent of $CDCl_3$ and CD_3OD, the NMR indicated a mixture of the starting dibromide (benzylic protons of **1** at δ 4.64), α-bromo-α'-phenyltelluro-*o*-xylene (those of **4** at δ 4.43 and at δ 4.37), and α,α'-bis(phenyltelluro)-*o*-xylene (those of **5** at δ 4.17). Heating the mixtute to 60 °C, the first two compounds disappeared and the Diels–Alder adduct had formed. While the peak for **5** remained unchanged. This result indicated that substitution of one of the bromine atoms on the benzylic positions of **1b** with benzenetellurolate anion is a fast reaction even at low temperatures, and that substitution of the second bromine atom with $PhTe^-$ may compete with the quinodimethane formation giving rise to **5** which is not a precursor to **2** but to **6**. This conclusion is also supported by the evidence that when excess benzenetellurolate anion was used, formation of the dialdehyde **6** predominated and quinodimethane formation was suppressed as shown in Fig. 1. The fact that the yield of the Diels–Alder adduct was very low when a stoichiometric amount of benzenetellurolate anion was used may indicate that Path A in which quinodimethane was formed by direct attack of $PhTe^-$ at one of the bromine atoms of **1** can be ruled out, or if any, can not be the main path. So the next question is which does $PhTe^-$ attack the halogen atom or the tellurium atom of **4** in the subsequent step of the reaction.

There are some precedents on the reaction of alkyl halides with chalcogenolate anions. The direct attack at halogen atoms by tellurolate anions was suggested in the dehalogenation of *vic*-dihalides supported by the stereochemistry of the olefinic products formed from stereochemically pure *vic*-dihalides, i.e., anti elimination.[14c] In similar reactions using PhSeNa,[22] *vic*-dibromide, 2-iodoalkyl chloride, and 2-(phenylseleno)alkyl chloride undergo anti elimination by the direct attack of $PhSe^-$ at bromine, iodine, and selenium atoms, respectively. On the other hand the elimination of *vic*-dichloride proceeds in net syn fashion, indicating that the displacement of one of the chlorine atoms with $PhSe^-$ preceded the subsequent anti elimination which is caused by the nucleophilic attack of $PhSe^-$ on selenium of the in situ formed 2-(phenylseleno)alkyl chloride.

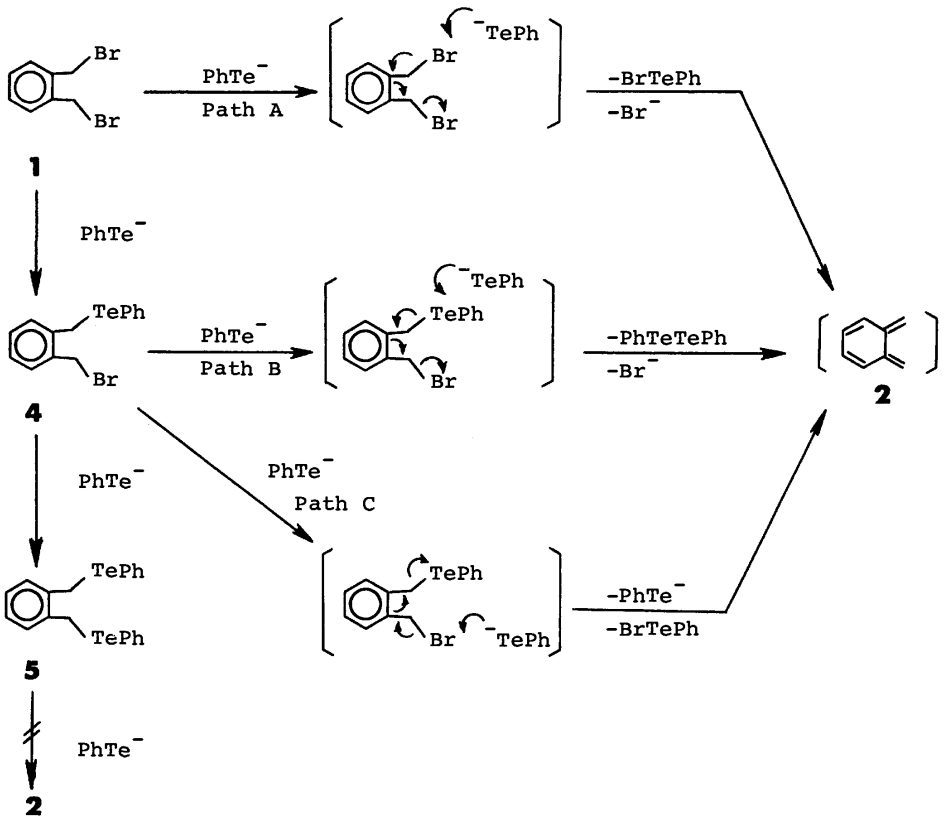
In the dehalogenation of α-halo ketones or α-halo amides to the parent ketones or amides by tellurolate anions, it has been proposed that the reduction is initiated by the displacement of the halide with $ArTe^-$ followed by the nucleophilic attack of a second molecule of tellurolate anion at the tellurium of the substituted intermediate.[13b] It has been previously reported that reactions of α-halo ketones[23] and benzyl halides[24] with thiolate and selenolate anions often give mixtures of reduction and substitution products depending on both the nature of the substrates and that of the reagents used as well as the reaction conditions. In the reaction with 3,7-dibromo-1,5-cyclooctadiene, thiolate and selenolate anions displaced bromide but tellurolate anion preferred the nucleophilic attack at one of the bromine atoms leading to the formation of a bicyclic compound.[16]

As described above, both examples of the nucleophilic attack of tellurolate anion at the halogen atoms and that at the chalcogen atoms are known, and both Path B and Path C seem probable. But we would like to propose that $PhTe^-$ attacks the tellurium atom of **4** than the halogen atom, since it is likely that bromide and iodide anions are expected to be better leaving groups than the benzenetellurolate anion from our knowledge obtained in the study about the tellurium chemistry in out laboratory. Contribution of iodide anion as the nucleophile to attack the tellurium or the iodine atoms of **4** or **5** can be ruled out by the fact that the presence of large excess of NaI in the reaction of **1c** with PhTeNa did not affect the yield of the adduct. The fact that **5** did not give the quinodimethane in the reaction with PhTeNa in the presence of NaI may also indicated that iodide anion does not substitute for the $PhTe^-$ group in the benzylic positions under these reaction conditions. So Path B seems to be the most probable, but the alternative pathways such as electron transfer[13c] in some stage of the reaction could not be ruled out.

In conclusion a new and facile homogeneous reaction for the generation of *o*-quinodimethane by use of benzenetellurolate anion has been discovered. The key step of this reaction is proposed to be the nucleophilic attack of benzenetellurolate anion at tellurium of intermediate **4**.

Experimental

General. Instruments used were as follows: melting points, Yanagimoto Micro Melting Point Apparatus; ^1H NMR, Hitachi R-24B or Japan Electron Optics JNM-PS-100; IR, Shimadzu IR-400; MS, Hitachi RMU-6A. Chemical shifts are expressed in parts per million using tetramethyl-



Scheme 2.

silane (TMS) as the internal standard.

Diaryl ditellurides and diphenyl diselenide were prepared as discribed in the literature[23b,25] or by similar procedures. α,α'-Dihalo-*o*-xylenes, dienophiles, solvent (tetrahydrofuran: THF), and other materials used were all purchased from commercial sources and used after purification by distillation or recrystallization.

Reaction of α,α'-Dibromo-*o*-xylene with NaTeH. Following the reported procedure,[17] NaTeH was prepared from Te (5 mmol, 650 mg) and $NaBH_4$ (19.8 mmol, 750 mg, added in three portions) in EtOH (20 ml) at the reflux, and to this solution was added diethyl maleate (10 mmol, 1.6 ml) under N_2. Deposition of tellerium was observed at this stage. α,α'-Dibromo-*o*-xylene (5 mmol, 1.32 g) was then added and the mixture was heated at reflux for 5 h. After the precipitates were filtered, the product was extracted into ether and dried over $MgSO_4$. The solvent and remaining diethyl maleate were removed in vacuo and the residue was chromatographed on silica gel (benzene/ether=9/1) to give 24% of diethyl 2,3-tetralindicarboxylate.[4n,8]

General Reaction, Reaction of α,α'-Dibromo-*o*-xylene with PhTeNa. To a solution of PhTeNa generated from Ph_2Te_2 (5 mmol, 2.05 g) and $NaBH_4$ (10.5 mmol, 400 mg) in EtOH (30 ml) at 25 °C, was added a THF (15 ml) solution of ethyl acrylate(50 mmol) and α,α'-dibromo-*o*-xylene (5 mmol, 1.32 g). The mixture was refluxed for 2 h with stirring. The resulting red solution was then stirred in contact with the air overnight at 25 °C. The red color faded and a white precipitate was formed. The precipitate was filtered, and the product was extracted into ether and dried over $MgSO_4$. The solvent was evaporated and the residue chromatographed on silica gel (benzene) to give a 45% yield of ethyl 2-tetralincarboxylate.[4n,9]

Reaction of α,α'-Dibromo-*o*-xylene with Sodium Benzeneselenolate. A THF solution (5 ml) of α,α'-dibromo-*o*-xylene (1 mmol, 264 mg) was added at 25 °C to an ethanol solution (10 ml) of ethyl acrylate (5 mmol, 0.53 ml) and PhSeNa (2 mmol) generated from diphenyl diselenide (1 mmol, 313 mg) and $NaBH_4$ (2.1 mmol, 80 mg). The reaction was continued at reflux for 2 h. The solution turned slightly yellow and white precipitates were observed. GLC analysis showed no formation of the Diels-Alder adduct. After the reaction was complete, 20 ml of benzene was added to the mixture. The precipitates were filtered and the solvent evaporated. The residue was chromatographed on silica gel (pentane/ether=95/5) to give 316 mg of α,α'-bis(phenylseleno)-*o*-xylene[26] (0.75 mmol, 75% based on α,α'-dibromo-*o*-xylene used) and 150 mg (0.58 mmol) of ethyl 3-(phenylseleno)propionate: IR (neat) 2980, 1732, 1583, 1220, 1025, 739, 694 cm^{-1}; ^1H NMR(TMS, CCl_4) δ=1.22 (t, 3H, J=7.2 Hz), 4.07 (q, 2H, J=7.2 Hz), 7.10—7.55 (m, 5H) and essentially two triplets (2H, each) centered at δ=2.60 and δ=3.03, each line shows further fine splitting due to partial conformational freezing; MS (m/z, ^{80}Se) 258 (M^+); Found: C, 51.12; H, 5.51%. Calcd for $C_{11}H_{14}O_2Se$: C, 51.37; H, 5.49%.

Formation of Phthalaldehyde 6 from 1b. To an ethanol solution of PhTeNa (10 mmol in 30 ml) formed as described above was added α,α'-dibromo-*o*-xylene (5 mmol, 1.32 g) in THF (15 ml) and the reaction was refluxed for 2 h. The resulting mixture was exposed to the air at 25 °C and stirred overnight. The product was extracted into ether and dried. Evaporation followed by column chromatography on silica gel (benzene) gave **6**[27] in 60% yield.

Intermediacy of 5 in the Formation of Phthalaldehyde 6. To an ethanol solution (20 ml) of PhTeNa formed from Ph_2Te_2 (4.5 mmol, 1.85 g) and $NaBH_4$ (9.5 mmol, 360 mg)

was added a THF (20 ml) solution of **1b** (4.5 mmol, 1.19 g). The solution turned yellow and a white precipitate formed immediately. The mixture was stirred at 25 °C for 2 h. The solvent was removed in vacuo and benzene (50 ml) was added to the residue. The precipitate was filtered under N_2 and the filtrate was evaporated to give 1.91 g of a red solid. The NMR spectrum showed two singlets at δ 4.17 and δ 6.87 with 1:1 ratio which was assigned to the methylene and the aromatic protons of **5**, respectively, together with the aromatic protons of the PhTe groups of **5** and Ph_2Te_2 as the impurity (δ=7.20—7.50, m and δ=7.70—8.00, m). By subtracting the integral due to Ph_2Te_2 in the ^1H NMR spectrum, the yield of **5** was estimated to be 66%. In the MASS spectrum of the mixture, a peak appeared at 311 (**5**, *m/z*, M^+—PhTe) together with the parent peak of Ph_2Te_2 (*m/z*=414), but the parent peak of **5** was not observed. Allowing the NMR sample to stand at r.t., the peaks at δ 4.17 and δ 6.87 gradually decreased and a new peak appeared at δ 10.45 which was assigned to aldehyde protons of **6**. An attempt for isolation and purification of **5** failed due to its instability toward oxygen and/or light.

Polymerization of Styrene Adsolubilized in Surfactant Adsorbed Bilayer on Pigments

(Received April 7, 1986)

The polymerization of styrene adsolubilized in a surfactant-adsorbed bilayer formed on the surface of inorganic pigments (iron oxide, titanium dioxide) was attempted in order to modify their surface properties. After the polymerization, the amount of polystyrene formed on the pigments gradually increased with an increase in the amount of styrene adsolubilized. Further, the molecular weight of the polystyrene formed changed with an increase in the amount of styrene. The surface properties of pigments after the polymerization were characterized by FTIR-PAS, turbidity, and zeta potential measurements.

Recently, seeded polymerization has been employed to modify the surface properties of particles. Cho et al.[1] have studied the mechanism with respect to the emulsion polymerization of PMMA-seeded styrene. Similar research has been achieved by Okubo,[2,3] Whang,[4] Hawkett,[5] Morgan,[6] and Hergeth.[7] From their studies, it has been confirmed that the polymerization of organic polymers on the surfaces of organic substances occurs easily. However, when the polymerization of organic monomers is performed in the presence of inorganic particles, it is known that seed nucleation and the growth of organic monomers progress independently of the inorganic particles due to a deficiency of the affinity between monomers and inorganic particles.[8]

On the other hand, it has been reported that inorganic particles can be encapsulated by organic polymers due to an enhancement of the interfacial affinity by a treatment of water-soluble polymers[8,9] or monomers of the hydrophilic acrylic series.[10] It is also well-known[11] that ionic surfactants form adsorbed bilayers on particle surfaces. By using such adsorbed bilayers, there is a great possibility that hydrophobic monomers can be adsolubilized into the surfactant adsorbed bilayers which exhibit hydrophobic properties and can then be polymerized.

In this work, styrene was adsolubilized into surfactant bilayers on the surface of a pigment and the polymerization of styrene adsolubilized was examined.

Experimental

Materials. Iron oxide (α-Fe_2O_3) and titanium dioxide (anatase) used were supplied by Titan Kogyo Co. Ltd. The surface area of the former was 3.4 $m^2 g^{-1}$, and 40.7 $m^2 g^{-1}$ for the latter. Sodium dodecyl sulfate (SDS) was supplied by Wako Pure Chemical Industries, Ltd., which was purified twice by recrystallization from ethanol. Styrene obtained from Wako Pure Chemical Industries, Ltd., was distilled under reduced pressure. Other chemicals were of all analytical grade.

Procedure. All the polymerization was performed in a 1-liter separable flask under nitrogen gas purging. The polymerization temperature was controlled at 70 °C by a thermostatic water bath. Before polymerization, 1 g of the pigment and 100 ml of aqueous electrolyte solution ($FeCl_3$ for iron oxide, $AlCl_3$ for titanium dioxide) were mixed in order to obtain a pigment with a high positive zeta potential.[11] Then, in order to form adsorbed bilayers of surfactant on the pigment, 100 ml of a 15 mM SDS solution was added, whereas the zeta potential of the adsorbed bilayer on pigment surface was negative. Styrene (as a monomer) was adsolubilized into the adsorbed bilayers of the surfactant on the pigment under 400 rpm of agitation speed for 2 h and then potassium peroxodisulfate (as an initiator) was added into the solution. The weight ratio of potassium peroxodisulfate to styrene was 1:100. The obtained products were washed several times with ethanol.

The amount of ethylbenzene adsolubilized was determined by using the same solution mentioned above; the concentration of ethylbenzene was obtained by measuring the absorbance at 260 nm.

Measurements. The coated amount of polystyrene on the pigments was determined gravimetrically: The total amounts of polystyrene on the pigments were obtained from the difference of weight before and after the calcination of the samples at 500 °C. The THF-unextractive coated amount of polystyrene was also determined gravimetrically.

The zeta potential of uncoated and polystyrene-coated pigments was measured with an Electrophoresis apparatus (Laser Zee 500, Pen Kem, Inc.) in ethanol. The zeta potential of styrene latex prepared by using SDS alone was also measured for a comparison.

The turbidity of pigments in water or hexane was measured as follows: A known weight of sample was put into a sedimentation tube in which deionized water or hexane was contained and then the obtained suspension was treated by sonication for ten minutes. After one hour standing, the absorbance of the suspension was measured at 500 nm with a spectrophotometer (Hitachi, Ltd., 220A).

The weight-average molecular weight of polystyrene which had been extracted from the coated pigments with THF was determined by gel permeation chromatography (Japan Spectroscopic Co. Ltd.).

The surfaces of the coated pigments were measured using a FTIR-PAS (FPA-84, Japan Spectroscopic Co., Ltd.).

Results and Discussion

It is known[11] that positively charged particles can be flocculated and redispersed by the addition of anionic surfactants, resulting in the formation of an adsorbed

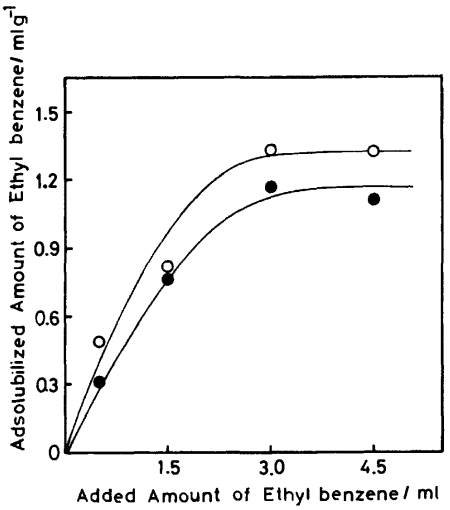

Fig. 1. The change in the amount of ethylbenzene adsolubilized into SDS-double layer on the pigment as a function of added amount of ethylbenzene at 25°C; (○) iron oxide, (●) titanium dioxide.

bilayer of surfactant on the particles. This adsorbed bilayer is expected to provide a field of polymerization of hydrophobic monomers since it exhibits hydrophobic property.

Figure 1 shows the amount of ethylbenzene adsolubilized into an SDS-adsorbed bilayer on the pigments as a function of the added amount of ethylbenzene at 25°C. Here, it is postulated that the amount of ethylbenzene adsolubilized is similar to that of styrene. In both pigments, the amount of ethylbenzene adsolubilized gradually increased and attained a constant value.

Then, the polymerization of adsolubilized styrene was carried out at 60°C using potassium peroxodisulfate as an initiator for 3 h. From a measurement of FTIR-PAS for the samples after polymerization, the absorption bands attributable to polystyrene (3200—2900 cm^{-1}, 1480—1360 cm^{-1}, 1130—1100 cm^{-1}) and SDS (1220 cm^{-1}, 1040 cm^{-1}) were observed, indicating that the surface of pigments are covered with a polystyrene layer.

Figure 2 shows the total amount of polystyrene and the THF-unextractive amount of polystyrene on pigments as a function of added amount of styrene. In the case of iron oxide, it is apparent that the THF-unextractive amount is approximately constant in spite of various added amounts. On the other hand, for titanium dioxide, the THF-unextractive amount was very small, but the THF-extractive amount increased with the added amount of styrene. The change in the weight-average molecular weight of the THF-extractive polystyrene as a function of the added amount of styrene is shown in Fig. 3. In the case of iron oxide, the weight-average molecular weight of the THF-extractive polystyrene decreased with an increase of the added amount of styrene. This result can be explained

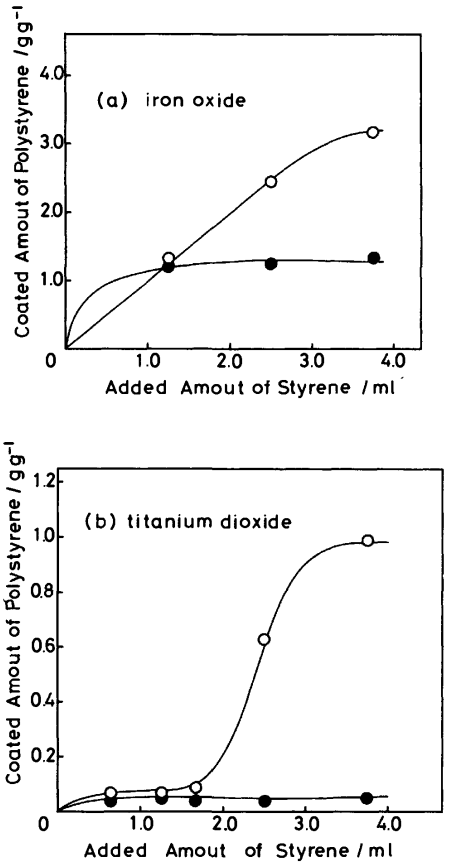

Fig. 2. The change in the coated amount of polystyrene on pigments as a function of added amount of styrene; (●) amount of unextractive polystyrene after THF extraction, (○) total coated amount of polystyrene.

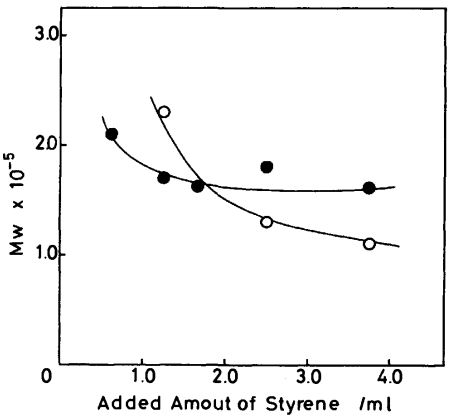

Fig. 3. The change in the weight-average molecular weight of THF-extractive polystyrene on pigment as a function of added amount of styrene; (○) iron oxide, (●) titanium dioxide.

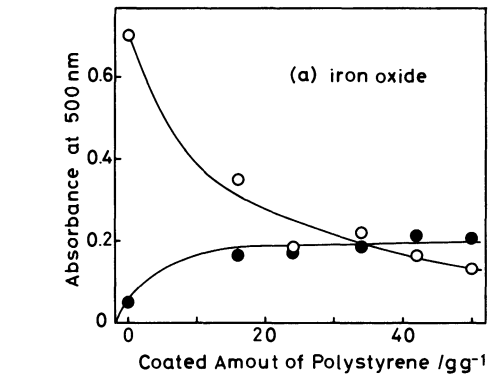
as follows: The adsolubilized amount of styrene gradually increases with the added amount of styrene, while the amount of the initiator becomes in excess against the adsolubilized amount of styrene, resulting in a decrease in the molecular weight. Similarly, in the case of titanium dioxide, the weight-average molecular



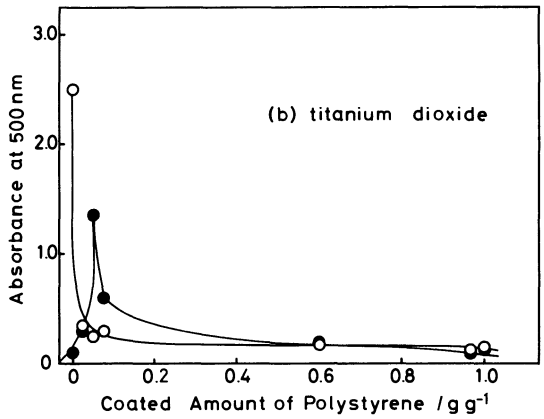


Fig. 4. The change in the absorbance at 500 nm as a function of coated amount of polystyrene on pigment; (○) in water, (●) in hexane.

weight decreases slightly. The zeta potential of the pigments after the polymerization was measured: the zeta potential was almost zero in ethanol compared with both the untreated sample and the latex prepared by using SDS alone having a large zeta potential, suggesting that the pigment surface is reasonably coated by polystyrene for both pigments.

Figure 4 shows the change in the absorbance of pigments after polymerization, in water and hexane, respectively. Here, a high absorbance value indicates a high stability. In water, the absorbance of both pigments decreased upon increasing the coated amount of polystyrene; however, in hexane an opposite change was observed for iron oxide, indicating that the surface of pigment becomes hydrophobic after polymerization. On the other hand, the absorbance of titanium dioxide in hexane showed a maximum value at some coated amount of polystyrene.

Schematics of the adsorbed bilayer of a surfactant adsolubilized with styrene and of pigment particles

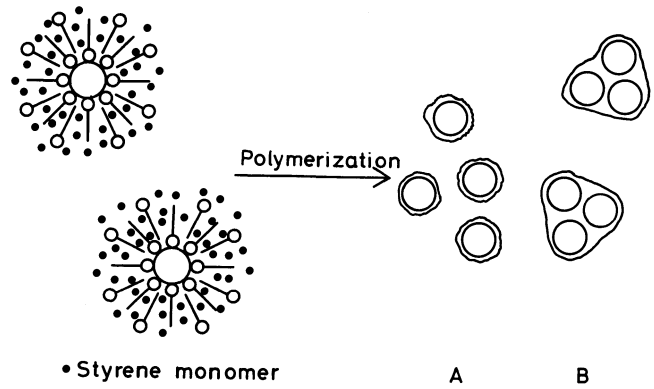

Fig. 5. Models of coated pigments by polystyrene.

after polymerization are presented in Fig. 5. For both iron oxide and titanium dioxide, there is a possibility that the coated pigments belong to model A or B since the coated amount of polystyrene and the molecular weight changed gradually with an increase in the added amount of styrene. Thus, it is concluded that this method of using a surfactant adsorbed bilayer is a useful encapsulation technique for the modification of a particle surface.

The authors are indebted to Japan Spectroscopic Co. Ltd., for measurement of FTIR-PAS.

State of Polarization of Light Scattered by Colored Spheroids

Yoh SANO* and Masayuki NAKAGAKI†
National Institute of Agrobiological Resources, Tsukuba Science City, Yatabe, Ibaraki 305

(Received April 9, 1986)

Using the light-scattering theory of Rayleigh–Gans for spheroids, theoretical expressions were derived for the polarization state of light scattered by randomly oriented small and colored spheroidal particles in the case of linearly polarized incident light with an angle of inclination of ψ to the scattering plane. The azimuth angle ζ of the ellipse of the scattered light did not depend on the axial ratio p and the relative complex refractive index m ($=m_0-ik_0$), but was a function of only the scattering angle θ and ψ; also, the ellipticity of the ellipse of the scattered light was always equal to 0 and the scattered light was partially linearly polarized for linearly polarized incident light. The degree of polarization of the scattered light for spheroidal particles, P, defined as the ratio of the polarized component to the intensity of the scattered light, depended strongly on p, m_0, k_0, and θ together with the angle ψ. This P was found to be smaller than 1. In the case of spherical particles, P was always equal to 1 at any θ; this means that the scattered light was perfectly polarized. It has been concluded that a determination of P as a function of ψ and θ gives good information regarding the shape and the optical constants (m_0 and k_0) of the colored spheroidal particles.

The light-scattering of colorless systems has been studied quite extensively by many investigators.[1,2] However, some biocolloids such as cytochrome C, hemoglobin, ferritin et al., dyes, membrane fragments or metal colloids are colored. These colored biocolloids or colloids often exhibit absorption maxima in the visible region. Under usual experimental conditions, incident light over a visible region is used. Therefore, the light-scattering phenomena are very complicated since we must take into consideration the effects of the absorption together with light scattering. In the case of colored spherical particles, the extinction, scattering and absorption of light have been theoretically studied by means of the Mie theory.[3,4] For absorbing spheroidal particles, the electrodichroic ratio has also been calculated as well as the effect of a complex refractive index and of the axial ratio of the spheroids upon the electrodichroic ratio.[5] However, to the author's knowledge no theory exists for taking into consideration the anisometry effect on the scattering and absorption of light by colored nonspherical particles.

Even if we use completely polarized incident light, the scattered light by anisotropic scatterers will generally be partially polarized and will contain an unpolarized component, since the direction of the induced dipole in an anisotropic particle is different from the direction of the electric vector of incident light. To give a complete description of a partially elliptically polarized beam of scattered light, we must state the intensity associated with both the polarized and unpolarized components, and also give the full specification of the polarized ellipse.

Three parameters must be used to completely define the elliptical polarization of the scattered light: that is, the ratio of the minor and the major axes of the ellipse, η (called the ellipticity), the inclination ζ of the major semi-axes of the ellipse with respect to the scattering plane (called the azimuth), and the direction of the motion of the end point of the electric vector of the light (similarly defined as for circular polarization). Ellipticity can vary between zero and unity, and the azimuth angle varies between 0 and $\pm 90°$. Linear and circular forms of polarization can be defined as special cases of elliptical polarization, that is, the ellipticity is 0 or 1, respectively.

The purpose of this work was to study the light scattering of a colored system having a complex index of refraction due to absorption in the above-mentioned visible region. For this purpose, the state of polarization of light scattered by randomly oriented, identical colored spheroidal particles was calculated on the basis of Rayleigh[6] and Gans[7] theorem. This will always be refered to as the Rayleigh–Gans theory of spheroids (RGS theory) in order to avoid any confusion with the well-known Rayleigh–Gans (RG) scattering theory involving the restrictive assumption that the refractive index of a particle is close to that of the surrounding medium.

Theory

General Consideration. Let us consider a system of colored and relatively small spheroidal particles dispersed in a colorless medium, where the dispersed phase (consisting of the particles) is optically isotropic and has neither intrinsic birefringence nor intrinsic dichroism. When linearly polarized incident light with its electric vector oriented obliquely to the scattering plane (observation plane) reaches the scattering volume element, the scatterer changes the state of light polarization and the scattered light generally becomes elliptically polarized, but contains unpolarized component as well.

All the possible states of the scattered light can be most easily analyzed by making use of Stokes parameters, and a Mueller or scattering matrix which depends only on the characteristics of the scattering medium.[8] The Stokes parameters (I, Q, U, and V), which completely characterize the intensity and the polarization properties of a beam of light, including

partially polarized and unpolarized light, is defined in terms of time averages of the electric-field components of an electromagnetic wave.

$$\begin{aligned} I &= \langle E_\pi E_\pi^* + E_\sigma E_\sigma^* \rangle, \\ Q &= \langle E_\pi E_\pi^* - E_\sigma E_\sigma^* \rangle, \\ U &= \langle E_\pi E_\sigma^* + E_\sigma E_\pi^* \rangle, \\ V &= \mathrm{i}\langle E_\pi E_\sigma^* - E_\sigma E_\pi^* \rangle. \end{aligned} \tag{1}$$

The subscripts π and σ refer to components of the electric field parallel and perpendicular, respectively, to the scattering plane, the brackets denote time averages, and an asterisk denotes a conjugate complex value. The four elements of the Stokes vector can be thought of as describing the total intensity (I), the excess π-polarization over the σ-polarization intensity (Q), the excess intensity of +45° linear polarization over −45° linear polarization (U), and the excess of right (as opposed to left) circular polarization intensity (V).

The Stokes vectors describing incident, $\boldsymbol{S}_0$, and scattered, $\boldsymbol{S}$, light are connected by a 4×4 matrix called Mueller's matrix or scattering matrix, $\boldsymbol{M}$,

$$\boldsymbol{S} = \boldsymbol{M}\boldsymbol{S}_0, \tag{2}$$

where $\boldsymbol{S}=[I, Q, U, V]$ and $\boldsymbol{S}_0=[I_0, Q_0, U_0, V_0]$ are the Stokes vectors of the incident and scattered light.

Scattering Matrix. The matrix elements are functions of Euler's angles, the scattering angle θ and the optical constants of the particle. If a particle is sufficiently small compared to the wavelength of light, it can be assumed that one dipole is introduced in the particle and that the oscillation of the dipole radiates scattered light according to a theorem proposed by Rayleigh[6] and Gans[7] (RGS theory). The scattering matrix $\boldsymbol{M}$ for randomly oriented spheroids in suspension is given by the following form (discussed by Van de Hulst[9]):

$$\boldsymbol{M} = \begin{pmatrix} S_{11} & S_{12} & 0 & 0 \\ S_{12} & S_{22} & 0 & 0 \\ 0 & 0 & S_{33} & 0 \\ 0 & 0 & 0 & S_{44} \end{pmatrix}, \tag{3}$$

where the matrix elements S_{11}, S_{12}, S_{22}, S_{33}, and S_{44} depend upon the shape of the particle and its complex refractive index. Averaging over Euler's angles for a completely random orientation of particles gives[10]

$$\begin{aligned} S_{11} &= F_1(1+\cos^2\theta) + 2|B|^2/15, \\ S_{12} &= F_1(\cos^2\theta - 1), \\ S_{22} &= F_1(\cos^2\theta + 1), \\ S_{33} &= 2F_1\cos\theta, \text{ and} \\ S_{44} &= (2F_1 - 2|B|^2/15)\cos\theta, \end{aligned} \tag{4}$$

where

$$F_1 = \{|A|^2 + 2[\mathrm{Re}A\cdot\mathrm{Re}B + \mathrm{Im}A\cdot\mathrm{Im}B]/3 + 2|B|^2/15\}/2. \tag{5}$$

ReA and ImA are the real and imaginary parts of A, respectively. In the case of a spheroidal particle, A and B are calculated as:

$$\begin{aligned} A &= \alpha^3(m^2-1)/\{3p^2[1+(m^2-1)L_b]\}, \text{ and} \\ B &= \alpha^3(m^2-1)/\{3p^2[1+(m^2-1)L_a]\} - A, \end{aligned} \tag{6}$$

where the parameter α is the relative particle radius defined by

$$\alpha = 2\pi a/\lambda. \tag{7}$$

Here, a is the length of semiaxis symmetry for the spheroid, and λ is the wavelength of light in the medium. The shape parameters L_i in the i-direction (i=a or b) are functions of the axial ratio p (=a/b) for a prolate ($p>1$) and an oblate ($p<1$) spheroid[11]

$$\begin{aligned} L_b(p>1) &= (1/2)[p^2/(p^2-1)][1-(1/\{p(p^2-1)^{1/2}\})\times \\ &\qquad \ln\{p+(p^2-1)^{1/2}\}], \\ L_b(p<1) &= (1/2)[p^2/(1-p^2)][(1/\{p(1-p^2)^{1/2}\})\arccos p - 1], \end{aligned} \tag{8}$$

and

$$L_a + 2L_b = 1. \tag{9}$$

The refractive index, n_2, of a colored particle is complex and can be written[9] as

$$n_2 = n_{20}(1-\mathrm{i}k). \tag{10}$$

Then, the relative complex refractive index, m, is

$$m = n_2/n_0 = m_0 - \mathrm{i}k_0, \tag{11}$$

where n_0 is the refractive index of the colorless medium; also,

$$m_0 = n_{20}/n_0 \text{ and } k_0 = m_0 k. \tag{12}$$

If the particle is colorless, k and k_0 are both zero.

State of Polarization of the Scattered Light. The scattered light is, in general, partially polarized. The partially polarized light behaves as an incoherent sum of the totally polarized, I_p (subscript "p" signify the polarized component), and the unpolarized, I_u (subscript "u" signify unpolarized), components. Both components are related to the Stokes parameters of the scattered light (I, Q, U, V) as follows:

$$\begin{aligned} I_p &= (Q^2+U^2+V^2)^{1/2}, \text{ and} \\ I_u &= I - I_p. \end{aligned} \tag{13}$$

In general, the polarized component is elliptically polarized, i.e., the end point of the electric vector moves periodically along an ellipse, which may, of course, reduce in special cases to a circle or a straight line. It is often convenient and sufficient for many experiments to give what is known as the degree of polarization of the light, together with a description of the shape,

azimuth and handedness of the ellipse of the polarized component of the scattered light. The degree of polarization, P, is defined as the ratio of the intensity of the polarized portion to the total intensity[12]

$$P = I_p/I. \tag{14}$$

It is generally known that the description of the polarization ellipse of the scattered light is also related to the Stokes parameters of the scattered light as follows:[12]

(1) The azimuth angle of the ellipse of the polarized component is

$$\zeta = (1/2) \arctan (U/Q), \text{ and} \tag{15}$$

(2) the ellipticity, η, of the ellipse is deduced from

$$2\eta/(1+\eta^2) = V/(Q^2+U^2)^{1/2}. \tag{16}$$

The linear polarization corresponds to $\eta=0$.

If we consider linearly polarized incident light with an electric vector that subtends an angle ψ with the scattering plane, the normalized Stokes parameters of the incident light beam are

$$I_0 = 1, Q_0 = \cos 2\psi, U_0 = \sin 2\psi, \text{and } V_0 = 0. \tag{17}$$

By substituting S_0 in Eq. 2, we can obtain the Stokes parameters of scattered light, and we can calculate the characteristics of each parameter of a partially polarized scattered light as follows:

$$\begin{aligned} &I_p = I_p^\circ(1-\sin^2\theta\cos^2\psi),\\ &I = I_p^\circ(1-\sin^2\theta\cos^2\psi) + I_u,\\ &I_u = 2|B|^2/15, I_p^\circ = 2F_1,\\ &\tan\zeta = \tan\psi/\cos\theta, \text{and}\\ &\eta = 0. \end{aligned} \tag{18}$$

According to the RGS theory for an electric dipole, the I_u term is only a function of B; this indicates an optical anisotropy. The term I_p is linearly polarized when the incident light is linearly polarized. This is because the direction of the induced dipole is different from the direction of the incident electric vector due to the anisometry of the particle.

The total intensity I during RGS scattering can be divided into two parts: one is the polarized component I_p which depends on the scattering angle θ together with ψ, m_0, k_0, and p, and the other is the unpolarized component I_u which is independent of the scattering angle and the angle of inclination of the incident light ψ.

According to Eqs. 6, 11, and 18, the intensities I and I_p are zero if k_0 is zero and m_0 is unity. That is, scattering does not occur in a colorless system if the refractive index of particles and the medium are equal. In the case of a colored system, however, scattering occurs even when m_0 is equal to unity. Generally, there exists no value of m_0 which can make the intensities I and/or I_p equal to zero when k_0 is not zero.

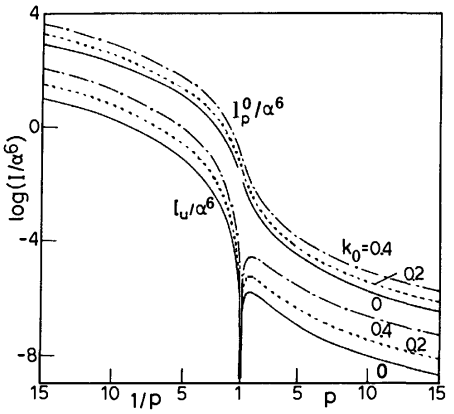

Fig. 1. Variation of $\log(I_u/\alpha^6)$ and $\log(I_p^\circ/\alpha^6)$ with the axial ratios p for spheroids of $m_0=1.20$ and various k_0 values; $k_0=0$ (——), $k_0=0.2$ (----), and $k_0=0.4$ (—·—). For the oblate ($p<1$) spheroids, $1/p$ (instead of p) is plotted on the abscissa to the left direction.

For an isotropic, spherical, colloidal particle, that is for Rayleigh scattering, the degree of polarization is always equal to 1 over the entire range of θ since $B=0$. In the case of spheroids, the degree of polarization is smaller than 1 and depends on m_0, k_0, and p, but it is independent of α in the RGS approximation.

In the case of linearly polarized incident light, the ellipticity, η, of the polarized component of the scattered light is equal to 0; this means that the component is linearly polarized. The azimuth angle of the polarized component, ζ, for the spheroids as well as for the spherical particles is equal to 90° in the case of $\theta=90°$ (according to Eq. 18) for both colored and colorless systems. The ζ is equal to ψ when $\theta=0°$; this means that the direction of the electric field of the forward-scattered light is equal to that of the incident light for both Rayleigh scattering as well as the RGS approximation (if the orientation of particles is completely random).

Numerical Results and Discussion

Variation of the Intensity of the Scattered Light. Numerical calculations were made with an ACOS 850/20 computer at the Computer Center of the Ministry of Agriculture and Forestry. Figure 1 shows the variation of the intensities of the scattered light for the unpolarized component I_u and the maximum of the polarized component I_p° for prolate and oblate spheroids in the case $k=k_0/m_0<1$ (that is $k_0<m_0$) as a function of the axial ratio p and of a given m_0 value (the case $m_0=1.20$ is given as an example). We call the quantity I (as well as I_p and I_u) the "intensity" of the scattered light; however, it is actually a dimensionless quantity which is equal to the Rayleigh ratio multiplied by $(2\pi/\lambda)^2$ per particle. The scattered intensities, I_u and I_p°, for a colored system become greater with increasing k_0 since they include absorp-

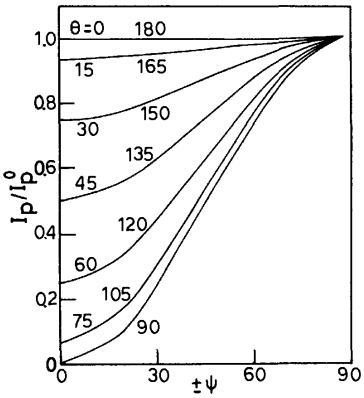

Fig. 2. Variation of I_p/I_p° with $\pm\psi$ (degree) for various values of θ. Dependences on m_0, k_0, α, and p are cancelled by taking the ratio of I_p to I_p°, in the RGS approximation.

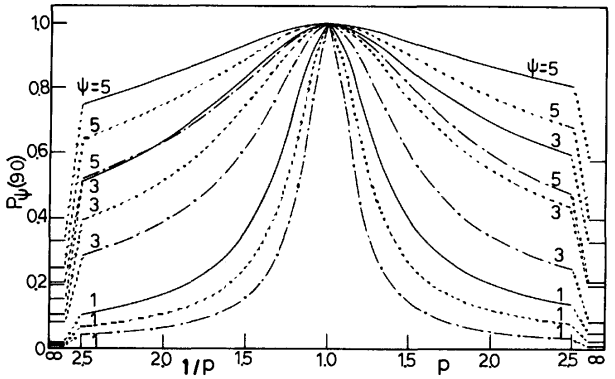

Fig. 3. Variation of the degree of polarization at $\theta=90°$, $P_\psi(90)$, with axial ratio of the prolate spheroid (p) or of the oblate spheroid ($1/p$) at $m_0=1.20$ and various k_0 values; $k_0=0$ (——), $k_0=0.2$ (– – –), and $k_0=0.4$ (—·—). Horizontal lines on both sides indicate the limiting values at $p\to\infty$ (infinitesimally thin rod) and $p\to0$ (infinitesimally thin disk), respectively.

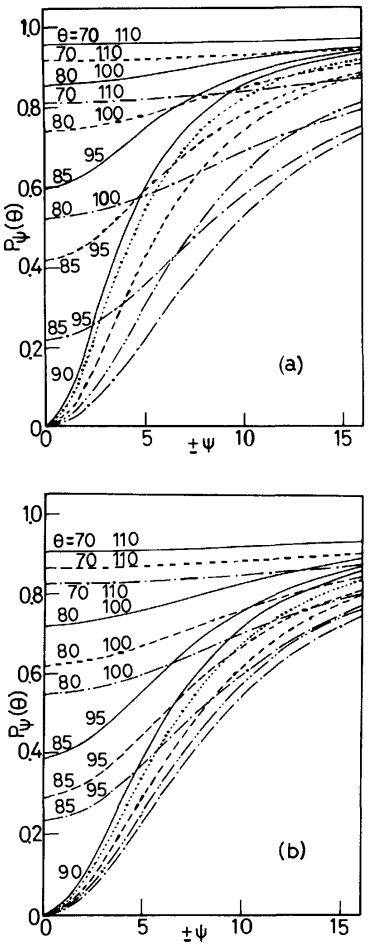

Fig. 4. Variation of the degree of polarization, $P_\psi(\theta)$ with ψ (degree) for (a) the prolate spheroid at $p=15$ and (b) the oblate spheroid at $p=1/15$ and $m_0=1.20$. Parameters are scattering angle θ (degree). The $P_\psi(\theta)$ for various k_0 values at $\theta=90°$ indicates $k_0=0$ (——), $k_0=0.1$ (------), $k_0=0.2$ (------), $k_0=0.3$ (—··—), and $k_0=0.4$ (—·—).

tion contributions to the scattering.

Figure 2 shows the variation of the polarized component I_p with the azimuth angle of the linearly polarized incident light ψ. By taking the ratio I_p/I_p°, all dependencies on m_0, k_0, α, and p can be cancelled just as in an RGS approximation. As shown in Eq. 18, the intensities I_p and I are functions of $\cos^2\theta$; therefore, they are symmetric around the $\theta=90°$ axis.

Variation of the Degree of Polarization. The degree of polarization P defined by Eq. 14 is, together with Eq. 18,

$$P_\psi(\theta) = (1-\sin^2\theta\cos^2\psi)/[(1-\sin^2\theta\cos^2\psi) + I_u/I_p^\circ]. \tag{19}$$

Thus, when $\theta=90°$,

$$P_\psi(90) = \sin^2\psi/(\sin^2\psi + I_u/I_p^\circ). \tag{20}$$

Figure 3 shows the variation of P_ψ (90) with the axial ratio p of the spheroids for various k_0 and ψ at $m_0=1.20$. The P_ψ (90) depends strongly on p and ψ, especially for a ψ value smaller than 5°. The P_ψ (90) is nearly equal to 1.0 if ψ is larger than 45° since I_u is about 1/100 of I_p° (Fig. 1). If $p=1$, P_ψ (90) is equal to 1.0 irrespective of the value of ψ and k_0 since I_u is equal to zero. The dependence of P_ψ (90) on p becomes greater as k_0 increases. Also, P_ψ (90) decreases monotonously upon increasing of p or $1/p$.

The horizontal lines in Fig. 3 are the limiting values for $p\to\infty$ ($L_a=0$ and $L_b=1/2$) on the right side and for $p\to0$ ($L_a=1$ and $L_b=0$) on the left side. The P_ψ (90) for an infinitesimally thin disk is much smaller than that for the rodlike particle.

Figure 4 shows the variation of the degree of polarization, $P_\psi(\theta)$, in Eq. 19 with $\pm\psi$ at various scattering angles θ. The cases of a prolate spheroid at $p=15$ and of an oblate spheroid at $p=1/15$ are shown here as examples. The intensities, I and I_p, are functions of $\sin^2\theta$; therefore, the degree of polarization is also symmetric around $\theta=90°$. At $\theta=90°$, $P_\psi(\theta)$ increases monotonously from 0 to almost 1 with an

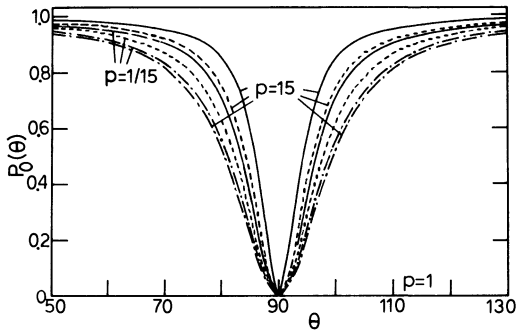

Fig. 5. Variation of the degree of polarization, at $\psi=0$, $P_0(\theta)$, for the prolate spheroid at $p=15$, the oblate spheroid at $p=1/15$, the spherical particle ($p=1$) of $m_0=1.20$ and various k_0 values; $k_0=0$ (——), $k_0=0.2$ (----), and $k_0=0.4$ (—·—).

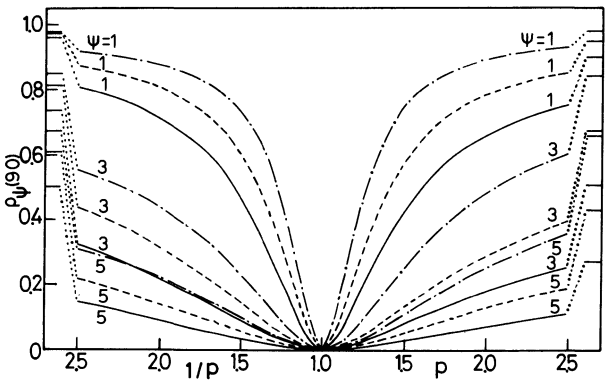

Fig. 6. Variation of the degree of depolarization at $\theta=90°$, $\rho_\psi(90)$, with axial ratio p or $1/p$ for $m_0=1.20$ and various k_0 values; $k_0=0$ (——), $k_0=0.2$ (----), and $k_0=0.4$ (—·—).
Horizontal lines on both sides indicate the limiting values at $p\to\infty$ (infinitesimally thin rod) and $p\to0$ (infinitesimally thin disk), respectively.

increase in $\pm\psi$; its value at a given ψ decreases with increasing k_0. The $P_\psi(\theta)$ at constant θ increases monotonously with an increasing $\pm\psi$. The dependence of $P_\psi(\theta)$ on $\pm\psi$ becomes smaller as the deviation of θ from 90° becomes larger and is larger as k_0 becomes larger. The variation of $P_\psi(\theta)$ for an oblate spheroid is shown in Fig. 4(b). The value of the degree of polarization $P_\psi(\theta)$ for an oblate spheroid at $p=1/15$ is a little smaller than that for a prolate spheroid at $p=15$ since an oblate spheroid has two major axes (b) which are responsible for producing an unpolarized component of scattered light while the prolate spheroid has only one major axis (a).

For $\psi=0°$, Eq. 19 can be rewritten as:

$$P_0(\theta) = \cos^2\theta/[\cos^2\theta + I_u/I_p^\circ] \tag{21}$$

Figure 5 shows the variation of $P_0(\theta)$; its value is symmetric around $\theta=90°$ and increase from 0 to almost 1. The $P_0(\theta)$ at $\theta=85°$ (or 95°) for a colorless system ($k_0=0$) is about 0.6, since $\cos^2 85°=0.0076$ (which is of the order of magnitude of $I_u/I_p°$). For a colored system $P_0(85)$ is about 2/3 of that for a colorless system at $k_0=0.2$ and about 1/3 at $k_0=0.4$.

Variation of the Degree of Depolarization. It has been said that the various kinds of degrees of depolarization to be defined can be given as combinations of two fundamental degrees of depolarization, ρ_π and ρ_σ:

$$\begin{aligned}\rho_\pi(\theta) &= I_{\pi\pi}(\theta)/I_{\pi\sigma}(\theta), \text{ and}\\ \rho_\sigma(\theta) &= I_{\sigma\pi}(\theta)/I_{\sigma\sigma}(\theta),\end{aligned} \tag{22}$$

where π and σ indicate the parallel and perpendicular directions, respectively, of the electric vector of light to the scattering plane. The first and the second subscripts are for incident and scattered light, respectively.[13] For example, the degree of depolarization for unpolarized incident light, ρ_u, is given by ρ_π and ρ_σ as

$$\rho_u = \frac{I_{u\pi}}{I_{u\sigma}} = \frac{I_{\pi\pi}+I_{\sigma\pi}}{I_{\pi\sigma}+I_{\sigma\sigma}} = \rho_\sigma\frac{1+\rho_\pi}{1+\rho_\sigma} \tag{23}$$

if the particles are either spherical or spheroids oriented completely randomly so that the following Krishnan reciprocity theorem holds.

$$I_{\pi\sigma} = I_{\sigma\pi}. \tag{24}$$

In the RGS approximation for completely random orientation,[14]

$$\begin{aligned}I_{\pi\pi}(\theta) &= I_p^\circ\cos^2\theta + (1/2)I_u,\\ I_{\pi\sigma}(\theta) &= I_{\sigma\pi}(\theta) = (1/2)I_u, \text{ and}\\ I_{\sigma\sigma}(\theta) &= I_p^\circ + (1/2)I_u.\end{aligned} \tag{25}$$

Therefore, for unpolarized incident light

$$\rho_u(\theta) = [\cos^2\theta + I_u/I_p^\circ]/[1+I_u/I_p^\circ]. \tag{26}$$

This is equal to $\cos^2\theta$ and is not equal to zero, even if the unpolarized component I_u is zero (if the angle θ is other than 90°). For $\theta=90°$,

$$\rho_u(90) = I_u/[I_p^\circ+I_u] = 1 - P_{90}(90), \tag{27}$$

where $P_{90}(90)$ is the degree of polarization for $\psi=90°$ and $\theta=90°$.

Instead of unpolarized light, if linearly polarized light with the azimuth angle of ψ is used as the incident light, the degree of depolarization is

$$\rho_\psi(\theta) = \frac{I_{\psi\pi}(\theta)}{I_{\psi\sigma}(\theta)} = \frac{I_{\pi\pi}(\theta)\cos^2\theta + I_{\sigma\pi}(\theta)\sin^2\theta}{I_{\pi\sigma}(\theta)\cos^2\theta + I_{\sigma\sigma}(\theta)\sin^2\theta} \tag{28}$$

In the RGS approximation,

$$\rho_\psi(\theta) = [2\cos^2\psi\cos^2\theta + I_u/I_p^\circ]/[2\sin^2\psi + I_u/I_p^\circ], \tag{29}$$

and, for $\theta=90°$

$$\rho_\psi(90) = I_u/[2I_p^\circ\sin^2\psi + I_u]. \tag{30}$$

These equations show that for $\psi=0°$, $\rho_0(90)=\rho_\pi(90)=1$; for $\psi=90°$, $\rho_{90}(\theta)=\rho_\sigma(\theta)=I_u/[2I_p°+I_u]$ which is independent of θ and is very small because $I_u/I_p°$ is the order of 10^{-2} as was shown in Fig. 1; for $\psi=45°$, $\rho_{45}(\theta)=\rho_u(\theta)$ is approximately equal to $\cos^2\theta$ if θ is different

from 90°, but at $\theta=90°$, $\rho_u(90)$ is nearly equal to $2\rho_\sigma$ and is very small at the order of 10^{-2}.

In the RGS approximation, the variation of $\rho_\psi(90)$ for various ψ values as a function of the axial ratio p of the particle for $m_0=1.20$ is shown in Fig. 6. It seems to be very similar to Fig. 3 if the direction of the ordinate is inverted.

For the Determination of Parameter Values. As is shown in Figs. 3—6, the degree of polarization or degree of depolarization strongly depends on the axial ratio p, m_0, and k_0 of the spheroids, and is independent of α. If we measure $P_\psi(\theta)$, $P_\psi(90)$, or $P_\psi(90)$, the axial ratio for a colorless system is determined directly if the value of m_0 is known. For a colored system, if we measure $P_\psi(\theta)$ at several values of ψ and θ, it is possible to determine both k_0 and p from the curve-fitting method to the theoretical values and to determine whether the particle is prolate or oblate. On the contrary, if the value of the axial ratio p of the colored spheroid is known from the other physicochemical techniques, it is also possible to determine both m_0 and k_0 values of the colored spheroid. In conjunction with the knowledge of the axial ratio, the value of α is also obtained from the values of the intensities (I, I_p, and I_u), which are obtained simultaneously. Knowledge about α and p immediately gives information regarding the molecular weight M of the spheroid (for both colored and colorless systems) if the partial specific volume is known separately.

The value of k_0 can be large if the particles are colored. It can even be infinitely larger if the particles are made of a good conductor; however, the extinction of the dispersed system as a whole can be made as small as possible in experiments by diluting the dispersed system. Therefore, extremely small k_0 values are experimentally interesting. In particular, the value of the refractive index of a colored system is not practically equal to that of a colorless system if the value of k_0 is larger than 10^{-4}.[3]

Measurement of Degree of Polarization with the Analyzer. The intensity of the irradiance transmitted through the analyzer with a transmission axis inclined by χ to the scattering plane, $I_{\psi\chi}(\theta)$, is calculated by using the Mueller matrix for an ideal linear analyzer as follows:[8]

$$I_{\psi\chi}(\theta) = (I_u/2) + I_p\{1+\cos 2(\chi-\zeta)\}/2 = I\frac{1+P_\psi(\theta)\cos 2(\chi-\zeta)}{2}, \quad (31)$$

where ζ is the azimuth angle of the scattered polarized component. In the case of the degree of depolarization the two special cases of $\chi=0°$ (parallel) and $\chi=90°$ (perpendicular to the scattering plane) is generally discussed.

The variation of $I_{\psi\chi}(\theta)$ is shown in Fig. 7. When χ is changed by rotating the analyzer, the intensity of the transmittance $I_{\psi\chi}(\theta)$ has maximum, $I_{max}(\theta)$, and minimum, $I_{min}(\theta)$, values at $\chi=\zeta$ and $\chi=\zeta+\pi/2$, respectively

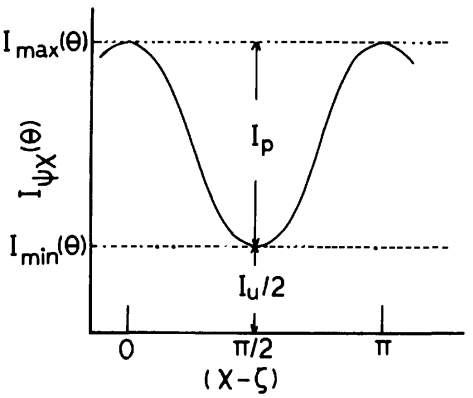

Fig. 7. Variation of transmitted intensity of the partially polarized light with analyzer orientation.

(Fig. 7). The degree of polarization can, therefore, be experimentally measured by rotating the analyzer by using

$$P_\psi(\theta) = [I_{max}(\theta)-I_{min}(\theta)]/[I_{max}(\theta)+I_{min}(\theta)]. \quad (32)$$

This is equivalent to thinking of the beam as being made up of two linearly polarized orthogonal incoherent beams with intensities $I_{max}(\theta)$ and $I_{min}(\theta)$.

As mentioned in the INTRODUCTION, it is important to determine the size and shape of the colored biocolloids such as cytochrome C, hemoglobin, ferritin et al., dyes, membrane fragments prepared from the plant plasma membrane, and/or the various kinds of metal colloids. It is also important to determine the k_0 values in order to determine the physico-chemical properties of these colored molecules. For this purpose, the theory presented in this paper can be efficiently applied to these colored systems.

(Received April 11, 1986)

The ESR spectra of spin-labeled sodium dodecyl sulfate were examined by changing the concentration, temperature, and ionic strength. The broadening of ESR lines due to a monomer surfactant could be explained in terms of an electron-spin exchange and a monomer-micelle exchange. The spin-exchange rate increased with increasing temperature and decreased with increasing ionic strength, i.e., the spin-exchange frequency was closely related to the viscosity of the medium. On the basis of an analysis of the line width above the critical micelle concentration, it was found that the aggregation number of the micelle of this compound and the monomer-micelle exchange frequency were dependent on the ionic strength.

Recent investigations on the micelle have stressed its dynamic properties. The diffusion coefficients of the micelles have been obtained by means of quasi-elastic light-scattering spectroscopy.[1,2] Kinetic studies of micellar systems by pressure-jump, temperature-jump, and ultrasonic absorption have shown that there are two relaxation processes for micelle formation.[3] The slow process, which is characterized by a relaxation time of the order of 10^{-3} s, represents the fluctuation of the total number of the micelles. On the other hand, the fast relaxation process of the order of 10^{-6} s corresponds to the association/dissociation equilibrium of monomeric ion to/from micelles. The NMR and ESR spectra also give useful information regarding the monomer-micelle exchange frequency. NMR data showed that its exchange frequency was below 10^{-5} s.[4] Nakagawa and Jizomoto[5] demonstrated that the lifetime of the spin probe molecules solubilized into micelle was 10^{-6} s. However, there are only a few reports on the dynamic properties of micelles composed of spin-labeled surfactants. Of these, Fox[6] studied the monomer-micelle exchange using cationic surfactant spin-labeled at polar head group and reported that the line broadening due to the monomer-micelle exchange was not observed. On the other hand, Schmidt et al.[7] have investigated the kinetics on micellization of spin-labeled lecithin and correlated the line broadening above the critical micelle concentration (cmc) to the monomer-micelle exchange reaction.

Here, it would be important to confirm the existence of the monomer-micelle exchange by the ESR spectra and, furthermore, to obtain information regarding the dynamic behavior of surfactant molecules in micellar solutions. From such a standpoint, we synthesized the spin-labeled sodium dodecyl sulfate (SL-SDS) labeled with a nitroxide radical.[8,9] Using this spin-labeled surfactant, we studied the properties of an aqueous SL-SDS solution in the absence of salt on the basis of its ESR spectra and conductivity data.[9] In the present work, the effect of added salt on the spin-exchange interaction and the micelle formation of SL-SDS is described.

Experimental

Materials. SL-SDS, sodium salt of 2-ethyl-2-[9-(hydroxysulfonyloxy)nonyl]-4,4-dimethyl-3-oxazolidinyloxyl, was synthesized by the procedure previously described.[8,9]

Viscosity. The viscosity of the medium containing NaCl was calculated according to the Othmer rule.[10,11]

Measurement of ESR. The samples were carefully deoxygenated by the repetitive freeze-thaw technique and then substituted by a dry nitrogen gas. ESR measurements were carried out with a JEOL FE-1X spectrometer equipped with a variable temperature accessory. The temperature control was checked with a copper-constantan thermocouple and was found to be stable within ±0.5°C. The usual spectrometer settings were 100 KHz modulation amplitude, 0.5 G; microwave power, 1 mW; scan range, 200 G; scan speed, 8 min.

Results and Discussion

As we have already noted regarding the properties of an aqueous SL-SDS solution without added salt, the three sharp ESR lines due to nitroxide radicals become broad and eventually coalesce into a single broad line with increasing radical concentration. Such spectral changes have been interpreted in terms of an electron-spin exchange.[9,12] On the basis of the conductivity data, it has been determined that the cmc of SL-SDS is 21.6 mmol kg^{-1} at 25°C and its aggregation number is about 6.[9] Because of a small aggregation number and its high cmc, such superimposed ESR signals due to monomer and micellar surfactants as seen above cmc in other spin-labeled surfactants[6,7] were not observed. Figure 1 shows the ESR spectra of 50 mmol kg^{-1} SL-SDS solutions containing various concentrations of NaCl (0.1—1.0 mol kg^{-1}). The ESR signal in the absence of NaCl was considerably distorted with an increased number of collisions between surfactant molecules. With an increasing NaCl concentration, however, the triplet lines due to monomer surfactant became sharp and a single broad line ascribed to the micelles gradually appeared at the central field. This suggests that, with increasing the amount of added salt, the aggregation number of the micelles increases and the monomer concentration decreases.

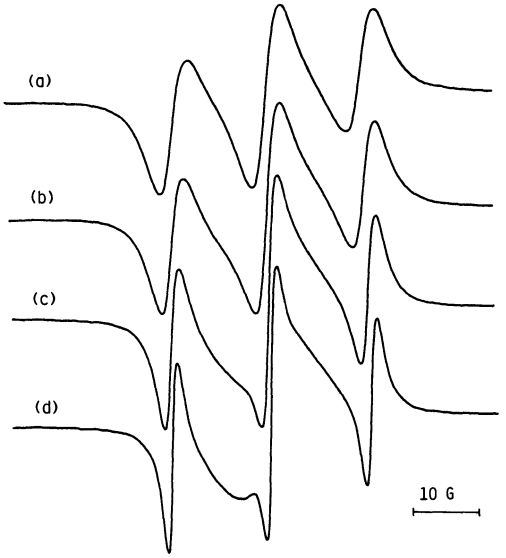

Fig. 1. ESR spectra of 50 mmol kg^{-1} SL-SDS solution containing a) 0, b) 0.1, c) 0.5, and d) 1.0 mol kg^{-1} NaCl, respectively, at 19°C.

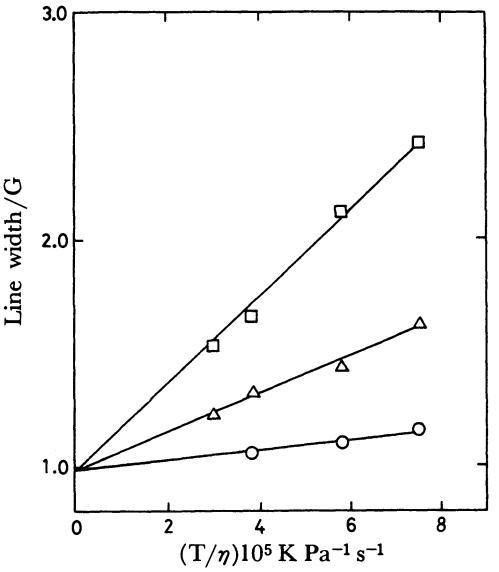

Fig. 3. Width of the $M=+1$ line vs. T/η for SL-SDS solution containing 1 mol kg^{-1} NaCl in 1 (○), 4 (△), and 8 mmol kg^{-1} (□), respectively.

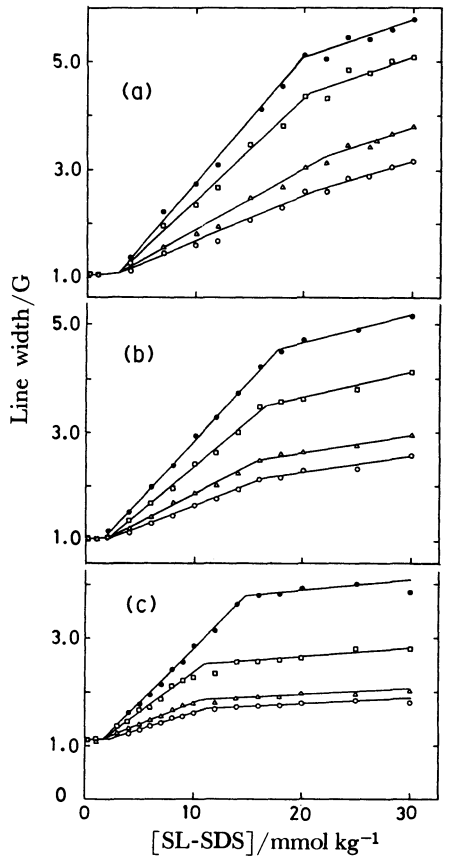

Fig. 2. Width of the $M=+1$ line vs. concentration of SL-SDS at 25 (○), 35 (△), 55 (□), and 70°C (●) in the presence of 0.1 (a), 0.5 (b), and 1.0 mol kg^{-1} NaCl (c).

As shown in Fig. 2, the relationship between the line width of the signal ($M=+1$ line, where M is the nuclear spin quantum number) at low field and SL-SDS concentration was examined at various temperatures (25, 35, 55, and 70°C) and NaCl concentrations (0.1, 0.5, and 1.0 mol kg^{-1}). The plots of the line width vs. the SL-SDS concentration show two inflection points. At low concentrations of SL-SDS (0.5 and 1.0 mmol kg^{-1}), the line widths were almost independent of both the temperature and the ionic strength. This indicates that the contribution of spin rotational relaxation[12] to the line width is negligibly small, regardless of the added salt. At a constant temperature and NaCl concentration, the line width became broader with increasing radical concentration. Generally, in free nitroxide radical molecules, the line broadening observed with increasing radical concentration can be attributed to either an electron-spin exchange or an electron spin-electron spin dipole interaction. The relaxation process due to the spin-exchange interaction is dependent on T/η, while that due to dipole-dipole interaction depends on η/T, where η is the viscosity of the medium and T is the absolute temperature.[13] Therefore, the relation of the line width vs. T/η was examined at various concentrations of SL-SDS in the presence of 1 mol kg^{-1} NaCl. As shown in Fig. 3, the line width varied linearly as a function of T/η. This indicates that spin exchange is predominant relaxation process in the range of this concentration. Thus, the line broadening observed between the two inflection points is attributed to the spin-exchange interaction. In the absence of NaCl, the plots of the line width vs. the SL-SDS concentration deviate from a straight line above about 20 mmol kg^{-1}.[9] However, this inflection point shifted to a lower concentration of SL-SDS with increasing NaCl concentration, i.e., it changed from 20 to 11 mmol kg^{-1} by an addition of 1 mol kg^{-1} NaCl. The linewidth variation with the SL-SDS concentration above the higher inflection point is small compared with

that below its inflection point. For micellar solutions, it is well known that the cmc decreases upon adding salts and the monomer concentration remains constant above cmc.[14] Taking these facts into account, it is considered that the inflection point at higher concentrations corresponds to the cmc of the surfactant molecules.

The spin exchange between SL-SDS molecules is regarded as a second-order reaction.[13] The second-order rate constants (k_2) are obtained from the slope of the line width vs. the radical concentration by

$$k_2 = \frac{3\sqrt{3}}{4}|\gamma_e|h, \tag{1}$$

where γ_e is a magnetogyric ratio of a free electron, and h is the slope of the line width-surfactant concentration plots. The obtained values of k_2 are given in Table 1. The values of k_2 decreased upon adding salts at each temperature. The values of k_2 in all cases were of the order 10^9 kg mol^{-1} s^{-1}, indicating that the spin exchange of SL-SDS is a diffusion-controlled process.[12,13] For such a reaction, the reaction rate is greatly influenced by the viscosity of the solvent. Using the theory of Smoluchowski,[15] we could obtain the rate constant (k_2') for the bimolecular encounters:

$$k_2' = \frac{N_A}{1000\,\rho}\frac{4kT}{3\eta}, \tag{2}$$

where N_A is Avogadro's number and ρ, the density of the solution. The values of k_2' are also given in Table 1. The values of k_2' are in agreement with those of $2k_2$. Similar results, i.e., $2k_2$, is equal to k_2', have also been reported by other workers.[12,16-18] The frequency of the spin exchange is markedly dependent on the charge and size of the radical. For example, the spin-exchange rate of anion radicals with a large repulsive charge increases due to the offset of a coulombic repulsion between these radicals with increasing ionic strength.[19] Eastman et al.[19] demonstrated that the spin-exchange rate of the di-*t*-butyl nitroxide radical decreased markedly with increasing ionic strength. In order to explain such a phenomenon, they have proposed that aggregates of the radicals are caused by the hydrophobicity of the *t*-butyl groups. In the present work, the spin-exchange rates of SL-SDS obtained in the presence and absence of NaCl were closely dependent on the viscosity of the medium, suggesting that neither the polar head group nor the hydrocarbon chain of SL-SDS molecule play any significant role in the spin-exchange interaction.

In spin-labeled surfactants, monomer amphiphilic molecules incorporated into micelles undergo a fast spin exchange, causing a line broadening. Therefore, the increase in line width above cmc (Fig. 2) can be ascribed to the monomer-micelle exchange and was examined according to the treatment of Schmidt et al.[7] On the basis of Aniansson's kinetic theory on the micellization, they have given the following kinetic expression on the monomer-micelle exchange in order to explain the ESR line broadening of the monomer surfactant above cmc.

$$\Delta W = \frac{k^+}{\bar{n}}(C - C_m), \tag{3}$$

where ΔW is the line-width variation in frequency unit, k^+ is the rate constant for the association of monomer to micelle, $\bar{n}$ is the aggregation number of the micelle, C_m is the critical micelle concentration, and C is the total concentration of the surfactant. According to Eq. 3, the slope of plots of the line width vs. the surfactant concentration equals to $k^+/\bar{n}$. As the aggregation number of SL-SDS without NaCl is about 6 at 25 °C,[9] 1.3×10^9 kg mol^{-1} s^{-1} is obtained as the value of k^+. This is in rough agreement with the value of 1.8×10^9 kg mol^{-1} s^{-1} obtained using Eq. 1 from the relation between the line width and the SL-SDS concentration above cmc. This suggests that the monomer surfactant becomes associated with the micelles as if a bimolecular reaction occurs. The values of the association constant k^+ reported for various surfactants are between 10^8 and 10^9 dm^3 mol^{-1} s^{-1}, which exist in the expected range for a diffusion-controlled reaction.[3,15] Therefore, it is considered that the values of k^+ characterized with the diffusion-controlled reaction should be approximately independent of ionic strength and hydrocarbon chain length of surfactants.[3,7] On the other hand, the rate constant (k^-) for the dissociation of one amphiphilic ion from the micelles is strongly dependent on the alkyl chain length of the surfactant and ionic strength.[3,7] The rate constant k^- is obtained from the following relation developed by Aniansson et al.,[3]

$$k^- = k^+ \cdot \text{cmc}. \tag{4}$$

The calculated value of k^- for SL-SDS is 2.8×10^7 s^{-1}. The values of k^+ and k^- obtained from the ESR line width for SL-SDS in this study are compared with those, i.e., $k^+=1.2\times10^9$ dm^3 mol^{-1} s^{-1} and $k^-=1.0\times10^7$ s^{-1}, from chemical relaxations for SDS by Aniansson et al.[3] It seems that the agreement is well satisfied. The temperature and ionic strength dependences of $k^+/\bar{n}$ are given in Table 2. At any temper-

a) Data from Ref. 9.

ature, the values of $k^+/\bar{n}$ decrease greatly with increasing ionic strength. As mentioned above, the changes in k^+ values for the ionic strength are small. On the other hand, the aggregation number of SL-SDS micelles increases drastically with increasing ionic strength (Fig. 1). Therefore, the decreases in $k^+/\bar{n}$ upon adding salt are mainly attributed to an increase in the aggregation number, whereas the change in $k^+/\bar{n}$ with temperature is small compared with that for the ionic strength. With increasing ionic strength, the temperature dependence of $k^+/\bar{n}$ becomes large. This can be interpreted in terms of both the increase in k^+ and the decrease in $\bar{n}$ with increasing temperature. In order to obtain detailed information concerning the effect of NaCl on the micellar kinetics of SL-SDS, it is necessary to examine the aggregation number of SL-SDS micelles in the presence of any added salt.

The authors wish to thank Mr. Toshihiko Kiyohara for his technical assistance.

On the Relationship Between the Chemical Structure and the Carcinogenicity of Polycyclic and Chlorinated Monocyclic Aromatic Compounds as Studied by Means of ^{13}C NMR

Yohko SAKAMOTO* and Shosuke WATANABE†
School of Pharmaceutical Science, Toho University, 2-2-1 Miyama, Funabashi, Chiba 274
†Nihon Junior College of Economics, 5-24-10 Sakai, Musashino, Tokyo 180
(Received April 12, 1986)

The relationship between chemical structure and carcinogenicity was investigated in thirty-eight polycyclic aromatic compounds and forty-four chlorinated aromatic hydrocarbons by means of ^{13}C NMR. As an "index" serving as a measure of the electronic structure of aromatic compounds, which is closely related to the carcinogenicity, the averaged ^{13}C NMR chemical shift over all the aromatic carbons in the molecule was used. In polycyclic aromatic compounds, the averaged chemical shifts of the carcinogenic compounds are within the range from 127.11 to 127.87 ppm, but those of the noncarcinogenic compounds are not within this range. In chlorinated monocyclic aromatic compounds, the carcinogenic compounds was within the range from 127.76 to 132.64 ppm. Thus, we proposed that the "index" is very useful for the discernment of the carcinogenicity of polycyclic and chlorinated monocyclic aromatic compounds.

It is known that aromatic compounds sometimes have carcinogenicity.[1-3] In order to obtain useful information about the detailed mechanism of their carcinogenicity, several approaches have been employed. One of them is the quantum-chemical approach,[4-10] which has provided insight into the close relationship between the carcinogenicity and the electronic structure and has also made possible an interesting prediction as to the carcinogenicity of aromatic compounds. Nevertheless, this approach is not practical for the discrimination of the carcinogenicity. Another approach is to relate the carcinogenicity to a physical quantity such as the ionization potential.[11-15]

It has been reported that aromatic hydrocarbons with an ionization potential within any specified range show carcinogenic activity and that the carcinogenicity increases with a decrease in the potential energy.

It is known that ^{13}C NMR chemical shifts of the aromatic compounds considered here are closely related to the electronic environments of the individual carbon and to the ionization potential.[16,17] This means that the ^{13}C NMR chemical shift of aromatic compounds provides a measure of whether or not the molecules have carcinogenic activity.

The purpose of this paper is to study the relationship between the carcinogenicity and the averaged ^{13}C chemical shifts over all the carbons in the ring structure of aromatic compounds, and to clarify whether or not the averaged ^{13}C chemical shift is useful for the discernment of the carcinogenicity.

The averaged chemical shifts employed in this work reflect the electronic structure and electronic state of the molecules as follows. The dominant factor governing the ^{13}C chemical shift of a nucleus i is the paramagnetic contribution as given by Eq. 1, with an average excitation energy approximation.

$$\delta_i \propto \frac{1}{\Delta E} \cdot Q_i, \tag{1}$$

where ΔE is the averaged excitation energy of a molecule and Q is a factor containing electron density and bond order. Thus, the averaged chemical shift defined above is expressed by Eq. 2:

$$\begin{aligned} \bar{\delta} &\propto \frac{1}{N} \sum_i^N \frac{1}{\Delta E} \cdot Q_i \\ &= \frac{1}{\Delta E} \cdot \frac{1}{N} \sum_i^N \cdot Q_i \\ &= \frac{1}{\Delta E} \cdot \bar{Q} \end{aligned} \tag{2}$$

$$\text{in which } \bar{Q} = \frac{1}{N} \sum_i^N Q_i,$$

where N is the number of carbon atoms considered here. As may be seen from this equation, the averaged chemical shift involves information on the averaged excitation energy and the averaged value of Q. Thus, we can indirectly get information on the electronic structure and electronic state of the aromatic compounds through the observation of the averaged chemical shift for all the carbons in the ring structure of the molecule.

Experimental

Twelve compounds (**1**)—(**12**) (see Table 1) and forty-four compounds (**1**)—(**44**) (see Table 2) were obtained from the Tokyo Kasei Co. and were used without further purification.

The ^{13}C NMR spectra were recorded with Fourier Transform spectrometers, Hitachi R-900 FT and JEOL GX-400 FT, operating at 22.6 MHz and 100.4 MHz respectively, at 35 °C and at 27 °C, using an external lock system and a deuterated lock system. Deuteriochloroform was used as the solvent. The concentration of the sample solution was 25—62%(w/v). The chemical shift was significantly independent of the concentration of the sample within this concentration range.

The chemical shifts were expressed in ppm relative to tetramethylsilane.

The number of accumulations is about 400—14000: data points, 16K or 32K: spectral width, 1800 Hz: flip angle, 25°,

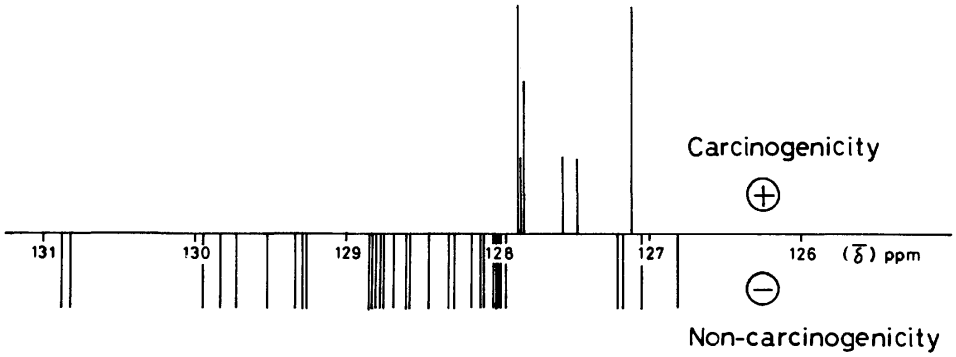

Fig. 1. The relationship between the averaged ^{13}C NMR chemical shifts (δav) of individual polycyclic aromatic compound and their carcinogenicity.

and interval of pulse to pulse, 3 s. (The detailed assignment of the ^{13}C NMR spectra for some samples is carried out by means of T_1 measurement,[18] selective decoupling[19a,b] and an isotope-label shift.[20])

Results and Discussion

Polycyclic Aromatic Hydrocarbons. The averaged ^{13}C NMR chemical shifts (δ av) over all the ring carbons in polycyclic aromatic compounds and their subsituted compounds, together with the ionization potential and the known carcinogenicity, are shown in Table 1, while the relationship between the averaged ^{13}C NMR chemical shifts (δ av) of the individual compounds and their carcinogenicities is shown in Fig. 1.

The averaged ^{13}C NMR chemical shift values for the compounds have already been estimated from the reported data.[23a,b] On the other hand, some compounds (**1**)—(**12**) with carcinogenicity have already been investigated.[4,5,17b,21,22,23b,25] Hawever, in many compounds the carcinogenicity is unknown. Thus, the compounds listed in Table 1 are divided into three groups: carcinogenic, noncarcinogenic, and undetermined groups. It has been reported that benz[*a*]anthracene (**4**), dibenz[*a*,*h*]anthracene (**8**), benzo[*a*]pyrene (**9**), 7-methylbenz[*a*]anthracene (**11**), and 7,12-dimethylbenz[*a*]anthracene (**12**) are carcinogenic.[4,22,23,25] The values of δ av for the corresponding compounds are within the range from 127.11 to 127.87 ppm. On the other hand, it is found that the averaged ^{13}C chemical shift values for naphthalene (**1**) and anthracene (**2**) are larger than 127.87 ppm, while those for 9,10-dimethylanthracene (**10**) and triphenylene (**6**) are smaller than 127.11 ppm. These compounds are not carcinogenic.[4,17,22,23b] These findings suggest that there is a correlation between the averaged chemical shifts and the carcinogenicity, and that the chemical shift range from 127.11 to 127.87 ppm, the "index range," can be used to discern whether or not compounds being considered are carcinogenic. For phenanthrene (**3**), contrary results on its carcinogenicity have been reported.[4,5] The averaged chemical shift was 128.68 ppm. Thus, according to the above "index" range, phenanthrene (**3**) can be expected to be noncarcinogenic. Next, let us consider pyrene (**5**) and dibenz[*a*,*c*]anthracene (**7**), which have been reoported to be noncarcinogenic.[4,5,17b,22]

The values of these compounds are slightly higher than that of 7,12-dimethylbenz[*a*]anthracene (**12**), which is carcinogenic: they are the lowest values in the "carcinogenic index." This means that it is not easy to determine clearly, by the use of the carcinogenic index, whether compounds which are near the lower limit of the carcinogenic index are carcinogenic or noncarcinogenic. When methyl groups were substituted into polycyclic aromatic hydrocarbons, the increase in carcinogenicity or the appearance of the carcinogenic activity were recognized in some compounds.[17a] For methyl-substituted benz[*a*]anthracene (**4**), the increase in the carcinogenicity has been well-confirmed in 7-methylbenz[*a*]anthracene (**11**) and 7,12-dimethylbenz[*a*]anthracene (**12**). However, methyl-substituted naphthalene and anthracene are known to be noncarcinogenic. Such experimental findings will be studied through the averaged ^{13}C chemical shifts of methyl-substituted aromatic hydrocarbons.

We predicted the carcinogenicity of the methyl-substituted compounds to be as is shown in Table 1; we did so on the basis of the averaged chemical shifts. The values of δ av for all methyl-substituted compounds, (**14**)—(**16**) and (**19**)—(**28**), appear at a field lower by from 0.17 to 2.54 ppm than that of naphthalene. This suggests that these compounds are noncarcinogenic. Also, the values of the δ av for 1-methylnaphthalene (**13**), 1,4-dimethylnaphthalene (**17**), and 1,5-dimethylnaphthalene (**18**) appear at a field higher than that of naphthalene by ca. from 0.05 to 0.09 ppm; these values are not in the range from 127.11 to 127.87 ppm. Therefore, it may be suggested that these compounds are noncarcinogenic. The values of δ av for di-, tri-, and tetramethyl-substituted anthracene, (**32**)—(**38**), showed a variety of shifts ranging from ca. 0.16 to 1.66 ppm.

None of them is carcinogenic, since all of them showed a field shift lower than the "index." 1-Methylanthracene (**29**) and 2-methylanthracene (**30**) also seem to be noncarcinogenic, judging from their low

chemical shifts. However, 9-methylanthracene (**31**) falls in the range of the "index." The carcinogenicity in the compound has not yet been determined, but the observed value of δ av suggests that the compound is carcinogenic. Most polycyclic aromatic compounds form charge-transfer complexes which consist of an electron-donor part and an acceptor part.

It has been proposed that any specified value of the ionization potential formation for charge-transfer complexes is associated strongly with the ionization potential. This causes steric hindrance effects to the DNA conformation, and so such compounds are carcinogenic. The relationship among the ionization potential, the averaged ^{13}C NMR chemical shift, and the carcinogenicity is shown in Table 1. The ionization potentials and their reciprocals in some compounds are shown in Table 1. It is known that carcinogenic compounds have ionization potentials of from 7.22 to 7.58 eV and that naphthalene (**1**), phenanthrene (**3**), and triphenylene (**6**), with higher ionization potentials than this range, are not carcinogenic. In the carcinogenic compounds, those with lower ionization potentials showed stronger carcinogenicities. However, 9,10-dimethylanthracene (**10**), which has the lowest ionization potential, anthracene (**2**) and pyrene (**5**), all within the range from 7.22 to 7.58 eV, are not carcinogenic. In these cases, the local electronic state in the molecules should be determined in addition to the ionization potential in order to estimate their carcinogenicity.

and the carcinogenicity of chlorinated monocyclic aromatic compounds is shown in Table 2 and Fig. 2. These compounds also were divided into three groups: the carcinogenic, noncarcinogenic, and undetermined groups. Chlorobenzene (**1**) and di-, tri-, tetrachlorobenzene (**2**)—(**8**), benzyl chloride and its derivatives (**10**)—(**13**), di-, tri-, and pentachlorophenol (**29**)—(**34**), and 2,4-dichlorophenoxyacetic acid (**36**) have all been reported to be carcinogenic. The averaged chemical shifts in these carcinogenic compounds were within the range from 127.76 to 132.64 ppm. The averaged chemical shift of two non-carcinogenic compounds, 2,6-dichlorobenzonitrile (**26**) and ethyl α-(*p*-chlorophenoxy)isobutyrate (**28**), were larger than those of the carcinogenic compounds. From these "index" values, we predicted the carcinogenicity of the *p*-chlorobenzyl chloride (**9**), (**14**)—(**25**), (**27**), whose carcinogenicities have not yet been studied. *p*-Chlorobenzyl chloride (**9**), chloroacetophenones (**14**)—(**17**), (**19**) chlorobenzene derivatives (**18**), (**20**), (**21**), (**27**), and 4-chloro-2-nitroanisole (**23**) would seem to be carcinogenic, since the averaged chemical shifts of these compounds are within the range of 127.76—132.64 ppm, the index of carcinogenic chlorinated

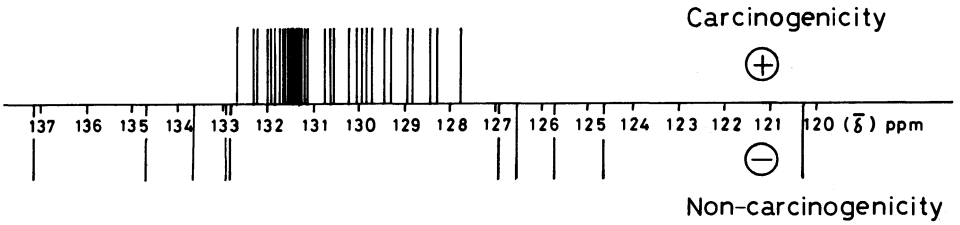

Fig. 2. The relationship between the averaged ^{13}C NMR chemical shifts (δav) of individual chlorinated-monocyclic aromatic compound and their carcinogenicity.

compounds. The averaged chemical shifts of 2-chloro-6-nitrotoluene (**22**), *p*-chlorofluorobenzene (**24**), and *p*-chlorobenzonitrile (**25**) were larger than the "index value" and similar to that of the noncarcinogenic compounds, (**26**) and (**28**). Therefore, we predicted that these compounds would be noncarcinogenic.

In 2-chloro-6-nitrotoluene (**22**), electrons in the ring are attracted by the high electronegativity of the Cl and NO_2 groups, and so the number of electrons in the ring decreased. This moved the averaged chemical shifts downfield. In compound (**24**), the electrons in the ring are attracted to subsituted halogen; this moves its averaged chemical shifts downfield. In *p*-chlorobenzonitrile (**25**) and 2,6-dichlorobenzonitrile (**26**), the electronegativity of the cyano group is so large that the electrons in the ring are attracted by the δ-I effect; therefore, the averaged chemical shifts move downfield as a whole. The larger the δ-I effect, the less the electron density in para positions within the benzene ring.

Next, let us consider the monocyclic chlorine-substituted compounds (**29**)—(**36**). In this table, all of the compounds except 4-chloro-*m*-cresol (**35**) have been reported to be carcinogenic.[29,30,31]

Compound (**35**) also would be carcinogenic judging from the "carcinogenic index" for chlorine-substituted aromatic compounds. The averaged chemical shift value of (4-chloro-*N*-methylanilino)cyanide (**44**) was 129.25 ppm; therefore, the compound seems to have carcinogenicity. The downfield shift may be due to the fact that electrons in the ring are attracted to the Cl group by its large electronegativity, and so the number of electrons in the ring is decreased. In the case of the alkaline compounds, it seems that the downfield shift occurs by means of the solvation in solution. The chlorine atom in the para position may decrease the electrons in the benzene ring rather than that in the meta position, and it seems to cause the averaged chemical shifts downfield as a whole. In general, acid and neutral monocyclic chlorine compounds seem to be carcinogenic, whereas alkaline ones are usually of no carcinogenicity.

As in the case of polycyclic aromatic hydrocarbons, there seems to be a correlation between the carcinogenicity and the ionization potential of the chlorinated aromatic hydrocarbons.

As is shown in Table 2, the ionization potentials of the carcinogenic compounds are within the range from 8.98 to 9.80 eV. We can see the correlation of the averaged ^{13}C NMR chemical shift, the ionization potential, and the carcinogenicity.

Our idea of using the averaged value of the ^{13}C NMR chemical shifts which link the electronic structure and the electronic state was carried out; we found that we could predict the carcinogenicity in aromatic compounds from the chemical-shift value.

The averaged chemical shifts of the known carcinogenic polycyclic aromatics are within the range from 127.11 to 127.87 ppm, while those of the known chlorinated aromatics are within the range from 127.76 to 132.64 ppm: the difference might reflect the slight difference in the mechanism of carcinogenicity between the two types of compounds. There are a few noncarcinogenic compounds that have averaged chemical shifts values within the "carcinogenic index". Therefore, there would be a secondary criterion to judge their carcinogenicity, such as a local electronic state, even though the averaged chemical shift remains the more primary, simple, and useful criterion for carcinogen. Furthermore, a close investigation of carcinogenic compounds and noncarcinogenic compounds with only slightly different chemical-shift values should give insight into the mechanism of carcinogenicity.

The authors are indebted to Dr. Isao Ando of the Tokyo Institute of Technology for his useful discussions and advice and are grateful to Professor Sinzo Tamura and Yasuoki Murakami of Toho University for their kind support and encouragement.

Magnetic Field Effects on the Primary Photoprocess of Anthrone in Micellar Solution by Laser Flash Photolysis and Two-Step Laser Excitation Fluorescence

Yoshifumi TANIMOTO,* Etsuko SHIMADA, and Michiya ITOH
Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920
(Received April 16, 1986)

The magnetic field effects on hydrogen abstraction reaction of anthrone have been studied in micellar solution by laser flash photolysis and two-step laser excitation (TSLE) fluorescence. The decaytime of the anthrone ketyl radical determined by laser flash photolysis increases from 370 ns at zero field to 890 ns at 80 mT. The results are in accordance with the magnetic field effects on the risetime of the cage product by the TSLE fluorescence. All of the results are discussed in terms of the radical pair model.

Particular interest has recently been taken in the effects of magnetic field on chemical reactions.[1] This is caused by versatile applicability such as the enrichment of nuclear magnetic isotopes. Mangetic field effects on photochemical reactions in condensed phase are interpreted mainly in terms of the radical pair model, where the lifetime of radical pair determines significance of the effects. In homogeneous solution, diffusion of radicals is so fast that the lifetime of the pair is as short as 10^{-8}—10^{-9} s, and usually no significant effects are expected for the chemical reaction. In this context, aqueous micellar solution will provide an excellent environment for enhancement of chemical reaction by magnetic field. Since organic compounds are solubilized in the micellar phase of normal micelle system due to hydrophobic interaction, the radical pair generated is confined in micellar cages; this results in long lifetime of 10^{-6} s or so. Based on this reason, we have studied the effects of magnetic field on photochemical reactions in micellar solution.[2-5]

In the present paper, we report results of the effect of magnetic field on the hydrogen abstraction reaction of anthrone in micellar solution by laser flash photolysis and two-step laser excitation (TSLE) fluorescence technique. Transient absorption of the anthrone ketyl radical and the TSLE fluorescence of cage product are strongly influenced by the magnetic field ($\leqslant$ 80 mT). All of the results are discussed in terms of the radical pair model.

Experimental

Anthrone (Tokyo Kasei Co.) and sodium dodecyl sulfate (Nakarai Co., for biological use, denoted as SDS hereafter) were used as received. Distilled water was further deionized. All solutions were deaerated by flowing nitrogen for 10 min.

In the laser flash photolysis, an N_2 laser (Molectron UV-12, 337 nm) and a xenon arc lamp were used as excitation and probe light sources, respectively. Two-step laser excitation (TSLE) fluorescence was measured by means of an excimer laser (Lambda Physik EMG-50E, 308 nm) and an N_2 laser pumped dye laser (Molectron UV-12 and DL-14, 406 nm), as the first and the second laser, respectively. Timing of each laser was adjusted with a home-made delay circuit. Magnetic field was applied with a home-made Helmholtz coil ($\leqslant$ 80 mT). Details of the systems were similar to those described elsewhere.[3,6] All measurements were carried out at room temperature.

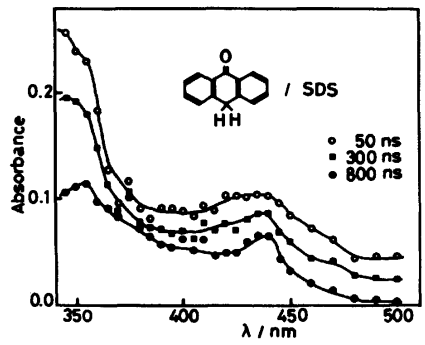

Fig. 1. Transient absorption spectra of anthrone (2×10^{-3} mol dm^{-3}) in SDS (0.4 mol dm^{-3}) micellar solution.

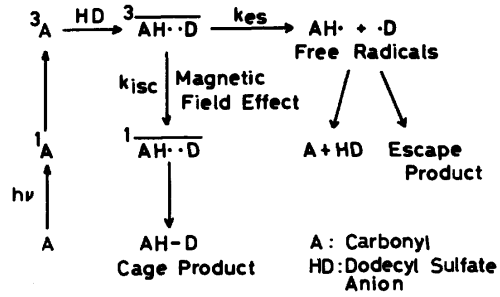
Results and Discussion

Transient Absorption and Mechanism. Figure 1 shows transient absorption spectra of anthrone in SDS micellar solution. The absorption band around 350 nm is assigned to the anthrone ketyl radical with reference to the literature,[7] though the spectrum at 50 ns delay is slightly shifted to shorter wavelength, because of the overlap with the short-lived triplet–triplet absorption band of anthrone. The risetime of the ketyl radical was estimated to be 40 ns. We have reported several hydrogen abstraction reactions of aromatic carbonyls in the triplet states,[2-4] whose reaction mechanism is shown in Scheme 1. By analogy with



Scheme 1. Photoreaction pathways of aromatic carbonyls in SDS micellar solution.

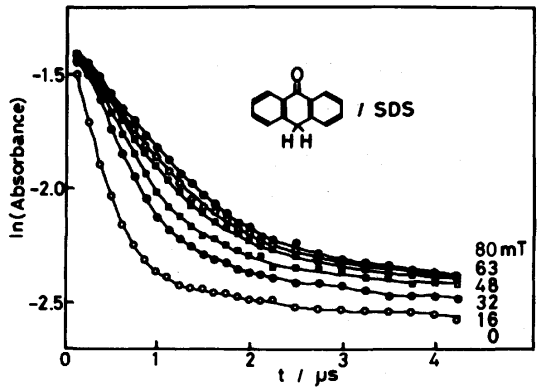


Fig. 2. Magnetic field effects on the decay of the anthrone ketyl radical at 355 nm.

the photoreactions of these carbonyls reported, the excited triplet anthrone may abstract a hydrogen atom from an SDS surfactant to yield a triplet pair between anthrone ketyl radical and dodecyl sulfate anion radical. The triplet pair disappears via two competing processes, i.e., the intersystem crossing to singlet pair followed by geminate cage reaction, and the dissociation of triplet pair into the component free radicals (escape products). The adduct of the ketyl radical with the surfactant seems responsible to the geminate cage reaction,[10] while 9-anthrol to the escape product. In a radical pair, the triplet-singlet intersystem crossing as well as relaxation within the triplet manifold occurs via electron-nuclear hyperfine interaction and these rates are decreased by applying a magnetic field because of the Zeeman splitting of the triplet sublevels.[1] Therefore, in a magnetic field, the decay rate of the triplet radical pair and also the formation rate of the cage product are expected to be reduced.

Figure 2 shows the effects of magnetic fields on the decay of ketyl radical observed at 355 nm. Without applying field, the decay of the radical appears to consist of fast and slow processes, though the decay does not proceed exponentially. In the presence of magnetic field, the decay rate of the fast process becomes slow and the apparent intensity at 4 μs delay increases. When the generation of the triplet pair and the geminate cage reaction are very fast and the decay of the ketyl radical escaped from the pair is slow enough within the time scale of microsecond, as shown in the Scheme, the absorption intensity of the ketyl radical, $I(t)$, can be expressed as follows:[2]

$$I(t) \propto I_f \exp(-k_f t) + I_s, \quad (1)$$

where $k_f = k_{isc} + k_{es}$, $I_f = k_{isc}/(k_{isc}+k_{es})$, and $I_s = k_{es}/(k_{isc}+k_{es})$. The first and the second terms in the right side of Eq. 1 represent the concentrations of the ketyl radical in the triplet pair and in the escaped free radical, respectively. Thus, Fig. 2 indicates that the external magnetic field reduces the decay rate of the triplet pair and enhances the yield of the escaped free radical. Decay curves in Fig. 2 were analysed by Eq. 1 in order to estimate k_f (Table 1).[11] In the presence of a magnetic field (80 mT), the decay rate of triplet pair is reduced by ≈60%, as expected from the Scheme.

Table 1. Magnetic Field Effects on k_f and k_r ($10^6\,s^{-1}$)

	H/mT					
	0	16	32	48	63	80
k_f	2.7	1.8	1.6	1.3	1.2	1.1
k_r	2.6					1.4

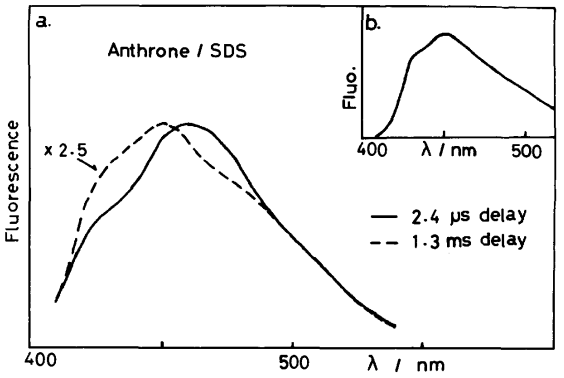

Fig. 3. (a) The TSLE fluorescence spectra of anthrone (3×10^{-4} mol dm^{-3}) in SDS (0.4 mol dm^{-3}) micellar solution. (b) Fluorescence spectrum of 9-anthrol in SDS micellar solution.

Two-Step Laser Excitation (TSLE) Fluorescence. In order to analyse the magnetic field effects on photoadduct formation, we examined the TSLE fluorescence of anthrone in SDS micellar solution; two steps consist of the initial laser excitation as the reaction light source and the following probe laser excitation. Figure 3a shows the TSLE fluorescence spectra of anthrone in the solution. The spectrum at 2.4 μs delay after the first laser excitation has a peak around 460 nm, and the peak shifts to the shorter wavelength by ≈10 nm at 1.3 ms delay. The lifetime of TSLE fluorescence seems to be composed of two decay components (3—4 and 12 ns). On the other hand, 9-anthrol, synthesized by reduction of anthrone, has a fluorescence band maximum around 450 nm (lifetime 12 ns) (Fig. 3b). Thus the TSLE fluorescence band around 450 nm, which appears at 1.3 ms delay after the first laser excitation, is attributable mainly to 9-anthrol. The TSLE fluorescence around 460 nm at 2.4 μs delay is likely to be due to the photoadduct of the anthrone ketyl radical with the SDS surfactant (a product of the geminate cage reaction). Figure 4 demonstrates the magnetic field effects on the time evolution of the TSLE fluorescence at 460 nm. The risetime $1/k_r$ was estimated to be 380 ns at zero field and 710 ns at 80 mT, k_r being the formation rate of the photoadduct. The TSLE fluorescence intensity at 6.4 μs delay decreases by ≈10% in the magnetic field (80 mT). These results imply that the rate of formation and the yield of cage product, the photoadduct, is reduced

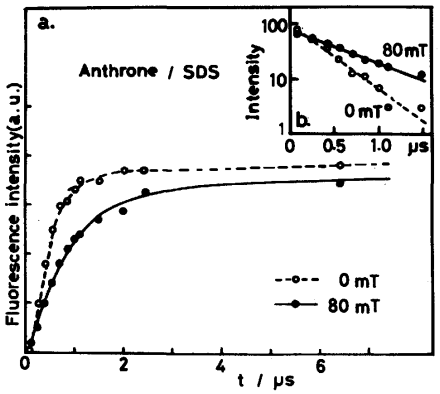

Fig. 4. (a) Magnetic field effects on the time evolution of the TSLE fluorescence at 460 nm. (b) Semilogarithmic plots of the intensities of (a), $I_\infty - I(t)$, the intensity at 5 μs delay, where it reaches plateau, being used as I_∞.

in the magnetic field.

Furthermore, the risetimes $1/k_r$ of the adduct with and without magnetic field (80 mT) determined by the TSLE fluorescence agree with the corresponding decaytimes $1/k_f$ of the anthrone ketyl radical by laser flash photolysis within experimental error (Table 1). This coincidence implies that the fast deactivation process of the triplet radical pair, composed of anthrone ketyl radical and dodecyl sulfate anion radical, is attributable to the intersystem crossing to the singlet pair followed by the fast geminate cage reaction as shown in Scheme 1. The decrease in the yield of cage product, determined by TSLE fluorescence, with concomitant increase in the escaped radical yield, determined by laser flash photolysis, in a magnetic field also supports the mechanism proposed (Scheme 1), in which both processes compete to each other.

In the previous papers,[3] we studied the transient absorption and the TSLE fluorescence of anthraquinone in SDS micellar solution in magnetic field. The decays and yields of anthrasemiquinone radical as well as those of photoadduct of semiquinone with surfactant are influenced by the external magnetic field. Present results agree well with those in the studies mentioned above.

In conclusion, by combining results by laser flash photolysis with those by TSLE fluorescence, it is unequivocally demonstrated that radical pair intervenes as a short-lived intermediate in the reaction and that intersystem crossing as well as relaxation of the radical pair is reduced by external magnetic field.

We wish to acknowledge the financial support from the Takeda Science Foundation for this research.

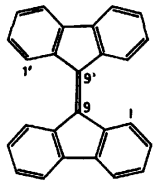
A Molecular Orbital Study of Conformational Behavior of 9,9′-Bifluorenylidene

Osamu KIKUCHI,* Ken-ichi MATSUSHITA, Kenji MORIHASHI, and Mitsunobu NAKAYAMA
Department of Chemistry, The University of Tsukuba, Sakura, Ibaraki 305
(Received April 28, 1986)

The conformation of 9,9′-bifluorenylidene and the $E \rightarrow Z$ isomerization of its derivatives were examined by a two-configuration SCF calculation with the MINDO/3 approximation. The twisted conformation was calculated to be more stable than the folded one. The E-Z isomerization occurs between two twisted conformers and the 90°-twisted structure is the transition state. The structural dependence of the rotational barrier of the isomerization is discussed.

Bifluorenylidene, **1**, is a highly overcrowded ethylene[1] and is expected to exist in one of the two possible conformations, the twisted or folded conformation, in order to avoid large repulsive interactions around the central C_9–$C_{9'}$ double bond. In the twisted form,

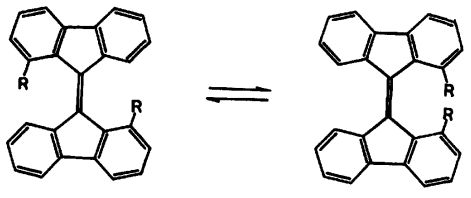


1

the two 9-fluorenylidene fragments make a large twist angle but maintain planarity. In the folded form, the fragments are folded away from each other without rotation about the C_9–$C_{9'}$ bond. The Newman projections of these two structures are shown in Fig. 1.

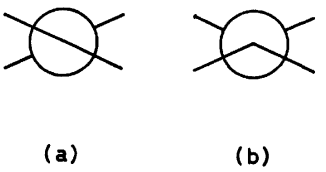
Gault et al.[2] assumed in their NMR study of substituted 9,9′-bifluorenylidenes in solution that the compounds existed in folded forms. In the solid state, an X-ray analysis showed that **1** has the twisted conformation with approximately planar 9-fluorenylidene fragments.[3] The substituted 9,9′-bifluorenylidenes have a barrier of 80—100 kJ mol^{-1} for a rotation about the C_9–$C_{9'}$ double bond in the E-Z isomerization.[4,5] These values are remarkably low in comparison with the rotational barrier of ethylene, 273 kJ mol^{-1}.[6]

Conformations and the E-Z isomerization of 9,9′-bifluorenylidenes have been studied by molecular



E **Z**

mechanics calculations.[7,8] As a molecular orbital calculation on 9,9′-bifluorenylidene, Meyer and Yinnon employed the π-electron calculation method to estimate the twist angle of 40°.[9] The present study examined the conformation of **1** on the basis of all-valence-electron MO calculations and analyze the E-Z isomerization process of substituted 9,9′-bifluorenylidenes.



(a) (b)

Fig. 1. Newman projections of 9,9′-bifluorenylidene. (a) Twisted form and (b) folded form.

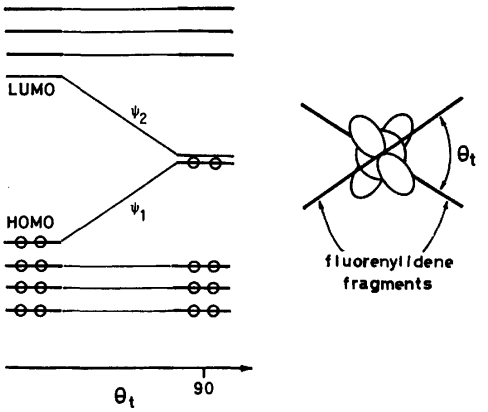


Fig. 2. Qualitative variation of orbital energies of 9,9′-bifluorenylidene with the twist angle about the central C–C double bond. The ψ_1 and ψ_2 orbitals are the bonding and anti-bonding π-orbitals of the ethylenic double bond, respectively.

Method

The electronic structure of the 90°-twisted 9,9′-bifluorenylidene can not appropriately be calculated by the closed-shell SCF method. It can be treated by the method applied to 10,10′-bianthrone.[10] As the twist angle about the 9–9′ double bond of 9,9′-bifluorenylidene increases, the energy separation between the bonding (ψ_1) and antibonding (ψ_2) π-orbitals associated with the C_9–$C_{9'}$ double bond decreases (Fig. 2). In the 90°-twisted 9,9′-bifluorenylidene, the ψ_1 and ψ_2 orbitals are degenerate, and the two closed-shell configurations, Φ_1 and Φ_2, contribute equally to the lowest singlet state.

$$\Phi_1 = |\cdots\psi_1\bar{\psi}_1|$$

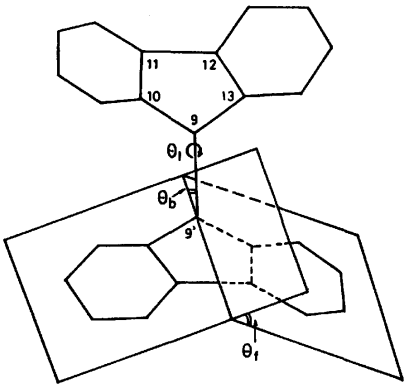

Fig. 3. Molecular parameters which represent the 9,9′-bifluorenylidene structure. For the six-membered ring, C-C=1.418 Å, C-H=1.084 Å, and all the valence angles=120° were fixed in the calculation.

and

$$\Phi_2 = |\cdots\psi_2\overline{\psi}_2|.$$

Thus, 9,9′-bifluorenylidene with a large twist angle should be calculated by two-configuration SCF (TCSCF) wave function,

$$\Phi_G = C_1|\cdots\psi_1\overline{\psi}_1| + C_2|\cdots\psi_2\overline{\psi}_2|. \quad (1)$$

9,9′-Bifluorenylidene is too large in size for ab initio calculations and the MINDO/3 approximation[11] was used. A small model compound cannot be used for the present purpose, since the conformational behavior of 9,9′-bifluorenylidene is essentially controlled by steric interactions. Only a part of molecular structure was optimized. The parameters are shown in Fig. 3. These parameters were determined by using a closed-shell SCF calculation. The TCSCF method was used for the energy calculation when the twist angle was changed from 0 to 90° and the other parameters were fixed at the optimized values.

In order to understand the energy change associated with the conformational change, the total energy of the TCSCF wave function was divided into three parts,

$$E_{total} = E_1 + E_2 + E_{1-2},$$

where E_1 and E_2 are the energies of two 9-fluorenylidene fragments and E_{1-2} is the inter-fragment energy between the two fragments.

Results and Discussion

The molecular structures are listed in Table 1. The calculated values of the twisted form agree well with experimental values.[3] The variations in the energy vs. the twist angle are shown in Fig. 4. The most stable conformation of 9,9′-bifluorenylidene was a twist form with θ_t=45°. This agrees with the structures in solid state[3] and of molecular mechanics calculations.[8] The lowest folded form has θ_t=0° and lies 27 kJ mol^{-1} above the twisted conformation. Table 2 shows the energy components in the twisted and folded forms. The energy of each 9-fluorenylidene fragment is lower in the twisted form by 58 kJ mol^{-1} due to the planarity of the fragments maintained in the twisted form. On the other hand, the interaction energy between two fragments, E_{1-2}, is lower in the folded form by 89 kJ mol^{-1}. This comes from the favorable resonance interaction between the C_9 and $C_{9'}$ atoms in the folded form; this stronger interaction can be seen in the shorter C_9–$C_{9'}$ bond in the folded form.

Table 1. Structure Parameters of Folded and Twisted Forms of 9,9′-Bifluorenylidene in Their Lowest Energy Conformations[a]

Parameter[b]	Folded	Twisted	Exp. (twisted)[c]
$R_{9-9'}$	1.381	1.392	1.377
R_{9-10}	1.538	1.529	1.48 — 1.49
α	53.1	51.9	52.5 — 53.4
β	108.4	109.4	106.7—109.5
θ_t	0	45.0	43
θ_f	27.7	0	0
θ_b	14.8	0	0

a) Bond lengths are in Å and bond angles are in degrees. b) α is the half of the C_{10}–C_9–C_{13} angle and β is the C_{11}-C_{10}–C_9 angle which are measured before folding the 9-fluorenylidene fragment. c) Ref. 3.

Table 2. Energy Components in the Folded and Twisted Structures

	Twisted(θ_t=45°)	Folded(θ_t=0°)	ΔE/kJ mol^{-1}
E_1	−1754.218 eV	−1753.619 eV	58
E_2	−1754.218	−1753.619	58
E_{1-2}	−17.990	−18.914	−89

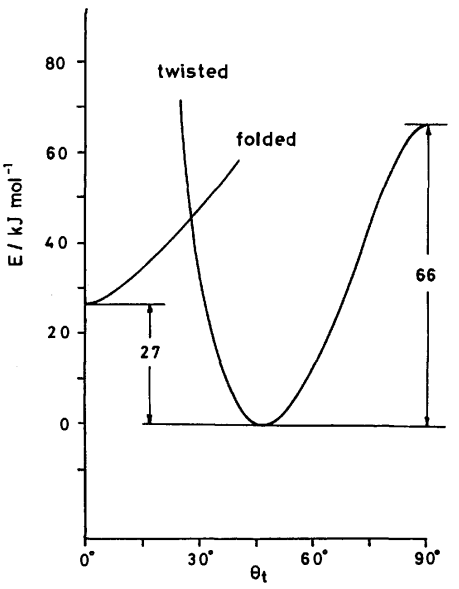

Fig. 4. Potential energy curves of 9,9′-bifluorenylidene with the twist angle θ_t. The energy is relative one with respect to the lowest twisted structure.

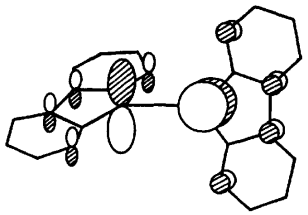


π_1 π_2

Fig. 5. Two π-orbitals of 9-fluorenylidene fragments. The ψ_1 and ψ_2 orbitals for $\theta_t=90°$ in Fig. 2 are expressed by linear combination of these two π-orbitals.

The contribution of the second configuration in Eq. 1 to the Φ_G wave function was 4—6% when $\theta_t \leqq 50°$. It increased when $\theta_t \geqq 60°$ and reached 50% at $\theta_t=90°$. The wave function of the 90°-twisted structure was, thus,

$$\Phi_G = \frac{1}{\sqrt{2}}|\cdots\psi_1\bar{\psi}_1| - \frac{1}{\sqrt{2}}|\cdots\psi_2\bar{\psi}_2|, \quad (2)$$

where the ψ_1 and ψ_2 orbitals were expressed by π_1 and π_2 orbitals each of which belongs to one of

$$\psi_1 = \frac{1}{\sqrt{2}}(\pi_1+\pi_2)$$
$$\psi_2 = \frac{1}{\sqrt{2}}(\pi_1-\pi_2) \quad (3)$$

the orthogonal 9-fluorenylidene fragment (Fig. 5). By using Eq. 3, Eq. 2 can be expressed in terms of the π_1 and π_2 orbitals by

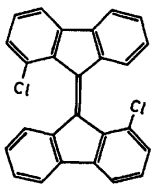
$$\Phi_G = \frac{1}{\sqrt{2}}\{|\cdots\pi_1\bar{\pi}_2| + |\cdots\pi_2\bar{\pi}_1|\},$$

indicating that the lowest singlet state of the 90°-twisted 9,9′-bifluorenylidene is a diradical in which the two orthogonal π_1 and π_2 orbitals are occupied by unpaired electrons.

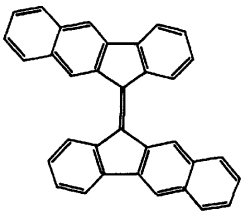
The present calculations show that *E*–*Z* isomerization is an interconversion between two twisted forms via the transition state of the 90°-twisted conformation. This is an interesting contrast with the *E*–*Z* isomerization of 10,10′-bianthrone where the 90°-twisted structure is not the transition state.[10,12] The barrier to the isomerization of 9,9′-bifluorenylidene was shown to be 66 kJ mol^{-1}, which is somewhat smaller than the value estimated from experiments, 108 kJ mol^{-1}.[13] Two factors need to be considered in an elucidation of structural effects on the low barrier for *E*–*Z* isomerization. First is the ground-state destabilization due to the steric repulsion around the 9–9′ bond, and the second is the stabilization of the diradical transition state by a large conjugated system. These two factors were examined by using the 1,1′-dichloro derivative, **2**, and the benzo-annelated compound, **3**. Table 3 shows the calculated energies of *E*-twisted, *Z*-twisted, and 90°-twisted structures of **2** and **3**. In the compound **2**, the *E*-form is more stable than the *Z*-form by 7 kJ mol^{-1}. This agrees with the experimental facts that in the 1,1′-disubstituted 9,9′-bifluorenylidenes, the *E*-form is more stable than the *Z*-form by 2—4 kJ mol^{-1}.[4,5] The activation energy calculated for the *E*→*Z* isomerization of **3**, 65 kJ mol^{-1}, is larger than that of **2**, 43 kJ mol^{-1}: this is parallel to the experimental findings.[4,5] The lowering of the rotational barrier by the introduction of chlorine atoms at the 1,1′-positions is attributed to the higher repulsion between fragments. This was reflected in the large twist angle, 53°, and was confirmed by the energy components analysis.

Table 3. Relative Energies of Conformers and the 90°-Twisted Structure of 9,9′-Bifluorenylidenes

Compound	Conformation	θ_t	Energy/kJ mol^{-1}
1	Twisted	45°	0
	90°-twisted	90°	66
2	*E*	53°	0
	Z	58°	7
	90°-twisted	90°	43
3	*E*	45°	0
	Z	45°	0
	90°-twisted	90°	65



2



3

The extension of the conjugated system is considered to stabilize the transition-state diradical and lower the barrier for the *E*–*Z* isomerization.[5] However, the lowering of the activation energy calculated for **3** was very small, 1 kJ mol^{-1}. The ground state is also expected to be stabilized by extension of the conjugated system, and the benzo-annelation stabilizes both the ground state and the transition state in the same extent.

Reaction of Hydroxide Ion with Electron Acceptors in Dimethyl Sulfoxide

Kisaburo UMEMOTO* and Nobuyuki OKAMURA
Department of Pure and Applied Sciences, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received October 24, 1985)

In dimethyl sulfoxide, the reaction of hydroxide ion with several electron acceptors—iodine, tetracyanoquinodimethan, Nitro Blue Tetrazolium chloride, 2,3,5-triphenyltetrazolium chloride, anthraquinone, and benzophenone—gave reaction products identical to those obtained by the reaction of these electron acceptors with electron donors. The reaction pathways of these electron acceptors were found to be composed of successive one-electron reactions similar to the electrochemical reduction of these electron acceptors. These results indicate that hydroxide ion acts as a reductant in dimethyl sulfoxide.

Hydroxide ion is known to be oxidized at +0.75 V vs. SCE in dimethyl sulfoxide,[1] but the reducing property of hydroxide ion is so weak in aqueous solution that hydroxide ion has been paid little attention as a reductant. Recently, 1-oxo-2,2,6,6-tetramethylpiperidinium salt,[2] anthraquinone,[3] and several electron acceptors[4] were found to be reduced by hydroxide ion in dichloromethane,[2] dimethyl sulfoxide,[3] and acetonitrile.[4] These observations are suggestive of the enhanced reducing power of hydroxide ion in nonaqueous aprotic solvents.

In the present paper, the reaction of hydroxide ion with several electron acceptors of various reduction potentials were studied in order to exemplify the reducing property of hydroxide ion. Dimethyl sulfoxide was used as the solvent, since this solvent is widely used as a useful nonaqueous solvent, while little has been known[3] about the reducing property of hydroxide ion in this solvent.

Experimental

As the sources of hydroxide ion, tetrabutylammonium hydroxide (0.38 M aqueous TBAOH), tetraethylammonium hydroxide (0.69 M aqueous TEAOH), and potassium hydroxide (1M aqueous KOH) were used (1 M=1 mol dm^{-3}). Potassium *t*-butoxide (tBOK, dissolved in ethanol in 0.03 M) and potassium hyperoxide (KO_2, dissolved in DMSO with 18-crown-6-ether in 0.002 M) were used as the electron donors. Iodine, tetracyanoquinodimethan (TCNQ), Nitro Blue Tetrazolium chloride (NBT), 2,3,5-triphenyltetrazolium chloride (TTC), anthraquinone (AQ), and benzophenone (BP) were used as the electron acceptors. Dimethyl sulfoxide (DMSO) was purified as described previously.[5]

The reaction of the hydroxides with the electron acceptors were carried out in a spectrophotometric cell equipped with an airtight sealing cap: a 3 ml of the DMSO solution containing (0.5—10)×10^{-5} M of an electron acceptor was taken in the cell, deaerated with nitrogen gas, and followed by the addition of the aqueous solution of 0.2—10 μl of hydroxide with a microsyringe. The concentration of the electron acceptor and the amount of the added hydroxide were chosen depending on the efficiency of each reaction. The ESR measurements were carried out by taking out an aliquot of the solution under nitrogen. The stopped-flow experiments carried out for observing the kinetic traces of the absorption spectra of the reaction intermediates were performed by using a Furue Science JP-V microfieder. The electrochemical studies were performed as described previously.[5] For the measurement of absorption spectra of electrochemically generated unstable species, the electrolysis was carried out by using an H-type cell as shown in Fig. 1, the cathode compartment of which was composed of a spectrophotometric cell. The cathode was a Pt gauze (0.5×2.0 cm) and the anode was a Pt wire. The salt bridge connected to the SCE was put in the anode compartment. Nitrogen gas was bubbled through both compartments in order to agitate the solution for an efficient electrolysis, to deaerate, and to secure the homogeneity of the solution.

Results and Discussion

Hydroxide ion is known to be gradually decomposed in DMSO, but 0.069 M TEAOH and 0.038 M TBAOH in DMSO were found to remain the same titers after 30 min of standing, indicating that hydroxide ion is stable in DMSO for the time period of ca. 30 min required for the measurement of each spectrum.

The identification of the reaction products and the reaction intermediates generated from the electron acceptors was performed by electrochemical, spectrophotometric, and ESR measurements as summarized as follows.

Iodine. Iodine reacts with the hydroxides and the electron donors very fast and the color of iodine disappeared instantaneously on addition of an excess amount of the hydroxides and the electron donors examined. The generation of iodate in the reactions

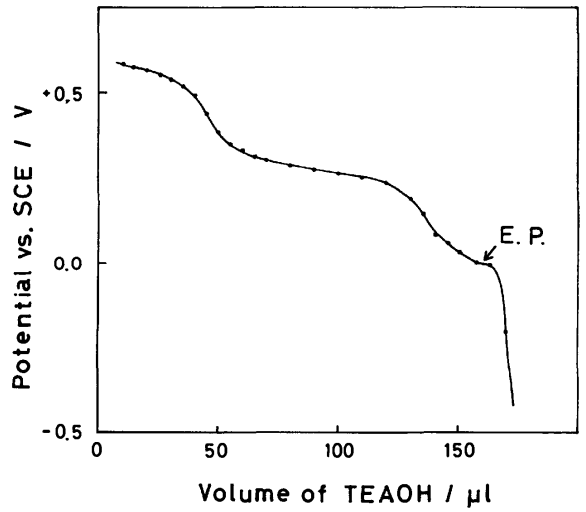

Fig. 2. Titration of iodine with TEAOH in DMSO. Iodine: 20 ml of 5.36 mM (as I) in DMSO. TEAOH: 0.69 M aqueous solution. End point (E.P.): 160 μl of TEAOH. Indicator electrode: Pt.

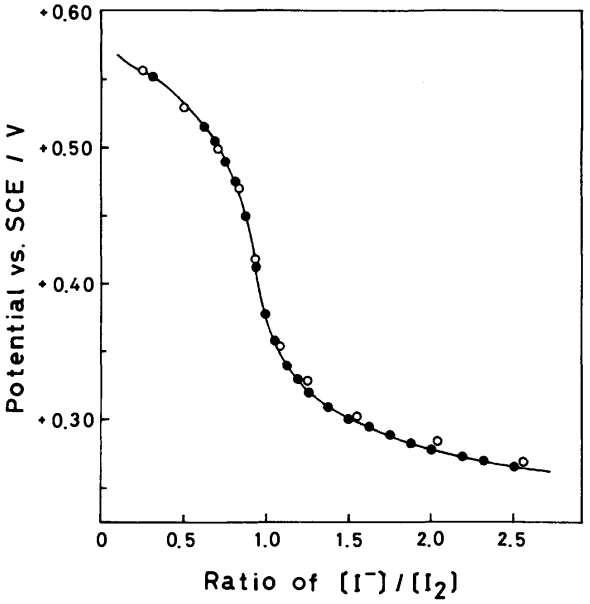

Fig. 3. The equiliblium potential change of I_2/I_3^- system in DMSO.

was ruled out since iodate is sparingly soluble in DMSO, while no precipitate was found in the solutions. The reaction of iodine with the hydroxides gave a redox titration curve as shown in Fig. 2. The potential change at the first inflection point agreed well with that obtained for the titration of iodine with KI as shown in Fig. 3, indicating iodine being reduced to iodide ion on reaction with hydroxide ion. By taking one-electron reaction, the clear-cut disappearance of

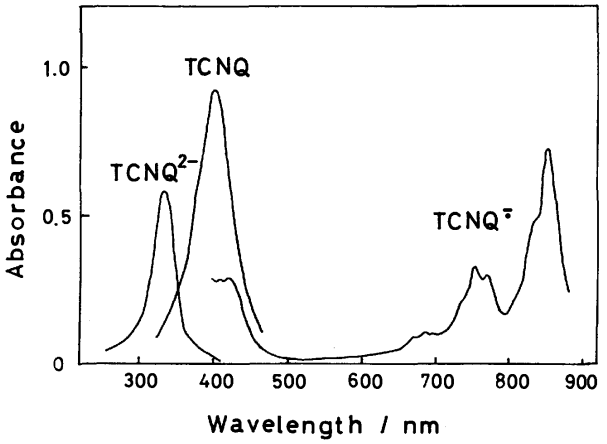

Fig. 4. Absorption spectra of reduction products of TCNQ obtained from 3.7×10^{-5} M of TCNQ in DMSO.

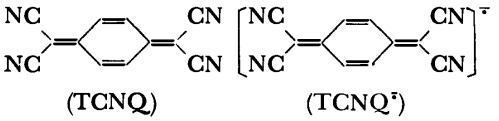

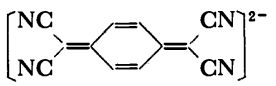

(TCNQ²⁻)

the color of iodine was found to occur at the stoichiometrically equivalent end point of the titration; a ratio of $[I]/[OH^-]=1:1.03$ was found experimentally.

TCNQ. The cyclic voltammogram of TCNQ showed two reversible one-electron redox waves with reduction potential of +0.25 and −0.30 V vs. SCE, respectively. By the controlled potential electrolysis at the first reduction wave, an ESR active green colored solution of $TCNQ^-$ was obtained. By the constant potential electrolysis at the second reduction wave, $TCNQ^-$ was reduced to the colorless $TCNQ^{2-}$. Upon addition of TCNQ to the solution containing $TCNQ^{2-}$ alone, $TCNQ^-$ was found to be generated. By taking these results, the redox reaction scheme of TCNQ is given as follows.

$$TCNQ \overset{e}{\rightleftharpoons} TCNQ^- \overset{e}{\rightleftharpoons} TCNQ^{2-} \quad (1)$$

$$TCNQ^{2-} + TCNQ \longrightarrow 2\,TCNQ^- \quad (2)$$

The absorption spectra of these reduction products are given in Fig. 4.

On reaction with the hydroxides and the electron donors examined, TCNQ gave $TCNQ^-$ when the concentration of the hydroxides or the electron donors is less than the equivalent amount of TCNQ and with the addition of an excess amount of the hydroxides or the electron donors, $TCNQ^-$ was reduced to $TCNQ^{2-}$. The rate of reaction of TCNQ with the hydroxides and the electron donors was so fast that the color change of the solution occurred instantaneously upon mixing the reactants. From the observations of the stepped

generation of $TCNQ^{\cdot-}$ and $TCNQ^{2-}$ from TCNQ, TCNQ is considered to be reduced by hydroxide ion by successive one-electron reactions as shown as follows.

$$TCNQ + OH^- \longrightarrow TCNQ^{\cdot-} + OH \quad (3)$$

$$TCNQ^{\cdot-} + OH^- \longrightarrow TCNQ^{2-} + OH \quad (4)$$

The hydroxy radical is known to be unstable to give oxygen and water[1] or hydrogen peroxide[2] according to the following reactions.

$$2\,OH \longrightarrow H_2O_2 \quad (5)$$

$$H_2O_2 \longrightarrow H_2O + \frac{1}{2}O_2 \quad (6)$$

The consumption of hydroxide ion in the reaction was detected by using a pH meter. As the response of the glass electrode in pure DMSO is not specified, the measurement was carried out after dissolving 10 ml of DMSO into 30 ml of water. In this solvent mixture, the 0.69 M TEAOH showed the same titer as in aqueous solution. The indicator of the pH meter was calibrated by adding a known amount of hydroxide in 10 ml of DMSO before mixing with 30 ml of water. When no hydroxide was added, the meter indicated at pH 5.0 (880 mV), and when 15 μl of 0.69 M TEAOH was added in 10 ml of DMSO (1.0×10^{-3} M), the meter indicated at pH 10.8 (530 mV). When 15 μl of 0.69 M TEAOH was added into 10 ml of DMSO containing 1.37×10^{-3} M TCNQ, the pH meter showed pH 5.3 (860 mV), indicating almost no hydroxide ion being left in the solution after the reaction with TCNQ proceeded. No oxygen was detected as the reaction product as evidenced by the observation of no oxygen wave at −0.8 V vs. SCE on the cyclic voltammogram taken after the reaction of hydroxide ion with TCNQ completed. The detection of hydrogen peroxide was unsuccessful because of the reactivity of DMSO on the permanganate method and of the color interference of TCNQ on the titanium chloride method. The hydroxy radical is known to react with some solvents,[6] but the reaction product of OH and DMSO was not confirmed or excluded in the present work.

NBT. On the cyclic voltammogram of NBT^{2+}, three predominant reduction waves were observed at −0.28, −1.28, and −1.66 V vs. SCE. The first wave which has a slight shoulder was attributed to the reduction of the tetrazolium ring as shown below. The second and the third waves are considered to correspond to the reduction of the nitro group of NBT^{2+}, since these potentials are close to those of para-substituted nitrobenzene derivatives. At the early stage of the constant potential electrolysis at −0.55 V vs. SCE, corresponding to the first reduction wave, a blue colored solution of monoformazan (MF, λ_{max}=680 nm) was obtained. The solution also gave an ESR spectrum identified to that of bitetrazole cation radical ($NBT^{\cdot+}$). The monoformazan thus generated turned to

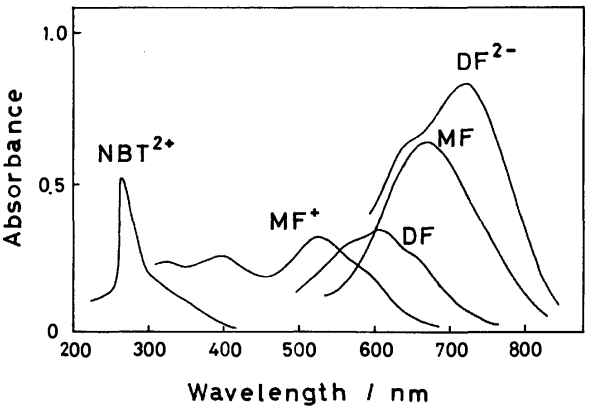

Fig. 5. Absorption spectra of reduction products of NBT obtained from 8.2×10^{-6} M of NBT in DMSO.

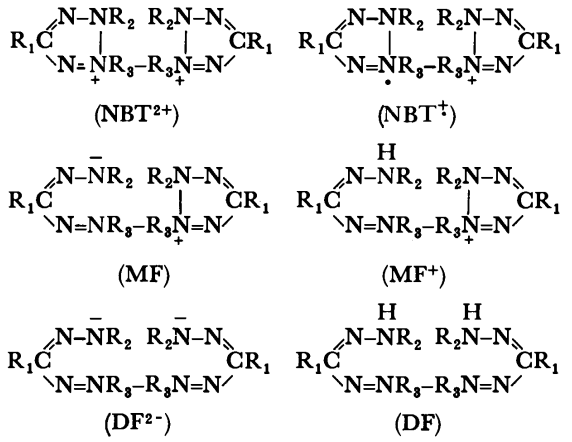

$R_1 = C_6H_5$, $R_2 = p\text{-}NO_2C_6H_4$, $R_3 = m\text{-}CH_3OC_6H_3$

the monoformazan ion (MF^+, λ_{max}=530 nm) on addition of acids. Upon completion of the controlled potential electrolysis at −0.55 V vs. SCE, a sky blue solution of biformazan dianion (DF^{2-}, λ_{max}=724 nm) was obtained with the consumption of overall four electrons for each molecule of NBT^{2+}. The biformazan dianion was turned to biformazan (DF) on addition of acids. The reaction scheme of NBT^{2+} was given as follows.[7]

$$NBT^{2+} \xrightarrow{e} NBT^{\cdot+} \xrightarrow{e} MF \xrightarrow{H^+} MF^+ \quad (7)$$

$$MF \xrightarrow{2e} DF^{2-} \xrightarrow{2H^+} DF \quad (8)$$

The characteristic absorption bands of these species are given in Fig. 5. The formation of MF according to the following disproportionation reaction of $NBT^{\cdot+}$ is also probable,[7]

$$2\,NBT^{\cdot+} \rightleftharpoons NBT^{2+} + MF \quad (9)$$

but it was not confirmed whether MF is formed by the electronation or the disproportionation of $NBT^{\cdot+}$. It is most reasonable to consider that both reactions are operative in the reduction process of NBT^{2+}.

On reaction with the hydroxides, NBT^{2+} immediately gave a blue-colored solution of MF. The solution

also gave an ESR spectrum identified to $NBT^{\ddagger}$. The MF and $NBT^{\ddagger}$ thus generated were converted to MF^+ on addition of acids. The reaction scheme of NBT^{2+} with hydroxide ion is considered to be as follows.

$$NBT^{2+} + OH^- \longrightarrow NBT^{\ddagger} + OH \quad (10)$$

$$NBT^{\ddagger} + OH^- \longrightarrow MF + OH \quad (11)$$

and/or

$$2\,NBT^{\ddagger} \rightleftharpoons NBT^{2+} + MF \quad (9)$$

The consumption of hydroxide ion in this reaction was confirmed by using a pH meter as in the case of TCNQ. The reaction of the hydroxides with NBT^{2+} was fast but not so effective as in the reactions of iodine and TCNQ. For example, by the reaction of 8.2×10^{-6} M NBT^{2+} with 1.64×10^{-5} M TEAOH required from the stoichiometry of the reactions shown by Eqs. 10, 11, or 9, only half amount of NBT^{2+} was reduced. As the reduction potential of NBT^{2+} is more negative than those of iodine and TCNQ, the electron donating property of hydroxide ion is considered to be less effective for NBT^{2+} than for iodine and TCNQ.

TTC. The electrochemical study of TTC showed that 2,3,5-triphenyltetrazolium ion (TT^+) is reduced to a tetrazolyl radical ($TT^{\cdot}$) and to 1,3,5-triphenylformazan anion (TF^-, λ_{max}=536 nm) at −0.49 and −0.74 V vs. SCE, respectively. TF^- was also generated by the disproportionation reaction of $TT^{\cdot}$ generated by the constant potential electrolysis at −0.55 V vs. SCE.[5] The reaction scheme of TT^+ is given as follows.[5]

$$TT^+ \xrightarrow{e} TT^{\cdot} \xrightarrow{e} TF^- \xrightarrow{H^+} TF \quad (12)$$

$$2\,TT^{\cdot} \rightleftharpoons TT^+ + TF^- \quad (13)$$

The characteristic absorption bands of these species are given in Fig. 6.

Upon reaction with the hydroxides, TT^+ gave a highly red colored solution of TF^-. The solution also gave an ESR spectrum identified to $TT^{\cdot}$. On addition of acids, the ESR spectrum disappeared and the solution gave an absorption spectrum characteristic to 1,3,5-triphenylformazan (TF, λ_{max}=485 nm). The reaction of TTC with hydroxide ion is given as follows.

$$TT^+ + OH^- \longrightarrow TT^{\cdot} + OH \quad (14)$$

$$TT^{\cdot} + OH^- \longrightarrow TF^- + OH \quad (15)$$

and/or

$$2\,TT^{\cdot} \rightleftharpoons TT^+ + TF^- \quad (13)$$

The reaction of TTC with hydroxide ion was less effective than the reactions of iodine, TCNQ, and NBT^{2+} as predicted from the reduction potential of TTC which is more negative than the reduction potentials of iodine, TCNQ, and NBT^{2+}. For example,

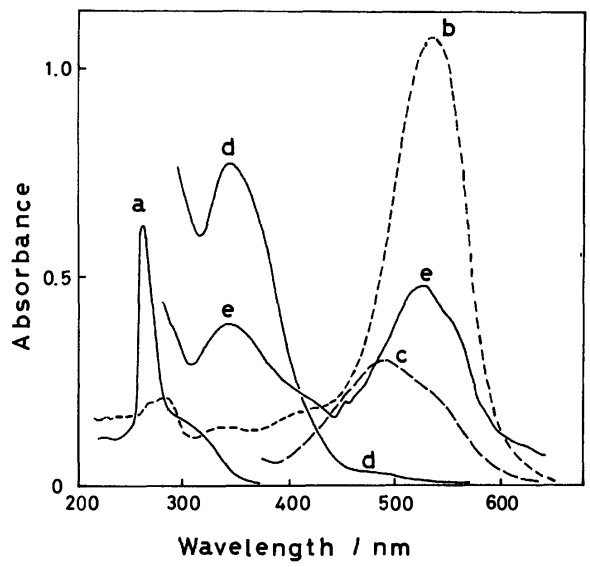

Fig. 6. Absorption spectra of (a): 3.5×10^{-5} M TTC, (b): TF^- generated from (a) by the reaction with TBAOH, (c): TF generated from (b) with the addition of benzoic acid, (d): $TT^{\cdot}$ generated by the reaction of TF^- with TT^+ in DMSO–benzene mixture (DMSO:benzene=20:80 in volume), (e): $TT^{\cdot}$ and TF^- obtained 2 s after mixing of 1.0×10^{-4} M TTC and 1.0×10^{-2} M TBAOH by flowing the solutions.

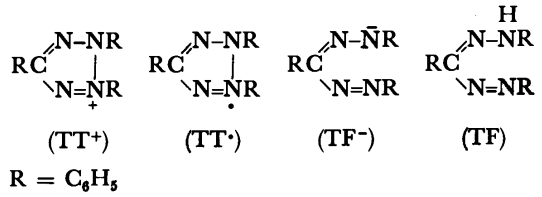

when 3.5×10^{-5} M TTC was reacted with 7.0×10^{-5} M TEAOH, only one third of the amount of TTC was reduced.

Although $TT^{\cdot}$ was detected by the ESR method in the reaction of TTC with an equimolar amount of hydroxide, any absorption band attributable to $TT^{\cdot}$ was not observed in pure DMSO. However, when benzene was added into the solution of TF^- with an excess amount of TTC, the color of the solution turned from red to yellow and a new absorption band appeared at 345 nm with the consumption of the absorption band of TF^- as shown in Fig. 6d. In a typical experiment, 1 ml of DMSO solution of TF^- generated by the reaction of 3.5×10^{-5} M TTC with 5×10^{-4} M TBAOH was added into 8 ml of pure benzene. The solution showed an absorption spectrum of TF^- alone. To this solution 1 ml of DMSO solution containing 3×10^{-3} M TTC was added. The color of the solution turned from red to yellow. The yellow colored solution gave an intense ESR spectrum identical to that of $TT^{\cdot}$ as shown in Fig. 7. Thus, the absorption band at 345 nm was identified to that of $TT^{\cdot}$. This band was gradually substituted by that of TF^- with the successive increase of the content of DMSO in the DMSO–benzene mixture. These observa-

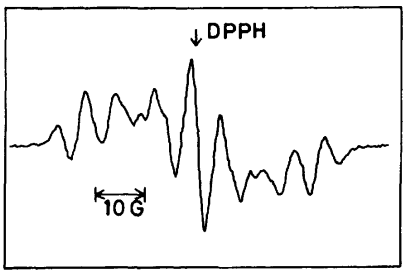

Fig. 7. ESR spectrum of TT·, generated by the reaction of TTC with TBAOH in DMSO.

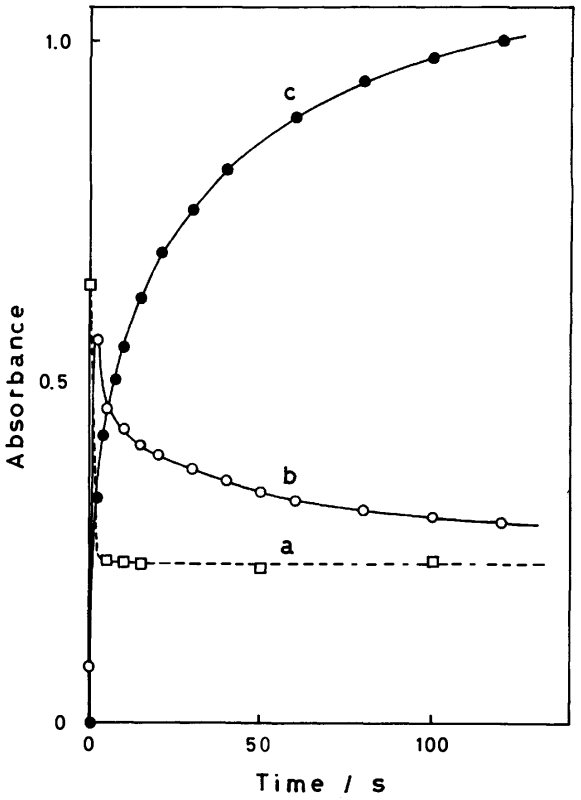

Fig. 8. Stopped-flow kinetic traces of absorption bands observed in the reaction of 7.0×10^{-5} M TTC with 7.6×10^{-3} M TBAOH in DMSO.
(a): TT^+ at 258 nm, (b) TT· at 345 nm (the range of absorbance: ×2), and (c): TF^- at 536 nm.

tions indicate that in pure DMSO the equilibrium constant of the disproportionation reaction (Eq. 13) is so large that the concentration of TT· is kept too low to be detected by the spectrophotometric method at the equilibrium state. However, if the reaction of TTC with hydroxide ion is induced by the electron transfer from hydroxide ion to TT^+, the transient accumulation of TT· should be observed at the early stage of the reaction. In order to verify the probable accumulation of TT·, the reaction was studied by a flow method. The reactants were introduced into a spectrophotometric flow-cell by using a double-channeled microfeeder. On the absorption spectrum taken immediately after mixing the reactants, absorption bands of both TT· and TF^- were observed as shown

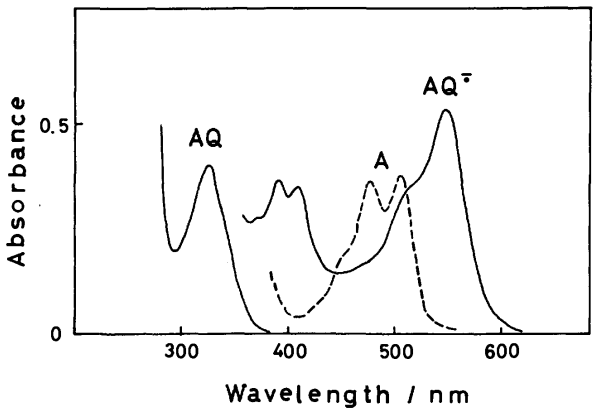

Fig. 9. Absorption spectra of reaction products of anthraquinone (AQ) in DMSO.
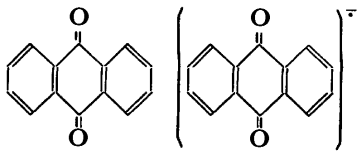
AQ: 8.0×10^{-5} M. AQ^- and A: generated from 2.3×10^{-3} M of AQ by the reaction with TEAOH.



in Fig. 6e. The stopped-flow kinetic traces of absorption bands of TT^+, TT·, and TF^- are given in Fig. 8. Although the time courses of these kinetic traces are not so simple as to allow a rigorous kinetic analysis; the rate of increase of TF^- is seen to be well intercorrelated with the rate of decrease of TT·, indicating that TT· is working as a precursor of TF^- in the reaction sequence.

Anthraquinone. The cyclic voltammetry of AQ showed that AQ is reversibly reduced to AQ^- and AQ^{2-} at −0.83 and −1.53 V vs. SCE, respectively. The constant potential electrolysis at the first reduction wave gave a red colored solution of AQ^- (λ_{max}=550 nm) as shown in Fig. 9.

On reaction with the hydroxides, AQ gave a red-colored solution of AQ^-. The solution showed an ESR signal. The reaction of AQ with the hydroxides was not so effective as in the reactions of iodine, TCNQ, NBT, and TTC as predicted from the reduction potential of AQ which is the most negative among these electron acceptors. In order to obtain an absorption spectrum of AQ^-, higher concentration of AQ was required as compared with the other electron acceptors examined. AQ^- turned gradually to a yellow colored species (shown by A in Fig. 9) on standing, which did not give any ESR signal and has not been identified yet.

Benzophenone. The electrochemical study of BP showed that BP is reduced to blue colored BP^- at −1.77 V vs. SCE. However, BP did not react with the hydroxides and the electron donors examined. The reduction potential of BP is too negative to be reduced by the hydroxides and the electron donors examined.

Conclusion. The reaction products and intermediates identified in the reactions of the electron

Table 1. Reaction Products Identified in the Reaction of Electron Acceptors with Hydroxides and Electron Donors in DMSO

BP	—	—	—	—	—	$BP^{\cdot-}$	−1.77

acceptors with the hydroxides and the electron donors in DMSO are summarized in Table 1. As shown in Table 1, the reaction of the electron acceptors with the hydroxides gave reaction products or intermediates identical to those obtained by the reaction of these electron acceptors with the electron donors. The efficiency of the reactions was shown to have a qualitative correlation with the reduction potentials of the electron acceptors: the less negative the reduction potential, the more efficiently the reaction proceeded. These observations would lead us to suppose that hydroxide ion acts as an electron donor in the reactions examined.

The reducing property of hydroxide ion is of interest, since this property may possibly play an essential role in some, not all, of the so-called base-catalyzed reactions. Further studies to clarify the role of hydroxide ion are also required in analytical chemistry, since the reducing property of hydroxide ion has been paid little attention in the acid-base reactions in nonaqueous solvents.

The authors thank Dr. Ryo Hirasawa and Master Kazuo Sakamoto for their kind permission and outstanding assistances in using their ESR spectrometer.

Ylide-Metal Complexes. XI.[1] The Preparation and Properties of VIA Group Metal (Te) Complexes of Alkylidenetriphenylphosphoranes and the Corresponding Selenium Compounds

Yoshihisa YAMAMOTO
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
(Received March 12, 1986)

Reactions of $(C_6H_5)_3P{=}CH_2$ (**L**) with $TeCl_4$ of mole ratios 2 : 1 and 3 : 1 yield new compounds: dichlorobis(methylenetriphenylphosphorane)tellurium dichloride, $[L_2TeCl_2]Cl_2$ (**1**), and chlorotris(methylenetriphenylphosphorane)tellurium trichloride, $[L_3TeCl]Cl_3$ (**2**), respectively. The reaction of ylide **L** with compound **1** yields a new compound: tetrakis(methylenetriphenylphosphorane)tellurium tetrachloride, $[L_4Te]Cl_4$ (**3**). The structure of compounds **1**—**3** is a distorted tetrahedron. The color of **1**—**3** is yellow. The electronic absorption spectra of compounds **2** and **3** show six absorption bands in the region 200—500 nm in dry dichloromethane. The reactions of ylide **L** with $(C_6H_5)_2SeCl_2$ of mole ratios 1 : 1 and 2 : 1 yield new compounds: chloro(methylenetriphenylphosphorane)diphenylselenium chloride, $[LSe(Cl)(C_6H_5)_2]Cl$ (**9**), and bis(methylenetriphenylphosphorane)diphenylselenium dichloride, $[L_2Se(C_6H_5)_2]Cl_2$ (**11**), respectively. The color of the selenium compounds is white. The tellurium and selenium compounds are thermally stable in the solid state.

A previous paper[2] of this series was concerned with a study of methylenetriphenylphosphorane, bis(methylenetriphenylphosphorane)gold(I) chloride and the corresponding copper(I) chloride by X-ray photoelectron spectroscopy. Also, we have been concerned with the preparation, properties and structures of ylide-metal complexes for I—IV group metals with unstable phosphoranes.[3-6] In the VIA group, the preparation of several selenium compounds with phosphoranes, $(C_6H_5)_3P{=}CHR$ (R: H, CH_3, SC_6H_5), has been reported.[7-10] However, the preparation of a tellurium compound with phosphorane has not been reported except for a tellurium compound with stable (ethoxycarbonylmethylene)triphenylphosphorane,[11,12] $(C_6H_5)_3P{=}CHCOOC_2H_5$. Very little is known of the preparation, properties and structures of selenium and tellurium compounds with phosphoranes[3,13-15] and arsoranes.[16,17] Thus, the present paper deals with the preparation and properties of dichlorobis(methylenetriphenylphosphorane)tellurium dichloride, $[\{(C_6H_5)_3PCH_2\}_2TeCl_2]Cl_2$, chlorotris(methylenetriphenylphosphorane)tellurium trichloride, $[\{(C_6H_5)_3PCH_2\}_3TeCl]Cl_3$, and tetrakis(methylenetriphenylphosphorane)tellurium tetrachloride, $[\{(C_6H_5)_3PCH_2\}_4Te]Cl_4$, and deals with the preparation of chloro(methylenetriphenylphosphorane)diphenylselenium chloride, $[(C_6H_5)_3PCH_2Se(Cl)(C_6H_5)_2]Cl$, and bis(methylenetriphenylphosphorane)diphenylselenium dichloride, $[\{(C_6H_5)_3PCH_2\}_2Se(C_6H_5)_2]Cl_2$.

Experimental

Measurements. The NMR spectra were measured with an R-40 (Hitachi) spectrometer, XL-200 (Varian) spectrometer for ^1H NMR, and with an FX-60 spectrometer (JEOL) for ^{13}C NMR. The electric conductivities of the solutions were determined by the use of a conductometric meter, CM-30 (Shimadzu) in dry methanol and dry dichloromethane. The electronic absorption spectra were recorded with a Shimadzu UV-210 recording spectrophotometer.

Starting Material. The methylene-[18] and ethylidene[19] triphenylphosphorane were prepared from the corresponding phosphonium bromide by the sodium amide method.

Preparation of Ylide–Metal Complexes. Dichlorobis(methylenetriphenylphosphorane)tellurium Dichloride (1): The methylene ylide (0.43 g, 1.56 mmol) was dissolved in dry THF (20 cm^3) at 0 °C under nitrogen. The THF solution was added to powder $TeCl_4$ (0.2 g, 0.74 mmol) at 0 °C. The mixture was stirred for 10 min at 0 °C. The precipitated light yellow complex was filtered and dried under vacuum. Yield: 0.50 g (82%). Decomp: 124 °C. Found: C, 56.00; H, 4.35%. Calcd for $C_{38}H_{34}P_2TeCl_4$ (MW 822.04) C, 55.52; H, 4.17%.

Chlorotris(methylenetriphenylphosphorane)tellurium Trichloride (2): The dry THF (20 cm^3) solution of methylene ylide (0.47 g, 1.70 mmol) was added to powder $TeCl_4$ (0.15 g, 0.56 mmol) under nitrogen. The mixture was stirred at room temperature for 1 d. The precipitated yellow complex was filtered, washed with pentane and dried under vacuum. Yield: 0.52 g (85%). Decomp: 106 °C. Found: C, 62.24; H, 5.01%. Calcd for $C_{57}H_{51}P_3TeCl_4$ (MW 1098.36) C, 62.33; H, 4.68%. Electronic absorption spectrum: 240 nm (ε=13100), 260 (9200), 267 (10100), 274 (8530), 350 (730), and 435 (1630) in dry dichloromethane. Λ=193 S cm^2 mol^{-1} in dry methanol solution at 19 °C; a 29.4 mg sample was dissolved 27-cm^3 of dry methanol. Complex **2** was also prepared from the reaction mixture of ylide and $TeCl_4$ in a mole ratio of 4:1 in THF.

Tetrakis(methylenetriphenylphosphorane)tellurium Tetrachloride (3): The dry THF (20 cm^3) solution of methylene ylide (0.31 g, 1.12 mmol) was added to powder $TeCl_4$ (0.15 g, 0.56 mmol) at 0 °C. The mixture was stirred for 10 min at 0 °C. Then, the THF solution (10 cm^3) of methylene ylide (0.34 g, 1.23 mmol) was added to the reaction mixture at 0 °C under nitrogen. The mixture was stirred for 150 min at room temperature. A deep-yellow complex was filtered, washed with pentane and dried. Yield: 0.63 g (82%). Decomp: 116 °C. Found: C, 66.15; H, 5.20%. Calcd for $C_{76}H_{68}P_4TeCl_4$ (MW 1374.67) C, 66.40; H, 4.99%. Electronic absorption spectrum: 238 nm (ε=18300), 262 (13000), 267 (14200), 275 (11700), 360 (900), and 447 (2030) in dry dichloromethane. Λ=328 S cm^2 mol^{-1} in dry methanol solution at 19 °C; a 34.9 mg sample was dissolved 25-cm^3 of dry methanol. Λ=75 S cm^2 mol^{-1} in dry dichloromethane solution at 21 °C; a 49.6 mg sample was dissolved in dry dichloromethane 36 cm^3.

Chloro(methylenetriphenylphosphorane)diphenylselenium Chloride (9): Diphenylselenium dichloride (0.19 g, 0.62

mmol) was added to a dry THF solution (8 cm^3) of methylene ylide (0.17 g, 0.62 mmol) under nitrogen. The mixture was stirred for 20 h. Then, the precipitated compound was filtered, washed with ether and dried. Yield: 0.19 g (52%). Decomp: 162 °C. Found: C, 64.48; H, 4.93%. Calcd for $C_{31}H_{27}PSeCl_2$ (MW 580.39) C, 64.15; H, 4.69%.

Chloro(ethylidenetriphenylphosphorane)diphenylselenium Chloride (10): Diphenylselenium dichloride (0.23 g, 0.76 mmol) was added to a dry THF solution (8 cm^3) of ethylidene ylide (0.25 g, 0.86 mmol) under nitrogen. The mixture was stirred for 18 h at room temperature. The precipitated white compound was filtered, washed with ether and dried. Yield: 0.28 g (62%). Decomp: 160 °C. Found: C, 64.35; H, 4.79%. Calcd for $C_{32}H_{29}PSeCl_2$ (MW 594.42) C, 64.66; H, 4.92%.

Bis(methylenetriphenylphosphorane)diphenylselenium Dichloride (11): Diphenylselenium dichloride (0.19 g, 0.62 mmol) was added to a dry THF solution (8 cm^3) of methylene ylide (0.37 g, 1.34 mmol) under nitrogen. The mixture was stirred for 1 d. The precipitated compound was filtered, washed with ether and dried. Yield: 0.28 g (52%). Decomp: 203 °C. Found: C, 70.35; H, 5.34%. Calcd for $C_{50}H_{44}P_2SeCl_2$ (MW 856.71) C, 70.10; H, 5.18%.

Bis(ethylidenetriphenylphosphorane)diphenylselenium Dichloride (12): Diphenylselenium dichloride (0.19 g, 0.62 mmol) was added to a dry THF solution (10 cm^3) of ethylidene ylide (0.40 g, 1.38 mmol) under nitrogen. The mixture was stirred for 20 h. The precipitated compound was filtered, washed with ether and dried. Yield: 0.30 g (54%). Decomp: 193 °C. Found: C, 70.43; H, 5.54%. Calcd for $C_{52}H_{48}P_2SeCl_2$ (MW 884.76) C, 70.59; H, 5.47%.

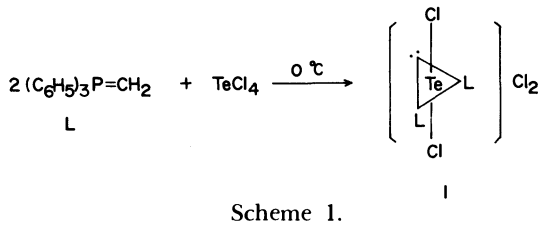
Results and Discussion

Dichlorobis(methylenetriphenylphosphorane)tellurium dichloride, $[\{(C_6H_5)_3PCH_2\}_2TeCl_2]Cl_2$ (**1**), and chlorotris(methylenetriphenylphosphorane)tellurium trichloride, $[\{(C_6H_5)_3PCH_2\}_3TeCl]Cl_3$ (**2**), were isolated from the reaction mixtures of methylenetriphenylphosphorane, $(C_6H_5)_3P{=}CH_2$ (**L**), and $TeCl_4$ in mole ratios of 2:1 and 3:1, respectively. Tetrakis(methylenetriphenylphosphorane)tellurium tetrachloride, $[\{(C_6H_5)_3PCH_2\}_4Te]Cl_4$ (**3**), was isolated from a reaction mixture of **L** and complex **1** in a mole ratio of 2:1. Complexes **1**—**3** are soluble in chloroform, dichloromethane, DMF, DMSO and water, but are insoluble in benzene, tetrahydrofuran (THF), pentane and ether. Complexes **1**—**3** in water give phosphonium chloride, $[(C_6H_5)_3PCH_3]Cl$ (**4**). Complexes **2** and **3** are stable in alcohols, though complex **1** is unstable. Their color is yellow, and they are thermally stable in the solid state.

The ^1H NMR spectra of **1**—**3** showed a doublet signal for methylene group at 2.9—3.3 ppm and a multiplet signal for phenyl groups at 7.4—8.1 ppm in a ratio of 2:15 at room temperature in dichloromethane-d_2. The coupling constant ($^2J_{HCP}$) of the methylene group is larger than that of **L**, and the chemical shift is at a lower field than that of **L** as is shown in Table 1. In the ^{13}C NMR spectra in dichloromethane-d_2, the chemical shift for methylene group is at a lower field than that of **L**, and the coupling constant (J_{CP}) for methylene group is smaller than that of **L** as is shown in Table 1. These spectral properties were similar to those of bis(methylenetriphenylphosphorane)-metal chloride, $[(C_6H_5)_3PCH_2\text{-}M\text{-}CH_2P(C_6H_5)_3]Cl_2$ (**5**) (M: IIB group metals),[5] and the corresponding ylide-metal complexes such as $[(C_6H_5)_3PCH_2\text{-}M\langle^{Cl}_{Cl}\rangle M\text{-}CH_2P(C_6H_5)_3]Cl_2$ (**6**) (M: IIA group metals)[3] and $[(C_6H_5)_3PCH_2\text{-}M(C_6H_5)_3]Cl$ (**7**) (M: IVA group metals).[4] Thus, the ylide in complexes **1**—**3** is bonded to the metal atom through the carbanionic donor atom.[19]

Complex **1** is not polymeric[20] since it is soluble in dichloromethane. The elemental analysis of **1** agreed with that of L_2TeCl_4. The structures of $TeCl_4$[21,22] and $(C_6H_5)_2TeBr_2$[23,24] (**8**) were found to be monomeric

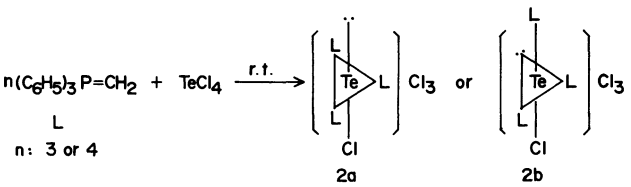
distorted tetrahedrons by X-ray diffraction, i.e., the observed bond angles were 178.0±0.2° for Br–Te–Br and 96.3±1.2° for C–Te–C. Two bromine atoms in **8** are bonded to the axial positions and are at a position cis for the lone pair. Thus, we suggest that the structure of **1** is a distorted tetrahedron as is shown in Scheme 1.



I

Scheme 1.

Complex **2** is not polymeric[20] since it is soluble in dichloromethane and alcohols. The elemental analysis of **2** agreed with that of L_3TeCl_4. Complex **2** has free anion, judging from the molar conductance (cf. Experimental section). Thus, the structure of **2** is either **2a** or **2b** (distorted tetrahedron) as is shown in Scheme 2. We believe that the structure of **2** is **2a**:



Scheme 2.

The chlorine atoms in complex **1** are substituted with ylides, and complex **1** changes to complex **3** (described below) which is not obtained from the reaction mixture of ylide and $TeCl_4$ in the mole ratio 4:1. This difference is due to the configuration (cis or trans) between the chlorine atom and lone pair in the complex. Thus, the chlorine atom in the position cis for the lone pair can be substituted with ylide. This was confirmed in the preparation of complexes **9**—**11** (described below), which were obtained from the mixture of ylide and diphenylselenium dichloride since the chlorine atoms in diphenylselenium dichloride are in a position cis for the lone pair according to X-ray diffraction.[24,25] Thus, the chlorine atom in **2** might be in a position trans to a lone pair such as **2a**.

Complex **3** is not polymeric[20] since it is soluble in dichloromethane and alcohols. The elemental analysis of **3** agreed with that of L_4TeCl_4. Complex **3** has free anion, judging from the molar conductance. Complex **3** has been isolated only from a reaction mixture of **L** and complex **1** in the mole ratio 2:1. Thus, we suggest that the structure of **3** is a distorted tetrahedron as is shown in Scheme 3.

The electronic absorption spectra of the ylide metal complexes were observed. The spectra of **2** and **3** showed six absorption bands in dry dichloromethane as

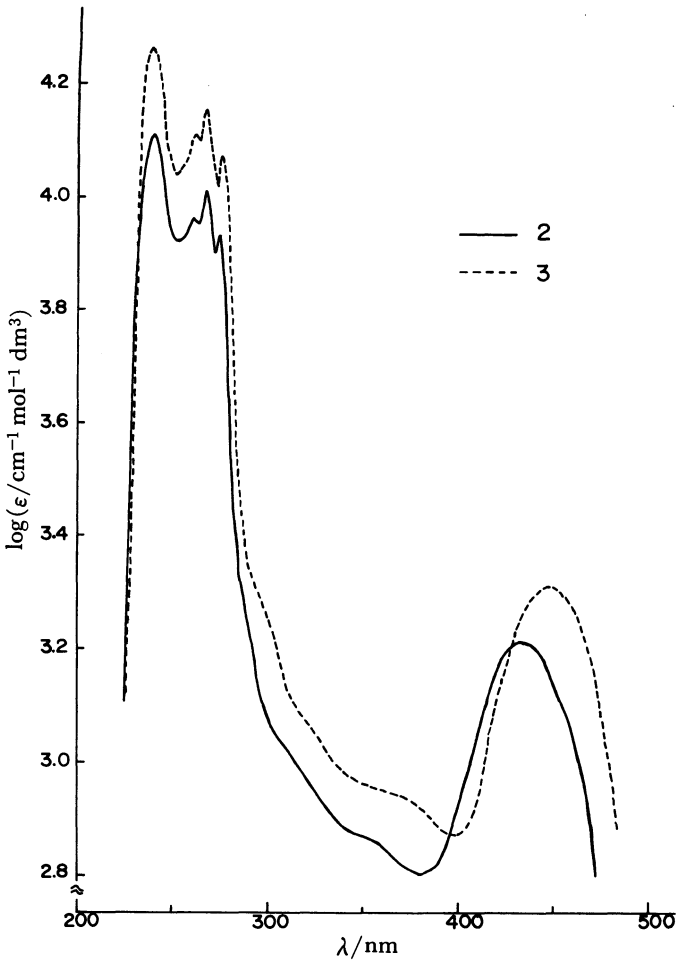


Fig. 1. The electronic absorption spectra of **2** and **3** complexes in dichloromethane.
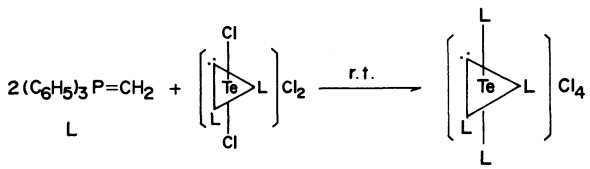
2: $[\{(C_6H_5)_3PCH_2\}_3TeCl]Cl_3$. **3**: $[\{(C_6H_5)_3PCH_2\}_4Te]$-$Cl_4$.

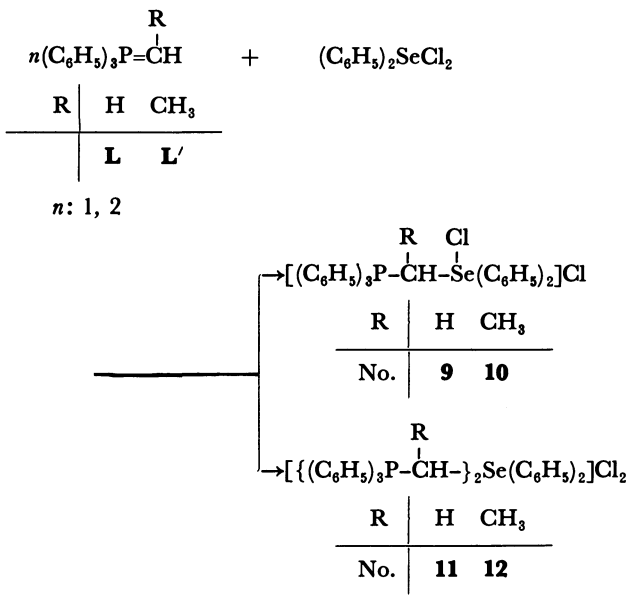


3

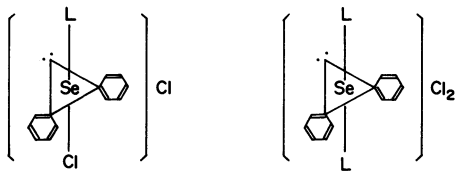
Scheme 3.

is shown in Fig. 1 and Experimental section. The absorption band at 435 nm or 447 nm can be assigned to the charge-transfer band. The absorption spectra[26] for phosphoranes did not show in the 400—500 nm region.

Chloro(methylene(or ethylidene-)triphenylphosphorane)diphenylselenium chloride (**9**, **10**) and bis(methylene(or ethylidene-)triphenylphosphorane)diphenylselenium dichloride (**11**, **12**) have been isolated from the reaction mixtures of diphenylselenium dichloride and methylene ylide (**L**) or ethylidenetriphenylphosphorane, $(C_6H_5)_3P=CH(CH_3)$ (**L'**), in the mole ratio 1:1 or 1:2.



They are soluble in alcohols, dichloromethane, chloroform, water, DMSO and DMF, but insoluble in benzene and acetone. The ^{1}H NMR spectra of **9—12** could not be observed since compounds **9—12** are unstable in alcohols, dichloromethane and chloroform at −80 °C and give the corresponding phosphonium salt (**4**). However, their decomposition temperatures differ from the melting points of the ylides **L** and **L'** and salt **4**. Their color is white, and they are thermally stable in the solid state. The elemental analyses of **9—10** and **11—12** agreed with those of [(**L** or **L'**)Se(Cl)(C_6H_5)$_2$]Cl, and [(**L** or **L'**)$_2$Se(C_6H_5)$_2$]Cl_2, respectively. Thus, the ylides are bonded to the Se atom in the solid state such as complexes **6** and **7**.[3,4] The structures of diphenylselenium dibromide, (C_6H_5)$_2$$SeBr_2$[24] (**13**), and di(*p*-tolyl)selenium dibromide, (*p*-$CH_3C_6H_4$)$_2$-$SeBr_2$[24,25] (**14**), and the corresponding dichloride[24,25] have been found to be monomeric distorted tetrahedron by X-ray diffraction. The observed C–Se–C bond angles were ca. 110° and the observed X–Se–X bond angles were ca. 180°; therefore two halogen atoms are in the position *cis* for the lone pair. Thus, the chlorine atoms in diphenylselenium dichloride are substituted with ylides, and complexes **9—12** are formed. From the above, we suggest that the structure of **9—12** is a distorted tetrahedron as is shown in Scheme 4.



9 11

Scheme 4.

The different characteristics between tellurium complexes **1—3** and selenium compounds **9—12** are their colors and stabilities in solution. The color of tellurium complexes is yellow, but that of the selenium compounds is white. The tellurium complexes are stable in methanol and dichloromethane at room temperature, but the selenium compounds are unstable in alcohols and dichloromethane at −80 °C.

Spectrophotometric Determination of Micro Amounts of Pentathionate via Permanganate Reaction

Yasuyuki MIURA* and Tomozo KOH
Department of Chemistry, Faculty of Science, Tokai University, 1117, Kitakaname, Hiratsuka, Kanagawa 259-12
(Received March 20, 1986)

A method has been developed for the determination of micro amounts of pentathionate. It is based on the reaction of pentathionate with a given amount of permanganate in a dilute sulfuric acid medium and on the spectrophotometric measurement of iodine as triiodide, which is formed by the oxidation of iodide with an excess of permanganate. The analytical conditions were established by varying the temperature, reaction time, and amounts of sulfuric acid and permanganate. The present method can be successfully applied to a determination of pentathionate in the range 2×10^{-7} to 1.4×10^{-5} mol dm^{-3} (0.5—35.9 μg $S_5O_6^{2-}$ in 10 cm^3) and gives a higher sensitivity than any previous method without solvent extraction. In eleven determinations for 10 cm^3 sample solutions containing 0.080 μmol of pentathionate, the present method gave a mean value of 0.080 μmol, with a standard deviation of 0.0006 μmol and a relative standard deviation of 0.75%.

A simple, accurate and sensitive determination of polythionates (tri-, tetra-, penta-, and hexathionate) is increasingly desirable from the viewpoint of sulfur chemistry. When polythionates react with cyanide, sulfite, hydroxide or mercury(II) thiocyanate, thiocyanate or thiosulfate (or both species equivalent to each of polythionates) is formed. Thiocyanate and thiosulfate can easily be measured spectrophotometrically with iron(III) and iodine, respectively. Therefore, various investigations have been made concerning the cyanolysis,[1-7] the sulfitolysis,[8-11] the alkaline decomposition[12,13] and the mercury(II) thiocyanate reaction[14] of polythionates and have led to the development of spectrophotometric methods for the determination of polythionates at concentrations as low as the 10^{-4} mol dm^{-3} level. Moreover, a sensitive method has been proposed for the determination of tetra-, penta-, and hexathionate, based on the solvent extraction of thiocyanate formed by their cyanolysis as an ion pair with Methylene Blue.[15] The cyanolysis and sulfitolysis of polythionates have also played a critical role in the development of methods for the analysis of mixtures of polythionates[16-20] as well as mixtures of sulfite, thiosulfate and each of the polythionates.[8-11] High-performance liquid chromatography (HPLC)[21-25] has been used for the separation of mixtures of polythionates. Takano et al.[24] sulfitolyzed polythionates prior to HPLC separation and determined even tri- and tetrathionate in mixtures with the other polythionates (which can not be separated chromatographically).

In a previous paper,[26] the present authors devised a sensitive method for the determination of thiocyanate up to 4×10^{-5} mol dm^{-3}; it was based on the consumption of permanganate by its reaction with thiocyanate in an acid medium. It has been found that pentathionate is also oxidized by permanganate. No consideration was given to the spectrophotometric determination of polythionates by means of their reactions with permanganate. In the present study, the optimal conditions under which pentathionate can be oxidized quantitatively by permanganate were established. The proposed method is based on the reaction of pentathionate with a given amount of permanganate in dilute sulfuric acid and on the spectrophotometric measurement of any formed iodine (as triiodide) after a reaction of excess permanganate with iodide to form iodine.

Experimental

Apparatus. All spectrophotometric measurements were made at 350 nm using a Shimadzu Model UV-240 recording spectrophotometer with 10-mm quartz cells. Desired temperatures were controlled by a Taiyo Coolnit Model CL-15 thermoregulator. In all the experiments, redistilled water was used, which was freed from any permanganate-consuming impurities with a Nippon Millipore, Ltd., Model Milli-QII apparatus.

Reagents. All chemicals were of analytical grade and were used without further purification.

Potassium pentathionate. Potassium pentathionate was prepared as described by Goehring and Feldmann.[27] The obtained pentathionate ($K_2S_5O_6\cdot1.5H_2O$) was recrystallized twice in an acid medium of 0.5 mol dm^{-3} hydrochloric acid, and then dried at room temperature before storage at -10 ± 2°C. The pentathionate was confirmed to be sufficiently pure for the present purpose; its purity was estimated by the sulfitolysis method[10] to be 92.5% as $K_2S_5O_6$.

Standard Pentathionate Solution. A 1×10^{-3} mol dm^{-3} pentathionate solution was prepared by dissolving 180.8 mg of potassium pentathionate in water and diluting to 500 cm^3. The stock solution of 1×10^{-3} mol dm^{-3} standard pentathionate could be used for at least four months without any measurable changes as long as it was stored at 5 ± 2°C. The working solution was prepared by suitable dilution.

Standard Permanganate Solution.[28] A 0.02 mol dm^{-3} permanganate solution was prepared by heating a potassium permanganate solution to boiling, keeping it at a temperature slightly below the boiling point for 1 h, and then allowing it to stand for 3 d at room temperature. After manganese dioxide had been filtered off by suction with a sintered glass filter (3SG4), the filtrate was standardized by titration with standard sodium oxalate. The stock solution of 0.02 mol dm^{-3} standard permanganate proved to be stable; even after six months, no measurable change was found by the present method when it was stored at room temperature in the dark. A working solution of 2×10^{-4} mol dm^{-3} permanganate

could be used for 2 d.

Standard Thiosulfate Solution. A 0.1 mol dm^{-3} thiosulfate solution was prepared by dissolving sodium thiosulfate pentahydrate in freshly boiled and cooled water containing a small amount of sodium carbonate as a stabilizer. The thiosulfate solution was standardized by iodimetry a week after preparation. A 5×10^{-4} mol dm^{-3} thiosulfate solution was obtained by diluting the standardized thiosulfate solution.

Iodide Solution. A 0.5 mol dm^{-3} iodide solution was prepared by dissolving 41.7 g of potassium iodide in water containing 200 mg of sodium carbonate as a stabilizer and by then diluting it to 500 cm^3.

Recommended Procedure. A mixture of 1.5 cm^3 of 1 mol dm^{-3} sulfuric acid and 4 cm^3 of 2×10^{-4} mol dm^{-3} standard potassium permanganate solution was placed in a 25 cm^3 volumetric flask. To this mixture, 10 cm^3 of a sample solution containing pentathionate up to 0.140 μmol was added. The mixture was then allowed to stand for 20 min at temperatures ranging from 5 to 40 °C to complete the oxidation of pentathionate. Then, 1 cm^3 of 0.5 mol dm^{-3} potassium iodide was added to form iodine equivalent to excess permanganate, and 3 cm^3 of 5×10^{-4} mol dm^{-3} sodium thiosulfate was added to decrease the absorbance of the iodine as triiodide to an appropriate value, otherwise the absorbance for the reagent blank becomes so high as much as 1.94. The flask was filled to the mark with water. The absorbance of a solution of the triiodide complex, thus formed, was measured against water at 350 nm about 5 min after the dilution.

A permanganate-free reagent blank was prepared by adding 1.5 cm^3 of 1 mol dm^{-3} sulfuric acid, 14 cm^3 of water in place of both 4 cm^3 of 2×10^{-4} mol dm^{-3} permanganate and 10-cm^3 of a sample solution containing pentathionate, and 1 cm^3 of 0.5 mol dm^{-3} iodide in a 25-cm^3 volumetric flask. After the flask had been filled to the mark with water, the absorbance was measured against water at 350 nm after about 5 min. This absorbance value was subtracted from each of the absorbances for pentathionate and the reagent blank, for iodide is susceptible to air-oxidation in an acid medium.

Results and Discussion

Reaction of Pentathionate with Permanganate. In order to determine the stoichiometric relationship between pentathionate and permanganate in an acid medium, the reaction was investigated by the molar-ratio method. For the application of this method, 4 cm^3 of permanganate with various molar concentrations and 10-cm^3 of each of 0.3×10^{-5}, 0.6×10^{-5}, 1×10^{-5} and 1.4×10^{-5} mol dm^{-3} pentathionate solutions were used with varying the molar ratio of permanganate to pentathionate. Pentathionate was allowed to react with permanganate for 20 min, where sodium thiosulfate was not added. The results are shown in Fig. 1. When straight portions of each graph were extrapolated, each line (dotted lines) intersected the abscissa at a point of 3.5. This fact proves that 2 mol of pentathionate reacted exactly with 7 mol of permanganate under the conditions of the recommended procedure.

Calibration Plots. Figure 2 shows the calibration graphs obtained by treating a series of standard solutions of pentathionate according to the recommended procedure, and the plots obtained by treating a series of standard permanganate solutions according to the recommended procedure except that 4 cm^3 of redistilled water was used instead of 4 cm^3 of 2×10^{-4} mol dm^{-3} permanganate. The graph for permanganate was prepared to confirm the stoichiometry and the completion

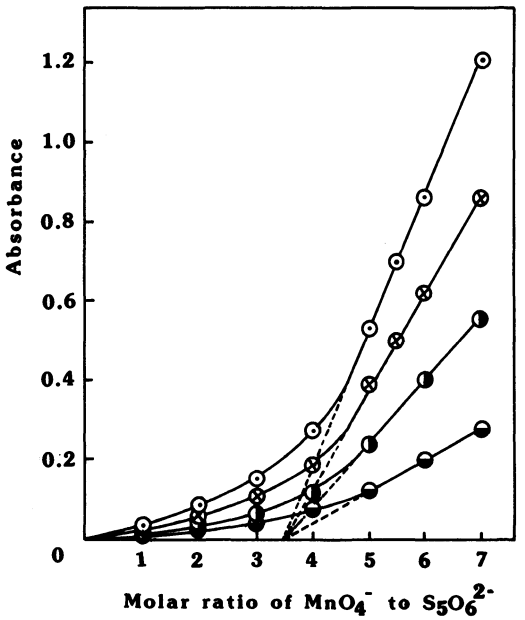

Fig. 1. Molar ratio plots for the reaction of pentathionate with permanganate.
⊙: 1.4×10^{-5} mol dm^{-3} $S_5O_6^{2-}$, ⊗: 1×10^{-5} mol dm^{-3} $S_5O_6^{2-}$, ◑: 0.6×10^{-5} mol dm^{-3} $S_5O_6^{2-}$, ◒: 0.3×10^{-5} mol dm^{-3} $S_5O_6^{2-}$.

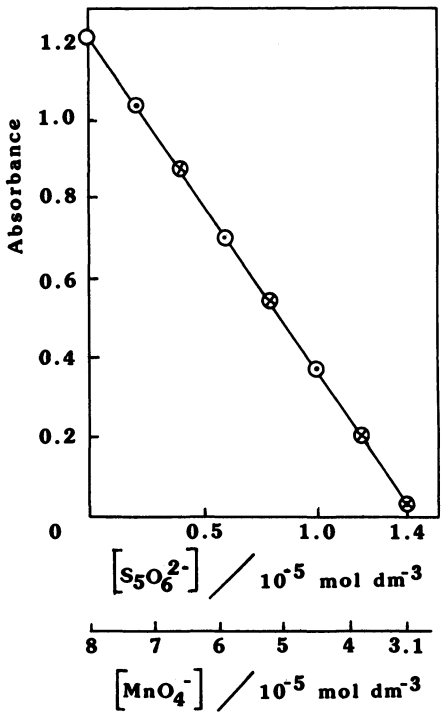

Fig. 2. Calibration plots.
○: Reagent blank, ⊙: $S_5O_6^{2-}$, ⊗: MnO_4^- (expected value).

of the reaction of pentathionate with permanganate. As described above, if 2 mol of pentathionate reacts with 7 mol of permanganate stoichiometrically, the graph for pentathionate should coincide with that for permanganate (the expected graph). Figure 2 proves that the reaction proceeded to stoichiometric completion under the conditions of the recommended procedure.

The precision was estimated from eleven results for 10-cm^3 aliquots of a solution containing 0.080 μmol of pentathionate. The present method gave a mean value of 0.080 μmol, with a standard deviation of 0.0006 μmol and a relative standard deviation of 0.75%. This method gives a higher sensitivity than previous methods without any need for solvent extractions.

Rate of Reaction of Pentathionate with Permanganate. The reaction rate was investigated at temperatures ranging from 5 to 40°C. The amounts of the reagents and the addition order were the same as in the above procedure. The results are given in Table 1. The reaction was gradually accelerated by an increase in the temperature. The absorbances for 1.2×10^{-5} mol dm^{-3} pentathionate reached those for 3.8×10^{-5} mol dm^{-3} permanganate, which are the expected values, in 20 min at 5°C, in 10 min at 10 and 20°C, in 5 min at 30°C and in 3 min at 40°C, and then kept constant until 60 min had passed. These facts confirm that the reaction proceeds to completion as long as the reaction is carried out for 20 min at temperatures of 5 to 40°C. On the other hand, when pentathionate was allowed to react with permanganate in a low-acidity solution using 1.5 cm^3 of 0.6 mol dm^{-3} sulfuric acid, the reaction did not proceed to completion. Therefore, the effect of acidity was investigated at 20°C. The results are shown in Table 2.

Table 1. Reaction Rate of Pentathionate with Permanganate at Various Temperatures

t / min	Absorbance of I_3^- (350 nm)				
	1.2×10^{-5} mol dm^{-3} $S_5O_6^{2-}$				
	5°C	10°C	20°C	30°C	40°C

a) Three cm^3 of 0.5 mol dm^{-3} NaF was added. b) One cm^3 of 0.05 mol dm^{-3} sulfamic acid was added.

The absorbances for 1.2×10^{-5} mol dm^{-3} pentathionate coincided with the expected value in 10 min with respect to 1.5 cm^3 of each of 0.8, 1, and 2 mol dm^{-3} sulfuric acid, and then remained constant. Consequently, 1.5 cm^3 of 1 mol dm^{-3} sulfuric acid was employed in this experiment.

Effect of Amounts of Permanganate. For measuring the effect of amounts of permanganate, pentathionate was allowed to react with various amounts of potassium permanganate for 20 min at 20 °C. In this experiment, thiosulfate, which is used in order to reduce the absorbance in the recommended procedure, was not added. The absorbance, therefore, increased with increasing amounts of permanganate employed. The resulting graphs given in Fig. 3 were normalized in such way that each calibration graph for pentathionate with various amounts of permanganate was permitted to shift in parallel fashion to cause each reagent blank to accord with that obtained under the conditions of the recommended procedure. When 2.5 and 3 cm^3 of 2×10^{-4} mol dm^{-3} permanganate were used, the reaction did not go to completion because the amounts of permanganate were insufficient; even in this case, the reagent blank gave high absorbances of 1.215 and 1.453, respectively. When 3.5, 4.0, or 4.5 cm^3 of the permanganate solution were used, the graphs for pentathionate yielded a straight line and coincided exactly with that obtained under the conditions of the recommended procedure. Consequently, 4 cm^3 of 2×10^{-4} mol dm^{-3} permanganate was employed, and 3 cm^3 of 5×10^{-4} mol dm^{-3} thiosulfate was added to decrease the reagent blank to an appropriate value by reducing the iodine formed.

Effect of Diverse Ions. A 10-cm^3 portion of a solution containing 20.5 μg of pentathionate and various amounts of diverse ions was treated exactly as in the recommended procedure. For the determination of pentathionate with an error of below 2% by the present method, foreign ions can be tolerated at the levels given in Table 3. Iron(II), nitrite, thiosulfate, sulfide, and sulfite gave positive errors, even when present in trace amounts, because they reduce permanganate. However, the interference of nitrite could be eliminated by decomposing it with sulfamic acid. Iron(III) gave a negative interference in amounts of 10 μg because it oxidizes iodide to form iodine, but its interference was removed by masking with fluoride. Trithionate gave a very weak interference, but tetrathionate and hexathionate gave strong interferences with the determination of pentathionate because they also were oxidized by permanganate.

Trachit Change of the $ZrSiO_4$ Single Crystal During Crystal Growth Studied by the $Na_2O \cdot 3V_2O_5$ Flux Method

Masumi USHIO* and Yoshihiro SUMIYOSHI
Department of Applied Chemistry, Faculty of Engineering, Gunma University, Tenjin-cho, Kiryu 376
(Received April 3, 1986)

The appearance and disappearance of the crystal faces of the $ZrSiO_4$ single crystal during crystal growth under the conditions of a growth temperature of 900 °C and a Δt value (temperature difference) of 1 °C have been studied by means of the $Na_2O \cdot 3V_2O_5$ flux method. A spherical seed prepared from a natural zircon single crystal was used. The c{001}, a{100}, and m{110} appeared at the earliest stage, and next appeared r{115}, u{015}, p{111}, e{011}, and q{021} after 20 h of growth time. However, the u-face, r-face, and q-face disappeared after 400 h, and the c-face and a-face began to disappear after 500 h. The final morphology after 1400 h was a first-order prism and a pyramid consisting of only the m-face and the p-face. It was found that the m-face and the p-face were dominant on a flux-grown $ZrSiO_4$ single crystal, and that this tendency was unchangeable after 2500 h.

$ZrSiO_4$ (zircon) is a widely distributed accessory mineral in ogneous rocks. Ushio et al.[1] have reported the growth of the $ZrSiO_4$ single crystal by means of the $Na_2O \cdot 3V_2O_5$ flux method, using a natural zircon seed, the growth rate with the time; the normal growth rates of the c-face, the a-face, the p-face, and the m-face; the growth patterns on the p-face and the m-face; the step-advanced rates of the growth layers on the p-face and the m-face, etc. In this crystal-growth procedure, when a spherical seed was used, the trachit change in the crystal face was observed according to the increase in the growth time. An attempt to reproduce this interesting phenomenon is elucidated in detail.

The trachit change in a crystal may be caused by the different rates of growth of the various faces. A large number of factors can affect the trachit change of a crystal, e.g., the type of solvent, the pH of the solution, the degree of supersaturation or supercooling, the temperature of the crystal growth, the presence of impurities, the rate of cooling, the degree of agitation, the presence of a surface-active agent (surfactant), the flow of solution, the presence of defects (dislocation, twinning, and so on.), the growth time, and frequency and intensity of applied ultrasonic waves.[2]

In this paper, the purpose is to investigate, in detail, the trachit change in the crystal face of a zircon crystal in the initial, intermediate, and final stages, when the zircon crystals are grown slowly by means of the $Na_2O \cdot 3V_2O_5$ flux method using of natural spherical seeds.

Experimental

The experimental apparatus and the configurations of the crucible were previously reported.[1] The inner volume of the platinum crucible was ca. 400 ml, and natural zircon single crystals from Viet Nam and Brazil were used as seeds. There was no difference between the two crystals except for the number of cracks and their colors. The natural zircon single crystals were cut and their surfaces polished to a spherical form close to a true sphere about 5 mm in diameter.

The starting materials of oxides (V_2O_5, ZrO_2, and SiO_2) and a carbonate (Na_2CO_3), used as flux and nutrient, were used as the first-class reagents.

Runs were carried out under the conditions of 900 and 1000 °C for growth temperature (near the upper part of the nutrient) and 0.5 to 5 °C for Δt, which signifies the temperature difference between the seed and the upper part of the nutrient. The growth temperature, the supersaturation, and, especially, the growth time may have a influence on the trachit change in the crystal surface. For this reason, these factors have been controlled electrically as much as possible.

A 800 g portion of the flux and 120 g of the nutrient were charged into the platinum crucible. After confirming the saturation by the nutrient dissolved into the flux melt, a spherical seed tied up with a platinum wire was inserted into the flux melt. The growing seed was pulled up from the flux melt after having soaked for the fixed growth time, and then washed a hot alkaline solution and acid to dissolve the flux solid adhering to the seed surface. After observing the crystal surface of the growing seed with microscopes, this seed was again soaked in the melt. This procedure of inserting the seed into the flux melt and then pulling it, was repeated 30 times.

To identify the grown crystal faces of the zircon seed, an inclination-angle microscope and a scanning electron microscope were used. The former was used mainly to measure the angle between the two grown crystal faces of zircon seed, but also to confirm the existence and shape of the grown crystal faces.

Results

A run carried out under the conditions of a growth temperature of 900 °C and a temperature difference of 1 °C will now be described.

After 20 h of growth time, c{001} appeared in the neighborhood of poles, and a{100} and m{110} in the equator, but at this early stage, all the faces developed as flats and did not yet come into contact with one another. Small pyramid faces of r{115}, u{015}, e{011}, and then q{021} appeared between the c-face and the m- or a-faces.

After 50 h, pairs of faces, namely, the c-face and the r-face, the c-face and the u-face, the p-face and the w-face, the e-face and the q-face, the w-face and the m-face, and the q-face and the a-face, came into contact with each other, and then, appearance marked each step. At the growth time between 120 and 250 h, two groups of steps consisting of c-u-e-faces and c-r-p-faces were observed. However, the u-face and the r-face, the e-face

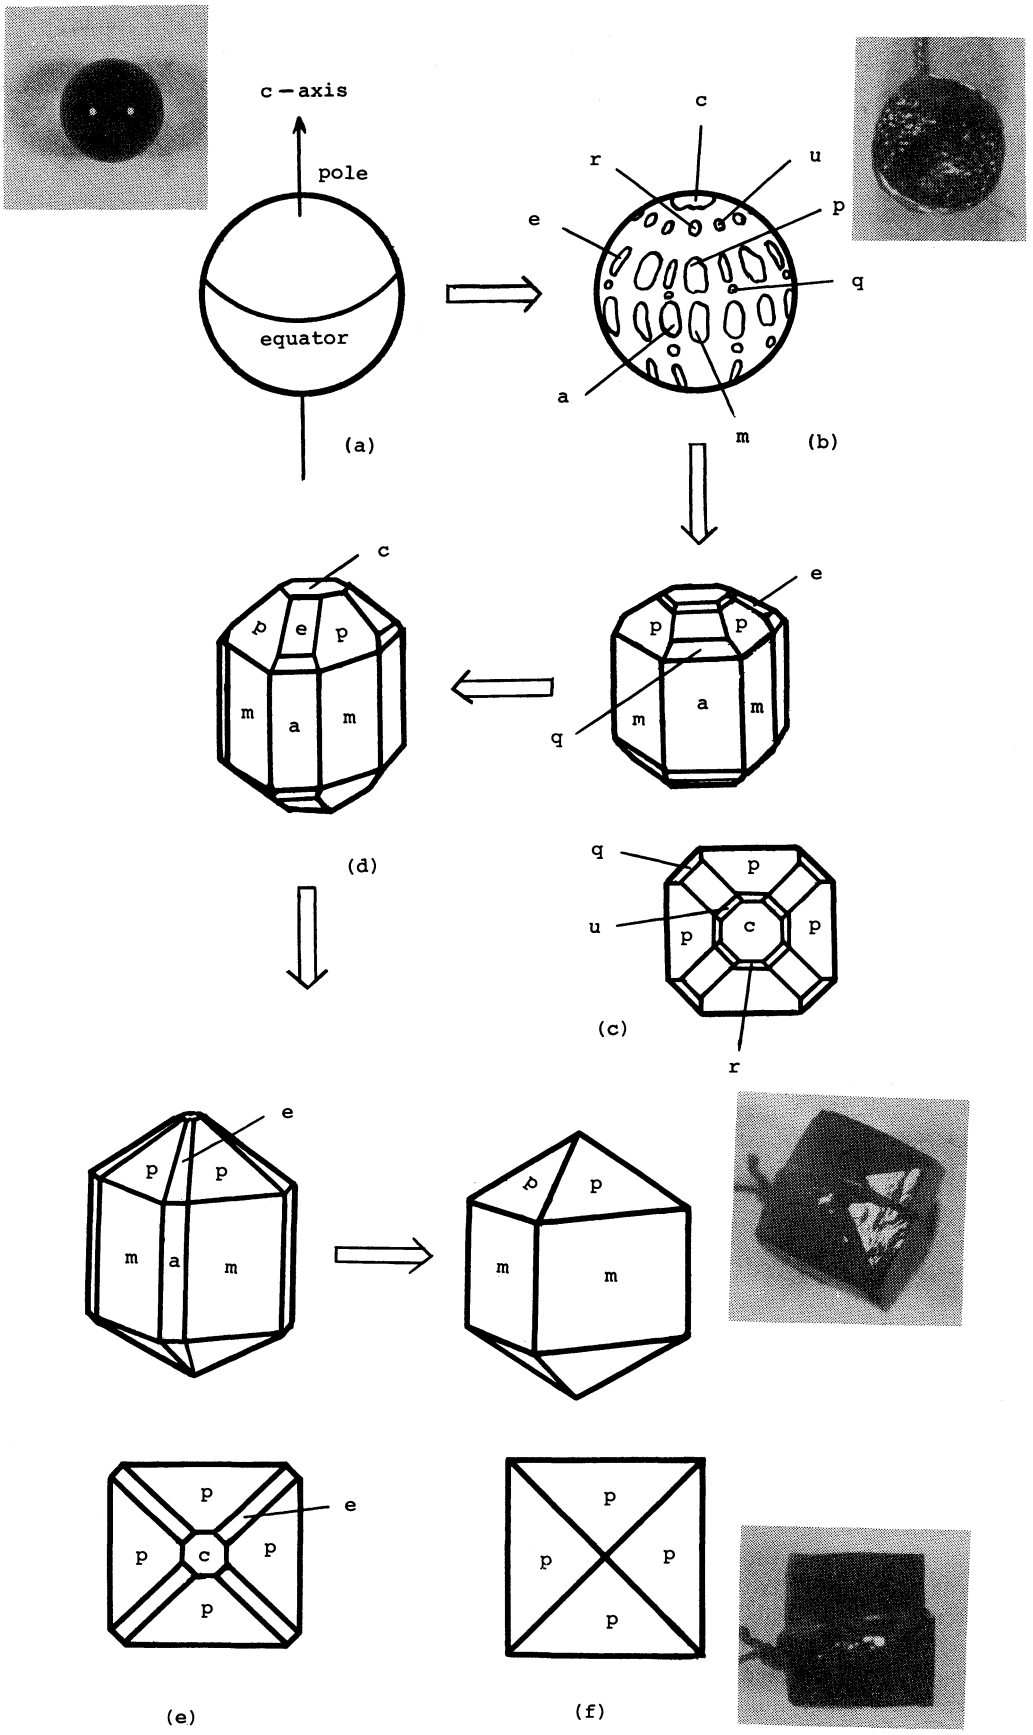

Fig. 1. Schematic drawing of appearance and disappearance of crystal faces during growth.
(a): Spherical seed. (b): after growth time between 20 and 100 h. (c): after 300 to 400 h. (d): 500 to 700 h. (e): after 900 to 1200 h. (f): after above 1400 h.

Table 1. Experimental Results of Interfacial Angle of Grown Zircon Xrystal

Angle between two faces	$Angle_{obsd}$
r{115}∧m{110}	79±0.5°
p{111}∧m{110}	45±0.5°
w{221}∧m{110}	29±0.5°
u{015}∧ a{100}	82±0.5°
e{011}∧ a{100}	57±0.5°
q{201}∧ a{100}	38±0.5°
e{011}∧e'{011}	46±0.5°
p{111}∧p'{111}	57±0.5°

and the p-face, and the m-face and the a-face did not make contact with each other.

After 300 h, the crystal domain of both c-u-e-faces and c-r-p-faces got much bigger, and the lateral faces of the a-face and the m-face came into contact with each other. The u-face, the r-face, the q-face, and the w-face disappeared after 400 h, while the c-face, the e-face, and the p-face grew further.

After 500 h, the p-face and the e-face were observed as pyramid faces, but the crystal-surface domain of the p-face was better developed than that of the e-face. After 700 h, the c-face and the a-face began to disappear. The e-face was also found to disappear.

After 900 h, only the p-face as a pyramid face and m-face as a lateral face grew much larger. The very small c-face, the e-face, and the a-face still remained, but these faces disappeared as growth went on.

The morphology after 1400 h was a first-order prism and a pyramid consisting of only the m-face and the p-face. The grown seed was elongated only in the direction of the *c*-axis after 2000 h and was bounded with the same faces. It was found that the m-face, and the p-face were dominant on the flux-grown $ZrSiO_4$ single crystal, and that this tendency was unchangeable after 2500 h.

A schematic drawing of the trachit changes during the growth of the $ZrSiO_4$ single crystal is shown in Fig. 1, while experimental results of the interfacial-angle measurements given in Table 1.

In the case a growth temperature of 1000°C, each face appeared and disappeared much faster than was the case at 900°C, while in the case of the same growth temperature, e.g., at 900°C, the increasing temperature difference had a tendency to promote the growth rate of each face.

Discussion

As has been mentioned above, the habit and trachit changes of a crystal are influenced by various factors.

The crystal faces most frequently observed in the natural zircon single crystal were c{001} as a basal face, m{110} and a{100} as prisms, and p{111}, u{331}, x{311} and e{011} as pyramids.[3]

By using a spherical and natural zircon single crystal as a seed, a basal c-face and prisms of the a-face and the m-face near the equator appeared mainly in the earliest stage, and then c-r-p-m-faces and c-u-q-a-faces appeared between the pole and the equator of a spherical seed. These faces made several flights of steps. Among these faces, the growth rate increase of the u-face, the r-face, and the q-face was much faster, and these faces also disappeared much faster. Judging from the experimental results on the order of disappearance, the u-face and the r-face disappeared almost simultaneously, and after a while the q-face disappeared. Then surface of the c-face became apparantly rough, and finally disappeared. The final crystal form was bounded by the p-face as a pyramid and the m-face as a prism in this experimental range. These faces were a prism and a pyramid of the first order. An a-face, etc., forming a prism and the pyramid faces of the second order disappeared. No w-face formed between the p-face and the m-face was observed because of the very high growth rate. A w-face belongs to the pyramid of the first order. Pyramid faces of the second order, e.g., the e-face, the u-face, and the q-face, remained from 900 to 1200 h.

From a stereographic projection for a crystal of zircon, a continuous series of steps of the c-u-e-q-a-faces would be observed in the direction of the *a*-axis if each face appeared, and we could expect a continuous series of steps of the c-r-p-w-m-faces to appear in the direction inclined at 30°C from the *a*-axis. No x-face was observed because of the higher growth rate.

Hartman[4] reported the morphology of zircon by applying the periodic-bond-chain theory, and calculated the lattice energy and the attachment energies of several faces. He concluded that, if it was assumed that the displacement velocities of the F-faces were proportional to the attachment energies, a "theoretical habit" of zircon crystals was bounded by two forms only: a{100} and e{011}.

These faces produced an "equilibrium form" and were a second-order prism and a pyramid. However, as has been stated previously, the "growth form" of the zircon single crystal prepared in this experiment was bounded by the first-order prism and pyramid faces, i.e, m{110} and p{111}. In comparison with the Kombinationspersistenz (*P*-value) and the Fundortspersistenz (*F*-value),[4,5] it was found that these values of crystal faces producing both forms, e.g., the equlibrium and growth forms, were relatively closer than those of the other faces. For this reason, it may be assumed that the ease of formation of both forms is influenced by the environmental conditions surrounding a zircon crystal, e.g., the kinds of the solute and the solvent and growth temperature.

From Hartman's result from the calculation of the attachment energies of the crystal faces of zircon by using the electrostatic energy, the order of attachment energy was found to be follows:

$$a\{100\} < m\{110\} < e\{011\} < p\{111\} < c\{001\}$$

The attachment energy of a {100} was the smallest one, m{110} ranked second, and so on. The F-face (flat face) is a{100}, m{110}, e{011}, if we considers the P.B.C vector numbers. It is possible that a F-face has a higher attachment energy than a S-face (stepped face) has. The c-face, the u-face, the r-face, the p-face, the m-face, and the a-face were observed in the initial stage of crystal growth, but trachit change was observed with the crystal growth proceeding and only the p-face and m-face were finally observed. In this experimental result, the growth form of zircon single crystal was a tetragonal prism with a bipyramid, bounded by the p-face and the m-face only. From these experimental findings concerning the appearance and disappearance of each face from the observed normal growth rates, the order of the normal growth rate for each face of zircon single crystal was determine to be as follows:

$$a\{100\} > c\{001\} > p\{111\} > m\{110\}$$

The observed value of the normal growth rate of the a-face was $5.0—7.0\times10^{-4}$ mm h^{-1}; the c-face, $2.0—3.5\times10^{-4}$ mm h^{-1}; the p-face, $1.2—2.0\times10^{-4}$ mm h^{-1}, and the m-face, $0.9—1.0\times10^{-4}$ mm h^{-1}.[1] From this fact, when a spherical crystal was used as a seed, the pyramid face appeared mainly in the initial stage, but almost disappeared in the intermediate stage because of the higher growth rates. A c-face as a basal face appeared mainly in the initial stage and remained until the final stage, but soon disappeared. Therefore, a normal growth rate for each face can be presumed to be one in which the trachit of growth in the zircon single crystal changes.

