acetonitrile or tetrahydrofuran decreased the retention times. This phenomenon can not be elucidated in terms of the stability of the complexes, for the alkali metal–B18C6 complexes are more stable in these solvents than in water.[20,21]

The effect of the temperature on the retention times can be seen from Fig. 11. It was observed that, at lower temperatures, the separation was slightly improved. However, Cs^+ was not separated successfully from Rb^+, not even at 15 °C.

Silica- and Resin-Based Columns. The alkali and alkaline earth metal cations were most successfully separated on the B18C6-modified columns, without distinction of the matrices. However, a detailed comparison of the matrices of different types is difficult because conditions, such as the particle size, the pore size, and the density of the crown moiety, are not the same for both types of matrices. The separation ability of the resin-based columns seems to be inferior to that of the silica-based ones. However, further research on the resin-based columns is not hopeless if the fact that the chromatographic peaks on these columns show a better symmetry is taken into account.

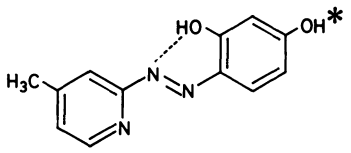
(Received December 16, 1985)

The acid-dissociation behavior of 1:1 and 1:2 complexes of transition metals with an *N,N,O*-terdentate ligand, 4-(4-methyl-2-pyridylazo)resorcinol (4-MePAR), is spectrophotometrically studied in ethanol at 25 °C. The values of apparent pK_a of the *p*-hydroxyl group of the ligand in the metal complexes are found to be in the order, Pd(II)<Co(III)<Ni(II)<Mn(II). The electronic structures of the *p*-hydroxyl oxygen atoms in the solid complexes of Mn(II), Ni(II), Pd(II), and Co(III) are examined on the basis of the data of X-ray photoelectron spectroscopy (XPS). The decrease in the electron density on the *p*-hydroxyl oxygen atom caused by the inductive effect through the azo nitrogen and the benzene ring of the coordination of the ligand to the central metal atom is larger in the Pd(II) and Co(III) complexes compared with that in the Ni(II) and Mn(II) complexes.

It is well-known that the reactivity and the electronic structure of organic compounds are affected by the coordination to the metal atom.[1,2] Corsini et al. potentiometrically pointed out that in aqueous dioxane solution the acid dissociation of *p*-hydroxyl group in an *N,N,O*-terdentate ligand, 4-(2-pyridylazo)resorcinol (PAR), is accelerated by the coordination to the transition metal ions.[3] However, despite the importance of the ligand PAR in the field of analytical chemistry and of coordination chemistry, no work on the electronic structures of PAR and its metal chelates has been reported so far. Recently, we found out, by the application of X-ray photoelectron spectroscopy (XPS), the characteristics of the chemical bonding of bivalent metal ions with donor atoms in analogous complexes of an *N,N,O*-terdentate ligand.[4] It is of interest to obtain the detailed information on the electronic structures of multidentate complexes in order to understand the reaction behavior of the complexes in solutions.

In the present paper, we report the acid-dissociation behavior of the metal chelates of an *N,N,O*-terdentate ligand, 4-(4-methyl-2-pyridylazo)resorcinol (4-MePAR), in ethanol; the electronic structures of



4-MePAR (LHH*)†

the isolated complexes are discussed on the basis of XPS measurements. The results of XPS measurements are correlated to the acid-dissociation behavior in ethanol of the *p*-hydroxyl groups in the metal–4-MePAR complexes.

† The ligand 4-MePAR is abbreviated to be LHH*, where H and H* denote the *ortho*- and the *para*-hydroxyl protons, respectively.

Experimental

Materials. Ethanol was dried with Molecular Sieves 3A or 4A for several days and distilled under argon atmosphere immediately before use. The ligand 4-MePAR (LHH*), its Ni(II) complex, $[Ni(LH^*)_2]^0$, and a terdentate Pd(II) complex of 5-dimethylamino-2-(2-pyridylazo)phenol (DAPAP) were prepared according to the literature.[4–6] The *N,N,O*-terdentate complexes of other bivalent or tervalent metal ions with 4-MePAR were prepared by the analogous method as described in the previous papers.[7,8] $[Pd(LH^*)Cl]^0$: Color: dark green. Found: C, 37.11; H, 3.05; N, 10.75; Cl, 8.97%. Calcd for $Pd(C_{12}H_{10}N_3O_2)Cl\cdot H_2O$: C, 37.14; H, 3.12; N, 10.83; Cl, 9.13%. The configuration around Pd(II) in the complex, $[Pd(LH^*)Cl]^0\cdot H_2O$, was identified to be essentially four-coordinated form by the XPS measurements: The $Pd(3d_{5/2})$ binding energy of the Pd(II)–4-MePAR complex, 338.6 eV, was almost equal to that of the corresponding four-coordinated complex of Pd(II) with DAPAP, $[Pd(dapapH_{-1})Cl]^0$, 338.0 eV.[9] $[Mn(LH^*)_2]^0$: Color: dark wine red. Found: C, 52.78; H, 3.87; N, 15.34%. Calcd for $Mn(C_{12}H_{10}N_3O_2)_2\cdot 0.6\,NaCl$: C, 52.75; H, 3.69; N, 15.38%. $[Co^{III}L(LH^*)]^0$: Color: dark wine red. Found: C, 53.13; H, 3.37; N, 15.97%. Calcd for $Co^{III}C_{24}H_{19}N_6O_4\cdot 0.5\,NaCl$: C, 53.03; H, 3.52; N, 15.46%. Bases employed here were of guaranteed reagent grade (Wako or Tokyo Kasei).

Measurements. Samples for XPS measurements were prepared in the form of a thin layer mounted on a nickel substrate covered with a fine gold mesh and dried overnight under 10^{-5}—10^{-7} Pa. XPS spectra of the samples were measured on a VG ESCA 3 spectrometer employing Mg $K\alpha$ (1253.6 eV) radiation under ca. 10^{-7} Pa at room temperature. In order to compensate for the charging of the insulating samples during the photoelectron ejection process, we referenced the spectra of all elements in each sample to the photoelectron line of C(1s). All raw binding energies were corrected to C(1s) value, 285.0 eV, of a

hydrocarbon.[6] The O(1s) peak in each complex was deconvoluted using two or three symmetric Gaussian curves.[4]

Visible absorption spectra of the samples in absolute ethanol were measured at 25.0±0.3 °C with a Hitachi EPS-3T spectrometer equipped with a 1 cm quartz cell. The preparations of the ethanol solutions for the measurements of visible spectra were carried out in a glove bag filled with argon. The concentrations of the solutions of the free ligand and the complexes were calculated from the weighed amount or the absorbance of the solution.

Results and Discussion

Reactions between Brønsted Bases and Metal-4-MePAR Complexes in Ethanol. Figure 1 shows the spectral change in the reaction of the *N,N,O*-terdentate chelate of Pd(II) with 4-MePAR with a Brønsted base, 2,6-lutidine, in ethanol. 2,6-Lutidine behaves exclusively as a Brønsted base; a very weak coordinating property of this base could be neglected. The spectrum of the Pd(II) complex has two absorption maxima in visible region at 442 ($\varepsilon_{max}=1.54\times10^4$) and around 590 nm ($\varepsilon_{max}=0.78\times10^4$ mol^{-1} dm^3 cm^{-1}) (Curve 1). Upon addition of a Brønsted base, 2,6-lutidine (pK_a in water (pK_a^W)=6.75), the absorbance around 440 nm decreased with the increase of that around 530 nm. The color of the solution changes from green to pink.[10] A set of isosbestic points for the spectral change was observed at 470 and 596 nm. This result shows the simple equilibrium for the reaction between the Pd(II)-4-MePAR complex and 2,6-lutidine. The final spectrum of the Pd(II) complex (Curve 4) possesses an absorption maximum at 535 nm ($\varepsilon_{max}=3.34\times10^4$ mol^{-1} dm^3 cm^{-1}). The reaction of [Pd(LH*)Cl]^0 is similar to the deprotonation in ethanol of the Mn(II)-4-MePAR complex or the Ni(II)-4-MePAR complex by triethylamine (pK_a^W=10.9), $[M(LH^*)_2]^0 \rightleftarrows [ML(LH^*)]^- + H^+ \rightleftarrows [ML_2]^{2-} + 2H^+$ (Fig. 2a).[11] The reaction of the Mn(II) and/or Ni(II) complexes with 2,6-lutidine showed no spectral change. On the other hand, a reaction of 2,6-lutidine with the Pd(II)-DAPAP complex, [Pd(dapapH$_{-1}$)Cl]^0, which has no dissociable hydroxyl group, did not indicate a large spectral change in the visible region. The above results exhibit that the large spectral change observed in the reaction of the Pd(II) complex, [Pd(LH*)Cl]^0, with 2,6-lutidine is attributed to the deprotonation of *p*-hydroxyl group, $[Pd(LH^*)Cl]^0 \rightleftarrows [PdLCl]^- + H^+$ (Fig. 1). The reaction of the Co(III) complex, [Co^{III}L(LH*)]^0, with 2,6-lutidine was interpreted in the same manner (Fig. 2b).[8]

The order of the values of the pK_a's of uni-positive conjugate acids does not show appreciable change with respect to the change in medium from water to ethanol.[12,13] Therefore, the values of acid-dissociation constants of the ligand 4-MePAR and its com-

plexes in water and in ethanol can be estimated by the spectral change in the reactions of these species with a Brønsted base of known pK_a value in two solvents. Figure 3 shows the plot of the absorbance of the Co(III) complex of 4-MePAR at 420 and 510 nm against the values of pK_a^{EtOH} of the added bases. From Fig. 3, the value of apparent pK_a of the Co(III) complex in ethanol was obtained; 6.4 for the reaction, $[Co^{III}L(LH^*)]^0 \rightleftarrows [Co^{III}L_2]^- + H^+$, 5.6 for $[Pd(LH^*)Cl]^0 \rightleftarrows [PdLCl]^- + H^+$, 7.3 for $LHH^* \rightleftarrows LH^- + H^+$.[14] The values of $(pK_{a1}^{EtOH} + pK_{a2}^{EtOH})/2$ for the reactions, $[M(LH^*)_2]^0 \rightleftarrows [ML(LH^*)]^- + H^+$, pK_{a1}^{EtOH}, and $[ML(LH^*)]^- \rightleftarrows [ML_2]^{2-} + H^+$, pK_{a2}^{EtOH}, were determined to be 9.3 and 10.1 for M=Ni(II) and Mn(II), respectively.[14] The order of the value of pK_a of the *p*-hydroxyl group of 4-MePAR and its complexes in ethanol was found to be Pd(II)<Co(III)<4-MePAR< Ni(II)<Mn(II). The order of acid-dissociation constants in the metal-4-MePAR system in ethanol was in good agreement with the corresponding order for the metal-PAR system in 50% aqueous dioxane solution, Pd(II) (5.38)<Cu(II) (5.5)<Co(III) (6.0)< PAR (7.0)<Ni(II) (pK_{a1}=7.7, pK_{a2}=9.2)≈Zn(II) (7.7, 9.3)<Mn(II) (8.8, 10.3).[3,15]

Possible Structures of the Species Formed in the Reactions of 4-MePAR or Its Complexes with Brønsted Bases in Ethanol. Ethanol is classified to a solvent of relatively low dielectric constant (24.3 at 25 °C).[16] The reaction equilibria, $AH + B \rightleftarrows A^- \cdot HB^+ \rightleftarrows A^- + HB^+$, would be present in ethanol, where AH and B denote a Brønsted acid and a Lewis base, respectively.[17] If an ion-pair species mainly formed under the experimental conditions,[18] then the association constant for the above reaction is approximately expressed by the equation, $K_A(B) = [A^- \cdot HB^+]/([AH][B])$. The absorbance A at wavelength λ (nm) of a mixed solution of the acid AH and the base B with initial concentrations $[AH]_0$ and $[B]_0$ (mol dm^{-3}) respectively is related to $K_A(B)$ as in the equation, $\log\{[B]_0 - (A-A_1)/\Delta\varepsilon\} = \log\{(A-A_1)/(A_2-A)\} - \log K_A(B)$, where $A_1 = \varepsilon_1[AH]_0$, $A_2 = \varepsilon_2[A^- \cdot HB^+] \simeq \varepsilon_2[AH]_0$, $\Delta\varepsilon = \varepsilon_2 - \varepsilon_1$, and ε_1 and ε_2 are the molar absorption coefficients (mol^{-1} dm^3 cm^{-1}) at λ of the acid, AH, and the ion pair, $A^- \cdot HB^+$, respectively.[18] If the above approximation is appropriate in ethanol, then the plot of $\log\{[B]_0 - (A-A_1)/\Delta\varepsilon\}$ (=log [B]) against $\log\{(A-A_1)/(A_2-A)\}$ (=$\log\{[A^- \cdot HB^+]/[AH]\}$) should give a straight line with a slope=1 and an intercept=$\log K_A(B)$. The plot of log [B] vs. $\log\{[A^- \cdot HB^+]/[AH]\}$ for the Co(III) complex in ethanol gave a straight line with a slope of 1.0. The similar results were obtained as for the plots for the Pd(II) complex (slope=0.9) and the free ligand 4-MePAR (1.3). The logarithms of the association constants, $\log K_A(B)$, are listed in Table 1 together with the spectral data. The order in $\log K_A(B)$ reflected the order of the acid-dissociation constants in ethanol of the *p*-hydroxyl group of the free ligand and its complexes. Further studies are necessary to clarify the structures of these ion-pair species in ethanol.

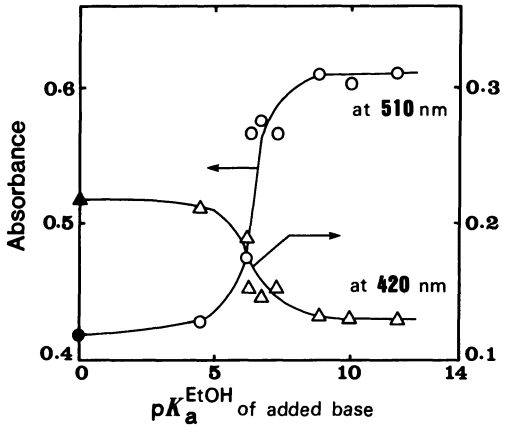

Fig. 3. Change of absorbance of the Co(III)–4-MePAR complex upon addition of a large excess of various Brønsted bases in ethanol at 25 °C.
$[Co^{III}L(LH^*)]_t = 9.30 \times 10^{-6}$ mol dm^{-3}. $[base]_t/[Co^{III}L(LH^*)]_t = 10^3$—$10^4$. Added base: *m*-chloroaniline (pK_a^{EtOH}=4.5), *p*-toluidine (6.24), 2,6-lutidine (≃6.8), imidazole (6.30, 7.3), triethanolamine (8.9), diethanolamine (10.0), triethylamine (11.9).[12,13] Full circle and triangle indicate the absorbance of the Co(III) complex in the absence of the Brønsted base.

XPS Evidence for the Increased Acid Dissociation of the *para*-Hydroxyl Group in Metal Complexes of 4-MePAR. Table 2 lists the XPS data for 4-MePAR and its metal complexes investigated here together with the electronegativities of the central metal atoms. The higher value of the core electron binding energy (BE) of the donor atom generally corresponds to the lower electron density on the donor atom.[4,19] Namely, the higher BE's of the N(1s) and the O(1s) in the *N,N,O*-terdentate complexes of 4-MePAR are attributed to the decrease in the electron densities on the donor atoms due to the formation of coordination bond. In general, the relative order of the O(1s) BE in a series of the same type of compounds is $O^{\delta-}$<M-O<M-OH.[20] From this fact, the highest peak of deconvoluted O(1s) BE was assigned to the peak of the *p*-hydroxyl oxygen in the *N,N,O*-terdentate complexes of 4-MePAR.[21] The ratio of the intensity of the deconvoluted O(1s) BE of the coordinated and the non-coordinated phenolic oxygen atoms was found to be almost 1:1 for the Ni(II) and the Mn(II) complexes. On the other hand, the ratio of the intensity in the deconvoluted O(1s) BE's for the Co(III) complex was found to be 1:2:1 from the lower BE to the higher BE, where the largest intensity ratio does indicate the presence of two atoms of the coordinated phenolic oxygen (see Table 2).

On the basis of the above assignments, the order of the values of BE of the *p*-hydroxyl oxygen atom in

the 4-MePAR complexes was obtained to be Pd(II)[22]≃Co(III)>Ni(II)≃Mn(II). The above order seems to reflect the acid-dissociation constants of the *p*-hydroxyl group in the complexes. The results of the O(1s) BE's deconvoluted show at least that the electron densities on the *p*-hydroxyl oxygen atoms in the Pd(II) and the Co(III) complexes are lower than those in the Ni(II) and the Mn(II) complexes.

The N(1s) BE's are directly affected by the electron-withdrawing effect of the central metal atom due to the formation of the M–N (azo and pyridyl) bonds, whereas the O(1s) BE's of the coordinated *o*-hydroxyl oxygen atoms in the resorcinol ring are not largely influenced by the coordination to the metal atom.[4] Therefore, the difference between the raw O(1s) and the raw N(1s) BE's, O(1s)−N(1s), in each complex appears to be the characteristic parameter for the extent of electron-withdrawing effect of the azo group on the *p*-hydroxyl group. The above discussion was supported by the linear correlation between the differences of BE's and the electronegativities of the central metal atoms: the lower value of O(1s)−N(1s) corresponds to the higher electron-withdrawing effect of the central metal atom. The plot of the difference of BE's, O(1s)−N(1s), against the apparent pK_a^{EtOH} of the *p*-hydroxyl group in the metal-4-MePAR com-

plexes is shown in Fig. 4. The acid dissociation of the *p*-hydroxyl group in the 4-MePAR complexes increased with the increase in the extent of the electron-withdrawing effect of the azo group coordinated to the central metal ions.

From XPS results, it is concluded that the coordination of the ligand 4-MePAR to the metal atom tends to decrease in the electron density on the *para*-hydroxyl oxygen atom in the ligand through inductive effect, thereby facilitating the acid dissociation of the *para*-hydroxyl group.

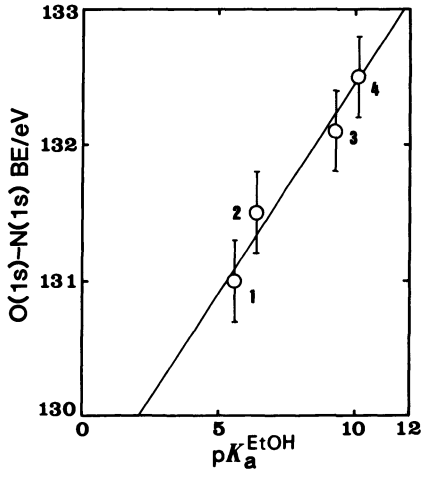

Fig. 4. Plot of the difference of BE's, O(ls)−N(1s), vs. the values of apparent pK_a in ethanol of the *N,N,O*-terdentate metal-4-MePAR complexes. Metal=Pd(II) (1), Co(III) (2), Ni(II) (3), and Mn(II) (4).

9) The abbreviation dapapH$_{-1}$ denotes the monoanionic form of the free ligand, DAPAP, in the complex.

10) The color change of the Pd(II) complex, $[Pd(LH^*)Cl]^0$, from green at pH≃4 to pink at pH≃7 was observed in aqueous solution.

11) The spectral change in ethanol coincided with that observed in the pH titration of $[Ni(LH^*)_2]^0$ in 10%(v/v) dioxane-water. In the pH titration, the *N,N,O*-terdentate complex, $[Ni(LH^*)_2]^0$, was found to dissociate two *p*-hydroxyl protons in the ligand to form $[NiL_2]^{2-}$.[6] From these results, the change observed upon addition of triethylamine is attributed to a liberation of two protons of *p*-hydroxyl groups in the terdentate 1:2 complex. The spectrum of the final complex, $[NiL_2]^{2-}$, showed a single absorption maximum at 498 nm (ε_{max}=5.89×10^4 mol^{-1} dm^3 cm^{-1}) in absolute ethanol.

12) The correlation between the value of pK_a for the conjugate acid HB^+ ($\rightleftarrows H^+ + B$) in aqueous solution and that in absolute ethanol is generally expressed by the equation, pK_a in ethanol (pK_a^{EtOH})=pK_a^W +1.0. See, M. Tanaka, "San to Enki (Acids and Bases)," 4th ed, Syokabo, Tokyo (1977), p. 69.

14) Values of apparent pK_a were obtained from the data at the half-neutralization, where [acid] = [conjugate base] and therefore the pK_a^{EtOH} of the added Brønsted base is equal to the pK_a of the Brønsted acid titrated. The values of pK_a^{EtOH} of the Mn(II) and Ni(II) complexes were obtained with average values for the pK_a^{EtOH}'s of the two *p*-hydroxyl groups.

15) T. Yotsuyanagi, H. Hoshino, and K. Aomura, *Anal. Chim. Acta*, **71**, 349 (1974). In this paper, they pointed out that the green Pd(II)-PAR complex in 50% aqueous dioxane solution has an *N,N,O*-terdentate structure with undissociated *o*-hydroxyl group or an *N,N*-bidentate one. However, in the present work, on the basis of the spectral data (see text) and the elemental analysis of the isolated complex, $[Pd(LH^*)Cl]^0 \cdot H_2O$, it is reasonable to assign the green Pd(II)-4-MePAR complex to the *N,N,O*-terdentate structure with the coordinated *o*-hydroxyl group. Also, in aqueous solution, it is impossible to form the *N,N*-bidentate complex. See, Y. Kudo, N. Yoshida, and M. Fujimoto, *Bull. Chem. Soc. Jpn.*, **59**, 795 (1986); Ref. 6.

16) E. J. King, "Acid-base Behavior," in "Physical Chemistry of Organic Solvent Systems," ed by A. K. Covington and T. Dickinson, Plenum Press, London (1973), p. 375.

17) The species, $A^- \cdot HB^+$ and A^-, could not generally be distinguished by the spectroscopic measurements used in the present work, so one may write the apparent equilibrium constant as $K_A(B)=[A^- \cdot HB^+ + A^-]/([AH][B])$. See, N. Tokura, "Yōbaiwa (Solvation)," 1st ed, Kagaku Dōjin, Kyoto (1972), p. 23; O. D. Bonner and P. R. Prichard, *J. Solution Chem.*, **8**, 113 (1979).

18) It has been reported that, in nonaqueous solvents of relatively low dielectric constants (D<30), the salts of bulky ions predominantly form the ion-pairing species, i.e., *p*-nitrophenol-amine complexes or imidazolium picrate. See, R. Scott, D. De Palma, and S. Vinogradov, *J. Phys. Chem.*, **72**, 3192 (1968); H. Collaer, M. C. Haulait-Pirson, and P. Huyskens, *J. Solution Chem.*, **6**, 73 (1977); M. Nakahara and J. Osugi, *Kagaku (Chemistry)*, **25**, 1026 (1969).

(Received December 26, 1985)

Protonation equilibria of glycinate (gly^-) ion and complex formation equilibria between nickel(II) and glycinate ions have been studied by potentiometry and calorimetry in water and in 0.2 mole fraction (55.0%w/w) dioxane-water mixture, each containing 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium at 25 °C. A series of mononuclear complexes, $[NiL_n]^{(2-n)+}$ (L^-=gly^- and n=1—3) were found in both solutions and their formation constants, enthalpies and entropies were determined. It elucidated that the stepwise Gibbs energies of formation of the metal complexes varied in the sequence, $\Delta G_1^\circ < \Delta G_2^\circ < \Delta G_3^\circ$, and the stepwise enthalpies, $\Delta H_1^\circ > \Delta H_2^\circ > \Delta H_3^\circ$, and thus, the stepwise entropies markedly decreased in the order, $\Delta S_1^\circ > \Delta S_2^\circ > \Delta S_3^\circ$. The result was discussed in relation to changes in the metal-water and metal-ligand bond lengths within $[NiL_n(H_2O)_{6-2n}]^{(2-n)+}$ (n=1—3) with n. As to the solvent effects, the formation constants of each metal complex increased with the addition of dioxane to water, the increase was caused by both enthalpies and entropies of formation of the complexes, the former mainly contributing to the formation of $[NiL_2]$ and the latter to $[NiL]^+$ and $[NiL_3]^-$. The Gibbs energies of transfer of single species from water to the dioxane-water mixture were also evaluated. The enthalpy and entropy of transfer of any ionic species mostly compensated each other, so that the Gibbs energies of transfer of ions were rather small.

In previous papers,[1,2] we discussed about the complex formation equilibria between ethylenediamine and bivalent metal ions, Ni(II) and Cu(II), in water and in dioxane–water mixtures.

Since ethylenediamine is a neutral ligand, charges of the ethylenediamine complexes of Ni(II) and Cu(II) are kept +2 for all the complexes formed. The stepwise formation constants of each metal complex in dioxane–water mixtures examined were appreciably larger than those in water. The corresponding enthalpies of formation became less negative by the addition of dioxane to water. Consequently, the corresponding entropies of formation markedly increased to result in more favorable formation of the complexes in the mixtures than that in water.

In the nickel(II)–glycinate system in contrast to the metal–ethylenediamine system, charges of the complexes change with the bound ligand number and a different solvent effect on the complex formation equilibria is expected.

In this work, therefore, the complexation of nickel(II) with glycinate ions has been studied by potentiometry and calorimetry in water and in 0.2 mole fraction dioxane–water mixture. The protonation equilibria of the ligand ion were separately investigated in the same solutions. On the basis of these results, the Gibbs energies of transfer of related species from water to the dioxane–water mixture were then evaluated.

Experimental

Reagents. *Nickel(II) perchlorate* was prepared as described elsewhere.[1] Bis(glycinato)nickel(II) crystals were prepared by dissolving freshly precipitated nickel(II) carbonate to an aqueous glycine solution, and then recrystallized from water. *Glycine* was recrystallized three times from an aqueous ethanol and was dried at 80—100 °C in an electric oven.

Other chemicals used were prepared and purified as described previously.[1]

Measurement. All of potentiometric and calorimetric measurements were carried out in a room thermostated at (25.0±0.2) °C. All test solutions used involved 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium throughout potentiometric and calorimetric titrations.

Potentiometric measurements were carried out in a liquid paraffin bath controlled at (25.00±0.02) °C. pH of a test solution was determined by using a glass electrode in combination with an Ag–AgCl reference electrode. The method of measurements was the same as that used in a previous work.[1]

Calorimetric measurements were carried out in a water bath thermostated at (25.000±0.007) °C. Details of measurements were described elsewhere.[1,3,4]

Solubilities of glycine and bis(glycinato)nickel(II) complex in water and in 0.2 mole fraction dioxane–water mixture were gravimetrically determined after the salts were equilibrated with the solvents without ionic medium for more than two weeks in a thermostated room at (25.0±0.2) °C.

Analysis of Potentiometric and Calorimetric Data. The protonation constants and enthalpies of protonation of glycinate ion, which had been determined in advance by separate experiments, were kept constant in the course of determining the formation constants and enthalpies of the metal–ligand complexation. Details of the analysis of potentiometric and calorimetric data were described previously.[1]

Results and Discussion

The formation function $\bar{n}$ plotted against $-\log([L^-]/\text{mol dm}^{-3})$($L^-$=gly$^-$) for the nickel(II)-glycinate system in water and in the 0.2 mole fraction dioxane-water mixture are depicted in Fig. 1. In each solvent experimental points obtained at various metal concentrations fell on a single curve, indicating that the only mononuclear complexes were formed in the solutions. Since the $\bar{n}_{exp}$ values in each solution approached 3, the potentiometric data were analyzed by assuming the formation of the $[NiL_n]^{(2-n)+}$ (n=1—3) complexes in both solutions. As shown by the solid lines in Fig. 1, the theoretical formation functions well fitted the experimental ones over the whole range of $-\log([L^-]/\text{mol dm}^{-3})$ examined.

Calorimetric titration curves obtained for the nickel(II)-glycinate system in water and in the dioxane-water mixture are depicted in Figs. 2 and 3, respectively. Enthalpies $\Delta H°/\text{kJ mol}^{-1}$ calculated by $\Delta H° = -q/(\delta v C_{H,tit})$ were plotted against the degree of neutralization X of glycinate ion in a solution, where q and δv denote the heat evolved and the volume of the titrant added at each titration point, respectively, and $C_{H,tit}$ stands for the concentration of $HClO_4$ in the titrant solution. The solid lines in Figs. 2 and 3 show the curves calculated by using the formation constants and enthalpies of formation of the complexes finally obtained, which well reproduced the experimental points.

The overall formation constants β_n and overall enthalpies $\Delta H°_{\beta_n}$ of formation of $[H_nL]^{(n-1)+}$ (n=1 and 2) and $[NiL_n]^{(2-n)+}$ (n=1—3) in these solutions are summarized in Tables 1 and 2, respectively.

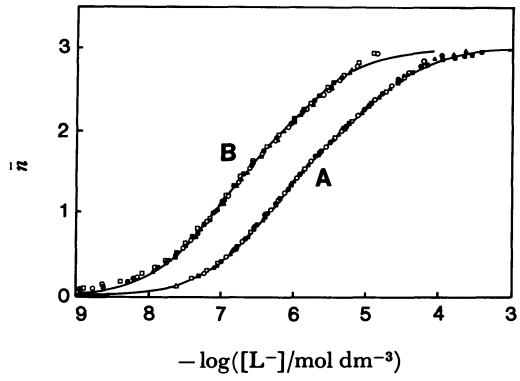

Fig. 1. Formation functions of the nickel(II) glycinate complexes in water (A) and in the 0.2 mole fraction dioxane-water mixture (B). Initial concentrations of metal and ligand ions, C_M and C_L/mol dm^{-3}: 0.00413, 0.02030(▲); 0.00609, 0.02014(○ and △); 0.00688, 0.03383(■); 0.01015, 0.03357 (□); 0.01522, 0.05035 (●) in water and 0.00201, 0.01108(□); 0.00335, 0.01847(○); 0.00405, 0.01405(■); 0.00503, 0.02270 (●); 0.00675, 0.02342(▲); 0.01012, 0.03512(△) in the mixture.

Thermodynamic quantities, $\log(K_n/\text{mol}^{-1}\text{ dm}^3)$, $\Delta G°_n/\text{kJ mol}^{-1}$, $\Delta H°_n/\text{kJ mol}^{-1}$, and $\Delta S°_n/\text{J K}^{-1}\text{ mol}^{-1}$, for the stepwise formation of $[H_nL]^{(n-1)+}$ and $[NiL_n]^{(2-n)+}$ are listed in Table 3, together with the differences, $P_n(\text{mix})-P_n(\text{w})$ (P=log K, $\Delta G°$, $\Delta H°$, and $\Delta S°$), in water (w) and in the dioxane-water mixture (mix).

Formation of Glycinato Complexes of Ni(II). As seen in Table 3, the $\Delta G°_n$ values in any solution examined varied, as usual, in the sequence, $\Delta G°_1 < \Delta G°_2 < \Delta G°_3$, the $\Delta H°_n$ values in the sequence, $\Delta H°_1 > \Delta H°_2 > \Delta H°_3$ and the $\Delta S°_n$ values, $\Delta S°_1 > \Delta S°_2 > \Delta S°_3$. Therefore, the decrease in $\Delta S°_n$ with n is responsible to the increase in $\Delta G°_n$.

The decreased values of $\Delta H°_n$ and $\Delta S°_n$ with n might be expected if stronger metal-ligand bonds are

The values in parentheses refer to three standard deviations.

formed within higher complexes. However, according to the results from the X-ray diffraction study of the structures of the complexes in water, the Ni–N bonds as well as the Ni–OH_2 bonds within $[NiL_n(H_2O)_{6-2n}]^{(2-n)+}$ elongate with n,[5-7] due, probably, to an electron donation from the ligands to the central metal ion, so that both metal-ligand and metal-water bonds are expected to be weaker within a higher complex. The enthalpy data obtained indicate that weakening of metal-ligand bonds may be more pronounced at the formation of a higher complex, and thus, the more negative values of ΔH°_n and ΔS°_n with n may result. The same conclusion was also obtained for the nickel(II)-ethylenediamine system.[1]

As to solvent effects, all the $\log K_n$ (n=1—3) values of the glycinatonickel(II) complexes, as well as the ethylenediamine ones,[1] increased by the addition of dioxane to water. In the nickel(II)-ethylenediamine system, the increase in the $\log K_n$ (the decrease in ΔG°_n) values was fully caused by the increase in the ΔS°_n (n=1—3) values, because the ΔH°_n (n=1—3) values also increased. On the other hand, in the nickel(II)-glycinate system as seen in Table 3, the ΔH°_n (n=1—3) values decreased and the ΔS°_n (n=1—3) values increased, and thus, both values were responsible to the increase in the $\log K_n$ (n=1—3) values. However, at the formation of $[NiL_2]$ the contribution of ΔH°_2 to the increased $\log K_2$ value in the mixture was more important than that of ΔS°_2 and the reverse was the case for the $[NiL]^+$ and $[NiL_3]^-$.

Table 3. Thermodynamic Quantities, $\log(K_n/\text{mol}^{-1}\,\text{dm}^3)$, ΔG°_n/kJ mol^{-1}, ΔH°_n/kJ mol^{-1} and ΔS°_n/J K^{-1} mol^{-1}, for the Stepwise Reactions, $H^+ + [H_{n-1}L]^{(n-2)+} = [H_nL]^{(n-1)+}$ ($L^- = gly^-$) and $[NiL_{n-1}]^{(3-n)+} + L^- = [NiL_n]^{(2-n)+}$, in Water and in Aqueous Dioxane of 0.2 Mole Fraction Dioxane Containing 3 mol dm^{-3} $LiClO_4$ at 25 °C, and their Differences in the Solvents

In a previous paper,[3] we reported the enthalpies of transfer ΔH°_t of the ethylenediamine and glycinato complexes of Ni(II) from water to the dioxane-water mixture. The ΔH°_t values of each species have significantly large absolute values. However, relatively small differences between the ΔH°_n values of the complexes in water and in the mixture was observed as seen in Table 3, because each difference involve the contributions of ΔH°_t of all species pertaining to the complex formation reaction which mostly compensate each other. The differences between the corresponding ΔG°_n values of the complexes in Table 3 were also small. The Gibbs energies of transfer of species involved in the complex formation reactions were then estimated as described in the following section.

Gibbs Energies of Transfer of Species from Water to the Dioxane-Water Mixture. The Gibbs energies of transfer of proton $\Delta G^\circ_t(H^+)$ from water to the

0.2 mole fraction dioxane-water mixture was 1.9 kJ mol^{-1} and the corresponding value of glycinate ion $\Delta G_t^\circ(L^-)$ was approximately estimated to be 6.0 kJ mol^{-1}.[8]

The Gibbs energies of transfer of $[H_nL]^{(n-1)+}$, $\Delta G_t^\circ(H_nL)$ (L^-=gly$^-$ and n=1 and 2), were then calculated by knowing the $\Delta G_t^\circ(H^+)$ and $\Delta G_t^\circ(L^-)$ values together with the overall Gibbs energies of formation of $[H_nL]^{(n-1)+}$, $\Delta G_{\beta n}^\circ$ (H_nL) ($=-RT\ln \beta_n$), in water and in the mixture given in Table 1:

$$\Delta G_t^\circ(H_nL) = \Delta G_{\beta n}^\circ(H_nL, \text{mix}) - \Delta G_{\beta n}^\circ(H_nL, \text{w}) + n\Delta H_t^\circ(H^+) + \Delta H_t^\circ(L^-). \quad (1)$$

Since the enthalpies of transfer ΔH_t° of the relevant species from water to the mixture have been reported,[3] the corresponding entropies of transfer ΔS_t° were calculated. The thermodynamic quantities of transfer of proton, glycinate ion and $[H_nL]^{(n-1)+}$ (n=1 and 2) thus obtained are summarized in Table 4.

The ΔG_t°(HL) value for glycine zwitterion thus obtained was 6.3 kJ mol^{-1}. The solubilities (α/mol dm^{-3}) of glycine zwitterion in water (α_w) and in the mixture (α_{mix}) were 3.23 and 0.154 mol dm^{-3}, respectively, which gave the $-RT\ln(\alpha_{mix}/\alpha_w)$ value to be 7.5 kJ mol^{-1}. The $-RT\ln(\alpha_{mix}/\alpha_w)$ value may be compared with the calculated ΔG_t°(HL) of glycine zwitterion as the first approximation.

The solubilities of the bis(glycinato)nickel(II) complex determined in water and in the dioxane-water mixture are given in Table 5. Since several glycinatonickel(II) complexes coexisted in the solutions, the distribution of species was calculated by using the formation constants of the complexes in each solution. The Gibbs energy of transfer of the neutral $[NiL_2]$ complex ΔG_t° (NiL_2) from water to the mixture was then calculated according to $\Delta G_t^\circ(NiL_2) = -RT\ln\{\alpha_{mix}(NiL_2)/\alpha_w(NiL_2)\}$, which, although being an approximate value, may be sufficient for the discussion given in a later section. By using the $\Delta G_t^\circ(NiL_2)$ and $\Delta G_t^\circ(L^-)$ values together with the Gibbs energies of formation $\Delta G_{\beta 2}^\circ$ of $[NiL_2]$ in water and in the mixture given in Table 2, the Gibbs energy of transfer of nickel(II) ion $\Delta G_t^\circ(Ni^{2+})$ from water to the mixture was calculated:

$$\Delta G_t^\circ(Ni^{2+}) = \Delta G_{\beta 2}^\circ(NiL_2, \text{w}) - \Delta G_{\beta 2}^\circ(NiL_2, \text{mix}) + \Delta G_t^\circ(NiL_2) - 2\Delta G_t^\circ(L^-). \quad (2)$$

The corresponding ΔG_t° values for $[NiL]^+$ and $[NiL_3]^-$ were then calculated by the similar procedure to that employed above. The ΔG_t° values of the glycinatonickel(II) complexes from water to the mixture thus obtained are summarized in Table 4, together with the corresponding enthalpies and entropies of transfer of the complexes.

As seen in Table 4, both enthalpy and entropy of transfer of proton from water to the mixture are significantly negative but compensate each other to result in a positive $\Delta G_t^\circ(H^+)$ value. The same trend is oserved for the corresponding ΔG_t°, ΔH_t°, and ΔS_t° values of $[H_2L]^+$. On the contary, both ΔH_t° and ΔS_t° values of glycinate ion are significantly positive but almost compensate each other to yield a relatively small positive $\Delta G_t^\circ(L^-)$ value. As to glycine zwitterion, the ΔH_t° value is positive and the ΔS_t° value negative, so that both values contribute to the positive ΔG_t°(HL) value.

Both ΔH_t° and ΔS_t° values for nickel(II) ion are especially largely negative, which also compensate each other to lead to a relatively small positive ΔG_t° value. Although the ΔH_t° values for $[NiL_n]^{(2-n)+}$ (n=1—3) vary from negative to positive with n, each ΔH_t° value is compensated with the corresponding ΔS_t° value and the resultant ΔG_t° values of the complexes are all positive.

As noted in a previous paper,[3] a negative or positive ΔH_t° value of an ion from water to the dioxane-water mixture may reflect the enhanced or weakened solvation structure around the ion in the secondary solvation shell in the mixture compared to that in water. It was then suggested that the solvation structures were enhanced around cations

Table 4. Thermodynamic Quantities of Transfer, ΔG_t°/kJ mol^{-1}, ΔH_t°/kJ mol^{-1}, and ΔS_t°/J K^{-1} mol^{-1}, of Single Species from Water to the 0.2 Mole Fraction Dioxane Mixture at 25 °C

Table 5. The Solubilities, α/mmol dm^{-3}, of the Bis(glycinato)nickel(II) Complex in Water and in an Aqueous Dioxane of 0.2 Mole Fraction Dioxane at 25 °C

Solvent	α_{tot}	$\alpha([NiL]^+)$	$\alpha([NiL_2])$	$\alpha([NiL_3]^-)$
Water	110.1	17.4	73.4	18.7
0.2 Mole Fraction Dioxane-Water Mixture	9.8	1.7	6.1	1.8

The distribution of species was calculated by using the formation constants in Tables 1 and 2.

but weakened around anions. If this consideration is applied to the entropies of transfer of ions, it is also indicated that the negative or positive values of ΔS_t° for cations or anions from water to the mixture should result. As seen in Table 4, the ΔS_t° values obtained were significantly negative for H^+, $[H_2L]^+$ and $[NiL]^+$ but positive for L^- and $[NiL_3]^-$, the result being consistent with those expected from the consideration above.

To conclude, it was also suggested by the entropies of transfer of ions from water to the dioxane–water mixture that the solvation structure around cations is enhanced but that around anions is weakened by the addition of dioxane to water. The change in the solvation structures around the ions with varying solvent compositions in dioxane–water mixtures may be related to the partially destroyed hydrogen-bonding structure of water in the bulk solvent mixtures. A dioxane molecule has oxygen atoms which can act as an electron donor and through which the hydrogen-bonds can be formed with water molecules, but it has a very poor electron acceptor ability. By forming the dioxane–water bonds, oxygen atoms of water which can not form sufficient hydrogen-bonds are generated in the mixture. The amount of the non-hydrogen-bonding oxygen atoms of water may increase with an increase in the dioxane content in the mixtures, so that the non-hydrogen-bonding oxygen atoms of water can favorably solvate to cations in the dioxane–water mixture, but solvation of anions may become less favorable due to the decreased acceptor ability of the solvent.

(Received December 26, 1985)

Oxidation of *trans*-[RuCl(NO)(py)$_4$]$^{2+}$ with NaClO gives oxo complex of Ru^{IV}, *trans*-[RuCl(O)(py)$_4$]$^+$, with bond breaking of the metal-nitrosyl ligand. An X-ray structural study revealed that the complex has a much longer Ru–O bond distance (1.862(8) Å) than those of known mono-oxo complexes. A facile reactivity of the oxoruthenium(IV) complex was observed: with methanol methoxo complex, *trans*-[RuCl(OMe)(py)$_4$]$^+$, was formed. With PPh_3, a two-electron transfer process was indicated by the formation of Ph_3PO.

Considerable attention has been focused on the chemistry of high-valent ruthenium complexes with Ru^{IV}=O^{2-} unit, in connection with their usefulness as an oxygen-transfer agent in the selective oxidation of oganic substrates.[1] Although several other oxoruthenium(IV) complexes have recently been prepared,[2,3] there was no structural information concerning the Ru^{IV}=O^{2-} unit until a preliminary report of the present work and a work by Che et al. appeared.[4,5] Here we describe the syntheses, properties and structures of new mono-oxo complexes of ruthenium(IV), *trans*-[RuX(O)(py)$_4$]$^+$ (X=Cl, Br), which were prepared by the oxidation of the corresponding nitrosyl complex, *trans*-[RuX(NO)(py)$_4$]$^{2+}$, with sodium hypochlorite solution. The present work to afford the mono-oxo complex by the oxidation of the nitrosyl complex appears to be valuable as a synthetic route for the mono-oxo type of complexes.

The nitrosyl ligand coordinated to Ru^{II} atom is believed to be remarkably stable and to persist through a variety of substitution reactions. This is certainly true for most complexes with Ru^{II}NO$^+$ moiety studied so far. The nitrosyl ruthenium complex described above was nevertheless used as a starting material, in order to explore a possible oxidation reaction for the nitrosyl ligand. Recently, Meyer et al. have studied the oxidation of a nitrosyl complex of Ru^{II}, *cis*-[RuCl(NO)(bpy)$_2$]$^{2+}$ (bpy: 2,2′-bipyridine), which gives the corresponding nitrato complex via a reactive nitro complex of Ru^{III}.[6] Their work, however, was mainly a survey on the oxidation at acidic or neutral conditions. The oxidation reaction under a basic condition has not been reported.

Experimental

IR spectra were measured on a Hitachi EPI G2 spectrometer. UV-vis spectra were recorded on a Hitachi 200-20 spectrophotometer. Magnetic moments were measured by the Gouy method using mercury tetrakis(thiocyanato)cobaltate(II) as the calibrant. Elemental analyses were performed by both the Sophia University Analytical Facility and the Institute of Chemical and Physical Research, Wako, Saitama 351. The cyclic voltammetry and the normal pulse voltammetry were carried out by using a Fuso Polarograph Model 321 and a Fuso Potential Scanning unit Model 321 with a stationary platinum disk electrode(ϕ=1.99 mm). All the potentials were measured against a silver-silver ion electrode (Ag/0.1 mol dm^{-3} $AgClO_4$ in acetonitrile). The measurements were carried out at 25 °C. Deoxygenation of solution was carried out with argon gas, which had been passed through two wash bottles containing acetonitrile kept at 25 °C.[7]

Syntheses. Starting material in this work, *trans*-[RuX(NO)(py)$_4$]Y$_2$ (X=Cl, Br. Y=ClO_4, PF_6) were prepared according to the method reported previously.[8]

Chloro(oxo)tetrakis(pyridine)ruthenium(IV) Perchlorate, [RuCl(O)(py)$_4$]ClO_4 1A: To a solution of *trans*-[RuCl(NO)(py)$_4$](ClO_4)$_2$ (0.5 g) in H_2O (15 cm^3), aqueous solution of NaClO (2 cm^3) was added.[9] A yellow precipitate, which formed immediately, became light green with stirring for 4 h at 23—26 °C. The crystalline product obtained was kept for 3 more hours, without stirring, and then filtrated out, washed with cold water, and dried in vacuo. Yield 90—95%. It should be noted that effective stirring of the mixed solution and keeping it warm (at 23—26 °C) are necessary for the synthesis in order to avoid contamination by the unoxidized material of the yellow precipitate described above. The mono-oxo complex is stable as a solid and remained unchanged for several months when stored in a desiccator. Found: C, 42.2; H, 3.4; N, 9.9%. Calcd for $C_{20}H_{20}O_5N_4Cl_2Ru$: C, 42.2; H, 3.5; N, 9.9%.

Chloro(oxo)tetrakis(pyridine)ruthenium(IV) Hexafluorophosphate, [RuCl(O)(py)$_4$]PF_6 1B, and Bromo(oxo)tetrakis(pyridine)ruthenium(IV) Perchlorate, [RuBr(O)(py)$_4$]ClO_4 2, were prepared by the same procedure using the corresponding nitrosyl complexes. For **1B** yield 90%. Found: C, 39.0; H, 3.2; N, 9.2; PF_6, 23.5%. Calcd for $C_{20}H_{20}N_4OClPF_6Ru$: C, 39.1; H, 3.3; N, 9.1; PF_6, 23.6%. For **2** yield 90%. Found: C, 39.0; H, 3.2; N, 9.1%.

Calcd for $C_{20}H_{20}O_5N_4BrRu$: 39.2; H, 3.3; N, 9.1%.

Chloro(nitro)tetrakis(pyridine)ruthenium(II), [RuCl(NO_2)(py)$_4$] 3: As was described in the preparation of **1A**, addition of NaClO solution to aqueous solution of *trans*-[RuCl(NO)(py)$_4$](ClO_4)$_2$ gave immediately a yellow precipitate. The precipitate filtered out, washed with water and dried in vacuo. Found: C, 46.1; H, 4.0; N, 13.2%. Calcd for $C_{20}H_{22}N_5O_3ClRu$ (as monohydrate): C, 46.4; H, 4.3; N, 13.5%.

Chloro(methoxo)tetrakis(pyridine)ruthenium(III) Hexafluorophosphate, [RuCl(OMe)(py)$_4$]PF_6 4A: Complex **1B** (50 mg) was dissolved in methanol (25 cm^3), using a Erlenmeyer flask, and kept at room temperature for 2 d in dark, until the solution color changed to greenish yellow. The volume of the solution was reduced to 5 cm^3 using a rotary evaporator to produce a red crystalline material. The product was filtered out, washed with acetone and then ether, and dried in vacuo. Yield 70%. Found: C, 40.0; H, 3.6; N, 8.8%. Calcd for $C_{21}H_{23}N_4OClPF_6Ru$: C, 40.1; H, 3.7; N, 8.9%.

Chloro(methoxo)tetrakis(pyridine)ruthenium(III) Perchlorate, [RuCl(OMe)(py)$_4$]ClO_4 4B, was prepared by almost the same procedure using the corresponding mono-oxo complex **1A**. Found: C, 43.4; H, 4.0; N, 9.6%. Calcd for $C_{21}H_{23}N_4O_5ClPF_6Ru$: C, 43.2; H, 4.0; N, 9.6%.

Intensity Data Collection. A crystal with dimensions of 0.16×0.14×0.30 mm^3 was used for the measurement without shaping. The crystallographic data are: $RuC_{20}H_{20}N_4O_5Cl_2$, F. W. 568.4, tetragonal, space group *P4/ncc*, Z=16, a=25.781(5), c=14.130(4) Å, U=9391(4) Å^3, D_x=1.61, D_m=1.59 g cm^{-3}, μ(Mo $K\alpha$) 9.21 cm^{-1}. The reflections were collected by the ω scan technique ($2\theta<55°$) on a Rigaku AFC-6A automated four-circle diffractometer, with graphite monochromated Mo $K\alpha$ radiation (0.7107 Å). The 2122 independent reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for the absorption. All the calculations were carried out on a HITAC M-200H computer at the Computer Center of the University of Tokyo, using the local version of UNICS.[10] The atomic scattering factors were taken from the table.[11]

Structure Determination. The structure was solved by a heavy-atom method. The position of ruthenium and chlorine atoms were obtained from a three-dimensional Patterson function, while the positions of all the non-hydrogen atoms were succesively located by Fourier syntheses. Since the positions of only a few hydrogen atoms were obtained by a difference-Fourier syntheses, all of the positions were calculated and fixed. Their isotropic temperature factors were assumed to be 5.0 Å^2.

All other positions and thermal parameter were refined by a repeated block-diagonal least-squares method. The weighting scheme was $W=1/[\{\sigma(|F_o|)\}^2+(0.04\times|F_o|)^2]$. In the last cycle of the refinement with anisotropic temperature factors for all non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value ($R=\sum||F_o|-|F_c||/\sum|F_o|$) was 0.076. The F_o—F_c data and the anisotropic temperature parameter are deposited as Document No. 8627 at the Office of the Editor of the Bulletin of the Chemical Society of Japan.

Results and Discussion

Syntheses. The reaction of *trans*-[RuX(NO)(py)$_4$]$^{2+}$ (X=Cl, Br) in a basic aqueous solution containing NaClO as an oxidant gave the mono-oxo complex, *trans*-[RuX(O)(py)$_4$]Y (**1A**; for X=Cl, Y=ClO_4. **1B**; for X=Cl, Y=PF_6. **2**; for X=Br, Y=ClO_4), in high yield. In the initial step of the reaction, nitro complex, [RuCl(NO_2)(py)$_4$] **3**, was formed by the known nitrosyl-nitro conversion reaction (Eq. 1)[12]

$$[Ru^{II}Cl(NO)(py)_4]^{2+} \xrightarrow{OH^-} [Ru^{II}Cl(NO_2)(py)_4] \quad (1)$$

The nitro complex **3** was isolable and its identity was confirmed by a direct comparison with an authentic sample reported previously.[8] The next step of the reaction appears to be an oxidation of the nitro complex of Ru^{II} to Ru^{III} which is followed by a Ru^{III}–NO_2^- bonding rupture, resulting in the corresponding hydroxo complex (Eqs. 2 and 3):

$$[Ru^{II}Cl(NO_2)(py)_4] \xrightarrow{-e^-} [Ru^{III}Cl(NO_2)(py)_4]^+ \quad (2)$$

$$\xrightarrow{-NO_2^-} [Ru^{III}Cl(OH)(py)_4]^+ \quad (3)$$

The oxidation was also attempted for the corresponding hydroxo nitrosyl complex, *trans*-[Ru(OH)(NO)(py)$_4$]$^{2+}$, which has been known as a poor electrophile compared to *trans*-[RuCl(NO)(py)$_4$]$^{2+}$ used as the starting material of the present reaction.[8] In this case, however, the nitrosyl–nitro conversion reaction did not occur under the conditions, and the isolated product, by adding PF_6^-, was *trans*-[Ru(OH)(NO)(py)$_4$]$^{2+}$.[13]

Nitro complex of Ru^{III} has been found to be chemically unstable.[6] In the electrochemical experiment, in fact, a facile reaction due to a decomposition of the nitro complex of Ru^{III} was observed when **3** in CH_3CN undergoes a one-electron oxidation. As is shown in cyclic voltammogram (Fig. 1), **3** in CH_3CN displays a one-electron oxidation wave (E_{pa}=0.28 V vs. Ag/$AgClO_4$ (0.1 mol dm^{-3} in CH_3CN)) in the potential region expected for the Ru^{II}/Ru^{III} couple. On scan reversal, a small reduction wave appeared at −0.12 V with decreasing of a cathodic responce, corresponding to a pair of oxidation wave observed at 0.28 V.[14] The next cycle showed a new oxidation peak at −0.07 V, not present in the original anodic cyclic voltammogram, which is presumed to be the couple with the small reduction wave at −0.12 V. The lack of the cathodic responce and the appearance of the new couple are evidently due to a rapid decomposition of the oxidized species [Ru^{III}Cl(NO_2)(py)$_4$]$^+$, although more study with coulometric experiments is needed to clarify the electrochemical

behavior in the oxidation reaction of **3**. The cyclic voltammogram observed here is similar to that of *cis*-$[RuCl(NO_2)(bpy)_2]$, where nitro-nitrito isomerization has been known to occur by the oxidation of the Ru^{II}-NO_2^- moiety.[6] The fate of the NO_2^- ligand released (Eq. 3) could not be elucidated; it is probably changed into NO_3^-.

The final step to generate $Ru^{IV}=O^{2-}$ moiety from the hydroxo complex (Eq. 4) is the same reaction as found in *cis*-$[RuCl(O)(bpy)_2]^+$ [1b]:

$$[Ru^{III}Cl(OH)(py)_4]^+ \xrightarrow{-e^-} [Ru^{IV}Cl(O)(py)_4]^+ \quad (4)$$

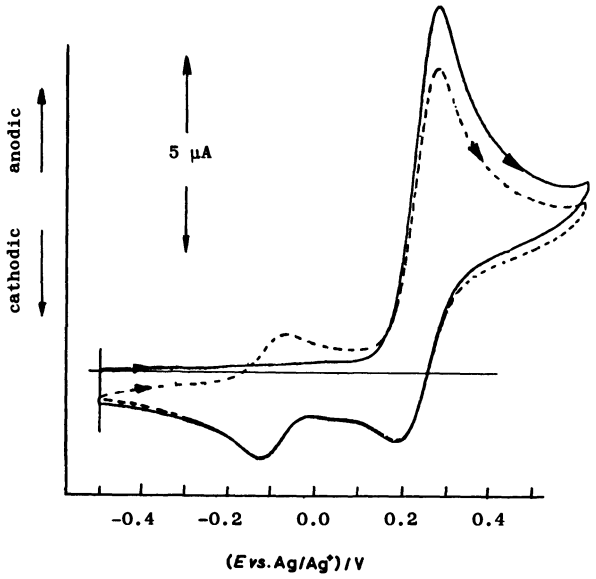

Fig. 1. The cyclic voltammogram of $[RuCl(NO_2)(py)_4]$ **3** (1.00 mol dm^{-3}) at a stationary platinum electrode (50 mV S^{-1}) in 0.1 mol dm^{-3} TEAP+AN at 25 °C. Initial potential: −0.5 V. The dashed curve shows the result of the second scan.

In the solid state, the complexes **1A**, **1B**, and **2** are stable indefinitely at room temperature. It was found, however, that the magnetic susceptibility of the complexes decreased markedly when the complexes were washed with organic solvents such as alcohols or acetone. Therefore, further purification by recrystallization was not attempted.

IR Spectra. The IR absorption band ascribed to Ru-O stretching vibration in **1A**, **1B**, and **2** was observed at the same frequency region, 800 cm^{-1} (Table 1). As reported previously, the absorption band due to the stretching vibration of the terminal oxo ligand occurs in 800—900 cm^{-1} for a variety of oxidation states of metal complexes.[15] This IR region, however, is almost the same as those for an antisymmetric stretching vibration (ν_3) of μ-oxo ruthenium complexes.[16] The absorption band due to ν_3 mode of a linear or quasi-linear M-O-M system has usually been regarded as a diagnostic for identifying the μ-oxo complexes.[16] Thus, the overlapping of these regions characteristic for both terminal- and bridging-oxo ruthenium complexes did not provide further information for identifying the present complex, and the choice in the correct formula between the mono-oxo complex, $[RuX(O)(py)_4]^+$, and the μ-oxo complex, $[Ru_2O(X)_2(py)_8]^{2+}$, could only be established by an X-ray structural determination.

Structure. The final atomic parameters are listed in Table 2, the interatomic distances in Table 3, and the bond angles in Table 4. The perspective drawing of the complex **1A** and the numbering scheme of the atoms are in Fig. 2. The cation is an oxo ruthenium(IV) complex ion, with trans octahedral geometry; it has four equatorial pyridine ligands, while the oxo and chloro ligands are coordinated in the axial direction. The oxo complex has a propeller-like

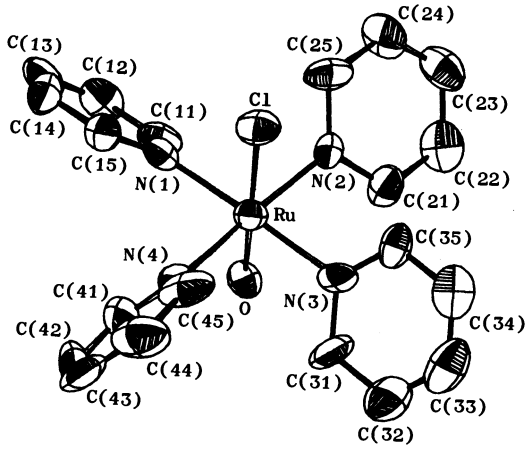

Fig. 2. The perspective drawing of $[RuCl(O)(py)_4]ClO_4$ **1A** and the numbering scheme of non-hydrogen atoms.

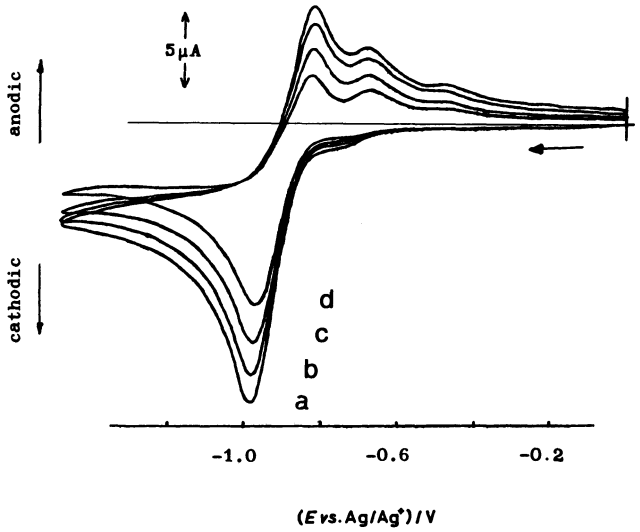

Fig. 3. The cyclic voltammograms of $[RuCl(O)(py)_4]ClO_4$ **1A** (1.07 mol dm^{-3}) at a stationary platinum disk electrode (scan rate/mV S^{-1}): (a) 100; (b) 80; (c) 60; (d) 40 in 0.1 mol dm^{-3} TEAP+AN at 25 °C.

structure similar to that of the nitrosyl complex, *trans*-$[RuCl(NO)(py)_4]^{2+}$, used as starting material for the present oxidation reaction.[17] The oxo and chloro ligands are almost on the line including the ruthenium: O-Ru-Cl, 178.2(3)°. The Ru-O bond distance, 1.862(8) Å, is considerably shorter than the sum of the single bond radii for Ru^{IV}-O^{2-} (1.97 Å) and it is significantly longer than the value 1.756 Å reported recently for similar mono-oxo complex, *trans*-$[Ru(O)(tmc)(MeCN)]^{2+}$, of which the bond length is consistent with the expected bond order of two.[5] The remarkably long bond distance of the Ru-O observed here may be important factor to the reactivity of the mono-oxo moiety in **1A**. It is worth noting that the observed Ru-O distance is comparable with values reported for both μ-oxo complexes of Ru^{III} and Ru^{IV}, as shown in Table 1.[18-22]

The Ru^{IV}-Cl distance, trans to the oxygen atom, is 2.419(4) Å. The distance is longer than Ru^{IV}-Cl distances, 2.317—2.364 Å reported in the complexes, $[Ru_2OCl_{10}]^{4-}$ and $[Ru_2NCl_8(H_2O)_2]^{3-}$.[23] An elongation of metal-Cl distance trans to nitrido ligand (N^{3-}), which has a multiple bonding order, has been reported in $[Os^{IV}NCl_5]^{2-}$;[24] the Os-Cl bond distance trans to the nitrido is 2.61 Å and that to cis is 2.36 Å, whereas such a lengthening has not been found for the Ru^{IV}-Cl distance, trans to bridging oxo ligand in $[Ru_2OCl_{10}]^{4-}$ (Ru-Cl(*trans*), 2.317(7) Å; Ru-Cl(*cis*), 2.362(2) Å.[18b] The Ru-N distance vary from 2.089(6) to 2.107(11) Å. These Ru-N distances are slightly shorter than those previously reported for *trans*-$[RuCl(NO)(py)_4]^{2+}$ (2.103—2.118 Å), $[Ru(py)_6]^{2+}$ (2.10—2.14 Å) and $[(py)_4Ru(ox)Ru(py)_4]^{2+}$ (2.096—2.113 Å).[17,25,26] The dihedral angles between the best plane of RuN_4 and those of the pyridine rings range from 44.1—54.1°. The angle between the two pyridine planes in trans position are 80.6—82.7°, which are little larger than those of *trans*-$[RuCl(NO)(py)_4]^{2+}$. The distances between adjacent pyridine carbons and those between pyridine carbon and axial chloro ligand are slightly longer than the corresponding distances in the nitrosyl complex. On the other hand, the distances between pyridine carbon and the chloro ligand are shorter.

One counter anion, ClO_4^-, is on the four-fold rotatory inversion axis, the second is on the four-fold rotation axis, and the third is on the two-fold rotation axis. A statistical distribution was observed at the oxygen of ClO_4^- on the four- and two-fold rotation axis, and their positions could not be determined.

The effective magnetic moments were found to be 2.92—2.94 B.M., as shown in Table 1. These are almost the same as those observed in the known oxoruthenium(IV) complexes and are close to spin-only value for two unpaired spins. The observation of two unpaired electrons is consistent with the orbital splitting scheme proposed by Meyer et al.,[1b] in which the existence of the half filled dπ* orbitals results in an extensive stabilization of the Ru-O bonding through a pπ(O^{2-})-dπ(Ru) interaction.

Electrochemical Behavior. A cyclic voltammogram of **1A** in acetonitrile is shown in Fig. 3.[27] The reductive sweep shows a single wave at a much more negative potential than those of the known Ru^{IV}/Ru^{III} couple (E_{pc}=−0.99 V vs. Ag/$AgClO_4$(0.1 mol

dm^{-3} in CH_3CN)). The cyclic voltammogram also shows an indistinct reduction wave observable near −0.85 V. The origin of the dim reduction wave is not clear, but it is thought to be caused by a partial decomposition of **1A** in the organic solvent. In the back sweeping, a small oxidation wave, which is the pair to the reduction wave at −0.99 V, appeared at −0.92 V with two additional oxidation waves. We compared the current heights, observed by the normal pulse voltammetry at the same experimental conditions, of the reduction wave at −0.99 V with those of other Ru^{IV}/Ru^{III};[28] the reduction wave appeared to be a metal-centered two-electron transfer comprising the Ru^{IV} and Ru^{II} oxidation states

$$[Ru^{IV}Cl(O)(py)_4]^+ + 2e^- \longrightarrow [Ru^{II}Cl(O)(py)_4]^- \quad (5)$$

Fig. 3 also illustrates that the electrochemically produced $[RuCl(O)(py)_4]^-$ is not stable and probably undergoes a facile solvolysis to give $[RuCl(CH_3CN)(py)_4]^+$, which is responsible for the appearance of the oxidation waves at −0.84 V. A one-electron reduced species involving $Ru^{III}-O^{2-}$ moiety was unobtainable by the electrochemical reduction in the aprotic solvent, while a succesive reduction of $Ru^{IV}=O^{2-}$ to give $Ru^{III}-OH^-$ and $Ru^{II}-OH_2$ moieties has been observed in aqueous solvent for certain oxoruthenium(IV) complexes.[1b] As was described above, **1A** exhibited the two-electron reduction wave at a surprisingly negative potential region, where the Ru^{III}/Ru^{II} redox potential is generally observed. The very negative potential in **1A**, compared to those of known Ru^{IV}/Ru^{III} couples, could be understood as showing that the presence of the oxo ligand leads to extensive stabilization of Ru^{IV} state.[1b]

Reactivity. The oxoruthenium(IV) complex in CH_3CN reacts easily with PPh_3. Such a reaction, which produces Ph_3PO with a reducing of the oxidation state of the metal atom, is characteristic for the complexes containing a reactive oxygen ligand. When **1A** in CH_3CN was mixed with PPh_3 (mole ratio 1:1.5) at room temperature, the mixed solution changed immediately from green to yellow. A brown material could be obtained by adding an excess amounts of ether to the yellow solution. The composition of the brown material agreed well with that of $[RuCl(CH_3CN)(py)_4]PF_6$. IR spectra of this material exhibited a sharp absorption band at 2245 cm^{-1}; this is assignable to ν(CN) of the coordinated CH_3CN. Another product, Ph_3PO, could also be obtained as a white precipitate from the filtrate of $[RuCl(CH_3CN)(py)_4]PF_6$ by adding ether (ν(P=O), 1182 cm^{-1}). While a stoichiometric study of the reaction could not be achieved, the above results giving both $[RuCl(CH_3CN)(py)_4]^+$ and Ph_3PO can be understood by the following equation:

$$[RuCl(O)(py)_4]^+ + PPh_3 \longrightarrow [RuCl(S)(py)_4]^+ + Ph_3PO \quad (6)$$
$$(S=CH_3CN)$$

The oxoruthenium(IV) complex **1A** is reactive even for organic solvents, such as alcohols and acetone. Upon recrystallization with methanol, the effective magnetic moment decreased from 2.94 to near 2.5 B.M. (calculated for the same formula as the mono-oxo complex), as was described above. Although the oxo ligand in $(Ru^{IV}=O^{2-})$ unit has been known to act as an oxygen-transfer agent toward organic substrates, there was no example where a product was isolated from these reactions, except for the case of the Ph_3PO. Attempt to isolate the solvolysis product from methanol, in the present case, yielded a red crystalline product. The experimental data obtained so far for the product as follows. Satisfactory elemental analyses were obtained, from which *trans*-$[RuCl(OMe)(py)_4]^+$ **4** could be confirmed.[29] The effective magnetic moment (2.32 B.M.), which was measured by the Gouy method, is in the range expected for Ru^{III} complexes. IR spectra show new bands at 2860, 2786, 1422, 1038, and 549 cm^{-1}, with disappearance of the ν(Ru=O) band characteristic of the oxo complexes. The assignment of the methoxo bands was verified by a comparison of those for the deuterated complex, $[RuCl(OCD_3)(py)_4]^+$, with the results reported by Hill et al.[30] Upon the deuteration, the methoxyl CH stretching vibration bands at 2860 and 2786 cm^{-1} shifted to 2172 and 2040 cm^{-1}, respectively. The methoxyl CH bending vibration band at 1422 cm^{-1} disappeared, and it is thought to shifted to near 1100 cm^{-1} region, where a strong absorption band due to ClO_4^- was observed. The band at 1038 cm^{-1}, which is believed to be methoxy CO stretching vibration, shifted to 1004 cm^{-1}. The Ru-O stretching vibration at 549 cm^{-1} is also shifted to 526 cm^{-1} in its deuterated complex. These shifts found in C-O and Ru-O stretching vibrations are regarded to be reasonable for the deuteration of a methoxo ligand coordinated to metal.[30]

Although further investigation is now in progress on the oxoruthenium(IV) complex, which acts as an oxidant toward organic substrates, we assume that the methoxo formation reaction involves a water condensation reaction between methanol and a hydroxo complex of Ru^{III}, $[RuCl(OH)(py)_4]^+$, which is formed by a one-electron reduction of **1A** (reverse of Eq. 4) with interaction of another methanol molecule

$$[RuCl(OH)(py)_4]^+ + MeOH \longrightarrow [RuCl(OMe)(py)_4]^+ + H_2O \quad (7)$$

The existence of the hydroxo complex could be presumed before the methoxo formation reaction occured.[31]

The authors wish to express their thanks to Professor Akira Ouchi and Dr. Mamoru Shimoi, the University of Tokyo, for the X-ray diffraction measurements and for their helpful discussions. They also would like to thank Dr. F. Scott Howell, Sophia University, for correcting the manuscript. Thanks are also due to Misses Mieko Kurihara and Kuniko Shirai for their technical assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 59540401 from the Ministry of Education, Science and Culture, and also by a grant from the Morimura Homei-kai (1983).

31) The chlorohydroxotetrakis(pyridine)ruthenium(III) complex has not been reported yet. The product obtained at this stage could reasonably be formulated as $[RuCl(OH)(py)_4]PF_6$ based on the following results. Anal. Found: C, 39.6; H, 3.6; N, 9.1%. Calcd for $C_{20}H_{21}N_4ClOPF_6Ru$: C, 39.1; H, 3.4; N, 9.1%. The IR spectra of the product (4000—750 cm^{-1}) are almost the same as to those of $[RuCl_2(py)_4]PF_6$, except that the product obtained exhibits a sharp absorption band which is assignable to ν(OH) at 3544 cm^{-1} (KBr). The cyclic voltammogram of the product in CH_3CN exhibits a reversible one-electron reduction wave at −0.68 V which is indicative the oxidation state of Ru^{III}.

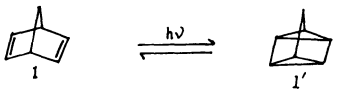
Synthesis of Photosensitive Poly(2,5-Norbornadien-7-yl Acrylate and Methacrylate)

Hiroyoshi KAMOGAWA* and Makoto YAMADA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received November 25, 1985)

2,5-Norbornadien-7-yl acrylate and methacrylate were synthesized by the esterification of 2,5-norbornadien-7-ol with acryloyl and methacryloyl chlorides, respectively. Polymerization of the monomers with AIBN provided vinyl polymers with pendant norbornadiene units, which could be made to clear films from CH_2Cl_2. UV-irradiations brought about remarkable changes in the 200 nm region of the absorption spectra of the films, indicating the formation of quadricyclane units. These could be partially converted back by immersion in a cobalt(II) 5,10,15,20-tetraphenylporphyrin solution.

It is well-known that norbornadiene (**1**) undergoes a reversible intramolecular [2+2] cycloaddition reaction on irradiation with ultraviolet light to afford the corresponding compound bearing a cyclobutane ring, quadricyclane (**1'**), as indicated in Eq. 1.[1-3]

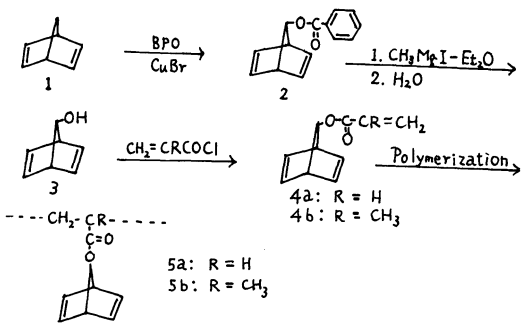


(1)

When the **1** unit is incorporated into the side chain of a vinyl polymer as pendant, a photosensitive polymer is obtained. This exhibits a reversible absorption spectrum change in response to UV irradiation in the solid state such as in a film.

The present study describes the first synthesis and polymerization of vinyl monomers bearing the **1** unit and the investigation of the photosensitivities of the films made of the resulting polymers from the standpoint of photomemory. The polymers made here may also be the first example of photosensitive polymers by the [2+2] cycloaddition mechanism.[4]

The polymers were synthesized via the following route (Eq. 2).



(2)

Absorption spectrum changes of **5a** and **5b** films in response with UV irradiations were also investigated.

Results and Discussion

The 2,5-norbonadien-7-yl group was chosen as the pendant in acrylic and methacrylic ester polymers because this pendant at the 7 position should exert the least steric hindrance to polymerization of the corresponding vinyl monomers as well as the subsequent photoreaction (Eq. 1).

2,5-Norbornadien-7-ol (**3**) was prepared starting with norbornadiene (**1**) via 2,5-norbornadien-7-yl benzoate (**2**).

Table 1. Polymerization Behavior of Norbornadiene Monomers

Monomer	Polymer						
	Conversion %	$[\eta]^{25}_{THF}$	IR(KBr) cm^{-1}	C[a] %	H[a] %	Iodine[a,b] Value	$\lambda^{CH_2Cl_2}_{max}$ nm
4a	27	0.45	3070, 2930, 2860, 1720, 1160	73.70 (74.06)	6.60 (6.22)	158 (157)	228 (ε 550)
4b	55	0.49	3070, 2980, 2930, 1720, 1150	74.68 (74.98)	7.07 (6.86)	149 (144)	228 (ε 400)

a) Figures in parentheses indicate calcd values. b) Wjis' method.

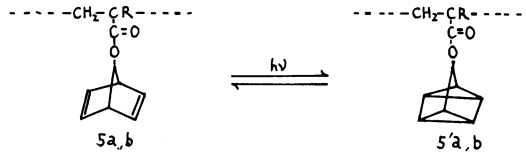
The 7h-reaction of **1** following the method of Tanida and Tsuji[5] provided **2** with satisfactory purity. Attempts to hydrolyze **2** under normal alkaline conditions using potassium hydroxide failed, so that the reaction of a Grignard reagent with the carbonyl group of **2** followed by hydrolysis as in the case of 2,5-norbornadien-7-yl acetate[6] was adopted to afford **3** in 61% yield. The latter was converted to acrylic and methacrylic esters (**4a** and **4b**) by conventional procedures. Thus, the reaction of **3** with acryloyl chloride in the presence of *N,N*-dimethylaniline as proton acceptor provided **4a** in 65% yield. With freshly distilled methacryloyl chloride, in the presence of pyridine, a 45% yield of **4b** was obtained. The purity of both products after column chromatography was satisfactory.

Free radical polymerizations of the monomers **4a** and **4b** with α,α'-azobisisobutyronitrile (AIBN) under mild conditions (50 °C, 72 h) provided soluble polymers as indicated in Table 1. Under more severe conditions (e.g., 10 fold monomer concentration) higher conversions were achieved accompanied by lower solubility, presumably due to the participation of the double bonds of the norbonadienyl moiety in polymerization. However, the polymers listed in Table 1 corresponded with **5a** and **5b** structures in all respects. The ultraviolet (UV) absorption spectra of polymer **5a** are indicated in Fig. 1.

The absorption maximum (228 nm) and shape of the curve in CH_2Cl_2 solution are almost identical with those of norbornadiene (**1**) as well as those (229 nm) of the corresponding monomer **4a** in the same solvent. For a film of **5a**, however, no peak is recognized above 200 nm and the absorbance continues to increase down to 189 nm with the decrease of the wavelength. Almost the same results were obtained for polymer **5b**. Both polymers **5a** and **5b** provided clear colorless films from CH_2Cl_2 solutions. This difference of absorption spectra between the film and solution states can be attributed to a solvent effect: Ethanol gives absorption peaks at 209, 212, and 208 nm for **4a**, **4b**, and **1**, respectively.

Films of **5a** and **5b** deposited on the inside walls of quartz cells were irradiated with UV light in a nitrogen atmosphere. Figure 2 and Table 2 indicate the results thus obtained.

The absorbance around 200 nm decreased with irradiation with simultaneous reductions in the iodine value and the 3070 cm^{-1} peak in the IR spectrum, indicating that the reaction given in Eq. 3 occurred.



(3)

This reaction is intramolecular and appears to require little dimensional change, so that a smooth photoconversion of **5a,b** to **5'a,b** may take place even in the solid state. The use of a triplet photosensitizer was avoided to assure [2+2] cycloaddition by the pericyclic mechanism.

It is known that Co(II) porphyrins catalyze the back reaction in Eq. 1.[7] When the films subjected to 48 h irradiation were immersed in a solution of cobalt(II) 5,10,15,20-tetraphenylporphyrin for 24 h, the UV and IR spectra and the iodine values recovered to some extent, indicating that the back

Table 2. Photosensitivities of Norbornadiene Polymer Films

Polymer	Irradiation[a] time / h	Absorbance (200 nm)	Iodine Value	IR (3070 cm^{-1})
5a	0	0.540	158(100)[c]	Strong
	24	0.395	—	Weak

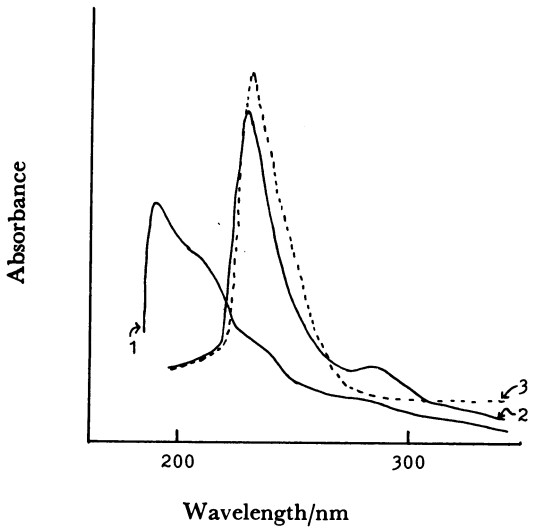

Fig. 1. Ultraviolet absorption spectra of norbornadiene polymer. 1: **5a**-Film; 2: **5a** in CH_2Cl_2; 3: Norbornadiene in CH_2Cl_2. The ordinate has no meaning other than to show the shapes of absorption curves.

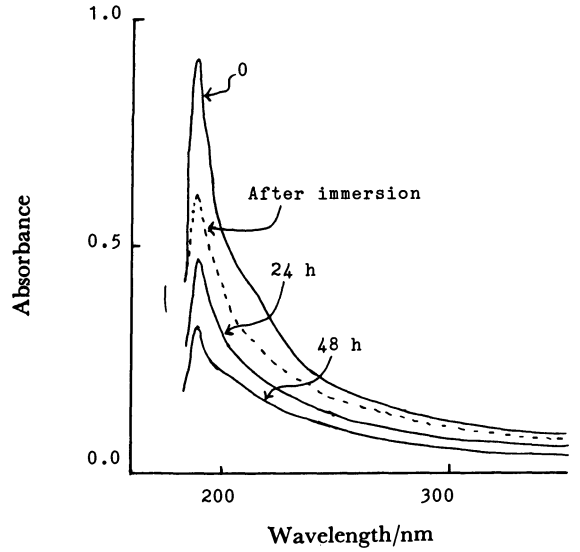

Fig. 2. Change of the absorption spectrum of a norbornadiene polymer (**5b**) film with UV irradiation. Figures in the diagram indicate the irradiation times in nitrogen atmosphere and the immersion was carried out after 48 h irradiation.

reaction shown in Eq. 3 occurred in the films. The rate and extent of the back reaction depend upon the diffusion of the catalyst into the films, so that a complete reversal would depend on the experimental conditions and the state of the films.

There was no indication of any degradation of the principal polymer chains or decomposition of the carboxyl portion judging from the values of intrinsic viscosity and IR spectra. In fact, the conversion as indicated in Eq. 3 could be repeated.

Experimental

Infrared, ^{1}H NMR, mass, and ultraviolet spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, a Hitachi RMU-6 spectrometer, and a Hitachi 200-10 spectrophotometer, respectively, under standard conditions. Elemental analyses were carried out with a Perkin-Elmer 250 instrument.

2,5-Norbornadien-7-yl Benzoate (2). Refluxing for 7 h of a mixture of norbornadiene (9.2 g, 0.10 mol), copper(I) bromide (50 mg), and benzoyl peroxide (BPO; 6.0 g, 0.025 mol) in benzene (80 ml) and subsequent working up provided colorless needles (mp 54—56 °C, bp 109 °C/0.4 mm; lit,[5] mp 53—54 °C) in 34% yield. Found: C, 79.26; H, 5.66%. Calcd for $C_{14}H_{12}O_2$: C, 79.23; H, 5.70%. IR (KBr) 3070 (CH=CH); 1730, 1280 (ester) cm.$^{-1}$ ^{1}H NMR (CCl_4) δ=3.7 (m, 2H, 2CH), 4.8 (s, 1H, CHO), 6.7 (d, 4H, 2CH=CH), 7.5 (m, 3H, ArH), 8.1 (m, 2H, ArH). Ms (*m/z*) 212 (M^+).

2,5-Norbornadien-7-ol (3). To a Grignard reagent, prepared from magnesium (2.4 g, 0.10 mol) and methyl iodide (14.2 g, 0.10 mol) in anhydrous ether (100 ml), **2** (4.2 g, 0.020 mol) was added slowly under a nitrogen atmosphere. The reaction mixture was stirred at room temperature for 1 h. Saturated aqueous sodium sulfate was added. The ether solution was decanted, washed with water, and dried over anhydrous sodium sulfate. The ether was removed and the product distilled to yield a VPC-pure fluid (bp 81 °C/57 mm; lit,[6] 79 °C/57 mm) in 61% yield. Found: C, 77.75; H, 7.21%. Calcd for C_7H_8O: C, 77.75; H, 7.46%. IR (CCl_4) 3560 (OH), 3070 (CH=CH) cm.$^{-1}$ ^{1}H NMR (CCl_4) δ=2.9 (s, 1H, OH), 3.4 (m, 2H, 2CH), 3.8 (s, 1H, CHO), 6.6 (m, 4H, 2CH=CH). Ms (*m/z*) 108 (M^+).

2,5-Norbornadien-7-yl Acrylate (4a). To a stirred solution of **3** (2.2 g, 20 mmol), hydroquinone (0.1 g), *N,N*-dimethylaniline (4.2 ml, 33 mmol) in anhydrous acetonitrile (50 ml) cooled in an ice bath was added dropwise acryloyl chloride (2.5 ml, 30 mmol) with exclusion of moisture. The reaction mixture was stirred at room temperature for 15 h and poured into ice-water containing conc. hydrochloric acid (20 ml). Ether extraction followed by conventional working up provided a crude product, which was subjected to silica-gel column chromatography (Wakogel C-300) using hexane-benzene (1:1 v/v) as eluting solvent to afford a clear fluid in 65% yield. Found: C, 73.70; H, 6.60%. Calcd for $C_{10}H_{10}O_2$: C, 74.06; H, 6.22%. IR (CCl_4) 3070 (CH=CH); 1720 (ester); 980, 900 (vinyl) cm^{-1}. ^{1}H NMR (CCl_4) δ=3.7 (m, 2H, 2CH), 4.6 (s, 1H, CHO), 5.8—6.4 (m, 3H, CH_2=CH), 6.7 (m, 4H, 2CH=CH). λ_{max}^{EtOH} 209 nm (ε 3400), $\lambda_{max}^{CH_2Cl_2}$ 229 nm (ε 440). MS (*m/z*) 162 (M^+).

2,5-Norbornadien-7-yl Methacrylate (4b). The same procedure as that for **4a** was applied using methacryloyl chloride (3.9 ml, 40 mmol), freshly distilled, and pyridine (3.6 ml, 44 mmol) instead of acryloyl chloride and *N,N*-dimethylaniline, respectively. Column chromatographic purification using hexane-benzene (1:1 v/v) as eluting solvent provided a clear fluid in 45% yield. Found: C, 74.63; H, 6.95%. Calcd for $C_{11}H_{12}O_2$: C, 74.98; H, 6.86%. IR (CCl_4) 3070 (CH=CH), 1720 (ester), 930 (methacryloyl) cm.$^{-1}$ ^{1}H NMR (CCl_4) δ=1.8 (s, 3H, CH_3), 3.6 (m, 2H, 2CH), 4.6 (s, 1H, CHO), 5.5 (s, 1H, CH_2=), 6.0 (s, 1H, CH_2=), 6.7 (m, 4H, 2CH=CH). λ_{max}^{EtOH} 212 nm (ε 8100), $\lambda_{max}^{CH_2Cl_2}$ 229 nm (ε 1100). Ms (*m/z*) 176 (M^+).

Polymerization of the Monomers. A solution of monomer (0.4 g) and α,α'-azobisisobutyronitrile (AIBN; 0.02 g) in tetrahydrofuran (8 ml) was put into a glass ampule, which was evacuated and sealed in a conventional manner. Polymerization was carried out at 50 °C for 72 h and the resulting polymer was precipitated into hexane-benzene (1:1 v/v) to afford a white powder. The result thus obtained are given in Table 1.

The IR-spectra of the polymers showed absorption in the 2900 cm^{-1} region characteristic of the vinyl polymer backbone with disappearance of the monomeric vinyl absorptions.

Measurements of Ultraviolet (UV) Spectra. Film: A solution of the polymer in dichloromethane was spread over either a quartz plate or an inside wall of a quartz cell, which was air-dried at room temperature overnight and stored for at least a week before measurement. The average thickness of the films thus prepared was 0.01 mm.

Measurement: UV-absorption spectra of films were recorded on a spectrophotometer. The UV irradiation source was a 75W mercury lamp (Toshiba SHL-100UV-2) and irradiation was effected at a distance of 10 cm from the lamp.

Treatment of Irradiated Film for Spectrum Recovery: The films subjected to irradiation were immersed in a 1% solution of cobalt(II) 5,10,15,20-tetraphenylporphyrin in benzene–dichloromethane (4:1 v/v) for 24 h, washed thoroughly with the same solvent mixture, and dried.

Preparation of Alkyl Dihydrogenphosphates with Monomeric Metaphosphate Anion Generated by Photochemical C-P Bond Cleavage of *p*-Nitrobenzylphosphonic Acid

Narimasa IWAMOTO, Yoshiki OKAMOTO,* and Setsuo TAKAMUKU
The Institute of Scientific and Industrial Research, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567
(Received November 30, 1985)

Alkyl dihydrogenphosphates were prepared by a procedure that probably involves a monomeric metaphosphate anion as an intermediate. The monomeric metaphosphate anions used in this reaction were generated by a photochemical C-P bond cleavage of the *p*-nitrobenzylphosphonate dianion. The photolysis of a 1:2 molar mixture of *p*-nitrobenzylphosphonic acid and 1,8-diazabicyclo[5.4.0]undec-7-ene (or 2,2,6,6-tetramethylpiperidine) in excess alcohol gave alkyl dihydrogenphosphate in fairly good yield.

In our previous study of the photolysis of *p*-nitrobenzylphosphonic acid (**1**) in an alkaline 80% ethanol solution, we observed the heterolytic cleavage of the C-P bond and the generation of monomeric metaphosphate anions (**2**) with a high efficiency (Eq. 1—4).[1]

For almost 30 years, metaphosphate (**2**) has been postulated as an intermediate in the hydrolysis of phosphate esters and has been suggested as an essential phosphorylating agent in reactions involving intermediary metabolism.[2] Excellent evidence that **2** acts as a phosphorylating agent in solution has been accumulating.[3-9] Recently, Ramirez et al. reported that alkyl dihydrogenphosphates were conveniently prepared by a procedure involving **2** as an intermediate: An acetonitrile solution of 2,4-dinitrophenyl dihydrogenphosphate, or (*erythro*-1-phenyl-1,2-dibromopropyl)-phosphonic acid containing 2 molar equivalents of the hindered tertiary amine behaves thermally as a source of **2** at ambient temperature. By this method, sensitive and valuable alcohols can be converted into alkyl dihydrogenphosphates.[10]

Kirby reported the photochemical phosphorylation of methanol with 3,5-dinitrophenyl dihydrogenphosphate.[11] When a 70% methanol solution of cyclohexylammonium 3,5-dinitrophenyl hydrogenphosphate (2.8 mmol dm^{-3}) at pH 9 was irradiated at room temperature, methyl dihydrogenphosphate was obtained in 58—68% yield.

We have now established a novel procedure for the photochemical phosphorylation of alcohol using **2** generated by the photolysis of **1** in the presence of an organic base. The acid **1** was readily made available through the nitration of benzylphosphonic acid.

Results and Discussion

An 80% ethanol solution of **1** (50 mmol dm^{-3}) at pH 12, was adjusted with sodium hydroxide in a Pyrex tube. Upon irradiation by a high-pressure mercury lamp at ambient temperature, a highly efficient C—P bond cleavage of **1** occurred. The course of the reaction was followed by a GLC analysis of 4-nitrotoluene (**5**). The quantum yield was 0.86, which was larger than that of the photolysis of sodium 3-nitrophenyl hydrogenphosphate (ϕ= 0.05—0.24).[12] The phosphorus compounds were analyzed by ^{31}P NMR spectrometry. The photolysis was completed within about 30 min, and dianions of ethyl dihydrogenphosphate $C_2H_5OPO_3^{2-}$ (**3b**), ^{31}P NMR (80% C_2H_5OH, pH 12) δ=3.6 (t, J_{PH}=5.6 Hz), and orthophosphoric acid $HOPO_3^{2-}$ (**4**), δ=2.6 (s) were formed in 28 and 72% yields, respectively.

The disodium salt of **1** is only slightly soluble in anhydrous alcohol, but its amine salts are soluble. The anhydrous ethanol solutions of **1** (30 mmol dm^{-3}) containing 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU, pK_a 11.5) were irradiated to give **3b**. The yield of **3b** reached a maximum upon the addition of 2 molar equivalents of DBU and decreased upon a further excess addition of the base (Fig. 1). This was explained by the inner filter effect of the DBU itself

and its photoproducts.[13] The quantum yield of the C–P bond cleavage of **1** under the best conditions was 0.57. The use of 2,2,6,6-tetramethylpiperidine (pK_a 11.1) also gave good results. However, the quantum yield of the C–P bond cleavage was low (ϕ=0.13). The yield of **3b** was not reduced even though an excess amount of the base was used. A large excess amount of triethylamine (pK_a 10.65) was required for obtaining **3b** in 50—60% yield, and the quantum yield of C–P bond cleavage was lower (ϕ=0.025). With pyridine (pK_a 5.17), the C–P bond cleavage did not occur. The photochemical C–P bond cleavage of **1** occurred only during its dianion.[1] The effect of the organic base can be explained by the degree of dissociation of **1**; with a weak base, triethylamine or pyridine, the acid **1** did not completely ionize into dianion. Thus, **2** was not generated.

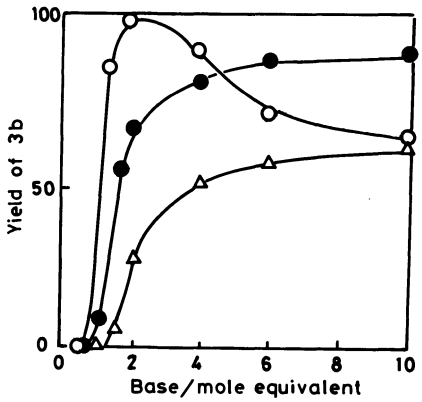

Fig. 1. Change of yields of **3b** by addition of organic bases.
○: DBU, ●: 2,2,6,6-tetramethylpiperidine, △: triethylamine.

Various alcohols were phosphorylated by a method in which a large excess amount of alcohol containing 2 molar equivalents of DBU were used. The phosphorylation proceeded without any detectable amount of a by-product. The yields and ^{31}P NMR chemical shifts of dianion of alkyl dihydrogenphosphates **3**, and the quantum yields of a C–P bond cleavage of **1** are summarized in Table 1. The quantum yields decreased in the order CH_3OH=C_2H_5OH>*i*-C_3H_7OH>*n*-C_4H_9OH>*n*-$C_5H_{11}OH$=*s*-C_4H_9OH>*t*-C_4H_9OH. This order is essentially the same as that for the polarity of alcohol used in these reactions. With increasing alcohol polarity, the acid **1** dissociated more completely and underwent highly efficient C–P bond cleavage.

Reactions using one molar equivalent of alcohol were performed in dichloromethane. The dichloromethane solutions of **1** (50 mmol dm^{-3}) containing a molar equivalent of alcohol and 2 molar equivalents of DBU were irradiated for 1 h. When cholesterol, borneol, and 1-dodecanol were used, the dianions of cholesteryl (**3j**), bornyl (**3k**), and dodecyl dihydrogenphosphate (**3l**) were obtained in 25, 35, and 27% yields, respectively. However, 72—78% of **1** were consumed during the irradiation. It was revealed by a ^{31}P NMR investigation that the greater part of **2** generated by irradiation was consumed during the formation of pyrophosphate ions (**8** or **9**) and a metastable intermediate (**10**) by a reaction with DBU.[4]

In the presence of a large excess of alcohol, metaphosphate (**2**) can react predominantly with the alcohol to give **3** in a quantitative yield (Eq. 2). When a comparable amount of alcohol was used, metaphosphate (**2**) reacted with alcohol (Eq. 2), its source (**1**) (Eq. 5), itself (**2**) (Eq. 6), **3** (Eq. 7), and

Table 1. The Yields of Alkyl Phosphates Ions (**3**) and Quantum Yields of C–P Bond Cleavage of **1**[a]

ROH	Product	Yield/%[b] of **3**	^{31}P NMR[c] δ ppm	Quantum yield[d] of C–P bond cleavage

R=Alkyl-

The same experiment with 2,2,6,6-tetramethylpiperidine was unsuccessfully carried out since the piperidinium salt of **1** is only slightly soluble in dichloromethane or acetonitrile. In another preparative experiment, **3l** was isolated in 32% yield.

Experimental

All the melting points are uncorrected. ^{31}P NMR spectra were recorded at 40.25 MHz on a JNM FX 100 using triphenylphosphine as an external standard (δ=−5.6 ppm) for measurements of their chemical shifts, and diethyl methylphosphonate as an internal standard (δ=29.7 ppm) for quantitative analysis, respectively. Chemical shifts are expressed in ppm from 85% H_3PO_4, higher positive values indicated lower shieldings. Quantitative measurements were carried out under the conditions of proton decoupling while taking into account the differences in T_1 and nuclear Overhauser effects.[14] GLC analyses were performed on a Shimadzu GC-7A using a 1-m glass column packed with Silicone OV 17 (2%) on Chromosorb W AW DMCS.

Materials. Dichloromethane and other solvents were dried and distilled by the usual method. Cholesterol, borneol, and 1-dodecanol were of reagent grade and used without further purification. Other alcohols and amines were used after distillation. *p*-Nitrobenzylphosphonic acid (**1**) was prepared by the nitration of benzylphosphonic acid and recrystallized from 50% ethanol, mp 228—229 °C; ^1H NMR (D_2O, DSS, pH 12), δ=2.98 (2H d, J_{HH}=20 Hz, CH_2), 7.2—8.2 (5H, m, arom.); ^{31}P NMR (80% C_2H_5OH, pH 12) δ=15.2 (t, J_{HP}=20 Hz); Dissociation constant (80% C_2H_5OH) pK^1_a 3.9; pK^2_a 9.3; UV_{max} (80% C_2H_5OH, pH 12) 305 nm (ε 10,500).

Irradiation of 1 in 80% Ethanol Solution. Five ml of an ethanol solution of **1** (50 mmol dm^{-3}) was adjusted at pH 12 with a 10% aqueous solution of sodium hydroxide. Nitrogen was bubbled through the solution before irradiation. The solution was irradiated in a Pyrex tube (ϕ 10 mm) with a high-pressure mercury lamp (350 W) for 1 h under cooling with running water. The progress of the photolysis was monitored by a GLC analysis of **5**. After irradiation, a fixed amount of a chloroform-*d* solution of diethyl methylphosphonate was added to the mixture, which was submitted to a ^{31}P NMR analysis using triphenylphosphine as an external standard.

Preparation of 3. Irradiation of 1 in Excess Alcohol: A 5-ml alcohol solution of **1** (50 mmol dm^{-3}) containing DBU (100 mmol dm^{-3}) was irradiated in the same manner previously described. After the irradiation, the mixture was employed for a ^{31}P NMR analysis (Table 1).

Irradiation of 1 in Dichloromethane: A 5 ml dichloromethane solution of **1** (50 mmol dm^{-3}) containing alcohol (50 mmol dm^{-3}) and DBU (100 mmol dm^{-3}) was irradiated in the same manner previously described. After irradiation, the mixture was employed for a ^{31}P NMR analysis. In the case of 1-dodecanol, besides the signals of dianion of dodecyl dihydrogenphosphate (**3l**, δ=1.50 ppm, yield 19%) and **4** (δ=1.98 ppm, 9%), two peaks were observed at δ=−11.22 (t, J_{PH}=16 Hz, yield 5.6%) and −8.97 (s, 19%). The former was assumed to be a metastable reaction intermediate (**10**), formed by the reaction of **2** with DBU[4] and the latter was pyrophosphate ion (**8**).[15] Fifty-three percent of the unreacted dianion of **1** remained.

Isolation of 3l: The acid **1** (1.1 g, 5 mmol) was added to a 100 ml dichloromethane solution of 1-dodecanol (0.9 g, 0.5 mmol) and DBU (1.5 g, 10 mmol). The homogeneous solution was irradiated employing a Pyrex doughnut-type cell at 20 °C in a nitrogen atmosphere for 2 h. After the solvent was evaporated, the residue was triturated with ether to remove **5** and any unreacted alcohol. The residue was dried for a few minutes at 20 °C (0.1 mmHg).† The diammonium hydrogenphosphate was dissolved in a 2:1 V/V chloroform/ethanol mixture. The solution was treated with 3:48:47 V/V chloroform/methanol/1 mol dm^{-3} aqueous HCl reagent (15 ml) in order to liberate the free phosphoric acid under the mildest conditions. The two-phase system was stirred for a few minutes. The lower organic phase was separated and resubmitted to the same acidification procedure. Finally, this phase was washed with 3:48:47 V/V chloroform/methanol/water (10 ml). The organic phase was evaporated at 20 °C (0.1 mmHg), and the residue was triturated with ether (10 ml) to remove any unreacted 1-dodecanol that may have remained as a contaminant. The product **3l** was dried at 20 °C for 3 h (0.1 mmHg). Yield 0.46 g (35%), mp 55—56 °C.[16]

Measurement of the Quantum Yield. The quantum yields were determined on the basis of generated **5** and chemical actinometry using 2-hexanone. The quantum yield of acetone formation was taken as 0.25 in 2,2,4-trimethylpentane at room temperature;[17] A 2 ml 2,2,4-trimethylpentane solution of 2-hexanone with the absorbance identical with that of the solution of **1** was

† 1 mmHg=133.322 Pa.

irradiated for 1 h in a merry-go-round apparatus employing 313-nm monochromatic light using a filter solution of 0.1% K_2CrO_4–0.1% K_2CO_3. The yields of **5** and acetone were determined by a GLC analysis. The photolyses were carried out with no more than 20% decomposition.

The authors are grateful to Mr. Yoshio Takai of Material Analysis Center in the Institute of Scientific and Industrial Research, Osaka University, for the measurement of ^{31}P NMR spectra.

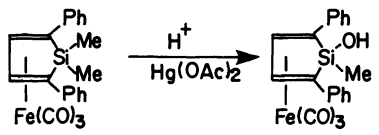
Preparations and Thermal Isomerization of Some Tricarbonyl(1-silacyclohexadiene) Iron Complexes. Silyl and Hydrogen Migration in the Diene and the Diene Complex[1)]

Yasuhiro NAKADAIRA,* Toshiaki KOBAYASHI, and Hideki SAKURAI*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received December 24, 1985)

The reaction of 1,1-dimethyl-2,5-diphenyl-1-silacyclohexa-2,4-diene with iron pentacarbonyl or diiron nonacarbonyl gave a mixture of tricarbonyl(1,1-dimethyl-2,5-diphenyl-1-silacyclohexa-2,4-diene)iron and tricarbonyl(1,1-dimethyl-3,6-diphenyl-1-silacyclohexa-2,4-diene)iron. Similarly, on treatment with iron pentacarbonyl 1,1-dimethyl-2,5-diphenyl-4-trimethylsilyl-1-silacyclohexa-2,5-diene yielded a mixture of tricarbonyl-(1,1-dimethyl-3,6-diphenyl-4-trimethylsilyl-1-silacyclohexa-2,4-diene)iron, tricarbonyl(1,1-dimethyl-2,5-diphenyl-4-trimethylsilyl-1-silacyclohexa-2,4-diene)iron, and tricarbonyl(1,1-dimethyl-2,5-diphenyl-6-trimethylsilyl-1-silacyclohexa-2,4-diene)iron as a result of migration of the hydrogen on the ligand competing with silyl migration. On thermolysis, 1,1-dimethyl-2,5-diphenyl-4-trimethylsilyl-1-silacyclohexa-2,5-diene underwent only 1,3-silyl-migration to yield 1,1-dimethyl-2,5-diphenyl-6-trimethylsilyl-1-silacyclohexa-2,4-diene. The mechanism of transition-metal assisted hydrogen-migration is discussed.

We have reported previously an interesting chemistry of the transition-metal complexes of silacyclopentadienes,[2)] which has been followed by several other workers.[3)] Our investigations of tricarbonyl-(silacyclopentadiene)iron complexes have shown that the exo-substituent on the silicon is highly activated toward electrophilic substitution; for example, tricarbonyl(1,1-dimethyl-2,5-diphenyl-1-silacyclopentadiene)iron (**1**) is readily converted stereospecifically into the silanol complex **2** by the treatment with mercury(II) acetate in the presence of perchloric acid.[2)] There are a few reports on the homologous complex, namely the transition-metal complexes of 1-silacyclohexadienes.[4,5)] We now describe our own result on the preparation and thermal isomerization of some tricarbonyl(1-silacyclohexadiene)iron complexes as well as of their ligands, 1-silacyclohexadienes.

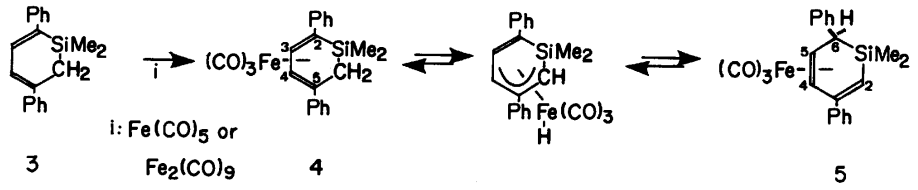


1 2

Results and Discussions

Treatment of 1,1-dimethyl-2,5-diphenyl-1-silacyclohexa-2,4-diene (**3**)[6)] with $Fe(CO)_5$ in xylene at 130 °C for 30 h afforded an isomeric mixture of tricarbonyl(1,1-dimethyl-3,6-diphenyl-1-silacyclohexa-2,4-diene)-iron (**5**) in 48.7% yield together with tricarbonyl(1,1-dimethyl-2,5-diphenyl-1-silacyclohexa-2,4-diene)iron (**4**) in 39.0% yield. **5** is a product of 1,5-H shift. These isomers could be separated each other by TLC on silica gel. Spectral properties, in particular NMR spectra served to distinguish between the two isomers, **4** and **5**. **4** shows two olefinic proton signals (H_3 and H_4) at 5.90 and 6.17 as doublet ($J_{3,4}$=5.4 Hz) together with AB type methylene proton signals (H_{6N} and H_{6X}, $J_{6N,6X}$=16.5 Hz) at 2.10 and 1.25, respectively. In contrast, with only one "internal" olefinic proton signal H_4 at 5.88, **5** has two "outside" complexed olefinic proton signals (H_2 and H_5) at 2.19 and 3.15, respectively. One proton signal due to H_6 is observed at 2.93. The configuration of H_6 is endo as described below. When **3** was allowed to react with diiron nonacarbonyl in benzene for 5 h at 90 °C, only **4** could be isolated in 78% yield together with the unreacted diene **3**. The equilibration between **4** and **5** was demonstrated as follows. When **4** was heated in a sealed tube at 130 °C for 48 h, it was converted into a 56:44 mixture of **4** and **5** without appreciable decomposition. Similarly, the thermolysis under similar conditions (140 °C, 22 h in a sealed tube), **5** gave a 48:52 mixture of **4** and **5**.[7)] These isomer ratios were determined after careful TLC separation of these thermolysates on silica gel. Inspection of these findings above indicates that treatment of the diene **3** with an iron carbonyl reagent gives **4** at first, which is then isomerized thermally to **5**, and the equilibrium constant between **4** and **5** is nearly unity.

1,1-Dimethyl-2,5-diphenyl-4-trimethylsilyl-1-silacyclohexa-2,5-diene (**6**) was obtained quantiatively by quenching the anion derived from **3** with trimethylchlorosilane. Thermolysis of **6** in a sealed tube at 170 °C for 38 h caused 1,3-sila-allyl rearrangement and gave 1,1-dimethyl-2,5-diphenyl-6-trimethylsilyl-1-silacyclohexa-2,4-diene (**7**) in high yield.[8,9)] The other possible isomers such as **8** and **9** were not detected in the reaction mixture and this shows that the trimethylsilyl group migrates to C_6 not to C_2 and 1,3- or 1,5-hydrogen migration does not compete with 1,3-silaallyl rearrangement effectively.[10)] 1,1-

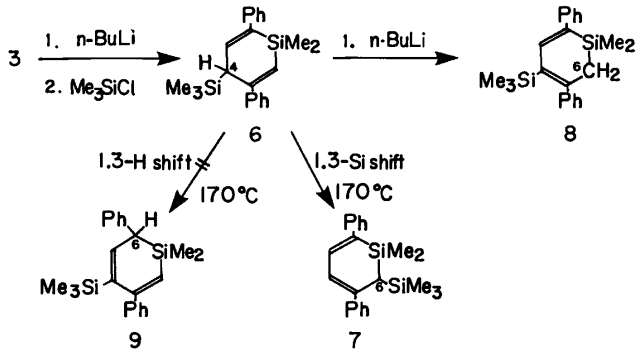


Scheme 1.

Table 1. Thermal Interconversion between 4 and 5

Complex	Temp	Time	Fe(CO)3(diene)		
	°C	h	% yield[a]		Relative yield
			4	5	4:5
4	130	48	52	42	56:44
5	140	22	41	43	48:52

a) Isolated Yields by TLC.



Scheme 2.

Dimethyl-2,5-diphenyl-4-trimethylsilyl-1-silacyclohexa-2,4-diene (**8**) was obtained by quenching the anion derived from **6** with water.

Treatment of dienes **6**, **7**, and **8** with $Fe(CO)_5$ led to the mixtures of complexes **10**, **11**, and **12** as shown in Table 2 and Scheme 3. These isomers could be separated by careful TLC on silica gel and their structures were readily characterized on the basis of NMR spectra. Thermolyses of **11** and **12** resulted in isomerization to give the equilibrium mixture as shown in Table 3. The results obtained here indicate that 1,3 and 1,5-hydrogen shift is considerably enhanced by the transition metal and can compete with the sila-allyl migration observed in thermolysis of **6**. This can be explained by assuming the intermediacy of a (π-allyl)metal hydrides such as **13**.[7,11] Coordination of the metal complex should occur from the less sterically hindered side of the diene and hence the trimethylsilyl group necessarily turns out to be exo in **10**.[15] This always allows to migrate the endo hydrogen to the metal center to form a π-allyl metal hydride such as **13**, which reverts to the diene complex, either **11** or **12**.

Table 2. Reactions of Dienes **6**, **7**, and **8** with $Fe(CO)_5$

Diene	Temp	Time	Fe(CO)3(diene)			
	°C	h	% yield[a]			
			10	**12**	**11**	**7**[b]
6	165	20	20.5	trace	26.4	42.0
7	170	37	44.0			34.3
8	160	22		23.4	37.5	

a) Isolated yields by TLC. b) A trace amount of **12** was detected on TLC.

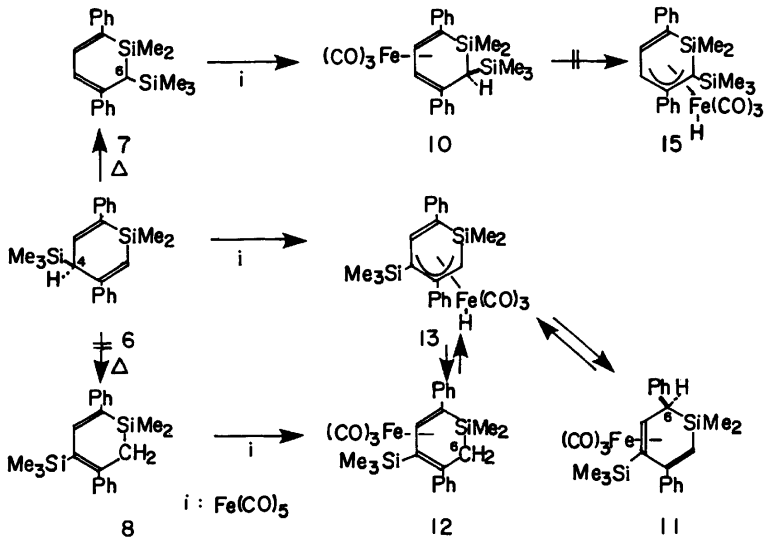
Table 3. Thermal Interconversion of **11** and **12**

Complex	Temp	Time	Fe(CO)3(diene)		
	°C	h	% yield[a]		Relative yield
			11	**12**	**11**:**12**
11	170	7	71	27	72:28
12	155—180	123	50	24	68:32

a) Isolated yields by TLC.

On the other hand, **10** did not isomerize thermally, namely no metal-assisted hydrogen migration was observed. This may be ascribed to a large steric hindrance emerging in **15**. To examine the reactivity of the substituent on the silicon of the tricarbonyl(silacyclohexadiene)iron complex, **4** was allowed to react with $Hg(OAc)_2$ in presence of $HClO_4$,[2] and was found to remain unchanged under these conditions.[12]

It is noteworthy to add some comments on NMR signals, especially Si-Me signals of these carbonyl(silacyclohexadiene)iron complexes (Table 4). The assignment of these Si-Me signals is made by analogy to that made in tricarbonyl(silacyclopentadiene)iron complexes in which exo Si-Me resonance always occurs at higher field than the endo one.[13] The difference in chemical shift between endo- and exo-Me signals is similar in these two types of diene complexes. The similar trend is observed in the chemical shifts of C_6-methylene protons in **4**, and **12**.[14] The endo-proton signal always appears at lower field.[15]



Scheme 3.

Table 4. NMR Spectra of Tricarbonyl(silacyclohexadiene)iron Complexes (δ in CCl_4)

Complex	Si-Me exo	Si-Me endo	H_{6X}[a]	H_{6N}[a]	H_2	H_3	H_4	H_5	$SiMe_3$
4	−0.02	0.44	1.25	2.10		6.17	5.90		
5	−0.42	0.35		2.93	2.19		5.88	3.14	
10	−0.05	0.38		1.71		6.03	5.91		−0.32
11	−0.22	0.47		3.00	1.91			3.25	0.05

a) H_{6X} and H_{6N} denote the exo- and endo-hydrogens at C_6, respectively.

Experimental

General Remarks. NMR spectra were obtained by using Varian A-60 and HA-100 instruments. Mass spectra were obtained by a Hitachi RMU-6 instrument. Infrared spectra were recorded on a Hitachi EPI-G2 grating spectrometer. NMR spectra were recorded in CCl_4 and chemical shift data are given in δ value. IR spectra were measured in a KBr disk and IR data are given in cm^{-1}.

Reaction of 1,1-Dimethyl-2,5-diphenyl-1-silacyclohexa-2,4-diene (3) with $Fe(CO)_5$. A mixture of **3** (478.5 mg, 1.73 mmol), $Fe(CO)_5$ (5 ml, ≈35 mmol) and dry xylene (5 ml) was heated in a small autoclave at 130 °C for 30 h. Solvent and excess $Fe(CO)_5$ were removed in vacuum and the residue was separated by TLC on silica gel. **4** (289.0 mg, 39.0%) and **5** (359.0 mg, 48.7%) were obtained. **4**: mp 80 °C; MS *m/z* M^+ 416; ^1H NMR −0.02 (3H, s, *exo*-SiMe), 0.44 (3H, s, *endo*-SiMe), 1.25 (1H, d, H_{6N}, $J_{6X,6N}$=16.5 Hz), 2.10 (1H, d, H_{6N}, $J_{6X,6N}$=16.5 Hz), 5.90 (1H, d, H_4, $J_{3,4}$=5.4 Hz), 6.17 (1H, d, H_3, $J_{3,4}$=5.4 Hz), 7.0—7.6 (10H, m, Ph); IR 2040, 1975, 1965 (CO), 1250 (SiMe); Anal. Calcd for $C_{22}H_{20}O_3SiFe$: C, 63.47; H, 4.84. Found: C, 63.49; H, 4.72, **5**: Mp 107 °C; MS *m/z* M^+ 416; ^1H NMR −0.42 (3H, s, *exo*-SiMe), 0.35 (3H, s, *endo*-SiMe), 2.19 (1H, d, H_2, $J_{2,4}$=1.8 Hz), 2.93 (1H, d, H_6, $J_{5,6}$=3.9 Hz), 3.14 (1H, dd, H_5, $J_{4,5}$=6.8 Hz, $J_{5,6}$=3.9 Hz), 5.88 (1H, dd, H_4, $J_{4,5}$=6.8 Hz, $J_{2,4}$=1.8 Hz), 6.8—7.6 (10H, m, Ph); IR 2050, 1990, 1970 (CO), 1250 (SiMe); Found: C, 63.39; H, 4.90%. Calcd for $C_{22}H_{20}O_3SiFe$: C, 63.47; H, 4.84%.

Reaction of 1,1-Dimethyl-2,5-diphenyl-1-silacyclohexa-2,4-diene (3) with $Fe_2(CO)_9$. A mixture of **3** (81.2 mg, 0.294 mmol), $Fe_2(CO)_9$ (148.2 mg, 0.407 mmol) and dry benzene (5 ml) was heated in an autoclave at 90 °C for 5 h. The solvent was removed under reduced pressure. The residual oil was separated by TLC on silica gel. Unchanged **3** (45.5 mg, 56.0%) was recovered and **4** (41.8 mg, 77.7%) was obtained.

Thermolysis of 4. **4** (54.0 mg, 0.130 mmol) was sealed under vacuum in a Pyrex tube and heated in an oil bath at 130 °C for 48 h. **4** (28.4 mg, 52.0%) were recovered and **5** (22.6 mg) were separated from the reaction mixture by TLC.

Thermolysis of 5. **5** (30.0 mg, 0.072 mmol) was sealed under vacuum in a Pyrex tube and heated in an oil bath at 140 °C for 22 h. The reaction mixture was separated by TLC. Starting material **5** (13.0 mg) was recovered and isomer **4** (12.2 mg) was obtained.

Preparation of 1,1-Dimethyl-2,5-diphenyl-4-trimethylsilyl-1-silacyclohexa-2,5-diene (6). In a 20 ml-flask was placed **3** (261.2 mg, 0.945 mmol) dissolved in dry ether (10 ml) containing *N,N,N',N'*-tetramethylethylenediamine (TMEDA) (0.5 g, ≈4 mmol). Then butyllithium in hexane

was added to the mixture and was stirred magnetically at room temperature for 10 min. Then excess amount of trimethylchlorosilane was added to the reaction mixture, and was hydrolyzed after 10 min and was extracted with ether. The ethereal solution was evaporated to dryness in vacuum. The residue was purified by TLC on silica gel to give **6** (301.0 mg, 91.4%). **6**: an oil; MS *m/z* M^+ 348; UV (hexane) $\lambda_{max}(\varepsilon)$ 245.5 nm (23900); ^{1}H NMR −0.08 (9H, s, $SiMe_3$), 0.27 (3H, s, SiMe), 0.41 (3H, s, SiMe), 3.70 (1H, d, H_4, $J_{3,4}$=5.4 Hz), 5.90 (1H, s, H_6), 6.83 (1H, d, H_3, $J_{3,4}$=5.3 Hz), 7.0—7.5 (10H, m, Ph); Found: C, 75.79; H, 8.29%. Calcd for $C_{22}H_{28}Si_2$: C, 75.59; H, 8.10%.

Preparation of 1,1-Dimethyl-2,5-diphenyl-6-trimethylsilyl-1-silacyclohexa-2,4-diene (7). **6** (121.2 mg, 0.248 mmol) was sealed under vacuum in a Pyrex tube and heated in an oil bath at 170 °C for 38 h. The reaction mixture was purified by TLC on silica gel. **7** (105.6 mg, 87.1%) was afforded as an oil. Other isomers such as **6** or **9** were not detected on TLC. **7**: an oil; MS *m/z* M^+ 348; UV (hexane) $\lambda_{max}(\varepsilon)$ 238 nm (14800), 350 nm (16800); ^{1}H NMR 0.02 (9H, s, $SiMe_3$), 0.43 (3H, s, SiMe), 0.45 (3H, s, SiMe), 1.89 (1H, s, H_6), 6.46 (1H, d, H_4, $J_{3,4}$=6.4 Hz), 6.83 (1H, d, H_3, $J_{3,4}$=6.4 Hz), 7.0—7.5 (10H, m, Ph); Found: C, 75.77; H, 8.10%. Calcd for $C_{22}H_{28}Si_2$: C, 75.79; H, 8.10%.

Preparation of 1,1-dimethyl-2,5-diphenyl-4-trimethylsilyl-1-silacyclohexa-2,4-diene (8). In a 30 ml-flask was placed 1,1-dimethyl-2,5-diphenyl-4-trimethylsilyl-1-silacyclohexa-2,4-diene (**6**) (166.5 mg, 0.478 mmol) dissolved in dry ether (10 ml) containing TMEDA (0.5 g, 4 mmol). Then butyllithium in hexane was added to the mixture and was stirred magnetically at room temperature for 10 min. The mixture was hydrolyzed and was extracted with ether. The ethereal solution was evaporated to dryness in vacuum. The residue was separated by TLC on silica gel to give unreacted **6** (61.0 mg, 36.6%) and **8** (55.5 mg, 52.6%). **8**: Mp 100 °C; MS *m/z* M^+ 348; UV (hexane) $\lambda_{max}(\varepsilon)$ 233 nm (11400), 322 nm (13200); ^{1}H NMR −0.16 (9H, s, $SiMe_3$), 0.25 (6H, s, $SiMe_2$), 1.96 (2H, s, H_6), 6.95 (1H, s, H_3), 7.0—7.4 (10H, m, Ph); Found: C, 75.89; H, 8.19%. Calcd for $C_{22}H_{28}Si_2$: C, 75.79; H, 8.10%.

Reaction of 4 with $Hg(OAc)_2$. In a 20 ml-flask equipped with a condenser and a nitrogen inlet tube, a mixture of **4** (38.0 mg, 0.0913 mmol), $Hg(OAc)_2$ (36.0 mg, 0.113 mmol), dioxane (10 ml) and one drop of 70% aq perchloric acid was placed and stirred magnetically at room temperature for 10 min. After addition of water, the reaction mixture was extracted with ether. The ethereal solution was evaporated to dryness to give an oil (37.0 mg). NMR spectrum of this oil indicated almost 100% recovery of **4**.

Reaction of 6 with $Fe(CO)_5$. In a small autoclave **6** (255.0 mg, 0.731 mmol), $Fe(CO)_5$ (5 ml, 35 mmol), dry toluene (10 ml) were heated at 165 °C for 20 h. The solvent and excess amount of $Fe(CO)_5$ are removed under vacuum and the residual oil was separated by TLC on silica gel. **10** (73.0 mg, 20.5%), **11** (94.0 mg, 26.4%) and **7** (107.4 mg, 42.0%) were afforded. Since **7** and **12** show same R_f value on TLC under various conditions, **7** thus obtained remained to be contaminated with a small amount of **12**. **10**: mp 140 °C; MS *m/z* M^+ 488; ^{1}H NMR −0.32 (9H, s, $SiMe_3$), −0.05 (3H, s, *exo*-SiMe), 0.38 (3H, s, *endo*-SiMe), 1.71 (1H, s, H_6), 5.91 (1H, d, H_4, $J_{3,4}$=5.1 Hz), 6.03 (1H, d, H_3, $J_{3,4}$=5.1 Hz), 6.9—7.4 (10H, m, Ph); IR 2040, 1975, 1950 (ν CO), 1250 (δ SiMe); Found: C, 61.64; H, 5.83%. Calcd for $C_{25}H_{28}O_3Si_2Fe$: C, 61.47; H, 5.78%. **11**: mp 95 °C; MS *m/z* M^+ 488; ^{1}H NMR −0.22 (3H, s, *exo*-SiMe), 0.05 (9H, s, $SiMe_3$), 0.47 (3H, s, *endo*-SiMe), 1.91 (1H, s, H_2), 3.00 (1H, d, H_6, $J_{5,6}$=4.2 Hz), 3.25 (1H, d, H_5, $J_{5,6}$=4.2 Hz), 6.8—7.6 (10H, m, Ph); IR 2050, 1980, 1970, 1960 (ν CO), 1260, 1250 (δ SiMe); Found: C, 61.73, H, 5.77%. Calcd for $C_{25}H_{28}O_3Si_2Fe$: C, 61.47; H, 5.78%. **12**: an oil; MS *m/z* M^+ 488; ^{1}H NMR 0.06 (3H, s, *exo*-SiMe), 0.20 (9H, s, $SiMe_3$), 0.42 (3H, s, *endo*-SiMe), 1.37 (1H, d, H_{6X}, $J_{6X,6N}$=16.5 Hz, 5.91 (1H, s, H_3), 7.0—7.6 (10H, m, Ph); IR (liquid film) 2050, 1975 (ν CO), 1250 (δ SiMe).

Reaction of 7 with $Fe(CO)_5$. A mixture of **7** (105.6 mg, 0.303 mmol), $Fe(CO)_5$ (2 ml, 14 mmol) and dry xylene (4 ml) was heated in an autoclave at 170 °C for 37 h. The solvent and excess $Fe(CO)_5$ were removed in vacuum. The residual oil was separated by TLC to give **7** (36.0 mg, 34.3%) and **10** (66.0 mg, 68.3%).

Reaction of 8 with $Fe(CO)_5$. A mixture of **8** (74.1 mg, 0.213 mmol), $Fe(CO)_5$ (2 ml, 14 mmol) and dry toluene (6 ml) was heated in an autoclave to 160 °C for 22 h. Solvent and unchanged $Fe(CO)_5$ were removed in vacuum. The residual oil was separated by TLC to afford **11** (39.1 mg, 37.5%) and **12** (24.3 mg, 23.4%). **12** was always contaminated with a trace of unidentified compound, which shows same R_f value as **12** on TLC under various conditions.

Thermolysis of 11. **11** (49.0 mg, 0.100 mmol) was sealed under vacuum in a Pyrex tube and was heated in an oil bath at 170 °C for 7 h. The reaction mixture was separated by TLC to give recovered **11** (34 mg) and isomer **12** (13.4 mg).

Thermolysis of 12. In an autoclave the mixture (87 mg) of **12** (0.0462 mmol) containing **7** (0.1848 mmol), $Fe(CO)_5$ (2 ml, 14 mmol) and dry toluene (5 ml) were placed, and heated in an oil bath at 155—180 °C for 123 h. The solvent and excess $Fe(CO)_5$ were removed in vacuum. The residual oil was separated by TLC to give **10** (43.2 mg, 0.0885 mmol), **11** (11.5 mg, 0.0236 mmol), and the mixture (21.0 mg) of **12** and **7**.

We thank Toshiba Silicone Co., Ltd. for a gift of chlorosilanes.

15) This enables us to assign the H_6 methylene proton signals in NMR spectra of these complexes. Since H_{6N} signal of **10** is located at 1.71, the higher field signal (1.25 in **4** and 1.37 in **12**) and the lower field signal (2.10 in **4** and 1.73 in **12**) can be assigned to those of H_{6N} and H_{6N}, respectively, by considering the substituent effect of the trimethylsilyl group on the chemical shift of H_{6N}. The chemical shift of H_6 signal is almost the same in **5** and **11**, and this shows that the configuration of H_6 should be same in these two complexes. On considerations of the effect of the α-phenyl group on the chemical shift of the H_6 signal, H_6 is reasonably assigned to be endo in both **5** and **11**.

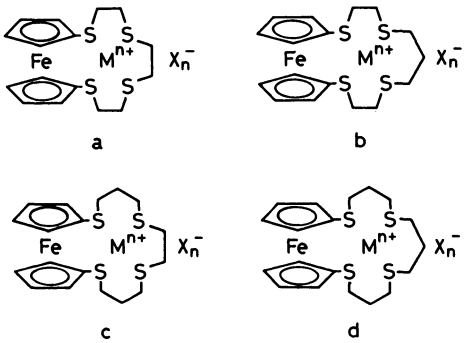
Copper(I), Silver(I), Mercury(II), and Palladium(II) Complexes of Tetrathia[*n*]ferrocenophanes

Masaru SATO,* Shinsuke TANAKA, Sadatoshi AKABORI,† and Yoichi HABATA†
Chemical Analysis Center, Saitama University, Urawa, Saitama 338
†Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274
(Received January 7, 1986)

The complexes of a series of macrocyclic tetrathioether ligands containing a ferrocene nucleus in the macrocycle, tetrathia[*n*]ferrocenophanes, with copper(I), silver(I), mercury(II), and palladium(II) salts were prepared and characterized. The stability of complexes seems to depend on the size of the macrocycles in tetrathia[*n*]ferrocenophanes. The interaction between the iron atom of a ferrocene nucleus and the metal ions incorporated in the macrocycles seems to be negligible in these complexes.

Much attention has recently been focused on organo heterobimetallic compounds from the catalytic and biochemical points of view.[1,2] An organometallic ligand can be an important starting material for preparing heterobimetallic complexes. It is well-known that sulfide ligands make stable complexes with soft metals,[3] and many complexes of the macrocyclic thioether with various metal salts were prepared and characterized.[4–9] The iron atom of ferrocene is a potential coordinate site and certain ferrocene derivatives can form complexes with metal salts.[10,11] We prepared a new type of macrocyclic thioether ligand containing a ferrocene nucleus; polythia[*n*]-[12] and oxathia[*n*]ferrocenophanes.[13] The complex of the latter with silver(I) nitrate was isolated and characterized.[13] We now report on the systematic preparation and some properties of the complex of tetrathia[*n*]ferrocenophanes (**1a—d**) with copper(I), silver(I), mercury(II), and palladium(II) salts.



1. $M^{n+} = X_n^- =$ none
2. $M^{n+} = Cu^+$ $X_n^- = ClO_4^-$
3. $M^{n+} = Ag^+$ $X_n^- = ClO_4^-$
4. $M^{n+} = Hg^{2+}$ $X_n^- = Cl_2^-$
5. $M^{n+} = Pd^{2+}$ $X_n^- = Cl_2^-$

Results and Discussion

Copper(I) Perchlorate Complexes. The addition of anhydrous diethyl ether to a solution of tetrathia[*n*]ferrocenophanes (**1a—d**) and copper(I) perchlorate in acetonitrile afforded the 1:1 complexes (**2a—d**), respectively. The ^{1}H NMR spectra of these complexes (Table 1) shows the proton signals of the Cp-rings at δ ca. 4.4 as a broad singlet or a pair of triplets in acetonitrile-d_3. In the ^{13}C NMR spectra of **2a—d**, the α- and β-carbon signals appeared only as a pair of singlets (Table 2), indicating that complexes

Table 1. ^{1}H NMR Spectral Data of the Ligands **1** and the Complex **2—5** in Acetonitrile-d_3

a) in DMSO-d_6.

2a—d have a symmetrical structure. However, it was confirmed by an X-ray analysis[14] that the Cu(I) atom had a tetrahedral coordination in the complex of 1,4,8,11-tetrathiacyclotetradecane with copper(I) perchlorate, although it was supposed[15] to be located in the central hole of a complex of 1,5,9,13-tetrathiacyclohexadecane with copper(I) tetrafluoroborate. Therefore, the appearance of symmetrical signals for the Cp-rings in the NMR spectra of **2a—d** seems to be due to a rapid dissociative equilibrium since in more coordinatable solvents (e.g. dimethyl-d_6 sulfoxide) complexes are completely dissociated to give NMR spectra of the corresponding free ligands. The IR spectra of **2a—d** (Table 3) showed a strong and broad band at 1140—1060 cm^{-1} and a sharp medium-strength band at about 620 cm^{-1}, indicating that there was only an uncoordinated perchlorate anion in the complexes.[16] A C–S–C medium-strength stretching vibration mode of the free ligand **1a—d** appeared near 680 cm^{-1}, but disappeared in **2b—d**. This suggests a considerably strong coordination of sulfur atoms to the copper(I) atom. In the ^{13}C NMR spectra (Table 2), complexes **2** showed a down-field shift of the α- and β-ring carbon signals, compared with the corresponding free ligands. The electronic spectra of **2** (Table 4) showed a hypsochromic shift and a decreased absorbance of the 440 nm band, assigned to the d–d transition.[17] These spectral data may suggest

Table 4. Electronic Spectral Data of the Ligands 1 and the Complexes **2—4** in Acetonitrile

Ligands / Metal salts		**1a**	**1b**	**1c**	**1d**
None		442 nm (ε 223)	443 nm (ε 196)	443 nm (ε 191)	443 nm (ε 190)
$CuClO_4$	(2)	440 (ε 137)	434 (ε 129)	430 (ε 122)	434 (ε 139)
$AgClO_4$	(3)	438 (ε 195)	437 (ε 185)	—	—
$HgCl_2$	(4)	442 (ε 140)	447 (ε 140)	—	445 (ε 170)[a]

a) The 1:2 complex.

that for complex **2**, Cu(I) atoms coordinate to the sulfur atoms attached to ferrocene nuclei, although the definite structure is unknown at present. As a result, the electron density on a sulfur atom is decreased, resulting in a down-field shift of Cp-ring carbons and a change in the 440 nm band. In complex **2a**, the down-field shift of the Cp-ring carbons in the ^{13}C NMR spectrum and the hypsochromic shift of the 440 nm band in the electronic spectrum was rather small, compared with those of **2b—d**. This suggests that the coordination mode described above may be somewhat different in **2a**.

Silver(I) Perchlorate Complexes. When a solution of the ligand **1a** and silver(I) nitrate in acetonitrile was diluted with anhydrous diethyl ether, a 1:1 complex was precipitated. The 1:1 complexes (**3a** and **3b**) of the tetrathiaferrocenophanes **1a** and **1b** with silver(I) perchlorate were similarly isolated by the reaction of **1a** and **1b** with silver(I) perchlorate, respectively. However, the reaction of **1c** and **1d** with silver(I) salts gave no stable complex. Thus, the complex formation of tetrathia[n]ferrocenophanes with silver(I) salt depends on the size of the thiacrown ether rings. Although some complexes of oxathiacrown ethers with silver(I) nitrate were known,[13,18] the corresponding thiacrown ether complexes are rare. 1,4,8,11-Tetrathiacyclotetradecane has been shown to give the 1:1 and 1:2 complexes with silver(I) perchlorate, though their structures were not confirmed.[19] The absorption for the C–S–C stretching vibration of **3a** and **3b** appeared at about 690 cm^{-1} with decreased intensity compared with that of the corresponding free ligand, suggesting a weak coordination of the sulfur atom to the silver(I) atom in these complexes. In the electronic spectra of **3a** and **3b**, the absorption band near 440 nm, characteristic of a ferrocene nucleus, showed a hypsochromic shift and a decreased absorbance, the extent of which were rather small compared with those of the Cu(I) complexes (vide supra). A similar trend has been observed in the $AgNO_3$-added solution of oxathia[n]-[13] and polythia[n]ferrocenophanes in acetonitrile.[12] Thus, the complexation of silver(I) atoms in the complexes **3a** and **3b** appears to be loose. In the ^1H NMR spectrum of **3a**, the Cp-ring protons of the ferrocene nucleus appears as a pair of triplets at δ 4.44 and 4.36 (J=1.7 Hz) and the methylene protons resonates as two singlets at δ 3.13 and 3.07. The proton signals for the Cp-rings and the methylene groups in **3b** appears at δ 4.42 and 3.3—2.9 as multiplets, respectively. Similar spectra were also obtained upon the addition of silver(I) nitrate to a solution of **1a—d** in CD_3CN–CD_3NO_2 (1:4), suggesting that **1c** and **1d** also formed similarly 1:1 complexes **3c** and **3d** in the solution although they could not be isolated. The size of a silver(I) ion (1.26 Å) is too large to be incorporated into the central hole of the polythia-macrocycle in the ligands **1a** and **1b**. Thus, complexes **3a** and **3b** must have an unsymmetrical structure. Therefore, the symmetrical pattern of the ring proton signals observed in the ^1H NMR spectra, which suggests a symmetrical structure of complex **3**, seems due to a rapid dissociative equilibrium in the solution described in the copper(I) complexes. In the ^{13}C NMR spectra of **3a** and **3b** (Table 2), the bridge-head carbon signal is shifted up-field and the α- anf β-ring carbon signals down-field, compared with those in the corresponding ligands. This also seems to support a loose coordination of silver(I) atoms to the thiacrown moiety of ligands **1**.

Mercury(II) Chloride Complexes. It is well-known that a soft mercury(II) salt forms a wide range of complexes with thioethers,[3] particularly a stable complex with thiacrown ether.[20,21] When an ethereal solution of mercury(II) chloride was added to a solution of **1a** in diethyl ether, the stable 1:1 complex **4a** was isolated in good yield. Similarly, the 1:1 complex **4b** was prepared. However, in a similar manner, **1c** gave no stable complex and **1d** gave the stable 1:2 complex **4d** with mercury(II) chloride. Thus, the complex formation of tetrathia[n]ferrocenophanes with mercury(II) chloride depends on the size of the thiacrown ether ring. In complexes of the thioethers with mercury(II) chloride, of which the crystal structure were determined by X-ray analysis, the coordination about the mercury(II) atom was approximately tetrahedral in the most cases. For example, the coordination mode of a mercury(II) atom in the 1:2 complex of 1,4,8,11-tetrathiacyclotetradecane with mercury(II) chloride is a distorted tetrahedral,[22] while an octahedral coordination is suggested from its IR spectrum in the 1:1 complex of 1,4,8,11-tetrathiacyclotetradecane with mercury(II) chloride.[20] The 1:1 complexes **4a** and **4b** show no blue shifts in their electronic spectra, although their absorbances decrease to a considerable degree. Regarding their ^1H NMR spectra of **4a** and **4b**, a broading of the singlet as well as a small down-field shift (0.1—0.2 ppm) of the Cp-ring protons was observed; but non-symmetrization of the Cp-ring proton signals was not recognized. These spectral data suggests that in **4a** and **4b** the mercury(II) atoms coordinate only to sulfur atoms far away from the ferrocene nucleus of **1a** and **1b**. This may be due to a rather large ion radius (r_{ion}=1.10 Å)[23] that cannot be fitted to the central hole of the ligands **1a** and **1b**. The additional $HgCl_2$ in the 1:2 complex **4d** is probably bonded to the mercury(II) atom coordinated to the sulfur atoms of the macrocycle through the bridging chloro atoms, because the ^1H NMR spectrum of **4d** was very similar with those of **4a** and **4b**.

Palladium(II) Chloride Complexes. The addition of a solution of dichlorobis(acetonitrile)palladium(II)

in acetonitrile to a solution of **1a** and **1c** in acetonitrile gave the stable 1:1 complexes **5a** and **5c**, respectively. Unstable complexes were obtained from **1b** and **1d** by a similar procedure, but could not be characterized. The isolated complexes **5a** and **5c** were very insoluble in almost organic solvents. The ^{1}H NMR spectrum (dimethyl-d_6 sulfoxide) of **5a** showed broad signals at δ 4.45 and 4.37 (1:2), suggesting an unsymmetrical structure of complex **5a**. By contrast, the ring protons in dichloro[1,1′-(bis(isobutylthio)ferrocene)]palladium[24] appears as a symmetric pattern at δ 5.28 and 4.42. In the far-IR spectra of **5a**, the absorption at 327 and 316 cm^{-1} is in the range reported for *cis*-$PdCl_2$ moieties,[25] indicating a monomeric structure, where the Pd atom coordinated to the two sulfur atoms far from the ferrocene nucleus, because of the steric hindrance of large $PdCl_2$ moiety. However, the polymeric structure in which the Pd atom builds a bridge across two ferrocenophanes also cannot be ruled out. Recently, the X-ray analysis of the complex of 1,4,7,10-tetrathia[10]ruthenocenophane with palladium(II) chloride was reported and confirmed that the two sulfur atoms far from a ruthenocene nucleus coordinated to the palladium(II) atom.[26] Therefore, **5a** is suggested to have the same coordination mode with the above complex.

Mössbauer Spectra. The *IS* and *QS* values in ^{57}Fe Mössbauer spectra (300° K) of the free ligands **1** and the metal complexes **2**—**5** are summarized in Table 5. The Mössbauer parameters are little changed in going from the free ligands to the metal complexes. A similar small change was also observed in the complex of 1,1′-bis(diphenylphosphino)ferrocene with mercury(II) chloride.[27] A large change in the *QS* value observed in the complex of [2]ferrocenophanes with mercury(II) chloride[10] and tin(IV) chloride,[11] suggests the direct interaction between the iron atom of a ferrocene nucleus and the metal atoms. The relatively small change observed here seems to indicate that the metal atoms incorporated in the polythia-macrocycle has no strong interaction with the iron atom of a ferrocene nucleus.

Table 5. Mössbauer Parameters of **1**—**5**

Compd	*IS*	*QS*
1a	0.46	2.38
1c	0.42	2.39

5a	0.42	2.33
5c	0.44	2.32

Experimental

Melting points are uncorrected. The electronic spectra were measured on a Hitachi 340 spectrometer. The IR spectra were measured on a JASCO IR-2 spectrometer. The ^{1}H and ^{13}C NMR spectra were obtained on a JEOL FX-90Q spectrometer, TMS being chosen as an internal standard.

Materials. Tetrathia[*n*]ferrocenophanes were prepared as described in a previous paper.[12] Mercury(II) chloride and silver(I) perchlorate were commercially available. Tetrakis(acetonitrile)copper(I) perchlorate[28] and dichlorobis(acetonitrile)palladium(II)[29] were prepared according to the literature.

(1,4,7,10-Tetrathia[10]ferrocenophane)copper(I) Perchlorate (2a). General Procedure. To a solution of 1,4,7,10-tetrathia[10]ferrocenophane (**1a**) (40 mg, 0.1 mmol) in hot acetonitrile (2.5 cm^3) was added a solution of tetrakis-(acetonitrile)copper(I) perchlorate (33 mg, 0.1 mmol) in acetonitrile (2.5 cm^3). The solution was refluxed for 15 min and then diluted with anhydrous diethyl ether (15 cm^3) to form yellow crystals. After the mixture was kept for 2 h in a refrigerator, the crystals were collected by filtration. Yellow leaflets (37 mg, 66%), mp 200 °C (decomp). Found: C, 34.63; H, 3.83%. Calcd for $C_{16}H_{20}ClO_4S_4FeCu$: C, 34.35; H, 3.61%.

(1,4,8,11-Tetrathia[11]ferrocenophane)copper(I) Perchlorate (2b). Yellow leaflets (68%), mp 208 °C (decomp). Found: C, 35.34; H, 3.92%. Calcd for $C_{17}H_{22}ClO_4S_4FeCu$: C, 35.61; H, 3.87%.

(1,5,8,12-Tetrathia[12]ferrocenophane)copper(I) Perchlorate (2c). Yellow crystals (75%), mp ≈214 °C (decomp). Found: C, 37.10; H, 4.16%. Calcd for $C_{18}H_{24}ClO_4S_4FeCu$: C, 36.80%; H, 4.16%.

(1,5,9,13-Tetrathia[13]ferrocenophane)copper(I) Perchlorate (2d). Yellow plates (55%), mp ≈204 °C (decomp). Found: C, 38.16; H, 4.45%. Calcd for $C_{19}H_{26}ClO_4S_4FeCu$: C, 37.93; H, 4.36%.

(1,4,7,10-Tetrathia[10]ferrocenophane)silver(I) Nitrate. To a solution of **1a** (400 mg, 1 mmol) in hot acetonitrile (20 cm^3) was added silver(I) nitrate (170 mg, 1 mmol). After heating for 15 min, the resulting crystals were filtered and washed with hot acetonitrile. Orange crystals (400 mg, 70%), mp ≈180 °C (decomp). ^{1}H NMR (CMSO-d_6) δ=4.46 (s, 8H), 3.18 (s, 8H) and 3.12 (s, 4H). IR (KBr): 2900, 1620, 1380, 1300, 1160, 1020, and 800 cm^{-1}. Found: C, 33.98%; H, 3.56; N, 2.74%. Calcd for $C_{16}H_{20}NO_2S_4FeAg$: C, 34.02; H, 3.56; N, 2.47%.

(1,4,7,10-Tetrathia[10]ferrocenophane)silver(I) Perchlorate (3a). General Procedure. To a solution of **1a** (40 mg, 0.1 mmol) in acetonitrile (10 cm^3) was added silver(I) perchlorate (21 mg, 0.1 mmol). The solution was evaporated up. The yellow oily residue was dissolved in acetonitrile (1 cm^3) and then diluted with anhydrous ether (ca. 2 cm^3). The solution was kept for overnight in a refrigerator. The crystals formed were filtered. Yellow rods (50 mg, 83%), mp ≈190 °C (decomp). Found: C, 32.08; H, 3.42%. Calcd for $C_{16}H_{20}ClO_4S_4FeAg$: C, 31.83; H, 3.34%.

(1,4,8,11-Tetrathia[11]ferrocenophane)silver(I) Perchlorate (3b). Yellow needles (88%), mp 185 °C (decomp). Found:

C, 33.05; H, 3.72%. Calcd for $C_{17}H_{22}ClO_4S_4FeAg$: C, 33.05; H, 3.56%.

Dichloro(1,4,7,10-tetrathia[10]ferrocenophane)mercury(II) (4a). General Procedure. To a solution of **1a** (50 mg, 0.13 mmol) in anhydrous ether (25 cm^3) was added a solution of mercury(II) chloride (35 mg, 0.13 mmol) in anhydrous ether (5 cm^3). The solution was refluxed for 15 min and then kept for overnight at room temperature. The resulting crystals were collected by filtration. Yellow leaflets (60 mg, 69%), mp ≈210 °C (decomp). Found: C, 28.77; H, 3.02%. Calcd for $C_{16}H_{20}Cl_2S_4FeHg$: C, 28.77; H, 3.02%.

Dichloro(1,4,8,11-tetrathia[11]ferrocenophane)mercury(II) (4b). Yellow fine needles (92%), mp 147 °C (decomp). Found: C, 30.11; H, 3.17%. Calcd for $C_{17}H_{22}Cl_2S_4FeHg$: C, 29.94; H, 3.25%.

Tetrachloro(1,5,9,13-tetrathia[13]ferrocenophane)dimercury(II) (4d). Yellow powdery crystals (46%), mp 151 °C (decomp). Found: C, 23.75; H, 2.97%. Calcd for $C_{19}H_{26}Cl_4S_4FeHg_2$: C, 23.25; H, 2.67%.

Dichloro(1,4,7,10-tetrathia[10]ferrocenophane)palladium (II) (5a). General Procedure. To a solution of **1a** (40 mg, 0.1 mmol) in acetonitrile (5 cm^3) was added a solution of dichlorobis(acetonitrile)palladium(II) (26 mg, 0.1 mmol). The solution was kept overnight at room temperature. The resulting crystals were collected by filtration. Brown needles (49 mg, 86%), mp ≈205 °C (decomp). Found: C, 33.80; H, 3.60%. Calcd for $C_{16}H_{20}Cl_2S_4FePd$: C, 33.50; H, 3.51%.

Dichloro(1,5,8,12-Tetrathia[12]ferrocenophane)palladium (II) (5c). Red brown fine crystals (87%), mp ≈185 °C (decomp). Found: C, 36.07; H, 3.91%. Calcd for $C_{18}H_{24}Cl_2S_4FePd$: C, 35.92; H, 4.02%.

^1H and ^{13}C NMR Spectra of the Complex of 1 with Silver(I) Nitrate. ^1H and ^{13}C NMR spectra were measured upon the addition of silver(I) nitrate (1.2 equiv) to a solution of **1a—d** in CD_3CN-CD_3NO_2 (1:4). The spectral data obtained were similar to those of **3a** and **3b** shown in Tables 1 and 2.

We thank Prof. I. Motoyama and Dr. M. Katada (Tokyo Metropolitan University, Department of Chemistry) for measurement of Mössbauer spectra. The present work was supported by a Grant-in-Aid for Science Research (No. 57540274) from the Ministry of Education, Science and Culture.

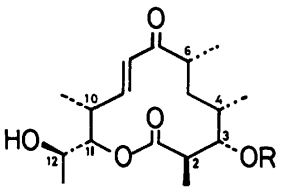
Total Synthesis of Neomethynolide

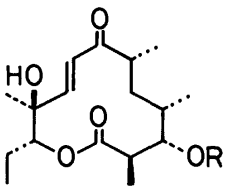
Junji INANAGA,* Yasuhiro KAWANAMI, and Masaru YAMAGUCHI
Department of Chemistry, Faculty of Science, Kyushu University 33,
Hakozaki, Higashi-ku, Fukuoka 812
(Received January 16, 1986)

Neomethynolide (**1**), the aglycone of a twelve-membered ring macrolide, neomethymycin, was totally synthesized in its optically active form via 8,9-didehydro-**1**. The construction of the skeleton was carried out by condensing a stereoselectively synthesized fragment, 4-*t*-butyldimethylsiloxy-5-(2-methoxyethoxymethoxy)-3-methyl-1-hexyne, with Prelog-Djerassi lactonic ester, and mixed anhydride method was used for the lactonization of an intermediary hydroxy acid. The full stereochemistry of **1** was established by this synthesis.

A total synthesis and consequent establishment of whole stereochemistry of neomethynolide (**1**), the aglycone of a macrolide antibiotic, neomethymycin (**2**), have recently been communicated.[1] The full details of the work will be disclosed here.



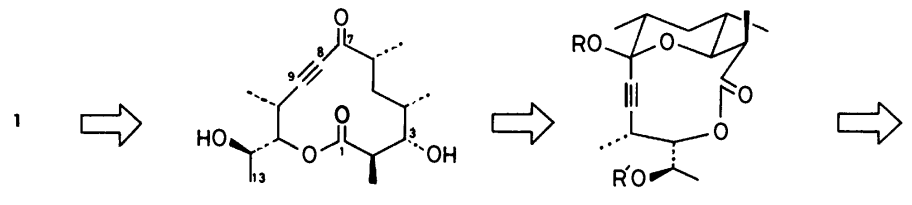
1 Neomethynolide (R=H)
2 Neomethymycin (R=Desosaminyl)



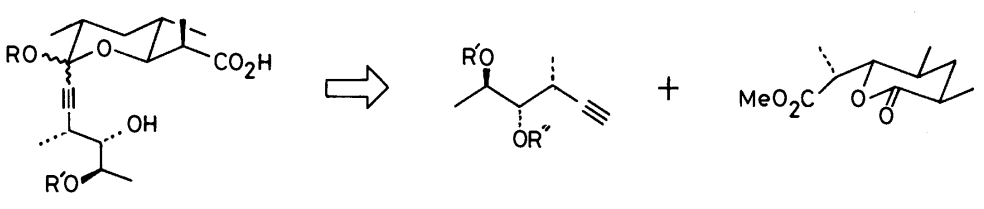
Methynolide (R=H)
Methymycin (R=Desosaminyl)

Neomethymycin belongs besides methymycin and YC-17,[2] to a twelve-membered ring family of typical macrolides and has been isolated from the culture filtrate of *Streptomyces* M-2140.[3a,c] Neomethynolide (**1**) was first obtained by the mild acid-hydrolysis of **2** as the authentic aglycone by Djerassi et al.,[3a,c] and Maezawa et al.[4] later reported that a mutant strain, *Streptomyces venezuelae* MCRL-0376 produced the aglcone **1** itself. Its chemical structure as 10-deoxy-12-hydroxymethynolide was given by Djerassi et al.[3b,c] and the partial stereochemistry, 2*R*, 3*S*, 4*S*, and 6*R*, was later established when Rickards et al.[5] carried out the precise ^{1}H NMR examination of a degradation product (Prelog–Djerassi lactonic acid) and its derivatives. From the analogy with methynolide[6] and on the basis of biogenetic consideration, **1** was also considered to have 10*R*, 11*S*, and 8,9-*trans* configuration though no experimental evidence was available. The present authors further postulated the 12*R* stereochemistry and carried out the synthesis of the compound having a structure represented by **1** in its optically active form.

The basic strategy in the present synthesis is similar in principle to that we previously adopted in the synthesis of methynolide.[7] The 8,9-double bond of the target molecule was introduced as triple bond and the latter was reserved until the later stage of the synthesis. This not only circumvented the instability of δ-hydroxy-α,β-enone structure in the molecule



1 **20** **16 or 17**



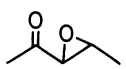
14 or 15 **7** **8**

which tended to undergo vinylogous retro-aldol type cleavage of 10,11-bond[8] but also enabled the choice of well-documented acetylenic ketone synthesis for the construction of basic skeleton by combining C(8)–C(13) (**7**) and C(1)–C(7) (**8**, Prelog–Djerassi lactonic ester) fragments. Instead of our previous procedure with silver acetylide and acid chloride,[7] the direct condensation[9] of lithiated **7** and **8** was adopted this time, which unnecessitated the tedious manipulation of **8** via several steps, and consequently much simplified the synthesis.

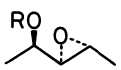
The next point is the use of hemi- or mixed acetal intermediates such as **9**—**17**. The 3-hydroxyl group and the conjugated 7-oxo group were thus intramolecularly protected at the same time minimizing protection-deprotection procedures and preventing the facile cleavage between triple bond and carbonyl group under alkaline hydrolytic conditions.

Lactonization to a highly strained bicyclic compound (**16** or **17**) by virtue of the very efficient mixed anhydride method[10] and the removal of 7-*O*-protection with the concomitant generation of 3-hydroxyl, 7-carbonyl, and monocyclic lactone structure should also be noted.

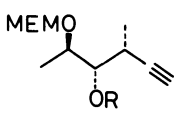
The stereoselective synthesis of the C(8)–C(13) fraction was started with 3,4-epoxy-2-pentanone (**3**).[11] We first examined the reduction of **3** to an *erythro*-epoxy alcohol (**4**) according to the method of Chautemps and Pierre[12] where the reduction with sodium borohydride in methanol at 0 °C was reported to give the *erythro*-isomer predominantly with over 95:5 ratio. However, we could not reproduce the result only obtaining a selectivity of about 72:28, and a number of other reducing agents were then examined under a variety of conditions to obtain higher selectivity. Some results are listed in the Table.



3



4 R=H
5 R=MEM



6 R=H
7 R=TBDMS

Although a sterically-crowded reagent prepared from sodium borohydride and 1-naphthol afforded fairly good *erythro*-selectivity (94:6), it was disadvantageous that excess reagent was required to complete the reaction and that the yield of the product was low (≈36%) mainly because of the difficulty of isolation from a large amount of naphthol which was liberated after aqueous workup (Entry 2). Reduction with sodium hydridobis(2-methoxyethoxy)aluminate (Red-Al), diisobutylaluminum hydride (DIBAL-H), or lithium tri-*t*-butoxyhydridoaluminate did not give satisfactory selectivity. Chelation controlled hydride reduction was then examined with a combination of sodium borohydride and appropriate metal salts. When zinc bromide or chloride was used, a highly stereoselective reduction took place accompanied with concomitant formation of 3-halo-1,2-diols as a result of nucleophilic attack of halogenide ions on epoxide ring (Entries 9 and 10). In order to prevent such ring openings, low nucleophilic counter anions such as fluoride or perchlorate were examined. Thus, by using a mixture of sodium borohydride and zinc perchlorate[13] in ether, the desired *erythro*-epoxy alcohol (**4**) was obtained exclusively in good yield (Entry 12).

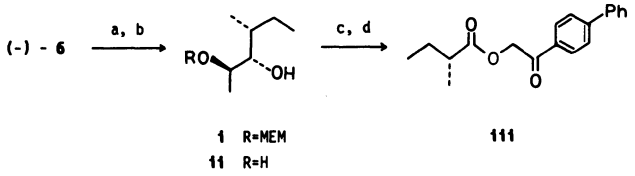
Table 1. Reduction of Epoxy Ketone (**3**) with Various Reducing Agents[a]

Entry	Reducing agent	Solv.	Temp	Time	Ratio[b] (E:T)[c]
1	$NaBH_4$	MeOH	0 °C	30 min	72:28
2	$NaBH_4+3C_{10}H_7OH$[d]	THF	RT	13 h	94: 6
3	Red-Al	THF	−78~0 °C	6 h	81:19
4	DIBAL-H	Toluene	RT	10 min	58:42
5	$LiAlH(OBu^t)_3$	THF	0 °C	10 h	60:40
6	$Zn(BH_4)_2$	DME	0 °C	30 min	60:40
7	$NaBH_4+LiCl$	Et_2O	RT	12 h	76:24[e]
8	$NaBH_4+CaCl_2$	THF	−100 °C	20 min	87:13
9	$NaBH_4+ZnBr_2$	Et_2O	−78~−20 °C	3 h	>95: 5[f]
10	$NaBH_4+ZnCl_2$	THF	−78 °C	6 h	96: 4[g]
11	$NaBH_4+ZnF_2$	Et_2O	RT	10 min	83:17
12	$NaBH_4+Zn(ClO_4)_2$[h]	Et_2O	−78~0 °C	2 h	>95: 5

a) The reaction was carried out in 1 mmol scale with 1.0—1.1 equiv of reducing agent. b) Ratio was determined by ^{13}C NMR analysis of a mixture of epoxy alcohols and/or GLC analysis (Silicone GE, SE-30) of its acetates. c) E=% *erythro*; T=% *threo*. d) $NaBH_4$ (1 equiv) and 1-naphthol (3 equiv) was stirred in THF for several hours until no more hydrogen gas was evolved. e) 4-Chloro-2,3-pentanediol (ca. 20%) was produced as a by-product. f) 4-Bromo-2,3-pentanediol (ca. 8%) was also produced. g) 4-Chloro-2,3-pentanediol (ca. 10%) was also formed. h) Zinc perchlorate hexahydrate was used.

Hydroxyl group of **4** was protected with 2-methoxyethoxymethyl (MEM) chloride and *N,N*-diisopropylethylamine to afford the corresponding MEM ether (**5**) in 80% yield. Reaction of **5** with lithium acetylide-ethylenediamine complex was best performed in dimethyl sulfoxide (DMSO)–hexamethylphosphoric triamide (HMPA) at room temperature to give 65% yield of the desired acetylenic alcohol (**6**).

Resolution of **6** was carried out via its optically active *O*-methylmandelates. Treatment of **6** with (*S*)-(+)-*O*-methylmandelic acid chloride in the presence of 4-dimethylaminopyridine gave a mixture of diastereomeric esters which could be easily separated by column chromatography on silica gel. The early fraction gave, upon hydrolysis, the (−)-alcohol (**6**) in 95% yield. According to the following scheme (−)-**6** was degraded to 2-methylbutyric acid and, on correlation to (*R*)-(−)-*p*-phenylphenacyl 2-methylbutyrate (**iii**),[14] it proved to have a (2*R*,3*S*,4*R*)-configuration required for the synthesis of **1**.

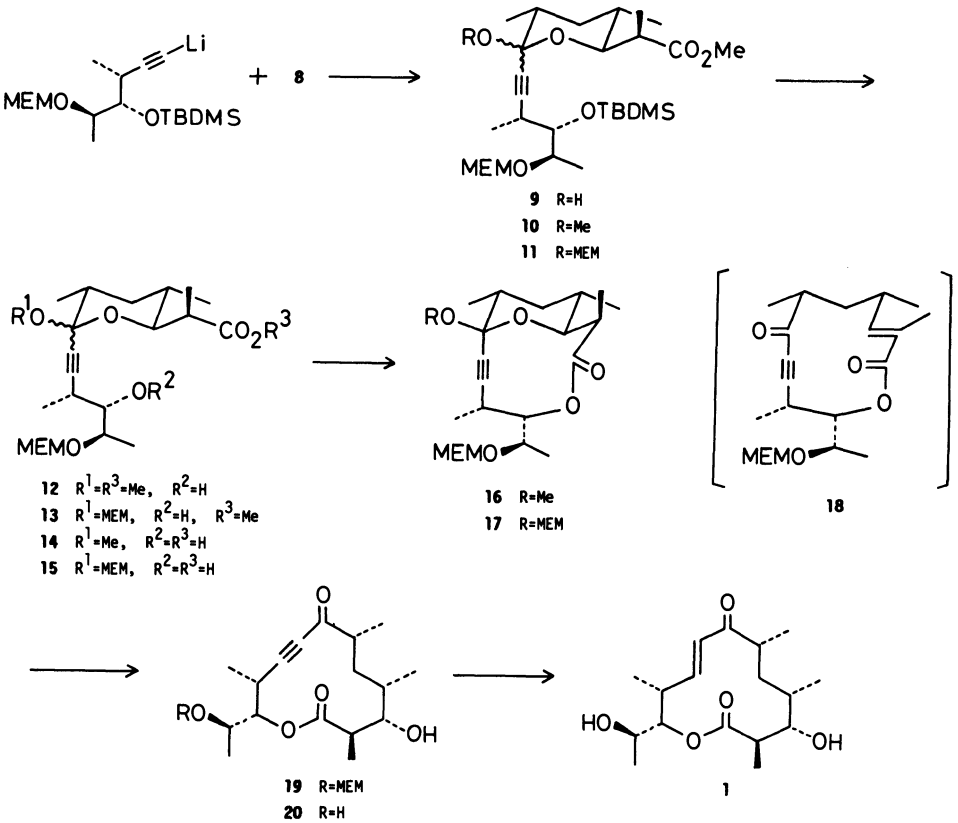


a: H_2/Pt, EtOH. b: HCl-MeOH. c: $NaIO_4$, $KMnO_4$, K_2CO_3, H_2O-Me_2CO. d: p-phenylphenacyl bromide, CsF.

The (−)-alcohol (**6**), thus obtained, was protected with *t*-butyldimethlysilyl (TBDMS) chloride and imidazole in *N,N*-dimethylformamide (DMF) to give the acetylenic silyl ether (**7**) in 98% yield as a key intermediate.

Another key intermediate, (+)-Prelog-Djerassi lactonic ester (**8**) was prepared in an non-stereoselective way according to the method used in the synthesis of methynolide.[15]

Condensation of the two fragments, lithium acetylide of (−)-**7** and (+)-**8**, was carried out in THF at −20 °C affording a mixture of hemiacetals (**9**, ca. 1:3.5 by ^{1}H NMR) in 90% yield. The major isomer was later found to have an equatorial hydroxyl group by converting the above mixture to the corresponding MEM ethers under nonequilibrium conditions followed by the examination of their ^{1}H NMR spectra as will be discussed later. The mixture **9** was treated with a catalytic amount of *p*-toluenesulfonic acid in methanol for 2 h to give an equilibrium mixture of the methyl acetals (**10**) which were difficult to separate. Since it is well-known that the anomeric methoxyl group of six-membered acetals preferentially occupies an axial position under equilibrium conditions,[16] the major isomer of the above methyl acetals (**10**) must have an axial methoxyl group. The relative intensity of the protons of anomeric methoxyl groups at C-7 in ^{1}H NMR spectrum was 3.5 (axial, δ=3.25):1 (equatorial, δ=3.35). On the other hand,



treatment of **9** with MEM chloride and *N,N*-diisopropylethylamine afforded a mixture of MEM ethers (**11**) in 90.4% yield which could be separated by preparative TLC on silica gel. Judging from ^{1}H NMR spectra of the above MEM ethers, the isomeric ratio of axial OMEM (δ=4.71 or 4.73)[17] to equatorial OMEM (δ=4.94)[17] was ca. 1:4, reflecting the original ratio of hemiacetals (**9**). The mixture of methyl acetals (**10**) was desilylated with tetrabutylammonium fluoride and the resulting alcohols (**12**) were hydrolyzed with aqueous methanolic sodium hydroxide to give a ca. 3 (axial OMe):1 (equatorial OMe) mixture of the hydroxy acids (**14**) in 83.3% overall yield. Alternatively, the major, less polar isomer with equatorial OMEM group **11** was converted into a single seco-acid (**15**) by the same procedures as above in 87.6% yield.

Lactonization of the seco-acid mixture **14** and that of **15** were carried out in refluxing benzene by mixed anhydride method using 2,4,6-trichlorobenzoyl chloride.[10] From the examination of molecular models it became apparent that the seco-acid having an axial methoxyl group (or OMEM group) has almost no chance of intramolecular cyclization, however it seems possible to lactonize the seco-acid having equatorial methoxyl group (or OMEM group) at C-7 position though they seem to still suffer from considerable strain in cyclization. In fact, the highly-strained bicyclic lactones (**16**) and (**17**) were obtained in 12.0% and 33.2% yield, respectively. The low yield of **16** compared with that of **17** seems to be due to the low content of the seco-acid with an equatorial methoxyl group in the mixture **14**. In both cases, the 2-unsaturated compound **18** was isolated as a by-product in 9—13% yield.

Deprotection of **16** with 1% trifluoroacetic acid (TFA) in dichloromethane for 14 h gave the mono-MEM ether (**19**) and the diol (**20**) in 61% and 16% yield, respectively. Prolonged reaction or high concentrations of TFA produced a complicated mixture. Pyridinium *p*-toluenesulfonate (PPTS) in refluxing ethanol did not give good result for the generation of the diol (**20**). Treatment of **17** with zinc bromide in dichloromethane also gave **19** and **20** in 38% and 44% yield, respectively. Since **19** could be further converted to **20** in 60% yield with zinc bromide, totally 67% yield of **20** was attained from **17**.

Reduction of 8,9-didehydroneomethynolide (**20**) by chromium(II) sulfate in aqueous DMF[18] at room temperature smoothly gave 65% yield of neomethynolide (**1**) as colorless needles. Melting point and combustion analysis of synthetic **1** revealed that it existed as monohydrate. All spectral data (NMR, IR, UV, Mass) of synthetic **1** as well as melting point of its diacetate were identical with those of the specimens of natural origin and hence the complete stereochemistry of neomethynolide (**1**) was established by the present total synthesis.

Experimental

Melting points and boiling points are uncorrected. IR spectra were determined on a Hitachi R-215, UV spectra on a Hitachi 200-10, and mass spectra on a Hitachi RML-6MG or JEOL JMS-OISG-2 spectrometer. ^{1}H NMR spectra were recorded at either 60 (Hitachi R-20B) or 90 MHz (JEOL JNM-FX90Q) as indicated and ^{13}C NMR spectra at 25 MHz (JEOL JNM-FX90Q) instrument. All NMR spectra were taken in deuteriochloroform solutions with tetramethylsilane as an internal standard. Optical rotations were determined on a Yanagimoto OR-50 Polarimeter.

Reactions were run under an atmosphere of nitrogen unless otherwise stated. Dry solvents were prepared according to the standard procedures. Anhydrous magnesium sulfate was used for drying solutions. Thin-layer chromatography (TLC) was carried out on Merck glass plates precoated with silica gel 60F-254 (0.25 mm).

3,4-Epoxy-2-pentanol (4). 3,4-Epoxy-2-pentanone[11] (**3**, 5.6 g, 56 mmol) was added to a cold (−78 °C) suspension of zinc perchlorate hexahydrate (23.5 g, 63 mmol) in dry ether (50 ml) and stirred for 10 min. Sodium borohydride (2.2 g, 58 mmol) was added all at once and the mixture was stirred vigorously at −78 °C for 1 h and at −78—0 °C for 1 h. The reaction was quenched carefully by the dropwise addition of saturated aqueous $NaHCO_3$ at 0 °C. The precipitate was filtered and washed well with ether. The combined ether solution was washed with saturated aqueous $NaHCO_3$, dried, and concentrated. The crude product was distilled to give **4** (4.4 g, 77%) as an oil: Bp 66—69 °C/2666 Pa; ^{1}H NMR (90 MHz) δ=1.25 (3H, d, J=6.4 Hz), 1.34 (3H, d, J=5.1 Hz), 2.73 (1H, dd, J=3.9 and 2.6 Hz), 3.07 (1H, dq, J=2.6 and 5.4 Hz), 3.18 (1H, broad s), and 3.86 (1H, dq, J=3.9 and 6.4 Hz); ^{13}C NMR δ=17.04, 18.69, 51.28, 62.55, and 65.07. This alcohol proved to be >95% pure *erythro*-**4** by the comparison of its ^{13}C NMR spectrum with that of an authentic mixture of the *erythro*- and the *threo*-epoxy alcohol which was obtained by sodium borohydride reduction of epoxy ketone (**3**) in methanol according to the literature.[12] *threo*-**4**: ^{13}C NMR δ=18.69, 19.42, 52.50, 63.50, and 67.36.

Gas chromatographic analysis (SE-30) of the acetate of **4** also showed the same purity of *erythro*-isomer. Retention time at 75 °C (column temp): *erythro*-**4**, 2.8 min; *threo*-**4**, 3.6 min.

2-(2-Methoxyethoxymethoxy)-3,4-epoxypentane (5). MEM chloride (2.22 ml, 19.4 mmol) was added dropwise to a cold (0 °C) solution of **4** (1.8 g, 17.6 mmol) and *N,N*-diisopropylethylamine (3.69 ml, 21.2 mmol) in methanol-free dichloromethane (18 ml) and the mixture was stirred at room temperature for 20 h. The solvent was evaporated in vacuo and the crude product was extracted with ether, washed successively with saturated aqueous NaCl, 3% aqueous phosphoric acid, and saturated aqueous $NaHCO_3$, dried, concentrated, and distilled to give **5** (2.69 g, 80%): A colorless oil; Bp 65 °C/400 Pa; ^{1}H NMR (60 MHz) δ=1.26 (3H, d, J=6.4 Hz), 1.33 (3H, d, J=5.2 Hz), 2.63 (1H, dd, J=4.8 and 2.4 Hz), 2.98 (1H, dq, J=2.4 and 5.4 Hz), 3.38 (3H, s) 3.3—3.9 (5H, m), and 4.73 (2H, s). Found: C, 56.62; H, 9.56%. Calcd for $C_9H_{18}O_4$: C, 56.82; H, 9.54%.

2-(2-Methoxyethoxymethoxy)-4-methyl-5-hexyn-3-ol (6). A mixture of **5** (190 mg, 1.0 mmol) and lithium acetylide-ethylenediamine complex (184 mg, 2.0 mmol) was stirred in a mixture of DMSO-HMPA (1:1, 2 ml) at room temperature for 60 h. After the addition of water (3 ml), the reaction mixture was saturated with NH_4Cl and extracted with diisopropyl ether. The extract was washed with aqueous NH_4Cl and brine, dried, and concentrated. The crude product was purified by preparative TLC (benzene-ethyl acetate, 8:2) to give the *dl*-acetylenic alcohol (**6**, 139 mg, 64%) as a colorless oil: R_f=0.4; ^{1}H NMR (60 MHz) δ=1.20 (3H, d, J=6.6 Hz), 1.32 (3H, d, J=6.6 Hz), 2.10 (1H, d, J=2.7 Hz), 3.40 (3H, s), 3.4—4.3 (6H, m), and 4.80 (2H, s). Found: C, 60.89; H, 9.42%. Calcd for $C_{11}H_{20}O_4$: C, 61.09; H, 9.32%.

Resolution of the *dl*-Alcohol (6). A mixture of the above *dl*-**6**, (2.40 g, 11.1 mmol), (*S*)-(+)-*O*-methylmandelic acid chloride[19] (2.46 g, 13.3 mmol), and 4-dimethylaminopyridine (1.76 g, 14.4 mmol) in dry dichloromethane was stirred at 40 °C for 65 h. The reaction mixture was diluted with ether and the resulting precipitate was filtered. The filtrate was washed successively with 2% aqueous phosphoric acid, saturated aqueous NaCl, and saturated aqueous $NaHCO_3$, dried, and concentrated. The crude mixture of diastereomeric esters was separated by column chromatography on silica gel (Merck) (petroleum ether-ethyl acetate, 9:1).

The less polar ester (1.83 g, 45.2%): A colorless oil; R_f=0.64 (benzene-ethyl acetate, 4:1); $[\alpha]_D^{23}$ +35.6° (*c* 1.41, $CHCl_3$); IR (neat) 3270 and 1750 cm^{-1}; ^{1}H NMR (90 MHz) δ=0.95 (3H, d, J=6.3 Hz), 1.11 (3H, d, J=6.8 Hz), 2.08 (1H, d, J=2.6 Hz), 2.67 (1H, m), 3.37 (3H, s), 3.44 (3H, s), 3.54 (4H, m), 4.02 (1H, m), 4.57 (2H, s), 4.80 (1H, s) 5.07 (1H, dd, J=8.1 and 4.2 Hz), and 7.2—7.6 (5H, m). Found: C, 65.57; H, 7.65%. Calcd for $C_{20}H_{28}O_6$: C, 65.91; H, 7.74%.

The more polar ester (1.69 g, 41.8%): A colorless oil; R_f=0.56 (benzene-ethyl acetate, 4:1); $[\alpha]_D^{23}$ +51.0° (*c* 1.35, $CHCl_3$); ^{1}H NMR (90 MHz) δ=0.79 (3H, d, J=6.0 Hz), 1.18 (3H, d, J=6.3 Hz), 2.00 (1H, d, J=2.6 Hz), 2.48 (1H, m), 3.39 (3H, s), 3.42 (3H, s), 3.63 (4H, m), 4.16 (1H, m), 4.67 (1H, d, J=7.2 Hz), 4.77 (1H, d, J=7.2 Hz), 4.79 (1H, s), 5.08 (1H, dd, J=8.8 and 3.7 Hz), and 7.2—7.6 (5H, m).

The less polar ester (1.839 g, 5.05 mmol) was stirred with NaOH (440 mg, 11 mmol) in methanol-water (1:1, 8.8 ml) at room temperature for 12 h. After the removal of methanol in vacuo and saturation of the solution with NaCl, the crude product was extracted with ethyl acetate, washed with saturated aqueous NaCl, dried, and concentrated to give (−)-**6** (1.036 g, 95%) as a colorless oil: $[\alpha]_D^{23}$ −24.4° (*c* 1.06, $CHCl_3$).

Similarly, the more polar ester was hydrolyzed to give (+)-**6**: $[\alpha]_D^{23}$ +23.1° (*c* 1.34, $CHCl_3$).

Determination of the Absolute Configuration of (+)-and (−)-Alcohol (6). A solution of (+)-**6** (197.4 mg, 0.913 mmol) in ethanol (2 ml) was shaken with platinum oxide (5 mg) at room temperature for 1 h under an atmosphere of hydrogen. After filtration of the catalyst, the filtrate was concentrated in vacuo to give a saturated alcohol (**i**, 191.6 mg, 95.3%) as a colorless oil: $[\alpha]_D^{23}$ +19.0° (*c* 1.16, $CHCl_3$); ^{1} NMR (60 MHz) δ=0.7—1.8 (12H, m), 2.3 (1H, broad s), 3.3—4.1 (6H, m) 3.40 (3H, s), and 4.77 (2H, s).

The alcohol (**i**, 218.1 mg, 0.99 mmol) was heated with 10% hydrochloric acid at 60 °C for 3 h. The reaction mixture was neutralized at 0 °C and then saturated at room temperature with anhydrous K_2CO_3. The crude product was extracted with ether, dried, concentrated, and subjected to preparative TLC (benzene-ethyl acetate, 1:1) to give the diol (**ii**, 75.3 mg, 58%) as a colorless oil: R_f=0.23; $[\alpha]_D^{23}$ −3.9° (*c* 1.28, $CHCl_3$); ^{1}H NMR (60 MHz) δ=0.7—2.0 (12H, m), 2.6 (2H, broad s), 3.40 (1H, dd, J=6.0 and 4.6 Hz), and 3.6—4.1 (1H, m).

A solution of the diol (**ii**, 25.5 mg, 0.19 mmol) in acetone (0.5 ml) was added to a stirred solution of $NaIO_4$ (123.8 mg, 0.58 mmol) in water (0.5 ml). To this mixture was added a solution of $KMnO_4$ (9.1 mg, 0.058 mmol) and K_2CO_3 (16.0 mg, 0.12 mmol) in acetone-water (1:1, 0.8 ml) and the whole mixture was stirred at 12 °C for 12 h. Insoluble material was filtered and washed with acetone. After evaporation of acetone, Na_2SO_3 (200 mg) was added and the mixture was acidified with 10% aqueous sulfuric acid to give a colorless solution, which was saturated with NaCl. The mixture was extracted with dichloromethane, dried, and concentrated to give crude 2-methylbutyric acid (13.8 mg) as a colorless oil. The acid thus obtained was mixed with CsF (44 mg) in acetonitrile (0.5 ml) and refluxed for 10 min. *p*-Phenylphenacyl bromide (58.4 mg) was added to this and the mixture was refluxed for 3 h. The precipitate was filtered and washed with acetone. After removal of solvents, the residue was subjected to preparative TLC (benzene) to give the pure ester (**iii**, 34.6 mg, 60% from the diol, **ii**) as a crystalline solid: R_f=0.30; $[\alpha]_D^{23}$ + 11.0° (*c* 1.73, C_6H_6); ^{1}H NMR (60 MHz) δ=1.01 (3H, t, J=6.9 Hz), 1.27 (3H, d, J=7.1 Hz), 1.4—2.0 (2H, m), 2.3—2.9 (1H, m), 5.37 (2H, s), and 7.3—8.2 (9H, m).

This ester (**iii**), upon hydrolysis, gave (*S*)-(+)-2-methylbutyric acid: $[\alpha]_D^{23}$ +25.2° (*c* 0.60, H_2O). Lit,[20] $[\alpha]_D^{21.2}$ +19.3° (neat).

(−)-**6** was also converted into the corresponding *p*-phenylphenacyl 2-methylbutyrate in the same manner: $[\alpha]_D^{23}$ −7.6° (*c* 1.06, C_6H_6). Lit,[14] $[\alpha]_D^{23}$ −4°.

4-*t*-Butyldimethylsiloxy-5-(2-methoxyethoxymethoxy)-3-methyl-1-hexyne (7). A mixture of (−)-**6** (1.03 g, 4.77 mmol), TBDMS chloride (1.44 g, 9.55 mmol), imidazole (1.30 g, 19.1 mmol), and dry DMF (5 ml) was stirred at room temperature for 65 h. After removal of solvent under reduced pressure the crude product was extracted with ethyl acetate, washed successively with 3% aqueous hydrochloric acid, saturated aqueous NaCl, and saturated aqueous $NaHCO_3$. Organic layer was dried and concentrated in vacuo to give the practically pure silyl ether (**7**, 1.55 g, 98.4%). Analytical sample was prepared by preparative TLC. A colorless oil; R_f=0.65 (benzene-ethyl acetate, 9:1); $[\alpha]_D^{23}$ −2.0° (*c* 1.01, $CHCl_3$); ^{1}H NMR (90 MHz) δ=0.09 (6H, s), 0.90 (9H, s), 1.14 (3H, d, J=6.3 Hz), 1.21 (3H, d, J=7.2 Hz), 2.07 (1H, d, J=2.6 Hz), 2.48 (1H, m), 3.39 (3H, s), 3.4—3.9 (5H, m), 4.06 (1H, dq, J=6.3 and 3.1 Hz), and 4.74 (2H, s). Found: C, 61.79; H, 10.34%. Calcd for $C_{17}H_{34}O_4Si$: 61.77; H, 10.37%.

Methyl (2*R*,3*S*,4*S*,6*R*,7*S*,10*R*,11*S*,12*R*)-11-*t*-Butyldimethylsiloxy-3,7-epoxy-7-hydroxy-12-(2-methoxyethoxymethoxy)-2,4,6,10-tetramethyl-8-tridecynoate and Its C-7 Epimer (9). A lithium acetylide solution was prepared from (−)-**7** (258 mg, 0.78 mmol) and butyllithium in hexane (1.6 mol

dm^{-3}, 819 μl) by stirring in dry THF (0.8 ml) at room temperature for 1 h. This solution was added dropwise to a cold (−20 °C) solution of (+)-Prelog-Djerassi lactonic acid methyl ester (**8**, 152 mg, 0.709 mmol) in THF (1.4 ml) and the reaction temperature was raised gradually to 0 °C over a period of 1 h. The reaction was quenched by the addition of saturated aqueous NH_4Cl. After evaporation of THF, the crude product was extracted with ethyl acetate, washed with saturated aqueous $NaHCO_3$, dried, and concentrated. The concentrate was subjected to preparative TLC (benzene–ethyl acetate, 3:1) to give a ca. 3.5:1 mixture of hemiacetals (**9**, 348 mg, 90%) as a colorless oil: IR (neat) 3350, 2200, and 1720 cm^{-1}; ^1H NMR[21] (90 MHz) δ=0.09 (3H, s), 0.10 (3H, s), 0.91 (9H, s), 3.38 (3H, s), 3.69 (3H, s), 4.68 (1H, d, J=7.2 Hz), and 4.78 (1H, d, J=7.2 Hz). Found: C, 61.68; H, 9.75%. Calcd for $C_{28}H_{52}O_8Si$: C, 61.73; H, 9.62%. The mixture was used for the next step without separation.

Methyl (2*R*,3*S*,4*S*,6*R*,7*R*,10*R*,11*S*,12*R*)-11-*t*-Butyldimethylsiloxy-3,7-epoxy-7-methoxy-12-(2-methoxyethoxymethoxy)-2,4,6,10-tetramethyl-8-tridecynoate and Its C-7 Epimer (10). A mixture of hemiacetals (**9**, 544 mg, 1.0 mmol) and *p*-toluenesulfonic acid monohydrate (9.7 mg, 0.05 mmol) in methanol (2.4 ml) was stirred at room temperature for 2 h. Saturated aqueous $NaHCO_3$ was added and methanol was removed in vacuo. The crude product was extracted with ethyl acetate, washed with saturated aqueous $NaHCO_3$, dried, and concentrated to give a practically pure mixture of C-7 epimeric methyl acetals (**10**, 550 mg, 98%), which were difficult to separate. The relative intensity of the protons of anomeric methoxyl groups at C-7 in NMR (90 MHz) spectrum was 3.5 (axial, δ=3.25):1 (equatorial, δ=3.35). Analytical sample was prepared by preparative TLC. A colorless oil: R_f=0.71 (benzene–ethyl acetate, 3:1). Found: C, 62.18; H, 9.67%. Calcd for $C_{29}H_{54}O_8Si$: C, 62.33; H, 9.74%.

Methyl (2*R*,3*S*,4*S*,6*R*,7*S*,10*R*,11*S*,12*R*)-11-*t*-Butyldimethylsiloxy-7,12-bis(2-methoxyethoxymethoxy)-3,7-epoxy-2,4,6,10-tetramethyl-8-tridecynoate and Its C-7 Epimer (11). A solution of **9** (458 mg, 0.84 mmol), MEM chloride (384 μl, 3.36 mmol), and *N*,*N*-diisopropylethylamine (644 μl, 3.70 mmol) in methanol-free dry dichloromethane (3.5 ml) was stirred at room temperature for 60 h. After removal of solvent, the crude product was extracted with ethyl acetate, washed with water, 3% aqueous phosphoric acid, brine, and saturated aqueous $NaHCO_3$. Organic layer was dried and concentrated to give a crude C-7 epimeric mixture of the MEM hemiacetals (**11**). The mixture was separated by preparative TLC (benzene–ethyl acetate, 3:1). The less polar zone gave the C-7 equatorial OMEM hemiacetal (384 mg, 72%) as a colorless oil: R_f=0.55; ^1H NMR (90 MHz) δ=0.08, 0.09, and 0.10 (6H, each s), 0.61 (3H, d, J=6.3 Hz), 0.91 (9H, s), 0.94 (3H, d, J=6.4 Hz), 1.11 (3H, d, J=6.1 Hz), 1.18 (3H, d, J=6.4 Hz), 1.26 (3H, d, J=7.0 Hz), 3.37 (3H, s), 3.38 (3H, s), 3.68 (3H, s), 4.73 (2H, s), and 4.94 (2H, s). Found: C, 60.97; H, 9.43%. Calcd for $C_{32}H_{60}O_{10}Si$: C, 60.73; H, 9.56%. The more polar zone gave C-7 axial OMEM hemiacetal (96 mg, 18%) as a colorless oil: R_f=0.41; ^1H NMR (90 MHz) δ=0.10 (6H, s), 0.90 (9H, s), 2.4—3.0 (2H, m), 3.3—4.1 (11H, m), 3.38 (6H, s), 3.68 (3H, s), 4.71 (2H, s), and 4.73 (2H, s).

Methyl (2*R*,3*S*,4*S*,6*R*,7*S*,10*R*,11*S*,12*R*)-3,7-Epoxy-11-hydroxy-7-methoxy-12-(2-methoxyethoxymethoxy)-2,4,6,10-tetramethyl-8-tridecynoate and Its C-7 Epimer (12). A solution of **10** (an epimeric mixture, 217 mg, 0.389 mmol) in dry THF (0.5 ml) was stirred with a THF solution of tetrabutylammonium fluoride (1 mol dm^{-3}, 1.93 ml, 0.82 mmol) at room temperature for 1.5 h. The reaction mixture was neutralized by the addition of saturated aqueous NH_4Cl. After removal of THF under reduced pressure, the crude product was extracted with ethyl acetate, washed with saturated aqueous $NaHCO_3$, dried, and concentrated. Purification by preparative TLC (benzene–ethyl acetate, 1:1) gave the alcohol (**12**, 147 mg, 85%, R_f=0.50) as a ca. 3.3 (axial OMe) : 1 (equatorial OMe) mixture of hemiacetals which were difficult to separate.

Methyl (2*R*,3*S*,4*S*,6*R*,7*S*,10*R*,11*S*,12*R*)-3,7-Epoxy-11-hydroxy-7,12-bis(2-methoxyethoxymethoxy)-2,4,6,10-tetramethyl-8-tridecynoate (13). To a stirred solution of **11** (the equatorial C-7 OMEM epimer, 344 mg, 0.544 mmol) in dry THF (1 ml) was added a tetrabutylammonium fluoride solution in THF (1 mol dm^{-3}, 2.14 ml) and the mixture was stirred at room temperature for 7 h. Similar workup as described above for desilylation of silyl ether (**10**) followed by preparative TLC (benzene–ethyl acetate, 1:1) of the crude product gave **13** (261 mg, 93%) as a colorless oil: R_f=0.43; ^1H NMR (90 MHz) δ=0.82 (3H, d, J=6.1 Hz), 0.94 (3H, d, J=6.6 Hz), 1.12 (3H, d, J=7.2 Hz), 1.26 (3H, d. J=6.1 Hz), 1.30 (3H, d, J=7.0 Hz), 2.46—2.94 (2H, m), 3.38 (3H, s), 3.40 (3H, s), 3.68 (3H, s), 4.78 (2H, m), 4.85 (1H, d, J=6.3 Hz), and 5.05 (1H, d, J=6.3 Hz). Found: C, 59.84; H, 8.85%. Calcd for $C_{26}H_{46}O_{10}$: C, 60.21, H, 8.94%.

(2*R*,3*S*,4*S*,6*R*,7*S*,10*R*,11*S*,12*R*)-3,7-Epoxy-11-hydroxy-7-methoxy-12-(2-methoxyethoxymethoxy)-2,4,6,10-tetramethyl-8-tridecynoic Acid and Its C-7 Epimer (14). An epimeric mixture of **12** (277 mg, 0.624 mmol), aqueous NaOH (1 mol dm^{-3}, 940 μl) and methanol (940 μl) was stirred at room temperature for 12 h. After removal of methanol under reduced pressure the crude product was diluted with a small amount of water and washed with ether. The aqueous alkaline layer was acidified (pH≈4) with 3% aqueous phosphoric acid. The organic acid was extracted with ethyl acetate, washed with saturated aqueous NaCl, dried, and concentrated to give **14** (263 mg, 98%) as a viscous oil. Anomeric isomers ratio was ca. 3 (axial OMe, δ=3.30) : 1 (equatorial OMe, δ=3.37).

(2*R*,3*S*,4*S*,6*R*,7*S*,10*R*,11*S*,12*R*)-3,7-Epoxy-11-hydroxy-7,12-bis(2-methoxyethoxymethoxy)-2,4,6,10-tetramethyl-8-tridecynoic Acid (15). A mixture of **13** (166.5 mg, 0.32 mmol), aqueous NaOH (1 mol dm^{-3}, 482 μl), and methanol (482 μl) was stirred at room temperature for 12 h. Usual workup as described above for saponification of **12** gave the hydroxy acid (**15**, 157 mg, 97%) as a viscous oil, which was dried over P_2O_5 under vacuum at 50 °C for 40 h. ^1H NMR (90 MHz) δ=0.84 (3H, d, J=6.1 Hz), 0.94 (3H, d, J=6.3 Hz), 1.12 (3H, d, J=6.8 Hz), 1.19 (3H, d, J=6.1 Hz), 1.35 (3H, d, J=6.8 Hz), 3.37 (3H, s), 3.40 (3H, s), 4.84 (2H, s), and 4.99 (2H, s).

(1*S*,2*R*,5*S*,6*R*,9*S*,10*R*,12*S*,1′*R*)-4,13-Dioxa-9-methoxy-5-[1-(2-methoxyethoxymethoxy)ethyl]-2,6,10,12-tetramethylbicyclo[7.3.1]tridec-7-yn-3-one (16). 2,4,6-Trichlorobenzoyl chloride[22] (90.9 μl, 0.566 mmol) was added to a solution of **14** (243.4 mg, 0.566 mmol) and triethylamine (85.8 μl, 0.679 mmol) in dry THF (1.5 ml). The mixture was stirred at room temperature for 4 h and then filtered through a Celite column. The filtrate was diluted with dry benzene (420 ml)

and added to a refluxing solution of 4-dimethylaminopyridine (414 mg, 340 mmol) in benzene (150 ml) over 24 h. After additional refluxing for 1 h the reaction mixture was washed successively with water, 3% aqueous phosphoric acid, saturated aqueous NaCl, and saturated aqueous $NaHCO_3$. Organic layer was dried and concentrated to give the crude product (219 mg), which was subjected to preparative TLC (benzene-ethyl acetate, 3:1). The bicyclic lactone (**16**, 28 mg, 12%): A coloress oil: R_f=0.60; $[\alpha]_D^{25}$ +5.64° (*c* 1.24, $CHCl_3$); ^1H NMR (90 MHz) δ=0.86 (3H, d, *J*=6.4 Hz), 0.89 (3H, d, *J*=6.3 Hz), 1.11 (3H, d, *J*=7.0 Hz), 1.24 (3H, d, *J*=5.1 Hz), 1.31 (3H, d, *J*=6.6 Hz), 2.6—3.2 (2H, m), 3.39 (6H, s), 3.4—4.0 (5H, m), 4.34 (1H, dd, *J*=10.3 and 2.2 Hz), 4.69 (1H, d, *J*=7.2 Hz), 4.83 (1H, dd, *J*=9.2 and 2.6 Hz), and 4.85 (1H, d, *J*=7.2 Hz). An elimination product (**18**, 26 mg, 12%): A colorless oil: R_f=0.53; $[\alpha]_D^{25}$ +97.3° (*c* 1.13, $CHCl_3$): IR ($CHCl_3$) 2200, 1700, and 1670 cm^{-1}; ^1H NMR (90 MHz) δ=1.07 (3H, d, *J*=6.8 Hz), 1.10 (3H, d, *J*=6.6 Hz), 1.33 (3H, d, *J*=6.1 Hz), 1.40 (3H, d, *J*=7.0 Hz), 1.87 (3H, d, *J*=1.3 Hz), 3.39 (3H, s), 4.72 (1H, d, *J*=7.2 Hz), 4.83 (1H, dd, *J*=3.5 and 7.4 Hz), 4.84 (1H, d, *J*=7.2 Hz), and 6.94 (1H, dq, *J*=10.9 and 1.3 Hz).

(1*S*,2*R*,5*S*,6*R*,9*S*,10*R*,12*S*,1′*R*)-4,13-Dioxa-9-(2-methoxyethoxymethoxy)-5-[1-(2-methoxyethoxymethoxy)ethyl]-2,6,10,12-tetramethylbicyclo[7.3.1]tridec-7-yn-3-one (17). 2,4,6-Trichlorobenzoyl chloride (50.0 µl, 0.311 mmol) was added to a solution of **15** (156.9 mg, 0.311 mmol) and triethylamine (47.1 µl, 0.342 mmol) in anhydrous THF (1 ml). After stirring at room temperature for 3 h, the resulting precipitate was filtered though a Celite column. The filtrate was diluted with dry benzene (150 ml) and added to a refluxing solution of 4-dimethylaminopyridine (227.6 mg, 1.87 mmol) in benzene (50 ml) over 20 h. Similar workup as described above for the lactonization of **14** gave the crude product (160.4 mg), which was subjected to preparative TLC (benzene-ethyl acetate, 3:1). The bicyclic lactone (**17**, 50.2 mg, 33.2%): A colorless oil: R_f=0.25; $[\alpha]_D^{25}$ +17.2° (*c* 0.29, $CHCl_3$): ^1H NMR (90 MHz) δ=0.85 (3H, d, *J*=5.6 Hz), 0.92 (3H, d, *J*=5.9 Hz), 1.08 (3H, d, *J*=7.0 Hz), 1.23 (3H, d, *J*=5.9 Hz), 1.30 (3H, d, *J*=6.3 Hz), 2.5—3.2 (2H, m), 3.39 (6H, s), 3.4—4.0 (8H, m), 4.36 (1H, dd, *J*=10.1 and 2.3 Hz), 4.68 (1H, d, *J*=7.2 Hz), 4.82 (1H, dd, *J*=9.0 and 2.6 Hz), 4.84 (1H, d, *J*=7.2 Hz), 4.93 (1H, d, *J*=5.9 Hz), and 5.06 (1H, d, *J*=5.9 Hz). Found: C, 61.65; H, 8.68%. Calcd for $C_{25}H_{42}O_9$: C, 61.70; H, 8.70%. The elimination product (**18**, 10.0 mg, 8.5%) was also isolated.

7,8-Didehydro-12-*O*-(2-methoxyethoxymethyl)neomethynolide (19) and 7,8-Didehydroneomethynolide (20). $ZnBr_2$ (42.8 mg, 0.19 mmol) was added to a solution of **17** (18.4 mg, 0.038 mmol) in dry dichloromethane (5 ml) and the mixture was subjected to ultrasonication at room temperature for 1 h. Another portion of $ZnBr_2$ (42.8 mg) was added and treated in a ultrasonic bath for 1 h. This procedure was repeated twice and then the mixture was further stirred at room temperature for 12 h. Saturated aqueous $NaHCO_3$ was added and the crude product was extracted with ethyl acetate, washed with saturated aqueous NaCl, dried, and concentrated. The concentrate was subjected to preparative TLC (benzene-ethyl acetate, 1:1) to give 8,9-didehydroneomethynolide (**20**) and its 12-*O*-MEM ether (**19**). **20**: colorless needles (5.5 mg, 44%): R_f=0.45; Mp 74—76 °C (monohydrate); $[\alpha]_D^{24}$ +27.0° (*c* 0.223, MeOH); IR ($CHCl_3$) 2200, 1725, 1660, and 1210 cm^{-1}; UV (EtOH) 220 nm (log ε=4.27); ^1H NMR (90 MHz) δ=0.97 (3H, d, *J*=6.3 Hz), 1.17 (3H, d, *J*=6.8 Hz), 1.22 (3H, d, *J*=6.1 Hz), 1.36 (6H, d, *J*=7.0 Hz), 3.24 (1H, m), 3.65 (1H, broad d, *J*=9.6 Hz), 3.86 (1H, m), and 5.03 (1H, dd, *J*=9.0 and 3.1 Hz); MS *m/z* 310 (M-18). Found: C, 62.21; H, 8.46%. Calcd for $C_{17}H_{26}O_5 \cdot H_2O$: C, 62.17; H, 8.59%.

19: A colorless oil (5.8 mg, 38%): R_f=0.59; $[\alpha]_D^{24}$ +15.5° (*c* 0.517, MeOH); ^1H NMR (90 MHz) δ=0.97 (3H, d, *J*=6.6 Hz), 1.16 (6H, d, *J*=6.3 Hz), 1.33 (3H, d, *J*=7.0 Hz), 1.35 (3H, d, *J*=6.6 Hz), 3.18 (1H, m), 3.39 (3H, s), 4.69 (1H, d, *J*=7.2 Hz), 4.83 (1H, d, *J*=7.2 Hz), and 5.11 (1H, dd, *J*=9.0 and 2.6 Hz).

19 (9 mg, 0.0226 mmol) and $ZnBr_2$ (127 mg, 0.564 mmol) were stirred in dichloromethane-nitromethane (10:1, 2.2 ml) at room temperature for 8 h. Similar workup as above followed by preparative TLC gave **20** (4.5 mg, 60%) and the starting **19** (1.5 mg, 17%).

8,9-Didehydroneomethynolide (20) from 16. A solution of **16** (8.8 mg, 0.0213 mmol) and trifluoroacetic acid (88 µl) in dry dichloromethane (8.8 ml) was stirred at room temperature for 14 h. Saturated aqueous $NaHCO_3$ was added and the crude product was extracted with ethyl acetate, washed with water, dried, and concentrated. The concentrate was subjected to preparative TLC (benzene-ethyl acetate, 1:1) to give **20** (1.1 mg, 16%) and **19** (5.2 mg, 61%).

Neomethynolide (1) Monohydrate. To a stirred solution of **20** (7.0 mg, 0.022 mmol) in absolute DMF (700 µl) was added an aqueous solution of chromium(II) sulfate[18] (1 mol dm^{-3}, 700 µl) and the mixture was stirred at room temperature for 10 h. The resulting deep green solution was saturated with ammonium sulfate, extracted with ethyl acetate, washed with saturated aqueous NaCl, dried, and concentrated in vacuo. The crude product was subjected to preparative TLC (benzene-ethyl acetate, 1:1) to give neomethynolide (**1**, 4.6 mg, 65%, R_f=0.28). Crystallization from acetone-hexane mixture gave colorless needles: Mp 92—93 °C (monohydrate) $[\alpha]_D^{24}$ +112.5° (*c* 0.160, MeOH); IR ($CHCl_3$) 1725, 1685, 1625, and 1215 cm^{-1}; UV (EtOH) 227 nm (log ε=4.08); ^1H NMR (90 MHz) δ=0.9—1.4 (15H, m), 3.57 (1H, broad d, *J*=10.7 Hz), 3.89 (1H, m), 4.83 (1H, dd, *J*=9.2 and 2.4 Hz), 6.42 (1H, dd, *J*=15.8 and 0.9 Hz), and 6.79 (1H, dd, *J*=15.8 and 5.0 Hz). Found: C, 61.54; H, 9.17%. Calcd for $C_{17}H_{28}O_5 \cdot H_2O$: C, 61.79; H, 9.15%. Found: *m/z* 312.1931. Calcd for $C_{17}H_{28}O_5$: M, 312.1935. Lit,[3c] Mp 90—120 °C (monohydrate); $[\alpha]_D$ +108° ($CHCl_3$); IR($CHCl_3$) 2.93, 5.75, 5.90, and 6.10 µ; UV (EtOH) 227.5 nm (log ε=4.10).

Neomethynolide Diacetate. This was prepared from **1** (monohydrate) and acetic anhydride in the presence of 4-dimethylaminopyridine. Colorless needles (acetone-hexane): Mp 198—199 °C; $[\alpha]_D^{25}$ +82° (*c* 0.123, MeOH); IR ($CHCl_3$) 1740, 1690, 1630, and 1240 cm^{-1}; ^1H NMR (90 MHz) δ=0.8—1.4 (15H, m), 2.08 (3H, s), 2.09 (3H, s), 4.9—5.3 (3H, m), 6.4 (1H, dd, *J*=5.5 and 0.9 Hz), and 6.76 (1H, dd, *J*=5.5 and 4.8 Hz); MS *m/z* 396 (M^+). Found: C, 63.53; H, 8.17%. Calcd for $C_{21}H_{32}O_7$: C, 63.61; H, 8.14%. Lit,[3c] Mp 199—201 °C; $[\alpha]_D$ +84° ($CHCl_3$); IR ($CHCl_3$) 5.71, 5.88, and 6.08 µ.

The authors are grateful to Dr. Akio Kinumaki of Microbiological Reseach Laboratory, Tanabe Seiyaku Company Ltd. for the generous supply of NMR data

of natural neomethynolide. This work was partially supported by a grant-in-Aid for Scientific Research No. 443008 from the Ministry of Education, Science and Culture.

Seebach, *Liebigs Ann. Chem.*, **1983**, 939. We further modified the latter method as follows giving a higher yield: To a cold solution of 1,3,5-trichlorobenzene (290 mg, 1.6 mmol) in dry THF (10 ml) at −78 °C was added slowly a hexane solution of *n*-BuLi (1.63 mol dm^{-3}, 1.0 ml) and the mixture was stirred for 2 h at the same temperature. Dry carbon dioxide was bubbled in over 15 min at −78 °C and then the cooling bath was removed. Gas evolution started around 0 °C. After stirring for 30 min at room temperature, solvent was evaporated. The resulting solid was dissolved in water and washed with ether. The aqueous layer was saturated with NaCl and acidified by the addition of aqueous HCl (5 mol dm^{-3}). The product was extracted with ether, dried over anhydrous Na_2SO_4, and concentrated to give the acid as white crystalline solid (343 mg, 95%). The sample had an enough purity (^1H NMR) for the conversion to the corresponding acid chloride.

The Effect of Triple-Ion Formation on the Electron-Exchange Reaction Rate between Quinone and Semiquinone Anion Radical

Tsuyoshi TAKIGUCHI,† Kosaku SUGA,* and Shigeru AOYAGUI
Department of Chemical Engineering, Tokyo Institute of Technology,
Ohokayama, Meguro-ku, Tokyo 152
(Received October 23, 1985)

The rate constant and activation parameters of electron-exchange reactions between duroquinone, *p*-benzoquinone and 2,5-di-*t*-butyl-*p*-benzoquinone and their respective semiquinone anions which form ion-pairs or triple-ions with Na^+ and K^+ were determined. The rate constants of triple-ions were smaller than those of corresponding ion-pairs; the rate constants of potassium ion pairs and triple-ions were larger than those of the corresponding sodium aggregates; and the rate constants of triple-ions decreased upon increasing the size of the substituent for quinone. These results were explained on the basis of a mechanism which is generally accepted for electron-exchange reactions of ion pairs of anion radicals.

Although a considerable amount of work concerning the rates of electron-exchange reactions between aromatic compounds and their anion radicals, forming ion pairs, have been published, few results have been reported for anion radicals forming triple-ions.[1] Szwarc et al. compared the rate constant of the electron-exchange reaction for a duroquinone (DQ)/duroquinone anion (DQ^-) ion-pair system with that for a DQ/DQ^- triple-ion system.[1] Their results, unfortunately, only showed that the conversion of the ion-pair into the triple-ion influenced the rate of the electron-exchange reaction very little.

In the present work, we report on systematic measurements of the rate constants and activation parameters of electron-exchange reactions between DQ, *p*-benzoquinone (BQ), and 2,5-di-*t*-butyl-*p*-benzoquinone (2,5-DBBQ) and their respective semiquinone anions which form ion pairs or triple-ions with Na^+ and K^+ ions. We also examine whether the mechanism is applicable to the case of triple-ions which is generally accepted for the electron exchange of ion-pairs of anion radicals.[2,3]

Experimental

BQ was purified by sublimation. Commercial 2,5-DBBQ, 2,6-DBBQ, DQ, and sodium tetraphenylborate (NaTPhB) were used as obtained. Potassium tetraphenylborate (KTPhB) was prepared by a double decomposition of NaTPhB and potassium chloride. Tetrahydrofuran (THF) was purified in the same way as previously described.[4] Semiquinone anion radicals (Q^-) were prepared in vacuo by reducing their parent molecules (Q) with an anthracene anion radical. Solutions of triple ions were prepared by adding a weighed amount of dry alkali metal tetraphenylborate into the solutions of Q^- ion pairs. The rate constants of electron-exchange reactions were determined from the broadening of ESR spectra peaks which did not overlap each other. When direct measurements of line widths were difficult because of overlapping, rate constants were determined by computer simulation using a modified Bloch equation. X-band ESR spectra were recorded on a JEOL FE3X1 ESR spectrometer equipped with a variable-temperature adapter.

Results and Discussion

In Figs. 1 and 2, as tentative examples, we show the ESR Spectra for solutions of sodium ion-pair of DQ^- ($DQ^-\cdot Na^+$) and the sodium triple-ion of DQ^- ($DQ^-\cdot Na_2^{2+}$) containing different amounts of DQ at room temperature. The parameters for the ESR spectra of ion pairs and triple-ions measured in this

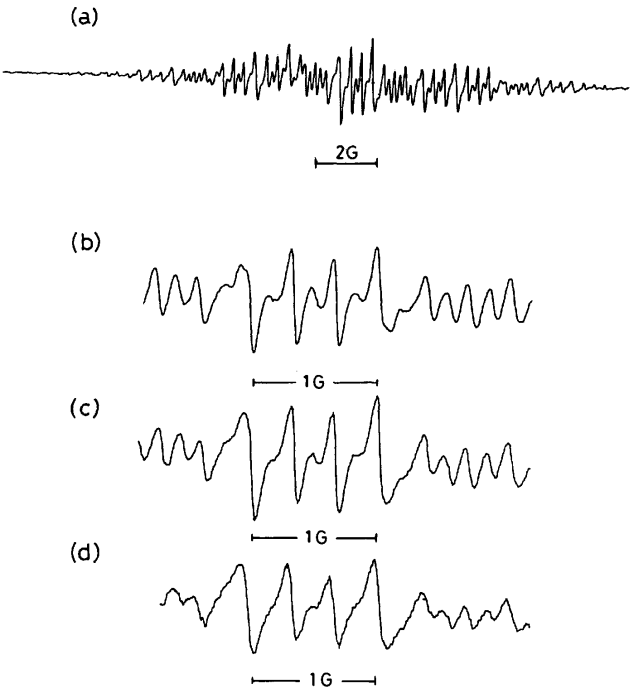

Fig. 1. ESR spectra for the ion-pair of DQ^- with sodium cation ($DQ^-\cdot Na^+$) in THF at 25 °C: (a) the whole spectrum; (b)—(d) central parts of the spectra in the presence of 0 mM, 0.67 mM, and 1.34 mM DQ respectively.

† Present address: Department of Electronic Chemistry, Graduate School of Nagatuta, Tokyo Institute of Technology, Nagatuta, Midori-ku, Yokohama 227.

experiment generally coincided with the values from the literatures.[5,6,7] In all cases, the line width of the ESR spectrum increased with the amounts of DQ as shown in Fig. 1 (b)—(d) and Fig. 2 (b)—(d). The rate constants and activation parameters obtained are shown in Table 1, where $Q^-\cdot M^+$ and $Q^-\cdot M_2^{2+}$ represent ion-pair and triple-ion, respectively. The free energy (ΔG^*), enthalpy (ΔH^*) and entropy (ΔS^*) of activation were determined by the use of Marcus' equation.

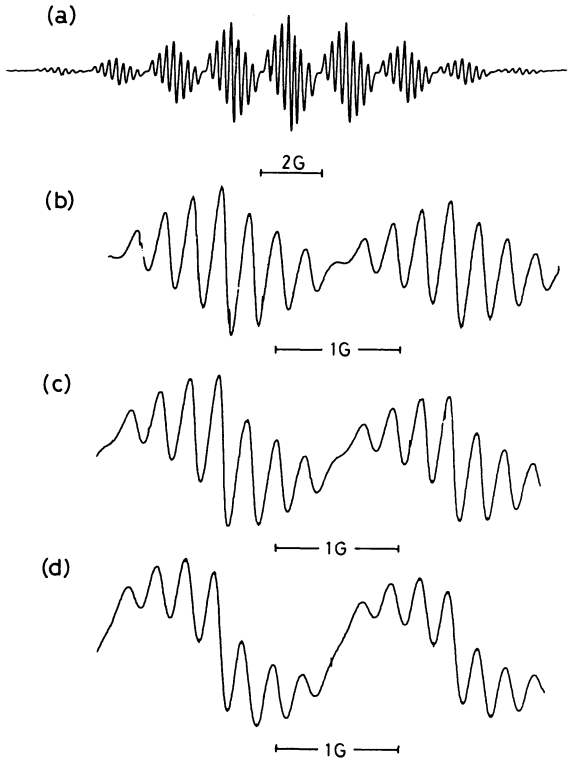

Fig. 2. ESR spectra for the triple-ion of DQ^- with sodium cations ($DQ^-\cdot Na_2^{2+}$) in THF containing 3.5 mM NaTPhB at 25 °C: (a) the whole spectrum; (b)—(d) the central parts of the spectra in the presence of 0 mM, 2.5 mM, and 5.0 mM DQ respectively.

The value of the rate constant for $DQ^-\cdot Na_2^{2+}/DQ$ listed in Table 1 agreed well with that reported by Szwarc et al.: $k=8.7\times10^7$ M^{-1} s^{-1}.[1] However, they have only showed that the rate constant for $DQ^-\cdot Na_2^{2+}/DQ$ was little different from k for $DQ^-\cdot Na^+$ in contrast to our results.

The results listed in Table 1 have the following marked trends without exceptions: (a) The rate constants for triple-ions are smaller than those for ion-pairs; (b) the rate constants for potassium ion-pairs and triple-ions are larger than those for the corresponding sodium aggregates respectively; (c) ΔG^* of $Q^-\cdot M_2^{2+}$ increases with the size of substituents of Q, and this tendency is more prominent in $Q^-\cdot Na_2^{2+}$ than in $Q^-\cdot K_2^{2+}$.

On the other hand, the activation parameters of these electron-transfer reactions, except ΔG^*, have no clear trends like the rate constants or ΔG^*. At present, it is difficult to discuss the contribution of ΔH^* and $-T\Delta S^*$ to ΔG^* in these electron-transfer reactions. Therefore, we will now discuss the trends of the rate constants or ΔG^* described above.

These trends can be explained as follows. According to studies on the electron exchange reactions of ion pairs and triple-ions of anion radicals, it has been concluded that counter cations should transfer simultaneously with electrons.[1,2] Cations which form ion-pairs and triple-ions with semiquinone anions are surrounded by solvation shells and, therefore, a substantial expenditure of energy is needed to reorganize them to make an activated complex with a symmetric configuration before and after an electron-exchange reaction. This energy may contribute to the activation free energy for the

a) At 25 °C. b) At 0 °C.

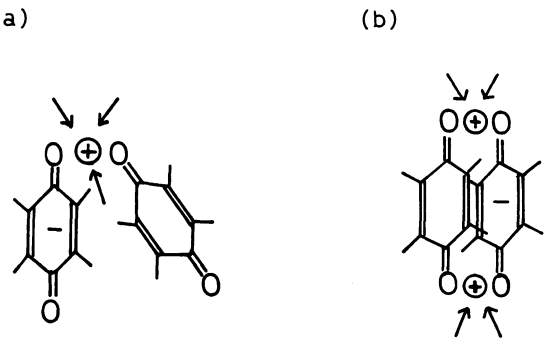

Fig. 3. Schematic illustration of activated complexes for the electron transfer reactions between quinone and its anion radical: (a) ion-pair; (b) triple-ion.

exchange reaction. When the cation is smaller, it is so much more strongly solvated that the energy barrier is higher and the rate of exchange reaction is smaller. Therefore, the rate constants of ion pairs or triple-ions with sodium ions are expected to be smaller than those for potassium aggregates. In the case of a triple-ion, where two counter ions interact with an anion, the reorganization energy of solvent molecules becomes larger than that in the case of an ion pair. Thus, trends (a) and (b) can be explained reasonably.

On the other hand, trend (c) can be interpreted as follows. The expected symmetric transition state involving semiquinone anion ion-pair might be schematically described as in Fig. 3(a). In this Figure, arrows indicate solvent orientations. It can be seen from this scheme that the relative angles between the both O–O axes and between the planes of two quinone molecules are variable. In contrast to the ion pair, in the case of triple-ion, the O–O axes of two quinone molecules must be parallel in symmetric transition state as illustrated schematically in Fig. 3(b). Therefore, as the size of substituents of Q become larger, the steric hindrance increases $\Delta G^{\ddagger}$ which is required to form the activated complex. This steric hindrance may be more prominent in $Q^{-}\cdot Na_2^{2+}/Q$ with smaller cation than in $Q^{-}\cdot K_2^{2+}/Q$. Thus, trend (c) also can be interpreted on the basis of the mechanism mentioned above, considering the steric hindrance in activation complexes.

These explanations indicate that the generally accepted mechanism of the electron-exchange reactions of ion-pairs of anion radicals can also be applied to the electron-exchange reactions of triple-ions.

We wish to thank Profs. Hiroshi Fukutomi and Hiroshi Tomiyasu for the use of facilities for the ESR measurement at The Research Laboratory for Nuclear Reactors in Tokyo Institute of Technology.

Adsorption of Cationic Surfactants on Phospholipid Membranes and Its Contributions to Membrane-Surface Potential

Hideo MATSUMURA,* Miyako IWAMOTO,† and Kunio FURUSAWA†
Electrotechnical Laboratory, Sakura-Mura, Ibaraki 305
†Department of Chemistry, The University of Tsukuba, Sakura-Mura, Ibaraki 305
(Received October 31, 1985)

The adsorption behavior of cationic surfactants (alkyltrimethylammonium ions) on the phospholipid (phosphatidylethanolamine) membranes has been studied by means of interfacial electrostatic measurements, i.e., the surface potential of the monolayer and the zeta potential of the vesicles, in order to elucidate the balance between hydrophobic and electrostatic interactions. The data have been analyzed in terms of the interfacial electrochemical concept; these analyses have revealed that the hydrophobic interaction of a surfactant with the phospholipid membrane is the main motive force for adsorption and there is a critical alkyl-chain length to promote the surfactant adsorption. Furthermore, it was found that the electrostatic interactions between the surfactant and the phospholipid membrane, and among the surfactants themselves, also play a role in their adsorption.

The interaction of surfactants with the lipid membrane, especially with the lipid vesicles, has been studied extensively out of interest in the solubilization or fusion of biological membranes and their antibacterial action. The nonionic surfactant has been utilized as a solubilizer of the biological membrane because of its mild property of not destroying the biological function of the membrane components. On the other hand, studies of ionic surfactants have focused on their antibacterial properties. Quaternary ammonium compounds are typical cationic surfactants, and the antibacterial activity of a series of aliphatic quaternary ammonium salts have been studied.[1,2] The length of the hydrocarbon chain is one of the most significant factors controlling the antibacterial activity.[1] Shelton et al.[2] reported that an alkyltrimethylammonium bromide which contains less than eight carbon atoms in its alkyl group shows little antibacterial activity.

As well as the above practical interest, the adsorption of ionic surfactants on various interfaces has been studied out of interest in interfacial electrochemistry. For example, the effect of the surfactant adsorption on the zeta potential of a solid–water interface[3] and that on the electrocapillary curve at the oil–water interface[4] have been studied by many researchers.

In this work, the adsorption behavior of alkyltrimethylammonium bromides on the lipid membranes has been studied from the viewpoint of interfacial electrochemistry. As lipid membranes, phospholipid vesicles and monolayers spread on the aqueous solution were employed, and the change in the interfacial electrostatic potentials, i.e., the zeta potential of the vesicles and the surface potential of monolayers, caused by the adsorption of cationic surfactants, was studied. The main object in this work is to elucidate the contribution of electrostatic and hydrophobic interaction to the adsorption of cationic surfactants on phospholipid membranes.

Experimental

Materials. The monolayers and vesicles were prepared using L-α-dipalmitoylphosphatidylethanolamine (DPPE), which had been purchased from the Sigma Chemical Co., Ltd. (USA). As cationic surfactants, several alkyltrimethylammonium bromide (carbon numbers: 6,10,12,and 16) and tetrapentylammonium chloride, which had been purchased from the Tokyo Kasei Kogyo Co. Ltd., were used. These were used without any further purification. All the solutions of these compounds and the subphase solution in the monolayer experiment were prepared with deionized (Barnstead, NANO pure system) and doubly distilled water.

Zeta Potential. The DPPE vesicles were prepared by sonication without using any buffer to eliminate any unexpected effect of the included buffer ions. Vesicle suspensions were mixed with various concentrations of cationic surfactants; the final salt condition was 10^{-3} mol dm^{-3} NaCl. The electrophoretic mobilities of large-sized vesicles were measured with a Rank Brother microelectrophoretic apparatus (Model MK-2) using a rectangular glass cell at 20 °C. The zeta potentials were calculated from the mobility data according to the method of Wiersema.[5] In this calculation, the radius (a) of the vesicle was assumed to be 1000 Å.

Surface Potential of Monolayers. Phospholipid monolayers were prepared by spreading DPPE from a chloroform–ethanol (3:1) solution on the surface of a subphase solution containing 0.1 mol dm^{-3} NaCl in 80 ml a Teflon trough. The packing density of the monolayers prepared in these experiments was about 1/60 (molecule/Å^2). After the addition of a concentrated surfactant solution to the subphase solution, the solution was stirred for more than 30 min; then the surface potentials of the monolayers were measured by the vibrating-electrode method at 23 °C.

Results and Discussion

The electrostatic potential profile through the membrane-solution interface can be described ap-

proximately as a combination of an inside membrane potential which originates from dipoles of polar-head groups of phospholipid molecules and an ionic diffuse-double layer potential.[6] These potentials and their combination will change upon the adsorption of ionic compounds (a cationic surfactant in this case). Therefore, it is expected that their adsorption behavior can be analyzed by measuring both the surface potential of the monolayers and the zeta potential of the vesicles.[7]

Contribution of Alkyl-Chain Length. In Fig. 1, the change in the surface potential of the monolayer ($\Delta\Delta V$) is plotted against the concentrations of several kinds of alkyltrimethylammonium ions (abbreviated as alkyl-TMA) on a log scale. It is found that decyl-(C_{10}) and hexyl-(C_6) TMA have little effect on $\Delta\Delta V$, whereas dodecyl-(C_{12}) and hexadecyl-(C_{16}) TMA make a considerable contribution on $\Delta\Delta V$ in the present experimental concentrations. It is interesting to notice that there is a great difference in their contributions to $\Delta\Delta V$ between C_{10} and C_{12} TMA. This fact suggests that there is a critical hydrocarbon-chain length for the interaction between a surfactant and phopholipid membranes. A simillar tendency has been observed in the electrophoresis experiments. (Fig. 2). The electrophoretic mobility of DPPE vesicles changes the sign of its value with the concentration of C_{12} and C_{16} TMA, but not with that of C_{10} TMA. These data indicate that hydrocarbon numbers larger than ten are necessary for the alkyl chain of the surfactants to interact effectively with the DPPE membrane. Figure 3 shows the relationship between the $\Delta\Delta V$ of the DPPE monolayer membrane and the concentration of tetrapentylammonium bromide in the solution. As is shown in Fig. 3, this molecule has only a slight effect on the surface potential of the DPPE monolayer membrane. Those results suggest that these four alkyl chains are too short to enter the membrane interior of DPPE deep enough to interact with the hydrophobic part of the membrane and that a certain bulky effect of this molecule may play a role in this phenomenon.

Effect of Ionization State of DPPE. A DPPE molecule is an amphoteric molecule, and it has two dissociable groups, i.e., $-\overset{+}{N}H_3$ and $-PO_4H$. Depending on the pH in the bulk solution, these groups change their ionization state, as is shown in Fig. 4. (The ionization behavior of the PE membrane is

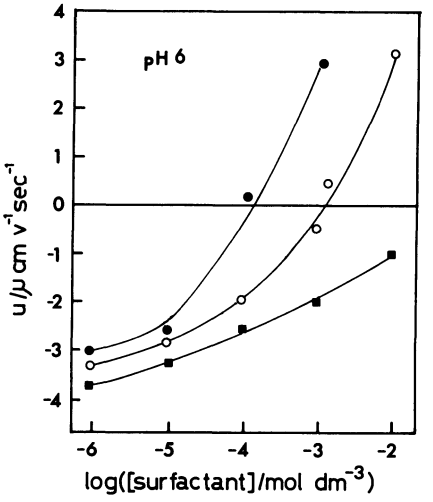

Fig. 2. Electrophoretic mobility of DPPE vesicles bathed in various concentration of several alkyltrimethylammonium bromide aqueous solution. (●): C_{16}, (○): C_{12}, (■): C_{10}.

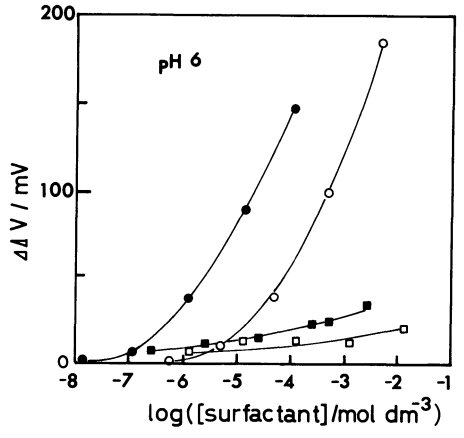

Fig. 1. Surface potential change of DPPE monolayer membrane vs. concentration of alkyltrimethyl ammonium bromide. (●): C_{16}, (○): C_{12}, (■): C_{10}, (□): C_6.

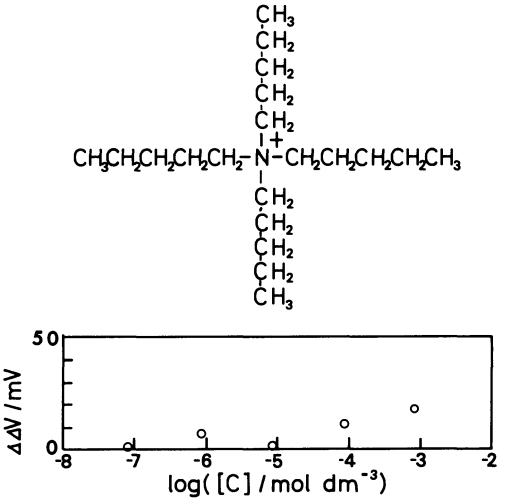

Fig. 3. Surface potential change of DPPE monolayer membrane vs. concentration of tetrapentylammonium bromide.

represented in Fig. 1 of Ref. 9.) Moreover, the ionization state of the phosphatidylethanolamine membrane has been reported by many researchers[8] to be different from that of the single molecule itself. In this work, three pH values, i.e., 3, 6, and 10, were selected in order to examine the effect of the ionization state on the adsorption of C_{12}-TMA onto the membrane. Figure 5 shows the change in the surface potential of the monolayer caused by the adsorption of C_{12}-TMA at the three pH values. $\Delta\Delta V$ begins to increase at a lower concentration of C_{12} TMA with an increase in the pH, i.e., in the order of: pH 10>pH 6>pH 3. This order is due to the change in the ionization state of the DPPE membrane; that is, at pH 10, the DPPE membrane has the most negative charges on the surface, whereas at pH 3, the DPPE membrane has the least negative charges or positive charges on it. As a result of the electrostatic interaction between C_{12} TMA and the DPPE membrane, the adsorption is promoted by the electrostatic attraction at pH 10, but is depressed by the repulsion at pH 3. Electrophoretic studies support this picture. Figure 6 shows the electrophoretic mobility of DPPE vesicles bathed in various concentrations of the C_{12} TMA solution at those three pH values. At pH 3, the DPPE vesicles have a positive value of mobility in the surfactant-free system. At pH 10, the electrophoretic mobility of the DPPE vesicles is comparable to that at pH 6. The adsorp-

tion of C_{12} TMA on the membrane causes a change in the zeta potential of the vesicles. The contribution of this surfactant to the mobility is greater at pH 6 and pH 10 than at pH 3. This behavior is almost the same as that shown in Fig. 5. In Fig. 7, the membrane surface potential (ψ_0), calculated from the data of electrophoretic mobilities by the method of Wiersema and the relation of $\psi_0=\zeta e^{\kappa d}$ (ζ: zeta potential, κ: Debye-Hückel parameter), is plotted together with the surface potential of the monolayer ($\Delta\Delta V$). In this calculation, the distance from the membrane surface to the slipping plane (d) is assumed to be 10 Å.[9] The two sets of data are compared with each other on the assumption that their values are equal at the surfactant concentration, 10^{-3} mol dm^{-3} (around this concentration the zeta potentials have a zero value at pH 6, and the surface potential can be taken to be zero.). This figure shows that $\Delta\Delta V$ resembles the change in the ψ_0 value of the vesicles (at pH 3 and pH 6). This means that the surfactants are adsorbed on the membrane surface in such a manner as their charges of the head group are located at the membrane-solution interface. The data of electrophoretic mobilities at pH 10 are not very different from those at pH 6. This may be due to the relaxation effect, because $\kappa a \simeq 5$ under these experimental condition; i.e., the electrophoretic mobility does not increase with the increase in the zeta potential above 100 mV.

Analytical Considerations

The adsorption behavior of charged molecules by the membrane can be described by the following simple relation:

$$[\text{surfactant}]_m = K_w K_e f [\text{surfactant}]_b, \quad (1)$$

where $[\text{surfactant}]_m$ is the concentration of C_{12} trimethylammonium ions adsorbed on the membrane; $[\text{surfactant}]_b$, its concentration in the bulk aqueous solution; K_w, the adsorption coefficient based on hydrophobic interaction, and f, the factor which originates from the mutual electrostatic repulsion of adsorbed ions and the next adsorbing ion and which determines the line shape of the adsorption curve. In other words, f denotes the discrete charge effects on the charged surface.[10] K_e is the constant of electrostatic interaction between the DPPE membrane and the surfactant molecules which arises from the ionization of DPPE molecules; it is denoted as follows:

$$K_e = e^{-\psi_0 e/kT}, \quad (2)$$

where ψ_0 is the membrane-surface potential.

The change in the surface potential of the monolayer ($\Delta\Delta V$) is approximated by the following equation:

$$\Delta\Delta V = \Delta q/C_c = e \cdot \Delta[\text{surfactant}]_m/C_c, \quad (3)$$

where Δq is the amount of charges adsorbed; e, the elementary electric charge, and C_c, the specific capacitance of the outer region of the monolayer.

The f factor, which determines the curvature of the figure, can be expressed as follows:

$$f = e^{-a \cdot \Delta\Delta V e/kT}, \quad (4)$$

where $0 \leqq a \leqq 1$. $a=0$ means that the mutual interaction of ions is absent, while $a=1$ means that the electrostatic potential produced by the adsorption of ions greatly influences the adsorption of the next adsorbing ion.

If one adopts here the diffuse double-layer theory instead of the simple capacitor model, Eq. 3 can be rewritten by the following equation:[11]

$$\sinh \frac{\Delta\Delta V}{51.4} = \frac{136.6 \cdot \Delta q}{\sqrt{C}}, \quad (5)$$

where C the concentration of indifferent ions.

These equations allow the analytical calculation of the a factor. The experimental data of $\Delta\Delta V$ for C_{12}-TMA are plotted, with their analytical curves, in Fig. 8. The solid lines are for Eq. 3, while the dashed ones are for Eq. 5. When we compare these data with the theoretical curves, $a=0.5$ is adequate. This means that these surfactant ions adsorb on the DPPE membrane partially hindered by electrostatic repulsion among the adsorbed ions themselves.

By comparing the data of $\Delta\Delta V$ and the electrophoretic mobility for C_{12}-TMA with those for C_{16}-TMA in Figs. 1 and 2, one can estimate the hydrophobic interaction per $-CH_2$ group. The adsorption coefficient of the hydrophobic part, K_w, is expressed as follows:

$$K_w = K \cdot e^{-(N-N_0)w/kT}, \quad (6)$$

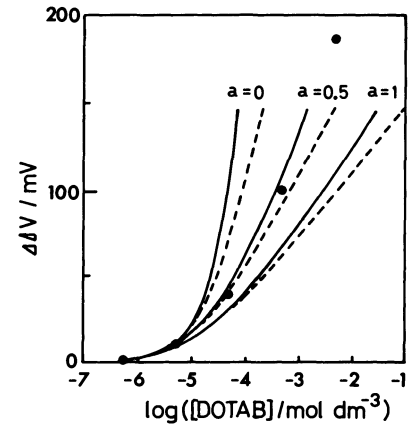

Fig. 8. Calculated curves from Eq. 3 —— and Eq. 5 ---- for surface potential change and experimental data of dodecyltrimethylammonium bromide.

where w is the hydrophobic interaction energy per CH_2 group; N, the number of CH_2 groups in the hydrocarbon chain; N_0, the critical number of CH_2 for hydrophobic interaction with the membrane, and K, the constant from other parts. The $\Delta\Delta V$ curves of C_{16}–TMA are shifted to the lower-concentration side by more than 1 order from that of C_{12}–TMA. Furthermore, the electrophoretic mobility curve of C_{16}–TMA is also shifted to a lower side by more than 1 order from that of C_{12}–TMA. These data make possible the calculation of the w-value through this relation: (shift value)$=e^{\Delta n \cdot w/kT}$; where $\Delta n=N(C_{16})-N(C_{12})=4$; i.e., Δn is the difference in CH_2 number. Then, w is obtained as $w=0.6—1.2\,kT$. By comparing this value with that of the hydrophobic interaction energy (1.1 kT) for the micelle formation of various surfactants, it can be said that the main motive force of adsorption is also hydrophobic interaction between the membrane and the ionic surfactants. In fact, Zaslavsky et al.[12] have studied the interaction between a series of N-acyl derivatives of amino acids and egg lecithin liposome and have reported that the binding free energy per CH_2 ranges from 0.24 Kcal mol^{-1}† (0.4 kT) to 1.05 Kcal mol^{-1} (1.8 kT).

Kinetic Studies of Fast Equilibrium by Means of High-Performance Liquid Chromatography. XIV.[1] Separation of Rotamers of Phenyl Methylcarbamates and Their Rotational Energy Barriers

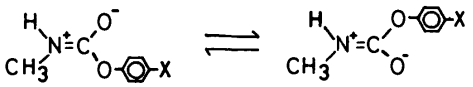
Masataka MORIYASU,* Chisako YAMAGAMI, Atsushi KATO, Yohei HASHIMOTO, and Narao TAKAO

Kobe Women's College of Pharmacy, Motoyamakita-machi, Higashinada-ku, Kobe 658

(Received December 9, 1985)

High-performance liquid chromatography(HPLC) of six phenyl methylcarbamates at low column temperatures on normal phase chromatography using hydroxyl-group chemically-bonded silica gel packing achieved the separation of rotamers. The population ratios of rotamers were determined for different conditions such as solvent composition and concentration. The rotational-energy barriers to intramolecular-bond rotation about the carbonyl-nitrogen bonds were determined for four *p*-substituted phenyl methylcarbamates, and it was found that the energy barriers were higher when electron-withdrawing groups were substituted.

In this research series, rotamers about the carbon–nitrogen bonds with partial double-bond characters, including metal dithiocarbamates,[2] anilides,[3–5] and *N*-alkylamides,[1] have been separated by means of HPLC at low column temperatures. The population ratios of rotamers in different conditions have been determined by this method, and the energy barriers to bond rotations have also been determined. This report deals with the separation of rotamers of *p*-substituted phenyl methylcarbamates and the determination of their rotational-energy barriers.[6]



cis(Z) trans(E)

The restricted rotation about the carbonyl–nitrogen bonds of amides has been extensively investigated by many workers by means of NMR[7] with a special technique entitled the dynamic NMR method. Our previous reports[1,3–5] have demonstrated that HPLC has also been a powerful tool for examining the restricted bond rotation of amides and even better than NMR when the content of the minor rotamers is very low. Different from amides, the number of reports on dynamic NMR studies of carbamates is relatively few and they are restricted to symmetrical *N,N*-disubstituted carbamates. These are attributable to the following. (1) Different from amides, the differences in chemical shifts of two rotamers of carbamates are usually very small. This makes dynamic NMR studies of carbamates very difficult and once led to an erroneous conclusion that, different from amides, there were no large energy barriers to the carbonyl–nitrogen bond rotation of carbamates.[8] This difficulty was partially resolved by the use of a large amount of lanthanoid shift reagents; thus, the rotational-energy barriers were determined for dimethylcarbamates.[9] It is debatable, however, whether the rotational-energy barriers in the absence and presence of shift reagents are identical since it is probable that interactions between the shift reagents and carbamate molecules cause a variation in the energy barriers as well as the population ratios to a considerable extent. In addition, other difficulties exist for *N*-monosubstituted carbamates. (2) For symmetrically *N,N*-disubstituted carbamates, due to the equal population ratios of "two rotamers" simple T_c method[10] can be applied to determine the energy barriers. Contrary to this, complicated total line-shape analysis is inevitable for unsymmetrically *N*-substituted carbamates. The proximity of chemical shifts of two rotamers not only makes the total line-shape analysis impossible, but also prevents a determination of the population ratios of two rotamers. (3) Owing to a strong intermolecular association, such as the hydrogen bonding of *N*-monosubstituted carbamates, the overall process observed by means of NMR might involve the making and breaking of hydrogen bonds as well as bond rotation. Thus, it is not clear that the data obtained by means of dynamic NMR correctly indicate the rotational energy barriers, even though a total line-shape analysis is possible. For these reasons, a determination of the rotational-energy barriers has not hitherto been carried out for *N*-monosubstituted carbamates.

Experimental

The following six *p*-substituted phenyl methylcarbamates were prepared and purified as described elswhere;[11] phenyl methylcarbamate, *p*-methylphenyl methylcarbamate, *p*-fluorophenyl methylcarbamate, *p*-nitrophenyl methylcarbamate, *p*-hydroxyphenyl methylcarbamate, and *p*-cyanophenyl methylcarbamate.

The HPLC apparatus for use in low-temperature measurements was detailed elswhere.[3,12] Several column packings of two different types, i.e., silica-gel packings (LiChrosorb SI 60, LiChrosorb SI 100, and Polygosil 60-5)

and hydroxyl-group chemically-bonded packings (LiChrosorb DIOL and Nucleosil 7OH), were tested and it was found out that the latter gave better results. Complete base-line separation of rotamers by silica-gel packings was difficult because the retention times of rotamers were relatively close to each other. For the determination of the population ratios of rotamers, column effluent was passed through a narrow stainless-steel tube (0.5 mm in internal diameter and 10 m in length) which was thermostated at 80 °C in an air bath prior to detection by means of UV detector.[4] Thus, the equilibrium of rotamers in eluent was reequilibrated.

Results and Discussion

Separation of Rotamers. These six phenyl methylcarbamates were dissolved in chloroform or ethanol (0.01 mol dm^{-3}), and sample solutions were submitted to normal phase HPLC at different column temperatures. Figure 1 exemplifies the chromatograms of phenyl methylcarbamate in a chloroform solution on hydroxyl-group chemically-bonded packings. Two peaks corresponding to two rotamers appeared and were separated at low column temperatures. A complete base-line separation of rotamers was attained when the column temperature was below −55 °C, although the column efficiency gradually decreased with the falling temperature. With similar procedures, the separation of rotamers of other *p*-substituted phenyl methylcarbamates was possible below −55 °C.

The identification of each peak was not easy because different from anilides and amides hitherto NMR were not available. We consider, however, that the former small peak will be attributable to the cis-form (*Z*-form) for the following reason. Owing to the ability to form ring dimer,[13] the dielectric constants of cis-form (*Z*-form) rotamers of amides and carbamates are much smaller than those of trans-form (*E*-form) rotamers.[14] It is a well-known fact that in the adsorption or normal phase partition chromatography, nonpolar species are eluted faster than polar ones. This was actually observed for anilides and *N*-alkylamides as can be seen in our previous reports.[1,3,4] It is quite likely that a similar elution sequence can also be observed for carbamates. Hereafter, it is assumed that the former small peak can be assigned as cis-form (*Z*-form), although some ambiguity still remains on the peak identification.

Equilibrium Ratios of Rotamers. The ratios of two rotamers in chloroform and in ethanol were determined for these six carbamates (0.01 mol dm^{-3}, 25 °C), and the results are summarized in Table 1. For *p*-methylphenyl methylcarbamate, the ratios of two rotamers were determined in a variety of solvents (0.01 mol dm^{-3}, 25 °C), and the percentages of cis-form (*Z*-form) are determined which are as follows: 24% (in hexane), 22% (in benzene), 29% (in carbon tetrachloride), 14% (in diethyl ether), 14% (in ethyl acetate), 14% (in acetonitrile), 13% (in tetrahydrofuran), and 14% (in methanol). The effect of the concentration was also examined for *p*-methylphenyl methylcarbamates in chloroform. The percentages of cis-form (*Z*-form) were as follows; 17% (3.0 mol dm^{-3}), 22% (0.1 mol dm^{-3}), and 24% (0.01 mol dm^{-3}). By summarizing these results it can be concluded that the percentages of cis-form (*Z*-form) of these carbamates are higher in nonpolar solvents and in lower concentrations which is similar to the case for

anilides and aliphatic amides.[1,4]

Determination of Rotational Energy Barriers. As described above, HPLC of phenyl methylcarbamates gave the separation of rotamers below −55 °C. Under the conditions of a baseline separation of rotamers, each peak was symmetrical and neither leading nor tailing was observed. With an increase in the column temperature, a partial transformation between two rotamers took place during the course of chromatography. In this case, complicated chromatograms were obtained. An approximate HPLC method for the determination of rotational-energy barriers[5] can be applied by observing the change in chromatographic patterns, provided that the rotational energy barriers are little affected by the adsorption or partition process of solute molecules on column packings. Figure 2 exemplifies the chromatograms of phenyl methylcarbamate at a column temperature of −35 °C for different flow rates. When the flow rate was low, a larger part of one rotamer transformed into other rotamer during the course of chromatography. The residual amount of cis-form (*Z*-form) was proportional to the product of the peak area of cis-form *S* and the flow rate *v* at a residence time *t* was plotted against *t*. Similar experiments were carried out at different column temperatures and the results are given in Fig. 3. From the slope of these linear curves, the rate constants to the bond rotation from cis-form (*Z*-form) to trans-form (*E*-form) k at different temperatures were calculated. The reverse rate constants k corresponding to the conversion from trans-form (*E*-form) to cis-form (*Z*-form) were also determined by the same way. The rate constants k and k_- for other carbamates including *p*-methylphenyl methylcarbamate, *p*-methoxyphenyl methylcarbamate, and *p*-nitrophenyl methylcarbamate were also determined with similar procedures. The activation energies of the forward E_a (from cis- to trans-form) and backward E_{-a} (from trans- to cis-form) reactions were calculated from the Arrhenius' plots as shown in Fig. 4. Thus, activation energies as well as rate constants can be determined. Table 2 summarizes the activation

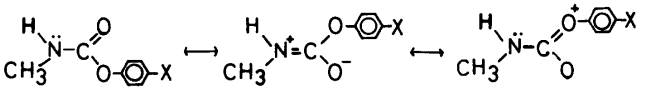
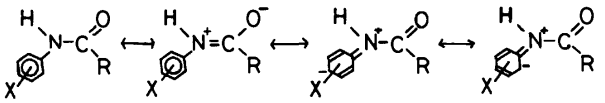
* Due to the tailing of trans-form (*E*-form) rotamer, the rate constants and energy barriers of the reverse reaction were not calculated.

energies and rate constants at −30 °C for these four phenyl methylcarbamates. These energy barriers were found to be smaller than those of aliphatic amides[7] and close to those of anilides.[5,7] When a hydrogen in *p*-position in phenyl ring is replaced by an electron-withdrawing group, rotational energy barriers increase. On the other hand, the substitution by an electron-donating group decreases the energy barriers. These phenomena are explained by the following way. The contribution of the canonical form 2, which is responsible for the partial double



1 2 3

bond character of carbonyl-nitrogen bonds, is reduced by the contribution of another canonical form 3 for carbamates. Thus, the rotational energy barriers of carbamates are usually smaller than those of alkylamides. Similarly, the partial double bond character of carbonyl-nitrogen bonds of anilides is also reduced by dint of the contribution of the canonical forms 6 and 7. The substitution of a



4 5 6 7

hydrogen atom in phenyl group by substituent X will bring about reverse effects on the rotatinal energy barriers for carbamates and anilides. In the case of anilides, the substitution of *o*- or *p*-hydrogen by an electron-donating group such as methoxy group will destabilize the canonical forms 6 and 7, and consequently the substitution will bring about an increase in the double-bond character and, thus, an increase in the energy barriers. Contrary to this, the substitution by an electron-withdrawing group such as nitro group will cause a decrease in the energy barriers. This phenomenon was actually observed by a dynamic NMR study for *p*-substituted *N*-methylformanilides.[15] The rotational energy barreirs of *p*-nitro-substituted *N*-methylformanilide and *p*-methoxy-substituted *N*-methylformanilide were 71.5 and 78.5 kJ mol^{-1}, respectively. The effects of substituents should differ for carbamates. The replacement of a hydrogen in the phenyl ring of phenyl methylcarbamates by an electron-donating group should stabilize the canonical form 3 and, thus, decreases the double-bond character of the carbonyl–nitrogen bonds. This is in agreement with the present experiments.

6) Due to the strong double bond character of the carbonyl nitrogen bond,  moiety is considered to lie on the same plane. In this report the prefixes cis- and trans- designate the configuration concerning C-O⁻ and N-H groups because the configuration seems to play an essential role. The alternative prefixes, *E*- and *Z*-, which were used for amides in our previous reports (Ref. 1,3,4, and 5), were shown in parentheses in this report because *Z*- and *E*-mean reverse configuration concerning C-O⁻ and N-H groups for amides and carbamates.

Bulk Copolymerization of Acrylonitrile with Allyl Chloride and Thermal Analysis of the Products

Masao Okamoto,* Kiyoshi Suenaga, and Osamu Ishizuka
Department of Polymer Materials Engineering, Faculty of Engineering,
Yamagata University, Jonan, Yonezawa 992
(Received September 28, 1985)

The bulk copolymerization of acrylonitrile (M_1) with allyl chloride (M_2), carried out at 40 °C, was initiated by 0.05 mol% of α,α'-azobisisobutyronitrile under nitrogen. The compositions of six copolymers were in the range of allyl chloride units, 0.63—6.32 mol%. The monomer reactivity ratios r_1 and r_2 were calculated to be 6.04 and 0.035, respectively. Only three copolymers were soluble in *N,N*-dimethylformamide and their intrinsic viscosities were found to be greater than 4.5 dL g^{-1}. The chlorine contents, although 0.42, 0.87, and 1.03 wt%, were sufficiently effective to cause a change in the behavior of the thermal degradation of polyacrylonitrile (PAN). In DTA curves measured at a rate of 5 °C min^{-1} under nitrogen for copolymers containing ca. 1 wt% of chlorine, a sharp exotherm due to the polymerization of cyano groups shifted to the higher-temperature side (ca. 40 °C) and the differential temperature decreased to about 1/6. Moreover, the weight loss at 350 °C decreased from 19 wt% for PAN to 13 wt%. A similar thermal-degradation behavior was also observed for acrylonitrile-α-chloroacrylonitrile (CAN) copolymers. However, there was a great difference between allyl chloride and CAN units concerning the effect on the thermal degradation of PAN. Namely, only 1.5 mol% of allyl chloride units corresponded to 10 mol% of CAN units.

In a preceding study[1] hydrogen chloride (HCl) accelerated the rate of polymerization of cyano groups at 220 °C in an isothermal heat treatment of polyacrylonitrile (PAN). The acceleration was thought to be the result of the action of chlorine atoms which were formed by the reaction of thermally degraded polymer radicals with HCl. Moreover, it was demonstrated that in both DTA curves for the PAN samples heat-treated under an HCl atmosphere and for acrylonitrile-α-chloroacrylonitrile (CAN) copolymers, a sharper exotherm due to the polymerization of cyano groups appeared more at the higher-temperature side than that for pure PAN. The differential temperature ΔT decreased upon increasing the chlorine content. This type DTA behavior was also considered to be attributable to the action of chlorine atoms. Grassie and McGuchan[2] have already observed similar behavior for copolymers of acrylonitrile with vinyl chloride, vinylidene chloride, and CAN (comonomer units, more than 5 mol%). Acceleration effects on the polymerization rate of cyano groups are thought to appear even for a low content of comonomer units by changing its chemical component. In order to clarify the above-mentioned problem, we tried to prepare acrylonitrile (M_1)-allyl chloride (M_2) copolymers. So far, it has been reported that this system should be ideal and the relative reactivity of allyl chloride toward the acrylonitrile-type radical is 0.18 at 60 °C.[3] Since this indicates $r_1=1/0.18$ and $r_2=0.18$, it was expected that favorable copolymers will easily be obtained.

Experimental

Preparation of Copolymers. Commercial acrylonitrile and allyl chloride were distilled in a nitrogen atmosphere. Bulk copolymerization carried out at 40 °C was initiated by 0.05 mol% of AIBN under nitrogen. Polymerization conditions are listed in Table 1. The reaction vessel was sealed to prevent the loss of both monomers during copolymerization. After 1.25—36 h, the copolymerization was terminated by adding of a small amount of hydroquinone. The copolymer was filtered, washed thoroughly with methanol, and finally dried in a vaccum at 30 °C.

Chlorine Analysis. The method was reported in a previous paper.[4]

Determination of Intrinsic Viscosity. The intrinsic viscosity [η] was measured in *N,N*-dimethylformamide (DMF) at 35 °C.

Measurement of IR Absorption Spectra. IR spectra were measured by a Shimadzu IR-435 spectrophotometer using a pellet method.

Differential Thermal Analysis (DTA). The method was reported in a previous paper.[1] Samples were heated to 350 °C at 5 °C min^{-1} rate under nitrogen.

Results and Discussion

Composition of Copolymers. The chlorine content and [η] of copolymers are shown in Table 1. It was found from these results that the copolymers obtained in Expt Nos. 2, 3, and 4 contained little chlorine and that the molecular weights were sufficiently high. The content of allyl chloride units incorporated in each copolymer was calculated from the chlorine content (Table 1). Figure 1 shows the IR spectra of PAN and copolymers obtained in Expt Nos. 6 and 8. It was supposed from the spectra that a side reaction would proceed simultaneously with copolymerization in Expt Nos. 8 and 9, because a strong absorption appeared at 1738 cm^{-1}. Accordingly, these two copolymers were not analyzed in the present research. Although two new absorptions appeared at 685 and 725 cm^{-1} in all copolymers, they

could be assigned to C–Cl stretching vibrations in allyl chloride units since their normalized absorbances[5] increased in proportion to the chlorine content.

During the present copolymerization the conversions were low as shown in Table 1. Therefore, the monomer reactivity ratios could be determined by the method of Fineman and Ross[6] using the composition of copolymers obtained in Expt Nos. 2—7. The values of r_1 and r_2 were calculated to be 6.04 and 0.035, respectively. Although the present copolymerization system was not ideal at 40 °C, it proved that favorable copolymers were obtained.

Thermal Analysis of Copolymers. Figure 2 shows the DTA curves for PAN and copolymers obtained in Expt Nos. 2, 3, 6, and 7. The weight losses at 350 °C are shown in Fig. 3. Even the DTA behavior of the copolymer which contained 0.42 wt% of chlorine (the content of allyl chloride units corresponding to 0.63 mol%) changed remarkably. Namely, the exotherm peak position due to the polymerization of cyano groups shifted more to the higher-temperature side (ca. 40 °C) than that for pure PAN. The value of ΔT became to about 1/3 in comparison with that for pure PAN. But the weight loss at 350 °C was not different from that for pure PAN (Fig. 3). When the chlorine content of the copolymer was 0.87, 1.03, or 1.64 wt% (the content of allyl chloride units corresponding to 1.31, 1.55, or 2.48 mol%), the exotherm peak position showed a somewhat greater shift to the higher-temperature side than that obtained for a

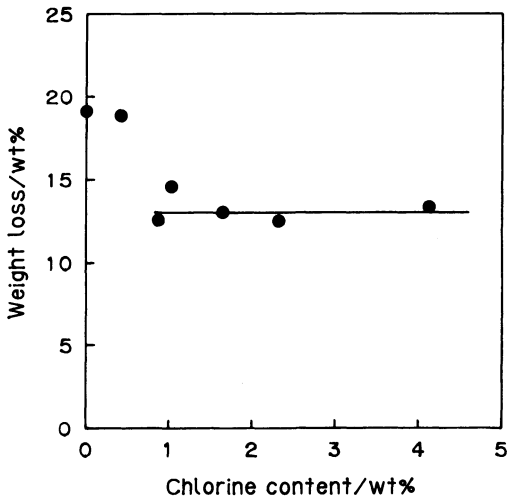

Fig. 3. Relationship between the chlorine content of copolymer and the weight loss at 350 °C.

copolymer containing 0.42 wt% of chlorine and ΔT decreased to about 1/6 in comparison with that for pure PAN. Moreover, the weight loss at 350 °C decreased from 19 wt% for PAN to 13 wt% for these copolymers (Fig. 3). Even if the chlorine content of copolymer was greater than 2 wt%, both ΔT and the weight loss didn't change again although the exotherm shifted to lower temperature side. Therefore, if allyl chloride is used as a comonomer, 1 wt% of chlorine is sufficient to change the behavior of the thermal degradation of PAN.

A similar behavior upon increasing the chlorine content has already been observed for acrylonitrile–CAN copolymers.[1,2] However, there was a great difference between allyl chloride and CAN units concerning the effect on the thermal degradation of PAN. When CAN was used as a comonomer, a sufficient chlorine content to change the behavior of thermal degradation of PAN was ca. 7 wt%. This indicates that regarding the effect of comonomer units, only 1.5 mol% of allyl chloride units corresponded to 10 mol% of CAN units. Consequently, HCl (and chlorine atoms) eliminated from the allyl chloride unit was more available than that eliminated from the CAN unit. This seems to have been caused by a difference in the temperature range in which each comonomer unit was dehydrochlorinated.

Finally, the chlorine and IR analyses of the copolymers which were heated to 350 °C at a rate of 5 °C min^{-1} were carried out. Since in every case both IR absorptions at 685 and 725 cm^{-1} disappeared after heating, it is clear that all allyl chloride units were dehydrochlorinated during heating. However, chlorine was detected in every case: after the heating of copolymers obtained in Expt Nos. 2—7, the chlorine contents were 0.11, 0.42, 0.44, 0.44, 1.06, and 1.35 wt%, respectively. The residual chlorine seems to have been combined as starting point of the polymerization of cyano groups.[1)]

School of Chemistry, Madurai Kamaraj University, Madurai-625 021, India
(Received April 25, 1985)

A kinetic study of oxidation of acetaldehyde, propionaldehyde, and butyraldehyde by peroxomonosulfate (PMS) in the presence of H^+ ion has been carried out. The reaction shows first order dependence each on [PMS] and [Aldehyde]. The reaction shows inverse first order over a particular concentration range of H^+ ion and beyond that first order dependence is observed with respect to [H^+]. The inverse hydrogen ion dependence on k_{obsd} may be due to the higher reactivity of SO_5^{2-} than HSO_5^- with aldehydes. The increase in k_{obsd} with increase in [H^+] beyond certain [H^+] can be explained by the formation of protonated carbonyl compounds. The Taft's plot gives ρ^* value of $\approx$5.0 indicating that the reaction is nucleophilic substitution at the carbonyl carbon which then rearranges to products.

In our previous paper[1] we have reported the results of kinetics of oxidations of formaldehyde, formic acid, and formate ion by peroxomonosulfate (PMS). We have observed, in the oxidation of formaldehyde by PMS, that SO_5^{2-} is more reactive than HSO_5^- and this is considered in favor of a nucleophilic substitution reaction of S_N2 type. Earlier workers[2] observed that the oxidation of aldehydes other than formaldehyde proceed through the enol form formed by the interaction between aldehydes and hydrogen ion. Since higher aldehydes, acetaldehyde, propionaldehyde, and butyraldehyde are enolizable, it would be interesting to study whether enol form of aldehydes will also involve in the kinetics. Aldehydes exist both in the hydrated form (*gem*-diol) as well as carbonyl form in aqueous solution.[3] Study of structure-reactivity relationship may throw some light on the nature of the aldehyde species involved in the oxidation reactions with PMS. With these views the kinetics of oxidations of the title aldehydes were undertaken and the results are discussed in this report.

Experimental

Acetaldehyde (SD's), propionaldehyde, butyraldehyde were purified by fractional distillation. Because of the high volatality of some of these aldehydes, the concentrations of the aqueous solutions were determined analytically; the Ponndorf's method[4] adopted by Seigel and Weiss[5] was used for all the aldehydes.

Potassium peroxomonosulfate (Du Pont) was used as such and all other chemicals were of analytical grade. The experimental details are discussed in Ref. 1.

Stoichiometry. The stoichiometry of the reactions were determined, at pH 4.0 and [H^+]=0.166 M (1 M=1 mol dm^{-3}), by taking a known excess of [PMS] over [Aldehydes]. The stoichiometry observed were identical at pH 4.0 and [H^+]=0.166 M and it could be represented as

$$RCHO + PMS \longrightarrow RCOOH \text{ (Product)}$$

Acetic acid was detected in the oxidation of acetaldehyde by spot tests.[6] Presence of carboxyl group in other two aldehydes were also confirmed.

Results and Discussion

Oxidations of the aldehydes were carried out under pseudo first-order conditions, with [Aldehydes] have been higher than, at least five times, that of [Peroxomonosulfate]. Analysis of the results indicates that the kinetics of oxidations of aldehydes by PMS are first order. Plots of log [PMS] versus time were linear even up to 70% conversion of [PMS]. The values of k_{obsd} were independent of [PMS]$_0$ and this shows that the order with respect to the [oxidant] is one.

An increase in the concentrations of the aldehydes causes a proportional increase in the rate constant at constant [H^+] and [PMS]. Plots of k_{obsd} versus [Aldehyde] are linear passing through origin (Fig. 1). This clearly proves the oxidations of aldehydes by PMS can be represented by the Eq. 1 as

$$\frac{-d[PMS]}{dt} = k'[\text{Aldehyde}][PMS], \quad (1)$$

where k' represents the rate constant at constant hydrogen ion concentration. The values of k' obtained are tabulated in Table 1.

The effect of hydrogen ion concentration on k_{obsd} was studied by varying the [H^+] from $\approx 10^{-4}$ to 0.166 M. In the high pH range, i.e. 4.4 to 3.6, the k_{obsd} decreases on decreasing the pH and the plots of k_{obsd} versus 1/[H^+] were linear with intercept (Fig. 2). The values of k_{obsd} are found to decrease with increase in [H^+] (3.5×10^{-3}—0.166 M) till a particular concentration of H^+ and then k_{obsd} increases with increase in [H^+] at constant [Aldehyde] (Table 2). The plots of k_{obsd} versus pH are found to be U-shaped curve (Fig. 3). This shows that different species are involved at different hydrogen ion concentration.

The change in ionic strength of the reaction medium shows a small increase in k_{obsd}. The kinetics

of the reactions were studied at four different temperatures (30—45 °C) and from the temperature dependence of k_{obsd} the $\Delta H^{\neq}$ values are calculated and tabulated (Table 1).

In order that the proposed mechanism is realistic in accounting for many of the observed kinetic data, it is necessary to have a knowledge of the possible species of both the oxidant and the substrate and from this the choice of the correct or the most probable species responsible must be made under the existing conditions of the experiment. Peroxomonosulfate, in solution exists as HSO_5^- and SO_5^{2-} due to the equilibrium as in Eq. 2.

$$HSO_5^- \rightleftharpoons SO_5^{2-} + H^+ \quad (2)$$

The pK_a of the equilibrium[7] is 9.4 and therefore under the experimental conditions namely at pH 4.0 the oxidant exists predominantly as HSO_5^- and to a smaller extent as SO_5^{2-}.

It is well known that aliphatic aldehydes in aqueous solution are partially hydrated.[3] Aldehydes in acidic or neutral medium give various species due to different reactions such as keto-enol tautomerism, hydration, protonation or deprotonation of the *gem*-diol forms.

It was observed that in the oxidations of aliphatic aldehydes by some metal oxidants the rate determining reaction is the enolization of the aldehyde[2] and this enolization reaction is acid catalyzed as

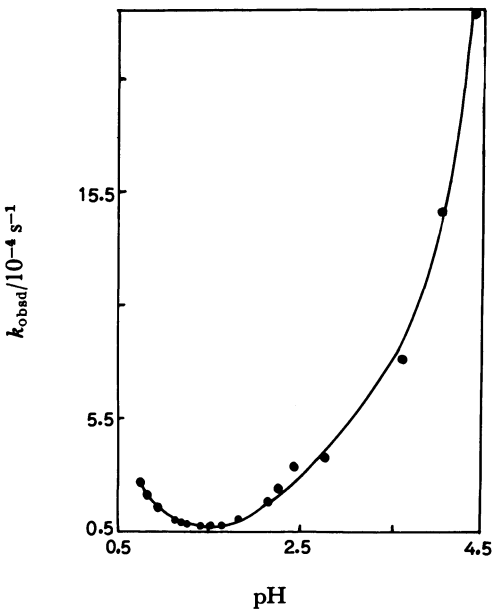

Fig. 3. Plot of k_{obsd} versus pH at 30 °C. [Acetaldehyde] $=5.6\times10^{-3}$ mol dm^{-3}; [PMS] $=10.5\times10^{-4}$ mol dm^{-3}; $\mu=0.25$.

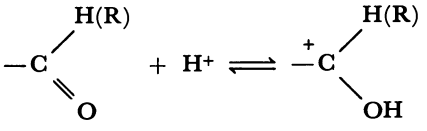
$$RCH_2CHO + H^+ \overset{\text{fast}}{\rightleftharpoons} (RCH_2CHOH)^+, \quad (3)$$

$$(RCH_2CHOH)^+ \xrightarrow[\text{determining}]{\text{rate}} RCH{=}CHOH + H^+. \quad (4)$$

If this enolization were the rate determining reaction in the oxidation by PMS, then the rate of oxidations would be zero order with respect to PMS and the observed stoichiometry for the reaction should be greater than 1:1. The observed experimental facts namely the first order dependence of rate on [PMS] and 1:1 stoichiometry even at [H$^+$]=0.166 M clearly show that enolization reaction can be neglected and it would never be the rate determining reaction under the experimental conditions employed in the oxidations of aldehydes by PMS.

Carbonyl compounds are partially hydrated by water, the reaction being catalyzed by acids and bases.[3] The vast majority of the reactions with carbonyl compounds involve nucleophilic attack on the carbonyl carbon atom and the electrophilic attack, usually protonation, on the oxygen. The product formed between carbonyl compound and H$^+$ is responsible for acid catalysis.[8] Usually protonation of aliphatic carbonyl compounds are depicted as in Eq. 5.



(5)

Extensive kinetic and spectral evidence indicates that protonated species is largely responsible for nucleophilic attack at the carbonyl carbon atom. Therefore we can safely assume that in aqueous solution and in the presence of hydrogen ion, aldehydes will exist as free aldehydic form, hydrated form (*gem*-diol) and protonated species.

Based on the experimental observation the most probable pathway will be

$$HSO_5^- \overset{K}{\rightleftharpoons} SO_5^{2-} + H^+, \quad (6)$$

$$\text{Aldehyde} + HSO_5^- \xrightarrow{k_1} \text{Products}, \quad (7)$$

$$\text{Aldehyde} + SO_5^{2-} \xrightarrow{k_2} \text{Products}. \quad (8)$$

As a first approximation, we can assume that at very low hydrogen ion concentration (pH 3.6 to 4.4) Eq. 5 can be neglected. Therefore at high pH the rate equation becomes

$$\frac{-d[PMS]}{dt} = k_1[\text{Aldehyde}][HSO_5^-] + k_2K\frac{[\text{Aldehyde}][HSO_5^-]}{[H^+]}$$

$$k_{obsd} = k_1[\text{Aldehyde}] + \frac{k_2K[\text{Aldehyde}]}{[H^+]}. \quad (9)$$

This equation explains the observed effect of [Aldehyde] and [H$^+$] (in the rage of pH 3.6 to 4.4) on k_{obsd}. At constant [H$^+$], the plots of k_{obsd} versus [Aldehyde] (Fig. 1) should give $(k_1+k_2K/[H^+])$ as slope which is equal to k' in Eq. 1. Similarly at constant [Aldehyde], plots of k_{obsd} versus $1/[H^+]$ should give k_2K[Aldehyde] as slope and k_1[Aldehyde] as intercept (Fig. 2). From the intercept and slope we can calculate the values of k_1 and k_2 knowing the literature value[7] of K as 3.98×10^{-10}. Perusal of the values in Table 1 shows that k_2 is approximately five order of magnitude greater than k_1. The higher reactivity of SO_5^{2-} than that of HSO_5^- may be considered to be in favor of nucleophilic attack by the peroxide.

Careful examination of the results in Table 2 shows that the protonation of the aldehydes (Eq. 5) is still less significant in the hydrogen ion concentration in the range of $1.75-21.0\times10^{-3}$ M (in the pH range of 1.68 to 2.76). In the k_{obsd} versus [H$^+$] curves, the effect of [H$^+$] in this range can also be explained by the Eq. 9. The values* for k_1' and k_2' are (at pH 1.68—2.76)

* For clarity the values of k_1 and k_2 obtained in the hydrogen ion concentrations ($1.75-21.0\times10^{-3}$ M) are denoted as k_1' and k_2'. In the plot of k_{obsd} versus $1/[H^+]$ the data point corresponding to [H$^+$] $=1.75\times10^{-3}$ M deviates from the straight line in all these three aldehydes. All other points fit well nicely in the plot and therefore the point corresponding to [H$^+$] $=1.75\times10^{-3}$ M was omitted in the plot to calculate k_1' and k_2'.

	k_1' $M^{-1}s^{-1}$	k_2' $M^{-1}s^{-1}$
Acetaldehyde	7.5×10^{-3}	4.5×10^{5},
Propionaldehyde	4.2×10^{-3}	3.4×10^{5},
Butyraldehyde	4.5×10^{-3}	2.6×10^{5}.

According to Eq. 9, the values of k_1 and k_2 should be independent of H^+ concentration range used. However, comparison of the values of k_1' and k_2' with those of k_1 and k_2 in Table 1 shows that k_1' is ten times smaller than k_1 and $k_2'\approx10k_2$. In this acid range (pH 1.68—2.76) the reactivity of SO_5^{2-} towards aldehyde is approximately eight order of magnitude greater than HSO_5^- which coincides with the results obtained in the oxidation of DMSO by PMS in acid media.[9] Similar discrepancy in the values of k_1 and k_2 with k_1' and k_2' was also observed in the oxidation of formaldehyde by PMS.[1] This discrepancy may probably be due to the fact that the equation used to calculate the concentrations of HSO_5^- and SO_5^{2-} may not be correct since the experimental pH was far away from the pK_a value of PMS (9.4).[7]

At very high hydrogen ion concentrations (35—166×10^{-3} M, pH 0.78 to 1.46), the observed effect of hydrogen ion on k_{obsd} can be explained by the catalytic effect of hydrogen ion due to the formation of protonated aldehydes as in Eq. 5. In this high hydrogen ion concentration range also the values of k_{obsd} were found to be independent of $[PMS]_0$ at constant $[H^+]$ and [Aldehyde]. This observation helps us to eliminate the possibility of the acid catalyzed hydrolysis of PMS similar to those observed in other peroxides. Further the plots k_{obsd} versus [Aldehyde] at constant $[H^+]$ were found to be linear passing through origin even at this high $[H^+]$. These observations clearly show that acid catalysis, the addition of H^+ on the RCHO to give $RCHOH^+$ which reacts with PMS to give product, is also occurring to a significant extent as

$$RCHO + H^+ \overset{K_1}{\rightleftharpoons} RCHOH, \quad (10)$$

$$RCHOH^+ + PMS \xrightarrow{k_3} \text{Products}, \quad (11)$$

$$RCHO + PMS \xrightarrow{k} \text{Products}. \quad (12)$$

Under these conditions, the rate law becomes

$$k_{obsd} = k_3K_1[RCHO][H^+] + k[RCHO] \quad (13)$$

and this equation explains the observed experimental facts at high $[H^+]$. The magnitude of K_1 may be small so that this catalytic effect have a pronounced effect on k_{obsd} only when $[H^+]>50\times10^{-3}$ M. No such catalytic effect was observed in the oxidation of formaldehyde by PMS even when $[H^+]>100\times10^{-3}$ M. The values of k_3K_1 obtained from the plot of k_{obsd} versus $[H^+]$ are grouped in Table 3.

So far the total analytical concentration of aldehyde is used to evaluate the kinetic parameters tabulated in Table 1. Turning now to the participation of the aldehydes in the keto or in the hydrated form, the relative rate constants can be computed by considering in turn one of the two forms as the only active species as

$$k^H = k_{total}(K_d+1)$$
$$k^{CO} = k_{total}(1+K_d^{-1})$$

where k^H, k^{CO}, and k_{total} represent the rate constants for the hydrated form, keto form, and observed rate constant for total analytical concentration of aldehydes, respectively. K_d represents the hydration equilibrium of aldehydes as

$$RCHO + H_2O \rightleftharpoons RCH(OH)_2$$
$$K_d=[RCHO]/[RCH(OH)_2]$$

In Table 4, the values of k_1, k_2, k_1^H, k_2^H, k_1^{CO}, and k_2^{CO} are given along with the values[10-13] of K_d and

Table 3.

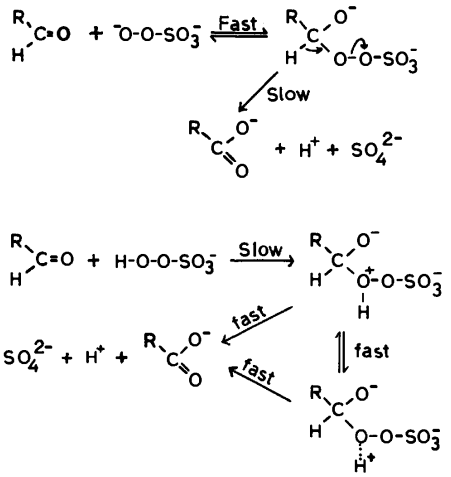
Taft's polar substituent constants[14] σ^*.

If RCHO (keto form) is the active form, the reactivity would be depressed by a factor of ca. $\approx 10^3$ between the extremes in the order HCHO>BuCHO and the values in Table 4 bring out our expectation, whereas no regularity is observed for the hydrated form.

The rates of PMS oxidation of the aldehydes relative to that of acetaldehyde can be obtained by dividing k_1/k_2 of the aldehyde by that of acetaldehyde.** A plot of log $(k_1/k_{1\,\text{acetaldehyde}})^{H}$ or log $(k_2/k_{2\,\text{acetaldehyde}})^{H}$ versus σ^* was much less satisfactory whereas log $(k_1/k_{1\,\text{acetaldehyde}})^{CO}$ or log $(k_2/k_{2\,\text{acetaldehyde}})^{CO}$ versus σ^* is a good straight line (Fig. 4) with a slope (reaction susceptibility constant ρ^*) of +5.0 and +4.75, respectively.

According to reactivity-selectivity principle,[15-17] the more reactive substrate/oxidant should be less selective than the less reactive one. Since SO_5^{2-} is $\approx 10^6$ times more reactive than HSO_5^-, it should be less selective and hence the observed ρ^* should be less than that for the HSO_5^-. But it would be surprising to note that the reaction susceptibility constants (ρ^*) for the oxidations by HSO_5^- and SO_5^{2-} are almost same and it seems to be an apparent violation of reactivity-selectivity principle. This can be explained if the following reaction schemes are considered for the oxidations by SO_5^{2-} and HSO_5^-.



According to the tetrahedral mechanism of nucleophilic substitution at the carbonyl group,[18] the nucleophile adds on to the trigonal carbonyl carbon to give a tetrahedral intermediate which then decomposes in the rate determining step to give the product. The observed ρ^*_{obsd} for the oxidations of aldehyde by SO_5^{2-} is the combination of the ρ^*s for nucleophilic addition ρ^*_{NA} and the elimination ρ^*_{ES}, i.e. the decomposition into the product as

** Because the values of k_1 and k_2 obtained at high pH range are assumed to be free from other side reactions, these values are used in the correlation analysis.

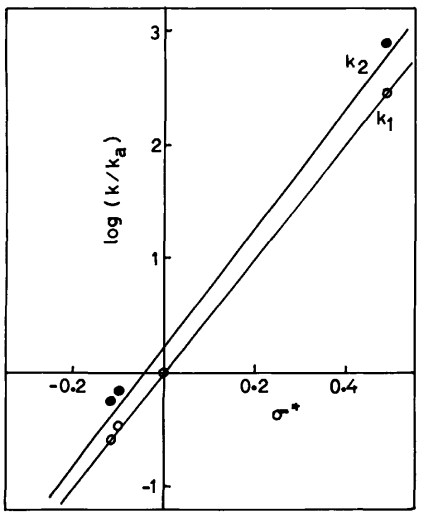


Fig. 4. Taft's plot. k_a represents the rate of acetaldehyde.

$$\rho^*_{obsd} = \rho^*_{NA} + \rho^*_{ES}$$

The value of ρ^*_{NA} should be positive and ρ^*_{ES} depends upon the combined opposing influence of the substituent on both the leaving groups/reactions; i.e. C–H which separates as H^+ and also C–O–O–SO_3^- group to give C=O and SO_4^{2-}. The large positive ρ^*_{obsd} shows that the ρ^*_{ES} may also be positive, otherwise ρ^*_{NA} would have a value greater than ρ^*_{obsd}. This means that the highly reactive nucleophile SO_5^{2-} is more selective and this is more unlikely. The observed ρ^*_{obsd} corresponding to k_1, i.e. oxidation by HSO_5^-, is only due to the nucleophilic substitution at the trigonal carbonyl carbon which may be a slow and rate determining step. This clearly explains that though it appears as a violation of reactivity-selectivity principle actually this is not the case since reactivity-selectivity principle can be applied only to the reactions involving same mechanistic pathways.[16,17] The same ρ^* values observed for k_1 and k_2 may be a fortuitous coincidence.

The structure-reactivity analysis can also be made for the acid catalyzed reaction also. The values of k_3K_1 corresponding to the keto form ($k_3K_1^{CO}$) are also given in Table 3. The electronic effect of the substituents would have opposing effects on K_1 and k_3; the electron-releasing substituents would increase the equilibrium constant K_1 whereas it would decreases the rate k_3. The Taft's plot for the hydrogen ion catalyzed reaction,

$$\log (k'/k'_{\text{acetaldehyde}}) = {}^{H^+}\rho^*_{obsd}\sigma^*,$$

where $k'=k_3K_1$, will give the susceptibility parameter (reaction constant) ${}^{H^+}\rho^*_{obsd}$ which is the combination of ${}^{H^+}\rho^*$ due to Eqs. 10 and 11 as

$${}^{H^+}\rho^*_{obsd} = {}^{H^+}\rho^*_{K_1} + {}^{H^+}\rho^*_{k_3}$$

The value of ${}^{H^+}\rho^*_{k_3}$ would be positive and greater than or at least equal to five since the ρ^* value for the aldehyde reactions with PMS is +5.0 (vide supra). Since the value of ${}^{H^+}\rho^*_{k_1}$ should be negative, the value of ${}^{H^+}\rho^*_{obsd}$ depends upon the magnitude of ${}^{H^+}\rho^*_{k_1}$. The value obtained for ${}^{H^+}\rho^*_{obsd}$ is +2.6 and this shows that the magnitude of ${}^{H^+}\rho^*_{k_1}$ is less than ${}^{H^+}\rho^*_{k_3}$. However it should be pointed out at this point that the above discussions are only qualitative since the Taft's plots are made only with the σ^* over a small and close range. The values of ρ^*s will not be accurate and we can not rely upon these numerical values. Therefore the above foregoing discussions should only be considered as an additional evidence which helps us in proposing the reaction scheme. However the value obtained in the analysis of acid catalyzed reaction helps us to explain why formaldehyde does not show the acid catalyzed reaction in our experimental conditions. According to the value of ${}^{H^+}\rho^*_{obsd}$, the value of k_3K_1 should be 8.3×10^{-3} which is hundred times lesser than the observed values of k_3K_1 for other aldehydes. Therefore we would have observed the acid catalyzed reaction of formaldehyde oxidation by PMS at very high hydrogen ion concentration. This shows although the results are qualitative in nature they are in the correct direction.

(Received June 20, 1985)

Viscosity *B*-coefficients of the Jones-Dole equation were determined for KCl, KBr, KI, NaBr, CsI, Me_4NBr, Et_4NBr, n-Pr_4NI, n-Bu_4NBr, and $Na[BPh_4]$ at 25 and 35 °C in various acetonitrile–H_2O mixtures. The *B*-coefficients were split into the ionic components and a comparison was made among different methods available. The effective flow volume, V_e° obtained from $B=2.5\,V_e^\circ$ was compared with the crystal ionic volume, V_{cryst}° and the ionic partial molar volume, $\overline{V}_{ion}^\circ$ determined from the density experiments simultaneously carried out. Ion-solvent and solvent-solvent interactions were discussed in terms of the above parameters.

Microviscosity determination of electrolytes in aqueous solutions as well as in nonaqueous solutions have been carried out in order to throw light on the nature of ion-solvent interactions. Recently, such measurements have also been reported for water-organic binary solvent system. In a previous communication,[1] we have tried to evaluate the nature of ion-solvent interactions in DMF–H_2O binary solvent. We found that the use of a large number of electrolytes of known behavior provided useful information on the effects induced by the cosolvent on the 'water-structure'. Interesting results were obtained by previous workers on the viscosity and transport properties of electrolytes in pure acetonitrile.[2] Recently some works have been reported on the ultrasonic,[3] transport,[4] and thermodynamic[5] properties of the binary mixture of acetonitrile–H_2O system. However, no work has been reported on the viscosity of electrolytes in acetonitrile–H_2O solvent system. We therefore, thought it timely to extend our previous work[1] to this solvent system. In this paper we report the viscosity and density data of large number of uni-univalent electrolytes in various acetonitrile–H_2O mixtures at 25 and 35 °C. The primary objective of this study is to investigate the nature of ion-solvent interactions and hence throw light on the nature of effects induced by acetonitrile on the 'water-structure'.

Experimental

KCl, KBr (BDH, AR), KI, NaBr (E. Merck), CsI (Sisco, >99% pure), and $Na[BPh_4]$ (Sigma) were used without further purification. Laboratory grade Me_4NBr (Fluka, USA) and Et_4NBr (BDH) were purified as described elsewhere.[6] n-Pr_4NBr and n-Bu_4NBr (Fluka, puriss) were purified as described by Conway et al.[7] n-Pr_4NI (Fluka, puriss) was recrystallized from acetone (E. Merck) by adding ether. The salts were stored in vacuum desiccator and dried for 3 to 4 h at 100 °C prior to use. Acetonitrile was purified as described elsewhere.[8] Its density, viscosity, and refractive index at 25 °C compared well with the reported values.[9] Laboratory grade distilled water was redistilled over $KMnO_4$ in an all glass unit. Freshly distilled water was used to make all solutions.

Densities of the solutions were measured using a 45 ml single stem capillary pycnometer having a capillary diameter of 1.5 mm and were vacuum corrected. The values are precise to 5×10^{-5} g cm^{-3}. Viscosity of dilute solutions were measured using an Ubbelohde suspended level viscometer having a fall time of 1130.2 s for water at 25 °C. The kinetic energy correction term for the viscometer fell in the region of experimental error and, therefore, was neglected. All measurements were carried out in a thermostatic water bath with an accuracy of ±0.01 °C. The relative viscosities determined were precise to 0.05%.

Results and Discussion

The relative viscosity of KCl, KBr, KI, NaBr, CsI, Me_4NBr, Et_4NBr, n-Pr_4NI, and n-Bu_4NBr at 25 and 35 °C and for $Na[BPh_4]$ at 25 °C were determined in 20, 40, 60, and 80% weight percent acetonitrile–H_2O binary mixtures corresponding to 0.099, 0.226, 0.397, and 0.637 mol fraction of acetonitrile. Viscosity data were analyzed by the Jones-Dole equation:[10]

$$\eta_r = \eta/\eta_o = 1 + AC^{1/2} + BC. \quad (1)$$

Plots of $(\eta_r-1)/C^{1/2}$ vs. $C^{1/2}$ for observed viscosity data were found to be linear. The least square values of A, B, and δ, the RMS deviation of the experimental and calculated relative viscosity values are presented in Table 1. The *B*-coefficients of KCl, KBr, KI, NaBr, CsI, and Me_4NBr increase with increase in acetonitrile concentration of the binary solvent. Et_4NBr has a *B*-value fairly constant and increases only at higher acetonitrile concentration. However, for each composition of the solvent the *B*-value changes in the order KCl>KBr>KI>CsI and NaBr>KBr. The *B*-value of n-Pr_4NI and n-Bu_4NBr shows an initial decrease with increase in acetonitrile concentration, reaches a minimum between 40 and 60% acetonitrile concentration, and then increases with further increase in acetonitrile concentration. It has been observed[1] that n-Pr_4NBr behaved in a qualitatively similar fashion in DMF–H_2O mixtures. However, n-

a) Weight % AN. b) Values of A and B for pure water (except for data of CsI; $10^4\delta=2.00$ and NaBr; $10^4\delta=1.11$ at 35 °C) from Refs. 14, 19, and 20.

Bu_4NBr did not exhibit a minimum in DMF-H_2O solvent system.

In order to get an accurate information about the ion-solvent interactions, it is necessary to evaluate the contribution of the individual ionic species to the viscosity B-coefficients. However, no absolute method of such a computation is available even for pure water solvent. The most popular method of dividing the viscosity B-coefficients into ionic components arises from the observation that K^+ and Cl^- ions behave very similarly in ionic mobility and, therefore, it is likely that $B_{K^+}=B_{Cl^-}$. This method was used by Gurney[11] and subsequently by Kaminsky[12] and others. However, the method has never been free of criticism. Nightingale[13] considered that from mobility grounds RbCl or CsCl should have been more appropriate than KCl. Subsequently Desnoyers and Perron[14] proposed a splitting method in which they assumed that Et_4N^+ ion is neither a structure-breaker nor a structure-former. By assuming the hydrodynamic volume to be equal to the partial molar volume, they calculated the B_{ion} value for Et_4N^+ ion to be 0.3593 $dm^3\,mol^{-1}$. Using this value the B_{ion} values calculated for other ions in water showed comparable values to those obtained by the method of Kaminsky, i.e., $B_{K^+}=B_{Cl^-}$. Very recently Jenkins and Pritchett[15] made use of Krumgalz's suggestions alternative to Gurney's assumption and came to the conclusion that $B_{Cs^+}=B_{I^-}$ is a more reasonable approximation.

In the light of the above discussions it is imperative that any method of splitting B-coefficients into the ionic components for binary solvent system is not likely to be free of the criticisms which apply in pure water. We, therefore, decided to compare the B_{ion} values obtained by the various methods from the experimental B-values. Table 2 lists the B_{ion} values obtained by three different methods, i.e., (i) on the basis of $B_{K^+}=B_{Cl^-}$; (ii) assuming $B_{Et_4N^+}=0.3593$ $dm^3\,mol^{-1}$ and (iii) by using $B_{Cs^+}=B_{I^-}$.

From Table 2 we find that the B_{ion} values obtained by methods (i) and (iii) are comparable only in water

and low concentration of acetonitrile. However, with increasing acetonitrile concentration the values by the above two methods deviate beyond experimental error. Also, B_{ion} values obtained by method (ii) do not agree in any rate either with those obtained by method (i) or (iii). Interesting results are obtained in 80% acetonitrile concentration where all the three methods give close results for B_{ion} with a deviation of ± 0.032 dm^3 mol^{-1} between methods (i) and (iii) and the results by method (ii) falling in between. This close agreement is surprising considering the large magnitude of the B_{ion} values of alkali and halide ions and also the normally large values of tetraalkylammonium ions.

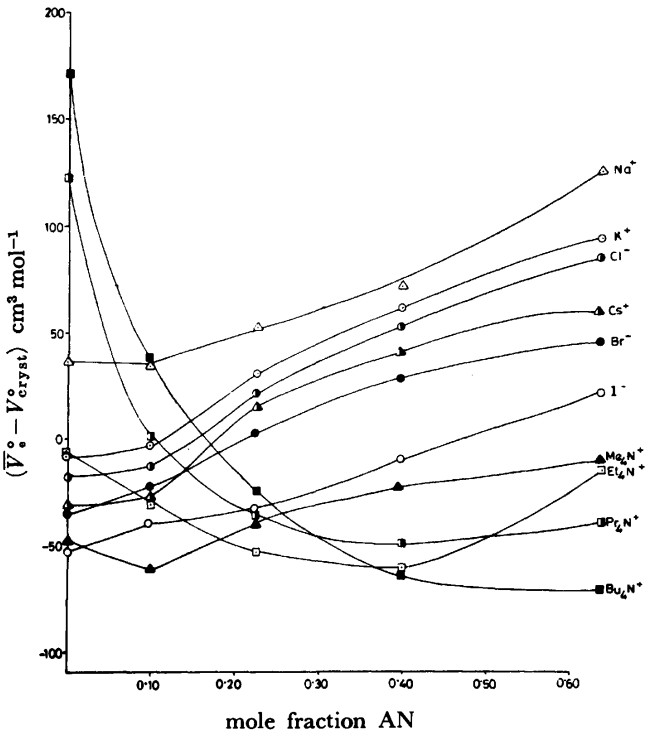

Fig. 1. Variation of $(\overline{V}^{\circ}_{e} - V^{\circ}_{cryst})$ with mole fraction of acetonitrile (AN) at 25 °C. B_{ion} on basis of $B_{K^+} = B_{Cl^-}$.

Eagland and Pilling[6] considered that $B = 2.5\, V^{\circ}_{e}$, where V°_{e} is the volume fraction of the solute molecules together with solvent molecules which are immobilized by the solute molecules because of the primary hydration. Like B_{ion}, $\overline{V}^{\circ}_{e}$ (for ion) would be sensitive to ion-dipole and structure-breaking effects. It would, therefore, be interesting to have a close look at the interaction effects by substracting V°_{cryst} from $\overline{V}^{\circ}_{e}$ values where V°_{cryst} is the crystal ionic volume derived from Pauling crystal radii. Figures 1—3 show the values of $(\overline{V}^{\circ}_{e} - V^{\circ}_{cryst})$ obtained by methods (i)—(iii), respectively. It is interesting to note that $(\overline{V}^{\circ}_{e} - V^{\circ}_{cryst})$ values for Na$^+$, K$^+$, Cs$^+$, Cl$^-$, Br$^-$, and I$^-$ in Fig. 1 increase slowly with increase in acetonitrile concentration of the binary solvent upto about 40% of acetonitrile followed by a steep increase with further increase of acetonitrile concentration. For n-Pr$_4$N$^+$ and n-Bu$_4$N$^+$, $(\overline{V}^{\circ}_{e} - V^{\circ}_{cryst})$ values steeply decrease initially with increase in acetonitrile concentration and finally show a slight increase for n-Pr$_4$N$^+$ only at 80% acetonitrile concentration. The behaviors of the above electrolytes are identical in Fig. 3. Me$_4$N$^+$ and Et$_4$N$^+$ show a more regular change in Fig. 3 compared to Fig. 1 (probably due to small experimental errors involved). However, a somewhat different trend is observed in Fig. 2; for K$^+$, Cs$^+$, and Me$_4$N$^+$ ions $(\overline{V}^{\circ}_{e} - V^{\circ}_{cryst})$ values first increase upto 60% acetonitrile concentration and then decrease at 80% acetonitrile concentration, and for Cl$^-$, Br$^-$, and I$^-$ ions the values first decrease and then increase. A

decrease of $(\bar{V}_e^\circ - V_{cryst}^\circ)$ for K^+, Cs^+, and Me_4N^+ ions with increase in acetonitrile concentration cannot be explained in view of the fact that all these ions have a stronger electrostriction in acetonitrile relative to water.[16] Therefore, $B_{Et_4N^+}$ probably cannot be taken as a constant for the splitting in this solvent. It is however, not possible to comment on the relative merit of methods (i) and (iii) without a detailed knowledge of the actual interactions taking place. But, for all practical purposes, both methods give B_{ion} values which are very close, particularly for mixtures of extreme composition (20 and 80% acetonitrile), so that a qualitative distinction is not possible.

It has been observed by earlier workers[17] that addition of acetonitrile to water breaks the ice-like structure of water liberating free water molecules thereby decreasing the structure. Therefore, *B*-values of the structure-breaking electrolytes should increase and that of the structure-forming electrolytes should decrease with the addition of acetonitrile as is observed in Table 1. However, in reality the picture does not seem to be so simple since $\Delta B/\Delta T$ for KCl, KBr, KI, and Et_4NBr first decreases and then increases with acetonitrile concentration (Table 3). In the case of NaBr, CsI, and Me_4NBr $\Delta B/\Delta T$ increases with acetonitrile concentration increasing. $\Delta B/\Delta T$ for *n*-

Pr_4NI and n-Bu_4NBr which is negative for the entire composition of the solvent mixture studied, shows a maximum negative value between 20 and 40% acetonitrile concentration. Therefore, solute-solvent interactions sensitive to temperature change exist at all the studied concentrations. This suggests preferential solvation of the electrolytes by acetonitrile molecules.

Table 4 shows a similarly interesting trend in the data on the differences in B-coefficients of two alkali salts with either the cation or the anion as the common member. This observation is common to both the temperatures studied. In both cases the difference observed in pure water first decreases and then increases with the concentration of acetonitrile upto the highest concentration studied. The difference between the halide ions which are normally small in water are surprisingly high in 80% acetonitrile. However, the differences between the alkali cations which are significantly high in water relative to halides are not so prominent in 80% acetonitrile as in case of halides. A decrease in the intermediate region is probably due to a decrease in overall structure of the solvent. Increase on the other hand indicates increase in ion-dipole interactions, probably with free water molecules.

The apparent molar volumes (ϕ_v) of the electrolytes were calculated by using the density data. The limiting apparent molar volume, ϕ_v° ($=\overline{V}^\circ$) was then calculated by the least square method. In order to calculate the ionic partial molar volumes, the $\overline{V}^\circ$ values, for Me_4NBr, Et_4NBr, n-Pr_4NBr, and n-Bu_4NBr were plotted against respective r^3 [r=ionic radii of the ammonium ions[18]] and the intercept gave the values for Br^- ions. With increasing acetonitrile, the ionic partial molar volumes decrease and become negative for chloride and bromide ions but are positive for Na^+, K^+, Cs^+, and I^- ions. Not much change is observed in the case of tetraalkylammonium ions. Because of electrostriction it is not possible to make a comparison of the B-values with the $\overline{V}^\circ$ values of the alkali and halide ions with respect to acetonitrile concentration, though such a comparison is possible in the case of the tetraalkylammonium and tetraphenylborate ions. Table 5 shows the $\overline{V}^\circ_{ion}$ and the $(B/\overline{V}^\circ)_{ion}$ values of the electrolytes vs. acetonitrile concentration. The ratio increases for Me_4N^+ alone but decreases for Et_4N^+, n-Pr_4N^+, n-Bu_4N^+, and $[BPh_4]^-$ ions. Marginal increase is observed for Et_4N^+ and n-Pr_4N^+ ions in 80% acetonitrile concentration. It is interesting to note that for Me_4N^+ and Et_4N^+ ions, the ratio tends to the ideal value (2.5) at 80% acetonitrile concentration.

We may therefore, say that acetonitrile destroys the ice-like structure of water. Ionic B-coefficients of simple monovalent ions are large in acetonitrile-H_2O solvent mixture due to the participation of acetonitrile molecules in the solvation process and small for large tetraalkylammonium ions because of the disappearance of hydrophobic hydration.

Table 5. Ionic Partial Molar Volumes $\overline{V}^\circ_{ion}$ (dm^3 mol^{-1}) and $(B/\overline{V}^\circ)_{ion}$[a] Values of Different Ions in Acetonitrile-H_2O Mixtures at 25°C

Compensation Effect in the Electrical Conduction Process in Some Nucleic Acid Base Complexes with Acriflavine Dye

Deepali SARKAR, Kapur Mal JAIN,† and Tridibendra Narayan MISRA*
Optics Department, Indian Association for the Cultivation of Science,
Jadavpur, Calcutta-700 032, India
(Received July 11, 1985)

The validity of the compensation rule is studied for nucleic acid bases, adenine, cytosine, and uracil complexes with acriflavine dye. The value of the semiconduction activation energy of a complex varies with dye concentration. It is shown that at low dye concentration, these semiconducting complexes follow the three parameter equation $\sigma(T)=\sigma_0'\exp(E/2kT_0)\exp(-E/2kT)$, where σ_0' and T_0 are constant for a particular base, other notations have their usual meaning. Consistent values for σ_0' and T_0 have been obtained by using various methods of evaluation. These results suggest that compensation effect has a physical origin.

In some earlier communications we have demonstrated the validity of the compensation rule in the electrical conduction process in some polyene[1,2] and nitro aromatic[3] semiconductors. The variation in the semiconduction activation energy was obtained by adsorbing various chemical vapors on the crystallite surfaces in a polycrystalline sandwich cell configuration. It has been shown that these organic semiconductors follow the three constant equation

$$\sigma(T) = \sigma_0' \exp(E/2kT_0)\exp(-E/2kT), \quad (1)$$

where $\sigma(T)$ is the specific conductivity at TK, E is the semiconduction activation energy and k is the Boltzmann constant. The parameters σ_0' and T_0 are constants for a particular semiconductor.

The activation energy of a semiconductor may be varied by other methods also e.g. hydration, doping of impurity, complex formation, physical mixing etc. The interaction of acridine dyes with DNA and nucleic acid bases is of considerable biological significance. Such interaction is involved in frame shift mutation, antibacterial activities and photodynamic action. The spectroscopic studies confirm the complex formation between flavins and the purine and pyrimidine bases.[4] The binding of the dye molecules with the bases are believed to bring about the biological effects. For interaction with DNA two modes of interaction are suggested depending upon the DNA/Dye ratio.[4] For complex formation with nucleic acid base, the site of attack in a base depend on the electronic properties of the dye.[5] However, the modes of binding of nucleic acid bases with dyes also depend on dye concentration.[6] We have studied the semiconductive properties of the complexes of acriflavine dye with nucleic acid bases, adenine, cytosine, and uracil at various dye concentrations. In this paper we show that in the low dye concentration range ($\lesssim 10^{-1}$ mol mol^{-1}), these semiconducting complexes show compensation effect.

† Present address: Govt. Arts and Science College, Durg, M. P. 491002. (National Associate, University Grants Commission, India).

Experimental

The purine and pyrimidine bases used in the present study are adenine, cytosine, and uracil. These were obtained from Sigma Chemical Company, U. K., Acriflavine, a mixture of 2,8- and 3,6-diamino-10-methylacridinium chloride and 2,8- and 3,6-diaminoacridine was also obtained from the same commercial source. The bases and the dye were extensively purified by repeated crystallization from distilled water and methanol respectively and finally dried under vacuum before use. For preparing the complexes, acriflavine dye and the bases were taken in required proportions and dissolved in distilled water and then evaporated in vacuum. The finely powdered sample pressed in a sandwich cell between a conducting glass and a stainless steel electrode was maintained at moderate pressure by clips. The separation between the electrodes was maintained by a three mil thick teflon spacer. The cell was placed in a suitably designed conductivity chamber. A d.-c. voltage of 27 volts from a dry battery pack was applied across the cell. Dark conductivity was measured in both nitrogen atmosphere and vacuum using an Electrometer amplifier EA 815 of ECIL, India. The thermo emf was measured by a digital panel meter model HIL 2301, India. The experimental procedure for the measurement of activation energy was similar to that described earlier.[1]

Results and Discussion

The semiconduction activation energies of the crystalline powders of pure adenine, crytosine, uracil bases, and various base-dye complexes were measured several times in dry nitrogen atmosphere and also in vacuum (10^{-3} Torr (1 Torr=133.322 Pa)). All measurements gave consistent values. Almost the same values were obtained in dry nitrogen and in vacuum. The activation energies of pure adenine, cytosine, uracil, and acriflavine are 2.10, 2.12, 2.15, and 2.25 eV, respectively. The room temperature (30 °C) specific conductivities of the bases and also of the dye is typically of the order of 10^{-16}—10^{-18} Ω^{-1} cm^{-1}.

The current voltage characteristics of all the pure samples and the complexes are observed to be ohmic in the low voltage region (36 V) of our studies. In

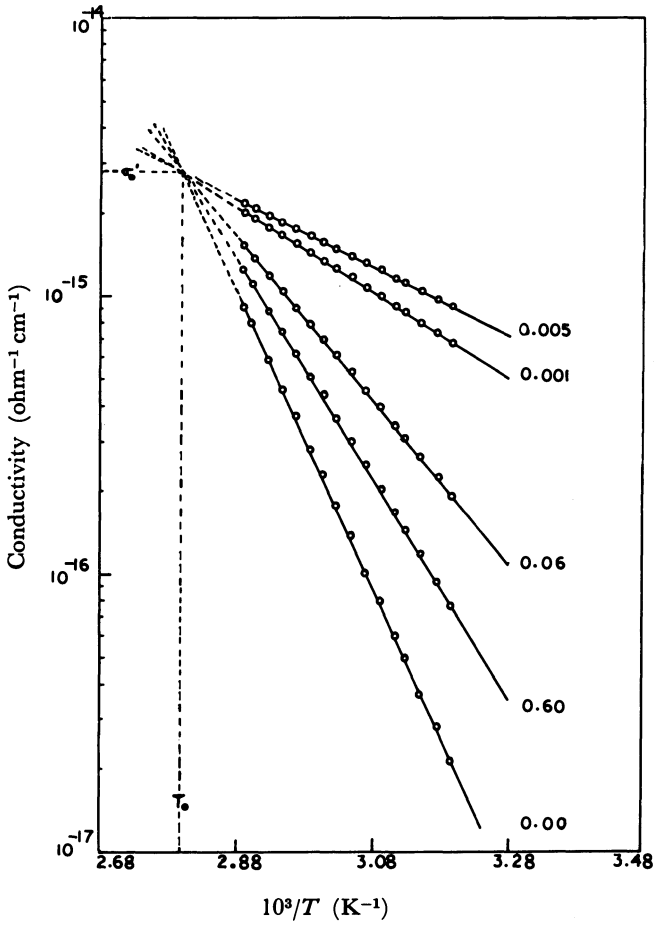

Fig. 2. $\log \sigma(T)$ vs. $1/T$ plot for cytosine-acriflavine dye complexes of different dye concentrations. The dye concentrations in mol mol^{-1} are shown in the diagram.

Fig. 1, we show the dye concentration dependence of activation energy for various complexes. As the dye concentration in a complex decreases from 1 mol mol^{-1} semiconduction activation energy decreases and reaches a minimum value at a certain dye concentration below which it starts increasing again and approaches the activation energy value of pure purine or pyrimidine base. For cytosine-acriflavine complex the minimum activation energy value obtained is 0.40 eV at 10^{-2} mol mol^{-1} dye concentration. For uracil-acriflavine and adenine-acriflavine complexes the minimum E value measured are 1.02 eV at 3×10^{-3} mol mol^{-1} dye concentration and 0.96 eV at 10^{-3} mol mol^{-1} dye concentration, respectively.

The binding of metal cations to nucleic acid bases and its relationship with electrostatic molecular potential of the bases have been discussed by Pullman and Pullman.[7] Their calculated electrostatic interaction energy is large for cytosine whereas it is small and is about the same magnitude for adenine and uracil. It is interesting to note that the change in semiconduction activation energy of our base-dye complexes also show a similar order.

In Fig. 2, we show the log σ (T) vs. $1/T$ plot for cytosine-acriflavine complexes of different dye concentration. It is seen that the extrapolated lines in these plots for complexes with different dye concentration intersect the ordinate at a wide variety of positions, but they all pass approximately through a single point at a temperature T_0. This result is in conformity with expression (1). At the characteristic temperature T_0, the value of $\sigma(T_0)$ gives the σ_0' value. For cytosine-acriflavine complexes, T_0=357 K and $\sigma_0'=2.8\times10^{-15}\ \Omega^{-1}\,\mathrm{cm}^{-1}$. In Figs. 3 and 4, we have shown similar log σ (T) vs. $1/T$ plot for uracil-acriflavine and adenine-acriflavine complexes. In these complexes, also the extrapolated lines pass through a single point. However in these complexes, the point of intersection is in the low temperature side of the working temperature region. From expression (1) we get that at any experimental temperature T_1K,

$$\sigma(T_1) = \sigma_0' \exp\left(\frac{1}{T_0} - \frac{1}{T_1}\right)\frac{E}{2k}.$$

The $\sigma(T_1)$ will show different behavior with variation of E depending on if $T_1>T_0$ or $T_1>T_0$. This is exactly what we see in the three complexes. In cytosine-acriflavine complex $\sigma(T_1)$ increases with

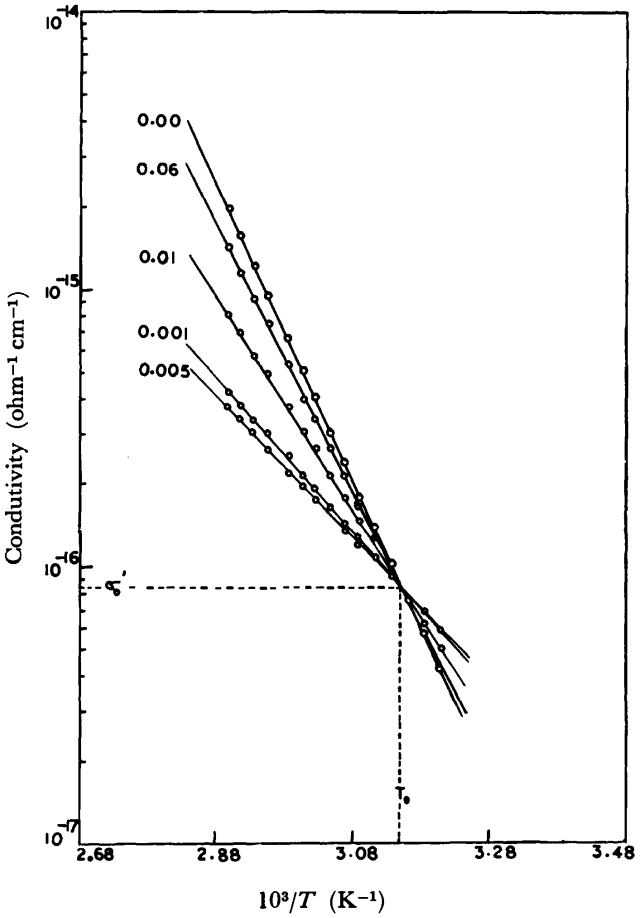

Fig. 3. $\log \sigma(T)$ vs. $1/T$ plot for uracil-acriflavine dye complexes of different dye concentrations. The dye concentrations in mol mol^{-1} are shown in the diagram.

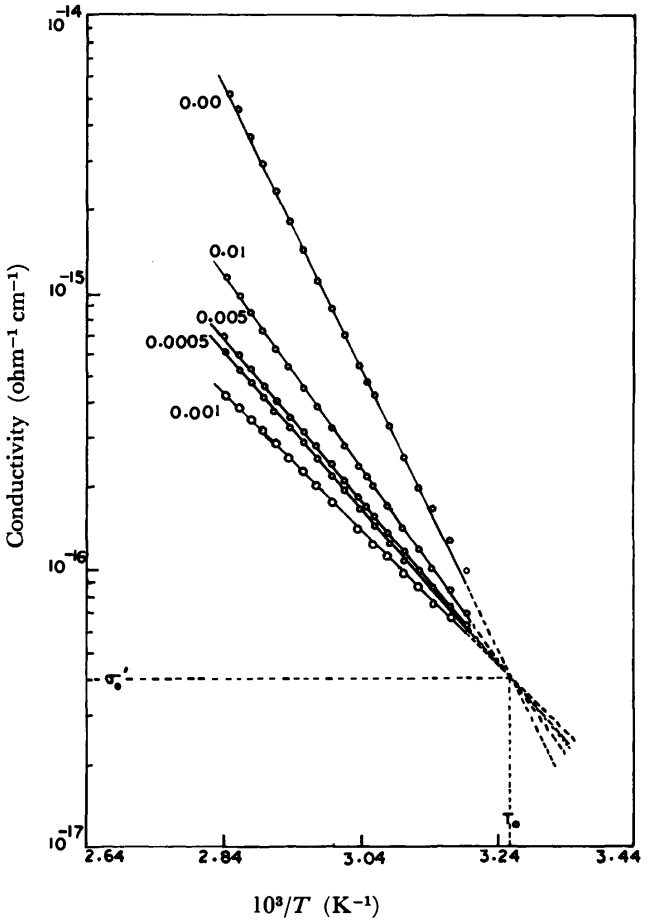

Fig. 4. $\log \sigma(T)$ vs. $1/T$ plot for adenine-acriflavine dye complexes of different dye concentrations. The dye concentrations in mol mol^{-1} are shown in the diagram.

decreasing E whereas in adenine-acriflavine and uracil-acriflavine complexes inverse behavior is observed. Inspite our measurement being limited by the electrometer sensitivity, we have been able to measure $\sigma(T)$ on both sides of T_0 in case of uracil-acriflavine complexes. To our knowledge, this is the first experimental demonstration of different behavior of change of $\sigma(T)$ with variation of E on two sides of a specific temperature in an organic semiconductor thus showing the physical significance of compensation temperature T_0.

It is now clear from experiments that the compensation temperature T_0 of a semiconductor plays an important role in dark conduction process. Acriflavine complexes with the three nucleic acid bases cytosine, adenine, and uracil have three distinct T_0 values. This result confirms our earlier observation with some polyenes[1,2] and some nitro aromatics[3] that T_0 is a molecular property.

"True" compensation effect is thought to arise from the existence of a linear relationship between the activation energy and the activation entropy of the system. It has been pointed out by Johnston and Lyons[6] that if a true linear free energy relation (LFER) does hold for dark conduction indicating a physical relationship between σ_0 and E, log (T_1) vs. E must also be linear where T_1 is a specific temperature. In Fig. 5, we show such plots for cytosine-acriflavine, adenine-acriflavine, and uracil-acriflavine complexes. T_0 and σ_0' are obtainable from the slopes and intercepts of these plots. These parameters can also be evaluated from plots made in alternate fashion as log σ_0 vs. E since log σ_0=log σ_0'+$E/2kT_0'$ σ_0 and E being experimentally measured. In Fig. 6, we show such plots for three different complexes. The plots are linear as expected from expression (1) and T_0 and σ_0' are obtained from the slopes and the intercepts respectively of these plots. In Table 1, we compare the values of T_0 and σ_0' for the complexes obtained by various methods of evaluation. The agreement is quite satisfactory. These results confirm that σ_0 and E are physically related and that T_0 has a physical origin. That we have observed compensation effect only in complexes of low dye concentra-

Studies in the Extraction of Cadmium with Some Sulfur Ligands

Roma LAHIRI and G. N. RAO*
Chemistry Department, Indian Institute of Technology, New Delhi-110016, India
(Received April 1, 1985)

Extraction of cadmium(II) with 2-(2-pyridyl)-2,3-dihydrobenzothiazole, *O,O'*-diethyl hydrogenphosphorodithioate, 1-phenyl-3-methyl-4-thiobenzoyl-5-pyrazolone, *N*-(2-naphthyl)mercaptoacetamide, and 2-(*o*-hydroxyphenyl)-2,3-dihydrobenzothiazole has been studied. Extraction constants (K_{ex}) have been calculated for these systems. These reagents have been compared with some common reagents used for the extraction of cadmium. Separation factors have been calculated for the separation of cadmium from zinc with some of these reagents.

Studies in the extraction of cadmium are somewhat limited. In spite of the fact that extraction of every metal has its own importance cadmium has a special significance owing to its toxicity and increasing concentration in the environment. In view of this a study has been undertaken to find effective reagents for cadmium extraction by investigating the extraction of cadmium with some sulfur ligands and by comparing the extraction data obtained with those for other reagents from the literature. Ligands containing donor sulfur atom have been chosen because cadmium which is a soft acid (in HSAB sense) is expected to form more stable complexes with soft bases.

The ligands chosen for the present study are 2-(2-pyridyl)-2,3-dihydrobenzothiazole(HPBT), *O,O'*-diethyl hydrogenphosphorodithioate(HDEDTP), 1-phenyl-3-methyl-4-thiobenzoyl-5-pyrazolone(HSBMPP), *N*-(2-naphthyl)mercaptoacetamide(HTN), and 2-(*o*-hydroxyphenyl)-2,3-dihydrobenzothiazole(H_2SATP).

Experimental

Apparatus and Reagents. A Pye Unicam SP 191 Atomic Absorption Spectrophotometer was used for measuring the metal concentrations. Measurements of pH was made using an expanded scale pH meter (Electronics Corporation of India Ltd.). A wrist action mechanical shaker was used for shaking.

Cadmium(II) solution was prepared by dissolving Analar grade cadmium acetate in distilled water, adding sufficient amount of acetic acid to prevent hydrolysis. The pH of the aqueous phase was maintained by using mixtures of potassium chloride and hydrochloric acid for pH 1—3, sodium acetate and acetic acid for pH 4—6, acetic acid and ammonia for pH 6—8 and ammonium chloride–ammonia for pH 8—10. A constant ionic strength (0.1) in the aqueous phase was maintained by using potassium nitrate solution. Where extraction was carried out from dilute hydrochloric acid solutions, potassium chloride was used to maintain the ionic strength.

The ligand HSBMPP was prepared by the method[1] reported by Chouhan and Rao. The compounds HPBT[2] and H_2SATP[3] were prepared by condensing 2-aminobenzenethiol (Kochlight) with 2-pyridinecarbaldehyde (Fluka), and salicylaldehyde(BDH), respectively. The other ligands used were HDEDTP (BDH) and HTN (E. Merck). Purity of the ligands was established on the basis of microanalysis and infrared spectra. Analar grade benzene, chloroform, carbon tetrachloride, and 1-butanol were used as solvents. Purification was done where necessary by standard methods.

Extraction Procedure. Ten ml of aqueous layer containing 2 ml of 100 ppm cadmium acetate solution, 5 ml of buffer solution and requisite volume of 1 M† potassium nitrate solution (to maintain the ionic strength at 0.1) was equilibrated with 10 ml of organic phase containing the required amount of the ligand in a stoppered bottle. The mixture was shaken in a mechanical shaker for a period sufficient for the attainment of equilibrium at 30±1 °C. The period of shaking was determined from preliminary experiments in all the systems studied. This was 60, 5, 120, 10, and 120 min with HPBT, HTN, HSBMPP, HDEDTP, and H_2SATP, respectively. Benzene was used as the solvent in the case of HSBMPP and H_2SATP while chloroform, carbon tetrachloride, and 1-butanol were used in the case of HTN, HDEDTP, and HPBT, respectively on the basis of preliminary solubility checks. After equilibration the aqueous layer was pipetted out. The concentration of the metal in the aqueous phase and the pH were then measured.

Results and Discussion

The extraction of a metal ion (M^{n+}) with a chelating ligand having a replaceable hydrogen atom (HA) may be represented as,

$$M^{n+}_{aq} + nHA_{org} \rightleftharpoons MA_{n\ org} + nH^{+}_{aq}. \quad (1)$$

The extraction constant (equilibrium constant) of this reaction is:

$$K_{ex} = \frac{[MA_n]_{org}[H^+]^n_{aq}}{[M^{n+}]_{aq}[HA]^n_{org}}. \quad (2)$$

Making the usual approximations[4] the ratio $[MA_n]_{org}/[M^{n+}]_{aq}$ in Eq. 2 may be considered equal to the distribution coefficient (D) and

$$K_{ex} = D\frac{[H^+]^n_{aq}}{[HA]^n_{org}} \quad (3)$$

or

$$\log K_{ex} = \log D - n\,pH - n \log [HA]_{org}. \quad (4)$$

Equation 4 implies that, (i) the slope of the plot

† 1 M=1 mol dm^{-3}.

of log D vs. pH at constant reagent concentration in the organic phase gives the number of protons released during complex formation and (ii) the slope of the plot of log D vs. log [HA] at constant pH gives the number of reagent molecules incorporated in the extracted complex.

Plots (Fig. 1) of log D vs. pH at constant ligand (HA) concentration and plots (Fig. 2) of log D vs. log [HA] at constant pH for HPBT, HTN, and HSBMPP gave slopes of ≈2. Thus the extraction of cadmium(II) with these ligands can be represented as occurring predominently according to the following equation:

$$Cd^{2+} + 2HA \rightleftharpoons CdA_2 + 2H^+$$

○: HPBT (0.001 M), △: HTN (0.0025 M), □: HSBMPP (0.01 M).

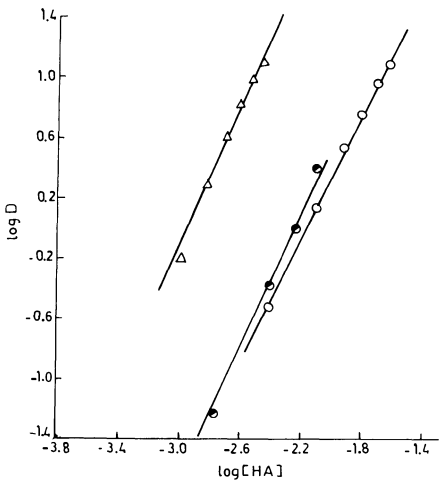

Fig. 2. Effect of ligand concentration on the extraction of Cd with HDEDTP, HSBMPP, and HTN.
○: HDEDTP ([HCl]=0.1 M, [KCl]=0.3 M), ◐: HSBMPP (pH=3.34), △: HTN (pH=5.1).

log K_{ex} values for these systems were calculated by using Eq. 4.

Since the extraction of cadmium(II) with HDEDTP took place from highly acidic solutions (quantitative extraction from 0.01—0.1 M HCl with 0.02 M reagent), a competing reaction in the aqueous phase would be the formation of the chloro complex of cadmium(II). A study of the effect of variation of chloride concentration showed that extraction fell with increase in chloride concentration. The plot (Fig. 2) of log D vs. log[HDEDTP] at constant hydrogen ion and chloride concentration gave a slope of ≈2 indicating the involvement of two moles of HDEDTP in the complex formation. The log K_{ex} value for this system was calculated from Eq. 5[5]

$$\log K_{ex} = \log D - n \log [HA]_{org} - n\,pH + \log \{1 + \beta_1[X^-] + \beta_2[X^-]^2 + \cdots\} \quad (5)$$

Here X^- is the complexing anion (Cl^-) and β_1 is the stability constant of the complex formation reaction.

The formula of the chelate species formed could not be determined in the case of Cd(II)-H_2SATP system as the log D vs. pH or log D vs. log [HA] plots were not regular. A $pH_{1/2}$ value (pH at 50% extraction) of 5.59 was obtained from the plot of percentage extration vs. pH with a 0.01 M solution of the ligand. An approximate K_{ex} value was calculated from this data assuming that the complex species formed here was similar to that in the other systems. Schweitzer et al. also observed irregularities in the extraction of cadmium(II) with salicylaldehyde oxime, acetylacetone, 2-methyl-8-quinolinol etc.[6]

The log K_{ex} values obtained in this study are listed in Table 1. The available K_{ex} values for the extraction of zinc(II) with these reagents are also included in this table.

From this data and other data available in literature[6,7,9,10] it may be concluded that ligands donating through sulfur would be more useful for the extraction of cadmium than their corresponding

Table 1. Extraction Constants for Cadmium(II) and Znic(II)

Reagent	log K_{ex} Cd(II)	Zn(II)	Solvent
2-(2-Pyridyl)-2,3-dihydrobenzothiazole	−6.8	−9.28[7]	1-Butanol
N-(2-Naphthyl)mercaptoacetamide	−4.27	−8.08[7]	Chloroform
3-Methyl-1-phenyl-4-thiobenzoyl-5-pyrazolone	−2.19	−2.68[8]	Benzene
O,O'-Diethyl hydrogenphosphorodithioate	3.67	—	Carbon tetrachloride
2-(*o*-Hydroxyphenyl)-2,3-dihydrobenzothiazole	−7.18	—	Benzene

Table 2. Separation Factors for Cadmium and Zinc

Reagent	Separation factor
2-(2-Pyridyl)-2,3-dihydrobenzothiazole	300
N-(2-Naphthyl)mercaptoacetamide	6500
3-Methyl-1-phenyl-4-thiobenzoyl-5-pyrazolone	3

oxygen analogues. The ligands HDEDTP, dithizone-(HDTZ),[11] sodium diethyldithiocarbamate (HDEDTC),[12] and HSBMPP appear to be most effective for the extraction of cadmium(II) if the K_{ex} values with these ligands are considered. The higher stability of HDEDTP in highly acidic solutions as compared to HDEDTC makes it a better reagent for analytical purposes.[13] Dithizone in spite of giving a high K_{ex} value is useful only at trace levels since the solubility of HDTZ itself and its chelates is very low in most of the organic solvents. On the other hand, both HDEDTP and its chelates are fairly soluble in organic solvents, and therefore can be useful at trace as well as macro levels. The ligands HPBT, HTN, 1,1,1-trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one,[10] 2-mercaptobenzothiazole,[6] 8-quinolinol,[14] and 5,7-dichloro-8-quinolinol,[6] by virtue of high K_{ex} values will also be useful for the extraction of cadmium. The oxygen donor ligands like β-diketones,[6,7,15] *N*-benzoyl-*N*-phenylhydroxylamine[15] etc. do not seem very attractive for the extraction of cadmium(II).

The possibility of utilizing these reagents for separating cadmium from zinc has been investigated by calculating the separation factor S which is the ratio of the distribution coefficients of the elements to be separated.[16] A separation in which not more than 1% of one element is coextracted will be obtained if $S \geq 10^4$ and the product of the distribution coefficients is close to unity. The separation factors for HPBT, HTN, and HSBMPP are given in Table 2.

Considering these separation factors and those for other reagents from literature[6-12,14,15,17] it can be concluded that benzoylacetone,[15] 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone,[8,9] and HTN would be more useful for the separation of cadmium from zinc.

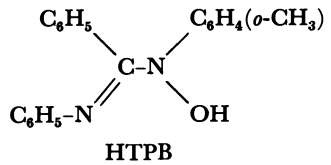
†Department of Chemistry, Ravishankar University, Raipur (M.P.), India
(Received April 25, 1985)

N-Hydroxy-*N*-*o*-tolyl-*N'*-phenylbenzamidine (HTPB) is presented as a new sensitive and highly selective reagent for determination of iron in drug, biochemical and biological samples in presence of thiocyanate. The red organge Fe(III)–HTPB–SCN mixed ligand complex is quantitatively extracted into benzene. The extraction of iron(III) as thiocyanato mixed ligand complex is quantitative in the acidity range between 0.2—0.7 M (1M=1 mol dm^{-3}) hydrochloric acid. The effective molar absorptivity of the complex is 12000 l mol^{-1} cm^{-1} with Sandell's sensitivity of 0.0046 μg of iron per cm^2. On the basis of this sensitive color reaction, a simple, rapid, selective, and highly reproducible method for the extractive spectrophotometric determination of microgram amounts of iron in various drug, biochemical and biological samples has been developed. The method is free from most of the common metal ions and commonly used sequestering agents.

Among the several methods reported for the spectrophotometric determination of iron in various complex materials,[1-13] the thiocyanate and 1,10-phenanthroline methods are used over a long period. The iron(III)–thiocyanate method is simple, rapid, and sensitive, but it suffers from interferences due to a large number of experimental factors. These include time of standing, thiocyanate concentration, deviation from Beer's law and reaction of the thiocyanate with other elements to give colored products. The iron(II)–1,10-phenanthroline method is widely applicable to routine determination of iron but it suffers from serious interference from common ions such as Ni(II), Cu(II), Bi(III), and Ag(I). Hence it is thought worthwhile to describe a better method for determination of iron in complex materials. In this communication, the reaction of *N*-hydroxy-*N*-*o*-tolyl-*N'*-phenylbenzamidine(HTPB) with iron(III) in



HTPB

presence of thiocyanate was investigated looking towards the possible use of this reagent for spectrophotometric determination of iron in biochemical and biological samples and separation from other metal ions associated in complex materials. The proposed method offers several advantages over other established methods.[1-13] It is sensitive and highly selective and can be used over wide acidity range. The reagent is easy to prepare and if kept in amber glass bottles, solution can be stored for at least a month without any deterioration. It is applicable for the determination of iron in all complex materials because most of the common ions do not interfere.

Experimental

Standard Iron(III) Solution. The standard solution of iron(III) was prepared by dissolving 1.0 g pure iron wire (E. Merck) in 50 ml of 1:3 nitric acid. The oxides of nitrogen were removed by boiling and diluted to one liter with distilled water. The metal content of the solution was evaluated gravimetrically with 8-quinolinol.[14]

Apparatus. A Carl-Zeiss specord recording ultraviolet spectrophotometer and an ECIL UV-VIS spectrophotometer model GS-865 equipped with 1-cm matched silica and quartz cells were employed for all photometric measurements.

Preparation of *N*-Hydroxy-*N*-*o*-tolyl-*N'*-phenylbenzamidine. *N*-*o*-Tolylhydroxylamine 3.2 g (0.027 mol) was taken in 50 ml absolute ether in a 500 ml conical flask. To this, 5.6 g (0.027 mol) of *N*-phenylbenzimidoyl chloride in 100 ml ether was added in small quantities during the course of 15 min with constant stirring. A light brown oil slowly separated out. Stirring and scratching were continued till the oil solidified and separated in the form of white crystals. This was filtered off and washed with 3×20 ml portions of ether and air dried. The resulting hydrochloride was treated with dilute aqueous ammonia to liberate the free base. This was recrystallized from petroleum ether–benzene (1:2) at 60—80°. Yield 45%, mp 131 °C. Analysis showed C, 79.08; H, 5.65; N, 8.98%. $C_{20}H_{18}N_2O$ requires: C, 79.47; H, 5.96; N, 9.27%.

Extraction Solution. A 0.1% W/v benzene solution of reagent was employed for the extraction work. 2% W/v aqueous solution of potassium thiocyanate was used throughout the experiment.

Recommended Procedure. Place and aliquot of iron(III) solution containing 40—80 μg of metal in a 100 ml separatory funnel. To this, add 5 ml of potassium thiocyanate solution. Adjust the volume of the solution to about 25 ml and the acidity to between 0.2 and 0.7 M with hydrochloric acid. Introduce 25 ml benzene solution of the reagent and equilibrate for 2 min. Allow the phases to separate. Dry the colored extract over anhydrous sodium sulfate 2 g in a 50 ml beaker. Measure the absorbance at wavelength of maximum absorption against reagent blank.

Results and Discussion

Absorption Spectra. The absorption spectra of the ternary iron(III) complex and the reagent in benzene are shown in Fig. 1. The Fe(III)-HTPB-SCN complex shows a sharp absorption maximum at 460 nm having the value for molar absorptivity to be 12000 l mol^{-1} cm^{-1}. As a reagent blank prepared under similar conditions does not absorb in the region 450—700 nm, it can be replaced by benzene.

Choice of Solvent. Various water immiscible organic solvents such as chloroform, benzene, carbon tetrachloride, toluene, xylene, etc. were found to extract the mixed ligand complex quantitatively. However, benzene was found to be the better extracting solvent as in this the sensitivity of the complex is enhanced and complete extraction is relatively rapidly accomplished.

Effect of Acidity. The acidity of the solutions was maintained with 2 M hydrochloric acid. If the hydrochloric acid concentration of aqueous phase lies in the range 0.01 to 1.0 M the position of the absorption band of the benzene extract remains intact. However, the optimum acidity range was found to be 0.2 to 0.7 M hydrochloric acid in which iron(III) was quantitatively extracted. The fatty acids and other inorganic acids were unsuitable for extraction work due to low absorbance of complex.

Effect of Reagents. A 30 and 120 fold molar excess of HTPB and thiocyanate respectively was found to be adequate for complete extraction of iron. A further excess of these (HTPB upto 100 fold and thiocyanate upto 5000 fold molar) did not interfere with the determination. The order of addition of reagents was not critical.

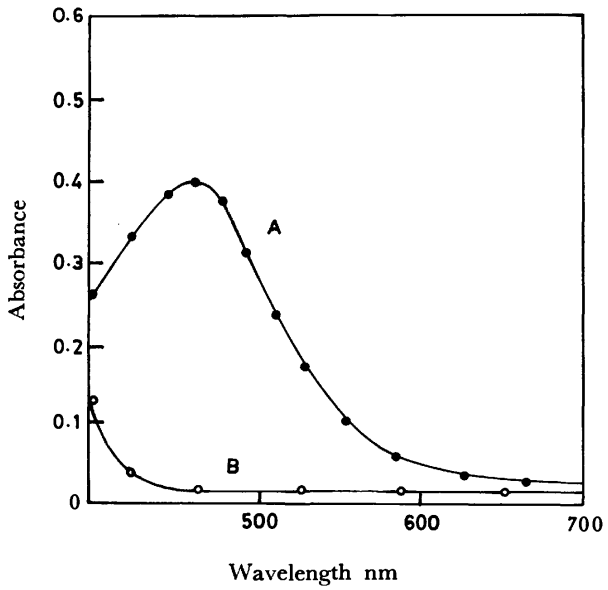


Fig. 1. Absorption spectra.
A: Fe(III)-HTPB-SCN complex (Fe=3.21×10^{-5}M),
B: *N*-Hydroxy-*N*-*o*-tolyl-*N'*-phenylbenzamidine 0.003 M in benzene.

Effect of Electrolytes, Volume of Aqueous Phase, Temperature, and Standing Time. The absorption of the colored system and the percentage extraction of iron(III) are not affected by electrolytes such as potassium chloride, ammonium chloride, and sodium chloride (2.0 M). The volume of the aqueous phase can vary between 10 to 60 ml without affecting the mixed complex formation and its subsequent extraction. Variation in temperature from 20 to 40 °C did not influence the absorbance value of the colored system. The extracts were stable for at least 40 h at 27±2 °C. A time of 1 min was sufficient for complete extraction of iron(III).

Beer's Law, Optimum Concentration, Sensitivity, and Precision. The orange-red iron(III) mixed complex adhered to Beer's law over the concentration range 0.2—4.5 ppm of the metal. The optimum concentration range on the basis of Ringbom plot[15] is 0.8 to 3.8 ppm of iron. The molar absorptivity and

a) Causing an error of less than 2%.

Sandell's sensitivity of the color reaction are found to be 12000 l mol^{-1} cm^{-1} and 0.0046 μg of iron per cm^2 at 460 nm. The precision of the method was evaluated by measuring the absorbance value of 10 samples, each containing 45 μg iron per 25 ml. A mean absorbance value of 0.388 was observed with a standard deviation of ±0.0025 absorbance unit and relative standard deviation of ±0.69%.

Composition. In iron(III)-HTPB-SCN mixed ligand complex, the ratio of iron to reagent and thiocyanate was determined by curve fitting method[16] (by plotting log absorbance versus log concentration of reagents in terms of molarity). The results obtained indicate the formation of 1:1:2 (metal: HTPB:SCN) mixed ligand complex in benzene.

Influence of Diverse Ions. For studying the influence of diverse ions on the determination, an aliquot of iron(III) solution containing 45 μg of the metal was transferred to a separatory funnel and to this was added a solution containing a known weight of diverse ions. The acidity was adjusted to 0.5 M with hydrochloric acid and the total volume to about 25 ml and iron was extracted with the reagent as described earlier. The effect of various ions in the determination of iron(III) is summarized in Table 1.

Application of the Method. To test the validity of the method, various drugs, biochemicals and biological samples were selected. Iron presented in the form of iron(II) sulfate, iron(II) succinate, and fumarate can be conveniently determined by this method.

A weighed amount of the sample was transferred into a Kjeldahl flask and heated gently with a mixture of concentrated nitric and sulfuric acids (10:1 v/v) until charring commenced. Addition of concentrated nitric acid and boiling were continued until either a colorless or a pale yellow solution was obtained. This was then cooled, a few mililiters of water was added and then solution was evaporated until white fumes were evolved. The procedure was repeated two or three times. A few mililiters of dilute hydrochloric acid were added and heating was continued until fumes of nitric acid had been removed. The solution was then diluted to an appropriate volume. An aliquot of the solution was pipetted and iron was determined by the procedure recommended earlier. The results were compared with those obtained by 1,10-phenanthroline method (Table 2).

Table 2. Determination of Iron in Drug Biochemical and Biological Samples

No. Sample	Calculated iron content[a]/%	
	1,10-Phenanthroline method	Hydroxyamidine method

Reaction of 2-Aminobenzohydrazides with Schiff Bases. A New Route to 3-Benzylideneamino-4(3*H*)-quinazolinones and 2-[2-(Methylamino)-phenyl]-5-aryl-1,3,4-oxadiazoles

Padi PRATAP REDDY, Cheppala KISTA REDDY, and Padala SATYANARAYANA N. REDDY*
Department of Chemistry, Osmania University, Hyderabad-500 007, India
(Received November 19, 1984)

Reaction of 2-aminobenzohydrazides with Schiff bases in methanol followed by $KMnO_4$ oxidation has resulted in the respective formation of 3-benzylideneamino-4(3*H*)-quinazolinones and 2-[2-(methylamino)-phenyl]-5-aryl-1,3,4-oxadiazoles, characterized by spectral and analytical methods.

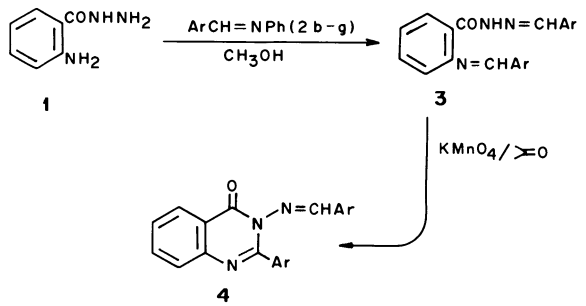
We have recently reported a facile one-step synthesis of 3,4-dihydro-5*H*-1,3,4-benzotriazepin-5-ones, the aza analogues of pharmacologically important 1,4-benzodiazepines, from isatoic anhydride and aroylhydrazines.[1] But the product yields in this reaction were moderate (30—50%) and the work-up involved extensive chromatography. We surmised that cyclization of 2-aminobenzohydrazide (**1**) by insertion of a carbon between the terminal nitrogens would provide a direct route to triazepin-5-ones. Schiff bases are known to participate in heterocyclization reactions acting as a source of carbon, sometimes more effectively than the corresponding carbonyl compounds.[2] Hence the reactions of 2-amino- and 2-(methylamino)benzohydrazides with *N*-benzylideneanilines were carried out and the results are discussed here.

Results and Discussion

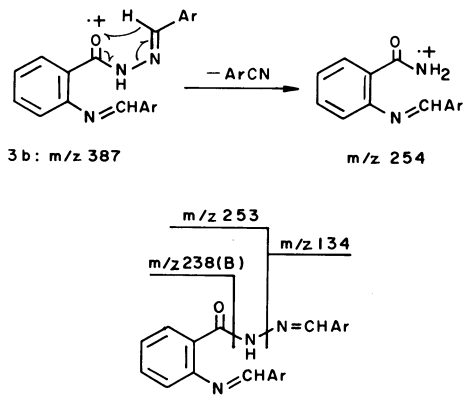
2-Aminobenzohydrazide (**1**) reacts with *N*-(4-methoxybenzylidene)aniline (**2b**) in methanol at ambient temperature, to give a colorless crystalline product, mp 221 °C, whose elemental analysis and molecular weight (M^+ at *m/z* 387) tallies with the molecular formula $C_{23}H_{21}N_3O_3$, formally derived from one mole of **1** and two moles of the Schiff base. The same product was formed irrespective of the stoichiometry of reaction. The infrared (KBr, ν_{NH} 3280, $\nu_{C=O}$ 1660, $\nu_{C=N}$ 1610 cm^{-1}) and ^1H NMR (DMSO-d_6) spectra suggested *N*-[2-(4-methoxybenzylideneamino)benzoyl]-*N'*-(4-methoxybenzylidene)hydrazine (**3b**) structure for the product. The two azomethine protons could be discerned in ^1H NMR spectrum by the chemical shift values at δ 8.9 and 8.95. The hydrazone structure, **3b** was preferred also by its fragmentation behavior under electron impact which is characteristic of aroylhydrazones.[3] The mass spectrum of **3b** thus showed intense fragmentation peaks formed by N–N bond fission and α-cleavage reactions of the molecular ion.

Attempts to cyclize **3b** to the triazepinone by permanganate oxidation gave a product **4b**, mp 185 °C, whose molecular weight (M^+ at *m/z* 385). indicated loss of two hydrogens from **3b**. However, the spectral data is more in confirmity with 3-benzylideneamino-2-aryl-4-(3*H*)-quinazolinone structure. The IR spectrum is devoid of NH absorptions, and the carbonyl peak at 1680 cm^{-1} is similar to that of 3-substituted 4(3*H*)-quinazolinone.[4] The ^1H NMR showed the presence of only one azomethine proton (at δ 8.6) and successive loss of two 4-methoxybenzonitrile moieties from the molecular ion was indicated in the mass spectrum.

The reaction of **1** with Schiff bases has been extended to six other benzylideneanilines (**2a—g**) and good yields of the corresponding *N*-[2-(4-substituted benzylideneamino)benzoyl]-*N'*-(4-substituted benzylidene)hydrazines (**3**) were isolated except in the case of *N*-benzylideneaniline (**2a**). **3** was oxidized with permanganate to give quantitative yields of 3-benzylideneamino-4(3*H*)-quinazolinones, providing a



Scheme 1.



Scheme 2. Mass spectral fragmentation of product, **3b**.

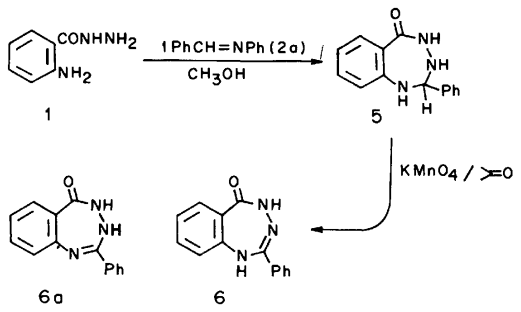
new route for the synthesis of **4**.

The reaction of **1** with **2a** proceeded in a different way and gave a product, mp 190 °C whose M^+ (*m/z* 239) in the mass spectrum indicated it to be a 1:1 product. The electronic λ_{max} (log ε) [206 (3.63), 219 (3.90), 252 (3.70), 292 (4.05), 303 (2.97), 341 (3.10)] and IR spectra (ν_{NH} 3280, $\nu_{C=O}$ 1670 cm^{-1}) are consistent with 2-phenyl-1,2,3,4-tetrahydro-5*H*-1,3,4-benzotriazepin-5-one (**5**) structure. Compound **5** was found not soluble in benzene, chloroform, dimethyl sulfoxide, and acetone in such concentrations for obtaining a good continuous sweep ^1H NMR spectrum. **5** on permanganate oxidation, or on reaction with one mole of *N*-benzylideneaniline in methanol, gave a product **6**, mp 152 °C. The mass spectrum of **6** (M^+ at *m/z* 237) showed it to be a dehydrogenated product of **5** and the appearance of a peak at 1610 cm^{-1} (C=N) in addition to 1670 cm^{-1} (C=O) corroborates the assumption. Based on these data **6** was assigned 2-phenyl-1,4-dihydro-5*H*-1,3-4-benzotriazepin-5-one structure. **6** was also formed in the 1:2 molar reaction of **1** and **2a**.

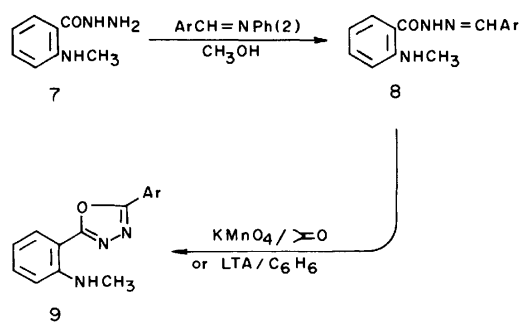
The product **6** is an isomer of **6a** (mp 179 °C)[1] which may be formally derived from proton transfer. However, attempts to convert **6** to **6a** (or vice versa) by 4 M HCl (1 M=1 mol dm^{-3}) did not succeed. Hence, the structures of **5** and **6** were tentatively assigned on the basis of spectral data.

The reason why the reaction of **1** with **2a** gives **5** instead of **3a** is not clear.

To prevent the possibility of diarylidene compounds, 2-(methylamino)benzohydrazide (**7**) was reacted with *N*-benzylideneanilines. An equimolar mixture of **7** and **2b** in methanol gave a colorless crystalline product, mp 176 °C at room temperature, whose structure was confirmed as *N*-[2-(methylamino)benzoyl]-*N'*-(4-methoxybenzylidene)hydrazine (**8b**) from its mass (M^+ 283) and IR spectra (ν_{NH} 3240 $\nu_{C=O}$ 1670 cm^{-1}). The permanganate oxidation of **8b** gave a product which showed the molecular ion at *m/z* 281, two amu less than the starting **8b**. Surprisingly the IR (ν_{NH} 3190, $\nu_{C=N}$ 1600 cm^{-1}] was devoid of carbonyl absorption suggesting 2-[2-(methylamino)phenyl]-5-(4-methoxyphenyl)-1,3,4-oxadiazole (**9b**) structure. The carbonyl group absorbs around 1670 cm^{-1} in a triazepinone,[1] whose formation is possible in this oxidation reaction. **9b** was also obtained when the oxidation was carried out using lead tetraacetate (LTA). Synthesis of 1,3,4-oxadiazoles by oxidative cyclization of *N*-benzoylhydrazones or semicarbazones of aldehydes has been reported.[5] The reaction of **7** and five other *N*-benzylideneanilines afforded corresponding hydrazones, (**8a—f**). **8** Underwent both permanganate and LTA oxidation reactions to give good yields of **9**. Further evidence for the assigned structure of **9** was provided by comparison with authentic samples.[6] Formation of **9** from **8** is likely to proceed through the intermediacy of an enol form and the preference for oxadiazole ring is due to its thermodynamic stability and steric implications of methylamino group in the cyclization step.



Scheme 3.



Scheme 4.

Experimental

Melting points are uncorrected. IR spectra were recorded on a Perkin-Elmer Infracord 337 spectrophotometer, ^1H NMR spectra on Varian A-60D instrument using TMS as internal standard and mass spectra on a Perkin-Elmer Hitachi RMU-6L instrument.

***N*-[2-(Benzylideneamino)benzoyl]-*N'*-benzylidene)hydrazines (3). General Procedure:** 2-Aminobenzohydrazide (**1**, 1 mmol) was dissolved in methanol (5 ml) and *N*-benzylideneaniline (**2**, 1 mmol) was added to it with thorough shaking and the mixture left aside for few minutes at room temperature. **3** Separated out from the clear solution, filtered and recrystallized from suitable solvent (Table 1).

3-Benzylideneamino-2-aryl-4-(3*H*)-quinazolinones (4). General Procedure: *N*-[2-(Benzylideneamino)benzoyl]-*N'*-benzylidenehydrazine (**3**, 10 mmol) was dissolved in dry acetone (100 ml) and $KMnO_4$ (1 gram) was added to it. The mixture was refluxed on water bath and further quantities of $KMnO_4$ were added to the boiling solution until pink color persisted. The solution was filtered and acetone was distilled off from the filtrate. The residue thus obtained was taken in water (25 ml) and excess $KMnO_4$ was destroyed with sodium sulfite solution (15 ml). The solution was extracted with chloroform (3×50 ml). The chloroform extract was dried over anhydrous sodium sulfate and the solvent was distilled off to yield crude product, **4**

Table 1. Characterisation Data of *N*-[2-(Benzylideneamino)benzoyl]-*N'*-benzylidenehydrazines (**3**), 3-Benzylideneamino-2-aryl-4(3*H*)-quinazolinones (**4**) and *N*-[2-(Methylamino)benzoyl]-*N'*-benzylidenehydrazines (**8**)

which was recrystallized from suitable solvent (Table 1).

2-Phenyl-1,2,3,4-tetrahydro-5*H*-1,3,4-benzotriazepin-5-one (5). 2-Aminobenzohydrazide (**1**, 0.15 g) was dissolved in methanol (6 ml) and *N*-benzylideneaniline (**2a**, 0.18 g) was added to it with thorough shaking and the mixture left aside for few minutes at room temperature. White-colored compound (**5**) that separated from the solution was filtered and recrystallized from benzene (mp 190 °C yield 76%).

Found: C, 70.44; H 5.41; N 17.45%. Calcd for: C, 70.30; H, 5.44; N, 17.57%.

2-Phenyl-1,4-dihydro-5*H*-1,3,4-benzotriazepin-5-one (6). Method 1. Oxidation of 5 Using $KMnO_4$. Tetrahydro compound **5** (0.24 g) was dissolved in acetone (50 ml) and $KMnO_4$ (1 g) was added to it. The mixture was refluxed on water bath for 8 h. The solution was filtered and acetone was distilled off from the filtrate. The residue thus obtained was taken in water (25 ml) and excess of $KMnO_4$ was destroyed with sodium sulfite solution (20 ml). The solution was extracted with chloroform (3×50 ml) and chloroform extract was dried over anhydrous sodium sulfate and the solvent was distilled off. The crude product thus obtained was recrystallized from pet. ether (60—80 °C)-benzene, mp 152 °C, yield 82%.

Found: C, 70.73; H, 4.60; N, 17.75%. Calcd for: C, 70.88; H, 4.64; N, 17.70%.

Method 2. Oxidation of 5 Using *N*-Benzylideneaniline (2a). Tetrahydro compound **5** (0.24 g) was dissolved in methanol (8 ml) and *N*-benzylideneaniline (**2a**, 0.18 g) was added to it. Reaction mixture was thoroughly shaken and left aside for few minutes. Separated light yellow-colored crystalline product (**6**) was filtered and recrystallized from pet. ether (60—80 °C)-benzene, mp 152 °C, yield 74%.

Method 3. From 2-Aminobenzohydrazide (1) and *N*-Benzylideneaniline (2a). 2-Aminobenzohydrazide (**1**, 0.15 g) was dissolved in minimum amount of methanol (6 ml) and *N*-benzylideneaniline (**2a**, 0.36 g) was added to it. Reaction mixture was thoroughly stirred and left aside for few minutes. Light yellow-colored crystalline compound separated out from the clear solution within few minutes. It was filtered and recrystallized from pet. ether (60—80 °C)-benzene, mp 152 °C, yield 72%.

***N*-(2-Methylaminobenzoyl)-*N'*-benzylidenehydrazines (8). General Procedure.** 2-(Methylamino)benzohydrazide (**7**, 1 mmol) was dissolved in methanol (7 ml) and an *N*-benzylideneaniline (**2**, 1 mmol) was added to it. The reaction mixture was stirred and left aside for few minutes. **8** separated immediately from the clear solution. It was filtered and recrystallized from suitable solvent (Table 1).

2-[2-(Methylamino)phenyl]-5-aryl-1,3,4-oxadiazoles (9). General Procedure. Method 1. Oxidation of Hydrazones 8 with $KMnO_4$. Hydrazone **8** (1 mmol) was dissolved in dry acetone (50 ml) and $KMnO_4$ (1 g) was added to it. The mixture was refluxed on water bath for 8 h. Further quantities of $KMnO_4$ were added to boiling solution until the pink color persisted. The solution was filtered and acetone was distilled off from the filtrate. The residue thus obtained was taken in water (20 ml) and excess of $KMnO_4$

was destroyed with sodium sulfite solution (20 ml). The solution was extracted with chloroform (3×50 ml) and chloroform extract was dried over anhydrous sodium sulfate and the solvent was distilled off. The crude product thus obtained was recrystallized from suitable solvent (Table 2).

Method 2. Oxidation of Hydrazones 8 with LTA. Hydrazone **8** (1 mmol) was dissolved in dry benzene (25 ml). Dry LTA (2 mmol, 0.886 mg) was added to it and the reaction mixture was refluxed on water bath for 15 min and then cooled. The mixture was extracted with 30% NaOH solution (3×50 ml). Benzene solution was dried over anhydrous sodium sulfate and the solvent removed under reduced pressure. The obtained brown residue was purified by recrystallization from suitable solvent (Table 2).

Synthesis of Standardized Building Blocks as a β-D-Mannosyl Donors with a Temporary Protection to be 3,6-Di-*O*-glycosyl Acceptors, for Constructing the Inner Core of Glycoproteins and Artificial Antigens

El Sayed H. El Ashry*,† and Conrad Schuerch
Department of Chemistry, State University of New York,
College of Environmental Science and Forestry,
Syracuse, New York 13210, U.S.A.
(Received April 8, 1985)

A synthetic scheme has been achieved for the core block of glycoproteins having D-mannose configuration, which is standardized to be a 3,6-di-*O*-glycosyl acceptor and react stereoselectively as a β-D-mannosyl donor. The synthesis was started by methyl 2,3-*O*-isopropylidene-α-D-mannopyranoside, which upon benzylation, deisopropylidenation, and selective acetolysis of the 6-*O*-benzyl group afforded the corresponding tetraacetate, which could be converted to 3,6-di-*O*-allyl-4-*O*-benzyl-1,2-*O*-(1-methoxyethylidene)-β-D-mannopyranose. The orthoester could be separated into the *exo* and *endo* isomers. Hydrolysis of the orthoester ring followed by reaction with mesyl chloride gave 3,6-di-*O*-allyl-4-*O*-benzyl-2-*O*-mesytl-α-D-mannopyranosyl chloride, that upon reaction via its 1-*O*-trifluoroethanesulfonate with 2-[4-(*p*-toluenesulfonamido)phenyl]-ethanol gave the corresponding glycosides in β:α ratio of 3:1. Deallylation of the β-glycosides gave the diol which are suitable for branching and could react selectively at the 6-position allowing its potential for glycosylation by different glycosyl donors.

Many glycoproteins existing at cell surfaces and in inter-cellular systems have a common feature[1-4] in which a 3,6-di-*O*-(α-D-mannopyranosyl)-D-mannopyranosyl moiety is linked via a 1,4-β-linkage to a chitobiose residue which is linked in turn to asparagine. Glycan chains in these glycoproteins can be classified[4-12] into three types according to their origin as well as the kind of the monosaccharide existing in the branched units of the glycan chains. The first type (**1**) is oligosaccharides having high mannose content which was isolated from calf thyroglobule, the second type (**2**) which is considered as complex one and was isolated from immunoglobulin, and the third type (**3**) which is a hybrid and was isolated from ovalbumin. They have various biological functions such as the recognition signals at cell surfaces.

The artificial antigen, prepared by coupling a carbohydrate residue to a protein support, produces antibodies specific for the carbohydrate moiety, when immunized to animals. This led to great efforts towards the estimation of the immunological determinants of various antigens, via selecting artificial antigen containing particular oligosaccharide which may provide homogeneous antibody of predefined specificity.[13-16] The availability of homogeneous antibody specific for the synthetic hapten may provide an approach for studying the antigen-antibody interaction. The success in the synthesis of artificial antigen is largely due to the recent advances[17-22] in the stereoselective synthesis of the requisite oligosaccharides in high yield as well as their involvement of functional groups capable of coupling to proteins. α-D-Manp-(1→6)-α-D-manp, and α-D-manp-(1→2)-α-D-manp have been described[16] as the antigenic backbone and side chain of the yeast mannan. α-D-Manp-(1→3)-α-D-manp has been also described[23] as the antigenic branching point of the glycoproteins.

The object of this synthetic project aimed to provide an efficient synthetic approach for the synthesis of the protein conjugate of the trisaccharide 3,6-di-*O*-(α-D-mannopyranosyl)-D-mannose (**4**) as artificial antigen which represents the core structure in the glycoproteins.[1-3] The prerequisite for that is the synthesis of a core block of the mannose moiety, standardised (such as **4a**) to act as a glycosyl acceptor in the 3 and 6 positions, and meantime could act stereoselectively as a β-D-mannosyl donor toward a hydroxyl group, which is not yet reported elsewhere because it is de facto the most problematic part, and therefore its synthesis is described in the present work.

The available methods[24-27] for the stereoselective synthesis of 1,2-*cis* glycosides of gluco and galacto

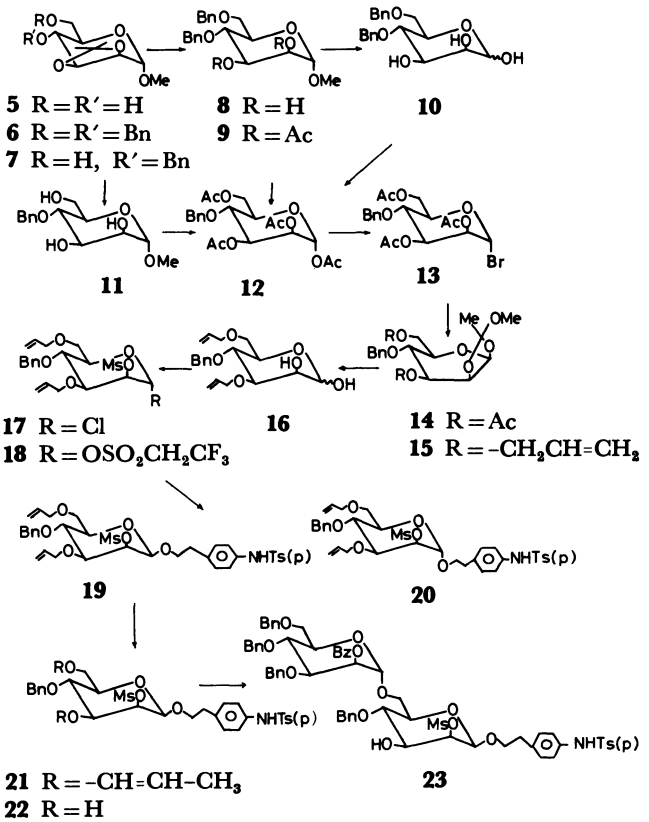
types are not of general utility for the synthesis of that of manno type. The use of glycosyl halides with *O*-2, *O*-3 bridging substituents that permit β-attack at *C*-1 has been reported.[28-31] This method does not allow the different temporary protection of *C*-2 and *C*-3 hydroxyl groups prior to the glycosidation of the mannosyl residue. The approach, which has found wide application in oligosaccharide synthesis,[32-35] utilises a suitably protected D-glucopyranosyl halide having a participating group at *C*-2 to favor β-linkage, followed by deacylation of *O*-2, oxidation and reduction of the resulting ketone to the manno epimer. A stereospecific synthesis of β-mannopyranosides with the use of insoluble silver catalysts has been also reported.[36] Enhancing the *C*-2-*O*-dipole by appropriate substitution has also been used to afford stereoselective synthesis[21,22] of β-D-mannosides. In a previous report,[22] a model study of the latter method with temporary blocking groups proved its successful application. Having this in mind, the design for the synthesis of 3,6-di-*O*-allyl-4-*O*-benzyl-2-*O*-mesyl-α-D-mannopyranosyl chloride (**17**) will provide a promising synthon to be used for synthesizing the target complex oligosaccharides by glycosidation to form the β-linkage followed by deallylation to generate hydroxyl groups at 3 and 6 positions, suitable for further construction.

Results and Discussion

Upon benzylation with benzyl chloride–powdered potassium hydroxide, methyl 2,3-*O*-isopropylidene-α-D-mannopyranoside (**5**)[37] gave the dibenzyl derivative (**6**) that upon deisopropylidenation afforded methyl 4,6-di-*O*-benzyl-α-D-mannopyranoside (**8**) in 82% yield. This dibenzyl derivative (**8**) is a potential starting material,* since it can be prepared on a large scale in crystalline form. The presence of two benzyl groups in **8** was confirmed form its ^{1}H and ^{13}C NMR spectra.

Moreover, the structure was also confirmed by its acetylation to give the diacetate (**9**) whose ^{1}H NMR spectrum showed the presence of two acetyl singlets at δ 2.15 and 1.93 and a downfield shift of H-2 and H-3 (δ 5.27 and 5.35, $J_{2,3}$ 4 Hz and $J_{3,4}$ 8 Hz). Acid hydrolysis of **8** by hydrochloric acid in aqueous dioxane afforded 89% yield of 4,6-di-*O*-benzyl-D-mannopyranose (**10**) based on the recovery of the starting material which could be recycled. The acetylation of **10** gave a mixture of the corresponding α- and β-tri-*O*-acetyl derivatives[23] in 55 and 30% yield, respectively. Acetolysis of **8** under controlled temperature and reaction time afforded 1,2,3,6-tetra-*O*-acetyl-4-*O*-benzyl-α-D-mannopyranose (**12**) in 73% yield. Compound **12** could also be obtained in 78 and 86% yield by acetolysis of **11**[38] and **10**, respectively. For convenience, direct conversion of **8** into **12** was found to be satisfactory. The structure of **12** was confirmed from ^{1}H NMR spectrum which showed the presence of four acetyl singlets in addition to the downfield shift of H-1, H-2, H-3, and H-6 signals, and from ^{13}C NMR spectrum which showed, in addition to the presence of one benzyl group, an upfield shift of the *C*-6. The acetate **12** was assigned the α-configuration based on its optical rotation. The reaction of **12** with hydrogen bromide afforded the bromide (**13**).

The orthoester **14** was prepared from **13** by reaction with methanol in the presence of 2,6-lutidine. It exists as a mixture of diastereoisomers in a ratio 1:12 as found from its ^{1}H NMR spectrum, and the major isomer could be crystallized in a pure form. Deacetylative allylation of the mixture of isomers of **14** gave the diallyl derivative (**15**), also as a mixture of isomers that could be separated by LC to give the major isomer **15a** as a crystalline derivative in 82% yield [singlets at δ 1.72 (CMe) and 3.30 (OMe)] and the minor isomer **15b** as a syrup in 6% yield [singlets at δ 1.53 (CMe) and 3.48 (OMe)]. For assignment of the diastereoisomeric orthoacetates, the chemical shifts for protons of the orthester ring could be used,[39] which fall into one of two patterns. From the fact that H-1, H-2, and CMe are less shielded and OMe more shielded in **15b**, than in **15a**, and the comparison of chemical shifts of OMe with that of



Scheme 2.

* This compound was used by V. K. Handa, V. V. Barlow, and K. L. Matta, *Carbohydr. Res.*, **76**, Cl (1979); but no data was given for it.

methanol, the isomer **15a** should tentataively have its OMe *exo*, and the other isomer *endo*. Opening of the orthoester ring of **15** with aqueous acetic acid afforded 85% yield of 3,6-di-*O*-allyl-4-*O*-benzyl-D-mannopyranose (**16**). Its ^{13}C NMR spectrum showed a ratio of ≈2.3:1.0 of α:β anomers, as indicated by the two signals of the anomeric carbon atoms at δ 94.17 and 94.63, respectively. The corresponding 3,4,6-tri-*O*-allyl analog[22] of **16** showed almost a similar ratio (≈2.5:1.0) for their anomeric carbon atoms. Reaction of **16** with mesyl chloride in 2,6-lutidine gave 68% yield of 3,6-di-*O*-allyl-4-*O*-benzyl-2-*O*-mesyl-α-D-mannopyranosyl chloride (**17**). Its ^{13}C NMR spectrum showed signals at δ 90.58 and 38.92 due to the anomeric carbon atom and the mesyl group, respectively.

The stereoselectivity and yield in glycosidation reactions can be optimized if the reactivity of *C*-1 is carefully balanced by an appropriate choice of *C*-1 leaving group. A wide spectrum of reactivities is now available by selecting the leaving group with the proper electronegativity, form the series of sulfonates (tosyl), 2,2,2-trifluoroethanesulfonyl (tresyl), or trifluromethanesulfonyl (triflyl). In the present work, the tresylate was selected as the leaving group, as it provides a moderate rate of glycosidation which may favor the β-glycosidation. Thus, reaction of **17** with silver tresylate followed by reaction with 2-[4-(*p*-toluenesulfonamido)phenyl]ethanol afforded 60% yield of the corresponding β-D-mannopyranoside (**19**) and 25% yield of α-anomer (**20**), after separation by LC. The assigned anomeric configurations was based on the comparison of the specific rotations of the two anomers, as well as their ^{1}H NMR spectral data. The β-anomeric proton appeared at δ 4.45 and that of α at δ 4.8, within the anticipated range[22,40] for β (δ 4.4—4.7) and α (δ 4.8—5.0), respectively. The ^{13}C NMR spectra showed *C*-1 at δ 98.03 and 98.64 for **20** and **19**, respectively. Rearrangement of the allyl groups in compound **19** into the 1-propenyl groups was achieved by action of tris(triphenylphosphine)rhodium chloride. Partial depropenylation of **21** was observed during the reaction and it was completed by the action with a mixture of mercury(II) oxide and mercury(II) chloride to give 77% yield of **22**. Although the 3- and 6-positions of **22** are available for glycosidation, but, the 6-position could be selectively glycosylated as shown by allowing its reaction with the tresylate derived from 2-*O*-benzoyl-3,4,6-tri-*O*-benzyl-α-D-mannopyranosyl chloride to give the disaccharide **23**.

In conclusion, the synthesis of the orthoesters **14** and **15** and the chloride **17** are of great value as precursors for complex oligosaccharides of biological significance, and actually the disaccharide **23** was successfully synthesized.

Experimental

Generals. ^{1}H NMR spectra were determined with a Varian A-60-A or XL-100-15 spectrometer for solutions in chloroform with tetramethylsilane as internal reference. ^{13}C NMR spectra were determined with Varian XL-100-15 or CFT-20 spectrometers in pulsed Fourier-transform proton-noise-decoupled mode on similar solutions. Optical rotations were determined with a Perkin-Elmer model 141 polarimeter in jacketed, 1-dm cells. Melting points were determined with a "Meltemp" apparatus with a 76-mm immersion thermometer. TLC was performed on "Baker flex" silica gel 1B-F (2.5×7.5 cm) plates; the solvents were ethyl acetate–hexane (1:1 solvent A; 2:1, solvent B; 1:3, solvent C). High pressure liquid chromatography (LC) was carried out using a Valvco septumless injector (1.0 ml), a Gleno pump, model HPLPS-1, and Waters differential refractometer R-401. A stainless-steel column (1×25 cm inside diameter) containing silica gel (Whatman, partisil M 9 10/25) was used. Preparative LC was performed on a Waters Prep-500 instrument, using a silica gel column.

Methyl 4,6-Di-*O*-benzyl-α-D-mannopyranoside (8). To a stirring mixture of methyl 2,3-*O*-isopropylidene-α-D-mannopyranoside[37] (46.8 g, 0.2 mol) and powdered potassium hydroxide (50 g) in toluene (200 ml) was added benzyl chloride (150 ml) gradually under heating. After 1 h, potassium hydroxide (50 g) was again added and the reaction was continued till TLC showed complete conversion into **6** (5 h). The mixture was cooled and filtered, and the filtrate wa washed with water, dried, and evaporated. The remaining oil was dissolved in methanol (200 ml) and 0.5 M hydrochloric acid (50 ml), and solution was heated under reflux until TLC showed complete hydrolysis (30 min), neutralized with excess of sodium hydrogencarbonate, and then filtered. The filtrate was evaported, and the residue was extracted with dichloromethane. The usual work-up of the extract gave the product which was crystallized from hexane (61.7 g, 82% yield); R_f=0.39 (solvent A); mp 101—103 °C; $[\alpha]_D^{29}$ +75.3° (c 2.0, chloroform); ^{1}H NMR δ=7.3 (m, 10 H, 2×Ph), 4.78, 4.64, 4.52, 4.50 (each d, 5 H, 2×CH_2Ph and hidden H-1), 3.7 (m, 6 H, H-2,3,4,5,6, and 6′), 3.32 (s, 3 H, OMe), 3.1 (bs, 2 H, 2×OH).

Found: C, 67.59; H, 6.95%. Calcd for $C_{21}H_{26}O_6$: C, 67.36; H, 7.00%.

1,2,3,6-Tetra-*O*-acetyl-4-*O*-benzyl-α-D-mannopyranose (12). a) A suspension of compound **8** (20.0 g, 0.05 mol) in acetic anhydride (80 ml) was cooled and treated with a cold solution on 1.0% sulfuric acid in acetic anhydride (160 ml). The mixture was stirred till complete dissolution and then kept at room temperature for 2 h. The resulting solution was poured onto crushed ice and the mixture was extracted with dichloromethane. The usual processing of the extract gave an oil that was purified by preparative LC with ethyl acetate–hexane (1:3) to give the pure product (17.0 g, 73% yield); R_f=0.59 (solvent B).

(b) A cooled solution of compound **8** (3.0 g, 8.0 mmol) in pyridine (10 ml) and acetic anhydride (6 ml) was left overnight in the ice box, poured onto crushed ice, and extracted with dichloromethane. The usual work-up of the

extract gave **9** that was purified by LC with ethyl acetate: hexane (1:3) as a solvent to give a pure product (3.1 g. 84% yield); $[\alpha]_D^{27}$+46.2° (c 1.0, chloroform); ^{1}H NMR δ=7.2 (m, 10 H, 2×Ph), 5.35 (dd, 1 H, $J_{2,3}$=4, $J_{3,4}$=8 Hz, H-3), 5.27 (dd, 1 H, H-2), 4.78—4.42 (m, 5 H, 2×CH_2Ph and H-1), 4.1—3.6 (m, 4 H, H-4,5,6, and 6′), 3.36 (s, 3 H, OMe), 2.15 and 1.93 (each s, 6 H, 2×Ac). Acetolysis of compound **9** showed similar results as in (a).

(c) Compound **7** was partially hydrolyzed with 0.5 M hydrochloric acid and the resulting compound **11** (0.2 g, 0.44 mmol) was treated with 0.67% sulfuric acid in acetic anhydride (2.5 ml) and the mixture was processed as before to give **12** (0.15 g, 78% yield).

(d) A solution of compound **8** (14.0 g, 0.04 mmol) in dioxane (150 ml) and 1 M hydrochloric acid (60 ml) was heated on a steam bath for 20 h. TLC indicated that further heating did not cause a complete transformation. The reaction mixture was cooled, neutralized with sodium hydrogencarbonate, concentrated under vacuum, and the remaining solid was extracted with ethyl acetate. The usual work-up of the extract gave a syrup that was crystallized from dichloromethane–hexane to give **10** (8.5 g); mp 110—112 °C. The mother liquor was evaporated and subjected to preparative LC with dichloromethane–ethyl acetate (1:1) to give a further crop (1.3 g) of **10**, in addition to the starting material (2.5 g) which could be recycled (the total yield based on recovery of the starting material was 89%); $[\alpha]_D^{27}$+29.8° (*c* 0.7, chloroform); ^{1}H NMR δ=7.2 (m, 10 H, 2×Ph), 5.22 (d, 1 H, $J_{1,2}\leq$1 Hz, H-1), 4.88—4.35 (m, 4H, 2×CH_2Ph, H-1), 4.1—3.3 (m, 6 H, H-2,3,4,5,6, and 6′), 3.08, 2.74, and 1.94 (each bs, 3 H, 3×OH).

A mixed cooled solution of **10** (1.8 g, 5.0 mmol) in acetic anhydride (7.0 ml) and 1.0% sulfuric acid in acetic anhydride (14.0 ml) was kept at room temperature for 1.5 h, poured onto crushed ice, and the mixture was processed as before to give, after separation by preparative LC the product (1.9 g, 86% yield); $[\alpha]_D^{27}$+60.2° (*c* 2.8 chloroform); ^{1}H NMR δ=7.3 (m, 5 H, Ph), 6.04 (d, 1 H, $J_{1,2}$=2 Hz, H-1), 5.37 (dd, 1 H, $J_{2,3}$=3.5, $J_{3,4}$=8.0 Hz, H-3), 5.26 (dd, 1 H, H-2), 4.7 and 4.6 (ABq, 2 H, *J*=12 Hz, CH_2Ph), 4.3 (m, 2 H, H-6 and 6′), 3.9 (m, 2 H, H-4 and 5), 2.12, 2.08, 2.04, and 1.99 (each s, 12 H, 4×Ac).

Found: C, 57.29; H, 5.84%. Calcd for $C_{21}H_{26}O_{10}$: C, 57.52; H, 5.98%.

2,3,6-Tri-*O*-acetyl-4-*O*-benzyl-α-D-mannopyranosyl Bromide (13). A cold solution of **12** (10.0 g, 22.8 mmol) in the least volume of dichloroemthane was added to a saturated solution of hydrogen bromide in dichloromethane (100 ml) at room temperature. The resulting solution was kept for 2 h, whereby TLC showed the disappearance of the starting material. Nitrogen was passed into the solution, then the usual processing gave a syrup that purified immediately by preparative LC with ethyl acetate–hexane (1:2) to give a pure product (7.1 g, 68% yield); R_f=0.63 (solvent B); ^{1}H NMR δ=7.3 (m, 5 H, Ph), 6.28 (d, 1 H, $J_{1,2}$=2 Hz, H-1), 5.71 (dd, 1 H, $J_{2,3}$=3.5, $J_{3,4}$=9 Hz, H-3), 5.45 (dd, 1 H, H-2), 4.70, and 4.64 (ABq, 2 H, *J*=12 Hz, CH_2Ph), 4.34 (m, 2 H, H-6 and 6′), 4.1 (m, 1 H, H-5), 3.95 (dd, $J_{4,5}$=9 Hz, H-4), 2.14, 2.07, and 1.99 (each s, 9 H, 3×Ac).

3,6-Di-*O*-acetyl-4-*O*-benzyl-1,2-*O*-(1-methoxyethylidene)-β-D-mannopyranose (14). A mixed solution of compound **13** (5.0 g, 10.9 mmol) in chloroform (15 ml), 2,6-lutidine (3 ml) and methanol (20 ml) was left at room temperature overnight, diluted with chloroform and water. The usual processing of the organic layer gave a crystallized product, that was recrystallized from dichloromethane–hexane to give colorless needles, (3.7 g, 83% yield); mp 150—151 °C; R_f=0.44 (solvent B); $[\alpha]_D^{23}$−4.3° (*c* 1.7, chloroform); ^{1}H NMR δ=7.3 (m, 5 H, Ph), 5.43 (d, 1 H, $J_{1,2}$=2.5 Hz, H-1), 5.14 (dd, 1 H, $J_{2,3}$=4, $J_{3,4}$=9 Hz, H-3), 4.7—4.6 (q, 2 H, CH_2Ph), 4.6 (m, 1 H, H-2), 4.36, and 4.21 (each q, $J_{5,6}$=3.0, $J_{5,6'}$=4.5, $J_{6,6'}$=12 Hz, H-6 and 6′), 3.89 (t, 1 H, H-4), 3.55 (m, 1 H, H-5), 3.27 (s, 3 H, OMe), 2.11, and 2.05 (each s, 6 H, 2×Ac), 1,72 (s, 3 H, CMe).

Found: C, 58.13; H, 6.29%. Calcd for $C_{20}H_{26}O_9$: C 58.53; H, 6.39%.

3,6-Di-*O*-allyl-4-*O*-benzyl-1,2-*O*-(1-methoxyethylidene)-β-D-mannopyranose (15). A hot solution of **14** (1.6 g, 2.4 mmol) and allyl bromide (6 ml) in benzene (30 ml) was treated with powdered potassium hydroxide (1.0 g), and the mixture was heated with stirring under reflux for 2 h, and then additional amount of powdered potassium hydroxide (1.0 g) was added and heating was continued for more 2 h. After cooling, the mixture was filtered. The usual processing of the filtrate gave a syrup composed from two diastereoisomers in a ratio 12:1, that separated on LC with 1:4 ethyl acetate–hexane as a solvent. The fast moving isomer was the minor product (0.1 g, 6% yield) R_f=0.55 (solvent B); $[\alpha]_D^{23}$ +13.1° (*c* 0.3, chloroform); ^{1}H NMR δ=7.3 (m, 5 H, Ph), 5.9 (m, 2 H, 2×CH in allyl), 5.2 (m, 4 H, 2×CH_2 in allyl), 5.16 (d, 1 H, $J_{1,2}$=3 Hz, H-1), 4.9, and 4.65 (ABq, 2 H, *J*=11 Hz, CH_2Ph), 4.3 (m, 2 H, H-2), 4.0 (m, 4 H, 2×OCH_2 in allyl), 3.7 and 3.5 (each m, 5 H, H-3,4,5,6, and 6′), 3.48 (s, 3 H, OMe), 1.53 (s, 3 H, CMe).

Found: C, 64.67; H, 7.58%. Calcd for $C_{22}H_{30}O_7$: C, 65.01; H, 7.44%.

The slow moving isomer was the major product that was crystallized from hexane (1.3 g, 82% yield); R_f=0.53 (solvent B); mp 43—44 °C; $[\alpha]_D^{23}$+25.8° (*c* 0.2, chloroform); ^{1}H NMR δ=7.3 (m, 5 H, Ph), 5.9 (m, 2 H, 2×CH of allyl), 5.34 (d, 1 H, $J_{1,2}$=3 Hz, H-1), 5.2 (m, 4 H, 2×CH_2 in allyl), 4.88, and 4.63 (ABq, 2 H, *J*=11 Hz, CH_2Ph), 4.48 (t, 1 H, H-2), 4.22 and 4.01 (each bd, 4 H, 2×OCH_2 in allyl), 3.65, and 3.45 (2m, 5 H, H-3,4,5,6, and 6′), 3.3 (s, 3 H, OMe), 1.72 (s, 3 H, CMe).

Found: C, 64.77; H, 7.88%. Calcd for $C_{22}H_{30}O_7$: C, 65.01: H, 7.44%.

3,6-Di-*O*-allyl-4-*O*-benzyl-D-mannopyranose (16). A solution of **15** (1.0 g, 2.46 mmol) in a mixture of glacial acetic acid (12 ml) and water (8 ml) was heated for 1 h on a steam bath and then concentrated in vacuo. The resulting syrup was dissolved in dichloromethane which was washed with aqueous sodium hydrogencarbonate, dried, and evaporated. The resulting syrup in a solution of methanol was deacetylated by catalytic amount of sodium methoxide for overnight at 5 °C, neutralized with acetic acid and evaporated. The residue was purified by LC with 1:1 ethyl acetate–hexane to give a pure syrup (0.74 g, 85%); $[\alpha]_D^{23}$+39.6° (*c* 1.3, chloroform); ^{1}H NMR δ=7.3 (m, 5 H, Ph), 5.9 (m, 2 H, 2×CH in allyl), 5.2 (m, 4 H, 2×CH_2 in allyl and H-1), 4.87 and 4.57 (ABq, 2 H, *J*=12 Hz, CH_2Ph), 4.68 (s, <1 H, H-1), 4.2—3.3 (m, 10 H, H-2,3,4,5,6,6′, and 2×OCH_2 in allyl).

Found: C, 64.51; H, 7.76%. Calcd for $C_{19}H_{26}O_6$: C, 65.12;

H, 7.48%.

3,6-Di-*O*-allyl-4-*O*-benzyl-2-*O*-mesyl-α-D-mannopyranosyl Chloride (17). To an ice-cooled solution of **16** (2.0 g, 5.7 mmol) in a mixture of dichloromethane (30 ml) and 2,6-lutidine (10 ml) was added dropwise with stirring mesyl chloride (2 ml), and the mixture was kept at 0 °C for 0.5 h and then at room temperature till TLC showed complete conversion (ca. 3 h). The usual processing of the reaction mixture gave a syrup which was purified by LC with 1:2 ethyl acetate-hexane (1.7 g, 68% yield); $[\alpha]_D^{27}$+75.3° (*c* 0.9, chloroform).

Found: Cl, 7.56%. Calcd for $C_{20}H_{20}ClO_7S$: Cl, 7.93%.

2-[4-(*p*-Toluenesulfonamide)phenyl]ethyl 3,6-Di-*O*-allyl-4-*O*-benzyl-2-*O*-mesyl-β- and α-D-Mannopyranoside (19 and 20). A solution of **17** (0.20 g, 0.45 mmol) in acetonitrile (2 ml) was treated with a solution of silver 2,2,2-trifluoroethanesulfonate in acetonitrile to form the corresponding 1-trifluoroethanesulfonate (**18**), whereby silver chloride precipitated out. After 1 h, the solution was filtered on 2-[4-(*p*-toluenesulfonamide)phenyl]ethanol (0.15 g, 0.51 mmol). All operations were performed on a high vacuum rack as described before. The reaction mixture was kept in the dark overnight, diluted with dichloromethane, washed with a solution of sodium hydrogencarbonate, sodium thiosulfate and water, and dried ($MgSO_4$). The usual processing of the extract and purification of the product with LC with 1:1 ethyl acetate-hexane as a solvent gave the major product **19** (0.19 g, 60% yield), in addition to a minor product 20 (0.08 g, 25% yield).

20: R_f=0.38 (solvent A); $[\alpha]_D^{23}$+22.1° (*c* 0.5, chloroform); ^{1}H NMR δ=7.65 (d, 2 H, *p*-substituted Ph), 7.2 (m, 12 H, aromatic and NH), 5.9 (m, 2 H, 2×CH in allyl), 5.2 (m, 4 H, 2×CH_2 in allyl), 4.8 (m, 2 H, H-1 and 2), 4.85 and 4.55 (ABq, 2 H, *J*=12 Hz, CH_2Ph), 4.1 (m, 5 H, H-3 and 2×OCH_2 in allyl), 3.6 (m, 6 H, H-4,5,6,6′ and OCH_2 in ethyl), 3.10 (s, 3 H, Ms), 2.8 (q, 2 H, CH_2 in ethyl), 2.36 (s, 3 H, Me).

Found: C, 57.94; H, 6.13%. Calcd for $C_{35}H_{43}NO_{10}S_2 \cdot H_2O$: C, 58.39; H, 6.02%.

19: R_f=0.33 (solvent A); $[\alpha]_D^{27}$−22.3° (*c* 0.3, chloroform); ^{1}H NMR δ=7.68 (d, 2 H, *p*-substituted Ph), 7.2 (m, 12 H, aromatic and NH), 5.9 (m, 2 H, 2×CH in allyl), 5.2 (m, 4 H, 2×CH_2 in allyl), 4.95 (m, 1 H, H-2), 4.9 and 4.55 (ABq, 2 H, *J*=11 Hz, CH_2Ph), 4.45 (s, 1 H, H-1), 4.1 (m, 5 H, H-3 and 2×OCH_2 in allyl), 3.6 (m, 6 H, H-4,5,6,6′ and OCH_2 in ethyl), 2.82 (bq, 2 H, CH_2 in ethyl), 2.80 (s, 3 H, Ms), 2.35 (s, 3 H, Me).

Found: C, 60.46; H, 6.00%. Calcd for $C_{35}H_{43}NO_{10}S_2$: C, 59.89; H, 6.18%.

2-[4-(*p*-Toluenesulfonamido)phenyl]ethyl 4-*O*-Benzyl-2-*O*-mesyl-β-D-mannopyranoside (22). The mixture of **19** (0.7 g, 1.0 mmol) and tris(triphenylphosphine)rhodium-(I) chloride (0.13 g) in 9:1 (v/v) ethanol-water (20 ml) was heated under reflux till TLC showed complete disappearance of **19** (2 h) and then evaporated to a syrup. The syrup was extracted with dichloromethane, and the usual processing of the extract gave a mixture of 1-propenyl and depropenylated derivatives which was heated with mercury(II) oxide (0.9 g) and mercury(II) chloride (0.9 g) in 9:1 (v/v) acetone-water under reflux for 15 min, filtered, and the filtrate was evaporated. The remaining residue was extracted with dichloromethane and the organic phase was washed with aqueous potassium iodide and water, dried ($MgSO_4$), and evaporated to a syrup, which was purified by using HPLC with ethyl acetate-hexane (0.48 g, 77% yield); $[\alpha]_D^{23}$ −20.0° (*c* 0.1, chloroform); ^{1}H NMR δ=7.66 (d, 2 H, *p*-substituted Ph), 7.3 (m, 12 H, aromatic and NH), 4.8 (d, 1 H, H-2), 4.83 and 4.63 (ABq, 2 H, *J*=11 Hz, CH_2Ph), 4.48 (s, 1 H, H-1), 4.01 (m, 1 H, H-3), 3.7—3.3 (m, 6 H, H-4,5,6,6′ and OCH_2 in ethyl), 2.81 (t, 2 H, CH_2 in ethyl), 2.8 (s, 3 H, Ms), 2.4 (bs, 2 H, 2×OH), 2.34 (s, 3 H, Me).

Found: C, 55.12; H, 5.75%. Calcd for $C_{29}H_{35}NO_{10}S_2 \cdot 0.5H_2O$: C, 55.22; H, 5.75%.

2-[4-(*p*-Toluenesulfonamide)phenyl]ethyl 6-*O*-(2-*O*-Benzoyl-3,4,6-tri-*O*-benzyl-α-D-mannopyranosyl)-4-*O*-benzyl-2-*O*-mesyl-β-D-mannopyranoside (23). Under high vacuum, **22** (0.1 g, 0.16 mmol), 2-*O*-benzoyl-3,4,6-tri-*O*-benzyl-α-D-mannopyranosyl chloride (1.5 equivalent) and silver tresylate were left in separate joined flask for 5 h at room temperature. Acetonitrile (2 ml) was distilled onto the chloride, and the resulting solution was mixed with silver tresylate. After 0.5 h, the solution of the tresylate was filtered over onto compound **22**. The resulting solution was kept for overnight at room temperature in the dark. The reaction mixture was diluted with dichloromethane, washed with saturated solution of sodium thiosulfate and sodium hydrogencarbonate, water and dried ($MgSO_4$). The resulting syrup after evaporation of the solvent, was separated on LC with ethyl acetate-hexane (2:3) to give the disaccharide as a syrup (0.12 g, 64% yield); $[\alpha]_D^{23}$ −4.3° (*c* 0.3, chloroform).

Found: C. 64.31; H, 5.75%. Calcd for $C_{63}H_{67}NO_{16}S_2 \cdot H_2O$: C, 64.32; H, 5.91%.

A Synthesis of Methyl 3-*O*-(β-D-Mannopyranosyl)-α-D-mannopyranoside from Sulfonate Intermediates

Laila Fathy AWAD, El Sayed H. EL ASHRY,†,* and Conrad SCHUERCH

(Received April 8, 1985)

Methyl 3-*O*-(β-D-mannopyranosyl)-α-D-mannopyranoside was synthesized by the reaction of 3,4,6-tri-*O*-benzyl-2-*O*-benzylsulfonyl-1-*O*-tresyl-D-mannopyranose with methyl 2,4,6-tri-*O*-benzyl- and 2,4,6-tri-*O*-(*p*-bromobenzyl)-α-D-mannopyranoside, followed by deprotection. The corresponding 1-*O*-(*p*-tolylsulfonyl) derivative gave better yield and stereoselectivity in the reaction with methanol, but was not sufficiently reactive to couple with a hindered secondary alcohol. The 2-*O*-benzylsulfonyl group is comparable in β-directing effect to 2-*O*-methylsulfonyl group, but its stereoselectivity is dependent on the structure of the reactant alcohol. It can be selectively removed by the reaction with sodium amide in *N*,*N*-dimethylformamide.

Stereoselectivity in syntheses of 1,2-*trans* and 1,2-*cis*-mannopyranosyl glycosides and oligosaccharides depends greatly on the protecting group at *O*-2 of the reactive mannosyl derivative and on its leaving group on *C*-1. In our previous paper[1] we investigated conditions for the formation of the 1,2-*trans* α-D-mannopyranosyl linkage using ester functions on *O*-2 and sulfonate leaving groups on *C*-1. β-D-Mannopyranosides are also of great interest because of their presence as structural elements in glycoproteins and the *O*-antigenic lipopolysaccharides,[2-8] and a number of methods have been proposed for their synthesis. Gorin and Perlin[9] first used 4,6-di-*O*-acetyl-2,3-*O*-carbonyl-α-D-mannopyranosyl bromide for the synthesis of β-D-mannopyranosides and it has since been used successfully for those of primary alcohols, while the stereoselectivity was uncertain[10-13] in cases of secondary alcohols. Garegg's method, using 2,3:4,6-di-*O*-cyclohexylidene-α-D-mannopyranosyl chloride and silver carbonate[14,15] or silver imidazole and mercury(II) chloride,[16] also gives better yields and stereoselectivity with primary alcohols. A widely used complex reaction sequence involves β-glucosidation, hydrolysis of a 2-*O*-acyl group, oxidation, and reduction.[17-21] 1,1-Dimannosides of various anomeric forms have been prepared with trifluoromethanesulfonyl (triflic) anhydride and 2,3,4,6-tetra-*O*-benzyl-D-mannose.[22] Silver silicate was successfully used by Paulsen and Lockhoff[23] as catalyst for the coupling of 6-*O*-acetyl-2,3,4-tri-*O*-benzyl-α-D-mannopyranosyl bromide to the equatorial 4-OH of a 1,6-anhydrogalactopyranose derivative to form the (1→4) β-linked disaccharide. β-D-Mannopyranosides have also been prepared by *O*-alkylation by Srivastava and Schuerch[24] and an interesting synthesis of β-D-mannopyranosides and -furanosides was recently reported by Schmidt, Reichrath and Morering,[25] in which 1-*O*-metallated derivatives are treated with alkyl triflates. The stereoselectivity is controlled by means of solvent and temperature. These methods are also presumably most useful for primary mannopyranosides. We have used a strongly electron-withdrawing, non-participating substituent on *O*-2 and a strongly electronegative leaving group at *C*-1 to control the stereoselectivity and yield of 1,2-*cis*-β-D-mannopyranosides and -β-L-rhamnopyranosides.[26-30] High β-selectivity has been observed in the formation of primary mannopyranosides, but results in the secondary positions of sugar derivatives were less satisfactory.[26,28,30]

The methylsulfonyl (mesyl) group has been used as a non-participating electron-withdrawing group on *O*-2, which can be removed selectively be reductive cleavage.[31] Herein we report the use of the benzylsulfonyl group as a substituent on *O*-2 and describe glycosidation results and the selective removal of the benzylsulfonyl group from the resultant glycosides and disaccharides.

Results and Discussion

3,4,6-Tri-*O*-benzyl-2-*O*-benzylsulfonyl-α-D-mannopyranosyl chloride (**2**) was prepared in 72% yield in one step by treating 3,4,6-tri-*O*-benzyl-D-mannose (**1**) in dichloromethane with excess benzylsulfonyl chloride in the presence of 2,6-lutidine. 3,4,6-Tri-*O*-benzyl-2-*O*-benzylsulfonyl-β-D-mannopyranose (**3**) was also separated as a by-product. The structure of both **2** and **3** was confirmed by ^{1}H and ^{13}C NMR spectroscopy. The methylene carbon of benzylsulfonyl group was found to have a characteristic signal in ^{13}C NMR, which resonate at δ 57.8 and 57.9 for **2** and **3**, respectively. The presence of the sulfonate function at *O*-2 caused a downfield shift of *H*-2 and it appeared as either a triplet in **2** or broad doublet in **3**. The β-configuration of **3** was confirmed by ^{13}C NMR and by its negative optical rotation. The chloride **2** was also obtained in 90% yield, when an ethereal solution of **3** was saturated with hydrogen chloride at 0 °C and worked up conventionally. The 1-*O*-(2,2,2-

† Present address: Chemistry Department, Faculty of Science, Alexandria University, Alexandria, Egypt.

trifluoroethylsulfonyl) (tresyl) derivative of **3** was prepared by the condensation of **2** and silver tresylate as described before[1] and was then coupled with absolute methanol to give methyl 3,4,6-tri-*O*-benzyl-2-*O*-benzylsulfonyl-α,β-D-mannopyranosides (**4**,**5**) in 57% yield with an α:β ratio of 2:3. When, instead of tresylate as leaving group, *p*-toluenesulfonate (tosylate) was used for the same coupling reaction, the stereoselectivity and the yield were improved with a 74% overall yield and α:β ratio of 18:82. Optical rotational values and ^1H and ^{13}C NMR spectra (see Experimental) confirmed the anomeric configuration of the anomers separated. When the 1-tosylate was prepared from **2** and treated with methyl 2,4,6-tri-*O*-(*p*-bromobenzyl)-α-D-mannopyranoside (**8**),[32] no reaction occurred and starting materials were recovered. However, the corresponding 1-tresytlate derived from **2** in the same reaction gave methyl 3-*O*-(3,4,6-tri-*O*-benzyl-2-*O*-benzylsulfonyl-α,β-D-mannopyranosyl)-2,4,6-tri-*O*-(*p*-bromobenzyl)-α-D-mannopyranosides (α:**10**, β:**14**) in 49% yield and in α:β ratio of 1:2. The structures of both **10** and **14** were confirmed by ^1H and ^{13}C NMR spectroscopy and optical rotation. The H-1′ proton of **10** and **14** appeared at δ 5.1—4.97 and 4.2—4.1, respectively. Anomeric carbons *C*-1′ in **10** and **14** resonated at δ 98.3 and 99.8, while the anomeric carbon *C*-1 of **14** resonated at δ 96.6. The *C*-5′ of β-isomer **14** was also observed in downfield as expected at δ 76.2.

An analogous reaction was carried out on the 1-*O*-tresyl derivative from **2** with methyl 2,4,6-tri-*O*-benzyl-α-D-mannopyranoside (**9**).[33] The disaccharide methyl 2,4,6-tri-*O*-benzyl-3-*O*-(3,4,6-tri-*O*-benzyl-α,β-D-mannopyranosyl) α-D-mannopyranosides (α:**11**, β:**15**) were obtained in an improved yield (70%) but poorer β-selectivity (α:β of 61:39). As in the case of compounds **10** and **14**, the β-anomeric carbon resonates in upfield (δ=97.2) than α-anomeric carbon (δ=99.6), and C-5′ of **15** was found as expected at δ=76.2.

There is a surprising difference in stereoselectivity of the reactions of the 1-*O*-tresyl derivative from **2** with **8** and **9**. These results may reflect differences in reaction conditions rather than reactivity differences between **8** and **9**. In the reaction with **8**, the formation of tresylate was allowed to proceed for 6 h before the addition of **8**. In reaction with **9**, **2** and silver tresylate were allowed to react for only 1 h and silver halide precipitation was far from complete, when **9** was added. In the first case, therefore, there was a much better chance for an S_N2-like mechanism or shielded S_N1 mechanism to control stereoselectivity predominantly. In the second case, the cation generated directly by reaction of **2** with silver ion may be less shielded and steric control was less effective.

There is also an interesting difference between reaction of the tosylate and tresylate derived from **2** with alcohols. The tosylate gave better β-selectivity than the tresylate on reaction with methanol, but was insufficiently reactive to form product with relatively hindered secondary alcoholic functions, at least at ambient temperatures.

In summary, the benzylsulfonyl group is comparable to mesyl as a β-directing group in mannoside syntheses. In both cases stereoselectivity also depends on the nature of the alcoholic function reacting, and is usually better with primary alcohols. For separation of anomeric products, the benzylsulfonate group was preferable as the substituent.

A second objective of this research is to achieve a selective deblocking of the 2-*O*-benzylsulfonyl group. Sulfonate substituents have been removed in many cases by reductive cleavage[34-39] and this method has been applied to the cleavage of 2-*O*-mesyl groups.[37] Alternatively aryl *p*-toluenesulfonates have been hydrolyzed by bases.[40-42] The mechanism involves nucleophilic attack on sulfur by amine or hydroxide, causing sulfur–oxygen bond fission.[40,43,44] This mechanism apparently requires a good leaving group on sulfur. Mesyl chloride[45] and aryl benzylsulfonates are more readily hydrolyzed or aminolyzed, and these reactions proceed by a stepwise elimination-addition mechanism with the formation of a sulfene intermediate in the rate-determining step which is rapidly scavenged by amine or base.[46,47]

$$ArCH_2\text{-}SO_2\text{-}O\text{-}Ar' + Et_3N \rightleftharpoons Et_3\overset{+}{N}H + Ar\overset{-}{C}H\text{-}SO_2\text{-}O\text{-}Ar'$$

$$Ar'O^- + ArCH{=}SO_2 \xrightarrow{+OH} ArCH_2\text{-}SO_3^-$$

The latter approach was tried in the present instance.

Various amines under a variety of conditions failed to remove the benzylsulfonyl group, presumably because the sugar anion is a poor leaving group, and a stronger base is required to remove benzylic proton and to form the sulfene intermediate. However, the stronger base, sodium amide, in *N,N*-dimethylformamide at room temperature readily removed the substituent without the formation of by-product from **4**, **5**, **10**, **11**, **14**, and **15**. Yields of product ranged from 65 to 95% with the higher recoveries due to purer reagents and improved work-up procedures. ^{1}H and ^{13}C NMR and optical rotations of **6** and **7** agreed with those in the literature.[27,31,48,49] ^{13}C NMR of **12**, **13**, **16**, and **17** showed an upfield shift of *C*-2 and elimination of the benzylsulfonyl methylene carbons.

Methyl 3-*O*-(β-D-mannopyranosyl)-α-D-mannopyranoside (**18**) was obtained in quantitative yield by catalytic hydrogenation of **17**, while **16** gave **18** together with some decomposition products. A comparison of the ^{13}C NMR spectrum of **18** and **17** showed that the peak positions of *C*-2, *C*-3′, *C*-6, and *C*-6′ moved 6 to 7 ppm upfield on debenzylation as expected. The same was apparently true of *C*-4 and *C*-4′, although in **17** these positions could not be clearly distinguished from the six benzylic methylene carbons. Also as expected, *C*-1, *C*-1′, *C*-2′, and *C*-5′ moved downfield from δ 2.3 to 4.6, while the position of *C*-5 in **17** was also uncertain. A comparison of the ^{13}C NMR of **18** with those of methyl α- and β-D-mannopyranoside[50] confirmed these assignments and the specific rotation of **18**, $[\alpha]_D^{23}$+5.76°, was consistent with a β-linkage in comparison with the rotation of the corresponding α-linked disaccharide.[51]

Experimental

Generals. ^{1}H NMR spectra were determined with a Varian EM 360 MHz spectrometer for solution in chloroform-*d* with tetramethylsilane. ^{13}C NMR, optical rotations, melting point, TLC, high pressure liquid chromatography (LC) and coupling reactions were done as described previously.[1,29] *N,N*-Dimethylformamide (DMF) was distilled on the high vacuum rack and dried over Molecular Sieve. Silver 2,2,2-trifluroethanesulfonate was prepared as described.[1]

3,4,6-Tri-*O*-benzyl-2-*O*-benzylsulfonyl-α-D-mannopyranosyl Chloride (2). To a stirred solution of 3,4,6-tri-*O*-benzyl-D-mannopyranose (**1**) (1 g, 2.2 mmol) in dichloromethane (10 ml) and dry 2,6-lutidine (0.614 g, 5.7 mmol) was added benzylsulfonyl chloride (1.058 g, 5.5 mmol), and the reaction mixture was stirred overnight, and concentrated. The resulting residue was extracted with ether. The extract was washed with 1 M† hydrochloric acid, sodium hydrogencarbonate and water, dried, and concentrated. The resulting syrup was separated on LC using ethyl acetate-hexane (1:2) to give **2** (1 g) as syrup in 72.5% yield; $[\alpha]_D^{22}$ +31.3° (*c* 1.04, chloroform); ^{1}H NMR δ=7.1—7.35 (t, 20H, aromatic), 5.84—5.9 (d, 1H, H-1), 5.0—5.13 (t, 1H, H-2), 4.26—4.96 (m, 8H, 3×CH_2Ph and O_2SCH_2Ph), 3.53—4.2 (m, 5H, H-3,4,5,6, and 6′); ^{13}C NMR δ=90.2 (C-1), 77.9 (C-3), 76.4, 75.5, 74.8, 73.6, and 73.1 (C-2,4,5, and 3×CH_2Ph), 68.2 (C-6), 57.8 (O_2SCH_2Ph). 3,4,6-Tri-*O*-benzyl-2-*O*-benzylsulfonyl-β-D-mannopyranose (**3**) was also separated as syrup in 23% yield (0.3 g); $[\alpha]_D^{23}$−14.7° (*c* 1.06, chloroform), ^{1}H NMR δ=7.45 (20H, aromatic), 5.1—5.19 (d, 1H, H-2), 4.25—4.93 (m, 9H, H-1, 3×CH_2Ph and O_2SCH_2Ph), 4.1—3.4 (5H, H-3,4,5,6, and 6′), 2.59 (s, 1H, exchange with D_2O, OH); ^{13}C NMR δ=86.1 (C-1), 80.5 (C-3), 79.8 (C-5), 79.2 (C-4), 75.4, 73.7, 73.5, and 72.9 (C-2 and 3×CH_2Ph), 68.7 (C-6), 57.9 (O_2SCH_2Ph).

Compound **2** was also obtained from **3** in 90% yield. A solution of **3** (0.2 g, 0.33 mmol) in dry ether (10 ml) saturated with hydrogen chloride at 0 °C was left overnight with stirring at room temperature, swept by bubbling nitrogen to remove hydrogen chloride, washed with sodium hydrogencarbonate and water, dried, and concentrated. Separation of the product by LC using ethyl acetate-hexane (1:2) gave **2** (185 mg).

Found: C, 65.18; H, 5.80; Cl, 5.71; S, 5.09%. Calcd for $C_{34}H_{35}ClO_7S$: C, 65.52; H, 5.66; Cl, 5.68; S, 5.14%.

Methyl 3,4,6-Tri-*O*-benzyl-2-*O*-benzylsulfonyl-α,β-D-mannopyranosides (4,5). The chloride **2** (366 mg, 0.588 mmol), silver tresylate (159 mg, 0.588 mmol) and absolute methanol (25 mg, 0.78 mmol) were left separately under vacuum on a high vacuum rack for 3 h at room temperature. Acetonitrile (2 ml) was then distilled onto **2** and the resulting solution was left to react with silver tresylate for 1 h in the dark. The reaction mixture was then mixed with absolute methanol and kept for 70 h at room temperature in the dark. The reaction mixture was diluted with dichloromethane, filtered, washed with sodium thiosulfate, sodium hydrogencarbonate and water, dried, and concentrated. After separation of syrupy product by LC using ethyl acetate-hexane (1:3), compound **4** was obtained in 23% (64 mg) yield and **5** in 34% (94 mg) yield. The chloride **2** was recovered in 23% yield (85 mg).

Compounds **4** and **5** were also obtained in 14 and 61% yield, when **2** (468 mg, 751 mmol), silver *p*-toluenesulfonate (210 mg, 751 mmol), and absolute methanol (36 mg, 1.125 mmol) were treated as described above. Compound **4**: $[\alpha]_D^{23}$ +6.9° (*c* 1.1, chloroform); ^{1}H NMR δ=7.38—7.0 (d, 20 H, aromatic), 5.0—4.78 (t adjacent to d, 2H, H-2 and 1), 4.75—4.2 (m, 8H, 3×CH_2Ph, O_2SCH_2Ph) and 3.93—3.45 (5H, H-3,4,5,6, and 6′), 3.3 (s, 3H, OMe); ^{13}C NMR δ=99.0 (C-1), 78.1 (C-3), 76.3 (C-4), 75.3 (C-2), 71.98 (C-5), 69.1 (C-6), 57.7 (O_2SCH_2Ph), 55.2 (OMe). Compound **5**: $[\alpha]_D^{25}$−37.5° (*c* 0.98, chloroform); ^{1}H NMR δ=7.5—7.0 (d, 20H, aromatic), 5.2—5.06 (d, 1H, H-2), 4.95—4.25 (m, 9H, H-1, 3×CH_2Ph and O_2SCH_2Ph), 3.75—3.56 (m, 5H, H-3,4,5,6, and 6′), 3.5 (s, 3H, OMe); ^{13}C NMR δ=99.6 (C-1), 79.8 (C-3), 77.2 (C-5), 76.0 (C-4), 74.4 (C-2), 69.3 (C-6), 57.1 (O_2SCH_2Ph), 56.9 (OMe). The overall yield for this coupling was 74.6% (0.308 g) and the ratio of α:β was 18:82.

Found: C, 67.43; H, 6.02; S, 4.90%. Calcd for $C_{35}H_{38}SO_8$: C, 67.94; H, 6.12; S, 5.18%.

Methyl 3,4,6-Tri-*O*-benzyl-α-D-mannopyranoside (6). A solution of **4** (50 mg, 0.08 mmol) in DMF (5 ml) was treated with sodium amide (30 mg, 0.08 mmol) at room temperature overnight with stirring under anhydrous conditions. Methanol (2 ml) was then added and the

† 1 M=1 mol dm^{-3}.

reaction mixture was neutralized with acetic acid. The reaction mixture was evaportated on the high vacuum rack without heating. The resulting residue was extracted with ether, and the extract was washed with sodium hydrogencarbonate and water, dried, and concentrated. After separation of the residue on LC using ethyl acetate–hexane (2:3), **6** was obtained in 65% (24 mg) yield as a syrup; $[\alpha]_D^{23}$ +57.2° (*c* 0.5, chloroform), ^{1}H and ^{13}C NMR agree with those in the literature.[31,48,49]

Methyl 3,4,6-Tri-*O*-benzyl-β-D-mannopyranoside (7). A solution of **5** (0.1 g, 0.161 mmol) in DMF (5 ml) was treated with sodium amide (6.5 mg, 0.166 mmol) as described for **6**. Separation of the product by LC using ethyl acetate–hexane (1:1) gave **7** in 67% (50 mg) yield. $[\alpha]_D^{23}$ −13.1° (*c* 0.94, chloroform); lit,[27,31] $[\alpha]_D^{20}$ −10.2° (*c* 0.45, chloroform), $[\alpha]_D^{20}$ −8.77° (*c* 1.0, chloroform).

Methyl 3-*O*-(3,4,6-Tri-*O*-benzyl-2-*O*-benzylsulfonyl-α,β-D-mannopyranosyl)-2,4,6-tri-*O*-(*p*-bromobenzyl)-α-D-mannopyranoside (10,14). Compound **8**[32] (526 mg, 0.75 mmol), **2** (467 mg, 0.75 mmol), and silver tresylate (302 mg, 1.12 mmol) were left under vacuum for 5 h on the high vacuum rack. Acetonitrile was distilled onto **2**, and the resulting solution was left to react with silver tresylate for 6 h in the dark with stirring. The formed 1-*O*-tresyl derivative was then treated with **8** for 40 h in the dark. The reaction mixture was processed as described for **4** and **5** to give **10**, in 17% (160 mg) yield as a syrup. $[\alpha]_D^{23}$+6.9° (*c* 1, chloroform), ^{1}H NMR δ=7.4—6.8 (m, 32H, aromatic), 5.1—4.97 (d, 1H, H-1′), 4.95—4.8 (t, 1H, H-2′), 4.73—4.1 (m, 15H, H-1, 3×$CH_2C_6H_4Br$-*p*, 3×CH_2Ph, and O_2SCH_2Ph), 4.0—3.35 (m, 11H, H-2,3,3′,4,4′,5,5′,6, and 6′), 3.2 (s, 3H, OMe); ^{13}C NMR δ=99.8 (C-1′), 98.3 (C-1), 79.4 (C-3′), 77.7 (C-2 and 3), 76.4 (C-4), 69.2 and 69.5 (C-6 and 6′), 57.6 (O_2SCH_2Ph), 54.9 (OMe), 75.2, 74.8, 74.5, 74.2, 73.7, 72.7, and 71.9 (C-2′,4′,5,5′, 3×CH_2Ph, and 3×$CH_2C_6H_4Br$-*p*).

The β-disaccharide (**14**) was separated as a syrup in 32% (0.31 g) yield, which crystallized from ether; mp 113 °C; $[\alpha]_D^{22}$ −12.8° (*c* 0.86, chloroform); ^{1}H NMR δ =7.5—6.75 (m, 32H, aromatic), 5.13—5.03 (d, 1H, H-2′), 4.93 (s, 1H, H-1), 4.85—4.25 (m, 14H, 3×CH_2Ph, 3×$CH_2C_6H_4Br$-*p*, and O_2SCH_2Ph), 4.2—4.1 (bd, 1H, H-1′), 3.4—4.06 (m, 11H, H-2,3,3′,4,4′,5,5′,6, and 6′), 3.3 (s, 3H, OMe); ^{13}C NMR δ=99.1 (C-1), 96.6 (C-1′), 80.5 (C-3′), 78.1 and 77.6 (C-3 and 2), 76.2 (C-5′), 75.5 and 75.4 (C-4 and 4′), 74.3, 73.7, 73.2, 72.8, 72.7, 71.9, and 71.6 (C-2′,5, 3×CH_2Ph, and 3×$CH_2C_6H_4Br$-*p*), 69.5 and 69.2 (C-6 and 6′), 57.8 (O_2SCH_2Ph), 54.9 (OMe).

Found for **9**: C, 57.36; H, 5.02; S, 2.83; for **10**: C, 57.95; H, 4.79; S, 2.38%. Calcd for $C_{62}H_{63}O_{13}SBr_3$: C, 57.81; H, 4.93; S, 2.48%.

Methyl 3-*O*-(3,4,6-Tri-*O*-benzyl-α-D-mannopyranosyl)-2,4,6-tri-*O*-*p*-bromobenzyl-α-D-mannopyranoside (12). A well stirred solution of **10** (80 mg, 0.0621 mmol) and sodium amide (12 mg, 0.31 mmol) in DMF (5 ml) was processed as described for **6** to give **12** (50 mg) as a syrup in 70% yield. $[\alpha]_D^{24}$+19.5° (*c* 0.8, chloroform); ^{1}H NMR δ=7.45—6.85 (m, 27H, aromatic), 5.06 (s, 1H, H-1′), 4.86 (s, 1H, H-1), 4.75—4.21 (m, 12H, 3×CH_2Ph, and 3×$CH_2C_6H_4Br$-*p*), 4.1—3.5 (m, 12H, H-2,2′,3,3′,4,4′,5,5′,6 and 6′), 3.23 (s, 3H, OMe); ^{13}C NMR δ=101.6 (C-1′), 98.7 (C-1), 80.2 (C-3′), 78.9, and 77.9 (C-3 and 2), 75.3, 75.1, 74.7, 74.2, 73.7, 72.8, 72.2, 71.9, and 71.6 (C-5,5′,4,4′, 3×CH_2Ph, and 3×$CH_2C_6H_4Br$-*p*), 69.7 and 69.3 (C-6 and 6′), 68.8 (C-2′), 55.0 (OMe).

Found: C, 59.15; H, 4.56%. Calcd for $C_{55}H_{57}O_{11}Br_3$: C, 59.24; H, 5.06%.

Methyl 3-*O*-(3,4,6-Tri-*O*-benzyl-β-D-mannopyranosyl)-2,4,6-tri-*O*-(*p*-bromobenzyl)-α-D-mannopyranoside (16). A solution of **14** (0.1 g, 0.078 mmol) and sodium amide (15 mg, 0.387 mmol) in freshly distilled DMF (5 ml) was processed as described for **6** to give **16** (83 mg) in 95% yield as a syrup. $[\alpha]_D^{22}$+11.6° (*c* 1, chloroform); ^{1}H NMR δ=7.45—6.86 (m, 27H, aromatic), 4.93—4.8 (s, 1H, H-1), 4.76—4.2 (m, 14H, H-1′,5′, 3×CH_2Ph, and 3×$CH_2C_6H_4Br$-*p*), 4.0—3.4 (m, 11H, H-2,2′,3,3′,4,4′,5,6, and 6′), 3.23 (s, 3H, OMe), 2.5—2.26 (bs, 1H, OH); ^{13}C NMR δ=98.9 (C-1), 97.6 (C-1′), 81.8 (C-3′), 76.7, 75.9, 75.4, 75.2, 74.3, 73.7, 72.8, 71.9, and 71.7 (C-5,5′,4,4′,3,2, 3×CH_2Ph, and 3×$CH_2C_6H_4Br$-*p*), 69.5 (C-6 and 6′), 68.8 (C-2′), 54.9 (OMe).

Found: C, 57.78; H, 4.96%. Calcd for $C_{55}H_{57}O_{11}Br_3$: C, 58.24; H, 5.06%.

Methyl 2,4,6-Tri-*O*-benzyl-3-*O*-(3,4,6-tri-*O*-benzyl-2-*O*-benzylsulfonyl-α,β-D-mannopyranosyl)-α-D-mannopyranoside (11,15). Compound **9**[33] (405 mg, 0.874 mmol), silver tresylate (320 mg, 1.18 mmol), and **2** (0.7 g, 1.124 mmol) were left for 3 h on the high vacuum rack. Acetonitrile (3 ml) was distilled onto **2**, and the resulting solution was mixed with silver tresylate. The reaction mixture was left for 30—60 min with stirring in the dark, mixed with **9**, and then processed as described for **4** and **5** to give **11** (394 mg) in 43% yield as a syrup. $[\alpha]_D^{24}$ +9.8° (*c* 1.04, chloroform); ^{1}H NMR δ=7.36—7.37 (d, 35H, aromatic), 5.23—5.13 (d, 1H, H-1′), 5.13—5.15 (bs, 1H, H-2′), 4.92 (s, 1H, H-1), 4.8—4.17 (m, 14H, 6×CH_2Ph and O_2SCH_2Ph), 4.13—3.5 (m, 11H, H-2,3,3′,4,4′,5,5′,6, and 6′), 3.25 (s, 3H, OMe): ^{13}C NMR δ=99.6 (C-1′), 98.4 (C-1), 79.1 (C-3′), 77.8 and 77.6 (C-2 and 3), 76.7, 74.9, 74.4, 73.5, 72.8, 72.7, 72.3, 72.2, and 72.0 (C-5,5′,4,4′,2′, and 6×CH_2Ph), 69.3 and 68.9 (C-6 and 6′), 57.6 (O_2SCH_2Ph), 54.8 (OMe). The compound **15** was separated in 28% yield (252 mg) as a syrup. $[\alpha]_D^{24}$−17.2° (*c* 0.83, chloroform); ^{1}H NMR δ=7.5—7.7 (m, 35H, aromatic), 5.18—5.06 (d, 1H, H-2′), ca. 5.4 (bm, 18H, H-1,1′, 6×CH_2Ph, O_2SCH_2Ph and 2H of sugar protons), 4.0—3.46 (bm, 9H, rest of the sugar protons), 3.36 (s, 3H, OMe); ^{13}C NMR δ=99.3 (C-1), 97.2 (C-1′), 80.2 (C-3′), 77.8 (C-3), 77.4 (C-2), 76.2 (C-5′), 75.5, 75.3, 74.9, 74.3, 73.7, and 73.4 (C-5 and 6×CH_2Ph), 72.5 (C-4′), 72.2 (C-4), 71.5 (C-2′), 69.7, 69.3 (C-6 and 6′), 57.8 (O_2SCH_2Ph), 54.9 (OMe).

Found for **11**: C, 70.25; H, 6.25; S, 3.13, and for **15**: C, 70.00; H, 6.05; S, 2.86%. Calcd for $C_{62}H_{66}SO_{13}$: C, 70.83; H, 6.32; S, 3.05%.

Methyl 2,4,6-Tri-*O*-benzyl-3-*O*-(3,4,6-tri-*O*-benzyl-α-D-mannopyranosyl)-α-D-mannopyranoside (13). Compound **11** (129 mg, 0.127 mmol) in freshly distilled DMF (5 ml) was left to react with pure sodium amide (24 mg, 0.613 mmol) for 48 h as described for **6** to give **13** (90 mg) in 82% yield. $[\alpha]_D^{22}$+25.2° (*c* 0.85, chloroform,); ^{1}H NMR δ=7.4—7.05 (m, 30H, aromatic), 5.18 (s, 1H, H-1′), 4.9 (s, 1H, H-1), 4.83—4.43 (m, 12H, 6×CH_2Ph), 4.4—3.5 (bm, 12H, H-2,2′,3,3′,4,4′,5,5′,6, and 6′), 3.3 (s, 3H, OMe), 2.65—2.93 (bs, 1H, OH); ^{13}C NMR δ=101.5 (C-1′), 98.8 (C-1), 80.2 (C-3′), 78.7 (C-2), 77.8 (C-3), 75.5, 75.01, 74.7, 73.6, 72.4, 72.2, 72.1 (C-5,5′,4,4′ and 6×CH_2Ph), 69.6 and 69.4 (C-6 and 6′), 68.9 (C-2′), 54.9 (OMe).

Found: C, 73.05; H, 6.83%. Calcd for $C_{55}H_{60}O_{11}$: C, 73.63; H, 6,74%.

Methyl 2,4,6-Tri-*O*-benzyl-3-*O*-(3,4,6-tri-*O*-benzyl-β-D-mannopyranosyl)-α-D-mannopyranoside (17). Pure so-

dium amide (24 mg, 0.623 mmol) was left to react with compound **15** (132 mg, 0.125 mmol) in freshly distilled DMF (5 ml) for 48 h as described for **6** to give **17** (0.1 g) as a syrup in 90% yield. $[\alpha]_D^{22}$+16.6° (*c* 0.72, chloroform); ^{1}H NMR δ=7.37—7.17 (m, 30H, aromatic), 4.92—4.90 (d, 1H, H-1), 4.87—4.43 (m, 12H, 6×CH_2Ph), 4.35—4.21 (d, 1H, H-1′), 4.39 (s, 1H, one of sugar protons), 3.9—3.69 (m, 11H, rest of sugar protons), 3.31 (s, 3H, OMe), 2.65—2.50 (bs, 1H, OH). ^{13}C NMR δ=98.9 (C-1), 97.2 (C-1′), 81.6 (C-3′), 76.3 and 76.0 (C-2 and 3), 75.3 (C-5′), 74.6, 73.7, 73.5, 72.5, 71.9, 71.7, 71.4 (C-5,4,4′, and 6×CH_2Ph), 69.6, and 69.4 (C-6 and 6′), 68.6 (C-2′), 54.9 (OMe).

Found: C, 73.74; H, 7.14%. Calcd for $C_{55}H_{60}O_{11}$: C, 73.63; H, 6.74%.

Methyl 3-O-(β-D-Mannopyranosyl)-α-D-mannopyranoside (18). A suspension of **17** (84 mg) and palladium over carbon (0.04 g), in methanol (15 ml) and water (5 ml) was hydrogenated for 48 h at room temperature with stirring. After filtration and freeze drying, **18** was obtained in quantitative yield. $[\alpha]_D^{23}$+5.8° (*c* 0.59, water), ^{13}C NMR δ=103.03 (C-1), 99.5 (C-1′), 79.8 (C-3), 78.7 (C-5′), 75.2 (C-5); 74.7 (C-3′), 73.2 (C-2′), 69.4 (C-2), 69.1 (C-4′), 67.5 (C-4), 63.3 (C-6 and 6′), 57.1 (OMe). The same compound was obtained from **16** in 30% yield by the same procedure.

This work was supported by Grant No. AI-12509 from the National Institute of Allergy and Infections Diseases, National Institutes of Health, U.S. Public Health Service. We thank Dr. R. Eby for his helpful assistance and discussions, and Dr. L. Anderson who suggested the usage of the benzylsulfonyl protecting group. We also thank Prof. J. Yoshimura for his valuable discussions.

Synthesis of New Arginine Derivatives as Substrates of Trypsin

Oyin SOMORIN* and Leo AMEGHASHITSI
Department of Chemistry, University of Lagos, Akoka, Yaba, Lagos, Nigeria
(Received July 10, 1985)

Eight new chromogenic arginine substrates: N^{α}-benzyloxy-carbonyl-L-arginine 3,5-dinitroanilide hydrochloride (L-ZADA·HCl), N^{α}-benzyloxycarbonyl-L-arginine 3-nitroanilide hydrochloride (L-ZANA·HCl), N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-chloroanilide hydrochloride (L-ZANCA·HCl), N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-bromoanilide hydrochloride (L-ZANBA·HCl), N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-fluoroanilide hydrochloride (L-ZANFA·HCl), N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-iodoanilide hydrochloride (L-ZANIA·HCl), N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-(methylsulfonyl)anilide hydrochloride (L-ZANMA·HCl), and N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-(trifluoromethyl)anilide hydrochloride (L-ZANTA·HCl) were synthesized by coupling 5-substituted 3-nitroanilines with N^{α}-benzyloxycarbonyl-L-arginine hydrochloride. These substrates were found to be susceptible to trypsin-catalyzed hydrolysis. These series of substrates are suitable for studying electronic effects on trypsin activity.

Several workers[1–12] have studied the dependence of the electronic effects of substituents in the substrate molecules on the reactivity of chymotrypsin, but there has been very few of such systematic studies on the activity of trypsin. Studies on the relationship of the electronic effects of substituents in the substrates and enzyme activity have been very useful in elucidating the mechanism of action of enzyme catalysis. Both chymotrypsin and trypsin exhibit some remarkable similarities. For example, trypsin and chymotrypsin are proteolytic enzymes which are protein in nature, containing no co-enzyme or prosthetic group and therefore the catalytic activity of these enzymes must be associated directly with the constituents of the protein.[13] Their precursors trypsinogen and chymotrypsinogen are both important constituents of pancreatic juice. These two strikingly similar enzymes are serine proteases with unique serine residue which reacts with organophosphorus compounds to yield inactive derivatives.[14] Besides possessing identical molecular weights both enzymes possess only one active site per molecule which is defined by the reactive serine residue and the common sequence Gly–Asp–Ser–Gly.[15,16] Chymotrypsin and trypsin have mechanistic similarities as evident from the various indications in the literature that trypsin-catalyzed hydrolyses, like those of chymotrypsin, proceed through an acyl-enzyme intermediate.[16] Hence it would be expected that the electronic factors which influence the reactivity of chymotrypsin could similarly influence the reactivity of trypsin.

In order to facilitate the study of these electronic effects, chromogenic substrates would be most desirable since such substrates offer the advantage of producing their own chromogen on enzymic hydrolysis which can easily be quantitatively estimated spectrophotometrically. Most of the substrates previously reported for the studies of the electronic effects on chymotrypsin activity are not chromogenic. In this paper, synthesis of new series of chromogenic substrates suitable for studying the electronic effects of substituents in the substrate molecules on the reactivity of trypsin is reported. The series include N^{α}-benzyloxycarbonyl-L-arginine 5-substituted 3-nitroanilide derivatives. The substrates are unique because of the presence of the nitro group at the 3-position (since the nitro group confers chromogenicity on the substrate) and the presence of various substituents at the 5-position which could be conveniently modified to yield a series of substrates that are suitable for studying the electronic effects on the trypsin activity. In this study the substituents at the 5-position include nitro, methylsulfonyl, trifluoromethyl, fluoro, chloro, bromo, and iodo groups.

Abbreviations: L-ZADA·HCl, N^{α}-benzyloxycarbonyl-L-arginine 3,5-dinitroanilide hydrochloride; L-ZANA·HCl, N^{α}-benzyloxycarbonyl-L-arginine 3-nitroanilide hydrochloride; L-ZANCA·HCl, N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-chloroanilide hydrochloride; L-ZANBA·HCl, N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-bromoanilide hydrochloride; L-ZANFA·HCl, N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-fluoroanilide hydrochloride; L-ZANIA·HCl, N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-iodoanilide hydrochloride; L-ZANMA·HCl, N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-(methylsulfonyl)anilide hydrochloride; L-ZANTA·HCl, N^{α}-benzyloxycarbonyl-L-arginine 3-nitro-5-(trifluoromethyl)anilide hydrochloride, and DMF, *N,N*-dimethylformamide.

Experimental

All the reagents used throughout this investigation are of analytical grades. The ultraviolet and visible absorption spectra were measured with a Zeiss PMQ3 Spectrophotometer attached to Haake F3 thermostated water bath. The optical rotations were measured with a Perkin Elmer recording polarimeter, Model 241MC. Elemental analyses were carried out by Yanagimoto CHN Corder Model MT-2 at the Analytical Laboratory of Hokkaido University, Sapporo, Japan. Melting points were determined by Reichert melting point apparatus. The elemental analysis and melting points for all known compounds were found to agree with the theoretical and literature values.

Buffer. 0.05 M(1 M=1 mol dm^{-3}) tris(hydroxymethyl)-aminomethane hydrochloride buffer solutions containing 0.04 M calcium chloride at pH values ranging from 6.5 to 9.5 were prepared.

Enzyme. Twice crystallized bovine pancreatic trypsin with a specific activity of 182 units mg^{-1} protein was purchased from Wako Pure Chemicals Industries, Japan. The trypsin activity was determined using L-TAME·HCl as a substrate according to the Worthington Procedure.[17]

Preparation of 5-Substituted 3-Nitroanilides. 3,5-Dinitroaniline, 3-nitro-5-chloroaniline 3-nitro-5-bromoaniline, 3-nitro-5-iodoaniline, 3-nitro-5-fluoroaniline, 3-nitro-5-(methylsulfonyl)aniline, and 3-nitro-5-(trifluoromethyl)-aniline were prepared according to the procedure reported by Dosumu.[18]

Synthesis of the Chromogenic Arginine Substrates, N^{α}-Benzyloxycarbonyl-L-arginine 5-Substituted 3-Nitroanilide Hydrochloride. The 3-nitro-5X-aniline (X=H, CF_3, NO_2, SO_2CH_3, F, Cl, Br, and I) was coupled to N^{α}-benzyloxycarbonyl-L-arginine hydrochloride by the method reported by Somorin et al.[19] Solution A containing the 3-nitro-5X-aniline (0.03 mol) and triethylamine (4.2 ml, 0.03 mol) in diethyl phosphonate (15 ml) was added to Solution B which contained phosphorus pentaoxide (8.55 g, 0.06 mol) in diethyl phosphonate (30 ml). Solution of N^{α}-benzyloxy-carbonyl-L-arginine (9.24 g, 0.03 mol) containing 85% phosphoric acid (2.1 ml, 0.03 mol) in diethyl phosphonate (30 ml) was added to the mixture of solutions A and B described above. The reaction mixture was heated on a water bath with stirring for 2 h in a well ventilated fume-cupboard. Diethyl phosphonate was removed in vacuo and the residual oil dissolved in 300 ml of 1M HCl after heating at 85 °C for about 5 minutes. On refrigerating, a semi-solid oil precipitated. The oil was separated by decanting off the acid solution, washed with cold water and dried. The oily product crystallized on triturating with ethyl acetate and was recrystallized from dilute hydrochloric acid. The mp, elemental analysis, and optical rotation of each chromogenic arginine substrate is recorded in Table 1.

Enzymatic Activity Determination. The initial rates of trypsin catalyzed hydrolyses of the anilide substrates were determined by continuous measurement of free 5-substituted 3-nitroaniline while the reaction proceeded in a themostated cuvette inserted in a Zeiss PMQ3 Model Spectrophotometer attached to a Haake F3 thermostated water bath. The concentration of the liberated substituted aniline was determined at 400 nm at which wavelength all the substrates have no contribution to the absorbance.

Results and Discussion

The synthesis of arginine substrates has always been a difficult task. The low basicity of the amino group in the 5-substituted 3-nitroaniline makes it difficult to couple with the carboxyl of arginine which has been activated by the azide, dicyclohexyl-carbodiimide or active ester method.[20] Therefore the activation of the amino group of the aniline derivatives seems to be essential for facilitating the coupling with the carboxyl group of arginine. The series of new arginine substrates reported in this paper were readily prepared without racemization through the condensation of 5-substituted 3-nitroanilines and N^{α}-benzyloxycarbonyl-L-arginine hydrochloride using the coupling procedure reported by Somorin et al.[19] The relative initial rates of trypsin catalyzed hydrolysis of the various substrates were determined and tabulated in Tables 2 and 3.

It has been reported that trypsin catalyses the hydrolysis of anilides via the acyl-enzyme intermediate.[16] The overall mechanism can be represented by the equation:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} ES^1 + P_1 \xrightarrow{k_3} E + P_2,$$

where k_2 and k_3 are the first-order rate constants for the acylation and deacylation steps respectively; P_1 and P_2 are products. It is known that the acylation step is the rate limiting step for amide and anilide substrates.[21,22] The same mechanism operates in the chymotrypsin-catalyzed hydrolysis of anilides and its acylation step has been studied in detail by varying the leaving group P_1. Through the determination of rate constant for the acylation step, k_2, several workers concluded that a proton transfer was involved in the acylation step.[5,6,8,11] Studies of

Parker and Wang[8] on the acylation step of α-chymotrypsin catalyzed hydrolysis of anilides suggest a pre-transition state protonation of the substrate followed by the usual nucleophilic attack of the protonated substrate by the serine residue.

The results in Table 1 suggest that the electron-withdrawing substituents (-F, $-CF_3$, and $-SO_2Me$) inhibit the rate of trypsin catalysed hydrolysis of the anilide substrates. It has been suggested that electron-withdrawing substituents hinder the rate of chymotrypsin catalyzed hydrolysis of anilides by inhibiting the proton transfer in the removal of the substituted aniline.[9] This is consistent with the mechanism proposed by Inward and Jencks[23] in which a conjugate acid of the catalyst (histidinium cation) donates a proton to the leaving group which is 5-substituted 3-nitroaniline.

The results in Table 2 show that the rates of enzyme-catalyzed hydrolysis of the halogen derivatives of the arginine substrates decrease in the order: iodo>bromo>chloro>fluoro. This unique sequence, which is characteristic of the halogen substituted chromogenic substrates, is the reverse of the order for the inductive effect which follows the order: fluoro>chloro>bromo>iodo. The details of the kinetics for the trypsin-catalyzed hydrolysis of these new arginine chromogenic substrates will be published elsewhere.

Silver *cis*-Tetrachlorohydroxonitrosylruthenate (2–)

Yasuhiro KAMATA,† Eiichi MIKI, Kunihiko MIZUMACHI, and Tatsujiro ISHIMORI*
Department of Chemistry, College of Science, Rikkyo University,
3-Chome, Nishi-Ikebukuro, Toshima-ku, Tokyo 171
(Received January 13, 1986)

Synopsis. A new chloronitrosylruthenate ion was separated from the hydrolysis mixture of $[RuCl_5(NO)]^{2-}$ by the anion-exchange method, and it formed $Ag_2[RuCl_4(OH)(NO)]$ on the addition of silver nitrate. The anion of the silver salt was found to have the cis form on the basis of its IR spectrum.

Silver and ammonium salts of $[RuCl_4(OH)(NO)]^{2-}$ were prepared from the hydrolysis mixture of $[RuCl_5(NO)]^{2-}$ by Mercer et al.[1–3] The anion of these salts and its protonated aqua complex have been considered to have the trans form.[1–3] Separation of the possible isomers of $[RuCl_4(H_2O)(NO)]^-$ was reported without identification of the isomers.[4] The authors isolated *cis*-$Ag_2[RuCl_4(OH)(NO)]$ from a component of the hydrolysis mixture of $[RuCl_5(NO)]^{2-}$.

Experimental

$(NH_4)_2[RuCl_5(NO)]$ was prepared by Fletcher's method.[5] Electronic spectra of complexes in aqueous solutions were recorded on a Hitachi 340 spectrophotometer, and IR spectra of the isolated complexes on JASCO A-202 and IR-F spectrometers.

Preparation of *cis*-$Ag_2[RuCl_4(OH)(NO)]$. A solution of $(NH_4)_2[RuCl_5(NO)]$ (2.4 g) in 0.01 mol dm^{-3} $HClO_4$ (40 cm^3) was heated at 50 °C for 6 h, and stored at 5 °C overnight. The species in the solution were separated with a QAE Sephadex A-25 column (the nitrate form, ϕ 4 cm×40 cm) at below 10 °C. After $[RuCl_2(H_2O)_3(NO)]^+$ and $[RuCl_3(H_2O)_2(NO)]$ had been eluted out of the column with 0.05 mol dm^{-3} HNO_3, the elution was continued until three separate adsorption bands appeared. Since $[RuCl_5(NO)]^{2-}$ was strongly adsorbed on the uppermost part of the column, the uppermost part was taken out of the column by using a suction pump. *trans*-$[RuCl_4(H_2O)(NO)]^-$ in the lower adsorption band of the remaining bands was eluted out with 0.1 mol dm^{-3} HNO_3. The species in the final adsorption band was eluted with 1 mol dm^{-3} $HClO_4$. The effluent was collected under cooling with ice-water and it gave a silver salt on the addition of 5 wt% $AgNO_3$ solution. The silver salt was filtered off, washed with dilute HNO_3 containing a small amount of $AgNO_3$ and dilute HNO_3 successively, and then dried in a vacuum desiccator with $CaCl_2$ and NaOH. Yield, 80 mg. Found: Ru, 20.1; Cl, 28.35; N, 2.85%. Calcd for $Ag_2[RuCl_4(OH)(NO)]$: Ru, 19.99; Cl, 28.10; N, 2.77%.

Electronic spectra of $[RuCl_2(H_2O)_3(NO)]^+$, $[RuCl_3(H_2O)_2(NO)]$, and *trans*-$[RuCl_4(H_2O)(NO)]^-$ in the effluents were the same as those reported by Mercer et al.[1] *trans*-$Ag_2[RuCl_4(OH)(NO)]$ was prepared according to Ref. 1 by the addition of 5 wt% $AgNO_3$ solution to the *trans*-$[RuCl_4(H_2O)(NO)]^-$ solution separated.

Results and Discussion

The silver salt newly prepared had the formula, $Ag_2[RuCl_4(OH)(NO)]$, and was isomeric with *trans*-$Ag_2[RuCl_4(OH)(NO)]$ prepared by Mercer et al.[1]

The IR data of the new salt are shown in Table 1, together with those of *trans*-$Ag_2[RuCl_4(OH)(NO)]$ prepared. The IR bands were assigned by referring to Refs. 2, 6, and 7. The spectra of the trans salt were the same as those reported by Mercer et al.[2] The IR spectrum of the new salt in the Ru–Cl stretching region was clearly different from that of the trans salt. The trans salt gave two bands assigned to a doubly degenerate Ru–Cl stretching vibration and a totally symmetric Ru–Cl stretching vibration. The new salt gave three bands due to nondegenerate Ru–Cl stretching vibrations. *cis*-$[PtCl_4(NH_3)_2]$[8] and *cis*-$[SnCl_4(bpy)]$[9] gave typically four bands due to the metal–Cl stretching vibtations. However, it has been also observed that the number of the Sn–X stretching bands for *cis*-$[SnX_4(L\text{–}L)]$(X=Cl, Br, or I; L–L=phen, 1,2-bis(methylthio)ethane, or 1,2-bis(diphenylphosphino)ethane) ranges from two to four.[9] The three bands observed for the new salt strongly indicate that the new salt is the silver salt of *cis*-$[RuCl_4(OH)(NO)]^{2-}$.

The N–O stretching frequencies of the two salts show that the anions of both salts are of the linear

Table 1. Wavenumbers/cm^{-1} and Assignments of IR Bands for *trans*- and the New $Ag_2[RuCl_4(OH)(NO)]$

Assignment	O–H str	N–O str	O–H bend	a)	Ru–OH str	Ru–Cl str

† Present address: Nihon Tokushu Noyaku Seizo K. K., Toyota, Hino, Tokyo 191.

{RuNO}^{6} type.[10] Both OH^- and Cl^- are largely σ-bonding ligands, while π-donor ability of OH^- is greater than that of Cl^-. The NO in trans salt's anion is considered to withdraw more π electron density from the Ru than the NO in new salt's anion of the cis form. This can explain the results that the N–O stretching frequency of the trans salt was smaller than that of the new salt and the frequencies of the skeletal vibrations due to the RuNO group of the trans salt were greater than those of the new salt. The same results were observed for *trans*-$[RuL(NH_3)_4(NO)]^{2+}$(L=OH, or Cl)[11]; the N–O stretching frequency for the chloro complex (1880 cm^{-1}) was greater than that for the hydroxo complex (1841 cm^{-1}) and the frequencies of the skeletal vibrations due to the RuNO group for the chloro complex (562 and 603 cm^{-1}) were smaller than those for the hydroxo complex (589 and 630 cm^{-1}).

In complexes of the linear {RuNO}^{6} type, the NO is such a good π-acceptor and poor σ-donor that rather than a competition between the NO and the *trans*-L ligand for the same orbitals, there is mutual reinforcement in both Ru–NO and Ru–L bonds when L is a good σ-donor and poor π-acceptor, e.g. Cl^- or OH^-.[12] Therefore, the OH^- trans to the NO is considered to bind to the Ru more strongly than the OH^- cis to the NO. This can explain the results that each frequency of ν_{O-H}, δ_{O-H}, and ν_{Ru-OH} of the new salt was smaller than that of the trans salt.

On the basis of the IR data discussed above, the anion of the new salt can be assigned to the cis form.

In $[RuCl_5(NO)]^{2-}$, the Ru–Cl bonds cis to the NO were found to be longer than that trans to the NO[13] and were also indicated to be weaker than that trans to the NO.[14] Hydrolysis of the Cl ligand in *cis*-$[RuCl(NH_3)_4(NO)]^{2+}$ was found to be faster than the corresponding hydrolysis in *trans*-$[RuCl(NH_3)_4(NO)]^{2+}$.[15] Consequently, the formation of *cis*-$[RuCl_4(H_2O)(NO)]^-$ can be expected in the first step of the hydrolysis of $[RuCl_5(NO)]^{2-}$ in an acid solution. For the process of the preparation of the new salt, it can be also considered that the *cis*-$[RuCl_4(H_2O)(NO)]^-$ is separated from the hydrolysis mixture and it forms *cis*-$Ag_2[RuCl_4(OH)(NO)]$ on the addition of silver nitrate.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 58470038 from the Ministry of Education, Science and Culture.

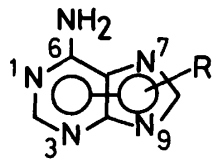
The Positional Dependence of Anodic Peak Potentials in *N*-Substituted Adenines[1)]

Takeo SATO,* Kentaro FUKUZAKI, and Tozo FUJII†
Department of Chemistry, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
†Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920
(Received November 8, 1985)

Synopsis. In order to determine the structural dependence on the anodic potential, cyclic voltammetric measurements were carried out for 1-, 3-, 7-, 9-, and N^6-alkyladenines in *N*,*N*-dimethylformamide (DMF) or in acetonitrile (AN). The anodic peak potential, E_{pa}, in DMF was found to be sensitive to the substitution and shifted anodic in the order, 7-<1-<3-, N^6-<9-substituted derivatives. These data, with the aid of solvent effects, are useful for determining the substitution pattern in *N*-alkyladenines.

Only 9-substituted adenines were previously found in biologically important nucleosides and nucleotides,[2)] although five *N*-substituted derivatives are possible, namely, 1-, 3-, 7-, 9-, and N^6-substituted derivatives (**1**). Until now, however, all five de-



1

rivatives have been isolated from natural sources and have been synthesized.[2)] This has led to investigation of methods for the selective formation and structural determination of *N*-alkyladenines.[2,3)]

Besides chemical methods, three approaches have been reported[3)] to distinguish substitution in *N*-alkyladenines. UV spectral maxima in acidic or basic media were used to differentiate each of the 1-, 9-, and N^6-substitutions from a group of 3- and 7-substitutions. The pK_a' values were shown to differentiate 3- and 7- or 9-substitutions, and the value of λ_{min} (pH 1)$-\lambda_{min}$ (pH 7) was used to distinguish 3- from 7- or 9-substituted adenines. Sometimes, the first approach may not clearly differentiate substitution among imidazole rings, e.g. 7- from 9-substitution.[3)] In this note, we survey the anodic peak potentials of alkyladenines and related compounds in order to obtain a complementary method for structural determinations.

Dryhurst and Elving[4)] have carried out the anodic oxidation of adenine in aq acetic acid on a porous graphite electrode and observed an initial oxidation similar to an enzymatic type, followed by deep-seated fragmentation. We carried out cyclic voltammetric measurements for all the *N*-positional isomers of methyl-, ethyl-, and benzyladenines together with 9-phenethyladenine in acetonitrile (AN) or in *N*,*N*-dimethylformamide (DMF) using a platinum anode. All compounds except for 1-methyladenine showed an E_{pa} between +1.1 and +1.8 V vs. SCE at a scan rate of 50—500 mV s^{-1} but failed to show a reduction wave upon potential reversal. The data measured in DMF showed a significant positional dependence, the results determined at a scan rate of 250 mV s^{-1} are summarized in Table 1.

Adenine showed an E_{pa} at +1.75 V in DMF and +1.45 V in AN. In either solvent, the anodic peak potentials were found to depend on the substitution pattern and were essentially similar among the methyl, ethyl, and benzyl derivatives. In DMF, the 9-alkyl derivatives showed E_{pa}s at the highest anodic potential, observable only as a shoulder at ca. +1.7 V. Those having an N^6-substituent showed a slight cathodic shift with E_{pa}s at ca. +1.6 V. The 1- and 3-substituted adenines showed E_{pa}s at ca. +1.4 and 1.5 V, respectively. A significant cathodic shift was observed for the 7-alkyl derivatives which showed E_{pa}s at ca. +1.2 V. The E_{pa}s for alkyladenines in DMF increase in the order:

7-<1-<3-, N^6-<9-substituted derivatives

1-Methyladenine was practically insoluble in DMF and no voltammogram was recorded. Kinetin showed an E_{pa} at +1.63 V (+1.45 V in AN) as expected from N^6-substitution. Adenosine showed an E_{pa} at +1.23 V, a considerable cathodic potential. This was not expected from a 9-substituted derivative, and indicated that a one-electron transfer occurred on the sugar moiety. The above data showed that E_{pa} is sensitive to substitution and enables one to differentiate between 7- and 9-substitution quite easily.

The solvent effect on the CV measurements was then investigated. In *N*,*N*-dimethylacetamide, the 7-substituted derivatives showed E_{pa}s between +1.1 and 1.3 V, similar to those observed in DMF. In AN, however, a significant solvent-induced shift was noticed as compared with the amide solvents. Table 2 summarizes peak potentials for *N*-benzyladenines as well as the solvent shift in E_{pa}, ΔE_{pa} (AN-DMF).

Table 1. Anodic Peak Potential Data for *N*-Alkyladenines[a)]

Position of R	R			
	Me	Et	$PhCH_2$	$PhCH_2CH_2$
1	—[b)]	1.41	1.40	
3	1.54	1.54	1.52	
7	1.17	1.17[c)]	1.19	
9	1.68[c)]	1.68[c)]	1.70[c)]	1.76
N^6	1.58	1.54[c)]	1.56[c)]	

a) The cyclic voltammetry was carried out in DMF-TBAP (0.1 mol dm^{-3}) using a platinum inlay electrode as an anode and SCE as the reference at 250 mV s^{-1}. b) The compound is insoluble in DMF. c) Shoulder.

Table 2. The Anodic Peak Potential Data for *N*-Benzyladenines in Various Solvents[a)]

Position of R		E_{pa} DMF	E_{pa} DMAc[b)]	E_{pa} AN	ΔE_{pa} (AN-DMF)
Pyrimidine moiety	1	1.40		1.10	−0.30
	3	1.52		1.50	−0.02
	N^6	1.56[c)]		1.48	−0.08
Imidazole moiety	7	1.19	1.10[c)]	1.67	+0.48
	9	1.70[c)]		1.62	−0.08

a) The measurements were carried out in the same way as described in Table 1. b) *N*,*N*-dimethylacetamide. c) Shoulder.

In AN, the 1- and N^6-substituted derivatives having a substituent in the pyrimidine moiety showed cathodic shifts of 0.3 and 0.1 V, respectively, whereas the 7-substituted derivatives showed an anodic shift of 0.5 V. The anodic shift for both 7-methyl- and 7-ethyladenines in AN was 0.4 V. Those substituted at the 3- and 9-positions showed no solvent-induced shift. This phenomena might be ascribable to the selective association between the 1- and N^6-positions of adenine with the amide solvent as in the adenine–thymine pair.

Whereas the UV, pK_a', and λ_{min} methods have been used to differentiate substitution between pyrimidine and imidazole rings of alkyladenines, the present CV method independently could differentiate not only substitution between 7- and 9- positions but also among pyrimidine rings, namely, 1-, 3-, and N^6-substitution, with the aid of solvent effects.

Experimental

Materials. The substrates used for the CV measurements were obtained commercially or were taken from stocks which had been prepared according to published procedures: 1-,[5)] 3-,[6)] 7-,[7)] 9-,[8)] and N^6-methyladenines;[9)] 1-,[10)] 3-,[11)] 7-,[7)] 9-,[8)] and N^6-ethyladenines;[10)] 1-,[12)] 3-,[13)] 7-,[13)] 9-,[8)] and N^6-benzyladenines;[12)] 9-phenethyladenine.[8)]

Cyclic Voltammetry. The measurements were carried out using a generator, Hokuto HB-107A, and a potentiostat, Hokuto HA-101. As an anode, a platinum inlay electrode, Beckman No. 39273, was used. To avoid contamination from moisture, the reference SCE was connected to a modified H-cell through two junction bridges each filled with a sat KCl solution and DMF or AN–tetrabutylammonium perchlorate (TBAP). Molecular sieve 1A (Wako chemicals) was added to the bridge directly immersed in the cell.

Sample concentrations were between 10^{-4} and 10^{-5} mol dm^{-3}. 1-Methyladenine was insoluble in DMF and no voltammogram was recorded. As an anolyte, TBAP was added to the solution to make 0.1 mol dm^{-3} solutions. The results recorded at 250 mV s^{-1} are shown in Tables 1 and 2. The data are expressed in +V vs. SCE. Highly anodic peaks, especially determined in DMF, appeared as a shoulder.

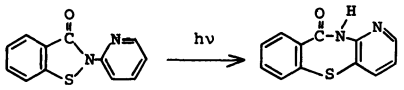
Photochemical Isomerization of 2-Pyridyl- and 2-Pyrazinyl-1,2-benzisothiazol-3(2*H*)-ones

Nobumasa KAMIGATA,* Hirokazu IIZUKA, and Michio KOBAYASHI
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received December 18, 1985)

Synopsis. The irradiation of 2-pyridyl- and 2-pyrazinyl-1,2-benzisothiazol-3(2*H*)-ones in benzene resulted in the formation of benzopyrido- and benzopyrazinothiazepinones, respectively. A mechanism involving a biradical species is proposed for this reaction.

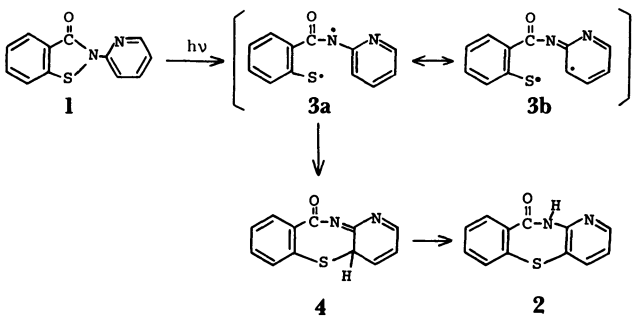
Considerable attention has been focused in recent years on the photochemistry of five-membered heterocyclic ring systems. By far the greatest area of activity in this field has been a study of the photoisomerization that results in a change in the heterocyclic nucleus.[1] We have reported a novel photochemical ring-expansion reaction of such five-membered heterocyclic compound as 2-aryl-1,2-benzisothiazolinones to seven-membered heterocyclic compound, dibenzothiazepinones.[2] As we have continuous interest in this novel photoisomerization, the photochemical reaction of 2-pyridyl- and 2-pyrazinyl-1,2-benzisothiazol-3(2*H*)-ones has been studied and the results are described herein.

When a solution containing 2-(2-pyridyl)-1,2-benzisothiazol-3(2*H*)-one (**1**) in benzene was irradiated under argon with 300-nm light, a single photoproduct was obtained. This material was assigned as benzo[*f*]pyrido[3,2-*b*][1,4]thiazepin-10(11*H*)-one (**2**) on the basis of its spectral data.



1 **2**

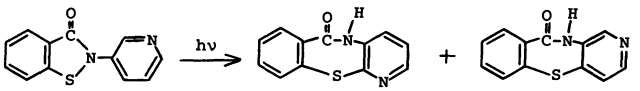
This reaction is of interest since it involves a medium-size seven-membered ring compound, is generally difficult to prepare and is obtained by photochemical isomerization from a five-membered compound involving a pyridine ring **1**. The photoreaction is presumed to proceeded via a homolytic cleavage of the S–N bond to generate a biradical **3**. The initially-formed thiyl radical of **3a** attacks the β-position of the *N*-(2-pyridyl) group to give a cyclized product **4**. A subsequent 1,7-hydrogen shift of the intermediate **4** leads to the final product **2** (Scheme 1).



1 **3a** **3b** **4** **2**

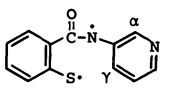
Scheme 1.

For this proposed mechanism to be adequate, it was expected that a photochemical reaction of 2-(3-pyridyl)-1,2-benzisothiazol-3(2*H*)-one (**5**) would afford two photoisomerized products. As expected, the irradiation of **5** in benzene in a similar way afforded two isomeric photoreaction products. They were assigned as benzo[*f*]pyrido[2,3-*b*][1,4]thiazepin-6(5*H*)-one (**6**) and benzo[*f*]pyrido[4,3-*b*][1,4]thiazepin-10(11*H*)-one (**7**) on the basis of their spectral data.



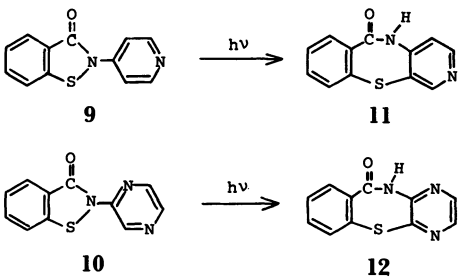
5 **6** **7**

The fact that almost equal amounts of photoisomeric products (**6** and **7**) were obtained in the photolysis of **5** suggests that the selectivity of the thiyl radical of the intermediate **8**, formed from **5** by the photochemical cleavage of the S–N bond, is extremely weak regarding on intramolecular attack on α- and γ-positions of the pyridine ring.



8

The photochemical reactions of 2-(4-pyridyl)-1,2-benzisothiazol-3(2*H*)-one (**9**) and 2-(2-pyrazinyl)-1,2-benzisothiazol-3(2*H*)-one (**10**) were also studied. In these cases, a single photoproduct, benzo[*f*]pyrido[3,4-*b*][1,4]thiazepin-6(5*H*)-one (**11**) and benzo[*f*]pyrazino[2,3-*b*][1,4]thiazepin-10(11*H*)-one (**12**) were isolated, respectively, for each reaction.



9 **11** **10** **12**

Experimental

All melting points were uncorrected. IR and UV spectra were recorded on a Hitachi EPI-G2 and a Hitachi 220A spectrometer. ^{1}H NMR spectra were measured with a

Hitachi R-90H (90 MHz) spectrometer using tetramethylsilane as an internal standard. Mass spectra were determined with a JEOL JMS-DX300 high-resolution mass spectrometer with a JEOL JMA5000 mass-data system at an ionization energy of 70 eV.

Materials. 2-Pyridyl- and 2-pyrazinyl-1,2-benzisothiazol-3(2*H*)-ones were prepared from 2,2'-dithiobis[benzoyl chloride] by treating with aminopyridine and aminopyrazine, respectively, according to a modified method of Reissert and Manns.[3] The yields, physical properties, and spectral data were as follows:

2-(2-Pyridyl)-1,2-benzisothiazol-3(2*H*)-one (1): Yield 84%; mp 194.5—195.5 °C (from $CHCl_3$); IR (KBr) 1675 cm^{-1}; ^1H NMR (DMSO-d_6) δ=7.07—7.90 (5H, m), 8.07 (1H, d, J=7.7 Hz), 8.41 (1H, d, J=5.1 Hz), and 8.75 (1H, d, J=8.4 Hz); ^{13}C NMR ($CDCl_3$) δ=114.39, 120.24, 120.61, 125.43, 126.57, 126.73, 132.74, 138.30, 140.98, 147.51, 150.36, and 163.95; MS, m/z 228 (M^+); HRMS, m/z 228.0419 ($C_{12}H_8N_2OS$ requires 228.0357); UV (methanol) 255 (log ε=3.98) and 335 nm (3.81).

2-(3-Pyridyl)-1,2-benzisothiazol-3(2*H*)-one (5): Yield 78%; mp 118.5—119.5 °C (from $CH_3CO_2C_2H_5$); IR (KBr) 1675 cm^{-1}; ^1H NMR (DMSO-d_6) δ=7.26—7.73 (4H, m), 8.11 (1H, dd, J=7.6 and 1.0 Hz), 8.15—8.27 (1H, m), 8.55 (1H, dd, J=4.7 and 1.3 Hz), and 8.95 (1H, d, J=2.4 Hz); ^{13}C NMR (DMSO-d_6) δ=120.18, 123.69, 124.01, 126.03, 127.13, 132.72, 134.41, 134.41, 139.60, 144.86, 147.46, and 164.27; MS, m/z 228 (M^+); HRMS, m/z 228.0339 ($C_{12}H_8N_2OS$ requires 228.0357); UV (methanol) 254 (log ε=4.11) and 330 nm (3.73).

2-(4-Pyridyl)-1,2-benzisothiazol-3(2*H*)-one (9): Yield 88%; mp 182.5—183.5 °C (from CH_3OH); IR (KBr) 1670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.43—8.14 (6H, m), 8.66 (2H, dd, J=4.3 and 1.2 Hz); ^{13}C NMR ($CDCl_3$) δ=115.84, 122.20, 126.16, 126.16, 126.49, 133.63, 139.60, 144.21, 146.16, 149.08, and 164.21; MS, m/z 228 (M^+); HRMS, m/z 228.0339 ($C_{12}H_8N_2OS$ requires 228.0357).

2-(2-Pyrazinyl)-1,2-benzisothiazol-3(2*H*)-one (10): Yield 87%; mp 152—153 °C (from CH_3OH); IR (KBr) 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.36—7.70 (3H, m), 8.08 (1H, d, J=7.9 Hz), 8.40 (1H, d, J=7.9 Hz), 8.42 (1H, s), and 10.03 (1H, s); MS, m/z 229 (M^+); HRMS, m/z 229.0294 ($C_{11}H_7N_3OS$ requires 229.0294); UV (methanol) 235 (log ε=3.60) and 345 nm (4.27).

Photolysis of 2-Pyridyl- or 2-Pyrazinyl-1,2-benzisothiazol-3(2*H*)-one. A solution containing 200 mg of **1**, **5**, **9**, or **10** in 230 cm^3 of benzene was irradiated using a 450-W Hanovia medium-pressure mercury lamp through a Pyrex filter sleeve for 40 h. The removal of the solvent under reduced pressure left a light-brown residue which was purified by silica-gel chromatography using dichloromethane–ethyl acetate 4:1 mixture as the eluent. The yield and physical and spectral data of these photoreaction products are as follows:

Benzo[*f*]pyrido[3,2-*b*][1,4]thiazepin-10(11*H*)-one (2): Yield 59%; mp 239—240 °C; IR (KBr) 2900—3200 (w, amide N-H) and 1650 cm^{-1} (s, amide C=O); ^1H NMR (DMSO-d_6) δ=7.20 (1H, dd, J=7.7 and 4.7 Hz), 7.46—7.75 (4H, m), 8.01 (1H, dd, J=7.7 and 1.8 Hz), 8.38 (1H, dd, J=4.7 and 1.8 Hz), and 10.98 (1H, s); MS, m/z 228 (M^+); HRMS, m/z 228.0465 ($C_{12}H_8N_2OS$ requires 228.0357).

Benzo[*f*]pyrido[2,3-*b*][1,4]thiazepin-6(5*H*)-one (6): Yield 23%; mp 300 °C; IR (KBr) 2900—3200 (w, amide N-H) and 1660 cm^{-1} (s, amide C=O); ^1H NMR (DMSO-d_6) δ=7.38—7.72 (6H, m), 8.28 (1H, dd, J=4.4 and 1.8 Hz), and 10.68 (1H, s); MS, m/z 228 (M^+); HRMS, m/z 228.0438 ($C_{12}H_8N_2OS$ requires 228.0357).

Benzo[*f*]pyrido[4,3-*b*][1,4]thiazepin-10(11*H*)-one (7): Yield 21%; mp 240—241 °C; IR (KBr) 2900—3200 (w, amide N-H) and 1660 cm^{-1} (s, amide C=O); ^1H NMR (DMSO-d_6) δ=7.40—7.77 (5H, m), 8.30 (1H, d, J=5.1 Hz), 8.43 (1H, s), and 10.82 (1H, s); MS, m/z 228 (M^+); HRMS, m/z 228.0384 ($C_{12}H_8N_2OS$ requires 228.0357).

Benzo[*f*]pyrido[3,4-*b*][1,4]thiazepin-6(5*H*)-one (11): Yield 40%; mp 244 °C; IR (KBr) 3170 (w, amide N-H) and 1660 cm^{-1} (s, amide C=O); ^1H NMR (DMSO-d_6) δ=7.20 (1H, d, J=5.3 Hz), 7.42—7.77 (4H, m), 8.42 (1H, d, J=5.3 Hz), 8.63 (1H, s), and 11.03 (1H, s); MS, m/z 228 (M^+); HRMS, m/z 228.0438 ($C_{12}H_8N_2OS$ requires 228.0357).

Benzo[*f*]pyrazino[2,3-*b*][1,4]thiazepin-10(11*H*)-one (12): Yield 45%; mp 232—233 °C; IR (KBr) 3100 (w, amide N-H) and 1650 cm^{-1} (s, amide C=O); ^1H NMR ($CDCl_3$) δ=7.40—7.47 (4H, m), 8.30 (2H, s), and 13.77 (1H, s); MS, m/z 229 (M^+); HRMS, m/z 229.0255 ($C_{11}H_7N_3OS$ requires 229.0305).

We are grateful to Dr. H. Matsumoto of Gunma University for recording the NMR spectra.

[Cr(acac)$_3$] as a New Calibrant for Magnetic Susceptibility Experiments

R. P. SHARMA* and K. K. BHASIN
Department of Chemistry, Panjab University, Chandigarh-160014, India
(Received August 12, 1985)

Synopsis. The merits of a common coordination compound, [Cr(acac)$_3$] obtained by a new and useful method, as a calibrant for magnetic susceptibility experiments are discussed.

Recently, we have described a new and useful method[1] for the preparation of a well documented coordination compound; tris(acetylacetonato)chromium(III), [Cr(acac)$_3$], in high yields by adding acetylacetone to a warm aqueous solution of $M_2Cr_2O_7$ ($M=NH_4^+$, Na^+, K^+) or M_2CrO_4 ($M=Na^+$, K^+). The purity of the sample has been checked by elemental analysis (C, H, Cr), melting point and infrared spectrum.

The advantages of our method over the already existing ones[2-4] are (i) the starting materials are readily available (ii) the method is quick (iii) the final product is purer and (iv) the yield of the product is not pH dependent.

One of the most important techniques used in coordination chemistry to find out the number of unpaired electrons in the transition metal ion so as to throw light on the environment around the central metal ion in a coordination compound is the magnetic susceptibility.[5] The first step to find out the magnetic susceptibility always involves the calibration of the Gouy's tube with a standard substance known as calibrant. A calibrant is selected so to fulfil the following requirements:

(i) The calibrant should be easy to prepare and the starting materials cheaply and readily available.
(ii) The method for its preparation should be simple and quick.
(iii) The calibrant should be of high purity and if need be, easy to purify.
(iv) The calibrant should be nonhygroscopic and fairly stable, i.e., it should possess good keeping properties.
(v) The magnetic moment value should be fairly large.

As it was relatively difficult earlier to prepare pure [Cr(acac)$_3$] (which may be usually contaminated with the buffer used) it was not thought as suitable for calibration purposes. The most commonly used calibrant[6-8] has always remained Hg[Co(SCN)$_4$] so far. In view of our convenient method for the preparation of [Cr(acac)$_3$] coupled with other advantages over Hg[Co(SCN)$_4$] (Table 1), the use of [Cr(acac)$_3$] as a calibrant is strongly recommended.

Molecular Rearrangements. XXIV. Thermolysis of Phenylhydrazones

Safaa Abd El-Salam MAHGOUB, Atiat Mohammed FAHMY, Morsy Mohammed ALY, and Mahmoud Zaif Amin BADR*
Department of Chemistry, Faculty of Science, Assiut University, Assiut, Egypt, A.R.E.
(Received April 10, 1984)

Synopsis. Thermolysis of acetophenone phenylhydrazone by reflux in air for 24 h gives ammonia, benzonitrile, acetophenone, biphenyl, aniline, *o*- and *p*-toluidines, together with 7-methyl-3-phenylindole, while that of benzophenone phenylhydrazone gives ammonia, benzophenone, *N*-benzhydrylideneaniline, biphenyl, aniline, benzonitrile, and 9-phenylacridine.

Thermolysis of phenylhydrazones of aldehydes and ketones was a matter of controversy, where Chattaway et al.[1] recorded the thermal breakdown of benzaldehyde phenylhydrazone into *N*-benzylideneaniline, stilbene, ammonia, benzene, and nitrogen.

Further extension of this reaction to other phenylhydrazones[2] leads to the conclusion that the reaction proceeds through a concerted fourcenter process rather than a free radical mechanism.

Repeating the above thermolysis reaction in one of our studies had resulted in different products than that recorded before. This prompted us to reinvestigate the reaction in an effort to gain further information about more generalized pyrolytic mechanism.

Thermolysis of benzophenone phenylhydrazone (**1**) by reflux in air for 24 h gives ammonia, benzophenone, biphenyl, aniline, benzonitrile, *N*-benzhydrylideneaniline (**2**), and 9-phenylacridine (**3**).

Formation of most of these products strongly points to a free radical mechanism starting by homolysis of N–N bond forming phenylaminyl and diphenylmethaniminyl radical pairs (Eq. 1) followed by H-abstraction to form aniline and diphenylmethanimine, respectively. The latter most probably on hydrolysis during working up procedure, gives rise to benzophenone and ammonia. Such a mechanism is to be expected on basis of bond energy values of the N–N and N–H bonds[3] being of the order 51 and 75 kcal mol^{-1}(1 cal=4.184 J), respectively.

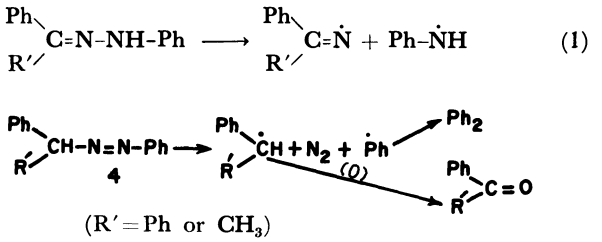
However, such mechanism can not correlate for the formation of biphenyl, **2** and **3**. Consequently we have to take into consideration an alternative pathway involving isomerization of the phenylhydrazone **1** to the corresponding phenylazoalkane **4** as observed by other workers[4] through a free radical mechanism initiated by free radicals present in the reaction medium. The isomerized phenylazoalkane undergoes nitrogen extrusion forming phenyl and diphenylmethyl free radicals. Phenyl free radical substitution on the phenylazoalkane followed by its fragmentation gives biphenyl, whereas atmospheric oxidation of diphenylmethyl free radicals gives benzophenone as described by other workers[5] in the oxidation of benzyl radicals to benzaldehyde (Scheme 1). Furthermore, coupling of phenyl and dipenylmethaniminyl radicals leads to the formation of *N*-benzhydrylideneaniline.

The **3** (a pyrolysis product of **1**) is reasonably assumed to be formed via **5** which results from C–C coupling of diphenylmethyl and phenylaminyl radicals (Scheme 2).

Acetophenone phenylhydrazone (**6**) behaves similarly on thermolysis under the same conditions forming ammonia, acetophenone, biphenyl, aniline, benzonitrile, *o*- and *p*-toluidines, and 7-methyl-3-phenylindole. The formation of these products can be interpreted as in the case of **1**. Moreover, the formation of benzonitrile and *o*- and *p*-toluidines is in favor of the four-center mechanism proposed earlier by Crow and Solly[2] leading to the formation of *N*-methylaniline that ultimately rearranges to *o*- and *p*-toluidines as observed in a previous work.[6] On the other hand, fragmentation of diphenylmethaniminyl radicals leads to the formation of benzonitrile and phenyl radicals.[2]

However, the *o*-toluidine so formed have been consumed in the formation of 7-methyl-3-phenylindole (**7**) through condensation with styrene which is considered to be formed along with phenylethane as a disproportionation product of 1-phenylethyl radicals, as shown in Scheme 3. Such indole structure was further confirmed by its IR spectrum which shows ν NH at 3400 cm^{-1} and its electronic spectrum which shows absorption maxima at 272 nm (ε 2680) and 285 nm (ε 1920) characteristic for indole moiety.[7]

Repeating the pyrolysis of **6** in absence of air by heating in a sealed tube filled with nitrogen leads to a great decrease in the amount of acetophenone to about one third of that obtained in the case of reflux in air in addition to a corresponding increase in the yield of **7** as expected mechanistically.



Scheme 1.

Dimerization of diphenylmethaniminyl radicals to form the corresponding azine was not observed due to the instability of the N–N bond.[8] Similarly, pyrolysis of **1** by heating in a sealed tube leads to an increase in the amount of **3** as compared with that obtained on reflux in air (cf. Table 1).

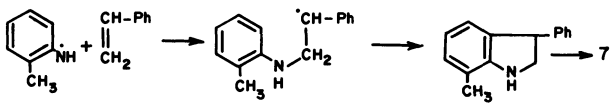

Scheme 3.

Experimental

All mp's are uncorrected. Thin-layer chromatography was carried out on glass plates covered with silica gel (25—40 mesh) and eluted with benzene/cyclohexane (2:1 v/v). The GLC analyses were carried out on a Pye-Unicam gas chromatograph, 'Series 104', equipped with a dual flame ionization detector, Model 24. The columns used were 4 ft(1 ft=0.3048 m)×5 mm packed with 20% SE 30 on Chromosorb W (35—80 mesh) or 10% SE 30 on Celite (60—80 mesh).

Thermolysis of Phenylhydrazones. **6** (mp 105—106 °C)[9] or **1** (mp 137 °C)[9] (20 g) was heated either under reflux in air or in a sealed tube under nitrogen atmosphere at 250 °C for 24 h. The ammonia evolved was detected by means of HCl and further absorbed in a trap containing sulfuric acid forming ammonium sulfate. The pyrolysate were treated similarly where in each case was dissolved in ether and shaken several times with dil HCl to extract the amine products. The ethereal layer containing either the neutral or the amine products was dried (Na_2SO_4) and evaporated to dryness leaving an oily material (15 g) which was separated by fractional distillation under reduced pressure into its constituents and identified by elemental analyses, TLC, GLC, UV, IR spectroscopy and/or mixed mp with authentic samples whenever possible. The results are shown in Table 1.

Induced Cholesteric Mesophases as a Probe for the Stereochemistry of Chiral Biphenyls

Giovanni GOTTARELLI,* Gian Piero SPADA, Kaoru SENO,† Sanji HAGISHITA,† and Kaoru KURIYAMA†

Istituto di Scienze Chimiche, Universita' di Bologna, Via S. Donato 15, 40127 Bologna, Italy

†Shionogi Research Laboratories, Shionogi Co., Ltd., Fukushima-ku, Osaka 553

(Received July 6, 1985)

Synopsis. In the studies of the induced cholesteric mesophases, the twisting powers of cisoid- and transoid-bridged 2,2′-diaminobiphenyl derivatives having *R*-configuration were found to be negative and positive respectively. In the cases where CD spectroscopy is inadequate, the liquid crystal method is sensitive to the helicity of the biphenyl moiety. The conformation of 2,2′-diamino-6,6′-dimethylbiphenyl is discussed.

The stereochemistry of chiral biaryl derivatives is a subject of continuous interest.[1]

In particular, chiroptical techniques have been extensively employed for the configurational and conformational analysis of the system.[2,3]

In several cases the chiroptical techniques are unable to characterize the skew sense (i.e. the cisoid or transoid conformation) of the biaryl moiety. In the exciton approximation,[3,4] this indetermination is connected to the fact that the dipole–dipole interaction potential is not zero for a dihedral angle θ=90°; the value of θ at which the potential goes to zero depends in fact on the locations and directions of the electric dipole transition moments of the chromophores and therefore also on the substituents present. This point was emphasized in the recent work of Hagishita et al.[1] where cisoid- and transoid-bridged biphenyls having the same absolute configuration and therefore opposite helicity of the biphenyl skeleton, were shown to display very similar circular dichroism spectra in several cases.

In a recent work[5] we have shown that the configurations of a number of chiral cisoid-bridged biaryls, having various chemical structures, can be correlated by comparing the handedness of the cholesteric mesophases induced by traces of these derivatives dissolved in nematic liquid crystals of the biphenyl type.

Bridged biaryls having M-helicity induce M-cholesterics, while those of P-helicity induce P-cholesterics. The method, which allows the determination of configurations for cisoid-bridged systems, could be useful for the conformational analysis of non-bridged compounds of known absolute configuration; however, we needed experimental proof that rigid transoid derivatives also follow the helicity rule summarized above.

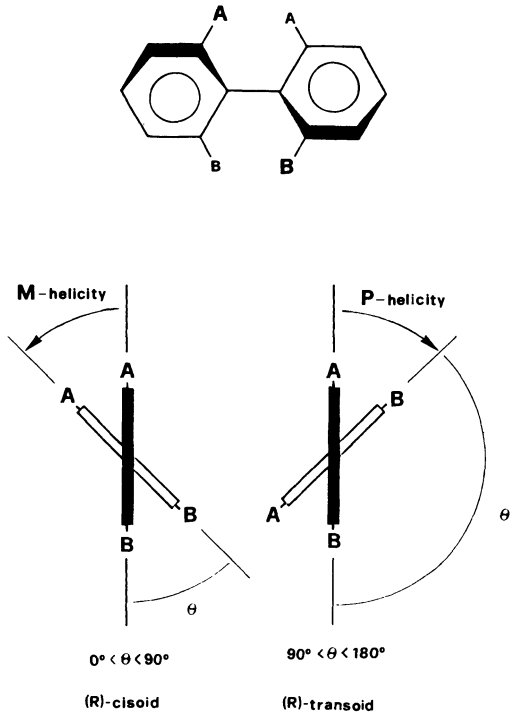

Fig. 1. Cisoid and transoid conformations of a chiral biphenyl derivative having *R*-configuration and the relative helicities of the biphenyl skeleton.

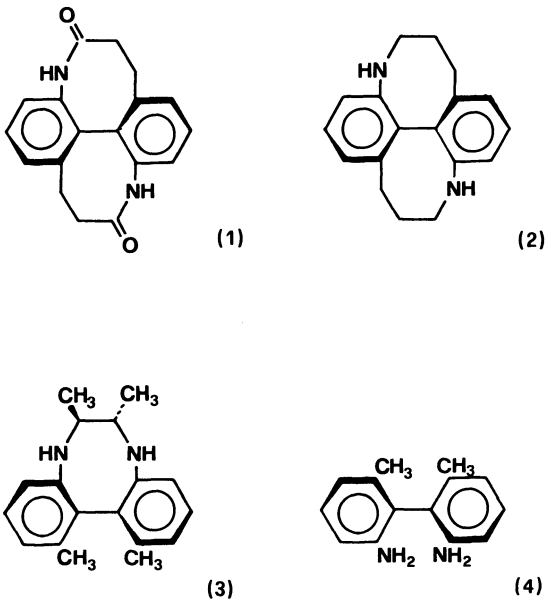

We report here the twisting powers β[6] of four diaminobiphenyls (Table 1), whose structure is known in detail from X-ray diffraction.[1] In particular, derivatives **1** and **2** constitute two examples of the rare trans-skew derivative (dihedral angle of 118° for **2**).[1]

Table 1. Characteristics of Derivatives **1**—**4** and Their Twisting Powers in a Biphenyl-Type Liquid Crystal

Compound	Absolute configur.	Dihedral angle[a]/°	Biphenyl helicity	$\beta/\mu m^{-1}$ in E7[b]	Cholesteric handedness
1	*R*		P	+58	P
2	*R*	118	P	+19.8	P
3	*R*	66	M	−21[c]	M
4	*R*	93	P	+2.0	P

a) From crystallographic data; Ref. 1. b) E7: A mixture of 4-cyano-4′-aryl and 4′-(normal alkyl)biphenyl from BDH Chemicals. c) The enantiomer was measured.

Indeed derivatives **1** and **2** also follow the rule proposed for cisoid compounds and show values of β of the order of magnitude expected:[7] their twisting powers have signs opposite to those of cisoid derivative **3** and other cisoid-bridged biaryls reported in Ref. 5. The liquid crystal method is therefore able to characterize the helicity of the biphenyl skeleton in the cases where CD spectroscopy fails.

Furthermore, derivatives **2** and **3**, which contain similar chemical groups, have quantitative values of β which are identical within the experimental error; this fact is a prerequisite for attempting the conformational analysis of non-bridged derivatives.

Derivative **4** has a small positive value of β indicating a P-helicity of the biphenyl system, which for the *R*-configuration is connected to a transoid conformation. The small value of β could be due either to the fact that the dihedral angle is very near to 90°,[7] or to the presence of cisoid and transoid conformers giving opposite contributions to the observed value with a slight prevalence of the transoid structure. X-Ray diffraction gives a dihedral angle of 93° (transoid), furthermore a comparison between the CD spectra measured in solution and in a KBr disc indicates a dihedral angle larger than 90°.[1]

The liquid crystal method therefore seems useful for the determination of the preferred conformation of chiral biphenyls in solution and could be a valid complement to circular dichroism studies. There are of course limitations due to the nature of substituents, which should not interfere with the alignment of the solute in the liquid crystal[7] or with the close contact between molecules of solvent and solute.[7]

Experimental

Measurements of the pitches were carried out with the "lens method"[8] with a standard Zeiss microscope.

The handedness of the cholesterics was deduced from the sign of the rotatory power[9] and cross-checked with the double spiral method.[10]

The synthesis and the characteristics of derivatives **1**—**4** are described in Ref. 1.

The liquid crystal mixture E7 is a commercial product from BDH Chemicals.

Synthesis and Characterization of Imidazolate-Bridged Binuclear Copper(II) Complexes

Naohide MATSUMOTO, Hiroyuki MURAKAMI, Toshifumi AKUI, Jukichi HONBO, Hisashi OKAWA,† and Akira OHYOSHI*
Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
†Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received October 4, 1985)

Synopsis. An unsymmetrical quadridentate copper(II) complex containing an imidazole moiety ([CuHL](ClO$_4$)) reacts with [1,4,7,10-tetraazacyclododecane]copper(II) perchlorate and [2-[2-(2-pyridyl)ethyliminomethyl]pyridine]-copper(II) perchlorate in the presence of one equivalent of triethylamine to give two discrete imidazolate-bridged binuclear copper(II) complexes, **1** and **2** respectively, where [H$_2$L] denotes the 1:1:1 condensation product of acetylacetone, ethylenediamine, and 4-formylimidazole. The analysis of the cryomagnetic data(ca. 80—300 K) on the basis of the Heisenberg model of a binuclear structure gave the antiferromagnetic interaction parameter($2J$) of -107.7 cm^{-1} for **2**.

Discrete imidazolate-bridged metal complexes are of current interest, since an imidazolate-bridged copper-(II)-zinc(II) center has been discovered in bovine erythrocyte superoxide dismutase (BESOD).[1] An X-ray crystallographic study of BESOD has indicated that the copper(II) and zinc(II) ions exist in distorted square planar and tetrahedral coordination environment respectively.[2] A number of imidazolate-bridged binuclear copper(II) complexes have been synthesized and characterized.[3] However, in most cases the two coordination spheres for the complexes are identical.

In this study, two imidazolate-bridged binuclear copper(II) complexes, **1** and **2**, in which the two coordination spheres of copper(II) ions are not identical, as is shown by the schemetic structures, have been prepared and characterized.

2

Experimental

Physical Measurements. The elemental analyses were performed by Mr. Shinichi Miyazaki at the Technical Service Center of Kumamoto University. The melting points were measured on a Yanagimoto micromelting points apparatus and were uncorrected. The electrical conductivity measurements were carried out on a Denki Kagaku AOC-10 conductometer on ca. 10^{-3} mol dm^{-3} solutions in methanol. The thermogravimetric analyses (TGA) were carried out on a Shimadzu TGC 20-type microthermobalance at the heating rate of 5 °C min^{-1}, using a ca. 10 mg sample for each run. The magnetic susceptibilities were obtained by the Faraday method from the temperature of liquid nitrogen to the ambient temperature, according to the procedure reported previously.[4] The susceptibilities were corrected for the diamagnetism of the component atoms by the use of Pascal's constants.

Syntheses. The copper(II) complex containing an imidazole moiety ([CuHL](ClO$_4$)) was prepared according to the method reported previously,[5] where [H$_2$L] denotes the unsymmetrical quadridentate Schiff-base ligand derived from acetylacetone, ethylenediamine, and 4-formylimidazole with a mole ratio of 1:1:1. [1,4,7,10-Tetraazacyclododecane]copper(II) perchlorate and [2-[2-(2-pyridyl)ethyliminomethyl]pyridine]copper(II) perchlorate hydrate were prepared by the method of the literature,[6,7] where the complexes are abbreviated as Cu[12]aneN$_4$(ClO$_4$)$_2$ and Cu(pip)(ClO$_4$)$_2$·H$_2$O respectively.

[CuLCu[12]aneN$_4$](ClO$_4$)$_2$·2.5H$_2$O 1. To a solution of [CuHL](ClO$_4$) (0.764 g, 2 mmol) in 30 cm^3 of 99% methanol was added a solution of triethylamine (0.202 g, 2 mmol) in 20 cm^3 of methanol. To the solution was added dropwise a solution of Cu[12]aneN$_4$(ClO$_4$)$_2$ (0.868 g, 2 mmol) in 20 cm^3 of methanol. The mixture was warmed at 50 °C for 30 min, after which the solution volume was reduced to one half. The solution was then kept for several days in a refrigerator. During that time, black prisms precipitated. They were collected by suction filtration, washed with methanol, and dried in vacuo. Attempts at recrystallization were unsuccessful. Found: C, 29.75; H, 5.24; N, 14.48%. Calcd for Cu$_2$Cl$_2$O$_9$N$_8$C$_{19}$H$_{34}$·2.5H$_2$O: C, 29.97; H, 5.16; N, 14.71%. Mp 225 °C(decomp), Λ_M 166.0 S mol^{-1} cm^2(MeOH), TGA, mass loss: 5.85 wt%; Calcd for 2.5H$_2$O: 5.91 wt%.

[CuLCu(pip)](ClO$_4$)$_2$·0.5H$_2$O 2. This complex was prepared by a similar method except that Cu(pip)(ClO$_4$)$_2$·H$_2$O instead of Cu[12]aneN$_4$(ClO$_4$)$_2$ was used. Blue-green microcrystalline material. Attempts at recrystallization were unsuccessful. Found: C, 37.60; H, 3.63; N, 12.78%. Calcd for Cu$_2$Cl$_2$O$_9$N$_7$C$_{24}$H$_{27}$·0.5H$_2$O: C, 37.71; H, 3.69; N, 12.84%. Mp 260 °C(decomp), Λ_M 174.1 S mol^{-1} cm^2(MeOH), TGA: mass loss, 1.15 wt%; Calcd for 0.5H$_2$O: 1.18 wt%.

Results and Discussion

The complex containing an imidazole moiety [CuHL]$^+$ reacts with [1,4,7,10-tetraazacyclododecane]-copper(II) and [2-[2-(2-pyridyl)ethyliminomethyl]pyridine]copper(II) in the presence of one equivalent of triethylamine to give the imidazolate-bridged binuclear copper(II) complexes, **1** and **2** respectively. The complexes crystallize as hydrates. The solvent molecules in the crystals were detected by TGA, where weight losses corresponding to those to be expected from the elemental analyses were observed. The molar electrical conductances of Complexes **1** and **2** are 166.0 and 174.1 S mol^{-1} cm^2 in methanol

respectively. These values are in the expected range of the 2:1 electrolyte in methanol (160—220 S mol^{-1} cm^2),[8] indicating that Complexes **1** and **2** have the formulas of [CuLCu[12]aneN$_4$]$^{2+}$(ClO$_4^-$)$_2$ and [CuLCu(pip)]$^{2+}$(ClO$_4^-$)$_2$ respectively.

The χ_A vs. T plots for Complexes **1** and **2** are shown in Fig. 1. The maximum in the χ_A vs. T plot of **1** is not observed in the temperature range studied(ca. 80—300 K), indicating that the magnetic interaction parameter ($|2J|$) is less than 89.5 cm^{-1} when obtained by means of the equation $|2J|=1.61\,kT_{max}$, where T_{max} is the temperature with the maximum magnetic susceptibility. The maximum at ca. 100 K in the plot of **2** is indicative of antiferromagnetic intramolecular exchange interaction. The magnetic susceptibility data of **2** were analyzed by means of a least-squares method using the SALS program,[9] in which the g and J values were refined as variable parameters on the basis of the Bleaney-Bowers Eq. 1 for isotropic exchange in a copper(II) dimer:

$$\chi_A = \frac{Ng^2\beta^2}{kT}\left[\frac{1}{3+\exp(-2J/kT)}\right] + N\alpha \qquad (1)$$

The temperature-independent paramagnetism($N\alpha$) was taken to be 60×10^{-6}, while the other symbols have their usual meanings. The best-fit values are $g=2.104$ and $2J=-107.7$ cm^{-1}, where the generalized R factor, $R=[\sum[\chi_A(\text{obsd})-\chi_A(\text{calcd})]^2/\sum\chi_A(\text{obsd})^2]^{1/2}$, using as a convenient statistical indicator of the quality of the least-squares fits, was calculated to be 0.005. In Fig. 1, theoretical curve with the parameters of g and J obtained is shown as a solid line.

Lippard and his co-workers pointed out that the magnitude of the exchange interaction parameter($2J$) for the imidazolate-bridged copper(II) complexes depends on the angles, ϕ and ϕ', defined in the drawing: i.e., increasing the ϕ and ϕ' angles leads to an increase in $|J|$.[3a] The X-ray analysis of

[CuHL](ClO$_4$) revealed the ϕ angle to be 143.1(1)°.[5] For the μ-Im[Cu(pip)]$_2$(NO$_3$)$_3$·2.5H$_2$O complex, it

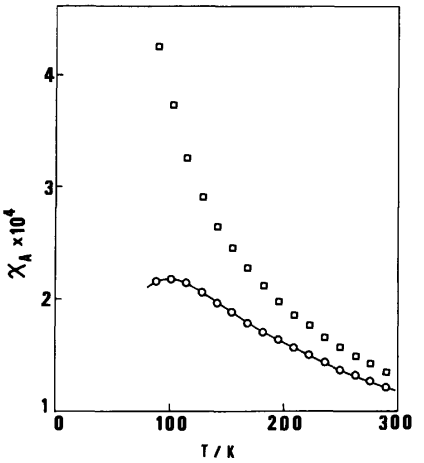

Fig. 1. Plots of χ_A vs. T for the binuclear copper(II) complexes **1** (□) and **2** (○), where the solid line represents the theoretical curve of Eq. 1 with the parameters of $g=2.104$, $2J=-107.7$ cm^{-1} for **2**.

was reported to have the ϕ angle of 120—128° and $2J=-53.8$ cm^{-1}.[3a] The larger $2J$ value of [CuLCu(pip)](ClO$_4$)$_2$·0.5H$_2$O **2** than that of μ-Im[Cu(pip)]$_2$(NO$_3$)$_3$·2.5H$_2$O is reasonable judging from the angles of ϕ and ϕ'.

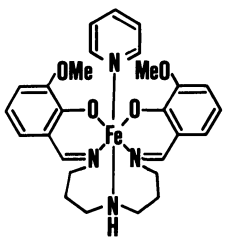
Spin-Equilibrium Behavior in Solution of an Iron(III) Complex [Bis-[3-(3-methoxysalicylideneamine)propyl]amino-*O,N,N',N'',O'*](pyridine)-iron(III) Tetraphenylborate

Akira Ohyoshi,* Jukichi Honbo, Naohide Matsumoto, Shoichi Ohta, and Shingo Sakamoto
Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received November 28, 1985)

Synopsis. The title iron(III) complex with a spin equilibrium between high-spin(S=5/2) and low-spin(S=1/2) has been investigated by means of the temperature dependences of the magnetic susceptibilities (the Evans ^{1}H NMR technique), the electronic spectra, and the cyclic voltammetry. The pure electronic spectra for high-spin and low-spin species were evaluated from the observed electronic spectra and the equilibrium constants obtained from the magnetic data. The electron-transfer entropy for the $Fe^{3+}+e \rightarrow Fe^{2+}$ process(ΔS_{et}) was obtained as 205 $JK^{-1}mol^{-1}$ from the temperature dependence of the cyclic voltammogram.

We have previously reported the syntheses and characterizations of new families of spin-equilibrium mononuclear and binuclear iron(III) complexes, in which the spin-equilibrium behavior in the solid states has been investigated by the temperature dependences of the magnetic susceptibilities and the Mössbauer spectra.[1,2]

In this study, the spin-equilibrium behavior in the solution state of the title complex, whose schematic structure is shown in the drawing, has been investigated by means of the temperature dependences of the magnetic susceptibilities (the Evans ^{1}H NMR technique), the electronic spectra, and the cyclic voltammetry.



Experimental

Synthesis. The title complex [Fe(py)L][BPh_4] was prepared by the general method reported previously,[1] in which 3-methoxy-salicylaldehyde instead of salicylaldehyde was used for this complex. Found: C, 71.52; H, 6.13; N, 6.26%. Calcd for $FeC_{51}H_{52}N_4O_4B$: C, 71.93; H, 6.15; N, 6.58%. Mp 167—169 °C.

Physical Measurements. Magnetic susceptibility measurements in dichloromethane solution were performed by the Evans ^{1}H NMR method,[3] using a JEOL JNM-FX 100 spectrometer, where the Me_4Si was used as the reference compound. The magnetic susceptibility was corrected by the diamagnetism of the component atoms by the use of Pascal's constants. The effective magnetic moment was calculated by means of the equation; $\mu_{eff}=2.828\sqrt{\chi_A T}$. The temperature dependence of the electronic spectra in a dichloromethane solution was recorded with a Hitachi spectrophotometer model 340, according to the procedure of the literature.[4] Variable temperature cyclic voltammetric measurements were obtained with a three-electrode system using a Hokuto Denki HB-103 linear scanner and a HA-201 potentiostat with a Rika Denki model RW-11 XY-recorder. The working electrode was a platinum button, and a platinum wire served as the counter electrode. A commercial saturated calomel electrode(SCE) was used as the reference electrode and was separated from the bulk of the solution by a fritted glass bridge with the same solvent and supporting electrolyte (tetrabutylammonium perchlorate). The cell was cooled by circulating cold methanol. The temperature of the solution was monitored by means of a Yokogawa-Hokushin Denki digital multi-thermometer, type 2572, and was kept constant within ±0.2 °C during the measurement.

Results and Discussion

The [Fe(py)L][BPh_4] complex showed a striking thermochromism both in the solid and in the solution, changing its color from black in the solid and violet in the solution at the ambient temperature to green at the temperature of liquid nitrogen, which is characteristic of a spin equilibrium. The temperature dependence of the electronic spectra of the complex was measured in several organic solvents (dichloromethane, chloroform, acetonitrile, acetone, methanol, and ethanol) in order to examine the solvent effect on the spin-equilibrium behavior. Among the temperature dependences of the electronic spectra measured in various organic solvents, the spectrum measured in dichloromethane showed the most drastic thermochromic behavior with a set of isosbestic points, so that the spin-equilibrium behavior of the complex was thereafter studied in the dichloromethane solution by the use of variable-temperature techniques of magnetic susceptibility, electronic spectrum, and cyclic voltammetry.

The magnetic susceptibilities were measured in a dichloromethane solution by the Evans ^{1}H NMR method.[3] The effective magnetic moments at various temperatures are as follows (μ_B (K)): 5.55 (281), 5.50 (276), 5.45 (271), 5.33 (267), 5.24 (260), 5.07 (254), 4.98 (250), 4.85 (244), 4.60 (239), 4.44 (235). The μ_{eff} decreases from 5.55 μ_B at 281 K to 4.44 μ_B at 235 K, indicating a spin equilibrium between high-spin(S=

5/2) and low-spin(S=1/2). The equilibrium constant, defined as K=[high-spin]/[low-spin], was calculated from the expression: $K=(\mu_{eff}^2-\mu_{LS}^2)/(\mu_{HS}^2-\mu_{eff}^2)$, where μ_{HS} and μ_{LS} are the limitting high-spin and low-spin magnetic moments respectively. The value of μ_{HS} was fixed at 5.92, the spin-only value for the ^{6}A state. The value of μ_{LS} was taken as 2.0. The equilibrium constant, K, can be related to the entropy and enthalpy differences between high-spin and low-spin species by means of Eq. 1:

$$RT\ln K = \Delta H - T\Delta S \quad (1)$$

A plot of log K vs. T^{-1} is shown in Fig. 1. The data gives a straightline plot of log K vs. T^{-1}, with a ΔH value of 19.6 kJ mol^{-1} and ΔS value of 82.8 JK^{-1} mol^{-1}. The ΔH value is similar to the values reported for the spin-equilibrium iron(III) complexes [Fe(X-salmeen)$_2$]$^+$ and [Fe(X-sal)$_2$trien]$^+$,[5,6] where X-salmeen denotes the tridentate ligand derived from salicylaldehyde and *N*-methylethylenediamine and where (X-sal)$_2$trien denotes the hexadentate ligand derived from salicylaldehyde and bis(3-aminopropyl)amine. The ΔS value is somewhat larger than the values reported for the [Fe(X-salmeen)$_2$]$^+$ and [Fe(X-sal)$_2$trien]$^+$ complexes.

The temperature dependence of the electronic spectrum of the [Fe(py)L][BPh$_4$] complex in the dichloromethane solution is shown in Fig. 2. The spectrum changes with the set of isosbestic points at 420, 620, and 820 nm, suggesting a thermal equilibrium between two different electronic isomers, i.e., high-spin and low-spin species. At a single wavelength, the absorbance, A, is given by Eq. 2, where ε_{obsd} is the observed molar extinction coefficient, and where ε_{LS} and ε_{HS} are the molar extinction coefficients of the low-spin and high-spin species respectively:

$$\begin{aligned} A &= \varepsilon_{obsd}([LS]+[HS]) \\ &= \varepsilon_{LS}[LS]+\varepsilon_{HS}[HS] \end{aligned} \quad (2)$$

Equation 2 can be written as Eq. 3, using the equilibrium constant K=[HS]/[LS]:

$$(K+1)\varepsilon_{obsd} = \varepsilon_{LS} + K\varepsilon_{HS} \quad (3)$$

Therefore, a plot of $(K+1)\varepsilon_{obsd}$ vs. K gives the values of ε_{HS} from the slope and ε_{LS} from the intercept, where the values of K were estimated from the magnetic moments and where seven K values below 273 K were used. The electronic spectra of the pure high-spin and low-spin species were determined from this calculation; they are shown in Fig. 2 as dotted lines. The calculated electronic spectrum of the high-spin species exhibits two absorption maxima, at 450 and 560 nm, with the molar extinction coefficients of 3400 and 3400 mol^{-1} dm^3 cm^{-1}, while that of the low-spin species exhibits an absorption maximum at 670 nm, with the molar extinction coefficient of 3300 mol^{-1} dm^3 cm^{-1}.