A small zircon single crystal grown by spontaneous nucleation formation at the bottom or on the wall of the crucible was bounded by the m-face and the p-face, which grew progressively greater, and by very small faces, e.g., the a-face, the q-face, and the c-face. At the bottom of the crucible, the growth rate of the zircon single crystal was usually slower in order to have a small temperature difference and a small convection velocity of the flux melt. Therefore, it was expected that a zircon single crystal was grown by a phenomenon close to the diffusion process. Small crystal faces of the a-face, the q-face, the c-face, etc. may remain without disappearing.

A process in which the solute molecule is carried to a seed by heat convection and incorporated in a seed surface may occur, but the process in which the solute is carried by a phenomenon close to heat convection, and therefore a seed grows, may more probably be expected.

Studies on Dissolved Metalloenzymes in Lake Water. II. Seasonal Variations in Phosphatase Activity in Lake Kasumigaura

Kensei KOBAYASHI,[a] Shinya HASHIMOTO, Koichi IWASE,[b] Akira OTSUKI,† Kitao FUJIWARA, Keiichiro FUWA, and Hiroki HARAGUCHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo 113
†National Institute for Environmental Studies, 16-2, Onogawa, Yatabe-machi, Ibaraki 305

(Received April 18, 1986)

Alkaline phosphatase activity in Lake Kasumigaura was determined periodically and characterized by high-performance liquid chromatography and isoelectric focusing electrophoresis. There are two peaks in dissolved alkaline phosphatase activity; the bigger one in summer and the smaller one in winter. Molecular weight of ca. 89000 and isoelectric points 5—6 were found for most phosphatases in samples collected during the summer. A considerable part of the winter alkaline phosphatases, however, have much higher molecular weights, and major isoelectric points for these were ca. 4. These alkaline phosphatases were metalloenzymes activated by zinc. The observations above suggest that there are seasonal changes in the dominant microbial species producing dissolved alkaline phosphatase; i.e., blue-green algae, a procaryote, in summer and diatoms and flagellates, eucaryotes, in winter. The peak of alkaline phosphatase activity in lake water was predictive of a following increase in algal species therein.

Phosphorus is recognized as a key to fertilization in natural waters, i.e., orthophosphate is one essential nutrient for microorganisms such as algae and bacteria. When studying the cycle of phosphorus and the regulation of microorganisms, alkaline phosphatase activity should be considered in both its intracellular and extracellular (dissolved) forms.

Alkaline phosphatase (orthophosphoric monoester phosphohydrolyase with activity optimum in alkaline pH) is a typical metalloenzyme, containing several zinc ions at its active sites, and these zinc ions are essentially related to the appearance of phosphatase activity.[1] In most organisms, from primitive procarytes such as bacteria to eucaryotes such as mammals, alkaline phosphatase is found mostly in their periplasmic spaces.[2,3]

Alkaline phosphatase activity in lake waters[4] and seawater[5–7] has been reported by several researchers: Reichardt et al. first determined phosphatase activity not only in unfiltered freshwater but also in water which had been filtered through a 0.6 μm membrane. This suggested the existence of extracellular (dissolved) phosphatase in lake waters.[8] Since then, several researchers have found activity attributed to dissolved phosphatase in lake waters[9–11] and seawaters,[12] and have considered its role in the phosphorus cycle in natural waters.[13,14] In the previous paper,[15] it was confirmed that dissolved phosphatase activity in natural waters was due to the metalloenzymes (zinc-containing alkaline phosphatase).

In the present paper, seasonal variations in alkaline phosphatase in Lake Kasumigaura are examined by high performance liquid chromatography and isoelectric focusing electrophoresis.

Field Description[16]

Lake Kasumigaura, the second largest lake in Japan, is situated in the eastern part of the Kanto Plain, about 50 km north-east of Tokyo. The lake basin is smooth and shallow, with a surface area of 171 km^2, a mean depth of 4 m, and a maximum depth of 7.4 m near the mouth of Takahamairi Bay. Due to the shallowness of the water and its constant agitation by wind, distinct thermal stratifications do not develop even in summer, except for a few calm days. Heavy blooms of blue-green algae are to be seen over the whole lake in summer. The bloom usually starts at the innermost parts of both Takahamairi and Tsuchiurairi Bays, which receive nutrient-rich inflowing waters, and gradually spreads to the center of the lake. By August, the bloom covers the whole lake.

Experimental

Chemicals. *E. coli* alkaline phosphatase purchased from Boehringer-Mannheim Co. (No. 15429) was used as a standard; its specific activity is 20 U mg^{-1} and molecular weight (M. W.) 89000.[12] In addition to *E. coli* alkaline phosphatase, the following enzymes purchased from Boehringer-Mannheim Co. were used as molecular weight standards for high performance liquid chromatography (HPLC): Urease (Jack bean; M. W. 480000); ferritin (indicator protein; M. W. 450000); Bovine carbonic anhydrase (M. W. 31000); and cytochrome c (indicator protein; M. W. 12500). To determine alkaline phosphatase activity, 1 mM (M=mol dm^{-3}) *p*-nitrophenyl dihydrogen phosphate (*p*-NPP) dissolved in 0.6 M tris(hydroxymethyl)methanamine (Tris) hydrochloride buffer (pH 8.0) was used as a substrate. LBK Ampholine Carrier Ampholite (pH 3.5—10) was used as an isoelectric focusing solution.

Instruments. A Shimadzu UV-210A spectrophotometer with a SFU-6 semiauto flow cell unit (optical path of absorption cell: 10mm) was used to determine enzymatic activity. A Shimadzu LC-3A high performance liquid chromatograph was used for HPLC separation, using Shimadzu aqueous

gel column Type W-71; detection was accomplished by using an SPD-2A spectrophotometric detector. An LBK Ampholine 8100-1 Electrofocusing Equipment (column volume: 110 mL) with a power supply (Atto Co., V-C Stabilizer SJ-1061; maximum voltage: 1000 V) was used for isoelectric focusing. Ultrafiltration was performed with an Amicon Diaflo Cell Type 202. A Thermostatic Bath Circulator (Thomas Scientific Co., Model TRL-111SP), a fraction collector (Toyo Kagaku Sangyo Co., Signal Fracon SF-60L), and a peristaltic pump (Toyo Kagaku Sangyo Co., Signal Pump TMP-6L) were also used in HPLC and electrophoresis fractionation.

Pretreatment of Lake Water Samples. Lake water was sampled at 10 points in Lake Kasumigaura (Ibaraki Prefecture), once a month as from April 1980 through March 1982 (see Fig. 1). The collected water was filtered with glass fiber membrane filters (pore size: 1.0 μm), and then filtered with Toyo Kagaku UK-2 membrane filters (pore size: 0.45 μm) or UK-4 (pore size: 0.2 μm) to exclude bioorganisms. All the filtrations were performed immediately after sampling, and the samples were then stored in a cold room (4 C).

An unfiltered sample, to which 2 v/v% of chloroform was added, was also kept in a cold room to determine total phosphatase activity.

Before separation by HPLC or electrophoresis, the 0.45 μm-filtered sample was concentrated ca. 1000 times by ultrafiltration, using a Toyo Kagaku UK-10 type ultrafilter, with which only molecules larger than M. W. 10000 can be concentrated. Samples were kept under constant temperature at 4 C throughout ultrafiltration and storage. Experimental vessels and containers were cleaned and sterilized by heating to 110 C, by soaking in 40% ethanol aqueous solution and/or by soaking in 7 M nitric acid.

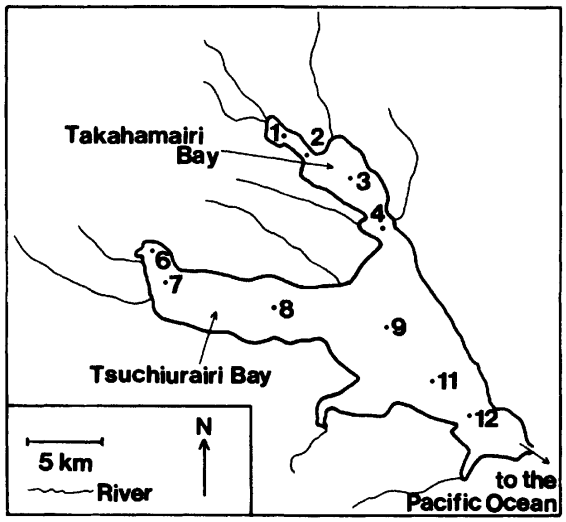

Fig. 1. Sampling stations in Lake Kasumigaura.

Determination of Phosphatase Activity. Alkaline phosphatase catalyzes the hydrolysis of *p*-NPP to *p*-nitrophenol:

$$O_2N\text{-}C_6H_4\text{-}OPO_3H_2 + H_2O \rightarrow O_2N\text{-}C_6H_4\text{-}OH + H_3PO_4 \quad (1)$$

The rate of production of the *p*-nitrophenol is followed spectrophotometrically and provides a measure of the concentration of the catalyst. Dissolved alkaline phosphatase activity was determined by using 0.2 μm-filtered lake water as a sample, as described in our previous paper.[15] Total alkaline phosphatase activity was determined in the same way as dissolved alkaline phosphatase activity, using an unfiltered sample; the *p*-NPP substrate was saturated with chloroform for its bacteriostatic effect.[17]

HPLC Chromatograms. For HPLC separation, two aqueous porous gel columns (both Type W-71) were available, one column 7.9 mm i.d.×30 cm and the other 7.9 mm i.d.×50 cm. Either column was used or both were joined to make an 80-cm length. Instead of the phosphate buffer, which is generally used as a carrier for the W-71 column, 0.1 M Tris-HCl buffer (pH 8.0) was used for determining the phosphatase activity of the untreated effluent, because phosphate ion inhibits phosphatase activity. The effluent was fractionated every 0.5—1.0 min (0.5—1.0 cm^3) with a fraction collector, and the phosphatase activity of the thirty or so individual fractions was then measured.

Isoelectric Focusing Chromatograms. Isoelectric focusing was carried out in accordance with the instruction manual of LKB Ampholine 8100 electrofocusing equipment. The solutions used in the present experiment are shown in Table 1. The system was thermostated, and electrofocusing was carried out at 4 C for 48 h. After the electrode solutions had been removed from the column, the electrofocused solution was fractionated every 2.5 cm^3 with a peristaltic pump and a fraction collector. The phosphatase activities of the individual fractions were determined by the method described earlier.

Results

Distribution of Phosphatase Activity in Lake Kasumigaura. Total phosphatase activity (TPA) and dissolved phosphatase activity (DPA) in Lake Kasumigaura from April, 1981 to March, 1982

Table 1. Solutions Used for Isoelectric Focusing

Solution	Content		Total Volume
Dense gradient solution	Sucrose	27 g	54 cm^3
	Ampholine	2 cm^3	
	concd. sample plus water	35 cm^3	
Light gradient solution	Sucrose	2.7 g	54 cm^3
	Ampholine	0.7 cm^3	
	concd. sample plus water	50.3 cm^3	
Cathode solution	0.25 M NaOH	10 cm^3	10 cm^3
Anode solution	Sucrose	15 g	25 cm^3
	0.25 M H_2SO_4	16 cm^3

a) DPA=Dissolved phosphatase activity. b) TPA=Total phosphatase activity.

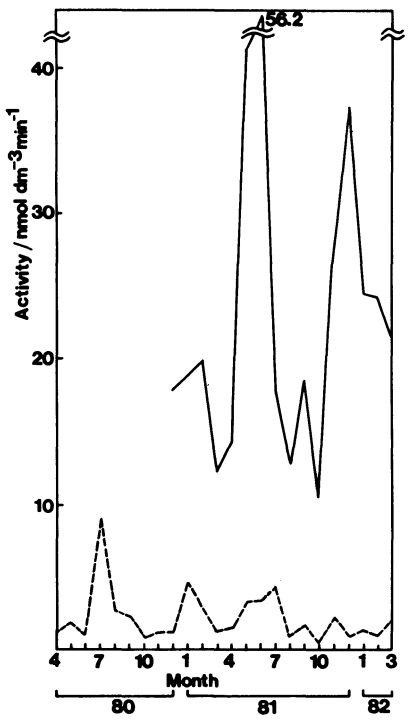

Fig. 2. Seasonal variations in total and dissolved phosphatase activities at Sta. 2 in Lake Kasumigaura. ——: Total alkaline phosphatase activity; -----: dissolved alkaline phosphatase activity.

are shown in Table 2. Average DPA levels in Lake Kasumigaura were ca. 1 nmol dm^{-3} min^{-1}, about the same as those determined in the Shinobazu pond[15] and in Lake Kinneret.[6] At each location, average TPA was about ten times higher than DPA, but phosphatase activity near the edge of the lake ((e.g., Stations (Stas.) 1, 2, 6, and 7)) was greater than in the center of the lake (e.g., Sta. 9). This trend was more obvious in the summer than in spring.

Seasonal Variations in Phosphatase Activity. Seasonal variations in DPA and TPA at Sta. 2 in Lake Kasumigaura are shown in Fig. 2. Very distinct peaks were observed in summer, and other smaller peaks were observed in winter. The patterns of the two curves are almost the same.

Alkaline phosphatase activity in lake water in all seasons was diminished when samples were treated with chelating agents, such as 2,6-pyridinedicarboxylic acid; the activity was restored on addition of zinc ion (see Table 3.)

HPLC Chromatograms. HPLC chromatograms of concentrated lake water sample in August and December, 1980, are shown in Figs. 3 and 4. In summer (Fig. 3), a very distinct single peak was seen at the elution time of *E. coli* alkaline phosphatase. The chromatograms for winter (Fig. 4) through spring had more complicated features, showing the presence

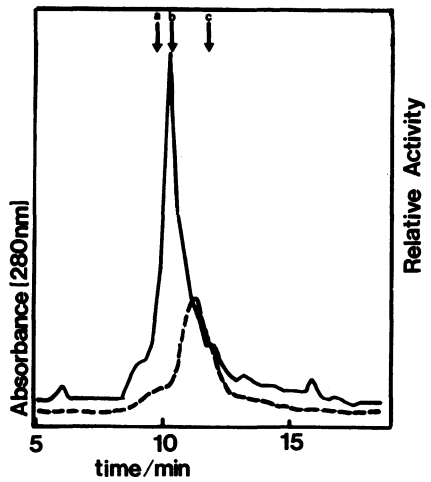

Fig. 3. HPLC chromatograms of concentrated lake water collected in August, 1980.
Sample: concentrated (×2300) water sample collected in Lake Kasumigaura (Sta. 2) on August 16, 1980; sample volume: 100 mm^3; column: Shimadzu aqueous porous gel column W-71 (7.9 mm i.d.×50 cm); carrier: 0.01 M Tris-HCl buffer (pH 8.0); flow rate: 1.0 $cm^3 min^{-1}$.
——: Phosphatase activity; -----: UV absorbance at 280 nm. Elution time of standard proteins are as follows:

of alkaline phosphatase with a greater molecular weight than those of *E. coli*.

Isoelectric Focusing Chromatograms. Figures 5 and 6 show the isoelectric focusing (IEF) chromatograms of concentrated lake water in October, 1980 and April, 1981, individually. All the chromatograms had several peaks of phosphatase activity, but the isoelectric points (pI) of the peaks showing high phosphatase activity were not the same. In summer and fall (Fig. 5), the peaks of phosphatase activity at pI 5—6 were significant, but those at ca. pI 4 were dominant in other seasons (Fig. 6). These results show seasonal changes in the composition of the isozymes of alkaline phosphatase in Lake Kasumigaura.

Discussion

Horizontal and Vertical Distribution of Phosphatase Activity. Lake Kasumigaura is notable as one of the most fertilized lake in Japan. This can be attributed mainly to its shallowness and the large inflow of nutrient-rich waters. The shallowness of the lake and the constant agitation of the water by the wind mean that there is little vertical variation of phosphatase activity in the water. Thus vertical variations of phosphatase activity can be ignored.[15]

As shown in Table 2, phosphatase activity varied appreciably with sampling location. Coastal waters in Takahamairi Bay (Stas. 1 and 2) or Tsuchiurairi Bay (Sta. 6) generally gave high TPA and DPA values that seemed to relate to the degree of fertilization or the biomass of microorganisms.

Seasonal Changes in Phosphatase Activity. In Lake Kasumigaura, heavy blooms of *Microcystis aeruginosa*, a species of blue-green algae, are to be seen covering the whole lake in summer. Other algae such as diatoms and flagellates can not breed during this period. When the blue-green algae decrease in autumn, other algae can increase.[18] The correlation between the peaks of DPA and of the biomass can be seen; the peak of DPA in summer corresponded to that of blue-green algae; the smaller peaks of DPA in winter and spring might correspond to those of diatoms and flagellates. The peaks of DPA (or TPA) slightly preceded the bloom of algae. This suggests that algae produce more alkaline phosphatase before multiplying.

Bacteria may also put alkaline phosphatase into the lake water, although the biomass of bacteria is much less than that of algae.[19] Thus, while most of the DPA originated from algae, DPA originating from bacteria could not be ignored.

HPLC and IEF Chromatograms. The seasonal variations described above are also shown as the HPLC and IEF chromatograms. Figures 3—6 show that various isozymes of alkaline phosphatase were present as dissolved enzymes in the lake water. The very distinct single peak in the HPLC chromatograms for summer (Fig. 3) is believed to be *Microcystis aeruginosa* alkaline phosphatase, whose molecular weight is close to that of *E. coli* alkaline phosphatase (89000). Alkaline phosphatases of higher molecular weight (eluted earlier than *E. coli* alkaline phosphatase) are seen in Fig. 4. These appear to be alkaline phosphatase originating from eucaryotes such as diatoms and flagellates. The eucaryotic alkaline phosphatase, unlike *E. coli* alkaline phosphatase, are glycoproteins, whose amino acid compositions, however, are strikingly similar to that of *E. coli* alkaline phosphatase.[20] Consequently eucaryotic alkaline phosphatase seems to elute rather sooner than might be estimated from the calibration curve for simple proteins.

There were several peaks in each IEF chromatogram, but the dominant peaks differed according to the sample. Unlike the HPLC chromatogram, which gave only a single dominant peak, a number of major peaks appeared in the IEF chromatogram for summer and fall (Fig. 5). This suggests that the procaryotic alkaline phosphatases, which could not be separated using a method based on molecular weight, can be separated using electrophoresis. The positions of the dominant IEF peaks (ca. pI 4) for winter and spring were markedly different from those for summer and fall (pI 5—6), and this also reflected the seasonal changes in the algae in Lake Kasumigaura.

Conclusion

Phosphatase activity in Lake Kasumigaura varied seasonally. The peak of phosphatase activity seemed to predict the increase in a certain species of algae. In addition to the change in total activity, a change in isozymes was observed in the HPLC and IEF chromatograms. This was interpreted as being caused by seasonal changes in phosphatase in natural water in Lake Kasumigaura; i.e., procaryotes (blue-green algae) in summer and eucaryotes (such as diatoms and flagellate) in winter and spring.

The various alkaline phosphatases found in the different seasons were all zinc-containing metalloenzymes, and are therefore also of interest as a significant source of zinc in natural water.[15,21] This suggests that other heavy metals may similarly be found in biochemical substances in natural water.

The amount of phosphatase in natural water is influenced not only by the biomass of microorganisms producing enzymes, but also by orthophosphate.[22] The nature of the relationship between alkaline phosphatase activity and concentration of various phosphorus compounds and the role of alkaline phosphatase in phosphorus cycles in lake water will be considered in the following paper.

The present authors thank Dr. Lawrence J. Sacks, Laboratory of Chemical Evolution, Department of Chemistry, University of Maryland, for his kind help in preparation of the manuscript.

Metallation of Aliphatic Carbon Atoms. IV. Syntheses and Characterization of the Cyclopalladated Complexes of 2-*t*-Butylbenzothiazole

Katsuma HIRAKI,* Yoshio FUCHITA, Motoharu NAKASHIMA, and Hirofumi HIRAKI
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852
(Received April 23, 1986)

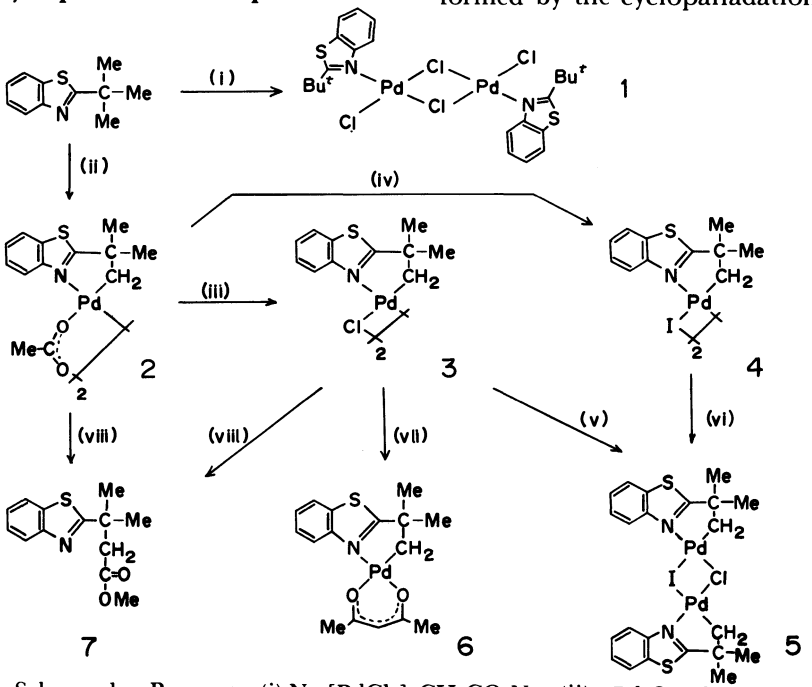
2-*t*-Butylbenzothiazole reacts with palladium(II) acetate in acetic acid to produce the cyclopalladated dimer [{Pd(CH_2CMe_2-C_7H_4NS)(μ-$MeCO_2$)}$_2$] (**2**) (C_7H_4NS=2-benzothiazolyl). Complex **2** shows temperature-dependent ^{1}H NMR spectra, which have been interpreted on the basis of the inversion motion of the acetato bridges. Metatheses of **2** with lithium chloride and sodium iodide result in the formation of the chloro- and iodo-bridged analogues, [{Pd(CH_2CMe_2-C_7H_4NS)(μ-Cl)}$_2$] (**3**) and [{Pd(CH_2CMe_2-C_7H_4NS)(μ-I)}$_2$] (**4**), respectively, each of which is found to be composed of cis and trans isomers. The ^{1}H NMR spectra of **3** and **4** depend on temperature and are ascribed to rapid exchange between the two isomers. Equimolar amounts of **3** and **4** afford a μ-chloro-μ-iodo binuclear complex, [(C_7H_4NS-CMe_2CH_2)Pd(μ-Cl)(μ-I)Pd(CH_2CMe_2-C_7H_4NS)]. The reaction of **3** with thallium(I) acetylacetonate [Tl(acac)] produces a mononuclear cyclopalladated complex [Pd(CH_2CMe_2-C_7H_4NS)(acac)]. Complexes **2** and **3** react with CO in methanol to give $MeO_2CCH_2CMe_2$-C_7H_4NS, the formation of which comfirms also the cyclopalladated structure of 2-*t*-butylbenzothiazole in **2** and **3**.

It has been demonstrated that the activation of C–H bonds in saturated organic compounds is one of the most intriguing goals of organometallic chemistry.[1,2] We have been challenging this theme through cyclometallation reactions. Up to date we have achieved the cyclopalladations of alkyl groups in 2-neopentylpyridine,[3] *N*,*N*-dimethylneopentylamine,[4] 1,3-di(2-pyridyl)propane,[5] and 2-(trimethylsilyl)pyridine[6] by using palladium(II) acetate as a metallating reagent. In this paper we wish to report the new C–H bond activation of *t*-butyl group in 2-*t*-butylbenzothiazole by palladium(II) acetate and the dynamic behavior of the resulting binuclear cyclopalladated complexes.

Results and Discussion

Synthesis of the Cyclopalladated Complexes. 2-*t*-Butylbenzothiazole reacted with an equimolar amount of sodium tetrachloropalladate(II) in the presence of sodium acetate at 80—85 °C to afford a crystalline complex **1**. The ^{1}H NMR spectrum of **1** was not clear owing to its low solubility. On the basis of the elemental analysis and the similarity of the IR spectrum of **1** to that of 2-*t*-butylbenzothiazole, **1** was assigned to a dinuclear addition complex [{(Pd(μ-Cl)Cl(CMe_3-C_7H_4NS)}$_2$] (C_7H_4NS=2-benzothiazolyl group).

2-*t*-Butylbenzothiazole and palladium(II) acetate reacted in acetic acid at 80—85 °C to give yellow crystals, [{Pd(CH_2CMe_2-C_7H_4NS)(μ-CH_3CO_2)}$_2$] (**2**). Its IR spectrum showed characteristic bridged acetato bands at 1415 and 1580 cm^{-1}.[7] The ^{1}H NMR spectrum of **2** at −22 °C showed an AB type quartet at δ 2.20 (2H, $\Delta\delta$=0.26, $^2J_{HH}$=8 Hz) and a singlet at δ 2.49 (2H), ascribable to methylene group, which was formed by the cyclopalladation of one methyl group



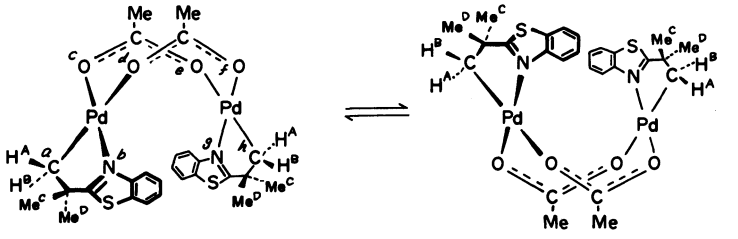
Scheme 1. Reagents: (i) $Na_2[PdCl_4]$-CH_3CO_2Na. (ii) $Pd(CH_3CO_2)_2$. (iii) LiCl. (iv) NaI. (v) **4**. (vi) **3**. (vii) Tl(acac). (viii) CO at 50 atm.

in 2-*t*-butylbenzothiazole. In addition, the spectrum exhibited three singlets due to the methyl protons of the bridging acetato ligands at δ 2.09 (1.5H), 2.15 (3.0H), and 2.21 (1.5H). The central singlet at δ 2.15 is assignable to a trans isomer with a C_2 symmetry, whereas the other two singlets at δ 2.09 and 2.21 are ascribable to a cis isomer with a C_s symmetry. On the basis of these results and the elemental analysis together with the characterization of derivatives from **2**, **2** was assigned to a 1:1 mixture of trans and cis isomers of novel binuclear cyclopalladated complex, di-μ-acetato-bis[2-(2-benzothiazolyl)-2-methylpropyl-C^1, N]dipalladium(II) [{Pd(CH_2CMe_2-C_7H_4NS)(μ-CH_3CO_2)}$_2$]. The trans isomer was palladated at *a*- and *h*-positions (**2-*ah***), as shown in Fig. 1, whereas the cis isomer was done at *a*- and *g*-positions (**2-*ag***). The formation of the two kinds of isomers has been observed in other several acetato-bridged cyclopalladated complexes.[3,4,6,8]

The acetato-bridged complex **2** was converted into the corresponding chloro-bridged analogue [{Pd(CH_2-CMe_2-C_7H_4NS)(μ-Cl)}$_2$] (**3**) and iodo-bridged one [{Pd(CH_2CMe_2-C_7H_4NS)(μ-I)}$_2$] (**4**) by the metathetical reactions of **2** with lithium chloride and sodium iodide, respectively, in THF. The equimolar mixture of these two complexes afforded an interesting mixed halogeno-bridged binuclear complex, [(C_7H_4NS-CMe_2-CH_2)Pd(μ-Cl)(μ-I)Pd(CH_2CMe_2-C_7H_4NS)] (**5**) in a high yield. Furthermore, mononuclear cyclopalladated complex **6**, [Pd(CH_2CMe_2-C_7H_4NS)(acac)] (acac=acetylacetonato) was obtained by treating **3** with Tl(acac) in dichloromethane. Characteristic *O*,*O*′-chelating acac bands were observed at 1510 and 1580 cm^{-1} in the IR spectrum of **6**.

All the complexes (**2**—**6**) synthesized in this study are fairly stable in air. Their elemental analyses, yields, and ^{1}H NMR data are summarized in Tables 1 and 2.

Dynamic Behavior of the Acetato-Bridged Dimer 2. Complex **2** showed temperature-dependent ^{1}H NMR spectra (Fig. 2). At −22 °C, the methylene protons of **2-*ah*** showed the AB type quartet and the protons of the two remaining methyl groups were nonequivalent, resonating as two singlets at δ 0.70 and 1.14. The methyl protons of **2-*ag*** appeared also as two singlets at δ 1.45 and 1.54. These facts indicate unambiguously that the both isomers of **2** have a folded structure,



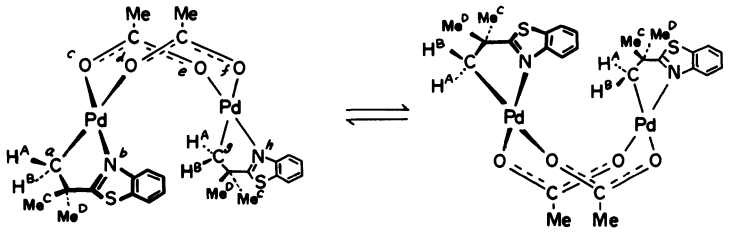


Fig. 1. Inversion motions of the isomers of **2**.

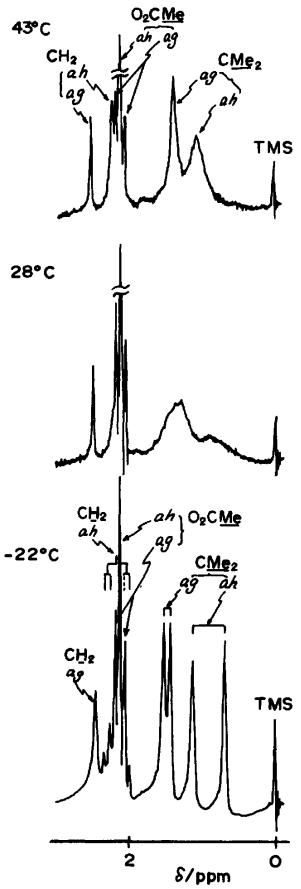

Fig. 2. The temperature-dependent ^{1}H NMR spectra of **2**.

as other acetato-bridged binuclear palladium(II) complexes have.[9-11] As for **2-*ah***, the protons of the both methyl groups resonated at higher fields in comparison with the corresponding methyl protons in **2-*ag***. This seems to be associated with the anisotropic shielding by the facing benzothiazolyl group.[10] Furthermore, the anisotropic shielding acts on one of the methylene protons situated at the innerside of the folded structure in **2-*ah***, shifting the resonance to the higher field (at δ 2.07). However, the methylene protons of **2-*ag*** do not undergo such anisotropic shielding owing to the mirror image relationship of the structure, resonating at δ 2.49 as a singlet.

On raising the measured temperature, the two methyl resonances in each of **2-*ah*** and **2-*ag*** coalesced at 28 °C, and then became broad singlets at δ 1.05 and 1.36, respectively, at 43 °C. However, these two singlets did not coalesce at 60 °C, indicating that the exchange between **2-*ah*** and **2-*ag*** did not occur even at this temperature. The temperature-dependency of the ^{1}H NMR spectra of **2** is attributable to such the typical inversion motion of the acetato bridges (Fig. 1) as the other acetato-bridged complexes exhibit.[4,6,10,11]

Dynamic Behavior of the Halogeno-Bridged Binuclear Complexes. The chloro-bridged dimer **3** also exhibited the temperature-dependent ^{1}H NMR spectra. At −32 °C palladium-bonded methylene protons resonated as two singlets at δ 2.50 (1.4H) and 2.59 (2.6H), whereas 4-H of the 2-benzothiazolyl moiety appeared as two doublets at δ 8.60 (0.7H) and 8.85 (1.3H). These data indicate that **3** consists of two isomers, trans type with (*a*-C, *b*-N; *e*-N, *f*-C) chelations and cis one with (*a*-C, *b*-N; *e*-C, *f*-N) chelations as seen in Fig. 3.

The former two singlets at δ 2.50 and 2.59 coalesced at 3 °C and changed to one sharp singlet at

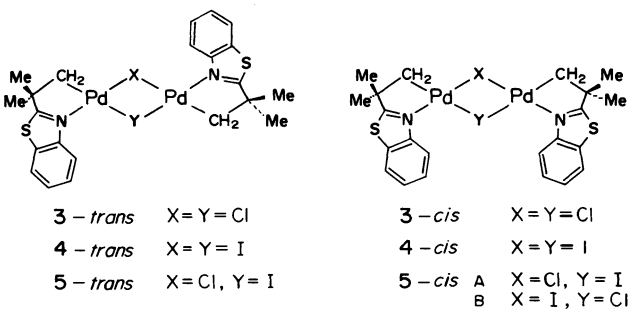

Fig. 3. Isomers of the halogeno-bridged binuclear complexes.

δ 2.56 at 54°C. Similarly, the latter two doublets at δ 8.60 and 8.85 were turned into one doublet at δ 8.80 at the same temperature. This temperature-dependent ^{1}H NMR spectra did not change at all by adding 10-fold excess of acetone or water to the NMR sample solution of **3** in $CDCl_3$. Such temperature dependence is attributed to an exchange between the cis and trans isomers rather than that between **3** and a mononuclear species [Pd(CH_2CMe_2–C_7H_4NS)ClL] (L=Me_2CO or H_2O). This is also supported by easy formation and isolation of the chloro-iodo-mixed bridged binuclear complex as stated later. The iodo-bridged dimer **4** also exhibited similar temperature-dependent ^{1}H NMR spectra in the range of −35—+50 °C (Table 2), indicating that **4** consisted of cis and trans isomers (Fig. 3) and a rapid exchange between the two isomers took place above −10°C. Galli et al.[12] reported recently the analogous exchange between the cis-trans isomers of halogeno-bridged cyclopalladated dimers of *t*-butyl methyl ketone *N*-methyl-*N*-phenylhydrazone [{Pd[CH_2CMe_2C(=N-NMePh)Me]-X}$_2$] (X=Cl, Br, and I).

When the ^{1}H NMR spectra of the equimolar mixture of **3** and **4** were measured in $CDCl_3$, only one set of signals, corresponding neither to **3** nor **4**, was obtained. Moreover, this species also showed temperature-dependent ^{1}H NMR spectra. At 50°C, the palladium-bonded methylene protons and 4-H of the 2-benzothiazolyl moiety resonated as one singlet at δ 2.40 and one doublet at δ 8.87, respectively. On lowering the temperature, these signals broadened at 18°C, and then changed again to one sharp singlet at δ 2.33 and one resolved doublet at δ 8.77 at −35°C. This species could be isolated as a chloro-iodo-bridged binuclear complex [(C_7H_4NS-CMe_2CH_2)-Pd(μ-Cl)(μ-I)Pd(CH_2CMe_2-C_7H_4NS)] (**5**). Of course, **5** showed the same temperature-depending ^{1}H NNR spectra as the above-mentioned mixture of **3** and **4**. It is interesting that **5** showed only one set of ^{1}H NMR signals, though there are three possible isomers, trans, cis-A, and cis-B, as shown in Fig. 3.

When the mixture of **3** and **4** in a molar ratio of 2:1 was run in a ^{1}H NMR tube, there appeared three sets of signals; one corresponded to **5** and the other two did to two sets observed for **3** at −35°C. On increasing the temperature all the three sets coalesced at 25°C, and then appeared as one single set of signals at 60°C. These results clearly indicate that the chloro-bridged dimer **3** as well as the iodo-bridged dimer **4** experiences exchange between cis- and trans-isomers. In other words at high temperature (ca. 50°C) the exchange between the two species is rapid, giving averaged single set of signals, and at low temperature (ca. −35°C) the exchange is actually quenched to result in affording two sets of signals corresponding to cis and trans isomers.

Carbonylation of the Cyclopalladated Complexes, 2 and 3. The acetato-bridged dimer **2** as well as the chloro-bridged one **3** reacted with carbon monoxide in methanol in an autoclave to give methyl 3-(2-benzothiazolyl)-3-methylbutyrate (**7**) in almost quantitative yields. This fact unambiguously indicates that metallation occurs on the methyl carbon of the 2-*t*-butylbenzothiazole, and that methoxycarbonyl group can be introduced quantitatively and regiospecifically onto one of the methyl groups via cyclopalladated complex.

Experimental

2-*t*-Butylbenzothiazole[13] and thallium(I) acetylacetonate[14] were synthesized as published. General procedures were as described previously.[8]

Reaction of 2-*t*-Butylbenzothiazole with $Na_2[PdCl_4]$. 2-*t*-Butylbenzothiazole (215 mg), sodium acetate (92 mg), and $Na_2[PdCl_4]$ (300 mg) were mixed in 20 cm^3 of acetic acid, and then the mixture was heated at 80—85°C for 6 h. The resulting precipitates were collected, and washed with water and diethyl ether. Recrystallization from benzene and hexane gave 170 mg of [{Pd(μ-Cl)Cl(CMe_3-C_7H_4NS)}$_2$] (**1**) as beige crystals.

Reaction of 2-*t*-Butylbenzothiazole with $Pd(CH_3CO_2)_2$. The mixture of 2-*t*-butylbenzothiazole (940 mg) and Pd-$(CH_3CO_2)_2$ (1000 mg) in 15 cm^3 of acetic acid was heated at 80—85°C for 2.5 h. The solvent was evaporated and the residue was chromatographed on a silica-gel column (200 mesh, 1.2×12 cm). A pale yellow-brown fraction eluted by THF/CH_2Cl_2 (1/1) was collected and evaporated to dryness. Recrystallization from dichloromethane and hexane afforded 800 mg of [{Pd(CH_2CMe_2-C_7H_4NS)(μ-CH_3CO_2)}$_2$] (**2**) as yellow crystals.

Metathesis of 2 with Lithium Chloride. Lithium chloride (107 mg) was added to a THF suspension (10 cm^3) of **2** (360 mg). The suspension became clear and was stirred for 1 d at room temperature. The solvent was removed and the residue was dissolved in 10 cm^3 of benzene. Pale beige crystals were precipitated after a few minutes, and were collected and washed with water, methanol, and then diethyl ether to give 295 mg of [{Pd(CH_2CMe_2-C_7H_4NS)(μ-Cl)}$_2$] (**3**).

Metathesis of 2 with Sodium Iodide. A clear THF solution (20 cm^3) of sodium iodide (421 mg) and **2** (400 mg) was left overnight and evaporated to dryness. The residue was extracted with dichloromethane. Hexane was added to the extract and 290 mg of [{Pd(CH_2CMe_2-C_7H_4NS)(μ-I)}$_2$] (**4**) was obtained as brown crystals.

Reaction of 3 with 4. Complex **3** (55 mg) was added to a dichloromethane solution (15 cm^3) of **4** (70 mg), and the

resulting mixture was stirred at room temperature for 12 h. After the mixture was evaporated to dryness, the residue was recrystallized from benzene and hexane to give 100 mg of [(C_7H_4NS-CMe_2CH_2)Pd(μ-Cl)(μ-I)Pd(CH_2CMe_2-C_7H_4NS)] (**5**) as yellow crystals.

Reaction of 3 with Thallium(I) Acetylacetonate. Thallium(I) acetylacetonate (286 mg) was added to a stirred solution of **3** (204 mg) in 10 cm^3 of dichloromethane. After 17 h, the resulting milk-white suspension was centrifugalized. The supernatant solution was purified through a short silica-gel column and evaporated at reduced pressure to 4 cm^3. Addition of hexane afforded 181 mg of [Pd(CH_2-CMe_2-C_7H_4NS)(acac)] (**6**) as pale yellow crystals.

Reaction of 2 or 3 with CO in MeOH. In 20 cm^3 of methanol, **2** (500 mg) was carbonylated at 80 °C under a carbon monoxide pressure of 50 atm for 20 h under stirring. The mixture was filtered to remove palladium black, and then evaporated to dryness. The product, methyl 3-(2-benzothiazolyl)-3-methylbutyrate (**7**), was isolated by extracting the resulting oil with pentane and evaporating and drying up in vacuo. Yield 268 mg (83%), colorless oil.

The compound **7** was also obtained from **3** by the similar way as described above. Yield, 200 mg (96%) from 300 mg of **3**.

Analytical and ^1H NMR data of **7** are also given in Tables 1 and 2, respectively.

We wish to thank Mr. Eiji Ueda of Shikamachi Technical High School for preparing the complex **1**. The present work was partially suported by a Grant-in-Aid for Scientific Research No. 58550572 from the Ministry of Education, Science and Culture.

^{17}O NMR Studies on a Series of Manganese Carbonyl Derivatives with Sn-Mn Bond(s)[1)]

(Received April 24, 1986)

^{17}O NMR spectra were measured for a series of manganese carbonyl derivatives, $(CH_3)_xCl_{3-x}Sn$-$Mn(CO)_{5-y}L_y$ and $(CH_3)_{3-x}Sn[Mn(CO)_{5-y}L_y]_{x+1}$(L=$P(OPh)_3$). ^{17}O chemical shifts were correlated with carbonyl stretching frequencies, ^{119}Sn-Mössbauer isomer shifts, and ^{55}Mn NMR chemical shifts. From these correlations, ^{17}O chemical shifts were interpreted in terms of σ- and π-electron acceptance of the tin moieties. It was also clarified that ^{17}O NMR spectroscopy is a direct method to study electronic nature around the oxygen atoms in metal cluster compounds such as $Me_2Sn[Mn(CO)_5]_2$ and $MeSn[Mn(CO)_5]_3$. ^{55}Mn NMR spectra were also measured for some of these compounds to corroborate the ^{17}O NMR results.

The tin atom forms a variety of compounds with transition metals.[2)] Their chemistry has been developed actively by Gorsich, Graham, Clark, Nesmeyanov, and others from the interests to extend the knowledge of "metal-metal bonds," and to look for potential models which emulate metal alloys of relevant metal stoms and/or to find effective new catalysts.[3)] Some series of these compounds have been also the targets of many kinds of spectroscopic studies such as IR, Raman, Mössbauer, NMR, and NQR to elucidate the bonding nature between the tin and transition metal atoms and/or to explore the influence of ligands which are coordinated to the tin and transition metal atoms on the tin-transition metal bonds.[4-7)] We reported similar spectroscpic studies on a series of $R_xX_{3-x}Sn$-$Mn(CO)_{5-y}L_y$-type compounds.[8)] In these studies, our attention was mainly focused on the change of the Sn-Mn, Sn-X, and Sn-R bondings as functions of R, X, and L. Variation of electron distribution around the oxygen and carbon atoms is usually investigated by normal coordinate analyses. Although we can get an insight into the bonding nature of the carbonyl groups in terms of C-O and Mn-C stretching force constants from normal coordinate analyses, the information obtained therefrom on the electronic nature of CO groups is somewhat indirect and obscured by introduction of several stretch-stretch interaction force constants to attain better agreement between the observed and calculated frequencies. However, recent technical improvement of NMR spectroscopy, that is, the pulsed FT-NMR technique, has made it possible to obtain ^{17}O NMR spectra of the metal carbonyl derivatives at the naturally abundant ^{17}O-level[9,10)] together with ^{13}C NMR spectra. Direct information on the electron distribution at the oxygen and carbon atoms is available from ^{17}O and ^{13}C NMR data. We have adopted a series of tin-manganese bonded compounds, $R_xCl_{3-x}Sn$-$Mn(CO)_{5-y}L_y$ and $R_{3-x}Sn[Mn(CO)_{5-y}L_y]_{x+1}$ for ^{17}O and ^{13}C NMR studies from our renewed interest in these types of compounds and to deepen our understanding on ^{17}O and ^{13}C NMR data by correlating these with other spectroscopic results obtained in the series of previous studies.[8)] During the course of this study, we have found that ^{13}C NMR spectra of CO groups are broad and unresolved for axial and equatorial carbonyls because of the nuclear quadrupole moment of ^{55}Mn, but the ^{17}O NMR spectra are reasonably sharp and clearly resolved for axial and equatorial carbonyls in these compounds. This observation promises that ^{17}O NMR which has recently been expeditiously employed as a structural and bonding prove for metal carbonyl derivatives,[9-11)] is an eligible alternative to ^{13}C NMR for investigating the bonding nature of CO groups and/or structures of these compounds. Kump and Todd reported similar observation during the course of this study.[10f)] We now report ^{17}O NMR spectra of some tin-manganese bonded compounds together with ^{55}Mn NMR data to supplement our previous spectroscopic studies on these compounds and to demonstrate how ^{17}O NMR is instrumental for disclosing the bonding of CO groups in metal carbonyl derivatives in which the nuclear quadrupole moment of the metal atom is greater than 1/2.

Experimental

Materials. All the syntheses were made under a purified nitrogen atmosphere. The series of $(CH_3)_xCl_{3-x}Sn$-$Mn(CO)_5$ compounds, that is Cl_3Sn-$Mn(CO)_5$ (**1**), $Cl_2(CH_3)Sn$-$Mn(CO)_5$ (**2**), $Cl(CH_3)_2Sn$-$Mn(CO)_5$ (**3**), and $(CH_3)_3Sn$-$Mn(CO)_5$ (**4**) were prepared according to the previous paper.[8b)] Literature methods were employed to obtain $(CH_3)_2Sn[Mn(CO)_5]_2$ (**5**)[12a)] and $CH_3Sn[Mn(CO)_5]_3$ (**6**).[12b)] The syntheses of $(CH_3)_3Sn$-$Mn(CO)_4L$ (**7**),[13)] $(CH_3)_2Sn[Mn(CO)_4L]_2$ (**8**),[13)] and $(CH_3)_3Sn$-$Mn(CO)_3L_2$ (**9**)[8m)] are described elsewhere.

NMR Measurements. ^{17}O and ^{55}Mn NMR spectra were measured for ca. 1 mol dm^{-3} toluene solutions at ca. 80 °C (**5** and **6**), benzene-d_6 solutions (**4**, **7**, **8**, and **9**) and chloroform-d solutions at 30 °C (**1**, **2**, and **3**) on a Varian FT-80A spectrometer operated at 10.782 and 19.708 MHz respectively with Fourier transform mode for naturally abundant levels (0.037 and 100% for ^{17}O and ^{55}Mn nuclei, respectively). The spectra were recorded using a 10 mm o.d. sample tube.

^{17}O NMR Spectra

Fig. 1. ^{17}O NMR spectra of $(CH_3)_3Sn$-$Mn(CO)_5$ in $CDCl_3$ and $(CH_3)_3Sn$-$Mn(CO)_4P(OPh)_3$ in C_6D_6.

Accumulated transients were ca. 5×10^5 (0.02 s acquisition time) for ^{17}O and ca. 10^6 (0.05 s) for ^{55}Mn with 90° pulses. The spectral widths were 8000 Hz both for ^{17}O and ^{55}Mn nuclei and available data points were 323 and 807 for ^{17}O and ^{55}Mn in the time-domain spectra by keeping the Fourier number at 16384. Chemical shifts were measured in parts per million as frequency shifts from synthesizer frequencies, 8.532 and 17.385 MHz respectively for ^{17}O and ^{55}Mn and they were recalculated in the sense that a positive chemical shift designates a resonance to a lower field than that of water oxygen (10.78317 MHz) for ^{17}O, while a positive chemical shift for ^{55}Mn designates a resonance to a higher field than that of potassium permanganate (19.70807 MHz). The ^{17}O NMR spectra of these compounds were reasonably sharp (half band widths of 20—30 Hz). The ^{55}Mn NMR spectra were also sharp for a series of $(CH_3)_xCl_{3-x}Sn$-$Mn(CO)_5$, $(CH_3)_2Sn[Mn(CO)_5]_2$, and $CH_3Sn[Mn(CO)_5]_3$, but the spectra were broad for **7** and **9**. The NMR data are collated in Table 1 together with $\nu(CO)$ frequencies.

Spectral Results, Assignment, and Trends

^{17}O NMR Spectra. The compounds **1—4** which possess four equatorial and one axial carbonyls show two peaks with relative intensity of 4:1, whereas the compounds **7** and **8** which contain only equatorial carbonyls display one peak (Fig. 1). The stronger peaks of **1—4** are assigned to the equatorial carbonyls and the weaker peaks to axial carbonyls. For **5** and **6** which

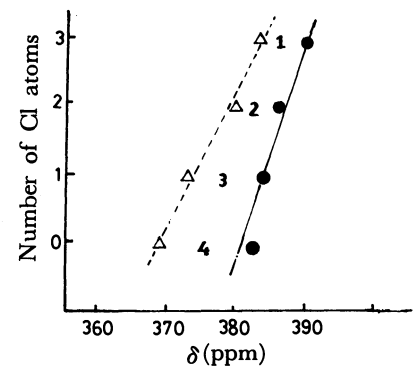

Fig. 2. Plots of ^{17}O chemical shifts vs. the number of the chlorine atoms for $(CH_3)_xCl_{3-x}Sn$-$Mn(CO)_5$.

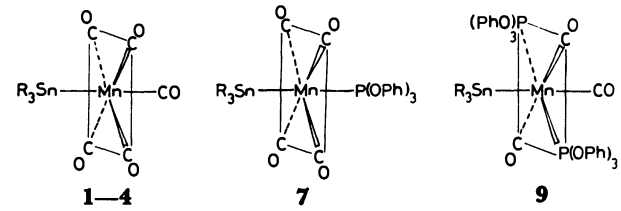
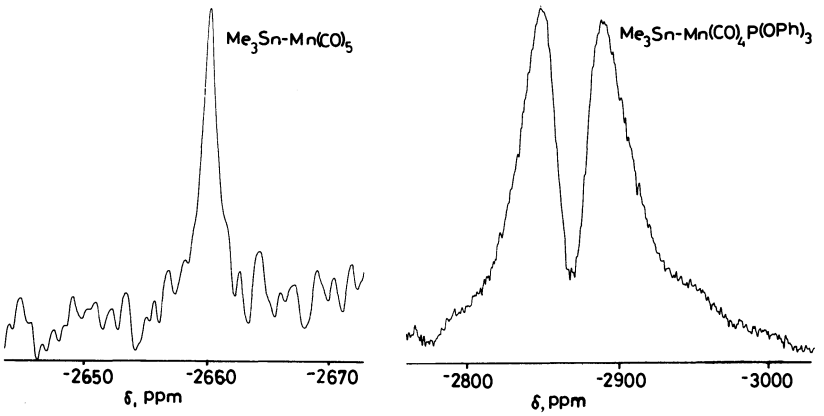
possess two kinds of carbonyl groups, that is, four cis carbonyls and one trans carbonyl for each $Mn(CO)_5$ group with respect to each Sn-Mn bond, we observe two peaks with relative intensity of 4:1; a similar assignment as above is applicable. All the ^{17}O NMR





^{55}Mn NMR Spectra

Fig. 3. ^{55}Mn NMR spectra of $(CH_3)_3Sn$-$Mn(CO)_{5-x}L_x$ in toluene.

signals are reasonably sharp (half-band width=20—40 Hz under these conditions). The spectrum of compound **9** which has two peaks with a relative intensity of 2:1 are overlapped and broad (half-band width=120 Hz), suggesting the presence of a number of conformers and the exchange process thereof. The spectral results is a good example to demonstrate that ^{17}O NMR is superior to IR spectroscopy for polynuclear metal carbonyl derivatives such as **5** and **6** to assess the electron distribution and/or bond order of CO groups; in IR spectra of **5** and **6**, several CO stretching peaks are observed. We are forced to carry out rather a laborious normal coordinate analysis in order to cull information on the electronic nature of CO groups. Attempts were also made to get ^{13}C NMR spectra of CO groups for the present compounds. However, unresolved broad peaks were observed for some of these compounds. For series of $(CH_3)_xCl_{3-x}Sn$-$Mn(CO)_5$ compounds, the resonances due to axial carbonyl oxygen show monotonous up-field shifts as large as 14 ppm, whereas those of equatorial carbonyls shift 8 ppm to up-field as we replace a chlorine atom with a methyl group (Fig. 2). The observation indicates that the axial carbonyl is more strongly influenced than equatorial carbonyls by this substitution. For a series of $(CH_3)_{3-x}Sn[Mn(CO)_5]_{x+1}$ compounds, **4**, **5**, and **6**, the resonances of the equatorial carbonyl oxygen shifts to downfield quite similarly to those of axial carbonyls with the increase of the number of the manganese carbonyl moiety. For the substitution of carbonyls with triphenyl phosphite(s), the equatorial carbonyls resonate at a higher field with the increase of the triphenyl phosphite ligand(s), while the axial carbonyls are less influenced by this substitution.

^{55}Mn NMR Spectra. In a series of $(CH_3)_{3-x}Sn[Mn(CO)_5]_{x+1}$ compounds, ^{55}Mn chemical shift moves only slightly to lower field and the line width remains almost constant at 27 Hz with the increase of x from 0 to 2. The one-bond Sn-Mn coupling cannot be observed. In contrast, ^{55}Mn NMR spectra exhibit a drastic change as we replace CO with triphenyl phosphite in $(CH_3)_3Sn$-$Mn(CO)_{5-y}L_y$; (**7**) shows a doublet signal with the separation of 782.2 Hz and the center of this split peaks is at ca. 210 ppm up-field compared with the resonance position of **4** (Fig. 3). For x=2, the signal is very broad ($\Delta\nu_{1/2}$=1340 Hz) and the center is further in the up-field. The observed splitting and broadening are probably due to spin-spin coupling with the phosphorus nucleus, although the ^{31}P NMR of **9** shows a slightly broadened singlet ($\Delta\nu_{1/2}$=31 Hz). It is very often the case that the nucleus with I=1/2 may not show splitting due to coupling but just broadening when coupled with a quadrupolar nucleus which relaxes with fast to intermediate rates.[14] An alternative possibility that this splitting could be derived from the presence of a stereoisomer of **7** where the triphenyl phosphite group occupies a cis position with respecpt to the Sn-Mn bond is rather unlikely, since ^{17}O NMR spectrum of **7** exhibits only one peak. The ^{55}Mn NMR spectra of a series of $(CH_3)_xCl_{3-x}Sn$-$Mn(CO)_5$ are reported in the previous paper.[8b]

Discussion

Correlation of ^{17}O NMR Chemical Shifts with Other Spectroscopic Data. A first attempt was made to correlate the ^{17}O NMR chemical shift values with previously obtained spectral data for **1**—**4**, **7**, and **9**. In Fig. 4 is given the relationship between ^{17}O chemical shifts of axial and equatorial carbonyls and CO stretching frequencies of the carbonyl groups, where A_1^2 mode denotes the symmetric stretching essentially due to equatorial carbonyls and A_1^1 mode denotes the symmetric stretching essentially due to axial carbonyl. It is generally understood that the electron taken up in the part of CO is situated in the antibonding orbital and therefore leads to lowering of the stretching frequencies. Good linear relationship holds for ^{17}O chemical shifts and CO stretching frequencies of A_1^2 mode. For axial carbonyl, however, the plot for **9** deviates conspicuously from the line. Figure 5 shows relationships between ^{17}O chemical shifts and ^{55}Mn chemical shifts for a series of $(CH_3)_xCl_{3-x}Sn$-

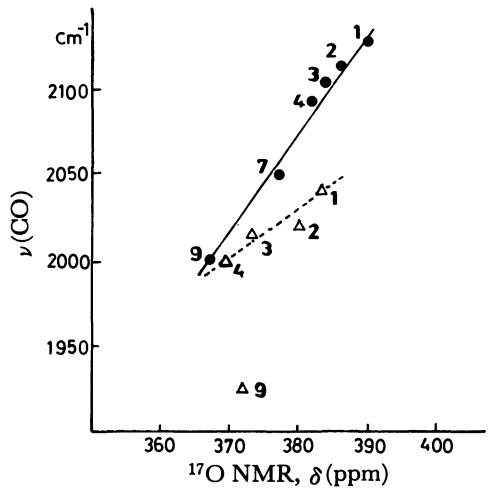


Fig. 4. Correlations of ^{17}O chemical shifts with carbonyl stretching frequencies for $(CH_3)_xCl_{3-x}Sn-Mn(CO)_{5-y}L_y$; ● denotes A_1^2 mode and △ denotes A_1^1 mode.

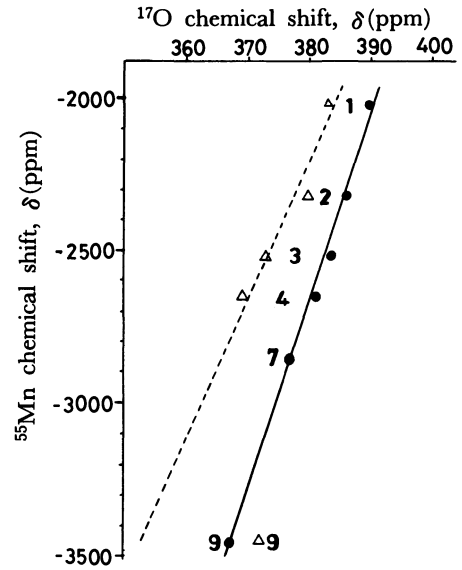

Fig. 5. Relationships between ^{17}O and ^{55}Mn NMR chemical shifts for $(CH_3)_xCl_{3-x}Sn-Mn(CO)_{5-y}L_y$; ● and △ represent chemical shifts for the equatorial and axial carbonyls, respectively.

$Mn(CO)_{5-y}L_y$ compound. Good linear relationship is observed for equatorial carbonyls, but the plot for axial carbonyl of **9** is far from the line drawn for plots of **1**—**4**. Significant deviation of ^{17}O chemical shift for axial carbonyl of **9** against ν(CO) and ^{55}Mn NMR chemical shift observed in Figs. 4 and 5 leads us to assume that a certain factor other than electronic origin might provoke anomaly of ^{17}O chemical shift of the axial carbonyl in **9**. In Fig. 6, correlation between ^{17}O chemical shifts and ^{119}Sn-Mössbauer isomer shifts is examined for a series of $(CH_3)_xCl_{3-x}Sn-Mn(CO)_5$ and a series of $(CH_3)_{3-x}Sn[Mn(CO)_5]_{x+1}$. ^{17}O chemical shifts move to lower field with the increase of ^{119}Sn isomer shift. Since the increase of ^{119}Sn-Mössbauer isomer shift means s-electron deposit on the tin nucleus,[8a]

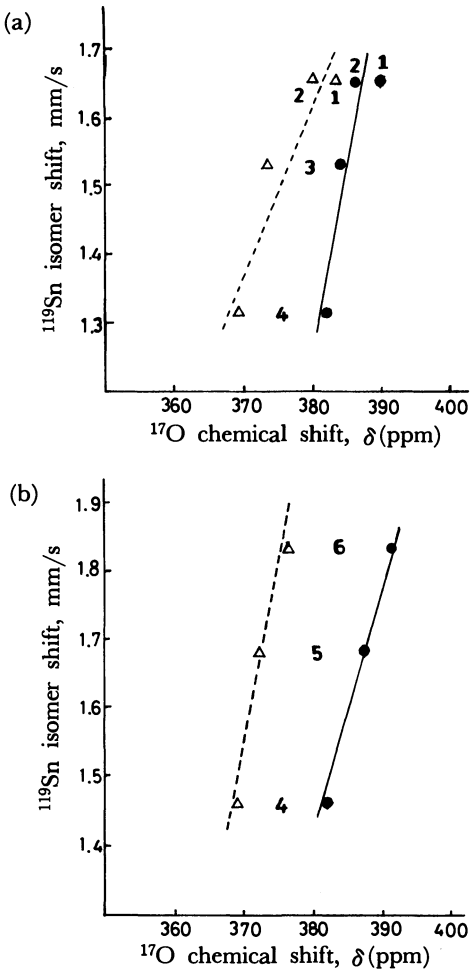

Fig. 6(a): Relationships between ^{17}O NMR chemical shifts and ^{119}Sn-Mössbauer isomer shifts for $(CH_3)_xCl_{3-x}Sn-Mn(CO)_5$. (b): Relationships between ^{17}O NMR chemical shifts and ^{119}Sn-Mössbauer isomer shifts for $(CH_3)_{3-x}Sn[Mn(CO)_5]_{x+1}$; ● represents data for equatorial carbonyls and △ for axial carbonyls.

the correlation indicates sσ-electron transfer from the manganese carbonyl moiety to the tin atom.

Interpretation of ^{17}O Chemical Shifts. The chemical shifts of ^{17}O NMR are dominantly determined by the local paramagnetic contribution to the total screening constant σ.[15,16] The paramagnetic screening σ_p is expressed by Pople in the form

$$\sigma_p = -\text{const} \langle \Delta E \rangle^{-1} \{ \langle r_p^{-3} \rangle (Q_{aa} + Q_{ab})_p \} \quad (1)$$

where ΔE is a mean excitation energy, $\langle r_p^{-3} \rangle$ is the mean inverse cube radius of the valence p-electron, and $(Q_{aa}+Q_{ab})_p$ terms are dependent on the charge imbalance in the ground state valence p-orbitals of the atom **a** and the bond order between the atom **a** and the adjacent atom **b**, respectively. In the previous report from this laboratory,[9b] it was demonstrated that ^{17}O chemical shift is dominantly determined by the change of electron density through σ-donating and π-accepting ability of the group R for $RMn(CO)_5$-type compounds, that is, Q_{aa} term is operative for

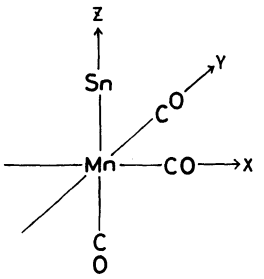

Fig. 7. Coordinate axes for $(CH_3)_xCl_{3-x}Sn-Mn(CO)_{5-y}L_y$.

paramagnetic shift of ^{17}O resonance. The series of $(CH_3)_xCl_{3-x}Sn-Mn(CO)_5$ type compounds, **1**—**4**, are appropriate to see the electronic effect of the tin moiety on the ^{17}O chemical shift. As is shown in Figs. 2 and 6(a), ^{17}O resonances of carbonyl groups are shifted to a lower field by replacing the methyl group with more electronegative chlorine atom and the trend of the shift is more pronounced for axial carbonyl than for equatorial carbonyls. If we choose coordinate axes as is shown in Fig. 7, the axial carbonyl can exploit two π-orbitals (d_{xz} and d_{yz}) which interact with the π-orbitals of the tin atom, whereas the equatorial carbonyl can utilize one π-orbital (d_{xz} or d_{yz}) for π bondings between carbonyls and manganese atom. From this symmetry consideration, we find that the increase of π-electron withdrawal by the more electronegative tin moiety reduces π-interactions between manganese and equatorial and axial carbonyls and the reduction of this π-interaction should be enhanced for axial carbonyl and σ-electron-withdrawing by the tin moiety reduces electron density of only axial carbonyl. Thus, the change of σ- and π-electron-withdrawing ability of the tin moiety should be more strongly reflected on the change of charge density around the oxygen atom of axial carbonyl than that of equatorial carbonyls. The observed trend of enhanced deshielding of ^{17}O nuclei for axial carbonyl than that for equatorial carbonyls is interpreted in terms of increased σ- and π-electron acceptance of the tin moiety with the increase of the number of chlorine atoms. Similar conclusion was obtained in the previous spectroscopic studies for this series of compounds,[8a–c] but the effect of the substitution is more adequately reflected on the ^{17}O chemical shift than, for instance, on a set of force constants of carbonyl groups; in the previous normal coordinate analyses, the effect of this substitution was enhanced for equatorial carbonyls than for axial carbonyls when the Mn–C and C–O stretching force constants of equatorial and axial carbonyls were compared for **1** and **4**.[8c]

The substitution of CO group(s) with triphenyl phosphite(s) which is a weaker π-accepting ligand than CO affects π-interactions between the tin and manganese atoms and between the remaining CO groups and the manganese atom in a similar manner. When the axial carbonyl is replaced with triphenyl phosphite, the π-interaction between the tin and manganese atoms and between the manganese atom and equatorial carbonyls should be enhanced. When equatorial carbonyls are replaced with triphenyl phosphites, the π-interactions between the manganese atom and axial carbonyl and between the manganese atom and the remaining equatorial carbonyls are increased. However, the π bond order between carbon and oxygen atoms is decreased by synergetic effect for both types of substitution. The change of the π-interaction between the tin and manganese atoms was already discussed in the previous ^{119}Sn-Mössbauer study[8d,81] and the attention is now focused on the ^{17}O chemical shift. By replacing axial and/or equatorial carbonyls with triphenyl phosphite as in the case of **7** and **9**, ^{17}O resonance of equatorial carbonyl shifts to a higher field. This observation is in agreement with our expectation that the π bond order between the carbon and oxygen atoms of the remaining carbonyls is reduced by this substitution and reduction of π bond order should lead to a higher field shift of ^{17}O resonance of equatorial carbonyls in **8** by substituting the triphenyl phosphite for axial carbonyl in **7**. However, ^{17}O chemical shift of the axial carbonyl in **9** shifts slightly to a lower field by this substitution. A plausible explanation of this anomaly is that deshielding effect due to diamagnetic phenyl groups which are arranged just in the position to deshield the axial carbonyl might contribute to a lower field shift to some extent, although exact discussion must wait for further study on ^{17}O chemical shift of similar metal carbonyl derivatives.

For a series of $Me_{3-x}Sn[Mn(CO)_5]_{x+1}$ compounds, ^{17}O resonances of both equatorial and axial carbonyls shift monotonously to a lower field with the increase of manganese carbonyl moiety. A heuristic treatment of ^{17}O chemical shifts is shown in Fig. 6(b), that is, a plot of ^{17}O chemical shifts versus ^{119}Sn-Mössbauer isomer shifts shows that ^{17}O chemical shift moves to a lower field with the number of the $Mn(CO)_5$ group and/or with the increase of ^{119}Sn-Mössbauer isomer shift. The result indicates that the more electronegnative tin atom accepts more sσ-electron from the manganese carbonyl moieties with the increase of $Mn(CO)_5$ groups[17] and σ-electron term in Eq. 1 is operative for ^{17}O chemical shift for this series of compounds.

The crux of the matter clarified in this study is that ^{17}O NMR spectroscopy is very convenient and useful technique to investigate the change of electron distribution of the carbonyl groups in metal cluster compounds such as **5** and **6**, and ^{17}O chemical shifts reflect σ- and π-electron acceptance of the tin moiety.

^{121}Sb Mössbauer and ^{1}H and ^{13}C NMR Spectroscopic Studies of a Series of Organoantimony(V) Compounds, R_3SbX_2

Makoto YANAGA,* Taichi MIURA, Kazutoyo ENDO, Hiromichi NAKAHARA, and Masuo TAKEDA†
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya, Tokyo 158

(Received April 26, 1986)

The ^{121}Sb Mössbauer spectroscopic and the ^{1}H and ^{13}C NMR nuclear magnetic resonance studies have been performed for a series of organoantimony(V) compounds: R_3SbX_2 (R=CH_3, C_6H_5, p-$CH_3C_6H_4$; X=F, Cl, Br, I). For the trimethylantimony dihalides, the isomer shifts and quadrupole coupling constants of the ^{121}Sb Mössbauer spectra indicated that the withdrawal of the bonding electrons from the antimony atom along Sb–X increased, as the electronegativity of the halogen increased. The chemical shifts of the ^{1}H and ^{13}C NMR spectra showed that the electron population around the methyl group increased with increasing electronegativity of halogen. For phenyl and p-tolyl derivatives, both ^{121}Sb Mössbauer and ^{13}C NMR data showed a trend similar to the methyl compounds. The results suggest that the electron cloud around the antimony atom spreads, with an increase in the electronegativity of the halogen, not only toward the halogen atoms but also toward the plane perpendicular to the bonding direction with the halogen atoms.

Mössbauer spectroscopy is a sensitive tool for studying the effect of the chemical environment on the electron density at and around a Mössbauer atom. Antimony contains 57.25% of the naturally occuring isotope ^{121}Sb. The nuclear radius factor, $\Delta R/R$, of ^{121}Sb is considerably large (about -1×10^{-3}).[1] Hence, a large change in the isomer shift can be expected for varieties of antimony compounds, although a large natural line width of 2.11 mm s^{-1} will result in an inaccuracy in the evaluation of the data.

If Mössbauer spectroscopy is used in combination with other spectroscopies, it is possible to elucidate how an electron is redistributed throughout a molecule when some ligands are varied.[2-5] For example, the effect of various ligands on the electron distribution, especially around tin atoms in the molecules of $R_{3-x}X_xSn$–$Mn(CO)_5$ (R=CH_3, C_6H_5; X=Cl, Br), was successfully studied by combining ^{119}Sn Mössbauer spectroscopy and ^{1}H and ^{55}Mn NMR.[3]

For trimethyl- and triphenylantimony dihalides, several structural studies by the X-ray diffraction method[6,7] and infrared and Raman spectroscopy[8-12] have been reported. ^{121}Sb Mössbauer spectra have also been reported for some of trimethyl- and triphenylantimony dihalides.[13-15]

In the present work, we have examined the correlation between the electronic state at antimony atoms, deduced from the isomer shifts and the nuclear quadrupole coupling constants of ^{121}Sb Mössbauer spectra, and the electron distributions of the ligands, revealed by their chemical shifts in ^{1}H and ^{13}C NMR spectra for a series of organoantimony(V) compounds, trimethylantimony dihalides $(CH_3)_3SbX_2$ (X=F, Cl, Br, I), triphenylantimony dihalides $(C_6H_5)_3SbX_2$ (X=Cl, Br, I), and tri-p-tolylantimony dihalides $(p$-$CH_3C_6H_4)_3SbX_2$ (X=Cl, Br, I). Mössbauer spectra were measured at 20 K and analyzed by using the transmission integral in order to take into account the effect of the thickness of the absorber on the spectra.

Experimental

Preparation of Compounds. All the compounds were prepared by methods described in the literature[8,16,17] or analogous methods. For example, tri-p-tolylantimony dichloride was synthesized by the following method. Antimony trichloride (25 g) dissolved in 250 ml of dry benzene was added slowly to the Grignard reagent prepared from 9.5 g magnesium and 72 g p-bromotoluene dissolved in 250 ml of absolute ether, and the mixture was boiled for thirty hours. The filtrate was distilled under reduced pressure, and the soluble residue was removed by extraction with small quantities of ethanol. The tri-p-tolylstibine was further purified by crystallization from carbon tetrachloride (yield; 20.5 g, 47.3%). Tri-p-tolylstibine (5 g), dissolved in 30 ml of carbon tetrachloride, was treated with chlorine until the solution became yellow. Most of the solvent and the excess chlorine were then removed using a steam bath. The tri-p-tolylantimony dichloride was separated from the cold concentrated solution, and recrystallized from carbon tetrachloride (yield; 3.2 g, 54.2%).

The purity of the compounds studied in the present work was checked by elemental analyses of carbon and hydrogen, and by IR and/or NMR.

Mössbauer Spectra. The ^{121}Sb Mössbauer absorption spectra were obtained using $\simeq$440 μCi $Ca^{121m}SnO_3$ source moving in a constant acceleration mode. The source and the absorber containing 13—25 mg cm^{-2} of Sb were both kept at 20 K in a cryostat[18] and the 37.14 keV resonance γ-rays were detected by counting the escape peak in a Xe–CO_2 proportional counter. Generally, the measurement was continued until $1-3\times10^4$ counts/channel was achieved. The velocity scale was calibrated by using a laser interferometer.

The spectra were analyzed by the program of least-squares fitting of transmission integrals,[19-22] edited by L. H. Bowen.[23] The value of 1.34 was used as a fixed parameter for $Q(7/2)/Q(5/2)$ in analyses.[24]

^{1}H and ^{13}C NMR Spectra. The ^{1}H and ^{13}C NMR spectra were observed at room temperature for the chloroform-d solution containing 1% tetramethylsilane (TMS) as the internal standard. A PMX 60SI spectrometer and a JNM-FX60, Fourier transform spectrometer were used for the measurement of ^{1}H and ^{13}C NMR, respectively.

Results and Discussion

The observed ^{121}Sb Mössbauer spectra for the trimethylantimony dihalides are shown in Fig. 1. The Mössbauer parameters obtained in the present work for a series of compounds are summarized in Table 1. The absolute value of the isomer shift (IS) decreases and that of the quadrupole coupling constant (e^2q_zQ) increases as the electronegativity of the halogen increases for all the trimethyl, triphenyl, and tri-*p*-tolyl compounds.

On the assumption that the contribution of the core electrons to the electron density at the nucleus of antimony is, as a first approximation, the same for all the compounds studied and that the shielding effect on the 5s electrons by 5d electrons is considerably smaller than that by the 5p electrons, 5s and 5p electrons can be considered mainly responsible for the observed Mössbauer parameters. As the absolute value of the IS is proportional to the electron density at the antimony nucleus, the trend of the IS shows that the s electron density decreases as the electronegativity of the ligand halogen atom increases. This fact implies the withdrawal of s electrons from the antimony atom along Sb–X.

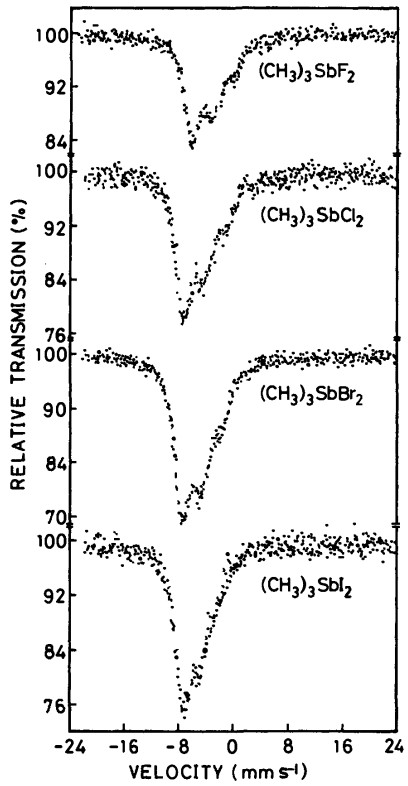

Fig. 1. ^{121}Sb Mössbauer spectra of $(CH_3)_3SbX_2$ (X=F, Cl, Br, I) against a $Ca^{121m}SnO_3$ source at 20 K.

All the compounds investigated are found to have large negative e^2q_zQ, indicating the main component of the electric field gradient, eq_z, is positive since the quadrupole moment, eQ, of the ^{121}Sb nucleus is negative.

X-Ray structural studies for R_3SbX_2 (R=CH_3, C_6H_5; X=Cl, Br, I) revealed that the trigonal bipyramidally coordinated antimony atom has two halogen atoms occupying the apical positions along the *z*-axis and three organic ligands situating in the *x*–*y* plane,[6,7] and the sp^3d hybrid is expected.[15] Neglecting 5d orbital contributions, the electric field gradient, eq_z, due to the asymmetric p electrons and the asymmetric factor, η, can be written in general as

$$eq_z = C\{-N_{Pz}+1/2(N_{Px}+N_{Py})\}$$

and

$$\eta = 3(N_{Px}-N_{Py})/\{-2N_{Pz}+(N_{Px}+N_{Py})\},$$

where N_{Pi} with $i=x, y, z$ represents the orbital population along the three directions and C is a constant with the positive sign. This axial symmetry allows us to put $N_{Px}=N_{Py}$ and $\eta=0$. The observed positive eq_z means that the p electron density along the *x* and *y* directions is greater than that along the *z*-axis. The trend that the electric field gradient at the antimony nuclear site increases as the electronegativity of the halogen atoms increases suggests that the electrons in the p_z orbital is withdrawn toward the halogen atom along Sb–X.

Two ^{121}Sb Mössbauer parameters, IS and e^2q_zQ, both show that the electron attraction by the halogen

Table 1. ^{121}Sb Mössbauer Parameters for R_3SbX_2 Compounds

increases, as the electronegativity difference between the halogen and antimony increases.

It is further noted that the absolute values of the IS decrease slightly for the same halogen atom in the order of $(CH_3)_3SbX_2$, $(C_6H_5)_3SbX_2$, and $(p\text{-}CH_3C_6H_4)_3SbX_2$ as shown in Table 1, when we compare the effects of ligands in the x-y plane. The electron releasing ability of these substituents is known to be in the order of methyl>p-tolyl>phenyl group. In fact, for the p-tolyl and phenyl derivatives, the electron density of the carbon bonded to the antimony atom was found to increase with this sequence, which will be shown later (^{13}C NMR data in Table 3). In the foregoing discussion, the shielding effects of the 5s electrons by 5d electrons were ignored in comparison to those due to the 5p electrons. However, as a minor effect, the s electron density at the ^{121}Sb nuclear site will slightly decrease with an increase of the density on the 5d orbitals. In the case of $(p\text{-}CH_3C_6H_4)_3SbX_2$, the electron-donating methyl group bonded to the phenyl ring may cause the π-electron density of the carbon bonded to the antimony higher. Although the X-ray diffraction data have not yet been available for the p-tolyl derivative, the π-orbital may interact with the vacant $5d_{xz}$ and $5d_{yz}$ orbitals of antimony. This interaction may enhance the shielding effects, resulting in the decrease of 5s electron density at the ^{121}Sb nuclear site. This will be one of the possible reasons for the observed Mössbauer parameters.

In order to examine in more detail the electron distribution around antimony, we compared the ^{1}H and ^{13}C NMR data with the ^{121}Sb Mössbauer data. The ^{1}H NMR spectra of trimethylantimony dihalides are shown in Fig. 2. In Fig. 3 is illustrated the relationship between the ^{121}Sb Mössbauer isomer shift and ^{1}H NMR chemical shift; ^{1}H chemical shift smoothly decreases as the absolute value of the isomer shift decreases. The values of the chemical shift, δ, of ^{1}H and ^{13}C NMR for trimethylantimony dihalides are listed in Table 2. Both ^{1}H and ^{13}C NMR chemical shifts are observed at higher fields as the electronegativity of the halogen coordinated to the antimony increases. This implies that the electron population becomes larger around the methyl group when the more electronegative halogen is attached to the antimony atom. The s electron density at the antimony itself decreases as shown by the Mössbauer isomer shift. The present NMR data are consistent with those on the streching force constant (k) of antimony-carbon atoms obtained for $(CH_3)_3SbX_2$ (X=F, Cl, Br) by far-infrared spectroscopy (k decreases in the order of X=F, Cl, Br).[11] The present observation is, however, contrary to the one reported on methyl halides CH_3X, where the chemical shifts of ^{1}H NMR are observed at lower fields as the electronegativity of the halogen increases.[25]

The values for ^{13}C chemical shift of the triphenyl and tri-p-tolylantimony dihalides are summarized in Table 3. In the case of triphenyl and tri-p-tolylantimony dihalides, the δ value for the carbon atom coordinated to the antimony atom shifts toward a higher field as the electronegativity of the halogen increases, indicating that the electron population increases at the carbon atom coordinated to the antimony atom. This trend agrees with the case of trimethylantimony dihalides. However, Table 3 also shows that the δ values of the o- and p-carbon atoms shift toward lower fields although

a) Relative to $(CH_3)_4Si$ (TMS).

the δ values for the *m*-carbon stays constant. This implies that the π-electron density is withdrawn from the phenyl or *p*-tolyl group to the antimony, indicating the electrophilic nature of the antimony atom.

These results may imply that the electron cloud around the antimony atom spreads in the x–y plane as well as in the z direction with an increase in the electronegativity of the halogen atom. Therefore, the electron density on the carbon coordinated to the antimony might be increased.

Conclusion

In a series of organoantimony(V) compounds R_3SbX_2 (R=CH_3, C_6H_5, *p*-$CH_3C_6H_5$; X=F, Cl, Br, I), the ^{121}Sb Mössbauer spectra and ^1H and ^{13}C NMR spectra were measured. Interesting information concerning the electron distribution around the antimony atom was obtained.

As the electronegativity of the halogen occupying the apical position along the z-axis in the trigonal bipyramidal structure increases, (1) the ^{121}Sb Mössbauer data show an increasing withdrawal of the electron density from the antimony atom to the halogen atom, and (2) the ^1H and ^{13}C NMR chemical shifts show the increase of the electron population at the methyl group in trimethylantimony dihalides and on the carbon coordinated to the antimony of the aromatic group in the triphenyl and tri-*p*-tolylantimony dihalides. These facts suggest that the cloud of the electrons around the antimony atom spread along the x and y directions with an increasing tendency for the withdrawal of the electron density from the antimony along the z-axis.

The authors gratefully acknowledge the cooperation of Drs. Yasuyuki Miyazawa, Haruo Matsuyama, and Masato Yoshida, and Prof. Dr. Michio Kobayashi of Tokyo Metropolitan University in the measurements of the ^1H and ^{13}C NMR spectra. We would also like to thank Dr. Masashi Takahashi of Toho University for measurements of the ^{121}Sb Mössbauer spectra. The authors are also indebted to Prof. Dr. Lawrence H. Bowen at North Carolina State University for a least-squares fitting program of transmission integrals.

(Received April 30, 1986)

The reaction of *cyclo*-triphosphate(P_{3m}) with mono-(MEA), di-(DEA), or triethanolamine(TEA) in an aqueous solution was investigated under various conditions (mixing ratio of MEA, DEA, or TEA to P_{3m}, pH, temperature, and reaction time). 1) In the pH region of 7—12, P_{3m} reacted with MEA or DEA to yield tri-, di-, and monophosphate derivatives of MEA or DEA. The phosphoric acid ester of MEA or DEA was not formed at all. 2) The reactivities of MEA and DEA to P_{3m} were in the order of MEA > DEA, and TEA did not react with P_{3m}. 3) The reactivity of P_{3m} with MEA or DEA decreased with the decrease in the pH, and no reaction took place under acidic conditions. 4) The maximum yields of triphosphate derivatives of MEA, *N*-(2-hydroxyethyl)-triphosphoramidate(P_3-(N)MEA) and of DEA, *N*-bis(2-hydroxyethyl)triphosphoramidate (P_3-(N)DEA), were about 75 and 60% respectively at a molar ratio of 1 : 1, at pH 12, and at room temperature. 5) P_3-(N)MEA and P_3-(N)DEA easily recyclized to the raw material, P_{3m}, under acidic conditions. 6) The mechanism of the reaction between P_{3m} and MEA or DEA was investigated.

Inorganic condensed phosphates can be roughly classified into the following three types: 1) linear polyphosphates, 2) cyclic phosphates, and 3) ultraphosphates (network-like phosphates).[1] Among them, linear poly- and ultraphosphates are widely used for drugs, food additives, fertilizers, detergents, water treating agents, and industrial chemicals.[2-4] However, as to cyclic phosphates, few practical applications[5-7] have been known, and few reports[8,9] have been presented on fundamental investigations of them. Since Feldmann reported, in 1965—1969, that P_{3m} reacts with alkylamines,[10] phenols,[11] and amino acids,[12] P_{3m} has been attracting much attention as a phosphorylating agent for organic compounds. Rabinowitz[13,14] reported the reaction of P_{3m} with amino acids (glycine and alanine); Saffhill,[15] the phosphorylation of nucleosides with P_{3m}, and Dombrovskii and Dorosh,[16] the reaction of P_{3m} with 1,6-hexanediamine. However, in these studies paper chromatography has been principally used to analyze the reaction products; it provides only a semiquantitative discussion. In the present study, the reaction of P_{3m} with mono- (MEA), di- (DEA), or triethanolamine (TEA) has been examined in order to develop studies of the application of P_{3m} as a phosphorylating agent. Both ^{31}P-NMR and anion-exchange chromatography have been used to determine the structure and the amounts of the reaction products. The reaction mechanism is also discussed.

Experimental

Chemicals. Sodium *cyclo*-triphosphate hexahydrate, $Na_3P_3O_9 \cdot 6H_2O$, was obtained by recrystallizing it three times from an aqueous solution of industrial-grade anhydrous sodium *cyclo*-triphosphate (98%) from Rasa Kogyo, Ltd. Unless otherwise stated, guaranteed grade mono-, di-, and triethanolamine were used without further purification.

Reaction between *cyclo*-Triphosphate and Ethanolamine. In the reaction of P_{3m} with MEA, DEA, or TEA, 50 cm^3 of a 0.5 mol dm^{-3} aqueous sodium *cyclo*-triphosphate (P_{3m}) solution and 50 cm^3 of a 0.5—5 mol dm^{-3} aqueous mono-, di-, or triethanolamine solution were mixed. The pH values of the mixed solution were about 12.0—12.5 in MEA, 11.6—11.9 in DEA, and 10.5—10.7 in TEA. These mixed solutions were then adjusted to the prescribed pH value (pH 12, 10, 7, or 4) by the use of a 6 mol dm^{-3} sodium hydroxide aqueous solution and hydrochloric acid, and the reaction was allowed to proceed at room temperature or 50 °C. Since the pH of the mixed solution gradually fell with the progress of the reaction, a sodium hydroxide solution was added to it to maintain the prescribed pH value.

Anion-exchange chromatography and the measurement of ^{31}P-NMR were carried out by the methods described in a previous paper.[17]

Results and Discussion

Reaction of P_{3m} with MEA. Aqueous solutions of P_{3m} and MEA were mixed in a molar ratio of 1 : 1. The pH of the mixed solution was adjusted to 12 with a sodium hydroxide solution, and the reaction was allowed to proceed at room temperature. With the progress of the reaction, the pH of the mixed solution gradually decreased to about 9.3 after 1 d. This fact indicates that P_{3m} reacts with water or MEA to produce linear phosphates or their derivatives. In order to examine this, the present authors investigated the reaction products and their amounts by the use of anion-exchange chromatography and ^{31}P-NMR.

As an example, two representative anion-exchange chromatograms of the reaction products are shown in Fig. 1. Immediately after the reaction, a large peak due to an unknown compound appeared at about 880 cm^3 of the effluent (designated as Compound C). The peak of the pyrophosphate (P_2) was also observed, though its amount was slight. The amount of Compound C increased with the passage of the reaction time, but in a reaction over a long period its amount gradually decreased due to hydrolysis. As can be seen from Fig. 1, when the reaction was allowed to proceed for 44 d, in addition to Compound C four peaks due to un-

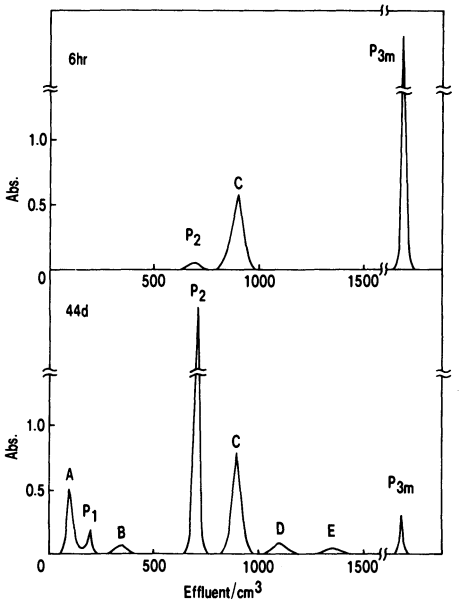

Fig. 1. Elution patterns of the reaction products of P_{3m} with MEA at pH 12.
P_{3m}: MEA = 0.5 mol dm^{-3}: 0.5 mol dm^{-3}.

known compounds (Compounds A, B, D, and E) were found at about 100, 350, 1150, and 1360 cm^3 of the effluent. Moreover, almost no production of triphosphate (P_3) was found in this reaction.

Figure 2 shows the ^{31}P-NMR spectra of the reaction products of P_{3m} and MEA at a molar ratio of 1 : 10 and pH 12. It can be seen that the main product, Compound C, is a triphosphate derivative of MEA, *N*-(2-hydroxyethyl)triphosphoramidate(P_3-(N)MEA). In the ^{1}H-decoupling spectrum of Fig. 2, the doublets at δ −0.5 and −4.3 ppm were assigned to the end phosphorus atoms of P_3-(N)MEA, P_α and P_γ, respectively, while the triplet at −20.3 ppm corresponded to the middle phosphorus atom, P_β. In the ^{1}H-coupling spectrum, each of the doublets of P_α ought to split into triplets because of the two hydrogen atoms of the methylene (-NHCH$_2$-) group, but actually a quintet was observed as a result of overlapping.

The ^{31}P-NMR spectra do not always indicate that Compound C is P_3-(N)MEA, with a P-N bond in the molecule. There is another possibility that Compound C is a triphosphoric acid ester of MEA, 2-aminoethyl triphosphate, with a P-O-C bond in the molecule. In order to check this possibility, an aqueous solution of Compound C was made acidic (pH 3). Since Compound C easily recyclized to P_{3m}, it was concluded that Compound C is a triphosphate derivative of MEA, P_3-(N)MEA, with a P-N bond in the molecule.[18,19] The singlet at δ 4.7 ppm in Fig. 2 is attributed to the phosphorus atom of a monophosphate derivative of MEA,

N-(2-hydroxyethyl)phosphoramidate$^-$O-P(=O)(O$^-$)-NHCH$_2$CH$_2$OH (P_1-(N)MEA).

This phosphorus atom splits into a triplet in the ^{1}H-coupling due to the influence of two hydrogen atoms of the methylene group. Compound A, whose amount is next to P_3-(N)MEA, was estimated to be a monophosphate derivative of MEA, P_1-(N)MEA, with a P-N bond in the molecule. Singlets at δ 4.0 and −5.1 ppm were attributed to PO_4^{3-} and $P_2O_7^{4-}$ ions.[20]

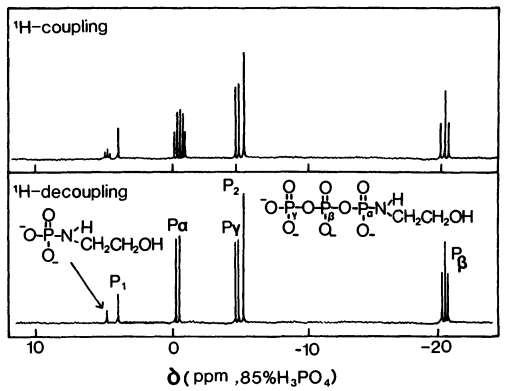

Fig. 2. ^{31}P-NMR spectra of the reaction products in the P_{3m}-MEA series.

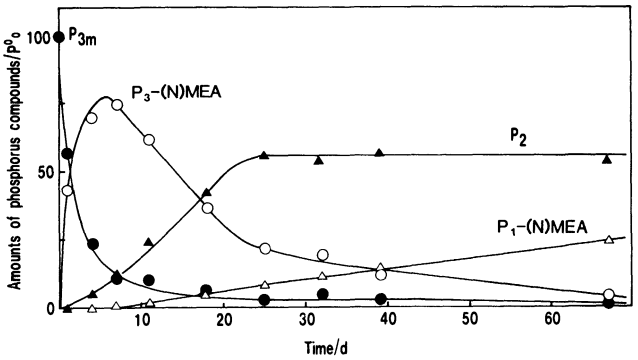

Fig. 3. Changes of the amounts of phosphorus compounds in the reaction of P_{3m} with MEA at pH 12.
P_{3m}: MEA = 0.5 mol dm^{-3}: 0.5 mol dm^{-3}.

The structures of Compounds B, D, and E have not yet been characterized because they were formed in only minute amounts and could not be isolated in a pure form. However, based upon the fact that, when a solution containing much of Compound B was made acidic (pH=3), it was hydrolyzed to produce P_2, Compound B was estimated to be *N*-(2-hydroxyethyl)diphosphoramidate(P_2-(N)MEA). On the other hand, the orthophosphoric acid ester of MEA, 2-aminoethyl dihydrogenphosphate, was not produced in the reaction of P_{3m} with MEA. Thus, it was found that the phosphorylation of MEA with P_{3m} takes place at the position of the NH_2 group in MEA.

Amounts of P_3-(N)MEA, P_2-(N)MEA, and P_1-(N)MEA. Figure 3 shows the changes in the amounts of the various phosphates formed by the reaction of P_{3m} with MEA at a molar ratio of 1 : 1, pH 12, and room temperature. P_3-(N)MEA began to be produced immediately after the start of the reaction; the yield reached

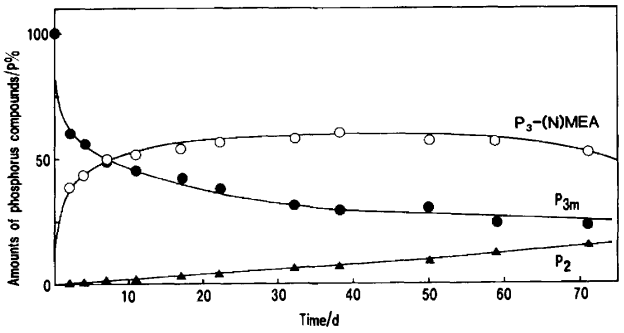

Fig. 4. Changes of the amounts of phosphorus compounds in the reaction of P_{3m} with MEA at pH 10.
P_{3m}: MEA = 0.5 mol dm^{-3}: 0.5 mol dm^{-3}.

about 75% after 7 d. After that, however, it gradually decreased as the reaction progressed. On the other hand, P_1-(N)MEA increased with the reaction time, attaining about 24% after 67 d. Also, the amount of P_2 increased with the progress of the reaction, and the crystals of tetrasodium pyrophosphate decahydrate, $Na_4P_2O_7 \cdot 10H_2O$, began to precipitate after 25 d. However, the amount of $Na_4P_2O_7 \cdot 10H_2O$ precipitated was not taken into consideration in Fig. 3. The amounts of P_1, P_2-(N)MEA, and Compounds D and E were so small (P_1, 4.4; P_2-(N)MEA, 4.7; Compound D, 6.6, and E, 11.5%) that they were omitted in Fig. 3.

Figure 4 shows the changes in the amounts of phosphorus compounds formed by the reaction between P_{3m} and MEA (P_{3m} : MEA = 1 : 1) at pH 10 and room temperature. The raw material, P_{3m}, gradually decreased with the progress of the reaction, showing that the reaction of P_{3m} with MEA at pH 10 was slower than that at pH 12. The main product, P_3-(N)MEA, attained to about 50% after 7 d. After that, the amount was constant (about 55—60%) until 60 d after the reaction. P_1, P_1-(N)MEA, P_2-(N)MEA, and Compounds D and E were not formed until 20 d after the reaction. No precipitate of $Na_4P_2O_7 \cdot 10H_2O$ was observed under these conditions.

In the reaction of P_{3m} with MEA at a molar ratio of 1 : 1, pH 7, and room temperature, the amount of P_3-(N)MEA was very small amounting only to about 2.3% even after 60 d. At pH 4, the phosphorylation of MEA with P_{3m} was not observed at all. Instead, the hydrolysis products of P_{3m}, i.e., P_3, P_2, and P_1 were obtained. From the above experimental results (pH 12, 10, 7, and 4), it can be concluded that P_{3m} and MEA react well in highly alkaline regions, that the reactivity decreases with the decrease in the pH, and that no reaction takes place under acidic conditions. This is ascribable to the formation of inactive $H_3{}^+NCH_2CH_2OH$ under acidic conditions.

Figure 5 shows the changes in the amounts of phosphorus compounds when the reaction was allowed to proceed at a molar ratio of 1 : 10, pH 12, and room temperature. P_{3m} rapidly decreased after the start of the reaction, and it became almost zero after several hours. On the contrary, P_3-(N)MEA began to be produced

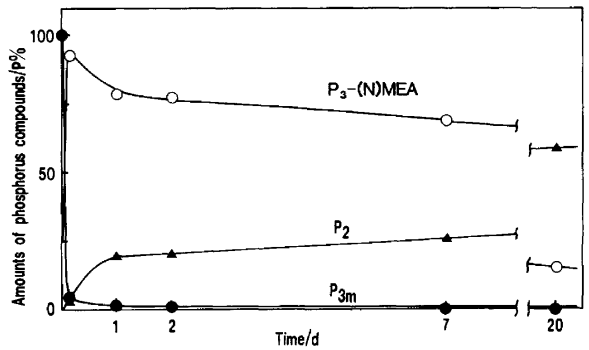

Fig. 5. Changes of the amounts of phosphorus compounds in the reaction of P_{3m} with MEA at pH 12.
P_{3m}: MEA = 0.5 mol dm^{-3}: 5 mol dm^{-3}.

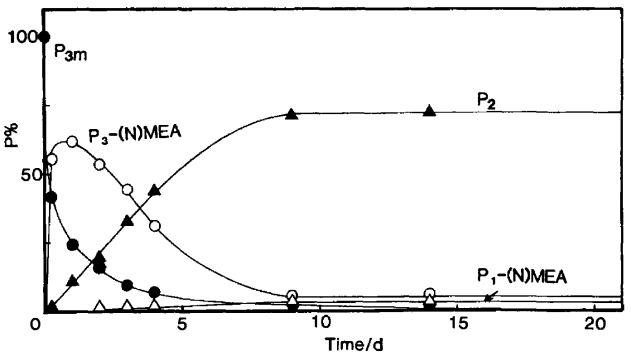

Fig. 6. Changes of the amounts of phosphorus compounds in the reaction of P_{3m} with MEA at 50 °C.
P_{3m}: MEA = 0.5 mol dm^{-3}: 0.5 mol dm^{-3}, pH 12.

rapidly, and it was produced about 92% within 3.5 h. The amount of P_3-(N)MEA gradually decreased after that with the lapse of the reaction time. The production rate of P_3-(N)MEA was faster, and its amount was larger at a molar ratio of 1 : 10 than that at 1 : 1 (Fig. 3). Since the amounts of P_1, P_1-(N)MEA, and P_2-(N)MEA were small (about 7.1, 8.0, and 2.7% respectively), they are not shown in Fig. 5. No Compound D or E was produced under these experimental conditions.

In Fig. 6, the amounts of P_3-(N)MEA, P_1-(N)MEA, and P_2 formed by the reaction of P_{3m} with MEA (molar ratio = 1 : 1) at pH 12 and 50 °C are plotted against the time. The reaction proceeded faster than that at room temperature (Fig. 3). The pattern of the formation of P_3-(N)MEA, P_1-(N)MEA, and P_2 was, however, similar to that at room temperature. The amount of P_3-(N)MEA increased to the maximum value of about 61% after 1 d, thereafter, it gradually decreased.

Reaction of P_{3m} with DEA. A representative anion-exchange chromatogram for the products resulting from the reaction of P_{3m} and DEA at a molar ratio of 1 : 1, pH 12, and room temperature is shown in Fig. 7. Other than the peaks of P_1, P_2, and P_3, three peaks due to unknown compounds were found at about 100, 440, and 815 cm^3 of the effluent (designated as Compounds I, II, and III). In the reaction of P_{3m} with DEA, the production of P_3 was remarkable. This may be due to the lower reactivity of

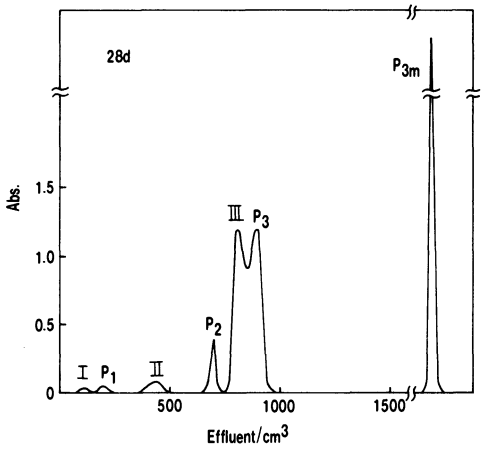

Fig. 7. Elution pattern of the reaction products of P_{3m} with DEA at pH 12.
P_{3m}: DEA = 0.5 mol dm^{-3}: 0.5 mol dm^{-3}.

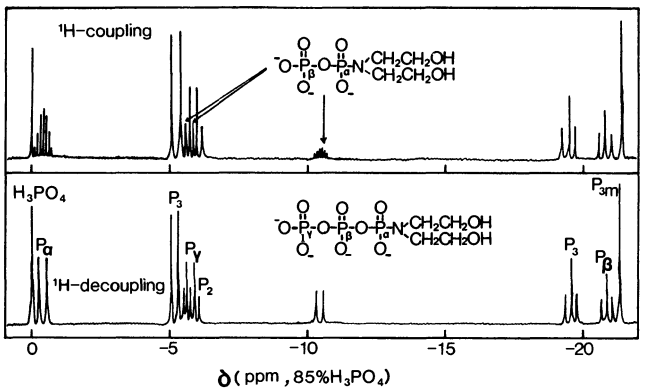

Fig. 8. ^{31}P-NMR spectra of the reaction products in the P_{3m}-DEA series.

P_{3m} with DEA compared with that with MEA. The hydrolysis of P_{3m} in such an alkaline solution can not be neglected in this case. In order to clarify the structures of Compounds I, II, and III, ^{31}P-NMR of the reaction products of P_{3m} and DEA was measured (Fig. 8). At δ −0.3, −5.4, and −20.8 ppm in the ^{1}H-decoupling spectrum, peaks due to P_α (doublet), P_γ (doublet), and P_β (triplet) of a triphosphate derivative of DEA, *N*-bis(2-hydroxyethyl)-triphosphoramidate (P_3-(N)DEA) are found. In the ^{1}H-coupling, the P_α of P_3-(N)DEA was split into seven peaks due to the four hydrogen atoms of two methylene groups,

$$\left(\text{P-N}\begin{matrix}\text{CH}_2\text{-}\\ \text{CH}_2\text{-}\end{matrix}\right).$$

Since P_β and P_γ are not influenced by these hydrogen atoms, no coupling due to a proton is recognized. It is interesting that, at δ −5.3 and −10.3 ppm, two doublets due to the P_β and P_γ of a diphosphate derivative of DEA, *N*-bis(2-hydroxyethyl)diphosphoramidate (P_2-(N)DEA), were found. One doublet (δ −5.1 ppm) and one triplet (δ −19.7 ppm) are due to phosphorus atoms of the end PO_4 and to the middle PO_3 of P_3[20] respectively. From the peak heights (amounts) of Compounds II and III on an anion-exchange chromatogram (Fig. 7), it was deduced that Compound II is a diphosphate derivative of DEA, P_2-(N)DEA, while III is a triphosphate derivative of DEA, P_3-(N)DEA. Another proof that Compound III is a triphosphate derivative of DEA with a P-N bond in the molecule is the fact that Compound III was easily recyclized to P_{3m} when the solution of Compound III was made acidic (pH 3).

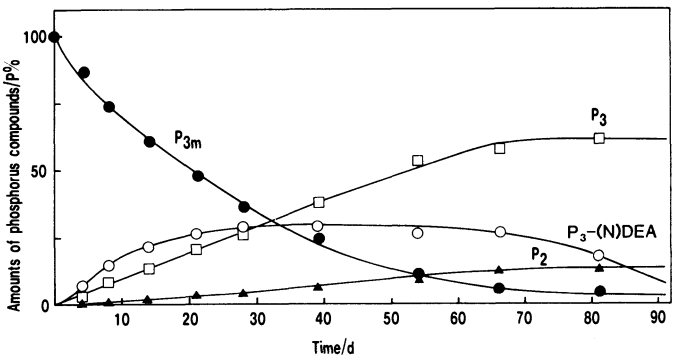

Fig. 9. Changes of the amounts of phosphorus compounds in the reaction of P_{3m} with DEA at pH 12.
P_{3m}: DEA = 0.5 mol dm^{-3}: 0.5 mol dm^{-3}.

From the fact that P_2-(N)DEA was not produced at the initial stage of the reaction, but was produced with the progress of the reaction, it can be considered that P_2-(N)DEA is produced by the hydrolysis of P_3-(N)DEA. That is, the P_3-(N)DEA formed at the initial stage of the reaction is gradually hydrolyzed to yield P_2-(N)DEA and P_1.

It was impossible to determine the structure of Compound I because of its small yield. However, it can be anticipated that Compound I is a monophosphate derivative of DEA, *N*-bis(2-hydroxyethyl)phosphoramidate (P_1-(N)DEA), because P_1 was produced when an aqueous solution of Compound I was made acidic (pH 3).

Amounts of P_3-(N)DEA, P_2-(N)DEA, and P_1-(N)-DEA. Figure 9 shows the changes in the amounts of phosphates formed by the reaction of P_{3m} and DEA at a molar ratio of 1 : 1, pH 12, and room temperature. Compared with the reaction of MEA, the production of P_3-(N)DEA was very slow; after 28 d it attained a maximum level of about 30%, smaller than that observed in the reaction of MEA. After that, it was gradually hydrolyzed. On the other hand, the amount of P_3 increased linearly up to 70 d, and it showed a constant value of about 60%. Since the amounts of P_1-(N)DEA, P_2-(N)DEA, and P_1 were very small (P_1-(N)DEA, 0.8; P_2-(N)DEA, 2.0; P_1, 0.5%), they are omitted in Fig. 9. A characteristic phenomenon is that the production of P_3 was dominant in the P_{3m}-DEA series, although the production of P_2 was remarkable in the P_{3m}-MEA series. Therefore, it is considered that, in the P_{3m}-MEA series, P_3-(N)MEA is produced at the first stage of the reaction and that this is hydrolyzed principally to P_1-(N)MEA and P_2. On the contrary, in the P_{3m}-DEA series, the

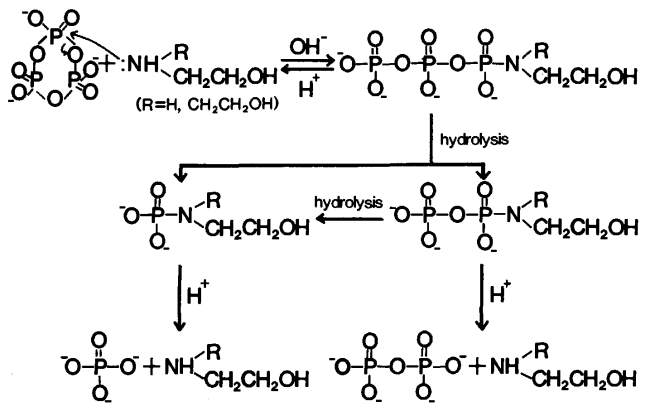

Fig. 10. The reaction mechanism of P_{3m} with MEA or DEA.

hydrolysis of P_{3m} to P_3 proceeded at the same time as the phosphorylation of DEA. With the lapse of the reaction time, P_3-(N)DEA was gradually hydrolyzed to P_2-(N)DEA and P_1.

The reaction of P_{3m} with TEA was allowed to proceed under the same conditions as those in the P_{3m}-MEA and P_{3m}-DEA series. However, no reaction took place in the P_{3m}-TEA series. This is due to the absence of a hydrogen atom directly bonded to the nitrogen atom in the TEA molecule. That is, no ring cleavage of P_{3m} takes place because of the absence of a dissociable hydrogen atom in TEA when the lone-pair of the nitrogen atom of TEA nucleophilically attacks the phosphorus atom of P_{3m}. On the other hand, Feldmann[10] reported that P_{3m} easily reacts with methylamine and dimethylamine to yield triphosphate derivatives of them, but not with trimethylamine. That is, P_{3m} easily reacts with primary and secondary amines in alkaline regions, but does not react with tertiary amines. This fact agrees well with our experimental results.

Mechanism of the Reaction of P_{3m} with MEA or DEA. The mechanism of the reaction of P_{3m} with MEA or DEA in alkaline solutions is shown in Fig. 10. The lone-pair of the nitrogen atom of MEA or DEA nucleophilically attacks the phosphorus atom of P_{3m}, causing a ring cleavage of P_{3m} to produce a triphosphate derivative of MEA or DEA, P_3-(N)MEA or P_3-(N)DEA, with a P-N bond in the molecule. These compounds are gradually hydrolyzed in the reaction solution to form di- and monophosphate derivatives of MEA or DEA. When P_3-(N)MEA and P_3-(N)DEA were made acidic (pH 3), they were easily recyclized to P_{3m}. From this fact, it is clear that the reaction of P_{3m} with MEA or DEA proceeds reversibly, depending upon the pH. When di- and monophosphate derivatives of MEA or DEA are made acidic, they are easily hydrolyzed to yield P_2 and P_1 respectively. Based upon the fact that the phosphoric acid ester of MEA or DEA was not formed in this reaction, it can be estimated that the reactivity of the NH_2 group to P_{3m} is higher than that of the OH group in ethanolamines. When the reaction of P_{3m} with MEA, DEA, or TEA was compared, the reactivity was in the order of MEA>DEA, and TEA did not react with P_{3m}.

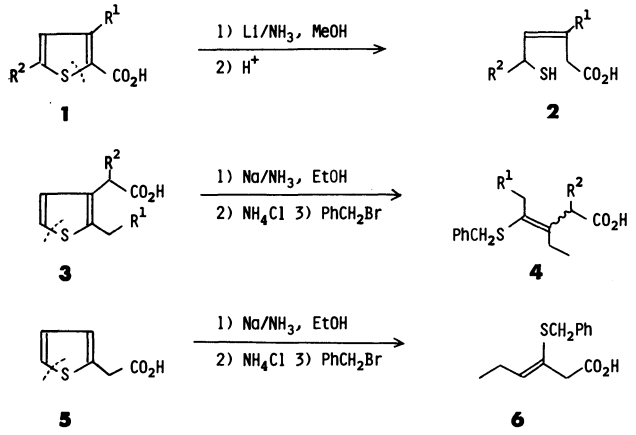
Ring-Opening Reactions of Thiophene Derivatives by the Use of the Birch Reduction

Takanobu KUMAMOTO,* Kumiko HOSOYA, Satoshi KANZAKI, Kazuhiro MASUKO, Mikio WATANABE, and Kozo SHIRAI
Department of Chemistry, Faculty of Science, Tokai University, Kitakaname, Hiratsuka, Kanagawa 259-12
(Received December 14, 1985)

It was found that the Birch reduction of 2-(2-thienyl)alkanoic acid and subsequent alkylation with benzyl bromide resulted in the formation of 2-alkyl-3-benzylthio-3-hexenoic acid selectively. Further, the Birch reduction of a 2,3-dialkylthiophene and subsequent alkylation with benzyl bromide gave a tetrasubstituted olefin which was formed by a selective C–S bond fission between the 1 and 5 positions of the thiophene nuclei. In contrast to these results, the Birch reduction of 3-thiophenecarboxylic acid derivatives and subsequent benzylation gave 2-alkyl-4-benzylthio-3-butenoic acid which was formed by a C–S bond fission between the 1 and 2 positions of the thiophene nuclei.

It is well-known that a Birch reduction of thiophene gives a mixture of dihydrothiophenes and ring-opening products, 2- and 3-butene-1-thiols.[1] In recent few years, several reports showed the formation of regioselective-ring-opening compounds by a Birch reduction of the thiophene derivatives. For example, Joullié et al. reported that the Birch reduction of 2-thiophenecarboxylic acid (**1**) gave (*Z*)-5-mercapto-3-pentenoic acid (**2**) which was formed by a reductive cleavage of the bond between the sulfur atom and C-2 of the thiophene nuclei.[2] However, we have reported that the product which was formed by the C–S bond fission between the 1 and 5 positions of the thiophene nuclei, 4-benzylthio-3-ethyl-3-alkenoic acid (**4**) or (*Z*)-3-benzylthio-3-hexenoic acid (**6**), was obtained by the Birch reduction of 2-(3-thienyl)alkanoic acid (**3**) or 2-thienylacetic acid (**5**) and subsequent alkylation with benzyl bromide.[3]

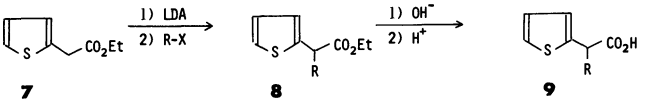


1 **2** **3** **4** **5** **6**

These results show that the regioselectivity of the C–S bond fission and the position of the double bond in the products are largely affected by the substituents of the thiophene derivatives. From this point of view, we investigated Birch reductions of several types of thiophenes in order to clarify the effects of the substituents on the regioselectivity of the ring-opening reactions.

Results and Discussion

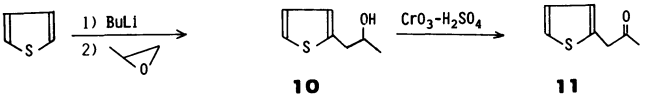
Preparations of Thiophenes. The preparations of 2-(2-thienyl)alkanoic acids (**9a—c**) were carried out as follows: The reaction of lithium enolate of ethyl 2-thienylacetate (**7**), prepared from **7** with lithium diisopropylamide (LDA) in THF, with alkyl halides gave ethyl 2-(2-thienyl)alkanoate (**8**) in good yields. Further, **9** was obtained by the hydrolysis of **8**.



7 **8** **9**

a: R = CH_3-, **b**: R = $CH_3(CH_2)_3$-, **c**: R = CH_2=CH-CH_2-

2-Thienylacetone (**11**) was prepared by the Jones oxidation of 1-(2-thienyl)-2-propanol (**10**) which was obtained by successive treatments of thiophene at −30 °C with butyllithium and propylene oxide.

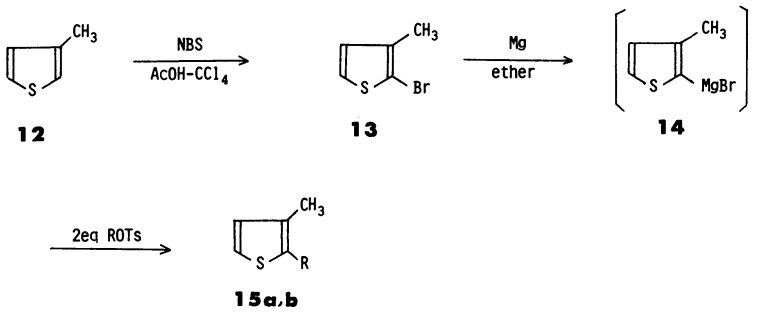


10 **11**

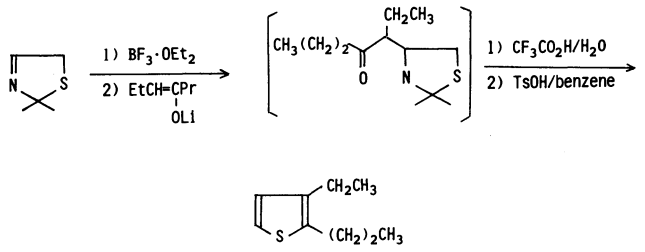
2,3-Dialkylthiophenes (**15a—c**) were prepared by the following two methods. Commercially available 3-methylthiophene (**12**) was used as the starting material for the preparation of 2-alkyl-3-methylthiophenes (**15a, b**). 2-Bromo-3-methylthiophene (**13**) was prepared from **12** and *N*-bromosuccinimide (NBS) by the procedure of Kellogg et al.[4] The resulting **13** was converted to the Grignard reagent **14** in ether and **14** was allowed to react with two equivalents of an alkyl *p*-toluenesulfonate[5] to give **15a, b** in good yields (Scheme 1).

3-Ethyl-2-propylthiophene (**15c**) was prepared by modifing the method reported by Meltz et al.[6] as shown in Scheme 2.

The Birch Reductions of Thiophenes. The Birch reduction of 2-(2-thienyl)propanoic acid (**9a**) with 5 equivalents of sodium in liquid ammonia in the presence of ethanol and a subsequent treatment with ammonium chloride and benzyl bromide resulted in

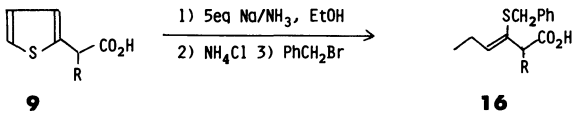


Scheme 1.

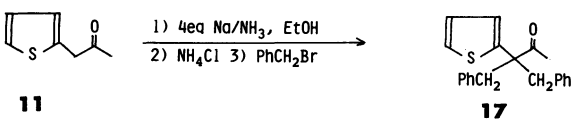


Scheme 2.

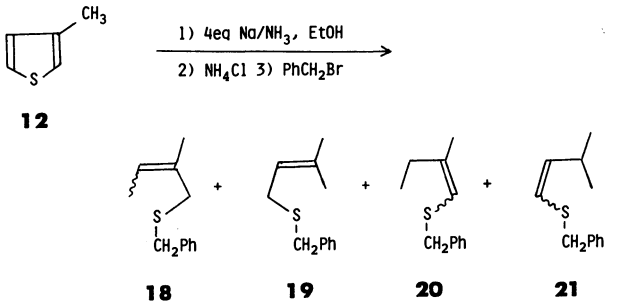
the formation of (*Z*)-3-benzylthio-2-methyl-3-hexenoic acid (**16a**) in 63% yield. The Birch reductions of 2-(2-thienyl)hexanoic acid (**9b**) and 2-(2-thienyl)-4-pentenoic acid (**9c**) under similar reaction conditions also gave (*Z*)-3-benzylthio-2-butyl-3-hexenoic acid (**16b**) and (*Z*)-2-allyl-3-benzylthio-3-hexenoic acid (**16c**) in 77 and 76% yields, respectively. These products were formed by the cleavage of the bond between the sulfur atom and C-5 of the thiophene nuclei.



However, the Birch reduction of 2-thienylacetone (**11**) (which contains a carbonyl group at the same position as **9**) did not give ring-opening products. When **11** was treated with 4 equivalents of sodium and benzyl bromide, a dialkylated compound **17** was obtained without the formation of ring-opening products. This result shows that the formation of a carbanion at the α-carbon of the carbonyl group of **11** is faster than the reduction of the thiophene nuclei.

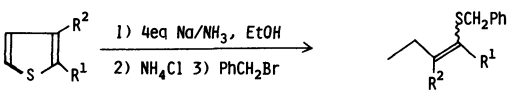


In a previous report,[3] we found that the Birch reduction of 2-propylthiophene under similar reaction conditions gave (*Z*)-4-benzylthio-3-heptene. In the present report, the Birch reduction and alkylation of 3-methylthiophene (**12**) was examined. The reduction of **12** with 4 equivalents of sodium under reaction conditions similar to those reported before gave a mixture of many products. A careful separation of the products by silica-gel column chromatography and an NMR study clarified that 1-benzylthio-2-methyl-2-butene (**18**), 1-benzylthio-3-methyl-2-butene (**19**), 1-benzylthio-2-methyl-1-butene (**20**), and 1-benzylthio-3-methyl-1-butene (**21**) were formed in the ratio of 10:4:4:1.



The ratio of the trisubstituted and disubstituted olefins in the above products was 18:1. This result indicates that the product distribution is dependent on the thermodynamic stability of the olefins. Therfore, Birch reductions of 2,3-dialkylthiophene (**15**) were examined with an expectation that tetrasubstituted olefins would be formed.

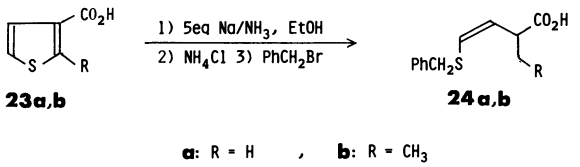
When 2-butyl-3-methylthiophene (**15a**) was allowed to react with 4 equivalents of sodium by the procedure reported previously, 4-benzylthio-3-methyl-3-octene (**22a**) was obtained in 60% yield as expected. Similarly, a Birch reduction of 3-methyl-2-octylthiophene (**15b**) and 3-ethyl-2-propylthiophene (**15c**) also gave tetrasubstituted olefins **22b** and **22c** in 37 and 52% yields, respectively. These results show that the reductive



a: R^1= $CH_3(CH_2)_3$- R^2= CH_3-
b: R^1= $CH_3(CH_2)_7$- R^2= CH_3-
c: R^1= $CH_3(CH_2)_2$- R^2= CH_3CH_2-

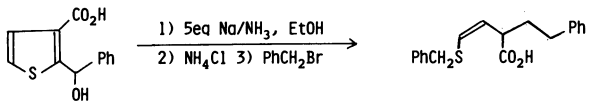
cleavage of the bond between the sulfur atom and C-5 of the thiophene nuclei gave thermodynamically stable tetrasubstituted olefins.

Next, it was found that the regioselectivity of the ring-opening reactions of 3-thiophenecarboxylic acid (**23a**) and its derivatives was different from that of the above-mentioned reactions. When **23a** was allowed to react with 5 equivalents of sodium and benzyl bromide, (*Z*)-4-benzylthio-2-methyl-3-butenoic acid (**24a**) was obtained in 51% yield. Similarly, the Birch reduction and alkylation of 2-methyl-3-thiophenecarboxylic acid (**23b**) gave (*Z*)-4-benzylthio-2-ethyl-3-butenoic acid (**24b**) in 69% yield. In these reactions, a reductive cleavage of the thiophene ring occurred between the sulfur atom and C-2 of the thiophene nuclei and the resulting products were disubstituted olefins rather than trisubstituted olefins. Further, the Birch reduction and alkylation of 2-(α-hydroxybenzyl)-3-thiophenecarboxylic acid (**25**) resulted in the formation of an over-reduced product, (*Z*)-4-benzylthio-2-(2-phenylethyl)-3-butenoic acid (**26**) in 48% yield.



23a,b **24a,b**

a: R = H , **b**: R = CH_3

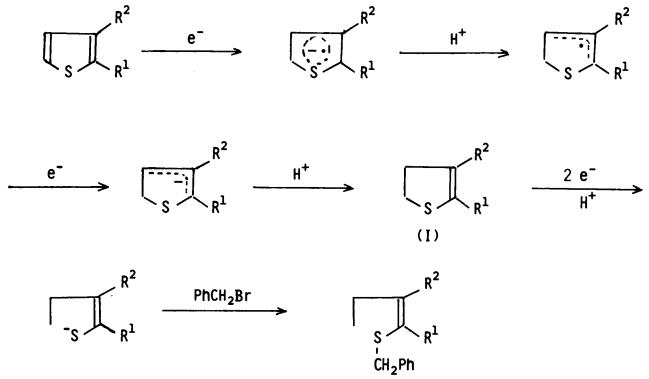


25 **26**

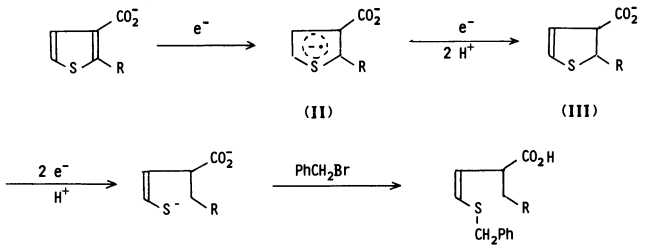
In conclusion, the ring-opening reactions of thiophene derivatives are classified into three types. (A) The ring-opening reaction occurs between the sulfur atom and C-5 of the thiophene nuclei and the double bond remains at the 2 position. Birch reductions of **3**, **5**, **9**, and **15** belong to type-A. (B) The ring-opening reaction occurs between the sulfur atom and C-2 of thiophene and the double bond remains at the 3 position. A Birch reduction of **1** belongs to type-B. (C) The position of a C-S bond fission is the same as type-B, but the double bond remains at the 4 position. Birch reductions of **23** and **25** belong to type-C.

These selectivities of the ring-opening reaction can be reasonably explained by the two mechanisms shown in Shemes 3 and 4.

In these mechanisms, the reduction and the protonation of the thiophene derivatives of type-A forms thermodynamically stable dihydrothiophene (**I**) as the intermediate (Scheme 3). The formation of 2,3-dihydrothiophene (**III**) as the intermediate in Scheme 4 by the reduction and the protonation of radical anion **II**, which is produced by the reduction of the thiophene derivatives of the type-C, can be affected by the



Scheme 3.



Scheme 4.

position of the carboxyl group. However, the reason of the formation of **III** is not clear.

Experimental

The Preparation of 2-(2-Thienyl)propanoic Acid (9a). A solution of ethyl 2-thienylacetate (**7**) (1.72g, 10 mmol) in 10 ml of THF was added into a solution of lithium diisopropylamide which was prepared from diisopropylamine (1.11 g, 11 mmol) and butyllithium (11 mmol) in 15 ml of THF at −30 °C under argon. After the addition of **7**, a white precipitate was observed in the reaction mixture. The reaction mixture was stirred for 0.5 h and was added to methyl iodide (2.13 g, 15 mmol) in 10 ml of THF at −30 °C. Additional stirring was continued for 1 h and the reaction mixture was quenched with 10% hydrochloric acid. The mixture was extracted with ether and the ether layer was dried over magnesium sulfate. After removing the solvent, the residue was chromatographed on silica gel using benzene as the solvent to give ethyl 2-(2-thienyl)propanoate (**8a**) [1.72 g (94%)]. IR (NaCl) 1730 cm^{-1} (C=O); NMR ($CDCl_3$) δ=1.27 (3H, t), 1.63 (3H, d), 4.03 (1H, q), 4.20 (2H, q), 6.90—7.47 (3H, m); MS *m/z* 184 (M^+).

Thus prepared, **8a** (1.66 g, 9 mmol) was stirred with 50 ml of 5% sodium hydroxide solution at room temperature for 2h. The reaction mixture was acidified with 10% hydrochloric acid and extracted with ether. The ether layer was washed with a saturated sodium chloride solution and dried over magnesium sulfate. After removing the solvent, the residue was chromatographed on silica gel using benzene–ether (2:1) as the solvent to give 2-(2-thienyl)propanoic acid (**9a**) [1.35 g (96%)]. Further purification of **9a** was performed by distillation, bp 138—140 °C (11 mmHg, 1 mmHg=133.32 Pa). IR (NaCl) 3600—2300 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR ($CDCl_3$) δ=1.63 (3H, d), 4.07 (1H, q), 6.87—7.43 (3H, m), 11.30 (1H, brs); MS *m/z* 156 (M^+).

Similarly, ethyl 2-(2-thienyl)hexanoate (**8b**), 2-(2-thienyl)-hexanoic acid (**9b**), ethyl 2-(2-thienyl)-4-pentenoate (**8c**), and 2-(2-thienyl)-4-pentenoic acid (**9c**) were prepared by the reactions of **7** with corresponding alkyl halides. The yields and spectral data are as follows.

8b: Yield 71%; IR (NaCl) 1720 cm^{-1} (C=O); NMR ($CDCl_3$) δ=0.75—1.62 (10H, m), 2.01 (2H, m), 3.92 (1H, t), 4.52 (2H, q), 6.92—7.53 (3H, m); MS m/z 226 (M^+).

9b: Yield 86%; IR (NaCl) 3600—2400 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR ($CDCl_3$) δ=0.72—2.22 (9H, m), 3.78 (1H, t), 6.72—7.18 (3H, m), 11.32 (1H, s); MS m/z 198 (M^+).

8c: Yield 87%; IR (NaCl) 1720 cm^{-1} (C=O), 1640 cm^{-1} (CH=CH_2); NMR ($CDCl_3$) δ=1.22 (3H, t), 2.17—3.04 (2H, m), 3.86 (1H, t), 4.05 (2H, q), 4.78—5.17 (2H, m), 5.35—6.03 (1H, m), 6.63—7.20 (3H, m); MS m/z 210 (M^+).

9c: Yield 99%; IR (NaCl) 3600—2300 cm^{-1} (CO_2H), 1710 cm^{-1} (C=O), 1650 cm^{-1} (CH=CH_2); NMR ($CDCl_3$) δ=2.23—3.08 (2H, m), 3.85 (1H, t), 4.76—5.19 (2H, m), 5.31—6.01 (1H, m), 6.67—7.19 (3H, m), 11.34 (1H, s); MS m/z 182 (M^+). Found: C, 54.17; H, 5.36%. Calcd for $C_9H_{10}O_2S$: C, 54.29; H, 5.54%.

The Preparation of 2-Thienylacetone (11). To a solution of thiophene (1.72 g, 20 mmol) in 20 ml of THF, a solution of butyllithium in hexane (22 mmol) was added at −30 °C with stirring under an argon atmosphere. After stirring for one hour at −30 °C, the reaction mixture was cooled to −70 °C. Into the reaction mixture, a solution of propylene oxide (1.22 g, 22 mmol) in 20 ml of THF was added at −70 °C. The reaction temperature was maintained at −70 °C for 0.5 h and then slowly raised to room temperature. Further, the reaction mixture was refluxed for 3 h. The mixture was acidified with 10% hydrochloric acid and extracted with ether. After the ether layer was washed with saturated sodium chloride solution, it was dried over magnesium sulfate. The solvent was removed under a reduced pressure and the residue was chromatographed on silica gel using benzene–ether (1 : 1) as the solvent to give 1-(2-thienyl)-2-propanol (**10**) [1.77 g (63%)]. IR (NaCl) 3500 cm^{-1} (OH); NMR ($CDCl_3$) δ=1.19 (3H, d), 2.31—2.62 (1H, brs), 3.89 (2H, d), 3.95 (1H, sex), 6.73—7.27 (3H, m); MS m/z 142 (M^+).

Into a solution of **10** (2.84 g, 20 mmol) in 50 ml of acetone, a mixture of chromium trioxide (2.60 g, 26 mmol), concd sulfuric acid (23 ml), and water (5 ml) was added at −20 °C over a period of 1 h. Further, additional stirring was continued for 1 h at −20 °C and the mixture was poured into 2-propanol (20 ml) and sodium hydrogencarbonate solution. After the precipitate was filtered, the filtrate was extracted with ether. The ether layer was washed with a saturated sodium chloride solution and was dried over magnesium sulfate. After removing the solvent, the residue was chromatographed on silica gel using benzene–petroleum ether (4 : 1) as the solvent to give 2-thienylacetone (**11**) [1.16 g (41%)]. IR (NaCl) 1700 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.22 (3H, s), 3.93 (2H, s), 6.92—7.48 (3H, m); MS m/z 140 (M^+).

Preparation of 2-Butyl-3-methylthiophene (15a). The preparation of 2-bromo-3-methylthiophene (**13**) was performed by the procedure of Kellog et al.[4] from 3-methylthiophene (**12**) and *N*-bromosuccinimide.

A solution of **13** (5.31 g, 30 mmol) in 25 ml of ether was added to magnesium (0.74 g, 31 mmol) with stirring at room temperature under nitrogen. The reaction mixture was stirred for 2.5 h at room temperature and was refluxed for 15 min. Into the reaction mixture, a solution of butyl *p*-toluenesulfonate (13.08 g, 60 mmol) in 25 ml of ether was added at reflux temperature. After refluxing was continued for 7.5 h, the solution was acidified with 10% hydrochloric acid. The resulting mixture was extracted with ether and the ether layer was washed with saturated sodium chloride solution. The layer was dried over magnesium sulfate. After removing the ether, the residue was chromatographed on silica gel and 2-butyl-3-methylthiophene (**15a**) was obtained by the elution with petroleum ether [2.27 g (49%)]. Thus prepared **15a** was further purified by distillation, bp 78—82 °C (18 mmHg). IR (NaCl) 700 cm^{-1} (thiophene); NMR ($CDCl_3$) δ=0.70—1.90 (7H, m), 2.09 (3H, s), 2.65 (2H, t), 6.83 (1H, d), 6.87 (1H, d); MS m/z 154 (M^+).

In a similar procedure, 3-methyl-2-octylthiophene (**15b**) was prepared. The spectral data and boiling point of **15b** are as follows: yield 60%, bp 140—142 °C (14 mmHg). IR (NaCl) 700 cm^{-1} (thiophene); NMR ($CDCl_3$) δ=0.63—1.81 (15H, m), 2.09 (3H, s), 2.65 (2H, t), 6.59 (1H, d), 6.81 (1H, d); MS m/z 210 (M^+).

The Preparation of 3-Ethyl-2-propylthiophene (15c). The preparation of 3-ethyl-2-propylthiophene (**15c**) was performed by the modified procedure of Meltz et al.[6] The adduct, prepared from 4-heptanone (3.42 g, 30 mmol) and 2,2-dimethyl-3-thiazoline (3.45 g, 30 mmol) by the reported method, was hydrolyzed with trifluoroacetic acid (3.5 ml) in ethanol (15 ml) and water (5 ml) under stirring for 1 h. After removing the solvent, the residue was refluxed in benzene (100 ml) for 10 h with catalytic amounts of *p*-toluenesulfonic acid using a water-separating apparatus. The reaction mixture was washed with 10% sodium hydrogencarbonate solution and a saturated sodium chloride solution. The benzene layer was dried over magnesium sulfate. After removing the solvent, the residue was chromatographed on silica gel and **15c** was obtained by the elution with petroleum ether [0.95 g (21%)]. IR (NaCl) 700 cm^{-1} (thiophene); NMR ($CDCl_3$) δ=0.98 (3H, t), 1.18 (3H, t), 1.45—2.12 (2H, m), 2.32—2.90 (4H, m), 6.77 (1H, d), 6.98 (1H, d); MS m/z 154 (M^+).

General Procedure for the Birch Reduction and Benzylation of Thiophene Derivatives. To a mixture of thiophene derivatives (10 mmol), absolute ethanol (4 ml) and liquid ammonia (50 ml), small pieces of sodium (4.4 or 5.5 equivalents) were added over a period of 1 h under reflux. After the mixture then had been stirred for 1 h in refluxing ammonia, solid ammonium chloride (3 equivalents) was added and the mixture was stirred for 0.5 h. Next, benzyl bromide (2.0 ml) was added to the mixture, and the mixture was stirred for 0.5 h. Further, additional benzyl bromide (1.0 ml) was added into the mixture and the mixture was stirred for 1 h with refluxing. The ammonia was then evaporated and the residue was added 20 ml of 10% hydrochloric acid and 20 ml of ether. The mixture was stirred for 1 h and then the ether layer was separated. The ether layer was washed with saturated sodium chloride solution and dried over magnesium sulfate. After removing the solvent, the residue was chromatographed on silica gel. The yield, the solvent of chromatography, spectral data, and analytical data of the products are as follows.

(*Z*)-3-Benzylthio-2-methyl-3-hexenoic acid (**16a**); yield 63% [elution with benzene–ether (5 : 1)]; an oily product; IR (NaCl) 3250—2950 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR ($CDCl_3$) δ=0.90 (3H, t), 1.34 (3H, d), 2.25 (2H, qu), 3.42 (1H, q), 3.87 (2H, s), 6.01 (1H, t, J=8.4 Hz), 7.35 (5H, s), 12.31 (1H, brs); MS m/z 206 (M^+). Found: C, 67.06; H, 7.72%. Calcd for

$C_{14}H_{18}O_2S$: C, 67.17; H, 7.26%.

(*Z*)-3-Benzylthio-2-butyl-3-hexenoic acid (**16b**); yield 77% [elution with benzene–ether (5:1)]; an oily product; IR (NaCl) 3700—2300 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR ($CDCl_3$) δ=0.70—1.97 (12H, m), 2.20 (2H, qu), 3.21 (1H, t), 3.81 (2H, s), 5.92 (1H, t, J=7.0 Hz), 7.19 (5H, s), 10.54 (1H, brs); MS m/z 248 (M^+). Found: C, 69.77; H, 8.46%. Calcd for $C_{17}H_{24}O_2S$: C, 69.82; H, 8.29%.

(*Z*)-2-Allyl-3-benzylthio-3-hexenoic acid (**16c**); yield 76% [elution with benzene–ether (4:1)]; an oily product; IR (NaCl) 3550—2200 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O), 1640 cm^{-1} (CH=CH_2); NMR ($CDCl_3$) δ=0.86 (3H, t), 1.92—2.66 (4H, m), 3.32 (1H, t), 3.82 (2H, s), 4.85—5.83 (3H, m), 5.96 (lH, t, J=7.0 Hz), 7.22 (5H, s), 11.40 (lH, brs); MS m/z 214 (M^+). Found: C, 69.64; H, 7.53%. Calcd for $C_{16}H_{20}O_2S$: C, 69.50; H, 7.31%.

4-Benzylthio-3-methyl-3-octene (**22a**); yield 60% (elution with petroleum ether); an oily product; IR (NaCl) 2950 cm^{-1} (CH_2), 2920 cm^{-1} (CH_2), 700 cm^{-1} (C_6H_5); NMR ($CDCl_3$) δ=0.63—1.62 (10H, m), 1.67 (3H, s), 1.97—2.42 (4H, m), 3.62 (2H, s), 7.02 (5H, s); MS m/z 248 (M^+). Found: C, 77.54; H, 9.63%. Calcd for $C_{16}H_{24}S$: C, 77.37; H, 9.74%.

4-Benzylthio-3-methyl-3-dodecene (**22b**); yield 37% (elution with petroleum ether); an oily product; IR (NaCl) 2920 cm^{-1} (CH_2), 2850 cm^{-1} (CH_2), 700 cm^{-1} (C_6H_5); NMR ($CDCl_3$) δ=0.61—1.64 (18H, m), 1.67 (3H, s), 1.97—2.46 (4H, m), 3.69 (2H, s), 7.27 (5H, s); MS m/z 304 (M^+). Found: C, 78.92; H, 10.72%. Calcd for $C_{20}H_{32}S$: C, 78.89; H, 10.59%.

4-Benzylthio-3-ethyl-3-heptene (**22c**); yield 52% (elution with petroleum ether); an oily product; IR (NaCl) 2950 cm^{-1} (CH_2), 2870 cm^{-1} (CH_2), 690 cm^{-1} (C_6H_5); NMR ($CDCl_3$) δ=0.64—1.12 (9H, m), 1.22—1.78 (2H, m), 1.80—2.50 (6H, m), 3.72 (2H, s), 7.21 (5H, s); MS m/z 248 (M^+). Found: C, 77.38; H, 10.20%. Calcd for $C_{16}H_{24}S$: C, 77.37; H, 9.74%.

(*Z*)-4-Benzylthio-2-methyl-3-butenoic acid (**24a**); yield 51% (elution with benzene); an oily product; IR (NaCl) 3400—2300 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR ($CDCl_3$) δ=1.26 (3H, d), 3.29—3.86 (1H, m), 3.92 (2H, s), 5.72 (1H, t), 6.20 (1H, d, J=10 Hz), 7.33—7.65 (5H, m), 11.29 (1H, s); MS m/z 222 (M^+). Found: C, 64.75; H, 6.60%. Calcd for $C_{12}H_{14}O_2S$: C, 64.85; H, 6.35%.

(*Z*)-4-Benzylthio-2-ethyl-3-butenoic acid (**24b**); yield 69% [elution with petroleum ether–ethyl acetate (1:1)]; an oily product; IR (NaCl) 3300—2200 cm^{-1} (CO_2H), 1690 cm^{-1} (C=O); NMR ($CDCl_3$) δ=0.98 (3H, t), 1.05—1.51 (2H, m), 1.51—2.13 (1H, m), 3.97 (2H, s), 5.79 (1H, t), 6.40 (1H, d, J=8 Hz), 7.56 (5H, s), 11.54 (1H, brs); MS m/z 236 (M^+). Found: C, 66.36; H, 7.01%. Calcd for $C_{13}H_{16}O_2S$: C, 66.08; H, 6.83%.

(*Z*)-4-Benzylthio-2-(2-phenylethyl)-3-butenoic acid (**26**); yield 48% [elution with petroleum ether–ethyl acetate (1:1)]; mp 104—105 °C (recrystallization from petroleum ether–benzene); IR (KBr) 3400—2300 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.00 (2H, q), 2.60 (2H, t), 3.50 (1H, q), 3.88 (2H, s), 5.65 (1H, t), 6.24 (1H, d, J=10 Hz), 7.05—7.52 (10H, m), 11.59 (1H, s); MS m/z 312 (M^+). Found: C, 73.64; H, 6.54%. Calcd for $C_{19}H_{20}O_2S$: C, 73.06; H, 6.45%.

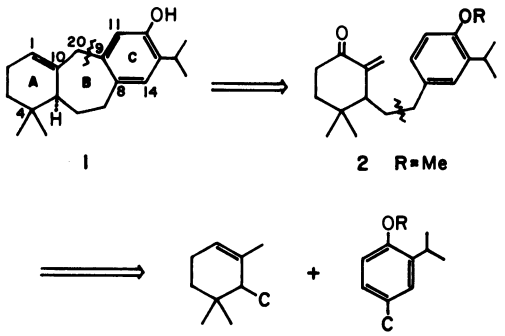
The Total Synthesis of (±)-Pisiferin

Takashi MATSUMOTO,* Sachihiko IMAI, Takashi YOSHINARI, and Shigeo MATSUNO
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received March 14, 1986)

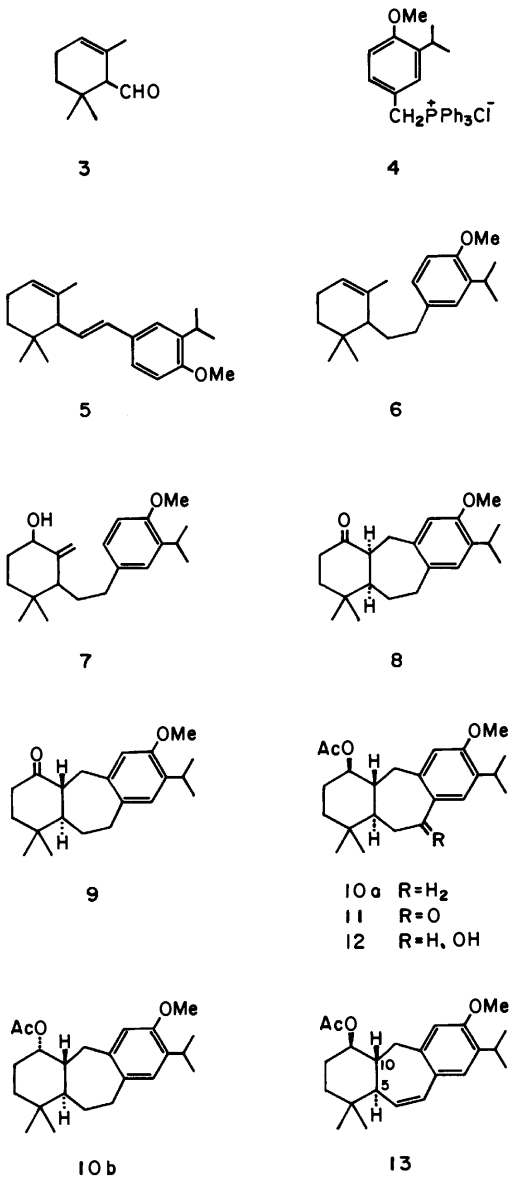
The conversion of racemic α-cyclocitral into 3-(3-isopropyl-4-methoxyphenethyl)-4,4-dimethyl-2-methylenecyclohexanone (**2**) was carried out in five steps via 3-(3-isopropyl-4-methoxyphenethyl)-2,4,4-trimethyl-1-cyclohexene. An intramolecular cyclization of **2** with polyphosphoric acid produced the corresponding two tricyclic ketones possessing *cis*- and *trans*-A/B ring junctions. Each of these ketones was further converted into 12-mesyloxy-9(10→20)-*abeo*-abieta-1(10),8,11,13-tetraene in four steps. The mesylate was reduced with lithium aluminium hydride to give (±)-pisiferin.

Pisiferin (**1**), a rare tricyclic diterpene phenol possessing a rearranged abietane skeleton, has been isolated from the leaves[1] and seeds[2] of *Chamaecyparis pisifera* (Cupressaceae). As a part of our synthetic studies in the naturally-occurring diterpenes, we have attempted a synthesis of pisiferin.[3] The synthetic strategy was developed from a retrosynthetic analysis of the natural product **1**, which involved the disconnection illustrated in Scheme 1. That is, two C_{10} units, including A and C rings of the natural compound, were first condensed to give a C_{20} unit which was converted into an α,β-unsaturated ketone (**2**). An intramolecular cyclization of **2** with acid led to the corresponding tricyclic ketone; this was then transformed into the natural compound.



Scheme 1.

The Wittig reaction[4] of racemic α-cyclocitral (**3**) with (3-isopropyl-4-methoxybenzyl)triphenylphosphonium chloride (**4**) in benzene in the presence of butyllithium gave 3-(3-isopropyl-4-methoxystyryl)-2,4,4-trimethyl-1-cyclohexene (**5**) in 75.3% yield. This was submitted to a partial catalytic hydrogenation to give the corresponding phenethyl derivative (**6**) in 86.3% yield. The oxidation of **6** with *m*-chloroperbenzoic acid in dichloromethane at room temperature afforded an epoxide which, without purification, was treated with lithium diethylamide[5,6] in refluxing hexane to give an alcohol (**7**) in 60.5% yield from **6**. The oxidation of **7** with pyridinium chlorochromate in dichloromethane at room temperature afforded the corresponding α,β-unsaturated ketone (**2**) in 89.1% yield. The IR spectrum of **2** showed a conjugated carbonyl band at 1693 cm^{-1} and its ^1H NMR spectrum showed two doublet signals at δ 4.91 (1H, J=2.5 Hz) and 5.69 (1H, J=2.5 Hz) due to an *exo*-methylene group. Intramolecular cyclization of **2** with polyphosphoric acid at 80—85 °C afforded two stereoisomers, **8** and **9**, in 73.2 and 17.4% yields, respectively. In order to determine the stereochemistry of the A/B ring junction in these tricyclic ketones, the following conversion was carried out. A reduction of the minor ketone **9** in ether with lithium aluminium hydride, followed by acetylation with acetic anhydride in pyridine, yielded a mixture of the C-1 epimeric acetates (**10a** and **10b**) in a ratio of ca. 7 : 3. The ^1H NMR spectrum of the mixture showed broad signals due to C-1 protons at δ 4.2—4.75 ($W_{1/2}$=19 Hz) for **10a** and at δ 5.10 ($W_{1/2}$=9 Hz) for **10b**, suggesting the presence of axial and equatorial C-1 protons, respectively. The crude mixture (**10a** and **10b**) in acetic acid was oxidized with chromium trioxide at room temperature to give a ketone (**11**) in 22.9% yield from **9**. The ^1H NMR spectrum of **11** showed a singlet signal due to a C-1 acetoxyl group at δ 2.18, a multiplet due to a C-1 proton at δ 4.35—4.75, and two singlets due to C-11 and C-14 aromatic protons at δ 6.46 and 7.60. The appearance of the C-14 proton signal in very low field (δ 7.60) suggested the presence of a carbonyl group at the C-7 position. The 7-oxo compound **11** was reduced with sodium borohydride in methanol to give a mixture of the C-7 epimeric alcohols (**12**), which was immediately dehydrated by refluxing with *p*-toluenesulfonic acid in benzene to give a tetraene derivative (**13**) in 97.8% yield from **11**. The ^1H NMR spectrum of **13** showed two double doublet signals due to the C-6 and C-7 olefinic protons at δ 5.78 (J=4 and 13 Hz) and 6.47 (J=2 and 13 Hz). When both olefinic proton signals at δ 5.78 and 6.47 were irradiated, the C-5 proton appeared at δ 1.88 as a doublet with a coupling constant of 12 Hz. The large coupling constant ($J_{5,10}$=12 Hz) indicated an axial-axial coupling and suggested that the relative configuration of the C-5 and C-10 protons in **13** is trans. Thus, the stereochemistries of the A/B ring junction in **8** and **9** were assigned to be cis and trans, respectively. A reduction of the major ketone **8** with lithium aluminium hydride afforded the C-1 epimeric alcohols, **14a** (82.2%) and **14b** (17.0%), which were converted into the corresponding acetates, **15a** and **15b**.



The stereochemistries of the acetoxyl groups in **15a** and **15b** were assigned, respectively, to be equatorial and axial conformations from their ^{1}H NMR spectra which showed signals due to the C-1 protons at δ 4.1—4.7 ($W_{1/2}$=19 Hz) and 5.09 ($W_{1/2}$=6 Hz). Thus, the conformations of the hydroxyl groups in **14a** and **14b** were also determined to be equatorial and axial, respectively. The *cis*-A/B-ring compound can exist in two A-ring chair conformations as shown in I and II. Of these two conformers, I is more stable than II because a 1,3-diaxial strain between the C-1 substituent (R=H, R'=OH or OAc) and the C-6 methylene group in I is fairly smaller than that between the C-4 methyl and the C-20 methylene groups in II. The other strains in the A-ring of both conformers are expected to be nearly equal. Thus, the *cis*-A/B-ring compound must exist in a preferred conformation I. From these considerations, the configurations of the hydroxyl groups in the C-1 epimeric alcohols were assigned to be an α disposition for **14a** and β for **14b**.

Mesylation of a mixture of **14a** and **14b** with mesyl chloride in pyridine at room temperature, followed by refluxing of the resulting mesylates (**16**) with 2,4-lutidine under a stream of nitrogen, produced a separable mixture of the disubstituted (**17**) and trisubstituted (**18**) olefins in 68.7% yield (ca. 2:9 ratio). A mixture of **17** and **18** was also obtained from a mixture of **14a** and **14b** by heating with hexamethylphosphoric triamide at 195—205 °C under a stream of nitrogen in 80.2% yield (ca. 5:8 ratio). Demethylation of **18** with anhydrous aluminium chloride and ethanethiol[7] in dichloromethane at room temperature provided only a dienone compound in 68.4% yield, but the desired pisiferin (**1**) could not be isolated. The dienone had the molecular formula $C_{20}H_{28}O$ based on the mass spectrum (M^+, m/z 284) and an elementary analysis. The IR spectrum indicated a conjugated carbonyl band at 1655 cm^{-1} but no hydroxyl band. The ^{1}H NMR spectrum showed signals at δ 0.95 (3H, singlet) and 1.03 (3H, singlet) due to a *gem*-dimethyl, at δ 1.06 (6H, doublet) and 2.98 (1H, multiplet) due to an isopropyl, and at δ 6.20 (1H, singlet) and 6.38 (1H, singlet) due to two olefinic protons. The ^{13}C NMR spectrum showed three singlet signals at δ 186.7, 176.1, 143.5, and two doublet signals at δ 147.2, 122.8 in the sp^2 carbon region, indicating the presence of a dienone moiety. The remaining fifteen carbons appeared in a δ 17—41 region as three singlets, two doublets, six triplets, and four quartets. From these spectral data the structure **19** was tentatively assigned to the dienone. Since the conversion of **18** into pisiferin (**1**) was unsuccessful, another synthetic route was examined. The alcohol **14a** was demethylated with anhydrous aluminium chloride and ethanethiol in dichloromethane to give a diol (**20a**) in 94.6% yield. On the other hand, a similar demethylation of **14b** gave only the dienone **19** in 90.3% yield. The expected diol **20b** corresponding to **20a** could not be isolated. These different results from demethylations of **14a** and **14b** can be explained as follows. The alcohol **14a** possessing an equatorial hydroxyl group was normally demethylated to give the expected diol **20a**, while under the same reaction conditions the epimer **14b** possessing an axial hydroxyl group was easily dehydrated by antiperiplanar elimination to give the trisubstituted olefin **18**. This was then demethylated and the resulting pisiferin (**1**) was further isomerized to the dienone **19**. Isomerization of **1** into **19** is described later. The diol **20a** was mesylated and the resulting dimesylate (**21**) was refluxed with 2,4-lutidine to give a mixture of the corresponding disubstituted (**22**) and trisubstituted (**23**) olefins in 87.1% yield (ca. 2:9 ratio), from which pure crystalline **23** was obtained by repeated column chromatography on silica gel and recrystallization. Treatment of **23** with lithium aluminium hydride in refluxing tetrahydrofuran afforded a phenolic compound (**1**) (98.4% yield) which gave an acetate (**24**). The ^{1}H NMR spectrum of the synthetic **1** was identical with that of natu-

ral pisiferin. The synthetic **1** was further isomerized to the dienone **19** by a treatment with anhydrous aluminium chloride and ethanethiol at room temperature in 93.0% yield. Similarly, the *trans*-ketone **9** was also converted into a mixture of the corresponding mesylates, **25** and **23** in 40.7% yield (ca. 1 : 4 ratio) from **9**.

Experimental

All melting points are uncorrected. The IR spectra were measured in chloroform and the ^{1}H NMR spectra in deuteriochloroform at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, q: quartet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

3-(3-Isopropyl-4-methoxyphenethyl)-2,4,4-trimethyl-1-cyclohexene (6). A solution of butyllithium in hexane (15%: 7.9 ml) was added at 7—9 °C to a suspension of (3-isopropyl-4-methoxybenzyl)triphenylphosphonium chloride (**4**) (5.816 g) in dry benzene (60 ml) under a stream of nitrogen. The mixture was stirred at 7—9 °C for 30 min and a solution of racemic α-cyclocitral[8] (**3**) (1.200 g) in dry benzene (2.0 ml) was added at 7—9 °C. After stirring at this temperature for 1 h and then at room temperature for 3 h, the mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo. The residue was triturated with hexane (100 ml) and the precipitated triphenylphosphine oxide was removed by filtration. The filtrate was evaporated and the residue was chromatographed on silica gel (40 g), using hexane as the eluent, to give 3-(3-isopropyl-4-methoxystyryl)-2,4,4-trimethyl-1-cyclohexene (**5**) as an oil (1.772 g: 75.3%).

A suspension of **5** (5.124 g) and 10% Pd-C (1.30 g) in ethanol (55 ml) was stirred at room temperature in an atmosphere of hydrogen. After one equivalent of hydrogen had been absorbed, the mixture was filtered. The filtrate was evaporated and the residue was purified by column chromatography on silica gel (70 g), using hexane as the eluent, to give **6** as an oil (4.450 g: 86.3%). The IR and ^{1}H NMR spectra of **6** were identical with those of an authentic optically-active sample.[3]

3-(3-Isopropyl-4-methoxyphenethyl)-4,4-dimethyl-2-methylenecyclohexanol (7). A solution of **6** (4.111 g) and 80% *m*-chloroperbenzoic acid (2.951 g) in dichloromethane (105 ml) was stirred at room temperature for 1.5 h and then diluted with ether. The solution was washed successively with 10% aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated in vacuo to give a crude epoxide as an oil (4.530 g). ^{1}H NMR (CCl_4) δ=0.83 (3H, s) and 0.88 (3H, s) (-C(CH$_3$)$_2$), 1.21 (6H, d, J=7 Hz, -CH(CH$_3$)$_2$), 1.29 (3H, s, -O-CCH$_3$), 3.23 (1H, m, -CH(CH$_3$)$_2$), 3.78 (3H, s, -OCH$_3$).

A solution of the crude epoxide (4.530 g) in dry hexane (38 ml) was added at −50—−60 °C for 15 min to a stirred solution of lithium diethylamide which was prepared from butyllithium in hexane (15%: 42.8 ml) and diethylamine (7.1 ml) in dry hexane (40 ml) at −45—−60 °C for 30 min under a stream of nitrogen. The mixture was stirred at room temperature for 30 min, refluxed for 5 h, cooled, and then poured into aqueous ammonium chloride. The mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo. The crude product was chromatographed on silica gel (220 g), using ether-benzene (1 : 99) as the eluent, to give **7** as an oil (2.621 g: 60.5%); IR 3600, 3435, 1645 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.71 (3H, s) and 0.90 (3H, s) -C(CH$_3$)$_2$), 1.18 (6H, d, J= 7 Hz, -CH(CH$_3$)$_2$), 3.21 (1H, m, -CH(CH$_3$)$_2$), ca. 3.65—4.1 (1H, m, overlap, -CH(OH)-), 3.77 (3H, s, -OCH$_3$), 4.74 (1H, bs) and 5.17 (1H, bs) (-C=CH$_2$), 6.46—6.9 (3H, m, aromatic protons). Found: C, 79.98; H, 10.39%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

3-(3-Isopropyl-4-methoxyphenethyl)-4,4-dimethyl-2-methylenecyclohexanone (2). A solution of **7** (1.736 g) in dichloromethane (9.5 ml) was added to a stirred suspension of pyridinium chlorochromate (2.010 g) in dichloromethane (19.0 ml) at room temperature for 15 min. After stirring for 3 h, the mixture was poured into aqueous sodium carbonate (10%: 30 ml) and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo. The residue was chromatographed on silica gel (60 g), using ether-benzene (1 : 99) as the eluent, to give **2** as an oil (1.537 g: 89.1%); IR 1693 cm^{-1}, ^{1}H NMR (CCl_4) δ=0.99 (3H, s) and 1.05 (3H, s) (-C(CH$_3$)$_2$), 1.18 (6H, d, J= 7 Hz, -CH(CH$_3$)$_2$), 3.22 (1H, m, -CH(CH$_3$)$_2$), 3.77 (3H, s,

$-OCH_3$), 4.91 (1H, d, J=2.5 Hz) and 5.69 (1H, d, J=2.5 Hz) ($-\underline{C}=CH_2$), 6.48—6.9 (3H, m, aromatic protons). Found: C, 80.28; H, 9.86%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

Intramolecular Cyclization of 2. Polyphosphoric acid was prepared from 85% phosphoric acid (25 ml) and phosphorus pentaoxide (25 g) by heating at 100 °C for 2 h.

A stirred mixture of **2** (2.172 g) and polyphosphoric acid (32.6 ml) was heated at 80—85 °C for 1 h. After cooling, the mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo. The residue was recrystallized from hexane to give 12-methoxy-9(10→20)-10α*H*-*abeo*-abieta-8,11,13-trien-1-one (**8**) (1.280 g: 58.9%), mp 155—156 °C; IR 1703 cm^{-1}, ^1H NMR (90 MHz, CCl_4) δ=0.98 (3H, s) and 1.01 (3H, s) ($-\underline{C}(CH_3)_2$), 1.15 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.19 (1H, m, $-C\underline{H}(CH_3)_2$), 3.75 (3H, s, $-OCH_3$), 6.43 (1H, s, C_{11}-H), 6.84 (1H, s, C_{14}-H). Found: C, 80.41; H, 9.64%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

The mother liquor of recrystallization was evaporated in vacuo and the residue was chromatographed on silica gel (40 g), using benzene as the eluent, to give an additional **8** (0.310 g: 14.3%) and 12-methoxy-9(10→20)-*abeo*-abieta-8,11,13-trien-1-one (**9**) as an oil (0.378 g: 17.4%); IR 1702 cm^{-1}, ^1H NMR (CCl_4) δ=1.00 (3H, s) and 1.02 (3H, s) ($-\underline{C}(CH_3)_2$), 1.14 (d, J=7 Hz) and 1.16 (d, J=7 Hz) (6H, $-CH(C\underline{H}_3)_2$), 3.75 (3H, s, $-OCH_3$), 6.54 (1H, s, C_{11}-H), 6.75 (1H, s, C_{14}-H).

1β-Acetoxy-12-methoxy-9(10→20)-*abeo*-abieta-8,11,13-trien-7-one (11). Lithium aluminium hydride (13 mg) was added to a stirred solution of **9** (70 mg) in dry ether (2.0 ml) with cooling in an ice-water bath. The mixture was stirred at room temperature for 1 h, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo. The residue was acetylated with acetic anhydride (0.5 ml) in pyridine (0.5 ml) at 75—80 °C for 2 h to give an oily mixture of the C-1 epimeric acetates (**10a** and **10b**) in a ratio of ca. 7:3. ^1H NMR of **10a** δ=0.76 (3H, s) and 0.94 (3H, s) ($-\underline{C}(CH_3)_2$), 1.18 (d, J=7 Hz) and 1.20 (d, J=7 Hz) (6H, $-CH(C\underline{H}_3)_2$), 2.15 (3H, s, $-OCOCH_3$), 3.79 (3H, s, $-OCH_3$), 4.2—4.75 (1H, m, $W_{1/2}$=19 Hz, C_1-H), 6.52 (1H, s, C_{11}-H), 6.86 (1H, s, C_{14}-H). ^1H NMR of **10b** δ=0.76 (3H, s) and 0.98 (3H, s) ($-\underline{C}(CH_3)_2$), 1.18 (d, J=7 Hz) and 1.20 (d, J=7 Hz), (6H, $-CH(C\underline{H}_3)_2$), 2.10 (3H, s, $-OCOCH_3$), 3.75 (3H, s, $-OCH_3$), 5.10 (1H, bs, $W_{1/2}$=9 Hz, C_1-H), 6.57 (1H, s, C_{11}-H), 6.86 (1H, s, C_{14}-H).

A stirred mixture of the C-1 epimeric acetates (**10a** and **10b**) was oxidized with chromium trioxide (43 mg) in acetic acid (2.0 ml) at room temperature for 5 h. The mixture was diluted with water and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and water. The dried solution was evaporated in vacuo. The residue was chromatographed on silica gel (10 g), using ether-benzene (2:98) as the eluent, to give **11** as an oil (19 mg: 22.9% from **9**); IR 1720, 1655 cm^{-1}; ^1H NMR, δ=0.92 (6H, s, $-\underline{C}(CH_3)_2$), 1.21 (6H, bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.18 (3H, s, $-OCOCH_3$), 3.86 (3H, s, $-OCH_3$), 4.35—4.75 (1H, m, C_1-H), 6.46 (1H, s, C_{11}-H), 7.60 (1H, s, C_{14}-H).

1β-Acetoxy-12-methoxy-9(10→20)-*abeo*-abieta-6,8,11,13-tetraene (13). Sodium borohydride (10 mg) was added to a stirred solution of **11** (19.0 mg) in methanol (2.0 ml) with cooling in a water bath. The solution was stirred at room temperature for 1 h, diluted with ether, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo to give an oily mixture of the C-7 epimeric alcohols (**12**); IR 3600, 3410, 1720 cm^{-1}.

A mixture of the above crude **12** and *p*-toluenesulfonic acid (10 mg) in dry benzene (2.0 ml) was refluxed for 1 h. After cooling, the mixture was diluted with ether and the solution was washed with brine. The dried solution was evaporated in vacuo and the residue was chromatographed on silica gel (5.0 g), using benzene as the eluent, to give **13** as an oil (17.8 mg: 97.8% from **11**); IR 1720 cm^{-1}, ^1H NMR (90 MHz) δ=0.88 (3H, s) and 0.96 (3H, s) ($-\underline{C}(CH_3)_2$), 1.18 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.10 (3H, s, $-OCOCH_3$), 3.25 (1H, m, $-C\underline{H}(CH_3)_2$), 3.80 (3H, s, $-OCH_3$), 4.45—4.8 (1H, m, C_1-H), 5.78 (1H, dd, J=13 and 4 Hz, C_6-H), 6.47 (1H, dd, J=13 and 2 Hz, C_7-H), 6.52 (1H, s, C_{11}-H), 6.92 (1H, s, C_{14}-H).

12-Methoxy-9(10→20)-10α*H*-*abeo*-abieta-8,11,13-trien-1α-ol (14a) and Its C-1 Epimer (14b). Lithium aluminium hydride (69.4 mg) was added to a stirred solution of **8** (1.150 g) in dry ether (50 ml) with cooling in an ice-water bath. The mixture was stirred at room temperature for 1 h, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and evaporated in vacuo. The residue was recrystallized from acetone-hexane to give **14a** (813 mg: 70.3%), mp 151—151.5 °C; IR 3600, 3430 cm^{-1}; ^1H NMR δ=0.75 (3H, s) and 0.94 (3H, s) ($-\underline{C}(CH_3)_2$), 1.18 (d, J=7 Hz) and 1.20 (d, J=7 Hz) (6H, $-CH(C\underline{H}_3)_2$), 3.78 (3H, s, $-OCH_3$), 6.58 (1H, s, C_{11}-H), 6.99 (1H, s, C_{14}-H). Found: C, 79.59; H, 10.41%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

The mother liquor of recrystallization was evaporated in vacuo and the residue was repeatedly chromatographed on silica gel, using benzene as the eluent, to give an additional **14a** (138 mg: 11.9%) and **14b** as an oil (196 mg: 17.0%); IR 3620, 3440 cm^{-1}; ^1H NMR δ=0.72 (3H, s) and 0.98 (3H, s) ($-\underline{C}(CH_3)_2$), 1.17 (d, J=7 Hz) and 1.20 (d, J=7 Hz) (6H, $-CH(C\underline{H}_3)_2$), 3.78 (3H, s, $-OCH_3$), 3.91 (1H, br, $W_{1/2}$=9 Hz, C_1-H), 6.54 (1H, s, C_{11}-H), 6.89 (1H, s, C_{14}-H).

Acetylation of 14a and 14b. a): The alcohol **14a** (100 mg) was acetylated with acetic anhydride (1.0 ml) in pyridine (1.0 ml) at 75—80 °C for 2 h to give a crude acetate (**15a**); IR 1718 cm^{-1}, ^1H NMR δ=0.77 (3H, s) and 0.96 (3H, s) ($-\underline{C}(CH_3)_2$), 1.19 (d, J=7 Hz) and 1.21 (d, J=7 Hz) (6H, $-CH(C\underline{H}_3)_2$), 2.18 (3H, s, $-OCOCH_3$), 3.23 (1H, m, $-C\underline{H}(CH_3)_2$), 3.80 (3H, s, $-OCH_3$), 4.1—4.7 (1H, m, $W_{1/2}$=19 Hz, C_1-H), 6.58 (1H, s, C_{11}-H), 6.84 (1H, s, C_{14}-H).

b): The alcohol **14b** was acetylated with acetic anhydride in pyridine to give a crude acetate (**15b**); IR 1718 cm^{-1}, ^1H NMR δ=0.73 (3H, s) and 1.00 (3H, s) ($-\underline{C}(CH_3)_2$), 1.15 (d, J=7 Hz) and 1.18 (d, J=7 Hz) (6H, $-CH(C\underline{H}_3)_2$), 2.11 (3H, s, $-OCOCH_3$), 3.78 (3H, s, $-OCH_3$), 5.09 (1H, bs, $W_{1/2}$=6 Hz, C_1-H), 6.52 (1H, s, C_{11}-H), 6.85 (1H, s, C_{14}-H).

12-Methoxy-9(10→20)-10α*H*-*abeo*-abieta-1,8,11,13-tetraene (17) and 12-Methoxy-9(10→20)-*abeo*-abieta-1(10),8,11,13-tetraene (Pisiferin Methyl Ether) (18). a): A mixture of **14a** and **14b** (100.7 mg) was mesylated with mesyl chloride (0.10 ml) in pyridine (0.7 ml) at room temperature for 3.5 h. The mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo to give a crude mesylate (**16**) (129 mg).

The crude **16** (129 mg) in 2,4-lutidine (0.7 ml) was refluxed for 2.5 h under a stream of nitrogen. The mixture was cooled, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with dilute hydrochloric acid, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated in vacuo and the residue was repeatedly chromatographed on silica gel, using hexane as the eluent, to give two oily products, **17** (12.0 mg: 12.6%) and **18** (53.2 mg: 56.1%). ^{1}H NMR (90 MHz) of **17** δ=0.73 (3H, s) and 0.94 (3H, s) (-C(CH$_3$)$_2$), 1.18 (d, J=7 Hz) and 1.20 (d, J=7 Hz) (6H, -CH(CH$_3$)$_2$), 3.28 (1H, m, -CH(CH$_3$)$_2$), 3.79 (3H, s, -OCH$_3$), 5.4—5.7 (2H, m, C$_1$-H and C$_2$-H), 6.61 (1H, s, C$_{11}$-H), 6.96 (1H, s, C$_{14}$-H). ^{1}H NMR (90 MHz) of **18** δ=0.88 (3H, s) and 0.92 (3H, s) (-C(CH$_3$)$_2$), 1.18 (d, J=7 Hz) and 1.20 (d, J=7 Hz)(6H, -CH(CH$_3$)$_2$), 3.23 (1H, m, -CH(CH$_3$)$_2$), 3.30 (2H, s, C$_{20}$-H$_2$), 5.43 (1H, t, J=4 Hz, C$_1$-H), 6.60 (1H, s, C$_{11}$-H), 6.90 (1H, s, C$_{14}$-H).

b): A mixture of **14a** and **14b** (400 mg) was heated with hexamethylphosphoric triamide (4.0 ml) at 195—205 °C for 1 h under a stream of nitrogen. The solution was cooled, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo. The crude product was purified by column chromatography on silica gel (100 g), using hexane as the eluent, to give an oily mixture of **17** and **18** (302 mg: 80.2%) in a ratio of ca. 5:8.

Demethylation of 18. Anhydrous aluminium chloride (13.3 mg) was added to a stirred solution of **18** (10.0 mg) and ethanethiol (0.015 ml) in dichloromethane (0.5 ml) with cooling in an ice-water bath. The mixture was stirred at room temperature for 4 h, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo. The residue was chromatographed on silica gel (10 g), using ether-benzene (1:99) as the eluent, to give a dienone (**19**) (6.5 mg: 68.4%) as a solid, whose IR and ^{1}H NMR spectra were identical with those of the authentic sample (vide infra).

Demethylation of 14a and 14b. a): A solution of **14a** (597.0 mg) in dichloromethane (8.0 ml) was demethylated with anhydrous aluminium chloride (754.6 mg) and ethanethiol (0.85 ml) at room temperature for 4 h. After the work-up as described above, the crude product was recrystallized from acetone-hexane to give a diol (**20a**) (510.0 mg: 89.4%), mp 183.5—184.5 °C; IR 3600, 3360 cm^{-1}; ^{1}H NMR δ=0.75 3H, s) and 0.93 (3H, s) (-C(CH$_3$)$_2$), 1.24 (6H, d, J=7 Hz, -CH(CH$_3$)$_2$), 4.89 (1H, bs, -OH), 6.50 (1H, s, C$_{11}$-H), 7.00 (1H, s, C$_{14}$-H). Found: C, 79.48; H, 10.30%. Calcd for C$_{20}$H$_{30}$O$_2$: C, 79.42; H, 10.00%. The mother liquor of recrystallization was evaporated in vacuo and the residue was chromatographed on silica gel (20 g), using ether-benzene (5:95) as the eluent, to give an additional **20a** (27.9 mg: 5.2%).

b): A solution of **14b** (111.0 mg) in dichloromethane (2.1 ml) was demethylated with anhydrous aluminium chloride (139.8 mg) and ethanethiol (0.15 ml) at room temperature for 4 h. After the work-up as described above, the crude product was chromatographed on silica gel (10 g), using ether-benzene (5:95) as the eluent, to give a dienone (**19**) (90.1 mg: 90.3%), which was recrystallized from hexane, mp 107—109 °C; IR 1655 cm^{-1}, UV λ_{max}^{EtOH}: 255 nm (ε 15300). ^{1}H NMR (90 MHz) δ=0.95 (3H, s) and 1.03 (3H, s) (-C(CH$_3$)$_2$), 1.06 (6H, d, J=7 Hz, -CH(CH$_3$)$_2$), 2.98 (1H, m, -CH(CH$_3$)$_2$), 6.20 (1H, s, C$_{11}$-H), 6.38 (1H, bs, C$_{14}$-H). ^{13}C NMR ($CDCl_3$) δ=17.6 (t), 20.0 (q), 21.9 (q), 21.9 (q), 24.1 (q), 25.9 (d), 27.7 (t), 30.5 (t), 31.0 (t), 34.7 (s), 35.8 (t), 35.8 (t), 37.2 (d), 39.7 (s), 40.4 (s), 122.8 (d), 143.5 (s), 147.2 (d), 176.1 (s), 186.7 (s); MS m/z 284 (M$^+$). Found: C, 84.39; H, 10.04%. Calcd for C$_{20}$H$_{28}$O: C, 84.45; H, 9.92%.

12-Mesyloxy-9(10→20)-10α*H*-*abeo*-abieta-1,8,11,13-tetraene (22) and 12-Mesyloxy-9(10→20)-*abeo*-abieta-1(10),8,11,13-tetraene (23). a): A mixture of **20a** (102.0 mg) and mesyl chloride (0.08 ml) in pyridine (1.0 ml) was allowed to stand at room temperature for 16.5 h and then diluted with ether. The ether solution was washed successively with dilute hydrochloric acid and brine. The dried solution was evaporated in vacuo to give a crude dimesylate (**21**) (130 mg) which was used, without purification, in the next reaction. ^{1}H NMR δ=0.79 (3H, s) and 0.96 (3H, s) (-C(CH$_3$)$_2$), 1.23 (d, J=7 Hz) and 1.25 (d, J=7 Hz) (6H, -CH(CH$_3$)$_2$), 3.12 (3H, s) and 3.19 (3H, s) (2-OSO$_2$CH$_3$), 4.1—4.6 (1H, m, C$_1$-H), 7.03 (1H, s) and 7.10 (1H, s) (C$_{11}$-H and C$_{14}$-H).

b): A solution of the crude **21** (130 mg) in 2,4-lutidine (1.5 ml) was refluxed for 2.5 h under a stream of nitrogen. The solution was cooled, diluted with ether, and washed successively with dilute hydrochloric acid and brine. The dried solution was evaporated in vacuo and the residue was purified by repeated column chromatography on silica gel and recrystallization from methanol to give **22** (18.6 mg: 15.2%) as an oil and **23** (87.9 mg: 71.9%) as a crystalline, mp 138—140 °C. ^{1}H NMR (90 MHz) of **22** δ=0.73 (3H, s) and 0.95 (3H, s) (-C(CH$_3$)$_2$), 1.21 (d, J=7 Hz) and 1.23 (d, J=7 Hz) (6H, -CH(CH$_3$)$_2$), 3.16 (3H, s, -OSO$_2$CH$_3$), 5.5—5.7 (2H, m, C$_1$-H and C$_2$-H), 7.02 (1H, s) and 7.08 (1H, s) (C$_{11}$-H and C$_{14}$-H). ^{1}H NMR (90 MHz) of **23** δ=0.88 (3H, s) and 0.92 (3H, s) (-C(CH$_3$)$_2$), 1.21 (d, J=7 Hz) and 1.23 (d, J=7 Hz) (6H, -CH(CH$_3$)$_2$), 2.7—2.9 (2H, m, C$_7$-H$_2$), 3.16 (3H, s, -OSO$_2$CH$_3$), 3.25 (1H, m, -CH(CH$_3$)$_2$), 3.31 (2H, s, C$_{20}$-H$_2$), 5.43 (1H, t, J=4 Hz, C$_1$-H), 7.00 (1H, s) and 7.02 (1H, s) (C$_{11}$-H and C$_{14}$-H). Found: C, 69.61; H, 8.21%. Calcd for C$_{21}$H$_{30}$O$_3$S: C, 69.57; H, 8.34%.

(±)-Pisiferin (1). A solution of **23** (23.4 mg) in dry tetrahydrofuran (2.0 ml) was reduced with lithium aluminium hydride (9.8 mg) by refluxing for 1.5 h. The mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo. The crude product was chromatographed on silica gel (5.0 g), using benzene as the eluent, to give **1** as an oil (18.1 mg: 98.4%); IR 3600, 3350 cm^{-1}; ^{1}H NMR (90 MHz) δ=0.88 (3H, s) and 0.91 (3H, s) (-C(CH$_3$)$_2$), 1.22 (d, J=7 Hz) and 1.24 (d, J=7 Hz) (6H, -CH(CH$_3$)$_2$), 2.74 (2H, m, C$_7$-H$_2$), 3.12 (1H, m, -CH(CH$_3$)$_2$), 3.27 (2H, s, C$_{20}$-H$_2$), 4.46 (1H, s, -OH), 5.41 (1H, t, J=4 Hz, C$_1$-H), 6.48 (1H, s, C$_{11}$-H), 6.88 (1H, s, C$_{14}$-H). The ^{1}H NMR spectrum of **1** was identical with that of natural pisiferin. MS m/z 284 (M$^+$).

Acetylation of 1. A solution of **1** (11.8 mg) and acetic anhydride (0.5 ml) in pyridine (0.5 ml) was heated at 75—80 °C for 2 h. After the usual work-up, the crude product was chromatographed on silica gel (5.0 g), using benzene as the eluent, to give an acetate (**24**) as an oil (12.2 mg: 90.4%), IR 1753 cm^{-1}, MS m/z 326 (M$^+$), ^{1}H NMR (90 MHz) δ=0.87 (3H, s) and 0.91 (3H, s) (-C(CH$_3$)$_2$), 1.18 (d, J=7 Hz) and 1.20 (d, J=7 Hz) (6H, -CH(CH$_3$)$_2$), 2.27 (3H, s, -OCOCH$_3$), 3.30 (2H, s, C$_{20}$-H$_2$), 5.42 (1H, t, J=4 Hz, C$_1$-H), 6.70 (1H, s, C$_{11}$-H), 6.98 (1H, s, C$_{14}$-H).

Conversion of 1 into 19. A solution of **1** (43.0 mg) and ethanethiol (0.07 ml) in dichloromethane (2.8 ml) was treated with anhydrous aluminium chloride (60.4 mg) at room temperature for 4 h. After the work-up as described above, the crude product was chromatographed on silica gel (10 g), using ether–benzene (5 : 95) as the eluent, to give **19** (40.0 mg: 93.0%), whose IR and ^{1}H NMR spectra were identical with those of the authentic sample.

Conversion of 9 into 23 and 12-Mesyloxy-9(10→20)-*abeo*-abieta-1,8,11,13-tetraene (25). The ketone **9** (261.1 mg) in dry ether (5.0 ml) was reduced with lithium aluminium hydride (15.8 mg) at room temperature for 1 h to give a mixture of the C-1 epimeric alcohols (240 mg).

A solution of the above crude alcohols (240 mg) and ethanethiol (0.37 ml) in dichloromethane (4.0 ml) was treated with anhydrous aluminium chloride (332.1 mg) at room temperature for 4 h. The crude product (235 mg) was immediately mesylated with mesyl chloride (0.2 ml) in pyridine (1.0 ml) at room temperature for 16 h and the resulting crude mesylate was refluxed with 2,4-lutidine (2.0 ml) for 2.5 h under a stream of nitrogen. After the work-up as described above, the crude product was chromatographed on silica gel (20 g), using hexane–benzene (1 : 1) as the eluent, to give a mixture of **23** and **25** (122.4 mg: 40.7% from **9**) in a ratio of ca. 4 : 1.

The authors are grateful to Professor Yoshiyuki Hirose, Science University of Tokyo, for kindly supplying the spectra of natural pisiferin and to Dr. Yasuto Uchio of this department for measurement of ^{13}C NMR spectrum.

(Received March 20, 1986)

Catalytic activity of γ-cyclodextrin bearing an imidazole moiety (**1**) was compared with that of the corresponding β-cyclodextrin derivative (**2**) in the hydrolysis of *p*-nitrophenyl acetate. The catalysts **1** and **2** hydrolyzed the ester 80 and 172 times, respectively, as fast in the complexes as the buffer without any catalyst. The binding of **1** for the ester was 40% weaker than that of **2**. When sodium 1-naphthaleneacetate was present in the catalytic systems, the hydrolysis rate was enhanced for **1**, but depressed for **2**. This rate enhancement of **1** suggests that sodium 1-naphthaleneacetate acts as a spacer which facilitates **1** to bind the substrate by narrowing the large γ-cyclodextrin cavity. The time dependency of *p*-nitrophenol formation under the conditions of large excess of *p*-nitrophenyl acetate to **1** or **2** exhibited that the inhibitory effect of the product was remarkable for **2**, but negligible for **1**.

Cyclodextrins (CDs) are a series of cyclic oligomers consisting of six or more α-1,4-linked D-glucopyranose units. The number of glucopyranose unit is designated by a Greek letter: α for six, β for seven, γ for eight, so on. They have a hydrophobic cavity in which various hydrophobic guests can be included.[1] Because of their remarkable ability to form inclusion complexes, CDs, particularly α- and β-CDs, have been used as enzyme models.[1,2] Ester hydrolysis accelerated by CDs has been extensively studied as a serine protease model in which an alkoxide anion of secondary hydroxyls of CDs attacks the carbonyl of bound substrates.[3-5] Since pK_a of the hydroxyls is 12.1,[4] the acceleration by CDs occurs only at high pHs, in contrast to chymotrypsin which exhibits maximal rate at pH 8. Another fault of native CDs as enzyme models is that they are not real catalyst because acylated CDs thus produced are stable. There have been many attempts to convert CDs to better enzyme models by attaching appropriate functional groups.[1] Imidazole is one of those functional groups, which itself works as a catalyst at around pH 8, and actually plays an important role in catalytic action of chymotrypsin. From this viewpoint, imidazole-modified α- and β-CDs have been studied as effective catalysts which have both binding site (CD unit) and functional group (imidazole).[6-8]

The use of γ-CD as a binding site of such enzyme models has not yet been attempted so far mainly due to its large cavity size. However, in recent years, γ-CD has excited much attention because it was shown that γ-CD can include two guest molecules in its large cavity.[9] It was also shown that good-sized molecules or attached moieties can act as spacers which enable γ-CD to include a variety of guests by narrowing the large cavity.[10-12] In connection with this unique property of γ-CD, we have prepared imidazole-appended γ-CD (**1**) in the present work to examine its catalytic activity, turnover ability and effects of additives by using the corresponding β-CD derivative (**2**) as a reference catalyst.

Table 1. Pseudo-First-Order Rate Constants for Ester Hydrolysis[a]

Catalyst	$10^5 k_{obsd}/s^{-1}$
None	4.83±0.27
β-CD	10.6±0.04
γ-CD	8.49±0.20
1	63.4±1.4
2	182±7
3	29.7±0.05

a) 25 °C in pH 8.16 (I=0.200 (KCl)) 0.05 mol dm^{-3} Tris-HCl buffer with 0.40% (v/v) acetonitrile added; [Catalyst]=2.5×10^{-3} mol dm^{-3}; [*p*-Nitrophenyl acetate]=2.5×10^{-5} mol dm^{-3}.

Results and Discussion

Table 1 shows the pseudo-first-order rate constants obtained at 25 °C in pH 8.16 buffer solution by using *p*-nitrophenyl acetate as a substrate. Even under these mild conditions, the ester decomposes spontaneously. β- and γ-CDs enhance the hydrolysis rate slightly, showing 2.2 and 1.8-fold larger values, respectively, than the simple buffer solution. The data suggest stronger binding ability of β-CD than that of γ-CD.[12] The imidazole-appended β-CD **2** revealed 38-fold increase in the rate constant, while the rate increase of the corresponding γ-CD derivative **1** was 13-fold. The inferior activity of **1** is probably due to the large cavity size of its γ-CD unit. It is obvious that the CD parts of **1** and **2** contribute remarkably as binding sites to the acceleration of the reaction, as shown by two and six times larger rate constants for **1** and **2**, respectively, than that of the reference imidazole compound **3**. The reaction, therefore, proceeds according to the Scheme 1,

$$\mathrm{ImCD} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ImCD \cdot S} \xrightarrow{k_2} \mathrm{ImCD \cdot S'} \xrightarrow{k_3} \mathrm{ImCD} + \mathrm{P_2}$$
$$\mathrm{ImCD \cdot S'} + \mathrm{P_1}$$

Scheme 1.

Table 2. Kinetic Parameters for Ester Hydrolysis by **1** and **2**[a)]

Catalyst	$10^3k_2/s^{-1}$[b)]	K_m/mmol dm^{-3}[c)]	$10(k_2/K_m)$/dm^3 mol^{-1} s^{-1}
1	3.86±0.42	14.9±2.0	2.60±0.07
2	8.33±0.28	8.90±0.08	9.35±0.23

a) Hydrolysis of *p*-nitrophenyl acetate at 25 °C in pH 8.16 (I=0.200 (KCl)) 0.05 mol dm^{-3} Tris-HCl buffer with 0.40% (v/v) acetonitrile added. b) Rate constant of intracomplex hydrolysis. c) Dissociation constant of the substrate-catalyst complexes.

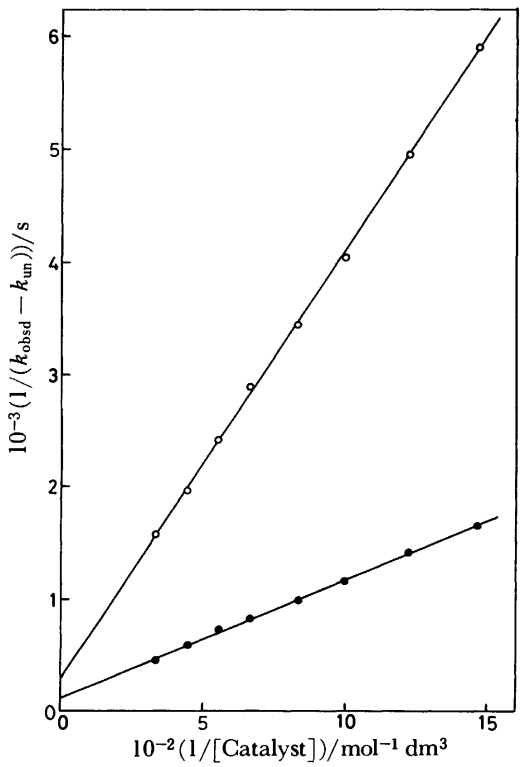

Fig. 1. Lineweaver-Burk plots for hydrolysis of *p*-nitrophenyl acetate with **1** (○) and **2** (●) (25 °C in pH 8.16 Tris-HCl buffer).

where ImCD is **1** or **2**, S is *p*-nitrophenyl acetate, P_1 is *p*-nitrophenol and P_2 is acetic acid.

The rate constants for the intracomplex reaction k_2 and the dissociation constants (Michaelis constants) K_m were evaluated by the Lineweaver-Burk plots[13)] of Eq. 1 (Fig. 1) as shown in Table 2,

$$\frac{1}{k_{obsd}-k_{un}} = \frac{K_m}{(k_2-k_{un})[Catalyst]} + \frac{1}{(k_2-k_{un})}, \quad (1)$$

where k_{obsd} and k_{un} denote the rate constants in the presence and absence of catalyst, respectively. The catalysts **1** and **2** hydrolyze the ester 80 and 172 times, respectively, as fast in the complexes as the buffer without any catalyst. The catalyst **2** has a dissociation constant that is 40% smaller than that of **1**. These data demonstrate that size-fitting between CD cavity and guest and positions of imidazole and ester carbonyl in the complex are better for **2**, resulting in 3.6-fold larger overall reaction rate k_2/K_m than that of **1**.

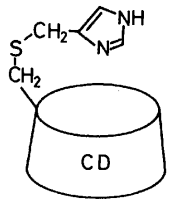
It seems interesting to examine the effect of additives

Table 3. Spacer Effect of Sodium 1-Naphthaleneacetate on Ester Hydrolysis Catalyzed by **1** and **2**[a)]

Catalyst	Spacer[b)]/mol dm^{-3}	$10^5k_{obsd}/s^{-1}$
1	0	63.4±1.4
1	0.005	74.9±0.3
1	0.01	78.7±0.04
2	0	182±7
2	0.005	162±0.3
2	0.01	150±4
3	0	29.7±0.05
3	0.005	29.7±0.06
3	0.01	29.9±0.04

a) 25 °C in pH 8.16 (I=0.200 (KCl)) 0.05 mol dm^{-3} Tris-HCl buffer with 0.40% (v/v) acetonitrile added; [Catalyst]=2.5×10^{-3} mol dm^{-3}; [*p*-Nitrophenyl acetate]=2.5×10^{-5} mol dm^{-3}. b) Sodium 1-naphthaleneacetate.

in the catalytic system of **1** since the additives might operate as spacers which enable the substrate to be included more strongly by narrowing the large γ-CD cavity. Table 3 shows the variation of the pseudo-first-order rate constant observed when sodium 1-naphthaleneacetate (**4**) was added as a spacer. The rate value for **2** diminished with increasing concentration of **4**, while **1** showed 24% increase in the value at [**4**]=0.01 mol dm^{-3}. The results imply that **4** acts as an inhibitor for **2** but as an effector for **1**. This effector behavior of **4** should be due to the spacer effect of **4** as shown in Fig. 3. This spacer effect was also confirmed by the fact that the catalyst **3**, which has no cavity, afforded the same rate value independently of the concentration of **4**. Since similar rate enhancement was



1 CD = γ-CD

2 CD = β-CD

4

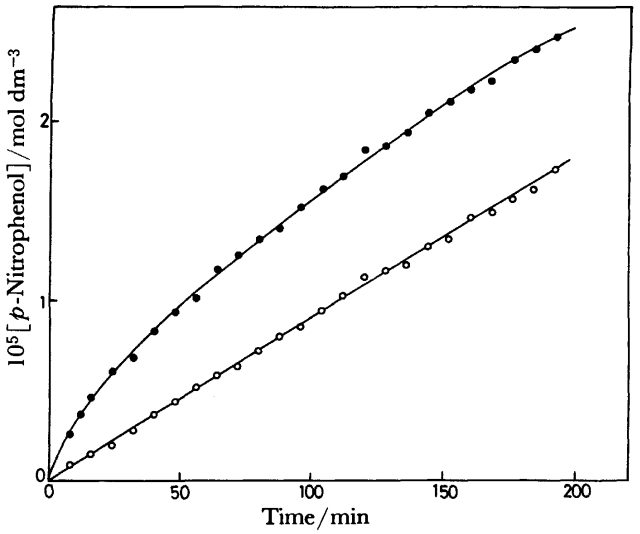

Fig. 2. Concentration of *p*-nitrophenol produced by hydrolysis of *p*-nitrophenyl acetate as a function of time under the conditions of large excess of substrate to **1** (○) or **2** (●) (25 °C in pH 7.02 (I=0.200 (KCl)) phosphate buffer). [*p*-Nitrophenyl acetate]=1.00×10^{-3} mol dm^{-3}. [**1**] or [**2**]=1.00×10^{-5} mol dm^{-3}.

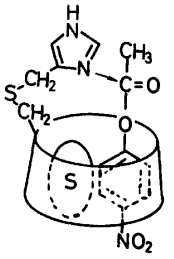

Fig. 3. Schematic representation of spacer(S)-assisted hydrolysis of *p*-nitrophenyl acetate in **1**.

observed when cyclohexanone and (−)-borneol were used in place of **4**,[14] this spacer effect is considered to occur widely in γ-CD systems.

The turnover abilities of **1** and **2** were examined under the conditions of large excess (100-fold) of *p*-nitrophenyl acetate. Figure 2 shows the time dependency of the amount of *p*-nitrophenol. The amounts of hydrolyzed *p*-nitrophenyl acetate are 1.7-fold and 2.5-fold larger for **1** and **2**, respectively, than the quantity of the catalysts at 200 min of the reaction time. This confirms that the deacylation step in Scheme 1 proceeds, regenerating the catalysts which can hydrolyze other substrate molecules again. The plots of *p*-nitrophenol vs. time exhibit different features for **1** and **2**, being curved for **2** and linear for **1**. The depressed rate observed for **2** in the period after the initial stage may be explained in terms of the inhibitory effect of produced *p*-nitrophenol. It means that the product competes with the substrate for complexing with **2**. In contrast to the remarkable binding ability of **2** to *p*-nitrophenol, the catalyst **1**, which has a large γ-CD cavity, seems hard to form 1:1 complex with *p*-nitrophenol. In other words, **1** is likely to be good host for the substrate and poor host for the product. Although the present study gave no data indicative of the formation of the ternary complex of **1**, substrate and *p*-nitrophenol, it is noted that *p*-nitrophenol may act as a spacer in the catalytic system of **1** as **4** does if its concentration is appropriate. The spacer-assisted or product-assisted binding of substrate cannot be expected to occur in α- and β-CD systems.

The present γ-CD system **1** was not a better catalyst than the β-CD system **2** even in the presence of spacers, but the results obtained here present guideline for designing effective catalytic systems of γ-CD. As an extension of this study, construction of some γ-CD systems having both spacer and catalytic moiety are now under way.

Experimental

Materials. β-CD (Tokyo Kasei) was recrystallized from water and dried in vacuo. γ-CD was kindly gifted from Nihon Shokuhin Kako Ltd., and was used without further purification. *p*-Nitrophenyl acetate (Tokyo Kasei) was recrystallized from ethanol. 4-(Hydroxymethyl)imidazole (Aldrich) and sodium 1-naphthaleneacetate (Tokyo Kasei) were used without further purification. Aqueous buffers were prepared with deionized water.

Tosyl-β-CD was prepared in pyridine, so that one of primary hydroxyls of β-CD was sulfonated.[15,16] The crude product was purified by repeated recrystallization from the mixed solvent of 1-butanol, ethanol, and water (5:4:3 by volume). The TLC of the obtained crystals showed a single spot on the plate (Merck, Kieselgel 60 F_{254}) when the plate was treated with *p*-anisaldehyde solution and then heated: R_f 0.49 (1-butanol: ethanol: water=5:4:3).

6-*O*-(2-naphthylsulfonyl)-γ-CD was prepared from 2-naphthalenesulfonyl chloride and γ-CD by the method previously reported.[17]

Measurements. The kinetic runs were performed with a Shimadzu UV-360 spectrophotometer. Reaction temperature was kept at 25±0.1 °C by using a Haake water circulation instrument. A kinetic run was initiated by injecting a solution of substrate in acetonitrile into the catalyst solution. The absorbance at 400 nm of *p*-nitrophenol was monitored as a function of time. The data were fitted to a simple exponential curve for a first-order reaction. The pseudo-first-order rate constants in Tables 1 and 3 were averages of at least two runs. The kinetic parameters shown in Table 2 represent the averages of three runs of Lineweaver-Burk plots. Figure 1 shows the results of one run of the plots for **1** and **2**.

6-Deoxy-6-(4-imidazolylmethylthio)-γ-cyclodextrin (1). 4-(Mercaptomethyl)imidazole hydrochloride (430 mg) and 6-*O*-(2-naphthylsulfonyl)-γ-CD (1 g) were dissolved in 200 ml of 30% aqueous ethanol solution. After adding sodium carbonate to adjust pH of the solution at 10.0, the solution was stirred 4 d under nitrogen. The reaction mixture was neutralized with 1M HCl (1M=1 mol dm^{-3}) and concentrated to 15 ml. Purification was performed by desalting with Bio-Bead ™SM-4 and SP-Sephadex C-25 resins, followed by column chromatography with Sephadex G-15 (yield 0.25 g (25%)). R_f=0.21 (28% aqueous NH_3: H_2O: AcOEt: 2-PrOH= 1:4:3:5); ^{1}H NMR (DMSO-d_6, 20 °C) δ=3.09—3.94 (br,

50H, CH_2 protons of mercaptomethyl-4-imidazole and CD protons other than C_1H and OH), 4.54 (7H, O_6H), 4.88 (8H, C_1H), 5.79 (16H, O_2H and O_3H), 6.63—7.17 (1H, aromatic), 7.52 (1H, aromatic), 11.90 (1H, NH); Found: C, 41.51; H, 6.51; N, 1.93; S, 2.19%. Calcd for $C_{52}H_{84}N_2O_{39}S \cdot 6H_2O$: C, 41.60; H, 6.45; N, 1.87; S, 2.14%.

6-Deoxy-6-(4-imidazolylmethylthio)-β-cyclodextrin (2). This compound was prepared previously.[18] In the present work, **2** was prepared according to the procedure described in the synthesis of **1** (yield 27%): R_f=0.28 (28% aqueous NH_3 : H_2O : AcOEt : 2-PrOH=1 : 4 : 3 : 5). Found: C, 43.56; H, 6.31; N, 1.95; S, 2.80. Calcd for $C_{46}H_{74}N_2O_{34}S \cdot 2H_2O$: C, 43.60; H, 6.20; N, 2.21; S, 2.53%.

We thank Nihon Shokuhin Kako Co Ltd. for providing γ-CD. Support of this work by a Grant-in-Aid (No. 60104003) for Special Project Research from the Ministry of Education, Science and Culture is gratefully acknowledged.

Stopped-Flow Investigation of Antioxidant Activity of Tocopherols

Kazuo MUKAI,* Yoshiko WATANABE, Yuichi UEMOTO, and Kazuhiko ISHIZU
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
(Received March 22, 1986)

It was observed by ESR measurement that the oxidation of α-, β-, γ-, and δ-tocopherols (vitamin E) with a stable phenoxyl radical in benzene immediately gives corresponding tocopheroxyl radicals. The rates of reaction of α-, β-, γ-, and δ-tocopherols with the stable phenoxyl radical in ethanol solution have been determined spectrophotometrically using stopped-flow technique, as a model reaction of tocopherols with unstable free radicals (ROO·, RO·, and HO·) in biological systems. The second-order rate constants obtained are $(5.12\pm0.36)\times10^3$ (α-Toc), $(2.24\pm0.04)\times10^3$ (β-Toc), $(2.42\pm0.16)\times10^3$ (γ-Toc), and $(0.51\pm0.01)\times10^3$ (δ-Toc), $M^{-1}s^{-1}$ in ethanol at 25.0 °C. The relative rates agree well with those obtained from studies of the reactivities of tocopherols toward poly(styrylperoxyl) and galvinoxyl radicals by O_2 consumption and by ESR method, respectively. The results suggest that the relative reactivities, that is, relative antioxidant activities of tocopherols do not depend on the kinds of unstable free radicals reacted.

Vitamin E (α, β-, γ-, and δ-tocopherols) is known to scavenge peroxyl, alkoxyl, and hydroxyl radicals.[1,2] The above free radical scavenging actions by vitamin E have been ascribed to the initial reaction of the phenolic hydroxyl group with the production of a tocopheroxyl* radical.[3,4] Therefore, several investigators have measured the oxidation rates k_1 of α-tocopherol by peroxyl radicals (ROO·), using different experimental methods such as chemiluminescence, pulse radiolysis, and O_2 consumption.[5–10]

$$ROO\cdot + Toc \longrightarrow ROOH + Toc\cdot \qquad (1)$$

However, considerable variations in the values of k_1 have been observed when different experimental methods were used, because the techniques employed to measure k_1 for α-tocopherol are indirect.[11]

Recently, Burton et al. have measured rate constants for reactions of the α-, β-, γ-, and δ-tocopherols with poly(styrylperoxyl) radicals, using O_2 consumption method.[11,12] They suggested that the reactivity of the tocopherols towards peroxyl radicals parallels their biological activity (α>β>γ>δ-tocopherol). Further, Niki et al. have measured the rate constants for reactions between galvinoxyl radical incorporated into dimyristoyl phosphatidylcholine (abbreviated to PC) liposomes and α-, β-, γ-, and δ-tocopherols incorporated into different dimyristoyl PC liposomes by ESR technique.[13] The observed pseudo-first-order rate constants of tocopherols decreased in the order of α>β≅γ>δ-tocopherol.

In this study we have used a stopped-flow technique to examine the reaction of tocopherols with a stable phenoxyl radical, i. e., 2,6-di-*t*-butyl-4-(4-methoxyphenyl)-phenoxyl (PhO·) (see Fig. 1), as a model reaction of tocopherols with unstable free radicals (ROO·, RO·, and HO·) in biological systems. The reactions were performed in the presence of excess tocopherol in ethanol, giving the pseudo-first-order rate constants, k_{obsd}. The second-order rate constants, k_s, may be immediately calculated from the k_{obsd} values, using the relation, $k_{obsd}=k_s[Toc]$. That is, the k_s value can be directly obtained from the above stopped-flow experiments. Therefore, this method will give more reliable values of rate constants than the other methods. By comparing the relative reactivities of α-, β-, γ-, and δ-tocopherols found by different experimental methods, we discussed the antioxidant activity of tocopherols.

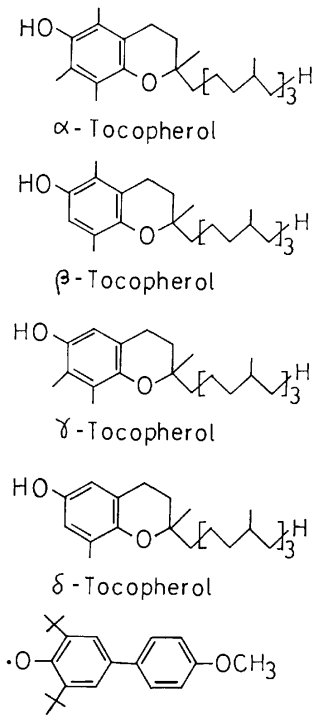

Fig. 1. Molecular structures of α-, β-, γ-, and δ-tocopherols and phenoxyl radical (PhO·).

Experimental

d-α-, d-β-, d-γ-, and d-δ-tocopherols were kindly supplied from Eisai Co., Ltd.

The 2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl (PhO·)

* The phenoxyl radicals generated from tocopherols are named in this paper as widely used tocopheroxyl radicals for convenience rather than tocopheryloxyl radicals that conform to rules of nomenclature.

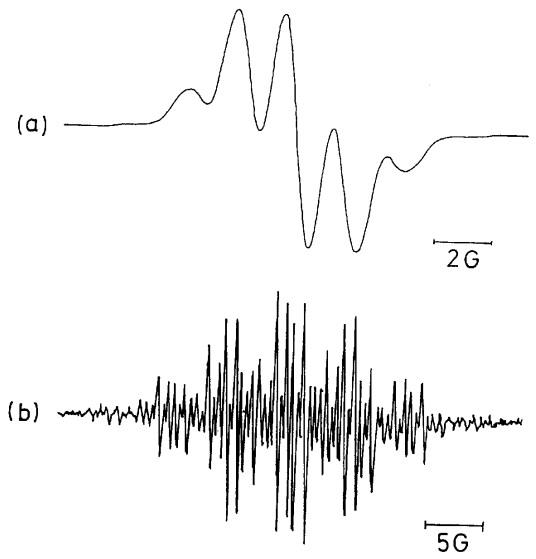

Fig. 2. ESR spectra of (a) phenoxyl radical and (b) α-tocopheroxyl radical at 25°C in benzene under vacuum.

(abbreviated to "phenoxyl" hereafter) was prepared according to the method of Müller et al.[14] Radical concentration of the phenoxyl radical was obtained from the results of the paramagnetic susceptibility measurements at 20°C, after correcting for the diamagnetic contribution ($\chi_{dia} = -0.220 \times 10^{-3}$ emu mol^{-1}) calculated by the Pascal's method. The value was 100% for phenoxyl, assuming the Curie law.

The ESR measurements were carried out using a JES-FE-2XG spectrometer with 100 KHz magnetic field modulation. UV. visible spectra were recorded on a JASCO UVIDEC-1 spectrophotometer. The stopped-flow data were obtained on a UNISOKU stopped-flow spectrophotometer Model RS-450 by mixing equal volumes of ethanol solutions of phenoxyl and tocopherol. The oxidation reactions were studied under pseudo-first-order conditions, and the observed rate constants, k_{obsd}, were calculated in the usual way using a standard least-squares analysis. All measurements were performed at 25.0 ± 0.5 °C.

Results and Discussion

ESR Studies of the Oxidation of Tocopherols with Phenoxyl Radical. Figure 2(a) shows an ESR spectrum of the phenoxyl radical in benzene at 25°C under vacuum.[15] When two benzene solutions containing 2.50 mM phenoxyl and 5.00 mM α-tocopherol (1 : 1 in volume), respectively, were mixed at 25°C under vacuum, phenoxyl disappeared instantaneously, and a new spectrum due to α-tocopheroxyl radical appeared (Fig. 2(b)). The above reaction can be represented by the following equation.

$$\text{PhO}\cdot + \text{Toc} \xrightarrow{k_s} \text{PhOH} + \text{Toc}\cdot \qquad (2)$$

Similarly, β-, γ-, and δ-tocopherols were reacted with the phenoxyl, and the ESR spectra due to β- and γ-tocopheroxyl radicals were observed. However, in the case of δ-tocopherol, the radical is very unstable, and the clear ESR spectrum cannot be observed. The observed hyperfine splittings are listed in Table 1. There have been many ESR studies of tocopheroxyl radicals published.[16] However, the spectrum is fairly complex and has only recently been completely resolved, first by Mukai (one of the present authors) et al.,[3,17] and, then, by Matsuo et al.[18] and Tsuchiya et al.[19] The hyperfine splittings in Table 1 show good accordance with those reported previously.[3,17]

Table 1. Hyperfine Couplings (a_i^H) of Tocopheroxyl Radicals in Benzene at 25°C

	a_5^H	a_7^H	a_4^H	a_8^H
α-Toc	6.04G	4.52G	1.48G	0.93G
β-Toc	6.39	4.63	1.76	0.81
γ-Toc	5.97	4.80	1.17	1.17
δ-Toc	—	—	1.52	1.04

Stopped-Flow Studies of the Reaction Rates of Tocopherols with Phenoxyl. The phenoxyl radical is stable in the absence of tocopherol, and shows absorption peaks at $\lambda_{max} = 376$ nm ($\varepsilon = 17600$ M^{-1} cm^{-1}) and 580 nm ($\varepsilon = 4280$ M^{-1} cm^{-1}) in ethanol. The phenol precursor of the phenoxyl and α-tocopherol show absorption peaks at $\lambda_{max} = 267$ nm ($\varepsilon = 19500$ M^{-1} cm^{-1}) and $\lambda_{max} = 295$ nm ($\varepsilon = 3610$ M^{-1} cm^{-1}), respectively, in ethanol; no absorptions were observed in the visible region.

By adding an ethanol solution of α-tocopherol (5.00 mM) to an ethanol solution of phenoxyl (0.10 mM) (1 : 1 in volume) at 25.0°C, the absorption spectrum of the phenoxyl immediately changed to that of α-tocopheroxyl. The absorption spectrum of α-tocopheroxyl shows weak absorption peaks at 425 and 405 nm.[20] However, the α-tocopheroxyl is unstable, and the absorption peaks rapidly disappeared. Similarly, the phenoxyl radical has been reacted with excess β-, γ-, and δ-tocopherols, showing rapid decrease of the absorption spectrum, respectively. On the other hand, the absorption spectra of the corresponding tocopheroxyls were not observed in these cases, because these tocopheroxyls are more unstable than α-tocopheroxyl.

Therefore, the oxidation rates of tocopherols by phenoxyl were studied spectrophotometrically using stopped-flow technique in the presence of excess tocopherol in ethanol. The rate was measured by following the decrease in absorbance at 376 and 580 nm of phenoxyl radical. The time dependence of the decrease in absorbance at 376 nm observed when 0.10 mM ethanol solution of phenoxyl is mixed with 5.00 mM ethanol solution of α-thcopherol (1 : 1 in volume; final concentration of phenoxyl is 0.05 mM) is shown in Fig. 3. A typical Guggenheim plot versus time was linear to >90% completion, as shown in Fig. 4. The pseudo-first-order rate constants, k_{obsd}, obtained by varying the concentration of phenoxyl and α-tocopherol are presented in Table 2. The stopped-flow reactions were performed at 25.0 ± 0.5 °C.

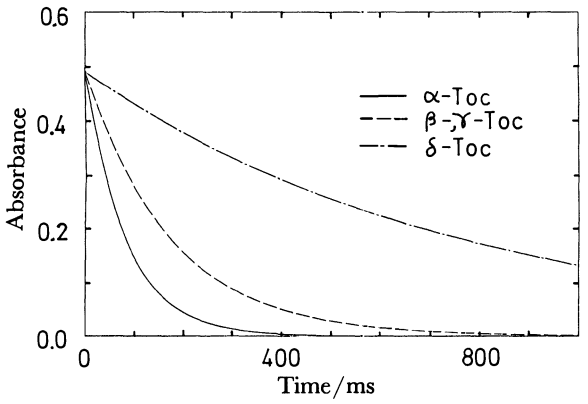

Fig. 3. The decay of phenoxyl radicals for the reaction of phenoxyls with α-, β-, γ-, and δ-tocopherols in ethanol at 25.0 °C.
$[PhO\cdot]_{t=0}$ 0.05 mM and $[Toc]_{t=0}$ 2.50 mM. At 376 nm.

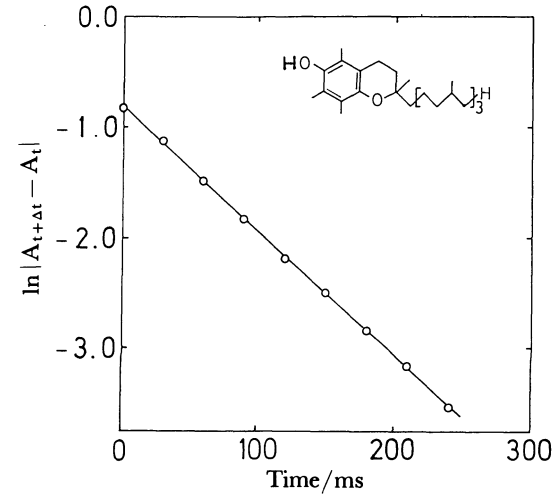

Fig. 4. First-order Guggenheim plot of the data of α-tocopherol in Fig. 3; $k_{obsd}=12.0\,s^{-1}$.

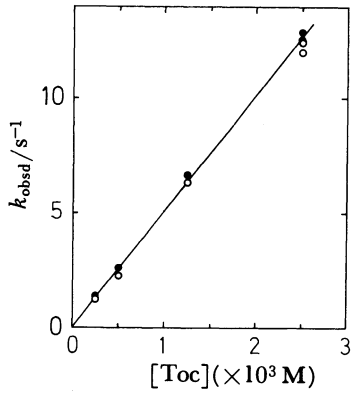

Fig. 5. The dependence of the pseudo-first-order rate constant, k_{obsd}, on [α-Toc] in ethanol. (○): observed at 376 nm. (●): observed at 580 nm.

The pseudo-first-order rate constants, k_{obsd}, observed at 376 and at 580 nm were linearly dependent on the concentration of tocopherol as shown in Fig. 5. Therefore, the rate law is expressed as

Table 2. Pseudo-First-Order (k_{obsd}) and Second-Order (k_s) Rate Constants for Oxidation of α-Tocopherol by the Phenoxyl Radical in Ethanol at 25.0 °C

λ_{max}	Ratio [PhO·]:[Toc]	k_{obsd} / s^{-1}	$10^{-3}k_s$ / $M^{-1}s^{-1}$

a) $[PhO\cdot]_{t=0}=0.05$ mM. For PhO·, see text and Fig. 1.

$$-d[PhO\cdot]/dt = k_{obsd}[PhO\cdot] = k_s[Toc][PhO\cdot], \quad (3)$$

where k_s is the second-order rate constant for oxidation of tocopherol by phenoxyl radical. The k_s values were calculated from k_{obsd} values in 12 independent experiments (0.25—2.50 mM tocopherol), respectively, and listed in Table 2. The average value for k_s was $(5.12\pm0.36)\times10^3\ M^{-1}\ s^{-1}$ in ethanol at 25.0 °C. Similarly, the second-order rate constants, k_s, were obtained for β-, γ-, and δ-tocopherols. For each tocopherol, k_s was measured in 4—12 independent experiments. The experimental error in k_s values was $<\pm7\%$ in every case. The values of the k_s observed are listed in Table 3. The results listed in Table 3 demonstrate that α-tocopherol is about two times as reactive as β-tocopherol, whereas β-tocopherol is, within our limits of error, as reactive as γ-tocopherol. However, δ-tocopherol is only ca. 10% as reactive as α-tocopherol.

Century and Horwitt reported that biological activities of tocopherols decrease in the order of $\alpha>\beta>\gamma>\delta$, and that in vivo and in vitro tests of their relative biological activities change depending on the kinds of test (see Table 2 in Ref. 21).[21] As described in a previous section, Burton et al. have reported absolute second-order rate constants, k_s', for the reaction of α-, β-, γ-, and δ-tocopherols with poly(styrylperoxyl) radicals, using the O_2 consumption method (see Table 3).[11,12] The suggested that the relative magnitude of the second-order rate constant, k_s', of α-, β-, γ-, and δ-, tocopherols is in agreement with in vivo and in vitro tests of their relative biological activities which yield: $\alpha>\beta>\gamma>\delta$-tocopherol.[21] Niki et al. have measured the pseudo-first-order rate constants (k_f) (see Table 3) for the reaction between galvinoxyl radical incorporated into dimyristoyl PC liposomes and α-, β-, γ-, and δ-tocopherols incorporated into different dimyristoyl PC liposomes, by ESR technique.[13] By comparing the k_f value for α-tocopherol with those found for β-, γ-, and δ-tocopherol, they suggested that the reactivities of

tocopherols toward galvinoxyl radical decrease in the order of $\alpha > \beta \cong \gamma > \delta$.

In the present work, we have measured the rate constants k_s for the reaction of α-, β-, γ-, and δ-tocopherols with the stable phenoxyl radical in ethanol, using a stopped-flow spectrophotometer. As listed in Table 3, the relative k_s values ($\alpha:\beta:\gamma:\delta = 1.00:0.44:0.47:0.10$) obtained by the stopped-flow technique are in good agreement with the values (1.00:0.51:0.49:0.20) obtained by the O_2 consumption method, except for δ-tocopherol, although the absolute k_s values are about 600 times smaller than those for the reaction of tocopherols with poly(styrylperoxyl) radical in chlorobenzene.[11,12] Further, the above relative magnitude of the second-order rate constants, k_s, of α-, β-, γ-, and δ-tocopherols is also in satisfactory agreement with that (1.00:0.54:0.50:0.47) of the pseudo-first-order rate constant, k_f, obtained by ESR technique, except for δ-tocopherol.[13] The results suggest that the relative reactivities, that is, relative antioxidant activities obtained by the three different experimental methods agree well with each other. In addition, the above results indicate that the relative antioxidant activities do not depend on the kinds of radicals (phenoxyl, poly (styrylperoxyl), and galvinoxyl radical) used, while the absolute rates are considerably different from each other. As described above, biological activities of tocopherols decrease in the order of $\alpha > \beta > \gamma > \delta$, and in vivo and in vitro tests of their relative biological activities change depending on the kinds of test.[21] For instance, the relative biopotencies of α-, β-, γ-, and δ-tocopherols have been reported as 100, 25, 18, and 0.3 in an erythrocyte hemolysis test and as 100, 55, 5, and 4 in respiratory decline test, respectively.[21] The result shows that the relative biological activity and antioxidant activity of tocopherols do not always agree with each other, suggesting that the function of tocopherols in biological system is not simple, but manifold.

We are very grateful to Prof. Yoichi Kitamura for use of stopped-flow spectrophotometer and his helpful discussions.

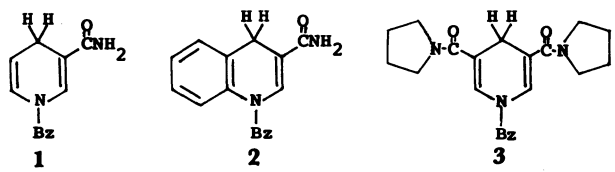
Mechanism of Carboxylic Acid-Catalyzed Reduction of Substituted Nitrosobenzenes by 1-Benzyl-3,5-bis(1-pyrrolidinylcarbonyl)-1,4-dihydropyridine in Acetonitrile

Hiroshi AWANO and Waichiro TAGAKI*
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3, Sumiyoshi-ku, Osaka 558
(Received March 20, 1986)

Mechanism of carboxylic acid-catalyzed reduction of substituted nitrosobenzenes by 1-benzyl-3,5-bis(1-pyrrolidinylcarbonyl)-1,4-dihydropyridine has been studied in acetonitrile at 25 °C. The major product was hydroxylamine when the dihydropyridine was used in excess over nitrosobenzene, while that was azoxybenzene in the reverse case. The observed second-order rate constant k_2^R are dependent on acid concentration in a first-order manner with the acid-catalyzed third-order rate constant k_H^R. The Hammett relationship for k_H^R for substituted nitrosobenzenes gave a ρ=−0.93. The Brönsted plot of log k_H^R vs. pK_a of acids gave a straight line with a slope of −0.34. The deuterium isotope effect for the catalysis by dichloroacetic acid was found to be k_H^R/k_D^R=2.80. These results indicate that a general acid catalysis by carboxylic acids plays an important role in the reduction of nitrosobenzene by dihydropyridine in acetonitrile.

Acid catalysis has been an interesting subject for the model studies of NAD(P)H coenzyme, since in certain dehydrogenases a protonated histidine residue is presumed to be involved as the general acid to activate substrate carbonyl group for hydride transfer from the coenzyme.[1,2] For the model studies of such acid catalysis, a problem is instability of conventional NADH analogs such as 1-benzyl-3-carbamoyl-1,4-dihydropyridine (**1**) toward acids.[3-6] This problem was solved by Shinkai et al. by the design of 1-benzyl-3-carbamoyl-1,4-dihydroquinoline (**2**) which is stable even in a strong aqueous acid solution.[7] Later, as reported previously,[8] we found that 1-benzyl-3,5-bis(1-pyrrolidinylcarbonyl)-1,4-dihydropyridine (**3**) is much more active reducing agent than **2** and more acid stable than **1** in the acid ($CHCl_2COOH$)-catalyzed reduction of substituted nitrosobenzenes in acetonitrile. In this paper, we wish to report the full accounts of the previous results[8] together with a more detailed study on the mechanism of this acid catalysis. Incidentally, it may be of interest to study the mechanisms of reduction of nitrosobenzene by NADH analogs in connection with the carcinogenesis in biological systems.[9-12]



Experimental

All melting points were uncorrected. Spectra were recorded by using the following instruments: IR, Hitachi 215; UV-visible, Hitachi 220 and 220A; NMR, JEOL JMM-PS-100 (100 MHz) and Hitachi R-20 (60 MHz). HPLC was performed by using JASCO UNIDEC-100-II, UNIFLOW-211 and Shimadzu C-R1B.

Materials. Anhydrous acetonitrile was obtained by distilling over phosphorus pentaoxide. The carboxylic acids as catalysts were commercial samples of special grade and purified by recrystallization or distillation if necessary. Substituted nitrosobenzenes were prepared by the reduction of the corresponding commercially available nitrobenzenes with zinc powder in aqueous solution containing ammonium chloride according to the literature methods and purified by recrystallization from ethanol-water: *p*-CH_3, mp 48 °C (lit,[13] 48.5°); *m*-CH_3, mp 53 °C (lit,[13] 53°); *p*-Cl, mp 97 °C (lit,[14] 90°); *p*-CF_3, mp 56—57 °C (lit,[15] 51—53°); H, commercial sample, mp 68 °C. The IR and UV spectra of these nitrosobenzenes were in accord with reported ones.[16,17]

1-Benzyl-3,5-bis(1-pyrrolidinylcarbonyl)-1,4-dihydropyridine (3) was prepared as usual by treating 3,5-pyridinedicarbonyl dichloride with an excess of pyrrolidine in chloroform. The diamide was reacted with benzyl chloride in acetonitrile under reflux to give the pyridinium chloride. The salt was then reduced by sodium dithionite in water. The reaction mixture was extracted with dichloromethane, and the usual work-up of the extract, purification by cellulose-column chromatography and recrystallization from ethanol-water gave **3**, mp 46 °C: overall yield, 65%; UV (CH_3CN), λ_{max}=355 nm (ε=6072 $M^{-1}cm^{-1}$); ^1H NMR (ppm (δ) in $CDCl_3$/TMS), 1.67—1.95 (8H, m, pyrrolidine ring CH_2), 3.25—3.65 (10H, m, dihydropyridine ring 4-CH_2 plus pyrrolidine ring NCH_2), 4.41 (2H, s, CH_2Ph), 6.55 (2H s, dihydropyridine ring 2-CH and 6-CH), 7.45 (5H, s, benzyl aromatic). Found: C, 71.51; H, 7.48; N, 11.42%. Calcd for $C_{22}H_{27}N_3O_2$: C, 72.30; H, 7.45; N, 11.50%.

1-Benzyl-3-carbamoyl-1,4-dihydropyridine (1) and 1-benzyl-3-carbamoyl-1,4-dihydroquinoline (2) were prepared according to the literature methods, mp 118 °C (decomp) (lit,[18] 120—122°) and mp 155 °C (lit,[19] 158—160°), respectively.

Dichloroacetic acid-d was prepared by the hydrolysis of dichloroacetic anhydride in D_2O. The deuterium incorporation was 82% measured by NMR method.

Product analysis was performed for unsubstituted nitrosobenzene (X=H) by HPLC method using JASCO Finepak SIL C18-column and acetonitrile/water (2:1) solvent. Examples of retention times (min) for the reaction components were: phenylhydroxylamine (**5**) (2.3), benzaldehyde (internal standard) (2.9), nitrosobenzene (**4**, X=H) (3.4), azoxybenzene (**6**) (6.6), 1-benzyl-3,5-bis(1-pyrrolidinylcarbonyl)-1,4-dihydropyridine (**3**) (8.3). The major product was **5** when **3** was used in excess over **4**, while that was **6** in

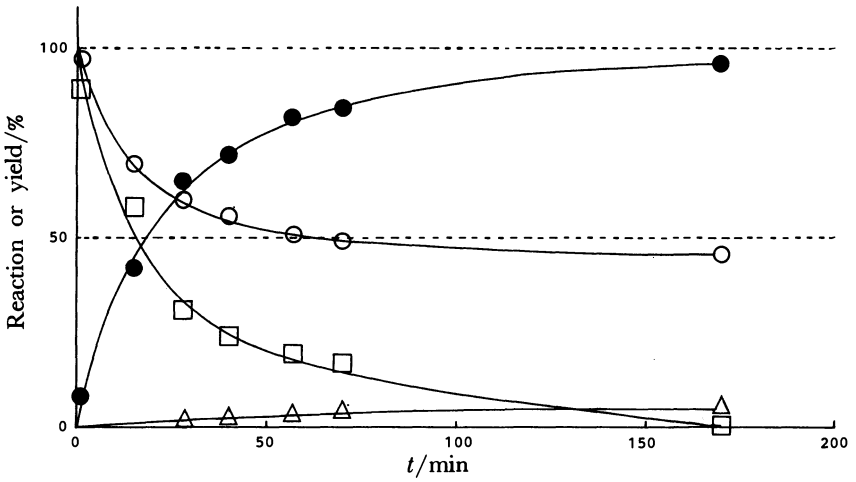


Fig. 1. Time dependent % reaction or yield: [**3**]=1.0×10^{-3} mol dm^{-3}, [**4**]=0.5×10^{-3} mol dm^{-3}, [$CHCl_2COOH$]=10.0×10^{-3} mol dm^{-3}, in acetonitrile, 25 °C. (**3**) (○), (**4**) (□), (**5**) (●), and (**6**) (△).

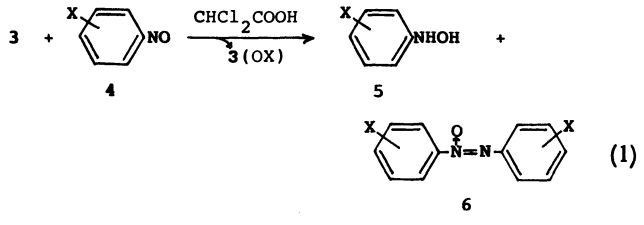
the reverse case. An example of the time course of a reaction mixture is shown in Fig. 1.

Kinetics. In a 1 cm quartz UV cell stoppered with a rubber septum cover was placed a 3 ml acetonitrile solution of a dihydropyridine and the solution was well bubbled with acetonitrile saturated pure nitrogen gas through inserted needles. Stock solutions of a carboxylic acid and nitrosobenzene were treated in the same way. Then the quartz cell was mounted on a water-jacketed UV cell holder and the acid and nitrosobenzene stock solutions in water bath were kept at 25 °C for 15 min. The reaction was started by adding acid and nitrosobenzene stock solutions to the quartz cell by a Hamilton microsyringe. The rates of reduction were followed by monitoring the decrease in absorbance of either dihydropyridine at 350 nm for **1** and **2**, and at 370 nm or 400 nm for **3** or nitrosobenzene near 307 nm. In most cases, the reaction was carried out under pseudo-first-order conditions with 20 molar excess of nitrosobenzene over a dihydropyridine.

Results

Products and Kinetics. The reduction reaction was carried out in anhydrous acetonitrile under the nitrogen atmosphere. The reaction was slow in the absence of an acid. The time-dependent composition of the reaction mixture could be successfully analyzed by HPLC. The results indicated the reaction to be quantitatively described by Eq. 1. As shown in Fig. 1, nitro-



(1)

sobenzene (**4**, X=H) was quantitatively reduced to phenylhydroxylamine (**5**, X=H) when reacted with two molar excess of **3** in the presence of dichloroacetic acid, accompanied by the formation of a small amount of azoxybenzene (**6**). Figure 1 also shows that the disappearance of **3** and **4**, and the appearance of **5** occurred in almost the same rate and much faster than the formation of **6**. Furthermore, the curve for **3** indicates that after completion of reduction the remaining excess **3** was fairly stable without undergoing appraciable decomposition promoted by an acid. Under reversed conditions of excess **4** over **3** the major product was **6** which appeared to be formed by the acid-catalyzed condensation reaction between **5** and remaining **4**. Azoxybenzene **6** was stable without undergoing further redution by **3** under the present reaction conditions. The reduction occurred similarly in the case of

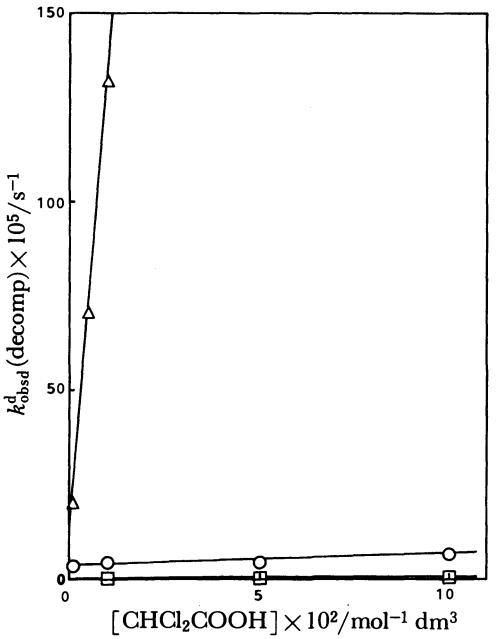


Fig. 2. Pseudo-first-order rate constants for the decomposition of (**1**) (△), (**2**) (□), and (**3**) (○) plotted as a function of the concentration of $CHCl_2COOH$ in acetonitrile at 25 °C.

Table 1. Rate Constants of the Acid-Catalyzed Decomposition of Dihydropyridines and of the Acid-Catalyzed Reduction of Nitrosobenzene by Dihydropyridines in Acetonitrile (25 °C)[a)]

Dihydropyridine	k_{un}^{d}	k_{H}^{d}	k_{un}^{R}	k_{H}^{R}
	s^{-1}	$mol^{-1}\,dm^3\,s^{-1}$	$mol^{-1}\,dm^3\,s^{-1}$	$mol^{-2}\,(dm^3)^2\,s^{-1}$
1	1.50×10^{-4}	1.09×10^{-1}	2.66	—
2	1.23×10^{-6}	7.50×10^{-6}	0.09	2.10
3	2.72×10^{-5}	3.72×10^{-4}	1.29	667

a) [**1**]=[**2**]=[**3**]=1.0×10^{-4} mol dm^{-3}, [**4**, X=H]=2.0×10^{-3} mol dm^{-3}.

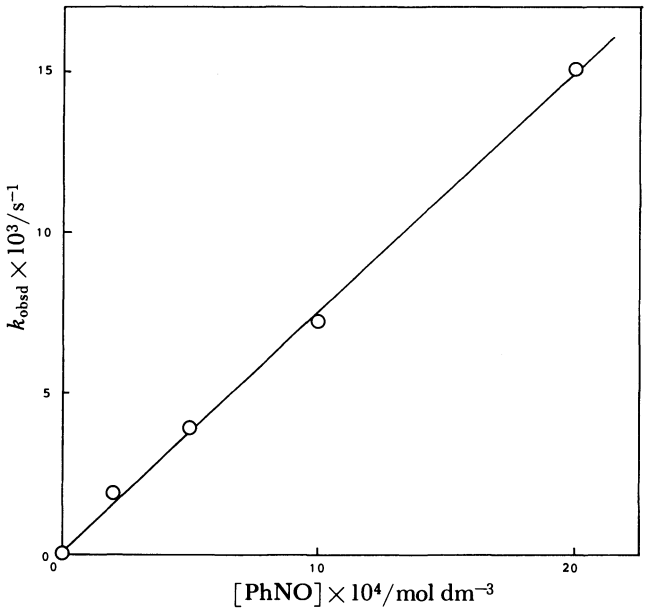

Fig. 3. A linear relationship between the observed pseudo-first-order rate constant and the concentration of nitrosobenzene in acetonitrile at 25 °C: [**3**]=1.0×10^{-4} mol dm^{-3}, [$CHCl_2COOH$]=1.0×10^{-2} mol dm^{-3}.

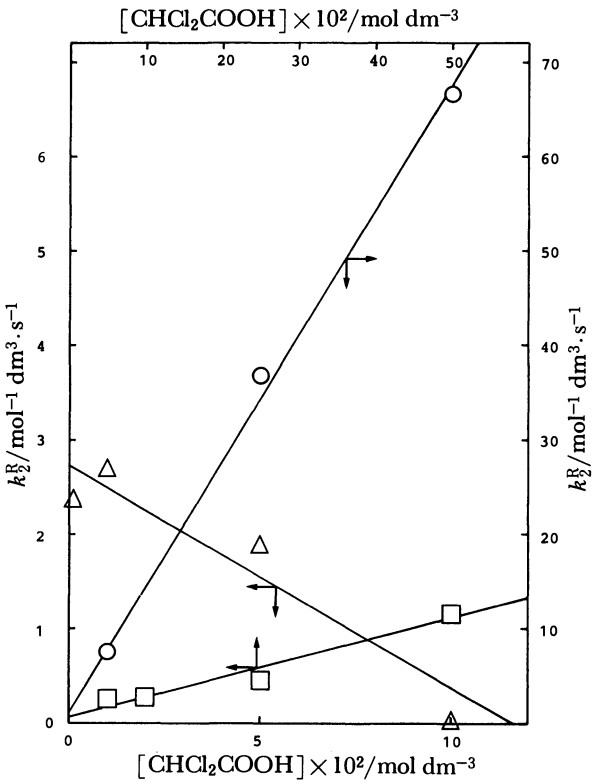

Fig. 4. Second-order rate constants for the reduction of nitrosobenzene by (**1**) (△), (**2**) (□), and (**3**) (○) plotted as a function of the concentration of $CHCl_2COOH$ in acetonitrile at 25 °C.

2, although the rate was much slower than in the case of **3**. The reduction was also observed with **1**, but the competing acid decomposition of **1** made the results complex. The decomposition of dihydropyridines by an acid were examined spectrophotometrically by measuring the rates of disappearance of dihydropyridine absorption (350 or 370 nm) in the absence of nitrosobenzene. As shown in Fig. 2, the pseudo-first-order rate constants for the decomposition (k_{obsd}^{d}) increase linearly with increasing concentration of dichloroacetic acid (AH) for all three dihydropyridines. Therefore the rate of decomposition can be represented by Eqs. 2 and 3.

$$\text{Rate(decomp)} = k_{obsd}^{d}[\text{dihydropyridine}] \quad (2)$$

$$k_{obsd}^{d} = k_{un}^{d} + k_{H}^{d}[AH] \quad (3)$$

The rate constants k_{un}^{d} obtained as the intercepts presumably arose from the air oxidation due to incomplete air extrusion from the reaction solutions. The rate constants k_{H}^{d} obtained as the slopes were those for the acid-catalyzed decomposition. These values are listed in Table 1. The Table indicates that the k_{H}^{d} value for **1** is far much larger than those for the other two. It is considered that **1** undergoes a ready acid promoted decomposition through an electrophilic addition of an acid on the enamine 5,6-double bond of dihydropyridine ring.[3-6)] Such an electrophilic addition seems to be much difficult to occur in the cases of **2** and **3** as discussed later.

The rates of reduction of nitrosobenzene were obtained similarly as the rates of disappearance of a dihydropyridine in the presence of nitrosobenzene (X=H). As shown in Fig. 3, the pseudo-first-order rate constants (k_{obsd}) were observed to increase linearly with increasing concentration of nitrosobenzene. Thus, combined with Eq. 2, the k_{obsd} value can be represented by Eq. 4 which allows to obtain a second-order rate constant for the reduction k_2^R as the slope of a straight line. Furthermore, as shown in Fig. 4, this k_2^R was observed to be linearly dependent on the acid con-

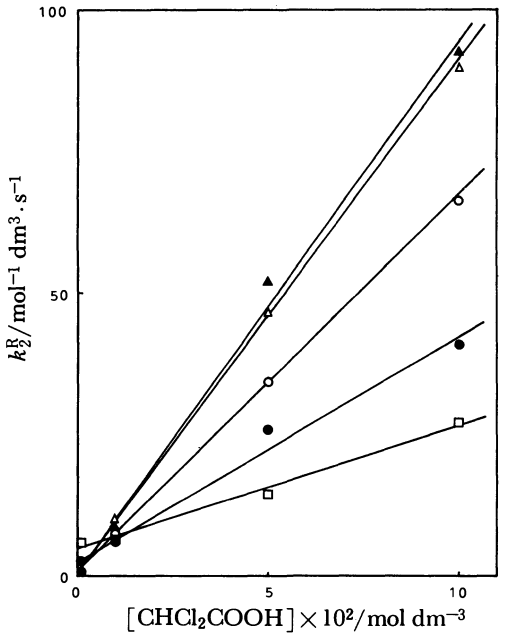

Fig. 5. Second-order rate constants for the reduction of substituted nitrosobenzenes by (**3**) as a function of the concentration of $CHCl_2COOH$ in acetonitrile at 25 °C: *p*-Me (△), *m*-Me (▲), H (○), *p*-Cl (●), and *p*-CF_3 (□).

centration and obeyed Eq. 5. Therefore, as summarized in Eq. 6, the k_{obsd} value is composed of four kinetic terms of decomposition and reduction. The corresponding four rate constants k_{un}^d, k_H^d, k_{un}^R, and k_H^R are shown in Table 1 for three dihydropyridines. As for the former two, it was described already.

$$k_{obsd} = k_{obsd}^d + k_2^R\,[\text{nitrosobenzene}] \quad (4)$$

$$k_2^R = k_{un}^R + k_H^R\,[AH] \quad (5)$$

$$k_{obsd} = k_{un}^d + k_H^d\,[AH] + k_{un}^R\,[\text{nitrosobenzene}] + k_H^R\,[AH][\text{nitrosobenzene}] \quad (6)$$

Of the two reduction rate constants, the uncatalyzed second-order one k_{un}^R indicates that a conventional dihydropyridine (**1**) is much more active than the other two (**2** and **3**) in the absence of an acid. However, Fig. 4 shows that the k_2^R for **1** decreases with increasing acid concentration with a line of negative slope, in contrast to the lines of positive slopes in the cases of **2** and **3**. The reason for such an inhibitory effect of an acid for **1** is not clear at present.[20] As discussed later, it may be conceivable that for more basic **1** than the other two, protonation of dihydropyridine moiety lowers its reducing activity together with the acid decomposition. On the other hand, the acid-catalyzed third-order rate constants k_H^R could be successfully obtained for **2** and **3**. As for the reactivities of **2** and **3**, the latter is much more active than the former in both uncatalyzed and catalyzed reaction: $k_{un}^R(\mathbf{3})/k_{un}^R(\mathbf{2})=15$ and $k_H^R(\mathbf{3})/k_H^R(\mathbf{2})=318$.

Hammett Substituent Effect. The present reduction is a hydride transfer from a dihydropyridine ring to the nitroso group.[21] Consequently, it is conceivable that the uncatalyzed (k_{un}^R) process is favored by an electron-withdrawing substituent of nitrosobenzene. On the other hand, if the above acid catalysis (k_H^R) is due to the activation of a nitroso group by protonation or hydrogen bonding, such process seems to be favored by an electron-donating substituent. What actually observed is shown in Fig. 5 which indicates that the plots of k_2^R vs. concentration of dichloroacetic acid give straight lines as seen for unsubstituted nitrosobenzene in Fig. 4. It is clear that the slopes of those straight lines (i.e. k_H^R) are larger for more electron-donating substituents. On the other hand, the intercepts (k_{un}^R) are larger for more electron-withdrawing substituent. These opposing substituent effects can be seen more clearly in the Hammett plots of Fig. 6, giving a positive $\rho=1.35$ for k_{un}^R and a negative $\rho=-0.93$ for k_H^R plot. As expected, the latter negative ρ value for k_H^R process suggests the activation of a substrate nitroso group by an acid, although its detailed mechanism, protonation or hydrogen bonding, is difficult to determine at this stage.

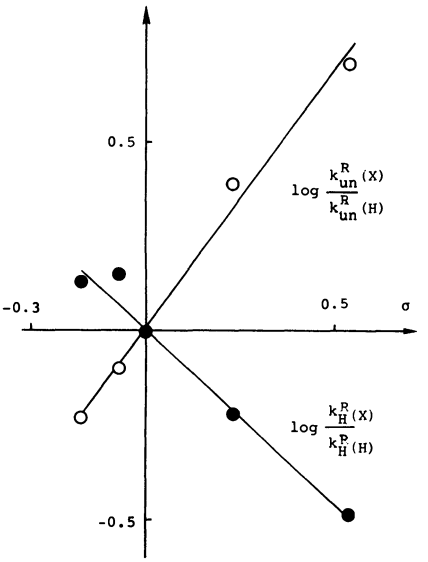

Fig. 6. Hammett plots of k_{un}^R(○) and k_H^R (●).

Brönsted Plots. The above k_H^R values for unsubstituted nitrosobenzene (X=H) were determined for eight carboxylic acids as shown in Table 2. The Table also lists the literature values of pK_a for the used carboxylic acids in water[22] and acetonitrile.[23] These values give two straight lines of Brönsted plots as shown in Fig. 7 and Eqs. 7 and 8. The α values are both negative,

$$\log k_H^R = -0.34\,pK_a(AN) + 6.88 \quad (7)$$

$$\log k_H^R = -1.17\,pK_a(\text{water}) + 4.77 \quad (8)$$

indicating a stronger acid being a more active catalyst.

Deuterium isotope effect was examined to get more insight into the mechanism of the above acid catalysis

Table 2. Acid-Catalyzed Rate Constants k_H^R with Eight Carboxylic Acids for the Reduction of Nitrosobenzene by (**3**) in Acetonitrile (25°C)[a)]

	Carboxylic acid	$(pK_a)_{AN}$[b)]	$(pK_a)_w$[c)]	k_H^d	k_H^R

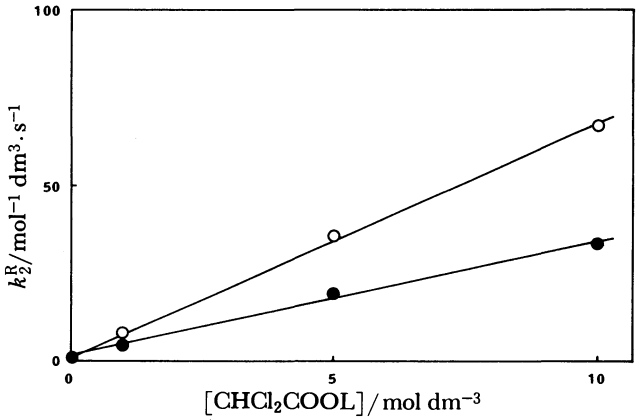

Fig. 8. Second-order rate constants for the reduction plotted as a function of the concentration of $CHCl_2COOH$ (○) and $CHCl_2COOD$ (●) in acetonitrile at 25°C. $[\mathbf{3}]=1.0\times10^{-4}$ mol dm^{-3}.

by using dichloroacetic acid-*d* (82% atom D-content), unsubstituted nitrosobenzene, and (**3**). The results are shown in Fig. 8. The slopes of the two straight lines are $k_D'(R)=315$ and $k_H^R=618$ in the unit of $mol^{-2}(dm^3)^2\cdot s^{-1}$ to give an isotope effect of $k_H^R/k_D'(R)=2.1$. This value can be corrected for the true isotope effect (k_H^R/k_D^R) based on Eqs. 9 and 10,

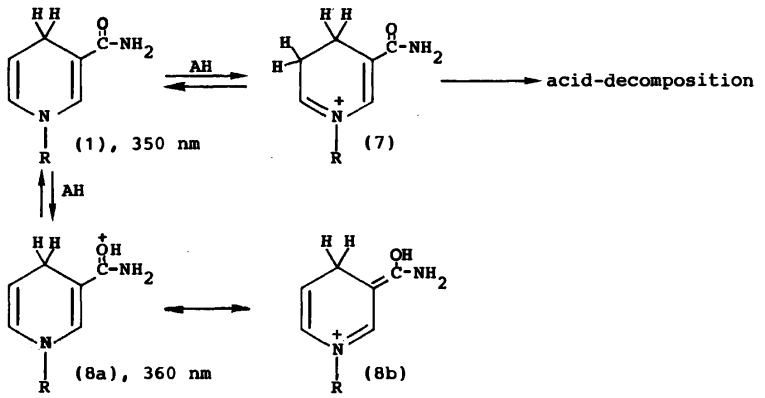
$$k'_D(R)([AD]+[AH]) = k_D^R[AD] + k_H^R[AH] \quad (9)$$

$$\frac{k_H^R}{k_D^R} = \frac{\gamma\cdot(k_H^R/k'_D(R))}{(1+\gamma)-(k_H^R/k'_D(R))} = 2.80 \quad (10)$$

where [AD] and [AH] are the concentrations of deuterium-labelled and unlabelled dichloroacetic acids, respectively, and $\gamma=[AD]/[AH]=82/18=4.56$ is used based on the above isotope content (82% D). In the same procedure, an isotope effect of $k_H^R/k_D^R=1.73$ was obtained for the reduction of *m*-nitrosotoluene.

Discussion

In the catalysis of lactate dehydrogenase and of related enzymes, the substrate carbonyl group is presumed to be activated by an acidic group toward the hydride transfer from NAD(P)H coenzyme.[1,2)] There have been known some model studies which support such acid catalysis. Salicylaldehyde[24)] or 3-hydroxy-4-pyridinecarbaldehyde[25)] undergoes a ready reduction by NADH analogs, in which the *o*-hydroxyl group is presumed to act as the acid to activate the neighboring carbonyl group through a hydrogen bonding. Intermolecular general acid catalysis was examined by using protonated amines as the acids.[26)] However, since protonated amines are usually very weak acids, they can only activate already activated substrates like hexachloroacetone[26a)] or Schiff base.[26b)] In order to examine the acid catalysis of stronger acids, one must make some device, such as to avoid a direct contact of a dihydropyridine moiety with an acid or to design a specially acid-stable NADH analog, since a conventional NADH analog like **1** is acid-unstable.[3-6)] Indeed Shinkai et al. was able to study the acid catalysis of a strong acid by using a specially designed acid-stable **2**[7)] Meanwhile we reported in the previous communications[8,27,28)] that **3** is also an acid-stable NADH analog having comparable reducing activity with that of **1**. A

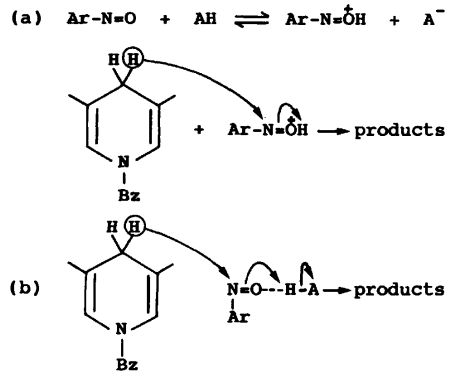


Scheme 1. Acid-promoted protonation and decomposition of (1).

more detailed features of acid catalysis of **3** are now reported for the reduction of nitrosobenzenes. Interests in the reduction of this substrate come from the following two reasons. One is from the mechanistic interests in that nitrosobenzene is much more reactive than carbonyl compounds and hence its reduction would allow to see more detailed features of acid catalysis by using acids of wide range of activity. The other is from the biochemical interests in the carcinogenesis promoted by the nitrosobenzene metabolism.[9-12]

As for the acid-stability, the data in Fig. 2 and Table 1 (k_H^d) indicate **1** to be the most acid-unstable among the three dihydropyridines examined. According to the literatures,[3-6] **1** undergoes a ready protonation to the 5,6-enamine double bond (Scheme 1, **7**). Such an electrophilic addition must be more difficult to occur in the cases of **2** and **3** because the 5,6-double bond is a part of aromatic ring in **2** and in conjugation with the carbonyl group at the 5-position in **3**. It is shown in Table 2 that the rates of decomposition (k_H^d) increase with increasing acidity (pK_a) of the acids. In a parallel way, the acid-catalyzed rates of reduction (k_H^R) also increase with increasing acid-acidity. However, it should be noticed that the rate of decomposition of **3** is negligibly small as compared to that of reduction, i.e. the oxidation of **3** by nitrosobenzene. For example, it can be calculated by using the rate data in Table 1 that the k_{obsd}^d of **3** is $6.44\times10^{-5}\,s^{-1}$ in the presence of 0.1 mol dm^{-3} dichloroacetic acid, while the corresponding k_{obsd} for reduction is $1.40\times10^{-1}\,s^{-1}$ in the presence of 2.0×10^{-3} mol dm^{-3} nitrosobenzene.

As for the reduction, the results in Fig. 4 may be the first to be discussed. The redution is inhibited by adding an acid in the case of **1** in contrast to the acceleration in the other two cases. In the case of **1**, concomitantly to the inhibition, a red-shift of dihydropyridine absorption occurs, even in a mixture of low concentration of [**1**]=[dichloroacetic acid]$=1.0\times10^{-4}$ mol dm^{-3}. Similar red shift is also observed for **3** (355 to 370 nm), but in the presence of a much higher acid concentration. In the case of **2**, the red shift is small or negligible. These red shifts are likely due to the protonation at the 3-carbamoyl group (Scheme 1, **8**).[3]



Scheme 2. Two possible mechanisms of acid catalysis.

Another protonation site is the 5-position **7**. Both of these protonation may deactivate the dihydropyridine ring as a hydride donor. Thus deactivation overcomes the catalysis in the case of **1**. On the other hand, since the protonation at 5-position is negligible in **2** or small in **3**, the total balance is over the catalysis rather than inhibition in these two cases.

The next to be discussed is the data in Figs. 6, 7, and 8, which were obtained by using **3**. In Fig. 6 are shown the two opposing Hammett plots. A positive $\rho=1.35$ for the uncatalyzed k_{un}^R indicates that, in the absence of an acid, an electron-withdrawing substituent helps the substrate to accept the hydride. On the other hand, a negative $\rho=-0.93$ for the acid-catalyzed k_H^R suggests that an electron-donating substituent helps the nitroso group to accept a proton from an acid and to become a better electrophile toward a hydride. Two mechanisms of acid catalysis are conceivable (Scheme 2): (a) Preequilibrium formation of protonated nitrosobenzene followed by a rate-limiting hydride transfer, and (b) a one-step concerted hydride transfer assisted by general acid-catalyzed proton transfer. These two mechanisms may be discernible by examining a Brönsted relationship and the H-D isotope effect. The Brönsted plots in Fig. 7 show a negative slope of $\alpha=-0.34$, based on the data in Table 2 and the pK_a of an acid in acetonitrile.[23] This result strongly suggests a mechanism of general acid catalysis,[29-31] i.e. the second mechanism (b) in Scheme 2. Namely the value 0.34 is

much smaller than 1.0, but rather close to 0.5, suggesting that the proton transfer is not complete, rather in a halfway at the transition state. The deuterium isotope effect shown in Fig. 8 also supports this general acid mechanism. A corrected value of $k_H^R/k_D^R=2.80$ is well in a range of primary isotope effect for general acid catalysis.[29-32]

The above general acid mechanism is of minor importance in aqueous buffer solutions, according to our previous observation.[27] The major mechanism observed at low pH is the hydronium ion (H_3O^+) catalysis, presumably similar to the first mechanism (a) in Scheme 2. Near neutral pH, the rates are independent of pH in aqueous media. These results indicate that the proton transfer is not important at the transition state in aqueous media. It seems to be reasonable that a general acid mechanism becomes important on changing the solvent from more polar water to less polar acetonitrile.

Conformational Study of Acyclic Alcohols by NMR Spectroscopic Analysis, Molecular Force Field and Ab Initio Calculations

Kazuhisa ABE,* Kohichi ITO, Hiroko SUEZAWA, Minoru HIROTA, and Motohiro NISHIO†
Department of Synthetic Chemistry, Division of Materials Science and Chemical Engineering, Faculty of Engineering, Yokohama National University, 156 Tokiwadai, Hodogaya-ku, Yokohama 240
†Central Research Laboratotries, Meiji Seika Kaisha, Ltd. Morooka, Kohoku-ku, Yokohama 222
(Received April 3, 1986)

Conformations of a series of acyclic alcohols ($CH_3CH(R)CH(OH)CH_3$, $CH_3CH(R)CH(OH)CH(R')CH_3$, and $CH_3CH(R)CH(OH)Bu^t$) were studied (1) by measuring vicinal H-H coupling constants ($^3J_{H\text{-}H}$), (2) by lanthanoid-induced shift (LIS) analysis, (3) by molecular mechanics calculations (MM2), and (4) by ab initio (STO-3G, 4-31G geometry optimization) calculations. In the case of conformationally flexible alcohol as exemplified by 2-butanol and 3-pentanol, population of conformers determined by the LIS method do not agree with those determined by the $^3J_{H\text{-}H}$, MM2, and ab initio methods. The discrepancy comes from the fact that the LIS measurement gives the most stable conformation of the alcohol in the LSR-alcohol complex and not of the free alcohol. In some flexible molecules, the most stable conformer in the complex can be different from that of the free molecule. In general, the conformational equilibrium is shifted by coordination of the shift reagent to the conformer whose alkyl chain stretches opposite to the direction of the coordination site of the shift reagent.

Lanthanoid-induced shift (LIS) analysis[1,2] by NMR is a convenient method to investigate the conformation of organic compounds. The authors have reported the usefulness of the LIS simulation to the conformational studies of rather rigid molecules.[3-6] But a question about the effectiveness of LIS analysis arises when it is applied to conformationally flexible molecules because the shift reagent is bulky and the enthalpies (ΔH) of the complex formation between shift reagents and some substrates are fairly large (8—10 kcal mol^{-1} (1 cal=4.184 J)).[7,8] The conformational equilibria for the flexible molecules can be shifted significantly by the coordination of the shift reagent to the substrates because the free energy differences among the conformers of flexible molecules are considerably less than the ΔH of the complex formation. Conformational changes by the coordination of the lanthanoid shift reagents (LSR) were evidenced by the LIS measurement on dioxaphosphorinane derivatives[9] and *t*-butoxycarbonyl α-amino acids esters.[10] Therefore, conformations of flexible secondary alcohols were studied both experimentally [(1) the $^3J_{H\text{-}H}$ method and (2) the LIS analysis] and theoretically [(3) MM2 and (4) ab initio calculations]. Populations of the stable conformers obtained by these methods were compared with each other, and the reliability and the limitation of each method was discussed.

Experimental

Methods for Conformational Analyses. Conformations of acyclic secondary alcohols were determined by the following four methods. ^{1}H NMR spectra at an ambient temperature were recorded on a JEOL FX-90Q or a GX-400 spectrometer.

(1) $^3J_{H\text{-}H}$ Method: $^3J_{H\text{-}H}$ was measured with a GX-400 spectrometer on a homo decoupling mode. As the observed $^3J_{H\text{-}H}$ values reflect the populations of stable conformers, they were determined from the observed $^3J_{H\text{-}H}$ by assuming that the observed coupling constant ($^3J_{obsd}$) is the averaged value of ^3J_g and ^3J_t in proportion to their populations and in reference to the reported vicinal H-H coupling constants[11] for which conformation of vicinal protons are gauche (J_g=1.9 Hz) and trans (J_t=11.1 Hz).

(2) LIS Analysis: Yb(fod)$_3$ was used as an LSR in $CDCl_3$ because the contribution of the contact shift to LIS is negligibly small.[12] LIS_i^{obsd} of a nucleus i was determined experimentally from the induced chemical shift vs. [LSR]/[substrate] plots in the range of [LSR]/[substrate] to be 0—0.3. LIS_i^{calcd} was calculated from the sterical factor ($3\cos^2\theta-1/r^3$) of the McConnel-Robertson equation.[13,14] From these LIS data (LIS_i^{obsd} and LIS_i^{calcd}), the agreement factor (R)[15] was calculated by Eq. 1 and the geometry in which R showed minimal value was assigned to the most stable conformation.

$$R = [\sum_i (LIS_i^{obsd} - LIS_i^{calcd})^2 / \sum_i (LIS_i^{obsd})^2]^{1/2} \quad (1)$$

In non-rigid molecules, effective chemical shifts are evaluated by averaging the intrinsic chemical shift weighted by the populations of each conformer. Therefore, we had better take into account the differences of coordination ability of LSR towards each stable conformer and the relative accessibility of LSR to each coordination site of conformers (vide infra). By this LIS simulation we can correctly evaluate the LIS_i^{calcd} and R in Eq. 1.

The coordination ability[16] of each conformer was estimated by the competitive LIS experiment between conformationally rigid model compounds in which Yb(fod)$_3$ competitively coordinated to two model compounds. The coordination ability index of conformer **A** and **B** (C_A and C_B) was defined by Eq. 2.

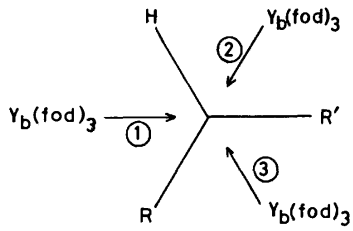
$$C_A/C_B = [S_A^m/S_A^s(1-S_B^m/S_B^s)]/[S_B^m/S_B^s(1-S_A^m/S_A^s)] \quad (2)$$

S_A^m or S_B^m: LIS value induced by the competitive coordination of Yb(fod)$_3$ towards conformer **A** and **B**.

S_A^s or S_B^s are LIS values of conformer **A** and **B** induced by Yb(fod)$_3$.

The relative accessibility of Yb(fod)$_3$ to each coordination site of conformers is not thought to be equally favorable.

At the coordination sites 1, 2, and 3 of conformer k of the secondary alcohol illustrated below, the calculated LIS of nucleus i for conformer k is given by Eq. 3.



$$S_{k,i} = A_1S_{k,i}(1) + A_2S_{k,i}(2) + A_3S_{k,i}(3) \quad (3)$$

Here, A_1, A_2, and A_3 are relative accessibility of LSR at the coordination sites 1, 2, and 3, respectively.

$S_{k,i}(1)$, $S_{k,i}(2)$, and $S_{k,i}(3)$ are the calculated LIS's for nucleus i of conformer k in case LSR coordinated to the coordination site 1, 2, and 3, respectively.

By use of coordination ability index, C, and $S_{k,i}$ determined by Eqs. 2 and 3, the calculated LIS corresponding to the observed LIS for nucleus i on NMR spectra is derived by Eq. 4, if a secondary alcohol molecule is assumed to have three stable conformers **I**, **II**, and **III**.

$$S_i^{calcd} = C_IX_IS_{I,i} + C_{II}X_{II}S_{II,i} + C_{III}X_{III}S_{III,i} \quad (4)$$

Where X_I, X_{II}, X_{III} are population of the stable conformer **I**, **II**, **III**, respectively.

(3) MM2 Calculation:[17] The calculations were performed on a HITAC M-280H using the MM2 program modified by E. Osawa[18]. The geometry optimization was carried out for the expected stable conformers and the steric energy was calculated. From the relative steric energies of stable conformers, the population of each conformer was calculated tentatively by applying Boltzmann's theorem.

(4) Ab Initio Calculation: The ab initio calculations were performed on a HITAC M-200H by use of the Gaussian 80 (QCPE 13) program at the Computer Center of the Institute for Molecular Science. This program allows 127 Contracted Gaussian Type Orbitals (CGTO) for the purpose of the Hartree-Fock SCF calculation. However, geometry optimization can be carried out on the molecules with CGTO≦70. Geometries of conformers were optimized with the Hartree-Fock methods with the STO-3G or 4-31G basis set within the limit for the number of CGTO's. As the optimized geometries and relative energies between stable conformers obtained by MM2 geometry optimization calculations were nearly identical with those obtained by ab initio geometry optimization calculations with the STO-3G or 4-31G basis set (CGTO<70), optimized geometries obtained by MM2 were used as the input geometries for ab initio calculations and the energies were calculated with the STO-3G basis set in the case when the optimization by ab initio calculation is limited (CGTO>70).

Preparation of Materials. Commercially available secondary alcohols were purified by distillation. As commercially available 2,6-dimethylcyclohexanol is a mixture of three stereoisomers, each isomer was separated by column chromatography on silica gel (eluant; benzene-ether (v/v 6:1)) and by gas chromatography (column; SE-30, column Temp; 90 °C).

$Yb(fod)_3$ was prepared by reacting 1,1,1,2,2,3,3-heptafluoro-2,2-dimethyl-3,5-octanedione ($H(fod)_3$) with ytterbium nitrate in aqueous methanol solution at pH 4—6[19-21] and purified by sublimation in vacuo.

Results and Discussion

Coordination Ability of $Yb(fod)_3$ to the Conformers. Coordination ability of $Yb(fod)_3$ to each stable conformer of a secondary alcohol was estimated from the LIS for conformationally rigid model compounds. *t*-2-Methyl-*t*-6-methyl-*r*-1-cyclohexanol (a), *trans*-2-methylcyclohexanol (b), cyclohexanol (c), and *t*(or *c*)-2-methyl-*c*(or *t*)-6-methyl-*r*-1-cyclohexanol (d) were chosen as rigid model compounds. From the LIS by sole (S^s) or competitive (S^m) coordination of $Yb(fod)_3$ to the model compounds, coordination ability index (C) in reference to cyclohexanol of each model compound was evaluated (Table 1) by using Eq. 2.

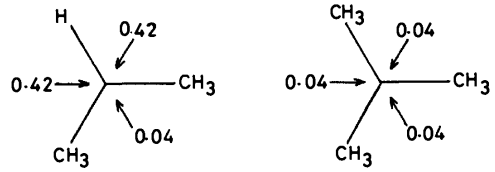
Relative Accessibility of $Yb(fod)_3$. Relative accessibility (A) of $Yb(fod)_3$ at each coordination site of some secondary alcohols was estimated from the competitive experiment where the LIS's for two different alcohols were induced by competitive coordination of $Yb(fod)_3$. In the case of isopropyl alcohol R, R'=CH_3, for example, relative accessibilities A_1, A_2 (A_1=A_2), and A_3 were estimated from the competitive LIS experiment using a mixture (1 : 1 mol/mol) of isopropyl alcohol and *t*-butyl alcohol. From the LIS of each alcohol we can determine the ratio of coordination ability indexes of isopropyl alcohol (C_{iso}) and *t*-butyl alcohol (C_{tert}) by Eq. 2.

$$S_{Iso}/C_{tert} = 0.70 \times (1-0.25)/0.25 \times (1-0.70) = 7$$
$$(S_{Iso}^m/S_{Iso}^s = 0.70 \quad S_{tert}^m/S_{tert}^s = 0.25)$$
$$C_{Iso} : C_{tert} = 0.88 : 0.12$$

Table 1. Coordination Ability Indexes of $Yb(fod)_3$ to the Model Compounds for LIS Simulation of Acyclic Secondary Alcohols

			(a) *t*-2-Methyl-t-6-methyl-*r*-1-cyclohexanol	(b) *trans*-2-Methyl-cyclohexanol	(c) Cyclohexanol	(d) *t*(or *c*)-2-Methyl-*c*(or *t*)-6-methyl-*r*-1-cyclohexanol
0.18	0.57	1.0	0.22

From this ratio, the relative accessibility for each coordination site of isopropyl and *t*-butyl alcohols can be estimated as shown below by assuming that the coordination is solely dependent on the steric effect and that the coordination from the direction between the two methyl groups is equally favored in isopropyl and *t*-butyl alcohols.



The relative accessibility at each coordination site of several secondary alcohols was determined in the same

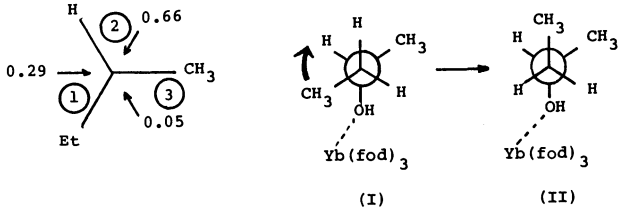
way (Table 2).

Conformational Equilibrium of Acyclic Secondary Alcohols. The LIS's for the proton and carbon resonances of acyclic secondary alcohols **1**—**7** are listed in Table 3.

Populations of stable conformers for various types of alcohols (**1**—**7**) were estimated both experimentally and theoretically and given in Tables 4, 5, and 6.

Conformational Equilibrium Determined by the LIS Analysis: The conformational distribution derived from the LIS analysis is different from those of ab initio, MM2, and $^3J_{H-H}$ in the cases of conformationally flexible alcohols shown in Tables 4 and 5. In the case of 2-butanol, ab initio, MM2, and $^3J_{H-H}$ methods lead to the same conclusion on the conformer distribution. The most stable conformer **I** has a stretched alkyl chain, and the population decreases in the order **I**, **II**, and **III**. On the contrary, the LIS method concludes that conformer **II** is the most stable. This can be explained that conformational equilibrium is shifted by the complexation to Yb(fod)$_3$ on 2-butanol. Conformational preferences of alcohol molecules in the

LSR-alcohol complexes can be quite different from those of uncomplexed alcohols since the complexes are apt to lessen the steric strain around the metal ion by the conformational change of the flexible alcohol component. In this aspect, we considered the sterical crowdedness at the coordination sites of 2-butanol. It is unlikely that the conformational equilibrium will be shifted by coordination of $Yb(fod)_3$ at site 2 (the relative accessibility is the highest: 0.66) because the sterical crowdedness is not large. However, the change of the conformational equilibrium by coordination of $Yb(fod)_3$ at site 1 (relative accessibility is 0.29) is probable because the sterical congestion after complexation is estimated to be very large and the ethyl group is flexible. Therefore, a part of conformer **I** is expected to isomerize to conformer **II** by the coordination of $Yb(fod)_3$ at site 1 to avert the sterical congestion.



In the case of 3-methyl-2-butanol (**2**), we also find that the LIS method again predicts a conformational distribution different from those obtained by the three other methods, i.e., the LIS method leads to a larger population of conformer **I** and a less population of conformer **III** than the populations of the corresponding conformers estimated from the $^3J_{H\text{-}H}$ method and MM2. This shift in conformational equlibrium is thought to come from the conformation change from **III** to **I** by the coordination of $Yb(fod)_3$. As the sterical congestion around OH group is large in conformer **III**, it is easily converted to conformer **I** to relax the crowdedness.

Table 5 shows the populations of conformers for $CH_3CH(R)CH(OH)CH(R')CH_3$ (**3**, **4**, and **5**). Alcohols of this type have 9 stable conformations (Fig. 1) arising from the internal rotations about C_2-C_3 and C_4-C_3 bonds. In the case of 3-pentanol (**3**) both ab initio and MM2 calculations predict that conformer **I** is the most stable and the predicted conformational distribution from these calculations is similar. But LIS method predicts that **II** and **IV** are the most stable conformers which are favorable for complex formation with $Yb(fod)_3$. The LIS data suggest that a part of the most stable conformer **I** is converted to conformer **II** or **IV** by the coordination of $Yb(fod)_3$ and the conformational equilibrium is shifted. The same trends are also noticed in the cases of 2-methyl-3-pentanol (**4**) and 2,4-dimethyl-3-pentanol (**5**), where the LIS methods again resulted in the dominating conformers with favorable coordination site (s). From the results discussed above, it is certain that the conformational equilibria of flexible acyclic alcohols are shifted by the coordination of the shift reagent towards the conformer whose alkyl chains stretch opposite to the direction of the coordination site of the shift reagent.

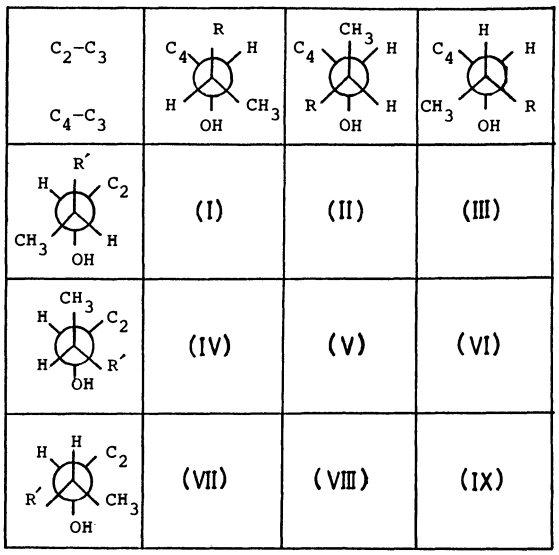


Fig. 1. Stable conformations for $CH_3CH(R)CH(OH)$-$CH(R')CH^3$-type alcohols.

On the contrary, the LIS method correctly predicts the conformational distribution of sterically congested $CH_3CH(R)CH(OH)Bu^t$-type secondary alcohols as shown in Table 6. In both cases (**6** and **7**) the conformational populations from the LIS method agreed with those from ab initio, MM2, and $^3J_{H\text{-}H}$ methods nearly quantitatively. All methods predict that the most stable conformer is **III** for **6** and **I** for **7**. Sterical congestion is so large in these alcohols that the conformational change during the complex formation with shift reagent becomes very difficult.[22]

Conformational Equlibrium Determined by MM2 and Ab Initio Calculations: In general, MM2 and ab initio calculations predict the conformational distribution correctly. From the geometry optimization study by MM2 and ab initio calculation on the every conformer of 2-butanol (**1**) (Table 3), it was shown that the populations and optimized geometries determined by the both calculations were almost the same. As proved by the several comparative studies shown above, the geometries and populations of the conformers can be predicted with enough accuracy by MM2. When we consider about the economical and technical restriction for ab initio calculation (CPU time, the number of CGTO), it is practical to use MM2 calculation for a conformational study of alcohols.

From the MM2 and ab initio studies, we considered the conformational equilibrium from a viewpoint of relative energy (ΔE) of each conformer. As shown in Table 4 and 5, ΔE's between the most stable and next stable conformers of **1**—**5** are very small (less than 1 kcal mol^{-1}). Therefore, we should recognize that the most stable conformers are convertible by the coordination of shift reagents in the cases of these conforma-

tionally flexible alcohols. The sequence of stability of the conformers can be perturbed by the complexation with shift reagents.

On the other hand, ΔE's between the most and the next stable conformers are pretty large in the cases of sterically congested alcohols. As shown in Table 6, ΔE's for **6** and **7** are larger (more than 2 kcal mol^{-1}) than those ΔE's for **1**—**5**. Sterical congestion in **6** and **7** is reflected on their optimized geometries determined by MM2. In the case of 2,2,4-trimethyl-3-pentanol (**6**), for example, widening of bond angles and deviation of dihedral angles from the normal values for both trans and gauche conformers were rationalized by the calculations. This fact, as well as their considerably large steric energies, suggests the presence of sterical congestion in these molecules. To avert the steric repulsion between gauche-positioned Bu^t, OH and CH_3 groups in the most stable conformer **III**, the dihedral angles between these groups Bu^t-C-C-CH_3, and HO-C-C-CH_3) are deviated from the normal value of 60° to ca. 90°.

Conformational Equilibrium Determined from the $^3J_{H\text{-}H}$: Application of the Karplus type equation on the observed $^3J_{H\text{-}H}$ predicts reasonable conformational distributions which agree with those obtained by MM2 and ab initio calculations. Though the $^3J_{H\text{-}H}$ method can not predict individual population of each conformer in the cases of **3**—**5** (Table 5), the summed-up populations ($X_1+X_2+X_3 : X_4+X_5+X_6 : X_7+X_8+X_9$) show fairly good agreement with those from the ab initio and MM2 calculations. The populations from the $^3J_{H\text{-}H}$ agreed even in the case of sterically congested alcohols (**6** and **7**). However, there remains a question whether $^3J_{H\text{-}H}$ method is applicable properly to the conformational equilibria of such distorted molecules.

In conclusion, the conformational equilibria for flexible alcohols can often be perturbed significantly by the complexation with LSR. Thus attention must be paid when the conclusions from the LIS analysis are compared with those from other theoretical and experimental methods. MM2 predicts the nearly identical populations of conformers and geometries with those derived from ab initio calculations and is proved to be a powerful tool in this field.

The authors are very grateful to Prof. Keiji Morokuma, the Institute for Molecular Science, for his kind permission to use a HITAC M-200H computer and the Gaussian 80 program and also for his valuable advice.

22) Alternative explanation that the steric hindrance prevents these alcohols from forming a strong LSR-alcohol complex seems possible. However, the magnitude of their induced shifts are comparable to those of less hindered alcohols, and the contribution of weaker coordinate bond should be at most subsidiary.

Preparation of 2-Azido-2-deoxypentose Derivatives

Hironobu HASHIMOTO,* Koichi ARAKI, Yoshihiro SAITO, Manabu KAWA, and Juji YOSHIMURA
Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received April 8, 1986)

2-Azido-2-deoxypentose derivatives having D-*xylo* and L-*arabino* configurations were prepared via azidonitration of 1,5-anhydro-2-deoxypent-1-enitols, that is, xylal and arabinal derivatives, respectively. The L-*ribo* isomer was prepared by substitution of 2-trifluoromethylsulfonyloxy and 2-(1-imidazolylsulfonyloxy) group with azide. The D-*xylo* isomer was converted into the corresponding D-*ribo* and D-*lyxo* isomers.

Recently 2-amino-2-deoxypentoses were reported as components of antibiotics such as glycocinnamoylspermidines (cinodine)[1] as well as adenine nucleosides[2] isolated from bacterial metabolites. On the other hand, 2-azido sugars have been used by preference on the occasion of synthesis of biologically important oligosaccharides[3] as a precursor of 2-amino sugars which are bonded through 1,2-cis glycosidic linkage. We have studied preparation of 2-azido-2-deoxypentoses as a part of total synthesis of cinodine which had an α-ureylene linkage through 2-amino-2-deoxy-D-xylose, while very recently this linkage was revised to be β in the course of structure elucidation of a closely related antibiotic, glycocinnasperimicin D.[4]

For the introduction of azido group the ring-opening reaction of epoxy derivatives and the substitution reaction have been used as the conventional methods. In the case of 2-azido-2-deoxypentopyranoside, however, both methods encounter synthetic difficulties. In the former, the conformational flexibility of pentopyransosides leads to lose the stereoelectronic control of the ring-opening reaction, that is, the reaction does not obey the Fürst-Plattner rule any more,[5] while in the latter the substitution at C-2 carbon are retarded by the neighboring anomeric center which has two polar carbon-oxygen bonds.[6] In this paper 2-azido-2-deoxypentopyranosides having D-*xylo* (and D-*lyxo* as minor component) and L-*arabino* configurations were prepared by the azidonitration method[7] and L-*ribo* isomer by substitution reaction of the reactive 2-*O*-sulfonyl derivatives with azide. Furthermore, D-*ribo* and L-*lyxo* isomers were derived from the D-*xylo* isomer by inversion of hydroxyl groups via the corresponding 3-ulose and 3,4-anhydro derivative, respectively.

Results and Discussion

Although the azidonitration of 3,4-di-*O*-acetyl-1,5-anhydro-2-deoxy-D-*threo*-pent-1-enitol (D-xylal diacetate, **1**) was first reported by Lemieux and Ratcliffe,[7] they reported only the ratio of D-*xylo* and D-*lyxo* isomers as 2:1. In this paper the isomer ratio was roughly estimated from the isolated yields after conversion into 1-acetates or methyl glycosides. For the former conversion once isolated and crude mixture of azidonitrates was acetylated with acetic anhydride and sodium acetate at 70 °C. For the latter methanol was added directly to the reaction solution of azidonitration. Methyl glycosides were obtained in higher yields than 1-acetates as shown in Table. In the case of **1**, it seems that the reaction temperature is one of the important factors controlling the ratio of two isomers (**3**/**6** or **4**/**7**) as reported for the azidonitration of D-glucal triacetate.[8] While at −10—−15 °C the ratio was about 2—3, at the lower temperature, albeit with higher molar ratios of cerium(IV) ammonium nitrate and sodium azide, the ratio increased to 12. However, more detailed experiments should be necessary for definitive explanation of the stereoselectivity. Thus,

Table 1. Azidonitration of 3,4-Di-*O*-acetyl-2-deoxy-D-*threo*-pent-1-enitol (**1**) and Its L-*Erythro* Isomer (**2**)

Glycal	Molar ratio[a]		Atmosphere	Temperature	Product	Ratio

1	4.3	2.3	air	−20	**3**(58), **6**(5)	12
1	4.0	2.0	air	−20	**4**(84), **7**[d]	>15
2	3.0	1.5	air	−10	**8**(55, α/β=1.8)	e)

a) Glycal=1.0. b) Cerium(IV) ammonium nitrate. c) eq=equatorial; ax=axial. d) Less than 5%. e) The product with ax-N_3 group colud not be isolated.

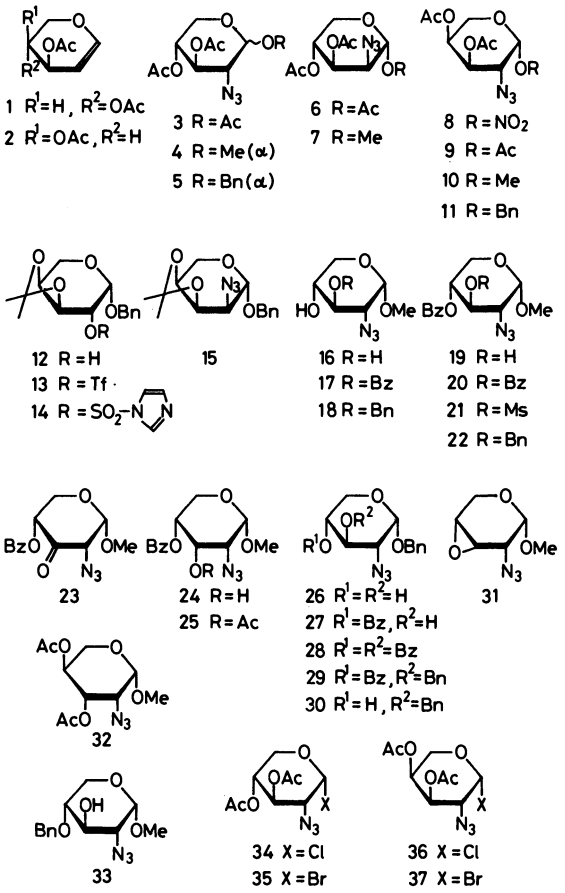
the reaction could be carried out even under aerobic conditions at −20 °C, for instance, to give **4** almost selectively in 84% yield, where the *lyxo* isomer (**7**) was obtained in trace amount.

On the other hand, the azidonitration of 3,4-di-*O*-acetyl-1,5-anhydro-2-deoxy-L-*erythro*-pent-1-enitol (L-arabinal diacetate, **2**), proceeded stereoselectively even at −10 °C to give D-*arabino* isomer (**9** or **10**) in a similar manner as D-galactal triacetate.[7] In this case the β-anomer of azidonitrate **8** could be isolated as crystals in 52% yield. The stereoselectivity can be explained by the steric hindrance of axially oriented 4-acetoxyl group in the half-chair conformation to favor the attack of azide radical from its opposite site.

The corresponding benzyl glycosides (**5** and **11**) were prepared by treatment of the azido nitrates with benzyl alcohol. The yield of **5** was 55% including the azidonitration step, while that of **11** from the nitrate **8** was 90%. Thus *xylo* and *arabino* isomers of 2-azido-2-deoxypentopyranose derivatives could be prepared by azidonitration method, and the remaining *ribo* and *lyxo* isomers was planned to be derived by different methods.

Preparation of 2-azido-2-deoxyribopyranosides was achieved by two methods. In the first method benzyl 3,4-*O*-isopropylidene-β-L-arabinopyranoside (**12**) was used as an easily-available starting compound and converted into the 2-triflate (**13**) and 2-(1-imidazole-sulfonate) (**14**), which are the derivatives of choice often used for the retarded substitution reaction.[9] Treatment of **13** and **14** with sodium azide gave the corresponding 2-azido derivative (**15**) in 27% (2 steps) and 80% yields, respectively. In the second method the configuration on C-3 of D-*xylo* isomer was inverted by oxidation and successive reduction. The deacetylated derivative (**16**) of **4** was benzoylated with benzoyl chloride and triethylamine in acetone at room temperature to give 3-benzoate (**17**), 4-benzoate (**19**), and 3,4-dibenzoate (**20**) in 5, 65, and 29% yields, respectively. Oxidation of **19** with dimethyl sulfoxide and trifluoroacetic anhydride followed by reduction of the resulting 3-ulose (**23**) with sodium borohydride afforded in 75% yield an another *ribo* isomer (**24**), which was further characterized as the 3-acetate (**25**). The corresponding benzyl glycoside derivatives (**26**—**28**) were prepared in a similar manner as described for the methyl glycosides (**16**, **19**, and **20**).

The remaining isomer of 2-azido-2-deoxypentose, that is, *lyxo* isomer could be also derived from the *xylo* isomer. The 3-mesylate (**21**) of **19** was treated with potassium hydroxide in methanol gave the 3,4-anhydro derivative (**31**) in 76% yield. Treatment of **31** with sodium acetate and acetic acid in *N*,*N*-dimethylformamide at 100 °C, followed by acetylation, gave the desired L-*lyxo* isomer (**32**) predominantly in 54% yield together with the D-*xylo* isomer **4** in 25% yield. Thus facile preparative methods of all stereoisomers of 2-azido-2-deoxypentose could be established.



Furthermore, some *O*-benzyl derivatives and glycosyl halides were also prepared. Methyl 2-azido-3-*O*-benzyl-2-deoxy-D-xylopyranoside (**18**) were easily derived via **22** in 74% yield, by treatment of **19** with benzyl bromide and silver oxide followed by debenzoylation. The corresponding benzyl glycoside (**30**) of **18** was also prepared similarly via **29** from **27**. On the other hand, treatment of 3,4-*O*-dibutylstannylene derivative of **16** with benzyl bromide and tetraethylammonium bromide[10] gave the 4-*O*-benzyl derivative (**33**) predominantly in 70% yield together with **18** in 13% yield. This regioselectivity between two equatorial hydroxyl groups may be noteworthy. Acetohalogeno sugars of D-*xylo* and L-*arabino* configurations were derived from the corresponding acetate (**3**) and nitrate (**8**), respectively. Treatment of **3** with titanium tetrachloride and tetrabromide gave α-chloride (**34**) and α-bromide (**35**) in 77 and 63%, respectively. For the latter, bromination with hydrogen bromide in acetic acid gave a better yield. On the other hand, substitution of **8** with halide ions using tetraethylammonium halides gave β-chloride (**36**) and β-bromide (**37**) in 80 and 55%, respectively. These derivatives should be useful as synthetic intermediates for 2-amino-2-deoxypentose-containing antibiotics such as cinodine.

Experimental

Melting points were determined with a Mel-Temp appara-

tus and are not corrected. Optical rotations were measured using a 0.5-dm tube and a Carl Zeiss LEP-Al or JASCO DIP-4 polarimeter. IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer. ^{1}H NMR spectra were recorded at 100 MHz with a JEOL PS-100 spectrometer in $CDCl_3$ with tetramethylsilane as the internal standard, unless stated otherwise. Column chromatography and preparative TLC were performed on Wakogel C-200 (Wako Pure Chemical Industries, Ltd.) and Kieselgel 60 HF_{254} (Merck), respectively. Evaporations were conducted under diminished pressure at 50 °.

Azidonitration of Glycals. To a solution of a glycal acetate (2.0 g, 10 mmol) in acetonitrile (70 ml) was added sodium azide (1.6—4.4 g, 11—30 mmol) and cerium(IV) ammonium nitrate (CAN, 10.9—23.5 g, 20—43 mmol) with stirring and cooling between −10 and −20 °C under nitrogen (occasionally under air). The solution was kept at the same temperature with stirring for 5—6 h, and mixed with ether and water. The ether layer was washed with water, dried and evaporated to give a crude syrupy mixture of 2-azido-1-nitrate derivatives.

1,3,4-Tri-*O*-acetyl-2-azido-2-deoxy-D-xylopyranose (3) and Its α-D-*Lyxo* Isomer (6). A crude mixture of azidonitrates obtained from **1** (17.0 g, 85 mmol), sodium azide (13 g, 200 mmol), and CAN (200 g, 365 mmol) at −20 °C under air as described above, was dissolved in acetic acid (100 ml) and heated at 70 °C for 2 h with stirring in the presence of sodium acetate (10 g). The reaction solution was evaporated and the residue was mixed thoroughly with chloroform and water. The organic layer was separated, dried and evaporated to give a syrup, which was fractionated on a silica-gel column with benzene-acetone (30 : 1) or toluene-ethyl acetate (19 : 1) to give **3** and **6** in 58 and 5% yields, respectively. Compound **3** was proved to be a mixture of α- and β-anomers with an approximate ratio of **10** by ^{1}H NMR.

3: Syrup, IR (NaCl) 2105 (azido) and 1750 (ester) cm^{-1}; ^{1}H NMR α-anomer δ=6.20 (d, $J_{1,2}$=3.9 Hz, H-1), 3.55 (dd, $J_{2,3}$=10.5 Hz, H-2), 5.44 (t, $J_{3,4}$=10.5 Hz, H-3), 4.99 (dt, $J_{4,5}$=10.5 Hz, $J_{4,5'}$=6.0 Hz, H-4), 3.67 (t, $J_{5,5'}$=10.5 Hz, H-5), 3.91 (dd, H-5′), 2.04, 2.12, and 2.18 (each s, OAc), β-anomer δ=5.50 (d, $J_{1,2}$=8.3 Hz, H-1), 3.60 (dd, $J_{2,3}$=9.0 Hz, H-2), 5.10 (t, $J_{3,4}$=9.0 Hz, H-3), 5.0 (H-4), 3.45 (dd, $J_{4,5}$=9.0 Hz, $J_{5,5'}$=11.8 Hz, H-5), 4.10 (dd, $J_{4,5'}$=4.9 Hz, H-5′), 2.04, 2.12, and 2.17 (each s, OAc).

Found: C, 43.89; H, 4.95; N, 13.95%. Calcd for $C_{11}H_{15}N_3O_7$: C, 43.86, H, 5.02; N, 13.95%.

6: Syrup, $[\alpha]_D$ +1.5° (*c* 1.0, $CHCl_3$). ^{1}H NMR δ=5.94 (d, $J_{1,2}$=5.1 Hz, H-1), 3.96 (dd, $J_{2,3}$=3.6 Hz, H-2), 5.36 (dd, $J_{3,4}$=7.1 Hz, H-3), 5.06 (m, H-4), 3.76 (dd, $J_{4,5}$=6.0 Hz, $J_{5,5'}$=12.0 Hz, H-5), 3.98 (dd, $J_{4,5'}$=3.8 Hz, H-5′) and 2.06—2.10 (OAc).

Found: C, 43.32; H, 5.07; N, 13.73%. Calcd for $C_{11}H_{15}N_3O_7$: C, 43.86; H, 5.02; N, 13.95%.

Methyl 3,4-Di-*O*-acetyl-2-azido-2-deoxy-α-D-xylopyranoside (4) and Its α-D-*Lyxo* Isomer (7). To a solution of the azidonitration reaction (**1** 2.4 g, NaN_3 1.57 g, CAN 26.6 g in CH_3CN 85 ml) carried out for 5.5 h in the same manner as described for **3** was added methanol (80 ml) together with chloroform (40 ml) and anhydrous magnesium sulfate. The mixture was stirred at room temperature for 16 h. Insoluble materials were filtered off and washed with chloroform. The filtrate was washed with water, dried and evaporated to give a syrup, which was fractionated on a silica-gel column with hexane-ethyl acetate (4 : 1) to give **4** in 84% yield and **7** in a trace amount. **4**: Syrup, $[\alpha]_D$ +128.5° (*c* 1.0, $CHCl_3$); IR (NaCl) 2103 (azido) and 1750 (ester) cm^{-1}; ^{1}H NMR δ=4.80 (d, $J_{1,2}$=3.3 Hz, H-1), 3.27 (dd, $J_{2,3}$=10.5 Hz, H-2), 5.46 (dd, $J_{3,4}$=9.6 Hz, H-3), 4.94 (dt, $J_{4,5}$=9.6 Hz, $J_{4,5'}$=6.0 Hz, H-4), 3.80 (dd, $J_{5,5'}$=10.8 Hz, H-5), 3.5 (H-5′), 2.04 and 2.11 (each s, OAc), and 3.46 (s, OMe).

Found: C, 44.39; H, 5.55; N, 15.11%. Calcd for $C_{10}H_{15}N_3O_6$: C, 43.96; H, 5.53; N, 15.38%.

7: Syrup, $[\alpha]_D$ −145.0° (*c* 1.0, $CHCl_3$). ^{1}H NMR δ=4.65 (d, $J_{1,2}$=2.7 Hz, H-1), 3.73 (dd, $J_{2,3}$=3.6 Hz, H-2), 5.10 (dd, $J_{3,4}$=6.3 Hz, H-3), 4.94 (dt, $J_{4,5}$=5.3 Hz, $J_{4,5'}$=3.8 Hz, H-4), 3.41 (dd, $J_{5,5'}$=12.2 Hz, H-5), 4.09 (dd, H-5′), 3.52 (s, OMe), 2.07 and 2.13 (each s, OAc).

Found: C, 43.73; H, 5.35; N, 15.14%. Calcd for $C_{10}H_{15}N_3O_6$: C, 43.96; H, 5.53; N, 15.38%.

Benzyl 3,4-Di-*O*-acetyl-2-azido-2-deoxy-α-D-xylopyranoside (5). A crude mixture of azidonitrates obtained from **1** (3.2 g, 16 mmol) in the same manner as described for **3**, was mixed with benzyl alcohol (7.8 ml, 69 mmol) in chloroform (30 ml). The solution was kept at room temperature for 24 h, washed with water, dried and evaporated to give a syrup, which was purified on a silica-gel column with benzene-acetone (30 : 1) to give **5** in 55% yield, $[\alpha]_D$ +104.7° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.98 (d, $J_{1,2}$=3.3 Hz, H-1), 3.22 (dd, $J_{2,3}$=10.4 Hz, H-2), 5.49 (dd, $J_{3,4}$=9.2 Hz, H-3), 2.04 and 2.10 (each s, OAc), 4.56 and 4.76 (ABq, J=12.8 Hz, CH_2 in Bn) and 7.36 (s, Ph).

Found: C, 54.83; H, 5.20; N, 11.65%. Calcd for $C_{16}H_{19}N_3O_6$: C, 55.01; H, 5.48; N, 12.03%.

3,4-Di-*O*-acetyl-2-azido-2-deoxy-1-*O*-nitro-β-L-arabinopyranose (8). Azidonitration of **2** (10 mmol) with sodium azide (15 mmol) and CAN (30 mmol) was carried out at −10 °C in the same manner as described for **3**. A crude azido nitrate was purified on silica-gel column to give a syrupy mixture of α- and β-nitrate (55%, α : β = 1.8 : 1) and only the β-anomer (**8**) was obtained as crystal from ether-hexane in 20% yield, mp 107—108.5 °C, $[\alpha]_D$ +18.4° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=5.57 (d, $J_{1,2}$=8.0 Hz, H-1), 3.86 (dd, $J_{2,3}$=9.7 Hz, H-2), 4.98 (dd, $J_{3,4}$=3.5 Hz, H-3), 5.26 (m, H-4), 4.10 (dd, $J_{4,5}$=2.6 Hz, $J_{5,5'}$=12.6 Hz, H-5), 3.78 (dd, $J_{4,5'}$=1.5 Hz, H-5′), 2.10 and 2.16 (each s, OAc).

Found: C, 35.85; H, 4.04; N, 18.05%. Calcd for $C_9H_{12}N_4O_8$: C, 35.53; H, 3.98; N, 18.42%.

1,3,4-Tri-*O*-acetyl-2-azido-2-deoxy-β-L-arabinopyranose (9). The glycosyl nitrate **8** (1.8 g, 5.6 mmol) was acetolyzed with acetic acid (10 ml) and anhydrous sodium acetate (0.8 g, 9.8 mmol) at 100 °C for 50 min. The residue obtained by direct evaporation of the reaction mixture was dissolved in chloroform. The solution was washed with water, dried and evaporated to give a syrup, which was purified on a silica-gel column with hexane-ethyl acetate (4 : 1) to afford **9** as crystal in 86% yield, mp 97—98 °C, $[\alpha]_D$ +128.2° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=6.28 (d, $J_{1,2}$=3.3 Hz, H-1), 3.96 (dd, $J_{2,3}$=10.5 Hz, H-2), 5.31 (dd, $J_{3,4}$=3.0 Hz, H-3), 5.31 (broad s, H-4), 3.80 (dd, $J_{4,5}$=1.8 Hz, $J_{5,5'}$=13.0 Hz, H-5), 4.04 (dd, $J_{4,5'}$=1.4 Hz, H-5′), 2.10 and 2.17 (each s, OAc).

Found: C, 44.12; H, 4.94; N, 13.75%. Calcd for $C_{11}H_{15}N_3O_7$: C, 43.86; H, 5.02; N, 13.95%.

Methyl 3,4-Di-*O*-acetyl-2-azido-2-deoxy-β-L-arabinopyranoside (10). The nitrate **8** (400 mg, 1.3 mmol) was dissolved in absolute methanol (10 ml) and the solution was kept at room temperature overnight with stirring in the

presence of molecular sieve 3 A. After removal of molecular sieve by filtration the filtrate was evaporated and the resulting syrupy residue was purified on preparative TLC on silica gel with benzene–acetone (40:3) to give **10** in 64% yield, $[\alpha]_D$ +218° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.89 (d, $J_{1,2}$= 3.4 Hz, H-1), 3.74 (m, H-2), 5.32 (dd, $J_{2,3}$=10.5 Hz, $J_{3,4}$=3.0 Hz, H-3), 5.29 (m, H-4), 3.70 (dd, $J_{4,5}$=1.8 Hz, $J_{5,5'}$=13.0 Hz, H-5), 3.96 (dd, $J_{4,5'}$=1.5 Hz, H-5'), 2.10 and 2.18 (each s, OAc), and 3.50 (s, OMe).

Found: C, 44.12; H, 5.27; N, 15.07%. Calcd for $C_{10}H_{15}N_3O_6$: C, 43.96; H, 5.53; N, 15.38%.

Benzyl 3,4-Di-*O*-acetyl-2-azido-2-deoxy-β-L-arabinopyranoside (11). The nitrate **8** (305 mg, 1.09 mmol) was stirred with benzyl alcohol (7 ml) and molecular sieve 3 A overnight at room temperature. The same work-up as described for **10** afforded **11** as a syrup in 90% yield, $[\alpha]_D$ +192° (*c* 1.0, $CHCl_3$); ^1H NMR δ=5.03 (d, $J_{1,2}$=3.3 Hz, H-1), 3.70 (dd, $J_{2,3}$=10.7 Hz, H-2), 5.36 (dd, $J_{3,4}$=3.3 Hz, H-3), 5.33 (broad s, H-4), 3.66 (dd, $J_{4,5}$=1.5 Hz, $J_{5,5'}$=12.5 Hz, H-5), 3.98 (dd, $J_{4,5'}$=1.3 Hz, H-5'), 2.07 and 2.14 (each s, OAc), 4.56 and 4.74 (ABq, J=12.8 Hz, CH_2 in Bn), and 7.34 (s, Ph).

Found: C, 54.82; H, 5.21; N, 12.41%. Calcd for $C_{16}H_{19}N_3O_6$: C, 55.01; H, 5.48; N, 12.03%.

Benzyl 2-*O*-(1-Imidazolylsulfonyl)-3,4-*O*-isopropylidene-β-L-arabinopyranoside (14). To a solution of **12** (1.6 g, 5.7 mmol) in pyridine (6 ml) was added imidazole (2.0 g, 30 mmol) and sulfuryl chloride (1.2 ml, 15 mmol) in two portions with stirring and cooling (ice-water). After being kept overnight at room temperature the mixture was poured into ice-water and extracted twice with chloroform. The extract was washed with water, dried and evaporated to give **14** (1.6 g) as a solid residue, which was characterized only by ^1H NMR δ=4.92 (d, $J_{1,2}$=2.7, H-1), 4.45 (H-2), 4.34 (dd, H-3), 4.20 (bd, H-4), 3.95 (bs, 2 H, H-5 and H-5'), 1.30 and 1.34 (each s, CMe_2), 4.45 and 4.69 (ABq, J=11.6 Hz, CH_2 in Bn), 7.03 (d), 7.87 (d), and 7.23 (dd) (Imidazyl), and 7.31 (s, Ph).

Benzyl 2-Azido-2-deoxy-3,4-*O*-isopropylidene-β-L-ribopyranoside (15). A. From 12 via Its 3-Triflate (13): To a solution of trifluoromethanesulfonic anhydride (1 ml, 7.1 mmol) in dichloromethane (20 ml) was added dropwise at −5—−10 °C a solution of pyridine (1 ml, 12 mmol) in dichloromethane (10 ml) and then a solution of **12** (1 g, 3.6 mmol) in dichloromethane (10 ml). The mixture was kept at the temperature for 0.5 h and then poured into ice-water containing sodium hydrogencarbonate. The dichloromethane layer was separated, washed with dilute hydrochloric acid, water, and sodium chloride solution, dried, and evaporated to give crude **13** as syrup, which was characterized only by ^1H NMR δ=5.09 (d, $J_{1,2}$=3.5 Hz, H-1), 5.37 (dd, $J_{2,3}$=6.9 Hz, H-2), 4.68 (d, H-3), 4.15 (H-4), 4.07 (bs, 2H, H-5 and H-5'), 1.40 and 1.56 (each s, CMe_2), 4.71 and 4.80 (ABq, J=10.0 Hz, CH_2 in Bn), and 7.36 (s, Ph).

A mixture of crude **13** and sodium azide (0.6 g, 9.2 mmol) in *N*,*N*-dimethylformamide (5 ml) was heated at 65—70 °C for 1 h, and then poured into ice-water, dried and evaporated to give a syrupy residue, from which was obtained the compound **15** by column chromatography on silica gel. Syrup, $[\alpha]_D$ +66.8° (*c* 1.1, $CHCl_3$); ^1H NMR δ=4.60 (d, $J_{1,2}$=3.6 Hz, H-1), 4.44 (dd, $J_{2,3}$=8.7 Hz, H-2), 4.7 (H-3), 4.18 (H-4), 4.0 (2 H, H-5 and H-5'), 1.34 and 1.50 (each s, CMe_2), 4.77 (s, CH_2 in Bn), and 7.33 (s, Ph).

Found: C, 58.76; H, 6.14; N, 13.42%. Calcd for $C_{15}H_{19}N_3O_4$: C, 59.01; H, 6.27; N, 13.76%.

B. From 14: A mixture of **14** (410 mg, 1.0 mmol), sodium azide (210 mg, 3.2 mmol), and tetrabutylammonium chloride (340 mg, 3.2 mmol) in toluene (5 ml) was heated under gentle reflux for 6 h. After addition of water the mixture was washed with water three times, dried and evaporated to give **14** (245 mg, 80%), which was identical with the 2-azido sugar described above.

Methyl 2-Azido-2-deoxy-α-D-xylopyranoside (16). Compound **4** (440 mg, 2.3 mmol) was dissolved in methanol containing catalytic amount of sodium. After standing at room temperature for 1 h and neutralization with acetic acid, the solution was evaporated and the residue was purified on a silica-gel column with ethyl acetate and hexane (3:2) to give **16** as a syrup in 82% yield, $[\alpha]_D$ +139.9° (*c* 1.0, methanol).

Found: C, 38.22; H, 5.84; N, 22.70%. Calcd for $C_6H_{11}N_3O_4$: C, 38.09; H, 5.86; N, 22.21%.

Benzoylation of 16. To a solution of **16** (6.11 g, 32.3 mmol) in acetone (70 ml) was added with stirring triethylamine (8.8 ml, 63.2 mmol) and benzoyl chloride (7.6 ml, 65.3 mmol), and the mixture was kept at room temperature for 36 h. After addition of water and further stirring for 2 h, the mixture was extracted with chloroform. The extract was washed with water, dried and evaporated to give a syrupy mixture of benzoates, which was fractionated on a silica-gel column with benzene–acetone (30:1) to give 3,4-dibenzoate (**20**), 4-benzoate (**19**) and 3-benzoate (**17**) in 29, 65, and 5%, respectively.

17: Syrup, $[\alpha]_D$ +134.9° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.82 (d, $J_{1,2}$=3.8 Hz, H-1), 3.40 (dd, $J_{2,3}$=10.5 Hz, H-2), 5.43 (dd, $J_{3,4}$=8.3 Hz, H-3), 3.6—4.1 (m, 3H, H-4, H-5, and H-5'), 3.46 (s, OMe), 7.2—7.6 and 8.0—8.1 (m, Ph).

Found: C, 53.34; H, 5.24; N, 13.96%. Calcd for $C_{13}H_{15}N_3O_5$: C, 53.24; H, 5.16; N, 14.33%.

19: Mp 85—89 °C, $[\alpha]_D$ +46.0° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.75 (d, $J_{1,2}$=3.6 Hz, H-1), 3.32 (dd, $J_{2,3}$=9.3 Hz, H-2), 4.23 (t, $J_{3,4}$=9.3 Hz, H-3), 5.05 (ddd, $J_{4,5}$=10.3 Hz, $J_{4,5'}$= 5.9 Hz, H-4), 3.63, (t, $J_{5,5'}$=10.6 Hz, H-5), 3.89 (dd, H-5'), 3.43 (s, OMe), 7.2—7.6 and 7.9—8.1 (m, Ph).

Found: C, 53.29; H, 5.03; N, 13.85%. Calcd for $C_{13}H_{15}N_3O_5$: C 53.24; H, 5.16; N, 14.33%.

20: Syrup, $[\alpha]_D$ +25.5° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.92 (d, $J_{1,2}$=3.8 Hz, H-1), 3.47 (dd, $J_{2,3}$=9.6 Hz, H-2), 5.95 (t, $J_{3,4}$=9.3 Hz, H-3), 5.31 (ddd, $J_{4,5}$=10.5 Hz, $J_{4,5'}$=6.0 Hz, H-4), 3.78 (t, $J_{5,5'}$=10.5 Hz, H-5), 4.04 (dd, H-5'), 3.52 (s, OMe), 7.3—7.6 and 7.9—8.2 (m, Ph).

Found: C, 59.82; H, 4.73; N, 10.80%. Calcd for $C_{20}H_{19}N_3O_6$: C, 60.45; H, 4.82; N, 10.58%.

Methyl 2-Azido-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (18). Compound **22** was debenzoylated with sodium methoxide in methanol in a conventional manner to give **18** in a quantitative yield, $[\alpha]_D$ +33.8°; ^1H NMR δ=4.66 (d, $J_{1,2}$=3.3 Hz, H-1), 3.2—3.8 (m, H-2—5), 3.47 (s, OMe), 4.68 and 4.88 (ABq, J=10.5 Hz, CH_2 in Bn), and 7.40 (s, Ph).

Found: C, 55.54; H, 6.09; N, 14.89%. Calcd for $C_{13}H_{17}N_3O_4$: C, 55.90; H, 6.14; N, 15.05%.

Methyl 2-Azido-4-*O*-benzoyl-2-deoxy-3-*O*-methylsulfonyl-α-D-xylopyranoside (21). Compound **19** was mesylated with methanesulfonyl chloride in pyridine in a conventional manner to give **21** in 85% yield, mp 53—54 °C, $[\alpha]_D$ −79.1° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.90 (d, $J_{1,2}$=3.5 Hz, H-1), 3.41 (dd, $J_{2,3}$=9.6 Hz, H-2), 5.08—5.36 (m, 3H, H-3, H-4, and H-5), 4.01 (dd, $J_{4,5'}$=5.4 Hz, $J_{5,5'}$=11.3 Hz), 3.47 (s, OMe), 3.04 (s, Ms) and 7.3—7.6 and 8.0—8.15 (m, Ph).

Found: C, 45.33: H, 4.51: N, 11.16; S, 8.85%. Calcd for $C_{14}H_{17}N_3O_7S$: C, 45.28; H, 4.61; N, 11.32; S, 8.63%.

Methyl 2-Azido-4-*O*-benzoyl-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (22). To a solution of **19** (527 mg, 1.8 mmol) in dry benzene (5 ml) was added benzyl bromide (0.85 ml, 7.1 mmol) and silver oxide (830 mg, 3.6 mmol) and the mixture was stirred under exclusion of light for 40 h. The undissolved material was filtered off and a residue obtained by evaporation of the filtrate was purified on a silica-gel column with hexane-ethyl acetate (7:1) to give **22** in 74% yield, syrup, $[\alpha]_D$ −52.2° (*c* 1.0, $CHCl_3$); IR (NaCl) 2100 (azido) and 1725 (ester) cm^{-1}; ^1H NMR δ=4.78 (d, $J_{1,2}$=1.2 Hz, H-1), 3.5 (H-2), 4.09 (t, $J_{2,3}=J_{3,4}$=9.5 Hz, H-3), 5.18 (ddd, $J_{4,5}$=10.5 Hz, $J_{4,5'}$=5.9 Hz, H-4), 3.60 (dd, $J_{5,5'}$=11.0 Hz, H-5), 3.90 (dd, H-5'), 3.46 (s, OMe), 4.72 and 4.80 (ABq, *J*= 11.4 Hz, CH_2 in Bn), 7.19 (s, Ph), 7.2—7.6 and 7.9—8.0 (m, Ph).

Found: C, 62.95; H, 5.60; N, 10.69%. Calcd for $C_{20}H_{21}N_3O_5$: C, 62.65; H, 5.52; N, 10.96%.

Methyl 2-Azido-4-*O*-benzoyl-2-deoxy-α-D-ribopyranoside (24). To a solution of **19** (1.7 g, 5.8 mmol) and dimethyl sulfoxide (2.3 g, 29.5 mmol) in dry dichloromethane (10 ml) was added with stirring at −78 °C a solution of trifluoroacetic anhydride (3.5 g, 1.8 mmol) in dry dichloromethane (5 ml), and then after 30 min, a solution of triethylamine (4.3 g, 43 mmol) in dichloromethane (5 ml). The temperature was kept for further 30 min and raised up to room temperature. Then, to the reaction solution was added with stirring methanol (20 ml) and sodium borohydride (0.43 g, 12 mmol) and the stirring was continued for 30 min. After addition of chloroform the reaction solution was washed with water, dried and evaporated to give a syrupy residue, which was purified on a silica-gel column with hexane-ethyl acetate (5:1) to afford **24** in 75% yield, $[\alpha]_D$ +110.3° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.78 (d, $J_{1,2}$=3.0 Hz, H-1), 3.43 (t, $J_{2,3}$=3.0 Hz, H-2), 4.43 (dt, $J_{3,4}$=3.0 Hz, $J_{3,OH}$=9.6 Hz, H-3), 5.07 (ddd, $J_{4,5}$=9.8 Hz, $J_{4,5'}$=5.1 Hz, H-4), 4.04 (dd, $J_{5,5'}$=11.4 Hz, H-5), 3.76 (dd, H-5'), 3.36 (d, OH), 3.56 (s, OMe), 7.3—7.6 and 8.0—8.2 (m, Ph).

Found: C, 53.83; H, 5.15; N, 14.03%. Calcd for $C_{13}H_{15}N_3O_5$: C, 53.24; H, 5.16; N, 14.33%.

Methyl 3-*O*-Acetyl-2-azido-4-*O*-benzoyl-2-deoxy-α-D-ribopyranoside (25). Acetylation of **24** in a usual manner gave **25** in 88% yield, syrup, $[\alpha]_D$ +60.2° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.66 (d, $J_{1,2}$=3.0 Hz, H-1), 3.5 (H-2), 5.54 (t, $J_{2,3}$=3.3 Hz, H-3), 5.21 (dt, $J_{3,4}$=3.3 Hz, H-4), 4.12 (dd, $J_{4,5}$=7.4 Hz, $J_{5,5'}$=11.6 Hz, H-5), 3.70 (dd, $J_{4,5'}$=3.9 Hz, H-5'), 2.13 (s, OAc), 3.55 (s, OMe), 7.3—7.6 and 7.9—8.1 (m, Ph).

Found: C, 53.41; H, 5.03; N, 12.20%. Calcd for $C_{15}H_{17}N_3O_6$: C, 53.73; H, 5.11; N, 12.53%.

Benzyl 2-Azido-2-deoxy-α-D-xylopyranoside (26). Compound **5** was deacetylated in the same manner as described for **16** and crude **26** was purified on a silica-gel column with hexane-ethyl acetate (2:1). Syrup, $[\alpha]_D$ +88.7° (*c* 1.0, methanol); ^1H NMR δ=4.91 (d, $J_{1,2}$=3.5 Hz, H-1), 3.15 (dd, $J_{2,3}$=9.5 Hz, H-2), 3.40—4.10 (m, other ring protons), 4.52 and 4.75 (ABq, *J*=12.0 Hz, CH_2 in Bn), and 7.35 (s, Ph).

Found: C, 54.10; H, 5.64; N, 15.81%. Calcd for $C_{12}H_{15}N_3O_4$: C, 54.33; H, 5.70; N, 15.84%.

Benzyl 2-Azido-4-*O*-benzoyl-2-deoxy-α-D-xylopyranoside (27) and Benzyl 2-Azido-3,4-di-*O*-benzoyl-2-deoxy-α-D-xylopyranoside (28). To a solution of **26** (2.42 g, 9.1 mmol) in acetone (30 ml) was added under cooling with ice-water triethylamine (2.5 ml, 18 mmol) and benzoyl chloride (1.6 ml, 14 mmol), and the mixture was stirred at room temperature for 16 h. A syrupy mixture of benzoates obtained by usual work-up was fractionated on a silica-gel column with benzene-acetone (100:1) to give 3,4-dibenzoate (**28**) and 4-benzoate (**27**) in 15 and 66% yields, respectively.

27: Mp 94—95 °C, $[\alpha]_D$ +64.5° (*c* 1.2, $CHCl_3$); ^1H NMR δ=5.04 (d, $J_{1,2}$=3.6 Hz, H-1), 3.37 (dd, $J_{2,3}$=10.5 Hz, H-2), 4.37 (t, $J_{3,4}$=9.3 Hz, H-3), 5.16 (m, H-4), 3.77 (t, $J_{4,5}=J_{5,5'}$=10.5 Hz, H-5), 3.99 (dd, $J_{4,5'}$=6.3 Hz, H-5'), 4.63 and 4.94 (ABq, *J*=11.4 Hz, CH_2 in Bn), 7.46 (s, Ph), 7.4—7.7 and 8.0—8.2 (m, Ph).

Found: C, 62.46; H, 5.18; N, 11.25%. Calcd for $C_{19}H_{19}N_3O_5$: C, 61.78; H, 5.19; N, 11.38%.

28: Syrup, $[\alpha]_D$ +37.9° (*c* 1.3, $CHCl_3$); ^1H NMR δ=5.17 (d, $J_{1,2}$=3.3 Hz, H-1), 3.49 (dd, $J_{2,3}$=10.2 Hz, H-2), 6.08 (dd, $J_{3,4}$=9.9 Hz, H-3), 5.40 (dt, $J_{4,5}$=9.9 Hz, $J_{4,5'}$=6.0 Hz, H-4), 3.90 (t, H-5), 4.14 (dd, $J_{5,5'}$=11.0 Hz, H-5'), 4.68 and 4.90 (ABq, *J*=11.6 Hz, CH_2 in Bn), 7.46 (s, Ph), 7.3—7.7 and 8.0—8.3 (m, Ph).

Found: C, 65.73; H, 4.87; N, 8.95%. Calcd for $C_{26}H_{23}N_3O_6$: C, 65.95; H, 4.90; N, 8.88%.

Benzyl 2-Azido-4-*O*-benzoyl-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (29). Compound **27** was benzylated in the same manner as described for **22** and the product was purified on a silica-gel column with hexane-ethyl acetate (1:0—4:1) to give **29** in 86% yield, syrup, $[\alpha]_D$ −6.2° (*c* 1.1, $CHCl_3$); ^1H NMR δ=5.04 (d, $J_{1,2}$=3.6 Hz, H-1), 3.50 (dd, $J_{2,3}$=10.1 Hz, H-2), 4.24 (t, H-3), 5.29 (ddd, $J_{3,4}$=9.6 Hz, $J_{4,5}$=10.2 Hz, $J_{4,5'}$=6.0 Hz, H-4), 3.74 (t, H-5), 4.01 (dd, $J_{5,5'}$=10.7 Hz, H-5'), 4.64 and 4.84 (ABq, *J*=12.0 Hz, CH_2 in Bn), 4.82 and 4.88 (ABq, *J*=11.3 Hz, CH_2 in Bn), 7.30 and 7.45 (each s, Ph), 7.3—7.7 and 8.0—8.3 (m, Ph).

Found: C, 67.92; H, 5.50; N, 8.86%. Calcd for $C_{26}H_{25}N_3O_5$: C, 67.96; H, 5.48; N, 9.15%.

Benzyl 2-Azido-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (30). Compound **29** was debenzoylated in the same manner as described for **18** to give **30** in a quantitative yield, mp 88—91 °C, $[\alpha]_D$ +50.9° (*c* 0.9, $CHCl_3$); ^1H NMR δ=4.97 (d, $J_{1,2}$=3.0 Hz, H-1), 3.33 (dd, $J_{2,3}$=9.0 Hz, H-2), 3.6—4.0 (m, 4H, H-3, H-4, H-5, and H-5'), 4.61 and 4.83 (ABq, *J*=12.0 Hz, CH_2 in Bn), 4.79 and 4.97 (ABq, *J*=11.3 Hz, CH_2 in Bn), and 7.44 (bs, Ph).

Found: C, 64.52; H, 5.94; N, 11.41%. Calcd for $C_{19}H_{21}N_3O_4$: C, 64.21; H, 5.96, N, 11.82%.

Methyl 3,4-Anhydro-2-azido-2-deoxy-α-D-ribopyranoside (31). Compound **21** (6.74 g, 18.1 mmol) was dissolved in 1.4 M (1M=1 mol dm^{-3}) methanolic potassium hydroxide (140 ml) and the solution was refluxed for 5 min. After addition of water the reaction mixture was extracted with chloroform. The extract was washed with water, dried and evaporated to give a syrupy residue, which was purified on a silica-gel column with benzene-ethanol (80:1). Yield 76%, mp 64—65 °C, $[\alpha]_D$ −16.8° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.60 (d, $J_{1,2}$=4.2 Hz, H-1), 3.2—3.6 (m, 3H, H-2, H-3, and H-4), 4.15 (bd, $J_{4,5}$=0.5 Hz, $J_{5,5'}$=13.7 Hz, H-5), 4.91 (dd, $J_{4,5'}$=3.0 Hz, H-5') and 3.50 (s, OMe).

Found: C, 44.05; H, 5.84; N, 20.49%. Calcd for $C_{10}H_{16}N_4O_5$: C, 44.11; H, 5.92; N, 20.58%.

Methyl 3,4-Di-*O*-acetyl-2-azido-2-deoxy-β-L-lyxopyranoside (32). To a solution of **31** (222 mg, 1.30 mmol) in dry *N*,*N*-dimethylformamide (10 ml) was added acetic acid (1 ml) and anhydrous sodium acetate (1 g), and the mixture was

heated with stirring at 100 °C for 16 h. After addition of acetic anhydride (3 ml) and pyridine (5 ml) the mixture was heated further at 100 °C for 1 h and then kept at room temperature for 4 h. The mixture was poured into ice-water and extracted five times with toluene. The extract was washed successively with water, 1 M hydrochloric acid, saturated sodium hydrogencarbonate, and water, and dried and evaporated to give a syrupy mixture. The mixture was fractionated on a silica-gel column with hexane–ethyl acetate (4 : 1) to give **32** (193 mg, 54%) and **4** (87 mg, 25%). **32**: Mp 79 °C (from ether), $[\alpha]_D$ +146.5° (*c* 1.8, $CHCl_3$), ^1H NMR δ=4.69 (d, $J_{1,2}$=3.0 Hz, H-1), 3.77 (t, $J_{2,3}$=3.5 Hz, H-2), 5.14 (dd, $J_{3,4}$=6.5 Hz, H-3), 4.97 (ddd, $J_{4,5}$=5.5 Hz, $J_{4,5'}$=3.5 Hz, H-4), 3.43 (dd, $J_{5,5'}$=12.5 Hz, H-5), 4.12 (dd, H-5′), 2.06 and 2.12 (each s, OAc), and 3.51 (s, OMe).

Found: C, 43.30; H, 5.48; N, 14.93%. Calcd for $C_{10}H_{15}N_3O_6$: C, 43.96; H, 5.53; N, 15.38%.

Methyl 2-Azido-4-*O*-benzyl-2-deoxy-α-D-xylopyranoside (33). A mixture of **16** (7.1 g, 38 mmol) and dibutyltin oxide (9.5 g, 38 mmol) in dry benzene (300 ml) was heated under reflux for 1 h. To this mixture was added benzyl bromide (9.1 ml, 77 mmol) and tetraethylammonium bromide (12.9 g, 61 mmol). Being heated under reflux for 17 h, the mixture was evaporated and the residue was fractionated on a silica-gel column with hexane–ethyl acetate (5 : 1) to give **33** and **18** in 70 and 13% yields, respectively. **33**: Syrup, $[\alpha]_D$ +94.5° (*c* 0.9, $CHCl_3$); IR (NaCl) 3450 (OH), and 2110 (azido) cm^{-1}. ^1H NMR δ=4.68 (d, $J_{1,2}$=3.9 Hz, H-1), 3.18 (dd, $J_{2,3}$=10.4 Hz, H-2), 3.38 (s, OMe), 4.64 (s, CH_2Ph), and 7.32 (s, Ph).

Found: C, 55.91; H, 5.81; N, 14.65%. Calcd for $C_{13}H_{17}N_3O_4$: C, 55.90; H, 6.14; N, 15.05%.

3,4-Di-*O*-acetyl-2-azido-2-deoxy-α-D-xylopyranosyl Chloride (34). To a solution of **3** (810 mg, 2.69 mmol) in dry dichloromethane (20 ml) was added titanium tetrachloride (1.0 g, 5.3 mmol). The solution was kept overnight at 25—30 °C diluted with chloroform, washed successively with ice-water, saturated aqueous sodium hydrogencarbonate, water, dried and evaporated to give crude **34** (660 mg, 88%), which was purified on a silica-gel column with hexane–ethyl acetate (4 : 1). Yield, 77%, mp 71—72 °C, $[\alpha]_D$ +149.4° (*c* 1.0, $CHCl_3$); ^1H NMR δ=6.10 (d, $J_{1,2}$=3.3 Hz, H-1), 3.78 (dd, $J_{2,3}$=9.8 Hz, H-2), 5.54 (t, $J_{3,4}$=9.8 Hz, H-3), 5.03 (dt, $J_{4,5}$=9.8 Hz, $J_{4,5'}$=6.9 Hz, H-4), 3.9—4.1 (m, H-5,5′), 2.07 and 2.10 (each s, OAc).

Found: C, 39.40; H, 4.37; N, 15.07%. Calcd for $C_9H_{12}N_3O_5Cl$: C, 38.93; H, 4.36; N, 15.13%.

3,4-Di-*O*-acetyl-2-azido-2-deoxy-α-D-xylopyranosyl Bromide (35). (a) With Titanium Tetrabromide: To a solution of **3** (430 mg, 1.43 mmol) in a mixture of dichloromethane (30 ml) and ethyl acetate (3 ml) was added titanium tetrabromide (2.10 g, 5.71 mmol). The mixture was kept at 25—30 °C for 36 h, poured into ice-water, and extracted with chloroform. A similar work-up of the extract as described for **34** gave a crude crystal (440 mg, 63%), mp 95—97 °C (dry ether), $[\alpha]_D$ +189.0° (*c* 1.5, $CHCl_3$); ^1H NMR δ=6.34 (d, $J_{1,2}$=4.0 Hz, H-1), 3.69 (dd, $J_{2,3}$=9.8 Hz, H-2), 5.47 (t, $J_{3,4}$=9.8 Hz, H-3), 5.00 (m, H-4), 3.88 (t, $J_{4,5}$=$J_{5,5'}$=10.5 Hz, H-5), 4.02 (dd, $J_{4,5'}$=6.3 Hz, H-5′), 2.06 and 2.12 (each s, OAc).

Found: C, 33.33; H, 3.63; N, 12.78%. Calcd for $C_9H_{12}N_3O_5Br$: C, 33.56; H, 3.76; N, 13.05%.

(b) With Hydrogen Bromide. To a solution of **3** (500 mg, 1.66 mmol) in dichloromethane (2 ml) was added dropwise a solution of 30% hydrogen bromide in acetic acid (0.6 ml) at 0 °C with stirring. The mixture was kept at the same temperature for 3 h and worked up in the same manner as described above to give **35** in 88% yield.

3,4-Di-*O*-acetyl-2-azido-2-deoxy-β-L-arabinopyranosyl Chloride (36). To a solution of **8** (3.5 g, 11 mmol) in acetonitrile (10 ml) was added tetraethylammonium chloride (7.0 g, 42 mmol). The mixture was stirred at room temperature for 16 h, diluted with chloroform, washed with water, dried and evaporated to give crude **36**, which was purified with hexane–ethyl acetate (4 : 1). Yield, 80%, mp 80—82 °C, $[\alpha]_D$ +185.7° (*c* 1.0, $CHCl_3$); ^1H NMR δ=6.16 (d, $J_{1,2}$=3.3 Hz, H-1), 4.12 (m, H-2), 5.34 (dd, $J_{2,3}$=10.5 Hz, $J_{3,4}$=3.0 Hz, H-3), 5.39 (dt, H-4), 3.89 (dd, $J_{4,5}$=1.8 Hz, $J_{5,5'}$=13.8 Hz, H-5), 4.26 (dd, $J_{4,5'}$=1.4 Hz, H-5′), 2.09 and 2.16 (each s, OAc).

Found: C, 38.65; H, 4.52; N, 14.86%. Calcd for $C_9H_{12}N_3O_5Cl$: C, 38.93; H, 4.36; N, 15.13%.

3,4-Di-*O*-acetyl-2-azido-2-deoxy-β-L-arabinopyranosyl Bromide (37). To a solution of **8** (1.0 g, 3.1 mmol) in acetonitrile (10 ml) was added lithium bromide (1.2 g, 14 mmol) and the mixture was kept at room temperature for 3 h. The same work-up as described for **36** gave **37** in 55% yield. ^1H NMR δ=6.47 (d, $J_{1,2}$=4.0 Hz, H-1), 4.03 (H-2), 5.32 (dd, $J_{2,3}$=9.5 Hz, $J_{3,4}$=3.6 Hz, H-3), 5.37 (broad s, H-4), 3.92 (dd, $J_{4,5}$=1.5 Hz, $J_{5,5'}$=13.8 Hz, H-5), 4.22 (dd, $J_{4,5'}$=0.9 Hz, H-5′), 2.07 and 2.15 (each s, OAc).

Found: C, 33.58; H, 3.91; N, 12.73%. Calcd for $C_9H_{12}N_3O_5Br$: C, 33.56; H, 3.76; N, 13.00%.

Synthetic Studies on Glycocinnamoylspermidine. II.[1] Synthesis of 4-*O*-(2-Azido-2-deoxy-D-xylopyranosyl)-2-azido-2-deoxy-D-xylopyranose Derivatives

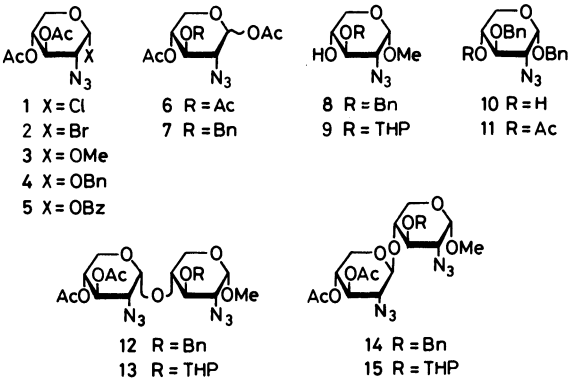
Koichi ARAKI, Manabu KAWA, Yoshihiro SAITO, Hironobu HASHIMOTO,* and Juji YOSHIMURA
Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received April 8, 1986)

Synthetic intermediates for the aminopentose disaccharide moiety of glycocinnamoylspermidine were synthesized from D-xylose.

2-Amino-2-deoxy-D-xylose and 2,3-diamino-2,3-dideoxy-D-xylose, which are rare components in the field of carbohydrate antibiotics, constitute the disaccharide moiety of glycocinnamoylspermidine (cinodine)[2] in which the disaccharide is linked through a unique ureylene linkage with *p*-(bacillosaminyloxy)cinnamoylspermidine. In this paper we should like to report a detail of the previous comminucation[3] on the synthesis of the disaccharide. The synthesis of the *p*-(bacillosaminyloxy)cinnamate moiety was previously reported.[1]

First of all the synthesis of 2-azido-2-deoxy-D-xylopyranose disaccharide having $\beta(1\rightarrow4)$ glycosidic linkage was examined. In order to reduce the kinds of necessary protecting groups for amino function, the 2-azido group, albeit having no anchimeric assistance for the formation of the interglycosidic β-linkage, seems to be convenient. This substituent have also been considered as favorable for the formation of α-ureylene linkage at the reducing end, which was, however, recently revised to be β.[4] Moreover, the authors showed easy availability of 2-azido-2-deoxypentose derivatives in the preceding paper.[5] Three disaccharides (**14**, **15**, and **34**) were chosen as feasible starting compounds for the construction of the aminopentose disaccharide moiety.

The Koenigs-Knorr method[6,7] and trimethylsilyl triflate (TMSOTf) method[8] were examined using 3,4-di-*O*-acetyl-2-azido-2-deoxy-α-D-xylopyranosyl halides (**1** and **2**) or 1,3,4-tri-*O*-acetyl-2-azido-2-deoxy-D-xylopyranose (**6**) as glycosyl donor, and methyl 2-azido-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (**8**) or the corresponding 3-*O*-tetrahydropyranyl (THP) derivative (**9**) as glycosyl acceptor. The latter acceptor was prepared by treatment of methyl 2-azido-4-*O*-benzoyl-2-deoxy-α-D-xylopyranoside with 3,4-dihydropyran and pyridinium *p*-toluenesulfonate, followed by debenzoylation. In the Koenigs-Knorr



reaction of glycosyl halide having no participating group at C-2, β-glycoside formation are favored generally by the use of insoluble silver salts such as silver carbonate and silver silicate, or mercury(II) salts such as mercuric cyanide and mercury(II) bromide, which have weak affinity for halogens to promote the S_N2 type substitution of α-halide. Both types of promoters, however, proved to be not effective for **1** and **2** as shown in Table 1. In the coupling of α-chloride (**1**) with **8** a mixture of α-linked (**12**) and β-linked disaccharide (**14**) was obtained only using mercury(II) cyanide in a polar solvent in a very low yield. Even in the

Table 1. Disaccharide Formation

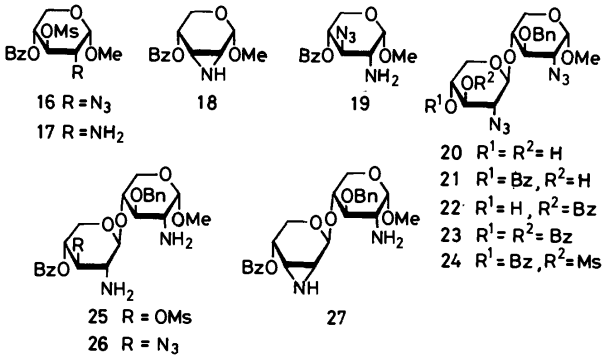
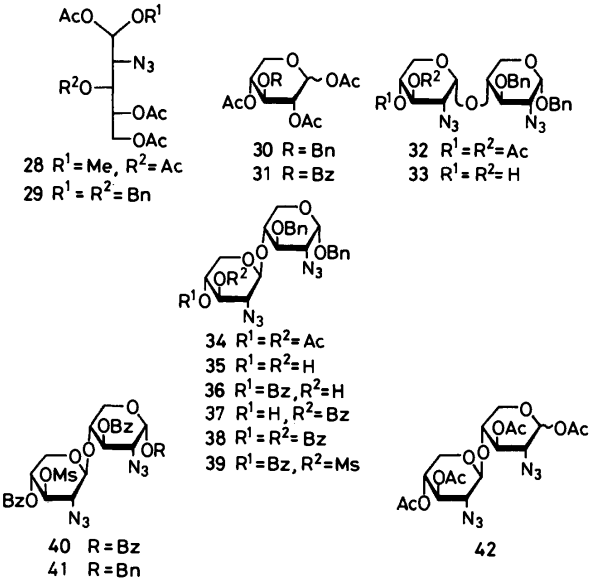
TMP: 2,4,6-Trimethylpyridine.

coupling of the more reactive α-bromide (**2**) with **9** only the α-linked disaccharide (**13**) was obtained in low yield with assistance of silver carbonate, silver oxide or mercury(II) bromide. Thus, 2-azido-2-deoxypentopyranosyl residue seems to be less reactive than the corresponding hexopyranosyl one. Therefore, glycosylation with silver perchlorate in nitromethane was examined in the presence of 2,4,6-trimethylpyridine. This method was proved to be suitable for β-glycoside formation in the cases of 3,4,6-triacetate of 2-*O*-benzyl- and 2-chloro-2-deoxy-α-D-glucopyranosyl chlorides.[9] The coupling of **1** and **8** gave **12** and **14** with predominance of the latter (4:5) in 73% yield, while the coupling of **1** with the benzyl glycoside (**10**) under the same conditions showed a slightly better selectivity to give a mixture of **32** and **34**, which were separated as *O*-deacetylated derivatives **33** and **35** in 29 and 46% yields, respectively. On the other hand, coupling of **1** with 3-*O*-THP derivative **9** exhibited a reverse selectivity to give α-linked (**13**) and β-linked disaccharide (**15**) in 41 and 6% yields, respectively. The result may be attributed to the lower reactivity of the 4-hydroxyl group in **9** due to the steric hindrance of bulky 3-*O*-THP moiety. Furthermore, coupling of 1-acetate (**6**) and **8** in the presence of TMSOTf gave **12** and **14** also with predominance of the latter (4:9) in 52% yield, respectively, to indicate a better selectivity for the formation of β-glycosidic linkage, albeit slightly in a lower yield. Considering that **6** consisted of almost α-anomer, S_N2 type substitution may predominate in this glycosylation.

Then, a precursor (**19**) of 2,3-diamino-2,3-dideoxy-D-xylose was derived via a 2,3-epimino derivative (**18**). 3-Mesylate (**16**) of methyl 2-azido-4-*O*-benzoyl-2-deoxy-α-D-xylopyranoside was hydrogenolyzed in the presence of platinum oxide to give 2-amino derivative (**17**) quantitatively, which was further converted into **18** in 73% yield, by treatment with sodium acetate in *N*,*N*-dimethylformamide at 80 °C. Azidolysis of **18** with sodium azide in the presence of tetraethylammonium chloride in 2-methoxyethanol-water at 95°C for 18 h afforded 3-azido derivative (**19**) preferentially in 85% yield. The structure of **19** was easily determined by ^{1}H NMR spectra, where $J_{2,3}$ and $J_{3,4}$ show 10.2 and 10.4 Hz, respectively, indicating *xylo* configuration.



The same conversion was also substantiated in the case of disaccharide. The deacetylated derivative (**20**) of **14** was partially benzoylated with 2 molar equivalents of benzoyl chloride and triethylamine in acetone to give 4′-benzoate (**21**) in 61% yield together with 3′-benzoate (**22**) and 3′,4′-dibenzoate (**23**). The 3′-mesylate (**24**) obtained in 97% by a usual mesylation of **21** was successively hydrogenolyzed and treated with sodium acetate in the same manner as described above without any purification of the intermediate diamine (**25**) to give 2′,3′-epimino derivative (**27**) in a quantitative yield. Azidolysis of **27** with the same reagent as described above at 110 °C for 4 h give a desired isomer **26** in 63% yield. For the total synthesis of cinodine this method may assure an easy conversion of 2-azido-2-deoxy-D-xylopyranose moiety at the nonreducing end of the pseudo trisaccharide having interglycosidic ureylene linkage into 2,3-diamino-2,3-dideoxy-D-xylose moiety.



Finally deprotection of glycoside was examined, because it is necessary for formation of the ureylene linkage. Acetolysis of the glycosides, one of the most frequently used methods, proved to be unsuccesful. Treatment of 2-azido-2-deoxy-D-xylopyranoside derivative such as methyl 3,4-di-*O*-acetyl-2-azido-2-deoxy-α-D-xylopyranoside (**3**) and a benzyl glycoside (**10**) with acetic anhydride in the presence of acid gave acyclic products **28** and **29**, respectively, as shown in Table 2. These results may be attributed to the retarding effect of C_2-N_3 dipole against the cleavage of C_1-OMe bond to facilitate consequently cleavage of the bond between C_1 and ring oxygen. Presence of benzyl or glycosyl substituents on the glycosyl moiety seems to have no effect on this situation. It was noteworthy that acetolysis of **3** and **10** in the presence of perchloric and trifluoroacetic acid, respectively, gave acyclic products **28** and **29** in a quantitative and 81% yields, respectively, which were obviously higher than those obtained in

Table 2. Acetolysis and Hydrolysis[a] of 2-Azido-2-deoxy-α-D-xylopyranoside Derivatives

Substrate	Acid	Concd	Solvent	Temperature °C	Time h	Product and Yield/%

a) Products were isolated after acetylation. b) 1 M=1 mol dm^{-3}.

the presence of sulfuric acid (Table 2). In the latter case, the ratio of two isomers was 3:2. Furthermore, hydrolytic deprotection of the benzyl glycoside was attempted. Benzyl glycoside (**10**) could be hydrolyzed selectively in 70% aqueous acetic acid containing 0.5—1 M (1M=1 mol dm^{-3}) sulfuric acid at 100 °C to give **7** after acetylation in good yields (Table 2). These conditions, however, proved to be not effective for selective hydrolysis of benzyl glycoside in the presence of interglycosidic linkage. For instance, the latter linkage was hydrolyzed preferentially in the case of **35**.

Finally the glycosidic linkage at the reducing end could be selectively deprotected using the benzyl glycoside as substrates by two methods. One is oxidative conversion of benzyl into benzoyl group with chromium trioxide in acetic acid.[10] This method proved to function nicely for both benzyloxy groups at C-1 and C-3 in the case of benzyl 3,4-di-*O*-acetyl-2-azido-2-deoxy-α-D-xylopyranoside (**4**) and 1,2,4-tri-*O*-acetyl-3-*O*-benzyl-α-D-xylopyranose (**30**),[11] respectively. Oxidation of **4** and **30** with chromium trioxide in acetic acid at room temperature gave the corresponding *O*-benzoyl derivatives **5** and **31** in 58 and 28% yields respectively. In the presence of sulfuric acid the yield for the latter increased up to 90%. The suitable disaccharide intermediate (**39**), which was derived from **35** via **36** in the same manner as described for the corresponding methyl glycoside, was oxidized by this method to give 1,3,4′-tri-*O*-benzoylated disaccharide (**40**) in 50% yield, together with small amount of selectively oxidized product (**41**). On the other hand, the second *O*-debenzylation method consists of bromination with *N*-bromosuccinimide and bromine in carbon tetrachloride followed by hydrolysis. The disaccharide **34** was converted by this method into **42** after acetylation in 56% yield. This reaction seems to be useful in a wide range of synthetic purpose and the further aspects will be published elsewhere.[12]

Experimental

General Methods. All melting points are uncorrected. The solutions were concentrated under diminished pressure at 50 °C (bath). Optical rotations were measured with a Carl Zeiss LEP-Al polarimeter. IR spectra were recorded with a Hitachi EPI-G2 grating spectrometer. ^{1}H NMR spectra were recorded with a JEOL PS-100 or a GX-400 spectrometer for solutions in $CDCl_3$ (internal Me_4Si) unless otherwise stated. ^{13}C NMR spectra were recorded with a JEOL FX-90 spectrometer for solutions in $CDCl_3$ unless otherwise stated. Chromatography was performed on Wakogel C-200, flash Chromatography on Wakogel C-300, and preparative TLC (PTLC) on silica gel 60 (Merck).

3,4-Di-*O*-acetyl-2-azido-1-*O*-benzoyl-2-deoxy-α-D-xylopyranose (5). To a solution of **4**[5] (114 mg, 0.33 mmol) in acetic acid (2.5 ml) was added chromium trioxide (200 mg, 2.0 mmol), and the mixture was stirred for 1 h at room temperature. The same work-up as described for **31** gave **5** in 58% yield; ^{1}H NMR δ=6.33 (d, $J_{1,2}$=3.9 Hz, H-1), 3.26 (dd, $J_{2,3}$=10.5 Hz, H-2), 5.47 (t, $J_{3,4}$=10.5 Hz, H-3), 4.96 (dt, $J_{4,5a}$=10.5 Hz, $J_{4,5b}$=6.0 Hz, H-4), 3.65 (t, $J_{5a,5b}$=10.5 Hz, H-5a), 3.90 (dd, H-5b), 1.98 and 2.08 (each s, Ac), and 7.32—8.06 (m, Ph).

1,4-Di-*O*-acetyl-2-azido-3-*O*-benzyl-2-deoxyl-D-xylopyranose (7). To a solution of **10**[5] (300 mg, 0.85 mmol) in acetic acid (72 ml) was added 0.62 M aqueous sulfuric acid (29 ml), and the solution was heated at 100 °C for 1 h. After addition of 0.93 M sulfuric acid (4.2 ml) the temperature was kept further 3 h. To the cooled solution was added sodium hydrogencarbonate (5 g), and the product was extracted 8 times with chloroform (total 80 ml). The residue obtained by evaporation of the dried extract was acetylated in a usual manner, and the product was purified on a silica-gel column with hexane–ethyl acetate (7:3) to give **7** as an anomeric mixture (α:β=9:11) and **11** in 60 and 35% yields, respectively. Compound **7**: ^{1}H NMR δ=6.16 (d, $J_{1,2}$=3.0 Hz, H-1α), 3.60 (dd, H-2α), 3.94 (t, $J_{2,3}$=$J_{3,4}$=9.0 Hz, H-3α), 4.10 (dd, $J_{4,5a}$=5.3 Hz, $J_{5a,5b}$=12.0 Hz, H-5aα), 3.56 (dd, H-5bα); 5.44 (d, $J_{1,2}$=8.0 Hz, H-1β), 3.62 (t, H-2β), 3.66 (t, $J_{2,3}$=$J_{3,4}$=9.0 Hz, H-3β), 3.93 (dd, $J_{4,5a}$=6.0 Hz, $J_{5a,5b}$=11.7 Hz, H-5aβ), 3.33 (dd, $J_{4,5b}$=9.6 Hz, H-5bβ); 2.01 and 2.18 (each s, Ac), 4.72 and 4.88 (ABq, J=11.7 Hz, CH_2 in Bn), 4.73 and 4.86 (ABq, J=11.6 Hz, CH_2 in Bn), and 7.34 (s, Ph).

Methyl 2-Azido-2-deoxy-3-*O*-tetrahydropyranyl-α-D-xylo-

pyranoside (9). To a solution of methyl 2-azido-4-*O*-benzoyl-2-deoxy-α-D-xylopyranoside[5] (1.5 g, 5.1 mmol) in dry dichloromethane (40 ml) was added 3,4-dihydropyran (0.65 g, 7.7 mmol) and a solution of pyridinium *p*-toluenesulfonate (125 mg, 0.5 mmol) in dichloromethane (15 ml). The mixture was kept at room temperature for 40 h, washed with aqueous sodium chloride, dried and evaporated to give 3-*O*-tetrahydropyranyl derivative as syrup quantitatively; IR (NaCl) 2100 (azido) and 1723 cm^{-1} (ester); ^1H NMR δ=4.84 (d, $J_{1,2}$=3.0 Hz, H-1), 3.26 (dd, $J_{2,3}$=10.0 Hz, H-2), 4.21 and 4.37 (each t, $J_{3,4}$=10.0 Hz, H-3), 5.14 (m, H-4), 3.63 (t, $J_{4,5a}$=$J_{5a,5b}$=10.0 Hz, H-5a), 3.89 (dd, $J_{4,5b}$=6.0 Hz, H-5b), 3.49 (s, OMe), 4.85 (dd, H-2 in THP), 1.2—2.0 (m, CH_2 in THP), 7.3—7.7 and 8.0—8.2 (m, Ph).

The 3-*O*-tetrahydropyranyl derivative was debenzoylated with sodium methoxide in methanol in a conventional manner to give **9** as syrup in 80% yield; IR (NaCl) 2095 cm^{-1} (azido); ^1H NMR δ=4.70 (d, $J_{1,2}$=3.3 Hz, H-1), 4.62 (m, H-2 in THP), 3.41 (s, OMe) and 1.35—2.1 (m, CH_2 in THP).

Found: C, 47.95; H, 7.36; N, 15.03%. Calcd for $C_{11}H_{19}N_3O_5$: C, 48.34; H, 7.01; N, 15.38%.

Methyl 4-*O*-(3,4-Di-*O*-acetyl-2-azido-2-deoxy-α-D-xylopyranosyl)-2-azido-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (12) and Its β-(1→4) Linked Isomer (14). A. Silver Perchlorate as a Promoter: To a solution of **8** (1.5 mmol) in nitromethane (2 ml) was added silver perchlorate (0.6 mmol), 2,4,6-trimethylpyridine (0.6 mmol) and Drierite (0.9 g), and the suspension was stirred with shielding from light at −10 °C for 1 h. To this suspension was added a solution of **1**[5] (0.5 mmol) in nitromethane (2 ml) and the temperature was kept for 60 h. Undissolved materials were filtered off and washed with chloroform. The filtrate was washed with water, dried and evaporated to give a syrupy residue, which was fractionated on a silica-gel column with benzene–acetone (6 : 1) to give **12** and **14** in 33 and 40% yields, respectively.

12: Syrup, $[\alpha]_D$ +41.3° (*c* 1.0, $CHCl_3$); IR (NaCl) 2100 (azido) and 1750 (ester) cm^{-1}; ^1H NMR δ=4.70 (d, $J_{1,2}$=3.6 Hz, H-1), 5.17 (d, $J_{1',2'}$=3.6 Hz, H-1'), 5.40 (dd, $J_{2',3'}$=9.3 Hz, $J_{3',4'}$=10.4 Hz, H-3'), 4.60—4.85 (m, H-4'), 3.2—4.1 (m, other ring protons), 2.04 and 2.10 (each s, Ac), 3.44 (s, OMe), 4.82 and 4.96 (ABq, J=9.8 Hz, CH_2 in Bn), and 7.32 (s, Ph).

Found: C, 51.20, H, 5.58; N, 15.82%. Calcd for $C_{22}H_{28}N_6O_9$: C, 50.77; H, 5.42; N, 16.15%.

14: Syrup, $[\alpha]_D$ +10.2° (*c* 1.0, $CHCl_3$); IR (NaCl) 2100 (azido) and 1750 (ester) cm^{-1}; ^1H NMR δ=4.67 (d, $J_{1,2}$=3.0 Hz, H-1), 4.35 (d, $J_{1',2'}$=8.1 Hz, H-1'), 4.76—5.10 (m, H-3' and H-4'), 3.1—4.1 (m, other ring protons), 2.03 and 2.11 (each s, Ac), 3.23 (s, OMe), 4.72 and 4.94 (ABq, J=10.2 Hz, CH_2 in Bn), and 7.34 (broad s, Ph).

Found: C, 50.65: H, 5.54; N, 16.46%. Calcd for $C_{22}H_{28}N_6O_9$: C, 50.77; H, 5.42; N, 16.15%.

B. Mercury(II) Cyanide as Promoter: To a solution of **1** (108 mg, 0.39 mmol) and **8**[5] (311 mg, 1.2 mmol) in dry benzene (2 ml) and nitromethane (2 ml) was added mercury(II) cyanide (240 mg, 0.88 mmol) and Drierite (0.3 g), and the mixture was stirred at 60 °C for 26 h. A similar work-up as described above and separation by preparative TLC gave **12** and **14** in 5.3 and 4.7% yields, respectively.

C. TMSOTf as a Catalyst: To a solution of **6** (104 mg, 0.38 mmol) and **8** (111 mg, 0.40 mmol) in dry 1,2-dichloroethane (2 ml) was added molecular sieve 4A (0.5 g) and TMSOTf (85 mg, 0.39 mmol) at 0 °C. The mixture was stirred at the same temperature for 24 h. Undissolved materials were filtered off and washed with chloroform. The filtrate was washed with saturated aqueous sodium hydrogencarbonate and water, dried and evaporated to give a syrupy residue, which was fractionated on PTLC to give **12** and **14** in 16 and 36% yields, respectively.

Methyl 4-*O*-(3,4-Di-*O*-acetyl-2-azido-2-deoxy-α-D-xylopyranosyl)-2-azido-2-deoxy-3-*O*-tetrahydropyranyl-α-D-xylopyranoside (13) and Its β-(1→4) Linked Isomer (15). A Silver Perchlorate as a Promoter: Compound **1** and **9** were coupled in the same manner as describe above to give **13** and **15** in 41 and 6% yields, respectively.

13: Syrup, $[\alpha]_D$ +94.0° (*c* 1.0, $CHCl_3$); IR (NaCl) 2940 (THP), 2100 (azido) and 1750 (ester) cm^{-1}; ^1H NMR δ=4.66 (d, $J_{1,2}$=3.2 Hz, H-1), 3.18 (d, $J_{2,3}$=9.5 Hz, H-2), 5.43 (d, $J_{1',2'}$=3.3 Hz, H-1'), 5.38 (t, $J_{2',3'}$=$J_{3',4'}$=9.0 Hz, H-3'), 4.81 (m, H-4'), 3.3—4.2 (m, other ring protons), 1.3—2.0 (m, CH_2 in THP), 2.04 and 2.09 (each s, Ac), and 3.39 (s, OMe).

Found: C, 46.47; H, 6.05; N, 16.02%. Calcd for $C_{20}H_{30}N_6O_{10}$: C, 46.69; H, 5.88; N, 16.34%.

15: Syrup, $[\alpha]_D$ −8.1° (*c* 1.0, $CHCl_3$); IR (NaCl) 2930 (THP), 2105 (azido) and 1750 (ester) cm^{-1}; ^1H NMR δ=4.74 (d, $J_{1,2}$=3.0 Hz, H-1), 3.28 (dd, $J_{2,3}$=9.5 Hz, H-2), 4.42 (d, $J_{1',2'}$=7.8 Hz, H-1'), 3.84—5.16 (m, H-3' and H-4'), 3.4—4.3 (m, other ring protons), 1.3—2.0 (m, CH_2 in THP), 2.04 and 2.12 (each s, Ac), and 3.44 (s, OMe).

Found: C, 47.02; H, 5.78; N, 15.98%. Calcd for $C_{20}H_{30}N_6O_{10}$: C, 46.69; H, 5.88; N, 16.34%.

B. Silver Carbonate as a Promoter: To a solution of **9** (270 mg, 1 mmol) in dry dichloromethane (6 ml) was added silver carbonate (550 mg, 2.2 mmol), molecular sieve 4A (1 g) and **2** (480 mg, 1.5 mmol). The mixture was stirred with shielding from light for 48 h at room temperature to give only **13** in 16% yield.

C. Silver Oxide-Iodine as Promoters: To a solution of **9** (137 mg, 0.5 mmol) in dry dichloromethane (3 ml) was added silver oxide (130 mg, 0.55 mmol) and molecular sieve 4A (0.6 g). After stirring under exclusion of light for 1 h iodine (30 mg) and a solution of **2** (161 mg, 0.5 mmol) in dry dichloromethane (2 ml) were added to the mixture. After 48 h at room temperature only **13** was obtained in 10% yield.

D. Mercury(II) Oxide-Mercury(II) Bromide as Promoters: To a solution of **9** (137 mg, 0.50 mmol) in dry dichloromethane (4 ml) was added mercury(II) oxide (119 mg, 0.55 mmol) and mercury(II) bromide (6 mg, 0.02 mmol). The mixture was stirred at room temperature with shielding from light for 30 min, and solution of **2** (161 mg, 0.50 mmol) was added. After 48 h at room temperature only **13** was obtained in 11% yields.

Methyl 2-Azido-4-*O*-benzoyl-2-deoxy-3-*O*-methylsulfonyl-α-D-xylopyranoside (16). Methyl 2-azido-4-*O*-benzoyl-2-deoxy-α-D-xylopyranoside[5] was treated with methanesulfonyl chloride in pyridine in a usual manner to give **16** in 85% yield, mp 53—54 °C, $[\alpha]_D$ −79.1° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.90 (d, $J_{1,2}$=3.5 Hz, H-1), 3.41 (dd, $J_{2,3}$=9.6 Hz, H-2), 5.08—5.36 (m, H-3 and H-4), 4.01 (dd, $J_{4,5a}$=5.2 Hz, $J_{5a,5b}$=10.6 Hz, H-5a), 3.66 (dd, $J_{4,5b}$=9.3 Hz, H-5b), 3.04 (s, Ms), 3.47 (s, OMe), and 7.26—7.63 and 8.00—8.16 (m, Ph).

Found: C, 45.33; H, 4.51; N, 11.16; S, 8.85%. Calcd for $C_{14}H_{17}N_3O_7S$: C, 45.28; H, 4.61; N, 11.32; S, 8.63%.

Methyl 2-Amino-3-azido-4-*O*-benzoyl-2,3-dideoxy-α-D-xylopyranoside (19). To a solution of **16** (0.2 mmol) in methanol (10 ml) was added platinum oxide (11 mg) and then introduced hydrogen until compound **16** disappeared

on TLC. The catalyst was filtered off and the filtrate was evaporated to give **17** quantitatively. To a solution of **17** in *N,N*-dimethylformamide–water (5 : 1, 2ml) was added sodium acetate trihydrate (122 mg). The solution was heated at 80 °C for 3 h, and evaporated to give a residue. Acetone was added to the residue and undissolved materials were filtered off. The filtrate was evaporated to give a syrup, which was purified on PTLC to give **18** in 73% yield; ^{1}H NMR δ=4.82 (d, $J_{1,2}$=3.4 Hz, H-1), 2.63 (dd, $J_{2,3}$=5.9 Hz, H-2), 2.79 (dd, $J_{3,4}$=3.9 Hz, H-3), 5.26 (ddd, $J_{4,5a}$=5.5 Hz, $J_{4,5b}$=7.3 Hz, H-4), 3.58 (dd, $J_{5a,5b}$=11.7 Hz, H-5a), 3.80 (dd, H-5b), 1.94 (NH), 3.45 (s, OMe), 7.20—7.60 and 7.95—8.10 (m, Ph).

To a solution of the epimino sugar **18** (0.5 mmol) in 2-methoxyethanol–water (14 : 1, 5 ml) was added sodium azide (2.5 mmol) and ammonium chloride (2.5 mmol). The mixture was heated at 95 °C for 18 h, and evaporated to give a residue. Acetone was added to the residue and undissolved materials were filtered off. The filtrate was evaporated to give a syrup, which was purified on PTLC to give **19** in 85% yield. This compound was characterized only by the following ^{1}H NMR data: δ=4.67 (d, $J_{1,2}$=3.3 Hz, H-1), 2.74 (dd, $J_{2,3}$=10.2 Hz, H-2), 3.59 (t, $J_{3,4}$=10.4 Hz, H-3), 5.00 (dt, $J_{4,5a}$=10.4 Hz, $J_{4,5b}$=5.4 Hz, H-4), 3.66 (t, $J_{5a,5b}$=10.4 Hz, H-5a), 3.94 (dd, H-5b), 2.02 (NH), 3.42 (s, OMe), 7.30—7.65 and 7.95—8.12 (m, Ph).

Methyl 2-Azido-4-*O*-(2-azido-2-deoxy-β-D-xylopyranosyl)-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (20). Deacetylation of **14** with sodium methoxide in methanol in a usual manner gave **20** quantitatively, $[\alpha]_D$ +41.3° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.76 (d, $J_{1,2}$=3.3 Hz, H-1), 4.36 (d, $J_{1',2'}$=7.5 Hz, H-1'), 3.1—4.1 (m, other ring protons) 3.48 (s, OMe), 4.80 and 5.03 (ABq, J=10.2 Hz, CH_2 in Bn), and 7.35—7.60 (m, Ph).

Found: C, 49.54; H, 5.56; N, 19.24%. Calcd for $C_{18}H_{24}N_6O_7$: C, 49.53; H, 5.54; N, 19.26%.

Partial Benzoylation of 20. To a solution of **20** (860 mg, 2.00 mmol) in acetone (8 ml) was added at 0 °C triethylamine (0.8 ml, 5.8 mmol) and benzoyl chloride (0.46 ml, 3.5 mmol), and the mixture was kept at room temperature for 18 h. After addition of water (2 ml) the mixture was stirred for 2 h, diluted with chloroform (30 ml), washed with water, dried and evaporated to give a mixture of three components, which was fractionated on a silica-gel column with benzene–acetone (30 : 1) to give **21**, **22**, and **23** in 61, 5, and 32% yields, respectively.

21: MP 118—122 °C, $[\alpha]_D$ −80° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.68 (d, $J_{1,2}$=3.6 Hz, H-1), 4.36 (d, $J_{1',2'}$=7.4 Hz, H-1'), 5.05 (dt, $J_{3',4'}$=$J_{4',5'a}$=9.0 Hz, $J_{4',5'b}$=5.5 Hz, H-4'), 4.14 (dd, $J_{5'a,5'b}$=11.6 Hz, H-5'b), 3.18—4.00 (m, other ring protons), 3.43 (s, OMe), 4.76 and 4.96 (ABq, J=10.2 Hz, CH_2 in Bn), 7.35 (s, Ph in Bn), and 7.24—7.66 and 7.93—8.08 (m, Ph in Bz).

Found: C, 56.01; H, 5.31; N, 15.79%. Calcd for $C_{25}H_{28}N_6O_8$: C, 55.55; H, 5.22; N, 15.55%.

22: Syrup, $[\alpha]_D$ +19.7° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.69 (d, $J_{1,2}$=3.2 Hz, H-1), 4.43 (d, $J_{1',2'}$=7.5 Hz, H-1'), 4.87 (dd, H-3'), 3.2—4.1 (m, other ring protons), 3.43 (s, OMe), 4.75 and 4.98 (ABq, J=11.7 Hz, CH_2 in Bn), 7.25—7.45 and 8.00—8.10 (m, Ph).

Found: C, 55.61; H, 5.29; N, 15.73%. Calcd for $C_{25}H_{28}N_6O_8$: C, 55.55; H, 5.22; N, 15.55%.

23: Syrup, $[\alpha]_D$ −61.2° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.72 (s, $J_{1,2}$=4.5 Hz, H-1), 4.59 (d, $J_{1',2'}$=7.5 Hz, H-1'), 5.49 (t, $J_{2',3'}$=$J_{3',4'}$=8.4 Hz, H-3'), 5.14 (dt, $J_{4',5'a}$=8.4 Hz, $J_{4',5'b}$=5.4 Hz, H-4'), 4.28 (dd, $J_{5'a,5'b}$=11.4 Hz, H-5'b), 3.18—4.04 (m, other ring protons), 3.47 (s, OMe), 4.80 and 5.02 (ABq, J=9.6 Hz, CH_2 in Bn), and 7.24—7.60 and 7.94—8.06 (m, Ph).

Found: C, 59.14; H, 5.00; N, 13.28%. Calcd for $C_{32}H_{32}N_6O_9$: C, 59.62; H, 5.00; N, 13.04%.

Methyl 2-Azido-4-*O*-(2-azido-4-*O*-benzoyl-2-deoxy-3-*O*-methylsulfonyl-β-D-xylopyranosyl)-3-*O*-benzoyl-2-deoxy-α-D-xylopyranoside (24). Treatment of **21** with methanesulfonyl chloride in pyridine in a usual manner gave **24** in 97% yield, mp 128—130 °C, $[\alpha]_D$ −32.3° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.53 (d, $J_{1,2}$=1.5 Hz, H-1), 4.45 (d, $J_{1',2'}$=7.7 Hz, H-1'), 4.53 (dd, $J_{2',3'}$=9.8 Hz, $J_{3',4'}$=9.0 Hz, H-3'), 5.10 (dt, $J_{4',5'a}$=9.0 Hz, $J_{4',5'b}$=5.1 Hz, H-4'), 4.26 (dd, $J_{5'a,5'b}$=12.0 Hz, H-5'b), 3.16—4.02 (m, other ring protons), 3.08 (s, Ms), 4.80 and 4.95 (ABq, J=10.2 Hz, CH_2 in Bn), and 7.28—7.64 and 7.98—8.16 (m, Ph).

Found: C, 50.42; H, 4.81; N, 13.55; S, 5.21%. Calcd for $C_{26}H_{30}N_6O_{10}S$: C, 50.48; H, 4.89; N, 13.59; S, 5.18%.

Methyl 2-Amino-4-*O*-(2-amino-3-azido-4-*O*-benzoyl-2,3-dideoxy-β-D-xylopyranosyl)-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (26). Azidolysis of **27** was carried out in the same manner as described for **19** to give **26** as a syrup in 63% yield, $[\alpha]_D$ −7.7° (*c* 1.0, $CHCl_3$); IR (NaCl) 3370 and 3300 (NH_2), 2100 (azido), and 1725 (ester) cm^{-1}; ^{1}H NMR δ=4.65 (d, $J_{1,2}$=1.5 Hz, H-1), 4.31 (d, $J_{1',2'}$=7.5 Hz, H-1'), 2.75 (dd, $J_{2',3'}$=10.2 Hz, H-2'), 5.10 (m, H-4'), 3.39 (s, OMe), and 7.28—8.16 (m, Ph).

Found: C, 57.93; H, 6.09; N, 13.29%. Calcd for $C_{25}H_{31}N_5O_7$: C, 58.47; H, 6.08; N, 13.64%.

Methyl 2-Amino-4-*O*-(4-*O*-benzoyl-2,3-dideoxy-2,3-epimino-β-D-ribopyranosyl)-3-*O*-benzyl-α-D-xylopyranoside (27). Hydrogenolysis of **24** in dichloromethane in the presence of platinum oxide in the same manner as described for **19** gave **25** quantitatively; ^{1}H NMR δ=4.66 (d, $J_{1,2}$=3.2 Hz, H-1), 2.80 (dd, $J_{2,3}$=9.2 Hz, H-2), 4.34 (d, $J_{1',2'}$=7.5 Hz, H-1'), 3.01 (dd, $J_{2',3'}$=9.3 Hz, H-2'), 3.80 (t, $J_{3',4'}$=9.3 Hz, H-3'), 5.22 (dt, $J_{4',5'a}$=9.3 Hz, $J_{4',5'b}$=6.0 Hz, H-4'), 4.27 (dd, $J_{5'a,5'b}$=12.0 Hz, H-5'b), 3.11—3.96 (m, other ring protons), 2.10 (NH), 3.01 (s, Ms), 3.40 (s, OMe), 4.62 and 5.00 (ABq, J=11.3 Hz, CH_2 in Bn), and 7.28—7.64 and 8.00—8.16 (m, Ph).

Treatment of **25** with sodium acetate in the same manner as described for **19** gave **27** as a syrup in 90% yield, $[\alpha]_D$ +47.9° (*c* 1.0, $CHCl_3$); IR (NaCl) 3360 and 3275 (OH and NH_2), and 1708 (ester) cm^{-1}; ^{1}H NMR (after D_2O exchange) δ=4.66 (d, $J_{1,2}$=3.0 Hz, H-1), 5.07 (s, H-1'), 2.30 (d, $J_{2',3'}$=5.0 Hz, H-2'), 2.8 (m, H-2 and H-3'), 4.96—5.14 (m, H-4'), 3.44—4.20 (m, other ring protons), 3.43 (s, OMe), 4.72 and 4.89 (ABq, J=11.4 Hz, CH_2 in Bn), 7.34 (s, Ph in Bn), and 7.26—7.62 and 7.96—8.14 (m, Bz).

Found: C, 63.53; H, 6.51; N, 5.66%. Calcd for $C_{25}H_{30}N_2O_7$: C, 63.82; H, 6.43; N, 5.95%.

1,3,4,5-Tetra-*O*-acetyl-2-azido-2-deoxy-D-xylose Methyl Hemiacetal (28). To a solution of **3**[5] (167 mg, 0.61 mmol) in acetic anhydride (1 ml) was added acetic anhydride (2 ml) containing one drop of 60% perchloric acid.

The mixture was kept at room temperature for 1 h, poured into saturated aqueous sodium hydrogencarbonate, and extracted with chloroform. The extract was washed with water, dried and evaporated to give **28** as a syrup quantitatively, $[\alpha]_D$ +21.2° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=5.74 (d, $J_{1,2}$=5.9 Hz, H-1), 3.67 (dd, $J_{2,3}$=3.0 Hz, H-2), 5.12—5.48 (m, H-3 and H-4), 3.98—4.44 (m, H-5a and H-5b), 3.51 (s, OMe) and 2.12 and 2.14 (Ac).

Found: C, 44.73; H, 5.57; N, 11.00%. Calcd for $C_{14}H_{21}N_3O_9$: C, 44.80; H, 5.64; N, 11.20%.

1,4,5-Tri-*O*-acetyl-2-azido-3-*O*-benzyl-2-deoxy-D-xylose Benzyl Hemiacetal (29). To a chilled solution of **10**[5] (58 mg, 0.16 mmol) in acetic anhydride (6 ml) was added trifluoroacetic acid (0.3 ml). The solution was kept at room temperature for 73 h and poured into saturated aqueous sodium hydrogencarbonate. Chloroform extract was washed with water, dried and evaporated to give a syrupy residue, which was purified on a silica-gel column with hexane-ethyl acetate (4:1) to give **29** in 81% yield. In its ^{1}H NMR spectrum signals due to two epimers were observed with a ratio of 3:2. ^{1}H NMR (400 MHz) major component δ=6.13 (d, $J_{1,2}$=6.8 Hz, H-1), 3.53 (dd, $J_{2,3}$=3.2 Hz, H-2), 3.98 (dd, $J_{3,4}$=6.2 Hz, H-3), 5.37 (dq, $J_{4,5a}$=7.0 Hz, $J_{4,5b}$=3.2 Hz, H-4), 4.20 (t, $J_{5a,5b}$=8.0 Hz, H-5a), 4.39 (dd, H-5b); Minor component δ=6.07 (d, $J_{1,2}$=5.4 Hz, H-1), 3.79 (t, $J_{2,3}$=4.2 Hz, H-2), 3.86 (t, $J_{3,4}$=4.4 Hz, H-3), 5.28 (dq, $J_{4,5a}$=7.0 Hz, $J_{4,5b}$=5.0 Hz, H-4), 4.17 (t, $J_{5a,5b}$=7.6 Hz, H-5a), 4.36 (dd, H-5b); 1.90—2.07 (m, Ac), 4.36—4.79 (m, CH_2 in Bn), and 7.20—7.40 (m, Ph).

Found: C, 59.79; H, 5.80; N, 8.19%. Calcd for $C_{25}H_{29}N_3O_8$: C, 60.11; H, 5.85; N, 8.41%.

1,2,4-Tri-*O*-acetyl-3-*O*-benzoyl-α-D-xylopyranose (31). To a mixture of acetic acid (2.5 ml) and acetic anhydride (0.2 ml) was added one drop of concd sulfuric acid, chromium trioxide (276 mg, 2.8 mmol) and **30**[10] (186 mg, 0.51 mmol). The mixture was kept at room temperature for 1 h, diluted with chloroform, and washed successively with water, aqueous sodium hydrogencarbonate, and water. The solution was dried and evaporated to give a syrup residue, which was purified on PTLC with hexane-ethyl acetate (7:3) to give **31** in 90% yield, $[\alpha]_D$ +48.8° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=6.29 (d, $J_{1,2}$=3.3 Hz, H-1),5.21 (dd, $J_{2,3}$= 9.8 Hz, H-2), 5.74 (t, $J_{3,4}$=9.8 Hz, H-3), 5.2 (m, H-4), 3.79 (t, $J_{4,5a}$=$J_{5a,5b}$=10.8 Hz, H-5a), 4.00 (dd, $J_{4,5b}$=6.0 Hz, H-5b), 1.93, 1.97 and 2.21 (each s, Ac), and 7.32—7.66 and 7.92—8.06 (m, Ph).

Found: C, 56.23; H, 5.08%. Calcd for $C_{18}H_{20}O_9$: C, 56.84; H, 5.30%.

Benzyl 2-Azido-4-*O*-(2-azido-2-deoxy-α-D-xylopyranosyl)-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (33) and Its β-Linked Isomer (35). Compounds **1** (1.51 g, 5.44 mmol) and **10** (3.80 g, 10.4 mmol) were coupled in the same manner as described for the preparation of **12** and **14** (Method A) to give a mixture of **32** and **34**, which was separated, after deacetylation with sodium methoxide in methanol, on a silica-gel column with benzene-acetone (6:1) to give **33** and **35** in 29 and 46% yields, respectively.

33: Syrup, $[\alpha]_D$ +88.2° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.92 (d, $J_{1,2}$=3.6 Hz, H-1), 3.36 (dd, $J_{2,3}$=9.8 Hz, H-2), 5.18 (d, $J_{1',2'}$=4.0 Hz, H-1'), 3.25 (dd, $J_{2',3'}$=10.2 Hz, H-2'), 3.48—4.10 (m, other ring protons), 4.32 (s, OH×2), 4.60 and 4.82 (ABq, J=11.7 Hz, CH_2 in Bn), 4.88 and 5.10 (ABq, J=9.9 Hz, CH_2 in Bn), and 7.48 (broad s, Ph).

Found: C, 56.43; H, 5.59; N, 16.27%. Calcd for $C_{24}H_{28}N_6O_7$: C, 56.24; H, 5.51; N, 16.40%.

^{1}H NMR data of 3',4'-diacetate (**32**): δ=4.93 (d, $J_{1,2}$=2.5 Hz, H-1), 4.38 (d, $J_{1',2'}$=8.0 Hz, H-1'), 4.53 and 4.75 (ABq, J=12.5 Hz, CH_2 in Bn), 4.85 and 4.97 (ABq, J=10.0 Hz, CH_2 in Bn), 2.03 and 2.11 (each s, Ac), and 7.35 (s, Ph).

35: Syrup, $[\alpha]_D$ +68.9° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.94 (d, $J_{1,2}$=3.6 Hz, H-1), 3.17 (dd, $J_{2,3}$=10.5 Hz, H-2), 4.34 (d, H-1').

Found: C, 55.88; H, 5.59; N, 15.99%. Calcd for $C_{24}H_{28}N_6O_7$: C, 56.24; H, 5.51; N, 16.40%.

^{1}H NMR data of 3',4'-diacetate (**34**): δ=4.90 (d, $J_{1,2}$=4.0 Hz, H-1), 3.35 (dd, $J_{2,3}$=10.5 Hz, H-2), 5.18 (d, $J_{1',2'}$=3.5 Hz, H-1'), 3.27 (dd, $J_{2',3'}$=10.0 Hz, H-2'), 5.46 (t, $J_{3',4'}$=8.5 Hz, H-3'), 4.51 and 4.77 (ABq, J=12.5 Hz, CH_2 in Bn), 4.87 and 5.03 (ABq, J=10.0 Hz, CH_2 in Bn), 2.00 and 2.07 (each s, Ac), and 7.38 (s, Ph).

Partial Benzoylation of 35. Treatment of **35** (1.80 g, 3.5 mmol) with benzoyl chloride (0.69 ml, 6.0 mmol) and triethylamine (1.4 ml, 10 mmol) in acetone (20 ml) in the same manner as described in the partial benzoylation of **21** gave, by separation on a silica-gel column with benzene-acetone (40:1), 4'-benzoate (**36**), 3'-benzoate (**37**), and 3'4'-dibenzoate (**38**) in 67, 13, and 17% yields, respectively.

36: Syrup, $[\alpha]_D$ +8.8° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.96 (d, $J_{1,2}$=3.3 Hz, H-1), 4.45 (d, $J_{1',2'}$=7.6 Hz, H-1'), 5.15 (dt, $J_{3',4'}$=$J_{4',5a'}$=9.8 Hz, $J_{4',5b'}$=5.3 Hz, H-4'), 4.22 (dd, $J_{5a,5b}$= 12.0 Hz, H-5'b), 3.24—4.10 (m, other ring protons), 4.61 and 4.83 (ABq, J=12.3 Hz, CH_2 in Bn), 4.85 and 5.06 (ABq, J=10.5 Hz, CH_2 in Bn), 7.46 (s, Ph in Bn), and 7.34—7.74 and 8.04—8.20 (m, Bz).

Found: C, 60.56; H, 5.16; N, 13.41%. Calcd for $C_{31}H_{32}N_6O_8$: C, 60.38; H, 5.23; N, 13.63%.

37: Syrup, $[\alpha]_D$ +30.1° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.95 (d, $J_{1,2}$=3.4 Hz, H-1), 4.50 (d, $J_{1',2'}$=8.1 Hz, H-1'), 3.56 (dd, $J_{2',3'}$=9.9 Hz, H-2'), 5.03 (t, H-3'), 3.17—3.45 (m, H-2 and H-4'), 3.75—4.20 (m, other ring protons), 4.60 and 4.82 (ABq, J=12.0 Hz, CH_2 in Bn), 4.86 and 5.08 (ABq, J=10.5 Hz, CH_2 in Bn), 7.45 (s, Ph in Bn), and 7.35—7.80 and 8.13—8.27 (m, Bz).

Found: C, 60.07; H, 5.35; N, 13.41%. Calcd for $C_{31}H_{32}N_6O_8$: C, 60.38; H, 5.23; N, 13.63%.

38: Syrup, $[\alpha]_D$ −28.1° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.97 (d, $J_{1,2}$=3.8Hz, H-1), 4.60(d, $J_{1',2'}$=7.7 Hz, H-1'), 5.55 (t, $J_{2',3'}$=$J_{3',4'}$=9.0 Hz, H-3'), 5.36 (dt, $J_{4',5'a}$=9.0 Hz, $J_{4',5'b}$=5.7 Hz, H-4'), 4.35 (dd, $J_{5'a,5'b}$=12.0 Hz, H-5'b), 3.32—4.16 (m, other ring protons), 4.62 and 4.82 (ABq, J=13.0 Hz, CH_2 in Bn), 4.86 and 5.09 (ABq, J=10.5 Hz, CH_2 in Bn), 7.45 (s, Ph in Bn), 7.35—7.70 and 7.96—8.20 (m, Bz).

Found: C, 63.21; H, 5.01; N, 11.93%. Calcd for $C_{38}H_{36}N_6O_9$: C, 63.33; H, 5.04; N, 11.66%.

Benzyl 2-Azido-4-*O*-(2-azido-4-*O*-benzyl-2-deoxy-3-*O*-methylsulfonyl-β-D-xylopyranosyl)-3-*O*-benzyl-2-deoxy-α-D-xylopyranoside (39). Methylsulfonylation of **36** in a usual manner gave **39** as a syrup quantitatively, $[\alpha]_D$ −10.3° (*c* 1.0, $CHCl_3$); ^{1}H NMR δ=4.96 (d, $J_{1,2}$=3.3 Hz, H-1), 3.25 (H-2), 4.50 (d, $J_{1',2'}$=8.3 Hz, H-1'), 3.56 (dd, $J_{2',3'}$=10.2 Hz, H-2'), 4.78 (t, $J_{3',4'}$=9.8 Hz, H-3'), 5.25 (dt, $J_{4',5'a}$=9.8 Hz, $J_{4,5'b}$=5.7 Hz, H-4'), 3.29 (dd, $J_{5'a,5'b}$=12.0 Hz, H-5'a), 4.29 (dd, H-5'b), 3.7—4.1 (m, other ring protons), 3.03 (s, Ms), 4.62 and 4.82 (ABq, J=12.0 Hz, CH_2 in Bn), 4.84 and 5.01 (ABq, J=10.8 Hz, CH_2 in Bn), 7.43 (s, Ph in Bn), and 7.32—7.66 and 8.0—8.22 (m, Bz).

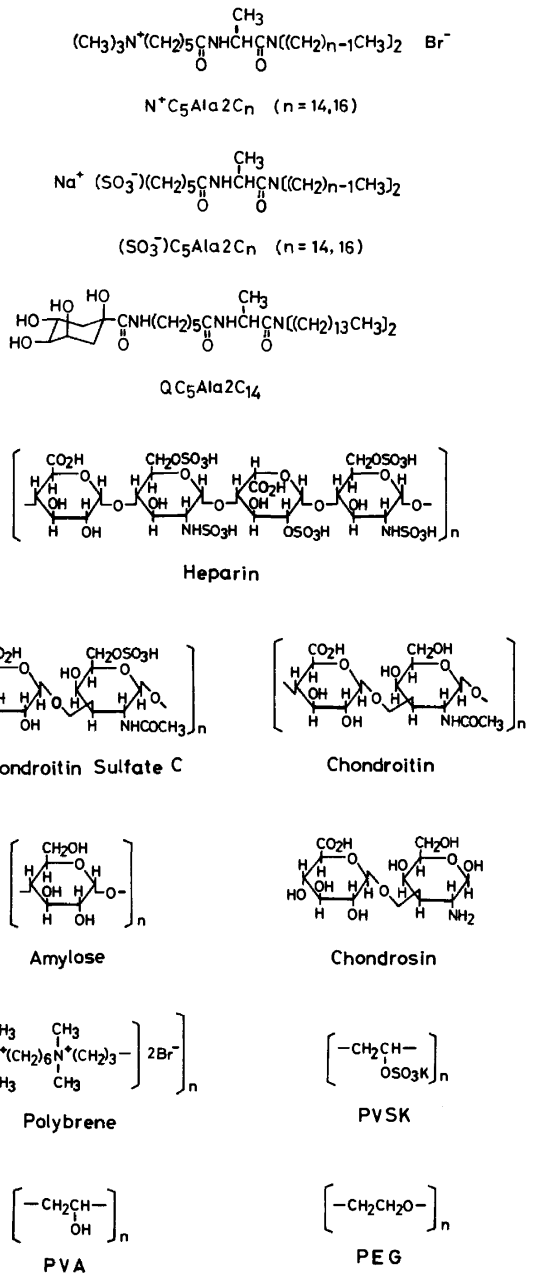
Fusogenic Behavior of Single-Walled Vesicles Composed of Synthetic Peptide Lipids†

Yukito MURAKAMI,* Jun-ichi KIKUCHI, and Toshihiko TAKAKI
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received April 9, 1986)

Fusogenic behavior of the single-walled vesicles formed with mixed or individual synthetic peptide lipids, $N^+C_5Ala2C_n$ and $(SO_3^-)C_5Ala2C_n$ (n=14, 16), was investigated in the presence of various water-soluble polymers or a nonbilayer-forming lipid by means of electron microscopy, differential scanning calorimetry, and turbidity measurements. The following ionic polymers having opposite charges to the net surface charges of the vesicles immediately induced fusion via vesicle aggregation; heparin, chondroitin sulfate C, chondroitin, and potassium salt of poly(vinyl sulfate) for the cationic vesicles, and polybrene for the anionic ones. On the other hand, ionic polymers having electrostatic charges identical with the vesicular surface charges and nonionic ones, such as amylose, poly(vinyl alcohol), polyethylene glycol 20000, and polyethylene glycol 6000, induced neither fusion nor aggregation. A nonbilayer-forming lipid, QC_5Ala2C_{14}, incorporated into the $N^+C_5Ala2C_n$ vesicles induced fusion at kinetic rates much slower than those triggered by the ionic polymers. The observations were discussed with attention to the dehydration effect and the participation of nonbilayer structures in the fusion process.

In the field of membrane mimetic chemistry,[1] synthetic lipid membranes have been widely used in place of liposomes formed with natural phospholipids, because the former aggregates attain greater morphological stability relative to the latter and provide specified functions through chemical modifications. In the light of the Brockerhoff's concept[2] which claims that the intramembrane hydrogen-belt domain is much important for morphological stabilization of biomembranes, we have prepared various peptide lipids; each composed of a polar head moiety, a hydrophobic double-chain segment, and an amino acid residue interposed between them as a hydrogen-bonding component.[3-5] We have previously clarified the characteristic morphological features of aggregates composed of the peptide lipids. In general, ionic peptide lipids form multiwalled bilayer membranes in the aqueous dispersion state and the corresponding single-walled vesicles are formed upon sonication of the aqueous dispersions,[3-5] in analogy with morphological behavior observed for liposomal membranes. Physicochemical stability of the single-walled vesicles formed with the cationic lipids, $N^+C_5Ala2C_n$, is much larger than that of the liposomal membrane formed with dimyristoylphosphatidylcholine under comparable conditions.[5] Meanwhile, nonbilayer structures such as inverted hexagonal (H_{II}) and inverted cubic (C_{II}) phases can be created with the peptide lipids by controlling intramembrane interaction among polar head moieties of the lipids.[6-10] Such nonbilayer structures have been often observed in biological systems and claimed to play crucial roles in the membrane fusion process as key intermediates.[11] Thus, the peptide lipid system can be utilized as a suitable model for investigation of the plausible mechanism of nonbilayer-mediated fusion. In the present work, we studied on morphological changes of the single-walled vesicles as induced by fusogens such as water-soluble polymers and nonbilayer-forming lipids.



†Contribution No. 831 from this Department.

Experimental

Materials. The following compounds were obtained from commercial sources as the purest grade available and used without further purification: heparin, chondroitin 6-(sodium sulfate) (chondroitin sulfate C), amylose (molecular weight, ca. 2900), potassium salt of poly(vinyl sulfate) (PVSK: degree of polymerization (DP), 162.2; degree of esterification, 94.5%) (all four species from Nakarai Chemicals, Kyoto); 2,6-pyridinedicarboxylic acid, poly(vinyl alcohol) (PVA; DP, 1500—1800), polyethylene glycol 6000 (PEG 6000; DP, ca. 7500), polyethylene glycol 20000 (PEG 20000; DP, 20000 ±5000) (all four compounds from Wako Pure Chemical Industries, Osaka); chondroitin, 2-amino-2-deoxy-3-*O*-(β-D-glucopyranuronosyl)-α-D-galactopyranose (chondrosin) (both from Seikagaku Kogyo Co., Tokyo); poly[(dimethyliminio)-1,3-propanediyl(dimethyliminio)-1,6-hexanediyl dibromide] (polybrene; from Sigma Chemical Co., Missouri, U.S.A.). Preparation of the following lipids has been reported previously: *N,N*-ditetradecyl-N^{α}-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide ($N^+C_5Ala2C_{14}$),[5] *N,N*-dihexadecyl-N^{α}-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide ($N^+C_5Ala2C_{16}$),[5] sodium *N,N*-ditetradecyl-N^{α}-(6-sulfonatohexanoyl)-L-alaninamide [(SO_3^-)-C_5Ala2C_{14}],[7] sodium *N,N*-dihexadecyl-N^{α}-(6-sulfonatohexanoyl)-L-alaninamide [(SO_3^-)C_5Ala2C_{16}],[7] and *N,N*-ditetradecyl-N^{α}-[6-(quinoylamino)hexanoyl]-L-alaninamide (QC_5Ala2C_{14}); quinoyl being the conventional name for 1,3,4,5-tetrahydroxy-[1*R*-(1α,3α,4α,5β)]cyclohexylcarbonyl.[6]

Measurements. Aqueous dispersions of lipids were prepared according to the previous method.[7] Whenever necessary, a dispersion sample was subsequently sonicated with a Heat Systems-Ultrasonics W-220F probe-type sonicator and allowed to stand for 20 min at room temperature. The sonicated solution was adjusted to an appropriate pH with aqueous hydrochloric acid or aqueous potassium hydroxide. A Beckman Φ71 pH meter equipped with a Beckman 39505 combined electrode was used for the pH measurements after calibration with a combination of appropriate standard aqueous buffers. Turbidity measurements were run at 400 nm on a Union Giken SM-401 high sensitivity spectrophotometer equipped with a cell of 10.0- or 1.0-mm path length. A Daini Seikosha SSC-560U calorimeter was used for differential scanning calorimetry (DSC). The phase transition parameters (T_m, temperature at a peak maximum of the DSC thermogram; ΔH, enthalpy change for phase transition) were determined in a manner similar to that reported previously.[7] Electron micrographs were taken on a JEOL JEM-2000FX electron microscope installed at the Research Laboratory for High Voltage Electron Microscopy of Kyushu University. Negatively stained samples for the measurements were prepared in a manner as described previously.[7]

Results

First, we examined aggregation behavior of the single-walled vesicles by means of turbidity measurements as typically shown in Fig. 1. Addition of anionic polymers immediately caused aggregation of the cationic single-walled vesicles composed of $N^+C_5Ala2C_{16}$ with the diameter range 250—800 Å. When heparin or PVSK was added to the vesicular solution,

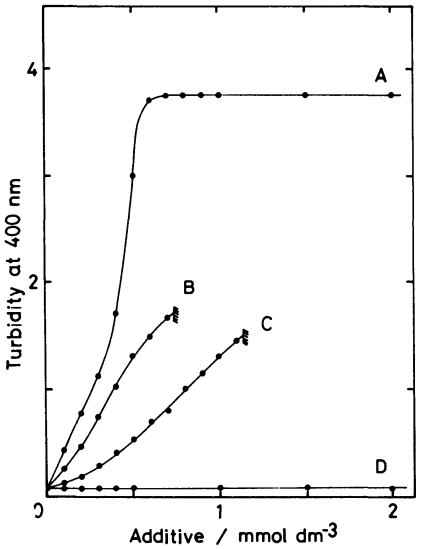


Fig. 1. Effects of additive-concentrations (in monosaccharide or monomer unit) on turbidity of the single-walled vesicles formed with $N^+C_5Ala2C_{16}$ (1.0 mmol dm^{-3}) at pH 7 and 40 °C.
A, heparin; B, chondroitin sulfate C; C, chondroitin; D, polybrene, PVA, PEG 20000, PEG 6000, amylose, or chondrosin.

turbidity increased and reached a maximum level under conditions that the whole cationic charges on the vesicular surfaces were completely neutralized with anionic charges involved in the polymer species at the 1 : 1 ratio of positive to negative charge, and further addition of the polymer gave no additional turbidity change (Fig. 1, line A). Addition of chondroitin sulfate C or chondroitin also resulted in an turbidity increase. However, precipitates were formed before neutralization of the cationic charges of the lipid vesicles with these anionic polymers (Fig. 1, lines B and C). On the other hand, a cationic polymer, polybrene, and nonionic ones, amylose, PVA, PEG 20000, and PEG 6000, did not trigger aggregation of the cationic vesicles (Fig. 1, line D) under the conditions employed here: [$N^+C_5Ala2C_{16}$], 1.0 mmol dm^{-3}; [polymer], 0—5 mmol dm^{-3} in a monosaccharide or a monomer unit. Anionic compounds with low molecular weights, chondrosin (measured at pH 5—11) and 2,6-pyridinedicarboxylic acid (measured at pH 6), also exhibited no capacity to induce aggregation of the $N^+C_5Ala2C_{16}$ vesicle.

The growth of single-walled vesicles to multiwalled lamellae was observed by negative staining electron microscopy (NSEM) for the $N^+C_5Ala2C_{16}$ membrane upon addition of one of the following anionic polymers; heparin (Fig. 2A), chondroitin sulfate C, chondroitin, and PVSK (Fig. 2B). On the other hand, the single-walled $N^+C_5Ala2C_{16}$ vesicle remained morphologically unchanged in the presence of any one of the following additives; polybrene (Fig. 2C), amylose, PVA, PEG 20000 (Fig. 2D), PEG 6000, chondrosin, and 2,6-pyridinedicarboxylic acid.

The vesicle growth observed by NSEM was also

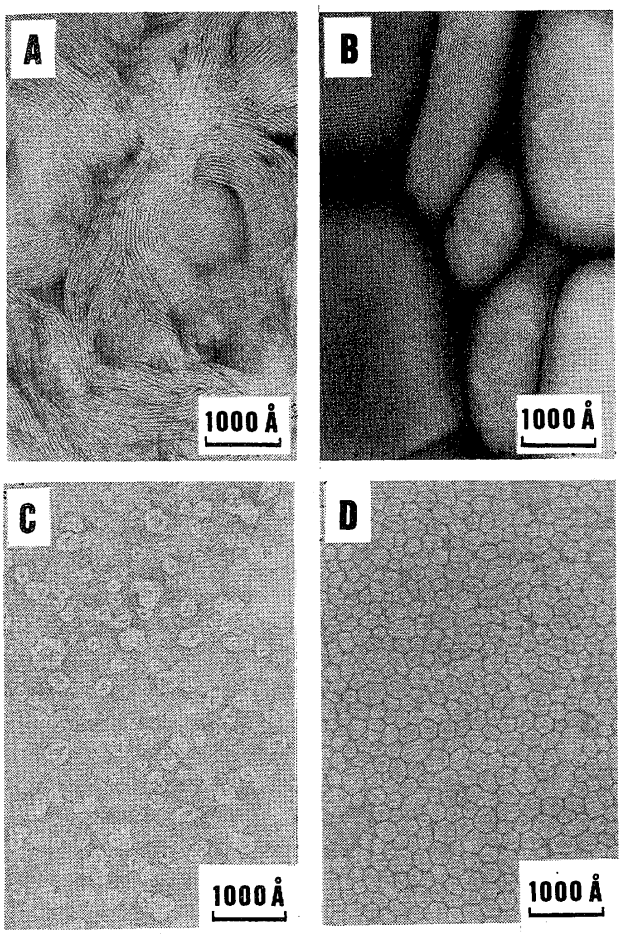

Fig. 2. Electron micrographs negatively stained with uranyl acetate.
Each specimen was prepared immediately after addition of the following additives to the single-walled vesicles formed with $N^+C_5Ala2C_{16}$ at pH 7 and 40 °C: A, heparin (2.5 mmol dm^{-3} in the anion unit); B, PVSK (0.8 mmol dm^{-3} in the monomer unit); C, polybrene (1.0 mmol dm^{-3} in the cation unit); D, PEG 20000 (5.0 mmol dm^{-3} in the monomer unit). Lipid concentrations: 5.0 mmol dm^{-3} for A and D; 1.0 mmol dm^{-3} for B and C.

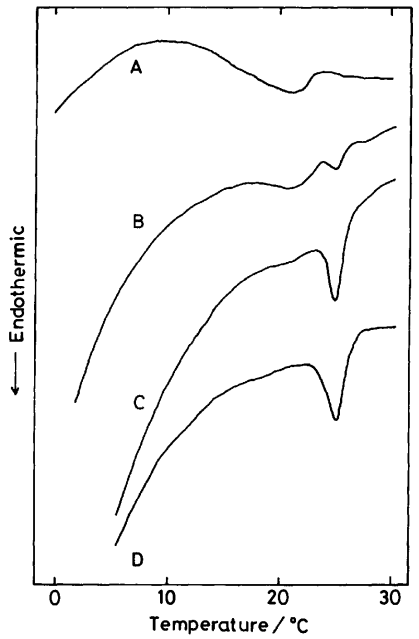

Fig. 3. Effect of added polymer on DSC behavior of the $N^+C_5Ala2C_{16}$ (5.0 mmol dm^{-3}) vesicle at pH 7.
A, aqueous solution sonicated for 3 min at 40 W without additives and incubated for 2 months at 20 °C; immediately after addition of heparin (B, 0.25 mmol dm^{-3}; C, 1.25 mmol dm^{-3}; D, 2.5 mmol dm^{-3}) at 20 °C to the aqueous solution sonicated for 3 min at 40 W. Concentrations of heparin are given in the anion unit.

confirmed by differential scanning calorimetry (DSC). The single-walled $N^+C_5Ala2C_{16}$ vesicle showed a broad phase transition at 20±5 °C (Fig. 3, curve A). The DSC thermogram remained unchanged after incubation without additives for 60 d at 20 °C or with PEG 20000 for 6 d at 20 °C. On the other hand, a phase transition peak, reflecting formation of the multi-walled bilayer membrane,[5] appeared immediately at 25.0 °C upon incubation of the vesicular solution in the presence of heparin. This DSC peak was intensified along with an increase in an amount of heparin added, and the peak originated from the single-walled vesicles nearly disappeared when a half portion of the positive charges of the lipid aggregates was neutralized with the negative ones of heparin (Fig. 3, curves B, C, and D). The results obtained from DSC measurements for the $N^+C_5Ala2C_{16}$ vesicle containing other additives, chondroitin sulfate C, chondroitin, PVSK, amylose, PVA, PEG 6000, chondrosin, and 2,6-pyridinedicarboxylic acid, were consistent with those from NSEM. Similar morphological behavior induced by anionic polymers was observed for the single-walled $N^+C_5Ala2C_{14}$ vesicle.

The aggregation-mediated vesicle growth was observed for the anionic vesicles formed with (SO_3^-)-C_5Ala2C_{16} upon addition of a cationic polymer, polybrene, as confirmed by NSEM and turbidity measurements. On the other hand, addition of heparin to the $(SO_3^-)C_5Ala2C_{16}$ vesicle did not cause any morphological changes.

In the mixed system composed of cationic and anionic peptide lipids, bilayer aggregates are formed under conditions that the total electrostatic charge on the membrane surface is not completely neutralized.[9] Multiwalled bilayers were observed in an aqueous dispersion of $N^+C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{14}$ mixed at the 3:1 molar ratio (Fig. 4A), showing a relatively sharp phase transition peak (T_m) at 17.8 °C with a transition enthaply change (ΔH) of 24 kJ mol^{-1} (Fig. 5, curve A). Even though these individual lipids show phase transitions at 25.5 and 2.1 °C for $N^+C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{14}$, respectively, in the aqueous dispersion state,[5,7] any phase separation between the cationic and anionic lipids was not detected by DSC when they were mixed. Upon sonication of the dispersion of the mixed lipid system for 2 min at 40 W, the

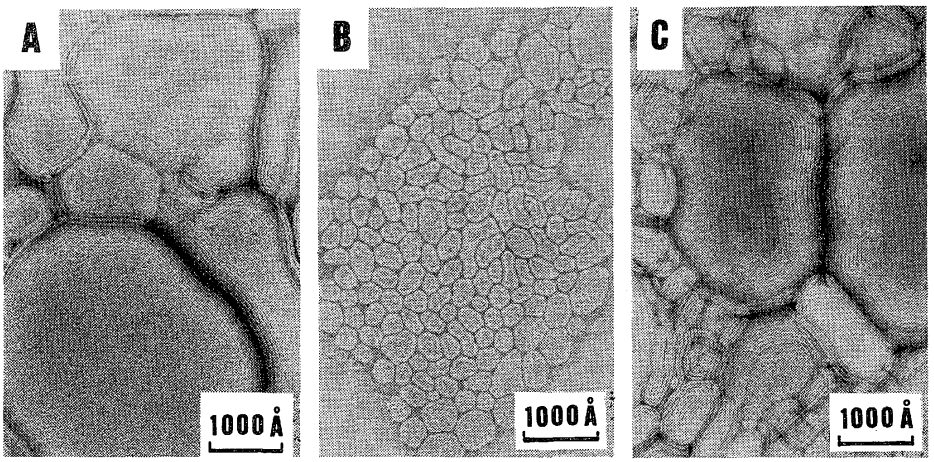

Fig. 4. Electron micrographs for a mixture of $N^+C_5Ala2C_{16}$ (1.88 mmol dm^{-3}) and $(SO_3^-)C_5Ala2C_{14}$ (0.63 mmol dm^{-3}), as negatively stained with uranyl acetate.
A, aqueous dispersion; B, aqueous solution sonicated for 3 min at 40 W; C, immediately after addition of heparin (2.0 mmol dm^{-3} in the anion unit) to B at pH 7 and 20 °C.

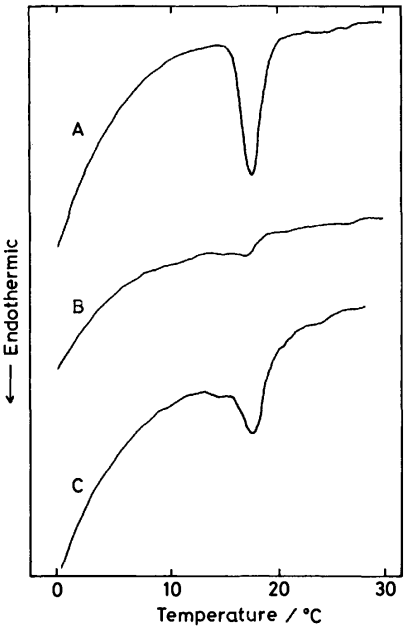

Fig. 5. DSC thermograms for a mixture of $N^+C_5Ala2C_{16}$ (1.88 mmol dm^{-3}) and $(SO_3^-)C_5Ala2C_{14}$ (0.63 mmol dm^{-3}).
Refer to the respective symbols (A, B, and C) in Fig. 4 for preparative conditions of samples.

aggregates were converted into the single-walled vesicles in the diameter range 250—800 Å (Fig. 4B), and a broad phase transition peak was observed at 17±5 °C (Fig. 5, curve B). Addition of heparin to the single-walled vesicles resulted in both aggregation and vesicle growth (Fig. 4C). The DSC thermogram showed a recovery of the sharp phase transition peak at 17.6 °C, without indicating any phase separation after such morphological changes (Fig. 5, curve C).

A mixed lipid system composed of the cationic $N^+C_5Ala2C_n$ and the nonionic QC_5Ala2C_{14} showed a unique vesicle-growing behavior in the absence of additives. The single-walled vesicles with the diameter range 200—500 Å were formed upon sonication of a homogeneous aqueous dispersion of $N^+C_5Ala2C_{14}$ and QC_5Ala2C_{14} at the 3:1 molar ratio (Fig. 6A). Although the vesicle aggregation was not detected by turbidity measurements, gradual growth of the aggregates was observed by NSEM. As shown in Fig. 6B, formation of elongated vesicles was observed in the specimen prepared after incubation for 0.5 h in addition to the original small single-walled vesicles. These aggregates were converted into larger vesicles with the diameter range 1000—4000 Å after incubation for 2 h (Fig. 6C). Such morphological changes were further examined with a combination of the cationic and nonionic lipids having different double-chain lengths. A homogeneous dispersion of $N^+C_5Ala2C_{16}$ and QC_5Ala2C_{14} at the 3:1 molar ratio showed a phase transition as detected by DSC: T_m, 19.9 °C; ΔH, 27 kJ mol^{-1}. A half-width of the endothermic peak is 3 °C and larger than that (2 °C) observed for the mixed lipid system composed of $N^+C_5Ala2C_{16}$ and (SO_3^-)-C_5Ala2C_{14} at the 3:1 molar ratio. This seems to indicate that the intramembrane domains formed by microscopic phase separation between the cationic and nonionic lipids are relatively larger than those in the cationic-anionic lipid system, although the nonlamellar phase formed with QC_5Ala2C_{14} alone was not detected by NSEM (Fig. 7A). Upon sonication of the dispersion, the multiwalled vesicles were converted into the single-walled ones with the diameter range 200—800 Å along with appearance of a broadened phase transition peak (T_m, 16±5 °C). The aggregate structure did not undergo an immediate change after sonication was performed (Fig. 7B). After the sonicated solution was allowed to stand for 3—6 d at 20 °C, very large vesicles in a diameter range of 1000—4000 Å were observed by NSEM (Fig. 7C). On the other hand,

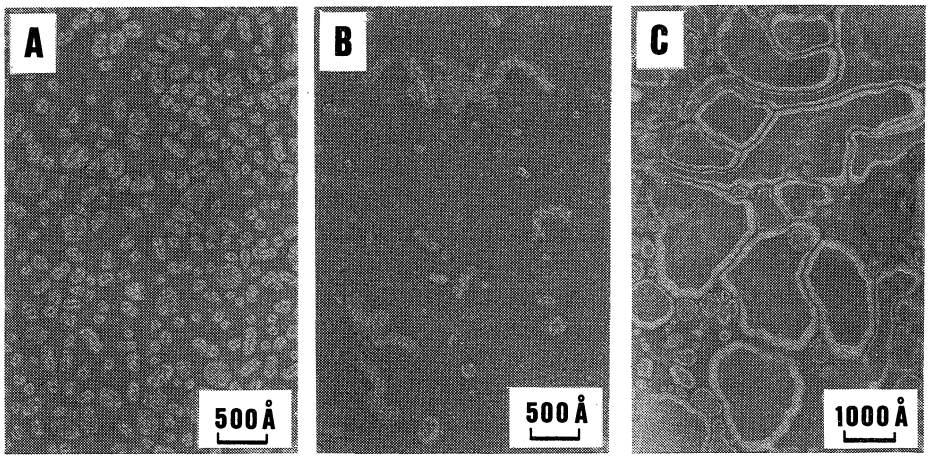

Fig. 6. Electron micrographs for a mixture of $N^+C_5Ala2C_{14}$ (3.75 mmol dm^{-3}) and QC_5Ala2C_{14} (1.25 mmol dm^{-3}), as negatively stained with uranyl acetate.
The aqueous solution sonicated for 3 min at 40 W was incubated at pH 7 and 20°C: A, immediately after sonication; B, for 0.5 h; C, for 2 h.

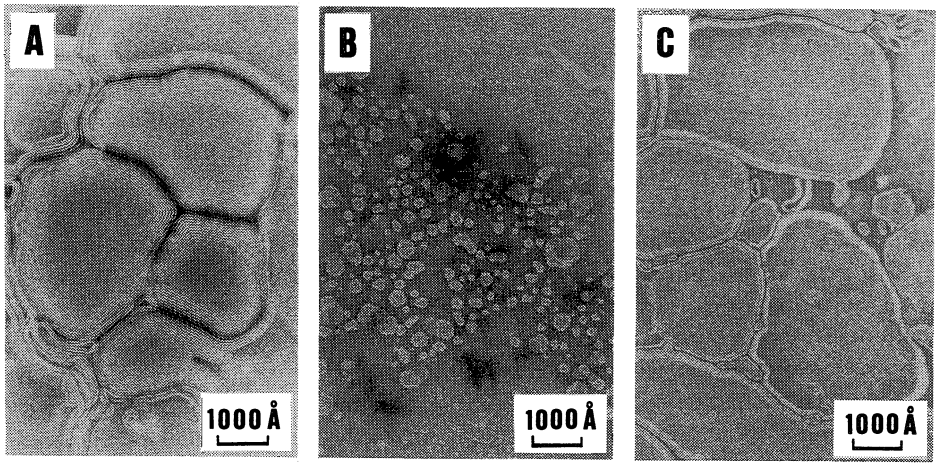

Fig. 7. Electron micrographs for a mixture of $N^+C_5Ala2C_{16}$ (3.75 mmol dm^{-3}) and QC_5Ala2C_{14} (1.25 mmol dm^{-3}), as negatively stained with uranyl acetate.
A, aqueous dispersion at pH 7 and 20°C; B, A being sonicated at pH 7 and 20°C for 3 min (40 W); C, B being left at 20°C for 6 d.

the DSC thermogram characteristic of single-walled vesicles remained practically unchanged even after incubation for 6 d.

Discussion

The membrane fusion is one of the most important phenomena for a wide variety of cellular activities, and molecular mechanisms involved in the fusion process have been extensively studied with the use of liposomal membranes.[12] The fusion of bilayer membranes is generally considered to proceed through the following sequential steps; (i) aggregation of vesicles, (ii) contact of two lipid bilayers at a limited area (adhesion), (iii) intermixing of lipid molecules by transient destabilization of bilayers at the contact point (joining), and (iv) restabilization of the bilayer structure by intermixing of separated aqueous compartments of vesicles (fission).[11a,13] Medium conditions such as temperature[13a,14] and pH,[14a,15] and many effectors such as divalent cations,[12b,16] polymers,[15,17] and lipophilic agents[18] have been reported to induce the fusion of liposomal membranes. Importance of local dehydration triggered by these fusogens has been emphasized for the adhesion step.[11b,19] Furthermore, deformation of the bilayer structure must take place in the joining step, and formation of nonbilayer structures (inverted micelles or small inverted hexagonal tubes) in the bilayer-connecting domain has been suggested.[11] In this article, we are to discuss the fusion behavior of the peptide lipid vesicles with attention to the dehydration effect and the participation of nonbilayer structures.

We have previously clarified fusogenic tendencies of the single-walled vesicles of $N^+C_5Ala2C_n$ by means of NMR, ESR, DSC, NSEM, and turbidity measurements.[3,5] The single-walled vesicles prepared upon sonication are so stable as to inhibit fusion of them under ordinary conditions and stay in solution over at

least a month without meaningful morphological change. Such structural stability of the peptide lipid vesicles is superior to that of liposomes and seems to originate partly from the formation of effective hydrogen-belt domains through intravesicular hydrogen-bonding interaction among the amino acid residues. On the other hand, nonlamellar assemblies composed of three-dimensional network of globular aggregates with small internal aqueous compartments (C_{II} phase) are formed with $N^+C_5Ala2C_n$ and $(SO_3^-)C_5Ala2C_n$ mixed at the 1 : 1 molar ratio in the aqueous dispersion state.[8,9] Since these cationic and anionic lipids form bilayer membranes individually, the polar head moieties of these lipids must be considerably dehydrated through an effective electrostatic interaction to afford such a nonlamellar phase.

It has been pointed out that the interbilayer hydration force is predominant at bilayer separations less than 20 to 30 Å and that the interaction between bilayers is dominated by electrostatic and van der Waals forces beyond about 30 Å separation.[11b,19] Thus, an essential part of fusion event must arise from the ability of membrane surfaces to overcome or circumvent the hydration barrier in order that bilayer surfaces get into contact with each other.[19] In our preliminary communication,[20] we have shown that fusion of the single-walled vesicles formed with peptide lipids takes place via formation of the intermediate nonlamellar phase as triggered by medium conditions, pH and/or temperature. Apparently, repulsion between the hydrated vesicular surfaces is circumvented by formation of the nonbilayer structure in which the lipid molecules are largely dehydrated due to an electrostatic intramembrane attraction. Dehydration of the peptide lipid bilayer may also be achieved through an electrostatic interaction on the membrane surface between lipid and additive molecules having opposite charges to each other. Indeed, fusion of the single-walled vesicles took place upon addition of polymers having the opposite charges (Figs. 2 and 3) via aggregation of the vesicles (Fig. 1). Thus, the electrostatic interaction between the vesicle and the polymer to give charge neutralization on the membrane surface becomes a potent driving force which allows not only the vesicles to aggregate but also the two membrane surfaces to come into contact. An amount of heparin, which neutralizes a half portion of the whole cationic charges of the lipid molecules present, is required for complete transformation of the cationic single-walled vesicle into the multiwalled bilayer, as confirmed by DSC (Fig. 3). This implies that the electrostatic interaction between the cationic vesicular surface and the anionic polymer is so large as to inhibit migration of the polymer molecule to the other vesicles. Since neither aggregation nor fusion was observed for the cationic vesicles in the presence of chondrosin or 2,6-pyridinedicarboxylic acid, the extended charge neutralization on the vesicular surface with polymer species seems to be essential to induction of the fusion. Accordingly, deformation of the bilayer structure can be achieved through strong electrostatic interactions between lipid and polymer molecules on the membrane surface and among charged head moieties of cationic and anionic peptide lipids.[8,9] Such changes in the packing mode of lipid molecules are accompanied undoubtedly with dehydration of lipid molecules so as to reduce the hydration barrier.