The electrochemical reduction of the [Fe(py)L][BPh$_4$] complex involves a reversible one-electron transfer attributable to an Fe(III)/Fe(II) redox process. The half-wave potential for the reduction is observed at 0.018 V, and the peak separation, $E_{pa}-E_{pc}$, is 67 mV at 287 K. The electrochemical reduction was investigated in a dichloromethane solution as a function of the temperature between 287 and 257 K. A linear plot of $E_{1/2}$ vs. T was observed; it is shown in Fig. 3. The entropy change(ΔS_{et}) for the electrochemical reduction may be calculated from Eq. 4:[7]

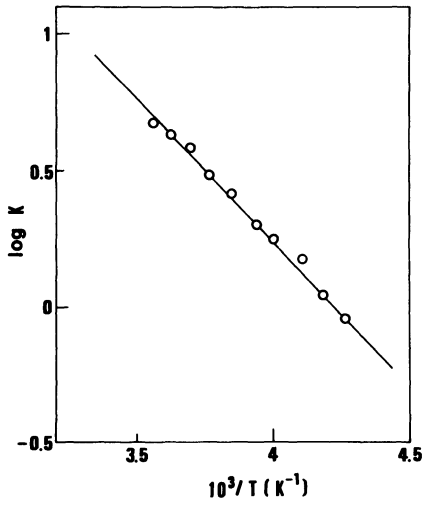


Fig. 1. A plot of log K vs. T^{-1} for [Fe(py)L][BPh$_4$], where K was calculated by the equation of $K=(\mu_{eff}^2-\mu_{LS}^2)/(\mu_{HS}^2-\mu_{eff}^2)$, and $\mu_{HS}=5.92$ and $\mu_{LS}=2.00$ were used.

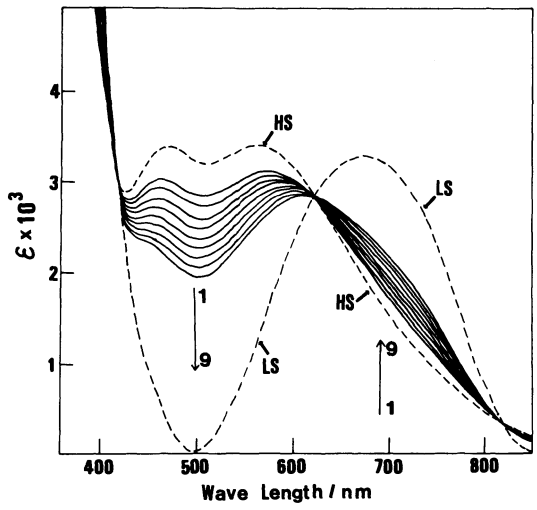

Fig. 2. Temperature dependence of the electronic spectrum for [Fe(py)L][BPh$_4$] in dichloromethane solution; 1(281.7 K), 2(277.7 K), 3(273.2 K), 4(268.2 K), 5(263.2 K), 6(258.2 K), 7(253.2 K), 8(248.2 K), 9 (243.2 K). The pure high-spin and low-spin spectra are shown as dotted lines.

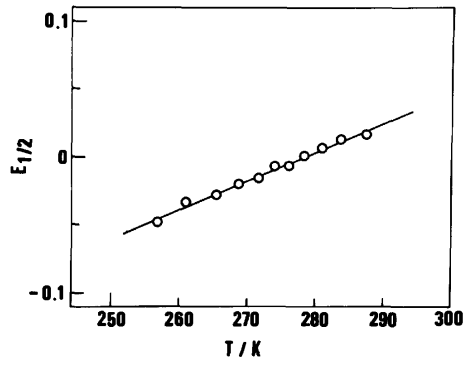

Fig. 3. A plot of $E_{1/2}$ vs. T for [Fe(py)L][BPh_4], where $E_{1/2}$ is relative to Saturated Calomel Electrode(SCE).

$$\Delta S_{et} = nF(\Delta E_{1/2}/\Delta T) \quad (4)$$

where n is the number of electrons transferred and where F is the Faraday constant. From Eq. 4, the value of ΔS_{et} was evaluated to be 205 $JK^{-1}mol^{-1}$. Kadish and his co-workers studied the electron-transfer properties of the spin-equilibrium iron(III) complexes and reported that the ΔS_{et} values varied from 88 to 146 $JK^{-1}mol^{-1}$ for [Fe(X-salmeen)$_2$]$^+$ and from 67 to 75 $JK^{-1}mol^{-1}$ for [Fe(X-sal)$_2$trien]$^+$.[8] Therefore, the ΔS_{et} value for the present complex is considerably larger than those for the [Fe(X-salmeen)$_2$]$^+$ and [Fe(X-sal)$_2$trien]$^+$.

We wish to thank the Institute for Molecular Science (Instrument Center) for use of the JEOL JNM-FX 100 NMR spectrometer and the Hitachi 340 spectrophotometer.

The Microwave Spectrum of Methyl Isoselenocyanate

Takeshi SAKAIZUMI,* Atsushi YASUKAWA, Hirobumi MIYAMOTO, Osamu OHASHI, and Ichiro YAMAGUCHI
Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo 102
(Received December 9, 1985)

Synopsis. The microwave rotational spectra of two isotopic species of methyl isoselenocyanate(CH_3NCSe with ^{80}Se and ^{78}Se) in the ground vibrational state(A-species) have been assigned in the 9 to 40 GHz frequency range and the rotational and centrifugal distortion constants for the ground vibrational state have been determined. Three r_0 structural parameters have been determined from the observed rotational constants of the two species.

Molecules with an isoselenocyanato group form rather intriguring compounds since the isoselenocyanato(NCSe) group is ambidexterous: the isoselenocyanato group is able to bond at the site of either the N or the Se atom, forming either a R-NCSe or a R-SeCN molecule. The isoselenocyanic acid(H-NCSe)[1] exists only as R-NCSe type in the gas phase, while methyl derivatives have been identified as CH_3-SeCN[2] and CH_3-NCSe.[3] The presence of methyl isoselenocyanate(CH_3-NCSe) has been detected by infrared spectroscopy.[3]

In the CH_3-NCX(X=O and S) type, a barrier to the internal rotation of the methyl group in CH_3NCO[4] and CH_3NCS[4] has been found to be 83 and 304 cal mol^{-1} from the splitting of the $K_{-1}=0$, $m=\pm3$ lines. On the other hand, in the CH_3-XCN(X=S and Se) type, the barrier to internal rotation in CH_3SCN[5] and CH_3SeCN[2] has been found to be 1600 and 1240 cal mol^{-1}.

We are interested in the bond angle for R-NCX (R=H, CH_3, C_2H_5 and X=O, S, Se) molecules. The angle of H-N-C for H-NCO,[6] H-NCS,[7] and H-NCSe[1] has been determined to be 123.9°, 131.7°, and 143°. In methyl derivatives, the angle of C-N-C of CH_3-NCO[4] and CH_3-NCS[4] has been determined to be 139.98° and 147.5°. Recently, the C-N-C equilibrium angle for CH_3NCO[8] and CH_3NCS[9] has been found to be 140.2° and 152.5°, using a quasi-symmetric top molecule approach. These data show a large increase of 7 to 12° in the R-N-C angle for R-NCX molecules when the oxygen atoms of R-NCO molecules are replaced by sulfur atoms. A further increase in the C-N-C angle is anticipated upon the replacement of the sulfur atom in CH_3NCS by a selenium atom.

In this paper the microwave spectrum and three structural parameters of methyl isoselenocyanate in the ground vibrational state are reported.

Experimental

Methyl isoselenocyanate was prepared by heating in chloroform a mixture of methyl isocyanide, which was synthesized according to the method of Schuster,[10] and selenium powder for 96 hours.[3] The sample was purified by trap-to-trap vacuum distillation. The melting point and the IR spectrum agreed with the literature.[3]

The rotational spectrum was observed in the frequency region from 9 to 40 GHz with a conventional 100-kHz square-wave Stark modulation spectrometer. The microwave sources employed were a singnal generator(HP-8672A) in the frequency region of 9 to 23 GHz and a YIG-tuned GaAs oscillator(WJ-5610-302FD) in the frequency region of 26.5 to 40 GHz. The wave-guide cell was cooled with dry ice to about 0—10 °C.

Results and Discussion

The observed spectrum was quite dense, presumably due to the presence of several isotopic species (^{82}Se, ^{80}Se, ^{78}Se, and ^{76}Se), their vibrationally-excited states, and the A-E splitting due to the internal rotation of the methyl group.

A typical spectrum showed a-type R-branch transitions with the characteristic K-structure. The assignment of each line for the ^{80}Se species was made on the basis of the Stark effect, the relative population of the ^{80}Se species, and the fact that the line intensity for a ground state is the strongest. The assignment of the spectrum for the ^{78}Se species was made according to the estimated isotopic shifts of lines, keeping in mind that the spectrum lines have the same Stark effect as the corresponding lines of the ^{80}Se species. The observed and calculated line frequencies of ^{80}Se and ^{78}Se species are in good agreement, as shown in Tables 1 and 2. The rotational and centrifugal distortion constants were obtained by the least-squares method; they are listed in Table 3. The transitions listed in Tables 1 and 2 are ascribed to the A-species in the ground vibrational state for ^{80}Se and ^{78}Se species because of their Stark effects and line intensities. Since no Q-branch lines were observed because of their low intensity, the rotational constants A could not be determined accurately.

The observed spectra of CH_3NCO[4] and CH_3NCS[4] could not be fitted by the usual semirigid internal-rotation treatment. A reasonable fit of the $K_{-1}=0$ lines was obtained only if a semiempirical nonrigid correction factor[4] was used. The observed spectrum of CH_3NCSe could be fitted by the rigid-rotor approximation. This may mean that the barrier to internal rotation of the methyl group in CH_3NCSe may be higher than that in CH_3NCS(304 cal mol^{-1}). The E-species lines could not be assigned because the observed spectrum was quite dense.

Three structural parameters, r(C-N), r(N=C), and ∠C-N-C, have been adjusted to make the calculated values fit the four observed rotational constants of B and C. Some assumptions were made in this procedure: the methyl group has C_{3v} symmetry and

∠H-C-H=109.5°, r(C-H)=1.091 Å, and ∠N=C=Se=180°. Table 4 shows the assumed and derived structural parameters. If the estimation error of r(C=Se) from the similar molecules is ±0.010 Å, the errors of r(C-N), r(N=C), and ∠C-N-C are ±0.009 Å,

±0.010 Å, and ±4° respectively. The rotational constants calculated from the derived structural parameters are consistent with the observed ones, as shown in Table 3.

The derived values of the bond lengths, r(C-N) and r(N=C), are in agreement with those of similar molecules within less than 0.01 Å, as shown in Table 5. The angle of C-N-C of 157° is much larger than the ones of CH_3NCO and CH_3NCS. A similar trend is seen for the case of the H-N-C angle in HNCO (124°), HNCS(132°), and HNCSe(143°).

(Received December 10, 1985)

Synopsis. Assignments of the out-of-plane normal vibrations of [$^1H_5$]- and [$^2H_5$]pyridines were reexamined based on the polarization behavior of the Raman bands and also through the normal coordinate calculation.

The normal vibrations of [$^1H_5$]- and [$^2H_5$]pyridines have been studied by many workers. Very recently Wong and Colson reviewed the previous works and reexamined the assignments of the normal vibrations of [$^1H_5$]- and [$^2H_5$]pyridines through the analysis of the high resolution FT-IR spectra.[1] There are, however, some ambiguous arguments in the assignments for the out-of-plane vibrations. They assigned the a_2 vibrations empirically using weak Raman, infrared(combination) and fluorescence bands and their assignments for the b_1 vibrations are reliable only for the infrared bands showing clear rotational band contour in vapor. Therefore, definite experimental evidences are needed for the reasonable assignments for the a_2 and b_1 vibrations.

In this paper the authors intend to give the most reliable assignments for the out-of-plane vibrations of [$^1H_5$]- and [$^2H_5$]pyridines through the analysis of the polarized Raman spectra in single crystals and the normal coordinate calculations.

Experimental

Materials. [$^1H_5$]- and [$^2H_5$]pyridines, obtained from Nakarai Chemical Company and Commissariat a l'Energie Atomique, respectively, were purified by repeated distillation under reduced pressure.

Optical Measurement. The polarized Raman spectrum was observed in a single crystal with a JEOL 400 T Laser Raman Spectrophotometer at −45 °C. Although a block of single crystal of the sample could be obtained by the Bridgman method, a cubic crystal sample could not be cut off because the crystal is very hygroscopic and also melts by pressing with a razor blade even in a Dry Ice box. Thus a single crystal was grown in a capillary glass tube of about 3 mm in diameter and 70 mm in length having a sharp conical end by cooling gradually in a Mini Subzero Tabai MC-81 Refrigerator. The direction of the crystal growth was found to be one of the crystal axis and other two crystal axes were found by rotating the crystal specimen around the crystal growth direction under the polarized light. The crystal growth direction and other two crystal axes thus determined are referred to as u, v, and w axes, respectively. The polarized Raman spectrum was observed in the following two crystal orientations. The u axis was directed parallel to the polarization direction of the excitation laser beam. The v and w axes were directed parallel to the propagation direction of the laser beam in the first and second crystal orientations, respectively. The Raman scattering was observed at right angles with the excitation light beam. Thus the uu, uv, and uw polarized Raman spectra were obtained, where the first letter refers to the direction of the polarization of the excitation light and the latter to that of the scattering light. The sample was excited with the 514.5 nm line from an Ar^+ ion laser.

Results and Discussion

A normal coordinate calculation for pyridine was performed through the standard GF matrix methods with a FACOM M-200 computer at Computer Center of Fukuoka University. The geometric parameters of the molecule were taken from the data determined by Bak et al.[2] The force constants used for the calculation of the out-of-plane vibrations are listed in Table 1. The notation of Q, q, P, p, and t are the same as those used by Whiffen.[3] The calculated frequencies and modes are given in Table 2.

The crystal structure of pyridine was studied by Mootz and Wussow.[4] Pyridine crystalizes in the orthorhombic system of the space group C_{2v}^9 with sixteen molecules in the unit cell. No factor group splitting was observed in the Raman bands of the molecular vibrations and therefore the relationship between the Raman tensors for the free molecule and the crystal was derived based on the simplified oriented gas model. The Raman tensors were calculated in the same way as described previously[5,6] and the results are given in Table 3. This table suggests that (1) the a_2 vibrations can be observed strongly in the aa, bb, and cc spectra while the b_1 and b_2 vibrations strongly in the ab, ac, and bc spectra and (2) if the crystal growth direction is along the crystal a or b axis, the b_1 and b_2 vibrations show different polarization behavior in the uv and uw spectra while if the direction is along the c axis, these vibrations show the same polarization behavior. The polarized Raman spectra of [$^1H_5$]- and [$^2H_5$]pyridines are shown in Figs. 1 and 2, respectively. These figures show that the depolarized Raman bands in liquid show two different types of polarization behavior in single crystals, that is, the relative intensity of the bands belonging to the first type is strong in the uu spectrum and very weak in the uv and uw spectra and

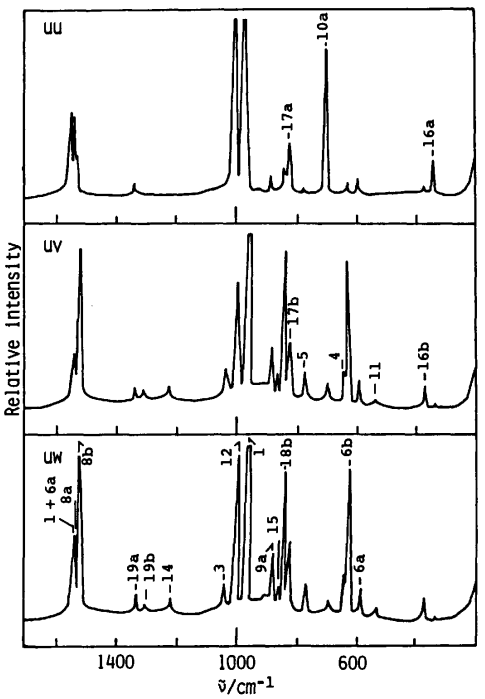

Fig. 2. Polarized Raman spectrum of [$^2H_5$]pyridine single crystal.

the relative intensity of the second type bands is strong in the uv and uw spectra and very weak in the uu spectrum. Comparing the observed relative intensity of the polarized Raman bands with the data given in Table 3, it can be concluded that the first type bands can be assigned to the a_2 vibrations and the second type bands to the b_1 or b_2 vibrations. These figures also show that the second type bands show almost equal polarization behavior in the uv and uw spectra. This observation indicates that the u axis should correspond to the crystal c axis. No infrared bands corresponding to the first type polarized Raman bands could be observed and this

fact supports the first type bands being to be assigned to the a_2 vibrations. The vibrational modes were determined based on the normal coordinate calculation.

[$^1H_5$]Pyridine. Depolarized Raman bands observed at 952, 878, 755, 715, and 408 cm^{-1} in liquid show the second type polarization in crystal. Thus these bands can safely be assigned to the ν_{17b}, ν_5, ν_4, ν_{11}, and ν_{16b} vibrations of b_1 species, respectively, because the non-totally symmetric in-plane vibrations except for the ν_{6b} vibration are expected to be observed in the region higher than 1000 cm^{-1} in this molecule. Although Wong and Colson[1] assigned the frequency of 1007 cm^{-1} to the b_1 vibration, this frequency could not be observed in the polarized Raman spectrum. Depolarized Raman bands at 975, 882, and 377 cm^{-1} in liquid show the first type polarization in crystal and thus these can definitely be assigned to the ν_{17a}, ν_{10a}, and ν_{16a} vibrations of a_2 species, respectively.

[$^2H_5$]Pyridine. Depolarized Raman bands at 763, 627, 528, and 362 cm^{-1} in liquid show the second type polarization in crystal. Thus these bands can be assigned to the ν_5, ν_4, ν_{11}, and ν_{16b} vibrations of b_1 species, respectively. A depolarized and broad Raman band around 820 cm^{-1} in liquid is clearly resolved into two bands at 820 and 813 cm^{-1} in crystal and show the second and first type polarization, respectively. Therefore, the former was assigned to the ν_{17b} vibration. Depolarized Raman bands at 813, 688, and 323 cm^{-1} in liquid show the first type polarization in crystal and thus these can be assigned to the ν_{17a}, ν_{10a}, and ν_{16a} vibrations of a_2 species, respectively. Wong and Colson presented the ν_5 and ν_{10b} modes for the hydrogen wagging vibrations of b_1 species in decreasing order of vibrational frequency, while the normal coordinate calculation used reasonably estimated force constants gives the ν_{17b} and ν_5 modes for these wagging vibrations, respectively.

The polarization behavior of the Raman bands gave clear and definite experimental justification for the assignments of the out-of-plane vibrations. The polarization behavior of the Raman bands also supports the assignments for the in-plane vibrations given by Wong and Colson except for the ν_{18b} vibration of [$^1H_5$]pyridine. Wong and Colson assigned weak infrared bands observed at 705.8 and 1690.9 cm^{-1} to the $\nu_{18b}-\nu_{16a}$ and $\nu_{18b}+\nu_{6a}$ vibrations, respectively, and gave the frequency of 1079 cm^{-1} for the ν_{18b} vibration. A Raman band observed at 1045 cm^{-1} as a shoulder of the strong ν_{12} band shows clearly the second type polarization in single crystal and the frequency is higher than 1000 cm^{-1}. Thus we assigned the frequency of 1045 cm^{-1} to the ν_{18b} vibration of [$^1H_5$]pyridine.

The Microwave Spectrum of (*E*)-(Propinaldehyde Oxime)

Kazuhiko YOSHIDA, Takeshi SAKAIZUMI, Osamu OHASHI,* and Ichiro YAMAGUCHI
Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102
(Received December 11, 1985)

Synopsis. Microwave spectra of propionaldehyde oxime and its deuterated derivatives ($CH_3CH_2CH{=}NOD$) were observed in the frequency region from 10 to 35 GHz. Several a-type R-branch transitions were identified and the following rotational constants(MHz) in the vibrationally ground state were determined to be: A=19400±400, B=2278.16±0.03, and C=2204.09±0.03 for the normal species, and A=19000±400, B=2194.31±0.02, and C=2128.40±0.02 for the deuterated species. The spectrum analyzed in this work has been concluded from the rotational constants to be due to a *ac*,*E*-conformer.

From its rotational spectrum propionic acid (CH_3CH_2COOH) has been shown to exist predominantly in a *sp*-conformation in which the methyl group eclipses the carbonyl bond and the hydroxyl hydrogen is located between the two oxygen atoms.[1] Acrylaldehyde oxime has been reported to exist predominantly in a *s-trans* form for both *E*- and *Z*-forms.[2,3]

Propionaldehyde oxime[4] has been reported by nuclear magnetic resonance spectroscopic study to exist in two stereoisomeric forms, termed *E*- and *Z*-forms with respect to the C=N bond, each form of which has four possible rotational conformations with respect to the C_2–C_3 bond if the OH bond is assumed to be at the trans position to the CN bond just as it has been found in such molecules as acrylaldehyde oxime[2,3] and acetaldehyde oxime,[6,7] as shown in Fig. 1.

Experimental

Propionaldehyde oxime was produced by reacting propionaldehyde with hydroxylamine hydrochloride according to Dunstan and Dymond's method.[5]

Deuterated species of propionaldehyde oxime ($CH_3CH_2CH{=}NOD$) was prepared in the absorption cell itself in the same way as that for acetylaldehyde oxime-d.[6,7]

The microwave spectrometer used was a conventional 100 KHz sinusoidal- and square-wave Stark modulation type with a phase sensitive detector. The spectra were observed at room temperature.

Results and Discussion

The rotational constants calculated from the assumed structural parameters as listed in Table 1 suggests that seven conformers of eight possible rotational conformers were near prolate symmetric top molecules in whose spectra bunches of the absorption lines are expected with the frequency interval of about (B+C).

A survey of the spectrum was made in frequency region of 8.5 to 32 GHz at the Stark fields between 200 and 300 V cm^{-1}. Groups of the absorption lines were found with the frequency interval of about 4500 MHz. The frequencies of the absorption lines which were assigned on the basis of their characteristic Stark effects are listed in Table 2 together with

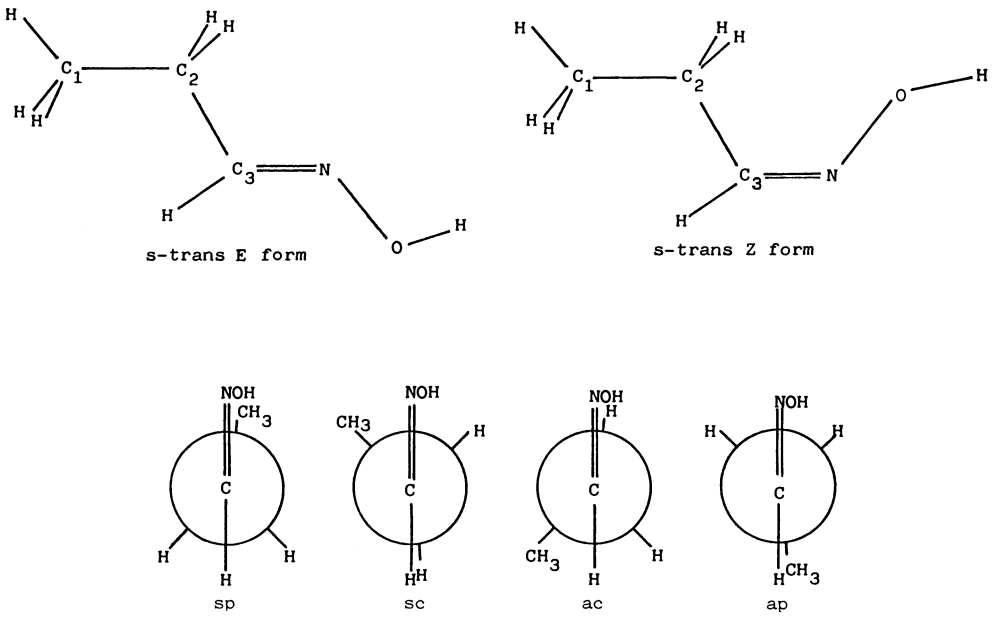

Fig. 1. Four possible rotational conformers and the numbering of carbon atoms of a *ap*-(*E*)-(propionaldehyde oxime) and a *ap*-(*Z*)-(propionaldehyde oxime).

a) $\Delta\nu=\nu_{obsd}-\nu_{calcd}$

the differences between the observed and calculated frequencies which were obtained by the least squares fitting. These lines should be attributable to a ground vibrational state because of their strong intensities, some of which were accompanied by relatively weak satellites in their vicinity and they might be ascribed to a vibrationally excited state.

The values of the rotational and centrifugal distortion constants were obtained from the least squares fit of all the assigned lines in which the Watson type Hamiltonian including the centrifugal distortion terms of Δ_J and Δ_{JK} was used and the results are listed in Table 3.

The spectrum of the deuterated species was analyzed with the same way as the normal species and its results are listed in Tables 2 and 3.

The derived values of the rotational constants and the values of $\Delta I=I_c-I_a-I_b$ have close correspondence with the values calculated for the *ac*,*E*-conformer as shown in Table 4.

The r_s coordinates of the hydroxyl hydrogen atom were calculated from the rotational constants of the normal and deuterated species, using the Kraitchman's equations,[8] as follows: $|a|=2.84\pm0.06$ Å, $|b|=0.3\pm0.5$ Å, and $|c|=0.7\pm0.3$ Å. These values are consistent with the values calculated for the *ac*,*E*-conformer which are $|a|=2.7$ Å, $|b|=0.06$ Å, and $|c|=0.53$ Å. Above discussion leads to the conclusion that the spectrum analyzed in this work is due to an *ac*,(*E*)-(propionaldehyde oxime).

Spectrophotometric Determination of Scandium(III) with *o*-Hydroxyhydroquinonephthalein in Cationic Micellar Media

Itsuo Mori,* Yoshikazu Fujita, Kinuko Fujita, Atsuko Usami, Hiroshi Kawabe, Yozo Koshiyama, and Takeshi Tanaka
Osaka University of Pharmaceutical Sciences, 2-10-65, Kawai, Matsubara, Osaka 580
(Received October 21, 1985)

Synopsis. A spectrophotometric method for determining trace amounts of scandium(III) has been established which makes use of formation of its ternary complex with *o*-hydroxyhydroquinonephthalein (Qnph) and *N*-hexadecylpyridinium chloride (HPC) as a cationic surfactant at pH 5.4. The molar ratio of the ternary complex among Qnph, scandium(III), and HPC is 3:2:6 in a weakly acidic medium, and its maximum absorbance is at 555 nm against a reagent blank. Beer's law holds in the concentration range 0—4.5 μg of scandium(III) in a final volume of 10 cm^3 at 555 nm. The apparent molar absorptivity is 1.0×10^5 $dm^3\,mol^{-1}\,cm^{-1}$ with a Sandell sensitivity of 0.0005 μg cm^{-2}. The coefficient of variation was 0.6% (n=5) for 2.7 μg of scandium(III).

Ternary complex formation reactions among organic reagents, metal ions, and cationic surfactants have proved[1-4] to result in markedly improved spectrophotometric properties–high molar absorptivity, stability over a wide pH range, and large bathochromic shift–in comparison with binary complex formation reactions between organic reagents and metal ions.

For scandium(III), various spectrophotometric determinations using Xylenol Orange (XO),[5] Methylthymol Blue (MTB),[6] Arsenazo III,[7] or Bromopyrogallol Red (BPR)[8] have been reported. However, most of these methods have disadvantages such as lacks in reproducibility, selectivity, or simplicity.

We have already reported that *o*-hydroxyhydroquinonephthalein (Qnph) is a useful reagent for spectrophotometric determination of various metal ions.[9-13] We have also noticed that similar methods utilizing cationic surfactants such as *N*-hexadecylpyridinium chloride (HPC) and *N*-hexadecyltrimethylammonium chloride (HTAC) are in lower pH regions, very sensitive, sharp in selectivity, and excellent in repeatability, in comparison with methods utilizing binary complex formation reactions without cationic surfactants.

In the present research, color reactions between Qnph and scandium(III) in the presence of various surfactants were first studied, and then essential conditions for simple, rapid, and sensitive spectrophotometric determination of scandium(III) were established with Qnph in the presence of cationic surfactant.

Experimental

Absorption spectra and absorbances were measured with recording spectrophotometers, Shimadzu Model UV-200 and UV-240 and a Hitachi Model 150-20, with 1.0 cm silica cells. Hitachi-Horiba Model F-7AD and M-5 pH glass electrode meters were used for pH measurement.

A 1.0×10^{-3} mol dm^{-3} solution of Qnph was prepared according to Ref. 9 and stored in a brown bottle. A stock solution (1.0×10^{-2} mol dm^{-3}) of scandium(III) was prepared by dissolving scandium chloride with a small amount of hydrochloric acid and deionized water. The concentration of the stock solution was determined by chelatometric titration, and a working solution (5.0×10^{-4} mol dm^{-3}) was prepared by dilution of this stock solution. A 1.0×10^{-2} mol dm^{-3} HPC solution was prepared by dissolving HPC in 20% methanol or water. Sodium acetate–acetic acid buffer solution 2.0×10^{-1} mol dm^{-3}; pH 5.4 was used for pH adjustment.

All the other reagents and materials were of analytical grade and used without further purification. Deionized water was used.

To a series of solutions containing 0—4.5 μg of scandium(III) were added 2.0 cm^3 of 1.0×10^{-2} mol dm^{-3} HPC solution, 3.0 cm^3 of sodium acetate–acetic acid buffer solution (pH 5.4), and 1.5 cm^3 of 1.0×10^{-3} mol dm^{-3} Qnph solution, mixed and diluted in several 10 cm^3 calibrated flasks to obtain suitable working solutions. After 10 min, the absorbance of the Qnph–scandium(III) complex solution was measured at 555 nm against a reagent blank (Qnph solution). The concentration of scandium(III) was determined by using a calibration graph.

Results and Discussion

In Fig. 1, curves A, B, C, and D show absorption spectra of Qnph and Qnph–scandium(III) complex solutions in the presence or absence of HPC as a cationic surfactant at pH 5.4. The Qnph–scandium(III)–HPC mixed solution shows a considerable bathochromic shift, and the absorbance is greater and stabler than that in the presence of poly(oxyethylene)sorbitan monolaurate (LT-221) as a nonionic surfactant. A maximum difference in absorbance between Qnph–scandium(III) and Qnph solutions is distinctly observed at 555 nm in the presence of HPC.

The absorbance at 555 nm is maximal and practically independent of pH in the range 4.7—5.8. Subsequent measurements were carried out pH 5.4 for determination of scandium(III).

The absorbance at 555 nm was constant when the volume of 1.0×10^{-3} mol dm^{-3} Qnph solution was varied between 1.0—2.5 cm^3. Hence 1.5 cm^3 of 1.0×10^{-3} mol dm^{-3} Qnph solution was chosen for determination of scandium(III).

HPC, HTAC, and zephiramine (Zp) as cationic surfactants were tested, and HPC showed a remarkably increasing effect on the stabilization and sensitivity. The effect of changing the concentration of HPC was studied. A maximum and constant

Application of Xanthene Derivatives for Analytical Chemistry, Part LIV. Part LIII, I. Mori, Y. Fujita, K. Fujita, Y. Koshiyama, H. Kawabe, T. Tanaka, and R. Munakata, *Bull. Chem. Soc. Jpn.*, **59**, 958 (1986).

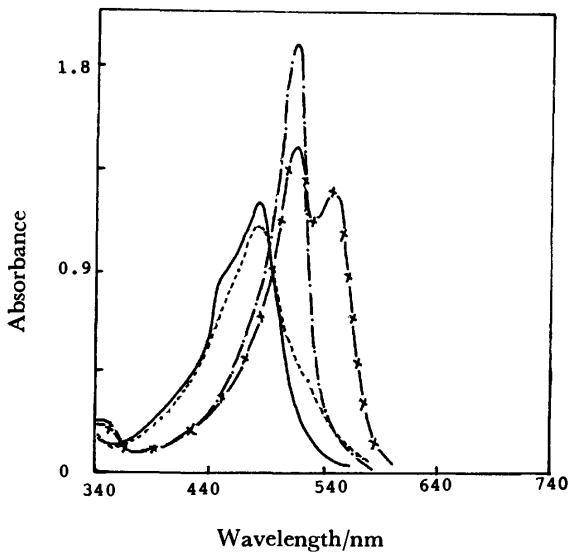

Fig. 1. Absorption spectra of scandium(III)-Qnph solution and Qnph solution in the presence and absence of HPC at pH 5.4.
Scandium(III): 1.0×10^{-5} mol dm^{-3}; Qnph: 4.0×10^{-5} mol dm^{-3}; HPC: 4.0×10^{-3} mol dm^{-3}; Reference: water; ——: Qnph solution in the presence of LT-221; ----: Qnph-scandium(III) solution in the presence of LT-221; —·—: Qnph solution in the presence of HPC; —×—: Qnph-scandium(III) solution in the presence of HPC.

absorbance of Qnph-scandium(III) solution against Qnph solution was observed upon addition of 1.0—4.0 cm^3 of 1.0×10^{-2} mol dm^{-3} HPC solution to the final volume of 10 cm^3. Thus, all further measurements were made with 2.0×10^{-3} mol dm^{-3} HPC as the final concentration.

A good linear relationship was observed over the range 0—4.5 μg of scandium(III) in the final volume of 10 cm^3 at 555 nm against a reagent blank. The apparent molar absorptivity is 1.0×10^5 dm^3 mol^{-1} cm^{-1}, and the Sandell sensitivity is 0.0005 μg cm^{-2}. The coefficient of variation (C.V.) for 5 replicate determinations is 0.6% for 2.7 μg of scandium(III), whereas C.V. in the presence of LT-221 is 4.5%.

The molar ratio of scandium(III) to Qnph was established by the molar-ratio and continuous-variation methods in the presence of high-concentration HPC. The results obtained indicate that the molar ratio of scandium(III) to Qnph is 2:3. On the other hand, the molar ratio of Qnph to scandium(III) in the coexistence of LT-221 is 3:2 as determined by both the molar-ratio and continuous-variation methods. Accordingly, the molar ratio of HPC to Qnph was subjected to determination by the molar-ratio method and found to be 2:1. Though further investigation is necessary, it is deduced from these results that the ternary complex formed in this reaction system may be expressed as $(Sc)_2(Qnph)_3(HPC)_6$.

Of the metal ions tested, iron(III), aluminium(III), thorium(IV), and copper(II), when each present in a small amount result in positive errors because of formation of colored complexes with Qnph in a weakly acidic medium. On the other hand, presence of iron(II), cobalt(II), or cadmium(II) causes no interference even when they are 2—50 times scandium(III) in amount, and large amounts of calcium(II) or magnesium(II) do not interfere. Though presence of citrate, oxalate, or phosphate ion results in negative errors, presence of tartrate or cyanide ion causes no interference when they are 5—20 times scandium(III). The results are summarized in Table 1.

Table 1. Effect of Foreign Ions

Foreign ions	Added as	Added		Absorbance at 555 nm	Found
		μg	molar ratio		μg
—	—	—	—	0.414	2.7

Scandium(III) taken: 2.7 μg/10 cm^3: Qnph: 1.5×10^{-4} mol dm^3; HPC: 2.0×10^{-3} mol dm^3; pH: 5.4; Reference: Reagent blank.

Scandium(III) is entirely masked by addition of large amounts of sodium fluoride solution as a masking agent. On the other hand, iron(III) or aluminium(III) is little affected by addition of small amounts (for example, 3.0×10^{-3} mol dm^{-3}) of sodium fluoride solution as a masking agent. Therefore, aluminium(III) or iron(III) can be determined by measuring at 555 nm absorbances, respectively, of Qnph-aluminium(III)-scandium(III)-sodium fluoride and Qnph-aluminium(III)-scandium(III) solutions, or Qnph-iron(III)-scandium(III)-sodium fluoride and Qnph-iron(III)-scandium(III) solutions, as shown in Fig. 2.

In conclusion, a simple, rapid, and sensitive spectrophotometric determination of scandium(III) by using Qnph-scandium(III)-HPC ternary complex has been established. The calibration curve is linear

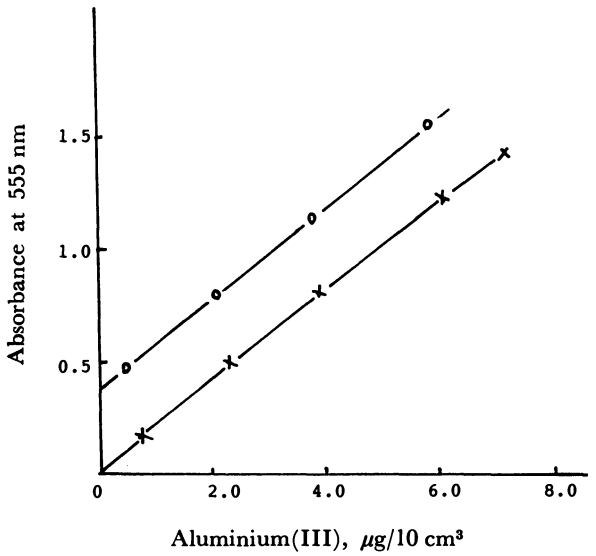

Fig. 2. Calibration curve for aluminium(III) in the presence of scandium(III) and fluoride ion.
Scandium(III): 5.0×10^{-6} mol dm^{-3}; HPC: 4.0×10^{-3} mol dm^{-3}; F^-: 3.0×10^{-3} mol dm^{-3}; Qnph: 1.5×10^{-3} mol dm^{-3}; pH: 5.4; Reference: Reagent blank; —×—: Aluminium(III)–F^-–scandium(III); —○—: Aluminium(III)-scandium(III).

in the concentration range 0—4.5 μg/10 cm³ for scandium(III). The apparent molar absorptivity is 1.0×10^5 dm³ mol^{-1} cm^{-1} for scandium(III) with a Sandell sensitivity of 0.0005 μg cm^{-2} at 555 nm. The sensitivity of the proposed method is about 4—5 times as high as those of the Arsenazo III, XO, MTB, and BPR methods.[5-8]

Moreover, the proposed method using the ternary complex may be used for separative assay of aluminium(III)-scandium(III) mixture or iron(III)-scandium(III) mixture solution by use of sodium fluoride as a masking agent.

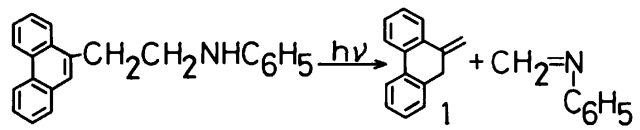
Site-Selective Photochemical Ene Reaction of 2-Methylene-1,2-dihydronaphthalene

Akira SUGIMOTO,* Satoshi SAKAMOTO, Kanji SUYAMA, and Shigeo YONEDA
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591
(Received October 4, 1985)

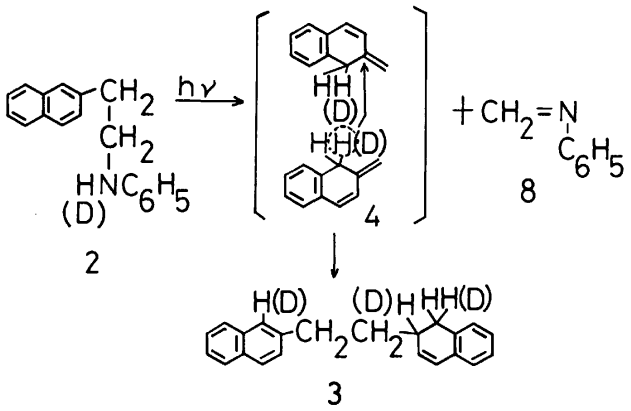
Synopsis. The title compound, formed by the photolysis of 2-(2-anilinoethyl)naphthalene, reacted with olefins having a conjugated double bond to give an ene reaction product under irradiation conditions.

In the course of our studies on the intramolecular photochemical reactions of aromatic compounds with the anilino group, we came across the photolytical formation of *exo*-methylene compounds such as 9-methylene-9,10-dihydrophenanthrene (**1**).[1] A



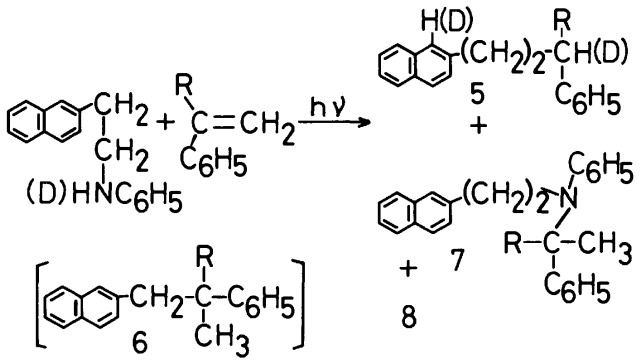
similar result was obserbed in the case of 1-(2-anilinoethyl)naphthalene.[2] Upon irradiation, 2-(2-anilinoethyl)naphthalene (**2**) afforded 2-[2-(2-naphthyl)ethyl]-1,2-dihydronaphthalene (**3**) seemed to be formed by the ene reaction of 2-methylene-1,2-dihydronaphthalene (**4**) (Scheme 1.).[2,3] We now give evidence for the transient existence of **4** and its ene reaction with various olefins.

Upon irradiation of a solution of **2** (1.6×10^{-2} mol dm^{-3}) in degassed benzene with a high-pressure mercury lamp, **3** was obtained as the main product.[4a] The identification of the structure of **3** was based on spectral data and the conversion of **3** to 1,2-di-2-naphthylethane.[5] The mass spectrum of **3**, isolated from the irradiated mixture in D_2O-saturated benzene, showed an M^+ ion peak at m/z=286.[4b] This indicated an incorporation of two deuterium atoms in **3** (vide infra).



Scheme 1.

On the other hand, the irradiation of **2** in the presence of a large excess of styrene (30 times) gave 2-(3-phenylpropyl)naphthalene (**5**), but not **6** (Scheme 2, R=H). When the same irradiation was carried out in D_2O-saturated benzene, monodeuterated **5** (confirmed by mass spectrum) was obtained. The formations of **3** and **5** may be reasonably interpreted in terms of the ene reaction of **4**, as illustrated in Schemes 1 and 2. The deuteration examination demonstrated that an ene reaction occurred between **4** and an enophile molecule (**4** or styrene). In the formation of **3**, almost all of **4** formed was consumed and no other photoreactions occurred because the yield of **3** was comparable to that of imine (**8**).



Scheme 2.

This ene reaction process was further confirmed by the irradiation of **2** in the presence of various olefins as an enophile. In these irradiations, the relative ratio of **2** and enophile had a great influence on the distribution of the photoproducts. For example, in the presence of equimolar of styrene, **2** exclusively afforded **3**, while in the presence of a large amount of styrene (10 times of **2** or more) it led to the formation of **5** together with **7**, the addition product of **2** to styrene (Scheme 2).[6] Similar results were observed in the presence of 2-phenylpropene. Therefore, irradiation of **2** was carried out in the presence of a large amount of olefins (30 times moles). The results are summarized in Table 1. Among the olefins shown, styrene, 2-phenylpropene, and 1,3-pentadiene afforded the ene reaction products together with **4**. Other olefins, however, gave no ene reaction product except for **3**. All isolated ene reaction products had such structures that a 2-naphthylmethyl group was site-selective bonded to the terminal carbon of the starting olefins. Namely, only terminal carbons were reactive. Terminal carbons of olefins such as 1,7-octadiene, hexene, and isobutyl vinyl ether, however, were not reactive. From these observations, it was deduced that the terminal carbon of a conjugated diene, including styrene and 2-phenylpropene, undergo an ene reaction with **4**. Upon irradiation without

(a) (b)

Fig. 1.

such olefins, **4**, which has terminal conjugated double bonds, reacted as an enophile.

The interactions of the HOMO of π-bond of **4** with the LUMO of the C-H bond of the 1-position of **4**, and the LUMO of the π-bond of enophile led to the formation of ene reaction products[7] (Fig. 1a). As the carbon atoms having the largest coefficients of the LUMO or HOMO interact with each other, an enophile reacted with terminal methylene carbon of **4** at the terminal carbon.[8] On the other hand, the secondary orbital interaction between the LUMO of an enophile (Fig. 1b) may facilitate the reaction of **4** with olefins having a conjugated double bond.

According to Murata et al.,[9] **4** was reported to be isolated and gradually changed to 2-methylnaphthalene. In the present investigation, neither **4** nor 2-methylnaphthalene was detected in the irradiated mixture of **2**, even under high-diluted conditions (3×10^{-4} mol dm^{-3}). These results suggested that the dimerization reaction of **4** occurred photochemically and a significant contribution of the LUMO of **4** to the ene reaction.[10]

Experimental

All melting points were uncorrected. The mass spectra were obtained on a Shimadzu-LKB 9000 Gas chromatograph-Mass spectrometer. Other spectrometers used here were described previously.[11]

All preparative irradiation was performed in a way similar to that described previously.[11]

2-(2-Anilinoethyl)naphthalene (2). 2-Naphthaleneacetic acid was converted to the corresponding anilide by a standard method via acid chloride, yield 81%: mp 155—156 °C; IR (KBr) 3280 (NH), 1660 cm^{-1} (CO). Found: C, 83.00; H, 5.78; N, 5.30%. Calcd for $C_{18}H_{15}NO$: C, 82.73; H, 5.79; N, 5.36%. This anilide was treated with $LiAlH_4$ in THF-ether (1:1, v/v) in the usual manner to afford **2** (yield 60%): mp 54—56 °C; IR (KBr) 3380 cm^{-1} (NH); λ_{max}(hexane) 276 nm (log ε 3.83); ^{1}H NMR ($CDCl_3$) δ=2.7—3.8 (5H, CH_2CH_2NH) and 6.3—7.8 (12H, m, aromatic); m/z=247 (M^+). Found: C, 87.40; H, 6.68; N, 5.60%. Calcd for $C_{18}H_{17}N$: C, 87.41; H, 6.93; N, 5.66%.

Photolysis of 2. A solution of **2** (79 mg, 0.32 mmol) in benzene (20 cm^3) was irradiated. The residue after solvent evaporation was chromatographed (Silica gel with benzene) to yield **3** (17 mg, 37%) and was found to be contaminated by a trace of hydrocarbon which was isolated by repeated chromatography with benzene-hexane (1:3. v/v). A solvent evaporation of the second fraction of the latter chromatography gave pure **3** (13 mg): mp 81—85 °C; λ_{max}(hexane) 266 nm (log ε 4.14); ^{1}H NMR ($CDCl_3$) δ=1.6—2.1 (2H, m, CH_2), 2.3—3.0 (5H, m, CH and CH_2), 5.86 (1H, dd, J=10 and 3 Hz, CH=), 6.36 (1H, d, J=10 Hz, CH=), and 6.9—7.8 (11H, m, aromatic); m/z=284 (M^+). Found: C, 93.01; H, 7.26%. Calcd for $C_{22}H_{20}$: C, 92.91; H, 7.09%. This compound changed to an unidentified hydrocarbon upon irradiation of a solution for 7.5 h (25 mg from 64 mg of **3**, and 36 mg of **3** was recovered); mp 115—117 °C. Found: C, 92.63; H, 7.10%.

Photoreaction Products in the Presence of Additives (30 times mole to 2). Styrene: The first eluent of the chromatography on silica gel with benzene-hexane (1:3, v/v) yielded **5** (31%); viscous oil; ^{1}H NMR ($CDCl_3$) δ=1.8—3.0 (6H, m, $CH_2CH_2CH_2$) and 6.8—7.9 (12H, m, aromatic); m/z=246 (M^+). Found: C, 92.51; H, 7.45%. Calcd for $C_{19}H_{18}$: C, 92.64; H, 7.36%. The second eluent yielded *N*-[2-(2-naphthyl)ethyl]-*N*-(1-phenylethyl)aniline **7** (12%); viscous oil; ^{1}H NMR ($CDCl_3$) δ=1.4—1.8 (3H, m, CH_3), 2.7—4.0 (5H, m, CH and CH_2), and 6.5—7.9 (17H, m, aromatic); m/z=351 (M^+). Found: 88.63; H, 7.53; N, 3.89%. Calcd for $C_{26}H_{25}N$: C, 88.85; H, 7.17; N, 3.98%. The third eluent gave the starting amine **2** (15%).

2-Phenylpropene: The first eluent of the chromatography with benzene-hexane (1:3, v/v) yielded 2-(3-phenylbutyl)naphthalene (21%); viscous oil; ^{1}H NMR ($CDCl_3$) δ=1.28 (3H, d, CH_3), 1.8—2.9 (5H, m, CH_2CH_2CH), and 7.0—8.0 (12H, m, aromatic); m/z=260 (M^+). Found: C, 92.24; H, 7.90%. Calcd for $C_{22}H_{20}$: C, 92.26; H, 7.74%. The

second eluent yielded *N*-[2-(2-naphthyl)ethyl]-*N*-(1-methyl-1-phenylethyl)aniline (14%); viscous oil; ^{1}H NMR ($CDCl_3$) δ=1.30 (6H, s, CH_3), 2.4—3.4 (4H, m, CH_2), and 7.0—8.0 (17H, m, aromatic); *m/z*=365 (M^+). Found: C, 88.93, H, 7.58; N, 3.80%. Calcd for $C_{27}H_{27}N$: C, 88.72; H, 7.45; N, 3.83%. The third eluent gave **2** (30%).

1,3-Pentadiene: The first eluent of the chromatography with benzene–hexane (1:3, v/v) afforded a product mixture of *cis*-and *trans*-2-(4-hexenyl)naphthalene [suggested by ^{1}H NMR spectrum and GC–MS signals at *m/z*=210 (M^+)]. This mixture was hydrogenated over Pd/C (5%, 40 mg) in benzene (15 cm^3) to give 2-hexylnaphthalene (27 mg, 20% from **2**, 158 mg) which was purified by TLC; viscous oil; ^{1}H NMR ($CDCl_3$) δ=0.7—2.1 (11H, m, $CH_3(CH_2)_4$), 2.75 (2H, t, CH_2Ar), and 7.0—7.9 (7H, m, aromatic); *m/z*=212 (M^+). Found: C, 90.41; H, 9.78%. Calcd for $C_{16}H_{20}$: C, 90.51; H, 9.49%. The ^{1}H NMR spectral pattern of this compound at the region of δ=0.7—3.0 was almost identical to that of hexylbenzene.[12] The second eluent gave **2** (41%).

1,2-Di-2-naphthylethane: A solution of **3** (35 mg, 124 mmol) and DDQ (104 mg, 373 mmol) in benzene (100 cm^3) was refluxed for 6.5 h. After evaporating the solvent, the residue was chromatographed on alumina with benzene, and then purified by TLC to give 1,2-di-2-naphthylethane (79%); mp 183.5—185 °C (lit,[5] 185—186 °C).

The present work was partially supported by a Grant-in-Aid for Scientific Reserch No. 59550600 from the Ministry of Education, Science and Culture.

(Received December 4, 1985)

Synopsis. Reactions of 2-methoxy-3,3-dimethyl-2-phenyloxirane or α-bromoisobutyrophenone and carbon dioxide in the presence of aliphatic α,ω-diamines were investigated. 1,4-Butanediamine, 1,6-hexanediamine, 1,8-octanediamine, and 1,4-bis(aminomethyl)benzene afforded corresponding 3-(ω-aminoalkyl)-4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinones and 3,3′-polymethylenebis[4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinones] derivatives, while ethylenediamine gave only mono(2-oxazolidinone) derivative.

Since carbon dioxide is the most common, important and nontoxic C_1 resource, several attempts to utilize it have been reported.[1] In such attempts, reactions are carried out under high pressure, at high temperature, in the presence of metal catalysts or caustic alkali, and/or combinations of those methods and so far.[1] We noticed that carbon dioxide forms ammonium carbamates by the reactions with aliphatic amines, and some of the carbamate salts are fairly stable.[2,3] We, and Yoshida and Inoue, found that carbon dioxide reacts with oxiranes (or their synthons) in the presence of aliphatic amines to give 2-oxazolidinones,[2] carbamate derivatives,[4,5] and tetrahydro-2*H*-1,3-oxazin-2-ones.[5] Furthermore, we reported that thermolysis of the oxazolidone derivatives yielded isocyanate derivatives corresponding to the used amines.[6] These results prompted us to study further extention of reactions of carbon dioxide with oxiranes (or thier synthons) in the presence of α,ω-diamines such as ethylenediamine or 1,6-hexanediamine expecting to obtain bis(2-oxazolidinone) derivatives. Because thermolysis of this type of bis(2-oxazolidinone) would give bis(isocyanate)s of which importance is well recognized in polymer chemistry.

The reactions were carried out as follows. After carbon dioxide was saturated in a methanol solution of a diamine, 2-methoxy-3,3-dimethyl-2-phenyloxirane (**1**) (or α-bromoisobutyrophenone (**2**)) was added to this solution, and then the solution was heated. IR spectrum of the product (**3a**) derived from ethylenediamine showed free amino group's frequencies at 3390 and 3210 cm^{-1}, and a carbonyl absorption at 1750 cm^{-1} corresponding to that of 2-oxazolidinone.[2] The molecular formula and weight ($C_{13}H_{18}O_3N_2$, and *m/z*: M^+, 250) of **3a** indicate that only one amino group of ethylenediamine was incorporated into the 2-oxazolidinone skeleton. Thus, the structure of **3a** is presented as 3-(2-aminoethyl)-4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone. On the other hand, 1,4-butanediamine, 1,6-hexanediamine, 1,8-octanediamine, and 1,4-bis(aminomethyl)-benzene gave two different kind of oxazolidone derivatives, respectivily. The first ones are mono(2-oxazolidinone) derivatives which possess a free amino group at the end of the methylene chain as shown in their IR spectra (see the Table). The second products did not show any free amino group frequencies, but showed very strong carbonyl absorption around 1750 cm^{-1}. Therefore, the latter products are bis(2-oxazolidinone) derivatives as shown in the Scheme such as **4**. The elemental analyses of them also support that those structures are correct. Fairly large amount (25—50%) of 1,1-dimethoxy-2-methyl-1-phenyl-2-propanol (**5**) was obtained together with **3** and **4**.

Table 1. Yields and IR Data of Reaction Products

R	product	Yield/%[a]		IR/cm^{-1}		
		1:1[b]	1:2[b]	C=O	NH

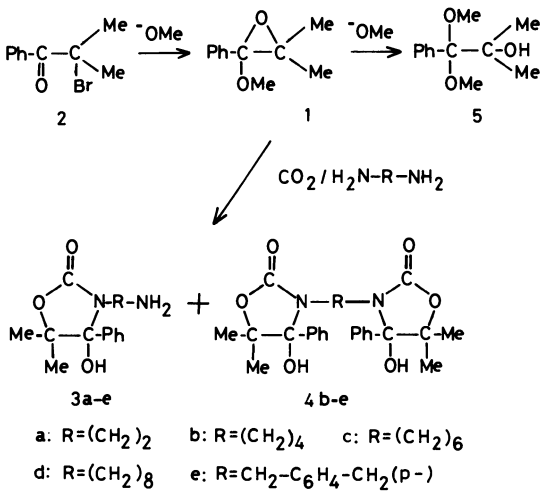
a) Yields are based on the oxirane (**1**), and yields in parenthesis are based on the bromo ketone (**2**). b) Mol ratio of **1** (or **2**): diamine.



Scheme 1.

The results are listed in the Table. Further treatment of 3-(8-aminooctyl)-4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone (**3d**) with the oxirane in the presence of carbon dioxide gave the corresponding bis(2-oxazolidinone) derivative (**4d**, 53%). However, **3a** did not give any bis(2-oxazolidinone) derivative under the same conditions. Although the reason was not clear, formation of oxazolidinones was not observed when 1,3-bis(aminomethyl)benzene was adopted as the diamine.

One of the reason for the low yield of the oxazolidinones formation is presumed to be steric hindrance of big carbamates derived from the diamines. Also, intra- or intermolecular hydrogen bond formation between the remained amino group and the formed carbamate carbonyl seems to make those group's reactivity toward the oxirane inactive. Formation of fairly large amount of **5** indicate that the attack of methoxide anion and carbamate anion take place in the same probability. Contrarily to this, carbamate anions smoothly react with the oxirane to give the oxazolidinones in good yields in the case of monoamines.[2] It seems likely that the reason why the second oxazolidinone ring does not form **3a** is as follows; the formed oxazolidinone ring near the remained amino group causes steric hindrance, and intramolecular hydrogen bond formation between the amino group and the carbonyl group in the oxazolidinone makes the amino groups inactive. The more data than we have now are needed in order to come the conclusion about the low yield of bis(2-oxazolidinone).

The yields are rather poor to fair, but the bis(2-oxazolidinone) formation suggests possibility of the bis(isocyanate)s formation from carbon dioxide and α,ω-diamines.

Experimental

All melting points were uncorrected. IR spectra were recorded on a Hitachi 285 spectrophotometer by KBr disk method. Mass spectra were measured on a JEOL JMS-300 mass spectrometer by EI, CI, and FD methods. The oxirane and the bromo ketone were prepared by the methods as reported previously.[2]

3-(2-Aminoethyl)-4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone (3a): Carbon dioxide was bubbled through the solution of ethylenediamine (4.2 g, 0.07 mol) in methanol (100 cm^3) until the colorless precipitates produced in the solution, and then the oxirane (**1**, 6.3 g, 0.035 mol) (or bromo ketone (**2**)) was added dropwise to the solution. The mixture was gently refluxed for 18 h with bubbling of carbon dioxide. The methanol was removed in vacuo, and the residue was dissolved in chloroform, washed with water, and dried ($MgSO_4$). After removal of the chloroform, the residue was treated with petroleum ether to afford **3a** as a precipitate. **5** was obtained from the petrolem ether layer. **3a**: Yield, 3.6 g (41%); colorless prisms (ethanol), mp 191—192 °C. Found: C, 62.41; H, 7.33; N, 11.21%; MS (*m/z*) 250 (M^+). Calcd for $C_{13}H_{18}O_3N_2$: C, 62.38; H, 7.25; N, 11.19%.

3-(4-Aminobutyl)-4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone (3b) and 3,3′-Tetramethylenebis[4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone] (4b): Under the same conditions as described above, **1** (6.3 g, 0.035 mol) was allowed to react with carbon dioxide and 1,4-butanediamine (6.3 g, 0.07 mol). After removal of the solvent, the residue was dissolved in chloroform, and washed with water. When the choloform was removed in vacuo and the residue was treated with petroleum ether, a white precipitates was obtained. The precipitate was treated with benzene to give colorless solid of **4b** as an insoluble part. The benzene filtrate was evaporated, and then the residue was recrystallized to afford **3b**. **5** was obtained from the petroleum ether layer. **3b**: Yield, 2.4 g (25%); colorless powder (benzene-hexane), mp 106—107 °C. Found: C, 64.11; H, 7.98; N, 9.77%; MS (*m/z*) 278 (M^+). Calcd for $C_{15}H_{22}O_3N_2$: C, 64.72; H. 7.97; N, 10.07%. **4b**: Yield, 0.7 g (9%); colorless powder (acetone), mp 294—295 °C. Found: C, 66.90; H, 7.12; N, 5.82%; MS (*m/z*) 469 (M^++1). Calcd for $C_{26}H_{32}O_6N_2$: C, 66.65; H, 6.88; N, 5.98%.

3-(6-Aminohexyl)-4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone (3c) and 3,3′-Hexamethylenebis[4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone] (4c): These compounds were synthesized in the manner similar to that of **3b** and **4b**. **3c**: Yield, 4.3 g (40%); colorless powder (ethanol-water), mp 80—81 °C. Found: C, 66.85; H, 8.29; N, 8.85%; MS (*m/z*) 306 (M^+). Calcd for $C_{17}H_{26}O_3N_2$: C, 66.64; H, 8.55; N, 9.14%. **4c**: Yield, 0.5 g (5%); colorless powder (chloroform), mp 239—240 °C. Found: C, 67.10; H, 7.41; N, 5.59%; MS (FD, *m/z*) 496 (M^+), 519 (M^++23). Calcd for $C_{28}H_{36}O_6N_2$: C, 67.52; H, 7.31; N, 5.64%.

3-(8-Aminooctyl)-4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone (3d) and 3,3′-Octamethylenebis[4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone] (4d): Under the same conditions described above, **1** (6.3 g, 0.035 mol) was allowed to react with carbon dioxide and 1,8-octanediamine (10.1 g, 0.07 mol). The methanol was removed in vacuo and the residue was dissolved in chloroform, and then the chloroform layer was washed with hydrochloric acid. **3d** was obtained as a precipitate from the aqueuos layer by addition of aqueous sodium hydroxide. The chloroform layer was washed with water, and concentrated under reduced pressure. The residue was treated with ether to afford **4d** as a precipitate. **5** was obtained from the ether layer. **3d**: Yield, 2.5 g (21%); colorless needless (ethanol-water), mp 79—80 °C. Found: C, 67.66; H, 8.77; N, 8.13%; MS (*m/z*) 334 (M^+). Calcd for $C_{19}H_{30}O_3N_2$: C, 68.23; H, 9.04%; N, 8.38%. **4d**: Yield, 0.7 g (6%); colorless prisms (ethanol), mp 197—198 °C. Found: C, 68.45; H, 7.88; N, 5.19%; MS (*m/z*) 525 (M^++1). Calcd for $C_{30}H_{40}O_6N_2$: C,

68.68; H, 7.69; N, 5.34%.

3-[*p*-(Aminomethyl)benzyl]-4-hydroxy-5,5-dimethyl-4-phenyl-2-oxazolidinone (3e): This compound was obtained in the manner similiar to that of **3d**. **3e**: Yield, 2.3 g (18%); colorless powder (ethanol), mp 68—69 °C. Found: C, 69.58; H, 6.95; N, 8.52%; MS (*m/z*) 327 (M^++1). Calcd for $C_{19}H_{22}O_3N_2$; C, 69.92; H, 6.79; N, 8.58%.

1,1-Dimethoxy-2-methyl-1-phenyl-2-propanol (**5**, mp 54—55 °C, from hexane)[7] was obtained together with **3** and **4**; the yield of 5 varied (25—50%) for the each run of the reactions.

Preparation of 4d from 3d: After carbon dioxide was saturated in a methanol solution of **3d** (3.6 g, 0.02 mol), **1** (3.3 g, 0.01 mol) was added to the solution and then the mixture was gently refluxed for 24 h with bubbling of carbon dioxide. After the removal of the methanol in vacuo, the residue was dissolved in chloroform. The chloroform layer was washed with hydrochloric acid, water, and dried. The chloroform was evaporated in vacuo to afford a residue which was recrystallized from ethanol to give **4d** (2.8 g, 53%).

Selective Photooxidation of Alkali Mandelates by a Flavin Bearing a Crown Ring as a Metal Recognition Site[1)]

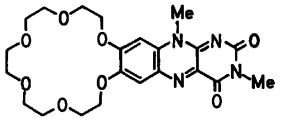
Seiji SHINKAI,* Hideki NAKAO, Kaori UEDA, Osamu MANABE, and Masayoshi OHNISHI

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

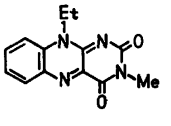
(Received November 4, 1985)

Synopsis. The quantum yields (Φ) for photooxidation of mandelate salts by a crown-containing flavin (CrFl) and 3-methyl-10-ethylisoalloxazine (MeEtIA) were determined in acetonitrile. MeEtIA photooxidized tetramethylammonium mandelate more selectively than potassium mandelate ($\Phi_{K^+}/\Phi_{Me_4N^+}$=0.42—0.64), while CrFl showed a high selectively for photooxidation of potassium mandelate ($\Phi_{K^+}/\Phi_{Me_4N^+}$=19—42).

The catalytic actions of coenzymes have attracted much attention of bioorganic chemists because they can catalyze the reactions to some extent even in the absence of apoenzymes. Thus, the model investigations on the coenzyme catalyses have provided many clues to elucidate the origin of the enzyme "activity" reasonably.[2,3)] In contrast, there are a few model investigations on the enzyme "selectivety" which is another important aspect of enzyme catalyses. In order to design such an enzyme model with a substrate selectivity one may add a recognition site (e.g., crown ether) to a coenzyme-based catalytic site.[4)] As an approach to model systems for flavoenzymes, we have synthesized a crown ether flavin mimic, 3,10-dimethyl-7,8-(1′,4′,7′,10′,13′,16′-hexaoxacyclooct-2′-eno)isoalloxazine (CrFl).[5)] Here we report that in photooxidation of mandelate salts CrFl not only acts as an excellent oxidizing agent but also shows a remarkable metal selectivity. In order to differentiate the contribution of the crown ring, we used 3-methyl-10-ethylisoalloxazine (MeEtIA) as a reference flavin.



CrFl



MeEtIA

Experimental

A standard actinometer (potassium trioxalatoferrate(III) was used for the quantum-yield determinations on the photochemical reaction of flavins and mandelate salts.[6)] Three-milliliter aliquots of the substrate solutions in a 1 cm quartz cell (10×10×45 mm) were deaerated and were irradiated under nitrogen with a 300 W high-pressure Hg lamp. The extraneous lines of the lamp other than 366 nm were filtered out using a combination of two solution filters ($CuSO_4$ and 5,7-dimethyl-1-azania-4-azacyclohepta-4,6-diene perchlorate) and of a glass filter (Corning 7-37). Light intensities at 366 nm were determined by trioxalatoferrate (III) actinometry.[6)] The quantum yields were determined by comparing the light intensities with the reduced flavins in the exactly same geometry.

Results and Discussion

The lowest singlet state (S1 band) of flavins corresponds to the polarization along the long axis of the molecule.[7)] The addition of $KClO_4$ (0.40 mM)* to CrFl (2.48×10^{-5} M) in acetonitrile (λ_{max} 459 nm, ε_{max} 19700) induced the blue shift of the absorption maximum (λ_{max} 455 nm, ε_{max} 18500). This indicates that the binding of K^+ to the crown ring suppresses the polarization from the benzene moiety to the uracil moiety along the long axis of CrFl. The addition of $NaClO_4$ and $CsClO_4$ also induced the blue shift although the magnitude was smaller than that in the presence of K^+. On the other hand, the absorption spectrum of MeEtIA was scarcely affected by these metal ions under the identical conditions. We estimated the association constants (K) for $MClO_4$+CrFl in acetonitrile at 30 °C from a decrease in the absorbance at 459 nm: $K=6.6\times10^3$ M^{-1} for Na^+, 2.5×10^4 M^{-1} for K^+, 4×10^3 M^{-1} for Cs^+, and less than 10^2 M^{-1} for Li^+.

Photoexcited flavins can oxidize mandelic acid to benzoic acid via dehydration followed by oxidative decarboxylation ($PhCH(OH)CO_2^- \rightarrow PhCOCO_2^- \rightarrow PhCO_2^- + CO_2$).[8)] We found that alkali and tetramethylammonium salts of mandelic acid are photooxidized by CrFl and MeEtIA in acetonitrile. The absorption bands of the oxidized flavins in the anaerobic solutions disappeared gradually with the photoirradiation time. Introduction of an O_2 stream

a) Room temperature, $[PhCH(OH)CO_2^-M^+]=4.24\times10^{-3}$ M, $[flavin]=2.00\times10^{-4}$ M. * Denotes that the salt is not soluble sufficiently.

into the final solution regenerated the oxidized flavins quantitatively, indicating that the light-mediated oxidation of mandelate salts occurs without the intervention of side reactions. The results are summarized in Table 1.

The inherent reactivity of CrFl and MeEtIA may be compared by the quantum yields (Φ) for tetramethylammonium (Me_4N^+) mandelate, because Me_4N^+ ion does not interact with the crown ether ring. As shown in Table 1, the Φ values for MeEtIA are greater by 2.8—3.2 fold than those for CrFl. The difference is attributed to the electron-donating effect of the 7,8-polyether groups in CrFl. Examination of Table 1 reveals several interesting aspects characteristic of the crown-metal interaction: (i) The reactivity order for MeEtIA is $Me_4N^+>Cs^+>K^+>Na^+>Li^+$, whereas that for CrFl is $K^+>Na^+\approx Cs^+>Me_4N^+>Li^+$ (Fig. 1), (ii) the Φ for CrFl+potassium mandelate in acetonitrile is greater than MeEtIA+Me_4N^+ mandelate, (iii) the Φ values decrease with increasing methanol concentration and the decrease in CrFl occurs more sensitively than that in MeEtIA, and (iv) the addition of monobenzo-18-crown-6 (B18C6) enhances the Φ for MeEtIA (except that for Me_4N^+ mandelate), whereas it slightly decreases the Φ for CrFl.

It is well-known that decarboxylation is extensively affected by solvent effects[9-11]: The rates are enhanced in dipolar aprotic solvents because of desolvation of carboxylate anions. Hence, the decarboxylation rate ($PhCOCO_2^-\rightarrow PhCO_2^-+CO_2$) should be enhanced in dipolar aprotic solvents. Similarly, the dehydration process ($PhCH(OH)CO_2^-\rightarrow PhCOCO_2^-$) would be facilitated by desolvation of the carboxylate anion. The rate decrease caused by methanol addition is thus ascribed to specific solvation of the carboxylato group through hydrogen bonding. The Φ for MeEtIA+potassium mandelate increased on the addition of B18C6. At the high B18C6 concentration the Φ (7.0%) is comparable with that for Me_4N^+ mandelate (8.1%) which is believed to exist as a free ion pair.[11] The order of the reactivity for MeEtIA is parallel to the cation size and is rationalized in terms of the formation of loose (e.g., Cs^+) or tight (e.g., Li^+) ion pairs. These findings all support that photooxidation by MeEtIA is governed by solvation of mandelate salts.

Interestingly, the Φ for CrFl+potassium mandelate is unusually enhanced: The Φ augmentation relative to Me_4N^+ mandelate corresponds to 42-fold in acetonitrile and the Φ is even greater than that for MeEtIA+Me_4N^+ mandelate. It is reasonable to propose that the unusual reactivity stems from the crown-metal interaction, because the order of the reactivity is exactly in accord with the spherical recognition pattern for an 18-crown-6 analogue (Fig. 1). Therefore, one reason for the high Φ should be the desolvation of the carboxylato group by the crown-K^+ complexation. However, this effect cannot fully rationalize the fact that the Φ (10.5%) for potassium mandelate is much greater than that for free-ion-like Me_4N^+ counterpart (0.25%). Conceivably, one must take two more important effects into consideration. Firstly, CrFl should become electron-dificient through the binding of K^+ to the crown ether moiety. A similar trend has been observed for the thermal oxidation of 1-benzyl-1,4-dihydronicotinamide by CrFl.[5] Secondly, one may expect the contribution of the proximity effect between the anionic mandelate and the cationic CrFl·K^+ complex in acetonitrile. The contribution of these two effects is supported by the finding that the addition of B18C6 suppresses the photooxidation of potassium mandelate by CrFl (Table 1). It is likely that added B18C6 binds K^+ competitively and interferes with the "pseudo-intramolecular" reaction process via the CrFl·$K^+\cdots PhCH(OH)CO_2^-$ complex. It seems reasonable to conclude, therefore, that the specific Φ

increase for CrFl+potassium mandelate is achieved by several synergistic effects.

These results indicate that CrFl can imitate several biological concept important in enzyme chemistry. The crown ether moiety not only recognizes metal cations but also "activates" the flavin molecule through complexation with M^+. The close imitation is achieved because CrFl has within a molecule flavin as a catalytic site and crown ether as a recognition site, which are the minimum constituents for enzyme models.

Hydrolysis of *p*-Nitrophenyl Hexanoate in Hydrophobic Aggregate System

Masato KODAKA,* Toshio FUKAYA, and Masayoshi KIKKAWA
National Chemical Laboratory for Industry, Tsukuba 305
(Received December 5, 1985)

Synopsis. Hydrolysis of *p*-nitrophenyl hexanoate in the presence of azide ion (N_3^-) was accelerated by tetraheptylammonium bromide (**1**), which has four long alkyl chains. In contrast to **1**, the other tetraalkylammonium salts which have shorter alkyl chains, (**2**)—(**5**), did not elevate the reactivity. *p*-Nitrophenyl acetate, less hydrophobic substrate, was not hydrolyzed so efficiently even in the presence of **1**.

An enzyme holds a specific conformation in an aqueous solution, where hydrophilic groups are situated on the outer surface and hydrophobic groups are placed inside. As micelles resemble enzymes in this respect, lots of studies have been undertaken about micelle-system reactions from an enzyme-mimetic point of view.[1-6] In micelle systems substrates are incorporated into or adsorbed on micelles by electrostatic and/or hydrophobic interactions and activated in specific environments. Other enzyme-mimetic systems such as vesicles[7-9] and aggregate of methyltrioctylammonium chloride[10,11] are also studied intensively, where reactions are activated as compared with aggregate-free ones. In the present report, we describe the effect of a new type of hydrophobic aggregate made up of tetraheptylammonium bromide **1**, which possesses four long alkyl chains, upon the hydrolysis of an active ester (*p*-nitrophenyl hexanoate) in the presence of azide ion (N_3^-).

Experimental

Tetraheptylammonium bromide (**1**) and tetrapentylammonium bromide (**3**) (Aldrich Chemical Co.), tetrahexylammonium iodide (**2**) (Tokyo Kasei Kogyo Co.), tetraethylammonium perchlorate (**4**) (Nakarai Chemicals), benzyltriethylammonium bromide (**5**) (Kanto Chemical Co.), sodium azide (Nakarai Chemicals), *p*-nitrophenyl hexanoate (*p*-NPH) (Tokyo Kasei Kogyo Co.), *p*-nitrophenyl acetate (*p*-NPA)(Aldrich Chemical Co.), and 8-anilino-1-naphthalenesulfonic acid magnesium salt (ANS) (Nakarai Chemicals) were used as supplied.

The reaction was carried out at pH 8.0, μ=0.5(KCl), buffered with 0.1 mol dm^{-3} KH_2PO_4–0.05 mol dm^{-3} $Na_2B_4O_7$. The reaction rate was determined by measuring the absorbance of liberated *p*-nitrophenol at 400 nm with a Beckman Model 34 spectrophotometer. Fluorescence intensity was measured under the same conditions as described above with a JASCO FP-4 fluorescence spectrophotometer.

Results

The reaction rate did not follow pseudo-first-order even when $[N_3^-] \gg [p\text{-NPH}]$, that is, $\ln\{c_0/(c_0-x)\}$ was not proportional to the reaction time (t) and the rate constant (the slope of the curve) decreased with time. Here, c_0 is the concentration of *p*-NPH at a time 0 and x is the concentration of *p*-nitrophenol at a time t. We have estimated the rate constant (k), therefore, from the slope of the curve at initial stage. On the other hand, the hydrolysis of *p*-NPH followed pseudo-first-order in the presence of N_3^- and hexadecyltrimethylammonium chloride (HTAC) micelle.

In Fig. 1 are shown the relations between k and the concentrations of the tetraalkylammonium salts (C), where k increased monotonously with increasing the concentration of **1** in the presence of N_3^- (5×10^{-4} mol dm^{-3}). In the absence of N_3^-, however, k remained fairly small in spite of the addition of **1** (5×10^{-5} mol dm^{-3}). The k value became more than 10 times larger upon addition of N_3^- (5×10^{-4} mol dm^{-3}), when the concentration of **1** was 5×10^{-5} mol dm^{-3}.

In the presence of **1** (5×10^{-5} mol dm^{-3}) k increased with increasing $[N_3^-]$, whereas the k value had a tendency to be saturated at higher $[N_3^-]$ (Fig. 2). When **1** was not present, k increased little even if N_3^- was added.

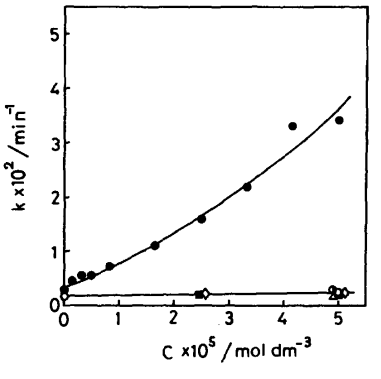

Fig. 1. Relationship between concentration of tetraalkylammonium (C) and rate constant (k) for hydrolysis of *p*-NPH in the presence of N_3^-; pH 8.0 (0.1 mol dm^{-3} KH_2PO_4–0.05 mol dm^{-3} $Na_2B_4O_7$ buffer solution), μ=0.5(KCl), 25 °C, [*p*-NPH]=5×10^{-5} mol dm^{-3}, [NaN_3]=5×10^{-4} mol dm^{-3}.

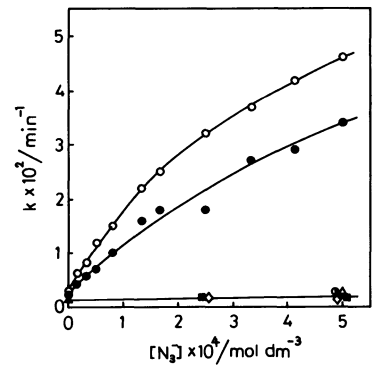

Fig. 2. Relationship between concentration of N_3^- ($[N_3^-]$) and rate constant (k) for hydrolysis of p-NPH in the presence of N_3^-; pH 8.0 (0.1 mol dm^{-3} KH_2PO_4 -0.05 mol dm^{-3} $Na_2B_4O_7$ buffer solution), μ=0.5 (KCl), 25 °C, [p-NPH]=5×10^{-5} mol dm^{-3}, [Tetraalkylammonium]=5×10^{-4} mol dm^{-3}. (—●—): **1**, (—○—): **1**, 29 °C, (—■—): **2**, (—▲—): **3**, (—◑—): **4**, (—◇—): **5**, (—△—): tetraalkylammonium free.

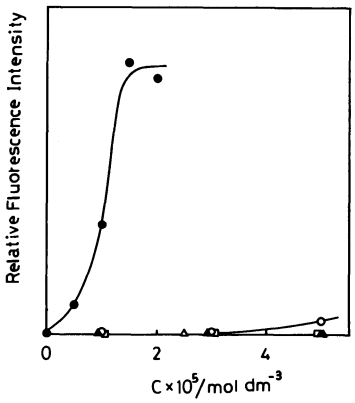

Fig. 3. Relationship between concentration of tetraalkylammonium (C) and relative fluorescence intensity of ANS; pH 8.0 (0.1 mol dm^{-3} KH_2PO_4-0.05 mol dm^{-3} $Na_2B_4O_7$ buffer solution), μ=0.5(KCl), 25 °C, [ANS]=1×10^{-4} mol dm^{-3}; excitation wavelength was 365 nm and emission wavelength was 490 nm. (—●—): **1**, (—○—): **2**, (—▲—): **3**, (—△—): **4**, (—□—) **5**.

Contrary to **1**, the other tetraalkylammonium salts, **2**—**5**, with less hydrophobic groups, did not accelerate the hydrolysis even in the presence of N_3^- (Figs. 1 and 2). Furthermore, the hydrolysis of p-NPA (less hydrophobic substrate than p-NPH) was not enhanced under the same conditions as those for p-NPH.

It is generally known that the fluorescence intensity of ANS is significantly increased when ANS is incorporated into hydrophobic environment.[12] Therefore we studied the effect of the tetraalkylammonium salts upon the fluorescence of ANS to see which ammonium salts form hydrophobic aggregates (Fig. 3). Relative fluorescence intensity was remarkably increased in the presence of **1** (≦2×10^{-5} mol dm^{-3}), while **2**—**5** scarcely increase the fluorescence.

Discussion

It seems very likely that the hydrolysis proceeds as follows.

$$CH_3(CH_2)_4COOC_6H_4NO_2 + N_3^- \longrightarrow CH_3(CH_2)_4CON_3 + {}^-OC_6H_4NO_2 \quad (1)$$

$$CH_3(CH_2)_4CON_3 + OH^- \longrightarrow CH_3(CH_2)_4COOH + N_3^- \quad (2)$$

Therefore in the present study we are discussing the first reaction (1) of the hydrolysis.

As described in the Results section, the hydrolysis of p-NPH in the presence of N_3^- and **1** did not follow pseudo-first-order plot. Taking into account the results that the hydrolysis was significantly accelerated upon addition of N_3^-, it seems very likely that N_3^- adsorbed on the aggregate should attack p-NPH very efficiently. As the concentration of **1** (≦5×10^{-5} mol dm^{-3}) is lower than that of N_3^- (≦5×10^{-4} mol dm^{-3}), the numer of N_3^- adsorbed on the aggregate is appreciably decreased as the reaction proceeds, for the liberated p-nitrophenol and/or hexanoic acid can be also adsorbed on the anion-binding site of the aggregate in competition with N_3^-. Therefore k will decrease as the hydrolysis proceeds. On the other hand, in the micelle system the concentration of HTAC (≧1×10^{-3} mol dm^{-3})was much higher than that of **1**, and so the number of N_3^- on the micelle may be virtually constant. The k value will be constant, therefore, during the reaction, as mentioned above.

In the presence of **1**, the k value increased but seemed to be saturated gradually as N_3^- was added (Fig. 2). This saturation may be attributed to the saturation of the amount of N_3^- on the **1**-aggregate. When **2**—**5** were added instead of **1**, the reaction was not accelerated even in the presence of N_3^- (Figs. 1 and 2). These results suggest that **2**—**5** cannot form aggregates in aqueous solution. This conclusion is also substantiated by the findings that the fluorescence intensity of ANS was remarkably increased by **1** but not by **2**—**5** (Fig. 3). An active ester, more hydrophilic than p-NPH, would not be included in **1**-aggregate. In fact, the hydrolysis of p-NPA was not activated in the presence of both **1** and N_3^-. Thus, it can be concluded that the rate enhancement of the hydrolysis of p-NPH in the presence of **1** and N_3^- is ascribed to the formation of the aggregate of **1** on which N_3^- and p-NPH are adsorbed and activated.

Synopsis. Two new quassinoids, shinjulactones M and N were isolated from root bark of *Ailanthus altissima* SWINGLE. The structures of these compounds were determined to be 11β,20-epoxy-1β,11α,12α,13β,21-pentahydroxypicras-3-ene-2,16-dione and 11β,20-epoxy-1β,2α,11α,12α,15β-pentahydroxypicrasa-3,13(21)-dien-16-one, respectively, by spectral and chemical means.

As a continuation of studies on the bitter principles of Simaroubaceous plants, we have been investigating bitter principles of *Ailanthus altissima* SWINGLE (Japanese name: Shinju or Niwaurushi).[1] We further examined bitter principles in aqueous extracts of root bark of *A. altissima*, and obtained two new bitter principles, shinjulactone M (**1**; 0.0005%) and shinjulactone N (**2**; 0.0002%) together with known quassinoids, ailanthone (**3**),[2] $\Delta^{13(18)}$-dehydroglaucarubolone (**4**),[3] shinjulactone A (**5**)[2], shinjulactone D[4] and shinjuglycoside D.[5] This paper describes structure determination of shinjulactones M and N (**1** and **2**) and chemical derivation of **1** from ailanthone (**3**).

Shinjulactone M (**1**), mp 260—264 °C (decomp), showed the presence of hydroxyl, δ-lactone, and α,β-unsaturated ketone by IR and UV spectra and gave a molecular peak at *m/z* 410 in the EI-MS spectrum, suggesting the molecular formula, $C_{20}H_{26}O_9$. In the ^{13}C NMR of **1**, signals were observed at $\delta_{(C)}$ 66.5 and $\delta_{(C)}$ 75.8, which were assignable to a hydroxymethyl carbon atom and a carbon atom bearing a tertiary hydroxyl group, respectively. The ^1H NMR spectrum of **1** showed the presence of a tertiary methyl and a vinyl methyl groups and the spectral feature was similar to that of ailanthone (**3**)[2] except for the absence of an *exo*-methylene group. Since the molecular formula of **1** possesses extra two hydrogen and two oxygen atoms in comparison with that of ailanthone (**3**), the structure of **1** would be deduced to be a vicinal hydroxylation product of the *exo*-methylene in ailanthone (**3**) from the spectral evidence; the structure with the primary hydroxyl group at C-21 and the tertiary hydroxyl group at C-13 would be proposed for shinjulactone M (**1**). The COSY, NOESY spectra and ^{13}C-^1H J-correlated two-dimensional spectrum for **1** confirmed the location of the tertiary hydroxyl group. The configuration of the C-13 carbon atom was determined by difference NOE measurement. Irradiation of a signal due to one proton of C-21 methylene resonating at δ 4.42, resulted in increase in area of signals at δ 3.41 and 3.49 due to C-15 methylene and at δ 4.19 due to the other proton of C-21 methylene, respectively. This observation indicates that the hydroxymethyl group at C-13 locates in α-orientation and therefore the tertiary hydroxyl group at C-13 in β-orientation. Thus the structure of shinjulactone M was determined to be 11β,20-epoxy-1β,11α,12α,13β,21-pentahydroxypicras-3-ene-2,16-dione (**1**).

The structure (**1**) proposed for shinjulactone M was firmly confirmed by a chemical conversion of ailanthone (**3**) into shinjulactone M (**1**). Ailanthone (**3**), on treatment with osmium tetraoxide, afforded a product derived from an attack of the reagent on a conjugated olefin between C-3 and C-4, because the reagent could not be accessible to the *exo*-methylene due to a steric hindrance of E-ring. Ailanthone triacetate (**6**),[6,7] however, reacted with the reagent to afford a dihydroxy derivative (**7**), $C_{26}H_{32}O_{12}$. Treatment of **7** with potassium methoxide gave shinjulactone M, identical with a natural specimen including an optical property.

Shinjulactone N (**2**), mp 245—251 °C (decomp), gave a molecular formula, $C_{20}H_{26}O_8$ by high-resolution mass spectrum and showed the presence of hydroxyl and δ-lactone groupings. Comparison of the ^1H NMR spectrum of **2** with those of shinjulactone A (**5**)[2] and $\Delta^{13(18)}$-dehydroglaucarubolone (**4**)[3] led to the proposed structure with the same A, B, C, and E ring-structures as those of **5** and with the same β-equatorial hydroxyl group at C-15 as that in **4**, the coupling constant, $J_{14,15}$, being 11.9 Hz (see Table). Therefore, 11β,20-epoxy-1β,2α,11α,12α,15β-pentahydroxypicrasa-3,13(21)-dien-16-one (**2**) was proposed for shinjulactone N. The ^{13}C NMR spectrum of shinjulactone N was compatible with the proposed structure (**2**). Shinjulactone N (**2**) is corresponding to the hydrolyzate of 13,18-dehydroexcelsin obtained from *Ailanthus excelsa*.[8]

Although more than twenty quassinoids and four quassinoid glycosides have been isolated from *A. altissima* so far, shinjulactone M (**1**) is the first example of 11β,20-epoxypicrasane which possesses a hydroxyl group at $C_{(21)}$-atom, and the picrasane [B] bearing hydroxyl groups on $C_{(13)}$- and $C_{(21)}$-atoms may be one of biogenetical intermediates yielding methyl 13β,20-epoxypicrasan-21-oate [C], such as brusatol from ailanthone-type precursor [A] (Scheme 1).

Scheme 1.

Experimental[9]

Extraction and Isolation of Shinjulactones M and N (1 and 2). The air-dried root bark (ca. 7 kg) was chipped and extracted with hot water twice (15 l and then 10 l). Evaporation in vacuo gave a concentrated extract (ca. 5 l), which was continuously extracted with dichloromethane (1 l×3) for 12 h. The aqueous layer was separated and concentrated to afford a solution (ca. 2 l), to which methanol (3 l) was added. After filtration, the filtrate was evaporated to give a residue (420 g), a part (317 g) of which was absorbed on silica gel (361 g) and placed on the top of silica-gel column (2 kg). Elution was performed with lower layer of chloroform–methanol–water in the following ratios successively; 50:12:3 (6.5 l), 65:35:10 (12 l), and 50:50:18 (5 l). Forty fractions (each 500 ml) were collected (column A).

Residues from fractions 19 and 20 of column A were combined (4 g) and separated by column chromatography on silica gel (80 g) eluted with 18% methanol in ethyl acetate (200 ml) and 20, 23, 26, 29, and 32% methanol in ethyl acetate (each 100 ml), and 8 fractions (each 100 ml) were collected (column B).

The residue from fraction 4 (581 mg) of column B was separated by partition chromatography on silicic acid (430 g) pretreated with water (287 g). Elution was performed with 0, 1, 3, 6, 9···24% ethanol in chloroform (each 1 l) and 33 fractions (each 250 ml) were collected (column C).

Residues from fractions 22—28 (117 mg) of column C were combined and separated by reversed phase chromatography using LiChroprep RP-8. Elution was performed with methanol-water (3:7) and 40 fractions (each 10 g) were collected. Fractions 13—17 afforded shinjulactone M (**1**; 32 mg). Combined residues (29 mg) of fractions 18—33 were further separated by gel column chromatography using Toyopearl HW-40S (2.4×100 cm) and methanol as an eluent. Seventy fractions (each 10 g) were collected. Fractions 50—52 gave shinjulactone N (**2**; 11 mg).

Shinjulactone M (1). Colorless prisms crystallized from methanol-ethyl acetate, mp 260—264 °C (decomp); $[\alpha]_D^{25}$ +37° (*c* 0.46, MeOH); IR (KBr) 3500, 2900, 1730, 1670, 1260, 1225, 1060, and 1030 cm^{-1}; UV (EtOH) 238 nm (ε 15600); ^1H and ^{13}C NMR (Tables 1 and 2); MS (EI) *m/z* (%) 410 (M^+; 2.2), 392 (3), 374 (13), and 107 (100); Found: *m/z* 410.1580. Calcd for $C_{20}H_{26}O_9$: M, 410.1577.

Shinjulactone N (2). Colorless amorphous solid from methanol-ethyl acetate, mp 245—251 °C; $[\alpha]_D^{25}$ +60.6° (*c* 0.32, MeOH), IR (KBr) 3420, 2870, 1720, 1625, 1610, and 1050 cm^{-1}; ^1H and ^{13}C NMR (Tables 1 and 2); MS (EI) *m/z* (%) 394 (M^+; 3.9), 376 (18), 361 (10), 332 (23), 105 (79), and 57 (100); Found: *m/z* 394.1616. Calcd for $C_{20}H_{26}O_8$: M, 394.1626.

Conversion of Ailanthone Triacetate (6) into Shinjulactone M (1). Ailanthone triacetate (**6**; 417.5 mg)[7] was treated with osmium tetraoxide (199 mg) in a mixture (8 ml) of pyridine-THF (1:1) at −72 °C for 9 h. After addition of sodium hydrogensulfite (0.36 g) in water (6 ml) and pyridine (3 ml), THF was removed by distillation in vacuo. The remaining solution was stirred at room temperature for 1 h. The usual work-up followed by separation by column chromatography on silica gel afforded shinjulactone M triacetate (**7**; 141 mg) together with the starting material (**6**; ca. 90 mg). **7**; colorless

needles from chloroform–ethyl acetate, mp 261—263 °C (decomp); $[\alpha]_D^{24}$ +10° (*c* 0.10, pyridine); IR (KBr) 3490, 3280, 1750, 1710, 1680, 1380, 1210, 1060, 1040, 900, and 600 cm^{-1}; UV (EtOH) 238 nm (ε 8800); ^1H NMR (C_5D_5N) δ 1.65 (3H, s; 10-Me), 1.79 (3H, s; 4-Me), 1.95, 2.10, and 2.15 (each 3H; OAc), 3.1—3.8 (3H, m; 14-H, 15-H, and 15-H′), 4.03 (2H, s; 21-H and 21-H′), 4.68 (1H, d, J=10.8 Hz; 20-H), 4.97 (1H, br s; 7-H), 5.31 (1H, d, J=10.8 Hz; 20-H′), 5.47 (1H, s; 1-H or 12-H), 5.66 (1H, s; 12-H or 1-H), and 6.03 (1H, br s; 3-H); ^{13}C NMR (C_5D_5N) δ 203.4, 191.6, 170.9, 170.3, 169.5, 169.2, 161.7, 126.5, 84.9, 81.0, 80.0, 78.0, 64.5, 64.1, 48.8, 44.7, 44.3, 42.1, 38.2, 28.4, 25.4, 21.9, 21.0, 20.7, 20.6, and 12.0; MS (EI) *m/z* (%) 536 (M^+; 6.2), 518 (2.4), 494 (5.6), 476 (13), 463 (4.3), 458 (5.4), 434 (9.6), 416 (11), 398 (20), 151 (19), 95 (32), and 60 (100); Found: *m/z* 536.1891. Calcd for $C_{26}H_{32}O_{12}$: M, 536.1892.

Shinjulactone M triacetate (**7**; 118 mg) was hydrolyzed with 0.3 M (1 M=1 mol dm^{-3}) potassium methoxide in methanol (10 ml) at room temperature for 1 h and, after the usual work-up, the hydrolyzate was purified by column chromatography on silica gel (5 g). Elution with 15% methanol in chloroform afforded shinjulactone M (**1**; 75.7 mg); mp 263—266 °C (decomp); $[\alpha]_D^{14}$ +20° (*c* 0.46, MeOH); the spectral data were completely identical with those of a natural specimen.

The authors wish to express their thanks to Associate Professor Hajime Nagano of Ochanomizu University for measurement of NMR, and Mr. Eiichi Ishii of the Botanical Gardens, the University of Tokyo, for collecting root of *A. altissima*.

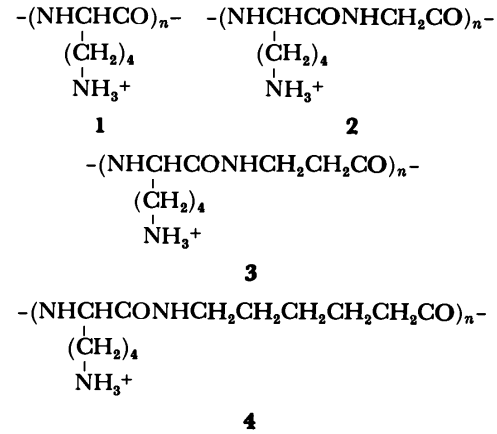
(Received December 24, 1985)

Synopsis. Aggregation of the sequential poly(Lys HCl-X) (X: Gly, βAla, and εAhx)-Methyl Orange (MO) complexes was studied by means of a circular dichroism (CD) measurement. The intensity of the induced CD was affected by the concentration of the complexes and time after preparing the complex solutions. When MO molecules which are electrostatically bound to lysine residues are separated from each other, the aggregation of the complexes takes place to a lesser degree.

The origin of induced optical activities arises from dipole-dipole interactions between two transition dipoles of the chromophores under chiral environmental conditions.[1,2] Recently, several groups reported the results on an induced CD due to chiral interaction between cationic poly(Lys)[3] and anionic azo dyes.[4-8] The structural isomer εpoly(Lys) has also been examined from the standpoint of binding affinity to small molecules such as dyes and metals,[9] and of the induced CD properties on complexation with MO.[10] The εpoly(Lys)-MO complex caused an interchain aggregation. The differences in the results between poly(Lys) and εpoly(Lys) have mainly been attributed to the intramolecular distance between the ammonium groups, to which anionic azo dyes interacted electrostatically. To clarify the effect of distance between chromophores, sequential polypeptides containing functional groups may be one of the most suitable systems. In this Note a series of sequential lysine polypeptides are described in order to add some knowledge regarding the induced CD of cationic biopolymer-dye complexes.



Scheme 1.

Experimental

Using lysyl-X dipeptides as precursors, three sequential lysine polypeptides, poly(Lys HCl-Gly) (2, degree of polymerization as total amino acid residues, DP,=40), poly(Lys HCl-βAla) (3, DP=60), and poly(Lys HCl-εAhx) (4, DP=90) were synthesized according to the racemization-free diphenyl phosphor azidate method.[11] Poly(Lys HBr) (1, DP=60) was purchased from Sigma and converted to poly(Lys HCl).[12] The chemical structures of the four polypeptides are shown in Scheme 1. Sodium 4-(4-dimethylaminophenylazo)benzenesulfonate (Methyl Orange, MO) was a guaranteed reagent from Wako. The mixtures were prepared by adding a dye solution to the polypeptide solutions. The final concentrations of lysine residues in polypeptides and MO were $1—7\times10^{-4}$ mol residue dm^{-3} and $2—14\times10^{-5}$ mol dm^{-3}, respectively, at residue/dye ratio (R/D)=5. The CD spectra were measured with a Jasco CD J-40A spectrometer. The molar ellipticity $[\theta]$ (degree $cm^2\,dmol^{-1}$) was expressed on the basis of the dye concentration.

Results and Discussion

The induced CD of the poly(Lys)-azo dye complexes has been studied[4-8] and the poly(Lys HCl)-MO complex used here (DP=60) exhibited intensities of $[\theta]_{371}=-25000$ and $[\theta]_{359}=25000$ at pH 6 and R/D=5. The induced CD spectra of the sequential lysine polypeptide-MO complexes were recorded by changing the concentration of the dye and keeping the R/D ratio constant at 5. Figure 1 shows the time dependence of the induced CD spectra of the poly(Lys HCl-Gly)-MO complex in water at pH 6 and dye concentration 10^{-4} mol dm^{-3}. Immediately after preparing the mixed solution, the complex exhibited no induced CD. After 1 h, a weak split-type induced CD spectrum with extrema at 371 nm (negative) and 359 nm (positive) was observed and their intensities at the extrema were found to increase on standing without stirring. After 23 h, the intensities were −16600 (371 nm) and 16100 (359 nm), and still increasing. Figure 2 shows the concentration and time dependence of the induced CD of the poly(Lys HCl-Gly)-MO complex in water at pH 6 (R/D=5). When the dye concentrations were less than 4×10^{-5} mol dm^{-3}, the system did not exhibit induced CD, even after 3 d. On the other hand, when the dye concentrations were greater than 6×10^{-5} mol

	405	0
	388	8200

a) MO 10^{-4} mol dm^{-3} and after 23 h.

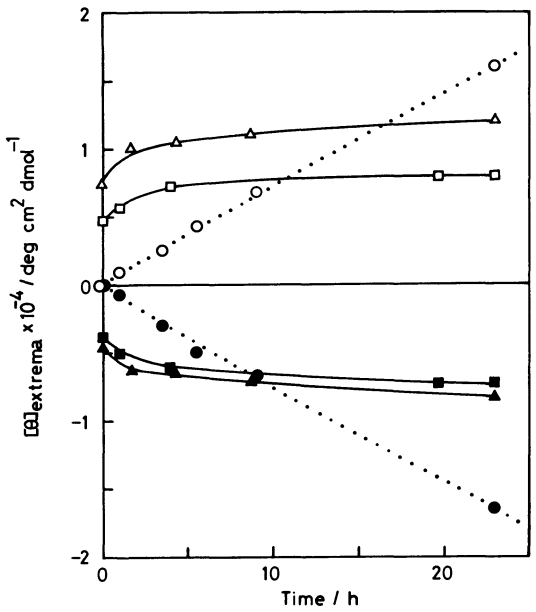

Fig. 3. Time dependence of the induced CD intensities of the poly(Lys HCl-X)-MO complexes in water at pH 6 and R/D=5; MO, 10^{-4} mol dm^{-3}. Poly(Lys HCl-βAla), △ at 397 nm and ▲ at 435 nm; poly(Lys HCl-εAhx), □ at 388 nm and ■ at 424 nm. Poly-(Lys HCl-Gly) (○ at 359 nm and ● at 371 nm) was partly reproduced from Fig. 2 (curve B).

dm^{-3}, the intensities of the induced CD were continued to increase after 2 d. This suggests that an intermolecular aggregation of the complex occurs. As listed in Table 1, the poly(Lys HCl-βAla)-MO complex exhibited the induced CD with the extrema at 435 nm (negative) and at 397 nm (positive), and poly(Lys HCl-εAhx)-MO complex at 424 nm (negative) and at 388 nm (positive). The induced CD spectra of the poly(Lys HCl-βAla)-MO and poly(Lys HCl-εAhx)-MO complexes, which have one and four more backbone atoms than poly(Lys HCl-Gly)-MO complex, exhibited smaller intensities and a little time dependence as depicted in Fig. 3. This suggests that, when MO molecules that are electrostatically bound to lysine residues are separated from each other, the intra- and intermolecular interactions are

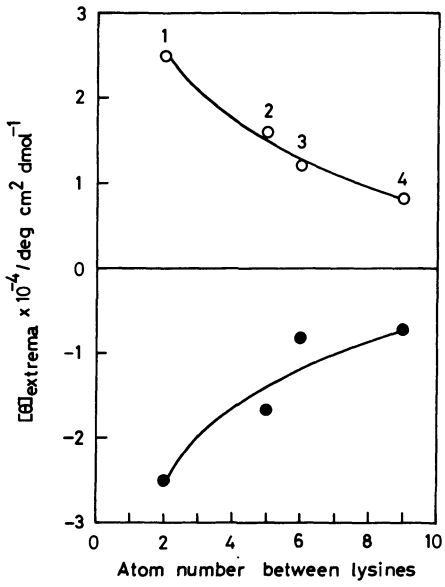

Fig. 4. Induced CD intensities at the extrema of the sequential polypeptide–MO complexes as a function of distance between lysine residues in water at pH 6 and R/D=5; MO, 10^{-4} mol dm^{-3}. After 23 h; samples 1—4, see text.

weaker.

At the beginning of the present study we expected to change the intramolecular interchromophoric distance using sequential polypeptides, although the problem was more complicated than anticipated. We tentatively plotted the induced CD intensities after 23 h at the extrema of four sequential polypeptide–MO complexes including poly(Lys HCl)–MO complex as a function of distance between C_α of the lysine residues in Fig. 4. Since the random coil conformations of the four sequential polypeptide–MO complexes did not allow an exact estimation of the distance between chromophores, the numbers of backbone atoms between lysine residues were plotted as abscissa. Boldly, it could be concluded that an increased distance between the N^ε-ammonium groups of lysine residues decreased the intensity of the induced CD (see also Fig. 3). The results in Fig. 4 are fundamentally similar to the results of the induced CD of the sequential poly(His)–MO complexes reported by us.[13] Since the DPs (40—90) of the sequential poly(Lys HCl–X) samples used here may be too low to investigate the intramolecular dye–dye interaction, very high DP samples with the same Lys HCl–X sequences might give additional information regarding the induced CD of the sequential lysine polypeptides.

Aryliminodimagnesium Reagents. X. The Mild Reagent Derived from 2-Aminopyridine and Formation of Highly Reactive Azoxypyridines in the Reaction with Nitrobenzenes

Masao Ōkubo,* Chieko Sugimori, Mitsunao Tokisada, and Toshiki Tsutsumi
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840
(Received November 2, 1985)

Synopsis. The reaction of iminodimagnesium reagent derived from 2-amino-4-methylpyridine with nitrobenzenes was examined. The relative yields of the azoxypyridine formed via condensation and the azopyridines via deoxygenation and oxidative dimerization were explained in terms of weak electron-donating ability of the reagent and the strong electron-accepting ability of the azoxypyridine.

As an application of the procedure using aryliminodimagnesium reagents(ArN(MgBr)$_2$, aryl-IDMg), the reaction of reagent ***A*** derived from 1,2-benzenediamine with nitrobenzenes was reported.[1] The product distribution is governed by the sterically hindered but strongly electron-donating nature of ***A***. In the preliminary study on IDMg condensation with carbonyl compounds,[2] reagent $\boldsymbol{B}^{H}$ derived from 2-aminopyridine gave low yield of anil of fluorenone but no anil of benzophenone.

In order to study the reason for the low reactivity of the reagent derived from 2-aminopyridines for the purpose of developing the IDMg procedure, the reaction of nitrobenzenes with reagent $\boldsymbol{B}^{Me}$ derived from 2-amino-4-methylpyridine was examined. The product distribution was compared with that obtained in the reaction of reagent $\boldsymbol{C}^{MeO}$ derived from *p*-methoxyaniline.[3] The result will be explained by the quite weak electron-donating ability of $\boldsymbol{B}^{Me}$ and the very strong electron-accepting ability of azoxypyridine formed in the present reaction.

Results and Discussion

The reagents $\boldsymbol{B}^{H}$ and $\boldsymbol{B}^{Me}$ were prepared without difficulty from 2-aminopyridine and its 4-methyl derivative, respectively, by treating with EtMgBr in THF.[2] Attempts to convert 3- and 4-aminopyridines into IDMg failed; a voluminous white precipitate appeared and no evolution of ethane was observed. The results are quite similar to the successful preparation of IDMg (***A***) from 1,2-benzenediamine and the failure of preparation of IDMg from 1,3- and 1,4-isomers.[1] The reagent $\boldsymbol{B}^{Me}$ was allowed to react with *p*-(Me, Cl, MeO)-substituted nitrobenzenes. Four products identified are shown in Scheme 1: **1** is formed via condensation, **2** via deoxygenation of **1**, and **3** via oxidative dimerization of reagent molecules.[3] While the formation of **1**—**3** is expected from the previous study using the reagents derived from anilines,[3] the formation of the *ortho*-substitution product **4** is observed for the first time in IDMg reactions of nitrobenzenes. Reaction conditions and yields of **1**—**4** are summarized in Table 1 (Runs 1—9).

In Runs 2—4 using small excess of $\boldsymbol{B}^{Me}$, the yields of azopyridine **2** are higher than those of azoxypyridine **1**; the relative yield is distinct from the higher yields of symmetrical azoxybenzene than the those of azobenzene obtained by use of small excess of reagent derived from aniline.[3] For the complete consumption of the substrate, the large amount of $\boldsymbol{B}^{Me}$ and prolonged heating are needed (Runs 5—7). The azoxypyridine **1** is also consumed completely and

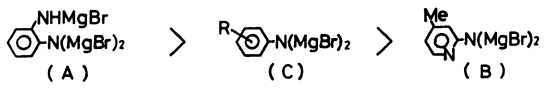
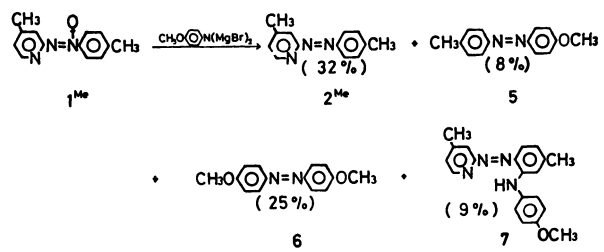
good yield of **2** is obtained (Run 6).

It was postulated previously that the distribution of "normal and abnormal" products in the reactions of organomagnesium reagents depends principally on the combination of electron-donating and -accepting abilities (EDA and EAA) of reactants.[4,5] According to the EDA–EAA concept, the mechanism of reaction of benzophenones with ArMgBr was distinguished successfully from that with IDMg.[6] In order to apply the concept to the present result, the polarographic oxidation peak potential of $\boldsymbol{B}^{Me}$ (1.295 V) was measured in THF using ferrocene as internal standard.[5] The value higher than that of $\boldsymbol{C}^{MeO}$ (0.921 V)[5] indicates the weak EDA of $\boldsymbol{B}^{Me}$ which is responsible for the low reactivity shown by the large amount of recovery in Runs except 6. It is also responsible for the deoxygenation ability of $\boldsymbol{B}^{Me}$ in the reaction with azoxyarenes. By the treatment of azoxybenzene with five molar equivalents of $\boldsymbol{B}^{Me}$ and $\boldsymbol{C}^{MeO}$ at 55 °C for 3 h, deoxygenation proceeds to the extents of 0.5 and 75%,[5] respectively. Taking the previous results[1,5] into account, the order of EDA of IDMg's is shown as follows.

EDA: Electron-donating Ability



The reduction potentials of *p*-substituted nitrobenzenes (MeO: −1.508 V; Me: −1.418 V; Cl: −1.254 V) and those of azoxyarenes including $\mathbf{1}^{Cl}$ (See Experimental) were also measured in THF using bisbiphenylchromium(I)tetraphenylborate(BCTB) as internal standard,[7] the latters being listed in Table 2. The EDA of azoxyarene is affected greatly by the aryl group locating opposite to the positive nitrogen.[8] The products and yields obtained in the reaction of $\mathbf{1}^{Me}$ with reagent $\boldsymbol{C}^{MeO}$ are given in Scheme 2($\mathbf{2}^{Me}$ and **5**—**7**). The product $\mathbf{2}^{Me}$ is formed via "normal" deoxygenation,[8] **5** via exchange,[8] **6** via oxidative dimerization of IDMg molecules, and **7** via *ortho*-substitution. Table 2 includes also the types of products obtained under the same reaction conditions in the previous[8] and present studies.



Scheme 2.

The results shown in Table 2 demonstrate that EAA of azoxyarenes are correlated to the distribution of types of products in IDMg reaction. In the reaction with $\boldsymbol{C}^{MeO}$ having strong EDA, azoxybenzenes having weak EAA undergo mild deoxygenation and those having strong EAA undergo rapid deoxygenation and exchange.[8] The azoxypyridine **1** having extremely strong EAA undergoes, additionally, oxidative dimerization of IDMg as well as *ortho*-substitution. The former process is indicative of involvement of electron transfer and is observed usually in the IDMg reaction with nitrobenzenes[3] having strong EAA. The latter process resembles the many examples of conjugate addition of Grignard reagents having strong EDA[5] with nitrobenzenes via electron transfer reported by Bartoli.[9] The strong EAA of $\mathbf{1}^{Me}$ and strong EDA of $\boldsymbol{C}^{MeO}$ are also responsible for the formation of an appreciable amount of unidentifiable black materials indicative of the decomposition via too much vigorous electron transfer.[4] Only a half amount of $\mathbf{1}^{Me}$ was converted into the identified products, $\mathbf{2}^{Me}$, **5**, and **7**.

In the reaction of Scheme 1, the large amounts of recovery in Runs except 6 are due to the weak EDA of $\boldsymbol{B}^{Me}$. In contrast to the reactions of nitrobenzenes with ordinary IDMg derived from anilines,[3] however, the azoxy compound formed first in the present reaction has EAA comparable to or stronger than that of substrate. Thus, the strong EAA of **1** not only gives rise to the higher yield of **2** than that of **1** (Runs 2—5 and 7—9) but also is responsible for the slight dependence of product distribution on the electronic effect of substituents of substrates (Runs 3, 8, and 9). The formation of **3** and **4** corresponding to **6** and **7**, respectively, is ascribed to the interaction of $\boldsymbol{B}^{Me}$ with **1**; the possibility of interaction with substrate is excluded from the large amount of recovery in Runs except 6.

The weak EDA of $\boldsymbol{B}^{H}$ and $\boldsymbol{B}^{Me}$ and also the strong EAA of **1** are ascribed to the electron-deficient pyridyl group shown by the lower reactivity of pyridines than that of benzenes toward electrophilic reagents.[10] The good yield of azopyridine (Run 6) suggests the further development of the present method.

Experimental

Melting points are uncorrected.

Materials, Reactions, and Products. 2-Amino-4-methylpyridine and nitrobenzenes were commercially available. The solution of $\boldsymbol{B}^{Me}$ in THF was prepared according to the reported procedure.[1,5] The reactions of Scheme 1 were carried out by adding the solution of nitrobenzenes (3.0 mmol) into the solution of given amount of $\boldsymbol{B}^{Me}$ at 0 °C. The reaction mixtures were stirred at 55 °C or at room temperature for the given period of time (See Table 1). Using the samples of $\mathbf{1}^{Me}$ formed in Runs 1—5 and 7, collected and purified, the reaction of Scheme 2 was carried out under the same conditions as those of the previous study.[8] The products formed in the reactions of Schemes 1 and 2 were separated by column and thin-layer chromatographies on silica gel.

The melting points, values of elemental analyses, and ^{1}H NMR spectra of products **1**—**4** and **7** are summarized in Table 3, those of the products **5** and **6** being reported previously.[3,8] The products $\mathbf{4}^{Cl}$ and $\mathbf{4}^{MeO}$ were not completely purified, and no elemental analysis was carried out.

Polarographic Measurements. The cyclic voltammetry was carried out by using a Yanaco P-1100 Model Voltammetric Analyzer. Using tetrabutylammonium perchlorate (0.2 M, 1 M=1 mol dm^{-3}) as supporting electrolyte, the oxidation peak potential of $\boldsymbol{B}^{Me}$ in THF was observed and normalized according to the reported procedure.[5] The reduction potentials of nitro- and azoxy-arenes given in the text are redox potentials observed and normalized similarly; no sample of $\mathbf{1}^{Me}$ was available because it had been used up for the reaction of Scheme 2. All the values of potentials are those vs. NHE. The two internal standard compounds used for the measurements of oxidation peak and reduction potentials, respectively, are given in the text.

The gift of samples of BCTB by Prof. G. Gritzner, University of Linz, and Prof. K. Izutsu, Shinshu University, is gratefully acknowledged. The authors thank Mr. Kōji Matsuo for the attempted preparation of IDMg from 3- and 4-aminopyridines. The authors are grateful to the Ministery of Education, Science, and Culture for a financial support by a Grant-in-Aid for Scientific Research (No. 60470026).

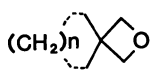
Reductive and Regioselective Cleavage of Oxetanes Assisted by the Neighboring Hydroxyl

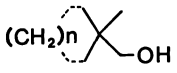
Michiharu KATO, Haruo KITAHARA, and Akira YOSHIKOSHI*
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai 980
(Received December 11, 1985)

Synopsis. On exposure to lithium aluminium hydride, 1,6-dioxadispiro[2.0.3.4]undecane and 5-methl-2-oxaspiro-[3.5]nonan-5-ol gave 1,2-dimethyl-*c*-2-(hydroxymethyl)-*r*-1-cyclohexanol (**5**) which was produced from regioselective C–O bond cleavage of oxetane rings by an intramolecular attack of hydride. The stereochemistry of **5** was confirmed by an unambiguous synthesis based on the Sharpless oxidation of 1-methyl-2-methylenecyclohexanemethanol.

On treatment with lithium aluminium hydride, oxetanes generally undergo reductive fission of their C–O bonds to produce alcohols.[1] On this reduction, it is known that boiling in tetrahydrofuran for several hours is an indispensable conditions for obtaining a reasonable reaction rate and yield.[2] While reduction of 2-oxaspiranes **1**(n=0—2) with this reductant led to the expected 1-methylcycloalkanemethanol **2**(n=0—2), 2-oxaspiro[3.5]nonane **1**(n=3) was reported to be exceptionally sluggish on the reduction.[3]

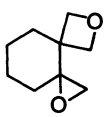


1

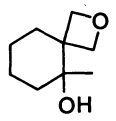


2

We wish to report here that treatment of 1,6-dioxadispiro[2.0.3.4]undecane (**3**) and 5-methyl-2-oxaspiro[3.5]nonan-5-ol (**4**),[4] derivatives of **1**(n=3) possessing additional oxygen functions, with lithium aluminium hydride resulted in unexpectedly facile and regioselective cleavage of their oxetane rings.

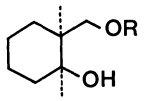


3



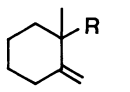
4

In the course of our synthetic study of a natural product, we have prepared hydroxy oxetane **4** in high yield by reduction of epoxy oxetane **3** with super hydride ($LiBHEt_3$).[4] When **3** was, on the other hand, treated with lithium aluminium hydride in place of the above reductant, the reduction proceeded smoothly even at room temperature, and the sole product obtained in 97% yield was not the hydroxy oxetane **4** but an unexpected diol, 1,2-dimethyl-*c*-2-(hydroxymethyl)-*r*-1-cyclohexanol (**5**). The diol **5** was also produced by treatment of **4** obtained above with lithium aluminium hydride under the same reaction conditions. Acetylation of the diol **5** with acetic anhydride in pyridine gave a crystalline acetoxy alcohol **6**, in which no evidence could be found for formation of its diastereomer.

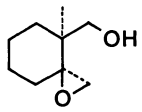


5 R=H
6 R=Ac

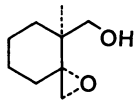
The stereochemistry of **5** was confirmed by an unambiguous synthesis starting with ethyl 1-methyl-2-oxo-cyclohexanecarboxylate.[5] Methylenation of the ester by the Wittig reaction with methylenetriphenylphosphorane provided unsaturated ester **7** in 60% yield, and the product was reduced with lithium aluminium hydride to the corresponding unsaturated alcohol **8** quantitatively. The alcohol **8** was then submitted to the Sharpless oxidation.[6] The reaction proceeded stereoselectively to provide hydroxy epoxide **9** in 73% isolated yield together with a small amount of its stereoisomer **10** (~1%).



7 R=CO_2Et
8 R=CH_2OH



9



10

It is reasonable to surmise that the stereoselectivity of the above reaction would be controlled by the syn-directive effect of the homoallylic hydroxyl group in **8**. In other words, the epoxide oxygen of the major product **9** can be expected to have a syn configuration with respect to the hydroxymethyl group on the basis of the well-documented stereoselectivity.[6] Finally, reduction of **9** with lithium aluminium hydride afforded a single diol, whose physical properties (IR and ^1H NMR) were identical with those of the diol **5** prepared from **3** or **4**.

Mechanistic rationalization for the facile and regioselective cleavage of the oxetane ring would be given as follows. Since treatment of 5-methylene-2-oxaspiro[3.5]nonane (**11**)[4] with lithium aluminium hydride also resulted in recovery of **11** in the same way as the reduction of **1**(n=3), it is demonstrated that the presence of a hydroxyl group α to the oxetane ring plays an important role for the reductive cleavage with great facility. Apparently, the hydride reacts initially with the hydroxyl group in **4** to afford an alkoxy hydride **12**, which is also derived from preferential reduction of the epoxide ring in the

course of reduction of **3**. Thus the facile reductive cleavage of the oxetane ring would occur by internal hydride attack based on neighboring assistance. In the intermediate **12**, energetically favorable chelation between the aluminium and oxetane oxygen atoms would be attained with the equatorially oriented alkoxide group, and this conformational fixation would also be convenient for the intramolecular attack of hydride at the oxetane methylene carbon in the anti position regarding to the alkoxide group.

Experimental

Melting points are uncorrected. IR spectra were obtained with a JASCO A-3 infrared spectrometer. ^{1}H NMR spectra were recorded on a JEOL FX90Q spectrometer. Gas chromatography was carried out on a JEOL JGL-20K gas chromatograph. Dry tetrahydrofuran (THF) was obtained by distillation over sodium benzophenone ketyl. Column chromatography was performed by using silica gel (Merck, kieselgel 60, 70—230 mesh), and kieselgel GF_{254} was employed for preparative thin-layer chromatography as an absorbent.

Lithium Aluminium Hydride Reduction of Oxetane 3. A mixture of **3**[4] (80 mg, 0.52 mmol), lithium aluminium hydride (30 mg, 0.78 mmol), and THF (5 ml) was stirred at room temperature for 5 h under nitrogen and quenched with wet ether. A solid was filtered and washed with ether, and the combined ethereal solutions were dried ($MgSO_4$). Removal of the solvent left an oil, which was purified by preparative thin-layer chromatography (50% ether in hexane as an eluent) and subsequent solvent removal gave 79 mg (96%) of **5** as a viscous oil: IR (neat) 3300 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.82 (3H, s, C-CH_3), 1.21 (3H, s, O-C-CH_3), 1.0—2.2 (8H, m), 3.0—3.9 (3H, m, CH_2-OH). The oil was used in the next reaction.

Acetylation of Diol 5. A mixture of **5** (45 mg), acetic anhydride (0.8 ml), and pyridine (0.4 ml) was stirred at room temperature for 20 h under nitrogen, and poured into ice-water. The solution was extracted with ether and the combined extracts were washed successively with water and brine, and dried ($MgSO_4$). Evaporation of the solvent left 54 mg (95%) of **6** as crystals. Analysis by gas chromatography (10%-SE-30, 2 m×1 mm; vaporizer, 250 °C; column temperature, 170 °C; helium flow, 1 kg cm^{-2}) indicated a single peak with retention time 2.8 min. An analytically pure sample was obtained by recrystallization from ether–hexane (1:1): mp 88—89 °C; IR (KBr) 3480, 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.99 (3H, s, C-CH_3), 1.21 (3H, s, O-C-CH_3), 1.2—1.8 (9H, m), 2.10 (3H, s, $COCH_3$), 4.13 and 4.23 (1H, d, J=11.1 Hz each, CH_2-O).

Found: C, 65.64; H, 10.02%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

Reduction of Hydroxy Oxetane 4 with Lithium Aluminium Hydride. A suspension of **4** (20 mg. 0.13 mmol) and lithium aluminium hydride (6 mg, 0.15 mmol) in THF (1 ml) was stirred at room temperature for 7 h under nitrogen and quenched with wet ether. A solid was filtered and washed with ether, and the combined extracts were dried ($MgSO_4$). Removal of the solvent left an oil, which was purified by filtration through a short silica gel column with 30% ether in hexane to give 18 mg (90%) of a viscous oil whose IR and ^{1}H NMR spectra were identical with those of diol **5** prepared above.

Ethyl 1-Methyl-2-methylenecyclohexanecarboxylate (7). To a stirred suspension of methyltriphenylphosphonium bromide (7.23 g, 20.2 mmol) in THF (40 ml) was added dropwise a solution of 1.5 M butyllithium in hexane (13.5 ml, 20.2 mmol) at 0 °C under nitrogen. The cooling bath was removed and the mixture was stirred at room temperature for 2 h. A solution of ethyl 2-methyl-2-oxo-1-cyclohexanecarboxylate (3.68 g, 20.2 mmol) in THF (5 ml) was added dropwise and stirring was continued for an additional hour at room temperature, and then at 60 °C for 10 h. After cooling to room temperature, water was added and the aqueous solution was extracted with ether. The combined extracts were washed successively with water and brine, and dried ($MgSO_4$). A residue obtained by concentration was chromatographed by eluting with 20% ether in hexane to give 2.04 g (60%) of **7** as a colorless oil: IR (neat) 3060, 1725, 1640, 890 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.23 (3H, t, J=7.2 Hz, $CO_2CH_2CH_3$), 1.30 (3H, s, C-CH_3), 1.1—1.8 (6H, m), 2.2 (2H, m, CH_2-C=), 4.18 (2H, q, J=7.2 Hz, $CO_2CH_2CH_3$), 4.78 and 4.87 (1H, br s each, C=CH_2).

Found: C, 72.15; H, 9.75%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

1-Methyl-2-methylenecyclohexanemethanol (8). To a stirred suspension of lithium aluminium hydride (237 mg, 6.25 mmol) in THF (10 ml) at 0 °C under nitrogen was added dropwise a solution of **7** (1.14 g, 6.25 mmol) in THF (2 ml). After removal of the cooling bath, stirring was continued for an additional 15 h at room temperature. The reaction was quenched by the addition of wet ether followed by a small amount of water. A solid was filtered and washed with ether, and the combined ethereal solutions were dried ($MgSO_4$). An oily residue obtained by evaporation was chromatographed by eluting with 50% ether in hexane to give 787 mg (90%) of **8** as a colorless oil: IR (neat) 3350, 3070, 1640, 900 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.08 (3H, s, CH_3), 1.1—1.8 (7H, m), 2.2 (2H, m, CH_2-C=), 3.38 (1H, d, d, J=10.4 and 7.2 Hz, C$H_a$$H_b$-O), 3.70 (1H, d, d, J=10.4 and 5.4 Hz, $CH_a$$H_b$-O), 4.75 and 4.87 (1H, s, with fine splittings each, =CH_2); ^{1}H NMR ($CDCl_3$-D_2O) δ=3.38 and 3.70 (1H, d, J=10.4 Hz each).

Found: C, 77.04; H, 11.80%. Calcd for $C_9H_{16}O$: C, 77.09; H, 11.50%.

Sharpless Oxidation of Homoallylic Alcohol 8. A solution of **6** (437 mg, 3.12 mmol) and vanadyl acetylacetonate (17 mg, 0.06 mmol) in dry benzene (8 ml) was warmed at 80 °C under nitrogen. A solution of 3M *t*-butyl hydroperoxide in toluene (1.2 ml, 3.43 mmol) was added dropwise to the above solution with stirring. Stirring was continued for an additional 2 h and, after cooling, the reaction was quenched by the addition of aqueous sodium hydrogensulfite solution followed by water. The benzene layer was separated and aqueous layer was extracted with benzene. The combined extracts were washed successively with water and brine, and dried ($MgSO_4$). An oily residue obtained by evaporation was chromatographed by eluting with 50% ether in hexane to give two products, **9** (355 mg, 73%) and **10** (4 mg, ~1%). **9**: IR (neat) 3400 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.98 (3H, s, CH_3), 1.1—2.2 (9H, m), 2.48 (1H, d, J=3.6 Hz, epoxide C$H_a$$H_b$), 2.9—3.58 (3H, m); ^{1}H NMR ($CDCl_3$-D_2O) δ=3.10 (1H, d, J=3.6 Hz, epoxide $CH_a$$H_b$), 3.15 and 3.44 (1H, d, J=11.2 Hz each, CH_2-O). Found: C, 69.20; H, 10.79%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%. **10**: IR (neat) 3400 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.13 (3H, s,

CH_3), 1.0—2.1 (9H, m), 2.55 (1H, d, J=3.6 Hz, epoxide CH_aH_b), 3.12 (1H, d, J=3.6 Hz with fine splittings, epoxide CH_aCH_b), 3.3—3.7 (2H, m); ^{1}H NMR ($CDCl_3$-D_2O) δ=3.25 and 3.55 (1H, d, J=11.2 Hz each, CH_2-O). Found: C, 68.90; H, 10.17%. Calcd for $C_9H_{16}O_2$: C, 69.12; H, 10.32%.

Reduction of Epoxy Alcohol 9 with Lithium Aluminium Hydride. A suspension of **9** (355 mg, 2.28 mmol) and lithium aluminium hydride (258 mg, 6.83 mmol) in THF (10 ml) was warmed with stirring at 50 °C for 15 h under nitrogen. After cooling to room temperature, the mixture was quenched with wet ether. A solid was filtered and the filtrate was dried ($MgSO_4$). Removal of the solvent left an oily residue which was purified by preparative thin-layer chromatography (70% ether in hexane as an eluent) to give 244 mg (93%) of a viscous oil, whose IR and ^{1}H NMR were identical with those of **5** prepared by reduction of **3**.

Treatment of Oxetane 11 with Lithium Aluminium Hydride. A suspension of **11** (25 mg, 0.18 mmol) and lithium aluminium hydride (14 mg, 0.36 mmol) in THF (2 ml) was stirred at room temperature for 20 h, and then at 60 °C for 5 h under nitrogen. After cooling to room temperature, the reaction was quenched with wet ether and a solid was filtered. The filtrate was dried ($MgSO_4$). An oily residue obtained by concentration was purified by passing through a short silica-gel column with 10% ether in hexane to give 21 mg of an oil whose ^{1}H NMR spectrum was identical with that of starting **11**.

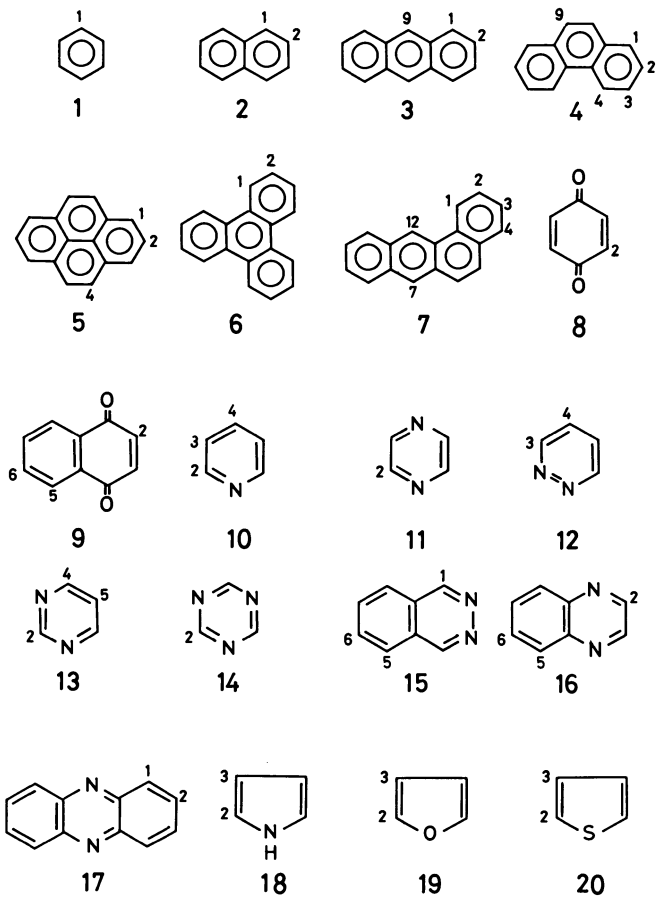
The H-1 NMR Solvent Shifts and Reactivity Parameters of Several Aromatic Compounds

Akihiro TAMAOKI and Kensuke TAKAHASHI*
Department of Industrial Chemistry, Nagoya Institute of Technology,
Gokiso-cho, Showa-ku, Nagoya 466
(Received September 25, 1985)

Synopsis. H-1 NMR solvent shifts were measured for 7 aromatic hydrocarbons and 13 heteroaromatic compounds. The chemical shifts can be correlated to the self-polarizabilities of the carbon atoms attached to the hydrogens in the aromatic hydrocarbons and will be of use in predicting the reactivities of the compounds. However, in the case of heteroaromatic compounds, no good correlation has been found between the reactivity parameters and the H-1 NMR solvent shifts.

The orientaion or, more quantitatively, the partial rate factor is an important problem in aromatic substitution reactions. The reactivities of the aromatic compounds can be expressed by various parameters. Several useful parameters are derived from the Hückel molecular orbital treatment.[1] Kuthan sought to present some correlation between the NMR chemical shifts and the reactivities.[2-6] However, Bartle and Jones[7,8] and Mallion[9] pointed out that the NMR shifts can be explained by the ring current and cannot be correlated with any reactivity parameters. We ourselves thought that the polarizability of the reaction center would be reflected in the solvent shifts of the relevant H-1 NMR and so have studied the correlation of the latter with various reactivity parameters.



Scheme 1.

Experimental

The reagents and solvents are from commercial sources. The reagents used and their numberings are given in Scheme 1. Three solvents, acetone, carbon tetrachloride, and cyclohexane, were used (hereafter they will be abbreviated as **S1**, **S2**, and **S3**). The H-1 NMR chemical shifts were obtained by extrapolating to an infinitely diluted state in the solvents. The values were referred to an internal TMS, with errors of ±0.03 ppm. If the solution was measured at a concentration under 0.3 mol%, its singly measured value was taken as the infinitely diluted one. Here, D is defined as $D=\delta(\mathbf{S1})-\delta(\mathbf{S3})$. Therefore, D is the difference between two infinitely diluted shifts in acetone and cyclohexane. The H-1 NMR spectra were recorded on a Hitachi R-20B spectrometer at 60 MHz and 31.5 °C. The Hückel MO calculations were carried out by a HITAC-8400 computer system installed in this Institute. The parameters used in the calculation are mostly taken from Streitwieser's book.[1]

Results and Discussion

The chemical shifts and D's of 7 alternant aromatic hydrocarbons and 13 heteroaromatic compounds are tabulated in Tables 1 and 2, along with several calculated reactivity parameters. The chemical-shift data shown in the tables are almost entirely consistent with those previously reported.[10-19]

Alternant Hydrocarbons. The hydrogens in question will hereafter be divided into two groups. One is a sterically compressed hydrogen (i.e., "angular protons" in Kuthan's nomenclature[4]), while the other is an ordinary one. The former is hydrogen which has a mutual interaction, such as the H-4 and the H-5 of phenanthrene.[4] The D values can be correlated with the self-polarizability, (π_{rr}),[20,21] of the carbon atom carrying the hydrogen in question, as is shown in Fig. 1. The compressed hydrogens are situated under a correlation line in Fig. 1. This means that the compressed hydrogens have small π_{rr} values or large D's. A correlated equation is derived for π_{rr} and D as follows: $\pi_{rr}=0.85D+0.26$. The correlation coefficient is about 0.885 for 15 data points except for three compressed hydrogens. The data show that the relative reactivities of the positions in a molecule can be evaluated well from the D values, but that those between different molecules are difficult to evaluate. For example, the calculated order of the π_{rr} values of three similarly positioned carbons is **3**-1>**2**-1>**4**-1, but the experimentally

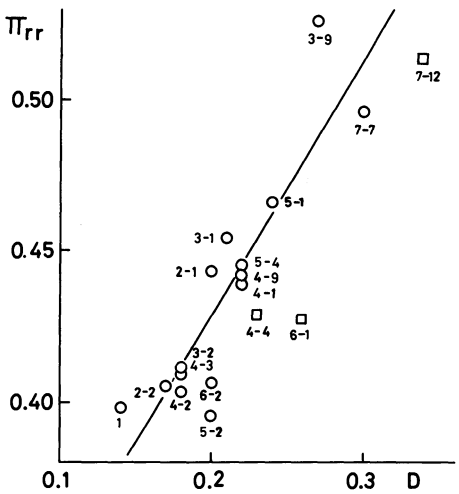

Fig. 1. Plot of self-polarizaility (π_{rr}, ordinate vs. solvent induced shift (D, abscissa). Rectangular show the values for the compressed hydrogens.

observed one of the D values is **4**-1>**3**-1>**2**-1. Here, **m**-n denotes the reference number of the compound (**m**) and the position (n) as given in Scheme 1. Large deviations of the self-polarizability from the correlation line in Fig. 1 were found for the hydrogens of **1**(0.019), **3**-9(0.037), **5**-2(−0.032), **6**-2(−0.024), and **7**-7(−0.019). It is strange that H(**3**-9) and H(**7**-7) show different signs for the deviation, although the hydrogens seem to be similar in their locations. The large deviation of **1** comes from its large π_{rr} value. Mallion stated that H(**5**-2) has a large deviation in the correlation between the chemical shifts and the free valences (F_r).[9] Bartle and Jones considered the

	(−0.039)	(0.893)	(−0.071)	(0.049)
π_{rr}	−0.098	0.445	−0.616	0.018
	(0.080)	(0.383)	(0.364)	(0.018)

a) The values are given for 10 sites except for those adjacent to the hetero atom, whose values are given separately in parentheses.

cause of the deviation to be the ring-current effect in the case of **5**.[7] On the other hand, Haigh et al. stated that the deviation of H(**5**-2) is smaller than either H(**5**-1) or H(**5**-4) in the correlation of the chemical shifts and ring current.[22] Therefore, the abnormally large deviation of H(**5**-2)(−0.032 in π_{rr}) cannot be explained only by the ring-current effect, as has been stated by Bartle and Jones.[7]

There are many reactivity parameters in addition to π_{rr}; several of them are given in Table 1, the values of which are mostly cited from Streitwieser's book.[1] The correlations between such parameters and D can, then, be evaluated by the following linear equation: $R=aD+b$, where R is a reactivity parameter and where a and b are constant parameters. The results are shown in Table 3. Among the four parameters in the table, S_r(E) has the best correlation coefficient, while π_{rr} has the smallest standard deviation. The latter parameters can now be evaluated from the H-1 NMR chemical shifts in order to compare the local positions in a molecule or those of several related molecules.[23]

Hetroaromatic Compounds. The heteroaromatic compounds studied are divided into 3 types: (A) 2 quinones (**8** and **9**), (B) 8 nitrogen-containing compounds (**10**—**17**), and (C) 3 five-membered compounds (**18**—**20**). The hydrogens adjacent to heteroatoms sometimes give abnormal D values. The correlations between the reactivity parameters and D are given in Table 4. As the table shows, the correlations are poor. One of the reasons for this is that the reactivity parameters are derived by the Hückel MO method, the simplest MO method, which may not be suitable even for a qualitative discussion of the properties of heteroaromatic compounds. One of the other reasons is the heteroatom effect. The heteroatoms considered here have lone-pair electrons. These will significantly affect the D values in various complex manners.

Dehydrogenation of Ethylbenzene on Potassium-Promoted Iron Oxide Catalysts Containing Various Transition Metal Oxides

Takenori HIRANO
Kasukabe Laboratory, Nissan Girdler Catalyst Co. Ltd.,
Ushijima 573, Kasukabe, Saitama 344
(Received November 12, 1985)

Synopsis. Various transition metal oxides, i.e., CeO_2, Cr_2O_3, ZrO_2, V_2O_5, WO_3, and MoO_3, were added to a potassium-promoted iron oxide catalyst to study their effects on the dehydrogenation activity of the catalyst. CeO_2 was found to promote styrene formation most strongly among the oxides examined, by lowering the activation energy.

The catalytic dehydrogenation of ethylbenzene is of importance in the manufacture of styrene, which is used for various processes such as the production of synthetic rubber and resins by polymerization. Potassium-promoted iron oxide with a minor amount of chromium oxide incorporated as a structural stabilizer, known as Shell 105, has widely been used in most dehydrogenation plants.[1] As the flow rate of ethylbenzene is high, even small improvements in the activity and selectivity of a catalyst bring about substantial advantages; it has recently been discovered that a potassium-promoted iron oxide catalyst containing minor but effective amounts of cerium oxide and molybdenum oxide but no chromium oxide exhibits a high selectivity at a high overall conversion level.[2] Dehydrogenation has extensively been studied on potassium-promoted iron oxide containing chromium oxide;[3] and reported in numerous patent papers, however, few basic studies on the catalysts containing other transition metal oxides, such as cerium oxide and molybdenum oxide, have been reported. In this work various transition metal oxides were added to the potassium-promoted iron oxide and the resulting effects upon the catalytic activity and selectivity were studied in the present work.

Experimental

All the catalysts examined were prepared by wet mixing of iron(III) oxide, potassium carbonate and a suitable amount of transition metal oxide; cerium(IV) oxide was initially added as carbonate, which decomposed to oxide in a calcination process. The resulting pastes were transformed into 3.2 mm dia. and 4—6 mm length extrudates; the extrudates were dried at 120 °C overnight and calcined at 600 °C for 4 h in the presence of air, then crushed into granules of 16/20 mesh before being used for the activity test. Each catalyst contained 28% potassium carbonate and 5 or 2.5% of a transition metal oxide, i.e., 5% of cerium(IV) oxide, chromium(III) oxide and zirconium(IV) oxide or 2.5% of vanadium(V) oxide, niobium(V) oxide, tungsten(VI) oxide, and molybdenum(VI) oxide, the rest was iron oxide. The activity test was carried out in a temperature range from 550 to 620 °C in the presence of steam; a steam to ethylbenzene molar ratio of 11.8 was maintained under atmospheric pressure. A differential-type reactor consisted of stainless steel (20 mm dia.) containing 3 g catalyst was used with a total SV of 39100 ml g^{-1} h^{-1}.** The products were condensed in an annular condenser; in addition to ethylbenzene (EB) and water, the condensate contained styrene (ST) and small amounts of benzene (Bz) and toluene (Tol). The surface area was measured by the BET method. The acidity and basicity of the catalysts were determined by the irreversibly adsorbed amounts of butylamine (nBA) at 80 °C and acetic acid (AA) at 130 °C, respectively, using the gas chromatographic pulse technique;[4] nBA pulses and AA pulses were fed into a U-tube containing 2 g of catalyst.

Results and Discussion

The activities measured for the various catalysts are given in Fig. 1: The natural logarithms of the rates of styrene, benzene and toluene formations at 580 °C are plotted against the electro-negativities (EN) of the transition metal oxides added; the EN values are the geometric means of Pauling's values[5] for the elements included in the oxides, calculated on the basis of the electronegativity equalization postulated by Sanderson.[6] It is found that all rates were

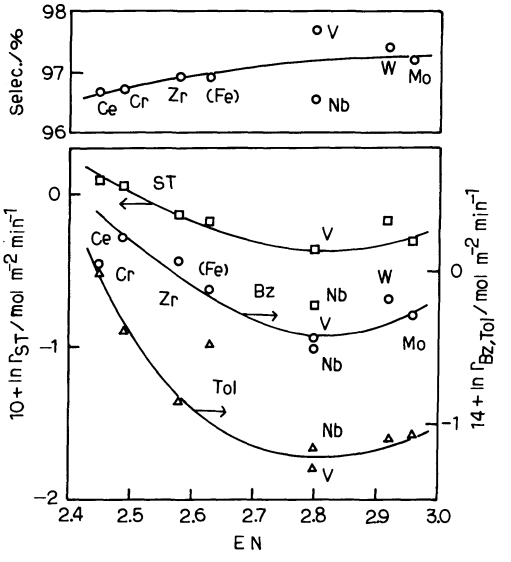

Fig. 1. Relations of the rates of ST, Bz, and Tol formation and the selectivity to ST with the EN of various transition metal oxides added to potassium-promoted iron oxide; 580 °C.

** The reaction rates were determined from the relation of $r=(F/S)\cdot X$, where F, S, and X represent the feed rate of ethylbenzene, the surface area of the catalyst, and the fraction of ethylbenzene converted into each product, respectively.

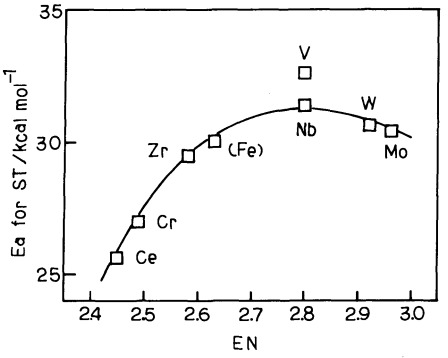

Fig. 2. Relation between the activation energies for ST formation and the *EN* of various transition metal oxides.

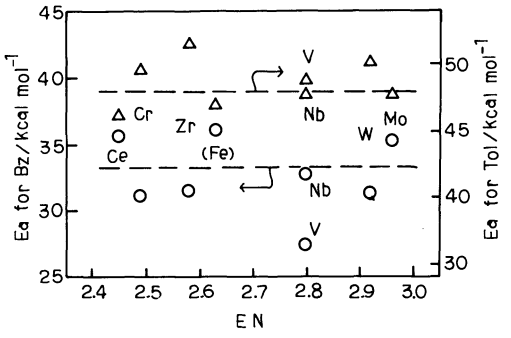

Fig. 3. Plots of the activation energies for Bz and Tol formations vs. *EN* of various transition metal oxides.

markedly influenced by the *EN* of the added oxides. All rates decreased with increasing the *EN*, then slightly increased after reaching the minimum at *EN* of 2.8, which corresponds to the promoters of vanadium oxide and niobium oxide. Since the extent of the initial reduction of the rate of toluene formation with the increase in *EN* was larger than those of styrene and benzene formations, the selectivity to styrene apparently increased with the increase in *EN*. Among the promoters examined, CeO_2 brought about the highest activity and V_2O_5 brought about the lowest activity, though the last promoter best improved the selectivity.

The activation energies (E_a) for the styrene, benzene and toluene formations over the various catalysts were obtained in a temperature range 550—620 °C, they are plotted in Figs. 2 and 3 against the *EN* values of the promoter oxides added. Indicated in Fig. 2 is a relation between the E_a for styrene formation and the *EN* of the promoters added. The change in E_a with *EN* seems to correspond to the behavior of the styrene formation rate with *EN*, given in Fig. 1: the E_a initially increased with the increase in *EN*, then slightly decreased after reaching a maximum. The CeO_2-containing catalyst had the lowest E_a of 25.6 kcal mol^{-1} (1 cal=4.184 J) and the highest rate of styrene formation. On the other hand,

Fe	—	15.0	2.15	0.34

a) Electronegativity of the transition metal oxide (M_aO_b) added to the potassium-promoted iron oxide catalyst, determined from the relation of $EN=(X_M{}^a \cdot X_O{}^b)^{1/(a+b)}$, where X_M and X_O mean Pauling's electronegativity of each element.[5,6] b) Adsorbed amount of butylamine at 80 °C. c) Adsorbed amount of acetic acid at 130 °C.

there seems to be no relation between the E_a for benzene or toluene formation and the *EN* of various promoters, as shown in Fig. 3. It is therefore suspected that the changes in the benzene and toluene formation rates with *EN*, shown in Fig. 1, are caused by the changes in the numbers of active sites for these formations by the additions of various promoter oxides.

The acid-base properties of the catalysts containing various promoter oxides were determined by the adsorption of butylamine at 80 °C and acetic acid at 130 °C, and are given in Table 1. It can be seen from the table that the *EN* of the promoter oxides added apparently influenced the acid-base property of the potassium-promoted iron oxide, although the correlation between the *EN* of promoters and the measured acid-base properties of the catalysts was not complete however there is a tendency that a promoter oxide of lower *EN* would give higher adsorbed amount of acetic acid, basicity, and lower adsorbed amount of butylamine, acidity, on the catalyst.

Consequently, it was found that the styrene formation rate increased and its E_a decreased as the *EN* of the transition metal oxide added decreased. Decreasing the *EN*, i.e., increasing the basicity of the promoter may give rise to the dehydrogenation activity of the catalyst, because each basic site is considered to abstract hydrogen from hydrocarbons,[7] especially β-hydrogen from ethylbenzene.[8] Cerium oxide was found to be the best promoter for accelerating the styrene formation, and a hydrogen-transfer reaction on this oxide was reported,[9] though the dehydrogenation itself has never occurred on a pure cerium oxide. Interestingly, increasing the *EN*, i.e., acidity, decreased the formations of benzene and toluene; this result is opposite to what has been considered: the decomposition of ethylbenzene has been considered to take place on the acidic sites of the

potassium-promoted iron oxide catalyst.[10]

(Received December 12, 1985)

Synopsis. 2-[4-(3-Methyl-2-butenyl)phenyl]propionic acid was synthesized in 82% yield via nickel(II) chloride or dichlorobis[η^5-cyclopentadienyl]titanium-catalyzed hydromagnesation of 1-(3-methyl-2-butenyl)-4-vinylbenzene obtained in ca. 63—68% yield by the coupling reaction of 4-(3-methyl-2-butenyl)phenylmagnesium chloride with vinyl chloride.

In the course of our synthetic study of analgesic and antiinflammatory drugs, attention was focused on a convenient synthesis of 2-[4-(3-methyl-2-butenyl)-phenyl] propionic acid (**1**).[1] As the prenyl moiety of **1** was relatively unstable in acidic media or in the presence of oxygen, the method previously employed[1] required multi-step reactions with troublesome handlings to obtain **1** of a high purity. On the other hand, it has been well known that the hydromagnesation reaction of styrene with nickel[2] or titanium[3] catalysts afforded 1-phenylethylmagnesium halides in good yield, which prompted us to apply this reaction to 1-(3-methyl-2-butenyl)-4-vinylbenzene (**3**). Herein we wish to describe a practical three-step synthesis of **1** starting from 1,4-dichlorobenzene (Scheme).

The coupling reaction of the Grignard reagent of 1-chloro-4-(3-methyl-2-butenyl)benzene (**4**)[4] with vinyl chloride was carried out by using iron(III)[5] or nickel(II)[6] catalysts (0.4 mol% vs. **4**) such as iron(III) acetylacetonate, iron(III) chloride, or [1,3-bis(diphenylphosphino)propane]dichloronickel(II) to obtain **3** in 63, 64, and 68% yield, respectively. Rectification of **3** was carried out under reduced pressure to separate (3-

a) 1.22 Equivalent (vs. **3**) of the Grignard reagent was used. b) Catalyst: Dichlorobis[η^5-cyclopentadienyl]titanium. c) Determined by GC (OV-1, 1m, 110 °C), using tridecane as the internal standard. d) Only polymerization was observed.

methyl-2-butenyl)benzene (10%), unreacted **4** (ca. 2%), and a trace amount of 4-(3-methyl-2-butenyl)phenol (ca. 0.2%). Then, the optimum conditions of the hydromagnesation reaction of **3** with nickel(II) catalysts were investigated by measuring the yield of 1-ethyl-4-(3-methyl-2-butenyl)benzene (**5**) generated from the intermediary Grignard reagents (**2a,b**) by quenching with water (Table 1). The best yield of **5** was achieved by using ethylmagnesium bromide in the presence of nickel(II) chloride catalyst (5 mol% vs. **3**) at 15—20 °C in THF solvent (Entry 3). Variation of the reaction temperature or the amount of catalyst resulted in the decrease of the yield of **5**. The Grignard reagents (**2a,b**) prepared according to the procedure of Entry 3, in turn, was reacted with carbon dioxide at −10 °C to obtain **1** in 82% yield with a trace amount of 3-[4-(3-methyl-2-butenyl)-phenyl]propionic acid (**6**, 1.5%).

An alternative method for hydromagnesation of **3** was also studied by using dichlorobis[η^5-cyclopentadienyl]titanium catalyst (Table 2). The Grignard reagents (**2a,b**) prepared according to the best procedure of Entry 12 was reacted with carbon dioxide to obtain **1** in also 82% yield. In this case, however, the undesirable regio-isomer (**6**) was formed up to 8% yield, which made the purification process troublesome to some extent.

In conclusion, we employed nickel(II) chloride as the catalyst of the hydromagnesation reaction of **3** in large scale experiments and succeeded in developing a practical three-step method for **1** starting from 1,4-dichlorobenzene.

Experimental

The boiling and melting points were uncorrected. The IR spectra were recorded with a Digilab FTS-20 C/D spectrometer. The NMR spectra were taken with a Varian XL-200 (with hexamethyldisiloxane as an internal standard). GC analyses were made by Shimadzu GC-7AG gas chromatograph using a 3 mm×100 cm column of OV-1 on Celite 545 with He as the carrier gas. 1-Chloro-3-methyl-2-butene is commercially available from Kuraray Co. Ltd., NIC-division.

1-Chloro-4-(3-methyl-2-butenyl)benzene (4). The procedure previously reported was used.[4] Into a solution of 4-chlorophenylmagnesium chloride in THF (2500 ml), prepared from 1,4-dichlorobenzene (438 g; 3 mol) and magnesium (80 g; 3.3 atom) was added 1-chloro-3-methyl-2-butene (343 g 3.3 mol) at 10—15 °C during 2 h. After stirring for 3 h, the reaction mixture was poured into aqueous ammonium chloride and extracted with ether to obtain **4** (361 g; 1.95 mol) in 65% yield. Bp 64—65.5 °C/0.38 mmHg (1 mmHg=133.322 Pa) [lit,[4] bp 84—88 °C/1.5 mmHg].

1-(3-Methyl-2-butenyl)-4-vinylbenene (3). Into a mixture of magnesium (87.6 g; 3.6 atom) in THF (84 ml) was dropped a solution of **4** (542 g; 3 mol) in THF (300 ml) at 110—120 °C during 2 h under nitrogen atmosphere and the mixture was stirred further for 5 h. Thus obtained viscid Grignard reagent of **4** was immediately diluted to 1.5 M solution (1M=1 mol dm^{-3}) by addition of 1630 ml of THF. The Grignard solution was added slowly into a mixture of vinyl chloride (250 g; 4 mol) and iron(III) acetylacetonate (4.5 g; 0.12 mol) in THF (1500 ml) maintaining the reaction temperature at 25—32 °C. After stirring for 2 h, the resulting mixture was poured into aqueous ammonium chloride and extracted with ether. Rectification of the products with a Shibata Fractional Distillation Apparatus Model HPC-A-1500-B(packing column, 70 theoretical plates) gave **3** (325 g; 1.9 mol) in 63% yield with a small amount of lower boiling products [bp 35—58 °C/0.1 mmHg] consisted of (3-methyl-2-butenyl)benzene (41 g; 0.285 mol), unreacted **4** (11 g; 60 mmol), and 4-(3-methyl-2-butenyl)phenol (1 g; 6 mmol). Bp 68—70 °C/0.2 mmHg. IR(neat) 2960, 2900, 1625, 1505, 980, 900, 820 cm^{-1}. ^1H NMR(in $CDCl_3$) δ=1.57—1.73 (m, 6H, 2×CH_3); 3.25 (d, J=7 Hz, 2H, CH_2); 5.0—5.4 (m, 2H, 2×=CH); 5.6 (d, J=18 Hz, 1H, =CH), 6.62 (dd, J=11 and 18 Hz, 1H, =CH); 7.0—7.35 (m, 4H, arom.). Found: C, 90.51; H, 9.42. Calcd. for $C_{13}H_{16}$: C, 90.64; H, 9.36.

2-[4-(3-Methyl-2-butenyl)phenyl]propionic Acid (1). Nickel-Catalyzed Hydromagnesation: Into a mixture of **3** (258 g 1.5 mol) and nickel(II) chloride (9.8 g; 75 mmol) in THF was slowly added a 1 M solution of ethylmagnesium bromide in THF (2250 ml; 2.25 mol) at 15—20 °C to react for 5 h. The reaction mixture was cooled to ca. −20 °C, and dry gaseous carbon dioxide was passed through the bottom of the apparatus maintaining the temperature below −10 °C. After the exothermic reaction stopped, the reaction mixture was poured into aqueous ammonium

chloride and extracted with diisopropyl ether. The organic layer was extracted with 10% aqueous sodium hydroxide (1200 ml; 3 mol). Then, the aqueous layer was neutralized with 0.5 M sulfuric acid and extracted with hexane. The product was purified by distillation under reduced pressure to obtain **1** (268 g; 1.23 mol) in 82% yield. Bp 130—135 °C/0.1 mmHg. IR (neat) 3450—2500, 1700, 1225, 750 cm^{-1}. ^1H NMR (in CCl_4) δ=1.42 (d, J=7.2 Hz, 3H, CH_3), 1.68; 1.8 (s, 6H, 2×CH_3); 3.20 (d, J=7.2 Hz, 2H, CH_2); 3.54 (q, J=7.2 Hz, 1H, CH); 5.18 (t, J=7.2 Hz, 1H, =CH); 6.80—7.12 (m, 4H, arom.); 11.83 (s, 1H, OH). Found: C, 76.94; H, 8.39. Calcd. for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31.

The distillation residue was purified by recrystallization from hexane to obtain 3-[4-(3-methyl-2-butenyl)phenyl]-propionic acid **6** (2.2 g; 10 mmol) in 0.7% yield. Mp 61—62 °C. IR (neat) 3300—2550, 1700, 1290, 940, 820 cm^{-1}. ^1H NMR (in $CDCl_3$) δ=1.72, 1.75 (s, 6H, 2×CH_3); 2.67 (t, J=8 Hz, 2H, CH_2) 2.92 (t, J=8 Hz, 2H, CH_2); 3.32 (d, J=7 Hz, 2H, CH_2); 5.33 (t, J=7 Hz, 1H, =CH); 7.13 (s, 4H, arom.); 10.88 (bs, 1H, OH). Found: C, 76.85; H, 8.35. Calcd. for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31.

Titanium-Catalyzed Hydromagnesation: Dichlorobis[η^5-cyclopentadienyl]titanium (75 mg; 0.3 mmol) was added to a mixture of **3** (1 g; 6 mmol) and propylmagnesium bromide in THF (7.2 mmol in 6 ml) at room temperature under argon atmosphere and the mixture was stirred for 5 h successively. After addition of a small pieces of solid carbon dioxide (ca. 3 g), the resulting mixture was treated as the same manner described before. The products were esterified with diazomethane and analyzed by GC (OV-1, 1 m, 140 °C) using nonadecane as an internal standard. The result showed the formation of **1** in 82% yield and **6** in 8% yield.

Thermically-Initiated Fluorinations at Saturated Carbon Atoms with Xenon Difluoride

Barbara ZAJC and Marko ZUPAN*
Institute "Jožef Stefan" and the Department of Chemistry, "E. Kardelj" University of Ljubljana, 61000 Ljubljana, Yugoslavia
(Received August 6, 1985)

Synopsis. The heating of several hydrocarbons with xenon difluoride at 95—120 °C in stainless steel reactors equipped with teflon jackets resulted in mono-, di-, and trisubstituted products.

It has been demonstrated that xenon difluoride reacts with several types of organic molecules but the main interest was directed towards the fluorination of alkenes, aromatic, and heteroaromatic molecules.[1-3] In most cases fluorinations have been carried out in a liquid phase and the presence of an appropriate catalyst has also been pointed out. On the other hand much less attention has been paid to reactions carried out at higher temperatures or in the vapor phase. Fourteen years ago Mackenzie and Fajer[4] reported that xenon difluoride also reacted with several aromatic molecules at temperatures between 100—200 °C but substitution reactions were also accompanied by the additional process, their extension depending on the structure of the substrate, molar ratio of xenon difluoride to the starting compound and temperature.

In our continuous interest in the fluorination of organic compounds with xenon difluoride we found it instructive to investigate reactions with several saturated hydrocarbons.

Results and Discussion

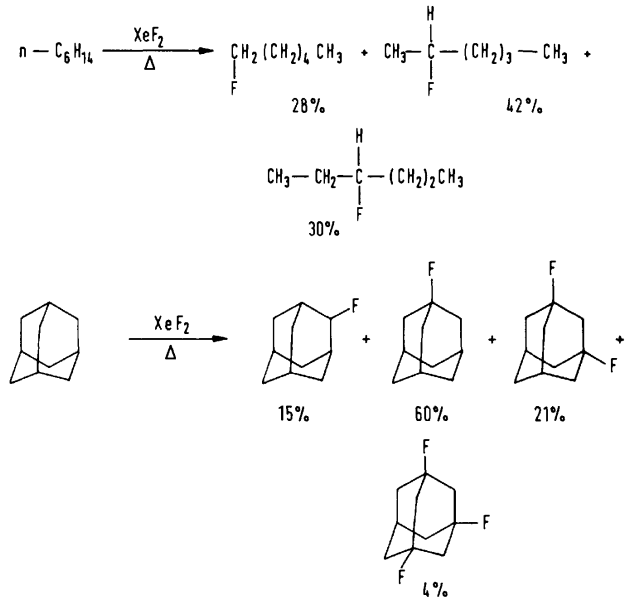
Direct substitution of hydrogen at a saturated carbon atom by fluorine represents a different problem from that of the introduction of chlorine or bromine[5] and several special techniques have been developed.[6] Adcock and coworkers[7] made an important contribution to direct fluorine introduction using a low temperature reaction of fluorine with an aerosol suspension of hydrocarbons. Barton and coworkers[8] recently found that functionalization of saturated carbon atoms is also possible with fluorine or CF_3OF but only one report on direct hydrogen atom substitution with xenon difluoride appeared and experimental details were so sparse that we were unable to repeat the direct fluorination of adamantane in CS_2 which should result in the formation of 1-fluoroadamantane.[9] Patrick and coworkers[10] have recently demonstrated that functionalization of a saturated carbon atom is also possible by xenon difluoride and they found that carboxylic acids are transformed to fluoro-substituted products by decarboxylation.

Mixtures of 2 mmols of several hydrocarbons, e.g. hexane or adamantane, with 2 mmols of xenon difluoride were heated in 20 ml sealed glass tubes up to 70 °C no reaction occurred. Further increases in temperature to 80—90 °C resulted in a violent reaction accompanied by flame and a complete decomposition of xenon difluoride, and the crude reaction mixture containing a small amount of unreacted substrate, hydrogen fluoride and tar was obtained. We then replaced the glass ampoules with 35 ml reflon jackets inserted in stainless steel containers and found that the heating of 2 mmols of cyclohexane and 2 mmols of xenon difluoride at 105 °C resulted in the complete decomposition of xenon difluoride. Again only tar was obtained. However, when the 35 ml teflon reactor was filled with 15 mmols of cyclohexane and 3 mmols of xenon difluoride and the mixture was heated for 2.5 h at 105 °C, the reaction mixture containing fluorocyclohexane with 18% yield (calculation based on xenon difluoride) was obtained. Reproducible fluorination of cyclohexane with xenon difluoride under the above-mentioned conditions could be observed only when the teflon jacket was thoroughly cleaned and dried.

The 2.5 h reaction of 15 mmols of hexane and 3 mmols of xenon difluoride at 105 °C resulted in the formation of three monofluoro-substituted products with a total yield of 15—20% (calculation based on xenon difluoride). Product distributions were determined by ^{19}F NMR and a good reproducibility of product distribution was observed (data stated in the Scheme are the average of three experiments and differ by only ±2%). It is evident from the product distribution that secondary carbon atoms are more reactive than primary to fluorine substitution by xenon difluoride.

Free radical reactions with adamantane have been studied in detail with the relative reactivity of C_1 and C_2 carbon strongly depending on the reagent, i.e. reaction with R_2N^+H proceeds 99% at C_1, reaction with $\cdot CCl_3$ proceeds 86% at C_1 while chlorination in CCl_4 yields nearly equivalent amounts of 1- and 2-chloroadamantane.[11] The 70 min reaction of 2 mmols of adamantane and 2 mmols of xenon difluoride in a teflon reactor at 105 °C gave a crude reaction mixture containing four fluoro-substituted products. Total yield of fluoro-substituted products, calculation based on xenon difluoride, was 18—20%. The yield of fluoro-substituted products was nearly doubled when instead of 2 mmols only 1 mmol of adamantane was used in the presence of 2 mmols of xenon difluoride while product distribution was only slightly influenced. Crude reaction mixtures were analyzed by ^{19}F NMR spectroscopy and product distribution resulting in the experiment using 2 mmols of adamantane is presented in the Scheme.

SCHEME



Pure samples of products were isolated by preparative GLC and structures were determined on the basis of spectroscopic data and their comparison with the literature. From the product distribution it is evident that the difference in reactivity between the secondary and tertiary carbon atoms in adamantane is much larger than that observed in hexane between the primary and secondary carbon atoms.

Experimental

IR spectra were recorded using a Perkin Elmer 727-B spectrometer and ^1H and ^{19}F NMR spectra by a Jeol JNM-PS-100 with Me_4Si or CCl_3F as the internal reference. Mass spectra and high resolution measurements were taken on a CEC-21-110 spectrometer. Gas liquid partition chromatography was carried out on a Varian 2700 Model.

Fluorination of Cyclohexane and Hexane. 15 mmols of hexane or cyclohexane and 3 mmols of xenon difluoride were placed in a teflon jacket (35 ml) which was inserted into a stainless steel container. The reaction mixture was heated for 150 min at 105±2 °C, cooled, after which 20 ml of ether was added to the reaction mixture, washed with aqueous $NaHCO_3$, water (twice), dried over Na_2SO_4, and the solvent partly evaporated under vacuum. Crude reaction mixtures were analyzed by ^{19}F NMR (octafluoronaphthalene was added as the internal standard). Fluorination of hexane resulted in the formation of three products with a total yield of 20% of fluoro-substituted products (calculation based on xenon difluoride). The crude reaction mixture contained the following three products: 1-Fluorohexane,[12] 2-fluorohexane,[13] and 3-fluorohexane[14] with relative yields of 28±2, 42±2, and 30±2%, respectively. The fluorination of cyclohexane gave only one product with a yield of 18% (calculation based on xenon difluoride) while pure fluorocyclohexane was isolated by preparative GLC (OV 17 10%, Chromosorb A 45/60, 60 °C), with 12% yield. Spectroscopic data are in agreement with those in the literature.[15]

Fluorination of Adamantane. 2 mmols of adamantane and 2 mmols of xenon difluoride were placed in a teflon jacket (35 ml) which was inserted into a stainless steel container. The reaction mixture was heated for 70 min at 105±2 °C, cooled and then 20 ml of ether were added to the reaction mixture, washed with aqueous $NaHCO_3$, water (twice), dried over Na_2SO_4, and the solvent evaporated under vacuum. The crude reaction mixture was analyzed by ^{19}F NMR, indicating the presence of four products: 1-fluoroadamantane, 2-fluoroadamantane, 1,3-difluoroadamantane, and 1,3,5-trifluoroadamantane with the following relative yields (determined by ^{19}F NMR): 60±2, 15±2, 21±3, and 4±0.5%, respectively. Separation of the combined crude reaction mixtures, obtained in three experiments, by GLC (OV-17 10%, Chromosorb A 45/60, 110 °C) gave pure 1-fluoroadamantane, 1,3-difluoroadamantane, and the mixture of 2-fluoroadamantane and 1,3,5-trifluoroadamantane, which were further separated by GLC (DNP 10% 3 m, Chromosorb W HP 80/100, 150 °C).

1-Fluoroadamantane: 35 mg (7.6%) of crystalline product, mp (sealed tube) 210—212° (mp_{lit} 210—212 °C),[16] NMR δF: −129.3 (broad s), δH: 1.6 (m, 6H), 1.9 (m, 6H), 2.2 (broad s, 3H). Mass spectrum: Calcd. for $C_{10}H_{15}F$ *m/z* 154.1158, found *m/z* 154.1155, *m/z* (rel intensity) 155 (M^++1, 11%), 154 (M^+, 87), 111 (20), 98 (39), 97 (100), 96 (34), 94 (21), 93 (31), 91 (10), 79 (19), 77 (14), 67 (12), 53 (10), 43 (26), 41 (24), 39 (27).

2-Fluoroadamantane: 8 mg (1.7%) of crystalline product, mp (sealed tube) 254—255 °C (mp_{lit} 254—255 °C),[17] NMR δF=−175 (dm, $^2J_{FH}$=51 Hz), δH=1.7 (m, 10H), 2.1 (m, 4H), 4.7 (dm, $^2J_{FH}$=51 Hz, 1H). Mass spectrum: Calcd for $C_{10}H_{15}F$ *m/z* 154.1158, found *m/z* 154.1160, *m/z* (rel intensity) 155 (M^++1, 12%), 154 (M^+, 100), 114 (41), 111 (12), 98 (14), 97 (27), 96 (13), 95 (15), 93 (34), 92 (26), 91 (19), 81 (13), 80 (21), 79 (51), 78 (15), 77 (17), 67 (17), 56 (12), 55 (10), 53 (12), 41 (25).

1,3-Difluoroadamantane: 13 mg (2.5%) of crystalline product, mp 239—240° (mp_{lit} 240—241 °C),[16] NMR δF=−137 (broad s), δH=1.5 (broad s, 2H), 1.8 (m, 8H), 2.1 (t, $^3J_{FH}$=5.5 Hz, 2H), 2.5 (broad s, 2H). Mass spectrum: Calcd for $C_{10}H_{14}F_2$ *m/z* 172.1063, found *m/z* 172.1065, *m/z* (rel intensity) 173 (M^++1, 8%), 172 (M^+, 66), 116 (25), 115 (89), 114 (31), 111 (32), 110 (10), 109 (10), 97 (52), 96 (17), 93 (15), 91 (10), 77 (13), 59 (14), 58 (44), 56 (19), 51 (10), 43 (100), 42 (13), 41 (22).

1,3,5-Trifluoroadamantane: 2.2 mg (0.5%) of crystalline product, mp (sealed tube) 243—245 °C (mp_{lit} 244—245 °C),[16] NMR δF=−142 (broad s), δH=1.8 (m, 6H), 2.1 (m, 6H), 2.5 (m, 1H). Mass spectrum: Calcd. for $C_{10}H_{13}F_3$ *m/z* 190.0969, found *m/z* 190.0966, *m/z* (rel intensity) 191 (M^++1, 10%), 190 (M^+, 91), 134 (22), 133 (81), 132 (28), 129 (28), 115 (100), 114 (14), 111 (26), 110 (10), 109 (16), 102 (10), 97 (18), 77 (13), 65 (10), 59 (26), 57 (14), 56 (67), 51 (17), 41 (18).

Rapid Spectrophotometric Determination of Scandium(III) with (Pyridylazo)- and (Thiazolylazo)naphthols

Chander Dhar SHARMA, Sujansingh G. NAGARKAR, and Muppalla C. ESHWAR*
Department of Chemistry, Indian Institute of Technology, Bombay-400 076, India
(Received April 15, 1985)

Synopsis. Scandium(III) reacts with 1-(2-pyridylazo)-2-naphthol [PAN] and 1-(2-thiazolylazo)-2-naphthol [TAN] in weakly acidic media to yield red colored 1:1 and 1:2 chelates, respectively. These complexes are sparingly soluble in water but readily soluble in ≥24% (v/v) acetone and ≥32% (v/v) methanol, giving maximum absorbances at 545 and 570 nm for the PAN and TAN complexes, respectively. Beer's law is obeyed over the concentration ranges of 0.16 to 1.40 μg and 0.08 to 1.40 μg of Sc(III) per ml with PAN and TAN. The scandium(III) complexes formed with PAN and TAN have the molar absorptivities of 1.90×10^4 and 2.93×10^4 $dm^3\,mol^{-1}\,cm^{-1}$ at their absorption maxima, respectively. The effect of diverse ions on the determination of scandium with these reagents is also investigated.

Pyridylazo and thiazolylazo dyes are sensitive chromogenic reagents for metal ions and a wide range of applications in analytical chemistry have been reported with these dyes. 5-Ethylamino-2-(2-pyridylazo)-*p*-cresol and 5-ethylamino-2-(2-thiazolylazo)-*p*-cresol[1] yield intensely colored complexes with scandium, but these reagents are relatively less selective for scandium(III). The reaction of scandium with 4-(2-pyridylazo)resorcinol [PAR] requires 10 min for complete color development[2] at room temperature and a large number of ions have been reported[2,3] to interfere. The complex formation between scandium(III) and 4-(2-thiazolylazo)resorcinol [TAR] is quite sensitive but a preliminary separation of scandium(III) by ion-exchange chromatography[4] is needed to prevent metal interferences. Among various other types of dyes, chrome azurol S has been widely studied[5–8] for the spectrophotometric determination of scandium. It has been found that the addition of various surfactants is very effective for obtaining intensely colored complexes. In the absence of surfactants, the method requires 90 min for full color development at room temperature. Even in the presence of surfactants, the reaction is not always instantaneous.[7,8] Similarly, the color development for the complexes with xylenol orange,[9] arsenazo I[10] and chromotrope 2B[11] requires 10 to 30 min at room temperature. The present method involves the instantaneous reactions of scandium(III) with 1-(2-pyridylazo)-2-naphthol [PAN] and 1-(2-thiazolylazo)-2-naphthol [TAN] at room temperature in the absence of any surfactant.

Experimental

Apparatus and Reagents. All absorbance measurements were made on a EC Spectrophotometer GS 866C with 10-mm cells. The absorption spectra were recorded on a Varian Superscan 3 UV-Visible Spectrophotometer. An EC-pH meter (Model 822) was used for pH measurements.

A 0.768 g amount of scandium oxide (AnalaR) was heated with 30 ml of concentrated nitric acid. The clear solution obtained was diluted to 250 ml with doubly distilled water and the scandium content [2.227×10^{-2} M(1 M=1 mol dm^{-3})] was verified complexometrically. A 0.5 g amount of 1-(2-pyridylazo)-2-naphthol, PAN [Fluka A.G. purum] was dissolved in 250 ml of acetone to give a 0.2% solution. A 0.1% (w/v) methanolic solution of TAN was prepared from 1-(2-thiazolylazo)-2-naphthol [Fluka A.G. purum]. A buffer solution of pH 5.0 was prepared from 0.05 mol dm^{-3} hydrochloric acid and 0.05 mol dm^{-3} hexamine (AnalaR) solutions.

General Procedure. An aliquot of solution containing ≤35 μg of scandium was taken, for both systems, in a 25 ml volumetric flask containing 5 ml of hexamine buffer adjusted to pH 5.0. After the addition of 3.5 ml of 0.2% PAN, the scandium(III) complex formed was dissolved in 10 ml of acetone. On the other hand, the scandium(III)–TAN complex obtained with 3.0 ml of 0.1% TAN was dissolved in 10 ml of methanol. The content was made upto 25 ml with doubly distilled water and the absorbance of the complex was measured against a reagent blank at 545 nm for the PAN complex or 570 nm for the TAN complex.

Results and Discussion

Scandium(III) reacts instantaneously with PAN and TAN in weakly acidic media to form sparingly soluble red-colored chelates, which are soluble in acetone and methanol, respectively.

Effect of pH. The pH of the reaction mixture was varied in both the systems from 1.0 to 10.0. A constant maximum absorbance was observed in the pH range 4.5—5.5 and 4.2—5.6 for the scandium(III)–PAN and scandium(III)–TAN systems, respectively. Hence all the studies were carried out in a hexamine–hydrochloric acid buffer solution adjusted to pH 5.0.

Effect of Reagents Concentration. Volume of 0.2% PAN was varied from 0.2 to 5.0 ml for 25 μg of scandium(III), a constant maximum absorbance being obtained on addition of ≥3.0 ml reagent. Similarly for the same amount of scandium(III), a constant maximum absorbance was obtained on addition of ≥2.2 ml of 0.1% TAN. Thus, 3.5 ml of 0.2% PAN or 3.0 ml of 0.1% TAN was employed in further studies.

Choice of Solvent. It was found that, of the solvents examined, acetone and methanol were the best solvents for dissolving the PAN and TAN complexes, respectively. Since these complexes exhibited maximum absorbance in the solutions containing ≥24% (v/v) acetone and ≥32% (v/v) methanol, 10 ml each of acetone and methanol was employed to dissolve the complexes with PAN and TAN, respectively.

Table 1. Effect of Diverse Ions
(Amount of scandium(III) 25 μg/25 ml)

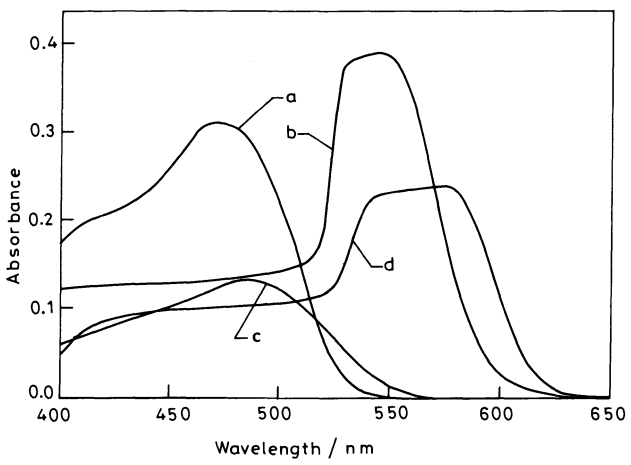

Fig. 1 Absorption Spectra.
Curves a): Reagent blank vs. solvent, [PAN] = 4.02×10^{-4} mol dm^{-3}. b): Sc(III)-[PAN] complex vs. reagent blank, [Sc(III)] = 1.78×10^{-5} mol dm^{-3}, [PAN] = 1.12×10^{-3} mol dm^{-3}. c): Reagent blank vs. solvent, [TAN] = 7.84×10^{-6} mol dm^{-3}. d) Sc(III)-TAN complex vs. reagent blank, [Sc(III)] = 7.77×10^{-6} mol dm^{-3}, [TAN] = 4.71×10^{-4} mol dm^{-3}.

Stability. The scandium(III) complexes thus formed are stable for 24 h (PAN complex) and 10 h (TAN complex).

Spectral Characteristics. The absorption spectra of the scandium(III) complexes with PAN and TAN and those of the respective reagent blanks are given in Fig. 1. The PAN and TAN complexes exhibited their absorption maxima at 545 and 570 nm, respectively.

Composition of Complex. The composition of the Sc(III)-PAN and Sc(III)-TAN complexes, established by the mole ratio method and the Job's method, was found to be 1:1 and 1:2, metal-to-ligand, ratios respectively.

Beer's Law and Sensitivity. The Sc(III)-PAN and Sc(III)-TAN complexes obeyed Beer's law over the concentration ranges 0.16 to 1.40 μg and 0.08 to 1.40 μg respectively of scandium(III) per ml, the molar absorptivities being 1.90×10^4 (at 545 nm) and 2.93×10^4 (at 570 nm) $dm^3\,mol^{-1}\,cm^{-1}$; the Sandell sensitivities, 2.30 and 1.50 ng cm^{-2}, respectively.

Effect of Diverse Ions. The effect of various anions and cations was studied in both the systems by setting the tolerance limit at an amount to cause an

error of ±2.0% in the determination of scandium. The effect of diverse ions is presented in Table 1.

Precision and Accuracy. The coefficient of variation and the relative mean error, calculated from ten replicate determinations with 25 μg of scandium(III), were found to be ±0.86 and ±0.98% for the scandium–PAN system and ±0.90 and ±1.41% for the scandium–TAN system.

A Study of the Reactivity of Surface-Adsorbed Oxygen Species with C_2H_6 on V_2O_5/SiO_2

Eiji IWAMATSU, Ken-ichi AIKA,* and Takaharu ONISHI
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227
(Received October 30, 1985)

The properties and reactivities of surface oxygen species including O^- on V_2O_5/SiO_2 were studied in connection with the oxidative dehydrogenation of C_2H_6 by N_2O. O^- was formed through N_2O on reduced V_2O_5 supported on SiO_2 which had been prepared from tetraethyl silicate, whereas it was not formed on V_2O_5 supported on SiO_2 obtained from other sources. One mole of O^- on V_2O_5/SiO_2 was found to react with one mole of C_2H_6 at 298K. No oxygen species other than O^- reacted with C_2H_6 at 298K. The surface reaction mechanism was discussed, and ethoxide was considered to be one of the surface intermediates. All the other surface oxygens but O^- reacted with C_2H_6 above 573K. Since a catalytic oxidative dehydrogenation reaction of C_2H_6 was active above 573K, the surface oxygens other than O^- were considered to be responsible for this reaction. The possibility of O^- as the reaction intermediate was also discussed.

Paramagnetic oxygen species, such as O^-, O_2^-, and O_3^- have been studied on oxide catalysts by means of EPR techniques.[1] O^- on the MgO surface has been found to react with alkanes under mild conditions, and the mechanism of the surface reaction has been studied.[2] On the other hand, as O^- is formed through N_2O, several attempts at getting useful products by means of the reaction of N_2O with alkane have been carried out. Methanol and formaldehyde have been obtained selectively over MoO_3/SiO_2 and other oxide systems by a reaction of CH_4 with N_2O in the presence of H_2O.[3,4] Phenol has also been obtained by a reaction of benzene with N_2O under similar conditions.[5] In these works, O^- is treated as an active intermediate.[3-5] However, since the conditions of O^- formation are very different from the conditions of the catalytic reactions, no relationship between the catalytic reactions and the surface reactions involving O^- have yet been studied well. The present authors intended to study both the catalytic reaction of C_2H_6 oxidation and the surface reaction of O^- with C_2H_6 on the same catalyst. C_2H_6 was used for the reactant because of the ease of handling and product analysis. V_2O_5/SiO_2 was chosen because it was an active catalyst of C_2H_6 oxidation and because it was a rare system in yielding O^- from O_2.[6] The reaction of O^- with hydrocarbons on this catalyst has not been studied extensively, although the reactivity of O_2^- has been studied well.[6] Thus, we will start by investigating the conditions of O^- formation and will thus study the surface reactivity of both O^- and other surface oxygen species on V_2O_5/SiO_2; finally, these results will be compared with the catalytic performance of the oxidative dehydrogenation reaction of C_2H_6 by the use of N_2O.

Experimental

Materials. Three kinds of SiO_2 were used as supports. SiO_2(A): A reference catalyst supplied by the Catalysis Society of Japan (JRC-SIO-1). SiO_2(B): Obtained by the hydration of tetraethyl silicate in a water–ethanol mixture at boiling point, followed by evaporation at 353K and calcination at 773 K for 5 h.[6] SiO_2(C): Commercial powdered silica (Cab-O-Sil). V_2O_5/SiO_2 was prepared by the impregnation of SiO_2 with 0.3 mol L^{-1} ammonia solution containing ammonium metavanadate (Wako Pure Chemical). The V_2O_5 content was 2.6% by weight. The supported catalysts were calcined at 773 K for 10 h. Unsupported V_2O_5 obtained from Wako Pure Chemical was also used.

Apparatus and Procedure. The surface reactions and catalytic reactions were carried out in a conventional closed-circulation system. Two g of the catalyst were used. The condensable gases are purified by vacuum distillation in the apparatus. The helium was purified through a copper-Kieselgur column. The reactants and products were analyzed by means of a gas chromatograph (FID, TCD) with Porapak Q and MS 5A columns. The EPR spectra were recorded with a JEOL JES-FE-1X spectrometer (X-band) at 77 K. The concentrations and g-factors of O^- were determined by a method similar to one described elsewhere.[2] The catalysts were evacuated at 773 K for 3 h and then oxidized with O_2 at the same temperature overnight before use (standard pretreatment). CO was used as a reduction agent, and the degree of reduction, as measured by CO_2 production, was represented by the percentage change of the V^{5+} ion to the V metal.

Results

Formations of Surface-Adsorbed Oxygen Species. N_2O decomposition took place at 298 K over V_2O_5/SiO_2(B), which had been reduced by CO at 693 K overnight. About 6×10^{-2} mmol of N_2 was produced in 15 min, but O_2 was not produced on this catalyst, unlike as in the Co-MgO system.[7] Following the N_2O decomposition, a concentration of the O^- thus produced was determined by the EPR measurement, while the amount of adsorbed oxygen was determined from the amount of N_2 produced. These values are plotted as a function of the reduction temperature in Fig. 1, where the degree of reduction is also shown. It may be seen that the amounts of O^- are much less than those of the total oxygen adsorbed. The material balance of N_2O suggested that a comparable number of N_2O atoms were also adsorbed as well as oxygen atoms. It

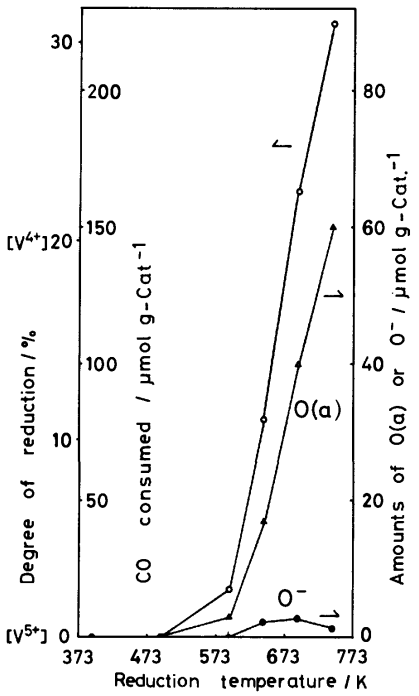

Fig. 1. Variation of the reduction degree of the catalyst and the amount of adsorbed oxygen and O^- after N_2O treatment as a function of the reduction temperature on 2.6wt%V_2O_5/SiO_2(B). 100% reduction corresponds to the whole reduction of V^{5+} ion to V metal.

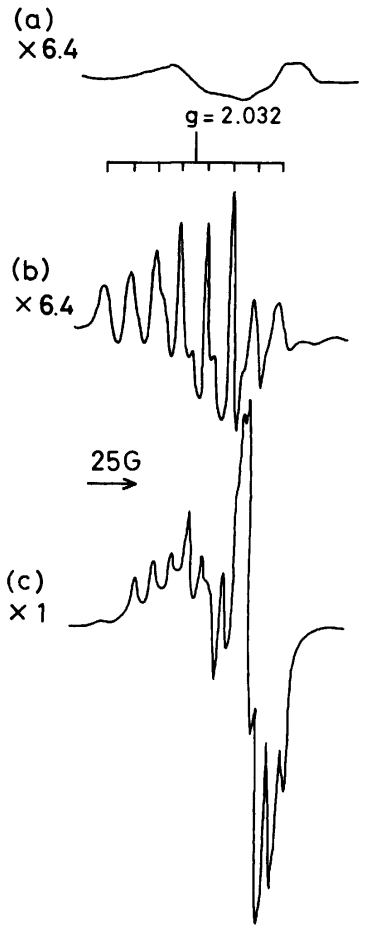

Fig. 2. EPR spectra of 2.6wt% V_2O_5/SiO(B); (a) sample reduced by CO at 693K for 15 h: (b) Sample contacted with N_2O at 298K after (a): (c) Sample contacted with O_2 at 298K after (b).

may also be seen that the concentration of O(a) is roughly proportional to the degree of reduction. It should be noted that O^- was not observed on other V_2O_5 systems, such as V_2O_5/SiO_2(A), V_2O_5/SiO_2(C), or unsupported V_2O_5, after the same pretreatment. O^- was not formed through O_2(1.5 Torr (1 Torr=133.3 Pa)), even on the well-reduced V_2O_5/SiO_2(B), where just O_2^- was produced. The amount of O_2^- produced from O_2 was about ten times more than that of the O^- produced from N_2O.

Stability of O^-. Figure 2 shows an EPR spectrum of V_2O_5/SiO_2(B) (a) after a standard pretreatment (reduction by CO at 693 K) and (b) after the introduction of N_2O at 298 K. The two peaks in Fig. 2(a) were assigned to parts of the octet spectra of the V^{4+} ions. The spectra in Fig. 2(b) was identified with O^- (g=2.032), for they show a hyperfine structure (A=13.2G) attributable to the V nucleus. After the gas phase had been evacuated, O_2 was introduced. The resultant EPR spectra are shown in Fig. 2(c); they should be identified with O_2^- ($g_{//}$=2.021, $A_{//}$=9.8G; $g_\perp$=2.003, $A_\perp$=6.0G).[6] Contrary to the cases of MgO[1] and Co-MgO,[7] where O^- reacted with O_2 giving O_3^-, no new signals showing O_3^- were observed. Instead, O_2^- was observed. The amount of O_2^- was about ten times that of O^-. As is observed at a low magnetic field in Fig. 2(c), a weak peak which is identified as a part of the O^- spectrum remains. This suggests that at least a part of the O^- does not react with O_2. Probably, O_2 is adsorbed on the other sites, independent of the sites for O^- formation.

The thermal stability of O^- was studied in an evacuated sample tube. The amounts of O^- were not changed, even after 260 h at 77 K. They decreased to two-thirds of the initial value after 100 h at 195 K. Finally, most of the O^- disappeared after 1 h at 373 K. The O^- on V_2O_5/SiO_2 was found to be thermally unstable above 373 K. Thus, it seems questionable that such O^- exists in a practical oxidation reaction at an elevated temperature.

A Surface Reaction between the O^- Anion Radical and C_2H_6. After the concentration of O^- had been determined, an excess amount of C_2H_6 was introduced to the catalyst at 298 K for 20 min. The O^- spectra (Fig. 2(b)) completely disappeared upon a reaction with C_2H_6 at 298 K. However, the V^{4+} signal (Fig. 2(a)) remained.

The reaction stoichiometry between O^- and C_2H_6 was also studied. The amount of O^- was controlled by changing the reduction conditions. The maximum concentration of O^- on V_2O_5/SiO_2(B) was several times larger than those on MgO[2] and Co-MgO.[9] As is shown

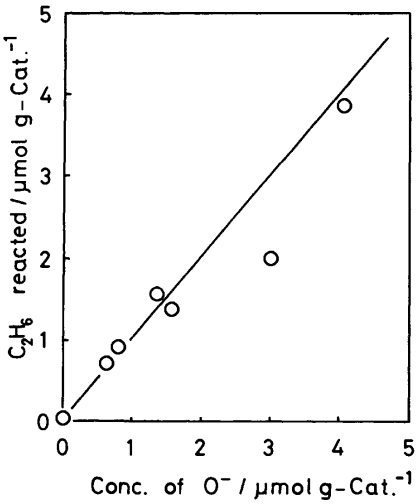

Fig. 3. Variation of the amount of C_2H_6 reacted with O^- at 298K as a function of the concentration of O^- evaluated from its EPR spectrum. 2g of 2.6wt% V_2O_5/SiO_2(B) was used as a sample.

in Fig. 3, one mole of O^- was proved to react with one mole of C_2H_6 as has been observed in the case of MgO.[2] It was also proved that C_2H_6 hardly reacted at all with other oxygen species on this catalyst at 298 K (see the zero point in Fig. 3). Contrary to this, it has been reported that adsorbed oxygen other than O^- also reacts with C_2H_6 at 298 K on Co-MgO.[9] No gas-phase products were observed by the surface reaction at 298 K.

TPD Behavior Following the Surface Reaction between O^- and C_2H_6 at 298 K. In order to assign the adsorbed species formed by the surface reaction between O^- and C_2H_6 on V_2O_5/SiO_2(B), temperature-programmed-desorption (TPD) experiments were carried out. After the gas phase had been evacuated, 100 Torr of He was introduced into the reactor. The temperature was then raised step-by-step while desorption products were trapped at 77 K in the closed circulation system. Figure 4 shows the accumulated amounts of desorption products as a function of the temperature. The main product, C_2H_4, desorbed above 473 K. The products recovered up to 773 K corresponded to 18% of the total carbon reacted. In order to discuss the adsorbed species, the TPD patterns of the model compounds were compared with the above results. The TPD pattern of adsorbed ethanol is shown in Fig. 5. However, the starting temperature of C_2H_4 desorption was higher in Fig. 5 that in Fig. 4. In this case, 94% of the adsorbed carbon source was recovered up to 773 K. On the other hand, the TPD products of adsorbed acetaldehyde, which were C_1 to C_4 alkanes and C_2H_4, were quite different from those in Fig. 4 and 5. In this instance, 41% of the adsorbed carbon source was recovered.

The Reaction between C_2H_6 and Adsorbed Oxygen Species other than O^- above 573 K. Following the N_2O decomposition on V_2O_5/SiO_2(B) at 298 K, the

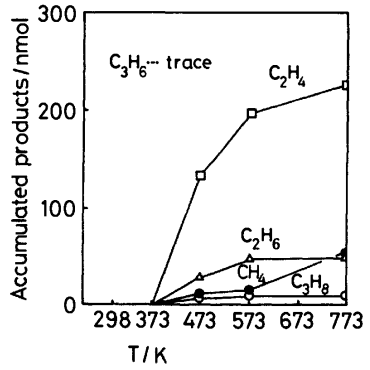

Fig. 4. TPD of surface species following the surface reaction of C_2H_6 and O^- at 298K on 2.6wt%V_2O_5/SiO_2(B) (2g).

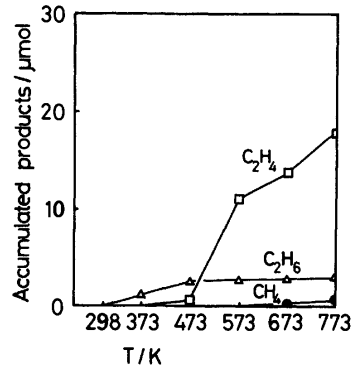

Fig. 5. TPD of C_2H_5OH adsorbed at 298K on 2.6wt%V_2O_5/SiO_2(B) (2g).

O^- produced was consumed by the reaction with C_2H_6 and the gas phase was evacuated. Then, C_2H_6-He gas was introduced again, and the temperature was raised. C_2H_6 reacted above 573 K yielding C_2H_4 as is shown in Fig. 6. The adsorbed oxygen was proved to be much less reactive than O^-.

Oxidative Dehydrogenation Reaction of C_2H_6 with N_2O above 573 K (Catalytic Reaction). In order to examine the role of O^- and the other oxygen species during the catalytic reaction over V_2O_5/SiO_2, a reaction between C_2H_6 and N_2O was carried out. Two kinds of catalysts, V_2O_5/SiO_2(A) and V_2O_5/SiO_2(B) (2 g each), were used. The catalysts were evacuated at 773 K for 3 h (Pretreatment a) or reduced by CO at 693 K overnight after the evacuation (Pretreatment b). Figure 7 shows a typical example of the time course of the reaction over V_2O_5/SiO_2(B) at 773 K after Pretreatment a. Both C_2H_4 and CO_2 were formed, while C_2H_4 was predominant in the early stage of the reaction. Figure 8 shows the conversions and the C_2H_4 selectivities of the reactions in 15 min over the two catalysts with the two kinds of pretreatments as a function of the reaction temperatures. When these figures are compared, the following facts are observed: 1) The reaction behavior over V_2O_5/SiO_2(B) (Fig. 8(c), (d)) and V_2O_5/SiO_2(A) (Fig. 8(a), (b)) resemble one another, although only the first sample can yield O^-. 2) The activity of N_2O

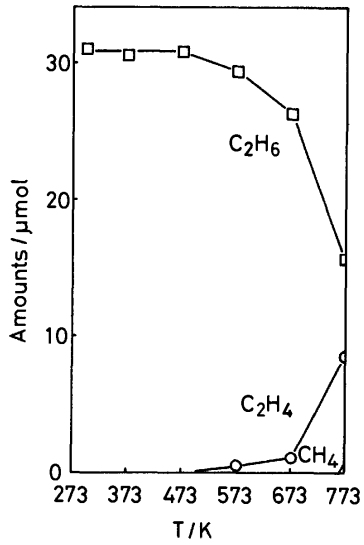

Fig. 6. Reaction of C_2H_6 with adsorbed oxygen other than O^- on 2.6wt%V_2O_5/SiO_2(B). Changes of the amount of the reactant and the products as a function of a reaction temperature.

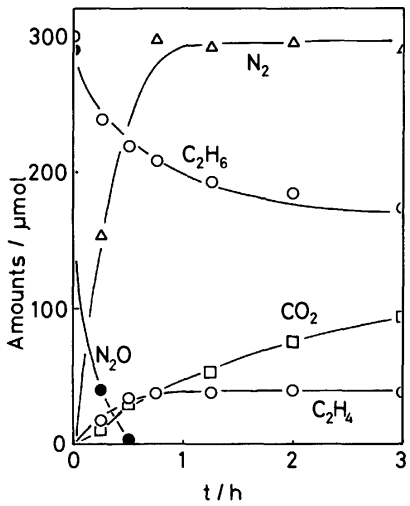

Fig. 7. Time course of the reaction between N_2O and C_2H_6 at 773K on V_2O_5/SiO_2(B) (2g) which is not reduced before the reaction.

decomposition at a lower reaction temperature was high over the samples treated with the Pretreatment b (Fig. 8(b), (d)), perhaps because N_2O was partly consumed to reoxidize the reduced V_2O_5. 3) On oxidized surfaces (Pretreatment a), the N_2O decomposition and the oxidation of C_2H_6 start at the same temperature (573 K in Fig. 8(a), (c)). This also roughly coincides with the temperature at which the adsorbed oxygen other than O^- reacts with C_2H_6 (Fig. 6). 4) The selectivity for C_2H_4 is rather high at higher temperatures (673 to 773 K).

Discussion

Conditions of O^- Formation. As is shown in Fig. 1, the O^- concentration is the highest under the reduc-

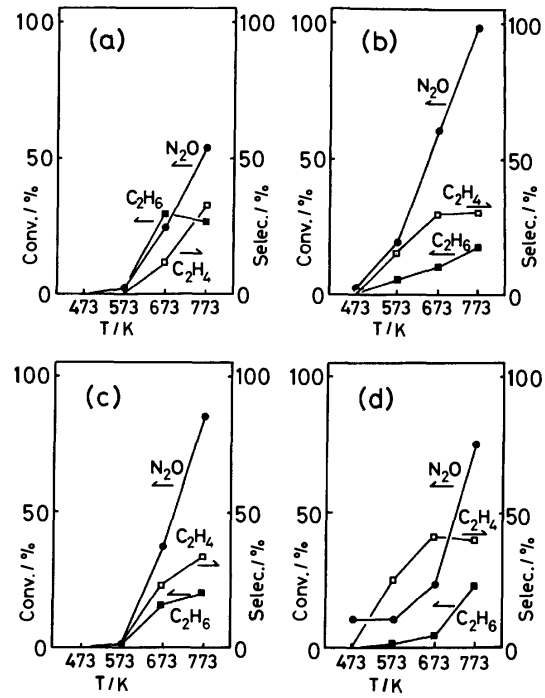

Fig. 8. Conversions and selectivities of the reaction between C_2H_6 and N_2O over 2g of various vanadium catalysts; (a) non reduced 2.6wt%V_2O_5/SiO_2(A): (b) reduced 2.6wt%V_2O_5/SiO_2(A): (c) non reduced 2.6wt%V_2O_5/SiO_2(B): (d) reduced 2.6wt%V_2O_5/SiO_2(B).

tion at 693 K, where the reduction of V^{5+} to V^{4+} is completed (22% of reduction). This suggests that V^{4+} ions are necessary for the formation of O^- ($V^{4+}+N_2O \rightarrow V^{5+}-O^-+N_2$). Furthermore, the formation conditions also depend upon the kind of support. Probably the circumstance of the vanadium ion, which might be controlled by the surface state of the SiO_2 support, is important. In order to investigate any differences among the vanadium ions of the samples, the EPR spectra of V^{4+} ions of the 4 samples used in this work were compared. The shapes of the EPR spectra of V^{4+} were classified into three kinds. However, the shapes of the spectra are not related to the conditions of O^- formation. V_2O_5/SiO_2(B) and V_2O_5/SiO_2(C) have spectra of the same shape, although only the former is active in O^- formation. The nature of the site for O^- formation could not be clarified in detail.

O^- could not be formed through O_2 under the same conditions as in the literature.[6] It has been reported that O^- is formed only when the pressure of O_2 is low (several Torr).[6] It seems that the conditions in our system are too restricted.

Surface Reactions of O^- and C_2H_6 at 298 K. One-to-one stoichiometry between O^- and C_2H_6 was found more clearly on V_2O_5/SiO_2 than on other systems. Thus, O^- is considered to abstract one hydrogen atom from C_2H_6, as has been suggested in the case of MgO.[2]

$$C_2H_6 + O^- \longrightarrow C_2H_5\cdot + OH^- \quad (1)$$

The subsequent reactions of the ethyl radical to form surface ethoxide and hydroxide are assumed to be as in Eqs. 2 and 3, because ethylene desorption still occurs at 573 K (Fig. 4), at which point ethoxide decomposition is observed (Fig. 5):

$$C_2H_5\cdot + O^{2-} + \square \longrightarrow C_2H_5O^- + \boxed{e^-} \quad (2)$$

$$C_2H_5O^- \longrightarrow C_2H_4 + OH^- \quad (3)$$

However, as is shown in Fig. 4, a majority of ethylene desorbs at lower temperature (473 K). This may suggest the existence of an other intermediate, for example, a carbonium ion, which releases ethylene at a lower temperature, as has been discussed in the case of MgO.[2]

$$C_2H_5\cdot + \square \longrightarrow C_2H_5^+ + \boxed{e^-} \quad (4)$$

$$C_2H_5^+ + O^{2-} \longrightarrow C_2H_4 + OH^- \quad (5)$$

Since the amount of recovered carbon atoms was low (18%), other processes, such as the polymerization of ethylene or further oxidation, might also occur.

Active Oxygen Species in the Oxidative Dehydrogenation of C_2H_6 by N_2O above 573 K. As has been described earlier, the adsorbed oxygen other than O^- is reactive above 573 K, where the catalytic reaction occurs. On the other hand, O^- reacts with C_2H_6 even at room temperature, and it is not thermally stable. After all, O^- is not considered to be present during the catalytic reaction conditions. The active species during the oxidative dehydrogenation above 573 K was considered to be the adsorbed oxygen other than O^-. This is also supported by the fact that the reactivity of V_2O_5/SiO_2 is not related to the ability to produce O^-.

If there are new circumstances under which only O^- is formed at a high temperature with a dynamic balance of O^- evolution and disappearance, the possibility that O^- is involved in the reaction should be discussed.[10] It should also be pointed out that an oxygen species which is not detected by EPR is also very active against C_2H_6, even at room temperature.[9] Regarding this system too, the authors suggest the importance of an adsorbed oxygen other than O^- as the active species of the reaction at the higher temperature.

Conclusions

The nature of O^- and the surface reaction mechanism between O^- and C_2H_6 were studied in order to elucidate the catalytic oxidative dehydrogenation of C_2H_6 with N_2O over V_2O_5/SiO_2. V_2O_5 must be supported on SiO_2 made from tetraethyl silicate in order to get O^-, and the amount of O^- formed is related to the concentration of V^{4+}. One mole of O^- is proved to react with one mole of C_2H_6 on V_2O_5/SiO_2 at 298 K. The adsorbed oxygen species other than O^- is less reactive than O^- toward C_2H_6. This species, EPR-undetectable oxygen, was found to be reactive with C_2H_6 above 573 K, and it is considered to be responsible for the catalytic reaction of C_2H_6 with N_2O above 573 K.

Phase-Shift Studies of the Quenching of NH($c^1\Pi$) by HN_3, NO, CO, and CO_2

Shun-ichiro SASAKI, Shigeru TSUNASHIMA,* and Shin SATO†
Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
†Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received December 26, 1985)

Absolute cross sections for quenching NH($c^1\Pi$) by the use of several inorganic molecules were determined at room temperature by using a phase-shift method. The NH($c^1\Pi$) radicals were produced by the photolysis of HN_3 using an amplitude-modulated Xe-resonance lamp. The results obtained were as follows: 0.01(He), 12(HN_3), 48(NO), 49(CO), and 30(CO_2) in units of 10^{-16} cm^2. In the case of NO, the 336 nm emission was enhanced, which suggests that NO quenches NH($c^1\Pi$) to NH($A^3\Pi$). From the phase difference between the 325 and 336 nm emissions, the quenching cross-section of NO for NH($A^3\Pi$) was estimated to be 60×10^{-16} cm^2.

A number of emission and absorption bands of NH radicals have been investigated by using the photolysis or electron impact of HN_3, NH_3, and HNCO.[1] The spectroscopic properties of NH radicals in the lower excited states are now well-known.[2] The energy-level diagram of the NH radical is shown in Fig. 1. The reactivities of these different states of NH radicals are, however, not well understood yet. Recently, we showed that the reactions of NH($a^1\Delta$) with hydrocarbons are very much similar to those of the isoelectronic species, O(^{1}D) and $CH_2(^1A_1)$: The NH($a^1\Delta$) radical inserts into the C–H bond and adds to the double bond of hydrocarbons.[3]

The quenching of the NH($b^1\Sigma^+$) state by various molecules was studied by Zetsch and Stuhl[4] and by Gelernt et al.[5] The rate constants of the quenching of NH($c^1\Pi$) and NH($A^3\Pi$) states by rare gases, H_2, and N_2 have been measured by Kawasaki et al., using the vuv photolysis of NH_3.[6] The quenching rates were estimated from the pressure dependence of the fluorescence intensities at 325 and 336 nm. On the other hand, the radiative lifetime of NH($c^1\Pi$) has been estimated to be 0.43[7] or 0.48[8] μs by the phase-shift method using a modulated electron beam. Since the bombardment of high-energy electrons produces not only NH($c^1\Pi$) but also the higher excited states of NH, the effect of the "cascading" from these excited states was taken into account.[7,8] Clerc et al. also estimated the lifetime of the NH($c^1\Pi$) state to be 0.50 μs from the decay rate of the fluorescence at 325 nm in the pulse radiolysis of NH_3.[9] Similar values were obtained in the studies of the pulse vuv photolysis of HNCO[10] and the 193-nm laser photolysis of HN_3.[11]

In the present study, a phase-shift method is used to determine the rate constants of the quenching of the NH($c^1\Pi$) state by several molecules, using an amplitude-modulated Xe resonance lamp. Here, the effect of the "cascading" may be ignored.

Experimental

A block diagram of the experimental arrangement is shown in Fig. 2. The light source used was a home-made Xe-discharge lamp. The power of the lamp was supplied by a home-made power generator which had been used for previous studies of the mercury photosensitized luminescence.[12] The intensities were modulated at a frequency of 100 or 120 kHz, using the reference signal of a lock-in amplifier (NF Circuit Design Block Co., LI 573). A mixture of He (≈20 Torr; 1 Torr=133.3 Pa) and Xe

(≈0.06 Torr) was circulated in the lamp by means of an all-glass-made fan. This mixture was found to be suitable for effective modulation at high frequencies. The light from the lamp illuminated a Pyrex fluorescence cell, 50 mm in length and 30 mm o.d., through a LiF window. In order to detect the transmitted light, another LiF window coated with sodium salicylate was attached to the opposite side of the cell.[13] The emission from sodium salicylate was measured at 415.5 nm with a photomultiplier (Hamamatsu Photonics, 1P28) through a monochromator (Japan Spectroscopic Co., CT-25N). The signal from the photomultiplier was fed into the lock-in amplifier, and its phase angle was measured relative to the internal signal of the lock-in amplifier. Since the radiative lifetime of sodium salicylate is about 10 ns,[13] the phase angle thus measured can be considered to be equal to that of the excitation light from the lamp.

The fluorescence cell had two side arms for circulating the reaction mixture by means of an all-glass-made fan. The reaction mixture was diluted with He, typically 20 or 13 Torr. The fluorescence from the cell was measured at right angles to the excitation light using the same monochromator and photomultiplier as were used for the measurement of the emission from sodium salicylate. The phase angle of the fluorescence was also measured relative to that of the internal signal of the lock-in amplifier.

The phase-control dial of the lock-in amplifier was calibrated with a phase shifter (NF Circuit Design Block Co., UP 725), while the phase shifter was calibrated by drawing a Lissajous figure on an oscilloscope (Iwatsu Co., SS-5100). The phase shifter was also used to shift the phase angle of the reference signal so that the measured phase angle was kept in the linearly changing region of the phase-control dial.

The HN_3 was synthesized and purified by the method described in a previous paper.[3] The He (Suzuki Shokan Co.) was used after having been passed through a column packed with reduced copper at 300 °C and a trap packed with molecular sieve 4A at −196 °C. The NO, CO, CO_2, and Xe (Takachiho Shoji Co.) were used after having been distilled at low temperatures.

Results

When 0.1 Torr of HN_3 diluted with 20 Torr of He was irradiated with the Xe lamp, fluorescence was observed at about 325 nm. The spectrum was the same as that observed by Okabe,[14] and it was identified as the emission from $NH(c^1\Pi)$. The phase angle of the fluorescence was measured within the initial few minutes of irradiation, since a long irradiation caused a decrease in the emission intensity and its phase angle.

The difference in the phase angle between the 415.5 and 326 nm emissions, ϕ_1, was measured at the modulation frequencies of 100 and 120 kHz, and at various pressures of HN_3 and He. From the measurements of ϕ_1, the decay rate of $NH(c^1\Pi)$, R_1, was estimated by means of this relation: $R_1=2\pi f/\tan\phi_1$, where f denotes the frequency of the modulation (for details, see below). The decay rates thus determined are plotted in Figs. 3 and 4 as functions of the pressures of HN_3 and He respectively. The plots shown in Fig. 3 give a straight line with an intercept of $(2.2\pm0.1)\times10^6\,s^{-1}$ and a slope of $(5.2\pm0.7)\times10^{13}\,cm^3\,mol^{-1}\,s^{-1}$. The intercept and the slope of the straight line in Fig. 4 were $(2.8\pm0.1)\times10^6\,s^{-1}$ and $(1.1\pm0.1)\times10^{11}\,cm^3\,mol^{-1}\,s^{-1}$ respectively. All error limits quoted in this paper correspond to one standard deviation.

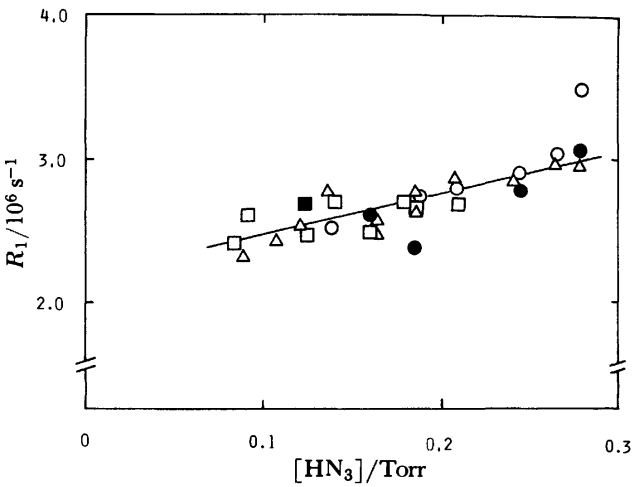

Fig. 3. Plots of R_1 against the pressure of HN_3: open symbols; f=100 kHz and closed symbols; f=120 kHz, [He]=20(○), 13.3(△), and 8.8(□) Torr.

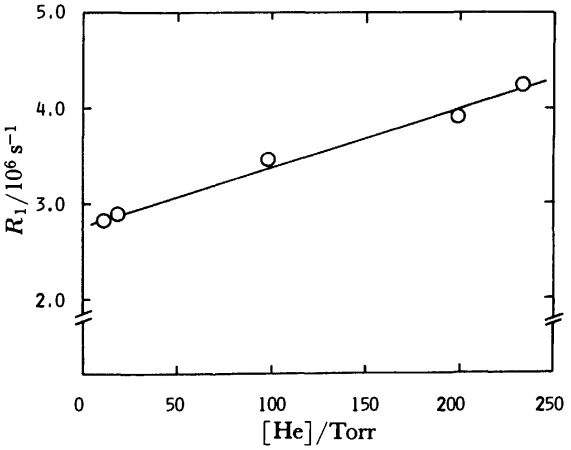

Fig. 4. Plots of R_1 against the pressure of He obtained at f=120 kHz and $[HN_3]$=0.244 Torr.

When a quencher, such as NO, CO, or CO_2, was added to a mixture of HN_3 (0.123 Torr) and He (20 Torr), the decay rate, R_1, increased. The decay rates are plotted as functions of the pressures of the quenchers in Fig. 5. The plots show straight lines for every quencher examined. The slopes and the intercepts of the straight lines are summarized in Table 1.

In the case of NO, a fluorescence at 336 nm was observed in addition to the 325-nm fluorescence. The spectrum was the same as that identified as the emission from $NH(A^3\Pi)$.[14] The phase difference between the 325 and 336-nm fluorescences, ϕ_3, was determined at various pressures of NO and HN_3. The $2\pi f/\tan\phi_3$

Discussion

Photolysis of HN_3. The fluorescence of the NH ($c^1\Pi$) radicals appears at 325 nm. In order to explain the observed phase difference between the excitation light and the fluorescence at 325 nm, ϕ_1, the following reaction mechanism was considered:

$$HN_3 + h\nu \longrightarrow NH(c^1\Pi) + N_2 \quad (1)$$

$$NH(c^1\Pi) \longrightarrow NH(a^1\Delta) + h\nu(325) \quad k_{10} \quad (2)$$

$$NH(c^1\Pi) + HN_3 \longrightarrow \text{products} \quad k_{1a} \quad (3)$$

$$NH(c^1\Pi) + He \longrightarrow \text{products} \quad k_{1h} \quad (4)$$

Assuming the above mechanism, the decay rate, R_1, can be expressed as follows:

$$R_1 = 2\pi f/\tan\phi_1 = k_{10} + k_{1a}[HN_3] + k_{1h}[He] \quad (5)$$

Here, f denotes the frequency of the modulation. According to Eq. 5, the plots of the decay rates against the pressure of HN_3 will give a straight line with an intercept of $k_{10}+k_{1h}[He]$ and a slope of k_{1a}. Under a constant pressure of HN_3, the plots of the decay rates against the pressure of He will give a straight line with an intercept of $k_{10}+k_{1a}[HN_3]$ and a slope of k_{1h}. From the values of the intercepts and the slopes of the straight lines in Figs. 3 and 4, the values of k_{10}, k_{1a}, and k_{1h} are estimated to be $(2.2\pm0.2)\times10^6\,s^{-1}$, $(5.2\pm0.7)\times10^{13}$, and $(1.1\pm0.1)\times10^{11}\,cm^3\,mol^{-1}\,s^{-1}$ respectively. The radiative lifetime of NH($c^1\Pi$), the reciprocal of k_{10}, was estimated to be (0.48±0.03) μs. The value obtained here agreed well with those estimated by the various other methods.[7-11] The quenching by He was about two orders of magnitude smaller than that of HN_3 and agreed with that obtained by Kawasaki et al.[6] Recently, Haak and Stuhl estimated k_{1a} to be $4.4\times10^{14}\,cm^3\,mol^{-1}\,s^{-1}$ by using the ArF-laser photolysis of HN_3; this value is about one order of magnitude larger than the present value.[11] The reaction mechanism may not be simple in their laser-photolysis system, since they observed that (a) products were

formed in an appreciable concentration, (b) the intensities of the fluorescence of NH($A^3\Pi$) varied from 1.4 to 1.9 powers of the laser intensities, and (c) the decay rate of NH($A^3\Pi$) was not a single exponential. Thus, the quenching process can be considered to be disturbed by the side reactions.

If NH($c^1\Pi$) is formed via a long-lived intermediate, such as an excited HN_3 molecule, the observed decay rate should be dependent on the frequency of the modulation. This is, however, not the case, as is shown in Fig. 3.

Quenching of NH($c^1\Pi$). In the presence of a quencher, such as NO, CO, or CO_2, Eq. 5 should be changed:

$$R_1 = k_{10} + k_{1h}[He] + k_{1a}[HN_3] + k_{1q}[Q] \quad (6)$$

Here, k_{1q} represents the rate constant for the quenching of NH($c^1\Pi$) by a quencher, Q:

$$NH(c^1\Pi) + Q \longrightarrow \text{products} \quad k_{1q} \quad (7)$$

When the pressures of HN_3 and He are kept constant, the plots of R_1 against the pressure of a quencher will give a straight line with a slope of k_{1q} and an intercept of $k_{10}+k_{1h}[He]+k_{1a}[HN_3]$ (see Fig. 5). Using the values of k_{10}, k_{1a}, and k_{1h} estimated in this study, the intercept was calculated to be $2.5\times10^6\,s^{-1}$, a value which agreed well with the observed values of the intercepts shown in Table 1; i.e., the slopes shown in Table 1 can be considered to represent k_{1q}. The quenching cross-sections, σ_{1q}, were estimated by the use of Eq. 8 and are listed in the fourth column of Table 1:

$$\sigma_{1q} = k_{1q}(\pi\mu/8kT)^{1/2} \quad (8)$$

The symbols in Eq. 8 represent their usual meanings. In the fifth column of Table 1, the literature values are also listed. The NO, CO, and CO_2 efficiently quench the NH($c^1\Pi$) state.

Quenching by NO. In the case of NO, the formation of NH($A^3\Pi$) was detected by the fluorescence at 336 nm. The following reactions can be considered to explain the results:

$$NH(c^1\Pi) + NO \longrightarrow NH(A^3\Pi) + NO^* \quad \alpha \quad (9)$$

$$\longrightarrow \text{other reactions} \quad 1-\alpha \quad (10)$$

$$NH(A^3\Pi) \longrightarrow NH(X^3\Sigma^-) + h\nu(336) \quad k_{30} \quad (11)$$

$$NH(A^3\Pi) + NO \longrightarrow \text{products} \quad k_{3n} \quad (12)$$

$$NH(A^3\Pi) + HN_3 \longrightarrow \text{products} \quad k_{3a} \quad (13)$$

where α denotes the branching ratio for the formation of NH($A^3\Pi$). In the above reactions, the quenching by He is neglected. Assuming the above reactions, the decay rates of the NH($A^3\Pi$), R_3, can be expressed as follows:

$$R_3 = 2\pi f/\tan\phi_3 = k_{30} + k_{3a}[HN_3] + k_{3n}[NO] \quad (14)$$

The slopes of the straight lines in Fig. 6 correspond to k_{3n}. The values of the slopes shown in Table 2 are almost constant for every pressure of HN_3 examined. From the value of k_{3n}, the quenching cross-section of NO was calculated to be $60\times10^{-16}\,cm^2$. Recently, Hofzumahaus and Stuhl have estimated the cross section of NO for quenching rotationally hot NH($A^3\Pi$) to be $17\times10^{-16}\,cm^2$.[15] They pointed out that rotation of NH radicals reduces the effect of the quencher. The present result corresponds to the quenching rate for rotationally relaxed NH radicals.

The branching ratio, α, could not be determined from the phase-shift studies, because no formation rate of NH($A^3\Pi$), k_9, appeared in Eq. 14. Since the energy difference between NH($c^1\Pi$) and NH($A^3\Pi$) is 167 kJ mol^{-1}, the NO* formed by Reaction 9 is probably not an electronically excited one. Reaction 9, however, is a spin-allowed process for NO. For CO and CO_2, similar quenching reactions are spin-forbidden processes unless CO or CO_2 is excited to a triplet state. No triplet states of these molecules, however, are assigned in such a low energy region. This explains why only the NO molecule can quench NH($c^1\Pi$) to NH($A^3\Pi$).

Phase-Shift Studies of the Quenching of NH($c^1\Pi$) and NH($A^3\Pi$) by Hydrocarbons

Shun-ichiro SASAKI, Akiko KANO, Shigeru TSUNASHIMA,* and Shin SATO†
Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
†Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received December 26, 1985)

The cross-sections for quenching NH($c^1\Pi$) and NH($A^3\Pi$) by hydrocarbons were determined at room temperature by using a phase-shift method. The NH($c^1\Pi$) was produced by the photolysis of HN_3 using an amplitude-modulated Xe-resonance lamp. The apparent decay rate of the NH($c^1\Pi$) was estimated from the difference in phase angle between the excitation light and the fluorescence of NH($c^1\Pi$) at 325 nm. In the presence of Xe, the fluorescence of NH($A^3\Pi$) at 336 nm was enhanced. The difference in the phase angle between the fluorescences at 325 and 336 nm was found to correlate with the decay rate of NH($A^3\Pi$). From the decay rates obtained in the presence of hydrocarbons, the quenching cross-sections were determined.

The NH radical is known to be an important intermediate in astronomical emission sources. The electron configuration, $(2s\sigma)^2(2p\sigma)^2(2p\pi)^2$, of the NH radical gives rise to the $X^3\Sigma^-$, $a^1\Delta$, and $b^1\Sigma^+$ states, while the $(2s\sigma)^2(2p\sigma)(2p\pi)^3$ configuration gives rise to the $c^1\Pi$ and $A^3\Pi$ states. Figure 1 shows a correlation diagram of the NH radical and the O atom. Many similarities have been found in the reactions of NH radicals in the first excited state, NH($a^1\Delta$), with those of isoelectronic species, O(^{1}D) and $CH_2(^1A_1)$.[1-11] The measurements of the quenching processes of these excited states are important in elucidating the mechanism of the energy transfer. The rate constants of the reaction of the NH($a^1\Delta$) state with various molecules have been measured by McDonald et al.[10] and Piper et al.[11] Carrington and his co-workers[12] and Zetsch and Stuhl[13] have determined the rate constants of the quenching of the NH($b^1\Sigma^+$) state by several molecules and found that the NH($b^1\Sigma^+$) state is less reactive than NH($a^1\Delta$), although the former is energetically higher than the latter. This trend is similar to that observed in the case of O(^{1}D);[14] i.e., O(^{1}D) is more reactive than O(^{1}S), although the former is about 200 kJ mol^{-1} energetically lower than the latter. A limited number of quenching rates for the NH($c^1\Pi$) and NH($A^3\Pi$) states have been reported.[15-20] Recent studies of NH($A^3\Pi$) by Hofzumahaus and Stuhl have shown that the NH($A^3\Pi$) was quenched by every three collisions and that the quenching cross-sections of many inorganic molecules were correlated with the intermolecular well depth.[19] No systematic studies of the quenching of these highly excited states by hydrocarbons have been reported, probably because these quencher molecules absorb the vuv light and decompose. One our previous paper showed that the phase-shift method is a convenient and suitable method for the measurements of the quenching rate, especially for a quencher which absorbs the excitation light.[20] In this paper, the cross-sections for the quenching of NH($c^1\Pi$) and NH($A^3\Pi$) by hydrocarbons are reported and possible quenching mechanisms are discussed.

Experimental

The experimental method has been fully described in the previous paper,[20] and so only a brief outline will be given here.

The apparatus consists of an amplitude-modulated Xe-resonance lamp, an oxygen shutter, and a fluorescence cell. The oxygen shutter, which separates the lamp from the cell, was used to cut off the light of wavelengths shorter than 200 nm during the mixing of the reactants and the stabilizing of the lamp before irradiation. The transmitted vuv light was converted to longer wavelengths by using sodium salicylate and was measured at 415.5 nm. The phase angles of the

transmitted light and the fluorescence of the NH radicals were measured by using a lock-in amplifier relative to its reference signal.

Hydrogen azide was synthesized from sodium azide and stearic acid and purified by the method described in the previous paper.[20] Research-grade hydrocarbons were used after several distillations at low temperatures.

Results

Quenching of NH($c^1\Pi$). When a small amount of ethane was introduced into the reactant (0.1—0.3 Torr of HN_3 and 20 Torr of He: 1 Torr=133.3 Pa), the phase difference between the transmitted light and the fluorescence at 325 nm, ϕ_1, decreased. Figure 2 shows the plots of $R_1(=2\pi f/\tan\phi_1)$ as a function of the pressure of ethane. Here, f denotes the frequency of the modulation of the lamp. As is shown in Fig. 2, the plots give straight lines with the same slope for different initial pressures of HN_3. The intercepts increased with an increase in the pressure of HN_3. Similar plots were obtained with other quenchers, such as CH_4, C_3H_8, c-C_3H_6, n-C_4H_{10}, i-C_4H_{10}, C_2H_4, C_3H_6, 1-C_4H_8, i-C_4H_8, and *cis*- and *trans*-Δ^2-C_4H_8. All of the plots gave

straight lines for every quencher examined. Some examples are shown in Fig. 3. The values of slope of each straight line are summarized in the third column of Table 1. The error limits show one standard deviation.

Effect of Xe on Fluorescence of NH. When Xe was added to a HN_3–He mixture, the intensity of the fluorescence of NH($c^1\Pi$) at 325 nm, decreased while that of NH($A^3\Pi$) at 336 nm increased. The phase-angle difference between the transmitted light and the emission at 336 nm, ϕ_3, was measured, like ϕ_1, at various pressures of HN_3 and Xe. The values of $R_1(=2\pi f/\tan\phi_1)$, $R_{13}(=2\pi f/\tan(\phi_1-\phi_3))$, and $R_3(=2\pi f/\tan\phi_3)$ are plotted as functions of the pressure of Xe in Fig. 4 and of that of HN_3 in Fig. 5.

Effect of Hydrocarbons on R_{13}. The phase-angle difference between the fluorescence of NH($c^1\Pi$) and that of NH($A^3\Pi$), $\phi_1-\phi_3$, was measured in the presence of hydrocarbon in a mixture of He(20 Torr)-HN_3(0.1 Torr)-Xe(0.7 Torr). The plots of R_{13} against the

pressure of hydrocarbon gave a straight line for every quencher examined. Some examples are shown in Fig. 6. The values of the slopes of the straight lines are summarized in the fifth column of Table 1.

Discussion

Quenching of NH(c¹Π) by Hydrocarbons. As was discussed in the previous paper,[20] the following reaction mechanism can be considered to explain the results shown in Figs. 2 and 3:

$$HN_3 + h\nu \longrightarrow NH(c^1\Pi) + N_2 \quad (1)$$

$$NH(c^1\Pi) \longrightarrow NH(a^1\Delta) + h\nu(325) \quad k_{10} \quad (2)$$

$$NH(c^1\Pi) + M \longrightarrow \text{products} \quad k_{1M} \quad (3)$$

where M denotes He, HN_3, or hydrocarbons.

Assuming the above reaction mechanism, the following relation can be derived for R_1:

$$R_1 = 2\pi f/\tan\phi_1 \quad (4)$$

$$= k_{10} + k_{1h}[He] + k_{1a}[HN_3] + k_{1q}[Q] \quad (5)$$

where k_{1h}, k_{1a}, and k_{1q} represent k_{1M} for He, HN_3, and the hydrocarbon used respectively. Under constant pressures of He and HN_3, the intercepts of the straight lines in Fig. 3 should be equal to $k_{10}+k_{1h}[He]+k_{1a}[HN_3]$. This R_1 value can be estimated to be $(2.3\pm0.4)\times10^6\ s^{-1}$ by using the previously obtained values of k_{10}, k_{1a}, and k_{1h} under the present experimental conditions; this value is in good agreement with the intercepts obtained in the present studies. Thus, the slope of the straight line shown in Table 1 corresponds to the value of k_{1q}. The quenching cross-sections were calculated from k_{1q} and are summarized in the fourth column of Table 1.

Effect of Xe. The results shown in Figs. 4 and 5 could not be explained by the addition of the following reactions to Reactions 1—3:

$$NH(c^1\Pi) + Xe \longrightarrow NH(A^3\Pi) + Xe \quad k_{1x} \quad (6)$$

followed by:

$$NH(A^3\Pi) \longrightarrow NH(X^3\Sigma^-) + h\nu(336) \quad k_{30} \quad (7)$$

$$NH(A^3\Pi) + M \longrightarrow \text{products} \quad k_{3M} \quad (8)$$

where M denotes a quencher such as He, HN_3, or Xe. If this mechanism is applicable, the following relation should hold for R_1:

$$R_1 = k_{10} + k_{1h}[He] + k_{1a}[HN_3] + k_{1x}[Xe] \quad (9)$$

That is, the plots of R_1 against the pressure of Xe should show a straight line with an intercept of $k_{10}+k_{1h}[He]+k_{1a}[HN_3]$, which is equal to $2.3\times10^6\ s^{-1}$ under the present experimental conditions. As is shown in Fig. 4, this is not the case. In order to explain the present results, then, the following reactions were considered in addition to Reactions 1—3 and 6—8:

$$Xe + h\nu(129.5) \longrightarrow Xe(^1P_1) \quad (10)$$

$$Xe + h\nu(147) \longrightarrow Xe(^3P_1) \quad (11)$$

$$Xe(^1P_1) \longrightarrow Xe + h\nu(129.5) \quad k_{20} \quad (12)$$

$$Xe(^1P_1) + HN_3 \longrightarrow Xe + NH(c^1\Pi) + N_2 \quad k_{2a} \quad (13)$$

$$Xe(^1P_1) + M \longrightarrow \text{products} \quad k_{2M} \quad (14)$$

$$Xe(^3P_1) \longrightarrow Xe + h\nu(147) \quad k'_{20} \quad (15)$$

$$Xe(^3P_1) + HN_3 \longrightarrow Xe + NH(A^3\Pi) + N_2 \quad k'_{2a} \quad (16)$$

$$Xe(^3P_1) + M \longrightarrow \text{products} \quad k'_{2M} \quad (17)$$

The spin-conservation rule was assumed to hold for Reactions 13 and 16.[21] Assuming the above reactions, the following relations were derived:

$$R_1 = AB/(A+B) \quad (18)$$

$$R_3 = (1/A+1/B+1/C)^{-1} \quad (19)$$

$$R_{13} = C \quad (20)$$

Here,

$$A = k_{10} + k_{1h}[He] + k_{1a}[HN_3] + k_{1x}[Xe] \quad (21)$$

$$B = k_{20} + k_{2a}[HN_3] \quad (22)$$

$$C = k_{30} + k_{3h}[He] + k_{3a}[HN_3] + k_{3x}[Xe] \quad (23)$$

where k_{3h}, k_{3a}, and k_{3x} represent k_{3M} for He, HN_3, and Xe respectively. To derive Eqs. 18—20, the following assumptions were made; (i) in the presence of Xe, the direct photolysis of HN_3 was negligible, (ii) the values of A, B, and C were larger than $2\pi f$, and (iii) $k'_{2a}[Xe(^3P_1)]$ was negligibly small compared with $k_{2a}[NH(c^1\Pi)]$ under the present experimental conditions.

From the slopes of the straight lines in the plots of R_{13} vs. [HN_3] and [Xe], the values of k_{3a} and k_{3x} were estimated to be $(6.0\pm1.1)\times10^{13}$ and $(2.8\pm0.1)\times10^{13}$ cm^3 mol^{-1} s^{-1} respectively. The latter value agreed well with that obtained by Hofzumahaus and Stuhl.[19] From the intercepts, the lifetime of NH($A^3\Pi$), $1/k_{30}$, was estimated to be 490 ± 40 ns using the value of $k_{3h}=4\times10^{10}$ cm^3 mol^{-1} s^{-1}.[19] The correction by the quenching of He at 20 Torr was less than 0.5%. The lifetime of NH($A^3\Pi$) estimated here agrees well with the literature value.[22] The solid lines in Figs. 4 and 5 are drawn by using Eqs. 18—20 with these values: $k_{10}+k_{1h}[He]=2.2\times10^6$ s^{-1}, $k_{1a}=5.2\times10^{13}$ cm^3 mol^{-1} s^{-1},[20] $k_{20}=2.1\times10^6$ s^{-1}, $k_{2a}=2.4\times10^{14}$ cm^3 mol^{-1} s^{-1}, and $k_{1x}=2.2\times10^{14}$ cm^3 mol^{-1} s^{-1}. Although the latter three values are not unique, the agreement is satisfactory, as Figs. 4 and 5 show.

Quenching of NH($A^3\Pi$) by Hydrocarbons. When a hydrocarbon is added to the He–HN_3–Xe mixture as a quencher, the following quenching reactions should be considered:

$$NH(c^1\Pi) + Q \longrightarrow \text{products} \qquad k_{1q} \quad (24)$$

$$NH(A^3\Pi) + Q \longrightarrow \text{products} \qquad k_{3q} \quad (25)$$

$$Xe(^1P_1) + Q \longrightarrow \text{products} \qquad k_{2q} \quad (26)$$

$$Xe(^3P_1) + Q \longrightarrow \text{products} \qquad k'_{2q} \quad (27)$$

By the addition of the above reactions, the terms of $k_{1q}[Q]$, $k_{2q}[Q]$, and $k_{3q}[Q]$ should be added to A, B, and C respectively. Under constant pressures of He, HN_3, and Xe, the following relation can be obtained:

$$R_{13} = 2\pi f/\tan(\phi_1-\phi_3) = C_0 + k_{3q}[Q] \quad (28)$$

where C_0 represents the R_{13} values in the absence of the quencher. That is, the slope of the straight line in Fig. 6 represents the k_{3q}. The cross-sections for quenching NH($A^3\Pi$), σ_{3q}, were calculated from the values of k_{3q}; they are listed in the sixth column of Table 1.

Comparison with Literature Values. No values have been reported for the cross-sections for quenching NH($c^1\Pi$) by hydrocarbons. For the quenching of NH($A^3\Pi$) by CH_4, the present results agree well with those obtained by Nishi et al.[17] and Hofzumahaus and Stuhl,[19] although the experimental methods are different.

Collision Complex Model. Recently, Hofzumahaus and Stuhl have measured the cross-sections for the quenching of NH($A^3\Pi$) by NH_3, NO, CH_4, H_2, CO, Xe, O_2, CO_2, Ar, N_2, and He, using the laser photolysis of NH_3. They found that the trend of the quenching cross-sections can be described by Parmenter's correlation, which suggests that the attractive force is effective for the quenching process.[19] In Parmenter's correlation, the quenching cross-sections, σ, are correlated with the intermolecular well depth, ε_{qq}:[23]

$$\ln\sigma = \ln C + \beta(\varepsilon_{qq}/k)^{1/2} \quad (28)$$

Here, $\beta=(\varepsilon_{A^*A^*}/kT^2)^{1/2}$, where $\varepsilon_{A^*A^*}$ is the well depth between the excited molecules, A*. Figures 7 and 8 show the plots for the quenching of NH($A^3\Pi$) and NH($c^1\Pi$) respectively by hydrocarbons. The numbers in Figs. 7 and 8 correspond to the compounds listed in Table 1. The well depth was approximated by $\varepsilon_{qq}/k=1.15\,T_b$, where T_b represents the boiling point.[24] The broken line in Fig. 7 shows the correlation obtained by Hofzumahaus and Stuhl. A good correlation is obtained for the quenching of NH($A^3\Pi$) by hydrocarbons:

$$\ln\sigma = (-1.2\pm0.8) + (0.30\pm0.05)(\varepsilon_{qq}/k)^{1/2} \quad (29)$$

The value of the slope is almost the same as that determined by Hofzumahaus and Stuhl.[19] The broken line in Fig. 8 is drawn by using Eq. 29. As is shown in Fig. 8, the trend of the cross-sections of paraffin for quenching NH($c^1\Pi$) is different from that of olefin, but it is similar to the case of the quenching of NH($A^3\Pi$). The quenching mechanism for olefin should be different from that of paraffin.

Following the method described by Hofzumahaus and Stuhl,[19] absolute cross sections were calculated. The method will be described here only briefly. The interaction potentilal, $V(r)$, is assumed to be in the form of Eq. 30:

$$V(r) = -C_3/r^3 - C_6/r^6 - C_6'/r^6, \quad (30)$$

where the C_3, C_6, and C_6' coefficients represent dipole–dipole ($C_3=2\mu_1\mu_2$), dipole-induced dipole ($C_6=2(\mu_1^2\alpha_2+\mu_2^2\alpha_1)$, and dispersion ($C_6'=1.5\,I_1I_2\alpha_1\alpha_2/(I_1+I_2)$) interactions respectively. The symbols μ, α, and I represent the dipole moment, the polarizability, and the ionization potential respectively. The effective potential, $V_{eff}(r)$, is given by Eq. 31 at the initial kinetic energy of E and the impact parameter of b:

$$V_{eff}(r) = V(r) + Eb^2/r^2 \quad (31)$$

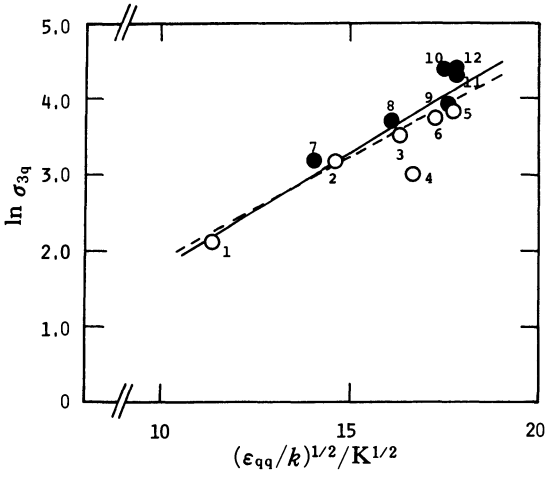

Fig. 7. Plots of $\ln\sigma_{3q}$ against $(\varepsilon_{qq}/k)^{1/2}$ for the quenching of NH($A^3\Pi$). The numbers correspond to the compound listed in Table 1. ○: paraffin, ●: olefin. The broken line shows the relation, $\ln\sigma=-0.82+0.275\,(\varepsilon_{qq}/k)^{1/2}$.[19]

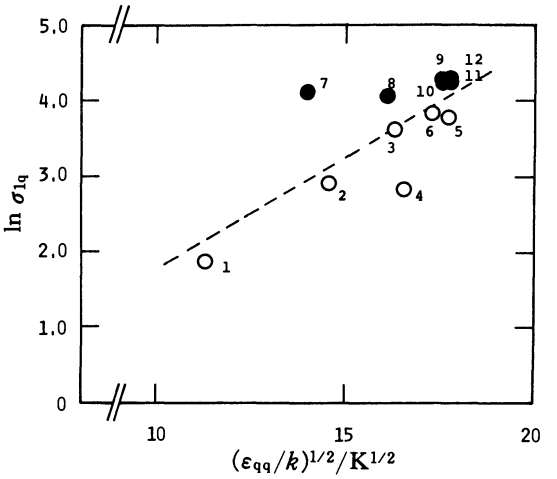

Fig. 8. Plots of $\ln\sigma_{1q}$ against $(\varepsilon_{qq}/k)^{1/2}$ for the quenching of NH($c^1\Pi$). The numbers correspond to the compound listed in Table 1. The broken line represents the best fit line obtained for the quenching of NH($A^3\Pi$).

The position of the centrifugal maximum, r_0, can be estimated, by the use of Eq. 32, as a function of E, where the orbiting condition, $E=V_{eff}(r_0)$, is satisfied:

$$\partial V_{eff}(r)/\partial r = 0 \quad \text{at } r = r_0 \tag{32}$$

Thus, the cross-section at the initial kinetic energy of E can be estimated by $\sigma(E)=\pi b^2=\pi r_0^2(1-V(r_0)/E)$. Thus, the thermally averaged cross-section, $\sigma(T)$, can be estimated by Eq. 33:

$$\sigma(T) = (1/kT)^2\int\sigma(E)\,E\exp(-E/kT)\mathrm{d}E \tag{33}$$

In Table 2, the calculated results are summarized, along with the parameters used in the calculation. Figures 9 and 10 show the plots of the cross-sections

observed against calculated ones. The observed cross-sections are smaller than the calculated ones except for higher olefins. Hofzumahaus and Stuhl evaluated the quenching probability $P=\sigma_{obsd}/\sigma_{calcd}$, to be about 0.3 by comparison with their results.[19] The results shown in Figs. 9 and 10, however, suggest that the probability depends on the molecular complexity.

Quenching Mechanism. In the case of O(^{1}D), the

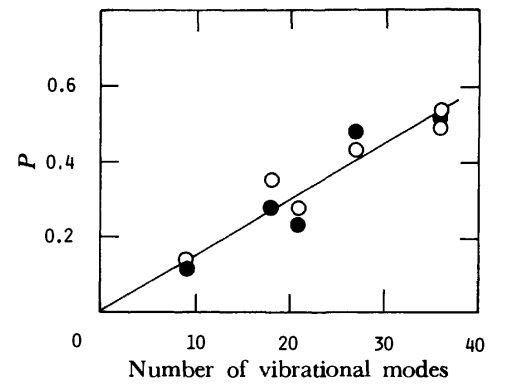

Fig. 13. Plots of quenching probabilities, P, against the number of vibrational modes of paraffin. O: NH($A^3\Pi$) and ●: NH($c^1\Pi$).

reaction rates of paraffin are known to be proportional to the number of C-H bonds included,[25] as is shown in Fig. 11. In the cases of the quenching of NH($A^3\Pi$) and NH($c^1\Pi$) by paraffin, the rate constants do not linearly increase with the number of C-H bonds included. This fact can not be explained by the term of the difference in the bond-dissociation energies, because n-C_4H_{10} quenches NH($A^3\Pi$) or NH($c^1\Pi$) as efficiently as i-C_4H_{10}, which has a weaker C-H bond than the former.

As is shown in Fig. 12, a good correlation was obtained between the quenching rates of paraffin and the number of the vibrational modes of quenchers in the cases of the quenching of NH($c^1\Pi$) and NH($A^3\Pi$). This fact may suggest that the intermolecular vibrational relaxation process in the collision complex is important. If the intermolecular vibrational relaxation is inefficient, the collision complex will decompose to the initial reactants; i.e., no quenching reactions will occur. That is, the quenching probability, P, becomes small for the molecules which have fewer vibrational modes. This trend is clearly shown in Fig. 13, where the quenching probabilities are plotted against the number of vibrational modes of the quenchers.

In the case of the quenching of NH($c^1\Pi$) by olefins, it is necessary to assign a large value of P, as may be seen from Fig. 10. A large value of P could not be explained by the term of the number of vibrational modes. In the above consideration, the rate of intermolecular vibrational relaxation is assumed to be an important factor in determining the probability. If the collision complex formed from olefin is considered to be tight enough for the efficient intermolecular vibrational relaxation, the collision probability will be high. Another possible explanation is that the rate of the decomposition to an exit channel is much faster than that of the returning to the initial reactants. At present, it is difficult to decide which mechanism is more important. The property of the collision complex is, in any event, an important factor in the quenching, although the validity of the assumption made for the

calculation of σ_{calcd} should be more carefully examined.