As for the mixed lipid systems composed of cationic and anionic peptide lipids, another characteristic feature was found to be present in the polymer-lipid interaction. The single-walled vesicles formed with $N^+C_5Ala2C_{16}$ and $(SO_3^-)C_5Ala2C_{14}$ at the 3 : 1 molar ratio underwent the heparin-induced fusion (Figs. 4 and 5), although the apparent surface charge density of the mixed-lipid vesicle is a half of that provided with the $N^+C_5Ala2C_{16}$ vesicle. Since homogeneous mixing of these ionic lipids was retained even after completion of the fusion as confirmed by DSC, a polymer-triggered phase separation does not seem to occur during the fusion. Thus, deformation of the bilayer structure, which results in the fusion, presumably comes from the cooperative assistance of polymer-lipid and lipid-lipid electrostatic interactions in the system.

QC_5Ala2C_{14} forms the inverted cubic phase through strong hydrogen-bonding interaction among the polar head moieties in the aqueous dispersion state.[6] Addition of this nonbilayer-forming lipid to the cationic peptide lipid, $N^+C_5Ala2C_n$, resulted in slow vesicle growth relative to the vesicle growth induced by ionic polymers (Figs. 6 and 7). In spite of such a disadvantage in the fusion rate, the membrane adhesion followed by deformation of the bilayer structure occurred in this system, QC_5Ala2C_{14} undoubtedly acting as a fusogen toward the vesicles. Formation of the elongated vesicles observed for the $N^+C_5Ala2C_{14}$-QC_5Ala2C_{14} (3 : 1) system (Fig. 6B) at the initial stage of morphological changes needs to be subjected to mechanistic consideration. Such vesicle growth to the transverse direction must be originated from a preferential fusogenic tendency of the vesicles at the surface domain having larger curvature. In fact, smaller liposomes formed with phosphatidylserine or phosphatidylcholine have an intrinsically greater capacity to fuse than larger vesicles.[14d,21] Relaxation of the packing strain imposed on the highly curved portion of the bilayers becomes a trigger of such vesicle growth. In the QC_5Ala2C_{14}-rich domains formed by microscopic phase separation as detected by DSC, such a strain effect must be much enhanced.

In conclusion, the fusion of single-walled vesicles formed with the ionic peptide lipids proceeds under the following conditions: (i) as for the vesicular systems of $N^+C_5Ala2C_n$ and $(SO_3^-)C_5Ala2C_n$ individually or mixed together to an extent that the surface charges are not completely neutralized, ionic polymers having the opposite charges to the net vesicular surface

charges are added; (ii) as for the $N^+C_5Ala2C_n$ vesicular system containing QC_5Ala2C_{14}, the latter lipid acts as a fusogen without polymer additives. Since vesicle aggregation is not always followed by fusion of bilayers,[21b,22] the present ionic polymers induce aggregation of the vesicles prior to the membrane adhesion and subsequently give out perturbation on the vesicular surface so that the bilayer structure is effectively deformed. Even in the absence of fusion-inducing polymers, incorporation of a nonbilayer-forming lipid into the vesicular system results in induction of the fusion process. Although the nonbilayer structure was not detected during the membrane fusion process under the present conditions, formation of such an intermediate phase in a microscopic portion of the bilayer-joining domain is much plausible as a consequence of dehydration of the polar head moieties of lipids.

Reaction of α,β-Unsaturated Carboxylic Acids with Manganese(III) Acetate in the Presence of Chloride Ion

Hiroshi YONEMURA, Hiroshi NISHINO, and Kazu KUROSAWA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received April 12, 1986)

The reaction of 3-phenylpropenoic acids with manganese(III) acetate-Cl^- complex yielded 1,2,2-trichloro-1-phenylethanes, 1-acetoxy-2,2-dichloro-1-phenylethanes, and 2,2-dichloro-1-phenylethanols. (*E*)-2,3-Diphenylpropenoic acids gave 2,2-dichloro-1,2-diphenylethanones and 2-acetoxy-1,2-diphenylethanones. 3,3-Diphenylpropenoic acids yielded 2,2-dichloro-1,1-diphenylethenes, 1-acetoxy-2,2-dichloro-1,1-diphenylethanes, 2,2-dichloro-1,1-diphenyl-1-ethanols, and 2-hydroxy-2,2-diphenylethanal. Fluorenylideneacetic acid gave 9-chloro-9-(dichloromethyl)fluorene, 9-acetoxy-9-(dichloromethyl)fluorene, and 9-fluorenone. 1-Cyclohexenecarboxylic acid yielded 1,2-dichlorocyclohexanecarboxylic acid and 1-acetoxy-2-chlorocyclohexanecarboxylic acid. The reaction can be explained in terms of a free-radical mechanism involving manganese(III) acetate-Cl^- complexation, addition of $Cl^\cdot$ radical, decarboxylation, and the oxidation of chloroethenes which are the reaction intermediates.

Although there are many investigations into the reaction of manganese(III) acetate,[1] the reaction of manganese(III) acetate in the presence of Cl^- ion which forms a complex[2] has not been fully examined. The reaction of aromatic compounds with this complex gave chlorine-substituted products,[3] while olefins yielded mainly addition products.[2,3] In a previous paper[4] we have reported that the reaction of aryl ketones with manganese(III) acetate-LiCl gave α-chlorinated ketones in good yield. We have examined the reactions of α,β-unsaturated carboxylic acids, such as 3-phenylpropenoic acids, (*E*)-2,3-diphenylpropenoic acids, 3,3-diphenylpropenoic acids, fluorenylideneacetic acid, and 1-cyclohexenecarboxylic acid with the complex. These acids were chosen for the reason that they may provide a variety of products which reflect the nature of the reaction and that the products will be easily characterized by spectrometry. The reactions of these acids yielded chlorine addition and substitution products accompanied by decarboxylation. We will describe these reactions and the possible mechanisms in this paper.

Results and Discussion

3-Phenylpropenoic Acids (1a—g). When a mixture of (*E*)-3-phenylpropenoic aicd (**1a**), manganese(III) acetate[5,6] and LiCl in a molar ratio of 1 : 10 : 20 in AcOH was heated under reflux, it gave 1,2,2-trichloro-1-phenylethane (**2a**) and 1-acetoxy-2,2-dichloro-1-phenylethane (**3a**). The reaction was conducted at various molar ratios of manganese(III) acetate and LiCl, and the yields changed with changing the amounts of manganese(III) acetate and LiCl (Table 1,

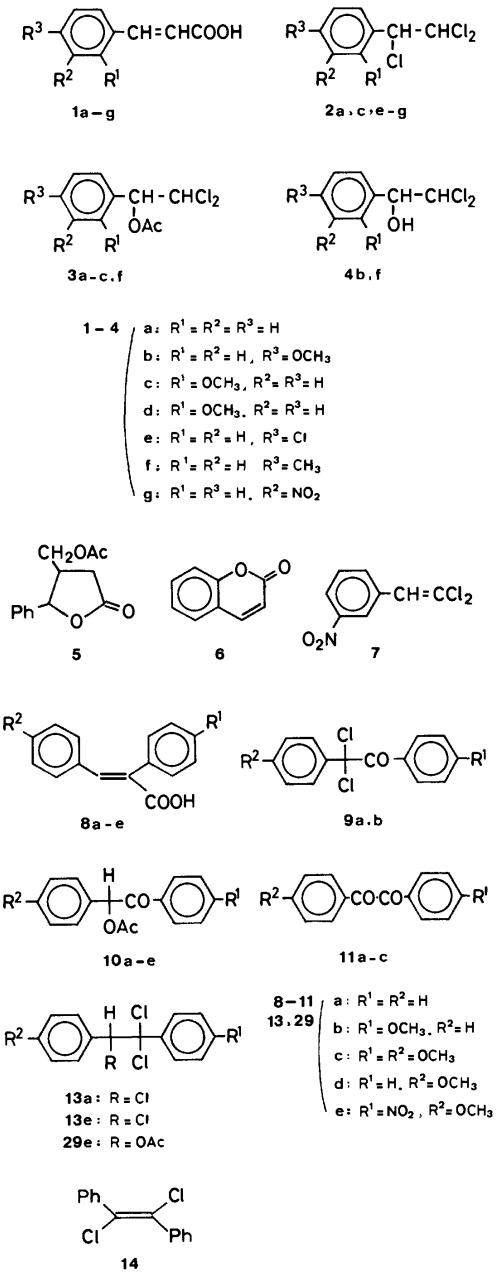
a) Substrate:Manganese(III) acetate:Salt. b) Isolated yields based on the substrate added. c) Ac_2O (20 equivalents) was added. d) **1e** was recovered (5%). e) 4-Methylbenzoic acid was obtained (13%). f) **1g** was recovered (40%).



Entries 1—5, 7). Addition of Ac_2O to the reaction mixture caused no appreciable change in the yield, but shortened the reaction time considerably (Entry 6). It was observed that changing the Cl^- ion source affected the yield and $CaCl_2$ was as good as LiCl, but it took a longer reaction time. In the reactions using NaCl, HCl, or KCl, 4-acetoxymethyl-5-phenyl-4-butanolide (**5**) was isolated. Hereafter we employed LiCl as the Cl^- ion source. Then the reactions of (*E*)-3-(**4**-methoxyphenyl)- (**1b**), (*E*)-3-(2-methoxyphenyl)- (**1c**), (*Z*)-3-(2-methoxyphenyl)- (**1d**), (*E*)-3-(4-chlorophenyl)- (**1e**), (*E*)-3-(4-methylphenyl)- (**1f**), and (*E*)-3-(3-nitrophenyl)propenoic acid (**1g**) were examined. The structures of the products were determined by studying their ^1H NMR, IR, mass spectra and elemental analyses. A summary of the reaction conditions and the yields of the products are presented in Table 1.

(*E*)-2,3-Diphenylpropenoic Acids (8a—d). The reaction of (*E*)-2,3-diphenylpropenoic acid (**8a**) with manganese(III) acetate–Cl^- complex gave 2,2-dichloro-1,2-diphenylethanone (**9a**), 2-acetoxy-1,2-diphenylethanone (**10a**), 1,2-diphenylethanedione (**11a**), benzoic acid (**12**), 1,1,2-trichloro-1,2-diphenylethane (**13a**) and (*E*)-1,2-dichloro-1,2-diphenylethene (**14**). The reaction of (*E*)-2-(4-methoxyphenyl)-3-phenylpropenoic acid (**8b**) yielded the corresponding ethanones (**9b** and **10b**) and an ethanedione (**11b**). The reactions of (*E*)-2,3-bis(4-methoxyphenyl)propenoic acid (**8c**) and (*E*)-3-(4-methoxyphenyl)-2-phenylpropenoic acid (**8d**) yielded no chlorinated compounds, but gave 2-acetoxy-1,2-diphenylethanones (**10c** and **10d**) and 1,2-diphenylethanediones (**11b** and **11c**) (Table 2). It should be pointed out that the carbonyl carbon in the ethanones is assigned by ^1H NMR to the carbon on which the carboxyl group of the acid had been located and that the acetoxyl group is introduced more readily to the carbon attached to a methoxyphenyl group than to a phenyl group.

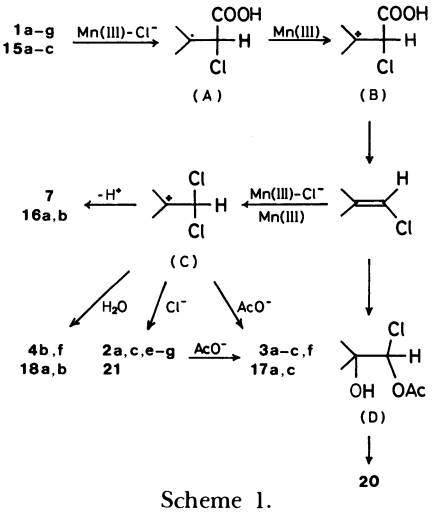
a) Substrate:Manganese(III) acetate:LiCl. b) Isolated yields based on the substrate added. c) Ac_2O (15 equivalents) was added.

acid (**15a**) was oxidized with manganese(III) acetate–Cl^- complex in AcOH, 2,2-dichloro-1,1-diphenylethene (**16a**) and 1-acetoxy-2,2-dichloro-1,1-diphenylethane (**17a**), 2,2-dichloro-1,1-diphenylethanol (**18a**) and benzophenone (**19a**) were obtained. A remarkable change has been observed when Ac_2O was added to the reaction mixture, i.e. **17a** became the major product (Table 3). The reaction of 3,3-bis(4-methoxyphenyl)-propenoic acid (**15b**) with the complex in a molar ratio of 1 : 4 : 8 ended in extremely short reaction time, giving 2,2-dichloro-1,1-bis(4-methoxyphenyl)ethene (**16b**), 2,2-dichloro-1,1-bis(4-methoxyphenyl)ethanol (**18b**), and 2-hydroxy-2,2-bis(4-methoxyphenyl)ethanal (**20**). The reaction of fluorenylideneacetic acid (**15c**) yielded 9-acetoxy-9-(dichloromethyl)fluorene (**17c**), 9-fluorenone (**19c**), and 9-chloro-9-(dichloromethyl)fluorene (**21**).

1-Cyclohexenecarboxylic Acid (22). The reaction of **22** gave 2,2,6,6-tetrachlorocyclohexanone (**23**) (7%), 1,2-dichlorocyclohexanecarboxylic acid (**24**) (17%), and 1-acetoxy-2-chlorocyclohexanecarboxylic acid (**25**) (24%). These acids were separated and identified after methylation with diazomethane. The configuration of these acids could not be determined.

The reactions of 3-phenyl- and 3,3-diphenylpropenoic acids with manganese(III) acetate-Cl^- complex yielded chlorine-substituted ethenes and ethanes. By contrast, 2,3-diphenylpropenoic acids yielded 2,2-dichloro-1,2-diphenylethanones and 2-acetoxy-1,2-diphenylethanones. Addition of an acetoxyl group in place of a chlorine atom is often observed in these reactions. As postulated in the reaction of olefins with manganese(III) acetate in the presence of Cl^- ion,[2] the first step in the reaction of the acids must be the formation of a manganese(III) acetate-Cl^- complex which produces a Cl· radical. The Cl· radical adds to the C-2 of the substituted propenoic acid, producing a secondary or tertiary carbon radical A which is then oxidized to the corresponding carbonium ion B (Scheme 1). It seems also possible that the acid coordinates to the manganese(III) acetate–Cl^- complex and a chlorine atom is then transferred from the complex to the C-2 of the propenoic acid, forming the radical A. When the carboxyl group is eliminated from B as CO_2, then a chloroethene (**26a,b**) is formed which may react further with manganese(III) acetate-Cl^- complex to give another carbonium ion C. It was confirmed that 2,3-dichloro-3-phenylpropanoic acid (**27**) which could be formed by the addition of chlorine to the C=C bond in **1a**, was only partially decarboxylated and chlorinated under the reaction conditions to give 1,1,2-trichloro-2-phenylethane (**2a**) (17%), suggesting that this route makes only a small contribution for the formation of **2a**. The carbonium ion C gives dichloroethenes, 1,2,2-trichloroethanes, and 1-acetoxy-2,2-dichloroethanes depending on either losing a proton on the adjacent carbon or taking up a Cl^- ion and an acetate ion. If H_2O which may be contained in the reaction mixture attacks C, then alcohols are formed. The fact that the formation of **18a** was suppressed when the reaction of **15a** was conducted under anhydrous conditions (Table 3) confirms this view. In the reactions of **1b—d** and **15a**, an acetoxyl group was preferentially introduced onto the carbon bearing two phenyl groups or a methoxyphenyl group. The chlorine atom at the benzylic position could be readily replaced by an acetate

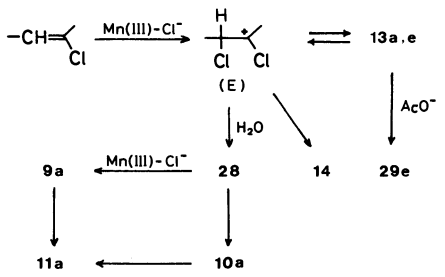
ion,[4] and **2c** was transformed into **3c** by heating in AcOH containing manganese(II) acetate. The formation of **10a** and **10b** in the reactions of **8a** and **8b** showed that the nucleophilic attack with acetate ion also takes place at the carbon attached to the phenyl group to a limited extent.



Scheme 1.

Chloroethenes as the postulated intermediates have not been found in the products, probably because they react faster than the original acid with manganese(III) acetate-Cl^- complex. In order to prove the involvement of chloroethenes as the reaction intermediate, 1-chloro-2-phenylethene (**26a**), which was prepared by an alternative method, was oxidized with the complex in AcOH and it did give the identical products with those from **1a** in a similar ratio (Table 1, Entry 20). Similarly, 2-chloro-1,1-diphenylethene (**26b**) was prepared and oxidized with the complex to yield **16a**, **17a**, and **18a** in a ratio similar to that from **15a** (Table 3). The formation of **20** in the reaction of **15b** deserves comment. It seems that because of the electron-donating effect of the two 4-methoxyphenyl groups in **15b**, the corresponding substituted 2-chloroethene, the intermediate, reacts with the complex via an electron-transfer mechanism[7] to give an α-glycol monoacetate (D) which can be hydrolyzed to **20**.

It has been mentioned already that the carbonyl carbon in 1,2-diphenylethanones (**9b** and **10b,d**) was assigned at the carbon on which the carboxyl group had been located. This was indicated by the presence of the characteristic lower field aromatic protons ortho to the carbonyl group of ethanones in their ^1H NMR spectra. This leads to a suggestion that the intermediate, 1-chloro-1,2-diphenylethene (**26c**), is converted into a 1,2-dichloro-1,2-diphenyl cation E which is in equilibrium with 1,1,2-trichloro-1,2-diphenylethane (**13a**) and eventually gives rise to 2-chloro-1,2-diphenylethanone (**28**) as shown in Scheme 2. In fact, the reaction of 1-chloro-1,2-diphenylethene (**26c**) gave **9a**, **11a**, **13a**, and **14** (Table 2) and the treatment of **13a** with manganese(II) acetate in AcOH yielded **28** in a



Scheme 2.

80% yield. For further confirmation of the mechanism for the formation of 2,2-dichloro-1,2-diphenylethanones and 2-acetoxy-1,2-diphenylethanones, the reaction of (*E*)-3-(4-methoxyphenyl)-2-(4-nitrophenyl)-propenoic acid (**8e**) with manganese(III) acetate-Cl^- complex was carried out. The corresponding 1,2-dichloro-1,2-diphenylethyl cation E from **8e** may be destabilized by the electron-withdrawing effect of the *p*-nitro group so that the equilibrium lies toward the right in favor of the formation of 1,1,2-trichloro (**13e**) and hence 2-acetoxy-1,1-dichloro derivative (**29e**). Accordingly, the cation E has less chance to form a 2-chloro-1,2-diphenylethanone (**28**). The reaction indeed yielded 2-acetoxy-1,1-dichloro-2-(4-methoxyphenyl)-1-(4-nitrophenyl)ethane (**29e**) as the major product (36%), accompanied with 2-acetoxy-2-(4-methoxyphenyl)-1-(4-nitrophenyl)ethanone (**10e**) (24%), and 1,1,2-trichloro-2-(4-methoxyphenyl)-1-(4-nitrophenyl)ethane (**13e**) (4%). The compound **28** can be either chlorinated to give **9a** or converted to **10a**,[4] and the routes to **11a** from **9a** and **10a** have been established.[8]

In the reaction of 1-cyclohexenecarboxylic acid (**22**) the yield of the decarboxylated product, 2,2,6,6-tetrachlorocyclohexanone (**23**), was poor, probably because the corresponding cation B is less stabilized and quickly takes up a chloride ion to form 1,2-dichlorocyclohexanecarboxylic acid (**24**). The compound **25** can be obtained from **24** on treatment with manganese(II) acetate in boiling AcOH.

It is thus concluded that the reaction of aryl-substituted propenoic acids with manganese(III)-Cl^- complex proceeds via chloro-substituted ethenes formed by chlorination and decarboxylation of the acids. Although there are several decarboxylation reactions to form alkyl or aryl halides[9,10] and our reaction is limited only to aryl-substituted propenoic acids, the use of manganese(III) acetate-Cl^- complex as a decarboxylating reagent is a method of choice when chloro-substituted phenylethanes and phenylethenes are needed.

Experimental

Measurements. The IR spectra were measured in chloroform solution on a JASCO A-102 infrared spectrometer. The ^1H NMR spectra were recorded on a Hitachi Perkin-Elmer R-24 spectrometer (60 MHz) with tetramethylsilane as an

internal standard; the chemical shifts are reported in δ values. The mass spectra were obtained with a JEOL JMS-DX300 and a JEOL JMS-DX303 mass spectrometer. The melting points were determined on a Yanagimoto micro-melting point apparatus and were not corrected.

Materials. (*E*)-3-(4-Methoxyphenyl)propenoic acid (**1b**),[11] (*E*)-3-(2-methoxyphenyl)propenoic acid (**1c**),[12] (*Z*)-3-(2-methoxyphenyl)propenoic acid (**1d**),[13] (*E*)-3-(4-methylphenyl)propenoic acid (**1f**),[14] fluorenylideneacetic acid (**15c**),[15] and 1-cyclohexenecarboxylic acid (**22**)[16] were prepared by the method described in the literature. (*E*)-2,3-Diphenylpropenoic acid (**8a**), (*E*)-2-(4-methoxyphenyl)-3-phenylpropenonic acid (**8b**), (*E*)-2,3-bis(4-methoxyphenyl)-propenoic acid (**8c**), (*E*)-3-(4-methoxyphenyl)-2-phenylpropenoic acid (**8d**), and (*E*)-3-(4-methoxyphenyl)-2-(4-nitrophenyl)propenoic acid (**8e**) were prepared from the corresponding arylacetic acid and benzaldehyde by Perkin condensation.[11]

(*E*)-2,3-Bis(4-methoxyphenyl)propenoic Acid (8c): Colorless needles; mp 212 °C (subl.); ^{1}H NMR (DMSO-d_6) δ=3.71 (3H, s, OCH_3), 3.79 (3H, s, OCH_3), 6.6—7.3 (8H, m, ar.H), 7.70 (1H, s, =CH-), and 12.3 (1H, br., COOH). Anal. ($C_{17}H_{16}O_4$) C, H.

3,3-Diphenylpropenoic acid (**15a**) and 3,3-bis(4-methoxyphenyl)propenoic acid (**15b**) were prepared from the corresponding benzophenone and ethyl bromoacetate by Reformatsky reaction.[17] (*E*)-3-Phenylpropenoic acid (**1a**), (*E*)-3-(4-chlorophenyl)propenoic acid (**1e**), and (*E*)-3-(3-nitrophenyl)-propenoic acid (**1g**) were purchased from Aldrich Chemical Company, Inc. and Wako Pure Chemical Industries, Ltd.

Oxidations of α,β-Unsaturated Carboxylic Acids with Manganese(III) Acetate-Cl^-. The general procedure for the oxidation of α,β-unsaturated carboxylic acids with manganese(III) acetate-Cl^- was as follows. To a heated solution of manganese(III) acetate[5] (4—10 mmol) and chloride anion (see Table 1) in AcOH (30 cm^3), a carboxylic acid (1 mmol) was added. The mixture was then heated under reflux until the brown color of the solution had become transparent. After removal of the solvent, 2 M (1 M=1 mol dm^{-3}) hydrochloric acid (40 cm^3) was added to the mixture, which was then extracted with benzene or chloroform (3×30 cm^3). The benzene (or chloroform) solution was washed with aqueous sodium hydrogencarbonate solution and evaporated in vacuo. The products were separated on preparative TLC (Kieselgel 60G or Wakogel B-10), with chloroform or benzene as the developing solvent. The aqueous sodium hydrogencarbonate solution was acidified with concd hydrochloric acid and extracted with either chloroform or ethyl acetate, which gave acidic products. The yields are summarized in Tables 1—3.

Oxidation Products of (*E*)-3-Phenylpropenoic Acid (1a). 1,2,2-Trichloro-1-phenylethane (2a): Bp 190 °C/2400 Pa (bath temperature); the ^{1}H NMR data agreed with those reported.[18]

1-Acetoxy-2,2-dichloro-1-phenylethane (3a): The ^{1}H NMR data agreed with those reported.[19]

4-Acetoxymethyl-5-phenyl-4-butanolide (5): Colorless liquid; bp 175 °C/1.3 Pa (bath temperature); IR 1780 (-COO-), 1755 cm^{-1} (OAc); ^{1}H NMR (CCl_4) δ=2.00 (3H, s, OAc), 2.0—3.0 (3H, m, >$CHCH_2$-), 4.17 (2H, d, J=5.4 Hz, -CH_2OAc), 5.21 (1H, d, J=6.0 Hz, >CH-O-), 7.32 (5H, m, ar.H). Anal. ($C_{13}H_{14}O_4$) C, H.

Oxidation Products of (*E*)-3-(4-Methoxyphenyl)propenoic Acid (1b). 1-Acetoxy-2,2-dichloro-1-(4-methoxyphenyl)-ethane (3b): Colorless liquid; IR 1747 cm^{-1} (OAc); ^{1}H NMR (CCl_4) δ=2.04 (3H, s, OAc), 3.66 (3H, s, OCH_3), 5.77 (1H, d, J=5.4 Hz, -$CHCl_2$), 5.93 (1H, d, J=5.4 Hz, >CHOAc), 6.76 (2H, m, H-3 and H-5), and 7.24 (2H, m, H-2 and H-6). Found: m/z 262.0154. Calcd for $C_{11}H_{12}{}^{35}Cl_2O_3$: M, 262.0164.

2,2-Dichloro-1-(4-methoxyphenyl)ethanol (4b): Colorless liquid; the ^{1}H NMR and IR spectra were identical with those reported.[20]

Oxidation Products of (*E*)-3-(2-Methoxyphenyl)propenoic Acid (1c) and (*Z*)-3-(2-Methoxyphenyl)propenoic Acid (1d). 1,2,2-Trichloro-1-(2-methoxyphenyl)ethane (2c): Colorless liquid; ^{1}H NMR (CCl_4) δ=3.84 (3H, s, OCH_3), 5.60 (1H, d, J=6.0 Hz, -$CHCl_2$), 6.06 (1H, d, J=6.0 Hz, -CHCl-), and 6.8—7.6 (4H, m, ar.H). Found: m/z 237.9735. Calcd for $C_9H_9{}^{35}Cl_3O$: M, 237.9719.

1-Acetoxy-2,2-dichloro-1-(2-methoxyphenyl)ethane (3c): Colorless needles; mp 108—109 °C (from ethanol); IR 1750 cm^{-1} (OAc); ^{1}H NMR ($CDCl_3$) δ=2.16 (3H, s, OAc), 3.78 (3H, s, OCH_3), 6.12 (1H, d, J=4.0 Hz, -$CHCl_2$), 6.57 (1H, d, J=4.0 Hz, >CHOAc), and 6.7—7.5 (4H, m, ar.H); MS m/z (rel intensity) 262, 264, 266 (M^+, 17), 179 (35), 137 (100), and 107 (45). Anal. ($C_{11}H_{12}Cl_2O_3$) C, H.

2*H*-1-Benzopyran-2-one (6): Mp 65—66 °C.

Oxidation Product of (*E*)-3-(4-Chlorophenyl)propenoic Acid (1e). 1,2,2-Trichloro-1-(4-chlorophenyl)ethane (2e): Colorless liquid.[21]

Oxidation Products of (*E*)-3-(4-Methylphenyl)propenoic Acid (1f). 1,2,2-Trichloro-1-(4-methylphenyl)ethane (2f): The ^{1}H NMR data agreed with those reported.[18]

1-Acetoxy-2,2-dichloro-1-(4-methylphenyl)ethane (3f): Colorless liquid.[22] **2,2-Dichloro-1-(4-methylphenyl)-ethanol (4f):** Colorless liquid.[23] **4-Methylbenzoic acid:** Mp 180 °C.

Oxidation Products of (*E*)-3-(3-Nitrophenyl)propenoic Acid (1g). 1,2,2-Trichloro-1-(3-nitrophenyl)ethane (2g): Colorless cubes; mp 59.8—60.7 °C (from methanol); IR 1534 and 1354 cm^{-1} (NO_2); ^{1}H NMR (CCl_4) δ=5.32 (1H, d, J=5.4 Hz, >CHCl), 6.05 (1H, d, J=5.4 Hz, -$CHCl_2$), 7.4—8.0 (2H, m, H-5 and H-6), and 8.1—8.4 (2H, m, H-2 and H-4). Anal. ($C_8H_6Cl_3NO_2$) C, H, N.

β,β-Dichloro-3-nitrostyrene (7): Colorless silky needles; mp 54.9—55.4 °C (from hexane); IR 1610 (C=C), 1531 and 1354 cm^{-1} (NO_2); ^{1}H NMR (CCl_4) δ=6.90 (1H, s, =CH-), 7.4—8.0 (2H, m, H-5 and H-6), and 8.0—8.5 (2H, m, H-2 and H-4). Anal. ($C_8H_5Cl_2NO_2$) C, H, N.

Oxidation Products of (*E*)-2,3-Diphenylpropenoic Acid (8a). 2,2-Dichloro-1,2-diphenylethanone (9a): Mp 62—63 °C (lit,[24] mp 61—62 °C). **2-Acetoxy-1,2-diphenylethanone (10a):** Mp 81—82 °C (lit,[25] mp 80—82 °C). **1,2-Diphenylethanedione (11a):** Mp 95 °C. **Benzoic acid (12):** Mp 122 °C. **1,2,2-Trichloro-1,2-diphenylethane (13a):** Mp 101—102 °C (lit,[26] mp 102—103 °C). **(*E*)-1,2-Dichloro-1,2-diphenylethene (14):** Mp 140.3—140.5 °C (lit,[27] mp 139 °C).

Oxidation Products of (*E*)-2-(4-Methoxyphenyl)-3-phenylpropenoic Acid (8b). 2,2-Dichloro-1-(4-methoxyphenyl)-2-phenylethanone (9b): Colorless needles; mp 57—58 °C (from ethanol); IR 1689 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=3.70 (3H, s, OCH_3), 6.71 (2H, m, H-3 and H-5), 7.1—7.8 (5H, m, Ph), and 7.76 (2H, m, H-2 and H-6). Anal. ($C_{15}H_{12}Cl_2O_2$) C, H.

2-Acetoxy-1-(4-methoxyphenyl)-2-phenylethanone (10b):

Mp 79.2—79.9 °C (lit,[28] mp 78—79 °C). **1-(4-Methoxyphenyl)-2-phenylethanedione (11b):** Mp 63 °C (lit,[29] mp 62—63 °C).

Oxidation Products of (*E*)-2,3-Bis(4-methoxyphenyl)propenoic Acid (8c). 2-Acetoxy-1,2-bis(4-methoxyphenyl)ethanone (10c): Mp 93.8—94.8 °C (lit,[30] mp 93.5 °C). **1,2-Bis(4-methoxyphenyl)ethanedione (11c):** Mp 132.7—133.3 °C (lit,[31] mp 133 °C).

Oxidation Products of (*E*)-3-(4-methoxyphenyl)-2-phenylpropenoic Acid (8d). 2-Acetoxy-2-(4-methoxyphenyl)-1-phenylethanone (10d): Colorless liquid.[32] **1-(4-Methoxyphenyl)-2-phenylethanedione (11b).**

Oxidation Products of 3,3-Diphenylpropenoic Acid (15a). 2,2-Dichloro-1,1-diphenylethene (16a): Mp 78.7—79.9 °C (lit,[33] mp 80 °C). **1-Acetoxy-2,2-dichloro-1,1-diphenylethane (17a):** Mp 98.7—99.2 °C (lit,[34] 102.4—104 °C). **2,2-Dichloro-1,1-diphenylethanol (18a):** Mp 95.7—96.7 °C (lit,[35] mp 94—97 °C). **Benzophenone (19a):** Mp 48 °C.

Oxidation Products of 3,3-Bis(4-methoxyphenyl)propenoic Acid (15b). 2,2-Dichloro-1,1-bis(4-methoxyphenyl)ethene (16b): Mp 110.3—110.6 °C (lit,[36] mp 109 °C).

2,2-Dichloro-1,1-bis(4-methoxyphenyl)ethanol (18b): Colorless cubes; mp 103.5—104.5 °C (from ethanol): IR 3568 cm^{-1} (OH): ^1H NMR ($CDCl_3$) δ=3.31 (1H, br s, OH), 3.65 (6H, s, 2×OCH_3), 6.47 (1H, s, -$CHCl_2$), 6.78 (4H, m, H-3′, H-3″, H-5′, and H-5″), and 7.37 (4H, m, H-2′, H-2″, H-6′, and H-6″). Found: *m/z* 326.0453. Calcd for $C_{16}H_{16}{}^{35}Cl_2O_3$: M, 326.0477.

2-Hydroxy-2,2-bis(4-methoxyphenyl)ethanal (20): Colorless liquid: IR 3488 (OH) and 1720 cm^{-1} (CHO); ^1H NMR ($CDCl_3$) δ=3.78 (6H, s, 2×OCH_3), 4.30 (1H, br s, OH), 6.84 (4H, m, H-3′, H-3″, H-5′, and H-5″), 7.24 (4H, m, H-2′, H-2″, H-6′, and H-6″), and 9.84 (1H, s, CHO). Found: *m/z* 272.1040. Calcd for $C_{16}H_{16}O_4$: M, 272.1049.

Oxidation Products of Fluorenylideneacetic Acid (15c). 9-Acetoxy-9-(dichloromethyl)fluorene (17c): Colorless cubes; mp 83.6—84.6 °C (from ethanol); IR 1745 cm^{-1} (OAc); ^1H NMR (CCl_4) δ=1.94 (3H, s, OAc), 6.79 (1H, s, -$CHCl_2$), and 7.1—7.8 (8H, m, ar.H). Anal. ($C_{16}H_{12}Cl_2O_2$) C, H.

9-Chloro-9-(dichloromethyl)fluorene (21): Colorless cubes; mp 88.0—88.6 °C (from ethanol); ^1H NMR (CCl_4) δ=6.14 (1H, s, -$CHCl_2$), and 7.0—7.7 (8H, m, ar.H). Anal. ($C_{14}H_9Cl_3$) C, H.

9-Fluorenone (19c): Mp 83 °C.

Oxidation Products of 1-Cyclohexenecarboxylic Acid (22). 2,2,6,6-Tetrachlorocyclohexanone (23): Mp 83.1—83.8 °C (lit,[37] mp 83 °C).

The acidic products of the oxidation of **22** were separated and identified after methylation with diazomethane.

Methyl 1,2-Dichlorocyclohexanecarboxylate (Methyl Ester of 24): Colorless liquid; IR 1740 cm^{-1} (-COO-); ^1H NMR (CCl_4) δ=1.0—2.7 (8H, m, -CH_2-), 3.73 (3H, s, OCH_3), and 4.52 (1H, br, -CHCl-); MS (for the acid **24**) *m/z* (rel intensity) 197, 199, 201 (100, $(M+1)^+$), 161, 163 (28), 133, 135 (51), and 127 (72).

Methyl 1-Acetoxy-2-chlorocyclohexanecarboxylate (Methyl Ester of 25): Colorless liquid; IR 1735 cm^{-1} (OAc and -COO-); ^1H NMR (CCl_4) δ=0.7—2.5 (8H, m, -CH_2-); 2.04 (3H, s, OAc), 3.70 (3H, s, OCH_3), and 4.19 (1H, br, -CHCl-); MS *m/z* (rel intensity) 235, 237 (100, $(M+1)^+$). Found: *m/z* 235.0729. Calcd for $C_{10}H_{16}{}^{35}ClO_4$: M, 235.0737.

Reaction of 2,3-Dichloro-3-phenylpropanoic Acid (27). A mixture of **27** (203 mg), manganese(III) acetate (497 mg), and lithium chloride (236 mg) in AcOH (25 cm^3) was heated under reflux for 110 min. The reaction mixture was diluted with water and extracted with benzene. After removal of the solvent in vacuo, the resulting substance was separated on TLC with chloroform as the developing solvent to give **2a** (33 mg, 17%) and **27** recovered (120 mg, 59%).

Conversion of 2c to 3c. A mixture of **2c** (86 mg), manganese(II) acetate tetrahydrate (704 mg), and acetic anhydride (1 cm^3) in AcOH (20 cm^3) was heated under reflux for 3 h. The reaction mixture was diluted with water and extracted with benzene. The solvent was evaporated in vacuo and the resulting substance was separated on TLC with benzene as the developing solvent to give **3c** (24 mg, 27%) and **2c** recovered (42 mg, 52%).

Oxidation of 1-Chloro-2-phenylethene (26a). The reaction of 1-chloro-2-phenylethene (**26a**)[38] under the reaction conditions similar to those for **1a** gave 1,2,2-trichloroethane (**2a**) and 1-acetoxy-2,2-dichloro-1-phenylethane (**3a**) (Table 1).

Oxidation of 2-Chloro-1,1-diphenylethene (26b). A similar reaction of 2-chloro-1,1-diphenylethene (**26b**) gave 2,2-dichloro-1,1-diphenylethene (**16a**), 1-acetoxy-2,2-dichloro-1,1-diphenylethane (**17a**), and 2,2-dichloro-1,1-diphenylethanol (**18a**) (Table 3).

Oxidation of 1-Chloro-1,2-diphenylethene (26c). The reaction of 1-chloro-1,2-diphenylethene (**26c**)[27] gave 2,2-dichloro-1,2-diphenylethanone (**9a**), 1,2-diphenylethanedione (**11a**), 1,1,2-trichloro-1,2-diphenylethane (**13a**), and (*E*)-1,2-dichloro-1,2-diphenylethene (**14**) (Table 2).

Conversion of 1,1,2-Trichloro-1,2-diphenylethane (13a) to 2-Chloro-1,2-diphenylethanone (28). A mixture of 1,1,2-trichloro-1,2-diphenylethane (**13a**, 260 mg), manganese(II) acetate tetrahydrate (1.79 g), and acetic anhydride (2.8 cm^3) in AcOH (25 cm^3) was heated under reflux for 3 h. After removal of the solvent in vacuo, the resulting substance was separated on TLC with chloroform as the developing solvent to give 2-chloro-1,2-diphenylethanone (**28**) (143 mg) and **13a** (39 mg) (80% conversion).

Oxidation of (*E*)-3-(4-Methoxyphenyl)-2-(4-nitrophenyl)propenoic Acid (8e). (*E*)-3-(4-Methoxyphenyl)-2-(4-nitrophenyl)propenoic acid (**8e**) gave 1,1,2-trichloro-2-(4-methoxyphenyl)-1-(4-nitrophenyl)ethane (**13e**), 2-acetoxy-1,1-dichloro-2-(4-methoxyphenyl)-1-(4-nitrophenyl)ethane (**29e**), 2-acetoxy-2-(4-methoxyphenyl)-1-(4-nitrophenyl)ethanone (**10e**), *p*-anisic acid, and *p*-nitrobenzoic acid.

1,1,2-Trichloro-2-(4-methoxyphenyl)-1-(4-nitrophenyl)ethane (13e): Colorless cubes; mp 127.3—127.8 °C (from ethanol); IR 1599 and 1350 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ= 3.78 (3H, s, OCH_3), 5.47 (1H, s, -CHCl-), 6.74 (2H, m, H-3″ and H-5″), 7.16 (2H, m, H-2″ and H-6″), 7.79 (2H, m, H-2′ and H-6′), and 8.18 (2H, m, H-3′ and H-5′); MS *m/z* (rel intensity) 359, 361, 363, 365 (M^+, 2), 289, 291 (11), 165 (18), and 154, 156 (100). Anal. ($C_{15}H_{12}Cl_3NO_3$) C, H, N.

2-Acetoxy-1,1-dichloro-2-(4-methoxyphenyl)-1-(4-nitrophenyl)ethane (29e): Colorless plates; mp 136.5—137.5 °C (from methanol); IR 1752 (OAc), 1529 and 1352 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=2.10 (3H, s, OAc), 3.74 (3H, s, OCH_3), 6.31 (1H, s, CHOAc), 6.68 (2H, m, H-3″ and H-5″), 7.03 (2H, m, H-2″ and H-6″), 7.76 (2H, m, H-2′ and H-6′), and 8.15 (2H, m, H-3′ and H-5′). Anal. ($C_{17}H_{15}Cl_2NO_5$) C, H, N.

2-Acetoxy-2-(4-methoxyphenyl)-1-(4-nitrophenyl)ethanone (10e): Colorless liquid; IR 1740 (OAc), 1704 (C=O), 1530 and 1347 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=2.19 (3H, s, OAc),

3.78 (3H, s, OCH_3), 6.79 (1H, s, $\geq$CHOAc), 6.90 (2H, m, H-3'' and H-5''), 7.40 (2H, m, H-2'' and H-6''), 8.00 (2H, m, H-2' and H-6'), and 8.23 (2H, m, H-3' and H-5'). Found: *m/z* 329.0860. Calcd for $C_{17}H_{15}NO_6$: M, 329.0899.

***p*-Anisic Acid:** Mp 183.5—184.0°C. ***p*-Nitrobenzoic Acid:** Mp 240°C (subl.).

Conversion of 2,2-Dichloro-1,2-diphenylethanone (9a) to 1,2-Diphenylethanedione (11a). A mixture of **9a** (80 mg), manganese(II) acetate tetrahydrate (450 mg), and acetic anhydride (0.7 cm^3) was heated under reflux for 1h. The reaction mixture was diluted with water and extracted with benzene. The solvent was evaporated in vacuo and the resulting substance was separated on TLC with benzene as the developing solvent to give **11a** (7 mg, 12%) and **9a** recovered (63 mg, 79%).

Conversion of 1,2-Dichlorocyclohexanecarboxylic Acid (24) to 1-Acetoxy-2-chlorocyclohexanecarboxylic Acid (25). A mixture of **24** (71 mg), manganese(II) acetate tetrahydrate (528 mg), and acetic anhydride (0.8 cm^3) in AcOH (20 cm^3) was heated under reflux for 3h. The reaction mixture was diluted with water and then extracted with benzene. After removal of the solvent in vacuo, a mixture of **24** and **25** was obtained in the molar ratio of **24**:**25**=3:2 (identified by ^1H NMR spectrum).

We wish to thank Professor Hitoshi Takeshita and Associate Professor Akira Mori of the Research Institute of Industrial Science, Kyushu University, for their measurements of the high-resolution mass spectra.

Reaction of Olefins with Malonic Acid Derivatives in the Presence of Manganese(III) Acetate

Noriyuki FUJIMOTO, Hiroshi NISHINO, and Kazu KUROSAWA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received April 15, 1986)

The reaction of methylmalonic acid with mono- and disubstituted olefins in the presence of manganese(III) acetate yielded 2-carboxy-2-methyl-4-butanolides in moderate to good yields. The reactions of bromomalonic acid and chloromalonic acid with a variety of olefins gave 2-halo-4-butanolides and/or 2-buten-4-olides. The reaction of ethyl hydrogen malonate with olefins in the presence of manganese(III) acetate yielded 2-ethoxycarbonyl-2-buten-4-olides, 2-ethoxycarbonyl-2-ethenyl-4-butanolide, 2,7-dioxaspiro[4.4]nonane-1,6-diones, 2-ethoxycarbonyl-4-butanolide, and ethyl 3-butenoate. These reactions can be accounted for in terms of a free-radical mechanism involving substituted dicarboxymethyl radicals.

The formation of γ-lactones is the most characteristic feature in the reaction of manganese(III) acetate with olefins.[1] In previous publications[2,3] it was described how the reaction of olefins with malonic acid in the presence of manganese(III) acetate yielded mainly 2,7-dioxaspiro[4.4]nonane-1,6-diones. We have continued the investigation into the reaction of olefins with malonic acid derivatives in order to obtain mono-γ-lactones rather than spirodi-γ-lactones because the former are encountered more frequently in synthetic organic chemistry. Therefore the reactions of methylmalonic acid, bromomalonic acid, chloromalonic acid, and ethyl hydrogen malonate with a variety of olefins in the presence of manganese(III) acetate were examined and the results are described in this paper.

Results and Discussion

Methylmalonic Acid. When a mixture of 1,1-diphenylethene (**1a**), methylmalonic acid, and manganese(III) acetate[4,5] in a molar ratio of 1 : 1 : 2 in AcOH was heated at 100 °C, 2-carboxy-2-methyl-4,4-diphenyl-4-butanolide (**2a**) was obtained as a sole product. The maximum yield was attained when the molar ratio was 1 : 1.2 : 2.4, but in this case a small amount of decarboxylated compound (**3a**) was also obtained. The reaction at 70 °C gave **3a** and 4,4-diphenyl-4-butanolide (**4**) in prolonged reaction time. Hereafter, we conducted all the reactions at 100 °C. The effects of additives such as Ac_2O and KOAc were next examined but neither showed any appreciable influence on the yield. The reaction was also carried out under an atmosphere of nitrogen, but it did not show any significant change either in the products or in the yield. The reactions of 1,1-bis(4-methoxyphenyl)ethene (**1b**), 1,1-bis(4-methylphenyl)ethene (**1c**), 2-phenylpropene (**1e**), acenaphthylene (**1f**), styrene (**1g**), methylenecyclohexane (**1h**), and 1-octene (**1i**) gave the corresponding 2-carboxy-2-methyl-4-butanolides (**2b**, **c**, **e**—**i**) in moderate to good yields under similar reaction conditions. In the case of **1f**, an acetoxy acid (**5**) was obtained together with **2f** and **3f**. The **2f** and **5** were isolated as their methyl esters. The reactions of 1,1,2-triphenylethene, phenanthrene, chalcone, and (*Z*)-α-acetoxystilbene did not

a) Isolated yields based on olefin added. b) A molar ratio of olefin: methylmalonic acid: Mn(III) was 1:1:2. c) At 70 °C. d) Ac_2O (4.8 molar equivalents) was added. e) KOAc (2.4 molar equivalents) was added. f) Under N_2 atmosphere. g) Isolated as a methyl ester. h) **1i**: methylmalonic acid: Mn(III) was 10:1:2. i) Yield based on Mn(III) added.

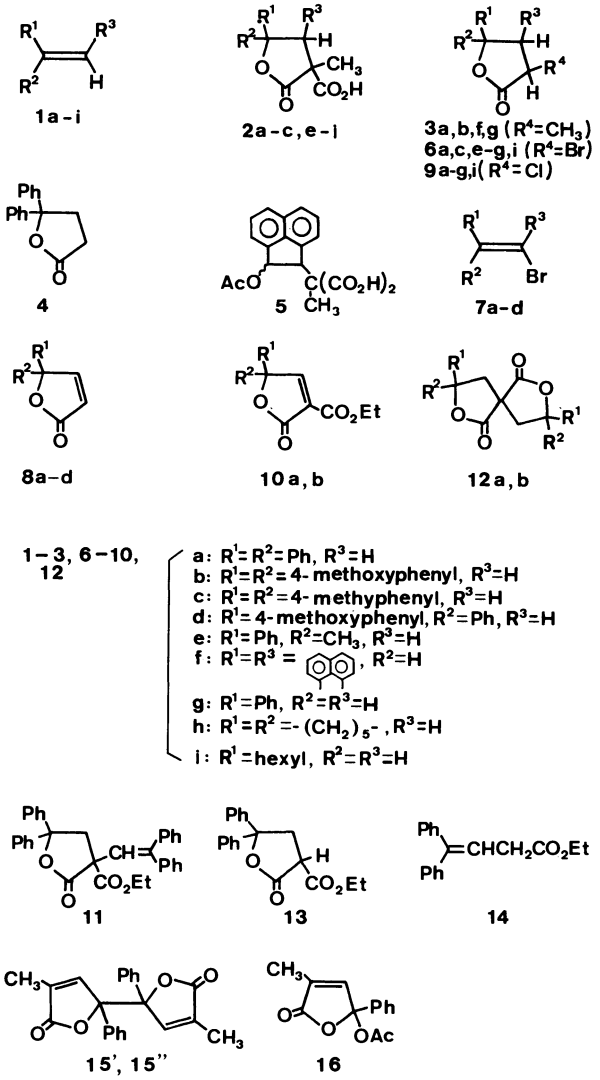

Fig. 1.

take place and the starting olefins were recovered. The 2-carboxy-2-methyl-4-butanolides obtained from **1e, g, i** were found to be a mixture of two diastereoisomers, their ratio being estimated by the ^{1}H NMR spectra or isolated yields. The stereochemistry of these lactones, however, could not be determined.

Bromomalonic Acid. When a mixture of **1a**, bromomalonic acid, and manganese(III) acetate in a molar ratio of 1:1.5:3 was heated at 100 °C, 2-bromo-4,4-diphenyl-4-butanolide (**6a**) was obtained together with 2-bromo-1,1-diphenylethene (**7a**). Similarly, **1e**, **1f**, and **1g** gave the corresponding 4-butanolides (**6e—g**). The olefin **1b** and 1-(4-methoxyphenyl)-1-phenylethene (**1d**), on the other hand, yielded 4,4-bis(4-methoxyphenyl)-2-buten-4-olides (**8b**) and 4-(4-methoxyphenyl)-4-phenyl-2-buten-4-olide (**8d**), respectively. The reaction of **1c** with bromomalonic acid-manganese(III) acetate gave 4,4-bis(4-methylphenyl)-2-buten-4-olide (**8c**) together with a small amount of 2-bromo-4,4-bis(4-methylphenyl)-4-butanolide (**6c**). These 2-bromo-4-butanolides (**6e—g**) consisted of two diastereoisomers which could be separated on TLC. The stereochemistry of each pair, however, could not be determined.

Chloromalonic Acid. The reaction of the olefins with chloromalonic acid-manganese(III) acetate gave results similar to those of bromomalonic acid except for the fact that the 2-chloro-4-butanolides (**9a—g, i**) are fairly stable.

Ethyl Hydrogen Malonate. When **1a** was oxidized with a mixture of ethyl hydrogen malonate and manganese(III) acetate in AcOH, it gave five products, i.e. 2-ethoxycarbonyl-4,4-diphenyl-2-buten-4-olide (**10a**), 2-ethoxycarbonyl-2-(2,2-diphenylethenyl)-4,4-diphenyl-4-butanolide (**11**), 3,3,8,8-tetraphenyl-2,7-dioxaspiro[4.4]-nonane-1,6-dione (**12a**), 2-ethoxycarbonyl-4,4-diphenyl-4-butanolide (**13**), and ethyl 4,4-diphenyl-3-butenoate

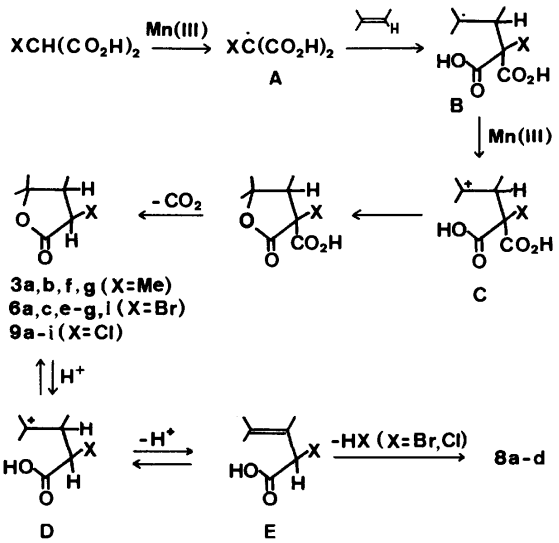
a) **1a**: ethyl hydrogen malonate: Mn(III). b) Isolated yields based on **1a** added. c) Ac_2O (16 molar equivalents) was added.

(**14**). The yield of **10a** was slightly improved with the increase of the amounts of ethyl hydrogen malonate and manganese(III) acetate at the expense of the yields of **11** and **12a**. In the reaction at a molar ratio of 1:1:2, the compounds **13** and **14** were formed in minor quantity along with **11** and **12a**. When the molar ratio was 2:1.2:4.8, **11** became the major product (Table 3, Entry 2). Addition of Ac_2O to the reaction mixture showed little effect on the product distribution. Similarly **1b** yielded **10b** (31%) and **12b** (8%).

The reaction of olefins with malonic acid derivatives-manganese(III) acetate proceeded smoothly at 100 °C in a few minutes to give substituted 4-butanolides and 2-buten-4-olides. As already described for the reactions of malonic acid[2] and malonamide[6] with olefin in the presence of manganese(III) acetate, the first step in the reaction of substituted malonic acid must be the formation of substituted malonic acid radical A as the result of the interaction between the malonic acid and manganese(III) acetate. The radical A reacts with an olefin to form a secondary or tertiary carbon radical B which is oxidized to the corresponding carbonium ion C. Upon cyclization followed by deprotonation, the carbonium ion C gives a 2-carboxy-4-butanolide which can be decarboxylated, while some 2-halo-4-butanolides are dehydrohalogenated to give 2-buten-4-olides. In fact, when 2-carboxy-2-methyl-4-butanolides (**2a, b, g**) were heated in AcOH, they gave the decarboxylated products (**3a, b, g**) in excellent yields. These are shown in Scheme 1. It should be pointed out that the substituted dicarboxymethyl radicals regiospecifically add to the less hindered site on the C=C bond. It should be noted also that the reactions of 4-methoxyphenyl (**1b** and **1d**) and 4-methylphenyl-substituted olefin (**1c**) with halomalonic acid tend to give 2-buten-4-olides rather than 2-halo-4-butanolides,

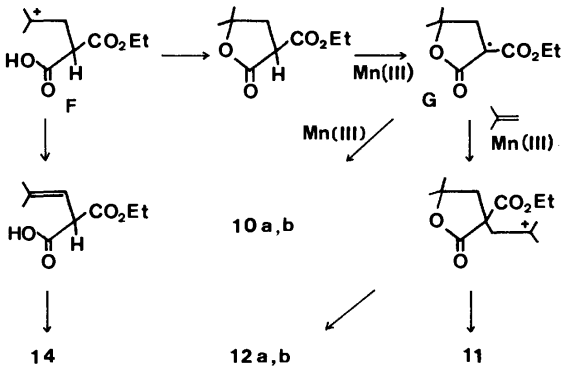


Scheme 1. Possible mechanisms for the formation of γ-lactones.

and some 2-bromo-4-butanolides having a 4-methoxyphenyl group also tend to give 2-buten-4-olides on spontaneous dehydrobromination. An attempt to dehydrohalogenate 4-phenyl-substituted 2-halo-4-butanolides with base failed to yield the corresponding 2-buten-4-olides. These facts may suggest that the carbonium ion D which is in equilibrium with 2-halo-4-butanolides suffered from deprotonation at the adjacent carbon to give 4,4-diaryl-2-halo-3-butenoic acid (E). The latter lactonized to give 2-buten-4-olides. In fact, **6a** was converted to **8a** in a 95% yield on heating in AcOH for 1 h. The formation of bromoethenes (**7a—d**) indicates that Br^- ion or $Br\cdot$ radical was produced in the reaction of bromomalonic acid with manganese(III) acetate.

The reactions of ethyl hydrogen malonate with olefins

in the presence of manganese(III) acetate are different from those of methyl-, bromo-, and chloromalonic acid. The reaction was previously reported by Fristad[3] and Corey[7] who both obtained 2-ethoxycarbonyl-4-butanoldie alone. When we repeated the reaction of **1a** with ethyl hydrogen malonate-manganese(III) acetate, it was found that several other products were also formed and the product distribution depended largely on the molar ratio of olefin and ethyl hydrogen malonate as shown in Table 3. The reaction of **13** with manganese(III) acetate gave **10a** (24%), and the reaction of **13** with a mixture of **1a** and manganese(III) acetate yielded **11** (79%) and **12a** (5%). Thus the pathway for the formation of **10a**, **11**, **12a**, and **14** can be depicted as shown in Scheme 2. Our results indicate that the reaction proved to be useful not only for the preparation of 2-ethoxycarbonyl-4-butanolides but also for the preparations of 2-ethoxycarbonyl-2-buten-4-olides and 2-vinyl-4-butanolides.



Scheme 2. Pathways for the reaction of olefins with ethyl hydrogen malonate in the presence of manganese(III) acetate.

The formation of 2-carboxy-2-methyl-4-butanolides (**2a—c**, **e—i**) by the reaction of an olefin with methylmalonic acid-manganese(III) acetate led us to investigate the reaction of acetylene with these reagents, since it might give rise to 2-methyl-2-buten-4-olides. The reaction of phenylacetylene with methylmalonic acid-manganese(III) acetate, however, yielded a mixture of isomeric 2,2′-dimethyl-4,4′-diphenyl-4,4′-bis(2-buten-4-olide) (**15′** and **15″**) (25%), and 4-acetoxy-2-methyl-4-phenyl-2-buten-4-olide (**16**) (7%). It was also observed that one of the isomers (**15″**) was converted to the other (**15′**) during recrystallization.

2-Methyl-4-butanolides and 2-chloro-4-butanolides were previously obtained by the reaction of an olefin with manganese(III) acetate in propionic acid[8] and in chloroacetic acid,[9] respectively, but in poor yields. The reaction of olefins with methylmalonic acid in the presence of manganese(III) acetate is a much better method for the preparation of 2-alkyl-4-butanolides, but for the preparation of 2-chloro-4-butanolides it was reported that the ruthenium(II)-catalyzed reaction of olefins with trimethylsilyl α-polychlorinated carboxylates gave γ-lactones in fairly good yields.[10] 2-Bromo-4-butanolides (**5a—c**, **e—i**) have not been synthesized before, therefore our reaction can be useful for the preparation of these compounds.

Experimental

Measurements. All the ^{1}H NMR spectra were recorded with a Hitachi Perkin-Elmer R-24 spectrometer (60 MHz) with tetramethylsilane as the internal reference. The IR spectra were measured in chloroform solution on a JASCO A-102 infrared spectrometer. The mass spectra were obtained with a Hitachi M-80B, a JEOL JMS-DX 300, and a JEOL JMS-OISG mass spectrometer. The melting points were determined with a Yanagimoto micromelting point apparatus and were not corrected.

Materials. The olefins (**1a—e**, h),[2] 1,1-bis(4-methylphenyl)-ethene (**1c**),[11] 1-(4-methoxyphenyl)-1-phenylethene (**1d**),[12] manganese(III) acetate,[4] bromomalonic acid,[13] and chloromalonic acid[13] were prepared by the method described in the literature. Acenaphthylene (**1f**), styrene (**1g**), and 1-octene (**1i**) were purchased from Wako Pure Chemical Industries, Ltd. Methylmalonic acid was commercially available from Aldrich Chemical Co.

Reaction of Olefins with Methylmalonic Acid in the Presence of Manganese(III) Acetate. To a heated solution of olefin (1 mmol) and methylmalonic acid (1.2 mmol) in AcOH (30 cm^3), manganese(III) acetate (2.4 mmol) was added. The solution was heated at 100 °C for the period of time shown in Table 1. After adding water (100 cm^3), the mixture was extracted with benzene. The solvent was removed under reduced pressure. When the resulting crude product was crystalline, the product was recrystallized from benzene and the filtrate was separated on TLC with benzene or chloroform as the developing solvent. In other cases, the product was separated on TLC with chloroform as developing solvent. In the cases of **2e**, g, i, the stereoisomers were further separated on TLC with 20—30% ether/light petroleum as the developing solvent after methylation with diazomethane.

Reaction Products of 1,1-Diphenylethene (1a) with Methylmalonic Acid-Mn(III). 2-Carboxy-2-methyl-4,4-diphenyl-4-butanolide (2a): Colorless plates (from benzene); mp 161.2—162.1 °C; IR 3600—2400 (COOH), 1777 (-COO-), and 1714 cm^{-1} (COOH); ^{1}H NMR (DMSO-d_6) δ=1.25 (3H, s, CH_3), 3.06 (1H, d, J=1.6 Hz, H-3), 3.55 (1H, d, J=12.6 Hz, H-3), 7.0 (1H, br. s, COOH), and 7.1—7.6 (10H, m, ar. H). Found: C, 72.75; H, 5.36%. Calcd for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%.

2-Methyl-4,4-diphenyl-4-butanolide (3a): Colorless plates (from methanol); mp 120.2—120.7 °C; IR 1770 cm^{-1} (-COO-); ^{1}H NMR ($CDCl_3$) δ=1.14 (3H, d, J=6.6 Hz, CH_3), 2.1—3.4 (3H, m, H-2 and 2×H-3), and 7.1—7.6 (10H, m, ar. H). Found: C, 80.90; H, 6.42%. Calcd for $C_{17}H_{16}O_2$: C, 80.93; H, 6.39%.

4,4-Diphenyl-4-butanolide (4): Colorless microcrystals (from ethanol); mp 89.9—91.1 °C (lit,[14] mp 87—90 °C).

Reaction Product of 1,1-Bis(4-methoxyphenyl)ethene (1b) with Methylmalonic Acid-Mn(III). 2-Carboxy-4,4-bis(4-methoxyphenyl)-2-methyl-4-butanolide (2b): Colorless needles (from benzene); mp 140.0—140.7 °C; IR 3600—2400 (COOH), 1773 (-COO-), and 1715 cm^{-1} (COOH); ^{1}H NMR ($CDCl_3$) δ=1.40 (3H, s, CH_3), 2.83 (1H, d, J=13.2 Hz, H-3), 3.53 (1H, d, J=13.2 Hz, H-3), 3.71 (3H, s, OCH_3), 3.75 (3H, s,

OCH_3), 6.6—7.5 (8H, m, ar. H), and 10.14 (1H, br. s, COOH). Found: C, 67.51; H, 5.37%. Calcd for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%.

Reaction Product of 1,1-Bis(4-methylphenyl)ethene (1c) with Methylmalonic Acid-Mn(III). 2-Carboxy-2-methyl-4,4-bis(4-methylphenyl)-4-butanolide (2c): Colorless needles (from benzene); mp 148.3—149.2 °C; IR 3600—2400 (COOH), 1775 (-COO-), and 1717 cm^{-1} (COOH); ^1H NMR ($CDCl_3$) δ=1.34 (3H, s, CH_3), 2.27 (3H, s, CH_3), 2.30 (3H, s, CH_3), 2.87 (1H, d, J=13.2 Hz, H-3), 3.51 (1H, d, J=13.2 Hz, H-3), 6.9—7.5 (8H, m, ar. H), and 10.53 (1H, br. s, COOH). Found: C, 74.10; H, 6.30%. Calcd for $C_{20}H_{20}O_4$: C, 74.06: H, 6.21%.

Reaction Product of 2-Phenylpropene (1e) with Methylmalonic Acid-Mn(III). Methyl Ester of 2-Carboxy-2-methyl-4-phenyl-4-pentanolide (2e'): From the upper fraction on TLC (developing solvent: 30% ether/light petroleum); liquid; IR 1771 (-COO-) and 1735 cm^{-1} ($COOCH_3$); ^1H NMR ($CDCl_3$) δ=1.35 (3H, s, CH_3), 1.74 (3H, s, CH_3), 2.47 (1H, d, J=13.2 Hz, H-3), 3.09 (1H, d, J=13.2 Hz, H-3), 3.80 (3H, s, $COOCH_3$), 7.31 (5H, s, Ph). Found: m/z 248.1065. Calcd for $C_{14}H_{16}O_4$: M, 248.1049.

Stereoisomeric Methyl Ester of 2-Carboxy-2-methyl-4-phenyl-4-pentanolide (2e''): From the lower fraction of TLC (developing solvent: 30% ether/light petroleum); colorless plates (from methanol); mp 91.7—92.2 °C; IR 1776 (-COO-) and 1736 cm^{-1} ($COOCH_3$); ^1H NMR ($CDCl_3$) δ= 1.57 (3H, s, CH_3), 1.72 (3H, s, CH_3), 2.31 (1H, d, J=13.2 Hz, H-3), 3.21 (3H, s, $COOCH_3$), 3.23 (1H, d, J=13.2 Hz, H-3), and 7.28 (5H, s, Ph). Found: C, 67.52; H, 6.40%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%.

Reaction Products of Acenaphthylene (1f) with Methylmalonic Acid-Mn(III). Methyl Ester of 9-Carboxy-9-methyl-*cis*-6b,9a-dihydroacenaphtho[1,2-*b*]furan-8(9*H*)-one (2f): Colorless needles (from benzene/hexane); mp 115.2—115.7 °C; IR 1773 (-COO-) and 1743 cm^{-1} ($COOCH_3$); ^1H NMR ($CDCl_3$) δ=1.80 (3H, s, CH_3), 2.88 (3H, s, $COOCH_3$), 4.25 (1H, d, J=7.8 Hz, H-6b), 6.23 (1H, d, J=7.8 Hz, H-9a), and 7.0—8.0 (6H, m, ar. H). Found: C, 72.36; H, 4.94%. Calcd for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

9-Methyl-*cis*-6b,9a-dihydroacenaphtho[1,2-*b*]furan-8(9*H*)-one (3f'): From the upper fraction on TLC (developing solvent: chloroform); liquid; IR 1766 cm^{-1} (-COO-); ^1H NMR (CCl_4) δ=1.48 (3H, d, J=7.8 Hz, CH_3), 2.2—2.8 (1H, m, H-7), 3.88 (1H, t, J=6.6 Hz, H-6b), 6.02 (1H, d, J=6.6 Hz, H-9a), and 7.0—8.0 (6H, m, ar. H). Found: m/z 224.0863. Calcd for $C_{15}H_{12}O_3$: M, 224.0837.

Stereoisomeric 9-Methyl-*cis*-6b,9a-dihydroacenaphtho-[1,2-*b*]furan-8(9*H*)-one (3f''): From the lower fraction on TLC (developing solvent: chloroform); colorless plates (from benzene/hexane); mp 123.9—124.2 °C; IR 1763 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=1.29 (3H, d, J=7.8 Hz, CH_3), 3.20 (1H, dq, J=7.8 and 10.8 Hz, H-7), 4.50 (1H, dd, J=6.6 and 10.8 Hz, H-6b), 6.16 (1H, d, J=6.6 Hz, H-9a), and 7.1—8.0 (6H, m, ar. H). Found: C, 80.31; H, 5.43%. Calcd for $C_{15}H_{12}O_2$: C, 80.34; H, 5.39%.

1-Acetoxy-2-[1,1-bis(methoxycarbonyl)ethyl]acenaphthene (Dimethyl Ester of 5): Liquid; IR 1731 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.23 (3H, s, CH_3), 2.07 (3H, s, OAc), 3.66 (3H, s, $COOCH_3$), 3.80 (3H, s, $COOCH_3$), 4.57 (1H, d, J=1.8 Hz, H-2), 6.65 (1H, d, J=1.8 Hz, H-1), and 7.1—7.9 (6H, m, ar. H). Found: m/z 356.1279. Calcd for $C_{20}H_{20}O_6$: M, 356.1260.

Reaction Products of Styrene (1g) with Methylmalonic Acid-Mn(III). Methyl Ester of 2-Carboxy-2-methyl-4-phenyl-4-butanolide (2g'): From the upper fraction on TLC (developing solvent: 30% ether/light petroleum); colorless plates (from benzene/hexane); mp 81.2—81.6 °C; IR 1778 (-COO-) and 1736 cm^{-1} ($COOCH_3$); ^1H NMR (CCl_4) δ=1.49 (3H, s, CH_3), 1.99 (1H, dd, J=10.2 and 13.8 Hz, H-3), 3.04 (1H, dd, J=6.0 and 13.8 Hz, H-3), 3.78 (3H, s, $COOCH_3$), 5.40 (1H, dd, J=6.0 and 10.2 Hz, H-4), and 7.33 (5H, s, ar. H). Found: C, 66.69; H, 5.97%. Calcd for $C_{13}H_{14}O_4$: C, 66.66; H, 6.02%.

Stereoisomeric Methyl Ester of 2-Carboxy-2-methyl-4-phenyl-4-butanolide (2g''): From the lower fraction on TLC (developing solvent: 30% ether/light petroleum); liquid; IR 1778 (-COO-) and 1741 cm^{-1} ($COOCH_3$); ^1H NMR (CCl_4) δ=1.50 (3H, s, CH_3), 2.45 (1H, dd, J=7.2 and 12.6 Hz, H-3), 2.67 (1H, dd, J=8.4 and 12.6 Hz, H-3), 3.62 (3H, s, $COOCH_3$), 5.38 (1H, dd, J=7.2 and 8.4 Hz, H-4), and 7.25 (5H, s, ar. H). Found: m/z 234.0876; Calcd for $C_{13}H_{14}O_4$: M, 234.0892.

Reaction Product of Methylenecyclohexane (1h) with Methylmalonic Acid-Mn(III). 3-Carboxy-3-methyl-1-oxaspiro[4.5]decan-2-one (2h): Colorless microcrystals (from benzene); mp 147.8—148.3 °C; IR 3600—2400 (COOH), 1762 (-COO-), and 1714 cm^{-1} (COOH); ^1H NMR ($CDCl_3$) δ=1.0—3.0 (10H, m, 5×CH_2), 1.59 (3H, s, CH_3), 1.99 (1H, d, J=13.2 Hz, H-4), 2.72 (1H, d, J=13.2 Hz, H-4), and 11.52 (1H, s, COOH). Found: C, 62.14; H, 7.34%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

Reaction Products of 1-Octene (1i) with Methylmalonic Acid-Mn(III). Methyl Ester of 2-Carboxy-2-methyl-4-decanolide (2i'): From the upper fraction on TLC (developing solvent: 20% ether/light petroleum); liquid; bp 110—115 °C (bath temp)/0.002 mmHg (1 mmHg=133.322 Pa); IR 1771 (-COO-) and 1735 cm^{-1} ($COOCH_3$); ^1H NMR (CCl_4) δ=0.6—2.0 (13H, m, C_6H_{13}-), 1.42 (3H, s, CH_3), 1.70 (1H, dd, J=6.6 and 12.6 Hz, H-3), 2.65 (1H, dd, J=5.4 and 12.6 Hz, H-3), 3.72 (3H, s, $COOCH_3$), and 4.1—4.7 (1H, m, H-4). Found for the stereoisomeric mixture: C, 64.31; H, 9.06%. Calcd for $C_{13}H_{22}O_4$: C, 64.44; H, 9.15%.

Stereoisomeric Methyl Ester of 2-Carboxy-2-methyl-4-decanolide (2i''): From the lower fraction on TLC (developing solvent: 20% ether/light petroleum); liquid; bp 110—115 °C/0.002 mmHg; IR 1771 (-COO-) and 1740 cm^{-1} ($COOCH_3$); ^1H NMR (CCl_4) δ=0.6—2.0 (13H, m, C_6H_{13}-), 1.41 (3H, s, CH_3), 2.18 (1H, dd, J=7.2 and 13.2 Hz, H-3), 2.38 (1H, dd, J=8.4 and 13.2 Hz, H-3), 3.71 (3H, s, CH_3), and 4.1—4.6 (1H, m, H-4). Found for stereoisomeric mixture: C, 64.31; H, 9.06%. Calcd for $C_{13}H_{22}O_4$: C, 64.44; H, 9.15%.

Reaction of Olefins with Bromomalonic Acid and Chloromalonic Acid in the Presence of Manganese(III) Acetate. To a heated solution of the olefin (1 or 2 mmol) and halomalonic acid (1.5 or 3 mmol) in AcOH (30 cm^3), manganese(III) acetate (3 or 6 mmol) was added. The solution was heated at 100 °C for the period of time shown in Table 2. After removal of the solvent under reduced pressure, 2M hydrochloric acid (50 cm^3) was added and the mixture was extracted with chloroform. The solvent was removed under reduced pressure and the resulting crude product was separated on TLC with benzene or chloroform as the developing solvent.

Reaction Products of 1a with Bromomalonic Acid-Mn(III). 2-Bromo-4,4-diphenyl-4-butanolide (6a): Liquid; IR 1788 cm^{-1} (-COO-); ^1H NMR (CCl_4) δ=3.06 (1H, dd, J=10.2 and 13.8 Hz, H-3), 3.51 (1H, dd, J=7.8 and 13.8

Hz, H-3), 4.35 (1H, dd, J=7.8 and 10.2 Hz, H-2), 7.0—7.5 (10H, m, ar. H). Found: m/z 316.0090, 318.0072. Calcd for $C_{16}H_{13}{}^{79}BrO_2$: M, 316.0099; $C_{16}H_{13}{}^{81}BrO_2$: M, 318.0079.

2-Bromo-1,1-diphenylethene (7a): Liquid (lit,[15] mp 42 °C).

Reaction Product of 1a with Chloromalonic Acid-Mn(III). 2-Chloro-4,4-diphenyl-4-butanolide (9a): Colorless microcrystals (from ethanol); mp 90.0—91.4 °C; IR 1789 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=2.95 (1H, dd, J=10.2 and 12.6 Hz, H-3), 3.51 (1H, dd, J=6.6 and 12.6 Hz, H-3), 4.44 (1H, dd, J=6.6 and 10.2 Hz, H-2), and 7.1—7.2 (10H, m, ar. H). Found: C, 70.35; H, 4.84%. Calcd for $C_{16}H_{13}ClO_2$: C, 70.46; H, 4.80%.

Reaction Products of 1b with Bromomalonic Acid-Mn(III). 2-Bromo-1,1-bis(4-methoxyphenyl)ethene (7b): Liquid (lit,[15] mp 80—82 °C). **4,4-Bis(4-methoxyphenyl)-2-buten-4-olide (8b):** Pale yellow needles (from ethanol); mp 133.2—134.2 °C; IR 1764 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=3.74 (6H, s, 2×OCH_3), 6.08 (1H, d, J=6.0 Hz, H-2), 6.7—7.3 (8H, m, ar. H), and 7.81 (1H, d, J=6.0 Hz, H-3). Found: C, 72.80; H, 5.47%. Calcd for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%.

Reaction Products of 1b with Chloromalonic Acid-Mn(III). 4,4-Bis(4-methoxyphenyl)-2-buten-4-olide (8b). 2-Chloro-4,4-bis(4-methoxyphenyl)-4-butanolide (9b): Liquid; IR 1788 cm^{-1} (-COO-); ^1H NMR (CCl_4) δ=2.88 (1H, dd, J=10.8 and 13.2 Hz, H-3), 3.44 (1H, dd, J=7.8 and 13.2 Hz, H-3), 3.75 (6H, s, 2×OCH_3), 4.27 (1H, dd, J=7.8 and 10.8 Hz, H-2), 6.6—7.4 (8H, m, ar. H). Found: m/z 332.0824, 334.0829. Calcd for $C_{18}H_{17}{}^{35}ClO_4$: M, 332.0815; $C_{18}H_{17}{}^{37}ClO_4$: M, 334.0786.

Reaction Products of 1c with Bromomalonic Acid-Mn(III). 2-Bromo-4,4-bis(4-methylphenyl)-4-butanolide (6c): Liquid; IR 1788 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=2.29 (6H, s, 2×CH_3), 2.99 (1H, dd, J=10.2 and 13.8 Hz, H-3), 3.45 (1H, dd, 7.8 and 13.8 Hz, H-3), 4.35 (1H, dd, J=7.8 and 10.2 Hz, H-2), 6.9—7.4 (8H, m, ar. H). Found: m/z 344.0336, 346.0412. Calcd for $C_{18}H_{17}{}^{79}BrO_2$: M, 344.0412; $C_{18}H_{17}{}^{81}BrO_2$: M, 346.0392.

2-Bromo-1,1-bis(4-methylphenyl)ethene (7c): Liquid (lit,[15] mp 55—57 °C). **4,4-Bis(4-methylphenyl)-2-buten-4-olide (8c):** Colorless needles (from methanol); mp 102.8—103.3 °C; IR 1763 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=2.32 (6H, s, 2×CH_3), 6.11 (1H, d, J=6.0 Hz, H-2), 7.31 (8H, s, ar. H), and 7.84 (1H, d, J=6.0 Hz, H-3). Found: C, 81.56; H, 6.09%. Calcd for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

Reaction Products of 1d with Bromomalonic Acid-Mn(III). 2-Bromo-1-(4-methoxyphenyl)-1-phenylethene (7d): Liquid (a mixture of (*E*)- and (*Z*)-isomers); ^1H NMR (CCl_4) δ=3.69 and 3.75 (3H, s, s, CH_3), 6.5—7.4 (10H, m, =CH- and ar. H); MS m/z 288, 290. **4-(4-Methoxyphenyl)-4-phenyl-2-buten-4-olide (8d):** Colorless needles (from ethanol); mp 118.6—119.6 °C; IR 1763 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=3.71 (3H, s, OCH_3), 6.06 (1H, d, J=5.4 Hz, H-2), 6.7—7.4 (9H, m, ar. H), 7.87 (1H, d, J=5.4 Hz, H-3). Found: C, 76.73; H, 5.33%. Calcd for $C_{17}H_{14}O_3$: C, 76.68; H, 5.30%.

Reaction Products of 1d with Chloromalonic Acid-Mn(III). 4-(4-Methoxyphenyl)-4-phenyl-2-buten-4-olide (8d). 2-Chloro-4-(4-methoxyphenyl)-4-phenyl-4-butanolide (9d): Liquid (a mixture of stereoisomers); IR 1790 cm^{-1} (-COO-); ^1H NMR (CCl_4) δ=2.5—3.1 (1H, m, H-3), 3.2—3.7 (1H, m, H-3), 3.69 (3H, s, OCH_3), 4.1—4.6 (1H, m, H-2), and 6.6—7.5 (9H, m, ar. H). Found: m/z 302.0667, 304.0692. Calcd for $C_{17}H_{15}{}^{35}ClO_3$: M, 302.0710; $C_{17}H_{15}{}^{37}ClO_3$: 304.0680.

Reaction Products of 1e with Bromomalonic Acid-Mn(III). 2-Bromo-4-phenyl-4-pentanolide (6e'): From the upper fraction on TLC (developing solvent: benzene); liquid; IR 1783 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=1.83 (3H, s, CH_3), 2.72 (1H, dd, J=8.4 and 13.2 Hz, H-3), 3.11 (1H, dd, J=8.4 and 13.2 Hz, H-3), 4.44 (1H, t, J=8.4 Hz, H-2), and 7.32 (5H, s, ar. H). Found: m/z 253.9951, 255.9910. Calcd for $C_{11}H_{11}{}^{79}BrO_2$: M, 253.9943; $C_{11}H_{11}{}^{81}BrO_2$: 255.9922.

Stereoisomeric 2-Bromo-4-phenyl-4-pentanolide (6e''): From the lower fraction on TLC (developing solvent: benzene); liquid; IR 1776 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=1.69 (3H, s, CH_3), 2.81 (1H, dd, J=7.2 and 13.8 Hz, H-3), 3.04 (1H, dd, J=7.2 and 13.8 Hz, H-3), 4.66 (1H, t, J=7.2 Hz, H-2), and 7.32 (5H, s, ar. H). Found: m/z 253.9949, 255.9954. Calcd for $C_{11}H_{11}{}^{79}BrO_2$: M, 253.9943; $C_{11}H_{11}{}^{81}BrO_2$: M, 255.9922.

Reaction Products of 1e with Chloromalonic Acid-Mn(III). 2-Chloro-4-phenyl-4-pentanolide (9e'): From the upper fraction on TLC (developing solvent: chloroform); liquid.[10]

Stereoisomeric 2-Chloro-4-phenyl-4-pentanolide (9e''): From the lower fraction on TLC (developing solvent: chloroform); liquid.[10]

Reaction Products of 1f with Bromomalonic Acid-Mn(III). 9-Bromo-*cis*-6b,9a-dihydroacenaphtho[1,2-*b*]furan-8(9*H*)-one (6f'): From the upper fraction on TLC (developing solvent: chloroform); pale yellow needles (from methanol); mp 127.6—128.5 °C; IR 1777 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=4.4—4.7 (2H, m, H-6b and H-7), 6.30 (1H, d, J=5.4 Hz, H-9a), and 7.0—8.0 (6H, m, ar. H). Found: C, 58.14; H, 3.13%. Calcd for $C_{14}H_9BrO_2$: C, 58.16; H, 3.14%.

Stereoisomeric 9-Bromo-*cis*-6b,9a-dihydroacenaphtho[1,2-*b*]furan-8(9*H*)-one (6f''): From the lower fraction on TLC (developing solvent: chloroform); colorless needles (from methanol); mp 172.6—173.1 °C; IR 1785 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=4.62 (1H, dd, J=6.0 and 10.2 Hz, H-6b), 5.10 (1H, d, J=10.2 Hz, H-7), 6.26 (1H, d, J=6.0 Hz, H-9a), and 7.3—8.0 (6H, m, ar. H). Found: C, 58.40; H, 3.14%. Calcd for $C_{14}H_9BrO_2$: C, 58.16; H, 3.14%.

Reaction Products of 1f with Chloromalonic Acid-Mn(III). 9-Chloro-*cis*-6b,9a-dihydroacenaphtho[1,2-*b*]furan-8(9*H*)-one (9f'): From the upper fraction on TLC (developing solvent: chloroform); pale yellow microcrystals (from benzene/hexane); mp 115.2—116.2 °C; IR 1782 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=4.4—4.8 (2H, m, H-6b and H-7), 6.38 (1H, d, J=6.0 Hz, H-9a), and 7.2—8.0 (6H, m, ar. H). Found: m/z 244.0254, 246.0278. Calcd for $C_{14}H_9{}^{35}ClO_2$: M, 244.0291; $C_{14}H_9{}^{37}ClO_2$: M, 246.0262.

Stereoisomeric 9-Chloro-*cis*-6b,9a-dihydroacenaphtho-[1,2-*b*]furan-8(9*H*)-one (9f''): From the lower fraction on TLC (developing solvent: chloroform); colorless plates (from benzene); mp 192.5—193.5 °C; IR 1787 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=4.68 (1H, dd, J=6.0 and 10.2 Hz, H-6b), 5.10 (1H, d, J=10.2 Hz, H-7), 6.22 (1H, d, J=6.0 Hz, H-9a), 7.2—8.0 (6H, m, ar. H). Found: m/z 244.0293, 246.0253. Calcd for $C_{14}H_9{}^{35}ClO_2$: M, 244.0291; $C_{14}H_9{}^{37}ClO_2$: M, 246.0262.

Reaction Products of 1g with Bromomalonic Acid-Mn(III). 2-Bromo-4-phenyl-4-butanolide (6g'): From the upper fraction on TLC (developing solvent: benzene); liquid; IR 1788 cm^{-1} (-COO-); ^1H NMR (CCl_4) δ=2.5—2.8 (2H, m, 2×H-3), 4.43 (1H, dd, J=3.0 and 5.4 Hz, H-2), 5.55 (1H, dd, J=6.6 and 7.8 Hz, H-4), and 7.26 (5H, s, Ph). Found: m/z 239.9777, 241.9780: Calcd for $C_{10}H_9{}^{79}BrO_2$: M, 239.9786;

$C_{10}H_9{}^{81}BrO_2$: M, 241.9766.

Stereoisomeric 2-Bromo-4-phenyl-4-butanolide (6g''): From the lower fraction on TLC (developing solvent: benzene); liquid; IR 1788 cm^{-1} (-COO-); ^1H NMR (CCl_4) δ=2.1—2.7 (1H, m, H-3), 2.9—3.5 (1H, m, H-3), 4.62 (1H, dd, J=8.4 and 9.6 Hz, H-2), 5.37 (1H, dd, J=6.6 and 9.6 Hz, H-4), and 7.23 (5H, s, Ph). Found: m/z 239.9801, 241.9808. Calcd for $C_{10}H_9{}^{79}BrO_2$: M, 239.9786; $C_{10}H_9{}^{81}BrO_2$: M, 241.9766.

Reaction Products of 1g with Chloromalonic Acid-Mn(III). 2-Chloro-4-phenyl-4-butanolide (9g'): From the upper fraction on TLC (developing solvent: chloroform); liquid.[10]

Stereoisomeric 2-Chloro-4-phenyl-4-butanolide (9g''): From the lower fraction on TLC (developing solvent: chloroform); liquid.[10]

Reaction Products of 1i with Chloromalonic Acid-Mn(III). 2-Chloro-4-decanolide (9i'): From the upper fraction on TLC (developing solvent: benzene); liquid.[16]

Stereoisomeric 2-Chloro-4-decanolide (9i''): From the lower fraction on TLC (developing solvent: benzene); liquid.[16]

Reaction of Olefins with Ethyl Hydrogen Malonate in the Presence of Manganese(III) Acetate. To a heated solution of olefin (1 or 2 mmol) and ethyl hydrogen malonate in AcOH (30 cm^3), manganese(III) acetate was added. The solution was heated under reflux for the period of time shown in Table 3. After adding water (100 cm^3), the mixture was extracted with benzene, and the solvent was removed under reduced pressure. The resulting crude product was separated on TLC with chloroform as the developing solvent.

Reaction Products of 1a with Ethyl Hydrogen Malonate-Mn(III). 2-Ethoxycarbonyl-4,4-diphenyl-2-buten-4-olide (10a): Colorless plates (from methanol); mp 107.9—109.4 °C; IR 1782 (-COO-), 1719 (-COOEt), and 1642 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=1.31 (3H, t, J=7.2 Hz, CH_3), 4.31 (2H, q, J=7.2 Hz, -CH_2-), 7.28 (10H, s, 2×Ph), and 8.57 (1H, s, =CH-). Found: C, 73.87; H, 5.21%. Calcd for $C_{19}H_{16}O_4$: C, 74.01; H, 5.23%.

2-Ethoxycarbonyl-4,4-diphenyl-2-(2,2-diphenylethenyl)-4-butanolide (11): Colorless needles (from benzene); mp 279.8—281.5 °C; IR 1776 (-COO-) and 1734 cm^{-1} (COOEt); ^1H NMR ($CDCl_3$) δ=0.94 (3H, t, J=7.2 Hz, CH_3), 2.72 (1H, d, J=12.6 Hz, H-3), 3.28 (1H, d, J=12.6 Hz, H-3), 3.62 (2H, q, J=7.2 Hz, -OCH_2-), 6.32 (1H, s, =CH-), and 6.9—7.6 (20H, m, 4×Ph). Found: C, 80.93; H, 5.58%. Calcd for $C_{33}H_{28}O_4$: C, 81.12; H, 5.78%.

3,3,8,8-Tetraphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (12a): Colorless needles (from benzene); mp 284.5—285.0 °C (lit,[2] mp 284.5—285.0 °C).

2-Ethoxycarbonyl-4,4-diphenyl-4-butanolide (13): Colorless prisms (from benzene/hexane); mp 67.4—68.5 °C; IR 1782 (-COO-) and 1735 cm^{-1} (COOEt); ^1H NMR ($CDCl_3$) δ=1.17 (3H, t, J=7.2 Hz, CH_3), 3.0—3.8 (3H, m, -CH_2- and >CH-), 4.13 (2H, q, J=7.2 Hz, OCH_2-), and 7.1—7.5 (10H, m, 2×Ph). Found: m/z 310.1187. Calcd for $C_{19}H_{18}O_4$: M, 310.1205.

Ethyl 4,4-diphenyl-3-butenoate (14): Liquid.[17]

Reaction Products of 1b with Ethyl Hydrogen Malonate-Mn(III). 2-Ethoxycarbonyl-4,4-bis(4-methoxyphenyl)-2-buten-4-olide (10b): Liquid; IR 1781 (-COO-), 1717 (COOEt), and 1640 cm^{-1} (C=C); ^1H NMR (CCl_4) δ=1.26 (3H, t, J=7.2 Hz, CH_3), 3.66 (6H, s, 2×OCH_3), 4.16 (2H, q, J=7.2 Hz, OCH_2-), 6.5—7.3 (8H, m, ar. H), and 8.46 (1H, s, =CH-). Found: m/z 368.1258. Calcd for $C_{21}H_{20}O_6$: M, 368.1260.

3,3,8,8-Tetrakis(4-methoxyphenyl)-2,7-dioxaspiro[4.4]-nonane-1,6-dione (12b): Amorphous solid.[2]

Decarboxylation of 2a, b, g. 2-Carboxy-2-methyl-4-butanolide (**2a, b,** g) (1 mmol) was heated in AcOH (30 cm^3) under reflux. After adding water (100 cm^3), the mixture was extracted with benzene and the solvent was evaporated in vacuo. The resulting crude product was purified on TLC with chloroform as the developing solvent, and in the case of **3g** further purification was made by TLC with ether/light petroleum 30 : 70 as the developing solvent.

2-Methyl-4,4-diphenyl-4-butanolide (3a): Heated for 9 h; 90% yield.

2-Methyl-4,4-bis(4-methoxyphenyl)-4-butanolide (3b): Heated for 6 h; 54% yield: Colorless prisms (from benzene/hexane); mp 100.1—100.4 °C; IR 1765 cm^{-1} (-COO-); ^1H NMR ($CDCl_3$) δ=1.23 (3H, d, J=6.0 Hz, CH_3), 2.1—3.3 (3H, m, H-2 and 2×H-3), 3.74 (6H, s, 2×OCH_3), and 6.6—7.5 (8H, m, ar. H). Found: C, 73.16; H, 6.47%. Calcd for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45%.

2-Methyl-4-phenyl-4-butanolide (3g) (a mixture of two diasteroisomers, **3g'** and **3g''**): Heated for 5.5 h; 71% yield. **3g'**: From the upper fraction on TLC; liquid.[18] **3g''**: From the lower fraction on TLC; liquid.[18]

Dehydrobromination of 6a in AcOH. The **6a** (53.2 mg) was heated in AcOH (5 cm^3) at 100 °C for 1 h. The solvent was removed in vacuo and the resulting crude product was purified on TLC with chloroform as the developing solvent, giving 4,4-diphenyl-2-buten-4-olide (**8a**) (37.9 mg, 95%), mp 131.7—132.7 °C (lit,[19] mp 131—131.5 °C).

Reaction of 13 with 1a in the Presence of Manganese(III) Acetate. To a heated solution of **1a** (211.5 mg) and **13** (128 mg) in AcOH (20 cm^3), manganese(III) acetate (347.2 mg) was added. The solution was heated under reflux for 55 min. After adding water (100 cm^3), the mixture was extracted with benzene. After removal of the solvent in vacuo the resulting crude product was separated on TLC with benzene as the developing solvent, giving **11** (79%) and **12a** (5%).

Reaction of 13 with Manganese(III) Acetate. To a heated solution of **13** (204.5 mg) in AcOH (20 cm^3), manganese(III) acetate (353.4 mg) was added. The solution was heated under reflux for 90 min. After adding water (100 cm^3), the mixture was extracted with benzene and purified on TLC with benzene as the developing solvent, giving **10a** (24%) and **4** (6%).

Reaction of Phenylacetylene with Methylmalonic Acid in the Presence of Manganese(III) Acetate. To a heated solution of phenylacetylene (204.6 mg) and methylmalonic acid (284.1 mg) in AcOH (30 cm^3), manganese(III) acetate (1.289 g) was added. The solution was heated at 100 °C for 2 min. After adding water (100 cm^3), the mixture was extracted with benzene. The solvent was removed in vacuo and then the resulting crude product was purified on TLC with benzene as the developing solvent, giving **15'**, **15''**, and **16**.

2,2'-Dimethyl-4,4'-diphenyl-4,4'-bi(2-buten-4-olide) (15'): 18% yield: Colorless needles (from benzene); mp 229.7—230.5 °C; IR 1762 (-COO-) and 1659 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=1.59 (6H, d, J=1.3 Hz, 2×CH_3), 7.31 (10H, s, 2×Ph), and 7.41 (2H, q, J=1.3 Hz, H-3 and H-3'). Found: C, 76.27; H, 5.23%. Calcd for $C_{22}H_{18}O_4$: C, 76.29; H, 5.24%.

Stereoisomeric 2,2'-Dimethoxy-4,4'-diphenyl-4,4'-bi(2-buten-4-olide) (15''): 7% yield: Colorless microcrystals (**15''** has changed to **15'** during recrystallization from benzene); IR

1763 (-COO-) and 1658 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=1.91 (6H, d, J=1.3 Hz, 2×CH_3), 7.15 (10H, s, 2×Ph), 7.33 (2H, q, J=1.3 Hz, H-3 and H-3′).

4-Acetoxy-2-methyl-4-phenyl-2-buten-4-olide (16): Liquid; IR 1783 (-COO-), 1748 (OAc), and 1664 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=1.95 (3H, d, J=1.3 Hz, CH_3), 2.04 (3H, s, OAc), 7.1—7.6 (5H, m, Ph), and 7.30 (1H, q, J=1.3 Hz, =CH-). Found: m/z 232.0731. Calcd for $C_{13}H_{12}O_4$: M, 232.0736.

We wish to thank Professor Hitoshi Takeshita and Associate Professor Akira Mori of the Research Institute of Industrial Science, Kyushu University, and Dr. Shinzaburo Hishida of Hitachi Ltd., for their measurements of the mass spectra.

Photochemical Addition of Benzyltriethylgermane and Dibenzyldiethylgermane to Olefins

Masanori KOBAYASHI, Masato YOSHIDA, and Michio KOBAYASHI*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received April 4, 1986)

A novel photochemical addition of a germyl radical to the olefinic double bond was discovered when benzyltriethylgermane or dibenzyldiethylgermane was irradiated with a medium-pressure mercury lamp in the presence of olefins.

There have been only scattered reports on the photochemical behavior of organogermanium compounds.[1] We have reported previously that the photolysis of aryltrialkylgermanes and diaryldialkyl-germanes generated germyl and aryl free radicals.[2] In order to widen the scope of this photochemical reaction, the photolysis of benzyltrialkylgermane and dibenzyldialkylgermane were investigated. Contrary to the arylalkylgermanes, which show no tendency to add to the olefinic double bond but to abstract a hydrogen atom from solvent hydrocarbon upon irradiation, the photolysis of benzylsubstituted germanes in the presence of olefins were found to readily form 1,2-adducts. Even in the absence of olefins, the photolysis of the Ge–benzyl bond of these benzylgermanes proceeded rapidly. The high photoreactivity of alkylbenzylgermanes makes a good contrast to the very low rate of conversion of analogous trimethylbenzylsilanes that have recently been reported.[3]

Results and Discussion

Photolysis of Benzyltriethylgermane and Diethyldibenzylgermane. The photolysis of benzyltriethylgermane (**1**) in hexane with a medium-pressure mercury lamp through a Vycor filter for 10 min resulted in the facile decomposition of **1** to give hexaethyldigermane (**2**)[5] and bibenzyl (**3**) as shown below:

$$\underset{\textbf{1}}{Et_3GeCH_2Ph} \xrightarrow[\text{hexane}]{h\nu,\ 10\text{min}} \underset{\textbf{2}\ 75\%}{(Et_3Ge)_2} + \underset{\textbf{3}\ 86\%}{(PhCH_2)_2} + \underset{\text{(recovered)}\ 9\%}{\textbf{1}}$$

The formation of the above two products can be explained by assuming the photochemical dissociation of the benzyl–germanium bond (Eq. 1) and a subsequent dimerization of triethylgermyl and benzyl radicals. Both the germyl radical (**4**) and the benzyl radical are known to be relatively inactive and to possess little ability to abstract hydrogen atoms from saturated aliphatic hydrocarbons such as hexane.[1]

$$Et_3GeCH_2Ph \xrightarrow{h\nu} \underset{\textbf{4}}{Et_3Ge\cdot} + PhCH_2\cdot \qquad (1)$$

When **1** was irradiated in benzene under similar conditions, a small amount of triethyl-*p*-tolylgermane (**5**) was detected among the products in addition to bibenzyl and digermane (**2**). The formation of **5** suggests an intramolecular rearrangement of the triethylgermyl group from the benzyl carbon to the benzene ring by recombination in a solvent cage of the benzyl radical and the triethylgermyl radical pair once generated by the homolysis of Ge–benzyl bond. A similar rearrangement was observed in the photolysis of trimethylbenzylsilane.[3] An intramolecular photorearrangement of the germyl group has also been observed in cinnamylgermanes.[4]

When dibenzyldiethylgermane (**6**) was irradiated in hexane under similar conditions for 3 min, about 40% of **6** was photolyzed to form bibenzyl (**3**) and 1,2-dibenzyl-1,1,2,2-tetraethyldigermane (**7**) as major products. However, in this case, small amounts of germane (**8**), toluene and heptylbenzene (**9**) were also detected.

$$\underset{\textbf{6}}{Et_2Ge(CH_2Ph)_2} \xrightarrow[\text{hexane}]{h\nu,\ 3\text{ min}} \underset{\textbf{7}\ 49\%}{(Et_2GeCH_2Ph)_2} + \underset{\textbf{3}\ 98\%}{(PhCH_2)_2} + PhCH_3 + \underset{\textbf{8}\ 12\%}{Et_2GeCH_2Ph} + \underset{\textbf{9}}{PhCH_2C_6H_{13}} \qquad (2)$$

The formation of bibenzyl and digermane (**7**) suggests the splitting of the Ge–benzyl bond under irradiation to give a diethylbenzylgermyl radical (**10**) and a benzyl radical, and a subsequent dimerization of each radical.

$$\textbf{6} \longrightarrow \underset{\textbf{10}}{Et_2\dot{G}eCH_2Ph} + PhCH_2\cdot \qquad (3)$$

$$\textbf{10} + \textbf{10} \longrightarrow (Et_2GeCH_2Ph)_2 \qquad (4)$$

$$2\,PhCH_2\cdot \longrightarrow (PhCH_2)_2 \qquad (5)$$

Since neither the germyl radical nor the benzyl radical can abstract hydrogen atom from a saturated hydrocarbon (as stated before), it is unreasonable to explain the formation of germane (**8**), toluene and **9** by the simple hydrogen abstraction of a germyl radical from hexane and a subsequent recombination of the hexyl and benzyl radicals. The formation of these products can be tentatively explained by the following reaction sequence:

$$\underset{\text{CH}_2\text{Ph}}{Et_2Ge\cdot} + PhCH_2\cdot \longrightarrow \underset{\textbf{8}}{Et_2GeHCH_2Ph} + \underset{\textbf{11}}{PhCH{:}} \qquad (6)$$

Table 1. Photochemical Addition of **1** to 1-Hexene

Product		Yield/%[a]
$Et_3GeCH_2\underset{\underset{CH_2Ph}{|}}{C}H(CH_2)_3CH_3$	(**12**)	50
$Et_3Ge(CH_2)_5CH_3$	(**13**)	35
$Et_3GeCH{=}CH(CH_2)_3CH_3$	(**14**)	
$Et_3GeCH_2CH{=}CH(CH_2)_2CH_3$	(**15**)	
$Et_3GeCH_2\underset{\underset{C_6H_{13}}{|}}{C}H(CH_2)_3CH_3$	(**17**)	15
$(PhCH_2)_2$	(**3**)	35

a) Yields were determined by GLC.

and

$$PhCH{:} + C_6H_{14} \longrightarrow \underset{\mathbf{9}}{PhCH_2C_6H_{13}} \qquad (7)$$

By a metathesis between **10** and benzyl radical or by a direct alpha elimination from **6**, phenylcarbene (**11**) which undergoes insertion into the C–H bond of the solvent (hexane) to give heptylbenzene (**9**).

Photolysis in the Presence of Olefins. When benzyltriethylgermane **1** was irradiated with a medium-pressure mercury lamp in the presence of 1-hexene for 1.5 h, **1** was completely consumed to give the following products (yields are shown in Table 1):

$$Et_3GeCH_2Ph + CH_3(CH_2)_3CH{=}CH_2 \xrightarrow{h\nu}$$
$$\underset{\mathbf{12}}{CH_3(CH_2)_3CH(CH_2Ph)CH_2GeEt_3} + \underset{\mathbf{13}}{CH_3(CH_2)_5GeEt_3} +$$
$$\underset{\mathbf{14}}{CH_3(CH_2)_3CH{=}CHGeEt_3} + \underset{\mathbf{15}}{CH_3(CH_2)_2CH{=}CHCH_2GeEt_3}$$
$$+ \mathbf{3} + C_{12}H_{26} \qquad (8)$$

This reaction can also be understood by assuming a splitting of the Ge–benzyl bond to give a triethylgermyl radical (**4**) and a benzyl radical (Eq. 1). **4** would add (Eq. 9) to 1-hexene to give a 1-(triethylgermylmethyl)-pentyl radical (**16**), which may recombine (Eq. 10) with a benzyl radical to form 1,2-adduct (**12**) or may disproportionate[2,5] (Eq. 11) to give 1-triethylgermylhexane (**13**) and 1-triethylgermyl-1-hexene (**14**) or 1-triethylgermyl-2-hexene (**15**), accompanying the dimerization of excess benzyl radicals to bibenzyl.

$$\underset{\mathbf{4}}{Et_3Ge\cdot} + C_4H_9CH{=}CH_2 \longrightarrow \underset{\mathbf{16}}{Et_3GeCH_2\dot{C}HC_4H_9} \qquad (9)$$

$$\mathbf{16} + PhCH_2\cdot \longrightarrow \mathbf{12} \qquad (10)$$

$$\mathbf{16} + \mathbf{16} \longrightarrow \mathbf{13} + \mathbf{14} + \mathbf{15} \qquad (11)$$

The formation of adduct **12** indicates the attack of a germyl radical to a terminal carbon atom of the olefinic double bond during the first step of the addition (Eq. 9), thus showing the higher addition ability of a germyl radical than that of a benzyl radical.

When **1** was photolyzed in the presence of cyclohexene under similar conditions for 1 h, the starting germane **1** was completely consumed. Products are summarized in Table 2.

Table 2. Photochemical Addition of **1** to Cyclohexene

Product		Yield/%[a]
	(**19**)	35 (cis:trans=1:4.4)
	(**20**)	22
	(**21**)	
	(**22**)	
	(**23**)	21 (cis and trans)
$(Et_3Ge)_2$	(**2**)	21
$(PhCH_2)_2$	(**3**)	45

a) Yields were determined by GLC.

The first step in this reaction was the cleavage of the Ge–benzyl bond (Eq. 1). The triethylgermyl radical (**4**) added to cyclohexene to form a 2-(triethylgermyl)cyclohexyl radical (**18**), which reacted either by recombination with a benzyl radical resulting in the formation of the 1,2-adduct (**19**), or by disproportionation to give triethylgermylcyclohexane (**20**), 1-(triethylgermyl)cyclohexene (**21**) and 3-(triethylgermyl)cyclohexene (**22**). Part of the triethylgermyl radical combined with **18** to form 1,2-bis(triethylgermy)cyclohexane (**23**) or dimerized to hexaethyldigermane (**2**).[5] About half of the benzyl radical dimerized to bibenzyl. The formation of digermane **2** and 1,2-digermyl compound **23** suggest that the triethylgermyl radical is rather stable and can diffuse out of the solvent cage to seek combinations with other free radicals.

1,2-Adduct **19** is a mixture of cis and trans isomers. The ratio of cis:trans is 1:4.4, indicating that the addition is mainly trans, but not strictly stereospecific. The formation of both cis and trans isomers indicates that addition is not concerted but proceeds by a two-step mechanism.

In order to survey the effects of substituents, the photolysis of **1** in the presence of di-, tri-, and tetrasubstituted olefins were also investigated.

Products of the photolysis of **1** in the presence of 2-hexene are shown in Table 3. Starting germane **1** was completely consumed in 1.5 h. Three types of 1,2-adducts (**24A**, **24B**, **24C**) were detected with GLC and GC-Mass but could not be separated from each other. Most probably, they are the 2- and 3-germyl isomers and their threo–erythro isomers.

Results of the photolysis of **1** in 2-methyl-2-pentene

are summarized in Table 4. The structure of 1,2-adduct **25** indicates that the attack of triethylgermyl radical (**4**) occurred at a less-hindered olefinic carbon to give a more stable tertiary carbon radical **26**. The low yield of the 1,2-adduct **25** suggests a steric inhibition toward the recombination between **26** and the benzyl radical. A larger part of radical **26** disproportionated to afford germylhexane (**27**) and germylhexenes (**28** and **29**).

In the case of the photolysis of **1** in the presence of 2,3-dimethyl-2-butene, the yield of 1,2-adduct, 2-benzyl-2,3-dimethyl-3-(triethylgermyl)butane (**30**) was only 3%. The major products were hexaethyldigermane (**2**) and bibenzyl. Small amounts of 2,3-dimethyl-2-(triethylgermyl)butane (**31**) and 2,3-dimethyl-3-(triethylgermyl)-1-butene (**32**) were also detected. The formation of these germylbutane and germylbutene derivatives can be explained by a disproportionation of the adduct radical **33**.

In the reaction of **1** with a series of the substituted olefins, the yields of the 1,2-adduct greatly decreased with an increase in the number of the substituents on the olefinic carbon; this indicates the important role played by steric hindrance.

Photolysis in the Presence of 1,3-Dienes. The reaction of benzylgermane **1** with 1,3-diene is also interesting. When **1** was photolyzed in the presence of 2,3-dimethyl-1,3-butadiene, 1,2-adduct (**34**) and 1,4-adduct (**35**), both having triethylgermyl group on terminal carbon atom, were obtained in a 2:3 molar ratio (see Table 6). The orientation of the germyl group in the adducts again indicated a more preferential addition of the germyl free radical to diene than benzyl radical to.

Photochemical Reaction of Diethyldibenzylgermane with 1,3-Dienes. When diethyldibenzylgermane **6** was irradiated in the presence of 2,3-dimethyl-1,3-butadiene for 2 h under similar conditions as in the case of **1**, the major products were 1,2-adduct (**36**) and 1,4-adduct (**37**) in almost the same molar ratio (Table 7). However, in this reaction (although in low yield), the formation of 1,1-diethyl-3,4-dimethylgerma-3-cyclopentene (**38**)[7] was confirmed by GC-MS. The formation of **38** clearly indicated the generation of diethylgermylene (**39**) by the photolysis of **6**. Dimethylgermylene, thermally generated from 7-dimethylgerma-2,5-norbornadiene, is known to add to styrenes or dienes to give germacyclohexane or germacyclopentene derivatives respectively.[8]

The formation of 1,2- and 1,4-dibenzyl adducts (**40** and **41**) shows that benzyl radical can add to 1,3-diene, which was not observed in the reaction with simple olefins.

Table 7. Photochemical Addition of **6** to 2,3-Dimethyl-1,3-butadiene

Product		Yield/%[a]
	(**36**)	29
	(**37**)	30
	(**38**)	2
	(**40**)	11
	(**41**)	
$(PhCH_2)_2$	(**3**)	17

a) Yields were determined by GLC based on the consumed **6**. 3% of **6** was recovered.

Experimental

IR and UV spectra were recorded on a Hitachi 260-10 IR spectrometer and Hitachi 220A UV spectrometer, respectively. The proton and ^{13}C NMR spectra were recorded with TMS as an internal standard in $CDCl_3$ or benzene-d_6 at 60 MHz by JNM-PMX-60 and Jeol FX-60, respectively. Mass spectra were measured with a Jeol-DX300 high-resolution mass spectrometer with a JMA-5000 Mass Data System. GLC and HPLC were performed on a Hitachi 163 Gas Chromatograph with SE-30 10% coated column (2 m) and a Hitachi 655 Liquid Chromatograph with a Hitachi 638-41 UV monitor.

Materials. Benzyltriethylgermane (1): Bromotriethylgermane (5.00 g; 20.9 mmol) in ether (50 cm^3) was added to benzylmagnesium bromide prepared from 5.35 g (31.3 mmol) of benzyl bromide and magnesium (0.76 g; 31.3 mg atm) in ether (100 cm^3). The reaction mixture was refluxed for one night, then hydrolyzed with ice and dilute hydrochloric acid. After the usual work-up and purification by silica-gel column chromatography with hexane as an eluant and fractional distillation, **1** was obtained in 97% yield. Bp 71—73 °C/0.45 mmHg (1 mmHg=133.322 Pa). UV; 270 nm (ε 420). ^1H NMR ($CDCl_3$) δ=0.43—1.43 (m, 15H), 2.17 (s, 2H), 6.76—7.33 (m, 5H). ^{13}C NMR ($CDCl_3$) δ=3.9, 8.8, 21.1, 123.6, 127.7, 128.1, 141.7. MS *m/z* 252 (M^+). Exact MS; Found: *m/z* 252.0872. Calcd for $C_{13}H_{22}{}^{74}Ge$: 252.0933.

Dibenzyldiethylgermane (6): Dibromodiethylgermane[9] (11.03 g; 0.038 mol) in ether (30 cm^3) was added to benzylmagnesium bromide prepared from benzyl bromide (19.5 g; 0.114 mol) and magnesium (2.77 g; 0.114 g atom) in ether (90 cm^3). The reaction mixture was refluxed for one night and hydrolyzed with ice water. The product was purified by silica-gel column chromatography with hexane–ether (50:1 mixture) as an eluant and fractional distillation. Yield 96%. Bp 120—122 °C/0.12 mmHg. ^1H NMR ($CDCl_3$) δ=0.37—1.40 (m, 10H), 2.19 (s, 4H), 6.76—7.47 (m, 10H). ^{13}C NMR ($CDCl_3$) δ=4.2, 8.6, 21.2, 123.8, 127.9, 128.2, 141.0. MS *m/z* 314 (M^+). Exact MS; Found: *m/z* 314.1032. Calcd for $C_{18}H_{24}{}^{74}Ge$: 314.1089. UV; 267 nm (ε 840).

Photolysis. A solution of 0.93 mmol of **6** in 230 cm^3 of hexane was irradiated with a medium-pressure mercury lamp through a Vycor filter for 3 min under an argon atmosphere. The products were separated by preparative GLC and identified by GC-Mass, ^1H NMR, ^{13}C NMR and IR spectroscopy. Yields were determined by GLC.

Photochemical Addition. General procedure is shown in the case of benzyltriethylgermane in the presence of 1-hexene.

A solution of 2.4 mmol of **1** and 14.3 mmol of 1-hexene in 140 cm^3 of hexane was irradiated with a medium-pressure mercury lamp through a Vycor filter for 1.5 h under an argon atmosphere. The starting material was completely disappeared at this point. Products were isolated by GPC, preparative GLC and silica-gel column chromatography, and identified by ^1H NMR, ^{13}C NMR, IR, and GC-MS. Yields were determined by GLC using nonane, dodecane or tetradecane as an internal standard.

Physical Properties of the Product. 1,2-Dibenzyl-1,1,2,2-tetraethyldigermane (7): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.67—1.47 (m, 20H), 2.27 (s, 4H), 6.77—7.37 (m, 10H). ^{13}C NMR ($CDCl_3$) δ=6.7, 10.3, 22.8, 124.3, 128.2, 128.6, 142.3. MS *m/z* 355 (M^+-PhCH_2). Ex MS Found: *m/z* 353.0583. Calcd for $C_{15}H_{27}{}^{74}Ge^{72}Ge$: 353.0546.

1-Triethylgermyl-2-benzylhexane (12): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.43—1.13 (m, 18H), 1.13—2.17 (m, 9H), 2.52 (d, J=7.2 Hz, 2H), 6.97—7.43 (m, 5H). ^{13}C NMR ($CDCl_3$) δ=4.7, 8.9, 14.2, 17.1, 23.0, 28.8, 35.8, 37.1, 43.5, 125.5, 128.0, 129.2, 141.8. MS *m/z* 307 ($M^+-C_2H_5$). EX MS Found: *m/z* 307.1435. Calcd for $C_{17}H_{29}{}^{74}Ge$: 307.1481.

Diethylbenzylgermane (8): Colorless liquid; ^1H NMR (benzene-d_6) δ=0.72—1.17 (m, 10H), 2.20 (d, J=3 Hz, 2H), 3.90—4.20 (m, 1H), 6.87—7.14 (m, 5H). IR (neat) 2001 cm^{-1} (ν_{Ge-H}). MS *m/z* 224 (M^+). EX MS Found: *m/z* 224.0679. Calcd for $C_{11}H_{18}{}^{74}Ge$: 224.0620.

1-(Triethylgermyl)-2-benzylcyclohexane (19) (cis: trans= 1:4 mixture): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.57—2.03 (m, 25H), 2.49 (m, 2H), 6.92—7.48 (m, 5H). ^{13}C NMR ($CDCl_3$) δ=4.6, 9.4, 22.0, 25.6, 26.4, 28.3, 29.1, 29.8, 32.1, 33.4, 37.4, 39.0, 42.0, 43.6, 125.7, 128.2, 129.2, 141.7. MS *m/z* 305 ($M^+-C_2H_5$). EX MS Found: *m/z* 305.1284. Calcd for $C_{17}H_{27}{}^{74}Ge$: 305.1325.

1,2-Bis(triethylgermyl)cyclohexane (23) (cis-trans mixture): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.50—1.33 (m, 32H), 1.33—1.87 (m, 8H). ^{13}C NMR ($CDCl_3$) δ=5.1, 9.2, 25.3, 26.5, 27.2, 27.6, 30.1, 30.5. MS *m/z* 404 (M^+). EX MS; Found: *m/z* 243.1125. Calcd for $C_{12}H_{25}{}^{74}Ge$ (M^+-Et_3Ge): 243.1082.

1,2-Adduct of 1 with 2-Hexene (24A, 24B, 24C) (mixture of **3** isomer): Colorless liquid; ^1H NMR ($CDCl_3$) δ= 0.50—1.77 (m, 27H), 2.30—2.93 (m, 2H), 6.80—7.30 (m, 5H). MS *m/z* 307 ($M^+-C_2H_5$). EX MS: Found Isomer **A**; *m/z* 307.1443. Isomer **B**; *m/z* 307.1504. Isomer **C**, *m/z* 307.1418. Calcd for $C_{17}H_{29}{}^{74}Ge$; ($M^+-C_2H_5$): 307.1481.

2-Methyl-2-benzyl-3-trimethylgermylhexane (25): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.65—1.14 (m, 27H), 2.54 (s, 2H), 6.97—7.30 (m, 5H). ^{13}C NMR ($CDCl_3$) δ=6.1, 8.9, 14.7, 17.4, 26.0, 27.5, 37.4, 44.2, 49.0, 125.6, 127.5, 130.7, 139.7. MS *m/z* 307 ($M^+-C_2H_5$). EX MS Found *m/z* 307.1394. Calcd for $C_{17}H_{29}{}^{74}Ge$ ($M^+-C_2H_5$): 307.1481.

2,3,3-Trimethyl-4-phenyl-2-(triethylgermyl)butane (30): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.76—1.23 (m, 27H),

2.58 (s, 2H), 7.07—7.28 (m, 5H). MS *m/z* 307 ($M^+-C_2H_5$). EX MS Found: *m/z* 307.1481. Calcd for $C_{17}H_{29}{}^{74}Ge$ ($M^+-C_2H_5$); 307.1481.

2,3-Dimethyl-3-benzyl-4-triethylgermyl-1-butene (34): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.52—1.32 (m, 20H), 1.83 (s, 3H), 2.54, 2.78 (AB q, J=13.8 Hz, 2H), 4.51 (s, 1H), 4.73 (m, 1H), 6.93—7.37 (m, 5H). ^{13}C NMR ($CDCl_3$) δ=5.7, 9.0, 20.4, 25.6, 26.1, 42.9, 50.1, 111.4, 125.8, 127.4, 130.5, 139.2, 150.8. MS *m/z* 334 (M^+). EX MS Found: *m/z* 334.1699. Calcd for $C_{19}H_{32}{}^{74}Ge$: 334.1716.

2,3-Dimethyl-5-phenyl-1-triethylgermyl-2-pentene (35): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.43—1.30 (m, 17H), 1.65 (s, 6H), 2.47 (m, 4H), 6.93—7.47 (m, 5H). ^{13}C NMR ($CDCl_3$) δ=5.0, 8.9, 18.8, 20.3, 20.6, 34.9, 37.0, 123.9, 125.6, 127.5, 128.2, 128.4, 142.9. MS *m/z* 334 (M^+). EX MS Found: *m/z* 334.1781. Calcd for $C_{19}H_{32}{}^{74}Ge$: 334.1716.

2,3-Dimethyl-3-benzyl-4-diethylbenzylgermyl-1-butene (36): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.43—1.24 (m, 12H), 1.57 (s, 3H), 1.66 (s, 3H), 2.20 (s, 2H), 2.33, 2.51 (AB q, J=9 Hz, 2H), 4.48 (s, 1H), 4.72 (m, 1H), 6.77—7.43 (m, 10H). MS *m/z* 396 (M^+). EX MS Found: *m/z* 396.1837. Calcd for $C_{24}H_{34}{}^{74}Ge$: 396.1872.

2,3-Dimethyl-5-phenyl-1-diethylbenzylgermyl-2-pentene (37): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.38—1.33 (m, 12H), 1.56 (s, 6H), 2.33 (s, 2H), 2.49 (m, 4H), 6.96—7.32 (m, 10H). MS *m/z* 396 (M^+). EX MS Found: *m/z* 396.1846. Calcd for $C_{24}H_{34}{}^{74}Ge$: 396.1872.

5-(Triethylgermylmethyl)undecane (17): Colorless liquid; ^1H NMR ($CDCl_3$) δ=0.43—1.80 (m, 40H), ^{13}C NMR ($CDCl_3$) δ=4.8, 9.0, 11.7, 14.0, 14.2, 23.2, 23.3, 30.2, 30.5, 32.7, 33.8, 36.9, 38.5. MS *m/z* 301 ($M^+-C_2H_5$). EX MS Found: *m/z* 245.1331. Calcd for $C_{12}H_{27}{}^{74}Ge$ ($M^+-C_6H_{13}$): 245.1324.

1,1-Diethylgermacyclo-3,4-dimethyl-3-pentene (38): Due to the low yield this product could not be isolated in pure state in the photoreaction of diethyldibenzylgermane and 3,4-dimethyl-1,3-butadiene. Its mass fragmentation pattern [*m/z* 214 (M^+), 185 ($M^+-C_2H_5$, base peak), 157 ($M^+-2\,C_2H_5$), 132 (Et_2Ge), 115, and 103 (EtGe)] is identical with that of the authentic sample prepared as described below.

Synthesis of 38: To a solution of trichlorogermane (0.025 mol) in ether (20 ml) was added 2,3-dimethyl-1,3-butadiene (0.027 mol) in ether (10 ml) with stirring at room temperature. Stirring was continued for 1 h, and a precipitated white solid was filtered off. A filtrate containing 1,1-dichloro-3,4-dimethyl-1-germacyclo-3-pentene was added dropwise to a solution of ethylmagnesium bromide, prepared from ethyl bromide (0.25 mol) and magnesium (0.25 mol) in ether (200 ml), under reflux. After refluxing for 3 h, excess Grignard reagent was hydrolyzed with a saturated ammonium chloride solution. The solvent was expelled at room temperature and the residue was purified by silica-gel chromatography (eluant: hexane) and GPC to give **38**. Yield 22%. Bp 60 °C/7 mmHg (lit,[7] 102 °C/26 mmHg (1 mm Hg=133.322 Pa)). ^1H NMR δ=0.54—1.30 (m, 10H, C_2H_5), 1.47 (s, 4H, CH_2), 1.68 (s, 6H, CH_3). ^{13}C NMR δ=5.8, 9.2, 19.5, 22.9, 131.0. Mass: *m/z* 214 (M^+), 185, 157, 132 (Et_2Ge), 115, 103, 83, 75.

Thanks are due to ASAI Germanium Research Institute for donating the germanium tetrachloride.

(Received April 15, 1986)

Optically active 3-(9-anthryl)alanine was synthesized for the first time and its cyclic dipeptide, cyclo(D-9-anthrylalanine)$_2$, was prepared. Conformation of the cyclic dipeptide in solution was investigated by means of ^{1}H NMR, absorption, circular dichroism (CD), and fluorescence spectroscopy. The coupling parameter $J_{NH\text{-}C^{\alpha}H}$, observed in the NMR spectra indicated a planar configuration for the 2,5-piperazinedione ring of the dipeptide. The cyclic dipeptide showed a moderately large exciton couplet in CD spectrum and a small splitting in the ^1B_b absorption band, but no excimer emission in fluorescence spectrum. These spectroscopic data suggest an unfolded-unfolded conformation for the side chains of the cyclic dipeptide.

Bichromophoric compounds in which two aromatic groups are linked to a ring system have been investigated.[1-3] Study on electronic interactions between two rigidly-fixed chromophores may provide basic information on photochemical processes in chromophoric assemblies, such as polymers, bilayers, and monolayers. In the previous paper, syntheses and conformational analyses of two cyclic dipeptides carrying 1- and 2-naphthyl groups, cyclo(L-1- and 2-naphthylalanine)$_2$ [c(1- and 2-napAla)$_2$] have been described.[4] The 2,5-piperazinedione ring of the two cyclic dipeptides was found to be nearly planar and the folded-unfolded asymmetric side-chain conformation was most populated. In this article, the same line of study was extended to a cyclic dipeptide carrying 9-anthryl group, cyclo(D-9-anthrylalanine)$_2$ [c(D-antAla)$_2$]. Its conformation in solution was studied by means of ^{1}H NMR, absorption, circular dichroism (CD), and fluorescence spectroscopy. The optically active 9-anthrylalanine was synthesized for the first time in this study. The determination of the absolute configuration of the amino acid has been described elsewhere.[5]

Experimental

Materials. D-3-(9-Anthryl)alanine and Cyclo(D-9-anthrylalanine)$_2$: Optically active 9-anthrylalanine was synthesized for the first time in this study. The cyclic dipeptide was prepared by a similar mannar as in the case of c(1- and 2-napAla)$_2$. The elimination of *N*-benzyloxycarbonyl group from a linear dipeptide was conducted by a catalytic hydrogenation using ammonium formate as a hydrogen donor.[6]

Ac-DL-9-antAla-OH[7]: Sodium (2.5 g) was dissolved in dry ethanol (200 ml) and diethyl acetamidomalonate (23.23 g) was added to the solution. 9-(Chloromethyl)anthracene (20 g) was then added and the mixture was refluxed for 4 h. After cooling to room temperature, sodium chloride was filtered off and the filtrate was evaporated. Diisopropyl ether (100 ml) was added to the residue and the mixture was cooled with ice to precipitate crude crystals of diethyl α-(9-anthrylmethyl)acetamidomalonate (25 g). The latter were dissolved in ethanol (200 ml) and 2M NaOH (100 ml, 1M=1 mmol dm^{-3}) was added. The mixture was heated to ca. 60 °C for 30 min and neutralized with concd HCl to pH= 3. Ethanol was evaporated and water was added to precipitate Ac-DL-antAla-OH. The curde material was redissolved in ethanol (100 ml) under heating and 2M NaOH (50 ml) was added. Crystalline precipitate was collected and treated with 1M HCl to obtain a free acid form of Ac-DL-antAla-OH, yield 15.9 g. Mp 265—267 °C. Found: C, 74.34; H, 5.28; N, 4.35%. Calcd for $C_{19}H_{17}NO_3$: C, 74.25; H, 5.57; N, 4.56%.

Resolution of Ac-DL-antAla-OH: The racemic acetylamino acid (14.8 g) was dissolved in ethanol (200 ml) under heating and *l*-ephedrine (9.5 g) was added. After standing overnight at room temperature the mixture was cooled with ice to precipitate Ac-D-antAla-OH *l*-ephedrine complex (the absolute configuration has been determined as described below). The complex was recrystallized twice from ethanol and redissolved in ethanol under heating. Concd HCl (10 ml) and water (300 ml) were added to the ethanol solution and the mixture was cooled with ice to precipitate Ac-D-antAla-OH, yield 3.3 g. Mp 269—270 °C. (Found: C, 74.04; H, 5.57; N, 4.47%). CD: $[\theta]_{258(max)}=1.12\times10^5$ (ethanol, $c=1.95\times10^{-4}$ M). Evaporation of the filtrate gave an L-rich Ac-antAla-OH *l*-ephedrine complex, from which the acetylamino acid containing more L-enantiomer was recovered.

Ac-D-antAla-OMe: Ac-D-antAla-OH was dissolved in methanol saturated with HCl and the solution was kept stirring at room temperature for 3 h. Evaporation gave crystals which was recrystallized from methanol/diisopropyl ether mixture. Mp 208—209 °C. Found: C, 74.53; H, 5.94; N, 4.41%. Calcd for $C_{20}H_{19}NO_3$: C, 74.75; H, 5.96; N, 4.36%.

D-antAla-OH·HCl: Ac-D-antAla-OH (3.3 g) was suspended in concd HCl (150 ml)/acetic acid (50 ml) mixture and refluxed for 4 h. After a further addition of water, the mixture was cooled with ice to precipitate crystalline D-antAla HCl, 2.84 g. Mp 244 °C. $[\alpha]_D=-43°$ (ethanol, $c=0.058$ g dl^{-1}, 21 °C).

D-antAla-OMe: D-AntAla·HCl (150 mg) was suspended in 1M HCl/methanol mixture and the suspension was refluxed for 1 h. The solvent was evaporated and the residual crystal was recrystallized from methanol/ether mixture to give D-antAla-OMe·HCl, yield 157 mg. Mp 229C°. The hydrochloride (50 mg) was treated with 3% $NaHCO_3$ and the free methyl ester was extracted with ethyl acetate, yield 30 mg. Mp 76 °C.

Absolute Configuration and Optical Purity of the 9-Anthryl-alanine Resolved by Using *l*-Ephedrine: The absolute configuration of the optically active amino acid was determined on the basis of the "Dnp-aromatic rule".[8] The *N*-dinitrobenzoyl derivative of the optically active antAla

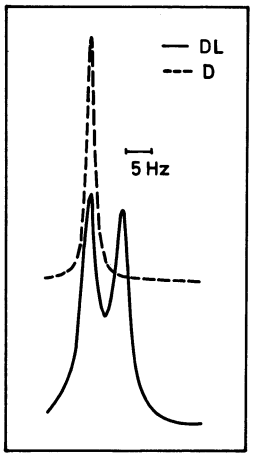

Fig. 1. Proton NMR spectra of D- and DL-antAla-OMe in the presence of 0.6 molar tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium-(III) in deuteriochloroform. (——): DL-isomer, (-----): D-isomer.

showed a positive Cotton effect around 400 nm, which is indicative of D-configuration. The detail has been reported elsewhere.[5]

^{1}H NMR spectra of D- and DL-antAla-OMe were measured in $CDCl_3$ in the presence of 0.6 equivalent molar tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III). Figure 1 shows the NMR spectra in the O-CH_3 proton region. The racemic compound showed two peaks whereas the D-isomer showed only one peak under the same conditions. The optical purity of the D-isomer is better than ca. 99%. It is interesting to note that the O-CH_3 signal of D-isomers of 1- and 2-naphthylalanine and 1-pyrenylalanine has been observed at lower field than that of the corresponding L-isomers. The present result in Fig. 1 conforms to this rule.

Z-D-antAla-OH: D-AntAla-OH·HCl (2.62 g) was dissolved in 1M NaOH (18 ml), and benzyloxycarbonyl chloride (2.0 ml) and 1M NaOH (9 ml) were added dropwise simultaneously at O°C under vigorous stirring. Precipitate appeared after one day. The mixture was acidified with HCl to pH=3 and the crystal precipitated was collected, washed with water and hexane, and dried. The curde crystal was recrystallized from ethyl acetate, yield 2.91 g. Mp 215—218°C.

Z-(D-antAla)$_2$-OMe: Z-D-antAla-OH (50 mg), D-antAla-OMe·HCl (39.5 mg), and triethylamine (17.4 l) were dissolved in DMF (2 ml), and water-soluble carbodiimide (26.4 mg) and 1-hydroxybenzotriazole hydrate (18.6 mg) were added under cooling with ice. The mixture was stirred under cooling for 4 h and at room temperature for 2 d. Precipitate, which appeared by the addition of 1M HCl (50 ml), was collected and washed with water, 3% $NaHCO_3$, and water. The crude solid was recrystallized from tetrahydrofuran/ethyl acetate mixture, yield 50 mg. Mp 238—240°C. Found: C, 78.02; H, 5.43; N, 4.53%. Calcd for $C_{43}H_{36}N_2O_5$: C, 78.16; H, 5.49; N, 4.24%.

Cyclo(D-antAla)$_2$: Z-(D-antAla)$_2$-OMe (40 mg) was dissolved in DMF (30 ml) and 10% palladium/activated carbon (100 mg) was added. Ammonium formate (40 mg) dissolved in methanol (5 ml) was added to the mixture under stirring at room temperature. The progress of the reaction was followed by TLC [Z-(D-antAla)$_2$-OMe, R_f=0.85, c(D-antAla)$_2$, R_f=0.4; ethyl acetate]. After 3 d, the catalyst was removed by filtration and the solvent was evaporated. The residual solid was reprecipitated from tetrahydrofuran (solvent)/methanol (nonsolvent), yield 10 mg, mp>300°C. TLC showed a single spot (chloroform, ethyl acetate). No impurity was found in IR, ^{1}H NMR (Fig. 2), UV (Fig. 3), and fluorescence (Fig. 5) spectra. IR (KBr disc): 1668 (amide C=O), 1438 (amide C-N) cm^{-1}.

Measurements. 90 MHz ^{1}H NMR spectra were recorded on a JEOL FX90Q instrument in DMF-d_7. Since the NH signal overlapped with the aromatic signals, the coupling parameter $J_{NH-C^\alpha H}$, was determined from the $C^\alpha H$ signals under irradiating $C^\beta H$ protons.

Circular dichroism was measured on a JASCO J-20 spectropolarimeter with quartz cells of 0.05 and 1.0 cm path lengths at the dipeptide concentration of 1.0×10^{-4} mol dm^{-3}. Fluorescence spectra were measured on a Hitachi MPF-4 instrument in a cuvette equipped with a stopcock. The sample solution was purged with nitrogen gas before each measurement.

Results and Discussion

Synthesis of Optically Active 9-Anthrylalanine. Synthesis of racemic 9-anthrylalanine has been reported[7] but its optical resolution has never been reported so far. Since optically active aromatic amino acids carrying large aromatic ring are important intermediate to prepare novel aromatic polypeptides in which aromatic groups are arranged regularly along a helical main chain, i.e., one-dimensional aromatic crystals, their preparation deserves special attention.

Optical resolution of antAla was attempted by a stereoselective deacylation of Ac-antAla with acylase at first, but the enzymic reaction did not occur at all. This contrasts the cases of 1- and 2-naphthylalanine, the acetyl derivatives of which were deacylated stereoselectively with acylase.[9,10] Enzymic deacylation of Ac-DL-pyrAla was also possible, although the yield was very low. The bulkiness of the 9-anthryl group may be the reason for the failure of the enzymic reaction.

Optical resolution by diastereomeric complex formation of Ac-DL-antAla-OH with 18 different chiral amino compounds was attempted. Only three of them, i.e., *l*-ephedrine, quinine, and *l*-cinchonidine formed ethanol-insoluble diastereomeric complex. These amines complexed preferentially with the D-enantiomer of Ac-antAla-OH. Among the three, the complex with *l*-ephedrine was most easily purified by recrystallization. The absolute configuration of antAla which forms insoluble complex with *l*-ephedrine was found to be a D-isomer according to the "Dnp-aromatic rule" as described above.[5]

Conformation of Cyclo(D-9-anthrylalanine)$_2$. ^{1}H NMR Spectra: Proton NMR spectrum of c(D-antAla)$_2$ in DMF-d_7 is shown in Fig. 2. The coupling parameter $J_{NH-C^\alpha H}$ was measured under irradiating $C^\beta H$ was protons and is shown in Table 1. The coupling parameter is related to the dihedral angle $\theta_{NH-C^\alpha H}$, which is approximately equal to ϕ+60° (for D-iso-

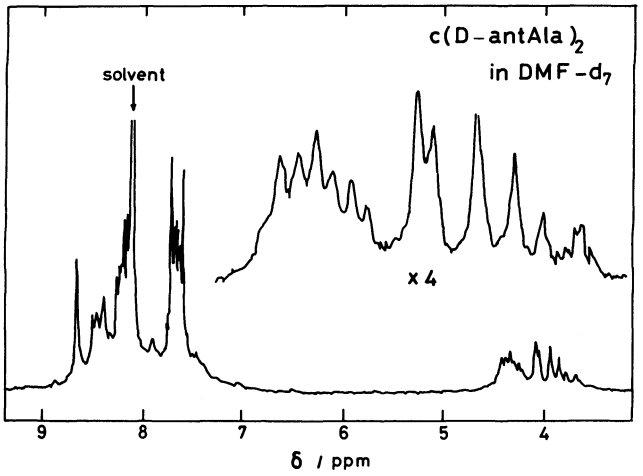

Fig. 2. Proton NMR spectrum of c(D-antAla)$_2$ in *N,N*-dimethylformamide-d_7. Concentration=4 mg/0.4 ml.

Table 1. The Coupling Parameter $J_{NH-C^{\alpha}H}$, and the Dihedral Angles $\theta_{NH-C^{\alpha}H}$, ϕ, and β for Cyclo(D-9-anthhrylalanine)$_2$ in *N,N*-Dimethylformamide-d_7

$J_{NH-C^{\alpha}H}$ (Hz)[a]	$\theta_{NH-C^{\alpha}H}$[b]	ϕ[c]	β[d]
2.6±0.2	±115°, ±57° (+57°)	−3°	3°

a) Estimated from the peak separation of $C^{\alpha}H$ signals under irradiating the $C^{\beta}H$ protons. b) θ was calculated according to the Bystrov equation: $J_{NH-C^{\alpha}H}=9.4\cos^2\theta-1.1\cos\theta+0.4$. c) $\phi=\theta-60°$. d) A supplement of the dihedral angle between two amide planes calculated assuming standard structural parameters for peptide bonds.

mer) where ϕ is the rotational angle of N-C^{α} bond defined according to the IUPAC-IUB nomenclature committee.[11] The dihedral angle and the rotational angle calculated according to the Bystrov equation[12] are also listed in Table 1. The Bystrov equation afforded four solutions for θ, but only one of the four, which is given in the parenthesis, corresponds to a reasonable skeletal conformation of the 2,5-piperazinedione ring. That is, the 2,5-piperazinedione ring is usually assumed to involve two planar amide bonds, and the dihedral angle between the two amide planes (β) may vary between ±45°. The θ value in the parenthesis corresponds to $\beta=3°$, whereas the other three solutions of the Bystrov equation gave β values outside the possible range. The determined β value indicates a planar conformation of the 2,5-piperazinedione ring of c(D-antAla)$_2$.

Circular Dichroism: CD and absorption spectra of c(D-antAla)$_2$ and Ac-D-antAla-OMe are shown in Fig. 3. The CD spectrum of the cyclic dipeptide shows a distinct exciton couplet at the ^1B_b absorption band. The molar ellipticities for one molar cyclic dipeptide are: $[\theta]_{248.5}=-3.1\times10^5$, $[\theta]_{262.5}=-5.3\times10^5$ deg cm^2 dmol^{-1}. According to the exciton coupling rule,[13]

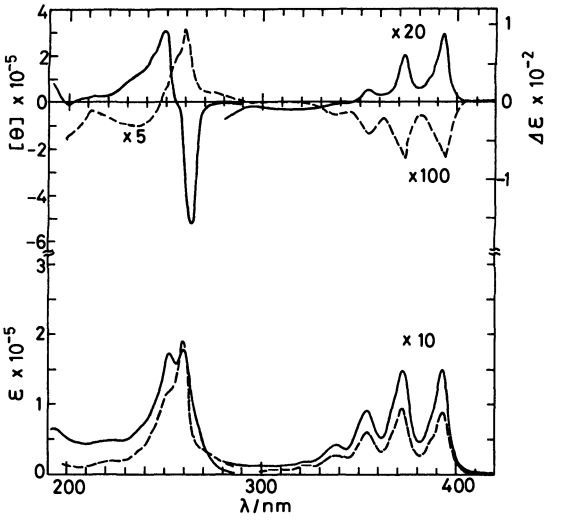

Fig. 3. Circular dichroism and absorption spectra of c(D-antAla)$_2$ (——) and Ac-D-antAla-OMe (----) in trimethyl phosphate. [antAla]=1.0×10^{-4} mol dm^{-3} for c(D-antAla)$_2$ and 1.9×10^{-4} mol dm^{-3} for Ac-D-antAla-OMe, room temperature. [θ] and ε are calculated with respect to two anthryl groups for c(D-antAla)$_2$ and one anthryl group for Ac-D-antAla-OMe.

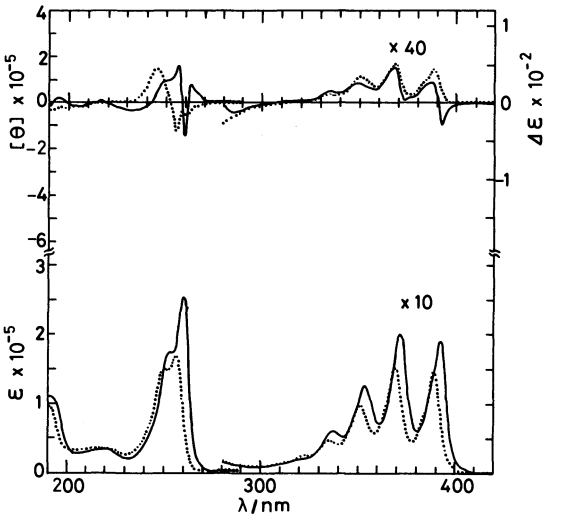

Fig. 4. Circular dichroism of Z-(D-antAla)$_2$ in trimethyl phosphate (—) and in 2,2,2-trifluoroethanol (·····). [antAla]=1.0×10^{-4} mol dm^{-3}, room temperature. [θ] and ε are calculated with respect to two anthryl groups.

the sign of the exciton couplet indicates that the transition dipole moments of the ^1B_b absorption which are parallel to the long axis of the anthryl group, are in a left-handed helical arrangement in c(D-antAla)$_2$.

Circular dichroic and absorption spectra of a linear dipeptide, Z-(D-antAla)$_2$-OMe in trimethyl phosphate (TMP) and in 2,2,2-trifluoroethanol (TFE) are shown in Fig. 4. A small and complex CD pattern is observed in TMP, whereas a small exction couplet at ^1B_b band in TFE. Two anthryl groups of the linear dipeptide may take a variety of orientations and the CD spectrum

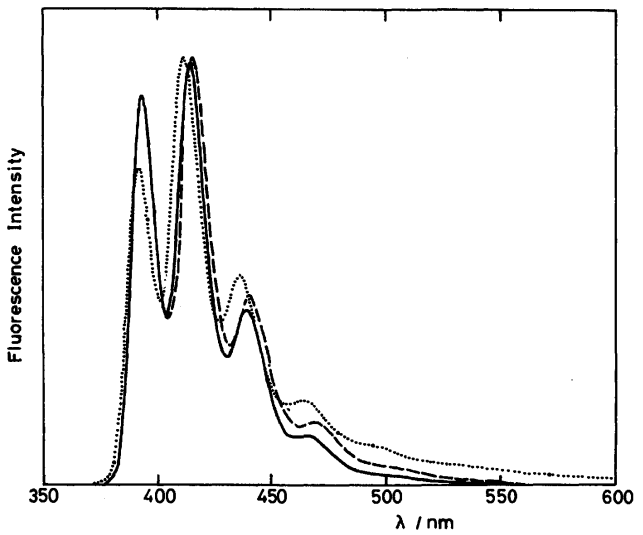

Fig. 5. Fluorescence spectra of c(D-antAla)$_2$ in trimethyl phosphate (—), and Z-(D-antAla)$_2$-OMe in trimethyl phosphate (-----) and in 2,2,2-trifluoroethanol (·····). [antAla]=1.0×10^{-5} mol dm^{-3}, room temperature.

should represent an average of these conformations. Rizzo and Jäckle[14] reported that linear dipeptides of aromatic amino acids (phenylalanine, histidine, tyrosine, and tryptophan) take extended conformations in aprotic solvents and folded conformations in protic solvents. This rule was also applicable to linear dipeptides of 1- and 2-naphthylalanines.[4] Hence the difference in CD spectrum in TMP (aprotic solvent) and TFE (protic solvent) may be interpreted by the different average conformations of Z-(D-antAla)$_2$-OMe in the two solvents.

Fluorescence Spectra: Figure 5 shows fluorescence spectra of c(D-antAla)$_2$ in TMP, and Z-(D-antAla)$_2$-OMe in TMP and in TFE. The cyclic dipeptide exhibits no excimer emission, indicating that the two anthryl groups are separated from each other by more than ca. 4 Å. The linear dipeptide shows no excimer in TMP but shows a small amount of excimer emission in TFE. The difference is consistent with the different conformations of the linear dipeptide in protic (TFE) and aprotic (TMP) solvent as described above. In the protic solvent the linear dipeptide takes folded compact conformations which favors excimer formation, whereas in the aprotic solvent the dipeptide takes extended conformations in which two anthryl groups are well separated from each other.

Conclusion on the Conformation of c(D-9-antAla)$_2$. Cyclo(D-antAla)$_2$ has a planar 2,5-piperazinedione ring in solution. It shows a moderately large exciton couplet in CD and a small exciton splitting in absorption spectrum, but no excimer emission in fluorescence spectrum. These spectroscopic properties suggest either folded-unfolded or unfolded-unfolded conformation of side chains. However, a CPK model analysis and a preliminary result of empirical conformational energy calculation[15] suggest that the folded (g$^+$) conformation is not allowed for the side chain of c(D-antAla)$_2$ due to a steric repulsion between the anthryl group and the 2,5-piperazinedione ring. Hence the side-chain conformation of c(D-antAla)$_2$ is concluded as unfolded-unfolded conformation. This conclusion is in contrast with the case of c(1- and 2-napAla)s, where folded-unfolded asymmetrical conformation was proposed.[4] In the latter two cases, the interaction between the 2,5-piperazinedione ring and the aromatic ring may not be so severe as to eliminate the folded conformation. In the unfolded-unfolded conformation of c(D-antAla)$_2$, the two anthryl groups are separated by about 10 Å. This interchromophore distance is evidently too far to form excimer in the excited state, but may be close enough to induce an exciton couplet in CD spectrum at the ^1B_b absorption band, which has very strong transition dipole moment.

The authors thank Mr. H. Sasaki for his assistance in preparing optically active anthrylalanine.

(Received April 16, 1986)

Various kinds of fatty acid esters of L-ascorbic acid were synthesized and their role as chain-breaking antioxidant was studied in the oxidation of methyl linoleate in homogeneous solution. Fatty acid esters of ascorbic acid at either 6- or both 5- and 6-positions were effective as antioxidant and suppressed the oxidation of methyl linoleate, whereas those having ester group at 2-position did not act as antioxidant. 5,6-Erythorbyl dipalmitate was also effective as an antioxidant. Ascorbic acid esters inhibited the oxidation cooperatively with α- and δ-tocopherols as observed for free ascorbic acid. The antioxidant activity was correlated with the reactivity toward galvinoxyl radical.

The oxidations of lipids by molecular oxygen in biological systems and foods have received much attention recently in connection with their pathological, toxicological, and nutritional effects.[1-12] Tocopherols **1** (vitamin E)[13-16] and L-ascorbic acid **2** (vitamin C)[17-27] have been known to function as oil-soluble and water-soluble antioxidants, respectively,both in vivo and in vitro. In spite of much work on ascorbic acid and also the commercial production in large quantities, the chemistry of ascorbic acid has not been established in a manner that is scientifically satisfactory. The chemistry of ascorbic acid is in fact complicated partly because ascorbic acid can function as a radical scavenger, but it may also act as a prooxidant in combination with metal ions such as iron and copper.[28]

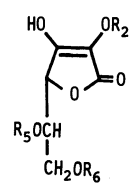
2



3

We have extended our study on the oxidation of lipids and its inhibition to study the role of ascorbic acid esters as chain breaking antioxidant in the oxidation of methyl linoleate in homogeneous solution. Various fatty acid esters of L-ascorbic acid **3** with different carbon numbers and positions have been prepared and examined. Erythorbic acid (D-isoascorbic acid) ester was also prepared and studied. Methyl linoleate was chosen as a substrate, since its oxidation has been shown to give four conjugated diene hydroperoxides quantitatively by a straight-forward mechanism.[29-31]

a) 5,6-Erythorbyl dipalmitate.

Experimental

Commercial methyl linoleate was purified by silica-gel column before use. Natural d-α-tocopherol and d-δ-tocopherol were provided by Eisai Co., Ltd. Various kinds of fatty acid esters of L-ascorbic acid were synthesized by the esterification of ascorbic acid at 2-, 5-, and 6-positions with corresponding fatty acids, followed by deacylation at 2-position in alcohol. Table 1 shows the ascorbic acid esters used in this study. 5,6-Erythorbyl dipalmitate was also synthesized similarly and studied. 2,2′-Azobis(2,4-dimethylvaleronitrile) (AMVN) was used as a radical initiator in order to generate initiating free radicals at a constant and known rate. Commercial galvinoxyl was used as received.

The oxidation was carried out at 37 °C under air in a glass ampoule immersed in a water bath. The rate of oxidation was measured in an automatic recording gas absorption apparatus by following the rate of oxygen uptake using a pressure transducer. The rate of free radical generation, that is, the rate of chain initiation was measured by conventional method from the induction period observed by the addition of a chain breaking antioxidant.[16] 2,6-Di-*t*-butyl-4-methylphenol (BMP) or α-tocopherol was used as the antioxidant. Commercial BMP was recrystallized from methanol before use. The rate of consumption of tocopherols was followed at 294 nm with a high-performance liquid chromatography (HPLC) by directly injecting 50 μl aliquots of the reaction mixture. The analytical system consisted of

JASCO liquid chromatograph equipped with a Finepak SIL-CN, 4.6×250 mm column, and samples were eluted with hexane–isopropyl alcohol–acetic acid (1000:15:1, v/v/v) at a flow rate of 1 ml min^{-1}. The rate of disappearance of ascorbic acid ersters was also measured with HPLC at 245 nm using 4.6×250 mm Finepak SIL-C_{18-5} column and metanol–water (85/15, v/v) containing 0.05% formic acid as an eluent (1 ml min^{-1}). The electron spin resonance (ESR) spectrum was recorded on X-band JEOL FE1X spectrometer.

Results and Discussion

Inhibition of Oxidation of Methyl Linoleate by Ascorbic Acid Esters. The rate of spontaneous autoxidation of methyl linoleate at ambient temperature is quite small, but it is oxidized at a constant rate without induction period in the presence of radical initiator AMVN. As shown in Fig. 1, when the fatty acid ester of ascorbic acid at either 6- or both 5-and 6-positions is added to the solution, the rate of oxidation was markedly suppressed and produced a clear induction period. During this induction period, the ascorbic acid ester was consumed linearly with time as shown in Fig. 2 and when it was depleted, the rate of oxidation increased to the same level as that without ascorbic acid ester. This is quite similar to the oxidation in the presence of α-tocoperhol and it clearly shows that ascorbic acid ester functions as a chain breaking antioxidant.

On the other hand, the ascorbic acid esters having ester group at 2-position did not show any antioxidant activity. 5,6-Erythorbyl dipalmitate was also effective in suppressing the oxidation.

Inhibition of Oxidation of Methyl Linoleate in Solution by the Combination of Ascorbic Acid Ester and Tocopherol. The pertinent results of the oxidations of methyl linoleate in chloroform initiated with AMVN and inhibited by both α-tocopherol and ascorbic acid ester are shown in Table 2. From the result of oxidation inhibited by α-tocopherol alone the constant ek_d was calculated as 2.87×10^{-6} s^{-1},

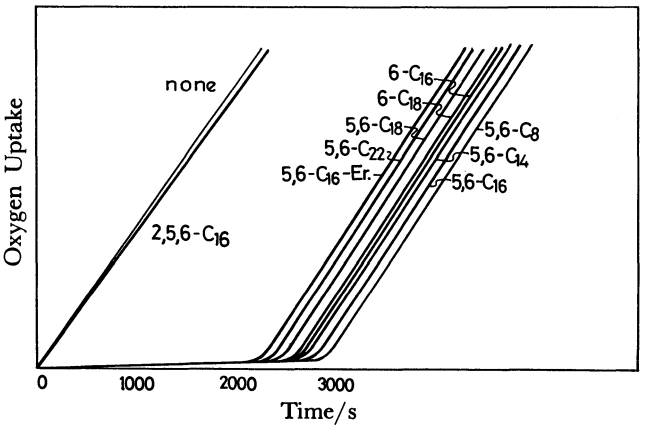

Fig. 1. Inhibition of oxidation of 145 mM methyl linoleate in solution by fatty acid esters of ascorbic acid at 37°C under air initiated with AMVN.

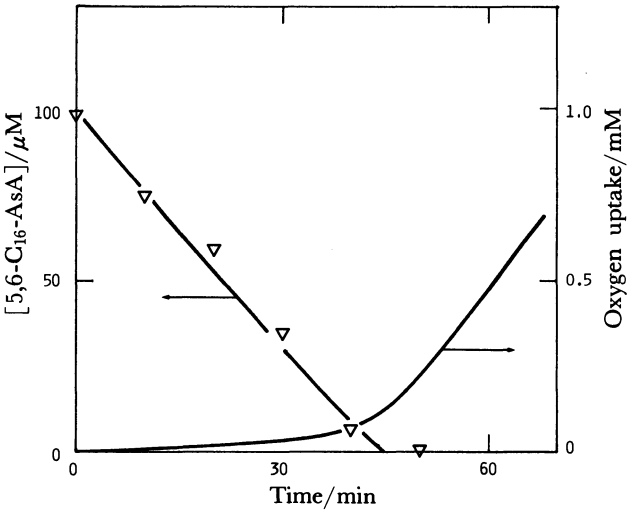

Fig. 2. Rates of oxygen uptake and consumption of 5,6-ascorbyl distearate in the oxidation of 159 mM methyl linoleate in benzene initiated with 10.1 mM AMVN at 37°C under air.

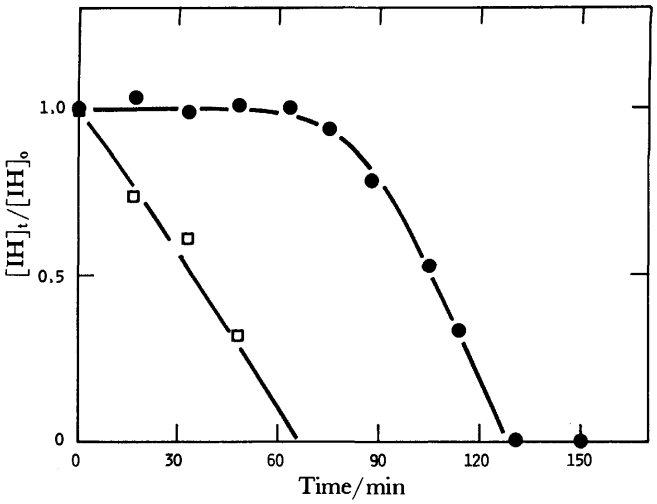

Fig. 3. Rate of consumption of antioxidant (IH) during the oxidation of 135 mM methyl linolate at 37°C. [AMVN]=18.1 mM, [α-tocoherol (●)]=50 mM, [5,6-C_{18}-AsA (□)]=500 mM.

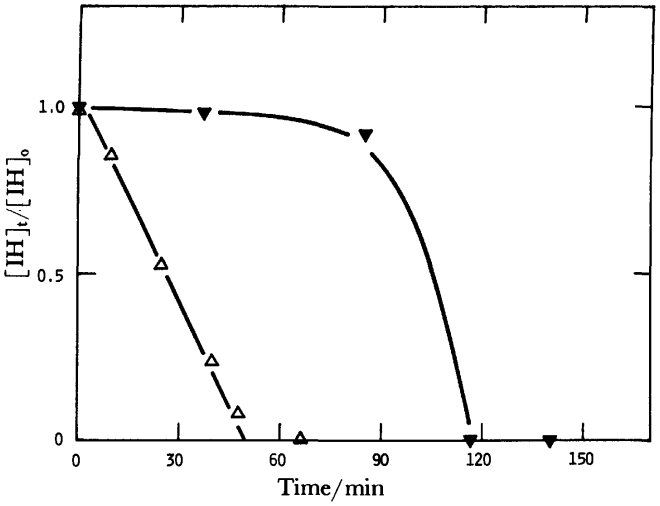

Fig. 4. Rate of consumption of antioxidant (IH) during the oxidation of 146 mM methyl linoleate under air at 37°C. [AMVN]=19.5 mM, [δ-tocopherol (▼)]=50 mM, [6-C_{18}-AsA (△)]=500 mM.

where A is $(CH_3)_2CHCH_2C(CH_3)CN-$ and e and k_d are the efficiency of free radical production and first-order rate constant for the decomposition of AMVN, respectively. The rate of chain initiation in other runs was calculated from Eq. 2 (M=mol dm^{-3}).

$$A\text{–}N{=}N\text{–}A \longrightarrow [A\cdot\ N_2\cdot\ A] \begin{cases} \nearrow 2eA\cdot & (1) \\ \searrow (1-e)A-A & (1') \end{cases}$$

$$R_i = 2ek_d[AMVN] = 5.74 \times 10^{-6}[AMVN]\ M\ s^{-1} \quad (2)$$

Both tocopherol and ascorbic acid esters (IH) scavenge peroxyl radicals by donating hydrogen atom (Eq. 3). The resulting radical, I·, may further trap peroxyl radicals (Eq. 4). The stoichiometric number of peroxyl radicals trapped by each antioxidant, n, is calculated from Eq. 5.

$$LO_2\cdot + IH \longrightarrow LOOH + I\cdot \quad (3)$$

$$(n-1)LO_2\cdot + I\cdot \longrightarrow \text{stable products} \quad (4)$$

$$n = R_i\cdot t_{inh}/[IH] \quad (5)$$

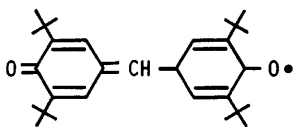
As Table 2 shows, the value of n in the absence of ascorbic acid is close to 2.0. That the apparent n values calculated from Eq. 5 are close to 2 in the presence of ascorbic acid esters which have ester group at 2-position suggests that these ascorbic acid esters do not function as radical scavenger. On the other hand, the apparent n values in the presence of 5,6-ascorbyl dipropionate, 5,6-ascorbyl dipalmitate, and 6-ascorbyl stearate are much higher than 2, suggesting that these ascorbic acid esters also function as hydrogen donor.

Figures 3 and 4 show that rate of consumption of tocopherol and ascorbic acid ester during the oxidation. Figure 3 shows that 5,6-ascorbyl distearate disappeared first linearly whereas α-tocopherol remained almost constant and it began to decrease after ascorbic acid ester was depleted. Similarly, as shown in Fig. 4, ascorbic acid ester was consumed first and δ-tocopherol was consumed after the ascorbic acid ester was depleted in the combination of δ-tocopherol and 6-ascorbyl stearate. Tocopherol (TH) must scavenge peroxyl radicals more rapidly than ascorbic acid ester (AH),[26] but the tocopheryl radical (T·) formed must react with ascorbic acid ester rapidly to regenerate tocopherol as observed in the combination of tocopherol and free ascorbic acid.[26,33,34]

$$LO_2\cdot \begin{cases} \overset{TH}{\nearrow} LOOH + T\cdot & (6) \\ \underset{AH}{\searrow} LOOH + A\cdot & (7) \end{cases}$$

$$T^{\cdot} + AH \longrightarrow TH + A\cdot \quad (8)$$

The ESR study supports the above conclusion. Galvinoxyl **4** is a stable phenoxyl radical, but it reacts with active hydrogens. For example, galvinoxyl reacts with good hydrogen donors such as tocopherols, ascorbic acid, cysteine, and glutathione.[35] As Fig. 5 shows, the ESR spectrum of galvinoxyl changed instantaneously to that of α-tocopheryloxyl radical when α-tocopherol was added to the benzene solution of galvinoxyl at 25°C. When 5,6-ascorbyl dipalmitate was added to the above solution, the ESR spectrum of α-tocopheryloxyl radical (Fig. 5, B) disappeared rapidly. On the other hand, when 2,5,6-ascorbyl tripalmitate was added instead of 5,6-ascorbyl dipalmitate, no change was observed for the ESR spectrum of α-tocopheryloxyl radical.



4

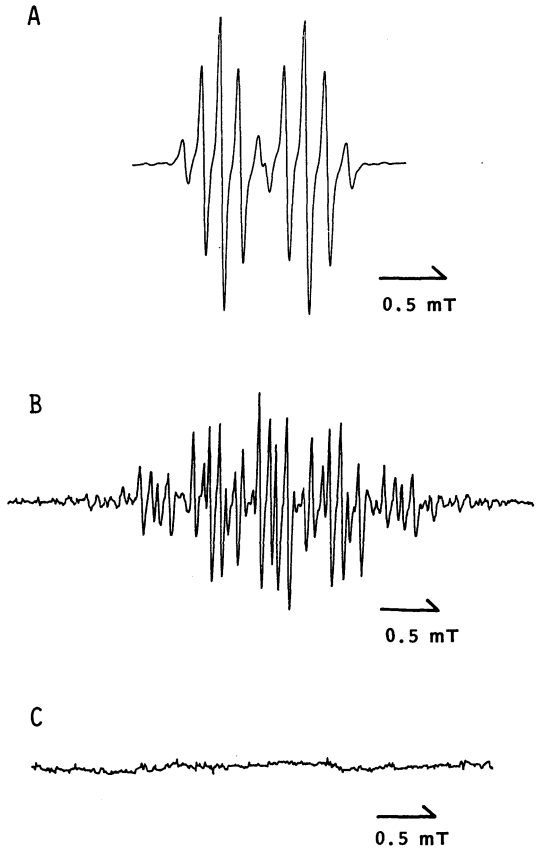


Fig. 5. Interaction of α-tocopheryloxyl radical with 5,6-ascorbyl dipalmitate in benzene at 25 °C under vacuum.
A: ESR spectrum of galvinoxyl radical in benzene. B: ESR spectrum observed when α-tocopherol was added to solution A. C: ESR spectrum observed when 5,6-ascorbyl dipalmitate was added to the solution B.

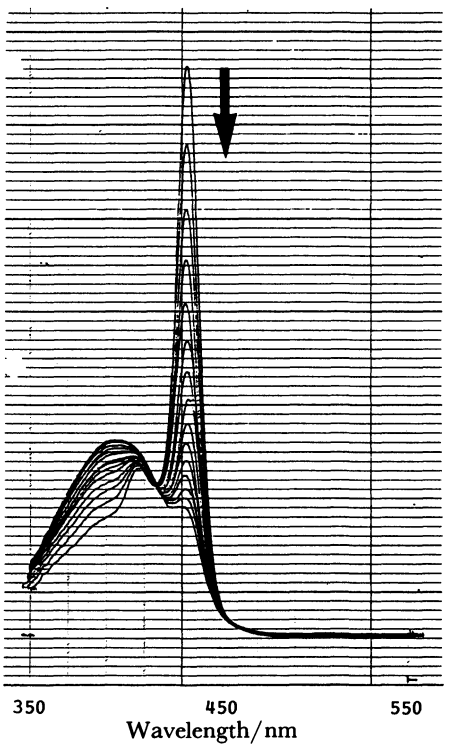

Fig. 6. Interaction of 20.8μM galvinoxyl with 28.9μM 5,6-ascorbyl dipropionate in chloroform at room temperature. The spectra were recorded every 2 min since 1 min after the mixing of galvinoxyl and 5,6-ascorbyl dipropionate.

When both tocopherol and ascorbic acid ester were depleted, the induction period was over and the rapid oxidation took place. Table 2 also shows the rate of oxygen uptake after the induction period. Under these conditions, the kinetic chain length is not very long, but nevertheless it is much larger than 1, suggesting that methyl linoleate is oxidized by a free radical chain mechanism. The oxidizability, $k_p/(2k_t)^{1/2}$, calculated from Eq. 9 is 0.020, where k_p and k_t are the rate constants for chain propagation and termination, respectively.

$$R_p = \frac{k_p}{(2k_t)^{1/2}}[LH]R_i^{1/2} \quad (9)$$

Interactions of Ascorbic Acid Esters with Galvinoxyl. The reactivity of hydrogen donor toward galvinoxyl gives the relative activity as a chain breaking antioxidant. Figure 6 shows the example of the result of interaction between galvinoxyl and ascorbic acid esters. It was found that all the ascorbic acid esters at either 6- or both 5- and 6-positions shown in Table 1 reacted with galvinoxyl at similar rate, whereas those substituted at 2-position did not interact with galvinoxyl.

The above results show that fatty acid esters of ascorbic acid and erythorbic acid at either 6- or both 5-and 6-positions act as chain-breaking antioxidant but that they are no more active as oxygen radical scavenger when ascorbic acid is esterified at 2-position. In other words, ascorbic acid esters function as antioxidant by donating the hydrogen atom at 2-position to oxygen radicals and interrupting free radical chain reaction. It may be worth noting, however, that even the ascorbic acid esters at 2-position may be effective as antioxidant in vivo when they are hydrolyzed by esterase.

Ascorbic acid derivatives have been previously prepared by several groups,[17,21,35] but many of the esters listed in Table 1 are novel compounds. Commercially available esters of ascorbic acid such as 6-ascorbyl palmitate and 6-ascorbyl stearate have solubility problem, but the fatty acid esters at both 5- and 6-positions of ascorbic acid improve the solubilities.

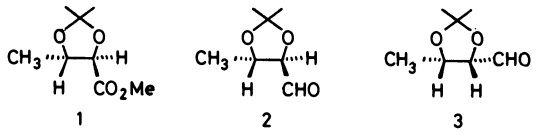
(Received April 21, 1986)

Reduction of ethyl 2-acetoxy-3-oxobutanoate (**4a**) with immobilized baker's yeast in calcium alginate gel gave a 18:19:63 mixture of ethyl (2*R*,3*S*)- and (2*S*,3*S*)-2-acetoxy-3-hydroxybutanoates and ethyl (2*S*,3*S*)-2,3-dihydroxybutanoate each with >95% e.e. in 58% yield. A similar treatment of a 2-benzoyloxy analog of **4a** afforded a 6:94 mixture of ethyl (2*R*,3*S*)- and (2*S*,3*S*)-2-benzoyloxy-3-hydroxybutanoates (>95% e.e.) in 70% yield. Their absolute configurations were determined by comparison with authentic (2*R*,3*S*)- and (2*S*,3*S*)-2,3-dihydroxybutanoic acids. Effects of the immobilization and the pH of culture solution on the product ratio are also discussed.

Chiral (2*S*,3*S*)- and (2*R*,3*S*)-2,3-dihydroxybutanoic acids and their derivatives have been proved to be versatile key intermediates in a variety of natural poroduct syntheses[1–5] and hence convenient synthetic procedure for these compounds is desirable. In the reported method for the preparation of methyl (4*R*,5*S*)-2,2,5-trimethyl-1,3-dioxolane-4-carboxylate (**1**)[1] and its aldehyde analog (**2**),[2] their chiralities are derived from (2*R*,3*R*)-tartaric acid. (4*S*,5*S*)-2,2,5-Trimethyl-1,3-dioxolane-4-carbaldehyde (**3**)[3] has been elaborated from (4*S*,5*R*)-2,2,4-trimethyl-5-(2-phenylethenyl)-1,3-dioxolane which is obtainable from the baker's yeast promoted reaction of cinnamaldehyde with acetaldehyde.[4] Recently, aldehyde **3** has also been prepared efficiently via diastereo- and enantioselective reduction of 2-(1,2-dioxoalkyl)-1,3-dithian with baker's yeast.[5] As shown in these examples, the use of baker's yeast has been growing as one of the powerful synthetic methods for chiral alcohols, because of its high enantioselectivity by a simple procedure.



1 2 3

We describe here a novel, highly enantioselective synthetic method for (2*R*,3*S*)- and (2*S*,3*S*)-2,3-dihydroxybutanoic acid derivatives by the reduction of ethyl 2-acyloxy-3-oxobutanoates (**4a** and **4b**) with baker's yeast which is used by itself (method A) or as an immobilized one in calcium alginate gel[6] (method B) (Table 1). The immobilization of baker's yeast in an appropriate matrix has been realized not only to attain obvious advantages in the isolation and purification procedures,[6] but also to cause a definite change in an optical yield and/or a direction of rotation.[7] These advantages have encouraged us to use immobilized yeast. It enhanced erythro stereoselectivity in the reduction of **4a,b** and optical yields were more than 95% both in methods A and B.

Results and Discussion

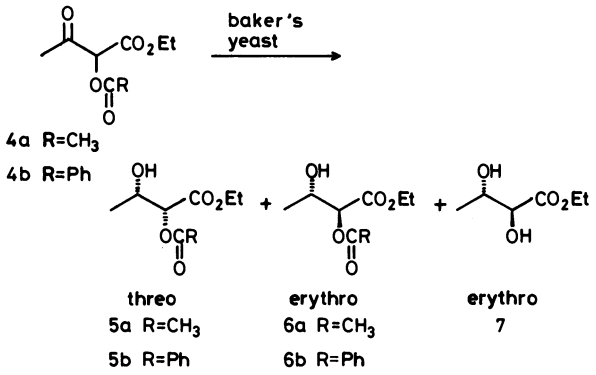
The baker's yeast reduction of ethyl 2-acetoxy-3-oxobutanoate (**4a**)[8] gave ethyl (2*R*,3*S*)- and (2*S*,3*S*)-2-acetoxy-3-hydroxybutanoates (**5a** and **6a**) and ethyl (2*S*,3*S*)-2,3-dihydroxybutanoate (**7**)[9] as a major product (Scheme 1 and Table 1). The relative stereochemistry of **5** (threo) and **6** (erythro) were determined on the basis of ^{1}H NMR analysis which showed $J_{2,3}$=2.3—2.5 Hz for **5** and $J_{2,3}$=4 Hz for **6**.[10] Compound **7** was assigned to erythro after conversion to its acetonide as discussed below. The use of immobilized yeast improved the erythro-selectivity as well as the total yield of the reduction products. Prolonged reaction increased the ratio of **7** up to 63%, and decreased that of **6a**. Threo-(2*R*,3*S*) isomer of **7**, which is expected to be derived

Table 1. Reduction of Ethyl 2-Acyloxy-3-oxobutanoates (**4a, b**) with Fermenting Baker's Yeast

Ester	Method	Reaction Time/h	Product Yield/%[a]	Product Ratio/%[b]		
				5[c]	6[c]	7[c]
4a	A[d]	48	45	28	18	54
4a	B[e]	12	37	19	58	23
4a	B[e]	43	49	18	26	56
4a	B[e]	53	58	18	19	63
4b	A[d]	23	61	14	86	0
4b	B[e]	21	70	6	94	0
4b	B[f]	21	62	51	49	0

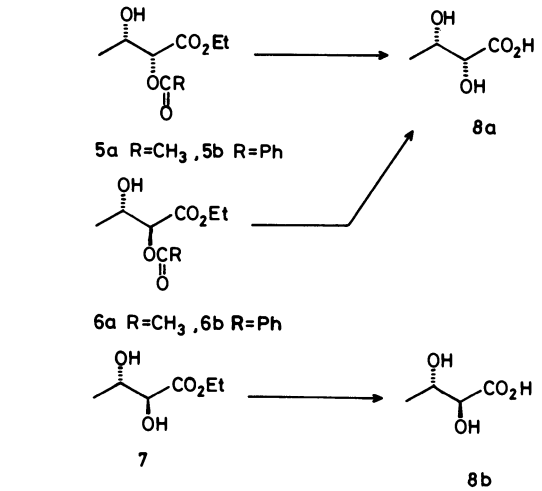
a) Isolated yield. b) Determined after separation by column chromatography. c) Optical purity is more than 95% e.e. d) A: Free baker's yeast was used. e) B: Immobilized baker's yeast was used. f) The pH of the calture solution was controlled at near 7 by addition of aqueous $NaHCO_3$.

from **5a**, was not detected in all cases. These facts suggest that only **6a** was hydrolyzed to **7** under the fermenting conditions. In a similar reduction of ethyl 2-benzoyloxy-3-oxobutanoate (**4b**), erythro-selectivity was further improved up to 94%. It is worth while to note here that the diastereoselection was not observed when the reaction was carried out under neutral conditions.



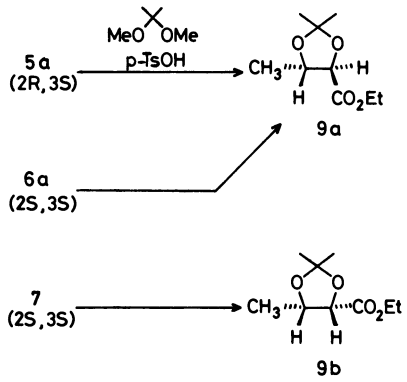
Scheme 1.

The absolute configurations of new chiral centers of these products were confirmed to be (3*S*) by comparison with authentic (2*R*,3*S*)- and (2*S*,3*S*)-2,3-dihydroxybutanoic acids (**8a** and **8b**) (Scheme 2). Thus the hydrolysis of threo esters **5a,b** and erythro ester **7** with 1 mol dm^{-3} methanolic $Ba(OH)_2$ gave the corresponding acids **8a** and **8b**, respectively. Interestingly, a similar treatment of erythro esters **6a,b** also afforded **8a** as a result of epimerization of C-2 position. The relative stereochemistry of **8a** and **8b** is distinguishable by means of ^{13}C NMR spectra (C-4 of **8a**: δ=19.3; that of **8b**[11]: 16.8). The stereochemical assignments are also acceptable in view of the Prelog rule.[12]



Scheme 2.

Optical purities of **5a**, **6a**, and **7** were estimated to be more than 95% e.e. based on the ^1H NMR spectral analysis with chiral shift reagent [Eu(hfc)$_3$] after conversion to acetonides **9a** and **9b** (Scheme 3). Namely, compounds **5a** and **7** could be converted to **9a** (trans) and **9b** (cis) with retention of the stereochemistry in a usual way by using 2,2-dimethoxypropane and *p*-toluensulfonic acid. However, erythro ester **6a** was transformed into **9a** with epimerization at C-2, as observed in the alkaline hydrolysis of **6a** to **8a**. The Eu(hfc)$_3$ induced ^1H NMR signal due to methyl group at C-5 in **9a** and **9b** thus obtained exhibited a doublet only, while that of the racemic ones, prepared from $NaBH_4$ reduction of **4a**, showed a couple of doublets with an equal intensity. The optical purities of **5b** and **6b** were also determined as >95% e.e. by comparing the ^1H NMR signal for C-4 proton in the presence of Eu(hfc)$_3$ with those for the $NaBH_4$ reduction products.



Scheme 3.

Experimental

Evaporative bulb-to-bulb distillation was done using a Büchi Kügelrohrofen. IR spectra were taken on a JASCO Model A-102 spectrometer. ^1H NMR spectra (60 MHz) were measured with a JEOL Model JNM-60 SI spectrometer and ^{13}C NMR spectra (25 MHz) were taken on a JEOL Model FX-100 spectrometer using Me_4Si as an internal standard. Preparative isolation by GLPC was done with Yanagimoto Model G-80 gas chromatograph (Apiezone Grease L on 10% Chromosorb, He 50 ml min^{-1}, oven temperature 140 °C). The preparative TLC was carried out on silica gel (Kieselgel 60 PF_{254}, Merck A. G. Darmstadt). Column chromatography was performed with silica gel (Silica Gel 60, 70—230 mesh, Katayama Chemical Co. Ltd., Tokyo). Elemental analysis was performed by E. A. Compound **4a** was prepared by the procedure of Henecka.[8]

Ethyl 2-Benzoyloxy-3-oxobutanoate (4b). A mixture of ethyl 2-chloro-3-oxobutanoate[8] (16.6 g, 0.101 mol), potassium benzoate·3H_2O (21.5 g, 0.10 mol), tetrabutylammonium bromide (1.51 g, 4.68 mmol) in benzene (150 ml) was heated under reflux for 3 h. The mixture was cooled, washed with aqueous $NaHCO_3$ and then with water, dried over $MgSO_4$, and concentrated. The residue was distilled under vacuum to give **4b** (16.2 g, 65% yield): Bp 115—122 °C (0.2 mmHg) (1 mmHg=133.322 Pa); IR (neat) 1760, 1730 cm^{-1}: ^1H NMR (CCl_4) δ=1.31 (3H, t, *J*=7 Hz), 2.31 (3H, s), 4.23 (2H, q, *J*=7 Hz), 5.53 (1H, s), 7.49 (3H, m), 8.09 (2H, m). Found: C, 62.62; H, 5.78. Calcd for $C_{13}H_{14}O_5$: C, 62.39; H, 5.64.

Preparation of Immobilized Baker's Yeast in Calcium Alginate Gel. The following preparation was done by the modification of the reported procedure.[6] Sodium alginate (14 g) was suspended in water (750 ml) by vigorous stirring at 50 °C for 1 h. To this was added dry baker's yeast

(14 g) (Oriental Yeast Co., Ltd., Tokyo; 98.5% yeast and 1.5% sorbitan fatty acid ester) and the mixture was stirred for additional 2 h untill it became as homogeneous as possible. The resulting suspension was added dropwise from a dropping funnel with a glass tube of 6 mm diameter into a 10% aqueous solution (750 ml) of $CaCl_2 \cdot 2H_2O$ with stirring to form small pieces of spherical calcium alginate gel with ca. 4 mm diameter immediately. Washing with water gave ca. 600 ml of immobilized baker's yeast gel which can be stored in a refrigerator for several weeks.

Typical Procedure for Baker's Yeast Reduction of Ethyl 2-Acyloxy-3-oxobutanoate. Reduction of Ethyl 2-Acetoxy-3-oxobutanoate (4a) with Immobilized Baker's Yeast. A culture solution involving $CaCO_3$ (2.5 g), $NH_4H_2PO_4$ (1 g), KH_2PO_4 (1 g), $MgSO_4$ (0.5 g, glucose (70 g) and boiled water (500 ml) was generally used. To this was added 350 ml of immobilized baker's yeast (8.2 g of baker's yeast) and stirred magnetically for 30 min at 35 °C. When brisk fermentation was confirmed by observing gel pieces to rise up to the surface of the mixture, compound **4a** (9.2 g, 48.9 mmol) was added and the stirring was continued for 20 h at 35 °C. Another batch of glucose (70 g) was added to the solution and the fermentation was continued for additional 23 h. The degree of its consumption was monitored by using glucose-test paper (Diasticks II, Mils-Sankyo Co. Ltd., Tokyo) in the course of the reaction and at the end of the reaction. The gel pieces and the aqueous layer were extracted with ethyl acetate separately. Combined organic layer was dried over $MgSO_4$ filtered and then concentrated. The residual oil was fractionated by column chromatography (140 g of silica gel; hexane-ethyl acetate-ether-acetic acid,30:10:10:0.5) to give **5a** (0.823 g, 9% yield), **6a** (1.19 g, 13% yield), and **7** (2.02 g, 28% yield). **5a**: $[\alpha]_D^{27}$ −30.0° (*c* 1.61, CH_2Cl_2); IR (neat) 3500, 1745 cm^{-1}: ^1H NMR (CCl_4) δ=1.27 (3H, t, *J*=7 Hz), 1.30 (3H, d, *J*=7 Hz), 1.96 (3H, s), 3.34 (1H, br s), 4.00 (1H, d, *J*=2.4 Hz), 4.18 (2H, q, *J*=7 Hz), 5.13 (1H, dq, *J*=2.4 Hz and 7 Hz); ^{13}C NMR ($CDCl_3$) δ=14.1 (q), 19.1 (q), 20.5 (q), 62.0 (t), 67.0 (d), 76.4 (d), 168.7 (s), 170.7 (s). Found: C, 50.59; H, 7.40. Calcd for $C_8H_{14}O_5$: C, 50.50; H, 7.42. **6a**: $[\alpha]_D^{27}$ +31.9° (*c* 1.71, CH_2Cl_2); IR (neat) 3490, 1742 cm^{-1}: ^1H NMR (CCl_4) δ=1.20 (3H, d, *J*=7 Hz), 1.27 (3H, t), 2.12 (3H, s), 3.19 (1H, br s), 3.8—4.30 (1H, m), 4.17 (2H, q, *J*=7 Hz), 4.76 (1H, d, *J*=4 Hz); ^{13}C NMR ($CDCl_3$) δ=14.2 (q), 16.1 (q), 20.9 (q), 62.0 (t), 71.1 (d), 73.0 (d), 170.2 (s), 172.3 (s). Found: C, 50.51; H, 7.69. Calcd for $C_8H_{14}O_5$: C, 50.50; H, 7.42. **7**: $[\alpha]_D^{27}$ +9.3° (*c* 1.69, CH_2Cl_2); IR (neat) 3440, 1730 cm^{-1}: ^1H NMR (CCl_4) δ=1.13 (3H, d, *J*=7 Hz) 1.30 (3H, t, *J*=7 Hz), 3.75—4.15 (2H, m), 4.20 (2H, q, *J*=7 Hz); ^{13}C NMR ($CDCl_3$) δ=14.2 (q), 17.3 (q), 61.6 (t), 69.2 (d), 74.8 (d), 172.7 (s). Found: C, 48.42; H, 8.15. Calcd for $C_6H_{12}O_4$; C, 48.64; H, 8.16.

Reduction of 4a with Free Baker's Yeast. To the culture solution (300 ml) prepared as before mentioned, was added dry baker's yeast (12 g) and stirred at 35 °C for 30 min. Compound **4a** (4.7 g, 25 mmol) was added and stirring was continued for 18 h at 35 °C. After addition of glucose (25 g) again, the mixture was stirred for additional 20 h. Celite was added to the mixture and filtered with suction. The organic layer was extracted with ethyl acetate and treated in a manner similar to that described above to give **5a** (607 mg, 13% yield), **6a** (390 mg, 8% yield), and **7** (898 mg, 25% yield).

Reduction of Ethyl 2-Benzoyloxy-3-oxobutanoate (4b) with Immobilized Baker's Yeast. A mixture of immobilized baker's yeast (50 ml) and **4b** (0.494 g, 1.97 mmol) in the culture solution (70 ml) was stirred at 35 °C for 20 h and worked up in a similar way. Crude products were fractionated by preparative TLC (hexane-ethyl acetate-ether, 1:1:1) to give ethyl (2*S*,3*S*)-2-benzoyloxy-3-hydroxybutanoate (**6b**) (R_f 0.47—0.70, 323 mg, 65.8% yield) and its (2*R*,3*S*)-isomer (**5b**) (R_f 0.70—0.75, 22 mg, 4.2% yield). **6b**: $[\alpha]_D^{21}$ +9.80° (*c* 1.96, CH_2Cl_2); IR (neat) 3500, 1730, 1600 cm^{-1}; ^1H NMR (CCl_4) δ=1.26 (3H, t, *J*=7 Hz), 1.27 (3H, d, *J*=7 Hz), 3.03 (1H, br s), 4.22 (2H, q, *J*=7 Hz), 4.00—4.30 (1H, m), 5.07 (1H, d, *J*=4 Hz, 2-H); ^{13}C NMR ($CDCl_3$) δ=14.0 (q), 19.2 (q), 61.7 (t), 67.3 (d), 76.6 (d), 128.5 (d), 129.2 (s), 129.9 (d), 133.4 (d), 166.0 (s), 168.6 (s).Found: C, 61.78; H, 6.40. Calcd for $C_{13}H_{16}O_5$: C, 61.90; H, 6.39. **5b**: $[\alpha]_D^{21}$ +21.4° (*c* 1.91, CH_2Cl_2); IR (neat) 3500, 1730, 1600 cm^{-1}; ^1H NMR (CCl_4) δ=1.16 (3H, t, *J*=7 Hz), 1.43 (3H, d, *J*=7 Hz), 2.96 (1H, s), 4.09 (2H, q, *J*=7 Hz), 4.00—4.35 (1H, m), 5.36 (1H, dq, *J*=2.5 Hz and 7 Hz), 7.40 (3H, m), 7.92 (2H, m); ^{13}C NMR ($CDCl_3$) δ=14.0 (q), 16.1 (q), 62.1 (t), 71.7 (d), 73.1 (d), 128.4 (d), 129.6 (d), 129.9 (s), 133.1 (d), 165.6 (s), 172.5 (s). Found: C, 61.96; H, 6.49. Calcd for $C_{13}H_{16}O_5$: C, 61.90; H, 6.39.

(2*R*,3*S*)-2,3-Dihydroxybutanoic Acid (8a). A mixture of ethyl (2*R*,3*S*)-2-acetoxy-3-hydroxybutanoate (**5a**) (300 mg, 1.6 mmol) in 5 ml of 1 mol dm^{-3} methanolic $Ba(OH)_2$ was stirred at room temperature for 10 h. After being acidified with 10% HCl and washed well with ether, the solvent was removed under reduced pressure. From the residue, organic material was extracted with several portions of methanol, bubled with carbon dioxide and filtered. Concentration of the filtrate gave an oil together with remaining inorganic materials. To this was added methanol and decanted. The procedure was repeated. Finaly, evaporation of the solvent gave spectroscopically pure **8a** (161 mg, 75% yield): $[\alpha]_D^{16}$ +8.8°[13] (*c* 1.0, H_2O) (lit,[11] $[\alpha]_D^{16}$ −13.51° (*c* 6.0, H_2O) for (2*S*,3*R*)-enantiomer); IR (neat) 3700—2300, 1735, 1310, 1238, 1146, 1083, 1070 cm^{-1}: ^1H NMR (CD_3OD) δ=1.22 (1H, d, *J*=6 Hz), 3.73—4.40 (2H, m),5.13 (3H, br s); ^{13}C NMR (CD_3OD) δ=19.6 (q), 69.7 (d), 75.7 (d), 176.2 (s).

A similar treatment of **5b**, **6a**, and **6b** also gave **8a**. The specific rotation[13] and yield in each experiment are as follows: $[\alpha]_D^{21}$ +13.1° (*c* 1.90, H_2O), 81% yield; $[\alpha]_D^{28}$ +9.1° (*c* 10.6, H_2O), 84% yield; $[\alpha]_D^{24}$ +8.4° (*c* 1.50, H_2O), 76% yield.

(2*S*,3*S*)-2,3-Dihydroxybutanoic Acid (8b).[11] Ester **7** was treated in a way similar to that described above to give **8b** (60% yield) as a viscous oil: $[\alpha]_D^{16}$ +8.8° (*c* 1.0, H_2O) [lit,[11] $[\alpha]_D^{20}$ +9.3° (*c* 0.5, H_2O)]; IR (neat) 3700—2300, 1735, 1260, 1220, 1190, 1082, 1060 cm^{-1}: ^1H NMR (CD_3OD) δ=1.19 (3H, d, *J*=6 Hz), 3.73—4.40 (2H, m), 5.13 (3H, br s); ^{13}C NMR (CD_3OD) δ=17.7 (q), 69.9 (d), 76.0 (d), 175.9 (s).

Ethyl (4*R*,5*S*)-2,2,5-Trimethyl-1,3-dioxolane-4-carboxylate (9a). A mixture of ester **5a** (130 mg, 0.68 mmol), 2,2-dimethoxypropane (140 mg, 1.34 mmol), and *p*-toluenesulfonic acid (1 mg, 0.006 mmol) in dichloromethane (0.75 ml) was heated under reflux for 45 h. The mixture was washed with aqueous $NaHCO_3$, dried over $MgSO_4$, and concentrated under reduced pressure. The residual oil was distilled to give **9a** (82 mg, 64% yield): Bp 60—65 °C (3 mmHg) (1 mmHg=133.322 Pa); $[\alpha]_D^{23}$ +15.2° (*c* 1.2, $CHCl_3$); IR (neat) 1760, 1730 cm^{-1}; ^1H NMR (CCl_4) δ=1.10—1.55 (12H, m), 3.65-4.20 (2H, m), 4.13 (2H, q); ^{13}C NMR ($CDCl_3$) δ=14.2 (q), 18.5 (q), 25.7 (q), 27.2 (q), 61.2 (t), 75.2 (d), 80.5 (d), 110.5 (s), 170.5 (s).

A similar treatment of compound **6a** also gave **9a** (73% yield): Bp 60—65 °C (3 mmHg).

Ethyl (4*S*,5*S*)-2,2,5-Trimethyl-1,3-dioxolane-4-carboxylate

(9b). Yield 72%; bp 60—65 °C (3 mmHg) (1 mmHg= 133.322Pa); $[\alpha]_D^{16}$ +24.7° (*c* 2.4, $CHCl_3$); IR (neat) 1760, 1730 cm^{-1}; ^1H NMR (CCl_4) δ=1.05—1.50 (12H, m), 4.07 (2H, q, *J*=7 Hz), 3.9—4.4 (2H, m); ^{13}C NMR ($CDCl_3$) δ=14.7 (q), 15.6 (q), 25.6 (q), 27.0 (q), 60.9 (t), 73.6 (d), 77.8 (d), 110.3 (s), 170.2 (s). Found: C, 57.74, H, 8.63. Calcd for $C_9H_{16}O_4$: C, 57.43; H, 8.57.

Ethyl (4*RS*,5*SR*)- and (4*RS*,5*RS*)-2,2,5-Trimethyl-1,3-dioxolane-4-carboxylates [(±)-9a and (±)-9b]. To a solution of ester **4a** (1.0 g, 5.26 mmol) in ethanol (5 ml), was added $NaBH_4$ (70 mg, 1.85 mmol). After being stirred at 4 °C for 10 min, the mixture was acidified with 10% HCl and ethanol was removed under reduced pressure. The residual oil[14] (762 mg) was added to a mixture of 2,2-dimethoxypropane (1.25 g, 12 mmol) and *p*-toluenesulfonic acid (5 mg, 0.03 mmol) in dichloromethane (3 ml). It was stirred under reflux for 12 h, cooled, washed with aqueous $NaHCO_3$, dried over $MgSO_4$, and then concentrated. The residue was purified by preparative TLC (hexane–ethyl acetate, 3:1; R_f 0.40—0.85) to give 228 mg (23% yield) of a mixture of (±)-**9a** and (±)-**9b**, which were separated by preparative GLPC [(±)-**9a**: retention time 7.3 min; (±)-**9b**: 9.3 min)].

Ethyl (2*RS*,3*SR*)- and (2*RS*,3*RS*)-2-Benzoyloxy-3-hydroxybutanoates [(±)-5b and (±)-6b]. Ester **4b** (504 mg, 3.02 mmol) was allowed to react with $NaBH_4$ (24.6 mg, 0.677 mmol) in ethanol (3 ml) at 0 °C for 5 min and worked up in a similar way. Crude products were fractionated by preparative TLC (hexane–ethyl acetate–ether, 1:1:1) to give (±)-**5b** (R_f 0.69—0.79, 165 mg, 33% yield) and (±)-**6b** (R_f 0.57—0.69, 49 mg, 10% yield).[15]

The present work was partly supported by a Grant-in-Aid for Special Project Research (No. 60119001) from Ministry of Education, Science and Culture.

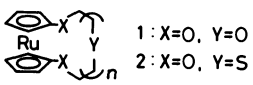
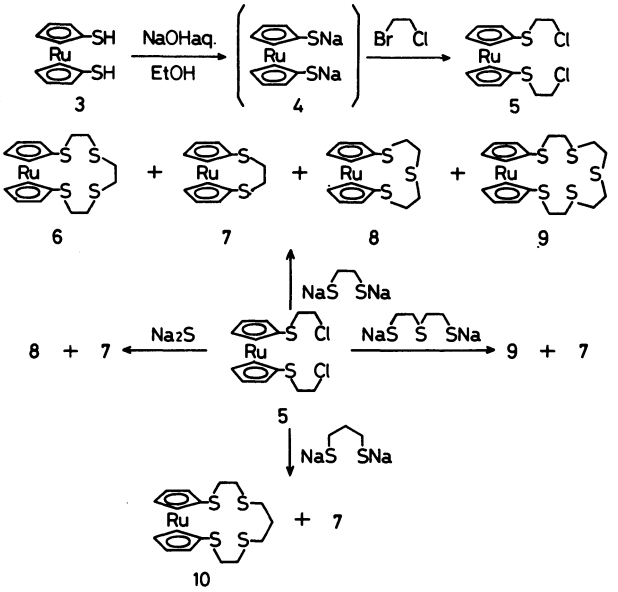
(Received April 23, 1986)

Polythia[n](1,1′)ruthenocenophanes were prepared by reaction of 1,1′-bis(2-chloroethylthio)ruthenocene with disodium alkanedithiolates in tetrahydrofuran/ethanol. The ruthenocenophanes efficiently formed 1 : 1 complexes with platinum and palladium dichlorides. X-Ray crystallography of complexes of the 1,4,7,10-tetrathia[n](1,1′)ruthenocenophane with $PtCl_2$ and $PdCl_2$ revealed that the Pt (or Pd) atom bonded selectively to the two sulfur atoms at the 4,7-positions among the four sulfur atoms in the bridge of the ligand with a slightly distorted cis square-planar configuration. The conformation of the organic moiety in the 1 : 1 complex is greatly changed from that of the metal-free ligand. Also, the 1 : 1 palladium complex is isomorphous with the 1 : 1 platinum complex.

Although a number of macrocyclic polyethers and their alkali and alkaline earth-metal complexes have already been reported,[1] few complexes of polythia-crown ethers with a platinum group metal are known.[2] We recently suggested[3,4] that the ruthenium atom of the complexes of polyoxa- and dioxapolythia[n](1,1′)-ruthenocenophanes (**1** and **2**) with soft cations such as mercury(II) and silver(I) ions interacted with the incorporated metal ions. Therefore, a similar interaction can be expected between the ruthenium atoms of ruthenocenocrown ethers and palladium(II) or platinum(II) ions which are soft cations. In a previous paper,[5] we reported an X-ray analysis of the Pt-complex with 4,7-dithia-1,10-dioxa[10]ruthenocenophane. In this complex, the platinum atom which has a slightly distorted square-planar configuration was selectively coordinated with two sulfur atoms at the 4,7-positions in the bridge. Therefore, the distance between the ruthenium and palladium atoms was too long to allow interaction. Furthermore, we have reported[6] on the syntheses of the polythia[n](1,1′)ruthenocenophanes (**6**, **7**, **8**, and **9**) by reactions of 1,1′-bis(2-chloroethylthio)ruthenocene with disodium 1,2-ethanedithiolate. Therefore, we have been interested in the stereochemistry of the complexes formed from polythia-[n](1,1′)ruthenocenophanes and *trans*-$[PdCl_2(CH_3CN)_2]$ (**11a**) or *cis*-$[PtCl_2(CH_3CN)_2]$ (**11b**). Here we report on the syntheses of complexes of polythia[n](1,1′)ruthenocenophanes with platinum group metals and their structural studies by spectral and X-ray crystallographic methods.



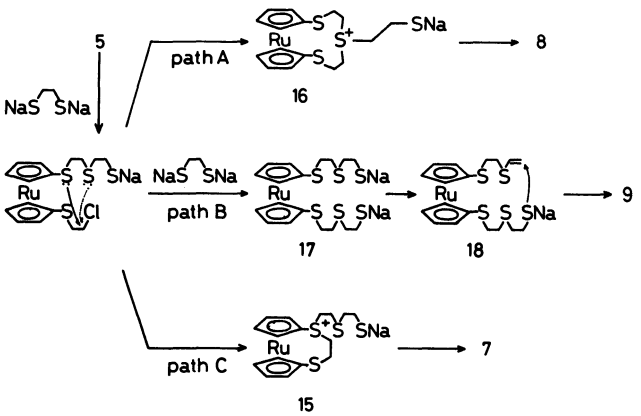
Syntheses of Polythia[n](1,1′)ruthenocenophanes. In order to obtain the starting material of polythia-[n](1,1′)ruthenocenophanes (**6**—**10**), ruthenocene-1,1′-dithiol (**3**),[6] which was prepared by the reduction of trithia[3](1,1′)ruthenocene, was reacted with 1-bromo-2-chloroethane in the presence of sodium hydroxide to give 1,1′-bis(2-chloroethylthio)ruthenocene (**5**) in 67% yield. A new series of polythia[n](1,1′)ruthenocenophanes were synthesized by the reaction of an equimolar amount of **5** with the disodium salt of 1,2-ethanedithiol and/or its homologs in several solvents. The best results were achieved when highly diluted conditions were realized by the combination of a slow addition and a high reaction temperature and when tetrahydrofuran (THF)–aqueous ethanol was used as the solvent. For example, the reaction of **5** with disodium 1,2-ethanedithiolate gave 1,4,7,10-tetrathia[10](1,1′)-ruthenocenophane (**6**) in 9.8% yield together with trace amounts of the unexpected 1,4-dithia[4](1,1′)ruthenocenophane (**7**), 1,4,7-trithia[7](1,1′)ruthenocenophane (**8**), and 1,4,7,10,13-pentathia[13](1,1′)ruthenocenophane (**9**).



Similarly, **5** reacted with disodium 1,3-propanedithiolate, the disodium salt of bis(2-mercaptoethyl) sulfide, and sodium sulfide to give 1,4,8,11-tetrathia[11](1,1′)ruthenocenophane (**10**) (15%), **9** (23%), and **8** (15%) as the main products, respectively. Furthermore, in addition to the normal products, an unexpected product **7**

Table 1. ^{1}H NMR Spectral Data of **6**, **9**, and Their Palladium(II) and Platinum(II) Complexes (DMSO-d_6)

Compd	α-Protons	β-Protons	Methylene protons
6	4.64 (t, J=1.8 Hz, 4H)	4.81 (t, J=1.8 Hz, 4H)	3.10—2.79 (m, 12H)
12a	4.95 (s, 2H), 4.88 (s, 2H)	4.71 (t, J=1.8 Hz, 4H)	3.48—2.91 (m, 12H)
12b	5.02—4.85 (m, 4H)	4.71 (t, J=1.8 Hz, 4H)	3.44—2.91 (m, 12H)
9	4.65 (t, J=1.8 Hz, 4H)	4.79 (t, J=1.8 Hz, 4H)	3.03—2.74 (m, 16H)
13a	5.20—4.78 (m, 4H)	4.68 (broad-s, 4H),	3.48—2.84 (m, 16H)
13b	5.27—4.46 (m, 4H)	4.65 (broad-s, 4H)	3.75—2.59 (m, 16H)



Scheme 1.

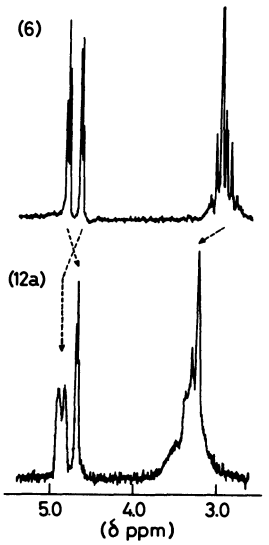


Fig. 1. ^{1}H NMR spectra of **6** and **12a**.

was also isolated in all cases. The structures of these products were established by their ^{1}H NMR and mass spectroscopic data and elemental analyses. A possible mechanism for the unexpected formation of **7**, **8**, and **9** in the reaction of **5** with disodium 1,2-ethanedithioate is proposed in Scheme 1. The formation of **7** can be rationalized in terms of the formation of the intermediate sulfonium ion **15** (path C) followed by dealkylation. The formation mechanisms of **8** and **9** can be interpreted similarly as follows (paths A and B): Dealkylation of **16** gives **8**, and elimination of SH^- from **17** gives the vinyl sulfide intermediate (**18**) followed by cyclization to give **9**. Also, a similar propagation reaction mechanism has been observed in the reaction of bis(2-chloroethyl) ether with sodium sulfide,[7] and the reaction of disodium 1,2-ethanedithiolate with 1,1′-bis(2-chloroethoxy)ferrocene[8] and 1,1′-bis(2-chloroethylthio)ferrocene.[9]

Palladium(II) and Platinum(II) Chloride Complexes of 6, 9, and 10. A solution of the ruthenocenothiacrown ether (**6**, **9**, and **10**) in acetonitrile was reacted with an equimolar amount of $MCl_2(CH_3CN)_2$ (**11a**: M=Pd or **11b**: M=Pt) in acetonitrile to give 1:1 complexes in 47—89% yields. The melting and decomposition points of these palladium and platinum complexes were higher than those of the corresponding metal-free ligands. As shown in Table 1 and Fig. 1, all of the α-protons of the ruthenocene nucleus and the methylene protons of complexes **12** and **13** were shifted downfield, and the signal shape of the α-protons became extremely complex. For example, the α- and the methylene protons of **12a**, compared with metal-free ligand **6**, shifted downfield by ca. +0.31—+0.24 and +0.38—+0.12 ppm, respectively, and the signal shape of the α-protons varied to two singlets from a triplet (J= 1.8 Hz). However, the β-protons of **12a** shifted upfield only a little (by −0.10 ppm). From the ^{1}H NMR spectral data, it is suggested that the palladium (or platinum) ion was coordinated with sulfur atoms outside of the polythia macrocyclic plane, so the structures of complexes **12** and **13** may be unsymmetrical. The far-IR spectra of **6** and **9** and their palladium and platinum complexes (**12** and **13**) were recorded using a CsI disk. These results are listed in Table 2. In complexes **12** and **13**, the Cp–Ru–Cp ring tilting and Cp–Ru stretching bands were slightly shifted to a lower frequency by ca. 10—20 cm^{-1}, respectively. In addition, new absorptions appeared at 2960 cm^{-1}, and 325 and 310 cm^{-1}, which were assigned to the C–H stretching vibrations of the Cp rings and *cis*-MCl_2 (M=Pd or Pt) stretching vibrations, respectively. The absorption bands at 325 and 310 cm^{-1} are in good agreement with the range reported for *cis*-MCl_2 (M=Pd or Pt) vibrations. These results suggest that the reaction of the ruthenocenocrown ethers with *trans*-$[PdCl_2(CH_3CN)_2]$ (**11a**) and *cis*-$[PtCl_2(CH_3CN)_2]$ (**11b**) gives only a cis-isomer.

a) W. C. Hamilton, *Acta Crystallogr.*, **12**, 609 (1959).

The metal free ligand **6** and its Pt complex **12b** were further characterized by X-ray crystallographic studies. The final atomic parameters are listed in Table 3, and bond lengths as well as bond and torsion angles are given in Tables 4 and 5 for **6** and **12b**, respectively. Perspective views of **6** and **12b** are shown in Fig 2.

For **6** the C–C bond lengths and C–C–C bond angles of the two Cp rings are in the range of 1.413(7)—

1.435(6) Å and 107.4(4)—108.7(4)° with average values of 1.429 Å and 108.0°, respectively. These average bond lengths and angles are in good agreement with those of ruthenocene.[11] In macrocyclic units, each average bond length of S-Csp^2, S-Csp^3, Csp^3-Csp^3 was 1.753, 1.816, and 1.508 Å; this is in agreement with each expected value. In the Cp moiety for **12b**, the bond lengths are in the range of 1.36(4)—1.48(3) Å with an average of 1.43 Å. Although the average value of the bond lengths is in good agreement with that of the metal-free ligand **6**, the bond lengths of C(3)-C(4), C(18)-C(19), and C(19)-C(20) are slightly shorter and C(2)-C(3), C(5)-C(1), and C(17)-C(18) are slightly longer than those found in the metal-free ligand **6**. The bond angles in the Cp rings are ranged over 104(2)—110(2)° with an average value of 108°. The difference (6°) of the bond angle is much larger than that (1.3°) in the free ligand **6**. The above results suggest a deformation of the Cp ring in the complex due to complexation. The Pt atom, which is complexed by the two S atoms of the tetradentate macrocyclic moiety, has a slightly distorted cis square-planar environment; the two S atoms at the 9- and 12-positions of the ligand occupy the other two cis positions. These results are consistent with those obtained from the IR spectral data. The Pt-S bond lengths are 2.249(5) and 2.239(7) Å. The bond lengths are slightly shorter than the sum of the covalent radii (2.32 Å)[12] and suggest that there is little π-bonding in the Pt-S bond. The Pt-Cl bond lengths have an average value of 2.315 Å, almost equal to the sum of the covalent radii, 2.28 Å. The interestingly selective coordination of the Pt atom to the S(9) and S(12) atoms is attributable to a steric hindrance of the two Cp rings to the S(6) and S(15) atoms. Moreover, the conformations of the organic ligand moiety differ greatly between ligand **6** and complex **12b**. The two Cp rings for both compounds take an eclipsed conformation and the dihedral angles between them are 2.5(2) and 2.4(10)° for **6** and **12b**, respectively. However, as shown in Fig. 1, the torsion angle (68°) between the C(1)-S(6) and S(15)-C(16) bonds around the z-axis of the ruthenocene nucleus in the complex **12b** is much larger than the corresponding one (5.3°) in the free ligand **6**. These results are quite similar to those obtained in 1,10-dioxa-4,7-dithia[10](1,1')ruthenocenophane.[5] Furthermore, X-ray crystal data, which are presented in the experi-

mental section, showed the two compounds (**12a** and **12b**) to be isostructural.

Experimental

The melting and decomposition points have not been corrected. The ^{1}H NMR spectra were obtained on a JEOL FX-90Q spectrometer with TMS as an internal standard. The mass spectra were measured on a Hitachi M80 mass spectrometer. The electronic spectra were recorded on a Hitachi 330 spectrometer. The IR spectra were taken by using a JASCO DS-701G Diffraction Grating Infrared Spectrometer in CsI pellets.

Materials. Ruthenocene,[13] 1-bromo-2-chloroethane,[14] dichlorobis(acetonitrile) complexes of palladium(II) and platinum(II)[10] were prepared according to previously reported methods. The synthesis of ruthenocene-1,1′-dithiol (**3**) was carried out as described previously.[4] All other solvents and reagents used were reagent grade.

1,1′-Bis(2-chloroethylthio)ruthenocene (5). 1-Bromo-2-chloroethane (25 g, 176 mmol) was added to a mixture of **3** (2.3 g, 7.0 mmol) and sodium hydroxide (0.70 g, 18 mmol) in ethanol (170 cm^3) containing water (5 cm^3). After the mixture was stirred for 4 h at room temperature, the reaction mixture was concentrated in vacuo and the residual solid was chromatographed on activated alumina (dichloromethane as eluent). The yellow fraction was collected and concentrated in vacuo. Recrystallization of the residual solid from benzene gave **5** as pale-yellow powder in 67% yield. Mp 92.5—93 °C. Found: C, 40.30; H, 3.80%. Calcd for $C_{14}H_{16}Cl_2S_2Ru$: C, 40.00; H, 3.84%. ^{1}H NMR ($CDCl_3$) δ=4.75 (t, J=1.8 Hz, 4H), 4.65 (t, J=1.8 Hz, 4H), 3.66 (t, J=6.1 Hz, 4H), 2.90 (t, J=6.1 Hz, 4H). MS (60 eV) m/z 421 (M^+).

1,4,7-Trithia[7](1,1′)ruthenocenophane (8). A mixture of **5** (0.31 g, 0.74 mmol) and sodium sulfide (0.22 g, 0.92 mmol) in THF–ethanol (1:4) (158 cm^3) was refluxed under nitrogen for 10 h. The reaction mixture was cooled, evaporated in vacuo and the residual solid was dissolved in dichloromethane (100 cm^3). After the insoluble material was filtered off, the filtrate was evaporated and then the residual solid was chromatographed on silica-gel TLC (benzene as eluent). The fourth (main) fraction was collected and evaporated. Recrystallization of the residual solid from hexane gave **8** as pale-yellow needles in 15% yield. Mp 154.0—154.6 °C. Found: C, 44.10; H, 4.20%. Calcd for $C_{14}H_{16}S_3Ru$: C, 44.07; H, 4.24%. ^{1}H NMR ($CDCl_3$) δ=4.83 (t, J=1.8 Hz, 4H), 4.61 (t, J=1.8 Hz, 4H), 3.22—2.88 (m, 8H). MS (60 eV) m/z 382 (M^+). From the third fraction, **7** was obtained in 9.8% yield. Mp 225.6—226.5 °C. Found: C, 44.56; H, 3.76%. Calcd for $C_{12}H_{12}S_2Ru$: C, 44.84; H, 3.77%. ^{1}H NMR ($CDCl_3$) δ= 5.06 (t, J=1.8 Hz, 4H), 4.57 (t, J=1.8 Hz, 4H), 3.14 (s, 4H). MS (60 eV) m/z 322 (M^+).

1,4,7,10-Tetrathia[10](1,1′)ruthenocenophane (6). **5** (0.58 g, 1.4 mmol) in THF (100 cm^3) and a mixture of sodium hydroxide (0.50 g, 13.0 mmol) and 1,2-ethanedithiol (0.50 g, 5.3 mmol) in 98% ethanol (100 cm^3) were added dropwise to the refluxing mixture of THF (200 cm^3) and ethanol (200 cm^3) in the same rate for a period of 3 h, and further refluxed for 14 h. The reaction mixture was cooled and evaporated, and the residue was extracted with three 50 cm^3 portions of chloroform. After the extracts were combined, the resulting solution was washed with water, dried and evaporated in vacuo. The residual oil was chromatographed on activated alumina (benzene as eluent). The third (main) fraction was collected and evaporated. Recrystallization of the residual solid from benzene gave **6** as pale-yellow needles in 9.8% yield. Similarly, trace amounts of **7**, **8**, and **9** were obtained from the first, second and fourth fractions, respectively. **6**: Mp 138.6—139.0 °C. Found: C, 44.48; H, 4.60%. Calcd for $C_{16}H_{20}S_4Ru$: C, 43.50; H, 4.57%. ^{1}H NMR ($CDCl_3$) δ=4.62 (t, J=1.8 Hz, 4H), 4.77 (t, J=1.8 Hz, 4H), 3.10 (s, 4H), 3.21—2.75 (m, 8H). MS (60 eV) m/z 441 (M^+). **9**: Mp 93.5—94.0 °C. Found: C, 42.82; H, 4.74%. Calcd for $C_{18}H_{24}S_5Ru$: C, 43.08; H, 4.83%. ^{1}H NMR ($CDCl_3$) δ=4.75 (t, J=1.8 Hz, 4H), 4.61 (t, J=1.8 Hz, 4H), 3.15—2.71 (m, 16H). MS (60 eV) m/z 501 (M^+). The structures of **7** and **8** were confirmed by comparison with the melting points, R_f values of TLC and the spectral data of the authentic samples.

1,4,7,10,13-Pentathia[13](1,1′)ruthenocenophane (9). Bis-(2-mercaptoethyl) sulfide (1.5 cm^3, 11 mmol) was reacted with **5** (0.80 g, 1.9 mmol) in the presence of sodium hydroxide (0.80 g, 20 mmol) under the same conditions described above. The reaction mixture was worked up according to the previously described procedure and chromatographed on activated alumina (benzene as eluent). The second (main) fraction was collected and evaporated. Recrystallization of the residual solid from hexane gave **9** as white needles in 27% yield. Also, **7** was obtained from the first fraction. The structures of these compounds were confirmed by comparison with the melting points, R_f values of TLC and the spectral data of the authentic samples.

1,4,8,11-Tetrathia[11](1,1′)ruthenocenophane (10). A mixture of 1,3-propanedithiol (0.55 g, 5.1 mmol) and **5** (0.50 g, 1.2 mmol) in THF (30 cm^3) was added to absolute ethanol (170 cm^3) containing sodium hydroxide (0.51 g, 13 mmol) at a refluxing temperature. After refluxing for 2 h, the reaction mixture was cooled, evaporated in vacuo and extracted with three 50 cm^3 portions of chloroform. The extracts were combined, washed with 10% of aq sodium hydroxide solution and concentrated, and then the residual solid was chromatographed on activated alumina (benzene as eluent). From the second (main) fraction, **10** was obtained in 15% yield. Mp 121.6—122.2 °C. Found: C, 45.03; H, 4.95%. Calcd for $C_{17}H_{22}S_4Ru$: C, 44.80; H, 4.88%. ^{1}H NMR ($CDCl_3$) δ=4.79 (t, J=1.8 Hz, 4H), 4.63 (t, J=1.8 Hz, 4H), 3.20—2.62 (m, 12H), and 2.08 (q, J=7.6 Hz, 2H). MS (60 eV) m/z 455 (M^+). Also, a trace amount of **7** was isolated from the first fraction.

Palladium(II) and Platinum(II) Complexes (12, 13, and 14) of Polythia[n](1,1′)ruthenocenophanes: General Procedure. Dichloro(1,4,7,10-tetrathia[10](1,1′)ruthenocenophane)platinum(II) (12b). **11** (35.6 mg, 0.102 mmol) in acetonitrile (5 cm^3) was slowly added to gently refluxing acetonitrile solution (10 cm^3) containing **6** (44.9 mg, 0.102 mmol). The resulting crystals were collected by filtration and washed with small amounts of acetonitrile to give **12b** in 51% yield as pale-yellow needles. Mp 257 °C (decomp). Found: C, 27.16; H, 2.85%. Calcd for $C_{16}H_{20}Cl_2S_4RuPt$: C, 27.19; H, 2.70%.

Dichloro(1,4,7,10-tetrathia[10](1,1′)ruthenocenophane)palladium(II) (12a). Yield (89%). Mp 248 °C (decomp). Found: C, 31.05; H, 3.26%. Calcd for $C_{16}H_{20}Cl_2S_4RuPd$: C, 30.98; H, 2.99%.

Dichloro(1,4,7,10,13-pentathia[13](1,1′)ruthenocenophane)palladium(II) (13a). Yield (79%). Mp 211—212 °C. Found: C, 31.39; H, 3.62%. Calcd for $C_{18}H_{24}Cl_2S_5RuPd$: C, 31.83; H, 3.56%.

Dichloro(1,4,7,10,13-pentathia[13](1,1′)ruthenocenophane)-

platinum(II) (13b). Yield (49%). Mp 218—218.5 °C. Found: C, 28.16; H, 3.15%. Calcd for $C_{18}H_{24}Cl_2S_5RuPt$: C, 28.06; H, 2.95%.

Dichloro(1,4,8,11-tetrathia[11](1,1')ruthenocenophane)palladium(II) (14a). Yield (73%). Mp 207—209 °C. Found: C, 32.26; H, 3.50%. Calcd for $C_{17}H_{22}Cl_2S_4RuPd$: C, 32.29; H, 3.47%.

Dichloro(1,4,8,11-tetrathia[11](1,1')ruthenocenophane)platinum(II) (14b). Yield (47%). Mp 212—213 °C. Found: C, 28.29; H, 3.07%. Calcd for $C_{17}H_{22}Cl_2S_4RuPt$: C, 28.15; H, 2.83%.

X-Ray Crystallography. Crystals of dimensions 0.4×0.15×0.1 mm for the metal-free ligand (**6**), 0.3×0.2×0.1 mm for the Pd-complex **12a**, and 0.4×0.1×0.05 mm for the Pt-complex **12b** were used for the X-ray crystallography. Crystal data are as follows: **6**, $C_{16}H_{20}S_4Ru$, MW=441.7. Triclinic, $P\bar{1}$, a=13.828 (2), b=11.890 (2), c=5.587 (2) Å, α=95.53 (2), β=105.39 (2), γ=102.22 (1)°, U=853.1 Å^3, Z=2, Dx=1.72 g·cm^{-3}, μ(Mo $K\alpha$)=1.4 mm^{-1}. **12a**, $C_{16}H_{20}Cl_2S_4RuPd$, MW=619.0, monoclinic, $P2_1/n$, a=9.925(4), b=28.148 (8), c=7.489 (3) Å, β=102.20 (3)°, U=2044.5 Å^3, Z=4, Dx=2.01 g·cm^{-3}, μ(Mo $K\alpha$)=2.3 mm^{-1}. **12b**, $C_{16}H_{20}Cl_2S_4RuPt$, MW=707.7, monoclinic, $P2_1/n$, a=9.912 (6), b=28.142 (9), c=7.521 (3) Å, β=102.08 (4)°, U=2053.3 Å^3, Z=4, Dx=2.29 g·cm^{-3}, μ(Mo $K\alpha$)=8.3 mm^{-1}.

An X-ray structural analysis was carried out on compounds **6** and **12b**, because **12a** was isostructural with **12b** as can be seen from each crystal data. Intensity data for 2θ=50° were recorded on a Rigaku AFC-5R with graphite-monochromatized Mo $K\alpha$ radiation. A Total of 3017 (**6**) and 3606 (**12b**) independent reflections were corrected for Lorentz and polarization factors but not for absorption. Both structures **6** and **12b** were solved by a combination of the heavy-atom technique and direct methods using MULTAN,[15] and refined by block diagonal least-squares methods. The positions of the hydrogen atoms were estimated using standard geometry. The final refinements with anisotropic temperature factors for the non-hydrogen atoms and isotropic temperature factors for the hydrogen atoms were lowered R values 0.031 (R_w=0.034, w=1.0, 2646 observed reflections with $F_o \geq 2\sigma(F_o)$) and 0.070 (R_w=0.055, $w=1/\sigma(F_o)$, 2528 observed reflections with $F_o \geq 2\sigma(F_o)$) for **6** and **12b**, respectively. Anomalous dispersion corrections were applied to the scattering factors of Pt, Ru, Cl, and S.[16]

Parameters for hydrogen atoms and the thermal parameters for non-hydrogen atoms (observed and calculated) as well as structure factors are kept at the Chemical Society of Japan (Document No. 8642).

The High Pressure Diels-Alder Reactions of 5-Methoxy-2-methyl-4-(*p*-nitrophenyl)oxazole with Ethylenic Dienophiles

Toshikazu IBATA,* Hiroyuki NAKAWA, Yasushi ISOGAMI, and Kiyoshi MATSUMOTO†
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
†College of Liberal Arts and Sciences, Kyoto University, Kyoto 606
(Received May 6, 1986)

The high pressure Diels-Alder reactions of 5-methoxy-2-methyl-4-(*p*-nitrophenyl)oxazole with ethylenic dienophiles such as *N*-methylmaleimide, *N*-phenylmaleimide, dimethyl maleate and dimethyl fumarate gave the corresponding adducts in good to excellent yields. The effects of pressure, temperature, solvents on the yields were investigated. The high pressure also increased the formation of 3-hydroxypyridine derivatives via the elimination of methanol from the adducts. The stereospecificity of the reaction was confirmed for the reactions with maleate and fumarate.

The Diels–Alder reactions of oxazoles have been studied extensively in connection with the synthesis of vitamin B_6.[1] The reasonable Diels–Alder reactivity of oxazoles opened their widespread use in organic synthesis.[2] The authors have reported the reactions with reactive dienophiles such as alkyl-substituted maleimides, diethyl azodicarboxylate, 4-phenyl-3*H*-1,2,4-triazole-3,5(4*H*)-dione, and dimethyl acetylenedicarboxylate.[3] However, some dienophiles were found to give adducts in very low yields or sometimes to give no adduct in the reactions under atmospheric pressure. As the acceleration of the cycloaddition reaction under high pressure is well documented,[4] the high pressure Diels–Alder reactions of 5-methoxy-2-methyl-4-(*p*-nitrophenyl)oxazole (**1**) with some typical ethylenic dienophiles were studied.

Results and Discussion

The Diels–Alder Reaction of 1 with *N*-Substituted Maleimides. *N*-Phenylmaleimide (**2a**) was reported to give Diels–Alder adducts with **1** in low yields under atmospheric pressure owing to the ready retro-Diels–Alder reaction.[3] In the reaction of **1** and **2a** at 40°C, the equilibrium lay to the side of the adducts but the rate was so slow that long time is required to reach the equilibrium. On the other hand, at 80°C the rate was fast enough but the equilibrium was on the side of the starting materials and the yields of the adducts became low. Therefore, the reaction was investigated under high pressure of 10 kbar. The reaction in benzene at 25°C and 10 kbar (Table 1, Run 4) gave the *endo* **3a** and the *exo*-adduct **4a** in 64.5 and 35.4% yields, without accompanying 3-hydroxypyridine derivative **5a**. Product ratios depend upon the reaction temperature and time (Table 1, Run 4—5), and the yield of the *exo*-adduct increased with the increase in reaction time.

This is ascribed to the fast retro-Diels–Alder reaction of the *endo*-adduct **3a** in comparison to that of the *exo*-adduct **4a**. That is to say, the **3a** produced preferentially at the initial stage of the reaction is decomposed by the retro-Diels–Alder reaction to give the starting **1** and **2a**, which affords **3a** and **4a** in the forward Diels–Alder reaction. In this manner, the yield of **4a** increased with the increase in the reaction time at the expense of the yield of **3a**. The retro-Diels–Alder reaction was not observed when the reaction was carried out for 2 h or less, showing constant product ratios within the experimental error (Table 2 (B)). When the reaction was continued more than 5 h, the retro-Diels–Alder reaction of **3a** apparently increased the composition of **4a** (Table 2(B)). The accelerating effect of the pressure was not enough under 1 kbar. However,

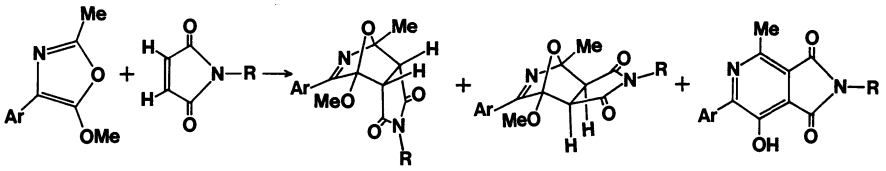
a) Compositions of the products were calculated on the basis of the NMR intensities of OCH_3 and CH_3 groups of the products and unreacted **1**. b) The reactions were carried out at 60°C using an equimolar amount (0.2 mmol) of **1** and **2a**.



3 kbar was found enough for acceleration of this reaction (Table 2(A)).

When the reaction of **1** and **2a** was carried out in dichloromethane or acetonitrile, the elimination of methanol from **3a** and **4a** occured, and *N*-phenyl-5-hydroxy-2-methyl-6-(*p*-nitrophenyl)-3,4-pyridinedicarboxyimide (**5a**) was obtained along with the adducts **3a** and **4a**. This may be brought out by the catalytic action of protic species such as water contained in the solvents. The fact that the reaction in methanol gave **5a** as the sole product (Table 2) also supported the above explanation. Similar result was obtained in the reaction of **1** with *N*-methylmaleimide (**2b**). In this system, the reaction in benzene at 10 kbar also gave **5b** in a high yield which was different from the reaction in atmospheric pressure. The difference in the yields of **5a** and **5b** (Table 1, Run 5 and 11) indicates that the high pressure acceleration of methanol elimination from adducts is faster for the adducts of **2b** than for those of **2a**.

In order to compare the ability of methanol elimination, the equimolar amount (100 mg) of **3a** and **4a** dissolved in wet benzene[5] was treated at 60°C under 10 kbar for 50 h. The NMR measurement of the reaction mixture revealed that the *endo*-adduct **3a** was present unchanged completely. On the other hand, survived **4a** was 82% and the corresponding amount (18%) of **5a** was present. This means that the elimination of methanol occurs to the *exo*-adduct more easily.

The Diels–Alder Reaction of 1 with Dimethyl Maleate and Dimethyl Fumarate. The reaction of **1** with dimethyl maleate at 60°C under 10 kbar gave two adducts **6a** (mp 129.0°C) and **6b** (mp 159.0°C) together with a methanol elimination product **7**. The large coupling constants (J=10.3 and 9.1 Hz) of methine protons of both adducts indicate that the methine protons of each adducts locate in *cis* configuration. The stereochemistry of the dienophile is retained in the adducts. The possible structures of the adducts are **5**-*endo*-**6**-*endo* (**6a**) or **5**-*exo*-**6**-*exo* (**6b**). The assignment of the structures of **6a** and **6b** was based on the chemical shift of the methine protons. The adduct having signals of the methine protons at lower fields (δ 3.56 and 3.68) was assigned to **6a**, and the adduct with the methine proton signals at higher fields (δ 3.01 and 3.18) to **6b**, on the analogy of the adducts of *N*-substituted maleimide with **1**.[3] A larger coupling

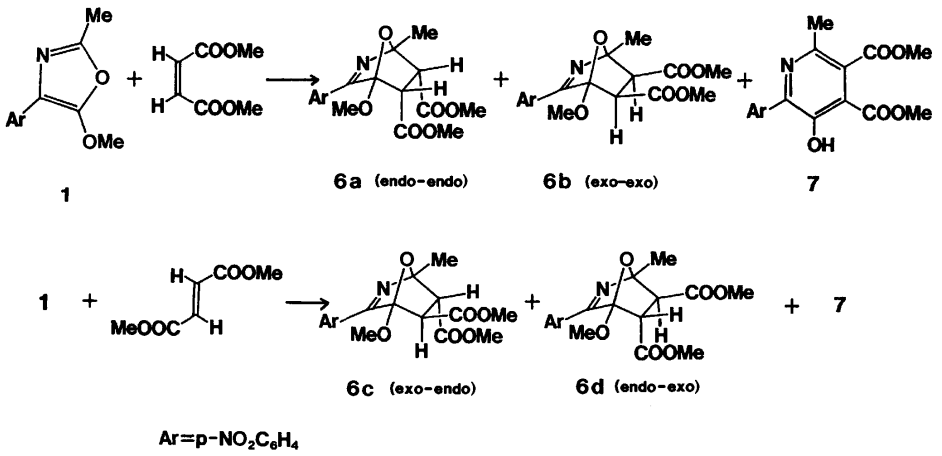
J/Hz				10.3	9.1	5.7	5.4	—

a) 76% of **1** was recovered. b) 89% of **1** was recovered. c) A considerable amount of oxazole was recovered. d) Doublet signals were observed. e) A broad singlet signal of hydroxyl group was observed at δ 11.02.



constant (J=10.3 Hz) of the *endo-endo*-adduct **6a** than the *exo-exo*-adduct **6b** (J=9.1 Hz)[6] supports the above assignment. In this case, the 5-*endo*-6-*endo*-adduct **6a** showed a C-CH_3 signal at a higher field (δ 2.00) than that of the 5-*exo*-6-*exo*-adduct **6b** (δ 2.15). This is probably caused by an anisotropic effect of closely located C=O of the ester group on C_6. The NMR spectrum of the third product shows two OCH_3 signals of ester groups (δ 3.98 and 4.02), a C-CH_3 (δ 2.55), an AB quartet of aromatic protons, and broad OH signal (δ 11.02). The absence of signals of third OCH_3 group and methine protons characterized the structure **7**, which was also supported by its IR spectrum and analytical data.

The reaction of dimethyl fumarate and **1** also gave two adducts and **7**. Although the adducts were difficult to isolate each other by silica gel column chromatography, NMR spectrum indicates that they are a mixture of two adducts which are different from **6a** and **6b**. Their smaller coupling constants (J=5.7 and 5.4 Hz) of methine protons indicate that the methine protons locate in *trans* configuration. The possible structures of the adducts having *trans* configuration are 5-*exo*-6-*endo* **6c** or 5-*endo*-6-*exo* **6d**, and the assignment was achieved by comparing of the chemical shift of the C-CH_3 group. The adduct having a C-CH_3 singlet at a higher field (δ 1.83) was assigned to 5-*exo*-6-*endo*-adduct **6c** by taking account of NMR feature of dimethyl maleate adducts described above. The reaction of dimethyl maleate was found to be faster than that of dimethyl fumarate in contrast to the usual Diels-Alder reaction.[7]

Experimental

The IR spectra were recorded on Perkin-Elmer model 983 and the ^{1}H NMR spectra were recorded in $CDCl_3$ solutions at 90 MHz on a Varian Spectrometer model EM390 using TMS as an internal standard.

Materials. 5-Methoxy-2-methyl-4-(*p*-nitrophenyl)oxazole (**1**) was prepared as described in the previous paper.[3] Solvents were dried in appropriate methods and stored over molecular sieves type 4A after distillation.

General Procedure of the High Pressure Diels-Alder Reaction of 1 with Maleimides. A solution of **1** (1.0 mmol) and maleimide (2.0 mmol) dissolved in 5 ml of a solvent was treated under the reaction conditions listed in the Table 1, using a Hikari Kouatsu high pressure reaction apparatus.[8] The reaction mixture was separated by silica gel column chromatography, and the isolated products were identified by comparison of its IR and NMR spectra with those of the samples obtained before.[3]

The Reaction of 1 with Dimethyl Maleate. A benzene solution of **1** (2.0 mmol) and dimethyl maleate (4.0 mmol) was treated under 10 kbar at 50°C for 25 h. After removal of solvent, the reaction mixture was separated by silica gel column chromatography to give three products.

First Product 6a: Pale yellow crystals; mp 128.0—129.0°C. Found: C, 54.17; H, 4.79; N, 7.38%. Calcd for $C_{17}H_{18}N_2O_8$: C, 53.97; H, 4.80; N, 7.41%.

Second Product 6b: Colorless crystals; mp 158.0—159.0°C. Found: C, 54.04; H, 4.75; N, 7.42%. Calcd for $C_{17}H_{18}N_2O_8$: C, 53.97; H, 4.80; N, 7.41%.

Third Product 7: Pale yellow needles; mp 198.0—200.0°C. Found: C, 55.38; H, 4.06; N, 8.04%. Calcd for $C_{16}H_{14}N_2O_7$: C, 55.49; H, 4.08; N, 8.09%.

The Reaction of 1 with Dimethyl Fumarate. The reaction was carried out in the same procedure as the reaction of dimethyl maleate. Column chromatography (silica gel/benzene–hexane) isolated **7** and a mixture of two adducts. However, the separation of the two adducts (**6c** and **6d**) was unsuccessful.

Selective Linear Codimerization of Terminal Acetylenes and 1,3-Butadienes Catalyzed by (η^4-1,5-Cyclooctadiene)(η^6-1,3,5-cyclooctatriene)ruthenium(0)-Trialkylphosphine

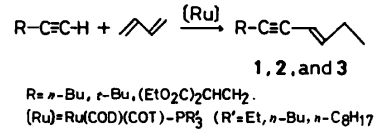
Take-aki MITSUDO,* Yoji HORI, and Yoshihisa WATANABE*
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606
(Received May 8, 1986)

The reaction of terminal acetylenes with 1,3-butadienes catalyzed by (η^4-1,5-cyclooctadiene)(η^6-1,3,5-cyclooctatriene)ruthenium [Ru^0(COD)(COT)]-PR_3 (R=ethyl, butyl, octyl) in various solvents at 80 °C afforded linear codimers in good to excellent yield with high chemo-, regio-, and stereoselectivities. Reactions of deuterated acetylenes were also examined.

Recently, much attention has been focused on finding novel organic reactions catalyzed by ruthenium complexes.[1-18] With regard to carbon–carbon bond formation, however, characteristic organic syntheses with ruthenium catalysts are still limited.[1-9] In the course of our study on organic syntheses catalyzed by low-valent ruthenium complexes,[1,2] the first example of the selective linear codimerization of terminal aliphatic acetylenes and 1,3-butadienes catalyzed by dihydridotetrakis(trialkylphosphine)ruthenium [$RuH_2(PR_3)_4$, R= ethyl or butyl] has been found.[2] We now report a novel and versatile catalytic system, (η^4-1,5-cyclooctadiene)(η^6-1,3,5-cyclooctatriene)ruthenium [Ru(COD)(COT)]-PR_3 system, for this linear codimerization. The optimum reaction conditions, the effects of various phosphine ligands and solvents, and the reaction path of the codimerization are investigated.

Results and Discussion

1-Hexyne and 3,3-dimethyl-1-butyne readily reacted with 1,3-butadiene in the presence of a catalytic amount of Ru(COD)(COT)-PBu^n_3 in benzene at 80 °C for 4 h to give (*E*)-3-decen-5-yne (**1**) and (*E*)-7,7-dimethyl-3-octen-5-yne (**2**), respectively (Table 1, Runs 1 and 2). The reaction of ethyl 2-ethoxycarbonyl-4-pentynoate with 1,3-butadiene gave ethyl (*E*)-2-ethoxycarbonyl-6-nonen-4-ynoate (**3**) in 80% yield (Run 3). On the other hand, the reaction of 1-hexyne



(1)

with methyl (*E*)-2,4-pentadienoate gave two isomers of the codimer, **4** and **5**, respectively (Run 4, Eq. 2).

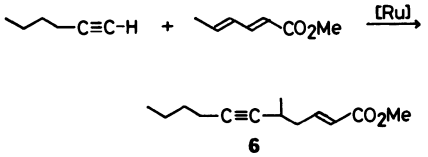
The reaction of 1-hexyne with methyl (*E,E*)-2,4-hexadienoate gave methyl (*E*)-5-methyl-2-undecen-6-ynoate (**6**) in 45% yield (Run 5, Eq. 3). The optimum



6 (3)

mole ratio of 1,3-diene/acetylene was 2 to perform the codimerization suppressing the homooligomerization of the acetylene. The high chemo-, regio-, and stereoselectivities observed are almost the same as those found in the reactions catalyzed by $RuH_2(PBu^n_3)_4$.[2] Since the preparation of Ru(COD)(COT) is much easier than that of $RuH_2(PBu^n_3)_4$ and the present catalyst system is easily modified by adding an appropriate phosphine, the present catalyst system is regarded to be an improved one. The effects of the amount of catalyst, the ratio of PBu^n_3/Ru, the reaction temperature and the reaction time in the reaction of 1-hexyne with 1,3-butadiene were examined and the results are summarized in Table 2. In the absence of PBu^n_3 under the reaction conditions shown in Run 7 of the Table 2, the yield of the codimer **1** was 1%. When a catalytic amount of PBu^n_3 was added, the yield of the codimer **1** increased dramatically (94%) (Run 9). The effect of the amount of the catalyst is shown in Fig. 1. The maximum yield of the codimer **1** was obtained by using 0.5 mol% of Ru(COD)(COT) and 1.0 mol% of PBu^n_3 at 80 °C for 4—8 h (yield 95%). The effect of the mole ratio PBu^n_3/Ru(COD)(COT) is shown in Fig. 2. When the ratio was 2—4, the codimer **1** was obtained in 94% yield. When the ratio was 20, the yield of the codimer decreased to 59%.

The effect of various phosphine ligands on the codimerization of 1-hexyne and 1,3-butadiene is summarized in Table 3. When triethylphosphine, tributylphosphine, or trioctylphosphine was added, the reac-

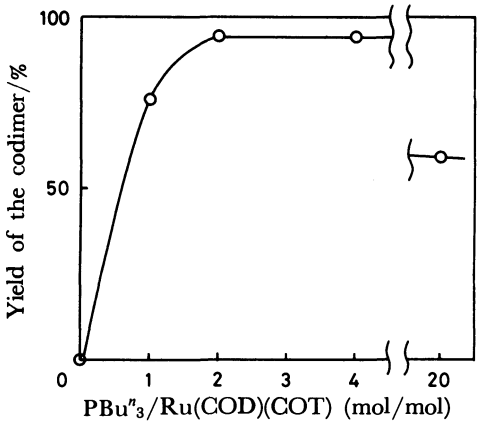

Fig. 2. The effect of the mole ratio PBu^n_3/Ru(COD)(COT). 1-Hexyne, 10 mmol; 1,3-Butadiene 20 mmol; Ru(COD)(COT) 0.5 mol%; 80 °C; 8 h.

tion proceeded rapidly and afforded the (*E*)-3-decen-5-yne (**1**) in the yields of 87, 95, and 90%, respectively (Runs 20—22). Trimethylphosphine, triisopropylphosphine, and tricyclohexylphosphine were not effective. When PEt_3, PBu^n_3, $P(C_8H_{17}{}^n)_3$, PMe_3, PPr^i_3, and $P(c\text{-}C_6H_{11})_3$ were compared, alkylphosphines with 130° of cone angle were effective. Neither phosphine ligands with an aryl group nor triisopropylphosphite with 130° of cone angle was effective.

The effects of various solvents on the codimerization of acetylenes and 1,3-butadiene are summarized in Table 4. The polarity of the solvents (benzene, THF, toluene, CH_3CN, CH_2Cl_2, DMF, or acetone) does not appreciably affect the yield of the codimers; the corresponding codimers were obtained in excellent yields (Runs 1, 2, 23—28). In pyridine, no reaction occurred (Run 29).

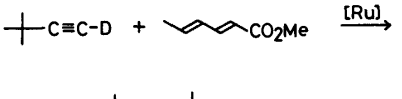
No codimer was obtained in the reactions of 1,3-butadiene with 3-hexyne, 2-propyn-1-ol, 2-methyl-3-butyn-2-ol, 2-propynyl acetate, ethyl 2-propynyl carbonate, 1-methoxy-2-propyne, or methyl propiolate.

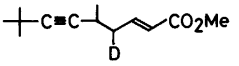
Table 3. The Ru-Catalyzed Linear Codimerization of 1-Hexyne and 1,3-Butadiene with Phosphine Ligands[a,b]

Run	Ligand (cone angle°)		Yield of (*E*)-3-decen-5-yne[c] / %
20	PEt_3	(132)	87
21	PBu^n_3	(130)	95
22	$P(C_8H_{17}{}^n)_3$	(—)	90

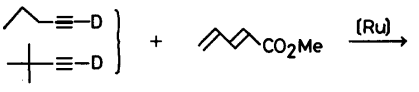
a) 1-Hexyne, 10 mmol; 1,3-butadiene, 20 mmol; Ru(COD)(COT), 0.05 mmol; Ligand, 0.1 mmol; Benzene, 5.0 cm^3; 80°C; 4 h. b) PMe_3(118°), PPr^i_3(160°), $P(c\text{-}C_6H_{11})_3$(170°), PMe_2Ph(122°), $PMePh_2$(136°), PPh_3(145°), $P(o\text{-Tol})_3$(194°), 1,2-Bis(diphenylphosphio)ethane, 1,2-Bis(diethylphosphino)ethane, and $P(OPr^i)_3$(130°) were not effective. c) Determined by GLC based on the amount of 1-hexyne.

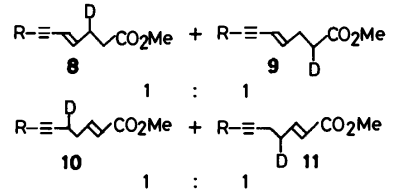
To obtain information on the reaction mechanism, the reactions of 1-pentyne-1-*d* or 3,3-dimethyl-1-butyne-1-*d* with 1,3-butadiene, methyl (*E,E*)-2,4-hexadienoate, or methyl (*E*)-2,4-pentadienoate were carried out. In the reaction of 3,3-dimethyl-1-butyne-1-*d* with methyl (*E,E*)-2,4-hexadienoate, erythro methyl (*E*)-5,8,8-trimethyl-2-nonen-6-ynoate-4-*d* (**7**) was obtained as a sole product (Eq. 4). The deuterium is introduced selectively at the 4 position of the codimer in a cis addition pathway.[2b] The reaction of 1-pentyne-1-*d* with methyl (*E*)-2,4-pentadienoate gave four isomers of the codimer, **8**—**11**. The ratio (**8**+**9**)/(**10**+**11**) was 6/4 and both ratios, **8**/**9** and **10**/**11** were 1/1 (Eq. 5). The reaction of 3,3-dimethyl-1-butyne-1-*d* with methyl (*E*)-2,4-pentadienoate also gave a result similar to that described above. It should be noted that no deuterium was introduced into the olefinic groups of the products. The reaction of 1-pentyne-1-*d* with 1,3-butadiene gave, to our surprise, (*E*)-3-





erythro **7** (4)



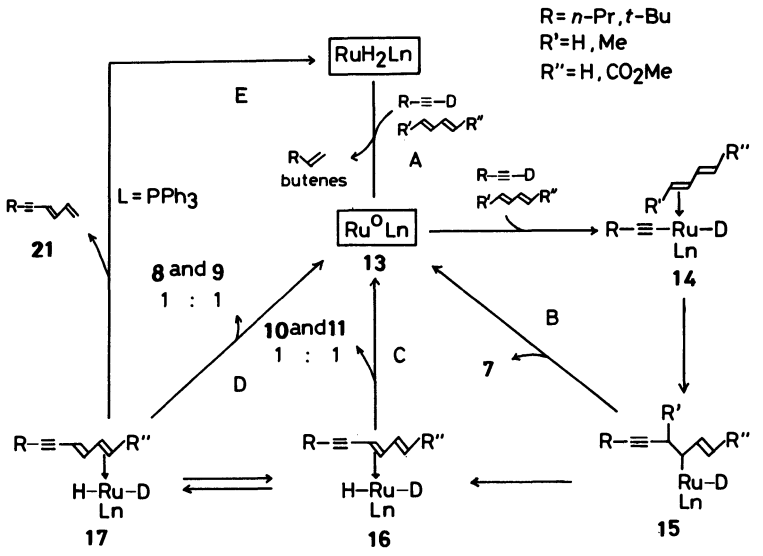


(5)

Table 4. The Ru-Catalyzed Linear Codimerization of Terminal Acetylenes with 1,3-Butadiene—Solvent Effects[a]

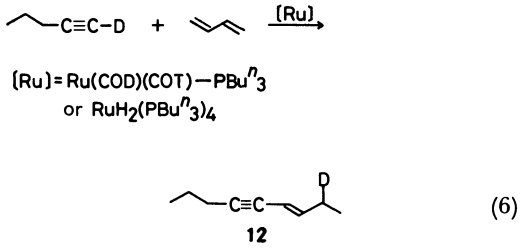
Run	Acetylene	Solvent	Product	Yield/%[b]
1		Benzene		**1** 94
2		Benzene		**2** 96
23		THF		**2** 96(91)
24		Toluene		**1** 88
25		CH_3CN		**1** 91(82)
26		CH_2Cl_2		**1** 85
27		DMF		**1** 97
28		Acetone		**1** 88
29		Pyridine	—	0

a) Acetylene, 10 mmol; 1,3-Butadiene, 20 mmol; Ru(COD)(COT), 0.1 mmol; PBu^n_3, 0.2 mmol; Solvent, 5.0 cm^3; 80°C; 4 h. b) Determined by GLC based on the amount of acetylene. Isolated yields were given in the parentheses.



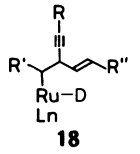
Scheme 1.

nonen-5-yne-2-*d* (**12**) as the sole product. Deuterium was introduced selectively at the 2 position of the codimer (Eq. 6). The reaction catalyzed by $RuH_2(PBu^n_3)_4$ also gave the same result.

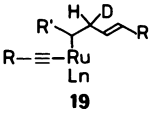


12 (6)

No clear-cut mechanism which explains these complicated results can be offered at the present time. Obviously, the mechanism of the formation of **7** is different from that of **12** because the position of the deuterium introduced is essentially different. The reaction path of the formation of the linear codimers **7** and **8—11** can be explained as follows (Scheme 1). Taking into account that both Ru(COD)(COT)-PBu^n_3 and $RuH_2(PBu^n_3)_4$ show almost the same catalytic activities and the identical distributions of the deuterium introduced in the reaction of deuterated acetylene (Eqs. 5 and 6), the reaction mechanism should be the same for both catalysts. The first step of the catalytic cycle would be the oxidative addition of acetylene to a zerovalent ruthenium complex **13** such as $Ru(PR_3)_n$ derived by the reaction of Ru(COD)-(COT) with trialkylphosphines or by the reaction of $RuH_2(PBu^n_3)_4$ with the dienes or acetylenes. It has been reported that the reaction of $RuH_2(PPh_3)_4$ with olefins such as ethylene or styrene gives zerovalent ruthenium complexes $Ru(olefin)(PPh_3)_3$[20] at the early step of the reaction.[21] The formation of a zerovalent ruthenium complex was also reasonably assumed in the [2+2] cross addition of norbornenes with acetylenes catalyzed by $RuH_2(PPh_3)_4$.[1] Then the η^2-coordination of the diene to the complex gives **14**. Insertion of the diene into the Ru-alkynyl bond would give **15**. If acetylene, instead of the diene, coordinates and inserts into the Ru-alkynyl bond, homooligomerization of acetylene proceeds. To prevent the insertion of acetylene, the mole ratio 2 of 1,3-diene/acetylene was required. When R′ and R″ in **15** are Me and CO_2Me, respectively, i.e. in the reaction of methyl (*E,E*)-2,4-hexadienoate, the reductive elimination of the ligands would give **7** selectively. Considering the high chemo- and regioselectivity of the reaction and the fact that deuterium is not introduced into the olefinic groups of **8—11**, the formation of an intermediate **18** with a branched skeletone or **19** derived by the insertion of the diene into the Ru-D bond is ruled out. Complex **18** will not give a linear codimer. Once **19** is formed, the formation of **8—11** having no deuterium at the olefinic group and the distributions of the deuterium can not be explained (vide infra).

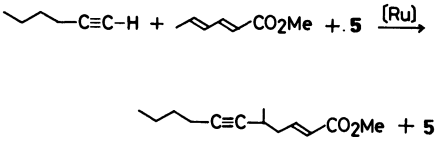


18



19

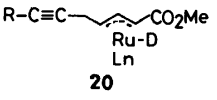
The possibility of the isomerization of **5** to **4** was investigated. The reaction of 1-hexyne with methyl (*E,E*)-2,4-hexadienoate was carried out in the presence of **5**; product **6** was obtained and **5** was recovered without the formation of **4** (Eq. 7). This fact and that



(7)

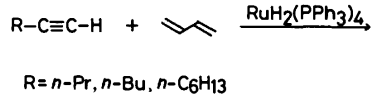
the deuterium is not introduced into the olefinic groups in **8—11** strongly suggest that when R′ is a hydrogen, i.e. in the reaction of methyl (*E*)-2,4-pentadienoate, β-elimination of **15** easily occurs giving the

equilibrium mixture of a deuteridohydrido(η^2-dienyne)-ruthenium complex **16** and its isomer **17**. The hydrogenation of the coordinated dienyne in **16** or **17** gives two pairs of olefins (**10** and **11**), and (**8** and **9**), in both pairs the equivalent amount of deuterium is introduced in the methylene groups and no deuterium is introduced into the olefinic groups. In these steps the zerovalent ruthenium complex **13** is reproduced (path C and D). It is unlikely that a π-allyl complex such as **20** plays the role of the key intermediate



20

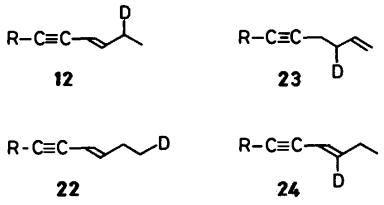
because the formation of **8**—**11** can not be explained. As has been reported in the previous paper,[2b] when the ligand L is triphenylphosphine and R″ is hydrogen in **16** or **17**, i.e. in the reaction of 1,3-butadiene, the dissociation of the dienyne easily occurs giving **21** (path E, Eq. 8). The main reason of the dissociation



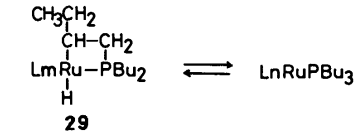
21 (8)

of **21** would be a larger cone angle of triphenylphosphine (145°) than that of tributylphosphine (130°).[22]

The explanation of the reaction path of the codimerization of 1-pentyne-1-*d* with 1,3-butadiene is confusing. The reaction path shown in the Scheme 1 should give **23** or the mixture of **12** and **22**; however, the result shows that the deuterium is selectively introduced into the 2 position of **12**. It is unlikely that the isomerization of **23** gives **12**, because in this case **24** should be detected in the products.

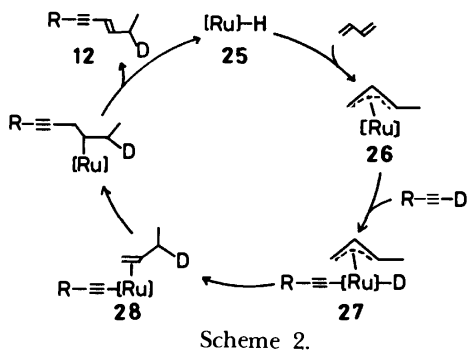


A speculated reaction path explaining these unusual results is shown in Scheme 2. If a monohydridoruthenium species **25** is present, a catalytic cycle via a π-allyl ruthenium complex could give **12** selectively. The first step of the reaction is a formation of a π-allyl ruthenium complex **26** by the coordination of 1,3-butadiene to hydridoruthenium species followed by the insertion of 1,3-butadiene to the hydrido-ruthenium bond. Oxidative addition of the 1-pentyne-1-*d* affords a π-allylalkynyldeuteridoruthenium complex **27**. Reductive elimination of the η^3-allyl group and the deuteride gives the alkynyl(π-olefin) complex **28**; insertion of the olefin into the alkynyl-Ru bond and β-elimination would give **12** selectively and the hydridoruthenium species again. As for the monohydridoruthenium species, it should be pointed out that complex **29** would be formed by the intramolecular oxidative addition of β-hydrogen of the tributylphosphine ligand (Eq. 9). Quite recently, similar intramolecular oxidative addition of an alkyl group of an alkylphosphine ligand has been reported.[19]



29 (9)

In conclusion, a versatile catalytic system for the selective linear codimerization of terminal acetylenes with 1,3-dienes was found providing a novel convenient tool for the construction of carbon skeletones with acetylenic and olefinic groups.



Scheme 2.

Experimental

All boiling points were uncorrected. Infrared spectra were recorded on a Hitachi Model 215 spectrometer and NICOLET 5-MX spectrometer as films. Proton nuclear magnetic resonance spectra were obtained on a JNM-FX-100 or NICOLET NT-300NB spectrometer as 20% solutions with tetramethylsilane as an internal reference. Carbon-13 nuclear magnetic resonance spectra were obtained on a JNM-FX-100 spectrometer as 30% solutions with tetramethylsilane as an internal reference. Mass spectra were taken on a JMS-01SG mass spectrometer. Microanalyses were performed by the Laboratory for Organic Elemental Microanalysis at the Faculty of Pharmaceutical Science at Kyoto University. Gas chromatographic analysis (GLC) were carried out on a 1.5 m×3 mm diameter column with OV 17. 1-Hexyne, 1,3-butadiene, methyl (*E*,*E*)-2,4-hexadienoate, and solvents were commercial samples and were purified by distillation under an atmosphere of argon before use. 3,3-Dimethyl-1-butyne,[23] 3,3-dimethyl-1-butyne-1-*d*,[24] and 1-pentyne-1-*d*[24] were prepared by the methods described in the literature. The complex Ru(COD)(COT) were prepared by the reported method.[25] All the catalytic reactions were carried out under an atmosphere of argon.

General Reaction Procedure. The reaction of 1-hexyne with 1,3-butadiene is representative. A mixture of 1-hexyne (0.82 g, 10 mmol), 1,3-butadiene (20 mmol), Ru(COD)(COT) (0.063 g, 0.2 mmol), PBu^n_3 (0.08 g, 0.4 mmol), and benzene (5.0 cm^3) was heated in a heavy-walled sealed tube at 80°C for 8 h. Careful vacuum distillation of the reaction mixture afforded 0.99 g (yield 73%) of (*E*)-3-decen-5-yne (**1**).

Other reactions were carried out in a similar manner. Codimers (**1**, **2**, **4**—**11**) were identified to be the products reported in the previous paper.[2b]

Ethyl (*E*)-2-Ethoxycarbonyl-6-nonen-4-ynoate (3). Colorless liquid, bp 108 °C (25 mmHg) (1 mmHg=133.322 Pa); IR (neat) 1745 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.08 (1H, dt, J=15.9 and 6.6 Hz), 5.39 (1H, dt, J=15.9 and 1.8 Hz), 4.22 (4H, q, J=7.1 Hz), 3.54 (1H, t, J=7.8 Hz), 2.86 (2H, dd, J=7.8 and 1.8 Hz), 2.09 (2H, qd, J=7.4 and 6.6 Hz), 1.28 (6H, t, J=7.1 Hz), and 0.98 (3H, t, J=7.4 Hz); ^{13}C NMR ($CDCl_3$) δ=167.9 (s), 145.5 (d), 108.7 (d), 83.8 (s), 81.1 (s), 61.5 (t), 51.6 (d), 26.1 (t), 19.4 (t), 14.1 (q), and 13.0 (q). MS m/z: 252. Found: C, 66.65; H, 8.15%. Calcd for $C_{14}H_{20}O_4$: C, 66.65; H, 7.99%.

(*E*)-3-Nonen-5-yne-2-*d* (12). Colorless liquid, bp 80 °C (85 mmHg); IR (neat) 2217 and 955 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.08 (1H, dd, J=15.6 and 6.3 Hz), 5.45 (1H, dm, J=15.6 Hz), 2.26 (2H, td, J=7.2 and 1.8 Hz), 2.09 (1H, m), 1.54 (2H, qt, J=7.2 and 7.2 Hz), 0.99 (3H, dm, J=7.5 Hz), 0.99 (3H, t, J=7.2 Hz); ^{13}C NMR ($CDCl_3$) δ=144.2 (d), 109.6 (d), 88.4 (s), 79.5 (s), 25.9 (t, J_{C-D}=19.5 Hz), 22.6 (t), 21.6 (t), 13.6 (q), and 13.2 (q).

The reaction of 1-Hexyne with Methyl (*E,E*)-2,4-Hexadienoate in the presence of 5. A mixture of 1-hexyne (8.2 mg, 0.1 mmol), methyl (*E,E*)-2,4-hexadienoate (12.7 mg, 0.1 mmol), methyl (*E*)-2-undecen-6-ynoate (**5**) (20 mg, 0.1 mmol), Ru(COD)(COT) (0.32 mg, 1 mol%), PBu^n_3 (0.40 mg, 2 mol%), and benzene (0.05 cm^3) was heated at 60 °C for 4 h. The GLC analysis showed the formation of the codimer **6** (yield 30%) and that **5** was completely recovered without the formation of **4**.

This work was partly supported by the Ministry of Education, Science and Culture (No. 60119001 and 61225012). We thank Dr. Richard M. Lain for helpful discussions.

Synthesis and Antitumor Activity of *N*-Acetylmuramyl-L-alanyl-D-isoglutamine 6-Phosphate and Its Lipophilic Derivatives

Masahiro IMOTO, Shigeki KAGEYAMA, Shoichi KUSUMOTO, Morihiro KOHNO,† Kensuke MATSUMOTO,† Shinjiro HASHIMOTO,† Akiko TOHGO,† and Tetsuo SHIBA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 12, 1986)

6-Phosphate of *N*-acetylmuramyl-L-alanyl-D-isoglutamine and its lipophilic derivatives, i.e., 6-(octadecyl hydrogenphosphate) and 6-(2-docosyltetracosyl hydrogenphosphate) were synthesized after the structural feature of mycobacterial cell walls for the purpose to modify and possibly to enhance the immunostimulating activity of the muramyl dipeptide which is the minimum requisite for the activity. As expected, the latter more lipophilic phosphate showed a high activity in a tumor regression test.

As already described,[1,2] *N*-acetylmuramyl-L-alanyl-D-isoglutamine (**1**) is the minimum partial structure of bacterial peptidoglycan required for the expression of the immunostimulating activity. Our successive study demonstrated that lipophilic 6-*O*-acyl derivatives of the muramyl dipeptide which were synthesized in imitation of the structural feature of mycobacterial cell walls exhibit an antitumor activity characteristic of these natural cell walls.[3,4] However, the potency of the synthetic derivatives to inhibit the growth of tumor was still much less significant than the natural cell walls. In this respect, we continue synthetic studies towards derivatives of the muramyl dipeptide with more potent activities. One direction is syntheses of compounds with longer glycan structures.[5–7] As the second approach for the same purpose, we describe in this paper synthesis and antitumor activities of 6-*O*-phosphorylated derivatives of the muramyl dipeptide **1**.[8]

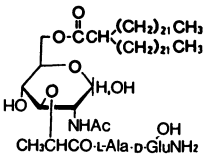
3b R = $CH_2CH\langle^{(CH_2)_{21}CH_3}_{(CH_2)_{21}CH_3}$



4

In cell walls of mycobacteria and related species, the 6-hydroxyl groups of muramic acid residues are bound through phosphodiester structures to arabinogalactan. It is further linked to mycolic acid, which is α-branched β-hydroxylated fatty acid with more than forty carbon atoms and thus render the cell wall highly lipophilic.[9] Since the 6-*O*-acylmuramyl dipeptides described above correspond to an oversimplified model of cell wall, both the phosphate and the polysaccharide parts being omitted and natural mycolic acid or analogous synthetic fatty acids being directly bound to the muramic acid residue, we were interested in testing the effect of the phosphate moiety on the biological activity of the molecule of the muramyl dipeptide. Especially, we anticipated that the simultaneous presence of the polar phosphate and the lipophilic part in the same molecule might have a significant effect. This consideration prompted us to synthesize *N*-acetylmuramyl-L-alanyl-D-isoglutamine 6-phosphate (**2**) and its lipophilic derivatives, i.e., the octadecyl derivative **3a** and the 2-docosyltetracosyl derivative **3b**. In the structures of **3a** and **3b**, the polysaccharide part is still lacking but the phosphodiester function is retained, the fatty acids present in the cell walls being replaced with long chain alcohols which are directly bound to the phosphate group.[10] In order to test the effect of different lipophilicity, two alcohols, i.e., 1-octadecanol and 2-docosyl-1-tetracosanol, were used. These two particular alcohols were chosen by taking into account the fact that 6-*O*-acylmuramyl dipeptides containing the fatty acids with the corresponding carbon chains showed characteristic activities. Namely, 6-*O*-stearoylmuramyl dipeptide showed the highest adjuvant activity among the acyl derivatives prepared,[11] and 6-*O*-(2-docosyltetracosanoyl)muramyl dipeptide **4** had a strong tumor suppressive activity.[4]

For the synthesis of 6-phosphate **2**, a known 4,6-*O*-benzylidene derivative of *N*-acetylmuramic acid α-benzyl glycoside (**5**) was prepared by slight modification of the reported conditions.[12] An improved yield was obtained at the formation of 2-carboxyethyl ether by reducing the amount of sodium hydride and by employing a lower reaction temperature. Benzyl esterification of **5** with phenyldiazomethane followed by acidic hydrolysis of the benzylidene group afforded **7** which is feasible for 6-*O*-phosphorylation.

When **7** was treated with diphenyl hydrogenphosphate[13] and 2,4,6-triisopropylbenzenesulfonyl chloride (TPS chloride) in pyridine, the desired 6-(diphenyl phosphate) **8** was obtained as a single product. The position of the phosphate moiety was confirmed by ^{13}C NMR, where a signal of methylene carbon (C-6) was observed which couples with ^{31}P of the phosphate group. After selective hydrogenolysis of the benzyl ester of **8**, the product was coupled with L-alanyl-D-isoglutamine benzyl ester to give the protected *N*-acetylmuramyl dipeptide 6-phosphate **9**, which was identified with the compound obtained via an alternative route described below. Deprotection of **9** was effected by catalytic hydrogenolysis in two steps, first with palladium black then with platinum oxide. Lyophilization from water gave the product **2** as colorless powder which gave a satisfactory result in elemental analysis. On treatment with diazomethane, **2** gave a trimethyl ester. Two of the methyl groups are bound to the phosphate residue as judged from the observation of through-three-bond H–P coupling in the ^1H NMR spectrum. Therefore, the presence of phosphomonoester structure in **2** was unequivocally assured, a possibility of the presence of a cyclic phosphodiester at 4 and 6 positions being thus excluded. The third methyl group was introduced at the carboxyl group of the isoglutamine residue.

Alternatively, the 6-phosphate **2** could be also prepared by phosphorylation after the dipeptide had been coupled with muramic acid. A partially protected derivative of muramyl dipeptide **10** prepared as an intermediate in our previous synthesis of 6-*O*-acyl muramyl dipeptide[14] was phosphorylated with the same reagents as above to give the 6-(diphenyl phosphate) which was identical with **9** obtained above. However, the yield of **9** was low (52%) because the undesired competitive dehydration occurred at the amide function of the isoglutamine residue to form a nitrile **11**. Consequently, the route described first was more favorable.

For the synthesis of lipophilic derivatives, **3a** and **3b**, the corresponding alkyl phenyl hydrogenphosphates were first prepared. Condensation of phenyl dihydrogenphosphate with 1-octadecanol or 2-docosyl-1-tetracosanol which had been prepared from methyl 2-docosyltetracosanoate by lithium aluminum hydride reduction was effected with dicyclohexylcarbodiimide (DCC) in pyridine. In case of the former alcohol, the reaction proceeded readily to give octadecyl phenyl hydrogenphosphate (**12a**) in a good yield. In contrast, the formation of the alkyl phenyl hydrogenphosphate was slow in case of the latter branched higher alcohol and more than 50% of the starting alcohol was recovered even after 70 h.

Octadecyl phenyl hydrogenphosphate was then treated with TPS chloride and muramic acid benzyl ester **7** in the same way as described for the synthesis of **2** to give a syrupy product **13a**, which was characterized by means of ^1H NMR and FD-MS. Hydrogenolysis of the benzyl ester of **13a** followed by condensation with the dipeptide benzyl ester afforded the protected muramyl dipeptide 6-(docosyl phenyl phosphate) **14a** as a solid after chromatographic purification. Hydrogenolysis in two steps followed by purification with a column of Bio-gel P-2 gave the muramyl dipeptide **3a** having octadecyl hydrogenphosphate at 6-position. Since the product gave a poorly resolved ^1H NMR spectrum due to aggregation, the structure was further characterized as its dibenzyl ester.

The 6-(2-docosyltetracosyl hydrogenphosphate) **3b** was also prepared in the same way. Like as the formation of the alkyl phenyl hydrogenphosphate **12b** described above, the yields of its condensation with muramic acid and the successive reaction with dipep-

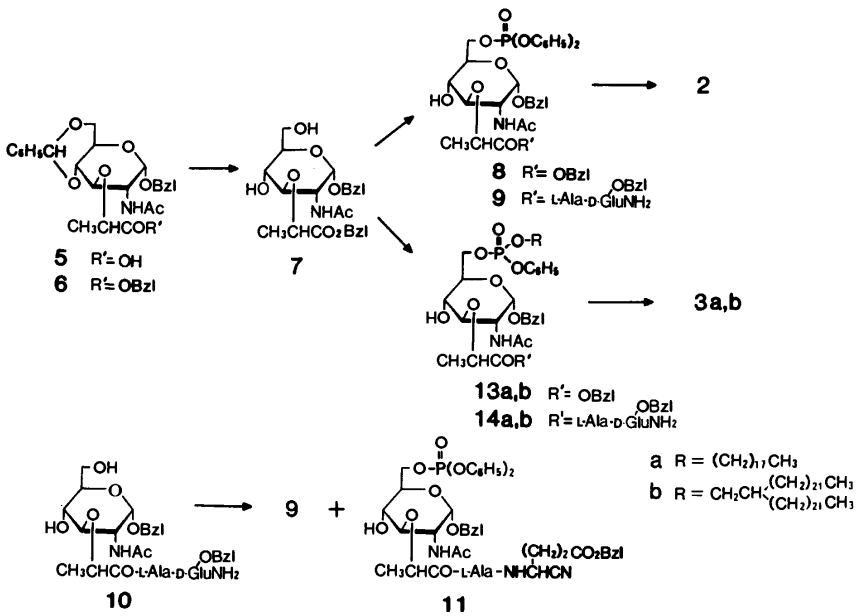


Table 1. Autitumor Effect of Synthetic Muramyl Dipeptide Derivatives on Meth-A Fibrosarcoma

Compound		Suppression Test[a]				Regression test[a]		
		Dose	Viability[b]	Suppression[c]	T/C[d]	Dose	Regression[c]	T/C[d]
		μg/mouse	%		%	μg/mouse		%
6-Phosphate	(**2**)	100	80	0/9	91.4			
6-(Octadecyl hydrogenphosphate)	(**3a**)	6.25	67	2/10	30.9			
6-(2-Docosyltetracosyl hydrogenphosphate)	(**3b**)	100	73	1/10	30.9	100	0/10	67.4
6-*O*-(2-Docosyl-tetracosanoate)	(**4**)	100	71	1/9	42.0	100	0/10	100.1
Nocardia CWS		100	96	2/9	32.1	100	0/8	59.2
Conrol		—	93	0/10	100	—	0/14	100

a) See the experimental part. b) The value represents the proportion of living/total cells before inoculation. c) Number of cured mice/number of treated mice. d) See Ref. 16 in the text.

tide were low presumably owing to a steric hindrance of the bulky alkyl group. The final product was also characterized after having been converted into the corresponding dibenzyl ester with phenyldiazomethane.

The antitumor activity of the synthetic compounds were first examined in the suppression test in which one can evaluate the ability of each compound to suppress the growth of tumor when tumor cells and the compound to be tested were simultaneously applied to animals.[15] Mice were inoculated intradermally with a mixture of the specified amount of the tumor cells and test materials given in Table 1. The weight of tumor was measured and compared with that of the control group where mice were given the tumor cells alone. The compound which gives smaller T/C value[16] is assumed to have higher suppression activity. The results are summarized in Table 1. While the hydrophilic 6-phosphate **2** showed no effect, both of the lipophilic derivatives, **3a** and **3b**, exhibited supression comparable to that obtained with *Nocardia* cell wall skeleton (CWS) which is known to have a potent antitumor activity.[17] 6-*O*-(2-Docosyltetracosanoyl)-muramyl dipeptide **4** of 6-*O*-acyl type prepared previously[4] also showed a similar activity in this test system. It should be noted here that the octadecyl derivative **3a** could not be used in higher doses because this compound kills the tumor cells by direct action probably due to its detergent-like character as shown by the decrease of viable tumor cells (Table 1). Tumor regression activity[18] of muramyl dipeptide 6-(2-docosyltetracosyl hydrogenphosphate) **3b** was then tested in comparison with *Nocardia* CWS and 6-*O*-(2-docosyltetracosanoyl)muramyl dipeptide **4**. In this test, growth inhibition with the compound is evaluated on the tumor which was previously inoculated and already grown up in mice. Therefore this system enables more strict estimation of the antitumor activity under conditions similar to actual immunotherapy. The result shown in Table 1 clearly indicate that compound **3b** prepared in this study shows high activity comparable to the natural cell wall preparation. On the contrary, 6-*O*-acyl type derivative **4** showed no effect in this regression test. Since **4** contains a carbon chain with the same length as that of **3b**, the difference in the biological activities could be attributed to the presence of the phosphate function in **3b**. As mentioned in the introduction of this paper, it could be speculated that simultaneous existence of both the phosphate moiety and the long alkyl chain would give a character like a phospholipid to the molecule and enhance the interaction with the membrane of host animals cells, resulting in expression of high biological activity.

Experimental

All melting points are uncorrected. Unless otherwise stated, ^{1}H and ^{13}CNMR spectra were measured at 100 and 22.5 MHz, respectively, for $CDCl_3$ solutions. FD mass spectra were obtained with a JEOL JMS-01SG mass spectrometer equipped with silicon emitter. Optical rotations were measured with a Perkin-Elmer 141 polarimeter. Column chromatography were carried out with Kieselgel 60 (0.063—0.2 mm), E. Merck.

Benzyl 2-Acetamido-4,6-*O*-benzylidene-3-*O*-[(*R*)-1-carboxyethyl]-2-deoxy-α-D-glucopyranoside (5). Sodium hydride (60% oil dispersion, 3.0 g, 75 mmol) was added to a solution of benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside[19] (15.0 g, 37.6 mmol) in dry dioxane (750 ml). The mixture was kept at 60°C with stirring. (*S*)-2-Chloropropionic acid (16.4 g, 151 mmol) was added to the mixture and stirring was continued at 60°C. Soon after addition of the acid, a large amount of small crystals separated out which made efficient stirring difficult. Stirring again became possible within 10 min. Then NaH (7.5 g, 188 mmol) was again added. Stirring was continued at the same temperature for further 40 min. After addition of water (800 ml), the mixture was washed with hexane and then acidified with 6M[††] HCl. The separated crystals were collected by filtration, washed thoroughly with water, and dried. Recrystallization was effected from $CHCl_3$; Yield 14.8 g (84%); mp 230—234°C decomp.

Benzyl 2-Acetamido-4,6-*O*-benzylidene-3-*O*-[(*R*)-1-(benzyloxycarbonyl)ethyl]-2-deoxy-α-D-glucopyranoside (6). To a solution of **5** (4.70 g, 10.0 mmol) in $CHCl_3$ (470 ml) was added a solution of phenyldiazomethane in hexane. After

[††] 1 M=1 mol dm^{-3}.

usual work-up, the product was recrystallized from acetone; yield 5.51 g (98%); mp 178—181 °C. Found: C, 68.31; H, 6.22; N, 2.57%. Calcd for $C_{32}H_{35}NO_8$: C, 68.44; H, 6.28; N, 2.49%.

Benzyl 2-Acetamido-3-*O*-[(*R*)-1-(benzyloxycarbonyl)ethyl]-2-deoxy-α-D-glucopyranoside (7). A suspension of **6** (5.00 g, 8.90 mmol) in 60% AcOH (250 ml) was heated in a boiling water bath with shaking for 20 min. After usual work-up, the product was recrystallized from $CHCl_3$–ether–hexane; yield 3.75 g (89%); mp 120—123 °C (with sintering at 115 °C). Found: C, 63.10; H, 6.58; N, 3.02%. Calcd for $C_{25}H_{31}NO_8$: C, 63.41; H, 6.60; N, 2.96%.

Benzyl 2-Acetamido-3-*O*-[(*R*)-1-(benzyloxycarbonyl)ethyl]-2-deoxy-α-D-glucopyranoside 6-(Diphenyl Phosphate) (8). A mixture of **7** (500 mg, 1.05 mmol), diphenyl hydrogenphosphate (528 mg, 2.11 mmol), and TPS chloride (639 mg, 2.11 mmol) in dry pyridine (5 ml) was stirred at room temperature for 13 h. Diphenyl hydrogenphosphate (264 mg, 1.05 mmol) and TPS chloride (320 mg, 1.05 mmol) was added, and the mixture was stirred at room temperature for additional 19 h. After addition of water, the solvent was evaporated in vacuo. The residue was dissolved in $CHCl_3$, washed with water, and dried ($MgSO_4$). The product was isolated by column chromatography on silica gel (50 g, $CHCl_3$–MeOH 50:1) as colorless syrup; yield 674 mg (91%); ^{1}H NMR δ=7.1—7.5 (21H, aromatic H and NH); ^{13}C NMR δ=67.75 ($J_{P\text{-}O\text{-}C}$=6.1 Hz, C-6).

Benzyl L-Alanyl-D-isoglutaminate *N*-Acylated with Benzyl 2-Acetamido-2-deoxy-3-*O*-[(*R*)-1-carboxyethyl]-α-D-glucopyranoside 6-(Diphenyl Phosphate) (9). a) From **8**. Compound **8** (280 mg, 0.40 mmol) was dissolved in THF (8 ml) and hydrogenolyzed at room temperature in the presence of Pd-black for 2 h. The catalyst was filtered off and the solvent was evaporated in vacuo. The residue was again dissolved in THF (3 ml). L-Alanyl-D-isoglutamine benzyl ester trifluoroacetate (200 mg, 0.47 mmol), *N*-hydroxysuccinimide (HONSu) (55 mg, 0.48 mmol), triethylamine (65 μl, 0.47 mmol) and DCC (98 mg, 0.48 mmol) were added to the solution at 0 °C with stirring. The mixture was stirred overnight, being allowed to warm up to room temperature during this period. After usual work-up, the syrupy product obtained was subjected to column chromatography on silica gel (45 g, $CHCl_3$–MeOH 20:1) and recrystallized from $CHCl_3$–ether–hexane; yield 256 mg (71%); mp 106—108 °C. It was identical with the product obtained by the following method b).

b) From **10**. To a suspension of benzyl L-alanyl-D-isoglutaminate *N*-acylated with benzyl 2-acetamido-2-deoxy-3-*O*-[(*R*)-1-carboxyethyl]-α-D-glucopyranoside (**10**)[14] (336 mg, 0.50 mmol) in pyridine (3 ml) were added diphenyl hydrogenphosphate (250 mg, 1.0 mmol) and TPS chloride (302 mg, 1.0 mmol). The mixture had been stirred at room temperature for 3 h and worked up as usual. The crude product was subjected to silica-gel column chromatography (48 g). Elution with a mixture of $CHCl_3$–MeOH (10:1) first gave the nitrile derivative **11**, which was recrystallized from $CHCl_3$–ether; yield 100 mg (23%); mp 75—77 °C; IR (KBr) 2250 cm^{-1} (CN). Found: C, 60.67; H, 5.92; N, 6.16%. Calcd for $C_{45}H_{51}N_4O_{13}P$: C, 60.94; H, 5.80; N, 6.32%.

Further elution with the same solvent afforded **9** which was recrystallized from $CHCl_3$–ether: yield 235 mg (52%); mp 107—110 °C; $[\alpha]_D^{22}$ +57.2° (*c* 0.50, $CHCl_3$). Found; C, 59.29; H, 5.99; N, 6.03%. Calcd for $C_{45}H_{53}N_4O_{14}P\cdot 0.5H_2O$: C, 59.14; H, 5.96; N, 6.13%.

L-Alanyl-D-isoglutamine *N*-Acylated with 2-Acetamido-2-deoxy-3-*O*-[(*R*)-1-carboxyethyl]-D-glucose 6-Phosphate (2). Compound **9** (90 mg, 0.10 mmol) was dissolved in AcOH (5 ml) and stirred under atmospheric pressure of H_2 in the presence of Pd-black for 7 h. After catalyst had been filtered off, PtO_2 was added to the filtrate. The mixture was stirred under H_2 (5 kg cm^{-2}) at room temperature for 14 h. The catalyst was removed by filtration and the solvent was removed in vacuo. The residue was again dissolved in water. The solution was filtered through a Milipore filter (pore size 0.45 μm) and subjected to lyophilization to give colorless powder: yield 60 mg (quantitative); $[\alpha]_D^{22}$ +45.9° (*c* 0.51, MeOH). Found: C, 36.91; H, 6.04; N, 9.07; P, 4.73%. Calcd for $C_{19}H_{33}N_4O_{14}P\cdot 2.5H_2O$: C, 36.96; H, 6.20; N, 9.07; P, 5.02%.

The compound was dissolved in MeOH and treated with an ethereal solution of CH_2N_2. After evaporation of the solvent, the product was directly subjected to ^{1}H NMR measurement: (in $CDCl_3$–CD_3OD) δ=3.81 (6H, d, $J_{P\text{-}O\text{-}C\text{-}H}$= 11 Hz, $PO(OCH_3)_2$), 3.60 (3H, s, $COOCH_3$).

Octadecyl Phenyl Hydrogenphosphate (12a). A solution of 1-octadecanol (3.00 g, 11.1 mmol), phenyl dihydrogenphosphate (2.32 g, 13.3 mmol) and DCC (2.75 g, 13.3 mmol) in pyridine (30 ml) was stirred at room temperature for 13 h. Phenyl dihydrogenphosphate (0.97 g, 5.5 mmol) and DCC (1.14 g, 5.5 mmol) were added and the mixture was stirred for further 37 h. After usual work-up, the product was recrystallized from MeOH; yield 3.80 g (80%); mp 56—58 °C. Found: C, 67.71; H, 10.14%. Calcd for $C_{24}H_{43}O_4P$: C, 67.58; H, 10.16%.

Benzyl 2-Acetamido-3-*O*-[(*R*)-1-(benzyloxycarbonyl)ethyl]-2-deoxy-α-D-glucopyranoside 6-(Octadecyl Phenyl Phosphate) (13a). TPS chloride (1.28 g, 4.22 mmol) was added to a solution of the muramic acid benzyl ester **7** (1.00 g, 2.11 mmol) and octadecyl phenyl hydrogenphosphate (**12a**) (1.80 g, 4.22 mmol) in pyridine (20 ml). After the mixture had been stirred at room temperature for 23 h, the solvent was evaporated in vacuo and the residue subjected to silica-gel column chromatography (90 g, $CHCl_3$–MeOH 50:1) to give a syrupy product: yield 1.33 g (72%); FD-MS: *m/z* 882 $(M+H)^+$.

Benzyl L-Alanyl-D-isoglutaminate *N*-Acylated with Benzyl 2-Acetamido-2-deoxy-3-*O*-[(*R*)-1-carboxyethyl]-α-D-glucopyranoside 6-(Octadecyl Phenyl Phosphate) (14a). Compound **13a** (500 mg, 0.567 mmol) was dissolved in THF (15 ml) and hydrogenolyzed in the presence of Pd-black catalyst at room temperature for 45 min. After the catalyst had been filtered off, the solvent was once evaporated in vacuo and the residue was again dissolved in THF (5 ml). L-Alanyl-D-isoglutamine benzyl ester trifluoroacetate (300 mg, 0.711 mmol), HONSu (82 mg, 0.712 mmol), triethylamine (96 μl, 0.69 mmol), and DCC (140 mg, 0.679 mmol) were added to the solution cooled to 0 °C. The mixture was stirred overnight and worked up as usual. The product was purified by column chromatography on silica gel (50 g, $CHCl_3$–MeOH 10:1) and lyophilized from dioxane: yield 235 mg (38%); ^{1}H NMR δ=7.1—7.5 (15H, aromatic H), 5.09 (4H, s, $C_6H_5C\underline{H}_2$–), 1.90 (3H, s, CH_3CO), 1.2—1.5 (32H, broad, $-CH_2$).

L-Alanyl-D-isoglutamine *N*-Acylated with 2-Acetamido-2-deoxy-3-*O*-[(*R*)-1-carboxyethyl]-D-glucose 6-(Octadecyl Hydrogenphosphate) (3a) and Its Dibenzyl Ester. Compound **14a** (50 mg, 4.6 μmol) was dissolved in MeOH (5 ml). After a few drops of AcOH and Pd-black catalyst had been added, the

mixture was stirred under H_2 atmosphere (5 kg cm^{-2}) at room temperature for 48 h. The catalyst was filtered off, and the solvent was evaporated in vacuo. The residue was again dissolved in MeOH (5 ml) and the solution stirred under H_2 (5 kg cm^{-2}) for 3 h after addition of PtO_2. The product was dissolved in water and purified by a column of Bio-gel P-2 (100—200 mesh, 17 ml). Lyophilization from AcOH afforded colorless powder; yield 27 mg (71%); $[\alpha]_D^{22}$ +25.1° (*c* 1.00, $CHCl_3$–MeOH 5:1). Found: C, 51.83; H,8.26; N, 6.79%. Calcd for $C_{37}H_{69}N_4O_{14}P \cdot 2H_2O$: C, 51.62; H, 8.55; N, 6.51%.

Compound **3a** obtained from **14a** (0.10 mmol) was dissolved in $CHCl_3$, washed once with 1M HCl and then treated with phenyldiazomethane. The product was purified by preparative TLC on silica gel and lyophilized from benzene to give the dibenzyl ester; yield 35 mg; ^{1}H NMR; δ=7.2—7.4 (10H, aromatic H), 5.08 (4H, $C_6H_5C\underline{H}_2$). Found: C, 58.74; H, 7.98; N, 5.42; P, 2.52%. Calcd for $C_{51}H_{81}N_4O_{14}P \cdot 2H_2O$: C, 58.83; H, 8.23; N, 5.38; P, 2.97%.

2-Docosyl-1-tetracosanol. A mixture of 2-docosyltetracosanoic acid (5.00 g, 7.38 mmol) and concd H_2SO_4 (0.5 ml) in MeOH (50 ml) and CH_2ClCH_2Cl (50 ml) was heated under reflux for 5 h. After usual work-up, recrystallization from acetone afforded methyl 2-docosyltetracosanoate; yield 4.94 g (97%); mp 68—70°C.

To a suspension of this methyl ester (4.94 g, 7.15 mmol) in anhyd ether (200 ml) and anhyd THF (100 ml), a suspension of $LiAlH_4$ (271 mg, 7.15 mmol) in anhyd ether (75 ml) was added dropwise with stirring during 30 min. The mixture was heated under reflux for 3 h, $LiAlH_4$ (540 mg, 14.3 mmol) being added after 1.5 h. After usual work-up, the product was recrystallized from acetone; yield 4.46 g (94%); mp 65—67°C.

2-Docosyltetracosyl Phenyl Hydrogenphosphate (12b). DCC (1.66 g, 8.04 mmol) was added to a mixture of 2-docosyl-1-tetracosanol (4.46 g, 6.72 mmol) and phenyl dihydrogenphosphate (1.40 g, 8.04 mmol) in pyridine (50 ml). The mixture was stirred at room temperature for 55 h. Phenyl dihydrogenphosphate (1.17 g, 6.72 mmol) and DCC (1.38 g, 6.72 mmol) were added to the mixture and stirring was continued for further 16 h. After the mixture had been worked up as described for **12a**, the product and the unchanged 2-docosyl-1-tetracosanol were separated by means of silica-gel column chromatography (225 g, $CHCl_3$–MeOH 20:1 to 10:1).

2-Docosyl-1-tetracosanol recovered was recrystallized from acetone; 2.47 g (recovery 55%).

The product eluted from the column was dissolved in $CHCl_3$ and washed with 1M HCl and water. The residue obtained by evaporation of the solvent was recrystallized from acetone; yield 2.05 g (37%); mp 57—60°C. Found: C, 75.94; H, 12.06%. Calcd for $C_{52}H_{99}O_4P$: C, 76.23; H, 12.18%.

Benzyl 2-Acetamido-3-*O*-[(*R*)-1-(benzyloxycarbonyl)ethyl]-2-deoxy-α-D-glucopyranoside 6-(2-Docosyltetracosyl Phenyl Phosphate) (13b). TPS chloride (640 mg, 2.11 mmol) was added to a solution of muramic acid benzyl ester (**7**) (500 mg, 1.05 mmol) and **12b** (1.73 g, 2.11 mmol) in anhyd pyridine (15 ml). The mixture was stirred at room temperature for 48 h and worked up as described for **13a**. The product was isolated by column chromatography on silica gel (50 g, $CHCl_3$–MeOH 50:1) as colorless syrup; yield 550 mg (41%); FD-MS *m/z* 1175 $(M+H)^+$.

Benzyl L-Alanyl-D-isoglutaminate *N*-Acylated with Benzyl 2-Acetamido-3-*O*-[(*R*)-1-carboxyethyl]-α-D-glucopyranoside 6-(2-Docosyltetracosyl Phenyl Phosphate) (14b). Compound **13b** (545 mg, 0.427 mmol) was dissolved in THF (20 ml) and hydrogenolyzed in the presence of Pd-black catalyst for 1 h. The product was dissolved without purification in THF (7 ml). L-Alanyl-D-isoglutamine benzyl ester trifluoroacetate (270 mg, 0.641 mmol), HONSu (74 mg, 0.64 mmol), triethylamine (90 μl, 0.65 mmol) and DCC (106 mg, 0.514 mmol) were added to the solution. The mixture was stirred at room temperature for 17 h, worked up as described for **14a**. Silica-gel column chromatography (50 g, $CHCl_3$–MeOH 20:1) followed by lyophilization from dioxane afforded colorless powder; yield 233 mg (37%); $[\alpha]_D^{22}$ +34.0° (*c* 0.51, $CHCl_3$). Found: C, 67.92; H, 9.47; N, 3.88%. Calcd for $C_{85}H_{141}N_4O_{14}P$: C, 68.01; H, 9.67; N, 3.73%.

L-Alanyl-D-isoglutamine *N*-Acylated with 2-Acetamido-2-deoxy-3-*O*-[(*R*)-1-carboxyethyl]-D-glucose 6-(2-Docosyltetracosyl Hydrogenphosphate) (3b) and Its Dibenzyl Ester. Compound **14b** (60 mg, 41 μmol) was dissolved in a mixture of THF (20 ml)–MeOH (10 ml)–AcOH (1 ml) and hydrogenolyzed in the presence of Pd-black under H_2 (7 kg cm^{-2}) for 48 h. After removal of the catalyst, PtO_2 was added to the filtrate and again hydrogenolyzed at 7 kg cm^{-2} for 12 h. The solvent was evaporated in vacuo, the residue was dissolved in $CHCl_3$–MeOH (10:1) and filtered through a Fluoropore filter disk (pore size 0.45 μm) to remove small particles of insoluble materials. After evaporation of the solvent in vacuo, the residue was lyophilized from a mixture of benzene–AcOH to give **3b** as colorless powder; yield 48 mg (quantitative); $[\alpha]_D^{21}$ +18° (*c* 0.12, $CHCl_3$–MeOH 5:1).

The product (27 mg) was dissolved in $CHCl_3$ (10:1, 30 ml), washed with 1M HCl and treated with phenyldiazomethane. Purification by preparative TLC on silica gel followed by lyophilization from dioxane afforded the dibenzyl ester as colorless powder; yield 12.2 mg. Found: C, 67.29; H, 10.03; N, 4.06; P, 1.92%. Calcd for $C_{79}H_{137}N_4O_{14}P \cdot 0.5H_2O$: C, 67.45; H, 9.89; N, 3.98; P, 2.20%.

Tumor Suppression and Regression Tests. Antitumor effects of the muramyl dipeptide derivatives against Meth-A fibrosarcoma were evaluated by two distinct test systems using syngeneic BALB/c male mice (5 week-old, purchased from Shizuoka Laboratory Animal Center, Shizuoka, Japan). The suppression test was conducted according to the method of Yamamura et al.[15]: Briefly, a mixture of 2×10^5 tumor cells and a test compound in phosphate-buffered saline was inoculated intradermally into the right flank of mice. In the regression test,[18] mice were injected the same number of the tumor cells as above on day 0 and then given intratumor injection of a test compound seven times every other days from day 7. In both tests, mice were sacrificed three weeks after tumor cell inoculation and tumor growth inhibition was measured.[16]

10) We first attempted to use 2-aminoethanol as a linkage between a long chain carboxylic acid and the phosphate moiety (see Ref. 8 above). However, when a 2-(acylamino)-ethyl phenyl hydrogenphosphate was subjected to coupling with the 6-hydroxyl group of muramic acid, the desired product could not be isolated in a pure state. It decomposed spontaneously losing the acyl moiety. Therefore we connected long-chain alcohols directly to the phosphate moiety in the present study.

13) When dibenzyl hydrogenphosphate was used in place of diphenyl hydrogenphosphate, the desired 6-(dibenzyl phosphate) could not be isolated. TLC analysis of the reaction mixture indicated the disappearance of the starting material **7** and the presence of a polar product which was assumed to have a phosphate function because of the positive reaction against Dittmer-Lester reagent. This result could be explained by assuming that the desired product was once formed but decomposed because of the instability of the benzyl ester function in the phosphotriester.

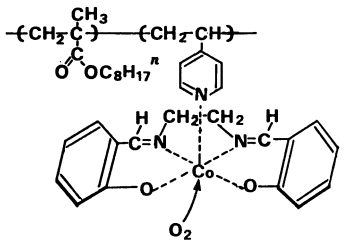
Dual-Mode Transport of Molecular Oxygen through the Membrane of the Poly(octyl methacrylate-co-4-vinylpyridine)(*N,N'*-disalicylideneethylenediaimine)cobalt(II) Complex

Hiroyuki NISHIDE, Manshi OHYANAGI, Hiroyoshi KAWAKAMI, and Eishun TSUCHIDA*
Department of Polymer Chemistry, Waseda University, Tokyo 160
(Received May 7, 1986)

Molecular oxygen transport through a polymeric membrane was enhanced in the membrane of poly(octyl methacrylate-co-4-vinylpyridine), complexed with (*N,N'*-disalicylideneethylenediamine)cobalt(II), which forms an oxygen adduct rapidly and reversibly. The cobalt complex in the membrane effectively acted as a fixed carrier on oxygen permeation. The oxygen-binding parameters determined spectroscopically were adequate to analyze the dual-mode transport model.

Recently there has been considerable interest in the production of oxygen-enriched air by the use of permselective membranes.[1] Metal complexes, such as iron porphyrin derivatives and cobalt Schiff base complexes, form oxygen adducts reversibly and have been successfully used for an oxygen-transporting fluid[2] and to an oxygen-separating liquid membrane.[3] However, an oxygen permselective membrane prepared from a polymer complexed with the metal complex acting as a fixed carrier on oxygen permeation has yet been reported. Recently the present authors preliminarily reported the preparation of polymer membranes containing the cobalt complexes as fixed carriers of oxygen which sorb and transport oxygen selectively by means of the Langmuir mode.[4,5] Drago and Balkus also recently reported that the cobalt-*N,N*-bis[3-(salicylideneamino)propyl]methylamine complex bound to a polystyrene membrane enhances the selectivity for oxygen permeation through a polystyrene membrane at low pressures.[6]

The present paper will describe the selective and dual-mode transport of molecular oxygen in a polymer complexed with a cobalt-Schiff base as a fixed carrier (Scheme 1). The polymer membrane was prepared by homogeneously complexing (*N,N'*-disalicylideneethylenediamine)cobalt(II) (CoS) to poly(octyl methacrylate-co-4-vinylpyridine)(POMP), whose sixth coordination site is vacant even in the solid state, to bind oxygen reversibly. Rapid and reversible oxygen binding to the polymer-bound complex (the fixed carrier) in the membrane was characterized in situ by means of spectroscopic methods. Oxygen permeation was measured in connection with the upstream oxygen pressure. The oxygen-permeation behavior through the membrane will be discussed in terms of the combination of the dual-mode transport theory and the spectroscopic data.



Scheme 1.

Experimental

Materials. (*N,N'*-disalicylideneethylenediamine)cobalt(II) (CoS) was synthesized as in the literature.[7] Poly(octyl methacrylate-co-4-vinylpyridine) (POMP) was obtained by the radical copolymerization of octyl methacrylate and 4-vinylpyridine, with azobisisobutyronitrile as an initiator. The vinylpyridine content and the molecular weight of POMP were determined to be 15 mol% and 150000 by elemental analysis and gel-permeation chromatography (with tetrahydrofuran as the solvent and polystyrene as the standard.), respectively. The toluene solution of POMP and CoS was carefully cast on a Teflon plate under an atmosphere without oxygen, followed by drying in vacuo, to yield a transparent and flexible membrane with thickness of 60 μm and containing 2.5 wt% CoS.

Spectroscopic Measurements. Reversible oxygen binding to the POMP–CoS complex in the membrane was observed with a spectral change in the visible absorption (using a highly sensitive spectrophotometer, Shimazu UV-2000). Rapid and reversible oxygen binding to the POMP–CoS complex in the membrane was also confirmed by means of flash photolysis (using a pulse and laser flash spectrophotometer equipped with a kinetic data processor; UNISOK FR-2000). The membrane was set at 45° to the laser-flash irradiation, and perpendicularily the rapid absorption change was recorded with a contact-type photomultiplier in order to cancel the noise signals caused by the scattering light.

Permeation Measurements. Oxygen and nitrogen permeation coefficients for various upstream gas pressures were measured with a low-vacuum permeation apparatus in the chamber for stable thermostating (Rika Seiki K-315 N-03).

Results and Discussion

Oxygen Binding to the Complex in the Membrane. The visible absorption spectrum of the transparent membrane is shown in Fig. 1. The color of the membrane was changed reversibly from brown to deep violet on exposure to oxygen and nitrogen. The spectral change in the membrane agreed with that of the polymer–CoS complex previously reported[2a]: UV and visible absorption maxima λ_{max}=555 nm (oxy: Co/O_2= 1/1 adduct), λ_{max}=345, 410 nm (deoxy: five-coordina-

tion), isosbestic points at 335, 423 nm.

The reversible oxy-deoxy spectral change occurred rapidly; e.g., for a 60 μm-thick membrane containing 2.5 wt% CoS, the oxygen-binding equilibrium was established within several minutes after the exposure to oxygen or in vacuo at 25°C. Although there have been several reports on the oxygen binding to a cobalt Schiff base complex or an iron porphyrin complex dispersed or bonded to the polymers in the solid state, oxygen adsorption and desorption to them occurred very slowly, even in a fine powder state with a large surface area.[8] It is important for a fixed carrier of oxygen that oxygen should be sorbed and desorbed rapidly in response to a partial oxygen pressure, even after fixation in a feasible membrane.

$$\text{POMP-CoS-O}_2 \xrightarrow{h\nu} \text{POMP-CoS} + \text{O}_2$$
$$\xrightarrow{k_{app}} \text{POMP-CoS-O}_2 \qquad (1)$$

$$\text{POMP-CoS} + \text{O}_2 \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} \text{POMP-CoS-O}_2 \qquad (2)$$

The photodissociation and recombination of the bound oxygen from and to the POMP-CoS complex in the membrane (Eq. 1) was successfully observed by means of pulse and laser flash spectroscopy. The oxygen-binding and -dissociation rate constants (k_{on} and k_{off} in Eq. 2) of the CoS complexed to the POMP membrane could be determined in situ as follows. By the changing in the monitoring wavelength from 300 to 600 nm, a differential spectrum before and after the flash photolysis was measured. The positive and negative extremes in the differential spectrum, 345 and 555 nm, were selected as the monitoring wavelengths for subsequent use (Fig. 2). These wavelengths agreed with the absorption maxima of the oxygen adduct and the deoxy complex in Fig. 1. The validity of these measurements is supported further by the following results: (i) The absorbance of 423 nm is kept constant before and after flash photolysis (Fig. 2); this wavelength agrees with the isosbestic point of the oxygen adduct and the deoxy complex as it shown in Fig. 1, and (ii) the absorbance changes followed at 345 and 555 nm are symmetric (Fig. 2).

The k_{on} and k_{off} values were estimated by means of pseudo-first-order kinetics and as given in Table 1. The k_{on} and k_{off} values of the CoS complexed to the POMP membrane were similar to those of the POMP-CoS complex in a toluene solution. This means that the CoS complex is active for the oxygen binding even, in the membrane, and that it acts as an effective fixed carrier of oxygen.

The oxygen-binding equilibrium constant ($K=k_{on}/k_{off}$) was determined by conducting oxygen-binding and -dissociation equilibrium measurements using Drago's equation.[9] The oxygen binding curves and the K values are given in Fig. 3 and Table 1. The K values of the complex in the membrane were much larger than those in the toluene solution. This result may be explained as follows: While the axial pyridyl group-ligation is in equilibrium in the solution system, the POMP-CoS complexation is completed and/or the pyridyl ligand in POMP is immobilized to

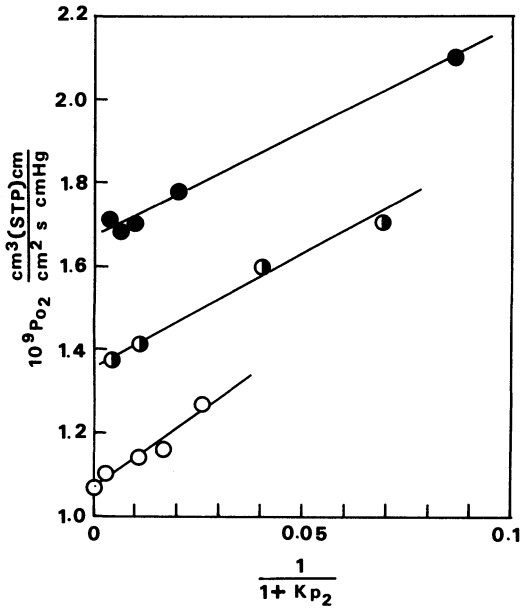

Fig. 5. Oxygen permeability in the POMP-CoS membrane plotted according to Eq. 3 at O: 25°C, ◑: 30°C, ●: 35°C.

CoS, which bring about a relatively stable oxygen adduct formation for the complex in the membrane. The thermodynamic parameters for the oxygen binding, as estimated from the temperature dependence of K, are also given in Table 1.

At any rate, the advantages of the membrane complexed with CoS are that the fixed carrier maintains its rapid and reversible binding capability of the penetrant even after fixation in the membrane and that the adsorption and desorption rates and the equilibrium constants of the penetrant to the carrier site can be evaluated in situ.

Oxygen Permeability in the Fixed Carrier Membrane. Figure 4 shows the effect of the upstream gas pressure (p_2) on the permeability coefficients (P_{O_2} and P_{N_2}) in a membrane containing 2.5 wt% CoS. Although the dependence of P on p_2 has been often reported for glassy polymers,[10] the glass-transition temperature was −8.0°C for the membrane containing CoS and the membrane was in a rubber state during permeability measurements. In fact, P_{N_2} was independent of $p_2(N_2)$, for the fixed carrier does not interact with nitrogen. P_{O_2} increases with a decrease in $p_2(O_2)$, which suggests that oxygen transport occurs by means of dual-mode transport[10] (Henry mode and additive Langmuir mode). That is, P is equal to the sum of a first term, representing the Henry mode, and the second term, for representing the Langmuir mode, which is a function of p_2:

$$P = k_D D_D[1+FR/(1+Kp_2)] \quad (3)$$

$$F = D_C/D_D,\ R = C_C'K/k_D$$

Here, P is the permeability coefficient, k_D is the solubility coefficient for Henry's law, D_D and D_C are the diffusion coefficients for Henry-type and Langmuir-type diffusions, C_C' is the saturated amount of oxygen reversibly bound to the binding site or the fixed carrier, K is the oxygen-binding and -dissociation equilibrium constant, and p_2 is the upstream gas pressure.

The effect of $p_2(O_2)$ on P_{O_2} was analyzed by using Eq. 3; that is, P_{O_2} was plotted against $1/(1+Kp_2)$ (Fig. 5). The plots show a linear relationship. The oxygen permeability in the membrane containing the complex as a fixed carrier can be explained in terms of the sum of the Henry mode attributed to the matrix and the Langmuir mode attributed to the fixed carrier, that is, the dual-mode theory.

The time lag (θ) for the oxygen permeation also depended on $p_2(O_2)$, as it shown in Fig. 6, in the same manner as the permeation coefficient. This behavior indicates that oxygen clearly interacts with the CoS complexed to the POMP membrane. This is further

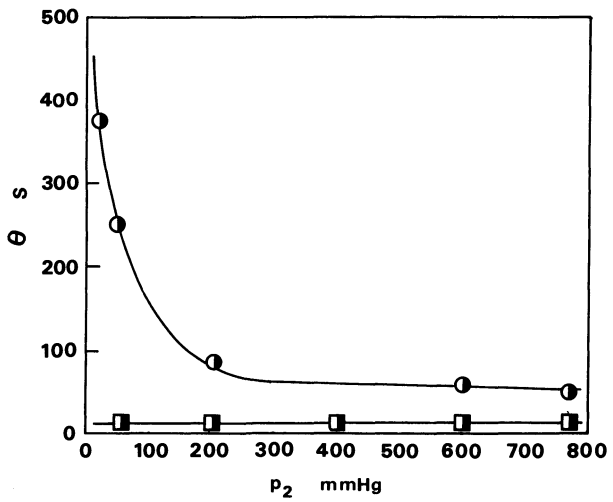

Fig. 6. Effect of upstream gas pressure on time lag for the POMP-CoS membrane. Oxygen: at ◑: 30°C, Nitrogen: at ◨: 30°C.

supported by the result that the value for the nitrogen permeation in the membrane containing the carrier is indepedent of the upstream gas pressures.

Although dual mode transport due to partial immobilization[10] has been reported for carbon-dioxide permeation in glassy polymers, the present authors have here verified the dual-mode transport by using a much simpler system.

Kinetics and Mechanism of Acid-Catalyzed Oxidation of Substituted Toluenes by Pyridinium Fluorochromate

Bharati BHATTACHARJEE, Manabendra Nath BHATTACHARJEE,* Mitra BHATTACHARJEE, and Apurba Krishna BHATTACHARJEE*,†

(Received November 25, 1985)

The kinetics of oxidation of substituted toluenes by pyridinium fluorochromate(VI) (PFC), $C_5H_5N\overset{+}{H}CrO_3F^-$, in aqueous acetic acid, in the presence of perchloric acid, have been studied. The main products are the corresponding aldehydes. While each of the oxidation is first order with respect to the oxidant, the rate is almost independent of the substrate concentration. The reactions depend on the first power of the concentration of acid. A kinetic isotope effect, $k_H/k_D=5.4$ at 30 °C, was observed. Electron-releasing groups were found to moderately facilitate the reaction, whereas the electron-withdrawing groups were found to have a retardation effect. Correlation with σ value yielded a ρ value of -2.0. The reaction does not induce polymerization of acrylonitrile. The effects of temperature and solvent compositions were studied and activation parameters evaluated. These and related data suggest that the initial reaction involves hydrogen abstraction forming an intermediate which subsequently produces the corresponding aldehyde.

Though the kinetics and mechanism of oxidation reactions using chromium(VI) oxidants are fairly well studied,[1–5] yet these reagents do not prove to be very satisfactory especially when some specific oxidations like oxidation of hydrocarbons, alcohols, thioethers etc. are desired. In recent years significant improvements were achieved by the use of pyridinium chlorochromate(VI) (PCC).[6–18] Of late, another effective chromium(VI) oxidant, pyridinium fluorochromate(VI) (PFC), $C_5H_5\overset{+}{N}HCrO_3F^-$, has been reported[19] which has several additional advantages over PCC, e.g., less acidity, selective oxidations under mild conditions, better solubility in nonaqueous solvents etc.

The oxidation of hydrocarbons is considerably less well understood and always present a mechanistic puzzle. In continuation with our interest in this subject,[20,21] we report in this investigation a detailed study of the kinetics and mechanism of the oxidation of side chains of mononuclear aromatic hydrocarbons such as toluene and substituted toluenes to their corresponding aldehydes. The common oxidizing agents (a) completely destroy the compound, (b) attack the nucleus, or (c) effect electrophilic substitution. The objective of the present investigation is not only to develop methods for oxidation of alkylarenes to the important aldehydes but also to get an insight to the reaction pathway.

Experimental

Materials. All the substrates were E. Merck grade and were purified by chromatography over alumina followed by distilation or recrystallization. Acetic acid (E. Merck) was distilled before use (bp 116 °C). Perchloric acid was a 'Baker analyzed' sample. $ArCD_3$ were prepared by the lithium aluminum deuteride reduction of their trichloromethyl derivative using the procedure reported earlier.[22] The materials used in the kinetic runs were repurified by chromatography and was shown to contain an insignificant amount of unlabeled, monodeuterio-, or dideuteriotoluenes, by the NMR spectra. Pyridinium fluorochromate (PFC) was synthesized by the method described in the literature.[19] The purity was checked by IR and UV analyses. The ionic strength of the medium was maintained constant by using sodium perchlorate, a Fluka purum product.

Kinetic Measurements. Both the substrate and oxidant solutions were thermostated and 30 °C for 3 h under nitrogen, and then mixed in equal volumes. The reaction mixture was homogeneous throughout the duration of the reaction. The reactions were followed by monitoring the absorption band at 444 nm, using a UV-VIS Beckmann spectrophotometer. This wavelength is the maximum absorption due to PFC, the absorption due to other reaction species being negligible. The reactions were performed under pseudo-first-order conditions by maintaining a large excess (10 times or greater) of the toluenes over PFC. Computations of the rate constants were made from the plot of log [PFC] against time. All infrared measurements were recorded on a Perkin-Elmer model 297 spectrophotometer and all NMR spectra were recorded on an EM-390 (Varian) 90-MHz spectrometer.

Product Analysis. The reactions were carried out in a manner similar to the kinetic experiments (using an excess of the substrate) and were allowed to proceed to completion in an atmosphere of nitrogen. The reaction mixture was diluted with ice-water saturated with sodium chloride, and was extracted several times with ether. The ether extract was washed with water, dried over anhydrous $MgSO_4$, and evaporated under reduced pressure. The material thus obtained was chromatographed over alumina, the toluene and xylenes being eluted with petroleum ether, and the corresponding aldehydes being eluted with 1:3 ether–petroleum ether. In each case, only toluene, xylenes, and the corresponding aldehydes were isolated. The aldehydes were characterized as the 2,4-dinitrophenylhydrazones, further characterized by using a standard method,[23] and confirmed by IR analyses.

Results and Discussion

Stoichiometry. Reaction mixtures containing an

excess of the oxidant (PFC) were allowed to react to completion under a nitrogen atomosphere at 30 °C and then analyzed spectrophotometrically for unchanged PFC and also by iodometric determination of the unreacted chromium(VI). The results gave a ratio of substrate and oxidant as 1:2, according to the equation:

$$XC_6H_4CH_3 + 2Cr^{6+} + H_2O \longrightarrow XC_6H_4CHO + 2Cr^{4+} + 4H^+ \quad (X=CH_3, OCH_3, Cl, Br). \quad (1)$$

This equation corroborates to a two-electron transfer and is in agreement with the proposal of Brown et al.,[24] who recently reported that the exact nature of the reaction product of PFC is not known. The idea is also supported from a recent report.[25] About 75—80% of the hydrocarbons were oxidized and about 80—85%, based on the hydrocarbons consumed, of the corresponding aldehydes were obtained.

Kinetic Results. The reactions were found to be first order with respect to the oxidant and near zero order in substrate (Table 1). The observed small but steady increase in the rate constant values for the hydrocarbons with increasing concentrations of the substrate and a plot of log k_1 against substrate concentrations show that the rates increase in very small fractions with the sequential increase in substrate concentration. This implies a probable complex formation between the substrate and the oxidant.

The order with respect to perchloric acid was determined in the same way (Table 1). A plot of log k_1 against log [H^+] gave a linear relationship with a slope of nearly unity. An attempt was made to correlate the rate data with the Hammett acidity function (H_o). Using H_o values from Wiberg's data,[5] plots of log k_1 against H_o gave slopes far different from unity. Thus under the present experimental conditions, it seemed appropriate to correlate the rates of these reactions with [H^+] rather than with H_o.

The rates of the reactions were found to be unaffected by changes in the ionic strength of the medium. Similar observations were also reported earlier.[26-28] The oxidation processes were also studied in solutions containing varying proportions of acetic acid and water (Table 2). The reaction rate decreases with increase in dielectric constant of the medium suggesting that more polar solvents may require longer reaction time for the oxidation.[15] A plot of log k_1 against the inverse of dielectric constants of the media is a straight line with positive slope and implies the occurrence of an interaction between a dipole and a positive ion.[29]

A kinetic isotope effect, k_H/k_D=5.4, was observed (Table 3), indicating that the rate-determining step

involved the cleavage of the carbon-hydrogen bond of the methyl group attached to the arene ring.

The oxidation was studied at different temperatures (vide Table 1) and the activation parameters have been evaluated (Table 5).

The effect of substituents was also determined (Table 4). A plot of the logarithm of the relative rates of reaction against the Hammett σ values gave a fair fit to a straight line with a slope of approximately −2.0 (Fig. 1).

The oxidation reaction, in an atmosphere of nitrogen, failed to induce polymerization of acrylonitrile. Further, no signal of radicals could be detected in the ESR spectra of each of the reactions carried out in a flow system (recorded on an E-4, Varian, EPR spectrometer). In control experiment without hydrocarbon, the concentration of PFC did not change.

The observed acid dependence of the reaction suggests that the reaction may be one between the alkylarenes and a protonated species of chromium(VI). This view is further supported[27] by the observance of linear plot of log k_1 against inverse of dielectric constant, and is in accord with the involvement of such species well established in chromium trioxide oxidation.[5,30] Again the observed ρ value (−2.0) does neither conclusively opt for a radical nor an ionic pathway. However, it implies that transfer of hydrogen nucleus is the essence of the mechanism of such reactions. The near constancy of the free energy of activation shows that the same mechanism is operative in all these oxidation processes.

Moreover, the order with respect to the substrate

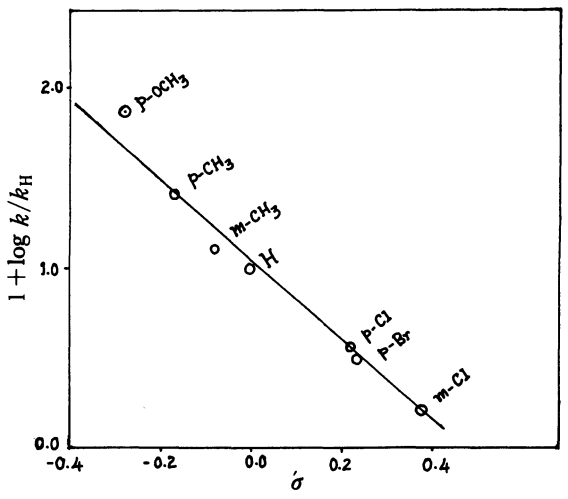

Fig. 1. Plot of log k/k_H against σ values for the oxidation of substituted toluenes at 30 °C (Hammett Plot).

(Table 1) is almost but not quite zero, suggesting a multistep reaction sequence via the formation of an intermediate complex between the substrate and PFC.

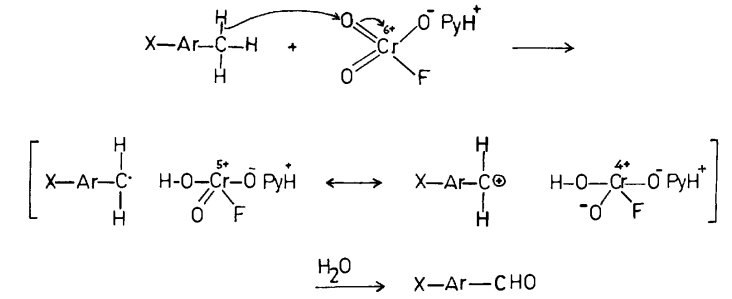
Though the reaction failed to give any significant ESR signal and to induce polymerization of acrylonitrile, the hydrogen abstraction mechanism cannot be ruled out as the initially-formed radical would be expected to react instantaneously with the Cr^{5+} species formed in the initial step. This observation is known to occur in the oxidation of saturated hydrocarbons by Cr(VI) compounds.[5,30] Again the large negative reaction constants (also ρ value) together with the substantial deuterium isotope effect indicate a considerable carbonium ion character in the transition state.

Thus the oxidation of the aromatic nuclei would appear to involve hydrogen transfer through an intermediate complex based on the following two mechanism:

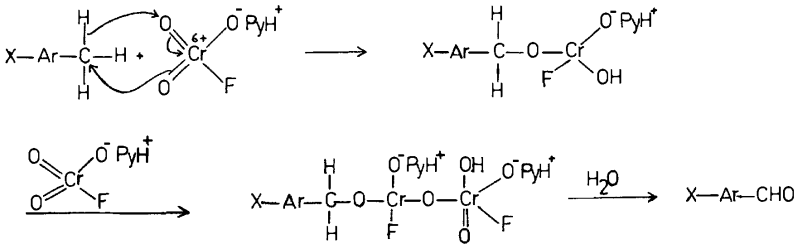
(i) The intermediate complex consisting of a radical and a Cr^{5+} species or a carbonium ion and a Cr^{4+} species (Sceheme 1). The ambiguity regarding the intermediate could be overcome by considering the complex as a resonance hybrid in which the carbon atom has both radical and carbonium ion characters. This type of intermediate has also been reported earlier.[21,31-34]

(ii) Alternatively, it could be via the formation of an Etard type[35] complex as the intermediate (Scheme 2). Though no precipitate of the complex was observed yet it may be argued that owing to immediate hydrolysis no isolation of the intermediate was possible. Similar observation has been reported earlier in the chromium trioxide oxidation in aqueous acetic acid solution.[36]

However, as the intermediate complex could not be isolated, neither magnetic susceptibility study nor ESR study of the complex could be performed.



Scheme 1.



Scheme 2.

Moreover, the formation of Etard complex is not very much favorable in acetic acid medium.[35] Thus it seems reasonable to believe that the oxidation mechanism shown in Scheme 1 is the likely one involved in the present cases. Since the hybrid would have a lower energy than either of the two pairs, the stability of the intermediate could be expected. A large negative entropy of activation obtained in the present study may also support the view.

So the overall oxidation of the substituted toluenes would appear to involve initial electron transfer from the substituent group of the side chain hydrocarbon to the oxidant and the subsequent reaction of the resulting intermediate with the nucleophiles in the reaction solution to the formation of the products.

The authors wish to thank the Instrumentation Centre of the Central Research School for Chemistry of the Hungarian Academy of Sciences, Budapest, for recording the ESR spectra. One of us (A.K.B.) expresses his gratitude to Miss A. M. Marbaniang, Principal, Lady Keane Girls' College, Shillong for granting permission to carry out the work.

Vibrational Spectrum of 2-Aminopyrazine

Arun Kumar KALKAR* and Comakshi C. ARS
Department of Chemical Technology, University of Bombay, Bombay 400 019, India
(Received January 16, 1986)

Infrared and polarized laser Raman spectra in the solid phase and in the solution phase in different solvents have been obtained within the spectral region between 4000 and 200 cm^{-1} and analyzed for the purpose of vibrational assignments. The impact of intermolecular hydrogen bonding on amino group frequencies has been discussed in length. The fundamentals arising out of aromatic nucleus in particular various assignments are consistent with predicted spectral changes due to the presence of strong electron-activating amino group resulting in considerable perturbation of the vibrational levels of "parent" molecule pyrazine.

Out of three diazabenzenes the optical spectroscopy of pyrazine has received considerable attention over the years. The pioneering work on vapor-phase ultraviolet spectrum by Innes et al.[1] is now well-known for the assignments of different transitions in n-π^* electronic transition. Nearly an ambiguous vibrational analysis of pyrazine has been also proposed by Innes et al.[2] and others.[3–13] Normal coordinate analysis of pyrazine has been carried out by many authors.[6,14,15] A complete and coherent vibrational spectral studies has been reported by Zarembowitch et al.[16] for pyrazine which supercedes all the previous reported work. By contrast, the spectroscopic studies of substituted pyrazines have received much less attention except the work on chloro-[17,18] and methylpyrazines.[18]

The present investigation is a part of the extensive program of work being undertaken on spectroscopic studies of various mono- and di-substituted pyrazines. Here the basic purpose of such studies is to study the effects of various electronic resonance interactions induced by different electron-activating and -deactivating substituent groups on electronic and vibrational transitions in pyrazine.

This paper is an endeavor to make precise assignments of the fundamental vibrational modes of 2-aminopyrazine, first time, based on our observations of the infrared and polarized Raman spectra of the solid and solution phases.

An introduction of an electron-activating group NH_2, at ortho position in pyrazine is expected to enhance the various electronic resonances by delocalizing and to some extent by relocalizing the (σ, π, n) electrons between parent molecule and substituent, resulting in the energy redistribution in various vibrational transitions. In the light of these electronic resonance interactions the assignments of different fundamentals have been made. Along with the infrared study of its isotopic modification containing ND_2 group, spectra with state of depolarization of Raman lines have been used in support of the assignments. In addition to these, the data from various papers and in particular by Innes et al.[2] and Zarembowitch et al.[16] on pyrazine,[4,8,11] and by Evans[19] and Tsuboi[20] on aniline have been extensively used.

Experimental

Chemically pure sample of 2-aminopyrazine obtained from M/s. Fluka AG was used without further purification. The solvents CCl_4, CS_2, and $CHCl_3$ used in recording infrared spectra, were of spectroscopic grade.

The infrared spectra of the sample in the solid state using KBr matrix and nujol mull were recorded. Various spectra were recorded carefully by changing the sample, and KBr powder mixture ratio and pressure used to prepare the KBr disc. The average peak values of different scan are used which were definitely differing by 2 to 3 cm^{-1}. Spectra were also recorded of polycrystalline form, formed on sodium chloride disc by using solvent evaporation method. The solution spectra in CCl_4, CS_2, and $CHCl_3$ were recorded at various concentrations using 0.1 mm path length solvent compensated liquid cells.

The isotopic exchange at amino group was obtained by various repeated exchange drying cycles, in a moisture-free nitrogen atmosphere by using 99.4% deuterated water (supplied by Bhabha Atomic Research Centre, Bombay), to obtain for the more complete deuteration. Absolute care was taken during deuterated sample mull preparation and spectra scan to avoid the rehydrogenation.

The maximum isotopic conversion, about 80%, was obtained by monitoring the relative intensity ratio of ND_2 bending mode to NH_2 bending mode.

All infrared measurements were carried out on a polystyrene film run calibrated Perkin-Elmer 397 spectrophotometer in the region 4000—400 cm^{-1}. A nicolet NIC-170SX (Model NIC-170SX) Fourier Transform interferometer was employed to scan the far infrared spectra in the region 400—200 cm^{-1}.

The Raman spectra were recorded on a Jobin Yvon Raman spectrophotometer equipped with double monochromator system consisting of concave halographic gratings with 2000 grooves per mm and one meter focal length. Spectra Physics Model 164 Ar^+ laser excitation at 488.0 nm was used as a excitation source. Calibration was done with the plasma lines from the laser.[21] Spectral widths of 3—5 cm^{-1} were used in recording the Raman spectra. The uncertainty of determination of wavenumber of around ±3 cm^{-1} in, infrared as well as in Raman spectra.

The samples were in the form of solid, sealed in glass capillaries. Polarization measurements were made by rotating the half-wave plate in two different, mutually perpendicular orientation.

Relatively low solubility, less than 25%, of 2-aminopyrazine in usual Raman solvents posed a major problem

to record solution phase Raman spectra. Finally, water was found to be the best Raman solvent in present case. Thus, essentially to ascertain the polarization character of fundamental vibrations obtained in solid phase, the solution phase polarized Raman spectra were recorded in aqueous solution.† Although the degree of polarization is high in aqueous phase rather than the solid phase, the polarizability confirmation in aqueous solution is the same as in the solid state. The uncertainty of measurement in depolarization ratio is of the order of ±0.02 in both the cases.

Results and Discussion

Molecular point group of 2-aminopyrazine has been reduced to C_s, due to inclusion of the nonplanar amino group, from its parent molecule which has D_{2h} point group and the vibrational fundamental modes become active as shown by diagram of correlation of point groups D_{2h}, C_{2v}, and C_s (Table 1).

The total thirty normal vibrations which are active both in the infrared and Raman spectra are divided into two categories:

i. 6 Vibrations of the NH_2 group

ii. 24 Vibrations of the aromatic nucleus

which reduces to 3a′+3a″ and 17a′+7a″ respectively. The Wilson[22] notation is used to label the various

†Few solution phase Raman spectra scans, were obtained on Spex Ramalog 1401 spectrometer from Spectroscopic Division, BARC, Bombay.

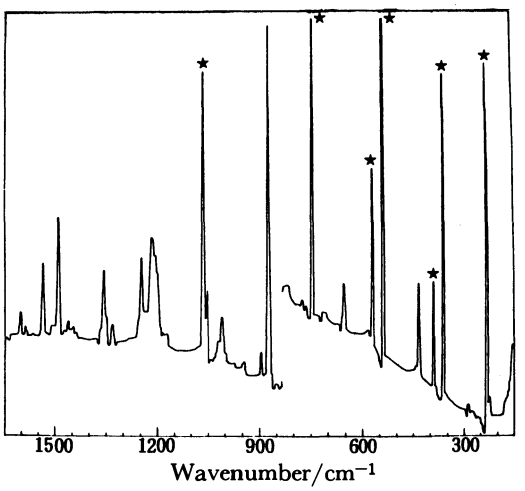

Fig. 2(a): Raman Spectrum of 2-aminopyrazine. Powder in capillary tube. Argon ion 480 nm excitation at 50 mW. Spectral slit width 5 cm⁻¹. ★ Plasma lines. (b): Raman spectrum of 2-aminopyrazine. Recorded on similar conditions as in Fig. 2a.

modes. As per symmetry selection rules, while the species a′ should give rise to polarized Raman lines, the species a″ will have depolarized Raman lines. However, exclusively on the basis of our depolarization measurement, it is interesting to note that some modes obey C_{2v} symmetry selection rules.

To facilitate the proper comparison in this paper, we follow the same set of molecular axis used by Innes et al.[2] for pyrazine, i.e. *Y* axis is taken perpendicular to the molecular plane and the *Z* axis through the two isoelectronic nitrogen atoms.

The infrared spectra recorded in KBr matrix and Raman spectra are reproduced in Figs. 1, 2(a), 2(b), and 3. The experimental observations and assignments are listed in Tables 2 and 3. Predominantly, the various band shapes have been used to relate the corresponding bands recorded in different phases to each other and listed in Table.[††] In following details, the different band values are from spectra recorded in KBr matrix.

Vibrations of the Amino Group: The spectra recorded at different concentrations clearly show that 2-aminopyrazine exhibits the dimer formation (Fig. 4) owing to intermolecular hydrogen bonding similar to 2-aminopyridine.

In general, it has been well established that vibrational spectra are significantly influenced by hydrogen-bond formation. This is particularly noticeable for stretching modes which are displaced to lower frequency upon association. This lowering of frequencies may be attributed to a decrease in force constant arising out of expected increased bond lengths upon association.[24]

All of the six normal fundamental vibrational modes arising out of the $-NH_2$ group and its isotopic modification containing the $-ND_2$ group motions have been assigned and listed in Table 2 along with aniline and 2-aminopyridine for comparison.

The 3500—3400 and 3250—3150 cm^{-1} regions shown two discrete sets of broad band profiles. Clearly, the bands at 3410 and 3510 cm^{-1} are due to symmetric (ν_s) and antisymmetric (ν_{as}), N-H stretches. It is reasonable to assume that the other two bands at 3165 and 3340 cm^{-1} are principally due to similar modes of

vibration in associated molecules. The corresponding bands in $-ND_2$ species are at 2485 and 2520 cm^{-1}, and 2400 and 2438 cm^{-1} for monomer and dimer respectively. In comparison to 2-aminopyridine[25,26] the large shift in bonded symmetric stretching frequency in present case may be due to the increased $=NH_2^+$ electronic nature[27] of the molecule resulting in increased strength of hydrogen bonding.[24] An advanced anharmonicity of 103 cm^{-1} is observed and calculated[28] bonded symmetric stretching viration resulting in extensive ∠HNH angle (143°)[29] opening very well reflects the stronger intermolecular hydrogen bond in present case.

Obviously, the effects of this strong intermolecular bond formation will be most pronounced on the various valence angle deformation modes rather than the resulting electronic activity out of animo group. Although, the enhanced electron attracting character of aromatic nucleus also contributes in raising the frequency and intensity markedly. The established range for NH (δ) scissoring mode is 1650—1590 cm^{-1} and in aniline[19,20] and 2-aminopyridine[25,26] this mode has been assigned to a band at 1620 cm^{-1}. One of the strongest band in present spectrum at 1662 cm^{-1}, with a shoulder at 1650 cm^{-1} has been assigned to this mode. The corresponding ND_2 species mode is found at 1168 cm^{-1}.

Under the same considerations, given for the scissoring mode, the other low frequency modes of the amino group, NH_2 twisting and wagging modes are assigned to the bands at 1210 and 685 cm^{-1} which shift to 1070 and 480 cm^{-1} respectively in the deuterated analog. The corresponding Raman band for twisting mode is at 1213 cm^{-1} and is polarized and weak in intensity.

The band at 218 cm^{-1} with a corresponding weak depolarized Raman band at 218 cm^{-1} is assigned to the low energy torsional motion around the C–N bond with its first overtone located at 431 cm^{-1}. The present torsional frequency agreement, with the value for 2-aminopyridine,[26,30] aniline,[31,32] and *m*-halo-substituted anilines[33] is excellent, and virtually localize the vibrational mode around 200—220 cm^{-1} in these molecules.

A particular aspect concerning the effect of the general anharmonicity induced by torsional motion of the amino group in present case has been visualized in enhanced intensity of combination bands with different amino internal deformation modes which even may contribute to frequency shifts to these characteristic group fundamentals.

Aromatic Nucleus Vibrations: Taking into account the effect of amino group substitution in present case, the phenyl nucleus vibrations are well identified and assigned by reference to instructive comprehensive analysis of the corresponding spectra of pyrazine[2,16] and the present work on 2-amino-d_2-pyrazine. The details are listed in Table 3 which is self explanatory. Only following few comments on spectral characteristic observations specially regarding

R(S)-Raman solid phase; R(L)-Raman liquid phase in H_2O; P-Polarized; dp-depolarized; ν-Stretching; β-in-plane deformation; γ-out-of-plane deformation; σ_L-Depolarization ratio liquid phase.

the various corresponding infrared inactive vibrations belonging to Au, B_{2g}, and B_{3g} symmetry species in pyrazine are worth mentioning.

The two infrared inactive Au species fundamentals are little effected in intensity gain due to reduction in symmetry in present case and are identified with weak bands at 355 cm^{-1} (ν_{16a}) and 955 (ν_{17a}) without corresponding Raman lines. Regarding the assignments of the B_{2g} species, planar Raman active fundamentals, our observation of the polarized 651 cm^{-1} Raman line strongly supports the 630 cm^{-1} weak band in infrared for ν_{6b} fundamental. The other two fundamentals ν_{8b} and ν_{7b} in this class show appreciable gain in intensity thus, it seems are sensitive to lowering of the symmetry. The strong infrared bands at 1540 and 3040 cm^{-1} with corresponding 1535 and 3045 cm^{-1} analogous Raman lines have been assigned to these fundamentals. Both the Raman lines are depolarized in character.

The remaining two Raman active nonplanar B_{3g} fundamentals have been identified with the weak infrared bands at 745 (ν_4) and 895 cm^{-1} (ν_5). The choice of these two infrared bands is based on the corresponding Raman lines at 755 and 895 cm^{-1} and their intensities in expected region. Here, the Raman lines are polarized in character.

Although our assignments for aromatic nucleus part are generally compatible with recent publications[11,16] there are some notable differences particularly in case of vibration ν_{14}. We prefer to localize this fundamental vibration at 1350 cm^{-1} with corresponding depolarised Raman line at 1355 cm^{-1} rather than 1149 cm^{-1} as proposed for pyrazine by Sbrane et al.[11] and Zarembowitch et al.,[16] spectrum does not show any strong band in the proposed region of 1150 cm^{-1}.

It is, however, important to note that the state of polarization of some of the Raman lines do not behave as per present C_s symmetry rules. Although, the symmetry of the molecule is C_s, an analogous assignments, considering higher C_{2v} symmetry, have been proposed in few cases. Assigning the vibrations in this way will give rise to an occasional depolarized B_1 Raman lines. Some of the vibrations belongs to B_{3u} and B_{2g} species fall under such characteristic class. This induced non-behaviorable character of these vibrations may be attributed to the coupling between the various NH_2 deformation modes, which ultimately results in various combination bands, particularly in the 3000—1700 cm^{-1} spectral region.

As mentioned earlier, 2-aminopyrazine form a dimer due to intermolecular hydrogen bonding. Various spectra recorded at low and higher concentrations, show that this bonding does not make a pronounced effect on the vibrational frequencies arising out of aromatic nucleus. In general the steady shift towards higher frequency side of these various fundamental modes in comparison to 2-aminopyridine clearly indicates that the heterocyclic aromatic nucleus here is more strong electron-accepting in nature and thus conjugate more with the amino nitrogen. However, the similarity of infrared spectrum with 2-aminopyridine is instructive.

In case of ring vibrations the behavior analogy with monosubstituted benzenes is remarkable. The symmetric hexagonal breathing mode ν_1 and trigonal breathing mode ν_{12} are closely coupled with the vibrational modes of the substituent groups in substituted benzens and has been discussed in detail.[34-36] Considering amino group as a light substituent,[34] one expect vibration ν_1 to show large decrement while ν_{12} remains relatively unchanged as is actually observed in present case.

Similar is the case with the degenerate ν_6 ring distortion vibration, of which the totally symmetric component decreases while the asymmetric component is somewhat localized.

Remaining other ring vibrations which get coupled predominantly with C-H in-plane deformation rather than other C-X vibrations and so are little effected on substitution.

We acknowledge the financial support made available under 19th Departmental Research Grant 1983—84, Department of Chemical Technology, University of Bombay, for this research project.

We are also thankful to Dr. V. B. Kartha, Spectroscopy Division, B. A. R. C., Bombay for providing necessary facilities for solution phase Raman Spectra.

Solvent Extraction Separation of Germanium with Aliquat 336S from Citric Acid Solutions

Chandrashekhar P. VIBHUTE and Shripad M. KHOPKAR*
Department of Chemistry, Indian Institute of Technology, Bombay 400 076, India
(Received April 22, 1985)

Germanium was quantitatively extracted with 0.1 mol dm^{-3} Aliquat 336S in xylene from 1×10^{-3} mol dm^{-3} citric acid solution adjusted to pH 3.5. It was stripped with 0.5 mol dm^{-3} hydrochloric acid and determined spectrophotometrically at 530 nm as the complex with phenylfluorone. It was effectively separated from binary as well as ternary mixtures by taking advantage of the difference in the stability of the citrate complexes with metal ions in mineral acids. The method was applied to the determination of germanium in coal fly ash.

Germanium was extracted with carbon tetrachloride.[1] Tributyl phosphate in toluene could extract germanium in the presence of salting out agent.[2] The extraction was not quantitative with diisopropyl ether.[1] Trioctylamine in butanol[3] or with oxine[4] in chloroform was also used for extraction of germanium. Germanium was separated from tin and lead with Amberlite LA-1 in xylene.[5] Trioctylamine in kerosene was used for the extraction of germanium from oxalic acid,[6,7] however germanium was not separated from associated elements.

This paper describes, therefore, a systematic investigation on the solvent extraction of germanium with Aliquat 336S from citric acid solutions. Novel methods are developed for the separation of commonly interfering ions. The method is applied to the determination of germanium in a standard coal fly-ash sample.

Experimental

Apparatus and Reagents. Spectrophotometer GS866C (ECIL, India) with matched Corex glass cells, Orion Research Microprocessor ion analyzer/901 (Orion Ltd., USA), with glass and calomel electrodes and Wrist action flask shaker (Toshniwal, India) were used.

A stock solution of germanium was prepared as follows: About 0.32 g of germanium dioxide was fused with equal amount of sodium hydroxide in a platinum crucible. The cooled mass was extracted with water and the solution was neutralized with hydrochloric acid. It was then made up to 100 cm^3 with water and standardized gravimetrically.[8] It contained 2.2 mg cm^{-3} of germanium. The working solution containing 22 μg cm^{-3} of germanium was prepared by exact dilution with water. Phenylfluorone (BDH, AnalR) (0.05% ethanolic solution), Gelatin (1% aqueous solution), Amberlite LA-1, Amberlite LA-2 (Rohm and Hass, Co. USA), Aliquat 336S (General Mills Ltd., England) and TOA (Riedel-Haen, Germany) were used without further purification. The extractant was converted into the citrate form as described earlier.[9]

General Procedure. To an aliquot of solution containing 22 μg of germanium, 5 cm^3 of 0.01 mol dm^{-3} citric acid was added. The pH of the solution was adjusted to 3.5 with 0.01 mol dm^{-3} sodium hydroxide or citric acid. The total volume of the aqueous phase was made up to 10 cm^3 and the solution was transferred to a separatory funnel. It was equilibrated with 10 cm^3 of 0.1 mol dm^{-3} Aliquat 336S in xylene for 5 min on wrist action flask shaker. After allowing the phases to settle and separate the aqueous phase was discarded and the organic phase was shaken with 10 cm^3 of 0.5 mol dm^{-3} hydrochloric acid to strip germanium. To the solution thus obtained 1 cm^3 of 1% gelatin and 2 cm^3 of 0.05% phenylfluorone in ethanol were added and the volume was made up to 25 cm^3 with distilled water. The absorbance of the yellow orange colored complex was measured at 530 nm against the reagent blank. The concentration of germanium was obtained from a calibration curve.[10]

Results and Discussion

Effect of pH. The pH for the quantitative extraction was ascertained by carrying out extractions between pH 1.0 and 8.0 with various liquid anion exchangers (Fig. 1). The extraction of germanium

5.00	93.1	13.5
6.25	96.6	29.5
7.50	99.9	999.0
8.75—10.0	99.9	999.0

Table 2. Effect of Citric Acid Concentration
Ge=22 μg; pH=3.5

Concentration of citric acid 10^{-4} mol dm^{-3}	Extraction/%	Distribution ratio
1	56.0	1.3
2	74.5	2.9
3	79.6	4.9
4	85.8	6.0
5	91.0	10.1
6	98.1	51.6
7	99.3	141.9
8-10	99.9	999.0

into xylene commenced below pH 1.0 for all the extractants except Amberlite LA-2. The extraction was quantitative from pH 3.0 to 6.0 with Aliquat 336S, pH 2.0 to 3.0 with Amberlite LA-2, pH 5.0 to 5.5 with Amberlite LA-1, and pH 4.0 to 4.5 with TOA in xylene. As the optimum pH range for the extraction was fairly broad. Aliquat 336S was used in further investigation. On the contrary the pH was quite broad (pH 3.0—6.0) with Aliquat 336S. Therefore Aliquat 336S was selected for further work.

Effect of Aliquat 336S Concentration. Germanium was extracted with varying concentrations of Aliquat 336S (1×10^{-2}—10^{-1} mol dm^{-3}) in xylene, while other factors were held at constant (Table 1). The extraction was almost quantitative when more than 7.5×10^{-2} mol dm^{-3} Aliquat 336S was used. Therefore 1×10^{-1} mol dm^{-3} Aliquat 336S was preferred throughout this investigation.

Effect of Citric Acid Concentration. The optimum concentration for the complete extraction was ascertained by extracting germanium from aqueous solution containing 1×10^{-4} to 10×10^{-3} mol dm^{-3} citrate. The extraction was incomplete below 5×10^{-4} mol dm^{-3} but quantitative above 7×10^{-4} mol dm^{-3} citrate (Table 2).

Effect of Various Diluents. A solution of 0.1 mol dm^{-3} Aliquat 336S was used in various diluents, such as, benzene, toluene, xylene, *n*-hexane, cyclohexane, carbon tetrachloride, chloroform, or nitrobenzene. The organic to aqueous phase volume ratio was maintained at 1:1. As shown in Table 3 chloroform and nitrobenzene are not effective as diluents perhaps due to their high polarities. The extraction was almost quantitative when xylene, *n*-hexane, cyclohexane, and carbon tetrachloride were used as diluents.

Effect of Stripping Agents. Germanium was stripped, after extraction, with 10 cm^3 of various concentrations of mineral acids and alkalis. Hydrochloric acid (0.5—4.0 mol dm^{-3}) and nitric, sulfuric, and hydrobromic acids (0.5—8 mol dm^{-3}) were capable of stripping germanium quantitatively. Similarly sodium hydroxide (0.1—2.0 mol dm^{-3}) or sodium carbonate (0.5—2.01 mol dm^{-3}) was also effective stripping agents. Hydrochloric acid was selected as a stripping agent considering its use in the separation and determination of germanium (Table 4).

Table 3. Effect of Various Diluents
Ge=22 μg, Citrate concentration=0.001 mol dm^{-3}, pH=3.5

Diluent	Dielectric constant	Extraction %	Distribution ratio
Benzene	2.28	94.0	15.6
Toluene	2.38	95.6	21.7
Xylene	2.30	99.9	999.0
Hexane	1.89	99.0	99.0
Cyclohexane	2.05	99.3	141.8
Carbon tetrachloride	2.24	98.3	57.8
Chloroform	4.8	45.6	0.6
Nitrobenzene	35.5	88.1	7.4

Nature of Extracted Species. The composition of the extracted species was investigated by plotting the logarithm of the distribution ratio of germanium against the logarithm of the concentration of Aliquat 336S at a constant citric acid concentration and the logarithm of the distribution ratio against the logarithm of the citric acid concentration at a constant concentration of Aliquat 336S. Linear relationship were obtained with slopes of 1.32 and 1.27, respectively. It is probable that the extracted species is $[R_4N^+\{Ge(OH)_2(Cit)^-\}]$. This postulation is supported by the observation of Pozhariskii et al.[12] who used trioctylamine in the extraction of germanium from citric and tartaric acid media.

Separation of Germanium from Foreign Metal Ions. Methods for the separation of germanium from foreign metal ions were investigated in the light of the difference in their complex forming abilities with citrate. Metal ions forming no complex or very weak complexes with citrate were not extracted and readily separated from germanium. A few metal ions forming weak complexes with citrate were readily removed from the organic extractant by washing with distilled water before stripping of germanium. Some metal ions forming stable complexes with citrate were strongly retained in the organic phase but these were effectively separated from germanium by using suitable stripping agents. Examples of the separation of germanium

from synthetic binary and ternary mixtures are given in Tables 5 and 6.

Application for the Determination of Germanium in Coal Fly Ash. About 0.5 g of a standard coal fly ash sample was dissolved in a mixture (10 ml cm^{-3}) of aqua regia and hydrofluoric acid (1:1) in a Teflon beaker. After removal of the excessive acids the content was dissolved in dilute hydrochloric acid and the solution was made up to 50 cm^3 [11] with distilled water. An aliquot of this solution was equilibrated with 10 cm^3 of 0.1 mol dm^{-3} Aliquat 336S in xylene as described above. Copper, cadmium, zinc, and cobalt were also extracted but these metals were readily removed by washing the extract with distilled water; thorium was then stripped with 6 mol dm^{-3} hydrochloric acid and finally germanium with 3 mol dm^{-3} hydrochloric acid. With duplicate determinations, the amount of germanium found was 18.7 and 18.5 ppm against the standard value of 19.0 ppm.

The separation of germanium from copper, zinc, lead, and antimony is interesting, as these elements are usually associated with each other in minerals. Similarly the separation of germanium from gallium, indium, and thallium is important because of their

Kinetics and Mechanism of Anation of Pentaammineaquarhodium(III) Ion by Malonate in Weakly Acidic Media[1)]

Chinmay CHATTERJEE* and Aya Singh BALI
Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400 076, India
(Received August 5, 1985)

Anation of pentaammineaquarhodium(III) ion by malonic acid, hydrogenmalonate, and malonate ions to form the hitherto unknown pentaamminemalonatorhodium(III) complex has been studied as a function of $[H^+]$ for the acidity range $1.4 \leq pH \leq 5.0$, [total malonate], 0.3 mol dm^{-3} in the temperature range of 60 to 80 °C and at ionic strength 1.0 mol dm^{-3} adjusted with sodium perchlorate. Ion pairing is not significant between the complex and malonic acid but kinetically identifiable with hydrogenmalonate and malonate ions. Ion pair association constants for the hydrogenmalonate (Q_1) and malonate ion (Q_2) at 60 °C are 1.8 and 7.5 $mol^{-1}dm^3$ respectively. The values of the rate constants at 60 °C for anation by malonic acid, hydrogenmalonate, and malonate ions are $k_0=3.04\pm0.2\times10^{-5}$ $mol^{-1}dm^3s^{-1}$, $k_1=1.73\pm0.2\times10^{-4}$ s^{-1}, and $k_2=3.46\pm0.4\times10^{-4}$ s^{-1}. The activation parameters, ΔH^* and ΔS^* corresponding to anation rate constants, k_0, k_1, and k_2 are reported and the results discussed with reference to analogous reactions of Rh(III) and Co(III).

The kinetics and mechanism of replacement of the aqua ligand in pentaammineaquacobalt(III) ion by various anionic ligands have been the subject of several investigations. In contrast, limited data exist for the analogous reactions of corresponding rhodium(III) substrate and receiving attention in recent years, as these provide important mechanistic information for a comparative analysis of the reactivity of related octahedral and isoelectronic systems. Though the anation reactions of analogous complexes of Co(III) and Rh(III) often exhibit similar rate law, they actually proceed by different mechanism due to bond formation by the entering group being more significant in the case of rhodium than in cobalt as evident from water exchange and anation reactions of the complexes of the type $[M(NH_3)_5(OH_2)]^{3+}$, where M=Co(III)[2-10] and Rh(III).[11-17] The general applicability of the pronounced nucleophilic participation of the anating ligand in the transition state can be tested by extending the study to the anation reaction of $[Rh(NH_3)_5(OH_2)]^{3+}$ by carboxylate ligands which, so far, have been only sparingly studied.[18-20] In the present work, anation of pentaammineaquarhodium(III) ion by malonate has been presented. The reaction has been studied in aqueous malonate buffer of varying pH in order to assess the anation rate profile of malonic acid, hydrogenmalonate, and malonate ions. The results presented here show indeed a difference in mechanistic behavior between Co(III) and Rh(III).

Experimental

Materials and Reagents. Pentaammineaquarhodium(III) perchlorate was prepared according to standard procedures[21)] and purified by recrystallization. Chemical analysis confirmed the purity, as did a comparison with published UV-visible spectral data.[22)]

Pentaamminemalonatorhodium(III) perchlorate was prepared for the first time by digesting an aqueous solution of pentaammineaquarhodium(III) perchlorate with slight excess of malonic acid at 80 °C for 3 h followed by slow evaporation of the reaction mixture to one third of its original volume. Aqueous perchloric acid (30%) was added to the ice-cold reaction mixture to obtain the desired product as perchlorate salt. The white crystals that separated were filtered, washed successively with cold dilute perchloric acid, ethanol, and ether. The product was finally dried in air. The purity of the complex was ascertained by elemental analysis. Found: C, 7.30; H, 3.62; N, 14.20%. Calcd for $[Rh(O_2CCH_2CO_2H)(NH_3)_5](ClO_4)_2$: C, 7.35; H, 3.67; N, 14.29%.

The positions and intensities of the d-d bands of the complex (λ_{max} 322 nm, ε 165 $dm^3mol^{-1}cm^{-1}$, λ_{max} 265 nm, ε 130 $dm^3mol^{-1}cm^{-1}$) corresponding to $^1A_{1g}\rightarrow{}^1T_{1g}$ and $^1A_{1g}\rightarrow{}^1T_{2g}$ transitions respectively match well with those of the pentaamminecarboxylatorhodium(III) (N_5O type) complexes. Infrared spectrum of Nujol mull of hydrogenmalonato complex reveals two strong bands at 1630 and 1725 cm^{-1} assignable to carbonyl asymmetric stretching frequencies of coordinated and free carboxyl groups in the complex. Presence of one equivalent of titrable proton unambigously confirms the mode of bonding of coordinated malonate ligand in the molecule. Other chemicals used were of reagent grade quality or prepared in the pure state by suitable methods.

Rate Measurements. The kinetic measurements were performed employing a Varian Superscan-3UV-visible spectrophotometer. The acidities of the experimental solutions were attained by the addition of sodium hydroxide and perchloric acid as the case may be and measured by means of a PHM 64 (Radiometer Copenhagen) research pH meter. The course of the anation reaction of pentaammineaquarhodium(III) ion with malonate over the acidity range $1.4\leq pH\leq5.0$, for total malonate concentration up to 0.3 mol dm^{-3} in the temperature range of 60 to 80 °C was followed by measuring the increase in absorbance at 322 nm, where extinction coefficients of $[Rh(O_2CCH_2CO_2H)(NH_3)_5]^{2+}$ and $[Rh(NH_3)_5(OH_2)]^{3+}$ ions were 165 and 102 $dm^3mol^{-1}cm^{-1}$ respectively. The rate studies were made at ionic strength 1.0 mol dm^{-3} ($NaClO_4$) by a batch sampling technique,[20)] with the thermostat controlled to ±0.1 °C. The composition of the experimental solutions was such that the pseudo-first-order rate law was applicable and the pseudo-first-order rate constants, k_{obsd}, were computed from the gradients of the linear plots of $\log(A_\infty-A_t)$ vs. t by means of a least-squares program. Reported k_{obsd} values represent the average of at least duplicate runs which agreed within ±3%.

Results and Discussion

Pentaammineaquarhodium(III) ion reacts with malonic acid, hydrogenmalonate ion, and malonate ion to form either $[Rh(O_2CCH_2CO_2H)(NH_3)_5]^{2+}$ or $[Rh(O_2CCH_2CO_2)(NH_3)_5]^{+}$ complex depending on the pH of the solution. The interpretation of the rate data, however, was not complicated by the presence of $[Rh(O_2CCH_2CO_2)(NH_3)_5]^{+}$ species at high pH, as it showed absorbance identical to that of protonated one at the experimental wavelength. In order to assess the anation rate profiles of malonic acid, hydrogenmalonate, and malonate ions, the reaction has been studied over a wide enough pH range to encompass all possible acidic and basic forms of anating species. The participation of $[Rh(NH_3)_5(OH)]^{2+}$ species is essentially eliminated by fixing the upper pH limit at 5.0 (pK_a of $[Rh(NH_3)_5(OH_2)]^{3+}$ at μ, 1.0 mol dm^{-3}=6.94[23]). Acid dissociation constant of $[Rh(O_2CCH_2CO_2H)(NH_3)_5]^{2+}$ at 25 °C and ionic strength 1.0 mol dm^{-3} was determined from conventional pH titrations employing a PHM 64 research pH meter. The pK_a value was estimated as 3.8±0.05, which is significantly lower than that of $CH_2C_2O_4H^-$ ion. This is ascribed to an increase in acidity of the ligand when coordinated to a metal ion. Values of the pseudo-first-order rate constant (k_{obsd}) under different sets of experimental conditions are summarized in Table 1. Representative plots of k_{obsd} versus malonate concentration for varying pH at 60 °C are illustrated in Fig. 1. The plots are noted to be linear at low pH, while curvature becomes apparent at pH≥2.5. Deviation from linearity at pH 2.5 and above suggests that the reactant association is not significant between aqua complex and malonic acid but kinetically identifiable with hydrogen malonate and malonate ions respectively, as the concentration of the latter species increases with increase in pH of the solution. Similar trends in k_{obsd} have also been noted at other experimental temperatures. The linearity of the plot at low pH suggests simple second-order kinetics for anation by malonic acid, as also reported for cobalt(III) analog.[10] The anation by basic forms of the anating ligand is thus proposed to involve the formation of ion pairs in a preequilibrium step followed by the rate determining interchange of coordinated aqua ligand by carboxylate ion. Consistent with the experimental results the anation scheme may be depicted as follows:

$$[Rh(NH_3)_5(OH_2)]^{3+} + CH_2C_2O_4H_2 \xrightarrow{k_0} [Rh(O_2CCH_2CO_2H)(NH_3)_5]^{2+} + H_3O^+$$

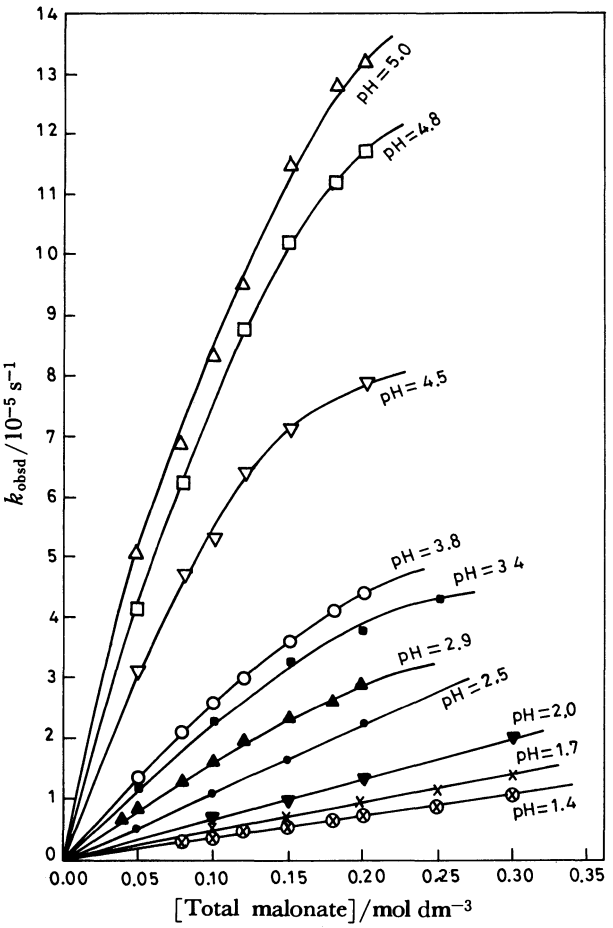

Fig. 1. k_{obsd} vs. [Total malonate] for various pH at 60.0±0.1 °C.
[Complex]; 0.002 mol dm^{-3}, μ; 1.0 mol dm^{-3}.

$$[Rh(NH_3)_5(OH_2)]^{3+} + CH_2C_2O_4H^- \overset{Q_1}{\rightleftharpoons} [Rh(NH_3)_5OH_2^{3+}\cdot CH_2C_2O_4H^-]$$

$$[Rh(NH_3)_5OH_2^{3+}\cdot CH_2C_2O_4H^-] \xrightarrow{k_1} [Rh(O_2CCH_2CO_2H)(NH_3)_5]^{2+} + H_2O$$

$$[Rh(NH_3)_5(OH_2)]^{3+} + CH_2C_2O_4^{2-} \overset{Q_2}{\rightleftharpoons} [Rh(NH_3)_5OH_2^{3+}\cdot CH_2C_2O_4^{2-}]$$

$$[Rh(NH_3)_5OH_2^{3+}\cdot CH_2C_2O_4^{2-}] \xrightarrow{k_2} [Rh(O_2CCH_2CO_2)(NH_3)_5]^{+} + H_2O,$$

where k_o signifies second order rate constant for anation of $[Rh(NH_3)_5(OH_2)]^{3+}$ by malonic acid, k_1, Q_1, and k_2, Q_2 are the rate and association constants of the hydrogenmalonate and malonate ion pair respectively. The theoretical rate law in accordance with the suggested scheme fits the equation

$$k_{obsd} = -\,d\ln[Rh(III)]_T/dt = \frac{k_0[CH_2C_2O_4H_2]+k_1Q_1[CH_2C_2O_4H^-]+k_2Q_2[CH_2C_2O_4^{2-}]}{1+Q_1[CH_2C_2O_4H^-]+Q_2[CH_2C_2O_4^{2-}]}. \quad (1)$$

At pH<3.5, the contribution of terms involving $CH_2C_2O_4^{2-}$ is too small to have any meaningful significance, and hence Eq. 1 reduces to

$$k_{obsd} = \frac{k_0[CH_2C_2O_4H_2]+k_1Q_1[CH_2C_2O_4H^-]}{1+Q_1[CH_2C_2O_4H^-]}. \quad (2)$$

At low pH, where mainly $CH_2C_2O_4H_2$ is present, the anation reaction follows simple second-order kinetics. Under these conditions, Eq. 2 can be simplified to

$$k_{obsd} = k_0[CH_2C_2O_4H_2]+k_1Q_1[CH_2C_2O_4H^-], \quad (3)$$

as $1+Q_1[CH_2C_2O_4H^-]\simeq 1$. The observed rate data under these conditions followed second-order kinetics such that

$$k_{obsd} = k_{an}[\text{total malonate}], \quad (4)$$

where k_{an} is the second-order rate constant. The Eqs. 3 and 4 on rearrangement leads to

$$k_{an} = k_0 + (k_1Q_1-k_0)\frac{[CH_2C_2O_4H^-]}{[\text{total malonate}]}. \quad (5)$$

The values of k_o at each experimental temperature were obtained from the intercept of k_{an} versus $[CH_2C_2O_4H^-]/[\text{total malonate}]$ plot. The Eq. 3 on rearrangement can be written as

$$\frac{k_{obsd}-k_0[CH_2C_2O_4H_2]}{[CH_2C_2O_4H^-]} = k_1Q_1-Q_1k_{obsd}. \quad (6)$$

The interchange rate constant (k_1) and association constant (Q_1) at each experimental temperature were evaluated from the slope and intercept of $\{k_{obsd}-k_0[CH_2C_2O_4H_2]\}/[CH_2C_2O_4H^-]$ versus k_{obsd} (Fig. 2) plot under the acidity range of pH≃pK_1 of malonic acid where the contribution of $CH_2C_2O_4H^-$ to the rate of reaction becomes significant. At pH≥4.0, the contribution of $k_0[CH_2C_2O_4H_2]$ to k_{obsd} is negligibly small and Eq. 1 reduces to

$$k_{obsd} = \frac{k_1Q_1[CH_2C_2O_4H^-]+k_2Q_2[CH_2C_2O_4^{2-}]}{1+Q_1[CH_2C_2O_4H^-]+Q_2[CH_2C_2O_4^{2-}]}. \quad (7)$$

The values of k_2 and Q_2 at each experimental temperature were estimated from the slope and intercept of the straight line plot of $\{k_{obsd}+(k_{obsd}-k_1)Q_1[CH_2C_2O_4H^-]\}/[CH_2C_2O_4^{2-}]$ versus k_{obsd} (Fig. 3). Activation parameters, ΔH^* and ΔS^* corresponding to anation rate constants were calculated using Eyring equation. Values of the anation rate constants and corresponding activation parameters together with their standard deviations as deduced by least-squares analysis are presented in Table 2. A comparison of the anating reactivity of malonic acid and its conjugate bases derived from second-order rate constants, k_o, k_1Q_1, and k_2Q_2 follow the sequence: $CH_2C_2O_4H_2 < CH_2C_2O_4H^- < CH_2C_2O_4^{2-}$. This can be explained satisfactorily considering higher reactivity of the deprotonated

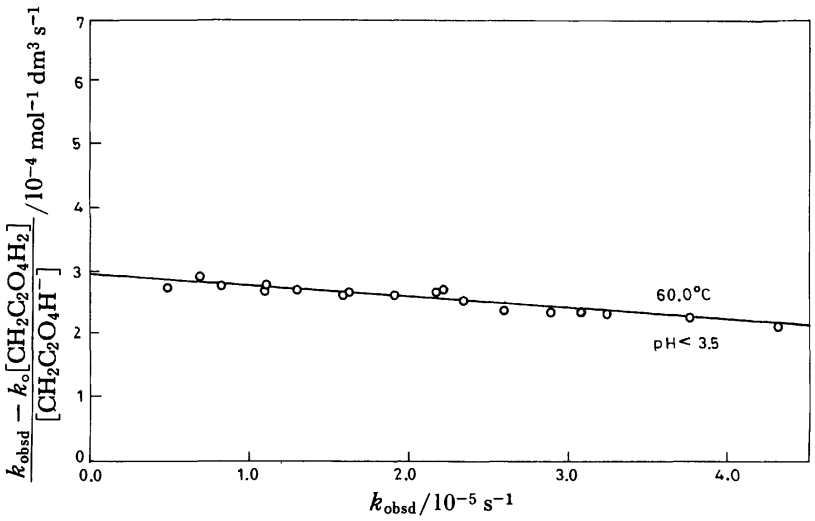

Fig. 2. $\frac{k_{obsd}-k_o[CH_2C_2O_4H_2]}{[CH_2C_2O_4H^-]}$ vs. k_{obsd} at 60.0±0.1℃.

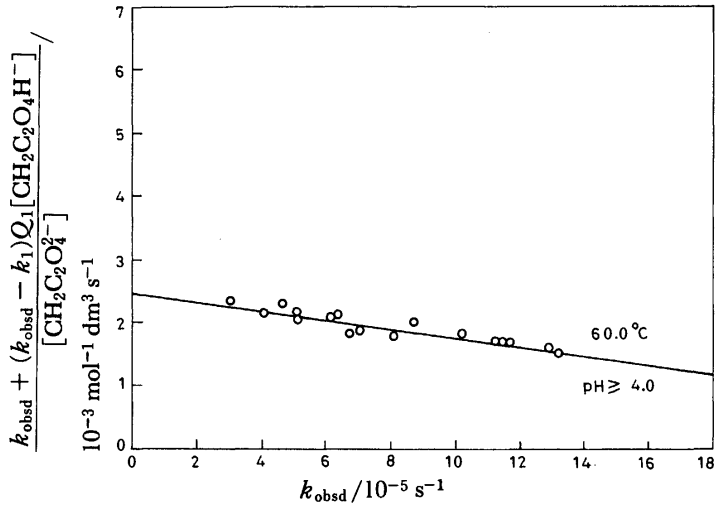

Fig. 3. $\frac{k_{obsd}+(k_{obsd}-k_1)Q_1[CH_2C_2O_4H^-]}{[CH_2C_2O_4^{2-}]}$ vs. k_{obsd} at 60.0±0.1℃.

Table 2. Rate and Activation Parameters for the Anation of $[Rh(NH_3)_5(OH_2)]^{3+}$ by Malonic Acid/Malonate Ions (μ=1.0 mol dm^{-3})

Rate parameter	Temperature/°C			Activation parameters	
	60.0±0.1	70.0±0.1	80.0±0.1	ΔH^*/kJ mol^{-1}	ΔS^*/J K^{-1} mol^{-1}
k_0/10^{-5} mol^{-1} dm^3 s^{-1}	3.04±0.2	7.22±0.2	15.44±0.3	79.0±2.9	−97.0±12.0
Q_1/mol^{-1} dm^3	1.7±0.1	1.8±0.3	1.9±0.2		
k_1/10^{-4} s^{-1}	1.73±0.2	5.96±0.5	16.93±0.7	104.0±5.6	−4.0±1.7
Q_2/mol^{-1} dm^3	7.1±0.3	7.8±0.3	7.6±0.4		
k_2/10^{-4} s^{-1}	3.46±0.4	9.1±0.7	24.24±1.0	96.5±6.0	−20.9±9.2

forms of the acid. Anation of pentaammineaquarhodium(III) ion by oxalic,[18] malonic, and propionic acid[20] studied so far offers a meaningful relation between k_o and pK values of the carboxylic acids. The value of k_o is found to decrease with an increase in pK value, i.e. with increasing basicity and O-H bond strength, of the acid, making the reaction more difficult to occur. This effect is accompanied by the increase in activation parameter as is expected for a less reactive species. The k_o value for the present system is comparable with the analogous reaction for cobalt(III) analog. In both cases no evidence for an ion pair is kinetically observed and the anation proceeded via a second-order kinetics, suggesting a simi-

larity in mechanism for both the systems. The observed rate constant for anation of $[Co(NH_3)_5(OH_2)]^{3+}$ ion by malonic acid at pH=1.5 is reported to decrease by a factor of 1.4 when D_2O instead of H_2O is used as solvent.[10] Based on the results of isotope effect and the relation between k_o and pK values of the carboxylic acid, the O-H bond fission on the -COOH group of the carboxylic acid has been suggested of significant importance in the rate-determining step of the anation mechanism.[10] Low ΔH^* and ΔS^* values corresponding to k_o for the complex under present investigation also corroborate the possibility of associative activation in the transition state. The value of essentially temperature-independent ion pair association constant (Q) is observed to be greater for malonate than for hydrogen malonate ion as expected on the basis of higher charge on the former, but are considerably higher than that for strong acid anions of the same charge viz., Cl^-, Br^-, SO_4^{2-}.[13] This may be attributed to the less extensive solvation of the carboxylates in comparison to that of strong acid anions.

According to Swaddle,[24] the magnitude of enthalpy of activation for anation rate constant offers better criteria to distinguish between the associative and dissociative character of interchange reactions. Similarity in ΔH^* and ΔS^* values corresponding to interchange rate constants, k_1 and k_2 for the present system seem to suggest near identity of the respective transition states. Moreover, both sets of activation parameters are observed to be fairly close to that of water exchange[11] of $[Rh(NH_3)_5(OH_2)]^{3+}$ ion as well as the substitution reaction involving replacement of coordinated aquo ligand by Cl^-, Br^-, I^-,[12,13] N_3^-, CH_3COO^-,[14] and $CH_3CH_2COO^-$[20] ions. The anation and water exchange reactions of $[Rh(NH_3)_5(OH_2)]^{3+}$ ion have been suggested to proceed by an interchange associative (I_a) mechanism. The negative volume of activations for the aquo exchange in $[Rh(NH_3)_5(OH_2)]^{3+}$ (ΔV^*, -4.1 ± 0.4 cm^3 mol^{-1})[16] and solvent exchange in $[Rh(NH_3)_5(dmf)]^{3+}$ (ΔV^*, -1.4 cm^3 mol^{-1}),[17] lend additional support to the associative character for rhodium(III) substrate. The ΔH^* values for the anation of $[Rh(NH_3)_5(OH_2)]^{3+}$ by hydrogenmalonate and malonate ions are observed to be 12—21 kJ mol^{-1} lower than for analogous reactions of cobalt(III) substrate. On the basis of the activation parameters, the anation of $[Co(NH_3)_5(OH_2)]^{3+}$ with hydrogenmalonate and malonate ions have proposed to take place by interchange dissociative (I_d) mechanism.[10] If the same type of mechanism is thought to be operative for the interchange reactions for the present system, owing to the greater loss of ligand field energy one would expect a higher enthalpy of activation for the Rh(III) complex compared to isostructural and isoelectronic (d^6) Co(III) substrate. The reverse trend in magnitude of ΔH^* cannot be explained by above mechanism but suggests significant bond formation by the entering group in the transition state in course of transformation of ion pair into the product complex. Moreover, a decrease in ΔS^* towards a more negative value, going from Co(III) to Rh(III) substrate, is also in conformity with a mechanism involving a more pronounced participation of the incoming nucleophile in the transition state for the latter.

Interaction of Dithiophosphinates of Cobalt and Nickel with Pyridine-Type Donors

Rabindra Nath MUKHERJEE,* Sanganabatla SHANKAR, and Denis Louis MASCARENHAS
Department of Chemistry, Indian Institute of Technology, Bombay 400 076, India
(Received September 17, 1985)

The relative isotropic ^{1}H NMR shifts of several pyridine-type base adducts of M(2,4-Me$_2$dtpi)$_2$ [where M=Co, Ni and 2,4-Me$_2$dtpi=bis(2,4-dimethylphenyl)dithiophosphinate] were measured. The opposite signs of ring and methyl proton resonance shifts in α- and γ-picoline complexes of nickel indicate that both σ- and π-mechanisms are operative. In the cobalt cases all proton resonances are shifted down-field suggesting a negative dipolar contribution in addition to contact interaction. The magnetic and electronic spectral studies on these compounds are consistent with either MS_4N or MS_4N_2 chromophores.

The proton isotropic shifts of pyridine-type donors in cobalt and nickel acetylacetonates[1] and β-keto esterates[2,3] have been reported. ^{1}H NMR studies on similar adducts of chelates of these metals with sulfur ligands have received much less attention.[4,5] Dithiophosphinates of transition metals were reported from our laboratory.[6,7] In the present article, complexes of bis(2,4-dimethylphenyl)dithiophosphinates of cobalt and nickel, M(2,4-Me$_2$dtpi)$_2$, with a series of pyridine-type donors have been subjected to magnetic, electronic, IR, and ^{1}H NMR investigations.

Experimental

All the chemicals used were either of analytical or chemically pure grade. Bis(2,4-dimethylphenyl)dithiophosphinic acid was synthesized by the procedure reported in literature.[8]

Preparation of Complexes. Co(2,4-Me$_2$dtpi)$_2$(L) (L= pyridine, α-picoline, β-picoline, γ-picoline, 2,6-lutidine, and 3,5-lutidine): The base (3 ml) was added to a methanolic solution (40 ml) of $CoCl_2 \cdot 6H_2O$ (1.1 g). Addition of methanolic solution (25 ml) of Na(2,4-Me$_2$dtpi) (3.1 g) afforded blue/greenish blue solid which was washed with methanol and dried.

Co(2,4-Me$_2$dtpi)$_2$(4-phenylpyridine): To a chloroform (25 ml) solution of Co(2,4-Me$_2$dtpi)$_2$ (1.5 g) methanolic solution (25 ml) of 4-phenylpyridine (0.4 g) was added. On slow addition of methanol (40 ml) bright green product precipitated out. This was washed with methanol and recrystallized from chloroform–methanol.

Co(2,4-Me$_2$dtpi)$_2$(L)$_2$ (L=pyridine and γ-picoline): A mixture of cobalt(II) chloride hexahydrate (1.3 g) and the base (10 ml) in methanol (40 ml) was treated with methanolic solution (30 ml) of sodium salt (3.7 g) of the ligand. The resulting pink crystalline solid was collected, washed with methanol containing a small amount of the base.

Ni(2,4-Me$_2$dtpi)$_2$(α-picoline): A chloroform solution (30 ml) of Ni(2,4-Me$_2$dtpi)$_2$ (1.5 g) was mixed with 3 ml of α-picoline. The resulting solution, on slow evaporation gave the brown adduct, which was washed with methanol and dried.

Ni(2,4-Me$_2$dtpi)$_2$(L) (L=β-picoline and γ-picoline): Nickel(II) chloride hexahydrate (1.1 g) in methanol (40 ml) was treated with 3 ml of base. Na(2,4-Me$_2$dtpi) (3.1 g) in methanol (25 ml) was added dropwise to this solution with stirring. The brown solid, which precipitated was isolated by filtration, washed with methanol and dried.

Ni(2,4-Me$_2$dtpi)$_2$(3,5-lutidine): A solution of Ni(2,4-Me$_2$dtpi)$_2$ (2.2 g) in chloroform (30 ml) was mixed with 3,5-lutidine (4 ml). The brown solid was forced from the resulting solution with methanol, filtered and then recrystallized from chloroform–methanol mixture in presence of small quantity of the base.

Ni(2,4-Me$_2$dtpi)$_2$(L)$_2$ (L=pyridine, β-picoline, and γ-picoline): The light green adduct was obtained by the interaction of a solution of Ni(2,4-Me$_2$dtpi)$_2$ (2.0 g) in chloroform (30 ml) with the base (6 ml) and on slow evaporation of the solvent. It was then recrystallized from chloroform–methanol in presence of base.

Ni(2,4-Me$_2$dtpi)$_2$(4-phenylpyridine)$_2$: A solution of 4-phenylpyridine (1.0 g) in chloroform (30 ml) was added slowly to a chloroform solution (30 ml) of Ni(2,4-Me$_2$dtpi)$_2$ (2.1 g). This solution on slow evaporation gave the green complex and was recrystallized from chloroform–methanol in presence of base.

Physical Measurements: A Pye-Unicam SP-2000 infrared spectrophotometer was used for recording IR spectra of the samples in KBr. The room-temperature magnetic measurements were carried out on a Gouy balance using Hg[Co(SCN)$_4$] as the standard. The electronic spectra were observed on a Varian Super Scan 3 UV-visible spectrophotometer. ^{1}H NMR spectra of the adducts in deuteriochloroform were recorded on a Varian XL-100 high resolution NMR spectrometer using tetramethylsilane as the internal calibrant.

Results and Discussion

The color, magnetic moment, analytical and thermal data of the complexes are given in Table 1.

The monoadducts of the composition Co(2,4-Me$_2$dtpi)$_2$(L) were obtained with pyridine, α-picoline, β-picoline, γ-picoline, 3,5-lutidine, 2,6-lutidine, and 4-phenylpyridine whereas the diadducts of the composition Co(2,4-Me$_2$dtpi)$_2$(L)$_2$ could be isolated only with pyridine and γ-picoline. Ni(2,4-Me$_2$dtpi)$_2$ forms 1:1 adducts with α-picoline and 3,5-lutidine whereas both 1:1 and 1:2 adducts have been obtained with β-picoline and γ-picoline. Electronic spectral studies show that a 1:2 adduct is also formed with 3,5-lutidine in solution. With pyridine and 4-phenylpyridine only 1:2 adducts could be isolated. Similar adducts with piperidine could not be isolated. However, the change in color of M(2,4-Me$_2$dtpi)$_2$ solution upon the addition of piperidine; electronic and

a) X=2,4-Me_2dtpi. b) M=Metal (Co or Ni). c) S=Sulfur. d) Loss of the pyridine-type donor on heating. e) Temperature at which the complex was heated to estimate the loss of base.

^{1}H NMR spectral studies on the resulting solution confirm the formation of adducts in solution.

The IR spectra of these complexes show ν_{as}P-S and ν_sP-S around 650 and 585 cm^{-1} respectively.[9] The bands around 1470 and 1610 cm^{-1} are assigned to both C=C and C=N stretching vibrations.

The magnetic moments for the monoadducts of cobalt and nickel fall in the range 4.63—4.70 and 3.12—3.23 BM respectively consistent with the penta-coordinate geometry.[10,11] For the diadducts these values are around 5.0 and 3.2 BM respectively as expected for hexa-coordinate cobalt(II) and nickel(II) complexes.

The reflectance and solution spectra of Co(2,4-Me_2dtpi)$_2$(L) are similar and the observed d-d bands around 14800, 15600, and 17250 cm^{-1} are in agreement with those reported for other penta-coordinate compounds.[12] Since the overall pattern of the absorption bands for both trigonal bipyramidal as well as square pyramidal cobalt complexes is the same, the choice between the geometries based upon the spectral data is not categorically possible. The reflectance spectra of the pink diadducts exhibit a multicomponent band in the region 14800—21700 cm^{-1} which is assigned to $^4T_{1g}\rightarrow{}^4T_{1g}(P)$ transition in an octahedral stereochemistry.[13] The very weak two electron $^4T_{1g}\rightarrow{}^4A_{2g}$ transition expected in this region is obscured by the stronger $^4T_{1g}\rightarrow{}^4T_{1g}(P)$ transition. Thermogravimetric analysis of these compounds show two distinct dissociation steps (115 and 140 °C for pyridine and 125 and 170 °C for γ-picoline adducts respectively) indicating the presence of two base molecules in the adducts. The complexes decompose on prolonged exposure to air and are soluble in nonpolar solvents producing blue-colored solutions, indicating dissociation to penta-coordinate species.

The reflectance spectra of the monoadducts of Ni(2,4-Me_2dtpi)$_2$ show two ligand field bands around 13000 and 21000 cm^{-1} with a shoulder in the intermediate region (18000 cm^{-1}) and are consistent with a square pyramidal penta-coordinate stereochemistry.[14,15] The solid-state spectra of the diadducts exhibit ligand field bands around 13900 and 21600 cm^{-1} and are assigned to $^3A_{2g}\rightarrow{}^3T_{1g}$ and $^3A_{2g}\rightarrow{}^3T_{1g}(P)$ transitions in a trans octahedral symmetry of the NiS_4N_2 chromophore. Dis-

Table 2. Relative Isotropic Shifts for Ligands Coordinated with Metal Complexes

Ligand	Proton	Isotropic shifts in Ni(2,4-Me_2dtpi)$_2$ adducts	Isotropic shifts in Co(2,4-Me_2dtpi)$_2$ adducts
Piperidine	α-CH_2	−10.00	−10.00
	β-CH_2	−4.95	−4.02
	γ-CH_2	−2.81	−0.70
Pyridine	α-CH	−10.00	−10.00
	β-CH	−3.53	−3.92
	γ-CH	−0.93	−0.87
α-Picoline	α-CH	−10.00	−10.00
	β-CH	−3.42	−3.00
	γ-CH	−1.81	−0.93
	α-CH_3	+0.74	−0.18
β-Picoline	α-CH	−10.00	−10.00
	β-CH	−3.45	−3.50
	γ-CH	−0.56	−0.21
	β-CH_3	−0.51	−0.42
γ-Picoline	α-CH	−10.00	−10.00
	β-CH	−3.40	−3.87
	γ-CH_3	+1.10	−0.87
3,5-Lutidine	α-CH	−10.00	−10.00
	γ-CH	−0.62	−0.37
	β-CH_3	−0.56	−0.49
4-Phenylpyridine	α-CH	−10.00	−10.00
	β-CH	−3.17	−3.76
	α'-CH	−0.12	−0.55
	β'-CH	+0.11	−0.12
	γ'-CH	+0.11	−0.12

sociation of these complexes in chloroform solution could be prevented by addition of the base.

^{1}H NMR has been used to determine the distribution of unpaired spin density in the ligands of paramagnetic complexes in which the effective electron spin relaxation time is short. The existence of an isotropic hyperfine contact interaction between unpaired electrons and magnetic nuclei leads to large shifts in the nuclear resonance frequencies. Such a shift may be of contact or dipolar origin or a combination of both.[16] The isotropic shifts found for nickel chelates are assumed to arise solely from a contact interaction[17] while for cobalt compounds both contact and dipolar interactions[18] contribute for these shifts.

The observed shifts for dithiophosphinate moiety are very small hence our discussion is confined only to the base proton shifts. As the actual shifts depend upon the solution composition only relative shifts have been discussed. Absorption peaks were assigned to particular ligand protons by observing the approach to the known diamagnetic spectra upon the addition of more and more ligand. The observed shifts have been normalized to give a value of −10.00 for the α-proton shifts. Negative shifts are shifts to lower applied fields and positive shifts to higher applied fields.

The relative isotropic shifts for the protons of different bases complexed with nickel and cobalt dithiophosphinates are included in Table 2. In the nickel adduct with piperidine all the base proton resonances are shifted down-field and attenuate with the increasing number of intervening bonds between the metal ion and relevant proton. This pattern is characteristic of σ-delocalization and is observed in a number of complexes.[19,20] Similar observation was made for pyridine adduct in which all the proton shifts are down-field and the order is $\alpha > \beta > \gamma$. In contrast, the methyl protons of both α- and γ-picoline compounds are shifted up-field indicating the presence of unpaired π-electron density in addition to σ-spin density.

The observed isotropic shifts in cobalt complexes are compared with the corresponding nickel adducts and that of cobalt(II) acetylacetonates to get information about the nature of dipolar shifts. For piperidine adduct of Co(2,4-Me_2dtpi)$_2$ all the observed shifts are down-field in contrast to the up-field shifts reported for corresponding cobalt acetylacetonate derivative. Since piperidine has no π-orbitals, π-delocalization of magnetic t_{2g} electrons is not possible. The observed shift pattern can be explained by considering a negative dipolar contribution in addition to contact interaction while positive dipolar contribution has been reported for Co(acac)$_2$. This is supported by the down-field shift of the methyl protons of α- and γ-picolines in Co(2,4-Me_2dtpi)$_2$. If the spin-transfer mechanisms for nickel

and cobalt adducts are assumed to be the same, which of course have been shown to be true,[1,21] the methyl protons would have shifted up-field in the presence of small positive dipolar shifts. The observation of negative shifts for these protons rules out the possibility of positive dipolar contribution in these cobalt adducts. This is further supported by the down-field shift for β' and γ' protons in 4-phenylpyridine adduct, the corresponding protons in the cobalt acetylacetonate show up-field shifts. In the nickel complex the β' and γ' proton resonances are shifted up-field similar to that in the $Ni(acac)_2$ compound.

Isotropic shifts for all β-picoline protons of nickel adduct were observed down-field and the signs of shifts for β-CH and β-CH_3 protons are identical. The observation is similar to that reported for the corresponding acetylacetonate adduct. This behavior is in contrast to the results obtained for the α- and γ-picoline adducts which were explained on the basis of $(\sigma-\pi)$ configuration interaction. Similar observation was made for 3,5-lutidine adduct of $Ni(2,4\text{-}Me_2dtpi)_2$ in which α-CH, γ-CH, and β-CH_3 protons are shifted down-field. However, for the corresponding cobalt complexes the observation is similar to those of α- and γ-picoline adducts.

In $Co(2,4\text{-}Me_2dtpi)_2$(2,6-lutidine) the observed shifts have been normalized to give -10.00 for β-protons and the values obtained for γ-CH and α-CH_3 are -4.12 and -0.11 respectively. The signs of the shifts are identical to those for other bases. The corresponding nickel adduct could not be isolated and ^1H NMR spectrum did not provide evidence for complex formation in solution.

Kinetics of the Iron(II) Reduction of Glycinatobis(malonato)-, *trans*-Bis(malonato)bis(pyridine)-, Nitrilotriacetato(malonato)-, and Nitrilotriacetato(oxalato)cobaltates(III)

Ramakrishnan VISWANATHAN and Venkatapuram Ramanujam VIJAYARAGHAVAN*
Department of Physical Chemistry, University of Madras, Guindy Campus, Madras 600 025, India
(Received September 17, 1985)

The kinetics of the iron(II) reduction of glycinatobis(malonato)-, *trans*-bis(malonato)bis(pyridine), nitrilotriacetato(malonato)-, and nitrilotriacetato(oxalato)cobaltates(III) have been studied in aqueous perchlorate medium at I=1.0 mol dm^{-3} ($LiClO_4$) and 30 °C in the [H^+] range 0.01—0.90 mol dm^{-3}. The reductions are found to be second order. The reduction of $[Co(gly)(mal)_2]^{2-}$ and $[Co(py)_2(mal)_2]^-$ is accelerated by H^+, while the reduction of $[Co(nta)(mal)]^{2-}$ and $[Co(nta)(ox)]^{2-}$ is independent of [H^+] in the range 0.1<[H^+]<0.9 mol dm^{-3}. The reduction of $[Co(nta)(mal)]^{2-}$ is, however, faster at [H^+]<0.1 mol dm^{-3}. The activation parameters for the reduction of $[Co(gly)(mal)_2]^{2-}$, $[Co(py)_2(mal)_2]^-$, $[Co(nta)(mal)]^{2-}$, and $[Co(nta)(ox)]^{2-}$ are respectively as follows:

$\Delta H^{\neq}$=49.8±4.8, 51.2±2.6, 41.1±3.2, and 41.4+3.6 kJ mol^{-1}

$\Delta S^{\neq}$=−98.3±8.3, −93.7±7.2, −119.2±9.7, and −114.6+9.6 J K^{-1} mol^{-1}.

The proposed mechanism invokes $[Co(L)(H_2O)(mal)(malH)]$ (L-py_2 or gly) formed in a H^+-assisted step as the reactive species for the bis(malonato) complexes. $[Co(nta)(mal)]^{2-}$ is proposed to be present as $[Co(nta)(malH)(H_2O)]^-$ while $[Co(nta)(ox)]^{2-}$ remains unaffected by H^+.

Extensive reports are available in literature on the inner-sphere reduction of cobalt(III) complexes, e.g. by Fe(II) and Cr(II). These studies indicate a variety of possibilities for the dependence of rate on [H^+].[1-5] The reduction rates of $[Co(en)(C_2O_4)_2]^-$,[1,2] $[Co(NH_3)_4(C_2O_4)]^+$,[3] and $[Co(en)_2(NH_2CH_2COO)]^{2+}$ [4] are independent of [H^+]. Rates showing an inverse dependence on [H^+] are observed in the reduction of $[Co(NH_3)_5(C_2O_4)]^+$ and $[Co(NH_3)_5(C_3H_2O_4)]^+$ $C_3H_2O_4^{2-}$= malonate ion (mal)[4] while the reduction of $[Co(C_3H_2O_4)_3]^{3-}$ [5] and $[Co(en)(C_3H_2O_4)_2]^-$ [2] is accelerated by H^+. Small increases in rates with increase in [H^+] have been attributed to medium effects, mainly when $NaClO_4$ is used as the ionic medium.[6] Extensive studies have been carried out in this laboratory to analyse the [H^+]-depencence of rates of reduction and the present report is in continuation of such studies.[2,7,8]

Experimental

Barium glycinatobis(malonato)cobaltate(III) sesqui-hydrate,[9] $Ba[Co(gly)(mal)_2]\cdot 1.5H_2O$, sodium *trans*-bis(pyridine)bis(malonato)cobaltate(III) dihydrate,[10] $Na[Co(py)_2(mal)_2]\cdot 2H_2O$, and disodium nitrilotriacetato(oxalato)cobaltate(III) monohydrate,[11] $Na_2[Co(nta)ox]\cdot H_2O$, were prepared and purified by literature methods. Disodium nitrilotriacetato(malonato)cobaltate(III) monohydrate $Na_2[Co(nta)(mal)]\cdot H_2O$ was prepared by a procedure similar to that for $Na_2[Co(nta)(ox)]$. The purities of the complexes were checked by UV-vis, IR, conductivity, and elemental analysis. Solutions of $Fe(ClO_4)_2$ were prepared by dissolving pure iron powder (Sarabhai M Chemicals) in ca. 2 M $HClO_4$ (1 M=1 mol dm^{-3}) in the presence of nitrogen and stored under nitrogen . [Fe(II)] and free [H^+] in the Fe(II) solution were determined by known methods.[12] Lithium perchlorate was prepared by neutralizing anhydrous Li_2CO_3 with $HClO_4$ and recrystallizing till free from Cl^- and SO_4^{2-} ions.[13] Perchloric acid (E Merck, reagent grade) was used as such. Doubly distilled water was used throughout the kinetic study.

Kinetics: Second order conditions were maintained in all kinetic runs, using equimolar concentrations of reactants. Solutions of the complexes and Fe(II) were thermostated separately and mixed at the time of reaction. Reactions were followed spectrophotometrically at 575 nm for $[Co(gly)(mal)_2]^{2-}$, 555 nm for $[Co(py)_2(mal)_2]^-$, 570 nm for $[Co(nta)(ox)]^{2-}$, and 563 nm for $[Co(nta)(mal)]^{2-}$ in a Carl Zeiss UV-vis recording spectrophotometer by measuring the absorbance at intervals of 30 seconds for 3 half lives. The reactions were studied in nitrogen atmosphere using serum caps to seal the cells. $HClO_4$ was used as the source of H^+. Studies at [H^+]-0.01 mol dm^{-3} were, however, in the presence of a glycine buffer. The ionic strength of the solutions was adjusted to 1 mol dm^{-3} with $LiClO_4$. Figure 1 shows the change in spectrum with time for the complex $[Co(py)_2(mal)_2]^-$ as an example. Rate constants were calculated from the slopes of $(A_o-A_t)(A_t-A_\infty)^{-1}$ versus time plots, where A_o is the initial absorbance, A_t- the absorbance at time t, and A_∞- the absorbance at the completion of the reaction. These plots were linear for three half-lives. Activation parameters were determined by carrying out the reactions at different temperatures ranging from 20 to 55 °C. The temperature dependence studies were made in the [H^+]-range in which the rates were [H^+]-independent.

The stoichiometry of the reactions was determined by measuring the Fe(III) and Co(II) produced from equimolar mixtures of the complex and Fe(II) after completion of reaction. Co(II) was determined as $CoCl_4^{2-}$ and Fe(III) as $Fe(NCS)_6^{3-}$ spectrophotometrically. The ratio of Fe(III) to Co(II) was found to be 1:1.

Results

Table 1 presents the second order rate constants k for the Fe(II) reduction of $[Co(gly)(mal)_2]^{2-}$ and $[Co(py)_2(mal)_2]^-$ in the range 0.01<[H^+]<0.7 mol dm^{-3}. Rate constants in the temperature range 30—55 °C are also given. The rate increases with [H^+] for both complexes, the increase being three to five-fold

over a ten-fold increase of $[H^+]$. Activation parameters were determined at $[H^+]=0.01$ mol dm^{-3}, the complexes being in the unprotonated form under these conditions. The values in the temperature range 30—55 °C are $\Delta H^{\neq}=49.8\pm4.8$ kJ mol^{-1}, $\Delta S^{\neq}=-98.3\pm8.3$ J K^{-1} mol^{-1} for $[Co(gly)(mal)_2]^{2-}$ and $\Delta H^{\neq}=51.2\pm2.6$ kJ mol^{-1}, $\Delta S^{\neq}=-93.7\pm7.2$ J K^{-1} mol^{-1} for $[Co(py)_2(mal)_2]^-$.

Table 2 presents the second order rate constants k for the Fe(II) reduction of $[Co(nta)(mal)]^{2-}$ and $[Co(nta)(ox)]^{2-}$. The rate constant decreases from

0.51 to 0.35 $dm^3 mol^{-1} s^{-1}$ in the range $0.01<[H^+]<0.1$ mol dm^{-3} and remains constant at ca 0.33 $dm^3 mol^{-1} s^{-1}$ at higher $[H^+]$ for $[Co(nta)(mal)]^{2-}$, while the value of k is 0.45 $dm^3 mol^{-1} s^{-1}$ in the range $0.01<[H^+]<0.8$ mol dm^{-3} for $[Co(nta)(ox)]^{2-}$. The activation parameters have been determined in the temperature range 20—45 °C and at $[H^+]=0.4$ mol dm^{-3}, the values being $\Delta H^{\neq}=41.1\pm3.2$ kJ mol^{-1}, $\Delta S^{\neq}=-119.2\pm9.7$ J $K^{-1} mol^{-1}$ for $[Co(nta)(mal)]^{2-}$ and $\Delta H^{\neq}=41.4\pm3.6$ kJ mol^{-1}, $\Delta S^{\neq}=-114.6\pm9.6$ J $K^{-1} mol^{-1}$ for $[Co(nta)(ox)]^{2-}$.

Discussion

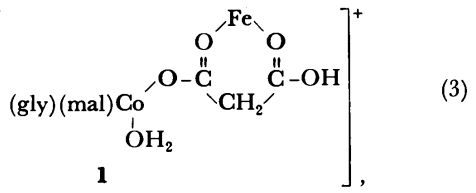
Fe(II) reduction of $[Co(gly)(mal)_2]^{2-}$ and $[Co(py)_2(mal)_2]^-$: The dependence of the rate constants on $[H^+]$ (Table 1) may be expressed in the form

$$k = k_1 + k_2[H^+], \quad (1)$$

k_1 being the rate constant due to the unprotonated species present at pH 2. H^+ accelerations similar to that observed here have been observed in the Fe(II) reduction of $[Co(edta)]^-$[14] $[Co(mal)_3]^{3-}$[5] and $[Co(en)(mal)_2]^-$,[2] explained in terms of the involvement of an aqua complex generated by the H^+-assisted dechelation of the complexes. One should thus expect the reaction to proceed through the following steps:

$$[Co(gly)(mal)_2]^{2-} + H^+ + H_2O \overset{K_1}{\rightleftharpoons} [Co(gly)(mal)(OCOCH_2COOH)(H_2O)]^-, \quad (2)$$

$$[Co(gly)(mal)(OCOCH_2COOH)(H_2O)]^- + Fe^{2+} \overset{K_2}{\rightleftharpoons} \mathbf{1}, \quad (3)$$



$$\mathbf{1} \xrightarrow[\text{slow}]{k_3} Co^{2+} + H_2mal + Fe^{3+} + gly, \quad (4)$$

k_2 being equal to $k_3K_1K_2$. K_1 and K_2 are too small in magnitude to permit observation of any limiting behavior. The values of k_2 for $[Co(gly)(mal)_2]^{2-}$ and $[Co(py)_2(mal)_2]^-$ are found to be 1.1—1.2 and 0.9 $dm^6 mol^{-2} s^{-1}$ respectively. These values suggest a significant kinetic advantage for the former due to $[H^+]$ acceleration. The values of k_1 for the two complexes are, however, similar, the values being 0.11 $dm^3 mol^{-1} s^{-1}$ for $[Co(gly)(mal)_2]^{2-}$ and 0.10 $dm^3 mol^{-1} s^{-1}$ for $[Co(py)_2(mal)_2]^-$.

Iron(II) reduction of $[Co(nta)(mal)]^{2-}$ and $[Co(nta)(ox)]^{2-}$: The rate constant (Table 2) for the reduction of $[Co(nta)(mal)]^{2-}$ decreases from 0.51 to 0.35 $dm^3 mol^{-1} s^{-1}$ as $[H^+]$ is increased from 0.01 to 0.1 mol dm^{-3} and reaches a limiting value of ca. 0.33 $dm^3 mol^{-1} s^{-1}$ in the range $0.1<[H^+]<0.9$ mol dm^{-3}. This is in contrast to the bis(malonato) complexes, where a $[H^+]$-assisted acceleration of reaction was observed. The observed $[H^+]$-dependence of rate for $[Co(nta)(mal)]^{2-}$ suggests the possibility of the presence of the species $[Co(nta)(H_2O)(OCOCH_2COO)]^{2-}$ and its protonated form in equilibrium. A similar inverse $[H^+]$-dependence has been observed in the Fe(II) reduction of $[Co(NH_3)_5(mal)]^+$ and $[Co(NH_3)_5(ox)]^+$.[4] The possibility of the presence of the species $[Co(nta)(H_2O)(OCOCH_2COO)]^{2-}$ was also verified by pH-titration of the complex with NaOH. The complex exhibited acid function as indicated by a buffer region in the pH range 4—6. No buffer region was observed for a similar titration with $[Co(nta)(ox)]^{2-}$. The possibility of the formation of the species $[Co(Hnta)(H_2O)(mal)]^-$, $[Co(Hnta)(H_2O)(ox)]^-$, $Co(Hnta)(H_2O)_2(Hmal)$, and $[Co(Hnta)(H_2O)(Hox)]$ may also be considered at high $[H^+]$. The formation of such species would be indicated by a $[H^+]$-dependent acceleration of rate, as observed for $[Co(gly)(mal)_2]^{2-}$, and *trans*-$[Co(py)_2(mal)_2]^-$. The absence of any acceleration of rate by H^+ for the Co(III)-nta complexes is an evidence against the possibility of $[Co(Hnta)(H_2O)_2(Hmal)]$ and the corresponding oxalato species.

Comparison of the rate constants for the Fe(II) reduction of $[Co(nta)(ox)]^{2-}$ with $[Co(nta)(mal)]^{2-}$ indicates an unusual trend. Generally the rates of reduction of oxalato complexes are higher by one or two orders of magnitude than the rates for the corresponding malonato complexes. For example, at $[H^+]$-0.4 mol dm^{-3} and at 30 °C the k values are 4.5×10^{-3} and 1.7×10^{-4} $mol^{-1} dm^3 s^{-1}$ for the Fe(II) reduction of $[Co(en)(ox)_2]^-$ and $[Co(en)(mal)_2]^-$ respectively[2] and 4.3×10^{-1} and 1.3×10^{-3} $mol^{-1} dm^3 s^{-1}$ for $[Co(NH_3)_5(ox)]^+$ and $[Co(NH_3)(mal)]^+$ respectively, at 25 °C.[4] However, the near similarity in rates viz. 0.46 and 0.32 $mol^{-1} dm^3 s^{-1}$ for $[Co(nta)(ox)]^{2-}$ and $[Co(nta)(mal)]^{2-}$ respectively in the $[H^+]$ range 0.4—0.8 mol dm^{-3} suggests a difference in the nature of the reactive species for the two complexes, viz. a chelated oxalate and a monodentate malonate. The reactivity of the latter is possibly due to precursor stabilization by chelation with Fe^{2+}.

(Received October 11, 1985)

Twenty-three samples of niobium(V) phosphate have been synthesized under different conditions using niobium sulfate and phosphoric acid solutions. The amorphous sample having the ion-exchange capacity of 1.06 mEq g^{-1} and niobium to phosphorus mole ratio of 0.670 was studied in detail for its cation-exchange behavior. Molar distribution coefficients for 25 cations have been studied on this gel at pH 1,2,3, and 5.5. Four quantitative separations of Mg^{2+}-Ca^{2+}, Mg^{2+}-Ba^{2+}, Zn^{2+}-Cd^{2+}, and Bi^{3+}-Zn^{2+} have successfully been achieved on it. The properties of this sample have been compared with those of niobium arsenate, niobium antimonate, and niobium molybdate. A tentative structural formula is proposed for this sample of niobium phosphate on the basis of chemical composition, cation-exchange capacity, pH-titration, IR spectra, T.G.A., water absorption, and heat treatment data.

Synthetic inorganic ion exchangers have been systematically studied during the last ten years owing to their resistance to heat and radiation. However, their analytical applications to the recovery of precious metals from radioactive wastes and to other chromatographic separations are of current interest. The inorganic ion exchangers based on zirconium have been most thoroughly studied followed by those based on tin, titanium and thorium. Very few studies have been reported on niobium(V) based inorganic ion exchanger.

Sukharev et al.[1-5] synthesized niobium phosphate and observed the effect of the presence of trivalent cation (Ce^{3+}, Fe^{3+}, or Cr^{3+}) upon its composition and sorptional behavior. The distribution coefficients were found higher for the precipitate prepared in the presence of trivalent ions. The phase synthesized at pH≤4 showed higher exchange capacity, improved kinetic parameters and ionic diffusion coefficients close to those in organic resin ($\simeq 10^{-8}$ cm s^{-1}). They also found that the amorphous niobium phosphate phases show a preferential uptake for $H_2[Fe(PO_4)_2]^-$ and $H_5[Fe(PO_4)_3]^-$. Shtin et al.[6,7] investigated the complexation of Nb(V) with phosphoric acid and the solubility of complexes of niobium phosphates $[Nb(OH)_3H_{4+z}(PO_4)_3$ where $z=2—5]$ as a function of H_3PO_4 concentrations within the ionic strength 2—20. They also studied the proton exchange in the coordination sphere of $Nb^{IV}(O_2^-)(OH^-)$ radical complexes. Posplev et al.[8,9] observed the effect of concentration of H_3PO_4 acid during synthesis on the properties of granular niobium phosphate $[NbO(OH)_3]_k[NbO(OH)_2]_l[HPO_4]_n[H_2O]_x$ and the effect of synthesis conditions on the composition and its properties. Chernokov et al.[10] prepared crystalline niobium phosphate having formula $NbO(PO_4)\cdot 2H_3PO_4\cdot 5H_2O$.

It is clear from what has been said above that considerable work has been done on the different phases of niobium(V) phosphate but no single phase has yet been exhaustively studied for its ion exchange behavior. Some aspects of these materials need elucidation and therefore we reinvestigated niobium phosphate in continuation of our systematic studies on niobium compounds such as niobium arsenate,[11-13] niobium antimonate,[14,15] and niobium molybdate.[16] The present manuscript describes our findings on a new phase of niobium phosphate.

Experimental

Reagents. Niobium pentaoxide was obtained from BDH (Poole, England). All other reagents of analytical reagent grade were used.

13.291 g Nb_2O_5 was heated with 400 ml of concd. H_2SO_4 containing 135 g $(NH_4)_2SO_4$ until a clear solution was obtained. After cooling the solution, 200 ml concd. H_2SO_4 was added to it and the whole mass was diluted to 1 liter with demineralized water (DMW) to give a 0.1 M solution (1 mol dm^{-3}) in niobium.

Apparatus. The following instruments were used. Elico pH-meter, Bausch and Lomb spectronic-710 colorimeter, DR-EL/4 (HATCH) spectrophotometer, IR Perkin Elmer Unit and Rich Seifort Iso Debyeflex 2002 X-ray diffractometer.

Synthesis. Numerous samples of niobium phosphate were synthesized by mixing acidic solution of 0.1 M niobium (sulfate) with phosphoric acid (Table 1). The concentration of H_3PO_4, mixing ratio, pH of precipitation, total refluxing time and the medium of reflux were the varying parameters. The precipitate so obtained was kept for 24 h with mother liquor to attain equilibrium. In each case the precipitate was separated from the mother liquor by decantation and washed with DMW until the wash solution had a pH of 6 and free from sulfate ions. The precipitate was dried at 40 °C and sieved to get the granules of 50—100 mesh size. The ion-exchange capacities were also determined by the column process for Na^+ ion. Sample 21 (NbP3) having the ion-exchange capacity (I.E.C.) of 1.06 mEq g^{-1} was chosen for detailed study.

Composition. 0.2 g NbP3 was dissolved in an acidic solution which was 10% in H_2SO_4 and 5% in HF. Niobium was determined as Nb_2O_5. It was precipitated with a 10% solution of cupferron[17] as niobium cupferronate. The white precipitate of niobium cupferronate was collected on ashless filter paper with repeated washings with 1% solution of cupferron. The precipitate with filter paper was first dried in

the IR radiations and then heated in a silica crucible up to 1000 °C to convert it into Nb_2O_5. Phosphorus was obtained as ammonium magnesium phosphate by double precipitation from the former filtrate. The precipitate was heated up to 1000 °C in a silica crucible and determined as magnesium pyrophosphate[18] gravimetrically.

Chemical Stability. 0.2 g of NbP3 sample was shaken by batch process with different solvents for 24 h. The undissolved material was filtered off. The solutions were then analysed spectrophotometrically for the presence of niobium and phosphorus. Niobium was determined with KSCN[19] and phosphorus with ammonium molybdate-tin(II) chloride reagent.[20] The results are given in Table 2.

Ion Exchange Capacity. The I.E.C's of the samples of niobium phosphate were determined by column operation[21] using a column of 0.5 cm. (i.d.). The H^+ ions were eluted by percolating the required cationic solution through the column of the exchanger. The feed was passed until its pH became equal to that of the effluent collected. The hydrogen ions so eluted were titrated against standardized 0.1 M NaOH (Tables 1 and 3).

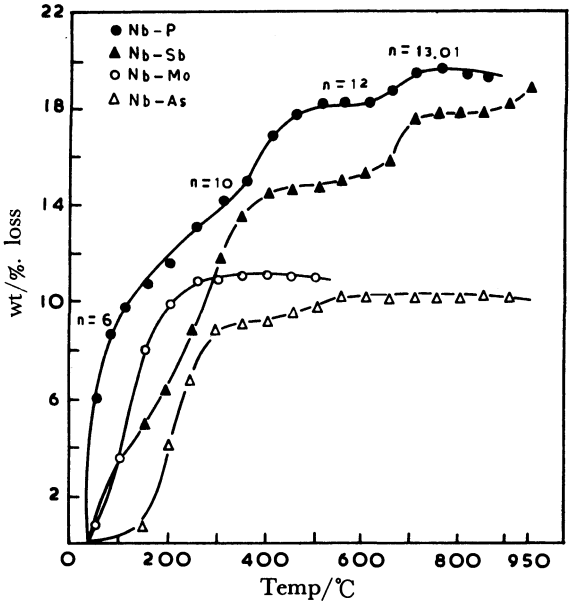

Fig. 2. T.G.A. curves of various inorganic ion-exchangers.

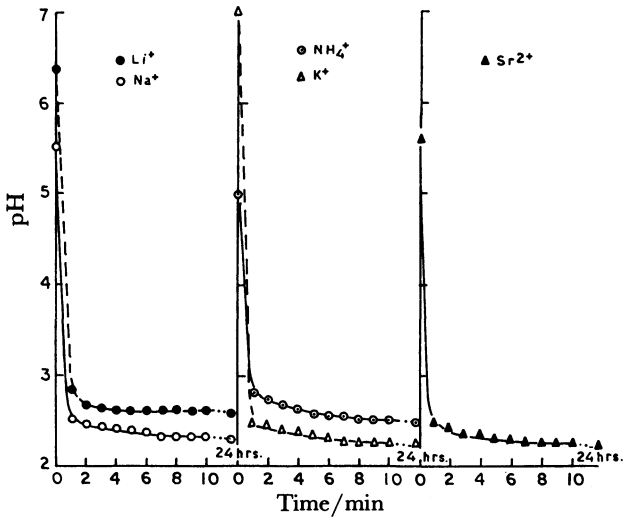

Fig. 3. Plots of pH as a function of time.

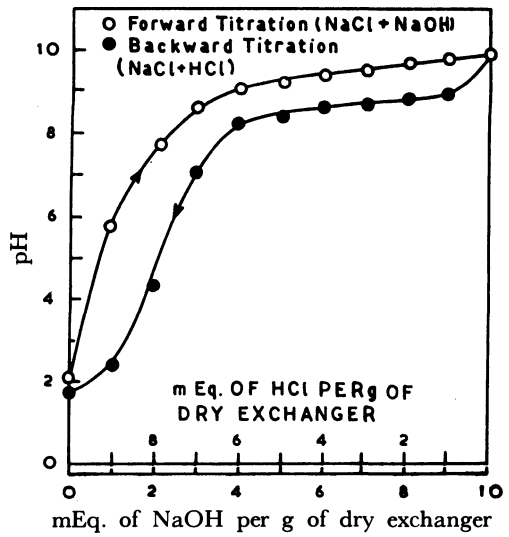

Fig. 4. pH titration curves for Na^+ on NbP_3.

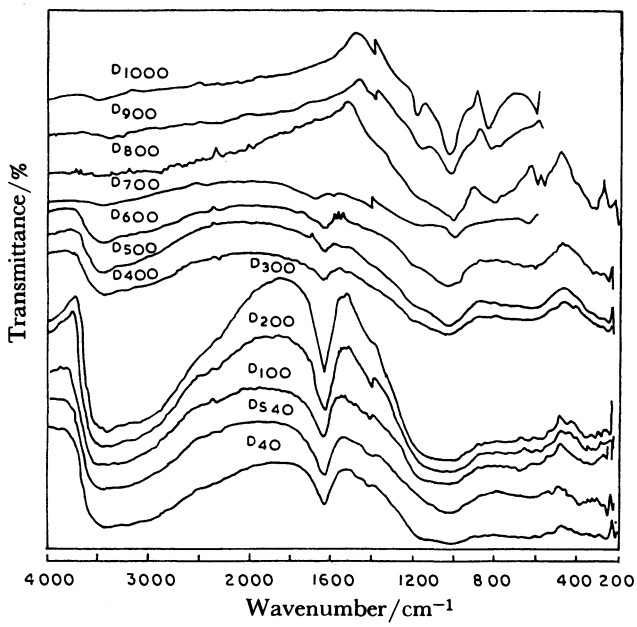

Fig. 5. IR spectra of niobium phosphate heated at various temperatures.
Abbreviations: D-sample 21 in H^+ form.
D_S-sample 21 in Na^+ form.
Subscripts 40—1000: Temperatures in °C.

Concentration Effect. 0.5 g samples of NbP3 in the H^+ form were equilibrated with 50 ml NaCl solution of different concentrations with intermittent shaking for 24 h in the stoppered conical flasks. The solid material was separated by decantation with repeated washings. The released hydrogen ions were titrated with standard NaOH solution.

Heat Treatment. To check the effect of temperature on the I.E.C. about 2 g of exchanger in the H^+ form was taken in different silica crucibles and each was heated in an automatic temperature controlled muffle furnace at different temperatures until the equilibrium reached. The I.E.C.'s of heated samples were determined with 1M NaCl without reconverting them to the H^+ form and plotted as a function of temperature in Fig. 1.

Thermogravimetric Analysis (T.G.A.). The thermogravimetric analysis was done by taking 0.5 g of the material in the H^+ form. It was heated at a rate of 10°C min^{-1} from 40 to 1000°C (accuracy ±5%) in an atmosphere of air and the weight loss as a function of temperature was recorded and shown in Fig. 2.

Water Absorption. 0.5 g of the sample in the H^+ form was heated at 100 and 200°C. The same sample in the Na^+ form was heated at 220°C for 1 h. The heated samples were stored in an air tight desiccator over a saturated solution of ammonium nitrate. The absorption of water was recorded at different time intervals.

Rate of Ion Exchange. The rate of ion exchange was measured by taking 50 ml of 1 M solution of the cation. The pH of the solution was measured and then 0.5 g of the exchanger in the H^+ form was added. The solution was shaken at short intervals and pH was recorded. The pH vs. time (in minutes) was plotted and shown in Fig. 3.

pH-Titration. The pH-titrations were performed by

the method of Topp and Pepper.[22] 0.1 g samples of dry exchanger in the H^+ form were shaken with 10 ml portions of 0.1 M (NaCl+NaOH) cationic solution in different conical flasks at 25±0.5°C. The ratio of NaCl/NaOH was varied from 0.1 M/0.01 M to 0.01 M/0.1 M in the equilibrating solution of the flasks. After 24 h the pH of the supernatant solution of each flask was recorded and plotted against the mEq of OH^- added per g of dry exchanger. For reverse titration, the Na^+ form of the exchanger was treated in a similar fashion with 0.1 M (NaCl+HCl) solution (Fig. 4).

X-Ray Diffractogram. Powder X-ray diffraction technique was used to take the diffractogram of the powdered sample using nickel filtered Cu $K\alpha$-radiation (λ=1.5404 Å).

IR Study. IR spectra of the material heated at various temperatures (i.e., from 40 to 1000°C) were recorded with the standard KBr disc technique. The spectrum of the material in the Na^+ form dried at 40°C was also recorded. The spectra are shown in Fig. 5.

Distribution Coefficients (K_d Values). K_d values of 25 cations on the exchanger sample were determined in DMW, 0.001, 0.01, and 0.1 M HNO_3 solutions (Tables 4a, 4b, 4c). The cations present in the solution were titrated with 10^{-3} M EDTA solution using the specific metal indicator. The distribution coefficient (K_d) was calculated as:

$$K_d(\text{ml g}^{-1}) = \frac{\text{Moles of metal ion per g of solid}}{\text{Moles of metal ion per ml of solution}}.$$

Separation Studies. The mixture of the metal ions were loaded on the exchanger and then the ions were eluted by suitable eluents. The flow rate of the effluent was maintained at 0.5 ml min^{-1} throughout the process. The released cations were estimated with standard 0.001 M EDTA solution (Table 5).

Results and Discussion

During these studies more than 20 samples of niobium phosphate have been synthesized under various conditions (results omitted to save space). Most of the samples were suitable for column operations and showed ion-exchange capacities varying from 0.16 to 1.2 mEq g^{-1} for the Na^+ ion. Only five of the samples (Table 1) were synthesized thrice, their ion-exchange capacities and chemical compositions were determined and found reproducible. They are designated as NbP1, NbP2,···, NbP5 respectively. The amorphous sample, NbP3 having Nb/P mole ratio of 0.67 and I.E.C. of 1.06 mEq g^{-1} was chosen first for detailed studies (reported in this manuscript). The studies on the rest of the samples is in progress and a part of it is reported elsewhere.[23]

Table 3 shows the ion-exchange capacities of samples 3 and 5 for various cations obtained by column process. The capacity increases as the hydrated radii of the cations decrease. The ion-exchange capacity of NbP3 increases from 0.86 to 1.06 mEq g^{-1} as the concentration of the eluent (NaCl) changes from 0.2 to 1 M and then becomes constant.