Kinetic and Equilibrium Studies of Complex Formation of Nickel(II) with Carboxylate Ligands at High Pressure. IV. Nickel(II) Malate and Nickel(II) Tartrate

Tohru INOUE,* Kiyotaka KOJIMA, and Ryosuke SHIMOZAWA
Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01
(Received January 21, 1986)

Kinetic and equilibrium measurements were carried out for the complexation reaction of nickel(II) malate and nickel(II) tartrate in an aqueous solution at 20 °C and at pressures up to 100 MPa. From the pressure dependence of the stability constant and the rate constant, the reaction volume, ΔV^0, and the activation volume, ΔV_f^*, for the complex formation were estimated as follows: $\Delta V^0=17.8\pm0.6\,cm^3\,mol^{-1}$ and $\Delta V_f^*=13.8\pm0.6\,cm^3\,mol^{-1}$ for nickel(II) malate, and $\Delta V^0=17.8\pm0.5\,cm^3\,mol^{-1}$ and $\Delta V_f^*=13.7\pm1.2\,cm^3\,mol^{-1}$ for nickel(II) tartrate. Comparing the ΔV^0 values with those obtained for other carboxylate ligands, it was inferred that both malate and tartrate ions form a six-membered chelate complex coordinated by carboxyl and hydroxyl oxygens. The rate-determining step of the overall complexation reaction was assigned to the first bond formation process based on the ΔV_f^* value with the correction for the volume change associated with the outer-sphere complex formation.

A pressure-variable study of a chemical reaction provides information about the volume change associated with the reaction.[1] The reaction volume and the activation volume are very useful parameters for understanding features of the reaction. We have been carrying out the kinetic and equilibrium measurements for the complexation reaction of nickel(II) with carboxylate ligands in an aqueous solution under pressure in order to interpret the course of the reaction through the volume profile.[2-4] Along the line of this series of studies, in the present study we investigated the complexation reactions of nickel(II) malate and nickel(II) tartrate under various pressures up to 100 MPa. From the pressure dependence of the stability constants and the rate constants of the complexation reactions, the values of reaction and activation volumes were estimated and compared with those previously obtained for other carboxylate ligand systems.

Experimental

Stock solutions of nickel(II) malate and nickel(II) tartrate were prepared from nickel sulfate and corresponding acids by the same procedure as described previously.[2] The concentration of the solution was determined by titrating with an EDTA solution standardized by a standard solution of zinc nitrate. Guaranteed grade reagents of nickel sulfate, L-malic acid, and DL-tartaric acid were obtained from Wako Pure Chemicals and used without further purification. Each sample solution was prepared by diluting the stock solution to the desired concentration. The pH's of the sample solutions were in the range of 6.1±0.2 for both nickel(II) malate and nickel(II) tartrate, where most of the ligands were considered to be in a fully dissociated form from the pK_a values of the acids; $pK_{a1}=3.28$ and $pK_{a2}=4.72$ for malic acid,[5] and $pK_{a1}=2.80$ and $pK_{a2}=3.96$ for tartaric acid.[5]

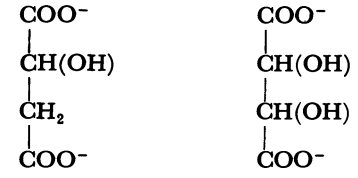
The stability constants of the complexes under various pressures were determined from conductivity measurements according to the Fuoss-Kraus method[6] as described previously.[2,4] The conductivity were measured for sample solutions of 20 different concentrations ranging from 2×10^{-4} to 1×10^{-3} mol dm^{-3} for nickel(II) malate and from 1×10^{-4} to 1.5×10^{-3} mol dm^{-3} for nickel(II) tartrate. A high-pressure pressure-jump apparatus[7] was used for kinetic measurements under pressure. The pressure-jump measurements were made for sample solutions of 11—13 different concentrations ranging from 8×10^{-4} to 1×10^{-2} mol dm^{-3} for nickel(II) malate and from 5×10^{-4} to 2×10^{-3} mol dm^{-3} for nickel(II) tartrate. The observed relaxation process was characterized by a single relaxation time. The temperature was kept at 20.0±0.1 °C and the pressure was maintained within ±0.5 MPa of the designated pressure for both equilibrium and kinetic measurements. The concentration in the molarity scale was corrected for compression under pressure using the density data of water.[8]

Results and Discussion

The complexation reaction under consideration is represented in Scheme 1.

$$Ni^{2+} + L^{2-} \overset{K}{\rightleftharpoons} NiL$$

L^{2-}: malate or tartrate



Scheme 1.

Stability constants of the complexes, K, determined from the conductivity data are listed in Table 1 (for details of the determination procedure, see Ref. 2). The reaction volume, ΔV^0, for the complexation reaction can be evaluated from the pressure dependence of the stability constant according to the relation[1]

$$RT\left(\frac{\partial \ln K}{\partial P}\right)_T = -\Delta V^0 - RT\kappa_0, \qquad (1)$$

where κ_0 represents the solution compressibility and other symbols have their usual meanings. In the above expression, $-RT\kappa_0$ is a correction term for the compression required when the concentration is expressed in terms of molarity and has a value of 1.1

Table 1. Stability Constants and Rate Constants for the Complexation Reaction of Nickel(II) Malate and Nickel(II) Tartrate as a Function of Pressure at 20°C and I→0[a)]

	Pressure/MPa

a) Standard deviations are shown in parentheses.

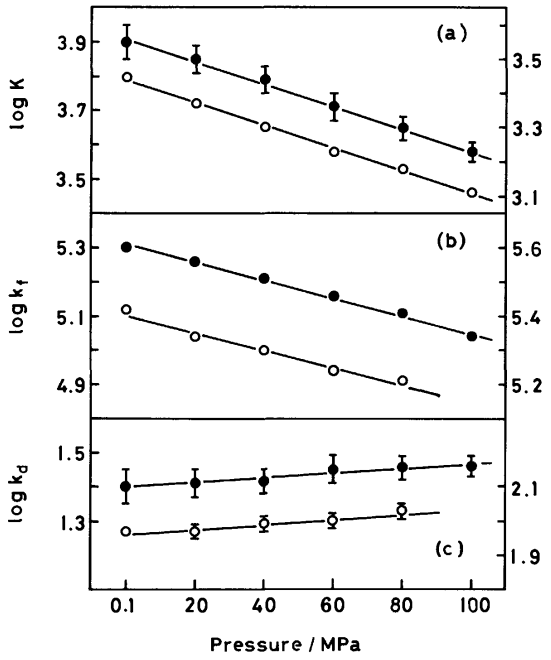

Fig. 1. Pressure dependence of (a) $\log K$, (b) $\log k_f$, and (c) $\log k_d$ at 20°C: ●, nickel(II) malate (left scale); ○, nickel(II) tartrate (right scale). Solid lines show the linear least-squares fits to the data points.

$cm^3\,mol^{-1}$ [1a)] for dilute aqueous solution as in the present case. Figure 1a shows plots of $\log K$ against pressure for nickel(II) malate and nickel(II) tartrate. In the measured pressure range, $\log K$ decreased linearly with increasing pressure. From the slope of the straight line fitted by a least-squares method, the values of reaction volume for the complexation reaction were estimated according to Eq. 1, and they are listed in Table 2 together with those obtained for other carboxylate ligands.

The rate constants for the complexation reaction were determined from the pressure-jump relaxation data according to the following relations; the details of the procedure were described elswhere.[2,4)]

$$1/\tau = k_f[\gamma_\pm^2(c_{Ni}+c_L) + 1/K]$$
$$k_d = k_f/K, \qquad (2)$$

where τ represents the relaxation time, k_f and k_d the rate constants for the complex formation and dissociation at zero ionic strength, c_{Ni} and c_L the equilibrium concentration of nickel(II) and ligand ions, and $\gamma_\pm$ the mean activity coefficient of the free ions at a given ionic strength. The values of the rate constants at various pressures are summarized in Table 1. The activation volume of the complexation reaction was estimated from the pressure dependence of the rate constants based on a relation analogous to Eq. 1.[1)] Plots of $\log k_f$ and $\log k_d$ against pressure are shown in Figs. 1b and 1c, respectively. In the measured pressure range, a linear relationship was obtained between the logarithm of the rate constant and the pressure. From the slope of the straight line, the values of the activation volume for the complex formation, ΔV_f^*, and dissociation, ΔV_d^*, were estimated. They are listed in Table 2 together with the activation volumes obtained for the complexation reaction with other carboxylate ligands.

It may be considered that the volume change associated with the complex formation in aqueous solution between metal ion and charged ligand consists of several contributions; i) the release of electrostriction due to the charge neutralization, ii) the elimination of solvated water around the coordinating group accompanied by the coordination bond formation, which produces free water, iii) the difference in coordination bond length between metal–water bond and metal-ligand bond, and iv) for chelating ligand, the increase of free volume, which is too small to be occupied by the solvent molecule, resulting from the formation of a ring structure. The contributions from i), ii), and iv) are positive for volume increase in the system, while the sign of the contribution from iii) may depend on the nature of the metal-ligand bond. According to the above consideration, it can be expected that the difference in the structure of the complex (e.g., monodentate or polydentate complex, or type of coordinating group(s) to metal ion) is reflected in the reaction volume.

The top five ligands in Table 2 have the same electrical charge(−2), and hence, the contribution i) is the same for these ligands. A succinate ion forms a

Table 2. Reaction Volumes, ΔV^0, and Activation Volumes, ΔV^*, for the Complex Formation of Nickel(II) with Carboxyl Ligands[a)]

Ligands	ΔV^0	ΔV_f^*	ΔV_d^*	$\Delta V_f^* - \Delta V_{os}^{0}$[b)]	Reference
Succinate	11.1±0.9	14.1±0.8	3.0±0.9	7.3	2
Malonate	13.5±1.0	14.7±0.5	1.2±1.2	7.5	4
Tartronate	13.3±0.7	15.2±0.5	1.9±0.8	8.0	4
Malate	17.8±0.6	13.8±0.6	−4.0±0.5	6.6	This work
Tartrate	17.8±0.5	13.7±1.2	−4.1±0.7	6.5	This work
Glycolate	17.3±1.0	14.7±0.5	−2.6±0.7	11.6	3
Lactate	17.6±0.9	13.5±0.4	−4.1±0.6	10.4	3

a) In $cm^3 mol^{-1}$; Errors are standard deviations estimated from the least-squares analysis. b) The values of ΔV_{os}^0 estimated from the Hemmes equation[14] are as follows; 6.8 $cm^3 mol^{-1}$ for succinate at 10°C, 7.2 $cm^3 mol^{-1}$ for malonate, tartronate, malate, and tartrate at 20°C, and 3.1 $cm^3 mol^{-1}$ for glycolate and lactate at 20°C.

monodentate complex rather than a seven-membered chelate complex,[9] while a malonate ion forms a six-membered chelate complex coordinated by two carboxyl oxygens.[10] This accords with a smaller ΔV^0 value for a succinate than for a malonate on considering the contributions ii) and iv). The similar ΔV^0 value for tartronate and malonate suggests that tartronate ion also forms a six-membered chelate complex by two carboxyl groups.[4]

Large ΔV^0 values for the complexation of nickel(II) malate and nickel(II) tartrate obtained in the present study indicate that malate and tartrate ions form a chelate complex with nickel(II). Some possible structures of the chelate complex are suggested from the molecular structure of malate and tartrate ions (shown in Scheme 1). Since a seven-membered chelate is unstable as seen in nickel(II) succinate, there remain two possibilities as a chelate structure; i.e., five-membered or six-membered ring coordinated by a carboxyl and a hydroxyl groups. The values of ΔV^0 for these two systems are quite similar, and they are also comparable to those for nickel(II) glycolate and nickel(II) lactate listed in Table 2. Glycolate and lactate ions form a five-membered chelate complex with nickel(II) by carboxyl and hydroxyl groups.[11,12] The similarity of ΔV^0 with glycolate and lactate systems might lead to the conclusion of a five-membered ring structure for nickel(II) malate and nickel(II) tartrate. However, the difference in the electrical charge between these two classes of ligands must be taken into account. Since glycolate and lactate ions have a charge of −1, the volume increase associated with charge neutralization (contribution i)) should be considerablly smaller than that for malate and tartrate ions. Thus, if nickel(II) malate and nickel(II) tartrate have a five-membered chelate ring, a somewhat larger ΔV^0 value should result rather than the observed value, because other contributions ii)—iv) may be regarded as to not differ significantly for these two classes of ligands. Hence, it may be considered that nickel(II) malate and nickel(II) tartrate form a six-membered chelate complex coordinated by carboxyl and hydroxyl groups.

The difference in ΔV^0 between malonate, tartronate systems and malate, tartrate systems, both of which form six-membered chelate complexes, may be attributed to the difference in coordinating groups. Since the interaction of a hydroxyl oxygen with a nickel(II) ion is weaker than that of a carboxyl oxygen, it may be expected that the bond length between a hydroxyl oxygen and a nickel(II) ion is longer than that between a carboxyl oxygen and a nickel(II) ion. Thus, larger ΔV^0 for malate and tartrate than malonate and tartronate can be partly explained in terms of contribution iii).

The metal complexation reaction has generally been interpreted in terms of a stepwise mechanism,[13] which can be represented by Scheme 2 for the bidentate chelate complex.

$$[Ni(H_2O)_6]^{2+} + L\text{-}L^{2-} \overset{K_{os}}{\rightleftharpoons} (H_2O)_5Ni(H_2O)L\text{-}L \qquad \begin{matrix} \text{I} \\ \\ \end{matrix} \qquad \begin{matrix} \text{II} \\ \\ \end{matrix}$$

$$\overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} (H_2O)_5Ni\text{-}L\text{-}L + H_2O \qquad \text{III}$$

$$\overset{k_2}{\underset{k_{-2}}{\rightleftharpoons}} (H_2O)_4Ni\begin{matrix}/L\\ \backslash L\end{matrix}\Big) + 2H_2O \qquad \text{IV}$$

Scheme 2.

In this scheme, I refers to the free ion, II the outer-sphere complex, III the monodentate complex, and IV the bidentate chelate complex, and K_{os} and k represent the outer-sphere complex formation constant and the rate constants of the respective steps.

It is reasonable to assume that the outer-sphere complex formation from the free ions is very rapid compared with the other steps because of its nature of an ion association process, and that the monodentate complex is in a steady state because an observed relaxation is characterized by a single relaxation time. Then, the observed rate constants for the complexation reaction are related to the outer-sphere complex formation constant and the rate constants of each step in Scheme 2 by

$$k_f = K_{os}k_1\left(\frac{k_2}{k_2+k_{-1}}\right) \qquad (3)$$

and

$$k_d = k_{-1}\left(\frac{k_{-2}}{k_2+k_{-1}}\right). \quad (4)$$

Two limiting cases can be distinguished, depending on the ratio of k_2/k_{-1}. If the first bond formation step (II⇄III) is rate-determining, i.e., $k_2 \gg k_{-1}$, Eq. 3 is reduced to

$$k_f \simeq K_{OS}k_1, \quad (5)$$

whereas, if the chelate-ring closure step (III⇄IV) is rate determining, i.e., $k_2 \ll k_{-1}$, Eq. 3 is reduced to

$$k_f \simeq K_{OS}K_1k_2, \quad (6)$$

where $K_1=k_1/k_{-1}$. The observed activation volume for these two limiting cases is approximately expressed by

$$\Delta V_f^* = \Delta V_{OS}^0 + \Delta V_1^* \text{ (for the former case)} \quad (7)$$

or

$$\Delta V_f^* = \Delta V_{OS}^0 + \Delta V_1^0 + \Delta V_2^* \text{ (for the latter case)}, \quad (8)$$

where ΔV_{OS}^0 is the reaction volume for the outer-sphere complex formation, ΔV_1^* and ΔV_1^0 are the activation volume and the reaction volume for the first bond formation after the outer-sphere complex formed, and ΔV_2^* is the activation volume for the ring-closure after the first bond formed. Thus, experimentally obtained ΔV_f^* is not a single but a composite term.

It is convenient to separate the outer-sphere complex formation process from the overall reaction. The value of ΔV_{OS}^0 can be estimated with considerable reliability according to Hemmes[14] as described in a previous paper.[2,3] The values of $\Delta V_f^*-\Delta V_{OS}^0$ for some carboxylate ligands are listed in Table 2. Those values for nickel(II) malate and nickel(II) tartrate obtained in the present study are regarded as essentially the same as that for nickel(II) succinate taking into account the error range. This leads to the conclusion that the rate-determining step for the complexation reaction of nickel(II) malate and nickel(II) tartrate is the first bond formation step, since the chelation step is lacking for nickel(II) succinate as mentioned before. The situation is also the same for nickel(II) malonate and nickel(II) tartronate. On the other hand, larger values of $\Delta V_f^*-\Delta V_{OS}^0$ for nickel(II) glycolate and nickel(II) lactate, for which the rate-determining step for the complexation reaction is the ring-closure step,[11,12] can be understood with the help of Eq. 8 as described in a previous paper.[3] Comparing the two classes of ligands, glycolate and lactate, and malate and tartrate, both of them form chelate complexes with nickel(II) coordinated by carboxyl and hydroxyl oxygens, but the size of chelate ring is different as mentioned before; the former class forms five-membered ring, whereas the latter forms six-membered ring. The difference in rate-determining step for these two classes of ligands may be attributed to

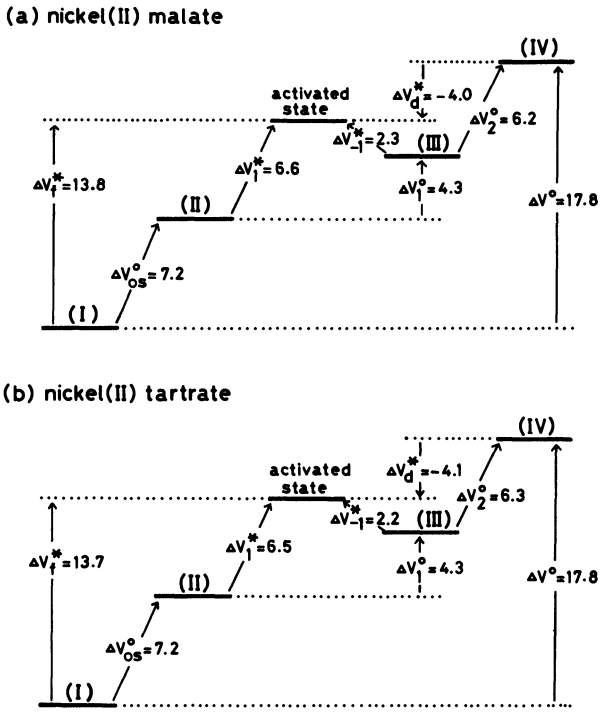

Fig. 2. Volume profile diagrams for the complexation reaction of nickel(II) malate (a) and nickel(II) tartrate (b). I, II, III, and IV in the figure correspond to the species in Scheme 2. The values of volume change in $cm^3\,mol^{-1}$ are shown in the figure.

the difference in the chelate-ring size. It is likely that a five-membered ring is imposed to take a sterically distorted structure, and hence, the ring closure becomes rate-determining for five-membered chelate formation.

It is worth noting that the values of $\Delta V_f^*-\Delta V_{OS}^0$ ($=\Delta V_1^*$) obtained for the complexation reaction for which the first bond formation is rate determining are very close to the activation volume of the water exchange of the aquanickel(II) ion, $\Delta V_{H_2O}^*=7.2\pm0.3$ $cm^3\,mol^{-1}$.[15] This suggests that the activated state for the first bond formation process is the same as that for the water exchange process, and is in accordance with the general picture drawn for the complexation reaction of labil metal ions.[13]

The volume profile diagrams obtained for the complexation reaction of nickel(II) malate and nickel(II) tartrate are shown in Fig. 2. The value of ΔV_1^0 representing the volume difference between II and III in Scheme 2 was estimated as $\Delta V^0-\Delta V_{OS}^0$ for nickel(II) succinate, based on the consideration that ΔV_1^0, the volume change associated with the first coordination-bond formation by a carboxyl group after the outer-sphere complex formed, is the same at different carboxylic acid. An initial volume increase occurs due to the release of electrostriction on forming the outer-sphere complex (II). It is followed by a volume increase due to the loosening of the water–nickel(II) bond to attain an activated state. Then, a volume decrease occurs on going from the activated state to the

monodentate complex (III) due to the completion of the first coordination-bond formation. It is again followed by a volume increase due to the second coordination-bond formation to lead a final chelate complex (IV). The remarkable feature of the volume profile for the complexation with malate and tartrate compared with those obtained previously with malonate and tartronate is that ΔV_d^* is negative for the former ligands, whereas ΔV_d^* for the latter ligands is positive. This difference can be partly attributed to the difference in the bond length of the second coordination bond; for nickel(II) malate and nickel(II) tartrate, the bond length between hydroxyl oxygen and metal ion may be longer and the final complex (IV) has a larger volume, which in turn results in the negative ΔV_d^*.

This work was supported financially in part by the Central Institute of Fukuoka University.

Studies of the Metal Complexes of Cyclohexane Derivatives. IX.[1] The Preparation and Properties of Platinum(II) Complexes Containing Methyl Derivatives of *cis*-1,2-Cyclohexanediamine

Reiko SAITO* and Yoshinori KIDANI†
Aichi Junior College of Nursing, Kamishidami, Moriyama-ku, Nagoya 463
†Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467
(Received November 2, 1985)

Four 1,2-diamine ligands, (1*RS*,2*SR*)-1-methyl-1,2-cyclohexanediamine(1m-chxn), (1*R*,2*S*,3*R*)-3-methyl-1,2-cyclohexanediamine(*R*,*S*,*R*-3m-chxn), (1*S*,2*R*,4*R*)-4-methyl-1,2-cyclohexanediamine(*S*,*R*,*R*-4m-chxn), and (1*R*,2*S*,4*R*)-4-methyl-1,2-cyclohexanediamine(*R*,*S*,*R*-4m-chxn), were prepared. The mixed-ligand complexes of the $[PtXL]^{2+}$ type (X=$(NH_3)_2$, 1,2-ethanediamine, *meso*-2,3-butanediamine, and 2,3-dimethyl-2,3-butanediamine, L=each m-chxn) were synthesized and characterized by means of their electronic, circular dichroism, and ^{13}C NMR spectra. The chelate ring formed by *S*,*R*,*R*-4m-chxn was almost conformationally fixed to take a δ conformation, while the chelate rings of 1m-chxn, *R*,*S*,*R*-3m-chxn, and *R*,*S*,*R*-4m-chxn easily interchange between δ and λ conformations. The stereochemistries of these three complexes are attributable to the conformational requirements for both the cyclohexane ring and the chelate ring, for which synchronous inversions are presumed.

The conformations of chelate rings of C-substituted 1,2-diamine complexes in solution have been extensively studied. Most of them may be classified into two types.

(1) In the complexes containing a chelate ligand with achiral carbon atoms or enantiotopic carbon atoms[2] in its chelate ring, such as 2,3-dimethyl-2,3-butanediamine(dmbn) and *meso*-2,3-butanediamine-(*m*-bn), the distributions of the two conformations in the $\delta \rightleftarrows \lambda$ equilibrium are equal as a result of the rapid interconversion.[3-5]

(2) In the complexes containing a chelate ligand with one chiral carbon atom or two diastereotopic carbon atoms,[2] such as (2*R* or 2*S*)-1,2-propanediamine and (2*R*,3*R* or 2*S*,3*S*)-2,3-butanediamine, the chelate rings take predominantly either a δ or a λ conformation.[3-5] However, the complexes formed by the other type of 1,2-diamine, which has an unsymmetrical structure due to constitutionally nonequivalent substituents attached to the chelate ring carbon atom(s), have not been so widely investigated.

Recently we have reported on the preparation and properties of the complexes containing the latter type of ligand, 1-aminomethyl-2-methylcyclohexylamine[6] or (1*R*,2*S*,3*S* or 1*S*, 2*R*,3*R*)-3-methyl-1,2-cyclohexanediamine (*R*,*S*,*S*- or *S*,*R*,*R*-3m-chxn).[1] In these complexs, the conformations of the chelate ring are almost fixed by means of the steric effect of the methyl group attached to the carbon atom outside the chelate ring. As an extention of these earlier studies, we have now synthesized some Pt^{II} complexes containing four new diamines (m-chxn), (1*RS*,2*SR*)-1-methyl-1,2-cyclohexanediamine-(1m-chxn), (1*R*,2*S*,3*R*)-3-methyl-1,2-cyclohexanediamine-(*R*,*S*,*R*-3m-chxn), (1*S*,2*R*,4*R*)-4-methyl-1,2-cyclohexanediamine(*S*,*R*,*R*-4m-chxn), and (1*R*,2*S*,4*R*)-4-methyl-1,2-cyclohexanediamine(*R*,*S*,*R*-4m-chxn). In this paper, the conformations of the m-chxn chelate rings will be discussed on the basis of the platinum-carbon coupling constants in the ^{13}C NMR spectra.

Experimental

Preparation of the Ligands. (1*RS*,2*SR*)-1-Methyl-1,2-cyclohexanediamine(1m-chxn): 1-Methyl-*r*-1,*c*-2-cyclohexanedicarboxylic acid was synthesized from butadiene and citraconic anhydride according to the literature.[7] From this acid, 1m-chxn was prepared by a method similar to that reported by Werner.[8] It was purified as the dihydrochloride. Found: C, 41.52; H, 8.99; N, 13.69%. Calcd for $C_7H_{16}N_2 \cdot 2HCl$: C, 41.80; H, 9.02; N, 13.93%.

(1*R*,2*S*,3*R*)-3-Methyl-1,2-cyclohexanediamine(*R*,*S*,*R*-3m-chxn): *t*-3-Methyl-*r*-1,*c*-2-cyclohexanedicarboxylic acid was obtained by a manner similar to that described in the literature.[9] (1*RS*,2*SR*,3*RS*)-3m-chxn was prepared by the same procedure as 1m-chxn. It was optically resolved using (2*R*,3*R*)-di-*O*-benzoyltartaric acid. The less soluble benzoyltartrate obtained, whose optical rotation could not be measured because of its low solubility, was recrystallized twice from EtOH–H_2O (1:2). Mp(decomp) 205—206°C. Anal. ($C_{25}H_{30}N_2O_8$) C, H, N. By treating this salt with a 3 mol dm^{-3} HCl solution, *R*,*S*,*R*-3m-chxn·2HCl was obtained. Found: C, 42.11; H, 9.18; N, 13.63%. Calcd for $C_7H_{16}N_2 \cdot 2HCl$: C, 41.80; H, 9.02; N, 13.93%. $[\alpha]_D = -33.8°$ (*c* 2.0, H_2O). The assignments of the absolute configurations of the three optically active diamines studied in this paper will be described in a later section.

(1*S*,2*R*,4*R*)- and (1*R*,2*S*,4*R*)-4-Methyl-1,2-cyclohexanediamine (*S*,*R*,*R*- and *R*,*S*,*R*-4m-chxn): Commercially available 4-methyl-1,2-cyclohexanedicarboxylic anhydride (Aldrich Co., Ltd.) was hydrolyzed. A white powder(**A**) was obtained nearly quantitatively; mp(decomp) 161—171°C. A suspension of 270 g of **A** in 480 cm^3 of 2-propanol was heated to bp and then cooled. A white powder (**B**, 150 g) was thus obtained; mp(decomp) 179—180°C. This was recrystallized twice from 2-propanol to give 48 g of acid **C**; mp(decomp) 185—186°C. This acid was *t*-4-methyl-*r*-1,*c*-2-cyclohexanedicarboxylic acid contaminated by a very small amount of the *c*,*c*-isomer. This contaminant could be removed during the course of optical resolution. To the

filtrate obtained after removing **B**, an excess amount of an aqueous ammonia solution was added. The resulting mixture was evaporated to dryness to yield 65 g of a crude mixture of monoammonium salt of *c,c*- and *t,c*-acid. This was recrystallized from EtOH–H_2O (1:2) to give 57 g of crystals. Treating this salt with a 3 mol dm^{-3} HCl solution gave 49 g of pure *c*-4-methyl-*r*-1,*c*-2-cyclohexanedicarboxylic acid(**D**; mp(decomp) 171—172°C).

From acid **D**, 1*SR*,2*RS*,4*RS*-4m-chxn was prepared by the same manner as was used for the synthesis of 1m-chxn and *R,S,R*-3m-chxn. This was optically resolved by the use of (2*R*,3*R*)-di-*O*-benzoyltartaric acid. The less soluble benzoyltartrate was recrystallized from EtOH–H_2O (1:2). Anal. ($C_{25}H_{30}N_2O_8 \cdot H_2O$) C, H, N. $[\alpha]_D = -68.6°$ (*c* 1.0, MeOH). Treating this salt with a 3 mol dm^{-3} HCl solution gave *S,R,R*-4m-chxn·2HCl. Found: C, 41.44; H, 9.04; N, 13.91%. Calcd for $C_7H_{16}N_2 \cdot 2HCl$: C, 41.80; H, 9.02; N, 13.93%. $[\alpha]_D = +23.0°$ (*c* 2.0, H_2O).

The *R,S,R*-4m-chxn compound was prepared from acid **C** by a similar Schmidt reaction.[8] It was optically resolved using the same resolving reagent as was used for *S,R,R*-4m-chxn. The less soluble diastereomeric salt obtained was recrystallized twice from H_2O–DMF (2:1); mp(decomp) 174—175°C. Anal. ($C_{25}H_{30}N_2O_8 \cdot 2H_2O$) C, H, N. $[\alpha]_D = -72°$ (*c* 0.5, MeOH). From this tartrate, *R,S,R*-4m-chxn·2HCl was obtained by a usual work up. Found: C, 42.05; H, 8.91; N, 13.87%. Calcd for $C_7H_{16}N_2 \cdot 2HCl$: C, 41.80; H, 9.02; N, 13.93%. $[\alpha]_D = +21.2°$ (*c* 2.1, H_2O).

Preparation of Complexes. $[Pt(NH_3)_2L]Cl_2$ (L= each m-chxn): These complexes were prepared by the reaction of $[PtCl_2L]$[10] with aqueous ammonia. Found: $[Pt(NH_3)_2$(1m-chxn)$]Cl_2 \cdot 0.5H_2O$, C, 19.00; H, 5.36; N, 12.74%. $[Pt(NH_3)_2$(*R,S,R*-3m-chxn)$]Cl_2 \cdot 0.5H_2O$, C, 19.11; H, 5.51; N, 12.98%. Calcd for $C_7H_{23}N_4O_{0.5}Cl_2Pt$: C, 19.23; H, 5.30; N, 12.81%. Found: $[Pt(NH_3)_2$(*S,R,R*-4m-chxn)$]Cl_2 \cdot H_2O$, C, 18.94; H, 5.35; N, 12.61%. Calcd for $C_7H_{24}N_4OCl_2Pt$: C, 18.84; H, 5.42; N, 12.55%. Found: $[Pt(NH_3)_2$(*R,S,R*-4m-chxn)$]Cl_2$, C, 19.61; H, 5.01; N, 12.92%. Calcd for $C_7H_{22}N_4Cl_2Pt$: C, 19.63; H, 5.18; N, 13.08%.

[Pt(en)L]Cl_2: These complexes were prepared by the reaction of $[PtCl_2(en)]$[11] with L in water. The aqueous solution of L was obtained from the m-chxn·2HCl solution by passing it through an anion-exchange resin column (Dowex, 1-X8, OH^- form). Found: [Pt(en)(1m-chxn)]-$Cl_2 \cdot 0.5H_2O$, C, 23.47; H, 5.28; N, 11.61%. [Pt(en)(*R,S,R*-3m-chxn)$]Cl_2 \cdot 0.5H_2O$, C, 23.00; H, 5.58; N, 12.15%. Calcd for $C_9H_{25}N_4O_{0.5}Cl_2Pt$: C, 23.33; H, 5.44; N, 12.09%. Found: [Pt(en)(*S,R,R*-4m-chxn)$]Cl_2$, C, 23.69; H, 5.22; N, 12.39%. [Pt(en)(*R,S,R*-4m-chxn)$]Cl_2$, C, 23.92; H, 5.26; N, 11.96%. Calcd for $C_9H_{24}N_4Cl_2Pt$: C, 23.79; H, 5.33; N, 12.33%.

[Pt(*m*-bn)L]Cl_2: The *m*-bn ligand was synthesized by a literature method.[12] The complexes were synthesized in a way similar to that used for the preparation of $[Pt(en)L]Cl_2$. Found: [Pt(*m*-bn)(1m-chxn)$]Cl_2$, C, 27.30; H, 5.79; N, 11.42%. [Pt(*m*-bn)(*S,R,R*-4m-chxn)$]Cl_2$, C, 27.39; H, 5.99; N, 11.93%. Calcd for $C_{11}H_{28}N_4Cl_2Pt$: C, 27.39; H, 5.85; N, 11.62%. [Pt(*m*-bn)(*R,S,R*-3m-chxn)$]Cl_2 \cdot 0.5H_2O$, C, 26.83; H, 5.93; N, 11.52%. [Pt(*m*-bn)(*R,S,R*-4m-chxn)$]Cl_2 \cdot 0.5H_2O$, C, 26.94; H, 5.89; N, 11.66%. Calcd for $C_{11}H_{29}N_4O_{0.5}Cl_2Pt$: C, 26.89; H, 5.95; N, 11.40%.

[Pt(dmbn)L]Cl_2: The dmbn ligand was prepared by the known procedure.[13] The complexes were obtained by the reaction of $[PtCl_2L]$ with an aqueous solution of dmbn. Found: [Pt(dmbn)(1m-chxn)$]Cl_2 \cdot 1.5H_2O$, C, 29.21; H, 6.34; N, 10.45%. [Pt(dmbn)(*R,S,R*-3m-chxn)$]Cl_2 \cdot 1.5H_2O$, C, 28.91; H, 6.47; N, 10.34%. [Pt(dmbn)(*S,R,R*-4m-chxn)$]Cl_2 \cdot 1.5H_2O$, C, 29.23; H, 6.47; N, 10.56%. Cacld for $C_{13}H_{35}N_4O_{1.5}Cl_2Pt$: C, 29.05; H, 6.56; N, 10.42%. Found: [Pt(dmbn)-(*R,S,R*-4m-chxn)$]Cl_2 \cdot H_2O$, C, 29.67; H, 6.55; N, 11.27%. Calcd for $C_{13}H_{34}N_4OCl_2Pt$: C, 29.55; H, 6.49; N, 10.60%.

Measurements. The CD and electronic spectra were measured using a JASCO J-40 spectropolarimeter and a Shimadzu UV-210-A spectrometer respectively. The optical rotations were measured with a JASCO DIP-4 polarimeter. The ^{13}C NMR spectra were recorded on a JEOL JNM-FX-100 spectrometer using D_2O as a solvent. The chemical shifts were reported relative to the dioxane (δ 67.70) added as an internal reference. The measurements of all the complexes except for the *R,S,R*-4m-chxn complexes were recorded with 8 K data points. For the *R,S,R*-4m-chxn complexes, the measurements were run with 16 K data words. The ^{13}C NMR spectra of some of the complexes, which were not sufficiently soluble in D_2O, were recorded after converting their counter anions to F^-.

Results and Discussion

Preparation of the Ligands. The diamines were

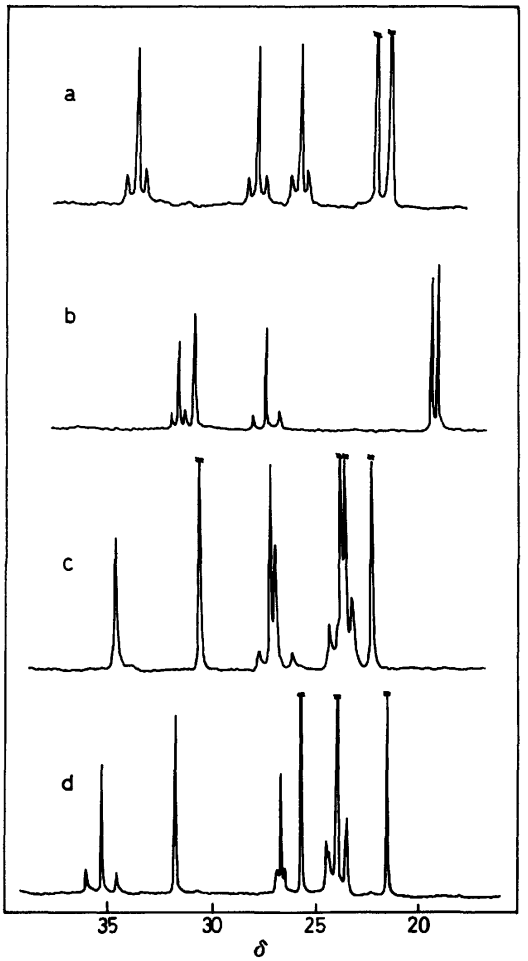

Fig. 1. ^{13}C NMR Spectra of $[Pt(NH_3)_2$(1m-chxn)$]$-Cl_2 (a), $[Pt(NH_3)_2$(*R,S,R*-3m-chxn)$]Cl_2$ (b), [Pt(dmbn)-(*S,R,R*-4m-chxn)$]Cl_2$ (c), and [Pt(dmbn)(*R,S,R*-4m-chxn)$]Cl_2$ (d).

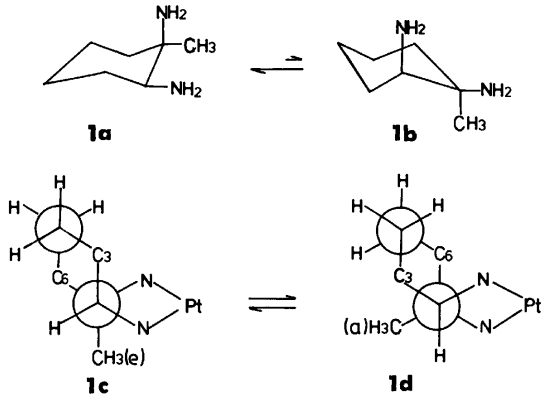
a) Carbon chemical shifts in ppm from external TMS measured vs. internal dioxane. b) Coupling constants (^{195}Pt-C) are found in parentheses in Hz. c) Two chemical shifts due to diamine-ring carbons of m-chxn and another diamine (X) appeared very close to one another. The signal with the stronger intensity was tentatively assigned to X. d) Platinum satellite peaks were observed as shoulders.

prepared from the corresponding methyl derivatives of *cis*-1,2-cyclohexanedicarboxylic acid. 1-Methyl-*r*-1,*c*-2-cyclohexanedicarboxylic acid was synthesized by the Diels-Alder reaction.[7] *t*-3-Methyl-*r*-1,*c*-2-cyclohexanedicarboxylic acid was prepared from the corresponding *c*,*c*-diastereomer by a literature method.[9] We found that the dicarboxylic aicd **A** obtained from commercially available 4-methyl-1,2-cyclohexanedicarboxylic anhydride was a mixture of *c*,*c*- and *t*,*c*-acid by comparing it with an authentic sample prepared according to the literature.[14] It could be separated into two isomers by the method presented in the Experimental section. The attempted optical resolution of 1m-chxn using (2*R*,3*R*)-di-*O*-benzoyltartaric acid was unsuccessful. For other diamines, each optically active enantiomer was prepared.

Conformations of the Chelate Rings. The possible conformations of the free m-chxn ligands and their chelate rings in each complex are shown in **1a—4d**. In the schematic structures of **c** and **d**, each ligand adopts a conformation illustrated in the corresponding structures, **a** and **b**. The symbols of (e) and (a) denote an equatorial and an axial methyl orientation respectively with respect to the cyclohexane ring. Some representative ^{13}C NMR spectra of the Pt^{II} complexes in the δ 10 to δ 40 region are shown in Fig. 1. The chemical shifts and platinum-carbon coupling constants are given in Table 1.

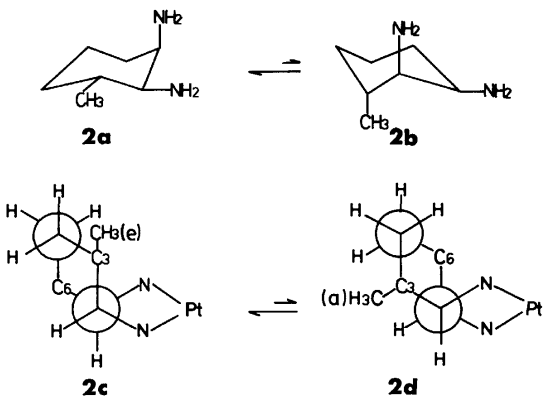
In the ^{13}C NMR spectra of 1m-chxn complexes, three platinum satellites were observed. Of the resonances with the satellite peak due to the skeletal carbons of the cyclohexane ring, one with $^3J_{Pt\text{-}C}$ of 23.2 Hz was assigned to C_6 carbon, applying the β-substituent parameter.[15] The methyl carbon and C_3 carbon, which occupy symmetrical positions about C_1–C_2 bond, showed a 20—22 Hz coupling. For $[Pt(NH_3)_2(m\text{-bn})]^{2+}$ and $[Pt(NH_3)_2(ibn)]^{2+}$ (ibn=2-methyl-1,2-propanediamine), both of which exist in equimolar conformations with a rapid ring inversion, the $^3J_{Pt\text{-}C}$ values have been reported to be 27.3 and 22.4 Hz respectively.[16] The small differences between $^3J_{Pt\text{-}C}$ values due to the three β carbons provide an indication of a roughly equal

probability of λ(**1c**) and δ(**1d**) conformations.



Based on the stereochemistry of the cyclohexane ring, the **1a** conformation, with the larger equatorial methyl and the smaller axial amino group, is more favorable than **1b**. Its conformational behavior prefers the **1c** conformation for the complex. On the other hand, concerning the effects of the substituents on the chelate ring, the **1c** conformation, having a chelate ring with C_3 carbon and the methyl group in axial orientations and C_6 carbon in an equatorial orientation, should be more unfavorable than the **1d** conformation. Because of these competitive steric effects, **1c** and **1d** conformations would seem to be almost equienergetic.

In the ^{13}CNMR spectra of the *R,S,R*-3m-chxn complexes, the signal around 32 ppm was assigned to the C_3 carbon by the aid of the off-resonance proton-decoupling technique. Two $^3J_{Pt-C}$ couplings, of about 18 and 32—33 Hz for C_3 and C_6 carbon respectively, were observed. The absense of additional peaks corresponding to each carbon indicated that the $\lambda \rightleftarrows \delta$ inversion was rapid on the NMR time scale. The



observed $^3J_{Pt-C_3}$ (and $^3J_{Pt-C_6}$) values must be the weighted averages of the **2c** and **2d** conformations, they can be expressed by the following equations:

$$^3J_{Pt-C_3}(\text{obsd}) = p\,{}^3J_{ax(2c)} + (1-p)\,{}^3J_{eq(2d)} \quad (1)$$

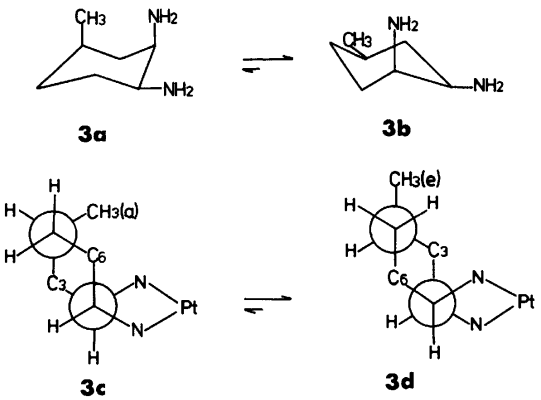
$$^3J_{Pt-C_6}(\text{obsd}) = p\,{}^3J_{eq(2c)} + (1-p)\,{}^3J_{ax(2d)} \quad (2)$$

where p denotes the population of the **2c** conformation and where $^3J_{eq(2c)}$ and $^3J_{ax(2c)}$ are, respectively, the values of $^3J_{Pt-C_6}$ and $^3J_{Pt-C_3}$ when the chelate ring is assumed to have exclusively a rigid conformation, **2c**. Similarly, $^3J_{eq(2d)}$ and $^3J_{ax(2d)}$ are, respectively, $^3J_{Pt-C_3}$ and $^3J_{Pt-C_6}$ when the **2d** conformation is assumed to be fixed. By refering to the literature,[17] $^3J_{eq(2c)}$ was assumed to be equal to $^3J_{eq(2d)}$, and $^3J_{ax(2c)}$ and $^3J_{ax(2d)}$ were assumed to be zero. Then, p is given by Eq. 3:

$$^3J_{Pt-C_6}(\text{obsd}) = p\{{}^3J_{Pt-C_3}(\text{obsd}) + {}^3J_{Pt-C_6}(\text{obsd})\} \quad (3)$$

A calculation from the data in Table 1 yielded p in the range of 0.64—0.67 for the *R,S,R*-3m-chxn complexes. Erickson et al.[17] have reported the p for [Pt(bpy)(pn)]$^{2+}$ (bpy=2,2′-bipyridine) to be 0.72. However, Yano et al.[18] have pointed out that a smaller $^3J_{Pt-C}$ value for an unsymmetrical complex such as a pn complex should be attributed to the puckering effect of the chelate ring rather than to the relative population. Our result showed one of a few cases in which the complex exhibited the intermediate relative population.

In both the **2c** and **2d** conformations of the *R,S,R*-3m-chxn complex, the two β carbons are located in an equatorial and an axial orientation respectively. The axial position in the **2d** conformation is less crowded than that in the **2c** conformation. Therefore the preference for the former conformation was expected. On the contrary, the **2d** conformer would not be preferable on the basis of the stereochemistry of the cyclohexane. The **2c**-conformation preference of about 65% obtained by the use of above NMR results indicated that this conformational equiribrium was influenced more pronouncedly by the stability of the cyclohexane ring than by the steric environment around the chelate ring.



For the *S,R,R*-4m-chxn complexes, there is no large difference between the conformational situations with regard to the chelate rings of **3c** and **3d**, thus, the conformer distribution seems to be exclusively controlled by the stabilities of the cyclohexane ring. The ring inversion between **3a** and **3b** seems improbable because of the 1,3-diaxial interaction. This should lead to a strong preference of one extreme

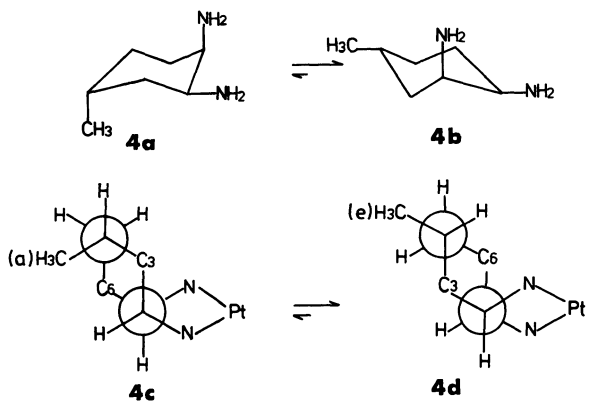
sh=shoulder.

conformation (**3d**) of the chelate ring. In the ^{13}C NMR spectra of these complexes, the $^3J_{Pt\text{-}C_6}$ coupling of 42—44 Hz and the $^3J_{Pt\text{-}C_3}$ coupling of ≈0 Hz were observed. These facts agree with the above prediction.



In the two conformations (**4c** and **4d**) of the *R,S,R*-4m-chxn complex, the steric effect of the methyl group attached to the γ carbon on the stability of the chelate ring seemed small, as in the *S,R,R*-4m-chxn complex.

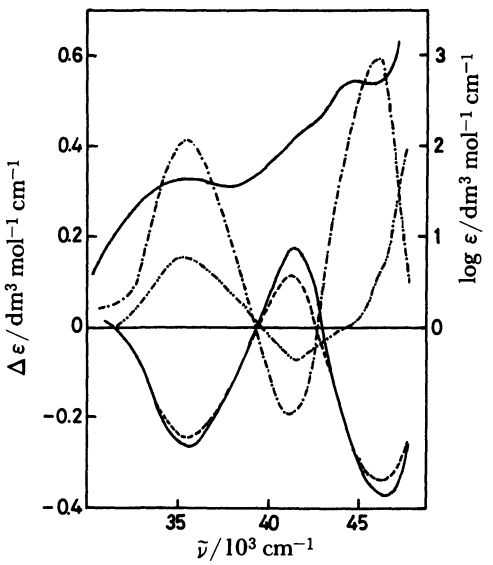


Fig. 2. Electronic and CD spectra of [Pt(en)(*R,S,R*-3m-chxn)]Cl_2 (—··—), [Pt(en)(*S,R,R*-3m-chxn)]Cl_2 (—·—),[1] [Pt(*m*-bn)(*S,R,R*-4m-chxn)]Cl_2 (——), and [Pt(*m*-bn)(*R,S,R*-4m-chxn)]Cl_2 (——).

Consequently, the conformer population of the chelate ring would seem to depend on the distribution of the two conformations of the free cyclohexane ring. The ^{13}C NMR spectra of the *R,S,R*-4m-chxn complexes indicated the existence of two conformers with a different molar ratio in the equilibrium, as in the case for the *R,S,R*-3m-chxn complexes. By a calculation similar to that used for the latter complexes, the population, *p*, of the **4d** conformation was found to be 0.80—0.83.

The conformational energy barriers for the complexes with a bulky counter ligand(X) might be expected to be higher than those with a smaller one. However, the spectral tendencies of the 1m-, *R,S,R*-3m, and *R,S,R*-4m-chxn complexes suggested that their conformational equilibrium was little affected by the mass of the X.

CD Spectra. The electronic and CD spectra of the complexes are shown in Fig. 2 and Table 2. The *R,S,R*-3m-chxn complexes showed a positive CD band(ca. 35000 cm^{-1}), a negative CD band(ca. 42000 cm^{-1}), and a positive CD band(shoulder ca. 46000 cm^{-1}). The signs and positions of the first two bands of these complexes were almost identical with those of the corresponding bands of the *S,R,R*-3m-chxn complexes[1] (Fig. 2), however, their CD strengths were weaker than those of the latter. Several reports[19-21] have shown that the chiral 1,2-diamine Pt^{II} complexes with a positive CD sign of the ^3E_g transition have a λ conformation. Thus, the λ conformation populated more largely was suggested for the *R,S,R*-3m-chxn complexes. Therefore, the absolute configuration of the present (−)-3m-chxn ligand can be identified as (1*R*,2*S*,3*R*). From the spectral results of both the 4m-chxn complexes, the δ conformations were reasonably deducible. It was concluded that the absolute configurations of the 4m-ligands, whose structures correspond to the *c,c*- and *t,c*-configurations, were (1*S*,2*R*,4*R*) and (1*R*,2*S*,4*R*) respectively.

Hawkins et al.[21] have reported the estimated value of the conformer population of $[Pt(NH_3)_2((S)$-3,3-dmbn$)]^{2+}$ (3,3-dmbn=3,3-dimethyl-1,2-butanediamine) from a comparison of the CD intensities of the ^1E_g band. Comparing the CD intensities of the present *R,S,R*-3m-chxn complexes with those of the *S,R,R*-3m-chxn complexes,[1] the intensity ratios were found to be 0.37 (the band around 35000 cm^{-1}) and 0.34 (the band around 41000 cm^{-1}) for $[Pt(NH_3)_2L]^{2+}$, and 0.37 (the band around 35000 cm^{-1}) and 0.35 (the band around 42000 cm^{-1}) for $[Pt(en)L]^{2+}$. If the contribution of the chiral atoms to the Cotton effect of the above bands is negligibly small, and if the $\Delta\varepsilon$ value of the *R,S,R*-3m-chxn complex, which presumably has an extremely fixed conformation, is nearly equal to that of the *S,R,R*-3m-chxn complex, the more favorable λ conformer populations of the *R,S,R*-3m-chxn complexes can be calculated to range from 0.65 to 0.68. These values were in excellent agreement with those estimated by means of NMR analyses. However, for the *R,S,R*-4m-chxn complexes the δ conformer population derived from a similar calculation did not agree with those obtained by NMR analyses. There remain some questions in these CD analyses, one of them being the lack of a common CD intensity value for the complexes with a fixed conformation.

We wish to thank the Instrument Center, Institute for Molecular Science, for the use of a NMR spectrometer (JEOL JNM-FX-100). We are also grateful to Miss Toshiko Naito of the Analytical Center of the Nagoya City University for her elemental analyses.

Solvation of Anions in Water-Acetonitrile Mixtures

Kiyoshi MIYAJI* and Kenichi MORINAGA
Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338
(Received December 26, 1985)

The enthalpies of transfer from water to mixtures with acetonitrile(ΔH_t°) for various anions reach maxima at a mole fraction of acetonitrile(x_{AN}) ca. 0.3, and decrease linearly and in parallel in the intermediate region. A linear relation is found between ΔH_t° at x_{AN} 0.3 and the hydration enthalpies for halide and symmetrical ions. This finding and the parallel x_{AN} dependence of ΔH_t° in the intermediate region are interpreted on the basis of the linear relation between the solvation enthalpies and the entropies for the halide ions. The reduction in the hydrogen-bonding interaction extending beyond the primary hydration sphere(ΔH_{INT}) for halide ions in the mixtures is estimated based on a modified Eley and Evans hydration model. At x_{AN} 0 to ca. 0.3, ΔH_{INT} compared with that in water agree well with the observed ΔH_t°, indicating that the increase in ΔH_t° is due to the reduction in the outer hydration sphere interaction. However, they split gradually at x_{AN} above 0.3. The adequacy of the modifications in the treatment of the solvation enthalpy cycle in the mixtures is re-evaluated from the structural viewpoint. The exothermic change in the intermediate region may be attributable to the reduction in the cavity formation energy.

Preferential solvation of ions has been studied in many kinds of mixed solvent systems by various methods.[1] Silver ion has been confirmed to be preferentially solvated by acetonitrile in water-acetonitrile mixtures by the measurements of the transference number,[2a] solubility,[2b] NMR,[2c] and the free energy of transfer.[2d] On the basis of this fact we have discussed the dependence of the ionic conductance[3] and ionic enthalpies of transfer (ΔH_t°)[4] on the solvent composition. Previously[4] the rapid changes of ΔH_t° for alkali and halide ions in the acetonitrile-rich region have been ascribed to the preferential hydration of smaller ions. The ΔH_t° maxima at a mole fraction of acetonitrile (x_{AN}) ca. 0.3 have been suggested to be due to the least favorable hydration for halide ions owing to the destruction of the water lattice caused by the addition of acetonitrile.

In this study we use a new approach to the discussion of the x_{AN} dependence of ΔH_t° for anions in the water-rich and in the intermediate regions from three viewpoints. The first viewpoint is ΔH_t° for anions in relation to the ionic enthalpy of hydration. Linear relations are found between ΔH_t° at x_{AN} 0.3 to 0.6 and the ionic hydration enthalpies, and the same relations are derived by using the entropies of transfer for halide ions. The second is an attempt to estimate the interaction in the outer hydration sphere for halide ions based on a modified Eley and Evans hydration model for the mixtures. It will be noted that the reduction in the interaction estimated from ionic solvation enthalpy cycle is found to be responsible for the endothermic process of ΔH_t° in the water-rich region. The third is ΔH_t° for anions in relation to the solvent structure of the mixtures. The adequacy of the correction for cavity formation energy in the mixtures arising from the change in the solvent structure is discussed. The change in ΔH_t° in the intermediate region is found to be due primarily to the reduction in the cavity formation energy.

Experimental

All chemicals used were of reagent grade. Sodium tetrafluoroborate was prepared from the acid and aqueous sodium carbonate solution, and recrystallized twice from water in a platinum dish. Other salts commercially available were once recrystallized from water. All salts were dried in vacuo, at 60 °C overnight and stored in a desiccator. Acetonitrile and water were distilled thrice and twice, respectively.[3] The enthalpy of solution was measured with a heat-exchange type calorimeter at 25±0.02 °C.[5] The reported standard enthalpy of solution (ΔH_s°) is the average of at least three determinations in a 10^{-3} to 10^{-2} mol dm^{-3} concentration range agreeing within ±0.4 kJ mol^{-1}.

Results and Discussion

tes are listed in Table 1. The ΔH_s° values for sodium bromate, chlorate and nitrite obtained in water agreed with the literature[6] values within ± 0.2 kJ mol^{-1} and ΔH_s° for sodium acetate within ± 0.8 kJ mol^{-1}.

The enthalpies of transfer from water to water-acetonitrile mixtures (ΔH_t°) for anions were calculated by using ΔH_t° value for Na^+ estimated previously[4] based on the TATB assumption ($\Delta H_t^\circ[Ph_4As^+] = \Delta H_t^\circ[Ph_4B^-]$).[7] Figure 1 shows the x_{AN} dependence of ΔH_t° for typical anions, although ΔH_t° for seventeen anions have been estimated in our laboratory.

The ΔH_t° values for anions reach maxima at x_{AN} ca. 0.3 except for some large anions containing phenyl groups. They decrease linearly and in parallel in the intermediate region, and reach minima at x_{AN} ca. 0.8. Those for small anions increase rapidly in the acetonitrile-rich region. From the extent of these rapid changes the order of the preference to water for anions has been determined.[4] The following order can be determined: $CF_3CO_2^- > Cl^- > Br^- > NCS^- > I^- > Pi^-$ (picrate) $> ClO_4^- \simeq BF_4^-$.

A Linear Relation between Enthalpies of Transfer at x_{AN} 0.3 and Enthalpies of Hydration for Anions. The enthalpies of transfer for anions from water to the mixtures at x_{AN} 0.3 ($\Delta H_t^\circ(x_{AN}=0 \rightarrow 0.3)$) are plotted against the ionic enthalpies of hydration (ΔH_W) in Fig. 2. The ΔH_W values for anions except BF_4^- were cited from the literature.[8] The ΔH_t° value for BF_4^- was estimated from a linear relation between ΔH_W and the reciprocal of the thermochemical radii of polyatomic anions.[9] Noticeably, the values for the halide and

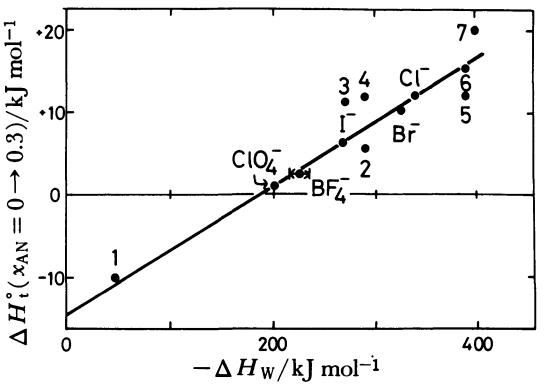

Fig. 2. The enthalpies of transfer from water to water-acetonitrile mixtures at the mole fraction of acetonitrile (x_{AN}) 0.3, ΔH_t° ($x_{AN}=0 \rightarrow 0.3$), plotted against the enthalpies of hydration, ΔH_W, for anions.

symmetrical anions lie on a straight line. This finding means that the more strongly hydrated is an anion, the more unfavorable will be its solvation in the mixtures.

The same relation will be derived by using the ionic solvation entropy as follows. Fortunately, the free energies of transfer (ΔG_t°) for alkali metal and halide ions in these mixtures have been published on TATB assumption.[10] The entropies of transfer (ΔS_t°) for these ions can be estimated ($-T\Delta S_t^\circ = \Delta G_t^\circ - \Delta H_t^\circ$) and are plotted against x_{AN} in Fig. 3. The ΔS_t° values for anions are considered to be nearly equal to each other in the range of x_{AN} 0 to ca. 0.6, while those for cations are differentiated in this range.

As suggested by Eley and Evans,[11] the more negative the ionic hydration enthalpy, the more negative the corresponding entropy. The same relation would be expected to hold in the mixtures. Figure 4 shows the analysis of the thermodynamic functions in water and in the mixtures. The values of the thermodynamic

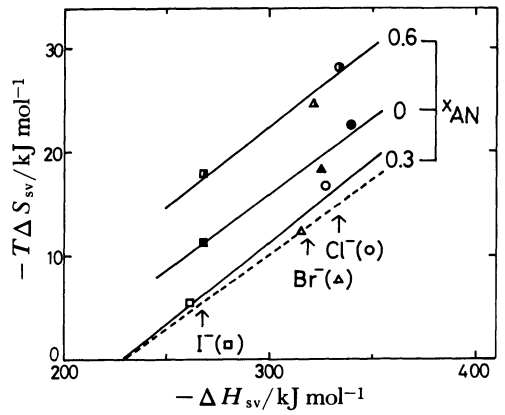

Fig. 4. The entropies of solvation, $-T\Delta S_{SV}$, plotted against the enthalpies of solvation, $-\Delta H_{SV}$, for halide ions in water and water-acetonitrile mixtures. Broken line indicates the plot of $-T\Delta S_{0.3}$ vs. $-\Delta H_W$.

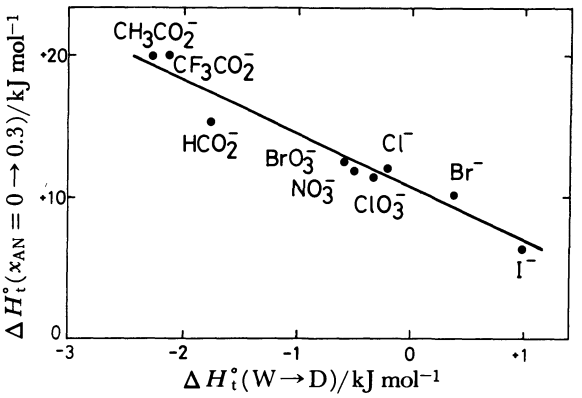

Fig. 5. The enthalpies of transfer from water to water-acetonitrile mixtures at the mole fraction of acetonitrile (x_{AN}) 0.3, $\Delta H_t^\circ(x_{AN}=0\rightarrow0.3)$, plotted against the enthalpies of transfer from normal water to heavy water, $\Delta H_t^\circ(W\rightarrow D)$ for anions.

functions in water (ΔS_W and ΔH_W) are cited from the literature,[8] and those in the mixtures are calculated from values of the transfer functions. The broken line represents $-T\Delta S_{0.3}$ plotted against $-\Delta H_W$ and intersects the line of $-T\Delta S_{0.3}$ plotted against $-\Delta H_{0.3}$ close to the same position on the abscissa.

Equations 1, 2, and 4 are derived from the plots of $-T\Delta S_{SV}$ vs. ΔH_{SV} in water and the mixtures of x_{AN} 0.3 and 0.5, respectively. Equation 3 is derived from the broken line. In those equations, the subscripts denote the solvent compositions.

$$-T\Delta S_w = -28.0 + 0.14_6(-\Delta H_w) \quad (1)$$

$$-T\Delta S_{0.3} = -36.3 + 0.15_8(-\Delta H_{0.3}) \quad (2)$$

$$-T\Delta S_{0.3} = -33.9 + 0.14_6(-\Delta H_w) \quad (3)$$

$$-T\Delta S_{0.5} = -29.0 + 0.15_9(-\Delta H_{0.5}) \quad (4)$$

$$\Delta H_t^\circ(x_{AN} = 0 \longrightarrow 0.3) = -15.2 + 0.076(-\Delta H_w) \quad (5)$$

By subtracting Eq. 1 from Eq. 2, the relation between ΔH_t° and ΔH_W is obtained. When the experimental value for $-T\Delta S_t^\circ$ (5.9 kJ mol^{-1}) is substituted in this relation, we obtain Eq. 5. The values of the slope and intercept of Eq. 5 are in good agreement with the experimental ones (slope 0.078, intercept 14.8).

In x_{AN} over the range 0.3 to 0.6, linear relations with the same slope as Eq. 5 can be derived in a similar manner as above, since the plots of $-T\Delta S_{SV}$ vs. $-\Delta H_{SV}$ have the same slope as that of Eq. 2. Therefore, the x_{AN} dependence of ΔH_t° is parallel in this range. Thus, we have been able to derive the linear relations between ΔH_t° at x_{AN} 0.3 to 0.6 and ΔH_W for halide ions by using ΔG_t° data.

Estimation of the Hydrogen-Bonding Interaction Extending beyond the Primary Hydration Sphere based on Modified Eley and Evans Hydration Model. The relation between $\Delta H_t^\circ(x_{AN}=0\rightarrow0.3)$ and the enthalpies of transfer from normal water to heavy water ($\Delta H_t^\circ(W\rightarrow D)$) is shown in Fig. 5. The $\Delta H_t^\circ(W\rightarrow D)$ values were cited from the literature.[12] Thus $\Delta H_t^\circ(x_{AN}=0\rightarrow0.3)$ was related closely to $\Delta H_t^\circ(W\rightarrow D)$. Anions which are more strongly hydrated by hydrogen-bonding interaction should have the more negative $\Delta H_t^\circ(W\rightarrow D)$ value, because heavy water has been shown to be more strongly hydrogen bonded than normal water.[12] Noticeably, those anions have the more positive $\Delta H_t^\circ(x_{AN}=0\rightarrow0.3)$ values. This finding suggests that the endothermicity in the mixtures results from an unfavorable interaction between the primary hydration sphere and the surroundings, since anions should be preferentially hydrated in the water-rich region. Accordingly we have developed the Eley and Evans treatment of the ionic hydration enthalpy cycle to estimate the outer sphere hydrogen-bonding interaction in the mixtures.

Several molecular models of the ionic hydration of the water structure, the orientation of the water dipole, various ion-water interactions and the water structure of the outer hydration sphere have been proposed,[13a-d] since Bernal and Fowler published their pioneer work in 1933. Eley and Evans have proposed a thought experiment involving the following steps to estimate theoretically the ionic hydration enthalpy for a tetrahydrated ion. (1) A cluster of five water molecules corresponding to the volume of the primary hydrated ion is removed from the liquid phase to the gas phase leaving a cavity in the liquid, $\Delta H_{CF}(>0)$. (2) The tetrahedral water cluster is dissociated into water monomers in the gas phase, $\Delta H_D(>0)$. (3) Four water molecules are coordinated to an ion in the gas phase, $\Delta H_{I\text{-}S(g)}(<0)$. (4) The hydrated ion is returned to the cavity, $\Delta H_{BC}(<0)$. (5) The water molecules of the returned hydrated ion interact with their neighbor, $\Delta H_{INT}(<0)$. In other words, ΔH_{INT} represents hydrogen-bonding interaction extending beyond the primary hydration sphere, namely the outer hydration sphere of anions. (6) Finally, one water molecule left in the gas phase is returned to the liquid phase, $\Delta H_C(<0)$.

a) From Ref. 8. b) From Ref. 4 (for tetrahedral hydration). c) From Ref. 24.

We propose a novel method to estimate the ΔH_{INT} term for the mixtures based on a modified hydration model.

Table 2 shows values of some terms used to estimate the sum of $\Delta H_{CF(W)}$ and ΔH_{INT} terms ($\Delta H_{CF(W)}+\Delta H_{INT}$) in aqueous solution according to the following equation:

$$\Delta H_{CF(W)} + \Delta H_{INT} = \Delta H_W - (\Delta H_{I-S(g)} + \Delta H_{BC} + \Delta H_D + \Delta H_C), \quad (6)$$

where $\Delta H_{1-S(g)}$ is the ionic hydration enthalpy in the gas phase measured with a mass spectrometer.[14] Stepwise enthalpies of hydration ($\Delta H_{3,4}$) for I^- are obtained by extrapolation of the $\Delta H_{n-1,n}$ vs. n plot. The ΔH_{BC} values are calculated by the Born equation in kJ mol^{-1}:

$$\Delta H_{BC} = 1398/2R_i \times (1 - 1/\varepsilon - 1/\varepsilon \times d\varepsilon/dT), \quad (7)$$

where $R_i(=r_c+2r_w)$ is the radius of the hydrated ion, r_c the crystal radius of the ion,[16] r_w the radius of the water molecule (1.38Å),[17] and $d\varepsilon/dT$ is the temperature coefficient of the dielectric constant of water (0.355/°C).[18] In this calculation the effect of dielectric saturation can reasonably be neglected, since the radius of the hydrated in is larger than 4Å in every case.[13b] The ΔH_D value is the enthalpy of breaking four hydrogen bonds in water (83.7 kJ mol^{-1})[15,17] and ΔH_C is the enthalpy of condensation of water (29.7 kJ mol^{-1}).[19]

Next we attempt to consider the solvation enthalpy cycle in the mixtures up to x_{AN} 0.6. We assume that an anion is preferentially hydrated in the primary hydration sphere in the mixtures. This assumption seems to be reasonable for the following reasons. An anion is more strongly solvated in water than in a dipolar aprotic solvent, since the positive charge end of the acetonitrile dipole is distributed over a large part of the molecule.[21] Furthermore, the activity of water in the intermediate region remains nearly constant as deduced from the marked positive deviation of the partial vapor pressure of water.[22] In fact, halide ions have been pointed out to be preferentially hydrated in those mixtures by the measurement of NMR on halide ion nucleus.[23]

Table 3. The Sum of the Enthalpies of Cavity Formation and Outer Hydration Sphere Interaction, $\Delta H_{CF(W)}+\Delta H_{INT}$, for Halide Ions in Water and Water-Acetonitrile Mixtures/kJ mol^{-1}

	x_{AN}						
	0	0.1	0.2	0.3	0.4	0.5	0.6
Cl^-	−37.5	−35.8	−25.6	−25.1	−26.3	−27.5	−29.0
Br^-	−34.5	−33.4	−23.9	−23.1	−23.8	−25.1	−27.2
I^-	−19.4	−20.5	−13.5	−12.6	−14.2	−15.6	−17.4

The ΔH_{CF} term in the mixtures is assumed to differ from that in water by $-5L_W$, the enthalpy of demixing five water molecules from the mixtures, and ΔH_C term by $+L_W$, the enthalpy of mixing one water molecule with the mixtures. Therefore, ($\Delta H_{CF}+\Delta H_C$) in the mixtures differ by $-4L_W$ from that in water, where L_W denotes the relative partial molar enthalpy for water in the mixtures and can be calculated from the excess enthalpy of mixing data[24,25] by an intercept method.[26] The ΔH_{BC} values in the mixtures are calculated in the same way as that in aqueous solution by using ε and $d\varepsilon/dT$ data.[18]

Values of ($\Delta H_{CF(W)}+\Delta H_{INT}$) estimated for the mixtures according to the following equation are shown in Tab. 3 together with those in water for comparison;

$$\Delta H_{CF(W)} + \Delta H_{INT(mix)} = -\Delta H_{SV(mix)} - (\Delta H_{I-S(g)} + \Delta H_{BC(mix)} + \Delta H_D + \Delta H_C) + 4L_W. \quad (8)$$

So, ΔH_t° is represented as follows:

$$\Delta H_t^\circ = -4L_W + \Delta\Delta H_{BC} + \Delta\Delta H_{INT}. \quad (9)$$

The smaller an anion, the more negative ($\Delta H_{CF(W)}+\Delta H_{INT}$) will be in water. If $\Delta H_{CF(W)}$ is assumed to be the latent heat of vaporization for water according to the suggestion of Buckingham,[13b] ΔH_{INT} for the chloride ion in water is approximately −60 kJ mol^{-1}.

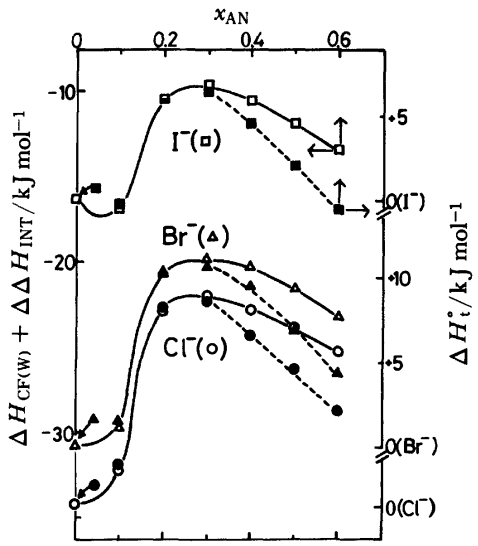

Fig. 6. The sum of the enthalpies of cavity formation and outer hydration sphere interaction, $\Delta H_{CF(W)}+\Delta H_{INT}$, and the enthalpies of transfer, ΔH_t°, for halide ions plotted against the mole fraction of acetonitrile (x_{AN}).

This means that several hydrogen bonds are formed in the outer hydration sphere for a halide ion through these cooperative effects.[20]

Figure 6 shows the comparison of $\Delta\Delta H_{INT}$ with ΔH_t° for halide ions. In this figure the broken curves represent the x_{AN} dependence of ΔH_t°, and the ordinate is adjusted so that the origin for each anion corresponds to $\Delta H_{CF(W)}+\Delta H_{INT}$ value in water. As shown in Tab. 2, the possibility of a ΔH_{BC} contribution to ΔH_t° is safely excluded, because the x_{AN} dependence of this term is negligible. If the ΔH_{CF} value in the mixtures can be correctly estimated by subtracting $5L_W$ from that in water, the left-hand ordinate will represent the $\Delta\Delta H_{INT}$. The two curves for each anion appear to show a similar trend in x_{AN} dependence. It can be said that the x_{AN} dependence of ΔH_t° at x_{AN} 0 to 0.6 may be explained semiquantitatively as the x_{AN} dependence of $\Delta\Delta H_{INT}$ based on the modified Eley and Evans hydration model. Noticeably, at x_{AN} 0 to ca. 0.3 the two curves agree well, while they split gradually with increasing x_{AN} beyond 0.3.

In the treatment of the solvation enthalpy cycle described above, hydration numbers for the halide ions were assumed to be four, although hydration numbers other than four have been reported.[27] The enthalpies of hydration in the gas phase have been reported up to the fourth water molecule for Cl^- and Br^-, and up to the third molecule for I^-, respectively.[14] It is possible to estimate approximately the hydration enthalpies in the gas phase up to the sixth water molecule by extrapolation. We have carried out a similar calculation to estimate ($\Delta H_{CF(W)}+\Delta\Delta H_{INT}$) for a hexahydrated ion by using such extrapolated values. The x_{AN} dependence of those values is very close to that for a tetrahydrated ion. So the same conclusion as before can be reached.

Solvation of Anions and Solvent Structure of Water–Acetonitrile Mixtures. In the previous section it has been clarified that the increase in ΔH_t° for halide ions in the range of x_{AN} 0 to ca. 0.3 was ascribed to the change in the ΔH_{INT} term. Accordingly the validity of the modified hydration model will now be discussed in relation to the solvent structure of the mixtures.

Three structurally different regions have been suggested to exist in those mixtures according to studies on the volumetric, viscosity and dielectric properties[18] and vapor pressure[22] measurements; (1) water-rich, (2) intermediate and (3) acetonitrile-rich regions. In the region (1) the voids inside the aqueous framework of the water lattice are considered to be progressively filled with acetonitrile. That is, no significant enhancement of the water lattice is caused by the addition of cosolvent in contrast to the other aqueous mixtures (water-*t*-butyl alcohol).[28a] This region, therefore, is stated as "essentially aqueous."[30] In the region (2), on the other hand, the large aggregates formed in the former region are considered to be progressively broken to smaller ones after the filling of the voids. The mixtures of x_{AN} ca. 0.3 seems to have the most compact solvent structure, since some physicochemical properties of the mixtures show extrema at this composition, such as excess volume[28a,b] and excess entropy[29] of mixing, energy-volume coefficient and isothermal compressibility.[30] Thus, this mixed solvent system can be classified as one of the simplest aqueous mixtures in which the added acetonitrile acts as a slightly weak structure maker of the water lattice in the water-rich region and a strong structure breaker in the intermediate region.

There is no doubt that the ΔH_t° maxima at x_{AN} ca. 0.3 may be closely associated with the most compact solvent structure at nearly the same solvent composition. As shown in Fig. 6, the estimated $\Delta\Delta H_{INT}(=\Delta H_t^\circ+4L_W-\Delta\Delta H_{BC})$ in x_{AN} range 0 to ca. 0.3 agree with the observed ΔH_t° better than expected. The proposed model may be applicable in this range, because the mixtures of x_{AN} 0 to ca. 0.3 can be regarded as the essentially aqueous solvent. Also from the above structural viewpoint, it is reasonable to interpret the increase in ΔH_t° with increasing x_{AN} in this region in terms of the reduction in the hydrogen-bonding interaction extending beyond the primary hydration sphere for smaller anions.

Since the observed ΔH_t° is clearly less than the estimated ΔH_{INT} in the intermediated region, the modified hydration model does not appear to work so well as in the water-rich region. As can be seen in Fig. 6, the x_{AN} dependence of $\Delta\Delta H_{INT}$ is reversed in going from the water-rich region to the intermediate region. If the correction for the ΔH_{CF} term has been made in the intermediate region as adequately as in the water-rich region, this reversal means the recovery of the outer hydration sphere disrupted somewhat in the water-rich

region. The possibility of this recovery, however, may be very low in consideration of the decrease in the water content. Reasonably, the outer hydration sphere which has been incompletely disrupted at x_{AN} ca. 0.3 is considered to reduce with increasing x_{AN} in this region though to a smaller extent. The interaction between the water cluster demixed from the mixtures and the surroundings was assumed to be equal to that in water in the above treatment of the solvation enthalpy cycle. This assumption, however, seems unreasonable in the intermediate region in which the water cluster has been broken to a certain extent. This interaction in the intermediate region should be weaker than that in water and should decrease with increasing x_{AN}. A consideration of this effect will lead to the reduction in the ΔH_{CF} value in this region. That is to say, the additional correction term besides $5L_W$ employed in this study seems to be needed for cavity formation in the intermediate region from the viewpoint of the solvent structure. Eventually, the exothermic change in ΔH_t° in the intermediate region may be considered to be due primarily to the decrease in ΔH_{CF} energy.

(Received January 9, 1986)

Two of the five possible geometrical isomers of $[RhCl_2(edpp)_2]^+$ were formed by reaction of $RhCl_3 \cdot 2H_2O$ with edpp (edpp=(2-aminoethyl)diphenylphosphine) in 1:2 molar ratio in ethanol. The chlorides of the isomers were separated by fractional crystallization from ethanol. The structures of the more soluble (main product) and the less soluble (minor product) complexes were determined by X-ray analyses to have the trans(Cl,Cl), cis(P,P) and cis(Cl,Cl), trans(P,P) configurations, respectively. Crystal data are: for *trans*(Cl,Cl), *cis*(P,P)-$[RhCl_2(edpp)_2]Cl \cdot 2C_2H_5OH$, triclinic, space group $P\bar{1}$, with $a=10.024(3)$, $b=18.865(3)$, $c=9.833(2)$ Å, $\alpha=97.66(1)$, $\beta=103.92(2)$, $\gamma=82.30(2)°$, and $Z=2$, and for *cis*(Cl,Cl), *trans*(P,P)-$[RhCl_2(edpp)_2]Cl \cdot 4H_2O$, triclinic, space group $P\bar{1}$, with $a=11.341(4)$, $b=17.780(6)$, $c=8.712(3)$ Å, $\alpha=95.60(4)$, $\beta=112.31(3)$, $\gamma=82.56(4)°$, and $Z=2$. The trans influence of the P atom on the Rh-N and Rh-P bond lengths is observed. The mean Rh-N and Rh-P bond lengths (2.125(4) and 2.300(1)Å) in the trans(Cl,Cl), cis(P,P) isomer are respectively longer and shorter than those of the cis(Cl,Cl), trans(P,P) isomer (2.078(12) and 2.336(3)Å). ^{13}C NMR and absorption spectra of the isomers were recorded and are discussed.

In a previous paper,[1] we reported the preparation of $[CoCl_2(edpp)_2]^+$, where edpp denotes (2-aminoethyl)diphenylphosphine. Although five geometrical isomers are possible for the $[MCl_2(edpp)_2]$-type complex (Fig. 1), the cobalt(III) complex formed only one isomer and the structure was determined to have the trans(Cl,Cl),cis(P,P) configuration by X-ray analysis.[2] Of the two trans(Cl,Cl) isomers, the formation of the sterically less favorable trans(Cl,Cl),cis(P,P) isomer might be attributable to the strong trans effect of the phosphorus donor atoms.[2] For the rhodium(III) complex, $[RhCl_2(edpp)_2]^+$ the magnitudes of the steric and trans effects should be different from those of the cobalt(III) complex, and other isomers than trans-(Cl,Cl),cis(P,P) might be expected to be formed.

This paper describes the preparation and X-ray structure analyses of the trans(Cl,Cl),cis(P,P) and the cis(Cl,Cl),trans(P,P) isomers of $[RhCl_2(edpp)_2]^+$. Also, the absorption and ^{13}C NMR spectra of the isomers are compared with each other and with those of related complexes.

Experimental

The edpp ligand was prepared according to a literature method,[3] and handled under an atmosphere of nitrogen until it formed air-stable rhodium(III) complexes. Absorption and ^{13}C NMR spectra were recorded on a Hitachi 323 spectrophotometer and a JEOL JNM-GX 400 spectrometer, respectively.

Preparation of *trans*(Cl,Cl),*cis*(P,P)-$[RhCl_2(edpp)_2]Cl \cdot 2C_2H_5OH$ (isomer A) and *cis*(Cl,Cl),*trans*(P,P)-$[RhCl_2(edpp)_2]Cl \cdot H_2O$ (isomer B). A deaerated ethanol solution (8 cm³) of $RhCl_3 \cdot 2H_2O$ (0.587 g, 2.39 mmol) was added to a stirred solution of edpp (1.098 g, 4.79 mmol) in deaerated ethanol (3 cm³) over a period of 15 min. The mixture was heated at 70 °C for 7 h and gave a yellow solution together with a small amount of pale yellow precipitate. The mixture was evaporated to dryness in vacuo and the residue washed with diethyl ether to remove excess edpp before it was exposed to the air. The washed residue was shaken repeatedly with hot ethanol (ca. 175 cm³) to extract the products until the extracts were colorless. The combined extracts were heated (ca. 70 °C) and filtered while hot, and the filtrate on evaporation to a volume of ca. 75 cm³ gave a pale yellow precipitate. This was collected by filtration (The mother liquor was treated as described below.) and recrystallized from ethanol to yield a yellow powder of isomer B. Yield: 0.032 g. Found: C, 48.75; H, 5.22; N, 4.07%. Calcd for $C_{28}H_{34}N_2Cl_3OP_2Rh = [RhCl_2(edpp)_2]Cl \cdot H_2O$: C, 49.04; H, 5.00; N, 4.08%. UV-

(CH_3CN) 28000 (sh, log ε=3.41), 33000 (sh, 4.21), 35400 (4.28), 36100 (sh, 4.28), and 45000 cm^{-1} (sh, 4.51). Single crystals of isomer B, $[RhCl_2(edpp)_2]Cl\cdot 4H_2O$ suitable for X-ray crystallography were obtained by slow evaporation of an acetonitrile solution of the chloride at room temperature. The presence of four molecules of water of crystallization was suggested by the density and microanalytical data of the crystals. Found: C, 45.33; H, 4.72; N, 3.76%. Calcd for $C_{28}H_{40}N_2Cl_3O_4P_2Rh$: C, 45.41; H, 5.44; N, 3.79%.

By evaporating the mother liquor to a small volume isomer A was obtained as yellow-orange crystals. They were collected by filtration, washed with ethanol, and air dried. Yield: 0.25 g. Found: C, 50.88; H, 5.51; N, 3.84%. Calcd for $C_{32}H_{44}N_2Cl_3O_2P_2Rh=[RhCl_2(edpp)_2]Cl\cdot 2C_2H_5OH$: C, 50.58; H, 5.84; N, 3.69%. UV(C_2H_5OH) 24450 (log ε=2.24), 29000 (sh, 2.2), 34500 (sh, 3.97), 38900 (4.40), and 45700 cm^{-1} (sh, 4.67). The crystals effloresce in the air giving off the ethanol of crystallization.

Crystal Structure Determination. Crystal data and experimental details are given in Table 1. Crystals of both (A) and (B) were sealed into capillary tubes together with their mother liquors and mounted on an automated four-circle diffractometer, Rigaku AFC-5. Intensities were measured up to 2θ=55° by θ—2θ scan technique with scan speed 6° min^{-1} in θ, graphite monochromatized Mo $K\alpha$ radiation being used. Lattice constants were determined from 25 2θ values ($20°<2\theta<30°$) with (Mo $K\alpha$)=0.71073 Å. After absorption correction, the structures were solved by the Patterson-Fourier method. Two ethanol molecules in (A) could be found from Fourier synthesis. From the difference synthesis 30 of the 32 hydrogen atoms except those of the ethanol molecules were found and others were calculated. One of the phenyl groups bonded to the P(2) atom in (B) exhibited orientational disorder. The two sets of positions for the C(24)—C(28) atoms were included with 50% population. The dihedral angle between the least squares planes in two possible orientations for the disordered phenyl group is 77.8°. The water molecules as well as the Cl^- ion could not be found from Fourier synthesis. The difference synthesis gave five positions with peak heights 3.7—4.7 e Å^{-3}, the distances between them being longer than 2.65(2) Å. We were unable to distinguish the disordered water molecules from the disordered Cl^- ions on the basis of the difference synthesis. In the present study we have tentatively assumed that the five positions are all occupied by Cl^- ions and we have estimated their population parameters by the trial and error method with the restriction that the isotropic thermal parameters of the Cl^- ions remain almost equal. Positional parameters of all the hydrogen atoms in (B) were calculated and not refined, although eight hydrogen atoms were found from difference synthesis. By introducing these calculated hydrogen atoms, the R factor reduced from 0.092 to 0.088. Anisotropic thermal parameters

were introduced for all the non-hydrogen atoms except for the ethanol molecules in (A) and for the disordered Cl^- ion and a phenyl group in (B). The function, $\sum w||F_o|-|F_c||^2$ was minimized by block-diagonal least squares. Complex neutral-atom scattering factors were used.[4] The calculations were carried out on a FACOM M380-R computer at Keio University with the UNICS III computation program system.[5] The final atomic parameters and bond lengths and bond angles are listed in Tables 2 and 3.[6]

Results and Discussion

Preparation, Absorption and ^{13}C NMR Spectra of the Two Isomers of $[RhCl_2(edpp)_2]^+$. Rhodium(III) chloride was reacted with edpp in a 1:2 molar ratio in ethanol to form a mixture of two isomers of $[RhCl_2(edpp)_2]Cl$. The mixture was separated into the isomers A and B by fractional crystallization from ethanol. Isomer B is much less soluble in ethanol than isomer A. The relative abundance of isomer B to isomer A was ca. 1:10. No isomerization of the isomers took place on refluxing in ethanol.

Figure 2 shows the absorption spectra of isomers A and B together with that of *trans*(Cl,Cl),*cis*(P,P)-$[CoCl_2(edpp)_2]^+$.[1,2] The spectral pattern of isomer A is quite similar to that of *trans*(Cl,Cl),*cis*(P,P)-$[CoCl_2(edpp)_2]^+$, although all the bands of isomer A are shifted by 7000—10000 cm^{-1} toward higher energy compared to the corresponding bands of the cobalt(III) complex. Thus isomer A is suggested to have the trans-(Cl,Cl),cis(P,P) configuration. The same structure was

suggested by the ^{13}C NMR spectrum, and the assignment was confirmed by the X-ray structure determination (vide infra). The lowest-energy absorption band at 24450 cm^{-1} of isomer A can be assigned to the split component (I_a) of the first absorption band, $^1A_{1g} \rightarrow {}^1T_{1g}$ (O_h). The band is at higher energy by 8550 cm^{-1} than the I_a band of the cobalt(III) complex. A similar energy difference (8550 cm^{-1}) is observed between the I_a bands of *trans*-$[RhCl_2(en)_2]^+$[7] and *trans*-$[CoCl_2(en)_2]^+$[8] (en=ethylenediamine). The *trans*-dichloro rhodium(III) complexes of dppe[9] (dppe=1,2-bis(diphenylphosphino)ethane) and en[7] show the I_a band at 23700 and 24600 cm^{-1}, respectively. Thus the spectrochemical series for the ligands can be determined as en≧edpp> dppe. The same order, en≧edpp has been reported for the *trans*-dichloro cobalt(III) complexes.[1,2] The spectral data of *trans*-$[CoCl_2(dppe)_2]^+$ is not available; the complex is reported to be extremely unstable.[10] However, dppe forms a stable cobalt(III) complex with two acac ligands (acac=2,4-pentanedionate ion). The

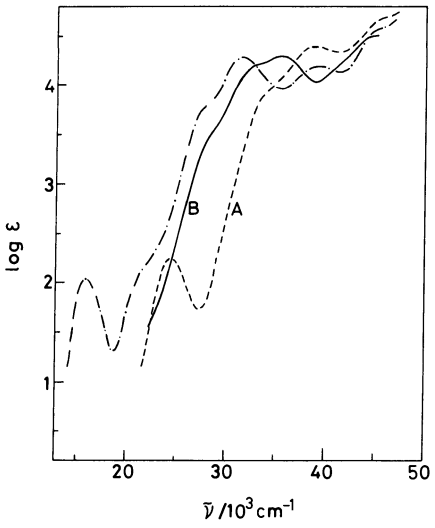

Fig. 2. Absorption spectra of *trans*(Cl,Cl), *cis*(P,P)-$[RhCl_2(edpp)_2]Cl \cdot 2C_2H_5OH$ (isomer A) in ethanol (---), *cis*(Cl,Cl), *trans*(P,P)-$[RhCl_2(edpp)_2]Cl \cdot H_2O$ (isomer B) in acetonitrile (——), and *trans*(Cl,Cl), *cis*(P,P)-$[CoCl_2(edpp)_2]Cl \cdot 2H_2O$ in methanol (—·—).

energy of the first absorption band of $[Co(acac)_2L]^+$ (L=dppe, edpp, en) decreases in the order dppe> edpp≧en.[11] This order is reversed to that for the *trans*-dichloro complexes. The apparent disagreement in the order may be ascribed to the difference in steric repulsion among the complexes. Examination of molecular models indicates that severe steric repulsions occur in *trans*-$[MCl_2(dppe)_2]^+$ (M=Co, Rh), whereas $[Co(acac)_2(dppe)]^+$ has no particular steric repulsions. In the absence of severe steric repulsions, therefore, it is apparent that the ranking of dppe in the spectrochemical series is higher than that of en. The I_b band of isomer A is observed as a shoulder (ca. 29000 cm^{-1}) and the second absorption band is hidden by the strong charge-transfer (CT) bands.

The first d-d absorption band of isomer B is almost hidden by strong bands in the higher energy region. However, the shoulder at ca. 28000 cm^{-1} can be assigned to a part of the first absorption band, since *cis*-$[RhCl_2(en)_2]^+$ shows the first d-d band maximum at nearly the same wavenumber (28400 cm^{-1}).[7] The shoulder of isomer B is at higher energy than that of the I_a band of isomer A. These positions correspond well to those of the lowest energy d-d transition bands of the cis (28800 cm^{-1}) and trans (24500 cm^{-1}) isomers of $[RhCl_2(dmpe)_2]^+$ [9] (dmpe=1,2-bis(dimethylphosphino)-ethane). From these results isomer B is suggested to have a cis(Cl,Cl) configuration. The first absorption band of isomer B is more intense than that of isomer A. Similar trends where cis-isomers exhibit more intense absorption bands than the corresponding trans-isomers were observed between the cis- and trans-isomers of $[RhX_2(en)_2]^+$ [7] (X=Cl, Br, I, etc.) and $[RhCl_2(dmpe)_2]^+$.[9] The bands around 33000 cm^{-1} in the absorption spectrum of isomer B may be assigned to a CT transition Rh^{III}–P.[10] Since the bands are at lower energy than the corresponding band of isomer A, isomer B would be assigned to have a trans(P,P) configuration. The trans(P,P) isomer of a bis(phosphine) cobalt(III) complex is reported to exhibit the Co^{III}–P CT band at lower energy than the corresponding cis(P,P) isomer.[12,13] Similar absorption spectral characteristics to those of isomers B and A have been observed for *cis*(NCS,NCS),*trans*(P,P)- and *trans*(NCS,NCS),*cis*(P,P)-$[Co(NCS)_2(edpp)_2]^+$.[14]

Figure 3 shows the ^{13}C NMR spectra of isomers A and B in dimethyl-d_6 sulfoxide. The spectral assignment was made according to previous work on bis(acac) cobalt(III) complexes of edpp and related ligands.[11] The mutual arrangement of the two chlorine donor atoms can be assigned on the basis of the number of the resonances. Isomer A exhibits six kinds of signals and can be assigned to either of the two trans(Cl,Cl) isomers (Figs. 1 and 3). This assignment is in accord with that given on the basis of the absorption spectrum. The spectrum of isomer B shows one kind of signal for each carbon of the two methylenes of the edpp ligands, while the two phenyl groups on each phosphorus atom are observed diastereotopically. Thus isomer B is suggested to have either cis(Cl,Cl),trans(P,P)(C_2) or cis(Cl,Cl),cis(P,P)(C_2) configuration from symmetry argument. One of the most noticeable aspects in the two spectra is the difference in line shape of the P–CH_2 and P–C_1 signals; the signals for isomer B appear as a 1:2:1 triplet, while those for isomer A as a five-line multiplet. Such differences can be explained on the basis of the difference in magnitude of the phosphorus–phosphorus coupling constant, $^2J_{PP}$ between the two isomers. The appearance of the phosphine α-carbon multiplet in the ^{13}C NMR spectrum of a bis(phosphine) complex has been shown to be a function of $^2J_{PP}$.[15,16] In a trans(P,P) complex $^2J_{PP}$ is usually large so that the signal appears as a 1:2:1 triplet (so-called virtually coupled triplet). On the other hand, a five-line multiplet is expected to appear only for a cis(P,P) complex. Hence isomers B and A can be assigned to cis(Cl,Cl),trans(P,P), and trans(Cl,Cl),cis-(P,P), respectively. These assignments are confirmed by the X-ray analyses.

Structures of (A) and (B). Figure 4 shows perspective drawings of the complex cations (A) and (B). The main product, (A) is the trans(Cl,Cl),cis(P,P) isomer. The lesser product, (B) is the cis(Cl,Cl),trans(P,P) isomer. The structures agree with the assignments based on the ^{13}C NMR and absorption spectra. Both complex cations have a pseudo twofold axis running through the Rh atom and the midpoint of the N(1) and N(2) atoms. The trans influence of the P atom on the Rh–N and Rh–P bond lengths is seen from Table 3. The mean Rh–N bond length, 2.125(4)Å, in (A) is longer than that in (B) by 0.047(12)Å. The mean Rh–P bond length, 2.336(3)Å, in (B) is longer than that in (A) by 0.036(3)Å. It is noted that the mean Co–P

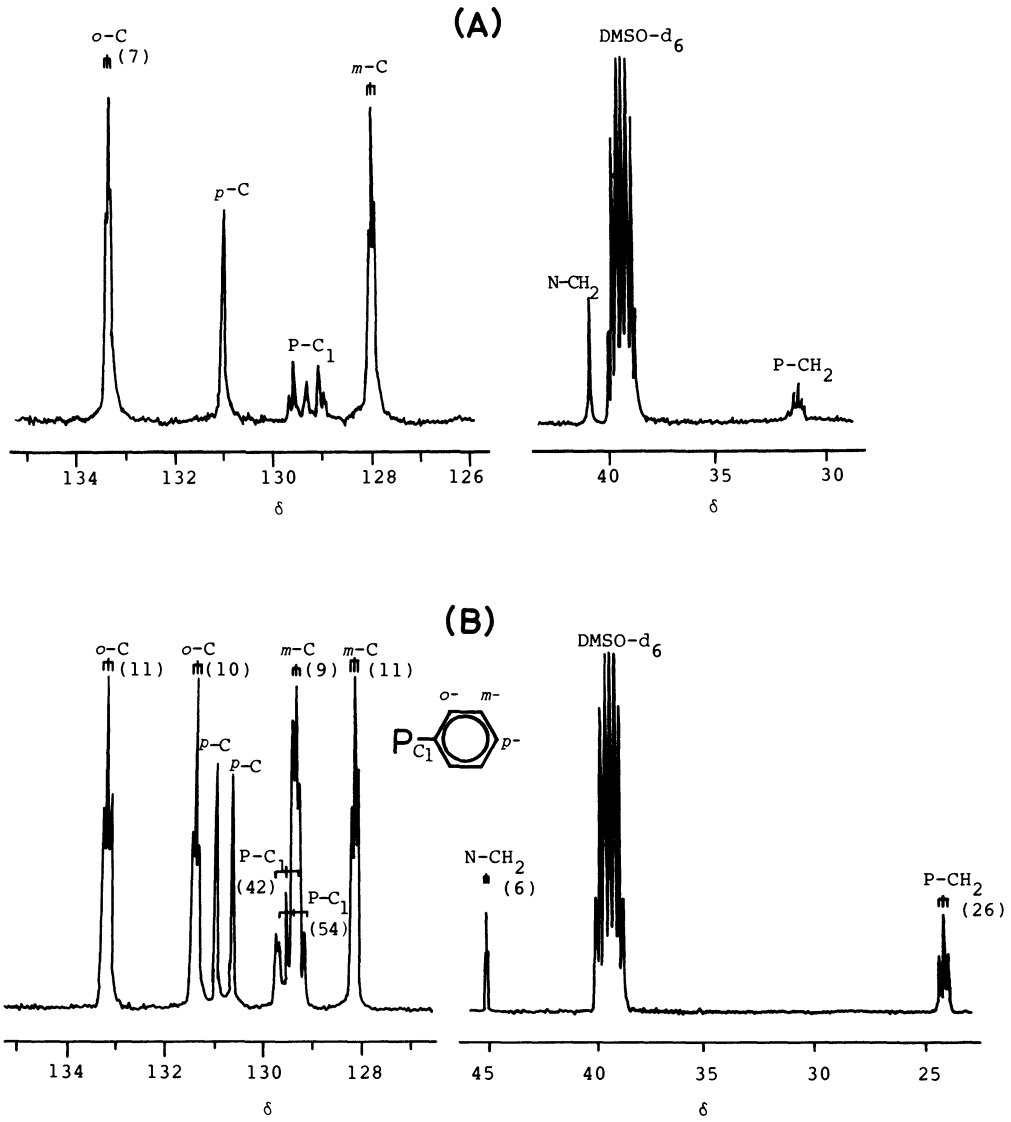

Fig. 3. ^{13}C NMR spectra of (A) *trans*(Cl,Cl), *cis*(P,P) (isomer A)- and (B) *cis*(Cl,Cl), *trans*(P,P) (isomer B)- $[RhCl_2(edpp)_2]^+$ in dimethyl-d_6 sulfoxide. The numbers in parentheses are the coupling constants in Hz of the triplet signals.

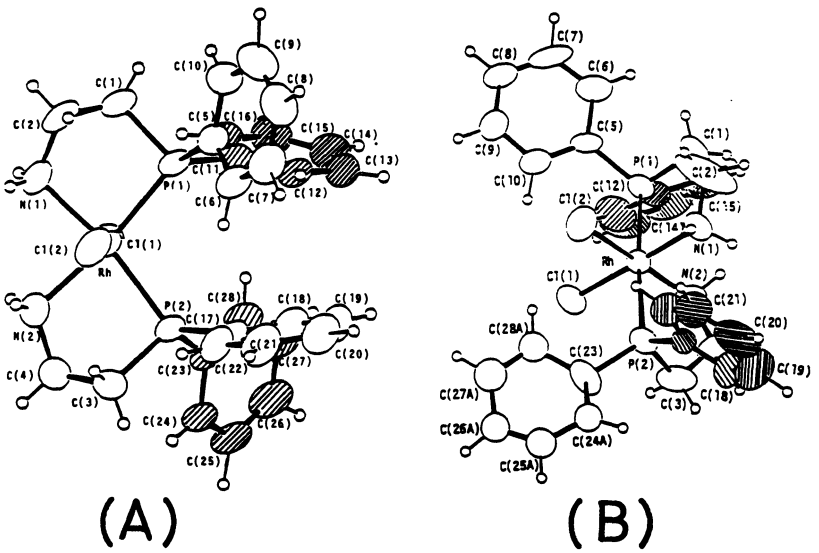

Fig. 4. Molecular structures of (A) and (B). Some of the phenyl rings are shaded for clarity.

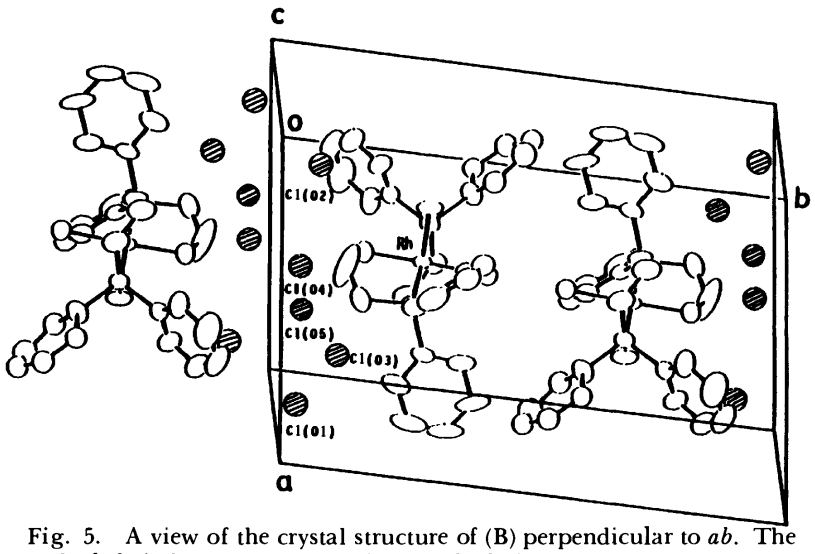

Fig. 5. A view of the crystal structure of (B) perpendicular to *ab*. The shaded circles represent the disordered Cl^- ion.

bond length in the trans(NCS,NCS),cis(P,P) isomer of $[Co(NCS)_2(edpp)_2]^+$ is almost the same as that in the cis(NCS,NCS),trans(P,P) isomer, although the mean Co–NH_2 bond length in the former is longer than that in the latter by 0.031(4) Å.[14] The molecular structure of (A) is essentially the same as that of the corresponding cobalt(III) complex.[2] The mean M–Cl and M–N bond lengths in (A) are longer than those in the cobalt(III) complex by ca. 0.10 Å.[2] On the other hand, the mean M–P bond length in (A) is longer than that in the cobalt(III) complex only by 0.045(3) Å. These results may indicate a stronger affinity of Rh^{3+} for P than Co^{3+} for P.

The close contact between the phenyl groups in (A) is avoided by the large P(1)–Rh–P(2) angle, 105.4(1)° and the appropriate orientations of the phenyl groups. The shortest non-bonded C···C distance is 3.516(8) Å for C(6)···C(17). The angle between the two coordination planes through Rh, N(1) and P(1), and through Rh, N(2) and P(2) atoms is 5.1°. The large thermal parameter of C(2) in (B) may be due to the puckering motion of the five-membered chelate ring. The crystal structure of (B) is shown in Fig. 5. The Cl^- ions are distributed over five sets of general positions with different population parameters and are between the layers of complex cations parallel to the *ac* plane; the shortest interatomic distance involving them is 3.04(2) Å for Cl(04)···N(1). Water molecules, which were not included in the structure refinement, might also be accommodated randomly in the hollow. The positional disorder of counter ions was also reported for $[Co\{(NH_2CH_2CH_2)_2NCH_2CH_2N(CH_2CH_2NH_2)_2\}]Br_3 \cdot H_2O$.[17]

Kinetic and Mechanistic Investigations of the Reduction by Radicals of Nitro to Hydroxyamino Groups in a Cobalt(III) Cage Compound

Keiichi TSUKAHARA
Department of Chemistry, Faculty of Science, Shimane University, 1060
Nishikawatsu-cho, Matsue, Shimane 690
(Received January 20, 1986)

A compound containing both a hydroxyamino and a nitro group in a cobalt(III) cage complex was detected and isolated in a $DQ^{\dagger}$ (1,1′-ethylene-2,2′-bipyridinium radical cation) reduction of the corresponding symmetric dinitro compound, $[Co(diNOsar)]^{3+}$ (diNOsar=1,8-dinitro-3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane). The nitro group of this compound was reduced to the hydroxyamino group by SO_2^-, $MDQ^{\dagger}$ (1,1′-ethylene-4,4′-dimethyl-2,2′-bipyridinium radical cation), and $PDQ^{\dagger}$ (1,1′-trimethylene-2,2′-bipyridinium radical cation). Rate constants for the various processes were obtained.

Sargeson et al.[1,2] have synthesized and developed the chemistry of a large number of macrocyclic metal cage compounds. The cobalt(III) cage complex containing two nitro groups $[Co(diNOsar)]^{3+}$ (**1**, X=Y=NO_2)[3] has interesting and unique redox properties. Compounds in various states of reduction between nitro and amino groups have been prepared by reductions with electrodes,[4] zinc dust,[1] and dithionite.[5] When the dithionite ion is used in excess, $[Co^{III}(diNOsar)]^{3+}$ is reduced to $[Co^{II}(diNOsar)]^{2+}$ and the latter is then followed by a reduction of the nitro to hydroxyamino groups with a concomitant oxidation of cobalt(II) to cobalt(III):[5]

$$[Co^{III}(diNOsar)]^{3+} \xrightarrow{e^-} [Co^{II}(diNOsar)]^{2+} \quad (1)$$

$$[Co^{II}(diNOsar)]^{2+} \xrightarrow{7e^-} [Co^{III}(diHAsar)]^{3+} \quad (2)$$

Dithionite ion is a very strong reductant of the formal redox potential −0.66 V at pH 7.[6] If we choose various reductants,[7] DQ^+ (**2a**, $E°=-0.35$ V), MDQ^+ (**2b**, −0.49 V), and PDQ^+ (**2c**, −0.55 V), it would be possible to obtain an intermediate compound in the formation process of $[Co^{III}(diHAsar)]^{3+}$ (**1**, X=Y=NHOH) from $[Co^{III}(diNOsar)]^{3+}$. Therefore, we decided to study the kinetics and to examine the products of this interesting reaction using the above radicals as well as SO_2^- ions which are effective reductants from dithionite ions. The kinetics of a one-electron reduction of $[Co(diNOsar)]^{3+}$ with viologen radicals as in Reaction 1 were reported previously.[8]

2c $PDQ^{\dagger}$ (n=3, R=H)

Fig. 1.

Experimental

Materials. $[Co(diNOsar)](ClO_4)_3 \cdot H_2O$ was prepared as described previously.[5,9] Its absorption spectrum in water (λ_{max}=474 nm (ε=159 $M^{-1}cm^{-1}$) and λ_{max}=345 nm (ε=128 $M^{-1}cm^{-1}$)) was in agreement with that described in the literature.[5] 1,1′-Ethylene-2,2′-bipyridinium dibromide, $(DQ)Br_2$, was obtained from Chemical Services. 1,1′-Ethylene-4,4′-dimethyl-2,2′-bipyridinium dibromide hydrate, $(MDQ)Br_2 \cdot H_2O$, and 1,1′-trimethylene-2,2′-bipyridinium dibromide hydrate, $(PDQ)Br_2 \cdot H_2O$, were prepared by the method of Homer and Tomlinson.[10] The other chemicals used were the purest commercial products. The viologen radicals (DQ^+, MDQ^+, and PDQ^+) were prepared by adding 0.95 equivalent of sodium dithionite to the oxidized viologens (DQ^{2+}, MDQ^{2+}, and PDQ^{2+}). $[Co(sep)]^{2+}$ was generated in situ by Zn/Hg reduction of $[Co(sep)]^{3+}$.[11] Aquapentacyanoferrate(II), $[Fe(CN)_5H_2O]^{3-}$, was prepared in situ by dissolving $Na_3[Fe(CN)_5NH_3]$ in water.

Kinetics. All kinetic measurements were carried out using a Gibson-Dionex stopped-flow spectrophotometer interfaced with an OLIS data-collecting system. The reactions with viologen radicals were followed by the loss of the radical at 760 nm, 25 °C, an ionic strength (I) of 0.50 M (1 M=1 mol dm^{-3}) with Na_2SO_4, and pH=7.8—8.2 (Tris-H_2SO_4 buffer, Tris=tris(hydroxymethyl)aminomethane) in an argon atmosphere. The molar absorption coefficients used were $\varepsilon_{760}=2.7\times10^3$ $M^{-1}cm^{-1}$ (DQ^+) and $\varepsilon_{760}=2.9\times10^3$ $M^{-1}cm^{-1}$ (MDQ^+).[7] The viologen radical (6.0×10^{-5}—2.9×10^{-4} M) was used in excess over the cobalt(III) complex (1.0×10^{-5}—5.0×10^{-5} M). Dithionite reductions were carried out at pH 6.3 (0.1 M MES buffer, MES=2-(*N*-morpholino)-ethane sulfonic acid) and pH 10.8 (0.02 M borate buffer), at 25 °C and I=0.50 M (Na_2SO_4). The cobalt(III) complex decomposed slowly at pH 10.8; therefore, neutral solutions of cobalt(III) complex in Na_2SO_4 were mixed with dithionite solutions at pH 11.1 (0.04 M borate buffer). The reactions were followed at the absorption maximum 505 nm of this complex at pH 10.8. Dithionite (5.0×10^{-3}—4.0×10^{-2} M) was used in excess over cobalt(III) complex (3.0×10^{-4}—5.0×10^{-4} M).

Product Analyses. Viologen radicals and dithionite ion

were used in five-to fifteen-fold excess over the cobalt(III) complex (1×10^{-4}—5×10^{-4} M). After the reactions were quenched by introducing air (reaction time was about half an hour at room temperature), the solutions were poured onto a CM-Sephadex C-25 (Na^+ form) column. The column was washed with water and the products were separated using different concentrations of NaCl solutions. Spectral measurements were carried out using a Cary 14 spectrophotometer and a Hitachi 260-50 IR spectrophotometer. Cyclic voltammetry was carried out in an argon atmosphere in an aqueous Tris-H_2SO_4 buffer (pH 7.8) with a BAS Model CV-1B Instrument. A three-electrode system was composed of a Pt auxiliary electrode and a Pt working electrode against a Ag/AgCl (3 M NaCl) reference electrode. Voltammograms were recorded on a Houston Instruments Omnigraphic 100 X-Y recorder at scan rate of 20—200 mV s^{-1}.

Results and Discussion

Product Analyses. When a viologen radical was mixed with $[Co(diNOsar)]^{3+}$, Reaction 1 was observed, being followed by a slow process. Stoichiometry determinations and kinetics were carried out on the MDQ^+ system where the slow process was sufficiently fast to be followed before an occurrence of a spontaneous decay of MDQ^+. Stoichiometric titrations monitored at an MDQ^+ radical peak showed $[MDQ^+]/[Co(III)]=8.0\pm0.1$ for the overall reaction; therefore a 7:1 stoichiometry was required for the second stage. The same result was obtained from the absorbance change in stopped-flow traces during the reaction; the ratio of the amplitude for the second stage and the first stage was 7.0±0.2 at 760 nm. The same stoichiometry was obtained in the PDQ^+ reduction.

When an excess of MDQ^+ was used over the cobalt(III) complex (at least 15 times), three products were separated on a Shephadex column. A pale-green species was eluted with a 0.1 M NaCl solution and was identified as MDQ^{2+}. A trace amount of a yellow species was eluted with a 0.4 M NaCl solution, but was not identified. A third orange species was eluted with a 0.5 M NaCl solution and was identified as $[Co(diHAsar)]^{3+}$ (>90%).

In the DQ^+ system the slow process could not be followed due to a spontanious decay of this radical. When an excess of DQ^+ was used over the cobalt(III) complex (ten times), four products were separated on the column. The first, a yellow species, was eluted with a 0.05 M NaCl solution and was found to be an air-oxidation product of DQ^+ (λ_{max}=419 nm), the yellow color being faded gradually. The same phenomenon has been reported in the O_2 oxidation of DQ^+ in methanol.[12] This is not the same species as that which arises from the oxidation of DQ^+ by hydrogen peroxide (λ_{max}=453 nm at pH 8). We have not identified these species. The second, a pale-brown species, was eluted with a 0.2 M NaCl solution and identified as DQ^{2+} which results from the oxidation of DQ^+ by cobalt(III). The third, an orange species,was eluted with a 0.4 M NaCl solution and identified as $[Co(diHAsar)]^{3+}$. It was isolated as a hydrogen chloride salt when it was eluted with 1 M HCl, evaporated to dryness, and washed with acetone. The IR spectrum showed the absence of an $-NO_2$ group. The fourth, an orange species, was eluted with a 0.5 M NaCl solution. The absorption spectrum in water has a λ_{max}=473 nm ($\varepsilon=150\pm20$ $M^{-1}cm^{-1}$) and there was no absorption maximum near 340 nm. It was isolated as a hydrogen chloride salt and its IR spectrum showed the presence of an $-NO_2$ group (1550 and 1350 cm^{-1}). From these results the fourth species was identified as $[Co(HANOsar)]^{3+}$ which contains a hydroxyamino and a nitro group (**1**, X=NHOH, Y=NO_2; analytical data for a hydrogen chloride salt, Found: C, 26.75; H, 6.10; N, 17.38%. Calcd for $[Co(C_{14}H_{33}O_3N_8)]Cl_4\cdot4H_2O$: C, 26.51; H, 6.53; N, 17.67%).

When a five-fold excess of DQ^+ was used over the cobalt(III) complex, an additional orange species was found on the top of the column. This was eluted with a 0.5 M NaCl solution and identified as the starting material, $[Co(diNOsar)]^{3+}$, by the IR and absorption spectra. This was easily recovered as a perchlorate salt.

These cobalt(III) complexes were also distinguished from each other using $[Fe(CN)_5H_2O]^{3-}$; with $[Co(diNOsar)]^{3+}$ a brown material, insoluble in water, is formed and with $[Co(diHAsar)]^{3+}$ a violet material is precipitated. Analytical data for the latter show the formula, $[Co(diHAsar)Fe(CN)_5]\cdot4H_2O$ (Found: C, 33.78; H, 5.62; N, 28.08%. Calcd: C, 34.39; H, 6.39; N, 27.45%). The IR spectrum shows the presence of -CN groups (2050 and 1620 cm^{-1}). $[Co(HANOsar)]^{3+}$ reacted with $[Fe(CN)_5H_2O]^{3-}$ to form a reddish violet species soluble in water (λ_{max}=490 nm). The absence of a nitroso group in $[Co(HANOsar)]^{3+}$ was confirmed by a Liebermann reaction[13] in which nitroso groups react with phenol to form deep-red species in sulfuric acid. These three complexes were also characterized by cyclic voltammetry. $[Co(diNOsar)]^{3+}$ and $[Co(diHAsar)]^{3+}$ showed quasi-reversible one-electron waves at +0.0 and −0.26 V vs. NHE, respectively. $[Co(HANOsar)]^{3+}$ showed a one-electron wave near −0.1 V, intermediate between those of $[Co(diNOsar)]^{3+}$ and $[Co(diHAsar)]^{3+}$. These values are in good agreement with those found in the literature.[4]

$[Co(sep)]^{2+}$ was also used as a reductant, its redox potential (−0.30 V) is slightly higher than that of DQ^+. When a five-fold excess of $[Co(sep)]^{2+}$ was used over $[Co(diNOsar)]^{3+}$, three orange species were separated on the column; these were identified as $[Co(sep)]^{3+}$, $[Co(HANOsar)]^{3+}$, and $[Co(diNOsar)]^{3+}$.

$[Co(HANOsar)]^{3+}$ was further reduced by MDQ^+ and dithionite. Two reactions were monitored in the dithionite reduction—a decrease in absorbance followed by an increase in absorbance at 480 nm. Stoichiometric titrations at 760 nm with MDQ^+ showed $[MDQ^+]/[Co(III)]=4.0\pm0.1$. This is in agreement with the $3e^-$ reduction for the second stage in which

Table 1. Rate Constants for Reduction of [Co(diNOsar)]$^{3+}$ by Dithionite at pH 10.8[a]

$[S_2O_4^{2-}]_0/10^{-3}$ M	First Stage[b] k_{obsd}/s^{-1}	Second Stage[c] k_{obsd}/s^{-1}	Third Stage $k_{obsd}/10^{-3}$ s^{-1}
7.0	0.91	0.042	1.3
14.3	1.30	0.073	1.9
20.0	1.61	0.083	2.2
30.0	1.90	0.108	2.1
40.0	1.89	0.129	2.1

a) 25 °C, I=0.50 M (Na_2SO_4), $[Co(III)]_0=5.0\times10^{-4}$ M, and λ=505 nm. b) Plots of k_{obsd} vs. $[S_2O_4^{2-}]_0^{1/2}$ were linear with zero intercept and k_1 was obtained as $(2.9\pm0.2)\times10^5$ M^{-1}s^{-1} using $K_d=1.4\times10^{-9}$ M^{-1} for the dissociation of $S_2O_4^{2-}$ to SO_2^-. D. O. Lambeth and G. Palmer, *J. Biol. Chem.*, **248**, 6095 (1973). c) Plots of k_{obsd} vs. $[S_2O_4^{2-}]_0^{1/2}$ were linear with zero intercept and k_2 was obtained as $(1.6\pm0.2)\times10^4$ M^{-1}s^{-1}.

[Co(diHAsar)]$^{3+}$ was produced.

When dithionite was used at pH 10.8 with [Co(diNOsar)]$^{3+}$, only [Co(diHAsar)]$^{3+}$ was produced. There was no evidence of further reductions of hydroxyamino to amino groups.

From the above observations it is considered that the following reactions occur successively after Reaction 1:

$$[Co^{II}(diNOsar)]^{2+} \xrightarrow{3e^-} [Co^{III}(HANOsar)]^{3+} \quad (3)$$

$$[Co^{III}(HANOsar)]^{3+} \xrightarrow{e^-} [Co^{II}(HANOsar)]^{2+} \quad (4)$$

$$[Co^{II}(HANOsar)]^{2+} \xrightarrow{3e^-} [Co^{III}(diHAsar)]^{3+} \quad (5)$$

Kinetics. Balahura et al.[5] have examined the dithionite reduction of [Co(diNOsar)]$^{3+}$ at pH 6.3. We have also measured this system at pH 10.8 and obtained similar results for the first and second stages (Table 1). A third very slow reaction, whose rate was independent of the concentrations of dithionite, may represent the decomposition of the cobalt(III) complex. The second-order rate constants are $(2.9\pm0.2)\times10^5$ M^{-1}s^{-1} (3.5×10^5 M^{-1}s^{-1} at pH 6.3[5]) for Reaction 1 and $(1.6\pm0.2)\times10^4$ M^{-1}s^{-1} (1.6×10^4 M^{-1}s^{-1} at pH 6.3[5]) for Reaction 2. This result is surprising because it is known that [Co(diNOsar)]$^{3+}$ is converted to a deprotonated species [Co(diNOsar-H)]$^{2+}$ (pK_a=8.85)[8] whose redox potential for the Co(III)/Co(II) couple shifts to a more negative value.[14] The rate-determining step of the reduction of the nitro to hydroxyamino groups in the cobalt(II) complex does not require hydrogen ions.

Dithionite reduction of [Co(HANOsar)]$^{3+}$ was carried out at pH 6.3 (0.1 M MES buffer), 25 °C and I=0.50 M (Na_2SO_4). The rate constants obtained are $k_4=(2.1\pm0.4)\times10^5$ M^{-1}s^{-1} for Reaction 4 and $k_5=(8.4\pm0.6)\times10^3$ M^{-1}s^{-1} for Reaction 5 (Table 2). Rates for Reactions 3 and 5 in the dithionite system are obviously comparable, suggesting that the attack of an electron on the $-NO_2$ group is rate determining and that the following intramolecular electron-transfer reactions and further reductions of nitroso groups are very fast ($\lessdot\gtrdot$ denotes sar),

Table 2. Rate Constants for Reduction of [Co(HANOsar)]$^{3+}$ by Dithionite[a]

$[S_2O_4^{2-}]_0/10^{-3}$ M	First Stage[b] k_{obsd}/s^{-1}	Second Stage[c] k_{obsd}/s^{-1}
5.0	0.68	0.022
10.0	0.72	0.030
20.0	1.4	0.046
30.0	1.6	0.053

a) 25 °C, I=0.50 M (Na_2SO_4), pH 6.3 (0.1 M MES buffer), $[Co(III)]_0=3.0\times10^{-4}$ M, and λ=480 nm. b) Plots of k_{obsd} vs. $[S_2O_4^{2-}]_0^{1/2}$ were linear with zero intercept and k_4 was obtained as $(2.1\pm0.4)\times10^5$ M^{-1}s^{-1} for the SO_2^- reduction. c) Plots of k_{obsd} vs. $[S_2O_4^{2-}]_0^{1/2}$ were linear with zero intercept and k_5 was obtained as $(8.4\pm0.6)\times10^3$ M^{-1}s^{-1} for the SO_2^- reducion.

Table 3. Rate Constants for Reduction of [Co(diNOsar)]$^{2+}$ and [Co(HANOsar)]$^{2+}$ by MDQ$^+$

$[Co(III)]_0$	$[MDQ^+]_0$	k_{obsd}	k_2 or k_5
10^{-6} M	10^{-4} M	s^{-1}	10^4 M^{-1}s^{-1}
[Co(diNOsar)]$^{2+}$

10	1.50	—	1.13[b]
[Co(HANOsar)]$^{2+}$			
2	0.90	1.28	1.4
2	1.30	3.05	2.3
2	1.50	3.96	2.6
17	1.43	—	1.7[c]

a) 25 °C, I=0.50 M (Na_2SO_4), pH 7.8 (0.1 M Tris-H_2SO_4 buffer) and λ=760 nm. b) Obtained from plots of $\ln[A_t/(A_t-A_\infty)]$ vs. t (Eq. 8). c) Obtained from plots of $\ln[A_t/(A_t-A_\infty)]$ vs. t (Eq. 9).

$$O_2N\lessdot Co^{II}\gtrdot NO_2^- \xrightarrow{fast} O_2N\lessdot Co^{III}\gtrdot NO \xrightarrow{fast} \quad (6)$$

$$HOHN\lessdot Co^{II}\gtrdot NO_2^- \xrightarrow{fast} HOHN\lessdot Co^{III}\gtrdot NO \xrightarrow{fast} \quad (7)$$

We also determined the rate constants for the MDQ$^+$ reductions of nitro to hydroxyamino groups in [Co(diNOsar)]$^{2+}$ and [Co(HANOsar)]$^{2+}$. Since the decay of MDQ$^+$ radical was monitored, the rate constants were obtained using the following equations, respectively:

$$\ln[A_t/(A_t-A_\infty)] = ([MDQ^+]_0-7[Co(II)]_0)k_2t + \ln[MDQ^+]_0/7[Co(II)]_0 \quad (8)$$

$$\ln[A_t/(A_t-A_\infty)] = ([MDQ^+]_0-3[Co(II)]_0)k_5t + \ln[MDQ^+]_0/3[Co(II)]_0 \quad (9)$$

where [ ]$_0$ represents the initial concentration of the given species and A_t and A_∞ denote the absorbances at time t and infinity, respectively. The plots of $\ln[A_t/(A_t-A_\infty)]$ vs. t for each system gave a linear relation for at least 3 half-lives. The second-order rate constant, k_2 or k_5, was calculated from the slope of this straight line. The results are shown in Table 3. Reaction-rate constants are similar to those for the dithionite system. Attempts to detect an intermediate

compound containing a nitroso group (-NO) were unsuccessful. However, we cannot completely rule out the possibility of the formation of a nitroso group since in these systems a small amount of cobalt(III) complex was separated which could not be identified.

The author would like to thank Professor Ralph G. Wilkins of New Mexico State University for support and encouragement. This work was supported by a grant from the National Science Foundation of U.S.A.

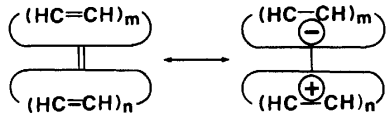
(Received, November 22, 1985)

5,10-Dimethyl-6,8-bisdehydroheptatridecafulvalene **10**, 10-methyl-6,8-bisdehydro-4,5-benzoheptatridecafulvalene **11**, 6,8-bisdehydro-4,5:10,11-dibenzoheptatridecafulvalene **12**, 5,10-dimethyl-6,8-bisdehydroheptapentadecafulvalene **13**, 5,10,15-trimethylheptapentadecafulvalene **14**, 7,12-dimethylheptaheptadecafulvalene **15**, and 7,12-dimethylheptanonadecafulvalene **16** were synthesized by a reaction of 8-oxoheptafulvene **8** with the corresponding bisdehydroannulenones **1**—**7**. Dibenzo derivatives of 5,10-dimethyl-6,8-bisdehydropentatridecafulvalene **23**, 10-methyl-6,8-bisdehydro-4,5-benzopentatridecafulvalene **24**, 6,8-bisdehydro-4,5:10,11-dibenzopentatridecafulvalene **25**, 5,10-dimethylpentapentadecafulvalene **26**, 5,10,15-trimethylpentapentadecafulvalene **27**, 7,12-dimethylpentaheptadecafulvalene **28**, and 7,12-dimethylpentanonadecafulvalene **29** were also synthesized by the reaction of 9-fluorenylidenemethanone **21** with the corresponding annulenones **1**—**7**. Furthermore, a benzo-annelated series of heptapentadecafulvalenes **30**—**35** was also synthesized. The ^{1}H NMR spectra of these hepta- and dibenzopentafulvalenes are discussed in connection with their tropicity. It can be concluded that a slight polarization of π-electrons through pinch bonds from the seven-membered rings to the many-membered rings in the heptafulvalene system and from the many-membered rings to the five-membered rings in the pentafulvalene system exist regardless of the size of the many-membered rings.

Recently, theoretical and experimental studies on the bicyclic polyene containing a cyclic cross conjugated π-electron system, fulvalene, have been extensively performed.[2)]

One group (A) of these compounds, in which one ring is $(4n+1)$-membered and the other is $(4n+3)$-membered, such as sesquifulvalene (pentaheptafulvalene) or triapentafulvalene (calicene), is potentially aromatic since the polarization of a π-electron through the central double bond (pinch bond) from $(4n+3)$ to $(4n+1)$-membered ring will make both rings a $(4n+2)$ π-electron system. The other group (B) in which both rings are $(4n+1)$- and/or $(4n+3)$-membered, such as pentafulvalene or heptafulvalene, is not potentially aromatic since the polarization of a π-electron through a pinch bond will make one ring a $(4n+2)$ system, and the other ring a $(4n)$ system.



We have investigated the syntheses of fulvalene containing a cycloheptatrienylidene moiety by a reaction of 8-oxoheptafulvene with various annulenones.[3)]

The reaction of 8-oxoheptafulvene with various many-membered annulenones such as trideca-, pentadeca-, heptadeca-, and nonadeca-annulenones may give, by [2+2] cycloaddition followed by an extrusion of carbon dioxide, fulvalenes containing a seven-membered ring in one ring and a many-membered ring in the other ring belonging to the group (A) or (B), depending on the size of the many-membered rings. Furthermore, a similar reaction using 9-fluorenylidenemethanone instead of 8-oxoheptafulvene might give dibenzo derivatives of the pentafulvalenes containing many-membered ring belonging to either group (A) or (B).

Although derivatives of pentaundecafulvalene[4)] belonging to the group (A) and pentatridecafulvalene,[5)] pentaphenafulvalene,[6)] and undecafulvalene[7)] belonging to group (B) are known as macrocyclic compounds of these types, systematic investigations of the syntheses and properties of fulvalenes containing many-membered rings have not been undertaken. Recently, the syntheses of pentafulvalenes containing 13-, 15-, 17-, and 19-membered macrocyclic rings have been reported.[8)]

In this paper, two series of fulvalenes, heptafulvalenes containing 13-, 15-, 17-, and 19-membered macrocyclic rings and dibenzopentafulvalenes containing the similar macrocyclic rings have been synthesized, and their tropicities are discussed in terms of an inspection of their ^{1}H NMR spectra.

Results and Discussion

Syntheses. We have reported that a reaction of 8-oxoheptafulvene with tropone and its derivatives afforded heptafulvalenes and [2+8] cycloadducts in a variety of ratios depend on the substituents.[3)] We applied the reaction to derivatives of bisdehydro [13]-, [15]-, [17]-, and [19]annulenones and objective heptafulvalenes were synthesized. The reactions of 5,10-dimethyl-6,8-bisdehydro[13]annulenone **1**,[9)] 10-methyl-6,8-bisdehydro-4,5-benz[13]annulenone **2**,[10)] 6,8-bisdehydro-4,5:10,11-dibenz[13]annulenone **3**,[10)] 5,10-dimethyl-6,8-bisdehydro[15]annulenone **4**,[11)] 5,10,15-trimethyl-6,8-bisdehydro[15]annulenone **5**,[12)] 7,12-dimethyl-8,10-bisdehydro[17]annulenone **6**,[11)] and 7,12-dimethyl-8,10-bisdehydro[19]annulenone **7**[11)] with an excess of 8-oxoheptafulvene **8**[3,13)] formed in situ by a reaction of tropylcarbonyl chloride **9** and triethylamine

in dry benzene at refluxing or room temperature afforded 5,10-dimethyl-6,8-bisdehydroheptatridecafulvalene **10**, 10-methyl-6,8-bisdehydro-4,5-benzoheptatridecafulvalene **11**, 6,8-bisdehydro-4,5:10,11-dibenzoheptatridecafulvalene **12**, 5,10-dimethyl-6,8-bisdehydroheptapentadecafulvalene **13**, 5,10,15-trimethyl-6,8-bisdehydroheptapentadecafulvalene **14**, 7,12-dimethyl-8,10-bisdehydroheptaheptadecafulvalene **15**, and 7,12-dimethyl-8,10-bisdehydroheptanonadecafulvalene **16** in 3.9, 67.3, 23.8, 36, 86, 52, and 74% yields, respectively.

In the case of **1** and **3**, [2+8] cycloadducts **17** and **18** were obtained in yields of 41 and 14%, respectively, both as pale-yellow crystals. 2,13-Dideuterio derivative of **3**[14] afforded the corresponding fulvalene **19** and [2+8] adduct **20** which were very useful compounds for NMR assignment of compounds **12** and **18**,[15] respectively.

The fulvalenes **10**—**16** were recrystallized from benzene or hexane–benzene to give deep-colored (dark-reddish or dark-brownish) moderately stable crystals. These gradually decomposed upon standing at room temperature or upon exposure to air and diffused light.

On the other hand, reactions of the annulenones **1**—**7** with 9-fluorenylidenemethanone **21** formed in situ by a reaction of 9-chlorofluorene-9-carbonyl chloride

22 with mercury afforded the corresponding dibenzo derivatives of the pentafulvalenes **23—29** containing 13-, 15-, 17-, and 19-membered rings in 28, 27, 4.4, 47, 8.3, 38, and 36% yields, respectively. These fulvalenes were also deep-colored and moderately stable compounds at low temperature and under nitrogen atmosphere.

Furthermore, we studied the synthesis of the series of benzoannelated heptapentadecafulvalenes. The reactions of 10-methyl-4,5-benzo-,[16,17] 5-methyl-10,11-benzo-,[16,17] 4,5:10,11-dibenzo-,[18] 10,15-dimethyl-4,5-benzo-,[16] 5,15-dimethyl-10,11-benzo-,[16] and 15-methyl-4,5:10,11-dibenzo-6,8-bisdehydropentadecaannulenones[16] with 8-oxoheptafulvene **8** afforded the corresponding benzoannelated heptapentadecafulvalenes **30** [81%, mp 119—123 °C (decomp)], **31** [29.4%, mp 108—110 °C (decomp)], **32** [23.6%, mp 150 °C (decomp)], **33** [87%, mp 89 °C (decomp)], **34** (23%, mp not clear), and **35** (77%, mp not clear), and [2+8] cycloadducts **36** [mp 215—225 °C (decomp)] and **37** [mp 189—191 °C (decomp)] in some cases. However, the reactions of 2,5,10-trimethyl-6,8-bisdehydropentadecaannulenone[12] and 2-methyl-4,5:10,11-dibenzo-6,8-bisdehydropentadecaannulenone[12] with **8** were very slow and yielded only

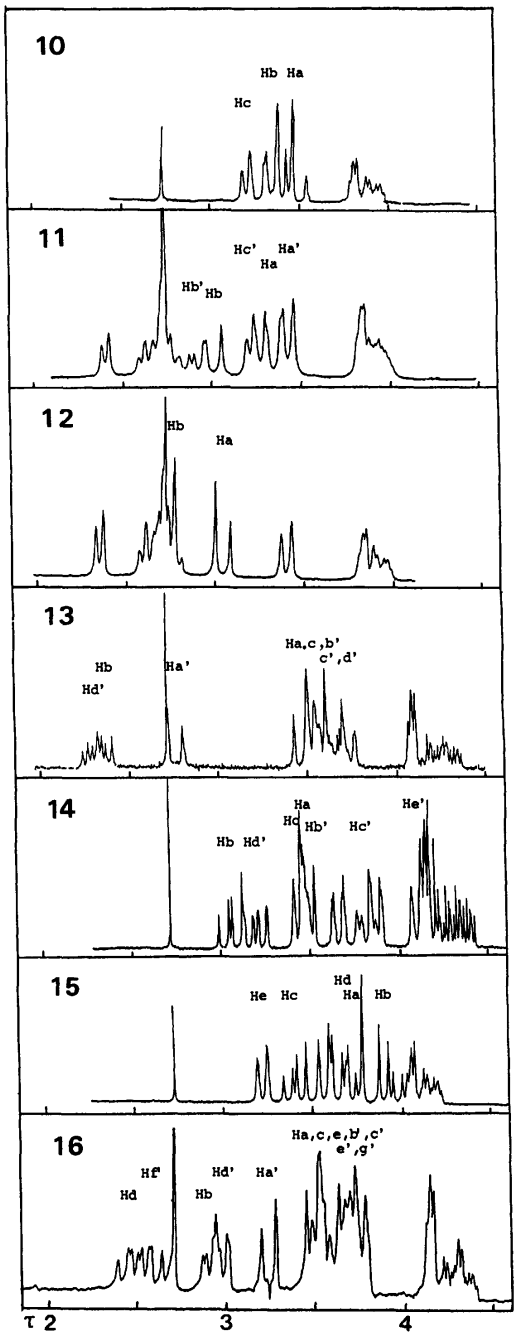

Fig. 1. ^{1}H NMR (200 MHz) Spectra (partial) of Heptafulvalenes **10—16** in $CDCl_3$ (τ values, internal standard, TMS).

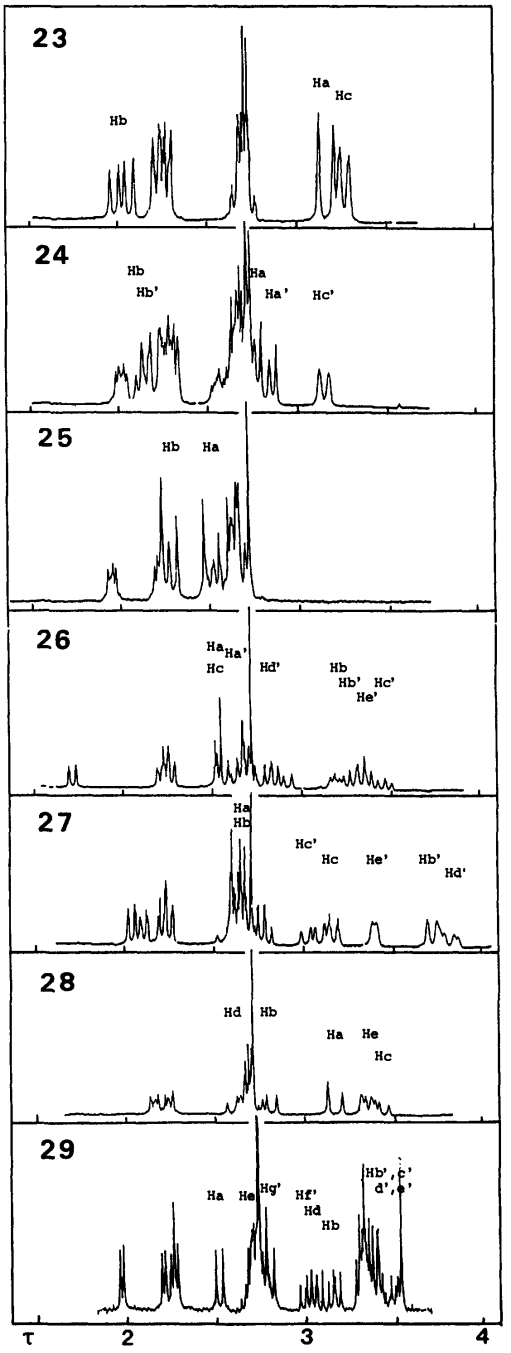

Fig. 2. ^{1}H NMR (200 MHz) Spectra (partial) of Pentafulvalenes **23—28** and ^{1}H NMR (400 MHz) Spectra of **29** in $CDCl_3$ (τ values, internal standard, TMS).

[2+8] cycloadducts **38** [mp 176°C (decomp)] and **39** [mp 193—194°C (decomp)], respectively.

^{1}H NMR. The ^{1}H NMR spectra at 200 MHz of the heptafulvalenes **10—16** and the pentafulvalenes **23—29** are illustrated in Figs. 1 and 2, respectively. The individual assignments were made on the basis of the multiplicities and coupling constants, which were determined by extensive decoupling experiments.

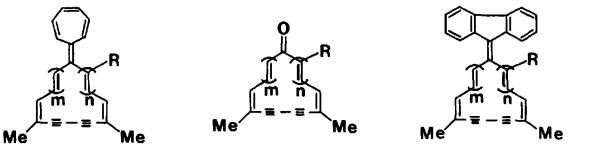
Differences of the outer and inner protons of the many-membered rings of all spectra were considerably smaller than those of starting annulenones; therefore, these fulvalenes have a more polyolefinic character than the starting annulenones.

Figure 1 shows that the seven-membered ring protons of **10**, **11**, **12**, and **15** resonate in a slightly higher magnetic field than those of **13**, **14**, and **16**; the former are almost the same as those of heptafulvalene itself[19] and the latter are almost the same as those of sesquifulvalene (pentaheptafulvalene).[20] On the other hand, the outer and inner protons of the many-membered rings of **10**, **11**, and **12** resonate with each other at lower and higher magnetic fields. The outer and inner protons of the many-membered rings of **13**, **14**, and **16** resonate with each other at higher and lower magnetic fields. These are in accord with that the compounds **10**, **11**, **12**, and **15**, belonging to the group (A), are potentially aromatic by polarization of the π-electrons which makes the seven-membered rings to 6π and the many-membered rings to 14π or 18π systems. Furthermore, it can be considered that the polarization of π-electrons from the seven-membered ring to the many-membered rings occurred even in compounds **13**, **14**, and **16**, belonging to the group (B). These make seven-membered rings to 6π and many-membered rings to paratropic having a 16π or a 20π system.

Figure 2 shows a reverse trend in the pentafulvalene compared to the heptafulvalene system. The outer and inner protons of the many-membered rings of **23**, **24**, **25**, and **28** resonate with each other at higher and lower fields. Those of **26**, **27**, and **29** resonate with each other at lower and higher fields. This shows that polarization of the π-electrons through a pinch bond from the many-membered rings to the five-membered rings occurred in all cases which make many-membered rings of **23**, **24**, **25**, and **28** to paratropic having 12π or 16π system and those of **26**, **27**, and **29** to diatropic having 14π or 18π system. In particular, relative chemical shifts of the corresponding inner protons of the many-membered rings of the hepta- and pentafulvalenes clearly show an inverse direction to each other. This indicates that the polarization of the π-electron from the seven-membered rings to the many-membered rings in the heptafulvalene series and from the many-membered rings to the five-membered rings in the pentafulvalene series occurred regardless of the size of the many-membered rings.

The ^{1}H NMR spectra of benzoannelated heptapentadecafulvalenes **30—35** were taken at 90 MHz, and the spectral patterns were similar to those of heptapentadecafulvalenes **11** and **12**; however, the signals were not separated. Therefore, we could not discuss the assignments and the tropicities.

Table 1. Chemical Shifts of Methyl Protons of Annulenones, and Hepta- and Pentafulvalenes



[13]-	R=H	**10** 8.08		**1** 8.26		**23** 8.12	
[15]-	R=H	**13** 8.18		**4** 7.82, 7.76		**26** 8.06, 8.02	
	R=Me	**14** 8.15, 8.06	8.13,	**5** 7.95, 7.79	7.90,	**27** 8.05, 7.77	8.04,
[17]-	R=H	**15** 8.00		**6** 8.23		**28** 8.06	
[19]-	R=H	**16** 8.14		**7** 7.87, 7.79		**29** 8.04, 8.00	

Furthermore, since the methyl groups of all fulvalenes were always outside of the rings and could be readily recognized in the NMR spectra, we inspected the methyl resonaces of these fulvalenes in the expectation of obtaining information concerning the tropicities.

The chemical shifts of the methyl resonances of the heptafulvalene **10**, **13**, **14**, **15**, and **16** and pentafulvalenes **23**, **26**, **27**, **28**, and **29** are listed in Table 1, together with those of the corresponding annulenones **1**, **4**, **5**, **6**, and **7**. We can see a remarkable alternation of the methyl resonace between $(4n+1)$ annulenones, [13]- and [17]annulenones which show a relatively high field, and $(4n+3)$ annulenones, [15]- and [19]annulenones which show relatively low field. These phenomena indicate paratropicity and diatropicity, respectively, owing to the polarization of the carbonyl group. The same alternation trend can be observed for the pentafulvalene series and a reverse alternation trend was observed for the heptafulvalene series, although the degree of the alternation for both series were much less than that for the annulenones.

Electronic Spectra. The electronic spectra of the heptafulvalenes **10**, **11**, and **12** and the pentafulvalenes **23**, **24**, and **25** are shown in Figs. 3 and 4, respectively. The electronic spectra of the heptafulvalenes **10**, **13**, **15**, and **16** and the pentafulvalenes **23**, **26**, **27**, **28**, and **29** are also shown in Figs. 5 and 6, respectively.

It can be seen from Figs. 3 and 4 that the longest wavelength bands exhibited absorption toward the longer wavelength in the order **10**>**11**>**12**, and **23**>**24**>**25**, respectively, as has been observed for the corresponding annulenones. This indicates that fused benzene rings inhibit the degree of conjugation of a π-electron systems in these fulvalene systems.

From Figs. 5 and 6, we can not see regularity depend on the ring size; the longest bands of nonadecafulvalenes **16** and **29** are shifted to shorter wavelength, which may due to the bending of the many-membered rings.

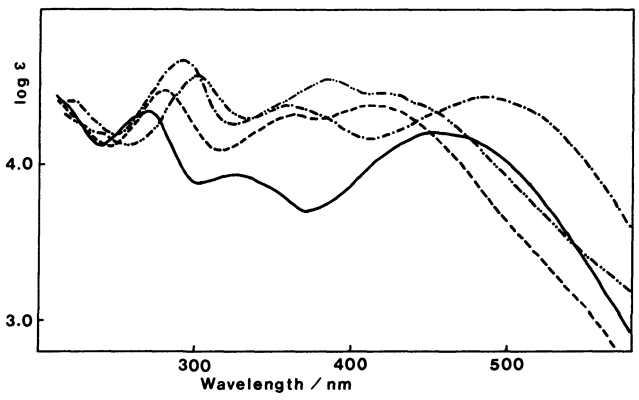

Fig. 5. Electronic Absorption Spectra of **10** (——), **13** (----), **15** (-·-·-), and **16** (-···-) in EtOH.

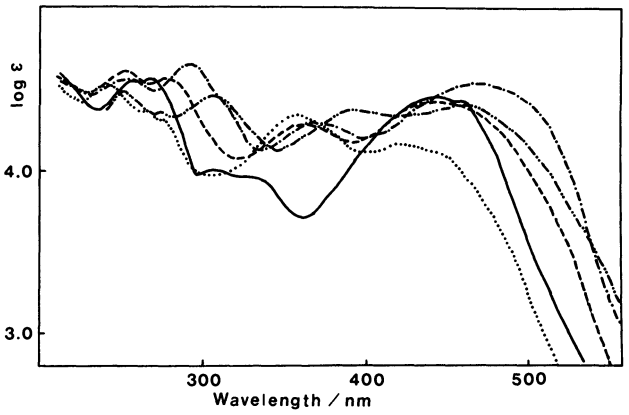

Fig. 6. Electronic Absorption Spectra of **23** (——), **26** (----), **27** (·····), **28** (-·-·-), and **29** (-···-), in EtOH.

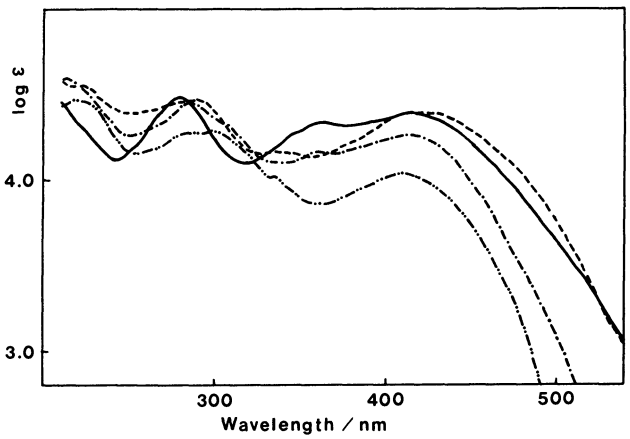

Fig. 7. Electronic Absorption Spectra of **13** (——), **30** (----), **31** (-·-·-), and **32** (-···-) in EtOH.

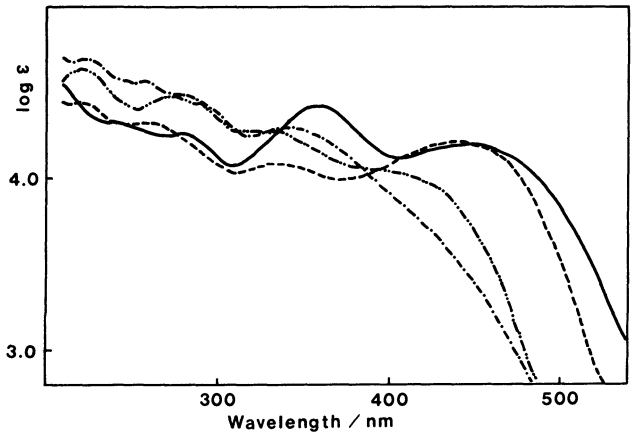

Fig. 8. Electronic Absorption Spectra of **14** (——), **33** (----), **34** (-·-·-), and **35** (-···-) in EtOH.

The spectral curves of the benzoannelated series of heptapentadecafulvelnes **30—32** and **33—35** are illustrated in Figs. 7 and 8 with those of **13** and **14**, respectively. The longest bands of the benzoannelated fulvalenes appeared at shorter wavelengths compared to those of **13** and **14**, as has been observed in Figs. 3 and 4.

Experimental

General. Melting points were determined on a hot-stage apparatus and were uncorrected. The IR spectra were obtained with a Hitachi 215 grating spectrophotometer. The electronic spectra were measured with a Hitachi 340

spectrophotometer. ^{1}H NMR spectra were recorded with a Varian XL-200 (200 MHz), JEOL JX-400 (400 MHz), or Hitachi R-22 (90 MHz) spectrometer in $CDCl_3$ solutions, tetramethylsilane being used as an internal standard; chemical shifts are reported in τ and coupling constants (J) show in Hz. Mass spectra were measured with a JMS D-200 spectrometer at 75 eV.

Reaction of [13]Annulenone 1 and 8-Oxoheptafulvene 8. A solution of tropylcarbonyl chloride **9** (154.6 mg, 1.0 mmol) in dry benzene (10 ml) was added dropwise to a solution of [13]annulenone **1** (104 mg, 0.5 mmol) and triethylamine (214 mg) in dry benzene (15 ml) during a period of 15 min at refluxing temperature under argon atmosphere, and the mixture was refluxed for further 15 min. The solution was submitted to column chromatography on silica gel, and eluted with a mixture of hexane and benzene. From reddish fraction heptatridecafulvalene **10** (5.5 mg, 3.9%) was obtained as dark reddish needles (from a mixture of hexane and benzene), color changed from around 110 °C and decomposed without melting.

From the yellow fraction, [2+8] cycloadduct **17** (67.0 mg, 41%) was obtained as pale-yellow prisms, mp 159—160 °C (decomp) (from benzene). **10**; IR (KBr) 2140 cm^{-1} (C≡C); ^{1}H NMR (200 MHz) τ=3.21 (d, J=9, Hc), 3.36 (d, J=12.5, H-1), 3.37 (d,d, J=15.5, 9, Hb), 3.51 (d, J=15.5, Ha), 3.79—3.98 (m, H-2,3), 8.08 (s, Me).

Found: C, 93.49; H, 6.16%. Calcd for $C_{22}H_{18}$: C, 93.57; H, 6.43%. **17**; IR (KBr) 2170 cm^{-1} (C≡C), 1745 (C=O); ES λ_{max} (EtOH) 258 nm (log ε 4.38), 316 (3.90); ^{1}H NMR (200 MHz) τ=2.86 (m, H-6), 3.25 (m, H-4, 5), 3.37 (d,d,q, J=5, 1, 1, Hc or Hc'), 3.49 (d,d,q, J=5, 1, 1, Hc' or Hc), 3.61 (d,d,q, J=15.5, 5, 1, Hb or Hb'), 3.75—3.95 (m, H-3), 3.95 (d,d,q, J=15.5, 5, 1, Hb' or Hb), 4.59 (d,d, J=9.6, 4, H-2), 4.79 (d,d, J=15.5, 1, Ha'), 4.83 (d,d, J=15.5, 1, Ha), 6.86 (m, H-1), 8.04 (d,d, J=1, 1, Me), 8.07 (d,d, J=1, 1, Me).

Found: C, 84.63; H, 5.53%. Calcd for $C_{23}H_{18}O_2$: C, 84.64; H, 5.56%.

Heptatridecafulvalene 11. A reaction of [13]annulenone **2** (34 mg, 0.14 mmol), chloride **9** (30 mg, 0.2 mmol), triethylamine (50 mg) in dry benzene (20 ml) was carried out in almost the same manner, conditions and purification procedure as in the case of 1. Heptatridecafulvalene **11** (29.8 mg, 67.3%) was obtained as dark-reddish crystals, mp 150 °C (decomp). IR (KBr) 2160 cm^{-1} (C≡C); ^{1}H NMR (200 MHz) τ=2.41 (d, J=7.5, 1H, Ar-H), 2.59—2.80 (m, 3H, Ar-H), 2.89 (d,d, J=16, 10.5, Hb'), 3.01 (d, J=16.5, Hb), 3.21 (d, J=10.5, Hc'), 3.26 (d, J=16.5, Ha), 3.43 (d, J=11.5, H-1,6), 3.45 (d, J=16, Ha'), 3.8—4.0 (m, H-2,3,4,5), 8.12(s, Me).

Found: C, 94.01; H, 5.61%. Calcd for $C_{25}H_{18}$: C, 94.30; H, 5.70%.

Heptatridecafulvalene 12. A solution of chloride **9** (154 mg, 1.0 mmol) in dry benzene (10 ml) was added dropwise to a solution of [13]annulenone **3** (140 mg, 0.5 mmol) and triethylamine (40 ml) at 80 °C under an argon atmosphere for 15 min. The reaction mixture was heated for an additional 30 min, submitted to column chromatography on alumina and eluted with benzene. From the reddish fraction heptatridecafulvalene **12** (42.2 mg, 23.8%) was obtained as dark-reddish crystals, mp decomposed from around 150 °C.

From pale yellow fraction, [2+8] cycloadduct **18** (29.1 mg, 14.5%) was obtained as pale-yellow crystals, mp 191—194 °C. **12**; IR (KBr) 2175 cm^{-1} (C≡C); ^{1}H NMR (200 MHz) τ=2.36 (d, J=8, 2H, Ar-H), 2.57—2.81 (m, 6H, Ar-H), 2.73 (d, J=16.5, Hb), 3.04 (d, J=16.5, Ha), 3.39 (d, J=11.5, H-1), 3.78—3.97 (m, H-2, 3).

Found: C, 94.62; H, 5.08%. Calcd for $C_{28}H_{18}$: C, 94.88; H, 5.12%. **18**; IR (KBr) 2190 cm^{-1} (C≡C), 1745 (C=O); ES λ_{max} (EtOH) 223 nm (log ε 4.81), 259 (4.52), 273 (4.50), 321 (4.18), 341 (4.16); ^{1}H NMR (200 MHz) τ=2.78 (m, 9H, H-6, Ar-H), 3.09 (d, J=16, Hb or Hb'), 3.22 (m, H-4, 5), 3.35 (d, J=16, Hb' or Hb), 3.54 (d, J=16, Ha'), 3.61 (d, J=16, Ha), 3.78 (d,m, J=10, H-3), 4.56 (d,d, J=10, 4, H-2), 6,99 (m, H-1).

Found: C, 87.37; H, 4.78%. Calcd for $C_{29}H_{18}O_2$: C, 87.41; H, 4.55%.

Heptapentadecafulvalene 13. A reaction of [15]annulenone **4** (78 mg, 0.33 mmol), chloride **9** (100 mg, 0.65 mmol), triethylamine (100 mg) in dry benzene (20 ml) was carried out in the almost same manner as in the case of 1. The usual work-up afforded the heptafulvalene **13** (36.9 mg, 36%) as dark-reddish crystals, mp 100—101.5 °C (decomp). IR (KBr) 2160 cm^{-1} (C≡C); ^{1}H NMR (200 MHz) τ=2.31 (d,d, J=14.5, 11, Hd'), 2.34 (d,d, J=15, 11.5, Hb), 2.76 (d, J=15.5, Ha'), 3.43—3.70 (m, Ha,c,b',c',e'), 3.56 (d, J=11.5, H-6), 3.73 (d, J=12, H-1), 4.08 (d,d, J=5, 3.5, H-3, 4), 4.25 (d,d,d, J=11.5, 5, 3.5, H-5), 4.27 (d,d,d, J=12, 5.5, 3.5, H-2), 8.18 (s, 2Me).

HRMS; Found: 308.1490. Calcd for $C_{24}H_{20}$: 308.1566.

Heptapentadecafulvalene 14. A reaction of a solution of [15]annulenone **5** (50 mg, 0.20 mmol) in dry benzene (10 ml) and a solution of chloride **9** (100 mg) in dry benzene (10 ml) was carried out in the similar manner in the case of **1**. The usual work-up afforded heptapentadecafulvalene **14** (45 mg, 86%) as dark-reddish crystals, mp 99—100 °C (decomp). IR (CCl_4) 2170 cm^{-1} (C≡C); ^{1}H NMR (200 MHz) τ=3.05 (d,d, J=15, 11.5, Hb), 3.19 (d,d,d, J=15.5, 10, 1, Hd'), 3.44 (d,d, J=11.5, 1.5, Hc), 3.49 (d, J=15, Ha), 3.51 (d, J=5, Hb'), 3.66 (d, J=11.5, H-6), 3.81 (d,d, J=15.5, 5, Hc'), 3.86 (d, J=12, H-1), 4.10 (d, J=10, He'), 4.15 (m, H-3, 4), 4.25 (d,d,d, J=11.7, 5.2, 3.7, H-5), 4.37 (d,d,d, J=12, 5, 4.5, H-2), 8.06 (d, J=1.5, Me), 8.13 (d,d, J=1.5, 1.5, Me), 8.15 (s, Me).

HRMS; Found: 322.1744. Calcd for $C_{25}C_{22}$: 322.1722.

Heptaheptadecafulvalene 15. A solution of [17]annulenone **6** (65 mg, 0.25 mmol), triethylamine (199 mg) in dry benzene (20 ml) and a solution of chloride **9** (100 mg, 0.6 mmol) in dry benzene (10 ml) was reacted, and the usual work-up afforded heptaheptadecafulvalene **15** (44.1 mg, 52%) as dark-brownish needles, mp 180—181 °C (decomp). IR (KBr) 2165 cm^{-1} (C≡C); ^{1}H NMR (200 MHz) τ=3.22 (br d, J=11, He), 3.39 (d,d, J=15, 10, Hc), 3.56 (d, J=11.5, H-1), 3.67 (d,d, J=15, 11, Hd), 3.73 (d, J=15.5, Ha), 3.93 (d,d, J=15.5, 10, Hb), 4.04 (d,d, J=4.5, 4, H-3), 4.15 (d,d,d, J=11.5, 4.5, 4, H-2), 8.00 (s, Me).

HRMS; Found: 334.1732. Calcd for $C_{26}H_{22}$: 334.1722.

Heptanonadecafulvalene 16. A solution of [19]annulenone **7** (50 mg, 0.17 mmol) and triethylamine (132 mg) in dry benzene (10 ml), and a solution of chloride **9** (100 mg) in dry benzene (10 ml) was reacted at room temperature for 20 min under argon atmosphere. The solution was passed through an alumina (deactivated by treating with ethyl acetate and water) column. The colored fraction was collected and purified by further column chromatography using the alumina to obtain heptafulvalene **16** (46.5 mg, 74%) as unstable dark-reddish crystals, mp 144—145 °C (decomp). IR (KBr) 2190 cm^{-1} (C≡C); ^{1}H NMR (200 MHz) τ=2.46 (d,d, J=15, 11, Hd), 2.57 (d,d, J=15, 11, Hf'), 2.93 (d,d, J=15, 11, Hb), 2.95 (d,d, J=15, 11, Hd'), 3.24 (d, J=16, Ha'), 3.45—4.00 (m, H-1, 6, a,c,e,b',c',e',g'), 4.14 (d,d, J=5, 3.5, H-3, 4), 4.19—4.39 (m, H-

2, 5), 8.14 (s, 2Me).

HRMS; Found: 360.1799. Calcd for $C_{28}H_{24}$: 360.1879.

Pentatridecafulvalene 23. A solution of [13]annulenone **1** (50 mg, 0.24 mmol), 9-chlorofluorene-9-carbonyl chloride **22** (150 mg, 0.57 mmol), in dry benzene (20 ml) in the presence of one drop of mercury was stirred at room temperature under an argon atmosphere for 3 d. The reaction mixture was directly submitted to column chromatography using silica gel, and the colored fraction was further purified by chromatography on silica gel. Pentatridecafulvalene **23** (24 mg, 28%) was obtained as dark-reddish crystals, mp 174—175 °C (decomp). IR (KBr) 2150 cm^{-1} (C≡C); ^1H NMR (200 MHz) τ=2.03 (d,d, J=16, 10, Hb), 2.20—2.30 (m, 4H, Ar-H), 2.64—2.77 (m, 4H, Ar-H), 3.07 (d, J=16, Ha), 3.27 (d, J=10, Hc), 8.12 (s, Me).

Found: C, 94.11; H, 5.44%. Calcd for $C_{28}H_{20}$: C, 94.34; H, 5.66%.

Pentatridecafulvalene 24. A solution of [13]annulenone **2** (50 mg, 0.2 mmol), chloride **22** (150 mg) in dry benzene (10 ml) in the presence of one drop of mercury was stirred at room temperature for 30 h under an argon atmosphere. The reaction mixture was submitted to column chromatography using alumina and eluted with benzene. The pentatridecafulvalene **24** (22 mg, 27%) was obtained as dark-reddish crystals, mp 190—192 °C (decomp). IR (KBr) 2165 cm^{-1} (C≡C); ^1H NMR (200 MHz) τ=1.97—2.31 (m, 5H, Hb, Ar-H), 2.10 (d,d, J=16.5, 10.5, Hb'), 2.49—2.72 (m, 8H, Ar-H), 2.78 (d, J=16.5, Ha), 2.82 (d, J=16.5, Ha'), 3.13 (d, J=10.5, Hc'), 8.00 (s, Me).

Found: C, 94.72; H, 4.84%. Calcd for $C_{31}H_{20}$: C, 94.86; H, 5.14%.

Pentatridecafulvalene 25. A solution of [13]annulenone **3** (50 mg, 0.18 mmol), chloride **22** (100 mg) and one drop of mercury in dry benzene (10 ml) was stirred at room temperature for 3 d. The usual work-up afforded pentatridecafulvalene **25** (3.4 mg, 4.4%) as dark-reddish crystals, mp 221—223 °C (decomp), and annulenone **3** (20 mg) was recovered. IR (KBr) 2190 cm^{-1} (C≡C); ^1H NMR (200 MHz) τ=1.97 (m, 2H, Ar-H), 2.20—2.32 (m, 2H, Ar-H), 2.26 (d, J=16.5, Hb), 2.46—2.71 (m, 12H, Ar-H), 2.49 (d, J=16.5, Ha).

HRMS; Found: 428.1488. Calcd for $C_{34}H_{20}$: 428.1566.

Pentapentadecafulvalene 26. A solution of [15]annulenone **4** (70 mg, 0.30 mmol), chloride **22** (150 mg) in dry benzene in the presence of one drop of mercury was stirred for 1 d at room temperature under an argon atmosphere. The usual work-up afforded pentapentadecafulvalene **26** (55 mg, 47%) as dark-reddish crystals, mp 153.5—155 °C (decomp). IR (KBr) 2160 cm^{-1} (C≡C); ^1H NMR (200 MHz) τ=1.70 (d, J=8, 1H, Ar-H), 2.30 (m, 3H, Ar-H), 2.58—2.86 (m, 4H, Ar-H), 2.52 (d, J=5, Ha), 2.53 (d, J=7, Hc), 2.60 (d, J=15.5, Ha'), 2.87 (d,d, J=15, 11, Hd'), 3.17 (d,d, J=7, 5, Hb), 3.28 (d,d, J=15.5, 7, Hb'), 3.32 (d, J=11, He'), 3.43 (d,d, J=15, 7, Hc'), 8.02 (s, Me), 8.06 (s, Me).

HRMS; Found: 382.1690. Calcd for $C_{30}H_{22}$: 382.1722.

Pentapentadecafulvalene 27. A solution of [15]annulenone **5** (50 mg, 0.20 mmol), chloride **22** (100 mg) and one drop of mercury in dry benzene (10 ml) was stirred at room temperature for 1 d under an argon atmosphere. The usual work-up afforded pentapentadecafulvalene **27** (6.6 mg, 8.3%) as dark-reddish crystals, mp 175—177 °C (decomp). IR (KBr) 2160 cm^{-1} (C≡C); ^1H NMR (200 MHz) τ=2.05 (d, J=7.5, 1H, Ar-H), 2.11 (br d, J=6.5, 1H, Ar-H), 2.21 (br d, J=6, 1H, Ar-H), 2.26 (br d, J=7.5, 1H, Ar-H), 2.52—2.82 (m, 6H, Ha,b, Ar-H), 3.05 (d,d,d, J=15, 11, 1.5, Hc'), 3.16 (d,m, J=9.5, Hc), 3.39 (br d, J=4.5, He'), 3.71 (d, J=11, Hb'), 3.81 (d,d, J=15, 4.5, Hd'), 7.77 (d, J=1.5, a'-Me), 8.04 (d, J=1.5, d-Me), 8.06 (d, J=1.5, f'-Me).

HRMS; Found: 396.1949. Calcd for $C_{31}H_{24}$: 396.1879.

Pentaheptadecafulvalene 28. A solution of [17]annulenone **6** (50 mg, 0.19 mmol), chloride **22** (150 mg, 0.57 mmol) and one drop of mercury in dry benzene (20 ml) was stirred at room temperature for 1 d under an argon atmosphere. The usual work-up afforded pentaheptadecafulvalene **28** (26.3 mg, 38%) as dark-reddish crystals, mp 273—274 °C (decomp). IR (KBr) 2155 cm^{-1} (C≡C); ^1H NMR (200 MHz) τ=2.15 (m, 2H, Ar-H), 2.24 (m, 2H, Ar-H), 2.65 (m, 4H, Ar-H), 2.63 (d,d, J=15.5, 11.5, Hd), 2.77 (d,d, J=15.5, 11, Hb), 3.17 (d, J=15.5, Ha), 3.34 (d, J=11.5, He), 3.40 (d,d, J=15.5, 11, Hc), 8.06 (s, Me).

HRMS; Found: 408.1868. Calcd for $C_{32}H_{24}$: 408.1879.

Pentanonadecafulvalene 29. A solution of [19]annulenone **7** (40 mg, 0.14 mmol), chloride **22** (150 mg) and one drop of mercury in dry benzene (10 ml) was stirred at room temperature for 1 d under an argon atmosphere. The usual work-up afforded pentanonadecafulvalene **29** (22 mg, 36%) as unstable dark-reddish-brown crystals, mp 123—124 °C (decomp). IR (KBr) 2160 cm^{-1} (C≡C); ^1H NMR (400 MHz) τ=1.97 (d, J=7, 1H, Ar-H), 2.21 (d, J=7, 1H, Ar-H), 2.26 (d, J=7, 1H, Ar-H), 2.28 (d, J=7, 1H, Ar-H), 2.56 (d, J=15, Ha), 2.65—2.8 (m, 4H, Ar-H), 2.7 (m, He), 2.7—2.8 (m, Ha'), 2.8 (m, Hg'), 3.0 (d,d, J=15, 11, Hf'), 3.06 (d,d, J=15, 11, Hd), 3.16 (d,d, J=15, 11, Hb), 3.3 (m, Hc), 3.35—3.65 (m, Hb',c',d',e'), 7.99 (s, Me), 8.04 (s, Me).

Syntheses and Properties of Pentatrideca-, Pentapentadeca-, Pentaheptadeca-, and Pentanonadecafulvalene Derivatives

Jūro Ojima,* Kazunori Itagawa, and Tetsuya Nakada
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930
(Received November 22, 1985)

5,10-Dimethyl-6,8-bisdehydropentatridecafulvalene **11**, 10-methyl-6,8-bisdehydro-4,5-benzopentatridecafulvalene **12**, 6,8-bisdehydro-4,5 : 10,11-dibenzopentatridecafulvalene **13**, 5,10-dimethyl-6,8-bisdehydropentapentadecafulvalene **14**, 7,12-dimethyl-8,10-bisdehydropentaheptadecafulvalene **15**, and 7,12-dimethyl-8,10-bisdehydropentanonadecafulvalene **16** were synthesized through the reaction of the corresponding bisdehydroannulenones **1**—**6** with cyclopentadienide. The tropic nature of these pentafulvalenes is discussed on the basis of ^{1}H NMR and electronic spectra as well as those of the corresponding heptafulvalene derivatives.

Syntheses of a series of paratropic dimethylbisdehydro[13]-**1**[1] and dimethylbisdehydro[17]annulenone **5**[2] and the diatropic dimethylbisdehydro[15]-**4**[2] and dimethylbisdehydro[19]annulenone **6**[2] as well as their α-methyl,[3] α-ethyl-substituted,[4] and benzo-annelated derivatives,[3] (e.g. **2** and **3**) have been described previously. Higher analogs of these annulenones, i.e., [21]-,[5] [23]-,[6] and [25]annulenone,[6] could also be synthesized, but only with difficulty. In view of the convenient and relatively easy preparation of compounds **1**—**6** they appeared to be the desirable starting materials for the synthesis of the cross-conjugated π-electron systems. In fact, the syntheses of the diphenylfulvene **7**[7] and the dichlorofulvene derivatives **8**[8] containing macrocyclic system by the reaction of these annulenones with diphenylketene and dichloroketene, respectively, have been achieved. Also, in the preceding paper,[9] of an another cross-conjugated system, fulvalene, which might be derived from the annulenones **1**—**6**, we reported the syntheses of heptafulvalenes **9** and dibenzo derivatives **10** of pentafulvalene using an addition reaction of ketene (8-oxoheptafulvene and 9-fluorenylidenemethanone) as similarly to preparation of **7** and **8**, and it was suggested that only a little π-electron polarization of the central double bond occurs in both the heptafulvalenes **9** and the dibenzopentafulvalenes **10** to form polar structures **9a** and **10a**. It can be seen from the polar structures that the heptafulvalene derivatives **9** polarize in such a way that the positive end of the dipole is localized in the 7-membered ring and the negative pole in the large ring, whereas the dibenzopentafulvalene derivatives **10** do in the reverse direction to **9**. Thus, the pentafulvalenes **10** are expected to exhibit the opposite polarization to those of the heptafulvalene derivatives **9**, but this potentiality would be diminished by benzo-annelation upon the 5-membered ring. Therefore, non-benzo-annelated pentafulvalene derivatives are more desirable to enhance the polarization of the central double bond and are expected to possess a greater extended π-electron system, compared with dibenzo-annelated fulvalenes **10**, and to show the reverse tropicity to the heptafulvalenes containing the same-membered large rings. Thus, starting from the annulenones, we were interested in syntheses of a series of the pentafulvalenes, in which the number of the double bond could be increased systematically and a study of their spectral properties and comparison with those of the heptafulvalene derivatives **9** appeared to be particularly informative.

This paper is concerned with the syntheses and

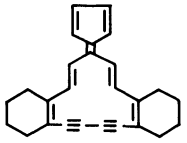
properties of fulvalene derivatives containing cyclopentadienylidene moiety, **11**, **14**—**16**, and the benzoannelated derivatives **12**, **13** of the pentatridecafulvalene derivative **11**.[11] The ^{1}H NMR and electronic absorption spectra of these pentafulvalenes as well as comparison with those of the heptafulvalene derivatives are described in connection with tropicity.

Results and Discussion

Synthesis. In 1977, Howes and Sondheimer reported a synthesis of bis(cyclohexene)-annelated pentatridecafulvalene **17** through the reaction of the corresponding bisdehydroannulenone with a large excess of cyclopentadienide, but did a conjugative addition product when they used a little excess of cyclopentadienide. Thus, although only the pentatridecafulvalene **17** had been obtained, no systematic discussion of the tropicity has been done. We advantageously applied this procedure to the synthesis of pentafulvalenes derived from the annulenones **1**—**6**.



17

We first attempted the reaction of the acyclic ketones (precursors of annulenones), with a large excess of sodium cyclopentadienide, since the corresponding acyclic compounds for the desired fulvalenes would be the most appropriate compounds to examine the tropicity of fulvalenes, as has been made for the fulvene derivatives **7** and **8**.[7,8] However, all attempts to prepare the acyclic model compounds for the desired pentafulvalenes were unsuccessful. The objective pentafulvalene derivatives were synthesized by treatment of the annulenones **1**—**6** with cyclopentadienide according to the procedure of Howes and Sondheimer.[12] Reaction of 5,10-dimethyl-6,8-bisdehydro[13]annulenone **1**,[1] 10-methyl-6,8-bisdehydro-4,5-benz[13]annulenone **2**,[3a] 6,8-bisdehydro-4,5:10,11-dibenz[13]annulenone **3**,[3a] 5,10-dimethyl-6,8-bisdehydro[15]annulenone **4**,[2] 7,12-dimethyl-8,10-bisdehydro[17]annulenone **5**,[2] and 7,12-dimethyl-8,10-bisdehydro[19]-annulenone **6**,[2] with a large excess of sodium cyclopentadienide in tetrahydrofuran at −10—0°C gave 5,10-dimethyl-6,8-bisdehydropentatridecafulvalene **11** (11%), 10-methyl-6,8-bisdehydro-4,5-benzopentatridecafulvalene **12** (7.8%), 6,8-bisdehydro-4,5:10,11-dibenzopentatridecafulvalene **13** (3.9%), 5,10-dimethyl-6,8-bisdehydropentapentadecafulvalene **14** (4.9%), 7,12-dimethyl-8,10-bisdehydropentaheptadecafulvalene **15** (4.6%), and 7,12-dimethyl-8,10-bisdehydropentanonadecafulvalene **16** (6.8%), respectively. These fulvalene derivatives **11**—**16** thus obtained decomposed on attempted melting-point determination, and proved to be rather unstable. These substances decomposed gradually on exposure to diffused light and air.

^{1}H NMR Spectra. The ^{1}H NMR spectra of the fulvalenes **11**, **14**—**16** and the corresponding heptafulvalene derivatives **9** at 200 MHz are illustrated in Figs. 1 and 2, respectively. The individual assignments were made on the basis of the multiplicities and coupling constants, given in the Experimental section. In contrast to the cases of the heptafulvalenes **9** and in accord with the cases of the dibenzopentafulvalenes **10**, containing the same-membered ring, it is predicted that the compounds of **11** and **15** are not aromatic, since polarization of the central double bond would make one ring a $(4n+2)\pi$-system, but the other a $(4n)\pi$-system. On the other hand, the compounds **14** and **16** are aromatic since polarization of the central bond would make both rings $(4n+2)\pi$-systems.

From the Figs. 1 and 2, it is seen that the outer protons of the large rings of the pentatrideca- **11** and the pentaheptadecafulvalene **15** resonate in a higher field than the inner protons, while the reverse is seen in the spectra of the corresponding heptatridecafulvalene and heptaheptadecafulvalene. Thus, the large rings of **11** and **15** are suggested to be paratropic, as expected of 12π- and 16π-electron systems, respectively, owing to polarization of the central double bond. On the other hand, in the spectra of the pentapentadeca- **14** and the pentanonadecafulvalene **16**, the olefinic protons of the large rings resonate in a very narrow region, whereas the outer protons of the heptapentadecafulvalene and the heptanonadecafulvalene resonate in a higher field

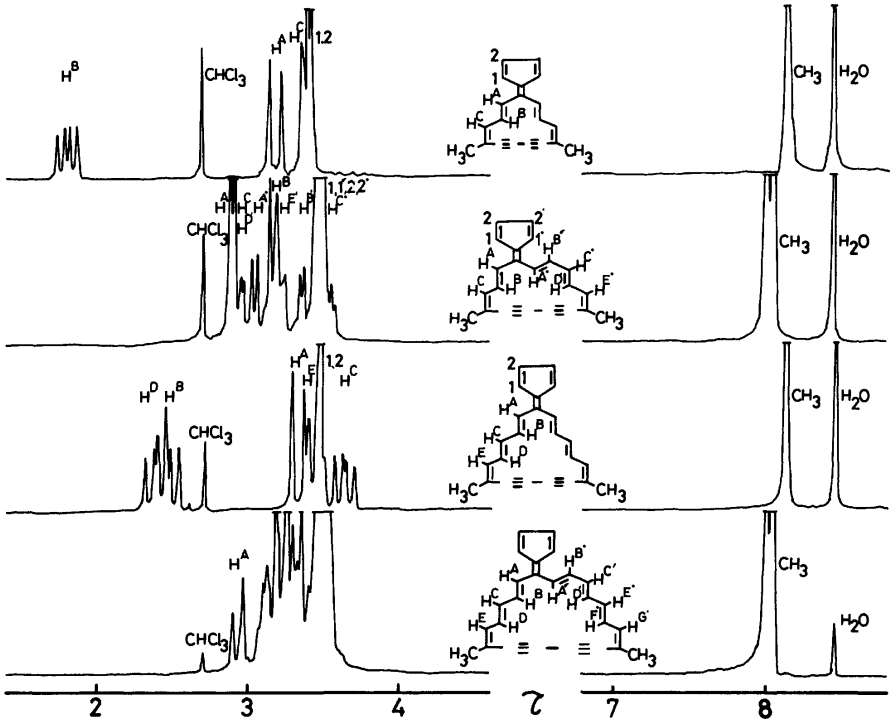


Fig. 1. ^{1}H NMR spectra of Pentatrideca- 11, Pentapentadeca- **14**, Pentaheptadeca- **15**, and Pentanonadecafulvalene **16** in $CDCl_3$ at 21 °C (200 MHz, τ values, internal standard, TMS).

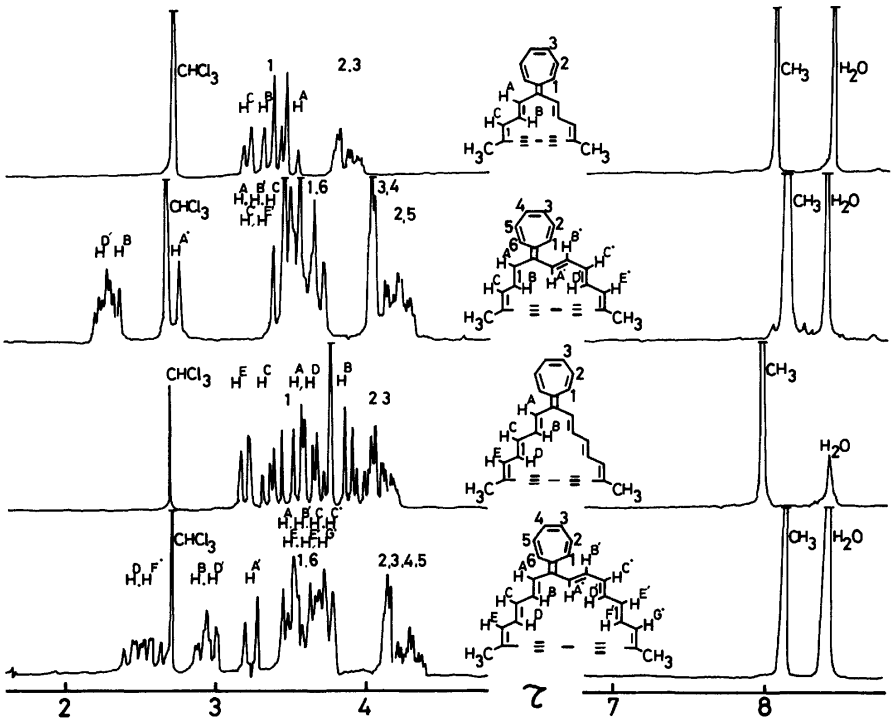

Fig. 2. ^{1}H NMR spectra of Heptatrideca-, Heptapentadeca-, Heptaheptadeca-, and Heptanonadecafulvalene in $CDCl_3$ at 21 °C (200 MHz, τ values, internal standard, TMS).

than the inner protons, as expected of 16π- and 20π-electron systems as before. Thus, although the large membered rings of **14** and **16** are suggested to be atropic, we considered that a systematic examination of the methyl resonances of these fulvalenes would provide a diagnostic tool to test the tropicity since the methyl groups must always be outside the ring and can readily be recognized.[2,6]

Table 1. The ^{1}H NMR Chemical Shifts of Methyl Protons of Compounds 1, **4—6** (90 MHz), **9** (200 MHz), and **11**, **14—16** (200 MHz) ($CDCl_3$, τ Value, at 21 °C

Large-membered ring	Annulenones **1**, **4—6**	Heptafulvalenes **9**	Pentafulvalenes **11**, **14—16**
[13]	8.26	8.08	8.13
[15]	7.76, 7.82	8.18	8.00, 8.05
[17]	8.23	8.00	8.12
[19]	7.79, 7.83	8.14	8.00, 8.04

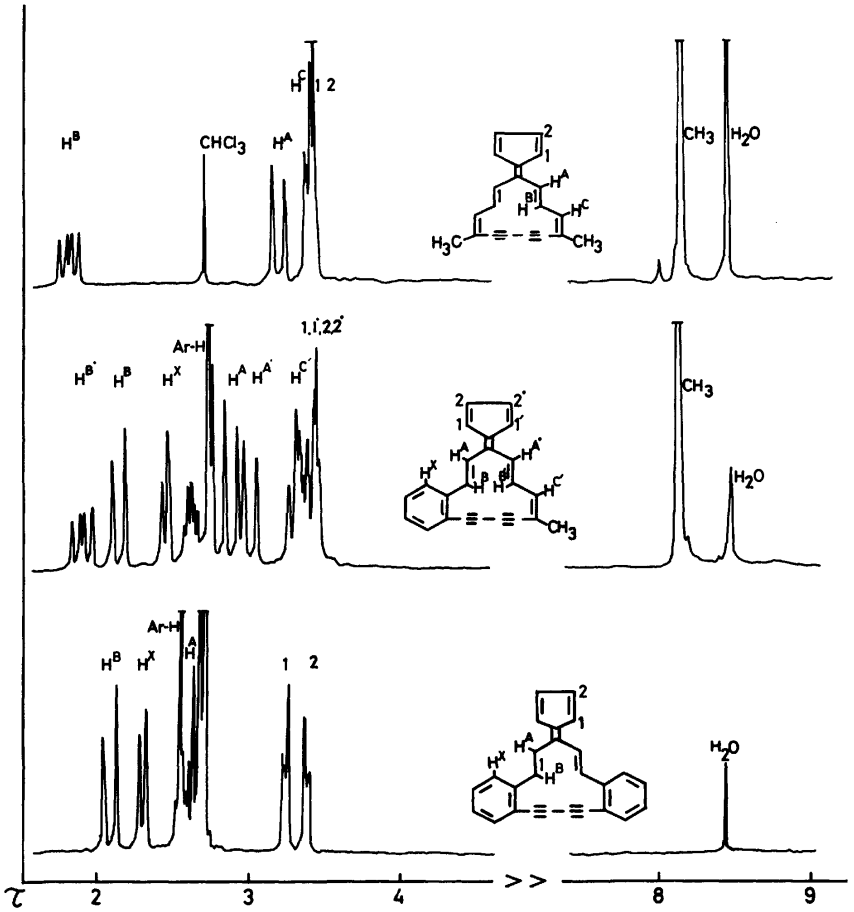

Fig. 3. ^{1}H NMR spectra of pentatrideca- 11, Benzpentatrideca- **12**, and Dibenzpentatridecafulvalene **13** in $CDCl_3$ at 21 °C (200 MHz, τ values, internal standard, TMS).

The chemical shifts of the methyl resonances of the pentafulvalenes **11**, **14—16** are listed in Table 1, altogether with those of the corresponding annulenones **1**, **4—6** and the heptafulvalenes **9**. As can be seen from the Table 1, the alternation of the methyl resonances between the [4*n*+1]annulenones ([13]- **1**, [17]annulenone **5**) (relatively high field) and [4*n*+3]annulenones ([15]- **4**, [19]annulenone **6**) (relatively low field) confirm the paratropicity of the former and the diatropicity of the latter,[2,6] owing to polarization of a carbonyl group. As expected from polarization of the central double bond of the pentafulvalenes, the alternation of the methyl resonances of the large-membered rings between the trideca- **11**, the heptadeca- **15** and pentadeca- **14**, the nonadecafulvalene **16** is seen in the same trend as that in the cases of annulenones **1**, **4—6**, albeit the degree of the alternation being much less than that of annulenones. On the other hand, the alternation of the methyl resonances between 13-, 17- and 15, 19-membered rings of the heptafulvalenes is seen in the reverse trend, as compared with that of annulenones and the pentafulvalenes, in agreement with that the heptafulvalenes **9** polarize from 7-membered ring to large ring. Thus, it can be suggested that a very little π-electron polarization from the large rings to 5-membered ring occurs in these pentafulvalenes **11**, **14—16**.

The ^{1}H NMR spectra of the pentatridecafulvalene **11** and its benzo-annelated derivatives **12**, **13** are shown in Fig. 3. As is seen from the Fig. 3, the differences of the chemical shifts between the inner

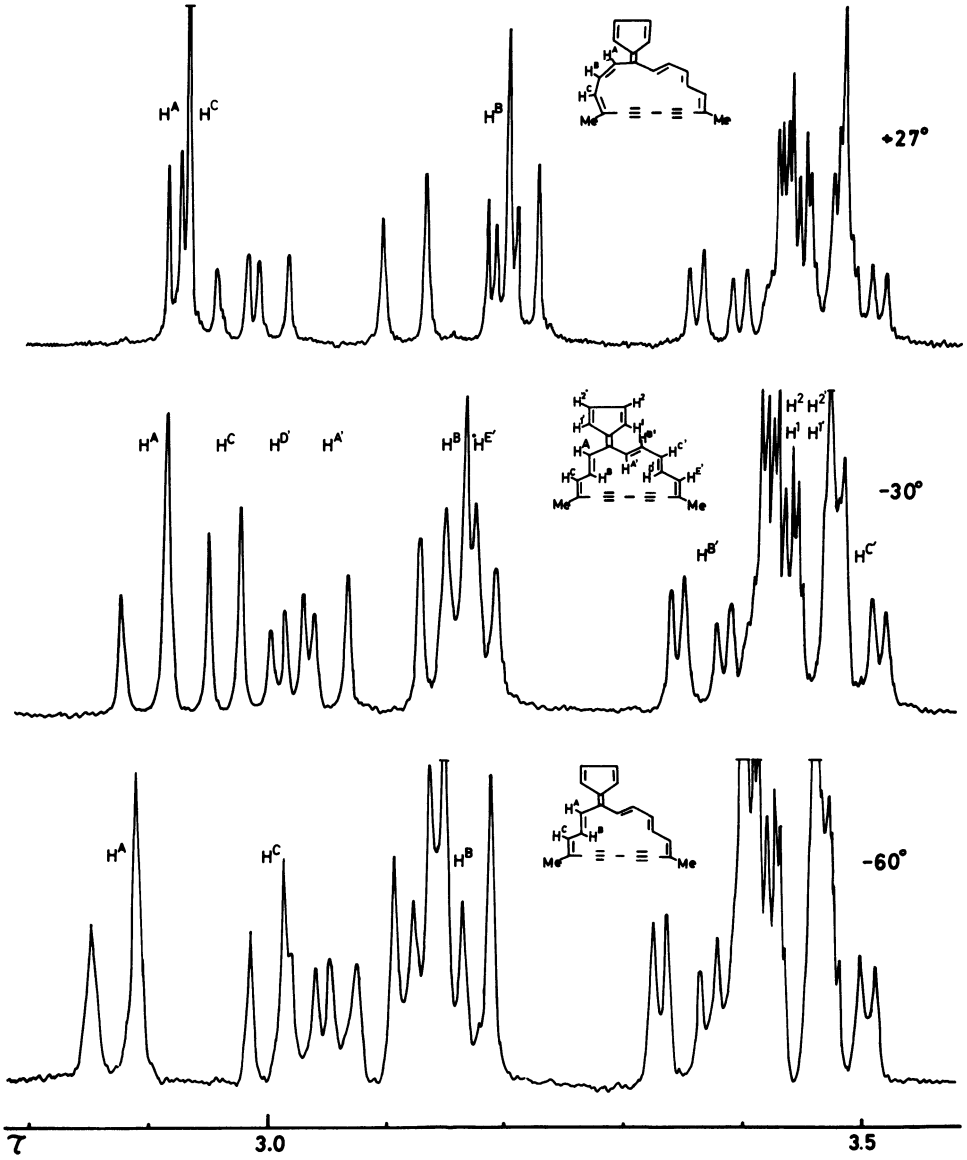

Fig. 4. ^{1}H NMR spectra of Pentapentadecafulvalene **14** at 27 °C, −30 °C, and −60 °C in $CDCl_3$ (400 MHz, τ values, internal standard, TMS).

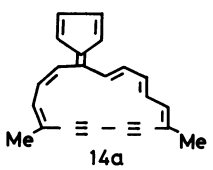
protons and the outer protons of the large rings, which can be regarded as an approximate measure of the tropicity, become small in the sequence of **11**>**12**>**13**, with increasing number of fused benzene rings on the large rings. This fact suggests that the benzo-annelated fulvalenes **12**, **13** have less delocalized π-electron systems than that of non-benzo-annelated one **11**, as evidenced from the electronic absorption spectra of these compounds (vide infra) and has been demonstrated for the annulene,[10] dehydroannulene,[10] and dehydroannulenone[3] system.

Variable-temperature ^{1}H NMR spectra of these fulvalenes were run at 200 MHz over the range of −60 to 60 °C, and the results show the spectra of the fulvalenes **11**—**13**, **15**, **16** to be essentially temperature-independent, excluding any change of the indicated conformations between these temperatures. On the other hand, the spectra of the pentapentadecafulvalene **14** are temperature-dependent, as illustrated in Fig. 4 which shows the spectra taken at 400 MHz and the resonances of only the olefinic protons.



14a

In rather surprisingly contrast to the cases of **11**, **15**, and **16**, the pentadecafulvalene does not exist in the conformation **14**, but in the more unlike conformation **14a** at room temperature. This follows from the fact that the value of $J_{B,C}$ value is 4.5 Hz, indicating an s-cis relationship of the CH^B-CH^C bond, and both the H^A and H^C protons resonate in almost same field. On

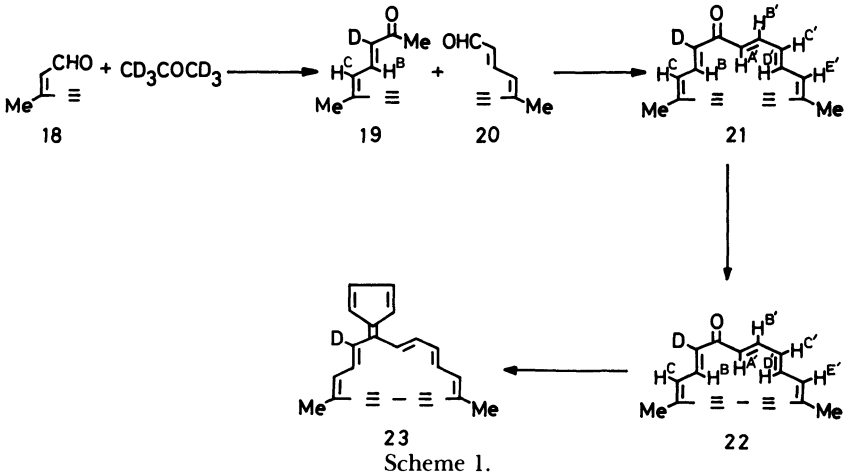


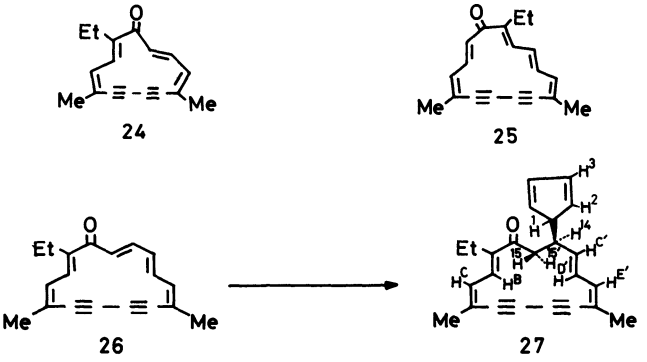
Scheme 1.

cooling, the H^A proton resonance moves to a slightly lower field and the H^C proton resonance to a slightly higher field, and the $J_{B,C}$ value varies to 10.5 Hz, indicating an s-trans relationship of the CH^B–CH^C bond at −30 °C. Further cooling results in an increasing separation of the H^A and H^C resonances. Thus, **14** exists in the similar conformation to those of **11**, **15**, and **16** at low temperature.

The observed temperature-dependency of the spectrum of **14** suggests that the molecular skeleton of **14** is mobile, particularly around CH^A–CH^B–CH^C moiety at room temperature, presumably due to a steric hindrance between H^1 and $H^{B'}$ protons. It is predicted that the pentanonadecafulvalene **16** would experience the similar hindrance, but the skeleton of **16** might presumably relieve the hindrance since a larger 19-membered ring would be more flexible than a 15-membered ring.[6]

We undertook a synthesis of 2-deuterio-labeled isomer **23** according to the reaction sequence in the Scheme 1 in order to understand the temperature-dependency of the ^1H NMR spectrum of **14** more exactly as well as to make the spectrum simple for assignment. However, the content of the deuterium of the isomer **23** obtained is quite small, and we could not get a significant result from comparison of the spectra between **14** and **23**.

We also attempted to obtain α-ethyl substituted pentafulvalenes as similarly as described for preparation of **11** and **14**, but we could not isolate any isomer from both 2-ethyl-5,10-dimethyl-6,8-bisdehydro-[13]annulenone (**24**)[4a] and 15-ethyl-5,10-dimethyl-6,8-bisdehydro[15]annulenone (**25**).[4b] From 2-ethyl-5,10-dimethyl-6,8-bisdehydro[15]annulenone (**26**),[4b] we isolated only the compound **27** which formed by conjugative addition between cyclopentadienide and **26**.



Electronic Spectra. The electronic absorption maxima of the pentafulvalenes **11—16**, determined in both tetrahydrofuran and acetonitrile, are listed in Table 2. As is seen from the Table 2, it is evident that all the bands of the fulvalenes **11—16** shows small bathochromic shift by changing the solvent from nonpolar (tetrahydrofuran) to polar solvent (acetonitrile). This solvent effect strongly supports the interpretation that a little π-electron polarization occurrs at the central double bond in the ground state of the pentafulvalene system, in agreement with the above-mentioned result from the examination of ^{1}H NMR spectra.

It is recognized that $(4n+2)\pi$-electron systems show the main maxima at higher wavelengths than $(4n)\pi$-systems in monocyclic annulenes,[13] dehydroannulenes,[13] dehydroannulenones,[2] and the fulvenes **7**, **8**.[7,8] Although the electronic spectra of these fulvalenes are not illustrated, the absorption curves are complex, but the spectra of the trideca- **11** and the pentadecafulvalene **14** are rather similar to those of the heptadeca- **15** and the nonadecafulvalene **16**, respectively. In the spectra of **11**, **14—16**, the main absorption bands exhibit a bathochromic shift as the ring size increases (Table 2), but it is not clear that the same sort of alternation of the main maxima occurrs between **11**, **15**, and **14**, **16**, as recognized in monocyclic $(4n+2)\pi$- and $(4n)\pi$-systems.[13]

The spectra of **11—13** are similar to one another as expected (Table 2),[11] and the medium bands shift to shorter wavelengths in the order of **13>12>11**, revealing that the fusion of benzene rings results in an appreciable bathochromic shift, as has been observed in benzo-annelated annulenes.[14] In contrast, the longest wavelength bands exhibit absorption toward longer wavelengths in the sequence of **11>12>13**, demonstrating that the fused benzene rings inhibit the degree of conjugation of π-electrons in these fulvalene system.[10]

Experimental

Melting points were determined on a hot-stage apparatus and are uncorrected. IR spectra were measured on Hitachi 260-50 spectrophotometer as KBr disk unless otherwise stated; only significant maxima are reported. Electronic spectra were determined on Hitachi 220A spectrophotometer (sh= shoulder). ^{1}H NMR spectra were measured on Varian XL-200 (200 MHz), JEOL FX-200 (200 MHz), or JEOL JX-400 (400 MHz) spectrometer and refer to solutions in $CDCl_3$, in τ-values with TMS as an internal standard. The coupling constants (J) are given in Hz. Assignments were assisted by decoupling experiments where necessary. Mass spectra were determined with JMS D-200 spectrometer at 75 eV using a direct inlet system. Alumina for column chromatography refers to Merck activity II-III. Reactions were followed by TLC aluminum sheets precoated with Merck Silica gel F_{254}. Freshly deoxygenated ether was used to minimize oxidation of the compounds employed for aldol condensation and was prepared by passing through a short column of Woelm basic alumina (activity I), followed by flushing with nitrogen, immediately before use. Organic extracts were dried over sodium sulfate prior to solvent removal.

5,10-Dimethyl-6,8-bisdehydropentatridecafulvalene (11). Freshly distilled cyclopentadiene (100 ml) was added to a stirred solution of sodium methoxide [from sodium (2.0 g) and dry methanol (350 ml)] during 15 min at −8 °C under nitrogen, and the solution was stirred for a further 10 min. A solution of [13]annulenone **1**[1] (453 mg, 2.17 mmol) in dry THF (100 ml) was then added at −8 °C during 25 min, and the solution was stirred for a further 1 h at the same temperature. After addition of ethyl acetate (50 ml), the mixture was poured into water. The separated aqueous layer was extracted with benzene and the combined organic extracts were washed with water. The residue after solvent removal was passed through a short column of alumina (3.7×3.0 cm) with 30% ether in hexane. The residual liquid obtained by concentrating the eluents was chromatographed on alumina (3.7×9.0 cm). The initial fractions, eluted with hexane, afforded fulvalene **11** (59.8 mg, 10.7%). It formed dark red needles, mp 103 °C, from hexane-benzene: MS m/z 256 (M^+, 39%) and 239 (100); mol wt 256.3; UV, see Table 2; IR 2150 (C≡C) and 970 cm^{-1} (*trans* HC=CH); ^{1}H NMR (200 MHz) τ=1.81 (dd, J=16, 10 Hz, 2H, H^B), 3.19 (d, J=16 Hz, 2H, H^A), 3.38 (d, J=10 Hz, 2H, H^C), 3.38—3.42 (m, 4H, H^1, H^2), 8.13 (s, 6H, Me), and see Fig. 1.

Found: C, 93.33; H, 6.43%. Calcd for $C_{20}H_{16}$: C, 93.71; H, 6.43%.

10-Methyl-6,8-bisdehydro-4,5-benzopentatridecafulvalene (12). To a cyclopentadienide solution, prepared from cyclopentadiene (100 ml), sodium (2.0 g), dry methanol (350 ml) as described for the preparation of **11**, was added dropwise a solution of benz[13]annulenone **2**[3a] (501 mg, 1.72 mmol) in dry THF (100 ml) during 25 min at −9 °C under nitrogen and the solution was stirred for a further 1 h at the same temperature. After work up as described for the isolation of **11**, the product was passed through a short column of alumina (3.0×4.0 cm) with hexane-ether (2:3). The residual red liquid after solvent removal was chromatographed on alumina (3.0×8.0 cm). The fractions eluted with 3% ether in hexane afforded fulvalene **12** (46.8 mg, 7.8%). It formed brown needles, mp 108 °C (decomp), from hexane-benzene: MS m/z 292 (M^+, 83%) and 276 (100); mol wt 292.3; UV, see Table 2; IR 2175 (C≡C) and 960 cm^{-1} (*trans* HC=CH); ^{1}H NMR (200 MHz) τ=1.91 (dd, J=16, 10.5 Hz, 1H, $H^{B'}$), 2.15 (d, J=16.5 Hz, 1H, H^B), 2.45 (d, J=7.5 Hz, 1H, H^X), 2.58—2.77 (m, 3H, Ar-H), 2.89 (d, J=16.5 Hz, 1H, H^A), 3.02 (d, J=16 Hz, 1H, $H^{A'}$), 3.29 (d, J=10.5 Hz, 1H, $H^{C'}$), 3.30—3.48 (m, 4H, H^1, $H^{1'}$, H^2, $H^{2'}$), 8.12 (s, 3H, Me), and see Fig. 3.

Found: C, 94.58; H, 5.32%. Calcd for $C_{23}H_{16}$: C, 94.48; H, 5.52%.

6,8-Bisdehydro-4,5:10,11-dibenzopentatridecafulvalene (13). To a cyclopentadienide solution, prepared from cyclopentadiene (100 ml), sodium (2.0 g), dry methanol (350 ml) as described above, was added dropwise a solution of dibenz[13]annulenone **3**[3a] (732 mg, 2.61 mmol) in dry THF (100 ml) during 30 min at −7 °C under nitrogen and the solution was stirred for a further 1.5 h at the same temperature. After work up as for the isolation of **11**, the product was passed through a short column of alumina (3.0×4.0 cm) with ether-hexane (1:1). The residue after solvent removal was chromatographed on alumina (3.7×7.5 cm). The fractions eluted with 3—5% ether in hexane afforded fulvalene **13** (33.0 mg, 3.85%). It formed brown needles, mp 173 °C (decomp), from hexane-benzene: MS m/z 328 (M^+, 96%)

and 326 (100); mol wt 328.3; UV, see Table 2; IR 2190 (C≡C) and 965 cm^{-1} (*trans* HC=CH); ^1H NMR (200 MHz) τ=2.09 (d, J=16.5 Hz, 2H, H^B), 2.30 (d, J=7.5 Hz, 2H, H^X), 2.59 (d, J=16.5 Hz, H^A), 2.52—2.74 (m, 6H, Ar-H), 3.22—3.26 (m, 2H, H^1), 3.36—3.40 (m, 2H, H^2), and see Fig. 3.

Found: C, 95.06; H, 4.75%. Calcd for $C_{26}H_{16}$: C, 95.05; H, 4.91%.

5,10-Dimethyl-6,8-bisdehydropentapentadecafulvalene (14). To a cyclopentadienide solution, prepared from cyclopentadiene (100 ml), sodium (2.0 g), dry methanol (300 ml) as described above, was added dropwise a solution of [15]annulenone **4**[2] (624 mg, 2.21 mmol) in dry THF (80 ml) during 20 min at −4 °C under nitrogen, and the solution was stirred for a further 40 min at the same temperature. After work up as for the isolation of **11**, the product was passed through a short column of alumina (3.7×3.5 cm) with ether. The residual red liquid after solvent removal was chromatographed on alumina (3.7×8.0 cm). The fractions eluted with 2% ether in hexane afforded fulvalene **14** (31.7 mg, 4.9%). It formed brown needles, mp 164 °C (decomp), from hexane-benzene: MS m/z 282 (M^+, 68%) and 265 (100); mol wt 282.3; UV, see Table 2; IR 2160 (C≡C), 980, and 960 cm^{-1} (*trans* HC=CH); ^1H NMR (400 MHz, 27 °C) τ=2.92 (d, J=7 Hz, 1H, H^A), 2.93 (d, J=4.5 Hz, 1H, H^C), 2.98 (dd, J=15, 11 Hz, 1H, $H^{D'}$), 3.13 (d, J=16 Hz, 1H, $H^{A'}$), 3.21 (dd, J=7, 4.5 Hz, 1H, H^B), 3.24 (d, J=11 Hz, 1H, $H^{E'}$), 3.41 (dd, J=16, 5 Hz, 1H, $H^{B'}$), 3.45—3.54 (m, 4H, H^1, $H^{1'}$, H^2, $H^{2'}$), 3.54 (dd, J=16, 5 Hz, 1H, $H^{C'}$), 8.00 (s, 3H, Me), 8.05 (s, 3H, Me), and see Figs. 1 and 4; (400 MHz, −60 °C) τ=2.87 (d, J=15 Hz, 1H, H^A), 3.00 (d, J=10.5 Hz, 1H, H^C), 3.04 (dd, J=15, 11 Hz, 1H, $H^{D'}$), 3.12 (dd, J=11 Hz, 1H, $H^{E'}$), 3.17 (d, J=15 Hz, 1H, $H^{A'}$), 3.18 (dd, J=15, 11 Hz, 1H, H^B), 3.35 (dd, J=16, 5 Hz, 1H, $H^{B'}$), 3.38—3.48 (m, 4H, H^1 and H^2), 3.49 (dd, J=16, 5 Hz, 1H, $H^{C'}$), 8.03 (s, 3H, Me), 8.07 (s, 3H, Me), and see Fig. 4.

3-Deuterio-6-methyl-3,5-octadien-7-yn-2-one (19). An ice-cooled solution of sodium hydroxide (0.65 M (1 mol dm^{-3}), 5.0 ml) in heavy water (D_2O) and ethanol-d_4 (5.0 ml) was added in one portion to an ice-cooled solution of (*Z*)-3-methyl-2-penten-4-ynal **18**[15] (1.70 g, 18.1 mmol) in acetone-d_6 (10.0 ml). The solution was stirred for a further 1 h at 0 °C and dilute sulfuric acid (2 M, 10 ml) was then added. The solution was poured into water and extracted with benzene. The combined extracts were washed successively with aqueous sodium hydrogencarbonate and brine. The residue after solvent removal was chromatographed on alumina (3.7×10.0 cm). The fractions eluted with 5% ether in hexane afforded the ketone **19** (1.01 g, 40%) as a yellow liquid: MS m/z 135 (M^+, 41%) and 120 (100); mol wt 135.2; IR (neat) 3300, 3250 (C≡CH), 2100 (C≡C), 1660 (C=O), 1610 (C=C), and 990 cm^{-1} (*trans* HC=CH); UV (EtOH) λ_{max} 299 nm (ε 17800); ^1H NMR (90 MHz) τ=2.49 (d, J=11 Hz, 1H, H^B), 3.59 (d, J=11 Hz, 1H, H^C), 6.51 (s, 1H, C≡CH), 7.69 (s, 3H, Me), 7.96 (s, 3H, Me).

6-Deuterio-3,13-dimethyl-3,5,8,10,12-pentadecapentaene-1,14-diyn-7-one (21). An ethanolic sodium ethoxide (3.0 ml) from sodium (380 mg) and dry ethanol (50 ml) was added in one portion to a solution of ketone **19** (1.01 g, 7.29 mmol) and (2*E*,4*Z*)-5-methyl-2,4-heptadien-6-ynal **20**[16] (1.0 g, 8.3 mmol) in deoxygenated ether (50 ml). After being stirred for a further 6 h at 3—5 °C, the reaction was quenched by addition of 2 M sulfuric acid (10 ml). After work up as for the isolation of **19**, the residue after solvent removal was chromatographed on alumina (4.0×9.0 cm). The fractions eluted with 30% ether in hexane afforded ketone **21** (606 mg, 35%). It formed yellow needles, mp 105—106 °C, from hexane-benzene: MS m/z 237.1237, calcd for 237.1263; UV (Et_2O) λ_{max} 230 (sh, ε 8000), 246 (sh, 12100), and 360 nm (32300); IR 3280 (C≡CH), 2100 (C≡C), 1655 (C=O), 1605, 1595 (C=C), and 1005 cm^{-1} (*trans* HC=CH); ^1H NMR (90 MHz) τ=2.32 (d, J=11 Hz, 1H, H^B), 2.61 (dd, J=16, 11 Hz, 1H, $H^{B'}$), 2.92 (dd, J=16, 11 Hz, 1H, $H^{D'}$), 3.45—3.66 (m, 4H, $H^{A'}$, H^C, $H^{C'}$, $H^{E'}$), 6.51 (s, 1H, C≡CH), 6.57 (s, 1H, C≡CH), 7.96 (s, 3H, Me), 8.00 (s, 3H, Me).

2-Deuterio-5,10-dimethyl-6,8-bisdehydro[15]annulenone (22). A solution of ketone **21** (1.25 g, 5.26 mmol) in pyridine and dry ether (3:1, 120 ml) was added dropwise during 4 h to a stirred solution of anhydrous copper(II) acetate (6.8 g) in pyridine and dry ether (3:1, 400 ml) at 50—52 °C. The solution was stirred for a further 30 min at the same temperature and was then cooled. The reaction mixture was

poured into water and extracted with benzene. The combined extracts were washed with 5% hydrochloric acid until it turned acidic, then with aqueous sodium hydrogencarbonate solution, successively. The dark red liquid after solvent removal was chromatographed on alumina (3.7×8.0 cm). The fractions eluted with 30% ether in hexane afforded annulenone **22** (427 mg, 25%). It formed yellow needles, mp 159°C (decomp), from hexane-benzene: MS *m/z* 235.1107, Calcd for 235.1107; UV (Et_2O) λ_{max} 245 (ε 11600), 257 (13100), 302 (35800), and 382 nm (5900); IR 2180 (C≡C), 1635 (C=O), 1605 (C=C), and 980 cm^{-1} (*trans* HC=CH); ^1H NMR (90 MHz) τ=2.46 (dd, *J*=16, 5 Hz, 1H, $H^{B'}$), 2.80 (d, *J*=11 Hz, 2H, H^{C}, $H^{E'}$), 3.20 (dd, *J*=16, 5 Hz, 1H, $H^{C'}$), 4.22 (d, *J*=11 Hz, 1H, H^{B}), 4.39 (d, *J*=16 Hz, 1H, $H^{A'}$), 4.57 (dd, *J*=16, 11 Hz, 1H, $H^{D'}$), 7.76 (s, 3H, Me), and 7.82 (s, 3H, Me).

2-Deuterio-5,10-dimethyl-6,8-bisdehydropentapentadecafulvalene (23). To a solution of cyclopentadienide, prepared from cyclopentadiene (100 ml), sodium (2.0 g), dry methanol (300 ml), was added dropwise a solution of annulenone **22** (363 mg, 1.54 mmol) in dry THF (50 ml) during 20 min at −6°C and the solution was stirred for a further 1 h at the same temperature. After work up as for the isolation of **11**, the product was passed through a short column of alumina (3.7×4.0 cm) with hexane-ether (3:2). The residual red liquid after solvent removal was chromatographed on alumina (3.7×8.0 cm). The fractions eluted with hexane afforded fulvalene **23** (10.6 mg, 2.3%). It formed brown needles, mp 158°C (decomp), from hexane-benzene: MS *m/z* 283.1543, Calcd for 283.1472; The IR, UV, and ^1H NMR were almost the same as those of **14**.

Attempts to obtain α-ethyl-substituted fulvalenes from the α-ethyl-substituted [13]annulenone **24**[4a] and [15]annulenone **25**[4b] were carried out as the exactly same conditions as for the isolation of **11**. However, none of fulvalene was isolated.

14-(2,4-Cyclopentadienyl)-2-ethyl-5,10-dimethyl-2,4,10,12-cyclopentadecatetraene-6,8-diyn-1-one (27). Conjugative Adduct of Cyclopentadiene and 26. To a solution of cyclopentadienide, prepared from cyclopentadiene (100 ml), sodium (2.0 g), dry methanol (250 ml), was added dropwise a solution of [15]annulenone **26**[4b] (770 mg, 2.94 mmol) in dry THF (100 ml) during 30 min at −8°C under nitrogen and the solution was stirred for a further 1 h at the same temperature. After work up as for the isolation of **11**, the product was passed through a short column of alumina (4.0×3.0 cm) with 30% ether in hexane. The residual red liquid after solvent removal was chromatographed on alumina (3.7×7.5 cm). The fractions eluted with 10% ether in hexane afforded the adduct **27** (513 mg, 56.3%). It formed yellow needles, mp 139—140°C, from hexane-benzene: MS *m/z* 328 (M^+, 100%); mol wt 328.4; UV (THF) λ_{max} 239 (sh, ε 11700), 250 (sh, 14400), 276 (sh, 35500), 287 (43700), 381 (6350), and 423 nm (sh, 4260); IR 2170 (C≡C), 1665 (C=O), 1630, 1600 (C=C), and 970 cm^{-1} (*trans* HC=CH); ^1H NMR (90 MHz) τ=2.10 (d, *J*=11 Hz, 1H, H^{C}), 2.88—3.06 (m, 8H, H^{B}, $H^{C'}$, $H^{D'}$, $H^{E'}$, H^{2}, H^{2}, H^{3}, H^{3}), 5.96—6.22 (m, 1H, H^{14}), 6.39 (dd, *J*=16.5, 3 Hz, 1H, $H^{15'}$), 6.92 (dd, *J*=16.5, 11 Hz, 1H, H^{15}), 7.05 (s, 1H, H^{1}), 7.63 (q, *J*=7 Hz, 2H, $-C\underline{H}_2CH_3$), 7.99 (s, 3H, Me), 8.13 (s, 3H, Me), and 9.06 (t, *J*=7 Hz, 3H, $-CH_2C\underline{H}_3$).

Found: C, 87.46; H, 7.36%. Calcd for $C_{24}H_{24}O$: C, 87.76; H, 7.36%.

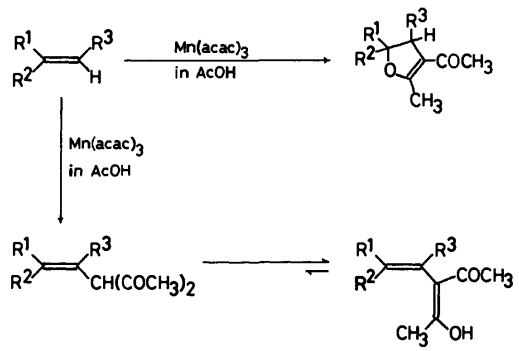
Direct Diacetylmethylation of Aromatic Compounds with Tris-(2,4-pentanedionato)manganese(III)

Hiroshi NISHINO
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received January 18, 1986)

The oxidation of naphthalenes with tris(2,4-pentanedionato)manganese(III) in acetic acid gave diacetylmethyl derivatives in good to moderate yields. Using excess amounts of the oxidant, the acetylmethyl-substituted naphthalenes were further oxidized and 3-acetoxy-3-naphthyl-2,4-pentanediones were obtained. The similar oxidation of anthracenes also produced (diacetylmethyl)anthracenes together with diacetylmethylene derivatives which were further oxidized. It was found that this direct diacetylmethylation was effective when the ionization potential of the aromatic compound was lower than 8.12 eV, and that the diacetylmethyl radical which was generated directly by the thermolysis of tris(2,4-pentanedionato)manganese(III) has an electrophilic nature based on the result of the oxidation of substituted naphthalenes. The reaction pathway for the oxidation of anthracene is also discussed.

Tris(2,4-pentanedionato)manganese(III), $Mn(acac)_3$, is a well-known catalyst in polymerization, autoxidation, and peroxide reactions.[1] However, the use as an oxidant itself is rare in the literature, although the oxidative coupling reaction of phenols[2] or thiols[3] and the oxidative intramolecular cyclization of phenolic oximes[4] have been reported. Recently, the present author has found that the oxidation of olefins with $Mn(acac)_3$ gave dihydrofurans in good yields.[5] This reaction has been explained as follows. Manganese(III) complexes generally tend to undergo a rapid exchange of ligands in a donor solvent such as acetic acid which can complex manganese(III) ions,[5] and therefore, $Mn(acac)_3$ will be easily decomposed in acetic acid to form diacetylmethyl radical, $\cdot CH(COCH_3)_2$. The attack of the $\cdot CH(COCH_3)_2$ radical on olefins and subsequent oxidative cyclization afforded dihydrofurans. In the case of 9-benzylidene-9,10-dihydroanthracene, the corresponding dihydrofuran was not obtained, but one of the methylenic hydrogens of the starting olefin was replaced by the $\cdot CH(COCH_3)_2$ radical (Scheme 1).[5] This led to the present investigation of



Scheme 1.

the reaction of aromatic compounds with $Mn(acac)_3$ in the hope that direct diacetylmethylation may take place. As for the similar reaction using manganese(III) complex, it is well-known that olefins are oxidized with manganese(III) acetate to give γ-lactones in good yields,[6] while the oxidation of aromatic compounds with manganese(III) acetate afforded carboxymethyl, acetoxymethyl,[7] diacetoxymethyl,[8] and carboxy derivatives.[9] These manganese(III) acetate oxidations involve the carboxymethyl radical, $\cdot CH_2CO_2H$.[7] In this paper, the author describes a new direct diacetylmethylation of aromatic compounds with $Mn(acac)_3$.

Results

When 2-methoxynaphthalene (**1a**) was oxidized with four molar equivalents of $Mn(acac)_3$ in acetic acid at 100 °C, the reaction was completed within 13 min to give **2a** (Table 1, Entry 1). The product **2a** showed a parent ion peak at m/z 256 in the mass spectrum and a broad absorption band in the IR spectrum which could be assigned to an enolized β-diketone. The ^1H NMR spectrum of **2a** indicated the presence of a 1-acetyl-2-hydroxy-1-propenyl group and an AB quartet (J=9.0 Hz) due to aromatic protons. Consequently, this spectroscopic evidence supported the structure of **2a** being 1-(1-acetyl-2-hydroxy-1-propenyl)-2-methoxynaphthalene. The reaction of **1a** with $Mn(acac)_3$ in another solvent, such as CH_3CN, did not occur.

Oxidation of 1-methoxynaphthalene (**1b**) under the same reaction conditions produced **3b** together with a diacetylmethyl derivative **2b** (Table 1, Entry 2). The structure of **3b** was determined to be 4-(1-acetoxy-1-acetyl-2-oxopropyl)-1-methoxynaphthalene on the basis of the spectral data. The ^{13}C-off-resonance decoupling of **3b** collapsed the peak at δ=102.613 (C-2) to a doublet, but the peak at δ=120.369 (C-4) did not collapse. This shows that the 1-acetoxy-1-acetyl-2-oxopropyl group was introduced at the C-4 position. Moreover, the position of the substituent group was also supported by comparing its ^1H NMR spectrum with that of **1b**. When this reaction was carried out at a molar ratio of 1:10 at reflux temperature, **3b** was obtained as the sole product (Table 1, Entry 3).

2,7-Dimethoxynaphthalene (**1c**) was oxidized with four molar equivalents of $Mn(acac)_3$ to give (acetylmethyl)naphthalene **2c**, while a nearly equimolar mixture of **2c** and **3c** was obtained in a 1:10 molar ratio reaction (Table 1, Entries 4 and 5). It was con-

Table 1. Oxidation of Naphthalenes with $Mn(acac)_3$ in Acetic Acid at 100 °C

Entry	Compound	Molar ratio of substrate : $Mn(acac)_3$	Time / min	Product (yield/%)[a]	
1	**1a**	1 : 4	13	**2a** (54)	
2	**1b**	1 : 2	10	**2b** (9)	**3b** (40)
3[b]	**1b**	1 : 10	2		**3b** (62)
4	**1c**	1 : 4	15	**2c** (52)	
5	**1c**	1 : 10	25	**2c** (36)	**3c** (31)
6	**1d**	1 : 4	14	**2d** (46)	
7	**1e**	1 : 4	10	**2e** (41)	
8	**1f**	1 : 4	14	**2f** (30)	
9	**1g**	1 : 4	13	**2g** (24)	
10	**1h**	1 : 4	15	**2h** (15)	
11	**1i**	1 : 4	15	**2i** (8)	
12	**2c**	1 : 2	3		**3c** (50)

a) The yields are based on the amount of the substrate consumed. b) The reaction was carried out at the reflux temperature.

firmed that the product **3c** was derived from the further oxidation of **2c** with $Mn(acac)_3$ since the diacetylmethyl derivative **2c** was oxidized under the same reaction conditions to give only the pentanedione **3c** (Table 1, Entry 12).

The oxidations of 2,6-dimethoxynaphthalene (**1d**), 2,3-dimethoxynaphthalene (**1e**), 1,8-dimethylnaphthalene (**1f**), acenaphthene (**1g**), 1-methylnaphthalene (**1h**), and naphthalene (**1i**) with $Mn(acac)_3$ were also carried out in acetic acid to yield the corresponding diacetylmethyl derivatives (**2d—i**) (Table 1, Entries 6—11). The reaction of 1-nitronaphthalene (**1j**) with $Mn(acac)_3$ did not occur under these conditions and **1j** was recovered. 1-Dimethylaminonaphthalene (**1k**) was oxidized with $Mn(acac)_3$ under the same reaction conditions to give intractable tarry materials and no diacetylmethylated products were detected.

Anthracene (**4**) gave four products (**5**, **6**, **7**, and **8**) (Table 2, Entries 1 and 2). The products **5** and **6** were determined to be anthracenes substituted by diacetylmethyl groups in their enol forms. The **7** showed characteristic carbonyl absorptions of diacetylmethyl group in the IR spectrum, and its ^1H NMR spectrum revealed an AB quartet (J=10.2 Hz) due to four protons which were assigned to methine protons of 9,10-dihydroanthracene and diacetylmethyl group. Therefore, the structure of **7** was considered to be 9,10-bis(diacetylmethyl)-9,10-dihydroanthracene. The spectroscopic data of **8** supported the symmetrical structure of 9,10-bis(diacetylmethylene)-9,10-dihydroanthracene which seemed to be formed by the further oxidation of **6** or **7**.

Acridine (**9**), xanthene (**11**), and pyrene (**17**) were oxidized with $Mn(acac)_3$ to give corresponding diacetylmethyl derivatives in good to moderate yields (Table 2, Entries 5, 6, 8, and 9). In the oxidation of

anthrone (**14**), however, a diacetylmethylene derivative **15** was obtained in poor yield, and a major product was a dimeric compound **16**. It has been reported that the product **16** was also obtained by the oxidation of **14** with manganese(III) acetate in acetic acid.[11b]

Discussion

The oxidation of aromatic compounds with manganese(III) acetate was studied in detail by Dewar et al.[10] and Heiba et al.[7] Methoxynaphthalenes (**1a** and **1b**) and anthracene (**4**) were oxidized with manganese(III) acetate in acetic acid to give naphthoquinones[10b,c] and anthraquinone,[11] respectively. These reactions were explained by the electron-transfer mechanism.[10] On the other hand, it is well-known that the free-radical mechanism involving the carboxymethyl radical, $\cdot CH_2CO_2H$, simultaneously competes with the electron-transfer process in the manganese(III) acetate-acetic acid system.[7] The attack of $\cdot CH_2CO_2H$ radicals on the aromatic ring and further oxidation mainly produces acetoxymethyl derivatives, $Ar\text{-}CH_2OAc$. Heiba and his co-workers proposed that the electron-transfer mechanism in the manganese(III) acetate-acetic acid system was observed only with aromatic compounds such as anthracene and 2-methylnaphthalene, having ionization potentials less than 8.0 eV.[7] It is also well-known that γ-lactones are obtained in good yields, when the $\cdot CH_2CO_2H$ radicals add to alkenes followed by oxidative cyclization. For this lactone annulation, it has been confirmed by subsequent experiments[12] that the lower ionization potential cutoff for useful alkenes was 8.2 eV; below this level the electron-transfer process occurred competitively. Accordingly, the free-radical mechanism in the manganese(III) acetate oxidation is characteristic for aromatic compounds and alkenes having ionization potential higher than about 8 eV.

The ionization potentials of the aromatic compounds used in this $Mn(acac)_3$ oxidation[13] and the total yields of their diacetylmethylated products are summerized in Table 3. As can be seen from this Table,

Table 3. Ionization Potentials of Aromatic Compounds and the Yields of Their Diacetylmethylated Products

Entry	Compound	Ionization potential / eV	Diacetylmethylated product yield/%[e]
1	Anthracene (**4**)	7.36[a]	75

a—d) Ref. 13. e) Total yields. f) An intractable mixture was obtained. g) No diacetylmethylated products were detected. h) This reaction did not occur and the starting material was recovered (see Experimental).

Table 4. Oxidation of Diacetylmethylated Products with $Mn(acac)_3$ in Acetic Acid at 100°C

Entry	Compound	Molar ratio of Subsrate:$Mn(acac)_3$	Time / min	Product (yield/%)[a]	Recovery / %
1	**5**	1:2	2	**6** (40) **8** (24)	29
2	**6**	1:2	2	**8** (66)	33
3	**7**	1:2	2		100
4	**7**	1:4	6	**8** (18)	77
5	**12**	1:2	2	**13** (29)	68

a) The yields are based on the amount of the substrated used.

it has been proved that the diacetylmethylation was effective when ionization potential of the aromatic compound was lower than 8.12 eV. This behavior as an oxidant is in contrast to that of manganese(III) acetate and it shows that $Mn(acac)_3$ is a weaker oxidant than manganese(III) acetate. The reason why the reaction of 1-dimethylaminonaphthalene (**1k**) with $Mn(acac)_3$ did not give any diacetylmethylated products in spite of the ionization potential was low is that a lone-pair electron on the nitrogen atom is more liable to be abstracted by $Mn(acac)_3$ than a π-electron of the aromatic ring, and then, another side-reaction such as polymerization might ensue.[15]

The existence of the $\cdot CH(COCH_3)_2$ radical in this reaction was proved indirectly by the isolation of 3-acetyl-4-hydroxy-3-hexene-2,5-dione (**21**), since **21** must be formed by a bimolecular coupling reaction of $\cdot CH(COCH_3)_2$ radicals. The **21** was produced regardless of the substrate used in the $Mn(acac)_3$-acetic acid system, and particularly, the formation of **21** was the best when the oxidation was carried out at room temperature (see Experimental and Reference).[14]

It has been suggested that the $\cdot CH(COCH_3)_2$ radical has an electrophilic nature like the $\cdot CH_2CO_2H$ radical generated in the manganese(III) acetate–acetic acid system,[7] since the diacetylmethyl group is situated at a position ortho or para to the electron-donating group in the oxidation of naphthalenes (Table 1 and Fig. 1).

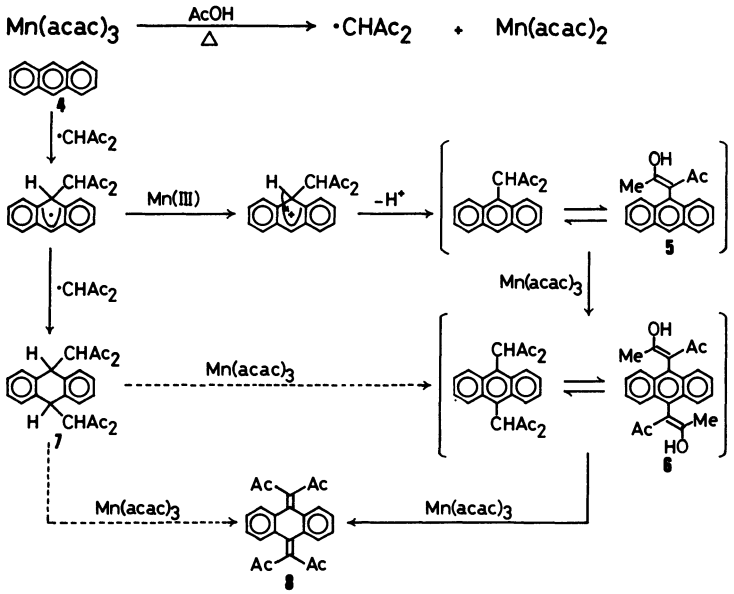
When the enol **5** was oxidized with two molar equivalents of $Mn(acac)_3$, the bis(enol) **6** and the bis(diacetylmethylene)anthracene (**8**) were obtained (Table 4, Entry 1). The oxidation of **6** under the same reaction conditions gave only **8** (Table 4, Entry 2). Although 9,10-bis(diacetylmethyl)-9,10-dihydroanthracene (**7**), on the other hand, did not react with $Mn(acac)_3$ in a molar ratio of 1:2, a small amount of **8** was formed in a molar ratio of 1:4 (Table 4, Entries 3 and 4). Therefore, the route from **7** to **8** is not important. The reaction pathway for the oxidation of anthracene (**4**) with $Mn(acac)_3$ is illustrated in Scheme 2.

Thus, it is concluded that this new direct diacetylmethylation i) takes place in $Mn(acac)_3$-acetic acid system, ii) is characteristic for aromatic compounds having ionization potential lower than about 8 eV, and iii) the $\cdot CH(COCH_3)_2$ radical involved in this oxidation system is somewhat electrophilic.

Experimental

Measurements. Melting points were determined with an Electrothermal apparatus and are uncorrected. The IR spectra were taken on a JASCO A-102 infrared spectrophotometer, and the IR spectral data are expressed in cm^{-1}. The ^1H and ^{13}C NMR spectra were recorded on a Hitachi Perkin-Elmer R-24 (60 MHz) and a JEOL FX-100 instrument at room temperature. Chemical shifts are recorded in the δ scale, relative to TMS as an internal standard. The mass spectra were obtained with a JEOL JMS-DX-300 mass spectrometer using a direct-insertion probe at an ionizing voltage of 70 eV.

Materials. $Mn(acac)_3$ was prepared by the method de-



Scheme 2.

scribed in the literature.[16] Methoxynaphthalenes (**1a—e**) were synthesized by the methylation of the corresponding naphthols with dimethyl sulfate. Other starting materials (**1f—k**, **4**, **9**, **11**, **14**, and **17**) were obtained from commercial samples from the Wako Pure Chemical Industries, Ltd.

General Procedure for the Oxidation of Aromatic Compounds with $Mn(acac)_3$. The oxidation of aromatic compound (1 mmol) with a suitable amount of $Mn(acac)_3$ (indicated in the Tables) was carried out in acetic acid (25 cm^3) at 100°C until an opaque dark brown mixture changed to a clear brown solution. The solvent was removed in vacuo, and the residue was triturated with 2 M (1 M=1 mol dm^{-3}) HCl (25 cm^3) and then extracted with chloroform. The products were separated on TLC (Wako gel B-10), with chloroform as the developing solvent. The yields are summarized in Tables 1, 2, and 4.

Oxidation Products. 1-(1-Acetyl-2-hydroxy-1-propenyl)-2-methoxynaphthalene (2a): Colorless needles (from ethanol), mp 133.5—134.5°C; IR ($CHCl_3$) 1620 (COC=COH) and 3300—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.71 (6H, s, 2×CH_3), 3.88 (3H, s, OCH_3), 7.29 (1H, d, J=9.0 Hz, H-3), 7.86 (1H, d, J=9.0 Hz, H-4), 7.2—7.9 (4H, m, ArH), and 16.90 (1H, s, OH); MS *m/z* (rel intensity), 256 (M^+, 100), 213 (40), 169 (30), 141 (20), and 43 (50). Found: C, 74.79; H, 6.18%. Calcd for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29%.

4-(1-Acetyl-2-hydroxy-1-propenyl)-1-methoxynaphthalene (2b): Colorless needles (from methanol), mp 114.0—114.5 °C; IR ($CHCl_3$) 1610 (COC=COH) and 3300—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.74 (6H, s, 2×CH_3), 3.96 (3H, s, OCH_3), 6.77 (1H, d, J=8.4 Hz, H-2), 7.17 (1H, d, J=8.4 Hz, H-3), 7.30—8.40 (4H, m, ArH), and 16.80 (1H, s, OH). Found: C, 74.67; H, 6.25%. Calcd for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29%.

4-(1-Acetoxy-1-acetyl-2-oxopropyl)-1-methoxynaphthalene (3b): Colorless cubes (from ethanol), mp 179.5—180.0°C; IR ($CHCl_3$) 1722 and 1749 (C=O); ^1H-NMR ($CDCl_3$) δ=2.223 (6H, s, 2×CH_3), 2.336 (3H, s, OAc), 4.034 (3H, s, OCH_3), 6.795 (1H, d, J=8.3 Hz, H-2), 7.373 (1H, d, J=8.3 Hz, H-3), and 7.258—8.400 (4H, m, ArH); ^{13}C NMR ($CDCl_3$)[17] δ=20.827 (q, CH_3), 27.525 (q, 2×CH_3), 55.665 (q, OCH_3), 95.359 (s, >C<), 102.613 (d, C-2), 120.369 (s, C-4), 122.826 (d, C-8), 124.903 (d, C-7), 125.664 (d, C-6), 126.775 (s, C-8a), 126.980 (d, C-3), 127.536 (d, C-5), 132.128 (s, C-4a), 157.080 (s, C-1), 170.330 (s, C=O), and 200.810 (s, 2×C=O); MS *m/z* (rel intensity), 314 (M^+, 10), 272 (20), 230 (50), 158 (30), and 43 (100). Found: C, 68.83; H, 5.81%. Calcd for $C_{18}H_{18}O_5$: C, 68.78; H, 5.77%.

1-(1-Acetyl-2-hydroxy-1-propenyl)-2,7-dimethoxynaphthalene (2c): Colorless needles (from methanol), mp 120.0—120.5 °C; IR ($CHCl_3$) 1624 (COC=COH) and 3300—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.77 (6H, s, 2×CH_3), 3.83 (3H, s, OCH_3), 3.88 (3H, s, OCH_3), 6.93—7.78 (3H, m, ArH), 7.15 (1H, d, J=9.6 Hz, H-3), 7.79 (1H, d, J=9.6 Hz, H-4), and 16.87 (1H, s, OH). Found: C, 71.16; H, 6.31%. Calcd for $C_{17}H_{18}O_4$: C, 71.31; H, 6.34%.

1-(1-Acetoxy-1-acetyl-2-oxopropyl)-2,7-dimethoxynaphthalene (3c): Colorless needles (from ethanol), mp 176—177°C; IR ($CHCl_3$) 1723 and 1760 (C=O); ^1H NMR ($CDCl_3$) δ=2.25 (9H, s, 2×CH_3 and OAc), 3.88 (3H, s, OCH_3), 3.92 (3H, s, OCH_3), 7.03 (1H, dd, J=9.0 and 2.4 Hz, H-6), 7.13 (1H, d, J=9.0 Hz, H-3), 7.39 (1H, d, J=2.4 Hz, H-8), 7.71 (1H, d, J=9.0 Hz, H-5), and 7.86 (1H, d, J=9.0 Hz, H-4). Found: C, 66.23; H, 5.96%. Calcd for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%.

1-(1-Acetyl-2-hydroxy-1-propenyl)-2,6-dimethoxynaphthalene (2d): Colorless prisms (from ethanol), mp 134—135°C; IR ($CHCl_3$) 1620 (COC=COH) and 3300—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.75 (6H, s, 2×CH_3), 3.88 (6H, s, 2×OCH_3), 7.0—7.7 (3H, m, ArH), 7.25 (1H, d, J=9.6 Hz, H-4), 7.78 (1H, d, J=9.6 Hz, H-5), and 16.89 (1H, s, OH). Found: C, 71.07; H, 6.39%. Calcd for $C_{17}H_{18}O_4$: C, 71.31; H, 6.34%.

1-(1-Acetyl-2-hydroxy-1-propenyl)-2,3-dimethoxynaphthalene (2e): Colorless needles (from methanol), mp 117—118°C; IR ($CHCl_3$) 1600 (COC=COH) and 3300—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.77 (6H, s, 2×CH_3), 3.89 (3H, s, OCH_3), 3.97 (3H, s, OCH_3), 6.91 (1H, s, H-4), 7.05—7.80 (4H, m, ArH), and 16.88 (1H, s, OH). Found: C, 71.10; H, 6.37%. Calcd for $C_{17}H_{18}O_4$: C, 71.31; H, 6.34%.

4-(1-Acetyl-2-hydroxy-1-propenyl)-1,8-dimethylnaphthalene (2f): Colorless needles (from methanol), mp 149—150°C; IR ($CHCl_3$) 1605 (COC=COH) and 3300—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.750 (6H, s, 2×CH_3), 2.965 (6H, s, 2×CH_3), 7.151 (1H, d, J=7.1 Hz, H-2 or 3), 7.284 (1H, d, J=7.1 Hz, H-3 or 2), 7.275—7.734 (3H, m, ArH), and 16.70 (1H, s, OH); ^{13}C NMR ($CDCl_3$)[17] δ=23.762 (q, 2×CH_3), 26.161

(q, CH_3), 26.249 (q, CH_3), 113.125 (s, $\succeq C=$), 124.328 (d, C-3 or 6), 125.762 (d, C-6 or 3), 128.511 (d, C-5), 129.243 (d, C-2 or 7), 129.798 (d, C-7 or 2), 133.045 (s, C-8a), 133.689 (s, C-4), 134.830 (s, C-4a), 136.000 (s, C-1 or 8), 136.175 (s, =C-O and C-8 or 1), 191.519 (s, C=O). Found: C, 80.06; H, 7.13%. Calcd for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13%.

5-(1-Acetyl-2-hydroxy-1-propenyl)acenaphthene (2g): Colorless needles (from methanol), mp 141.5—142.5 °C; IR ($CHCl_3$) 1603 (COC=COH) and 3100—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.79 (6H, s, 2×CH_3), 3.40 (4H, s, 2×CH_2), 7.17—7.47 (5H, m, ArH), and 16.79 (1H, s, OH). Found: C, 80.77; H, 6.47%. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%.

4-(1-Acetyl-2-hydroxy-1-propenyl)-1-methylnaphthalene (2h): Colorless plates (from methanol), mp 122 °C; IR ($CHCl_3$) 1600 (COC=COH) and 3200—3600 (OH): ^1H NMR ($CDCl_3$) δ=1.75 (6H, s, 2×CH_3), 2.74 (3H, s, CH_3), 7.21 (1H, d, J=7.2 Hz, H-2 or 3), 7.37 (1H, d, J=7.2 Hz, H-3 or 2), 7.20—8.11 (4H, m, ArH), and 16.80 (1H, s, OH). Found: C, 79.67; H, 6.73%. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

1-(1-Acetyl-2-hydroxy-1-propenyl)naphthalene (2i): Pale orange needles (from methanol), mp 105—106 °C; IR ($CHCl_3$) 1600 (COC=COH) and 3200—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.75 (6H, s, 2×CH_3), 7.2—8.0 (7H, m, ArH), and 16.80 (1H, s, OH). Found: C, 79.38; H, 6.25%. Calcd for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24%.

9-(1-Acetyl-2-hydroxy-1-propenyl)anthracene (5): Colorless needles (from ethanol), mp 176—177 °C; IR ($CHCl_3$) 1597 (COC=COH) and 3200—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.59 (6H, s, 2×CH_3), 7.32—8.17 (8H, m, ArH), 8.49 (1H, s, H-10), and 16.97 (1H, s, OH). Found: C, 82.43; H, 5.79%. Calcd for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84%.

9,10-Bis(1-acetyl-2-hydroxy-1-propenyl)anthracene (6): Colorless needles (from ethyl acetate), mp over 300 °C; IR ($CHCl_3$) 1598 (COC=COH) and 3200—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.65 (12H, s, 4×CH_3), 7.51—8.22 (8H, m, ArH), and 16.98 (2H, s, 2×OH). Found: C, 76.91; H, 6.05%. Calcd for $C_{24}H_{22}O_4$: C, 76.98; H, 5.92%.

9,10-Bis(diacetylmethyl)-9,10-dihydroanthracene (7): Colorless plates (from ethanol), mp 215—216 °C; IR ($CHCl_3$) 1695 and 1735 (C=O); ^1H NMR ($CDCl_3$) δ=2.10 (12H, s, 4×CH_3), 4.44 (2H, d, J=10.2 Hz, H-9 and H-10), 4.89 (2H, d, J=10.2 Hz, 2×$\succeq$CH-), and 7.12 (8H, s, ArH). Found: C, 76.69; H, 6.49%. Calcd for $C_{24}H_{24}O_4$: C, 76.57; H, 6.43%.

9,10-Bis(diacetylmethylene)-9,10-dihydroanthracene (8): Colorless needles (from ethanol), mp 219 °C; IR ($CHCl_3$) 1686 (C=O); ^1H NMR ($CDCl_3$) δ=2.27 (12H, s, 4×CH_3), and 7.24—7.56 (8H, m, ArH). Found: C, 77.34; H, 5.56%. Calcd for $C_{24}H_{20}O_4$: C, 77.40; H, 5.41%.

9-(1-Acetyl-2-hydroxy-1-propenyl)acridine (10): Pale yellow needles (from ethanol), mp 189—190 °C; IR ($CHCl_3$) 1610 (COC=COH) and 3100—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.65 (6H, s, 2×CH_3), 7.35—8.44 (8H, m, ArH), and 17.05 (1H, s, OH). Found: C, 77.89; H, 5.60; N, 4.96%. Calcd for $C_{18}H_{15}O_2N$: C, 77.96; H, 5.45; N, 5.05%.