It is clear from Fig. 3 that the exchange is initially fast and then it slows down after one minute. Li^+, NH_4^+, and Sr^{2+} do not exchange as efficiently as Na^+ and K^+ ions.

The pH-titration of the material with NaOH in the presence of the added salt reveals its monofunctional behavior as it shows only one inflection point. The

behavior appears to be reversible at lower pH values, i.e., pH 1—2. A hysteresis loop occurs at higher pH values. This may be due to the hydrolysis of niobium and phosphate groups at higher pH values which results in a totally different phase formation. This is in accordance with the chemical stability data that the material gets hydrolyzed in alkaline solution. It gave an ion-exchange capacity of 1.68 mEq g^{-1} for Na^+ ion.

The chemical dissolution data (Table 2) show that NbP3 is highly stable in 4 M HNO_3 and 4M HCl. It dissolves frequently in 4 M H_2SO_4, 1 M tartaric acid, 4 M ammonia and in 0.1 M KOH solutions probably due to complex formation. Its stability in 4 M HCl is remarkable as most exchangers which are stable in 4 M HNO_3 are unstable in 4M HCl. The comparison of NbP3 with the arsenate, antimonate, and molybdate of niobium shows that in most solutions NbP3 in only next to niobium antimonate in chemical stability.

In order to obtain some informations regarding the empirical formula and theoretical ion-exchange capacity of NbP3, thermoanalytical investigations were carried out. It is clear from Fig. 1 that the ion-exchange capacity of the various ion exchangers decreases with increase in temperature. It also shows that NbP3 is more thermally stable than niobium arsenate and antimonate as far as its ion-exchange behavior is concerned.

X-Ray diffraction studies of the material dried at 40°C revealed its amorphous behavior while the material heated above 400°C showed some signs of crystallinity. Only two weak lines viz. at d=8.01 and d=3.22 Å appeared in these samples. The intensities of these lines increased with increase in temperature.

The comparison of T.G.A. curves of various exchangers in the H^+ form (Fig. 2) shows that the curves of niobium molybdate and niobium arsenate are simple and similar up to 500°C. However, the T.G.A. of NbP3 is more complicated than that of the former compounds. It resembles more the curve for niobium antimonate. The most remarkable aspect of this curve is the highest weight loss than for any of the four compounds. Another interesting feature is the three-step weight loss which shows that there are at least three types of dehydrations occurring in this compound. This unusual behavior is probably due to the great affinity of the phosphate groups for water molecules and also due to large content of hydroxo-phosphate anionic part.

For niobium phosphate the weight loss is maximum (19.65%) up to 700°C. Assuming that at this temperature the composition of the sample is $2Nb_2O_5 \cdot 3P_2O_5$ (Nb:P=2:3, by chemical analysis) the number of moles of water lost per formula weight of the exchanger corresponding to the weight loss at different temperatures was calculated by the method of Alberti, et al.[24] and shown in Table 6.

If n is the number of moles of water per mole of "mixed oxide," then

$$\% \text{ weight loss} = \frac{1800\,n}{958+18\,n}, \tag{1}$$

(where mol. wt. of "mixed oxide" = 958).

From this equation the empirical formula can be obtained as follows:

Suppose

W_H = % weight loss in H^+-form of exchager up to 800 °C,

W_{Na} = % weight loss in Na^+-form of exchanger up to 800 °C,

n_H = number of moles of water corresponding to W_H,

n_{Na} = number of moles of water corresponding to W_{Na},

n_{ex} = number of moles of water from –OH groups responsible for exchange,

n_{ab} = number of moles of water absorbed or the water of crystallization,

then

$$n_{ex} = n_H - n_{Na}, \tag{2}$$

$$n_{ab} = n_H - n_{ex}. \tag{3}$$

Treatment of the experimental data according to Eqs. 1, 2, and 3 gives

$$n_{ex} = 2.96,$$

$$n_{ab} = 10.05.$$

Hence we can assign the following formula to NbP3 sample:

$$2Nb_2O_5 \cdot 3P_2O_5(H_2O)_{2.96}10.05\ H_2O.$$

Hence,

$$\text{the theoretical I.E.C.} = \frac{2.96 \times 2 \times 1000}{1192.18}$$

$$= 4.96\ \text{mEq g}^{-1}.$$

The sodium ions are exchanged only up to 1.63 mEq g^{-1} in alkaline medium. It is very low as compared to the theoretical exchange capacity (4.96 mEq g^{-1}) and corresponds to two protons per formula weight of the exchanger. It seems that under our experimental conditions only the surface protons take part in the exchange reaction as the ingoing cations are not able to reach all the exchange sites (six protons) in amorphous niobium(V) phosphate. Hence only a part (two protons) of the H^+ present are exchangeable.[25-31]

The exchanger in the H^+ form when heated to 100 and 200 °C shows a weight loss of 10.2% (n=6.04) and 11.8% (n=7.12), respectively. Upon storing these dried samples in air-tight desiccator over a saturated solution of NH_4NO_3 solution, the former reabsorbs 100% water within 20 h while the latter could absorb only 86.06% water (n=6.01) after 100 h. This shows that the loss of water at 100 °C is completely reversible while at 200 °C only 86% reversibility is obtained. When the same sample in the Na^+ form was heated to 200 °C and stored over a saturated solution of NH_4NO_3, it regained the lost water molecules at a slightly higher rate than that of the H^+ form. It recovered approximately all the weight loss within 100 h. This reveals that the hydrated Na^+ ion lies within the cavity and keeps it slightly expanded thus facilitating the reabsorption of the water molecules into the cavity.

The IR spectra of NbP3 heated at various temperatures are given in Fig. 5. All the spectra refer to the niobium phosphate in the H^+ form. Only D_{s40} refers to that of Na^+ form dried at 40 °C. A comparison of D_{40} and D_{s40} spectra is very interesting. Since the band between 3000 and 3600 cm^{-1} refer to strong hydrogen bonds between-OH groups of water molecules and hydrogen-bearing oxygen of phosphate groups, therefore this band may be attributed to the long hydrogen bond P-O-H····O-H and P-O-H····$O\langle^{H}_{H}$.[32] When the hydrogen ion of the P-OH group is replaced by Na^+, the hydrogen bonding is diminished and the band becomes narrower. A similar effect is observed for the band between 940 and 1180 cm^{-1}. This band can be assigned to the symmetric and antisymmetric vibrations for the phosphate groups.[32] When the hydrogen ion of P-OH is replaced by Na^+, which is more strongly ionized we obtain a much narrower peak in D_{s40} spectra in this region at 1020 cm^{-1}. The effect of heating on the band between 3000 and 3600 cm^{-1} and the peak at 1630 cm^{-1} can be interpreted as follows:

Since the band is due to P-O-H····$O\langle^{H}_{H}$ and the peak due to deformation vibration of H_2O and -OH groups it is possible that in the beginning, i.e., from 40 to 300 °C, the absorbed water molecules are lost and therefore the band and the peak become narrower as one goes from 40 to 300 °C. However, at 400 °C the P-OH groups of the phosphates begin to condense and this condensation is complete up to 800 °C. Therefore, at 800 °C (D_{800}) the band and the peak completely disappear. The effect of heat on the band between 940 and 1180 cm^{-1} is quite different. Since this band is due to P-O vibrations[32] it remains unaffected up to 300 °C with the loss of water molecules. Above 300 °C the band becomes narrower due to condensation of P-OH groups and the increase in the concentration of P-O-P groups. At 800 °C all the P-OH groups condense and hence a very sharp peak is obtained owing to the presence of P-O-P groups at 1020 cm^{-1}. This phase also shows some more peaks at 850, 620, 580, 350, and at 250 cm^{-1} corresponding O-P-O and O-Nb-O interatomic stretching vibrations.[32] In this way we can say that D_{800} is completely a new phase having no hydroxyl group or water of free ionic sites responsible for ion exchange.

Theoretical Interpretation of the Heating Effect. The schematic diagram and Fig. 1 show the amount and the type of water molecules lost with temperature. At 100 °C six water molecules attached to $\overset{*}{H}PO_4$ groups are lost. Up to 200 °C, 1.12 more water molecules are irreversibly removed from the cavity resulting in the cavity shrinkage and a negligible effect on the I.E.C. Up to 350 °C all the rest absorbed (probably coordinated to niobium) water molecules are lost. The condensation of phosphate groups starts above 400 °C and up to 550 °C two water molecules are lost as a result of intermolecular condensation of four phosphate groups.

$$(\overset{*}{H}PO_4^{2-})_2(HPO_4^{2-})_4 \xrightarrow[\approx 550°C]{-2H_2O} (\overset{*}{H}PO_4^{2-})_2(P_2O_7^{4-})_2$$

Intermolecular Condensation of Monomers

At 650 °C the dimer formation starts due to intramolecular condensation of the monomers and 0.5 water molecule per formula weight is lost from one of the $\overset{*}{H}PO_4^{2-}$ group and thus the I.E.C. is reduced to half.

$$2[(\overset{*}{H}PO_4^{2-})_2(P_2O_7^{4-})_2] \xrightarrow[\sim 650°C]{-H_2O} (\overset{*}{H}PO_4^{2-})_2(P_2O_7^{4-})_5$$

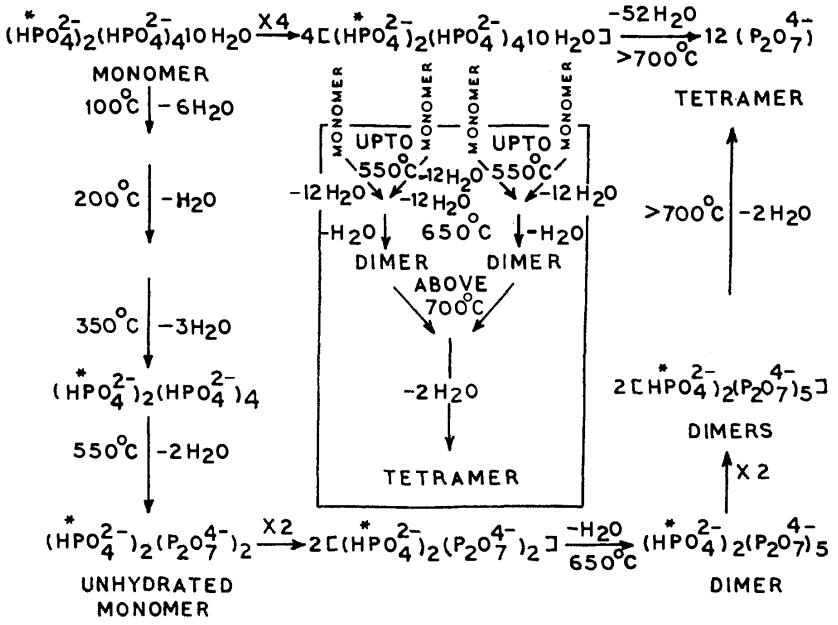
Monomers Dimer

Intramolecular Condensation

Above 700 °C two dimers combine together to give a tetramer. The condensation is complete up to 800 °C and at this stage all the exchange sites are exhausted.

$$2[(\overset{*}{H}PO_4^{2-})_2(P_2O_7^{4-})_5] \xrightarrow[>700°C]{-2H_2O} (P_2O_7^{4-})_{12}$$

Dimers Tetramer



Schematic Representation of Heating Effect on Niobium Phosphate

The condensation process in this way agrees with IR, X-ray, T.G.A., and I.E.C. data and the niobium to phosphorus mole ratio remains constant at all the temperatures studied.

The K_d values of 25 metal ions on niobium phosphate (NbP3), niobium arsenate (Nb-As), niobium molybdate (Nb-Mo), and niobium antimonate (Nb-Sb) in DMW are given in Table 4a. All these materials show a high uptake for Cu^{2+}, Bi^{3+}, La^{3+}, Pr^{3+}, Y^{3+}, Sm^{3+}, and Gd^{3+}. Table 4b lists the K_d values on NbP3, Nb-As, Nb-Sb, and Nb_2O_5 which reflects that these exchangers show no absorption of Mg^{2+}, high or preferential uptake of Hg^{2+}, Pb^{2+}, Zr^{4+}, and V^{5+} and moderate preference towards lanthanides in 10^{-1} M HNO_3. Distribution coefficients on NbP3 in 10^{-2} M and 10^{-3} M HNO_3 decrease upon increasing the acid concentration as is evident from Table 4c.

The study of distribution coefficients in nitric acid solutions reveals the appreciable differences among the K_d values of a number of metal ions. The exchanger appears to be selective for Co^{2+} and Zr^{4+} in all the media. It seems that it can be used for the separation and purification of rare earth from various metal contaminants. These studies will require a careful examination of the problem. At present no attempt has been made in this direction, or rather, four quantitative separations of common cations namely, Mg^{2+}-Ca^{2+}, Mg^{2+}-Ba^{2+}, Zn^{2+}-Cd^{2+}, and Bi^{3+}-Zn^{2+} have been tried and successfully achieved on amorphous niobium(V) phosphate column. The results are presented in Table 5 which show that the recoveries of the metal ions lie within the limit of experimental errors.

(Received July 15, 1985)

The cis-trans photoisomerization of 5-styryl-1,3-dimethyluracil is investigated. The fluorescence and photoisomerization quantum yields in various solvents of different viscosity and polarity, the effect of salt, pH, and heavy atom on the fluorescence and photoisomerization, the triplet sensitization of the photoisomerization, and the azulene quenching of the direct and sensitized isomerization indicate the singlet mechanism for the direct photoisomerization of the compound. The laser flash photolysis at room temperature showed a weak triplet-triplet absorption indicating some intersystem crossing from the excited singlet state to the triplet state.

The photochemical cis-trans isomerization of olefinic compounds has been extensively studied and is one of the best-known photoreactions.[1-4] Nonetheless, its mechanistic details have been the subject of much controversy.

From the theoretical calculations and spectroscopic observations for stilbene, it was proposed that the activated internal rotation about the central double bond in the excited ^1S state should be followed by internal conversion of ^1S to ^2S with a minimum energy for the twisted geometry leading to $^2S \rightarrow {}^0S$ internal conversion thereby isomerizing.[5-7]

The photochemical and photophysical properties of heteroaromatic compounds has been given much attention because the (n,π^*) states introduced by the heteroatom affect the photochemical behavior. The proximity of (n,π^*) states to the lowest (π,π^*) states increases radiationless transitions to deactivate the excited molecules. Azastilbenes, typical examples of olefins with heteroaromatic moiety, have attracted some interests.[8-11] With photoisomerization, a variety of reactions including photochemical addition, reduction, substitution, and elimination processes have been observed which evidently originate via hydrogen atom abstraction by an electron-deficient nitrogen.[12,13] The styrylpyridines (StP's) and 1,2-dipyridylethylenes (DPE's) have very low fluorescence and photoisomerization quantum yields when the heteroatom is in the ortho or para position[9,10] due to the fast deactivation of the excited singlet state through efficient internal conversion. The singlet mechanism has been proposed for the direct photoisomerization of StP's and DPE's.[9,10]

Pyrimidine nucleosides substituted at the C-5 position constitute a class of biologically significant molecules[14,15] and it is interesting to study the photochemical behavior of these molecules. We report here the cis-trans photoisomerization of (*E*)-5-styryl-1,3-dimethyluracil (5(*E*)-SDU) as a model for C-5 modified pyrimidine bases.

X = N, 2,2'-DPE

Experimental

Materials. (*E*)-5-Styryl-1,3-dimethyluracil (5(*E*)-SDU) was prepared by palladium-catalyzed reaction[16,17] of styrene and 1,3-dimethyluracil.[18] The reaction mixture was resolved on a silica-gel column using ethyl acetate-cyclohexane-chloroform (1/1/2, v/v) as the eluent, and recrystallized from 1-octanol: Mp 145.5—147.5 °C; Mass spectrum *m/z* 242 (molecular ion) 157 ($M^+-C_3ON_2H_5$) 115 ($M^+-C_5O_2N_2H_7$); UV ($CHCl_3$) λ_{max} 316 nm (ε 24500); ^1H NMR ($CDCl_3$) δ=7.25 (m, 5H, aromatic), 7.4 (d, 1H, phCH=), 6.8 (d, 1H, U-CH=), 3.53, 3.5 (s, 3H, N-CH_3). 5(*E*)-SDU in acetonitrile was irradiated with benzophenone as a sensitizer at 350 nm in a Rayonet photochemical reactor for 2 h after the solution was degassed by bubbling with N_2 gas for 1 h. 5(*Z*)-SDU was separated by column chromatography over silica gel and recrystallized from ethanol: UV ($CHCl_3$) λ_{max} 255, 305 nm (ε 5000); ^1H NMR ($CDCl_3$) δ=7.25 (m, 5H, aromatic), 7.3 (d, 1H, phCH=), 6.5 (d, 1H, U-CH=), 3.4, 3.2 (s, 3H, N-CH_3).

Benzophenone (Sigma) was recrystallized from cyclohexane. Azulene (Aldrich) was purified by vacuum sublimination. Commercially available styrene, uracil, mercury(II) acetate, trimethyl phosphate (Aldrich), and palladium chloride (Inuisho) were used without further purification. Extra pure solvents were used as received or after purification by distillation or standard methods.[19,20]

Spectra. NMR spectra were measured on a Varian T-60A spectrometer. Mass spectra were determined with a Hewlett Packard 5985 A GC/MS system by electron impact method. UV spectra were recorded on a Cary 17 spectrophotometer. Fluorescence spectra were recorded on an Aminco Bowman spectrofluorometer. Fluorescence quantum yields were determined using quinine hydrogen sulfate (Φ_f=0.546) as a reference. The fluorescence lifetime was measured at room temperature with SLM Model 480 phase modulation spectro-

Table 1. Phtoisomerization and Fluorescence Quantum Yields, Fluorescence Lifetimes, and Rotation Barriers of 5(*E*)-SDU and Other Stilbene Derivatives[9,10,24]

photofluorometer.

Quantum Yields of Isomerization. Three ml samples in Pyrex ampoules were degassed by freeze-pump-thaw method and then sealed. These samples were irradiated in a merry-go-round apparatus with Hanovia 450 W medium-pressure mercury arc lamp (Type 697A36). Corning glass filters CS 0-52 and 7-37 were used to isolate 366 nm UV light. Light intensities were measured by trioxalatoferrate(III) actinometry.[21] Samples were analyzed by HPLC on a Waters Associates Model 244 liquid chromatograph. Reactions were carried out to less than 5% conversion to avoid competition with the back reaction.

Laser Flash Photolysis. The nanosecond laser photolysis apparatus has been described elsewhere.[22] A XeF (351 nm) and a KrF (248 nm) excimer laser (Lambda Physik EMG101E) were used as excitation light sources. The concentrations (1.5×10^{-5}—5.9×10^{-5} M[†]) of 5(*E*)- and 5(*Z*)-SDU were adjusted such that suitable amount of the laser light was absorbed. The lifetime for decay of the transient of 5(*E*)-SDU was obtained from oscillograms.

Results and Discussion

Fluorescence Studies. The fluorescence quantum yield and lifetime of 5(*E*)-SDU are lower and shorter than those of stilbene and meta-isomers of StP's and DPE's, but higher and longer than those of ortho- and para-isomers of StP's and DPE's (Table 1). The lone-pair electrons of N-atoms are conjugated with olefinic π-electrons more easily in ortho- and para-positions than in meta-position, so that the $^1(n,\pi^*)$ electronic configuration, inducing the nonradiative process, is involved to more extent in the former positions than in the latter one. The results suggest that the lone-pair electrons of N-atoms in 5(*E*)-SDU is not sufficiently delocalized as in 3-StP[10,23] and 3,3′-DPE and give less contribution to radiationless transition than in 2- and 4-StP's and 2,2′- and 4,4′-DPE's. The fluorescence quantum yield is strongly enhanced at liquid nitrogen temperature and the laser flash photolysis experiments show low Φ_{isc} for 5(*E*)-SDU at room temperature. Therefore, the deactivation of 5(*E*)-SDU at room temperature is mainly attributable to internal conversion rather than to intersystem crossing.

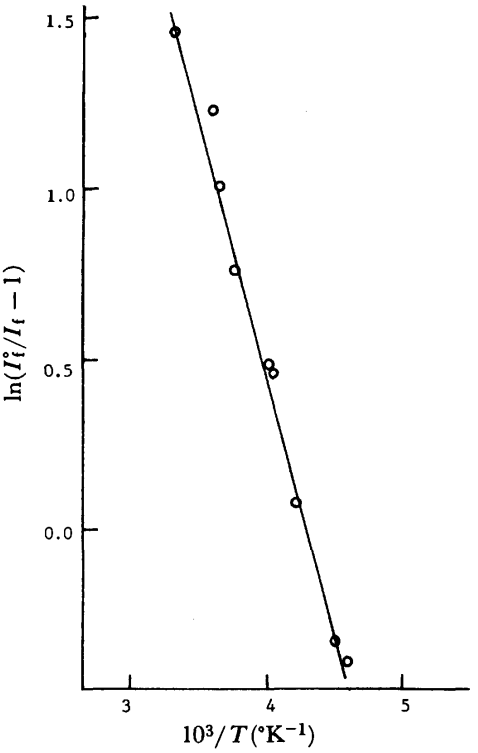

Fig. 1. Arrhenius plot for the temperature dependence of fluorescence intensity of (*E*)-5-styryl-1,3-dimethyluracil in methylcyclohexane-isopentane (1:1, v/v).

The fluorescence quantum yield depends on solvent viscosity (Table 2) and temperature (Fig. 1). If twisting in the first excited singlet state is postulated to be the activated process competing with fluorescence, the suggested mechanism for decay of 5(*E*)-SDU singlet state follows the scheme shown below.

$$t \xrightarrow{h\nu} {}^1t \quad (1)$$

$${}^1t \xrightarrow{k_f} t + h\nu \quad (2)$$

$${}^1t \xrightarrow{k_{ic}} t \quad (3)$$

$${}^1t \xrightarrow{k_{isc}} {}^3t \quad (4)$$

$${}^1t \xrightarrow{k_p} {}^1p \quad (5)$$

$${}^1p \xrightarrow{k_d} \alpha t + (1-\alpha)c \quad (6)$$

Here, t, c, and p represent trans, cis, and twisted geometry of 5-SDU, while k_f, k_{ic}, k_{isc}, k_p, and k_d are the rate constants for fluorescence, internal conversion, intersystem crossing, twisting, and decay, respectively. The fluorescence quantum yield is given by Eq. 7.

$$\Phi_f = k_f/(k_f + k_{ic} + k_{isc} + k_p) \quad (7)$$

Since step 5 is temperature dependent, k_p may be described by the Arrhenius equation (Eq. 8),

$$k_p = Ae^{-E_a/RT}. \quad (8)$$

The limiting fluorescence quantum yield at low temperature where the rate of twisting is too slow to compete with the other decay processes is

$$\Phi_f^0 = k_f/(k_f+k_{ic}+k_{isc}). \quad (9)$$

Therefore,

$$\frac{\Phi_f^0}{\Phi_f} = \frac{k_f+k_{ic}+k_{isc}+Ae^{-E_a/RT}}{k_f+k_{ic}+k_{isc}}$$

$$\ln(\Phi_f^0/\Phi_f-1) = \ln(I_f^0/I_f-1)$$
$$= \ln(A/(k_f+k_{ic}+k_{isc})) - E_a/RT.$$

If steps (2), (3), and (4) vs. step (5) is relatively independent of the temperature, plots of $\ln(I_f^0/I_f-1)$ vs. $1/T$ will be linear with a slope of $-E_a/R$. Values for I_f were estimated by modifying the method of Kirby and Steiner[40] and the best straight line relationship was obtained for $I_f^0=79$. An activation energy of 3.0 kcal mol^{-1} (1 cal=4.184 J) for the excited 5(*E*)-SDU is obtained from the slope.

In the fluorescence excitation polarization with λ_{em} 410 nm in ethanol, the 320 nm band is highly positive polarized ($P_{320\,nm}$=0.42) and flat in the longer wavelength, while the shoulder of 270 nm is relatively little positive polarized ($P_{270\,nm}$=0.21). The fluorescence polarization of 5(*E*)-SDU with excitation of 320 nm in ethanol is also highly positive polarized. This results imply that the lowest excited singlet state has (π,π^*) configuration in ethanol. 5(*Z*)-SDU has very weak fluorescence at room temperature, probably due to the fast internal conversion.

5(*E*)-SDU has very weak phosphorescence with the maxima of 580 and 620 nm in ethanol and isopentane–ethyl ether (1:1, v/v) at 77 K. The phosphorescence polarization of 5(*E*)-SDU with the excitation of 320 nm in ethanol is highly negative polarized. Accordingly, the lowest triplet state is thought to be $^3(\pi,\pi^*)$ state. Phosphorescence lifetime is shorter in ethanol (τ_{ph}=0.38 s) than in isopentane–ethyl ether (1:1, v/v) (τ_{ph}=0.41 s) and 5(*Z*)-SDU has no phosphorescence even at 77 K in ethanol.

Direct Photoisomerization. Direct photoisomerization quantum yields of 5-SDU in various solvents are reported in Table 2. The previous papers reported that the photoisomerization and fluorescence of stilbene depends on solvent viscosity[26] and couple with varying temperature in a highly viscous media.[27,28] This was explained by assigning the thermally activated process which competes with fluorescence and leads to isomerization to the twisted form from the fluorescing transoid form.[29] In solvents of low viscosity, there is an inherent thermal barrier to twisting about the central double bond. In certain viscosity regions the solvent imposes an additional barrier which must also be overcome before twisting about take place. Therefore, quantum yield of fluorescence increases and that of trans–cis photoisomerization decreases as solvent viscosity increases.

Both fluorescence and photoisomerization quantum yields of 5(*E*)-SDU are very low compared to stilbene, probably due to the presence of (n,π^*) state which can lead to very rapid radiationless decay. The photoisomerization quantum yield of 5(*E*)-SDU is similarly influenced by solvent viscosity (Table 2) as that of fluorescence while it is little affected by the solvent polarity. The energy levels of (π,π^*) and (n,π^*) states in 5-SDU are not close enough to affect the radiationless processes by solvent polarity in contrast to those of StP's.[11b,30] Effect of solvent viscosity suggest the presence of small energy barrier for the internal rotation around the central double bond as calculated in the fluorescence studies.

The quantum yield of cis→trans photoisomerization, $\Phi_{c\to t}$ of 5(*Z*)-SDU, is smaller than that of trans→cis photoisomerization, $\Phi_{t\to c}$ (Table 2) probably due to the shorter lifetime of the excited 5(*Z*)-SDU compared to 5(*E*)-SDU and/or to the fast competing reaction, photocyclization. Study of the direct cis–trans photoisomerization is complicated because of the facile photocyclization.[31]

Sensitized Photoisomerization. The quantum yields of benzophenone sensitized photoisomerization for 5-SDU in various solvents are given in Table 3. While the direct photoisomerization is very inefficient, 5-SDU undergoes fairly efficient photoisomerization when sensitized by benzophenone, indicating that the intersystem crossing in 5-SDU does not occur with measurable efficiencies and that the direct and sensitized isomerization pathways probably do not involve a common excited state. The azulene quenching studies lend further support to this contention. As the concentration of benzophenone increases, the photoisomerization quantum yield increases upto certain concentration of benzophenone and then decrease. When the concentration of benzophenone is low, benzophenone molecules do not absorb all the exciting radiation and the yield of the olefin triplet is low while self-quenching and triplet–triplet annihilation of benzophenone[32] becomes significant decreasing the energy transfer to 5-SDU at high benzophenone concentration. As Table 3 shows, the sensitized photoisomerization is strongly affected by the sol-

vent polarity in contrast to the direct photoisomerization which is affected by the solvent viscosity only. The sensitized photoisomerization quantum yield decreases with increasing the solvent polarity.

This result agrees with the observation that the lifetime of phosphorescence is shorter in the polar solvent than in the nonpolar solvent.

Salt, pH, and Heavy Atom Effect. The photoisomerization and fluorescence of 5(*E*)-SDU are little influenced by proton or salts supporting the results of solvent polarity effect. These results are in contrast with 2- and 4-StP.[30,36-38] The proton and alkali metal cation are expected to raise the energy level of $^{1}(n,\pi^{*})$ state in the similar manner like the polar solvents. The small Φ_{f} and short τ_{f} of 5(*E*)-SDU imply significant contribution of $^{1}(n,\pi^{*})$ state to the lowest excited singlet state and this leads to the reduction of isomerization efficiency occurring in the twisted $^{1}(\pi,\pi^{*})$ state. However, the results of pH and salt effects suggest that the $^{1}(n,\pi^{*})$ level is not close enough to $^{1}(\pi,\pi^{*})$ level and that even though the energy level of $^{1}(n,\pi^{*})$ state is raised by acids and salts, the fluorescent and isomerizable $^{1}(\pi,\pi^{*})$ state is little affected.

Fluorescence of 5(*E*)-SDU is quenched by ethyl iodide and photoisomerization increases with potassium iodide as shown in Table 4 suggesting that the triplet excited state increases due to the enhanced intersystem crossing induced by heavy atoms. The isomerization in the triplet state is more efficient than the direct isomerization as shown in the benzophenone sensitized photoisomerization. The results indicate that direct irradiation does not populate the triplet state significantly and radiative or radiationless deactivation processes from the singlet states determine the photoreactivity of 5-SDU.

Azulene Effect. Azulene quenches only the transoid singlet and triplet states of stilbene on direct and sensitized excitation,[26,39] but short lived cisoid excited state was not quenched. The following Stern-Volmer equation is derived assuming the selective quenching of transoid excited state by azulene and using the steady state approximation on excited species.

$$\Phi_{t\to c}^{0}/\Phi_{t\to c} = 1 + k_{q}\tau[Az],$$

where, k_{q} is the diffusion controlled quenching constant, τ is the lifetime of quenched species, and $\Phi_{t\to c}^{0}$ and $\Phi_{t\to c}$ are trans→cis photoisomerization quantum yields in the absence and presence of azulene, respectively.

Azulene effect on the direct and sensitized photoisomerization of 5(*E*)-SDU is summarized in Table 5. The results show much smaller slope for the direct isomerization compared to that for the benzophenone sensitized isomerization. The same phenomena were observed in the case of stilbene,[26] StP's, and DPE's.[11b]

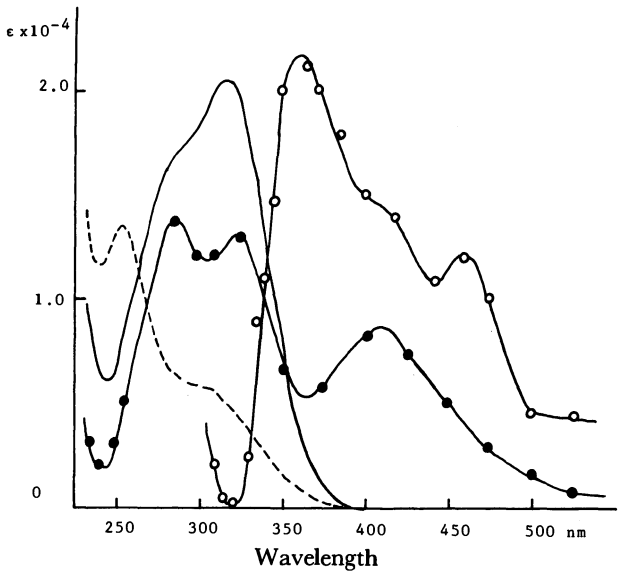

Fig. 2. UV absorption (——; 5(*E*)-SDU, -----; 5-(*Z*)-SDU) and triplet-triplet absorption spectrum (-O-O-O-: 5(*E*)-SDU, -●-●-●-: 5(*Z*)-SDU) of 5-SDU in ethanol.

This is consistent with a singlet mechanism for the direct isomerization.

Laser Flash Photolysis. Nanosecond time-resolved absorption spectra of 5-SDU in ethanol are shown in Fig. 2. In order to determine the molar absorption coefficient for triplet-triplet absorption, benz[*a*]anthracene which has molar absorption coefficient of 2.0×10^4 $M^{-1}cm^{-1}$ † at 455 nm is used as a reference compound. The intersystem crossing quantum yield, Φ_{isc}, of ca. 0.052 was obtained indicating that intersystem crossing of 5(*E*)-SDU is small but detectable and that the possibility of the involvement of triplet mechanism for direct photoisomerization is very small but cannot be excluded.

Irradiation of *cis*-stilbene in benzene gave only a long-lived absorption centered around 450 nm[34] which was attributed to 9,10-dihydrophenanthrene. Only long-lived transient of 5(*Z*)-SDU is observed at room temperature probably due to the formation of 9,10-dihydrophenanthrene derivative just like in the case of *cis*-stilbene.

The triplet energy of 5(*E*)-SDU was determined by the energy transfer method. Addition of *trans*-stilbene (E_T=50 kcal mol^{-1}) does not affect the transient absorption at 375 nm. With 9,10-diphenylanthracene (E_T= 41.8 kcal mol^{-1}), strong triplet-triplet absorption of 9,10-diphenylanthracene at 425 and 480 nm was observed. As benz[*a*]anthracene (E_T=47.2 kcal mol^{-1}) is added, strong triplet-triplet absorption of benz[*a*]-anthracene at 475 nm is detected with and without 5(*E*)-SDU. *trans*-1,3,5-Hexatriene gave no effect on the transient absorption curve of 5(*E*)-SDU. From these results, the triplet energy of 5(*E*)-SDU is estimated to lie between 41.8 and 47 kcal mol^{-1}. The plot of log A (absorbance) vs. time (ns) showed the straight line following first-order kinetics. From the decay curve of triplet-triplet absorption, the lifetime of triplet state for 5(*E*)-SDU was determined to be ca. 93 ns. This value is consistent with the triplet lifetime calculated by azulene quenching studies (Table 5) for the sensitized isomerization, assuming the diffusion controlled quenching ($k_q=1.2\times10^{10}$ $dm^3\,mol^{-1}\,s^{-1}$ at 20 °C in chloroform).

Conclusion

Fluorescence quantum yield of 5-SDU depends on the temperature and solvent viscosity increasing markedly at low temperature and high viscosity. The proton and salts have no effect on the fluorescence and photoisomerization. Addition of heavy atom affects the intensity of fluorescence and the quantum yield of direct photoisomerization strongly. The large difference is observed in the azulene quenching of the direct and sensitized photoisomerization. These observations strongly indicate the singlet mechanism for the direct photoisomerization and the intersystem crossing is not an important decay path at room temperature even though the laser flash photolysis shows detectable intersystem crossing at room temperature.

This investigation was supported by the Korea Science and Engineering Foundation. Authors thank Drs. K. Yoshihara and N. Nakashima of the Institute for Molecular Science, Okazaki, Japan and Dr. K. H. Chae of Chon Nam National University, Korea for the laser flash photolysis data.

A ^{15}N NMR Study of the Tautomeric Equilibria of Some 5-Substituted Tetrazoles

Elzbieta BOJARSKA-OLEJNIK, Lech STEFANIAK,* Michał WITANOWSKI, and Graham A. WEBB*,†
Institute of Organic Chemistry, Polish Academy of Sciences, 01-224 Warsaw, Kasprzaka 44/52, Poland
†Department of Chemistry, University of Surrey, Guildford, Surrey, U. K.
(Received December 28, 1985)

^{15}N NMR shielding data are presented for some 5-tetrazolones and some 5-tetrazolethiones. CNDO/S-SOS nitrogen shielding calculations are also performed for these compounds. The results obtained show that the compounds studied exist almost entirely in the oxo and thioxo forms, rather than the hydroxy or mercapto forms respectively, in DMSO solution.

We have previously reported some ^{15}N NMR data for both unsubstituted tetrazole[1] and some 5-mercapto-substituted[2] tetrazoles. In the case of some 5-hydroxy-tetrazoles electronic spectral data have been reported. Prototropic tautomerism is of some considerable interest in the field of azole chemistry.[4] The results reported indicate that the tetrazoles studied exist almost entirely in the thioxo and oxo forms rather than the mercapto and hydroxy forms respectively.

Our earlier studies have revealed that prototropic tautomerism of both unsubstituted and 5-(methylthio)-tetrazoles give rise to a predominance of the structure with a proton attached to N-1. In both cases this structure is reported to be present to the extent of about 85%.[1,2]

We now propose to investigate the possibility of prototropic tautomerism in 5-mercaptotetrazole and 1-methyl-5-hydroxytetrazole.

Results and Discussion

The results of a ^{15}N NMR investigation of 5-tetrazolone, 5-tetrazolethione and some related compounds are given in Table 1 together with the results of some CNDO/S-SOS nitrogen shielding calculations. The latter are reported on the absolute scale, whereas the experimental ^{15}N shieldings are given with respect to that of nitromethane. Consequently a one-to-one correspondence between these two sets of shielding data is not to be anticipated. However, for a given compound the calculated relative order of nitrogen shielding data is sufficiently reliable to permit their use for signal assignment purposes.[1]

In addition to the CNDO/S-SOS shielding results the nitrogen shielding assignments presented in Table 1 are obtained from a knowledge that pyrrole-type nitrogen atoms are highly shielded[5] with respect to pyridine-type nitrogen atoms. Bonding to another nitrogen atom produces a deshielding of the first nitrogen and bonding to two other nitrogens gives rise to a further nitrogen deshielding.[5]

Compounds **2** and **3** are studied as models for compound **1** which, in principle may exist as a tautomeric mixture of structures A, B, C, and D in DMSO. The structures of compounds **2** and **3** are known from literature data,[2] preparation and the assignments given in Table 1 of their ^{15}N NMR spectra are consistent with this.

The experimental data given in Table 1 for compound **1** is very similar to that of compound **3** which, of neccesity, exists as structure A. Therefore structure A is clearly the predominant one for compound **1**. However, we had initially anticipated that compound **1** would have existed mainly, if not entirely, in form B. Our reason for supposing this is by comparison with compound **2** which is demonstrated to consist of form B.[1] A possible explanation of our observation of form A for compound **1** is that solvent interactions lead to a preference of form A over form B.

Turning now to a consideration of the nitrogen shielding data for compounds **4** and **5**. In principle compound **4** may exist as a mixture of tautomers. In order to investigate this possibility compound **5** has been studied as a model compound.

The nature of the tautomeric equilibria in which compound **4** may be involved is as follows:

From a comparison of the results given in Table 1 for compounds **4** and **5** it is apparent that compound **4** exists in DMSO predominantly as form E. Any amount

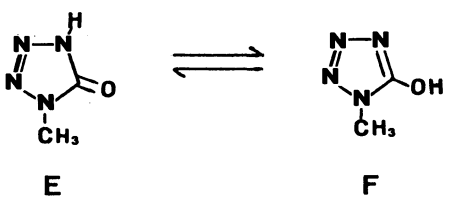

Fig. 2.

Table 1. ^{15}N NMR Shielding Data[a] for Some 5-Tetrazolones and Some 5-Tetrazolethiones Obtained by Experiment and Calculation by the CNDO/S-SOS Procedure

Number	Compound[a]	Nitrogen atom	Experimental results in DMSO	Theoretical results[b,c]
1		N-1	82.2	38.2
		N-2	70.4	35.1
		N-3	−3.9	−52.1
		N-4	50.4	−38.5
2		N-1	151.9	70.1
		N-2	25.4	−32.4
		N-3	17.4	−33.1
		N-4	145.7	64.2
3		N-1	97.3	61.4
		N-2	70.9	45.2
		N-3	−4.5	−56.1
		N-4	47.7	−39.7
4		N-1	193.1	68.2
		N-2	43.2	−33.7
		N-3	33.6	−34.6
		N-4	187.7	62.4
5		N-1	193.2	70.7
		N-4		
		N-2	39.1	−41.0
		N-3		
6		N-1	100.5	55.3
		N-4		−10.2
		N-2	4.5	−26.1
		N-3		−36.3
7		N-1	158.1	70.1
		N-2	7.1	−27.1
		N-3	−11.1	−36.9
		N-4	55.6	−9.8
8		N-1	81.6	−27.6
		N-2	101.4	42.4
		N-3	−2.3	−50.9
		N-4	53.4	−35.3

a) All shielding data are reported in ppm. The experimental results relate to external nitromethane as standard; a possible increment corresponds to a shielding increase. b) The structures given are predominant in DMSO solutions and the theoretical shielding results relate to these structures. c) The theoretical results relate to absolute shieldings.

of form F present is predicted to be less than 5%. In the case of compound **4** the assignment of the N-2 and N-3 signals is consistent both with the deshielding influence of a β-effect and with the predictions of the CNDO/S-SOS shielding data. The relative assignments of the N-1 and N-4 signals are based on a comparison of the assignment of compound **2**, the shielding results observed for compound **5** and those calculated by the CNDO/S-SOS procedure for compound **4**.

In conclusion we observe that ^{15}N NMR spectroscopy is a very satisfactory procedure for investigating tautomeric equilibria of some 5-substituted tetrazoles. Additionaly, we note that CNDO/S-SOS parametrized shielding calculations are suitable for estimating the relative shieldings of the nitrogen atoms in the tetrazole ring.

Experimental

Compounds **1**,[6], **4**,[7] and **5**[7] were prepared by previously published procedures, while compound **2** was obtained commercially. Compound **3** was prepared by methylating the sodium salt of 2-methyl-5-mercaptotetrazole with dimethyl sulfate in equimolar amounts in methanol as solvent according to procedure published elsewhere.[1] The purity of all compounds employed was varified by means of ^{1}H and ^{13}C NMR measurements.

The ^{15}N NMR spectra were obtained on a Bruker WH 400 spectrometer using 10 mm sample tubes for 0.5 M (1 M=1 mol dm^{-3}) solutions at ambient temperatures. Nitromethane was used as an external standard. Typical operating conditions employed a delay of about 2s between pulses, a pulse angle of about 70° and an aquisition time of 0.5s. Gated

decoupling was used to suppress possible NOE effects.

The CNDO/S-SOS shielding calculations were performed on the CDC 7600 system of the University of London using a modified version of QCPE 174. The details of the calculations are presented elsewhere.[8] Standards geometries were used in the calculations.[9]

We are grateful for SERC enabling us to gain access to the regional NMR facility at the University of Warwick and to Drs. O. W. Howarth and E. Curzon for recording the spectra.

XPS Study of Silica-Supported Copper Catalyst Derived from Binuclear Copper(II) Acetate Monohydrate or Mononuclear Tetraammine Copper(II) Complex

Noriyoshi KAKUTA, Akio KAZUSAKA,* and Koshiro MIYAHARA
Research Institute for Catalysis, Hokkaido University, Sapporo 060
(Received February 28, 1986)

Synopsis. The surface copper(II) species on a CuO/SiO_2 catalyst derived from binuclear copper(II) acetate monohydrate has been studied using XPS in comparison with that from the mononuclear tetraammine copper(II) complex. From the binding energy of Cu $2p_{3/2}$ peak and the peak ratio of Cu $2p_{3/2}$ and Si 2p together with the results by EXAFS, it was deduced that the highly dispersed one or two dimensional copper oxide cluster, which is interacted more weakly with SiO_2, is developed on the copper(II) acetate monohydrate derived catalyst.

An active site on heterogeneous catalysts has become of interest in the recent year. We have examined to prepare a supported binuclear copper oxide catalyst from typical binuclear copper(II) acetate monohydrate [$Cu_2(CH_3COO)_4 \cdot 2H_2O$], and have compared it with a conventional catalyst from a mononuclear tetraammine copper(II) complex.[1-6] The recent EXAFS study, however, suggested that the one or two dimensional copper oxide cluster was developed on SiO_2 instead of the binuclear copper oxide.[6] Also, the copper(II) species derived from copper(II) acetate monohydrate has been found to show following properties: 1) It reacts easily with acetic acid to give the binuclear structure of copper(II) ions, which was identified by ESR[1,2] or IR,[2] 2) it shows a tremendous high catalytic activity for CO oxidation with N_2O, CO isotope equilibriation reaction,[1,2] or oxygen isotope-exchange reaction between CO and CO_2,[5] 3) it is reduced easily to metallic copper with CO under mild conditions.[3,6]

To obtain a further detailed information about it, we have applied a X-ray photoelectron spectroscopy (XPS) technique to above two kinds of silica-supported copper catalyst, finding that the acetate derived catalyst retains a highly dispersed copper oxide cluster.

Experimental

Two kinds of silica-supported copper catalyst were prepared from copper(II) acetate monohydrate (denoted Ac-Cu/SiO_2) and a copper(II) tetraammine complex (denoted Am-Cu/SiO_2), as described in earlier papers.[1,2] Each sample was found to contain copper of 3.7 or 3.4 wt%, respectively. A Vacuum Generators ESCA 3 system was used with Mg $K\alpha$ radiation (1253.6 eV) for XPS measurements. The samples pressed into disk were pretreated by the way similar to that in the previous paper[1,2] with an IR lamp in the preparation chamber of ESCA instrument. CuO was also used for reference measurements. The binding energies (BEs) were referenced to the Si 2p peak at 103.4 eV, or the C 1s peak at 285.0 eV. The binding energies reported here are in accuracy with ±0.2 eV.

Results and Discussion

Figure 1a shows the XPS spectrum in the Cu $2p_{3/2}$ region, which was obtained on the Ac—Cu/SiO_2 catalyst activated under vacuum from room temperature to 300°C and calcined with 100 Torr (1Torr=133.322Pa) of oxygen at 300°C; the binding energy of Cu $2p_{3/2}$ is evaluated at 933.8 eV. The identical value was obtained on the reference sample of CuO. The satelite peak usually observed for typical Cu(II) compounds was unable to detect clearly on this sample. It might be due to the low loading of copper on it. We have used the Ac-Cu/SiO_2 catalysts containing rather a small amount of copper, because the specific features described previously were found to be lost by increaseing it above ca.7 wt%. An effort to detect the satelite peak due to the Cu(II) species was made at liquid nitrogen temperature, but only the spectrum similar to that of Fig. 1a was observed on it. This result indicates that the Cu(II) species was not reduced during the XPS measurement, as pointed out by Kevan et al.[7]

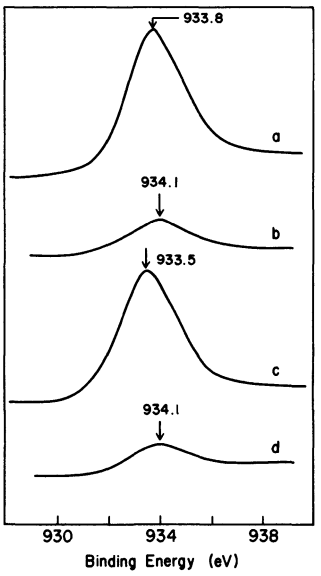

Fig. 1. Cu $2p_{3/2}$ XPS spectra of calcined Ac-Cu/SiO_2 (a), calcined Am-Cu/SiO_2 (b), reduced Ac-Cu/SiO_2 (c) or reduced Am-Cu/SiO_2 (d). All spectra were measured at room temperature.

Figure 1b shows the spectrum observed on the Am-Cu/SiO_2 catalyst, which was activated under vacuum at 300°C for 1 h and followed by calcining with 100 Torr of oxygen at 300°C for 1 h. This was also unable to identify the satelite peak in the Cu $2p_{3/2}$ region. The BE is evaluated at 934.1 eV. This value is higher than that of the Ac-Cu/SiO_2 catalyst or CuO.

In general, it is known that the BEs for metal oxides on supported catalysts tend to be higher than those of metal oxide themselves.[8,9] The authors have ascribed it to a coordination effects of supports or

Table 1. Surface Composition of Cu and Si on Ac-Cu/SiO_2 or Am-Cu/SiO_2

Treatment	$Cu(2p_{3/2})/Si(2p)$[a]	
	Ac-Cu/SiO_2	Am-Cu/SiO_2
Calcined	1.36	0.23
CO reduction	0.95	0.20

a) Estimated uncertainty is within ±5%.

the formation of the new compounds like MAl_2O_4, $MSiO_3$ etc. (M: metal cations). In this point of view, the copper(II) ions on the Ac-Cu/SiO_2 catalyst interacts more weakly with SiO_2 than those on the Am-Cu/SiO_2 catalyst.

The surface composition of Cu and Si can be evaluated from the peak intensities of their spectra. The ratios of Cu and Si are summarized in Table 1. Although both catalysts contain almost the same amount of copper as described previously, the Ac-Cu/SiO_2 catalyst has ca. 6 times higher concentration of the surface copper species than the Am-Cu/SiO_2 catalyst on their calcined states. These results are in agreement with those by EXAFS study[6]; it was found that one or two dimensional copper oxide cluster was loaded on the Ac-Cu/SiO_2 catalyst, while three dimensional one on the Am-Cu/SiO_2 catalyst.

When the calcined Ac-Cu/SiO_2 catalyst was reduced with 100 Torr of CO at 300°C for 1 h, followed by outgassing it at 300°C for 1 h, the spectrum was changed as shown in Fig.1c, giving the peak at 933.5 eV for Cu $2p_{3/2}$. It is somewhat higher than Cu_2O or metallic copper in literature.[10] The EXAFS study, however, showed that metallic copper was developed on the reduced Ac-Cu/SiO_2 catalyst.[6] The BE shift by the CO reduction therefore should be reflected by the presence of metallic copper.

On reducing the calcined Am-Cu/SiO_2 catalyst with 100 Torr of CO at 300°C, a little change was observed in the spectrum (Fig.1d). However, it seems to be broadened, suggesting that a small part of the copper(II) species was reduced by CO at 300°C. The Cu(I) species was detected by EXAFS experiment on it. The surface compositions of Cu and Si on the reduced samples are listed in Table 1.

In conclusion, the Ac-Cu/SiO_2 catalyst retains the highly dispersed low dimensional copper oxide cluster on silica, which is interacted weakly with the silica support. We believe that these features must give several particular catalytic properties different from the Am-Cu/SiO_2 catalyst.

We thank Prof. Nobutsune Takezawa of Hokkaido University for the valuable discussion.

A Time-Resolved ESR Study on the Photochemical Reduction of Nitrobenzene Derivatives in Alcoholic Solution

Kimio Akiyama, Yusaku Ikegami,* Tsuneo Ikenoue, and Shozo Tero-Kubota
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira 2-1-1, Sendai 980
(Received May 6, 1986)

Synopsis. Time-resolved ESR experiments have been carried out to elucidate the initial process in the photochemical reduction of aromatic nitro compounds. The first observation of CIDEP due to nitrobenzene anion radicals in the presence of an electron donor proved that radical generation takes place through a triplet mechanism.

A number of organic and physicochemical studies on the photoreduction and photosubstitution reactions of aromatic nitro compounds have been reported and various intermediates in these reactions have been detected. Among these, ESR studies revealed several types of intermediates in photochemical reactions involving nitrobenzenes. In the presence of electron donors, the observed ESR spectra could be interpreted as the photoreductive generation of anion radicals of the parent compounds. On the other hand, neutral radicals are generated from excited triplet states of aromatic nitro compounds by hydrogen abstraction and a successive reaction in the presence of hydrogen donors.[1] It is thought that the operative excited state in these reactions is the $n\pi^*$ triplet state by an analogy with the $n\pi^*$ excitation of aromatic carbonyl compounds, regardless of the low quantum yield of the excitation compared with that of the latter.

The present paper reports the initial process of the photoreduction of nitrobenzene derivatives contains the anisotropic intersystem crossing from the $n\pi^*$ singlet state to the triplet state. The study was carried out by means of time-resolved ESR spectroscopy for the photoreduction systems of unsubstituted (**1**), 4-methoxy- (**2**), and 4-chloro-nitrobenzenes (**3**).

Experimental

A transient ESR signal from the preamplifier output of a Varian E-109E EPR spectrometer was taken without any field modulation at arbitrary times after a laser pulse into a two-channel boxcar integrator. A nitrogen laser (5 mJ per pulse, 10-Hz repetition rate) was used as the source of the light pulse.[2] The sample solution was flowed in the ESR cavity in order to prevent any secondary reaction of the photochemical products formed from the nitrobenzene. All sample solutions were deoxygenated by bubbling of pure nitrogen gas before measurements.

Results and Discussion

Figure 1 shows the transient ESR spectra observed during the photoreduction of **1**—**3** in the presence of triethylamine (TEA) in 2-propanol. These spectra were confirmed to be due to the anion radicals of the corresponding nitro compounds by comparing them with the steady-state spectra measured under the same condition with continuous light irradiation.[1] The totally emissive CIDEP (chemically induced dynamic electron spin polarization) pattern of the spectra indicated that an electron transfer occurred between the excited triplet state of a nitro compound and the added electron donor. Obeying the interpretation of the CIDEP phenomena,[3] the emissive (E) polarization arises from an anisotropic intersystem crossing of the $n\pi^*$ excited singlet state to the triplet state in which the spin is most populated at the P_+ level; the electron transfer would proceed rapidly prior to a relaxation of the polarization in the excited triplet state.

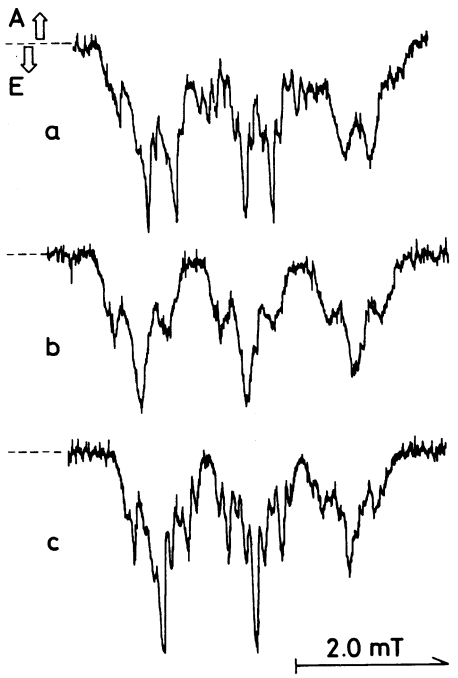

Fig. 1. Transient polarized ESR spectra of the anion radicals generated by photoreduction of unsubstituted (a), 4-methoxy- (b), and 4-chloronitrobenzenes (c) at room temperature. The spectra were taken at 1.0 μs after the laser pulse.

The same E polarization was observed for the CIDEP spectra of the anion radicals of **1**—**3** in the presence of dimethylamine (DMA) instead of TEA. According to Barltrop and Bunce,[4] the photoreduction products of nitrobenzenes varied depending on the reaction condition; also, the relative ratio of the produced aniline and azobenzene became reversed in the presence of TEA and DMA. However, the time-resolved ESR experiments showed the same CIDEP patterns in the presence of these two amines and gave no signal due to the hydrogen abstraction products. This suggests that the major photoreduction process is initiated by an electron transfer. Hydrogen abstraction from the α position of TEA is relatively slow and the polarization conserved in the hydrogen adduct may be very weak or completely diminished by the fast relaxation

of polarization within the excited triplet state of the aromatic nitro compound. Thus, the present behavior obviously differs from the CIDEP observations for the photolysis of aromatic carbonyl compounds in the presence of TEA in an alcoholic solution, which showed the spin polarization in the hydrogen-abstraction products.[5] A relatively lowered reduction potential of the aromatic nitro compounds may cause an efficient electron transfer from TEA to form anion radicals.

Since the ESR spectra of the hydrogen-abstraction products of nitrobenzene derivatives have been observed in photolysis under continuous light irradiation, it is expected that the polarized spectra of the hydrogen adducts can be observed. An examination to observe the polarized spectra of $ArNO_2H^{\cdot}$, however, has been unsuccessful, even for the active 4-chloronitrobenzene, by the use of good hydrogen donors: 2,6-di-*t*-butylphenol, benzhydrol, and cumene. Presumably, the hydrogen-abstraction rate of the triplet state of nitrobenzenes is slower than the rate of spin relaxation within the excited triplet state, even in the presence of reactive hydrogen donors.

The coexistence of hydrogen and electron donors in the above photoreduction systems also resulted in the same CIDEP spectra as that from the anion radicals. If equilibrium between the anion and its conjugated acid ($ArNO_2^{-}+H^{+}\rightleftharpoons ArNO_2H^{\cdot}$) is accompanied by a fast exchange, the appearance of another polarized signal is expected. Referring to the suggestion by Cu and Testa,[6] that the conversion rate between these two radical species should be the order of 10^8 s^{-1} in an acidic solution, the present result suggests that the spin polarization relaxed rapidly before conversion in the present neutral solution.

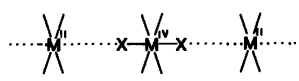
(Received May 19, 1986)

Synopsis. The EXAFS spectra of $[Pd(en)_2X_2Pt(en)_2](ClO_4)_4$ (en=ethylenediamine, X=Cl, Br, and I) were measured for Pd K and Pt L_{III} edges. The Fourier transforms of the Pd K- and Pt L_{III}- edge EXAFS show clearly that the halogen atoms are forming a chemical bond only to Pt(IV) and Pt-Cl, Pt-Br, and Pt-I bond lengths are 2.34, 2.47, and 2.83Å respectively.

Recently halogen-bridged one-dimensional mixed-valence complexes of Pt, Pd, and Ni have attracted much attention from the viewpoint of chemistry and physics of low-dimensional compounds.[1-4]

The compounds with the general formula of $[M(II)(AA)_2][M(IV)X_2(AA)_2]Y_4$ (M=Pt, Pd, and Ni; X=Cl, Br, and I; $(AA)_2$=(diamines)$_2$, linear tetramines, and tetraaza macrocycles; Y=ClO_4, BF_4 etc.) show various interesting phenomena such as strong inter-valence charge transfer, progressive resonance Raman spectra, and luminescence with a large Stokes shift. The effects of the metals, bridging halogens, counter anions, and in-plane ligands on the electronic structures of the complexes have been investigated by use of various different kinds of experimental methods.[5-12]

In the crystal structures, the four-coordinated M(II) and six-coordinated M(IV) units are stacked alternately, with bridging halogen atoms, constructing an infinite linear chain. The bridging halogen atom is located not at the middle point between M(II) and M(IV) atoms, but at the point closer to M(IV). In the compound of this type, the ratio of M(IV)-X and M(II)···X distances depends on metals, bridging halogens, counter anions, and in-plane ligands.



Toriumi and Yamashita[13] recently performed preliminary single-crystal X-ray structure analysis on the compounds where M(II)=Pd, M(IV)=Pt, AA= ethylenediamine, Y=ClO_4, and X=Cl, Br, or I, and showed that there is a disorder with regard to the position of bridging halogen atom. The halogen atom occupies two positions equidistant from the midpoint between the two metal atoms, Pt and Pd, with a half occupancy factor. Because of this disorder, it is hard to distinguish Pt and Pd sites, so that the metal sites are represented as(1/2)(Pt+Pd). Thus the state of halogen-metal bonding is not clear in the results of single-crystal X-ray structure analyses of those compounds. In order to establish the bonding of halogens to metals, we studied Pd K- and Pt L_{III}-edge EXAFS of the above-mentioned compounds. The measurements were carried out by use of the EXAFS facility at BL 10B[14] in

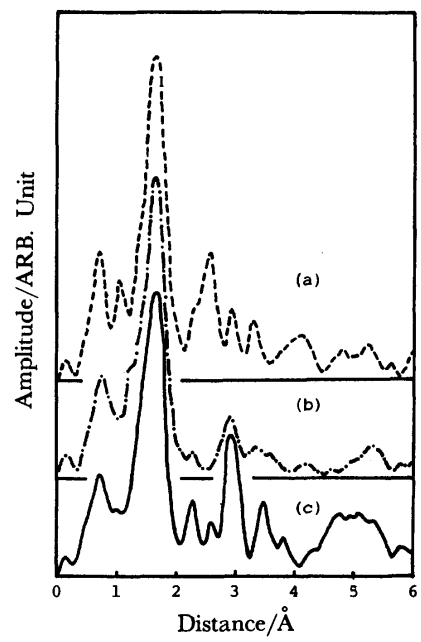


Fig. 1. The Fourier transforms for Pd K edge of (a) X=Cl, (b) X=Br, and (c) X=I.

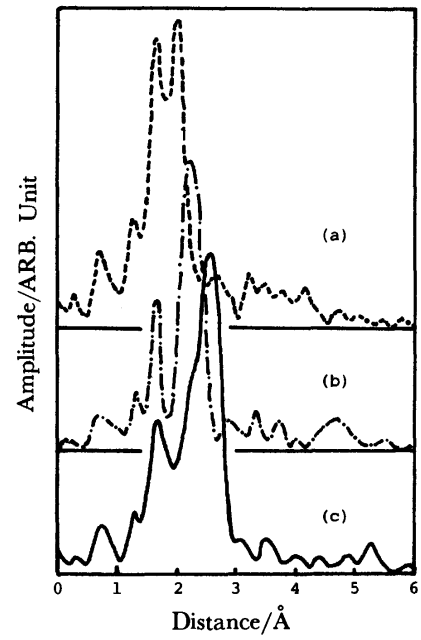

Fig. 2. The Fourier transforms for Pt L_{III} edge of (a) X=Cl, (b) X=Br, and (c) X=I.

Table 1. Bond Lengths/Å Obtained from the Analysis of EXAFS Data

	Pt-X	Pt-N	Pd-N
X=Cl	2.34	1.99	2.05
X=Br	2.47	2.05	2.06
X=I	2.83	2.08	2.05

the Photon Factory, National Laboratory for High Energy Physics (KEK-PF) utilizing a silicon (311) channel-cut monochromator.

The Fourier transform for Pd K edge EXAFS shows only one prominent peak (see Fig. 1). The position of this peak is the same for all the three compounds, therefore, the observed peak is attributable to Pd–N (in-plane ligand). We could not find a peak attributable to Pd-halogen. The Fourier transform for Pt L_{III} edge EXAFS (see Fig. 2) show two prominent peaks. The position of the peak at shorter distance remains the same for the three compounds, whereas the position of other peak shifts to longer distance as the halogen is changed from Cl to Br and to I. Thus we can attribute the former peak to Pt–N (in-plane ligand) and the latter to Pt–X. The results mentioned here clearly indicate that the bridging halogen atoms in the chain are at the position close to Pt(IV), possibly forming a chemical bond with Pt atom. Therefore, these results with XPS results[6] together indicate that these compounds are formulated as $[Pd(II)(en)_2][Pt(IV)X_2(en)_2](ClO_4)_4$.

Performing the inverse Fourier transformation over the region of the prominent peak of each Fourier transform, we carried out a further analysis for the obtained EXAFS oscillation by means of the nonlinear least square curve fitting method. The results are shown in Table 1. Previously it was reported that M(IV)-X distance is almost independent on the kinds of metals, in-plane ligands, and counter anions, although it is dependent on the kind of halogens. The results obtained in this study are quite consistent with those so far reportd.[4]

The data analyses were carried out on the HITAC M-280H computer system at the Computer Center of the University of Tokyo using the program, EXAFS1.[15]

Part of the present work was partially supported by a Grant-in-Aid for Scientific Research No.5947007 from the Ministry of Education, Science and Culture.

The Preconcentration and Separation of a Trace Amount of Copper(II) in Water as Its Silica-Immobilized Salicylaldimine Chelate by Means of Column Chromatography

Takaharu HONJO* and Tetsuji MAKINO
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920
(Received March 31, 1986)

Synopsis. The behavior of a trace amount of copper(II) in solid-liquid extraction and back extraction has been examined with silica-immobilized salicylaldimine; the results have also been applied to the preconcentration and separation of a trace amount of copper(II) in water as its silica-immobilized salicylaldimine chelate by means of column chromatography.

Extraction chromatography has been applied to the concentration and separation of a trace amount of cobalt(II) in sea water as its 1-nitroso-2-naphtholate.[1] However, this technique has a weak point—the loss of 1-nitroso-2-naphthol from the stationary phase during the chromatographic process; this may decrease the usefulness of the column for the preconcentration of a trace amount of cobalt(II) in sea water. It has been generally known that salicylaldimine specifically reacts with copper(II) among transition metals to form a green chelate. After preliminary experiments on the solid-liquid extraction behavior of metals like copper(II), iron(III), nickel(II), palladium(II), cobalt(II), manganese(II), and zinc(II) with silica-immobilized salicylaldimine, it was found that copper(II) and iron(III) especially have high reactivities in a weakly acidic solution.

In this investigation, the behavior of a trace amount of copper(II) in solid-liquid extraction and back extraction with silica-immobilized salicylaldimine of a bidentate Schiff base has been examined in detail; the results have also been applied to the preconcentration and separation of a trace amount of copper(II) in water as its silica-immobilized salicylaldimine chelate by means of column chromatography. Some silica-immobilized salicylaldimines have already been prepared by the reaction of salicylaldehyde on silylated silica gel, and microgram amounts of iron(III), cobalt(II), nickel(II), copper(II), lead(II), vanadium(V), chromium(VI), and zinc(II) have also been collected with silica-immobilized salicylaldimine from weakly acidic and neutral solutions by means of solid-liquid extraction for subsequent X-ray fluorescence analysis.[2]

Experimental

The "aminopropyl silica gel" was prepared by a slight modification of the method of Aue and Hastings.[3] Silica-immobilized salicylaldimine was prepared as follows: A 50 g portion of aminopropyl silica gel was added to 100 cm³ of 5% salicylaldehyde in acetone, after which the mixture was stirred in a sealed flask for 2 h at about 50 °C. The product thus obtained was washed with acetone and dried under a vacuum at room temperature. The color of the product was brown. The solid-liquid extraction of copper(II) in water was carried out with silica-immobilized salicylaldimine as follows: A 0.1—2 g portion of the silica-immobilized salicylaldimine and 10 cm³ of a 1—1000 ppm copper(II) solution adjusted to pH 1—7 with 0.1M HCl (1M=1 mol dm^{-3}), 0.1M CH_3COOH 0.1M CH_3COONa, and 0.1M NaOH were

Cu(II) spike/μg	Solution volume/cm³	Silica-immobilized salicylaldimine/g	Cu(II) recovery/%
100	10	1.0	100±2
100	100	1.0	97±2
10	500	1.0	100±2
10	1000	1.0	62±2
10	1000	2.0	100±2

Table 2. Content of Copper(II) in Distilled Water and Tap Water of Kanazawa University

Sample	Solution volume/cm³	Cu(II) collected/μg	Cu(II) collected/ppb
Distilled water	500	12.0, 13.5, 12.5	25.3±2.2
	1000	23.2, 23.7, 27.0, 24.0	24.5±1.5
	2000	46.6, 52.8	24.9
Tap water	2000	1.0, 1.4, 1.2	0.6±1

placed into a 30-cm³ centrifuged tube, and the mixtures were shaken for 1—30 min. The capacity of the silica-immobilized salicylaldimine was determined by adding 0.1 g silica-immobilized salicylaldimine to 10 cm³ of a 100 ppm copper(II) solution adjusted to pH 5.2, after which the mixtures were shaken for 30 min. The concentration of copper(II) in water was determined by the atomic-absorption method. The chromatographic column was prepared as follows: A 1.0—2.0 g portion of silica-immobilized salicylaldimine was added to a 0.1M acetate buffer solution of pH 5.0—6.0, and the mixtures were poured into a chromatographic glass tube (1 cm in inner diameter and 30 cm in length) with a fritted glass filter. The top of the column was covered with a small amount of glass fiber.

Results and Discussion

Silica-immobilized salicylaldimine was stable in the region of pH 3.5—7.0, and it reacted rapidly with copper(II) in water to form a green chelate.

When the behavior of a trace amount of copper(II) in solid-liquid extraction and back extraction has been studied with 1.0 g of silica-immobilized salicylaldimine, the quantitative extraction of 100 μg copper (II) is attained at pH 5.0—7.0 in about 1 min shaking (Fig. 1). Copper extracted as the silica-immobilized salicylaldimine chelate was easily back-extracted with an aqueous solution of 0.1—1M hydrochloric acid. On the basis of the experimental results described above, the chromatographic behavior of a trace amount of copper(II) in water was studied by means of 1.0 g of silica-immobilized salicylaldimine in a glass column at the flow rate of 0.8—200 $cm^3 min^{-1}$ under suction. The column capacity of silica-immobilized salicylaldimine with copper(II) was 0.10 $mmol g^{-1}$ at pH 5.2. A 10—1000 cm³ portion of 10—100 μg copper-(II) in water adjusted at pH 5.0—6.0 was passed through the column. It was found that the quantitative preconcentration of 0.01—10 ppm copper(II) was accomplished at the flow rate of 0.8—24 $cm^3 min^{-1}$ (Fig. 2). The results of the recovery (Table 1) of copper(II) in water adjusted at pH 5 with silica-immobilized salicylaldimine indicated that the preconcentration of trace amounts of copper(II) in water was quantitatively accomplished by using 1—2 g of silica-immobilized salicylaldimine. Foreign ions added, up to 100 μg of nickel(II), cobalt(II), manganese(II) and zinc(II) each, and 1000 μg of iron(III), did not interfere with the preconcentration of 10 μg copper in a 500 cm³ solution. Copper(II), probably held on silica-immobilized salicylaldimine by the 1:1 metal-chelate formation, as is seen in the case of metal-ion chelation chromatography on silica-immobilized 8-quinolinol,[4] was easily eluted with 10 cm³ of 1.0M hydrochloric acid within 1 min under increased pressure with air in order to prevent both the tailing of copper(II) and the hydrolysis of the silica-immobilized salicylaldimine during the process. About 70% of the collection ability of copper(II) with this reagent was lost when it was placed in contact with 1.0M hydrochloric acid for 30 min; however, there is no problem in concentrating traces of copper(II) for at least a few times by the procedure described above. The copper(II) was determined by the atomic-absorption method. The content of copper(II) in distilled water and tap water at Kanazawa University was determined by the preconcentration method described above. The results (Table 2) revealed that the concentration of copper(II) in distilled water prepared by means of an electric distillation apparatus constructed with copper plate (YAMATO WS-5) was about 25 ppb, while that of copper(II) in tap water was 0.6±1 ppb, which is compatible with the value of 0.5 ppb obtained with the column of 2-mercaptobenzothiazole supported on silica gel.[5]

The authors wish to thank the Ministry of Education for its Scientific Research Grant (No 56540340).

Thanks are also due to Prof. Kikuo Terada of Kanazawa University for his valuable advice.

Reaction of Bis(4-methyl-8-quinolinolato)nitrosylpyridinecobalt(II) with Nitrogen Monoxide in Dichloromethane

Eiichi MIKI,* Mikio TANAKA,† Kunihiko MIZUMACHI, and Tatsujiro ISHIMORI
Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171
†Laboratory of Chemistry, Nippon Medical School, Kosugi, Nakahara-ku, Kawasaki 211
(Received April 16, 1986)

Synopsis. [Co(4mqn)$_2$(NO)(py)] (4mqn=4-methyl-8-quinolinolate ion, $C_{10}H_8NO^-$; py=pyridine) reacted with nitrogen monoxide in dichloromethane to produce a new compound, [NO][Co(4mqn)$_2$(NO$_3$)(py)], with liberation of dinitrogen oxide. The solid product was characterized by IR (including the ^{15}N-isotopic shifts), magnetic, and MS measurements.

It is well-known that transition-metal complexes react with nitrogen monoxide, NO, to make the NO disproportionation and transition-metal nitrosyls with NO^- group also react with NO to cause electrophilic attack by NO on the nitrosyl group.[1,2]

We have reported the reaction of NO with [$Co^{II}L_2$] (L=8-quinolinolate ion or its derivatives) or [$Co^{III}L_2$(NO)] with NO^- group in organic solvents.[3–6] In CH_2Cl_2 inhering poor coordinating ability to metal ion, [CoL_2] is nitrosylated or the nitrosyl group in the resulting nitrosyl complex reacts further with NO to give NO_3^-, NO_2^-, NO^+ (nitrosyl cation), and N_2O.[3,4] On the other hand, on the reaction of [CoL_2] with NO in pyridine having strong coordinating ability, [CoL_2] is nitrosylated followed by electrophilic attack of NO on the nitrosyl group to give NO_3^- or NO_2^-, and N_2O.[5,6]

In this paper, we report the reaction of [Co(4mqn)$_2$(NO)(py)] (4mqn=4-methyl-8-quinolinolate ion, py=pyridine) with NO in CH_2Cl_2. The solid product was [NO][Co(4mqn)$_2$(NO$_3$)(py)], the gaseous one being N_2O. The reaction is shown as follows;

$$Co^{3+} + NO^-(\text{coord}) + 5NO \longrightarrow Co^{2+} + NO^+ + NO_3^-(\text{coord}) + 2N_2O \quad (\text{coord} = \text{coordinating}).$$

Experimental

Dichloromethane was dried over Zeorum A-4, distilled and stored under argon. Nitrogen[^{15}N] monoxide was derived from $K^{15}NO_3$ (^{15}N atom%=99). The reactants, [Co(4mqn)$_2$(NO)(py)] with NO^- group and its ^{15}NO-labeled compound (^{15}N atom%=99), were prepared according to the literature.[6] Anal. ($CoC_{25}H_{21}O_3N_4$) Co, C, H, N.

The reactions were carried out using a vacuum line. Dichloromethane was degassed by three cycles of freeze-pump-thaw before use. The degassed CH_2Cl_2 (10 cm^3) was transferred to the reaction vessel containing the nitrosyl complex (0.3 mmol) and NO (5 mmol) which had been kept at the temperature of liquid nitrogen. The contents were stirred for ca. 50 h at room temperature after having been thawed under running water. The original yellowish khaki complex reacted rapidly with NO to give dark brown solution and gradually precipitate a khaki product in process of the reaction. The product was collected by filtration, washed with diethyl ether, and dried under vacuum. Yield: 60% (ca. 100 mg). Found: Co, 11.1; C, 54.6; H, 3.9; N, 12.8%. Calcd for [NO][Co($C_{10}H_8NO$)$_2$(NO$_3$)(C_5H_5N)] ($CoC_{25}H_{21}O_6N_5$): Co, 10.8; C, 55.0; H, 4.0; N, 12.8%.

The magnetic susceptibility of the solid product was measured by the Gouy method. The IR spectra of the solid products were measured as Nujol and poly(chlorotrifluoroethylene) oil mulls in the 200—4000 cm^{-1} region. The gaseous products were identified by a Hitachi M-80 double-focusing mass spectrometer equipped with a Hitachi M-003 data processor and by the IR bands (including ^{15}N-isotopic shifts) in the 1000—4000 cm^{-1} region.[6] The negative SIMS (secondary ion mass spectrometry) spectrum of the solid product was measured by the mass spectrometer with a SIMS unit and a negative ion measurement unit. The product was dissolved or suspended in a glycerol/3-mercapto-1,2-propanediol, glycerol/sulfolane, or diethanolamine/3-mercapto-1,2-propanediol matrix, and placed on a silver plate probe tip. Xenon was used to produce the primary ion.[7]

Results and Discussion

The khaki product in the solid state is stable in air but is decomposed in polar organic solvents such as DMF and DMSO.

The IR spectrum of the solid product showed some absorption bands characteristic of nitrosyl cation and

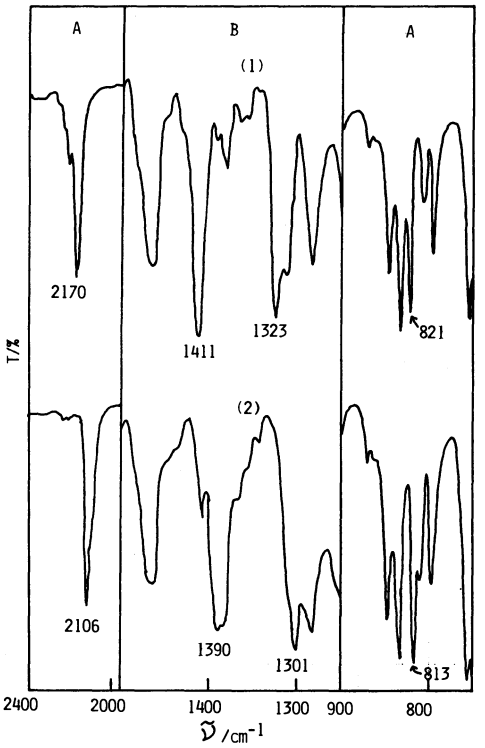

Fig. 1. IR spectra of [NO][Co(4mqn)$_2$(NO$_3$)(py)] (4mqn=4-methyl-8-quinolinolate ion, py=pyridine). (1): ^{14}N-complex, (2): ^{15}N-complex (^{15}N atom%=99). A region: Nujol mull, B region: poly(chlorotrifluoroethylene) oil mull.

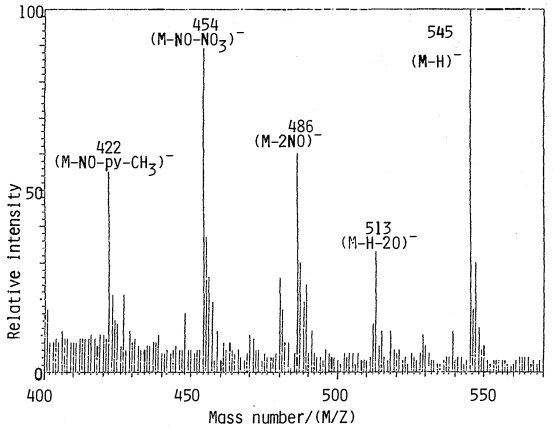

Fig. 2. Negative SIMS spectrum of [NO][Co(4mqn)$_2$-(NO_3)(py)] (4mqn=4-methyl-8-quinolinolate ion, py=pyridine) in the matrix, diethanolamine/3-mercapto-1,2-propanediol.

unidentate nitrate ion. These bands shifted downwards upon ^{15}N-substitution as shown in Fig. 1; the strong band at 2170 cm^{-1} shifted to 2106 cm^{-1}, and was assigned to the stretching vibration of nitrosyl cation.[3,4] The strong bands at 1411, 1323, and 821 cm^{-1} shifted to 1390, 1301, and 813 cm^{-1}, respectively, which were assigned to the NO_2 antisymmetric stretching, the symmetric stretching, and the out-of-plane bending vibrations of the NO_3^-, respectively.[3-6] The strong band at 327 cm^{-1} was assigned to the Co–N(pyridine) stretching vibration.[6]

The negative SIMS spectrum in diethanolamine/3-mercapto-1,2-propanediol showed the peaks at m/z= 545, 513, 486, 454, and 422. These ions correspond to $(M-H)^-$, $(M-H-2O)^-$, $(M-NO-NO)^-$, $(M-NO-NO_3)^-$, and $(M-NO-py-CH_3)^-$ where M is the molecular ion with m/z=546, respectively (see Fig. 2). These peaks were also observed in glycerol/3-mercapto-1,2-propanediol and glycerol/sulfolane matrices.

The elemental, IR, and MS analyses indicate that the solid compound is [NO][Co(4mqn)$_2$(NO_3)(py)] containing cobalt(II). The effective magnetic moment was 1.66 BM at 295 K, supporting low-spin d^7 configuration of the cobalt ion.

The IR and MS measurements clearly showed that the gaseous product was only dinitrogen oxide.

For tracing the nitrogen atoms in the reaction of the nitrosyl group with NO, the following isotopic combinations were used and the residual NO and the liberated N_2O were analysed by the mass spectrometer; A (the reaction of the ^{14}NO-complex with ^{15}NO gas) and B (the reaction of the ^{15}NO-complex with ^{14}NO gas). The molar ratio of ^{14}NO to ^{15}NO observed after the reaction was equal to that calculated from the amounts of the reactants before the reaction; the calculated and observed ratios in the case of A were 0.045 and 0.050±0.001, respectively, and those in the case of B, 19 and 20±3, respectively. This shows that the ^{14}N–^{15}N scrambling between the nitrosyl group and the NO gas occurred. Such a phenomenon has been observed for the reaction of [CoL_2(NO)] (L=8-quinolinolate ion or its derivatives) with NO in solvents having coordinating ability to metal ion.[5,6,8] The reproducibility of the same measurements for the liberated N_2O as the NO was poor, but the ^{14}N–^{15}N scrambling was also observed for N_2O. These scrambling phenomena suggest that the nitrosyl complex liberates NO in dissolution and the liberated NO together with original reactant, NO, reacts with the resulting cobalt(II) complex to attain the following equilibrium; Co^{II}+ $NO \rightleftarrows Co^{III}$–$NO^-$.[5,6] Thus, the reaction mechanism could not be elucidated.

In CH_2Cl_2, [Co(4mqn)$_2$(NO)] did not react with NO. The N–O stretching bands of [Co(4mqn)$_2$(NO)] and [Co(4mqn)$_2$(NO)(py)] are observed at 1658 and 1616 cm^{-1}, respectively, suggesting that electrophilicity of the nitrosyl group in the latter is stronger than that in the former due to coordination of pyridine. Thus, even in solvent having poor coordinating ability, the electrophilic attack of NO on the nitrosyl group would proceed to produce NO_3^-, NO^+ (nitrosyl cation), and N_2O as observed for the reaction of [Co(qn)$_2$(NO)] (qn=8-quinolinolate ion) with NO in CH_2Cl_2.[3]

There is a possibility that [Co(4mqn)$_2$L(py)] (L= NO_3^- or NO_2^-) is formed as a minor product in the present reaction considering our last paper.[6] However, the negative SIMS spectra showed no peaks corresponding to their molecular ion regions.

The present overall reaction can be represented as

$$Co^{3+} + NO^-(\text{coord}) + 5NO \longrightarrow Co^{2+} + NO^+ + NO_3^-(\text{coord}) + 2N_2O(\text{coord} = \text{coordinating}).$$

(Received May 9, 1986)

Synopsis. The crystal and molecular structure of the title complex was determined by means of a single-crystal X-ray diffraction method. A crystal of $Ni_2C_{46}H_{54}N_{10}S_4$, F. W. 992.67, is triclinic with a space group $P\bar{1}$, a=13.259(4), b=15.627(5), c=6.5150(16) Å, α=90.60(3), β=93.64(2), γ=112.601(19)°, U=1242.9(6) Å^3, Z=1, D_m=1.32(3), D_x=1.33 Mg m^{-3}, and μ(Mo $K\alpha$)=9.60 cm^{-1}. The central metal atom is hexa-coordinated, being ligated with three benzylamine and two thiocyanato (SCN) nitrogen atoms as well as one SCN sulfur atom. Two metal atoms are bridged by two SCN ions; however, the Ni-S bond length is 2.639(3) Å, which is a little longer than the sum of the Shannon's ionic radii. The distance Ni···Ni is 5.717(3) Å and the dimeric complexes are discrete in a crystal.

It has already been found that in Lewis-base adducts of thiocyanate (SCN) complexes, where the central metal is relatively soft (such as mercury, cadmium, or silver), the SCN ion bridges the metal atoms forming linear, planar, or three-dimensional networks.[1-7] On the other hand, in cases of the adducts of nickel(II) thiocyanate, many of them are monomeric and the metal atom is in an octahedral geometry.[8-10] However, Lipkowski has reported that in the case of 4-methylpyridine (pic) adduct, $[Ni(SCN)_2(pic)_3]_2$ (**2**), the adduct takes a dimer structure where two metal atoms are bridged by two SCN ions.[11] Since such types of nickel(II) complexes which include SCN bridges are not common, we started to find another example and obtained the title complex. Its structure was determined by an X-ray diffraction method using its single crystal.

Experimental

Synthesis of Bis(μ-thiocyanato)-bis[tris(benzylamine)(thiocyanato)nickel(II)] (1). Anhydrous nickel(II) thiocyanate (0.87 g, 5.0 mmol) and benzylamine (bza) (1.59 g, 15 mmol) are dissolved into warm methanol (20 cm^3), and the solution was left standing at ambient temperature. Pale-blue needle-like crystals were deposited, filtered off, washed with methanol and dried over a silica-gel desiccator. Yield: 1.9 g, 75%. Anal. ($Ni_2C_{46}H_{54}N_{10}S_4$), Ni, C, H, N.

Single-Crystal X-Ray Analysis. The crystal used for the structure determination was about 0.3×0.25×0.2 mm^3 in size, and was used without shaping. The reflections in the range of $3°<2\theta<60°$ were collected on a Rigaku AFC-6A automated 4-circle X-ray diffractometer with graphite-monochromated Mo $K\alpha$ radiation, by means of ω—2θ scan technique (scan speed, 4°min^{-1}: scan width 1.40+0.5 tanθ°(θ)). The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction. Of 7285 independent reflections collected, 3110 reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination. All the calculations were carried out on a HITAC M-280H computer at the Computer Center of the University of Tokyo, using the local version of UNICS.[12] The scattering factors were taken from Reference 13.

The structure was solved by the heavy-atom method. The positional parameters of all the non-hydrogen atoms converged, but as the equivalent isotropic temperature factors of C(35), C(36), and C(37) were found to be large, at the final refinement process, the positions of these three atoms were fixed at respective positions assuming their B_{iso} to be 15.0. Applying the anisotropic temperature factors for the other atoms, the final R value,[14] thus obtained, was 0.086.

Results and Discussion

The selected bond lengths and bond angles are shown in Table 1.[15] A projection of the complex together with the numbering scheme of the atoms is shown in Fig. 1, and the crystal packing diagram in Fig. 2.

The metal atom is hexa-coordinated and is in an octahedral geometry. Two nickel atoms are bridged by two SCN ions, where each nickel atom is ligated by the nitrogen atom of one ligand and the sulfur atom of the other. The eight-membered ring, which consists of

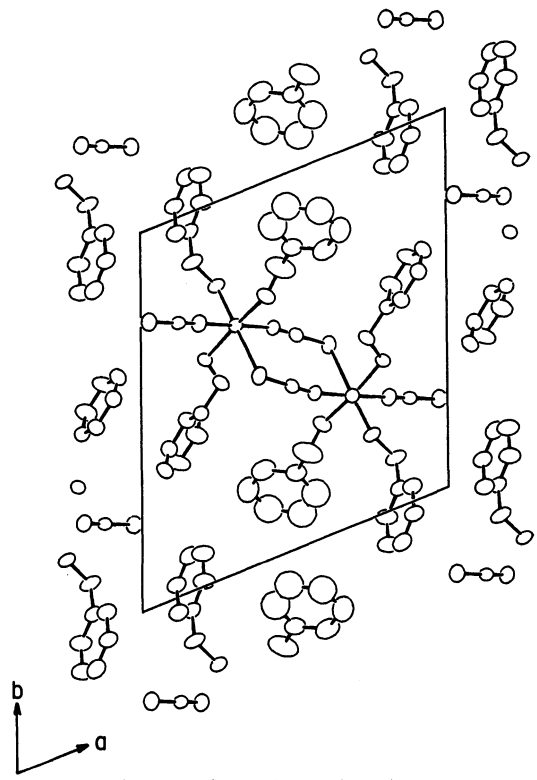

Fig. 2. Crystal packing diagram.

two nickel atoms and two bridging SCN ions, is about on a plane (average deviations of the atomic positions is 0.008 Å). A nitrogen atom of another SCN ion, as well as three bza nitrogen atoms, are coordinated to each metal atom. Each dimer complex is discrete in the crystal; neither ligand bridgings nor hydrogen bondings are found between them. Two SCN nitrogen atoms take trans configuration, and the sulfur atom of SCN ion is in the cis orientation from both of these nitrogen atoms; the other three positions are occupied by the bza nitrogen atoms. The bond length Ni–S(1) is 2.639(3) Å, which is a little longer than the sum of the Shannon's ionic radii, 2.53 Å (r_{Ni}=0.690 and r_S=1.84 Å).[16] The bond length Ni–N(bza) is 2.118 Å on the average, a little longer than that for Ni–N(SCN), 2.049 Å on the average. The latter value is a little shorter than the sum of the Shannon's ionic radii, 2.15 Å (where r_N=1.46 Å), probably due to the delocalization of the charge on the nitrogen atoms of the SCN ions.

Although the properties of bza and pic are quite different and their adducts of the metal complexes are expected to take different structures from each other, the structure of **1** is essentially similar to that of **2**: the orientation of the ligated atoms around the metal atom is the same in **1** and **2**.

However, in **2**, the Ni–S bond length (2.583 Å), as well as the Ni–N(pic) ones (2.085 Å on the average), are much shorter than the corresponding bond lengths of **1**, while those of Ni–N(SCN) are about the same.[11] Therefore, in **1** the Ni–S and Ni–N(Lewis base) bonds are thought to be weaker than the corresponding bonds of **2**. This fact may be, at least partially, due to the bulkiness of the bza ligand, which has a methylene group between the ligand nitrogen atom and the phenyl group; the ligand is not planar and it is hardly packed into a crystalline space, while the pic molecule is planar except for the methyl hydrogen atoms. Therefore, in the crystal packing, the steric hindrance of the Lewis base ligands makes the approach of the ligated atoms to the metal atoms in **1** more difficult than in **2**.

Synopsis. 2-(Arylmethylene)tetralin-1-thione and 1-aryl-3-phenyl-2-propene-1-thione (thiochalcone) reacted with diphenylcyclopropenone across the =C–CO bond giving a thiophene derivative and a polysubstituted phenol with the arylketene/sulfur elimination, whereas the reaction with diphenylcyclopropenethione took place at the C=S bond affording a spiro compound.

Cyclopropenones and cyclopropenethiones have been known to be highly reactive compounds. Especially, many informations on the chemistry of cyclopropenones have accumulated in numerous papers and their cycloadditions were found to occur across the C=O, C=C, or the C–CO bond of the ring.[1,2] Previously, we reported that the α,β-unsaturated thiones such as 2-(arylmethylene)tetralin-1-thiones (**2**) and thiochalcones (**4**), which were generated by thermolysis of their dimers **1** and **3**, underwent cycloaddition reactions with various dienophiles to give 1:1-adducts.[3] As a continuation of the work, reactions of these thiones with diphenylcyclopropenone (**5**) and diphenylcyclopropenethione (**6**) have been investigated in the present study.

A mixture of 2-(phenylmethylene)tetralin-1-thione dimer, **1a**, and **5** in dry benzene was refluxed for 2.5 h. After the reaction was completed, the mixture was chromatographed to give 4,5-dihydro-2,3-diphenylnaphtho[1,2-*b*]thiophene (**7**) in a yield of 57%. Evidently, the product showed no band for a carbonyl group in the IR spectrum, and the ^{1}H NMR spectrum exhibited only signals of ethylene protons (4H) and aromatic protons (14H). In the mass spectrum, a molecular ion peak was observed at *m/z* 338 (100% intensity) which corresponded to that of *m/z* 456 (1:1-adduct) −118 (C_8H_6O). Since it is obvious from these spectral data that not less than one phenyl moiety was eliminated from a 1:1-adduct, reactions of 2-(*p*-methoxybenzylidene)tetralin-1-thione dimer (**1b**) and 2-(*p*-chlorobenzylidene)tetralin-1-thione dimer (**1c**) with **5** were examined. The product obtained in each case was the same compound **7** in which no *p*-methoxy- or *p*-chlorophenyl moiety was contained. The reaction of thiochalcone dimer, **3a**, with **5** afforded 2,3,5-triphenylthiophene (**8**) and 2,3,4,6-tetraphenylphenol (**9**) (Table 1). These interesting results are rationalized in terms of the [4+3]cycloaddition of the α,β-unsaturated thiones (**2**, **4**) and **5** with fission of the =C–CO bond of **5** and the subsequent elimination of the arylketene/sulfur atom from the intermediary 1:1-adducts (**10**, **11**). However, attempt to trap the ketene by methanol was unsuccessful. On the other hand, treatment of **1a** with **6** in refluxing benzene for 1 h gave a 1:1-adduct in a yield of 56%. The ^{1}H and ^{13}C NMR spectra of the adduct indicated the presence of a ethylene group, a methine group, and a quarternary carbon atom of the cyclopropene ring in addition to the olefinic and the aromatic moieties. The results suggest that both regioisomeric structures, **12** and **13**, are plausible for the adduct. We prefer the 1,3-dithiin structure because their mass fragmentation pattern[4] showed extrusion of a thiobenzaldehyde molecule from **12**, not from **13**. Similarly, the reactions of **1b**, **c** and **3a—c** with **6** gave the 1,3-dithiins **12b**, **c** and **14a—c**, respectively (Table 1).

Marked contrast between the reactions of the α,β-unsaturated thiones (**2**, **4**) with **5** and **6** can be recognized by the fact that thiocarbonyl group is usually more susceptible than carbonyl group to various addition reactions.[5] Actually, **2** and **4** react readily with ordinary thioketones such as thiobenzophenone to give the similar 1,3-dithiin adducts, whereas no reaction takes

place with ketones or aldehydes under the same reaction conditions.[6]

Experimental

All melting points are uncorrected. IR spectra were measured on a Hitachi Model 260-10 spectrometer. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 spectrometer and/or a JEOL PMX-60SI spectrometer in a $CDCl_3$ solution using tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi double focusing mass spectrometer RMU-7M and/or M-80 with a data processing system M-003, operating at an ionizing potential of 100 or 70 eV. Elemental analyses were performed using a Yanagimoto Model MT-3 CHN corder.

2-(Arylmethylene)tetraline-1-thione dimers (**1a—c**) and thiochalcone dimers (**3a—c**) were prepared according to the method described previously.[3] Diphenylcyclopropenone (**5**)[7] and diphenylcyclopropenethione (**6**)[8] were prepared by the method given in the literature.

General Procedure for Reaction of the Thione Dimers (1, 3) with Diphenylcyclopropenone (5) or Diphenylcyclopropenethione (6). A mixture of **1** or **3** (4 mmol as a monomer) and **5** or **6** (4 mmol) in dry benzene (6 ml) was refluxed for a required period under a nitrogen atmosphere. After the reaction was completed, the solvent was removed and the residue was chromatographed on silica gel (Wakogel C-200) with benzene–hexane as an eluent. The crude product was recrystallized from an appropriate solvent.

Synopsis. SEM of MF-aluminas (M=Na, K, and Cs, loaded at 2 mmol g^{-1} and dried at 90 °C/2.7 kPa), showed similar salt dispersions and surface morphologies, with salt clusters of ca. 1 μm diameter evident on the external surfaces. Less reactive, highly dried or highly loaded, reagents showed extensive surface crystallization. KCl- and KOH-aluminas showed the effect of anion basicity, giving greater clustering and surface destruction respectively.

Although supported inorganic salts have been employed in a wide variety of organic reaction types,[1,2] only in a few recent cases has the full potential of improved reagent selectivity, reactivity and stereospecificity begun to be realized, by careful study and optimization of predispersed reagent preparations.[3,4]

KF–Alumina is a most noteworthy supported reagent which acts as an efficient and convenient heterogeneous base.[5–7] We have previously shown that different loading and drying conditions can produce quite large changes in chemical reactivity, notably for noncatalytic base promoted reactions,[7] and that supported alkali metal fluoride reagents show the same cation effect on activity as do the unsupported salts ($NaF \ll KF < CsF$).[5] The reasons for the dramatic increase in MF basicity, when impregnated on Al_2O_3, and the subsequent reactivity variations have remained somewhat obscure despite IR, solids NMR, thermal, titrimetric and surface area analyses being performed.[7] The active basic species may involve a coordinatively unsaturated fluoride ion center, exhibiting basicity through its strong H-bonding capacity, but the basicity of species formed by reaction of F^- with Al_2O_3 cannot be discounted. In order to directly observe the effects of MF salt impregnation on the Al_2O_3 surface morphology and allow comparison with some related salts, we have now used scanning electron microscopy (SEM).

For the neutral chromatographic grade γ-alumina used, a 2 mmol g^{-1} loading of salt is calculated to give an approximate theoretical "monolayer" of ion pairs over the hydroxylated surface.[8] Although KF–alumina "monolayer" loadings and lower gave highly efficient basic catalysis, the optimum reagent preparation for a noncatalytic *O*-methylation of phenol involved a significantly higher loading (5 mmol g^{-1}, dried at 90 °C/2.7 kPa),[7] suggesting that surface coverage of salt, and active basic sites, are not maximized at the 2 mmol g^{-1} loading. Whereas X-ray powder diffraction of the reagents reveals little at these loadings (only at ca. 10 mmol g^{-1} does it give clear evidence for KF clustering and fluoroaluminate formation by chemisorption[7]), SEM directly shows the extent of salt clustering and surface deterioration.

A sample of deactivated alumina (aqueous washed, dried at 90 °C/2.7 kPa) shows that most of the particles have generally smooth surfaces (Fig. 1a) at

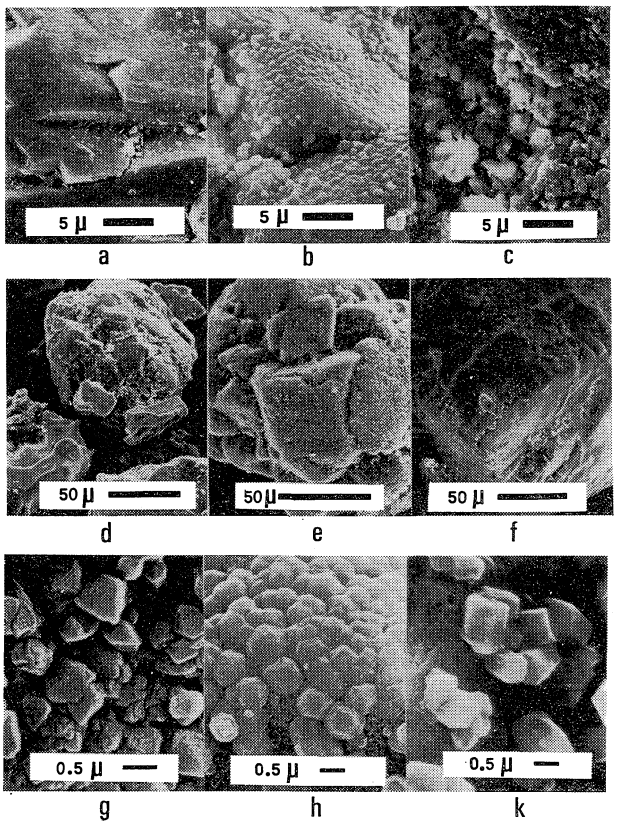

Fig. 1. Scanning electron microscopy of: (a) alumina, water washed and dried at 90 °C/2.7 kPa; (b), (e), and (h) KF-alumina 2 mmol g^{-1}, dried at 90 °C/2.7 kPa; (c) KF-alumina 2 mmol g^{-1}, dried at 600 °C; (d) KCl-alumina 2 mmol g^{-1}, dried at 90 °C/2.7 kPa; (f) KOH-alumina 2 mmol g^{-1}, dried at 90 °C/2.7 kPa; (g) NaF-alumina 2 mmol g^{-1}, dried at 90 °C/2.7 kPa; (k) CsF-alumina 2 mmol g^{-1}, dried at 90 °C/2.7 kPa.

magnification which cannot reveal their porous structure. Comparison with KF–alumina (Fig. 1b) at the 2 mmol g^{-1} loading, clearly shows the salt, in microcrystalline clusters of 0.5—1 μm diameter, well dispersed over the external surface. Microclusters of this size must contain in the order of 10^{10} KF ion pairs suggesting that a large amount of the 2 mmol of KF loaded is accommodated on the external surface in such clusters. It thus seems evident that "monolayer coverage" is not being obtained at this level of loading, and the 5 mmol g^{-1} KF–alumina may owe its optimum activity to the greater amount of KF available; a) to achieve greater coverage of the internal surface and b) to further cover the external alumina surface with salt microclusters. For reactions such as phenol alkylation, strong surface adsorption of reactants may well

hinder reaction if it takes place at unactive sites. Thus elimination of these sites, by more complete KF coverage, will be important for obtaining optimum reagent reactivity.[7]

Drying KF–alumina at up to 200 °C/13 Pa produced only limited local crystallization of the salt clusters, however 600 °C calcination produced a drastic change in the surface morphology (Fig. 1c) as chemisorption of KF is promoted. The surface crystallization is accompanied by a large drop in surface area (from 96 to 18 $m^2 g^{-1}$ Al_2O_3), a loss of noncatalytic activity, and also is associated with the detection of K_3AlF_6 by X-ray powder diffraction.[7]

Comparison of the alumina-supported potassium salts, KCl, KF, and KOH at 2 mmol g^{-1} loading (Fig. 1d, e, and f) shows the effect of salt basicity and surface affinity on the salt loading. The weakly basic chloride has little affinity for the alumina surface and the majority of the salt is deposited in large crystalline clusters of irregular size and shape, up to ca. 10—50 μm dimension. In contrast the highly basic hydroxide is deposited on the alumina surface in a fairly regular manner which produces some severe erosion of the surface, presumably by aluminate formation. The KF–alumina appears intermediate in terms of both the clustering of external salt, and the degree of surface damage caused by chemisorption reaction. Adsorption of KF causes little apparent surface erosion for the reagents dried at 90 °C.

The sequence of alumina-supported alkali metal fluorides, NaF, KF, and CsF at 2 mmol g^{-1} loading (Fig. 1g, h, and k) show that in all cases the external surface is covered with well dispersed microcrystalline clusters, of approximately 1 μm dimension. Although there is a large variation in the aqueous solubilities of these fluorides, increasing ca. 100 times in the above order, the similar appearance of the reagents suggests that the rate of salt precipitation onto the surface, during preparation by aqueous evaporation, does not greatly influence the cluster size and distribution. Rather, the high surface affinity of fluoride seems determinant. The clusters on all of these reagents must contain much of the salt loaded, but they do represent much smaller particles than could be obtained by conventional grinding procedures, consequently the reagents have a high salt surface area. The cation effect on the reactivity of the reagents is also in agreement with small salt clusters, rather than highly dispersed ion pairs, being responsible for the basicity.

Samples of KF- and KCl–alumina loaded at 10 mmol g^{-1} showed distinctly different external surface morphology, the fluoride having multilayers of clustered salt particles (2—3 μm size), whilst the chloride had relatively few crystal growths, covering large areas (typically 100—1000 μm^2). The greater interaction of KF, than KCl, with the alumina is also apparent in the measured BET surface areas of the two reagents.[7] KF–Aluminas continue to lose surface area with loading (38 $m^2 g^{-1}$ Al_2O_3 at 10 mmol g^{-1}) whereas the KCl–aluminas only lose surface area due to blockage of small pores, thus loadings at 2 and 10 mmol g^{-1} have quite similar surface areas, 104 and 93 $m^2 g^{-1}$ Al_2O_3 respectively.

In summary, SEM analysis has directly shown that MF–Al_2O_3 reagents possess most of their salt in microcrystalline clusters, which nevertheless are far smaller particles than would otherwise be obtainable. The KF salt dispersion and the KF–Al_2O_3 surface deterioration are intermediate between those of KCl– and KOH–Al_2O_3's further supporting the idea, from the reactivity order dependence on the MF cation ($Na \ll K < Cs$), that the supported reagent basicity largely originates from a great increase in salt surface area. Thus the enhanced basicity of MF–Al_2O_3 reagents would seem to be more a result of improved fluoride ion strong H-bonding ability than of F^-–Al_2O_3 reaction generating an alternative strong base.

Experimental

Preparation of Samples. The supported reagents were prepared by adding 5 g of alumina (Merck 90, neutral for chromatography) to the calculated weight of salt dissolved in ca. 30 ml of water, followed by rotary evaporation at ca. 50 °C and subsequent drying under the stated conditions (Fig. 1). Samples were mounted with double-sided sticky tape and coated with 10—15 nm of gold[9] in an evaporative ion coater. Observation by SEM was accomplished with a Hitachi S-500AS microscope operating at 15—25 kV accelerating voltage.

We thank the Japan Society for the Promotion of Science and the Royal Society (for a Fellowship to DGC) and Morita Kagaku Kogyo Co., Ltd for chemicals. We also thank Mr. Shinobu Nishitani for helpful discussions and assistance.

The Reaction of 1,2-Epoxyalkylsilanes with Azidotrimethylsilane. A Novel Stereoselective Synthesis of (Z)-1-Alkenyl Azides

Shuji TOMODA,* Yuzo MATSUMOTO, Yoshito TAKEUCHI, and Yujiro NOMURA

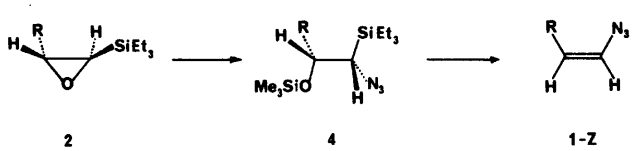
(Received April 25, 1986)

Synopsis. The reaction of *trans*-1,2-epoxyalkylsilanes with azidotrimethylsilane in the presence of boron trifluoride-diethyl ether complex afforded regio- and stereoselectively (*Z*)-1-alkenyl azides.

1-Alkenyl azides, or more commonly vinyl azides, constitute an intriguing class of compounds because of their versatile utility in organic synthesis[1] as well as theoretical interests.[2] Methods available for the synthesis of these are rather limited, among which Hassner's procedure involving 2-iodoalkyl azides, prepared by addition of iodine azide to alkenes, has been most frequently employed.[3] Since this method fails to provide 2-substituted vinyl azides (**1**) except 3,3-dimethyl-1-butenyl azide, several attempts at synthesizing **1** have been made including azidoselenenylation[4] and azidosulfenylation[5] of alkenes.

In a synthetic project, we required stereochemically defined 2-substituted vinyl azides. With regard to the well-known stereoselective alkene synthesis originally reported by Peterson,[6] we thought that the reaction of 1,2-epoxyalkylsilanes (**2**)[7] with azide ion might ultimately afford the desired vinyl azides (**1**) stereoselectively. Herein we wish to report the novel reaction.

The azide ion source we have employed was azidotrimethylsilane (**3**).[8] Initial attempts at the reaction between **2** and **3** were uniformly unsuccessful in the absence of catalysts. After thorough screening of catalysts, it was found that boron trifluoride-diethyl ether is most effective for this reaction. Thus a 1:2 mixture of **2** and **3** was allowed to react at 0 °C to room temperature for 0.5 h in the presence of excess boron trifluoride-diethyl ether. The usual ethereal workup followed by chromatography provided **1** in the yields and stereoselectivities shown in Table 1. Five *trans*-1,2-epoxyalkylsilanes (**2a—e**) were employed. It should be noted that controlled experiments in NMR tube showed essentially quantitative conversion in all cases except **2e**, which gave mainly polymeric materials.



2 4 1-Z

As shown in Table 1, the stereoselectivity of the reaction is greater than 93%. ^{1}H NMR spectral analysis has shown that the olefinic proton resonances at C-2 of (*Z*)-isomers (δ=4.81—4.82) occur at higher field than those of (*E*)-isomers (δ=5.29—5.32) and that the coupling constants between the vinylic protons for (*Z*)-isomers (J=7.5—7.8 Hz) are less than those for (*E*)-isomers (J=13.5—14 Hz), thus confirming the stereochemical assignments discussed above. Virtually exclusive formation of (*Z*)-isomers is entirely consistent with the results of related reactions of **2** previously reported by Hudrlik et al.[9] As shown in Eq. 1, selective nucleophilic displacement by azide ion at the C-1 of **2** would produce intermediate **4**, which would then undergo *trans*-elimination to afford **1-Z**.

Table 1. Synthesis of 2-Substituted Vinyl Azide (**1**) from *trans*-1,2-Epoxyalkylsilanes (**2**)[a]

	2 R	**1** Isolated Yield/%	$Z:E$[b]
a	n-C_8H_{17}	91	93:7
b	n-C_6H_{13}	95	93:7
c	$Me_2CH(CH_2)_2$	88	95:5
d	$Ph(CH_2)_2$	93	95:5
e	Ph	8	100:0

a) Reactions were performed as described in Experimental Section. b) Determined by ^{1}H NMR.

It should be mentioned that the present method cannot be applied to *cis*-1,2-epoxyalkylsilanes, which generally undergo rapid polymerization in the presence of Lewis acids. For example, the cis isomer of **2a** was much less reactive toward **3** under the above conditions to provide a 2:3 mixture of **1-Z** and **1-E** in 12% isolated yield in addition to untractable white solids.

In summary, we have shown that (*Z*)-1-alkenyl azides (**1**) can be easily and stereoselectively obtained by a one-pot reaction from *trans*-1,2-epoxyalkylsilanes (**2**) in good yields. Although the reaction is not very successful for the case of **2e** (R=Ph), it clearly compensates the existing method.[3]

Experimental

Measurements and Materials. All reactions were performed under dry inert conditions. Solvents used were purified by distillation over appropriate drying agent under argon atmosphere. 1,2-epoxyalkylsilanes (**2**) were prepared from the corresponding alkenylsilanes according to the method of Stork.[7,10] Azidotrimethylsilane (**3**) was purchased from Chisso Chem. Co. and was distilled once under argon before use. Infrared spectra were measured on a JASCO DS403G spectrometer. ^{1}H NMR spectra were obtained as $CDCl_3$ solutions with a Varian EM-390 spectrometer at 90 MHz. ^{13}C NMR spectra were recorded in $CDCl_3$ on a JEOL FX90-Q spectrometer operated at 22.5 MHz. All chemical shifts were reported in relative to internal tetramethylsilane.

General Procedure to Prepare 1-Alkenyl Azides (1). To a mixture of **2** and **3** (2 molar equivalent) was added boron trifluoride-etherate (2 molar equivalent) at 0 °C and the mixture was stirred for 0.5 h at room temperature. It was then diluted with ether. The usual aqueous workup with saturated sodium hydrogencarbonate solution and anhydrous magnesium sulfate provided an oil after evaporation of the

solvent, which was purified by column chromatography on silica gel (Kieselgel 60, eluent hexane).

The yields of 1-alkenyl azides (**1**) are shown in Table 1. Analytical and spectroscopic data of the products **1** follow.

(Z)-1-Decenyl Azide (1a). Bp 43 °C/67 Pa. Selective Oxidation of 2-Bromo-*m*-xylene to 2-Bromo-3-methylbenzoic Acid or 2-Bromoisophthalic Acid

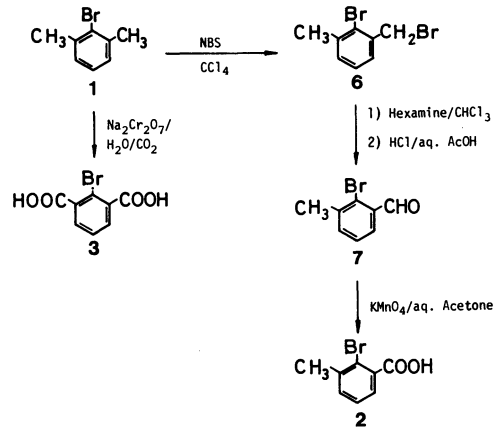
Sotaro MIYANO,* Hiroshi FUKUSHIMA, Hideho INAGAWA, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980
(Received May 1, 1986)

Synopsis. Aqueous sodium dichromate oxidation of 2-bromo-*m*-xylene (**1**) under a carbon dioxide pressure gave 2-bromoisophthalic acid (58%), while NBS-bromination of **1** followed by Sommelet oxidation to aldehyde and then potassium permanganate oxidation enabled the isolation of 2-bromo-3-methylbenzoic acid in 42% yield.

Herein, we wish to report that 2-bromo-*m*-xylene (**1**) serves as readily available starting material for the synthesis of 2-bromo-3-methylbenzoic acid (**2**) and 2-bromoisophthalic acid (**3**) (Scheme 1), both



Scheme 1.

of which have been obtained with difficulty by the literature procedure. In the course of our study on the construction of axially chiral biaryl skeletons,[1] we needed **2** as a coupling component in the Ullmann biaryl synthesis. Unexpectedly, a search of the literature revealed only one precedent synthesis of **2** by Bunnett and Rauhut which involes bromination of *p*-nitrotoluene and then treatment of the resulting 2-bromo-4-nitrotoluene with KCN in water (the von Richter reaction).[2,3] The process was not appealing to us for large scale synthesis because of the low overall yield of **2** (7—8% based on *p*-nitrotoluene) and the tedious handling of massive quantities of toxic cyanide.

We have recently reported an improved oxidation of 1-bromo-2-methylnaphthalene (**4**) to 1-bromo-2-naphthoic acid (**5**) by an aqueous sodium dichromate under a carbon dioxide atmosphere according to the method of Yamashita et al.[4,5] The simplicity of the procedure, along with availability of sufficiently pure **1**,[6] encouraged us to apply it for oxidation of **1**, and Table 1 summarizes the results. In view of the tendency that initially formed monobasic acid **2** was oxidized more readily than starting **1**, probably due to their solubility differences in the aqueous reaction medium, the dichromate oxidation should more advantageously be utilized for selective synthesis of dicarboxylic acid **3**. This was realized by the use of three molar amounts of the oxidant affording **3** in fairly good yield (Run 5). The synthesis of **3** via oxidation of **1** is not new; as long ago as 1937 Coulson used aqueous potassium permanganate as the oxidant.[7,8] However, the procedure has suffered seriously from the concomitant formation of a significant amount of 2-hydroxyisophthalic acid which requires tedious separation from **3**.[7,9] It should be pointed out here that **3** itself is of potential importance as the building block for not only biaryls[7,8] but also diarylamines including acridones of pharmaceutical interest,[11] but that only limited success in the preparation of **3** seems to have restricted its wide use.

As the synthetically passable route to **2**, we eventually resorted to the stepwise oxidation of **1** (Scheme 1) which is essentially an extention of the method used by Bergmann and Szmuszkovicz,[12] and Hall and Turner[13] for transformation of **4** to **5**. Upon treatment with slightly excess amounts of *N*-bromosuccinimde (NBS) almost all of **1** reacted, indicating that preferential bromination of both of the methyl substituents did not so much matter. Crude 2-bromo-3-(bromomethyl)toluene (**6**) was converted to hexamethylenetetramine (hexamine) adduct, which was then hydrolyzed to 2-bromo-3-methylbenzaldehyde (**7**) as needles on standing the reaction mixture (the Sommelet reaction). Conversion of **7** to **2** was effected well with potassium permanganate according to the method of Hall and Turner with slight modifications.[13]

The above procedure was repeated several times with

Table 1. Oxidation of **1** with Aqueous $Na_2Cr_2O_7$ Under CO_2[a]

slightly changing the reaction variables giving the overall yields of **2** ranging from 25 to 42% based on starting **1**. As frequently encountered in the Sommelet reaction,[14] the low yield in the hydrolysis step is one limiting factor, but the straightforward and simple reaction sequence provides a considerable improvement over the conventional preparation of **2**.[2]

Experimental

Preparation of 3 (Run 5 in Table 1). A mixture of **1** (5.38 g, 0.0291 mol), $Na_2Cr_2O_7 \cdot 2H_2O$ (26.0 g, 0.0872 mol), and 90 ml of water placed in a 300 ml autoclave was allowed to react[4] under the conditions cited in Table 1. After the reaction, acidic products were taken into ether and treated as usual. Removal of the solvent left white solid, which was heated at reflux in 100 ml of toluene and filtered hot. The solid was then recrystallized from 2 M HCl (1 M=1 mol dm^{-3}) to give **3** as colorless needles (4.15 g, 0.0169 mol); mp 218—220 °C (lit,[7] mp 218 °C); δ (acetone-d_6) 7.3—7.9 (3H, m, ring-Hs) and 11.0 (2H, br, -COOH); IR (KBr) 1710 and 1685 cm^{-1} (νCO). Anal. ($C_8H_5BrO_4$) C, H, Br.

The toluene filtrate was concentrated to about 20 ml volume. After precipitated solid had been filtered off (70 mg, mp 216—220 °C), the solvent was removed from the filtrate and then crystallization from H_2O-EtOH gave **2** (80 mg, 0.37 mmol), mp 133—136 °C.

Preparation of 2. A mixture of **1** (25.8 g, 0.139 mol), NBS (25.8 g, 0.145 mol), and 0.1 g of benzoyl peroxide was refluxed in 75 ml of CCl_4 for 3 h. The cool reaction mixture was filtered, and evaporation of the solvent left crude **6** as a pale yellow oil; δ (CCl_4) 2.35 (3H, s, $-CH_3$), 4.50 (2H, s, $-CH_2Br$), and 7.0—7.4 (3H, m, ring-Hs).

To the mechanically stirred **6** in 180 ml of $CHCl_3$ was added 24.4 g of hexamethylenetetramine (0.174 mol). After 1 h heating at reflux, the amine adduct was filtered and dried under reduced pressure. The adduct was boiled in 280 ml of 50% aqueous AcOH for 2 h, and then for further 1 h after adding 30 ml of concd HCl. The mixture was allowed to stand overnight at room temperature to give **7** as needles[15] (13.7 g, 49.4% based on **1**); mp 53—54 °C; δ ($CDCl_3$) 2.40 (3H, s, $-CH_3$), 7.2—7.8 (3H, m, ring-Hs), and 10.4 (1H, s, -CHO); IR (KBr) 1680 cm^{-1} (νCO). Combustion analysis suggested the presence of about 5—6% of 2-bromoisophthalaldehyde (Found: C, 46.57; H, 3.38; Br, 38.45%. C_8H_7BrO requires C, 48.27; H, 3.54; Br, 40.14%).

To a boiling solution of **7** (13.2 g, 66.3 mmol) in 420 ml of acetone was added dropwise a $KMnO_4$ solution (13.8 g, 87.3 mmol) in 250 ml of water for 1/2 h, and the heating was continued for another 1 h. Sulfur dioxide was passed through the cool, dark brown mixture until it became clear solution, to which was added 2 l of water and 200 ml of 28% NH_3. The mixture was passed through a short silica-gel column to remove brown precipitates, acidified with concd HCl, and extracted with ether. After the usual work-up, the solvent was evaporated, and the residue was recrystallized from H_2O-EtOH to give **2** as colorless needles (12.2 g, 85.6% based on **7** and 42.3% based on **1**), mp 135—137 °C (lit,[2a] mp 135—137 °C); δ ($CDCl_3$) 2.40 (3H, s, $-CH_3$), 7.0—7.8 (3H, m, ring-Hs), and 11 (1H, br, -COOH); IR (KBr) 1690 cm^{-1} (νCO). Anal. ($C_8H_7BrO_2$) C, H, Br.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60550599 from the Ministry of Education, Science and Culture.

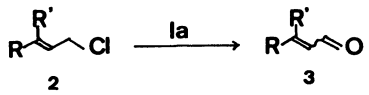
Synopsis. Tertiary amine *N*-oxides were found to be effective for converting allylic chlorides to α,β-unsaturated aldehydes.

Oxidation of allylic chlorides provides a convenient method for synthesizing α,β-unsaturated aldehydes. Unfortunately, however, only a few successful results have been reported which had recourse to dimethyl sulfoxide oxidation[1,2] or a potassium salt of 2-*aci*-nitropropane-tetrakis(triphenylphosphine)palladium system[3] whereas allylic bromides proved to be oxidized by a potassium salt of 2-*aci*-nitropropane[4] or potassium chromate.[5,6] In our continuing efforts to develop an efficient method to synthesize α,β-unsaturated compounds as a raw material for the vitamin A synthesis,[7] we have now disclosed that tertiary amine *N*-oxides (**1**) effect a smooth conversion of allylic chlorides into α,β-unsaturated aldehydes.

Various tertiary amine *N*-oxides were reported to oxidize benzylic halides successfully.[8-10] We have found that treatment of primary allylic chlorides **2** with 3 equiv of *N*-ethylmorpholine *N*-oxide (**1a**) in DMF at 50°C for 4 h affords the desired α,β-unsaturated aldehydes **3** in excellent yields according to Eq. 1 (Table 1, Entries 1—5) (Method A). Other tertiary amine *N*-oxides derived from *N*-methylmorpholine, *N*-methylpyrrolidine, *N*-methylpiperidine, trimethylamine, *N*,*N*-dimethylcyclohexylamine, *N*,*N*-dicyclohexylmethylamine, and *N*,*N*-diethylcyclohexylamine gave rise to lower yields of **3**.



2 3 (1)

When this reaction was applied to secondary allylic chlorides **5**, no satisfactory results were obtained. The difficulty was overcome, however, by conducting the reaction in the presence of an alkali metal iodide such as lithium iodide (Table 1, Entries 6 and 7) (Method B) or in the presence of a catalytic amount of copper (I) chloride (Table 1, Entry 8) (Method C). Since **5** can be readily prepared by the ene-type chlorination of the corresponding alkenes **4**,[11] the effective method for converting **4** into **6** has been established (Eq 2). The

reaction can be viewed as proceeding via initial formation of the primary allylic halides **7**.[12]

Experimental

Reaction of Primary Allylic Chlorides with *N*-Ethylmorpholine *N*-Oxide (1a): Method A (Typical Procedure). A DMF solution (3 cm^3) of geranyl chloride (346 mg, 2 mmol) and **1a** (787 mg, 6 mmol) was stirred at room temperature for 1 h and at 50 °C for additional 4 h under an argon atmosphere. The reaction mixture was combined with 2.5% H_2SO_4 (10 cm^3) and ethyl acetate (10 cm^3). The organic layer was washed successively with 2.5% H_2SO_4, saturated $NaHCO_3$, and 10% Na_2SO_3 solutions. Drying ($MgSO_4$) followed by evaporation afforded a crude oil which was distilled to give 3,7-dimethyl-2,6-octadienal (268 mg, 88%, *E*/*Z*=70:30, bp 93 °C/400 Pa, .Kugelrohr bath temperature).

Reaction of Secondary Allylic Chlorides with Tertiary Amine *N*-Oxide: Method B (Typical Procedure). A DMF solution (3 cm^3) containing (*E*)-6-chloro-3,7-dimethyl-2,7-octadienyl acetate[11] (461 mg, 2 mmol), **1a** (787 mg, 6 mmol), and $LiI \cdot 2H_2O$ (680 mg, 4 mmol) was stirred at room temperature for 1 h and at 50 °C for additional 4 h. Workup as described above and column chromatogrpahy of the crude oil on silica gel (10:1 hexane-ethyl acetate) gave 8-acetoxy-2,6-dimethyl-2,6-octadienal (298 mg, 71%, 2*E*/2*Z* 68:32).

Method C: A dioxane solution (5 cm^3) containing (*E*)-6-chloro-3,7-dimethyl-2,7-octadienyl acetate (2.17 g, 9.41 mmol), triethylamine *N*-oxide (**1b**) (3.47 g, 29.6 mmol), and copper(I) chloride (92 mg, 0.93 mmol) was stirred at 50 °C for 10 h. Workup and chromatographic purification as described above gave (2*E*,6*E*)-8-acetoxy-2,6-dimethyl-2,6-octadienal (1.21 g, 61%). In this reaction, **1a** gave rise to a lower yield.

Synthesis of 1,3,6,8-Tetrakis(dimethylamino)pyrene Having Low Oxidation Potential

Naomi UEDA, Yoshiteru SAKATA,* and Soichi MISUMI
The Institute of Scientific and Industrial Research, Osaka University, Mihoga-oka, Ibaraki, Osaka 567
(Received May 23, 1986)

Synopsis. 1,3,6,8-Tetrakis(dimethylamino)pyrene (**1**) was synthesized starting from the corresponding tetranitro compound. The first oxidation potential of **1** shows the lowest value ($E^1_{1/2}$=−0.12 V vs SCE) among those of aromatic amines reported so far.

It is well known that the substitution of olefinic or aromatic protons with dimethylamino groups results in lowering the oxidation potential. Typical examples are tetrakis(dimethylamino)ethylene[1] and 1,4-bis(dimethylamino)benzene,[2] whose oxidation potentials ($E^1_{1/2}$) are −0.75 V and 0.04 V vs SCE, respectively. The former value is the lowest among those of all organic compounds so far reported. Our previous study[3] on the synthesis of 2,7-bis(dimethylamino)pyrene ($E^1_{1/2}$= 0.37 V) and -tetrahydropyrene ($E^1_{1/2}$=0.14 V) with fairly low oxidation potentials prompted us to prepare 1,3,6,8-tetrakis(dimethylamino)pyrene (**1**) with a view to powerful donor.

1: R = -NMe_2
2: R = -NO_2
3: R = -NH_2·HCl

Results and Discussion

1,3,6,8-Tetranitropyrene (**2**), prepared by nitration of pyrene according to the literature,[4] was reduced with tin powder in 6M HCl to give **3** in 87% yield. Because of the instability of free amine, **3** was used for the subsequent reaction without further purification. Methylation of **3** was carried out with dimethyl sulfate to give the desired compound **1** in 37% yield. Although **1** is very sensitive to oxygen, **1** can be kept for several months at ordinary temperature under inert atmosphere.

Figure 1 shows a cyclic voltammogram for 1 mM (mmol dm^{-3}) of **1** in 0.1 M tetraethylammonium perchlorate in acetonitrile, recorded with a scan rate of 50 mV s^{-1}. It exhibits two reversible redox waves. Judging from the peak separation (ca. 30 mV) two electron-transfer process is involved in each wave. In agreement with the initial expectation, the oxidation potentials of **1** are very low ($E^1_{1/2}$=−0.12 V, $E^2_{1/2}$=−0.05 V vs SCE). It is noteworthy that the value of $E^1_{1/2}$ is less than that of 1,4-bis(dimethylamino)benzene, which is the lowest among those of aromatic amines so far reported.

1 forms charge-transfer complex with iodine.

Experimental

All the melting points are uncorrected. The IR, NMR, MS, and electronic spectra were measured on a Hitachi EPI-G2 and a Hitachi 345, a JEOL JNM-FX-100, a Hitachi RMU-7, and a Hitachi EPS-3T spectrometer, respectively. The cyclic voltammetry was carried out at room temperature under argon using the combination of a generator of Hokuto HB-107 A and a potentiostat of Hokuto HA-104. A glassy carbon electrode (Yanagimoto P-13) was used as the anode, and platinum wire was used as the counter electrode.

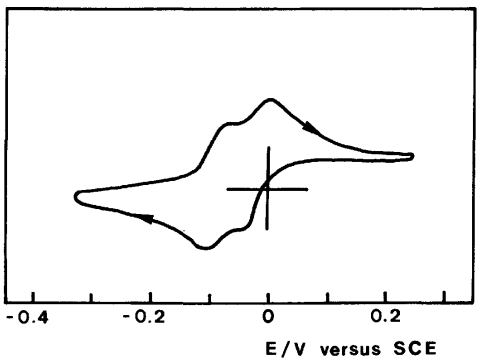

Fig. 1. Cyclic voltammogram of **1** in acetonitrile.

1,3,6,8-Tetrakis(dimethylamino)pyrene (1). To a suspension of 1,3,6,8-tetranitropyrene (**2**) (200 mg 0.52 mmol) in 15 ml of 6M hydrochloric acid was added tin powder (372 mg, 3.13 mmol) in small portions under nitrogen and the mixture was warmed at 50—60 °C for 3.5 d. After cooling, precipitates of ammonium salt **3** were collected, washed with 6M HCl and dried to give 184 mg (87%) of **3**, which was used for the next step without further purification [**3**: MS 262 (M^+); IR (nujol mull) 3570, 3475, 3200—2300, and 1605 cm^{-1}].

To a stirred aqueous solution (5 ml) of crude **3** (184 mg, 0.45 mmol) was added an aqueous solution (6 ml) of sodium hydrogencarbonate (1.818 g, 21.64 mmol) and dimethyl sulfate (908 mg, 7.21 mmol) under nitrogen at room temperature. Stirring was continued at room temperature for 1 h and then at 50—60 °C for 4 h. After cooling, 2-aminoethanol (3 ml) was added and the mixture was heated at 120—130 °C for 3 h with stirring. After cooling, yellow precipitates of **1** were collected, washed with water and dried to give 102 mg of crude **1**. Purification by sublimation gave 62 mg (37%) of **1**: Yellow prisms, mp 212—213 °C; ^{1}H NMR ($CDCl_3$) δ=3.02 (24H, s), 7.43 (2H, s), and 8.17 (4H, s); IR (KBr disk) 1585 cm^{-1}; UV (CH_3CN) 228 (ε 4.10×10^4), 302 (2.25×10^4), and 414 nm (3.04×10^4). Found: C, 76.69; H, 8.11; N, 15.18%. Calcd for $C_{24}H_{30}N_4$: C, 76.97; H, 8.07; N, 14.96%.

Complexation of 1 with Iodine. Under nitrogen atmosphere, a solution of **1** (10 mg, 0.03 mmol) in benzene (2 ml) and a solution of iodine (33 mg, 0.15 mmol) in the same solvent(3 ml) were mixed at room temperature. Precipitated dark purple microcrystals were filtered, washed with benzene, and dried to give 8 mg (80% yield based on **1**) of **1**-I_2: black fine crystals, decomp>180 °C; IR (KBr disk) 1550 cm^{-1}: UV (CH_3CN) 220 (sh, ε 5.33×10^4), 256 (4.26×10^4), 296 (1.28×10^5). 368 (6.39×10^4), 456 (2.79×10^4), and 532 nm (1.06×10^4). Found: C,19.16; H,2.01; N, 3.73; I, 74.66%. Calcd for $C_{24}H_{30}N_4$·4.4I_2: C, 18.93; H, 2.10; N, 3.84; I, 74.33%.

^{17}O- and ^{33}S-Hyperfine Splittings for Aromatic RCONSAr Radicals. Complete Evaluation of ESR Parameters[1)]

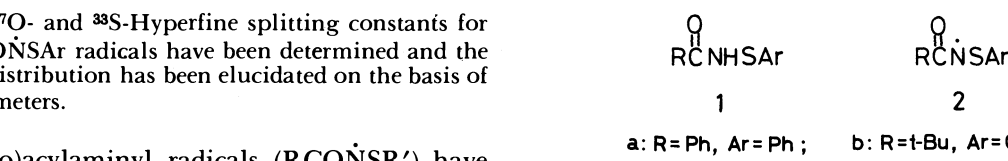
Yozo MIURA,* Yoshitaka SHIBATA, and Masayoshi KINOSHITA
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received March 27, 1986)

Synopsis. ^{17}O- and ^{33}S-Hyperfine splitting constants for aromatic RCONSAr radicals have been determined and the spin density distribution has been elucidated on the basis of the ESR parameters.

N-(Arylthio)acylaminyl radicals (RCONSR′) have interesting structures in which both an electron-accepting (C=O) and an electron-donating substituent (SR′) attach directly to the radical center. In an earlier paper,[2)] we showed that in the radicals the unpaired electron resides mainly on the nitrogen and the phenylthio group on the basis of large a_N and a_H values (due to the phenylthio benzene ring protons). However, owing to a lack of the a_{17O} and a_{33S} values, we could not fully elucidate the unpaired-electron distribution pattern. We report herein the a_{17O} and a_{33S} values for the radicals.

Results and Discussion

Type-**2** radicals were generated at room temperature by the photolysis of solutions of the corresponding *N*-(arylthio)amides **1** in 1:4 (v/v) di-*t*-butyl peroxide–benzene using a 1 kW xenon lamp. Under these experimental conditions we could unequivocally detect ^{33}S-hyperfine splittings (hfs) without any enrichment of the ^{33}S atoms in each wing of the ESR spectra obtained at high gain (see Fig. 2). On the other hand, ^{17}O-hfs's could only be detected (see Fig. 1) when the radical was enriched by ^{17}O-atoms (5.9 atom%). The experimentally obtained intensity ratios of the ^{17}O (0.96%) and ^{33}S (0.20%) satellite lines to the parent peaks coincided satisfactorily with the theoretical values (^{17}O, 0.98%; ^{33}S, 0.19%), respectively. The ESR parameters obtained are listed in Table 1.



Type-**2** radicals can be represented by the following four possible canonical structures (A, B, C, and D) as reported in an earlier paper.[2)] However, the very low a_{17O} value obtained for **2a** reveals clearly that the canonical structure D is much less important. The π-

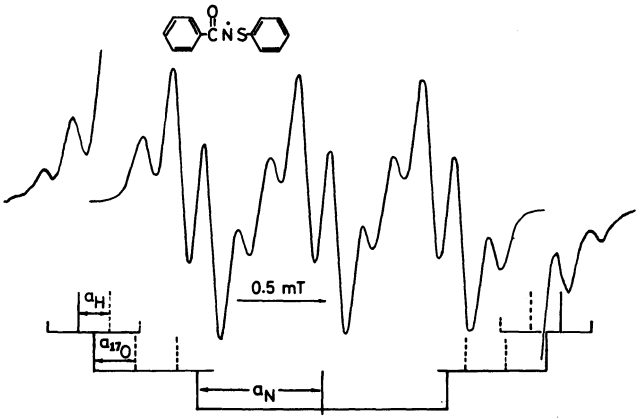


Fig. 1. ESR spectrum of ^{17}O-enriched (5.9%) **2a** recorded during photolysis of a solution of ^{17}O-enriched (5.9%) **1a** in 1:4 (v/v) di-*t*-butyl peroxide–benzene at 17°C. The wings are shown at high gain (20 times). The stick diagram represents a part of the theoretical reconstruction of the splittings due to ^{14}N, ^{1}H, and ^{17}O. The experimentally observed satellite lines due to ^{17}O are shown by the full lines.

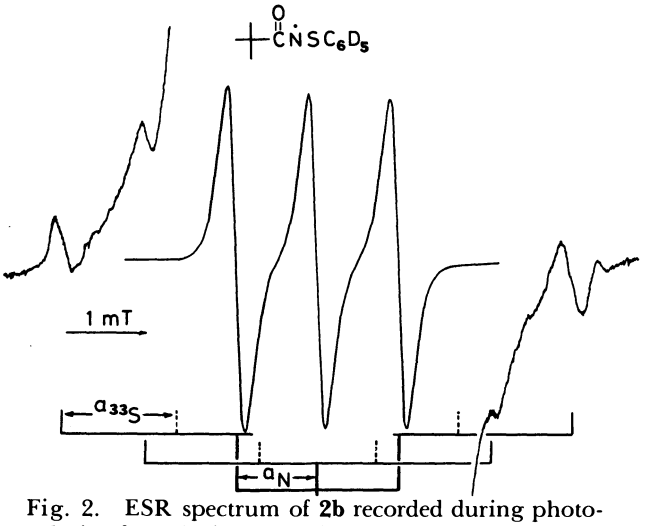

Fig. 2. ESR spectrum of **2b** recorded during photolysis of a solution of **1b** in 1:4 (v/v) di-*t*-butyl peroxide–benzene at 17°C. The wings are shown at high gain (100 times). The stick diagram represents a part of the theoretical reconstruction of the splittings due to ^{14}N and ^{33}S. The experimentally observed satellite lines due to ^{33}S are shown by the full lines.

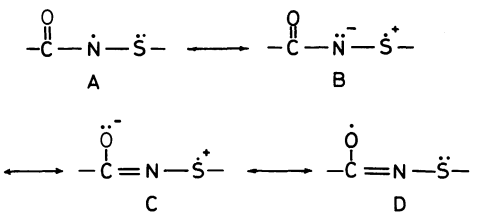
t-BuCONSPh	0.749[e)]	0.169 (3)[e)]		2.0082[e)]

a) Hyperfine splitting constants are given in mT. b) Solvent 1:4 (v/v) di-*t*-butyl peroxide–benzene. c) Temperature 17±1°C. d) Numbers in parentheses refer to the number of equivalent protons. e) Taken from Ref. 2. f) The ortho and para protons on the phenylthio benzene ring. g) The value obtained for the ^{17}O-enriched (5.9 atom%) **2a**.



orbital spin density ($\rho_{o\pi}$) on the oxygen can be derived by using Silver's equation,[3,4] where the contribution to a_{17O} from $\rho_{c\pi}$ of the carbonyl carbon is neglected. The $\rho_{o\pi}$ value obtained is only 0.055.

$$\rho_o^\pi = a_{17O}/Q_o = a_{17O}/-4.1\ \text{mT}$$

On the other hand, the a_{33S} values (1.06 and 1.07 mT) are much higher than the a_{17O} value and is strongly indicative of a high π-orbital spin density ($\rho_{s\pi}$) on the sulfur. Consequently, it can be concluded on the basis of the large a_N and a_{33S} values that in **2** the unpaired electron resides mainly on the nitrogen and sulfur. Accordingly, type-**2** radicals can be best represented by three canonical structures: A, B, and C.

Furthermore, we note that the a_{33S} values for **2** are substantially higher than those (0.46—0.74 mT) for the radicals of the type RNSR′ (R, R′=alkyl, aryl).[5,6] The only radical having a comparable magnitude of a_{33S} among the thioaminyls studied is **3**,[7] in which both an electron-accepting (SO_2) and an electron-donating substituent (SAr) attach directly to the radical center in a manner similar to **2**. The somewhat higher a_N and a_{33S} values for **3** can be accounted for by the fact that there is no ability of the sulfonyl group to delocalize an unpaired electron.[8]

3

$a_N = 0.79-0.894$ mT

$a_{33S} = 1.19-1.23$ mT

In an earlier paper,[5] we showed that the π-orbital spin density ($\rho_{s\pi}$) on the sulfur in RNSR′ radicals can be derived from the a_{33S} values by using the following established equation through an investigation of the ^{33}S-hfs's of a variety of RNSR′ radicals. From

$$\rho_S^\pi = a_{33S}/Q_S = a_{33S}/2.3\ \text{mT}$$

this equation we can estimate the $\rho_{s\pi}$ value for **2** to be 0.47. On the other hand, the $\rho_{s\pi}$ values for the RNSR′ radicals derived from the a_{33S} values of 0.46—0.74 mT are 0.20—0.32. This increased $\rho_{s\pi}$ value for **2** can be readily rationalized in terms of the contribution of canonical structure C; that is, it can be interpreted as a consequence of a synergetic effect of the electron-accepting carbonyl group and the electron-donating arylthiyl group. Therefore, we are interested in this result in connection with the hypothesis concerning captodative stabilization of radicals.[9] Further investigations are under way.

Experimental

Melting points, and IR and ^{1}H NMR spectra were taken as previously reported.[10] Benzenesulfenyl chloride,[11] deuterated benzenesulfenyl chloride,[11] and ^{17}O-enriched (5.9 atom%) benzamide[1,12] were prepared by the previously described procedures.

***N*-(Phenylthio)benzamide (1a).** This amide was prepared by the previously reported procedure,[2] with some modifications. To a solution of 200 mg (1.65 mmol) of benzamide in 15 cm^3 of dry THF was added 79 mg (2.0 mmol) of NaH (60 wt%) and the mixture was stirred for 3 h at room temperature. To this mixture was added, in one portion, at 0—5 °C with stirring a solution of 290 mg (2.0 mmol) of freshly distilled benzenesulfenyl chloride in 1 cm^3 of dry hexane. After 2 h of stirring at room temperature, 0.5 cm^3 of Et_3N was added and the resultant mixture was stirred for an aditional 0.5 h. Filtration, evaporation, column chromatography (alumina, Merck Art 1097, column size 3×10 cm, 1:100 ethanol-benzene), and crystallization (benzene-hexane) gave **1a** in 67% yield (260 mg, 1.1 mmol); mp 123—124 °C (lit,[2] 122—124 °C).

^{17}O-Enriched **1a** was prepared by the same method; mp 123—123.5 °C.

***N*-(Phenylthio-d_5)pivalamide (1b).** To a stirred solution of 2.02 g (20 mmol) of pivalamide and 4 cm^3 of Et_3N in 300 cm^3 of dry ether was added dropwise at 0—5 °C a solution of 3.59 g (24 mmol) of benzenesulfenyl-d_5 chloride in 20 cm^3 of dry ether. After being stirred for 3 h at the same temperature, the mixture was filtered, evaporated, and chromatographed as described above. Crystallization from hexane gave colorless needles in 21% yield (0.91 g, 0.42 mmol); mp 98—99 °C; IR (KBr) 3250 (NH), 1670 (C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.16 (s, *t*-Bu, 9H), 7.91 (s, NH, 1H). Anal. ($C_{11}H_{10}D_5NOS$) C, H, N.

ESR Measurements. A 10—20 mg portion of amide **1** and 0.40 cm^3 of 1:4 (v/v) di-*t*-butyl peroxide-benzene were placed in an ESR cell. The cell was then degassed by three freeze-pump-thaw cycles using a high-vacuum system and sealed off. Type-**2** radicals were generated in the cavity of an ESR instrument by direct irradiation using a 1-kW xenon lamp (Wacom UV-10X). The ESR spectra were recorded during irradiation on a JEOL JES-FE-2XG spectrometer equipped with an X-band microwave unit and 100-kHz field modulation. Hyperfine-splitting constants and *g* values were determined by a comparison with Fremy's salt in K_2CO_3 aqueous solution (a_N=1.309 mT, *g*=2.0057).

Synthesis of Phosphirane Oxide Derivatives Promoted by Introduced Phenylsulfinyl Groups and Their Pummerer Reaction

Tatsuo OSHIKAWA* and Mitsuji YAMASHITA
Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432
(Received October 7, 1985)

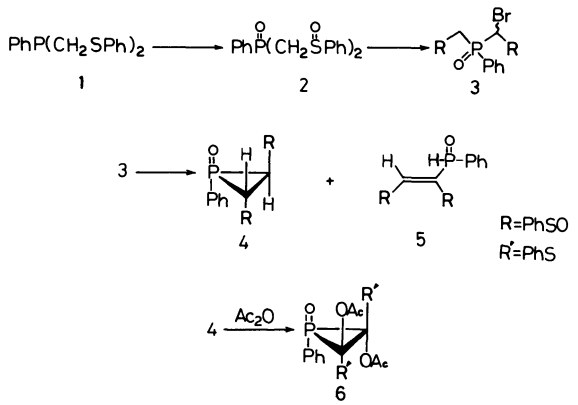
Synopsis. Phosphirane oxide derivatives were first successfully synthesized in good yield under mild conditions wherein carbon-carbon bond formation was promoted by two phenylsulfinyl groups on the α and α' carbons of the phosphorus atom. A structure determination of the formed phosphirane oxide derivatives as well as the stereochemistry of the Pummerer reaction product revealed a trans geometry for the phosphirane oxide.

In the field of three-membered heterocycles, many papers concerning aza and thia analogues have been published; however, little is known about the syntheses of phosphiranes via reactions of phosphides with epoxides[2] and via the formation of two carbon-phosphorus bonds were reported.[3] This paper describes the first attempt to introduce activating groups, such as phenylsulfinyl groups, on the α and α' carbons of phosphorus atom in order to promote regioselectivity in a coupling reaction leading to phosphirane oxides via carbon-carbon bond formation.

Results and Discussion

Compound **1** was prepared by a reaction of phenylphosphonous dichloride with a Grignard reagent of chloromethyl phenyl sulfide. Phosphine **1** was oxidized with hydrogen peroxide to give compound **2**, the bromonation of which was then carried out with an *N*-bromosuccinimide/bromine/pyridine system[4] to afford α-bromophosphine oxide **3**. Compound **3** consisted of diastereomers, being used for a further transformation without separation. The treatment of **3** with a variety of bases, such as DBU and triethylamine, in tetrahydrofuran at room temperature brought about dehydrobromination to afford a phosphirane oxide **4**. When DBU, a strong dehydrobromination reagent, was used an olefinic product **5** was obtained as the major product (yield of **4** and **5** were 3 and 73%, respectively).

Phosphiranes have been known to be unstable towards bases and heat; therefore, it may be difficult to produce phosphirane as the sole product.[1,2] The amount of the olefinic product which was formed as the by-product depended on the base, since the base catalyzed a ring opening of the phosphirane oxide **4** to open the three-membered ring. Therefore, the major product was an olefinic type when a strong dehydrobromination reagent such as DBU was used. On the other hand, triethylamine remarkably improved the formation of phosphirane oxide **4** by a 1,3-elimination of hydrogen bromide (yield of **4** and **5** were 75 and 3%, respectively). Quast and Heuschmann[5] obtained a single stereoisomer of a phosphirane oxide having a configuration where the C-H vs. C-H was syn and P=O vs. C-H was an anti form from the diastereomeric α-bromo precursor. Four isomers can possibly exist for the phosphirane oxide **4**; however, the substituent R's (PhSO) should be anti to each other, as shown in the Scheme since only the Z-isomer **5** was produced in the ring-opening transformation of the phosphirane oxide **4**. The vinyl proton of compound **5** showed small values for the H-P coupling constant[6] in the ^{1}H NMR spectrum (J_{HCCP}=15.0 Hz), indicating a Z-geometry (as cis for H-C=C-P or R-C=C-R bond) compared with the large coupling constant for the E-isomer.[6] Since the cleavage of the carbon-phosphorus bond of phosphirane oxide 4 having trans R's proceeds in a conrotatory fashion from the Woodward-Hoffmann rule (as shown in the literature[7]) the cis-geometry for the phenylsulfinyl groups on the carbon-carbon double bond to form the Z-isomer **5** should be brought about in consequence of the three-membered ring opening.



Scheme.

The product of a Pummerer reaction[8] of the phosphirane oxide **4** (i.e., compound **6**) gave additional strong information regarding the structure of compound **4**. If the Pummerer reaction product **6** has a trans configuration for two acetoxyl groups or for two phenylthio groups, the two methyl protons of the acetoxyl groups should be observed separately from the two singlet signals in the ^{1}H NMR spectrum. On the other hand, if the configuration of **6** is cis for these two groups, the two methyl protons should be observed as one singlet, owing to the symmetry. The treatment of compound **4** with acetic anhydride afforded a crystalline phosphirane oxide derivative **6** which had two acetoxyl groups on the α and α' positions of the phosphorus atom. The ^{1}H NMR spectrum of compound **6** clearly showed two kinds of acetoxyl signals at δ 3.00 and 3.32 (three protons each). These observations clearly established the structure of phosphirane oxide **4** to be either (2*S*, 3*S*) or (2*R*, 3*R*) as shown in the scheme. The sp^3 α and α' carbon signals of the phosphorus atom were observed downfield (69.5 and 73.6 ppm) compared with various publish-

ed reports[2,5] regarding ^{13}C NMR spectrum, since the carbon atoms are connected to oxygen and sulfur atoms.

Experimental

Apparatus. The IR spectra were measured on a Japan Spectroscopic Co., Ltd. JASCO A-3 spectrophotometer; the ^1H NMR spectra were run on a Hitachi R-24B (60 MHz) spectrameter; the mass spectra were measured by a Hitachi RMU, DMG, GC-MS spectrometer; the high-performance liquid chromatography was carried out using a Japan Spectroscopic Co., Ltd. UNIFLOW-211 and melting points were measured on a Yanagimoto Seisakusho micro melting-point apparatus.

Synthesis of Bis(phenylthiomethyl)phenylphosphine (1). A Grignard reagent was prepared from chloromethyl phenyl sulfide (3.7 g, 23.4 mmol) and magnesium metal (0.57 g, 23.4 mg atom) in freshly distilled tetrahydrofuran or ether (30 ml) under a dry nitrogen atmosphere. Phenylphosphonous dichloride (2.0 g, 11.2 mmol) in tetrahydrofuran (20 ml) was added to a solution of the Grignard reagent and the resulting solution was stirred for 5 h at room temperature. An aqueous solution of ammonium chloride (20 ml) was added to the reaction mixture; then, the solution was extracted with ether (3×30 ml). The organic layer was washed with water (3×10 ml). and dried over anhydrous sodium sulfate; the solvent was then evaporated. The residue was separated by column chromatography on silica gel (eluent: hexane) to afford compound **1** as colorless crystals in 45% yield, mp 71—72°C (from ethanol). ^1H NMR ($CDCl_3$) δ=2.92 (s, 4H, $2CH_2$) and 6.98 (br s, 15H, 3Ph).

Found: C, 74.54; H, 5.96%. Calcd for $C_{20}H_{19}PS$: C, 74.51; H, 5.94%.

Synthesis of Bis(phenylsulfinylmethyl)phenylphosphine Oxide (2). A 30% aqueous solution of hydrogen peroxide (0.37 g) was added to a solution of compound **1** (0.5 g, 1.55 mmol) in acetic acid (10 ml) and was stirred for 1 h at 0°C. The reaction mixture was allowed to warm to room temperature and was stirred for an additional 0.5 h, followed by the usual work-up. Isolation of the product by column chromatography on silica gel (eluent: benzene/ethyl acetate=1/1 in v/v) afforded compound **2** as a white crystalline material in 80% yield, mp 125—127°C. ^1H NMR ($CDCl_3$) δ=2.92 and 3.20 (s×2, 4H, $2CH_2$), and 7.36—7.43 (m, 15H, 3Ph). IR (ν_{max}^{KBr}) cm^{-1}, 1100 (P=O) and 1150 (S=O).

Found: C, 64.82; H, 5.15%. Calcd for $C_{20}H_{19}PSO_3$: C, 64.85; H, 5.17%.

Synthesis of 3. After the addition of a dichloromethane (20 ml) solution of bromine (0.25 g, 1.59 mmol), *N*-bromosuccinimide (0.14 g, 0.76 mmol), and pyridine (1 ml) to a solution of compound **2** (0.28 g, 0.76 mmol) in dichloromethane (10 ml), the mixture was stirred for 3 h at room temperature. The reaction mixture was poured into water (30 ml) and the organic layer was separated, washed with water, dried over anhydrous sodium sulfate, and then the solvent was evaporated. The separation of the product by thin-layer chromatography on silica gel afforded a crystalline compound **3** in 60% yield, mp 119—124°C. Compound **3** was a mixture of diastereoisomers which were detected by an HPLC retention time of 4.2 and 4.4 min (eluent: chloroform/methanol=20/1 in v/v) at the ratio of 1.5 to 1.0, respectively. ^1H NMR ($CDCl_3$) δ=3.09—3.81 (m, 2H, CH_2), 4.81—5.30 (m, 1H, CH-Br), and 7.43—7.85 (m, 15H, 3Ph); IR (ν_{max}^{KBr}) cm^{-1}, 1100 (P=O), 1160 (S=O), and 690 (C-Br); MS, *m/z*, 480 (M^+) and 482 (M^++2).

Found: C, 49.57: H, 3.69%. Calcd for $C_{20}H_{18}PS_2BrO_3$: C, 49.90; H, 3.77%.

Synthesis of 1-Phenyl-2,3 -bis(phenylsulfinyl)phosphirane 1-Oxide (4). A solution of compound **3** (0.1 g, 0.21 mmol) and an excess amount of triethylamine (3 ml) in tetrahydrofuran 5 ml) was stirred for 12 h at room temperature. The solvent was evaporated and the residue was separated by thin-layer chromatography on silica gel (eluent: benzene/ethyl acetate=1/1 in v/v) to afford the phosphirane oxide, **4**, and the olefinic product, **5**, in 75 and 3% yields, respectively. The phosphirane oxide, **4**, (syrup): ^1H NMR ($CDCl_3$) δ=4.34 (dd, J_{PCH}=7.5 Hz, 2H, 2CH) and 7.55—7.93 (m, 15H, 3Ph); IR (ν_{max}^{KBr}) cm^{-1}, 1450 (P-C_{arom}), 1130 (P=O), 1050 (S=O), and 700 (P-C); MS *m/z*, 400 (M^+).

Found: C, 60.11; H, 4.31%. Calcd for $C_{20}H_{17}O_3PS_2$: C, 59.99; H, 4.28%.

The olefinic product,**5**,(syrup): ^1H NMR ($CDCl_3$) δ=6.10 (d, J_{HCCP}=15.0 Hz, 1H, $P\diagdown C{=}C\diagup H$), 7.00 (d, J_{HP}=444.0 Hz, 1H, PH), and 7.2—7.6 (m, 15H, 3Ph); IR (ν_{max}^{neat}) cm^{-1}, 2350 (P-H), 1580 and 840 (C=C); MS *m/z*, 400 (M^+).

Pummerer Reaction of Phosphirane Oxide Derivative 4 with Acetic Anhydride. A solution of phosphirane oxide **4** (0.1 g, 0.25 mmol), acetic anhydride (0.06 g, 0.55 mmol), and a trace of *p*-toluenesulfonic acid in dichloromethane (5 ml) was stirred for 12 h at room temperature; then, the solvent was evaporated. The isolation of the crude product by thin-layer chromatography on silica gel afforded (2*S*, 3*S* or 2*R*, 3*R*)-1-phenyl-2,3-diacetoxy-2,3-bis(phenylthio)phosphirane 1-oxide (**6**) in 85% yield, mp 135—136°C. ^1H NMR ($CDCl_3$) δ=3.00, 3.32 (s, 6H, 2OAc), and 7.52 (m, 15H, 3Ph); ^{31}P NMR ($CDCl_3$) δ_P=−62.7 ppm (from 85% H_3PO_4); ^{13}C NMR ($CDCl_3$) δ=34.2 (s, CH_3), 34.5 (s, CH_3), 69.5 (d, J_{CP}=37.8 Hz, C^{α}), 73.6 (d, J_{CP}=35.2 Hz,$C^{\alpha'}$, 127.4 (P-arom), 128.1 (P-arom), 129.3 (P and S arom), 129.5 (S-arom), 130.4 (S-arom), 140.9 (S-arom), 143.3 (P-arom), 226.3 (s, C=O), 230.3 (s, C=O); IR (ν_{max}^{KBr}) cm^{-1}, 1590 (C=O), 1450 (P-Ph), 1150 (P=O), 750 (C-S-C), and 690 (C-P); MS *m/z*, 484 (M^+).

Found: C, 59.52; H, 4.34%. Calcd for $C_{24}H_{21}O_5PS_2$: C, 59.50; H, 4.37%.

The authors wish to express their thanks to Dr. Masaaki Yoshifuji for his kind discussions and measurements of the NMR spectra.

Chromotropisms of Imidazole Derivatives. III.[1,2] Crystal Structure of 4,5-Bis(4-methoxyphenyl)-2-(4-nitrophenyl)-1*H*-imidazole

Yoshinobu INOUYE* and Yoshiko SAKAINO†
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
†Department of Chemistry, Faculty of Education, Gunma University, Maebashi 371
(Received April 30, 1986)

Synopsis. The molecular and crystal structure of the title compound was determined by the single-crystal X-ray analysis. The crystal is orthorhombic with a space group *Pbca*, a=15.161 (9), b=25.805 (5), c=9.948 (1) Å, and Z=8. The 4-nitrophenyl ring is nearly on a same plane with the imidazole ring, while the other two benzene rings make angles of 26.5° and 47.7°.

In the course of our study on the chromotropic behavior of the dimers of 2,4,5-triarylimidazolyl radicals obtained by the oxidation of 2,4,5-triaryl-1*H*-imidazole,[3] we have recently found that 4,5-bis(4-methoxyphenyl)-2-(4-nitrophenyl)-1*H*-imidazole (**I**) crystallized in several colored states under different conditions. Crystallization of **I** from aqueous acetic acid gave an orange-yellow imidazolium acetate dihydrate (**I**), which exhibits sensitive color change from orange-yellow to red by drying, trituration, or heating.[1] The crystal structure of **I** showed that the solvents of crystallization played an essential role in crystal packing.[2] On the other hand, crystallization from dry benzene gave initially red needles (**II**), which changed their color and crystal form to light orange prisms (**III**) when the solution containing **II** had been allowed to stand for several days at room temperature. When exposed to AcOH-H_2O vapor, pulverized **III** changed to **I** after three days.

In order to clarify the relation between the color and the structure, a single-crystal X-ray analysis of **III** has been carried out.

Experimental

Data Collection. **III**; $C_{23}H_{19}N_3O_4$, F. W. 401.42, D_m= 1.35 g cm^{-3} (aqueous KI), D_x=1.37 g cm^{-3}, μ (Mo$K\alpha$)=1.02 cm^{-1}. The unit-cell dimensions were refined on a Rigaku automated four-circle diffractometer with graphite monochromated Mo$K\alpha$ radiation (50 kV, 160 mA). The diffraction intensities were measured for a single crystal with approximate dimensions of 0.25×0.20×0.12 mm^3 on the diffractometer by the ω—2θ scan technique at room temperature. The intensities of three standard reflections, measured after every 56 reflections, were stable within a 1% fluctuation. In the range of 2θ values up to 45°, 1252 independent structure factors ($|F_o|>3\sigma(F_o)$) were used for the structure determination. The intensities were corrected for Lorentz and polarization effects but not for absorption. All calculations were carried out on a FACOM M-380 computer at the Science Information Processing Center, University of Tsukuba.

Structure Dtermination. The structure was solved by the direct method (MULTAN 80).[4] All the 30 non-hydrogen atoms were found on the first E map calculated with 320 $|E|$'s greater than 1.54. The atomic parameters were refined by the full-matrix least-squares method.[5] The atomic scattering factors, given by Cromer and Mann[6] for C, N, or O, and listed[7] on the table for H were used.

Refinement with isotropic temperature factors for C, N, O lowered the R factor to 0.216. One reflection 020 had $|F_o|$ abnormally lower than $|F_c|$. As it seemed to suffer the secondary extinction, the subsequent refinements were carried out without this reflection. Refinement with anisotropic temperature factors for non-hydrogen atoms reduced the R value to 0.093. All the hydrogen atoms were revealed on a difference Fourier map, which were included in the refinement with isotropic temperature factors. Finally the R value reduced to 0.037 (R_w=0.041). The residuals in the difference map were within in the range of +0.47—−0.22 e Å^{-3}. The atomic parameters[8] are listed in Table 1 (for the numbering diagram, see Fig. 1).

Results and Discussion

The selected bond distances and angles are shown in

Table 1. Atomic Coordinates of the Non-Hydrogen Atoms (×10^4) and Equivalent Isotropic Temperature Factors with e.s.d.'s in Parentheses

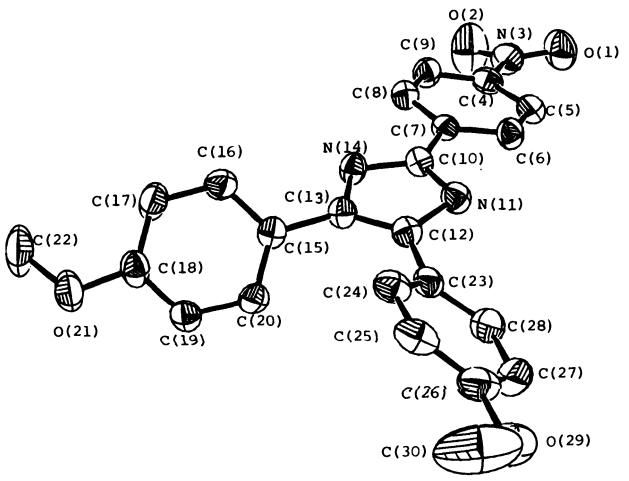

Fig. 1. A perspective view (ORTEP)[9] of the molecule with the atom numbering scheme. Non-hydrogen atoms are represented by thermal ellipsoids at 50% probability level.

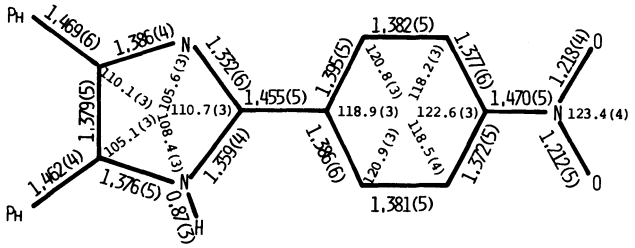

Fig. 2. Selected bond lengths and angles with estimated standard deviation in parentheses.

Fig. 2. Neither unusual bond distances nor angles in the molecule were observed. The molecular geometry of **III** is similar to that of **I**. The conformation of the molecule is illustrated in Fig. 1. The imidazole ring and the 4-nitrophenyl ring are nearly on a same plane. The dihedral angle [15.1°] between both rings is slightly larger than that [9.1°] in **I**. The other two benzene rings in **III** makes angles of 26.5° and 47.7° with the imidazole ring, while in **I** of 39.9° and 40.4°, respectively. This discrepancy is due to the presence of the solvents of crystallization in **I** and, by those, the benzene ring were forced to twist as to minimize the steric interaction between the ring and the water molecules.

Molecular packing of both compounds, on the other hand, are quite different with each other. The solvents of crystallization played an essential role in molecular packing in **I** and the molecules were packed in sheet parallel to the *ac* plane by the three-dimensional hydrogen-bonding network.[2] In **III**, as shown in Fig. 3, only a weak intermolecular hydrogen bonding was observed: N(11)(x,y,z)···H(14)–N(14)(x, $1/2-y,1/2+z$) 3.190(5)Å and N(11)···1H(14) 2.46(3)Å, H(14)–N(14) 0.87(3)Å, and ϕ [N(11)–H(14)–N(14)] 141.8°. Other intermolecular atomic contacts are usual van der Waals distances and the shortest one is O(1)(x, y,z)···O(1) ($1-x,-y,1-z$) 3.129(5)Å.

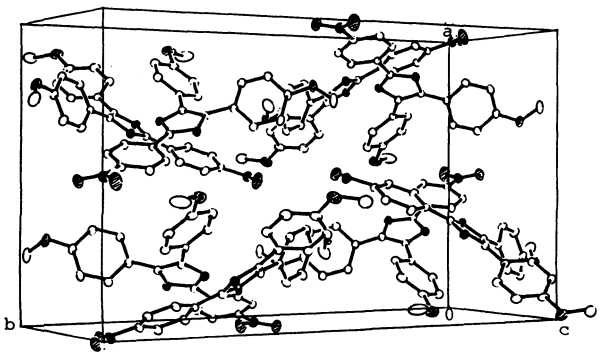

Fig. 3. The molecular packing diagram. O: Carbon, ●: nitrogen, ⊘: oxygen.

As no significant π–π interaction between molecules was estimated from the crystal packing, the orange color of **III** is due to the absorption of the chromophore of **I** itself. This is consistent with the similarity of the longest UV maximum in solution (EtOH, 405 nm) to that in solid state (in Nujol, 410 nm).

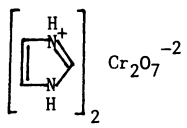
Imidazolium Dichromate. A New Reagent for the Oxidation of Alcohols to Carbonyl Compounds

Sunggak KIM* and Dong Chul LHIM
Department of Chemistry, Korea Advanced Institute of Science and Technology, Seoul 131, Korea
(Received September 21, 1985)

Synopsis. Imidazolium dichromate, a stable yellow crystalline compound, is found to be a mild selective reagent for the oxidation of allylic and benzylic alcohols to the corresponding carbonyl compounds.

Among many useful and reliable oxidation methods available in the literature,[1] the use of chromium(VI) reagents is the most convenient and efficient. Chromium trioxide–pyridine complex,[2] pyridinium chlorochromate,[3] and pyridinium dichromate,[4,5] have been widely utilized as oxidizing agents in most cases.

We have had occasion to study chromium trioxide–imidazole complex as an oxidizing agent and found that imidazolium dichromate (IDC) is very useful and reliable for the oxidation of allylic and benzylic alcohols to the corresponding carbonyl compounds in high yields under mild conditions.



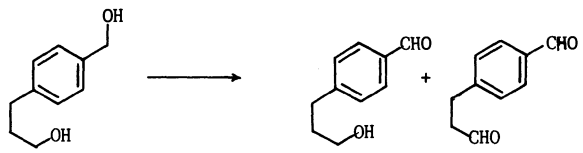
IDC

IDC is conveniently prepared by the addition of imidazole to a solution of an equimolar amount of chromium trioxide in a minimum of water and obtained in 80% yield as a nonhygroscopic and air-stable yellow crystals. IDC is readily soluble in *N,N*-dimethylformamide and dimethyl sulfoxide, while very slightly soluble in dichloromethane, chloroform, and acetone.

The choice of solvent in the oxidation of alcohols with IDC appeared to be important. The oxidation of 1-phenylethanol with 2 equiv of IDC in dichloromethane at room temperature for 16 h gave 35% of acetophenone along with the recovery 55% of the original alcohol, while the reaction in *N,N*-dimethylformamide under the same conditions was complete, yielding acetophenone in 83% yield. Thus, remaining reactions were carried out with 2 equiv of IDC in *N,N*-dimethylformamide at room temperature.

Table 1 includes several experimental results and shows the efficiency, the applicability, and the scope of this method. Under the present conditions, allylic alcohols such as cinnamyl alcohol and carveol were rapidly oxidized to α,β-unsaturated carbonyl compounds in high yields. The oxidation of geraniol to geranial resulted in isomerization of double bond to some extent. GLC analysis indicated the 6% E→Z isomerization at double bond took place. The oxidation of benzylic alcohols was somewhat slower than that of allylic alcohols and required 4—16 h for completion of the reaction.

The oxidation of saturated aliphatic alcohols occurred very slowly. For example, when the oxidation of 1-undecanol was carried out with 2 equiv of IDC in *N,N*-dimethylformamide at room temperature for 24 h, undecanal was obtained in 38% yield along with the recovery of the starting material in 53% yield. Similar results were realized with several saturated aliphatic alcohols, though relatively sterically-hindered cyclohexanol derivatives such as 2-*t*-butylcyclohexanol and 3,3,5-trimethylcyclohexanol were cleanly and completely oxidized to the corresponding carbonyl compounds in high yields under the same conditions.



Since the possibility of selective oxidation of benzylic and allylic alcohols in the presence of saturated aliphatic alcohols was indicated by the oxidation results obtained herein, the oxidation of an equimolar mixture of isophorol (3,5,5-trimethyl-2-cyclohexen-1-ol) and 1-nonanol with 2 equiv of IDC was carried out in *N,N*-dimethylformamide at room temperature for 1 h. GLC analysis indicated the presence of a 98:11 mixture of isophorone and nonanal. Even better selectivity was obtained with *p*-(3-hydroxypropyl)benzyl alcohol. Reaction of *p*-(3-hydroxypropyl)benzyl alcohol with 2 equiv of IDC in *N,N*-dimethylformamide at room temperature for 4 h gave *p*-(3-hydroxypropyl)-benzaldehyde in 68% yield along with less than 3% of the corresponding dialdehyde. The selectivity achieved with IDC is comparable to 4-(dimethylamino)pyridinium chlorochromate.[5]

In conclusion, the use of imidazolium dichromate as an oxidizing agent offers some distinct advantages such as easy preparation and stability of the reagent, the selective oxidation of allylic and benzylic alcohols, and mild conditions.

Experimental

Preparation of Imidazolium Dichromate. Imidazole (13.6 g, 0.2 mol) was slowly added to a cooled solution of chromium trioxide (20.0 g, 0.2 mol) in water (16 ml). After 0.5 h, the reaction mixture was diluted with acetone (20 ml) and cooled to −20 °C. The yellow crystals were collected, washed with acetone (40 ml), and dried in vacuo at room temperature to give imidazolium dichromate (28.3 g, 80%). Mp 130—131 °C (decomp); NMR (DMSO-d_6) δ=7.50 (s, 2H), 8.96 (s, 1H), 12.37 (s, 2H); IR (KBr) 930, 890, 765 cm^{-1}. Found: C, 20.80; H, 2.90; N, 16.19%. Calcd for $C_6H_{10}O_7N_4Cr_2$: C, 20.35; H, 2.85; N, 15.82.

Table 1. Oxidation of Alcohols to Carbonyl Compounds with IDC in DMF at Room Temperature[a)]

Alcohol	Time/h	Yield/%[b)]	Alcohol	Time/h	Yield/%[b)]
t-C_6H_5-CH=CH-CH_2OH	1	91		16	83
t-C_6H_5-CH=CH-CH(OH)CH_3	1	94			
Geraniol	2	82 [c)]		12	93
	2	88			
	2	91		24	84
	6	75		24	87
	6	75		24	58(25)
	6	71	$CH_3CH(OH)(CH_2)_8CH_3$	24	77(13)
			$CH_3(CH_2)_9CH_2OH$	24	38(53)

a) The reaction was carried out with 2 equiv of IDC. b) The yields refer to isolated products. The numbers in parentheses indicate the isolated yields of the recovered starting materials. c) 6% E→Z isomerization was detected by GLC.

General Procedure for Oxidation of Alcohols. To a solution of an alcohol (2 mmol) in *N,N*-dimethylformamide (5 ml) was added imidazolium dichromate (4 mmol) and the reaction mixture was stirred at room temperature. After completion of the reaction, water (30 ml) was added to the reaction mixture and the product was extracted three times with diethyl ether. The ether extracts were washed with water and aqueous $NaHCO_3$, dried over anhydrous $MgSO_4$, and evaporated to dryness. The crude product was purified by distillation with a Kugelrohr apparatus or crystallization. The oxidation products obtained here were known products in all cases and were readily available compounds in most cases.

Selective Oxidation of *p*-(3-Hydroxypropyl)benzyl Alcohol. To a solution of *p*-(3-hydroxypropyl)benzyl alcohol (165 mg, 1 mmol) in *N,N*-dimethylformamide (3 ml) was added imidazolium dichromate (705 mg, 2 mmol) and the mixture was stirred at room temperature for 4 h. After usual workup as described above, the crude product was subjected to silica-gel column chromatography with dichloromethane–ethyl acetate (4:1) as an eluant to yield *p*-(3-hydroxypropyl)-benzaldehyde (112 mg, 68%) and 3-(4-formylphenyl)propanal (4 mg, 3%). *p*-(3-Hydroxypropyl)benzaldehyde: NMR ($CDCl_3$) δ=1.80—2.30 (m, 2H), 2.77 (s, 1H), 2.93 (t, 2H, J=6 Hz), 3.80 (t, 2H, J=6 Hz), 7.40—7.98 (m, 4H), 10.10 (s, 1H). IR (film) 1700 cm^{-1}. 3-(4-Formylphenyl)propanal: ^1H NMR ($CDCl_3$) δ=2.45—3.21 (m, 4H), 7.31—7.85 (m, 4H), 9.81 (s, 1H), 9.95 (s, 1H).

Electrochemical Properties of Adriamycin Adsorbed on Pyrolytic Graphite Electrodes Modified by Phospholipid Monomolecular Membranes

Tomonori KONSE, Kenji KANO, Rika KANO, and Tanekazu KUBOTA*
Gifu Pharmaceutical University, 6-1 Mitahora-higashi, 5-Chome, Gifu 502
(Received February 24, 1986)

Synopsis. Electrochemical equilibrium and kinetic parameters have been determined by means of numerical simulation of d.c. voltammograms based on the theory of a two-step surface-redox reaction for the case of the redox system of adriamycin adsorbed on a basal-plane pyrolytic graphite electrode (BPGE) which is modified by a phospholipid monomolecular membrane. Comparison of these parameters with those obtained at a bare BPGE has shown that the semiquinone formation reaction is thermodynamically favorable and that the electron transfer rate constant decreases in these lipid membranes.

The toxic mechanism of adriamycin (anticancer drug), especially its cardiotoxicity, is not yet fully understood. The most acceptable mechanism is due to the bioreductive formation of the adriamycin semiquinone free radical as an intermediate catalyzed by NADPH-cytochrome P-450 reductase,[1] which is a membrane-bound enzyme. In addition, it is noted that the affinity of adriamycin for the phospholipid membrane is high.[2] These circumstances suggest that the elucidation of the redox property of adriamycin in the lipid membrane is fundamentally very important. In previous papers,[3,4] we have proposed a technique based on a numerical simulation of the quasi-reversible d.c. cyclic voltammograms in order to determine the electrochemical equilibrium and kinetic parameters pertinent to a two-step surface-redox reaction; $O_{ad}+e \rightleftarrows S_{ad}$ and $S_{ad}+e \rightleftarrows R_{ad}$. Here O_{ad}, S_{ad}, and R_{ad} stand for the oxidized, semiquinone, and reduced species in the adsorbed form, respectively.

In this study using the above analytical technique, we report the redox behavior of the quinone moiety in an adriamycin molecule adsorbed on a BPGE modified by two kinds of phospholipid monomolecular membranes, i.e., lecithin (phosphatidylethanolamine) and cardiolipin. The electrochemical equilibrium and kinetic parameters thus obtained are then compared with those determined at a bare BPGE.

Experimental

Chemicals. Adriamycin hydrochloride was kindly supplied by Kyowa Hakko Co. and used as received. Soybean lecithin (Wako Pure Chemical) and bovine heart cardiolipin (Sigma Chemical), both commercially available, were employed as received. Other chemicals were of reagent grade quality.

Preparation of BPGE Modified by a Phospholipid Monomolecular Membrane. BPGE's were prepared as described in a previous paper.[4] The phospholipid monomolecular layer was obtained according to the simplified Blodgett method.[5] The cleaned surface of triply-distilled water in a vessel was divided into two parts by a nylon thread. Upon the one part of the surface, a benzene solution of phospholipid was added dropwise and extended. On the other part, distilled rapeseed oil was extended as a piston oil.[6] The new plane surface of the BPGE was horizontally contacted to the phospholipid monomolecular layer. After the adhesion the modified electrode surface was sonicated for ca. 30 s in distilled water, and then air-dried at room temperature.

Electrochemical Measurement. The phospholipid membrane modified electrode was immersed in 3 ml of an acetate buffer (0.2 mol dm^{-3}, pH 4.5, ionic strength I=0.5) containing 3×10^{-5} mol dm^{-3} of adriamycin for 30 s under stirring. After the electrode had been washed by triply-distilled water, it was ultrasonically washed in distilled water and air-dried at room temperature. This electrode was immersed into a de-aerated electrolysis solution (0.2 mol dm^{-3} acetate buffer, pH 4.5, I=0.5) without adriamycin, and the voltammograms were then recorded. All other electrochemical measurements were described in previous papers.[3,4,7]

Results and Discussion

Lecithin-Monomolecular-Layer Modified BPGE (LT-BPGE). Adriamycin adsorbed or bound strongly on an LT-BPGE shows a reversible surface redox wave at a sweep rate v=10 mV s^{-1}. The peak potential, E_p^{rev}, and the half-peak width, $\Delta E_{p/2}^{rev}$, of these reversible waves are −0.500 V vs. SCE and 77—82 mV, respectively. These waves can be ascribed to the redox reaction of the quinone moiety in the adriamycin[7] and are analyzed on the basis of the theory regarding a two-step one-electron surface-redox reaction.[3,8] Assuming that the surface activity coefficients of O_{ad}, S_{ad}, and R_{ad} of adriamycin are equal, the semiquinone formation constant, K, is defined as:

$$K = [S_{ad}]^2/[O_{ad}][R_{ad}] = \exp[F(E'_{o1}-E'_{o2})/RT], \quad (1)$$

where $[j_{ad}]$'s (j=O, S, R) are the surface concentrations of j_{ad}, and E'_{o1} and E'_{o2} are the standard surface redox potentials of the couples O_{ad}/S_{ad} and S_{ad}/R_{ad}, respectively. The K value was estimated to be 2.2—2.8 from $\Delta E_{p/2}^{rev}$.[7,8]

At large v such as 1 V s^{-1} a typical quasi-reversible voltammogram is recorded as shown in Fig. 1A (solid line). Here we observed that the cathodic and anodic peak currents and also the cathodic and anodic half-peak widths are respectively almost the same within an experimental error. The average of the anodic and cathodic peak potentials is equal to E_p^{rev}. In other words, this quasi-reversible wave is symmetrical about the point of $E=E_p^{rev}$ and i=0. These results confirm the following two assumptions[3,4]: a) the apparent rate constants, k_{sap}, of the first and the second single electron transfer steps at E'_{o1} and E'_{o2} are equal and b) the transfer coefficient for the electron transfer of each step is 0.5. Under these conditions, the current (i)-potential (E)-surface concentration (Γ) characteristics can be expressed by the Butler-Volmer equation:[3,8]

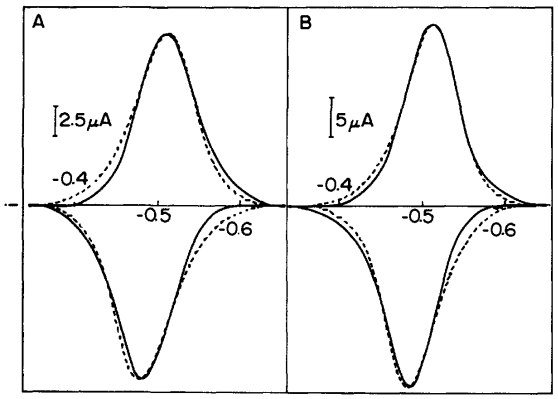

Fig. 1. Background-corrected cyclic d.c. voltammograms of adriamycin adsorbed on A) LT-BPGE and B) CL-BPGE. Voltage scanning was done with v=1 V s^{-1}. The solid lines and broken lines represent the experimental and the regression curves, respectively. See text for the parameters used for calculation.

$$i = FAk_{sap}\{\Gamma_S[(\rho/\sqrt{K})^{0.5} - (\rho\sqrt{K})^{-0.5}] - \Gamma_O(\rho/\sqrt{K})^{-0.5} + \Gamma_R(\rho\sqrt{K})^{0.5}\} \quad (2)$$

where Γ_j's (j=O, S, R) are the surface concentrations of j species, and A is the surface area. The standard surface redox potential of the O_{ad}/R_{ad} couple is given by E'_o [$=(E'_{o1}+E'_{o2})/2=E_p^{rev}$], and $\rho=\exp[F(E-E'_o)/RT]$. Other symbols have their usual meanings. Using Eq. 2 and the other fundamental equations with regard to the cyclic voltammetry on the surface-redox reaction, we can draw a quasi-reversible current-potential curve by the technique of numerical calculations.[3]

We have now analyzed the voltammogram shown in Fig. 1A by applying the technique of numerical simulation using two parameters,[3,4] k_{sap} and K, at E'_o=−0.500 V and the electricity Q=1.29 μC, here $Q=2FA\Gamma_t$, Γ_t being the sum of Γ_O, Γ_S, and Γ_R. The refined parameters are k_{sap}=65.7±5.0 s^{-1} and K=2.61±0.29. The resultant regression curve is depicted in Fig. 1A as a broken line. The K value obtained is in agreement with those estimated from the reversible voltammogram (K=2.2—2.8). The analysis of the voltammograms at various Q's shows that, within the experimental error, the values of K and k_{sap} are independent of Q in the range of 1.3 to 2.6 μC[9] that is in the possible limit of the present experiment. The average K value evaluated in this Q range is 2.32, and the k_{sap} is 62.4 s^{-1} in the same Q range. Alternatively, we calculated the theoretical current-potential curves[3] at v=100 and 200 mV s^{-1} by using the above average values of K and k_{sap}. These theoretical curves well reproduce the experimental one. These results indicate that the electrochemical behavior of adriamycin adsorbed on an LT-BPGE can be well interpreted on the base of the theory of a two-step one-electron surface-redox reaction, and that these refined parameters would be considered to be physically significant.

Cardiolipin-Monomolecular-Layer Modified BPGE (CL-BPGE). The electrochemical redox behavior of adriamycin adsorbed on a CL-BPGE was fundamentally the same as that observed on an LT-BPGE. In Fig. 1B the solid line shows an observed quasi-reversible wave at v=1 V s^{-1} and Q=2.00 μC (solid line), and the regression curve is given by the broken line. The refined parameters are k_{sap}=73.7±4.8 s^{-1} and K=1.75±0.17. The K value is equivalent to 73 mV of $\Delta E_{p/2}^{rev}$,[7,8] which agrees well with the experimental value (71—76 mV) of the reversible wave recorded at v=10 mV s^{-1}. It was also observed that the K and k_{sap} values at this electrode are independent of Q within an experimental error in the range of the experimentally obtainable Q (1.5—2.0 μC), and the average values are 1.69 and 77.9 s^{-1} for K and k_{sap}, respectively, in the above Q range. The reliability of the parameters was supported by the same method as in the case of LT-BPGE.

Table 1. Electrochemical Data of Adriamycin on a Bare BPGE and Two Kinds of Phospholipid Membrane Modified Electrodes

	E'_o	k_{sap}	K	$\Delta G°$
	V vs. SCE	s^{-1}		kJ mol^{-1}
Bare-BPGE	−0.497	115[a]	0.21	+3.85
LT-BPGE	−0.500	62	2.32	−2.10
CL-BPGE	−0.500	78	1.69	−1.30

a) The value at θ_A (the surface coverage of adriamycin)→1 is used.

Comparison with the Behavior at Bare BPGE. Table 1 summarizes the electrochemical data of the adriamycin adsorbed on the two types of phospholipid membrane modified BPGE as well as those on a bare BPGE. The E'_o values are almost the same in all three cases. However, it is to be noted that the K values at the phospholipid membrane modified electrodes are almost ten times larger than that at the bare one, and the free energy changes, $\Delta G°(=-RT\ln K)$, of the semiquinone radical formation equilibrium ($O_{ad}+R_{ad} \rightleftarrows 2S_{ad}$) are lower by about 5—6 kJ mol^{-1} than that at the bare one. In other words, the semiquinone radical is stabilized in the hydrophobic environment in the phospholipid membranes. On the other hand, the k_{sap} values at the phospholipid membrane modified electrodes are about one-half the value of that obtained at the bare electrode. The above decrease in k_{sap} may be attributed in part to the attructive interaction between adriamycin and the phospholipid molecule,[3,8,10] and in part to the slow rate of the proton transfer in phospholipid membranes immediately following the electron transfer.

The aforementioned properties of adriamycin in phospholipid membranes are important from the viewpoint of the cardiotoxicity of this drug. It is evident that the toxicity is associated with the inhibition of mitochondrial electron transport in the lipid bilayer and with the generation of oxyradicals, such as superoxide anion radical, by an auto-oxidation of the semiquinone radical intermediate.[11] It has been suggested that the adriamycin-mediated oxyradicals are responsible for the adriamycin-caused DNA and enzyme damage and also for the adriamycin-enhanced

peroxidation of unsaturated phospholipids.[12] The high stability of the semiquinone radical in lipid membranes and the high affinity of adriamycin for the membranes may bring about the increase of the semiquinone-related cardiotoxicity.

The authors wish to express their many thanks to Kyowa Hakko Kogyo Co. for the kind gift of adriamycin hydrochloride. This work was supported in part by a Grant-in-Aid for Scientific Research (No. 59390012) from the Ministry of Education, Science and Culture.

Photocatalytic Decomposition of Formic Acid on Platinized n-Type Silicon Powder in Aqueous Solution

Hiroshi YONEYAMA,* Nobuyuki MATSUMOTO, and Hideo TAMURA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka 2-1, Suita, Osaka 565
(Received March 15, 1986)

Synopsis. Photocatalytic decomposition of aqueous formic acid was successfully achieved by using platinized n-type silicon powder as a photocatalyst under the conditions that the photocatalyst was spread on the bottom of a reaction cell.

Light-induced heterogeneous reactions at semiconductor photocatalysts in solution have recently gained popularity especially from the viewpoint of solar energy utilization in chemical synthesis. The semiconductors used as a medium for solar energy conversion should be matched well to the solar spectrum. In this respect, CdS,[1-6] CdS–CdSe solid solutions,[7] and CdS–ZnS composites,[8,9] have been employed as the photocatalysts.

Silicon is one of the best materials suitable for solar energy conversion. Our interests lie in the use of this material as photocatalysts in aqueous solution systems, because a variety of synthetic reactions involving hydrogen evolution and hydrogenation of organic substances are conceivable in the presence of water. It is well-known, however, that silicon is easily passivated in aqueous solutions, requiring stabilization prior to use as photocatalysts. In a previous paper,[10] it was shown that platinum-coated n-type silicon single crystal wafers served as photocatalysts for decomposition of formic acid in aqueous solutions. The covered platinum films in that case were 1—2 nm in thickness. The photocatalytic activity appeared under conditions that platinum-coated smooth etched surfaces were illuminated and platinum-coated damaged back surfaces were in the dark. It is expected that silicon powder has both defect-free surface and defective surface in individual particle. Platinization of n-type silicon powder particles will then attach activities and stabilities to the powder as photocatalysts. The present paper will demonstrate the validity of such an idea with the use of decomposition of formic acid as a photocatalytic reaction. It will be shown that the conversion efficiency obtained was low, and main causes for this will be briefly discussed referring to preliminary results on other synthetic reactions such as decomposition of alcohols.

Experimental

The n-type silicon powder was prepared with the same manner as described previously.[11] After etched in 48% HF for 15 min, the powder was suspended in a 0.2 mol dm^{-3} H_2PtCl_6 methanol solution, the volume of which was chosen to give a desired amount of platinum coating. The methanol was then evaporated under reduced pressure, and the resulting H_2PtCl_6-loaded silicon powder was heated in a hydrogen stream at 150 °C for 1 h, followed by heating at 400 °C for 15 min under 1.3×10^{-3} Pa. Hydrogen and carbon dioxide as the reaction products were determined by means of gas chromatography. Molecular sieve 5A was used as a column for the former, while Porapak Q for the latter.

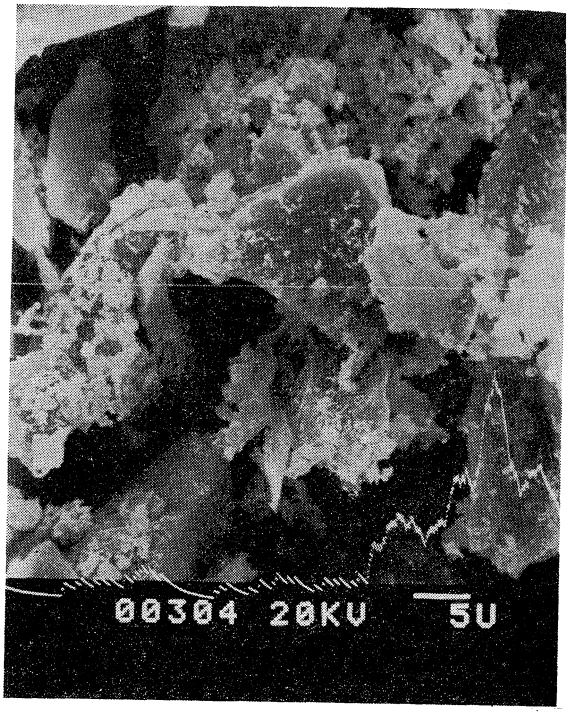

Fig. 1. SEM photograph of Pt-coated Si powder (10 wt% Pt) used as the photocatalyst and a distribution profile of the coated Pt given by a rugged white line in a lower part of the figure for microanalysis of the line direction shown in the center of the figure.

Photocatalytic decomposition of formic acid was studied using an Erlenmyer flask as a reaction cell. The top of the cell was equipped with a gas inlet and an outlet in a concentric position, and a port for sampling gases was also contained in the side wall of the cell. The platinized silicon powder (10 wt% platinum) of 110 mg was spread on the bottom of the cell and 20 ml of a 2.7 mol dm^{-3} formic acid solution was poured into the cell. Before illumination of the photocatalysts from the bottom of the cell, nitrogen was flushed for 30 min to purge the solution of disolved oxygen, and then the cell was closed with stopcocks. A 500 W high pressure mercury arc lamp was used as a light source and light from the lamp was passed through a Toshiba UV-39 filter to eliminate light of wavelengths shorter than 390 nm. The light intensity at the bottom of the cell was 0.2 W cm^{-2}.

Results and Discussion

Observations by a scanning electron microscope (SEM) of platinum-loaded silicon (10 wt%) powder particles shown in Fig. 1 revealed that platinum covered the powder surface rather inhomogeneously. Some parts of the surface were covered with relatively thick platinum, and the other parts were covered with thin platinum, as shown by a distribution profile with a rugged white line in a lower part of the figure.

E_{decomp}: theoretical decomposition voltage. CB: conduction bands, VB: valence bands.

Hydrogen evolution occurred with the time course shown in Fig. 2. It is known that formic acid is decomposed by a thermal process in the presence of platinum. The contribution of this possibility was then examined by employing photoinactive catalysts. The photoinactive catalysts were prepared by heating the n-type silicon powder in air at 800 °C for 3 h to give an insulating oxide layer on the powder surface and then by depositing platinum on this surface with the same procedures as used in the preparation of platinized n-type silicon photocatalysts. Results obtained at this photocatalyst are also included in Fig. 2. It is confirmed from this figure that not the covered platinum alone but photoexcitation of the silicon powder plays a key role in evolving hydrogen under our experimental conditions. The photogenerated electrons and positive holes move to the covered platinum at defective surfaces and at smooth surfaces, respectively, with the energetics discussed previously for silicon single crystal photocatalysts,[10] leading to decomposition of formic acid. In the case of platinized oxide-covered n-type silicon, the photogenerated charge carriers cannot reach the covered platinum owing to the presence of the insulating oxide between the semiconductor substrate and the covered platinum.

The achievement of photocatalytic decomposition of formic acid was confirmed by determining both hydrogen and carbon dioxide produced; evolution of 7.8 μmol hydrogen was accompanied with 6.0 μmol carbon dioxide. The quantum efficiency for the hydrogen evolution was 0.02%, as determined by a 25 mW He-Ne laser as a light source.

It is desired from the viewpoint of perfect utilization of irradiated photons that experiments are performed using well-suspended photocatalysts. Photocatalytic experiments were then conducted by magnetically stirring the photocatalyst in the formic acid solution. The rate of hydrogen evolution obtained in that case was more than ten times of that achieved when the photocatalyst was spread on the bottom of the reaction cell. It was found, however, that evolution of carbon dioxide did not take place in the suspension system. Observations by SEM of morphology of the photocatalyst before and after the photocatalytic experiments for 100 h revealed that silicon particles were finely ground by the stirring during the course of the experiments. These results on the suspension system lead to the conclusion that hydrogen evolution in that case mainly came from anodic oxidation of bare surfaces of the particles that were created when the powder particles were ground. Thus, the covered platinum on the smooth surfaces of silicon did not significantly contribute to the anodic sites of the photocatalysts in that case.

The activities of the photocatalysts observed were quite low, as described above. It was found that activities were null for hydrogen evolution from aqueous ethanol, 2-propanol, and oxalic acid, adjusted pH to that of the formic acid solution, when the photocatalysts were palced on the bottom of the reaction cell. Current-potential measurements showed that the onset potentials of anodic photocurrents due to oxidation of these organic substances at platinum-covered smooth electrodes under illumination were more positive than those of cathodic currents due to hydrogen evolution at platinum-covered damaged electrodes in the dark. The observed correlation of the onset potentials does not allow the photocatalytic hydrogen evolution,[12] as observed.

The observed inactivity seems to reflect the situation that the bandgap (E_g) of the semiconductor photocatalyst (1.1 eV) is short of the sum of the theoretical decomposition voltage of each photocatalytic reaction and overvoltages of an anodic and a cathodic process of the photocatalytic reaction. As shown in Fig. 3, a light-induced hydrogen evolution occurs under conditions that positive holes have potentials more positive than the redox potential of an organic substance ($E(Ox/R)$) plus the overvoltage for the oxidation reaction and photogenerated electrons have potentials more negative than the hydrogen electrode potential plus the overvoltage for hydrogen evolution. The larger the bandgap of semiconductors used as photocatalysts are, the more easily the energy requirements are fulfilled. This view is supported by the results previously reported by

other investigators. Fujii et al.[13] found that CdS (E_g=2.4 eV), SiC (E_g=3.0 eV), TiO_2 (E_g=3.0 eV), Fe_2O_3 (E_g=2.2 eV), and In_2O_3 (E_g=2.7 eV) showed remarkable activities for hydrogen evolution from aqueous ethanol, but GaAs (E_g=1.4 eV), CdSe (E_g=1.68 eV), MoS_2 (E_g=1.2 eV), WO_3 (E_g=2.8 eV), and CdO (E_g=2.1 eV) did not. The latter two materials should be treated as exceptions, because not hydrogen evolution but hydrogen insertion into the semiconductor occurs at WO_3[14] and reduction of oxide itself rather than hydrogen evolution seems likely to occur at CdO. Furthermore, Kambe et al.[7] reported that activities of platinized CdS-CdSe solid solutions for hydrogen evolution from aqueous methanol and ethanol decreased with decreasing the bandgaps from 2.4 eV (CdS) to 1.68 eV (CdSe).

The theoretical decomposition voltages of formic acid, methanol, ethanol, 2-propanol, and oxalic acid to give hydrogen evolution are −0.2, 0.19, 0.19, 0.15, and −0.49 V, respectively. The minus sign means that the decomposition reaction is thermodynamically feasible. Anyway overvolatges, especailly that for oxidation of these organic substances seem to be large, resulting in inactivities of platinized silicon except for the reaction of fromic acid decomposition. Considering this overvoltage problem, semiconductors having good matching to solar spectrum does not necessarily suitable for photochemical synthesis using solar energy.

An Electron Spin Resonance Study of 1,2,3,4-Tetrahydro-3-methyl-2,4-dioxo-1-quinazoliyloxyl Radical

Yoshimi SUEISHI* and Norio NISHIMURA
Department of Chemistry, School of Science, Okayama University, Okayama 700
(Received March 31, 1986)

Synopsis. The ESR spectra of the title radical have been obtained in various solvents, and the assignments have been made. It is found that the solvent effects on the hyperfine coupling constants(hfc) for hydrogens on the benzene ring were small, while the nitrogen hfc ($a_{N(1)}$) remarkably increased in polar solvents. The solvent dependence of the nitrogen hfc has been explained in terms of a substantial contribution of dipolar resonance structures through the N-O bond.

Oxidation with lead dioxide converts 1-hydroxy-3-methyl-2,4(1*H*,3*H*)-quinazolinedione (**1**) into its *N*-oxyl radical (**2**) which has the half-life of about 1.5 h at room temperature in solution. The ESR spectrum of this radical consists of nine lines (Fig. 1). Baldock et al.[1] have ascribed the stability of the radical to the canonical resonance structures (**2a** and **2b**) in Scheme 1.

They assigned the spectrum to the two nitrogen atoms. However, this is questionable since the simulated spectrum on the basis of their hfc-values does not reproduce the observed one at all.

It has been recognized that the stability of free radicals is controlled by both mesomeric and steric

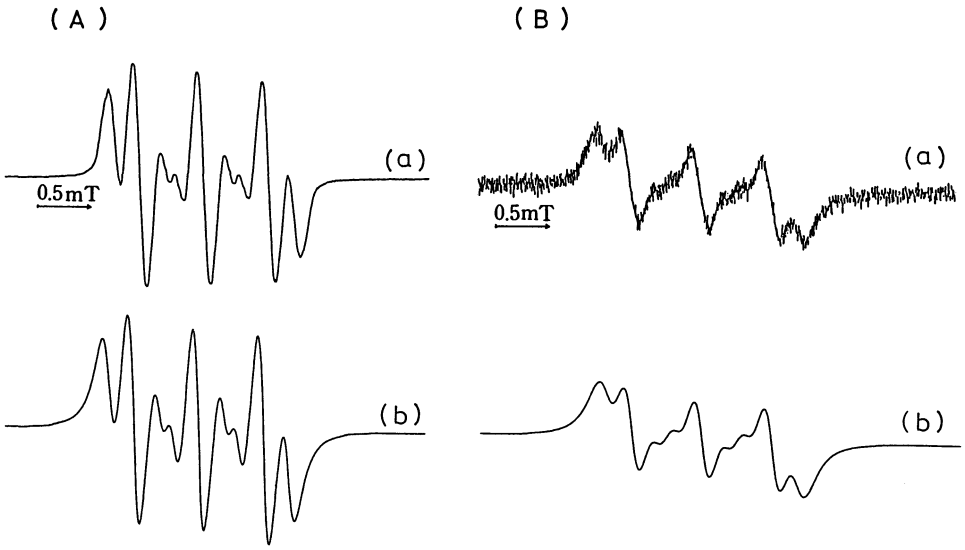

Fig. 1. ESR spectra of *N*-oxyl radical **2** in CCl_4 (A) and acetonitrile (B). (a): experimental spectra, (b): spectra simulations using parameters given in Table 1.

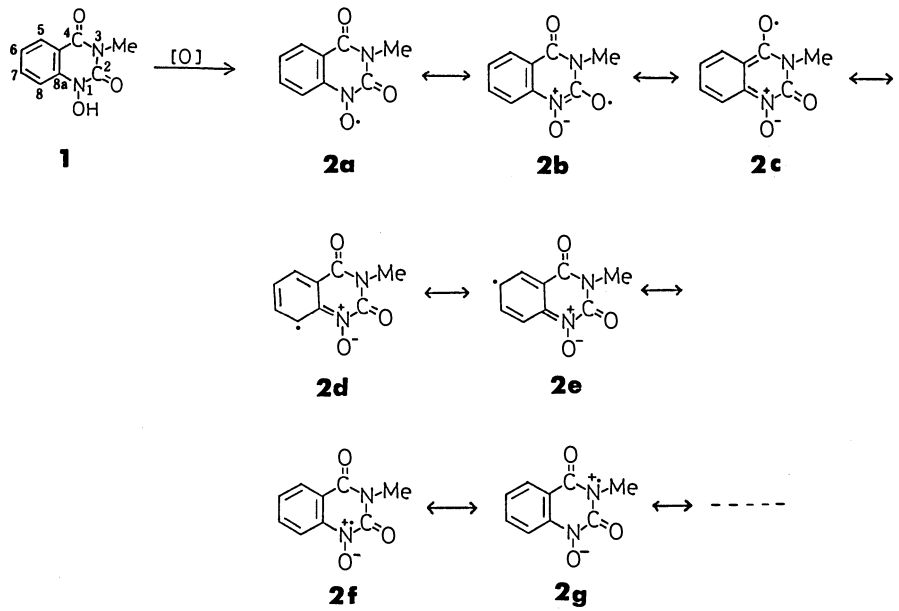

Scheme 1.

factors.[2] Knauer and Napier[3] have shown that the linear correlation between the E_T-value and the nitrogen hfc of aliphatic nitroxide radicals in various solvents exists, and the hfc variation is a useful empirical solvent polarity parameter. In cases where molecules in question have polarized resonance structures, it seems necessary to take into account special interactions between solute and solvent molecules in order to explain the solvent dependency of hfc.

In this paper, we would like to report a modified assignment of **2** and the solvent dependency of the hfc.

Experimental

Materials. The reagent grade solvents were purified and distilled in the usual manner just before use. The solvents were purged with nitrogen. The substance **1** was prepared according to the method by Baldock et al.[1] and recrystallized from ethanol; mp 246—247 °C (lit,[1] 254—257 °C). The product was checked by IR and NMR spectra.

Procedure. Radical **2** was prepared by oxidation of **1** (ca. 10^{-4} mol dm^{-3}) with PbO_2 in various solvents. ESR spectra were obtained with a JEOL JES-FE 3XG equipped with a 100 kHz field modulator. The magnetic field sweep was calibrated using Fremy's salt.[4] Computer-simulated spectra were obtained according to an attached program by using a DEC RT-11 computer. The accuracy of the coupling constants obtained from these simulations was within 4 μT.

Results and Discussion

The ESR spectra of **2** in CCl_4 and acetonitrile are shown in Fig. 1. Since the dielectric loss for acetonitrile is large and **1** is sparingly soluble in acetonitrile, the spectrum was very weak and not well-resolved. The spectra in other solvents are rather similar to that in CCl_4. As may be seen in Fig. 1, the spectrum consists of nine lines. Baldock et al.[1] assumed the planar structure for this molecular skeleton, and showed two canonical forms **2a** and **2b**. They ascribed the nine-line spectrum to the two nitrogen atoms (a=612, 210 μT), hydrogen atoms causing only broadening. If these hyperfine coupling constants are used, a nine-line spectrum with the same intensity and approximately the same peak-to-peak distance could be expected. The spectra in Fig. 1 are, however, quite different.

We have inspected these spectra and simulations have been made so as to reproduce the observed spectra best. Representative computer simulated spectra are shown in Fig. 1. The hfc values of N(1), H(6,8), and H(5,7) are given in Table 1. From these data, some interesting points may be noticed. (1) The hfc $a_{N(1)}$ increases as the solvent polarity increases, and the value is considerably small compared with those of similar nitroxide radicals.[3,5] (2) The dependencies of the hfc of the hydrogen atoms in the benzene ring on the solvent polarity are small compared with that of the nitrogen. However, there is a trend that $a_{H(6,8)}$ increases, while $a_{H(5,7)}$ decreases as the solvent polarity increases. (3) The hyperfine structure due to N(3) was not observed. Here, we wish to comment the above findings.