Oxidation of Xanthene (11). A mixture of xanthene (**11**) (364.4 mg; 2 mmol) and $Mn(acac)_3$ (1.4160 g; 4 mmol) was heated in acetic acid (25 cm^3) at 100 °C for 5 min, followed by treatment in a manner similar to that mentioned above, which gave a mixture of **12** and its enol form (263.3 mg), **13** (79.2 mg), and **11** (recovered 122.3 mg). The ratio of keto and enol was 2:1 based on the ^1H NMR spectrum. The mixture was recrystallized from ethanol and only the keto compound (**12**) was isolated.

9-(Diacetylmethyl)xanthene (12): Colorless needles (from ethanol), mp 142.5 °C; IR ($CHCl_3$) 1697 and 1731 (C=O); ^1H NMR ($CDCl_3$) keto form δ=1.84 (6H, s, 2×CH_3), 4.08 (1H, d, J=9.6 Hz, H-9), 4.84 (1H, d, J=9.6 Hz, $\succeq$CH-), and 6.95—7.30 (8H, m, ArH); enol form δ=1.84 (6H, s, 2×CH_3), 5.30 (1H, s, H-9), 6.8—7.4 (8H, m, ArH), and 17.16 (1H, s, OH). Found: C, 77.20; H, 5.90%. Calcd for $C_{18}H_{16}O_3$: C, 77.12; H, 5.75%.

9-(Diacetylmethylene)xanthene (13): Pale yellow needles (from ethanol), mp 144—145 °C; IR ($CHCl_3$) 1676 and 1706 (C=O); ^1H NMR ($CDCl_3$) δ=2.20 (6H, s, 2×CH_3) and 6.95—7.57 (8H, m, ArH). Found: C, 77.44; H, 5.06%. Calcd for $C_{18}H_{14}O_3$: C, 77.68; H, 5.07%.

Oxidation of Anthrone (14). 10-(Diacetylmethylene)anthrone (15): Colorless needles (from ethanol), mp 161 °C; IR ($CHCl_3$) 1669 and 1707 (C=O); ^1H NMR ($CDCl_3$) δ=2.22 (6H, s, 2×CH_3) and 7.5—8.4 (8H, m, ArH). Found: C, 78.59; H, 4.91%. Calcd for $C_{19}H_{14}O_3$: C, 78.60; H, 4.85%.

10,10′-Bianthrone (16): Pale yellow needles (from $CHCl_3$), mp 268—269 °C (lit, [11b] mp 230—250 °C); IR (KBr) 1657 (C=O); ^1H NMR ($CDCl_3$) δ=4.69 (2H, s, H-10 and 10′) and 6.70—7.98 (16H, m, ArH). Found: C, 86.91; H, 4.66%. Calcd for $C_{28}H_{18}O_2$: C, 87.02; H, 4.69%.

Oxidation of Pyrene (17). 1-(1-Acetyl-2-hydroxy-1-propenyl)pyrene (18): Pale orange needles (from ethanol), mp 158.0—158.5 °C; IR ($CHCl_3$) 1602 (COC=COH) and 3200—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.76 (6H, s, 2×CH_3), 7.69—8.26 (9H, m, ArH), and 16.86 (1H, s, OH). Found: C, 83.87; H, 5.35%. Calcd for $C_{21}H_{16}O_2$: C, 83.98; H, 5.37%.

1-(1-Acetoxy-1-acetyl-2-oxopropyl)pyrene (19): Colorless needles (from ethanol), mp 178.0—178.5 °C; IR ($CHCl_3$) 1722 and 1749 (C=O); ^1H NMR ($CDCl_3$) δ=2.26 (6H, s, 2×CH_3), 2.39 (3H, s, OAc), and 7.82—8.43 (9H, m, ArH). Found: C, 76.79; H, 5.06%. Calcd for $C_{23}H_{18}O_4$: C, 77.08; H, 5.06%.

1-(1-Acetoxy-1-acetyl-2-oxopropyl)-6-(1-acetyl-2-hydroxy-1-propenyl)pyrene (20): Colorless needles (from methanol), mp 218—219 °C; IR ($CHCl_3$) 1603 (COC=COH), 1722 (C=O), 1749 (OAc), and 3300—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.77 (6H, s, 2×CH_3), 2.26 (6H, s, 2×$COCH_3$), 2.39 (3H, s, OAc), 7.90 (1H, d, J=9.0 Hz, ArH), 7.99 (1H, d, J=9.0 Hz, ArH), 8.27 (1H, d, J=9.0 Hz, ArH), 8.47 (1H, d, J=9.0 Hz, ArH), 8.0—8.2 (4H, m, ArH), and 16.84 (1H, s, OH). Found: C, 73.46; H, 5.23%. Calcd for $C_{28}H_{24}O_6$: C, 73.67; H, 5.30%.

Oxidation of 1-Nitronaphthalene (1j). 1-Nitronaphthalene (**1j**) (198.7 mg; 1 mmol) was oxidized with $Mn(acac)_3$ (1.4298 g; 4 mmol) in acetic acid (25 cm^3) at 100 °C. The reaction was terminated after 15 min and **1j** (173.0 mg) was recovered.

Formation of 21 in the $Mn(acac)_3$ Oxidation. 1-Methoxynaphthalene (**1b**) (319.2 mg; 2 mmol) and $Mn(acac)_3$ (1.4240 g; 4 mmol) were heated at 100 °C in acetic acid (30 cm^3) for 10 min, affording **2b** (17.4 mg), **3b** (93.7 mg), and **21** (105.2 mg). The **21** was formed in all the $Mn(acac)_3$-acetic acid oxidation.

3-Acetyl-4-hydroxy-3-hexene-2,5-dione (21): Colorless prisms (from benzene), mp 115—116 °C; IR ($CHCl_3$) 1668, 1708 (C=O), and 3000—3600 (OH); ^1H NMR ($CDCl_3$) δ=1.607 (3H, s, CH_3), 2.389 (3H, s, CH_3), 2.605 (3H, s, CH_3), and 6.395 (1H, s, OH); ^{13}C NMR ($CDCl_3$) δ=197.558 (s, C=O), 196.910 (s, C=O), 194.919 (s, C=O), 112.959 (s, C=C), 106.294 (s, C=C), 29.648 (q, CH_3), 21.810 (q, CH_3), and 18.816 (q, CH_3); MS m/z (rel intensity), 170 (M^+, 6), 127 (80), 85 (50), 67 (100), and 43 (97). Found: C, 56.38; H, 5.95%. Calcd for $C_8H_{10}O_4$: C, 56.46; H, 5.92%.

Oxidation of 2c. The **2c** (102.2 mg; 0.36 mmol) and $Mn(acac)_3$ (258.5 mg; 0.72 mmol) were heated in acetic acid (15 cm^3) at 100 °C for 3 min. The reaction mixture was treated in a manner similar to that described above to give **3c** (29.0 mg) and **2c** (recovered 53.6 mg).

Oxidation of 5. The (diacetylmethyl)anthracene (**5**) (99.1 mg; 0.36 mmol) was oxidized with $Mn(acac)_3$ (266.4 mg; 0.72 mmol) in acetic acid (20 cm^3) at 100 °C for 2 min. After separation by TLC, **6** (53.9 mg; 40%), **8** (32.2 mg; 24%), and **5** (recovered 28.7 mg; 29%) were obtained.

Oxidation of 6. A mixture of bis(diacetylmethyl)anthracene (**6**) (103.5 mg; 0.28 mmol) and $Mn(acac)_3$ (198.2 mg; 0.56 mmol) was heated in acetic acid (20 cm^3) at 100 °C for 2 min, affording **8** (67.5 mg; 66%) and **6** (recovered 33.8 mg; 33%).

Oxidation of 7. The reaction of **7** (50.8 mg; 0.135 mmol) and $Mn(acac)_3$ (103.4 mg; 0.27 mmol) was carried out in acetic acid (10 cm^3) at 100 °C for 2 min. After work-up, however, only **7** was recovered. On the other hand, **7** (52.0 mg; 0.135 mmol) was oxidized with $Mn(acac)_3$ (199.5 mg; 0.54 mmol) in acetic acid (10 cm^3) at 100 °C for 6 min, giving **8** (9.2 mg; 18%) and **7** (recovered 40 mg; 77%).

Oxidation of 12. 9-(Diacetylmethyl)xanthene (**12**) (102.6 mg; 0.37 mmol) and $Mn(acac)_3$ (262.0 mg; 0.74 mmol) were heated on a water bath for 2 min. After the treatment described above, 9-(diacetylmethylene)xanthene **13** (29.9 mg; 29%) and **12** (recovered 69.3 mg; 68%) were obtained.

Oxidation of 1a with $Mn(acac)_3$ in CH_3CN. The reaction of **1a** (175.3 mg; 1 mmol) with $Mn(acac)_3$ (1.4146 g; 4 mmol) was carried out in CH_3CN (25 cm^3) at 100 °C for 3 h. The solvent was removed under diminished pressure and the residue was triturated with 2 M HCl (25 cm^3). The aqueous mixture was extracted with $CHCl_3$ and separated on TLC, which gave only **1a** (recovered 136.1 mg).

The author would like to express his grateful acknowledgment to Dr. Naoki Sato of the Department of Chemistry, Kumamoto University, for his helpful discussion and providing some data for ionization potentials of organic compounds. Thanks are also due to Mr. Teruyoshi Marunaka of the Taiho Pharmaceutical Co., Ltd., Tokushima, for his measurements of the mass and ^{13}C NMR spectra. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60740282 from the Ministry of Education, Science and Culture (1985).

NMR and XPS Studies of Some Diselenocarbamates. Bond Switch in Bis(dimethylselenocarbamoyl) Triselenide

Keiji KOBAYASHI,* Hideyuki TUKADA, Koichi KIKUCHI,† and Isao IKEMOTO†
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
†Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received January 23, 1986)

The hindered rotation about the C-N bond in dimethyldiselenocarbamates Me_2N-CSe-SeR has been investigated by variable temperature NMR spectroscopy. The barrier to the rotation was almost independent of the partial structure of R (R= -Me, -CSe-NMe_2), being 19 kcal mol^{-1}* at around 93 °C. However, for bis(dimethylselenocarbamoyl) triselenide (R= -Se-Se-CSe-NMe_2) (**1**), no splitting of *N*-methyl signals was observed in the ^1H and ^{13}C NMR spectra at subambient temperature. The equivalence of the methyl groups is discussed in terms of the bond switch between C=Se and C-Se moieties. The existence of the bond switch in **1** was also suggested by the XPS studies; the binding energy of the four selenium atoms was found to lie between those of C=Se and -Se- types of the selenium atoms, indicating that **1** takes an intramolecular coordination structure rather than a linear triselenide structure in the solid state, thereby facilitates the bond switch in solution.

There have been many examples of hindered internal rotation about the nitrogen-carbon bond in amide compounds since the classical studies of *N,N*-dimethylformamide.[1] Much of the subsequent work has been expanded to amide analogues involving sulfur in place of oxygen such as thioamide.[2] However, little attention has been given to the selenium analogues of amides.[3] Our present study began with the dynamic NMR of diselenocarbamates, as no data have been reported previously for the internal rotation of such selenium compounds. During the course of the study, we observed the magnetic equivalence of *N*-methyl protons in bis(dimethylselenocarbamoyl) triselenide (**1**) in sharp contrast to other selenocarbamates which exhibited nonequivalent *N*-methyl protons due to the restricted rotation about the C-N bond at room temperature. This unexpected behavior of **1** prompted us to suspect the triselenide structure of **1** represented as **A**. If **1** has the structure **B** composed of a positively charged central selenium atom and two negatively charged diselenocarbamato ligands, in analogy with bis(diselenocarbamato)metal (II) complexes, the NMR spectra of **1** should give the equivalent *N*-methyl protons, as was actually observed. The X-ray photoelectron spectra (XPS) might be helpful in distinguishing **A** from **B**, as these provide the ionic character of the selenium bond through inner-shell electron binding energies. Therefore, we have also made XPS studies. In this article we describe the results of the NMR and XPS studies of several diselenocarbamates, in particular, focussing on the characterization of the selenium bond in **1**. Based on these data we demonstrate the fast bond switch of carbamate **1** in solution and the intramolecular coordination structure in the solid state.

Results and Discussion

NMR Spectroscopy. The ^1H NMR spectra were measured for four diselenocarbamates, **1**, methyl dimethyldiselenocarbamate (**2**), bis(dimethylselenocarbamoyl) selenide (**3**), and bis(dimethyldiselenocar-

bamato)nickel (II) (**4**). The ^{1}H chemical shifts of these selenocarbamates are collected in Table 1. Also summarized in Table 1 are the ^{13}C and ^{77}Se NMR spectral data. Some of the ^{13}C and ^{77}Se chemical shifts could not be obtained because the solubility was extremely low for detecting the signals.

Carbamate **2** exhibited a singlet for the Se-Me protons and a doublet for the *N*-Me protons in the ^{1}H NMR spectra at room temperature. This was also the case in the ^{13}C NMR spectra. The nonequivalent methyl groups showed a large aromatic solvent-induced shift (ASIS) on the relative ^{1}H chemical shifts; the distance between the two peaks increased up to 0.65 ppm on replacement of $CDCl_3$ by benzene. The higher field peak was mainly responsible for this shift, being analogous to the ASIS behavior observed in *N,N*-dimethylacetamide.[4] Thus, the peak at δ 3.38 in $CDCl_3$ was assigned to the methyl protons *trans* to the selenocarbonyl group and the peak at δ 3.67 was to the *cis* protons.

For carbamate **2** two conformational isomers, *s-cis* and *s-trans* with respect to the CSe-Se single bond, may be considered. However, even on lowering the temperature down to −65 °C, no signals attributable to another conformer have been observed in the ^{1}H and ^{13}C NMR spectra. This indicates extremely high predominance of one isomer over another. The prefered isomer may be assigned to the *s-cis* conformer by analogy with the corresponding sulfur compound, methyl dimethyldithiocarbamate, for which the *s-cis* conformer has been reported to be more stable than the *s-trans* conformer on the basis of the NMR and MO studies.[5]

In compound **3** the nonequivalent *N*-Me protons were again observed, as shown in Table 1, indicating restricted rotation about the C-N bond. No additional peaks were observed in the ^{1}H NMR or in the ^{13}C NMR spectra at low temperature of −65 °C. Thus, solely one conformation of the possible three is permissible for **3**. Among the three conformers depicted below, the *s-cis*, *s-trans* conformer should exhibit four nonequivalent methyl signals. The *s-trans*, *s-trans* conformer is unlikely to exist because of the steric repulsion between the *N*-methyl groups. Therefore, the most stable isomer observed in the NMR spectra can be assigned to the *s-cis*, *s-cis* isomer.

On raising the temperature the *N*-Me doublet of **2** collapsed to a singlet, as shown in Fig. 1, due to rapid

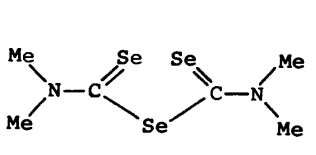
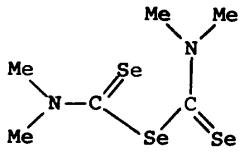
rotation about the C–N bond. The coalescence temperature of 93 °C and the chemical shift difference of 19.3 Hz allowed us to estimate the energy barrier to the rotation about the C–N bond in DMSO by means of the coalescence temperature method[6] and gave a value of 18.8 kcal mol^{-1} at 93 °C. In a nonpolar solvent such as tetrachloroethylene, the barrier was apparently lower than that obtained in DMSO, as shown in Table 2. It is reasonable to assume that the contribution of the polar resonance structure in the ground state is more enhanced in polar solvents than in nonpolar solvents, hence the double bond character of the CSe–N bond is increasing to raise the barrier to the rotation in DMSO.

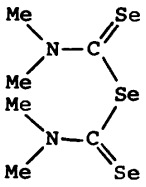
Carbamate **3** showed a similar dynamic NMR behavior and led to the estimation of 19.1 kcal mol^{-1} for the barrier at the 94 °C of coalescence temperature. It is interesting to note that the barriers of **2** and **3** fall to almost the same value at the similar coalescence temperature. These observations suggest that the rotational barrier in dimethyldiselenocarbamates is almost independent of the residual structure other than the diselenocarbamate moieties. Close similarity of the rotational barrier has also been found among dithiocarbamates.[7]



s-cis, s-cis **3**



s-cis, s-trans **3**



s-trans, s-trans **3**

The activation energies for the rotation in **2** and **3** seem to be slightly lower than those reported for *N*,*N*-dimethylselenoamide.[3] The resonance structure of the cross-conjugated species as represented in **c** probably contributes to the hybrid structure in diselenocarbamates, which should reduce the double bond character of the C–N bond and thus decrease the barrier to rotation.

Triselenide **1** exhibits the most unexpected part of this study; no splitting of *N*-methyl signals was observed in the ^{1}H NMR spectra at room temperature. Although the low temperature spectra could not be obtained below 5 °C in DMSO, down to this temperature the *N*-Me protons showed only a sharp singlet. Despite our anticipation that the ^{13}C chemical shift difference for the methyl signals might be relatively large, resulting in higher temperatures of decoalescence and permitting observations of the individual resonances at about 5 °C, the ^{13}C NMR spectra exhibited no splitting. By assuming 15.0 Hz for the chemical shift difference of the *N*-methyl protons, which corresponds to the value observed in **3**, and 0 °C for the coalescence temperature, the rotational barrier of **1** was estimated to be less than 14 kcal mol^{-1}. This energy value is apparently low as compared with those of **2** and **3** and unusual as well in view of the close similarity of the barrier in diselenocarbamates **2** and **3**.

It would be possible to interpret a single peak for the *N*-methyl protons of **1** by assuming the structure of a metal complex as represented in **B** rather than the triselenide structure **A**. The structure involving two diselenocarbamato ligands should show a singlet peak

Table 3. Binding Energies of the Se 3d Core Electron Peak/eV[a)]

1	3	4
54.5 (1 Se)	55.0 (2 C=Se)	55.0 (4 C⩵ Se⁻)
55.6 (4 Se)	56.5 (1 -Se-)	

a) Relative peak intensity and assignment are given in parentheses.

for the *N*-methyl signals, as was the case in the complex **4** which exhibited singlet signals at δ 3.30 in DMSO. An alternative explanation may be given by assuming the occurence of rapid interconversion of the *N*-methyl groups through a rate determining process other than bond rotation about the C–N bond. Thus, we can postulate the existence of the rapid bond switch as depicted in **c**, wherein the *N*-methyl protons should appear as a singlet even if the bond rotation is slow. To distinguish the structural possibilities **A**, **B**, and **C**, the ^{77}Se NMR spectrum and its low temperature variation should offer the most potentially useful means. However, the solubility of **1** was extremely low and we were unable to carry out dynamic NMR experiments by monitoring the ^{77}Se nuclei.

XPS Studies. We have also approached the problem on the binding character from the chemical shift differences in the XPS. The binding energies of Se 3d core levels obtained by the XPS measurements are listed in Table 3. All measurements were made on solid samples at room temperature. The data for compound **2** were not obtained, as the sample sublimed under the experimental conditions.

Among the three compounds, compound **4** exhibited the narrowest peak with a half width of 1.9 eV, since the four selenium atoms in **4** have all equivalent bonding properties. For the spectrum of **3** graphical separation of the overlapped peaks was accomplished on the bases of the peak profile of **4** and the normalization of the number of selenium atoms involved in the carbamates. Thus, the spectrum of **3** resulted in two peaks at 55.0 and 56.5 eV in an intensity ratio of 2:1 as shown in Fig. 2. The stronger peak with lower binding energy should be assigned to the C=Se selenium atoms and the weaker one with higher energy to the ether type of selenium atom. The energy value of the former peak is almost the same as that of **4**, indicating that negative charge is appreciably developed in the selenoketone type of selenium atom. On the other hand, the binding energy of the ether type of selenium atom is relatively high. The increase in binding energy corresponds to a more pronounced positive charge on the selenium atom and thus implies a great contribution of the dipolar structure due to cross-conjugation. This XPS result for the selenoether selenium atom in **3** is consistent with the ^{77}Se NMR chemical shift; the shift was significantly downfield as compared with that of **2**.

The peak profile of **1** was not broadened as much as for a triselenide structure with the three different types

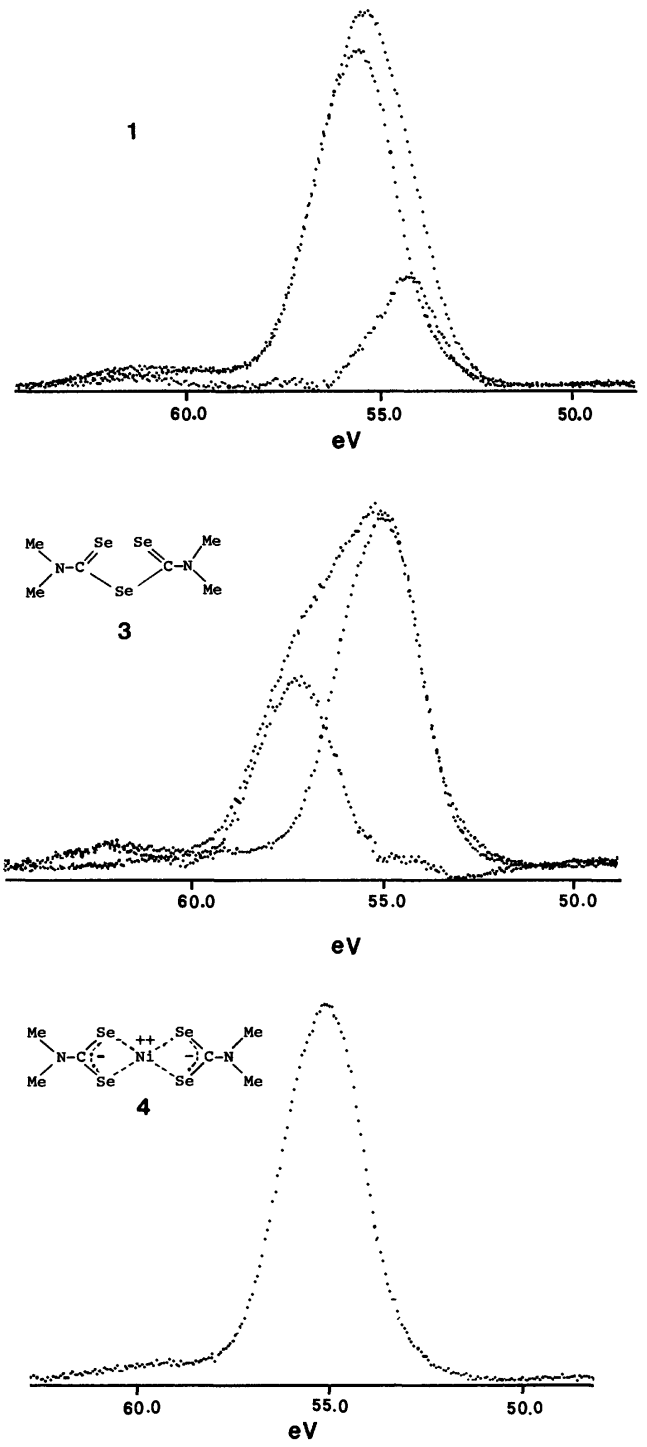


Fig. 2. The XPS peaks of Se 3d electrons in 1, 3, and 4.

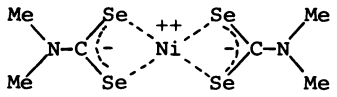
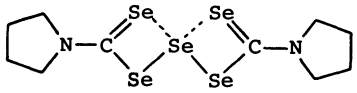
of selenium atoms. The peak separation disclosed a small peak corresponding to one selenium atom at 54.5 eV besides a major peak at 55.6 eV due to four equivalent selenium atoms. Involvement of four equivalent selenium atoms in **1** rules out the linear triselenide structure **A** and is reminiscent of the metal complex structure **B**. The binding energy of these four selenium atoms, however, is larger than that observed in a typical bis(diselenocarbamato)metal (II) complex,

i. e. complex **4**. This may imply that four equivalent selenium atoms are not included as negatively charged diselenocarbamato ligands. Moreover, one selenium atom, which might correspond to the central one, has extremely low binding energy. On this selenium atom a negative charge must be developed rather than a positive charge. These observations clearly show that **1** is represented neither as the metal complex **B** nor the triselenide structure **A**; the XPS data suggest the contribution of the resonance form **D** to the overall structure of **1** even though it is less important than the others. This may be most reasonably explained by a structure in which the lone-pair electrons in the two selenocarbonyl groups are donated to the central selenium atom in the triselenide moiety. Thus, the bonding character of the selenium atoms in the selenocarbonyl functionality C=Se must be close to that of the selenium atoms of -Se-C- moiety and thereby exhibits approximately equal binding energies as was observed in the XPS.

Huesbye has reported the X-ray structure of the diselenocarbamate **5**, a compound of the same family of **1**.[8] This compound is a trapezoid planar four-coordinated complex, wherein two of the central atoms to the ligand bonds are intramolecular and the other two are weak intramolecular bonds. Binding energies of the selenium atoms involved in the former and the latter bonding probably could not be distinguished from the XPS spectra because the difference is small. Therefore, the present XPS data are consistent with the X-ray results.



4



5

Concerning the structure of **1** in solution, the closer intramolecular approach of the two selenocarbonyl groups to the central selenium atom should facilitate the bond switch in the solution as illustrated in **C**. Thus both the bonding character revealed in the solid state and the equivalence of the *N*-methyl signals in the NMR spectra provide strong evidences for the occurence of the fast bond switch in bis(dimethylselenocarbamoyl) triselenide (**1**).

Experimental

The ^{1}H NMR spectra were measured on a Varian EM 390 spectrometer (90 MHz) with tetramethylsilane as the internal reference. The variable temperature ^{1}H NMR spectra were obtained on the EM 390 spectrometer equipped with a variable temperature probe and temperature controller, which was calibrated by the peak separations obtained with an ethylene glycol sample. The ^{13}C NMR spectra were obtained on a JEOL 400 GX spectrometer operating at 76.245 MHz equipped with a 10 mm probe. The spectra were recorded with proton noise decoupling for 5 kHz spectral width and with 45° pulse. Usually 100 scans were accumulated with a 3.5 s pulse interval after each pulse. The ^{77}Se NMR spectra were obtained on the JEOL 400GX spectrometer. About 2000—4000 average transients at a pulse repetition rate of 1 s with proton-noise decoupling were accumulated, employing 45° pulse. The chemical shifts were determined relative to external dimethyl selenide, which was observed to resonate at 76244285 Hz in $CDCl_3$.

The XPS data were obtained on a SHIMADZU ESCA 750 using Mg $K\alpha$ exciting radiation at room temperature, the source vacuum being ca. 10^{-7} mmHg**. Powdered samples were pressed onto an aluminum substrate. The binding energies of photoelectron peaks were calibrated by using the Au $4f_{7/2}$ peak (83.8 eV) of a thin gold film deposited on the sample surface. Peak positions and areas were obtained by graphical fitting of the peak profile of compound **4** to the experimental data.

Bis(dimethylselenocarbamoyl) triselenide (**1**) and bis(dimethylselenocarbamoyl) selenide (**3**) were prepared according to the procedures given in literature.[9] The melting points were in agreement with the literature values and the NMR spectra showed no trace of impurities.

Methyl Dimethyldiselenocarbamate (2). Hydrogen selenide, generated by the addition of water to 6.89 g (23.7 mmol) of aluminum selenide, was passed through a cooled solution (−10 °C) of 9.9 ml (71.0 mmol) of freshly distilled triethylamine in 250 ml of chloroform. The hydrogen selenide stream was then replaced by a stream of argon. To this solution 9.9 ml of triethylamine and 5.72 g (35.2 mmol) of *N,N*-dimethyldichloromethaniminium chloride were added at 0 °C in quick succession. The mixture was stirred at room temperature for 2 h and then treated with a solution of 4.50 g (31.9 mmol) of iodomethane in 10 ml of chloroform over 10 min. The resulting mixture was stirred at room temperature for 2 h, the solvent was removed under vacuum, and the residue was extracted with ether. The ether was evaporated to afford pale yellowish plates. Recrystallization from benzene-haxane gave 3.8 g (52%) of **2** as white plates, mp 85—86 °C. Found: C, 20.85; H, 4.22; N, 6.11%. Calcd for $C_4H_9NSe_2$: C, 20.96; H, 3.96; N, 6.12%.

Bis(dimethyldiselenocarbamato)nickel (II) (4). This complex was prepared by a modification of the method reported by Woodbridge,[10] using hydrogen selenide in place of carbon diselenide. A solution of 2.2 g (17.0 mmol) of unhydrous nickel chloride in a mixture of 150 ml of methanol and 20 ml of water was added to a solution of triethylammonium dimethyldiselenocarbamate in chloroform, which was prepared from 5.72 g of *N,N*-dimethyldichloromethaniminium chloride and hydrogen selenide as descrived above. The mixture was stirred for 2 h at room temperature and the resulting precipitate was filtered, washed with water, and dried to give 3.89 g (47%) of crude **4**. A portion of this solid was recrystallized from 1,1,2-trichloroethane to give pure **4** as dark greenish solids with

**1 mmHg=133.322 Pa.

high mp (>310°C). Found: C, 14.29; H, 2.59; N, 5.63%. Calcd for $C_6H_{12}N_2Se_4Ni$: C, 14.81; H, 2.49; N, 5.76%.

$AlCl_3$-Promoted Conjugate Reduction of α,β-Unsaturated Carbonyl Compounds with 1,3-Dimethyl-2-phenylbenzimidazoline

Hidenori CHIKASHITA* and Kazuyoshi ITOH
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564
(Received February 3, 1986)

The reduction of a variety of α,β-unsaturated carbonyl compounds, except for α,β-unsaturated aldehyde, to the corresponding saturated carbonyl compounds was effectively performed by using 1,3-dimethyl-2-phenylbenzimidazoline (DMBI) as a reducing agent with the aid of $AlCl_3$. The reduction is discussed on the basis of the hydride-donating ability of DMBI, together with the role of $AlCl_3$ as an electrophilic activator for the substrates. The catalytic efficiency of Lewis acids was found to be proportional to the efficiency to form a complex with a carbonyl group. The reduction of 2-cinnamoylpyridine with 2-deuterated DMBI revealed that in the reduction product, a deuterium atom was located at the β-position with respect to the carbonyl group. On the other hand, the reduction of the same substrate with DMBI followed by quenching with D_2O gave a reduced product which contained a deuterium label at the α-position. These results were interpreted in terms of a mechanism involving an enolate intermediate produced by either a one-step hydride transfer or a sequential transfer of an electron (e) and a hydrogen atom (H·) from the reducing agent to the substrate.

Many useful methods for obtaining functionalizing organic compounds have been developed in recent years by employing various types of heterocyclic compounds, either as mediate or immediate reagents.[1] On the other hand, the selective reduction of organic functional groups is one of the important and frequently encountered synthetic subjects in organic syntheses. However, despite much work in these fields, little attention has been given to the use of heterocycles having a hydrogen-donating ability as practical reducing agents for such selective reductions. Therefore, it could become one of the useful methods in this field if such heterocycles could be used as direct and selective reducing agents. Although more recently, several reports[2] have appeared concerning the use of 1,4-dihydropyridine derivatives (so-called NAD(P)H model compounds) such as 1,4-dihydronicotinamides or 3,5-bis(ethoxycarbonyl)-1,4-dihydro-2,6-dimethylpyridine as reducing agents from an above synthetic viewpoint, reductions with NAD(P)H-models have, so far, been mainly investigated with regard to biological, biomimetic, or mechanical interests. To the best of our knowledge, there has only been two sources[3] concerning the synthetic utility of other heterocycles as practical and selective reducing agents. In previous papers from our laboratory, it was revealed that dihydrobenzazoles such as 2-phenylbenzimidazoline or 2-phenylbenzothiazoline were useful reducing agents for the selective reduction of carbon–carbon double bonds of α,β-unsaturated dinitriles,[4] 2-aryl-1-nitroalkenes,[5] and α,β-unsaturated carbonyl compounds.[6] As a continuation of this work, we have investigated the potential reducing ability of *N*-methylated 2-phenylbenzazolines in a reduction of α,β-unsaturated carbonyl compounds in the presence of a Lewis acid. We found that 1,3-dimethyl-2-phenylbenzimidazoline (DMBI) is the most powerful component in this reaction relative to the other heterocycles. In this paper, we report on the details of an $AlCl_3$-promoted conjugate reduction of α,β-unsaturated carbonyl compounds with DMBI and show the mechanical features of these reactions.

Results and Discussion

In contrast to 2-phenylbenzimidazoline, which should be prepared in situ from *o*-phenylenediamine and benzaldehyde in a solvent because it is an unstable intermediate and rapidly oxidized automatically to 2-phenylbenzimidazole in the absence of an appropriate hydrogen acceptor, DMBI can be prepared by a reaction of *N*,*N*′-dimethyl-*o*-phenylenediamine with benzaldehyde or the quaternization of 2-phenylbenzimidazole followed by a reduction with lithium aluminum hydride or sodium borohydride. It can be isolated as a handlable substance consisting of colorless needles.[7] DMBI is very stable in an atmospheric environment and can be stored in a sealed bottle for a long time.

For preliminary assays of the present study, we chose benzylideneacetone as a model compound and the reaction of the enone with DMBI in the presence or absence of a Lewis acid was carried out under the conditions shown in Table 1. Although the reduction of the enone with DMBI did not occur without a Lewis acid (Run 1), it was found that the reduction can proceed with 1 equivalent of DMBI in the presence of a slight excess of a Lewis acid in dry acetonitrile

Table 1. Reduction of Benzylideneacetone to Benzylacetone with DMBI in the Presence or Absence of Lewis Acid

Run	Lewis acid	Molar ratio[a] Enone:Lewis acid	Temp/°C	Time/h	Yield/%[b]

8	MBO	$AlCl_3$	1:1.2	0.5	0

a) All the reactions were carried out in acetonitrile at 80°C. b) 1.2:1 Molar ratio of MBT and MBO to the enone was used. c) Yield determined by GLC analysis.

at 80°C. In all cases, the conjugate reduction product, 3-phenyl-2-butanone, was obtained in complete selectivity, and none of 4-phenyl-3-buten-2-ol, corresponding to the 1,2-reduction product, or 4-phenyl-2-butanol was detected. The change in the Lewis acid did not change the selectivity of the reduction, but the reaction employing $AlCl_3$ was very rapid and was completed within 30 min to give the product in quantitative yield (Run 5). In addition, this $AlCl_3$-promoted reduction proceeded well even at room temperature to give a nearly quantitative yield of the product (Run 6). As to the catalytic efficiency of the Lewis acid, Table 1 indicates that it is proportional to its efficiency to form a complex with a carbonyl group:[8] the latter efficiency increases in the order $ZnCl_2 < SnCl_4 < FeCl_3 < AlCl_3$. Thus, a Lewis acid can be regarded as an electrophilic activator to polarize a carbon–carbon double bond due to the formation of a complex with a carbonyl group of the enone. The use of a 1.2 equivalent of $AlCl_3$ to the enone is sufficient to promote the reaction, while the use of 0.5 or 0.25 equivalents of $AlCl_3$ to the enone gave the reduced product in 49 and 23% yields, respectively (Runs 7 and 8). This shows that the present conjugate reduction requires a stoichiometric amount of the Lewis acid.

A brief survey of the potential reducing ability of a series of *N*-methylated 2-phenylbenzazolines on the reduction of benzylideneacetone was conducted. As shown in Table 2, the reduction with 3-methyl-2-phenylbenzothiazoline (MBT) also proceeded in the presence of a Lewis acid with a similar trend shown on the DMBI-reduction (Runs 1—7) while the reduction with 3-methyl-2-phenylbenzoxazoline (MBO) did not occur at all (Run 8). Although the reaction with MBT proceeded well in the presence of $AlCl_3$ to give 3-phenyl-2-butanone in quantitative yield after a reaction time of 48 h (Run 5), it is apparent from Tables 1 and 2 that DMBI is superior to MBT in terms of its power.

We have demonstrated the general applicability of the present DMBI-reduction regarding a variety of α,β-unsaturated ketones. The results are summarized in Table 3. Generally, the reduction of linear enones by the present method can be performed easily to give nearly quantitative yields of the corresponding saturated ketones (Runs 1—7). β-Ionone, corresponding to an α,β:γ,δ-unsaturated carbonyl compound, was selectively reduced to dihydro-β-ionone in quantitative yield (Run 7). 1,2-Dibenzoylethylene, corresponding to an α,β-unsaturated diketone, was also reduced with no difficulty to 1,4-diphenyl-1,4-butanedione in quantitative yield (Run 3). In all cases, the conjugate reduction products were obtained in complete selectivity, and other by-products were not detected at all. Compared with a similar reduction with 2-phenylbenzothiazoline,[6] the present DMBI-reduction of linear enones is more rapid. In addition, 3-methyl-4-phenylbutenone could be effectively reduced with DMBI within 4 h, in contrast to the reduction by 2-phenylbenzothiazoline in which the butenone was

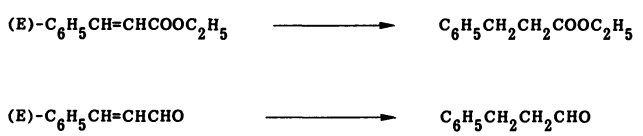
a) 1.2:1 Molar ratio of DMBI and $AlCl_3$ to enone was used. b) Yield determined by GLC analysis. c) Spectral data of the reduced products were in satisfactory agreement with those of the corresponding authentic samples or expected values. d) Reaction at 60°C. e) Yield of isolated, pure product. f) Yield of isomeric mixture. g) Mp of 2,4-dinitrophenylhydrazone derivative.

sluggishly reduced to the same in 26% yield after a 24 h reaction. On the other hand, the reduction of cyclic enones was generally slower than that of linear enones but afforded moderate yields of saturated cyclic ketones (Runs 8—10). As pointed out regarding the reduction of linear enones, DMBI also seems to be more powerful in the reduction of cyclic enones than 2-phenylbenzothiazoline. In short, the $AlCl_3$-promoted conjugate reduction of a variety of α,β-unsaturated ketones can be practically performed in good yields with complete regiospecificity together with no side reactions. Thus, although there are several methods available to bring about such conversions, we consider the present method to be a useful addition. The relative reactivities of the enones were found to decrease in the order α,β-disubstituted linear enone>α,β,β-trisubstituted linear enone>α,α,β-trisubstituted linear enone>cyclic enone.

The conjugate reduction of an α,β-unsaturated ester and a similar aldehyde were also examined under similar conditions (Scheme 3). Methyl cinnamate

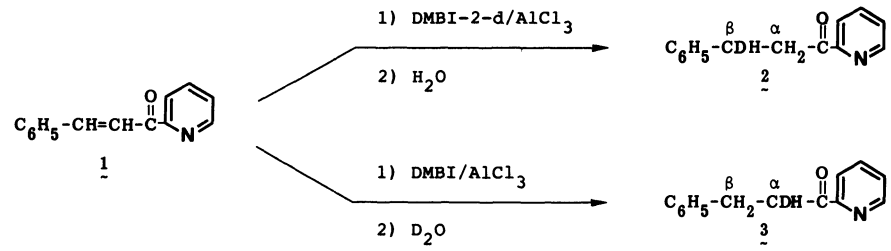


Scheme 3.

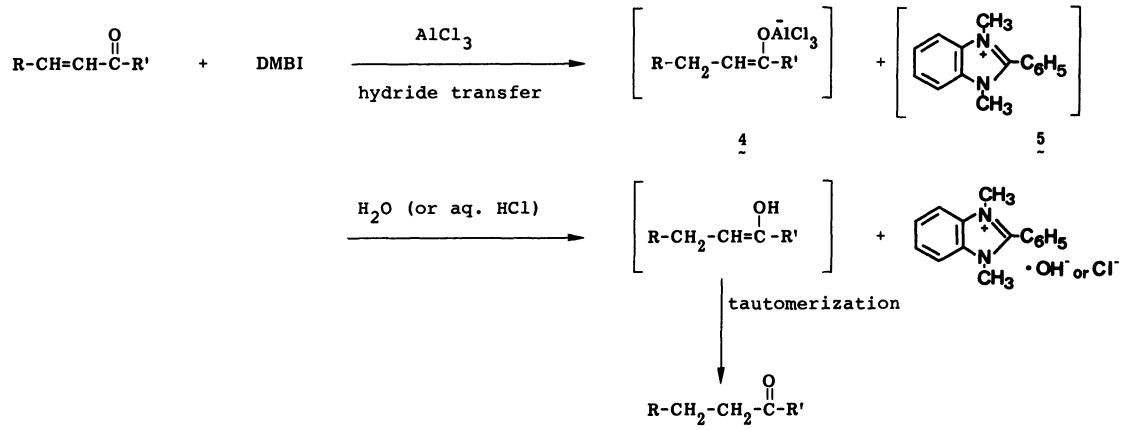
was less effectively reduced to the corresponding 3-phenylpropionate in 30% yield after a reaction time of 30 min. However, the reduction of cinnamaldehyde under the same conditions gave only a trace amount of the expected saturated aldehyde, 3-phenylpropanal. The latter result may show that the present method is, as yet, inapplicable to the conjugate reduction of α,β-unsaturated aldehydes.

The functional selectivity of the present DMBI-reduction should be noted since it is of importance in an organic synthesis and of interest to organic chemists. We have found that functional groups such as carbonyl, carboxylic ester, acid, nitro, isolated C=C, isolated C≡C, and the common carbon-halogen bond are inert to the present reducing system. These selective properties might enhance the utility of the present reducing method.

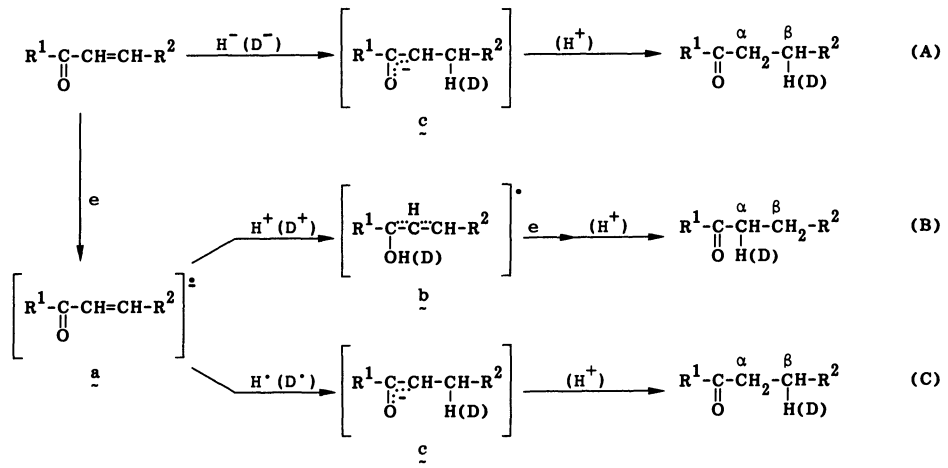
Mechanism. In an attempt to determine the destination of a hydrogen atom at the C-2 carbon of DMBI, we reduced 1-(2-pyridyl)-3-phenyl-2-propen-1-one (**1**) with 2-deuterated DMBI which can be easily prepared by the reduction of 2-phenylbenzimidazolium iodide with lithium aluminum deuteride (Scheme 4). The product of this reaction was found to be the saturated ketone (**2**) containing one deuterium atom at its β-carbon to the carbonyl group. This result shows that the hydrogen atom at C-2 carbon of DMBI surely transfers to the β-carbon of the substrate as a hydride, because the carbon at the β-position of the substrate is very nucleophilic due to the formation of a complex of $AlCl_3$ with the carbonyl group of the enone (**1**) and the pathway involving an isomerization of an allylic



Scheme 4.



Scheme 5.



Scheme 6.

intermediate produced by the 1,2-reduction can be excluded according to the results reported by Gase et al.[9] When azachalcone (**1**) was reduced by DMBI, the α-deuterated ketone (**3**) was obtained in 65% yield after a workup with D_2O (Scheme 4). This indicates that the incorporation of a hydrogen atom from the water of the workup takes place and shows that the hydrogen atom at the α-position of the reduced product comes from the water for the workup after completion of the reaction. Considering these facts, a mechanism involving the hydride transfer followed by protonation of the aluminum enolate (**4**) by quenching water can be proposed for the present conjugate reduction as shown in Scheme 5. These processes fully conform to the driving force of the formation of stable benzimidazolium ion (**5**).

Recently, the mechanism of a hydride-equivalent transfer in a reduction with 1,4-dihydropyridine derivatives has been extensively discussed, and it has been proposed in some cases[10] that the reduction is most likely composed of an initial electron transfer followed by the transfer of a hydrogen nucleus or radical. Although the initial hydride transfer shown in Scheme 5 may be viewed as simply a one-step hydride transfer (mechanism A), schemes involving sequential transfers of e+H· (mechanism C) and e+H⁺+e (mechanism B) are also possible in theory (Scheme 6). The transfer of a hydride ion to the unsaturated ketone system (mechanism A) should give the saturated ketone in which the hydrogen atom of DMBI would be introduced at the β-carbon. In considering mechanisms B and C, it is expected that the radical

anion intermediate **a** formed by the addition of an electron to the substrate would undergo protonation (mechanism B) at the oxygen site to give the allylic intermediate **b**, while the addition of a hydrogen atom to the same (mechanism C) should result in anion **c**. As a consequence, upon completion of the reaction, the hydrogen atom of DMBI would be introduced at the α-carbon of the product obtained via mechanism B and that found via mechanism C would carry at the β-position. Thus, in light of the forementioned observation that the reduction of azachalcone (**1**) with 2-deuterated DMBI leads to the corresponding saturated ketone (**2**) which contains one deuterium atom at the β-carbon, mechanisms A and C are both candidates for the initial hydride transfer shown in Scheme 5. In addition, the role of the Lewis acid in the present reduction can be well understood according to these mechanisms as follows. First, a Lewis acid activates the substrate as an electrophilic activator. Second, a Lewis acid stabilizes the resulting enolate anion **c** by coordination.

Experimental

Melting points were recorded on a Yanagimoto micro melting-point apparatus and are uncorrected. ^{1}H NMR spectra were measured with a JEOL PMX-60 spectrometer at 60 MHz using tetramethylsilane as an internal reference. IR spectra were recorded on a JASCO A-202 spectrophotometer. Mass spectra were obtained on a JMS-QH100 GC-Mass spectrometer. GLC analyses were carried out on a Shimadzu Gas Chromatograph GC-6AM equipped with a hydrogen flame ionization detector using glass columns (1.5 m) packed with 2% Silicone OV-7 on Uniport HP (60—80 mesh). The yields by quantitative GLC were measured on the same columns by internal standard method, using pentylbenzene as an internal standard. Silica gel (Wakogel C-300) was used for short column chromatography.

Materials. DMBI, mp 97.5—98.5 °C (lit,[11] 96 °C) was prepared from 2-phenylbenzimidazole by the slight modification of the method of Craig et al.[12] DMBI-2-*d*, mp 97—98 °C was prepared by the reduction of 2-phenylbenzimidazolium iodide with $LiAlD_4$ according to the same procedure, that was fully deuterated material by ^{1}H NMR; no azomethine proton absorption was detected. MBT, mp 113—114.5 °C (lit,[13] 112—113 °C), and MBO, bp 151—152 °C/3 mmHg (lit,[14] 146—149 °C/2 mmHg (1 mmHg= 133.322 Pa)) were prepared according to the literature procedures.[13,14] Commercially available $AlCl_3$, $FeCl_3$, $SnCl_4$, and $ZnCl_2$ were used without purification. Acetonitrile was distilled three times on phosphorus pentaoxide before use. Mesityl oxide, β-ionone, isophorone, methyl cinnamate, and cinnamaldehyde were commercially supplied and purified by distillation. The following derivatives were prepared according to the literature and identified by spectroscopic (NMR and IR) methods: benzylideneacetone, bp, 110—112 °C/4.5 mmHg; mp 40—42 °C (lit,[15] bp 123—128 °C/8 mmHg; mp 40—42 °C); benzylideneacetophenone, mp 55—57 °C (lit,[16] 55—57 °C); (*E*)-1,2-dibenzoylethylene, mp 109—110 °C (lit,[17] 109—110 °C); (*E*)-3-methyl-4-phenyl-3-buten-2-one, bp 91 °C/2 mmHg (lit,[18] 80—93 °C/1 mmHg); 4a-methyl-4,4a,5,6,7,8-hexahydronaphthalen-2(3*H*)-one, bp 109—111 °C/1 mmHg (lit,[19] 112—115 °C/5 mmHg); 2-methyl-2-cyclohexen-1-one, bp 64.5—65.5 °C/16 mmHg (lit,[20] 83—85.5 °C/35 mmHg); 2-cinnamoylpyridine, mp 71—72 °C (lit,[21] 71—72 °C).

General Procedure for the Conjugate Reduction of α,β-Unsaturated Carbonyl Compounds with DMBI. A solution of an unsaturated carbonyl compound (1.0 mmol) in dry acetonitrile (2 ml) and $AlCl_3$ (0.16 g, 1.2 mmol) were mixed in a glass tube under ice-water cooling. After the $AlCl_3$ was completely dissolved, DMBI (0.27 g, 1.2 mmol) was added and the mixture was degassed several times in vacuo. The tube was sealed in vacuo and kept at 80 °C for the appropriate time (see Tables). After 0.1 M HCl (2 ml (1 M= 1 mol dm^{-3})) was added to the mixture in the tube under ice-water cooling, the aqueous mixture was extracted with chloroform. The chloroform extract was washed thoroughly with water and the organic layer was analyzed by quantitative GLC. The results are given in Tables. An identification of the products isolated by short-column chromatography on silica gel was performed by spectroscopic (NMR, IR, and MS) methods. These spectral data were in satisfactory agreement with those of the corresponding authentic samples or expected values.

In a large-scale synthesis, the reaction could be carried out in a three-necked flask under nitrogen and the same reaction conditions. After a workup, as previously described, the products could be isolated by distillation or short-column chromatography on silica gel.

Reduction of 2-Cinnamoylpyridine (1). A solution of azachalcone (1) (0.10 g, 0.5 mmol) in dry acetonitrile (1 ml) and $AlCl_3$ (0.08 g, 0.6 mmol) were mixed in a glass tube under ice-water cooling. After the $AlCl_3$ was completely dissolved, DMBI (0.13 g, 0.6 mmol) was added and the mixture was degassed several times in vacuo. The tube was sealed in vacuo and kept at 60 °C for 1 h. After water (1 ml) had been added to the mixture in the tube under ice-water cooling, the aqueous mixture was extracted with chloroform. The chloroform extract was thoroughly washed with water and dried with anhydrous Na_2SO_4. The oily residue obtained by evaporation of solvent was subjected to short column chromatography on silica gel to give 1-(2-pyridyl)-3-phenyl-1-propanone (73 mg, 69%), ^{1}H NMR ($CDCl_3$) δ=2.93 (t, 2H, β-CH_2), 3.43 (t, 2H, α-CH_2), 7.04 (s, 5H, Ph), and 7.17—8.42 (m, 4H, C_5H_4N); MS *m/z* 211 (M^+).

Azachalcone (1) (0.10 g, 0.5 mmol) was similarly reduced with DMBI-2-*d* (0.14 g, 0.6 mmol). The chromatographic purification of the crude product gave fully β-deuterated ketone (**2**) (81 mg, 76%), ^{1}H NMR ($CDCl_3$) δ=2.92 (t, 1H, β-CDH), 3.43 (d, 2H, α-CH_2), 7.04 (s, 5H, Ph), and 7.17—8.42 (m, 4H, C_5H_4N); MS *m/z* 212 (M^+).

Azachalcone (**1**) (0.10 g, 0.5 mmol) was similarly reduced with DMBI (0.13 g, 0.6 mmol). After quenching with D_2O (2 ml) under ice-water cooling, the aqueous mixture was extracted with chloroform and dried with anhydrous Na_2SO_4. Chromatographic purification of the crude product gave the fully α-deuterated ketone (**3**) (69 mg, 65%), ^{1}H NMR ($CDCl_3$) δ=2.92 (br, 2H, β-CH_2), 3.39 (t, 1H, α-CDH), 7.04 (s, 5H, Ph), and 7.17—8.42 (m, 4H, C_5H_4N); MS *m/z* 212 (M^+).

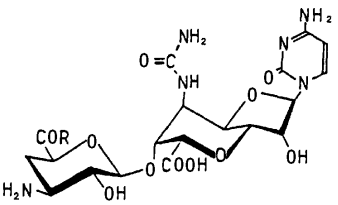
(Received January 7, 1986)

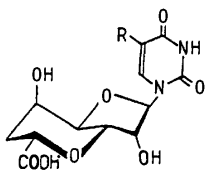
Ezomycins were discovered in a fermentation beer of Streptomyces species as antibiotics, which consisted of aminoocturonic acid, aminoglucuronic acid and base. As a part of a total synthesis of ezomycins, the title compounds have been synthesized. A KF-catalyzed Henry reaction between a nitropentose and a glyceraldehyde derivative gave a nitro alcohols mixture. Hydrogenation of the intact mixture, followed by *N*-acetylation afforded three diastereomers. The absolute configurations of the newly-introduced chiral centers were established by chemical methods and a X-ray crystal structure analysis.

Nucleoside antibiotic ezomycins were found in a fermentation broth of a strain which was very similar to Streptomyces Kitazawaensis.[1] The antibiotics exhibit antimicrobial activity against limited species of phytopathogenic fungi, such as Sclerotinia and Botritis. The molecular structures were established by a degradation study and a spectroscopic analysis.[2-4] A higher-carbon carbohydrate involved in ezomycins A_1, A_2, B_1, B_2, C_1, and C_2 is 5-amino-3,7-anhydro-5-deoxyocturonic acid, in which a furanoid ring is trans-



Ezomycin A_1 R = $NHCHCH_2CH_2SCH_2CHNH_2$ (COOH, COOH)

A_2 R = OH



Octosyl acids A_1 R = COOH

A_2 R = CH_2OH

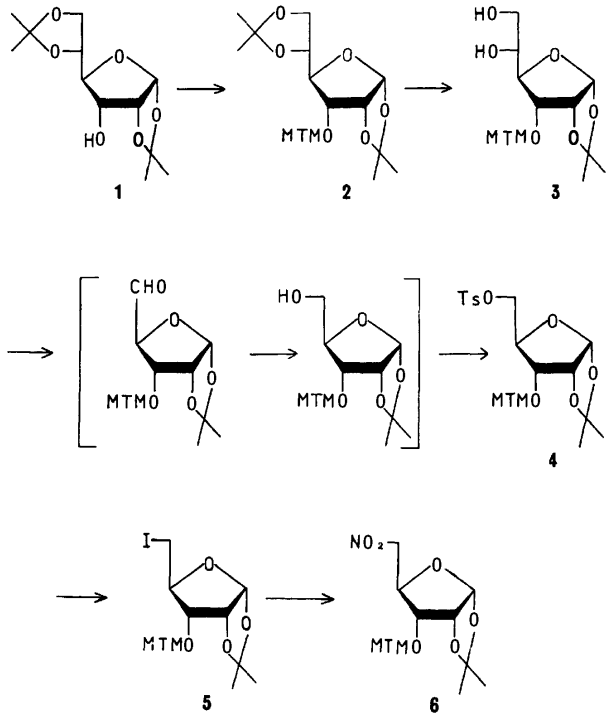
Scheme 1.

fused to a pyranoid ring. This particularly interesting structure was also found in antibiotic octosyl acids.[5] Several synthetic studies toward 3,7-anhydrooctose have been reported.[6-8] However, no derivatives with full function have been synthesized. Now, we have attempted to synthesize 5-amino-5-deoxyoctofuranose as a first step of the synthesis of ezomycins.

In a preceding paper,[9] a generally-applicable facile synthesis of higher-carbon carbohydrates has been developed by a KF-catalyzed Henry reaction between a nitro sugar and a sugar aldehyde, which is applied for the synthesis of 5-amino-5-deoxyoctofuranose-(1,4) derivatives in the present study.

Results and Discussion

In the KF-catalyzed Henry reaction, 5-deoxy-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-5-nitro-α-D-ribofuranose (**6**) was used as a nitro component and 2,3-*O*-isopropylidene-L-glyceraldehyde (**8**) was used as an aldehyde component. Compound **6** was prepared from known 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose[10] (**1**) by a **7** steps-reaction. Protection of 3-OH with chloromethyl methyl sulfide and sodium hydride in dioxane gave methylthiomethyl (MTM) ether (**2**) in 62%

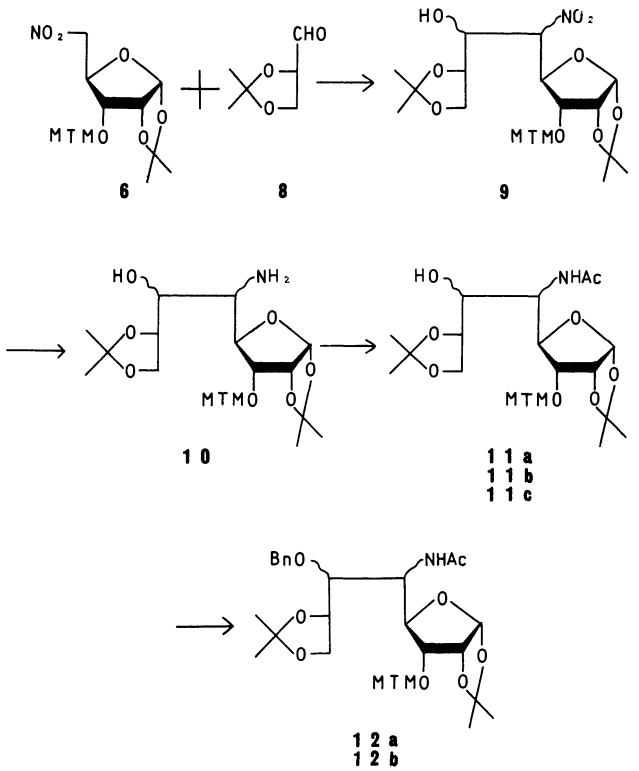


MTM: $-CH_2SCH_3$

Scheme 2.

yield. A selective removal of the 5,6-*O*-isopropylidene group by hydrolysis of **2** in aqueous acetic acid afforded the glycol (**3**) in 92% yield. Oxidative cleavage of the 5,6-diol with sodium periodate and successive reduction with sodium borohydride, followed by tosylation with *p*-toluenesulfonyl chloride in pyridine gave the tosylate (**4**) in 79% yield. Displacement of **4** with sodium iodide in 2-butanone afforded the iodide (**5**) in 94% yield. Replacement of **5** with sodium nitrite in dimethyl sulfoxide (DMSO) yielded the nitro compound (**6**) in 54% yield. On the other hand, the aldehyde **8** was prepared by a modified method of a known procedure.[11]

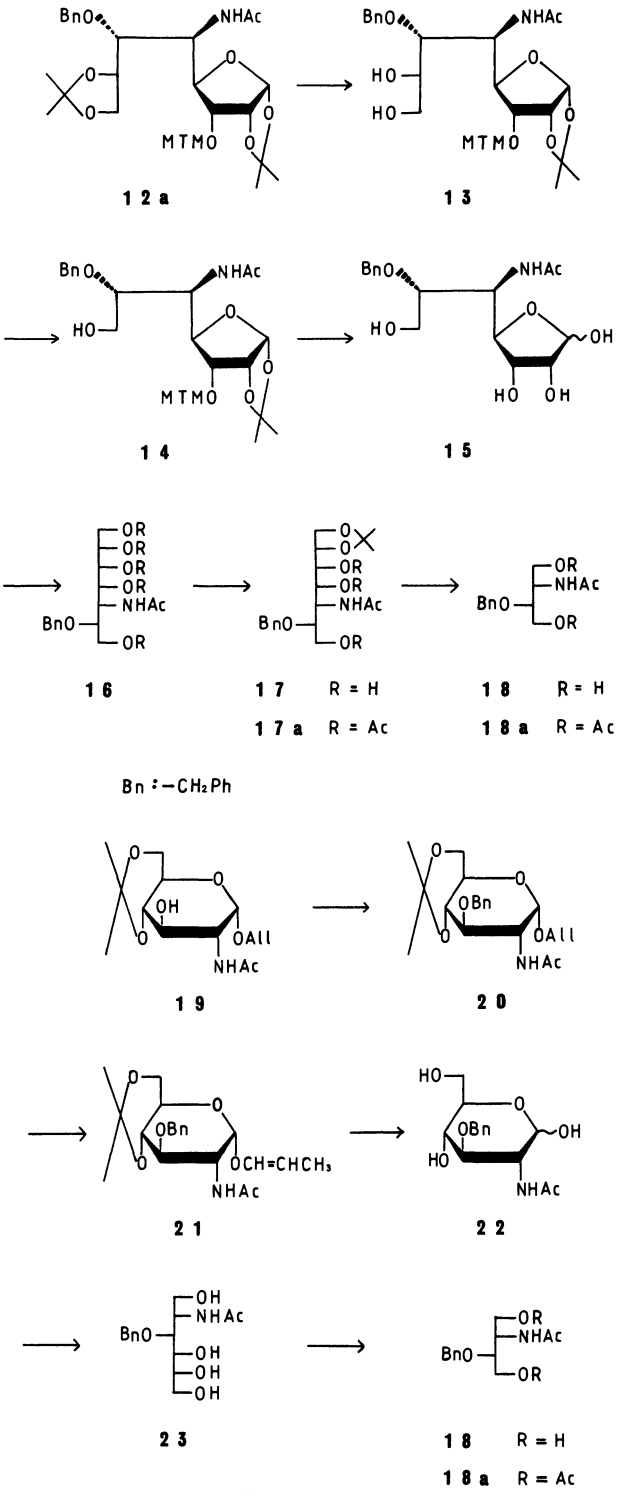
The Henry reaction of **6** and **8** was carried out in a toluene solution under the presence of KF and tetrabutylammonium iodide to give 5-deoxy-5-nitrooctose (**9**) as a mixture of diastereomers. Catalytic hydrogenation of the intact mixture **9** in the presence of Raney Ni, followed by *N*-acetylation afforded a mixture of three 5-acetamido-5-deoxyoctofuranoses (**11a**, **11b**, and **11c**). Compound **11c** was isolated in a homogeneous state by silica-gel chromatography in a poor yield of 5%. Compound **11b** was obtained by repeated fractional



Scheme 3.

recrystallization. But the major product **11a** was contaminated with **11b** which showed the same chromatographic behavior in several solvent systems. *O*-Benzylation of a mixture (67% from **6**) of **11a** and **11b** with benzyl bromide and sodium hydride in *N*,*N*-dimethylformamide (DMF) gave the corresponding benzyl ethers (**12a** and **12b**), which were readily isolated in homogeneous states by silica-gel chromatography in 49 and 30% yield, respectively.

A stereochemistry of the newly-introduced chiral centers on C-5 and C-6 of the major product **12a** was established by converting **12a** to 2-acetamido-3-*O*-benzyl-2-deoxy-L-threitol (**18**) as follows. Hydrolysis of **12a** with aqueous acetic acid resulted in a preferential removal of the 7,8-*O*-isopropylidene group giving a diol (**13**). Oxidative cleavage of **13** with sodium

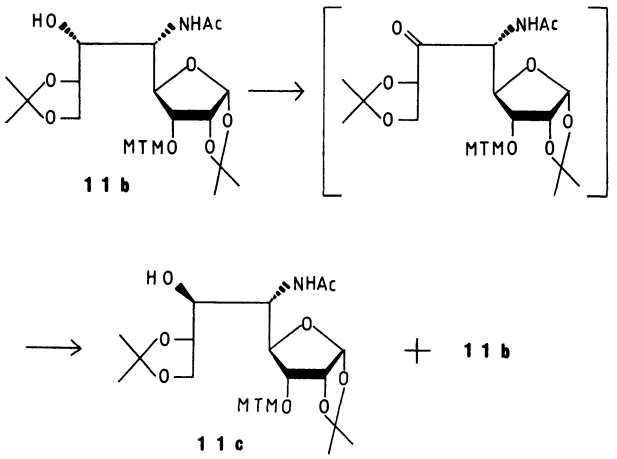


Scheme 4.

periodate and successive reduction with sodium borohydride afforded a heptose derivative (**14**). Removal of protective groups of **14** with aqueous trifluoroacetic acid gave a heptose derivative (**15**). Reduction of **15** with sodium borohydride afforded a heptitol derivative (**16**). Partial protection of **16** with 2-methoxypropene in the presence of *p*-toluenesulfonic acid yielded 1,2-*O*-isopropylidene derivative (**17**). Oxidative cleavage of **17** with sodium periodate and subsequent reduction with sodium borohydride afforded a C_4-alditol (**18**). Compound **18** was found to be identical with an authentic sample prepared as follows. *O*-Benzylation of allyl 2-acetamido-2-deoxy-4,6-*O*-isopropylidene-α-D-glucopyranoside[12] (**19**) with benzyl bromide and sodium hydride gave benzyl ether (**20**). Isomerization of the allyl group of **20** with Wilkinson's catalyst[13] afforded 1-propenyl ether (**21**). Hydrolysis of **21** with diluted hydrochloric acid resulted in a removal of the 1-propenyl and 4,6-*O*-isopropylidene groups giving **22**. Reduction of **22** with sodium borohydride yielded a hexitol (**23**). Oxidative cleavage of **23** with sodium periodate and successive reduction with sodium borohydride afforded the same C_4-alditol (**18**). Therefore, the absolute configurations on C-5 and C-6 were established as *R*-configurations. Consequently, **12a** has the same configurations on C-5 and C-6 as those of ezomycins.

A stereochemistry of **11b** was established by means of X-ray crystal structure analysis. Figure 1 shows a perspective drawing of **11b**. The absolute configurations on C-5 and C-6 are S and R, respectively. The torsion angle of both C(4)–C(5)–C(6)–C(7) and N–C(5)–C(6)–O(4) are almost 180°. Interatomic distance O(4)···O(5)($x-1/2$, $-y+3/2$, $-z+1$) is 2.722(7), suggesting an existence of an O(4)–H(04)···O(5) hydrogen bond.

The configurations of **11c** were determined by a fact that **11c** was derived from **11b** by oxidation with DMSO



Scheme 5.

and dicyclohexylcarbodiimide (DCC) and successive reduction with sodium borohydride. That is, **11c** was an epimer of **11b** at C-6. Therefore, *S*-configurations were established on C-5 and C-6.

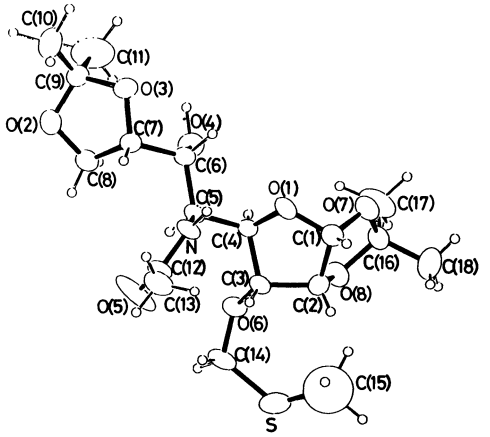


Fig. 1.

In the present case, the KF-catalyzed reaction between **6** and **8** seems to proceed without any predominant stereoselectivity.

Experimental

Melting points were determined on a Büchi 510 capillary melting point apparatus and are uncorrected. Optical rotations were measured with a Jasco DIP-4 polarimeter. IR spectra were recorded on a Hitachi 225 spectrometer. ^{1}H NMR spectra were recorded on a Varian EM-390 (90 MHz) spectrometer with a reference to tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi M-80 or a Hitachi M-80A mass spectrometer. Solutions were dried over anhydrous sodium sulfate and concentrated below 45 °C. TLC was carried out on glass plates coated with Merck Kieselgel 60 F_{254}, and compounds were detected by spraying with a H_2SO_4 followed by heating. Chromatography was performed on a silica-gel (Merck Kieselgel 60 Art. 7734) column.

1,2:5,6-Di-*O*-isopropylidene-3-*O*-methylthiomethyl-α-D-allofuranose (2). To a stirred solution of **1** (20.0 g) in anhydrous dioxane (200 ml), sodium hydride (60% dispersion in mineral oil, 10.0 g) and chloromethyl methyl sulfide (10.0 ml) were added under ice cooling and the mixture was stirred overnight at room temperature. After addition of methanol, the reaction solution was concentrated and the residue was dissolved in ethyl acetate. The solution was washed with water repeatedly, dried and concentrated to dryness. The oily residue was chromatographed (5:1 (v/v) toluene–ethyl acetate) to give crystals. Recrystallization from hexane afforded 16.0 g (62%) of **2**: R_f=0.27 on TLC (5:1 (v/v) toluene–ethyl acetate); mp 58—60 °C; $[\alpha]_D^{23}$ +123° (*c* 0.8, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ=1.37, 1.43, 1.55 (total 12H, s×3, CMe_2×2), 2.17 (3H, s, SMe), 4.77 (2H, s, CH_2S), 5.75 (1H, d, *J*=4 Hz, H-1).

Found: C, 52.52; H, 7.45; S, 9.90%. Calcd for $C_{14}H_{24}O_6S$: C, 52.48; H, 7.55; S, 10.01%.

1,2-*O*-Isopropylidene-3-*O*-methylthiomethyl-α-D-allofuranose (3). Compound **2** (6.7 g) was dissolved in 80% aqueous acetic acid (100 ml) and the solution was allowed to stand overnight at room temperature. The solution was coevaporated with toluene and the residue was chromatographed (1:2 (v/v) toluene–ethyl acetate) to give 5.4 g (92%) of **3** as a colorless syrup: R_f=0.41 on TLC (ethyl acetate); $[\alpha]_D^{25}$ +198° (*c* 1.0, $CHCl_3$); IR ($CHCl_3$) 3550 cm^{-1} (OH); ^{1}H NMR ($CDCl_3$)

δ=1.33, 1.57 (total 6H, s×2, CMe_2), 2.20 (3H, s, SMe), 4.77 (2H, s, CH_2S), 5.78 (1H, d, J=4 Hz, H-1).

Found: C, 46.87; H, 6.97; S, 11.40%. Calcd for $C_{11}H_{20}O_6S$: C, 47.13; H, 7.19; S, 11.44%.

1,2-*O*-Isopropylidene-3-*O*-methylthiomethyl-5-*O*-*p*-tolylsulfonyl-α-D-ribofuranose (4). An aqueous solution (560 ml) of sodium periodate (44.9 g) was added dropwise to an aqueous solution (560 ml) of **3** (56.0 g) under ice cooling. After 20 min, sodium borohydride (10.6 g) was added to the solution and the mixture was stirred for 20 min under ice cooling. The mixture was extracted with chloroform and the organic layer was dried and concentrated to dryness. To a solution of the residue in dry pyridine (300 ml) was added *p*-toluenesulfonyl chloride (45.7 g). After 12 h at room temperature, the mixture was concentrated and the residue was partitioned between saturated aqueous sodium hydrogencarbonate and ethyl acetate. The organic layer was washed twice with water, dried and concentrated to dryness. The residue was recrystallized from cyclohexane to afford 63.6 g (79%) of **4**: R_f=0.32 on TLC (5:1 (v/v) toluene–ethyl acetate); mp 80—81 °C; $[\alpha]_D^{23}$ +99° (c 1.4, $CHCl_3$); IR (KBr) 1360 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=1.33, 1.57 (total 6H, s×2, CMe_2), 2.13 (3H, s, SMe), 2.50 (3H, s, $SO_2C_6H_4Me$), 4.73 (2H, s, CH_2S), 5.67 (1H, d, J=4 Hz, H-1), 7.38 (2H, d, J=9 Hz, C_6H_4), 7.85 (2H, d, J=9 Hz, C_6H_4).

Found: C, 50.51; H, 5.95; S, 15.57%. Calcd for $C_{17}H_{24}O_7S_2$: C, 50.48; H, 5.95; S, 15.85%.

5-Deoxy-5-iodo-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-α-D-ribofuranose (5). To a solution of **4** (45.1 g) in 2-butanone (450 ml) was added sodium iodide (58.5 g) and the mixture was heated for 2 h under reflux. The solution was concentrated and the residue was partitioned between water and ethyl acetate. The organic layer was washed twice with water, dried and concentrated to dryness to give 37.7 g (93.9%) of **5** as an almost homogeneous syrup: R_f=0.55 on TLC (5:1 (v/v) toluene–ethyl acetate); ^1H NMR ($CDCl_3$) δ=1.37, 1.57 (total 6H, s×2, CMe_2), 2.20 (3H, s, SMe), 4.73 (2H, s, CH_2S), 5.80 (1H, d, J=4 Hz, H-1).

The product was used in the next step without any purification.

5-Deoxy-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-5-nitro-α-D-ribofuranose (6). To a solution of **5** (37.7 g) in DMSO (370 ml) were added phloroglucinol monohydrate (28.9 g) and sodium nitrite (14.5 g). After stirring for 4 d at ambient temperature, the mixture was poured into water and extracted with ethyl acetate. The organic layer was washed with water repeatedly, dried and concentrated to dryness. The residue was chromatographed (10:1 (v/v) toluene–ethyl acetate) to yield crystalline solids. Recrystallization from cyclohexane–toluene (2:1 v/v) afforded 15.8 g (54.2%) of **6**: R_f=0.36 on TLC (5:1 (v/v) toluene–ethyl acetate); mp 89—90 °C; $[\alpha]_D^{25}$ +167° (c 1.5, $CHCl_3$); IR (KBr) 1560, 1380 cm^{-1} (NO_2); ^1H NMR ($CDCl_3$) δ=1.37, 1.57 (total 6H, s×2, CMe_2), 2.17 (3H, s, SMe), 4.78 (2H, s, CH_2S), 5.80 (1H, d, J=4 Hz, H-1).

Found: C, 43.14; H, 6.09; N, 5.10; S, 11.61%. Calcd for $C_{10}H_{17}NO_6S$: C, 43.00; H, 6.13; N, 5.01; S, 11.48%.

2,3-*O*-Isopropylidene-L-glyceraldehyde (8). To an ice-cooled solution of 4,5-*O*-isopropylidene-L-arabinose diethyl thioacetal[14] (**7**, 10.0 g) in ethyl acetate (100 ml) was added lead tetraacetate (20.0 g) and the mixture was vigorously stirred for 5 min. To the mixture was added sodium carbonate (30 g) and the mixture was vigorously stirred for 2 h under ice cooling. After the salts were filtered off, the filtrate was concentrated to give a pale yellow syrup. It was rapidly chromatographed (3:2 (v/v) hexane–ethyl acetate) to afford 3.1 g (70%) of **8** as a colorless syrup: $[\alpha]_D^{29}$ −48.9° (c 1.02, C_6H_6) (lit,[15] $[\alpha]_D^{22}$ −67.9° (C_6H_6)). The IR and ^1H NMR spectra were superimposable on those of D-isomer, prepared by oxidative cleavage of 1,2:5,6-di-*O*-isopropylidene-D-mannitol.

The product was used in the successive reaction without further purification.

5-Acetamido-5-deoxy-1,2:7,8-di-*O*-isopropylidene-3-*O*-methylthiomethyl-β-L-erythro-L-talooctofuranose-(1,4) (11b) and 5-Acetamido-5-deoxy-1,2:7,8-di-*O*-isopropylidene-3-*O*-methylthiomethyl-β-L-threo-L-talooctofuranose-(1,4) (11c). To a solution of **6** (1.0 g) in toluene (3 ml) were added **8** (0.75 g), anhydrous potassium fluoride (0.25 g) and tetrabutylammonium iodide (0.75 g). The total mixture was stirred for 2 h 30 min at room temperature. The mixture was diluted with ethyl acetate, washed with water repeatedly, dried and concentrated to dryness. The residue was dissolved in a mixture of ethyl acetate (20 ml) and acetic acid (1 ml), and hydrogenated in the presence of Raney Nickel T-4[16] (ca. 2.5 g) under a pressure of 5.5 kg cm^{-2} for 20 h. After the catalyst was filtered off, the filtrate was added with sodium carbonate (5 g) and the mixture was stirred for 1 h at room temperature. The precipitates were filtered off, and the filtrate was concentrated to give a syrup. The residue was dissolved in a mixture of methanol (20 ml) and acetic anhydride (1 ml), and the mixture was allowed to stand for 10 min at room temperature. Coevaporation with toluene gave a syrup, which was chromatographed (ethyl acetate) to afford 1.01 g (67.0%) of a mixture of **11a** and **11b**, and 72 mg (4.7%) of **11c** as a colorless syrup. The mixture of **11a** and **11b** was dissolved in toluene (10 ml), and the solution was stored at −20 °C overnight. The crystals of **11b** were collected by filtration and washed with toluene. Recrystallization from toluene yielded an analytical sample. Furthermore, recrystallization from ethyl acetate–cyclohexane afforded nice single crystals for X-ray structure analysis.

11b: R_f=0.36 on TLC (ethyl acetate); mp 138—139 °C; $[\alpha]_D^{23}$ +25.9° (c 1.0, $CHCl_3$); IR (KBr) 1660 cm^{-1} (NHCO); ^1H NMR ($CDCl_3$) δ=1.33, 1.36, 1.42, 1.58 (total 12H, s×4, CMe_2×2), 2.04 (3H, s, NHAc), 2.18 (3H, s, SMe), 2.65 (1H, d, J=8 Hz, OH), 4.78 (2H, s, CH_2S), 5.72 (1H, d, J=4 Hz, H-1), 5.93 (1H, d, J=13 Hz, NH).

5-Acetamido-6-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-β-L-glycero-D-alloheptofuranose-(1,4) (14). To a stirred solution of **13** (103 mg) in 50% aqueous ethanol (2 ml) was added a solution of sodium periodate (49 mg) in 50% aqueous ethanol (2 ml) under ice cooling. After 60 min, the solution was diluted with water and extracted with dichloromethane repeatedly. The combined extract was dried and concentrated to dryness. The residue was dissolved in 50% aqueous ethanol (3 ml). To the stirred solution was added sodium borohydride (17 mg) under ice cooling. After 30 min, the reaction mixture was diluted with water and extracted with dichloromethane repeatedly. The extract was dried and concentrated to dryness. The residue was chromatographed (1:1 (v/v) toluene–ethyl acetate) to give 84 mg (87%) of **14** as crystals: R_f=0.44 on TLC (ethyl acetate); mp 148—150 °C; $[\alpha]_D^{26}$ +37.2° (*c* 1.02, $CHCl_3$); IR (KBr) 1665 cm^{-1} (NHCO); ^1H NMR ($CDCl_3$) δ=1.35, 1.55 (total 6H, s×2, CMe_2), 1.97 (3H, s, NHAc), 2.16 (3H, s, SMe), 5.77 (1H, d, *J*=4 Hz, H-1), 5.89 (1H, d, *J*=8 Hz, NH), 7.34 (5H, s, Ph).

5-Acetamido-6-*O*-benzyl-5-deoxy-L-glycero-D-alloheptose (15). Compound **14** (83 mg) was dissolved in 90% aqueous trifluoroacetic acid (1.7 ml), and the solution was allowed to stand for 55 min under ice cooling. The reaction solution was concentrated to dryness, and the residue was chromatographed (10:1 (v/v) dichloromethane–methanol) rapidly to afford 58 mg (90%) of **15** as an amorphous solid. The compound was unstable and was not characterized.

3-Acetamido-2-*O*-benzyl-3-deoxy-L-glycero-L-altroheptitol (16). To an ice-cooled solution of **15** (70 mg) in 50% aqueous ethanol (4 ml) was added sodium borohydride (62 mg), and the solution was stirred for 2 h under ice cooling. After deionized with Amberlite IR-120 (H^+), the solution was concentrated to dryness. The residue was chromatographed (8:1 (v/v) dichloromethane–methanol) to yield 54 mg (78%) of **16** as a pale yellow syrup: R_f=0.44 on TLC (5:1 (v/v) dichloromethane–methanol); $[\alpha]_D^{30}$ −36.7° (*c* 1.25, MeOH); IR (neat) 1645 cm^{-1} (NHCO); ^1H NMR (CD_3OD) δ=1.99 (3H, s, NHAc), 7.32 (5H, bs, Ph).

Found: M+H, 344. Calcd for $C_{16}H_{26}NO_7$: *m/z*, 344.

3-Acetamido-1,4,5-tri-*O*-acetyl-2-*O*-benzyl-3-deoxy-6,7-*O*-isopropylidene-L-glycero-L-altroheptitol (17a). To a stirred solution of **16** (146 mg) in anhydrous DMF (2 ml) were added 2-methoxypropene (0.24 ml) and *p*-toluenesulfonic acid monohydrate (7 mg). After 5 h at room temperature, the solution was added with dry pyridine (6 ml) and acetic anhydride (6 ml) under ice cooling. After 1 h 45 min at room temperature, the solution was concentrated to dryness. The residue was dissolved in ethyl acetate, and the solution was washed three times with water. The organic layer was dried and concentrated to dryness. The residue was chromatographed (3:2 (v/v) toluene–ethyl acetate) to give 64 mg (30%) of **17a** as a colorless syrup: R_f=0.65 on TLC (ethyl acetate); $[\alpha]_D^{28}$ −27.6° (*c* 0.98, $CHCl_3$); IR ($CHCl_3$) 1735 (OAc), 1675 (NHCO) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.35 (6H, s, CMe_2), 2.00 (3H, s, NHAc), 2.04, 2.07 (total 9H, s×2, OAc×3), 6.36 (1H, d, *J*=10 Hz, NH), 7.33 (5H, s, Ph).

Found: M+H, 510. Calcd for $C_{25}H_{36}NO_{10}$: *m/z*, 510.

5-Acetamido-6-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-L-glycero-D-alloheptitol (17). Compound **17a** (64 mg) was dissolved in ice-cooled 0.1 M methanolic sodium methoxide (2 ml (1 M=1 mol dm^{-3})). After 45 min under ice cooling, the solution was deionized with Amberlite IR-120 (H^+) and concentrated to dryness. The residue was chromatographed (1:8 (v/v) toluene–ethyl acetate) to afford 40 mg (83%) of **17** as a colorless syrup: R_f=0.16 on TLC (ethyl acetate); $[\alpha]_D^{29}$ −20.2° (*c* 1.98, $CHCl_3$); IR ($CHCl_3$) 1655 cm^{-1} (NHCO); ^1H NMR ($CDCl_3$) δ=1.34, 1.40 (total 6H, s×2, CMe_2), 2.00 (3H, s, NHAc), 6.41 (1H, d, *J*=9 Hz, NH), 7.34 (5H, s, Ph).

Found: M+H, 384. Calcd for $C_{19}H_{30}NO_7$: *m/z*, 384.

Allyl 2-Acetamido-3-*O*-benzyl-2-deoxy-4,6-*O*-isopropylidene-α-D-glucopyranoside (20). To a stirred solution of **19** (2.91 g) in anhydrous DMF (30 ml) were added benzyl bromide (1.35 ml) and sodium hydride (580 mg) under ice cooling. After 1 h under ice cooling, the solution was partitioned between water and ethyl acetate. The organic layer was washed twice with water, dried and concentrated to dryness. The residue was chromatographed (2:1 (v/v) toluene–ethyl acetate) to give 3.01 g (79.6%) of **20** as an amorphous solid: R_f=0.31 on TLC (1:1 (v/v) toluene–ethyl acetate); $[\alpha]_D^{20}$ +107° (*c* 0.62, $CHCl_3$); IR (KBr) 3290 (NH), 1640 (NHCO) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.42, 1.48 (total 6H, s×2, CMe_2), 1.89 (3H, s, NHAc), 5.47 (1H, d, *J*=8 Hz, NH), 5.72 (1H, m, $CH_2\underline{CH}{=}CH_2$), 7.32 (5H, m, Ph).

Found: M+H, 392. Calcd for $C_{21}H_{30}NO_6$: *m/z*, 392.

1-Propenyl 2-Acetamido-3-*O*-benzyl-2-deoxy-4,6-*O*-isopropylidene-α-D-glucopyranoside (21). To a solution of

20 (81 mg) in 75% aqueous ethanol (1.6 ml) were added 1,4-diazabicyclo[2.2.2]octane (12mg) and chlorotris(triphenylphosphine) rhodium(I) (38 mg). After refluxing for 20 min, the reaction mixture was filtered to remove the catalyst. The filtrate was concentrated and the residue was chromatographed (3:1 (v/v) toluene–ethyl acetate) to yield 70 mg (86%) of **21** as a colorless syrup: R_f=0.38 on TLC (1:1 (v/v) toluene–ethyl acetate); $[\alpha]_D^{29}$+134° (*c* 3.49, $CHCl_3$); IR ($CHCl_3$) 1670 cm^{-1} (NHCO); ^1H NMR ($CDCl_3$) δ=1.42—1.69 (total 9H, CMe_2, CH=CHC$\underline{H}_3$), 1.87 (3H, s, NHAc), 4.58 (1H, d, *J*= 12 Hz, CH_2Ph), 4.83 (1H, d, *J*=12 Hz, CH_2Ph), 4.99 (1H, d, *J*=3 Hz, H-1), 7.32 (5H, s, Ph).

Found: M+H, 392. Calcd for $C_{21}H_{30}NO_6$: *m/z*, 392.

2-Acetamido-3-*O*-benzyl-2-deoxy-D-glucose (22). A solution of **21** (40 mg) in 0.2 M HCl in 70% aqueous dioxane (4 ml) was allowed to stand for 20 h at room temperature. After neutralized with silver carbonate, the reaction mixture was filtered to remove the precipitates and the filtrate was concentrated to dryness. The residue was chromatographed (5:1 (v/v) dichloromethane–methanol) to give 29 mg (91%) of **22**: R_f=0.43—0.51 on TLC (5:1 (v/v) dichloromethane–methanol; $[\alpha]_D^{30}$ +2.7° (*c* 1.43, H_2O); IR (KBr) 1645 cm^{-1} (NHCO); ^1H NMR (CD_3OD) δ=1.93 (3H, s, NHAc), 5.08 (1H, d, *J*=3 Hz, H-1), 7.34 (5H, bs, Ph).

Found: M+Na, 334. Calcd for $C_{15}H_{21}NO_6Na$: *m/z*, 334.

2-Acetamido-3-*O*-benzyl-2-deoxy-D-sorbitol (23). To a stirred solution of **22** (37 mg) in water (2 ml) was added sodium borohydride (46 mg). After 12 h, the solution was deionized with Amberlite IR-120 (H^+) and concentrated to dryness. The residue was chromatographed (5:1 (v/v) dichloromethane–methanol) to give 28 mg (75%) of **23** as crystals. Recrystallization from 2-propanol yielded an analytical sample: R_f=0.38 on TLC (5:1 (v/v) dichloromethane–methanol); mp 125—127 °C; $[\alpha]_D^{30}$ −16.5° (*c* 1.19, MeOH); IR (KBr) 1635 cm^{-1} (NHCO); ^1H NMR (CD_3OD) δ=1.94 (3H, s, NHAc), 7.42 (5H, bs, Ph).

Found: C, 57.73; H, 7.32; N, 4.18%. Calcd for $C_{15}H_{23}NO_6$: C, 57.50; H, 7.40; N, 4.47%.

2-Acetamido-1,4-di-*O*-acetyl-3-*O*-benzyl-2-deoxy-L-threitol (18a) and 2-Acetamido-3-*O*-benzyl-2-deoxy-L-threitol (18). (A) from 17: To a stirred solution of **17** (21 mg) in methanol (0.5 ml) was added a solution of sodium periodate (47 mg) in water (1.0 ml) under ice cooling. After 1 h 35 min, sodium borohydride (21 mg) was added to the reaction solution under ice cooling. After 35 min, the reaction mixture was deionized with Amberlite IR-120 (H^+). The resin was filtered off, and the filtrate was concentrated to dryness. The residue was dissolved in a mixture of dry pyridine (1 ml) and acetic anhydride (0.5 ml) and the solution was allowed to stand for 1 h 10 min at room temperature. Coevaporation with toluene gave a syrupy residue, which was chromatographed (1:1 (v/v) toluene–ethyl acetate) to yield 12 mg (66%) of **18a** as a syrup: R_f=0.44 on TLC (ethyl acetate); $[\alpha]_D^{30}$ +14.7° (*c* 0.72, $CHCl_3$); IR ($CHCl_3$) 1735 (OAc), 1670 (NHCO) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.98, 2.06 (total 9H, s×2, NHAc, OAc×2), 4.52 (1H, d, *J*=12 Hz, CH_2Ph), 4.74 (1H, d, *J*=12 Hz, CH_2Ph), 5.79 (1H, d, *J*=9 Hz, NH), 7.36 (5H, s, Ph).

Found: M+H, 338. Calcd for $C_{17}H_{24}NO_6$: *m/z*, 338.

Compound **18a** (11.4 mg) was dissolved in ice-cooled 0.1 M methanolic sodium methoxide (1 ml), and the solution was stirred for 1 h under ice cooling. The reaction mixture was deionized with Amberlite IR-120 (H^+). The resin was filtered off, and the filtrate was concentrated to dryness. The residue was chromatographed (20:1 (v/v) dichloromethane–methanol) to give 8.5 mg (99%) of **18** as crystals: R_f=0.48 on TLC (5:1 (v/v) dichloromethane–methanol); mp 133—135 °C; $[\alpha]_D^{27}$ −46.5° (*c* 0.76, MeOH); IR (KBr) 1655 cm^{-1} (NHCO); ^1H NMR (CD_3OD) δ=1.96 (3H, s, NHAc), 7.37 (5H, bs, Ph).

Found: M+H, 254.1366. Calcd for $C_{13}H_{20}NO_4$: *m/z*, 254.1390.

(B) from 23: To a stirred solution of **23** (28 mg) in water (1.5 ml) was added a solution of sodium periodate (96 mg) in water (1.5 ml) dropwise under ice cooling. After 2 h, the reaction solution was added with sodium borohydride (17 mg) under ice cooling. After 40 min, the reaction solution was deionized with Amberlite IR-120 (H^+). The resin was filtered off, and the filtrate was concentrated to dryness. The residue was dissolved in a mixture of dry pyridine (4 ml) and acetic anhydride (3 ml), and the mixture was allowed to stand overnight at room temperature. The solution was coevaporated with toluene to dryness to give a pale brown syrup. The residue was chromatographed (1:1 (v/v) toluene–ethyl acetate) to afford 27 mg (89%) of **18a** as a colorless syrup: $[\alpha]_D^{30}$+14.7° (*c* 1.25, $CHCl_3$). IR, ^1H NMR and MS spectra were superimposable on those of the product derived from **17**.

The product was deacylated by the same procedure described in the preparation (A) to yield **18** (quantitative yield): mp 134—135 °C; $[\alpha]_D^{28}$ −46.3° (*c* 1.91, MeOH). IR, ^1H NMR and MS spectra were superimposable on those of the product derived from **17**.

Treatment of 11b with DMSO–DCC Followed by Sodium Borohydride. To a stirred solution of **11b** (300 mg), toluene (0.1 ml), phosphoric acid (0.02 ml) and pyridine (0.04 ml) in DMSO (1.5 ml) was added DCC (440 mg). After 3 h at room temperature, to the mixture was added a solution of oxalic acid (250 mg) in methanol (1 ml) under ice cooling. After 30 min under ice cooling, the mixture was diluted with ethyl acetate and the insoluble materials were filtered off. The filtrate was washed with aqueous sodium hydrogencarbonate and water, and concentrated to dryness. The residue was dissolved in 50% aqueous ethanol (6 ml), and to the solution was added sodium borohydride (40 mg). After 30 min at room temperature, the reaction mixture was deionized with Amberlite IR-120 (H^+). The resin was filtered off, and the filtrate was concentrated to dryness. The residue was chromatographed (ethyl acetate) to give 86 mg (29%) of **11c** and 126 mg (42%) of **11b**.

X-Ray Crystal Structure Analysis of 11b. A crystal of 0.4×0.4×0.6 mm^3 was mounted on an automated Rigaku AFC-5 four-circle diffractometer. The cell dimensions were refined from 25 2θ values (60°<2θ<70°) with λ(Cu $K\alpha_1$)= 1.54056 Å. The crystal data are: $C_{18}H_{31}NO_8S$, FW 421.5; orthorhombic, space group $P2_12_12_1$, a=13.938(1), b=27.866(2), c=5.5524(5) Å, V=2156.5(3) $Å^3$, Z=4, D_m(benzene/tetrachloromethane)=1.29(1), D_x=1.30 $Mg\,m^{-3}$, μ=1.66 mm^{-1}. Intensity measurement was performed to 2θ=120° by θ—2θ scan technique with scan speed 6° min^{-1} (θ). 2523 reflections were measured and 2322 reflections were observed [$|F_o|>3\sigma(|F_o|)$]. Absorption correction was neglected. The structure was solved by direct methods,[17] and refined by block-diagonal least square.[18] The minimized function is $\sum w||F_o|-|F_c||^2$, where $w=[\sigma^2(|F_o|)+0.025|F_o|^2]^{-1}$. The position of a methyl C(15) atom bonded to S was difficult to be found on Fourier synthesis, suggesting positional disorder. Only one possible position of C(15) was found on difference

synthesis. However, its thermal parameter became greater than 20Å^2 when anisotropic thermal parameters were introduced. In the last three cycles of least square calculation, the anisotropic thermal parameters of the C(15) atom were refined with damping factor 0.1. The positional parameters for all the hydrogen atoms were calculated and refined with damping factor 0.1 because only four hydrogen atoms among 31 hydrogen atoms could be found on difference synthesis. Final R=0.108, wR=0.169, and S=6.2.[19] Rather large R value may be attributed to the positional disorder of the MTM group. Any molecules of mother liquor, ethyl acetate and cyclohexane, will not exist judging from its density and the difference synthesis. Complex neutral-atom scattering factors were taken from International Tables for X-ray Crystallography.[20] The final atomic parameters are listed in Table 1. The absolute structure was determined with reference to the known absolute configuration of D-glucose.[21]

The authors express their sincere thanks to Mr. Masayuki Ito, Meiji Seika Kaisha, Ltd., and Dr. Kinichi Tadano for the mass spectra and Mr. Saburo Nakada and Mr. Akio Takahashi for their elemental analyses.

Zeolite-Promoted Benzylation of Alcohols

Makoto ONAKA,* Motomitsu KAWAI, and Yusuke IZUMI
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received January 13, 1986)

Zeolite-promoted benzylation of alcohols with benzyl chloride has been investigated. By use of a series of cation-exchanged zeolites, which have the same crystalline structure but different acid and base properties, it is confirmed that the cooperative function of acid sites and base sites of zeolite is required for the effective benzylation of alcohols although both acid and base strengths are low. It is also found that alcohols show different reactivities in zeolite from those in solution depending on their molecular structures because the benzylation is promoted inside the narrow cavities of zeolite.

Recently heterogeneous organic reactions effected by inorganic porous solids or reagents adsorbed on those solids are attracting much attention to organic chemists because of attainment of high selectivity, mild reaction conditions, and simple operations.[1] However, what a role these porous solids play in promotion of organic reactions is still not completely elucidated.

Among inorganic porous solids we have been particularly concerned with zeolites and applied them to liquid-phase organic reactions.[2] The most remarkable feature of zeolites is that 1) zeolites have rigid and homogeneous crystalline structures (a definite pore size) and 2) acid-base properties of zeolites can be easily altered by exchange of cations in zeolite without any change of the crystalline structure.[3] We applied a series of cation-exchanged zeolites which have different acid and base properties with the same crystalline structure to benzylation of alcohols and investigated the influence of the zeolite properties on the benzylation. We have reported our preliminary results,[4] and this paper presents in detail our results of zeolite-promoted benzylation and a role of zeolite as an activator.

Results and Discussion

Benzylation of alcohols to benzyl ethers is one of familiar methods for protection of hydroxyl groups,[5] and is generally carried out by use of strong bases such as NaH[6] and KOH.[7] New benzylation methods under milder reaction conditions are required. Thus the application of inorganic porous solids to the benzylation of alcohols was examined.

$$ROH + PhCH_2Cl \longrightarrow ROCH_2Ph + HCl$$

The reaction of 1-decanol with an equimolar amount of benzyl chloride was chosen as a model reaction, and investigated in hexane in the presence of various types of inorganic solids such as alkali cation (M^+)-exchanged X and Y type zeolites (abbreviated as MX and MY, respectively) which have uniform cavities (about 13 Å in diameter),[3b] γ-alumina (neutral and basic) for column chromatography, and KF impregnated on γ-alumina (KF/Al_2O_3).[8] The results are summarized in Table 1.

Between the two types of zeolites, zeolite Y was more effective than zeolite X. Especially the use of potassium cation-exchanged Y type zeolite (KY) showed the highest yield (73%) and 23% of the starting alcohol was remained intact.

The zeolite acts not only as a promoter of the benzylation but also as a base which traps the hydrogen chloride evolved during the reaction.

Alumina (neutral and basic) and KF/Al_2O_3 also promoted the reaction. In these cases, however, dibenzyl ether was obtained as a by-product in 5—16% yields. Residual water on the alumina surface easily hydrolyzed benzyl chloride to benzyl alcohol which

Table 1. Benzylation of 1-Decanol with Benzyl Chloride[a]

Additive (Amount)	Yield/%[b]		Recovery/%[b]

a) Neutral alumina.

Table 5. Zeolite KY-Promoted Benzylation of Various Alcohols[a]

Alcohol	Yield/%[b]	Recovery/%[b]
	Benzyl ether	Unreacted alcohol
Benzyl alcohol	57	33
1-Decanol	73 (84)[c]	23 (15)[c]
1-Octanol	69	24
2-Octanol	51 (61)[d]	25 (15)[d]
4-Octanol	40 (30)[e]	22 (64)[e]

a) Reaction of an alcohol (1 mmol) with benzyl chloride (1 mmol) and zeolite KY (0.8 g) was carried out in hexane under reflux for 5 h. b) Determined by GLC using diphenylmethane as an internal standard. c) Benzyl chloride (1.5 mmol) was used. d) Benzyl chloride (2 mmol) was used. e) Reaction was carried out at r.t. for 100 h.

was in turn benzylated to produce dibenzyl ether. In contrast with alumina, residual water in the zeolites did not cause the side reaction (Table 1).

Bases such as powdered potassium carbonate and triethylamine could not induce the benzylation of 1-decanol in hexane.

In various solvents was studied the benzylation of 1-decanol with zeolite KY as shown in Table 2. Nonpolar solvents such as hexane and carbon tetrachloride were most suitable for the reaction. In benzene was produced diphenylmethane in 28% yield based on benzyl chloride in addition to the benzyl ether. The acid sites of zeolite KY were considered to cause the Friedel-Crafts reaction of benzene with benzyl chloride. When chlorobenzene was employed as a solvent instead of benzene, the Friedel-Crafts reaction was suppressed and the yield of benzyl decyl ether improved.

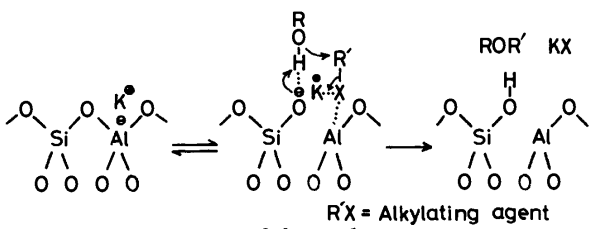
The use of relatively polar solvents like chloroform and tetrahydrofuran (THF) drastically retarded the reaction. THF is relatively basic and hence acid sites of zeolite were neutralized by THF.

It is assumed that the difference of effectiveness in the benzylation between the zeolites was ascribed to those of intrinsic acid and base properties of zeolites. Thus we examined acid and base properties of the zeolites and alumina, and related them to the results of benzylation of 1-decanol.

According to the reported method[9] we measured distribution of acid-base strength of the zeolites and the alumina which were employed in the present study by use of Hammett indicators, butylamine, and trichloroacetic acid.

In the zeolite Y series, the maximum acid strength was in the order of NaY>KY>CsY (Table 3), whereas the maximum base strength was in the order of CsY>KY>NaY (Table 4).

When the effectiveness of the zeolites as a promoter was judged in terms of the yield of benzyl ether, the order was KY>CsY>NaY, which was not consistent with the order of the maximum base strength of the zeolites. This result indicates that the benzylation is not promoted only by a base site of the zeolite, but the cooperative function of an acid site and a base site of the zeolite is necessary for the effective benzylation of alcohols although both acid and base strengths are relatively low. We assume that, in the transition state of benzylation, within a cavity of the zeolite two molecules of an alcohol and benzyl chloride are oriented such a way that nucleophilicity of a hydroxyl group of the alcohol can be enhanced by a base site and benzyl chloride can be activated by an acid site concertedly depicted below.



Scheme 1.

Table 6. Effects of Molecular Size of Alcohols on Benzylation

Alcohol	Method A[a]	Method B[b]
	Yield/%[c] (Relative yield)[e]	Yield/%[d] (Relative yield)[e]
1-Decanol	73 (1)	73 (1)
Benzyl alcohol	57 (0.78)	80 (1.10)
Cyclohexylmethanol	58 (0.79)	80 (1.10)
Neopentyl alcohol	53 (0.73)	77 (1.05)
1-Adamantylmethanol	15 (0.21)	80 (1.10)

a) Method A: Reaction of an alcohol (1 mmol) with benzyl chloride (1 mmol) and zeolite KY (0.8 g) was carried out in hexane under reflux for 5 h. b) Method B; Sodium alkoxide (20 mmol) which was prepared from an alcohol (20 mmol) and NaH (25 mmol) was treated with benzyl bromide (20 mmol) in THF under reflux for 5 h. c) Yield determined by GLC. d) Isolated yield. e) (Yield of corresponding benzyl ether of alcohol)/yield of benzyl decyl ether).

Neutral alumina was found to have analogous acid-base character to zeolite KY. The activity difference between the zeolite KY and the alumina may be attributed to the different mutual location of acid and base sites which is decisive to promote the reaction efficiently.

Table 5 shows the results of the benzylation of various alcohols. In comparison with primary alcohols, secondary alcohols were subject to dehydration and the yields of benzyl ethers decreased.

Zeolite Y consists of uniform cavities (13 Å in diameter) which incorporate various organic molecules and the external surface area of zeolite Y is only 0.5—1.3% of the total surface area.[3a] In Fig. 1 are shown adsorption isotherms for 1-decanol, cyclohexylmethanol, and 1-adamantylmethanol on zeolite KY in benzene at 30 °C. Bulky alcohols like 1-adamantylmethanol can be adsorbed in the zeolite. Hence in the present benzylation most of alcohols are considered to be adsorbed inside the cavities to undergo benzylation.

The molecular size of an alcohol and the steric bulkiness around a hydroxyl group of the alcohol are expected to influence the reaction rate of benzylation in zeolite. Thus the benzylation of five primary alcohols was studied by use of zeolite KY in comparison with the results obtained by a conventional method (the use of sodium hydride and benzyl bromide in THF) shown in Table 6. The steric hindrance around hydroxyl groups of the alcohols examined was estimated by use of the CPK molecular model in the following order: 1-decanol<benzyl alcohol<cyclohexylmethanol<neopentyl alcohol<1-adamantylmethanol. From the results of the conventional method it was confirmed that the five alcohols have almost the same reactivity in a solution. In the zeolite-promoted benzylation, however, it was observed that the reactivities of the alcohols decreased in the order of 1-decanol>benzyl alcohol≈cyclohexylmethanol≈neopentyl alcohol ≫1-adamantylmethanol. The adsorption isotherms for 1-decanol, cyclohexylmethanol, and 1-adamantylmethanol on zeolite KY in benzene in Fig. 1 show that the adsorption amount of cyclohexylmethanol is larger than those of 1-decanol and 1-adamantylmethanol. This fact means that the benzylation of alcohols inside the zeolite cavities is not governed by the ability of the alcohols to be adsorbed.

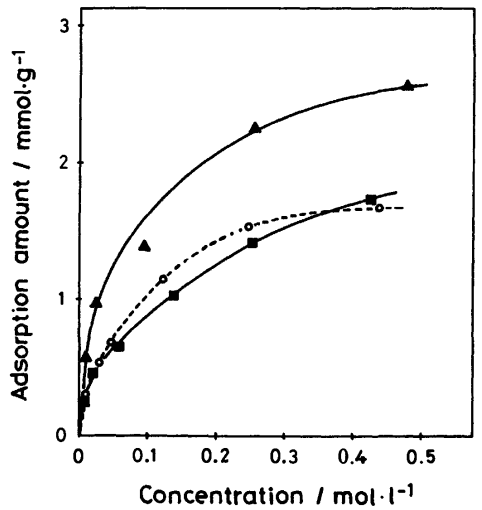


Fig. 1. Adsorption isotherms of alcohols on zeolite KY in benzene at 30 °C: 1-Decanol (○), Cyclohexylmethanol (▲), 1-Adamantylmethanol (■).

Table 7. Zeolite KY-Promoted Alkylation of 1-Octanol with Various Alkylating Agents[a]

R'X	Solvent	Yield of ether/%[b]
$PhCH_2Cl$	Hexane	69
$CH_2=CHCH_2Br$	CCl_4	58
n-$C_6H_{13}I$	Heptane	32
$CH_3OCH_2CH_2OCH_2Cl$	Hexane	0
CH_3SCH_2Cl	Hexane	0

a) Reaction of 1-octanol (1 mmol) with an alkylating agent (1 mmol) was carried out in solvent under reflux for 5 h. b) Isolated yield.

On the basis of the facts described above, we assume that the benzylation is greatly affected by whether the molecules of benzyl chloride and alcohol can be adequately arranged to the acid and base sites (Scheme 1) or not. Thus 1-adamantylmethanol may be too sterically hindered to be oriented in close proximity to a benzyl chloride molecule inside a cavity of zeolite.

In order to survey the limitations of reactions promoted by zeolite were investigated reactions of various

Table 8. Benzylation of Phenol[a)]

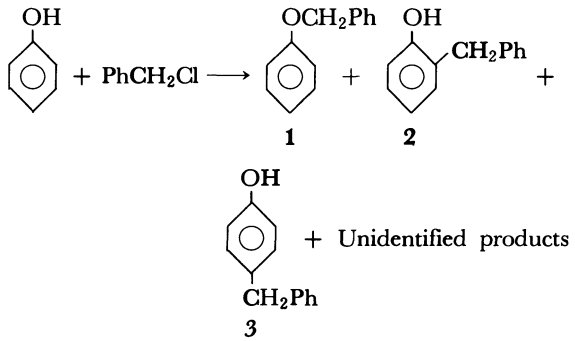
alkylating agents with alcohols and benzylations of phenolic hydroxyl groups and amino groups. In Table 7 are shown alkylations of alcohols by use of allyl bromide, hexyl iodide, 2-methoxyethoxymethyl chloride, and chloromethyl methyl sulfide.

Benzylation of phenol is expected to occur in two ways: *O*-benzylation and *C*-benzylation (Table 8).



CsY, which is more basic than KY, induced *O*-benzylation more preferably than *C*-benzylation although the yield was low. Interestingly, by use of neutral alumina, *C*-benzylation products were mainly obtained and benzyl phenyl ether was not produced.

Besides alcohols, amines and amides were successfully benzylated to give the corresponding monobenzylation products selectively by use of zeolite KY.

Experimental

Materials. Unless otherwise noted, reagents were all commercial ones and used without further purification. THF was dried over sodium benzophenone ketyl. Chlorobenzene was distilled over calcium hydride. Chloroform was passed through a column of neutral alumina. Other solvents were dried over molecular sieve 3A. Zeolite NaX (Union Showa Co.), zeolite NaY (a reference catalyst from the Catalysis Society of Japan: JRC-Z-Y4.8, SiO_2/Al_2O_3=4.8), alumina (neutral)(Woelm 200 neutral, activity super I), and alumina (basic)(Woelm 200 basic, activity super I) were used. Potassium ion-exchanged X and Y type zolites were prepared from NaX and NaY according to the ion exchange technique. Preparation of KY from NaY shown as a typical example is as follows: Powdered zeolite NaY (100 g) was immersed in an aqueous 0.5 M (1 M=1 mol dm^{-3}) KCl solution (1000 ml) at 70 °C for 3 h with occasional stirring, and the zeolite was filtered on a Buchner funnel. This procedure was repeated 10 times. The ion-exchanged zeolite was washed with deionized water until no chloride ion could be detected in the washings by use of $AgNO_3$, dried at 110 °C for 12 h, and kept in a desiccator. Cesium ion-exchanged zeolite Y (CsY) was prepared by treatment of KY with an aqueous CsCl solution in the similar manner to that described above. The content of cations in zeolites was determined by atomic absorption analysis: NaX (Na^+ 100%), KX (K^+ 93%, Na^+ 7%), NaY (Na^+ 100%), KY (K^+ 99%, Na^+ 1%), and CsY (Cs^+ 68%, K^+ 32%). Zeolite and alumina were dried again at 500 °C for 5 h prior to the use. The activities of the zeolites and the aluminas remained unchanged after a few weeks' storage in a desiccator.

The KF impregnated on Al_2O_3 (Merck 90 neutral, Art. 1077) reagent was prepared according to the method reported by Ando et al.[8)]

All zeolites and aluminas were handled in the atmosphere as quickly as possible.

Analysis. GLC analyses were performed by a Shimadzu GC-8A gas chromatograph with columns (10% Silicone SE30 (Uniport B), 25% Silicone DC550 (Uniport B), and 10% PEG20M (Uniport B)), a flame ionization detector and a System Instruments 5000E integrator.

All the reaction products were identified as being identical with authentic samples. Yields of the products and recoveries of the starting materials were determined by GLC using internal standards unless otherwise mentioned.

Reaction Procedure. Use of Zeolite and Alumina: In a flask were placed zeolite (0.8 g)(or alumina (1.2 g)) and solvent (2 ml) under nitrogen. To the flask was added a solution of an alcohol (1 mmol) and an alkylating agent (1 mmol) in solvent (3 ml), and the suspended mixture was allowed to be stirred under the conditions shown in Tables. As work-up, water (3 ml) was added, and the resulting mixture was heated under reflux for 0.5 h. This work-up procedure is necessary in order to extract organic products in the zeolite completely. After the mixture was cooled, the zeolite was filtered off and organic products were extracted with ethyl acetate from the filtrate. The extract was dried over sodium sulfate, filtered and analyzed.

Use of NaH: To a suspension of sodium hydride (25 mmol) in 15 ml of THF under nitrogen at 0 °C was dropwise introduced a solution of an alcohol (20 mmol) in 15 ml of THF. The mixture was stirred at 50 °C for 1 h. To it was added a solution of benzyl bromide (20 mmol) in 15 ml of THF at 0 °C. The mixture was allowed to be stirred under reflux for 5 h. After the flask was cooled to 0 °C, excess 1 M HCl solution was added to quench the reaction. The organic layer was extracted with ethyl acetate, dried over sodium sulfate, filtered, and concentrated in vacuo. Distillation of the residue afforded benzyl ether.

Measurement of the Distribution of Acid and Base Strength. According to the literature,[9)] we measured acid-

base properties of zeolites and aluminas which were applied to the present study. The acid strengths and amounts of a solid were measured by titrating the solid suspended in hexane with a solution of butylamine in hexane using Hammett indicators (pK_a value): 4-phenylazo-*N*-phenylaniline (+1.5), 4′-amino-2,3′-dimethylazobenzene (+2.0), 4-dimethylaminoazobenzene (+3.3), 4-phenylazo-1-naphthylamine (+4.0), and Neutral Red (+6.8). The base strengths and amounts of a solid were measured by titrating the solid suspended in hexane with a solution of trichloroacetic acid in hexane using the same indicators as those listed above.

The authors thank Professors Yuichi Murakami and Tadashi Hattori and Drs. Miki Niwa and Hirofumi Itoh of Nagoya University for helpful advice concerning zeolites. They also thank Dr. Kuniyuki Kitagawa of Nagoya University for advising atomic absorption analyses.

Synthesis of 29-Norlanostane Derivatives[1)]

Misuzu NAORA (nee NAMIKAWA), Tatsushi MURAE, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received January 16, 1986)

As authentic samples for identification of 29-norlanostane derivatives isolated from plant fossil, 29-norlanostan-24-one and -23-one, 29-norlanost-9(11)-en-24-one, -23-one, and -3-one, 29-norlanost-7-en-3-one, and 29-norlanostan-3-one were synthesized from a commercial lanosterol containing dihydrolanosterol.

The presence of 29-norlanostane derivatives in very minute quantities was demonstrated in a plant fossil collected at the south deposit, Ningyo-toge in Tottori Prefecture by gas chromatography-mass spectrometry, IR and ^{1}H NMR spectra. In order to identify these compounds, several 29-norlanostane derivatives were synthesized as authentic samples. This paper describes the synthesis of 29-norlanostan-24-one and -23-one (**1** and **2**), 29-norlanost-9(11)-en-24-one, -23-one, and -3-one (**3**, **4**, and **5**), 29-norlanost-7-en-3-one (**6**), and 29-norlanostan-3-one (**7**) from a commercial lanosterol (**8**) containing dihydrolanosterol (**9**).

9 R= $-CH_2CH_2CH(CH_3)_2$

Demethylation of 4,4-dimethyl group of a commercial lanosterol (a mixture of lanosterol (**8**) and dihydrolanosterol (**9**)) was effected by the Pinhey's method.[2)] The mixture (**8** and **9**) was subjected to oxidation, oximation, and abnormal Beckmann rearrangement to afford a mixture of seconitrile (**10**) and dihydroseconitrile (**11**)[2)] in about 50% yield. On treatment with *m*-chloroperbenzoic acid (MCPBA) in dichloromethane at 0 °C, the seconitrile (**10**) afforded a seconitrile epoxide (**12**), which was easily separated from the dihydroseconitrile (**11**) remained intact by column chromatography. The epoxide (**12**) showed peaks at δ 1.28, 1.32, and 2.70 due to two methyl groups and a proton on the oxirane ring, respectively, and δ 1.77 (3H), 4.69 (1H), and 4.95 (1H) assignable to an isopropenyl group in the ^{1}H NMR spectrum. The epoxide (**12**) reacted with boron trifluoride etherate ($BF_3 \cdot OEt_2$)[3)] to give a mixture of a 24-keto derivative (**13**) and a rearranged aldehyde (**14**) in a ratio of 3:1. Optimization of the reaction conditions to improve the yield of the ketone (**13**) was attempted, but failed. Analytical samples of **13** and **14** were obtained by preparative thin-layer chromatography (TLC) and their structures were confirmed by ^{1}H NMR spectrum; the ketone (**13**) showed the signals at δ 1.10 (6H, d, J=7 Hz) and 2.50 (1H, septet, J=7 Hz), indicating the presence of an isobutyryl group, while the aldehyde (**14**) showed a singlet signal at δ 9.47 due to the aldehyde proton. Chromatographic behaviors of **13** and **14** being similar, the mixture of **13** and **14** in a large quantity was separated after reduction. Reduction with sodium borohydride followed by chromatographic separation afforded a secondary alcohol (**15**) and a primary one (**16**). In the ^{1}H NMR spectrum of 24-hydroxy seconitrile (**15**), a multiplet signal assignable to a methine proton of the secondary alcohol was observed at δ 3.30.

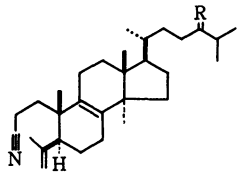
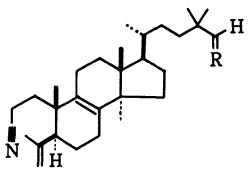
12



13 R=O
15 R=H,OH



14 R=O
16 R=H,OH

The 24-hydroxy seconitrile (**15**) was epoxidized with MCPBA at 0 °C for 2 d to afford 4,28-epoxy-24-hydroxy seconitrile (**17**) in 86% yield together with its C-4 epimer in a small amount. The main hydroxy epoxide (**17**), after acetylation, was treated with $BF_3 \cdot OEt_2$ to yield 24-acetoxy-29-norlanost-8-en-3-one (**19**) in a good yield. The α-configuration of the methyl group at C-4 of **19** was demonstrated by the axial-axial coupling (J=11 Hz) observed between $C_{(4)}$–H and

$C_{(5\alpha)}$-H.

Oxidation of 24-acetoxy-29-norlanost-8-en-3-one (**19**) with chromium trioxide[4] afforded 24-acetoxy-29-norlanost-8-ene-3,7,11-trione (**20**), whose molecular formula, $C_{31}H_{46}O_5$, was determined by high-resolution mass spectrum (HR-MS). The Δ^8-triketo derivative (**20**) was then subjected to reduction with zinc in acetic acid[4] to yield a saturated triketone (**21**), to which the molecular formula, $C_{31}H_{48}O_5$, was assigned by HR-MS.

Wolff-Kishner reduction of the saturated triketone (**21**) under usual conditions[5] gave a mixture of 24-hydroxy-29-norlanostan-11-one (**22**) and 29-norlanostan-24-ol (**23**). Since an examination on the reaction conditions revealed that vigorous conditions enhanced the formation of **23**,[6] the following modification was made. The excess hydrazine hydrate was distilled off under reduced pressure before raising temperature. This additional process could suppress the formation of **23**. No occurrence of $C_{(4)}$-CH_3 epimerization in the Wolff-Kishner reduction was proved by the following observation. Reduction of 29-norlanost-8-en-3-one (**24**) (vide infra) under the same conditions as above gave a product (**25**), which was identical with that obtained by hydride reduction of 29-norlanost-8-en-3β-yl mesylate (**26**). 29-Norlanostan-24-ol (**23**) was oxidized to the corresponding 24-one (**1**).

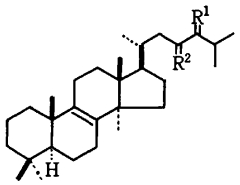
Reduction of 24-hydroxy-29-norlanostan-11-one (**22**) with lithium aluminium hydride (LAH) afforded a pair of C-24 epimeric diols (**27a,b**)[5]. After selective acetylation of the hydroxyl group at C-24, dehydration of each acetoxy alcohol (**28a,b**) was effected by phosphoryl chloride in pyridine[5] to give 29-norlanost-9(11)-en-24-yl acetate (**29a,b**). On deprotection and oxidation, both **29a** and **29b** gave the same compound, 29-norlanost-9(11)-en-24-one (**3**), which showed a multiplet signal at δ 5.27 due to $C_{(11)}$-H and doublet signal at δ 1.09 (6H) due to geminal methyl groups on a carbon atom adjacent to the carbonyl group at C-24. Thus the synthesis of 29-norlanost-9(11)-en-24-one (**3**) was achieved from lanosterol (**8**) in ca. 2% total yield through 17 steps.

Next we investigated transposition of the carbonyl group at C-24 into C-23 without degradation of the side chain using lanost-8-en-24-one (**31**) as a model compound, which was prepared from lanosta-8,24-diene. Although several procedures for 1,2-carbonyl transposition have been reported,[7-10] most of them are limited to cyclic ketones. Application of these procedures to the conversion of 24-one into 23-one was unsuccessful due to unexpectedly large steric effect caused by the presence of bulky lanostane skeleton.

We developed a new synthetic route utilizing reduction of a masked α-diketone. Regioselective sulfenylation at C-23 of lanost-8-en-24-one (**31**) was accomplished by application of the inverse addition of the reagent.[9] The anion produced under kinetically controled conditions (see Experimental) was added a solution of diphenyl disulfide in tetrahydrofuran (THF) and hexamethylphosphoric triamide (HMPA) to give a mixture of 23-phenylthiolanost-8-en-24-ones (**32a,b**), which was shown to be C-23 epimers by characteristic septet of $C_{(25)}$-H at 2.92 and 2.97 and double doublet at δ 3.88 and 3.80 due to $C_{(23)}$-H in the ^{1}H NMR spectrum. The mixture was separated by TLC to afford **32a** and **32b**. According to the procedure reported by Trost et al.[9] the α-phenylthio ketones (**32a,b**) were treated with lead tetraacetate in benzene-acetic acid to yield a masked ketone (**33**), which was converted into a dimethyl acetal (**34**) by treatment with iodine in methanol. The carbonyl group in dimethyl acetal (**34**) was then reduced with LAH to give an α-ketol (**35**), the structure of which was supported by ^{1}H NMR spectrum; a double doublet signal at δ 4.66 (J=2.5 and 5 Hz) changed into a doublet signal on addition of D_2O. Acetylation of **35** gave an α-keto acetate (**36**), showing a characteristic signal at δ 4.87 (d, J=4 Hz) in the ^{1}H NMR spectrum. Finally the α-acetoxy ketone (**36**) was reduced with calcium in liquid ammonia to afford the expected product, lanost-8-en-23-one (**37**), total yield of which from the 24-one (**31**) was ca. 20% through 6 steps. Direct deoxygenation of **33**



31 R^1=O, R^2=H_2

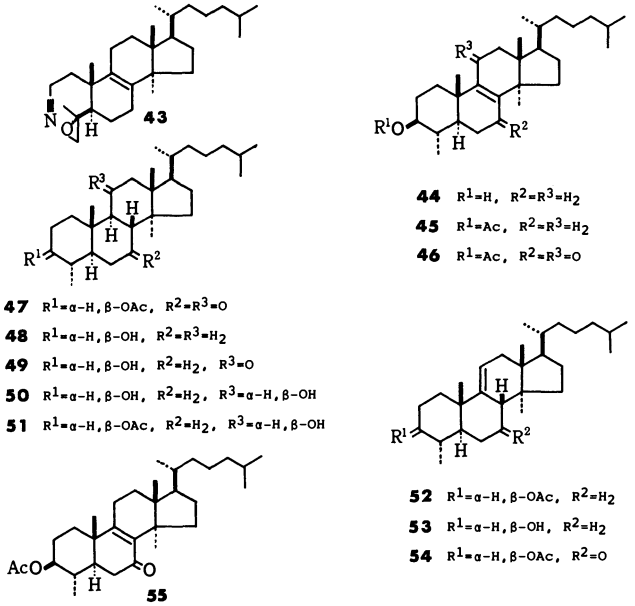
and **34** by Wolff–Kishner reduction resulted in a formation of only a hydrocarbon mixture.

The method mentioned above was applied to the transposition of the carbonyl group of 29-norlanost-9(11)-en-24-one (**3**) into the corresponding 23-one (**4**). Sulfenylation of **3** afforded epimeric 23-phenylthio ketones (**38a,b**), which were subsequently converted into an α-acetoxy-α-phenylthio ketone (**39**), a dimethyl acetal (**40**), and an α-ketol (**41**). On acetylation followed by reduction with calcium in liquid ammonia, **41** gave 29-norlanost-9(11)-en-23-one (**4**) via **42**. The synthesis of a target molecule (**4**) from lanosterol (**8**) was successfully accomplished utilizing the newly developed reduction of a masked α-diketone in 0.4% total yield through 23 steps. 29-Norlanostan-23-one (**2**) was easily derived from **4** by hydrogenation and oxidation. The synthesis of 29-norlanost-9(11)-en-3-one and -7-en-3-one (**5** and **6**) and 29-norlanostan-3-one (**7**) was carried out through similar routes to the compounds **4** and **2**.

The dihydroseconitrile (**11**),[2] prepared from dihydrolanosterol (**9**) (vide supra), was converted into a demethyl derivative, 29-norlanost-8-en-3-one (**24**)[11] through a seconitrile epoxide (**43**). On reduction followed by acetylation, **24** gave an acetate (**45**), which was subjected to allylic oxidation, reduction with zinc, and Wolff–Kishner reduction in turn to afford 29-norlanostan-3β-ol (**48**) and 3β-hydroxy-29-norlanostan-11-one (**49**). The former (**48**), on Jones oxidation, afforded 29-norlanostan-3-one (**7**) and the latter (**49**) was converted into 29-norlanost-9(11)-en-3β-ol (**53**)[12] by reduction, partial acetylation, dehydration, and hydrolysis, which on oxidation gave 29-norlanost-9(11)-en-3-one (**5**).

On the other hand, oxidation of 29-norlanost-8-en-3β-yl acetate (**45**) with chromyl chloride afforded 3β-acetoxy-29-norlanost-9(11)-en-7-one (**54**), which was isomerized by treatment with $BF_3 \cdot OEt_2$ into a conjugate enone (**55**).[13] Wolff–Kishner reduction[14] of **55** following oxidation of the resultant alcohol afforded a mixture of 29-norlanost-7-en-3-one (**6**) and -8-en-3-one (**24**) in a ratio of ca. 2:1. The mixture showed a similar fragmentation to that of 9(11)-en-3-one (**5**) in the mass spectra. In the ^1H NMR spectrum of the mixture, three singlet signals at δ 0.69 (18-Me), 0.86 (30-Me), and 1.09 (19-Me) and a doublet signal at δ 1.00 (28-Me) are assignable to 7-ene (**6**) derivative. Separation of **6** from **24** could not be attained.



Experimental

General Procedures. Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and uncorrected. IR spectra were obtained on a Hitachi 260-30 spectrometer in Nujol mull. ^1H NMR spectra were taken on a Hitachi R-20B (60 MHz) or a Varian EM-390 (90 MHz) or a Brucker WH-270 (270 MHz) spectrometer for solutions in $CDCl_3$ with tetramethylsilane as an internal standard. Mass spectra were run on a JEOL JMS-D300 mass spectrometer at 70 eV, and the relative intensities were indicated in the parentheses. Optical rotations were measured on a JASCO DIP-181 spectrometer in $CHCl_3$ (*c* 0.10) unless otherwise stated, and UV spectra on a Hitachi 340 spectrometer. TLC was carried out on Kieselgel 60 GF_{254} (E. Merck) coated in 0.25 mm thickness (for analytical) and in 0.5 mm thickness (for preparative). Wakogel C-200 (Wako) was used for column chromatography. Dry solvents were purified by distillation from desiccants as follows: ether/LAH; THF/Na-benzophenone; dichloromethane and carbon tetrachloride/P_2O_5; benzene/Na; toluene and HMPA/CaH_2; pyridine/BaO. Organic extracts were dried over anhydrous sodium sulfate.

Epoxidation of a Mixture of Seconitriles (10 and 11). The seconitrile mixture (**10** and **11**) was obtained by the method described by Pinhey et al.[2] in ca. 50% yield from a commercial lanosterol (**8**) (E. Merck, containing ca. 30% of dihydrolanosterol (**9**)).

The seconitrile mixture (43 g) in dichloromethane (3.4 l) was kept at 0 °C and reacted with MCPBA (16 g) in dichloromethane (0.4 l) in a refrigerator for 3 h. The reaction product was washed with successively cold 5% potassium iodide solution, water, and brine, and dried. Evaporation of the solvent and addition of hexane yielded crystals (6.67 g), which were identified as seconitrile epoxide (**12**), mp 119.5—121.5 °C (needles from hexane); IR 2240 and 1636 cm^{-1}; ^1H NMR (60 MHz) δ=0.75 (3H, s; 18-Me), 0.94 and 0.98 (each 3H, s; 19- and 30-Me), 1.28 and 1.32 (each 3H, s; $C\overset{O}{\diagup\!\diagdown}C(Me)_2$), 1.77 (3H, br s; C=C-Me), 2.70 (1H, t, *J*=6 Hz; $C\overset{O}{\diagup\!\diagdown}C$-H), 4.69 and 4.95 (each 1H, m; $C=CH_2$); Found *m/z* 437.3653. Calcd for $C_{30}H_{47}ON$: M, 437.3656.

The filtrate was separated by silica-gel chromatography (silica gel: 410 g). Elution (each fraction: 1/4 column volume) was performed with 10% ether–hexane (frs 1—10) and 20% ether–hexane (frs 11—25). Crystallization of frs 6—9 from methanol afforded dihydroseconitrile (**11**; 9.1 g).[2] Fractions 13—22 gave additional seconitrile epoxide (**12**; 14.5 g).

Treatment of Seconitrile Epoxide (12) with $BF_3 \cdot OEt_2$. $BF_3 \cdot OEt_2$ (1.5 ml) was added to a solution of the seconitrile epoxide (**12**; 1.2 g) in toluene (120 ml) and the reaction mixture was stirred at room temperature for 20 min.

Addition of water and extraction with ether furnished a mixture (1.18 g) of seconitrile ketone (**13**) and seconitrile aldehyde (**14**). A part of the mixture (145 mg) was separated by preparative TLC (developed three times with 20% ether–hexane) to afford seconitrile aldehyde (**14**; 21.7 mg) and seconitrile ketone (**13**; 67.9 mg). **13**: Mp 98—99 °C; IR 2240, 1705, 1635, and 894 cm^{-1}; ^1H NMR (60 MHz) δ= 0.74 (3H, s; 18-Me), 0.94 and 0.98 (each 3H, s; 19- and 30-Me), 1.10 (6H, d, J=7 Hz; O=C-CH<u>Me</u>$_2$), 1.78 (3H, br s; C=C-Me), 2.50 (1H, septet, J=7 Hz; O=C-C<u>H</u>Me$_2$), and 4.69 and 4.94 (each 1H, m; C=C<u>H</u>$_2$); MS m/z (%) 437 (M^+; 82), 422 (90), 394 (15), 383 (62), 254 (33), 242 (44), and 71 (100); Found: m/z 437.3663. Calcd for $C_{30}H_{47}ON$: M, 437.3656. **14**: An oil; ^1H NMR (60 MHz) δ=0.74 (3H, s; 18-Me), 0.94 and 0.98 (each 3H, s; 19- and 30-Me), 1.06 (6H, s; $C_{(24)}$-Me's), 1.78 (3H, br s; C=C-Me), 4.69 and 4.94 (each 1H, m; C=C<u>H</u>$_2$), and 9.47 (1H, s; H-C=O); MS m/z (%) 437 (M^+; 50), 422 (37), 409 (15), 383 (43), 254 (20), 242 (43), and 55 (100).

Reduction of the Mixture of Seconitrile Ketone (13) and Seconitrile Aldehyde (14). The mixture (6.8 g) of **13** and **14** was treated with sodium borohydride (0.6 g) in methanol (250 ml) at room temperature for 20 min. The usual work-up afforded a mixture (6.8 g) of alcohols, which was separated by silica-gel column chromatography (silica gel: 210 g) eluted with 30% ether–hexane (each fraction: 1/4 column volume). Fractions 7—10 gave a secondary alcohol (**15**; 3.9 g; 57% yield from **12**), and frs 12—14 a primary alcohol (**16**; 1.4 g; 20.5% yield from **12**). **15**: Mp 112.5—113 °C (needles from hexane); IR 3450, 2245, 1635, and 895 cm^{-1}; ^1H NMR (60 MHz) δ= 0.75 (3H, s; 18-Me), 0.83—1.04 (total Me×5), 1.77 (3H, br s; C=C-Me), 3.30 (1H, m; <u>H</u>-C-OH), and 4.68 and 4.93 (each, 1H, m; C=C<u>H</u>$_2$); MS m/z (%) 439 (M^+; 100), 424 (25), and 421 (2); Found: m/z 439.3787. Calcd for $C_{30}H_{49}NO$: M, 439.3812.

Epoxidation of 24-Hydroxy Seconitrile (15). To a solution of 24-hydroxy seconitrile (**15**; 610 mg) in dichloromethane (70 ml) was added MCPBA (453 mg) and the reaction mixture was stood for 2 d in a refrigerator. After the usual work-up, chromatographic separation (silica gel: 30 g, each fraction: 1/4 column volume) eluted with 30% ether–hexane afforded 4,28-epoxy-24-hydroxy seconitrile (**17**; 545.6 mg, 86.2% yield) from frs 25—34, and its epimer at C-4 from frs 21—23. **17**: Mp 112—113 °C; IR 3450 and 2245 cm^{-1}; ^1H NMR (60 MHz) δ=0.75 (3H, s; 18-Me), 0.91 (3H, s; Me), 0.80—1.03 (total Me×3), 1.08 (3H, s, 19-Me), 1.33 (3H, s; C<u>O</u>C-Me), 2.69 (2H, s; C<u>O</u>C<u>H</u>$_2$), and 3.30 (1H, m; <u>H</u>-C-OH); MS m/z (%) 455 (M^+; 45), 440 (18), 437 (15), 422 (72), 404 (28), 394 (12), 383 (42), and 354 (31); Found: m/z 455.3748. Calcd for $C_{30}H_{49}NO_2$: M, 455.3761.

Acetylation of 24-Hydroxy Seconitrile Epoxide (17). 24-Hydroxy seconitrile epoxide (**17**; 545 mg) was acetylated in the usual manner and the reaction product was purified by column chromatography (silica gel: 25 g). Elution with 40% ether–hexane afforded 24-acetoxy-4,28-epoxy-3,4-secolanost-8-ene-3-nitrile (**18**; 554 mg; 93% yield) as colorless oil, IR (liquid) 2250, 1740, and 1250 cm^{-1}; ^1H NMR (60 MHz) δ= 0.75 (3H, s; 18-Me), 0.80—1.0 (total Me×4), 1.09 (3H, s; 19-Me) 1.33 (3H, s; C<u>O</u>C-Me), 2.05 (3H, s; OAc), 2.69 (2H, s; C<u>O</u>C<u>H</u>$_2$), and 4.70 (1H, m; <u>H</u>-C-OAc); MS m/z (%) 497 (M^+; 12), 482 (10), 479 (3), 464 (3), 454 (4), 443 (12), 437 (10), 422 (100), 404 (28), 394 (20), and 383 (26).

Cyclization of 24-Acetoxy-4,28-epoxy-3,4-secolanost-8-ene-3-nitrile (18). $BF_3 \cdot OEt_2$ (1.5 ml) was added to a solution of the seconitrile epoxide (**18**; 553 mg) in toluene (200 ml) at room temperature under nitrogen and the reaction mixture was heated under reflux for 1.5 h. After addition of water, the reaction product was extracted with ether and the extract was washed with sodium hydrogencarbonate solution and brine, and dried. Evaporation and separation by chromatography on silica gel (25 g) eluted with 15% ether–hexane gave a mixture (58.5 mg) of olefinic compounds from frs 5 and 6 (each fraction: 1/4 column volume) followed by 24-acetoxy-29-norlanost-8-en-3-one (**19**; 229 mg, 44% yield) from frs 9—14. **19**: Mp 140—144 °C (needles from ether–hexane); IR (liquid) 1740, 1708, and 1240 cm^{-1}; $[\alpha]_D$ +35°; ^1H NMR (270 MHz) δ=0.73 (3H, s; 18-Me), 0.85—0.95 (total Me×4), 1.03 (3H, d, J=6 Hz; 28-Me), 1.21 (3H, s; 19-Me), 2.06 (3H, s; OAc), 2.32 (1H, dq, J=11 and 6 Hz; O=C-C<u>H</u>Me), and 4.73 (1H, m; <u>H</u>-C-OAc); MS m/z (%) 470 (M^+; 14), 455 (22), 410 (6), 395 (100), 311 (26), 283 (10), 257 (27), 243 (23), and 231 (25); Found: m/z 470.3757. Calcd for $C_{31}H_{50}O_3$: M, 470.3758.

Allylic Oxidation of 24-Acetoxy-29-norlanost-8-en-3-one (19). A solution of chromium trioxide (200 mg) in 90% acetic acid (2 ml) was added to a refluxing solution of 24-acetoxy-29-norlanost-8-en-3-one (**19**; 285 mg) in hexane–acetic acid (1:4, 10 ml). After reflux for 1.5 h, the reaction mixture was poured into a cold aqueous solution of sodium hydrogensulfite. The reaction product was extracted with ether and the extract was washed with 1 M (1 M=1 mol dm^{-3}) sodium hydroxide solution and then with brine. Evaporation gave a residue, which was chromatographed on silica gel (15 g) eluted with 35% ether–hexane (each fraction: 1/4 column volume) to give 24-acetoxy-29-norlanost-8-ene-3,7,11-trione (**20**; 115 mg from frs 16—24; 38% yield) as yellow needles or plates (from ether–hexane), mp 133.5—134.5 °C; IR 1735, 1715, 1690, 1670, and 1240 cm^{-1}; UV (EtOH) 269 nm (log ε 3.86); $[\alpha]_D^{26}$ +103.0°; ^1H NMR (90 MHz) δ=0.85 (3H, s; 18-Me), 0.91 (9H, d, J=7 Hz), 1.06 (3H, d, J=7 Hz; 28-Me), 1.20 (3H, s), 1.49 (3H, s), 2.05 (3H, s; OAc), 2.71 (1H, br s), 3.15 (1H, m), and 4.70 (1H, m; <u>H</u>-C-OAc), MS m/z (%) 498 (M^+; 20), 483 (3), 470 (3), 456 (6), 438 (45), 423 (15), 413 (10), 327 (15), 273 (20), 272 (25), 260 (27), 245 (30), 234 (15), and 55 (100); Found: m/z 498.3338. Calcd for $C_{31}H_{46}O_5$: M, 498.3343.

Reduction of 24-Acetoxy-29-norlanost-8-ene-3,7,11-trione (20). To a refluxing enone (**20**; 1.81 g) in acetic acid (100 ml), zinc dust (1.5 g) was added portionwise during 1.5 h and the heating was continued for 1 h. Zinc was filtered and washed with hot acetic acid. The filtrate and washings were combined and diluted with ether and the solution was washed with a saturated solution of sodium hydrogencarbonate and brine. The product was crystallized from methanol to give 24-acetoxy-29-norlanostane-3,7,11-trione (**21**; 1.28 g). The filtrate was subjected to silica-gel column chromatography to afford an additional **21** (240 mg). The total yield of **21** was 83.5%. **21**: Mp 182—185.5 °C (colorless stick); IR 1730, 1710, 1690, and 1240 cm^{-1}; $[\alpha]_D^{26}$ +47.5°; ^1H NMR (60 MHz) δ=0.76 (3H, s; 18-Me), 0.80—1.00 (total Me×3), 0.98 (3H, d, J=7 Hz; 28-Me), 1.23 (3H, s; 30-Me), 1.49 (3H, s; 19-Me), 2.05 (3H, s; OAc), and 4.70 (1H, m; <u>H</u>-C-OAc); MS m/z (%) 500 (M^+; 3), 485 (1), 456 (2), 440 (12), 425 (10), 370 (50), 328 (30), 302 (20), 260 (20), 220 (25), 193 (40), and 109 (100); Found: m/z 500.3492. Calcd for $C_{31}H_{48}O_5$: M, 500.3500

Wolff–Kishner Reduction of 24-Acetoxy-29-norlanostane-3,7,11-trione (21). A mixture of the trione (**21**; 200 mg), hydrazine hydrate (80%, 2 ml), and diethylene glycol (10 ml)

was refluxed at 130°C for 1.5 h, and the excess hydrazine hydrate was removed in vacuo. Potassium hydroxide (200 mg) was added to the mixture and nitrogen was bubbled for a while. After reflux for 3 h, the mixture was worked up as usual. Addition of methanol to the residue yielded crystals (58 mg), which were identified as 24-hydroxy-29-norlanostan-11-one (**22**). The filtrate was separated by column chromatography (silica gel: 10 g). Elution (each fraction: 1/4 column volume) with 20% ether–hexane (25 ml) and then with 30% ether–hexane (30 ml) gave 29-norlanostan-24-ol (**23**; 8.3 mg) from frs 6—8, and 24-hydroxy-29-norlanostan-11-one (**22**; 72 mg) from frs 13—17. **22**: Mp 156.5—157.5°C (needles from methanol); IR 3500 and 1695 cm^{-1}; $[\alpha]_D^{25}$ +63°; ^1H NMR (270 MHz) δ=0.72 (3H, s; 18-Me), 0.80 (3H, d, J=6 Hz), 0.90 (3H, d, J=7 Hz), 0.92 (6H, d, J=6 Hz), 1.02 (3H, s), 1.09 (3H, s), 2.01 (1H, d, J=13 Hz; $C_{(12)}$-H), 2.53 (1H, d, J=13 Hz; $C_{(12)}$-H'), 2.66 (1H, d, J=13 Hz; $C_{(9)}$-H), and 3.30 (1H, m; H-C-OH); MS m/z (%) 430 (M^+; 64), 415 (6), 412 (8), 397 (3), 387 (7), 319 (14), 311 (8), 273 (10), 260 (15), 233 (8), 223 (7), 191 (100), and 163 (16); Found: m/z 430.3768. Calcd for $C_{29}H_{50}O_2$: M, 430.3809. **23**: Mp 82.5—84.5°C (needles from methanol); IR 3400 cm^{-1}; $[\alpha]_D^{25}$ +35°; ^1H NMR (90 MHz) δ=0.78 (3H, s), 0.80 (3H, s), 0.84 (3H, s), 0.89 (3H, d), 0.93 (6H, d, J=6 Hz; 26- and 27-Me), and 3.31 (1H, m; H-C-OH); MS m/z (%) 416 (M^+; 12), 398 (13), 383 (10), 315 (12), 313 (9), 285 (82), 260 (15), 245 (100), 231 (10), 217 (32), 176 (70), 163 (38), and 109 (60); Found: m/z 416.4005. Calcd for $C_{29}H_{52}O$: M, 416.4016.

Retention of the Configuration at C-4 of 29-Norlanost-8-en-3-one (24) in the Wolff–Kishner Reduction. Wolff–Kishner reduction of 29-norlanost-8-en-3-one (**24**; 50 mg) under the same conditions as those used for 24-acetoxy-29-norlanostane-3,7,11-trione (**21**) afforded 29-norlanost-8-ene (**25**; 21.3 mg) after purification by silica-gel column chromatography, which was completely identical with that obtained by the following procedure.

To a solution of 29-norlanost-8-en-3β-ol (43 mg) in pyridine (5 ml), methanesulfonyl chloride (0.05 ml) was added and the mixture was allowed to stand overnight in a refrigerator. The usual work-up afforded 29-norlanost-8-en-3β-yl mesylate (**26**; 47 mg), a part (24 mg) of which was dissolved in THF (2 ml) and the solution was refluxed for 5 h with lithium triethylhydroborate (in excess) under nitrogen. The excess hydride was destroyed by addition of water and the mixture was extracted with ether. The crude mixture was separated by column chromatography on silica gel (3 g). Elution with hexane gave 29-norlanost-8-ene (**25**; 16.7 mg).

Oxidation of 29-Norlanostan-24-ol (23). A solution of the alcohol (**23**; 13 mg) in acetone (2 ml) was oxidized with Jones reagent at 0°C for 30 min. The usual work-up gave 29-norlanostan-24-one (1; 11 mg) as needles (from methanol), mp 92—93°C; IR 1705 cm^{-1}; $[\alpha]_D^{22}$ +22° (c 0.18, $CHCl_3$); ^1H NMR (90 MHz) δ=0.75—0.93 (total Me×5), 1.09 (6H, d, J=7 Hz; O=C-CH$\underline{Me}_2$), and 2.60 (1H, septet, J=7 Hz; O=C-C$\underline{H}$Me$_2$); MS m/z (%) 414 (M^+; 25), 399 (8), 328 (3), 313 (7), 287 (18), 260 (50), 245 (100), 231 (6), 217 (32), 204 (17), 190 (10), and 176 (38); Found: m/z 414.3843. Calcd for $C_{29}H_{50}O$: M, 414.3859.

Reduction of 24-Hydroxy-29-norlanostan-11-one (22). To a solution of 24-hydroxy-11-one (**22**; 300 mg) in ether (50 ml), LAH (50 mg) was added, and the reaction mixture was stirred for 2 h at room temperature. The usual work-up and chromatographic separation on silica gel (15 g) eluted with 20% ether–hexane (each fraction: 1/4 column volume) afforded 29-norlanostane-11,24-diol (**27a**; 83.5 mg) from frs 13—16 and its isomer (**27b**; 82.2 mg) from frs 19—24. Fractions 17 and 18 (100 mg) were further separated in the same manner to give **27a** (29.7 mg) and **27b** (46.0 mg). **27a**: Mp 140.5—141°C (fine needles from methanol); IR 3500 cm^{-1}; $[\alpha]_D^{25}$ +55°; ^1H NMR (90 MHz) δ=0.78 (3H, s), 0.80—1.10 (total Me×6), 3.30 (1H, m; H-$C_{(24)}$-OH), and 4.21 (1H, m; H-$C_{(11)}$-OH); MS m/z (%) 432 (M^+; 6), 414 (16), 399 (10), 396 (4), 381 (4), 285 (4), 276 (6), 258 (20), 245 (14), 243 (14), 240 (16), 229 (3), 217 (6), 193 (22), and 175 (12); Found: m/z 432.3935. Calcd for $C_{29}H_{52}O_2$: M, 432.3965. **27b**: Mp 160—163°C (needles from ether–methanol); IR 3300 cm^{-1}; $[\alpha]_D^{25}$ +39°; ^1H NMR (90 MHz) δ=0.78 (3H, s), 0.80—1.00 (total Me×6), 3.29 (1H, m; H-$C_{(24)}$-OH), and 4.22 (1H, m; H-$C_{(11)}$-OH); MS m/z (%) 432 (M^+; 4), 414 (18), 399 (14), 396 (3), 381 (10), 285 (4), 276 (4), 258 (17), 245 (10), 243 (14), 240 (10), 229 (6), 217 (6), 193 (17), and 175 (10); Found: m/z 432.3926. Calcd for $C_{29}H_{52}O_2$: M, 432.3965.

Acetylation of 29-Norlanostane-11,24-diols (27a and b). The diols (**27a**; 106.9 mg and **27b**; 114.9 mg) were dissolved in pyridine (3 ml) and acetic anhydride (1.5 ml) and stood for 5 h at room temperature, respectively. The usual work-up afforded 24-acetoxy-29-norlanostan-11-ols (**28a**; 123.8 mg and **28b**; 120.4 mg), respectively. **28a**: Mp 148.5—149.5°C (needles from methanol); IR 3540, 1715, and 1260 cm^{-1}; $[\alpha]_D^{26}$ +33°; ^1H NMR (90 MHz) δ=0.77 (3H, s; 30-Me), 0.88 (12H, d, J=7 Hz), 0.99 (3H, s), 1.07 (3H, s), 2.04 (3H, s; OAc), 4.20 (1H, m; H-C-OH), and 4.66 (1H, m; H-C-OAc); MS m/z (%) 474 (M^+; 5), 456 (38), 441 (38), 396 (24), 381 (78), 297 (14), 283 (100), 258 (22), 243 (30), 229 (26), 217 (26), 193 (28), and 109 (46); Found: m/z 474.4014. Calcd for $C_{31}H_{54}O_3$: M, 474.4071. **28b**: Mp 160.5—161°C (fine needles from methanol); IR 3545, 1712, and 1260 cm^{-1}; $[\alpha]_D^{26}$ +49°; ^1H NMR (90 MHz) δ=0.77 (3H, 30-Me), 0.89 (12H, d, J=7 Hz), 0.99 (3H, s), 1.07 (3H, s), 2.04 (3H, s; OAc), 4.22 (1H, m; H-C-OH), and 4.68 (1H, m; H-C-OAc); Found: m/z 474.4053. Calcd for $C_{31}H_{54}O_3$: M, 474.4071.

Dehydration of 24-Acetoxy-29-norlanostan-11-ols (28a and b). Phosphoryl chloride (0.2 ml) was added to a solution of the monoacetate (**28a**; 96.3 mg) in pyridine (5 ml), and the mixture was heated at 90—100°C for 3 h. The reaction mixture was poured into ice-water and extracted with ether. The usual work-up afforded 24-acetoxy-29-norlanost-9(11)-ene (**29a**) in a quantitative yield, mp 102—102.5°C (fine needles from methanol); IR 1730 and 1245 cm^{-1}; $[\alpha]_D^{23}$ +70°; ^1H NMR (90 MHz) δ=0.66 (3H, s; 18-Me), 0.75 (3H, s; 30-Me), 0.76—0.97 (total Me×5), 2.05 (3H, s; OAc), 4.68 (1H, m; H-C-OAc), and 5.28 (1H, m; C=C-H); MS m/z (%) 456 (M^+; 45), 441 (50), 396 (25), 381 (100), 297 (15), 283 (80), 257 (7), 243 (13), 229 (18), 217 (18), and 203 (9); Found: m/z 456.3983. Calcd for $C_{31}H_{52}O_2$: M, 456.3967.

The epimeric acetoxy alcohol (**28b**) was dehydrated in the same procedure to afford 24-acetoxy-29-norlanost-9(11)-ene (**29b**), mp 109.5—110.5°C (glistening plates from methanol); IR 1735 and 1240 cm^{-1}; $[\alpha]_D^{23}$ +81°; ^1H NMR (90 MHz) δ=0.65 (3H, s; 18-Me), 0.74 (3H, s; 30-Me), 0.76—0.97 (total Me×5), 2.04 (3H, s; OAc), 4.68 (1H, m; H-C-OAc), and 5.26 (1H, m; C=C-H); MS m/z (%) 456 (M^+; 27), 441 (40), 396 (26), 381 (100), 297 (14), 283 (75), 257 (6), 243 (14), 229 (18), 217 (16), and 203 (9); Found: m/z 456.3927. Calcd for $C_{31}H_{52}O_2$: M, 456.3967.

Deprotection of 24-Acetoxy-29-norlanost-9(11)-enes (29a and b). The acetate (**29a**; 58.9 mg) in ether was stirred with

LAH (ca. 20 mg) for 1 h at room temperature to afford 29-norlanost-9(11)-en-24-ol (**30a**; 54.9 mg), mp 91—92 °C (colorless plates from methanol); IR 3450 and 1630 cm^{-1}; $[\alpha]_D^{24}$ +76°; ^1H NMR (90 MHz) δ=0.67 (3H, s; 18-Me), 0.75 (3H, s; 30-Me), 0.75—0.97 (total Me×5), 3.30 (1H, m; H-C-OH), and 5.53 (1H, m; C=C-H); MS *m/z* (%) 414 (M^+; 52), 399 (86), 396 (14), 381 (58), 311 (4), 297 (14), 283 (20), 243 (15), 229 (20), 217 (20), and 203 (14); Found: *m/z* 414.3795. Calcd for $C_{29}H_{50}O$: M, 414.3860.

29-Norlanost-9(11)-en-24-ol (**30b**) was obtained from **29b** by the same method as above. **30b**: Mp 95—96 °C (fine needles from methanol); IR 3300 and 1635 cm^{-1}; $[\alpha]_D^{24}$ +54°; ^1H NMR (90 MHz) δ=0.66 (3H, s; 18-Me), 0.75 (3H, s; 30-Me), 0.82 (3H, d, *J*=7 Hz; 28-Me), 0.90 (6H, d, *J*=7 Hz), 0.92 (3H, d, *J*=6 Hz), 0.95 (3H, s; 19-Me), 3.32 (1H, m; H-C-OH), and 5.27 (1H, m; C=C-H); MS *m/z* (%) 414 (M^+; 50), 399 (100), 381 (64), 311 (4), 297 (15), 283 (22), 243 (20), 229 (24), 217 (25), 203 (15), and 119 (45); Found: *m/z* 414.3831. Calcd for $C_{29}H_{50}O$: M, 414.3860.

Oxidation of 29-Norlanost-9(11)-en-24-ols (30a and b). Jones reagent was added to a solution of 29-norlanost-9(11)-en-24-ol (**30a**; 42.6 mg) in acetone (5 ml) at 0 °C and the mixture was stirred for 20 min. The usual work-up afforded 29-norlanost-9(11)-en-24-one (**3**; 40.4 mg). The same ketone (**3**) was obtained from **30b** in the same manner. **3**: Mp 84—85 °C (colorless plates from methanol); IR 1712 and 1630 cm^{-1}; $[\alpha]_D^{24.5}$ +79°; ^1H NMR (90 MHz) δ=0.66 (3H, s; 18-Me), 0.76 (3H, s; 30-Me), 0.82 (3H, d, *J*=6 Hz; 28-Me), 0.87 (3H, d, *J*=5 Hz; 21-Me), 0.95 (3H, s; 19-Me), 1.09 (6H, d, *J*=7 Hz; O=C-CH$\underline{Me_2}$), 2.40 (2H, dd, *J*=6 and 7.5 Hz), 2.52 (1H, septet, *J*=7 Hz; O=C-C$\underline{H}$Me$_2$), and 5.27 (1H, m; C=C-H); MS *m/z* (%) 412 (M^+; 24), 397 (100), 379 (5), 311 (5), 273 (8), 243 (14), 229 (11), 217 (10), 203 (8), and 127 (30); Found: *m/z* 412.3798. Calcd for $C_{29}H_{48}O$: M, 412.3705.

Lanost-8-en-24-one (31). Lanosta-8,24-diene (540 mg) in THF (40 ml) was stirred with borane solution in THF (BH_3·THF, 1 M, 5 ml) for 1 h at 0 °C. Water (5 ml), 3 M sodium hydroxide (5 ml), and 30% hydrogen peroxide (7 ml) were added and the solution was warmed at ca. 40 °C for 2 h. After the usual work-up, the residue (585 mg) was crystallized from methanol to give lanost-8-en-24-ol (mp 85—89 °C, M^+ 428), which was oxidized with Jones reagent in acetone (20 ml) at 0 °C to afford lanost-8-en-24-one (**31**; 383 mg), mp 88—89 °C (colorless plates from methanol); IR 1715 cm^{-1}; ^1H NMR (270 MHz) δ=0.69 (3H, s; 18-Me), 0.84 (3H, s), 0.88 (6H, s), 0.89 (3H, d, *J*=7 Hz; 21-Me), 0.98 (3H, s; 19-Me), 1.09 (6H, d, *J*=7 Hz; O=C-CH$\underline{Me_2}$), 2.40 (1H, dd, *J*=6 and 8 Hz; O=C-C-H), and 2.53 (1H, septet, *J*=7 Hz; O=C-C$\underline{H}$Me$_2$); MS *m/z* (%) 426 (M^+; 34), 411 (100), 393 (4), 287 (6), 273 (8), 257 (5), 243 (6), 229 (9), and 127 (16); Found: *m/z* 426.3816. Calcd for $C_{30}H_{50}O$: M, 426.3859.

23-Phenylthiolanost-8-en-24-ones (32a and b). Diisopropylamine (0.3 ml; distilled from calcium hydride) was added to a solution of butyllithium (1.25 ml, 1.95 mmol) in THF (5 ml) containing 2,2′-bipyridyl as an indicator at −70 °C under argon atmosphere. After stirring for 40 min at room temperature, the solution was cooled to 0 °C and HMPA (1.5 ml) was added, and then the solution was cooled to −78 °C. A solution of the ketone (**31**; 393 mg, 0.92 mmol) in THF (5 ml) was added dropwise to the solution of lithium diisopropylamide (LDA) above obtained, and stirred for 30 min. Then the resulting anion was put into a solution of diphenyl disulfide (420 mg, 1.9 mmol) in a mixture of THF (2.5 ml) and HMPA (1.25 ml) at room temperature using a syringe. The mixture was stirred for 1.5 h and quenched with 10% ammonium chloride solution. The product was separated by column chromatography on silica gel (32 g). Elution (each fraction: 1/4 column volume) was performed with hexane (frs 1—12) and 2% ether-hexane (frs 13—30) to afford a mixture of α-phenylthio ketones (360 mg) from frs 25—27, which showed peaks at *m/z* 534 (M^+; 35), 519 (100), 463 (25), 411 (28), 409 (32), and 326 (33) in the mass spectrum. The mixture was further separated by preparative TLC (developed twice with 4% ether-hexane). The less polar isomer (**32a**; 153 mg) and the more polar one (**32b**; 180 mg) were obtained. **32a**: Mp 135—136 °C (colorless needles from methanol); $[\alpha]_D^{24}$ −61°; IR 1698, 1580, 1238, 1208, 1097, 900, 740, and 683 cm^{-1}; ^1H NMR (90 MHz) δ=0.62 (3H, s; 18-Me), 0.83 (3H, s; 30-Me), 0.87 (6H, s; 28- and 29-Me), 0.93 (3H, d, *J*=7 Hz), 0.96 (3H, s; 19-Me), 1.04 and 1.09 (each 3H, d, *J*=7 Hz; O=C-CH$\underline{Me_2}$), 2.92 (1H, septet, *J*=7 Hz; O=C-C$\underline{H}$-Me$_2$), 3.88 (1H, dd, *J*=3 and 12 Hz; O=C-C$\underline{H}$-SPh), and 7.3 (5H, m; SPh); Found: *m/z* 534.3878. Calcd for $C_{36}H_{54}OS$: M, 534.3893. **32b**: Mp 65—67 °C (amorphous powder from methanol); $[\alpha]_D^{24}$ +119°; IR (liquid) 1708, 1582, 1240, 908, 735, and 690 cm^{-1}; ^1H NMR (90 MHz) δ=0.72 (3H, s; 18-Me), 0.85 (3H, s; 30-Me), 0.89 (6H, s; 28- and 29-Me), 0.94 (3H, d, *J*=7 Hz; 21-Me), 0.99 (3H, s; 19-Me), 1.04 and 1.06 (each 3H, d, *J*=7 Hz; O=C-CH$\underline{Me_2}$), 2.97 (1H, septet, *J*=7 Hz, O=C-C$\underline{H}$-Me$_2$), 3.80 (1H, dd, *J*=3 and 11 Hz; O=C-C$\underline{H}$SPh), and 7.3 (5H, m; SPh); Found: *m/z* 534.3844. Calcd for $C_{36}H_{54}OS$: M, 534.3893.

Reaction of 23-Phenylthiolanost-8-en-24-ones (32a and b) with Lead Tetraacetate. To a solution of α-phenylthio ketone (**32a**; 45 mg) in a mixture of acetic acid (1 ml) and benzene (9 ml), lead tetraacetate (200 mg containing acetic acid) was added under nitrogen. The mixture was refluxed overnight and then ethylene glycol was added to destroy the excess lead tetraacetate. Brine was added and the mixture was extracted with toluene. After the usual work-up, a residue was purified by column chromatography on silica gel (5 g) eluted with 10% ether-hexane. The α-acetoxy-α-phenylthio ketone (**33**; 28.3 mg) was obtained. The isomeric α-phenylthio ketone (**32b**) afforded the same compound (**33**) on the same treatment. **33**: Mp 170—172 °C; IR 1750, 1720, 1240, 1230, 1210, 760, 750, 710, and 695 cm^{-1}; ^1H NMR (90 MHz) δ=2.08 (3H, s; OAc), 2.37 (1H, dd, *J*=2 and 14 Hz; $C_{(22)}$-H), 2.59 (1H, dd, *J*=2 and 14 Hz; $C_{(22)}$-H′), 3.03 (1H, septet, *J*=6 Hz; O=C-C$\underline{H}$Me$_2$), and 7.35 (5H, m; SPh); MS *m/z* (%) 592 (M^+; 2), 532 (100), 517 (48), 480 (27), 461 (27), 423 (37), 369 (20), 325 (24), 311 (42), 295 (31), 283 (24), and 233 (72); Found: *m/z* 532.3747. Calcd for $C_{36}H_{52}OS$ (M−AcOH): 532.3739.

23,23-Dimethoxylanost-8-en-24-one (34). The α-acetoxy-α-phenylthio ketone (**33**; 70 mg) and iodine (870 mg) were refluxed in methanol (70 ml) overnight. An aqueous solution of sodium thiosulfite was added to the mixture and the solvent was evaporated in vacuo. Extraction with ether and evaporation of the solvent afforded a solid, which was crystallized from methanol to afford 23,23-dimethoxylanost-8-en-24-one (**34**; 41.8 mg), mp 141—143 °C; $[\alpha]_D^{25}$ +46°; IR 1720, 1150, 1090, 1045, 975, and 951 cm^{-1}; ^1H NMR (90 MHz) δ=0.65 (3H, s; 18-Me), 0.77—1.0 (total Me×4), 1.08 (6H, d, *J*=7 Hz; O=C-CH$\underline{Me_2}$), 3.17 and 3.20 (each 3H, s; OMe); MS *m/z* (%) 454 (M^+−MeOH; 16), 439 (11), 415 (38), and 155 (100).

Reduction of Dimethyl Acetal (34). To a solution of the dimethyl acetal (**34**; 33 mg) in ether (6 ml), LAH (ca. 20 mg)

was added with stirring. After 20 min, aqueous ether was added to destroy the excess hydride, and then 0.2 M hydrochloric acid was added to acidify the mixture. The usual work-up gave 24-hydroxylanost-8-en-23-one (**35**; 23.9 mg), amorphous solid; ^{1}H NMR (90 MHz) δ=0.67—1.16 (total Me×8), 2.22 and 2.42 (each 1H, br d, J=9 Hz; $C_{(22)}$-H), 3.37 and 3.43 (total 1H, ca. 2:1, d, J=6 Hz; CH-OH, disappeared on addition of D_2O), 3.98 and 4.06 (total 1H, ca. 1:2, dd, J=3 and 6 Hz; O=C-CH-OH, changed to a doublet (J=3 Hz) on addition of D_2O); MS m/z (%) 442 (M^+; 38), 427 (100), 409 (10), 311 (50), 256 (18), and 230 (19); Found: m/z 442.3778. Calcd for $C_{30}H_{50}O_2$: M, 442.3808.

Acetylation of α-Ketol (35). The α-ketol (**35**; 23.9 mg) was acetylated to afford 24-acetoxylanost-8-en-23-one (**36**; 26.8 mg), an oil; ^{1}H NMR (90 MHz) δ=2.14 (3H, s; OAc), 4.84 and 4.87 (total 1H, ca. 1:2, d, J=4 Hz; O=C-CH-OAc); MS m/z (%) 484 (M^+; 23), 469 (97), 409 (20), 311 (100), 285 (17), and 255 (36); Found: m/z 484.3882. Calcd for $C_{32}H_{52}O_3$: M, 484.3915.

Lanost-8-en-23-one (37). A solution of the α-keto acetate (**36**; 29 mg) in ether (2 ml) was added dropwise to a solution of metalic calcium (20 mg) in liquid ammonia (10 ml, distilled from sodium) at −78 °C with stirring. After 1.5 h, ammonium chloride was added and then ammonia was evaporated. Brine was added and the mixture was extracted with ether. The ether extract was worked up and a residue crystallized from methanol to give lanost-8-en-23-one (**37**; 25.1 mg), mp 82—82.5 °C; $[\alpha]_D^{25}$ +54°; IR 1710 cm^{-1}; ^{1}H NMR (270 MHz) δ= 0.76 (3H, s; 18-Me), 0.87 (3H, s; 30-Me), 0.90 (3H, s), 0.91 (3H, s), 0.92 (3H, d, J=6 Hz), 0.93 (3H, d, J=6 Hz), 0.95 (3H, d, J=6 Hz), 1.00 (3H, s; 19-Me), 2.28 (2H, d, J=6 Hz; $C_{(24)}$-H), and 2.46 (1H, dd, J=2 and 15 Hz; $C_{(22)}$-H); MS m/z (%) 426 (M^+; 26), 411 (100), 393 (6), 369 (2), 326 (3), 311 (62), 273 (10), 257 (10), 229 (16), and 85 (52); Found: m/z 426.3883. Calcd for $C_{30}H_{50}O$: M, 426.3861.

Sulphenylation of 29-Norlanost-9(11)-en-24-one (3). The 9(11)-en-24-one (**3**; 124.8 mg) was treated in the same manner as **31** to yield epimers of 23-phenylthio-29-norlanost-9(11)-en-24-ones, **38a** (less polar; 61.0 mg) and **38b** (more polar; 60.5 mg). **38a**: Mp 131 °C (needles from methanol); IR 1710, 1700 (sh), 1630, 740, and 690 cm^{-1}; $[\alpha]_D^{24.5}$ −57°; ^{1}H NMR (90 MHz) δ=0.58 (3H, s; 18-Me), 0.73 (3H, s; 30-Me), 0.82 (3H, d, J=6 Hz; 28-Me), 0.90 (3H, d, J=6 Hz; 21-Me), 0.93 (3H, s; 19-Me), 1.05 and 1.10 (each 3H, d, J=7 Hz; O=C-CHMe$_2$), 2.93 (1H, septet, J=7 Hz; O=C-CHMe$_2$), 3.88 (1H, dd, J=4 and 12 Hz; H-C-SPh), 5.25 (1H, m; H-C=C), and 7.3 (5H, m; SPh); MS m/z (%) 520 (M^+; 7), 505 (4), 449 (100), 411 (6), 339 (14), 313 (10), 283 (7), 245 (8), 243 (8), 229 (16), 217 (20), 203 (21), and 109 (30); Found: m/z 520.3735. Calcd for $C_{35}H_{52}OS$: M, 520.3737. **38b**: An oil; IR (liquid) 1710, 1630, 745, 735, and 690 cm^{-1}; $[\alpha]_D^{24.5}$ +118°; ^{1}H NMR (90 MHz) δ=0.69 (3H, s; 18-Me), 0.73 (3H, s; 30-Me), 0.83 (3H, d, J=7 Hz; 28-Me), 0.93 (3H, d, J=7 Hz; 21-Me), 0.97 (3H, s; 19-Me), 1.04 and 1.07 (each 3H, d, J=7 Hz; O=C-CHMe$_2$), 2.97 (1H, septet, J=7 Hz; O=C-CHMe$_2$), 3.83 (1H, dd, J=4 and 10 Hz; H-C-SPh), 5.27 (1H, m; H-C=C), and 7.3 (5H, m; SPh); MS m/z (%) 520 (M^+; 8), 449 (100), 411 (8), 339 (14), 313 (10), 283 (6), 245 (12), 243 (12), 229 (16), 217 (20), 203 (24), 194 (30), and 109 (30); Found: m/z 520.3681. Calcd for $C_{35}H_{52}OS$: M, 520.3737.

Reaction of 23-Phenylthio-29-norlanost-9(11)-en-24-ones (38a and 38b) with Lead Tetraacetate. The α-phenylthio ketone (**38a**; 46.7 mg) reacted with lead tetraacetate in the same manner as **32a**, and the product was separated by column chromatography on silica gel (5 g). Elution with 10% ether-hexane gave the starting material (**38a**; 14.4 mg) and 23-acetoxy-23-phenylthio-29-norlanost-9(11)-en-24-one (**39**; 29 mg, 56% yield). The same compound (**39**) was obtained from the isomer (**38b**). **39**: Mp 137—138.5 °C (needles from methanol); IR 1750, 1720, 1630, 1215, 965, and 745 cm^{-1}; $[\alpha]_D^{25}$ +64°; ^{1}H NMR (90 MHz) δ=0.63 (3H, s; 18-Me), 0.72 (3H, s; 30-Me), 0.83 (3H, d, J=6 Hz; 28-Me), 0.94 (3H, s; 19-Me), 1.03 (3H, d, J=7 Hz; 21-Me), 1.08 and 1.14 (each 3H, d, J=7 Hz; O=C-CHMe$_2$), 2.08 (3H, s; OAc), 2.58 (1H, d, J=14 Hz; $C_{(22)}$-H), 3.03 (1H, septet, J=7 Hz, O=C-CHMe$_2$), 5.25 (1H, m; C=C-H), and 7.3 (5H, m; SPh); MS m/z (%) 518 (M^+−AcOH; 24), 503 (6), 447 (3), 409 (4), 297 (22), 283 (63), 243 (10), 234 (50), 217 (12), 206 (100), 191 (20), 163 (60), and 115 (70); Found: m/z 518.3571. Calcd for $C_{35}H_{50}OS$ (M−AcOH): 518.3581.

23,23-Dimethoxy-29-norlanost-9(11)-en-24-one (40). Treatment of **39** (81.8 mg) with iodine by the same method as **33** furnished a dimethyl acetal (**40**), which was purified by column chromatography on silica gel (5 g). Elution with 4% ether-hexane afforded 43.9 mg (66% yield) of **40** as needles (from methanol), mp 122.5—125 °C; IR 1720, 1630, 1270, 1150, 1090, 1065, 1040, 1020, 970, and 950 cm^{-1}; $[\alpha]_D^{26}$ +66°; ^{1}H NMR (90 MHz) δ=0.63 (3H, s; 18-Me), 0.74 (3H, s; 30-Me), 0.82 (3H, d, J=6 Hz; 28-Me), 0.94 (3H, s; 19-Me), 1.09 (6H, d, J=7 Hz; O=C-CHMe$_2$), 3.15 (1H, septet, J=7 Hz; O=C-CHMe$_2$), 3.19 and 3.22 (each 3H, s; OMe), and 5.27 (1H, m; C=C-H); MS m/z (%) 440 (M^+−MeOH; 2), 425 (0.2), 401 (100), 313 (2), 283 (2), 245 (2), 231 (1), 229 (1), 217 (2), and 203 (10); Found: m/z 440.3554. Calcd for $C_{30}H_{48}O_2$ (M−MeOH): 440.3652.

Reduction of 23,23-Dimethoxy-29-norlanost-9(11)-en-24-one (40). The dimethyl acetal (**40**; 43 mg) was reduced and hydrolyzed and the resulting product was purified by chromatography on silica gel (5 g) eluted with 10% ether-hexane to give 24-hydroxy-29-norlanost-9(11)-en-23-one (**41**; 31.6 mg, 81% yield) as white powder (from methanol), mp 112—115 °C; IR (liquid) 3500, 1710, 1635, 1280, 1260, 1180, 1130, 1020, and 760 cm^{-1}; $[\alpha]_D^{26}$ +53°; ^{1}H NMR (90 MHz) δ= 0.70 (3H, s; 18-Me), 0.76 (3H, s; 30-Me), 0.72 (3H, d, J=7 Hz; 21-Me), 0.84 (3H, d, J=6 Hz; 28-Me), 0.96 (3H, s; 19-Me), 0.91 and 1.09 (each 3H, d, J=7 Hz; CHMe$_2$), 2.55 (1H, br d, J= 13 Hz; $C_{(22)}$-H), 3.37 and 3.43 (total 1H, ca. 3:2, d, J=5 Hz; H-C-OH, disappeared on addition of D_2O), 3.97 and 4.06 (total 1H, ca. 2:3, dd, J=3 and 5 Hz; H-C-OH, changed into a doublet (J=3 Hz) on addition of D_2O), and 5.28 (1H, m; C=C-H); MS m/z (%) 428 (M^+; 22), 413 (100), 395 (8), 355 (15), 312 (15), 297 (60), 283 (13), 243 (18), 229 (13), 217 (17), 215 (20), 203 (20), and 189 (20); Found: m/z 428.3703. Calcd for $C_{29}H_{48}O_2$: M, 428.3653.

Acetylation of 24-Hydroxy-29-norlanost-9(11)-en-23-one (41). The α-ketol (**41**; 31 mg) was acetylated to give 24-acetoxy-29-norlanost-9(11)-en-23-one (**42**) quantitatively, mp 93.5—95 °C (needles from methanol); IR 1745, 1730, 1720, 1235, and 1025 cm^{-1}; $[\alpha]_D$ +71°; ^{1}H NMR (90 MHz) δ=0.70 (3H, s; 18-Me), 0.75 (3H, s; 30-Me), 0.81 (3H, d, J=8 Hz; 21-Me), 0.96 (3H, s; 19-Me), 0.91 and 0.99 (each 3H, d, J=7 Hz; CHMe$_2$), 2.15 (3H, s; OAc), 4.35 and 4.38 (total 1H, ca. 2:3, d, J=4 Hz; H-C-OAc), and 5.28 (1H, m; C=C-H); MS m/z (%) 470 (M^+; 12), 455 (80), 410 (3), 395 (12), 355 (12), 312 (26), 297 (100), 283 (15), 243 (18), 230 (11), 229 (10), 217 (13), 215 (17), 203 (14), 201 (14), and 189 (17); Found: m/z 470.3823. Calcd for $C_{31}H_{50}O_3$: M, 470.3760.

29-Norlanost-9(11)-en-23-one (4). The keto acetate (**42**;

26 mg) was treated in the same manner as **36**, and the product was separated by column chromatography on silica gel (5 g). Elution with 5% ether–hexane gave 29-norlanost-9(11)-en-23-one (**4**; 14.8 mg, 65% yield). Further elution with 10% ether–hexane afforded an epimeric mixture of 29-norlanost-9(11)-en-23-ols (4.3 mg). **4**: Mp 88—89 °C (needles from methanol); IR 1715 and 1630 cm^{-1}; $[\alpha]_D^{22}$ +89° (*c* 0.20, $CHCl_3$); ^1H NMR (270 MHz) δ=0.70 (3H, s; 18-Me), 0.75 (3H, s; 30-Me), 0.83 (3H, d, *J*=6 Hz; 28-Me), 0.88 (3H, d, *J*=7 Hz; 21-Me), 0.905 and 0.92 (each 3H, d, *J*=6 Hz; 26- and 27-Me), 0.95 (3H, s; 19-Me), 2.25 (2H, d, *J*=6 Hz; $C_{(24)}$-H_2), 2.43 (1H, dd, *J*=2 and 15 Hz; $C_{(22)}$-H), and 5.28 (1H, m; C=C-H); MS *m/z* (%) 412 (M^+; 21), 398 (20), 397 (100), 312 (45), 297 (67), 283 (8), 230 (20), 215 (16), and 119 (36); Found: *m/z* 412.3750. Calcd for $C_{29}H_{48}O$: M, 412.3705. HR-MS *m/z* 397.3490 ($C_{28}H_{45}O$), *m/z* 312.2837 ($C_{23}H_{36}$), *m/z* 297.2592 ($C_{22}H_{33}$), *m/z* 283.2430 ($C_{21}H_{31}$), *m/z* 230.2080 ($C_{17}H_{26}$), and *m/z* 215.1808 ($C_{16}H_{23}$).

29-Norlanostan-23-one (2). A solution of 29-norlanost-9(11)-en-23-one (**4**; 28 mg) in acetic acid (2 ml) was stirred with platinum oxide (25 mg) under hydrogen at 90 °C overnight. The catalyst was filtered off and washed with ether. The filtrate and washings were combined, evaporated, and chromatographed on silica gel (5 g). Elution (each fraction: 1/4 column volume) was performed with 5% ether–hexane (frs 1—8) and 20% ether–hexane (frs 9—22). An epimeric mixture of 29-norlanostan-23-ols was eluted in frs 12—21 (18 mg), and was treated with Jones reagent in acetone (5 ml) at 0 °C for 20 min. The usual work-up and crystallization from methanol afforded 29-norlanostan-23-one (**2**; 17.8 mg) as needles in 63.3% yield from **4**. **2**: Mp 103.5—105 °C; IR 1710 cm^{-1}; $[\alpha]_D^{22}$ +25° (*c* 0.39, $CHCl_3$); ^1H NMR (270 MHz) δ= 0.80 (3H, d, *J*=6 Hz), 0.80 (3H, s), 0.82 (3H, s), 0.83 (3H, s), 0.86 (3H, d, *J*=6 Hz), 0.90 (3H, d, *J*=7 Hz), 0.91 (3H, d, *J*= 6 Hz), 2.10 (1H, d, *J*=15 Hz; $C_{(22)}$-H), 2.24 (2H, d, *J*=6 Hz; $C_{(24)}$-H_2), and 2.42 (1H, br d, *J*=15 Hz; $C_{(22)}$-H′); MS *m/z* (%) 414 (M^+; 4), 399 (4), 314 (100), 299 (44), 245 (63), 217 (16), 203 (8), and 176 (46); Found: *m/z* 414.3810. Calcd for $C_{29}H_{50}O$: M, 414.3860. HR-MS *m/z* 399.3526 ($C_{28}H_{47}O$), *m/z* 314.3011 ($C_{23}H_{38}$), *m/z* 299.2772 ($C_{22}H_{35}$), *m/z* 245.2301 ($C_{18}H_{29}$), *m/z* 217.1930 ($C_{16}H_{25}$), *m/z* 203.1803 ($C_{15}H_{23}$), and *m/z* 176.1546 ($C_{13}H_{20}$).

29-Norlanost-8-en-3β-ol (44). 29-Norlanost-8-en-3-one (**24**, mp 105.5—107 °C; lit,[11] 109—111 °C), obtained from the dihydroseconitrile (**11**), was reduced with LAH to give 29-norlanost-8-en-3β-ol (**44**) in a quantitative yield, mp 140.5—142 °C (lit,[15] 135—137 °C); IR 3300 and 1020 cm^{-1}; ^1H NMR (90 MHz) δ=0.72 (3H, s; 18-Me), 0.84 (3H, s; 30-Me), 0.92 (Me×3), 0.99 (3H, s; 19-Me), and 3.11 (1H, m; H-C-OH); MS *m/z* (%) 414 (M^+; 20), 399 (100), 381 (20), 273 (10), 259 (12), and 245 (8).

Acetylation of 29-Norlanost-8-en-3β-ol (44). The alcohol (**44**; 100 mg) was acetylated to give 29-norlanost-8-en-3β-yl acetate (**45**; 80 mg) after crystallization from methanol, mp 98—98.5 °C (lit,[15] 89—90 °C); IR 1740 and 1245 cm^{-1}; ^1H NMR (90 MHz) δ=0.71 (3H, s; 18-Me), 0.84 (3H, s; 30-Me), 0.91 (Me×3), 0.99 (3H, s; 19-Me), 2.05 (3H, s; OAc), and 4.41 (1H, dt, *J*=5 and 10 Hz; H-C-OAc); MS *m/z* (%) 456 (M^+; 34), 441 (100), 396 (3), 381 (52), 287 (8), 273 (13), 259 (3), 241 (8), 229 (8), and 227 (10).

Allylic Oxidation of 29-Norlanost-8-en-3β-yl Acetate (45). The acetate (**45**; 417 mg) was oxidized with chromium trioxide in acetic acid, and the reaction product was separated by chromatography on silica gel (16 g). Elution (each fraction: 15 ml) was carried out successively with 5, 10, 15, 20, 25, and 30% ether–hexane (each 30 ml). Fractions 9—12 afforded 3β-acetoxy-29-norlanost-8-ene-7,11-dione (**46**; 327 mg), mp 154—155 °C (yellow needles from methanol); IR 1740, 1680, and 1245 cm^{-1}; ^1H NMR (90 MHz) δ=0.80—0.95 (total Me×3), 1.21 (3H, s), 1.33 (3H, s), 2.06 (3H, s; OAc), and 4.44 (1H, dt, *J*=5 and 10 Hz; H-C-OAc); MS *m/z* (%) 484 (M^+; 26), 424 (12), and 409 (4); Found: *m/z* 484.3512. Calcd for $C_{31}H_{48}O_4$: M, 484.3552.

3β-Acetoxy-29-norlanostane-7,11-dione (47). The dienone (**46**; 240 mg) was dissolved in acetic acid (10 ml) and treated with zinc dust (1.2 g). The resulting residue (240 mg) was crystallized from methanol to afford 3β-acetoxy-29-norlanostane-7,11-dione (**47**; 140 mg), mp 180.5—181 °C; IR 1730, 1710, and 1245 cm^{-1}; ^1H NMR (90 MHz) δ=0.72 (3H, s), 0.76—0.92 (total Me×4), 1.24 (3H, s), 1.27 (3H, s), 2.06 (3H, s; OAc), and 4.41 (1H, dt, *J*=5 and 10 Hz; H-C-OAc); MS *m/z* (%) 486 (M^+; 100), 471 (16), 426 (25), 373 (12), 318 (20), 287 (40), 250 (15), 237 (30), 220 (30), 207 (30), and 177 (52); Found: *m/z* 486.3683. Calcd for $C_{31}H_{50}O_4$: M, 486.3708.

Wolff–Kishner Reduction of 3β-Acetoxy-29-norlanostane-7,11-dione (47). A mixture of the dione (**47**; 230 mg), hydrazine hydrate (2 ml), and diethylene glycol (4 ml) was refluxed at 130 °C for 1.5 h, and then potassium hydroxide (0.8 g) was added after the reaction mixture was cooled to room temperature. The excess hydrazine hydrate was removed by distillation until the vapor temperature reached ca. 200 °C, and the solution was refluxed for 2 h. After the usual work-up, the reaction product was crystallized from methanol to give 29-norlanostan-3β-ol (**48**; 87 mg). The filtrate was chromatographed on silica gel (12 g) eluted with 10% ether–hexane (frs 1—2), 20% ether–hexane (frs 3—4), 30% ether–hexane (frs 5—6), 40% ether–hexane (frs 7—8), and 50% ether–hexane (frs 9—12). Fractions 9 and 10 afforded 29-norlanostan-3β-ol (**48**; 29 mg) and fractions 11 and 12 gave 3β-hydroxy-29-norlanostan-11-one (**49**; 60 mg). **48**: Mp 154.5—155 °C; IR 3300 cm^{-1}; ^1H NMR (90 MHz) δ=0.79—1.0 (Me× 7), and 3.09 (1H, dt, *J*=5 and 10 Hz; H-C-OH); MS *m/z* (%) 416 (M^+; 26), 411 (3), 276 (35), 261 (100), 232 (20), and 192 (66); Found: *m/z* 416.4022. Calcd for $C_{29}H_{52}O$: M, 416.4017. **49**: Mp 153 °C (needles from methanol); IR 3300, 1700, 1165, 1040, and 970 cm^{-1}; ^1H NMR (90 MHz) δ=0.72 (3H, s; 18-Me), 0.83—0.90, (Me×3), 0.95 (3H, d), 1.03 (3H, s), 1.09 (3H, s), 2.39 (1H, s), 2.48 (1H, br s), 2.76 (1H, dt, *J*=13.5 and 3 Hz), and 3.07 (1H, dt, *J*=5 and 10 Hz; H-C-OH); MS *m/z* (%) 430 (M^+; 26), 412 (5), 303 (26), 276 (8), and 207 (100); Found: *m/z* 430.3808. Calcd for $C_{29}H_{50}O_2$: M, 430.3809.

29-Norlanostan-3-one (7). Jones oxidation of **48** (29 mg) furnished 29-norlanostan-3-one (**7**; 27 mg), mp 118—119 °C (needles from methanol); IR 1710, 1180, 1140, and 980 cm^{-1}; $[\alpha]_D^{22}$ +42° (*c* 0.12, $CHCl_3$); ^1H NMR (270 MHz) δ=0.79 (3H, s), 0.81 (3H, s), 0.87 (9H, d, *J*=6 Hz), 0.97 (3H, d, *J*=6 Hz; 28-Me), and 1.11 (3H, s; 19-Me); MS *m/z* (%) 414 (M^+; 8), 399 (5), 274 (42), 259 (100), 245 (7), 231 (30), 218 (28), and 190 (48); Found: *m/z* 414.3857. Calcd for $C_{29}H_{50}O$: M, 414.3860.

29-Norlanostane-3β,11β-diol (50). A solution of the hydroxy ketone (**49**; 47 mg) in ether (5 ml) was refluxed with LAH (38 mg) for 2 h. The usual work-up gave a residue (52 mg), which crystallized from methanol to give 29-norlanostane-3β,11β-diol (**50**) as needles, mp 173.5 °C; IR 3400, 1040, 1030, and 975 cm^{-1}; ^1H NMR (90 MHz) δ=0.75—0.91 (Me×5), 1.01 (3H, s), 1.12 (3H, s), 3.09 (1H, dt, *J*=5 and

11 Hz; H-C(3)-OH), and 4.25 (1H, m; H-C(11)-OH); MS *m/z* (%) 432 (M^+; 3), 414 (13), 399 (15), 381 (15), 274 (44), 259 (26), 241 (16), 224 (66), 209 (40), and 208 (44); Found: *m/z* 432.3959. Calcd for $C_{29}H_{52}O_2$: M, 432.3965.

Acetylation of 29-Norlanostane-3β,11β-diol (50). The diol (**50**; 46 mg) was acetytlated to afford 3β-acetoxy-29-norlanostan-11β-ol (**51**; 51.3 mg), mp 167—168 °C (needles from methanol); IR 3480, 1710, 1280, 1035, and 980 cm^{-1}; ^1H NMR (90 MHz) δ=0.78 (3H, s; 30-Me), 0.87 (9H, d, *J*=6 Hz), 0.89 (3H, d, *J*=5 Hz), 1.00 (3H, s), 1.12 (3H, s), 2.05 (3H, s; OAc), 4.25 (1H, m; H-C-OH), and 4.40 (1H, dt, *J*=5 and 10 Hz; H-C-OAc); MS *m/z* (%) 474 (M^+; 2), 456 (6), 441 (6), 414 (1), 316 (28), 256 (15), 250 (38), 241 (24), and 224 (57); Found: *m/z* 474.4093. Calcd for $C_{31}H_{54}O_3$: M, 474.4073.

Dehydration of 3β-Acetoxy-29-norlanostan-11β-ol (51). Dehydration of the 11β-ol (**51**; 50 mg) was effected in the same way as that used for **28a** and **28b**. The product was purified by chromatography on silica gel (5 g) to afford 29-norlanost-9(11)-en-3β-yl acetate (**52**; 29 mg), mp 114 °C (needles from methanol) (lit,[12a] mp 113.5—115 °C); IR 1740, 1635, 1250, 1030, and 980 cm^{-1}; ^1H NMR (90 MHz) δ=0.66 (3H, s; 18-Me), 0.74—0.95 (total Me×5), 1.00 (3H, s; 19-Me), 2.05 (3H, s; OAc), 4.40 (1H, m; H-C-OAc), and 5.34 (1H, m; C=C-H); MS *m/z* (%) 456 (M^+; 68), 441 (100), 396 (7), and 381 (35); Found: *m/z* 456.3983. Calcd for $C_{31}H_{52}O_2$: M, 456.3967.

29-Norlanost-9(11)-en-3β-ol (53). The acetate (**52**; 27 mg) was hydrolyzed with potassium hydroxide in boiling methanol to give 29-norlanost-9(11)-en-3β-ol (**53**; 23 mg) after crystallization from methanol as needles. **53**: Mp 148—149 °C; IR 3300, 1635, 1040, 1020, and 975 cm^{-1}; ^1H NMR (90 MHz) δ=0.66 (3H, s; 18-Me), 0.75 (3H, s; 30-Me), 0.88 (9H, d, *J*=6 Hz), 0.97 (3H, d, *J*=6 Hz; 28-Me), 0.99 (3H, s; 19-Me), 3.10 (1H, dt, *J*=5 and 10 Hz; H-C-OH), and 5.35 (1H, m; C=C-H); MS *m/z* (%) 414 (M^+; 21), 399 (100), 381 (20), 311 (4), 273 (7), 259 (9), 245 (6), and 243 (8).

29-Norlanost-9(11)-en-3-one (5). The alcohol (**53**; 21 mg) was oxidized with Jones reagent to afford 29-norlanost-9(11)-en-3-one (**5**) quantitatively, mp 102—102.5 °C (needles from methanol); IR 1720, 1205, 1150, 1140, and 980 cm^{-1}; $[\alpha]_D^{22}$+71° (*c* 0.07, $CHCl_3$); ^1H NMR (270 MHz) δ=0.69 (3H, s; 18-Me), 0.74 (3H, s; 30-Me), 0.868 (3H, d, *J*=6.4 Hz), 0.872 (3H, d, *J*=6.6 Hz), 0.882 (3H, d, *J*=6.1 Hz), 1.01 (3H, d, *J*=6.4 Hz; 28-Me), 1.23 (3H, s; 19-Me), and 5.35 (1H, dd, *J*=5.5 and 4.5 Hz); MS *m/z* (%) 412 (M^+; 18), 397 (100), 299 (6), 285 (2), 257 (7), 243 (12), 231 (12), and 217 (4); Found: *m/z* 412.3726. Calcd for $C_{29}H_{48}O$: M, 412.3705.

Oxidation of 29-Norlanost-8-en-3β-yl Acetate (45) with Chromyl Chloride. Chromyl chloride (0.015 ml) in dichloromethane (0.8 ml) was added to a solution of 29-norlanost-8-en-3β-yl acetate (**45**; 50 mg) in dichloromethane (1 ml) at −60 °C, and the solution was stirred for 1 h at −30 °C. Sodium hydrogensulfite solution was added to the solution and the product was extracted with ether. The usual work-up afforded 9(11)-en-7-one (**54**), which was isomerized immediately by $BF_3 \cdot OEt_2$ in benzene (3 ml). After 2 d, the solution was diluted with ether and washed with sodium hydrogencarbonate solution and dried. On evaporation and crystallization from hexane, 3β-acetoxy-29-norlanost-8-en-7-one (**55**; 27.6 mg) was obtained. The filtrate was chromatographed on silica gel (5 g) eluted with 10% ether-hexane, 15% ether-hexane, and then 20% ether-hexane (each 20 ml) to afford additional crystals of **55** (8 mg) from frs 18—20 (each fraction: 1/4 column volume). **55**: Mp 143.5 °C (cubics from hexane); IR 1740, 1650, 1580, and 1245 cm^{-1}; UV (EtOH) 252 nm (log ε 4.0); ^1H NMR (90 MHz) δ=0.67 (3H, s), 0.87 (9H, d, *J*=7 Hz), 0.93 (3H, s), 1.19 (3H, s), 2.05 (3H, s; OAc), and 4.8 (1H, m; H-C-OAc); MS *m/z* (%) 470 (M^+; 50), 455 (100), 410 (3), 395 (4), 357 (10), 302 (11), 264 (6), 229 (12), and 215 (9); Found: *m/z* 470.3779. Calcd for $C_{31}H_{50}O_3$: M, 470.3759.

A Mixture of 29-Norlanost-7-en-3-one (6) and 29-Norlanost-8-en-3-one (24). A mixture of the enone (**55**; 25 mg), hydrazine hydrate (0.5 ml), and diethylene glycol (2 ml) was refluxed at 130 °C for 2 h. After cooling, potassium hydroxide (3 pellets) was added to the mixture and the temperature was raised at 220 °C. Reflux was continued for 2 h and the mixture was worked up as usual to afford a mixture of alcohols.

Without purification, the mixture of alcohols was oxidized with Jones reagent in acetone to afford a mixture of 29-norlanost-7-en-3-one (**6**) and 29-norlanost-8-en-3-one (**24**), which was purified by chromatography on silica gel (5 g). Elution (each fraction: 1/2 column volume) was performed with 10% ether-hexane. Fractions 4—6 gave crystals (13.6 mg), which were shown to be a 2:1 mixture of **6** and **24** by ^1H NMR measurement. The mixture of **6** and **24**: IR 1715, 1310, 1230, 1185, 1175, and 820 cm^{-1}; MS *m/z* (%) 412 (M^+; 36), 397 (100), 299 (6), 285 (4), 257 (16), 243 (13), and 231 (20). ^1H NMR (270 MHz) signals ascribable to **6** δ=0.69 (3H, s; 18-Me), 0.86 (3H, s; 30-Me), 1.00 (3H, d, *J*=7 Hz; 28-Me), 1.09 (3H, s; 19-Me), and 5.21 (1H, m; H-C=C≺).

The authors wish to express their thanks to Professor Tatsuo Miyazawa of The University of Tokyo for obtaining NMR spectra at 270 MHz.

Photochemical Reaction of 2,3-Dichloro-1,4-naphthoquinone with Enol Silyl Ethers

Kazuhiro MARUYAMA,* Seiji TAI, and Hiroshi IMAHORI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received January 17, 1986)

2-Oxoalkylated 1,4-naphthoquinones were obtained in the photochemical reactions of 2,3-dichloro-1,4-naphthoquinone with 2-trimethylsiloxy-1-alkenes. Application of this method afforded a wide variety of functionalized 2-oxoalkylated 1,4-naphthoquinones. The photochemical reactions of 2,3-dichloro-1,4-naphthoquinone with 1-alkyl-2-(trimethylsiloxy)ethylenes gave naphthol derivatives. However, 1,1-dialkyl-2-(trimethylsiloxy)ethylenes gave none of products.

The photochemistry of quinones with olefins is one of the most important fields of study because quinones exist widely in nature and play an important role. The photochemical reactions of 2,3-disubstituted 1,4-naphthoquinones with 2-methoxy-1-alkenes and subsequent hydrolysis were found to yield 2-oxoalkylated 1,4-naphthoquinones.[1,2] These quinones have possibilities to serve as precursors of naturally occurring and/or antitumor antibiotic quinonoid compounds. However, despite many studies on acylation[3-5] and allylation[3,4,6-10] of quinones, direct 2-oxoalkylation of quinones has never been reported.

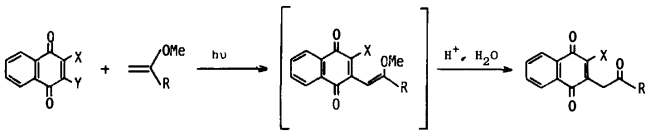

Fig. 1.

In this paper the photochemical reactions of 2,3-dichloro-1,4-naphthoquinone (**1**) with 2-trimethylsiloxy-1-alkenes **2** as well as other substituted enol silyl ethers **3** are discussed.

Results and Discussion

A benzene solution of quinone **1** and a mixture of 2-trimethylsiloxy-1-alkene **2** and its isomer **3** was irradiated with a high-pressure Hg arc lamp in the presence of pyridine at room temperature. Because **2** synthesized from 2-alkanone is contaminated with **3**, it is difficult to isolate **2** from the mixture of **2** and **3**. Then, the mixture of **2** and **3** was used for the reaction. Composite ratios of enol silyl ethers **2** and **3** in the mixture were summarized in Table 1. After hydrolysis of the reaction mixture, purification of products by column chromatography on silica gel gave two discrete classes of final products; 2-chloro-3-(2-oxoalkyl)-1,4-naphthoquinones **4** and 2,3-dichloro-4-(2-oxoalkoxy)-1-naphthols **5**. The results of the photochemical reactions of **1** with the mixture of **2** and **3** were summarized in Table 2. 2-Oxoalkylated 1,4-naphthoquinones **4** were obtained in good yields. In addition naphthol derivatives **5** were obtained. Products **5a—e** were obtained in yields of 10—30%, but **5f** was obtained only a little. On the other hand **4a—g** were obtained constantly as major products. From these results **5** were supposed to be derived from alkenes **3**, and **4** from **2**. To prove this pure enol silyl ethers **3** were synthesized from symmetrical ketones and an aldehyde, and were subjected to the photochemical reactions with quinone **1**. The results of the photochemical reactions of quinone **1** with substituted enol silyl ethers **3** were summarized in Table 2. Actually naphthol derivatives **5** were obtained from the photochemical reactions of quinone **1** with substituted enol silyl ethers **3m—n** and none of 2-oxoalkylated 1,4-naphthoquinones **4** were obtained at all.

These selectivities of products are attributed to the difference of steric effect between **2** and **3**. We have demonstrated that these reactions occur via photoinduced electron transfer and ion radical pair or exciplex exists as an intermediate.[2] In the reaction of **1** with **2**, radical cation $\mathbf{2}^{+}$ can easily attack the carbon atom at 2 or 3 site of radical anion $\mathbf{1}^{-}$ because of little steric effect and **4** is produced. But in the reaction of **1** with **3** (R_3=H, R_4=alkyl group), $\mathbf{3}^{+}$ is hard to approach to the carbon atom at 2 or 3 site of $\mathbf{1}^{-}$ owing to

Table 1. Isomer Ratio of Enol Silyl Ethers **2** and **3** (%)[a]

Enol silyl ether	**2**	**3**
2a : **3a**	80	20

a) Isolated yield based on starting quinone consumed. b) Irradiated for 2 h. c) R_1 contains a hydroxymethyl group. d) In the absence of pyridine.

the steric effect between chlorine atom and R_4. Thus, it is probable that 3^+ is trapped on the oxygen atom in 1^- and **5** is produced. In the reaction of **1** with **3** (R_3, R_4=alkyl group), 3^+ can approach to neither the carbon atom at 2 or 3 site of 1^- nor the oxygen atom in 1^- because of the large steric repulsion between the two reactive species. These are reflected in the fact that the chlorine atom is eliminated after coupling between radical cation and anion.

After all, the photochemical reactions of quinone **1** with enol silyl ethers **2** gave 2-oxoalkylated 1,4-naphthoquinones **4**. The reactions with enol silyl ethers **3a—f** and **3k—n** (R_3=H, R_4=alkyl group) gave naphthol derivatives **5a—f** and **5k—n**, respectively. However, the reactions with enol silyl ethers **3g,o,p** (R_3, R_4=alkyl group) gave no products.

Further, we introduced a hydroxyl group or a double bond into enol silyl ethers **2** as a functional group. The functionalized 2-trimethylsiloxy-1-alkenes **2** gave successfully the corresponding functionalized 2-oxoalkylated 1,4-naphthoquinones **3**. The results of the photochemical reactions of **1** with **2**, **3h—l** were summarized in Table 2.

In conclusion the photochemical reactions of quinone **1** with enol silyl ethers **2** and **3** afforded different products depending upon the substitution mode of enol silyl ethers.

Experimental

All melting points were determined with a Yanagimoto micro melting point apparatus and uncorrected. Mass spectra were taken on a JEOL JMS-DX300 mass spectrometer. ^{1}H NMR spectra were taken by using a JEOL PS-100 spectrometer and ^{13}C NMR were taken by using a JEOL FX-400 spectrometer. IR spectra were obtained by using a JASCO IRA-1 spectrometer on KBr pellets. Elemental analyses were performed at the Microanalysis Center of Kyoto University.

Material. Quinone **1** was used after recrystallization of commerical reagent. Enol silyl ethers **2** and **3** were synthesized according to the reported methods.[11-13]

General Procedures. Quinone **1** (1 mmol), enol silyl ether (2 mmol), and pyridine (2 mmol) were dissolved in benzene (25 ml) and irradiated in a Pyrex tube with a high-pressure Hg arc lamp for 2—3 h. After hydrolysis the reaction mixture was washed with brine, dried, concentrated, purified by chromatography on silica gel, and subjected to further examination for structure determination.

Identification of Products. 2-Chloro-3-(2-oxobutyl)-1,4-naphthoquinone (4a): Yellow needles from hexane-chloroform; mp 134—135 °C. MS; *m/z* 262 and 264 (M^+). Found: C, 63.74; H, 4.21; Cl, 13.58%. Calcd for $C_{14}H_{11}O_3Cl$: C, 64.01; H, 4.22; Cl, 13.50%. IR (KBr); 1705 and 1660 cm^{-1} (C=O). ^{1}H NMR ($CDCl_3$) δ=8.18 (2H, m), 7.82 (2H, m), 4.03 (2H, s), 2.70 (2H, q, J=7.0 Hz), and 1.15 (3H, t, J=7.0 Hz).

2-Chloro-3-(2-oxopentyl)-1,4-naphthoquinone (4b): Yellow plates from hexane-chloroform; mp 108—109.5 °C. MS;

m/z 276 and 278 (M^+). Found: C, 65.09; H, 4.61; Cl, 12.96%. Calcd for $C_{15}H_{13}O_3Cl$: C, 65.11; H, 4.74; Cl, 12.81%. IR (KBr); 1705 and 1670 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.11 (2H, m), 7.78 (2H, m), 3.98 (2H, s), 2.63 (2H, t, *J*=7.0 Hz), 1.69 (2H, sextet, *J*=7.0 Hz), and 0.98 (3H, t, *J*=7.0 Hz).

2-Chloro-3-(2-oxohexyl)-1,4-naphthoquinone (4c): Yellow plates from hexane–chloroform; mp 104—105.5 °C. MS; *m/z* 290 and 292 (M^+). Found: C, 66.04; H, 5.15; Cl, 12.23%. Calcd for $C_{16}H_{15}O_3Cl$: C, 66.10; H, 5.20; Cl, 12.19%. IR (KBr); 1705 and 1665 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.16 (2H, m), 7.80 (2H, m), 4.01 (2H, s), 2.66 (2H, t, *J*=7.0 Hz), 1.2—1.9 (4H, m), and 0.96 (3H, t, *J*=7.0 Hz).

2-Chloro-3-(2-oxoheptyl)-1,4-naphthoquinone (4d): Yellow needles from hexane–chloroform; mp 104—105 °C. MS; *m/z* 304 and 306 (M^+). Found: C, 66.77; H, 5.71; Cl, 11.70%. Calcd for $C_{17}H_{17}O_3Cl$: C, 67.00; H, 5.62; Cl, 11.63%. IR (KBr); 1710 and 1670 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.16 (2H, m), 7.77 (2H, m), 4.00 (2H, s), 2.66 (2H, t, *J*=7.0 Hz), 1.2—2.0 (6H, m), and 0.96 (3H, br-t, *J*=7.0 Hz).

2-Chloro-3-(2-oxooctyl)-1,4-naphthoquinone (4e): Yellow needles from hexane–chloroform; mp 107—108 °C. MS; *m/z* 318 and 320 (M^+). Found: C, 67.74; H, 6.04; Cl, 11.21%. Calcd for $C_{18}H_{19}O_3Cl$: C, 67.82; H, 6.01; Cl, 11.12%. IR (KBr); 1705 and 1670 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.18 (2H, m), 7.81 (2H, m), 4.01 (2H, s), 2.66 (2H, t, *J*=7.0 Hz), 1.1—1.9 (8H, m), and 0.92 (3H, br-t, *J*=7.0 Hz).

2-Chloro-3-(4-methyl-2-oxopentyl)-1,4-naphthoquinone (4f): Yellow needles from hexane–chloroform; mp 94—95.5 °C. MS; *m/z* 290 and 292 (M^+). Found: C, 65.86; H, 5.19; Cl, 12.17%. Calcd for $C_{16}H_{15}O_3Cl$: C, 66.10; H, 5.20; Cl, 12.19%. IR (KBr); 1705, 1675, and 1660 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.16 (2H, m), 7.18 (2H, m), 4.00 (2H, s), 2.53 (2H, d, *J*=7.0 Hz), 2.24 (1H, nonet, *J*=7.0 Hz), and 1.00 (6H, d, *J*=7.0 Hz).

2-Chloro-3-(3-methyl-2-oxobutyl)-1,4-naphthoquinone (4g): Yellow needles from hexane–chloroform; mp 112—113 °C. MS; *m/z* 276 and 278 (M^+). Found: C, 64.84; H, 4.67; Cl, 12.76%. Calcd for $C_{15}H_{13}O_3Cl$: C, 65.11; H, 4.74; Cl, 12.81%. IR (KBr); 1695, 1675, and 1655 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.14 (2H, m), 7.78 (2H, m), 4.06 (2H, s), 2.86 (1H, septet, *J*=7.0 Hz), and 1.24 (6H, d, *J*=7.0 Hz).

2-Chloro-3-(3-hydroxymethyl-2-oxopentyl)-1,4-naphthoquinone (4h): Yellow needles from hexane–chloroform; mp 116—118 °C. MS; *m/z* 307, 308, and 309 (M^+). Found: C, 62.73; H, 4.77; Cl, 11.55%. Calcd for $C_{16}H_{15}O_4Cl$: C, 62.65; H, 4.93; Cl, 11.56%. IR (KBr); 3360 (OH), 1700, and 1650 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.05 (2H, m), 7.69 (2H, m), 4.05 (2H, s), 3.74 (2H, m), 2.85 (1H, br-s), 2.63 (1H, tt), 1.57 (2H, m), and 0.91 (3H, t, *J*=8.4 Hz).

2-Chloro-3-(3-hydroxymethyl-2-oxohexyl)-1,4-naphthoquinone (4i): Yellow needles from hexane–chloroform; mp 118—120 °C. MS; *m/z* 321, 322, and 323 (M^+). Found: C, 63.42; H, 5.29; Cl, 11.28%. Calcd for $C_{17}H_{17}O_4Cl$: C, 63.66; H, 5.34; Cl, 11.05%. IR (KBr); 3380 (OH), 1720, 1680, and 1670 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.01 (2H, m), 7.68 (2H, m), 4.04 (2H, s), 3.74 (2H, m), 3.20 (1H, br-s), 2.71 (1H, tt), 1.39 (4H, m), and 0.90 (3H, t, *J*=6.0 Hz).

2-Chloro-3-(3-hydroxymethyl-2-oxooctyl)-1,4-naphthoquinone (4j): Yellow plates from hexane–chloroform; mp 87—88 °C. MS; *m/z* 349, 350, and 351 (M^+). Found: C, 65.70; H, 6.03; Cl, 10.29%. Calcd for $C_{19}H_{21}O_4Cl$: C, 65.42; H, 6.07; Cl, 10.16%. IR (KBr); 3360 (OH), 1700, 1670, and 1660 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.00 (2H, m), 7.66 (2H, m), 4.01 (2H, s), 3.79 (2H, d, *J*=6.0 Hz), 2.90 (1H, m), 2.38 (1H, br-s), 1.35 (8H, br-s), and 0.90 (3H, br-t).

2-Chloro-3-(2-oxo-5-hexenyl)-1,4-naphthoquinone (4k): Yellow needles from hexane–chloroform; mp 96—98 °C. MS; *m/z* 288 and 290 (M^+). Found: C, 66.82; H, 4.38; Cl, 12.56%. Calcd for $C_{16}H_{13}O_3Cl$: C, 66.56; H, 4.54; Cl, 12.28%. IR (KBr); 1700, 1670, and 1650 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.22 (2H, m), 7.86 (2H, m), 5.90 (1H, m), 5.15 (2H, dd, *J*=9.9 and 9.9 Hz), 4.04 (2H, s), 2.80 (2H, *J*=7.6 Hz), and 2.50 (2H, t, *J*=7.6 Hz).

2-Chloro-3-(6-methyl-2-oxo-5-heptenyl)-1,4-naphthoquinone (4l): Yellow needles from hexane–chloroform; mp 99—100.5 °C. MS; *m/z* 316 and 318 (M^+). Found: C, 67.97; H, 5.37; Cl, 11.29%. Calcd for $C_{18}H_{17}O_3Cl$: C, 68.25; H, 5.41; Cl, 11.19%. IR (KBr); 1700, 1660, and 1650 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.07 (2H, m), 7.72 (2H, m), 5.10 (1H, m), 3.94 (2H, s), 2.65 (2H, td, *J*=6.6 and 6.6 Hz), 2.38 (2H, t, *J*=6.6 Hz), 1.71 (3H, s), and 1.65 (3H, s).

2,3-Dichloro-4-(1-methyl-2-oxopropoxy)-1-naphthol (5a): Pink crystals from hexane–chloroform; mp 132.5—133.5 °C. MS; *m/z* 298, 300, and 302 (M^+). Found: C, 55.98; H, 3.77; Cl, 23.68%. Calcd for $C_{15}H_{14}O_3Cl_2$: C, 56.21; H, 4.04; Cl, 23.70%. IR (KBr); 3420 (OH) and 1730 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.11 (2H, m), 7.55 (2H, m), 6.30 (1H, br-s), 4.79 (1H, q, *J*=6.1 Hz), 2.53 (3H, s), and 1.39 (3H, d, *J*=7.0 Hz). ^{13}C NMR ($CDCl_3$) δ=208.3 (s), 145.1 (s), 143.5 (s), 128.3 (m), 127.4 (d), 126.6 (d), 122.8 (d), 122.2 (m), 122.1 (m), 121.2 (m), 112.4 (s), 84.2 (d), 26.0 (q), and 17.0 (q).

2,3-Dichloro-4-(1-ethyl-2-oxopropoxy)-1-naphthol (5b): Orange crystals from hexane–chloroform; mp 147—148 °C. MS; *m/z* 312, 314, and 316 (M^+). Found: C, 57.25; H, 4.43; Cl, 22.54%. Calcd for $C_{15}H_{14}O_3Cl_2$: C, 57.53; H, 4.51; Cl, 22.64%. IR (KBr); 3250 (OH) and 1690 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.17 (2H, m), 7.59 (2H, m), 6.14 (1H, br-s), 4.64 (1H, t, *J*=6.7 Hz), 2.48 (3H, s), 1.99 (2H, qd, *J*=6.7 and 7.0 Hz), and 0.99 (3H, t, *J*=7.0 Hz).

2,3-Dichloro-4-(1-propyl-2-oxopropoxy)-1-naphthol (5c): White needles from hexane–chloroform; mp 118—119 °C. MS; *m/z* 326, 328, and 330 (M^+). Found: C, 58.47; H, 4.92; Cl, 21.83%. Calcd for $C_{16}H_{16}O_3Cl_2$: C, 58.73; H, 4.93; Cl, 21.67%. IR (KBr); 3210 (OH) and 1700 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.12 (2H, m), 7.54 (2H, m), 6.11 (1H, br-s), 4.68 (1H, t, *J*=6.1 Hz), 2.44 (3H, s), 1.90 (2H, td), 1.48 (2H, qt), and 0.88 (3H, t, *J*=7.6 Hz).

4-(1-butyl-2-oxopropoxy)-2,3-dichloro-1-naphthol (5d): White crystals from hexane–chloroform; mp 103.5—104.5 °C. MS; *m/z* 340, 342, and 344 (M^+). Found: C, 59.99; H, 5.14; Cl, 20.85%. Calcd for $C_{17}H_{18}O_3Cl_2$: C, 59.84; H, 5.32; Cl, 20.78%. IR (KBr); 3200 (OH) and 1700 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.13 (2H, m), 7.55 (2H, m), 6.10 (1H, br-s), 4.67 (1H, t, *J*=5.8 Hz), 2.44 (3H, s), 1.91 (2H, td), 1.29 (4H, m), and 0.85 (3H, t, *J*=6.1 Hz).

2,3-Dichloro-4-(1-pentyl-2-oxopropoxy)-1-naphthol (5e): White crystals from hexane–chloroform; mp 52—54 °C. MS; *m/z* 354, 356, and 358 (M^+). Found: C, 60.68; H, 5.51; Cl, 19.75%. Calcd for $C_{18}H_{20}O_3Cl_2$: C, 60.86; H, 5.67; Cl, 19.96%. IR (KBr); 3520 (OH) and 1710 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.14 (2H, m), 7.55 (2H, m), 6.14 (1H, br-s), 4.68 (1H, t, *J*=6.1 Hz), 2.46 (3H, s), 1.88 (2H, td), 1.27 (6H, m), and 0.84 (3H, t, *J*=6.1 Hz).

2,3-Dichloro-4-(1-isopropyl-2-oxopropoxy)-1-naphthol (5f): White crystals from hexane–chloroform; mp 158—159 °C. MS; *m/z* 326, 328, and 330 (M^+). Found: C, 58.89; H, 4.82;

Cl, 21.92%. Calcd for $C_{16}H_{16}O_3Cl_2$: C, 58.73; H, 4.93; Cl, 21.67%. IR (KBr); 3290 (OH) and 1690 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.16 (2H, m), 7.55 (2H, m), 6.02 (1H, br-s), 4.65 (1H, d, J=4.2 Hz), 2.37 (3H, s), 1.68 (1H, m), and 1.08 (6H, d, J=6.7 Hz).

2,3-Dichloro-4-(1-methyl-2-oxobutoxy)-1-naphthol (5m): White needles from hexane–chloroform; mp 119—120 °C. MS; m/z 312, 314, and 316 (M^+). Found: C, 57.53; H, 4.51; Cl, 22.64%. Calcd for $C_{15}H_{14}O_3Cl_2$: C, 57.53; H, 4.51; Cl, 22.68%. IR (KBr); 3410 (OH) and 1690 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.05 (2H, m), 7.49 (2H, m), 6.24 (1H, br-s), 4.82 (1H, q, J=7.0 Hz), 2.93 (2H, q, J=7.3 Hz), 1.37 (3H, d, J=6.7 Hz), and 1.17 (3H, t, J=6.7 Hz).

2,3-Dichloro-4-(1-ethyl-2-oxopentyloxy)-1-naphthol (5n): White crystals from hexane–chloroform; mp 90.5—91.5 °C. MS; m/z 340, 342, and 344 (M^+). Found: C, 59.75; H, 5.32; Cl, 20.91%. Calcd for $C_{17}H_{18}O_3Cl_2$: C, 59.83; H, 5.32; Cl, 20.78%. IR (KBr); 3320 (OH) and 1690 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ=8.12 (2H, m), 7.54 (2H, m), 6.07 (1H, br-s), 4.67 (1H, t, J=6.0 Hz), 2.78 (2H, qd), 1.93 (2H, t, J=7.2 Hz), 1.70 (2H, qd, J=7.2 and 7.2 Hz), and 0.95 (3H, t, J=4.8 Hz).

Synthesis of Oligodeoxyribonucleotides Involving a Rapid Procedure for Removal of Base-Protecting Groups by Use of the 4,4′,4″-Tris(benzoyloxy)trityl (TBTr) Group

Mitsuo SEKINE,* Narihiro MASUDA, and Tsujiaki HATA*
Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received January 18, 1986)

Fully protected building units for oligodeoxyribonucleotide synthesis in the phosphoramidite approach were prepared in high yields by the 5′-dimethoxytritylation of *N*-[4,4′,4″-tris(benzoyloxy)trityl]deoxyribonucleosides followed by the 3′-phosphitylation with methoxymorpholinochlorophosphine. The solid phase synthesis of oligodeoxyribonucleotides on a controlled pore glass gel using the amidite units was examined. The efficiency of condensation was discussed in detail. The 4,4′,4″-tris(benzoyloxy)trityl (TBTr) group was removed rapidly from a protected tetramer synthesized on the controlled pore glass gel to give dGpCpApT.

Recent developments of oligodeoxyribonucleotide synthesis have enabled us to synthesize relatively long DNA fragments in short time.[1] Reaction velocity of condensation has been dramatically accelerated by introduction of new technologies such as the tetrazole-catalyzed phosphoramidite approach[2] and the *N*-methylimidazole[3] or 4-substituted pyridine-*N*-oxide-promoted phosphotriester approach.[4] The use of sterically hindered diaryl phosphorochloridates also improved markedly the condensation time.[5] However, only little attention has been paid to the deprotection procedure of fully protected DNA fragments.[6] Especially, removal of *N*-acyl protecting groups from oligomers was the most sluggish in the whole synthetic procedures. Some improvements have been reported in this direction but they required rather drastic conditions such as elevated temperatures.[7]

In this paper, we report basic studies on improvement of the deprotection procedure for *N*-protecting groups by the use of 4,4′,4″-tris(benzoyloxy)trityl (TBTr) as a universal base-protecting group.

Results and Discussion

In a previous paper,[8] we showed that the TBTr group could be introduced into the four common base moieties by using the transient protection strategy. The glycosyl bond of *N*-TBTr-deoxyadenosine (**2c**) was also found to be 4 times more stable to 2% dichloroacetic acid in dichloromethane (CH_2Cl_2) than that of N^6-benzoyldeoxyadenosine. Since the TBTr group was rather resistant to acids owing to its electronic effect derived from the three benzoyloxy substituents, the 4,4′-dimethoxytrityl (DMTr) group could be used as the 5′-hydroxy protecting group in combination with the TBTr group. Therefore, we chose the latter as the *N*-protecting group in the phosphoramidite approach using the morpholino group as an activatable phosphite protecting group.

Preparation of Fully-Protected Deoxyribonucleoside Amidite Units (3b—d). *N*-[4,4′,4″-Tris(benzoyloxy)-trityl]deoxyribonucleosides (**1b—d**) were allowed to

react with 4,4′-dimethoxytrityl chloride (DMTrCl) to give the corresponding 5′-tritylated products (**2b—d**) in 92—98% yields (Table 1). The amidite units (**3a—d**) were synthesized by a method similar to that described by Caruthers.[2b] Reaction of **2b—d** with methoxymorpholinochlorophosphine (MMCP) in the presence of *N,N*-diisopropylethylamine in CH_2Cl_2 gave the desired products (**3b—d**). The phosphoramidites **3b—d** were obtained in more than 90% yields by reprecipitation from CH_2Cl_2 into hexane. However, the purities of the precipitated materials were less than 70% from their NMR spectra. Several experiments were conducted to purify **3b—d** by using silica-gel or alumina column chromatography developed with various solvent systems. Because of the lability of the TBTr group to secondary amines such as morpholine the inert tertiary amines, triethylamine and *N*-methylpyrrolidine, were used with CH_2Cl_2–hexane or benzene. By the use of these solvent systems, **3b—d** were satisfactorily purified and their purities increased to more than 90% as shown in Chart 1. The impurities were found to be the hydrolyzed products (**4a—d**) of **3b—d** and the 3′–3′ linked dimer (**5b—d**). The former could be removed by chromatographic separation but the latter remained to a degree of 3—5% even after rechromatography. Nevertheless, the amidite units were used without further purification since the 3′–3′ by-products were inert during condensation and could be washed off from solid supports. The amidites appeared at −144 ppm in their ^{31}P NMR spectra as shown in Table 2.

Polymer Supported Synthesis of Oligodeoxyribonucleotides. Recent studies on the solid phase synthesis of oligodeoxyribonucleotides in the phosphoramidite approach pioneered by Caruthers[2] have shown that controlled pore glass (CPG)[9] was very effective as a nonswellable polymer support. Therefore, we employed two kinds of CPG gel supports, 3-aminopropyl CPG (P-CPG) and long-chain amino CPG (L-CPG) purchased from Funakoshi Co. Ltd. The latter has a hexamethylene chain in the spacer. Both the supports were bound to 4,4′-*O*-dimethoxytritylthymidine (DMTrT) via the succinate linker according to the well established procedure.[10] The loading amounts of DMTrT were 35.9 and 13.9 $\mu mol\,g^{-1}$ for P-CPG and L-CPG, respectively.

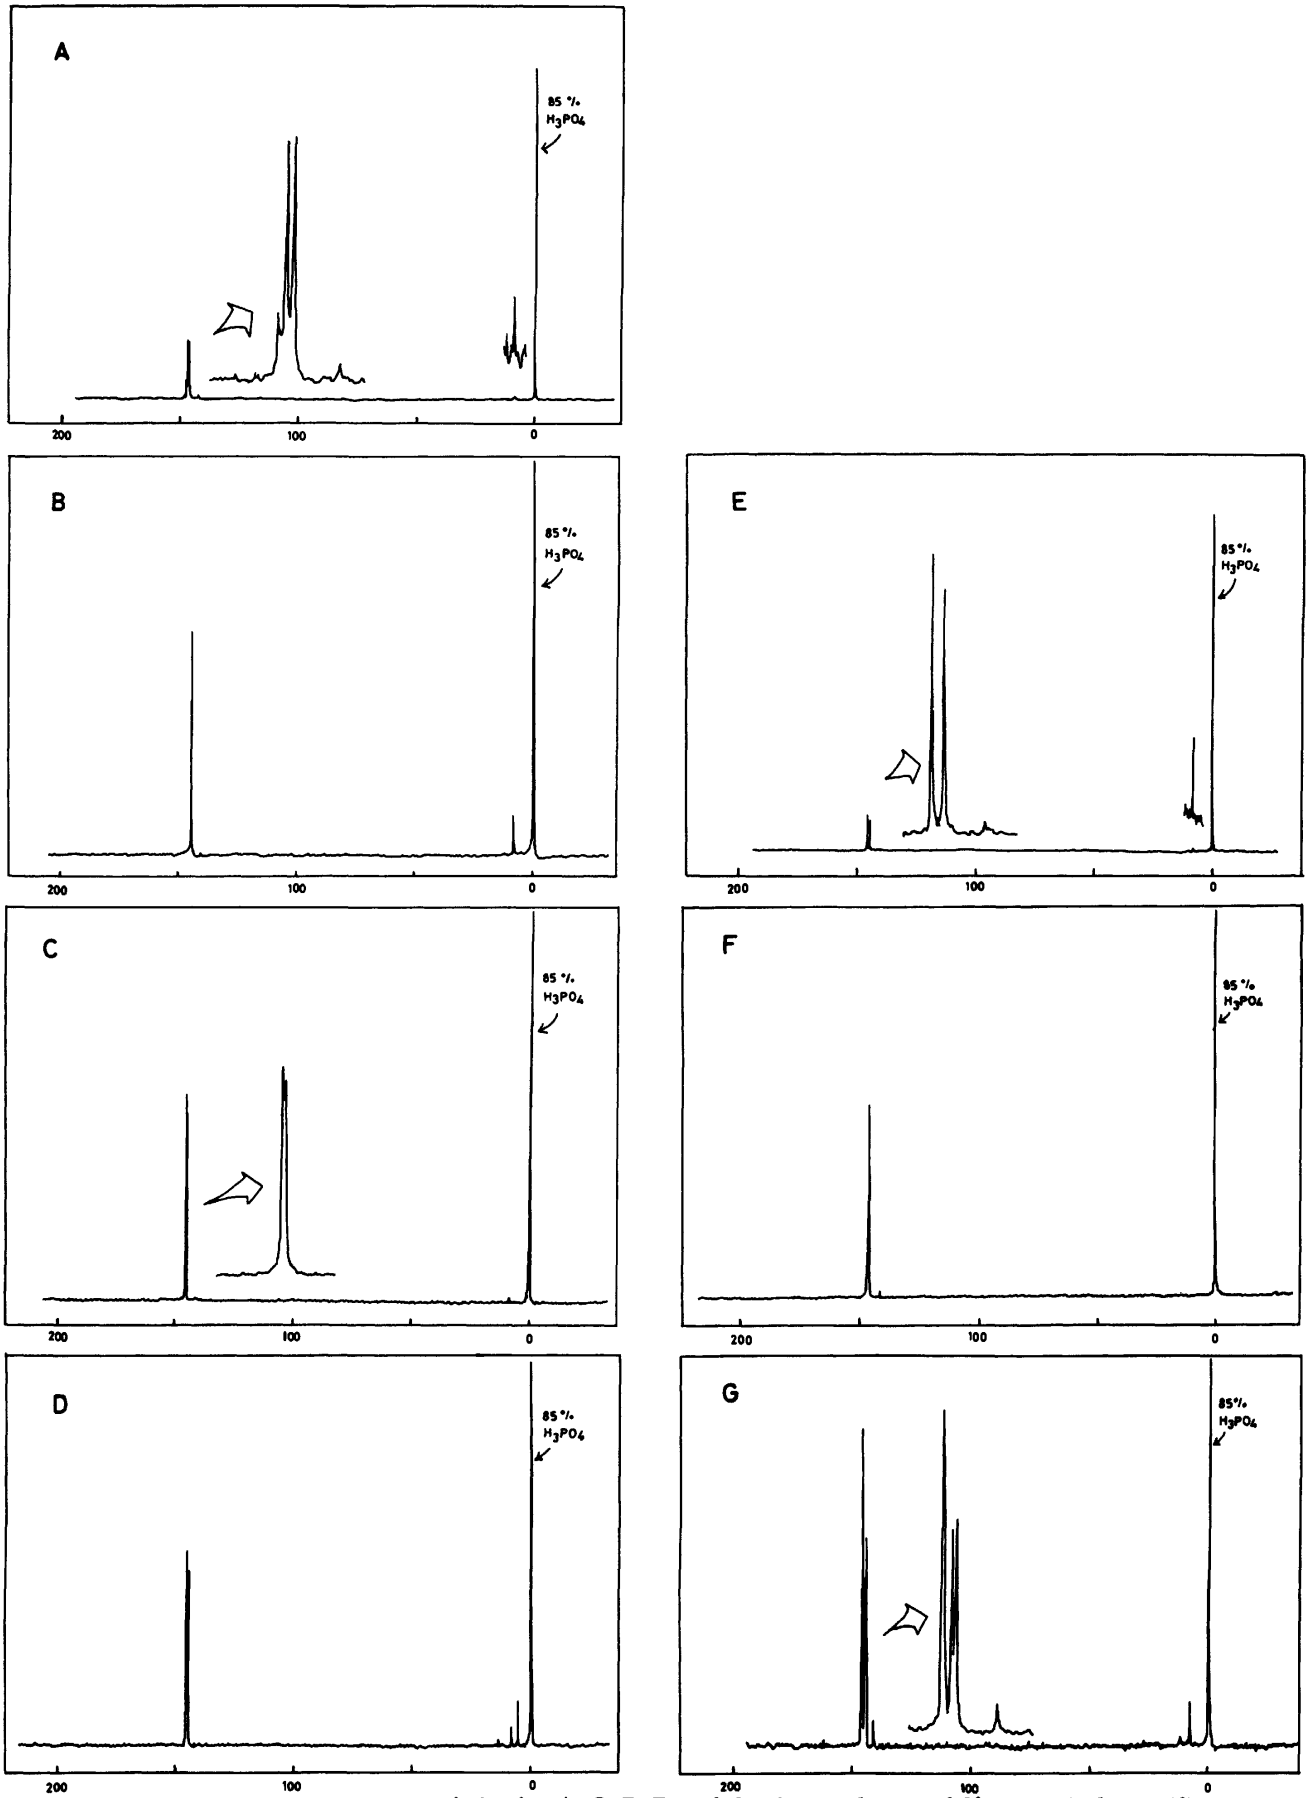

Chart 1. The ^{31}P NMR spectra of **3b**—f.· A, C, E, F, and G: **3b**, **3c**, **3d**, **3e**, and **3f**, respectively, purified by silica-gel or alumina column chromatography; B and D: **3c** and **3d**, respectively, obtained by reprecipitation from CH_2Cl_2 into hexane after the extractive workup.

Table 3. Elongation Cycle for Polymer Support Synthesis of Oligoribonucleotides

Step	Manipulation	Time/min	Volume/ml
1	1% TFA/CH_2Cl_2	2	3
2	Wash with CH_2Cl_2, MeCN	1	5
3	0.2M phosphoramidite (20 equiv)/MeCN (0.18 ml)+0.4M tetrazole (40 equiv)/MeCN (0.18 ml)	5 or 10	0.36
4	Wash with MeCN, THF		
5	0.1M I_2/2,6-lutidine-THF-H_2O (1:2:2, v/v/v)	1	1
6	Wash with MeCN, THF	1	5
7	0.07M DMAP/Ac_2O-THF-lutidine (2:6:1, v/v/v)	2	3
8	Wash with THF, CH_2Cl_2	1	5

DMTrT-CPG (35.9 μmol/g, 50 mg, 1.8 μmol) was used in each experiment.

Prior to condensation of **3b—d** on these supports, we reconfirmed suitable conditions of coupling cycle by using a modification of the procedure reported by Adams.[2c] The modified cycle for the polymer-supported synthesis is shown in Table 3.

Condensation of **3a** with T-L-CPG was repeated three times under the different conditions using 0.05 and 0.1 M† solutions of **3a**. However, the average coupling yields, which were estimated by the DMTr cation assay, were only 83 and 86% in the case of 0.05 and 0.1 M solutions of **3a**, respectively.

amidite(M)	time	solvent	T—T—T—T—— [L-CPG]
3a (0.05)	5 min	MeCN	87 87 74 (%) av. 83 %
3a (0.1)	5 min	MeCN	95 89 73 86

Although a relatively long spacer was involved in L-CPG like a long alkylated CPG (LA-CPG) used by Gilham,[9a] Adams,[2c] and Köster,[9d] the unexpected results were obtained. This is due probably to lack of affinity of the activated phosphorylated species of **3a** for the aliphatic hexamethylene chain. The presence of somewhat polar bonds like LA-CPG seems to be important for smooth coupling. However, the coupling of T-P-CPG with **3a** was found to proceed more effectively than that of T-L-CPG under the same conditions. Under the conditions of 10 min and 0.1 M solution of **3a**, the average coupling yield increased to 98% satisfactorily as reported in the original paper.[2b]

	94 98 97 99 99 104 98		

We feel that the coupling time requires at least 10 min when the morpholino group is used. A relatively long reaction period has already been employed by Köster.[2d,8d]

However, the guanosine unit **3d** was found to form a gel in acetonitrile. The other new amidite units **3b,c** were soluble in this solvent. Therefore, a mixed solvent of 1,2-dichloroethane(DCE)-acetonitrile (1:1, v/v) was chosen during the condensation step to compare the reactivities of the three amidite units **3b—d** under the same conditions. In the case of the deoxycytidine unit **3b**, the coupling yields increased gradually with an increase in chain length and finally up to more than 95% after the five consecutive couplings. Compared with this result, the coupling yields in the case of **3c** were constant with an average yield of 79%. The average coupling yield was improved by the use of only acetonitrile to 89%.

amidite(M)	time	solvent

	77 79 83 78 88 69 (%) 79 %		
	— 90 87 87 94 87 (%) 89 %		

A mixed solvent with 1,2-dichloroethane was somewhat inferior to acetonitrile in our coupling system. In an attempt to improve the coupling yield, a little more acidic catalyst, 5-(4-nitrophenyl)tetrazole (NPT), reported by Matteucci,[11] was employed. How-

† 1 M=1 mol dm^{-3}.

ever, this catalyst was ca. one-forth less soluble in acetonitrile than tetrazole so that a relatively dilute solution of NPT (0.1 M) had to be used. As a consequence, high yield couplings were attained at the second and third condensations although the first coupling was ineffective.

amidite(M)	NPT(M)	time	solvent
3c (0.1)	0.1	10 min	DCE–MeCN (1:1, v/v)

A—A—A—T—— [P-CPG]
97 89 35 (%) av. 74 %

However, a large amount of precipitate appeared 1 min after the tetrazole was added at every coupling stage. This precipitate, probably, morpholinium salt of NPT, caused difficult shaking during the reaction.

In the case of deoxyguanosine, the average coupling yield was very low in 1,2-dichloromethane–acetonitrile. It was observed that the coupling yields after the second condensation were considerably lower than that obtained in the first coupling. This low reactivity of **3d** led us to examine if the reagent was stable in 1,2-dichloroethane–acetonitrile. The same coupling cycle was repeated after **3d** was left in the mixed solvent in the presence of tetrazole for 5 h. However, a similar result was obtained.

25 26 57 36

*In this case, **3d** was used 5h after tetrazole was added.

Next, in order to see if the low yield is due to side reactions at the guanine moiety, several experiments were conducted. First, the four consecutive couplings of T-P-CPG with a newly-synthesized amidite unit (**3e**) of deoxyguanosine were carried out. The compound **3e** was obtained in 67% yield from the deoxyguanosine derivative (**2e**) as the substrate which could eliminate any side reactions on the guanine moiety since the reactive amidite site was blocked completely with the diphenylcarbamoyl (DPC) group.[12]

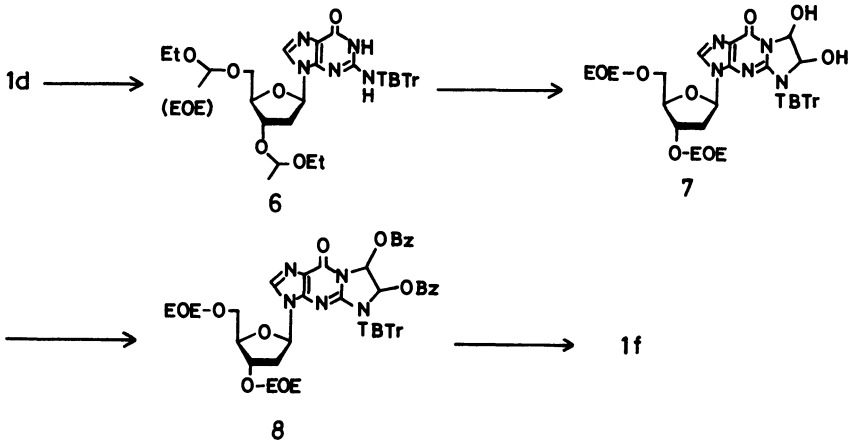
G*—G*—G*—G*—G*—G*—T—— [P-CPG]
83 85 83 79 81 89 (%) av. 83 %

G* refers to 2-*N*-propionyl-*O*^{6}-diphenylcarbamoyldeoxyguanosine.

Consequently, a nearly constant average yield of 83% was obtained. Since we aimed to develop rapid deprotection procedures through this study and removal of the DPC group required somewhat long periods of time, the double protection mode using glyoxal was employed. As expected from our previous paper, 1,2-bis(acyloxy)ethylene groups such as the 1,2-bis(isobutyryloxy)ethylene group[13] would be removed readily under mild basic conditions. The compound **1d** was treated with ethyl vinyl ether in the presence of trifluoroacetic acid in CH_2Cl_2 to give a bis(1-ethoxyethyl)ated derivative (**6**), which was in situ converted to a glyoxal adduct (**7**) by a method similar to that reported previously.[13] The two hydroxyl groups of **7** were further acylated with benzoic anhydride. The resulting product (**8**) was partially deblocked with 1 M zinc bromide in CH_2Cl_2–2-propanol[14] to give the key intermediate (**1f**) in an overall yield of 55% from **1d**.

It was found that the 1,2-bis(benzoyloxy)ethylene (BBE) group was rapidly eliminated from **1f** by treatment with 0.5 M NaOH–pyridine (1:1,v/v) at room temperature for 20 min. Under these conditions, the TBTr group was simultaneously removed to afford deoxyguanosine. It was also found that compound **1f** was stable to iodine in THF–lutidine–water like **1a**—



Scheme 2.

e. On the TFA treatment, **1f** has a relatively long half time of 24 h toward depurination. These results led us to synthesize a new deoxyguanosine amidite unit (**3f**). The compound **1f** was tritylated with DMTrCl to give **2f** in 93% yield. The subsequent phosphitylation of **2f** with MMCP gave **3f** in 95% yield. A high yield synthesis of **2f** was achieved with the aid of the highly lipophilic protecting groups contained in the molecule, which facilitated elution of the product from an alumina column.

The coupling reaction of the unit **3f** with T-P-CPG was tested under various conditions. However, unsatisfactory results were obtained. In 1,2-dichloroethane–acetonitrile, the coupling yields at the first and second condensations were 56 and 27% yields, respectively.

60 62 47 49 74	58

G′ refers to 2-*N*-TBTr-N^1,N^2-bis(benzoyloxy)ethylene-deoxyguanosine.

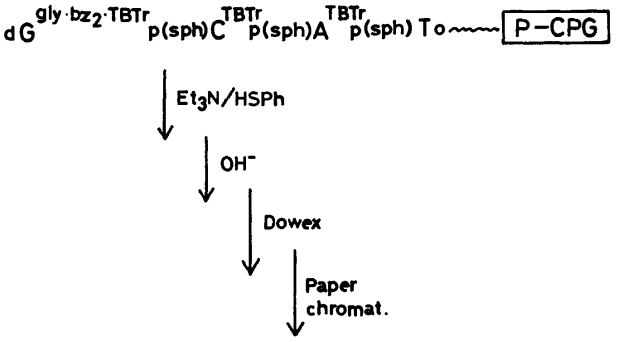
When the time for the condensation was prolonged to 60 min, remarkable improvements were not made. When acetonitrile was used in place of the mixed solvent, somewhat better results were obtained. These results indicate that the low coupling yield in the case of **3d** may be due to the steric hindrance of the TBTr group attached to the exo amino group. In fact, the CPK model suggests that the TBTr residue can approach to the 3′-position. An alternative way to solve this problem should be studied.

In spite of the problem on the deoxyguanosine unit, we demonstrated rapid deprotection procedure after coupling using the four phosphoramidite units, **3a—c** and **3f**, on CPG gel. In order to see if the TBTr group can be smoothly removed from CPG gel, we synthesized a sequence of dGpCpApT on P-CPG. The results are shown below.

amidite(M)	time	solvent
3b, 3c, 3f (0.1 each)	10 min	MeCN

G′—C—A—T——	[P-CPG]
45 84 86 (%)	av. 72 %

The CPG gel loading this sequence was first treated with benzenethiol–Et_3N–dioxane (1:1:1, v/v)[2a] and then with 0.5 M NaOH–pyridine (1:1, v/v) at room temperature for 30 min. It was confirmed that under the latter conditions the succinate linker and the TBTr and BBE groups were rapidly removed as expected.[8,15] The reaction could be easily monitored by the strength of color of rosolic acid, which was generated as the deprotection proceeded. Since the sensitivity of this color test was as good as that of the DMTr cation assay under acidic conditions, the completion of deprotection can be confirmed directly by eyes.



Scheme 3.

These properties will be advantageous when applied to automated synthesis of oligodeoxyribonucleotides. Rosolic acid and benzoic acid generated were easily removed by extraction with ether. The mixture obtained from the aqueous layer was chromatographed on Whatman 3 MM papers with 1-propanol–concentrated aqueous ammonia–H_2O (55:10:35, v/v/v) to afford dGpCpApT in 70% yield. The tetramer was characterized by enzymatic digestion with snake venom phosphodiesterase which gave G, pC, pA, and pT in the ratio of 1.08:0.85:1.00:0.88.

Conclusion

As shown in the present study, the TBTr and BBE groups could be removed promptly from the oligomer chain within 30 min. Since the phosphodiester linkage is rather stable under alkaline conditions[7] compared with phosphotriester linkage, relatively strong alkali like NaOH is available for removal of base protecting groups after elimination of the methyl group with benzenethiol. The conventional protecting groups of acyl-type were, however, resistant to alkali such as dilute NaOH except for labile acyl groups like the acetyl group on N^4-acetyldeoxycytidine[16] which can not be utilized in oligodeoxyribonucleotide synthesis. Therefore they have been removed mostly by treatment with concentrated aqueous ammonia. It is noteworthy that the TBTr and BBE groups are removed simply under mildly alkaline conditions that can be applied to the "full" automated-synthesis of DNA fragments which involves the deprotection procedure. The color

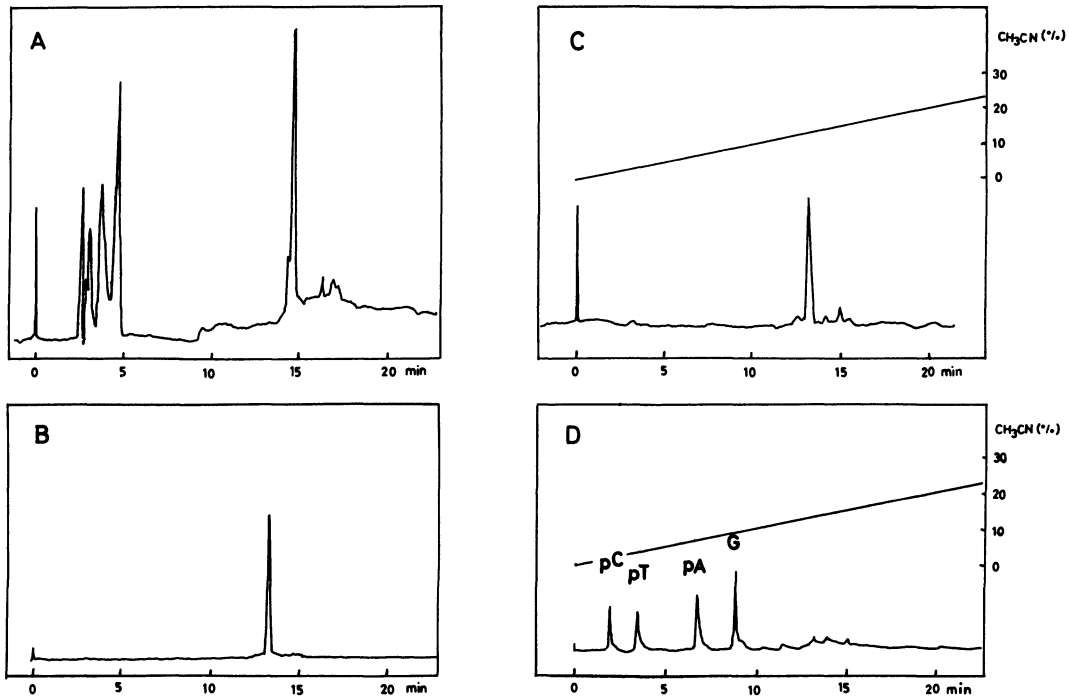


Chart 2. A: The ion-exchange HPLC profile of the mixture obtained after the protecting groups and linker were removed; B: The reverse-phase HPLC profile of dGpCpApT separated by paper chromatography; D: The reverse-phase HPLC profile of the mixture obtained by enzyme digestion of dGpCpApT with snake venom phosphodiesterase.

marker of rosolic acid enabled us to observe visibly the degree of the complete deprotection since the succinate linker and the BBE group were eliminated under the conditions where the TBTr group was removed. However, some improvements are needed for obtaining higher coupling yields. Especially, more suitable alkali-labile protecting groups should be explored for our purpose. We are now challenging to solve these problems in this derection.

Experimental

^{1}H NMR spectra were recorded at 100 MHz on a JEOL UNM PS-100 spectrometer using tetramethylsilane as an internal standard. UV spectra were obtained on a Hitachi 220A spectrophotometer. Paper chromatography was performed by use of a descending technique with Whatman 3 MM papers using the following solvent system: Solvent I (1-propanol–concentrated aqueous ammonia–water, 55:10:35, v/v/v). Column chromatography was performed with silica gel C-200 purchased from Wako Co. Ltd. or alumina Woelm B-Supper I from Kanto Co. Ltd., and a minipump for a goldfish bowl was conveniently used to attain sufficient pressure for rapid chromatographic separation. TLC was performed on precoated TLC plates of silica gel 60 F-254 (Merck) or aluminium oxide 60 F-254 (Merck).

Ion-exchange HPLC was performed on a JASCO TRI ROTAR type II apparatus equipped with a Whatman Partisil 10 SAX column (3.9×250 mm), a GP-A30 solvent programmer, a UVIDEC 100-II UV detecter and an RC-225 recorder. A linear gradient (0→99%) starting with buffer A (0.005 M KH_2PO_4, 20% CH_3CN, pH 6.54) and applying buffer B (0.5 M KH_2PO_4, 20% CH_3CN, pH 6.54) was used at a flow rate of 2 ml min^{-1} for 32 min for analysis and purification of dGpCpApT. Reverse phase HPLC was performed on a Waters Model A25 using a μ-Bondapack C-18 column using a linear gradient starting from buffer C (0.1 M NH_4OAc, pH 7.0) and applying CH_3CN at a flow rate of 2 ml min^{-1} for 30 min.

Deoxyribonucleosides were purchased from Yoshitomi Co. Ltd. Compounds **1b—d**,[8] **2a**,[17] and **2e**[12] were prepared to the published procedures. Pyridine was distilled two times from *p*-toluenesulfonyl chloride and from calcium hydride and then stored over molecular sieves 3A. Acetonitrile was distilled over calcium hydride and stored over molecular sieves 3A. 1,2-Dichloroethane was dried over P_4O_{10}, decanted, distilled over K_2CO_3, and stored over molecular sieves 3A.

Venom phosphodiesterase was purchased from Boehringer Co. Ltd. Elemental analyses were performed by the Microanalytical Laboratory, Tokyo Institute of Technology, at Nagatsuta.

General Procedure for Synthesis of 2b—f. An appropriate *N*-TBTr deoxyribonucleoside[7] (**1b—f**, 5 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (50 ml). To the solution was added DMTrCl (1.05—1.20 equiv), and the mixture was kept for 3—5 h. Then ice-water was added and the mixture was extracted with CH_2Cl_2. The organic layer was washed with satd $NaHCO_3$ solution, dried over Na_2SO_4, filtered, and evaporated to a gum. The residue was evaporated several times with toluene and chromatographed on silica gel (70 g) with CH_2Cl_2→CH_2Cl_2–MeOH in the presence of 0.3% pyridine to give **2b—f** as listed in Table 1.

General Procedure for Synthesis of 3b—f. An appropriate *N*-TBTr-5′-*O*-DMTr-deoxyribonucleoside (**2b—f**, 1 mmol) was

rendered anhydrous by coevaporation with dry pyridine and then with dry toluene two times each and finally dissolved in dry CH_2Cl_2 (10 ml). To the solution were added successively diisopropylethylamine (609 μl, 3.5 mmol) and MMCP (224 μl, 1.5 mmol). After being stirred at room temperature for 10 min, the mixture was dissolved with ethyl acetate (20 ml) which had been washed with satd $NaHCO_3$ solution. The organic phase was again washed with satd $NaHCO_3$ solution (20 ml). After drying over Na_2SO_4, the extract was filtered and evaporated to a foam. The foamy material was chromatographed on a silica-gel or alumina column as shown in Table 2. The elemental analyses and ^{31}P NMR spectra of **3b—f** are also given in Table 2.

Introduction of DMTrT to CPG. To a suspension of P-CPG (pore size 569 Å, NH_2 97 μmol g^{-1}) or L-CPG (pore size 569 Å, NH_2 123 μmol g^{-1}) were added triethylamine (3 equiv), 4-(dimethylamino)pyridine (0.75 equiv), and 5′-*O*-dimethoxytrityl-3′-*O*-[3-(pentachlorophenoxycarbonyl)propionyl]thymidine (1.5 equiv). After the mixture was rotated slowly in a sealed flask by using a rotary evaporator for 20 h, the gel was washed with CH_2Cl_2 and dried over P_4O_{10} and NaOH in vacuo. The resulting gel was used for condensation with **3**.

***N*²-[4,4′,4″-Tris(benzoyloxy)trityl]-*N*¹,*N*²-bis(benzoyloxy)-ethylenedeoxyguanosine (8).** To a mixture of **1d** (2.31 g, 2.61 mmol) and ethyl vinyl ether (5.07 ml, 53 mmol) was added trifluoroacetic acid (408 μl, 5.3 mmol). The solution was stirred at room temperature for 100 min and the solvent and the ether was removed under reduced pressure. The residue was coevaporated successively with toluene and dry pyridine two times each and then dissolved in 2.5 M solution of glyoxal in dry pyridine (10 ml). The mixture was evaporated ten times with dry pyridine (20 ml) and finally dissolved in CH_2Cl_2 (100 ml). The CH_2Cl_2 solution was washed five times with water (100 ml), dried over Na_2SO_4, filtered, and evaporated to a gum. The gum was rendered anhydrous by repeated coevaporation with dry pyridine and then evaporated several times with dry toluene to remove the last traces of pyridine. The residue was dissolved in dry CH_2Cl_2 (25 ml) and treated with benzoic anhydride (4.72 g, 20.9 mmol), triethylamine (2.9 ml, 20.9 mmol), 4-(dimethylamino)pyridine (32 mg, 0.26 mmol). After the resulting mixture was kept at room temperature for 17 h, water was added. The dibenzoate was extracted three times with CH_2Cl_2 and the extract was washed with satd $NaHCO_3$ solution. The extracts were combined and evaporated to dryness under reduced pressure. To the residue was added 1 M solution of zinc bromide in CH_2Cl_2–2-propanol (85:15, v/v, 26 ml), and the mixture was stirred for 1 h. Then pyridine was added and the resulting precipitate was removed by filtration. The filtrate was partitioned between CH_2Cl_2 and satd $NaHCO_3$ solution. The organic layer was collected, dried over Na_2SO_4, filtered, and evaporated to a foam under reduced pressure. The residue was chromatographed on silica gel with CH_2Cl_2–MeOH to give **8** (1.63 g, 55%); ^1H NMR ($CDCl_3$) δ=2.02 (2H, m, 2′-H), 3.52 (2H, m, 5′-H), 3.87 (1H, m, 4′-H), 4.29 (1H, m, 3′-H), 5.71 (1H, m, 1′-H), 6.24, 6.50 (2H, br s, N-CH-O), 7.04—7.80 (22H, m, ArH), 7.96 (4H, m, ArH), 8.17 (6H, br d, J=8 Hz, ArH). Calcd for $C_{66}H_{49}N_5O_{14}$: C, 69.77; H, 4.35; N, 6.16%. Found: C, 68.75; H, 4.10; N, 6.03%.

Solid Phase Synthesis of dGpCpApT on P-CPG. This synthesis was done by using DMTrT-P-CPG (50 mg, 1.8 μmol). The final DMTr cation assay showed that 0.575 μmol of the tetramer was formed.

Isolation of dGpCpApT. The P-CPG gel containing fully-protected tetramer was treated with benzenethiol–triethylamine–dioxane (1:1:2, v/v/v, 4 ml) at room temperature for 45 min with gentle rotation using a rotary evaporator. The gel was washed successively with MeOH and ether and then allowed to react with 0.5 M NaOH in pyridine–water (1:1, v/v, 1 ml) for 30 min using a rotary evaporator to keep constant rotation. The gel was removed by filtration and washed with pyridine–water (1:1, v/v, 5 ml). The eluant and washings were combined and passed through Dowex 50 W×2 (100—200 mesh, pyridinium form, 5 ml). The resin was washed with pyridine–water (1:1, v/v, 5 ml). The eluant and washing were combined and evaporated and then the residue was evaporated three times with a small amount of concentrated aqueous ammonia to remove the last traces of pyridine. Part (71%) of the residue was applied to Toyo Roshi No 51 Å papers. Chromatography developed with Solvent I afforded dGpCpApT (10.2 OD, 70% based on the assumption of 15% hypochromicity using ε 3.55×10⁴ at 258 nm).

Enzymic Assay of dGpCpApT. The tetramer (2.4 OD unit at 258 nm) was dissolved in Tris-HCl buffer (0.05 M, pH 8.0, 50 μl) and snake venom phosphodiesterase (10 μl) was added. The mixture was incubated at 37 °C for 1.5 h. After being heated at 100 °C for 3 min, the mixture was analyzed by reverse phase HPLC. The calculated ratio of dG, pC, pA, and pT was given in the text. The following ε values at 254 nm were used for calculation: 5630, 6080, 13400, and 14100 for pC, pT, pA, and dG, respectively.

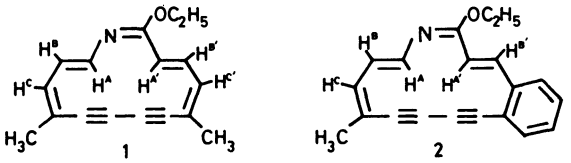
Syntheses and Properties of α-Alkyl-Substituted Bisdehydroaza[14]-annulenes and the Related Benzannelated Derivatives

Jūro Ojima,* Yasuhiro Yagi, Emiko Ejiri, Shuichi Ishizaka, and Tadahito Kato
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930
(Received January 22, 1986)

14-Ethoxy-2,5,10-trimethyl-6,8-bisdehydroaza[14]annulene, 14-ethoxy-2-ethyl-5,10-dimethyl-6,8-bisdehydroaza-[14]annulene, 2-ethoxy-3,11-dimethyl-5,6-benzo-7,9-bisdehydroaza[14]annulene, and 2-ethoxy-11,14-dimethyl-5,6-benzo-7,9-bisdehydroaza[14]annulene were synthesized. Influence of α-alkyl substitution and benzannelation upon the skeleton of the bisdehydroaza[14]annulene ring system is discussed on the basis of ^{1}H NMR and UV spectra of these azaannulenes and their α-alkyl unsubstituted ones.

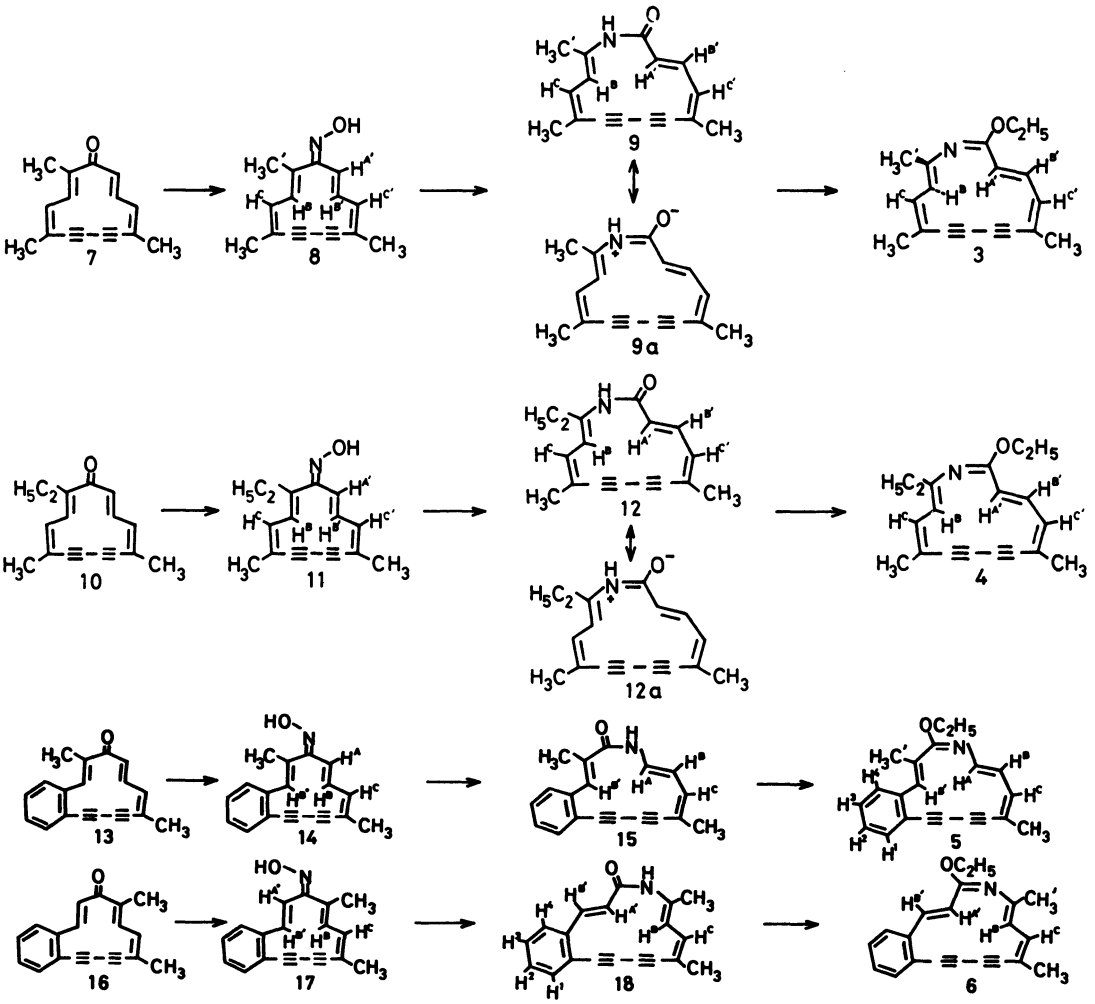
In a previous paper,[1] we reported the synthesis of the diatropic 14-ethoxy-5,10-dimethyl-6,8-bisdehydroaza-[14]annulene **1** and its benzannelated derivative **2** and showed that both the azaannulenes **1** and **2** proved to keep the conformations indicated between −60 to 60 °C, suggesting the rather high skeletal rigidity of **1** and **2**, in contrast to the cases of related 1,3-bisdehydro-[14]annulene series.[2]

This result as well as a prediction from molecular model led us to expect that the azaannulenes **1** and **2** might set α-alkyl substituent inside the ring properly. In order to investigate this possibility, it was decided to prepare α-alkyl derivatives of the compounds **1** and **2**. However, all the azaannulenes **3**—**6** obtained do not have α- or β-alkyl group inside the ring properly, by an analysis of their ^{1}H NMR spectra.[3]



Results and Discussion

Synthesis. Aza[14]annulenes **3**—**6** were prepared by the same procedure to that for synthesis of compounds **1** and **2**.[1] Treatment of the trimethylbisdehydro[13]-annulenone (**7**)[4] with a large excess of hydroxyl-



amine hydrochloride afforded only the isomer **8** of the two possible stereoisomeric oximes in 88% yield. The reaction of compound **8** with phosphorus pentachloride aroused Beckmann rearrangement to give the lactam **9** in 13% yield. The structure of compound **9** was determined by its ^{1}H NMR spectrum. Since Beckmann rearrangement is recognized to proceed usually in *anti*-migration with respect to hydroxyl group, the precursor of the lactam **9**, the oxime **8** should have the structure indicated.[5] The compound **9** reacted with a large excess of triethyloxonium tetrafluoroborate to yield the desired aza[14]annulene **3** in 38% yield. Similarly, the ethyldimethylbisdehydro[13]annulenone (**10**)[6] was led to the oxime **11** as a sole product in 52% yield, which was converted to the lactam **12** in 52% yield. Lactam **12** gave the azaannulene **4** in 14% yield. The dimethylbenzobisdehydro[13]annulenone (**13**)[4] was led to the oxime **14** (50%) as a sole product which was converted to the lactam **15** in 33% yield. The lactam **15** gave the benzazaannulene **5** in 10% yield. Thus, the formation of only the isomer **14** of the oxime from compound **13** prevented the possible preparation of an another α-methylated azaannulene, and instead led to the β-methylated one **5**. The oxime **17** (34%), obtained from the dimethylbenzobisdehydro[13]annulenone (**16**),[4] was led to the lactam **18** in 40% yield, which was

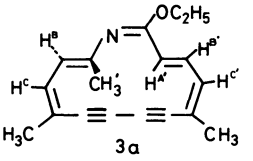
converted to the benzazaannulene **6** in 43% yield.

^{1}H NMR Spectra. The ^{1}H NMR chemical shifts of the azaannulenes **1**—**6** are listed in Table 1, and the spectra of the azaannulenes **1**, **3**, and **4** are shown in Fig. 1 and the spectra of the benzannelated azaannulenes **2**, **5**, and **6** are shown in Fig. 2. The assignments of the resonances in these azaannulenes are based on the multiplicities and coupling constants. As is seen from both the Table 1 and Fig. 1, it is noted that comparison of the chemical shift differences between the olefinic outer and inner protons which can be regarded as an approximate measure of tropicity, or of the chemical shifts of $-OC\underline{H}_2CH_3$ and CH_3 protons that the diatropicity of these azaannulenes decreases in the order of the dimethyl- **1**>the α-ethyl- **4**>the α-methyl-substituted azaannulene **3**, demonstrating that the perturbation caused by the α-alkyl substitution for the aza[14]annulene **1** greatly reduces the planarity of the molecular skeleton and it is larger in the α-methyl substitution than in the α-ethyl one. This also permits the safe conclusion that both **3** and **4** do not set their α-alkyl groups inside the ring properly.

The similar observation is made from comparison of the ^{1}H NMR chemical shifts (Table 1 and Fig. 2) of the benzannelated azaannulenes **2**, **5**, and **6**. Comparison of the chemical shifts of $-OC\underline{H}_2CH_3$ and CH_3 protons again indicates that the tropicity decreases in the order of benzaza- **2**>β-methylated benzaza- **6**>α-methylated benzazaannulene **5**, suggesting that the α- or β-methyl substitution in **2** reduces the planarity of the molecular skeleton. It eliminates the weak diatropicity of **2**,[1] rendering both **5** and **6** to be atropic.



3a

Variable-temperature ^{1}H NMR spectra of these azaannulenes **1**—**6** were taken over the range of −60 to 60 °C and their chemical shifts are summarized in Table 2. As we see from Table 2, the spectra of **1** and **2** are essentially temperature-independent between these temperatures, although the resonances of the inner and outer protons of **1** and **2** move to a slightly higher and lower field, respectively, reflecting that the higher planarity of the azaannulene rings of **1** and **2** at lower temperature.[1] In contrast, the spectra of trimethylazaannulene **3** show temperature-dependency, as illustrated in Fig. 3. In particular, moving of the resonances of CH_3' and H^B proton toward higher and lower field, respectively, along with decreasing temperature, is notable. This fact as well as examination from molecular model leads us to believe the following. The molecule **3** exists in conformations such as **3** and **3a**, in which the vibrating CH_3'-C=CH^B

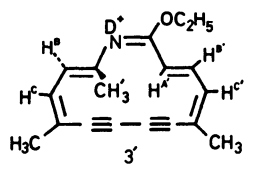
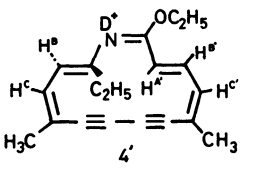
moiety deviates from a molecular lane as depicted: The observed, relatively high-field, resonance of CH_3' protons and low-field resonance of H^B proton at −60 °C, suggests that the conformation **3a** is the preferred form at this temperature.

The similar behavior which is different from that for the cases of **1** and **2**, is observed in the variable-temperature spectra of **4**—**6** (Table 2), but the variation of their spectra is smaller than that of **3** between these temperatures. In the case of **4**, this might be attributable to the bulky α-ethyl group which hardly locates inside the ring, as compared with the case of **3**.





The ^{1}H NMR chemical shifts of the azaannulenes **1'**—**4'** and **6'**, taken in deuteriochloroform solution with a few drops of deuteriotrifluoroacetic acid, are also listed in Table 1. In these spectra, it is apparent that the resonances of almost all the protons including ethoxyl and methyl protons in these azaannulenes move to low field. This seems to be attributable to diminished π-electron perimeter, arising from withdrawal of electrons by deuteration. However, the movings of CH_3' and H^C protons in **3**, and of the CH_3, $-C\underline{H}_2CH_3$, and H^C protons in **4**, to high field, as compared with moving of the other protons in **3** and **4**, to low field, are rather large. This might also suggest that the CH_3'-C=CH^B-CH^C moiety in **3** and the C_2H_5-C=CH^B-CH^C one in **4** are mobile in their molecular perimeters. In particular, the high-field resonances of the CH_3' protons in the deuterated **3'** and the $-C\underline{H}_2CH_3$ and $-CH_2C\underline{H}_3$ protons in the deuterated **4'**, as compared with those of **3** and **4**, respectively, suggest that these deuterated species might exist in conformations indicated.

The ^{1}H NMR chemical shifts of the lactams **9** and **12**, which are the precursors of the azaannulenes **3** and **4**, respectively, are listed in Table 3. The fourteen-membered lactams **9** and **12** are also diatropic, since the inner $H^{A'}$ and H^B proton resonances appear at high field and the outer protons including CH_3, CH_3' protons in **9**, and $-C\underline{H}_2CH_3$, $-CH_2C\underline{H}_3$ protons in **12**, do at low field. Thus, the lactams **9** and **12** can be considered to exist in zwitter ionic forms **9a** and **12a**, as has been discussed previously.[1]

Electronic Spectra. The electronic absorption spectra, taken in tetrahydrofuran, of the bisdehydroaza-[14]annulenes **1**, **3**, and **4**, and of the benzannelated ones **2**, **5**, and **6** are illustrated in Figs. 4 and 5, respectively. As is seen from both Figs. 4 and 5, the longest wavelength band shift toward longer wavelength in the order of **1**>**4**>**3** (Fig. 4), **2**>**6**>**5** (Fig. 5), respectively, demonstrating the sequence for the degree of extended conjugation of π-electron system in these aza[14]annulene systems, conforming the results

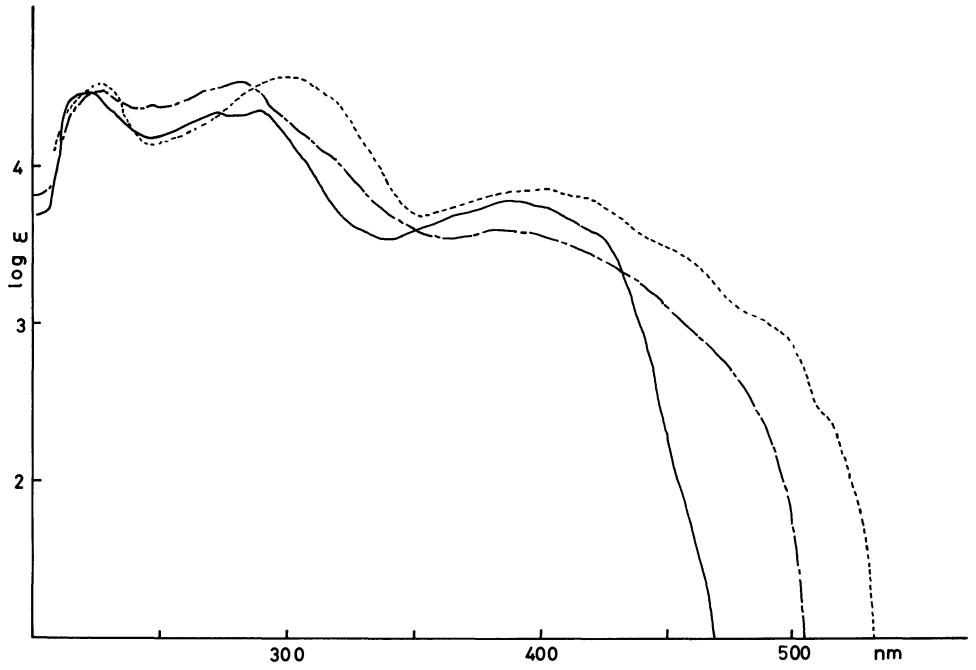


Fig. 5. Electronic spectra of **2** (------), **5** (——), and **6** (------) in THF.

from the ^{1}H NMR spectra.

All these results show that the conformation indicated for compound **1** is most appropriate for a conjugation of π-electrons in this bisdehydroaza[14]annulene system.

Experimental

All melting points are uncorrected. IR spectra were measured on Hitachi 260-50 spectrophotometer as KBr disk unless otherwise stated; only significant maxima are reported. Electronic spectra on Hitachi 220A spectrophotometer were measured in tetrahydrofuran solutions and recorded in nm. ε-Values are given in parentheses, shoulders being denoted by sh. Mass spectra were measured with JEOL JMS-200 spectrometer at 75 eV using a direct inlet system, ^{1}H NMR spectra were taken on JEOL FX-90Q (90 MHz) or Varian XL-200 spectrometer, and refer to solution in $CDCl_3$, unless otherwise specified, in τ-values with TMS as an internal standard. The coupling constants (J) are given in Hz. The individual assignments are made on the basis of multiplicities and coupling constants. Alumina (II–III) was used for column chromatography. Progress of most reactions was followed by TLC using Merck precoated alumina. Preparative TLC was carried out on 20×20 cm silica-gel plates (Merck, 0.5 or 2 mm thick). Dichloromethane was distilled over calcium hydride before use. Tetrahydrofuran (THF) was refluxed over potassium hydroxide pellets and distilled before use. Organic extracts with dichloromethane or chloroform were dried over anhyd calcium chloride prior to solvent removal.

1-Hydroxyimino-2,5,10-trimethylcyclotrideca-2,4,10,12-tetraene-6,8-diyne (8). To a stirred soln of the trimethylbisdehydro[13] annulenone (**7**)[4] (1.82 g, 8.20 mmol) in methanol (340 ml) and THF (85 ml) was added a soln of hydroxylamine hydrochloride (5.7 g, 82 mmol) in water (25 ml) at 38°C in one portion. After stirring for further 3 h at the same temp, further quantities of hydroxylamine hydrochloride (each 5.7 g in water (25 ml)) were added after every 10 h. After stirring for a total of 27 h, the soln was poured into an aq sodium hydrogencabonate soln. The mixture was extracted with chloroform. The combined extracts were washed with aq sodium chloride soln, dried, and evaporated. The residue after solvent removal was chromatographed on alumina (3.7×7 cm). The early fractions eluted with benzene gave the recovered annulenone **7** (64 mg). The following fractions eluted with 5% ethanol in chloroform gave the oxime **8** (1.71 g, 88%) as a solid. Recrystallization from hexane–chloroform afforded orange needles: Mp 164—165°C (decomp); MS m/z 237 (M^+, 89%) and 204 (100); mol wt 237.2; IR 3240 (-OH), 2170 (-C≡C-), and 980 cm^{-1} (trans C=C); UV_{max} 213 (29900), 275 (30900), and 350 nm sh (7740); ^{1}H NMR (90 MHz, DMSO-d_6) τ=−1.95 (s, 1H, OH, exchangeable with D_2O), 2.44 (d, 9, 1H, H^B), 2.45 (dd, 17, 9, 1H, $H^{B'}$), 2.99 (d, 10, 1H, $H^{C'}$), 3.23 (d, 10, 1H, H^C), 3.30 (d, 17, 1H, $H^{A'}$), 8.02 (s, 3H, CH_3'), and 8.18 (s, 6H, CH_3).

Found: C, 80.72; H, 6.22; N, 5.96%. Calcd for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90%.

6,11,14-Trimethylazacyclotetradeca-3,5,11,13-tetraene-7,9-diyn-2-one (9). Phosphorus pentachloride (4.46 g, 21.4 mmol) was added in one portion to a stirred soln of the oxime **8** (1.01 g, 4.27 mmol) in THF (240 ml) at 1—3°C. After stirring for 4 h at the same temp, the soln was poured into water, and an aq sodium hydrogencarbonate soln was added (pH 8). The soln was warmed on a steam-bath, and then the mixture was extracted with chloroform. The combined extracts were washed with aq sodium hydrogencarbonate soln, and aq sodium chloride soln, and dried. The dark red semi-solid obtained after solvent removal was chromatographed on alumina (3.7×7.0 cm). The fractions eluted with 2% chloroform in benzene afforded the lactam **9** (129 mg, 13%) as a solid. Recrystallization from hexane–chloroform afforded dark red cubes: Mp 186—188°C (decomp); MS m/z 237 (M^+, 62%) and 194 (100); mol wt 237.2;

IR 3180, 3060 (NH), 2160 (-C≡C-), 1655 (C=O), 1605 and 1590 cm^{-1} (C=C); UV_{max} 298 sh (36700), 306 (38800), 365 sh (5330), and 436 nm (3280); ^1H NMR (200 MHz) τ=2.13 (dd, 15.5, 7.5, 1H, $H^{B'}$), 2.33 (br s, 1H, NH), 2.88 (d, 10, 1H, H^{C}), 3.21 (d, 7.5, 1H, $H^{C'}$), 4.55 (d, 15.5, 1H, $H^{A'}$), 5.58 (d, 10, 1H, H^{B}), 7.79 (s, 3H, CH_3'), 7.87 (s, 3H, CH_3), and 7.91 (s, 3H, CH_3).

Found: C, 81.09; H, 6.38; N, 5.93%. Calcd for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90%.

14-Ethoxy-2,5,10-trimethyl-6,8-bisdehydroaza[14]annulene (3). To a stirred soln of the lactam **9** (93.4 mg, 0.394 mmol) in dichloromethane (50 ml) was added dropwise a soln of triethyloxonium tetrafluoroborate (2.2 g, 12 mmol) in dichloromethane (30 ml) during 30 min at room temp under argon. After stirring for 1 h, further quantities of the oxonium salt (each 1.5 g in dichloromethane (20 ml)) were added every day, and stirring was continued for 3 d. Then the soln was cooled in an ice-bath and aq 50% potassium carbonate soln (50 ml) was cautiously added. Then the mixture was poured into water and extracted with dichloromethane. The residue after solvent removal was chromatographed on alumina (3.7×6.0 cm). The initial fractions eluted with 5% ether in hexane gave the azaannulene **3** (39.2 mg, 37.5%) as a red liquid: MS *m/z* 265 (M^+, 54%) and 208 (100); mol wt 265.3; IR (neat) 2150 (-C≡C-), 1575 (C=C), 1290, 1255, and 1055 cm^{-1} (-O-); UV_{max} 277 sh (19200), 307 (26100), 386 sh (4030), 470 sh (1760), 511 sh (1160), and 553 nm sh (520), and see Fig. 4; ^1H NMR (200 MHz) τ=2.55 (dd, 16, 7, 1H, $H^{B'}$), 2.93 (d, 8, 1H, H^{C}), 3.22 (d, 7.5, 1H, $H^{C'}$), 4.99 (d, 16, 1H, $H^{A'}$), 5.74 (q, 7, 2H, $-OC\underline{H}_2CH_3$), 6.04 (d, 7.5, 1H, H^{B}), 7.79 (s, 3H, CH_3), 7.88 (s, 3H, CH_3), 8.23 (s, 3H, CH_3'), and 8.63 (t, 7, 3H, $-OCH_2C\underline{H}_3$), and see Figs. 1 and 3; **3'** (200 MHz, CF_3COOD in $CDCl_3$) τ=2.36 (dd, 16, 8, 1H, $H^{B'}$), 3.19 (d, 7.5, 2H, H^{C} and $H^{C'}$), 4.18 (s, 1H, H^{B}), 4.29 (d, 16, 1H, $H^{A'}$), 5.29 (q, 7, 2H, $-OC\underline{H}_2CH_3$), 7.76 (s, 3H, CH_3), 7.87 (s, 3H, CH_3), 8.45 (t, 7, 3H, $-OCH_2C\underline{H}_3$), and 8.53 (s, 3H, CH_3').

Found: C, 81.64; H, 7.50; N, 5.00%. Calcd for $C_{18}H_{19}NO$: C, 81.47; H, 7.22; N, 5.28%.

The later fractions eluted with chloroform gave the recovered lactam **9** (40 mg).

2-Ethyl-1-hydroxyimino-5,10-dimethylcyclotrideca-2,4,10,12-tetraene-6,8-diyne (11). To a stirred soln of the ethyldimethylbisdehydro[13]annulenone (**10**)[6] (1.24 g, 5.27 mmol) in methanol (150 ml) was added in one portion a soln of hydroxylamine hydrochloride (4.0 g, 5.8 mmol) in water (20 ml) was added. Then after stirring for 16 h, further quantities of hydroxylamine hydrochloride (each 4.0 g in water (20 ml)) were added after every 4 h. After stirring for a total of 34 h, the soln was worked up as in the preparation of **8**. The residue after solvent removal was chromatographed on alumina (4.0×7.5 cm). The early fractions eluted with benzene gave the recovered annulenone **10** (26 mg). The following fractions eluted with 2% ethanol in chloroform gave the oxime **11** (692 mg, 52%) as a solid. Recrystallization from hexane-chloroform afforded orange needles: Mp 155—156°C (decomp); MS *m/z* 251 (M^+, 84%) and 204 (100); mol wt 251.3; IR 3250 (-OH), 2170 (-C≡C-), 1000, and 990 cm^{-1} (trans C=C); UV_{max} 217 (20100), 274 (31000), and 351 nm sh (7200); ^1H NMR (90 MHz, DMSO-d_6) τ=−1.89 (s. 1H, OH, exchangeable with D_2O), 2.49 (dd, 17, 8.5, 1H, $H^{B'}$), 2.60 (d, 11, 1H, H^{B}), 3.03 (d, 10.3, 1H, H^{C}), 3.26 (d, 8.5, 1H, $H^{C'}$), 3.29 (d. 17, 1H, $H^{A'}$), 7.50 (q, 7.4, 2H, $-C\underline{H}_2CH_3$), 8.17 (s, 6H, CH_3), and 9.03 (t, 7.4, 3H, $-CH_2C\underline{H}_3$).

Found: C, 81.17; H, 6.92; N, 5.64%. Calcd for $C_{17}H_{17}NO$: C, 81.24; H, 6.82; N, 5.57%.

14-Ethyl-6,11-dimethylazacyclotetradeca-3,5,11,13-tetraene-7,9-diyn-2-one (12). A soln of phosphorus pentachloride (4.85 g, 23.3 mmol) in THF (330 ml) was added dropwise during 40 min to a stirred soln of the oxime **11** (1.17 g, 4.66 mmol) in THF (200 ml) under ice-bath. The soln was allowed to rise to room temp and stirring was continued for 3.5 h at same temp. Then the mixture was worked up as in the preparation of **9**. The residue after solvent removal was chromatographed on alumina (3.7×8.0 cm). The early fractions eluted with benzene-chloroform (2:3) gave the lactam **12** (610 mg, 52%) as a solid. Recrystallization from hexane-chloroform afforded red needles: Mp 189—191°C (decomp); MS *m/z* 251 (M^+, 75%) and 222 (100); mol wt 251.3; IR 3170, 3060 (NH), 2155 (-C≡C-), 1655 (C=O), 1600, and 1590 cm^{-1} (C=C); UV_{max} 218 (13800), 299 sh (28200), 307 (29900), and 441 nm sh (2500); ^1H NMR (200 MHz) τ=2.11 (dd, 15, 7, 1H, $H^{B'}$), 2.42 (br s, 1H, NH), 2.84 (d, 10, 1H, H^{C}), 3.20 (d, 6.4, 1H, $H^{C'}$), 4.58 (d, 15.7, 1H, $H^{A'}$), 5.68 (d, 10, 1H, H^{B}), 5.01 (q, 7.5, 2H, $-C\underline{H}_2CH_3$), 7.79 (s, 3H, CH_3), 7.91 (s, 3H, CH_3), and 8.85 (t, 7.5, 3H, $-CH_2C\underline{H}_3$).

Found: C, 81.31; H, 6.78; N, 5.33%. Calcd for $C_{17}H_{17}NO$: C, 81.24; H, 6.82; N, 5.57%.

The later fractions eluted with 5% ethanol in chloroform afforded the recovered oxime **11** (139 mg).

14-Ethoxy-2-ethyl-5,10-dimethyl-6,8-bisdehydroaza[14]annulene (4). To a stirred soln of the lactam **12** (703 mg, 2.80 mmol) in dichloromethane (250 ml) was added dropwise a soln of triethyloxonium tetrafluoroborate (7.97 g, 42 mmol) in dichloromethane (80 ml) during 1 h at room temp. After stirring for a further 2.5 h, further quantities of the oxonium salt (each 10 g in dichloromethane (50 ml)) was added every 15 h. After stirring for a total of 48 h, the mixture was worked up as in the preparation of **3**. The residue after solvent removal was chromatographed on alumina (3.7×8.0 cm). The early fractions eluted with 3% ether in hexane gave a red liquid, which was further purified by preparative TLC. The fast moving, red band on evaporation afforded the azaannulene **4** (111 mg, 14.2%) as a red liquid: MS *m/z* 279 (M^+, 51%) and 222 (100); mol wt 279.3; IR (neat) 2140 (-C≡C-), 1575 (C=C), 1290, 1250, and 1050 cm^{-1} (-O-); UV_{max} 219 (17100), 298 sh (27700), 308 (30900), 383 sh (4200), and 422 nm sh (1940), and see Fig. 4; ^1H NMR (200 MHz) τ=2.37 (dd, 15.5, 7.5, 1H, $H^{B'}$), 2.69 (d, 9, 1H, H^{C}), 3.15 (d, 7.5, 1H, $H^{C'}$), 5.40 (d, 15.5, 1H, $H^{A'}$), 5.72 (q, 7, 2H, $-OC\underline{H}_2CH_3$), 6.71 (d, 9, 1H, H^{B}), 7.65 (q, 7.5, 2H, $-C\underline{H}_2CH_3$), and 7.75 (s, 3H, CH_3), 7.85 (s, 3H, CH_3), 8.67 (t, 7, 3H, $-OCH_2C\underline{H}_3$), and 9.01 (t, 7.5, 3H, $-CH_2C\underline{H}_3$), and see Fig. 1; **4'** (200 MHz, CF_3COOD in $CDCl_3$) τ=2.33 (dd, 16, 8, 1H, $H^{B'}$), 3.14 (d, 5.5, 1H, H^{C}), 3.18 (d, 8, 1H, $H^{C'}$), 4.39 (d, 15.5, 1H, $H^{A'}$), 4.58 (d, 5.5, 1H, H^{B}), 5.31 (q, 7, 2H, $-OC\underline{H}_2CH_3$), 7.76 (s, 3H, CH_3), 7.87 (s, 3H, CH_3), 8.07 (q, 7.5, 2H, $-C\underline{H}_2CH_3$), 8.46 (t, 7, 3H, $-OCH_2C\underline{H}_3$), and 9.16 (t, 7.5, 3H, $-CH_2C\underline{H}_3$).

Found: C, 81.55; H, 7.88; N, 4.94%. Calcd for $C_{19}H_{21}NO$: C, 81.68; H, 7.58; N, 5.01%.

The later fractions eluted with chloroform gave the recovered lactam **12** (425 mg).

1-Hyroxyimino-2,10-dimethyl-4,5-benzocyclotrideca-2,10,12-triene-6,8-diyne (14). To a stirred soln of bisdehydrobenz-[13]annulenone (**13**)[4] (2.63 g, 10.2 mmol) in methanol (350 ml) and THF (200 ml) was added in one portion a soln of

hydroxylamine hydrochloride (14.2 g, 0.204 mmol) in water (30 ml) at room temp. After stirring for 13 h, further quantities of hydroxylamine hydrochloride (each 7.1 g in water (30 ml)) were added after every 5 h. After for a total of 27 h at 40 °C, the mixture was worked up as in the preparation of **8**. The residue after solvent removal was chromatographed on alumina (4.5×7.0 cm). The early fractions eluted with benzene gave the recovered annulenone **13** (26 mg). The following fractions eluted with benzene–chloroform (1:1) gave the oxime **14** (1.64 g, 59%) as a solid. Recrystallization from hexane–chloroform afforded yellow plates: Mp 160—162 °C (decomp); MS *m/z* 273 (M^+, 40%) and 258 (100); mol wt 273.2; IR 3250 (-OH), 2180 (-C≡C-), and 975 cm^{-1} (trans C=C); UV_{max} 225 (34100), 253 sh (25000), 266 (37800), 279 (47100), 328 sh (5820), 350 sh (7650), 371 (9460), and 392 nm sh (7520); ^1H NMR (90 MHz, DMSO-d_6) τ=−1.44 (s, 1H, OH, exchangeable with D_2O), 2.50 (dd, 16, 11, 1H, H^B), 2.42—2.80 (m, 4H, benzenoid H), 3.09 (d, 10, 1H, H^C), 3.49 (s, 1H, $H^{B'}$), 3.57 (d, 16, 1H, H^A), and 8.20 (s, 6H, CH_3).

11,14-Dimethyl-5,6-benzazacyclotetradeca-3,5,11,13-tetraene-7,9-diyn-2-one (18). A soln of phosphorus pentachloride (2.63 g, 2.23 mmol) in THF (210 ml) was added to a stirred soln of the oxime **17** (869 mg, 3.18 mmol) in THF (150 ml) during 1 h under ice-bath. After stirring for 5 h at room temp the mixture was worked up as in the preparation of **9**. The residue after solvent removal was chromatographed on alumina (4.2×7.0 cm). The early fractions eluted with benzene–chloroform (1:1) gave the lactam **18** (346 mg, 39.8%) as a solid. Recrystallization from hexane–chloroform afforded orange needles: Mp 210—212 °C (decomp); MS *m/z* 273 (M^+, 84%) and 244 (100); mol wt 273.3; IR 3190, 3060 (NH), 2190 (-C≡C-), 1660 (C=O), and 980 cm^{-1} (trans C=C); UV_{max} 227 (28600), 268 sh (26200), 281 (32300), 295 sh (26300), 300 sh (23900), and 379 nm (7160); ^1H NMR (200 MHz, DMSO-d_6) τ=0.37 (s, 1H, NH), 1.90 (d, 16, 1H, $H^{B'}$), 2.21 (d, 7.7, 1H, H^4), 2.31 (d, 7.3, 1H, H^1), 2.30—2.48 (m, 2H, H^2 and H^3), 2.88 (d, 8.5, 1H, H^C), 3.53 (d, 16, 1H, $H^{A'}$), 4.77 (d, 8.5, 1H, H^B), 8.02 (s, 3H, CH_3), and 8.03 (s, 3H, CH_3).

Found: C, 83.19; H, 5.51; N, 5.25%. Calcd for $C_{19}H_{15}NO$: C, 83.49; H, 5.53; N, 5.13%.

The later fractions eluted with chloroform gave the recovered oxime **17** (166 mg).

2-Ethoxy-11,14-dimethyl-5,6-benzo-7,9-bisdehydroaza[14]-annulene (6). To a stirred soln of the lactam **18** (336 mg, 1.23 mmol) in dichloromethane (50 ml) was added dropwise a soln of triethyloxonium tetrafluoroborate (2.33 g, 12.3 mmol) in dichloromethane (30 ml) during 1 h at room temp under argon. After stirring for 2 h, a further quantity of the oxonium salt (1.2 g) in dichloromethane (20 ml) was added, and stirring was continued for further 8.5 h at room temp. Then the reaction mixture was worked up as in the preparation of **3**. The residue after removal of solvent was chromatographed on alumina (3.7×6.5 cm). The ini-

tial fractions eluted with 2% ether in hexane gave the azaannulene **6** (159 mg, 43%) as a solid. Recrystallization from hexane–benzene afforded orange plates: Mp 100—101 °C; MS *m/z* 301 (M^+, 75%) and 244 (100); mol wt 301.3; IR 2190, 2110 (-C≡C-), 1595 (C=C), 1250, 1050 (-O-), 975, and 960 cm^{-1} (trans C=C); UV_{max} 228 (29400), 245 sh (23800), 271 sh (30800), 281 (34200), 322 sh (9860), and 386 nm (3830), and see Fig. 5; ^1H NMR (200 MHz) τ=2.43 (d, 16, 1H, $H^{B'}$), 2.51—2.74 (m, 4H, benzenoid H), 3.24 (d, 16, 1H, $H^{A'}$), 3.36 (d, 5.5, 1H, H^{C}), 4.80 (d, 5.5, 1H, H^{B}), 5.74 (q, 7, 2H, $-OCH_2CH_3$), 8.02 (s, 3H, CH_3), 8.24 (s, 3H, CH_3'), and 8.60 (t, 7, 3H, $-OCH_2CH_3$), (200 MHz, CF_3COOD in $CDCl_3$) τ=1.95 (d, 16, 1H, $H^{B'}$), 2.33—2.45 (m, 4H, benzenoid H), 2.95 (d, 16, 1H, $H^{A'}$) 3.48 (s, 1H, H^{C}), 3.74 (s, 1H, H^{B}), 5.26 (q, 7, 2H, $-OCH_2CH_3$), 7.94 (s, 3H, CH_3), 8.23 (s, 3H, CH_3), and 8.35 (t, 7, 3H, $-OCH_2CH_3$).

Found: C, 83.91; H, 6.42; N, 4.76%. Calcd for $C_{21}H_{19}NO$: C, 83.69; H, 6.35; N, 4.65%.

The later fractions eluted with 5% ethanol in chloroform gave the recovered lactam **18** (192 mg).

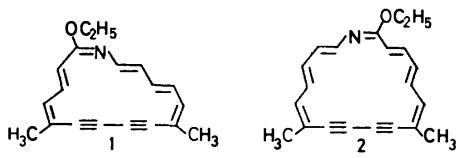
Syntheses and Properties of Two Ethoxytrimethylbisdehydroaza-[16]annulenes and Ethoxytrimethylbisdehydroaza[18]annulene

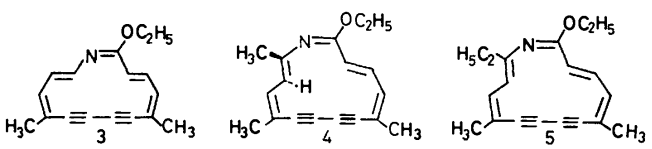
Jūro Ojima,* Yasuhiro Yagi, Sumio Manaka, Tetsuya Nakada, and Yasunao Shiraiwa
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930
(Received January 22, 1986)

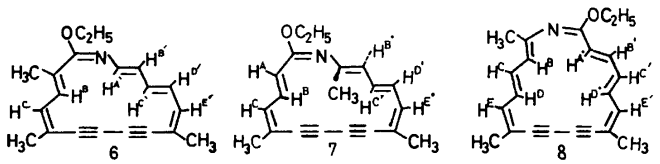
Syntheses of 2-ethoxy-3,6,11-trimethyl-7,9-bisdehydroaza[16]annulene, 2-ethoxy-6,11,16-trimethyl-7,9-bisdehydroaza[16]annulene, and 18-ethoxy-2,7,12-trimethyl-8,10-bisdehydroaza[18]annulene are described. It was found that the molecular skeletons of these α- or β-methylated aza[16]- and -[18]annulene are less planar than those of α- or β-methyl unsubstituted aza[16]- and aza[18]annulene, from examination of their ^{1}H NMR and electronic spectra.

In the previous paper, we have reported the synthesis of the paratropic dimethylbisdehydroaza[16]annulene (**1**) and the diatropic dimethylbisdehydroaza[18]-annulene (**2**).[1] In the preceding paper, we showed that the diatropicity, i.e., the planarity of the aza[14]annulene ring system decreases in the sequence of **3**> **5**>**4** on the basis of the chemical shifts of the olefinic protons. Also, the dimethylaza[14]annulene **3** can not set the α-alkyl group inside the ring and the trimethylaza[14]annulene **4** is a conformationally mobile molecule.[2]

Bearing these results in mind, we were interested in examining the properties of the higher analogs of the trimethylaza[14]annulene (**4**), and we expected that the aza[16]annulene **1** and the aza[18]annulene **2** with a larger π-electron cavity than the aza[14]annulene **3** might have the α-methyl group inside the ring. This paper is concerned with the syntheses and properties of the title compounds **6**—**8**, as well as comparison of the properties of **1** and **2**.[3]

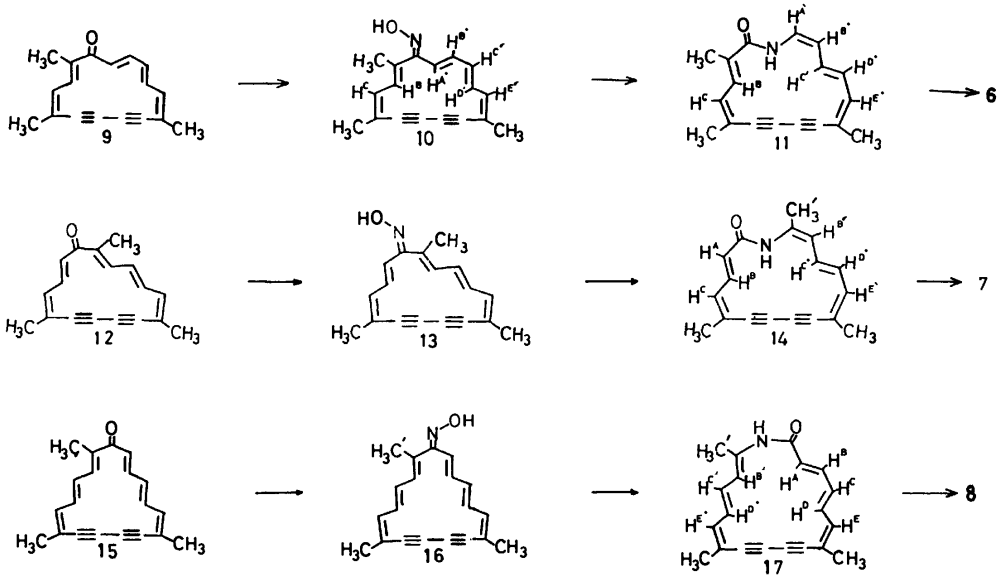






Results and Discussion

Synthesis. Synthesis of the azaannulenes **6**—**8** was carried out by the same procedure as that used for **1** and **2**. Treatment of the trimethylbisdehydro[15]annulenone (**9**)[4] with a large excess of hydroxylamine hydrochloride afforded only the isomer **10**[5] of the desired oxime in 58% yield. The reaction of **10** with phosphorus pentachloride led to the lactam **11** in 45% yield, which was converted to the unstable aza[16]annulene **6** in 0.4% yield by the reaction with triethyloxonium tetrafluoroborate. Similarly, the trimethylbisdehydro[15]annulenone (**12**)[4] was led to the



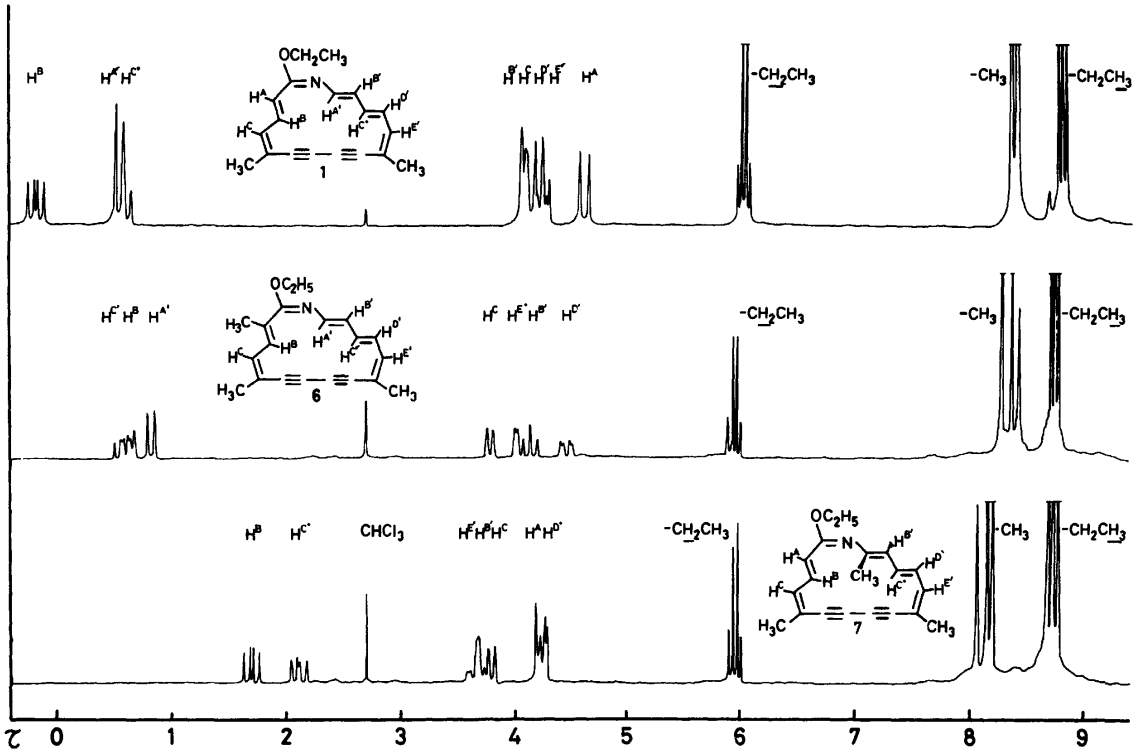


Fig. 1. The 200 MHz ^{1}H NMR spectra of the aza[16]annulenes **1**, **6**, and **7** in $CDCl_3$ (internal standard, TMS).

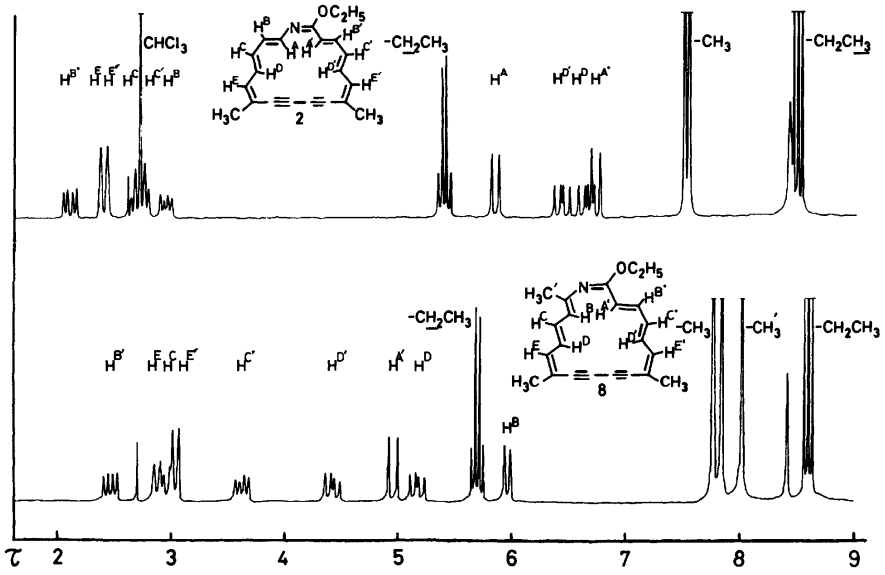

Fig. 2. The 200 MHz ^{1}H NMR spectra of the aza[18]annulenes **2** and **8** in $CDCl_3$ (internal standard, TMS).

oxime **13** (88%) as a sole product, which was converted to the lactam **14** in 47% yield. Lactam **14** gave the unstable aza[16]annulene **7** in 2.6% yield.

The oxime **16** (73%), obtained from the trimethylbisdehydro[17]annulenone (**15**)[6] was led to the lactam **17** in 46% yield, which was converted to the aza[18]annulene **8** as stable crystals in 11% yield.

^{1}H NMR Spectra. The ^{1}H NMR spectra of the trimethylaza[16]annulenes **6** and **7** are shown in Fig. 1, together with that of the dimethylaza[16]annulene **1**. The assignments of the resonances to the individual protons were made on the basis of multiplicities and coupling constants, and rigorously follow from decoupling experiments. Comparison of the chemical shift differences between the olefinic inner and outer protons indicate that the paratropicity of these azaannulenes decreases in the order of **1**>**6**>**7**, suggesting that the α-methyl substitution for the aza[16]annulene **1** greatly reduces the planarity of the molecular skeleton. This also indicates that the

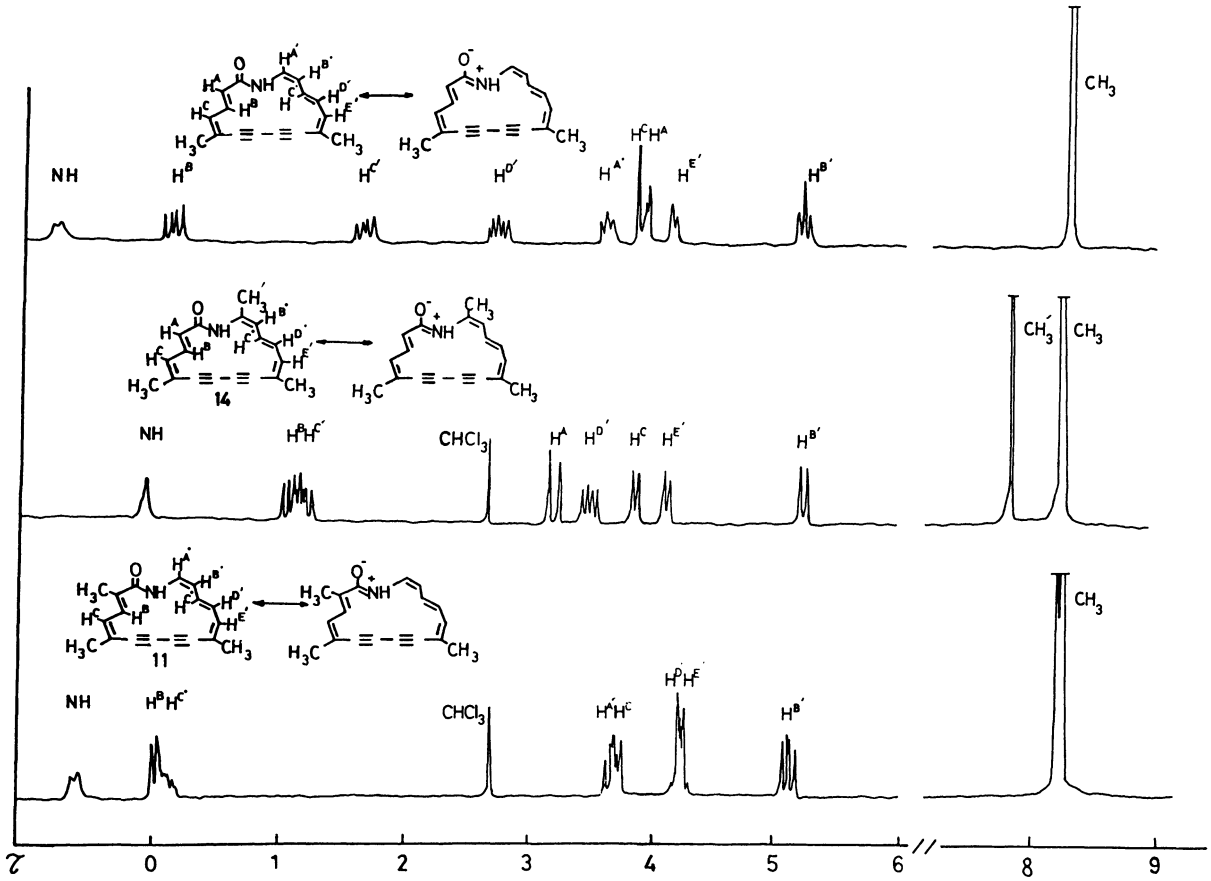

Fig. 3. The 200 MHz ^{1}H NMR spectra of the sixteen-membered lactams in $CDCl_3$ (internal standard, TMS).

trimethylaza[16]annulene **7** does not set the α-methyl group inside the ring properly. The extreme thermal unstability of **6** and **7**, as compared with **1**, might be due to low planarity of their molecular skeletons.

The ^{1}H NMR spectra of the dimethylaza[18]annulene **2** and the trimethylaza[18]annulene **8** are shown in Fig. 2. Comparison of the chemical shift differences of the olefinic inner and outer protons or of the chemical shifts of $-OCH_2CH_3$ and CH_3 protons between **8** and **2** indicates that the diatropicity of **8** is smaller than that of **2**. This again suggests that the perturbation caused by α-methyl substitution for the aza[18]annulene **2** changes the configuration and reduces the planarity of the molecular skeleton. It also indicates that the α-methyl group of **8** does not locate inside the ring.

Variable-temperature ^{1}H NMR spectra of the trimethylaza[18]annulene **8** were taken at 90 MHz over the range of −60 to 60 °C, and the chemical shifts of the protons are listed in Table 1. As we see from Table 1, the spectra of **8** which is the higher analog of the conformationally mobile trimethylaza[14]annulene **4**,[2] proved to be essentially temperature-independent between these temperatures. Thus, no notable change around the potentially mobile, CH_3-C=CH^B moiety occurred, in contrast to the case of the trimethylaza[14]annulene **4**, indicating that the molecular skeleton of **8** is more rigid and less strained than that of **4**. One possible explanation for this behavior is that in the case of aza[18]annulene **8**, the steric strain caused by α-methyl substitution can be relieved over the whole of a larger molecular skeleton of **8**, as compared with the case of **4**.

The ^{1}H NMR chemical shifts of the deuterated species **8′**, taken in deuteriochloroform solution admixed with a few drops of deuteriotrifluoroacetic acid are

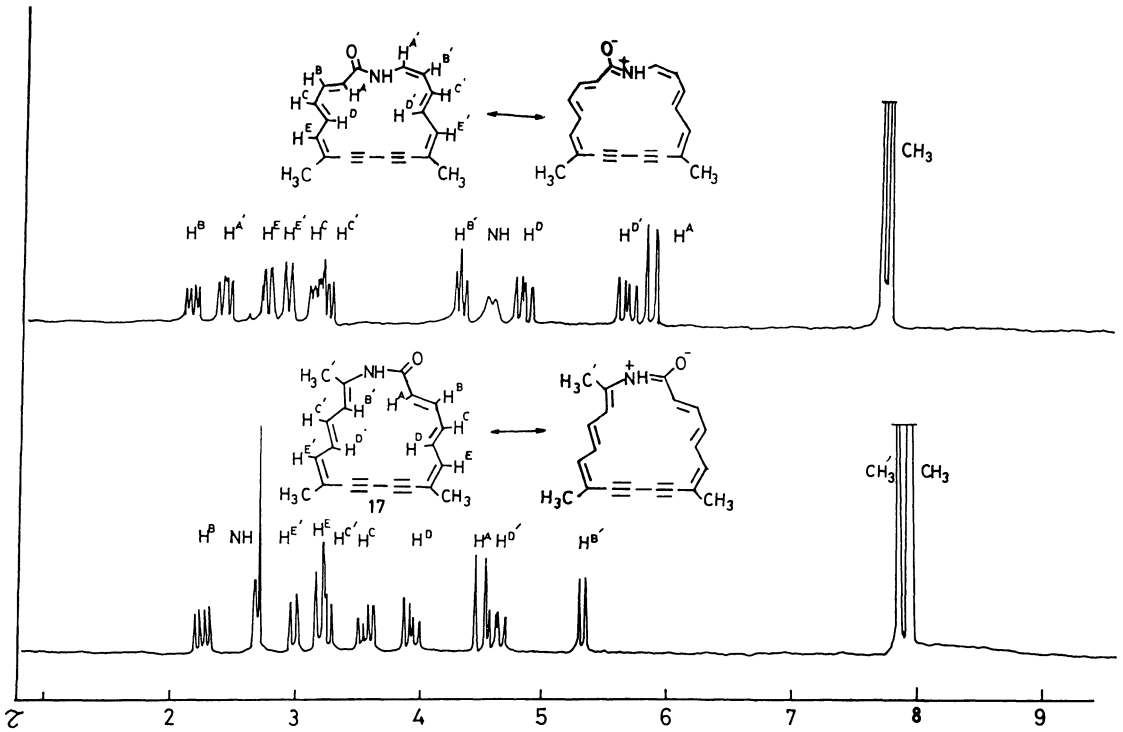

Fig. 4. The 200 MHz ^{1}H NMR spectra of the eighteen-membered lactams in $CDCl_3$ (internal standard, TMS).

also given in Table 1. It is apparent that the resonances of almost all the protons including ethoxyl and methyl protons in **8** shift toward lower field, except the protons nearby the nitrogen atom. This seems to be attributable to diminished π-electron perimeter in azaanulene **8**, arising from withdrawal of electrons by deuteration.

The ^{1}H NMR spectra of the lactams **11** and **14**, which are the precursors of the azaannulenes **6** and **7**, respectively, are shown in Fig. 3, together with that of the dimethylated lactam of the precursor of **1**, and the spectra of the lactam **17** and of the dimethylated lactam of the precursor of **2** are shown in Fig. 4. As can be seen from Fig. 3, the sixteen-membered lactams **11** and **14** as well as the dimethylated one show the inner proton resonances at low field and the outer proton (including methyl protons) resonances at high field. On the other hand, as we see from Fig. 4, the eighteen-membered lactam **17** as well as the dimethylated lactam shows the inner proton resonances at high field and the outer proton (including methyl protons) resonances at low field. Thus, it is noted that the spectra of these lactams are parallel to those of the corresponding azaanulenes with respect to the high-field and low-field shifts due to the olefinic and methyl protons. These results indicate that the sixteen-membered lactams **11** and **14** are paratropic, while the eighteen-membered lactam **17** is diatropic, and these lactams can be considered to exist in zwitter ionic forms, as indicated in Figs. 3 and 4, constructing fully conjugated macrocycles, as has been discussed previously.[1b] Furthermore, from Fig. 3, the chemical shift differences between the olefinic outer and inner protons as well as the chemical shifts of the methyl protons are almost the same in these lactams, indicating that the paratropicity, i.e., the planarity of the molecular skeletons of the sixteen-membered lactams are nearly the same. This fact is in contrast to the cases of the corresponding azaannulene series **1**, **6**, and **7** (Fig. 1), albeit both their lactams and the azaannulenes have the similar conformations each other. This suggests that the lactam ring have a more flexible perimeter for the steric strain, as compared with the azaannulene ring, presumably due to two single bonds on both sides of a nitrogen atom.

As we see from Fig. 4, the diatropicity decreases in the order of the dimethylated lactam>the trimethylated lactam **17** as similarly to the cases of the corresponding azaannulenes between **2** and **8**. This is reasonably attributed to the fact that the configurations both between the lactam **17** and the corresponding dimethylated lactam, and between the azaanulenes **2** and **8** are different.

Electronic Spectra. The electronic absorption spectra, taken in tetrahydrofuran, of the bisdehydroaza[16]annulenes **1**, **6**, and **7**, and of the bisdehydroaza[18]-annulenes **2** and **8** are illustrated in Fig. 5 and 6, respectively. As is seen from both Figs. 5 and 6, the longest wavelength bands shift toward longer wavelengths in the order of **1**>**6**>**7** (Fig. 5), **2**>**8** (Fig. 6), demonstrating the sequence for the degree of extended conjugation of π-electron system in these aza[16]- and

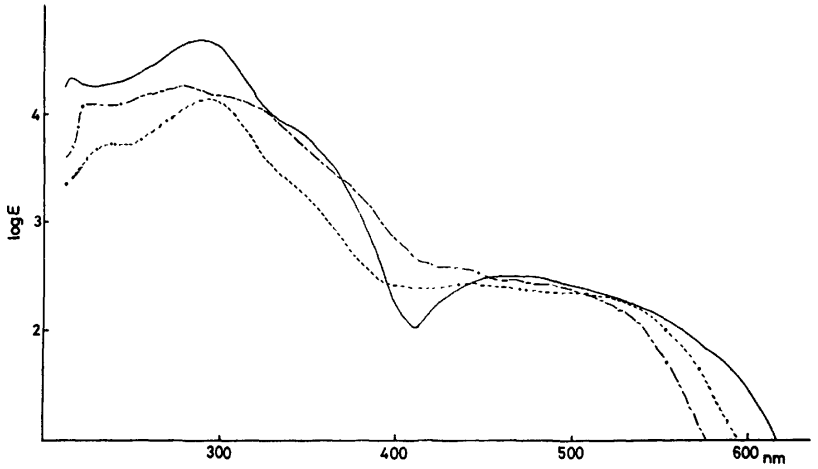

Fig. 5. Electronic spectra of the aza[16]annulenes **1** (——), **6** (------), and **7** (—·—·—) in THF.

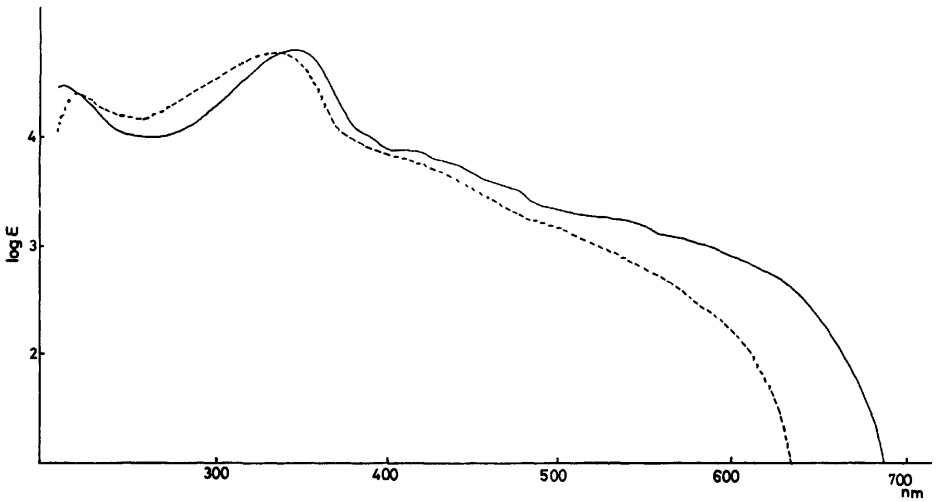

Fig. 6. Elelctronic spectra of the aza[18]annulenes **2** (——) and **8** (------) in THF.

-[18]annulene systems, respectively, as revealed above by examination from ^{1}H NMR spectra.

These results show that the conformations indicated for **1** and **2** are most appropriate for conjugation of π-electrons in these bisdehydroaza[16]- and -[18]annulene systems, respectively.

Experimental

All melting points are uncorrected. IR spectra were measured on Hitachi 260-50 spectrophotometer as KBr disk; only significant maxima are reported. UV spectra were taken on Hitachi 220A spectrophotometer and were recorded in nm, in tetrahydrofuran solution. ε-Values are given in parentheses, the shoulders being denoted by sh. Mass spectra were measured with JEOL JMS-200 spectrometer at 75 eV using a direct inlet system. ^{1}H NMR spectra were taken on JEOL FX-90Q (90 MHz) or Varian XL-200 (200 MHz) spectrometer, and refer to solutions in $CDCl_3$, unless othewise stated, in τ-values with TMS as an internal standard. The coupling constants (J) are given in Hz. Alumina (II-III) was used for column chromatography. Preparative TLC was carried out on 20×20 cm silica-gel plates (Merck, 0.5 or 2.0 mm thick). Dichloromethane was distilled over calcium hydride before use. Tetrahydrofuran (THF) was refluxed over potassium hydroxide pellets and distilled before use. Organic extracts with dichloromethane or chloroform were dried over anhyd calcium chloride prior to solvent removal.

1-Hydroxyimino-2,5,10-trimethylcyclopentadeca-2,4,10,12,14-pentaene-6,8-diyne (10). To a stirred soln of the trimethylbisdehydro[15]annulenone (**9**)[4] (1.70 g, 6.8 mmol) in methanol (250 ml) and THF (80 ml) was added a soln of hydroxylamine hydrochloride (19.0 g, 0.273 mol) in water (50 ml) at 38 °C in one portion. After stirring for further 24 h at 38—45 °C, further quantities of hydroxylamine hydrochloride (each 10 g in water (10 ml)) were added after every 24 h. After stirring for a total of 78 h, the soln was poured into aq sodium hydrogencarbonate soln and extracted with chloroform. The combined extracts were washed with aq sodium chloride soln, dried, and evaporated. The residue after solvent removal was chromatographed on alumina (3.7×7.5 cm). The early fractions eluted with hexane–chloroform (1:1) gave the recovered annulenone (**9**) (167 mg). The following fractions eluted with chloroform gave the oxime **10** (1.04 g, 58%) as a solid. Recrystallization from hexane–chloroform afforded orange needles: Mp 192 °C (decomp); MS m/z 263 (M^+, 37%)

230 (100); mol wt 263.3; IR 3230 (-OH), 2160 (-C≡C-), 990, and 970 cm^{-1} (trans C=C); UV_{max} 279 (27300), 309 (39200), and 395 nm sh (3400); ^1H NMR (90 MHz, DMSO-d_6) τ=−1.70 (s, 1H, OH, exchangeable with D_2O), 2.67 (dd, 16, 4, 1H, $H^{B'}$), 2.72—3.54 (m, 5H, H^B, H^C, $H^{C'}$, $H^{D'}$, and $H^{E'}$), 3.81 (d, 16.5, 1H, $H^{A'}$), 8.00 (s, 3H, CH_3), 8.02 (s, 3H, CH_3), and 8.08 (s, 3H, CH_3).

Found: C, 82.14; H, 6.45; N, 5.28%. Calcd for $C_{18}H_{17}NO$: C, 82.10; H, 6.51; N, 5.32%.

3,6,11-Trimethylazacyclohexadeca-3,5,11,13,15-pentaene-7,9-diyn-2-one (11). A soln of phosphorus pentachloride (5.0 g, 24 mmol) in THF (80 ml) was added to an ice-cooled, stirred soln of the oxime **10** (902 mg, 3.4 mmol) in THF (200 ml). The soln was stirred for a further 4 h at 25—28 °C, and then was poured into water. Then an aq sodium hydrogencarbonate soln was added (pH 8). The mixture was extracted with chloroform. The combined extracts were washed with aq sodium chloride soln, and dried. The residue after solvent removal was chromatographed on alumina (3.7×9.0 cm). The fractions eluted with hexane–benzene (3:2) gave the lactam **11** (405 mg, 45%) as a solid. Recrystallization from hexane–benzene afforded purple brown needles: Mp 187—189 °C; MS *m/z* 263 (M^+, 100%); mol wt 263.3; IR 3280 (NH), 2180 (-C≡C-), 1680 (C=O), 1620 (C=C), and 970 cm^{-1} (trans C=C); UV_{max} 265 sh (23500), 293 (38100), 310 sh (29200), 341 sh (9420), and 464 nm (1050); ^1H NMR (200 MHz) τ=−0.65 (d, 11, 1H, NH), −0.05 (d, 11, 1H, H^B), −0.04—0.12 (m, 1H, $H^{C'}$), 3.69 (dd, 11, 9.5, 1H, $H^{A'}$), 3.74 (d, 11.5, 1H, H^C), 4.24 (dd, 15, 11.5, 1H, $H^{D'}$), 4.28 (d, 11, 1H, $H^{E'}$), 5.16 (dd, 11, 9, 1H, $H^{B'}$), 8.25 (s, 3H, CH_3), 8.28 (s, 3H, CH_3), and 8.30 (s, 3H, CH_3), and see Fig. 3.

Found: C, 82.37; H, 6.46; N, 5.21%. Calcd for $C_{18}H_{17}NO$: C, 82.10; H, 6.51; N, 5.32%.

2-Ethoxy-3,6,11-trimethyl-7,9-bisdehydroaza[16]annulene (6). To a stirred soln of the lactam **11** (581 mg, 2.21 mmol) in dichloromethane (100 ml) was added dropwise a soln of triethyloxonium tetrafluoroborate (4.19 g, 22.1 mmol) in dichloromethane (30 ml) during 30 min at room temp under argon. After stirring for 1.5 h at the same temp, further quantities of the oxonium salt (each 4.19 g in dichloromethane (30 ml)) were added twice every 6 h. After stirring for a total 18 h, the soln was cooled in an ice-bath and an aq potassium carbonate soln was added dropwise (pH 8). The mixture was poured into water and extracted with dichloromethane. The combined extracts were washed with saturated aq sodium chloride soln, and dried. The residue after solvent removal was chromatographed on alumina (3.7×8.0 cm). The initial fractions eluted with 3% ether in hexane gave a dark red liquid, which was further purified by preparative TLC. The fast moving, red band on evaporation afforded the aza[16]annulene **6** (2.4 mg, 0.37%) as an unstable solid. Recrystallization from hexane–benzene afforded brown needles: Mp 114—115 °C; IR 2180 (-C≡C-), 1575 (C=C), and 1260 cm^{-1} (-O-); UV_{max} 237 (5270), 292 (13400), 340 sh (2210), and 455 nm (260), and see Fig. 5; ^1H NMR (200 MHz) τ=0.64 (dd, 16, 12, 1H, $H^{C'}$), 0.70 (d, 10, 1H, H^B), 0.88 (d, 13, 1H, $H^{A'}$), 3.83 (d, 11, 1H, H^C), 4.05 (d, 5.5, 1H, $H^{E'}$), 4.17 (t, 12, 1H, $H^{B'}$), 4.49 (dd, 16, 5, 1H, $H^{D'}$), 5.96 (q, 7, 2H, $-OC\underline{H}_2CH_3$), 8.28 (s, 3H, CH_3), 8.36 (s, 3H, CH_3), 8.43 (s, 3H, CH_3), and 8.74 (t, 7, 3H, $-OCH_2C\underline{H}_3$), and see Fig. 1.

HRMS: Found: 291.1607. Calcd for $C_{20}H_{21}NO$: 291.1620.

1-Hydroxyimino-5,10,15-trimethylcyclopentadeca-2,4,10,12,14-pentaene-6,8-diyne (13). To a stirred soln of the trimethylbisdehydro[15]annulenone (**12**)[4] (1.33 g, 5.34 mmol) in methanol (223 ml) and THF (65 ml) was added in one portion a soln of hydroxylamine hydrochloride (7.42 g, 0.107 mol) in water (8 ml) at room temp. After stirring for 17 h at room temp, a further quantity of hydroxylamine hydrochloride (14.8 g, 0.214 mmol) in water (15 ml) was added to the soln, and stirring was continued for a further 15 h. Then the soln was worked up as in the preparation of **10**. The residue after solvent removal was chromatographed on alumina (3.7×7.5 cm). The fractions eluted with 5% ethanol in chloroform gave the oxime **13** (1.24 g, 88%) as a solid. Recrystallization from hexane–chloroform afforded orange needles: Mp 198—200 °C (decomp); MS *m/z* 263 (M^+, 46%) and 231 (100); mol wt 263.3; IR 3250 (NH), 2150 (-C≡C-), 975, and 960 cm^{-1} (trans C=C); UV_{max} 278 sh (36100), 300 (50600), and 385 nm sh (20300); ^1H NMR (90 MHz, DMSO-d_6) τ=−1.37 (s, 1H, OH, exchangeable with D_2O), 2.79—3.94 (m, 7H, olefinic H), 8.02 (s, 3H, CH_3), 8.07 (s, 3H, CH_3), and 8.13 (s, 3H, CH_3).

Found: C, 82.19; H, 6.40; N, 5.46%. Calcd for $C_{18}H_{17}NO$: C, 82.10; H, 6.51; N, 5.32%.

6,11,16-Trimethylazacyclohexadeca-3,5,11,13,15-pentaene-7,9-diyn-2-one (14). A soln of phosphorus pentachloride (7.08 g, 34.0 mmol) in THF (210 ml) was added dropwise during 40 min to a soln of the oxime **13** (1.79 g, 6.80 mmol) in THF (210 ml) with stirring at 2—6 °C. After stirring for a further 2 h at the same temp, a further quantity of phosphorus pentachloride (1.42 g) in THF (22 ml) was added and stirring was continued for a further 1 h. Then the mixture was worked up as in the preparation of **11**. The residue after solvent removal was chromatographed on alumina (4.0×8.5 cm). The fractions eluted with 5% chloroform in benzene gave the lactam **14** (853 mg, 47%) as a solid. Recrystallization from hexane–chloroform afforded purple cubes: Mp 202—203 °C; MS *m/z* 263 (M^+, 100%); mol wt 263.3; IR 3300 (NH), 2180 (-C≡C-), 1650 (C=O), 1630, 1615 (C=C), and 970 cm^{-1} (trans C=C); UV_{max} 291 (26800), 342 sh (6380), and 459 nm (1110); ^1H NMR (200 MHz) τ=0.01 (s, 1H, NH), 1.17 (dd, 16.5, 9.0, 1H, H^B), 1.27 (dd, 15.8, 10.6, 1H, $H^{C'}$), 3.26 (d, 16.5, 1H, H^A), 3.56 (dd, 15.9, 8.6, 1H, $H^{D'}$), 3.93 (d, 9.2, 1H, H^C), 4.18 (d, 8.6, 1H, $H^{E'}$), 5.29 (d, 10.8, 1H, $H^{B'}$), 7.89 (s, 3H, CH_3'), 8.27 (s, 3H, CH_3), and 8.29 (s, 3H, CH_3), and see Fig. 3.

Found: C, 82.31; H, 6.51; N, 5.39%. Calcd for $C_{18}H_{17}NO$: C, 82.10; H, 6.51; N, 5.32%.

The later fractions eluted with 10% ethanol in chloroform gave the recovered oxime **13** (250 mg).

2-Ethoxy-6,11,16-trimethyl-7,9-bisdehydroaza[16]annulene (7). To a stirred soln of the lactam **14** (481 mg, 1.83 mmol) in dichloromethane (200 ml) was added a soln of triethyloxonium tetrafluoroborate (6.92 g, 36.5 mmol) in dichloromethane (60 ml) dropwise during 45 min with stirring at room temp under argon. After stirring for 3 h at the same temp, a further quantity of the oxonium salt (1.73 g) in dichloromethane (15 ml) was added, and stirring was continued for 21 h. Then the mixture was worked up as in the preparation of **6**. The dark red liquid after solvent removal was chromatographed on alumina (3.7×7.0 cm). The early fractions eluted with hexane gave an unstable red liquid, which was further purified by preparative TLC. The fast moving, red band on evaporation afforded the aza[16]-annulene **7** (13.6 mg, 2.6%) as a brown liquid: IR (neat) 2170 (-C≡C-), 1605 (C=C), and 1280 cm^{-1} (-O-); UV_{max} 266 sh (16700), 278 (18600), 304 (14800), 321 sh (11900), and 380

nm sh (1730), and see Fig. 5; ^{1}H NMR (200 MHz) τ=1.74 (dd, 16, 11, 1H, H^B), 2.16 (dd, 15.5, 11.5, 1H, $H^{C'}$), 3.71 (d, 4, 1H, $H^{E'}$), 3.73 (d, 11.5, 1H, $H^{B'}$), 3.82 (d, 11, 1H, H^C), 4.25 (d, 16, 1H, H^A), 4.27 (dd, 11.5, 4, 1H, $H^{D'}$), 5.91 (q, 7, 2H, $-OCH_2CH_3$), 8.07 (s, 3H, CH_3), 8.16 (s, 3H, CH_3), 8.20 (s, 3H, CH_3), and 8.73 (t, 7, 3H, $-OCH_2CH_3$), and see Fig. 1.

HRMS: Found: 291.1598. Calcd for $C_{20}H_{21}NO$: 291.1621.

The later fractions eluted with 5% ethanol in chloroform gave the recovered lactam **14** (76 mg).

1-Hydroxyimino-2,7,12-trimethylcycloheptadeca-2,4,6,12,14,16-hexaene-8,10-diyne (16). A soln of hydroxylamine hydrochloride (6.60 g, 95.0 mmol) in water (10 ml) was added in one portion to a stirred soln of trimethylbisdehydro[17]annulenone (**15**)[6] (657 mg, 2.40 mmol) in methanol (130 ml) and THF (40 ml) at room temp. After stirring for 19 h at 40 °C, a further quantity of hydroxylamine hydrochloride (6.6 g) in water (10 ml) was added and stirring was continued for a further 21 h at the same temp. Then the soln was worked up as in the preparation of **10**. The residue after solvent removal was chromatographed on alumina (4.2×7.5 cm). The fractions eluted with 5% ethanol in chloroform gave the oxime **16** (505 mg, 73%) as a solid. Recrystallization from hexane–chloroform afforded orange needles: Mp 218—220 °C (decomp): MS *m/z* 289 (M^+, 100%); mol wt 289.3; IR 3230, 3140 (-OH), 2170 (-C≡C-), 970, and 950 cm^{-1} (trans C=C); UV_{max} 300 (48800), 307 (48700), 370 sh (9490), and 398 nm sh (7180); ^{1}H NMR (90 MHz, DMSO-d_6) τ=−1.51 (s, 1H, OH, exchangeable with D_2O), 2.70—3.67 (m, 9H, olefinic H), 8.04 (s, 3H, CH_3'), and 8.15 (s, 6H, CH_3).

Found: C, 83.31; H, 6.63; N, 4.82%. Calcd for $C_{20}H_{19}NO$: C, 83.01; H, 6.62; N, 4.84%.

8,13,18-Trimethylazaoctadeca-3,5,7,13,15,17-hexaene-9,11-diyn-2-one (17). A soln of phosphorus pentachloride (2.44 g, 11.7 mmol) in THF (100 ml) was added dropwise during 30 min at −10 °C to a stirred soln of the oxime **16** (484 mg, 1.67 mmol) in THF (100 ml) and stirring was continued for a further 3.5 h at room temp. Then the soln was worked up as in the preparation of **11**. The residue after solvent removal was chromatographed on alumina (3.7× 9.0 cm). The fractions eluted with benzene–chloroform (1:1) gave the lactam **17** (221 mg, 46%) as a solid. Recrystallization from hexane–chloroform afforded dark brown cubes: Mp 202—204 °C (decomp); MS *m/z* 289 (M^+, 100%); mol wt 289.3; IR 3170, 3050 (NH), 2160 (-C≡C-), 1655 (C=O), 1605, 1585 (C=C), and 960 cm^{-1} (trans C=C); UV_{max} 327 (52100) and 403 nm sh (6250); ^{1}H NMR (200 MHz) τ=2.29 (dd, 15.5, 8.5, 1H, H^B), 2.70 (s, 1H, NH), 3.01 (d, 11, 1H, $H^{E'}$), 3.21 (d, 10.5, 1H, H^E), 3.25 (dd, 15, 11, 1H, $H^{C'}$), 3.58 (dd, 15.5, 8.5, 1H, H^C), 3.95 (dd, 15.5, 9.5, 1H, H^D), 4.50 (d, 15.5, 1H, H^A), 4.63 (dd, 15, 10.5, 1H, $H^{D'}$), 5.32 (d, 11, 1H, $H^{B'}$), 7.84 (s, 3H, CH_3'), 7.92 (s, 3H, CH_3), and 7.93 (s, 3H, CH_3), and see Fig. 4.

Found: C, 82.87; H, 6.80; N, 4.90%. Calcd for $C_{20}H_{19}NO$: C, 83.01; H, 6.62; N, 4.84%.

18-Ethoxy-2,7,12-trimethyl-8,10-bisdehydroaza[18]annulene (8). To a stirred soln of triethyloxonium tetrafluoroborate (4.05 g, 21.3 mmol) in dichloromethane (40 ml) was added a soln of the lactam **17** (206 mg, 0.712 mmol) in dichloromethane (35 ml) during 30 min at room temp under argon. After stirring for 17 h, a further quantity of the oxonium salt (2.5 g) in dichloromethane (20 ml) was added to the soln, and stirring was continued for a further 6 h. Then the soln was worked up as in the preparation of **6**. The residue after solvent removal was chromatographed on alumina (3.7×8.0 cm). The early fractions eluted with 2% ether in hexane gave the aza[18]annulene **8** (23.0 mg, 11.2%) as a solid. Recrystallization from hexane–benzene afforded dark brown needles: Mp 106—108 °C; MS *m/z* 317 (M^+, 88%) and 258 (100); mol wt 317.4; IR 2170 (-C≡C-), 1620, 1600, 1560 (C=N, C=C), 1280, 1265, 1055 (-O-), and 960 cm^{-1} (trans C=C); UV_{max} 291 sh (27000), 333 (55500), 412 sh (5660), and 510 nm sh (1270), and see Fig. 6; ^{1}H NMR (200 MHz) τ=2.51 (dd, 15.5, 8, 1H, $H^{B'}$), 2.92 (d, 10, 1H, H^E), 3.04 (dd, 15, 10.5, 1H, H^C), 3.08 (d, 10, 1H, $H^{E'}$), 3.66 (dd, 15, 8, 1H, $H^{C'}$), 4.46 (dd, 15, 10, 1H, $H^{D'}$), 4.99 (d, 15.5, 1H, $H^{A'}$), 5.20 (dd, 15, 10, 1H, H^D), 5.73 (q, 7, 2H, $-OCH_2CH_3$), 5.99 (d, 10.5, 1H, H^B), 7.79 (s, 3H, CH_3), 7.86 (s, 3H, CH_3), 8.04 (s, 3H, CH_3'), and 8.62 (t, 7, 3H, $-OCH_2CH_3$), and see Fig. 2, (200 MHz, CF_3COOD in $CDCl_3$) τ=1.84 (dd, 15.5, 8, 1H, $H^{B'}$), 2.75 (d, 10.5, 1H, H^E), 2.92 (d, 8, 1H, $H^{E'}$), 3.05 (dd, 15.5, 10.5, 1H, H^C), 3.78 (dd, 15.5, 8, 1H, $H^{D'}$), 3.91 (dd, 15.5, 8, 1H, $H^{C'}$), 5.25 (dd, 15.5, 10.5, 1H, H^D), 5.26 (q, 7, 2H, $-OCH_2CH_3$), 5.46 (d, 15.5, 1H, $H^{A'}$), 5.74 (d, 10.5, 1H, H^B), 7.64 (s, 3H, CH_3), 7.74 (s, 3H, CH_3), 7.87 (s, 3H, CH_3'), and 8.37 (t, 7, 3H, $-OCH_2CH_3$).

Found: C, 83.42; H, 7.24; N, 4.57%. Calcd for $C_{22}H_{23}NO$: C, 83.24; H, 7.30; N, 4.41%.

Stereoselectivity of Cycloaddition of *N*-(Cyanomethyl)- and *N*-(α-Cyanobenzyl)imines with Olefinic Dipolarophiles. Synthetic Equivalents of Nitrile Ylide 1,3-Dipoles

Otohiko Tsuge,* Kazunori Ueno, Shuji Kanemasa, and Kiyotaka Yorozu
Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received January 27, 1986)

N-(Cyanomethyl)- and *N*-(α-cyanobenzyl)imines derived from a variety of aldehydes and ketones can tautomerize into *N*-protonated azomethine ylides which undergo cycloadditions with olefinic dipolarophiles. These cycloadditions are often accompanied by the elimination of HCN, mostly in a stereospecific manner, showing these imines to be synthetic equivalents of nonstabilized nitrile ylides. Stereoselectivity of the cycloadditions is discussed.

Since the discovery of imine–azomethine ylide tautomerism of the imines derived from α-amino esters,[1–3] a wide range of 1,3-dipolar cycloaddition reactions utilizing such imines have been applied to the synthesis of pyrrolidine- and pyrrole-2-carboxylates.[4,5] However, quite rare are cycloaddition examples leading to the formation of stereoselective cycloadducts.[1] Generally, a mixture of two or even more stereoisomers of cycloadducts is formed.[2,4,6]

It is only quite recent that stereochemical features of cycloaddition of heteroaromatic *N*-ylides as peripheral azomethine ylides with olefinic dipolarophiles have been unveiled.[7] Although a lot of examples for the cycloadditions of open-chained azomethine ylides have been reported,[8–15] it is so far very difficult to predict stereoselectivity of a given example of cycloaddition of an azomethine ylide with an olefin. This difficulty results partly from the lack of information on the structure of azomethine ylide which has participated in the cycloaddition.

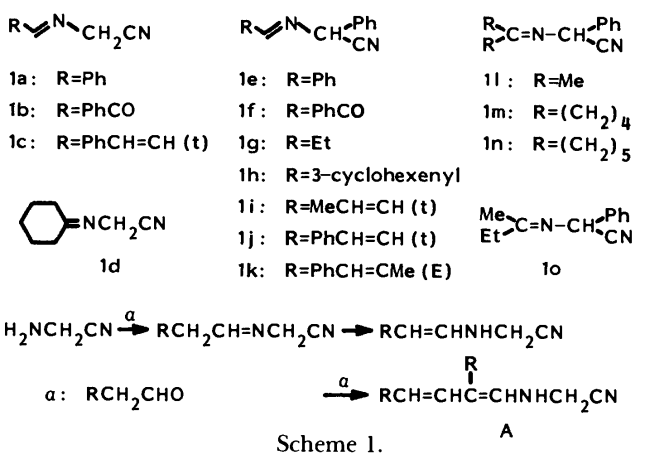
An *N*-protonated azomethine ylide generated through tautomerism of imine lies in equilibrium with the starting imine under the conditions of cycloaddition. Therefore, the most stable isomer of all possible *N*-protonated azomethine ylides should participate in the cycloaddition. Geometry of the most stable ylide isomer may be readily predictable on the basis of structure of the starting imine.[16]

In the previous communications, we have found that *N*-benzylidene derivatives of cyanomethylamine[17] and α-cyanobenzylamine[18] undergo cycloadditions with olefins as *N*-protonated azomethine ylides of cyano-stabilized type. Elimination of HCN from the cycloadducts leads to pyrrolines which correspond to cycloadducts of nonstabilized nitrile ylides with olefins. It is important that these azomethine ylides directly afford cycloadducts one oxidation state higher than those expected from simple azomethine ylides, because there is no general route available for nonstabilized nitrile ylides.

The analysis of stereoselectivity in cycloadditions of *N*-protonated azomethine ylides of cyano-stabilized type is a major purpose of the present report. Structures incorrectly assigned for some cycloadducts described in the previous communication[18] are to be revised here.

Results and Discussion

A variety of *N*-(cyanomethyl)- **1a—d** and *N*-(α-cyanobenzyl)imines **1e—o** were examined as possible tautomeric precursors of *N*-protonated azomethine ylides of cyano-stabilized type (Scheme 1). The imines are readily accessible from reactions of aldehydes or ketones with cyanomethylamine or α-cyanobenzylamine. In some cases, imines were generated only in situ and used for the cycloadditions without isolation. Although the corresponding imines are similarly formed from cyanomethylamine and aliphatic aldehydes, they have a tendency to react further with the second molecule of the aldehyde as reactive enamines to give dienamines **A** even when no excess of the aldehyde is used.



Scheme 1.

All the imines **1a—c** and **1e—k** derived from aldehydes are found to exist in single isomeric forms in solution (^{1}H NMR in $CDCl_3$), presumably in *E*-forms.[19]

In the present work, these imines **1** were subjected to react with olefinic dipolarophiles such as *N*-methyl- **2a**, *N*-(*p*-nitrophenyl)maleimide **2b**, dimethyl

Table 1. Cycloaddition of **1a** with **2** Under Various Conditions

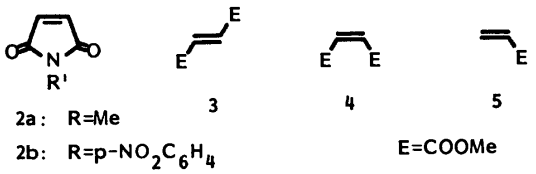
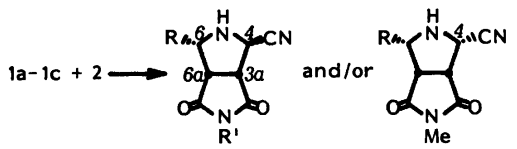
a) Isolated yield. b) Determined by ^{1}H NMR.

fumarate **3**, dimethyl maleate **4**, and methyl acrylate **5**. On the basis of stereostructure of cycloadducts formed, geometry of *N*-protonated azomethine ylides involved in the cycloaddition as well as stereoselectivity



and stereospecificity of the cycloaddition is to be figured out. Synthetic versatility of these *N*-protonated azomethine ylides as synthons of nitrile ylides is next tested by elimination of HCN from the cycloadducts.

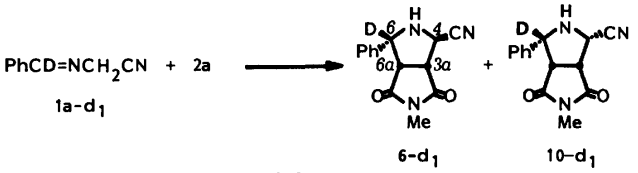
Reaction of *N*-(Cyanomethyl)imines with Maleimides. The reaction of *N*-(cyanomethyl)benzylideneamine **1a** with *N*-methylmaleimide **2a** took place cleanly, under reflux in toluene, to give a quantitative yield of cycloadduct **6** as a single stereoisomer (Scheme 2 and Table 1). However, under reflux in such a polar solvent as acetonitrile, the major product **6** was accompanied by its stereoisomer **10** in a 3:1 ratio (Entry 2 in Table 1). After investigation of the same reaction under a variety of conditions, it was found that this reaction was effectively catalyzed by weak acids such as acetic acid and oxalic acid (Entries 3 and 4).[20] Catalyzed cycloadditions occurred even at room temperature, a mixture of **6** and **10** being again obtained. Neither strong acids (CF_3COOH, *p*-TsOH) nor Lewis acids ($BF_3 \cdot Et_2O$, $Ti(OPr^i)_4$, $Al(OEt)_3$) were found to serve as effective catalysts, leading to recovery of the starting materials or complex mixture of many products.



Scheme 2.

Similarly **1a** reacted with *N*-(*p*-nitrophenyl)maleimide **2b** to give single cycloadduct **7**, regardless of reaction conditions (Entries 6 and 7).

Stereostructures of **6** and **10** were assigned to be 3a,4-*trans*:6,6a-*cis* and 3a,4-*cis*:6,6a-*cis* cycloadducts, respectively, on the basis of spectral data, especially of the vicinal coupling constants (**6**: J_{3a-4}=0 and J_{6-6a}= 8.0 Hz; **10**: $J_{3a-4}=J_{6-6a}$=7.5 Hz). Signal assignment for the 6-H, a terminal of four consecutive methine hydrogens sitting on the newly formed five-membered ring, was accomplished by deuterium labeling. Monodeuterio derivatives **6**-d_1 and **10**-d_1 were prepared in the acid-catalyzed reaction of **1a**-d_1 with **2a** (Scheme 3).



Scheme 3.

Under non-catalytic conditions, which have shown high stereoselectivity in the reaction of **1a**, *N*-(cyanomethyl)benzoylmethyleneamine **1b** and -cinnamylideneamine **1c** reacted with **2a** giving 3a,4-*trans*:6,6a-*cis* cycloadducts **8**, **9** and 3a,4-*cis*:6,6a-*cis* isomer **11** (Scheme 2 and Table 2).

Four geometrical isomers **B1**—**4** are possible for the *N*-protonated azomethine ylides formed through tautomerism of **1a**—**c**, and these ylides can be interconverted readily to each other via an imine form under the reaction conditions (Fig. 1). Relative stability

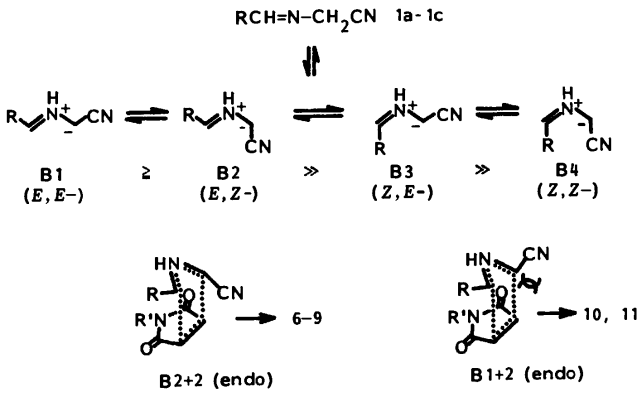


Fig. 1. Geometry of *N*-protonated azomethine ylides B generated from **1a**—**c** and stereochemistry of the cycloaddition with maleimides **2**.

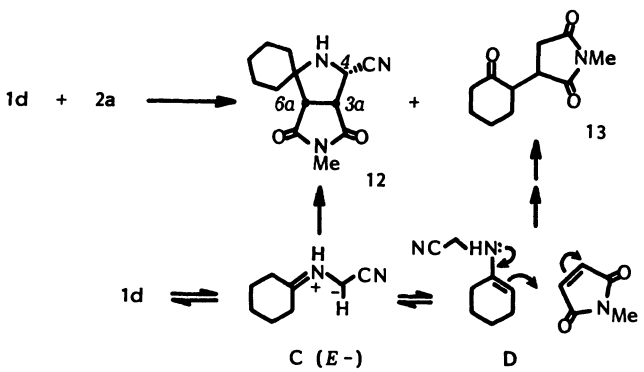
a) All isolated yields as single isomer or as mixture of isomers. b) Determined on the basis of ^1H NMR spectrum of crude reaction mixture. c) The endo:exo ratio with respect to the imine carbon of **1**. d) The yields of **12** (15%) and **13** (50%). e) In the presence of AcOH (10 mol%). f) The yields of **16**+**18** (60%) and **20**+**22** (1:4, 40%). g) The yields of **17**+**19** (92%) and **21**+**23** (1:1, 8%). h) In the presence of AcOH (5 mol%). i) The yields of **48** (24%) and **52** (29%). j) Each two stereoisomers are included. k) **60** consists of two stereoisomers. l) The ratio of regioisomers (4-carboxylates: 3-carboxylates). m) The combined yield.

among them could be evaluated on the ground of steric repulsion.

Cyano moiety is only slightly bigger than hydrogen atom, while substituent R (Ph, PhCO, or PhCH=CH (t)) is much bulkier than any other substituents. Accordingly, the order of stability must be **B1**≧**B2**≫**B3**≫**B4**. The stereoselective cycloadducts **6**—**9** correspond to the ones formed through an endo approach of **2** to the second stable ylide **B2**, and the isomers **10** and **11** are endo cycloadducts of the most stable ylide **B1**. In the endo approach of **B1**, there exists some small steric repulsion between the cyano group and a carbonyl moiety of the maleimide **2**. So far we have no satisfactory explanation toward a question why acid catalysts have lowered stereoselectivity of the cycloaddition so much.

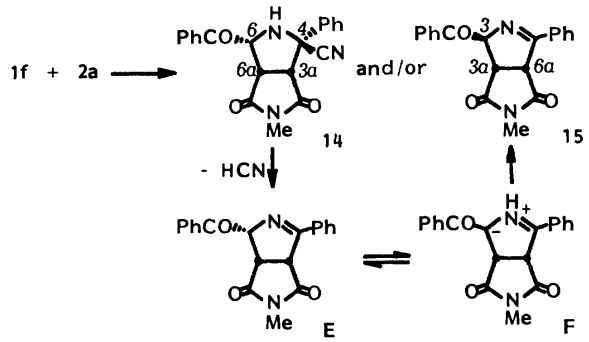
N-(Cyanomethyl)cyclohexylideneamine **1d**, generated in situ from cyclohexanone and cyanomethylamine under reflux in chloroform, reacted with **2a** under reflux in toluene to give only 15% of 3a,4-*cis* cycloadduct **12** (Scheme 4 and Table 2). Major product **13** was the Michael type adduct between cyclohexanone and **2a**. As described above (Scheme 1),



Scheme 4.

the imines derived from aliphatic aldehydes and cyanomethylamine readily tautomerize into enamines. In this case also, imine **1d** experienced competitive tautomerization, or the first formation of azomethine ylide and subsequent enamine formation, generating *N*-protonated azomethine ylide **C** and enamine **D**. The cycloaddition of **C**, that occupies sterically less hindered *E*-geometry, with **2a** produces **12** and the Michael addition of **D** forms a betaine intermediate which is then hydrolyzed into **13**.[21] Under acidic conditions (AcOH) both at room temperature and under reflux in acetonitrile, the Michael adduct **13** was the only product. This result looks reasonable since such polar conditions favor the Michael addition which is known to take place through a polar transition state.

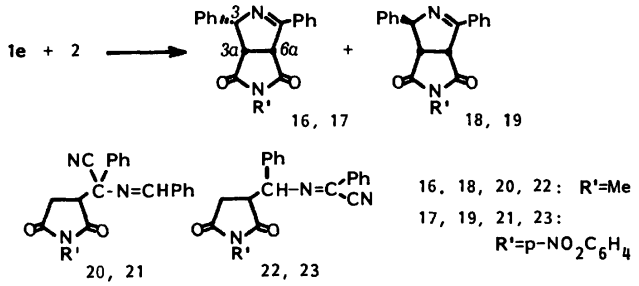
Reaction of *N*-(α-Cyanobenzyl)imines with Maleimides. *N*-(α-Cyanomethyl)benzoylmethyleneamine **1f** is found reactive toward maleimides. Thus, the reaction of **1f** with **2a** was completed in 5 min under reflux in chloroform to give a stereoselective cycloadduct **14** in a quantitative yield, which was assigned as one of 6,6a-*cis* isomers as shown in Scheme 5. Stereochemistry at the 4-position was tentatively determined on the basis of the most stable geometry for the *N*-protonated azomethine ylide generated from **1f**. This point will be discussed later.



Scheme 5.

When chromatographed over silica gel,[22] **14** underwent quantitative elimination of HCN to give **15** as a single stereoisomer in which the configuration of the 3-position was inverted. The prolonged reaction of **1f** with **2a** also furnished **15** as a side product. Probably **14** was first transformed into cis isomer **E** which then isomerized into **15** as a thermodynamically more stable product via azomethine ylide tautomer **F** (Scheme 5). In this isomerization, such a strongly electron-withdrawing substituent as benzoyl moiety is essential since imine-azomethine ylide tautomerism takes place only if α-hydrogen of imine is highly acidic.

A mixture of cis **16** and trans isomer **18** of HCN-eliminated cycloadduct was obtained in the reaction of *N*-(α-cyanobenzyl)benzylideneamine **1e** with **2a** under reflux in acetonitrile or toluene (Scheme 6, **16**:**18**=3.5—2.3:1). Under catalytic conditions (AcOH),



Scheme 6.

were formed two additional isomers **20** and **22** which were identified to be regioisomeric Michael adducts.

Similar reaction of **1e** with **2b** gave two HCN-eliminated cycloadducts **17**, **19** (3:1) and the Michael adducts **21**, **23** as minor products even under non-catalytic conditions (Table 2).[23]

This poor stereoselectivity between the 3- and 3a-positions of **16** and **18** (or **17** and **19**) is quite surprising. Four isomeric forms **G1—4** are again possible for the *N*-protonated azomethine ylide **G** formed by tautomerism of **1e** (Fig. 2). Unlike the preceding case (**B** in Fig. 1), **G1** must be by far the most stable since the additional phenyl moiety causes unfavorable steric repulsion in **G2**. Therefore, it is easily understood that only **G1** has participated in cycloaddition with **2**. Endo and exo approaches of **2a** to **G1** lead to the corresponding cycloadducts **H** and **I** whose stereospecific elimination of HCN produces cis **16** and trans isomer **18**. If this is the case, what is the reason for such poor stereoselectivity?

Before we try to explain this poor selectivity, we should rule out a possibility that **18** as a thermodynamically more stable isomer could have been secondarily derived from endo selective cycloadduct

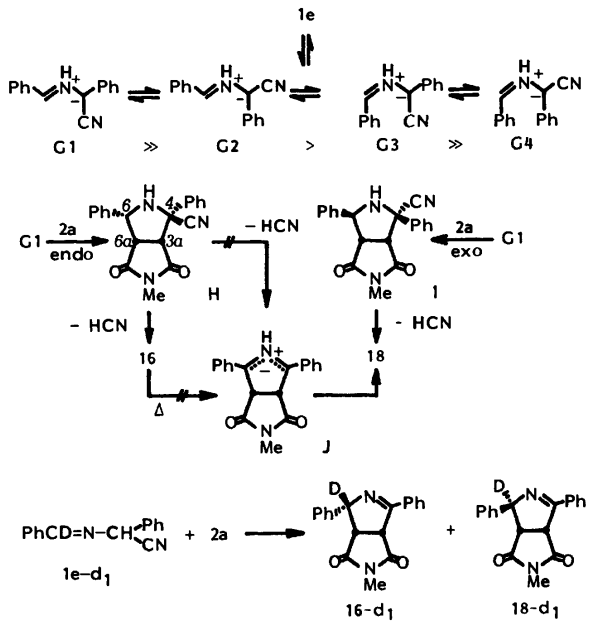


Fig. 2. Geometry of *N*-protonated azomethine ylide G generated from **1e** and stereochemistry of the cycloaddition with a maleimide **2a**.

H. Isomerization of **16** into **18** via azomethine ylide intermediate **J**, which resembles the inversion of **14** into **15** via **F** (Scheme 5), was first excluded by the fact that no trace of **18** was even detected on heating **16** under the reaction conditions of cycloaddition.[24] Direct formation of peripheral azomethine ylide intermediate **J** from **H** by 1,3-elimination of HCN was also excluded.[25] Cycloaddition of monodeuterio imine **1e**-d_1 with **2a** under the same conditions provided only a mixture of monodeuterio derivatives **16**-d_1 and **18**-d_1 of HCN-eliminated cycloadduct, indicating that stereochemistry at the 3-position of **16** and **18** has been already built up as it is now in the corresponding initial cycloadducts **H** and **I**. Thus, it is concluded that cycloaddition of **1e** with **2a** is nonstereoselective, forming two stereoisomeric cycloadducts **H** and **I**.

Both the phenyl substituents of **G1** can attractively interact with the carbonyl conjugation of **2a** allowing endo approach of both reagents.[26] However, this endo attractive interaction should be hindered by steric repulsion simultaneously growing among the same positions of these reacting molecules. As the phenyl groups are discouraged to share the same plane with the azomethine ylide triangle of **G1**,[27] steric repulsion on the endo approach becomes inevitable in this case. Accordingly the endo approach leading to **H** competes with the exo approach leading to **I**.

Similarly, *N*-(α-cyanobenzyl)alkylideneamines **1g—h** and -alkenylideneamines **1j—k** reacted with **2a** as *N*-protonated azomethine ylides to give 3,3a-*cis* **24—28** and/or 3,3a-*trans* isomers **29** and **30** of HCN-eliminated cycloadducts (Scheme 7 and Table 2). Stereoselectivity was found to depend upon substituents of imines **1**, and the cycloadditions of **1g—h** and **1k** were exclusively *endo*-selective.

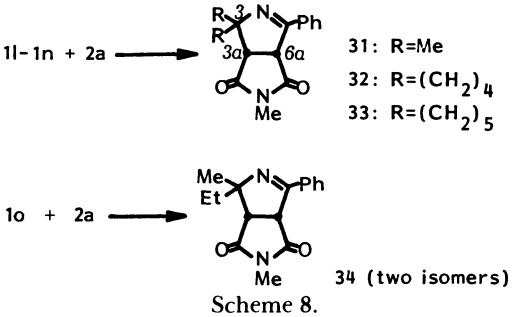
Scheme 7.

N-(α-Cyanobenzyl)imines **1l—o** derived from aliphatic ketones also reacted with **2a** giving HCN-eliminated cycloadducts **31—34** in good yields (Scheme 8 and Table 2).

Elimination of HCN from the Maleimide Cycloadducts. As mentioned above, most of the cycloadducts formed in the reactions of *N*-(α-cyanobenzyl)-imines **1e—o** with maleimides **2** undergo spontaneous elimination of HCN under the conditions of cycloaddition, indicating that these imines are useful



31: R=Me

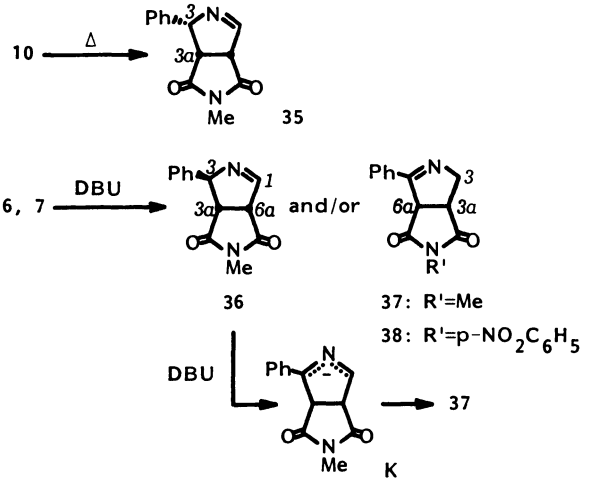
34 (two isomers)

Scheme 8.

as synthetic equivalents of benzonitrile methylides. On the other hand, the cycloadducts from *N*-(cyanomethyl)imines **1a—d** are substituted with a cyano moiety. Therefore, some of these cycloadducts were subjected to thermal or base-catalyzed elimination of HCN.

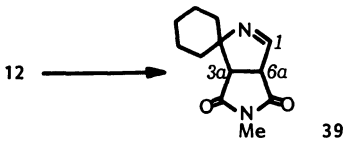
On heating in xylene, the all-*cis* cycloadduct **10** underwent slow elimination of HCN to give **35** with retention of configuration (Scheme 9 and Table 3), while its isomer **6** was recovered unchanged under the same conditions. In the presence of a catalytic amount of DBU, elimination occurred to give a mixture of 3,3a-*trans* isomer **36** and double bond-migrated product **37** whose ratio was found to change depending upon reaction time. The thermodynamically most stable isomer **37** was quantitatively obtained when **36** was heated in xylene for a long time in the presence of DBU. It is understood that both inversion of stereochemistry at the 3-position and double bond migration have occurred via the common anionic intermediate **K**.



Scheme 9.

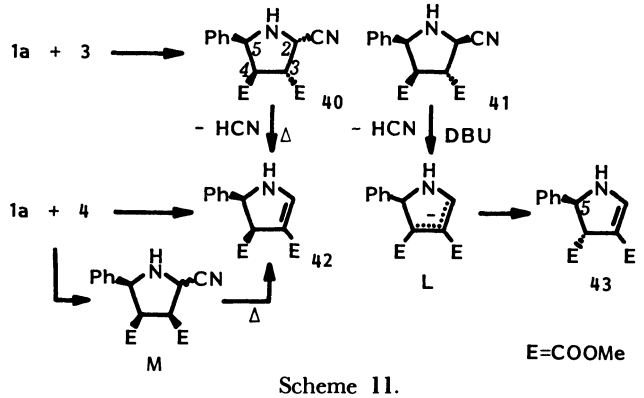
As spiro cycloadduct **12** has no possibility of secondary change after elimination of HCN, its elimination was carried out under reflux in xylene in the presence of a catalytic amount of DBU. A quantitative yield of **39** was obtained (Scheme 10 and Table 3).

Reaction with Fumarate, Maleate, and Acrylate. We further continued to study cycloaddition reactions of **1** with acyclic olefins such as dimethyl fumarate



Scheme 10.

3 and maleate 4. Reaction of 1a with 3 gave two stereoisomeric cycloadducts 40 and 41 whose ratio was found to depend upon reaction conditions (Scheme 11 and Table 2). They were assigned as *r*-2, *c*-3, *t*-4, *t*-5 40 and *r*-2, *t*-3, *c*-4, *c*-5 isomer 41 on the basis of the corresponding coupling constants as well as the magnetic shielding by a phenyl group at the 5-position toward the adjacent ester moiety cis to the phenyl.



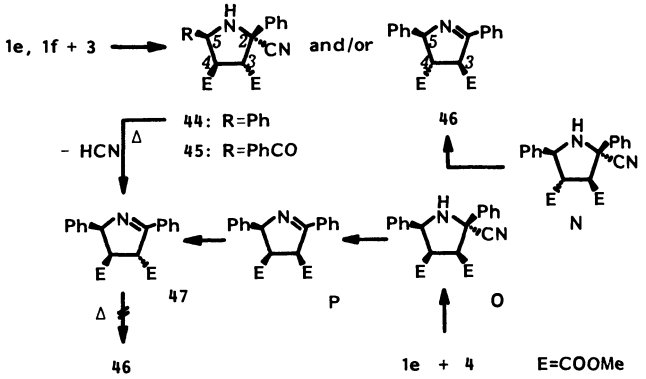
Scheme 11.

Cycloadduct 40 experienced slow elimination of HCN when heated in toluene to afford 4,5-*cis* 2-pyrroline 42 in which cis configuration at the 4- and 5-positions was retained. On the other hand, its isomer 41 suffered from no elimination until it was heated under reflux in toluene in the presence of a catalytic amount of DBU. The only product was 4,5-*trans* 2-pyrroline 43. This inversion leading to 43 as a thermodynamically more stable isomer was presumably caused via allyl anion intermediate L.

Reaction of 1a with the maleate 4 under reflux in toluene did not stop at a stage of cycloaddition but further reached to the complete elimination of HCN. The formation of 4,5-*cis* 2-pyrroline 42 as a single product indicates that cycloaddition between 1a and 4 was exclusively *endo*-selective to form cis cycloadduct M.

Thus, cycloadditions of 1a with both 3 and 4 are so highly stereoselective around one of the two newly formed C-C bonds that cycloadducts formed are exclusively 4,5-*cis* isomers. In contrast, reaction of 1e bearing an additional phenyl substituent with 3 showed poor stereoselectivity.

Reaction of 1e with 3 under reflux in benzene produced a mixture of 4,5-*cis* cycloadduct 44 and 4,5-*trans* isomer 46 of HCN-eliminated cycloadduct in a 3:1 ratio (Scheme 12 and Table 2). Under reflux in toluene, 4,5-*cis* isomer 47 of HCN-eliminated cycloadduct was newly formed (44:47:46=1.5:1.5:1), which was found to produce in a quantitative yield by thermal elimination of HCN of 44 with retention of stereochemistry. As 47 did not isomerize into 46 under the conditions of cycloaddition, 46 must be a product formed from 4,5-*trans* cycloadduct N through stereospecific HCN elimination reaction. After all, endoselectivity around the 4- and 5-positions was only 75% in this case.



Scheme 12.

Similar cycloaddition of 1e with 4, however, occurred very cleanly to give a quantitative yield of 47 as a single isomer. As we now know that epimerization at the 5-position of 1-pyrroline hardly takes place under thermal conditions, formation of 47 is easily explained by the following mechanism: Cycloaddition between 1e and 4 first forms 4,5-*cis* cycloadduct O which then loses HCN under the conditions of cycloaddition. *r*-3, *c*-4, *c*-5 1-Pyrroline P undergoes epimerization at the 3-position through imine-enamine tautomerism.[28] Such tautomerization is frequently observed on pyrroline ring systems in which double bond is settled to the thermodynamically most stable location as seen in some examples 42, 43, 46, and 47.[29]

Not only to maleimides (Scheme 5) but also to 3, reactive imine 1f underwent stereoselective cycloaddition under mild reaction conditions to give 4,5-*cis* cycloadduct 45.

High stereoselectivity in cycloadditions of 1a with both 3 and 4 was predictable on the ground of attractive interaction working between the phenyl moiety of 1a and one of esters of 3 and 4. As shown in Fig. 3, this is the only possible attractive interaction and there exists no serious steric hindrance among substituents. As a result, stereochemistry of cycloaddition was controlled by this interaction providing 4,5-*cis* products 40—42 in all cases. On the other hand, there are two possible endo interactions in the reaction of 1e with 3 since 1e participates to cycloaddition in the most stable form G1. Accordingly, stereoselectivity between the 4- and 5-positions was poor and a mixture of 4,5-*cis* 44 and 4,5-*trans* cycloadduct N was formed. In the cycloaddition of 1e with 4, the both ester groups of 4 can possitively interact with the both phenyl groups of G1. Unlike the rigid

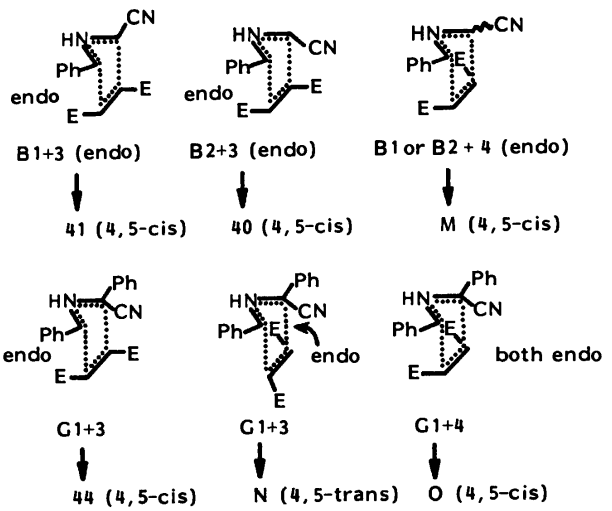


Fig. 3. Stereochemistry of cycloaddition of **1a** and **1e** with fumarate **3** and maleate **4**.

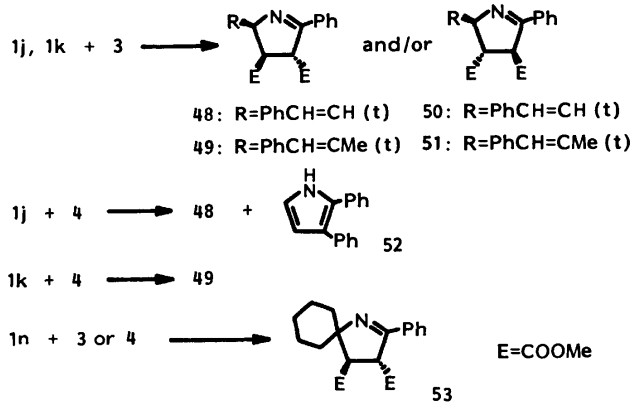
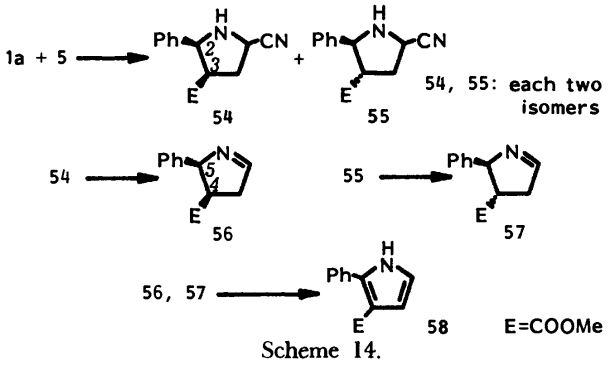
carbonyl conjugation of maleimides **2**, the ester groups of **4** can rotate around a C–C bond in such a direction as steric repulsion is minimized and also attractive interaction is maximized. Accordingly, the cycloaddition of **1e** with **4** was highly *endo*-selective forming cycloadduct **O**.

Similar reactions of **1j—k** with **3** furnished both mixtures of 4,5-*cis* **48**, **49** and 4,5-*trans* isomers **50**, **51** of HCN-eliminated cycloadducts (Scheme 13 and Table 2). However, the cycloadditions with **4** were exclusively *endo*-selective. 4,5-*cis* Isomers **48** and **49** were the only products in the reactions of **1j** and **1k**, respectively. Pyrrole **52** is the product formed by a 1,5-cyclization of imine **1j** followed by elimination of HCN. Spiro 1-pyrroline **53** carrying two ester groups trans to each other was obtained in either of reactions of **1n** with **3** and **4**.



Scheme 13.

Although reaction of **1a** with methyl acrylate **5** gave only very poor yields of cycloadducts or HCN-eliminated cycloadducts under reflux in toluene or in acetonitrile in the absence or presence of AcOH, heating **1a** in **5** gave a quantitative yield of mixture of four cycloadducts. Two of the four were separated from the other two and they were assigned as mixtures of two isomers of 2,3-*cis* **54** and 2,3-*trans* cycloadduct **55** on the basis of the following conversion as well as spectral data (Scheme 14). The both mixtures **54** and **55** underwent smooth elimination of HCN affording 4,5-*cis* **56** and 4,5-*trans* 1-pyrroline **57** with retention of configuration, respectively. Both 1-pyrrolines **56** and **57** were further converted into the same pyrrole-3-carboxylate **58** by dehydrogenation with chloranil, indicating that the cycloaddition of **1a** with **5** was exclusively regioselective. As regioselectivity in this and related cycloadditions is most likely to result, at least in part, from endo attractive interaction among the substituents as shown later, comparable formation of *exo*-cycloadducts **55** in this case is



Scheme 14.

Table 3. Elimination of Hydrogen Cyanide from Cycloadducts

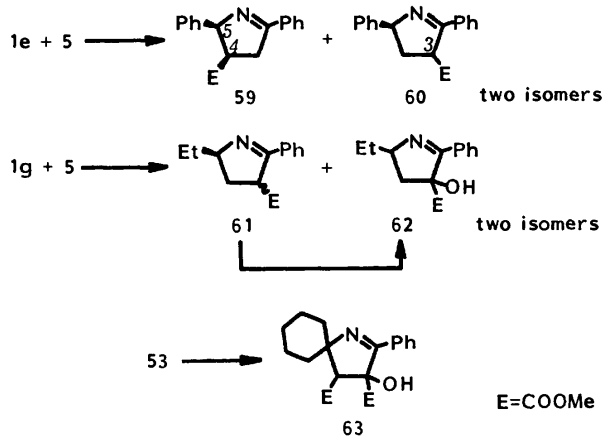
quite surprising. We have so far no idea for the origin of exo cycloaddition.

Imine **1e** carrying two phenyl groups which can possitively interact with ester moiety reacted with **5** providing two regioisomeric HCN-eliminated cycloadducts **59** and **60** (Scheme 15 and Table 2). Stereochemistry at the 3-position of **60** is not important since easy epimerization is known to take place at this position.[29]



Scheme 15.

As anticipated, reaction of **1g** with **5** was regioselective giving single regioisomer **61** of HCN-eliminated cycloadduct. Probably endo interaction between the phenyl and ester groups resulted in such outstanding regioselectivity.

Surprisingly, **61** was easily air-oxidized at the 3-position forming mixture of two stereoisomeric 3-hydroxy-1-pyrrolines **62**. Similar air oxidation took place on **53** which was quantitatively oxidized into **63** under oxygen atmosphere.

Experimental

General. Melting points were determined on a Yanagimoto micro melting point apparatus and uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C NMR spectra on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as internal standard. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 70 eV of ionization energy. Elementary analyses were performed on a Hitachi 026 CHN micro analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or of aluminum oxide 60 F-254 type-E (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako) and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size 0.04—0.063 mm). Preparative high performance liquid chromatography (HPLC) was performed on a Kusano KHLC-201 apparatus with a UV-detector Uvilog-III using a column (22×300 mm) packed with silica gel (Wakogel LC-50H). Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise cited.

Benzene, toluene, and xylene were distilled over sodium and stored on sodium wire.

General Procedure for the Preparation of 1. A mixture of each equimolar amounts of cyanomethylamine or α-cyanobenzylamine and carbonyl compounds was refluxed in an appropriate solvent under the elimination of water formed by means of a Dean-Stark trap. The solvents and reaction times are as follows: In chloroform: **1b** (10 min); **1c** (1.5 h); **1d** (5 h); **1e** (30 min); **1f** (5 min); **1g** (4 h); **1i** (30 min); **1k** (30 min); **1m** (4 h); **1n** (2.5 h); **1o** (2.5 h). In dichloromethane: **1a** (1 h). In toluene at 60 °C: **1j** (15 min). In acetone: **1l** (30 min). These imines are not highly stable and **1b**, **1f**, and **1j** are too unstable to be separated. Accordingly, the most imines **1** were prepared immediately prior to their use and they were used for the following cycloaddition reactions after the evaporation of solvent in vacuo. Some spectral and analytical data are given as follows: **1a**: IR (neat) 2240 and 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.53 (2H, d, *J*=2.0 Hz, CH_2), 7.30—7.75 (5H, m, Ph), and 8.42 (1H, d, *J*=2.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=45.73 (t, CH_2), 115.49 (s, CN), 128.06, 128.26, 131.23 (each d), 134.35 (s), and 164.27 (d, CH=N). **1c**: ^{1}H NMR ($CDCl_3$) δ=4.43 (2H, br, CH_2), 6.78—7.45 (7H, m, Ph and CH=CH), and 8.09 (1H, br d, *J*=7.5 Hz, CH=N). **1d**: ^{1}H NMR ($CDCl_3$) δ=1.55—1.90 (6H, m, CH_2), 2.15—2.40 (4H, m, CH_2), and 4.14 (2H, s, CH_2). **1e**: Colorless prisms (hexane); mp 51.5—52 °C; IR (KBr) 2210 and 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.80 (1H, d, *J*=2.0 Hz, CH), 7.10—8.20 (10H, m. Ph), and 8.65 (1H, d, *J*=2.0 Hz, CH=N); MS *m/z* 220 (M^+). Found: C, 81.71; H, 5.46; N, 12.68%. Calcd for $C_{15}H_{12}N_2$: C, 81.79; H, 5.49; N, 12.72%. **1g**: ^{1}H NMR ($CDCl_3$) δ=1.10 (3H, t, Et), 2.36 (2H, m, Et), 5.41 (1H, br s, CH), 7.26 (5H, br s, Ph), and 7.95 (1H, br d, CH=N). **1h**: ^{1}H NMR ($CDCl_3$) δ=1.30—2.75 (7H, m, CH_2 and CH), 5.46 (1H, s, CH), 5.60 (2H, m, CH=CH), 7.26 (5H, br s, Ph), and 7.90 (1H, d, *J*=4.5 Hz, CH=N). **1i**: IR (neat) 2230 and 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.84 (3H, d, *J*=5.0 Hz, Me), 5.45 (1H, s, CH), 6.20 (2H, m, CH=CH), 7.15—7.30 (5H, m, Ph), and 8.05 (1H, dd, *J*=7.0 and 1.5 Hz, CH=N); MS *m/z* 184 (M^+). HRMS Found: *m/z* 184.0970. Calcd for $C_{12}H_{12}N_2$: M, 184.0999. **1j**: ^{1}H NMR ($CDCl_3$) δ=5.55 (1H, d, *J*=1.5 Hz, CH), 6.80 (1H, dd, *J*=16.0 and 7.5 Hz, PhCH=CH), 7.05 (1H, d, *J*=16.0 Hz, PhCH=CH), 7.10—7.40 (10H, m, Ph), and 8.22 (1H, dd, *J*=7.5 and 1.5 Hz, CH=N). **1k**: Colorless prisms (hexane); mp 68—70 °C; IR (KBr) 2230 and 1615 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.07 (3H, s, Me), 5.55 (1H, s, CH), 6.80 (1H, br s, CH=), 7.10—7.40 (10H, m, Ph), and 8.14 (1H, s, CH=N); MS *m/z* 260 (M^+). Found: C, 82.85; H, 6.24; N, 10.78%. Calcd for $C_{18}H_{16}N_2$: C, 83.04; H, 6.20; N, 10.76%. **1l**: IR (neat) 2190 and 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.95, 2.05 (each 3H, s, Me), 5.26 (1H, s, CH), and 7.10—7.50 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=19.65, 54.36, 119.19, 127.48, 129.24, 135.95, and 174.77. **1m**: ^{1}H NMR ($CDCl_3$) δ=1.70—2.30 (8H, m, CH_2), 4.89 (1H, s, CH), and 7.10—7.50 (5H, m, Ph). **1n**: ^{1}H NMR ($CDCl_3$) δ=1.50—2.50 (10H, m, CH_2), 5.43 (1H, s, CH), and 7.10—7.50 (5H, m, Ph). **1o**: ^{1}H NMR ($CDCl_3$) δ= 1.05 (3H, t, Et), 2.10 (3H, s, Me), 2.34 (2H, m, Et), 4.76 (1H, s, CH), and 7.10—7.50 (5H, m, Ph).

The deuterio derivatives **1a**-d_1 and **1e**-d_1 were similarly

prepared from the reactions with benzaldehyde-d_1 which was synthesized from phenylglyoxlic acid.[30]

General Procedure for the Cycloadditions of 1 with 2. The reactions of 1 with **2** were performed according to the following general procedure unless otherwise stated: A mixture of each equimolar amounts of 1 and **2** in a solvent (10—15 ml for 1 mmol of 1 or **2**) was allowed to react until either of the starting materials was all consumed (checked on TLC). The solvents and reaction conditions are listed in Tables 1 and 2. After the solvent was evaporated to dryness in vacuo, the residue was subjected to a ^{1}H NMR measurement to know the purity of products and then chromatographed over silica gel using chloroform, chloroform–diethyl ether, or chloroform–ethyl acetate (10—20:1 v/v). When a reaction was carried out in the presence of catalyst, the crude reaction mixture was first poured into water and extracted with chloroform or dichloromethane. The extract was washed with aqueous sodium hydrogencarbonate and water, dried over anhydrous magnesium sulfate, and evaporated in vacuo.

Reaction of 1a with 2a Leading to 6 and/or 10. The results are given in Table 1 (entries 1 to 5). **6**: Colorless prisms (benzene–hexane); mp 152—153 °C; IR (KBr) 3300, 2220, and 1690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.40 (1H, br, NH), 2.85 (3H, s, NMe), 3.45 (1H, t, J_{6a-3a}=J_{6a-6}=8.0 Hz, 6a-H), 3.54 (1H, d, J_{3a-6a}=8.0 Hz, 3a-H), 4.66 (1H, s, 4-H), 4.78 (1H, d, J_{6-6a}=8.0 Hz, 6-H), and 7.18—7.38 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.14 (q, NMe), 47.66, 49.51, 49.85 (each d, 3a-, 4-, and 6a-C), 63.26 (d, 6-C), 118.66 (s, CN), 126.99, 128.45, 128.55, 136.00 (s), 174.01, and 175.24 (each s, CON); MS *m/z* (rel. intensity, %) 255 (M$^+$, 29), 144 (76), 143 (base peak), and 77 (49).

Found: C, 66.04; H, 5.13; N, 16.24%. Calcd for $C_{14}H_{13}N_3O_2$: C, 65.87; H, 5.13; N, 16.46%.

10: Colorless prisms (acetone–hexane); mp 199—200 °C; IR (KBr) 3300, 2250, and 1690 cm^{-1}: ^{1}H NMR (DMSO-d_6) δ=2.50 (1H, br, NH), 2.72 (3H, s, NMe), 3.42 (1H, t, J_{6a-3a}=J_{6a-6}=7.5 Hz, 6a-H), 3.56 (1H, t, J_{3a-4}=J_{3a-6a}=7.5 Hz, 3a-H), 4.22 (1H, d, J_{4-3a}=7.5 Hz, 4-H), 4.32 (1H, d, J_{6-6a}=7.5 Hz, 6-H), and 7.16—7.32 (5H, m, Ph); ^{13}C NMR (DMSO-d_6) δ=24.46 (q, NMe), 46.59, 47.85, 48.58 (each d, 3a-, 4-, and 6a-C), 62.91 (d, 6-C), 117.44 (s, CN), 127.09, 127.62, 137.62 (s), 174.40, and 174.99 (each s, CON); MS *m/z* (rel. intensity, %) 255 (M$^+$, 13), 228 (33), 144 (70), 143 (base peak), 117 (70), 115 (72), 90 (50), 89 (56), and 77 (39).

Found: C, 65.71; H, 5.09; N, 16.11%. Calcd for $C_{14}H_{13}N_3O_2$: C, 65.87; H, 5.13; N, 16.46%.

Reaction of 1a with 2b Leading to 7. The results are given in Table 1 (Entries 6 and 7): Colorless needles (benzene–hexane); mp 148—149 °C; IR (KBr) 3350, 2230, and 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.53 (1H, br, NH), 3.64 (1H, t, J_{6a-3a}=J_{6a-6}=8.0 Hz, 6a-H), 3.76 (1H, d, J_{3a-6a}=8.0 Hz, 3a-H), 4.80 (1H, s, 4-H), 4.96 (1H, d, J_{6-6a}=8.0 Hz, 6-H), 7.22—7.40 (7H, m, Ar), and 8.10—8.30 (2H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=47.56, 49.90, 50.20 (each d, 3a-, 4-, and 6a-C), 63.64 (d, 6-C), 118.13 (s, CN), 124.35, 126.28, 126.93, 128.75, 129.05, 135.39 (s), 136.62, 146.89 (each s), 172.20, and 173.43 (each s, CON); MS *m/z* (rel. intensity, %) 362 (M$^+$, 6), 143 (53), 117 (47), 115 (51), 90 (base peak), and 89 (53).

Found: C, 63.26; H, 3.91; N, 15.27%. Calcd for $C_{19}H_{14}N_4O_4$: C, 62.98; H, 3.89; N, 15.46%.

Reaction of 1b with 2a Leading to 8. A mixture of cyanomethylamine (162 mg, 2.89 mmol) and phenylglyoxal (440 mg, 2.89 mmol) in chloroform (30 ml) was heated under reflux for 10 min. After **2a** (321 mg, 2.89 mmol) was added, the mixture was allowed to react under the conditions shown in Table 2 to give **8**: Colorless prisms (benzene); mp 210—211 °C; IR (KBr) 3310, 2240, 1780, and 1700 cm^{-1}; ^{1}H NMR (CD_3CN) δ=2.71 (3H, s, NMe), 3.32 (1H, m, NH), 3.65 (1H, dd, J_{3a-4}=1.4 and J_{3a-6a}=7.7 Hz, 3a-H), 3.91 (1H, t, J_{6a-3a}=J_{6a-6}=7.7 Hz, 6a-H), 4.66 (1H, dd, J_{4-3a}=1.4 and J_{4-NH}=5.2 Hz, 4-H), 5.03 (1H, dd, J_{6-6a}=7.7 and J_{6-NH}=9.0 Hz, 6-H), 7.30—7.70 (3H, m, Ph), and 7.85—8.06 (2H, m, Ph); ^{13}C NMR (DMSO-d_6) δ=24.94 (q, NMe), 49.42, 50.18, 51.66 (each d, 3a-, 4-, and 6a-C), 64.59 (d, 6-C), 119.95 (s, CN), 128.42, 128.95, 133.77 (each d), 136.07 (s), 175.54 (2×C, s, CON), and 195.31 (s, PhCO); MS *m/z* (rel. intensity, %) 283 (M$^+$, 1), 178 (base peak), 106 (68), 93 (38), and 77 (25).

Found: C, 63.58; H, 4.67; N, 14.64%. Calcd for $C_{15}H_{13}N_3O_3$: C, 63.60; H, 4.63; N, 14.83%.

Reaction of 1c with 2a Leading to 9 and 11. A mixture of cyanomethylamine (112 mg, 2 mmol) and cinnamaldehyde (264 mg, 2 mmol) in chloroform (20 ml) was heated under reflux for 1.5 h on molecular sieves 4A. The molecular sieves was filtered off and the chloroform was evaporated in vacuo. To the residue were added dry toluene (20 ml) and **2a** (222 mg, 2 mmol). The mixture was allowed to react under the conditions shown in Table 2 to give a mixture of **9** and 11. **9**: Colorless needles (acetone–hexane); mp 175—176 °C; IR (KBr) 3450, 3320, 2220, 1765, and 1690 cm^{-1}; ^{1}H NMR (CD_3CN) δ=2.86 (3H, s, NMe), 3.44 (1H, t, J_{6a-3a}=J_{6a-6}=8.0 Hz, 6a-H), 3.60 (1H, d, J_{3a-6a}=8.0 Hz, 3a-H), 4.22 (1H, dd, J_{6-6a}=8.0 and $J_{6\text{-}CH=}$=7.2 Hz, 6-H), 4.51 (1H, s, 4-H), 6.10 (1H, dd, $J_{=CH\text{-}6}$=7.2 and J_{trans}=16.0 Hz, PhCH=C<u>H</u>), 6.66 (1H, d, J_{trans}=16.0 Hz, PhC<u>H</u>=CH), and 7.20—7.50 (5H, m, Ph); MS *m/z* (rel. intensity, %) 281 (M$^+$, 83), 170 (base peak), and 169 (74).

Found: C, 68.50; H, 5.44; N, 14.78%. Calcd for $C_{16}H_{15}N_3O_2$: C, 68.31; H, 5.37; N, 14.94%.

11: Colorless prisms (acetone–hexane); mp 209—210 °C; IR (KBr) 3450, 3310, 2230, 1765, and 1690 cm^{-1}; ^{1}H NMR (CD_3CN) δ=2.88 (3H, s, NMe), 3.30 (1H, t, J_{6a-3a}=J_{6a-6}=7.5 Hz, 6a-H), 3.49 (1H, t, J_{3a-4}=J_{3a-6a}=7.5 Hz, 3a-H), 3.89 (1H, dd, J_{6-6a}=7.5 and $J_{6\text{-}CH=}$=7.1 Hz, 6-H), 4.14 (1H, d, J_{4-3a}=7.5 Hz, 4-H), 6.14 (1H, dd, $J_{=CH\text{-}6}$=7.1 and J_{trans}=16.0 Hz, PhCH=C<u>H</u>), 6.60 (1H, d, J_{trans}=16.0 Hz, PhC<u>H</u>=CH), and 7.20—7.50 (5H, m, Ph); MS *m/z* (rel. intensity, %) 281 (M$^+$, 40), 254 (46), 170 (45), 169 (68), 168 (38), 143 (54), 115 (base peak), and 77 (35).

Found: C, 68.07; H, 5.31; N, 15.16%. Calcd for $C_{16}H_{15}N_3O_2$: C, 68.31; H, 5.37; N, 14.94%.

Reaction of 1d with 2a Leading to 12 and 13. A mixture of cyanomethylamine (153 mg, 2.73 mmol) and cyclohexanone (276 mg, 2.73 mmol) in dry chloroform (30 ml) was heated under reflux for 5 h. The solvent was removed by evaporation in vacuo. To the residue were added dry toluene (30 ml) and **2a** (303 mg, 2.73 mmol). The mixture was allowed to react under the conditions shown in Table 2 and chromatographed over silica gel. An elution with chloroform–diethyl ether (20:1) gave **13** (285 mg, 50%) and the followed fraction with chloroform–diethyl ether (10:1) afforded **12** (101 mg, 15%). The same reaction in the presence of acetic acid gave only **13** (70—72%).

12: Colorless prisms (benzene–hexane); mp 158—159 °C; IR (KBr) 3330, 2920, 2840, 2240, 1770, and 1695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.20—2.20 (10H, m, CH_2), 2.50 (1H, br,

NH), 2.94 (1H, d, J_{6a-3a}=7.8 Hz, 6a-H), 3.00 (3H, s, NMe), 3.50 (1H, t, $J_{3a-4}=J_{3a-6a}$=7.8 Hz, 3a-H), and 4.28 (1H, d, J_{4-3a}=7.8 Hz, 4-H); ^{13}C NMR ($CDCl_3$) δ=22.59, 23.00 (each t, CH_2) 25.24 (2×C, t and q, CH_2 and NMe), 34.47, 36.00 (each t, CH_2), 47.06, 47.94, 53.59 (each d, 3a-, 4-, and 6a-C), 64.65 (s, 6-C), 117.59 (s, CN), 174.95, and 175.48 (each s, CON); MS *m/z* (rel. intensity, %) 247 (M^+, 20), 204 (base peak), 191 (28), and 119 (38).

Found: C, 62.99; H, 6.94; N, 16.92%. Calcd for $C_{13}H_{17}N_3O_2$: C, 63.14; H, 6.93; N, 16.99%.

13: Colorless needles (benzene-hexane); mp 122—123 °C; IR (KBr) 2900, 2830, and 1680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.40—2.84 (12H, m, CH_2 and CH), and 3.00 (3H, s, NMe); ^{13}C NMR ($CDCl_3$) δ=24.94 (q, NMe), 24.77, 27.06, 31.83, 31.94 (each t, CH_2), 41.18 (d, CH), 41.77 (t, CH_2), 50.36 (d, CH), 177.01, 179.54 (each s, CON), and 210.54 (s, CO); MS *m/z* (rel. intensity, %) 209 (M^+, 35), 113 (base peak), and 97 (88).

Found: C, 63.27; H, 7.26; N, 6.82%. Calcd for $C_{11}H_{15}NO_3$: C, 63.14; H, 7.23; N, 6.69%.

Reaction of 1f with 2a Leading to 14 and/or 15. A mixture of α-cyanobenzylamine (563 mg, 3.7 mmol) and phenylglyoxal (489 mg, 3.7 mmol) in dry chloroform (30 ml) was heated under reflux for 5 min and **2a** (411 mg, 3.7 mmol) was added. The mixture was refluxed for 5 min and the solvent was evaporated in vacuo to give **14** (1.328 g, 100%). Continued heating for 1 h afforded a mixture of **14** and **15** (1:1). The latter **15** was obtained in a quantitative yield when **14** was chromatographed over silica gel with chloroform–diethyl ether (3:1).

14: Colorless prisms; mp 157—158 °C; IR (KBr) 3350, 1780, 1710, and 1685 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=2.70 (3H, s, NMe), 4.16 (1H, dd, J_{6a-3a}=9.0 and J_{6a-6}=10.0 Hz, 6a-H), 4.96 (1H, d, J_{3a-6a}=9.0 Hz, 3a-H), 6.20 (1H, br, NH), 6.36 (1H, d, J_{6-6a}=10.0 Hz, 6-H), and 7.20—8.10 (10H, m, Ph); MS *m/z* (rel. intensity, %) 332 (M^+—HCN, 10), 142 (22), 115 (65), and 105 (base peak).

Found: C, 70.14; H, 4.82; N, 11.58%. Calcd for $C_{21}H_{17}N_3O_3$: C, 70.18; H, 4.77; N, 11.69%.

15: Pale yellow prisms (acetone-hexane); mp 285—286 °C; IR (KBr) 1740 and 1690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.88 (3H, s, NMe), 4.30 (1H, dd, J_{3a-3}=2.6 and J_{3a-6a}=8.5 Hz, 3a-H), 4.66 (1H, dd, J_{6a-3}=2.9 and J_{6a-3a}=8.5 Hz, 6a-H), 6.02 (1H, dd, J_{3-3a}=2.6 and J_{3-6a}=2.9 Hz, 3-H), and 7.20—8.30 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.25 (q, NMe), 45.79 (d, 3a-C), 56.60 (d, 6a-C), 79.55 (d, 3-C), 128.28, 128.63, 129.57, 131.45, 131.69, 133.86, 134.74, 167.44 (s, 1-C), 173.01, 177.54 (each s, CON), and 193.62 (s, PhCO); MS *m/z* (rel. intensity, %) 331 (M^+—H, 8), 330 (33), 140 (29), 113 (24), 105 (40), and 77 (base peak).

Found: C, 72.48; H, 4.30; N, 8.63%. Calcd for $C_{20}H_{16}N_2O_3$: C, 72.28; H, 4.85; N, 8.43%.

Reaction of 1e with 2a Leading to 16, 18 and/or 20, 22. Under the conditions shown in Table 2, a mixture of **16**, **18** and/or **20**, **22** was obtained. **16**: Colorless prisms (benzene); mp 178—179 °C; IR (KBr) 1780, 1700, and 1615 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.60 (3H, s, NMe), 3.94 (1H, dd, J_{3a-3}=10.0 and J_{3a-6a}=9.0 Hz, 3a-H), 4.60 (1H, dd, J_{6a-3a}=9.0 Hz, 6a-H), 5.85 (1H, d, J_{3-3a}=10.0 Hz, 3-H), 6.96—7.50 (8H, m, Ph), and 8.10 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=24.72 (q, NMe), 49.49 (d, 3a-C), 56.71 (d, 6a-C), 77.20 (d, 3-C), 127.11, 128.16, 128.34, 128.46, 129.57, 131.63, 131.86, 137.09, 144.59, 144.84, 167.26 (s, 1-C), 173.01, and 174.14 (each s, CON); MS *m/z* (rel. intensity, %) 306 (M^+, 5), 304 (base peak), 219 (23), and 115 (48).

Found: C, 74.10; H, 5.83; N, 9.27%. Calcd for $C_{19}H_{18}N_2O_2$: C, 74.49; H, 5.92; N, 9.15%.

Reaction of 1n with 2a Leading to 33. A mixture of cyclohexanone (100 mg, 1.02 mmol) and α-cyanobenzylamine (119 mg, 0.902 mmol) in dry chloroform was heated under reflux for 2.5 h. The solvent was removed through evaporation in vacuo and **2a** (111 mg, 1 mmol) in dry toluene (10 ml) was added to the residue. The mixture was allowed to react under the conditions shown in Table 2 affording **33**: Colorless prisms (benzene-hexane); mp 200—201°C; IR (KBr) 2890, 1750, 1680, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.25—2.20 (10H, m, CH_2), 2.89 (3H, s, NMe), 3.24 (1H, d, J_{3a-6a}=8.5 Hz, 3a-H), 4.58 (1H, d, J_{6a-3a}=8.5 Hz, 6a-H), 7.25—7.50 (3H, m, Ph), and 8.00—8.20 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=23.18 (q, NMe), 22.88, 24.88, 25.77, 34.94, 41.83 (each t, CH_2), 54.47 (d, 3a-C), 56.30 (d, 6a-C), 78.24 (s, 3-C), 128.42, 129.54, 131.07 (each d), 132.83 (s), 161.77 (s, 1-C), 173.66, and 175.95 (each s, CON); MS *m/z* (rel. intensity, %) 296 (M^+, 40), 241 (20), 185 (36), 168 (24), 157 (20), 156 (82), 155 (240), 154 (23), 115 (base peak), and 104 (54).

Found: C, 73.13; H, 6.79; N, 9.36%. Calcd for $C_{18}H_{20}N_2O_2$: C, 72.95; H, 6.80; N, 9.45%.

Reaction of 1o with 2a Leading to 34. A mixture of 2-butanone (75 mg, 1.04 mmol) and α-cyanobenzylamine (119 mg, 0.902 mmol) in dry chloroform (10 ml) was heated under reflux for 2.5 h. The solvent was evaporated in vacuo and **2a** (111 mg, 1 mmol) in dry toluene (10 ml) was added to the residue. The mixture was allowed to react under the conditions shown in Table 2 giving **34** as mixture of two stereoisomers (1:1) whose separation through chromatography was unsuccessful: ^1H NMR ($CDCl_3$) δ=0.92 (2×3H, t, Et), 1.32, 1.44 (each 3H, s, Me), 1.55—2.10 (2×2H, m, Et), 2.86, 2.89 (each 3H, s, NMe), 3.26, 3.30 (each 1H, d, J_{3a-6a}= 9.0 Hz, 3a-H), 4.53, 4.61 (each 1H, d, J_{6a-3a}=9.0 Hz, 6a-H), 7.20—7.50 (2×3H, m, Ph), and 7.90—8.15 (2×2H, m, Ph).

General Procedure for the Elimination of HCN from the Maleimide Cycloadducts. The elimination reactions were performed under the conditions shown in Table 3. After the reactions were completed, the solvent was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (9:1). The results are given in Table 3.

35: Obtained as mixture with the starting material **10** (**35**:**10**=6:4) which could not be removed through chromatography. ^1H NMR of **35** (in CD_3CN) δ=2.59 (3H, s, NMe), 3.69 (1H, dd, J_{3a-3}=10.0 and J_{3a-6a}=8.8 Hz, 3a-H), 4.19 (1H, dt, J_{6a-1}=J_{6a-3}=1.3 and J_{6a-3a}=8.8 Hz, 6a-H), 5.60 (1H, ddd, J_{3-1}=2.7, J_{3-3a}=10.0, and J_{3-6a}=1.3 Hz, 3-H), 6.85—7.10 (3H, m, Ph), 7.16—7.32 (2H, m, Ph), and 7.72 (1H, dd, J_{1-3}= 2.7 and J_{1-6a}=1.3 Hz, 1-H).

36: Colorless prisms (benzene-hexane); mp 153—154°C; IR (KBr) 1700 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.99 (3H, s, NMe), 3.41 (1H, dd, J_{3a-3}=3.0 and J_{3a-6a}=8.5 Hz, 3a-H), 4.26 (1H, dd, J_{6a-3a}=8.5 and J_{6a-1}=2.0 Hz, 6a-H), 5.64 (1H, dd, J_{3-1}=5.5 and J_{3-3a}=3.0 Hz, 3-H), 7.16—7.50 (5H, m, Ph), and 7.78 (1H, br, 1-H); MS *m/z* (rel. intensity, %) 228 (M^+, 38), 143 (28), 117 (base peak), 115 (34), and 77 (17).

Found: C, 68.61; H, 5.40; N, 12.03%. Calcd for $C_{13}H_{12}N_2O_2$: C, 68.41; H, 5.30; N, 12.27%.

37: Colorless prisms (benzene-hexane); mp 125—126 °C; IR (KBr) 1765, 1700, 1690, and 1630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.89 (3H, s, NMe), 3.64 (1H, dt, J_{3a-3}=6.0, 8.0 and J_{3a-6a}=8.0 Hz, 3a-H), 4.32—4.66 (3H, m, 1- and 6a-H), and 7.26—8.20 (5H, m, Ph); MS *m/z* (rel. intensity, %) 228 (M^+, 40), 117 (base peak), 115 (23), and 77 (13).

38: Yellow prisms (benzene-hexane); mp 133—134°C; IR (KBr) 1710 and 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.90 (1H, ddd, J_{3a-3}=6.0, 7.5 and J_{3a-6a}=9.0 Hz, 3a-H), 4.57 (2H, m, 3-H), 4.79 (1H, dt, J_{6a-3}=2.0 and J_{6a-3a}=9.0 Hz, 6a-H), 7.20—7.60 (5H, m, Ar), and 8.00—8.32 (4H, m, Ar); MS *m/z* (rel. intensity, %) 335 (M^+, 21), 117 (base peak), and 77 (25).

Found: C, 64.80; H, 4.42; N, 12.00%. Calcd for $C_{18}H_{13}N_3O_4$: C, 64.48; H, 3.91; N, 12.53%.

39: Colorless needles (hexane); mp 92—93°C; IR (KBr) 2930, 2840, 1755, 1690, and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20—2.20 (10H, m, CH_2), 2.90 (3H, s, NMe), 3.05 (1H, d, J_{3a-6a}=8.5 Hz, 3a-H), 4.14 (1H, dd, J_{6a-1}=1.0 and J_{6a-3a}=8.5 Hz, 6a-H), and 7.45 (1H, d, J_{1-6a}=1.0 Hz, 1-H); ^{13}C NMR ($CDCl_3$) δ=22.88, 23.00 (each t, CH_2), 24.94 (q, NMe), 25.47, 34.59, 41.24 (each t, CH_2), 51.77 (d, 3a-C), 58.71 (d), 90.36 (s, 3-C), 155.95 (d, 1-C), 173.54, and 175.83 (each s, CON); MS *m/z* (rel. intensity, %) 220 (M^+, 70), 113 (29), 109 (60), 108 (28), 81 (23), 66 (37), 58 (35), and 42 (base peak).

Found: C, 65.48; H, 7.35; N, 12.46%. Calcd for $C_{12}H_{16}N_2O_2$: C, 65.43; H, 7.32; N, 12.72%.

General Procedure for the Cycloadditions of 1 with 3 and 4. A mixture of each equimolar amounts of **1** and **3** (or **4**) in a solvent (10—15 ml for 1 mmol of **1**) was allowed to react until either of the starting materials was consumed (checked on TLC). After the solvent was evaporated in vacuo, the residue was subjected to a ^1H NMR measurement to know the purity of products and then chromatographed over silica gel using chloroform, chloroform-diethyl ether, or chloroform-ethyl acetate (10:1). The solvents, reaction conditions, and results are listed in Table 2.

Reaction of 1a with 3 Leading to 40 and 41. This reaction under reflux in toluene or at room temperature in acetonitrile in the presence of acetic acid gave **40** and **41** which were separated through column chromatography over silica gel with chloroform–diethyl ether (10:1). **40**: Colorless prisms (benzene–hexane); mp 123—124 °C; IR (KBr) 3320, 2980, and 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.44 (1H, br, NH), 3.09 (3H, s, 4-COOMe), 3.77 (1H, dd, J_{4-3}=8.6 and J_{4-5}=9.6 Hz, 4-H), 3.78 (3H, s, 3-COOMe), 4.02 (1H, dd, J_{3-2}=7.2 and J_{3-4}=8.6 Hz, 3-H), 4.68 (1H, d, J_{2-3}=7.2 Hz, 2-H), 4.88 (1H, d, J_{5-4}=9.6 Hz, 5-H), and 7.16—7.40 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=49.47, 49.59 (each d, 3- and 4-C), 50.36, 51.83 (each q, COOMe), 52.89 (d, 2-C), 63.06 (d, 5-C), 118.65 (s, CN), 127.77, 128.36 (each d), 138.42 (s), 169.72, and 171.36 (each s, COOMe); MS *m/z* (rel. intensity, %) 288 (M^+, 5), 177 (82), 169 (39), 144 (56), 143 (base peak), 119 (26), 117 (31), 116 (44), 115 (67), 104 (34), and 77 (36).

Found: C, 62.60; H, 5.67; N, 9.78%. Calcd for $C_{15}H_{16}N_2O_4$: C, 62.49; H, 5.59; N, 9.72%.

41: Colorless prisms (benzene–hexane); mp 97—97.5 °C; IR (KBr) 3290, 2200, and 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.50 (1H, br, NH), 3.18 (3H, s, 4-COOMe), 3.54 (1H, dd, J_{3-2}=8.4 and J_{3-4}=6.5 Hz, 3-H), 3.77 (3H, s, 3-COOMe), 3.90 (1H, dd, J_{4-3}=6.5 and J_{4-5}=9.6 Hz, 4-H), 4.30 (1H, d, J_{2-3}=8.4 Hz, 2-H), 4.60 (1H, d, J_{5-4}=9.6 Hz, 5-H), and 7.20—7.36 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=49.65, 50.53 (each d, 3- and 4-C), 51.95, 52.42 (each q, COOMe), 53.06 (d, 2-C), 64.48 (d, 5-C), 119.12 (s, CN), 127.24, 128.48 (each d), 137.95 (s), 170.89, and 171.18 (each s, COOMe); MS *m/z* (rel. intensity, %) 288 (M^+, 4), 177 (81), 169 (29), 162 (21), 144 (base peak), 143 (90), and 115 (29).

Reaction of 1a with 4 Leading to 42. The result is shown in Table 2: Colorless prisms (benzene–hexane); mp 120—122 °C; IR (KBr) 3300, 1720, and 1670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.08 (3H, s, 4-COOMe), 3.61 (3H, s, 3-COOMe), 4.12 (1H, dd, J_{4-5}=12.3 and J_{4-2}=1.0 Hz, 4-H), 4.84 (1H, br, NH), 5.30 (1H, dd, J_{5-1}=1.6 and J_{5-4}=12.3 Hz, 5-H), 7.20—7.36 (5H, m, Ph), and 7.46 (1H, dd, J_{2-1}=3.0 and J_{2-4}=1.0 Hz, 2-H); ^{13}C NMR ($CDCl_3$) δ=50.48, 51.12 (each q, COOMe), 52.14 (d, 4-C), 66.08 (d, 5-C), 100.29 (s, 3-C), 127.14, 127.96 (each d), 137.66 (d), 150.62 (d, 2-C), 166.07, and 171.24 (each s, COOMe); MS *m/z* (rel. intensity, %) 261 (M^+, 35), 202 (base peak), 170 (45), 143 (50), 117 (21), and 115 (34).

Found: C, 64.38; H, 5.84; N, 5.57%. Calcd for $C_{14}H_{15}NO_4$: C, 64.36; H, 5.79; N, 5.36%.

Elimination of HCN from 40 and 41 Leading to 42 and 43. When **40** was heated under reflux in xylene, **42** was obtained. In the presence of a catalytic amount of DBU, **41** was converted into **43**. The reaction conditions and results are given in Table 3.

43: Colorless liquid; IR (neat) 3320, 1730, 1670, 1650, and 1585 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.64, 3.74 (each 3H, s, COOMe), 3.80 (1H, br, NH), 3.82 (1H, dd, J_{4-5}=7.0 and J_{4-2}=1.0 Hz, 4-H), 5.11 (1H, d, J_{5-4}=7.0 Hz, 5-H), 7.10—7.40 (5H, m, Ph), and 7.45 (1H, d, J_{2-4}=1.0 Hz, 2-H); ^{13}C NMR ($CDCl_3$) δ=50.77, 52.47 (each q, COOMe), 55.24 (d, 4-C), 67.65 (d, 5-C), 100.53 (s, 3-C), 126.07, 128.42, 129.13 (each d), 142.19 (s), 149.24 (d, 2-C), 166.19, and 174.60 (each s, COOMe); MS *m/z* (rel. intensity, %) 261 (M^+, 17), 202 (67), 201 (70), 170 (60), 158 (22), 143 (65), 142 (26), 131 (34), 117 (60), 116 (33), 115 (base peak), 104 (23), 103 (28), 90 (42), 89 (42), and 77 (39).

HRMS Found: *m/z* 261.0994. Calcd for $C_{14}H_{15}NO_4$: M, 261.1000.

Reaction of 1e with 3 Leading to 44, 46, and/or 47. The separation of these products was carried out as follows: Column chromatography of the mixture over silica gel with chloroform gave pure **44** and a mixture of **46** and **47**. This mixture was then subjected to HPLC (solvent: diethyl ether–hexane (7:3)), **46** and **47** being separated.

44: Colorless prisms (benzene–hexane); mp 131—133 °C; IR (KBr) 3350, 2230, and 1740 cm^{-1}; ^1H NMR (CD_3CN) δ=3.06 (3H, s, 4-COOMe), 3.56 (1H, br, NH), 3.62 (3H, s, 3-COOMe), 3.80—4.05 (2H, m, 3- and 4-H), 5.00 (1H, m, changed to dd (J=6.0 and 3.0 Hz) when treated with D_2O, 5-H), and 7.30—8.10 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=50.56 (d, 4-C), 51.72, 52.51 (each q, COOMe), 58.42 (d, 3-C), 62.13 (d, 5-C), 66.33 (s, 2-C), 119.20 (s, CN), 126.64, 127.80, 128.16, 128.34, 128.65, 129.38, 136.93 (s), 137.97 (s), 169.21, and 171.16 (each s, COOMe); MS *m/z* (rel. intensity, %) 337 (M^+—HCN, 43), 277 (base peak), and 115 (29).

Found: C, 69.21; H, 5.53; N, 7.69%. Calcd for $C_{21}H_{20}N_2O_4$: C, 69.09; H, 5.62; N, 7.61%.

46: Colorless prisms (benzene–hexane); mp 138—140 °C; IR (KBr) 1740 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.50 (1H, t, J_{4-3}=J_{4-5}=8.0 Hz, 4-H), 3.60, 3.76 (each 3H, s, COOMe), 4.70 (1H, dd, J_{3-4}=8.0 and J_{3-5}=2.0 Hz, 3-H), 5.52 (1H, dd, J_{5-4}=8.0 and J_{5-3}=2.0 Hz, 5-H), 7.20—7.42 (8H, m, Ph), and 7.87 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=52.76 (2×C, q, COOMe), 56.30 (d, 4-C), 79.24 (d, 3-C), 127.13, 127.42, 127.90, 128.37, 128.83, 131.36, 133.01, 142.30, 168.54 (s, 2-C), 171.90, and 173.18 (each s, COOMe); MS *m/z* (rel. intensity, %) 337 (M^+, 19), 277 (base peak), and 115 (39).

This compound **47** was also obtained from the reaction of **1e** with **4** (Table 2).

Reaction of 1f with 3 Leading to 45. The result is shown in Table 2: Colorless prisms (benzene–hexane); mp 96—97 °C; IR (KBr) 3300, 1730, and 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.72 (1H, br, NH), 3.26, 3.66 (each 3H, s, COOMe), 3.86 (1H, d, J_{3-4}=9.0 Hz, 3-H), 4.22 (1H, t, J_{4-3}=J_{4-5}=9.0 Hz, 4-H), 5.30 (1H, d, J_{5-4}=9.0 Hz, 5-H), and 7.30—8.04 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=50.06, 52.18 (each q, COOMe), 52.83 (d, 3-C), 59.42 (d, 4-C), 62.00 (d, 5-C), 67.95 (s, 2-C), 119.30 (s, CN), 126.42, 128.77, 129.01, 129.19, 129.71, 134.18, 135.24, 136.42, 168.95 (s, COOMe), 170.77 (s, COOMe), and 196.25 (s, PhCO); MS *m/z* (rel. intensity, %) 365 (M^+—HCN, 9), 105 (base peak), and 77 (36).

Found: C, 67.47; H, 5.16; N, 7.10%. Calcd for $C_{22}H_{20}N_2O_5$: C, 67.34; H, 5.14; N, 7.14%.

Reaction of 1j with 3 Leading to 48 and 50. A mixture of cinnamaldehyde (132 mg, 1 mmol) and α-cyanobenzylamine (132 mg, 1 mmol) in toluene (10 ml) was heated under reflux for 15 min. After **3** (144 mg, 1 mmol) was added, the mixture was allowed to react under the conditions shown in Table 2. Although **48** and **50** could not be separated each other through

column chromatography, **48** was identical with one of two products (**48** and **52**) formed in the reaction of **1e** with **4** (Table 2).

48: Viscous liquid; IR (neat) 1700, 1680, and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.53, 3.60 (each 3H, s, COOMe), 3.75 (1H, dd, J_{4-3}=6.0 and J_{4-5}=9.0 Hz, 4-H), 4.72 (1H, dd, J_{3-4}=6.0 and J_{3-5}=2.0 Hz, 3-H), 5.30 (1H, ddd, J_{5-3}=2.0, J_{5-4}=9.0, and $J_{5\text{-}CH=}$=8.0 Hz, 5-H), 5.96 (1H, dd, J_{trans}=15.0 and J=8.0 Hz, PhCH=C<u>H</u>), 6.62 (1H, d, J_{trans}=15.0 Hz, PhC<u>H</u>=CH), 7.07—7.33 (8H, m, Ph), and 7.80 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=52.24 (2×C, q, COO<u>Me</u>), 52.89 (d, 4-C), 56.83 (d, 3-C), 75.89 (d, 5-C), 125.83, 126.78, 127.30, 128.01, 128.42, 128.77, 131.42, 132.96, 133.60, 136.83, 169.25 (s, <u>C</u>OOMe), and 171.42 (s, <u>C</u>OOMe); MS *m/z* (rel. intensity, %) 363 (M^+, 53), 304 (59), 272 (57), and 115 (base peak).

Found: C, 72.94; H, 5.64; N, 3.85%. Calcd for $C_{21}H_{21}NO_4$: C, 72.71; H, 5.82; N, 3.85%.

50: Contaminated with **48**; ^1H NMR ($CDCl_3$) δ=3.36 (1H, t, J_{4-3}=J_{4-5}=6.0 Hz, 4-H), 3.60, 3.70 (each 3H, s, COOMe), 4.60 (1H, dd, J_{3-4}=6.0 and J_{3-5}=2.0 Hz, 3-H), and 5.06 (1H, dt, J_{5-3}=2.0 and J_{5-4}=$J_{5\text{-}CH=}$=6.0 Hz, 5-H); MS *m/z* 363 (M^+).

Found: C, 72.58; H, 5.79; N, 4.02%. Calcd for $C_{21}H_{21}NO_4$: C, 72.71; H, 5.82; N, 3.85%.

52: Colorless prisms (hexane); mp 130—131 °C; IR (KBr) 3350 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.30 (1H, t, J_{4-5}=J_{4-NH}=2.0 Hz, 4-H), 6.72 (1H, t, J_{5-4}=J_{5-NH}=2.0 Hz, 5-H), 7.04—7.30 (10H, m, Ph), and 8.00 (1H, br, NH); MS *m/z* 219 (M^+).

Found: C, 87.70; H, 6.20; N, 6.38%. Calcd for $C_{16}H_{13}N$: C, 87.64; H, 5.98; N, 6.39%.

Reaction of 1k with 3 Leading to 49 and 51. This reaction under the conditions shown in Table 2 afforded a mixture of **49** and **51** which could not be separated each other through column chromatography. The isomer **49** was also obtained as a single product in the reaction of **1k** with **4** (Table 2).

49: Viscous liquid; IR (neat) 1730 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.82 (3H, d, J=1.5 Hz, Me), 3.53, 3.62 (each 3H, s, COOMe), 3.85 (1H, dd, J_{4-3}=5.0 and J_{4-5}=9.0 Hz, 4-H), 4.75 (1H, dd, J_{3-4}=5.0 and J_{3-5}=1.5 Hz, 3-H), 5.26 (1H, dd, J_{5-3}=1.5 and J_{5-4}=9.0 Hz, 5-H), 6.47 (1H, br s, CH=), 7.10—7.40 (8H, m, Ph), and 7.85 (2H, m, Ph); MS *m/z* (rel. intensity, %) 377 (M^+, 42), 318 (35), and 115 (base peak).

Found: C, 72.84; H, 6.02; N, 3.58%. Calcd for $C_{23}H_{23}NO_4$: C, 73.19; H, 6.14; N, 3.71%.

51: Contaminated with **49**; ^1H NMR ($CDCl_3$) δ=1.90 (3H, d, J=1.5 Hz, Me), 3.50 (1H, dd, J_{4-3}=6.0 and J_{4-5}=5.0 Hz, 4-H), 3.57, 3.72 (each 3H, s, COOMe), 4.62 (1H, dd, J_{3-4}=6.0 and J_{3-5}=2.0 Hz, 3-H), 4.95 (1H, dd, J_{5-3}=2.0 and J_{5-4}=5.0 Hz, 5-H), and 6.40 (1H, br s, =CH); MS *m/z* 377 (M^+).

Found: C, 73.27; H, 6.18; N, 3.74%. Calcd for $C_{23}H_{23}NO_4$: C, 73.19; H, 6.14; N, 3.71%.

Reaction of 1n with 3 or 4 Leading to 53. The both reactions under the conditions shown in Table 2 gave the same product **53** as single isomer: Colorless viscous liquid; IR (neat) 1720 and 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16—2.20 (10H, m, CH_2), 3.20 (1H, d, J_{4-3}=7.5 Hz, 4-H), 3.60, 3.72 (each 3H, s, COOMe), 4.70 (1H, d, J_{3-4}=7.5 Hz, 3-H), 7.20—7.40 (3H, m, Ph), and 7.70—7.85 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=22.76, 23.41, 25.94, 34.47, 39.77 (each t, CH_2), 52.06, 52.53 (each q, COO<u>Me</u>), 56.77, 58.71 (each d, 3- and 4-C), 78.71 (s, 5-C), 128.02, 128.54, 130.60 (each d), 133.89 (s), 163.95 (s, 2-C), 172.25, and 172.30 (each s, <u>C</u>OOMe); MS *m/z* (rel. intensity, %) 329 (M^+, base peak), 270 (94), 242 (41), 210 (26), 185 (61), 182 (22), and 104 (35).

HRMS Found: *m/z* 329.1689. Calcd for $C_{19}H_{23}NO_5$: M, 329.1626.

General Procedure for the Cycloadditions of 1 with 5. These cycloadditions were carried out acoording to the general procedures mentioned above for the reactions with **2—4**, except that methyl acrylate **5** was used in large excess or as a reaction solvent. The reaction conditions and results are listed in Table 2.

Reaction of 1a with 5 Leading to 54 and 55. This reaction gave four stereoisomers of the corresponding cycloadduct. Mixture of two isomers **54** was separated from mixture of the other two **55** (**54**:**55**=1.5:1) through sequential procedures of column chromatography over silica gel (chloroform–diethyl ether (20:1)) and preparative thin layer chromatography on silica gel (the same eluent as above).

54: A 4:5 mixture of two stereoisomers; colorless liquid; IR (neat) 3330, 2230, 1730, and 1595 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.10—2.80 (3H, m, CH_2 and CH), 3.07, 3.15 (3H, each s, COOMe), 3.20—4.70 (3H, m, CH and NH), and 7.14 (5H, br s, Ph); ^{13}C NMR ($CDCl_3$) δ=32.41, 33.06 (each t, 4-C), 46.00, 47.12, 47.83, 48.77 (each d, 3- and 5-C), 63.65, 64.12 (each d, 2-C), 120.72, 121.30 (each s, CN), 126.89, 127.54, 127.71, 127.95 (each d), 138.48, 139.19 (each s), 171.66, and 172.31 (each s, <u>C</u>OOMe); MS *m/z* (rel. intensity, %) 230 (M^+, 13), 177 (19), 162 (19), 144 (base peak), 143 (79), 117 (25), and 104 (18).

HRMS Found: *m/z* 230.1050. Calcd for $C_{13}H_{14}N_2O_2$: M, 230.1054.

55: A 2:3 mixture of two stereoisomers; colorless liquid; IR (neat) 3320, 2205, 1725, and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.10—3.00 (3H, m, CH_2 and CH), 3.30—4.80 (3H, m, CH and NH), 3.57, 3.62 (3H, each s, COOMe), and 7.18 (5H, br s, Ph); MS *m/z* (rel. intensity, %) 230 (M^+, 30), 229 (42), 183 (22), 169 (22), 156 (55), 154 (69), 143 (47), 117 (57), 116 (61), 115 (base peak), and 91 (88).

HRMS Found: *m/z* 230.1048. Calcd for $C_{13}H_{14}N_2O_2$: M, 230.1054.

Elimination of HCN from 54 and 55 Leading to 56 and 57. The elimination was performed under the conditions listed in Table 3. The HCN-eliminated products **56** and **57** were purified through column chromatography over silica gel with chloroform–diethyl ether (5:1).

56: Pale yellow liquid; IR (neat) 1730 and 1625 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.80 (2H, m, 3-H), 3.08 (3H, s, COOMe), 3.50 (1H, ddd, J_{4-3}=9.6, 6.0 and J_{4-5}=9.2 Hz, 4-H), 5.52 (1H, ddd, J_{5-2}=2.0, J_{5-3}=4.0, and J_{5-4}=9.2 Hz, 5-H), 7.00—7.44 (5H, m, Ph), and 7.80 (1H, dt, J_{2-3}=1.0, 1.0 and J_{2-5}=2.0 Hz, 2-H); ^{13}C NMR ($CDCl_3$) δ=40.24 (t, 3-C), 46.30 (d, 4-C), 51.36 (q, COO<u>Me</u>), 78.83 (d, 5-C), 127.66, 128.13 (each d), 138.07 (s), 167.24 (d, 2-C), and 172.65 (s, <u>C</u>OOMe); MS *m/z* (rel. intensity, %) 203 (M^+, 15), 144 (34), 143 (20), 117 (42), 90 (23), and 43 (base peak).

HRMS Found: *m/z* 203.0932. Calcd for $C_{12}H_{13}NO_2$: M, 203.0945.

57: Pale yellow liquid; IR (neat) 1735, 1720, and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.90—3.04 (3H, m, CH_2 and CH), 3.70 (3H, s, COOMe), 5.36 (1H, m, 5-H), 7.00—7.44 (5H, m, Ph), and 7.66 (1H, br, 2-H); ^{13}C NMR ($CDCl_3$) δ=41.53 (t, 3-C), 49.18 (d, 4-C), 52.36 (q, COO<u>Me</u>), 79.89 (d, 5-C), 126.54, 127.60, 128.83 (each d), 142.54 (s), 165.59 (d, 2-C), and 174.77 (s, <u>C</u>OOMe); MS *m/z* (rel. intensity, %) 203 (M^+, 22), 144 (66), 143 (61), 117 (base peak), 116 (27), 115 (54), 104 (34), 91 (33), 90 (66), 89 (55), and 77 (28).

HRMS Found: *m/z* 203.0907. Calcd for $C_{12}H_{13}NO_2$: M,

203.0945.

Dehydrogenation of 56 and 57 Leading to 58. A mixture of equivalent amounts of **56** (or **57**) and DDQ in dry benzene was heated under reflux for 30 min. The residue was chromatographed over silica gel with chloroform–diethyl ether (10:1) to give pure **58** (41% from **56**: **42% from 57**): Beige liquid; IR (neat) 3310, 1700, 1685, and 1560 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.69 (3H, s, COOMe), 6.70, 6.74 (each 1H, d, J=1.0 Hz, 4- and 5-H), 7.20—7.60 (5H, m, Ph), and 8.50 (1H, br, NH); ^{13}C NMR ($CDCl_3$) δ=50.90 (q, COOMe), 111.68 (s, 3-C), 112.09 (d, 4-C), 117.88 (d, 5-C), 128.12, 128.88 (each d), 132.10 (s), 137.25 (s, 2-C), and 165.62 (s, COOMe); MS *m/z* (rel. intensity, %) 201 (M^+, 66), 170 (base peak), 115 (61), 114 (29), and 89 (17).

HRMS Found: *m/z* 201.0790. Calcd for $C_{12}H_{11}NO_2$: M, 201.0790.

Reaction of 1e with 5 Leading to 59 and 60. The crude reaction mixture was chromatographed over silica gel with chloroform to give pure **59** and mixture of stereoisomers **60** of HCN-eliminated cycloadduct. This mixture could not be separated by HPLC.

59: Colorless prisms (hexane); mp 104—105 °C; IR (KBr) 1730 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.12 (3H, s, COOMe), 3.06—3.28 (1H, m, one of 3-H), 3.46—3.83 (2H, m, the other of 3-H and 4-H), 5.85 (1H, m, 5-H), 7.04—7.48 (8H, m, Ph), and 7.92 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=37.88 (t, 3-C), 47.89 (d, 4-C), 51.12 (q, COOMe), 78.39 (d, 5-C), 127.54, 127.95, 130.93, 133.66, 138.48, 172.41 (s, COOMe), and 173.18 (s, COOMe); MS *m/z* (rel. intensity, %) 279 (M^+, 35), 220 (72), 193 (base peak), and 115 (25).

Found: C, 77.48; H, 6.17; N, 5.10%. Calcd for $C_{18}H_{17}NO_2$: C, 77.39; H, 6.13; N, 5.01%.

60: A 2:1 mixture of two stereoisomers; colorless liquid; IR (neat) 1740 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.96—2.28 (1H, m, one of 4-H), 2.66—3.05 (1H, m, the other of 4-H), 3.54, 3.60 (3H, each s, COOMe), 4.16 (1/3H, dt, J=8.0, 2.0, and 2.0 Hz, 3-H), 4.34 (2/3H, dt, J=8.0, 2.0, and 2.0 Hz, 3-H), 5.26 (1/3H, dt, J=8.0, 8.0, and 2.0 Hz, 5-H), 5.47 (1H, dt, J=8.0, 8.0, 2.0 Hz, 5-H), 6.15—6.40 (8H, m, Ph), and 6.76—7.00 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=38.00, 38.88 (each t), 52.41 (q, 2×C), 54.29, 54.59 (each d), 75.55, 75.77 (each d), 124.36, 126.72, 127.00, 127.30, 128.01, 128.42, 128.71, 129.36, 130.89, 131.12, 133.36, 133.65, 143.12, 143.83, 169.40 (s), 169.77 (s), 172.42, and 173.12 (each s); MS *m/z* (rel. intensity, %) 279 (M^+, 40), 220 (65), 193 (93), 192 (base peak), and 115 (49).

Found: C, 77.14; H, 5.89; N, 4.94%. Calcd for $C_{18}H_{17}NO_2$: C, 77.39; H, 6.13; N, 5.01%.

Reaction of 1g with 5 Leading to 61 and 62. A mixture of propionaldehyde (530 mg, 9.14 mmol) and α-cyanobenzylamine (792 mg, 6 mmol) was heated under reflux in chloroform (60 ml) in the presence of molecular sieves 5A for 6 h. The molecular sieves was filtered off and the solvent was evaporated in vacuo. To the residue was added methyl acrylate **5** (3g, 30 mmol) and the mixture was refluxed for 22 h. The solvent was evaporated in vacuo and the residue was chromatographed over silica gel to give **61** (from chloroform–diethyl ether (20:1), 896 mg, 65%) and **62** (from chloroform–diethyl ether (10:1), 443 mg, 30%). Cycloadduct **61** gradually changes into **62** when its solution is allowed to stand on exposure to air. The other product **62** consists of two stereoisomers which can be separated by repeated column chromatography over silica gel.

61: Pale yellow liquid; IR (neat) 1730 and 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90—2.20 (7H, m, Et and CH_2), 3.56 (3H, s, COOMe), 3.60 (1H, m, 3-H), 4.20 (1H, m, 5-H), 7.10—7.40 (3H, m, Ph), and 7.60—7.90 (2H, m, Ph); MS *m/z* (rel. intensity, %) 231 (M^+, 19), 212 (55), 172 (19), 170 (36), 145 (29), 144 (base peak), 130 (40), 116 (42), 115 (27), and 104 (86).

HRMS Found: *m/z* 231.1256. Calcd for $C_{14}H_{17}NO_2$: M, 231.1258.

One isomer of **62**: Colorless needles (benzene–hexane); mp 129—130 °C; IR (KBr) 3100, 2960, 1755, and 1615 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.06 (3H, t, Et), 1.40—2.16 (2H, m, Et), 1.88 (1H, dd, J_{gem}=13.3 and J_{4-5}=7.0 Hz, one of 4-H), 2.66 (1H, dd, J_{gem}=13.3 and J_{4-5}=7.0 Hz, the other of 4-H), 3.74 (3H, s, COOMe), 3.86 (1H, s, OH), 4.12 (1H, m, 5-H), 7.20—7.48 (3H, m, Ph), and 7.70—7.90 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=10.82 (q, Et), 29.47 (t, Et), 44.83 (t, 4-C), 53.65 (q, COOMe), 71.24 (d, 5-C), 86.83 (s, 3-C), 128.01, 128.65, 130.65 (each d), 132.42 (s), 168.65 (s, 2-C), and 175.60 (s, COOMe); MS *m/z* (rel. intensity, %) 247 (M^+, 28), 144 (base peak), 130 (28), 104 (72), 102 (26), 85 (26), and 77 (24).

Found: C, 67.86; H, 6.93; N, 5.68%. Calcd for $C_{14}H_{17}NO_3$: C, 67.99; H, 6.93; N, 5.66%.

The other isomer of **62**: Colorless needles (benzene–hexane); mp 147—148.5 °C; IR (KBr) 3100, 1740, and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.04 (3H, t, Et), 1.40—2.45 (4H, m, Et and CH_2), 3.68 (3H, s, COOMe), 4.00 (1H, br s, OH), 4.30 (1H, m, 5-H), 7.20—7.44 (3H, m, Ph), and 7.64—7.84 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=11.13 (q, Et), 29.10 (t, Et), 45.21 (t, 4-C), 53.52 (q, COOMe), 72.27 (d, 5-C), 86.52 (s, 3-C), 127.83, 128.66, 130.61 (each d), 132.56 (s), 167.91 (s, 2-C), and 175.85 (s, COOMe); MS *m/z* (rel. intensity, %) 247 (M^+, 25), 144 (base peak), 130 (37), 104 (90), 103 (22), 102 (29), and 83 (29).

Found: C, 68.15; H, 6.96; N, 5.73%. Calcd for $C_{14}H_{17}NO_3$: C, 67.99; H, 6.93; N, 5.66%.

Air Oxidation of 53 Leading to 63. A solution of **53** in chloroform was stirred at room temperature under oxygen atmosphere for 2 d. The solvent was evaporated in vacuo to give a quantitative yield of **63**: Colorless prisms (hexane); mp 124—125 °C; IR (KBr) 3460, 1710, and 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.01—2.20 (10H, m, CH_2), 3.24 (1H, s, 4-H), 3.71, 3.78 (each 3H, s, COOMe), 4.30 (1H, s, OH), 7.20—7.44 (3H, m, Ph), and 7.70—7.90 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=22.59, 23.48, 26.06, 33.77, 40.71 (each t), 52.18, 53.89 (each q, COOMe), 68.95 (d, 4-C), 78.53 (s, 5-C), 87.77 (s, 3-C), 128.25, 128.60, 130.72 (each d), 132.42 (s), 164.78 (s, 2-C), 170.77, and 173.99 (each s, COOMe); MS *m/z* (rel. intensity, %) 345 (M^+, 22), 242 (base peak), 210 (20), 185 (22), 183 (21), 182 (39), 155 (22), 129 (30), 123 (30), 122 (23), 104 (40), and 77 (22).

Found: C, 66.00; H, 6.69; N, 4.29%. Calcd for $C_{19}H_{23}NO_5$: C, 66.07; H, 6.71; N, 4.06%.

Cis-Trans Isomerism among the Octahedral Anionobis(*C*-substituted ethylenediamine)nickel(II) Complexes Obtained by Thermal Reactions

Yoshinori IHARA,* Yutaka FUKUDA,† and Kozo SONE†
Laboratory of Chemistry, Faculty of Education, Kanazawa University, Marunouchi, Kanazawa 920
†Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
(Received December 24, 1985)

Ten octahedral anionobis(*C*-substituted ethylenediamine)nickel(II) complexes were obtained by thermal reactions of corresponding diaqua salts, and their electronic and IR spectra were examined to see whether they are cis or trans. Most of them were found to be trans, but $[Ni(NO_3)(m\text{-bn})_2](NO_3)$ and $[NiCl_2(i\text{-bn})_2]$ were cis.

We have previously reported on the thermal reactions of the nickel(II) complexes with *C*-substituted ethylenediamines in solid phase.[1] It was found that octahedral anionobis(diamine) complexes, $[NiX_2(NN)_2]$,[2] are obtained as the final products of the following thermal reactions:

a) $[Ni(H_2O)_2(NN)_2]X_2$ (Oh) $\xrightarrow[\Delta]{-2H_2O}$ $[NiX_2(NN)_2]$[2] (Oh′)

b) $[Ni(H_2O)_2(NN)_2]X_2$ (Oh) $\xrightarrow[\Delta]{-2H_2O}$ $[Ni(NN)_2]X_2$ (Sp) $\xrightarrow[\Delta]{}$ $[NiX_2(NN)_2]$[2] (Oh′)

c) $[Ni(NN)_2]X_2$ (Sp) $\xrightarrow[\Delta]{}$ $[NiX_2(NN)_2]$[2] (Oh′)

Here Oh (or Oh′) and Sp represent an octahedral species and square planar one, respectively.

Whether these aniono complexes are cis or trans is an interesting problem, which is also fundamental for understanding the nature of their formation reactions. Unfortunately, the literature on such geometrical isomers of octahedral Ni(II)-bis(diamine) complexes is scanty; the number of known examples of such isomers is not so many, and the methods of their identification by means of the visible and IR spectra are not so well-established as in the case of the Co(III) and Cr(III) complexes.

Recently, however, there appeared several experimental and theoretical works on the electronic spectra of tetragonal Ni(II) complexes.[3-7] In particular, Lever et al. studied the electronic states of the bis(*N*-substituted ethylenediamine)nickel(II) complexes by the normalized spherical harmonic Hamiltonian (NSH) method in detail,[8-13] showing that the feature of the electronic spectrum in near IR region is especially useful for the identification of a cis or a trans isomer of such a complex. In this study, we tried to apply their results to our nickel(II) complexes with *C*-substituted ethylenediamines to see whether each of them is cis or trans.

Experimental

Preparation of the ligands(1-phenyl-1,2-ethanediamine (phenen), 2-methyl-1,2-propanediamine(*i*-bn), *meso*- or *dl*-butanediamine(*m*-bn or *dl*-bn), and *dl*-1,2-diphenyl-1,2-ethanediamine(*dl*-stien)), and that of the anionobis(diamine)-nickel(II) complexes with them were described in the literature.[1,14,15] The electronic spectra in solid phase were measured by the diffuse reflectance method with a Hitachi 340 spectrophotometer equipped with reflection attachments for the visible (800—300 nm) and near IR (1400—800 nm) parts of the spectrum. The latter region was measured with special care for the discussion of the complex geometry. Common IR spectra were recorded with a JASCO IR-A3 spectrophotometer in Nujol mulls.

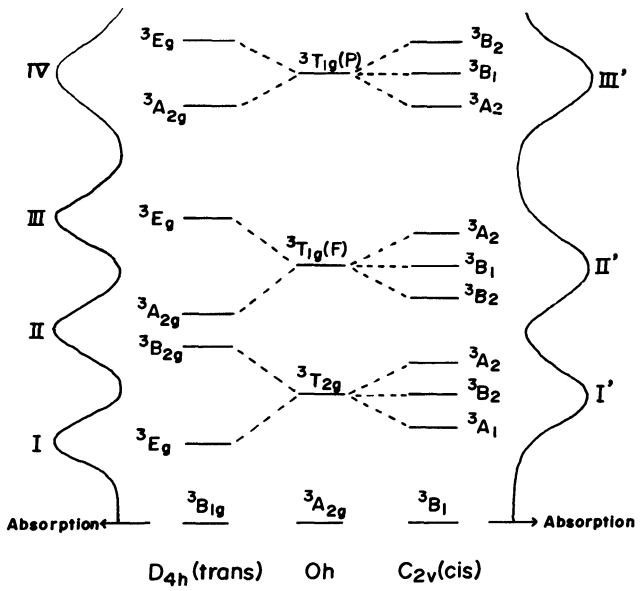

Fig. 1. Energy level diagrams of a d^8 system in ligand fields of different symmetries.[16] Sketches of the absorption spectra of the cis and trans isomers of NiX_2(diamine)$_2$ are also given. (After Lever[13]).

Results and Discussion

The energy levels derived from F and P terms of a d^8 system (Ni^{2+}) in ligand fields of different symmetries (Oh, D_{4h}(trans), and C_{2v}(cis)) are shown in Fig. 1. In a tetragonal system(D_{4h}), six spin-allowed transitions are anticipated, among which four or sometimes five bands are observed in practice.[7,8,13] The band due to the $^3B_{1g} \rightarrow {}^3A_{2g}$ (from $^3T_{1g}(P)$) transition is scarcely observable as a discrete band, but may appear as a

shoulder of the band of $^3B_{1g} \rightarrow {}^3E_g$ (from $^3T_{1g}(P)$) transition (Band IV shown in Fig. 1, which is sometimes obscured under the strong CT or ligand band in near UV region). The band due to $^3B_{1g} \rightarrow {}^3E_g$ (from $^3T_{1g}(F)$) transition, Band III, is normally observed at ca. 17—18×10³ cm⁻¹. The band of $^3B_{1g} \rightarrow {}^3A_{2g}$ (from $^3T_{1g}(F)$) transition seems to lie very close to that of $^3B_{1g} \rightarrow {}^3B_{2g}$ transition, giving only one peak, also around this region (Band II). The band at the lowest energy, Band I, is assigned to the $^3B_{1g} \rightarrow {}^3E_g$ transition.

On the other hand, in a C_{2v} system, the splittings of the respective terms are small; so, when the complex is cis, three rather broad bands (bands I′, II′, and III′ shown in Fig. 1) are observed as in the case of the regular Oh system.[7,12,13,18]

The electronic spectra of the three aniono complexes are now shown in Fig. 2, where the Roman numerals on the curves are the band assignments shown in Fig. 1. The spectra of [NiBr$_2$(*dl*-stien)$_2$] and [Ni(NO$_3$)$_2$(phenen)$_2$] have the same feature, differing from that of Ni(NO$_3$)$_2$(*m*-bn)$_2$ in the near IR region. The additional band observed at ca. 13×10³ cm⁻¹ in the *dl*-stien and phenen complexes can be attributed to Band II, i. e., the overlapping of the transition to $^3A_{2g}$ from $^3T_{1g}(F)$) and $^3B_{2g}$ (from $^3T_{2g}$) levels. The four bands observed are thus assigned to the transitions from $^3B_{1g}$ to the lowest ^3E_g (band I), $^3B_{2g}$ and $^3A_{2g}$ (band II), ^3E_g (band III), and $^3A_{2g}$ (from $^3T_{1g}(P)$) and ^3E_g (from $^3T_{1g}(P)$) (band IV), respectively, in the order of increasing energy. The shoulder at 12.5×10³ cm⁻¹ of the phenen complex is probably the transition to $^3B_{2g}$ state. Consequently, both of these complexes are clearly trans. On the other hand, the *m*-bn complex, whose spectrum scarcely show any splitting, is clearly cis.

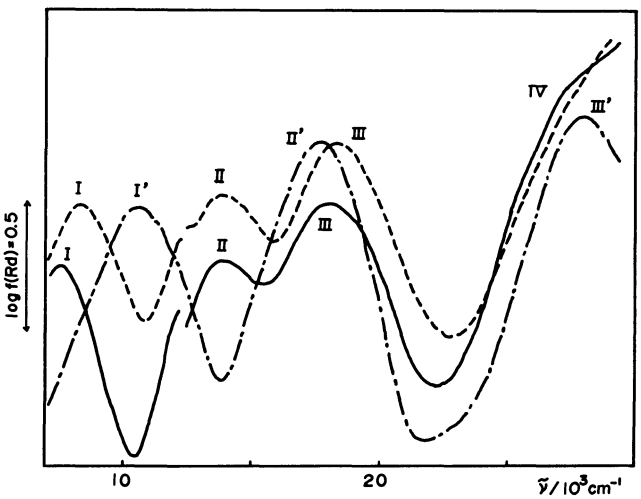

Fig. 2. Reflectance spectra of [NiBr$_2$(*dl*-stien)$_2$] (——), [Ni(NO$_3$)$_2$(phenen)$_2$ (----), and [Ni(NO$_3$)(*m*-bn)$_2$](NO$_3$) (—·—).

Table 1 summarizes the coordination structures of ten complexes deduced in the same way, their electronic spectral data and the thermochemical reactions used to prepare them. Most of these complexes are trans, and only two, i.e., Ni(NO$_3$)$_2$(*m*-bn)$_2$ and NiCl$_2$(*i*-bn),[19,20] are cis.

The mode of coordination in the three nitrato complexes in Table 1 was also studied by means of their IR spectra. In general, an NO_3^- ion in a metallic complex gives rise to a weak combination band in the range of 1700—1800 cm⁻¹. When it exists as an uncoordinated ion, this band is not split, but when it is coordinated as a monodentate ion, a small splitting into two components (less than 25 cm⁻¹) takes place. When it acts as a bidentate ligand, the splitting becomes much larger (20—50 cm⁻¹).[21,22]

Figure 3 indicates the IR spectra of the nitrate complexes of *dl*-stien and *m*-bn, together with those of their mother complexes having the free nitrate ions, [Ni(H$_2$O)$_2$(diamine)$_2$](NO$_3$)$_2$. A peak at 1746 cm⁻¹ assignable to the free NO_3^- ions in the spectrum of the mother complex with *dl*-stien is split into two peaks at 1749 and 1767 cm⁻¹ with a separation of 18 cm⁻¹ in that of the nitrato complex. This indicates that, in the latter, the two NO_3^- ions are coordinated at the axial positions as a unidentate ligands to form the *trans*-octahedral complex.[23] On the other hand, the nitrato

Table 1. Electronic Spectral Data of the Complexes

Complex	Absorption Bands $\tilde{\nu}/10^3\,cm^{-1}$				Preparation Method[a]

	I′	II′	III′		
cis-[NiCl$_2$(*i*-bn)$_2$]	10.5	17.7	28.0		(c)
cis-[Ni(NO$_3$)(*m*-bn)$_2$](NO$_3$)	10.2	17.2	27.2		(c)

a) The symbols a, b, or c correspond to the thermal reactions used to obtain the complexes (see text).

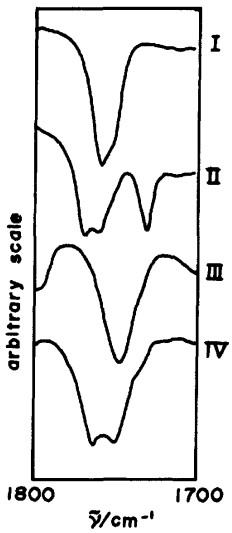

Fig. 3. IR spectra of $[Ni(m\text{-bn})_2](NO_3)_2$(I), $[Ni(NO_3)(m\text{-bn})_2](NO_3)$(II), $[Ni(H_2O)_2(dl\text{-stien})_2](NO_3)_2$(III), and $[Ni(NO_3)_2(dl\text{-stien})_2]$(IV).

complex with *m*-bn has the three peaks at 1732, 1758, and 1768 cm^{-1}. The peak at 1758 cm^{-1} appears at nearly the same position as that of the mother complex, showing that a part of the NO_3^- ions remains uncoordinated. The large separation (36 cm^{-1}) between the other two peaks indicates that the coordinated NO_3^- ions are acting as bidentate ligand. Therefore, the nitrato *m*-bn complex can be formulated as *cis*-$[Ni(NO_3)(m\text{-bn})_2](NO_3)$, having both free and bidentate nitrate ions.

The problem why only the nitrato complex of bis(*m*-bn) and the chloride complex of bis(*i*-bn) form the *cis*-octahedral structure is of interest. It is well known that the bis-type Ni(II) complexes with *m*-bn or *i*-bn strongly prefer a diamagnetic square planar structure,[1,24,25] so the generation of octahedral species with these diamines is quite unusual. In particular, the nitrato complex is the first example of an octahedral bis(*m*-bn) complex. Both of these novel complexes of *cis*-octahedral structure can be obtained only by the same type of thermal reaction (c), and they are converted into the original square planar complexes on cooling for some days, showing the reversibility of the structural changes.[26]

The work was partially supported by a Grant-in-Aid for Scientific Research No. 60303009 from the Ministry of Education, Science, and Culture.

16) It is important to recognize that, depending upon the specific operators which survive from the cubic parent, there are three distinguishable C_{2v} systems, C_{2v}(I), C_{2v}(II), and C_{2v}(III), where the Roman numerals designate the surviving operators.[17] For example, *trans*(*X*,*Y*)-MX_2Y_2ZZ' is a C_{2v}(I) system, while *trans*-$M(X\text{-}X)_2ZZ'$ is a C_{2v}(II) one. The geometry of the cis complexes described in this study(*cis*-$M(X\text{-}X)_2Z_2$) just belongs to C_{2v}(III), and here the ground state($^3A_{2g}$) and $^3T_{2g}$ state of Oh system are transformed into $^3B_1$ and $^3A_1+^3A_2+^3B_2$, respectively,[9] as shown in Fig. 1.

26) The cis-trans isomerism among the diaqua complexes, which are the starting complexes of the thermal reactions, is also an interesting problem. Here, however, the situation is more complicated than in this study, and, in certain cases, mixtures of cis-trans isomers are obtained according to the preparative methods. Details on this topic will be reported elsewhere.

Ni(II)-Bearing Green Rust II and Its Spontaneous Transformation into Ni(II)-Bearing Ferrites

Yutaka TAMAURA
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received January 25, 1986)

When solutions containing Fe(II), Ni(II), and SO_4^{2-} ions were oxidized by a mixed gas of air and nitrogen at pH 7.1 (25 °C), a Ni(II)-bearing green rust II (GR-II), which is a uniform crystalline precipitate with a definite chemical composition, was formed. The Ni(II) content in the Ni(II)-bearing GR-II increased with an increase in the Ni(II) concentration in the reaction solution. The Ni(II)-bearing GR-II was spontaneously transformed into Ni(II)-bearing ferrite under a nitrogen atmosphere without any oxidant. The metal mole ratio of $[Ni(II)/Fe(III)]_{fer}$ in the ferrite increased linearly with an increase in that of $[Ni(II)/Fe(III)]_{grn}$ in the Ni(II)-bearing GR-II (slope=0.193). From this relationship, the spontaneous transformation reaction was described as

$$2(Ni^{2+})_x(Fe^{2+})_{2-x}(Fe^{3+})(SO_4^{2-})(OH^-)_5 \longrightarrow Ni_{0.39x}Fe_{3-0.39x}O_4 + (2-1.61x)Fe^{2+} + 1.61xNi^{2+} + Fe(OH)_2 + 2SO_4^{2-} + 4H_2O.$$

This equation shows that Fe(II) ion in the GR-II is more readily incorporated into the ferrites than Ni(II) ion.

The formation and transformation of iron oxides, hydroxide oxides in aqueous systems have been studied by many workers.[1-15] The transformation reaction of γ-FeO(OH) to α-FeO(OH) was studied by Schwertmann and Taylor,[10] Oosterhout,[11] and Inoue et al.[15] Music et al.[1] reported the transformation reaction of β-FeO(OH) to α-FeO(OH). We reported that γ-FeO(OH) is transformed to Fe_3O_4 by the adsorption of Fe(II) ion.[12,13] Green rusts (hexagonal plates), which are composed of Fe(II), Fe(III), and sulfate or halogenide ions, are transformed to iron oxides or hydroxide oxides by oxidation of the Fe(II) ions. Recently,[14] we have found that the green rust II spontaneously transforms into Fe_3O_4 without any oxidation reaction (spontaneous transformation reaction). The term "spontaneous" will be used hereafter to distinguish from the oxidation reaction of the green rust II.

A green rust I is formed by the oxidation of Fe(II) ion in an aqueous solution containing Cl^-, Br^-, and F^- ions, and a green rust II, in that containing SO_4^{2-} ions. In the previous paper,[14] we presented a new method for the preparation of the green rust II having a definite chemical composition; The green rust II with the chemical composition of $(Fe^{3+})(Fe^{2+})_2(SO_4^{2-})(OH^-)_{5-2n}(O^{2-})_n$ was synthesized by air oxidation of Fe(II) ion in an aqueous solution containing a high concentration of SO_4^{2-} ion (the air oxidation method). For the reaction solutions containing Fe(II) and Zn(II) ions, Zn(II)-bearing green rust II's (GR-II) with definite chemical compositons were synthesized by the air oxidation method.[16] The present paper describes the synthesis of the Ni(II)-bearing GR-II's with definite chemical compositions by the air oxidation method, and the spontaneous transformation reaction of the Ni(II)-bearing GR-II's to Ni(II)-bearing ferrites.

Experimental

Chemicals. All the chemicals were of analytical grade, and distilled water was used for the preparation of solutions.

Apparatus. The reaction vessel (1 dm^3) of a separable type flask used in the previous paper was adopted.[14] The reaction solution was vigorously stirred with a magnetic stirring bar. An alkaline solution was added using a pH-stat instrument (TOA Electronics, Model HSM-10A). A teflon tube for the addition of the alkaline solution (φ 3 mm×40 cm) was connected to the pH-stat instrument, and the capillary tube (φ 0.2 mm×5 cm) was fitted to the end of the teflon tube. The tip of the capillary tube was fixed just above the stirring bar and near the glass electrode. A gas mixer with a gas flow controller was used to mix air and nitrogen.

Chemical Analysis. The Fe(II) and Fe_{total} contents were determined by means of the 2,2′-bipyridyl method[17] after dissolving the samples in an HCl solution (1:1). The Fe_{total} was determined after reducing Fe(III) to Fe(II) with hydroxylamine. The content of Ni(II) ions was determined using an atomic absorption spectrometer (Varian Model AA-875). The SO_4^{2-} content was determined by X-ray fluorescence (Toshiba X-ray spectrometer Model AFV 777) from the intensity of sulfur in a $BaSO_4$ precipitate collected on a glass fiber filter (Toyo Roshi GA 100 type). The OH^- content was estimated from the consumed amount of the alkaline solution during the reaction.

Synthesis of Ni(II)-Bearing GR-II. After passing nitrogen gas into a 0.7 dm^3 of the distilled water for 2 h to remove the dissolved oxygen, 25 g of Na_2SO_4, 10 g of $FeSO_4 \cdot 7H_2O$, and 0—2 g of $NiSO_4 \cdot 6H_2O$ were dissolved. The pH of the reaction solution was adjusted to 7.1 by adding a 2.0 mol dm^{-3} NaOH solution. The resultant reaction solution was almost transparent and slightly greenish. When the solution was turbid due to the formation of hydroxides, the solution was allowed to stand until the hydroxides dissolved completely. When the deaeration had not been enough to remove the dissolved oxygen, some Fe(III) hydroxide oxides were formed and we could not obtain the GR-II with definite chemical compositions.

The reaction was initiated by passing the mixed gas of air and nitrogen (air/N_2=1:1, flow rate; 3.0 dm^3 min^{-1}) at pH 7.1±0.1 and 25 °C. During the oxidation, an alkaline solution (2.0 mol dm^{-3}) was added to maintain a pH of 7.1. After 20 min, nitrogen gas was passed through in place of the mixed gas, and the reaction vessel was cooled in a water bath chilled

with ice. The greenish precipitates formed were collected by centrifugation in a nitrogen atmosphere, washed with distilled water freed from oxygen, and suspended in distilled water. The Ni(II)-bearing GR-II was stable in a nitrogen atmosphere at room temperature.

Electron Microscopy, IR Spectroscopy, and X-Ray Diffractometry for the Ni(II)-Bearing GR-II. A small portion of the Ni(II)-bearing GR-II suspension was taken into an evacuated glass capillary tube, and then sealed. The sample was mounted in a nitrogen atmosphere on a sample holder for electron microscopy. For the IR spectroscopy, the Ni(II)-bearing GR-II was washed with acetone freed from oxygen, dried in a nitrogen atmosphere, and suspended in Nujol. The IR spectrum was taken by a Shimazu IR spectrometer, Model IR 400, using a KBr cell in a nitrogen atmosphere.

Spontaneous Transformation Reaction of the Ni(II)-Bearing GR-II. The suspension of the Ni(II)-bearing GR-II (0.04 dm^3) was transferred in a nitrogen atmosphere to 0.3 dm^3 of a flask with a cap, sealed with Sealon Film (Fuji Co.), and wrapped with a nylon bag to prevent the oxidation. After keeping the flask in the water bath (60 °C) for 12 h, the product was isolated by transferring the reaction suspension to 0.6 dm^3 of a tartaric acid solution (10 w/v%, pH 5.5) and allowing to stand the suspension for 10 h. The product was collected by centrifugation in a nitrogen atmosphere, washed with oxygen-free water and acetone, successively, and dried in a nitrogen atmosphere. The dried product was examined by means of X-ray diffractometry and IR spectroscopy. The IR spectra were measured by the KBr-disc technique.

Results and Discussion

Synthesis of Ni(II)-Bearing GR-II. When the mixture of air and nitrogen gas was passed through the reaction solution, greenish precipitate was formed, and its amount increased with the oxidation time. The X-ray diffraction pattern of the precipitate obtained corresponded to that of the green rust II.[4] In the IR spectrum strong bands of SO_4^{2-} ion (1100 cm^{-1}) appeared. In the electron micrograph, hexagonal plate particles characteristic of the green rust II were observed. Chemical analysis showed that the greenish precipitate contained Fe(II), Fe(III), and Ni(II) metal ions. The metal mole fraction of Ni(II) in the greenish precipitate increased with an increase in the mole ratio of Ni(II)/Fe(II) in the initial reaction solution, as shown by Curve A in Fig. 1. Contrarily, the mole fraction of Fe(II) decreased (Curve C). However, the mole fraction of Fe(III) (Curve B) remained nearly constant. Table 1 shows the mole ratio of bivalent metal ions [Ni(II)+Fe(II)] to trivalent ions [Fe(III)] in the greenish precipitates. The mole ratios are nearly equal to 2:1, which corresponds to that of Fe(II) to Fe(III) ions in the green rust II having no other metal ions.[14] This suggests that the Fe(II) ions in the green rust II are preferentially replaced by the Ni(II) ions. As seen from Fig. 1, the Ni(II)-bearing GR-II having a Ni(II) mole ratio above 0.33 could not be obtained even from a solution of high Ni(II) concentrations. This

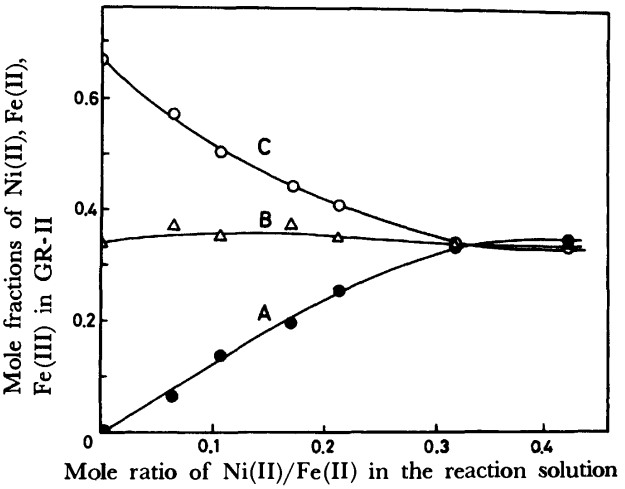

Fig. 1. The relationship between the mole fractions of metal ions [Ni(II); Curve A, Fe(III); B, and Fe(II); C] in the Ni(II)-bearing GR-II and the mole ratio of Ni(II)/Fe(II) in the initial reaction solution.

Table 1. Ratio of Bivalent Metal Ion [Fe(II)+Ni(II)] to Trivalent Metal Ion [Fe(III)] in the Ni(II)-Bearing GR-II

Mole ratio of Ni(II)/Fe(II) in the reaction solution	[Fe(II)+Ni(II)]/Fe(III) in the Ni(II)-bearing GR-II
0.0635	1.72
0.106	1.82
0.169	1.76
0.212	2.19
0.317	2.07
0.423	2.18

suggests that only one out of the two Fe(II) ions in the GR-II can be preferentially replaced by Ni(II) ion. The Chemical analysis showed that the chemical composition of the Ni(II)-bearing GR-II was given by $(Ni^{2+})_x(Fe^{2+})_{2-x}(Fe^{3+})(SO_4^{2-})(OH^-)_5$.

Formation of Ni(II)-Bearing Ferrites From the Ni(II)-Bearing GR-II. The X-Ray diffraction pattern of the black precipitate formed from the Ni(II)-bearing GR-II by the spontaneous transformation corresponded to that of a spinel type compound. Electron microscopic observation showed that the hexagonal particles characteristic of the GR-II changed to shperical or cubic particles characteristic of ferrites. In the IR spectrum, only bands corresponding to the ferrite appeared (strong band at 570 cm^{-1}). Thus, the Ni(II)-bearing GR-II spontaneously transformed into a Ni(II)-bearing ferrite in a nitrogen atmosphere without any oxidant (spontaneous transformation reaction).

When we used the Ni(II)-bearing GR-II's with various Ni(II) contents, the Ni(II)-bearing ferrites having various Ni(II) contents were formed by the spontaneous transformation reaction. Their chemical compositions are given by Fig. 2 [ternary diagram (FeO–Fe_2O_3–NiO)]. The broken line connecting Fe_3O_4 and $NiFe_2O_4$ shows the stoichiometric composition of

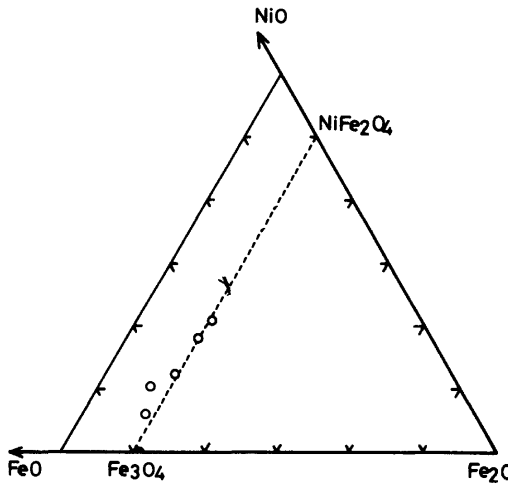

Fig. 2. Chemical compositions (FeO-Fe_2O_3-NiO system) of the Ni(II)-bearing ferrites formed from Ni(II)-bearing GR-II by the spontaneous transformation.

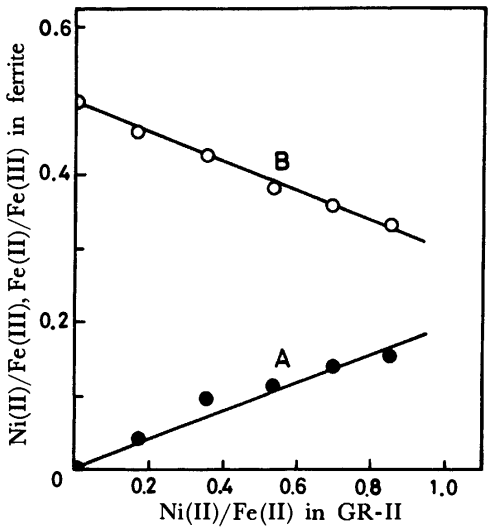

Fig. 3. The relationship between the mole ratios of $[Ni(II)/Fe(III)]_{fer}$ (Curve A) and $[Fe(II)/Fe(III)]_{fer}$ in the Ni(II)-bearing ferrites and the mole ratio of $[Ni(II)/Fe(III)]_{grn}$ in the Ni(II)-bearing GR-II.

the Ni(II)-bearing ferrites. As can be seen here, the chemical compositions of the Ni(II)-bearing ferrites formed by the spontaneous transformation are nearly stoichiometric with respect to oxygen. The limitation in the Ni(II) content in the ferrites is due to the fact that there is a limitation in the Ni(II) content in the Ni(II)-bearing GR-II as described above.

Incorporation of Ni(II) Ions into Ferrites in the Spontaneous Transformation Reaction. Figure 3 shows how the metal mole ratios of $[Ni(II)/Fe(III)]_{fer}$ (Curve A) and $[Fe(II)/Fe(III)]_{fer}$ (Curve B) in the ferrites change with the metal mole ratio of $[Ni(II)/Fe(III)]_{grn}$ in the Ni(II)-bearing GR-II. As can be seen here, the $[Ni(II)/Fe(III)]_{fer}$ increases linearly with an increase in the $[Ni(II)/Fe(III)]_{grn}$ (contrarily, the $[Fe(II)/Fe(III)]_{fer}$ decreases linearly). Since the spontaneous transformation reaction of M(II)-bearing GR-II is generally written by

$$2(M^{2+})_x(Fe^{2+})_{2-x}(Fe^{3+})(SO_4^{2-})(OH^-)_5 \longrightarrow M^{2+}{}_yFe^{2+}{}_{1-y}Fe^{3+}{}_2O_4 + (2x-y)M^{2+} + (3-2x+y)Fe^{2+} + 2SO_4^{2-} + 4H_2O + 2OH^-, \quad (1)$$

the linear relationship of Curve A in Fig. 3 is given by $y/2=0.193x$. With this, Eq. 1 is rewritten for the Ni(II)-bearing GR-II by

$$2(Ni^{2+})_x(Fe^{2+})_{2-x}(Fe^{3+})(SO_4^{2-})(OH^-)_5 \longrightarrow Ni_{0.39x}Fe_{3-0.39x}O_4 + (2-1.61x)Fe^{2+} + 1.61xNi^{2+} + Fe(OH)_2 + 2SO_4^{2-} + 4H_2O. \quad (2)$$

As reported previously[16] for the spontaneous transformation reaction of the Zn(II)-bearing GR-II, the linear relationship between $[Zn(II)/Fe(III)]_{fer}$ and $[Zn(II)/Fe(III)]_{grn}$ was obtained. Thus, in the spontaneous transformation reaction, there seems to exist a linear relationship betweeen $[M(II)/Fe(III)]_{fer}$ and the $[M(II)/Fe(III)]_{grn}$. When the slope of the line of the linear relationship is t, $y=2tx$. To evaluate what bivalent metal ions (M^{2+}) studied here are more readily incorporated into the ferrites in the spontaneous transformation reaction, we compared ratios of $[M(II)/Fe(III)]_{grn}$ with those of $[M(II)/Fe(III)]_{fer}$. These mole ratios are given by

$$[M(II)/Fe(III)]_{grn} = x, \quad (3)$$

and

$$[M(II)/Fe(III)]_{fer} = y/2 \quad (=tx). \quad (4)$$

For the ferrites, t and x should range from 0 to 1. The difference, D, bewteeen $[M(II)/Fe(III)]_{brn}$ and $[M(II)/Fe(III)]_{fer}$ is given by $(1-t)x$. Table 2 shows the relationship bewteen D and t in the spontaneous transformation reaction of the Zn(II)-, Fe(II)-, and Ni(II)-bearing GR-II's. The value of t for Zn(II)-bearing GR-II was evaluated from the data of the previous work ($t=0.48$).[16] For the Fe(II)-bearing GR-II, $t=0.25$, since $[Fe(II)/Fe(III)]_{grn}=2$, and $[Fe(II)/Fe(III)]_{fer}=1/2$. As can be seen from Table 2, Zn(II) ion is more readily incorporated into the ferrites in the spontane-

Table 2. Relationship between D ($[M(II)/Fe(III)]_{fer}$-$[M(II)/Fe(III)]_{grn}$) and t (Slope of the Linear Relationship between $M(II)/Fe(III)]_{fer}$ and $[M(II)/Fe(III)]_{grn}$ for the Transformation Reaction of the Zn(II)-, Fe(II)-, and Ni(II)-Bearing GR-II)

GR-II	t	D	$\log K_h$
Zn(II)-Bearing GR-II	0.460	0.540×	−8.96
Fe(II)-Bearing GR-II	0.250	0.750×	−9.5
Ni(II)-Bearing GR-II	0.193	0.807×	−9.86

$x=[M(II)/Fe(III)]_{grn}$, K_h; hydrolysis constant of MOH^+.

ous transformation reaction compared with Fe(II) and Ni(II) ions, and Ni(II) ion is the most difficult metal ion to be incorporated. This seems to come from the ease of the hydrolysis of those metal ions, considering the hydrolysis constants (log K_h) of −8.96, −9.5, and −9.86 for Zn^{2+}, Fe^{2+}, and Ni^{2+}, respectively.[18]

Since the particle shapes of the green rust II (hexagonal plate) and the ferrites (cubic) are different, it is assumed that the spontaneous transformation reaction proceeds via a dissolution-precipitation process. The mole ratio of the hydrolyzed species of the metal ions to the hydrolyzed Fe(II) ions is given by

$$\frac{[MOH^+]}{[FeOH^+]} = [M(II)/Fe(II)]_{grn} \frac{K_h^M}{K_h^{Fe}}, \quad (5)$$

where we assumed that the metal mole ratio of M(II)/Fe(II) near the surface of the GR-II, where the reaction takes place, is $[M(II)/Fe(II)]_{grn}$. K_h^M and K_h^{Fe} are the hydrolysis constants of M^{2+} and Fe^{2+} ions, respectively (in the pH range studied here, the main hydrolyzed species are $FeOH^+$ and MOH^+). On the other hand, from Eq. 1, the mole ratio of $[M(II)/Fe(II)]_{fer}$ in the ferrites is given by

$$[M(II)/Fe(II)]_{fer} = 2tx/(1-2tx). \quad (6)$$

The mole ratios of $MOH^+/FeOH^+$ evaluated from Eq. 5 for Zn(II) and Ni(II) with x in the range of 0—1, and those of $[M(II)/Fe(II)]_{fer}$ evaluated from Eq. 6 derived from the experimental results are given in Table 3. As can be seen here, the values evaluated from Eq. 5 are in fair agreement with those from Eq. 6. This suggests that the hydrolyzed species are preferentially incorporated into the ferrites, and that t can be related to the ease of the hydrolysis of the metal ions released from the green rust II.

The ligand field stabilizing energy (LFSE) would also affect the incorporation of metal ions into the spinel structure in the spontaneous transformation reaction. In theGR-II's, the metal ions occupy the octahedral sites. In the ferrites, Fe(II) and Ni(II) ions situate on the octahedral sites, but Zn(II) ion on the tetrahedral site. This means that differences in LFSE of these metal ions between GR-II's and ferrites are zero, indicating that the data (Table 2) can not be explained satisfactorily by LFSE.

Table 3. Comparison of the Values Evaluated from Eqs. 5 and 6 for Zn(II) and Ni(II) with x in the Range of 0—1

x	Ni(II)		Zn(II)	
	Eq. 5	Eq. 6	Eq. 5	Eq. 6
0.2	0.0484	0.0837	0.384	0.225
0.4	0.109	0.183	0.865	0.582
0.6	0.187	0.301	1.48	1.23
0.8	0.291	0.447	2.31	2.79

The Determination of a Small Amount of a Biological Constituent by the Use of Chemiluminescence. VI. The Flow-Injection Analysis of Protein Using a 1,10-Phenanthroline-Hydrogen Peroxide System

Tadashi HARA,* Takashi EBUCHI, Akihiro ARAI, and Masakatsu IMAKI†
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
†Horiba Ltd., Kisshoin, Minami-ku, Kyoto 601
(Received November 13, 1985)

Since the catalytic activity of copper(II) for the chemiluminescent reaction between 1,10-phenanthroline and hydrogen peroxide decreased in the presence of protein, this phenomenon was applied to the determination of protein. The determination of protein was carried out by a flow-injection method, and the conditions for the determination of protein were established. The catalytic activity of copper(II) was enhanced by using an amino acid instead of the conventional biuret reagent. Similar calibration curves were obtained for human serum albumin, bovine serum albumin, human serum γ-globulin, bovine serum γ-globulin, and ovalbumin. According to the present flow-injection method using a chemiluminescent reaction, a small amount of protein could be conveniently and economically determined over a wide range of concentrations, 5.0×10^{-6} g dm^{-3}—1.0×10^{-1} g dm^{-3} at the rate of about 20 samples per hour, with the detection limit of 250 pg as the injected amount and the coefficient of variation of 5.9% (n=9). The sensitivity of the present method was about 40 times that of the previous luminol-hydrogen peroxide system.

In the previous paper,[1] several proteins in the concentration range of 2.0×10^{-4} g dm^{-3}—1.0×10^{-1} g dm^{-3} were determined by the use of the fact that the catalytic activity of copper(II) for the chemiluminescent (CL) reaction between 5-amino-2,3-dihydro-1,4-phthalazinedione(luminol) and hydrogen peroxide (H_2O_2) decreased in the presence of proteins. Though the method was sensitive, non-labeled, and applicable to the detection of an amino acid as well as protein,[2] its sensitivity was not yet satisfactory for the determination of a trace amount of a constituent in a human serum sample.

According to the authors' knowledge about the reaction between copper(II) and protein at high temperatures, a more sensitive method for the copper(II) determination was necessary for the determination of a smaller amount of protein than that in the previous paper. With this in mind, the CL reaction between 1,10-phenanthroline(phen) and H_2O_2, which had previously been used for the determination of ultratraces of copper(II),[3] was applied to the determination of a protein in the present paper. The present method showed a wider linear dynamic range and a smaller detection limit than those in the previous papers. The catalytic activity of copper(II) in a phen–H_2O_2 system was enhanced in the presence of an amino acid in opposition to that in a luminol–H_2O_2 system. On the basis of this phenomenon, bovine serum albumin (BSA) could be determined more sensitively in the presence of an amino acid.

Since the present method was expected to be useful for the development of a sensitive, rapid, and inexpensive detector by which a trace amount of protein could be determined without labeling it, the optimum conditions for the determination of protein, the improvement of the detection limit, and so on were examined.

Experimental

Reagents. All the reagents used were of a commercially available special grade. Ion exchange water was distilled for use. A 1.0×10^{-7} mol dm^{-3} copper(II) solution (biuret reagent) was prepared by diluting a 2.0×10^{-2} mol dm^{-3} copper(II) stock solution[4] with a buffer solution (pH 10.19) consisting of 0.1 mol dm^{-3} boric acid and 0.1 mol dm^{-3} potassium hydroxide. A phen solution containing ethylhexadecyldimethylammonium bromide (EHDAB), tetraethylenepentamine (TEPA), and sodium hydroxide (NaOH), and a H_2O_2 solution were prepared daily. The sample solution of BSA and bovine serum γ-globulin (BγG) from Sigma Chemical Co., and human serum albumin (HSA) and human serum γ-globulin (HγG) from ICN Pharmaceuticals, Inc., and control serum (Q-PAC-Chemistry Control Serum I) from HYLAND were prepared by diluting them in buffer solution. All α-amino acids were from Kyowa Hakko Co., Ltd.

Apparatus and Procedure. A schematic diagram of the apparatus used for the present flow-injection analysis is shown in Fig. 1. All the tubes and connectors used were made of Teflon except for the flow cell. Each solution of phen(a) and H_2O_2(b), held at 25°C by means of a thermostat(n) (Netsudenshi Kogyo Co., Ltd.), and copper(II) (c), held at room temperature, was fed by means of 5.0×10^5 Pa gauge pressure of nitrogen gas; the flow rates were all adjusted to 1.0 cm^3 min^{-1} by the use of a needle valve (h) (GILMONT). A buffer solution(d) was fed at the flow rate of 1.0 cm^3 min^{-1} by means of a pump(i) (Pharmacia High-precision Pump P-500).

A 50 mm^3 portion of a protein sample solution was injected into the buffer solution line through the sampling loop(k) and the six-way cock(j). The protein sample solution was first mixed with a copper(II) catalyst solution and then passed through a reaction tube(o) (0.40 m), held at 95°C, and a cooling tube(p) (0.64 m), held at 0°C, in that order. Then the reacting solution was further mixed with

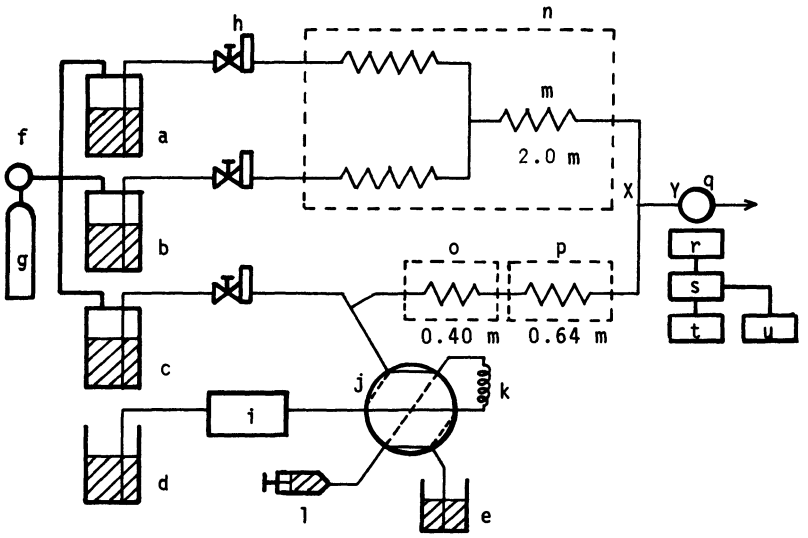

Fig. 1. Schematic diagram of the flow-injection system.
a: Phen solution, b: H_2O_2 solution, c: copper(II) catalyst solution, d: buffer solution, e: sample solution, f: regulator, g: N_2 cylinder, h: flowmeter equipped with a needle valve, i: pump, j: six-way cock, k: sampling loop, l: syringe, m: mixing coil, n: thermostat, o: reaction tube, p: cooling tube, q: flow cell, r: photomultiplier, s: amplifier, t: recorder, and u: integrator.

the phen-H_2O_2 solution, which had been thoroughly premixed by means of a 2.0 m mixing coil(m); the solution thus obtained was passed through a flow cell(q) (25 cm×0.8 mm i.d. poly(vinyl chloride) tube). The CL intensity of the solution passing through the cell was measured by means of a photomultiplier(r) (Hamamatsu TV Co., Ltd., R928), amplified with an amplifier(s) (Horiba Ltd., OPE-214), and recorded on a recorder(t) (Yokogawa Electric Works, Ltd., 3046), followed by the measurement of the peak area by the use of an integrator(u) (Shimadzu Chromatopac E1A or C-R2A). The distance between X and Y was 3 cm.

The CL intensity of a protein-free sample was recorded as a base line, while that of a protein-containing sample was recorded as a negative peak because the CL intensity was weakened due to the formation of a complex compound between copper(II) and protein.

Results and Discussion

Determination of Analysis Conditions. BSA was used as a model protein for the determination of the analysis conditions. The length of the reaction tube and the cooling tube and the reaction temperature were the same as in the previous paper. The flowing paths of both phen and H_2O_2 and the mixing coil were passed through a thermostat at 25 °C to keep them from the effect of the room temperature. A 2.0 m mixing coil was experimentally selected on the basis of its maximum CL intensity. The relationships between the peak area obtained by injecting a definite amount of BSA and phen, EHDAB, TEPA, NaOH, H_2O_2, and copper(II) solutions are shown in Figs. 2—7. From these results, the following optimum concentrations for the maximum peak area were chosen: 5.0×10^{-5} mol dm^{-3} phen; 4.0×10^{-5} mol dm^{-3} EHDAB; 2.0×10^{-7} mol dm^{-3} TEPA; 1.0×10^{-1} mol dm^{-3} NaOH; 5% H_2O_2; and 1.0×10^{-7} mol dm^{-3} copper(II).

Conditions: 5.0×10^{-5} mol dm^{-3} phen, 4.0×10^{-3} mol dm^{-3} EHDAB, 2.0×10^{-7} mol dm^{-3} TEPA, 1.0×10^{-1} mol dm^{-3} NaOH, and 5% H_2O_2.

Determination of Various Proteins. The calibration curves of BSA and BγG were obtained under the above-mentioned conditions (Fig. 8). As can be seen from Fig. 8, each linear response was obtained over a wide range of concentrations, and 2×10^{-5}—1×10^{-1} g dm^{-3} BSA and 2×10^{-5}—5×10^{-2} g dm^{-3} BγG could

be determined. The detection limit (S/N=2) of the present method (a biuret reagent containing copper(II) and tartrate) was 1 ng BSA; this corresponded to one-tenth that in the previous paper. The coefficient of variation was 4.9% for ten measurements of 1×10^{-3} g dm^{-3} BSA.

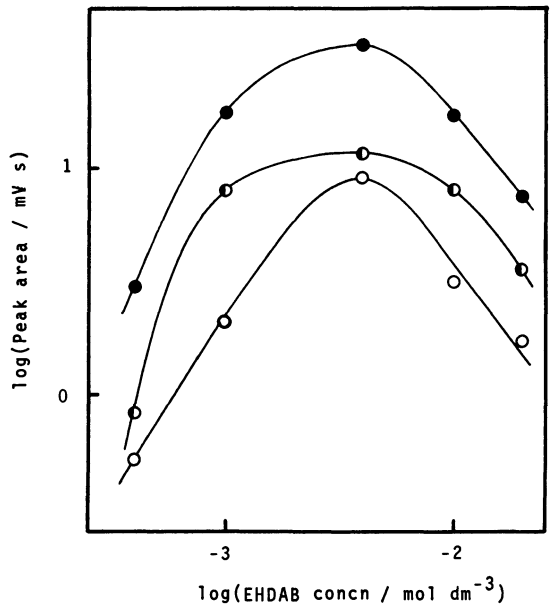

Fig. 5. Relationship between EHDAB concn and peak area.

A similar sensitivity was also obtained for HSA, HγG, and ovalbumin. Furthermore, the rapid formation of a very stable complex compound between copper(II) and protein by heating was suggested because the calibration curves were still linear, even at the limit of the detection of BSA and BγG. Therefore, the

feasibility for the determination of a much smaller amount of copper(II) was expected to improve the sensitivity of protein determination.

Copper(II) Catalyst Containing α-Amino Acid. The present method was applied to the determination of α-amino acid; the signals of L-aspartic acid (Asp) as a model are shown in Fig. 9. The shape of the signals was quite different from that in the luminol-H_2O_2 system; examination showed a first positive peak after the injection of an amino acid solution, followed by a second negative peak based on the formation of a copper(II)-Asp complex compound. The

Table 1. The Relative Responses of Various Amino Acids (5.0×10^{-5} mol dm^{-3}) Based on the Response of L-Aspartic Acid

α-Amino acid	Positive peak height	Positive peak area	Negative peak area	Formation constant*) $\log K_1K_2$
Asp	1.00	1.00	1.00	15.35[a)]
Gly	0.96	0.81	0.67	15.67
Pro	0.91	0.85	0.61	16.58[b)]
Ala	0.90	0.75	0.64	15.52
His	0.85	0.84	3.50	18.53
Glu	0.83	0.74	0.51	14.16
Lys	0.75	0.65	0.28	13.90
Arg	0.67	0.57	0.31	13.76

*) Temp: 25°C, Method: glass electrode, almost the same ionic strength. (The Chemical Society, "Stability Constant," Special Publication No. 17, London (1964)). a) 30°C. b) 20°C.

peak height corresponding to the positive catalytic activity increased with an increase in the Asp concentration and then decreased through the maximum value at 1×10^{-3} mol dm^{-3} Asp, while the peak area corresponding to the negative catalytic activity increased with an increase in the Asp concentration. These phenomena were also observed for such other amino acids as L-glutamic acid(Glu), L-glycine (Gly), L-alanine (Ala), L-proline (Pro), L-lysine hydrochloride (Lys), L-arginine hydrochloride (Arg), and L-histisine hydrochloride (His), and for ethylenediamine and 2,2′-bipyridine. However, a negative peak alone was obtained in the presence of such a ligand as triethylenetetramine, ethylenediaminetetraacetic acid, and diethylenetriaminepentaacetic acid, which contained more than four donor atoms and which formed a stable copper(II) complex compound. A negative peak alone was also obtained, even in the presence of ethylenediamine, when the mole ratio of ethylenediamine to copper(II) was very large ([ethylenediamine]/[copper(II)]=10^6). These results suggest that the final response rate has a close relation with the compositional structure of a copper(II) complex compound. A detailed investigation of the positive and negative peaks is now in progress. The response of each amino acid relative to that of Asp is shown in Table 1. Though the negative peak area of His was abnormally large, this seemed to be attributable to a larger formation constant of a copper(II)–His complex compound.

Since the positive cytalytic activity of copper(II) was much more enhanced in the presence of an amino acid than in that of a tartrate, while the negative catalytic activity alone of copper(II) was observed in the presence of protein, an attempt was made to determine microamounts of protein by using an amino acid instead of a tartrate contained in a biuret reagent. The relationship between the Arg concentration and the negative peak area was obtained by adding definite amounts of BSA to a solution containing a definite amount of copper(II) and various amounts of Arg as a coexisting amino acid (Fig. 10).

The calibration curves of BSA shown in Fig. 11 were obtained by adding various amounts of BSA to

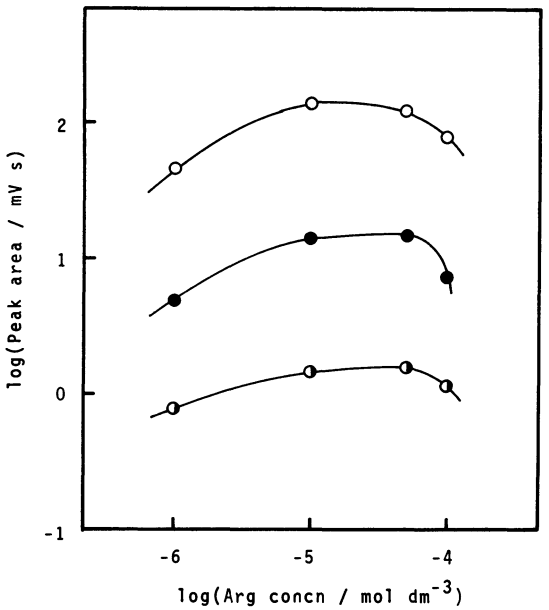

Fig. 10. Relationship between Arg concn and peak area.
○: 1.0×10^{-2} g dm^{-3}-, ●: 1.0×10^{-3} g dm^{-3}-, and ◑: 1.0×10^{-4} g dm^{-3}-BSA.
Conditions: 5.0×10^{-5} mol dm^{-3} phen, 4.0×10^{-3} mol dm^{-3} EHDAB, 2.0×10^{-7} mol dm^{-3} TEPA, 1.0×10^{-1} mol dm^{-3} NaOH, 1.0×10^{-7} mol dm^{-3} copper(II), and 5% H_2O_2.

a copper(II)–Arg solution, a copper(II)–biuret reagent solution, and a copper(II)–Asp solution, and by then measuring their peak areas. As can be seen from Fig. 11, the present modified method enabled us to determine 5.0×10^{-6}—1.0×10^{-1} g dm^{-3} BSA and showed the detection limit of 250 pg BSA. This value was one-fourth that in a biuret reagent and about one-fortieth that in the luminol–H_2O_2 CL system reported in the previous paper. The coefficient of variation obtained for nine measurements of 1×10^{-4} g dm^{-3} BSA was 5.9%. The other proteins, such as BγG, and HSA also showed a sensitivity similar to that in BSA (Fig. 12).

Though the present method was developed as a detector for high performance liquid chromatography, it was also applied to a human serum sample. First

Conditions: 5.0×10^{-5} mol dm^{-3} phen, 4.0×10^{-3} mol dm^{-3} EHDAB, 2.0×10^{-7} mol dm^{-3} TEPA, 1.0×10^{-1} mol dm^{-3} NaOH, 5% H_2O_2, 1.0×10^{-7} mol dm^{-3} copper(II), and 8.0×10^{-7} tartrate or 5.0×10^{-5} mol dm^{-3}-amino acids.