If radical **2** is planar (as could be presumed by the CPK model), a considerable flow of lone-pair electrons to the benzene rings would be expected and we could write down various types of polar structures besides **2a** and **2b**, as shown in Scheme 1. Botrel and coworkers[6] have calculated the electron densities of 4-[2-(1-methyl-4-pyridino)ethyl]phenolate by means of the CNDO/SCI method in which solvation is taken into account. They have shown that polar structures are favored in polar solvents. By applying McRae's formula, we have also shown that solvent-induced solute polarization plays an important role in the cis-trans thermal isomerization of push-pull azobenzenes, recently.[7] In Fig. 2, the nitrogen and hydrogen hfc's are plotted against the E_T-value which could be regarded as a measure of solvent polarity parameter. The $a_{N(1)}$ clearly shows a trend to increase with the increase in the E_T-value. If the contributions of the canonical polar structures such as **2b** and **2c**

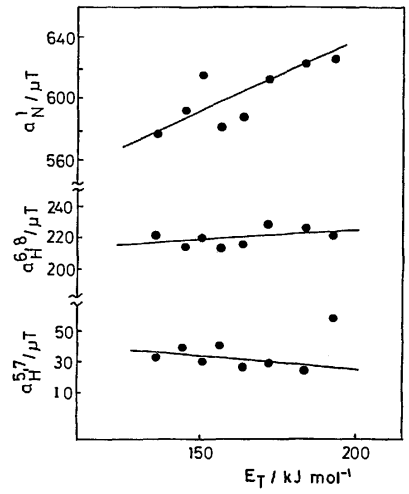

Fig. 2. Relationship between the nitrogen and hydrogen coupling constants and solvent polarity parameters, E_T.

Acetonitrile	193	627	223	58

a) kJ mol^{-1}.

are dominant as proposed,[1] the reverse should be true. Therefore, the proposed canonical resonance structures alone cannot give a resonable explanation for the solvent dependency. It would be natural to consider that, among the canonical forms in Scheme 1, **2f** plays the most important role. Then, the solvent dependency on $a_{N(1)}$ could be understood well.

The hfc $a_{N(1)}$ for **2** (≈600 μT) is considerably small compared with those of similar nitroxide radicals. For example, a_N is ca. 1500 μT, 1000 μT, and 900 μT, for di-*t*-butyl nitroxide radical[3] diphenyl nitroxide radical,[5] and phenyl nitroxide radical,[9] respectively. The remarkably small value of $a_{N(1)}$ can be ascribed to the contibution of **2b** and possibly **2c** for which the unpaired electron moves to the adjacent carbonyl oxygen.[8] It should be noted that the hfc due to the N(3) atom has not been observed. This indicates that the contribution of **2g** is negligibly small. There is a possibility that the hetero-ring is not coplanar, or that sp^2 hybridizations are imperfect(decrease of s-character). This might be responsible for the small value of $a_{N(1)}$, and $a_{N(3)}=0$. According to our view, however, the steric hindrance is not so severe for **2** that the mesomeric stabilization through coplanar structure will overwhelm the steric factor, and **2a—f** will play an important role, thus accounting for our results. Negligible contribution of **2g** could be ascribed to the strong electron-attracting carbonyl groups adjacent to the N(3) atom rather than to the imperfect sp^2-hybridization.

On the assumption that the hybridization of the nitrogen atom in the phenyl nitroxide radical is sp^2, Kikuchi and Someno[9] estimated the spin densities on the benzene ring (0.128 for the 2,4-positions and 0.043 for the 3 position) and compared these with the calculated values on the basis of McLachlan's method. By referring to their results, we have assumed that $a_{H(6)} \approx a_{H(8)} \gg a_{H(5)} \approx a_{H(7)}$. This assumption may be valid because of the contribution of **2d** and **2e**. Applying the relationship $a_H = Q^H_{CH} \cdot \rho_c$,[10] where Q^H_{CH} (=2250 μT) is a constant, and using the data in Table 1, we have estimated the spin densities $\rho_{C(6,8)}=0.096$ and $\rho_{C(5,7)}=0.018$. As stated above, there are trends that $a_{H(6,8)}$ increases, while $a_{H(5,7)}$ decreases with an increase in the solvent polarity. Mukai et al.[5] reported similar results for the 2,6-di-*t*-butyl-4-methylphenoxyl radical and explained trends in terms of a variation in the π-electron spin density due to an electrostatic interaction between the radical and the solvent molecules. The $a_{H(5,7)}$-value in acetonitrile clearly deviates upward even if the large experimental uncertainty, as pointed out above, is taken into account, and this exceptionally large $a_{H(5,7)}$ causes to change the pattern of the ESR spectrum compared with that in other solvents (Fig. 1). The reason is not clear; however, we can say that a specific solvation of acetonitrile to the  group might be operating and might modify the spin density on H(5) and H(7), as has been discussed by Leach and Tabner.[11]

The authors wish to thank Professor Keiji Kuwata of Osaka University for his helpful discussion.

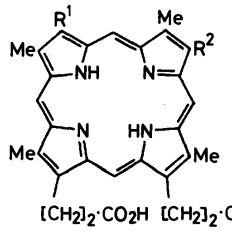
(Received April 9, 1986)

Synopsis. Hematoporphyrin and two derivatives in aqueous solution undergo the molecular association to form each dimer. The association constant of 8(3)-(1-hydroxyethyl)-3(8)-vinyldeuteroporphyrin isomers is much larger than that of hematoporphyrin. No significant difference has been observed in the photophysical properties of their excited singlet and triplet states.

With regard to tumor phototherapy, much attention has been paid to the photochemistry and photophysics of hematoporphyrin (HP) and its derivatives, as reviewed by Kessel.[1] The use of a mixture of chemically treated HP, called "hematoporphyrin derivative (HPD)," has currently been recommended for clinical purposes. It is suggested that the predominant pathway of tumor phototherapy using HPD is attributable to the singlet oxygen generated by energy transfer from excited triplet HPD to ground-state molecular oxygen.[2,3] The superiority of HPD over HP may be understood from the following points of view: The first is high affinity of HPD with tumor cell, and the second is the efficiency for generating cytotoxic molecular singlet oxygen. To verify these questions, we have examined the photophysical properties of three porphyrins which are the main components of HPD,[4] by absorption and emission spectroscopic techniques.

Experimental

Hematoporphyrin (HP, Sigma) was purified by preparative thin layer chromatography. *O,O'*-Diacetylhematoporphyrin (HPdiAc) and the mixture of 8(3)-(1-hydroxyethyl)-3(8)-vinyldeuteroporphyrin isomers (HVD), supplied by Hamari Yakuhin Co. Ltd., were used as received.



HP : $R^1 = R^2 = CH(OH)Me$
HVD : $R^1 = CH{=}CH_2$; $R^2 = CH(OH)Me$
or
$R^1 = CH(OH)Me$; $R^2 = CH{=}CH_2$
HPdiAc: $R^1 = R^2 = CH(OAc)Me$

Spectrograde methanol was used as received. Distilled water used was further deionized. Porphyrins were dissolved in a phosphate buffer (pH 7.2) solution with vigorous stirring. Sample solutions were deaerated by freeze-pump-thaw cycles, when necessary.

Absorption spectra were measured with Hitachi 224 spectrophotometer using quartz cells of 0.1, 0.5, 1.0, 2.0, and 2.5 cm path length. The fluorescence lifetime was determined by a time-correlated single-photon counting system (Ortec) with a D_2 nanosecond light pulser (PRA model 510) and a cut-off filter (Toshiba R-60, ≥600 nm). The transient absorption lifetime was determined by an excimer laser (Lambda Physik EMG-50E, 308 nm) and a monitoring xenon arc lamp system. All the measurements were carried out at room temperature.

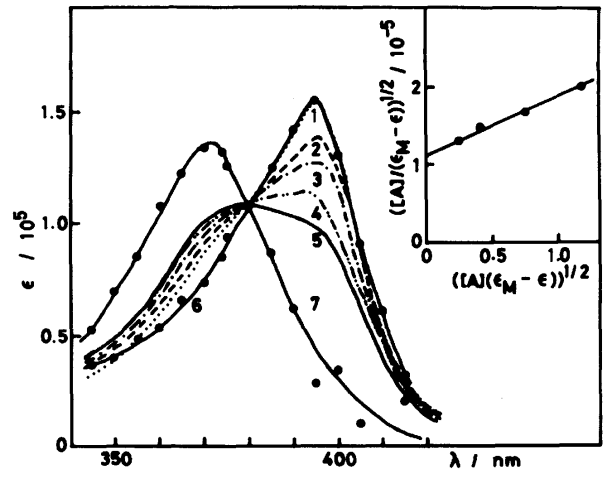


Fig. 1. Soret-band absorption spectra of HP in aqueous buffer solution, pH 7.2; 1, 1.6×10^{-6} M; 2, 3.1×10^{-6} M; 3, 6.3×10^{-6} M; 4, 1.3×10^{-5} M; 5, 2.5×10^{-5} M. 6 and 7 are the calculated absorption spectra of the monomer and the dimer, respectively. Insert: Plot of Eq. 1 for ε's at 394 nm, where ε_M is assumed to be 155000.

Results and Discussion

Ground-State Monomer-Dimer Equilibrium. Figure 1 shows the concentration dependence of absorption spectra (the Soret band) for HP. At low HP concentration the band appears at 394 nm, and a new band appears around 375 nm with increasing concentration, suggesting that the molecular association of HP takes place. To estimate the aggregation number of HP, the absorption intensity at 394 nm was analysed by the Zanker's method, which was successfully applied to the analysis of aggregation of organic dyes.[5,6] The analysis gave the mean aggregation number of two. This fact strongly indicates that the spectral changes in Fig. 1 are attributable to the monomer-dimer equilibrium. Thus, we further analysed the data according to the procedure proposed by Tipping et al.[7] The following equation should hold for the dimerization,

$$\left\{\frac{[A]}{\varepsilon_M-\varepsilon}\right\}^{1/2}=\frac{2}{2\varepsilon_M-\varepsilon_D}\{[A](\varepsilon_M-\varepsilon)\}^{1/2}+\left\{\frac{1}{K_D(2\varepsilon_M-\varepsilon_D)}\right\}^{1/2}. \quad (1)$$

Table 1. Fluorescence Lifetime of HP, HPdiAc, and HVD[a]

	Buffer solution		Methanol solution		
	Deaerated	Aerated	Deaerated	Aerated	k_q[b]
	ns	ns	ns	ns	$10^{10}\,M^{-1}\,s^{-1}$
HP	16.0	15.6	18.1	12.4	1.2
HPdiAc	16.1	15.9	18.4	12.3	1.3
HVD	16.4	15.9	18.5	12.3	1.3

a) Concentrations are 10^{-5} M. b) Quenching rate constants by oxygen, estimated by assuming that oxygen concentration in aerated methanol is 2.12×10^{-3} M.[15]

Here, $[A]$ represents the total concentration of hematoporphyrin in terms of monomer, ε is the observed molar extinction coefficient, ε_M and ε_D are the molar extinction coefficients of the monomer and dimer, respectively, and K_D is the monomer-dimer association constant. The plot of $\{[A]/(\varepsilon_M-\varepsilon)\}^{1/2}$ against $\{[A](\varepsilon_M-\varepsilon)\}^{1/2}$ gives a straight line. The intercept and slope can be used to calculate K_D and ε_D. Insert of Fig. 1 shows the plot of Eq. 1 for HP. The linear relationship in the figure strongly supports the formation of HP dimer in this concentration region, giving the association constant K_D of 0.3×10^5 M^{-1} (M=mol dm^{-3}).

Similar spectral changes were observed for other derivatives and analysed according to the preceding procedure. The K_D's obtained were $0.7\times10^5\,M^{-1}$ (HPdiAc) and 1.8×10^5 M^{-1} (HVD). The association constant of HVD is about six times larger than that of HP.

The aggregation of porphyrins in an aqueous solution was reported by Brown et al.[8] They suggested that dimerization occurs at a very low concentration ($\leqslant4\times10^{-6}$ M) and that the spectral changes in higher concentration region is attributable to "micellarization," i.e., the generation of large aggregates of unknown size. On the other hand, Tipping et al.[7] reported that the absorption-spectral changes of HP caused by the monomer-dimer equilibrium were observed in the concentration range of $0-200\times10^{-6}$ M. The present result agrees with that of the latter authors.

Excited Singlet States. The position of fluorescence spectra of porphyrins in methanol appearing in 600—700 nm region is insensitive to the side-group substitution of porphyrin ring. The fluorescence decays exponentially at a concentration of 10^{-5} M in both methanol and aqueous solution as shown in Table 1. Lifetime values of HP in aerated methanol and aqueous solution agree with those of HP monomer reported by Andreoni et al.[9] The absence of any shorter component due to the dimer in aqueous solution is attributable to wide pulse width of the excitation light source (2—3 ns) in the present study. The quenching rate constants (k_q) of the excited singlet porphyrins by oxygen estimated in methanol are given in Table 1. The rate seems to be diffusion-controlled. No significant difference has been shown in the photophysical properties of the excited singlet porphyrins.

Excited Triplet States. Photophysical properties of the excited triplet porphyrins were studied by laser flash photolysis. In the laser flash photolysis of HP in methanol, a transient absorption band appears in 430—600 nm region, which is assigned to the triplet-triplet absorption of HP with reference to the reported data.[10-12] Since the decay curves of the intense triplet-triplet absorption at 450 nm are strongly influenced by the laser excitation intensity, the lifetime of porphyrins was determined at a low laser intensity where the decay is exponential. The results are shown in Table 2. The lifetime values for three porphyrins are similar to each other. The triplet lifetime of HP was reported to be about 20 μs in acetone and 90% methanol/water mixture.[11] This short lifetime seems to be due to the effect of the triplet-triplet annihilation caused by intense laser excitation used.

Table 2. Triplet Lifetime of HP, HPdiAc, and HVD in Methanol[a]

	Deaerated	Aerated	k_q'[b]
	μs	μs	$10^9\,M^{-1}\,s^{-1}$
HP	77.8	0.30	1.6
HPdiAc	61.8	0.27	1.7
HVD	76.3	0.21	2.2

a) Concentrations are 10^{-5} M. b) Quenching rate constants by oxygen, estimated by assuming that oxygen concentration in aerated methanol is 2.12×10^{-3} M.[15]

In an aerated solution, the lifetime becomes shorter, where the quenching rate constants of the excited triplet porphyrins by oxygen were in the order of 10^9 $M^{-1}\,s^{-1}$. These values are about one order of magnitude smaller than those for the quenching in excited singlet states. Although molecular oxygen quenches both the excited singlet and triplet states efficiently, molecular singlet oxygen is exclusively generated via the excited triplet energy-transfer process as was discussed by Turro.[13] The relative yield of singlet oxygen for these porphyrins is similar to each other.

From the results mentioned above, the monomer-dimer association constant of HVD in the ground-state is larger than those of HP and HPdiAc, while there are no significant difference in the photophysical properties of their excited states. The molecular association (dimer formation) of porphyrins in aqueous solution is relevant to hydrophobicity of the compounds. On the other hand, affinity of porphyrins to tumor cell relates to their hydrophobicity, since photo-induced damage has been reported to occur at the cell membrane which is highly hydrophobic.[14] It is likely, therefore, that the dimer association constant of porphyrins reflects their affinity to tumor cell.

The present results showing similar yields of singlet oxygen for three porphyrins indicate that the affinity of porphyrins to tumor cell is one of determinants for the efficiency of phototherapy.

A Convenient One-Pot Synthesis of Acenaphthenequinones from 1-Acenaphthenones by NBS–DMSO Oxidation

Jiro TATSUGI,* Shigeo OKUMURA, and Yasuji IZAWA
Department of Applied Chemistry, Aichi Institute of Technology, Yakusa, Toyota 470-03
(Received February 3, 1986)

Synopsis. Acenaphthenequinone was obtained in 95% yield when the reaction of 1-acenaphthenone with *N*-bromosuccinimide was carried out in dimethyl sulfoxide at room temperature. Under similar conditions, several acenaphthenequinones were prepared from the corresponding 1-acenaphthenones in good yields.

Acenaphthenequinones are interesting with regard to photochemistry,[1] synthetic photochemistry,[2] and versatile synthetic intermediates to polycyclic hydrocarbons[3] and heterocyclic compounds.[4] The most widely used methods for the preparation of acenaphthenequinones are the oxidation of acenaphthenes with various oxidizing agents[5] and the Friedel–Crafts reaction of naphthalenes with oxalyl dichloride.[6] However, the yields of acenaphthenequinones by these methods are low due to the formation of by-products such as naphthalic anhydrides and 1,1′-biacenaphthylidene-2,2′-diones. In the course of our studies on the chemistry of 1-acenaphthenones, we found that the reaction of 1-acenaphthenones with *N*-bromosuccinimide (NBS) in dimethyl sulfoxide (DMSO) gave the corresponding acenaphthenequinones in good yields. We now report on a convenient preparation of acenaphthenequinones using NBS in DMSO.

1-Acenaphthenones (**1**) and NBS were dissolved in anhydrous DMSO. The mixture was stirred at room temperature under nitrogen atmosphere until all the substrate had been consumed to give the corresponding acenaphthenequinones (**2**) in good yields. The oxidation products were identified by their melting points, and by IR, ^{1}H NMR, and MS spectra.

The reaction of **1** with NBS in DMF gave only 5-bromo-1-acenaphthenone in 84% yield and with *N*-chlorosuccinimide (NCS) in DMF gave only 5-chloro-1-acenaphthenone in 47% yield. By contrast, 5-halo-1-acenaphthenone could not be isolated at all when the reaction was carried out in DMSO at room temperature. The results of the reaction of **1** with several halogenating agents, such as NBS, *N*-bromoacetamide (NBA), 2-oxopyrrolidinium tribromide (OB), phenyltrimethylammonium perbromide (PTAB), pyridinium tribromide (PB), 2,4,4,6-tetrabromo-2,5-cyclohexadien-1-one (TCD), iodine, bromine, and NCS in DMSO at room temperature are summarized in Table 1. As shown in Table 1, the reactions gave **2** in good to excellent yields except for that with NCS. The chlorination of DMSO took place exclusively when the reaction of **1** with NCS was carried out in DMSO at room temperature. This result suggests that NCS reacts with DMSO faster than with **1**.[7] The reactions of **1** with various molar ratios of NBS were carried out in order to find the most suitable reaction conditions for the preparation of **2**. The results are summarized in Table 2. The optimum yield was achieved when the reaction was carried out using an equivalent of NBS to **1** at room temperature for 24 h. The oxidation of some substituted 1-acenaphthenones (**1a—l**) to the corresponding acenaphthenequinones (**2a—l**) was carried out under similar conditions. The results are summarized in Table 3. As shown in Table 3, the compounds **1a—l** were oxidized into **2a—l** in good yields. In the cases of **1j**, **1k**, and **1l**, however, the corresponding 1,1′-biacenaphthyliden-2-ones were produced as by-products in 22, 5, and 6% yields, respectively.

a) Isolated yield.

To ascertain the reaction pathways leading to the quinones, the DMSO–oxidation of 2-bromo-1-acenaphthenone was carried out. The reaction of **1** with NBS in dichloromethane gave 2-bromo-1-acenaphthenone[12] in 59% yield, and the reaction of the resulting 2-bromo-1-acenaphthenone with DMSO at room temperature for 24 h afforded **2** in quantitative yield. On the basis of these facts and the results for related reactions,[13] it is clear that the course of the reaction involves α-bromination of **1** with NBS and then oxidation[14] of the resultant 2-bromo-1-acenaphthenones with DMSO to (2-oxo-1-acenaphthenyloxy)sulfonium bromides which then decomposes to give **2** and dimethyl sulfide as shown in Scheme 1.

1 2

Scheme 1.

In conclusion, the advantages of the present preparation of **2** using NBS in DMSO are: 1) the yields of 2 are satisfactory, 2) the experimental set up and work up are exceedingly simple, 3) the reactions are performed under mild conditions, 4) the reagents are easy to handle and are commercially available, and 5) there is no need to isolate the α-bromo ketone intermediate, which is somewhat unstable, from the reaction mixture.

Experimental

Melting points are uncorrected. IR, ^{1}H NMR, and MS spectra were recorded on a shimadzu IR-440, a JEOL JNM-PMX 60SI, and a Hitachi M-80B spectrometers, respectively.

Materials. DMSO was fractionated over CaH_2. NBS was purified by recrystallization from water. 1-Acenaphthenone (**1a**),[15] 3-methyl-1-acenaphthenone (**1b**),[16] 5-methyl-1-acenaphthenone (**1c**),[16] 3-ethyl-1-acenaphthenone (**1d**),[17] 5-bromo-1-acenaphthenone (**1h**),[18] 6-bromo-1-acenaphthenone (**1i**),[18] and 5-nitro-1-acenaphthenone (**1j**)[19] were prepared as described in the literature. 6-Ethyl-1-acenaphthenone (**1e**) and 6-chloro-1-acenaphthenone (**1g**) were prepared from the corresponding 5-substituted acenaphthenes by a similar method to the preparation of **1i**.[18]

1e: 35% yield; mp 67—68 °C. (petroleum ether); IR (KBr) 1710 (C=O), 1603, 1495, 835, 765, and 660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.37 (t, 3H, *J*=7.6 Hz), 3.11 (q, 2H, *J*=7.6 Hz), 3.69 (s, 2H), and 7.3—7.9 (m, 5H); MS *m/z* 196 (M^+). **1g**: 32% yield; mp 142—143 °C (EtOH); IR (KBr) 1725 (C=O), 1485, 840, 763, and 663 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.72 (s, 2H), and 7.2—8.3 (m, 5H); MS *m/z* 202 (M^+) and 204 (M^++2). 5-Chloro-1-acenaphthenone (**1f**) was prepared from **1a** and NCS in DMF at room temperature for 2 d. **1f**: 47% yield; mp 173—174 °C (EtOH); IR (KBr) 1705 (C=O), 1390, 825, and 760 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3,77 (s, 2H), and 7.3—8.4 (m, 5H), MS *m/z* 202 (M^+) and 204 (M^++2). 5-Cyano-1-acenaphthenone (**1k**) and 6-cyano-1-acenaphthenone (**1l**) were prepared via the corresponding cyano-1-acenaphthenols which were obtained by Rosenmund-von Braun synthesis.[20] **1k**: 30% yield (based on 5-bromo-1-acenaphthenol); mp 263—265 °C (EtOH), IR (KBr) 2210 (CN), 1718 (C=O), 1495, 1385, 820, and 770 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=3.98 (s, 2H), and 7.7—8.4 (m, 5H); MS *m/z* 193 (M^+). **1l**: 37% yield (based on 6-bromo-1-acenaphthenol); mp 157—158 °C (EtOH); IR (KBr) 2210 (CN), 1720 (C=O), 850, 785, and 660 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=3.93 (s, 2H), and 7.6—8.7(m, 5H); MS *m/z* 193 (M^+).

General Procedure. A mixture of 1-acenaphthenone (**1**) (5 mmol), NBS (5 mmol) and anhydrous DMSO (5 ml) was stirred at room temperature under nitrogen atmosphere. The progress of the reaction was monitored by TLC on silica gel using dichloromethane as eluent. After disappearance of **1**, 100 ml of water was added to the resultant mixture, and the precipitates were collected by filtration and then washed with water. The product was recrystallized from dichloromethane.

Spectral data of acenaphthenequinones are as follows.

3-Methylacenaphthenequinone (2b). IR (KBr) 1720 and 1738 cm^{-1}, (C=O); ^{1}H NMR ($CDCl_3$) δ=2.73 (s, 3H), and 6.8—8.0 (m, 5H); MS *m/z* 196 (M^+).

5-Methylacenaphthenequinone (2c). IR (KBr) 1720 and 1735 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=2.83 (s, 3H), and 7.3—8.4 (m, 5H); MS *m/z* 196 (M^+).

3-Ethylacenaphthenequinone (2d). IR (KBr) 1720 and 1735 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.37 (t, 3H, *J*=8 Hz), 3.33 (q, 2H, *J*=8 Hz), and 7.6—8.3 (m, 5H); MS *m/z* 210 (M^+).

5-Ethylacenaphthenequinone (2e). IR (KBr) 1720 and 1737 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.37 (t, 3H, *J*=8 Hz), 3.07 (q, 2H, *J*=8 Hz), and 7.4—8.2 (m, 5H); MS *m/z* 210 (M^+).

5-Cyanoacenaphthenequinone (2k). IR (KBr) 1730, 1745 (C=O), and 2250 cm^{-1} (CN); ^{1}H NMR (DMSO-d_6–$CDCl_3$) δ=8.0—8.7 (m, 5H); MS *m/z* 207 (M^+).

Synthesis of the Cyclotetrasilanes of the Type[(PhRSi)$_4$] (R=*t*-Bu; *t*-BuCH$_2$)

Hideyuki MATSUMOTO,* Atsushi SAKAMOTO, Masahiko MINEMURA, Kenji SUGAYA, and Yoichiro NAGAI*
Department of Chemistry, Gunma University, Kiryu, Gunma 376
(Received March 13, 1986)

Synopsis. The cyclotetrasilanes of the type [(PhRSi)$_4$] (R=*t*-Bu; *t*-BuCH$_2$) were prepared by the reductive coupling of the corresponding dichlorosilanes (PhRSiCl$_2$) with lithium.

As part of our continuing study of the chemistry of small-membered cyclopolysilanes bearing bulky alkyl substituents, we attempted to prepare alkylphenylcyclotetrasilanes of the type [(PhRSi)$_4$]. The cyclotetrasilanes so far obtained are limited to rings such as (Me$_2$Si)$_4$,[1] (Et$_2$Si)$_4$,[2] (*i*-Pr$_2$Si)$_4$,[3-5] (*s*-Bu$_2$Si)$_4$,[5] (*i*-Bu$_2$Si)$_4$,[5] [(*t*-BuCH$_2$)$_2$Si]$_4$,[6] [(Me$_3$SiCH$_2$)$_2$Si]$_4$,[7] [(Me$_3$Si)$_2$Si]$_4$,[8] (*t*-BuMeSi)$_4$,[9] (EtMeSi)$_4$,[10] [*t*-Bu(n-Pr)Si]$_4$,[5] [(*t*-BuCH$_2$)$_2$Si]$_2$(*i*-Pr$_2$Si)$_2$,[11] [(*t*-BuCH$_2$)$_2$Si]$_2$ (*t*-BuMeSi)$_2$,[11] (Ph$_2$Si)$_4$,[12] and [(*p*-MeC$_6$H$_4$)$_2$Si]$_4$.[13] We report here the synthesis of the novel cyclotetrasilanes, (*t*-BuPhSi)$_4$, **1**, and [(*t*-BuCH$_2$)PhSi]$_4$, **2**.

The cyclotetrasilane **1** was prepared by the reaction of *t*-BuPhSiCl$_2$, **3**, with lithium (Eq. 1). The yield of the

$$4\,t\text{-BuPhSiCl}_2(\mathbf{3}) + 8\,\text{Li} \longrightarrow (t\text{-BuPhSi})_4(\mathbf{1}) + 8\,\text{LiCl} \quad (1)$$

cyclotetrasilane strongly depended upon the choice of reaction conditions. Optimum conditions involve the treatment of **3** with 3 equiv of lithium at 0°C for 0.5 h in THF. Under these conditions, the cyclotetrasilane **1** was formed in 45% yield, as shown by a GLC analysis. The usual workup and recrystallization from MeOH/EtOH (1/1) led to the isolation of **1** in 36% yield. The reaction of the dichlorosilane **3** with sodium was also examined (toluene, 60—70°C, 3h), but no trace of the desired compound was obtained.

The first step in the reductive coupling of the dichlorosilane **3** seems to be the formation of Cl(*t*-Bu)PhSiSiPh(Bu-*t*)Cl, **4**, which would then react with lithium to give the cyclic tetramer **1**. The formation of peralkylcyclotetrasilanes from 1,2-dichloro-1,1,2,2-tetraalkyldisilanes has been reported previously.[5,6,10] The observation that if the dichlorosilane **3** is treated with a deficiency of lithium, the reaction mixture contains the dichlorodisilane **4** as its major component, is in agreement with this view.

To explore the scope of the present approach further, (*t*-BuCH$_2$)PhSiCl$_2$, **5**, was also allowed to react with lithium. In this case, the use of a 1:1 mixture of THF and benzene as the solvent led to a higher yield of the tetraneopentyltetraphenylcyclotetrasilane **2** than did the use of THF alone. Thus, stirring a mixture of the dichlorosilane **5** with 2.4 equiv. of lithium at 0°C for 2 h in the mixed solvent resulted in the formation of the cyclic tetramer **2** in 54% yield, as shown by the GLC analysis. The same cyclotetrasilane was also prepared by the reaction of Cl(*t*-BuCH$_2$)PhSiSiPh(CH$_2$Bu-*t*)Cl, **6**, with lithium (a slight excess) in 57% yield under nearly the same conditions.

Both **1** and **2** are air-stable, evidently owing to a steric protection by the *t*-butyl and neopentyl substituents, respectively. The UV absorption spectra of these four-membered rings are shown in Fig. 1. The longest wavelength bands for these rings at ca. 315 nm are slightly lower in energy than the corresponding absorptions for peralkylcyclotetrasilanes [e.g., 300 nm for (*t*-BuMeSi)$_4$[9] and 286 nm for [(*t*-BuCH$_2$)$_2$Si]$_4$[6]], presumably due to perturbation of the electronic structures of the Si$_4$ frameworks by the phenyl substituents.[14] In the mass spectra, good agreement is found between the observed isotope ratios for the parent clusters and those calculated, in support of the assignments for **1** and **2**.

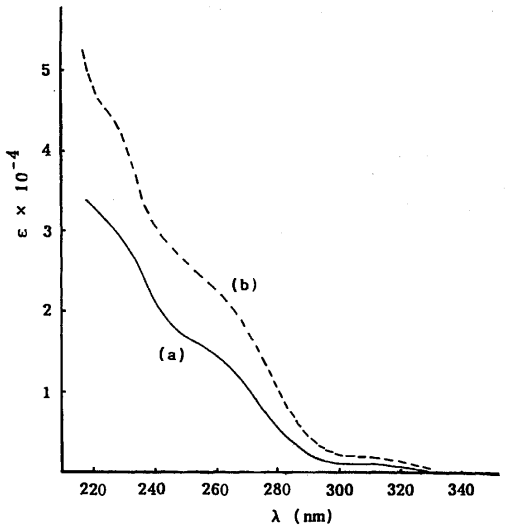

Fig. 1. UV absorption spectra for 1,2,3,4-tetraalkyl-1,2,3,4-tetraphenylcyclotetrasilane: (a): **1**, (b): **2**.

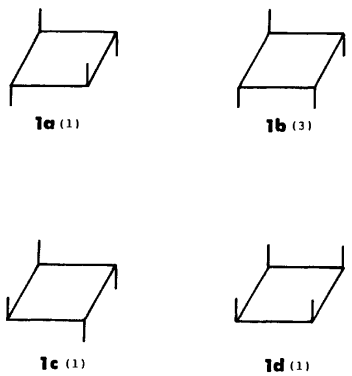

Fig. 2. The possible geometrical isomers of the cyclotetrasilane **1** in planer conformations and the number of expected β-methyl NMR resonances of the *t*-butyl substituents.

The presence of the two different substituents on each silicon atom should give rise to the four isomers. For example, the possible isomers for **1** and the number of expected β-methyl resonaces of the *t*-butyl groups in the NMR are shown in Fig. 2.[9,10] Both ^{1}H and

$^{13}C\{^1H\}$NMR show six β-methyl signals, respectively, suggesting the presence of all four isomers **1a—d**. Further work to determine the isomeric distribution of the products is in progress.

In short, the present reductive couplings can provide a useful route to the novel 1,2,3,4-tetraalkyl-1,2,3,4-tetraphenylcyclotetrasilanes **1** and **2**, which might be latent sila-functional cyclotetrasilanes since it has been shown by Hengge and coworkers that phenylcyclopolysilanes can be converted to the corresponding halocyclopolysilanes via the dephenylation with hydrogen halides.[15]

Experimental

Melting and boiling points were uncorrected. ^1H (90 MHz) and ^{13}C (22.64 MHz) NMR spectra were recorded on a Hitachi R-90H spectrometer. IR spectra were recorded on a JASCO A102 spectrometer. UV spectra were taken on a Hitachi 200-10 spectrometer. Mass spectra were recorded on a JEOL DX-300 spectrometer. GLC analyses were carried out using an Ohkura 103 gas chromatograph equipped with 1 m×0.4 cm Pyrex glass columns packed with 10% Silicone SE-30 and 10% Silicone KF-96 on Celite 545 SK (60—80 mesh).

Benzene and THF were distilled from sodium benzophenone ketyl prior to use. All reactions were carried out under an atmosphere of dried nitrogen.

The dichlorosilane **3** was prepared according to literature direction.[16] (t-BuCH$_2$)PhSiCl$_2$, **5**, and Cl(t-BuCH$_2$)PhSiSiPh(CH$_2$Bu-t)Cl, **6**, were prepared by the methods shown (Eqs. 2 and 3).[17,18]

$$PhSiCl_3 \xrightarrow{t\text{-}BuCH_2Li} \mathbf{5}\ (73\%) \qquad (2)$$

$$PhHSiCl_2 \xrightarrow{t\text{-}BuCH_2Li} (t\text{-}BuCH_2)PhHSiCl\ (69\%) \xrightarrow{Li} H(t\text{-}BuCH_2)PhSiSiPh(CH_2Bu\text{-}t)H\ (\mathbf{7})\ (56\%) \xrightarrow[PdCl_2]{CCl_4} \mathbf{6}\ (77\%) \qquad (3)$$

For **5**: Bp 113—115 °C (32 mmHg); ^1H NMR (CCl_4) δ=1.03 (s, 9H, t-Bu), 1.21 (s, 2H, -CH$_2$-), and 7.3—7.7 (m, 5H, Ph). Found: C, 53.50; H, 6.53%. Calcd for $C_{11}H_{16}SiCl_2$: C, 53.44; H, 6.52%.

For **7**: Bp 135—138 °C (0.20 mm Hg); IR (neat) principal absorptions, 2130, 1420, 1260, and 1110 cm^{-1}; ^1H NMR (CCl_4) δ=0.88 (s, 9H, t-Bu), 0.93 (s, 9H, t-Bu), 1.23 (s, 4H, -CH$_2$-), 4.41 (m, 2H, SiH), and 7.25 (m, 10H, Ph); Found: C, 74.28; H, 9.76%. Calcd for $C_{22}H_{34}Si_2$: C,74.50; H, 9.66%.

For **6**: Bp 149—155 °C (0.15 mmHg); IR (neat) principal absorptions, 1425, 1260, 1230, 1115, and 1100 cm^{-1}; ^1H NMR (CCl_4) δ=0.80 (s, 9H, t-Bu), 0.94 (s, 9H, t-Bu), 1.21 (s, 2H, -CH$_2$-), 1.38 (s, 2H, -CH$_2$-), and 7.2—7.8 (m, 10H, Ph); Found: C, 62.41; H, 7.54%. Calcd for $C_{22}H_{32}Si_2Cl_2$: C, 62.38; H, 7.62%.

Reaction of t-BuPhSiCl$_2$, 3, with Lithium: A 200 ml flask equipped with a magnetic stirrer and a nitrogen inlet was charged with lithium cut (0.60 g, 87 mg-atom) and THF (60 ml). The flask was cooled to 0 °C by an ice-water bath, and the dichlorosilane **3** (7.0 g, 30 mmol) was added dropwise over 5 min. The mixture was stirred for an additional 0.5 h and filtered. A GLC analysis showed that (t-BuPhSi)$_4$, **1**, had been produced in 45% yield. Approximately 100 ml of cyclohexane was added, and the solution was washed with water and dried over anhydrous MgSO$_4$. Evaporation of the solvents yielded a half-solid that was recrystallized from MeOH/EtOH (1/1) to give 1.9 g (36% yield) of **1** as fine colorless powders.

In another run, a mixture of **3** (4.63 g, 20 mmol), lithium (0.14 g, 20 mg-atom), and THF (48 ml) was stirred at 0 °C for 7 h. A GLC analysis showed that 68% of **3** had been consumed and that Cl(t-Bu)PhSiSiPh(Bu-t)Cl, **4**, had been produced in 27% yield together with a trace amount of **1**.

For **1**: Mp 280—310 °C; IR (KBr disk) principal absorptions, 1415, 1260, and 1095 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.77 (s, 4.5H, t-Bu), 0.81 (s, 3.1H, t-Bu), 0.98 (s, 5.2H, t-Bu), 1.03 (s, 11.4H, t-Bu), 1.42 (s, 8.9H, t-Bu), 1.51 (s, 2.9H, t-Bu), and 6.74—7.89 (m, 20H, Ph); $^{13}C\{^1H\}$NMR ($CDCl_3$) δ=21.13, 21.56, 22.62, 23.20, 23.63, 24.42 (Me$_3$C), 30.21, 30.58, 31.07, 31.28, 32.07, 32.44 (CH$_3$), 125.98—123.39 (phenyl carbons), and 135.57—139.12 (phenyl carbons); MS (70 eV) m/z (isotope ratios for parent clusters) Obsd: 696 (100), 697 (67), 698 (41), 699 (21). Calcd: 696 (100), 697 (67), 698 (34), 699 (16); UV$_{max}$ (cyclohexane) 233 (ε 28000), 263 (ε 14200), and 317 nm (ε 522). Found: C, 73.95; H, 9.02%. Calcd for $C_{24}H_{72}Si_4$: C, 74.03; H, 8.70%.

For **4**: ^1H NMR (CCl_4) δ=0.85 (s, 18H, t-Bu) and 7.28—7.75 (m, 10H, Ph); exact mass for M$^+$ measd 394.1101. Calcd 394.1106, dev 0.5 mmu.

Reaction of (t-BuCH$_2$)PhSiCl$_2$, 6, with Lithium: A 300 ml flask was charged with lithium cut (0.94 g, 135 mg-atom), THF (65 ml), and benzene (65 ml). The flask was cooled to 0 °C by ice-water bath, and **5** (14.5 g, 59 mmol) in THF (10 ml) and benzene (10 ml) was added dropwise over 1 h. The mixture was stirred for an additional 1 h and filtered. A GLC analysis showed that the cyclotetrasilane **2** had been produced in 54% yield. The filtrate was washed with water and dried over anhydrous MgSO$_4$. Evaporation of the solvents and recrystallization from MeOH/EtOH (3/1) afforded 1.12 g (28% yield) of **2** as colorless powders.

For **2**: IR (KBr disk) principal absorptions, 1420, 1355, 1250, 1090, 720, 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.70 (s, 2.0H, t-Bu), 0.74 (s, 4.7H, t-Bu), 0.79 (s, 16.0H, t-Bu), 0.81 (s, 2.0H, t-Bu), 0.90 (s, 7.7H, t-Bu), 0.99 s, 3.6H, t-Bu), 1.35—1.58 (m, 8H, -CH$_2$-), and 6.70—7.90 (m, 20H, Ph); $^{13}C\{^1H\}$NMR ($CDCl_3$) δ=30.73—31.97 (Me$_3$C and -CH$_2$-), 32.07, 32.14, 32.99, 33.10, 33.26, 33.32 (CH$_3$), 126.7—128.2 (phenyl carbons), and 136.8—137.4 (phenyl carbons); MS (70 eV) m/z (isotope ratios for the parent clusters) Obsd: 704 (100), 705 (71), 706 (40), 707 (16). Calcd: 704 (100), 705 (71), 706 (38), 707 (14); UV$_{max}$ (cyclohexane) 230 (ε 42600), 264 (ε 22500), 313 nm (ε 1900). Found: C, 74.86; H, 9.14%. Calcd for $C_{44}H_{64}Si_4$: C, 74.93; H, 9.14%.

Reaction of the Dichlorodineopentyldiphenyldisilane 6 with Lithium: A mixture of **6** (0.25 g, 0.55 mmol), lithium cut (9.0 mg, 1.3 mg-atom), THF (1.4 ml), and benzene (1.4 ml) was stirred at 0 °C for 2 h. A GLC analysis showed that the cyclotetrasilane 2 had been produced in 57% yield together with a trace amount of the dihydrodisilane **7**.

We thank Professor Nobumasa Kamigata, Tokyo Metropolitan University, for mass spectral analysis.

A Convenient Synthesis of *N*-Substituted Formamidines by Desulfurization of the Corresponding Thioureas

Choji KASHIMA,* Masao SHIMIZU, Takeshi ETO, and Yoshimori OMOTE
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received March 17, 1986)

Synopsis. *N,N'*-Di- and *N,N,N'*-trisubstituted thioureas were easily desulfurized by Raney nickel to yield the corresponding formamidines, while *N*-monosubstituted thioureas gave *N,N'*-disubstituted formamidines.

Amidines are important compounds for the syntheses of heterocycles as well as their pharmaceutical chemistries owing to their biological activities.[1] Although amidines are generally prepared by the condensation of nitriles and amines, or the substitution of imidates with amines, the syntheses of formamidines require special methods, such as the treatment of amines with chloroimines or imidates,[1] and the treatment of isonitriles and amines with Co(I) catalysis.[2]

The desulfurization of carbon–sulfur bonds using Raney nickel is known as a convenient method for the syntheses of various organic compounds.[3] However, the desulfurization of thioureas with Raney nickel has scarcely been reported and consistent results can not be found. For example, unsubstituted thiourea afforded formamidine hydrochloride in the presence of ammonium chloride[4] or as a mixture of methane, ammonia, and methylamine[5]; *N*-benzylthiourea gave a mixture of methane, ammonia, and toluene[6]; and *N*-(*o*-tolyl)thiourea gave *o*-toluidine.[7] Although Ashworth reported that *N,N'*-diarylthioureas afforded the corresponding formamidines, he did not describe in detail such matters as yeilds and the activities of Raney nickel. Furthermore, in the case of *N*-(*p*-chlorophenyl)thiourea, he obtained only an unidentified basic liquid.[8]

In this paper, we wish to describe the convenient synthesis of many types of substituted formamidines by the desulfurization of the corresponding thioureas as well as and the scope and the limitations of the Raney nickel desulfurization of thioureas.

First, the desulfurization of *N*-monosubstituted thioureas was reinvestigated. When *N*-phenylthiourea was treated with Raney nickel in methanol, the ^{1}H NMR spectrum exhibited a new singlet at δ=7.63 which is characteristic of the formyl proton. Actually, when picric acid was added to the reaction mixture prior to purification, *N*-phenylformamidine picrate was successfully isolated in 15% yield after recrystallization. However, the chromatographic purification of the crude reaction product could not afford the expected *N*-phenylformamidine. The isolated products were *N,N'*-diphenylformamidine and formanilide. By the same treatment of some *N*-monosubstituted thioureas, the corresponding *N,N'*-disubstituted formamidines were obtained (Table 1). Yields resulted in one mole of formamidines **2** formed from two mole of thioureas **1**; also, one mole of the formamide derivatives **3** was formed from one mole of thioureas **1**.

Table 1. Desulfurization of *N*-Monosubstituted Thioureas

	R	Yield/%	
		2	**3**
1a	C_6H_5	41	7
1b	p-$CH_3C_6H_4$	60	34
1c	p-$CH_3OC_6H_4$	47	6
1d	$C_6H_5CH_2$	0	27

Since Roberts[9] and McNab[10] noted an amine exchange reaction involving *N*-(*p*-methylphenyl)-*N'*-phenylformamidine with aniline or *p*-toluidine, the exchange reaction proceeded even in the case of *N*-phenylformamidine; volatile ammonia was given off from the system. Therefore, *N,N'*-disubstituted formamidines were secondary products from an amine exchange reaction between the *N*-monosubstituted formamidines and the anilines which were generated by the hydrolysis of *N*-monosubstituted formamidines owing to air moisture during the work-up. Actually, when **1a** was treated with Raney nickel in the presence of methylamine hydrochloride and diethylamine, *N*-methyl-*N'*-phenyl- and *N,N*-diethyl-*N'*-phenylformamidine were obtained in 46 and 41% yields, respectively. These facts support the idea that amine exchange reaction occurs between an unsubstituted amino group and the secondary mediated amine. Moreover, it was suggested that the desulfurization of unsubstituted thiourea might afford *N,N'*-disubstituted formamidine in the presence of amines. Actually, by the desulfurization of thiourea in the presence of *p*-toluidine, *N,N'*-bis(*p*-methylphenyl)formamidine was isolated. However, its yield was low (9%) since there was almost no separation between the desired formamidine and *p*-toluidine.

Next, the desulfurizations of various *N,N'*-di- or *N,N,N'*-trisubstituted thioureas were investigated. In these series, the corresponding formamidines were respectively obtained without amine exchange reactions. The results are shown in Table 2. *N,N'*-Disubstituted formamidines were obtained in better yields than that for *N,N,N'*-trisubstituted. When the desulfurization of cyclic *N,N,N'*-trisubstituted thioureas was carried out in the same manner, the corresponding cyclic formamidines were obtained (Table 3).

Consequently, although *N,N'*-di- or *N,N,N'*-trisubstituted thioureas gave the corresponding formamidines by desulfurization with Raney nickel, *N*-monosubstituted thioureas afforded *N,N'*-disubstituted formamidines via an amine exchange reaction on account of the instability of the primary *N*-monosubstituted formamidines.

Experimantal

Melting points were measured on a Yanagimoto micro melting point apparatus and are uncorrected. IR spectra were measured on a Jasco IRA-1 infrared spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on Hitachi R-24 and JEOL-100 spectrometer, respectively, using tetramethylsilane as an internal standard.

Preparation of Active Raney Nickel. Sodium hydroxide pellets (2.0 g) were added to nickel-aluminum alloy (Wako Pure Chemical Industries Ltd., 50%, 1.6 g) in distilled water (20 mL) with vigorous stirring at room temperature. After 15 min, the reaction mixture was immersed in an oil bath (bath temperature 70°C) for 20 min, and then the alkaline solution was decanted. The nickel was washed four times by suspension in distilled water and underwent decantation. The washing procedure was repeated four times with methanol.

Desulfurization of Thioureas; Typical Procedures. The mixture of thiourea (2 mmol) and the activated Raney nickel (prepared from 1.6 g nickel-aluminum alloy) in methanol (20 mL) was warmed at 50°C for 1 h and then refluxed for 2 h. After removing the catalyst by filtration, the filtrate was diluted with water and extracted with dichloromethane. It was then dried over anhydrous magnesium sulfate. After evaporating the solvent, the crude product was chromatographed on silica gel with a mixture of hexane-acetone-diethylamine (13:6:1) or benzene-ethyl acetate (3:1). Picrate was prepared as follows. To a solution of formamidine (2 mmol) in ethanol (5 mL), the solution of picric acid (2 mmol) in ethanol was added. After standing for 15 h, the resulting precipitate was recrystallized from ethanol.

Desulfurization of *N*-Phenylthiourea in the Presence of Amines. To a mixture of *N*-phenylthiourea (**1a**, 2 mmol) and methylamine hydrochloride or diethylamine (10 mmol), Raney nickel (0.8 g) was added in a sealed tube and then warmed at 50°C for 1 h and at 80°C for 2 h. The following procedure is the same as that described above.

***N*-Phenylformamidine (4).** ^1H NMR ($CDCl_3$) δ=3.81 (s, 2H, NH_2), 6.6—7.3 (m, 5H, Ar), 7.63 (s, 1H, =CH). Picrate: Mp 198—200°C. (lit,[11] 191°C). Found: C, 44.49; H, 3.18; N, 20.02%. Calcd for $C_{13}H_{11}N_5O_7$: C, 44.70; H, 3.17; N, 20.05%.

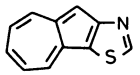
Synthesis of 2-Methylazuleno[1,2-*d*]thiazoles

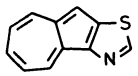
Kunihide FUJIMORI,* Hiroyuki KITAHASHI, Satoshi KOYAMA, and Kameji YAMANE
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received April 1, 1986)

Synopsis. 2-Methylazuleno[1,2-*d*]thiazoles were synthesized from diethyl 2-mercapto-1,3-azulenedicarboxylate, which was prepared by a treatment of diethyl 2-(2-methoxycarbonylethylthio)-1,3-azulenedicarboxylate with sodium ethoxide in five steps.

Among the two possible isomers of azulenothiazoles which are formed by a condensation of thiazole with azulene at the 1,2-position, azuleno[2,1-*d*]thiazole (**I**) as well as its 2-amino and 2-methyl derivatives have been synthesized.[1)]



I



II

We now wish to report the synthesis of azuleno[1,2-*d*]thiazoles (**II**). The reaction of diethyl 2-chloro-1,3-azulenedicarboxylate (**1**)[2)] with methyl 3-mercaptopropionate in pyridine gave diethyl 2-(2-methoxycarbonylethylthio)-1,3-azulenedicarboxylate (**3**) in 93% yield. When the ester **3** was treated with sodium ethoxide in dry ethanol, diethyl 2-mercapto-1,3-azulenedicarboxylate (**4**), a reversal Michael's addition reaction product, was obtained in 96% yield, and methyl acrylate was also detected. The IR and ^{1}H NMR spectra of **4** show an absorption band at 2434 cm^{-1} and a signal at δ=7.71 due to the mercapto group, respectively. Compound **4** has also been obtained by a reaction of **1** with thioacetic acid or hydrogen sulfide in the presence of sodium ethoxide.[3)] However, the present method is unaccompanied by the formation of other by-products, such as thioether or disulfide, and is preferred as a method for the preparation of **4**.

Heating **4** with 100% phosphoric acid at 90°C resulted in deethoxycarbonylation giving ethyl 2-mercapto-1-azulenecarboxylate (**5**) in an almost quantitative yield. Further, the treatment of **5** with acetic anhydride gave 2-(acetylthio)azulene derivative **6** in 91% yield. The nitration of **6** with nitric acid in acetic anhydride at −30°C gave ethyl 2-acetylthio-3-nitro-1-azulenecarboxylate (**7**) in 44% yield. Compound **7**, upon treatment with zinc dust in acetic acid and acetic anhydride at room temperature, gave a mixture of ethyl 2-acetylthio-3-acetylamino-1-azulenecarboxylate (**8**) and ethyl 3-acetylamino-1-azulenecarboxylate (**9**). Compound **8** was treated with a potassium hydroxide solution in tetrahydrofuran–ether, followed by a treatment with hydrochloric acid by cooling with ice under an inert atmosphere to give ethyl 2-methylazuleno[1,2-*d*]thiazole-9-carboxylate (**10**). Furthermore, the demethoxycarbonylation of **10** by heating with 100% phosphoric acid gave 2-methylazuleno[1,2-*d*]thiazole (**11**) in 87% yield. The difference between the vicinal coupling constants, $\Delta J = J_{7,8} - J_{4,5}$, in ^{1}H NMR of **11** is 1.3 Hz, indicating that the 7-membered ring exhibits some bond alternation in analogy with azuleno[2,1-*d*]thiazole.[1)]

The electronic spectra of **10**, **11**, and 2-methylazuleno[2,1-*d*]thiazole[1)] are shown in Fig. 1.

Experimental

Melting points are uncorrected. ^{1}H NMR spectra were record-

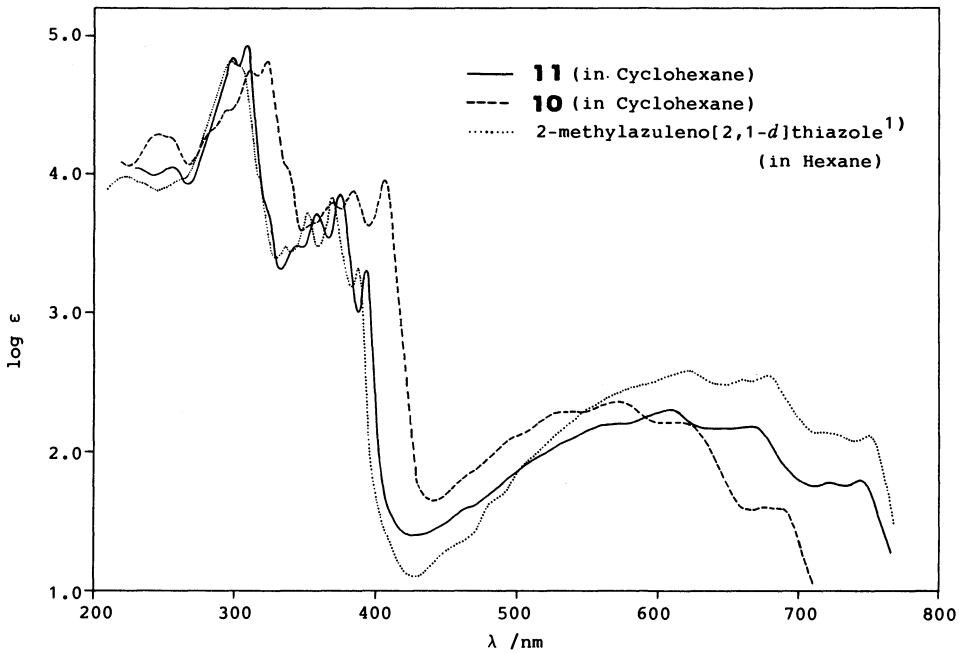


Fig. 1. Electronic spectra of **10**, **11**, and 2-methylazuleno[2,1-*d*]thiazole.

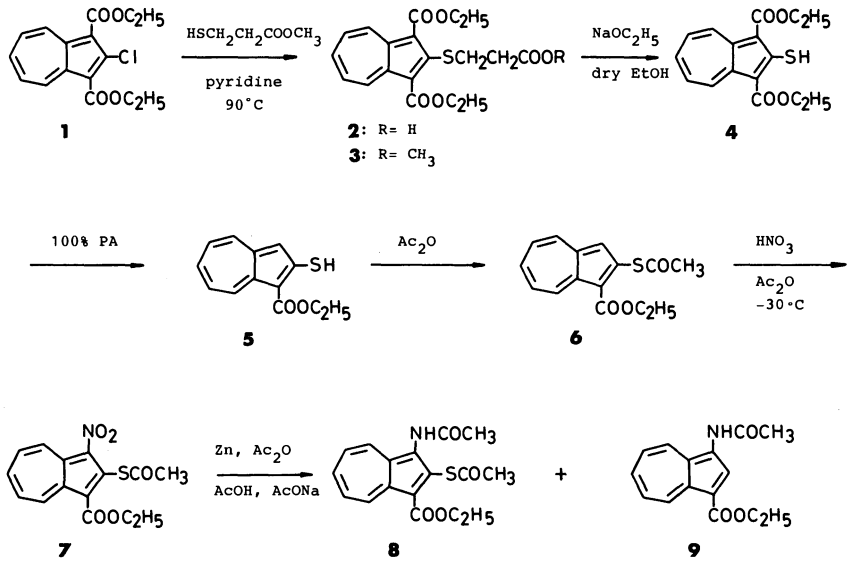

Fig. 2.

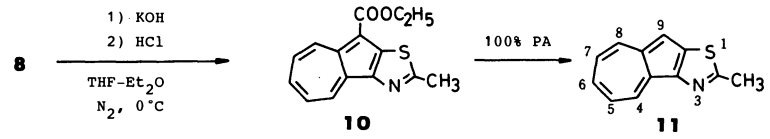

Fig. 3.

ed with a JEOL 90Q spectrometer using tetramethylsilane as an internal standard. The IR spectra were taken on a Hitachi 345 infrared spectrometer and the electronic absorption spectra were measured with a Hitachi 200-20 spectrometer.

Diethyl 2-(2-Methoxycarbonylethylthio)-1,3-azulenedicarboxylate (3). A mixture of diethyl 2-chloro-1,3-azulenedicarboxylate (**1**) (600 mg) and methyl 3-mercaptopropionate (310 mg) in pyridine (30 ml) was heated at 90°C for 1 h. After cooling, the reaction mixture was poured into water and extracted with dichloromethane. The dichloromethane layer was washed with 3M sulfuric acid and water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue was chromatographed on a silica-gel column with benzene. The red effluent was freed from the solvent to give **3** (711 mg, 93%) as red micro needles; mp 70.5—71 °C; ^{1}H NMR (90 MHz, in $CDCl_3$) δ=1.49 (6H, t, J=7.2 Hz, $COOCH_2C\underline{H}_3$), 2.61 (2H, t, J=7.7 Hz, $SCH_2C\underline{H}_2COOMe$), 3.34 (2H, t, J=7.7Hz, $SC\underline{H}_2CH_2COOMe$), 3.64 (3H, s, $SCH_2CH_2COOC\underline{H}_3$), 4.51 (4H, q, J=7.2 Hz, $COOC\underline{H}_2CH_3$), 7.4—7.9 (3H, m, H-5,6,7), and 9.17 (2H, dm, J=9.6 Hz, H-4,8). Found: C, 61.35; H, 5.56; S, 8.24%. Calcd for $C_{20}H_{22}O_6S$: C, 61.52; H, 5.68; S, 8.21%. The second red effluent gave a trace of diethyl 2-(2-carboxyethylthio)-1,3-azulenedicarboxylate (**2**) as a red solid; ^{1}H NMR (90 MHz, in $CDCl_3$) δ=1.50 (6H, t, J=7.2 Hz, $COOCH_2C\underline{H}_3$), 2.66 (2H, t, J=7.7 Hz, $SCH_2C\underline{H}_2COOH$), 3.33 (2H, t, J=7.7 Hz, $SC\underline{H}_2CH_2COOH$), 4.51 (4H, q, J=7.2 Hz, $COOC\underline{H}_2CH_3$), and 10.7 (1H, bs, $COO\underline{H}$).

Diethyl 2-Mercapto-1,3-azulenedicarboxylate (4). Into a solution of **3** (6.25 g) in anhydrous ethyl alcohol (100 ml), a sodium ethoxide solution which was prepared from sodium metal (583 mg) and anhydrous ethanol (50 ml) was added. The mixture was stirred for 2 h at room temperature. The reaction mixture was diluted with water, neutralized with 2M hydrochloric acid (1 M=1 mol dm^{-3}), and extracted with benzene. The extract was washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue was chromatographed on a silica-gel column. From the benzene effluent, **4** was obtained as orange needles (4.69 g, 96%); mp 88.5—89°C (lit, 3, 85—86°C); ^{1}H NMR (90 MHz, in $CDCl_3$) δ=1.53 (6H, t, J=7.2 Hz, $COOCH_2C\underline{H}_3$), 4.51 (4H, q, J=7.2 Hz, $COOC\underline{H}_2CH_3$), 7.71 (1H, s, S$\underline{H}$), 7.5—7.8 (3H, m, H-5,6,7), and 9,3—9.5 (2H, m, H-4,8); IR (KBr) 2434 cm^{-1} (SH). (Found: C, 63.38; H, 5.39; S, 10.36%).

Ethyl 2-Mercapto-1-azulenecarboxylate (5). A mixture of **4** (3.93 g) and 100% phosphoric acid (50 ml) was heated for 30 min at 90°C. After cooling, the reaction mixture was poured into water and extracted with benzene. The extract was washed with water, dried, and evaporated. The residue was chromatographed on a silica-gel column with benzene-hexane (1:1). The red effluent was freed from the solvent to give **5** (3.00 g, ca. 100%) as red oil; ^{1}H NMR (90 MHz, in $CDCl_3$) δ=1.49 (3H, t, J=7.2 Hz, $COOCH_2C\underline{H}_3$), 4.47 (2H, q, J=7.2 Hz, $COOC\underline{H}_2CH_3$), 5.35 (1H, s, S$\underline{H}$), 7.30 (1H, s, H-3), 7.1—7.7 (3H, m, H-5,6,7), 8.02 (1H, dm, J=9.8 Hz, H-4), and 9.24 (1H, dm, J=9.8 Hz, H-8). Found: C, 67.00, H, 5.10; S, 13.85%. Calcd for $C_{13}H_{12}O_2S$: C, 67.24; H, 5.17; S, 13.81%. From the purple effluent, a trace of 2-mercaptoazulene[3] was obtained as bluish purple crystals; mp 112—113°C; IR (KBr) 2538 cm^{-1} (SH); ^{1}H NMR (90 MHz, in $CDCl_3$) δ=3.87 (1H, s, S$\underline{H}$), 7.11 (2H, s, H-1,3), 6.9—7.6 (3H, m, H-5,6,7), and 8.04 (2H, dm, J=9.7 Hz, H-4,8); ^{13}C NMR (22.5 MHz, in $CDCl_3$) δ=116.8, 124.5, 133.1, 135.4, 140.7, and 140.9.

Ethyl 2-Acetylthio-1-azulenecarboxylate (6). A mixture of **5** (3.00 g) and acetic anhydride (55 ml) was heated for 30 min at 90°C. The reaction mixture was evaporated under reduced pressure, and the residue was diluted with water. The solution was then neutralized with a aqueous sodium carbonate solution and extracted with benzene. The benzene layer was dried over anhydrous sodium sulfate and evaporated under reduced pressure. The residue was chromatographed on a silica-gel column with benzene-hexane (1:1). The purple

effluent gave **6** (3.22 g, 91%) as dark purple prisms; mp 72—73°C; ^{1}H NMR (90 MHz, in $CDCl_3$) δ=1.48 (3H, t, J=7.2 Hz, $COOCH_2C\underline{H}_3$), 2.56 (3H, s, $SCOC\underline{H}_3$), 4.47 (2H, q, J=7.2 Hz, $COOC\underline{H}_2CH_3$), 7.2—7.8 (3H, m, H-5,6,7), 8.26 (1H, dm, J=9.8 Hz, H-4), and 9.46 (1H, dm, J=9.8 Hz, H-8). Found: C, 65.60; H, 5.15; S, 11.57%. Calcd for $C_{15}H_{14}O_3S$: C, 65.67; H, 5.14; S, 11.69%.

Ethyl 2-Acetylthio-3-nitro-1-azulenecarboxylate (7). Into a solution of **6** (500 mg) in acetic anhydride (240 ml) which had been cooled at −30°C, nitric acid was added, drop by drop; the solution was then stirred for 8 h. The reaction mixture was diluted with water, neutralized with a 6M sodium hydroxide aqueous solution, and extracted with dichloromethane. The extract after being dried and freed from solvent yielded a residue. The residue was chromatographed on a silica-gel column with benzene. The effluent gave **7** (258 mg, 44%) as dark red prisms; mp 144.5—145°C; ^{1}H NMR (90 MHz, in $CDCl_3$) δ=1.46 (3H, t, J=7.2 Hz, $COOCH_2C\underline{H}_3$), 2.56 (3H, s, $SCOC\underline{H}_3$), 4.44 (2H, q, J=7.2 Hz, $COOC\underline{H}_2CH_3$), 7.7—8.2 (3H, m, H-5,6,7), and 9.5—9.7 (2H, m, H-4,8). Found: C, 56.48; H, 4.08; N, 4.13; S, 9.99%. Calcd for $C_{15}H_{13}NO_5S$: C, 56.41; H, 4.07; N, 4.42; S, 10.04%. From purple effluent, **6** (175 mg, 35%) was recovered.

Ethyl 3-Acetylamino-2-acetylthio-1-azulenecarboxylate (8) and Ethyl 3-Acetylamino-1-azulenecarboxylate (9). A mixture of **7** (300 mg), acetic anhydride (75 ml), sodium acetate (5.28 g), and zinc dust (10.7 g) in acetic acid (75 ml) was stirred for 21 h at room temperature. The reaction mixture was diluted with water and unchanged zinc dust was removed by filtration. The filtrate was neutalized with potassium carbonate and extracted with dichloromethane. The extract was dried and the solvent was removed. The resulting residue was chromatographed on a silica-gel column. **8** (109 mg, 35%, purple needles, mp 113—114°C); IR (KBr) 3264, 1711, 1684, 1644, and 1528 cm^{-1}; ^{1}H NMR (90 MHz, in $CDCl_3$) δ=1.45 (3H, t, J=7.2 Hz, $COOCH_2C\underline{H}_3$), 2.26 (3H, s, $NHCOC\underline{H}_3$), 2.52 (3H, s, $SCOC\underline{H}_3$), 4.45 (2H, q, J=7.2 Hz, $COOC\underline{H}_2CH_3$), 6.90 (1H, bs, $N\underline{H}COCH_3$), 7.1—7.9 (3H, m, H-5,6,7), 8.30 (1H, dm, J=9.6 Hz, H-4), and 9.49 (1H, dm, J=9.6 Hz, H-8). Found: C, 61.50; H, 5.15; N, 4.20; S, 9.65%. Calcd for $C_{17}H_{17}O_4NS$: C, 61.61; H, 5.17; N, 4.23; S, 9.68%. **9** (66 mg, 27%, greenish blue micro needles, mp 181—181.5°C); IR (KBr) 3266, 1695, 1659, and 1541 cm^{-1}; ^{1}H NMR (90 MHz, in $CDCl_3$) δ=1.40 (3H, t, J=7.2 Hz, $COOCH_2C\underline{H}_3$), 2.25 (3H, s, $NHCOC\underline{H}_3$), 4.36 (2H, q, J=7.2 Hz, $COOC\underline{H}_2CH_3$), 7.0—7.8 (3H, m, H-5,6,7), 7.97 (1H, dm, J=9.6 Hz, H-4), 8.47 (1H, s, H-2), and 9.49 (1H, dm, J=9.6 Hz, H-8); ^{13}C NMR (22.5 MHz, in $CDCl_3$) δ=14.6, 23.7, 59.9, 114.6, 124.0, 125.4, 127.3, 133.3, 133.9, 134.5, 137.9, 138.1, 139.5, 165.2, and 169.2. Found: C, 70.28; H, 5.91; N, 5.52%. Calcd for $C_{15}H_{15}NO_3$: C, 70.02; H, 5.88; N, 5.44%.

Ethyl 2-Methylazuleno[1,2-*d*]thiazole-9-carboxylate (10). To a solution of **8** (78 mg) in tetrahydrofuran (7 ml) and ether (14 ml) which had been cooled in an ice bath, a solution of potassium hydroxide (148 mg) in water (7 ml) was added, drop by drop, under an atmosphere of nitrogen, after which the solution was stirred for 20 min. Further, hydrochloric acid (7 ml) was added and then the solution was stirred for 12 h at room temperature. The reaction mixture was diluted with water and extracted with dichloromethane. The extract was washed with water, and evaporated. The residue was chromatographed on a silica-gel column with benzene–ethyl acetate (9:1). The purple effluent was freed from the solvent to give **10** (42 mg, 41%) as purple prisms; mp 107.5—108°C; IR (KBr) 1683, 1437, 1417, and 1196 cm^{-1}; ^{1}H NMR (90 MHz, in $CDCl_3$) δ=1.51 (3H, t, J=7.2 Hz, $COOCH_2C\underline{H}_3$), 2.96 (3H, s, $C\underline{H}_3$-2), 4.52 (2H, q, J=7.2 Hz, $COOC\underline{H}_2CH_3$), 7.4—8.0 (3H, m, H-5,6,7), 8.97 (1H, dm, J=9.0 Hz, H-4), and 9.68 (1H, dm, J=10.3 Hz, H-8); ^{13}C NMR (22.5 MHz, in $CDCl_3$) δ=14.7, 20.5, 60.3, 106.4, 127.6, 128.2, 131.6, 133.7, 137.2, 138.6, 142.2, 146.8, 148.6, 164.2, and 168.2. Found: C, 66.68; H, 4.80; N, 5.23; S, 11.95%. Calcd for $C_{15}H_{13}NO_2S$: C, 66.40; H, 4.83; N, 5.16; S, 11.82%.

2-Methylazuleno[1,2-*d*]thiazole (11). A mixture of **10** (23 mg) and 100% phosphoric acid (5 ml) was heated for 1 h at 90°C. After cooling, the reaction mixture was diluted with water and extracted with benzene. The dried extract was evaporated to give a residue. The residue was chromatographed on a silica-gel column with benzene. The blue effluent was from the solvent to give **12** (15 mg, 87%) as deep blue prisms; mp 139—139.5°C; IR (KBr) 1574, 1514, 1378, 1146, and 786 cm^{-1}; ^{1}H NMR (90 MHz, in $CDCl_3$) δ=2.90 (3H, s, $C\underline{H}_3$-2), 7.0—7.7 (3H, m, H-5,6,7), 7.33 (1H, s, H-9), 8.22 (1H, dm, J=10.3 Hz, H-8), and 8.81 (1H, dm, J=9.0 Hz, H-4); ^{13}C NMR (22.5 MHz, in $CDCl_3$) δ=20.6, 105.7, 122.8, 123.5, 128.0, 131.9, 136.5, 136.8, 140.4, 144.2, 150.1, and 166.0. Found: C, 72.55; H, 4.47; N, 6.72; S, 16.20%. Calcd for $C_{12}H_9NS$: C, 72.32; H, 4.55; N, 7.03, S, 16.09%.

Reactions of Schiff Bases with Superoxide Ion in Acetonitrile

Katsuyoshi SHIBATA,* Yoshiyuki SAITO, Katsuyoshi URANO, and Masaki MATSUI
Department of Industrial Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu 501-11
(Received April 2, 1986)

Synopsis. The reactions of Schiff bases such as *N*-benzylideneanilines with superoxide ion in acetonitrile under mild conditions gave the cyanomethyl adducts, 3-arylamino-3-arylpropionitriles, as the main products in relatively good yields. In the case of *N*-(4-nitrobenzylidene)aniline, the adduct was further oxidized to β-anilino-4-nitrocinnamonitrile. No oxidative products such as amides were obtained except in the reactions of *N*-(4-chloro- and 4-nitrobenzylidene)aniline.

Although superoxide ion reacted with many organic compounds as oxidant, reductant, nucleophile, base, or radical,[1] there have been only a few reports on carbon–nitrogen double-bonds with superoxide ion. These reports have been on the oxidations of iminium fluorosulfates and nitrones to the corresponding amide and hydroxamic acids respectively;[2] the reaction of hydrazine to azine,[3] and the reactions of oximes to *O,O'*-methylenebis(oxime)s in the presence of Pd(II) and dichloromethane.[4]

We found that *N*-benzylideneanilines (**1**) with a C=N bond reacted with superoxide ion and acetonitrile in the presence of dicyclohexano-18-crown-6(DCC), resulting in the formation of 3-anilino-3-phenylpropionitriles (**2**) as the main product. This paper will describe the reactions of the various Schiff bases with superoxide ion in acetonitrile.

Results and Discussion

Substituted *N*-benzylideneanilines (**1**) and DCC were dissolved in dry acetonitrile, after the addition of powdered KO_2, the mixture was stirred for 1 h under an argon atmosphere at room temperature. Then the solution was treated with water to decompose the unreacted KO_2, and extracted with ether. The results are summarized in Scheme 1 and Table 1. Cyanomethyl adducts (**2a—d**, **2f—i**) to the C=N bond of **1** were obtained as the main products in 32—71% yields. In addition, benzaldehydes (**4**), anilines (**5**), *trans*- and *cis*-cinnamonitriles (**6** and **7**), and benzyl alcohols (**8**) were obtained in low yields. In these cases of R_1=Cl and NO_2 (**1d** and **1e**), the **3d** and **3e** amides, derived from the oxidation of the C=N bond with superoxide ion, were obtained in about 15% yields. No 3-anilino-3-(4-nitrophenyl)propionitrile (**2e**) was afforded from 4-nitrobenzylideneaniline (**1e**). It can be assumed that **2e** was further dehydrogenated by superoxide ion to form

a) This signal was varied from m to t by the addition of D_2O.

the olefin **9e**. Compound **1** might be decomposed to **4** and **5** by base (O_2^- or HO_2^-). Compound **4a** reacts with superoxide ion in acetonitrile to yield **6a—8a**.[5] We also observed the formations of **6a—8a** under the same conditions as the reaction of **1a**.

Shrader has obtained **2a** in a 54% yield by photo-ring-opening reaction of 1,5-diphenyl-2-pyrazoline under 22 h irradiation.[6] On the other hand, the method using superoxide ion, (**2a**) has given a better yield (71%) in a shorter reaction time (1 h).

Similar reactions were carried out with cyclohexyl-, 1-naphthyl-, and 2-naphthyl-substituted compounds instead of the phenyl group of **1**. The results are summarized in Table 2. When *N*-(hexahydrobenzylidene)aniline (**10**) reacted with superoxide ion for 1 h at 60°C, the cyanomethyl adduct (**11**) was obtained in a 12% yield: however, no cyanomethyl adduct was afforded from *N*-benzylidenecyclohexylamine (**12**) even 20 h at 60°C. In the cyanomethylations of naphthyl-substituted Schiff bases, no difference in reactivity was observed between 1-naphthyl- and 2-naphthyl-substituted Schiff bases. *N*-Naphthyl-substituted Schiff bases (**13**, **15**, **21**) gave cyanomethyl adducts (**14**, **16**, **22**) in lower yields than C-substituted ones (**17**, **19**). The physical properties of cyanomethyl adducts are summarized in Tables 3 and 4.

On the basis of the results mentioned above, the formation of **2** is explained by Scheme 2. In the reaction of **1**, superoxide ion abstracts the hydrogen atom from acetonitrile, thus giving cyanomethyl radical. This cyanomethyl radical attacks the carbon of the C=N bond and gives cyanomethyl adducts (**2**) via radical

Table 4. Melting Points and Analytical Data of 3-Anilino-3-cyclohexylpropionitrile (**11**) and 3-Aryl-3-(arylamino)propionitriles (**14**, **16**, **18**, **20**, **22**)

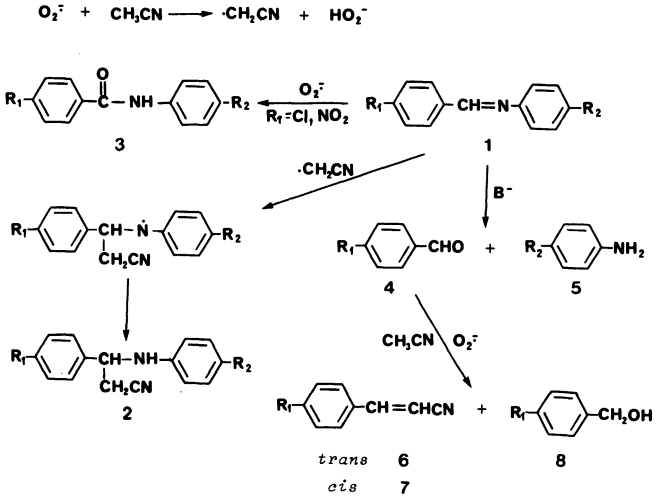

Scheme 2.

intermediates. Oae et al. have reported that diaryl sulfide reacted with superoxide ion in acetonitrile to yield bis(arylthio)acetonitrile as the main product; its formation mechanism might be via the cyanomethyl radical.[7] When R_1=NO_2 and Cl, the electron density of the carbon of the C=N bond is decreased, and **3** are obtained by the nucleophilic attack of superoxide ion. In the case of R_1=NO_2, the resulting adduct is further oxidized to **9e**. On the other hand, **1** are decomposed to **4** and **5** by bases, and **4** further reacts with acetonitrile and superoxide ion to yield **6**—**8**.

Experimental

Melting points are uncorrected. NMR spectra were measured by the use of a JEOL GX-270 Spectrometer in a $CDCl_3$ solution; the chemical shifts were expressed in units from the internal Me_4Si. Mass spectra were measured by means of a Hitachi M-52 Spectrometer (20 eV). IR spectra were recorded over KBr disks with a JASCO A-302 Spectrometer. Gas chromatography was performed on a Shimadzu 4C-PF Gas chromatograph (2% OV-1 or 5% FFAP).

Materials. *N*-Benzylideneanilines (**1**) and the various Schiff bases were prepared from the corresponding aldehydes and amines. The resulting Schiff bases were recrystallized from ethanol. Pottasium superoxide (Alfa) was crushed and pulverized in a dry atmosphere. The acetonitrile was purified by distillation in the presence of P_2O_5 and stored Molecular Sieves (3A, 1/16). Dicyclohexano-18-crown-6 (Tokyo Kasei) was used as received.

General Procedure. *N*-Benzylideneaniline (**1a**) (300 mg, 1.65 mmol) and DCC (300 mg, 0.81 mmol) were dissolved in dry acetonitrile (50 cm^3). After powdered KO_2 (500 mg, 7.04 mmol) has been added to the solution, the mixture was stirred under an argon atmosphere. After 1 h, water (50 cm^3) was slowely added to decompose the residual KO_2. The mixture was extracted with ether in the presence of NaCl. The ether layer was dried over $MgSO_4$ and evaporated (rotary). The extract was separated by thin-layer chromatography (Merck, Silica Gel 60 PF_{254}; hexane:dichloromethane=1:2).

(Received April 28, 1986)

Synopsis. The title compounds (indolo[2,3-*b*][1]azaazulenes) were synthesized from 2-hydrazino-1-azaazulene and cyclohexanone utilizing Fischer's indole synthesis, followed by dehydrogenation of the *N*-acetylated tetrahydro precursor with DDQ. Structures of the neutral and cationic species of these compounds were discussed on the basis of the spectral data.

We have prepared several troponoid compounds fused with an indole ring.[2] We now wish to report herein the synthesis of the first examples of 1-azaazulene[3] fused with a pyrrole or an indole ring.

Condensation of 2-hydrazino-1-azaazulene (**1**)[4] with various ketones and an aldehyde readily gave the corresponding hydrazones: i.e. **2** (with cyclohexanone), **3** (with cycloheptanone), **4** (with acetone), **5** (with ethyl methyl ketone), and **6** (with phenylacetaldehyde). Among these hydrazones, only **2** was managed to be led to the pyrrolo[2,3-*b*][1]azaazulene derivative (**7**) by the application of Fischer's indole synthesis, whereas on employing the similar procedures the conversion of other hydrazones **3**—**6** into the corresponding pyrrolo-[2,3-*b*][1]azaazulenes has remained unsuccessful because of the profound decomposition of the starting materials accompanied by the formation of many complex products.

Attempts of dehydrogenation of **7** with chloranil or DDQ (2,3-dichloro-5,6-dicyano-*p*-benzoquinone) failed mainly due to the exclusive precipitation of an unidentified, dark blue solid, from which no desired product was liberated. However, treatment of its *N*-acetyl derivative **8** with DDQ yielded the dehydrogenated *N*-acetyl compound (**9**), which in turn was led to the parent title compound (indolo[2,3-*b*][1]-azaazulene, **10**) on acid or alkaline hydrolysis.

Physical data for the structural proof for all these compounds are given in the Experimental section. Usful ^{1}H NMR parameters of the pryyolo- and indolo-1-azaazulenes **7**—**10** are summarized in Table 1. The position (N-5) of the acetyl group of **8** and **9** are derived from the evidence of the considerable down-field shifts (0.5 and 1.2 ppm) of H-4 signals of these compounds (compared with those of **7** and **10**, respectively) apparently due to an anisotropic effect of the *N*-acetyl group.[5] Moreover, since the UV spectra of **7** and **10** closely resemble those of **8** and **9**, respectively, these compounds are considered to exist predominantly in 5*H*-cyclohepta[4,5]pyrrolo[2,3-*b*]indole forms (**7** and **10**) rather than in their tautomeric 6*H*-forms. An appreciable down-field shift (0.6 ppm) observed for H-1 signal of **10** (in $CDCl_3$, when compared with that of H-4) can be explained by an anisotropic effect caused by the ring current of the 1-azaazulene moiety that is situated in the vicinity.[6] The divergences of the vicinal coupling constants suggests some degree of bond alternation in the seven-membered ring of **7**—**10**, as was observed in the case of azuleno[1,2-*b*]thiophene.[7]

The signals of the seven-membered ring protons of **7**

and **10** in trifluoroacetic acid-*d* show a down-field shift of 0.2—0.55 ppm (when compared with the corresponding compounds measured in $CDCl_3$, whereas those of the benzene ring protons of **10** show an almost negligible shift (ca. 0.1 ppm) in the acid (see Table 1). This suggests that the positive charge of the cation derived from **10** in trifluoroacetic acid is delocalized mostly over the 1-azaazulene ring (as in **11**) rather than over the 18π peripheral tetracyclic ring system **12**.

Experimental†

Melting points were determined with a Yanagimoto MP-S3 and are uncorrected. Column chromatography was performed with Wako C-200 silica gel. UV and IR spectra were taken on Hitachi 345 and Shimadzu Multipurpose MPL 50L spectrophotometers, respectively. NMR spectra were recorded with a JEOL JNM-4H-100 (100 NHz at 30 °C) or JEOL GX400 (400 MHz, for **9** and **10**) with TMS as an internal standard. The assignments of all signals were made by employing a first-order analysis with the aid of decoupling technique and the parameters were confirmed by a computer-assisted simulation analysis using an NEC 9801F Personal Computer[8]; those values are summarized in Table 1. Mass spectra were taken on a Hitachi RMS-4 low-resolution instrument at 70 eV, and are given in terms of *m/z* (rel intensity).

Cyclohexanone Cyclohepta[*b*]pyrrol-2-ylhydrazone (2). A solution of 4.5 g (27 mmol) of **1**[4] and 3.9 g (40 mmol) of cyclohexanone in 86 cm^3 of ethanol was refluxed for 15 min. The solvent and excess cyclohexanone was evaporated in vacuo and the residue was recrystallized from acetonitrile to give **2** as dark brown plates (4.9 g, 76%): mp 152—153 °C; UV (MeOH) 279, 288, 316, 435, and 490 sh nm (log ε 4.43, 4.40, 4.22, 4.07, and 3.52); IR (KBr) 3185 (NH), 1620 sh, and 1600 cm^{-1} (C=N, C=C); ^1H NMR ($CDCl_3$) δ=1.5—2.0 (6H, m, 2H-3',4',5'), 2.3—2.6 (4H, m, 2H-2',6'), 6.85 (1H, brs, H-3), 7.1—7.5 (3H, m, H-5,6,7), and 7.7—8.0 (3H, m, H-4,8, NH); MS *m/z* 239 (M^+, 100), 196 (76), 144 (90), 116 (40), and 41 (79).

Found: C, 75.47; H, 7.26; N, 17.32%. Calcd for $C_{15}H_{17}N_3$: C, 75.28; H, 7.16; N, 17.56%.

Cycloheptanone Cyclohepta[*b*]pyrrol-2-ylhydrazone (3). Similar procedures for **2** were followed. Thus 3.7 g (23 mmol) of **1** and 2.6 g (23 mmol) of cycloheptanone in refluxing ethanol (75 cm^3, for 45 min) gave **3** as dark brown plates (4.3 g, 74%): mp 121—122 °C (from hexane); UV (EtOH) 280, 288, 324, 385, 398, 444, 463 sh, and 495 sh nm (log ε 4.43 4.40, 4.18, 4.03, 4.01, 3.83, 3.75, and 3.33); IR (KBr) 3165 (NH), 1620 sh, and 1600 cm^{-1} (C=N, C=C); ^1H NMR ($CDCl_3$) δ=1.4—2.1 (8H, m, 2H-3',4',5',6'), 2.4—2.8 (4H, m, 2H-2',7'), 7.00 (1H, brs, H-3), 7.2—7.6 (3H, m, H-5,6,7), and 7.8—8.3 (3H, m, H-4,8, NH); MS *m/z* 253 (M^+, 100), 252 (47), 196 (55), 144 (81), and 116 (27).

Found: C, 75.74; H, 7.51; N, 16.57%. Calcd for $C_{16}H_{19}N_3$: C, 75.85; H, 7.56; N, 16.59%.

Acetone Cyclohepta[*b*]pyrrol-2-ylhydrazone (4). Similar procedures for **2** were followed. Thus 100 mg of **1** and 30.4 mg of acetone in refluxing ethanol (20 cm^3, for 60 min) gave **4** as dark amber plated (86 mg, 69%): mp 147—147.5 °C (from hexane); UV (EtOH) 280, 288, 325, 386, 400, 444, and 495 sh nm (log ε 4.51, 4.46, 4.18, 4.02, 4.01, 3.84, and 3.32); IR (KBr) 3170 (NH), 1608, and 1600 cm^{-1} (C=N, C=C); ^1H NMR ($CDCl_3$) δ=1.93 (3H, s, Me), 2.09 (3H, s, Me), 7.00 (1H, brs, H-3), 7.2—7.6 (3H, m, H-5,6,7), 7.8—8.1 (2H, m, H-4,8), and 8.85 (1H, m, NH); MS *m/z* 199 (M^+, 73), 184 (100), 143 (40), 116 (51), and 89 (30).

Found: C, 72.45; H, 6.64; N, 21.14%. Calcd for $C_{12}H_{13}N_3$: C, 72.34; H, 6.58; N, 21.09%.

Ethyl Methyl Ketone Cyclohepta[*b*]pyrrol-2-ylhydrazone (5). Similar procedures for **2** were followed. Thus 100 mg of **1** and 38 mg of ethyl methyl ketone gave **5** as dark amber needles (90 mg, 67%) after purification by chromatography in a column of alumina with CH_2Cl_2 as an eluant: mp* 113.5—114 °C (from hexane); UV* (EtOH) 280, 288, 322, 332, 382, 400, 447, 464 sh, and 496 sh nm (log ε 4.48, 4.44, 4.18, 4.17, 4.02, 4.00 3.81, 3.73, and 3.31); IR* (KBr) 3160 (NH), 1605, and 1595 cm^{-1} (C=N, C=C); ^1H NMR* ($CDCl_3$) δ=1.17 (3H, t, J=6.5 Hz, CH_3-CH_2-), 1.89 (3H, s, Me), 2.38 (2H, q, J=6.5 Hz, CH_2), 7.03 (1H, brs, H-3), 7.2—7.6 (3H, m, H-5,6,7), 7.8—8.1 (2H, m, H-4,8), and 8.95 (1H, m, NH), besides these, there exist signals due to a small proportion (ca. 15%) of **5** (presumably in the Z-form) at δ=1.08 (t). 2.06 (s), and 2.30 (q); MS* *m/z* 213 (M^+, 35), 184 (100), 144 (27). 143 (27), and 116 (36).

Found*: C, 73.10; H, 6.85; N, 19.60%. Calcd for $C_{13}H_{15}N_3$: C, 73.21; H, 7.09; N, 19.70%.

Phenylacetaldehyde Cyclohepta[*b*]pyrrol-2-ylhydrazone (6). Similar procedures for **2** were followed. Thus 120 mg of **1** and 75.5 mg of phenylacetaldehyde in refluxing ethanol (25 cm^3, for 30 min) gave **6** as dark brown needles (125 mg,

†We are greatly indebted to Mr. H. Kuwano, Dr. T. Kinoshita, and Mr. K. Ono, the Sankyo Co., Ltd., for the measurements of the 400 MHz NMR, mass spectra, and the elemental analysis.

*For specimen consisting of a ca. 85 : 15 mixture of E- and Z-form (by NMR), because their separation could not be achieved by recrystallization or chromatography.

63%): mp 143.5—144°C (from benzene–hexane); UV (EtOH) 278, 287, 317, 380, 398, 440, 462 sh, and 495 sh nm (log ε 4.47, 4.47, 4.22, 4.01. 3.95, 3.83, 3.76, and 3.31); IR (KBr) 3170 (NH) and 1610 cm^{-1} (C=N, C=C); ^1H NMR ($CDCl_3$) δ= 3.80 (2H, d, J=4.5 Hz, CH_2), 6.80 (1H. brs, H-3), 7.1—7.9 (12H, m, H-4,5,6,7,8, CH, C_6H_5, NH); MS m/z 261 (M^+, 18), 170 (100), 144 (22), 116 (18), and 91 (17).

Found C, 78.09; H, 5.73; N, 15.96%. Calcd for $C_{17}H_{15}N_3$: C, 78.13; H, 5.79; N, 16.08%.

1,2,3,4-Tetrahydro-5*H*-cyclohepta[4,5]pyrrolo[2,3-*b*]indole (7). A solution of 4.9 g of **2** in 247 cm^3 of 1 M sulfuric acid (1 M=1 mol dm^{-3}) was refluxed for 5 h. After cooling, the mixture was diluted with cold water, brought to pH 9—10 with 2 M NaOH, and extracted with benzene. The organic layer was dried (Na_2SO_4), treated with active carbon, and evaporated in vacuo. The residue was recrystallized from ethanol to give **7** as dark red needles (1.64 g, 36%): mp 243—244°C; UV (MeOH) 233, 258, 312, 340, 417, 522, and 560 sh nm (log ε 4.16, 4.34, 4.63, 4.22, 3.75, 2.69, and 263), (MeOH+0.1 M HCl) 230, 259, 265, 322, and 350 sh nm (log ε 4.31, 4.38, 4.35, 4.19, and 4.35); IR (KBr) 3100 (NH), 2930, 2840 (CH_2), and 1605 cm^{-1} (C=N and C=C); ^1H NMR, see Table 1.

Found: C, 80.67; H, 6.07; N, 11.92%. Calcd. for $C_{15}H_{14}N_2$: C, 81.05; H, 6.35; N, 11.60%.

5-Acetyl-1,2,3,4-tetrahydro-5*H*-cyclohepta[4,5]pyrrolo[2,3-*b*]indole (8). A mixture of 1.0 g of **7** and 10 g of acetic anhydride was gently refluxed for 2 h. After cooling, it was diluted with water and brought to pH 8—9 with a saturated aqueous $NaHCO_3$. The ppt was filtered off and the filtrate was extracted with $CHCl_3$. The organic layer was evaporated in vacuo. The residue combined with the above ppt was chromatographed in a column of silica gel with chloroform as an eluant, giving **8** as red-violet needles (1.2 g, 70%): mp 133—135°C. (from cyclohexane): UV (MeOH) 232, 258, 313, 341, 417, 510, and 550 sh nm (log ε 4.14, 4.32, 4.59, 4.17, 3.71, 2.61, and 2.55); IR (KBr) 2930, 2850 (CH_2) and 1700 cm^{-1} (C=O); ^1H NMR, see Table 1.

Found: C, 77.03; H, 6.02; H, 10.74%. Calcd for $C_{17}H_{16}N_2O$: C, 77.25; H, 6.10; N, 10.60%.

5-Acetyl-5*H*-cyclohepta[4,5]pyrrolo[2,3-*b*]indole (9). A solution of 0.5 g (1.9 mmol) of **8** and 0.9 g (4 mmol) of DDQ in 80 cm^3 of dry benzene was refluxed for 5 h. After cooling, the ppt was filtered off and the filtrate was evaporated in vacuo. The residue and the above ppt were combined and triturated with $CHCl_3$. The combined $CHCl_3$ solution was washed with saturated aqueous $NaHCO_3$ and concentrated in vacuo. The residue was chromatographed over silica gel with $CHCl_3$ as an eluant, giving **9** as red-violet needles (0.34 g, 69%): mp 200—202°C (from benzene); UV (MeOH) 241, 284, 297, 325, 480, 500, and 545 sh nm (log ε 4.27, 4.28, 4.29, 4.56, 3.12, 3.11, and 2.83); IR (KBr) 1695 cm^{-1} (C=O); ^1H NMR, see Table 1; MS m/z 260 (M^+, 39), 218 (100), 190 (14), and 164 (5).

Found: C, 78.22; H, 4.44; N, 10.79%. Calcd for $C_{17}H_{12}N_2O$: C, 78.44; H, 4.65; N, 10.76%.

5*H*-Cyclohepta[4,5]pyrrolo[2,3-*b*]indole (10). A solution of 0.1 g of **9** in 10 cm^3 of 6 M HCl was refluxed for 5 h and then, after cooling, diluted with 10 cm^3 of water. The ppt was filtered off and recrystallized from ethanol, giving **10** as red-brown needles (0.084 g, 100%): mp>300°C (decomp); UV (MeOH) 240, 284, 296, 325, 472, 495, and 545 sh nm (log ε 4.30, 4.33, 4.32, 4.57, 3.17, 3.16, and 2.84), (MeOH+0.1 M HCl) 263, 282, 335, and 415 sh, nm (log ε 4.30, 4.31, 4.25, and 3.94); IR (KBr) 3050 (NH), 1620, and 1605 cm^{-1} (C=N, C=C); ^1H NMR, see Table 1; MS m/z 218 (M^+, 100), 190 (16), 164 (5), and 109 (4).

Found: C, 82.73; H, 4.65; N, 12.87%. Calcd for $C_{15}H_{10}N_2$: C, 82.54; H, 4.62; N, 12.84%.

Hydrolysis of **9** with 2 M NaOH similarly gave **10** in a quantitative yield.

We are grateful to Professor Toyonobu Asao and Dr. Tadayoshi Morita (Tohoku University) for valuable discussions, and to Mr. Shuji Ohmichi and Professor Seiichi Hirakawa (Shinshu University) for their kind cooperation in preparing some of the hydrazones and measuring the mass spectra.

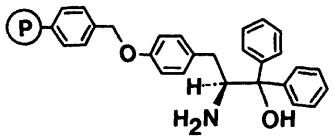
Synopsis. When THF-borane (1/1) and aromatic ketone were supplied continuously to the column containing polymer-supported (*S*)-(−)-2-amino-3-(*p*-hydroxyphenyl)-1,1-diphenyl-1-propanol, the chiral product, secondary benzylic alcohol, could be obtained successfully (>90% ee). Large quantities of highly optically pure alcohol could be produced by the continuous flow system by the use of only a small amount of polymeric auxiliary.

Though many procedures have been known for syntheses of optically active alcohols by the asymmetric induction in solutions,[1] there are relatively few methods involving the use of the chiral polymer-supported reagent.[2] We have reported that polymer-supported (*S*)-(−)-2-amino-3-(*p*-hydroxyphenyl)-1,1-diphenyl-1-propanol (**1**) was an excellent chiral auxiliary reagent for asymmetric reduction of ketones with BH_3·THF.[3] This insoluble cross-linked polystyrene gel



1

supporting chiral amino alcohol, which was prepared from L-tyrosine, could be readily recovered as its hydrochloride by simple filtration after acidic hydrolysis of the reaction mixture. Recovered polymer-supported hydrochloride was neutralized and could be reused. Chiral product secondary alcohol was obtained from the filtrate quantitatively with high enantioselectivity (>90% ee). Indeed the high chemical and enantiomeric yields were reproducible during several recyclings.[3,4]

During studies for the asymmetric reduction with polymer-supported chiral amino alcohol **1**-borane complex, an interesting fact was observed. After reduction of ketone with the polymeric reagent, careful filtration of the reaction mixture under a dry nitrogen stream without hydrolytic process gave the THF solution, which was successively hydrolyzed to yield the optically active secondary alcohol quantitatively with high enantioselectivity. Even after the filtration the chiral polymer containing the amino alcohol-borane complex had the ability to induce chirality in the ketone reduction with borane. Thus, if borane and substrate ketone are supplied continuously to the polymer complex, the chiral product may be obtained successively.

In a preliminary experiment, repeated asymmetric reduction in the batch system was attempted. Glassware being made up of two flasks (**A**, **B**) and glass filter was used for this system (Fig. 1). A THF solution of the chiral product yielded in the asymmetric reduction in the flask **A** was filtered into the flask **B**. Table 1 lists the results obtained from the batch system in the asymmetric reduction of valerophenone with **1**-BH_3 complex. In the first run valerophenone was reduced asymmetrically (90% ee) with the reagent prepared from **1** and 2 equiv of BH_3. Reaction was completed within a few minutes in THF at ambient temperature. After separation of the product by filtration under nitrogen 2 equiv of borane and 0.8 equiv of valerophenone were added again (flask **A**). Another optically active 1-phenyl-1-pentanol was obtained in 82% ee from the filtrate (Batch No. 2). In this batch system optical yields were reproducible on five repeated runs. Accumulated yield of isolated optically active alcohol was about 2.4 times the molar quantity of the chiral auxiliary reagent **1** after five repetitions. Although the conversion of ketone to alcohol was 100% by GC analysis, isolated yield was somewhat low owing to handling loss during the purification by distilling a small amount of the product in each fraction. Asymmetric reduction of some other alkyl phenyl ketones was performed. Large amount of optically active purified alcohols were isolated in this system. Results are summarized in Table 2.

The fact that the product was not bonded covalently to the polymeric chiral complex and optically active alcohol was obtained from the filtrate successively by hydrolysis implies this reaction could be conducted

Table 1. Asymmetric Reduction of Valerophenone in Batch System

Batch No.	Optical yield[a]/% (Config)	[Isolated yield]/[**1**] (Accumulated)

a) 2.49 g (4.27 mmol) of **1** was used. b) Only eluent (THF) was made to flow. c) 1-Phenylpentanol remained in gel.

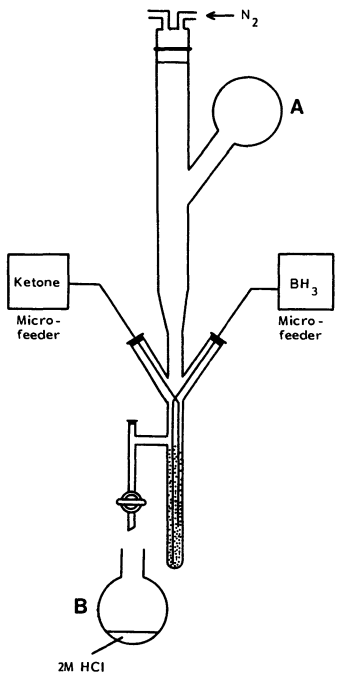

Fig. 2. Apparatus for conducting continuous flow reaction.

by a continuous flow system which avoids the repetition of a batch system process. Thus, large quantities of the highly optically pure product could be yielded through the continuous flow system by the use of only a small amount of polymeric chiral auxiliary **1**.

The procedure found to be most effective involves the two slow injections of 0.8:1.0 molar ratio of valerophenone and borane in THF to the bottom of a THF-presaturated column containing polymeric **1**–BH_3 complex through a syringe needle (Fig. 2). The polymeric **1**–BH_3 complex was prepared in the flask **A** prior to use this system. The flow rate and the ratio of borane and the ketone was controlled by means of microfeeder. The overflowed THF solution was collected in the flask **B** in which alkoxyborane was hydrolyzed with 2M HCl (1 M=1 moldm^{-3}) to give the optically active alcohol continuously in high enantioselectivity (83—93% ee, Table 3). Optically active alcohol of 2.6 equiv to the chiral auxiliary **1** was obtained from six fractions. Rate of injection seems not to be an important factor for the asymmetric reduction in this system (Fraction No. 1—3).

A noteworthy feature of the continuous flow method is the absence of destruction of the chiral gel since no stirring was required. The chiral gel column method reported in this note offers several advantages over alternative modes, especially with regard to the extreme tractability of the reaction and the yield of large quantities of optically active alcohol by the use of the small amount of chiral auxiliary. Such a procedure as well as high enantioselectivity would be required for the practical asymmetric synthesis.

Experimental

All reactions were carried out under an atmosphere of nitrogen. Tetrahydrofuran (THF) was heated under reflux over sodium metal and distilled from lithium aluminum hydride in a nitrogen atmosphere. Valerophenone, acetophenone, and propiophenone commercially purchased were dried and distilled over calcium hydride and checked for purity by GLPC and ^1H NMR. Borane was prepared by the reaction of sodium borohydride with trifluoroborane–diethyl ether (1/1) according to the procedure of Brown.[5] (*S*)-Tyrosyne (from Kyowa Hakko Co.) was used without purification. Polymer-supported (*S*)-(−)-2-amino-3-(*p*-hydroxyphenyl)-1,1-diphenyl-1-propanol (**1**) was prepared from chloromethylated polystyrene gel (2% cross linking, 2.92 meq Cl/g) by method described previously.[3,6] GLPC analysis was performed on a Yanaco G180 instrument with a stain-

less steel analytical column (3 mm×3 m) packed with PEG20M on Diasolid L. ^{1}H NMR spectra were recorded by a JEOL JNM PMX-60 spectrometer. Optical rotations were measured with a microcell. IR spectra were recorded by JASCO A-3 instrument for Nujol mulls. TLC was run on silica gel 60F-254 precoated plates with chloroform as mobile phase.

Repeated Asymmetric Reduction of Valerophenone with Polymer-Supported Chiral Amino Alcohol (1)-Borane Complex in Batch System. In the flask **A** (Fig. 1) the asymmetric reducing agent was prepared from **1** (1.6 meq amino alcohol/g, 3.0 g) and 2 equiv of borane (9.6 mmol) at first by the method described previously.[3] After addition of THF solution of valerophenone (0.6 g, 3.7 mmol) reaction was checked by TLC. When no ketone was detected by TLC the polymer was filtered through glass filter under nitrogen. THF solution collected in the flask **B** was hydrolyzed with 2M HCl and THF was evaporated. The ether extract was washed with saturated NaCl (2×10 ml), dried ($MgSO_4$) and evaporated to give a colourless oil. The conversion was checked by GLPC (100%). The crude product was then distilled by bulb-to-bulb distillation to give 1-phenyl-1-pentanol (0.33 g); α_D^{20} +1.80° (neat, l=1.0 cm), corresponding to an enantiomeric excess of 90% ee.[7] To the polymer kept in the flask **A** THF (10 ml), borane (9.6 mmol), and valerophenone (3.7 mmol) was added again. After ketone was reduced the same work up as above was used to give (*R*)-1-phenyl-1-pentanol of 82% ee.

Asymmetric Reduction of Valerophenone Using Continuous Flow System. The polymer-supported chiral reagent prepared in the flask **A** (Fig. 2) from **1** (1.71 meq of amino alcohol/g, 2.49 g) and 2 equiv of borane (8.5 mmol) by the method described previously, was transfered into the column by turning the apparatus upside down. The column (the inside diameter of 1 cm) was filled with a 14 cm of the column of the chiral gel. Borane (0.14 mmol min^{-1}) and ketone (0.11 mmol min^{-1}) were injected at the bottom of the column through the syringe needle by means of microfeeder. The overflow was collected in the flask **B** containing 2M HCl. After 30 min collected fraction was worked up according to the procedure outlined above to give (*R*)-1-phenyl-1-pentanol of 87% ee. After four fractions were collected only eluent (THF) was made to flow to give the same alcohol of 83% ee (Fraction No. 5). by means of hydrolysis of the chiral gel taken out of the column, the another fraction of the same alcohol was obtained in 85% ee (Fraction No. 6).

Synopsis. A mild, simple, and direct method for the synthesis of some new 1-alkoxycarbonylamino-3-sulfonylpyrrole derivatives by reaction of (alkoxycarbonylazo)alkenes with β-keto sulfones is reported.

The chemistry of the pyrrole ring received considerable attention by several authors, mainly due to the fact that this heterocycle is present in some natural products. In addition, several pyrrole derivatives manifested to have attractive biological and pharmacological activities.[1]

Considering this wide interest, during the last few years we particularly intended to a detailed and systematic elaboration of a synthetic strategy able to provide a large number of unknown 1-aminopyrrole derivatives containing various functional groups both at the carbon atoms of the pyrrole ring and, especially, on the amino group linked to the nitrogen heteroatom. The direct preparative procedure of 1-aminopyrrole derivatives investigated in our laboratories is in general based on the nucleophilic attack by an activated methylene group on the heterodiene system of a conjugated azoalkene, affording the formation of the 1,4-adduct intermediate. This preliminary 1,4-conjugate addition (Michael-type) may be followed by an intramolecular condensation between the C=N nitrogen atom and a ketonic carbonyl group in δ-position (esteric carbonyl group showing to be inactive), producing the pyrrole ring closure. In rather different way for each case, these reactions were frequently observed to more satisfactorily take place under copper(II) ions catalysis,[2] affording interesting 1-aminopyrrole derivatives that should result to be with difficulty synthesized by other methods.[1,3] NMR spectra,[4] X-ray crystal structures,[5] and biological activities[6] in part have been already examined and in part are presently in progress. Since the synthesis of variously functionalized 1-aminopyrroles appears to be largely dependent on the nature of conjugated azoalkenes, also the preparation of new classes of these latter derivatives have been extensively studied.[7] By these studies, conjugated azoalkenes demonstrated to represent versatile products and useful intermediates in organic chemistry.

Continuing these investigations, in this paper we report the synthesis of new 1-alkoxycarbonylamino-3-sulfonylpyrroles (**4**) by reaction of (alkoxycarbonylazo)alkenes (**1**) with β-keto sulfones (**2**). These reactions easily proceed at room temperature under magnetic stirring, often showing at first the 1,4-adduct intermediate (**3**) formation. This adduct is unambigously revealed by NMR spectra, exhibiting two doublets at δ=4—5 and δ=5.5—6.5 ppm ascribable to the two CH vicinal protons, in accordance with our previous findings on this matter.[2] The subsequent conversion of this 1,4-adduct intermediate (**3**) into related 1-alkoxycarbonylamino-3-sulfonylpyrrole is then observed, and these latter compounds are isolated in good yields without complicated procedures.

Experimental

Materials and Methods. Yields are of pure isolated products (see Table 1). The reaction times are reported in Table. Melting points were determined in capillary tubes with a Büchi apparatus, and are uncorrected (see Table 1). The products often decompose at melting point. IR spectra were recorded in Nujol mull on a Perkin-Elmer 298 spectrophotometer, and values are expressed in cm^{-1}. ^1H NMR spectra were measured in deuteriochloroform with tetramethylsilane (TMS) as internal standard, using a Varian EM-360L spectrometer at 60 MHz. The chemical shifts are expressed in ppm in respect to TMS, and the coupling constants J in hertz (Hz). The abbreviations used are as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad; D_2O ex, D_2O exchange. Kieselgel 60 was used for chromatography. All the compounds obtained showed a satisfactory elemental analysis. (Alkoxycarbonylazo)alkenes (**1**) were prepared as previously reported.[2] The β-keto sulfones (**2**) were commercial materials, and were used without further purification.

Preparation of 1-Alkoxycarbonylamino-3-sulfonylpyrroles (4a—j). General Procedure. The (alkoxycarbonylazo)alkene (**1**) (2.0 mmol) and β-keto sulfone (**2**) (2.0 mmol) were

a) Melting points are uncorrected and occur with decomposition.

dissolved in tetrahydrofuran (2 ml) and the reaction was allowed to stand at room temperature under magnetic stirring (for reaction time see Table 1) until the reaction is complete (monitored by TLC silica gel). In some cases the formation of the 1,4-adduct intermediate (**3**) was at first observed, and then its conversion into related 1-aminopyrrole (**4**) was revealed. Sometimes the precipitated product (**4**) was isolated in satisfactory purity by filtration, or otherwise tetrahydrofuran was removed under reduced pressure obtaining the crude product (**4**) as residue (for yield see Table 1). The products (**4a—j**) can be further purified by recrystallization from dichloromethane–petroleum ether (40—60 °C) or tetrahydrofuran–pentane (for melting point see Table 1). In some cases, a preliminary purification of the crude product (**4**) by column chromatography on silica gel may be necessary (at first elution with cyclohexane and then with cyclohexane–ethyl acetate mixtures, gradually increasing the amount of ethyl acetate to a 80/20 (v/v) ratio).

Following compounds were prepared by this procedure.

1-Methoxycarbonylamino-2,5-dimethyl-3-methoxycarbonyl-4-(methylsulfonyl)pyrrole (4a). IR: 3275 (NH), 1750, and 1715 (COO), 1290, and 1145 (SO_2). ^{1}H NMR δ=2.27 (6H, s, 2Me), 3.32 (3H, s, SO_2Me), 3.77 (3H, s, COOMe), 3.83 (3H, s, COOMe), 8.91 (1H, s, br, NH, D_2O ex). Found: C, 43.65; H, 5.01; N, 9.02%. Calcd for $C_{11}H_{16}N_2O_6S$: C, 43.42; H, 5.30; N, 9.21%.

1-Methoxycarbonylamino-2,5-dimethyl-3-methoxycarbonyl-4-(*p*-tolylsulfonyl)pyrrole (4b). IR: 3270 (NH), 1765 and 1710 (COO), 1600 (Ar), 1290 and 1150 (SO_2). ^{1}H NMR δ=2.25 (3H, s, Me), 2.4 (3H, s, Me), 2.47 (3H, s, Ar<u>Me</u>), 3.66 (3H, s, COOMe), 3.83 (3H, s, COOMe), 7.52 (4H, q, Ar, J=8.7 Hz), 8.73 (1H, s, br, NH, D_2O ex). Found: C, 53.51; H, 5.42; N, 7.43%. Calcd for $C_{17}H_{20}N_2O_6S$: C, 53.68; H, 5.30; N, 7.37%.

1-Methoxycarbonylamino-2-methyl-3-methoxycarbonyl-4-(phenylsulfonyl)-5-phenylpyrrole (4c). IR: 3275 (NH), 1755 and 1720 (COO), 1600 and 1585 (Ar), 1290 and 1140 (SO_2). ^{1}H NMR δ=2.23 (3H, s, Me), 3.52 (3H, s, COOMe), 3.67 (3H, s, COOMe), 7.13—7.92 (10H, m, Ar), 8.28 (1H, s, br, NH, D_2O ex). Found: C, 59.01; H, 4.69; N, 6.38%. Calcd for $C_{21}H_{20}N_2O_6S$: C, 58.88; H, 4.71; N, 6.54%.

1-Methoxycarbonylamino-2,5-dimethyl-3-ethoxycarbonyl-4-(methylsulfonyl)pyrrole (4d). IR: 3260 (NH), 1760 and 1710 (COO), 1290 and 1150 (SO_2). ^{1}H NMR δ=1.37 (3H, t, COOEt), 2.28 (6H, s, 2Me), 3.33 (3H, s, SO_2Me), 3.82 (3H, s, COOMe), 4.32 (2H, q, COOEt), 8.95 (1H, s, br, NH, D_2O ex). Found: C, 45.03; H, 5.69; N, 9.02%. Calcd for $C_{12}H_{18}N_2O_6S$: C, 45.28; H, 5.70; N, 8.80%.

1-Ethoxycarbonylamino-2,5-dimethyl-3-methoxycarbonyl-4-(*p*-tolylsulfonyl)pyrrole (4e). IR: 3280 (NH), 1755 and 1710 (COO), 1600 (Ar), 1295 and 1145 (SO_2). ^{1}H NMR δ=1.3 (3H, t, COOEt), 2.27 (3H, s, Me), 2.37 (3H, s, Me), 2.47 (3H, s, C_6H_4<u>Me</u>), 3.67 (3H, s, COOMe), 4.23 (2H, q, COOEt), 7.5 (4H, q, Ar, J=8.9 Hz), 8.82 (1H, s, br, NH, D_2O ex). Found: C, 54.99; H, 5.47; N, 7.00%. Calcd for $C_{18}H_{22}N_2O_6S$: C, 54.82; H, 5.62; N, 7.10%.

1-Ethoxycarbonylamino-2,5-dimethyl-3-ethoxycarbonyl-4-(*p*-tolylsulfonyl)pyrrole (4f). IR: 3290 (NH), 1755 and 1715 (COO), 1600 (Ar), 1290 and 1150 (SO_2). ^{1}H NMR δ=0.92—1.52 (6H, m, 2COOEt), 2.27 (3H, s, Me), 2.37 (3H, s, Me), 2.47 (3H, s, C_6H_4<u>Me</u>), 3.87—4.5 (4H, m, 2COOEt), 7.5 (4H, q, Ar, J=8.8 Hz), 8.87 (1H, s, br, NH, D_2O ex). Found: C, 55.69; H, 6.06; N, 6.93%. Calcd for $C_{19}H_{24}N_2O_6S$: C, 55.88; H, 5.92; N, 6.86%.

1-(*t*-Butoxycarbonylamino)-2,5-dimethyl-3-methoxycarbonyl-4-(*p*-tolylsulfonyl)pyrrole (4g). IR: 3330 (NH), 1750 and 1730 (COO), 1600 (Ar), 1290 and 1150 (SO_2). ^{1}H NMR δ=1.52 (9H, s, CMe_3), 2.25 (3H, s, Me), 2.37 (3H, s, Me), 2.45 (3H, s, C_6H_4<u>Me</u>), 3.63 (3H, s, COOMe), 7.47 (4H, q, Ar, J=9.0 Hz), 8.46 (1H, s, br, NH, D_2O ex). Found: C, 56.69; H, 6.47; N, 6.69%. Calcd for $C_{20}H_{26}N_2O_6S$: C, 56.87; H, 6.20; N, 6.63%.

1-(*t*-Butoxycarbonylamino)-2-methyl-3-methoxycarbonyl-4-phenylsulfonyl-5-phenylpyrrole (4h). IR: 3295 (NH), 1755 and 1725 (COO), 1600 and 1585 (Ar), 1275 and 1150 (SO_2). ^{1}H NMR δ=1.3 (9H, s, CMe_3), 2.23 (3H, s, Me), 3.65 (3H, s, COOMe), 7.17—8.0 (10H, m, Ar and NH; 1H, D_2O ex). Found: C, 61.45; H, 5.63; N, 5.69%. Calcd for $C_{24}H_{26}N_2O_6S$: C, 61.27; H, 5.57; N, 5.95%.

1-(*t*-Butoxycarbonylamino)-2-methyl-3-methoxycarbonyl-4-(*p*-tolylsulfonyl)-5-phenylpyrrole (4i). IR: 3290 (NH), 1745 and 1725 (COO), 1600 (Ar), 1300 and 1150 (SO_2). ^{1}H NMR δ=1.3 (9H, s, CMe_3), 2.27 (3H, s, Me), 2.37 (3H, s, C_6H_4<u>Me</u>), 3.68 (3H, s, COOMe), 6.93—7.9 (10H, m, Ar and NH; 1H, D_2O ex). Found: C, 62.15; H, 5.86; N, 5.98%. Calcd for $C_{25}H_{28}N_2O_6S$: C, 61.98; H, 5.83; N, 5.78%.

1-(*t*-Butoxycarbonylamino)-2-methyl-3-ethoxycarbonyl-4-phenylsulfonyl-5-phenylpyrrole (4j). IR: 3280 (NH), 1740 and 1715 (COO), 1600 and 1585 (Ar), 1300 and 1150 (SO_2). ^{1}H NMR δ=1.13—1.5 (12H, s, CMe_3 and COOEt), 2.28 (3H, s, Me), 4.22 (2H, q, COOEt), 7.17—7.97 (11H, m, Ar and NH; 1H, D_2O ex). Found: C, 61.87; H, 5.69; N, 5.61%. Calcd for $C_{25}H_{28}N_2O_6S$: C, 61.98; H, 5.83; N, 5.78%.

Electrocatalysis of the Heat-Treated (5,10,15,20-Tetraphenylporphyrinato)-manganese(III) Halides for Cathodic Reduction of Oxygen

Osamu IKEDA,* Toyosei KOJIMA, and Hideo TAMURA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received December 20, 1985)

Electrocatalysis of the heat-treated (5,10,15,20-tetraphenylporphyrinato)manganese(III) halides (Mn^{III}(TPP)X, X:F^-, Cl^-, Br^-, I^-) for the O_2 reduction in an alkaline solution has been studied by rotating ring-disc electrode technique, and the result was correlated with properties of the heat-treated Mn^{III}(TPP)X, such as magnetic moment and electrical resistivity. The axial ligand X showed noticeable effect on the catalytic activity. The catalytic activity estimated from the overpotential changed in the following order: $F^->Cl^->Br^->I^-$. The catalytic activity for reducing oxygen to OH^- was low, but the same order of activity as the above applies. The order was interpreted by the σ-donating ability of halide ion X to d_{z^2} orbital. The active site of the Mn^{III}(TPP)X heat-treated at 700 °C for O_2 reduction is ascribed to the metal ion, coordinated to slightly degraded or perfect N_4 center, but not degradation products of the relevant compounds.

Many transition metal complexes with macrocycles such as porphyrin, phthalocyanine, and tetraaza-annulene show catalytic activity for the cathodic reduction of oxygen. When these metallomacrocycles are applied to practical electrocatalyst for O_2 reduction, however, many of them are unstable in strong acid and alkaline electrolytes. Jahnke et al.[1] showed that this defect is overcome by the heat treatment in an inert atmosphere, and that the catalytic activity improved by the treatment. The disclosure accelerated the study on the heat treatment of metallomacrocycles for the cathodic reduction of oxygen.[2-15] However, the active site and the electrocatalysis of the heat-treated metallomacrocycles have not been fully elucidated. The active site suggested so far is (i) metal ion in the N_4 center,[7,16] (ii) carbonaceous substance formed by the degradation of N_4 center,[4] and (iii) an intermediate between (i) and (ii), namely, metal ion coordinated to partially degraded N_4 center.[13] The finely dispersed metal such as β-cobalt, which is formed by the heat treatment of cobalt(II) porphyrins, is examined.[11]

Recently, we studied the cathodic reduction of oxygen on unheated Mn^{III}(TPP)X, whose various properties are influenced by the axial ligand because of the strong π-mixing between metal and porphyrin ring.[17-20] It follows that the catalytic activity for O_2 reduction strongly depends on the axial ligand.[21] The porphyrins seem to be suitable to investigate active site and the electrocatalysis of heat-treated metallo-porphyrins for O_2 reduction, because the axial ligand affects the electrocatalysis, if the metal ion is the active site.

Experimental

Materials. In analogy with octaethylporphyrinatoiron-(III) halides,[22] Mn^{III}(TPP)X (X:F^-, Cl^-, Br^-, I^-) were prepared by the ligand-exchange reaction of Mn^{III}(TPP)($OCOCH_3$) with aqueous NaX as described elsewhere.[21] Plates (10×10 mm^2) and rods (6 mmϕ) of glassy carbon (G.C., Tokai Carbon, GC20) were used as the base electrode, onto which one of the Mn^{III}(TPP)X was coated. These G.C. electrodes were polished to a mirror surface with alumina powder, and washed in an ultrasonic bath to remove alumina powder. 1 M(=mol dm^{-3}) KOH was used as the electrolyte, which was saturated with pure oxygen at the cathodic reduction experiments. Pt net and Hg/HgO electrode in 1 M KOH were used as counter and reference electrodes, the potential of the latter against normal hydrogen electrode (NHE) being +0.098 V.

Heat Treatment. The chloroform solution of each Mn^{III}(TPP)X was coated onto the G.C. plate (1 cm^2) and top surface of the rod (0.28 cm^2) using a microcyringe, and the coating amount was fixed to 3×10^{-7} mol cm^{-2}. After drying in air, the electrodes were placed in a quarz tube, and then filled with highly pure Ar (O_2<1—2 ppm) by alternate degassing and filling. The Mn^{III}(TPP)X-coated G.C. in the tube was heated in an electric furnace for 10 min at each temperature and cooled in air. Electrochemical data for heat-treated Mn^{III}(TPP)X varied with the amount of coating, probably due to imperfect coating and sublimation up to less than 1×10^{-7} mol cm^{-2}. However, the data became nearly constant at the coating over 1×10^{-7} mol cm^{-2}.

The heat treatment of Mn^{III}(TPP)X powder, for the measurement of bulk properties, was carried out by the same manner as described above by putting the powder in a small quarz beaker.

Electrochemical Measurements. The G.C. rod coated with heat-treated Mn^{III}(TPP)X was used as the ring (Pt)-disc electrode. The Pt ring was cleaned by a potential sweep cycling between O_2 and H_2 generation potentials in 0.5 M H_2SO_4 before use. In the cathodic reduction of oxygen, the ring potential was fixed to +0.25 V (vs. Hg/HgO in 1 M KOH), where the diffusion limiting current for HO_2^- oxidation was observed.

The G.C. plate coated with heat-treated Mn^{III}(TPP)X was installed into a Teflon holder with a window of 0.5 cm^2 open to the electrolyte solution, and was used in the cyclic voltammetry to evaluate catalytic activity and stability.

Other Measurements. The mass magnetic susceptibility

* Present address: Laboratory of Chemistry, College of Liberal Arts, Kanazawa University, 1-1 Marunouchi, Kanazawa 920.

χ_g of heat-treated $Mn^{III}(TPP)X$ was measured by Gouy method using a magnetic balance (Shimadzu, MB-11) at room temperature, usually 25 °C. The χ_g was corrected for ferromagnetic impurities by extrapolating the plot of (mass magnetization)/(magnetic field strength) $[(M)/(H)]$ against $(1/H)$ to $(1/H)=0$. The molar magnetic susceptibility χ_M was evaluaded by determining the molecular weight (M.W.) of the porphyrin unit per manganese ion, using the relation: $\chi_M=\chi_g\times$M.W. Thermogravimetry (TG) and differential thermal analysis (DTA) for $Mn^{III}(TPP)X$ were carried out by means of Rigaku DG-ClH Thermoflex, at a heating rate of 5 °C min^{-1} in Ar stream. Electrical resistivity of heat-treated $Mn^{III}(TPP)X$ was measured by the two-probe method for powdered sample pressed between metal rods in a thick glass tube.

Results and Discussion

Thermal Behavior of $Mn^{III}(TPP)X$. Thermal reactions taking place during the heat treatment were elucidated from the DTA and TG curves. The results for four $Mn^{III}(TPP)X$ ($X:F^-$, Cl^-, Br^-, I^-) examined are shown in Fig. 1. The DTA curve of each porphyrin has two endo/exothermic peaks at nearly same temperature regions: The first is between 400° and 500 °C, and the second around 850 °C. An obvious weight loss was observed in TG curves at the first DTA peak, but not at the second DTA peak. The first thermal reaction between 400° and 500 °C is speculated to be the condensation reaction due to release of phenyl groups and hydrogen, indicating formation of an extended π-electron system, because the resistivites of $Mn^{III}(TPP)X$ decreased from $>10^9\ \Omega$ cm to 10^5—$10^4\ \Omega$ cm with this reaction. The second thermal reaction seems to be the degradation of porphyrin skeleton, because manganese monoxide (MnO) was detected by X-ray diffraction in the samples heated above 850 °C.

The following analyses examine the changes in the heat treatment of $Mn^{III}(TPP)X$. Some properties of $Mn^{III}(TPP)X$ heat-treated at 700 °C were compared, where the catalytic activity for O_2 reduction is maximum.

Molecular Weight. Since $Mn^{III}(TPP)X$ heat-treated above 500 °C are insoluble in organic solvents, the molecular weight per manganese ion was evaluated by determining Mn ion in the ashed samples on heating in air. Table 1 summarizes the results. The accuracy of this measurement is ±3% from the results for unheated $Mn^{III}(TPP)X$. The molecular weight decreased with the heat treatment at 700 °C by 60—90. This suggests a release of one phenyl group during the heat treatment. Release of hydrogen atoms on phenyl groups may occur at 700 °C, because the condensation products show no solubility in organic solvents and have low resistivity of about $10^2\ \Omega$ cm.

Atomic Ratio. In order to examine the stability of N_4 center during the heat treatment, the atomic ratio of N to Mn was evaluated using the manganese content and the nitrogen content obtained from the elemental analysis. Figure 2 shows the results as a function of the heat-treatment temperature. The N/Mn ratio for unheated $Mn^{III}(TPP)X$ was about 4,

Table 1. Molecular Weight Per Manganese Ion for Unheated and Heat-Treated $Mn^{III}(TPP)X$

X	Heat-treatment temperature/°C			
	unheated	500	700	900
F^-	670	630	600	580
Cl^-	720	—	630	—
Br^-	760	—	700	—
I^-	800	—	740	—

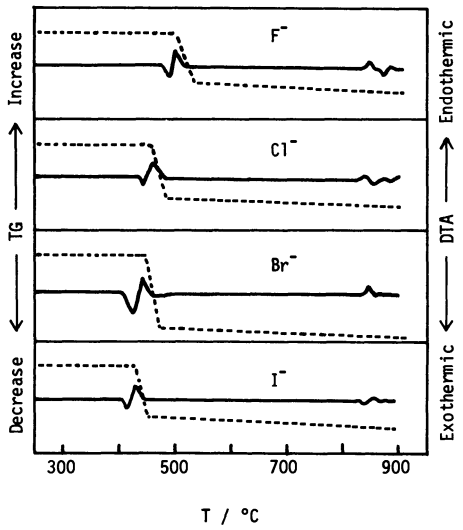

Fig. 1. Differential thermal analysis (——) and thermogravimetry (----) curves for $Mn^{III}(TPP)X$ (X: F^-, Cl^-, Br^-, I^-) in Ar stream. Heating rate, 5 °C min^{-1}.

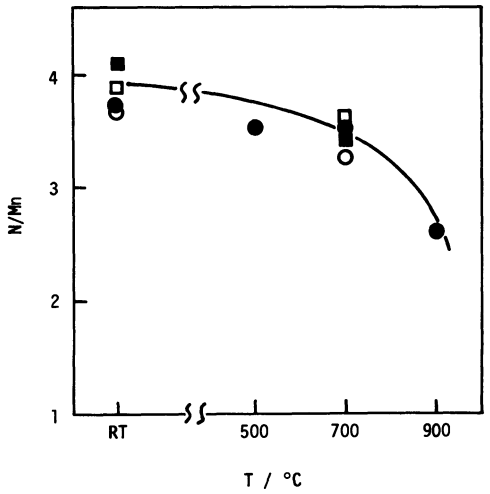

Fig. 2. Variation of N/Mn ratio with the heat-treatment temperature for $Mn^{III}(TPP)X$. X: (●) F^-; (■) Cl^-; (□) Br^-; (○) I^-. RT(room tempereature) means the unheated $Mn^{III}(TPP)X$.

while the ratio gradually decreased to 3.5 with the heat treatment up to 700 °C, and greatly fell to 2.6 at 900 °C. The results suggest that the N_4 center is maintained up to 700 °C, but it is degraded at 900 °C where the second DTA peak appears and MnO is detected by X-ray diffraction.

Next, we determined the ratio of X to Mn to estimate the stability of Mn–X bond in the heat treatment, using the molecular weight per manganese ion and the X content from the elemental analysis. The X/Mn ratio for $Mn^{III}(TPP)X$ heat-treated at 700 °C, except for $Mn^{III}(TPP)F$ whose elemental analysis for F was impossible, was 0.8—0.9. This suggests that most of the manganese sites are coordinated by the axial ligand even after the heat treatment at 700 °C.

Magnetic Moment. Magnetic moment for $Mn^{III}(TPP)X$ heat-treated at 700 °C was evaluated to estimate the spin state of central manganese ion. The effective magnetic moment μ_{eff} was calculated by the following relation for magnetically diluted substances: $\mu_{eff}=2.84\sqrt{\chi_M T}$, where T is the temperature at the measurement. The μ_{eff} for all $Mn^{III}(TPP)X$ (X: F^-, Cl^-, Br^-, and I^-) heat-treated at 700 ° were in the range of 5.0—5.3 μ_B (Bohr Magneton) and were in good agreement with the values of 5.0—4.8 μ_B for unheated $Mn^{III}(TPP)X$ (X: Cl^-, Br^-, and I^-), a fact indicating high-spin $Mn^{III}(d^4)$ complex which has the theoretical μ_{eff} of 4.9 μ_B. The μ_{eff} of unheated $Mn^{III}(TPP)F$ was 3.8 μ_B. The result indicates that an intermediate-spin changed to the high-spin complex by the heat treatment, as can be seen from Fig. 3. We confirmed previously that the unheated $Mn^{III}(TPP)F$ has the highest π-mixing with ring orbitals among $Mn^{III}(TPP)X$.[21] Extended π-electron system due to the heat treatment seems to weaken the π-mixing, resulting in high-spin state.

Electrocatalysis for O_2 Reduction. We have discussed the electrocatalysis of heat-treated $Mn^{III}(TPP)X$ based on two methods to examine the catalytic activity: One is the overpotential and the other the capability of reducing oxygen to OH^- or the so-called 4-electron reducibility.

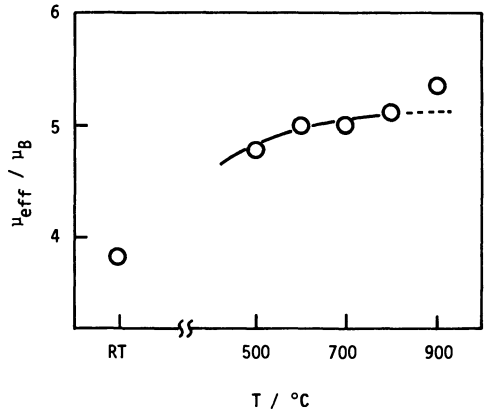

Fig. 3. Variation of the effective magnetic moment (μ_{eff}) of $Mn^{III}(TPP)F$ with heat-treatment temperature. RT(room temperature) means the unheated $Mn^{III}(TPP)F$.

Figure 4 shows the voltammograms of $Mn^{III}(TPP)F$ heat-treated at different temperatures for the O_2 reduction by rotating disc electrode. The catalytic activity based on the overpotential or the current at a constant potential showed a complicated change with the heat-treatment temperature: It decreased with the temperature up to 600 °C, and then increased showing a maximum at 700 °C. The same change was also observed in the cyclic voltammograms by use of plate electrode. The catalytic activity fluctuated at 800 °C: Low reproducility at 800 ° seems to be related with that the temperature is in the vicinity of the degradation temperature of N_4 center. The low catalytic activity of $Mn^{III}(TPP)F$ heat-treated at 900 °C is caused by the degradation of N_4 center. The diffusion limiting current for O_2 reduction became lower by the heat treatment, indicating the change in reduction pathway from the 4-electron pathway ($O_2+2H_2O+4e^-\rightarrow 4OH^-$) to the 2-electron pathway ($O_2+H_2O+2e^-\rightarrow HO_2^-+OH^-$), as will be discussed later.

Figure 5 shows the cyclic voltammograms of $Mn^{III}(TPP)X$ heat-treated at 700 °C. Under more negative potentials, the reduction peak in the cyclic voltammogram was observed for $Mn^{III}(TPP)Br$, but unobservable for $Mn^{III}(TPP)I$. However, the catalytic

activity estimated from the overpotential was in the order: $F^->Cl^->Br^->I^-$. Stability of the catalysts was improved by the heat treatment, because there appeared only a small change in the cyclic voltammograms at the first and 1000 cycles (Fig. 5). Since the instability of unheated Mn^{III}(TPP)X depends upon the ligand exchange of X with OH^-,[21] the improved stability suggests the formation of a dense structure without pores which prevents from penetrating of electrolyte.

Figure 6 shows the voltammograms at the rotating ring (Pt)-disc (G.C. coated with Mn^{III}(TPP)X heat-treated at 700 °C) electrode. The lower curves represent the disc currents for O_2 reduction and the upper curves the ring currents for the oxidation of HO_2^- as a reduction intermediate of O_2.

In order to elucidate the 4-electron reducibility of the heat-treated Mn^{III}(TPP)X for oxygen, the apparent number of electrons consumed in the O_2 reduction (n_{app}) was evaluated using the ring and disc currents around −0.3 V in Fig. 6. In the evaluation of n_{app}, it was assumed that the O_2 reduction at the disc consists of a mixed reaction of the 2-electron pathway ($O_2+H_2O+2e^-\rightarrow HO_2^-+OH^-$) and the 4-electron pathway ($O_2+2H_2O+4e^-\rightarrow 4OH^-$). Thus n_{app} was estimated by the next relation:[15,23] $n_{app}=4I_{Disc}/(I_{Disc}+I_{Ring}/N_{corr})$, where N_{corr} is the collection efficiency for HO_2^-, corrected for a deviation from the coplanality between the Pt ring and the Mn^{III}(TPP)X-coated disc, which is about 0.1 for various ring-disc electrodes.

The result for Mn^{III}(TPP)X heat-treated at 700 °C is shown in Fig. 7. Also, the result for Mn^{III}(TPP)F heat-treated at different temperatures is shown in Fig. 8. As can be seen from Fig. 7, the n_{app} shows some

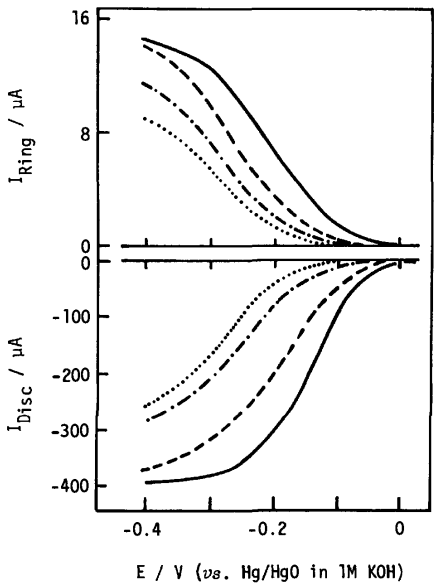

Fig. 6. Voltammograms at the rotating ring(Pt)-disc (glassy carbon coated with Mn^{III}(TPP)X heat-treated at 700 °C) electrode for the cathodic reduction of oxygen in O_2-saturated 1 M KOH. Ring potential, 0.25 V (vs. Hg/HgO in 1 M KOH); sweep rate at the disc, 20 mV s^{-1}; rotation rate, 1000 r.p.m.; surface area of the disc, 0.28 cm^2.

dependence on the axial ligand, and the n_{app} value decreases from 2.3 for F^- to 2.0 for I^-. On the other hand, it is observed from Fig. 8 that the high 4-electron reducibility of unheated Mn^{III}(TPP)F is considerably lost by the heat treatment.

Effect of Axial Ligand on Electrocatalysis. The catalytic activity of heat-treated Mn^{III}(TPP)X, based

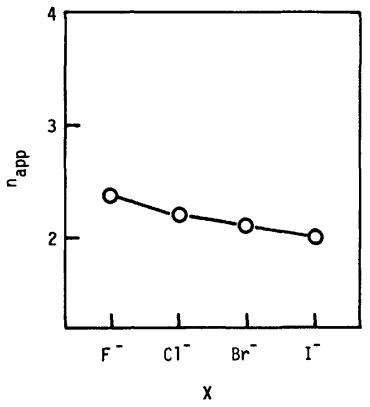

Fig. 7. Variation of the apparent number of electrons consumed in O_2 reduction (n_{app}) with the axial ligand of $Mn^{III}(TPP)X$ heat-treated at 700 °C.

on the overpotential and the 4-electron reducibility, depends markedly on the axial ligand. As for the property of the axial ligand affecting the catalytic activity, the most probable one seems to be the electron-donating ability of X, which influences on interaction with O_2 molecule on manganese site through a change in the d-electron population.

The coordination mode of oxygen to metal has been considered to be an important factor for the catalysis or the reaction pathway in the cathodic reduction of oxygen. The end-on coordination (Pauling model[24]) leads to the 2-electron pathway, while the side-on coordination (Griffith model[25]) leads to the 4-electron pathway. Therefore, the d-electron configuration leading to the 4-electron pathway is considered to be empty d_{z^2} orbital which accepts electrons of oxygen $1\pi_u$ to form σ-bond, and filled d_{xz} and d_{yz} (d_π) orbitals which enable the back donation to oxygen $1\pi_g^*$ orbital.[26]

Figure 9 represents (a) the low-spin and (b) the high-spin d-electron configuration for a manganese(III) porphyrin, respectively.[27] Though the high-spin

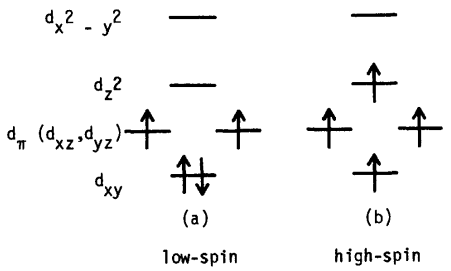

Fig. 9. The d-electron configurations for (a) low-spin and (b) high-spin d^4 manganese(III) porphyrin.

$Mn^{III}(TPP)X$ has half-filled d_π orbitals, the O_2 reduction on it occurs virtually through the 2-electron pathway. The presence of unpaired electron on d_{z^2} orbital seems to form predominantly the end-on coordination of oxygen through an interaction with $1\pi_g^*$ orbital, leading to the 2-electron pathway. The high 4-electron reducibility of unheated $Mn^{III}(TPP)F$ is ascribed to the intermediate spin, i.e., periodical or partial formation of the low-spin state with high affinity with the side-on coordination of oxygen. The 4-electron reducibility lowered by the heat treatment can be accounted for by the alteration into the high-spin state (Figs. 3 and 8). Irrespective of the high-spin state, the σ-donation by axial ligand onto d_{z^2} orbital seems to favor slightly the 4-electron reducibility because the character of unpaired electron of the d_{z^2} orbital is diluted by the donated electrons. In this context, the order of the electron-donating ability of X[17] ($F^- > Cl^- > Br^- > I^-$) explains the change in the 4-electron reducibility of heat-treated $Mn^{III}(TPP)X$ with X (Fig. 7).

The electron-donating ability of X thus explains the catalytic activity based on the overpotential (Fig. 5), because the increased population of electron on d_{z^2} orbital facilitates the interaction with O_2 molecule, as in the case of [tetrakis(methoxyphenyl)porphyrinato]-cobalt(II) with electron-donating methoxy groups.[28]

A particular phenomenon observed for heat-treated $Mn^{III}(TPP)X$ was the occurrence of large background current in Fig. 5. Moreover, the magnitude of the background current appears to represent the catalytic activity. This current is considered to be a capacitive current, as has already been confirmed for thick cobalt-phthalocyanine film,[29] which presumably has a characteristic surface state. As the surface state in the heat-treated $Mn^{III}(TPP)X$, delocalized π-electron in the extended π-system or metal may be conceivable. It has been noted for hydrophobic iron-porphyrin[23] that only the outermost layer of multiple layer on the electrode is effective on the electrocatalysis. Accordingly, the surface state described above will assist the electron transfer to oxygen molecule coordinated on the metal.

A Molecular Dynamical Study of the Mutual Diffusion Coefficient and Cooperative Motion in a 2-Dimensional Aqueous Solution

Yosuke KATAOKA
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received December 24, 1985)

Constant-temperature constant-pressure molecular dynamics simulations of a two-dimensional aqueous solution-like system are performed at many temperatures under a constant pressure. The total number of molecules in the system is 576, and the mole fraction of the solute is 0.5. The mutual diffusion coefficient, the kinetic diffusion coefficient, and the velocity correlation between different molecules are thus obtained. The reduced kinetic diffusion coefficient has a maximum at an intermediate temperature under a constant pressure. This feature is consistent with the temperature dependence of the mean-square-concentration fluctuations. The lifetime of the local structure is estimated from the cross-correlation function of displacement, which is computed from the time-averaged configurations, where the average period is several times longer than the velocity-autocorrelation time. The correlation length of the local concentration fluctuations is obtained and compared with the snapshots of the configurations at several temperatures. The dynamical properties are qualitatively in agreement with those of an alcohol–water mixture.

Local fluctuations of concentration afford information which is useful for understanding the mixing of liquids from a molecular point of view.[1] In order to discuss the state of mixing from a dynamical standpoint, the lifetime of local structures should be taken into account.[1] For these reasons, quasi-elastic light scattering, NMR, and Rayleigh–Brillouin scattering experiments are performed in order to determine the mean-square-concentration fluctuations, the mutual diffusion coefficients, and the correlation length.[1–25] In such studies, solutions with a lower critical solution temperature are often examined because many thermodynamical quantities of such solutions show a prominent temperature- and concentration-dependence. Binary mixtures of an alcohol and water are typical examples. For the present, it is difficult to simulale such systems with a sufficient number of molecules by either the Monte Carlo or molecular dynamics (MD) method using realistic models at many temperatures and concentrations for a systematic study, although some works have been published reporting on work at a few temperatures and concentrations.[26–29]

In a previous paper,[30] a Monte Carlo study of a 2-dimensional (2-D) aqueous solution-like system was carried out by making use of the 2-D water-like model.[31] This solution model was designed to simulate binary mixtures of an alcohol and water. This is suitable for the systematic Monte Carlo calculation and molecular dynamics of solutions. The mean-square-concentration fluctuation was calculated as a function of the temperature, the density and the concentration. The mean-square-concentration fluctuation has a maximum at an intermediate temperature. This feature is similar to those of solutions with upper and lower critical solution temperatures.[30] The concentration dependence of the thermodynamic properties at low temperatures is qualitatively in agreement with that of an alcohol–water mixture.[30] We perform molecular dynamical calculations on the same model in this work.

The purpose of the present study is to see dynamical properties of a system where the concentration fluctuates to a considerable extent and to obtain the mutual diffusion coefficient, the velocity correlation between different molecules, and the lifetime of the local structure.

We adopt the 2-dimensional (2-D) aqueous solution-like model.[30] The solvent is a 2-D water-like model, which reproduces the well-known anomalous behavior of liquid water.[31,32] The water-solute interaction is anisotropic. The solute–solute interaction is assumed to be of the Lennard–Jones type for the sake of simplicity.

The merits of low dimensions are as follows. (i) We can save computing time and memory size. This point is important because we are going to perform many simulations at various temperatures. (ii) The linear dimension of the basic cell in the simulation is larger than that of a three-dimensional cell (3-D) ($576=24^2\simeq 8.3^3$) provided that the total number of molecules is fixed. Thus, the effect of the periodic boundary condition would be smaller in the case of 2-D than that in the 3-D calculation with the same number of molecules. Despite theoretical predictions that transport coefficients in a 2-D system will diverge, a computer simulation of a small system can be used to study the transport properties.[33] The shortcoming of our simulation on a 2-D solution is that there are no experimental results on any 2-D aqueous-like solution and that our results must, therefore, be qualitatively compared with experimental results; we shall use reduced units.[31]

The constant-temperature and constant-pressure MD(T-P-MD) method is used, because this method is more convenient for obtaining the temperature dependence of the system. By T-P-MD, the mutual diffusion coefficient D[35,36] is calculated for the system with 576 molecules in a square cell. As the mean-square-concentration fluctuation of the system has a maximum around $x_s=0.5$ (x_s is the mole fraction of

the solute),[30] the mole fraction of the solute is 0.5 in this work. The kinetic diffusion coefficient, L, is derived from the mutual diffusion coefficient D and the mean-square-concentration fluctuation. We want here to discuss the temperaure dependence of the kinetic diffusion coefficient L. The kinetic diffusion coefficient L includes the L_0 term, which equals L when the velocity correlation between different molecules can be neglected. As this term L_0 also depends on the temperature, the temperature dependence of L will be discussed by means of the reduced quantities L/L_0. Its temperature dependence will be qualitatively compared with that in an alcohol-water mixture.[21]

In order to estimate the lifetime of the local structure, the cross-correlation function of translation will be studied using the time-averaged positions of molecules, where the average period is several times longer than the velocity-autocorrelation time.[32] From the analysis of the cross-correlation of translation, the size of the "moving unit" will also be estimated; the "moving unit" is a group of molecules which move together for a time much longer than the velocity-autocorrelation time.[1] This size will be compared with the static correlation lenght of the local-concentration fluctuations. It will be shown that these are consistent with the snapshots of the configurations at several temperatures.

Molecular Dynamics Method

The 2-D model of an aqueous solution-like system was described in the previous paper.[30] The constant-temperature constant-pressure MD method was shown in another paper.[32] Therefore, the model and the MD method will be described only briefly here.

The pair potential U_{AB} between molecules A and B is given as follows (the suffixes A and B will be used to express water or a solute, unless otherwise stated):

$$U_{WW} = U_{LJ}^{WW}(R_{WW}) + U_{ANISO}^{WW}(R_{WW}, \varphi_{W1}, \varphi_{W2}), \quad (1)$$

$$U_{WS} = U_{LJ}^{WS}(R_{WS}) + U_{ANISO}^{WS}(R_{WS}, \varphi_{W}, \varphi_{S}), \quad (2)$$

$$U_{SS} = U_{LJ}^{SS}(R_{SS}). \quad (3)$$

Here, U_{WW} is the water-water interaction energy,[31] R_{AB} denotes the distance between two molecules A and B, and φ_A and φ_B, the orientation of the respective molecules, as is shown in Fig. 1 in Ref. 30. The first terms in Eqs. 1—3 $U_{LJ}^{AB}(R_{AB})$ are the Lennard-Jones potential functions. The parameter of these functions and the anisotropic interaction between water and a solute U_{ANISO}^{WS} are given in Ref. 30.

The mass M_A and the moment of inertia I_A of the A molecule are assumed as follows for the sake of simplicity:

$$M_W = M_S = 18 \text{ (in units of atomic weight)} \quad (4)$$

$$I_W = I_S = 3.34 \times 10^{-44} \text{ gm}^2. \quad (5)$$

We use the following reduced units.[31] The energy E is measured in units of ε_0=24.68 kJ mol^{-1}, ($-\varepsilon_0$ is the absolute minimum of the pair potential energy U_{WW}); the temperature in units of ε_0/k_B (k_B is the Boltzmann constant,) and the length, in units of R_0=0.276 nm which is the hydrogen-bond length in U_{WW}. The pressure P is measured in units of ε_0/R_0^2.

The T-P-MD simulations of the system mentioned above[30] are performed at many temperatures under a constant pressure (P=0.17 ε_0/R_0^2). This value of the pressure is a representative one in the 2-D aqueous solution.[30] The system consists of 576 molecules in a square unit cell with the periodic boundary condition. The mole fraction of the solute x_S is 0.5 in this work, since a solution with this concentration is interesting because of the large mean-square-concentration fluctuation.[30] The dynamical equations are integrated with the time increment:

$$\Delta t = 0.435 \times 10^{-15} \text{ s} \quad (6)$$

by the predictor-corrector method. In our standard run, 60000 steps are spent for the aging of the system. After this, the 60000-step run is performed twice a least; from these runs the statistical averages are obtained.

The constant-temperature MD mehod by Nosé[34] is used, combined with the constant-pressure MD method of Andersen.[37] Some things special to these methods has heen described elsewhere.[32]

Mutual Diffusion Coefficient

In a binary liquid system there are three diffusion coefficients, viz. the two self diffusion coefficients and the mutual diffusion coefficient. The former are calculated from the mean-square displacement or from the velocity autocorrelation[35] in the MD simulation. The latter is interesting in solutions with local concentration fluctuations.[1] The mutual diffusion coefficient can be obtained from the mean-square displacement of the center of mass of all water molecules $\langle R_{WCM}(t)^2 \rangle$ as follows:[35]

$$D = \frac{Q}{4Nc_W c_S}\left[\left(\frac{M_W}{M_S}\right)c_W + c_S\right]^2 \lim_{t\to\infty} \frac{\partial}{\partial t}\langle R_{WCM}(t)^2 \rangle, \quad (7)$$

where c_A is the concentration (number density) of the species A, the velocity of the center of the mass of the system is fixed as 0, N is the total number of molecules in the system and M_A is the mass of the species A. The quantity Q is often called the thermodynamic factor and is defined as:

$$Q = \frac{x_W x_S}{N\langle(\Delta x)^2\rangle}, \quad (8)$$

where x_A is the mole fraction of the species A and where $\langle(\Delta x)^2\rangle$ is the mean-square-concentration fluctuation.[30] The mean-square-concentration fluc-

Table 1. Thermodynamic and Transport Properties of the 2-D Aqueous Solution Using Micro Canonical MD and Constant-Temperature Constant-Pressure MD

T is the temperature, P is the pressure, A is the total area of the system, E is the potential energy, $\langle(\Delta x)^2\rangle$ is the mean square concentration fluctuation, D_W and D_S are the self diffusion coefficients of the water and the solute, and D is the mutual diffusion coefficient. The mole fraction of solute $x_S=0.5$, the total number of molecules in the system $N=576$.

tuation is calculated using the radial-distribution function.[30]

Although it has been proved that the sufficient averages of the static quantities are the same in micro canonical MD and in T-P-MD,[34,38] nothing is known about the mutual diffusion coefficient. For this reason, typical examples of calculations in the two methods are compared in Table 1. The results are not very different from each other for the micro canonical MD and T-P-MD.

As the mutual diffuion coefficient D has the thermodynamic factor Q, the kinetic diffusion coefficient L is more directly related to velocity correlation functions between different molecules:[39]

$$D = QL, \tag{9}$$

with:

$$L = L_0 + x_W x_S(D_{WW} + D_{SS} - 2D_{WS}) \tag{10}$$

$$L_0 = x_S D_W + x_W D_S, \tag{11}$$

$$D_{AB} = \frac{N}{2}\int_0^\infty \langle v_{Ai}(t)\cdot v_{Bj}(0)\rangle dt, \qquad (i \neq j) \tag{12}$$

where v_{Ai} is the velocity of an i-th molecule of the species A. D_A is the self-diffusion coefficient of the species A. By the use of Eq. 10, the trend of the cooperative translation in the binary mixture can be seen from the comparison of L with L_0, because the second term in Eq. 10 comes from the velocity correlations between different molecules. At the same time, we would like to discuss the temperature dependence of L by means of the reduced quantity L/L_0 since the first term L_0 in Eq. 10 also depends on the temperature. The temperature dependence of L/L_0 is shown in Fig. 1. The reduced kinetic diffusion coefficient L/L_0 has a maximum value around $T=0.24\ \varepsilon_0/k_B$. The mean-square-concentration fluctuation also has a maximum value around the same temperaure (Fig. 7 in Ref. 30). The second

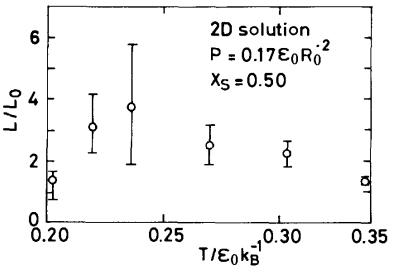

Fig. 1. Plot of the reduced kinetic diffusion coefficient L/L_0 vs. temperature T, at $P=0.17\ \varepsilon_0/R_0^2$, $x_S=0.5$.

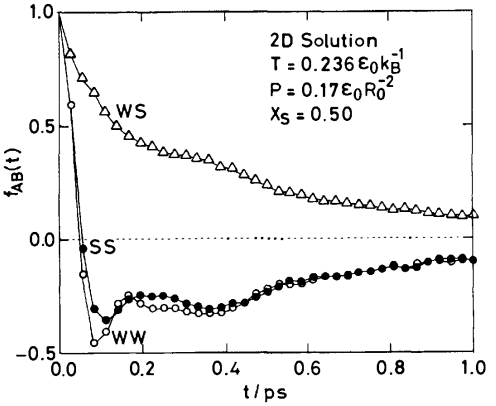

Fig. 2. The correlation function of velocity $f_{AB}(t)$ vs. time t. $T=0.236\ \varepsilon_0/k_B$, $P=0.17\ \varepsilon_0/R_0^2$, $x_S=0.5$.

point to be mentioned about Fig. 1 is that the value of L/L_0 is larger than 1.

The experimental values in a binary solution of t-butyl alcohol and water are as follows: L/L_0= about 2 at 24 °C and about 5 at 63 °C.[21] The order of magnitude of L/L_0 shown in Fig. 1 is comparable to the experimental results.[21] The temperature dependence below about $0.24\ \varepsilon_0/k_B$ in Fig. 1 is qualitatively in agreement with such results.[21]

As the value of L/L_0 is larger than 1, the general

tendency for the same species to move in the same direction is seen in this solution. In order to see this more directly, the correlation functions of velocities between the different molecules are shown in Fig. 2. The correlation functions of velocities $f_{AB}(t)$ are defined as follows:

$$f_{AB}(t) = \frac{\langle \boldsymbol{v}_{Ai}(t)\cdot\boldsymbol{v}_{Bj}(0)\rangle}{\langle \boldsymbol{v}_{Ai}(0)\cdot\boldsymbol{v}_{Bj}(0)\rangle}, \quad (i \neq j). \tag{13}$$

The normalization constants at temperature T=0.236 ε_0/k_B are given below:

$$\left.\begin{aligned} \langle \boldsymbol{v}_{Wi}(0)\cdot\boldsymbol{v}_{Wj}(0)\rangle &= -0.7\times10^6\ \mathrm{m^2\,s^{-2}},\\ \langle \boldsymbol{v}_{Wi}(0)\cdot\boldsymbol{v}_{Sj}(0)\rangle &= -0.8\times10^6\ \mathrm{m^2\,s^{-2}},\\ \langle \boldsymbol{v}_{Si}(0)\cdot\boldsymbol{v}_{Sj}(0)\rangle &= -0.7\times10^6\ \mathrm{m^2\,s^{-2}}. \end{aligned}\right\} \tag{14}$$

From Eqs. 12—14 and Fig. 2 it may be seen that D_{WW} and D_{SS} are positive, while D_{WS} is negative. The tendency mentioned above for the same species generally to move in the same direction may be seen again in Fig. 2.

There are two time constants in the correlation functions in Fig. 2. They are 0.05 ps and 1 ps. As these time constants are derived from all the pairs in the system they are not adequate for an examination of the lifetime of the local structure. For this reason, the lifetime will be studied in a different way in the next section.

Lifetime of the Local Structure

In this section, we will estimate the lifetime of the local structure due to fluctuations in the concentration. An oscillatory motion of water molecules is seen at low temperatures and densities, as is shown in Ref. 32. Therefore, we use the time-averaged configuration in order to obtain the lifetime of the local structure.[32] The configuration is averaged over a period of 0.13 ps which is several times longer than the velocity autocorrelation time. We calculate the cross-correlation of displacement as in the case of the estimation of the lifetime of the hydrogen-bonded local structure in 2D water.[32] When the position $\boldsymbol{r}_i$ of i-th molecule at time t=0 is denoted as $\boldsymbol{r}_i^0$, the displacement of the molecule i is $\boldsymbol{r}_i-\boldsymbol{r}_i^0$. Figure 3 shows the cross-correlation of the displacement of the molecules i and j $\langle(\boldsymbol{r}_i-\boldsymbol{r}_i^0)\cdot(\boldsymbol{r}_j-\boldsymbol{r}_j^0)\rangle$ where the following conditions, with the molecular distance R_{ij} set at t=0:

$$\left.\begin{aligned} &1.5R_0<R_{ij}(0)<2.5R_0 \quad (\text{i.e. } R_{ij}(0)\text{—}2R_0),\\ &3.5R_0<R_{ij}(0)<4.5R_0 \quad (\text{i.e. } R_{ij}(0)\text{—}4R_0),\\ &5.5R_0<R_{ij}(0)<6.5R_0 \quad (\text{i.e. } R_{ij}(0)\text{—}6R_0). \end{aligned}\right\} \tag{15}$$

The linear part of the cross-correlation function extends up to 3×10 ps in the case of $R_{ij}(0)$—$2R_0$. The tangent of this linear part is about 25% as large as that in the case of i=j. Thus, this figure shows that the molecules i and j with R_{ij}—$2R_0$ at t=0 move collectively in nearly the same direction over a period

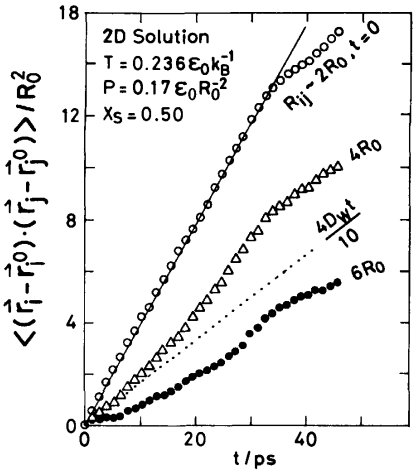

Fig. 3. The cross correlation function $\langle(\boldsymbol{r}_i-\boldsymbol{r}_i^0)\cdot(\boldsymbol{r}_j-\boldsymbol{r}_j^0)\rangle$ vs. time t. The initial conditions in statistics are indicated in the figure. T=0.236 ε_0/k_B, P=0.17 ε_0/R_0^2, x_S=0.5.

of about 3×10 ps.

As the molecular distance at t=0 increases, the cross-correlation decreases, as is shown in Fig. 3. We tentatively use one-tenth of the correlation in the case of i=j (the dotted line in Fig. 3) as the criterion to determine whether or not the cross-correlation is sufficiently large. By this criterion, we see that the correlation length of translation is about $4R_0$ in Fig. 3.

The cross-correlation time and the length of the solute-solute pair are about the same as those of the water-water pair at T=0.236 and 0.270 ε_0/k_B. At low temperatures, the length of the MD run was not enough to determine the correlation length. The temperature dependence of the cross-correlation time τ and length ξ_{trans} are as follows:

$$\left.\begin{aligned} &\tau(T=0.202\,\varepsilon_0/k_B) = 9\times10\ \mathrm{ps}, \quad \text{run length} = 131\ \mathrm{ps},\\ &\tau(T=0.236\,\varepsilon_0/k_B) = 3\times10\ \mathrm{ps}, \quad \xi_{trans}=4R_0,\\ &\qquad\qquad\qquad\qquad\qquad\qquad \text{run length} = 131\ \mathrm{ps},\\ &\tau(T=0.270\,\varepsilon_0/k_B) = 4\ \mathrm{ps}, \quad \xi_{trans}=3R_0,\\ &\qquad\qquad\qquad\qquad\qquad\qquad \text{run length} = 104\ \mathrm{ps}, \end{aligned}\right\} \tag{16}$$

where the length of the MD run used in the analysis is also shown. The value of the correlation time at T=0.202 ε_0/k_B listed above is only a tentative one, because the MD run was not long enough to determine such a long correlation time (9×10 ps).

Correlation Length of Concentration Fluctuation

In the preceding section, the cross-correlation length of translation was estimated. Now we are going to obtain the static correlation length of the local fluctuation of concentration.

There are many definitions of the correlation length in a solution.[25] We define the following function using radial-distribution functions:

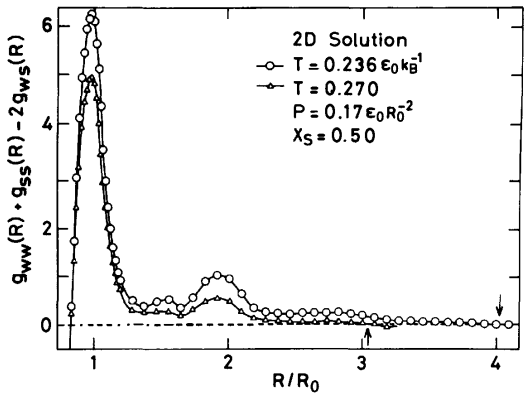

Fig. 4. The distribution function $\Delta g(R)$ defined in Eq. 17, at T=0.236 and 0.270 ε_0/k_B, P=0.17 ε_0/R_0^2, x_S=0.5.

$$\Delta g(R) = g_{ww}(R) + g_{ss}(R) - 2g_{ws}(R) \tag{17}$$

because the integration of this function with respect to the molecular distance R is proportional to the excess mean-square fluctuation in the concentration (cf. Eqs. 2.12, 2.19 in Ref. 30):

$$N\langle(\Delta x)^2\rangle = x_w x_S + \frac{N}{\langle A\rangle}(x_w x_S)^2\int_0^\infty \Delta g(R)\mathrm{d}^2R, \tag{18}$$

where A is the total area of the system.

This function $\Delta g(R)$ is plotted at T=0.236 and 0.270 ε_0/k_B in Fig. 4. At the point shown by an arrow, the function is 0. As the function $\Delta g(R)$ is positive in the $0.8R_0<R<4R_0$ range at T=0.236 ε_0/k_B, we can see that, in this case, the same species have a tendency to gather in the region where the molecular distance is less than $4R_0$. This length $4R_0$ is identified with the static correlation length of the local-concentration fluctuation in this work. The correlation length at T=0.270 ε_0/k_B is $3R_0$. It was difficult to estimate the correlation length at low temperatures by this method because the radial-distribution functions oscillate frequently with a large amplitude (cf. Fig. 18 in Ref. 30).

In order to confirm the correlation length mentioned above, typical configurations at several temperatures are shown in Fig. 5. Circles with a rectangular indication are water molecules; circles without a rectangular indication mean solutes. The stable pair with a pair energy larger than 0.55 ε_0 is connected by a straight line.

There are many water-rich regions and solute-rich regions at T=0.236 ε_0/k_B, and the characteristic radius of these regions is about $4R_0$. The radius of these regions at T=0.270 ε_0/k_B is seen as about $3R_0$. These values are in agreement with the correlation length determined by $\Delta g(R)$. The radius of the water-rich region at a low temperature (T=0.202 ε_0/k_B) is read as 5 ± 1 R_0 while that of the solute-rich region is about 3 ± 1 R_0.

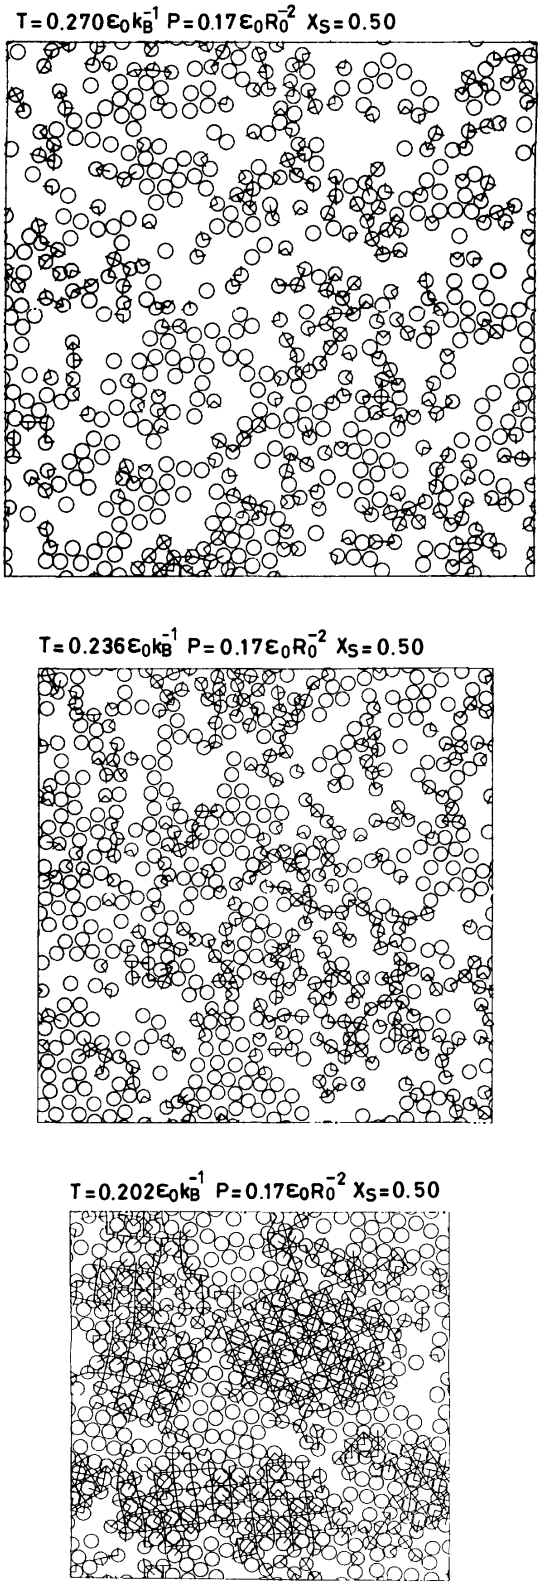

Fig. 5. Some examples of configurations. Circles with a rectangular indication are water molecules, where the diameter is the Lennard-Jones parameter σ_{ww} (=0.212 nm). Circles without a rectangular indication mean solute and the diameter is σ_{ss}(=0.228 nm). The stable pair with bond energy larger than 0.55 ε_0 is connected by a straight line. P=0.17 ε_0/R_0^2, x_S=0.5.

Although the present model is too simple, let us compare the correlation length obtained with that in the real system, as we have no experimental results on any 2-D aqueous-like solution. The correlation length observed in a 2-butoxyethanol-water mixture at 23 °C is about 2 nm.[25] The order of magnitude of our correlation length ($5R_0 \simeq 1$ nm) is in agreement with such an experimental result.[25]

A few configurations are shown in Fig. 5 because it is easier to see some examples of configurations in a 2-D solution than in a 3-D solution. However, it should be noted that the configurations shown in Fig. 5 are special, as they depend on the model assumed. The present model has a tendency toward phase separation at an intermediate temperature (around $T=0.236\ \varepsilon_0/k_0$) This feature is seen by the temperature dependences of the mean-square-concentration fluctuation, the reduced kinetic diffusion coefficient, and the free energy.[30] The temperature dependence of the mean-square-concentration fluctuation is as follows:

$$\left.\begin{aligned} N\langle(\Delta x)^2\rangle &= 0.55 \pm 0.05, \quad T = 0.202\ \varepsilon_0/k_B, \\ N\langle(\Delta x)^2\rangle &= 1.3 \pm 0.3, \quad T = 0.236\ \varepsilon_0/k_B, \\ N\langle(\Delta x)^2\rangle &= 0.67 \pm 0.08, \quad T = 0.270\ \varepsilon_0/k_B, \end{aligned}\right\} \tag{19}$$

where pressure $P=0.17\ \varepsilon_0/R_0^2$.

The author would like to thank Dr. Tadashi Kato, Tokyo Metropolitan University for his valuable discussions. He also thank Mr. Mitsuhiro Matsumoto for reading the manuscript carefully. This work was supported in part by a grant in aid for Science Research (Nos. 59340025, 60129031, 60121013) from the Ministry of Education, Science and Culture, and also by the Kyoto University Data Processing Center. The author thank the Computer Center of the Institute for Molecular Science, for the use of the HITAC M-200H computer. The computations were also done by the FACOM VP-100 and M-382 computer at the Kyoto University Data Processing Center.

Removal of Some Alkali Salts from Aqueous Solution by Active-Charcoal Electrode

Masao Ichinose, Takashi Yasuoka,* Shunmei Mitsuzawa, and Tsunetaka Sasaki
Department of Chemistry, Faculty of Science, Tokai University,
Kitakaname, Hiratsuka 259-12
(Received February 18, 1986)

An electrolytic removal of potassium and sodium sulfates from aqueous solutions was worked out by using an active-charcoal cathode and a platinum anode with a porous porcelain septum between them. Maximum removal of nearly 99% was attained for these salts. The mechanism of removal was confirmed to be based on the facts that potassium and sodium ions are entrapped and concentrated as hydroxides in the pores of the active-charcoal cathode while sulfate ions are removed from the solution and concentrated as sulfuric acid in the anode chamber.

As regards the removal of inorganic salts in aqueous solutions using an active charcoal, a simple adsorption method is not available, since the amount of adsorption is generally too small of the order of 0.01 to 0.5 mmol g^{-1} from 0.01 to 0.1 mol dm^{-3} aqueous solutions,[1] and the method of electrolysis using charcoal as an electrode has been reported[2,3] or patented[4]. However these studies mainly concern with the removal by the electrolytic formation of the substance of low solubility resulting in gas evolution or precipitation. In the present study, a method was devised to remove electrolytes by the electrolysis which locally concentrated and immobilized cations in pores of the active-charcoal cathode and entrapped anions in the anode chamber.

Experimental

Materials. The potassium and sodium sulfates used were commercial products of a guaranteed grade which were used without further purification. The active charcoal used as an electrode was the product of Wako special grade, charcoal activated, granulated. The active charcoal together with the porous porcelain tube used as a septum was carefully washed with distilled water until it showed no increase in electric conductance after washing.

Apparatus and Procedure. The apparatus used consisted of three parts, an electrode chamber, a circulation pump, and a reservoir, as shown in Fig. 1. The anode was a platinum wire coiled around the porous porcelain tube of 4 cm in diameter and 15 cm in height, while the cathode consisted of a poly(vinylidene dichloride) bag which contained a central graphite rod surrounded by the active charcoal.

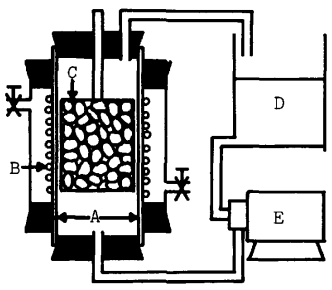

Fig. 1. Apparatus for the removal of electrolyte.
A: Porous porcelain tube (diameter 4 cm, height 15 cm), B: Platinum wire anode, C: Active-charcoal cathode with central graphite rod, D: Reservoir, E: Circulation pump (rate of circulation 3.2 dm^3 min^{-1}).

To carry out the removal experiment, 1 dm^3 of 1.25×10^{-4} mol dm^{-3} potassium or sodium sulfate was introduced in the apparatus and was circulated at the rate of 3.2 dm^3 min^{-1}. A direct current was then applied and the voltage was controlled so as to keep the current constant to 50 mA. During the electrolysis, small portions of the solution were withdrawn from the reservoir at the time interval of 20 min, and the concentrations of cations and anions were measured by the atomic absorption spectrophotometry using Hitachi 508 type Atomic Absorption Spectrophotometer and by the ion chromatography using Shimadzu LC-5A Liquid Chromatograph, respectively. The weight percentage of removal of each ions was then calculated. Conductance and pH measurements were further made to trace the removal of the electrolyte.

In order to study the mechanism of the electrolytic removal of electrolyte, measurements were made in addition for potassium sulfate under the same conditions as mentioned above excepting the following conditions: 1 without electrolysis, 2 without active charcoal, 3 with active charcoal placed outside the electric field, 4 without the circulation of the solution.

Results and Discussion

The percentage of removal obtained under various experimental conditions was plotted against the time of electrolysis as shown in Fig. 2. In the case of measurement 4, only one plot was made for the solution circulated after 100 min's electrolysis. As seen in this figure, the measurements 1 through 4 showed no removal of potassium ions. Compared with these results, nearly 99% of potassium and sulfate ions were found to be removed from the solution under circulation by 100 min's electrolysis at 50 mA using active-charcoal cathode. Conductance measurement also showed a decrease from 45 μs cm^{-1} for initial potassium sulfate solution to 1.6 μs cm^{-1} for the solution after 100 min's electrolysis, the latter being equal to the value for distilled water after sufficient electrolysis. A slight increase of pH observed during electrolysis of the solution which could be noticed also

for the electrolysis of distilled water may be due to the removal of dissolved carbon dioxide. Thus it was confirmed that the electrolysis under the circulation of the solution using active-charcoal cathode and platinum anode with porous porcelain septum between them effectively removed the potassium sulfate from an aqueous solution.

As regards the mechanism of the removal of the electrolyte, sulfate ions were considered to be exclusively removed by concentrating in the anode chamber as sulfuric acid as was confirmed by the coincidence of the initial amount of sulfate ions with the decrease of pH observed in the anode chamber assumed to be due to the formation of sulfuric acid and by the absence of sulfate ions in the circulating solution after electrolysis.

As for the mechanism of the removal of potassium ions, up-take by charcoal as potassium hydroxide is expected, since electrolysis of an aqueous potassium sulfate is known to result in the evolution of hydrogen and the formation of potassium hydroxide at a cathode.

To confirm this possibility, the active-charcoal electrode after being used for 100 min's electrolysis was placed in distilled water together with a platinum wire electrode, then the current was flowed in the reverse direction to the case of the removal experiment and the amount of potassium ions released, if any, from the charcoal was measured. The amount of hydroxide ions taken up was measured by the titrations of the active charcoal with hydrochloric acid.

The results of these measurements showed that the amounts of potassium and hydroxide ions taken up by the active-charcoal electrode were found to be nearly equivalent, being 1:1.08 in mol ratio. This fact together with the fact that graphite cathode without active charcoal could not remove potassium sulfate as shown in Fig. 2 confirmed the mechanism of removal that potassium ions are concentrated and entrapped as potassium hydroxide in the pores or cavities of the active-charcoal electrode.

As regards the active-charcoal electrode, the action of so called bipolar electrode has been reported,[3,5] according to which both ends of all particles of charcoal electrode act as anodes and cathodes. When we apply this mechanism in our case, inner and outer parts of charcoal electrode should equally contribute to the removal of potassium ions. To check the contribution of this bipolar action in the present experiment, potassium ions taken up by the outermost layer of active-charcoal electrode after being used for the removal of potassium sulfate were extracted by treating the charcoal with concentrated hydrochloric acid. The amount of potassium ions thus obtained was measured and was expressed as the percentage of the total amount of potassium ions removed. The value of 88% was obtained which confirmed the fact that the surface layer of active charcoal mainly acted to remove electrolytes and bipolar action played a minor role. In this connection, the removal of potassium ions by using a graphite cathode surrounded by a single layer of active charcoal particles was attempted. The result is shown in Fig. 3, together with the result

obtained by using the apparatus shown in Fig. 1 for comparison. The removal of potassium ions was only slightly less in the former case as was expected. This may suggest the effective and economical use of active charcoal.

With regard to the action of porous porcelain tube it is considered to hinder the sulfuric acid formed at the anode from mixing with circulating solution, as is evident from the comparison of the removal experiments using the apparatuses with and without the porous porcelain tube as shown in Fig. 4.

The rate of removal of potassium ions was further measured by using several active-charcoal of different origin as cathodes. The results are shown in Fig. 5. As seen, the nature of the active charcoal did not influence the efficiency of the removal of potassium ions as far as the present study was concerned. This may suggest that for the removal of electrolyte according to the present method, any porous substance having an electric conductance can be effectively used as the cathode irrespective of its nature.

The present studies were mainly made for potassium sulfate, but similar results could be obtained for several other salts, an instance of which is shown for sodium sulfate in Fig. 6. The maximum removal of 99% was also attained.

Finally it may be mentioned that in the case of the practical application of the present method for the removal of electrolytes, the reproduction of charcoal for the repeated use is the problem which cannot be disregarded. But the electrolytic removal of potassium ions mentioned above might be expected to facilitate the reproduction.

(Received February 12, 1986)

Azobenzene-linked, single-chain ammonium amphiphile ($C_{12}AzoC_5N^+Br^-$), $C_{33}H_{54}N_3O_3Br$, was crystallized from their solutions in water and ethanol. The crystals are triclinic with the space group $P\bar{1}$, $Z=2$, $a=3.4243(6)$, $b=0.8525(1)$, $c=0.6073(1)$nm, $\alpha=73.45(1)$, $\beta=88.03(1)$, and $\gamma=93.32(1)°$. The structure was solved by the direct method and refined anisotropically by the block-diagonal least-squares procedure: $R=0.06$ for 2917 observed reflections ($2\theta<105°$, Cu $K\alpha$, $\lambda=0.154184$ nm). The crystal structure consists of regularly stacking bimolecular layers in which $C_{12}AzoC_5N^+Br^-$ molecules incline about 30° to the layer surface. As expected from spectroscopic analyses, the azobenzene chromophore shows a head-to-tail (J-like) aggregation between adjacent molecules. The pronounced planarity of the azobenzene chromophore found in this crystal structure enables parallel stacking of phenyl groups in the J-like aggregation.

Biological membranes are organized assemblies consisting mainly of proteins and lipids. Their gross organization has been proposed by Singer and Nicolson[1] in the form of a fluid mosaic model, in which lipid molecules are assembled in the bilayer form. For better understanding of structural details of biological membranes and their relation to specific functions, it is essential to accumulate structural information about various lipid bilayers on the atomic level. However, it has been difficult to obtain single crystals of amphipathic lipids suitable for X-ray diffraction, which could provide the most detailed information about their preferred molecular conformations and interactions. Such information has been obtained so far only for a few amphipathic lipids.[2]

In order to establish the physicochemical basis of the biological membrane and to develop membrane-related chemical processes, one of the authors (T. K) has studied the formation of the bilayer structure using a large variety of amphiphiles containing a single,[3] double,[4] and triple[5] alkyl chains as the hydrophobic tail part. It has been shown that many of these compounds form stable molecular (monolayer and bilayer) membranes spontaneously when dispersed in water. Furthermore, in the case of dialkyldimethylammonium bromides with alkyl chain lengths of $n=18$ and 16, single crystals suitable for X-ray diffraction could be provided[6] and detailed structure analyses are now in progress. In the case of single-chain ammonium amphiphiles containing azobenzene chromophore (abbreviated as $C_nAzoC_mN^+Br^-$, hereafter, the general formula shown in Fig. 1), a

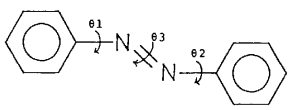
* Molecule has an inversion symmetry at the center of azobenzene moiety. ** Torsion angles are defined as follows:



series of compounds were synthesized to investigate the relationship between their aggregation behavior and the alkyl chain length in the tail(n) and spacer(m) portions.[7] In terms of absorption spectroscopy, their molecular aggregation states were classified into four types. They are the monomeric chromophore in micelles and in molecularly dispersed solutions, the dimeric chromophore in the liquid crystalline bilayer, and the H-aggregate and the J-like aggregate in the crystalline bilayer (Table 5 in Ref. 7). The latter two aggregates are particularly interesting because of their chromophore orientations. The H-aggregate implies the highly parallel chromophore orientation and the J-like aggregate implies the head-to-tail orientation (Fig. 2). We already investigated the structure of the H-aggregate in a cast film of $C_8AzoC_{10}N^+Br^-$ by the X-ray diffraction technique.[8]

In this paper, we discuss the detailed structure of the J-like aggregate in a single crystal of $C_{12}AzoC_5N^+Br^-$ on the basis of the structure obtained by X-ray crystal analysis. Since this is the first analysis of a totally synthetic amphiphile on the atomic level, the results will be useful for the better understanding of the biological membrane. Furthermore, it will also play an important part in the elucidation of the energy transfer mechanism, which occurs characteristically in the azobenzene-linked amphiphiles with J-like chromophore orientation.

Experimental and Structure Determination

$C_{12}AzoC_5N^+Br^-$ (25 mg) was dissolved in a boiling solution (30 ml) of water and ethanol (water/ethanol=1/1 by volume rotio). Yellow, plate-like crystals with thickness of about 0.02 mm were obtained by keeping the solution for a week or two at room temperature. However, these plate-like crystals were usually multiple crystals with the common axis normal to the plate surface. Needle-like crystals were also obtained by storing the solution in a refrigerator. In this case crystals were very thin (about 0.01 mm) and small

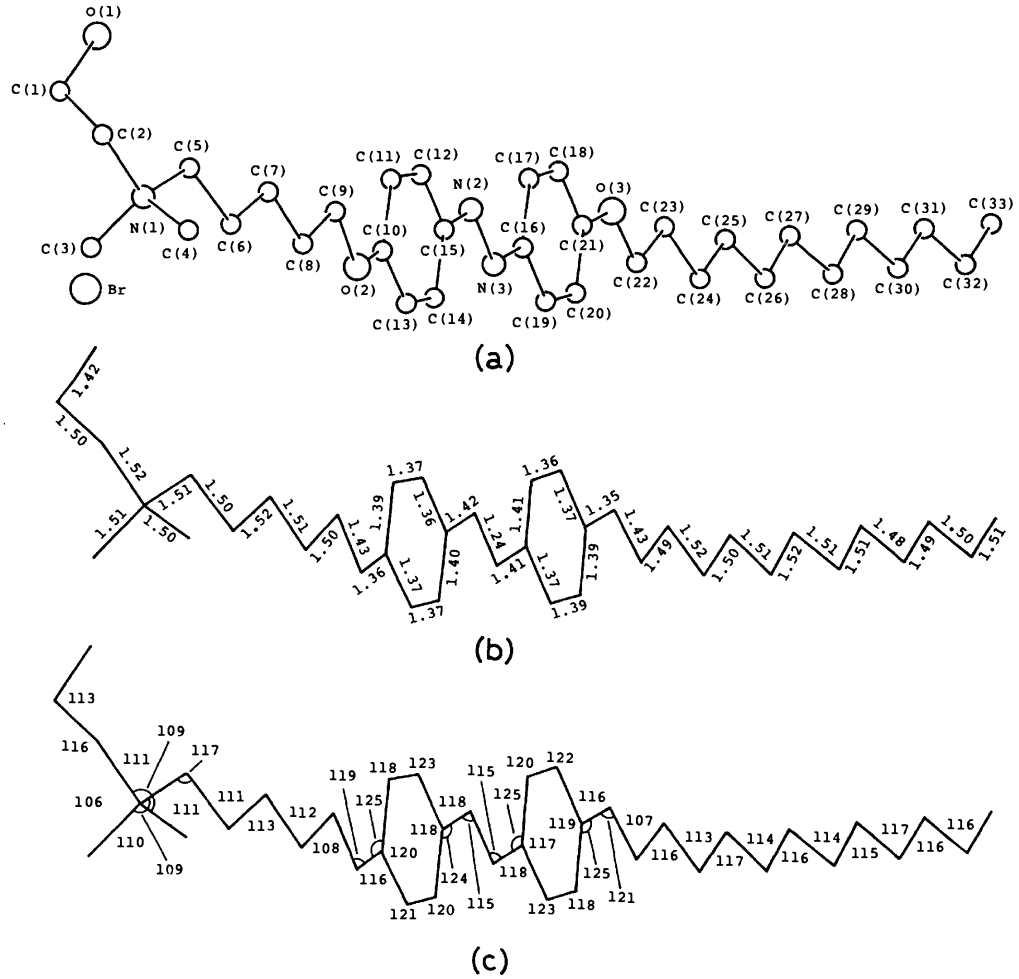


Fig. 3. Atomic labelling (a) and bond lengths (1×10/nm) (b) and angles (ϕ/°) in $C_{12}AzoC_5N^+Br^-$. Maximum estimated standard deviations for bond lengths and angles are 0.002 nm and 1°, respectively.

in width (about 0.1 mm) but long (2—3 mm). Diffraction experiments showed that these two types of crystals have identical lattice constants and intensity distribution. One of the latter type of crystals was used for the intensity measurements.

Lattice parameters and diffraction intensities were measured on a Rigaku four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation (λ=0.154184 nm). The lattice parameters were refined by the least-squares fit using 25 reflections in the 2θ range of 15—66°. By using the ω-scan mode at a scan rate of 6°/min, intensities of 4423 reflections were measured up to 105° in 2θ. The scan width was $\Delta\omega=(2.8+0.15\tan\theta)°$. Three reference reflections monitored every 50 reflections showed no significant intensity deterioration during the data collection. Corrections were made for the Lorentz and polarization factors, but not for absorption and extinction effects. A total of 2917 reflections greater than $3\sigma(F_o)$ were used in the following analysis, where $\sigma(F_o)$ is the standard deviation estimated from the counting statistics.

Crystal Data: $C_{33}H_{54}N_3O_3Br$, $F.W.$=620.7, triclinic, space group $P\bar{1}$, Z=2, a=3.4243(6), b=0.8525(1), c=0.6073(1) nm, α=73.45(1), β=88.03(1), γ=93.32(1)°, V=1.6941(4) nm^3, D_x=1.215, D_m=1.21 gcm^{-3}.

Determination and Refinement of the Structure

The direct method with the *MULTAN* 78 program[9] was applied for $P1$ and $P\bar{1}$ space groups. Only for the latter space group, a rigid azo moiety and two planar zigzag alkyl chains could be readily discerned. The vector between two bromide ions related by the centrosymmetric operation was clearly appeared in the three-dimensional Patterson map, which also supported the $P\bar{1}$ space group for the $C_{12}AzoC_5N^+Br^-$ crystal. After several cycles of block-diagonal least-squares refinement starting from the atomic coordinates obtained by the direct method, difference Fourier syntheses revealed the remaining two carbon atoms in the alkyl chain and a terminal oxygen atom in the hydrophilic head group. After an anisotropic refinement of non-hydrogen atoms, hydrogen atoms located on their calculated positions with isotropic temperature factors were included in the refinement. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with w=1.0 for all reflections. After several cycles some hydrogen atoms with unacceptable geometry were

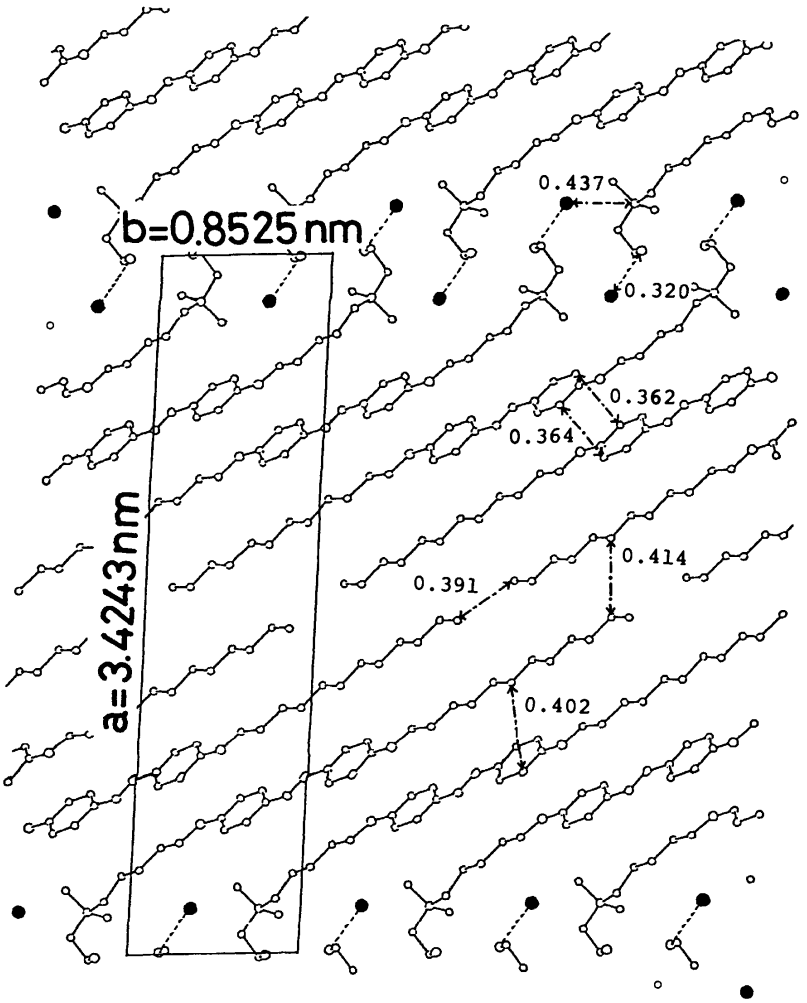

Fig. 4. Packing of $C_{12}AzoC_5N^+Br^-$ projected onto the *c*-plane. Hydrogen bonds between bromide anions and hydroxyl groups are indicated by broken lines (ORTEP[22] drawing).

excluded from further calculations. At the final stage of refinements the full-matrix least-squares calculation was carried out but no significant improvement was obtained. The final R value was 0.059 (R_w=0.060) for all nonhydrogen atoms and 51 hydrogen atoms. The final atomic parameters for non-hydrogen atoms are given in Table 1.[10]

The atomic scattering factors were taken from International Tables for X-Ray Crystallography, Vol. IV.[11] Computations were done on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University and on a HITAC M-280H computer at the Computer Center, University of Tokyo.

Results and Discussion

Molecular Structure of $C_{12}AzoC_5N^+Br^-$. Bond distances and angles are shown in Fig. 3, together with its atomic labelling. The average bond length between carbon atoms in the benzene rings is 0.138 nm. Judging from the bond distances in Fig. 3, there are no evidence for the quinonoid character in both benzene rings, unlike in 4,4′-dimethylazobenzene[12] and 4-amino-2′,3-dimethylazobenzene.[13] The C(11)-C(10)-O(2), C(14)-C(15)-N(2), C(17)-C(16)-N(3) and C(20)-C(21)-O(3) bond angles deviate by 4—5° from the standard value (120°) for sp^2 carbon atoms, presumably in order to relieve the close approach between the C(9) and C(11), C(14) and N(3), C(17) and N(2), and C(20) and C(22) atoms, respectively. This type of deviation has been found in many other compounds,[12-15] in which substituent groups are located approximately in the benzene ring plane. The mean C-C bond distance and C-C-C bond angle in the alkyl spacer and tail parts are 0.150(1) nm and 115(1)°, respectively. They are in good agreement with values previously found in other amphiphilic compounds with long hydrocarbon chains.[16,17]

The most striking feature of the $C_{12}AzoC_5N^+Br^-$ molecule is the planarity of the azobenzene chromophore. Table 2 shows two torsion angles (θ_1 and θ_2) between the azo group and the benzene rings, and at the azo group itself (θ_3) for various compounds. In

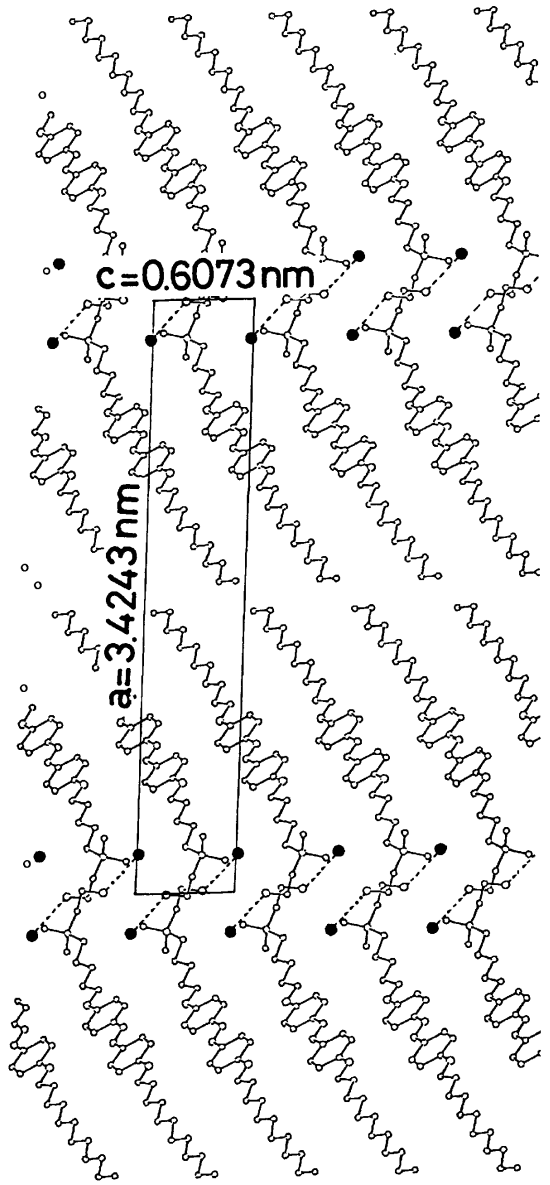

Fig. 5. Packing of $C_{12}AzoC_5N^+Br^-$ projected onto the *b*-plane (ORTEP[22]).

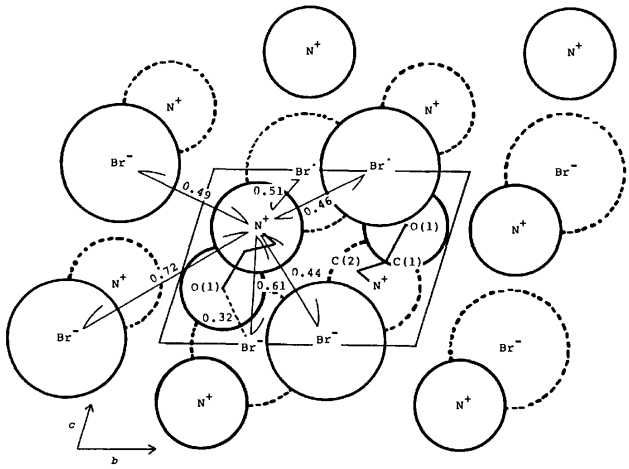

Fig. 6. Schematic illustration of hydrophillic layer of $C_{12}AzoC_5N^+Br^-$ projected onto the *a*-plane. Solid and broken circles represent atoms on the upper and lower side of the hydrophillic layer, respectively. Distances (*l*/nm) are indicated.

many cases, the deviation from the planar conformation is more than 6°, while in the $C_{12}AzoC_5N^+Br^-$ case the deviation is less than 2.3°. So far, this kind of planarity for an azobenzene chromophore has been found only in the case of 1,4-bis(phenylazo) benzene,[14] where adjacent molecules along the *b*-axis had very strong interactions and are separated by only 0.325 nm. Another example of the comparatively good planarity has been found in 4-amino-2′,3-dimethylazobenzene where there is delocalization of π-electrons between phenyl groups and an azo moiety.[13] The pronounced planarity of the azobenzene moiety in the $C_{12}AzoC_5N^+Br^-$ crystal enables parallel stacking of head and tail phenyl rings in the J-like aggregation (Fig. 4). Furthermore, the zigzag planes of the spacer alkyl and the tail alkyl parts of $C_{12}AzoC_5N^+Br^-$ are linked to the azobenzene plane with small torsion angles, 7.3° and 4.1°, respectively. Consequently, the whole molecule is like a long thin plate (Figs. 4 and 5).

Crystal Structure of $C_{12}AzoC_5N^+Br^-$. The crystal structure of $C_{12}AzoC_5N^+Br^-$ can be considered as a structure regularly stacked by the bimolecular layers along the *a* direction (Figs. 4 and 5). Within the bimolecular layer, two molecules related by the inversion symmetry face each other in the tail-to-tail fashion with the contact distance of 0.391 nm and their molecular axes inclined by about 30° to the layer surface (Fig. 4). The structure also can be seen as an alternation of the hydrophobic and hydrophilic layers stacked along the *a* direction. The hydrophilic layer, consisted of ammonium cations, bromide anions and terminal hydroxyl groups from both sides of bimolecular layers, coincides in position with the (100) plane of the crystal (Figs. 4 and 5). In particular, ammonium cations and bromide anions make a plane parallel to the (100) plane within the deviation of 0.004 nm. Two such planes are contained in one hydrophilic layer. This type of planarity among charged atoms in an amphiphilic salt crystal have been found in many other cases.[23,24] Figure 6 shows one of the planes composed of charged atoms and 2-hydroxyethyl groups. A nitrogen cation is surrounded by six bromide anions (four on the same plane and two on the other plane in the same hydrophilic layer). Terminal atoms, $N(1)^+$, C(2), C(1), and O(1) are nestled near the center of four equivalent bromides. A nitrogen cation locates at the point with long distances (0.61 and 0.72 nm) from bromide anions on the same side as O(1) atom. The distances from the other side of bromides are rather short (0.44—0.51 nm). The terminal hydroxyl group, which is the

only one potential hydrogen bonder in the $C_{12}AzoC_5N^+Br^-$ molecule, takes part in the hydrogen bond formation with bromide anion. Hydrogen bond distance (0.32 nm) and angle ($\angle OHBr^-=160.7°$) are those of commonly observed. In addition to this hydrogen bond, electrostatic interactions between ammonium cations and bromide anions stabilize the hydrophilic phase and link the neighboring bimolecular layers tightly, while hydrophobic alkyl chains and azobenzene moieties are stabilized only by the van der Waals interactions.

The cross-section of the benzene ring, S_B which is the largest part in the hydrophobic chain, could be estimated as 0.234 nm^2 by using van der Waals radii 0.18 and 0.12 nm for atoms C and H, respectively. While it is possible to calculate the molecular area, S_M, at the bilayer surface from the lattice constants: $S_M=0.497$ nm^2($=bc\times\sin\alpha$). In order to balance the cross-sections of the hydrophilic and hydrophobic part, molecules have to incline by 62° ($=\cos^{-1}(S_B/S_M)$) from the layer normal. Thus, the azobenzene chromophores are obliged to form J-like aggregate (head-to-tail orientation). On the other hand, hydrophobic chains from both sides interdigitate each other in the bilayer of the cast film of $C_8AzoC_{10}N^+Br^-$.[8] This is another stable aggregation (H-aggregate), since the cross-section of the interdigitated hydrophobic chain, 2 S_B is comparable to the molecular area S_M.

Some short interatomic distances between the neighboring azobenzene chromophores are shown in Fig. 4 together with those between alkyl tail parts. Absorption spectra of azobenzene in J-like aggregates of $C_nAzoC_mN^+Br^-$ show a shift to longer wavelength (red shift) than those of the molecularly dispersed azobenzene chromophores. This shift has been attributed to the intermolecular interactions between azobenzene chromophores in J-like aggregates.[7] The distance about 0.36 nm between overlapped phenyl groups seems to be short enough for red shift by reference to theoretical calculations for dye molecules in J-aggregates.[25] In order to clarify the relationship between a molecular and/or packing structure and spectroscopic behavior, further analyses for several compounds with different n and m of $C_nAzoC_mN^+Br^-$ are now carring on.

Dichroism Analysis of Oriented Polyenes Produced in Poly(vinyl alcohol) Film

Kazunori MARUYAMA and Yoshié TANIZAKI*
Department of Materials Science and Technology, Technological University of Nagaoka, Nagaoka, Niigata 940-21
(Received March 14, 1986)

Dichroic spectra of polyenes $-(CH=CH)_n-$ produced in heat-treated poly(vinyl alcohol) [PVA] film were determined for two cases; stretch (at 85 °C) after heat (120 °C), (Δ,S), and heat after stretch, (S,Δ). The dichroic ratios Rd_n of component polyenes (n=2—6) were estimated by means of simulation. In both cases (Δ,S) and (S,Δ), the relation of Rd_n vs. Rs (stretch ratio) kept the theoretical equation of the dichroism analysis. The relative angles among the transition moments μ_n (n=2—6) were in accordance with those obtained by drawings of *trans*-polyenes. The idea of an azimuth vector in the stretched PVA substrate was justified. The relation of $Rd_n(\Delta,S)>Rd_n(S,\Delta)$ was always observed at any Rs. This was explained by the thermal orientation-relaxation of polymer chains.

Stretched PVA film colored by heating is utilized as a polarizing film.[1] In such a film, various kinds of π electron systems must be produced and oriented to the stretched direction. Therefore, the whole dichroism has to be dependent upon the respective polarization characteristics of the π electron systems. But the detailed analysis of the dichroism has not been investigated yet, though the dichroic ratio of the stretched and heat-treated PVA film has been reported.[2]

Up to date, the conventional dichroism analysis by the technique of stretching the PVA film[3] has succeeded in explaining the correlation between the transition moment and the geometrical structure of many molecules.[4] This analysis is based on a distribution function of an azimuth vector postulated for the PVA substrate.[3]

Previously, we have made assignments for the polyenes produced in heat-treated PVA film[5] and have further attempted to estimate the concentrations of the polyenes by simulations.[6]

When the dichroism analysis is combined with the method of simulation, it is expected that the correlation between the whole and the component dichroisms of the polyenes in a stretching state can be analyzed. Since the polyenes should be formed along the polymer chains in this case, the orientation aspect of the polyenes is regarded to be the same as that of the polymer chains. In other words, the orientation vector of the polyenes as an absorption species is the same as the azimuth vector of the substrate. This is important because, in the conventional dichroism analysis, it is assumed that an orientation vector of a guest molecule acts with the same behavior as the azimuth vector concomitant with the substrate itself. For that reason, the respective orientation directions of polyenes must be identical with a single direction which is common to all. This will be checked by the geometrical relation between the common azimuth direction and the molecular structure of the polyene.

The purpose of the present study is the following. The first is to seperate the total dichroism of polyenes into the component dichroisms by simulation and then to determine the relative directions of the transition moments μ_n. The second is to verify the justification of an azimuth vector, for which the distribution function is fundamental to the conventional dichroism analysis.

Experimental

PVA films treated with $NaBH_4$ according to the method reported previously[5] were digested in 0.05 M HCl solution (1 M=1 mol dm^{-3}) or 0.05 M H_2SO_4 solution for 3 h and dried for 1 d at room temperature. Further, they were treated by the following processes (A) or (B).

(A) After the film was heated at 120 °C to turn it red, it was digested in distilled water for 1 d, dried at room temperature for 1 d, and then stretched. The stretched film was fixed on a metal holder.

(B) At first the film was stretched and fixed on a metal holder. Then it was heated at 120 °C for about 15 min.

In order to distinguish between (A) and (B) by the sequence of heating (Δ) and stretching (S), the notations (Δ,S) and (S,Δ) will be used, respectively.

The film was uniaxially stretched at 85±5 °C and the stretch ratio (Rs) was defined in the same way as reported previously.[3] That the stretched film is ideally deformed was checked by assuring that the dimensional requirement for the theory of dichroism analysis was satisfied with respect to the length, width and thickness of film before and after stretching.[7] The heat treatment of the sample film was carried out in a heating compartment under conditions of 0.5 dm^3 min^{-1} flow of nitrogen.

The absorption spectra were measured using a Shimadzu UV-360 Spectrophotometer equipped with a rotatory Rochon-type prism. The net absorption of the sample film was obtained by compensation for the absorption of a colorless PVA film before heating. The dichroic ratio Rd is defined as $A_\parallel/A_\perp$, where $A_\parallel$ and $A_\perp$ are the absorbances for the incident polarized light, of which the electric vector is parallel and perpendicular to the stretching direction of film, respectively. The Rd curves were obtained by a data processor, Sapcom-1, attached to the spectrophotometer.