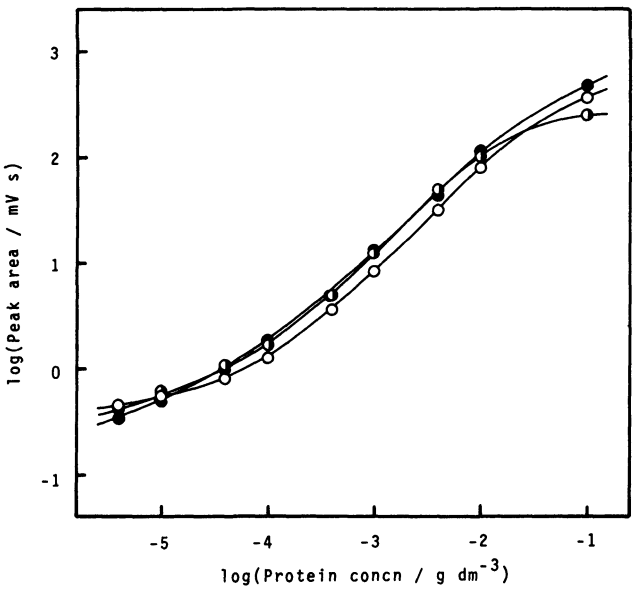

Fig. 12. Calibration curves of various proteins.
○: HSA, ●: BSA, and ◑: BγG.
Conditions: 5.0×10^{-5} mol dm^{-3} phen, 4.0×10^{-3} mol dm^{-3} EHDAB, 2.0×10^{-7} mol dm^{-3} TEPA, 1.0×10^{-1} mol dm^{-3} NaOH, 5% H_2O_2, 1.0×10^{-7} mol dm^{-3} copper(II), and 5.0×10^{-5} mol dm^{-3} Arg.

of all, the effect of the coexisting constituents in a human serum sample on the determination of HSA by the present modified method was examined. Various amounts of HSA were estimated in either the presence or absence of a definite amount of control serum (diluted to a volume of 10^5 times with a buffer solution), and the relationship between HSA concentration and

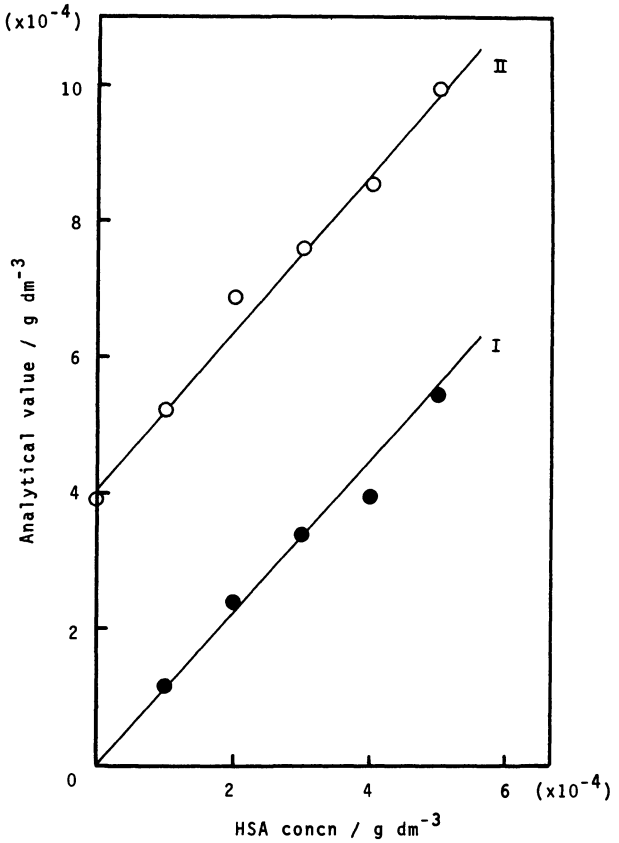

Fig. 13. Relationship between HSA concn and analytical value.
●: HSA and ○: HSA+control serum.
Conditions: 5.0×10^{-5} mol dm^{-3} phen, 4.0×10^{-3} mol dm^{-3} EHDAB, 2.0×10^{-7} mol dm^{-3} TEPA, 1.0×10^{-1} mol dm^{-3} NaOH, 5% H_2O_2, 1.0×10^{-7} mol dm^{-3} copper(II), and 5.0×10^{-5} mol dm^{-3} Arg.

the analytical value was obtained by the use of the calibration curve shown in Fig. 12. All the analytical values of the ordinate in Fig. 13 were represented as the amount of HSA. The difference between the two straight lines, I and II, in the analytical value was approximately equal to the amount of protein in the added control serum. This means that the present method was applicable to the sensitive determination of protein in a serum sample without being interfered with by coexisting constituents, when a sample solution is diluted to a volume of 10^5 times with a buffer solution and then measured.

The present method may be expected to be useful for the development of a sensitive, rapid, and inexpensive detector by which a trace amount of protein can be determined without labeling it.

Transition-Metal Complexes of Pyrrole Pigments. XXII. Photoredox Behavior of Oxo(tetra-*p*-tolylporphinato)-molybdenum(V) Complexes†

Yoshihisa MATSUDA, Toshihiko TAKAKI, and Yukito MURAKAMI*
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received November 16, 1985)

Photochemical reduction of oxomolybdenum(V) complexes of 5,10,15,20-tetra-*p*-tolylporphine, [$Mo^{V}O(X)$(ttp)], was investigated under irradiation with the visible light in benzene, where X stands for an axial ligand placed trans to the oxo group. Irradiation of [$Mo^{V}O(X)$(ttp)] resulted in a homolytic cleavage of the Mo-X bond to afford [$Mo^{IV}O$(ttp)] and a radical species generated from the axial ligand (X). The reduction rate was controlled by the nature of the Mo-X bond, and a complex with less ionic character of the axial bond was more reactive in the homolysis process. The bulkiness of the axial alkoxo ligands may provide two different effects which are opposite to each other on the reactivity: (i) The repulsive interaction between an axial ligand and the equatorial ttp accelerates the homolysis of the Mo-X bond; (ii) the diffusion rate of the radical species, generated by the photochemical cleavage of the axial coordinate bond, from the coordination sphere is progressively retarded as the bulkiness of the alkoxo ligand increases. The second effect seems to be more pronounced for the present photochemical reaction. The photochemical reduction of [$Mo^{V}O(X)$(ttp)] is essentially composed of two sequential steps, photochemical cleavage of the Mo-X bond and diffusion of the radical species from the coordination sphere. Reoxidation of [$Mo^{IV}O$(ttp)] under aerobic irradiation conditions afforded [$Mo^{V}O$-(OH)(ttp)] and [$(Mo^{V}O(ttp))_2O$] via the postulated intermediate formation of [$Mo^{V}(OO\cdot)$(ttp)].

The redox chemistry of metalloporphyrins and the reaction behavior of their various axial ligands have attracted much attention in connection with the development of oxygen carriers, oxygenation catalysts, and photochemical catalysts. We have investigated the redox behavior of some molybdenum[1] and niobium[2] complexes of 5,10,15,20-tetraphenylporphine by means of electrochemical methods. The redox potentials for couples of Mo^{V}/Mo^{IV} and Nb^{V}/Nb^{IV} as observed for these porphine complexes have been found to vary depending upon the nature of axial ligands, and fall in the region between 0 and −0.8 V vs. SCE. We have found recently that irradiation of tri-μ-oxo-bis(5,10,15,20-tetra-*p*-tolylporphinato)niobium(V) in benzene with the visible light under aerobic conditions afforded two paramagnetic species at room temperature.[3] One of the paramagnetic species, which is ESR silent, oxidized heterocyclic bases, while the other species, which is detectable by ESR, oxidized olefins catalytically to afford the corresponding epoxides selectively. On the other hand, Ledon and his associates have reported that the photo-assisted reduction of molecular oxygen to hydrogen peroxide took place in the presence of methoxooxo(5,10,15,20-tetraphenylporphinato)molybdenum(V).[4] In order to clarify axial ligand effects on the photoreduction process, oxo(tetra-*p*-tolylporphinato)molybdenum(V) complexes with various axial ligands, [$Mo^{V}O(X)$(ttp)] (X stands for an axial ligand placed trans to the oxo group), were employed and their photoreduction behavior was investigated from kinetic and structural viewpoints in this work. Reoxidation of the resulting oxomolybdenum(IV) species was also studied under aerobic conditions by spectroscopic means.

Experimental

ESR spectra were recorded on a JEOL JES-ME-3 X-band spectrometer equipped with a 100-kHz field modulation unit; a standard MgO/Mn^{II} sample calibrated with a NMR magnetometer was employed for calibration of the magnetic field. Electronic and IR absorption spectra were measured with a Hitachi 340 recording spectrophotometer and a JASCO DS-403G grating spectrophotometer, respectively.

Materials. Benzene was purified by the standard method and distilled under nitrogen just before use. Nitrosobenzene of Tokyo Kasei Kogyo Co. was purified by sublimation at 38 °C under reduced pressure (930 Pa). 5,10,15,20-Tetra-*p*-tolylporphine, H_2ttp, was prepared from pyrrole and *p*-tolualdehyde according to a procedure similar to that adopted for the synthesis of 5,10,15,20-tetraphenylporphine, H_2tpp.[5,6] Oxomolybdenum(V) complexes of the former equatorial ligand with methoxo, ethoxo, chloro, and acetato moieties as the axial ligands were prepared in the light of reported procedures for the preparation of the corresponding complexes of the latter equatorial ligand.[1,7]

Methoxooxo(5,10,15,20-tetra-*p*-tolylporphinato)molybdenum-

†Contribution No. 816 from this Department.

(V), [$Mo^{V}O(OCH_3)$(ttp)]: Yield 47%; Vis_{max} (benzene) 455, 583, and 623 nm; IR (KBr) 906 cm^{-1} (Mo=O). Found: C, 70.97; H, 4.42; N, 7.52%. Calcd for $C_{45}H_{31}N_4O_2Mo$: C, 71.52; H, 4.13; N, 7.42%.

Ethoxooxo(5,10,15,20-tetra-*p*-tolylporphinato)molybdenum-(V), [$Mo^{V}O(OC_2H_5)$(ttp)]: Yield 54%; Vis_{max} (benzene) 456, 580, and 620 nm; IR (KBr) 898 (Mo=O) and 519 cm^{-1} (Mo-O). Found: C, 72.70; H, 5.05; N, 6.78%. Calcd for $C_{50}H_{41}N_4O_2Mo$: C, 72.72; H, 5.00; N, 6.78%.

Chlorooxo(5,10,15,20-tetra-*p*-tolylporphinato)molybdenum-(V), [$Mo^{V}O(Cl)$(ttp)]: Yield 61%; Vis_{max} (benzene) 347, 422, 502, 630, and 677 nm; IR (KBr) 943 cm^{-1} (Mo=O). Found: C, 67.61; H, 4.37; N, 6.57%. Calcd for $C_{48}H_{36}ClN_4OMo \cdot HCl$: C, 68.00; H, 4.56; N, 6.43%.

Acetatooxo(5,10,15,20-tetra-*p*-tolylporphinato)molybdenum-(V), [$Mo^{V}O(OCOCH_3)$(ttp)]: Yield 51%; Vis_{max} (benzene) 409 sh, 482, 611, and 645 nm; IR (KBr) 914 and 947 cm^{-1} (Mo=O). Found: C, 69.48; H, 4.92; N, 6.33%. Calcd for $C_{50}H_{39}N_4O_3Mo \cdot CH_3CO_2H$: C, 69.41; H, 4.82; N, 6.23%.

Oxomolybdenum(V) complexes with butoxo and benzyloxo moieties as the axial ligands were prepared from [$Mo^{V}O(Cl)$(ttp)] according to the following procedure. An alcohol (1-butanol or benzyl alcohol; 20 mL) saturated with KOH was added to a dichloromethane solution (200 mL) containing [$Mo^{V}O(Cl)$(ttp)] (100 mg). After the mixture was evaporated to dryness in vacuo, the residue was extracted with dichloromethane. The extract was applied on a column of neutral aluminum oxide (Woelm, activity grade I) and eluted with dichloromethane containing the same alcohol species (1% v/v). The product fraction was evaporated to dryness in vacuo, and the residue was recrystallized from dichloromethane containing the same alcohol (ca. 1% v/v).

Butoxooxo(5,10,15,20-tetra-*p*-tolylporphinato)molybdenum-(V), [$Mo^{V}O(OC_4H_9)$(ttp)]: Yield 90%; Vis_{max} (benzene) 455, 582, and 622 nm; IR (KBr) 905 cm^{-1} (Mo=O). Found: C, 73.14; H, 5.31; N, 6.56%. Calcd for $C_{52}H_{45}N_4O_2Mo$: C, 72.54; H, 5.29; N, 6.38%.

(Benzyloxo)oxo(5,10,15,20-tetra-*p*-tolylporphinato)molybdenum (V), [$Mo^{V}O(OCH_2C_6H_5)$(ttp)]: Yield 70%; Vis_{max} (benzene) 458, 584, and 624 nm IR (KBr) 898 and 907 cm^{-1} (Mo=O). Found: C, 74.25; H, 5.20; N, 5.83%. Calcd for $C_{55}H_{43}N_4O_2Mo \cdot 1/4C_6H_5CH_2OH$: C, 74.50; H, 4.96; N, 6.12%.

Photoreduction Measurements. A benzene solution of [$Mo^{V}O(X)$(ttp)] (ca. 1×10^{-3} mol dm^{-3}) was sealed in a quartz tube (diameter, 5 mm) after evacuation of gas. The sample solution placed in an ESR cavity was irradiated with a 500-W tungsten lamp from a distance of 20 cm. ESR spectra were recorded under irradiation conditions. For detection of radical species, nitrosobenzene (ca. 5×10^{-2} mol dm^{-3}) was added to the sample solution to afford the corresponding spin adducts.

Benzene and [$Mo^{V}O(X)$(ttp)] were mixed in a spectrophotometric cell of 1-cm path length after both complex and solvent were degassed separately. The sample solution, containing ca. 4×10^{-6} mol dm^{-3} [$Mo^{V}O(X)$(ttp)], was irradiated with a 500-W tungsten lamp from a distance of 20 cm, and electronic absorption spectra were measured at appropriate time intervals.

Results and Discussion

Photoreduction of [$Mo^{V}O(X)$(ttp)]. The present oxomolybdenum(V) complexes, [$Mo^{V}O(X)$(ttp)], show characteristic ESR spectra in benzene, which consist of nine intense lines originated from the superhyperfine interaction of one d electron with four nitrogen nuclei of the equatorial ligand.[7] Although the ESR signals for the complexes with axial alkoxo ligands in benzene were subjected to change very slowly due to hydrolysis or dimerization of the complexes, the complexes dissolved in sufficiently dried and freshly distilled benzene remained stable without such decomposition for several hours in the dark at room temperature. The ESR signals for the present complexes except for [$Mo^{V}O(Cl)$(ttp)] underwent intensity decrease upon irradiation with the visible light under anaerobic conditions as shown in Fig. 1. The signals for the complexes with the alkoxo ligands disappeared in about 4 h and were recovered upon addition of alcohol species corresponding to the axial ligands under aerobic conditions, while the complexes remained ESR silent so long as anaerobic conditions were retained. These observations indicate that the irradiation results in reduction of the central metal atom along with elimination of the axial ligand as a radical species as shown by Eq. 1. The ESR signal for a benzene solution

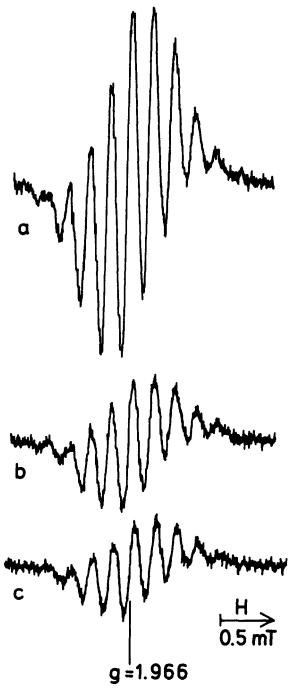

Fig. 1. ESR spectra for [$Mo^{V}O(OCH_3)$(ttp)] in benzene (ca. 1×10^{-3} mol dm^{-3}) under anaerobic conditions at room temperature: a, before irradiation; b, irradiated for 30 min; c, irradiated for 1 h.

$$\begin{array}{c} X \\ | \\ Mo^{V}(ttp) \\ \| \\ O \end{array} \xrightarrow{h\nu} \begin{array}{c} \\ \\ Mo^{IV}(ttp) \\ \| \\ O \end{array} + X\cdot \qquad (1)$$

of [$Mo^{V}O(X)$(ttp)] also underwent intensity decay in the presence of nitrosobenzene as a spin-trapping agent upon anaerobic irradiation, but a new signal, which is

Table 1. Spin Hamiltonian Parameters for Spin Adducts of Nitrosobenzene and Radical Species Generated from [$Mo^{V}O(X)(ttp)$] in Benzene under Aerobic Irradiation at Room Temperature

Mother complex	g-Value	(Hyperfine splitting constants)[a]$\times 10^4$/T			
		A_N	$A_{o,p}$	A_m	A_β

[$Mo^{V}O(OC_2H_5)(ttp)$]	2.00	15.61	3.04	1.04	0.56
[$Mo^{V}O(OC_4H_9)(ttp)$]	2.00	15.54	3.07	1.06	0.68
[$Mo^{V}O(OCH_2C_6H_5)(ttp)$]	2.00	15.66	3.40	1.07	0.53

a) Hyperfine splitting constants are defined as follows: A_N, due to the nitrogen nucleus of nitrosobenzene; $A_{o,p}$, due to the proton nuclei placed at ortho and para positions of the benzene moiety; A_m, due to the proton nuclei placed at meta positions of the benzene moiety; A_β, due to the proton nuclei placed at β-position of the alkoxo moiety.

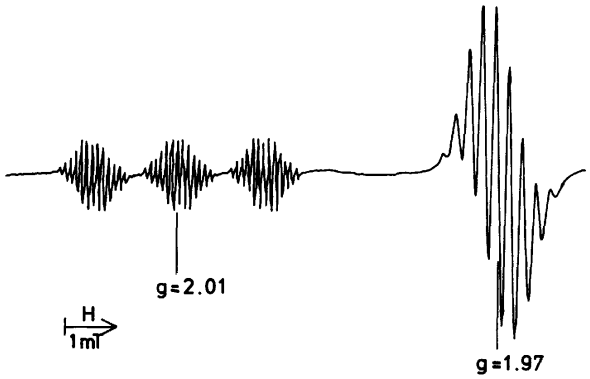

Fig. 2. ESR spectrum for [$Mo^{V}O(OCH_3)(ttp)$] in benzene (ca. 1×10^{-3} mol dm^{-3}) containing nitrosobenzene (ca. 5×10^{-2} mol dm^{-3}); irradiated for 30 min at room temperature.

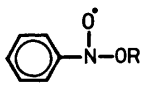
attributed to the alkoxyl radical–nitrosobenzene adduct (**A**), appeared as shown in Fig. 2. Hyperfine splitting



A

constants for several alkoxy adducts are listed in Table 1. The ESR behavior is in agreement with that observed during the photoreduction of methoxooxo(5,10,15,20-tetraphenylporphinato)molybdenum(V).[4]

The photoreduction of all the complexes other than [$Mo^{V}O(Cl)(ttp)$] was also examined by means of electronic spectroscopy as typically shown for [$Mo^{V}O(OC_2H_5)(ttp)$] in Fig. 3. The absorption bands at 456, 580, and 620 nm for the Mo^{V} species underwent intensity decay, and a new set of bands attributable to the Mo^{IV} species appeared at 434, 512(sh), 566, and 592 nm. The latter bands were further enhanced in their intensities along with the progress of photochemical reaction. Since isosbestic points were clearly observed at 396, 443, 535, 566, 598, and 648 nm, any additional reaction other than that given by Eq. 1 does not take place under the present conditions. Correlations between intensity of the Soret band and irradiation time are shown in Fig. 4. These correlations indicate that the photoreduction follows the first-order kinetics. Ledon et al. observed that the excitation of [$Mo^{V}O$-

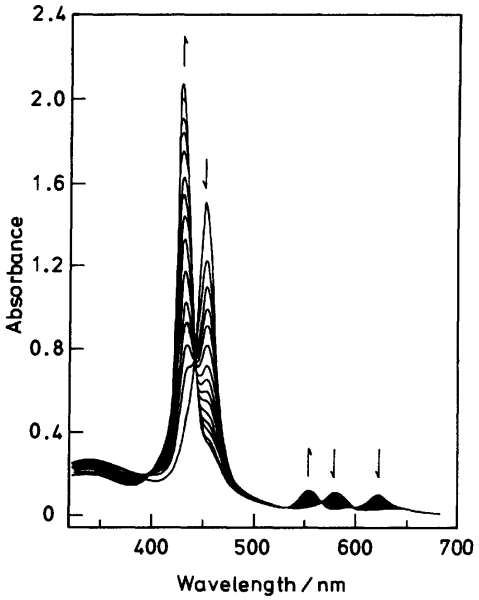


Fig. 3. Visible spectral change for [$Mo^{V}O(OC_2H_5)$-(ttp)] in benzene (ca. 4×10^{-6} mol dm^{-3}) under irradiation at room temperature. Trends of spectral change with time are shown by arrows; measurements were carried out at 20 s intervals.

$(OCH_3)(tpp)]$ was effective exclusively with the Soret band energy for the photoreduction.[4] Since the Soret bands of $[Mo^{V}O(X)(ttp)]$ and $[Mo^{IV}O(ttp)]$ do not show significant overlap between them (Fig. 3), light quanta absorbed by the former Mo^{V} species must be exclusively used for the photoreduction even after generation of the latter Mo^{IV} species. This may provide the reason why the clear first-order kinetics (Fig. 4) was observed for the present photochemical reaction.

Rate constants for the photoreduction are listed in Table 2 along with reduction potentials and Mo=O stretching frequencies for the oxomolybdenum(V) complexes having various axial ligands. The bonding mode of the axial coordinate bond, Mo–X, varies in a wide range as controlled by the electronegativity of axial ligand X. The covalent character decreases as goes downwards for the complexes listed in Table 2. The axial coordinate bond in $[Mo^{V}O(Cl)(ttp)]$ must be highly ionic in the light of structural determination of $[Mo^{V}O(Cl)(tpp)]$ by means of the single-crystal X-ray diffraction measurements.[8] The axial bonding character is reflected on the Soret band energy, the Mo=O stretching frequency, and the reduction potential for an electrochemical process given by Eq. 2.

$$\begin{array}{l} X \\ | \\ Mo^{V}(ttp) \\ \| \\ O \end{array} \xrightarrow{e^-} \begin{array}{l} \\ \\ Mo^{IV}(ttp) \\ \| \\ O \end{array} + X^- \qquad (2)$$

On the basis of the data listed in Table 2, a complex with less ionic character of the axial coordinate bond is more reactive in the photoreduction process. The Soret band is plausibly assigned to a charge-transfer transition from the porphine ligand to the metal.[9] Then, the excited electron seems to occupy ultimately an antibonding orbital localized in the Mo–X bond for complexes having a highly covalent axial bond, and consequently the axial coordinate bond is destabilized. The excited state is plausibly represented for the case of the axial coordination with large ionic character as $\{[Mo^{IV}O(ttp^+)]^+\cdots X^-\}$ which is regarded as a charge transfer complex, while the excited state for the covalent axial coordination may be given as $\{[Mo^{III}O(ttp^+)]\cdots X\cdot\}$. As a result, the electrostatic attraction between X^- and $[Mo^{IV}O(ttp^+)]^+$ is operative in the former case, while no such interaction would be expected in the latter. Therefore, a less electronegative axial ligand more readily undergoes the homolytic cleavage upon irradiation with the visible light.

Rate constants for the complexes with various axial alkoxo ligands are listed in Table 3 along with relevant spectral parameters. The rate of photoreduction decreases in the following order with respect to the alkoxo ligands: $OCH_3 \cong OC_2H_5 > OC_4H_9 > OCH_2C_6H_5$. In the light of the Soret band energies and the stretching frequencies of the Mo=O bond, there are no significant differences in the axial bonding character among these complexes. Therefore, differences in the reactivity must come from stereochemical origin. The bulkiness of the axial alkoxo ligand may provide two different effects which are opposite to each other on the reactivity. First, the repulsive interaction between an axial ligand, OR, and the equatorial one, ttp, accelerates the homolysis of the coordinate bond. Second, the diffusion rate of the radical species, generated by the photochemical cleavage of the axial coordinate bond, from the coordination sphere is progressively retarded as the bulkiness of the alkoxo ligand increases. The slow diffusion is in favor of recombination of the radical species and the reduced central metal. The second effect seems to be more pronounced for the present

photochemical reaction in the light of the kinetic data given in Table 3.

On the basis of the above discussion, the present photochemical reduction of [$Mo^{V}O(X)(ttp)$] is essentially composed of two sequential steps, photochemical cleavage of the axial coordinate bond and diffusion of the radical species from the coordination sphere as shown by Eq. 3. The overall reaction rate for the complexes with smaller axial ligands is primarily controlled by the first step which is enhanced as the axial coordinate bond becomes more covalent, while the second step becomes the rate-determining one for the reaction of the complexes with more bulky axial ligands.

$$X\text{-}Mo^{V}(ttp)(=O) \underset{\text{(step 1)}}{\overset{h\nu}{\rightleftharpoons}} \left[X\cdot \;\cdots\; Mo^{IV}(ttp)(=O) \right] \xrightarrow[\text{(step 2)}]{} Mo^{IV}(ttp)(=O) + X\cdot \qquad (3)$$

Reoxidation of [$Mo^{IV}O(ttp)$]. The photochemically reduced complex, [$Mo^{IV}O(ttp)$], was reoxidized under aerobic conditions in benzene to afford the starting complexes when the corresponding alcohols were added. The reoxidation process showed the second-order dependence on the molybdenum complex for all cases investigated here, and is in accord with the earlier work for [$Mo^{IV}O(tpp)$] in the presence of methanol.[4]

The fate of [$Mo^{V}O(X)(ttp)$] in benzene under aerobic irradiation conditions was monitored by electronic spectroscopy in the absence of an alcohol. The aerobic irradiation with the visible light resulted in appearance of absorption bands attributable to [$Mo^{IV}O(ttp)$]. The intensity increase of these bands, however, was found to level off within an hour at a lower level relative to that observed under anaerobic conditions; about 80% of the original complex was reduced. The observation indicates that the reoxidation of [$Mo^{IV}O(ttp)$] takes place by molecular oxygen under aerobic conditions. In a few hours under aerobic irradiation conditions, the absorption bands attributable to [$Mo^{IV}O(ttp)$] began to decrease in their intensities along with appearance of a new absorption band at 484 nm and precipitation of a dark crystalline material. The crystalline solid was slightly soluble in benzene and dichloromethane and exhibited electronic absorption spectra shown in Fig. 5. The absorption spectrum observed in benzene is identical with that for the μ-oxo dimer, [$\{Mo^{V}O(ttp)\}_2O$], while that in dichloromethane is identical with that for [$Mo^{V}O(OH)(ttp)$].[10] The ESR spectrum observed for the crystalline solid is shown in Fig. 6; $D=940\times10^{-4}\,cm^{-1}$, $E\cong0$. Consequently, this material is confirmed to be the μ-oxo dimer and hydrolyzed readily by a trace amount of water present in dichloromethane to afford [$Mo^{V}O(OH)(ttp)$]. Two fractions were recovered from the mother solution, obtained from the aerobic photochemical reaction of

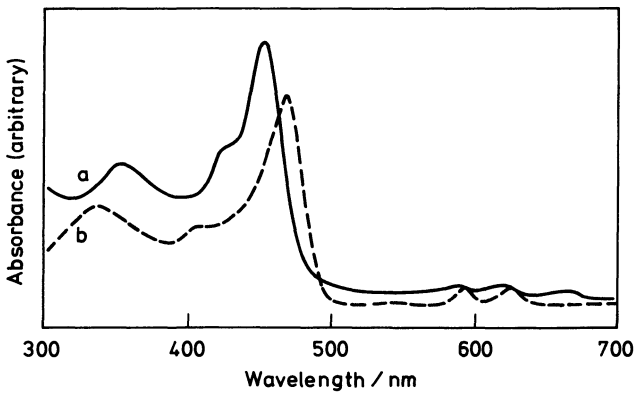

Fig. 5. Visible absorption spectra for the precipitated complex developed during reoxidation of [$Mo^{IV}O(ttp)$] in benzene without alcohols; measured in benzene (a) and dichloromethane (b).

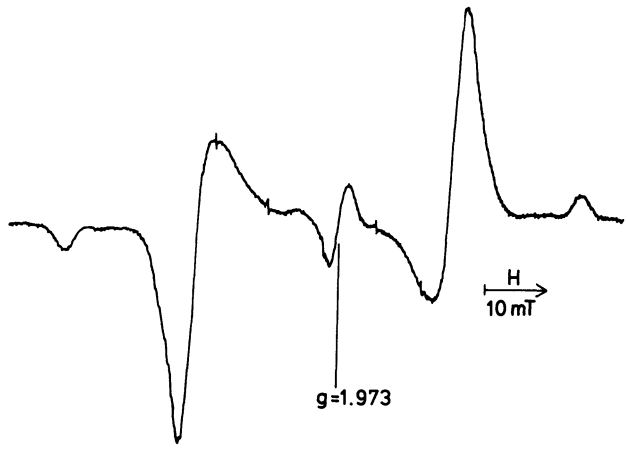

Fig. 6. ESR spectrum for the precipitated complex developed during reoxidation of [$Mo^{IV}O(ttp)$]; in solid state at room temperature.

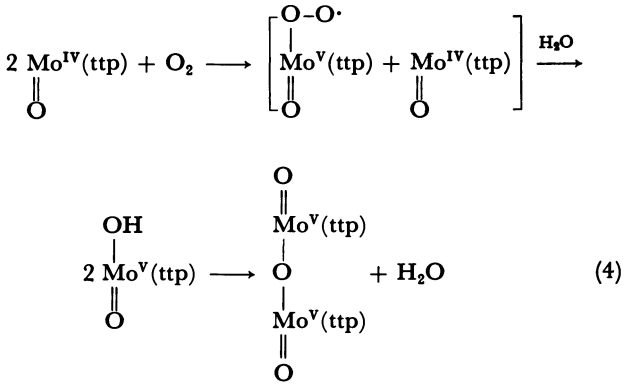
[$Mo^{V}O(X)(ttp)$] in benzene, by column chromatography [aluminum oxide (Woelm), activity grade III; eluant, dichloromethane]. The first fraction was identified as [$Mo^{V}O(OH)(ttp)$], while the second fraction was not identified with known species; the latter showing a Soret band at 484 nm. However, we may plausibly assign the peroxo complex, [$Mo^{V}O(OO\cdot)(ttp)$], to this species on the following grounds. (i) The absorption due to [$Mo^{IV}O(ttp)$] decreased in its intensity along with appearance of the 484-nm band (vide supra). (ii) Imamura et al. reported that [$Mo^{V}O(X)(tpp)$] is reduced via its reaction with KO_2.[12] They assigned [$Mo^{V}O(OO\cdot)(tpp)$] to an intermediate showing a Soret band in the 480—490-nm range. (iii) Ledon et al. proposed that the reoxidation of [$Mo^{IV}O(tpp)$] takes place via intermediate formation of [$Mo(O_2)(OO\cdot)(tpp)$] in a benzene–methanol mixture.[4] However, they did not identify the intermediate. (iv) [$Nb^{IV}O(ttp)$], which was generated from [$\{Nb^{V}(ttp)\}_2O_3$] under photochemical conditions, was reoxidized by the atmospheric oxygen to afford [$Nb^{V}O(OO\cdot)(ttp)$].[3]

In addition to the above conclusion, [$Mo^{V}O(OH)$-

(tpp)] has been found to undergo dehydration to afford [{$Mo^{V}O(tpp)$}$_2O$] as precipitates in benzene.[11] Therefore, the reoxidation pathway for [$Mo^{IV}O(ttp)$] in benzene without an alcohol may be represented by Eq. 4 with participation of a trace amount of water from the open atmosphere.



(4)

We have reported recently that tri-μ-oxo-bis(5,10,15,20-tetra-*p*-tolylporphinato)niobium(V) is capable of catalyzing the epoxidation of olefins by the atmospheric oxygen under irradiation with the visible light.[3] Since the catalytically active species in this reaction was confirmed to be [$Nb^{V}O(OO\cdot)(ttp)$], the peroxo molybdenum species, [$Mo^{V}O(OO\cdot)(ttp)$], which is likely formed under the present conditions, is also expected to act as an effective catalyst for the selective epoxidation of olefins in a similar manner.

Flameless Atomic-Absorption Spectrometric and Differential-Pulse Polarographic Determination of Cadmium after Coprecipitation with Hafnium Hydroxide

Joichi UEDA* and Natsuko YAMAZAKI
Department of Chemistry, Faculty of Education, Kanazawa University, Marunouchi, Kanazawa 920
(Received December 11, 1985)

Using the coprecipitation method with hafnium hydroxide, the flameless atomic-absorption spectrometric and the differential-pulse polarographic determinations of cadmium have been studied. The collecting ability of hafnium hydroxide for cadmium is excellent; from 0.01 to at least 1000 μg of cadmium in 50—400 cm^3 of a sample solution is coprecipitated quantitatively. The presence of hafnium hydroxide does not interfere with either method of determining cadmium. Of the diverse ions examined, there are no ions which interfere with the flameless atomic-absorption spectrometric determination, even if they are present in a concentration of at least 5000 times that of cadmium; as for the differential-pulse polarographic determination, only indium interferes when present in small amounts. The linear calibration curves through the point of origin were obtained over the range of 0.4—4 ng cm^{-3} of cadmium for the former method and 0.04—40 μg cm^{-3} for the latter method. In the proposed methods, the flameless atomic-absorption spectrometric determination was successfully applied to the analysis for trace amounts of cadmium in river-water samples.

The coprecipitation method is one of the most useful methods for the concentration of cadmium, and various techniques for the determination of trace cadmium, coupled with a preconcentration procedure by means of coprecipitation, have been proposed; inductively coupled plasma-atomic emission spectrometry using hydroxide of indium[1] or lanthanum[2] as a coprecipitant; X-Ray fluorescence using 1,3:2,4-di-*O*-benzylidene-D-glucitol[3] and 1,10-phenanthroline-sodium tetraphenylborate;[4] flame atomic-absorption spectrometry using naphthalene,[5] soybean protein,[6] strontium carbonate,[7] aluminium hydroxide,[8] and tris(1-pyrrolidinecarbodithioato)cobalt(III),[9] and flameless atomic-absorption spectrometry using iron(III) hydroxide[10] and cobalt 1-pyrrolidinecarbodithioate(cobalt-APDC).[11] Moreover, tin(IV) hydroxide[12] has also been proposed as a useful collector of cadmium as a result of investigation using the radiotracer method.

In a previous paper,[13] the present authors suggested that hafnium hydroxide is effective as a collector of trace amounts of lead; it can be satisfactorily analyzed by means of differential-pulse polarography in the presence of large amounts of hafnium. This time, we have recognized that hafnium hydroxide also coprecipitates quantitatively over a wide concentration range of cadmium almost entirely without the coprecipitation of alkali and alkaline earth metals and that this concentration method can be successfully combined with the cadmium determination by means of flameless atomic-absorption spectrometry or differential-pulse polarography. Both methods proposed here are simple, fairly free from the effect of diverse ions, and give good reproducibilities. Cadmium determination by a combined coprecipitation-differential-pulse polarography has not yet been tried. Concerning combined coprecipitation-flameless atomic-absorption spectrometry, however, as has been mentioned above, several methods have been reported. Among those, though, the method using iron(III) hydroxide as a collector[11] can not avoid the coprecipitation of large amounts of alkaline earth elements which may interfere with cadmium determination, and in the case of cobalt-APDC,[12] it is troublesome to digest the precipitate in order to reduce the matrix effect because of the presence of cobalt-APDC itself. This paper will describe the fundamental conditions for the coprecipitation of cadmium with hafnium hydroxide and for the flameless atomic-absorption spectrometric and the differential-pulse polarographic determination of cadmium.

Experimental

Apparatus. All the atomic-absorption measurements were carried out with a Hitachi 170-70 Zeeman-effect atomic-absorption spectrometer with a hollow cadmium cathode lamp (Hitachi 2082008) and a cup-type graphite furnace (Hitachi 170-5104). A Yanagimoto voltammetric analyzer, model p-1000, was used for the differential-pulse polarographic measurements, operating in a three-electrode configuration with a dropping-mercury electrode, a saturated calomel reference electrode, and a platinum counter electrode. A Hitachi-Horiba model M-5 glass electrode pH meter was also used for the pH measurements.

Reagents. Standard Cadmium Solution: A solution containing about 1 mg cm^{-3} of cadmium was prepared by dissolving guaranteed reagent-grade cadmium nitrate in a small amount of nitric acid and by then diluting it with distilled water. The solution was subsequently standardized by complexometric titration.

Hafnium Solution: A solution containing about 5 mg cm^{-3} of hafnium was prepared by dissolving hafnium chloride (Nakarai Chemicals Co.) in 2 mol dm^{-3} of hydrochloric acid and standardized by complexometric back titration.

All the other reagents used were of a guaranteed reagent grade and were purified with a chelate resin when necessary.

Recommended Procedures. Flameless Atomic-Absorption Spectrometric Determination: To a sample solution (50—400 cm^3) containing 0.01—0.1 μg of cadmium, 10 mg of hafnium is added and the pH is adjusted to about 9.5

Table 1. Operating Conditions for Flameless Atomic-Absorption Spectrometry

Analytical wavelength	228.8 nm

with 1:1 aqueous ammonia in order to precipitate hafnium hydroxide. After the solution has then been allowed to stand for more than 20 min, the precipitate is filtered by suction using a 3G4 sintered-glass filter, washed with aqueous ammonia of pH 9.5, and dissolved with 1 cm^3 of concd. nitric acid. After the solution is diluted to 25 cm^3 with distilled water, measurements of the atomic absorbance are carried out under the optimum operating conditions, which are shown in Table 1.

Differential-Pulse Polarographic Determination: To a sample solution (50—400 cm^3) containing 1—1000 μg of cadmium, 10 mg of hafnium is added and then precipitated as hafnium hydroxide at about pH 9.5 with 1:1 aqueous ammonia. After allowing the solution to stand for more than 20 min, the precipitate is filtered by suction using a 3G4 sintered-glass filter, washed with aqueous ammonia of pH 9.5, and dissolved with 2 cm^3 of concd hydrochloric acid (with two 1-cm^3 portions of concd hydrochloric acid at about a 5-min interval). The solution is then diluted to 25 cm^3 with distilled water and deaerated with pure nitrogen for 5 min. Then, the polarogram is recorded under the operating conditions shown in Table 2 and the cadmium is determined by the current peak height at −0.64 V.

Results and Discussion

Study of Optimum Conditions for Coprecipitation. The effect of the pH on the coprecipitation of cadmium with hafnium hydroxide was examined by coprecipitating 0.1 or 30 μg of cadmium from 100 cm^3 of the sample solution. As is shown in Fig. 1, almost 100% recoveries of cadmium were obtained over the pH range from 7.0 to 12.0 for 0.1 μg of cadmium and from 7.5 to 12.0 for 30 μg of cadmium. Hence, a pH of about 9.5 was used for the coprecipitation in the further experiments. The amount of hafnium which is required for the quantitative coprecipitation of cadmium increases gradually with an increase in

the volume of the sample solution. As a result of the examinations for portions of the sample solution from 50 to 400 cm^3, we found that more than 5 mg of hafnium was needed for 400 cm^3. In this study, 10 mg of hafnium was used. The coexistence of a large amount of hafnium does not interfere with the determinations; that is, the presence of 0.08 to at least 2 mg cm^{-3} of hafnium does not affect the flameless atomic-absorption spectrometric determination, nor does the presence of from 0.08 to at least 1 mg cm^{-3} interfere with the differential-pulse polarographic determination. The investigation of the aging time of the precipitate for the cadmium recovery led to the result that standing for more than 20 min at room temperature was suitable for the quantitative collection of cadmium, because almost a 100% recovery was attained about 15 min after the precipitation of hafnium hydroxide and this percentage remained almost constant for at least 10 h.

Choice of Acids for Dissolution of Precipitate. For the dissolution of hafnium hydroxide, several acids,

such as nitric, hydrochloric, sulfuric, and perchloric acid, were examined. Hafnium hydroxide dissolves easily in nitric, hydrochloric, and perchloric acids, but not easily in sulfuric acid. The effects of these acids on the atomic absorbance or the polarogram of cadmium are diverse. In Fig. 2, the effects of the concentrations of these acids on the peak height on the flameless atomic-absorption spectrometric determination are shown. The addition of increasing amounts of these acids decreases the peak heights of cadmium. In the case of nitric acid, however, the magnitude of the decrease is small over the concentration range from about 0.3 to 1.1 mol dm^{-3}, and in this concentration range, the use of this acid gives the highest peak height. On the basis of these results, the nitric acid was used to dissolve the precipitate for the flameless atomic-absorption spectrometric determination. For the differential-pulse polarographic determination, it was found that the hydrochloric acid was adequate as a supporting electrolyte for the dissolution of hafnium hydroxide and for obtaining well-defined polarograms. Since the presence of this acid over the concentration range from 0.5 to at least 3 mol dm^{-3} did not affect the current peak height of cadmium, an acidity of about 1 mol dm^{-3} was adopted in this experiment.

Optimum Operating Conditions. According to the recommended procedure, the instrumental parameters, such as the drying, ashing, and atomizing conditions and the flow rate of argon gas, were examined using a solution which contained 0.1 μg/25 cm^3 of cadmium. An almost constant absorbance was obtained when the drying, ashing, and atomizing currents were within 19 to 22 A, 45 to 85 A, and 220 to 280 A respectively. The times of drying, ashing, and atomizing also did not affect the absorbance within the time ranges examined, that is, 50—90 s, 10—40 s, and 4—10 s respectively. The change in the flow rate of the sheath gas from 1 to 5 l min^{-1} had no effect on the cadmium absorbance, but the increase in the flow rate of the carrier gas made the absorbance decrease gradually. From these results and the results of the examinations of other instrumental conditions, such as the lamp current, the slit width, and the injection volume, the optimum conditions for the measurement of the cadmium absorbance were determined to be as shown in Table 1. For the differential-pulse polarography, the conditions which are summarized in Table 2 were adopted as the optimum operating conditions.

Calibration Curves. The straight lines through the point of origin were obtained over the concentration range from 0.4 to 4 ng cm^{-3} of cadmium for the flameless atomic-absorption spectrometry and from 0.04 to 40 μg cm^{-3} for the differential-pulse polarography. The reproducibility of the AAS method, expressed by the relative standard deviation obtained from five repeated determinations, was 2.8% for 4 ng cm^{-3} of cadmium, while that one of the polarographic method was 1.3% for 1.2 μg cm^{-3} of cadmium.

Influence of Diverse Ions. The results of the influence of the diverse ions examined by the recommended procedures are summarized in Table 3. For the flameless atomic-absorption spectrometry, large amounts of sodium, potassium, magnesium, and calcium were found not to interfere with the determination. Some ions, such as beryllium, indium, bismuth(III), copper(II), zinc, and chromium(III), can also coexist, at least up to 5000 times of the amount of cadmium, and there are no ions among the examined ones which have a serious influence on the determi-

Table 4. Amounts of Coprecipitation of Alkali and Alkaline Earth Metals

Ion*	Amount added	Recovery
	mg/100 cm³	%

* Coprecipitated at about pH 9.5 using 10 mg of hafnium. The final volume of the solutions was made up to 25 cm³.

nation. For the differential-pulse polarographic determination, only indium interferes even present in only a small amount.

The Amounts of the Coprecipitation of Alkali and Alkaline Earth Metals. The amounts of the coprecipitation of alkali and alkaline earth metals were also studied. The amount of the coprecipitation of each ion was determined by measuring the amount of the ion remaining in the aqueous phase after the coprecipitation had been carried out and by subtracting this amount from the original amount of the ion. Flame photometry was used for the measurement of sodium, potassium, strontium, and barium, and the complexometric titration method, for magnesium and calcium. The results obtained are shown in Table 4. From this, it is obvious that alkali and alkaline earth metals hardly coprecipitate with hafnium hydroxide; this suggests that the use of hafnium hydroxide is effective for the separation of some kinds of elements from a sample solution containing large amounts of alkali and alkaline earth metals.

Application to River Water. Of the proposed methods, flameless atomic-absorption spectrometry was used for the determination of cadmium in the Kakehashi river system. The river-water samples were filtered through a membrane filter (Toyo Roshi TM-2p; pore size 0.45 μm) and acidified with hydrochloric acid to about pH 2 as soon as possible after sampling. Then cadmium was determined according to the recommended procedure. As is summarized in Table 5, the results which were obtained from the calibration and from the standard addition methods were in good agreement.

Table 5. Results for Cadmium in River Water

Kakehashi river system sampling point	Sample volume	A	B
		Cd found	Cd found
	cm³	ng cm⁻³	ng cm⁻³

Analytical Use of Luminescence Induced Ultrasonically in Solution. I. Sonic Chemiluminescence of Luminol for Determination of Cobalt(II) at Sub-pg Levels by Flow Injection and Continuous Flow Methods

Takayuki KOMATSU, Minoru OHIRA, Masaaki YAMADA,* and Shigetaka SUZUKI
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received December 18, 1985)

Ultrasonic irradiation of alkaline luminol solution produces intense light emission (sonic chemiluminescence) as a result of the reaction of luminol with reactive species which are generated ultrasonically from water molecule. For the analytical application of ultrasound-induced luminescence, the sonic chemiluminescence of luminol is first utilized for the determination of ultratraces of cobalt(II) by flow injection and continuous flow methods. This novel method is based on the measurement of sonic chemiluminescence enhanced by the presence of cobalt(II); it provides analytical characteristics comparable to those for the conventional luminol chemiluminescence method using hydrogen peroxide as an oxidizing agent. The limit of detection is 0.06 pg(10-μl sample injection) or 0.06 pg ml^{-1} (continuous sample flow), the linear dynamic range is 3 orders of magnitude (10-μl sample injection), the sampling rate is 120 h^{-1}, and the relative standard deviation is 3.9% for 6 pg Co(II) ($n=10$). The method is successfully applied to real samples. Possible explanation of sonic chemiluminescence is also presented; the mechanism involving superoxide anion radical is proposed for the cobalt(II)-catalyzed sonic chemiluminescence.

Ultrasound is widely used in various fields, e.g., diagnosis and therapy, disintegration of biological materials, metal processing, cleaning, etc. Recently, the chemical uses of ultrasound have received considerable attention because of its chemical effects like redox-action and acceleration of chemical reaction.[1-7] Such chemical effects arise from acoustic cavitation which occurs when high intensity ultrasound (>3.5 kW m^{-2}) is propagated through a liquid medium. The acoustic cavitation is a three-stage process consisting of the formation, growth, and collapse of gas or vapor-filled bubbles suspended in the liquid phase; the presence of dissolved gas reduces the liquid strength and hence favors the initiation of cavity formation.[8] The most striking characteristics of the acoustic cavitation is the liberation of a high energy through the process; the collapse generates transient hot-spots with local temperatures and pressures of several thousand K and hundreds of atmospheres.[4] This leads to the thermal decomposition of the cavity contents and the formation of free radicals. For example, in aqueous solutions the primary reaction in the cavitation of water gives hydrogen atoms and hydroxyl radicals in the absence of any volatile solute.[1]

It is known that the cavitation is frequently accompanied by a faint light emission called sonoluminescence (SL).[9,10] The intensity and spectrum of SL depend on the nature of liquid, the nature of dissolved gas, the liquid temperature, the presence of solute, and the ultrasonic intensity.[11] In air-saturated water, the SL spectrum consists of characteristic bands based on OH*, H_2O^*, NO_2^*, and radiative recombination (HO_2+H) which are overlaying a broad continuum arising from the radiative recombination (H+OH).[10] The presence of inorganic species like metal ions sometimes provides their characteristic emissions.[12-14] On the other hand, in an alkaline aqueous solution of luminol (5-amino-2,3-dihydro-1,4-phthalazinedione) containing dissolved oxygen the cavitation causes an intense light emission (sonic chemiluminescence, SCL) which is essentially luminol chemiluminescence, in addition to the SL.[9,15,16] Our attention has been focused on the introduction of these luminescence phenomena into the field of analytical chemistry. We already made it clear in the preliminary works that the SL and SCL were likely to be usable as analytical tools. That is to say, the SL and SCL techniques permit the determinations of water in methanol with no use of reagents[17] and of traces of cobalt(II) by monitoring the cobalt(II)-catalyzed SCL of luminol,[18] respectively. Our ultimate goal is to evaluate the utility and limit in the analytical use of the ultrasonically induced luminescence. In this paper, we describes the details of the luminol SCL for the determination of cobalt(II) at sub-pg levels, namely, further exploration of the SCL technique, its analytical characteristics, the comparison with the conventional luminol chemiluminescence (CL), and the mechanistic study of the cobalt(II)-catalyzed SCL.

Experimental

Apparatus. A schematic diagram of the flow system is given in Fig. 1. It is basically as before,[18] except that a flow line R_2 is newly placed. An aqueous solution containing luminol and sodium hydroxide is supplied through a flow line R_1. R_2 represents a carrier stream for cobalt(II) and other species. This is an aqueous cobalt(II) solution for the continuous flow method, or pure water or surfactant solution when cobalt(II) and other species are injected by means of a 10-μl rotary valve injector S (injection method). The streams are delivered by peristaltic pumps P_1 and P_2. The alkaline luminol solution is sonicated in a glass sonication cell C

Recommended conditions: $R_1=5\times10^{-5}$ M luminol, 0.16 M NaOH, $R_2=0.03$ M SDS; Flow rates (ml min^{-1}) $F_1=1.3$, $F_2=1.6$, $F_3=2.8$.

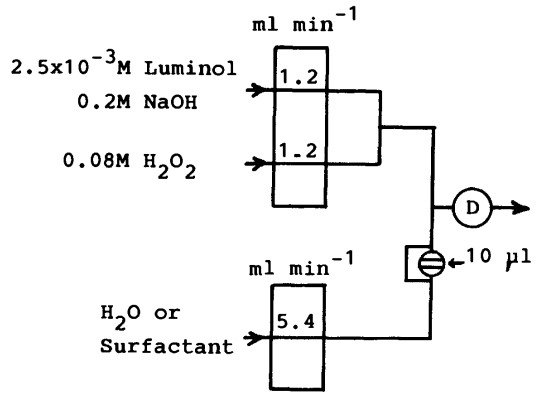

Fig. 2. Flow diagram for conventional chemiluminescence (CL) method.
Recommended conditions are specified in the figure.

by means of an exponential horn H (cross section: 0.05 cm^2) directly immersed in the solution, oscillated with an oscillator O (Tomy Seiko Co., Handy Sonic Model UR-20P; 28 kHz, max. 20 W). The luminol solution within the sonication cell is kept to be a constant volume (ca. 1.3 ml) during sonication by use of the pump tubes for the pump P_1 with different diameters. In order for adequate and stable cavitation to occur continuously, the luminol solution is cooled in an ice-water bath B before sonication. The luminol solution sonicated is drawn by a peristaltic pump P_3 and mixed with R_2 at a Y-joint J to be a flow line R_3. The cobalt(II)-catalyzed SCL is monitored at a spiral flow cell D ca. 15 cm apart from J, the minimum distance which can be achieved. Flow lines and a light-detecting device including the spiral flow cell have been described elsewhere.[19] In the system, there is no oxidizing agent intentionally added.

For the comparison of the present SCL method with an conventional CL method using hydrogen peroxide as an oxidizing agent, the flow system as shown in Fig. 2 was also assembled. Recommended conditions are given in the figure.

Absorption spectra of luminol were measured by a Shimadzu UV-240 spectrophotometer.

Reagents. Chemicals of analytical grade were used as received. The water used was prepared by distillation of Millipore (milli-R) water in an all-Pyrex glass apparatus, with a Teflon membrane inserted to block mist evolved. Stock solutions (10^{-2} M, 1 M=1 mol dm^{-3}) of various species were prepared by dissolving chlorides or nitrates, or sodium or potassium salts in water otherwise stated elsewhere. Luminol solution were prepared daily.

Analysis of Real Samples. Pepperbush or Pond Sediment (0.5 g) was boiled with 10—20 ml of concentrated nitric acid on a hot plate until the appearance of white fumes, and with concentrated sulfuric acid until the solution became colorless. After cooling, the solution was diluted to 100 ml. A 1 ml portion was added to each of several 100 ml volumetric flasks for standard addition of cobalt before dilution to volume, and cobalt was determined as described above.

Results and Discussion

Reagent Concentrations. The concentrations of luminol and sodium hydroxide were optimized at $F_1=1.8$, $F_2=2.7$, and $F_3=4.1$ ml min^{-1}, where F_1,F_2, and F_3 were the flow rates of R_1, R_2, and R_3, respectively. There is a reagent concentration giving the highest signal as shown in Figs. 3 and 4. The concentrations of 5×10^{-5} M for luminol and 0.16 M for sodium hydroxide were chosen for further experiments. These concentrations are several times higher than those in the previous system[18] because of the dilution of reagent solution with water of R_2, but the luminol concentration is one-fiftieth of that in the conventional CL system. From the absorption spectra, it was confirmed that there was no appreciable decrease in the luminol concentration due to the sonication.

Flow Rates of the Reagent Solutions. The effect of the flow rates F_1, F_2, and F_3 on the signal is represented in Fig. 5. In the experiment, F_1 is set at the lowest flow rate, 1.3 ml min^{-1} which can be achieved readily because the longer the resident time of luminol solution in the sonication cell, the higher the signal. As can be seen from the figure, the higher signal is obtained at each F_2 when F_3 is nearly equal to F_1+F_2, the highest signal being obtained at 1.6 for F_2 and 2.8 ml min^{-1} for F_3. With F_2 over 1.6 ml min^{-1}, further increased signal was not observed because of excess dilution of the sonicated luminol solution with water.

Effect of Surfactants. Surfactants (amphiphilic molecules) which have distinct hydrophobic and hydrophilic regions spontaneously form molecular aggregates in solution called micelles when they reach a certain concentration (critical micelle concentration, cmc). Organized molecular assemblies like micelles have currently been utilized in many types of analytical method,[20,21] because solutes accommodated in molecular assemblies often achieve a great degree of organization compared to homogeneous solution. In CL measurements, for instance, the use of micellar solution as reaction medium is very attractive because of the acceleration of CL reaction and the solubilization of CL reagents insoluble in water. So far there have been several reports on the analytical application of CL in micellar solution.[22-26]

In order to investigate whether micellar media func-

tion effectively for the present SCL system, various surfactants were examined by adding to the carrier stream R_2. The results are shown in Table 1. Anionic surfactants increased the signal (max. 6 times increase for 0.03 M sodium dodecyl sulfate, SDS), whereas for cationic surfactants significant decreases in the signal were observed. This might be rationalized in terms of the following micellar effect. Owing to its charge, luminol monoanion (the most abundant species of luminol in the present alkaline solution) migrates easily on the cationic micellar surface. From the absorption spectra of luminol showing that λ_{max} at 300 and 349 nm in water are red-shifted by ca. 5 nm in the hexadecyltrimethylammonium bromide (CTAB) micellar solution, it is reasonable to consider that luminol monoanion is solubilized in the Stern layer where is less polar than in bulk water. This is supporte by the fact that the degree of the red shift is equivalent to that in 50% ethanol solution, namely, the hydrophobicity in the solubilization site is corresponding to that in 50% ethanol solution. For SDS, Triton X-100, and Brij 35 micellar solutions, no spectral changes were observed. This means that luminol monoanion is mainly solubilized in bulk water. Superoxide anion radical (a reactive species in the present SCL system) also migrates easily on the cationic micellar surface and hence reacts with luminol monoanion noncatalytically through a pathway in which cobalt(II) does not participate as stated later. On the other hand, cobalt ion is repelled electrostatically from the cationic micellar surface, but attracted to and concentrated on the anionic micellar surface. Consequently, the positively charged micellar surface causes the decrease in superoxide anion radical participating in Co(II)-catalyzed SCL reaction and/or the decreased cobalt ion-luminol monoanion interaction due to the charge separation, resulting in the suppression of Co(II)-catalyzed SCL reaction. In contrast, the concentration of cobalt ion on the negatively charged micellar surface favors the Co(II)-catalyzed

SCL reaction.

The results for the conventional CL system are also shown in the table, indicating that any surfactants tested slightly increased the signal. This suggests that a cobalt(II)–hydrogen peroxide complex which is considered to work as a catalyst in the conventional CL system[27] may be noncharged species. And also this strongly suggests that the mechanism of SCL is different from that of the conventional CL.

Analytical Characteristics of the SCL System. Under the recommended conditions (as specified in Fig. 2), the analytical characteristics of the system were investigated. The results are summarized in Table 2. The SCL method has extremely high sensitivity and good reproducibility; the analytical characteristics are comparable to those for the conventional CL system. The detection limit is 10 times lower than that by the gallic acid CL method developed previously by the authors[28] which is more sensitive than any other method. For the measurement by continuous sample flow, the presence of SDS did not serve to improve sensitivity because it caused high background and severe noise; this was also the case for both types of the measurement in the conventional CL system. The logarithmic calibration graph for 10-μl sample injection exhibited a straight line with a slope of unity and linear dynamic range of 10^3. For continuous sample flow it gave a slightly larger slope and narrow linear dynamic range as well as in the conventional CL system.

Effect of Other Substances. Most of classical solution CL methods suffer from poor selectivity. Especially, the luminol CL method permits 30 species to enhance the luminescence reaction.[29] The present SCL system is very selective as shown in Table 3, despite of the use of luminol. Only strong oxidizing agents like hexacyanoferrate(III) and permanganate provided CL signals 0.1% of that for cobalt(II); other species enhanced the emission very weakly or gave rise to no emission. The selectivity for the conventional CL system is also represented in the table, the selectivity being equivalent to that for the SCL system. This means that the SCL technique itself does not yield such high selectivity. The high selectivity presumably derives from the measurement in flow. In general, a flow injection system often provides better selectivity than the corresponding batch system.

Table 3. Selectivity

Species[a]	Relative molar signal	
	SCL method	CL method
Co(II)	1000	1000
$[Fe(CN)_6]^{3-}$	2	0.2

	DABCO[d)]	10^{-5}	110	100
		10^{-4}	140	100
		10^{-3}	130	90

a) 10-μl injection of 10^{-8} M solution. b) The value 100 means no effect. c) Nitro Blue Tetrazolium (Registry No. 38184-50-8). d) 1,4-Diazabicyclo[2.2.2]octane. e) No signal.

species eliciting no emission or very weak emission per se suppressed the Co(II)-catalyzed emission, except permanganate and hexacyanoferrate(III). The suppressions due to anionic species are based on the complexation or precipitation reaction with cobalt(II). Although the suppressions due to cationic species can not be fully explainable, such cationic species at high concentration levels may compete the site on the anionic micellar surface with cobalt, resulting in inhibition of the interaction between cobalt and luminol monoanion (and/or superoxide anion radical) and/or may catalyze effectively the disproportionation reaction of superoxide anion radical[30,31] on the anionic micellar surface, resulting in decrease in the superoxide anion radical concentration. Accordingly, the presence of SDS seems to cause or amplify the suppression . In fact, for instance, the suppressive interferences due to lead and calcium were no longer observable in the absence of SDS; these species at 10^{-4} M increased the Co(II)-catalyzed signals by 10 and 20%, respectively and 10^{-5} M they did not interfere. Therefore, no addition of SDS to the system may be recommended in order to reduce or eliminate interferences, although the sensitivity decreased slightly. Needless to say, the interferences can be reduced by dilution.

Mechanistic Study of the SCL. As stated above, the effect of surfactants on the Co(II)-catalyzed signal strongly suggests the difference in luminescent reaction mechanism between the SCL and the conventional CL. In order to confirm this suggestion, various trappers for reactive species which were considered to react luminously with luminol were added to the carrier stream R_3. The results are summarized in Table 5. Remarkable decrease in the Co(II)-catalyzed SCL signal was led to by the addition of Nitro Blue Tetrazolium (NBT), indicating that superoxide anion radical ($O_2^{\cdot-}$) contributed to the Co(II)-catalyzed SCL reaction. It is well known that luminol react with $O_2^{\cdot-}$ to emit light.[32] On the contrary, any trapper tested did not cause appreciable change in the Co(II)-catalyzed CL signal. Therefore, it can be said that these reactive species do not take part in the conventional CL reaction. This is consistent with the idea that a Co(II)–hydrogen peroxide complex plays an important role in the Co(II)-catalyzed CL reaction.[27]

Superoxide anion radical is generated ultrasonically in alkaline solution. The irradiation of strong ultrasound first leads to the dissociation of water molecule to hydrogen atom (·H) and hydroxyl radical (·OH). The ·H produced reacts with dissolved oxygen molecule to form hydroperoxide radical,[33,34] which immediately deprotonates to form $O_2^{\cdot-}$ in alkaline solution.

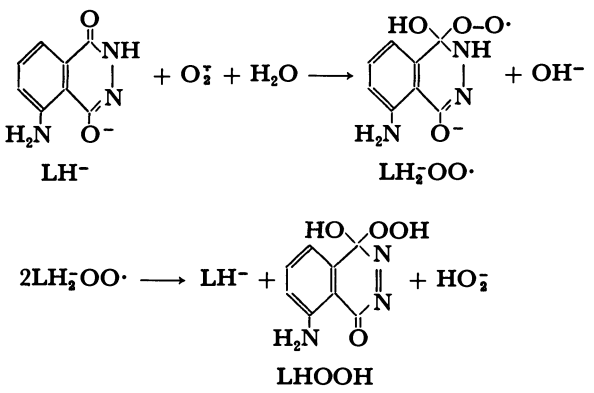
$$\cdot H + O_2 \longrightarrow HO_2^{\cdot}$$

$$HO_2^{\cdot} \rightleftharpoons O_2^{\cdot-} + H^+ \quad (pK_a = 4.8)$$

Superoxide anion radical is unstable in water, but its stability is greatly increased in alkaline solution;[35] the half-life of its decay is 10 s at pH 11.3.[32] In fact, the sonication of alkaline solution without luminol (in this case, luminol is added to the stream R_3) also provided Co(II)-catalyzed signal, about half the signal in the sonication of alkaline luminol solution. Although how much $O_2^{\cdot-}$ is produced by the sonication is unknown, its concentration will not exceed 10^{-5} M, the concentration produced upon electron irradiation of alkaline solution without luminol but with methanol or formate as a trapper for ·OH which consumes $O_2^{\cdot-}$.[32] In the present SCL system, the presence of luminol and furthermore the absence of such trapper will enable the $O_2^{\cdot-}$ concentration at the mixing joint J (see Fig. 1) to be far below 10^{-5} M. This low concentration of $O_2^{\cdot-}$ might cause in part

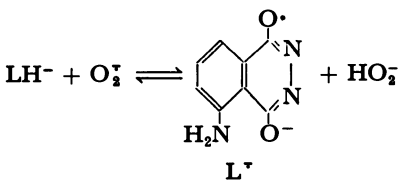
severe interferences due to other substances as stated above.

According to the pulse radiolysis experiments by Merényi et al.,[32] there are two routes where luminol (LH_2) may react with $O_2^{\cdot-}$ to chemiluminesce, that is,



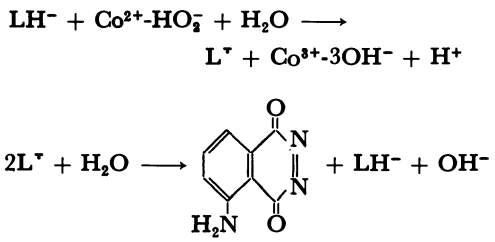
Scheme 1.

The hydroperoxide LHOOH formed, a short-lived CL intermediate, affords the excited aminophthalate through a rearrangement to the endoperoxide and a two-step decomposition.[36]



Scheme 2.

The SCL signal in the absence of Co(II), i.e., the background signal is conceivably based on reaction Scheme 1 with very small luminescence quantum efficiency (10^{-6}).[32] In contrast, the quantum efficiency for the luminescence arising from reaction Scheme 2 is 10^{-2}—10^{-3},[32] the same order of that for the conventional CL reaction whose reaction mechanism is proposed by Burdo and Seitz as shown in Scheme 3.[27]



Scheme 3.

The diazaquinone L produced gives LHOOH through nucleophilic attack by hydroperoxide ion HO_2^-.[34,37] That the SCL method has the analytical sensitivity comparable to that for the conventional CL method, implies that both methods have the same order of luminescence quantum efficiency. Therefore, it is reasonable to consider that reaction Scheme 2 operates in the presence of cobalt(II). Furthermore, considering the similarity that the formation of luminol radical ($L^{\cdot-}$) appears in reaction Schemes 2 and 3, it seems likely that cobalt(II) works catalytically on the direct electron-transfer reaction to form $L^{\cdot-}$. At present stage, however, we can not say how cobalt(II) contributes to the electron transfer reaction.

Application to Real Samples. The applicability of the proposed method was evaluated by assaying NIES (National Institute for Environmental Studies) standard reference materials (Pepperbush[38] and Pond Sediment[39]). Standard additions of cobalt to acid-digested samples indicated that the results obtained for Pepperbush (23, 24 $\mu g\,g^{-1}$) by the 10-μl sample injection method with SDS and Pond Sediment (30, 29 $\mu g\,g^{-1}$) by the continuous sample flow method without SDS were within the certified values (23±3 and 27±3 $\mu g\,g^{-1}$, respectively).

Conclusion

In this paper, we have indicated the analytical utility of ultrasound-induced luminescence in solution through the determination of ultratraces of Co(II) using luminol SCL phenomenon. This novel SCL method is unique in being capable of detecting Co(II) selectively at sub-pg or sub-pg ml^{-1} levels with no use of oxidizing agents intentionally added, in contrast with the conventional luminol CL method. No other method can surpass the SCL method with regard to the sensitivity, the detection limit (0.00006 $ng\,ml^{-1}$) being much lower than those for flameless atomic absorption (0.2 $ng\,ml^{-1}$) and fluorescence methods (1 $ng\,ml^{-1}$), neutron activation analysis (0.5 $ng\,ml^{-1}$), and inductively coupled plasma emission method (0.1 $ng\,ml^{-1}$). We have also made it clear that the mechanism of SCL reaction is different from that of conventional CL reaction and ultrasonically generated $O_2^{\cdot-}$ plays a key role in the Co(II)-catalyzed SCL emission.

Although the SCL method could not be superior to the conventional CL method with respect to the analytical characteristics, the present work revealed that strong ultrasound was of great value as an energy source for eliciting luminescence. Accordingly, there is much possibility of finding out new luminescence systems usable in analysis because the reactive species ultrasonically generated react luminously with various organic compounds in solution and because the direct excitation of chemical species in solution by ultrasound leads to sonoluminescence (SL). These investigations are now in progress.

(Received January 16, 1986)

The electrolyte effect on the homogeneous chemical equilibria of $Ni(bfac)_2$, $Ni(ftac)_2$, and $Ni(ttac)_2$ in dimethyl sulfoxide has been studied by means of polarographic and ultraviolet spectral measurements, where $bfac^-$, $ftac^-$, and $ttac^-$ represent the enolate anions of benzoyltrifluoroacetone, 2-furoyltrifluoroacetone, and 2-thenoyltrifluoroacetone respectively. The chemical equilibria of these complexes in 0.05 mol dm^{-3} TBAP solutions found previously:

$$Ni(bi\text{-}L)_2 \rightleftharpoons Ni(bi\text{-}L)(uni\text{-}L) \rightleftharpoons Ni(bi\text{-}L)^+ + L^- \rightleftharpoons Ni(uni\text{-}L)^+ + L^-$$

shifted more to the right in the presence of one of the electrolytes ($NaClO_4$, $KClO_4$, $RbClO_4$, $CsClO_4$, TMAP, or TEAP) at the same concentrations as TBAP; bi- and uni- mean that the ligands coordinate to the metal as bidentate and unidentate respectively. Under the conditions of $[NiL_2]=1$ mmol dm^{-3} and $[MClO_4]=0.05$ mol dm^{-3}, the molar fractions of the species of the $Ni(bi\text{-}L)_2$ type decreased with an increase in the inverse of the cationic radii. Such a tendency was explained mainly in terms of the interaction between the π-electron system of $Ni(bi\text{-}L)_2$ and those cations. For the same metal perchlorates, except $NaClO_4$, the stability of $Ni(bi\text{-}L)_2$ decreased in the order of: $bfac^- > ftac^- > ttac^-$.

The homogeneous chemical equilibria and the electrode reactions of ten bis(β-diketonato)nickel(II) complexes in dimethyl sulfoxide (DMSO) were investigated by means of conductivity and electronic spectral measurements, cryoscopy, polarography, and cyclic voltammetry.[1-5] It was found polarographically that five complexes, viz., $Ni(bzac)_2$,[1,6] $Ni(dbm)_2$,[2,6] $Ni(bfac)_2$,[2] $Ni(ftac)_2$,[2] and $Ni(ttac)_2$,[2] were involved in the following homogeneous chemical equilibria:

$$Ni(bi\text{-}L)_2 \rightleftharpoons Ni(bi\text{-}L)(uni\text{-}L) \rightleftharpoons Ni(bi\text{-}L)^+ + L^- \rightleftharpoons Ni(uni\text{-}L)^+ + L^- \quad (1)$$

where bi- and uni- mean that the ligands coordinate to the metal as bidentate and unidentate respectively.

The present paper deals with the electrolyte effect on the above chemical equilibria of $Ni(bfac)_2$, $Ni(ftac)_2$, and $Ni(ttac)_2$ in DMSO polarographically and spectrophotometrically, where $bfac^-$, $ftac^-$, and $ttac^-$ indicate the enolate anions of benzoyltrifluoroacetone, 2-furoyltrifluoroacetone, and 2-thenoyltrifluoroacetone respectively.

Experimental

Reagents. The alkali metal perchlorates,[1] tetrabutylammoium β-diketonates (n-Bu_4NL),[2] and DMSO[7] were the same as those described previously. Tetramethylammonium perchlorate (TMAP) and tetraethylammonium perchlorate (TEAP), purified for polarographic measurements, were obtained from Nakarai Chemicals, Ltd. These salts were recrystallized once from ethanol, followed by drying in vacuo at 60 to 70 °C for a minimum of 10 h. Tetrabutylammonium perchlorate (TBAP) was prepared in the usual way.[8]

Apparatus, etc. The apparatus was the same as that described in a previous paper.[7] The scan rate of polarographic measurements was 2 mV s^{-1}. Two dropping-mercury electrodes were used. The A electrode had an m value of 0.890 mg s^{-1} and a drop time, t_d, of 6.60 s at −1.0 V vs. SCE when measured in an air-free 0.05 mol dm^{-3} TBAP–DMSO solution at a height of 50 cm in the mercury reservoir. The B electrode had an m value of 1.055 mg s^{-1} and a t_d value of 5.48 s at −1.0 V when measured under the above conditions.

The current-potential curves and ultraviolet spectra were obtained at 25.0±0.2 and 25.0±0.5 °C respectively, except in the temperature-effect experiments.

Results

Polarography. The polarographic behavior of $Ni(bfac)_2$, $Ni(ftac)_2$, and $Ni(ttac)_2$ was studied in DMSO containing 0.05 mol dm^{-3} TBAP as a supporting electrolyte.[2] In Fig. 1, three typical polarograms of $Ni(bfac)_2$ in other supporting-electrolyte solutions are shown in the potential range less negative than

1) Each in 0.05 mol dm^{-3}. 2) The $\bar{i}_j/\bar{i}_t$ ratios were obtained at a concentration of 1 mmol dm^{-3} under a controlled drop time, where j=1—4. The meanings of $\bar{i}_j$ and $\bar{i}_t$ are shown in Fig. 1. 3) The first wave split into two peaks in differential-pulse polarography.

−2.0 V.[9] In this potential range, Ni(bfac)$_2$, Ni(ftac)$_2$, and Ni(ttac)$_2$ each gave four reduction waves in DMSO containing an electrolyte—$KClO_4$, $RbClO_4$, $CsClO_4$, TMAP, TEAP, or TBAP—at a concentration of 0.05—0.1 mol dm^{-3}. When $NaClO_4$ was used as the supporting electrolyte, these complexes each gave three d.c. polarographic waves, of which the first wave at less negative potential split into two peaks differential-pulse (DP) polarographically.[10] The d.c. polarographic data assembled in Table 1 are those for the complexes obtained in the presence of either $NaClO_4$ or $KClO_4$ at a concentration of 0.05 mol dm^{-3}.

Because of partial overlapping, the polarographic properties of the following waves could not be examined in detail: (a) the second and the third waves of Ni(bfac)$_2$ in a TEAP solution and of Ni(ftac)$_2$ in $KClO_4$, $RbClO_4$, $CsClO_4$, and TEAP solutions; (b) the first and the second waves of Ni(ttac)$_2$ in $KClO_4$, $RbClO_4$, and TEAP solutions. The temperature effect on these DP polarograms, however, was closely similar to that observed previously.[2]

In other cases except in $NaClO_4$ solutions, most of the polarographic and cyclic voltammetric properties were the same as those in 0.05 mol dm^{-3} TBAP solutions;[2] the $\bar{i}_j/\bar{i}_t$ values only were dependent on the cations of the supporting electrolytes used (the meanings of $\bar{i}_j$ and $\bar{i}_t$ are shown in Fig. 1). The half-wave potentials ($E_{1/2}$) of the four waves shifted to more negative potentials with a decrease in t_d. When either $KClO_4$, $RbClO_4$, $CsClO_4$, TMAP, or TEAP is chosen as the supporting electrolyte, therefore, it is reasonable to presume the same electrode reaction as that proposed previously.[2] That is to say, the four waves for the complexes are due to the irreversible two-electron reduction of different species with the Ni(II) involved in the homogeneous chemical equilibria (1) but for which the rate of the reestablishment of the equilibria is slow:[11,12] the first, the second, the third, and the fourth waves come from the reduction of Ni(uni-L)$^+$, Ni(bi-L)$^+$, Ni(bi-L)(uni-L), and Ni(bi-L)$_2$ respectively.

In $NaClO_4$ solutions, the first limiting currents ($\bar{i}_1$) were diffusion-controlled for all the complexes. The plots of $\bar{i}_1$ against the mole ratio (L/Ni) indicated that the respective first waves were due to the reduction of the corresponding mono-complexes. Furthermore, the polarographic properties of the second and the third waves in $NaClO_4$ solutions were similar to those of the third and the fourth waves respectively in the other supporting-electrolyte solutions. Thus, the polarographic behavior of the complexes in $NaClO_4$ solutions can be explained by the following electrode reaction:

$$\mathrm{NiL^+} \overset{\text{slow}}{\rightleftharpoons} \mathrm{Ni(bi\text{-}L)(uni\text{-}L)} \overset{\text{slow}}{\rightleftharpoons} \mathrm{Ni(bi\text{-}L)_2}$$

$$\downarrow 2e \qquad \downarrow 2e \qquad \downarrow 2e$$

1st wave 2nd wave 3rd wave

On the basis of the splitting of the d.c. polarographic first waves into DP polarographic peaks mentioned above, it seems likely that the respective first waves result from the reduction of the two mono-complexes.

Assuming that the diffusion coefficients for the different species in the solution are equal, the polarographic current ratios, the $\bar{i}_j/\bar{i}_t$ values, represent their molar fractions for the total complex concentration

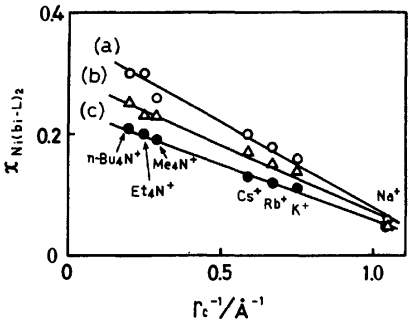

Fig. 2. Plots of the molar fraction of Ni(bi-L)$_2$ vs. the inverse of the cationic radii of supporting electrolytes.

Supporting electrolyte; (a): 0.1 mol dm^{-3} TBAP, (b): 0.02 mol dm^{-3} $NaClO_4$+0.08 mol dm^{-3} TBAP, (c): 0.05 mol dm^{-3} $NaClO_4$+0.05 mol dm^{-3} TBAP, (d): 0.1 mol dm^{-3} $NaClO_4$. Modulation amplitude: 50 mV, pulse interval: 1.0 s. With the DME (B).

(see Table 1). The degree of the dissociation of Ni(bi-L)$_2$ increased with a decrease in the crystallographic (unsolvated) radii of the cations of the supporting electrolytes; linear relationships were obtained between the molar fractions of species of the Ni(bi-L)$_2$ type, the $\bar{i}_4/\bar{i}_t$ values, and the inverse of the cationic radii ($1/r_c$), as is depicted in Fig. 2. For the same metal perchlorates, except $NaClO_4$, the stability of Ni(bi-L)$_2$ decreased in the order of: bfac$^-$>ftac$^-$>ttac$^-$. On the other hand, no difference in their stabilities could be detected in $NaClO_4$ solutions. As can be seen from the DP polarograms in Fig. 3, the sodium ion significantly influenced the chemical equilibria (1) (see also the $\bar{i}_j/\bar{i}_t$ values in Table 1). The first peak at the least negative potential in Curve (a) was detected only at a high sensitivity, because the complex concentration measured was low. It appears that the shift of the peak potentials (E_p) to less negative potentials with an

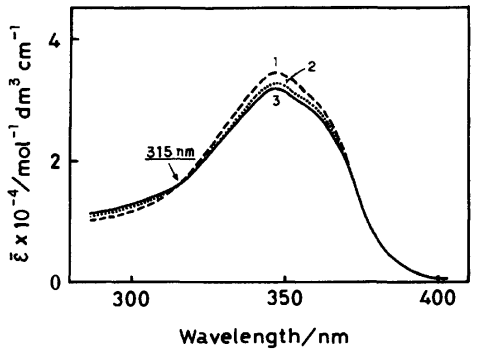

Fig. 4. UV spectra of Ni(ttac)$_2$ at different concentrations in DMSO.
Concn (mol dm^{-3}); (1): 4.0×10^{-6}—1.0×10^{-5}, (2): 1.0×10^{-4}, (3): 7.0×10^{-4}.

increase in the sodium-ion concentration is attributed to the interaction between the reduction products and the sodium ion, e.g., the formation of ion pairs.[13] In addition, the slope of the regression line is considered as the measure of the sensitivity of the stability of Ni(bi-L)$_2$ to the effect of electrolyte cations for a given complex. From this point of view, the stability of Ni(bi-L)$_2$ was subject to the cationic effect in the order of: bfac$^-$>ftac$^-$>ttac$^-$.

Ultraviolet Spectra. In Fig. 4, the electronic spectra of Ni(ttac)$_2$ in the near-ultraviolet region are shown at different concentrations. In this region, similar spectra were obtained for all the complexes. There were isosbestic points at 298, 308, and 315 nm respectively for Ni(bfac)$_2$, Ni(ftac)$_2$, and Ni(ttac)$_2$, though their spectra did not change with time. In the vicinity of the absorption maxima, the apparent molar absorption coefficients ($\bar{\varepsilon}$)[14] increased with a decrease in the concentration of the complexes. Such a tendency corresponds to the dissociation of the complexes, compared with that of some bis(β-diketonato)-nickel(II)[4] and -cobalt(II)[7,15] complexes in the same solvent.

The electronic spectra of the complexes varied slightly in the presence of any one of the electrolytes except $NaClO_4$, while they varied considerably upon the addition of $NaClO_4$. The effects of the sodium ion on the electronic spectra of Ni(bfac)$_2$ and Ni(ttac)$_2$ are illustrated in Figs. 5 and 6 respectively, where the total concentration of the electrolyte is adjusted to 0.1 mol dm^{-3} with TBAP. The addition of the sodium ion at different concentrations to a certain complex solution gave two isosbestic points, of which the one at the shorter wavelength was in agreement with that described above. The isosbestic points for Ni(bfac)$_2$, Ni(ftac)$_2$, and Ni(ttac)$_2$ at longer wavelengths were 347, 352, and 358 nm respectively. They were values near to the isosbestic points observed in the corresponding *n*-$Bu_4NL/NaClO_4$ media—that is, 342, 353, and 358 nm for L$^-$=bfac$^-$, ftac$^-$, and ttac$^-$ respectively.

Discussion

It was described in a previous paper[2] that the dissociation of Ni(bfac)$_2$, Ni(ftac)$_2$, and Ni(ttac)$_2$ in DMSO was enhanced by the presence of TBAP as the supporting electrolyte for polarographic measurements. From the linear relationships given in Fig. 2, it may be concluded that the chemical equilibria (1) in 0.05 mol dm^{-3} TBAP solutions found previously[2] shift more to the right in the presence of one of the electrolytes ($NaClO_4$, $KClO_4$, $RbClO_4$, $CsClO_4$, TMAP, or TEAP) at the same concentrations as TBAP and that the sodium ion is the most effective among the cations used here.

The cationic effect on the chemical equilibria (1) is first considered from the standpoint of the lowering of the activity of the DMSO as a result of the solvation of the electrolyte cations. This effect can be estimated conveniently on the basis of the chemical equilibria (2):

$$\begin{aligned} &\text{Ni(bi-L)}_2\cdot(\text{DMSO})_m \\ &\rightleftharpoons \text{Ni(bi-L)(uni-L)}\cdot(\text{DMSO})_{m+1} \\ &\rightleftharpoons \text{Ni(bi-L)}^+\cdot(\text{DMSO})_{m+2} + \text{L}^-\cdot(\text{DMSO})_n \\ &\rightleftharpoons \text{Ni(uni-L)}^+\cdot(\text{DMSO})_{m+3} + \text{L}^-\cdot(\text{DMSO})_n \end{aligned} \quad (2)$$

Since the solvation of the Ni(II) species on the right hand requires more DMSO molecules, the above equilibria will shift to the left when the addition of a large amount of smaller cations lowers the activity of DMSO; this is contrary to the observed trend.

The isosbestic points at shorter wavelengths (shown in Figs. 4—6) are interpreted as being caused by one of the chemical equilibria (1), and those at longer wavelengths (shown in Figs. 5 and 6), by the interaction of the sodium ion with L^- or a free carbonyl oxygen of the unidentate ligand of Ni(bi-L)(uni-L). Such ion-pair or complex formation should shift the chemical equilibria (1) to the right; however, it seems unlikely to be responsible for the promotion of the dissociation of the Ni(II) complexes in the case of the other cations, especially tetraalkylammonium ions.

Kalinowski and Galazka[16] found that bis(acetylacetonato)copper(II) was involved in complicated equilibria in the presence of the lithium ion in various organic solvents. It was suggested spectrophotometrically that the lithium ion might interact in the unsolvated form. Furthermore, it was stated that the interaction of the lithium ion with the π-electron system of acetylacetonato groups in cyclic form was the more probable of the two possibilities. It is plausible that the linear relationships shown in Fig. 2 are also caused by such an interaction, that is, the interaction between the π-electron system of Ni(bi-L)$_2$ and the cations, though no definite statement can be made at the moment concerning the degree of solvation for the interacting cations. A smaller ion generates in its vicinity a more powerful electrostatic field than a large ion of the same charge. The above interaction seems to be the reason for the complication of the quantitative treatment of the chemical equilibria (1). The stability of Ni(bi-L)$_2$ observed, i.e., bfac$^-$> ftac$^-$>ttac$^-$, did not coincide in order with that to be expected from the aromaticity of the substituents,[17] the pK_a values of the ligands,[18] and the carbonyl ^{13}CNMR chemical shifts of the ligands in DMSO,[19] i.e., bfac$^-$>ttac$^-$>ftac$^-$. As has been suggested from the order of susceptibility of the stability of Ni(bi-L)$_2$ to the cationic effect, i.e., bfac$^-$>ftac$^-$>ttac$^-$, it is necessary to take into account the competitive interaction of the cations and the DMSO molecules with Ni(bi-L)$_2$.

The authors wish to acknowledge the useful suggestions of Professor Nobuo Suzuki, of Tohoku University, and Dr. Kazuko Tanaka, of the Institute of Physical and Chemical Research, in the field of solution chemistry.

The Distribution and Characterization of ^{137}Cs in Shallow Water Sediments

Kikuo TERADA,* Madoka HAMANO, Kazuhisa KOMURA,† and Ken MATSUMOTO
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa 920
†Low Level Radioactivity Laboratory, Faculty of Science, Kanazawa University, Wake, Tatsunokuchi, Ishikawa 923-12
(Received January 22, 1986)

The distribution and characterization of ^{137}Cs in shallow water sediments are investigated. The concentration of ^{137}Cs in surface sediments which have been collected from the 10—20 m depth of Tsukumo Bay, Noto Peninsula, tends to decrease with an increase in the distance from the inner part of the bay to the outer part. Vertically, ^{137}Cs contents gradually decrease to the 10 cm depth and then steeply decrease beyond this depth, until at the 15 cm depth no activity is observed. A sequential extraction technique with several kinds of extractants has been employed to survey the chemical form of the nuclide in the sediments. ^{137}Cs is completely extracted with an ammonium nitrate solution suggesting that the nuclide is strongly adsorbed in the crystal lattice of some clay minerals and is exchangedly desorbed from the sediment phase by ammonium ions in a high concentration. A core sample has been elutriated in five components of different grain sizes, and the contents of sodium, potassium, and ^{137}Cs have been determined. It has been revealed that a unit amount of the finest component contains about three times as much of the nuclide as that of the coarsest one. On the contrary, the potassium contents slightly decrease with the decrease in the particulate size.

The behavior of ^{137}Cs at the seawater/sediment interface, especially in esturine or shallow water, is of very interest because radionuclides of a moderately long half-life have been distributed a world-wide scale as a result of nuclear-weapons testing and reprocessing plants of nuclear power and have thus been introduced into the ecological system in these shallow water regions, closely correlated human activity.

Radiocesium is considered to be present in seawater, principally as a simple Cs^+ ion like ^{90}Sr, and to be scarcely captured at all by suspended substances such as marine planktons.[1,2] On the other hand, Nagaya et al.[3] have found that up to about 6% of ^{137}Cs exists in coastal seawater, bound to particulate materials. In addition, several investigations have been carried out studying the sorption behavior of the nuclide by means of some clay minerals, rocks, and soil components.[4-8] However, these studies have been concerned with purified soil components, a few synthetic mixtures of clay and soil, or laboratory experiments using natural sediment; little information has appeared in the literature on the distribution of ^{137}Cs in marine sediments. The present paper will describe the distribution and characterization of this nuclide, as correlated with other alkali metals in shallow water sediments which have been elutriated into five components of different grain sizes, the extraction property of ^{137}Cs with several kinds of extractants from the sediment, the sorption and desorption behavior of this nuclide on each elutriated component, and the determination of the sorption capacities of these components for ^{137}Cs.

Experimental

Apparatus and Reagents. An ORTEC 8501-1523S true coaxial Ge(Li) detector (80 cm^3; resolution of ^{60}Co at 1330 keV:1.9 keV; relative efficienty: 15.1%), coupled to an ORTEC Model-6200, 4000-channel pulse height analyzer, was used for the low-level background counting of ^{137}Cs at the Low Level Radioactivity Laboratory, Kanazawa University. A Shimadzu AA-646 atomic absorption/flame-emission spectrophotometer was used for the analyses of sodium and potassium. A Rigaku Denki X-ray powder diffractometer and a Hitachi 20PR refrigerated centrifuge and 500-cm^3 polyethylene centrifuge bottle were also used.

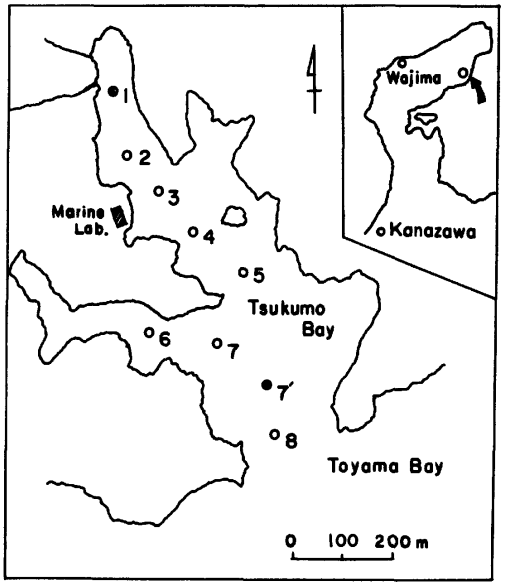

Fig. 1. Sampling Station in Tsukumo Bay.

All the reagents used were of a guaranteed reagent grade.

Materials. Sediment samples were collected from a depth of about 10—20 m in Tsukumo Bay, Noto Peninsula, with a Smith-Mackintire sampler and a Phleger gravity corer. The sampling sites are illustrated in Fig. 1. After sampling, core samples were immediately collected, by using a polyacrylic resin cylinder (i.d. 50 mm), from the sample collected by means of the Smith-Mackintire sampler. The core was cut into three layers, each 30 mm long. Each layer of the core was immediately centrifuged at 7000 G for 30 min at 5 °C to remove any interstitial water. The centrifuged samples were then submitted to elutriation as follows: About 30 g of the

sample was placed in a polycarbonate resin beaker, stirred with 800 cm^3 of distilled water, and then allowed to stand for 3 min. After thus standing, the suspension was transferred into another polycarbonate resin beaker. The residual sediment in the first beaker was treated as has been described above, using fresh distilled water, until the supernatant became almost clear. The suspensions were collected in the second beaker. The deposited fraction was named 3MP. The contents of the second beaker were stirred vigorously and then allowed to stand for 10 min. The suspensions obtained by the same procedure were collected in the third beaker. The deposited sediment fraction was named 10MP. Then, the suspension was sequentially elutriated into the fractions deposited after standing 1 h and 5 h and suspended after standing 5 h, these fractions being named 1HP, 5HP, and 5HS respectively. At the same time, in a small portion of the first suspension the chloride concentration was determined by Mohr's method in order to evaluate the contribution of seawater to the determination of sodium and potassium in the sediment.

Determination of ^{137}Cs. About 0.7—10 g of a dry sample was used for the γ-counting of ^{137}Cs. The samples available in amounts larger than 3 g were made into a disc 20 or 50 mm diameter by pressing, while the others were shielded in a small polyethylene pouch; then γ-counting was performed. In the sequential extraction procedure, about 30 g of the dry sample was used.

Determination of Sodium and Potassium. About 0.2 g of the sample was decomposed with an acid mixture (0.5 cm^3 of 60% perchloric acid+3 cm^3 of concd nitric acid+ 5 cm^3 of 47% hydrofluoric acid) in a PTFE beaker by heating on a hot plate at ca. 120 °C. This treatment was repeated 3—4 times. The residue was then dissolved in 5 cm^3 of 6 mol dm^{-3} hydrochloric acid and filtered through Toyo No. 5B filter paper. The filtrate was made up to 25 cm^3 with pure water. After appropriate dilution, sodium and potassium were analyzed by means of flame photometry at the wavelengths of 589.3 and 766.2 nm respectively.

Sequential Extraction of ^{137}Cs from the Sediment. About 30 g of a dry surface sediment sample containing 0.30± 0.014 pCi $^{137}Cs\,g^{-1}$ was put into a 100 cm^3 stoppered polyethylene centrifuge tube and shaken with 50 cm^3 of a methanol-acetone mixture (1:1 v/v) for 30 min. After centrifugation at 3000 rpm for 20 min, the supernatant was separated, evaporated to a small volume in a PTFE beaker, and then transferred into a shallow plastic dish 50 mm in diameter in order to dry it up. Finally, the contents of the dish were submitted to γ-counting. Next, to the sample remaining in the centrifuge tube 50 cm^3 of a 0.5 mol dm^{-3} magnesium chloride solution was added; the contents were then shaken and centrifuged as has been described above. The γ-counting of the magnesium chloride extract was also carried out. Then, the residual sediment was treated successively with a 0.5 mol dm^{-3} sodium hydroxide solution, 1 mol dm^{-3} hydrochloric acid, and a 50% ammonium nitrate solution. Finally, the residual sediment, which had been reduced to 23.6 g during the extraction procedure, was dried and pressed into a disc 50 mm in diameter for γ-counting.

Sorption Experiments of ^{137}Cs Using the Sediments. Filtered seawater which had been collected from the surface of Tsukumo Bay was spiked with ^{137}Cs (nitrate form) so as to make its concentration about 20000 cpm cm^{-3} and then allowed to stand for 1 d in order to attain equilibrium. An air-dried elutriated sample was pulverized to under 400 mesh with an agate mortar and placed (1.0 g) in a polycarbonate resin beaker. Then about 400 cm^3 of the ^{137}Cs-spiked sea water was added to it, after which the contents were vigorously stirred and allowed to stand with a loose cover. After one day, 3 cm^3 of supernatant was pipetted out and filtered through a small piece of dry filter paper. One cm^3 of the filtrate was pipetted out into a polyethylene test tube, and the radioactivity was measured by means of a NaI(Tl) scintillation counter. The contents of the beaker were then stirred and allowed to stand for one more day. The measurement of the radioactivity of the supernatant was carried out as has been described above until an equilibrium was attained.

Table 1. Contents of Potassium and ^{137}Cs in Surface Sediments (Tsukumo Bay, 1983-9-19)

Station	Depth	K	^{137}Cs	$^{137}Cs/K$
	m	%	pCi/g dry	pCi/meq
1	10	1.19	0.45±0.02	1.4_8
2	16	1.14	0.35±0.03	1.1_9
3	21	1.23	0.35±0.02	1.1_1
4	23	1.40	0.24±0.03	0.6_7
5	24	1.34	0.26±0.02	0.7_6
6	20	1.56	0.20±0.03	0.5_0
7	21	1.30	0.27±0.03	0.8_1
8	22	1.11	0.17±0.03	0.5_9

Measurement of Distribution Coefficient, K_d. Each sediment sample which adsorbed ^{137}Cs in the above experiment was separated from the supernatant by decantation, followed by centrifugation using a 50 cm^3 polyethylene bottle. The sediment in the bottle was washed with a small portion of seawater, and the washing was rejected by centrifugation. This procedure was repeated several times. Finally, 40 cm^3 of filtered seawater was put into the bottle, and the bottle was shaken for 24 h. After centrifugation, the radioactivity of the supernatant was measured as above.

Measurement of Sorption Capacity for ^{137}Cs. Cesium chloride (3.75 g) was dissolved in 200 cm^3 of the ^{137}Cs-spiked seawater. About 0.5 g of the powdered elutriated sample was then added to 25 cm^3 of the above seawater containing 1.39 meq of cesium (about three times the contents of sodium and potassium), and the contents were shaken for 20 h. After centrifugation, 1 cm^3 of the supernatant was submitted to γ-counting and the sorption capacity was calculated.

X-Ray Powder-Diffraction Measurement. In order to estimate the mineral composition of each elutriated sample, X-ray powder diffractometry was carried out. In particular, in order to distinguish the peaks of the clay minerals, measurements were performed after treating the sample with several kinds of reagents, e.g., ethylene glycol for montmorillonite and haloisite, ammonium nitrate for magnesium vermicurite, hydrochloric acid for kaolinite, vermicurite and chlorite, and potassium acetate for kaolinite minerals. The parameters used were Cu K_α (15 mA, 35 kV), a Ni filter, and a slit system (1°—0.3 mm—1°).

Results and Discussion

Distribution of ^{137}Cs in the Sediments. The ^{137}Cs contents of surface sediments of Tsukumo Bay are given in Table 1. The ^{137}Cs contents tend to decrease

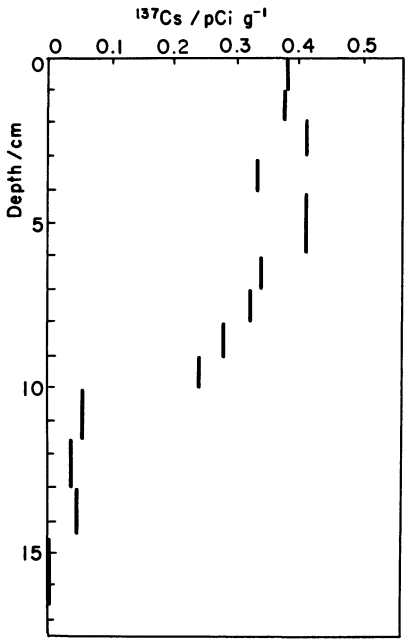

Fig. 2. Vertical distribution of ^{137}Cs in a sediment core.

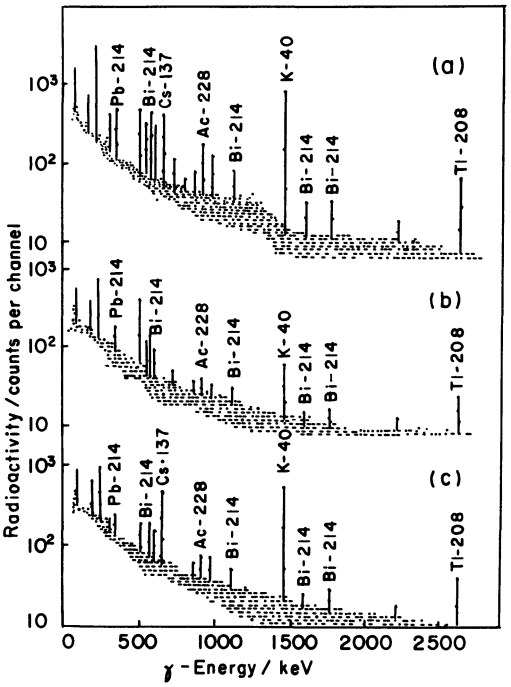

Fig. 3. Gamma-spectra of the raw sediment and extracts. (a) raw sediment, (b) extract with 1 mol dm^{-3} HCl, (c) extract with 50% NH_4NO_3.

with an increase in the distance from the inner part of the bay to the outer part. This fact suggests that, after ^{137}Cs has been transferred into the bay in several ways, e.g., through the river water and precipitation, and from the surroundings, this nuclide should sink down rather quickly and be captured by bottom sediments.

A core sample collected at St. 7' with the Phleger gravity corer was cut in 10 mm sections, and the γ-activity was measured. The vertical profile of the ^{137}Cs contents thus obtained is illustrated in Fig. 2. At 7—8 cm from the surface, the ^{137}Cs contents decrease to about one half-of that at the surface; beyond a depth of 10 cm the radioactivity of ^{137}Cs steeply decreases, until no activity is observed at the depth of 15 cm.

At the same time, the age of each section was determined by means of the ^{210}Pb method. The depth vs. time curve showed a straight line between depths of 30 mm and 110 mm, corresponding to about 44 years. As can be seen from Fig. 2 and the results of the age determination, ^{137}Cs can only slowly migrate downward through the sediment layers after deposition.

Extraction of ^{137}Cs from the Sediment Phase. Figure 3 (a)—(c) show the γ-spectra of the raw sediment, the extracts with 1 mol dm^{-3} hydrochloric acid, and 50% ammonium nitrate solutions. No measurable peak for ^{137}Cs is found in the spectra of the extracts with the methanol-acetone mixture, magnesium chloride, and sodium hydroxide solutions, as in the final residual sediment as hydrochloric acid extract (b). On the other hand, the extract with the ammonium nitrate solution gave a sharp peak of the nuclide, and the radioactivity of ^{137}Cs in the extract indicates that an almost complete extraction has been attained. Thus, scarcely ^{137}Cs seems to be present bound to any organic substances such as a humic substance, weakly or electostatically adsorbed on sediment surfaces, or in acid-soluble form. Miettinen et al.[9] have also reported that only 5% of the ^{134}Cs was eluted with 0.1 mol dm^{-3} hydrochloric acid from a ^{134}Cs-labelled sediment which had been collected from the Gulf of Finland. In the present experiments, however, about 15% of the initial amount of ^{137}Cs in the raw sediment was lost during the sequential extraction; this could not be measured in each extract. Therefore, an unmeasurable amount of the nuclide might be extracted in every extraction step according to the sorption-desorption equilibrium. On the other hand, the fact that almost all the ^{137}Cs was extracted in the 50% ammonium nitrate solution indicates that the nuclide in the sediments is contained in the phase of clay minerals and is exchangedly desorbed from the sediment by ammonium ions in a high concentration, because the effective ionic radii of ammonium ions and cesium ions resemble each other,[10] so the former ion can intrude into the crystal lattice of clay minerals and replace the latter ion.

Distribution of ^{137}Cs in the Components of Different Grain Sizes of the Sediments. Two samples collected from St. 1 and 7' were investigated for the distribution of ^{137}Cs, depending on the difference in the grain sizes of the components of the sediments.

The amount of each component obtained by elutriation, the contents of ^{137}Cs, sodium and potassium,

	5HS	13.9	0.17	0.90	0.64±0.14	2.7_8

a) Grain sizes of the components are; 3MP: 31—16 μm, 10MP: 16—7.8 μm, 1HP: 7.8—3.9 μm, 5HP: 3.9—1.9 μm, 5HS: <1.9 μm.

and the ^{137}Cs/K ratios (pCi/meq) in these components are shown in Table 2. The weight percentages of the coarsest component most abundant in both sediments are above 62 and 42% respectively in St. 1 and 7′. The next most abundant component consists of the finest particulates in both sediments; their weight percentages are above 12 and 14% for St. 1 and 7′ respectively. This tendency is observed in every three layer of the sediment core. The concentration of ^{137}Cs in the unit amount of each component of the elutrilated sediment sample shows a more marked tendency, that is, the finer the grain size of the component, the higher the concentration of ^{137}Cs. The finest component contains about three times the quantity of the nuclide as the coarsest ones. On the contrary, the potassium contents slightly decrease with the decrease in grain size. Subsequently, the ^{137}Cs/K ratios show a remarkable increase with the decrease in the grain size of the components. In St. 1 and 7′, the ratios for the finest components amount to more than 6 and 10 times, respectively, those of the coarsest ones. These facts indicate that the nuclide tends to concentrate in the fine components of the sediment, in spite of its lower sodium and potassium contents. As a result of the X-ray powder diffraction measurements, it was observed that the peak height of potassium feldspar was highest for the coarsest component, while that of cristobalite was dominant in the finest component, except for calcite in St. 7′. However, because, unfortunately, no detailed information has been obtained on clay minerals in the present study, it is still obscure to what kinds of clay minerals the highest concentration of ^{137}Cs in the finest componet of the sediments should be attributed. In any event, it can be thought that the fine components contain a large number of exchangeable sites for cesium and that they probably exist in some clay minerals such as montmorillonite and kaolinite, as has been reported many authors.[4-8]

5HS	1.105	3650	3850

Table 4. Sorption Capacity for Cesium and Exchange Balance between the Correlated Elements

Sample	Sorption capacity for Cs	Na contents	K contents	Cs sorbed/(Na+K) ratio
	meq g^{-1}	meq g^{-1}	meq g^{-1}	
3MP	0.32	0.61	0.39	0.32
10MP	0.15	0.46	0.34	0.19
1HP	0.20	0.30	0.31	0.33
5HP	0.23	0.13	0.23	0.64
5HS	0.29_7	0.06_5	0.23	1.01

In the present investigation, laboratory experiments using ^{137}Cs tracer have been performed to clarify the above postulation.

Sorption of ^{137}Cs on the Sediments. The results obtained by sorption experiments on the ^{137}Cs on the elutriated components of sediments are shown in Fig. 4. A blank experiment no sorption of the nuclide on the walls of the beakers used was observed. During 24 h standing, the sorption equilibrium seems almost to be attained, since the decrease in the radioactivity in the aqueous phase becomes significantly slow after one-day standing. After seven days, the sorption equilibrium is completely attained, when about 81.2% of ^{137}Cs has been adsorbed by the coarsest component, while by the finest component about 90% of the initial activity is captured from seawater in a volume 400 as much as the sediment phase. Furthermore, it was observed that the latter component adsorbed ^{137}Cs more quickly than the former one.

The distribution coefficients of ^{137}Cs between the sediments and seawater are shown in Table 3. (The 10MP sample was mistested because the sorption behavior very closely resembled the 5HP component.) The results show that the K_d values increase with the decrease in the grain size of the sediment components. In the present study, the components of different grain sizes were pulverized to under 400 mesh; therefore, the surface areas are thought to be not so very different and to have no effect on the K_d value or the sorption capacity. Thus, the K_d value for the finest component is about 1.8—1.9 times that for the coarsest ones. As can be seen from Table 3, a fairly good agreement is observed between the K_d values which were obtained by the two opposing experiments: the sorption of ^{137}Cs by the sediment component from 400 cm^3 of seawater and the desorption of nuclide adsorbed on the sample with 40 cm^3 of seawater.

In Table 4, the sorption capacities of the components for cesium are shown, together with the concentrations of sodium and potassium, and the ratio of cesium to sodium plus potassium. From the results given in the table, it can be seen that only 20—30% of the alkali metals are replaced by cesium for the coarsest components, while in the case of the finest component almost all the alkali metals are exhanged with cesium. Another experiment using seawater containing one half the amount of cesium and the tracer gave very similar capacity values. These results may indicate that the fine component of the elutriated sediments has a larger number of exchangeable sites for ^{137}Cs than the coarse ones; this is probably the reason for the higher ^{137}Cs contents in the finest component of the sediment in spite of the rather lower contents of sodium and potassium.

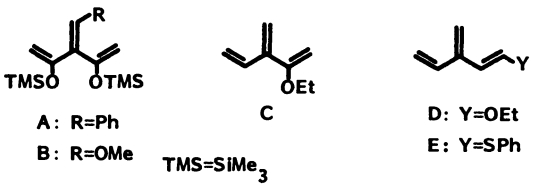
Double Diels-Alder Reaction of *trans*-3-Methylene-1,4-hexadiene and 1-Methyl-3-methylene-4-pentenyl Tosylate

Shuji KANEMASA, Hirohiko SAKOH, Eiji WADA, and Otohiko TSUGE*
Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received November 25, 1985)

A cross-conjugated triene, *trans*-3-methylene-1,4-hexadiene, is accessible from the Grignard reagent of chloroprene and methyloxirane via 1-methyl-3-methylene-4-pentenyl tosylate. The diene-transmissive Diels-Alder reaction of the triene and the stepwise sequence of double Diels-Alder reaction of the tosylate are investigated. Stereo- and regioselectivity of these reactions in the presence or absence of Lewis acid catalyst are discussed.

The diene-transmissive Diels–Alder reaction of cross-conjugated trienes such as 3-benzylidene- **A**,[1] 3-methoxymethylene-2,4-bis(trimethylsilyloxy)-1,4-pentadiene **B**,[2] and 2-ethoxy-3-methylene-1,4-pentadiene **C**[3] is useful for the synthesis of stereochemically defined and functionalized [6.6] bicyclic systems.[1–7] Stepwise sequence using synthetic equivalents of the cross-conjugated trienes offers a convenient route to cross bis-cycloadducts in which two different dienophiles are incorporated,[3,8,9]

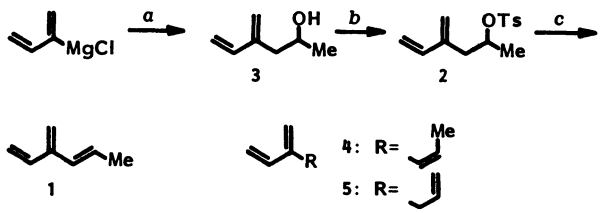


It has been found that triene **C** undergoes the first Diels–Alder reaction exclusively across the 2-monosubstituted diene moiety since the other 2,3-disubstituted diene moiety can hardly occupy an *s-cis* conformation which is essential in the transition state of Diels–Alder cycloaddition.[3] Although cross-conjugated trienes **D** and **E** carrying a diene-activating substituent at the 1-position selectively react with a dienophile across the 1,3-disubstituted triene, they are unfortunately too unstable to be employed as starting materials.[10]

The present article describes the diene-transmissive Diels–Alder reaction of *trans*-3-methylene-1,4-hexadiene (**1**) and the stepwise double cycloaddition of 1-methyl-3-methylene-4-pentenyl tosylate (**2**), a precursor of **1**.

Results and Discussion

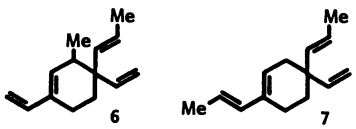
In a study of organic synthesis utilizing cross-conjugated trienes, a general and simple preparative method of trienes starting from readily available materials is required. Our synthetic plan of **1** starts from an industrial material, chloroprene, and an epoxide as shown in Scheme 1. 4-Methylene-5-hexen-2-ol (**3**), which is readily accessible by the regioselective reaction of the Grignard reagent of chloroprene with



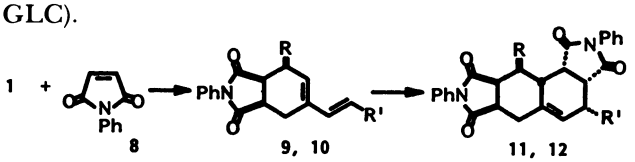
a: 2-methyloxirane, *b*: TsCl-pyridine, *c*: DBU

Scheme 1.

methyloxirane,[11] was tosylated in pyridine at 0 °C to give tosylate **2** in 80% yield. When **2** was heated at 100—110 °C with DBU under reduced pressure, the desired triene **1** was obtained in 64% yield as thermally labile liquid. Although the triene **1** thus obtained was only 90% pure (GLC), its separation from contaminants, the 2:1 mixture of **4** and **5**,[12] by vacuum distillation was unsuccessful. The contaminants could not be removed by distillation under higher vaccum, and under lower vacuum **1** underwent partial dimerization to give a mixture of **6** and **7** in the ratio 74:26 (GLC). Thus, the triene **1** of this purity was used for the following reactions.



The reaction of **1** with an equivalent amount of *N*-phenylmaleimide (**8**) at room temperature gave a mixture of two isomeric bis-cycloadducts **11** and **12** in 92% yield in the ratio 5:1 (^{1}H NMR) as shown in Scheme 2. Even in a similar reaction below −50 °C, the bis-cycloadducts **11** and **12** (68%, **11**:**12**=4:1 by ^{1}H NMR) were formed together with two isomeric mono-cycloadducts **9** and **10** (24%, **9**:**10**=81:19 by GLC).

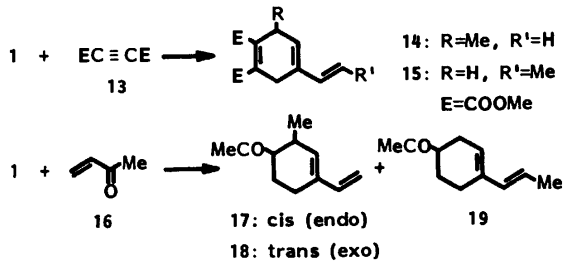


9, 11: R=Me, R'=H
10, 12: R=H, R'=Me

Scheme 2.

As it will be presented later, the minor bis-cycloadduct **12** can be obtained as a single stereoisomer in the reaction of **8** with **10** which is available from the cycloadduct derived from diene tosylate **2** and **8** (Schemes 4, 5, and 6). Accordingly, the major bis-cycloadduct **11** has to be the stereoselective cycloaddition product derived from the other mono-cycloadduct **9**. The structure of **11** was confirmed to be the endo cycloadduct of **8** across 1,3-disubstituted diene moiety of **1** on the basis of spectral data.[13] After all, the Diels-Alder reaction of **1** with **8** has occurred not only across the 1,3-disubstituted diene part but also across the 2-monosubstituted diene, and chemoselectivity between the both dienes does not depend upon the reaction conditions. The selectivity in favor of the methyl-substituted diene in the reaction with **8** was 81—83%.

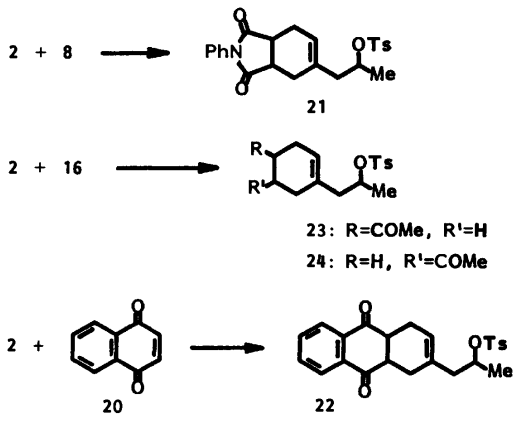
On the other hand, the Diels-Alder reaction of **1** with an equimolar amount of dimethyl acetylenedicarboxylate (DMAD, **13**) at room temperature led to a mixture of two isomeric monocycloadducts **14** and **15** in 77% yield. The chemoselectivity between the 1,3-disubstituted and 2-monosubstituted dienes of **1** was 78:22 (GLC) (Scheme 3). When excess **13** was used and the reaction was carried out in refluxing benzene, a complex mixture containing two mono- and bis-cycloadducts along with their partly or fully aromatized derivatives.



Scheme 3.

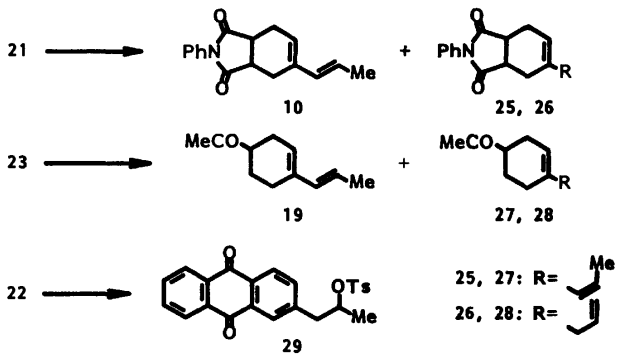
To our surprise, regioselectivity in the first Diels-Alder reaction of **1** was found unexpectedly high. For example, the reaction with methyl vinyl ketone (**16**) as an unsymmetrically substituted dienophile at room temperature gave three regioselective monocycloadducts in 76% yield, two of which are endo **17** and exo cycloadduct **18** across the methyl-substituted diene (**17**:**18**=70:30 by GLC) and the other **19** is the cycloadduct across the 2-monosubstituted diene (**17**+**18**:**19**=69:31 by GLC).[14] When this reaction was carried out in the presence of an equimolar amount of ethylaluminum dichloride as a Lewis acid in toluene at −78°C for 0.5 h, the *endo*-selectivity increased to 98% (**17**:**18**=98:2). However, the chemoselectivity could not be improved (**17**+**18**:**19**=71:29 by GLC).[15] Since the chemoselectivity between both diene moieties of **1** in the first Diels-Alder reaction was low, we had to give up the route involving diene-transmissive Diels-Alder cycloaddition of triene **1**. Therefore, stepwise sequence of double Diels-Alder reaction using diene tosylate **2** was instead investigated hereafter.

The Diels-Alder reactions of **2** with **8** or 1,4-naphthoquinone (**20**) gave cycloadduct **21** or **22** in 99 or 72% yield, respectively (Scheme 4). Although the regioselectivity found in the reaction of **2** with **16** in refluxing benzene was very low (74%, **23**:**24**=64:36 by GLC),[16,17] a similar reaction in the presence of ethylaluminum dichloride at −50 to −70°C was exclusively *para*-selective. 67% Yield of **23** was the only isolated product.



Scheme 4.

The elimination of *p*-toluenesulfonic acid from **21** was readily performed by heating with DBU under reflux in toluene to give a mixture of three elimination products in 73% yield (Scheme 5). It was found that purity of the expected trans diene **10** was 91%, and that the contaminants consisted of the corresponding cis isomer **25** and unconjugated diene **26** (9%, **25**:**26**=2:1 by ^{1}H NMR).[18] One-pot procedure for the Diels-Alder reaction of **2** with **8** and the diene formation into **10** was successful: **10** was obtained in 70% yield (**10**:**25**:**26**=91:6:3 by GLC).

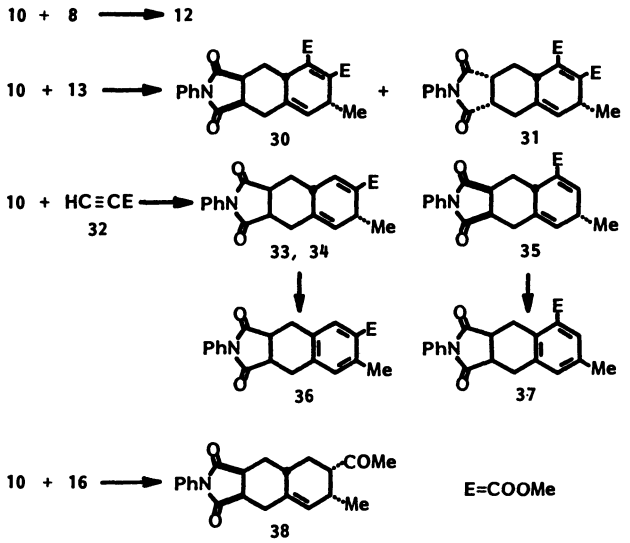


Scheme 5.

The elimination reaction of **23** under similar conditions afforded trans diene **19** as major product, which had been previously obtained as minor product in the reaction of **1** with **16**, together with two isomeric dienes **27** and **28** (76%, **19**:**26**:**27**=87:8:5 by GLC). However, naphthoquinone adduct **22** resulted in the dehydrogenation into **29** instead of the elimination of sulfonic acid.[19]

The second Diels–Alder reaction step of the stepwise sequence was investigated by utilizing diene **10**. Since it was unsuccessful to remove the contaminants **25** and **26**, the diene **10** of 91% purity was used for subsequent reactions. These isomeric dienes **25** and **26** did not affect the second Diels–Alder cycloaddition and were recovered unchanged.

The reaction of **10** with **8** readily took place at room temperature to give bis-cycloadduct **12** as a single stereoisomer in 78% yield, which is identical with the minor bis-cycloadduct formed in the reaction of **1** with **8** (Scheme 6). Therefore, both regioisomeric bis-cycloadducts **11** and **12** are now accessible from the triene **1** and the diene tosylate **2**, respectively, both as either major or single product. This facile and stereoselective cycloaddition may occur because the diene moiety of **10** is not sterically crowded at the side opposite to the fused five-membered ring to allow the endo approach **F** of **8** from this direction (Fig. 1).



Scheme 6.

Compared to high stereoselectivity of the reaction with **8**, the reaction of **10** with DMAD **13** gave two stereoisomers **30** and **31** in 79 and 8% yields, respectively. The major product **30** corresponds to the cycloadduct formed by the attack of **13** from sterically less hindered side of diene **10**.

Regioselectivity of this type of reaction was found very low. For example, three isomers **33**—**35** were formed in 62% yield in the reaction with methyl propynoate (**32**) (**33**:**34**:**35**=2:1:1 by ^{1}H NMR, 25% of **10** was recovered). As **33** and **34** were converted into the same dehydrogenated derivative **36** and **35** was dehydrogenated into its isomer **37**, **33** and **34** are assigned as stereoisomers to each other and **35** is one of their regioisomers.

The stereochemistry of **30**, **31**, and **33**—**35** were determined on the basis of spectral data as well as the stereochemical mode of reactions which are illustrated in Fig. 1. Thus, the major cycloadduct **30** has

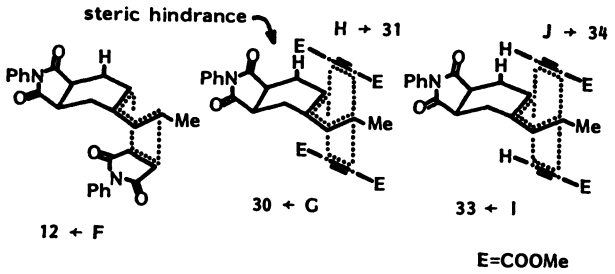


Fig. 1. Stereochemistry of the cycloaddition of **10**.

been formed through the approach **G** of **13** from the side opposite to the fused maleimide ring. The other approach **H** leading to **31** causes some steric repulsion between the ester moiety of **13** and a quasi-axial hydrogen adjacent to the diene moiety or the fused maleimide ring. On the other hand, in the approaches **I** and **J** giving **33** and **34**, one substituent on the dienophile **32** is hydrogen which brings about only negligible steric repulsion at both sides of the diene. Accordingly, the stereoselectivity on the formation of **33** and **34** may have been reduced. It is readily understood that **35** has been formed in a highly stereoselective manner.

The reaction of **10** with methyl vinyl ketone (**16**) as an unsymmetrically substituted dienophile was performed in the presence of ethylaluminum dichloride at −70 °C. The regioselective, *endo*-selective, and face-selective cycloadduct **38** was obtained in 78% yield (Scheme 6).

It is concluded that the stepwise sequence of double Diels–Alder reaction of **2** can be performed in a highly selective fashion for the combination of two different olefinic dienophiles, either in the presence or absence of Lewis acid.

Experimental

General. Melting points were determined on a Yanagimoto micro melting point apparatus and uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C NMR spectra on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as internal standard. Mass spectra were measured with a JEOL JMS-OlSG-2 spectrometer at 70 eV of ionization energy. GC-Mass spectra as well as high resolution mass spectra were also obtained on the same instrument. Elementary analyses were performed on a Hitachi 026 CHN micro analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or of aluminum oxide 60 F-254 type-E (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako) and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—

0.063 mm). Preparative high-performance liquid chromatography (HPLC) was performed on a Kusano KHLC-201 apparatus with a UV-detector Uvilog-III using a column (22×300 mm) packed with silica gel (Wakogel LC-50H). Gas-liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatograph (Yanagimoto) with an ionization detector using a glass column (SE-30, 3×2000 mm) or a glass capillary column (Sillicone GE, SE-30, 0.25×5000 mm). Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Tetrahydrofuran was distilled over sodium wire and then over lithium aluminum hydride prior to its use. Benzene and toluene were also distilled over sodium and stored on sodium wire. The solvents for column chromatography (hexane and ethyl acetate) were used without further purification.

4-Methylene-5-hexen-2-ol (3). Methyloxirane (7 ml, 0.1 mol) in dry THF (25 ml) was slowly added to the 0.1 M solution (1 M=1 mol dm^{-3}) of 1-methylenepropenylmagnesium chloride in THF (100 ml, 0.1 mol) and the mixture was heated at 50—60 °C for 2 h. After cooled to room temperature, the mixture was hydrolyzed with 3N-HCl. The organic layer was separated, and the aqueous layer was extracted with ether (100 ml). The combined organic layer was washed with 5% aqueous sodium hydrogen carbonate, then with brine, and dried over magnesium sulfate. After the solvent was removed by evaporation, the residue was distilled under vacuum (20 mmHg) to give **3** (purity 80% (GLC), 4.66 g, 42%). Repeated vaccum distillation gave pure **3**: Colorless liquid; bp 55—60 °C/2399 Pa (lit,[11] bp 56—60 °C/2660 Pa); ^{1}H NMR ($CDCl_3$) δ=1.20 (3H, d, J=6.5 Hz, Me), 2.29 (1H, ddd, J_{gem}=14.0, J_{2-1}=7.5, J_{long}=1.0 Hz, one of 2-H), 2.34 (1H, s, OH), 2.44 (1H, ddd, J_{gem}=14.0, J_{2-1}=5.0, J_{long}=1.0 Hz, the other of 2-H), 3.93 (1H, m, 1-H), 4.96—5.40 (4H, m, =CH_2), and 6.36 (1H, dd, J_{4-5}=11.0 and 17.5 Hz, 4-H).

1-Methyl-3-methylene-4-pentenyl Tosylate (2). A mixture of **3** (0.655 g, 5.84 mmol), *p*-toluenesulfonyl chloride (1.11 g, 5.84 mmol), and pyridine (2 ml) was allowed to stand in a freezer for 36 h. Pyridine hydrochloride precipitated was removed by filteration and the filtrate was chromatographed over silica gel with hexane-ethyl acetate (9:1) to give **2** (1.243 g, 80%): Colorless liquid; IR (neat) 1360, 1190, and 1175 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.25 (3H, d, J=6.0 Hz, Me), 2.34 (1H, dd, J_{gem}=14.0 and J_{2-1}=8.0 Hz, one of 2-H), 2.42 (3H, s, *p*-Me), 2.66 (1H, dd, J_{gem}=14.0 and J_{2-1}=6.0 Hz, the other of 2-H), 4.68 (1H, ddq, J_{1-2}=8.0, 6.0 and J_{1-Me}=6.0 Hz, 1-H), 4.84—5.16 (4H, m, =CH_2), 6.16 (1H, dd, J_{4-5}=11.0 and 17.5 Hz, 4-H), 7.28, and 7.74 (each 2H, d, J=8.0 Hz, ArH); ^{13}C NMR ($CDCl_3$) δ=20.47, 21.54 (each q, Me), 39.03 (t, 2-C), 78.36 (d, 1-C), 114.03, 119.53 (each t, 3-CH_2= and 5-C), 127.77, 129.62 (each d), 137.71 (d, 4-C), 140.93 (s, 3-C), 144.44 (s); MS m/z (rel. intensity, %) 266 (M^+, 4), 199 (9), 155 (96), 94 (53), 91 (base peak), and 79 (51).

Found: C, 63.06; H, 6.84%. Calcd for $C_{14}H_{18}O_3S$: C, 63.13; H, 6.81%.

***trans*-3-Methylene-1,4-hexadiene (1).** A mixture of **2** (0.62 g, 2.32 mmol) and DBU (0.709 g, 4.64 mmol) was heated in a micro distilling apparatus, at 110 °C at 2660 Pa for 30 min, to give **1** (0.141 g, 64%, purity 90% (GLC)) which was collected in a receiver cooled in a Dry Ice bath (−78 °C): Colorless liquid; ^{1}H NMR ($CDCl_3$) δ=1.78 (3H, d, J=5.0 Hz, Me), 5.00 (2H, s, 3-CH_2=), 5.04 (1H, dd, J_{gem}=1.5 and J_{1-2}=10.5 Hz, one of 1-H), 5.36 (1H, dd, J_{gem}=1.5 and J_{1-2}=17.5 Hz, the other of 1-H), 5.84 (1H, dq, J_{5-4}=16.0 and J_{5-6}=5.0 Hz, 5-H), 6.14 (1H, d, J_{4-5}=16.0 Hz, 4-H), and 6.40 (1H, dd, J_{2-1}=17.5 and 10.5 Hz, 2-H); ^{13}C NMR ($CDCl_3$) δ=18.32 (q, Me), 113.60, 115.13 (each t, 1-C and 3-CH_2=), 127.28 (d, 5-C), 129.75 (d, 4-C), 136.68 (d, 2-C), and 144.43 (s, 3-C); GC-MS m/z 94 (M^+).

Found: m/z 94.0769. Calcd for C_7H_{10}: M, 94.0782.

The residue which was left in a distilling flask after the vaccum distillation of **1** was chromatographed over silica gel using hexane-ethyl acetate (19:1) to afford a mixture of **6** and **7** (74:26 checked by GLC). **6**+**7**: Colorless liquid; ^{1}H NMR ($CDCl_3$) δ=0.92 (d, J=7.0 Hz, Me), 1.64, 1.68 (each d, J=5.0 Hz, Me), 1.40—2.40 (m, CH_2 and CH), 4.90—6.10 (m, CH_2= and CH=), and 6.31 (dd, J=17.5 and 11.0 Hz); ^{13}C NMR ($CDCl_3$) δ=16.66, 18.21, 18.31 (each q, Me), 21.53, 22.17, 30.08, 30.32, 32.08, 35.10 (each t, CH_2), 38.38, 38.62 (each d, CH), 41.11, 44.09 (each s), 110.55 (t), 111.96, 112.55, 113.72, 121.63, 122.95, 123.63, 124.61, 124.75, 134.47 (d), 134.71, 137.30, 137.55, 139.84 (each d), 142.67, and 145.26 (each s); GC-MS m/z (rel. intensity, %) **6**: 188 (M^+, 5), 95 (23), 94 (13), 79 (base peak), and 77 (12); **7**: 188 (M^+, 10), 95 (22), 94 (11), 79 (base peak), and 77 (11).

Reaction of 1 with 8 Leading to 11, 12 or 9—12. i) A mixture of **1** (purity 90%, 0.033 g, 0.32 mmol) and **8** (0.060 g, 0.35 mmol) in dry benzene (1 ml) was stirred at room temperature under nitrogen for 20 h. The solvent was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (2:1) to provide the 5:1 mixture (^{1}H NMR) of **11** and **12** (0.071 g, 92%) which were separated from each other through HPLC using hexane-ethyl acetate (2:1). ii) To a solution of **1** (purity 90%, 0.104 g, 1 mmol) in dry toluene (2 ml) was added **8** (0.191 g, 1.1 mmol) at −70 °C. The mixture was stirred below −50 °C for 2 h. The solvent was removed by eveporation in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acatate (4:1) to afford a mixture of **9** and **10** (0.7 g, 24%, 81:19 (GLC)) whose separation was unsuccessful. Further elution with hexane-ethyl acetate (2:1) gave the 4:1 mixture (^{1}H NMR) of **11** and **12** (0.163 g, 68% based on **8**). The data for **9**, **11**, and **12** are given below, and **10** was assigned by the comparison of its spectral data with those of the authentic sample prepared from the reaction of **21** with DBU.

9: ^{1}H NMR ($CDCl_3$) δ=1.39 (3H, d, J=7.0 Hz, Me), 2.00—3.40 (5H, m, CH_2 and CH), 5.02 (1H, d, J=11.0 Hz, one of =CH_2), 5.38 (1H, d, J=17.5 Hz, the other of =CH_2), 5.70 (1H, m, 5-H), 6.32 (1H, dd, J=11.0 and 17.5 Hz, 6-C<u>H</u>=CH_2), and 7.00—7.50 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=16.65 (q, Me), 22.88 (t, 7-C), 31.53 (d, 4-C), 40.30 (d, 7a-C), 44.42 (d, 3a-C), 113.12 (t, =CH_2), 126.60 (d, 2×C), 128.60 (d), 129.13 (d, 2×C), 132.13 (s, 6-C), 133.36, 136.72 (each d, 5-C and <u>C</u>H=CH_2), 137.36 (s), 177.07, and 178.66 (each s, CON); GC-MS m/z (rel. intensity, %) 267 (M^+, 42), 120 (base peak), and 105 (75).

11: Colorless prisms (ethanol); mp 242—243 °C; IR (KBr) 1765 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.53 (3H, d, J=6.5 Hz, Me), 1.76—3.44 (10H, m, CH_2 and CH), 5.76 (1H, m, 5-H), and 7.00—7.52 (10H, m, Ph); MS m/z (rel. intensity, %) 440 (M^+, 73), 267 (base peak), and 174 (58).

Found: C, 73.51; H, 5.49; N, 6.45%. Calcd for $C_{27}H_{24}N_2O_4$: C, 73.62; H, 5.49; N, 6.36%.

12: Colorless needles (ethanol); mp 228—229 °C; IR (KBr) 1765 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.44 (3H, d, J=7.0 Hz, Me), 2.00—3.48 (10H, m, CH_2 and CH), 5.60 (1H, br

s, 5-H), and 7.00—7.60 (10H, m, Ph); MS *m/z* (rel. intensity, %) 440 (M^+, base peak), 267 (21), and 174 (26).

Found: C, 73.88; H, 5.59; N, 6.33%. Calcd for $C_{27}H_{24}N_2O_4$: C, 73.62; H, 5.49; N, 6.36%.

Reaction of 1 with 13 Leading to 14 and 15. A mixture of **1** (purity 90%, 0.028 g, 0.27 mmol) and **13** (0.042 g, 0.3 mmol) in dry benzene (1 ml) was stirred at room temperature under nitrogen for 20 h. The solvent was evaporated in vacuo and the residue was chromatographed over silica gel using hexane-ethyl acetate (4:1) to afford a mixture of **14** and **15** (0.051 g, 77%, 78:22 (GLC)) as colorless liquid, which could not be separated from each other. Their spectral data are given below:

14: ^{1}H NMR ($CDCl_4$) δ=1.17 (3H, d, J=7.0 Hz, Me), 2.90—3.44 (3H, m, CH_2 and CH), 3.75, 3.76 (each 3H, s, COOMe), 5.04 (1H, d, J=11.0 Hz, one of $=CH_2$), 5.13 (1H, d, J=17.5 Hz, the other of $=CH_2$), 5.64 (1H, m, 4-H), and 6.36 (1H, dd, J=11.0 and 17.5 Hz, 5-C<u>H</u>=CH_2); GC-MS *m/z* (rel. intensity, %) 206 (M^+−30, 41), 205 (20), and 117 (base peak).

15: ^{1}H NMR ($CDCl_3$) δ=1.76 (dd, J=6.5 and 0.5 Hz, Me). Other signals are hidden in those of **14**; GC-MS *m/z* (rel. intensity, %) 235 (M^+−1), 234 (29), and 203 (base peak).

Reaction of 1 with 16 Leading to 17—19. i) A mixture of **1** (purity 90%, 0.065 g, 0.62 mmol) and **16** (0.097 g, 1.38 mmol) in dry benzene (1 ml) was stirred at room temperature under nitrogen for 20 h. The solvent was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (19:1) to give a mixture of the dimers **6** and **7** (0.004 g, 7%, 79:21 (GLC)). Further elution with hexane-ethyl acetate (9:1) afforded a mixture of **17**, **18**, and **19** (0.084 g, purity 93% (GLC), 76%, **17**:**18**:**19**=48:21:31 (GLC)), none of which could be separated in pure form from the other two. ii) To a solution of **16** (0.078 g, 1.12 ml) in dry toluene (1 ml) was added the 1 M solution of ethylaluminum dichloride (in hexane, 1 ml) by use of a syringe at −78 °C. After 0.5 h, **1** (0.105 g, purity 90%, 1 mmol) in dry toluene (1 ml) was introduced and then the mixture was stirred for an additional 0.5 h at the same temperature. Usual hydrolytic work-up with aqueous sodium hydrogencarbonate was followed by the extraction with benzene (10 ml ×2). The benzene was dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel using hexane-ethyl acetate (9:1) to provide a mixture of **17**, **18**, and **19** (0.077 g, 46%, **17**:**18**:**19**=71:2:26 (GLC)). Structural assignment of these products was carried out as follows: The isomer **19** was first identified by the comparison of its spectral data with those of the authentic sample prepared from the reaction of **23** with DBU. The signals of **19** were taken away from the spectrum of the mixture obtained in the Lewis acid-catalyzed reaction. The remaining signals are those of **17**, which make possible to assign the structure of **17**. Finally, the signals for **18** are available in the spectrum of the mixture obtained in the upper reaction. Their spectral data are given below:

17: ^{1}H NMR ($CDCl_3$) δ=0.86 (3H, d, J=7.0 Hz, Me), 1.50—2.92 (6H, m, CH_2 and CH), 2.14 (3H, s, COMe), 4.93 (1H, d, J=11.0 Hz, one of $=CH_2$), 5.08 (1H, d, J=18.0, the other of $=CH_2$), 5.56—5.76 (1H, m, 2-H), and 6.32 (1H, dd, J=11.0 and 18.0 Hz, 1-C<u>H</u>=CH_2); ^{13}C NMR ($CDCl_3$) δ=15.77 (q, Me), 23.59 (t, 2×C, 5- and 6-C), 28.59 (q, CO<u>Me</u>), 31.41 (d, 3-C), 51.47 (d, 4-C), 111.36 (t, $=CH_2$), 133.77 (d), 135.42 (s, 1-C), 139.54 (d), and 210.90 (s, <u>C</u>OMe); GC-MS *m/z* (rel. intensity, %) 164 (M^+, 73), 149 (45), 121 (92), 94 (98), 92 (48), and 79 (base peak).

18: ^{1}H NMR ($CDCl_3$) δ=0.96 (3H, d, J=7.0 Hz, Me), 2.15 (3H, s, COMe), 4.93 (1H, d, J=11.0 Hz, one of $=CH_2$), 5.06 (1H, d, J=18.0 Hz, the other of $=CH_2$), 5.56—5.76 (1H, m, 2-H), and 6.32 (1H, dd, J=11.0 and 18.0 Hz, 1-C<u>H</u>=CH_2); ^{13}C NMR ($CDCl_3$) δ=20.12 (q, Me), 25.53 (t, 2×C, 5- and 6-C), 32.24 (d, 3-C), 55.59 (d, 4-C), 111.07 (t, $=CH_2$), 134.54 (d), and 211.89 (s, <u>C</u>OMe). Other signals are overlapping with those of **17**; GC-MS *m/z* (rel. intensity, %) 164 (M^+, 71), 149 (54), 121 (base peak), 94 (91), 92 (52), and 79 (76).

Reaction of 2 with 8 Leading to 21. A mixture of **2** (0.346 g, 1.3 mmol) and **8** (0.225 g, 1.3 mmol) in dry benzene (5 ml) was heated under reflux under nitrogen for 15 h. The solvent was removed by evaporation in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (1:1) to afford the 1:1 mixture of two diastereomers of **21** (0.568 g, 99%): Colorless liquid; IR (neat) 1780, 1710, 1380, 1190, and 1175 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.12, 1.18 (each 3H, d, J=6.5 Hz, Me), 1.90—2.72 (6H, m), 2.36 (3H, s, *p*-Me), 2.92—3.10 (2H, m), 4.20—4.40 (1H, m, C<u>H</u>Me), 5.48—5.72 (1H, m, 6-H), 7.04—7.50 (5H, m, Ph), 7.24, and 7.72 (each 2H, d, J=8.0 Hz, ArH); ^{13}C NMR ($CDCl_3$) δ=20.22, 21.25 (each q, Me), 24.02, 24.12, 27.09, 27.83 (each t), 38.50, 38.59, 39.18 (each d), 44.10, 44.34 (each t), 77.09, 78.55 (each d, <u>C</u>HOTs), 123.97, 124.31 (each d, 6-C), 125.97, 127.23, 127.33, 128.06, 128.59, 129.48 (each d), 131.77, 133.81, 133.96, 134.83, 135.03, 144.24, 144.34 (each s), 178.30, and 178.55 (each s, CON); MS *m/z* (rel. intensity, %) 439 (M^+, 4), 267 (55), 120 (66), and 91 (base peak).

Found: C, 65.34; H, 5.82; N, 3.41%. Calcd for $C_{24}H_{26}NO_5S$: C, 65.59; H, 5.73; N, 3.19%.

Reaction of 2 with 20 Leading to 22. A mixture of **2** (0.141 g, 0.53 mmol) and **20** (0.084 g, 0.53 mmol) in dry benzene (2 ml) was refluxed under nitrogen for 36 h. The benzene was evaporated in vacuo and the residue was chromatographed over silica gel using hexane-ethyl acetate (3:1) to give the 1:1 mixture of two diastereomers of **22** (0.165 g, 72%): Colorless solid; IR (KBr) 1685, 1590, 1355, and 1170 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.04, 1.05 (each 3H, d, J=6.0 Hz, Me), 1.80—2.60 (8H, m), 2.39, 2.43 (each 3H, s, *p*-Me), 3.00—3.20 (2H, m), 4.68 (1H, m, C<u>H</u>OTs), 5.40 (1H, m, 3-H), 7.28, 7.30 (each 2H, d, J=8.0 Hz, ArH), and 7.60—8.10 (6H, m, ArH); MS *m/z* (rel. intensity, %) 424 (M^+, 5), 252 (51), and 91 (base peak).

Found: C, 68.08; H, 5.74%. Calcd for $C_{24}H_{24}O_5S$: C, 67.91; H, 5.70%.

Reaction of 2 with 16 Leading to 23 and/or 24. i) A mixture of **2** (0.246 g, 0.92 mmol) and **16** (0.3 ml, 3.7 mmol) in dry benzene (2 ml) was refluxed under nitrogen for 48 h. The solvent and excess **16** were evaporated in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (3:1) to give a mixture of **23** and **24** (0.222 g, 74%) whose separation failed. The isomer ratio was determined after their conversion into a mixture of **19** and its regioisomer by the reaction with DBU (**23**:**24** was calculated as 64:36). ii) To a solution of **16** (0.1 ml, 1.23 mmol) in dry toluene (1 ml) was added ethylaluminum dichloride (1 M solution in hexane, 0.6 ml, 0.6 mmol) at −70 °C. After 0.5 h at the same temperature, **2** (0.164 g, 0.62 mmol) in toluene (1 ml) was added and the mixture was allowed to react below −50 °C for 1 h. Usual hydrolytic work-up with aqueous sodium hydrogen carbonate was followed by the extraction with benzene (10 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The re-

sidue was chromatographed over silica gel using hexane-ethyl acetate (3:1) to provide **23** (0.139 g, 67%).

23: Colorless liquid; IR (neat) 1710, 1355, 1190, and 1175 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22, 1.24 (each 3H, d, J=6.2 Hz, Me), 1.30—2.50 (9H, m), 2.12 (3H, s, COMe), 2.42 (3H, s, *p*-Me), 4.64 (1H, m, CHOTs), 5.36 (1H, m, 2-H), 7.24, and 7.72 (each 2H, d, J=8.0 Hz, ArH); ^{13}C NMR ($CDCl_3$) δ=20.82, 21.59 (each q, Me), 24.65, 26.88, 27.94 (each t), 27.94 (q, Me), 44.59, 44.77 (each t), 46.65, 46.77 (each d, 4-C), 78.83 (d, CHOTs), 123.83 (d, 2-C), 127.83, 129.95 (each d), 132.54 (s, 1-C), 134.66, 144.77 (each s), and 211.48 (s, COMe); MS *m/z* (rel. intensity, %) 336 (M^+, 4), 164 (29), 121 (59), and 43 (base peak).

Found: C, 64.41; H, 7.23%. Calcd for $C_{18}H_{24}O_4S$: C, 64.26; H, 7.19%.

24: ^1H NMR ($CDCl_3$) δ=1.26 (3H, d, J=6.2 Hz, Me), 1.30—2.50 (9H, m), 2.12 (3H, s, COMe), 2.42 (3H, s, *p*-Me), 4.64 (1H, m, CHOTs), 5.36 (1H, m, 2-H), 7.24, and 7.72 (each 2H, d, J=8.0 Hz, ArH); ^{13}C NMR ($CDCl_3$) δ=44.89, 45.00 (each d, 5-C), 125.07 (d, 2-C), 131.30 (s, 1-C), and 211.19 (s, COMe). Other signals are overlapping with those of **23**.

Reaction of 21 with DBU Leading to 10. A mixtute of **21** (0.233 g, 0.53 mmol) and DBU (0.105 g, 0.69 mmol) in dry toluene (4 ml) was refluxed for 6 h. The toluene was evaporated in vacuo and the residue was subjected to a column chromatography over silica gel using hexane-ethyl acetate (2:1) to give a mixture of **10**, **25**, and **26** (0.104 g, 73%). The isomer ratio **10**+**25**:**26** was determined as 97:3 by GLC. Although **10** and **25** showed the same retention time in the GLC, the mixture of **25** and **26** was recovered unchanged in the reaction of the above mixture with **13** and their ratio was 2:1 (^1H NMR). After all, the ratio among them was calculated as **10**:**25**:**26**=91:6:3.

10 (purity 91% (GLC)): Colorless oil; IR (neat) 1780 and 1715 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.74 (3H, d, J=6.0 Hz, Me), 2.00—3.40 (6H, m, CH_2 and CH), 5.40—5.92 (2H, m, =CH), 6.04 (1H, d, J=16.0 Hz, 5-CH=CHMe), and 7.04—7.48 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=18.18 (q, Me), 23.41, 24.59 (each t, 4- and 7-C), 39.41 (d, 2×C, 3a- and 7a-C), 123.36, 124.42, 126.54, 128.54, 129.13 (each d), 131.89 (d), 132.25, 137.83 (each s), and 178.95 (s, 2×C, CON); MS *m/z* (rel. intensity, %) 267 (M^+, 20) and 91 (base peak).

Found: C, 76.38; H, 6.41; N, 5.24%. Calcd for $C_{17}H_{17}NO_2$: C, 76.45; H, 6.46; N, 5.34%.

25+**26**: ^1H NMR ($CDCl_3$) δ=1.74 (d, J=6.0 Hz, Me), 2.00—3.40 (m, CH_2 and CH), 5.00 (m, =CH_2), 5.32—5.90 (m, =CH), and 7.04—7.48 (m, Ph).

One-Pot Synthesis of 10. A mixture of **2** (0.39 g, 1.46 mmol) and **8** (0.254 g, 1.46 mmol) in dry toluene (6 ml) was heated at 80 °C under nitrogen for 15 h. After DBU (0.29 g, 1.9 mmol) was added, the mixture was refluxed for 6 h. The solvent was evaporated in vacuo and the residue was chromatographed over silica gel using hexane-ethyl acetate (2:1) to give **10** (0.272 g, 70%, purity 91% (GLC), the contaminants are **25** and **26** in the ratio 2:1 (GLC)).

Reaction of 23 with DBU Leading to 19. A mixture of **23** (0.119 g, 0.35 mmol) and DBU (0.07 g, 0.46 mmol) in dry toluene (3 ml) was refluxed under nitrogen for 12 h. The toluene was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (9:1) to give a mixture of **19**, **27**, and **28** (0.044 g, 76%, **19**:**27**:**28**=87:8:5) whose separation failed.

19: ^1H NMR ($CDCl_3$) δ=1.73 (3H, d, J=6.5 Hz, Me), 1.40—2.70 (7H, m, CH_2 and CH), 2.16 (3H, s, COMe), 5.32—5.72 (2H, m, =CH), and 6.02 (1H, d, J=16.0 Hz, 1-CH=CHMe); ^{13}C NMR ($CDCl_3$) δ=18.18 (q, Me), 24.24, 24.71, 27.41 (each t, CH_2), 28.00 (q, COMe), 47.59 (d, 4-C), 122.36, 124.48, 134.01 (each d), 135.54 (s, 1-C), and 211.66 (s, COMe).

27+**28**: ^1H NMR ($CDCl_3$) δ=1.73 (d, J=6.5 Hz, Me), 1.40—2.70 (m, CH_2 and CH), 2.17 (s, COMe), 4.98 (m, =CH_2), and 5.32—5.72 (m, =CH).

Reaction of 22 with DBU Leading to 29. A mixture of **22** (0.092 g, 0.22 mmol) and DBU (0.043 g, 0.28 mmol) in dry toluene (2 ml) was stirred at room temperature under nitrogen for 2 h. The mixture was chromatographed over silica gel with hexane-ethyl acetate (3:1) to give **29** (0.051 g, 56%): Pale yellow needles (ethanol); mp 122—124 °C; IR (KBr) 1670, 1595, 1185, 1170, 885, 760, and 710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.43 (3H, d, J=6.0 Hz, Me), 2.04 (3H, s, COMe), 2.96 (2H, d, J=6.5 Hz, CH_2), 4.78 (1H, tq, J=6.0 and 6.5 Hz, CHOTs), 6.96 (2H, d, J=8.0 Hz, ArH), 7.32—7.42, 7.68—7.86 (each 3H, m, ArH), 8.00 (1H, d, J=8.0 Hz, ArH), and 8.10—8.36 (2H, m, ArH); MS *m/z* (rel. intensity, %) 420 (M^+, 5), 248 (38), and 91 (base peak).

Found: C, 68.64; H, 4.91%. Calcd for $C_{24}H_{20}O_5S$: C, 68.56; H, 4.79%.

Reaction of 10 with 8 Leading to 12. A mixture of **10** (purity 91%, 0.042 g, 0.14 mmol) and **8** (0.027 g, 0.16 mmol) in dry benzene (1 ml) was stirred at room temperature for 20 h. The solvent was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (1:1) to afford **12** (0.049 g, 78%) whose spectral data were shown above.

Reaction of 10 with 13 Leading to 30 and 31. A mixture of **10** (purity 91%, 0.102 g, 0.35 mmol) and **13** (0.108 g, 0.76 mmol) in dry benzene (3 ml) was refluxed under nitrogen for 60 h. The solvent was evaporated in vacuo and the residue was chromatographed over silica gel using hexane-ethyl acetate (2:1) to provide **30** (0.112 g, 79%) and then **31** (0.012 g, 8%).

30: Colorless needles (ethanol); mp 177—178 °C; IR (KBr) 1775, 1735, 1710, 1375, and 795 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (3H, d, J=7.0 Hz, Me), 1.32—1.66, 1.92—2.26 (each 1H, m, CH_2), 2.64—3.32 (6H, m, CH_2 and CH), 3.76 (6H, s, COOMe×2), 5.55 (1H, dd, J_{5-6}=4.0 and J_{5-8a}=1.5 Hz, 5-H), and 7.10—7.56 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=21.83 (q, Me), 30.94 (t, 9-C), 33.41 (d, CH), 35.00 (t, 4-C), 36.53, 40.71, 42.00 (each d, CH), 52.30 (q, 2×C, COOMe), 124.06 (d), 126.36 (d, 2×C), 128.53 (d), 129.24 (d, 2×C), 131.66, 132.13, 133.42, 140.18 (each s), 167.31, 168.65 (each s, COOMe), 176.95, and 177.83 (each s, CON); MS *m/z* (rel. intensity, %) 409 (M^+, 2), 377 (22), and 362 (base peak).

Found: C, 67.29; H, 5.61; N, 3.58%. Calcd for $C_{23}H_{23}NO_6$: C, 67.47; H, 5.66; N, 3.42%.

31: Colorless solid; mp 63—65 °C; IR (KBr) 1775, 1735, and 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.14 (3H, d, J=7.0 Hz, Me), 1.10—1.40, 2.26—2.56 (each 1H, m, CH_2), 2.68—3.40 (6H, m, CH_2 and CH), 3.76 (6H, s, COOMe×2), 5.56 (1H, dd, J_{5-6}=3.5 and J_{5-8a}=1.5 Hz, 5-H), and 7.10—7.56 (5H, m, Ph); MS *m/z* (rel. intensity, %) 409 (M^+, 3), 377 (49), and 362 (base peak).

Found: *m/z* 409.1517. Calcd for $C_{23}H_{23}NO_6$: M, 409.1524.

Reaction of 10 with 32 Leading to 33—35. A mixture of **10** (purity 91%, 0.152 g, 0.52 mmol) and **32** (0.24 g, 2.85 mmol) in dry benzene (3 ml) was refluxed under nitrogen for 40 h. The

solvent was evaporated in vacuo and the residue was chromatographed over silica gel using hexane-ethyl acetate (2:1) to give **33** (0.042 g, 23%), the mixture of **33**, **35**, **10**, **25**, and **26** (0.092 g, the isomer ratio was 26:16:40:7:3 (GLC)), and **34** (0.028 g, 15%). The isomer **35** was separated from the mixture through HPLC.

33: Colorless solid; mp 138—139 °C; IR (KBr) 1775, 1700, 1380, and 1250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (3H, d, J=7.0 Hz, Me), 1.45 (1H, dt, J_{gem}=14.5 and J_{9-8a}=J_{9-9a}=6.0 Hz, one of 9-H), 1.90—2.24 (1H, m, the other of 9-H), 2.52—3.32 (6H, m, CH_2 and CH), 3.72 (3H, s, COOMe), 5.57 (1H, m, 5-H), 6.77 (1H, d, J_{8-8a}=4.0 Hz, 8-H), and 7.16—7.56 (5H, m, Ph); MS m/z (rel. intensity, %) 351 (M^+, 3), 336 (27), 319 (35), and 304 (base peak).

Found: C, 71.95; H, 5.99; N, 4.28%. Calcd for $C_{21}H_{21}NO_4$: C, 71.78; H, 6.02; N, 3.99%.

34: Colorless solid; mp 149—151 °C; IR (KBr) 1775, 1705, 1375, and 1255 cm^{-1}; ^1H MMR ($CDCl_3$) δ=1.09 (3H, d, J=7.0 Hz, Me), 1.10—1.48 (1H, m, one of 9-H), 2.20—3.50 (7H, m, CH_2 and CH), 3.71 (3H, s, COOMe), 5.57 (1H, m, 5-H), 6.72 (1H, d, J_{8-8a}=4.0 Hz, 8-H), and 7.12—7.56 (5H, m, Ph); MS m/z (rel. intensity, %) 351 (M^+, 10), 336 (13), 319 (63), and 304 (base peak).

Found: C, 71.87; H, 6.14; N, 4.21%. Calcd for $C_{21}H_{21}NO_4$: C, 71.78; H, 6.02; N, 3.99%.

35: Colorless needles (ethyl acetate-hexane); mp 227—228 °C; IR (KBr) 1770, 1700, 1370, and 1255 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (3H, d, J=7.0 Hz, Me), 1.10—1.54, 2.00—2.32 (each 1H, m, 9-H), 2.48—3.28 (6H, m, CH_2 and CH), 3.75 (3H, s, COOMe), 5.49 (1H, br s, 5-H), 6.89 (1H, dd, J_{7-6}=3.0 and J_{7-8a}=1.5 Hz, 7-H), and 7.10—7.56 (5H, m, Ph); MS m/z (rel. intensity, %) 351 (M^+, 6), 336 (38), 319 (40), and 304 (base peak).

Found: C, 71.77; H, 6.09; N, 4.16%. Calcd for $C_{21}H_{21}NO_4$: C, 71.78; H, 6.02; N, 3.99%.

Dehydrogenation of 33—35 Leading to 36 and 37. i) A mixture of **33** (0.026 g, 0.097 mmol) and chloranil (0.027 g, 0.11 mmol) in dry toluene (1 ml) was refluxed for 15 h. The toluene was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (2:1) to afford **36** (0.025 g, 97%). ii) The isomer **34** was readily dehydrogenated giving **36** when exposed to the air. iii) A mixture of **35** (0.02 g, 0.057 mmol) and chloranil (0.021 g, 0.085 mmol) in dry toluene (1 ml) was refluxed for 15 h. The same procedure as mentioned above gave **37** (0.016 g, 80%).

36: Colorless prisms (ethanol); mp 170—171 °C; IR (KBr) 1770, 1700, 1390, and 1265 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.53 (3H, s, Me), 2.70—3.50 (6H, m, CH_2 and CH), 3.84 (3H, s, COOMe), 6.76—6.92 (2H, m, Ph), 7.04 (1H, s, 8-H), 7.20—7.40 (3H, m, Ph), and 7.72 (1H, s, 5-H); MS m/z (rel. intensity, %) 349 (M^+, 5), 318 (39), and 317 (base peak).

Found: C, 72.14; H, 5.47; N, 4.11%. Calcd for $C_{21}H_{19}NO_4$: C, 72.19; H, 5.48; N, 4.01%.

37: Colorless solid; mp 58—60 °C; IR (KBr) 1770 and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.30 (3H, s, Me), 2.80—3.48 (5H, m, CH_2 and CH), 3.86 (3H, s, COOMe), 4.06 (1H, dd, J_{gem}=15.0 and J_{4-3a}=3.0 Hz, one of 4-H), 6.70—6.96 (2H, m, Ph), 7.11 (1H, br s, 8-H), 7.20—7.40 (3H, m, Ph), and 7.56 (1H, br s, 6-H); MS m/z (rel. intensity, %) 349 (M^+, 18), 318 (31), and 317 (base peak).

Found: m/z 349.1306. Calcd for $C_{21}H_{19}NO_4$: M, 349.1313.

Reaction of 10 with 16 Leading to 38. To a solution of **16** (0.074 ml, 0.9 ml) in dry toluene (1 ml) was added ethylaluminum dichloride (1 M solution in hexane, 0.9 ml, 0.9 mmol) at −70 °C. After 0.5 h, **10** (purity 91 %, 0.237 g, 0.81 mmol) in toluene (1 ml) was added and the mixture was stirred at the same temperature for 2 h. Usual work-up with aqueous sodium hydrogen carbonate was followed by the extraction with benzene (10 ml×2). The benzene was dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (2:1) to give **38** (0.211 g, 78%): Colorless solid; mp 111—112 °C; IR (KBr) 1770 and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.78 (3H, d, J=7.0 Hz, Me), 1.10—3.28 (11H, m, CH_2 and CH), 2.10 (3H, s, COMe), 5.48 (1H, dd, J_{5-6}=4.0 and J_{5-8a}=2.0 Hz, 5-H), and 7.10—7.52 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=16.47 (q, Me), 25.65 (t), 28.35 (q, COMe), 29.01, 29.77 (each t), 31.00, 33.36, 39.41, 39.71 (each d), 51.36 (d, 7-C), 126.42 (d, 2×C), 127.95, 128.48 (each d), 129.13 (d, 2×C), 132.25, 134.18 (each s), 178.89 (s, 2×C, COOMe), and 210.31 (s, COMe); MS m/z (rel. intensity, %) 337 (M^+, base peak), 319 (42), 295 (65), 294 (99), 91 (54), and 77 (30).

Found: C, 74.88; H, 6.94; N, 4.40%. Calcd for $C_{21}H_{23}NO_3$: C, 74.75; H, 6.87; N, 4.15%.

We are grateful to Toyo Soda Manufactural Company for a generous sample of chloroprene.

10) The trienes **D** and **E** can be synthesized by the reaction of the Grignard reagent of chloroprene with 2-bromovinyl ethyl ether and 2-bromovinyl phenyl sulfide in the presence of Ni(dppp)Cl_2 at −78 °C to room temperature, respectively. They can be only isolated as solution in THF because of the ready polymerization. They react with *N*-methylmaleimide to give the corresponding bis-cycloadducts as single isomers (Our unpublished results).

11) S. Nunomoto and Y. Yamashita, *J. Org. Chem.*, **44**, 4788 (1979).

12) GLC analysis of this mixture showed only two peaks in the ratio 90:10. However, cycloaddition of this mixture with *N*-phenylmaleimide (**8**) produced bis-cycloadducts **11** and **12** as major products and two monocycloadducts of **4** and **5** (GLC and ^1H NMR).

13) Stereostructures of **9**, **11**, and **12** can not be determined only on the basis of the spectral data. Endo structure of **9** and that of the second six-membered ring of **12** are based on

a rule that cyclic dienophiles undergo highly *endo*-selective cycloaddition (J. Sauer, *Angew. Chem. internat. Edit.*, **6**, 16 (1967)). As **11** and **12** are the only stereoisomers formed, the second molecule of **8** is most likely to have attacked **9** and **10** from the less hindered side of diene, opposite to the preexistent fused maleimide ring. Similar stereoselectivity has been previously reported (Ref. 6).

14) Endo and exo structures of **17** and **18** were confirmed on the basis of chemical shifts of the ring methyl and also of the fact that **17** was mainly obtained in the Lewis acid-catalyzed cycloaddition (T. Inukai and T. Kojima, *J. Org. Chem.*, **31**, 2032 (1966)).

15) An example of Lewis acid-catalyzed Diels-Alder reaction: T. Inukai and T. Kojima, *J. Org. Chem.*, **32**, 869 (1967).

16) The ratio between **23** and **24** was determined by GLC analysis after their conversion into the corresponding dienes. The para:meta ration in the Diels-Alder reaction of 2-methyl-1,3-butadiene with **16** was reported as 71:29 (E. F. Lutz and G. M. Bailey, *J. Am. Chem. Soc.*, **86**, 3899 (1964)).

17) Regiochemistry of **23** and **24** was determined by the fact that **23** is the only regioisomer formed in the Lewis acid-catalyzed Diels-Alder reaction of **2** and **16**.

18) When **10** containing 9% of **25** and **26** is subjected to a Diels-Alder cycloaddition, **25** and **26** as contaminants can be recovered unchanged. It is known that cis 1-substituted 1,3-diene is much less reactive than the trans isomer (See the reference in Ref. 13).

19) Such dehydrogenation which presumably took place via an enol intermediate can be seen in a literature (K. Hayakawa, K. Ueyama, and K. Kanematsu, *J. Org. Chem.*, **50**, 1963 (1985)).

(Received November 30, 1985)

Aryldiazenyl radicals were formed at −104 — −116 °C by photoirradiation of cyclopropane solutions of 1-aryl-2-(arylthio)diazenes and of 1-aryl-3,3-dimethyltriazenes in the presence or absence of olefins, and also by irradiation of cyclopropane solutions of substituted 1,2,3-benzothiadiazoles in the presence of di-*t*-butyl peroxide. The ESR spectra were analyzed and the hfs constants were assigned by reference to the spectra of methyl, ^{2}H, and ^{15}N-labelled aryldiazenyl radicals and to the results of CINDO calculations. Aryldiazenyl radicals are relatively persistent and the -N=N group rotates about the C-N^{2} bond axis. The preferred conformations of the radicals were considered.

Aryldiazenyl radicals have been the subject of much interest in organic chemistry during the last decades.[2)] The appearence of the radicals in transient states was suggested by chemical facts such as the formation of compounds derived from the aryldiazenyl radicals,[3,4)] and of isomeric azo compounds.[5)] The most conclusive evidence for the radicals was the isolation of phenylazotriphenylmethane in the thermolysis of α-(phenylazo)cumene in the presence of triphenylmethyl radicals.[6)] Aryldiazenyl radicals have, however, not yet been directly characterized by any spectroscopic method, and the physical and chemical properties of the radicals have remained unclear. We report here on the detection and identification of aryldiazenyl radicals by the ESR method and on their possible conformations by reference to theoretical calculation of the hfs constants.

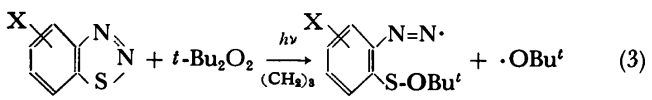
Results and Discussion

(1) Formation and Detection of Aryldiazenyl Radicals. Cyclopropane solutions of ortho-, meta-, and para-substituted 1-phenyl-2-(arylthio)diazenes were irradiated in the ESR cavity using a Xe lamp (1 kW) through a filter of 420 nm at −104 — −116 °C to afford radicals which will be later identified as substituted phenyldiazenyl radicals (Reaction 1). From 1-(4-methylphenyl)- and 1-(4-methoxyphenyl)-3,3-dimethyltriazenes we obtained radicals with the same constitution as those from diazenes, more conveniently by using a N_2 Laser (Molectron UV-14) than by using a Xe lamp (Reaction 2). Starting with 1-(4-dimethylaminophenyl)-3,3-dimethyltriazene we could not observe the ESR spectrum of the corresponding radicals, because of its poor solubility in cyclopropane at low temperatures. From these two kinds of starting compounds we obtained the spectra of the same nitrogen-centered radicals. This confirmed that the radicals we observed were indeed the primary radicals formed by the photolysis of diazenes and triazenes, and not the radicals formed secondarily by any radical addition reaction to diazenes or triazenes. This conclusion was further supported by experiments using neat or mixed solvents of olefins and cyclopropane for 1-aryl-2-(arylthio)diazenes: Olefinic solvents such as 1-butene, *cis*-2-butene, and propene did not cause any change in the ESR spectra observed (Reaction 1). Olefinic solvents caused some acceleration in the decay rate of the aryldiazenyl radicals, on which we will reported in the next paper.

The third type of starting compounds for the nitrogen-centered radicals of the same sort were substituted 1,2,3-benzothiadiazoles, whose thiadiazole rings were opened photochemically by using di-*t*-butyl peroxide (Reaction 3).

$$\underset{(R=H,\ 4\text{-}Bu^t)}{Ar\text{–}N=N\text{–}S\text{–}C_6H_4\text{–}R} \xrightarrow[(CH_2)_3+R^1CH=CHR^2]{h\nu} Ar\text{–}N^2=N^1\cdot + \cdot S\text{–}C_6H_4\text{–}R \qquad (1)$$

$$Ar\text{–}N=N\text{–}N(CH_3)_2 \xrightarrow[(CH_2)_3]{h\nu} Ar\text{–}N=N\cdot + \cdot N(CH_3)_2 \qquad (2)$$



(3)

The hyperfine splitting constants of the radicals observed during these reactions together with *g*-values are listed in Table 1.

Photolysis of 1-(4-*t*-butylphenylthio)-2-phenyldiazene (No. 9) gave an ESR spectrum of nine 1:2:1 triplets (1.2 G†) in a pattern of 1:1:1 triplet (22.5 G) of 1:1:1 triplets (9.45 G). This pattern of triplet of triplets, together with the low *g*-value of 2.0002, is the characteristic feature of the spectra of all the radicals we observed in the reactions 1, 2, and 3. In the following, we are going to identify them as aryldiazenyl radicals by examining the reactions of their formation and by analyzing the ESR spectra.

(2) Identification of the Aryldiazenyl Radicals. The pattern of triplet (1:1:1) of triplets (1:1:1) characteristic of the ESR spectra obtained in this work, shows that the

a) The ESR spectra of (perdeuterio-, 2-F-, 4-Br-, 3- and 4-$CH_3C(O)$-, 3- and 4-NC-, 4-$CH_3OC(O)$-, and 5-CH_3-2-CH_3S-phenyl)diazenyl radicals showed the same pattern as those in Table 1 and the spectra were in accordance with the discussions in this report. b) 1 Gauss=1×10^{-4} T. c) x denotes the position of the hydrogen atom on the benzene ring which gives rise to the hfs constant a_H.

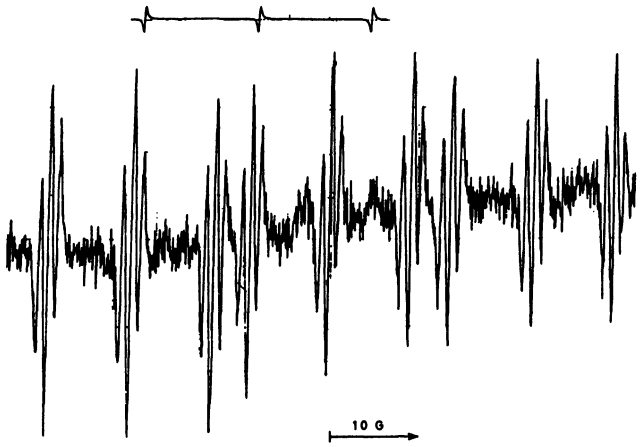

Fig. 1. ESR spectrum of (4-chloro-2,6-dideuteriophenyl)-diazenyl radical.

Fig. 2. ESR spectrum of (3-methoxyphenyl)diazenyl radical.

unpaired electron is coupled to two ^{14}N nuclei. This is further proved by the specific ^{15}N-labelling discussed below. The large splitting constants point to nitrogen centered radicals as expected for aryldiazenyls.

The additional small coupling of 0.5 to 2.0 G must then be ascribed to at least some of the aryl ring protons. In order to identify these protons, we compared the ESR spectra of specifically substituted or deuterated species.

Substitution of hydrogen-4 of the phenyl group by methoxyl (from No. 9 to No. 2) and by chlorine (No. 12), and further substitution of hydrogen-2 and -6 by deuterium (Nos. 3 and 13) did not cause any change of the 1:2:1 triplets, attributed to hydrogen hfs. (Fig. 1) In the case of 1-(4-*t*-butylphenylthio)-2-(3-methoxyphenyl)diazene (No. 11) the spectrum pattern was, however, converted into nine doublets (1.15 G). (Fig. 2)

1-(4-*t*-Butylphenylthio)-2-(3,5-dimethylphenyl)diazene (No. 8, Fig. 3) and 1-(4-*t*-butylphenylthio)-2-(3,5-dideuteriophenyl)diazene (No. 10) both gave nine singlets

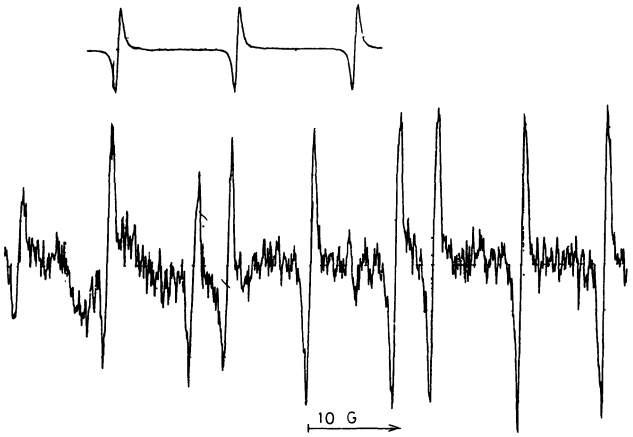

Fig. 3. ESR spectrum of (3,5-dimethylphenyl)diazenyl radical.

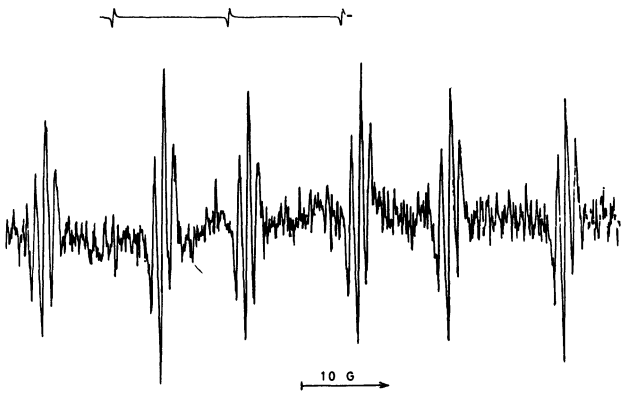

Fig. 4. ESR spectrum of (4-chlorophenyl)diazenyl-1-^{15}N radical.

in a pattern of 1:1:1 triplet (22.7 and 22.9 G, respectively) of 1:1:1 triplets (9.45 and 9.45 G, respectively). The successive disappearence of the hydrogen hfs from No. 9 to 11 to Nos. 8 and 10 proves that the hfs results from the meta hydrogens of the aryl group.

When 2-^{14}N of 1-(4-chlorophenyl)-2-(phenylthio)diazene was replaced by ^{15}N via diazotization of chloroaniline using sodium nitrite-^{15}N in the preparation of the diazene, the pattern of the ESR spectrum of the nitrogen nuclei changed from a triplet of triplets into a triplet of doublets: 1-(4-Chlorophenyl)-2-(phenylthio)diazene-2-^{15}N (No. 14) gave a spectrum composed of six 1:2:1 triplets (1.1 G) in an arrangement of 1:1:1 triplet (23.0 G) of doublets (13.3 G, Fig. 4).

A similar change in the spectrum pattern due to the nitrogen isotope was observed in the experiments using ^{15}N-triazenes. If 2-^{14}N of 1-(4-methylphenyl)-3,3-dimethyltriazene was replaced by ^{15}N (No. 5), then the spectrum pattern (triplet of triplets as in the case of No. 4) changed into a 1:1:1 triplet (23.0 G) of doublets (13.45 G, Fig. 5). If on the other hand the 1-^{14}N of the original triazene was replaced by ^{15}N (No. 6), then it gave a spectrum of a doublet (31.6 G) of 1:1:1 triplets (9.65 G, Fig. 6). Triazene-1,2-$^{15}N_2$ (No. 7) gave a spectrum of a doublet (31.4 G) of doublets (13.3 G, Fig. 7).

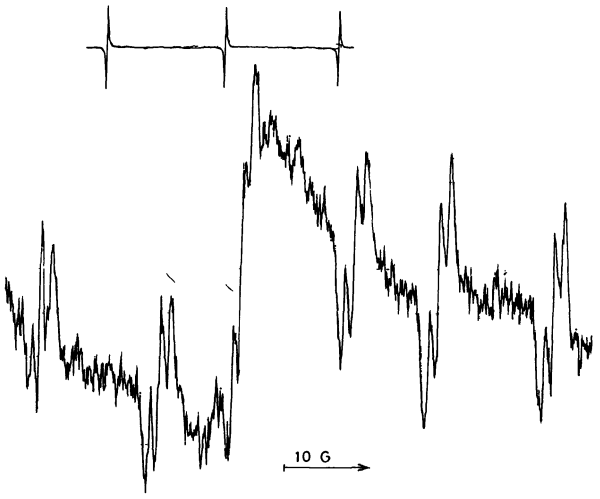

Fig. 5. ESR spectrum of (4-methylphenyl)diazenyl-1-^{15}N radical.

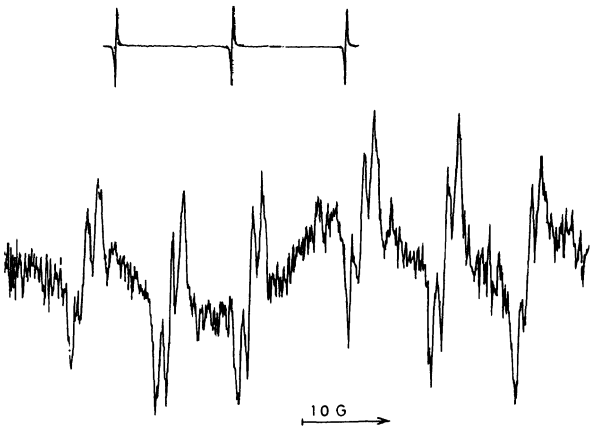

Fig. 6. ESR spectrum of (4-methylphenyl)diazenyl-2-^{15}N radical.

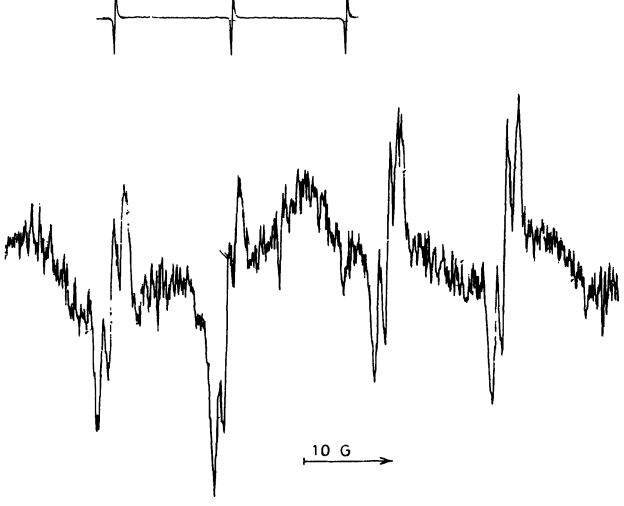

Fig. 7. ESR spectrum of (4-methylphenyl)diazenyl-1,2-$^{15}N_2$ radical.

In every case, the small triplet splitting (1.1—1.2 G), attributed to the meta ring protons, was also resolved. The ratios, 13.4 G/9.7 G and 31.5 G/23.0 G, are in

good accordance with the magnetogyric ratio of $|^{15}N/^{14}N|=1.40$. These results assigned the hfs constants of 23.0 G to 2-^{14}N and that of 9.7 G to 1-^{14}N of the aryldiazenyl radical structure.

The *g*-values of these nitrogen centered radicals were low, 2.0003 on the average, except for the *g*-value of (2-bromophenyl)diazenyl, 2.0024 (No. 29, see below). These values are lower than those of carbon radicals such as triphenylmethyl radical (2.00266[7]), aminyl radicals such as *N*-aryl-*t*-butylaminyls (2.0035[8]), and thiyl radicals derived from cysteine (2.025[9]). They are, however, very close to those of 2-butenoyl radicals, 2.0005,[10] to those of nitrosobenzene cation radicals, 2.0007,[11] and to those of benzoyl radicals, 2.0014.[12] The latter three radicals are reported to be σ-radicals.

From these remarkable ESR features (large nitrogen hfs, small *meta*-ring proton hfs, low *g*-values) we may draw two conclusions: (i) The data exclude the possibility of the radicals being some kind of *N*-centered radicals such as 2-substituted 2-(arylthio)-1-phenylhydrazyl, Ar-S-N(X)-$\dot{N}$-C_6H_5, because the hydrazyl radicals should have a *g*-value of about 2.0035, as high as that of phenylaminyl radicals.[8] Moreover, phenylaminyl radicals are π-radicals and afford measurable hfs constants of ortho and para hydrogens of the aryl ring, which is, however, not the case with the present radicals. The possibility that they are 2-substituted 1-(arylthio)-2-phenylhydrazyl radicals, C_6H_5-N(X)-$\dot{N}$-S-Ar, is also very small, because arylthioaminyl radicals should have a *g*-value of ca. 2.006,[13] a high value due to the conjugation of the nitrogen radical center with the arylthio group. Arylthioaminyl radicals should also give appreciable hfs constants of ortho and para hydrogens of the arylthio group, which in our case was not detected, on substitution of the 4-*t*-butyl group by hydrogen.

The assignment of the structure of hydrazyl radicals as those cited above to our nitrogen centered radicals can also be excluded if we consider the reaction conditions of radical formation in olefinic solvents, Reaction 1. Finally, such radicals should not be formed from triazenes, Reaction 2. (ii) The low *g*-values of the aryldiazenyl radicals can be explained by assuming a σ-radical structure.

The relatively high *g*-value of 2.0024 for the (2-bromophenyl)diazenyl (No. 29), contrary to the *g*-value of 2.0006 for the (4-iodophenyl)diazenyl radical (No. 15), is remarkable. The very small increase in the *g*-value for the (4-iodophenyl)diazenyl, (as compared to Nos. 9 and 12), thus gives evidence for a very small spin density at the 4-position of the phenyl group because of the σ-radical nature. The *g*-value of 2.0024 of (2-bromophenyl)diazenyl may also be an indication of a through-space interaction between bromine and the radical center. (2-Chlorophenyl)diazenyl radicals (Nos. 26—28) showed a much smaller increase in *g*-values, to ca. 2.0007. From 1-(4-*t*-butylphenylthio)-2-(2-iodophenyl)diazene we could not observe any definitely interpretable spectrum.

Phenyldiazenyl radical (No. 9), as already mentioned, revealed hfs due to the meta hydrogens, and not to the ortho and para hydrogens. Furthermore, methyl substitution for the meta hydrogens completely suppressed the original hydrogen hfs (No. 8). This fact is not generally true for π-radicals, and also gives support for the σ-radical nature of aryldiazenyl radicals.

(2,4,6-Trimethylphenyl)diazenyl radical (No. 19), on the other hand, revealed a hydrogen hfs which was ascribed to the protons of the ortho methyl groups. A similar methyl-hydrogen hfs was reported for 2,4,6-trimethylbenzenesulfonyl radicals.[14] (See discussion on page 1883.) Based on the chemical methods of formation, Reactions 1—3, and on the analysis of the ESR spectra observed, we concluded that the radicals obtained were aryldiazenyl σ-radicals.

Apparently, two groups of *ortho*-substituted phenyldiazenyl radicals exist, as based on the hydrogen hfs analysis: 1) (2-Substituted phenyl)diazenyl radicals showing two different hfs constants of the meta hydrogens, to which (2-fluoro-, 2-methoxy-, and 2-methylthiophenyl)diazenyl radicals belong, and 2) (2-substituted phenyl)diazenyl radicals revealing only one hydrogen hfs constant of hydrogen-5, to which (2-methyl-, 2-chloro-, and 2-bromophenyl)diazenyl radicals belong.

(2-Methoxyphenyl)diazenyl radical of group 1) showed hfs constants of 0.50 G for hydrogen-3 and of 1.30 G for hydrogen-5, and the assignment was confirmed by experiments Nos. 22—24. The hfs constants of (2-fluoro- and 2-methylthiophenyl)diazenyl radicals were assigned in analogy to (2-methoxyphenyl)diazenyl radical ($a_{H-5}>a_{H-3}$) and partly supported by experiments.*) In the case of (2-fluorophenyl)diazenyl, the highest non-nitrogen hfs constant observed was attributed to fluorine, based on the calculated values.

(2-Methyl- and 2-chlorophenyl)diazenyl radicals of group 2) revealed only one hydrogen hfs constant each, 1.85 and 1.65 G, respectively (Nos. 16 and 26), and the assignments were based on the experiments Nos. 18 and 28. The hydrogen hfs of (2-bromophenyl)diazenyl radical was assigned to hydrogen-5 in analogy to (2-chlorophenyl)diazenyl radical. Hydrogen hfs constants of some representative aryldiazenyl radicals are reproduced in Fig. 8.

(3) Possible Conformations of Aryldiazenyl Radicals. a) A Model of Rotation of the N=N Group about the C-N^2 Bond Axis, with a Preference of Staying in a Position out of the Plane of the Benzene Ring: Phenyldiazenyl radicals are very similar to benzoyl radicals, as regards σ-radical character and hydrogen hfs. In order to obtain a qualitative picture

*) (2-Fluorophenyl)diazenyl radical gave the same ESR spectrum as that of (2-fluoro-4,6-dideuteriophenyl)diazenyl (No. 25). The assignment of 1.22 G to hydrogen-5 for (2-methylthiophenyl)diazenyl was supported by comparison with (5-methyl-2-methylthiophenyl)diazenyl radical (g= 2.0002, a_{H-3}=0.50 G).

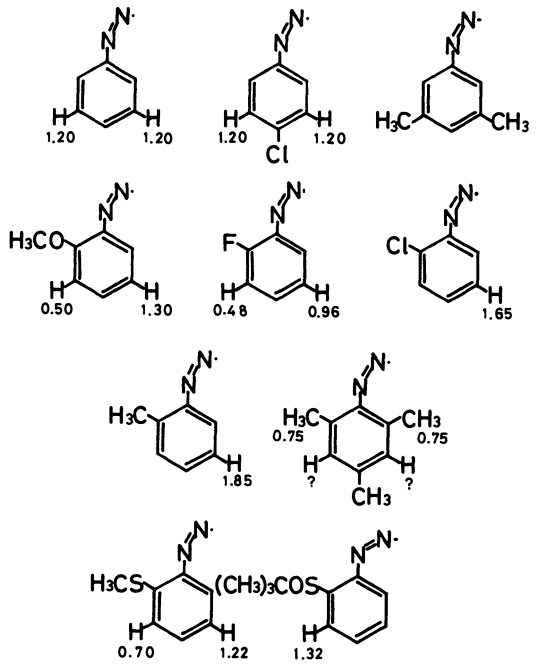

Fig. 8. Hyperfine splitting constants of aryldiazenyl radicals.

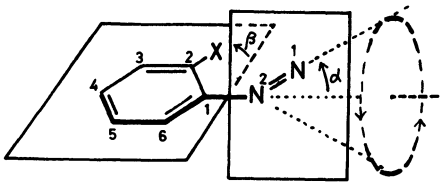

Fig. 9. Conformation of aryldiazenyl radicals with rotating N=N group about the C-N^2 bond axis. X stands for the substituent group.

of the conformation of aryldiazenyl radicals we performed INDO calculations[15] on phenyldiazenyl radical and on (2-fluoro-, 2-methyl-, 2-methoxy-, and 2,6-dimethylphenyl)diazenyl radicals. These calculations suggested that phenyldiazenyl radicals have conformations in which the azo group rotates about the C-N^2 bond axis with a preference in the "vertical" form: The N^1 atom of the radical is raised out of the plane of the benzene ring, forming an angle between the bonds C-N^2 and ^{1}N-N^2 (angle α, Fig. 9) of 40°, and an angle between the plane of the benzene ring and the plane C-N^2-N^1 (angle β) of 90°.

In the INDO calculations we have, first of all, searched for a conformation of the minimum total energy, and it was the vertical form for phenyldiazenyl radical with the total energy (T.E.)=−67.017750 a.u. The calculated highest hfs constants 0.80 G, of hydrogen-3 and -5 for this vertical conformation were in fairly good agreement with the symmetric spin distribution observed in the ESR experiments ($a_{H-3}=a_{H-5}=1.20$ G).

The molecular dimensions in the vertical form were as follows: Normal benzene ring; C-N^2=1.40 Å; N^1-N^2=1.20 Å; the angle α=40°, and the angle β=90°. The bond length C-N^2 used in the calculations was that of azobenzene,[16] but the length N^1-N^2 was shortened by 0.03 Å from that of azobenzene. The angle α was decreased from 60° of azobenzene to 40°.

a) Calculation was performed using α=40°, C-N^2= 1.40 Å, and N^1-N^2=1.20 Å. b) 1 Gauss=1×10^{-4} T.

Similar calculations by this method were also reported by Kasukhin and others for phenyldiazenyl radicals with a planar conformation,[17a] and by Seifert and Gerhart on a vertical conformation.[17b] Our results of INDO calculations for the vertical form affording the highest hfs constant for the hydrogen-3 and -5 differed from those of Seifert and Gerhart[17b] which revealed the highest hfs constants for 2,6-hydrogens. This difference is probably due to the different molecular dimensions used by these authors.

The calculation on a planar form with the same molecular dimensions except for β=0°, yielded a total energy higher than that of the vertical form by 4.17 kcal/mol†, and an asymmetric spin distribution over the aromatic hydrogens, as was reported by Kasukhin and others[17a] (Table 2). Since the difference between the total energies of the vertical and planar conformations was rather low, it is plausible to assume that the azo group of the phenyldiazenyl radical rotates about the C-N^2 bond axis with a high probability that it stays in the vertical form.

By using the bond lengths of phenyldiazenyl radical, we also calculated the hfs constants for the planar conformations of (2-fluoro-, 2-methyl-, 2-methoxy-, and 2,6-dimethylphenyl)diazenyl radicals with a smaller extent of variation of α. It turned out that the angle α=40° characterized the most stable planar conformation for all aryldiazenyl radicals considered. The vertical form of these aryldiazenyl radicals were found to be more stable by 2 to 4 kcal/mol than the corresponding planar conformations.

To a first approximation, these minima in T. E. sug-

a) The molecular dimensions for the calculations were α=40°, C-N^2=1.40 Å, and N^1-N^1=1.20 Å. b) 1 Gauss=1×10^{-4} T. c) The difference in total energies: T.E.$_\beta$−T.E.$_{\beta=0°}$. d) 1 cal=4.184 J. e) The angle β which gave the best fit of calculated hyperfine splitting constants to the experimental data.

gest that for aryldiazenyl radicals carrying 2-fluoro, 2-methyl, 2-methoxy-, and 2,6-dimethyl substituents, the N=N group rotates about the C-N^2 bond axis. A best fit of the calculated hydrogen hfs constants and the experimental data was, however, not found in the conformation with β=90° but in a certain nonplanar form except for (2,6-dimethylphenyl)diazenyl radical (Table 3). We are not going into further discussion on the conformations of the aryldiazenyl radicals, because of the limited accuracy of our calculations. In any case, it is plausible to assume a rotation of the N=N group with energy barriers of several kcal/mol, with a preference of a certain specified conformation.

In benzoyl radical[12] and in benzenesulfonyl radicals,[14] the groups C=O and SO_2 were reported to rotate about the bond connecting them to the benzene ring. Nitrosobenzene cation radical was presumed to be in a specified conformation, holding the oxygen atom above the plane of the benzene ring at an angle β of ca. 70°.[11]

The (2,4,6-trimethylphenyl)diazenyl radical revealed a hfs of nine septes (0.75 G). This suggested a symmetrical spin distribution on the six ortho methyl hydrogens. The INDO calculations for (2,6-dimethylphenyl)diazenyl in the vertical conformation gave hfs constants of 0.68 G for the ortho methyl hydrogens and 0.78 G for the 3,5-hydrogens. Thus, the observed proton hfs may also be of the nonet type, with two signals disappearing in the wings of the spectrum due to low intensity. At present, we cannot finally decide between a septet or a nonet structure.

We do not know why (2-methylphenyl)diazenyl radical (No. 16) gave a doublet and (2-methoxyphenyl)-diazenyl (No. 21) a double doublets structure of the proton hfs. Comparison of the calculated hydrogen-3 hfs constants of these radicals in the vertical form may give some indication. The constant of (2-methoxyphenyl)diazenyl, 1.02 G, was higher than that of (2-methylphenyl)diazenyl, 0.74 G, and this higher value might lead to the experimantally observed hfs of hydrogen-3 in the methoxy compound. We could not ascribe these differences simply to the electronegativity of the substituents.

b) A Model of Planar Conformation with N^1 in the Side Opposite to the 2-Substituent, Maintaining a High Angle α: The ESR experiments Nos. 30—32 suggested that the hfs constant of (2-*t*-butoxythiophenyl)diazenyl radical resulted from hydrogen-3. In order to gain insight into this exceptional hfs, we carried out CNDO calculations on (2-methylthiophenyl)diazenyl radical as a model by varying the angle α from +80° to −80° for the planar conformations (β=0°), and also by varying α for the vertical forms (β=90°). Although the agreement of the calculated hfs constants with the experimental ones was very poor, the best fit of the hydrogen hfs in the case of (2-*t*-butoxythiophenyl)diazenyl radical was found in the conformation with α=−80° in a planar form. The results of calculations for the vertical forms were completely unsatisfactory. It is of significance here to see that the INDO calculation for the planar conformation of (2-methylphenyl)diazenyl radical with α=−80° afforded the highest hydrogen hfs constant for hydrogen-3.*)

The angle of α=−80° may be understood, if one assumes that the ring opening of the thiadiazole by the attack of a *t*-butoxyl radical on the sulfur atom is followed by the rotation of the azo group about the C-N^2 bond axis by 180° to the opposite side of the 2-*t*-butoxythio substituent, and that the repulsion between the substituent and the lone pair electrons of N^2 is very high.

Experimental

(1) Syntheses of 1-Aryl-2-(arylthio)diazenes. 1-Aryl-2-

*) The calculation on (2-methylphenyl)diazenyl radical using α=−80°, β=0°, C-N^2=1.42 Å, and N^1-N^2=1.20 Å, gave $a_{N}1$=7.89 G, $a_{N}2$=8.30 G, $a_{3\text{-H}}$=0.99 G, $a_{4\text{-H}}$=0.49 G, $a_{5\text{-H}}$=−0.15 G, and $a_{6\text{-H}}$=−0.09 G.

(arylthio)diazenes were prepared according to the method of Zwet and Kooyman[18] by the reaction between arenediazonium chloride and sodium arenethiolate at ca. −5°C, and recrystallized from methanol or ether–methanol. The diazenes prepared are listed in Table 4.

(2) Syntheses of 1,2,3-Benzothiadiazoles. 1,2,3-Benzothiadiazoles were prepared by the method of Jacobson and Janssen[20] by diazotization of 2-mercaptoanilines and purified by distillation (Table 5).

(3) Syntheses of Triazenes. 1-Aryl-3,3-dimethyltriazenes (Ar=4-tolyl, 4-methoxyphenyl) were prepared by the reaction of arenediazonium salts with dimethylamine in aqueous alkaline solution,[21] and purified by sublimation.[22,23] 1-(4-Dimethylaminophenyl)-3,3-dimethyltriazene was obtained by a variant of this method, described by Rondestvedt and Davis.[24] However, the yield was only poor, and the compound decomposed slowly even at room temperature. The triazenes prepared are listed in Table 6.

(4) Isotope-Labelling Experiment. a) Deuterium-Labelling: The deuterium-labelled compounds were prepared by heating the parent anilines to 100°C in an excess of deuterium oxide (Merck UVASOL, *d*-99.75%)–deuterium chloride for 24 h whereupon the process was repeated 3 times each with a freshly prepared mixture of deuterium oxide–deuterium chloride.

The deuterium exchange was monitored and determined by ^{1}H NMR spectroscopy of aniline deuteriochloride in deuterium oxide.

Diazotization of the deuteriated aniline was also performed in deuterium oxide–deuterium chloride.

For the preparation of 1-(4-*t*-butylphenylthio)-2-(3,5-dideuteriophenyl)diazene, we used 3,5-dideuterioaniline (*d*-98%), obtained from perdeuterioaniline (Merck Co.) by ^{1}H-exchange reaction using H_2O–hydrogen chloride.

b) ^{15}N-Labelling: For the preparation of 1-(4-chlorophenyl)-2-(phenylthio)diazene-2-^{15}N, we diazotizated 4-chloroaniline using sodium nitrite-^{15}N (Prochem Co., ^{15}N-95%).

The ^{15}N-labelled triazenes (Nos. 5—7) were prepared according to the general procedure[21,22] using the respective ^{15}N-labelled starting materials (sodium nitrite-^{15}N, *p*-toluidine-^{15}N, ^{15}N-95%).

(5) ESR Experiment. ESR spectra were taken on a Varian E-109E spectrometer at −104 — −116°C. About 50 mg of azo sulfide and 2 ml of cyclopropane were sealed in vac. in a Pyrex tube (ϕ 10 mm), carrying a quartz side arm (ϕ 4 mm). The irradiation of the sample was carried out by using a Xe lamp (1 kW) of USHIO Electric Co. Type UXL-1000D-0, Pyrex cylinder lens, a filter glass (420 nm), and a 10 cm water cell filter. Triazenes were irradiated with a Molectron UV-14 and a quartz cylinder lens.

1,2,3-Benzothiadiazoles were illuminated using a Xe lamp and a quartz lens without 420 nm filter in the presence of di-*t*-butyl peroxide, ca. 200 mg.

The *g*-values were determined by reference to the *g*-value of 2.0054[25] of potassium nitrosodisulfonate in a slightly ammoniacal solution.

(6) CINDO Calculations. We employed the standard CNDO and INDO programs[15] on a MELCOM-COSMO 700

From Penicillin to Penem and Carbapenem. IX. C_1-Unit Introduction and the Carbapenam Synthesis from the Penicillin Molecule[1)]

Katsumi FUJIMOTO, Yuji IWANO, and Koichi HIRAI*
Chemical Research Laboratories, Sankyo Co., Ltd., 1-2-58, Hiromachi, Shinagawa-ku, Tokyo 140
(Received December 18, 1985)

An effective method for (*R*)-1-hydroxyethylation of benzyl bis(phenylseleno)penicillanate is described. The hydroxyethylated product was transformed into the 4-methylsulfonyl- and 4-phenylsulfonyl-2-azetidinone derivatives. These monocyclic compounds were reacted with potassium cyanide under two-phase conditions to give the 4-cyano-2-azetidinone derivative (C_1-unit introduction) in high yield. The cyano group was then converted into the iodomethyl group. Using the 4-iodomethyl-2-azetidinone derivative an isopenam derivative was synthesized. Furthermore, carbapenam derivative were also constructed by a novel [3+2] cyclization reaction between 4-iodomethyl-2-azetidinone and dimethyl 2-methylthio- and 2-phenylthiofumarate.

Since the discovery of thienamycin (**1**),[2)] a potent new broad spectrum antibiotic from Streptomyces cattleya, intense studies on the synthesis and structure-activity relationship of this and related compounds have revealed that the high antibiotic activity and stability against β-lactamase are linked to the combination of the *R* configuration of the 1-hydroxyethyl substituent and the trans configuration on the β-lactam ring.[3)]

There have been several reported syntheses starting from various materials; for example, 3-oxopentadioate, acetoxybutadiene, 2,2-dimethoxypropiononitrile oxide, L-aspartic acid, D-glucose, 6-bromo-3-oxobicyclo[2.2.1]heptan-7-carboxylate etc.[4)] We planned to utilize the β-lactam ring in the penicillin molecule for the synthesis of the carbapenem derivatives; in this case, however, there seemed to be three problems to be solved. The first one is how to introduce the (*R*)-1-hydroxyethyl substituent at the 6-position in the penicillin molecule, the second is concerned with introduction of a carbon substituent at the C-4 position of the 2-azetidinone ring, and the last is associated with the construction of the carbapenem skeleton. In this report we describe our approach for solving these three problems.

Concerning the first problem, we have already reported a method using methyl dibromopenicillanate[5)] as a starting material. However, our continuing interest in developing new methods prompted us to develop another route for the introduction of the (*R*)-1-hydroxyethyl substituent utilizing benzyl 6,6-bis(phenylseleno)penicillanate **3a**.

The starting materials **3a**, **4a**, and **5a** were prepared from the known diazo compound **2**[6)] by the reported method as shown in Scheme 1.

The phenylthio analogues **3b** (mp 100—103 °C), and **5b** (mp 84—86 °C) were prepared analogously, but **4b** could not be obtained by tributylstannane reduction of **3b**.

The compounds **3**—**5** were treated with methylmagnesium bromide or butyllithium in tetrahydrofuran (THF) to generate the enolates, which were reacted with acetaldehyde to yield the desired 6-hydroxyethylated products (**6**, **7**, and **8**).

As shown in Table 1, the diphenylthio derivative **3b** (Entries 1 and 2) gave no hydroxyethylated products. This is due to the well-known phenomena that

the selenoacetal generates a carbanion by releasing one of the seleno-parts on base treatment (i.e. pseudo halide), but this is not the case for the thioacetal. It is noteworthy that the α-phenylseleno (**5a**, Entries 4 and 5) and α-phenylthio (**5b**, Entry 8) derivatives gave the desired products, but the β-phenylseleno (**4a**, Entry 3) derivative gave only the diphenyldiselenide (about 50%). The diphenylseleno derivative (**3a**, Entries 6 and 7) gave **6**, **7**, and **8** in the ratio of 2:3:2 using butyllithium as base, and when methylmagnesium bromide was used as base **3a** gave **6** highly selectively in the ratio of **6**:**7**:**8**=30:1:0 in 78% isolated yield.

The structure of these products was determined by ^{1}H NMR and degradation study. As shown in Table 2, the two methyl groups of the compounds with β-phenylseleno group appeared at 1.70—1.78 and 1.31—1.45, and those of the compounds with an α-phenylseleno group appeared at 1.55—1.57 and 1.28—1.33. In the case of **6** and **7** these methyl group appeared at 1.55 and 1.28, and 1.78 and 1.45, respectively. These data strongly suggested that the product **6** has an α-phenylseleno group at C-6, and the product **7** has a β-phenylseleno group. Furthurmore the structures were confirmed by the chemical degradation study.

The high stereoselectivity observed in Entry 6 (Table 1) can be explained as follows: The magnesium enolate is less reactive than lithium enolate, therefore the transition state is rather product like and the bulkiness of the phenylseleno group affected the course of the approach of acetaldehyde to attack preferentially from the β-side of the molecule. In this approach the steric repulsion between the thiazolidine group and the methyl group in acetaldehyde forced the direction of aldehyde approach as shown in Fig. 2, therefore the β-(*R*)-1-hydroxyethylated product was obtained in a high selectivity.

Recently, Ishiguro and Nakatsuka calculated the energy of the enolate configuration by means of MNDO, and they announced that the most stable

Table 2. The Chemical Shifts of Methyl Groups

Compound	Me^1	Me^2
4a	1.40	1.70
5a	1.33	1.57
3a	1.31	1.70
6	1.28	1.55
7, **8**	1.45	1.78

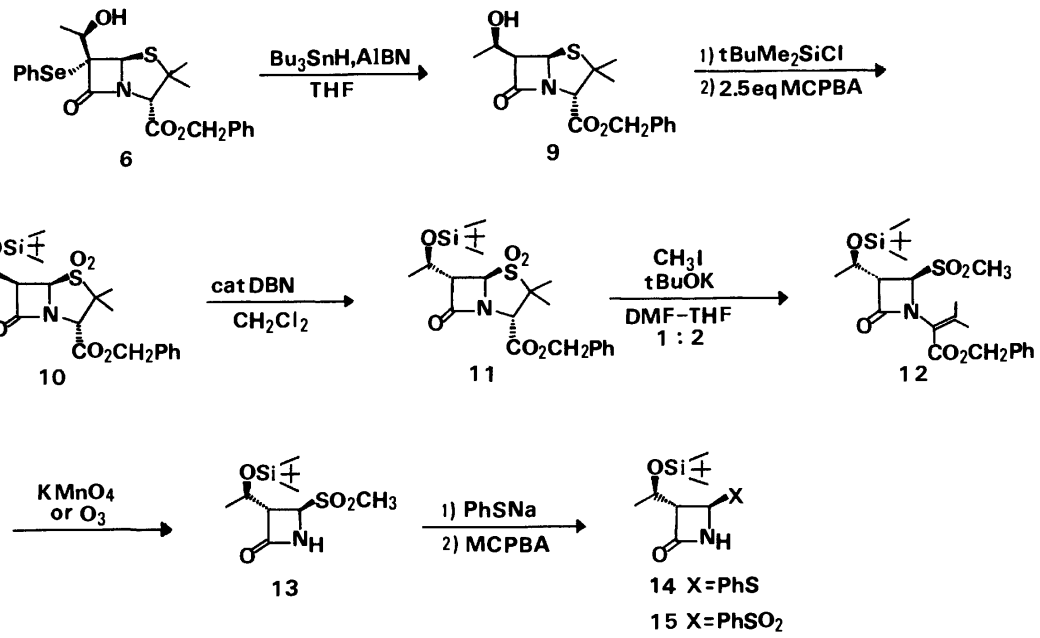
A

Fig. 3.

conformer is that as shown in Fig. 3.[7] In this conformer the upper face (β-face) is less sterically hindered than the α-face, so the metal coordination occurs on the β-face, and acetaldehyde has more chance to come from the β-face of the conformer.

With the desired product **6** in hand, we next turned our attention to conversion of **6** to 3,4-*trans*-disubstituted 2-azetidinone derivative. By tin hydride reduction, the phenylseleno group was removed to give 6β-(*R*)-1-hydroxyethylated product **9** in 95% isolated yield.[8] The coupling constant between the protons on the β-lactam ring is 4.4 Hz (cis) and the structure was confirmed as **11a** by comparison with an authentic



Scheme 3.

sample prepared from the known benzyl 6α-bromo-6β-(*R*)-1-hydroxyethylpenicillanate[9] by tin hydride reduction. After the protection of the hydroxyl group in 6, the product was oxidized with 2.5 equiv of *m*-chloroperbenzoic acid to afford the cis sulfone derivative **10** (mp 118 °C).

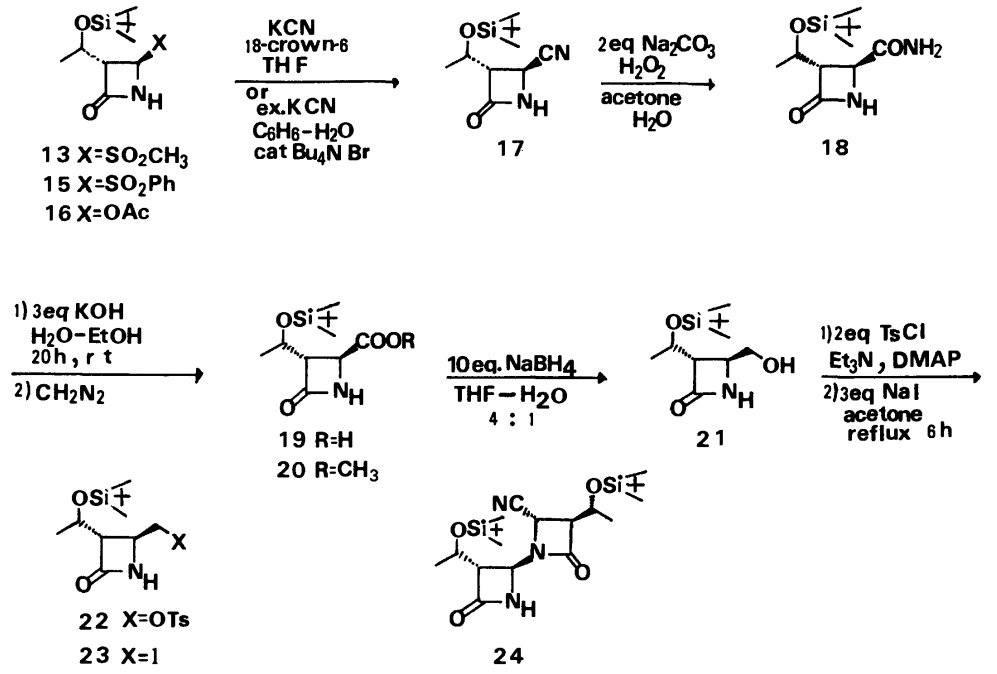
The crucial step for the isomerization of *cis*-**10** to *trans*-**11** was satisfactorily achieved by adding a catalytic amount of 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) to a solution of **10** in dichloromethane at 20—25 °C. The isomerization occurred within 30 min to afford the trans product **11**.

The ring opening of the trans sulfone **11** was smoothly achieved by excess methyl iodide and potassium *t*-butoxide (2.5 equiv) in THF: DMF (1:2) to yield the monocyclic β-lactam **12**. In this ring opening reaction sodium hydride was not effective. The *N*-substituent in **12** was oxidatively removed by potassium permanganate or ozonolysis to give the desired monocyclic β-lactam **13**, mp 100 °C, $[\alpha]_D^{22}$ −12.8° (*c* 1, $CHCl_3$). The sequence of the reaction in Scheme 3 was successfully applicable to benzyl 6α-bromo-6β-(1-hydroxyethyl)penicillanate to afford the same monocyclic β-lactam **13**. The methylsulfonyl group in **13** was transformed into phenylthio group in **14**, which was oxidized to the phenyl sulfone derivative **15** by the reported procedure.[10]

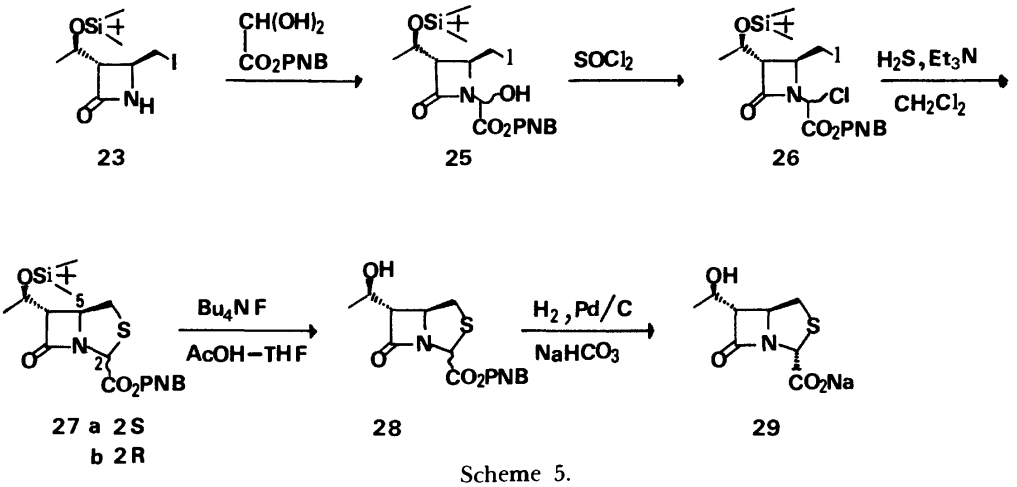
The next step to be solved was the carbon unit introduction at the C-4 position of the 2-azetidinone ring. To the best of our knowledge no method has been reported for the cyano group substitution at the C-4 position of 4-acetoxy-2-azetidinone.[11] In the case of our β-lactams **13**, **15**, and **16** which have a 1-hydroxyethyl substituent at the C-3 position we found that the cyano group was introduced in high yield at the desired position. Thus, the 2-azetidinone **15** or **16** was treated with an excess of potassium cyanide in THF in the presence of 18-crown-6 (0.1 equiv) or more conveniently with potassium cyanide under two-phase conditions (benzene–water, catalytic amount of tetrabutylammonium bromide) for 18 h to give the crystalline cyano derivative **17** in 68% isolated yield.

The dimeric product **24** was obtained in 10% yield as a by-product, but when the methylsulfonyl derivative **13** was used instead of **15** or **16** the formation of the dimeric product **24** was supressed to less than 10% of the monomer **17**. Manipulation of the cyano group in **17** was carried out as follows. Alkaline hydrolysis of **17** in the presence of hydrogen peroxide gave the amide derivative **18** in 85% isolated yield, which was further hydrolyzed to the acid **19**. Esterification with diazomethane gave the ester derivative **20**; $[\alpha]_D^{20}$ −12.8 (*c* 1.01, $CHCl_3$), which was then converted to the alcohol **21**. This was tosylated to the tosyl derivative **22**. The Finkelstein substitution reaction (NaI in acetone) of **22** was successfully performed to afford the 4-(iodomethyl)-2-azetidinone derivative **23** in 95% yield.

Compound **23** has been previously converted to thienamycin (**1**),[12] and was thought to be a useful precursor for the synthesis of isopenam derivative **29**. The aminal **25**, prepared via reaction of **23** with *p*-nitrobenzyl glyoxylate refluxing benzene, was chlorinated (thionyl chloride, 2,6-lutidine/THF) to give **26**, which was then transformed into isopenam derivative **27a** and **27b** (5:3) with hydrogen sulfide and triethylamine in dichloromethane. These structures were deduced from ^1H NMR spectra. The NMR spectra of 4,5-fused β-lactam system (i.e. penicillin) normally show the C-2 proton in the "natural" series



Scheme 4.

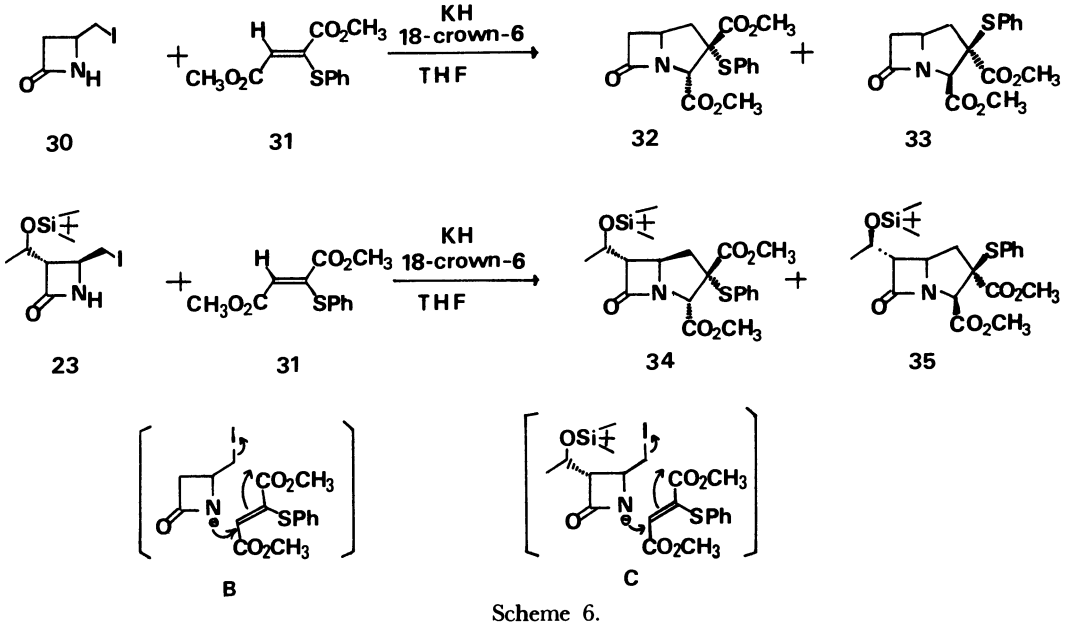


Scheme 5.

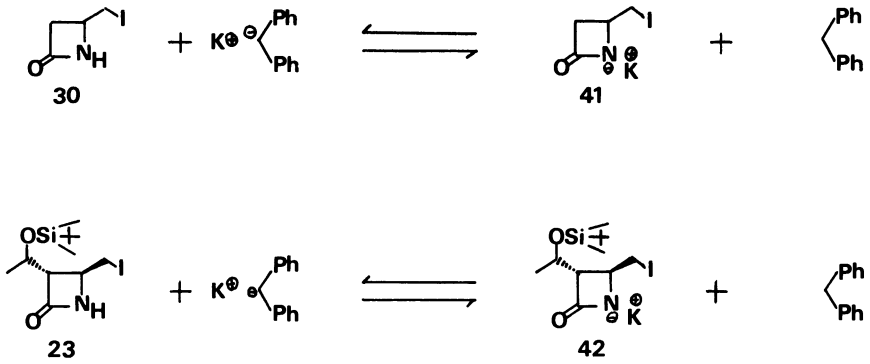
(2,5-trans) at a 0.5—1 ppm lower field than that of the corresponding "unnatural" series (2,5-cis).[13] In our case **27a** and **27b** showed the C-2 protons at δ 4.82 and 5.49 respectively. Therefore **27b** was the "natural" form (2,5-trans). Under the deprotection conditions (tetrabutylammonium fluoride, acetic acid–THF) both **27a** and **27b** gave the same alcoholic derivative **28**. In the presence of one equivalent of aqueous sodium hydrogencarbonate **28** was subjected to hydrogenolysis to give the sodium salt **29**, which has no remarkable antibacterial activity, MIC: Staphylococcus aureus 56, 200 $\mu g\,ml^{-1}$.

The following two methods are representative for constructing the carbapenem (or carbapenam): The first one is the internal Wittig type of reaction between C-2 and C-3 originally developed by Woodward in the field of penem synthesis, and the second one is the Merck method of the carbene insertion reaction between C-2 and N1-H to build up the 3-oxocarbapenam molecule. Beside these, several other methods have been reported, one of which is the aldol type reaction between C-2 and C-3, or C-3 and C-4 under basic conditions. We have already succeeded in the synthesis of Δ^3-carbapenem by aldol condensation between C-3 and C-4 using a dialdehyde intermediate.[14] Our continuing interest in constructing the carbapenam molecule by ring closure between C-3 and C-4 prompted us to develop another method for the synthesis of this unique carbapenam molecule.

Our 4-iodomethyl-2-azetidinone (**23**) has the nucleophilic center and at the same time the electrophilic center in itself. The nitrogen anion of **23** is sufficiently active to attack the α,β-unsaturated carbonyl compound (the Michael reaction) and the resulting



Scheme 6.



Scheme 7.

enolate has a chance to capture the electrophilic center (e.g. iodomethyl part) to give the cyclic compound.

On the basis of these hypotheses we investigated the reaction of 4-iodomethyl-2-azetidinone (**30**) with dimethyl 2-(phenylthio)fumarate (**31**) under basic conditions. The nitrogen anion **41** was generated by treatment of **30** with potassium hydride and 18-crown-6 in THF and reacted with **31** for 3 h at −78—0 °C. After the usual work-up the products were purified by careful TLC method to give **32** and **33** (1:1) in 27% isolated yield.

Likewise, the compound **23** gave the corresponding cyclized products (**34** and **35**) under the same conditions in 15% isolated yield.

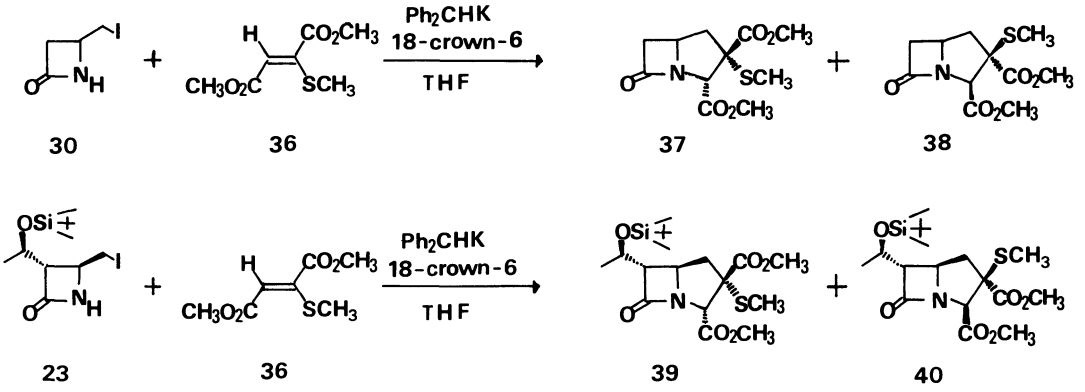
As compounds **32**, **33**, **34**, and **35** have both phenylthio substituent and methoxycarbonyl group at C-3 position, we attempted an oxidative decarboxylation, but the desired 3-oxopenam derivative was not obtained on *N*-chlorosaccinimide (NCS) treatment of the corresponding sodium salt. Therefore we changed the phenylthio group to methylthio group.

The reaction of 2-(methylthio)fumarate (**36**) with **30** and **23** did not give the expected cyclized products. Therefore, we checked the base effect on our cyclization and found that 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), potassium fluoride, triphenylmethylpotassium, and lithium diisopropylamide faild to give the desired compound, but gave the polymeric or intractable products. We thought that these undesirable side reactions occured because of the high concentration of the nitrogen anions. In other to suppress these side reactions the nitrogen anion **41** and **42** should be kept in low concentration. Therefore we took advantage of the generation of these anions under the equilibrium conditions using diphenylmethanide (pK_a=33).

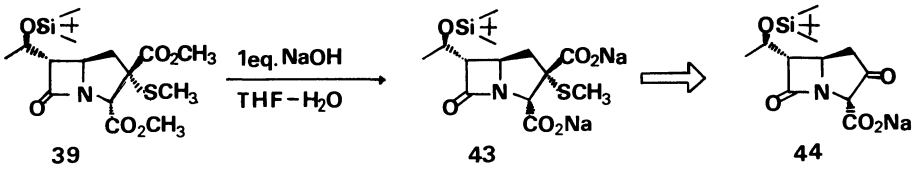
Diphenylmethylpotassium was prepared by the reaction of diphenylmethane with potassium hydride and 18-crown-6 in THF at room temperature. The 2-azetidinone **23** was added to the above solution and the mixture was stirred for 2 h at −40 °C to generate the nitrogen anion **42**. Dimethyl 2-(methylthio)fumarate was added to react with **42** for 2 h at −40—−20 °C to give **39** and **40** (2:1) in 18% yield.

Under the same conditions compound **30** gave the carbapenams **37** and **38** in 9% yield.

The purified compound **39** was carefully hydrolyzed



Scheme 8.



Scheme 9.

with aqueous sodium hydroxide to give the disodium salt **43**.

The structure of **32**, **33**, **34**, **35**, **37**, **38**, **39**, and **40** were determined by the same considerations as described for isopenam derivatives.

We are now investigating conversion of **43** to the 3-oxocarbapenam derivative (**44**) via Trost's oxidative decarboxylation method.[15] Compound **44** is an important intermediate for the synthesis of thienamycin and related carbapenem antibiotics.

Experimental

General. All melting points are uncorrected. Specific rotations were measured on a Perkin-Elmer 241 polarimeter. IR spectra were recorded on JASCO A102 and JEOL A320 Infrared spectrometers. NMR spectra were taken using a Varian EM 360L spectrometer (60 MHz) and the chemical shifts are expressed in ppm units using TMS as internal standard: s, singlet; d, doublet; dd, doublet of doublet; ddd, doublet of doublet of doublet; t, triplet; q, quartet; dq, doublet of quartet; m, multiplet; br, broad. Mass spectra (MS) were measured on JEOL JMS 01SG and JMS D300 mass spectrometers. (Preparative) TLC was carried out on Merck TLC-plates silica-gel F_{254} Pre-coated, layer thickness: (2 mm) 0.25 mm and spots were made visible by ultraviolet irradiation.

Benzyl (2*S*,5*R*,6*S*)-3,3-Dimethyl-7-oxo-6-phenylseleno-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate [(2*S*,5*R*,6*S*)-6-(Phenylseleno)penicillanate] (5a), Benzyl (2*S*,5*R*,6*S*)-6-(Phenylthio)penicillanate (5b), and Benzyl (2*S*,5*R*)-6,6-Bis(phenylseleno)penicillanate (3a): These materials were synthesized according to the method of Giddrings et al.[16]

5a: ^{1}H NMR ($CDCl_3$) δ=1.32 (3H, s), 1.57 (3H, s), 4.45 (1H, s), 4.46 (1H, d, J=2 Hz), 5.08 (2H, s), 5.17 (1H, d, J=2 Hz), 7.0—7.8 (10H, m).

5b: ^{1}H NMR ($CDCl_3$) δ=1.36 (3H, s), 1.59 (3H, s), 4.43 (1H, d, J=2 Hz), 4.50 (1H, s), 5.10 (2H, s), 5.19 (1H, d, J=2 Hz), 7.0—8.2 (10H, m).

3a: Mp 104—105 °C (recrystallized from ethanol); ^{1}H NMR ($CDCl_3$) δ=1.30 (3H, s), 1.70 (3H, s), 4.36 (1H, s), 4.90 (1H, AB type, J=12.6 Hz), 5.00 (1H, AB type, J=12.6 Hz), 5.33 (1H, s), 7.0—8.1 (15H, m).

Benzyl (2*S*,5*R*)-6,6-Bis(phenylthio)penicillanate (3b): To a mixture of benzyl 6-diazopenicillanate and diphenyldiselenide in dichloromethane was added a catalytic amount of boron trifluoride etherate. The solvent was removed under reduced pressure to give **3b**: Mp 99—103 °C (recrystallized from acetone-hexane); ^{1}H NMR ($CDCl_3$) δ=1.35 (3H, s), 1.70 (3H, s), 4.41 (1H, s), 5.04 (2H, s), 5.46 (1H, s), 7.15—7.80 (15H, m).

Found: C, 63.97; H, 4.93; N, 2.55%. Calcd for $C_{27}H_{25}NO_3S_3$: C, 63.82; H, 4.96; N, 2.76%.

Benzyl (2*S*,5*R*,6*R*)-6-(Phenylseleno)penicillanate (4a): To a solution of 317 mg (0.527 mmol) of benzyl 6,6-bis(phenylseleno)penicillanate (**3a**) in 10 ml of THF was added 367 mg of tributylstannane and a catalytic amount of AIBN. The solution was refluxed for 2 h and the solvent was removed under reduced pressure. The residue was purified by flash column chromatography (benzene-ethyl acetate, 10:1 v/v) to give 153 mg (65%) of **4a**: ^{1}H NMR ($CDCl_3$) δ=1.40 (3H, s), 1.70 (3H, s), 4.52 (1H, s), 4.76 (1H, d, J=4 Hz), 5.15 (2H, s), 5.54 (1H, d, J=4 Hz), 6.9—7.9 (10H, m).

Benzyl (2*S* 5*R*,6*S*)-6-[(*R*)-1-Hydroxyethyl]-6-(phenylselenopenicillanate (6): To a solution of 6.0 g of methyl 6,6-bis(phenylseleno)penicillanate (**5a**) in 60 ml of THF was added 15 ml of methylmagnesium bromide in THF (1 mol dm^{-3}, Tokyo Kasei), keeping the reaction temperature below −50 °C. After stirring for 80 min at −78 °C, 4 ml of acetaldehyde was added and the whole mixture was stirred for 40 min. The reaction was quenched at −78 °C with 60 ml of a saturated aqueous ammonium chloride. The Dry-Ice acetone bath was removed, and the mixture was stirred to become two phase at ambient temperature. The organic phase was separated and the aqueous phase was extracted with ethyl acetate three times. The combined extracts were washed with saturated aqueous sodium chloride, and dried over anhydrous magnesium sulfate. After removal of the solvent

under reduced pressure the crude product was purified by dry column chromatography (benzene–ethyl acetate, 5:1 v/v) to give 3.68 g of **6** (74%): R:S=30:1.

Benzyl (2*S*,5*R*,6*R*)-6-[(*S*)-1-Hydroxyethyl]-6-(phenylseleno)-penicillanate (7): R_f=0.5 (benzene–ethyl acetate, 10:1 v/v); mp 195 °C; ^{1}H NMR ($CDCl_3$) δ=1.28 (3H, d, J=6.4 Hz), 1.45 (3H, s), 1.78 (3H, s), 1.8—2.5 (1H, m), 3.5—4.1 (1H, m), 4.53 (1H, s), 5.17 (2H, s), 5.47 (1H, s), 7.0—8.0 (10H, s).

Found: C, 56.25; H, 5.15; N, 2.77; S, 6.53%. Calcd for $C_{23}H_{25}NO_4SSe$: C, 56.32; H, 5.14; N, 2.86; S, 6.53%.

Benzyl (2*S*,5*R*,6*S*)-[(*R*)-1-Hydroxyethyl]-6-(phenylseleno)-penicillanate (6): R_f=0.41 (benzene–ethyl acetate, 10:1 v/v); ^{1}H NMR ($CDCl_3$) δ=1.28 (3H, s), 1.33 (3H, d, J=6.0 Hz), 1.55 (3H, s), 2.89 (1H, br s), 4.30 (1H, s), 4.46 (1H, q, J=6.0 Hz), 4.7—5.3 (2H, m), 5.12 (1H, s), 6.9—7.8 (10H, m).

All other aldol type reactions were performed by the same procedure.

Benzyl (2*S*,5*R*,6*R*)-6-[(*S*)-1-Hydroxyethyl]-6-(phenylthio)-penicillanate (7): Mp 179 °C; IR (nujol) 3475, 1780, 1750 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.23 (3H, d, J=6.5 Hz), 1.38 (3H, s), 1.70 (3H, s), 3.7—3.9 (1H, m), 4.49 (1H, s), 5.19 (2H, s), 5.58 (1H, s), 7.2—7.85 (10H, m).

Found: C, 62.14; H, 5.63; N, 3.16; S, 14.57%. Calcd for $C_{23}H_{25}NO_4S_2$: C, 62.28; H, 5.68; N, 3.16; S, 14.46%.

Benzyl (2*R*,5*R*,6*R*)-6-[(*R*)-1-Hydroxyethyl]penicillanate (9): A solution of 3.5 g of **6**, 4.0 g of tributylstannan, and catalytic amount of AIBN in 35 ml of THF was stirred for 2 h at 60 °C. The solvent was removed under reduced pressure and the residue was purified by TLC (benzene–ethyl acetate, 5:1 v/v) to give 2.65 g of **9** (quantitative): R_f=0.2 (benzene–ethyl acetate, 10:1 v/v); ^{1}H NMR ($CDCl_3$) δ=1.22 (3H, d, J=6 Hz), 1.41 (3H, s), 1.66 (3H, s), 2.88 (1H, OH), 3.49 (1H, dd, J=4.4 and 9 Hz), 3.8—4.5 (1H, m), 4.48 (1H, s), 5.20 (2H, s), 5.40 (1H, d, J=4.4 Hz), 7.43 (5H, m).

Benzyl (2*S*,5*R*,6*R*)-6-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-penicillanate 1,1-Dioxide (10): To a stirred solution of 2.65 g of **9** in 20 ml of DMF was added 680 mg of imidazole and 1.5 g of *t*-butylchlorodimethylsilane at room temperature. After 20 h ethyl acetate was added to the mixture, and the solution was washed with water and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure and the residue was purified by column chromatography (benzene–ethyl acetate, 20:1 v/v) to give 1.9 g of the silyl ether.

To a stirred solution of 1.9 g of the silyl ether thus obtained in 25 ml of dichloromethane was added 2.2 g of *m*-chloroperbenzoic acid at room temperature. After 2 h the mixture was diluted with dichloromethane and washed with 5% aqueous potassium hydroxide. The solvent was removed under reduced pressure and the residue crystallized from ether to give **10**: Mp 118 °C (recrystallized from ether); R_f=0.36 (benzene–ethyl acetate, 20:1 v/v); IR (nujol) 1810, 1750 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.10 (3H, s), 0.15 (3H, s), 0.91 (9H, s), 1.26 (3H, s), 1.28 (3H, d, J=7 Hz), 1.52 (3H, s), 3.80 (1H, dd, J=5.5 and 10 Hz), 4.46 (1H, s), 4.59 (1H, d, J=5.5 Hz), 4.85 (1H, m), 5.20 (2H, br s), 7.40 (5H, s).

Found: C, 57.29; H, 7.31; N, 2.87; S, 6.60%. Calcd for $C_{23}H_{35}NO_5SSi$: C, 57.35; H, 7.32; N, 2.91; S, 6.60%.

Benzyl (2*S*,5*R*,6*R*)-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-penicillanate 1,1-Dioxide (11): To a stirred solution of 1 g of the cis sulfone derivative **10** in 5 ml of chloroform was added 0.05 ml of DBN. After 1 h the completion of the reaction was checked by ^{1}H NMR. The mixture was washed successively with 1% hydrochloric acid and water and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure to give 980 mg of **11**: ^{1}H NMR ($CDCl_3$) δ=0.10 (6H, s), 0.91 (9H, s), 1.26 (3H, d, J=7 Hz), 1.31 (3H, s), 1.55 (3H, s), 3.66 (1H, dd, J=2.0 and 3.8 Hz), 4.2—4.55 (1H, m), 4.39 (1H, s), 4.61 (1H, d, J=2 Hz), 5.22 (2H, s), 7.42 (5H, s).

Benzyl 2-[(3*S*,4*R*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-methylsulfonyl-2-oxo-1-azetidinyl]-3-methyl-2-butenoate (12): To a stirred solution of 100 mg (0.208 mmol) of the trans sulfone **11** in 2 ml of THF–DMF (2:1) was added 0.5 ml of methyl iodide and 70 mg of potasium *t*-butoxide successively. After about 30 min the completion of the reaction was checked by TLC and ethyl acetate was added. The mixture was washed with water and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure and the residue was purified by TLC (benzene–ethyl acetate, 10:1 v/v) to give 78 mg of **12**: IR (neat): 1780, 1722, 1630 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.07 (3H, s), 0.13 (3H, s), 0.92 (9H, s), 1.30 (3H, d, J=7 Hz), 2.06 (3H, s), 2.22 (3H, s), 2.56 (3H, s), 3.55 (1H, dd, J=2.5 and 4 Hz), 4.1—4.6 (1H, m), 5.17 (1H, d, J=2.5 Hz), 4.9—5.5 (2H, m), 7.35 (5H, s).

(3*S*,4*R*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-(methylsulfonyl)-2-azetidinone (13): To a stirred solution of 68 mg of the seco derivative **12** and 0.05 ml of acetic acid in 8 ml of acetone was added slowly a solution of 50 mg of potassium permanganate in 5 ml of water. After 16 h the reaction mixture was filtered through Celite, and the solvent was evaporated. The residual solution was extracted with ethyl acetate and the combined extracts were washed with water and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure and the crude product was purified by TLC (benzene–ethyl acetate, 1:1 v/v) to give 40 mg (94%) of **13**: Mp 100 °C; $[\alpha]_D^{20}$ −12.8° (*c* 1 $CHCl_3$); IR (nujol): 3350, 1795, 1780, 1737 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.09 (6H, s), 0.88 (9H, s), 1.28 (3H, d, J=6 Hz), 2.94 (3H, s), 3.54 (1H, t, J=2 Hz), 4.1—4.5 (1H, m), 4.70 (1H, d, J=2 Hz), 6.95 (1H, br s).

Found: C, 46.66; H, 8.18; N, 4.33; S, 10.57%. Calcd for $C_{12}H_{25}NO_4SSi$: C, 46.87; H, 8.20; N, 4.56; S, 10.43%.

(3*S*,4*R*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-(phenylthio)-2-azetidinone (14): To a stirred solution of 3.38 g (10.99 mmol) of 4-(methylsulfonyl)-2-azetidinone **13** in 40 ml of absolute ethanole was added sodium phenyl sufide in absolute ethanol (prepared from 12.86 mmol of sodium ethoxide in ethanol and 12.05 mmol of thiophenol) at 5 °C. After 2 h, 600 ml of ethyl acetate was added, washed successively with neutral phosphate buffer (pH 6.86) three times and brine, and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure and the residue was purified by flash chromatography (benzene–ethyl acetate, 95:5 v/v) to give 3.42 g (95%) of **14**: ^{1}H NMR ($CDCl_3$) δ=0.07 (6H, s), 0.83 (9H, s), 1.22 (3H, d, J=6.0 Hz), 3.08 (1H, dd, J=2.0 and 4.0 Hz), 3.90—4.5 (1H, m), 4.85 (1H, d, J=2.0 Hz), 6.70 (1H, br s), 7.20—7.60 (5H, m).

(3*S*,4*R*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-(phenylsulfonyl)-2-azetidinone (15): A solution of 4.12 g (12.2 mmol) of phenylthioazetidinone **14** in 150 ml of ethyl acetate was cooled in an ice bath. Sodium acetate (1.66 g, 12.2 mmol), 0.26 g of manganese(II) acetylacetonate, and 12.4 ml (73.2 mmol) of 40 % peracetic acid was added and the mixture was stirred for 2 h. Ethyl acetate was added and the reaction mixture was washed successively with aqueous sodium hydro-

gensulfite two times, saturated sodium hydrogencarbonate and brine two times and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure, and the residue was purified by flash column chromatography (benzene–ethyl acetate,95:5 v/v) to give 3.3 g (73%) of **15**: ^{1}H NMR ($CDCl_3$) δ=0.05 (6H, s), 0.83 (9H, s), 1.25 (3H, d, J=6.0 Hz), 3.45 (1H, dd, J=2.0 and 3.5 Hz), 3.90—4.40 (1H, m), 4.56 (1H, d, J=2.0 Hz), 6.85 (1H, br s), 7.6—8.1 (5H, m).

(3*S*,4*S*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-cyano-2-azetidinone (17): i) To a solution of 57 mg of methyl sulfone **13** in 2 ml of benzene was added a solution of 57 mg of potassium cyanide in 2 ml of water and a catalytic amount of tetrabutylammonium bromide. The mixture was stirred for 24 h and the organic layer was separated. The aqueous layer was extracted with dichloromethane. The combined extracts were dried over anhydrous magnesium sulfate and evaporated. The residue was purified by TLC (benzene–ethyl acetate, 5:1 v/v) to give 42 mg (89%) of **17**.

ii) To a solution of 150 mg of **16** in 4 ml of anhydrous THF was added 100 mg of finely powdered potassium cyanide and 14 mg of 18-crown-6. The mixture was stirred vigorously for 2—8 h. The completion of the reaction was checked by TLC (benzene–ethyl acetate, 5:1 v/v). Ethyl acetate was added and the solution was washed with brine and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure and the residue was purified by TLC (benzene–ethyl acetate, 5:1 v/v, R_f=0.38) to give 70 mg of **17**: Mp 136—138 °C (recrystallized from dichloromethane–hexane); IR (nujol): 3220, 2240, 1780, 1755 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.08 (6H, s), 0.88 (9H, s), 1.25 (3H, d, J=6 Hz), 3.65 (1H, t, J=2.5 Hz), 4.35 (1H, d, J=2.5 Hz), 4.30 (1H, dq, J=2.5 and 6 Hz), 6.65 (1H, br s).

Found: C, 56.57; H, 8.66; N, 11.00%. Calcd for $C_{12}H_{22}N_2O_2Si$: C, 56.65; H, 8.72; N, 11.01%.

(3*S*,4*R*)-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-[(3*S*,4*S*)-3-[(*R*)-1-(*t*-butyldimethylsilyloxy)ethyl]-4-cyano-2-oxo-1-azetidinyl]-2-azetidinone (24): Mp 158 °C (recrystallized from chloroform–hexane); IR (nujol): 3225, 1775 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.10 (12H, s), 0.90 (18H, s), 1.25 (6H, d, J=5.6 Hz), 3.5—3.9 (2H, m), 4.0—5.3 (2H, m), 4.48 (1H, d, J=2 Hz), 5.45 (1H, d, J=2 Hz), 6.23 (1H, br s).

(3*S*,4*S*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-carbamoyl-2-azetidinone (18): To a stirred solution of 163 mg of **17** in 3 ml of acetone was added 0.1 ml of 30% aqueous hydrogen peroxide and 1.4 ml of 0.5 mol dm^{-3} aqueous sodium carbonate at room temperature. After 30 min ethyl acetate was added and the organic layer was washed with water and dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure and the residue was purified by TLC (benzene–ethyl acetate, 1:2 v/v, R_f=0.2) to give 130 mg of **18** as crystals: Mp 87 °C (recrystallized from acetone–hexane); IR (nujol): 3100—3600, 1750, 1730, 1685, 1670 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.09 (6H, s), 0.90 (9H, s), 1.26 (3H, d, J=6.5 Hz), 3.21 (1H, dd, J=2.5 and 4.0 Hz), 4.15 (1H, d, J=6.5 Hz), 4.20 (1H, dq, J=4.0 and 6.5 Hz), 6.76 (2H), 7.36 (1H).

Found: C, 52.48; H, 8.98; N, 10.15%. Calcd for $C_{12}H_{24}N_2O_3Si$: C, 52.91; H, 8.88; N, 10.28%.

Methyl (3*S*,4*S*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-2-oxoazetidine-4-carboxylate (20): i) To a stirred solution of 210 mg of **17** in 6 ml of ethanol was added a solution of 100 mg of sodium hydroxide in 2.6 ml of water and 0.15 ml of 30% aqueous hydrogen peroxide. After 15 min the mixture was warmed up to 50 °C and stirred for 1.5 h at that temperature. After cooling, water and ethyl acetate was added and the organic layer was separated. From the organic layer 60 mg of **17** was obtained. The aqueous layer was acidified (about pH 2) with hydrochloric acid and the mixture was extracted with ethyl acetate. The combined extracts were washed with water and dried over anhydrous magnesium sulfate. After filtration, a solution of diazomethane in ether was added to the filtrate. The solvent was removed under reduced pressure to give 95 mg of **20** as crystals.

ii) To a solution of 180 mg of **18** in 4 ml of ethanol was added a solution of 40 mg of sodium hydroxide in 1 ml water. The reaction mixture was warmed up to 50 °C and stirred for 1 h at 50 °C. After cooling the solution was washed with ethyl acetate and acidified with hydrochloric acid. The organic layer was extracted with ethyl acetate and dried over anhydrous magnesium sulfate. After filtration a solution of diazomethane in ether was added and the solvent was removed under reduced pressure to give 90 mg of **20**: R_f= 0.4 (cyclohexane–ethyl acetate, 2:1 v/v); mp 78 °C; $[\alpha]_D^{25}$ −12.8° (c 1.01, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ=0.09 (6H, s), 0.89 (9H, s), 1.24 (3H, d, J=6 Hz), 3.25 (1H, m), 4.28 (1H, d, J=2.5 Hz), 4.2 (1H, m), 6.4 (1H, br s).

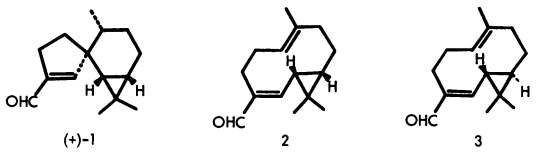
Total Synthesis of (−)-Vitrenal and Its Biological Activity

Mitsuaki KODAMA,** Usman S. F. TAMBUNAN, Tetsuto TSUNODA, and Shô ITÔ*
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980
(Received December 25, 1985)

(−)-Vitrenal, the enantiomer of the natural sesquiterpene aldehyde isolated from a liverwort, has been synthesized starting from (+)-3-carene, and its activity as a plant-growth regulator has been tested.

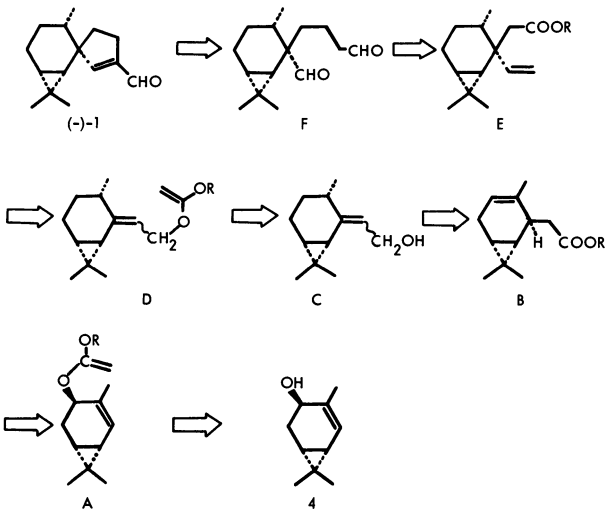
(+)-Vitrenal ((+)-**1**) is a tricyclic sesquiterpene aldehyde isolated by Matsuo et al. from a liverwort, *Lepidozia vitrea*, together with its possible biogenetic precursor, isobicyclogermacrenal (**2**), and lepidozenal (**3**).[1] All of these compounds have been shown to possess potent plant-growth inhibitory activity.[1] Because



of its unique carbon skeleton as well as the biological activity, we have attempted a total synthesis of (−)-vitrenal ((−)-**1**), the enantiomer of the natural product, from easily accessible (+)-3-carene. Successful synthesis of (−)-**1** would provide us with a rare chance to test the growth-regulating activity of unnatural enantiomer. Although a synthesis of (±)-vitrenal has been reported by Magari et al.,[2] and our approach is somewhat similar to theirs, we describe our synthesis herein because we have successfully achieved stereocontroled C–C bond formation in two crucial steps by employing Claisen rearrangement. We also describe the result of our biological test.