Theoretical

When a PVA film undergoes an ideal uniaxial stretching, the width and thickness of the film shrink at the same rate. In this case, the following relation must hold,

$$A = k(A_{\parallel} + 2A_{\perp}) \tag{1}$$

where A is the absorbance before stretching and k is a constant depending on the film dimensions deformed. Equation 1 also holds in the case of respective polyenes. Using the same constant k, the absorbance of n-polyene -(CH=CH)$_n$- is given by

$$A_n = k(A_{n\parallel} + 2A_{n\perp}) = \varepsilon_n C_n d \tag{2}$$

where ε_n and C_n are the extinction coefficient and the concentration of n-polyene, and d is the film thickness. The dichroic ratio is defined as usual:

$$Rd_n = A_{n\parallel}/A_{n\perp} \tag{3}$$

From Eqs. 2 and 3, the $A\parallel$ and $A\perp$ spectra of the whole system can be represented as follows,

$$\left.\begin{aligned} A_{\parallel} &= \sum_n A_{n\parallel} = (d/k)\sum_n \varepsilon_n C_n (1+2/Rd_n)^{-1} \\ A_{\perp} &= \sum_n A_{n\perp} = (d/k)\sum_n \varepsilon_n C_n (2+Rd_n)^{-1} \end{aligned}\right\} \tag{4}$$

Therefore, the following relation between Rd and Rd_n is obtained.

$$Rd = \frac{\sum_n \varepsilon_n C_n (1+2/Rd_n)^{-1}}{\sum_n \varepsilon_n C_n (2+Rd_n)^{-1}} \tag{5}$$

Strictly speaking, on account of the molecular vibration, the ratio of $A_{n\parallel}$ to $A_{n\perp}$ of the dichroic spectra of A_n depends on the wavelength, namely, Rd_n is not constant over the whole absorption region. But, its variation in the main part is generally small. At the present stage, therefore, all of Rd_n are assumed to be invariable in the respective absorption regions.

By simulation of the absorption spectra of polyenes produced in PVA film,[6] the concentrations C_n of Eq. 2 can be estimated, using the known ε_n, from the simulated spectrum A of Eq. 1 together with the relation $A=\sum_n A_n$. From these and the observed Rd values, Rd_n of respective polyenes can be determined so as to satisfy Eq. 5.

According to the theory of dichroism analysis using uniaxially stretched PVA film,[3] the anisotropy of the substrate can be described by a distribution function $f(Rs)$ of an azimuth vector (OD vector) for the stretching direction. And the dichroic ratio Rd_n is derived from $f(Rs)$. An important point to be noticed here is that the direction which keeps the distribution $f(Rs)$ is not the transition vector μ_n itself but the projective part (μ_{na}) of μ_n upon the direction of OD. For that reason, the Rd_n equation involves Rs and a parameter r_n, $Rd_n=F(Rs, r_n)$, where r_n is defined as

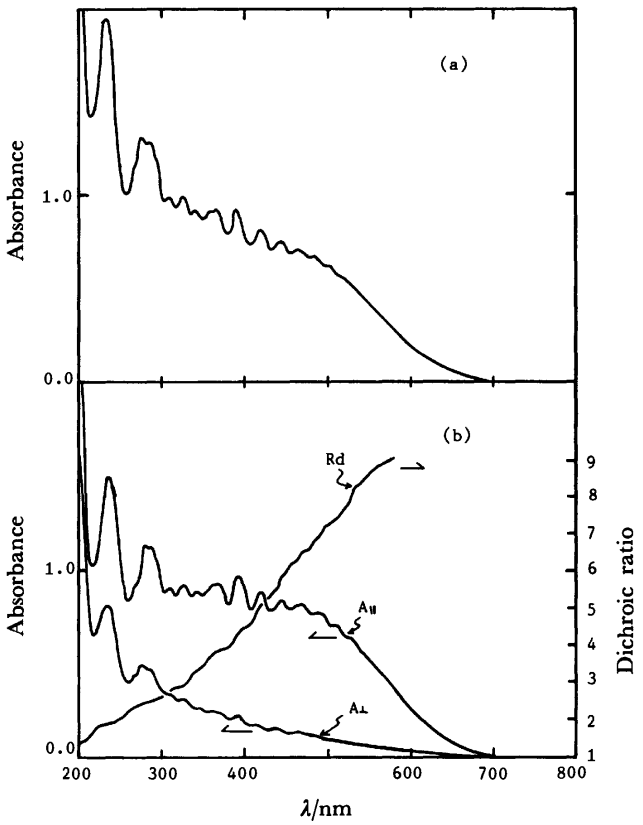

Fig. 1. Isotropic (a) and polarized absorption spectra (b) of PVA film for the case of (Δ,S), which is stretched (Rs=5.7) after heating at 120 °C for 15 min. Rd is dichroic ratio. Film thickness is 195 μm (a) and 110 μm (b).

$r_n=|\mu_{na}/\mu_{nb}|$, and μ_{na} and μ_{nb} are the components of μ_n along OD and its normal direction, respectively.

Finally, Rd_n is expressed by Rs and r_n as follows.[3]

$$\left.\begin{aligned} Rd_n &= \frac{2+2(r_n^2-1)T}{(2r_n^2+1)-(2r_n^2-1)T} \\ \text{where} \\ T &= \frac{Rs^2}{Rs^2-1}\left[1-\left\{\frac{\pi}{2}\tan^{-1}(Rs^2-1)^{-1/2}\right\}(Rs^2-1)^{-1/2}\right]. \end{aligned}\right\} \tag{6}$$

The inclination of μ_n for OD can be given by

$$\alpha_n = \cot^{-1} r_n \tag{7}$$

where α_n is called the orientation angle of μ_n.

Results

Figure 1(a) shows the absorption spectrum of a PVA film heated to red, and Fig. 1(b) the dichroic spectra and the Rd curve of the same film stretched to Rs=5.7. The spectrum A calculated by Eq. 1 using $A\parallel$ and $A\perp$ of Fig. 1(b) coincided with that of Fig. 1(a) when k=0.66. This indicates that the deformation of PVA substrate was ideal and that the absorption species did not change chemically by stretching.

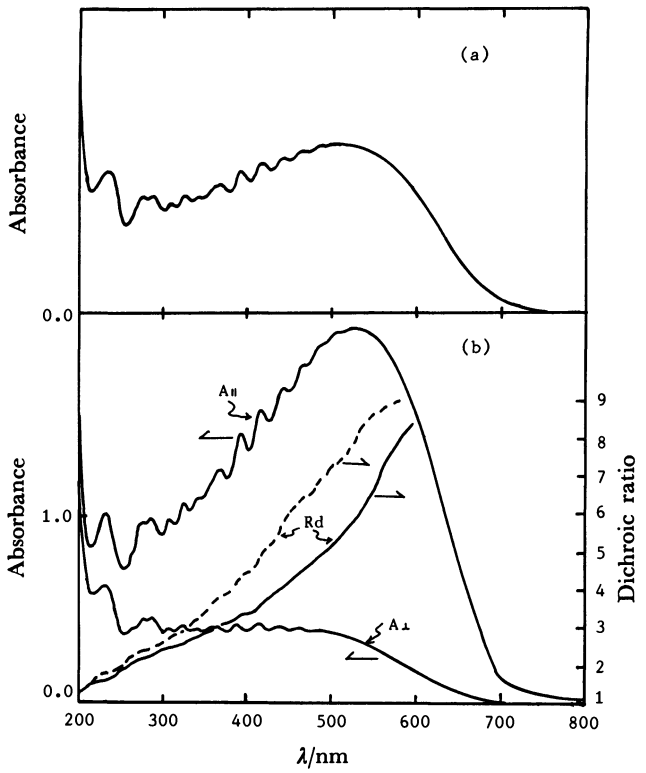

Fig. 2. Isotropic (a) and polarized absorption spectra (b) of PVA film for the case of (*S*,*Δ*), which is heated at 120 °C for 15 min after stretching (*R*s=6.2). Fig. (a) is obtained from $(A_{\parallel}+2A_{\perp})/3$ of Fig. (b). Film thickness is 98 μm. Broken line in (b) indicates *R*d curve in Fig. 1(b).

Figure 1(b) is for the case of (*Δ*,*S*). In contrast to this, the film for (*S*,*Δ*) is reddish purple and its dichroic spectra at *R*s=6.2 are measured as shown in Fig. 2(b). Figure 2(a) shows the isotropic spectrum *A* determined by Eq. 1 using $A_{\parallel}$ and $A_{\perp}$ of Fig. 2(b).

From the comparison of Figs. 1(a) and 2(a), it is clear that the absorption spectrum of a film is changed by reversing the procedure, heat (*Δ*) and stretch (*S*); the relative intensities in the short and long wavelength regions are exchanged. The absorption in the long wavelength region is more intensive for the case of (*S*,*Δ*) than for (*Δ*,*S*).

The *R*d curve rises toward the long wavelength in either case (Figs. 1(b) and 2(b)), but the *R*d value at each wavelength is smaller for (*S*,*Δ*) (solid line in Fig. 2(b)) than for (*Δ*,*S*) (broken line), though *R*s of the former is larger than that of the latter.

The concentrations C_n of Eq. 2 were obtained using litetature values of ε_n.[8] The Rd_n values at *R*s=5.7 were calculated from the data of Fig. 1(b), in such a way that *R*d of Eq. 5 becomes equal to the observed *R*d. The Rd_n values thus determined at the wavelength corresponding to the 1←0 transition of *n*-polyenes are listed in Table 1 together with the *R*d values at the same wavelengths. In Table 1, only the results of *n*=2—7 are presented, being left out those of $n \geqq 8$,

Table 1. Simulated Rd_n and Observed *R*d at 1←0 Transitions of *n*-Polyenes[a]

n	Rd_n	*R*d
2	1.9	1.9 (234)
3	2.3	2.3 (274)
4	2.6	2.8 (310)
5	3.1	3.3 (342)
6	4.2	3.9 (366)
7	4.3	4.5 (390)

a) Observed *R*d is the case of *R*s=5.7 (Fig. 1(b)). ( ) indicates wavelength of 1←0 transition of *n*-polyene.

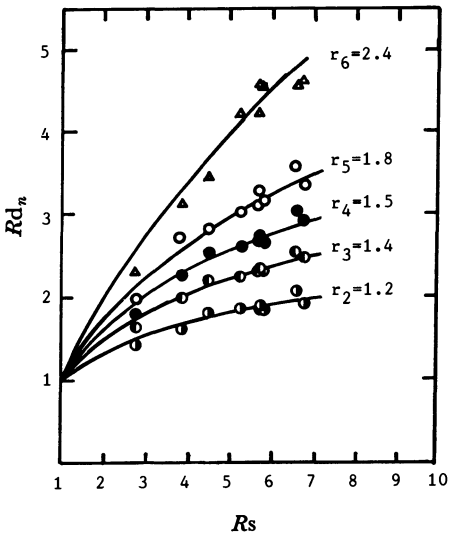

Fig. 3. Relationship of Rd_n(*Δ*,*S*) vs. *R*s for *n* which is the number of double bonds of *n*-polyene. Marks are experimental and lines are obtained from Eq. 6 using the parameters r_n listed in Table 2. ◑: *n*=2, ◐: *n*=3, ●: *n*=4, ○: *n*=5, △: *n*=6.

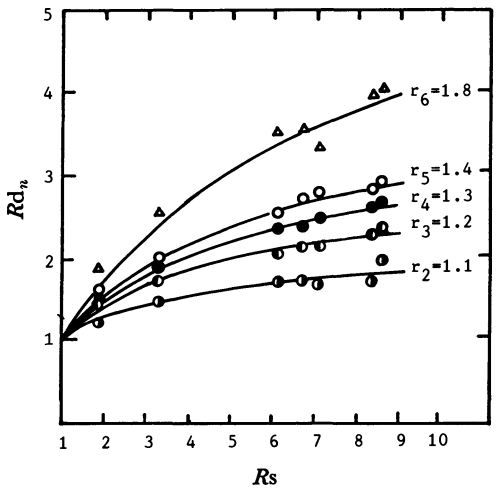

Fig. 4. Relationship of Rd_n(*S*,*Δ*) vs. *R*s for *n* which is the number of double bonds of *n*-polyene. Marks are experimental and lines are obtained from Eq. 6 using the parameters r_n listed in Table 2. ◑: *n*=2, ◐: *n*=3, ●: *n*=4, ○: *n*=5, △: *n*=6.

Table 2. r_n and Orientation Angle of n-Polyene[a)]

n	(Δ, S)			(S, Δ)		
	r_n	α_n°	α_n	r_n	α_n°	α_n
2	1.2	41°	41°	1.1	44°	44°
3	1.4	36°	36°	1.2	39°	39°
4	1.5	33°	33°	1.3	37°	36°
5	1.8	29°	31°	1.4	35°	34°
6	2.4	22°	30°	1.8	29°	33°

a) Orientation angle: α_n° is observed, α_n is from drawing (see Fig. 6).

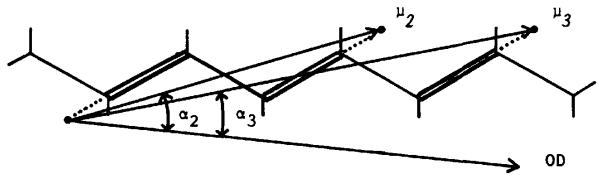

Fig. 6. Drawing of $\mu_n(n=2, 3)$ and OD for polyene skeleton. Terminals of transition vector μ_n are at two points taken at halves as long as the terminal bond on the outer extension lines. α_n is the orientation angle of μ_n against OD (orientation direction) of polymer chain.

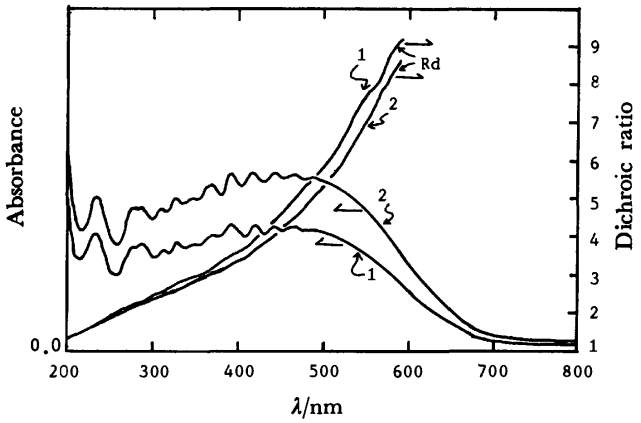

Fig. 5. Absorption spctra of PVA film for the case of (S,Δ), stretched (Rs=6.8) and heated at 120 °C for 16 min (curve 1) and 20 min (curve 2). Film thickness is 68 μm.

because these concentrations computed are not dependable.[6)]

In the same way as above, the Rd_n values at various Rs were determined. The relation Rd_n vs. Rs is plotted in Fig. 3 for individual polyenes. The curves drawn in Fig. 3 are those obtained theoretically by Eq. 6 using the parameters which fit for the Rd_n-Rs plot. Figure 4 shows the same relation for the case (S,Δ), where the heating times were kept at 15 min, because the Rd value was dependent upon the length of the heating period (see Fig. 5). The r_n values of Figs. 3 (Δ,S) and 4 (S,Δ), and the orientation angles α_n° obtained from Eq. 7 are listed in Table 2.

Figure 5 shows the absorption spectra and the Rd curves for the different heating times (1:16 min, 2:20 min) of a film for the case of (S,Δ), in which the spectra are derived from Eq. 1 using the observed $A\parallel$ and $A\perp$. Figure 5 reveals an interesting phenomenon that the longer the heating time, the stronger the absorption and at the same time the lower the Rd values.

Discussion

Orientation Angles of Polyenes. As shown in Figs. 3 and 4, the Rd_n values agree well with the theoretical curves. This means that μ_{na} is acting with the same behavior as the OD vector which is common to all polyenes. For that reason, the inclinations of μ_n can be compared by the orientation angles α_n° against only one OD vector.

Table 2 shows that α_n° becomes smaller with increase of n in both cases, (Δ,S) and (S,Δ). This indicates that the OD vector points to a certain lengthwise direction close to the zigzag chain of polyene skeleton.

In order to investigate α_n° in Table 2 by a molecular diagram, the transition directions of μ_n with respect to the same geometry of polyene-skeleton were made in the following way. The direction of μ_n is regarded as the direction through the two points which are respectively half as long as the C-C bond on the outer extension line of each of the terminal double bonds of n-polyene as shown in Fig. 6. Assuming that an angle α_2 between μ_2 and OD by drawing is equal to α_2°, other α_n are obtained as listed in the right columns of (Δ,S) and (S,Δ) in Table 2.

In both cases, (Δ,S) and (S,Δ), the experimental α_n° are in good agreement with the drawing α_n in the range n=2—5. This fact indicates that the distribution of the OD vector agrees with the theoretical distribution function and that the concept of an azimuth vector is justified.

Relaxation Phenomenon of Orientation. Inspecting the same n, the following relations are recognized: $\alpha_n^\circ(\Delta,S)<\alpha_n^\circ(S,\Delta)$ in Table 2 and $Rd_n(\Delta,S)>Rd_n(S,\Delta)$ at any Rs in Figs. 3 and 4. The latter relation may correspond to some reduction of $Rs(S,\Delta)$ by heating after stretching. However the film was fixed tightly on a metal holder during the heat treatment and any appreciable deformation of film could not be observed by heating, accordingly the reduction of the Rs of the film itself cannot be considered. Therefore, the apparent reduction of Rs by heating may be due to some orientation-relaxation by the thermal motion of the polyene chains.

If the reduction of apparent Rs is regarded as a relaxation phenomenon, a stationary state of orientation must exist at a given temperature. Let f_1 and f_2 be the distribution functions for stationary states at temperature T_1 and T_2 ($T_1<T_2$), respectively, the time

dependent change from f_1 to f_2 may be described as follows,

$$f(t) = f_2 + (f_1 - f_2)\exp(-t/\tau) \quad (8)$$

where τ is the relaxation time.

Since the orientation relaxation is induced by thermal motion, the change of Eq. 8 should be directed towards the isotropic state. Consequently, Rd must be lowered with the period of heating time. In fact, as shown in Fig. 5, the Rd curve in the whole wavelength region is lowered with the heating time. This is considered evidence for the relaxation phenomenon of orientation.

Stretching Effect on Polyenes Formation. In spite of the equal heating temperature (120 °C), the relative intensity of absorption in the long wavelength region was greater for the stretched film (Fig. 2(a)) than for the unstretched one (Fig. 1(a)). This stretching effect on polyenes formation, however, cannot be analyzed at the present stage.

Adsorption of Tetrachloro-*p*-benzoquinone from Various Solvents on Metal Oxides

Kunio Esumi,* Kazuaki Miyata, Fumio Waki, and Kenjiro Meguro
Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received March 17, 1986)

Adsorption of tetrachloro-*p*-benzoquinone(chloranil) from basic and acidic solvents on metal oxides, such as alumina and titania was carried out to understand the acid-base interaction at the interface. The amount of chloranil adsorbed decreases with an increase of acid-base interaction between the basic solvent and chloranil and also decreases with an increase of acid-base interaction between the acidic solvent and electron donor sites of the metal oxides for both metal oxides. Furthermore, the change in concentration of chloranil radicals formed on their metal oxides by the adsorption is correlated with the acid-base interaction at the interfaces.

Recently, the acid-base theory has been applied to colloidal systems. Fowkes et al.[1,2] have studied the interactions between inorganic solids and basic adsorbates by using the Drago correlation of the heats of acid-base interaction and have determined the Drago parameters for several solids, such as silica, rutile, and magnetite. Esumi et al.[3,4] have examined the adsorption of a strong electron acceptor such as tetracyanoquinodimethane from various solvents on metal oxides and they have demonstrated that the acid-base interaction is an important factor for the adsorption.

In this work, further to confirm the importance of acid-base interaction at solid-liquid interface, the adsorption of chloranil similar to TCNQ on metal oxides was performed.

Experimental

Materials. Alumina and titania were used as metal oxides. These metal oxides were prepared as follows: excess aqueous methanol (water:methanol=4:1 in weight) was vigorously added to a 1-butanol solution of each alkoxide. Stirring was continued for 5 h at about 90°C. The precipitate obtained was separated by centrifuging, washed with methanol, finely ground, and then evacuated at 100°C. Finally, the dried products were calcined for 2 h at 500°C, and used as samples.

Chloranil was obtained from Tokyo Kasei Ltd., and purified by repeated recrystallization from toluene. The solvents used in this study were dried by the use of molecular sieves.

Procedure. The metal oxide was placed in an L-type test tube and a solution of chloranil in an organic solvent was then poured in. After the tube had subsequently been shaken for 2 h at 25°C, the metal oxide was collected by centrifuging and dried at room temperature in vacuo. The dried sample was then used for an ESR measurement.

The ESR spectra were measured by means of a Japan Electrons Optics Laboratory ESR spectrometer (JES-FE3X) operating with an X-band microwave 100 kHz field modulation. The radical concentrations were estimated by comparing the area under the absorption curves for the sample and for standard solutions of 2,2-diphenyl-1-picrylhydrazyl in benzene.

The amount of chloranil adsorbed was determined from the difference in concentrations before and after the adsorption. The absorbance of chloranil was measured by means of an UV spectrophotometer (Hitachi 220A). The maximum absorption wavelengths of the absorption band of chloranil in three basic solvents were 367 nm in acetonitrile, 365 nm in ethyl acetate, and 286 nm in 1,4-dioxane while the maxima of the two acidic solvents were 372 nm in dichloromethane and 375 nm in chloroform.

The specific surface areas of the samples were determined with a Sorptograph, Model ADS-1B(Shimadzu Seisakusho Co., Ltd.): alumina, 227.4 $m^2 g^{-1}$ and titania, 54.7 $m^2 g^{-1}$.

Results and Discussion

The amount of chloranil in solutions adsorbed on the surfaces of alumina and titania was determined from three basic and two acidic solvents. The adsorption isotherms of chloranil are shown in Fig. 1; it is seen that their isotherms are of the Langmuir type for both metal oxides. Table 1 gives the saturated amounts of chloranil adsorbing on the metal oxides estimated from the Langmuir plots. In order to interpret this adsorption result in terms of the acid-base theory, the Drago equation[5] is employed:

$$-\Delta H^{ab} = C_A C_B + E_A E_B$$

where E and C are the Drago constants for the acidic compound(A) and the basic compound(B). It has been demonstrated[5] for the above equation that ΔH^{ab} values can be predicted within 3%. Furthermore, a useful approach for relating the interfacial inter-

Table 1. Data of Chloranil Adsorption

Sample	Saturated amount($\times 10^4$ mmol m^{-2})		
	Acetonitrile	Ethyl acetate	1,4-Dioxane
Alumina	3.82	1.49	1.05
Titania	5.33	0.32	0
	Dichloromethane		Chloroform
Alumina	3.59		2.85
Titania	1.97		1.80

actions quantitatively has been the Drago equation of enthalpy changes in acid-base complexation. To apply the Drago equation to this work, the E and C values for the solvents and chloranil should be known, the former is available, but the latter is not reported in the literature.[5] However, from the enthalpy values[6,7] of chloranil and some electron donor solvents, the E and C values of chloranil can be calculated using the Drago equation. The Drago constants and their enthalpy values are listed in Table 2. Figure 2 shows that the saturated amounts of chloranil adsorbed on both metal oxides decrease with an increase of acid-base enthalpy between chloranil and their basic solvents. The behavior of the saturated amounts of chloranil adsorbed in the system of the acidic solvents is similar to that for the basic solvent systems; the saturated amounts of chloranil adsorbed decrease also with an increase of acid-base enthalpy between the acidic solvents and the electron donor sites of metal oxides. In addition, the adsorption results show that the saturated amount of chloranil on alumina is considerably larger than that on titania for both basic

Table 2. Acid-Base Parameters

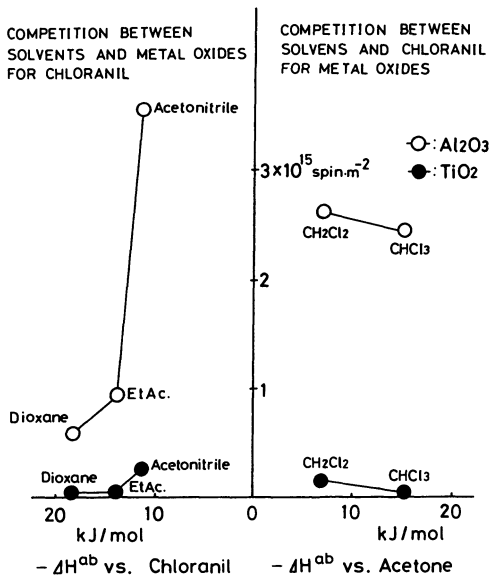

Fig. 3. The Change in the Chloranil radical concentration on metal oxides as a function of the basicity or acidity of the solvent.

and acidic solvent systems.

When chloranil is adsorbed on the metal oxides from the basic and acidic solvents, the surfaces develop characteristic colors; the colors for both alumina and titania were violet, whereas the color strength was dependent on the kind of solvent. It has been reported[8–10] that the colored oxide samples obtained by adsorption of electron acceptors exhibit ESR signals indicating the presence of the free anion radicals of their acceptors. In the present study, the colored samples obtained by the adsorption of chloranil gave an unresolved ESR spectra having a g-value of 2.011.[11] To compare the concentration of the chloranil anion radicals formed on the surfaces as a function of acid-base enthalpy, their concentrations obtained at corresponding to the half-value of the saturated amounts, are given in Fig. 3. It is apparent that the concentrations of chloranil anion radicals decrease with an increase of the acid-base interaction between basic solvents and chloranil or between acidic solvents and electron donor sites on their oxides. Furthermore, it is noteworthy that the concentrations of these radicals formed on alumina are higher than those on titania in all the solvent systems, implying that the electron donor sites on alumina provide a higher electron donicity than those on titania, for which the result is in good agreement with previous data.[3]

Thus, the results obtained from the adsorption of chloranil show a similar trend to those from the adsorption of TCNQ for the acid-base interaction.

For the electron donor sites for both metal oxides, surface hydroxide ions are responsible, because they exist at a relatively low activation temperature. Further, Flockhart et al.[12,13] have confirmed that such hydroxide ions are formed below 500°C which are correlated with electron donicity. Also, Che et al.[14] have reported that electron donor sites for titania at relatively low temperature (<500 °C) are assigned to surface hydroxide ions.

Phase Transition of Unsymmetric Bis(quaternary alkyl bromide) Salts of 1,4-Diazabicyclo[2.2.2]octane, C_{10}-DABCO-C_n-Br_2 ($11 \leqq n \leqq 22$)

Jun SHIMIZU, Kengo IMAMURA, Takashi NOGAMI,* and Hiroshi MIKAWA†
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565
(Received April 23, 1986)

Phase transitions of unsymmetric bis(quaternary alkyl bromide) salts of 1,4-diazabicyclo[2.2.2]octane (DABCO)(C_{10}-DABCO-C_n-Br_2, $11 \leqq n \leqq 22$) were studied on the basis of measurements of differential scanning calorimetries, infrared absorption spectroscopy, and bromide-anion conductivities. The DSC measurements showed two transition temperatures (T_{c1} and T_{c2}, $T_{c1} > T_{c2}$); this exhibits the existence of the metastable phase for the DABCO salts (C_{10}-DABCO-C_n-Br_2, $12 \leqq n \leqq 22$). The metastable phase was converted to the stable phase within several days except for C_{10}-DABCO-C_n-Br_2 (n=12, 22). The temperature dependence of the infrared absorption spectra revealed that the band progressions due to two different alkyl chains disappeared at T_{c1} and appeared again at T_{c2}. This shows that the *trans*-zigzag conformation of the alkyl chains in the low temperature phase is destroyed by the conformational change above T_{c1} and then recovered again below T_{c2}. Abrupt increases in the bromide-anion conductivities by 100—1380 times were observed at around T_{c2} for the samples annealed beforehand above T_{c1}. However, the virgin samples showed much broader increases in the conductivities below T_{c1}; no conductivity jump was observed. The conductivity increase was caused by the conformational change in the alkyl groups. The concomitant formations of the voids facilitate the bromide-anion transport.

As an extension of the studies of the halide-anion conductivities of crown ether–metal halide complexes,[1] cryptand 222-metal halide complexes,[2] quaternary tetraalkylammonium halides,[3] and quaternary tetraalkylphosphonium halides,[4] we have studied the halide-anion conductivities of the symmetric bis(quaternary alkyl halide) salts of 1,4-diazabicyclo[2.2.2]octane (DABCO).[5] A first order solid-solid phase transition was observed for the DABCO salts, with concomitant increases in the halide-anion conductivities by two to three orders of magnitude. The phase transition was also studied by means of DSC, IR absorption spectroscopy, and powdered X-ray diffraction. The temperature dependence of the IR absorption spectra of the DABCO salts exhibited the abrupt disappearance of the band progressions above the transition temperatures.[6] Thus, the phase transition was found to be caused by the conformational change in the alkyl groups. Powdered X-ray diffraction revealed a reversible change in the crystal structure at the transition temperature.[5] Unlike the case of the symmetric salts, the existence of the metastable phase was clarified for the unsymmetric bis(quaternary alkyl bromide) salts of DABCO by means of DSC and a study of the IR absorption spectra.[7] The unsymmetric DABCO bromide salts studied previously possess two alkyl groups; the difference in their carbon numbers was fixed at two.[7] Since the unsymmetric salts exhibited different phenomena from the symmetric salts for the phase transition, it seemed interesting to see how the phase transition would be modified for the unsymmetric salts by changing the difference in the carbon numbers of two alkyl groups attached to DABCO nitrogens. The unsymmetric DABCO bromide salts in this study possess two alkyl groups; one is fixed to the decyl group, while the other is changed systematically from n-$C_{11}H_{23}$ to n-$C_{22}H_{45}$. The materials studied are shown in Fig. 1. The names of the materials are abbreviated by the numbers of alkyl carbons. For example, *N*-decyl-*N'*-tetradecyl-1,4-diazoniabicyclo[2.2.2]octane dibromide is abbreviated as C_{10}-DABCO-C_{14}-Br_2. Thus, the materials in Fig. 1 can be described generally as C_{10}-DABCO-C_n-Br_2 ($11 \leqq n \leqq 22$).

C_{10}-DABCO-C_{14}-Br_2

Experimental

Materials. All of the materials and the solvents were purified before the synthesis of the quaternary DABCO salts, as has been described previously.[6,7]

† Present address: Department of Environment and Safety Engineering, Faculty of Engineering, Fukui Institute of Technology, Gakuen-cho, Fukui 910.

Syntheses of Unsymmetric Bis(quaternary Alkyl Bromide) Salts of DABCO. The syntheses of mono(quaternary alkyl bromide) salts of DABCO were described in a previous paper.[7] The unsymmetric bis(quaternary alkyl bromide) salt of DABCO was synthesized by the reaction of the mono(quaternary salt) with alkyl bromide. The synthesis of unsymmetric salts will be described for C_{10}-DABCO-C_{14}-Br_2 as a typical example. The methanol (20 ml) solution of *N*-decyl-1-aza-4-azoniabicyclo[2.2.2]octane bromide (2 g, 6 mmol) and tetradecyl bromide (1.66 g, 6 mmol) was refluxed for 48 h. After it had then been cooled to room temperature, it was poured into diethyl ether (500 ml) to obtain a white precipitate. The crude product was recrystallized three times from the mixed solvent of ethyl acetate and ethanol (5:1). Essentially the same reaction conditions were adopted for the other materials. The solvents of recrystallization are acetonitrile for C_{10}-DABCO-C_n-Br_2 (n=11, 12, 13, 15, 16, 17, 18) and a mixed solvent of ethyl acetate and ethyl alcohol (5:1) for C_{10}-DABCO-C_n-Br_2 (n=14, 22) respectively.

Measurements. The measurements of the bromide-anion conductivities, DSC, and IR spectra were made by the methods described before.[5,6]

Results and Discussion

DSC Measurements. The DSC measurements were made while changing the temperature by 5 °C min^{-1}. Most of the virgin samples (C_{10}-DABCO-C_n-Br_2, $n \geqq 13$) showed single and reproducible endothermic signals (the values are designated as $\Delta H_{en,1}$) at the transition temperatures (designated as T_{c1}) when they were heated from room temperature. When they were cooled after they had once been heated above T_{c1}, much smaller exothermic signals ($\Delta H_{exo,1}$) were observed at much lower temperatures (T_{c2}) than T_{c1}; i.e., $\Delta H_{en,1} > \Delta H_{exo,1}$, and $T_{c1} > T_{c2}$. The succeeding heating-cooling cycles showed reproducible endothermic ($\Delta H_{en,2}$) and exothermic ($\Delta H_{exo,1}$) signals at around T_{c2}. The absolute values of $\Delta H_{en,2}$ were close to those of $\Delta H_{exo,1}$. Figure 2 shows the observed result of C_{10}-DABCO-C_{18}-Br_2 as a typical example of the above observations (T_{c1}=86 °C, T_{c2}=34 °C). However, when most of the samples ($13 \leqq n \leqq 18$) were kept at room temperature after they had once been heated above T_{c1}, the transition temperatures (T_{c2}) tended to increase slowly. After several days, the sample was converted to the original phase; it showed the endothermic signal ($\Delta H_{en,1}$) at T_{c1}. These facts can be explained by the free energy (F)-temperature (T) relation shown in Fig. 3. When the sample was heated from room temperature across the transition temperature, and then cooled, it followed the F-T curve by the sequence of 1→2→3→4→5 shown in Fig. 3. A detailed explanation of this F-T relation was given in the previous paper.[7] C_L, C_M, and C_H in Fig. 3 are the low temperature phase, the metastable phase, and the high-temperature phase respectively. The most important characteristic of the present materials is the existence of the metastable phase. The metastable phase was found to be converted to the stable phase (C_L) by keeping the sample at room temperature for several days. The gradual increase in the transition temperature can be explained as follows. When the C_M phase was left at room temperature, it was converted to another metastable phase ($C_{M'}$)[8] (Fig. 3). When a DSC measurement is made for the resultant $C_{M'}$ phase, its transition temperature ($T_{c2'}$) should be found between T_{c2} and T_{c1}; $T_{c2} < T_{c2'} < T_{c1}$. As the metastable phase approaches the C_L phase, the transition temperature increases until it is converted to the C_L phase where the phase transition takes place at T_{c1}. Thus, the greatest difference in the present systems (C_{10}-DABCO-C_n-Br_2, $13 \leqq n \leqq 18$) from the previous systems (C_n-DABCO-C_{n+2}-Br_2) is that the metastable phase can be converted to the stable phase in the former systems, whereas the conversion rate is too slow to be followed in the latter systems.[7] The larger the difference in the carbon numbers of the two alkyl groups, the faster was the conversion rate from

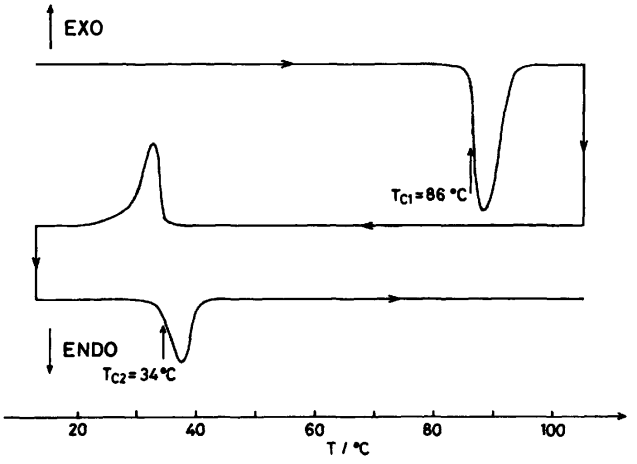

Fig. 2. DSC thermogram of C_{10}-DABCO-C_{18}-Br_2.

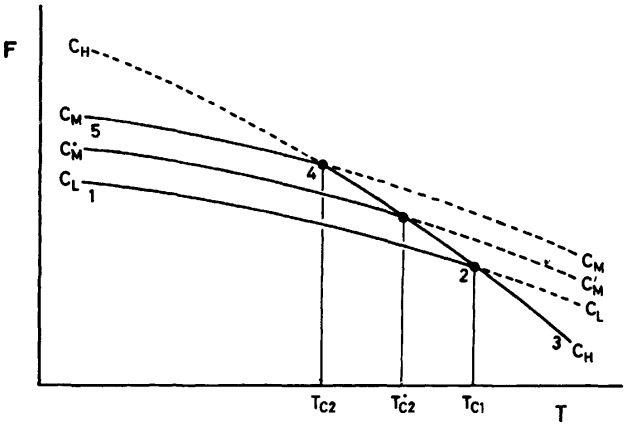

Fig. 3. Free energy (F)-temperature (T) relation of the unsymmetric bis(quaternary alkyl bromide) salts of DABCO. C_L, C_M, and C_H denote low temperature phase, metastable phase, and high temperature phase. respectively. C_M' denotes another metastable phase.

C_M to C_L.[9] For example, the conversion rates of C_{10}-DABCO-C_{14}-Br_2 and C_{10}-DABCO-C_{18}-Br_2 were one week and 1 d respectively. However, the C_M phases of C_{10}-DABCO-C_n-Br_2 (n=12, 22) did not go back to the C_L phases. C_M was not observed for C_{10}-DABCO-C_{11}-Br_2, which is similar to the cases of the symmetric bis(quaternary alkyl halide) salts of DABCO.[6]

Part of Table 1 shows some materials, T_{c1}, $\Delta H_{en,1}$, $\Delta S_1(=\Delta H_{en,1}/T_{c1})$, T_{c2}, $\Delta H_{en,2}$, and $\Delta S_2(=\Delta H_{en,2}/T_{c2})$. Here ΔS_1 and ΔS_2 denote the transition entropies at T_{c1} and T_{c2} respectively. The transition temperatures were obtained by the onsets of the endothermic peaks. The characteristic points of the salts are discussed below. Figure 4 plots T_{c1} and T_{c2} against the carbon

a) No phase transition occurred at T_{c2}. b) This value is a summation of the transition enthalpies at the two transition temperatures. The two signals could not be separated because of the proximity of the two transition temperatures. c) No correct ΔS_2 could be obtained.

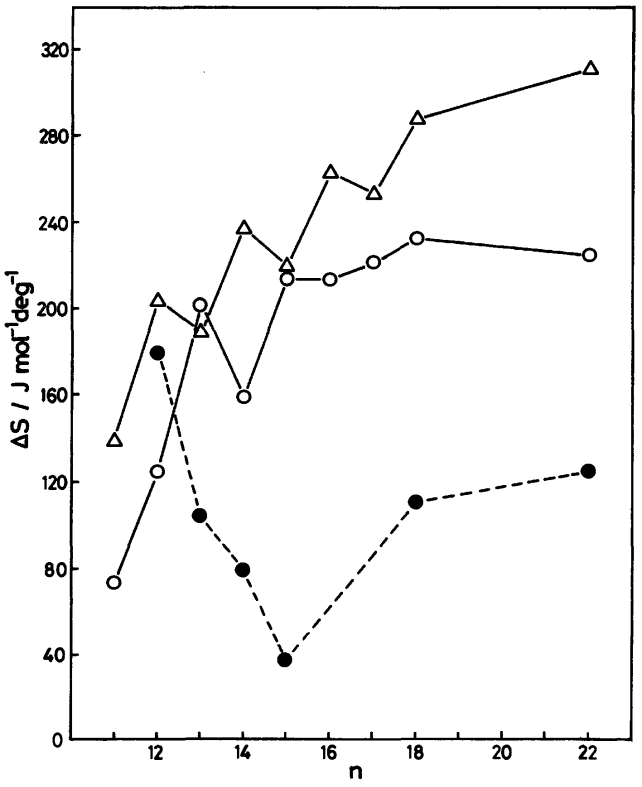

Fig. 6. The plots of the transition entropies against the carbon numbers of alkyl groups.
○: ΔS_1 of C_{10}-DABCO-C_n-Br_2, ●: ΔS_2 of C_{10}-DABCO-C_n-Br_2, △: ΔS of C_n-DABCO-C_n-Br_2.

numbers of the alkyl groups. This figure also shows the transition temperatures of the symmetric salts (C_n-DABCO-C_n-Br_2)[6] for the sake of comparison. Although complex behavior was observed for the T_{c1} of C_{10}-DABCO-C_n-Br_2 ($11 \leqq n \leqq 14$), the T_{c1}'s of C_{10}-DABCO-C_n-Br_2 ($15 \leqq n \leqq 22$) have a parallel relation to those of the symmetric salts; the former are slightly lower than the latter. The parallel relation suggests that the transition at T_{c1} is mainly governed by the longer alkyl chain of the two. On the other hand, T_{c2} decreases with the increase in the alkyl-chain length and levels off at around 30 °C for the DABCO salts, which possess longer alkyl chains than C_{12}. The differences between T_{c1}'s and T_{c2}'s were found to be in the range of 20—61 °C. Figures 5 and 6 plot the transition enthalpies ($\Delta H_{en,1}$ and $\Delta H_{en,2}$) and transition entropies (ΔS_1 and ΔS_2) respectively. These figures also show the transition enthalpies and transition entropies of the symmetric salts[6] for the sake of comparison. Since $\Delta H_{en,2}$ and ΔS_2 correspond to the transition enthalpy and the transition entropy from the metastable phase to the high temperature phase, the observed values are connected with dotted lines in these figures. $\Delta H_{en,2}$ and ΔS_2 are much smaller than $\Delta H_{en,1}$ and ΔS_1 respectively for C_{10}-DABCO-C_n-Br_2 ($n \geqq 13$). However, they are close to each other for C_{10}-DABCO-C_{12}-Br_2. The above results lead to the following assumptions for the phase transitions. The virgin sample (C_L)[10] possesses a close-packed crystal structure. This is confirmed by the IR absorption spectra, as will be described later. Therefore, T_{c1} is high, and $\Delta H_{en,1}$ and ΔS_1 are large, as a result of the considerable change in the crystal and molecular structures at the transition temperature. When it was once annealed[10] above T_{c1} and then cooled to room temperature, the conformational change in the alkyl chain and possibly the translational shift and rotational change of the molecule, all of which had been produced in the C_H phase, remained to some extent in the C_M phase at room temperature. This gave rise to a large number of disorders which facilitate the conformational, translational, and rotational movements of the molecule. Thus, when C_M was heated again, the phase transition due to these movements occurred at much lower temperatures (T_{c2}) than T_{c1}. From the Boltzmann relation, $\Delta S = R \ln W$, the ratios of the numbers of sites (W) before and after the phase transition can be estimated. W are estimated to be in the range of 10^6—10^{12} for the transitions at T_{c1} and in that of 10^2—10^9 for the transitions at T_{c2}. The fact that the former are much larger than the latter also exhibits how the metastable phase contains the above-mentioned disorder. In other words, the structural change from C_L to C_H is much larger than that from C_M to C_H. This results in the smaller enthalpy and entropy changes at T_{c2} than at T_{c1}.

Infrared Absorption Spectroscopy. The temperature dependence of the IR absorption spectra was measured for the KBr pellet sample in order to obtain more information on the phase transition and on the metastable phase. We have already reported the temperature dependences of the IR spectra of C_{14}-DABCO-C_{14}-Br_2[6] and C_{14}-DABCO-C_{16}-Br_2[7] as typical examples of the symmetric and unsymmetric DABCO salts respectively. In the former case, an abrupt change in the IR spectra was observed at the transition temperature. The spectral change was reversible, which was consistent with the DSC measurements. The band progressions in the low-temperature phase disappeared completely at the transition temperature. This was explained by the conformational change in the alkyl groups above the transition temperature. In the latter case, the band progressions disappeared at T_{c1} and were recovered again at lower temperatures (T_{c2}) than T_{c1}; $T_{c2} < T_{c1}$. These observations show the existence of the metastable phase in the latter case. Thus, the change in the IR spectra of the symmetric bis(quaternary salt) was quite different from that of the unsymmetric bis(quaternary salt). In order to see the effect of the difference in the carbon numbers of the two alkyl groups on the IR spectra, we measured the temperature dependence of the IR spectra of C_{10}-DABCO-C_{22}-Br_2, which possesses the largest difference in the

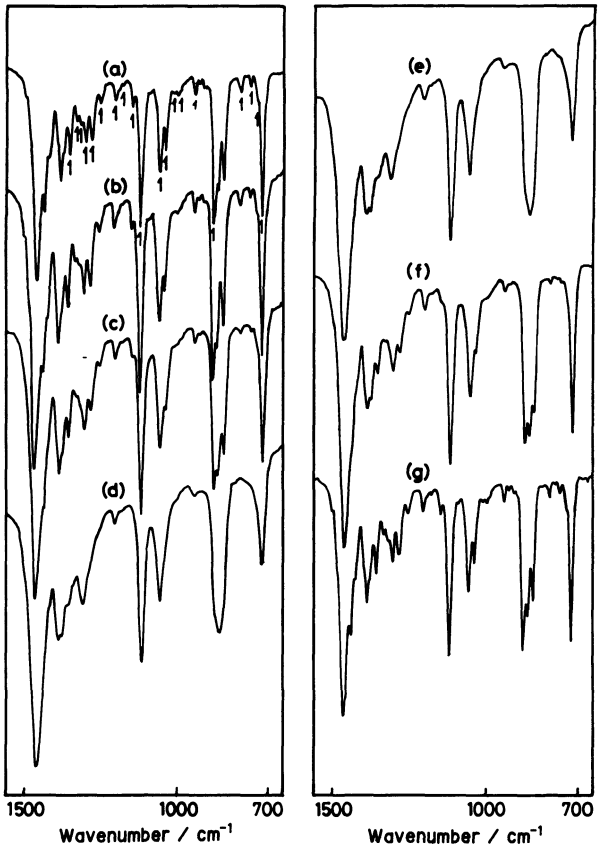

Fig. 7. Temperature dependence of the IR absorption spectra of C_{10}–DABCO–C_{22}–Br_2 for KBr disk sample obtained by heating the sample from room temperature to 94 °C, and then by cooling from 94 °C to 23 °C. The arrows in the spectrum (a) show the band progressions of the two alkyl groups.
(a): 29 °C, (b): 71 °C, (c): 90 °C, (d): 94 °C, (e): 70 °C, (f): 23 °C, (g): kept overnight at room temperature.

carbon numbers of the two alkyl groups.

Figure 7 shows the temperature dependence of the IR absorption spectra of C_{10}–DABCO–C_{22}–Br_2 for the KBr disk sample when the sample was heated from room temperature to 94 °C and then cooled to room temperature. The resulting IR spectra are shown sequentially from the upper left to the lower right. The IR spectra of the virgin sample[10] at 29 °C (a) exhibited the several structures shown by the arrows. The absorption positions of these structures were compared with the band progressions of n-$C_{11}H_{24}$ and n-$C_{23}H_{48}$,[11] which have the same numbers of CH_2 units as the alkyl groups of C_{10}–DABCO–C_{22}–Br_2. The good coincidence leads to the conclusion that the structures in Fig. 7 may be assigned to the band progressions of the two alkyl groups. The band progressions originating from 720 cm^{-1} are known as the CH_2-rocking mode. Since a single absorption was observed at 720 cm^{-1}, the molecules of the DABCO salts seem to possess a parallel-packed layered structure in the crystal.[12]

The absorption spectra at 29 °C (a) and 71 °C (b) were not very different. When the temperature of the sample approached T_{c1}, all of the absorptions were broadened (see Spectrum (c) at 90 °C), but the band progressions could still be seen. However, all of the band progressions disappeared at T_{c1} (94 °C) (d). This shows that the *trans*-zigzag conformation of the alkyl group of the low-temperature phase is destroyed at T_{c1}. When the temperature of the sample was lowered after it had once been raised above T_{c1}, no band progression appeared between T_{c1} and T_{c2}. For example, the IR Spectra (b) and (e) were measured at almost the same temperature, but they were quite different; Spectrum (b) exhibited the band progressions, but (e) did not show them. This is consistent with the free energy-temperature relation shown in Fig. 3, because Spectra (b) and (e) correspond to the C_L and C_H phases respectively. The *trans*-zigzag conformation of the alkyl chain is still destroyed in Spectrum (e). Only after the temperature had been lowered below T_{c2} (33 °C) did the band progressions appear again (see Spectrum (f)). Comparing Spectrum (a) with (f), however, the latter are broader than the former. This suggests that the conformational disorder still exists in (f). When the sample was left overnight at room temperature, the spectrum gradually became shaper to give Spectrum (g), which can not be differentiated from Spectrum (a). Thus, it is clear that the conformational change in the alkyl chain takes place slowly at room temperature. This is a distinct difference from C_n–DABCO–C_{n+2}–Br_2 ($10 \leqq n \leqq 16$), reported previously.[7] The band progressions recovered quickly below T_{c2} for these systems after they had once been heated above T_{c1}. Although Spectra (a) and (g) could not be differentiated from each other, their DSC results were quite different; the annealed sample[10] was converted to the metastable phase, but exceptionally, it did not go back to the stable phase.[9] A similar change in the IR absorption spectra was also observed for the other materials (C_{10}–DABCO–C_n–Br_2, $13 \leqq n \leqq 18$). However, the metastable phases of these materials are converted slowly to the stable phase by keeping the sample at room temperature. The conversion process could not be followed by IR spectroscopy, because the two phases possess identical IR absorption spectra. The powdered X-ray diffraction gave a distinct difference between the stable and metastable phases; the former gave sharp diffraction patterns, but the latter gave broader ones. Thus, the crystallinity of the latter is lower than that of the former.

Bromide-anion Conductivities. All of the samples have already been confirmed as bromide-anion conductors.[5,6,7] Ionic conductivities were measured for the compressed pellet samples by an AC method.[5,6] The temperature dependences of the bromide-anion conductivities were measured while raising the

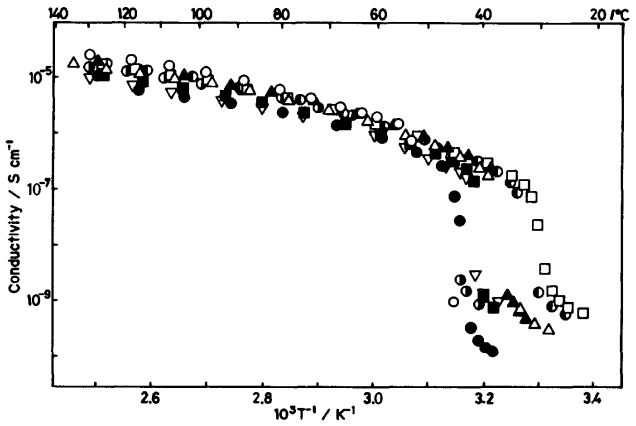

Fig. 9. Temperature dependences of the bromide-anion conductivities of the annealed samples (C_{10}-DABCO-C_n-Br_2).
○: n=11, ●: n=12, △: n=13, ▲: n=14, □: n=15, ■: n=16, ◐: n=17, ◑: n=18, ▽: n=22.

temperature of the sample slowly (0.5 °C min^{-1}) from room temperature. Conductivities less than 10^{-9} S cm^{-1} are below the limit of our measurements. Since the materials (C_{10}-DABCO-C_n-Br_2, $n \geqq 12$) exhibited phase transitions at T_{c1} and T_{c2}, we focused our attention mainly on the conductivity changes at these transition temperatures. The conductivity changes at around T_{c1} were measured for the virgin samples[10] dried in a vacuum overnight at room temperature. On the other hand, the conductivity changes at around T_{c2} were measured for the samples dried in a vacuum overnight above T_{c1}. Thus, the samples had already been converted to the metastable phase before the measurements. The proton conduction due to moisture seems to be negligible after the complete drying procedure.

Figure 8 shows the temperature dependences of the bromide-anion conductivities of the virgin samples.[10] Most of them consist of gradual increases in the conductivities in the low-temperature range and slow increases in the high-temperature range. Conductivity jumps like C_n-DABCO-C_n-Br_2,[6] C_n-DABCO-C_{n+2}-Br_2,[7] and the present materials in the metastable phase (see below) were not observed except for C_{10}-DABCO-C_{11}-Br_2. Thus, the conductivity change below the transition temperature is much broader than in the previous systems. The behavior in the low-temperature range was classified phenomenologically into two cases for C_{10}-DABCO-C_n-Br_2: (1) a considerable increase in the conductivity occurs below T_{c1} (n=12, 15, 16, 17, 18, 22), and (2) T_{c1} is located in the temperature range of the gradual increase in the conductivity (n=13, 14). At any rate, gradual increases in the conductivities occurred over wide temperature ranges. This suggests that the local movement of the alkyl chain sets in more than twenty degrees below T_{c1} for the virgin samples. Regarding the high-temperature phase, a considerable conformational movement of the alkyl group occurs. Thus, the activation energy of the conductivity was low (about 30 kJ mol^{-1}) as a result of the formation of a large number of transport channels of the bromide anion.

Figure 9 shows the temperature dependence of the bromide-anion conductivities of the annealed samples.[10] Unlike the case of the virgin samples,[10] an abrupt increase in the bromide-anion conductivities was observed at around T_{c2}. Part of Table 1 shows the ratios of the conductivities before (σ_l) and after (σ_h) the phase transitions; i.e., σ_h/σ_l. The σ_h/σ_l values were found to be in the range of 100—1380. Thus, they are smaller than those of C_n-DABCO-C_n-Br_2[6] and C_n-DABCO-C_{n+2}-Br_2.[7] If we define T_{c2}* as the middle point of the conductivity jump,[14] the following relations are obtained: T_{c2}*<T_{c2} for n=11, 12, and T_{c2}<T_{c2}* for $13 \leqq n \leqq 22$. The differences between T_{c2} and T_{c2}* were found to be in the range of 3—11 °C. The above relations suggest that the conductivity jumps begin before the considerable structural change for n=11, 12, and do after the change for $13 \leqq n \leqq 22$. It is noteworthy that the conductivities above T_{c1} of the virgin sample and those above T_{c2} of the annealed sample lie on the same σ-T curve. Figure 10 shows the temperature dependences of the bromide-anion conductivities of C_{10}-DABCO-C_{18}-Br_2 for the virgin sample and for the annealed sample as a typical example of this observation. Thus, the F-T relation in Fig. 3 is clearly demonstrated by Fig. 10. Since the ratios of the sites (W) before and after the phase transition are very large, as has been described before, the conformational change in the alkyl group seems to occur at every site of the CH_2 units. This gives rise to a large number of voids, which facilitate the bromide-anion transport above the transition temperature.

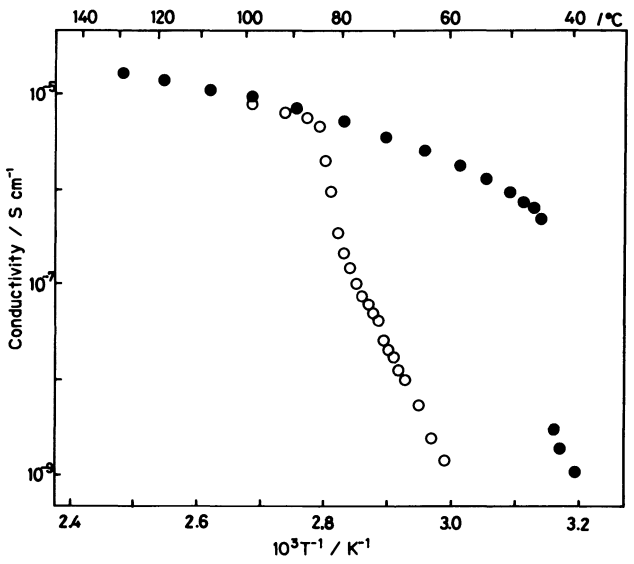

Fig. 10. Temperature dependences of the bromide-anion conductivities of C_{10}–DABCO–C_{18}–Br_2 for the virgin and annealed samples.
○: Virgin sample, ●: annealed sample.

Summary. Phase transitions of the unsymmetric bis(quaternary alkyl bromide) salts of DABCO (C_{10}–DABCO–C_n–Br_2, $11 \leqq n \leqq 22$) were studied by means of the measurements of the DSC, the IR absorption spectra, and the bromide-anion conductivities. The DSC measurements revealed the existence of a metastable phase. The metastable phase was found to be converted gradually to the stable phase for $13 \leqq n \leqq 18$ when the sample was kept at room temperature. The larger the difference in the carbon numbers of the two alkyl groups, the faster the conversion rate. The stable phase was not recovered from the metastable phase for $n=12$ and 22. The temperature dependence of the IR absorption spectra showed that the band progressions in the low-temperature phase disappeared above T_{c1} and appeared again at T_{c2}. The band progressions of the annealed sample became sharper when it was kept at room temperature. These facts can be explained by the conformational change in the alkyl group above the transition temperature, by the existence of the metastable phase, and by the slow recovery of the stable conformation at room temperature. Abrupt increases in the bromide-anion conductivities by two to three orders of magnitude were found at around T_{c2} for the annealed samples. The conductivity jump could be explained by the formation of voids attributable to conformational disorder above the transition temperature. On the other hand, the virgin sample did not show any conductivity jump. Instead, they exhibited broad conductivity changes below T_{c1}.

We are grateful to Professor Shigekazu Kusabayashi and Dr. Shunsuke Takenaka, Faculty of Engineering, Osaka University, for the use of the DSC apparatus.

Theoretical Studies on the Catalytic Oxidation of Carbon Monoxide on Nickel Clusters

A. K. Srivastava,† Isao Kojima,†† and Eizo Miyazaki*
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received April 25, 1986)

Complete neglect of differential overlap (CNDO) molecular orbital calculations using the method of Anno and Sakai for the evaluation of the valence orbital ionization potential (VOIP) were performed with the aim of studying the oxidation of carbon monoxide on nickel clusters. A cluster surface was assumed to be preadsorbed with oxygen and the variation of various bond energies with the approach of a carbon monoxide molecule was studied for different models. Various possibilities for the reaction path are discussed in the light of the theoretical findings and it is suggested that at a low coverage of oxygen the reaction may follow a Langmuir-Hinshelwood path, whereas at a high coverage, an Eley-Rideal path might be more probable.

A catalytic reaction on a solid surface is not simple, but comprises several reaction steps in which a reaction cycle must be formed, starting from an initial chemisorption process of reactants to a closing process by desorbing final products from the surface. Under such requirements for a catalytic reaction, the most stable chemisorbed state among the several possible states is not always the most effective one for completing the catalytic reaction, since this kind of chemisorbed state occasionally remains persistently on the surface without desorbing into the gas phase. The above-mentioned concept should be important for studying, as a whole, a reaction mechanism on heterogeneous catalysts. In order to do so, calculations of all the bond energies as well as the total energies involved in the catalytic cycle are required. In the present paper, we have attempted a new approach to this problem through, as an example, an oxidation reaction of carbon monoxide on a Ni surface using the CNDO molecular-orbital method.

The oxidation of carbon monoxide over active metal catalysts (e.g. Pt, Pd, Rh, Ru, and Ni) has been investigated by numerous workers under well defined conditions with single crystals[1-11] as well as with polycrystalline surfaces.[12-16] The individual steps which are possibly involved in the oxidation of carbon monoxide can be given as follows:

$$CO \rightleftharpoons CO_{ad} \quad (1)$$

$$O_2 \longrightarrow 2O_{ad} \quad (2)$$

$$O_{ad} + CO_{ad} \longrightarrow CO_2 \quad (3)$$

$$O_{ad} + CO(g) \longrightarrow CO_2 \quad (4)$$

$$O_2(g) + 2CO_{ad} \longrightarrow 2CO_2 \quad (5)$$

A dissociative adsorption of oxygen is well established above 100 K as can be concluded from isotopic exchange experiments[17] and also from the absence of features in the UPS spectrum that could be assigned to adsorbed molecules;[18,19] hence, the reaction steps involving O_{2ad} need not be taken into consideration. Step (3) represents a Langmuir-Hinshelwood path, which predicts a reaction between both the reactants in a chemisorbed state. Steps (4) and (5) represent an Eley-Rideal mechanism in which one of the reactants is in its normal chemisorbed state(O_{ad}) and the second reacts either through a direct collision from the gas phase or from a weakly held physisorbed or molecular state. At present it is widely believed that the oxidation of CO on noble metal surfaces (such as Pd and Pt) follows a predominantly Langmuir-Hinshelwood type machanism; evidence for this was earlier obtained from nonstationary studies[2,4,6] and its dominance has been mainly proposed by recent molecular-beam experiments.[7,8] However, in addition to these extreme possibilities a precursor mechanism including an Eley-Rideal like path has also been suggested by many authors.[20-22]

The formation of carbon dioxide through a catalytic oxidation of carbon monoxide is of significant practical importance, particularly in connection with pollution problems. Thus, one must also consider the fact that although recently a wide variety of theoretical techniques such as EHT (extended Hückel theory),[23-25] CNDO,[26-33] DV(discrete variational)-Xα-SCF,[34-37] LCMTO(linear combination of muffin-tin orbital),[38,39] Localized orbital approach[40,41] and ab initio[42-44] have been applied for studying complex phenomenon on solid surfaces, most of these were aimed at obtaining a clear understanding of the chemisorption process in which the chemical reaction could be well described by the splitting of one bond and the formation of other bonds. The changes in various bond energies may, therefore, throw some interesting light on the disruption(weakening) and formation of various bonds; hence, the CNDO method as described here might become a good technique for studying simple reactions on metal surfaces, particularly since the bond energy is explicitly defined within its framework.

Method of Calculation

Semiempirical methods like CNDO are flexible and convenient because of their inherent parametrized treatment; however, the involvement of many parameters makes them somewhat tedious and of lesser importance for systems containing transition metals. In the present paper the local core matrix elements U's have been estimated from atomic data using the following expressions:

$$U_{ii} = -I_p(i) - (N-1)\gamma_{ss} - M\gamma_{sd} \quad (i=s \text{ or } p)$$

and

$$U_{dd} = -I_p(d) - (M-1)\gamma_{dd} - N\gamma_{sd}.$$

Here, I_p is the valence-state ionization potential, N denotes the total number of electrons in the valence "s" and "p" orbitals and M represents the number of electrons in "d" orbitals. The I_p's have been calculated by using the method of Anno and Sakai,[45] where the valence orbital ionization potential (VOIP) was calculated with the help of the quadratic equation,

$$\text{VOIP} = A_0 + A_1Z + A_2Z^2. \quad (7)$$

Here, Z is the atomic number. A_0 and A_1 were evaluated with the help of

$$A_0 = a_0 + a_1M + a_2M^2 \quad (8)$$

and

$$A_1 = b_0 + b_1M. \quad (9)$$

The values of a_0, a_1, a_2, b_0, and b_1 were taken from Ref. 45. The exchange integral H_{ij} were calculated with the help of the Wolfsberg-Helmholtz approximation:[46]

$$H_{ij} = KS_{ij}\,(H_{ii}+H_{jj})/2. \quad (10)$$

An electronic configuration of $3d^M4s4p$ was assumed for the ground state of the Ni atom. Veigele[47] orbital exponents were used for Ni and Slater values were used for C and O. Thus, in the present calculation only K (=1.50) was empirically chosen. The total energy was calculated from

$$E_t = 1/2 \sum_{r,s} P_{rs}\,(H_{rs}+F_{rs}) + \sum_{A<B} Z_AZ_BR_{AB}. \quad (11)$$

The bond energies between atoms A and B have been evaluated by the following equation:

$$E_{AB} = \sum_{r}^{A}\sum_{s}^{B}(2P_{rs}\beta_{rs} - 1/2P_{rs}^2\gamma_{AB}) + (Z_AZ_BR_{AB}^{-1} - P_{AA}V_{AB} - P_{BB}V_{BA} + P_{AA}P_{BB}\gamma_{AB}). \quad (12)$$

In the above equations P_{rs} represents the density matrix, Z_A and Z_B represent the charge on nucleus A and B, respectively, V terms represent the potential integrals, R_{AB} represents the internuclear seperation, β_{rs} is the resonance integral and γ_{AB} represents interelectronic repulsion between any electron on atom A and any electron on atom B.

Results and Discussion

1. Reaction of Carbon Monoxide and Oxygen Atom. The aim of this section is to at least show the qualitative utility of the present method when it is applied to study a simple chemical reaction. The reaction of an oxygen atom with carbon monoxide has been studied in detail with the frontier orbital concept and is known to proceed as

$$O + :C{\equiv}O \longrightarrow O{=}C{=}O. \quad (13)$$

This reaction should cause a strong stabilization in the energy of the 3σ orbital of CO. In fact, the photoelectron spectra of CO and CO_2 show that the first σ orbital of CO_2 ionizes at 18 eV, whereas the 3σ of CO ionizes at 14 eV,[48] consequently, the 3σ of CO is stabilized by about 4 eV. In the present calculations the ionization potential for the first σ orbital of CO_2 was found to be 17.9 eV and the energy of the 3σ orbital for CO came out to be 13.25 eV, which gives a stabilization energy of about 4.6 eV. This is in fairly good agreement with the experimental results.

The C-O_a ("a" denotes the oxygen atom of CO) bond length was assumed to have a fixed value of 1.15 or 1.19 Å and the approaching oxygen atom O_b was

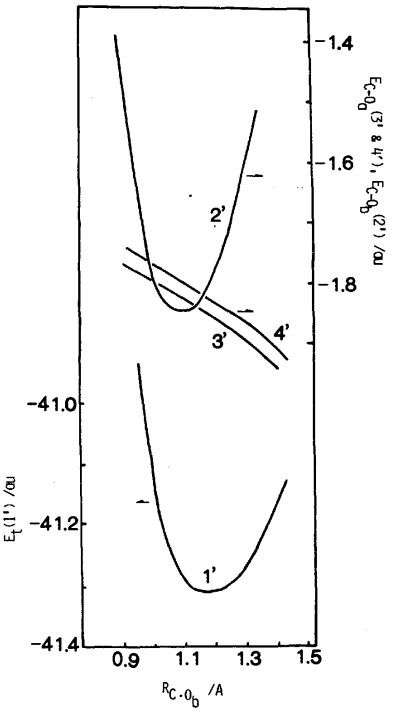

Fig. 1. Evaluation of total energy (E_t) at $R_{C\text{-}O_a}$= 1.15 Å and bond energies ($E_{C\text{-}O}$) as a function of the bond length, $R_{C\cdot O}$ at fixed bond lengthes of C–O_a. 1': E_t, 2': $E_{C\cdot O_b}$, 3': $E_{C\text{-}O_a}$ at $R_{C\cdot O_a}$=1.15 Å and 4': $E_{C\text{-}O_a}$ at $R_{C\cdot O_a}$=1.19 Å.

considered to exist along a linear path for calculating the total energy E_t, the bond energy of the C-O_b bond (the new bond being formed, i.e. $E_{C\text{-}O_b}$) and the bond energy of the C-O_a bond (i.e. $E_{C\text{-}O_a}$).

Figure. 1 contains plots of E_t, $E_{C\text{-}O_b}$, and $E_{C\text{-}O_a}$ against $R_{C\text{-}O_b}$ (the distance between C and O_b). The total-energy curve 1′ shows a minimum at 1.18 Å whereas the bond-energy curve 2′ has a minimum at 1.13 Å. Both of these equilibrium distances are in fairly good agreement with the experimental bond length 1.16 Å for CO_2.

The reaction path to form the CO_2 product (i.e. the formation of a new bond C-O_b) is clearly depicted by curve 2′; however, curves 3′ or 4′ represent a weakening of the C-O_a bond due to the approaching O_b. This is caused by a delocalization of p_π electrons of the approaching oxygen atom into the LUMO of CO, resulting in a simultaneous strengthening of the C-O_b bond. It should be mentioned here that even for a different value of the C-O bond length (1.19 Å), the curves for the total energy E_t and the bond energy $E_{C\text{-}O_b}$ were found to be almost identical and showed very little change. However, as expected, curve 4′ for $E_{C\text{-}O_a}$ is slightly different but runs almost parallel to the earlier curve 3′. This makes it clear that even if the bond length in CO is held constant, the curves representing the changes in various bond energies are capable of showing a weakening of the C-O_a bond as well as the formation of a new bond between C and the approaching O atom.

Studies on this simple reaction have shown both qualitatively and quantitatively satisfactory results and have also made it very clear that the bond energy not only follows the pattern of the total energy of the system, but is also capable of depicting the weakening as well as the strengthening of various bonds.

In the next section the present method is applied to the CO oxidation on two types of clusters of nickel containing two and five atoms, respectively. Throughout this paper a value of 2.50 Å is used for the Ni-Ni distance (the same as that in bulk Ni) and 1.15 Å for the bond length of a CO molecule.

2. Oxidation of CO on Ni_2 Cluster. For Ni_2, two different positions were considered for the preadsorbed O, namely: SYMMETRICAL and UNSYMMETRICAL. As shown in Fig. 2, in the first case two different sites were chosen for the coadsorption of CO (labeled as ON TOP (Model 1) and ADJACENT VERTICAL (Model 4)). However, in addition to the perpendicular models a slightly angular (ϕ=30°) approach of CO (labeled as ADJACENT BENT (Model 3)) was included in the calculations. In the second case, the three similar types were also considered (Models 2, 5, 6). CO was supposed to be ON TOP (Model 2); an ADJACENT VERTICAL (Model 5) and an angular approach were also considered (ϕ=30°, Model 6). In the models 5 and 6, CO was supposed to be on top of

one Ni atom, which models arise from the conclusion by Li and Tong by analysis of the LEED patterns of CO adsorption on Ni(100) surface.[49]

A plot of the total energy of the system E_t as a function of $R_{C\text{-}O_{ad}}$ is given in Fig. 3; it can be said that the total energy of the system remains almost the same for all the models under study.

Figure 4 contains plots of $E_{C\text{-}O_{ad}}$ as a function of $R_{C\text{-}O_{ad}}$ and a comparative study of the various curves shows that for the bond formation between C and O_{ad} three favourable arrangements are:

(1) O preadsorbed symmetrically and CO on top,
(2) O preadsorbed at an unsymmetrical site with CO lying on top,
and
(3) O preadsorbed symmetrically and CO adsorbed at an adjacent site in a bent form (ϕ=30°). An increase or decrease in this angle by 10—15° was found to have an adverse effect on bond formation.

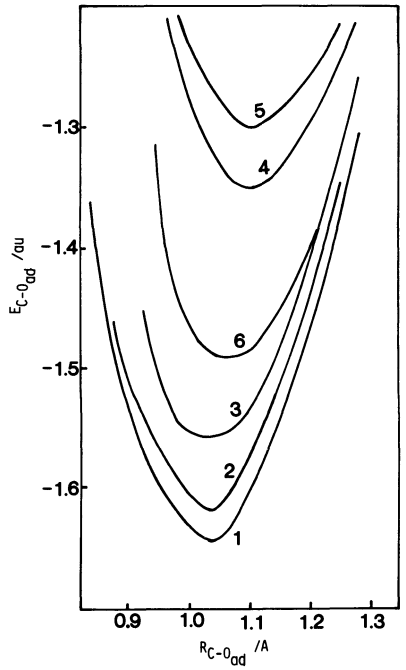

Fig. 4. Plots of $E_{C-O_{ad}}$ vs. $R_{C-O_{ad}}$.
Notations of curves correspond to the numbers of models in Fig. 2.

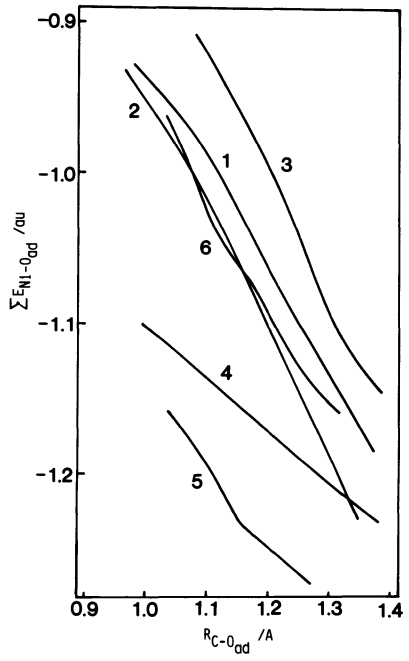

Fig. 5. Plots of $E_{Ni-O_{ad}}$ vs. $R_{C-O_{ad}}$.
Notations of curves correspond to the numbers of models in Fig. 2.

Figure 5 shows the plots of the total bond energies between two Ni atoms and O_{ad}: $\Sigma E_{Ni-O_{ad}}$ against $R_{C-O_{ad}}$. All of the curves shown here clearly indicate a weakening of the Ni–O_{ad} bond, one of the requirements for the formation of a catalytic cycle. However, evidently this weakening is a maximum when O is symmetrically adsorbed and CO is adsorbed at an adjacent site in a bent form; the next best choice seems to be a symmetrical site for preadsorbed O with CO lying on top of it.

Plots of ΣE_{Ni-C} vs. $R_{C-O_{ad}}$ are given in Fig. 6. It can be inferred from the nature of the various curves that CO may be attacking from the gas phase when it lies on top of either symmetrically or unsymmetrically adsorbed O; in other cases it seems to be adsorbed rather strongly.

In order to evaluate the possibility of a desorption of CO_2, the total energy of all the Ni–O_{ad} and Ni–C bonds has been plotted against $R_{C-O_{ad}}$ (Fig.7) and the nature of the curves suggests that the desorption of CO_2 should be easiest when O is symmetrically preadsorbed and CO lies on top of it, followed by unsymmetrical-on-top and symmetrical-adjacent-bent models.

3. Oxidation of CO on Ni_5 Cluster. The Ni_5 cluster model contains four atoms in the first layer; the fifth atom lies below in the second plane (Fig. 8). In all the cases, oxygen was supposed to be preadsorbed at a multi-center symmetrical site which lies on top of

the fifth Ni atom. For CO, however, in addition to a site on top of O_{ad} (Model 7), two other sites were also chosen:
(a) CO adsorbed at an adjacent BRIDGE site as shown in Model 8. (b) CO adsorbed at a site on the DIAGONAL (Model 9).. However, in this case in order to study the effect of the preadsorbed O on the adsorption of CO, two different sites were selected

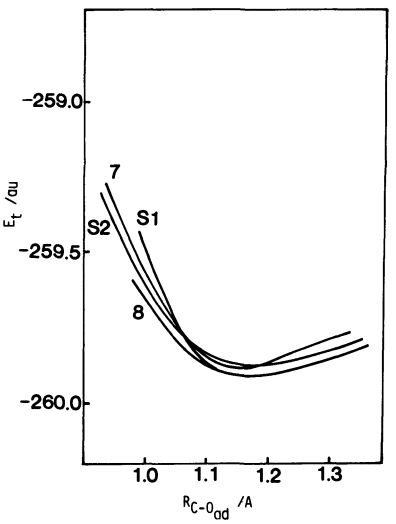

Fig. 9. Plots of E_t vs. $R_{C-O_{ad}}$.
Curves 7,8, S1, and S2 correspond to models 7,8,9-S1 and 9-S2 in Fig. 8, respectively.

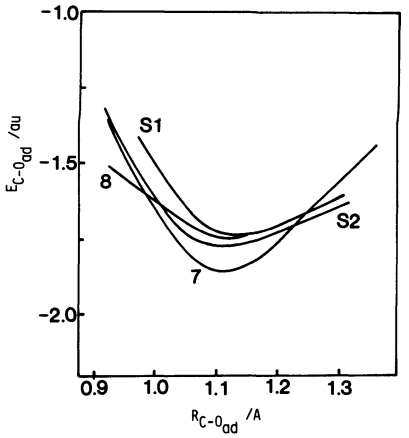

Fig. 10. Plots of $E_{C-O_{ad}}$ vs. $R_{C-O_{ad}}$.
Notations of curves are the same to those in Fig. 9.

which are denoted as S1 and S2, respectively, in Model 9. Relying on our previous experience with Ni_2 where the bent approach was found to be more appropriate for the formation as well as desorption of CO_2, we decided to consider only the angular approach of CO for adsorption (ϕ=30°).

Figure 9 shows plots of E_t as a function of $R_{C-O_{ad}}$, from which it becomes evident that the total energy of the system dose not differ appreciably for different models.

Figure 10 contains different curves for a plot of $E_{C-O_{ad}}$ as a function of $R_{C-O_{ad}}$ and a comparative study suggests that an on-top site may be slightly more favourable for the formation of CO_2.

Figure 11 represents a plot of $\Sigma E_{Ni-O_{ad}}$ against $R_{C-O_{ad}}$. Although no clear-cut observation can be made since in all the cases the Ni–O_{ad} bond shows a tendency of becoming weaker with the approach of CO the DIAGONAL-S2 site for CO adsorption may be

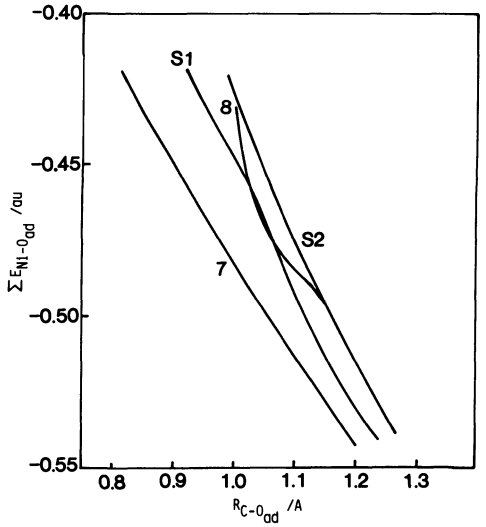

Fig. 11. Plots of $\Sigma E_{Ni-O_{ad}}$ vs. $R_{C-O_{ad}}$.
Notations of curves are the same to those in Fig. 9.

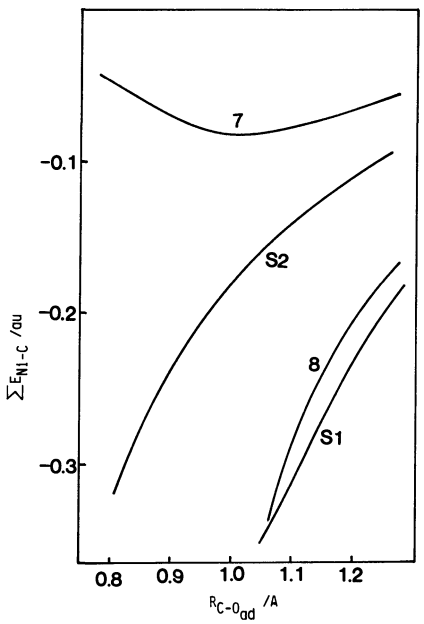

Fig. 12. Plots of ΣE_{Ni-C} vs. $R_{C-O_{ad}}$.
Notations of curves are the same to those in Fig. 9.

slightiy more favorable for such a weakening.

Figure 12 shows plots of ΣE_{Ni-C} against $R_{C-O_{ad}}$; these curves show some interesting features regarding the adsorption of CO on Ni preadsorbed with O. A comparison of curves S1 and S2 shows that as CO moves closer to the preadsorbed O, the strength of Ni–C bond decreases considerably. The effect of preadsorbed electronegative atoms on the adsorption of CO and H_2 has been studied by Kiskinova[50] using thermal desorption, LEED and AES. It was found that the presence of electronegative atoms causes a reduction in the adsorption rate, the adsorption bond strength and the capacity of the Ni surface for CO and H_2 adsorption. The same conclusion was reached by Madix[51] for the case of iron. Our theoretical results

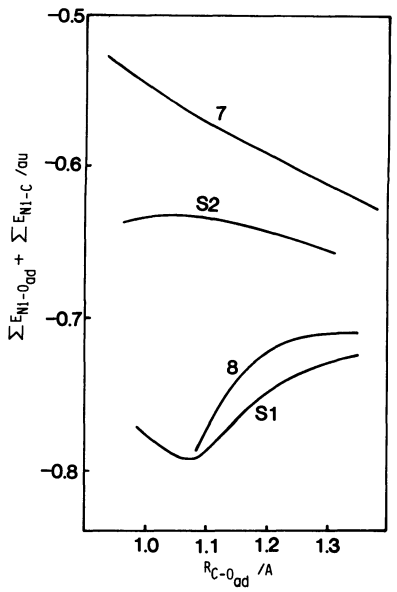

Fig. 13. Plots of $\Sigma E_{Ni-O_{ad}} + \Sigma E_{Ni-C}$ vs. $R_{C-O_{ad}}$.
Notations of curves are the same to those in Fig. 9.

are in agreement with these results, clearly indicating a predominant role for the preadsorbed O.

Figure 13 contains plots of the sum of ΣE_{Ni-C} and $\Sigma E_{Ni-O_{ad}}$ against $R_{C-O_{ad}}$. On the basis of these curves it is suggested that ON BRIDGE and ON DIAGONAL-S1 which are comparatively far from the O_{ad} may not be suitable for the desorption of CO_2, which is otherwise known to desorb immediately from the surface at usual catalytic temperatures (>100°C[52]). The remaining two possibilities (namely ON TOP and ON DIAGONAL-S2) are, perhaps, good adsorption sites as far as the desorption of CO_2 is concerned. In order to evaluate the effect of neighbouring O_{ad} atoms, it was considered appropriate to include four such nearest-neighbour O_{ad} atoms in one calculation set for both on-top and on-diagonal sites. It was also found that the various bond energies remain almost unaffected, probably due to the large distance.

On the basis of the qualitative studies presented in this paper it is suggested that the reaction of CO and O_2 on nickel might consist of the following stages:

(1) **Preadsorption of Ni with Oxygen:** Engel et al.[53] have observed that the chemisorbed oxygen is the primary surface species formed by an interaction of O_2 with the surface of platinum metals and that this species generally exihibits a higher reactivity towards CO. They further suggest that as long as the actual concentration of oxygen under a steady-state condition is low it may be safely concluded that if the temperature is not extremely high the chemisorbed atomic oxygen is the only species that enters into the catalytic oxidation of CO. Our studies of Ni_2 clusters suggest that the symmetrical site is more suitable both for the formation and desorption of CO_2; this is in agreement with the findings based upon LEED

studies.

(2) Oxidation of Carbon Monoxide at Low Coverage of Oxygen: It has been concluded by Engel[53] that if both kinds of particles (i.e. CO and O) are present on the surface, the CO can be regarded as moving within an essentially fixed matrix of O_{ad} atoms. On the basis of the present studies regarding both Ni_2 and Ni_5, it is suggested that at a low coverage of oxygen, CO might be adsorbed at an adjacent site and that in the transition state this adsorbed mobile species assumes a bent configuration which has been found to be more favorable for the formation (as well as desorption) of CO_2. The possibility of an angular form of adsorbed CO in the transition state has also been suggested by Anderson[54] while describing the mechanism of CO oxidation on Pt. Obviously, the oxidation of CO at low coverage of oxygen can be assumed to follow the Langmuir-Hinshelwood path.

(3) Oxidation of Carbon Monoxide at High Coverage of Oxygen: Behm et al.[55] have noted that for a reaction of preadsorbed oxygen during exposure to CO on Pt(100) at 355 K and at pressures upto 1×10^{-4}Pa the CO coverage is negligibly small as long as $\theta_0>0.05$. With respect to the relative rates of adsorption, reaction and desorption, this means that the latter two processes must be at least as fast as CO adsorption. It has also been found that the lifetime of a chemisorbed CO adjacent to a chemisorbed O on Pt is $\approx10^{-4}$ s. It has reaction probability of unity for each chemisorbed CO; however, at a high coverage of O_{ad} or in the case of CO_{ad} exposed to O_2, the CO_{ad} is held by a matrix of surrounding oxygen atoms and such islands of the two species can coexist on the surface for hundreds of seconds with very little reaction probability for CO_2 formation. The theoretical results on Ni_2 and Ni_5 in the present paper suggest that under such conditions there is a high probability of a reaction between adsorbed oxygen and CO from the gas phase follwing an Eley-Rideal type mechanism including a "precursor state."

One of the authors (A. K. S.) would like to express sincere thanks to Ministry of Education, Japan and UNESCO for being awarded a fellowship. Thanks are also due to Dr. K. Shimokoshi for his help in computations and his fruitful discussions. The computations were performed at the computer center of Tokyo Institute of Technology, as well as the Institute for Molecular Science at Okazaki.

(Received May 10, 1986)

An attempt was made to prepare [*Ser*-3,3-$^2H_2$]- and [*Ala*-3,3,3-$^2H_3$]-fibroins by feeding respective amino acids DL-[3,3-$^2H_2$]-serine (Ser) and [3,3,3-$^2H_3$]-alanine (Ala), respectively, to silkworms, *Bombyx mori* and *Philosamia cynthia ricini* together with daily artificial diet. We recorded ^2H powder-pattern NMR spectra of [*Ser*-3,3-$^2H_2$]- and [*Ala*-3,3,3-$^2H_3$]-cocoons and fibroins (10—20% deuteration) by means of the quadrupole echo method. It was found that separation of the ^2H quadrupole splittings is 125 and 39 kHz, respectively, for [*Ser*-3,3-$^2H_2$]- and [*Ala*-3,3,3-$^2H_3$]-cocoons and fibroins, respectively. Accordingly, it was concluded that side-cain reorientation of Ser residue is virtually frozen irrespective of differences in conformations of silk I and silk II, suggesting that the hydroxyl groups in these cases might be hydrogen-bonded to C=O or NH groups in intra or interchain. On the other hand, side-chain methyl group of Ala residue in [*Ala*-3,3,3-$^2H_3$]-fibroin turned out to undergo rapid three-fold rotation about the C_α-C_β axis, as viewed from data of the quadrupole splittings.

Silk fibroin from *Bombyx mori* is a fibrous protein whose major amino acid composition consists of Gly, Ala, and Ser residues (over 85%) and its ratio Gly:Ala:Ser is 3:2:1.[1-4] Lucas et al.[5,6] showed the presence of the following long hexapeptide sequence for the crystalline fraction (C_p fraction) obtained as precipitate (60% of the original material) after digestion by chymotrypsin: Ser-Gly-Ala-Gly-Ala-Gly. Accordingly, X-ray powder diffraction patterns of this hexapeptide and its polymer were found to be similar to those obtained in powdered cocoon samples.[7,8] This model could be further simplified to repetition of Ala-Gly sequence, if the difference of side chains in Ala and Ser were ignored. To support this view, secondary structure of silk I and silk II from *B. mori* fibroin turned out to be very similar to that of forms II and I of poly(alanylglycine), respectively, on the basis of X-ray powder diffraction studies.[2,3,9] We further confirmed this conclusion on the basis of the similarity of ^{13}C chemical shifts of Gly and Ala residues between corresponding forms of silk and poly(alanylglycine),[10] because displacement of the ^{13}C chemical shifts due to a conformational change are found to be very useful as a novel means to examine conformational features of a variety of peptides, polypeptides, and proteins.[11-18]

Nevertheless, it seems important to clarify the role of side chains in Ser residues in stabilization of these secondary structures in the solid state, because half of Ala residues is replaced by Ser in *B. mori* fibroin. If the amount of Ser residues is smaller than this ratio, α-helix form is stabilized instead of silk I form, as in *P. c. ricini* fibroin. To gain insight into the manner of side-chain orientation, it has been demonstrated that analysis of the quadrupole splittings in ^2H NMR spectra of ^2H-labeled samples provides one unequivocal means to assess molecular reorientation or motions.[19-21]

In the present paper, we aimed to analyze the manner of side-chain reorientation in Ser residues of silk fibroins as compared to that of Ala residues, on the basis of ^2H NMR spectra of [^2H]-labeled fibroins from *B. mori* and *P. c. ricini* which were prepared by incorporation of deuterated amino acids, DL-[3,3-$^2H_2$]-serine (Ser) and L-[3,3,3-$^2H_3$]-alanine (Ala), to artificial diet. We found from analysis of ^2H NMR spectra that reorientation of side chains in Ser residues is virtually frozen, for any form of fibroin (silk I, silk II and α-helix), as a result of plausible involvement of OH groups in hydrogen bonds which cause stabilization of these individual conformations. On the contrary, separation of the motionally averaged quadrupole-splittigs of Ala residue is 39 kHz due to the presence of the three-fold rotation of the methyl groups and is found to be identical among various types of backbone conformations such as silk I, silk II and α-helix forms.

Experimental

Silkworms of *Bombyx mori*, a hybrid between strains Nichi 140 and Shi 140, were reared with an artificial diet. During the period of 5 d before maturation, 2.5% DL-[3,3,-$^2H_2$]Ser (98 atom%, Sigma Chemical Company, USA; Lot No. 985-H) or L-[3,3,3-$^2H_3$]Ala (99.4 atom%, Sigma Chemical Company, USA; Lot No. 2010-I) were fed with an artificial diet (Silkmate 2M, Nippon Nosan Kogyo, Tokyo). Selectively deuterated cocoons thus obtained were degummed twice, to remove sericin, with 0.5% Marseilles soap solution at 100 °C, for 30 min. and washed by distilled water. Silk II sample thus obtained was dissolved in 9M LiBr aqueous solution (40 °C) and dialyzed against distilled water for 4 h and lyophilized (Silk I sample). Prior to measurements of ^2H NMR spectra of the individual forms,

these structural modifications were monitored by examination of infrared or high-resolution ^{13}C solid-state NMR spectra.

[*Ala*-3,3,3-$^2H_3$]-cocoon and fibroin from *P. c. ricini* were prepared by feeding 2.5% (w/w) L-[3,3,3-$^2H_3$]Ala to the silkworms together with an artificial diet during 5 d before maturation. At the same time, silkworms fed with [3,3,3-$^2H_3$]-Ala were excised and liquid silk was directly removed from the middle silk gland portion of *P. c. ricini*. The liquid silk thus obtained was dried gently over film of poly(vinyldene chloride).

Infrared spectra were obtained with a Shimadzu IR-435 spectrometer. 75.46 MHz high-resolution solid-state ^{13}C NMR spectra were recorded on a Bruker CXP-300 spectrometer by cross polarization-magic angle spinning (CP-MAS) method. Samples were contained in an Andrew-Beams type rotor machined from perdeuterated poly(methyl methacrylate) and spun as fast as 3—4 kHz by compressed air. In some instances, spinning side bands from quaternary carbons were suppresed by means of pulse sequence of the total side-band suppression (TOSS) by Dixon.[22] Chemical shifts were calibrated by the peak position of benzene at 128.5 ppm from TMS.

46.06 MHz high-power ^2H NMR spectra[19-21] were recorded on a Bruker CXP-300 spectrometer utilizing the quadrupole-echo pulse-sequence, 90°_x-t-90°_y-t-echo.[23] The experiments were done on resonance so that negative frequencies of the symmetry spectrum are folded over on top of the positive frequencies on transformation. Samples were contained in a 10 mm sample tube placed in a transverse solenoid coil. Duration of 90° pulse was usually 4 μs. Spectral width, spacing of the two 90° pulses t, and data points were 250 kHz (125 kHz×2), 40—60 μs, and 2 K, respectively. Repetition time was 0.5 s. Spectra were usually accumulated more than 120000 times.

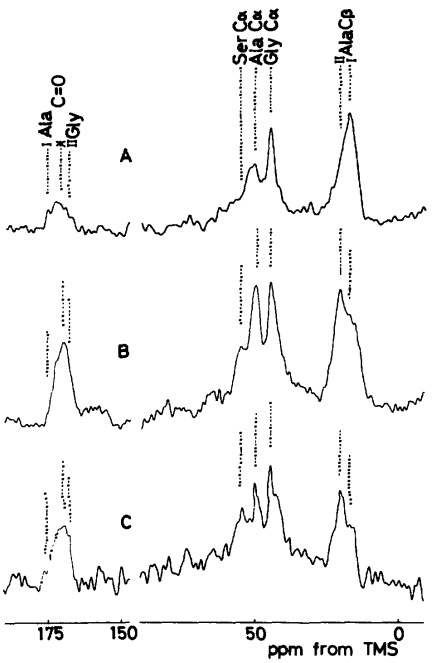

Fig. 1. 75.46 MHz ^{13}C CP-MAS NMR spectra of [*Ser*-3,3-$^2H_2$]cocoon and fibroin taking a variety of crystalline forms. The asterisked peak is ascribed to the carbonyl carbons other than silk I peak of Ala residue and silk II of Gly residue. A. silk I, B. silk II and C. cocoon.

Results

We obtained [*Ser*-3,3-$^2H_2$]- and [*Ala*-3,3,3-$^2H_3$]-cocoons and fibroin samples from biosynthesis by feeding respective deuterated amino acids to silkworms and resultant degumming procedure, as described in the previous section.[24] Before recording individual ^2H NMR spectra of each samples, we first examined change of spectral features due to structural modifications by the ^{13}C CP-MAS NMR spectra, as demonstrated in Fig. 1. The ^{13}C CP-MAS NMR spectra of [*Ser*-3,3-$^2H_2$]cocoon or fibroin are not strongly different from those of undeuterated samples previously recorded,[10,14] because degree of deuteration at Ser C_β carbon is at most 10—20%, as estimated by examination of high-resolution ^{13}C NMR spectra in aqueous solution. Apparently, expected conformational modification of the present samples was effectively achieved, because each silk I and silk II samples contain the respective forms as major components (≈80%), as manifested from the ^{13}C NMR peak-positions of Ala C_β or C=O peaks.

Figure 2 illustrates ^2H powder-pattern NMR spectra of corresponding [*Ser*-3,3-$^2H_2$]-cocoon and fibroin

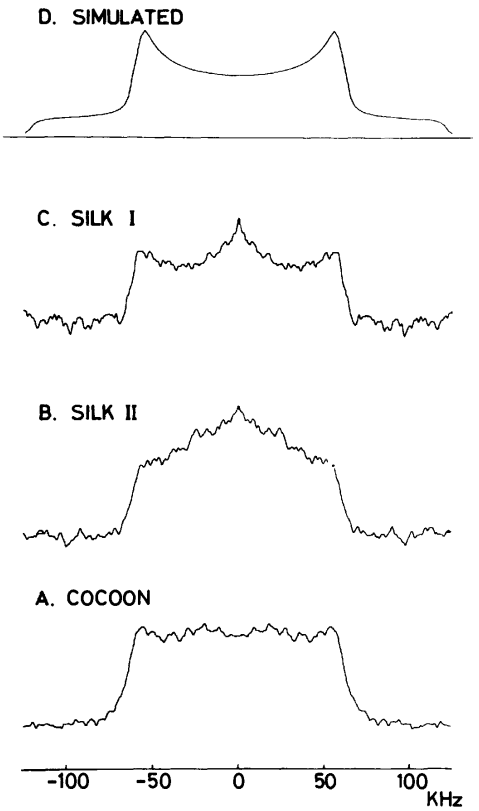

Fig. 2. 46.06 MHz ^2H NMR spectra of [*Ser*-3,3-$^2H_2$]-cocoon and fibrion. A. cocoon, B. silk II, C. silk I, and D. calculated spectrum with e^2qQ/h=180 kHz.

samples from *Bombyx mori* taking silk I and silk II forms. Obviously, these ^{2}H NMR spectra arose from superposition of at least two kinds of powder patterns, the wider and narrow components. It appears that no appreciable change in the spectral patterns of the wider components was noted among cocoon, silk I and silk II samples. In principle, any difference in spectral feature between the cocoon and silk II samples could be ascribed to the presence or absence of sericin which is a protein consisting of a large proportion of Ser residue. Therefore, it is now clear that there exists no appreciable change in the ^{2}H NMR spectra of side-chain orientation as seen from the wider component in the deuterated fibroin and sericin. The spectral feature and the separation of peaks (D_q) due to the quadrupole splittings (125 kHz) were well reproduced by spectral simulation[33,34] assuming the quadrupole coupling constant e^2qQ/h as 180 kHz, as shown in the top trace. In particular, the separation of peaks in the doublet signals is[19]

$$D_q = 3/4\,(e^2qQ/h) \qquad (1)$$

It is difficult, however, to record correctly the outer edges portion with separation of $2D_q$ (250 kHz) because of experimental limitation (spectral width 250 kHz).

On the contrary, we observed ^{2}H powder-pattern NMR spectra with reduced spectral separation as large as 39 kHz for [3,3,3-$^2H_3$]Ala(A), silk II(cocoon; B) and silk I (C) of *Bombyx mori*, α-helical sample obtained as dried liquid silk removed from the middle silk gland (D) and cocoon (E) from *P. c. ricini* (Fig. 3). Conformational feature of dried liquid silk sample from *P. c. ricini* is rather heterogeneous because of the presence of both the α-helix (about 30%[35]) and random coil form (about 70%) (Fig. 4). Nevertheless, it is obvious that Ala residues are mainly involved in the α-helix form, as far as the peak positions of the ^{13}C CP-MAS NMR spectra are concerned (Fig. 5).[36] Consistent with our previous finding,[17] the peak positions of the ^{13}C NMR peaks in Ala C_α, C_β and C=O carbons of [*Ala*-3,3,3-$^2H_3$]-fibroin in the solid state are in good agreement with those obtained from $(Ala)_n$ taking α-helix form.

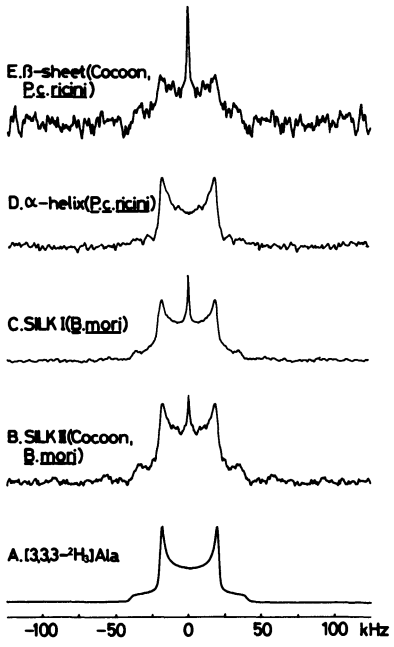

Fig. 3. 46.06 MHz ^{2}H NMR spectra of [*Ala*-3,3,3-$^2H_3$]-cocoons and fibroins from *Bombyx mori* and *P. c. ricini*. A. [3,3,3-$^2H_3$]alanine, B. cocoon from *Bombyx mori*, C. silk I from *B. mori*, D. α-helical portin of dried liquid silk from *P. c. ricini*, and E. cocoon of *P. c. ricini*.

Discussion

It is conceivable that side-chain moiety of Ser in silk fibroins, CD_2OH group, might participate in stabilization of secondary conformation in the solid state, because OH group has ability to form hydrogen bonding with C=O group of the same molecular

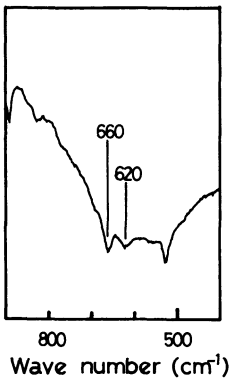

Fig. 4. Infrared spectrum of dried liquid silk from *P. c. ricini*.

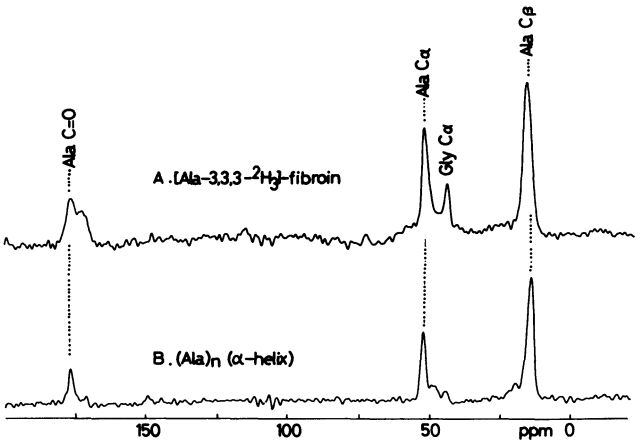

Fig. 5. ^{13}C CP-MAS NMR spectra of dried liquid silk [*Ala*-3,3,3-$^2H_3$]-fibroin from *P. c. ricini* and α-helical $(Ala)_n$. Spinning side bands were suppressed by the pulse sequence of TOSS.

chain. On the basis of survey of X-ray diffraction data on 19 or 43 globular proteins, Janin et al.[37] or Gray and Matthews[38] respectively, showed that approximately 70% of serine residue have their O_γ atom within hydrogen-bonding distance (3.5 Å) of at least one carbonyl group, with an acceptable angular geometry for OH··O bond. They showed that the χ_1 angle distribution of Ser side chain is almost equal among g^- (38%), t (28%), and g^+ (34%), suggesting the lesser steric hindrance created by the hydroxyl group, which in turn results in a smaller barriers for the rotation about the C_α-C_β bond.[37,38] Nevertheless, most of these observed hydrogen bonds involve a main chain carbonyl group as acceptor (83%), though side chain to side chain bonds may coexist with side chain to main chain bonds. It is further obvious that these hydrogen bonds are determined by the conformation of the main chain which fixes the position and orientation of the acceptor oxygens. In the case of the β-sheet form, intramolecular hydrogen bond can occur either between OH and C=O of the preceding (i-1) residue or of the same residue (i).[37] In the case of the α-helix, similar hydrogen bond can be formed between the OH of i th residue and C=O of i-4 residue.

It is now obvious that ^{2}H NMR spectra of side-chain methylene (CD_2) group of Ser residues can be analyzed as static and the separation of the quadrupole splittings was also unchanged among the cocoon, silk II and silk I samples. This finding implies that side chain reorientation of Ser residue is virtually frozen irrespective of differences in backbone conformations (silk II (β-sheet) or silk I). Undoubtedly, the β-sheet or silk II form could be further stabilized by taking the above-mentioned intrachain hydrogen bonds. As to a silk I model of *B. mori* silk fibroin in the solid state, crankshaft-type model has been proposed by Lotz et al.[3,9] and later, three kinds of revised loose helix models have been reported.[39] Therefore, we examined any possibility of forming intramolecular hydrogen bonds between the OH group of given Ser residue and backbone carbonyl groups in the chain of partial sequence Ala-Gly-Ser-Gly-Ala-Gly-Ala taking several conformations for models of silk I form. Basically, it was found by model-building that most of these models are feasible to form intramolecular hydrogen bonds (<3.5 Å) between the OH hydrogen and the C=O oxygen of the Gly residue in the preceding (i-1) residue in a similar manner to the case of the β-sheet form.

Therefore, it is natural to consider that almost all of side-chain hydroxyl group of Ser residue in fibroin could participate in the formation of intra- or interchain hydrogen bonds. In addition, it appears that in cocoons side chain hydroxyl groups of Ser in sericin are mostly hydrogen-bonded to proton acceptors of fibroin in cocoon, as inferred from the data of Fig. 2. This view might be important in connection with understanding of a manner of sericin-fibroin interaction in the cocoons. Further, it is worthwhile to point out that there appears no difference in the dynamic aspect of these main chains, because particular motions, if any, could significantly influence the ^{2}H NMR spectral features.

As illustrated in Fig. 3, however, the quadrupole splittings of [3,3,3-$^2H_3$]Ala and [*Ala*-3,3,3-$^2H_3$]-cocoon and fibroins were equally reduced to 39 kHz, as a result of motionally averaged reduction in the quadrupole interaction of the methyl group. Apparently, these spectral patterns arose from the presence of axially symmetric field gradient. Therefore, the simplest such a motion is the three-fold rotation about the C_α-C_β axis. The separation of the doublet peaks due to the quadrupole interaction is then reduced to

$$D_q' = 3/8\,(e^2qQ/h)(3\cos^2\alpha - 1) \qquad (2)$$

where α is the angle between the C-D vector and C_α-C_β axis. The calculated quadrupole splitting D_q' from this case is obtained as 42.6 kHz by using α= 109° 44′ and this value is slightly larger than the observed value (39 kHz).[21] In other systems, the quadrupole splittings of deuterated methyl groups are in the range of 35 kHz for palmitic acid[40] and nonadecane.[41] Again, there appears no variation in the above-mentioned value among alanine monomer and fibroins of α-helix, β-sheet, and silk I forms, reflecting the absence of major change in the dynamic state of main chains in these systems.

In conclusion, we successfully recorded powder-pattern ^{2}H NMR spectra of [*Ser*-3,3-$^2H_2$]- and [*Ala*-3,3,3-$^2H_3$]-cocoons and fibroins taking various types of secondary structure. The quadrupole splitting for CD_2OH side chain of Ser residue was found to be 125 kHz, indicating the presence of static side chain, whereas the splitting of the CD_3 side chain of Ala residue was reduced to 39 kHz, as a result of fast three-fold rotation. Accordingly, it is plausible that the hydroxyl groups of the side chains in Ser residue might participate in the formation of the intrachain hydrogen bonds which are effective in stabilization of particular forms irrespective of differences in backbone conformation in the cocoon, silk I, and silk II forms. Then, it is expected that the present approach might be useful as a new means to gain insight into molecular organization of fibroin samples as related to several kinds of physical properties of fibroins.

We are grateful to Dr. Takeshi Yamanobe and Professor Isao Ando of Tokyo Institute of Technology for use of their computer program for simulation of powder pattern. This work was supported, in part, by a Grant-in-Aid from the Ministry of Education, Science and Culture.

24) It is already known that there is a possibility of conversion of fed deuterated serine or alanine to other amino acids such as glycine, alanine or serine within a body of silkworm (Ref. 25—29). It appears that the extent of amino-acid conversion is not larger than 10% for alanine and glycine, as inferred from our previous experience on biosynthetic experiment utilizing [1-^{13}C]-labeled amino acids (Ref. 30). However, it is well known that serine is the most important source of glycine biosynthesis in mammalian system (Ref. 31). In a similar manner, Muramatsu et al. showed that radioactivity of glycine rose to nearly 60% of that of [1-^{14}C]-serine by 20 min after injection to *B. mori* silkworms (Ref. 29). They showed that radioactivity from [1-^{14}C]-serine is retained only in the carboxyl carbons. This finding is consistent with that the conversion of serine to glycine in insect is catalyzed by serine hydroxymethylase in the presence of tetrahydrofolic acid (Ref. 32). In this connection, deuterium atoms from deuterated hydroxymethyl group in the side chain of serine are thus not any more retained in converted glycine by this reaction. By contrast, conversion of serine to alanine was very low (2%) and no other amino acids were synthesized from serine (Refs. 25 and 29). Accordingly, we neglected, in this paper, a plausible contribution from any converted amino acid residues. Further, it is emphasized that the present conclusion as to the orientation of side-chains in serine to be described later remains unchanged, even if deuterium atoms are incorporated into glycine to some extent by an unidentified mechanism from the deuterated serine (see text).

Temperature Effect on the Association of Aqueous Europium and Sulfate Ions from Luminescence Decay Measurement

Fujio TANAKA,* Yoshiko KAWASAKI, and Shigeru YAMASHITA
College of Integrated Arts and Sciences, University of Osaka Prefecture,
Mozu-umemachi, Sakai, Osaka 591
(Received May 14, 1986)

The luminescence lifetime for $Eu_2(SO_4)_3$ and $EuCl_3$ in H_2O and D_2O has been measured at 0.01 and 0.001 mol dm^{-3} of Eu^{3+} and at various temperatures from 5 to 45 °C. The average number of water molecules coordinated to Eu^{3+} ion, q, is evaluated from the difference of the luminescence decay constants in the H_2O and D_2O solutions. By using the q value of 8.3 for aquaeuropium(III) ion in $EuCl_3$ solutions, q values for $Eu_2(SO_4)_3$ solutions were determined as a function of concentration and temperature. The average number of water molecules released from the primary hydration sphere by the inner-sphere complexation between Eu^{3+} and SO_4^{2-} ions is given as $\Delta q=8.3-q$, and Δq value increases with concentration and temperature. From the values of Δq and the known equilibrium constants on the overall complexation, it is revealed that for both the unis(sulfato) and bis(sulfato) complexation the ratio of inner-sphere complex to outer-sphere complex increases with temperature and that about one water molecule is released from the inner hydration sphere surrounding Eu^{3+} ion on the formation of an inner-sphere unis(sulfato) complex. The coordination state of the unis(sulfato) complex and the thermodynamic quantities for the equilibrium between outer- and inner-sphere complexes are discussed.

The ion-association is one of the most important problems in the chemistry of electrolyte solutions. In addition to conventional methods, modern techniques have been used to clarify this phenomenon. Ion complexes are classified into two types: inner- and outer-sphere complexes. It is rather difficult to identify them and, therefore, conflicting conclusions have frequently been reported. Some of the spectroscopic methods reflect not only inner-sphere interaction but also outer-sphere interaction. Thermodynamic data are useful for the examination of average characteristics of the complexes.

Recently, the luminescence decay measurement has been utilized in various fields as a method to investigate the coordination state of Eu^{3+} ion.[1-4] This method is based on the fact that the difference between the observed luminescence decay constants for H_2O and D_2O solutions is proportional to the number of inner-sphere water molecules surrouding Eu^{3+} ion. The information acquired by this method reflects only the inner-sphere interaction. In a previous work we showed the formation of an inner-sphere complex between Eu^{3+} and SO_4^{2-} ions by this method.[5] For revealing the details of ion-association in this system more quantitatively, the luminescence lifetime for H_2O and D_2O solutions of $Eu_2(SO_4)_3$ and $EuCl_3$ has been measured as a function of temperature. The combination of the present result with the known equilibrium constants for the overall complexation[6] will provide new information on the equilibrium between outer- and inner-sphere complexes.

Experimental

$EuCl_3 \cdot 6H_2O$ and $Eu_2(SO_4)_3 \cdot 8H_2O$ were prepared by dissolving Eu_2O_3 into HCl and H_2SO_4, respectively, as described previously.[5] Deuterated salts were obtained from hydrated salts by repeating D_2O addition and evaporation. D_2O of 99.95% grade(Merck) was used. A few modifications were made in the previous procedure and instrument for the lifetime measurement.[5] 1-Acetylnaphthalene was used as a photosensitizer instead of 2-acetylnaphthalene, because the fluorescence of the former was much weaker than that of the latter and so optical and electric interference due to the fluorescence from sensitizer reduced significantly. A transient memory(10 bits, Kawasaki Electronica TMR-10) was used. Data were analyzed by the least-squares method by means of a microcomputer system. Temperature was controlled by circulating thermostated water inside the cell holder.

Results and Discussion

Luminescence decay constants of Eu^{3+} ion in H_2O and D_2O, k^{H_2O} and k^{D_2O}, are related to the number of inner-sphere water molecules, q, as follows:[1-3,5]

$$\Delta k = k^{H_2O} - k^{D_2O} = A \cdot q, \quad (1)$$

where A is the proportionality constant, which corresponds to the rate constant of nonradiative deactivation caused by one molecule of H_2O. Luminescence decay constants measured for $EuCl_3$ and $Eu_2(SO_4)_3$ in H_2O and D_2O are shown in Table 1. It shows that at different Eu^{3+} concentrations and temperatures Δk is smaller for $Eu_2(SO_4)_3$ than for $EuCl_3$ and that at both the concentrations Δk increases for $EuCl_3$ and decreases for $Eu_2(SO_4)_3$ with the rise of temperature. It has been known that inner-sphere complexes are not formed in $EuCl_3$ solutions under the present conditions and the inner coordination sphere surrounding Eu^{3+} ion is occupied solely by water molecules.[5,7,8] The hydration number of aquaeuropium(III) ion has been determined to be 8.3 by X-ray diffraction for the $EuCl_3$ solution of 3.23 mol kg^{-1}.[7] Apart from its absolute value, we reported previously by the luminescence lifetime measurement that the hydration number for $EuCl_3$ solutions is nearly constant over a wide range of concentration.[5] We, therefore, use the q value of 8.3 for $EuCl_3$ solutions irrespective of concentration and temperature, and the values of A at each of conditions are obtained from Eq. 1. Subsequently, q values for $Eu_2(SO_4)_3$ solutions are determined by using these A values.[9] The q values shown in Table 2 are smaller than 8.3, indicating that water molecules are partially removed from the primary hydration sphere of Eu^{3+} ion by the formation of inner-sphere sulfato complexes. As predicted from the chemical equilibrium, the value of q for 5×10^{-3} mol dm^{-3} is smaller than that for 5×10^{-4} mol dm^{-3} at respective temperatures.

Hale and Spedding investigated this system in detail by the UV absorption method.[6] They suggested that their data were related to the equilibrium of overall complexation including both the outer-sphere and inner-sphere complexes. By using their data, we have calculated the fractions of unis(sulfato) and bis(sulfato) europium ions to total europium ions,[10] fractions being denoted by $f_{EuSO_4^+}$ and $f_{Eu(SO_4)_2^-}$, respectively. On the other hand, the average loss of inner-sphere water molecules caused by the inner-sphere complexation is obtained from the relation, $\Delta q=8.3-q$. The values of f's and Δq are given in Table 2. The values of Δq and f's, and the ratio of Δq to the sum of fractions ($f_{EuSO_4^+}+f_{Eu(SO_4)_2^-}$) increase with the rise of temperature.

The temperature effect on the ion-association between various cations and the sulfate ion were studied by electrical conductivity and spectroscopic methods. The enthalpy change for the overall ion-association has a positive value in most cases.[11-14] The enthalpy changes(ΔH) for formation of unis(sulfato) europium complex obtained by Hale and Spedding are 17.1 and 22.5 kJ mol^{-1} at 25 °C for the ionic strength of 0.045 mol kg^{-1} and infinite dilution, respectively.[6] They also gave ΔH of 25.9 kJ mol^{-1} at 25 °C and the ionic strength of 0.045 mol kg^{-1} for the formation of bis(sulfato) complex.[6]

We now consider the equlibrium between outer- and inner-sphere complexes by using the values of f's and Δq. The effect of temperature on the equilibrium can be expressed qualitatively by the value of $\Delta q/f$, where f denotes the sum of $f_{EuSO_4^+}$ and $f_{Eu(SO_4)_2^-}$. This

value seems to be relevant to the ratio of inner-sphere complexes to the total complexes. The fact that the value of $\Delta q/f$ increases with temperature makes it conceivable to conclude that for both the unis(sulfato) and bis(sulfato) complexes the temperature elevation shifts the equilibrium between outer- and inner-sphere complexes toward the inner-sphere complex.

For the formation of the unis(sulfato) complex the following equations are derived.

$$K^{T} = \frac{[EuSO_4^+]_{out}+[EuSO_4^+]_{in}}{[Eu^{3+}][SO_4^{2-}]} = K^{out}(1+K^{io}) \quad (2)$$

$$K^{out} = \frac{[EuSO_4^+]_{out}}{[Eu^{3+}][SO_4^{2-}]} \quad (3)$$

$$K^{io} = \frac{[EuSO_4^+]_{in}}{[EuSO_4^+]_{out}} \quad (4)$$

K^{out} can be estimated by the Fuoss equation,[15]

$$K = \frac{4\pi N_A \mathring{a}^3 e^b}{3000} \quad \text{and} \quad b = \frac{|z_i z_j| e^2}{\varepsilon k T \mathring{a}}, \quad (5)$$

where N_A=Avogadro's number, $\mathring{a}$=distance of closest approach of ions, ε=dielectric constant, k=Boltzmann constant, z=charge on the ion, and e=charge on the electron. Using the complex $[Eu(H_2O)SO_4]^+$, in which two ions are separated by one water molecule, as a model of the outer-sphere complex, we have calculated K^{out} at infinite dilution by Eq. 5 with two $\mathring{a}$ values of 6 Å and 7 Å.[16] K^{out} at the equilibrium ionic strength was evaluated by the Eq. 12 of Ref. 6, and K^{io} by Eq. 2 using calculated K^{out} and K^{T} given by Hale and Spedding.[10] On the other hand, in the 5×10^{-4} mol dm^{-3} solution, where the formation of the bis(sulfato) complex is almost negligible, K^{io} is correlated with Δq as follows:

$$K^{io} = \frac{[EuSO_4^+]_{in}}{[EuSO_4^+]_{out}} = \frac{(1/l)\cdot\Delta q}{f_{EuSO_4^+}-(1/l)\cdot\Delta q}, \quad (6)$$

where l represents the number of water molecules released from the inner hydration sphere by the inner-sphere coordination of sulfate ion to Eu^{3+} ion. The values of l calculated from Δq, $f_{EuSO_4^+}$, and K^{io} by Eq. 6 are shown in Table 3 along with K^{T}, K^{out}, and K^{io} values.

The l values are close to 1, the result meaning that one water molecule is released from the inner hydration sphere on the formation of inner-sphere unis(sulfato) complex. If the average coordination number of Eu^{3+} ion is invariant in the aqua ion and the inner-sphere complex, the sulfate ion seems to act as a unidentate ligand. Further, it is postulated that aquaeuropium(III) ion exists as an equilibrium mixture of $[Eu(H_2O)_8]^{3+}$ and $[Eu(H_2O)_9]^{3+}$. The average hydration number of 8.3 assessed by X-ray diffraction indicates that the ratio of $[Eu(H_2O)_8]^{3+}$ to $[Eu(H_2O)_9]^{3+}$ is approximately 2.[7] The result that l is unity suggests that the inner-sphere complex $[Eu(H_2O)_7SO_4]^+$ is formed from a bidentate sulfate ion and an octaaqua europium(III) ion. Since the l values estimated are reasonable, dividing of K^{T} into K^{out} and K^{io} in Eq. 2, followed by application of the Fuoss equation, is considered to be appropriate.

Finally, it is interesting from the thermodynamic viewpoint to compare ΔH and ΔS corresponding to K^{out} and K^{io}. ΔH^{out} and ΔS^{out} at infinite dilution are calculated by the Fuoss equation. ΔH^{io} was calculated from ΔH^{T} and ΔH^{out} according to a relation based on Eq. 2, $\Delta H^{T}=\Delta H^{out}+[K^{io}/(1+K^{io})]\cdot\Delta H^{io}$, and ΔS^{io} was obtained by $\Delta S^{io}=\Delta H^{io}/T+R\ln K^{io}$. The results at 25 °C are listed in Table 4, together with Hale and Spedding's ΔH^{T} and ΔS^{T}. It indicates that the predominance of inner-sphere complex in this system is ascribed to the fairly large value of ΔS^{io}.

9) We have assumed that the A value is dependent on temperature and concentration. It is probable that the hydration number of aquaeuropium(III) ion is dependent on these conditions and the A value is constant. However, the small difference caused by the two different treatments does not substantially influence on the following discussion.

10) The complex formation constants are calculated by using the equations in Ref. 6. For the unis(sulfato) complexation, the equation on the temperature dependence of k_1° and Eq. 12 with the value of D=0.6 were used. For the bis(sulfato) complexation, the values of K_2 and ΔH_2 at ionic

strength of 0.045 mol kg^{-1} and Eq. 12 with the value of D=0.3 were used. By repeating the calculation for Eq. 12, K's and f's were evaluated at respective concentrations and temperatures.

Equilibrium and Kinetic Studies of the Dimerization of Acridine Orange and Its 10-Alkyl Derivatives

Kiyofumi MURAKAMI,* Katsumi MIZUGUCHI, Yukio KUBOTA, and Yasuo FUJISAKI
Department of Chemistry, Faculty of Science, Yamaguchi University,
Yoshida 1677-1, Yamaguchi 753
(Received May 15, 1986)

The thermodynamics and kinetics of the dimerization of Acridine Orange (AO, 3,6-bis(dimethylamino)-acridinium chloride) and its 10-alkyl derivatives in 0.1 M NaCl solution have been studied by spectrophotometry and temperature-jump method. Dimerization constants, which were determined spectrophotometrically, become large with an increase in the length of the introduced alkyl chain; this behavior is the same as that in water and a dilute HCl solution. The association and dissociation rate constants determined from the temperature-jump measurements also depend on the length of the alkyl chain. Especially, the rate constants for methyl-AO are unexpectedly small. Both the effect of added salt on the thermodynamic parameters and the kinetic results are discussed in view of the structure of hydration water surrounding dye molecules. ^{1}H NMR data for AO and methyl-AO suggest that the planes of two component molecules in a dimer are parallel to each other. This result is consistent with the spectrophotometric and kinetic data.

Aggregation of metachromatic dyes in aqueous solution has extensively been studied as the most fundamental model system for the self-aggregation of biomolecules and the interaction between small molecules and biological macromolecules. Among these, Acridine Orange (AO) has particularly attracted many interests[1-15] because of its bacteriostatic and mutagenic activities as well as the ability of binding with nucleic acids.

In recent years, equilibrium studies on the dimerization of 10-alkyl derivatives of AO have been performed to elucidate the role of hydrophobic interaction.[11,13] As a result, the dimerization constant, the enthalpy and entropy changes for the dimerization were found to become large with an increase in the length of the introduced alkyl chain; the behavior has been interpreted in terms of the enhanced hydrophobic interactions. Kinetic studies for AO[3,7], 10-octyl- and 10-decyl-AO[8] have also shown that the greater stabilities of dimer for the long alkyl chain derivatives are realized by the small dissociation rate constants.

However, the mechanism of the dimerization is still not completely elucidated. The present paper describes the details of the thermodynamics and kinetics of the dimerization, using various 10-alkyl derivatives of AO. Our goal is to establish a plausible reaction mechanism for the dimerization.

Experimental

Materials. AO (3,6-bis(dimethylamino)acridinium chloride) and D_2O (99.8 atom% in deuterium) were purchased from Merck. The 10-alkyl derivatives of AO (methyl-AO, ethyl-AO, propyl-AO, pentyl-AO, and octyl-AO), shown in Fig. 1, were synthesized according to the method of Miethke and Zanker.[16] All dyes were purified by column chromatography on alumina, using methanol as an eluent; no trace of impurity was detected by the method of thin-layer chromatography for each dye. All other chemicals used were reagent grade and water was glass-redistilled. Spectrophotometric and kinetic experiments were conducted in 0.1 M† NaCl and 5 mM phosphate buffer solution (ionic strength I=0.11; pH=6.9).

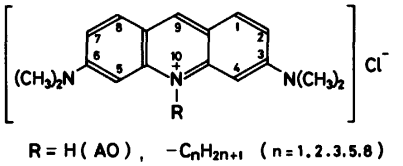

Fig. 1. Structural formulas of AO and its 10-alkyl derivatives.

Method. Spectrophotometric measurements were carried out with a Shimadzu UV-200S spectrophotometer. ^{1}H NMR spectra of AO and methyl-AO were recorded using a 200-MHz JOEL FX-200 Fourier transform spectrometer. The measurements were performed in the concentration range 10^{-2} M to 5×10^{-4} M. The sample solutions were prepared in D_2O so as to contain a small amount of internal reference sodium 2,2-dimethyl-2-silapentane-5-sulfonate(DSS). Kinetic experiments were performed with a Unisoku TF-102 fluorescence temperature-jump spectrophotometer. This equipment is one of joule-heating type. The light source was a 250 W halogen lamp and the path length of the cell was 5 mm. The time cource of temperature rise could be approximated by an exponential function and its time constant (τ_r) was in the range of 4—5 μs, depending on temperature and concentration of salt. Data were obtained at the temperature rise of 5 °C. Since the relaxation times (τ) for the present systems were close to τ_r, especially at high temperatures and high concentrations of dye, they were determined by the deconvolution method.[17] The relaxation curve observed by an imposition of an exponential type perturbation can be expressed by

$$X(t) = X_0\left\{\frac{\tau}{\tau-\tau_r}\exp(-t/\tau) - \frac{\tau_r}{\tau-\tau_r}\exp(-t/\tau_r)\right\} \quad (1)$$

† 1 M=1 mol dm^{-3}.

where X and X_0 are an observable and its relaxation amplitude, respectively. τ was evaluated using a nonlinear regression analysis. All the calculations were carried out on an NEC ACOS-850 computer system.

Results

Equilibrium constants and Thermodynamic Parameters of Dimerization. Figure 2 shows typical absorption spectra observed for methyl-AO in 0.1 M NaCl solution. Similar spectral changes were also obtained with AO and other 10-alkyl derivatives. The presence of clear isosbestic points (475 and 518 nm) in the absorption spectra indicates an equilibrium between two spectral species, monomer and dimer (Fig. 2). Hence, the data were analyzed on the basis of monomer-dimer equilibrium.

$$2D \overset{K_D}{\longleftarrow} D_2 \tag{2}$$

The apparent molar extinction coefficient (ε) at a given wavelength can be expressed by

$$\varepsilon = \varepsilon_M\alpha + \varepsilon_D(1-\alpha) = (\varepsilon_M-\varepsilon_D)\alpha + \varepsilon_D, \tag{3}$$

where ε_M and ε_D are the molar extinction coefficients per monomer unit in the monomer and dimer forms, respectively, and α is the fraction of dye present in the monomer form. α can be estimated from the dimerization constant K_D and the total concentration of dye C_T as

$$\alpha = \frac{(1+8K_DC_T)^{1/2}-1}{4K_DC_T}. \tag{4}$$

The value of K_D was determined by the reiteration method. First an arbitrary K_D is chosen and then the corresponding values of α for several concentrations are calculated using Eq. 4. For each wavelength, the best straight-line fit of ε vs. α is found by linear least-squares method. The procedure is repeated to self-consistency. Dimer and monomer spectra were obtained from the intercepts of the straight lines at α=0 and α=1. Assuming that the planes of two component molecules in a dimer are parallel to each other, intermolecular distance R was estimated according to the method of Monahan and Blossey.[18] From temperature dependence of K_D, standard enthalpy and entropy changes of dimerization were also determined. These results are summarized in Table 1.

a) 1 mM phosphate buffer (pH=6.9) at 25 °C.[6,7] b) Water, at 25 °C.[13] c) 1 mM HCl, at 20 °C.[10,11] Listed values for K_D at 25 °C were calculated from $\Delta H°$ and $\Delta S°$ using the equation $K_D=\exp\{-(\Delta H°-T\Delta S°)/RT\}$.

Configuration of AO and Methyl-AO Dimers. Figure 3 shows ^1H NMR spectra of AO and methyl-AO in D_2O. In agreement with the assignment reported by Blears and Danyluk,[14] the NMR spectrum of AO was assigned, in order of decreasing field, to resonances due to methyl protons (3.02 ppm), 4,5-protons (5.92 ppm), 2,7-protons (6.89 ppm), 1,8-protons (7.51-ppm), and 9-proton (8.19 ppm). A clear splitting due to long-range coupling between 2,7- and 4,5-protons was also observed (Fig. 3). In the case of methyl-AO, an additional resonance due to the methyl protons at the position 10 was observed at 3.51 ppm (Fig. 3). Concentration dependence of the spectra shows similar dilution shifts to low field as observed for AO by Blears and Danyluk.[14] Table 2 lists the dilution shift of each resonance, given in terms of the difference between two concentrations 10^{-2} M and 5×10^{-4} M.

Kinetic Parameters. The square of the reciprocal relaxation time for the dimerization reaction (Eq. 2) can be expressed by[19]

$$\tau^{-2} = 8k_F k_B C_T + k_B^2, \quad (5)$$

where k_F and k_B are the forward and backward rate constants, respectively. Figure 4 shows plots of τ^{-2} vs. C_T for AO and its five 10-alkyl derivatives, indicating that the linear relationship does hold for the present system in agreement with Eq. 5. The rate constants and K_D ($=k_F/k_B$) obtained from these plots are listed in Table 3. This table also summarizes thermodynamic parameters (ΔH^0 and ΔS^0) determined kinetically and activation parameters determined according to Eyring's absolute rate theory. Activation enthalpy for the forward reaction ΔH_F^* has the value nearly equal to zero for all dyes ($\Delta H_F^* \sim 0\pm6$ kJ mol^{-1}), while that for the backward reaction ΔH_B^* has the value in the range 60—70 kJ mol^{-1} (Table 3). The forward and backward activation entropies were found to be $\Delta S_F^* = -40$—-80 JK^{-1} mol^{-1} and $\Delta S_B^* = 60$—95 JK^{-1} mol^{-1}, respectively (Table 3). The experimental error for the rate constants was estimated to be ±10—20%, while that for the thermodynamic parameters was ±20—30%. Considering this point, it seems likely that both kinetically and spectrophotometrically determined thermodynamic parameters are in agreement with each other.

Table 2. Observed Dilution Shifts for AO and 10-Methyl-AO, and Ring Current Shielding

Proton	Dilution shift of AO in ppm	Dilution shift of 10-methyl-AO in ppm	Ring current shielding in ppm

Discussion

Constantino et al.[11] and Septinus et al.[13] found that the values of K_D, ΔH^0, and ΔS^0 for the dimerization of 10-alkyl derivatives of AO in water and a dilute HCl solution have a tendency to become large with an increase in the length of the alkyl chain (Table 1). They attributed this tendency to the increase of

hydrophobic interactions, that is, to the stabilization of water structure surrounding the introduced alkyl group. Septinus et al.[13] also pointed out that the longer the alkyl chain becomes, the more the tendency is pronounced. The values of ΔH^0 and ΔS^0 in 0.1 M NaCl solution (Table 1) exhibit no clear dependence on the length of the alkyl chain, whereas the K_D value clearly shows that the stabilization of dimer due to the introduction of alkyl chain takes place as in the case of water and a dilute HCl solution. Furthermore, the comparison of the present results with those in water and a dilute HCl solution shows that the presence of salt leads to the increase of K_D. This can be interpreted in terms of the stabilization of dimer by the electrostatic screening of positive charges.[6] Table 1 also shows that NaCl has a significant effect upon ΔH^0 and ΔS^0. The change in ΔH^0 by the presence of NaCl is compensated by the corresponding change in ΔS^0 to minimize the change in ΔG^0. Such enthalpy-entropy compensation has scarecely been reported for the dimerization of dye molecules. By comparison of two reports concerning the dimerization of proflavine,[20,21] however, one can find the same behavior; $\Delta H^0=-23$ kJ mol^{-1} and $\Delta S^0=-25$ JK^{-1} mol^{-1} in 0.05 M acetate buffer solution[20] and $\Delta H^0=-60$ kJ-mol^{-1} and $\Delta S^0=-150$ JK^{-1} mol^{-1} in 0.2 M KCl solution.[21] The marked decrease in ΔH^0 and ΔS^0 upon addition of salt suggests an alteration in the hydration structure surrounding dye molecules. In this connection, it should be noted that Cl^-, which forms a negative charge cloud around dye molecules, is well-known as an order-destroying ion of water structure.[22] The effect of Cl^- upon water structure may be responsible for the change in the thermodynamic parameters. The origin of this effect is at present unclear but is being explored in our laboratory.

As can be seen in Table 2, the dilution shifts of proton resonances of AO and methyl-AO show almost the same behavior, suggesting the same dimer configuration. Using the theory of Johnson and Bovey[23] and assuming that the dye molecules are arranged in parallel so that the centers of adjacent acridine rings are exactly superimposed or they are laterally displaced,[14] the shielding due to the ring currents of adjacent rings was estimated as a function of the interplanar distance (R) and the distance by which adjacent rings are off-center with respect to each other (B). The relative shifts[14] of proton resonance were found to agree well with the ring current schieldings calculated for the configuration in which ring nitrogens of adjacent dye molecules are in opposite direction and R=6 Å and B=0.5 Å (Table 2). This interplanar distance (6 Å) coincides with the values obtained from the spectrophotometric analysis (Table 1). Furthermore, the magnitude of the dilution shifts for 10-methyl protons is several times larger than that for dimethylamino protons, showing that the 10-methyl group is placed at a position where the protons are readily exposed to the field due to the ring currents of adjacent rings. Such a position can be attained by the lateral displacement between the centers of adjacent rings; this is in harmony with the above dimer configuration.

Table 3 shows that the association and dissociation rate constants vary, in a complex manner, with increasing length of the introduced alkyl chain. To understand this behavior in more detail, it is necessary to examine the following general mechanism for the dimer formation.

$$D + D \underset{k_{-1}}{\overset{k_1}{\longleftrightarrow}} D, \quad D \underset{k_{-2}}{\overset{k_2}{\longleftrightarrow}} D_2. \tag{6}$$

The first step is the diffusion-controlled formation of an outer-sphere complex. The second step is the formation of a stable dimer accompanying a rearrangement of dye monomers and ejection of water molecules. Applying the steady-state assumption to the outer-sphere complex, the observed rate constant can be expressed by

$$k_F = \frac{k_1 k_2}{k_{-1}+k_2}, \qquad k_B = \frac{k_{-1}k_{-2}}{k_{-1}+k_2}. \tag{7}$$

The diffusion controlled-rate constants k_1 and k_{-1} for AO can be theoretically calculated[24] to be $k_1=4.5\times10^9$ M^{-1} s^{-1} and $k_{-1}=5.3\times10^9$ s^{-1}, assuming that the diffusion coefficient of AO is 5×10^{-10} m^2 s^{-1}[17] and the encounter distance is 9 Å; the encounter distance was

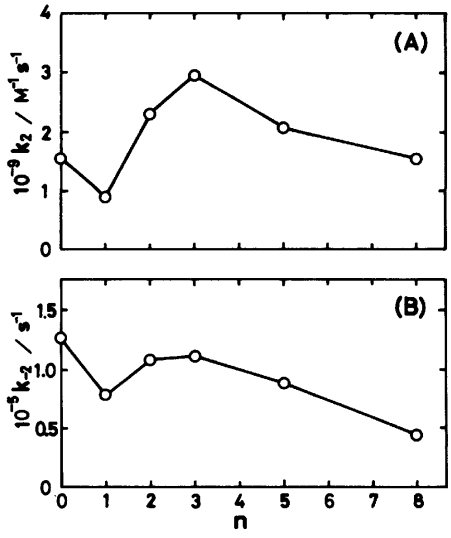

Fig. 5. The dependence of the rate constants associated with the second step in Eq. 8 on the length of the introduced alkyl chain. Abscissa shows the number of carbon atoms in the alkyl chain. (A): forward rate constant, (B): backward rate constant.

estimated as the sum of the interplanar distance in dimer (6 Å) and the diameter of water molecule (2.8 Å). Substituting these values and the values of k_F and k_B (Table 3) into Eq. 7, the rate constants associated with the second step can be determined. The rate constants for other dyes can also be estimated in the same manner by using the diffusion coefficients evaluated with the Stokes-Einstein relation for a spherical model. The evaluation of the diffusion coefficients may not be strictly valid. However, the uncertainty is unlikely to affect the conclusions of the present paper. Figure 5 indicates that both k_2 and k_{-2} vary with the length of the alkyl chain in a similar manner as k_F and k_B (Table 3). In the case of methyl-AO, the relatively slow rates can be ascribed either to a high-energy activated state, or to the stabilization of the outer-sphere complex and the dimer, or to both. The dimer configuration determined from the ^{1}H NMR spectra suggests that an alteration in the hydration structure rather than a direct interaction between the introduced methyl groups plays a significant role. The rate constants for ethyl- and propyl-AO have somewhat larger values, suggesting that the alkyl chains containing two or three carbon atoms make the activated configuration be easily accessible. For AO-derivatives having more longer alkyl chains, the rate decrease with an increase in the chain length. This effect may be attributed to the stabilization of both the outer-sphere complex and the dimer by direct hydrophobic interactions between hydrocarbon chains.[13] Dewey et al.[25,26] have shown that specific solvent-solute interactions play an important role in the kinetics of the dimerization of proflavine and thionine in aqueous alcohol solutions. In the case of methyl-AO, such interactions may be responsible for the relatively slow rates.

The authors wish to express their thanks to Mr. Yoshiaki Ishida, Mr. Masakatsu Hatakenaka, and Mr. Tsuyoshi Arai of Department of Analytical Chemistry Corporate Research and Development UBE Industries for their supports in NMR measurements. We also would like to thank Dr. Kohto Migita for his helpful discussions.

Stopped-Flow Kinetic Study of the Complex Formation between Pyridoxal 5′-Phosphate and Bovine Serum Albumin

Kiyofumi MURAKAMI,* Yukio KUBOTA, Yasuo FUJISAKI, and Takayuki SANO†
Department of Chemistry, Faculty of Science, Yamaguchi University,
Yoshida 1677-1, Yamaguchi 753
†Department of Chemistry, Faculty of Science, Hiroshima University,
Higashisenda-machi, Naka-ku, Hiroshima 730
(Received May 15, 1986)

The complex formation between pyridoxal 5′-phosphate (PLP) and bovine serum albumin at pH=7.0 and 25 °C was characterized by four relaxation processes. The dependence of the reciprocal relaxation times upon reactant concentrations was found to be consistent with a mechanism in which a rapid bimolecular binding step is followed by three sequential isomerization steps. The eight rate constants for this mechanism were determined and then combined to calculate an overall equilibrium constant which is in agreement with the literature value. Absorption spectra of the complexes formed by the two faster steps were determined from absorbance changes associated with them; the spectrum corresponding to the first complex has two bands at 330 nm and 360 nm and an additional 410 nm band, while the spectrum corresponding to the second complex has a large single band at 375 nm. Comparing these spectra with those reported for other PLP-enzyme systems, we speculate that four steps in the proposed mechanism may correspond to the rapid formation of a carbinolamine, which is in very rapid equilibrium with a Schiff base form, followed by the deprotonation of the ring nitrogen, the formation of an ionic hydrogen-bonded Schiff base, and the final formation of a nonionic hydrogen-bonded Schiff base.

Pyridoxal 5′-Phosphate (PLP), which is an important cofactor of many enzymes, has been found to be transported in plasma by albumin molecules.[1] Dempsey and Christensen[2] have studied the binding of PLP with bovine serum albumin (BSA) and have shown that there are at least two kinds of strong binding sites, i.e., the primary site characterized by the 332 nm absorption band and the association constant $K_{ass}>10^6\ M^{-1}$ †† and the secondary site characterized by the 415 nm band and $K_{ass}\sim10^5\ M^{-1}$. The bindings occur at ε-amino lysine groups of the protein. On the basis of the irreducibility by $NaBH_4$ and the abundance of lysyl residues in the neighborhood of the primary binding site, Dempsey and Christensen[2] and Anderson et al.[3] have suggested that the structure of PLP bound to the primary site is not a Schiff base but a substituted aldimine. On the other hand, recent polarographic[4] and circular dichroism[5] studies have claimed that a nonionic hydrogen-bonded Schiff base structure is responsible for the primary complex. Although this structure seems to be plausible, the process of its formation has not been well elucidated.

The present study describes the kinetics of the interaction of PLP with BSA. Our goal is to establish an overall reaction mechanism for the binding of PLP to the primary site.

Experimental

Materials. Albumin (fraction V from bovine serum) was purchased from Wako Pure Chemical Industries and used without further purification. The dimer content was about 5%. The molar concentration of BSA was determined from the absorbance at 280 nm ($E^{1\%}_{1\,cm}=6.6$[6]), assuming its molecular weight of 67000. Pyridoxal 5′-phosphate was purchased from Tokyo Kasei and used without further purification. All the sample solutions were prepared in 0.1 M phosphate buffer at pH=7.00±0.02.

Methods. Absorption spectra were measured with a Union Giken SM401 Spectrophotometer. Kinetic measurements were performed using a Union Giken stopped-flow apparatus (RA401 and RA1100). In order to investigate the binding to the primary site all the measurements were carried out at P_0/L_0 (protein to ligand ratio)≧1. The temperature was controlled to be 25±0.2 °C.

Results and Discussion

Relaxations and Their Characteristics. The stopped-flow and spectrophotometric measurements revealed that the binding of PLP to BSA occurs through four distinct relaxations. Typical traces observed are shown in Fig. 1. Among these, the two slower relaxations have already been reported by Dempsey and Christensen.[2] They showed that an increase of absorbance around 415 nm within 100 s is followed by a very slow increase of that at 332 nm with a loss of the 415 nm band, exhibiting an apparent isosbestic point at 350 nm. However, the two faster relaxations have not been reported so far.

The relaxation time (τ) for each relaxation was determined from a semi-logarithmic plot of the trace. Figures 2—5 show the concentration dependence of the reciprocal relaxation times. As can be seen in Figs. 4(A) and 5(A), the concentration dependence of τ^{-1} at $L_0=5\times10^{-5}$ M for each of the two slower relaxations exhibits a sharp increase within a narrow range of the protein concentration above $P_0=5\times10^{-5}$ M. Only with these data it is difficult to perform an accurate determination of kinetic parameters. Hence, the concentration dependence of τ^{-1} at $P_0/L_0=1$ (Figs.

†† 1 M=1 mol dm^{-3}.

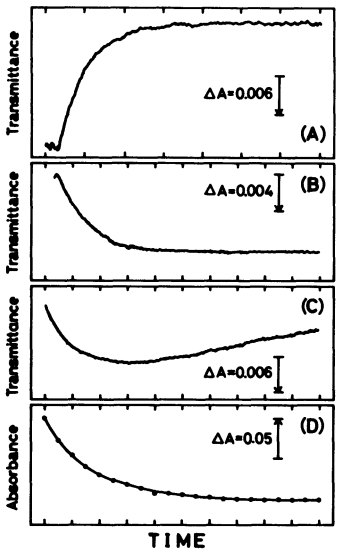

Fig. 1. Typical traces of the reaction observed after the mixing of PLP (1×10^{-4} M) and BSA (1×10^{-4} M). (A): Transmittance change at 390 nm. (B): Transmittance change at 390 nm. (C): Transmittance change at 415 nm. (D): Absorbance change at 415 nm. The abscissa scale is (A) 2.5 ms per division, (B) 100 ms per division, (C) 100 s per division, and (D) 1 h per division. The three faster relaxations were observed by the stopped-flow method, while the fourth one by spectrophotometry. The arrow designated for each trace shows the magnitude and the direction of the positive absorbance change.

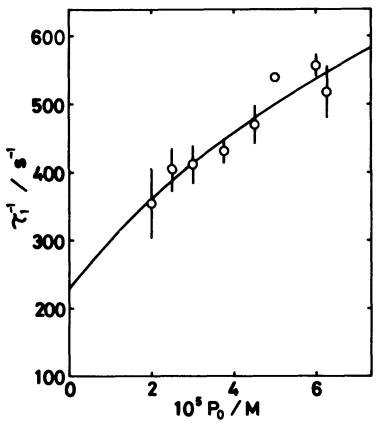

Fig. 2. Concentration dependence of τ_1^{-1} at P_0/L_0 (protein to ligand ratio)=1. The abscissa indicates the initial concentration after mixing. The solid line represents the theoretical curve calculated using the equilibrium and rate constants listed in Table 1. Legends are also the case for Figs. 3—5.

4(B) and 5(B)), which exhibits a more gradual increase with protein concentration, was also measured and analyzed together with the previous data. τ_1^{-1} increases progressively with an increase in the protein concentration, while τ_2^{-1}, τ_3^{-1}, and τ_4^{-1} increase at low concentrations but tend toward constant values at

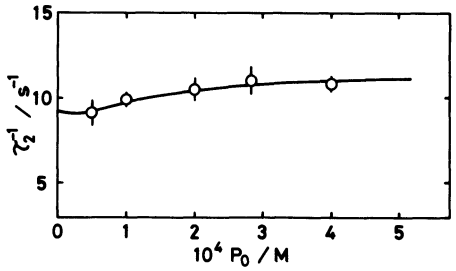

Fig. 3. Concentration dependence of τ_2^{-1} at $L_0=5\times10^{-5}$ M.

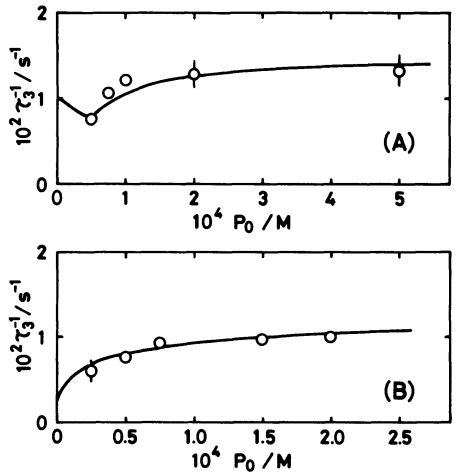

Fig. 4. Concentration dependence of τ_3^{-1}. (A) Concentration dependence at $L_0=5\times10^{-5}$ M. (B) Concentration dependence at $P_0/L_0=1$.

high concentrations. This behavior suggests a reaction scheme that a bimolecular rapid binding step is followed by three sequential isomerization reaction steps.

Reaction Scheme. In order to interpret the concentration dependence of the reciprocal relaxation times, the following model is examined.

$$\mathbf{L}+\mathbf{P} \underset{k_{-1}}{\overset{K_1\ k_1}{\rightleftarrows}} \mathbf{C}_1 \underset{k_{-2}}{\overset{K_2\ k_2}{\rightleftarrows}} \mathbf{C}_2 \underset{k_{-3}}{\overset{K_3\ k_3}{\rightleftarrows}} \mathbf{C}_3 \underset{k_{-4}}{\overset{K_4\ k_4}{\rightleftarrows}} \mathbf{C}_4, \tag{1}$$

where **L**, **P**, and **C** denote free ligand, free protein and complex species, respectively, and K_i, k_i, and k_{-i} are the equilibrium constant, the forward and backward rate constants of the ith step. This mechanism predicts four relaxation times, defined by

$$\tau_1^{-1} = k_1(L+P) + k_{-1}, \tag{2}$$

$$\tau_2^{-1} = k_2\frac{K_1(L+P)}{1+K_1(L+P)} + k_{-2}, \tag{3}$$

$$\tau_3^{-1} = k_3\frac{K_1K_2(L+P)}{1+K_1(1+K_2)(L+P)} + k_{-3}, \tag{4}$$

$$\tau_4^{-1} = k_4\frac{K_1K_2K_3(L+P)}{1+K_1\{1+K_2(1+K_3)\}(L+P)} + k_{-4}, \tag{5}$$

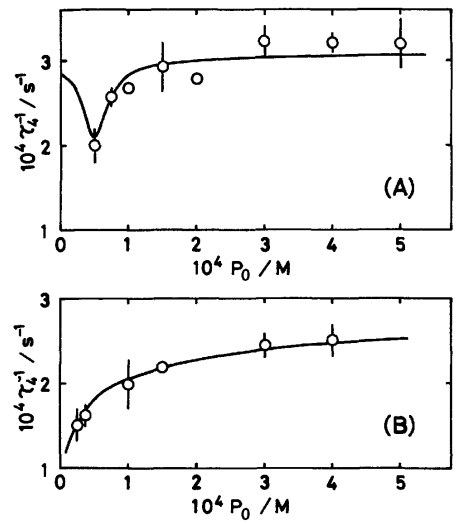

Fig. 5. Concentration dependence of τ_4^{-1}. (A) Concentration dependence at $L_0=5\times10^{-5}$ M (B) Concentration dependence at $P_0/L_0=1$.

where L and P, respectively, denote free ligand and free protein concentrations at the end of each step and where the rapid equilibrium of the preceding step has been assumed in each case, since the relaxation times observed for the present system are well separated each other (Fig. 1).

The data of Figs. 2—5 were fitted to Eqs. 2—5 by linear or nonlinear regression analysis, using the following protocol. First, an arbitrary K_1 was chosen to calculate the equilibrium concentrations, L and P, at the end of the first step. Then the best straight-line fit of τ_1^{-1} vs. $(L+P)$ was found to obtain k_1, k_{-1}, and K_1. The procedure was iterated until all the parameters converge. The estimate of K_1 was used with Eq. 3 to fit the data of Fig. 3 and to obtain k_2, k_{-2}, and K_2. The estimated values for K_1 and K_2 were used with Eq. 4 to obtain k_3, k_{-3}, and K_3 from the data of Fig. 4. Finally, k_4, k_{-4}, and K_4 were determined using Eq. 5 and the data of Fig. 5. The solid lines in Figs. 2—5 indicate the best least-squares fits, and the kinetic parameters obtained are summarized in Table 1.

The overall association constant for Scheme 1 is given by

$$K_{ass} = K_1(1+K_2+K_2K_3+K_2K_3K_4). \quad (6)$$

From the kinetic data of Table 1, we calculate an overall association constant of 5.27×10^6 M^{-1}. This value is consistent with the prediction by Dempsey and Christensen[2] that K_{ass} for the primary site should be larger than 1×10^6 M^{-1}. Independently of the first step, K_1 can be estimated by nonlinear regression analysis using Eq. 3 and the data of Fig. 3. The result is $K_1=2.02\times10^4$ M^{-1}, a value in excellent agreement with the estimate of K_1 in Table 1. The agreement of these values lends considerable confidence to the validity of Scheme 1 as a plausible reaction scheme.

Table 1. Equilibrium and Rate Constants Associated with the Mechanism of Eq. 1

Step	K_i	k_i	$\frac{k_{-i}}{s^{-1}}$
1	1.94×10^4 M^{-1}	4.41×10^6 M^{-1} s^{-1}	227
2	0.702	4.77 s^{-1}	6.80
3	13.5	3.03×10^{-2} s^{-1}	2.25×10^{-3}
4	27.5	3.49×10^{-4} s^{-1}	1.27×10^{-5}

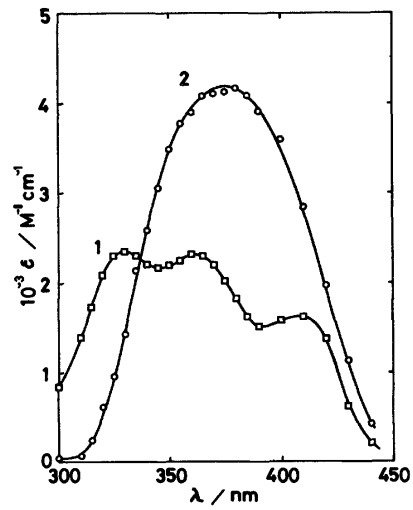

Fig. 6. Absorption spectra of C_1 (curve 1) and C_2 (curve 2).

Structures of the Intermediate Species. To investigate the structures of the intermediate species in Scheme 1, the molar extinction coefficients were determined as follows. At the end of the first step, the absorbance of the sample at a given wavelength can be expressed by

$$A_1 = \varepsilon_L L + \varepsilon_P P + \varepsilon_1 C_1, \quad (7)$$

where ε_L, ε_P, and ε_1 are molar extinction coefficients of the free ligand, the free protein and the first complex, respectively. Using the change in absorbance associated with the first step (ΔA_1), A_1 can also be expressed as

$$A_1 = A_0 + \Delta A_1, \quad (8)$$

where A_0 is the absorbance of the sample after mixing but before initiation of the reaction. Combining Eqs. 7 and 8, ε_1 becomes

$$\varepsilon_1 = \frac{A_0+\Delta A_1-\varepsilon_L L-\varepsilon_P P}{C_1}. \quad (9)$$

In this equation, ε_L, ε_P, and A_0 can be estimated from spectrophotometric data for the reactants, and the concentrations L, P, and C_1 can be calculated with the value of K_1 in Table 1. ΔA_1 was determined taking into account the dead time of the apparatus. Sub-

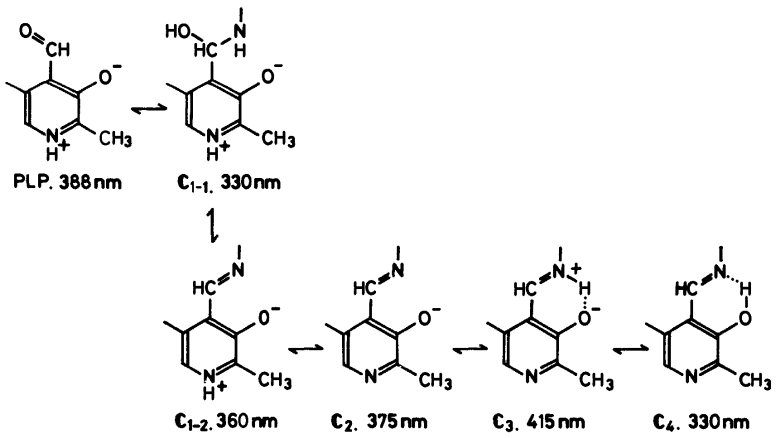

Fig. 7. Mechanism for the isomerization of PLP at the primary site.

stitution of these values into Eq. 9 yields the molar extinction coefficient of C_1 (ε_1). The molar extinction coefficient of C_2 (ε_2) was also determined in a similar manner. The absorption spectra of C_1 and C_2 thus obtained are displayed in Fig. 6. The absorption spectra of C_1 (curve 1) has two maxima at 330 nm and 360 nm and a small peak around 410 nm, suggesting the existence of more than one spectral species, while that of C_2 (curve 2) exhibits a single strong band having a peak at 375 nm. These 360 and 375 nm bands have not been reported for the PLP-albumin system.

Considering the present kinetic data and other results reported so far, we propose a mechanism for the complex formation at the primary site (Fig. 7). Three possible structures, i.e., substituted aldimine,[2,7] carbinolamine[2] and nonionic hydrogen-bonded Schiff base,[4,5,8] have been proposed for 330 nm band. Among these the carbinolamine (C_{1-1}) is the most suitable structure for the 330 nm band in curve 1 of Fig. 6 because it is an intermediate structure[9] for a subsequent Schiff base formation. The 360 nm band, which has been observed as a stable species for PLP-aspartate β-decarboxylase[10] and PLP-aspartate aminotransferase[11-15] systems, is now generally recognized as due to a Shiff base structure (C_{1-2}). Considering that the relaxation time for the formation of C_{1-1} was indistinguishable from that of C_{1-2}, it seems reasonable to conclude that these structures are in very rapid equilibrium with each other.

Matsushima and Martell[16] have observed a single strong band for pyridoxylidenevaline (373 nm) and pyridoxal phosphate valine Schiff base (350 nm) in alkaline methanol solutions, and assigned the band to the π_1 band of the anionic form of the Schiff base. The resemblance of the present absorption spectrum (curve 2 in Fig. 6) to those bands suggests that the anionic Schiff base structure is responsible for C_2.

The 415 nm band is attributed to an ionic hydrogen bonded Schiff base structure (C_3), with or without protonation of the ring nitrogen.[3,4,16,17] Considering that the ring nitrogen is already deprotonated in the previous step ($C_{1-2} \rightarrow C_2$), it is reasonable to expect that the ring nitrogen of C_3 is deprotonated rather than protonated.[8] The appearance of the band around 410 nm in curve 1 of Fig. 6 implies the existence of another path of the rapid formation of an ionic hydrogen-bonded Schiff base at a different site, which may correspond to the secondary site.

Based on the irreducibility of the complex by $NaBH_4$ and the presence of three lysyl residues in the neighborhood of the primary binding site, Dempsey and Christensen[2] and Anderson et al.[3] have suggested a substituted aldimine, in which the ring nitrogen is protonated, for the final and stable complex (330 nm band). However, the mechanism shown in Fig. 7 suggests that the nonionic hydrogen-bonded Schiff base in hydrophobic environment rather than the substituted aldimine is plausible for C_4. It is likely that the hydrophobic environment causes the irreducibility of the Schiff base by $NaBH_4$. This structure is consistent with the conclusion obtained from polarographic studies[4] and circular dichroism and spectrophotometric investigations.[5,8] The proposed mechanism (Fig. 7) indicates that the structure of bound PLP changes, step by step, from the polar form to the nonpolar one. Perhaps PLP first binds to a polar site at the surface of the protein and migrates to a more hydrophobic region.

The authors wish to express their thanks to Professor Tatsuya Yasunaga of Kinki University for his helpful discussions.

Fluorescence and Nonradiative Relaxation from Vibronic Levels of S_1 Pyrimidine: Effects of Molecular Rotation and Intramolecular Vibrational Redistribution

Osamu Sekiguchi,† Nobuhiro Ohta, and Hiroaki Baba*
Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received May 19, 1986)

Emission characteristics of pyrimidine vapor which were measured after excitation into various S_1 vibronic levels with relatively low excess vibrational energies (ΔE) below 2650 cm^{-1} were found to depend markedly upon ΔE. The emission from a vibronic level with $\Delta E<1000$ cm^{-1} (e.g., $6a^1$ or 1^1) is sharp and attributable to the fluorescence from the initially prepared vibronic level (IPL), and that from a vibronic level with $\Delta E>1000$ cm^{-1} (e.g., 12^1, $6a^2$, or 12^2) involves broad fluorescence besides the IPL fluorescence. At low pressure, the broad fluorescence consists of fast and slow components with lifetimes comparable to those for the corresponding components of the IPL fluorescence. The broad fluorescence exhibits another slow component which is characterized by a less tendency to undergo collisional quenching. The quantum yield of the slow component of the IPL fluorescence clearly depends upon molecular rotation, whereas that of the broad fluorescence appears to show little or no rotational-level dependence. On the basis of these observations, the broad fluorescence is assigned to the one originating from S_1 vibronic levels that can be reached directly from the IPL through intramolecular vibrational redistribution (IVR) or indirectly via triplet levels. There exists no evidence to show that the IVR is affected by molecular rotation.

When an isolated molecule is optically excited, the excitation energy may be transferred nonradiatively from the initially prepared vibronic level to the other isoenergetic levels through redistribution of the vibrational energy.[1-4] Understanding of this sort of intramolecular vibrational redistribution (IVR) is important not only in elucidating intramolecular dynamics but also in exploring the possibility of state selective chemistry. The IVR phenomena have been investigated extensively within the first excited singlet state (S_1) under bulk gas conditions at room temperature or ultracold supersonic jet conditions.[3,4] Most of these investigations were performed with aromatic hydrocarbons and their alkyl or halogen derivatives,[3,4] all of which belong to the statistical limit case in radiationless electronic relaxation.

The IVR process is known to occur usually at vibronic levels with relatively high excess vibrational energies, ΔE. Thus, IVR occurs at $\Delta E=3000$ cm^{-1} in benzene itself[5] and at $\Delta E=2000$ cm^{-1} in *p*-difluorobenzene and *p*-fluorotoluene,[6] though IVR can be recognized at a small ΔE value of 530 cm^{-1} in substituted benzenes with a long side chain.[4,7] The times required for IVR range from sub-picosecond to microsecond, but those reported in recent papers are mostly of the order of picosecond.[8] The anharmonic interaction is considered to induce IVR, but the Coriolis coupling is sometimes regarded as responsible for IVR. Recently, Riedle et al. showed that the Coriolis coupling plays an important role in IVR in the third channel region of benzene.[9]

Pyrimidine is known to have an intermediate-case level structure and gives fast and slow components of fluorescence under collision-free conditions.[10,11] It has been established that, so far as the fluorescence resulting from excitation at the 0-0 absorption band or a lower vibronic band is concerned, the characteristics of the slow fluorescence component of an intermediate-case molecule undergo considerable variation across the rotational contour.[12-15] On the other hand, little attention has been directed to IVR in the intermediate-case molecules except for the work by Lim and his collaborators, who observed the IVR induced by excitation at the 12_0^2 absorption band of pyrimidine.[16]

In the present study, fluorescence and nonradiative relaxation in pyrimidine vapor have been observed after exciting the molecule into various S_1 vibronic levels with relatively low excess vibrational energies ranging from 600 to 2650 cm^{-1}. The purpose of the study is twofold. First, attention is given to the change in the effect of molecular rotation on electronic or vibrational relaxation with excess energy. Second, an attempt is made to elucidate the kinetic mechanism of the occurrence of IVR. It will be shown in this paper that, in the case of pyrimidine, IVR appears to take place at vibronic levels whose energies are much lower than usually expected.

Experimental

Pyrimidine obtained from Aldrich Chemical Co. was purified by repeated vacuum sublimation. Commercially available sulfur hexafluoride (SF_6) from Seitetsu Chemicals was used as an inert foreign gas without further purification. The pressure of pyrimidine was determined by measuring the absorption intensity or by using a capacitance manometer (MKS Baratron type 170).

All the optical measurements were carried out at room temperature. Absorption and fluorescence spectra, fluores-

† Present address: Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Nagano 380.

cence excitation spectra, and fluorescence decays were measured with a laser spectrophotometric system.[17] The procedures for these measurements are essentially the same as those reported in previous papers.[13,17] In the spectrophotometric system, a pulsed dye laser (Molectron DL 14) is pumped by a nitrogen laser (Molectron UV 22). The frequency of the dye laser is doubled by a KDP crystal to generate UV laser pulses, which are used for exciting the sample. The UV laser pulses have a linewidth of 0.5 cm^{-1} and a duration of 3 ns. Emission measurements were made with a 3.5 cm cubic quartz cell. Absorption spectra and fluorescence-excitation spectra were measured simultaneously. The excitation spectra were obtained by monitoring the fluorescence emission dispersed by a grating monochromator (Nikon G250) and were corrected for fluctuation of the laser intensity. A relative quantum yield spectrum is derived as a ratio of a corrected excitation spectrum to the corresponding absorption spectrum. No correction was made for the spectral sensitivity of the detecting system. Fluorescence decays were measured with a single photon counting lifetime apparatus equipped with a time-to-amplitude converter. The lifetimes of the fast fluorescence of pyrimidine were determined by the convolution method.

Results

The emission spectrum of pyrimidine vapor changes markedly in shape with the excess vibrational energy (ΔE) of the S_1 vibronic level excited. Figure 1 shows the emission spectra from 0^0, $6a^2$, and $6a^1 12^2$ levels of S_1 pyrimidine at a low pressure of 80.8 mTorr.† See Table 1 for the values of ΔE for the individual levels.[18,19] When ΔE is small (Fig. 1(a)), the emission spectrum consists of sharp fluorescence bands which are due to vibronic transitions starting from the initially prepared vibronic level (IPL). As ΔE increases, the intensity of the IPL fluorescence decreases, and a broad, structureless emission appears instead at longer wavelengths (Fig. 1(b)). From now on, the latter emission will be referred to as "broad fluorescence." It is seen in Fig. 1(c) that the emission from the $6a^1 12^2$ level having a large ΔE value consists almost solely of the broad fluorescence.

Thus, according to the results of the present study, the fluorescence from vibronic levels with $\Delta E < 1000$ cm^{-1} is attributable solely to the IPL fluorescence, while that from vibronic levels with $\Delta E > 1000$ cm^{-1} involves the broad fluorescence in addition to the IPL fluorescence. The features of the fluorescence and nonradiative relaxation from some representative vibronic levels in S_1 pyrimidine will be described in the following.

$6a^1$ Level (ΔE=613 cm^{-1}) and 1^1 Level (ΔE=941 cm^{-1}). Absorption, fluorescence excitation, and fluorescence quantum yield spectra at a low pressure are shown in Fig. 2(a) for the rotational contour of the $6a_0^1$ absorption band. It was found that the excitation spectrum does not change in shape and position with the fluorescence band monitored. The quantum yield

spectrum gives a prominent peak for excitation frequencies near the band origin, that is, for low values of the total rotational angular momentum quantum number J', the prime referring to the excited state S_1; furthermore, the yield is found to decrease with increasing J'. As is seen in Fig. 2(b), at high pressure, the excitation and absorption spectra agree with each other, giving a flat fluorescence quantum yield spectrum.

Experimental results similar to those given in Figs. 2(a) and 2(b) have been obtained with the 1_0^1 absorption band. Thus, with respect to the rotational-level dependence of fluorescence, the situation in the $6a_0^1$ and 1_0^1 bands is essentially the same as that in the 0-0 band.[13] Note that $\Delta E<1000\,cm^{-1}$ for the $6a^1$ and 1^1 levels.

$6a^2$ Level (ΔE=1291 cm^{-1}). The fluorescence characteristics change in many respects when ΔE becomes higher than $1000\,cm^{-1}$. Figures 3(a) and 3(b) show fluorescence spectra obtained by excitation at two different positions within the rotational contour of the $6a_0^2$ absorption band of pyrimidine at a low pressure of 80.8 mTorr. In either case, both the IPL and the broad fluorescence appear. However, the fluorescence intensity distribution in Fig. 3(b) is different from the one in Fig. 3(a). In fact, the relative contribution of the IPL fluorescence is larger in Fig. 3(b) than in Fig. 3(a).

Reflecting the change in intensity distribution of the fluorescence spectrum with the rotational level excited, the excitation spectrum at low pressure changes in shape with the region of the fluorescence monitored, as illustrated in Fig. 4. The excitation spectrum in Fig. 4(b), which is related (mainly) to the broad fluorescence, resembles the absorption spectrum more closely than does the excitation spectrum in Fig. 4(a) related to the IPL fluorescence.

The quantum yield spectra for the IPL and broad fluorescence, shown in Figs. 4(a) and 4(b) respectively, vary across the rotational contour of the $6a_0^2$ band with a peak near the band origin. However, the variation of the quantum yield is obviously small in the case of the broad fluorescence. The IPL fluorescence is considered to be involved, to some extent, in the emission at 390 nm, i.e., at the monitoring wavelength in Fig. 4(b). Then the variation of the quantum yield for the broad fluorescence alone should be even smaller than what is seen in Fig. 4(b). It may thus be said that the actual quantum yield of the broad fluorescence will show little or no rotational-level dependence.

Extrapolating spectral data at low pressures, including those given in Fig. 4, to zero pressure, we have reached the conclusion that the broad fluorescence exists even at zero pressure; in other words, the

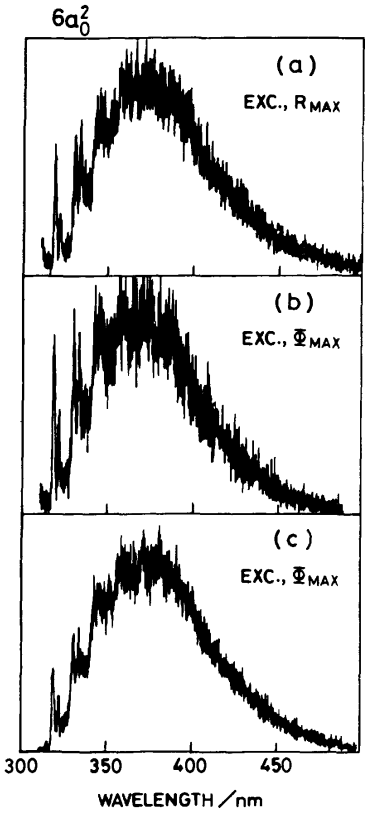

Fig. 3. Fluorescence spectra from the $6a^2$ level of pyrimidine. Sample vapors: (a, b) 80.8 mTorr of pyrimidine; (c) 156 mTorr of pyrimidine plus 36 Torr of SF_6. Excitation positions in the $6a_0^2$ band: (a) maximum of the R branch (R_{max}); (b, c) maximum of the quantum yield spectrum (Φ_{max}).

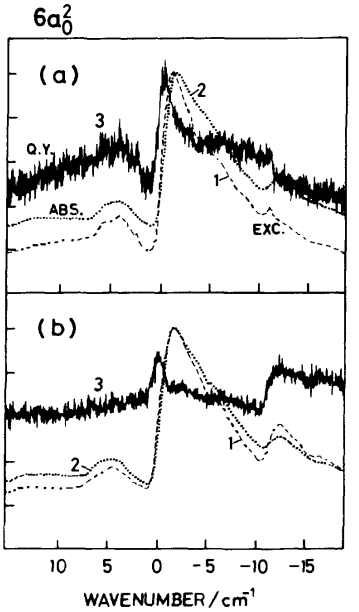

Fig. 4. Spectra for the $6a_0^2$ band of pyrimidine at 80.8 mTorr: (1,----) fluorescence excitation spectrum; (2,·····) absorption spectrum; (3,——) fluorescence quantum yield spectrum. broad fluorescence occurs as an intramolecular phenomenon.

Let us now turn to pyrimidine vapor at high total pressure. Figure 3(c) shows the fluorescence spectrum excited at the $6a_0^2$ absorption band of pyrimidine (156 mTorr) in the presence of 36 Torr of SF_6. Here the excitation position corresponds to the maximum of the quantum yield spectrum; it should be noted, however, that the fluorescence spectrum was found to be independent of excitation position within the $6a_0^2$ band. It is seen in Fig. 3(c) that the broad fluorescence appears at high pressure also. The excitation spectra at high pressure (Fig. 5) obtained by monitoring the fluorescence at 321 and 390 nm agree fairly well with the absorption spectrum, so that in both cases the quantum yield spectra are nearly flat over the rotational contour.

Figures 6(a) and 6(b) show the decays of the IPL and broad fluorescence following excitation within the $6a_0^2$ band at a pressure of 80.8 mTorr. The decay curves of Figs. 6(b) and 6(c) were obtained under the same conditions except for the time scales. It is seen from Fig. 6(b) that the broad fluorescence also involves fast and slow components which are analogous to the fast and slow components of the IPL fluorescence found in Fig. 6(a). In each of the IPL and broad fluorescence emissions, the fast and slow components will be called component I and component II, respectively, for the sake of simplicity. Note that, with the time resolution employed in the case of Fig. 6, the photoelectron pulses corresponding to the fast component of fluorescence fall on the first and second channels in (a) and (b), and on the first channel in (c).

The lifetime of the slow component II (τ_{II}) at 80.8 mTorr is found to be 72 ns from Fig. 6(a) for the IPL fluorescence and 81 ns from Fig. 6(b) for the broad fluorescence. Allowing for experimental error, however, the two lifetime values should be regarded as practically equal to each other (vide infra).

The broad fluorescence is thus similar to the IPL fluorescence in the lifetime of component II and also in the ratio of the amount of component I to that of component II. However, as is seen in Fig. 6(c), the broad fluorescence involves another slow component, which will be referred to as component III. The lifetime of component III (τ_{III}) at 80.8 mTorr is about 470 ns, which is much longer than τ_{II} at the same pressure.

The reciprocal lifetimes (τ^{-1}) for components II and III of the broad fluorescence as well as that for component II of the IPL fluorescence are plotted against pressure in Fig. 7. Allowing for experimental error, in the pressure range concerned, one cannot find any appreciable difference in lifetime between

Fig. 5. Fig. 6. Fluorescence decays for pyrimidine at 80.8 mTorr after excitation at the maximum of the R branch of the $6a_0^2$ band: (a) obtained by monitoring selectively the IPL fluorescence at 319.5 nm; (b, c) obtained by monitoring mainly the broad fluorescence at 390 nm under the same conditions except for the time scales.

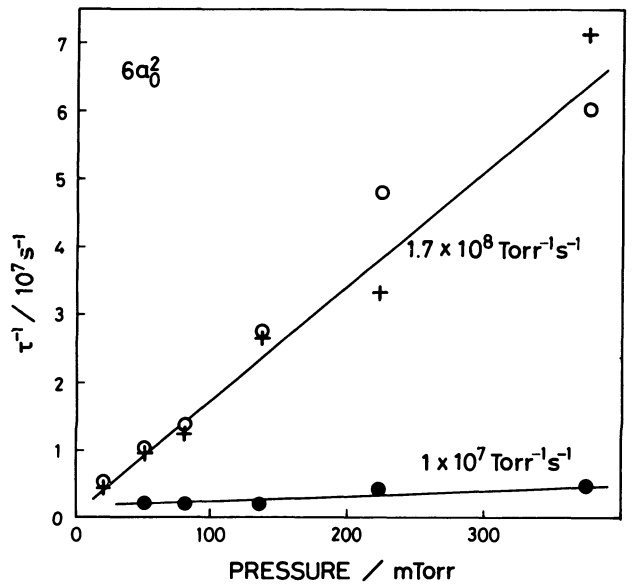

Fig. 7. Plots of τ^{-1} against pressure for $6a^2$ of pyrimidine: O, component II of the IPL fluorescence; +, component II of the broad fluorescence; ●, component III of the broad fluorescence.

components II of the IPL and broad fluorescence, and these two kinds of components II are quenched in essentially the same manner with increasing pressure. Thus, in either case, the quenching rate constant is evaluated to be about 1.7×10^8 Torr^{-1} s^{-1}, which is more than one order of magnitude larger than the hard sphere collision rate constant ($k_{hsc}\approx1\times10^7$ Torr^{-1} s^{-1}). This indicates that the quenching of components II results from a long-range, weak collision leading to rotational relaxation, as in the case of the slow fluorescence from the 0^0 level.[13]

Component III of the broad fluorescence, on the other hand, is quenched with a rate constant of 1×10^7 Torr^{-1} s^{-1}, which is equal to k_{hsc}. It can thus be said that, among the slow fluorescence components, component III is characterized by a less tendency to undergo collisional quenching. It is to be noted that the lifetime values for components II and III of the broad fluorescence are fairly close to each other at pressures lower than 10 m Torr.

It may be noted here that the occurrence of component I in the decay of the broad fluorescence (Fig. 6) is consistent with the observation that the broad fluorescence exists even at such high pressures that the slower components, II and III, are almost fully quenched.

12^1 Level (ΔE=1012 cm^{-1}). The ΔE value for this level is smaller than that for the $6a^2$ level, but is larger than 1000 cm^{-1}. Figure 8 shows excitation, absorption, and quantum yield spectra for the 12_0^1 band. Actually, the band appears to consist of two overlapping vibronic bands. This situation is clearer in the excitation spectrum obtained under supersonic

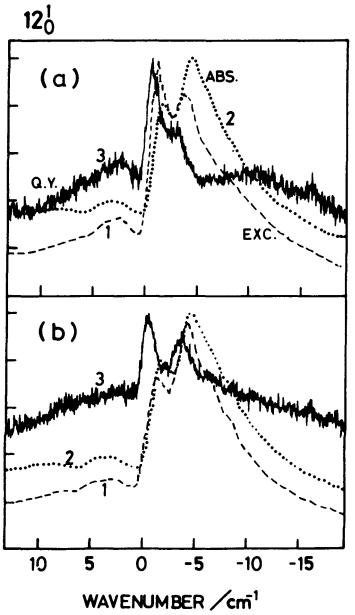

Fig. 8. Spectra for the 12_0^1 band of pyrimidine at 80.8 mTorr: (1,----) fluorescence excitation spectrum; (2,·····) absorption spectrum; (3,——) fluorescence quantum yield spectrum. Excitation and quantum yield spectra: (a) obtained by monitoring selectively the IPL fluorescence at 321 nm; (b) obtained by monitoring mainly the broad fluorescence at 390 nm. The band origin is denoted by 0.

jet conditions.[20] It is seen from Fig. 8(a) that the quantum yield for the IPL fluorescence varies greatly across the rotational contour. As in the case of the $6a_0^2$ band, the variation of the quantum yield for the broad fluorescence (Fig. 8(b)) is small compared with that for the IPL fluorescence.

The fluorescence decay after excitation into the 12^1 level is similar in nature to the decay after excitation into the $6a^2$ level. The IPL fluorescence and the broad fluorescence decay in similar manners, and both involve components I and II. The lifetimes of components II of the two types of fluorescence are nearly equal to each other at any pressure concerned in the present study. On the other hand, in the case of the 12^1 excitation, component III which is characterized by a less tendency to undergo collisional quenching makes only a negligibly small contribution to the broad fluorescence.

12^2 Level (ΔE=2025 cm^{-1}). Figures 9(a) and 9(b) show, respectively, decay curves for the IPL and broad fluorescence at two different pressures after excitation within the 12_0^2 band. It is seen that the IPL fluorescence consists of components I and II. The broad fluorescence also consists of fast and slow components. The former corresponds to component I. On the other hand, inspection of the decay curves given in Figs. 9(a) and 9(b) clearly shows that the slow component of the broad fluorescence is less liable to be quenched by collisions than component II of the IPL fluorescence,

indicating that the slow component of the broad fluorescence corresponds to component III. Although a small amount of component II can be detected in a decay curve of the broad fluorescence obtained at a higher time resolution, it may be said that the broad fluorescence resulting from excitation into the 12^2 level consists mainly of components I and III. One can thus conclude that the contribution of component III to the broad fluorescence notably increases with increasing ΔE.

The lifetimes of the fast component (component I),

a) From Refs. 11, 18, and 19.

τ_1, were obtained from decay curves for high-pressure samples by the convolution method. The results are summarized in Table 1 for the IPL and broad fluorescence emitted from some vibronic levels including 12^1, $6a^2$, and 12^2. For any level listed in Table 1, the value of τ_1 for the broad fluorescence is larger than the corresponding τ_I value for the IPL fluorescence.

Discussion

The results of the present experiments indicate that the fluorescence of pyrimidine vapor optically excited into an S_1 vibronic level with $\Delta E > 1000$ cm^{-1} involves broad fluorescence besides the IPL fluorescence. Each of the two types of fluorescence gives fast and slow components, I and II. The broad fluorescence gives another slow component, III, which is less liable to undergo collisional quenching than component II; the ratio of the yield of component III to that of component II increases with increasing ΔE.

In the following discussion, we shall give special attention to the mechanism by which the broad fluorescence is generated. It has turned out that general treatment of this subject is mathematically too difficult. Therefore, we first treat three simplified and rather extreme cases on the basis of kinetic schemes shown in Fig. 10. Here, solid and wavy arrows represent radiative (R) and nonradiative (NR) processes, respectively. S is the initially prepared vibronic level (IPL) belonging to S_1. U denotes the emitting levels of the broad fluorescence; it is assumed that these levels also belong to S_1, as will be shown

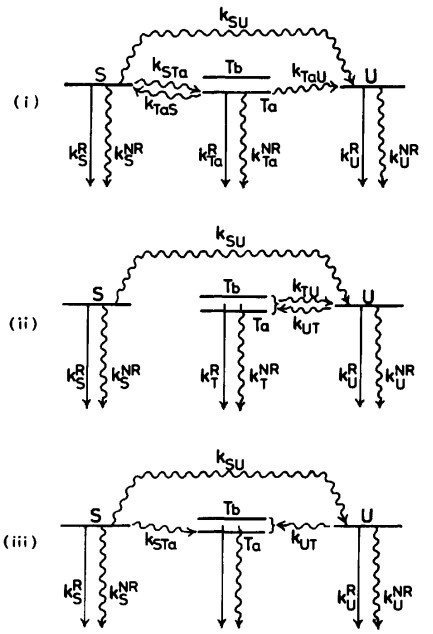

Fig. 10. Kinetic schemes and various rate constants (k) for pyrimidine. R and NR refer to radiative and nonradiative processes, respectively. See text for other symbols.

later. Ta stands for the triplet levels coupled directly to S, and Tb stands for the other triplet levels that are quasidegenerate with S and U. Note that the number of the levels of Ta may be much smaller than the total number of the triplet levels isoenergetic with S and U. The rate constants associated with the individual processes are also given in the figure. For levels with $\Delta E<1000\,\mathrm{cm}^{-1}$, the broad fluorescence is absent, so that we are concerned only with S and Ta.

Case (i). This corresponds to scheme (i) in Fig. 10. In this case, k_{SU} is assumed to be much smaller than k_{STa}. Hence, the population of U will be small in at least the early stage of relaxation, so that the processes U ⇝ Ta, U ⇝ Tb, and Tb ⇝ U are neglected in scheme (i). It is to be noted, however, that the nonradiative rate constant k_U^{NR} is assumed here to include the value of the rate constant which would be associated with U ⇝ T (=Ta+Tb).

According to scheme (i), the concentrations of the molecule existing in the S and U levels, denoted by [S] and [U] respectively, are found to be given, as a function of time t, by

$$[S] = [S]_0\left\{\frac{k_S-\lambda_2}{\lambda_1-\lambda_2}\exp(-\lambda_1 t)+\frac{\lambda_1-k_S}{\lambda_1-\lambda_2}\exp(-\lambda_2 t)\right\}, \tag{1}$$

$$\begin{aligned}[U] = {}& [S]_0\frac{(k_S-\lambda_2)k_{SU}-k_{TaU}k_{STa}}{(\lambda_1-\lambda_2)(k_U-\lambda_1)}\exp(-\lambda_1 t)\\ &+ [S]_0\frac{k_{SU}(k_{Ta}-k_U)+k_{TaU}k_{STa}}{(k_U-\lambda_1)(k_U-\lambda_2)}\exp(-k_U t)\\ &+ [S]_0\frac{(\lambda_1-k_S)k_{SU}+k_{TaU}k_{STa}}{(\lambda_1-\lambda_2)(k_U-\lambda_2)}\exp(-\lambda_2 t),\end{aligned} \tag{2}$$

where

$$\left.\begin{aligned}\lambda_{1,2} &= \frac{1}{2}\{(k_S+k_{Ta})\pm\sqrt{(k_S-k_{Ta})^2+4k_{TaS}k_{STa}}\},\\ k_S &= k_S^R + k_S^{NR} + k_{STa} + k_{SU},\\ k_U &= k_U^R + k_U^{NR},\\ k_{Ta} &= k_{Ta}^R + k_{Ta}^{NR} + k_{TaS} + k_{TaU},\end{aligned}\right\} \tag{3}$$

and $[S]_0$ means [S] at $t=0$; note that $\lambda_1>\lambda_2$. The quantum yield of the IPL fluorescence (Φ_{IPL}) and that of the broad fluorescence (Φ_{broad}) are then expressed as

$$\Phi_{IPL} = \frac{k_S^R k_{Ta}}{k_S k_{Ta}-k_{STa}k_{TaS}} = G^{-1}k_S^R(k_{Ta}^R+k_{Ta}^{NR}+k_{TaS}+k_{TaU}) \tag{4}$$

with

$$\begin{aligned}G = {}& (k_S^R+k_S^{NR}+k_{STa}+k_{SU})(k_{Ta}^R+k_{Ta}^{NR}+k_{TaU})\\ &+ k_{TaS}(k_S^R+k_S^{NR}+k_{SU}),\end{aligned}$$

$$\Phi_{broad} = \frac{k_U^R}{k_U}\left(\frac{k_{SU}}{k_S^R}\Phi_{IPL}+\frac{k_{TaU}}{k_{Ta}^R}\Phi_{Ta}\right) \tag{5}$$

with

$$\Phi_{Ta} = \frac{k_{Ta}^R k_{STa}}{k_S k_{Ta}-k_{STa}k_{TaS}} = G^{-1}k_{Ta}^R k_{STa}. \tag{6}$$

Case (ii). This corresponds to scheme (ii) in Fig. 10. In this case, it is assumed that $k_{STa} \ll k_{SU}$, and the interaction between S and Ta is neglected accordingly. The nonradiative rate constant k_S^{NR}, however, is assumed here to include the value of the rate constant which would be associated with S ⇝ Ta. Note that in scheme (ii) U is considered to interact with both Ta and Tb. Thus, in Fig. 10, T represents collectively all the triplet levels belonging to Ta and Tb.

According to scheme (ii), [S] and [U] are given by

$$[S] = [S]_0\exp(-k_S t), \tag{7}$$

$$\begin{aligned}[U] = {}& [S]_0\frac{\alpha}{k_{UT}}\left\{(k_T-k_S)\exp(-k_S t)\right.\\ &+ \frac{(k_T-\gamma_1)(\gamma_2-k_S)}{\gamma_1-\gamma_2}\exp(-\gamma_1 t)\\ &\left.+ \frac{(k_T-\gamma_2)(k_S-\gamma_1)}{\gamma_1-\gamma_2}\exp(-\gamma_2 t)\right\},\end{aligned} \tag{8}$$

where

$$\left.\begin{aligned}\gamma_{1,2} &= \frac{1}{2}\{(k_U+k_T)\pm\sqrt{(k_U-k_T)^2+4k_{UT}k_{TU}}\},\\ k_S &= k_S^R + k_S^{NR} + k_{SU},\\ k_T &= k_T^R + k_T^{NR} + k_{TU},\\ k_U &= k_U^R + k_U^{NR} + k_{UT},\\ \alpha &= \frac{k_{UT}k_{SU}}{(k_S-\gamma_1)(k_S-\gamma_2)}.\end{aligned}\right\} \tag{9}$$

Note that $\gamma_1>\gamma_2$.

Case (iii). This corresponds to scheme (iii) in Fig. 10. In this case, processes Ta ⇝ S and T ⇝ U are neglected.

According to scheme (iii), [S] and [U] are given by

$$[S] = [S]_0\exp(-k_S t), \tag{10}$$

$$[U] = [S]_0\frac{k_{SU}}{k_S-k_U}\{-\exp(-k_S t)+\exp(-k_U t)\} \tag{11}$$

Here, only the fast fluorescence emissions occur. The quantum yields for the fast components of the IPL fluorescence and broad fluorescence, denoted by Φ_{IPL}^I and Φ_{broad}^I respectively, are given by

$$\Phi_{IPL}^I = k_S^R/k_S, \tag{12}$$

$$\Phi_{broad}^I = \frac{k_U^R}{k_U}\frac{k_{SU}}{k_S}. \tag{13}$$

In Eqs. 10—13, k_S and k_U are defined as

$$\left.\begin{aligned}k_S &= k_S^R + k_S^{NR} + k_{STa} + k_{SU},\\ k_U &= k_U^R + k_U^{NR} + k_{UT}.\end{aligned}\right\} \tag{14}$$

Interpretation of Experimental Results at Low Pressure. Using the kinetic schemes presented in Fig. 10, we first discuss the results of experiments made at low pressure.

Let us first consider case (i). According to Eq. 1, the IPL fluorescence gives fast and slow components, I

and II, with lifetimes $1/\lambda_1$ and $1/\lambda_2$, respectively. It may be noted that $1/\lambda_1<1/\lambda_2$, since $\lambda_1>\lambda_2$. Let us assume here that in Eq. 2

$$\lambda_1>k_U>\lambda_2. \tag{15}$$

It can then be shown that in Eq. 2 the preexponential factor for $\exp(-\lambda_1 t)$ is negative, but that the factors for $\exp(-k_U t)$ and $\exp(-\lambda_2 t)$ are both positive. Therefore, Eq. 2 indicates that the broad fluorescence should give a biexponential decay preceded by a rise. It is natural to consider that $1/k_U$ is the lifetime of component I. The third term on the right hand side of Eq. 2 decays with a lifetime of $1/\lambda_2$ which is equal to the lifetime of component II of the IPL fluorescence, so that the third term in question can be assigned to component II of the broad fluorescence. Thus, the dynamics of pyrimidine excited into the 12^1 level corresponds closely to case (i). The behavior of pyrimidine after excitation into the $6a^2$ level can be described by case (i), except that component III appears weakly upon $6a^2$ excitation. It may be noted that component III does not occur in case (i); it results from reversible intersystem crossing between U and T(=Ta+Tb), as seen in scheme (ii) of Fig. 10. To sum up, aside from component III mentioned above, case (i) accounts for our observations that (1) the broad fluorescence resulting from the excitation into $6a^2$ or 12^1 level shows at least approximately a biexponential decay similar to the one of the IPL fluorescence and (2) the lifetimes of components II of the broad fluorescence and the IPL fluorescence agree with each other. However, we could not detect the rise portion in the change in intensity of the broad fluorescence with time. It may be noted that the assumption of inequalities (15) is considered to be valid, because $\lambda_1>k_S$ and moreover k_U would be smaller than k_S by a value corresponding to k_{SU} (see Table 1), and because λ_2 is of the order of the reciprocal lifetime of the triplet state.

Most of the fluorescence properties of pyrimidine that are observed after 12^1_0 or $6a^2_0$ excitation can be explained, at least approximately or qualitatively, in terms of case (i) by assuming that only the rate constant k_{TaS} depends on the rotational level excited. It is reasonable to consider that, in Eq. 4, $k_{STa} \gg k_S^R+k_S^{NR}+k_{SU}$ and that k_{TaS} is comparable in magnitude to $k_{Ta}^R+k_{Ta}^{NR}+k_{TaU}$. The factor G will then be insensitive to the variation of k_{TaS}. One may thus expect that Φ_{IPL} given by Eq. 4 is an approximately linear function of k_{TaS}. According to Eq. 6, on the other hand, Φ_{Ta} is insensitive to the variation of k_{TaS}, so that it follows from Eq. 5 that there is a linear relation between Φ_{broad} and k_{TaS}. Owing to the existence of the constant term, $k_U^R k_{TaU}\Phi_{Ta}/k_U k_{Ta}^R$, Φ_{broad} varies with k_{TaS} to a lesser extent than does Φ_{IPL}. Thus, the rotational level dependence of the quantum yield of the broad fluorescence (Φ_{broad}) at low pressure would be small compared with that of the IPL fluorescence (Φ_{IPL}) in agreement with our observation.

We now proceed to the fluorescence emissions from the 12^2 and $6a^112^2$ levels at low pressure. Suppose here that case (ii) holds true. Then it follows from Eq. 7 that the IPL fluorescence lacks component II. Further, since one can assume that $k_{SU} \gg k_S^R+k_S^{NR}$, Φ_{IPL} should be much smaller than Φ_{broad}. On the assumption that

$$k_S>\gamma_1>k_T>\gamma_2, \tag{16}$$

it can readily be verified that the broad fluorescence is characterized by a rise due to $-\exp(-k_S t)$, a fast decay (component I) due to $\exp(-\gamma_1 t)$ and a slow decay due to $\exp(-\gamma_2 t)$ (see Eq. 8). This slow decay is attributable to component III, since the quenching rate constant of component III is expected to be much smaller than that of component II, as will be seen later. It is to be noted that component III associated with case (ii) results from reversible intersystem crossing between U and T which includes the triplet levels uncoupled to S (see γ_2 in Eq. 9). On the other hand, component II of the broad fluorescence associated with case (i) results from reversible intersystem crossing between S and Ta which is directly coupled to S (see λ_2 in Eq. 3). Thus, in case (ii), the broad fluorescence consists of components I and III without involving component II.

The foregoing considerations indicate that the dynamics of pyrimidine excited into the $6a^112^2$ level just corresponds to case (ii). For excitation into the 12^2 level, the dynamics appears to be close to case (ii), but the observed IPL fluorescence from 12^2 includes component II as well as I (Fig. 9(a)). Therefore, the relaxation processes from 12^2 cannot fully be explained by case (ii).

Interpretation of Experimental Results at High Pressure. At high pressures where the slower components II and III are fully quenched, leaving the fast component I free from the collisional perturbation, the recurrence from Ta and/or Tb to S and/or U can be neglected, because the collision-induced vibrational relaxation in the triplet state is to be very fast. Consequently, for any initially excited level leading to the broad fluorescence, the situation at high pressure may be described in terms of case (iii).

According to Eq. 10, the IPL fluorescence shows an exponential decay due to $\exp(-k_S t)$, which is associated with the fast component I. Equation 11 indicates that the broad fluorescence also shows an exponential decay due to $\exp(-k_U t)$, associated with component I; in this case, however, the decay is preceded by a rise due to $-\exp(k_S t)$.

As will be mentioned later, U is assigned to rovibronic levels belonging to S_1 and isoenergetic with S. It may then be assumed, though very roughly, that

$$k_S^R + k_S^{NR} + k_{STa} \approx k_U^R + k_U^{NR} + k_{UT}. \tag{17}$$

It follows from Eqs. 14 and 17 that

$$k_S - k_U \approx k_{SU}. \quad (18)$$

As expected from this relation, the observed lifetime of component I (τ_I) of the IPL fluorescence, $1/k_S$, is shorter than the corresponding lifetime of the broad fluorescence, $1/k_U$, for all the excited vibronic levels studied (see Table 1). These lifetime data enable one to obtain approximate values of k_{SU} from Eq. 18. The resulting k_{SU} values are given in Table 1, from which it is seen that k_{SU} ranges in magnitude from 10^8 to 10^9 s^{-1} in the ΔE range 1000—2000 cm^{-1}. It may be noted that the rise of the broad fluorescence, which is predicted from Eq. 11, could not be detected with the present time resolution.

Behavior of Component III. As has been mentioned in the section of results, there is a substantial difference in rate of collisional quenching between component II and component III. In fact, the quenching rate constants for components II of the IPL fluorescence and broad fluorescence are ten times as large as k_{hsc}, whereas that for component III of the broad fluorescence is nearly equal to k_{hsc}. It is to be recalled here that the slow component of the (IPL) fluorescence from lower vibronic levels of intermediate-case molecules,[13,14] including pyrimidine, is known to have a quenching rate constant much larger than k_{hsc}.

According to a quantum-mechanical treatment of the behavior of intermediate-case molecules,[10,11,21] the slow fluorescence components, II and III, are emitted from mixed levels that result from coupling of singlet and triplet levels. In terms of the kinetic model, the same coupling is described by reversible conversion between the singlet and triplet levels,[21] as shown in Fig. 10 with forward and backward wavy arrows. Note that U is here assumed to represent singlet levels.

Let us first consider the collisional quenching of component II of the IPL fluorescence. This component originates from S-Ta mixed levels. At a lower vibronic level S, prepared initially, the singlet rovibronic level density is low. Hence a weak collision can transfer pyrimidine molecule from the S-Ta mixed levels to pure triplet rovibronic levels, which are not coupled to any singlet level, resulting in quenching of the IPL fluorescence.[11] At a high vibronic level S, such as 12^2 or $6a^112^2$, the singlet rovibronic level density is very high. Hence, there is a large probability that a weak collision will transfer the molecule from the S-Ta mixed levels to triplet rovibronic levels which are coupled to singlet levels. However, even if the latter rovibronic levels may give emission, the emission must be different from the IPL fluorescence. Accordingly, in this case also, the IPL fluorescence itself is quenched by a weak collision. It should be noted in this connection that, when we were concerned with the behavior of the IPL fluorescence, we measured its intensity by monitoring selectively an appropriate peak in the IPL fluorescence spectrum. From the foregoing discussion it can be concluded that, whether the initially prepared vibronic level S is low or high, the IPL fluorescence is quenched very efficiently with a rate much greater than that of the hard sphere collision.

Since component II of the broad fluorescence is closely associated with component II of the IPL fluorescence (see scheme (i) in Fig. 10), the former component II is also expected to undergo efficient collisional quenching as in the case of the latter.

Now, component III, which originates from U-T mixed levels, appears in the broad fluorescence from the pyrimidine molecule excited into its higher vibronic levels, such as 12^2 and $6a^112^2$. At these levels, the singlet rovibronic level density is so high that only a hard collision that can remove an energy of hundreds of cm^{-1} will transfer the molecule from the U-T mixed levels to pure triplet levels and thereby will quench component III. This accounts for the observation that, unlike component II, component III has as small a collisional quenching constant as k_{hsc}. In the above argument, the following has been assumed implicitly: When the pyrimidine molecule undergoes collisional transfer (owing to a weak collision) from the U-T mixed levels to other triplet levels with singlet character, the fluorescence from the latter levels is similar in spectral shape and position to, and hence indistinguishable from, component III of the broad fluorescence emitted from the U-T mixed levels; apparently, therefore, the collisional transfer in question does not lead to quenching of component III.

Mention should be made here of a study by Spears and El-Manguch[11] on the dual fluorescence of pyrimidine vapor. On the basis of the pressure dependence of the fluorescence decay, these authors reported that the collisional quenching constant of the slow component of fluorescence is remarkably smaller for higher vibronic levels (12^2 and $6a^112^2$) than for lower levels (0^0, $6a^1$, 12^1, and $6a^112^1$), and that the higher levels have quenching constants close (or equal) to k_{hsc}. They interpreted these experimental results in terms of the energy level dependence of the singlet level density in much the same way as we have done in our discussion. In the study by Spears and El-Manguch, however, the total fluorescence was monitored, with no attention being given to the fact that the fluorescence from pyrimidine vapor may contain not only the IPL fluorescence but also the broad fluorescence in our definition. In their experiments on the higher levels (12^2 and $6a^112^2$), the observed slow emission should be regarded as consisting largely of component III of the broad fluorescence.

Spears and El-Manguch[11] reported also that the

behavior of pyrimidine fluorescence observed when the pressure is increased up to 0.5 Torr is unusual. On excitation to vibronic levels higher than $6a^1$, they observed varying degrees of nonexponential decay for the slow component of fluorescence in the pressure range 0.1—0.5 Torr. Especially for excitation to the 12^2 and $6a^112^2$ levels, the increase in pressure to 0.5 Torr causes the appearance of a large background that appears to be flat over the time scale of the experiment.

The above observations by Spears and El-Manguch can readily be understood by taking account of component III of the broad fluorescence. As the pressure is increased, component II is quenched to a far greater extent than is component III, so that the amount of III may become comparable or superior to the amount of II. This leads to the nonexponential decay of the slow fluorescence or to the appearance of the background, which can be assigned naturally to component III.

Intramolecular Vibrational Redistribution (IVR). It was suggested in our previous papers[14,22] that in the case of 1,3,5-triazine the emitting levels of the broad fluorescence, U, are those vibronic levels which belong not only to S_1 but also to another singlet electronic state. This is rationalized by the observation that the radiative rate constant of the 1,3,5-triazine molecule increases with increasing excess vibrational energy.[22] On the contrary, in pyrimidine the radiative rate constant is largest for the 0^0 level and it decreases roughly monotonically with increasing excess energy.[19] One may thus reasonably assign U to S_1 vibronic levels which are isoenergetic with S. In other words, the conversion from S to U corresponds to the IVR, which is considered to occur in pyrimidine vapor not only directly from S but also via triplet levels.

For the fluorescence from the 12^2 level of pyrimidine, Lim et al.[16] reported experimental results similar to ours. On the basis of their experiments on the bulk gas and on a supersonic jet,[16] they pointed out that the fluorescence spectrum of pyrimidine vapor excited into its 12^2 level consists of a subspectrum with a sharp spectral feature and a subspectrum with a broad feature. The former was attributed to resonance fluorescence from the 12^2 level and the latter to fluorescence from levels which are populated through IVR. Furthermore, they found, as we did, that the excitation spectra with respect to the two fluorescence subspectra are different from each other in shape. This, along with temperature dependence of the characteristics of the subspectra, led them to the conclusion that the IVR process shows rotational level dependence which is to be predicted from the Coriolis interaction. Thus, their conclusion agrees with ours in the sense that the broad fluorescence is emitted from levels populated through IVR, but it is discrepant from our view concerning the nature of the IVR.

The data available in the present experiments indicate that, at high pressure, the quantum yields of the IPL and broad fluorescence emissions obtained by excitation at a vibronic band are independent of the rotational level excited. This means that $\Phi^{\mathrm{I}}_{\mathrm{IPL}}$ and $\Phi^{\mathrm{I}}_{\mathrm{broad}}$ are constant irrespective of the rotational level, since only the fast fluorescence components survive at high pressure. The quantum yields of the fast components, $\Phi^{\mathrm{I}}_{\mathrm{IPL}}$ and $\Phi^{\mathrm{I}}_{\mathrm{broad}}$, are given by Eqs. 12 and 13. For any vibronic level, the radiative rate constants $k^{\mathrm{R}}_{\mathrm{S}}$ and $k^{\mathrm{R}}_{\mathrm{U}}$ can reasonably be regarded as independent of the rotational level. Then the constancy of $\Phi^{\mathrm{I}}_{\mathrm{IPL}}$ ensures that k_{S} is independent of the rotational level (Eq. 12). This along with the constancy of $\Phi^{\mathrm{I}}_{\mathrm{broad}}$ indicates that $k_{\mathrm{SU}}/k_{\mathrm{U}}$ also is independent of the rotational level (Eq. 13). The rate constant k_{U} defined by Eq. 14 seems to be independent of the rotational level. Furthermore, it is hardly conceivable that k_{SU} and k_{U} vary with the rotational level in the same manner so that the ratio $k_{\mathrm{SU}}/k_{\mathrm{U}}$ may become constant. It can be concluded, therefore, that k_{SU} as well as k_{U} does not depend appreciably on the rotational level excited.

In their work already mentioned,[16] Lim et al. interpreted their observation of rotational contour dependence of the fluorescence of pyrimidine by presuming that Coriolis coupling plays an important role in IVR. According to these authors, the rate constant of IVR is governed by a factor $\sqrt{J(J+1)-K(K+1)}$, which appears in the matrix element of the second-order Coriolis interaction. Note that the pyrimidine molecule is here regarded as a symmetric top, and that J and K are the rotational quantum numbers. In other words, the rate constant k_{SU} (in our notation) should depend strongly on the rotational level belonging to S in marked contrast to our conclusion.

We have already shown in Fig. 9 the fluorescence decays of pyrimidine after excitation at the 12^2_0 band. It is seen in Fig. 9(a) that the IPL fluorescence contains the slow component, II. The content of component II is found to be about 15 percent of the total IPL fluorescence at 80.8 mTorr, which pressure is close to the one employed by Lim et al. in their experiment on the bulk gas. If we take account of this observation and of the fact that the yield of the slow component of the IPL fluorescence varies with the rotational level excited, then on the assumption that k_{SU} is independent of the rotational level we are able to explain most of the experimental results reported by Lim et al. We, therefore, believe that the rate of the IVR does not depend on the rotational level; in other words, the Coriolis coupling plays no significant role in the IVR process.

Up to now, the occurrence of IVR has been noticed