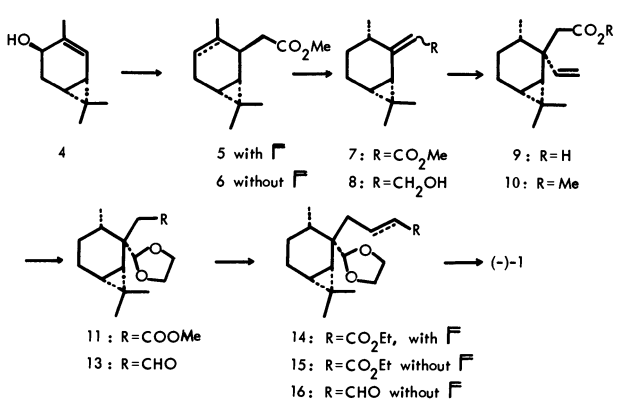
Results and Discussion

Our synthetic strategy is shown in the form of retrosynthesis. The first Claisen rearrangement (A→B) would proceed in high stereoselectivity. The reduction of double bond in B would proceed from β-face due to the presence of a bulky dimethylcyclopropyl ring. Introduction of double bond, the formation of C, may not be selective, but both geometrical isomers would afford the same carboxylic ester E after the 2nd Claisen rearrangement, as long as the vinyl terminus approaches the allyl part from the less hindered and therefore favored β-face. Elongation of ester chain and cleavage of double bond in E to the dialdehyde F, and its aldol condensation should be unambiguous.



Starting with 2-caren-4β-ol (**4**), obtained by the known procedure,[3] the first Claisen rearrangement was performed: Heating **4** at 137° with excess triethyl orthoacetate in the presence of propionic acid induced vinyl ether formation and its Claisen rearrangement in one pot to afford, after hydrolysis and methylation, the methyl ester **5** in 65% yield. Catalytic hydrogenation (Pd–C) of **5** afforded the saturated ester **6** in quantitative yield. However, gas chromatographic analysis of **6** revealed the presence of stereoisomers in the ratio of 95:5. Assignment of the stereochemistry for the major isomer rests on the consideration of steric requirement in hydrogenation described above. Since the separation of the isomers was possible only by gas chromatography, the mixture was used in the following steps.

Phenylselenylation followed by oxydative deselenylation of **6** gave the unsaturated ester **7** in 75% yield. As was expected (vide supra), **7** was a 1:1 mixture of geometrical isomers. Although the isomers were separated by gas chromatography and properly characterized, the mixture was used without separation for further steps. The ester **7** was reduced with diisobutylaluminum hydride (DIBAL) to give the allylic alcohol **8** in 91% yield. The geometrical isomers were

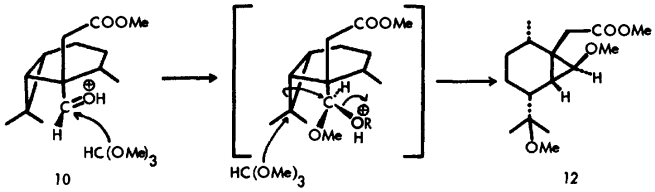


**Present address: Faculty of Pharmaceutical Sciences, Tokushima Bunri University, Tokushima 770.

possible to separate only by gas chromatography.

For the introduction of the second carbon chain, Claisen rearrangement was again applied on the mixture **8**. Heating **8** with excess triethyl orthoacetate under the conditions similar to the previous reaction, and the subsequent alkaline hydrolysis furnished a single crystalline acid **9** in 56% yield. Its methyl ester **10** gives a single peak on GLC, while the methyl ester of the acidic mother liquor exhibited the same major peak along with a minor peak. Thus both geometrical isomers must have yielded the same acid **9** as expected.[4] We have thus removed the undesired stereoisomer on the secondary methyl group simultaneously at this stage.

With chemically and optically pure acid **9** in hand, we have proceeded to the construction of the cyclopentene ring. The double bond in the ester **10** was ozonized and the formyl group formed was protected by ethylene glycol to give the acetal carboxylate **11** in 72% yield. When the protection was attempted with trimethyl orthoformate in the presence of *p*-toluenesulfonic acid, the product **12** obtained has the rearranged structure. It may be formed through the sequence shown.



DIBAL reduction of **11** and pyridinium chlorochromate (PCC) oxidation of the resulted alcohol gave the acetal aldehyde **13** in 90% yield. Wittig reaction of **13** with (ethoxycarbonylmethylene)triphenylphosphorane went smoothly and the unsaturated ester **14** was obtained in 95% yeild. Catalytic reduction of **14** (to **15**) and subsequent DIBAL reduction followed by PCC oxidation afforded the acetal aldehyde **16**. Finally, treatment of **16** with hydrochloric acid accomplished deacetalization and aldol condensation in one pot to afford (−)-**1**. IR and NMR spectra of the product were identical and the specific rotation ($[\alpha]_D^{18}$ −113°) is completely opposite with those of natural vitrenal ($[\alpha]_D$ +107°).[1]

Although the biological activities of enantiomers have extensively been investigated in the field of insect pheromones,[5] the similar studies on growth regulators are rather scarce probably because natural regulators usually have rather complicated structures and synthesis of the unnatural enantiomer is not easy. The present synthesis of (−)-**1** gave us a good opportunity to compare the activity of the enantiomeric pair. Thus, we have carried out biological test using rice seedling and lettuce hypocotyl. While natural (+)-**1** shows a strong inhibition (I_{50}=18 ppm),[1] (−)-**1** exhibited a weak promotion (P_{50}=2.18×10³ ppm) in the former test and a weak inhibition (I_{50}=27.79×10³ ppm) for the latter. To the best of our knowledge, this is the first enantiomeric pair tested for the growth-regulating activity in higher plants.

Experimental

General. Melting points reported herein were taken with a YANACO melting point apparatus and are uncorrected. The ^{1}H NMR spectra were obtained on a Varian EM-390, a Varian XL-200 and/or a JEOL FX 90Q spectrometer. Chemical shifts are reported in ppm downfield from internal tetramethylsilane. Infrared spectra were recorded on a JASCO IR-2 diffraction grating infrared spectrometer. Mass spectra were measured on a HITACHI M-52 mass spectrometer and high resolution mass spectra on a JEOL JMS-01S02 mass spectrometer. Elemental analyses were performed on a YANAGIMOTO-CHN Coder. Gas chromatogram were recorded on a Shimadzu GC-6A. Optical rotation was measured on a UNION Automatic Digital Polarimeter, PM101.

(+)-Methyl 2β-(3-Caren-2-yl)acetate (5). A mixture of 2-caren-4-ol[3] (**4**, 10.6 g), propionic acid (0.6 ml) and triethyl orthoacetate (129 ml, 6.0 equiv) was heated at 136—137 °C for 20 h, and the reaction mixture was hydrolyzed with KOH (25.76 g) in 50% aq methanol (600 ml) under reflux for 4 h. After cooling, the reaction mixture was diluted with water and washed with ether. Separated aqueous layer was neutralized with 2 M HCl (1 M=1 mol dm^{-3}), and then extracted with ether. After washed with water and brine and dried over anhydrous $MgSO_4$, the ether extract was treated with diazomethane at room temperature for 30 min, and the solvent was distilled off. The residue was chromatographed on SiO_2 column (hexane:ether=10:1) to give 9.437 g (65% yeild) of **5**. Bulb-to-bulb distillation at 75 °C, 0.05 mmHg (1 mmHg=133.322 Pa), furnished the analytical sample as a colorless oil: IR (neat) 1734 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.88, 1.03 (2s, 6H, $2CH_3$), 1.63 (s, 3H, CH_3), 3.63 (s, 3H, $COOCH_3$), 5.21 (s, b, 1H, C=CH); MS *m/z* 208 (M^+); $[\alpha]_D^{24}$ +6.5° (*c* 1.75, MeOH). Found: C, 75.25; H, 9.70. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68.

(−)-Methyl 2β-(2-Caranyl)acetate (6). **5** (3.00 g) was hydrogenated (3 Atm) in methanol (75 ml) at room temperature over palladium charcoal (600 mg) for 3 h. Filtration of the catalyst and evaporation of the solvent gave 3.027 g (100% yield) of **6**, colorless liquid. Gas chromatography of **6** disclosed the presence of two isomers in the ratio of 95:5 (DEG-S 15%, 130 °C). Preparative gas chromatography furnished the analytical sample of **6**, colorless oil: IR (neat) 1734 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.93 (d, 3H, *J*=10.5 Hz, CH_3), 0.96 (s, 6H, $2CH_3$), 3.66 (s, 3H, $COOCH_3$); MS *m/z* 210 (M^+); $[\alpha]_D^{24}$ −150° (*c* 1.28, MeOH). Found: C, 73.96; H, 10.56. Calcd for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54.

Methyl 2-Caranylideneacetate (7). To a solution of lithium diisopropylamide (22.8 mmol) in dry tetrahydrofuran (50 ml) was added **6** (11.4 mmol) dropwise at −78 °C under argon atmosphere. After stirring for 30 min, benzeneselenenyl chloride (4.336 g) in dry tetrahydrofuran (5 ml) was added dropwise rapidly, and stirring was continued overnight at room temperature. Addition of water, extraction with ether, drying over anhydrous $MgSO_4$ and evaporation of the solvent gave, after short SiO_2 column chromatography (hexane:ether=10:1), 3.281 g (76% yield) of phenylseleno

compound.

To the phenylseleno compound in methanol (50 ml) was added $NaIO_4$ (4.438 g) in water (50 ml) with vigorous stirring. After 2 h, the product was extracted with ether. The extract was washed with water, saturated $NaHCO_3$ and brine, and dried over anhydrous Na_2SO_4. Evaporation of the solvent and SiO_2 chromatography of the residue (hexane:ether=50:1) gave 1.790 g (75%) of **7** as a colorless oil. Gas chromatographic analysis showed two peaks in the ratio of nearly 1:1 (DEG-S 15%, 160°C). Each peak was separated by preparative gas chromatography to give analytical specimens. **7a**: IR (neat) 1710, 1610 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.82, 1.04 (2s, 6H, $2CH_3$), 1.19 (d, 3H, J=7.2 Hz, CH_3), 3.71 (s, 3H, $COOCH_3$), 5.82 (t, 1H, J=1.8 Hz,C=CH); MS m/z 208 (M^+). **7b**: IR (neat) 1704, 1604 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (s, 3H, CH_3), 1.09 (d, 3H, J=7.2 Hz, CH_3), 1.10 (s, 3H, CH_3), 3.67 (s, 3H, $COOCH_3$), 5.84 (s, 1H, C=CH); MS m/z 208 (M^+).

2-(2-Caranylidene)ethanol (8). A mixture of **7a** and **7b** (800 mg) in dry hexane (20 ml) was stirred at 0°C for 2 h with 1 M DIBAL solution (11 ml) under argon atmosphere. After saturated NH_4Cl (10 ml) was added, organic layer was separated and aqueous layer was extracted with ether. The organic layer was washed with water and brine, dried over anhydrous Na_2SO_4 and then solvent was evaporated. The residue was chromatographed on SiO_2 (hexane:ether=1:1) to give 700 mg (91%) of **8** with two components as a colorless oil. Preparative gas chromatography (DEG-S 15%, 160°C) separated each component **8a**: IR (neat) 3317, 1634 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.85 (s, 3H, CH_3), 1.02 (d, 3H, J=7.2 Hz, CH_3), 1.09 (s, 3H, CH_3), 4.24 (t, 2H, J=7.2 Hz, $=HCCH_2O$), 5.58 (t, 1H, J=7.2 Hz, C=CH); MS m/z 180 (M^+). **8b**: IR (neat) 3300, 1635 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (s, 3H, CH_3), 0.95 (d, 3H, J=7.2 Hz, CH_3), 1.05 (s, 3H, CH_3), 4.23 (m, 2H, $=CH-CH_2O$), 5.58 (t, 1H, J=7.2 Hz, C=CH); MS m/z 180 (M^+).

(−)-(2-Vinyl-2-caranyl)acetic Acid (9). A mixture of **8** (500 mg) and triethyl orthoacetate (6.3 ml) was heated in benzene (30 ml) at 140°C for 10 h in the presence of a trace of propionic acid. After evaporation of the excess triethyl orthoacetate, the reaction mixture was heated under reflux overnight with KOH (454 mg) in 50% aq methanol (50 ml). The reaction mixture was diluted with water and washed throughly with ether to remove neutral materials. The aqueous solution was neutralized with 2 M HCl, and then extracted with ether. The $MgSO_4$-dried ether extract gave, after evaporation of the solvent, 350 mg (56% yield) of crystals. Recrystallization in 20% aq methanol gave 311 mg of **9**, colorless needles, mp 85—87°C: IR (KBr) 1693, 1634 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.83 (d, 3H, J=6.5 Hz, CH_3), 0.99, 1.08 (2s, 6H, $2CH_3$), 2.62 (s, 2H, CH_2CO_2), 4.9—5.1 (m, 2H, $C=CH_2$), 5.96 (dd, 1H, J=17.5, 10.5 Hz, C=CH); MS m/z 222 (M^+); $[\alpha]_D^{24}$ −145° (c 1.12, MeOH). Found: C, 75.62; H, 10.06. Calcd for $C_{14}H_{20}O_2$: C, 75.63; H, 9.97.

(−)-Methyl(2-vinyl-2-caranyl)acetate (10). Treatment of **9** (250 mg) with diazomethane furnished, after SiO_2 chromatography (hexane:ether=10:1), the methyl ester **10** (267 mg, 100%) as a colorless oil. IR (neat) 1736, 1676 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.82 (d, 3H, J=7.5 Hz, CH_3), 1.02, 1.10 (2s, 6H, $2CH_3$), 2.58 (s, 2H, CH_2CO_2), 3.63 (s, 3H, OCH_3), 4.9—5.1 (m, 2H, $C=CH_2$), 5.94 (dd, 1H, J=17.5, 10.5 Hz, CH=C); $[\alpha]_D^{24}$ −125° (c 1.12, MeOH). Found: m/z 236.1787. Calcd for $C_{15}H_{24}O_2$: M, 236.1775.

Acetal Carboxylate 11. Ozone was passed through a solution of **10** (200 mg) in methanol (10 ml) at −78°C for 1 h and reductive (Me_2S) work up of the reaction mixture gave an oily aldehyde (180 mg) which was converted without purification to **11** by heating it with ethylene glycol in dry benzene in the presence of catalytic amount of p-toluenesulfonic acid. Chromatographic separation on SiO_2 column (hexane:ether=10:1) afforded 173 mg (72% yield) of **11** as a colorless oil: IR (CCl_4) 1726 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.93 (d, 3H, J=7.5 Hz, CH_3), 1.00, 1.15 (2s, 6H, $2CH_3$), 2.49 (d, 1H, J=13.5 Hz, CH_2CO_2), 2.70 (d, 1H, J=13.5 Hz, CH_2CO_2), 3.63 (s, 3H, OCH_3), 3.6—4.0 (m, 4H, $O(CH_2)_2O$), 4.78 (s, 1H, $HC<^{O}_{O}$); $[\alpha]_D^{24}$ −135° (c 1.12, MeOH). Found: m/z 282.1847. Calcd for $C_{16}H_{26}O_4$: M, 282.1830.

Compound 12. Methyl ester **10** (40 mg), OsO_4 (2 mg), and $NaIO_4$ (90 mg) were stirred overnight in 50% aq tetrahydrofuran. After dilution, the reaction mixture was extracted with ether. Normal work-up and evaporation yielded an oily aldehyde (40 mg). Without purification, the aldehyde was stirred overnight with trimethyl orthoformate (291 mg), and p-toluenesulfonic acid (catalytic amount). Neutralization, extraction with ether, drying, evaporation and finally SiO_2 chromatography afforded 31 mg (68%) of **12**, a colorless liquid. IR (neat) 1726 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.91 (d, 3H, J=7.0 Hz, CH_3), 1.18, 1.22 (2s, 6H, $2CH_3$), 2.25 (d, 1H, J=16.3 Hz, CH_2CO_2), 2.62 (d, 1H, J=16.3 Hz, CH_2CO_2), 3.04 (d, 1H, J=3.2 Hz, CHO), 3.19, 3.31 (2s, 6H, $2OCH_3$), 3.68 (s, 3H, CO_2Me); MS m/z 284 (M^+).

Acetal Aldehyde 13. Compound **11** (130 mg) was reduced with DIBAL in hexane at −78°C for 30 min. The reaction was quenched with water (1 ml) and the product was extract with ether. Evaporation of the solvent gave 123 mg of the mixture of **13** and the corresponding alcohol.

Without purification, the mixture (123 mg) was oxidized with pyridinium chlorochromate (278 mg) in dichloromethane (10 ml). After stirring for 1 h, ether (10 ml) was added and stirred for 5 min and then filtrated. Evaporation of the solvent, and SiO_2 chromatography (hexane:ether=1:1) of the residue gave 102 mg (90%) of **13**, a colorless oil: IR (CCl_4) 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96 (d, 3H, J=7.5 Hz, CH_3), 1.02, 1.17 (2s, 6H, $2CH_3$), 2.34 (dd, 1H, J=15.0; 3.6 Hz, CH_2CO), 2.76 (dd, 1H, J=15.0; 3.6 Hz, CH_2CO), 3.7—3.9 (m, 4H, $O(CH_2)_2O$), 4.78 (s, 1H, $HC<^{O}_{O}$), 9.89 (t, 1H, J=3.6 Hz, CHO); $[\alpha]_D^{24}$ −122.5° (c 1.12, MeOH). Found: m/z 208.1456 ($-C_2H_4O$). Calcd for $C_{15}H_{24}O_3$: M, 252.1724.

Wittig Reaction of 13 (synthesis of 14). Benzene (10 ml) solution of **13** (100 mg) and (ethoxycarbonylmethylene)triphenylphosphorane (331 mg) was heated under reflux for 12 h. The solvent was removed in vacuo, and the residue was chromatographed on SiO_2 column (CH_2Cl_2) to give **14** (116 mg, 95%) as a colorless oil: IR (CCl_4) 1713, 1642 cm^{-1}; ^1H NMR (CCl_4) δ=0.88 (d, 3H, J=6.6 Hz, CH_3), 1.01, 1.14 (2s, 6H, $2CH_3$), 1.28 (t, 3H, J=6.6 Hz, OCH_2CH_3), 2.45 (d, 2H, J=9.0 Hz, CH_2), 3.8—4.0 (m, 4H, $O(CH_2)_2O$), 4.11 (q, 2H, J=6.6 Hz, OCH_2CH_3), 4.73 (s, 1H, $HC<^{O}_{O}$), 5.73 (d, 1H, J=15.6 Hz, $CH=CHCO_2Et$), 6.91 (dd, 1H, J=15.6; 6.6 Hz, $CH=CH-CO_2Et$); $[\alpha]_D^{24}$ −83° (c 1.12, MeOH). Found: m/z 322.2142. Calcd for $C_{19}H_{30}O_4$: M, 322.2142.

Acetal Butanoate 15. Catalytic reduction of **14** (50 mg) in methanol (3 ml) over palladium charcoal (5 mg) furnished, after filtration of the catalyst and evaporation of the solvent, **15**, a colorless oil, in quantitative yield. IR (CCl_4) 1712 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (d, 3H, J=7.2 Hz, CH_3), 0.99, 1.15 (2s, 6H, $2CH_3$), 1.26 (t, 3H, J=7.2 Hz, OCH_2CH_3), 3.4—3.9 (m,

4H, $O(CH_2)_2O$), 4.13 (q, 2H, J=7.2 Hz, OCH_2CH_3) and 4.75 (s, 1H, $HC(O)$); $[\alpha]_D^{24}$ −75° (*c* 1.12, MeOH). Found: *m/z* 324.2257. Calcd for $C_{19}H_{32}O_4$: M, 324.2299.

Acetal Aldehyde 16. Compound **15** (36 mg) was reduced with 1.2 equivalent of DIBAL at −78 °C in dry hexane (2 ml) under argon atmosphere. After stirring for 30 min, the reaction was quenched with water. Extraction with ether furnished a mixture (30.2 mg) of **16** and the corresponding alcohol.

The mixture was oxidized in CH_2Cl_2 (1 ml) with pyridinium chlorochromate (78 mg). After stirring for 1 h, ether (5 ml) was added and the reaction mixture was filtrated. Evaporation of the solvent and SiO_2 chromatography (hexane: ether=1:1) gave 28.6 mg (85%) of **16** as a colorless oil. IR (CCl_4) 1716, 1453 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (d, 3H, J=7.2 Hz, CH_3), 0.99, 1.15 (2s, 6H, $2CH_3$), 3.66—3.99 (m, 4H, $O(CH_2)_2O$), 4.74 (s, 1H, $HC(O)$), 9.77 (t, 1H, J=2.3 Hz, CHO); $[\alpha]_D^{20}$ −102.5° (*c* 0.5, MeOH). Found: *m/z* 280.2037. Calcd for $C_{17}H_{28}O_3$: M, 280.2037.

(−)-Vitrenal ((−)-1). Compound **16** (20 mg) in THF (2.4 ml) was heated for 6 h under reflux with 10% of aq HCl (0.6 ml). The reaction mixture was diluted with water, neutralized by saturated aq $NaHCO_3$, and extracted with ether. Evaporation of the solvent and short column SiO_2 chromatography afforded 14.7 mg (94%) of (−)-**1**. IR (CCl_4) 1680, 1614, 854 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.77 (d, 3H, J=5.5 Hz, CH_3), 0.94, 1.17 (2s, 6H, $2CH_3$), 6.86 (t, 1H, J=1.5 Hz, CH=C), 9.76 (s, 1H, CHO); $[\alpha]_D^{18}$ −113° (*c* 0.4, MeOH). Found: *m/z* 218.1673. Calcd for $C_{15}H_{22}O$: M, 218.1670.

The authors express their gratitude to Dr. N. Okagami, Tohoku University, for the tests of biological activity and to Dr. A. Matsuo, Hiroshima University, for the spectra of natural vitrenal.

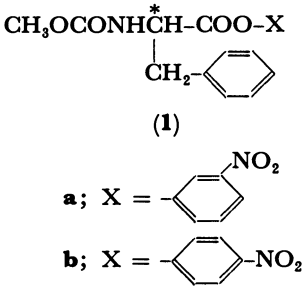
(Received January 6, 1986)

The rate constants for hydrolysis of the enantiomers of amino acid nitrophenyl esters have been determined at pH 9.00 and pH 10.0 in the presence of α- or β-cyclodextrin. α- and β-Cyclodextrins cause stereoselective acceleration in the hydrolysis of *m*-substituted enantiomers. On the other hand, less stereoselectivity is observed in the hydrolysis of *p*-substituted enantiomers. The stereoselective properties are discussed in the light of cyclodextrin-ester dissociation constants and thermodynamic parameters of the reaction.

Stereoselectivity and high catalytic reactivity are among the most interesting properties of enzyme action.[1] Several model studies on micellar,[2-9] polymer,[2,10-14] and macrocyclic[2,15-19] catalyzed reactions have been investigated in order to gain further insight into the stereoselective nature of enzyme reactions. In the course of our study on stereoselective micellar catalysis,[20,21] we found that comicelles of optically active *N*-acylhistidine or dipeptide derivatives containing histidyl residues and cationic surfactant are effective stereoselective catalysts for the hydrolysis of enantiomeric esters.

Cyclodextrin (CD) is often used as models of enzymatic reactions[22] since particular interest has attended the processes in which a substrate binds into a CD cavity and then undergoes reaction with one of CD's secondary hydroxyl groups. Stereoselectivities by CD have been reported for a number of reactions, particularly a very large selectivity was exhibited in the cleavage of chiral organophosphates such as isopropyl methylphosphonofluoridate,[16] or in the acylation of specific rigid substrates such as *p*-nitrophenyl *trans*-2-ferrocenylpropenoate.[18b] Recently, a remarkable stereoselectivity has also been reported in the hydrolysis of activated enantiomeric ester.[23]

In the present paper, the rate constants for hydrolysis of the enantiomers of amino acid *m*- and *p*-nitrophenyl esters (**1a** and **1b**) have been determined at pH 9.00 and pH 10.00 in the presence of α- or β-cyclodextrin. The substrate-binding properties, and the effect of temperature and of added surfactant on the rate constants were investigated to study the kinetic stereoselectivity.



Experimental

Materials. α- and β-Cyclodextrins were commercially available highest grade reagents (Tokyo Kasei Co. and Nakarai Chemicals Co., Japan) and were used without further purification. *m*-Nitrophenyl esters of *N*-methoxycarbonyl-D- and L-phenylalanine were prepared by standard methods.[24] Other materials have been described elsewhere.[20,21]

Kinetic Measurements. Reactions were generally monitored on a Hitachi 200 spectrophotometer or a Shimadzu 140 spectrophotometer with a thermostated cell holder. In general procedure, a solution (25 μl) of substrate in aceto nitrile was added to a buffer solution (3.00 cm^3) containing the cyclodextrin or the catalyst and surfactant at desired concentrations. The formation of *m*- or *p*-nitrophenolate ion was followed spectrophotometrically at 390 or 400 nm, respectively. The pseudo-first-order rate constants were obtained from plots of log $(A_\infty - A_t)$ versus time (t) and calculated by the least-squares method. Correlation coefficients were >0.999.

Results and Discussion

Kinetics of Hydrolysis of 1 in the Presence of Cyclodextrin (CD). Kinetic studies were first examined at 25 °C using pH 9.00 sodium borate buf-

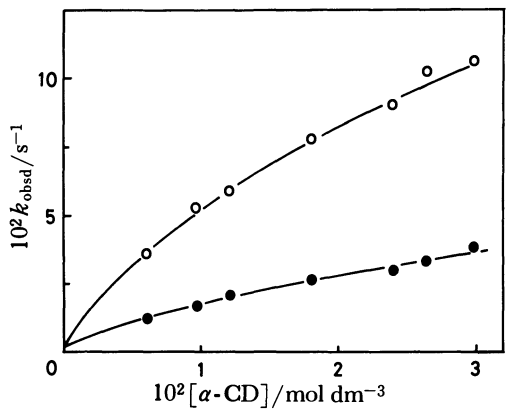


Fig. 1. Pseudo-first-order rate constants (k_{obsd}) for the hydrolysis of **1a** as a function of the concentration of α-CD at pH 9.00, 0.02 mol dm^{-3} borate buffer (I=0.2, KCl), and 25 °C; (●) D-**1a**, (○) L-**1a**, [**1a**]=1.00×10^{-4} mol dm^{-3}.

	1b D	(13.3)	(50.9)	(3.83)	(0.261)	(1.19)
	L	(13.0)	(60.5)	(4.65)	(0.428)	

a) At pH 9.00, 0.02 mol dm^{-3} borate buffer (I=0.2, KCl), and 25 °C, [**1a**]=1.0×10^{-4} mol dm^{-3}, [**1b**]=1.0×10^{-5} mol dm^{-3}. The values of parentheses are at pH 10.0, 0.02 mol dm^{-3} carbonate buffer (I=0.2, KCl).

fer or pH 10.00 sodium carbonate buffer, I=0.2 in 0.83% (v/v) acetonitrile-water. Under the conditions [CD]≫[substrate], pseudo-first-order rate constants (k_{obsd}) were evaluated by monitoring the release of *m*- or *p*-nitrophenoxide ion spectrophotometrically at 390 or 400 nm. Examples of the observed pseudo-first-order rate constants, k_{obsd}, against the varying cyclodextrin concentrations are shown in Fig. 1. The data were treated by the Michaelis-Menten pathway, applicable to much of enzyme kinetics described by Scheme 1, where CD is the cyclodextrin, S is the substrate, CD·S is the CD-substrate complex, K_{diss} is the dissociation constant, and k_{un} and k_2 are the rate constants for the alkaline hydrolysis and for the reaction of the complexed ester at infinite cyclodextrin concentration, respectively. The kinetic parameters are calculated by least squared method and given in Table 1.

$$\mathrm{CD} + \mathrm{S} \underset{}{\overset{K_{diss}}{\rightleftharpoons}} \mathrm{CD{\cdot}S} \xrightarrow{k_2} \mathrm{Products}$$
$$\mathrm{S} \xrightarrow{k_{un}} \mathrm{Products}$$

Scheme 1.

In the presence of CD, the rates of hydrolysis of **1a** are accelerated (6.7—180 fold) when compared (k_2/k_{un}) to alkaline hydrolysis under the same conditions. α-CD causes much greater rate accelerations than β-CD. Similarly, α-CD shows higher stereoselectivity, k_2(L)/k_2(D), than β -CD. The K_{diss} values are not very different for the enantiomeric D and L esters. Thus, the stereoselective rate accelerations are unrelated to the strength of binding. In this system, D and L esters may bind equally in the cavity of CD, but the binding of the D ester leads to the wrong orientation between the hydroxyl group of the CD and the carbonyl group of the esters.

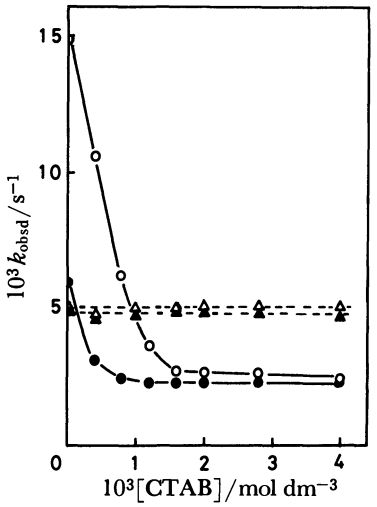

Fig. 2. Effect of CTAB on the hydrolysis of **1** catalyzed with α-CD at pH 9.00, 0.02 mol dm^{-3} borate buffer (I=0.2, KCl), and 25 °C; (——) **1a** (●) D-**1a**, (○) L-**1a**, (----) **1b**, (▲) D-**1b**, (△) L-**1b**; [**1a**]=1.00×10^{-4} mol dm^{-3}, [**1b**]=1.00×10^{-5} mol dm^{-3}, [α-CD]=2.0×10^{-3} mol dm^{-3}.

The rates of hydrolysis of **1b** are slightly accelerated (1.5—12 fold) at pH 9.00 and 10.0, and also a less stereoselectivity than **1a** is observed in the presence of α and β-CD. These results clearly indicate that the large stereoselective effect accords with the large rate enhancement of the reaction. Bender et al.[18a)] showed that β-CD hydrolyzed *N*-acetyl-L-phenylalanine *m*-nitrophenyl ester 2 times faster than the D-enantiomer, while β-CD inhibited the hydrolysis of both *N*-acetyl-L- and D-phenylalanine *p*-nitrophenyl esters. The data obtained by us are different from those of theirs in the case of *p*-substituted enantiomers. This may be mainly due to differences in experimental conditions such as the pH and the structure of substrates.

Effect of Surfactant on CD Catalyzed Hydrol-

ysis. The hydrolysis of **1** in the presence of CD and hexadecyltrimethylammonium bromide (CTAB) was carried out at pH 9.00 borate buffer and 25 °C. As shown in Fig. 2, reaction rates of **1a** are decreased upon addition of CTAB to the reaction mixture. This is attributed to the complex formation between the surfactant and CD. In contrast, hydrolysis of **1b** shows no significant effect on rates in the presence of CTAB. Thus, the hydrolysis of **1b** is not inhibited under the same conditions. It should be noted here that **1b** is more reactive than **1a** with increasing concentrations of CTAB. These results indicate that the inhibitive effect of CTAB on the reaction of **1a** is attributed to the strong interactions between CD and CTAB. On the other hand, no inhibitive effect on the reaction of **1b** indicates that there are no significant differences in reactivity between CD and CTAB. The strong binding of ionic surfactants with CD was widely discussed upon the basis of conductimetric measurements.[25a]

In the case of **1a**, the competitive inhibition constants, K_i, are determined by the method of Bender et. al,[26] Eq. 1. By plotting the inhibitor concentration, [I], against $(k_2-k_{obsd})/(k_{obsd}-k_{un})$ an approximately straight line is obtained with a y intercept of equal to $-K_i$ and a slope of $[CD]K_i/K_{diss}$, and the results are given in Table 2. The values of K_i obtained from both enantiomeric esters are very similar with those obtained from *m*-nitrophenyl acetate.[25b]

$$[I] = \left(\frac{k_2-k_{obsd}}{k_{obsd}-k_{un}}\right) \cdot \left(\frac{[CD]K_i}{K_{diss}}\right) - K_i \qquad (1)$$

Temperature Dependence of Reaction Rates. The effect of temperature change (5—35 °C) on the reaction rates for hydrolysis of **1a** in the presence of α- and β-cyclodextrin was examined at pH 9.00 in 0.02 mol dm^{-3} borate buffer (I=0.2 with KCl) and the kinetic parameters thus evaluated are listed in Tables 3 and 4. As discussed in previous section, stereoselective recognition is exercised in the reaction process rather than in the binding process over the whole temperature range. The stereoselectivity based on reaction rates slightly increases as the temperature is lowered. The highest stereoselectivity (2.71) is observed in the presence of α-CD at 5 °C.

In order to calculate the thermodynamic parameters accompanying the reaction process the least-squares slope was computed of the line formed by plotting $\ln(k_2/T)$ against $1/RT$. The calculated values are listed in Table 5. The $\Delta G^{\ddagger}$ values of α-CD are ca. 1.1—1.2 kcal mol^{-1} (1 cal=4.184 J) smaller than those of β-CD in both D and L esters. These results are compatible with those of Table 1. On the other hand, for both α- and β-CD, the $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ values of L substrate are ca. 0.4—0.5 kcal mol^{-1}, 1.0—1.1 kcal mol^{-1}, and 1.6—2.3 cal mol^{-1}K^{-1} smaller than those of D ester. The effect of enantiomeric selectivity is primarily to lower $\Delta H^{\ddagger}$ for activation. This is partly balanced by a small unfavorable change in the entropy of activation.

Stereoselective Nature of CD Catalysis. Although stereoselective effects in the present catalytic systems are relatively small, it is now clear that (1) α- and β-CD cause stereoselective acceleration in the hydrolysis of **1a**, while a less stereoselectivity is observed in the hydrolysis of **1b**. (2) The hydrolysis of **1a** with CD is inhibited by added CTAB, whereas there is no significant effect for **1b** hydrolysis in the presence of CTAB. For the reaction with CD, the esters are incorporated

Table 2. Inhibition by CTAB on the Hydrolysis of 1a Catalyzed with Cyclodextrin[a]

Ester	α-CD	β-CD
	10^4K_i/mol dm^{-3}	10^4K_i/mol dm^{-3}
D-1a	1.8±0.4	3.3±0.5
L-1a	1.3±0.3	3.6±0.7

a) At pH 9.00, 0.02 mol dm^{-3} borate buffer (I=0.2, KCl), and 25 °C, [α-CD]=2.00×10^{-3} mol dm^{-3}, [β-CD]=1.00×10^{-3} mol dm^{-3}, [1a]=1.0×10^{-4} mol dm^{-3}.

a) At pH 9.00, 0.02 mol dm^{-3} borate buffer (I=0.2 with KCl), [1a]=1.00×10^{-4} mol dm^{-3}.

Table 5. Thermodynamic Parameters for Hydrolysis of **1a** in the Presence of Cyclodextrin[a]

	α-CD		β-CD	
	D	L	D	L
$\Delta G^{\ddagger}$[b]/kcal mol^{-1}	19.0	18.5	20.1	19.7
$\Delta H^{\ddagger}$/kcal mol^{-1}	24.9	23.9	22.0	20.9
$\Delta S^{\ddagger}$/cal mol^{-1} K^{-1}	19.8	18.2	6.45	4.14

a) At pH 9.00, 0.02 mol dm^{-3} borate buffer (I=0.2, KCl). The parameters were calculated by plotting the data of Tables 3 and 4 in the form of $\ln(k_2/T)$ versus $1/RT$. b) For the values at 298.2°K.

into the cavity of CD and react with a hydroxyl group. Thus, *meta* is better than *para* in stereoselectivity. This is attributable to the nature of the catalyst.

The differences in reactivity between D and L enantiomers in the hydrolysis of **1a** depend on the catalytic rate constants (k_2) rather than the dissociation constant of the complex formation (K_{diss}). In the cleavage of 2,2,5,5-tetramethyl-3-(*m*-nitrophenoxycarbonyl)-1-pyrrolidinyloxyl by α-CD,[17] k_2 for the (+) enantiomer is 6.9 times larger than that for the (−) enantiomer. However, the K_{diss} values are almost equal for the two enantiomers. On the other hand, in the cleavage of chiral organophosphates,[16] the reactivity depends on both k_2 and K_{diss}. Thus, the stereoselectivity is very large in this reaction. As described by Bender and Komiyama,[22] the larger enantiomeric specificity in the cleavage of organophosphates than in the cleavage of esters is attributable to the fact that the reaction takes place directly at the asymmetric center (phosphorus atom), whereas in the cleavage of esters it occurs at the carbonyl carbon atom, which is adjacent to the asymmetric center. However, a remarkable stereoselectivity has recently been reported in the hydrolysis of activated enantiomeric esters which contain relatively-long-chain alkyl groups.[23] These results suggest that more effective stereochemical features may be obtained by different combinations of substrates than those used in the present system. In connection with this work, we have also investigated in order to gain the stereoselective nature of micellar reaction.[20,21]

We thank Professor Myron L. Bender for helpful comments, Yoshimi Nakahara, Fumiko Nishimura, Satoe Furuya, Akemi Akiyama, and Hiroko Yamamoto for technical assistance.

Kinetics and Mechanism of the Oxidative Deamination of Amines by Coenzyme PQQ

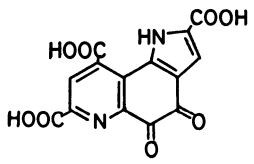
Shinobu ITOH, Yutaka KITAMURA, Yoshiki OHSHIRO,* and Toshio AGAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565
(Received January 27, 1986)

Kinetic studies on the oxidative deamination of amines by coenzyme PQQ are carried out under anaerobic conditions. The reaction is first-order in the appearance of the reduced PQQ and in the total amine concentrations. A large kinetic isotope effect (k_H/k_D=7.24) in the oxidation of α,α-dideuteriobenzylamine indicates that the C-H bond cleavage is a rate-determining step. From the results of formation of two types of reduced PQQ (quinol and aminophenol) and low reactivities of secondary and tertiary amines, we propose the mechanism via covalent addition of the amine to the quinone followed by rate-limiting α-proton removal.

Amine oxidases are known to catalyze the oxidative deamination of amines in the presence of molecular oxygen as an electron acceptor to produce the corresponding carbonyl compounds, hydrogen peroxide, and ammonia (Eq. 1).[1]

$$RCH_2NH_2 + O_2 + H_2O \longrightarrow RCHO + H_2O_2 + NH_3 \quad (1)$$

They are divided into two classes: Copper-containing amine oxidases and FAD-containing ones. However, the chromophore of the former enzymes, which has a carbonyl function,[2] has not been identified despite of the presence of many investigations extended over a long period of time.[1-3] Recently, Ameyama and his coworkers demonstrated that 4,5-dihydro-4,5-dioxo-1*H*-pyrrolo[2,3-*f*]quinoline-2,7,9-tricarboxylic acid (PQQ, methoxatin) is the coenzyme of a methylamine dehydrogenase and copper-containing amine oxidases from beef plasma, pig kidney, and *Aspergillus niger*.[4] Duine and his co-workers simultaneously indicated the possible occurrence of PQQ in bovine serum amine oxidase, a mammalian copper-containing amine oxidase.[5]



PQQ

PQQ is a novel coenzyme which was originally discovered and identified in methanol dehydrogenases of methylotropic bacteria.[6] In addition to methanol dehydrogenases from various methanol-grown microorganisms,[7] several types of alcohol, aldehyde, and glucose dehydrogenases have been revealed to be PQQ-containing enzymes (quinoproteins).[8] Methylamine dehydrogenase of *Pseudomonas* AM-1 has also been shown to be a quinoprotein in which PQQ is attached to the enzyme protein via a covalent bond.[9] Total syntheses[10] and some chemical properties[11] of PQQ have already been reported. A mechanism for alcohol and amine oxidation by quinoprotein, however, has not been clarified, though a few enzymological studies have been developed.[12,13]

As a model system of amine oxidases, we have already demonstrated the micellar enhanced oxidative deamination of amines catalyzed by coenzyme PQQ by two electron transferring from the amine to molecular oxygen.[14] We wish to demonstrate here the kinetics of the oxidative deamination of amines by PQQ and product analysis of the reduced PQQ to elucidate the mechanism of the reaction under anaerobic conditions.[15]

Experimental

PQQ was prepared according to the reported method.[10a] All amines investigated (except for α,α-dideuteriobenzylamine) and CTAB (hexadecyltrimethylammonium bromide) were obtained commercially and purified by the standard method.[16] α,α-Dideuteriobenzylamine was prepared according to the known method,[17] and the ^{1}H NMR indicated that the content of the deuterated compound was more than 99%.

Ultraviolet and visible absorption spectra were recorded on Shimadzu UV-240 spectrophotometer equipped with a temperature controlled cell holder, Shimadzu TCC-240. Measurements of pH were performed by using Horiba pH-meter F-8. HPLC analysis was performed by using Waters Model 510 (pump)-Lambda-Max Model 481 (UV-monitor)-Radial Compression Separation System (C_{18}).

Kinetics. The kinetic measurements of the oxidation of amines with PQQ were carried out in a carbonate buffer solution (0.05 M (1 M=1 mol dm^{-3}) pH 10.1, μ=0.2 with KCl) at 35 °C under anaerobic conditions. Typically, 1.5 ml of an aqueous bufffer solution containing CTAB (4.0×10^{-3} M) and an amine (8.0×10^{-3} M) was mixed with 1.5 ml of an aqueous buffer solution containing PQQ (8.0×10^{-5} M) in a Thunberg cuvette. Both solutions were degassed by bubbling N_2 through them before the reaction. The progress of the reaction was followed by monitoring the appearance of the reduced PQQ at 320 nm.

Product Analysis of Reduced PQQ. After the reaction of PQQ (20 mg, 5.7×10^{-2} mmol) and benzylamine (2.9×10^{-1} mmol) in a carbonate buffer solution (0.1 M, pH 10, 20 ml) under anaerobic conditions (N_2) for 24 h, the reduced product (19.2 mg) was precipitated by adding 2 M HCl (2 ml). HPLC analysis and UV spectrum revealed that there were at least two types of reduced compounds from PQQ;

HPLC, column: radial pack cartridge C_{18}(Waters), solvent: MeOH/H_2O/85% H_3PO_4, 45/54.5/0.5, v/v/v, flow rate: 2.0 ml min^{-1}, retention time: 4.9 min (for **1**) and 3.3 min (for **2**), (ratio of peak area, **1**:**2**=82:18), UV-spectrum (λ_{max}, CH_3CN), 320 nm (**1**) and 301 nm (**2**). Both products, **1** and **2**, were readily converted into PQQ by treating with an alkaline aqueous solution under aerobic conditions. The main product **1** was identical with $PQQH_2$ (quinol)[11b] in HPLC analysis, ^1H NMR spectrum, and UV spectrum in the mixture.

Results and Discussion

The reaction of benzylamine with PQQ was studied under pseudo-first-order conditions of total benzylamine concentration (4.0×10^{-3} M) greatly exceeding [PQQ]=4.0×10^{-5} M in the presence of CTAB (2.0×10^{-3} M) in a carbonate buffer solution (0.05 M, pH 10.1, μ=0.2 with KCl) at 35 °C. Monitoring of an appearance of the product from PQQ at 320 nm established a short lag phase followed by the first-order appearance of the product ($k_{obsd}=1.75\times10^{-3}$ s^{-1}, Fig. 1). Introduction of O_2 into the final reaction mixture led to quantitative regeneration of PQQ. The reaction was also first-order in total benzylamine concentrations (Fig. 2). In this oxidation reaction, the free amine is considered to be an active species.

$$k_{obsd} = k_2[\text{Amine}]_f = k_2\frac{K_a}{K_a+a_H}[\text{Amine}]_T \qquad (2)$$

$[\text{Amine}]_f$: free amine concentration

$[\text{Amine}]_T$: total amine concentration

Thus, the second-order rate constant k_2 is calculated to be 5.36×10^{-1} $M^{-1}s^{-1}$ (at pH 10.1) from Eq. 2 by using the pK_a value of 9.45 for benzylamine determined by volumetric titration under the kinetic conditions. The second-order rate constants at pH 10.1 for the other amines are listed in Table. Interestingly, β-phenethylamine and cyclohexylamine were oxidized faster than the benzylic amines. Incorporation of the substrates into the hydrophobic core of the micelle may be an important factor.[18]

It should be noted that *N*-methylbenzylamine was

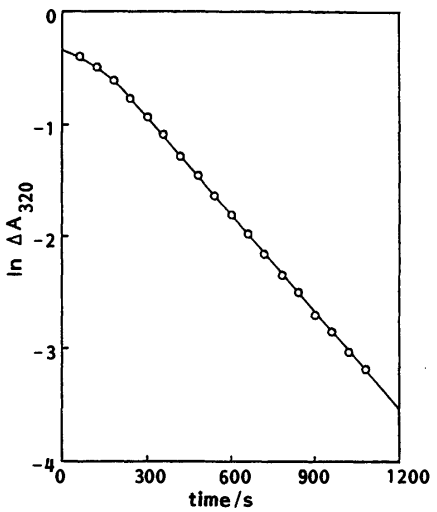


Fig. 1. Pseudo-first-order plot for the oxidation. PQQ (4.0×10^{-5} M), $PhCH_2NH_2$ (4.0×10^{-3} M), CTAB (2×10^{-3} M), pH 10.1 with 0.05 M carbonate buffer (μ=0.2 with KCl), 35 °C, anaerobic conditions (N_2).

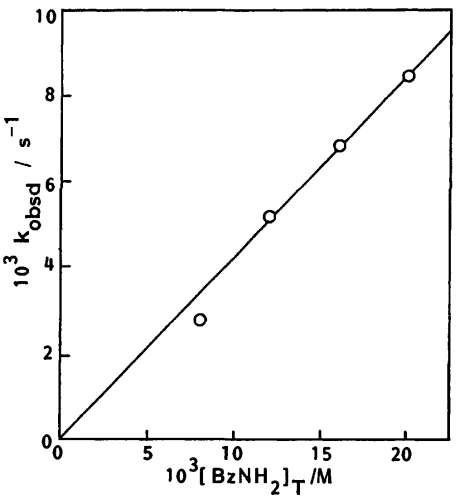

Fig. 2. Dependence on total benzylamine concentration of the pseudo-first-order rate constant (k_{obsd}). pH 10.1 with 0.05 M carbonate buffer (μ=0.2 with KCl), 35 °C.

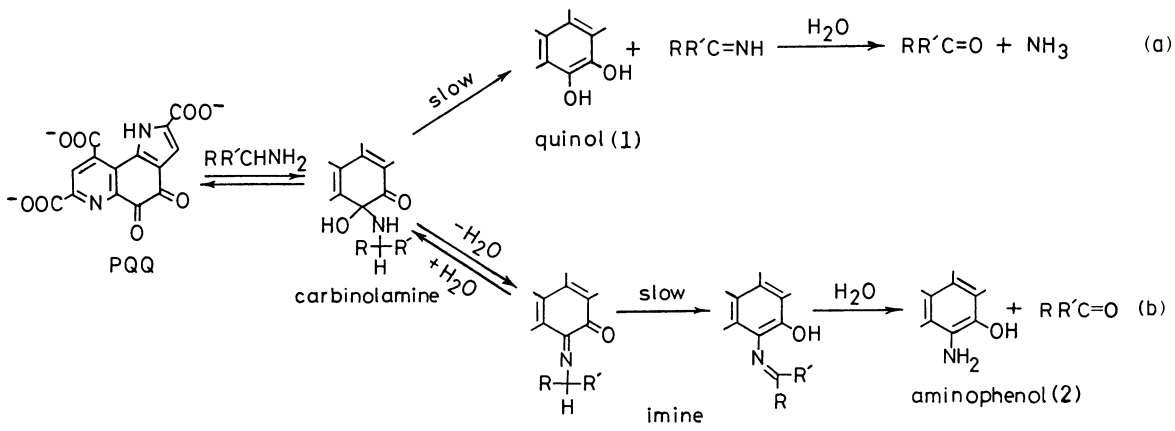
Table. The Second-Order Rate Constant for the Oxidation of Amines by PQQ

Amine	$10^3 k_{obsd}$ / s^{-1}	pK_a	10^3[Amine]$_f$[a] / M	k_{obsd}/[Amine]$_f$ / $M^{-1}s^{-1}$
$PhCH_2NH_2$	17.5	9.45	3.26	0.536
$PhCH(CH_3)NH_2$	7.69	9.33	3.42	0.225
$Ph(CH_2)_2NH_2$	45.1	9.78	2.71	1.67
Cyclohexylamine	9.69	10.33	1.49	0.650
$PhCH_2NHCH_3$	0.81	9.57	3.10	0.026
$PhCH_2N(CH_3)_2$	0	9.02	3.70	0

a) Free amine concentrations at pH 10.1 calculated from the pK_a values determined by volumetric titration under the kinetic conditions. [PQQ]=4.0×10^{-5} M, [Amine]$_T$=4.0×10^{-3} M, 0.05 M carbonate buffer (μ=0.2 with KCl, pH 10.1) 35 °C, anaerobic conditions.



Scheme.

oxidized very slowly (k_2=2.6×10^{-2} $M^{-1}s^{-1}$) and *N,N*-dimethylbenzylamine was not oxidized under the same conditions. Thus, the order of the reactivities of the amines is primary>secondary≫tertiary. Furthermore, a large kinetic isotope effect (k_H/k_D=7.24) was observed for the reaction with benzylamine-d_2, indicating the C–H bond cleavage is a rate determining step.

Bruice and his co-workers recently investigated the chemical behavior of model compounds of PQQ and their reactions with various amines.[19,20] They suggested that the oxidation of primary amines by the model compounds proceeds via two competing covalent addition base-catalyzed elimination mechanisms through intermediate carbinolamine and imine, respectively, and they confirmed the formation of two types of reduced compounds (quinol and aminophenol).[20] Thus, we tried to isolate the reduced compound of PQQ in the reaction of PQQ with an amine, and found the formation of two types of reduced PQQ. Since the main product (**1**) was identical with $PQQH_2$ (quinol), the minor product (**2**) is assumed to be an aminophenol type one, though these two compounds could not be separated because of their instability in the mixture.

From these results, the mechanism of the reaction of the amines and PQQ is considered to be similar to that proposed by Bruice and his co-workers for the reaction of a PQQ-model, 7,9-didecarboxymethoxatin with amines (Scheme). That is to say, the oxidation of the amine by PQQ proceeds mainly via covalent addition of the amine to the quinone to form the carbinolamine intermediate followed by rate determining α-proton removal providing the quinol **1** (path a).[21] The reaction through the formation of the imine intermediate between PQQ and the amine followed by successive rearrangement and α-proton removal to provide the aminophenol **2** (path b) is considered to compete with the path a, but this may be the minor process. As in fact, appearance of absorptions at 385 and 403 nm which may be due to the imine intermediate were observed in the course of the reaction at pH 7 under anaerobic conditions. These absorptions are not for a semiquinone radical of PQQ because these absorptions do not disappear by aeration of the reaction mixture. On the other hand, the reaction was much decelarated above pH 12, which may be attributed mainly to hydration of the quinone group of PQQ.

At the present time, the mechanism via rate-determining one-electron transfer from the amine to PQQ may be dismissed because of lower reactivity of the secondary amine and of no reactivity of the tertiary amine. Considering the fact that the peak oxidation potentials of amines increase in general as in following order: primary>secondary>tertiary, the secondary and the tertiary amines should be oxidized more smoothly if the reaction should proceed via electron-transfer mechanism. It has been shown that the rate for chlorine dioxide oxidation of amines, which proceeds via electron transfer mechanism, increases with decrease of the peak oxidation potentials of amines.[22] A large kinetic isotope effect also contradicts the rate-limiting one-electron-transfer mechanism.

A possibility of the hydride-transfer mechanism from the α-position of the amine to the quinone is also considered to be discarded, since the oxidation potential of PQQ is relatively low ($E_{1/2}$=90 mV)[11b] compared with those of ordinary quinones in a neutral aqueous solution. As in fact, dehydrogenation of allylic and benzylic alcohols and carbonyl compounds such as succinate does not occur in the reaction with PQQ under suitable conditions. To obtain further insight into the mechanism of the oxidation, we are now synthesizing varieties of fused heteroaromatic *o*-quinones and examining their reactivities.

The present work was partially supported by a Grant-in-Aid for Special Project Research (No. 60104005) from the Ministry of Education, Science, and Culture to which our thanks are due.

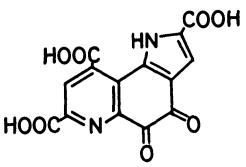
Reaction of Reduced PQQ ($PQQH_2$) and Molecular Oxygen

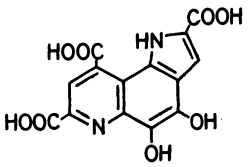
Shinobu Itoh, Yoshiki Ohshiro,* and Toshio Agawa
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565
(Received January 27, 1986)

Reduced PQQ ($PQQH_2$) is prepared by the reaction of PQQ with thiophenol, 1-benzyl-1,4-dihydronicotinamide (BNAH), sodium dithionite, or sodium borohydride. Oxidation of $PQQH_2$ to PQQ by molecular oxygen in aqueous solutions is investigated kinetically. The oxidation is accelerated gradually with proceeding of the reaction, which may be attributed to the side reaction of $PQQH_2$ and H_2O_2 produced by the reaction of $PQQH_2$ and O_2. As in fact, the yield of H_2O_2 is found to be 50% based on $PQQH_2$. Initial rate is first-order in oxygen concentration. The pH-rate profile suggests that an active species in the reaction is $PQQH^-$. Autocatalysis of O_2^- and PQQ itself is scarcely detected in this reaction. The mechanism of the oxidation is also discussed.

It has been well-known that copper-containing amine oxidases constitute important sources of H_2O_2 in biological systems.[1] However, the reaction of this group of enzymes with O_2 has been less explored, because the true character of the second prosthetic group of the enzymes has not been clear. Meanwhile, Ameyama and Duine simultaneously indicated the possible occurrence of PQQ (4,5-dihydro-4,5-dioxo-1*H*-pyrrolo[2,3-*f*]quinoline-2,7,9-tricarboxylic acid, a newly discovered coenzyme) in copper-containing amine oxidases.[2,3]



PQQ



$PQQH_2$

We have already demonstrated the autorecycling PQQ-catalyzed oxidation of amines, which can be regarded as a model system of PQQ-containing amine oxidases.[4] And in the preceding paper, we investigated the mechanism of the reaction between PQQ and an amine under anaerobic conditions.[5] Moreover, existence of reduced PQQ (4,5-dihydroxy-1*H*-pyrrolo[2,3-*f*]-quinoline-2,7,9-tricarboxylic acid, $PQQH_2$) and its importance in a quinoprotein have also been reported by Duine and his co-workers.[6] Thus in this paper, we wish to investigate the reaction of $PQQH_2$ and O_2 in order to clarify the redox systems of PQQ in more detail. The reaction of hydroquinone and catechol derivatives with O_2 has not been studied so widely that the mechanism has not been clear.[7,8]

Experimental

Ultraviolet and visible absorption spectra were recorded on Shimadzu UV-240 spectrophotometer equipped with a temperature controlled cell holder, Shimadzu TCC-240. Measurements of pH were performed by using Horiba pH-meter F-8. Oxygen concentrations were determined by using Unicon oxygen meter. Superoxide dismutase (SOD) was obtained commercially, and catalase was supplied by Dr. K. Kobayashi (Osaka University). Other chemicals used were purchased at the highest purities available.

Preparation of $PQQH_2$ (quinol). Reduction of PQQ to $PQQH_2$ was performed with thiophenol, 1-benzyl-1,4-dihydronicotinamide (BNAH),[9] sodium dithionite, or sodium borohydride (Table). A typical procedure is as follows. After quantitative hydrolysis of PQQTME[10] (trimethyl ester of PQQ, 12.7 mg, 3.4×10^{-2} mmol) to PQQ in 0.05 M Na_2CO_3 (10 ml (1 M=1 mol dm^{-3})) at 30 °C for 24 h, the solution was neutralized (pH 6.8) with 2 M HCl. The solution was placed in the bottom of a Thunberg vessel (30 ml), and 10-fold excess of thiophenol (0.34 mmol) in acetonitrile (3 ml) was deposited in the side arm of the vessel. Both solutions were degassed for 30 min by bubbling N_2 through them, which were then mixed to start the reaction. After 2 h, the reaction mixture was acidified with 2 M HCl (1 ml), and was stood overnight. The precipitated product was collected by centrifugation and was washed with acetonitrile (5 ml). The product was dried in vacuo over P_2O_5, and recrystallized from dimethyl sulfoxide–acetonitrile (84% yield). The spectral data of the product were in good agreement with those reported by Duine and his co-workers.[6] BNAH, $Na_2S_2O_4$, $NaBH_4$ could also be reacted in the same way, and $PQQH_2$ was obtained in 77, 99, and 99% yield, respectively. Reduction of PQQ with phenylhydrazine (pH 3.1) and catalytic hydrogenation of PQQ (H_2 (1 atm)/PtO_2, pH 6.7) were carried out in the similar way reported elsewhere (82 and 65%, respectively).[6]

Oxidation of $PQQH_2$ by Molecular Oxygen. The reaction between $PQQH_2$ and O_2 was performed in 0.1 M acetate, phosphate, and carbonate buffer solutions (μ=0.3 with KCl, containing 5% dimethyl sulfoxide) at 30 °C under air atmosphere. An air saturated buffer solution (2.85 ml, $[O_2]=2.28\times10^{-4}$ M) was placed into a cuvette, and the reaction was started by adding 0.15 ml of an anaerobic DMSO solution of $PQQH_2$ (2.86×10^{-4} M). The reaction was followed by observing the disappearance of $PQQH_2$ at 320 nm. Hydrogen peroxide product was determined by adding 1 M NaI aqueous solution (0.5 ml) to the final reaction mixture, and monitoring the appearance of I_3^- at 353 nm (ε=25000 $M^{-1}cm^{-1}$). The rate constant was found to be identical with that for the reaction of I^- with authentic H_2O_2 at the pH employed. The yield of H_2O_2 was determined from the increase of A_{353} and was calculated to be about 50% based on $PQQH_2$. Oxygen concentration were controlled by mixing a O_2-saturated buffer solution and a N_2-saturated one.

Results and Discussion

Synthesis of $PQQH_2$. PQQ is reduced in the reac-

Table. Synthesis of $PQQH_2$[a]

Reductant[b] (Solvent, ml)	pH[c]	Time h	Isolated Yield[d] %
PhSH (CH_3CN, 3 ml)	6.8	2	84
BNAH (CH_3CN, 3 ml)[e]	6.8	3	77
$Na_2S_2O_4$ (H_2O, 1 ml)	11.4	5	99
$NaBH_4$ (H_2O, 1 ml)	7.2	4	99
$PhNHNH_2$ (CH_3CN, 3 ml)	3.1	3	82

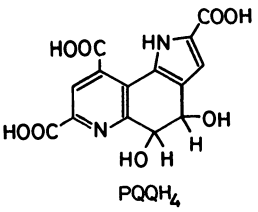
a) PQQ was generated by hydrolysis of PQQTME (0.032—0.036 mmol) in 0.05 M Na_2CO_3 (10 ml). b) 10-fold excess over PQQ. c) The pH of a PQQ-aqueous solution was adjusted with 2 M HCl. d) Based on PQQ. e) In the dark.

tion with amines, but a mixture of the quinol and the aminophenol was obtained.[5] On the other hand, we found that only $PQQH_2$ (quinol) was produced in the reaction of PQQ with thiophenol,[11] BNAH, $Na_2S_2O_4$, and $NaBH_4$ (Table). Formation of PhSSPh and BNA^+ was detected in the reaction of PQQ with PhSH and BNAH by HPLC, respectively.

It should be noted that 99% of $PQQH_2$ was isolated in the reaction with $NaBH_4$, though Duine and his co-workers reported the formation of $PQQH_4$ in the reaction with $NaBH_4$.[12] Probably, they used so excess $NaBH_4$ over PQQ that further reduction might take place. The reaction with $PhNHNH_2$ (under acidic conditions) and catalytic hydrogenation (H_2/PtO_2, under neutral conditions) could be applied to the preparation of $PQQH_2$, but removal of the catalyst from the reaction mixture caused the autoxidation in the latter case.

The present methodology was applicable to the preparation of reduced PQQTME (trimethyl 4,5-dihydroxy-1*H*-pyrrolo[2,3-*f*]quinoline-2,7,9-tricarboxylate, $PQQTMEH_2$) which was obtained in 80% yield in the reaction of PQQTME and PhSH in acetonitrile under anaerobic conditions for 24 h.[13] BNAH, $NaBH_4$, and $PhNHNH_2$ were also applicable to the prepara-



$PQQH_4$

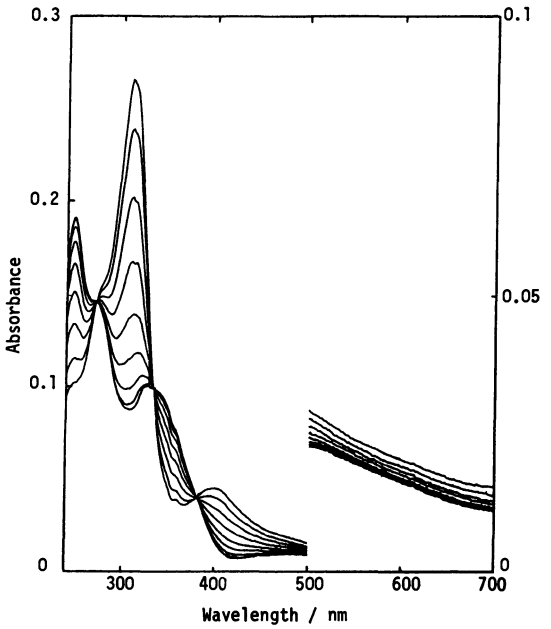


Fig. 1. Spectral change along the progress of the reaction of $PQQH_2$ (1.5×10^{-5} M), and O_2 (2.28×10^{-4} M), in 0.1 M acetate buffer (pH 3.81, μ=0.3 with KCl, containing 5% DMSO) at 30°C.

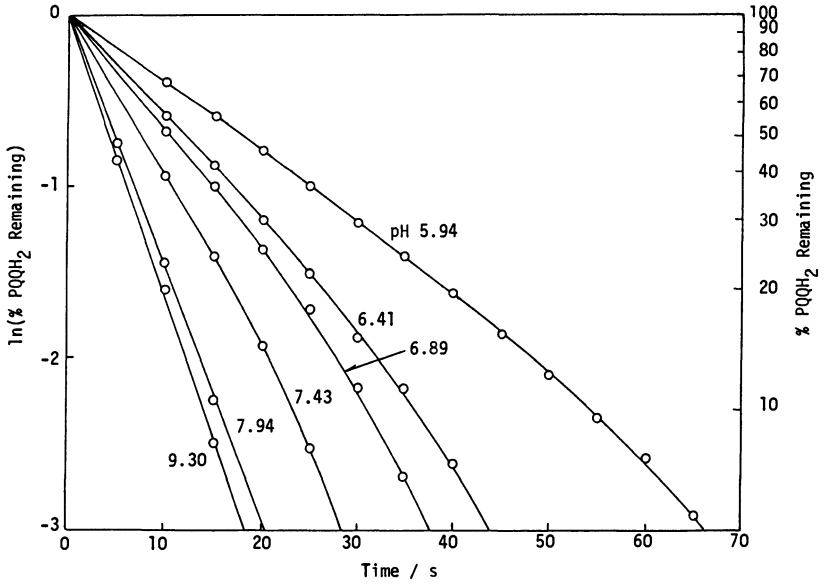

Fig. 2. Time course of the oxidation of $PQQH_2$ (1.5×10^{-5} M), by O_2 (2.28×10^{-4} M), in 0.1 M acetate (pH 5.94), phosphate (pH 6.41, 6.89, 7.43, 7.94), and carbonate (pH 9.30) buffer solutions (μ=0.3 with KCl, containing 5% DMSO) at 30°C.

tion of PQQTMEH$_2$ (70, 65, and 82% yield, respectively).

Oxidation of PQQH$_2$ by O$_2$ was studied under pseudo-first-order conditions of $[PQQH_2]_T=1.5\times10^{-5}$ M under air atmosphere ($[O_2]=2.28\times10^{-4}$ M at 30 °C) in 0.1 M buffer solutions (μ=0.3 with KCl, containing 5% DMSO). The progress of the reaction was followed by monitoring the disappearance of PQQH$_2$ at 320 nm (Fig. 1). PQQH$_2$ was oxidized rapidly to PQQ with isosbestic points at 272, 333, and 379 nm at pH 3.81 (0.1 M acetate buffer containing 5% DMSO) and the yield of H_2O_2 was determined to be about 50% based on PQQH$_2$ by iodometric titration. An intermediate such as a semiquinone or a covalent adduct of O$_2$ to PQQH$_2$ was not detected by UV-visible absorption spectroscopy in the course of the reaction.

The reaction did not follow the first-order kinetics, namely it is accelerated gradually with proceeding of the reaction (Fig. 2). Thus, the initial rate constant (k_i) was calculated from the initial slope of the pseudo-first-order plots. The initial rate (pH 6.90) was first-order in oxygen concentration (Fig. 3). As shown in Fig. 2, the rate increases as the pH is increased from 5.94 to 9, though the dependence of the initial rate on pH is somewhat complicated. The acid-base dissociation constant (K_a) for the quinol function of PQQH$_2$ was determined spectrophotometrically to be 7.08×10^{-10} M (pK_a=9.15) under the anaerobic kinetic conditions. Moreover, PQQH$_2$ was relatively stable in an organic solvent such as dimethyl sulfoxide even under aerobic conditions. These results indicate that PQQH$^-$ is considered to be an active species in the oxidation of PQQH$_2$ by O$_2$ as shown in Eq. 1.

$$PQQH_2 \underset{+H^+}{\overset{-H^+}{\rightleftharpoons}} PQQH^- \xrightarrow{k_2[O_2]} PQQ + H_2O_2 \qquad (1)$$

$$pK_a = 9.15$$

Why does the reaction deviate from the first-order rate law? To solve the problem, the reaction was carried out in the presence of catalase (10^{-7} M) under the same conditions (Fig. 4). In this case, the reaction followed the first-order rate law and such a deviation was not observed. On the other hand, the presence of SOD (superoxide dismutase, 10^{-7} M) in addition to catalase hardly affected the time course compared with the case of autoxidation of reduced flavins.[14] Furthermore, the presence of PQQ (1.5×10^{-5} M) in the reaction mixture also did not alter the time course of the reaction. From these results, we consider that the main cause for the deviation from the pseudo-first-order rate law is a side reaction of PQQH$_2$ with H_2O_2 (Eq. 4) formed by the reaction of PQQH$_2$ and O$_2$ (Eq. 3). As in fact, the yield of H_2O_2 was found to be about 50% based on PQQH$_2$, and PQQH$_2$ actually reacted with H_2O_2 comparably

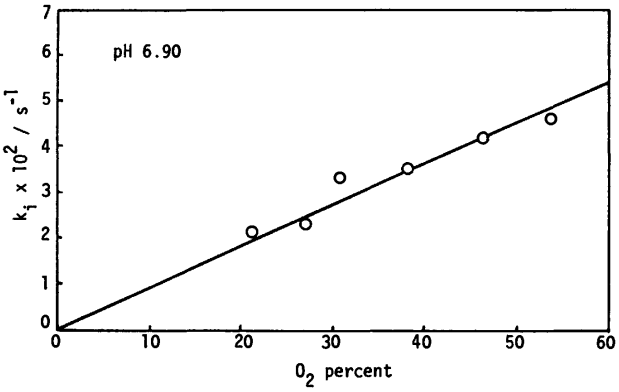

Fig. 3. Initial rate constant (k_i) for the O$_2$ oxidation of PQQH$_2$ (1.5×10^{-5} M) plotted as a function of O$_2$ percent (determined by oxygen meter based on O$_2$- saturated solution: 100%) in 0.1 M phosphate buffer (pH 6.90, μ=0.3 with KCl, containing 5% DMSO) at 30 °C.

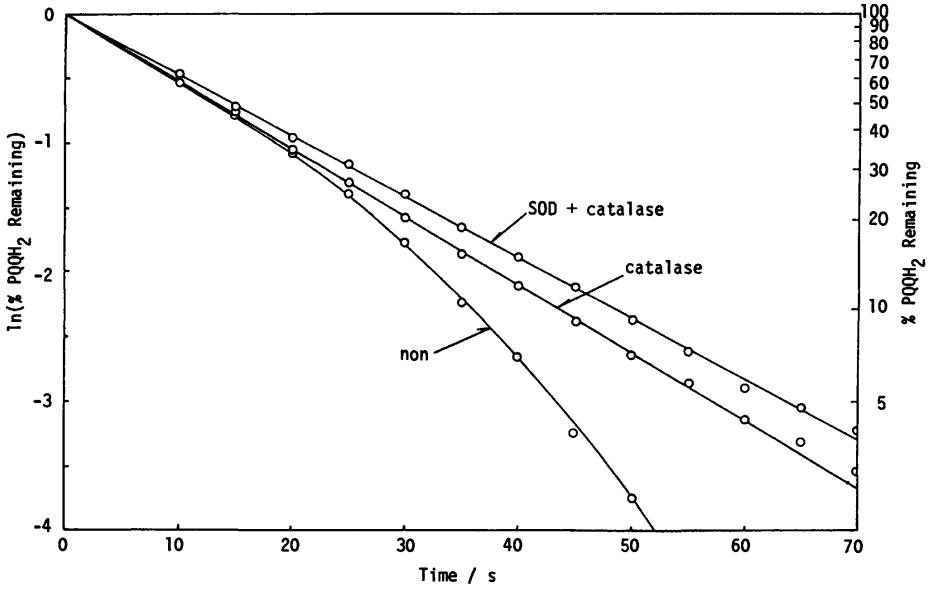

Fig. 4. Effect of catalase (10^{-7} M) and superoxide dismutase (SOD, 10^{-7} M) on the oxidation of PQQH$_2$ (1.5×10^{-5} M) by O$_2$ (2.28×10^{-4} M) in 0.1 M phosphate buffer (pH 6.90, μ=0.3 with KCl, containing 5% DMSO) at 30 °C.

fast in the absence of O_2. On the other hand, there may be little participation of autocatalysis by $O_2^{\cdot-}$ and PQQ itself (Eq. 5—7).

$$PQQH_2 + O_2 \longrightarrow PQQ + H_2O_2 \quad (3)$$

$$PQQH_2 + H_2O_2 \longrightarrow PQQ + 2H_2O \quad (4)$$

$$PQQH_2 + PQQ \rightleftharpoons 2PQQH^{\cdot} \quad (5)$$

$$PQQH^{\cdot} + O_2 \longrightarrow PQQ + O_2^{\cdot-} + H^+ \quad (6)$$

$$PQQH^{\cdot} + O_2^{\cdot-} \xrightarrow{H^+} PQQ + H_2O_2 \quad (7)$$

As molecular oxygen contains two unpaired electrons and is paramagnetic in the ground state, the concerted two electron reduction of O_2 to H_2O_2 is highly restricted by symmetry consideration.[15] Thus, the reduction of O_2 with $PQQH_2$ is assumed to occur in two ways: (a) By binding to the electron donor, $PQQH_2$, the molecular orbitals of O_2 are perturbed, or (b) the reduction of O_2 via two univalent electron transfer (stepwise). The standard redox potential (E_0') values (pH=7.0) of $O_2/HO_2^{\cdot}$ couple has been calculated to be −0.59 V (Eq. 8).[16] On the other hand, Duine and his co-workers determined the midpoint potentials (E_m) of the quinone/semiquinone and semiquinone/quinol couples for PQQ at pH 13.0 to be −0.218 and −0.242 V, respectively (Eqs. 10, 11).[6] Although the standard redox potentials (pH 7.0) for these couples of PQQ have not been defined, they are considered to be higher than those E_m (pH 13). Thus, one electron reduction of O_2 to $O_2^{\cdot-}$ by either $PQQH_2$ or the semiquinone appears thermodynamically unfavorable. Absence of autocatalysis by $O_2^{\cdot-}$ and the semiquinone may also discard the possibility of the reduction of O_2 via two univalent electron transfer (free radical mechanism, type b). Ultimately, it reminds us a mechanism via covalent addition of O_2 to quinol carbon of $PQQH^-$ followed by elimination of H_2O_2 (type a). The mechanistic details of the reaction is currently under investigation.

$$O_2 + H^+ + e^- \longrightarrow HO_2^{\cdot} \quad E_0' = -0.59\,V \quad (8)$$

$$HO_2^{\cdot} + H^+ + e^- \longrightarrow H_2O_2 \quad E_0' = 0.98\,V \quad (9)$$

$$\text{quinone/semiquinone} \quad E_m = -0.218\,V\ (pH=13) \quad (10)$$

$$\text{semiquinone/quinol} \quad E_m = -0.242\,V\ (pH=13) \quad (11)$$

The present work was partially supported by a Grant-in-Aid for Special Project Research from the Ministry of Education, Science, and Culture and by the Mishima-Kaiun Memorial Foundation to which our thanks are due. We also acknowledge Dr. Kazuo Kobayashi of Osaka University for his kind supply of catalase.

Synthesis of ara-Cadeguomycin. 2-Amino-3,4-dihydro-4-oxo-7-(β-D-arabinofuranosyl)-7*H*-pyrrolo[2,3-*d*]pyrimidine-5-carboxylic Acid

Kaoru Okamoto, Tadao Kondo,†,* and Toshio Goto*

(Received January 31, 1986)

2-Amino-3,4-dihydro-4-oxo-7-(β-D-arabinofuranosyl)-7*H*-pyrrolo[2,3-*d*]pyrimidine-5-carboxylic acid, an analogue of cadeguomycin, has been synthesized via glycosylation of 3-methoxymethyl-5-methyl-2-methylthio-7*H*-pyrrolo[2,3-*d*]pyrimidin-4(3*H*)-one with 2,3,5-tri-*O*-benzyl-D-arabinofuranosyl chloride.

The arabinofuranosyl nucleosides such as ara-A[1] and ara-G[2] of naturally occurring purine and pyrimidine bases of nucleic acids have been synthesized to investigate their biological activities. It has been revealed that they act as inhibitors of ribonucleotide reductase or DNA polymerase.[3] 4-Amino-7-(β-D-arabinofuranosyl)pyrrolo[2,3-*d*]pyrimidine (ara-tubercidin),[4] resists to deactivation by deaminases and shows antiviral activity. Recently, 2-amino-7-(β-D-arabinofuranosyl)-pyrrolo[2,3-*d*]pyrimidin-4(3*H*)-one (7-deaza-ara-G) was also synthesized[5] to avoid deactivation by the above reason. These properties of arabinofuranosyl nucleosides prompted us to synthesize the ara-analogue (**2**) of cadeguomycin (**1**), which was isolated from the culture broth of *Streptomyces hygroscopicus* IM7912T as a minor component concomitant with tubercidin.[6] Cadeguomycin (**1**) inhibits growth of IMC carcinoma and metastasis of Lewis lung carcinoma, and enhances cell-mediated immunity and macrophage activity,[7] but shows no significant antimicrobial activity against bacteria and fungi in contrast to tubercidin.[6]

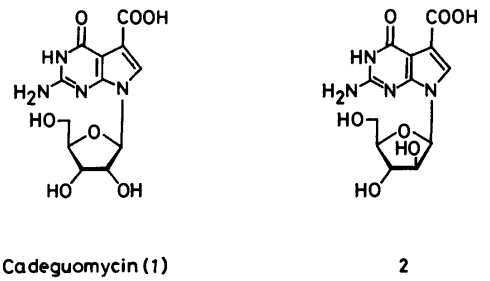

Fig. 1.

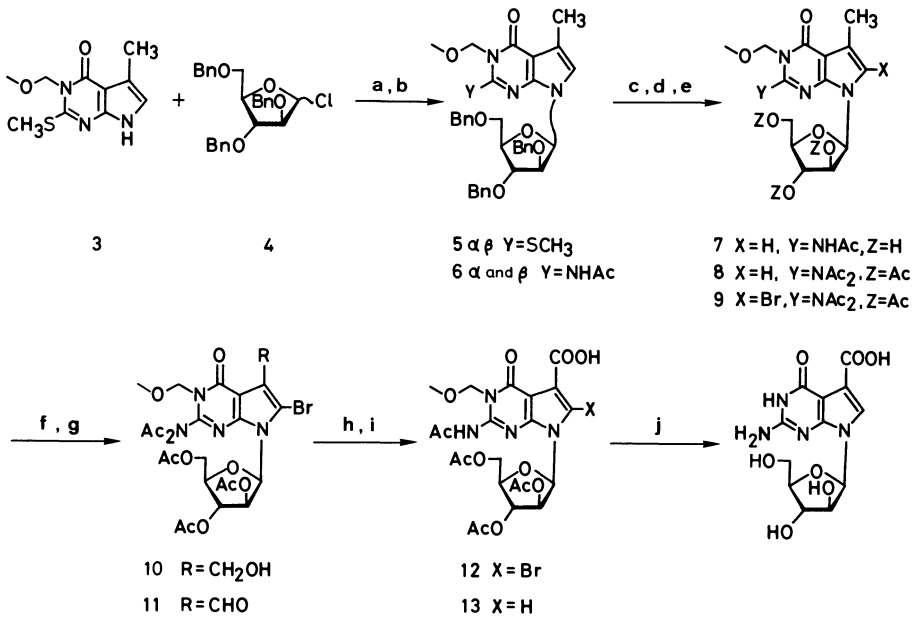
As a base moiety for the synthesis of ara-cadeguomycin (**2**) we have chosen 3-methoxymethyl-5-methyl-2-methylthio-7*H*-pyrrolo[2,3-*d*]pyrimidin-4(3*H*)-one (**3**) which has been applied to the syntheses of cadeguomycin (**1**),[8] nucleoside Q, preQ$_0$, and preQ$_1$.[9] The glycosylation reaction of the base **3** with 2,3,5-tri-*O*-benzyl-D-arabinofuranosyl chloride (**4**), which was prepared from 2,3,5-tri-*O*-benzyl-1-*O*-(*p*-nitrobenzoyl)-D-arabinofuranose according to the Fletcher's method,[10] was carried out in the same manner as the synthesis of cadeguomycin (**1**), etc.[8,9] Thus, treatment of **3** with **4** in the presence of sodium hydride in DMF gave **5αβ** as a 1:5 mixture of α and β isomer in 99% yield. The structural assignment of the anomers was achieved by comparison of chemical shifts of the anomeric protons in ^{1}H NMR spectra with those of known 7-(β-D-arabinofuranosyl)pyrrolo[2,3-*d*]pyrimidin-4(3*H*)-one analogues.[5,11] Generally the anomeric proton signal of the β isomer appears in a low field (≈6.53 ppm) compared with that of the α isomer (≈6.27 ppm) and has a larger vicinal coupling constant (5.4 Hz) in contrast to the α isomer (3.9 Hz) in ^{1}H NMR spectra. As this glycosylation products, **5αβ**, could not be separated by the usual silica-gel column chromatography, the mixture was subjected to the next acetylamination reaction. The conversion of the 2-methylthio group of **5αβ** into an acetylamino group was carried out by the method which has been used for the synthesis of nucleoside Q.[12] Thus, the mixture was treated at 100 °C with acetamide anion generated by fusion of sublimed acetamide and sodium hydride to give a mixture of **6α** and **6β** in 64% yield. In this stage, the anomeric mixture **6αβ** was easily separated into β (53% yield) and α isomer (11% yield) by use of a silica-gel column. The protecting benzyl groups on the sugar moiety were changed to acetyl groups since the benzyl groups are intolerable to the subsequent allylic bromination. Debenzylation of **6β** was accomplished with 10% Pd–C under hydrogen atmosphere to give the triol **7** in 67% yield. Treatment of **7** with acetic anhydride and anhydrous pyridine gave the acetylated compound **8** in 99% yield. The compound **8** was brominated with *N*-bromosuccinimide (NBS) in benzene at room temperature to afford the bromide **9** in 99% yield. The bromide **9** was further brominated with NBS in carbon tetrachloride to give a dibromide, which was converted into the bromo alcohol **10** by hydrolysis with silver carbonate in dioxane–water. The overall yield from **8** was 76%. Without isolation of the bromide **9** direct conversion of **8** with 2 equivalents of NBS into **10** resulted in a low yield (ca. 30%). Oxidation of the bromo alcohol **10** with active manganese (IV) dioxide in acetonitrile caused partial deacetylation and, therefore, the product was reacetylated with acetic anhydride and pyridine to give the aldehyde **11** in 67% yield. Further oxidation of **11** with NBS[13] in carbon tetrachloride under irradiation by a reflecting photolamp at room temperature gave the acid bromide, which was hydrolyzed by addition of water and then deacetylated with aqueous ammonia to afford the



Scheme. 1. Reaction conditions: (a) NaH, DMF, 0°C, 2 h (97%); (b) NaH, CH_3CONH_2, 100°C, 40 min (64%); (c) 10% Pd-C/H_2, MeOH, rt, 7 h (67%); (d) Ac_2O, pyridine, rt, 1 h (99%); (e) NBS, benzene, rt, 30 min (99%); (f) NBS, benzoyl peroxide, K_2CO_3, CCl_4, reflux, 2 h; Ag_2CO_3, dioxane-water, rt, 1.5 h (76%); (g) MnO_2, CH_3CN, rt, 8 h (67%); (h) NBS, $h\nu$, K_2CO_3, CCl_4, rt, 45 min; 2M HCl (67%); (i) 10% Pd-C/H_2, MeOH-water, rt, 30 min (84%); (j) NH_4OH, MeOH, rt, 14 h; TFA-water (3/1), 70°C, 1 h (86%).

bromo carboxylic acid **12** in 64% yield. Finally, deprotection was accomplished stepwise. The compound **12** was debrominated with 10% Pd-C in the presence of potassium acetate giving the carboxylic acid **13** in 84% yield. Hydrolysis of **13** with aqueous ammonia in methanol followed by trifluoroacetic acid (TFA) afforded ara-cadeguomycin (**2**) in 86% yield, which was crystallized from ethanol-water to give pure ara-cadeguomycin (**2**).

Experimental

Melting points were determined on a Mitamura Riken flat-bulb thermometer with a heating metal block and uncorrected. Elemental analyses were performed on a Perkin-Elmer 240C elemental analyzer. Nuclear magnetic resonance spectra (NMR) were recorded with a JEOL FX-200 instrument in the FT mode. Chemical shifts were expressed in δ values relative to tetramethylsilane as an internal standard unless otherwise noted. Coupling constants (J) were given in hertz (Hz) and splitting pattern abbreviations are: s, singlet; d, doublet; t, triplet; q, quartet; dd, doublet of doublets; ddd, doublet of double doublets; br, broad; m, multiplet. Mass spectra (MS) were obtained on a JEOL DX-300 spectrometer. Infrared spectra (IR) were recorded on either a Shimadzu IR 435 or a JASCO A-3 spectrometer. Ultraviolet spectra (UV) were measured on a Hitachi 228 spectrometer. Optical rotations $[\alpha]_D$ were recorded on a JASCO DIP-181 digital polarimeter.

Analytical thin-layer chromatography (TLC) was done on precoated TLC glass sheets (silica gel 60F-254, layer thickness 0.25 mm) manufactured by E. Merck. Preparative silica-gel thick-layer chromatography was performed on 20×20 cm glass plates coated with silica gel PF-254 (E. Merck, Darmstadt). Column chromatography was performed with Merck silica gel 60 (70—230 mesh).

Glycosylation of the Base 3 with 4. Dry hydrogen chloride was bubbled into a solution of 2,3,5-tri-*O*-benzyl-1-*O*-(*p*-nitrobenzoyl)-D-arabinofuranose[7] (5.8 g, 10.2 mmol) in dichloromethane (36 ml) at 0°C until no further *p*-nitrobenzoic acid precipitated. After standing for 2 h, the precipitate was filtered and washed with dichloromethane. The combined filtrates were evaporated in vacuo to give the halogenose **4** as a viscous syrup, which was dissolved in anhydrous DMF (5.5 ml). A mixture of **3** (1.8 g, 7.5 mmol) and sodium hydride (50% oil suspension, 0.45 g, 9.4 mmol) in anhydrous DMF (7.0 ml) was stirred for 0.5 h and to this was added above DMF solution of **4** at 0°C under argon atmosphere. The reaction mixture was allowed to warm to room temperature, stirred for 6 h, poured into ice-water, and extracted with ethyl acetate. The extracts were washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a viscous residue, which was applied to a silica-gel column and eluted with hexane-ethyl acetate (gradient elution from 3:1 to 2:1) to give 3-methoxymethyl-5-methyl-2-methylthio-7-(2,3,5-tri-*O*-benzyl-D-arabinofuranosyl)-7*H*-pyrrolo[2,3-*d*]pyrimidin-4(3*H*)-one (**5**$\alpha\beta$) (4.8 g, 99%) as a 1:5 mixture of α and β isomer (detected by ^{1}H NMR): UV (MeOH) 308 nm; ^{1}H NMR ($CDCl_3$)

δ=2.30 (d, J=1.0 Hz, β-CH_3-5), 2.36 (d, J=1.0 Hz, α-CH_3-5), 2.48 (s, α-CH_3S), 2.55 (s, β-CH_3S), 3.44 (s, β-CH_3O), 3.46 (s, α-CH_3O), 3.49—3.78 (m, α,β-H-5′), 4.0—4.7 (m, α,β-H-2′ and 3′, OCH_2Ph), 5.57 (br. s, OCH_2N), 6.27 (d, J=3.9 Hz, α-H-1′), 6.53 (d, J=5.4 Hz, β-H-1′), 6.70 (q, J=1.0 Hz, α-H-6), 6.82 (q, J=1.0 Hz, β-H-6), and 6.9—7.4 (m, ArH); IR (neat) 1685 (amide I), 1534 (amide II), and 1512 cm^{-1}; MS (EI) m/z 641 (M^+).

2-Acetylamino-3-methoxymethyl-5-methyl-7-(2,3,5-tri-*O*-benzyl-β-D-arabinofuranosyl)-7*H*-pyrrolo[2,3-*d*]pyrimidin-4(3*H*)-one (6β) and Its α Isomer (6α). To a mixture of sodium hydride (50% oil suspension, 1.3 g) and acetamide (13 g, sublimed just before use) was added **5αβ** (2.6 g, 4.1 mmol) and heated for 40 min at 100 °C under argon atmosphere. Excess acetamide was removed in vacuo and the residue was carefully acidified with acetic acid under ice-cooling and extracted with benzene. The extract was washed with water, saturated $NaHCO_3$, and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a syrup, which was chromatographed on a silica-gel column (hexane–ethyl acetate, gradient elution from 2:1 to 1:1). The more rapidly migrating zone was the isomer **6α** (0.3 g, 11%) and the slower, the isomer **6β** (1.4 g, 53%) as a viscous syrup; **6α**: UV (MeCN) 306 nm (ε 9580); $[\alpha]_D^{21}$ +23.6° (c 0.1, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.35 (3H, d, J=1.0 Hz, CH_3-5), 2.38 (3H, s, CH_3CON), 3.44 (3H, s, CH_3O), 3.60 (1H, dd, $J_{5',4'}$=5.1 Hz, $J_{5',5'}$=10.5 Hz, H-5′), 3.63 H, dd, $J_{5',4'}$=4.6 Hz, $J_{5',5'}$=10.5 Hz, H-5′), 4.15—4.28 (1H, m, H-4′), 4.35—4.66 (8H, m, H-2′ and 3′, 3×OCH_2Ph), 5.52 and 5.53 (2H, AB quartet, J=11.5 Hz, OCH_2N), 6.20 (1H, d, $J_{1',2'}$=3.9 Hz, H-1′), 6.77 (1H, q, J=1.0 Hz, H-6), 7.1—7.4 (15H, m, ArH), and 8.41 (1H, br. s, NH); IR (neat) 1685 (amide I) and 1570 (amide II) cm^{-1}; MS (EI) m/z 652 (M^+).

6-Bromo-2-diacetylamino-5-hydroxymethyl-3-methoxymethyl-7-(2,3,5-tri-*O*-acetyl-β-D-arabinofuranosyl)-7*H*-pyrrolo[2,3-*d*]-pyrimidin-4(3*H*)-one (10). A mixture of **9** (650 mg, 1.0 mmol), NBS (210 mg, 1.2 mmol), anhydrous potassium carbonate (660 mg, 4.78 mmol), and benzoyl peroxide (20 mg) in carbon tetrachloride (60 ml) was refluxed with stirring for 2 h under argon atmosphere. The reaction mixture was cooled and the precipitate was removed through a glass filter and washed with carbon tetrachloride. The combined filtrates were

evaporated in vacuo to give a dibromide, which was dissolved in dioxane (40 ml) and water (14 ml). To this solution was added silver carbonate (800 mg, 2.9 mmol) and the mixture was stirred for 1.5 h at room temperature and filtered, and the filtrate was evaporated in vacuo to give a syrup, which was chromatographed on a silica-gel column (benzene–ethyl acetate, gradient elution from 1:1 to 2:3) to give **10** (507 mg, 76%) as a viscous syrup: UV (MeCN) 306 (ε 7290) and 269 nm (5830); $[\alpha]_D^{22}$ −44.7° (*c* 0.1, $CHCl_3$); ^1H NMR ($CDCl_3$) δ= 1.72 (3H, s, CH_3COO), 2.05 (3H, s, CH_3COO), 2.12 (3H, s, CH_3COO), 2.41 (3H, s, CH_3CON), 2.45 (3H, s, CH_3CON), 3.44 (3H, s, CH_3O), 4.16 (1H, ddd, $J_{4',3'}$=7.3 Hz, $J_{4',5'}$=3.7 and 7.6 Hz, H-4'), 4.24 (1H, dd, $J_{5',4'}$=7.6 Hz, $J_{5',5'}$=11.3 Hz, H-5'), 4.44 (1H, dd, $J_{5',4'}$=3.7 Hz, $J_{5',5'}$=11.3 Hz, H-5'), 4.73 (2H, s, OCH_2-5), 5.32 and 5.40 (2H, AB quartet, J=10.4 Hz, OCH_2N), 5.53 (1H, t, $J_{2',1'}=J_{2',3'}$=7.3 Hz, H-2'), 6.25 (1H, t, $J_{3',2'}=J_{3',4'}$= 7.3 Hz, H-3'), and 6.58 (1H, d, $J_{1',2'}$=7.3 Hz, H-1'); IR (neat) 3450 (OH), 1740 (COO), 1710, and 1690 (amide I); MS (EI) *m/z* 644 and 646 (M^+).

Found: C, 44.36; H, 4.37; N, 8.35%. Calcd for $C_{24}H_{29}N_4O_{12}Br$: C, 44.66; H, 4.53; N, 8.68%.

6-Bromo-2-diacetylamino-5-formyl-3-methoxymethyl-7-(2,3,5-tri-*O*-acetyl-β-D-arabinofuranosyl)-7*H*-pyrrolo[2,3-*d*]-pyrimidin-4(3*H*)-one (11). To a solution of **10** (480 mg, 0.74 mmol) in acetonitrile (25 ml) was added active MnO_2 (7.0 g) in seven portions every 30 min with stirring. After stirring for further 5 h, the mixture was filtered through a Celite 545 bed and the solid was washed well with acetone. The combined filtrates were evaporated in vacuo and the resultant syrup, which was deacetylated partially, was treated with acetic anhydride (1.5 ml) and anhydrous pyridine (3.0 ml) for 0.5 h at room temperature. The mixture was condensed to a syrup, which was purified by chromatography on a silica-gel column (benzene–ethyl acetate, 1:1) to give a colorless syrup 11 (319 mg, 67%): UV (MeCN) 296 (ε 12530) and 239 nm (14280); $[\alpha]_D^{22}$ −57.6° (*c* 0.2, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=1.72 (3H, s, CH_3COO), 2.05 (3H, s, CH_3COO), 2.14 (3H, s, CH_3COO), 2.42 (3H, s, CH_3CON), 2.47 (3H, s, CH_3CON), 3.46 (3H, s, CH_3O), 4.15—4.32 (2H, m, H-5'), 4.35—4.50 (1H, m, H-4'), 5.34 and 5.42 (2H, AB quartet, J=10.7 Hz, OCH_2N), 5.59 (1H, t, $J_{2',1'}=J_{2',3'}$=7.3 Hz, H-2'), 6.27 (1H, $J_{3',2'}=J_{3',4'}$=7.3 Hz, H-3'), 6.74 (1H, d, $J_{1',2'}$=7.3 Hz, H-1'), and 10.47 (1H, s, CHO); MS(EI) *m/z* 642 and 644 (M^+).

Found: C, 44.47; H, 4.41; N, 8.93%. Calcd for $C_{24}H_{27}N_4O_{12}Br$: C, 44.80; H, 4.32; N, 8.71%.

2-Acetylamino-6-bromo-3,4-dihydro-3-methoxymethyl-4-oxo-7-(2,3,5-tri-*O*-acetyl-β-D-arabinofuranosyl)-7*H*-pyrrolo-[2,3-*d*]pyrimidine-5-carboxylic Acid (12). To a mixture of **11** 310 mg, 0.48 mmol) and anhydrous potassium carbonate (460 mg, 3.3 mmol) in carbon tetrachloride (70 ml) was added NBS (100 mg, 0.56 mmol). The mixture was irradiated by a 500 W reflecting photo-lamp with stirring for 45 min at room temperature. The mixture was cooled to 0°C and dioxane–water (3/1 v/v, 6 ml) was added to it. The reaction mixture was stirred for 30 min, acidified with 2 M HCl (1 M=1 mol dm^{-3}), and extracted with dichloromethane. The organic layer was washed with water and brine, dried over anhydrous Na_2SO_4, and evaporated in vacuo to give a syrup, which was treated with 28% aqueous ammonia (1 drop) in methanol (5 ml) for 5 min to hydrolyze the remaining *N,N*-diacetyl groups. After evaporation, the residual oil was purified by preparative silica-gel TLC (dichloromethane–methanol, 20:1) to give the bromo carboxylic acid **12** (190 mg, 64%) as a viscous syrup: UV (MeCN) 287 nm (ε 11650); $[\alpha]_D^{21}$ −71.4° (*c* 0.1, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=1.78 (3H, s, CH_3COO), 2.07 (3H, s, CH_3COO), 2.14 (3H, s, CH_3COO), 2.38 (3H, s, CH_3CON), 3.51 (3H, s, CH_3O), 4.0—4.3 (2H, m, H-5'), 4.4—4.6 (1H, m, H-4'), 5.54 and 5.79 (2H, AB quartet, J=11.2 Hz, OCH_2N), 5.63 (1H, t, $J_{2',1'}=J_{2',3'}$=7.3 Hz, H-2'), 6.29 (1H, br. t, J=6.9 Hz, H-3'), 6.79 (1H, d, $J_{1',2'}$=7.3 Hz, H-1'), 8.40 (1H, br. s, NH), and 13.95 (1H, br, COOH); IR (neat) 1738 (COO), 1700 (sh, COOH), 1640 (amide I), and 1500 (amide II) cm^{-1}; MS (FAB) *m/z* 616 and 618 (M+H).

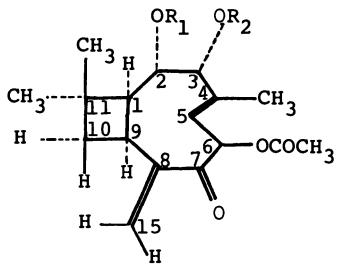
(Received January 31, 1986)

The molecular structure of naematolin 3-*p*-bromobenzoate has been determined by X-ray diffraction analysis. Unlike known caryophyllene derivatives isolated so far, the stereochemistry of the ring juncture is *cis* (1*S*,9*S*) form. The absolute configurations of five chiral centers of this compound are 1*S*,2*S*,3*R*,6*R*, and 9*S*, and the geometry of endocyclic double bond is *E* mode. This is the first example of a *cis*-fused 1*S*,9*S*-caryophyllane sesquiterpenoids confirmed by X-ray structure determination. Crystal data and the final *R* factor are: Mr=491.36, orthorhombic, space group $P2_12_12_1$, a=10.650(2), b=20.650(6), c=10.526(2) Å, U=2315(1) Å^3, Z=4, D_c=1.410 Mg m^{-3}, μ=1.791 mm^{-1}, R=0.084 for 1666 observed unique reflections.

Naturally occurring caryophyllane sesquiterpenoids either plant or animal origins consist generally of *trans*-bicyclo[7.2.0]undecane skeleton. Some of their structures were determined by X-ray analyses.[1-8] The structure of a sesquiterpenoid naematolin isolated from *Naematoloma sublateritium* by Backens et al. was also assigned to have *trans*-fused configuration on the basis of the spectral data.[9] With only exception, 9-*epi*-caryophyllene possessing *cis*-bicyclo[7.2.0]undecane skeleton, was described by Bohlmann et al.[10]

Very recently, the structure of naematolin (**1**) has been reported to be described as **1**, indicative of 1-e_imeric caryophyllene derivative.[11] This compound **1** was first isolated by Ito et al. in 1967 as one of metabolites of *Naematoloma fasciculare* (Basidiomycetes).[12]

In order to confirm the stereochemistry and to clarify the absolute configuration of naematolin, the structure determination of its 3-*p*-bromobenzoate (**2**) was carried out by X-ray analysis.



1 $R_1=R_2=H$
2 $R_1=H$, $R_2=p$-BrC_6H_4CO
3 $R_1=R_2=COCH_3$
4 $R_1=R_2=C_6H_5CO$

Experimental

Crystal Data. $C_{24}H_{27}O_6Br$, Mr=491.36, orthorhombic, space group $P2_12_12_1$, a=10.650(2), b=20.650(6), c=10.526(2) Å, U=2315(1) Å^3, Z=4, D_c=1.410 Mg m^{-3}, μ=1.791 mm^{-1}.

The sample for X-ray analysis was crystallized from ether-hexane. A 0.4×0.4×0.15 mm, colorless and plate crystal, was used for the measurement. The reflections within the range of $2\theta<55°$ were collected on a Rigaku AFC-5 four-circle automated X-ray diffractometer with graphite monochromatized Mo $K\alpha$ radiation (λ=0.7073 Å) by means of the ω scan ($2\theta<30°$) and ω—2θ scan ($2\theta>30°$) techniques. From the 2580 observed reflections, 1666 independent reflections with $|F_o|>3\sigma(F_o)$ were used for the structure analysis. The intensities were corrected for the Lorentz and polarization factors, and for the absorption. All the calculations were carried out on a FACOM M-380 computer at this Institute, using UNICS III program system.[13] The scattering factors and anomalous dispersion terms were taken from the International Tables.[14] The structure was solved by MULTAN,[15] and was refined by the block-diagonal least-squares method. The calculated hydrogen atom positions were included in the refinement with isotropic temperature factors. The final refinement was done through full-matrix least-squares method including extinction corrections with the weight $1/\sigma(F_o)^2$.[16] The final R was 0.084. Positional parameters for non-hydrogen atoms are given in Table 1.**

The Determination of the Absolute Configuration. The absolute configuration was determined with Mo $K\alpha$ data. The size of the crystal was 0.5×0.5×0.28 mm.

Eleven indices with $|\Delta F_c|/\sigma(F_o)>13$ were selected for the determination of the absolute configuration, where ΔF_c is the difference between the $|F_c|$ for the Bijvoet pairs. For each index, the diffraction intensities were measured for all eight combinations of plus and minus signs, and the mean values of equivalent indices were compared with the calculations. Signs of ΔF_o agree with those of ΔF_c without exception. Thus the parameters in Table 1 represent the correct absolute configuration without doubt.

Discussion of the Structure

A perspective drawing and the bond parameters are given in Figs. 1 and 2. The structure of **2** is best described as the conformation **5** (Fig. 3), where 4-membered ring having gem dimethyl groups is fused to 9-membered ring with *cis* fashion. The 9-membered ring moiety contains hydroxyl, *p*-bromobenzoyloxyl, allylic methyl, acetoxyl, carbonyl, and exocyclic methylene groups. The geometry of endocyclic double

Positional parameters are multiplied by 10^4. Thermal parameters are given by the equivalent temperature factors.

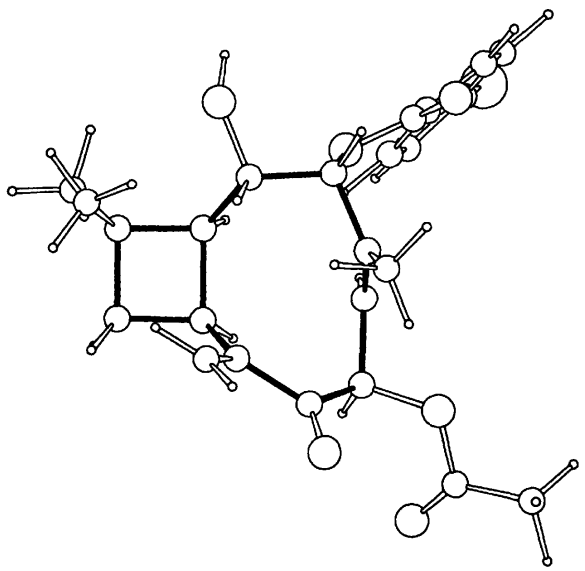

Fig. 1. Perspective drawing of the molecule.

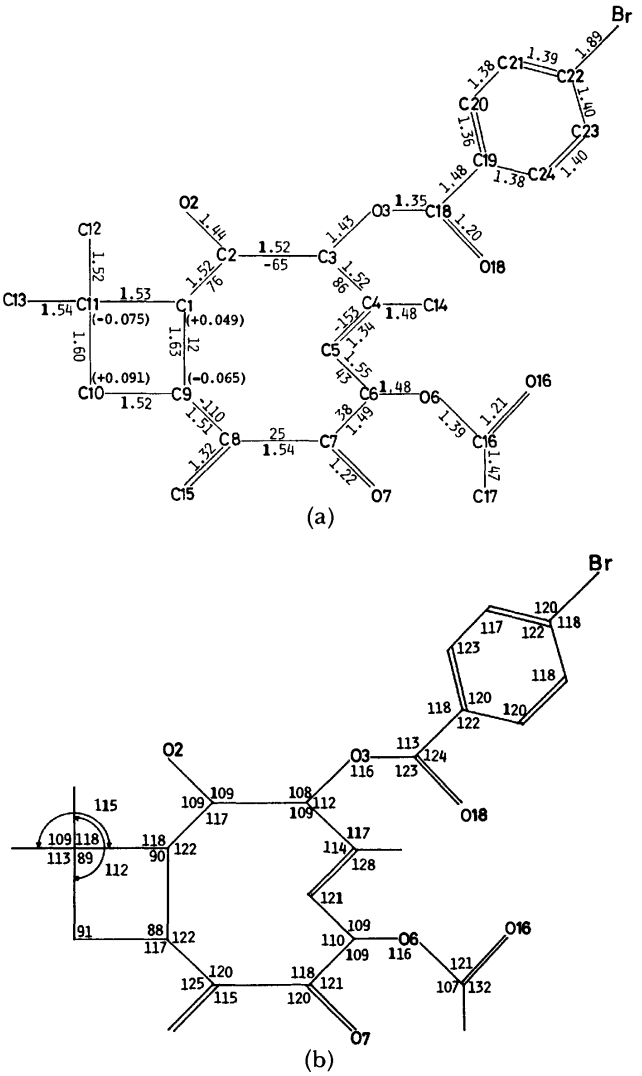

Fig. 2. Bond parameters.
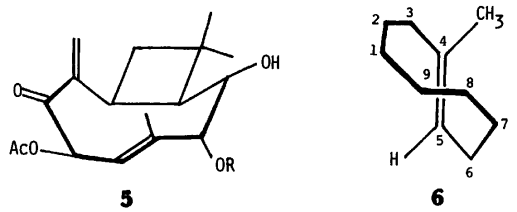
(a) Bond lengths (l/Å) and torsion angles(ϕ/°). Torsion angles around the 9-membered ring are expressed by the figures inside the ring. The atomic displacements (Å) from the least-squares 4-membered plane are given in parentheses. (b) Bond angles (ϕ/°).
The standard deviations are: bond lengths: 0.03 Å; torsion angles: 2°; bond angles: 2°; atomic displacements: 0.008 Å.



5 6

Fig. 3. Conformation of naematolin and chirality of 9-membered ring.

bond is E mode, and the configuration of the sp^2 plane chirality arising from the double bond is R as illustrated in **6**. (Fig. 3). Thus the configurations of the present compound are 1*S*, 2*S*, 3*R*, 4*E*, 6*R*, and 9*S*, respectively. Although *cis*-1*R*,9*R*-fused related compound has already been known as described above,[10] this is the first example of a *cis*-fused 1*S*,9*S*-caryophyllane sesquiterpenoid. The result agrees well with the

stereochemistry deduced from the spectral data, and the application of the dibenzoate chirality rule[17] to the dibenzoate **4** led also to the same conclusion.[11]

The markedly short nonbonded contacts are found between C(4) and C(8), and C(5) and C(8), 3.02(2), 2.90(2) Å, respectively. In fact, transannular cyclization in caryophyllene system occurs to give β-caryophyllene alcohol or the other tricyclic derivatives.[1,2,5]

Very large transannular H–H repulsions are supposed among hydrogen atoms H(C9), H(C5), and H(C6), and H(C2), H(C15-2) and H(C12-1) as observed by NOE experiments of ^{1}H NMR of the diacetate **3**.[11] The transannular hydrogen interactions may relieve even slightly by deviation of bond angle from the normal tetrahedral one and the carbonyl group occupies corner position. The conformation of fused 4-membered ring is essentially planar as given in Fig. 2(a), although that of *trans*-fused caryophyllene is usually nonplanar. The bond angles keep nearly 90°, and the fairly long bond lengths are observed between C(1) and C(9), and C(10) and C(11). This elongation of the bond lengths may release the repulsion between them.

The 9-membered ring takes [13113]*** and a boat-chair (BC) conformation as shown in Fig. 4. The lowest calculated conformation for flexible unsubstituted and saturated cyclononane is the triangular [333] and twist boat-chair (TBC) form of D_3 symmetry.[18] The corresponding cyclic ketone, cyclononanone, in a crystalline $HgCl_2$ complex has been shown to take an unsymmetric, quinquangular of type [12222], and a twist chair-boat (TCB) conformation of C_2 symmetry.[19,20] However, the ring in the present compound forces to take the BC conformation by the steric requirement.

β,γ-Unsaturated carbonyl compound can form inherently chiral chromophoric system.[21] In the circular dichroism spectrum of **1**, the negative relatively high rotational strength, $\Delta\varepsilon_{327}$ −3.16°, originates probably from this chirality. The sign of the n-π* Cotton effect agrees with the negative direction in the chirality rule as shown in Fig. 5. The dihedral angle of two planes in **2** is found to be 112°.

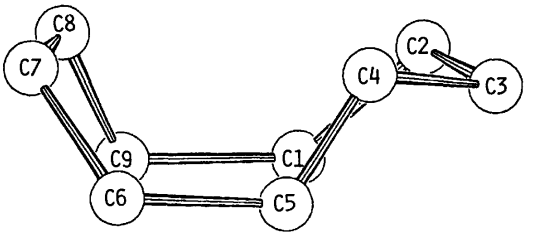


Fig. 4. Conformation of 9-membered ring.

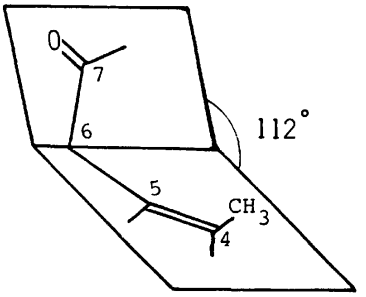

Fig. 5. Helicity with respect to β,γ-unsaturated ketone.

*** The conformation type is expressed by a series of numbers within brackets, each giving the number of bonds in one side. (Y. Dale, *Acta Chem. Scand.*, **27**, 115 (1973)).

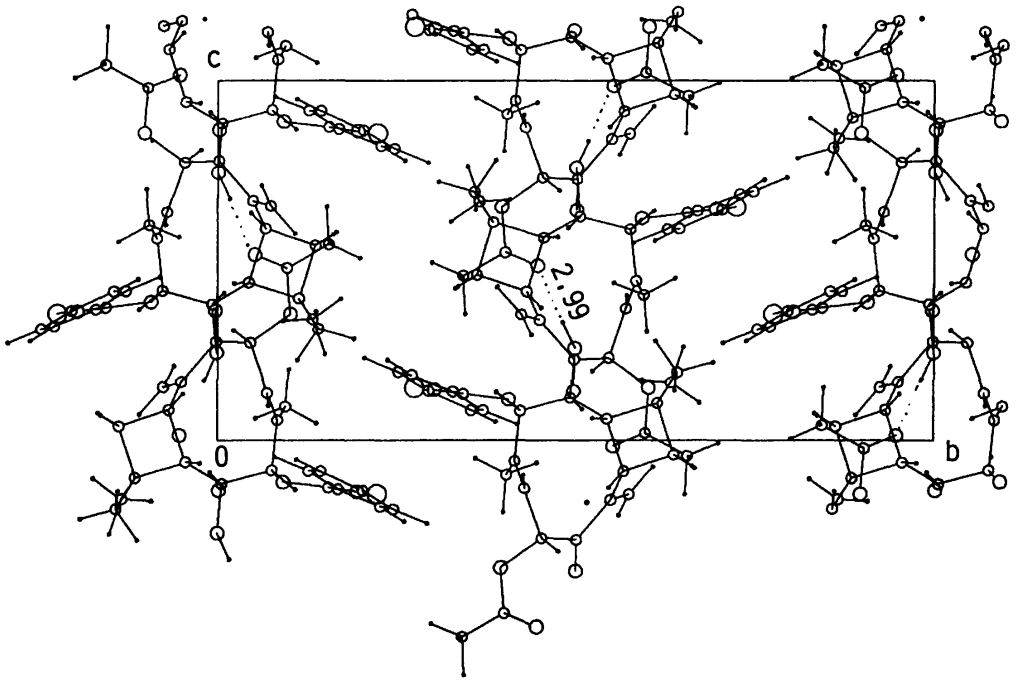

Fig. 6. Crystal structure, projection along **a**.

Conjugation of an α,β-unsaturated ketone tends to keep coplanarity unless a steric repulsion exists. In **2**, however, the terminal double bond and keto group are twisted to each other (23°). This means that a planar geometry is prevented by the unusual highly strained ring conformation. The deformation from coplanarity causes decrease in the optical density at the maximum in absorption spectrum of **1** compared with that of an isomer of naematolin, which was assgined to have trans juncture.[9]

Only one relatively weak intermolecular hydrogen bond is observed between O(2) and O(16), 2.99(2)Å, and there is no short (<3.3Å) intermolecular contacts as shown in Fig. 6. The relatively large R index may be due to the low-density packing.

Authors express their sincere thanks to Dr. Tetsuzo Ito of this Institute for his cooperation in extinction calculation. Helpful discussions with Dr. Yasuo Ohtsuka and the technical assistance of Mr. Tsuneharu Inoue are also gratefully acknowledged.

Base-Catalyzed Hydrolysis of Acetylcholine Chloride in the Presence of Anionic and Nonionic Surfactants

Masayuki NAKAGAKI and Shoko YOKOYAMA*
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-Shimoadachi-cho, Sakyo-ku, Kyoto 606
(Received July 1, 1985)

Base-catalyzed hydrolysis of acetylcholine chloride (Ach) in the presence of anionic and nonionic surfactants was investigated. The rate of hydrolysis was determined by measuring the rate of disappearance of Ach with a spectrophotometer. At a constant pH of 9.0, addition of heptaethylene glycol dodecyl ether (HED) at concentrations above the critical micelle concentration (cmc) results in a slight increase in the apparent rate, v, which is expressed by two reaction rates, v_f and v_m, in the aqueous and micellar phases, respectively. The increase in the apparent rate is due to increase in v_m. In the presence of sodium dodecyl sulfate (SDS), the apparent rate constant, k_{app}, is approximately constant at concentrations below the cmc, and k_{app} decreases above the cmc. In the presence of SDS-HED mixed micelles, k_{app} decreases with the mole fraction of SDS. In these cases, the decrease in the apparent rate is due to the decrease in both v_f and v_m. These two k_{app} decreases are due, respectively, to the decrease in Ach in the aqueous phase and the electrostatic repulsion between OH^- and DS^- at the micelle surface in conformity with the Gouy-Chapman theory.

Micellar catalysis has been a subject of interest in various fields: Hydrolysis of acetylcholine chloride (Ach) is widely studied in various kinetic model experiments for stability prediction,[1] and also studied in relation to its chemical and enzymatic stability. Studies carried out since 1930 have established the dependence on pH and temperature,[2-4,7] an salt effect,[5] and the enthalpy[6] of hydrolysis of Ach. Regarding the influence of surfactants on the hydrolysis of Ach, Nogami et al.[8] have revealed a retardation of base-catalyzed hydrolysis of Ach by sodium dodecyl sulfate (SDS) micelle by comparing half lives of Ach in the absence and presence of SDS. However, any kinetic analysis on the hydrolysis in the presence of surfactant has not yet been carried out.

In this investigation, a kinetic study on the base-catalyzed hydrolysis of Ach has been carried out in the presence of anionic surfactant, nonionic surfactant, or mixed micelles of anionic and nonionic surfactants. The relation between the rate of hydrolysis and the surface potential of micelle also has been made clear by taking into account the accurate critical micelle concentration (cmc) of surfactant in the presence of Ach[9] and the distribution of Ach between micellar and bulk phases.[10]

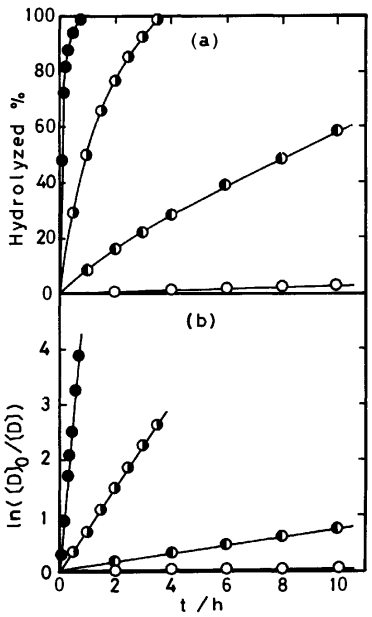

Fig. 1. Effect of pH on hydrolysis of Ach in the absence of surfactant.
(a) Hydrolyzed %, and (b) $\ln([D]_0/[D])$ vs. time.
pH: ○ 7.60, ◐ 9.00, ◑ 9.94, ● 11.00.
Concentration of Ach $[D]_0$: 5 mmol dm^{-3}.

Experimental

Materials. Acetylcholine chloride (Ach) from Nakarai Chemicals Co. was of guaranteed reagent grade and was used without further purification. Sodium dodecyl sulfate (SDS) supplied by Nihon Emulsion Co. was purified as described previously.[9-12] Heptaethylene glycol dodecyl ether (HED) from Nikkol Chemicals was of guaranteed reagent grade and was used without further purification. SDS-HED mixed micelles were prepared as described previously.[11]

Method of Measurement. The disappearance rate of Ach was followed at a constant pH and 25 °C by determining the concentration of Ach by the method described by Hestrin.[13] This method is the same as that employed in our previous study[10] and that used by Nogami et al.[8]

Procedures. Ach was dissolved in 100 ml of aqueous surfactant solution, and the pH was adjusted by adding aqueous sodium hydroxide solution. The test solution was connected with a pH-stat equipped with a 1 ml glass syringe as described previously[12] to keep the pH at a constant value during the reaction period, because acetic acid is produced by the hydrolysis of Ach.[14,15] The test solution was collected in 0.1 ml portions at suitable intervals, and the concentration of Ach was determined spectrophotometrically.

Results

Effect of pH on the Hydrolysis of Ach. The pH dependence of the hydrolysis of Ach in the absence of surfactant was examined. The percentage of Ach hydrolyzed is plotted against reaction time in Fig. 1(a).

The apparent rate constant for the hydrolysis, k_{app},

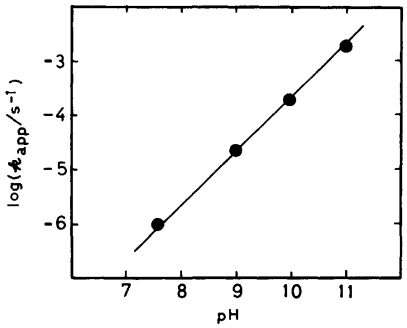

Fig. 2. Relation between pH and apparent rate constant for hydrolysis of Ach in the absence of surfactant.

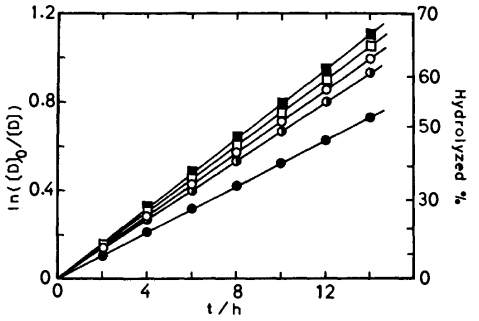

Fig. 3. Hydrolysis behavior of Ach in the presence of surfactants.
Hydrolyzed % vs. time, and ln([D]$_0$/[D]) vs. time.
Surfactants and concentrations: HED □: 2, ■: 20 mol dm^{-3} SDS ○: 2, ◑: 10, ●: 20 mmol dm^{-3}. pH: 9.0. [D]$_0$: 5 mmol dm^{-3}.

is defined by

$$\ln \frac{[D]_0}{[D]} = k_{app} \cdot t, \quad (1)$$

where [D]$_0$ is the initial concentration of Ach and [D] is the concentration of Ach at time t. Plots of ln([D]$_0$/[D]) vs. t are shown in Fig. 1(b), indicating a good proportionality. The relation between pH and the rate constant obtained from the slope of Fig. 1(b) is shown in Fig. 2.

As can be seen in Fig. 2, the plot of log k_{app} vs. pH is linear with a slope of +1, which indicates that the hydrolysis reaction is of apparent first order in hydroxide ion concentration and can be expressed by

$$k_{app} = k_{2,app}[OH^-], \quad (2)$$

where $k_{2,app}$ is the rate constant of second order reaction.

The value of k_{app} at pH 9 and 25 °C, 2×10^{-5} s^{-1}, is well consistent with the value, 1.9×10^{-5} s^{-1}, obtained by Showen et al.,[4] which is in support of the validity of the results obtained here.

Effect of Surfactant on the Hydrolysis of Ach. Effect of surfactants on the hydrolysis of Ach were examined at pH 9.0. It has been found that the surfactants used here are relatively stable at pH 9.0,[12,16-21] so that the decomposition of surfactants can be ignored.

In order to determine the value of k_{app}, values of ln([D]$_0$/[D]) are plotted against t according to Eq. 1 in Fig. 3 for several examples in the presence of surfactants. In Fig. 3, the percentage of Ach hydrolyzed also is given at the right-side ordinate. In all cases, good proportionality is observed. The hydrolysis of Ach in the presence of surfactants can, therefore, be expressed by the equation of apparent first order in hydroxide ion concentration.

Values of k_{app} obtained from Fig. 3 are shown in Fig. 4 against the total concentration of surfactants, C_t. In the presence of nonionic surfactants HED, k_{app} increases slightly above the cmc (0.066 mmol dm^{-3}).[11] In the presence of SDS, the dependence of k_{app} on surfactant concentration changes in three regions of

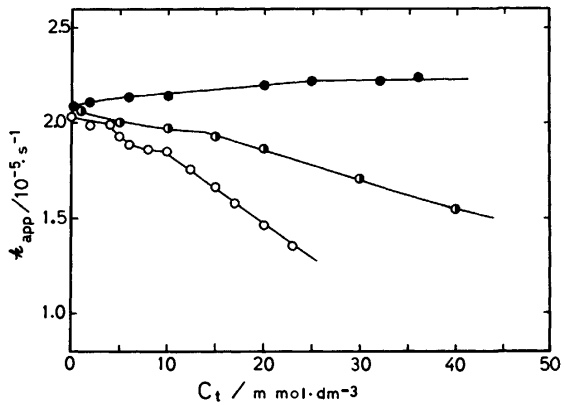

Fig. 4. Effect of surfactant on apparent rate constant for hydrolysis of Ach, k_{app}.
Surfactants: ●: HED alone, ○: SDS alone. ◑: HED-SDS mixed system (X_{SDS}=0.4). pH: 9.0. [D]$_0$: 5 mmol dm^{-3}.

surfactant concentration. In the presence of HED-SDS mixed micelle (X_{SDS}=0.4), the change in k_{app} is similar to that in the presence of SDS alone, but the first region cannot be found because the value of cmc is as low as 0.1 mmol dm^{-3} for the HED-SDS mixed system (X_{SDS}=0.4) in the presence of 5 mmol dm^{-3} Ach.

The effect on k_{app} of the composition of HED-SDS mixed system at the total concentration of 20 mmol dm^{-3} is shown by symbols ◑ in Fig. 5(a). The value of k_{app} decreases with the mole fraction of SDS, X_{SDS}.

Effect of Concentrations of Ach and SDS on the Hydrolysis of Ach. To investigate the effect of SDS on the hydrolysis of Ach in a little more detail, experiments were carried out with Ach solutions of 3 and 10 mmol dm^{-3} as well as 5 mmol dm^{-3}, plots of k_{app} against the concentration of SDS being shown in Fig. 6. The first break points correspond to the cmc of SDS in the presence of Ach of each concentration: 4.9, 4.0, and 2.5 mmol dm^{-3} for Ach of 3, 5, and 10 mmol dm^{-3}, respectively.[9] The k_{app} varies with the SDS concentration differently in three regions: k_{app} is approximately constant below the cmc (first region);

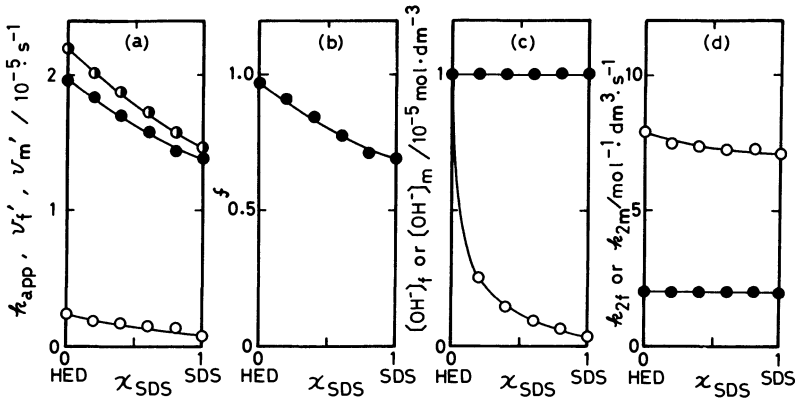

Fig. 5. Effect of HED-SDS mixed system on hydrolysis rate (a), Distribution ratio of Ach in the aqueous phase (b),[10] Concentration of OH^- (c) and Second order rate constant (d).
(a): ◑ k_{app}, ● v'_f, ○ v'_m. (b): $f=[D_f]/[D]$, $[D]=[D_f]+[D_m]$. (c): ● $[OH^-]_f$, ○ $[OH^-]_m$. (d): ● k_{2f}, ○ k_{2m}.
Total concentration of surfactants C_t: 20 mmol dm^{-3}. pH: 9.0. $[D]_0$: 5 mmol dm^{-3}.

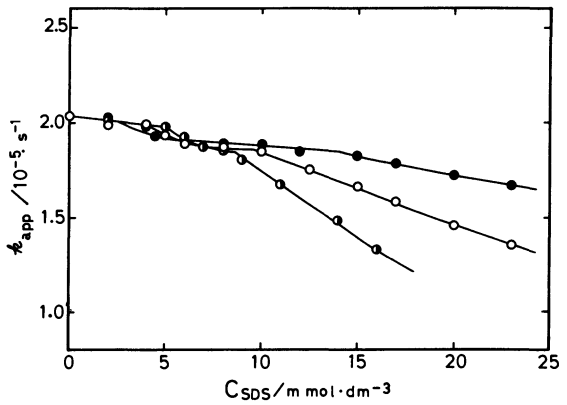

Fig. 6. Effect of SDS on k_{app} with varying concentration of Ach.
$[D]_0$: ◑ 3, ○ 5, ● 10 mmol dm^{-3}. pH: 9.0.

k_{app} decreases slowly above the cmc (second region); k_{app} decreases faster than in the second region (third region). The higher the concentration of Ach is, the longer the second region is and the slower the decrease in k_{app} in the third region is.

The decrease in k_{app} in the presence of SDS at concentrations above the cmc is considered to be due to the fact that the percentage of Ach included in the micellar phases increases with increasing concentration of the micelle[10] and that the approach of OH^- to Ach in the micellar phase is suppressed by the electrostatic repulsion of negatively charged micelle.

Discussion

Derivation of Rate Constants for the Hydrolysis of Ach in the Bulk and Micellar Phases. Ach is distributed between the micellar and bulk phases at surfactant concentrations above the cmc. The rate of the hydrolysis of Ach is, therefore, considered to be a sum of two terms:

$$-\frac{d[D]}{dt} = k_{app}[D] = v = v_f + v_m, \quad (3)$$

where v_f and v_m are the rates of hydrolysis in the aqueous and micellar phases, respectively.

Next, k_{app} can be represented as follows[22] by using the value of distribution ratio of Ach in the aqueous phase, f:[10]

$$k_{app} = k_f f + k_m(1-f), \quad (4)$$

where k_f and k_m are the first order rate constants of hydrolysis in the aqueous and micellar phases, respectively, and the value of $(1-f)$ means the distribution ratio of Ach in the micellar phase. Equation 4 is expressed from Eq. 2 as

$$k_{2,app}[OH^-] = k_{2,f} f[OH^-]_f + k_{2,m}(1-f)[OH^-]_m \quad (5)$$

where $k_{2,f}$ and $k_{2,m}$ are the second order rate constants of hydrolysis in the aqueous and micellar phases, respectively. When the total concentration of added surfactants, C_t, is lower than the cmc, namely C_t<cmc, Eq. 5 simply becomes

$$k_{2,app} = k_{2,f} \text{ (for } C_t < \text{cmc)}, \quad (6)$$

since f=1 and $[OH^-]_m$=0.

The rates of hydrolysis in the aqueous and micellar phases, v'_f and v'_m, are defined from Eq. 5 as

$$v'_f = k_{2,f} f[OH^-]_f, \quad (7)$$

$$v'_m = k_{2,m}(1-f)[OH^-]_m, \quad (8)$$

where v'_f and v'_m are related to v or k_{app} by

$$v'_f + v'_m = v' = \frac{v}{[D]} = k_{app}, \quad (9)$$

and $[OH^-]_m$ is expressed as

$$[OH^-]_m = [OH^-]_f \exp\left(-\frac{zF_A\psi}{RT}\right), \quad (10)$$

where z is the valency of OH^-, F_A is the Faraday constant, ψ is the surface potential at the micelle surface, T is the absolute temperature, and R is the gas constant. Therefore, $k_{2,m}$ is calculated from Eq. 11 as

$$k_{2,m} = \frac{(k_{2,app} - k_{2,f}f)}{(1-f)} \exp\left(\frac{zF_A\psi}{RT}\right). \quad (11)$$

With the values $z=-1$, $F_A=9.648\times10^4$ ($C\,mol^{-1}$), $R=8.314$ ($J\,mol^{-1}\,K^{-1}$), and $T=298.15$ K at 25 °C, Eq. 11 is rewritten into

$$k_{2,m} = \frac{(k_{2,app} - k_{2,f}f)}{(1-f)} \exp\left(0.03892\,\frac{\psi}{mV}\right). \quad (12)$$

Effect of HED–SDS Mixed Micelles on the Hydrolysis of Ach. The apparent rate of the hydrolysis of Ach in the presence of HED-SDS mixed micelles decreases with the mole fraction of SDS, as shown by symbols ◑ in Fig. 5(a). The values of $k_{2,f}$ are 2.02 $mol^{-1}\,dm^3\,s^{-1}$ for the HED-SDS mixed system (X_{SDS}= 0—0.8) and 1.99 $mol^{-1}\,dm^3\,s^{-1}$ for the single SDS system, as observed at the cmc (the first break point in Fig. 4) or estimated by Eqs. 2 and 6. Next, the values of $k_{2,m}$ in the presence of HED-SDS are calculated from Eq. 12 by using the values of f and ψ obtained in our previous study.[10] (Here, the values of $k_{2,m}$ and ψ are practically unknown quantities. In order to determine the value of $k_{2,m}$, we use the value of ψ[10] obtained for the HED-SDS mixed micelle system under conditions that C_t=20 mmol dm^{-3} and $[D]_0$=5 mmol dm^{-3}). The values of $k_{2,m}$ thus obtained are shown in Fig. 5(d), together with $k_{2,f}$, and the hydrolysis rates of Ach in the aqueous and micellar phases, v_f' and v_m' are calculated from Eqs. 7 and 8 and shown in Fig. 5(a), together with the data of k_{app}. In addition, the values of f[10] and $[OH^-]_m$ obtained from Eq. 10 are shown in Figs. 5(b) and (c), respectively.

The decrease in v_m' with the mole fraction of SDS (Fig. 5(a)) is due to the decrease in $[OH^-]_m$ as shown in Fig. 5(c). The electrostatic effect is well-known with micellar catalyses of various surfactants.[16,23-25]

Effect of Concentrations of Ach and SDS on the Hydrolysis of Ach. The second break point indicated in Fig. 6 may be considered to be the limit point where the number of negative charge supplied from SDS micelle is nearly equal to the number of positive charge supplied from Ach in the micelle (above the second break point, the number of negative charge> the number of positive charge). If the apparent distribution coefficient K' ($K'=([D_m]/[S])/([D_f])$[10]) of Ach between the micellar and aqueous phases is independent of the concentration of surfactant, the number of negative charge {(negative charge)−(positive charge)} increases with increasing concentration of SDS. Values of K' obtained for sufficient concentrations of micelle were found to be independent of the concentration of surfactant at a given concentration of Ach.[10] However, values of K' for insufficient concentrations of micelle were not exactly constant. This leads to the result that the number of negative charge is nearly equal to the number of positive charge below the second break point. The limit point was calculated on the basis of the result[10] on the distribution of Ach between the micellar and aqueous phases obtained by ultrafiltration. The dissociation degree, α, of micellar SDS was assumed to be 0.11 for the calculation. This value of α is in agreement with the previously obtained value of 0.102.[11] The limit points were found to be the points where C_{SDS} are 8.6, 9.6, and 14.0 mmol dm^{-3} in the presence of Ach of 3, 5, and 10 mmol dm^{-3}, respectively.

The third region is considered to be the region where the number of negative charge supplied by SDS micelle exceeds the number of positive charge supplied by Ach existing in the micelle. Therefore, the larger decrease in k_{app} in the third region is considered to be due to the larger decrease in v_m'. The decrease in v_m' in the third region can be explained in terms of the surface potential of the SDS micelle, ψ. For the hydrolysis rate of Ach in the third region shown in Fig. 6, the value of v_f' is calculated from Eq. 7 by using the values of f[10] and $k_{2,f}$ observed at the cmc of SDS in the presence of Ach of various concentrations shown in Fig. 6. The values of v_m' for the hydrolysis of Ach in the third region shown in Fig. 6 are calculated from Eq. 9 by subtracting the value of v_f' from the value of k_{app} ($=v_f'+v_m'$) which is obtained experimentally. The decrease in v_m' is considered to be due to the decrease in $[OH^-]_m$ which depends on the surface potential of the micelle, although $k_{2,m}$ of Eq. 8 is the same ($k_{2,m}$=7.023 $mol^{-1}\,dm^3\,s^{-1}$ for SDS micelle, which is shown in Fig. 5(d)). The value of $[OH^-]_m$ is, therefore, calculated from Eq. 8 by using the values of $k_{2,m}$ and f. The values of v_f', v_m', and $[OH^-]_m$ thus obtained are shown in Figs. 7(a) and (b). Furthermore, the values of surface potential of the SDS micelle, ψ, which have not been determined except the values of ψ[10] obtained for the HED-SDS mixed micelle system under conditions that C_t=20 mmol dm^{-3} and [D]=5 mmol dm^{-3}, are calculated by

$$\frac{\psi}{mV} = -59.16 \log\frac{[OH^-]_f}{[OH^-]_m}, \quad (13)$$

where the values of $[OH^-]_m$ can be calculated from Eq. 8 by using the values of v_m', $k_{2,m}$, and f which are obtained already. The values of ψ thus obtained are shown in Fig. 8.

The surface potential of the SDS micelle becomes more negative with increasing concentration of SDS.

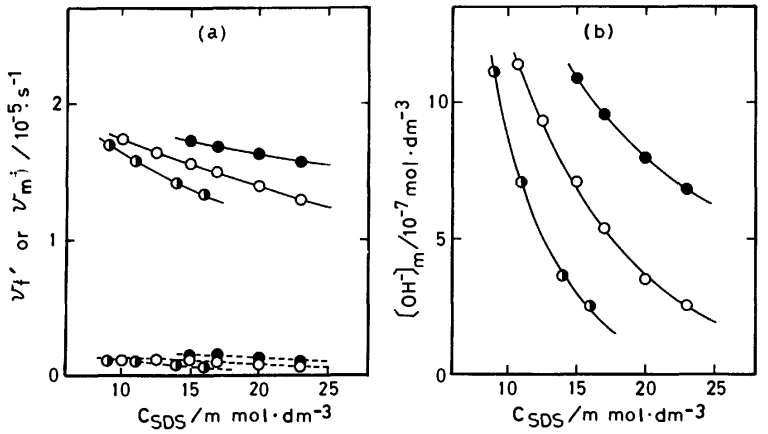

Fig. 7. Relation between (a) Hydrolysis rate and C_{SDS}, and (b) $[OH^-]_m$ and C_{SDS}.
(a) Solid line: $v't$, dotted line: v'_m. $[D]_0$: ◑ 3, ○ 5, ● 10 mmol dm^{-3}. These were calculated for the third region of relation between k_{app} and C_{SDS} shown in Fig. 6.

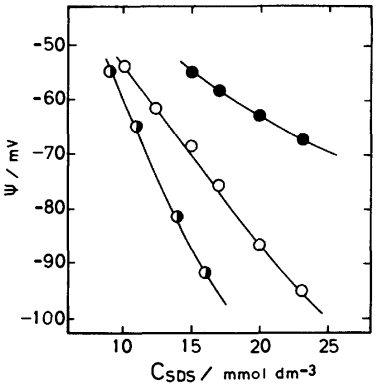

Fig. 8. Relation between surface potential of SDS micelle, ψ, and C_{SDS} in the presence of various concentrations of Ach $[D]_0$: ◑ 3, ○ 5, ● 10 mmol dm^{-3}. These were calculated for the third region in Fig. 6.

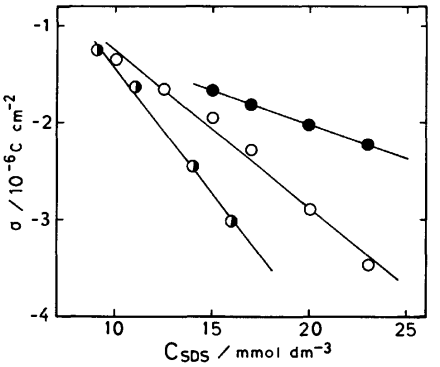

Fig. 9. Relation between surface charge of SDS micelle, σ, and C_{SDS} in the presence of various concentrations of Ach.
$[D]_0$: ◑ 3, ○ 5, ● 10 mmol dm^{-3}. These were calculated from the values of ψ shown in Fig. 8 by the Gouy-Chapman equation.

This is considered to be due to the decrease in the adsorbed amount of Ach per SDS micelle.

The change in the surface potential according to the increase in SDS concentration is largest when the concentration of Ach is as low as 3 mmol dm^{-3}.

According to the Gouy-Chapman theory, the relation between the surface potential, ψ, and the surface charge density, σ, is expressed as

$$\frac{\sigma}{C_{cm^{-2}}} = -5.8673 \times 10^{-6} \sqrt{\sum_i \left[\left(\frac{C_i}{\text{mol dm}^{-3}}\right)\left\{\exp\left(-\frac{z_i F_A \psi}{RT}\right)-1\right\}\right]}, \quad (14)$$

where 78.54[26] is used as the value of relative dielectric constant of water at 25 °C, C_i is the concentration of ion (Ach^+, Cl^-, Na^+, DS^-, OH^-, H^+), and z_i is the valency of ion. The value of σ obtained from ψ by using Eq. 14 is shown in Fig. 9. The value of σ becomes more negative with increasing concentration of SDS.

The relation between the surface charge density, $|\sigma|$, and the molar number of SDS per unit area, n, which contributes to the supply of the negative charge at the third region shown in Fig. 6, is expressed as

$$\frac{n}{\text{mol cm}^{-2}} = \frac{|\sigma|}{F_A}. \quad (15)$$

The relation between ($|\sigma|/F_A$) and (ΔC_{SDS}–[D_m]) is shown in Fig. 10, where ΔC_{SDS} is the concentration of micellar dissociated SDS (that is, $\Delta C_{SDS}=(C_{SDS}-\text{cmc})\times\alpha$). In Fig. 10, the zero value of (ΔC_{SDS}–[D_m]) corresponds to the second break point in Fig. 6 (the value of ψ is −52.5 mV). The relation between ($|\sigma|/F_A$) and (ΔC_{SDS}–[D_m]) is found to be embodied by a straight line independent of the concentration of Ach. Therefore, regarding the third region for the k_{app}–C_{SDS} profile shown in Fig. 6, it is evident that σ is determined by the subtraction of concentrations of micellar dissociated SDS and Ach existing in the micellar phase, which is caused by the increase in the molar

These were calculated from the values of σ shown in Fig. 9 and the results of distribution of Ach[10] for the third region in Fig. 6.

number of SDS per unit area.

Conclusion

The apparent rate of the base-catalyzed hydrolysis of Ach is decreased by the presence of SDS micelle or HED-SDS mixed micelles because of the decrease in both the rates in the aqueous and micellar phases. It has been concluded that this result can be explained in terms of two parameters, the distribution of Ach between the aqueous and micellar phases and the electrostatic effect at the micelle surface: (1) The decrease in the rate in the aqueous phase is due to the decrease in Ach in the aqueous phase, and (2) the decrease in the rate in the micellar phase is due to the approach of OH^- to Ach in the micellar phase being suppressed by the electrostatic repulsion of negatively charged micelle, which is in conformity with the Gouy-Chapman theory.

Vapor-Phase Isomerization of *o*-Chlorotoluene over H-Mordenite Treated with CF_3Cl

Susumu OKAZAKI* and Hirofumi JOUHOUJI
Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Nakanarusawa, Hitachi 316
(Received October 29, 1985)

Vapor phase-isomerization of *o*-chlorotoluene was somewhat promoted by H-mordenite (HM). The catalytic activity was appreciably enhanced by treatment with CF_3Cl and other chlorofluorocarbons such as CF_2ClCF_2Cl and CF_2ClCF_3. In particular, maintenance of the HM catalyst activity was remarkably improved by CF_3Cl treatment. The CF_3Cl-treated HM also promoted vapor phase isomerizations of *p*- and *m*-chlorotoluene. The catalytic activity was relatively long-lasting for the isomerization of *p*-chlorotoluene. Enlargement of the HM pore size on treatment with CF_3Cl and other chlorofluorocarbons may contribute to increasing the catalytic activity and then maintaing it.

Chlorotoluene is an important intermediate for syntheses of agricultural chemicals, dyes, and pharmaceuticals. It is prepared, in general, by chlorination of toluene, in which ortho isomer is preferably formed together with some para isomer owing to the directing effect of the methyl group. Accordingly, when *m*-chlorotoluene (MCT) is required in large amounts, it is desirable to isomerize the *o*-chlorotoluene (OCT) to MCT. In addition, the isomerization of OCT to *p*-chlorotoluene (PCT) is important because the para isomer is especially useful as a raw material for agricultural chemicals.

Hitherto isomerizations of halotoluenes have been known to occur only in the presence of a strong acid catalyst such as HF-BF_3[1] and $AlCl_3$.[2] However, these catalysts are unstable, and they are very difficult to recover. Furthermore, they are remarkably corrosive to reaction vessels.

Recently, acidic zeolites such as a proton-exchanged mordenite (HM) and H-ZSM-5 have been reported to be useful as a catalyst for the isomerization of chlorotoluene.[3] However, the isomerization, as catalyzed by the acidic zeolite, is carried out only in the liquid phase at a high temperature in a closed system.

From an industrial viewpoint, it is desirable for isomerization to proceed in the gas phase by using a continuous flow system under an atomospheric pressure. Hence, a search was carried out to seek a suitable catalyst for the gas phase isomerization of OCT. For comparison with the OCT isomerization, the vapor phase isomerizations of MCT and PCT were attempted in the presence of the treated HM. The results obtained for these isomerizations of chlorotoluenes are compared with those of the xylene isomerization, which is performed over the same catalyst, i.e., the CF_3Cl treated HM.[4]

Experimental

Materials. The HM used in this study was prepared by the heat-treatment of the NH_4 mordenite at 500 °C for 3 h. The NH_4 mordenite was prepared from a commercial Na mordenite (Toyo Soda Co., TSZ, SiO_2/Al_2O_3 mol ratio=9.75, 15.4, 19.0 or 22.7) by ion exchange with 1.0 M NH_4Cl (1 M=1 mol dm^{-3}) solution followed by the necessary washing. The proton-exchanged Y type zeolite (HY) was supplied by Toyo Soda Co. (TSZ 352). Before use as a catalyst or treatment with CF_3Cl, the HY was heat-treated in air at 500 °C for 3 h, similar to HM and other metal oxides. The treatments with CF_3Cl and other halocarbons were carried out by the previously reported methods.[4-6] Unless otherwise noted, the treatments were run at 450 °C for 15 min.

The Al_2O_3 catalyst was obtained by hydrolysis of aluminum isopropoxide (Wako Chemical Co.) followed by heat-treatment in air at 600 °C for 3h. The SiO_2–Al_2O_3 (Nikki Chemical Co., N-631L, Si/Al (atomic ratio)=85/15) was used to evaluate the catalytic activity of typical solid acid.

Reaction Procedure. The isomerization was carried out under ordinary pressure using a continuous flow reactor. The products were collected every 30 min and analyzed by gas chromatography using a column (3 mm×6.3 m) packed with 4,4′-azoxydianisole supported on Uniport HP (60—80 mesh) at 100 °C (oven temperature). Unless otherwise noted, the value representing the catalyic activity and activity maintenance was the one obtained for the first 30 min period.

Determination of Surface Properties. In order to know whether the Brönsted or the Lewis type acid site should promote the isomerization, the effect of 2,6-lutidine pretreatment[7] on the catalytic activity for the isomerization was examined together with that of pyridine pretreatment. In addition, CO_2 addition was examined for its effect on the basic sites of HM.

To evaluate the acid amount and acid strength, temperature-programmed desorption (TPD) of NH_3 (5 ml) was carried out on a sample (50 mg, 32—42 mesh) which was heat-treated in air at 500 °C for 3 h. Immediately before the TPD, the samples were heat-treated in the test apparatus at 500 °C for 1 h in an atmosphere of He. The temperature was raised to 500 °C at a rate of 40 °C min^{-1}.

Structure and Surface Composition. The structure of HM before and after treatment with CF_3Cl was determined from the powder-diffraction patterns obtained with a Rigaku Geigerflex X-ray diffractometer using filtered Cu $K\alpha$ radiation. The compositions in the surface layer were dertermined by XPS using a Shimadzu ESCA-750 apparatus. The spectra were measured with Mg $K\alpha$ radiation. The base pressure of the spectrometer was usually below 10^{-7} Torr (1 Torr=133,322 Pa) during the experiments. The compositions were calculated from the areas of the spectral peaks (i.e., the maximum in the counting rate) on the basis of the photoionization cross section at 1254 eV in units of the C ls cross section of

22200 barns.[8]

Results and Discussion

Comparison of Catalytic Activities of Various Solid Acids. Table 1 shows the results of the isomerization of OCT to other chlorotoluenes over various solid acids. Among these solid acids, HM exhibited the highest catalytic activity. HY also showed some catalytic activity, though the typical solid Lewis acid Al_2O_3 and the strong solid acid, $SiO_2 \cdot Al_2O_3$ were catalytically inactive. These facts are in contrast to observations that the isomerization of *o*- and *p*-xylenes are readily promoted by Al_2O_3–HX (X=halogen)[9] or SiO_2–Al_2O_3.[10]

After treatment with CF_3Cl at 450°C, HM became much more active, and SiO_2–Al_2O_3 became somewhat active. On the other hand, Al_2O_3 was still inactive as a catalyst, and HY completely lost its catalytic activity. It has been observed that Al_2O_3 becomes strongly acidic and catalytically active for paraffin isomerization[6] and CH_3OH conversion to olefins,[5] which are promoted by only extremely strong solid acids. So, the evidence that the CF_3Cl-treated Al_2O_3 was unable to promote the isomerization suggests that strong acidity is not the only essential factor for catalytic activity. Some other factors, for example the zeolytic structure, are needed for catalytic activity in the chlorotoluene isomerization. The loss of the catalytic activity of HY after the CF_3Cl-treatment is then explicible by the collapse of the zeolytic structure during the treatment with CF_3Cl, which was observed by XRD.

Effects of Treatment with Various Fluorochlorocarbons or HF Acid. Table 2 summarizes the results relating to the effect of treatment using various simple fluoro- or fluorochlorocarbons, CCl_4 or HF acid.

As is shown in this table, CF_3Cl was the most effective treatment agent, while other chloropolyfluorocarbons such as CF_2ClCF_3, CF_2ClCF_2Cl, and CF_2Cl_2 also showed some effect. Abrupt increases in temperature were observed during the treatment of HM with these agents. Approximate values of the increase in temperature for the different agents were as follows: $CFCl_3$, 60°C; CF_2ClCF_2Cl, 50—60°C; CF_2Cl_2, 40°C; CF_3Cl, 30—40°C; CF_3CF_2Cl, 20°C; CF_4, CF_3CF_3, 0°C. For the CCl_4-treatment, the value could not be measured since the increase was too rapid and too sudden.

The increases in temperature are assignable to the surface reaction of HM with the treatment agent. Infact, the compositions were remarkably changed by the treatment. For example, as Table 3 shows, F and Cl components were incorporated in the surface layer by the treatment with CF_3Cl, and were retained after use as a catalyst. For the sample treated with fluoropolychlorocarbons or polychlorocarbon such as $CFCl_3$ and CCl_4, an extensive degradation of mordenite structure was confirmed by XRD determination. This probably resulted from the violent reaction between the HM surface and these polychlorocarbons which have a relatively weak C–Cl bond.[11] On the other hand, perfluorocarbons such as CF_4 and CF_3CF_3 were unable to react with the HM surface because of the very strong C–F bond in their molecules.[12] Thus the high bond strength in CF_4 and CF_3CF_3 may account for the inertness of the perfluorocarbons as a treatment agent for the HM surface.

Finally, chloropolyfluorocarbons such as CF_3Cl, CF_2ClCF_2Cl, and CF_2ClCF_3 may gently and moderate-

Table 2. Catalytic Activities of H-Mordenite Treated with Various Halocarbons or HF Acid

a) SiO_2/Al_2O_3 mol ratio=19.0. b) The treatment was carried out at 450°C for 8 min.

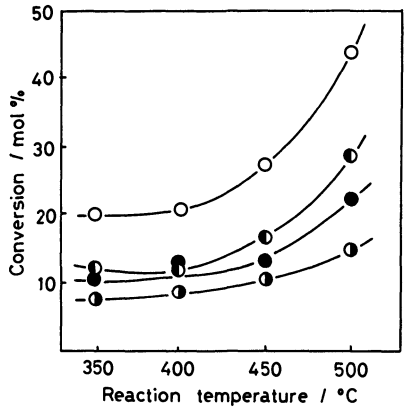

Fig. 1. Effect of reaction temperature on conversion of OCT. HM catalyst having SiO_2/Al_2O_3 mol ratio of 19.0 was used as a catalyst after treatment with CF_3Cl; the treatment was carried out at 450 °C for 8 min. W/F=64.9 gh/mol. Symbols used in this figure are as following.
○: Total conversion to MCT and PCT, ◐: conversion to MCT, ◑: conversion to PCT, ●: conversion to CB.

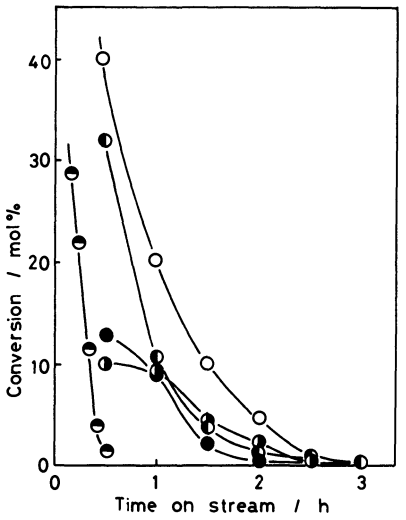

Fig. 2. Effect of process time on conversion of OCT. HM catalyst (SiO_2/Al_2O_3 mol ratio=19.0) was used after CF_3Cl-treatment. The CF_3Cl-treatment and the catalytic reactions were carried out under the same conditions as those described above (Fig. 1). Symbols are as following.
○: Total conversion to MCT and PCT, ◒: total conversion to MCT and PCT in the presence of untreated HM, ◐: conversion to MCT, ◑: conversion to PCT, ●: conversion to CB.

ly react with the HM surface through their C-Cl bonds of the right strength. That is, since these chloropolyfluorocarbons have a C-Cl bond which is fairly strong compared to those of chlorocarbons (such as CCl_4) and fluoropolychlorocarbons (such as $CFCl_3$), they are not so reactive as to destroy the mordenite structure. Similarly the C-F bond in the CF_2X group is fairly strong compared to that in the CFXY group (X and Y are atoms other than F),[12] although it is not as excessively strong as that in perfluorocarbon. Also this moderately high strength in the C-F bond should contribute to prevention of the violent reaction of the treatment agent with mordenite. Thus, CF_3Cl and chlofluoroethanes, containing not CFXY, but the CF_2X group may be the most suitable treatment agent for HM.

Although HF acid is widely used as the treatment agent for Al_2O_3, SiO_2-Al_2O_3 and various other metal oxides,[13] it was unsuitable for HM treatment. A significant formation of crystalline aluminum fluoride was observed by XRD measurement for the HF acid-treated HM, thus partial degradation of mordenite structure or deposition of the crystalline fluoride in the pores or channels of the mordenite may be the reason for the pronounced decrease in the catalytic activity.

Effect of Reaction Temperature. As Fig. 1 shows, the conversions of OCT to MCT and PCT considerably increased at temperatures higher than 400 °C. However, dechlorination or CB formation became important at high temperatures like 500 °C. So, the selectivity of the isomerization was maximal around 450 °C. Although the data are not shown here, other products such as benzene and polychloro aromatic compounds were formed in small amounts at temperature higher than 500 °C.

Changes of Catalytic Activity and Selectivity with Time on Stream. As is shown by the total conversion of OCT to other chlorotoluene in Fig. 2, the catalytic activity of HM abruptly decreased with reaction time. On treatment CF_3Cl at 450 °C, the catalytic activity was significantly enhanced, and a decrease in activity with process time became less prominent.

As Fig. 2 shows, at the beginning of OCT isomerization, MCT was preferentially formed. Then the amount of MCT product remarkably decreased with time, and finally became less than that of PCT.

It is probable that the pore size was decreased by the deposition of decomposed materials or carbonized products. So, transfer of the product from active sites by diffusion through the pore become more difficult for MCT than for PCT, because the former molecules have a larger cross-sectional area.

Isomerizations of MCT and PCT. As Figs. 3 and 4 show, the isomerizations of MCT and PCT were promoted by the CF_3Cl-treated HM as well as that of OCT. Furthermore, for these isomerizations of MCT and PCT, the activity maintenance of the treated HM catalyst was better than that for the OCT isomerization. Especially for the isomerization of MCT, the amount of PCT formation was still high even 3 h after the reaction was begun. This is explained as follows. Namely, the para isomer, which has the smallest cross-sectional area among the chlorotoluenes, should be most readily and easily transferred from the pores as soon as it is produced there. Thus, clogging of the pore is fairly slow in the isomerization of MCT when PCT is the main reaction product.

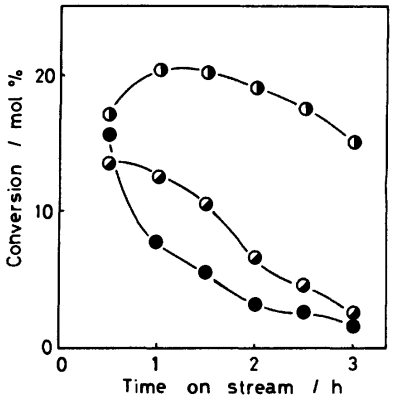

Fig. 3. Effect of process time on conversion of MCT. The HM catalyst (SiO_2/Al_2O_3=19.0) was used also in this reaction. The conditions employed in this reaction were the same as those employed in the OCT isomerization (shown in Figs, 1 and 2). The symbols used here were as following.
◑: Conversion to PCT, ◕: conversion to OCT, ●: conversion to CB.

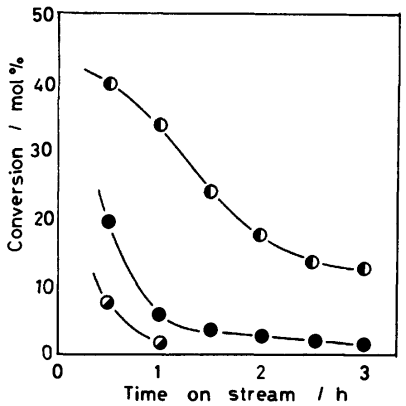

Fig. 4. Effect of process time on conversion of PCT. SiO_2/Al_2O_3 ratio of the HM catalyst=19.0. The conditions of the CF_3Cl treatment and the reaction were the same as those employed for the isomerization of OCT (Figs, 1 and 2) or MCT (Fig. 3). The symbols used in this figure are as following.
◐: Conversion to MCT, ◕: conversion to OCT, ●: conversion to CB.

Appreciably high conversion was obtained at the initial stage of the PCT isomerization process (Fig. 4). This result may be due to the ease with which the PCT molecule is able to reach the active sites in the mordenite pore as compared to other chlorotoluene molecules. However, the conversion decreased somewhat rapidly with reaction time, since the main product, MCT, was not readily removed from the active sites, in accordance with reduction of pore size which occurs with passing reaction time.

Poisoning of Active Sites. The results of poisoning with amines are shown in Table 4 together with those of CO_2 addition used as a reference. The active sites were poisoned with 2,6-lutidine as well as pyridine. It is already known that the 2,6-lutidine molecule is unable to react with Lewis acid sites because the electron-donating N atom in the molecule is sterically hindered by the two adjacent CH_3 groups.[7] Hence, the fact that the active sites were poisoned by the 2,6-lutidine suggests that the active sites on the treated HM are acid sites of not the Lewis, but the Brönsted type.

Table 4. Effect of Poisoning on Isomerization Activity of HM[a)]

	Product distribution/mol%		
	MCT	PCT	Chlorobenzene
Before treatment	31.6	10.8	13.0
Pyridine	4.4	6.0	2.4
2,6-Lutidine	8.1	6.0	9.1
Carbon dioxide	15.3	10.5	14.9
Ref.[b)]	16.6	12.9	13.6

a) SiO_2/Al_2O_3 mol ratio=19.0. b) The reference run was carried out by flowing 80 ml N_2, instead of CO_2, to examine the effect of CO_2 addition.

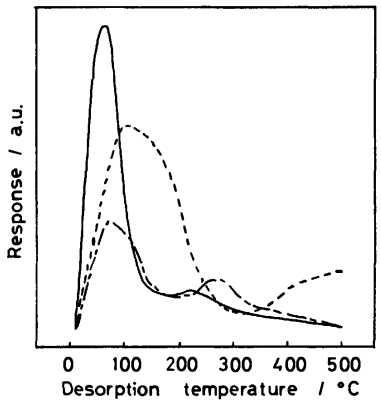

Fig. 5. TPD curves for H-mordenite.
---: Before treatment, ——: after treatment, ——: after use as a catalyst at 450°C for 3 h. The CF_3Cl treatment was carried out at 450°C for 8 min.

On the other hand, CO_2 addition gave almost the same results as that of the dilution with an inert gas, N_2. Thus, it is possible, that the basic sites, if they were present on the CF_3Cl-treated HM, had hardly any effect on the isomerization.

TPD Regarding Acid Strength Distribution. Figure 5 shows the TPD curves of HM before and after treatment with CF_3Cl. The TPD curve of the treated HM after use as a catalyst is also exhibited there.

As is represented by the dotted line, a fair amount of NH_3 was adsorbed by the untreated HM even at a temperature as high as 500°C. For HM treated with CF_3Cl, the adsorption of NH_3 at such a high temperature was no longer observed. Thus, two peaks around 80 and 280°C became observable in the TPD curve as is represented by the broken line. These facts suggested that excessibly strong acid sites on the untreated HM disappeared and moderately strong acid sites, relating to the peak around 280°C appeared during CF_3Cl treatment. For the treated HM which became catalytically less active after use as a catalyst for 3 h,

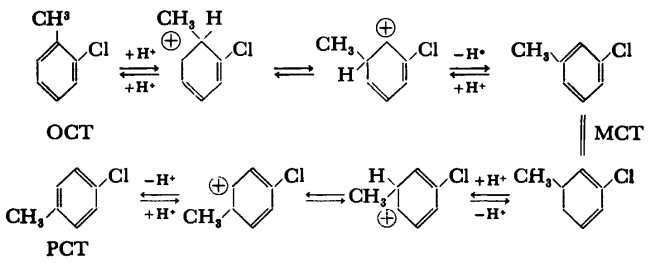
the peak at higher temperature almost completely disappeared, and a weak peak became observable around 220°C. Thus, the moderately strong acid sites represented by the peak around 280°C, may be most suitable for isomerization promotion.

Demethylation. As Figs. 1—4 show, demethylation also occurred in the early stages of the isomerization. The demethylation was especially pronounced at temperatures higher than 450°C as was exhibited in Fig. 1. On the other hand, hardly any dechlorination occurred under reaction conditions employed in this study, especially at temperatures lower than 500°C, although the bond strength of $Cl-C_6H_5$ (88 kcal mol^{-1} [14] (1 cal= 4.184 J)) is less than that of $H_3C-C_6H_5$ (91 kcal mol^{-1} [14]). So, demethylation is considered to be promoted by acid sites in a manner similar to the isomerization of chlorotoluene. In fact, the demethylation was subject to suppression by poisoning with amines as was already shown in Table 4. However, the acid strength essential to the promotion of demethylation must be fairly high, since demethylation was promoted only in beginning of a run, when appreciably strong acidity can be maintained without poisoning by product formation.

Reaction Pathway. In view of the evidence collected so far, the isomerization of chlorotoluene is expected to proceed similar to the isomerization of xylene.[15] However, the isomerization of chlorotoluene reached levels of 20—40% only with great difficulty at temperatures as high as 450°C in the presence of the CF_3Cl treated HM, while a conversion level of higher than 50% was obtained at the lower temperature of 300°C for xylene isomerization promoted by the same catalyst. Such a difference between the reactivities of chlorotoluene and xylene is ascribable to the difference in the activating effects of the substituent on the benzene ring. That is, when a carbon sp^3 orbital is attached to sp^2 orbital of carbon, there is an electron donation in the direction of sp^2 carbon, because the sp^2-hybridized carbon atom is somewhat more electronegative. Thus, a CH_3 group attached to the benzene ring activates it. In particular, the C atom directly bound to the CH_3 group is easily attacked by protons.

On the other hand, the chlorine atom should deactivate the benzene ring because the inductive effect of chlorine (−I) wins out over the resonance effect (+R). Thus, the activity of chlorotoluene is not as high as that of xylene.

Nevertheless chlorotoluene is less active than toluene as mentioned above, the electron-enriched C atom bound to the CH_3 group in chlorotoluene molecule should be first attacked by the Brönsted acid sites as in the case of the xylene isomerization.[4] Then, isomerization of the chlorotoluene can proceed according to the following reaction pathway.



Since the C atom bound to Cl atom is expected to be positive in charge as described above, the C atom may not be attacked by the Brönsted acid on the HM catalyst. In fact, toluene which is produced by the dechlorination was not appreciably formed under the reaction conditions employed in this study.

Effect of CF_3Cl Treatment on Catalytic Activity of HM. In the isomerization of chlorotoluene, excessively strong acid sites are considered to be unsuitable because they do not readily release the product molecule, and thus they promote the decomposition or carbonization of the molecules in the mordenite pores. The treatment with CF_3Cl or some fluorochlorocarbons may be effective for modification of the too strong acidity of some active sites, possibly due to a slight change in the mordenite structure.

Besides the modification of the acid strength described above, the enlargement of the pore size of the HM seems to be another reason for enhancement of the catalytic activity and activity maintenance. It is well known that mordenite has only a one-dimentional channel.[16] Accordingly, resistance to molecular diffusion and clogging of the channel are serious problems in the reaction catalyzed by the mordenite. So, enlargement of the pores or channels through reaction of the CF_3Cl with the Si and Al components in the mordenite may contribute to the improvement of the catalytic activity and activity maintenance in this vapor phase isomerization of chlorotoluene. The enlargement of the pore by the treatment with CF_3Cl has already been seen in the increased amount of formation of the bulky molecule, 1,3,5-trimethylbenzene, in the isomerization and disproportionation of *m*-xylene.[4] Details of the pore enlargement are now being studied by adsorptions of gases of various cross-sectional areas.

The authors express their gratitude to K. I. Kasei Co., for their financial support to this study.

The Formal Potentials of Quinones$^{0/-}$ and Quinones$^{-/2-}$ in an Aqueous Solution

Kosaku SUGA* and Shigeru AOYAGUI
Department of Chemical Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152
(Received October 31, 1985)

Cyclic voltammograms of *p*-benzoquinone and its methyl derivatives are measured in a strongly alkaline aqueous solution. All of them have shown one reversible or quasi-reversible wave corresponding to the reduction of the quinones. Except for the 2,3,5,6-tetramethyl-*p*-benzoquinone (duroquinone), they have all also shown one or two additional small waves corresponding to the reduction of the OH^- adducts of the quinones. Their main waves can reasonably be explained by the calculated values of $E_1°$ and $E_2°$, which have been determined by the two-electron reduction potential and the several equilibrium constants of the quinones. The differences in the $E_1°$ and $E_2°$ values for these quiones are very small (0.007—0.046 V) in contrast to those in an aprotic solvent.

The quinone/hydroquinone (Q/QH_2) couple is known as a typical organic redox system in an aqueous solution.[1] In aprotic solvents, such as *N*,*N*-dimethylformamide (DMF) and acetonitrile (AN), the voltammograms for the reduction of *p*-benzoquinone and its methyl derivatives exhibit, respectively, two well-defined one-electron steps separated by ca. 0.6 V in the half-wave potential.[2] In an aqueous solution, however, they exhibit only one two-electron step each, the half-wave potential of which depends on the pH.[1] Such a situation as this is usually attributed to the fast protonation of the reduction products. If this is true, two one-electron waves should be observed in a highly alkaline solution, where protonation is negligible. However, this has never been realized, possibly because of the instability of these quinones in strong alkaline solutions.

This paper deals with the relation between the half-wave potentials of *p*-benzoquinone derivatives (Q) in a strongly alkaline aqueous solution and the formal potentials of $Q^{0/-}$ ($E_1°$) and $Q^{-/2-}$ ($E_2°$), which are calculated from the formal potential of Q/QH_2, the disproportionation constant of $2Q^- \rightleftarrows Q^{2-}+Q$, and the dissociation constants of QH_2 and QH^-. The $E_1°$ and $E_2°$ values may also easily be calculated from the corresponding formal potentials of protonated species, i.e., the formal potentials of Q/QH and QH/QH_2, which were calculated by Ilan et al.[3] However, their calculation makes use of the dissociation constant of QH, which is unnecessary for obtaining $E_1°$ or $E_2°$ values; this may introduce some additional errors into the resultant $E_1°$ and $E_2°$ values. Therefore, we have calculated the values of $E_1°$ and $E_2°$ directly from the original data.

Experimental

Commercial *p*-benzoquinone (BQ), 2-methyl-*p*-benzoquinone (MBQ), 2,5-dimethyl-*p*-benzoquinone (DMBQ), and 2,3,5,6-tetramethyl-*p*-benzoquinone (DQ) were purified by sublimation and recrystallization. The electrolysis cell used for cyclic voltammetry was of a three-electrode arrangement with a Mitsubishi Kasei Model 01 hanging-mercury-drop electrode (HMDE) as the working electrode and a saturated calomel electrode (SCE) as the reference electrode. Each test solution contained 0.5 mM (M=mol dm^{-3}) of a quinone, 0.1 M of Na_2SO_4, and 0.1 M of NaOH in water. Since the quinones used were unstable in a strongly alkaline solution, a 1 M NaOH solution was added to the test solution, which was deoxygenated by bubbling with nitrogen gas, immediately before measurement. Cyclic voltammetric experiments were carried out at (20±2)°C with a scan rate of 0.1 V s^{-1}.

Results and Discussion

Calculation of $E_1°$ and $E_2°$. The following equilibria in an aqueous solution and at an electrode have been established for a quinone and its reduced species in an aqueous solution:

$$Q + e^- \rightleftharpoons Q^-; E_1° \quad (1)$$

$$Q^- + e^- \rightleftharpoons Q^{2-}; E_2° \quad (2)$$

$$Q + 2H^+ + 2e^- \rightleftharpoons QH_2; E_m° \quad (3)$$

$$2Q^- \rightleftharpoons Q + Q^{2-}; K_d \quad (4)$$

$$Q^{2-} + H^+ \rightleftharpoons QH^-; K_1 \quad (5)$$

$$QH^- + H^+ \rightleftharpoons QH_2; K_2 \quad (6)$$

where $E_m°$ is the formal potential of Eq. 3 and where the K's are the conditional equilibrium constants defined as follows:

$$K_d = [Q][Q^{2-}]/[Q^-]^2 \quad (7)$$

$$K_1 = [QH^-]/[Q^{2-}][H^+] \quad (8)$$

$$K_2 = [QH_2]/[QH^-][H^+] \quad (9)$$

Among these quantities there exist the following relations (see Appendix):

$$(E_1° + E_2°)/2 = E_m° - (RT/2F)\ln[K_1K_2(C°)^2] \quad (10)$$

and:

$$E_1° - E_2° = (RT/F)\ln K_d \quad (11)$$

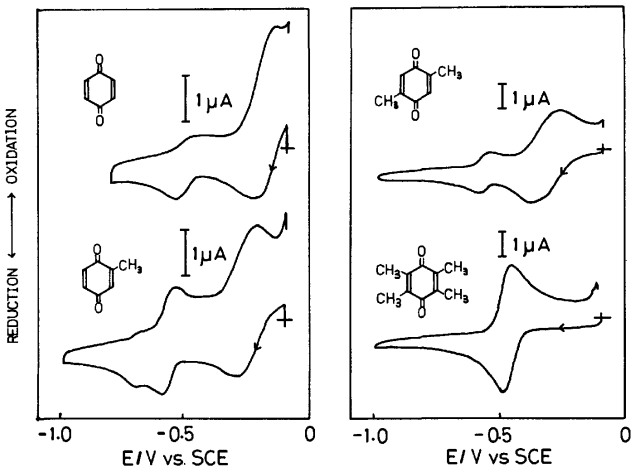

Fig. 1. Cyclic voltammograms for p-benzoquinone and its methyl derivatives in 0.1 M NaOH+0.1 M Li_2SO_4 aqueous solutions. Scan rate: 0.1 Vs^{-1}.

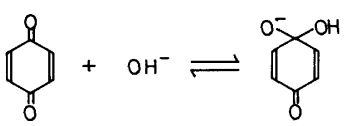
where C° is the standard molar concentration: C°=1 mol dm^{-3}. Table 1 lists the $E_1°$ and $E_2°$ values for BQ and related substitutes calculated from these equations and also the experimental values of $E_m°$, K_1, K_2, and K_d used in the calculation.

Cyclic Voltammetry of p-Benzoquinone and Its Methyl Derivatives in a Strongly Alkaline Aqueous Solution. Figure 1 shows cyclic voltammograms for the reduction of BQ, MBQ, DMBQ, and DQ in an aqueous 0.1 M NaOH solution. These quinones give one or more quasi-reversible steps: DQ gives one; MBQ, three; and the others, two. The most positive step of each cyclic voltammogram corresponds to the redox reactions of the quinones, and the others to the redox reactions of OH^- adducts which are in equilibrium with the parent quinones, as is shown by the following equation:[5]



(12)

The finding that only the cyclic voltammogram of MBQ has three steps can be explained by the fact that only the OH^- adduct of MBQ has two isomers. The cyclic voltammogram of DQ, which has only one step suggests that this compound hardly forms the OH^- adduct at all, as has been pointed out by Bishop and Tong.[6]

The apparent half-wave potentials, $E_{1/2}$, determined from the midpoint of the cathodic and the anodic peak potentials of each first step are listed in Table 2, together with the peak separation, ΔE_p. The calculated values of $(E_1°+E_2°)/2$ and $E_1°-E_2°$ are also listed. Recently, Richardson and Taube[7] have calculated the simulation curve for a cyclic voltammogram which has two charge-transfer steps, with various half-wave potential differences. From their results, we can calculate the apparent peak separation, ΔE_p, of the cyclic voltammogram for two-step electron-transfer reactions with small half-wave potential differences. In Table 2, the $(\Delta E_p)_{th}$ values of the quinones thus calculated by using each value of $E_1°$ and $E_2°$ are shown together.

The agreement between the $E_{1/2}$ and $(E_1°+E_2°)/2$ values is excellent. The observed values of ΔE_p are generally somewhat larger than the calculated values, $(\Delta E_p)_{th}$, but the order of the magnitude of ΔE_p and $(\Delta E_p)_{th}$ are in fair agreement with each other. The small difference between the observed and calculated values of ΔE_p may be attributed to the difference between the standard electrode potential and the half-wave potential, or the difference in the compositions of the solution with which the half-wave potential and the other equilibrium constants have been measured.

The difference between the calculated values of $E_1°$ and $E_2°$ are very small in contrast to those in acetonitrile, as shown in Table 2. Peover[2] has measured the polarograms of several quinols in 75% ethanol containing 0.1 M NaOH as the supporting electrolyte; he has thus obtained a value of about 0.15 V as the difference between the first and second half-wave potentials. Hayano and Fujihira[4] have measured polarograms of p-benzoquinone in DMF–ethanol mixtures and have found that the difference between the two half-wave potentials decreased from about 0.8 V in DMF to 0.15 V in ethanol. These small differences between two half-wave potentials in a protic solvent such as ethanol have been explained by these authors as the effect of hydrogen bonding between the quinone and these protic solvents. The results obtained by us in water are, therefore, not unreasonable.

From the results presented above, we can conclude that the calculated one-electron reduction potentials shown in Table 1 are reasonable as the formal potentials for Q/Q^- and Q^-/Q^{2-} in an aqueous solution, and that the first and the second one-electron reduction potentials without protonation reactions for p-

Table 2. Half-Wave Potentials, $E_{1/2}$, and the Peak Separations, ΔE_p, of *p*-Benzoquinone Derivatives[a)]

Quinone	In water					In acetonitrile[b)]	
	Experimental		Calculated				
	$-E_{1/2}$/V	ΔE_p/V	$-(E_1°+E_2°)/2$	$(E_1°-E_2°)$	(ΔE_p)th/V	$-(E_{1/2})_1$/V	$-(E_{1/2})_2$/V

benzoquinone and its methyl derivatives in an aqueous solution have very close values in contrast to the values of the first and the second half wave potentials of these quinones in an aprotic solvent.

Appendix

Derivation of Equation 10. $E°^1$, $E°^2$, K_{2a1}, and K_{2a2} in Eqs. IIa and IIIa of Ref. 3 correspond to $E_1°$, $E_2°$, $1/K_2$, and $1/K_1$ respectively in this paper. Furthermore, E_o^1 and E_o^2 in these equations are the formal potentials of the following electrode reactions:

$$Q + H^+ + e^- \rightleftharpoons QH;\ E_o^1 \qquad (A1)$$

$$QH + H^+ + e^- \rightleftharpoons QH_2;\ E_o^2 \qquad (A2)$$

From Eqs. IIa and IIIa of Ref. 3, the following equation can be obtained:

$$(E_o^1 + E_o^2)/2 = (E°^1+E°^2)/2 - (RT/2F)\ln[K_{2a1}K_{2a2}(C°)^{-2}] \qquad (A3)$$

It is apparent from Eqs. A1 and A2 that $(E_o^1+E_o^2)/2$ is equal to $E_m°$ in this paper. Therefore, using the notation of this paper, Eq. 10 is obtained:

$$(E_1° + E_2°)/2 = E_m° + (RT/2F)\ln[K_1K_2(C°)^2] \qquad (10)$$

Analysis of Proton-Transfer Reaction in Aqueous Solutions of Butylamines by Ultrasonic Methods

Yukio YOSHIDA and Sadakatsu NISHIKAWA*
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received November 2, 1985)

Ultrasonic absorption has been measured in an aqueous solution of *s*-butylamine over the frequency range 6.5—220 MHz and the concentration range 0.0115—3.18 mol dm^{-3} at 25 °C. The single relaxational phenomenon observed in a range less than 1 mol dm^{-3} was found to be associated with a perturbation of the equilibrium; R-NH_3^++OH^- ⇄ R-NH_3^+···OH^-. The rate constants of the forward and backward reactions, k_{12} and k_{21}, have been determined to be 2.1×10^{10} s^{-1} mol^{-1} dm^3 and 1.8×10^8 s^{-1}, respectively. It was also determined that the next step, R-NH_3^+···OH^- ⇄ R-NH_2+H_2O, which had been thought to have a considerable influence on the first step, was not very effective regarding the ultrasonic absorption observed in the MHz frequency range. The equilibrium constant in the second step, K_{32}, has been determined to be 3.5×10^{-2}. The standard volume change of the reaction has been calculated to be 26 cm^3 mol^{-1} from the concentration dependence of the maximum excess absorption per wavelength. The relaxation observed in a range greater that 1 mol dm^{-3} has been estimted to be associated with a molecular aggregation reaction. An ultrasonic study in an aqueous solution of butylamine has also been performed in order to determine the rate constants associated with a proton-transfer reaction at 25 °C.

The hydrogen atom has the simplest atomic structure and its properties have been experimentally and theoretically investigated.[1,2] Kinetic studies concerning proton-transfer reactions of amino acids, amines and carboxylic acids,[3-5] as well as the catalytic effect on the reaction[6-8] have been published using relaxation methods. Such information is very important in relation to biological reactions. It has been known that the proton-transfer process in aqueous amine solutions can be observed within the range of the ultrasonic pulse frequency 1—250 MHz. A theoretical approach which was originally proposed by Eigen,[9] seems to have become established. However, an analysis of the absorption associated with a proton-transfer may give us some unreasonable results, though the present authours[10,11] have also reported kinetic results regarding proton-transfer reaction in aqueous solutions of some amines according to his theory. In this situation, we consider that a reexamination of the analysis procedure should be undertaken. Another purpose of this report is to examine the isomeric effect of a proton-transfer reaction of butylamines. To this end, *s*-butylamine was chosen and the ultrasonic absorption and velocity results are given in this paper.

Experimental

s-Butylamine and butylamine were purchased from Tokyo Kasei Co. Ltd and Wako pure Chemicals, respectively, and distilled once. The desired concentrations of the aqueous solutions were prepared with doubly distilled water by weight. An improved ultrasonic pulse method was used for absorption measurements in the frequency range 6.5 to 220 MHz with 0.5, 5, and 20 MHz X-cut quartz transduceres. The procedure of the semiautomatic absorption measurement has been described elsewhere.[12] The sound velocity was measured by a sing around meter at 1.92 MHz and an interferometer at 2.5 MHz. The density of the solution was determined by a standard pyconometer of about 4 cm^3. The pH of the solution was measured by a HITACHI-HORIBA pH meter with a glass electrode. A saturated aqueous solution of $Ca(OH)_2$ was used as the standard reference of the electrode at pH=12.45 along with a standard buffer solution at 9.18 at 25 °C. All pH and ultrasonic measurements were carried out under a dry nitrogen gas because of the high basicity of the solution. They were all measured at 25 °C.

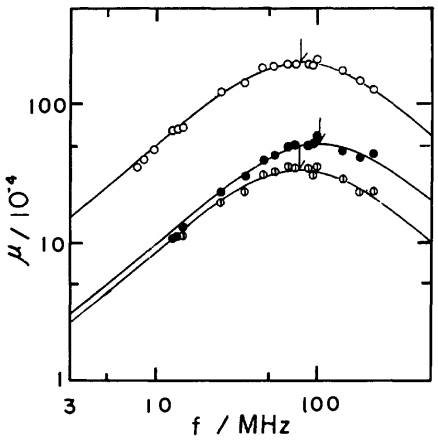

Fig. 1. The representative ultasonic absorption spectra in aqueous solution of *s*-butylamine at 25 °C. ○: 1.67 mol dm^{-3}, ●: 0.500 mol dm^{-3}, ⊕: 0.144 mol dm^{-3}.

Results and Discussion

Typical ultrasonic spectra for an aqueous solution of *s*-butylamine are shown in Fig. 1. In general, the frequency dependence of the absorption coefficient, α, due to a single process with a relaxation frequency, f_r, can be expressed as

$$\alpha/f^2 = A/\{1 + (f/f_r)^2\} + B \quad (1)$$

or

$$\mu = Afc/\{1+(f/f_r)^2\}, \quad (2)$$

were μ is the excess absorption per wave length, f the frequency, A the amplitude of the excess absorption,

B the background absorption, and c the sound velocity. The solid curves in Fig. 1 were calculated using ultrasonic parameters determined by a nonlinear least-mean-square method. The agreement between experimental and calculated values was very good. The obtained ultrasonic parameters are listed in Table 1 along with the measured solution density, ρ. Figure 2 shows the dependence of the ultrasonic parameters on the concentration. In the concentration range less than 1 mol dm^{-3}, both A and B maintain a plateau. However, in a range greater than 1 mol dm^{-3}, A increases dramatically and shows a peak at about 2.4 mol dm^{-3} while B increases monotonously with the concentration. This indicates that the cause of the absorption in the high-concentration range is different from that observed in the low-concentration range.

In this paper, the relaxation phenomenon observed at less than 1 mol dm^{-3} is mainly considered. There have been many reports concerning ultrasonic absorption in aqueous solutions of various amines.[4,10,11,13–15] A process associated with an unimolecular reaction, such as rotational isomerization, might be ruled out since the relaxation frequency strongly depends on the concentration. In such a relatively dilute aqueous solution, the most feasible absorption mechanism is related to a hydrolysis of an amine. This can be expressed by

$$\text{R-NH}_3^+ + \text{OH}^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} \text{R-NH}_2 + \text{H}_2\text{O}, \qquad (3)$$

where k_f and k_b are the forward and backward rate constants, respectively. The relationship between the relaxation time, τ, and the reactant concentrations is given by

$$2\pi f_r = \tau^{-1} = \gamma^2 k_f\{[\text{R-NH}_3^+] + [\text{OH}^-]\} + k_b, \qquad (4)$$

where γ is an activity coefficient calculated using Davies equation,[16] $-\log\gamma = 0.5[I^{1/2}/(I^{1/2}+1) - 0.3I]$. I is the ionic strength. The ion concentrations were obtained from pH measurements in the solution. Plots of f_r vs. $\gamma^2[\text{OH}^-]$ which are shown in Fig. 3 provide us

a) The dissociation constants have been calculated by Eq. 12.

the rate constants from the slope and the intercept. The results are shown in Table 2. Though the equilibrium constant, which might be calculated from the ratio of the two rate constants, should be the same as that determined by a static methods,[17] they are different from each other by at least a factor of ten. Equation 4 can be expressed in terms of the analytical concentration, C_0, by

$$(2\pi f_r)^2 = \tau^{-2} = 4\gamma^2 k_f k_b C_0 + k_b^2. \quad (5)$$

Then, the forward and backward rate constants can also be obtained from the plots of f_r^2 vs. $\gamma^2 C_0$. They are also listed in Table 2 and are indicated as k_{f0} and k_{b0}. However, the rate constants, especially the forward rate constants, obtained by the above two procedures are very different as can be seen in Table 2. In order to test the accuracy of the ion concentrations in the solutions, we have estimated the dissociation constant using

$$K_b = \gamma^2[OH^-]^2/(C_0 - [OH^-]). \quad (6)$$

The calculated dissociation constant is $(2.8\pm1.6)\times10^{-4}$ mol. This is close to the literature value.[17] This means that the ion concentrations are not incorrect. These dynamic and static results indicate that the hydrolysis of amine proceeds through more complicate steps. The more detailed proton-transfer reaction mechanism has been originally proposed by Eigen,[9] which is expressed by Eq. 7 and it seems to have been successfully applied to the ultrasonic analysis for many aqueous solutions of amines and amino acids.[3,4]

$$R\text{-}NH_3^+ + OH^- \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} R\text{-}NH_3^+\cdots OH^- \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} R\text{-}NH_2 + H_2O \quad (7)$$

where k_{ij} represents the rate constant at each step. According to the procedure of the analysis used so far,[3,4,18] the rate constants of k_f and k_b in Eq. 3 are connected by the next equation on the assumption that the first step is much slower than the second.

$$k_f = k_{12} \text{ and } k_b = k_{21}k_{32}/k_{23} \quad (8)$$

If the above procedure is correct, the ratio k_b/k_f should be close to the dissociation constant, K_b, because $K_b \cong k_b/k_f = (k_{21}/k_{12})(k_{32}/k_{23})$. However, this did not hold since these values were calculated using the rate constants in Table 2. An agreement can not be produced, even if the error of the intercept is taken into account. In the analysis procedure previously used, the rate constant, k_f, was determined using Eq. 5 with the help of a dissociation constant in the literature. The backward rate constant was then calculated and the results appear to be consistent. However, the intercept of plots of the experimental relaxation frequency vs. the ion or analytical concentration seems to be an actual high value although it should have been very close to the origin of the coordinate axes. Also, there is no kinetic experimental evidence concerning the dissociation rate constant. Only an estimation using the theoretical equation proposed by Eigen has been performed. Dickson et al.[18] have analyzed the proton-transfer reaction for aqueous solutions of some diamines in terms of a strong coupling two-step reaction scheme. They seem to have considered the intermediate to consist of a hydrogen-bonded complex, although they have not touched upon the intermediate exactly. If the elementary step of the proton-transfer is taken into account, there should be an ion-pair formation process before the making of a hydrogen bond. Then, it should be necessary to assume another step between the reactants, $R\text{-}NH_3^+\cdots OH^-$ and $R\text{-}NH_2$, in Eq. 7. Such a step has been also proposed by Eigen.[1] Even if such a complicated reaction mechanismis considered, the reactants, $R\text{-}NH_3^+\cdots OH^-$ and $R\text{-}NH_2\cdots OH_2$, are not distinguishable because the intramolecular proton-transfer reaction is expected to be too fast to be detected. Then, the reaction scheme of Eq. 7 is the same as that being taken into account such another intermediate, $R\text{-}NH_2\cdots OH_2$. Under these circumstances, we have simply considered that the observed relaxation in the concentration range of 0.0115 to 1 mol dm^{-3} is assumed to be only due to the first step and the influence of the other steps is approximately negligible within the experimental error even if such process exists in a higher or lower frequency range. Then, the rate constants obtained from the plots of the relaxation frequency vs. $\gamma^2[OH^-]$ in Fig. 3 may be those of the first step, k_{12} and k_{21}. From this hypothesis, it is possible to estimate the equilibrium constants, K_{32} and K_b, as follows. The equilibrium constants of the first and second steps are expressed as

$$K_{21} = k_{21}/k_{12} = \gamma^2[\text{R-NH}_3^+][\text{OH}^-]/[\text{R-NH}_3^+\cdots\text{OH}^-] \quad (9)$$

and

$$K_{32} = k_{32}/k_{23} = [\text{R-NH}_3^+\cdots\text{OH}^-]/[\text{R-NH}_2],$$

respectively. The dissociation constant or the equilibrium constant, K_b, can be precisely expressed by the next equation when the intermediates are taken into account.

$$K_b = K_{21}/(1+K_{32}^{-1}) \quad (10)$$

When the concentration of the $\text{R-NH}_3^+\cdots\text{OH}^-$ is small, K_b is approximately equal to $(k_{21}/k_{12})(k_{32}/k_{23})$. It is possible to calculate the equilibrium constant, K_{32}, with the help of Eq. 10 since K_{21} is obtained from k_{12} and k_{21}. The result is shown in Table 2. The small value of K_{32} indicates that the intermediate of the amine hydrolysis does not exist to a great extent. Using Eqs. 9 and 10, and the analytical concentration, Eq. 4 is transformed to

$$2\pi f_r = \tau^{-1} = k_{12}\{-K_b+(K_b^2+4\gamma^2C_0K_b)^{1/2}\} + k_{21}. \quad (11)$$

Consequently, solving for K_b, we obtain

$$K_b = [(\tau^{-1})^2 + k_{21}^2 - 2\tau^{-1}k_{21}]/[k_{12}(4\gamma^2C_0k_{12} + 2k_{21} - 2\tau^{-1})] \quad (12)$$

Fig. 4 indicates the calculated K_b against C_0, where k_{12} and k_{21} obtained from the slope and the intercept in Fig. 3 are used. The obtained K_b listed in Table 2 is very close to that found in the literature.[17] The above analysis of the amine hydrolysis makes us believe that the observed relaxation is approximately due to a perturbation of the first step. In a determination of the rate constants, k_{12} and k_{21}, according to the analytical concentration, it is no wonder that the same rate constants, k_{12} and k_{21}, as those obtained by Eq. 4 are availabel if Eq. 11 is used in order to determine them. The rate constant, k_{12}, is consistent with the diffusion-controlled reaction predicted by Debye's equation.[9] However, the backward rate constant, k_{21} is small when compared to that predicted by the theoretical equation using the ordinary parameters such as the reaction radius, diffusion coefficient and dielectric constant. It should be of the order of $10^{10}\,s^{-1}$ according to the theory while the experimental value of k_{21} is of that of $10^8\,s^{-1}$. However, there is no direct observation that dissociation rate constant, k_{21}, is of the order predicted by theory. Applegate et al.[19] have also reported that in their proton-transfer reaction study, the decomposition of the reaction into two steps was arbitrary.

Another important parameter obtained by ultrasonic absorption and velocity measurements is the maximum absorption per wavelength, μ_{max}, expressed as

$$\mu_{max} = \pi\rho c^2\Gamma(\Delta V-\alpha_p\Delta H/\rho C_p)^2/2RT, \quad (13)$$

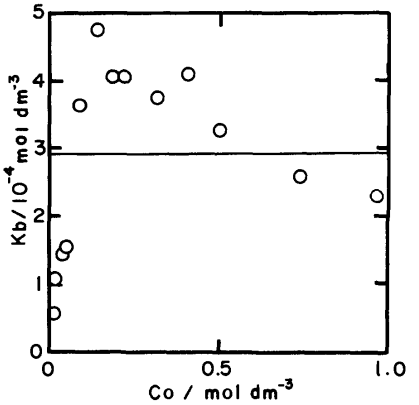

Fig. 4. The dissociation constants in aqueous solutions of *s*-butylamine calculated by Eq. 12 at 25 °C.

where ΔV is the standard volume change of the reaction, ΔH the standard enthalpy change of the reaction, α_p the thermal expansibility, C_p the specific heat, and Γ the concentration term which is expressed for the reaction under consideration as

$$\Gamma = \{1/[\text{R-NH}_3^+] + 1/[\text{OH}^-] + 1/[\text{R-NH}_3^+\cdots\text{OH}^-]\}^{-1}. \quad (14)$$

In the proton-transfer reaction, the enthalpy term can be quite small compared with the volume term in Eq. 13. Then, plots of μ_{max} vs. $\rho c^2\Gamma$ provide the standard volume change of the reaction. The result is given in Table 2.

A similar experiment and the analysis for an aqueous solution of butylamine have been performed at 25 °C. The kinetic results are also shown in Table 2. Also, the analyses of other butylamine solutions for which ultrasonic experimental results have been reported so far[10,21] have been performed. The calculated rate and thermodynamic constants are listed in Table 2. Inconsistent values are also obtained when it is assumed that the second step influences the first step. However, an analysis based on the assumption that the ultrasonic absorption is only due to the perturbation of the equilibrium associated with the first step has been shown to be reasonable.

In conclusion, the ultrasonic relaxation observed in the MHz frequency range in relatively dilute aqueous solutions of butylamines can be attributed to the hydrolysis which proceeds in an intermediate state. The first process of ion-pair formation is associated with the observed relaxation. However, it seems to be hard to distinguish the difference in the kinetic parameters of the four isomeric butylamines. This means that the association process is a diffusion-controlled reaction which depends mainly on the coefficients of the hydroxide ions in the solutions. However, it is hard to say whether the dissociation process is also the diffusion-controlled reaction as predicted by Eigen.

Next, we briefly discuss an excess absorption me-

chanism which was observed in a concentration range greater than 1 mol dm^{-3}. As can be seen in Fig. 2, the amplitude of the relaxational absorption has a maximum. The sound velocity also has a maximum. Such dependences on the concentration have been found in some aqueous solutions of amines with relatively large hydrophobic groups, such as in the solution of pentylamine.[20] On the other hand, such phenomena are not observed in solutions in which solutes consist of a small hydrophobic group.[11,20] From these experimental facts, we conclude that the aggregate associated with a hydrophobic interaction might be created in butylamine aqueous solutions. Unfortunately, it has not been possible to distinguish two relaxation processes at greater than 1 mol dm^{-3}. All measured spectra can be approximately expressed by a single relaxational equation, though the relaxation frequency shows a discontinuous dependence on the concentration at around 1 mol dm^{-3}. This means that the coupling between the hydrolysis and the aggregation reaction is quite strong in butylamine solutions. In the case of a pentylamine aqueous solution,[20] two such distinguishable relaxations have been clearly observed.

We are considering that the relaxation observed in the concentrated aqueous solutions of amines with relatively large hydrophobic groups might be closely related to those observed in aqueous solutions of some alcohols or ethers since both aqueous solutions may indicate quite similar ultrasonic characters. In order to determine the correlations between them, it is required to accumulate more ultrasonic data for aqueous solutions of various nonelectrolytes as functions of the concentration and frequency.

Chemical Effectiveness of Elastic and Inelastic Energy Loss of He^+, Ar^+, and Xe^+ Ions Bombarding Solid Potassium Nitrate†

Shin-ichi OHNO,* Katsutoshi FURUKAWA, and Takeshi SOGA
Department of Chemistry, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11
(Received December 5, 1985)

Decomposition of crystalline potassium nitrate due to He^+-, Ar^+-, and Xe^+-ion bombardment was studied in the energy range from 20 to 100 keV. The cross sections for producing nitrite ions were for the first time determined to be 5.7×10^{-20} m^2, 12.6×10^{-20} m^2, and 22.0×10^{-20} m^2 for 100 keV He^+, Ar^+, and Xe^+ ion, respectively. Comparing the values of these cross sections with the rate of an elastic and inelastic energy loss of these incident ions, which were calculated on the basis of the theory of Lindhard et al., it may be concluded that inelastic energy is about five times more efficient than elastic energy for the decomposition of the solid potassium nitrate.

Energetic particles lose energy in traversing matter because of two different processes:[2,3]

a) elastic collisions leading to atomic displacements, which are called "nuclear stopping" of the matter for the incident particle,

b) inelastic collisions leading to electronic excitations (ionizations and charge-exchange processes included), which are called "electronic stopping" of the matter. Both "nuclear" and "electronic" collisions may initiate chemical reactions in the material.[1,2,4]

Decomposition of potassium nitrate via electronic excitations has been studied in many works[1,5-12] using α-rays,[7] γ-rays,[5,8-10] or electron beams.[6,12] The only end-products reported are the nitrite ion and molecular oxygen, the initial process being the dissociation of an N-O bond:[7-9]

$$NO_3^- \longrightarrow NO_2^- + O. \quad (1)$$

On the other hand, elastic collisions are frequent phenomena at relatively low impact energies (≈keV region).[2,3] The energy transferred from incident ions to atomic constituents is so high compared to the binding energy for a molecular and crystalline structure that a chemical reaction may take place in the solid. Thus, Logan and Moore interpreted their results on the decomposition of potassium nitrate by incident 2 keV D^+ and He^+ as due to the atomic displacements.[11]

The present authors reported in a previous communication[1] that potassium nitrate decomposed during bombardment with 100 keV ions generated from discharge of deuterium, helium, nitrogen, and oxygen. The observed results suggested that the reaction proceeded mainly via electronic excitations.

The purpose of the present paper is to clarify the relative importance of electronic and atomic displacement excitations in chemical reactions in potassium nitrate. We aim at obtaining cross sections of the each ion decomposing potassium nitrate which should be determined from the yield-dose curve for He^+-, Ar^+-, and Xe^+-ion bombardment. These noble gas ions transfer their kinetic energy to KNO_3 without themselves taking part in chemical reaction. (cf. H_2^+ or O_2^+; see Ref. 1). The second step to our end is to know the relative amount of energy going into elastic and inelastic processes. We obtain this information from the calculation of stopping power according to the theory of Lindhard, Scharff and Schiøtt.[13,14]

By comparing the cross sections for the reaction with the electronic and nuclear stopping power thus obtained, one may determine the relative effectiveness of elastic and inelastic energy losses of the energetic particles bombarding solid potassium nitrate. Potassium nitrate was chosen because its radiolytic behavior toward ionizing radiations was well known; The only radiolytic products reported are nitrite ions and molecular oxygen.[10,11]

Experimental

Experimental method was the same as that reported previously.[1] Energetic ions were produced by discharge of He, Ar, and Xe in a radio-frequency source,[16] and accelerated at desired energies and were focussed through an aperture (8 mmφ) onto the sample.

The sample was a pressed disk of polycrystalline potassium nitrate. Irradiations were carried out at room temperature in vacuum (ca. 10^{-5} Pa). The current density was 10 μA cm^{-2}. After irradiations, the samples were dissolved in water and the concentration of nitrite ions produced was determined spectrophotometrically[17] by adding 1-naphthylamine and sulfanilic acid.

Results and Discussion

Yield-Dose Curve for the He^+-, Ar^+-, and Xe^+-Ion Bombardment. The amounts of nitrite ion as a function of the incident ion dose are shown in Figs. 1, 2, and 3 for the bombardment of He^+, Ar^+, and Xe^+ ion, respectively. As is seen from the figures, the yields depend on both the mass and energy of the bombarding ions. The rapid initial decomposition is followed by a decline in rate in all the cases examined.

We may assume here that each yield-dose curve includes of two regions: An initial decomposition the rate of which is linear with dose and a final plateau

†Chemical Reactions Induced by Energetic Particles. III.[1]

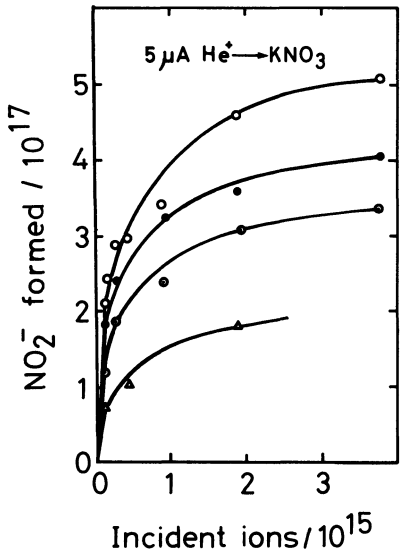

Fig. 1. Nitrite ion formation in potassium nitrate as a function of the energy of incident He^+ ions. Ion energy: (△) 20 keV, (⊙) 50 keV, (●) 80 keV, and (○) 100 keV; Ion beam intensity: 6.25×10^{13} ions $cm^{-2}s^{-1}$.

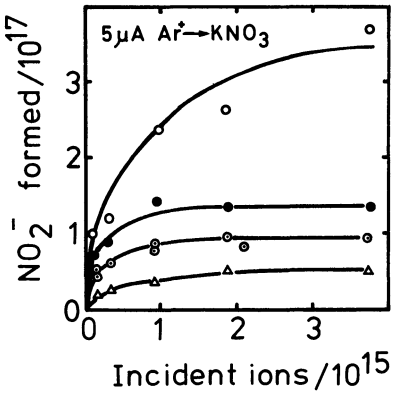

Fig. 2. Nitrite ion formation in potassium nitrate as a function of incident Ar^+ ion. Ion energy: (△) 20 keV, (⊙) 50 keV, (●) 80 keV, and (○) 100 keV; Ion beam intencity: 6.25×10^{13} ions $cm^{-2}s^{-1}$.

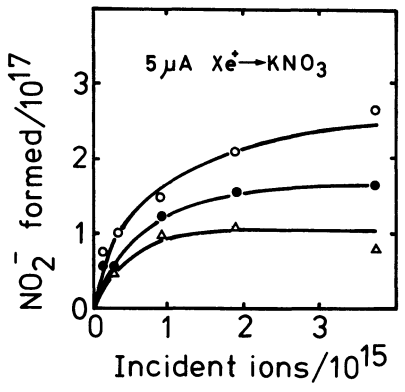

Fig. 3. Nitrite ion formation in potassium nitrate as a function of incident Xe^+ ions. Ion energy: (△) 50 keV, (●) 80 keV, and (○) 100 keV; Ion beam intensity: 6.25×10^{13} ions $cm^{-2}s^{-1}$.

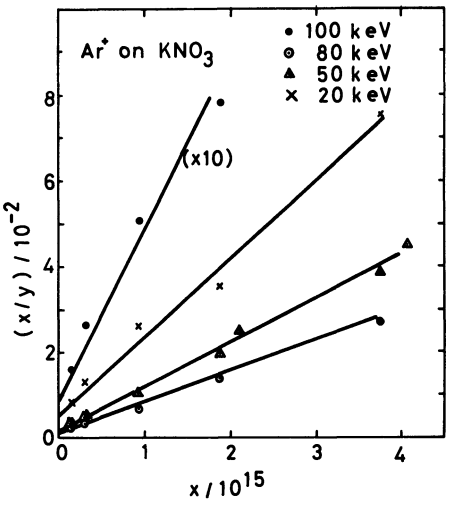

Fig. 4. Plots of x/y vs. x for 20 (×), 50 (△), 80 (⊙), and 100 (●) keV Ar^+ ions, where x and y are the number of incident ions and nitrite ions formed, respectively.

region which would be obtained at high doses. If we represent these relation as $y=ax$ and $y=b$, respectively, where y is the amount (=number) of nitrite ion and x is the dose (=number) with a and b being constants, we may obtain an expression:

$$\frac{x}{y}=\frac{1}{a}+\frac{1}{b}\cdot x. \tag{2}$$

The experimental points in Figs. 1—3 were replotted according to Eq. 2 (See Fig. 4, as an example) to obtain values of a and b for each yield-dose curve. Thus, an initial rate of NO_2^- formation, $Y=(dy/dx)_{x=0}$, and a "saturation yield," $(y)_{x=\infty}$, were calculated respectively from the values of a and b above obtained for incident He^+, Ar^+, and Xe^+ ions at an energy of T. The results are included in Fig. 5 and in Table 1, respectively.

The "saturation yields" shown in Table 1 probably represent a steady state between decomposition of NO_3^- to give NO_2^- (Reaction 1) and disappearence of NO_2^- either via a reverse reaction (Reaction 3) or via a further decomposition by incoming ions (Reaction 4):†

$$NO_2^- + 1/2O_2(O, O^+, O^-, O_2^-, \text{or } O_3) \longrightarrow NO_3^-, \tag{3}$$

$$NO_2^- \longrightarrow NO^- + O \text{ (or } NO+O^-). \tag{4}$$

Oxygen-containing species in Reaction 3 may diffuse away from the reaction zone; This prevents the reformation reaction of nitrate ion. Thus, analyses of the "saturation yield" seem very complex; we will hereafter strict our discussion on the initial rate of NO_2^- formation.

Calculation of the Stopping Power. The total stopping power, S_t, can be divided into two parts: $S_t=S_e+S_n$ where S_e and S_n are the electronic and nuclear

†In 1.4 keV electron-beam irradiation, there is no indication for futrher decomposition of the nitrite ion formed (Ref. 12).

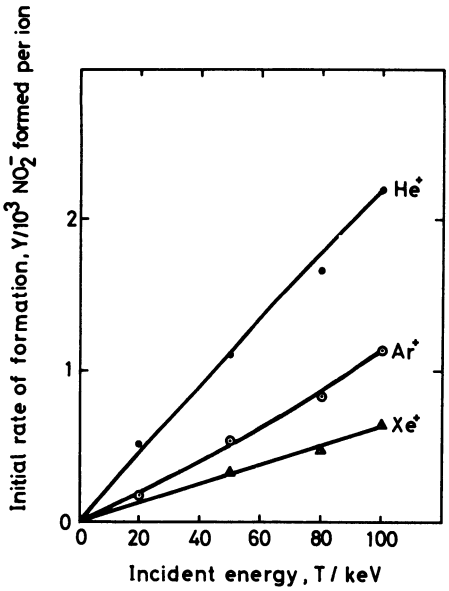

Fig. 5. The initial rate of formation of NO_2^-, $Y=(dy/dx)_{x=0}$, as a function of the incident ion energy, T, for He^+, Ar^+, and Xe^+ ions bombarding potassium nitrate.

Table 1. Saturation Yield (=b)/10^{17} NO_2^- for He^+, Ar^+, and Xe^+ Ions Incident on Potassium Nitrate at Various Energies

Ion energy/keV	20	50	80	100
He^+	2.1	3.7	4.3	5.5
Ar^+	0.56	0.96	1.45	4.0
Xe^+	—	1.46	1.9	3.0

stopping powers, respectively, as discussed in the introduction of this paper.

The electronic stopping power for a particle moving at the velocity v was calculated according to the theory of Lindhard, Scharff, and Schiøtt:[13,15]

$$S_e = 8\pi e^2 N a_0 Z_1^{7/6} Z_2 (Z_1^{2/3}+Z_2^{2/3})^{-3/2} v/v_0 \quad (5)$$

where a_0 is the Bohr radius of the hydrogen atom; v_0 is the Bohr velocity; Z_1 and Z_2 are the atomic number of the projectile and the target, respectively; N is the atom density of the target material.

The nuclear stopping power was calculated using[14,15]

$$S_n = s_n(8.462 Z_1 Z_2 M_1)/[(M_1+M_2)(Z_1^{2/3}+Z_2^{2/3})^{1/2}] \quad (6)$$

and

$$s_n = 0.5 \ln(1+\varepsilon)/(\varepsilon + 0.107^{0.375}) \quad (7)$$

Here, ε is the reduced energy of the ion and is defined as:

$$\varepsilon = 32.53 M_2 E/[Z_1 Z_2 (M_1+M_2)(Z_1^{2/3}+Z_2^{2/3})^{1/2}], \quad (8)$$

where the ion energy, E, is in keV; M_1 and M_2 are the ion and target masses in amu, respectively.

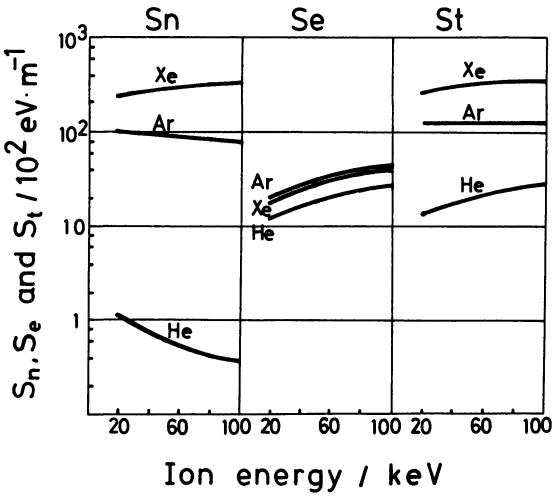

Fig. 6. The stopping powers of potassium nitrate (KNO_3: 10^{23} m^{-3}) for He^+, Ar^+, and Xe^+ ions in the energy range from 20 to 100 keV.
S_n: Nuclear stopping, S_e: Electronic stopping, S_t: Total stopping, $S_t=S_n+S_e$.

For the stopping power of compounds, e.g., KNO_3, the stopping powers of the constitutional element (i.e., K, N, and O) were weighted by their relative abundance; this is called Bragg's Rule. The results of the calculation are shown in Fig. 6, where the electronic, nuclear and total stopping powers in eV m^{-1} of potassium nitrate ($N=10^{23}$ m^{-3}) for He^+, Ar^+, and Xe^+ ions in the energy range 20—100 keV are plotted. We notice from Fig. 6 that He^+ ion in the energy range 20—100 keV dissipates most of their energy into electronic excitations, while Xe^+ ion in the same energy range into atomic displacement collisions.

Determining the Cross Sections for the Reaction Induced by Energetic Ions. The cross section for reaction of an energetic particle with a molecule in the solid is a function of the kinetic energy of the particle. The initial rate of NO_2^- formation, $Y=(dy/dx)_{x=0}$, for the incident energy at T_0, that is the number of the product formed per incident ion, is expressed as follows:

$$Y = N\int_0^{T_0} Q(T)\, ds \quad (9)$$

Here, N is the number density of KNO_3 in the medium, $Q(T)$ is the cross section that the product, NO_2^-, will be formed in a collision with the particle of the kinetic energy T, and ds is the distance traversed by the particle while in the energy range between $T+dT$ and T. In the continuous slowing-down approximation,[18] ds may be replaced by $dT/S(T)$, $S(T)$ being the total stopping power:

$$Y = N\int_0^{T_0} \frac{Q(T)}{S(T)}\, dT. \quad (10)$$

or

$$\frac{S(T)}{N}\frac{dY}{dT} = Q(T). \quad (11)$$

We assume here that the product yield from reaction of the recoil atoms or secondary electrons is negligibly small since their kinetic energy is no more sufficient in the majority of the case to initiate further chemical reactions. The cross sections, $Q(T)$, for producing NO_2^- from KNO_3 may be deduced from the slope of the Y-T curves of Fig. 5 and the total stopping-power values presented in Fig. 6 with the aid of Eq. 11. The results are included in Fig. 7; The cross sections for He^+, Ar^+, and Xe^+ ions at 100 keV are 5.7×10^{-20} m^2, 12.6×10^{-20} m^2, and 22.0×10^{-20} m^2, respectively, and they slightly depend on the ion energy T. These values are comparable to the cross sections estimated from the known atomic radius of He, Ar, and Xe, respectively.

Chemical Effectiveness of the Electronic and Nuclear Energy Losses in the Decomposition of Potassium Nitrate. Consider that an ion of the energy T travels a unit distance in the solid (KNO_3). From Eq. 2, the number of the product per unit path length of the ion of the energy at T is $N\,Q(T)$ where N is the number density of the target molecule. The energy expended in this reaction is provided from the energy deposited to this zone (=the unit path length) from the traversing ion, i.e., the total stopping power, $S_t=S_e+S_n$. If we designate the effectiveness of the energy contributed from S_e and S_n for the chemical reaction as f_e and f_n, respectively, the fraction of the deposited energy which is utilized to nitrite production, $N\,Q(T)$, is $f_eS_e+f_nS_n$. Thus, one may expect a linear relationship holds between $Q(T)$ and the value of $(f_eS_e+f_nS_n)/(f_e+f_n)$ or $(S_e+pS_n)/(1+p)$ where p represent f_n/f_f. In Fig. 8 are plotted the value of $Q(T)$ (shown in Fig. 7) as a function of $(S_e+pS_n)N^{-1}(1+p)^{-1}$ with p as a parameter. It is clearly demonstrated that an expected linear relationship holds when p is around 0.2. This suggests that, in the decomposition of KNO_3 due to the transmitted energy from the incident ion, an electronic energy is about five times more effective than a nuclear energy.

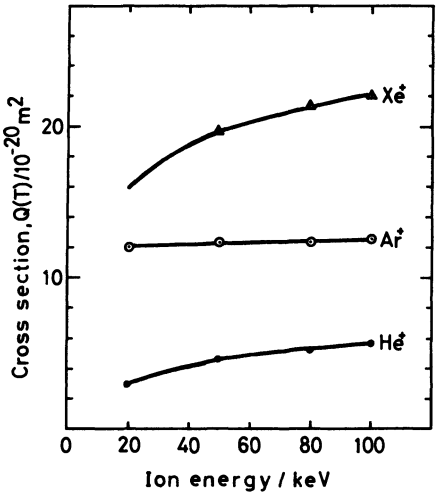

Fig. 7. Cross sections, $Q(T)$, for producing NO_2^- from KNO_3 for He^+, Ar^+, and Xe^+ ions in the energy range from 20 to 100 keV.

Mechanism of the Reaction. Mechanism of decomposition of the radiolyzed nitrates have been studied in many works.[5-11] An important role of atomic oxygen as an intermediate has repeatedly been emphasized (Reaction 1).[7-9]

Elastic "nuclear" collisions may lead to atomic displacements in potassium nitrate. However,the energy transmitted to potassium ions is most probably dissipated as heat; the collision with NO_3^- does not necessarily lead to breaking of the N-O bond. The momentum large enough to break the bond must be effectively trasferred to an O atom (the dissociation energy of the N-O bond is reported to be 3.9 eV[19]). Threshold energies for displacement of O-atoms from the oxide lattices, i.e. ZnO and MgO, are reported to be around 60 to 90 eV.[20] Though, a corresponding energy for KNO_3 has not yet been reported, it is very likely to exceed greatly the dissociation energy of the N-O bond. Thus, it is not surprising to notice that only a small portion of the deposited energy is converted to chemical energy and the remaining energy is degraded to thermal energy.

On the other hand, inelastic collisions may pro-

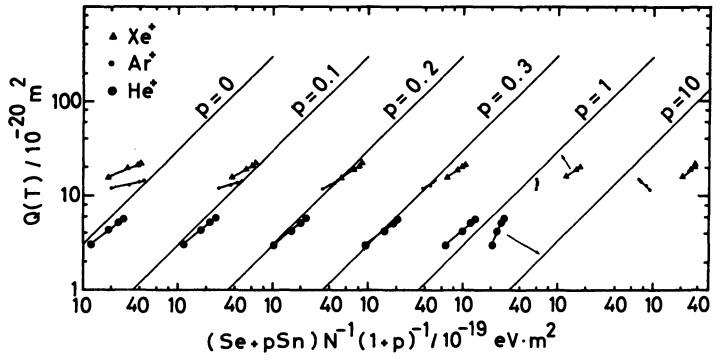

Fig. 8. Test of the linear relationship between $Q(T)$ and $(S_e+pS_n)N^{-1}(1+p)^{-1}$ with p as a parameter; Data taken from Figs. 6 and 7.

duce electronic excited states of the NO_3^- ion. A weak ($\pi^* \leftarrow n$) transition at about 4.1 eV and an allowed ($\pi^* \leftarrow \pi$) transition at about 6.2 eV are well-known.[21,22] These transitions may not lead to the N-O bond breaking, however, since in these transitions an electron is removed from an orbital which is not strongly bonding in nature. An oxygen atom, if it generates without sufficient kinetic energy, will not necessarily escape the parent NO_3^- group owing to some kind of a "cage effect."[10] Excitation of an electron from a bonding (=sp^2 hybrid) orbital is much more likely responsible for the bond dissociation. Excitations of an N- or O-core orbital followed by Auger processes[23] may be even more effective for the bond breaking. A dissociated O-atom may react with other NO_3^- ions,[7]

$$NO_3^- + O \longrightarrow NO_2^- + O_2 \quad (12)$$

or it may react with the NO_2^- ions produced (see Reaction 3):

$$NO_2^- + O \longrightarrow NO_3^-. \quad (13)$$

Reactions 12 and 13 have been studied in aqueous solutions and their rate constants relative to that for O_2 were reported to be 5.6 and 37, respectively.[24]

In both cases, i.e. elastic and inelastic collisions, an actual mechanism is probably more complex than above mentionned, possibly involving reactions of several ionic and free radical species. The cross sections which we have derived for the first time in this paper are for an overall reaction to give nitrite ions. Since the occurrence of the many thermal reactions are the same for the both cases, one may possibly state that an inelastic (=electronic) excitation is five times more efficient than an elastic (=atomic displacement) collision for the dissociation of the N-O bond in the solid potassium nitrate.

Benzo-15-crown-5 Linked Spirobenzopyran. I. Photocontrol of Cation-Binding Ability and Photoinduced Membrane Potential Changes

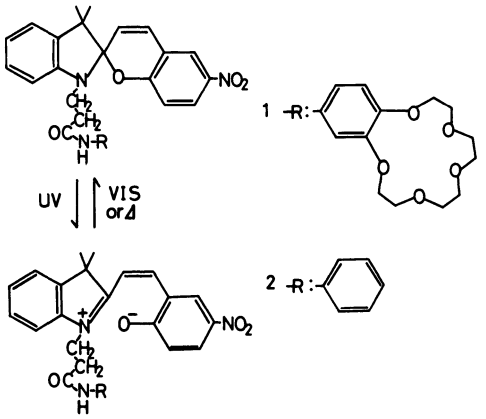
Hiroshi SASAKI, Akihiko UENO, Jun-ichi ANZAI, and Tetsuo OSA*
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
(Received December 26, 1985)

Benzocrown ether-linked spirobenzopyran (**1**) and its analogue (**2**) which has no crown ring were synthesized. The binding abilities of **1** for alkali metal cations (Na^+, K^+, Rb^+, Cs^+) were found to change by UV light irradiation, while **2** did not bind these cations before and after UV light irradiation. The plasticized poly(vinyl chloride) (PVC) membrane entrapping **1** or **2** showed photoinduced potential changes reversibly by UV and visible light irradiation. In the membranes of both **1** and **2** showed normal photochromism of spirobenzopyran. In the case of **1**, the magnitude of the photoinduced potential change depended upon kind and concentration of alkali metal cations. However, the magnitude of photoinduced potential change of the membrane entrapping **2** was hardly affected by kind and concentration of alkali metal cations. The results are explained in terms of cooperative action of both crown ether and spiropyran.

Spirobenzopyran derivatives are well known photoresponsive organic compounds which can be reversibly isomerized by UV and visible light irradiation. This character was utilized to regulate polymer comformation,[1] viscosity of polymer solution,[2] enzyme activity,[3] membrane potential,[4-8] and ion permeation using liquid membrane,[9] etc. Crown ether derivatives have cation binding ability, and are widely studied not only in labolatory but also in industry. We have already reported the ion permeability[10,11] and the membrane potential change[12-17] which occurs reversibly upon photoirradiation across the poly(vinyl chloride) (PVC) membrane containing azobenzene-modified crown ethers.

In the present study, we synthesized spirobenzopyran derivatives bearing benzo-15-crown-5 and phenyl units (**1** and **2**, respectively), and examined photoresponsive cation binding ability of them by liquid–liquid extraction method, and by measuring membrane potentials across the PVC membranes entrapping **1** (PVC(**1**) membrane) and **2** (PVC(**2**) membrane).

From the different point of view, **1** is regarded as a photoresponsive crown ether. Photoisomerism of azobenzene has been used in many photoresponsive crown ethers.[10-22] The present system works based on the different isomerism performed by spiropyran, so **1** belongs to a new family of functional molecules showing photoresponsiveness.



Experimental

Materials. Poly(vinyl chloride)(PVC) (polymerization degree of 1100) was purchased from Wako Pure Chemical Industry Ltd. and used without further purification. Dibutyl phthalate (DBP), tetrahydrofuran (THF), and alkali metal chlorides (NaCl, KCl, RbCl, and CsCl) were of extra pure reagent grade. Alkali metal picrates were prepared according to the Fuoss method.[23] Double-distilled water was used throughout.

3′,3′-Dimethyl-6-nitro-1′-[2-[3,4-(1,4,7,10,13-pentaoxatridecane-1,13-diyl)phenylcarbamoyl]ethyl]spiro[2*H*-1-benzopyran-2,2′-indoline] (1). 1′-(2-Carboxyethyl)-3′,3′-dimethyl-6-nitrospiro[2*H*-1-benzopyran-2,2′-indoline][24] (1 g, 2.62 mmol) and 4′-aminobenzo-15-crown-5[25] (0.75 g, 2.65 mmol) were dissoloved in 50 ml of the mixed solvent of chloroform and DMF (9:1 in volume). After dicyclohexylcarbodiimide (DCC) (0.54 g, 2.62 mmol) was added to the mixture at −5 °C, the mixture was stirred for 24 h, and then the formed *N,N′*-dicyclohexylurea was filtered off. The filtrate was subjected to silica-gel column chromatography (dichloromethane:EtOH=15:1 in volume). The obtained crude product was recrystallized from methanol to give 0.64 g (38%) of **1**. Mp 114 °C. Found: C, 64,49; H, 6.22; N, 6.47%. Calcd for $C_{35}H_{39}N_3O_9$: C, 65.10; H, 6.09; N, 6.51%. ^{1}H NMR ($CDCl_3$) δ=1.1, 1.25 (6H, s, CH_3 of pirrole ring), 1.5—1.9 (2H, broad, $-NCH_2-$), 2.4—2.8 (2H, m, $-CH_2-CO-$), 3.3—4.2 (16H, m, $-CH_2-$ crown ether), 5.75 (1H, d, J=16 Hz C<u>H</u>=CH-nitrobenzene), 6.3—7.2 (9H, m, aromatic H of 3*H*-indole and benzocrown, -NH-, and CH=C<u>H</u>-nitrobenzene), 7.7—8.1 (3H, m, aromatic of nitrobenzene). IR (KBr) $\delta_{C=O}$ 1655 cm^{-1} (amide I), ν_{N-H} 1610 cm^{-1} (amide II).

3′,3′-Dimethyl-6-nitro-1′-[2-(phenylcarbamoyl)ethyl]spiro[2*H*-1-benzopyran-2,2′-indoline] (2). Compound **2** was synthesized from 1′-(2-carboxyethyl)-3′,3′-dimethyl-6-nitrospiro[2*H*-1-benzopyran-2,2′-indoline] (0.5 g, 1.31 mmol) and aniline (0.12 g, 1.29 mmol) using a method analogous to that used for **1**. Purification of **2** was performed by recrystallization from isobutyl alcohol to give 0.40 g (68%) of **2**. Mp 120 °C. Found: C, 70.85; H, 5.93; N, 9.10%. Calcd for $C_{27}H_{25}N_3O_4$: C, 71.19; H, 5.53; N, 9.22%. ^{1}H NMR ($CDCl_3$) δ=1.1, 1.25 (6H, s, CH_3 of pirrole ring), 1.5—1.9 (2H, broad, NCH_2-), 2.4—2.9 (2H, m, $-CH_2-CO-$), 5.75 (1H, d, J=16 Hz -C<u>H</u>=CH-nitrobenzene), 6.5—7.3 (10H, m, aromatic H of 3*H*-indole and aniline, -NH-, and -CH=C<u>H</u>-nitrobenzene), 7.7—8.1

(3H, m, aromatic of nitrobenzene). IR (KBr) $\delta_{C=O}$ 1650 cm^{-1} (amide I), ν_{N-H} 1605 cm^{-1} (amide II).

Benzo-15-crown-5(**3**) was synthesised according to the Pedersen's method.[26]

Preparation of Membranes. (PVC(**1**)) or (PVC(**2**)) membrane was prepared by pouring the mixture of PVC (235 mg), DBP (0.54 ml), **1** (24.8 mg) or **2** (17.7 mg), and THF (20 ml) onto a flat Petri dish (9.2 cm diameter) and allowing the solvent to evaporate. The prepared membranes have a thickness of ca. 0.1 mm, and their mechanical strength was satisfactory for the spectroscopic and electrochemical measurements. The membrane entrapping both **2** and **3** was prepared in the same manner as that of PVC(**2**) membrane, except for addition of **3** (10.5 mg).

Absorption Spectra. Photoisomerization of **1** and **2**, which proceeds in solution or in the membranes, was monitored by measuring the absorption spectra.

Liquid–Liquid Extraction. At 25 °C, a 2 ml aqueous solution containing alkali metal picrate (1×10^{-5} mol dm^{-3}) and alkali metal chloride (1 mol dm^{-3}) was vigorously shaken in quartz UV cell with the equal volume of dichloromethane solution containing **1**, **2**, or **3**. After sufficient agitation, the picrate concentration in the aqueous layer was determined by the absorbance change at 354 nm. To obtain the data after UV irradiation, the liquid–liquid extraction was carried out under UV light.

Membrane Potential Measurements. All measurements were carried out at 25 °C with a U-shaped glass cell illustrated in Fig. 1. Double junction type of saturated calomel electrodes were employed. Both solutions were stirred vigorously. The effective membrane area of the cell was 2.54 cm^2. The composition of the electrochemical cell for the membrane potential measurements was as follows; Hg_2Cl_2 (s), Hg | KCl (sat.) | 0.1 mol dm^{-3} $(CH_3)_4NCl$ | electrolyte solution (c) | membrane | electrolyte solution (c) | 0.1 mol dm^{-3} $(CH_3)_4NCl$ | KCl (sat.) | Hg_2Cl_2 (s), Hg. The electrolyte solution of the left side was earthed. Photoirradiation was performed with 500 W xenon lamp (Ushio Electric Inc.) using cut off filters Toshiba UV D-35 and Y-45 for isolating UV ($320\,nm<\lambda<400\,nm$) and visible ($450\,nm<\lambda$) light, respectively. Photoirradiation was done from the right side.

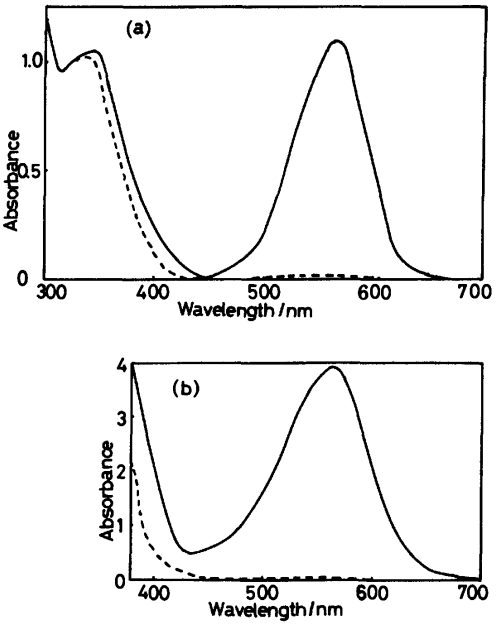

Fig. 2. (a) Absorption spectra of **1** in dichloromethane solution (1×10^{-4} mol dm^{-3}) before (---) and after (——) UV irradiation. (b) Absorption spectra of **1** in PVC membrane before (---) and after (——) UV irradiation.

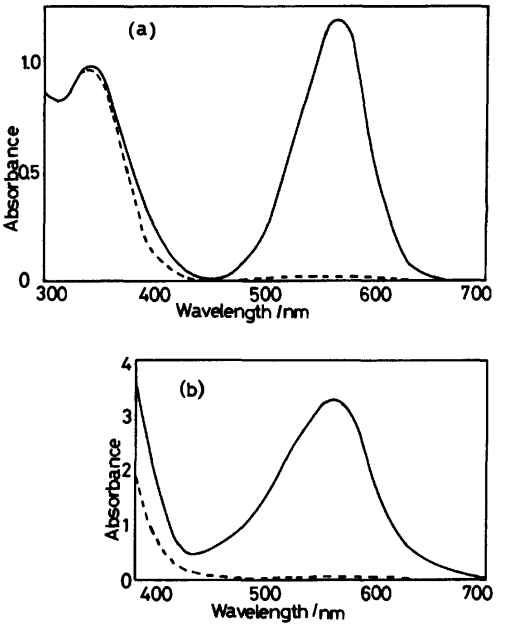

Fig. 3. (a) Absorption spectra of **2** in dichloromethane solution (1×10^{-4} mol dm^{-3}) before (---) and after (——) UV irradiation. (b) Absorption spectra of **2** in PVC membrane before (---) and after (——) UV irradiation.

Results and Discussion

Photochemical and Thermal Isomerization of 1 and

2. The absorption spectra of **1** and **2** in dichloromethane are shown in Fig. 2 (a) and Fig. 3 (a), respectively. In dichloromethane, the closed form of **1** showed an absorption band at 340 nm (ε=10200) and the solution was colorless. After UV irradiation (ca. 2 min), the absorption band at 340 nm was shifted to 345 nm (ε=10500) and a new absorption band was observed at 567 nm (ε=11000), the color of the solution being purple. This spectral change indicates that **1** was isomerized from closed form (closed-**1**) to opened form (opened-**1**).[4-7] By visible light irradiation of the solution of opened-**1**, the original spectral pattern of closed-**1** was recovered quickly (ca. 20 s). Opened-**1** was also isomerized thermally with the half life of ca. 80 s in the dark (at 25 °C). The compound **2** showed similar spectral changes to those of **1**. As shown by the absorption changes from 340 nm (ε=9700) of closed **1** to 345 nm (ε=10000) and 567 nm (ε=12000) of opened **2**. The photoinduced absorption changes of **2** in dichloromethane also occurred reversibly by alternate UV and visible light irradiation. The half life of opened **2** was ca. 80 s in the dark (at 25 °C).

The photoisomerization of **1** and **2** occurred also in PVC membranes. The absorption spectra of PVC(**1**) membrane and PVC(**2**) membrane were shown in Fig. 2 (b) and Fig. 3 (b), respectively. These membranes were soaked in 10 mmol dm^{-3} NaCl solutions. The closed forms of **1** and **2** showed no absorption in the wavelength region between 480 and 700 nm, so the membranes were colorless. After UV irradiation, the membranes turned purple, and a new absorption band appeared at 560 nm for PVC(**1**) and at 557 nm for PVC(**2**) membrane, respectively. These changes of the absorption spectra mean clearly that isomerization of **1** and **2** from closed form to opened one was achieved in the membranes. By visible light irradiation of the UV irradiated membranes, the colorless membranes were again obtained. The spectral changes completed within ca. 30 s. Opened **1** and **2** in PVC membranes were also isomerized thermally, with the half lives of ca. 4 and 3 min in the dark, respectively. The UV induced absorption changes of PVC(**2** and **3**) membrane were similar to those of PVC(**2**) membrane with a slightly different half life of ca. 6 min.

Liquid–Liquid Extraction. The results of liquid–liquid extraction with **1**, **2**, and **3** were shown in Table 1. In the dark, **1** showed different binding abilities for alkali metal ions, the magnitude of binding ability lying in the order of $K^+ > Na^+ > Rb^+ > Cs^+$. In contrast, **2** showed no cation-binding ability. The binding ability of the compound **3** was in the order of $K^+ > Na^+ > Rb^+ > Cs^+$, which was the same as that of **1**. The cation-binding ability of **1** slightly diminished for all alkali metal cations by UV irradiation. The depressed cation-binding ability of opened **1** might be explained in terms of the electrorepulsive interaction between a positive charge of the nitrogen atom of the spiropyran part and the alkali metal cation trapped by benzo-15-crown-5 moiety in **1**.

Table 1. Effect of UV Irradiation on Liquid–Liquid Extraction

	Condition	Picrate extracted/%

1	Dark	38	58	31	24
1	UV irradiated	35	52	28	18
2	Dark	0	0	0	0
2	UV irradiated	0	0	0	0
3		23	36	17	13

a) Organic phase (2 ml of dichloromethane): [**1**], [**2**], or [**3**]=1×10^{-4} mol dm^{-3}. Aqueous phase (2 ml of water): [Alkali metal picrate]=1×10^{-5} mol dm^{-3}, [Alkali metal chloride]=1 mol dm^{-3}.

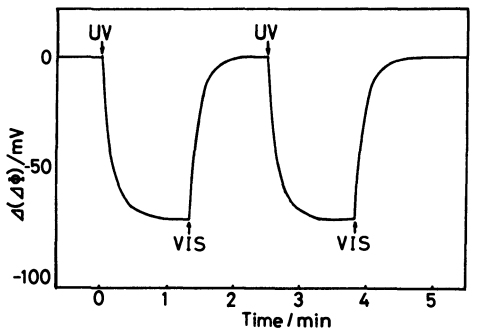

Fig. 4. Photoresponse of the membrane potential to alternate UV and VIS irradiation. PVC(**2**) membrane was used. Electrolyte was NaCl solution (1000 mmol dm^{-3}).

Photoinduced Potential Change. Figure 4 illustrates time response of the membrane potential change induced by alternate UV and visible light irradiation, which was obtained with the PVC(**2**) membrane. A negative shift of membrane potential was induced by UV irradiation. The membrane potential reached to a steady state under UV light within 30 s, and then returned to the initial potential by visible light irradiation within 30 s. It was reported in other membranes containing spirobenzopyran derivatives[4-8] that photoinduced potential changes occurred synchronously with photoisomerization between closed and opened forms. Since we also observed the purple-colorless change of the PVC(**2**) membrane associated with UV and visible light irradiation, the present photoinduced potential change should occur on the same basis. Table 2 shows the effects of the kind and concentration of alkali metal salts on the photoinduced potential change ($\Delta(\Delta\Phi)$) across the PVC(**2**) membrane. The $\Delta(\Delta\Phi)$ value was not dependent upon the kind of alkali metals except for Na^+, and was hardly affected by the alkali metal concentrations. Table 3 shows the photoinduced potential change $\Delta(\Delta\Phi)$ across the PVC(**1**) membrane. The $\Delta(\Delta\Phi)$ value remarkably depended upon both the kind and concentration of the alkali metals. With increasing concentration, the $\Delta(\Delta\Phi)$ value became less negative or more positive. The tendency for shifting toward more positive poten-

Table 2. Photoinduced Potential Changes, $\Delta(\Delta\Phi)$/mV, across PVC(2) Membrane

Electrolyte	Electrolyte concentration/mmol dm^{-3}		
	10	100	1000

tial lay in the order of $K^+>Rb^+>Na^+>Cs^+$. In the case of PVC membrane entrapping azobenzene-linked (bis crown ethers),[3-8] which had stronger binding ability for alkali metal ions after UV irradiation, the $\Delta(\Delta\Phi)$ value was reported to be negatively shifted by photoinduced enhancement of cation-binding ability. The opposite shifts observed here therefore seem reasonable since cation-binding ability of **1** decreases by UV irradiation. Table 4 shows the photoinduced potential changes $\Delta(\Delta\Phi)$ across PVC(**2** and **3**) membrane. Although the extent was smaller than that for PVC(**1**) membrane, the $\Delta(\Delta\Phi)$ value was affected by both the kind and concentration of alkali metals, the absolute value of the negative potential change becoming smaller with increasing alkali metal concentration. This phenomenon may be due to the decreased contribution of the photoinduced charge density to total charge density on the membrane surfaces, which was caused by the amount of alkali metal cations trapped by crown ether **3**.

Conclusion

We have shown by liquid–liquid extraction that the cation selectivity of spirobenzopyran **1** changes by photoirradiation. When **1** was entrapped in PVC membrane, the membrane exhibited marked photoinduced membrane potential changes, which were dependent upon the alkali metal species. This kind of photoexcitable membranes will be useful for construction of new photosensors, with which alkali metal concentrations can be measured.

A High-Resolution Solid-State ^{23}Na NMR Study of Sodium Complexes with Solvents, Small Ligand Molecules, and Ionophores. ^{23}Na Chemical Shifts as Means for Identification and Characterization of Ion-Ion, Ion-Solvent, and Ion-Ligand Interactions

Ryoko TABETA, Misako AIDA, and Hazime SAITÔ*

(Received December 26, 1985)

We have recorded static and magic angle spinning (MAS) ^{23}Na NMR spectra of a variety of inorganic salts, solvent complexes, and complexes with small ligand molecules and ionophores in the solid state, in order to obtain the ^{23}Na chemical shifts of the ion-ion, ion-solvent, and ion-ligand interactions, respectively. In all cases, MAS resulted in considerable reduction of the linewidths. The observed ^{23}Na chemical shifts were corrected by subtracting the displacements by the quadrupole interaction when the quadrupole coupling constants cannot be ignored. We found that the range of the ^{23}Na chemical shifts found in the solid state is about 60 ppm and the ^{23}Na chemical shift of $NaBPh_4$ appears at the highermost region (−52 ppm). The ^{23}Na NMR chemical shifts of these complexes exhibited their characteristic peak positions, depending on variety of ligand molecules (H_2O, ether, or carbonyl) and Na-O interatomic distances but independent of the type of counterion. Finally, an attempt was made to relate the ^{23}Na chemical shifts to the magnitude of electron transfer from the ligand molecules to 3p orbital of Na^+ ion, by means of an ab initio molecular orbital method.

In recent years, coordination chemistry of alkali and alkaline earth metal ions has gained much interest in relation to understanding the vital role of these metal ions in biological systems and the manner of their specific interaction with naturally occurring ionophores or synthetic analogues such as crown ethers and cryptands.[1] As an excellent means of probing the behavior of the sodium ion in particular, high resolution ^{23}Na NMR spectroscopy has been extensively utilized to analyze the ion-ion, ion-solvent, and ion-ligand interactions in the solution state.[2-16] These ^{23}Na signals, however, cannot be observed separately but are seen as time-averaged single peaks due to rapid chemical exchange processes among several kinds of such short-lived species. Separate ^{23}Na NMR signals of free and complexed states were observed only when BPh_4 was used as a counterion stabilized as a solvent-separated ion pair[8] in solution or ligands of higher association constant such as cryptands were used.[10,12-16]

By contrast, it is expected that high-resolution ^{23}Na NMR studies in the solid state could provide unambiguous ^{23}Na chemical shifts of the individual species of the ion-ion, ion-solvent, and ion-ligand interactions, being free from interference due to chemical exchange processes as encountered in solution state. Undoubtedly, the collection of such data is invaluable because these parameters can be readily used as a diagnostic tool as well as reference data for the interpretation of solution ^{23}Na NMR studies. In addition, these data are very useful as viewed from the theoretical interpretation of the ^{23}Na chemical shifts in terms of electronic structures, because detailed molecular parameters are available from X ray diffraction studies. The displacement of the ^{23}Na chemical shifts was previously interpreted in terms of electron transfer from electron donors such as solvents to the 3p orbital of the Na^+ ion.[17] No detailed study, however, has been done as to the extent of such electron transfer to be compared with the experimental data.

For this purpose, it is known that magic angle spinning (MAS) can be effectively utilized for line-narrowing of the central $1/2 \leftrightarrow -1/2$ transition of quadrupolar nuclei with spin number of half-integer such as ^{23}Na in the solid state, if the line-splitting of the central line by the second-order quadrupole interaction can be neglected.[18] Otherwise, rapid sample spinning about an axis other than the magic angle is more favorable for line-narrowing.[19] In the present paper, we aimed to record ^{23}Na MAS NMR spectra of a number of inorganic salts,[20] solid solvent complexes, and complexes with small ligand molecules or ionophores, to obtain the ^{23}Na chemical shifts of the individual ion-ion, ion-solvent, and ion-ligand interactions, respectively. At the same time, static ^{23}Na NMR spectra were examined with the same samples to evaluate the quadrupole coupling constants, because the quadrupole interaction, if any, would cause the center of gravity in the ^{23}Na MAS NMR signals to shift upfield.[21]

Being consistent with our expectation, all samples studied here which possess octahedral or distorted octahedral arrangement of solvents or ligands gave single resonance lines because of negligible contribution of the quadrupole interaction, although correction of the ^{23}Na chemical shifts by the quadrupole interaction was necessary for crystals of inorganic salts such as rhombohedral, monoclinic and tetragonal structures. Interestingly, the range of the ^{23}Na chemical shifts in the solid state is about 60 ppm and the ^{23}Na NMR signal of $NaBPh_4$ is resonated at the highermost position (−52 ppm) which is very close to the data of the Na^- anion. In addition, the ^{23}Na chemical shifts of a variety of sodium complexes are varied significantly with type of ligand molecules (H_2O, ether or carbonyl group) and stereochemistry of these complexes including the Na-O distances as the most important parameter. Qualitatively, it appears

that the extent of electron transfer from the ligand molecules to Na^+ ion, as evaluated by an ab initio molecular orbital method with 6—31 G basis set, is in parallel with the displacement of ^{23}Na chemical shifts.

Experimental

Materials. Inorganic salts were of reagent grade and were used without further purification. The following sodium complexes were purchased from commercial sources: $Na_2SO_4 \cdot 10H_2O$ (Kanto Chemical Inc., Tokyo), sodium deoxyadenosine 5′-monophosphate hexahydrate (Na dAMP·$6H_2O$, Sigma Chemical Company, MI, USA), $Na_2HAsO_4 \cdot 7H_2O$, $Na(CH_3COO) \cdot 3H_2O$ (Wako Chemicals, Osaka), and trisodium nitrilotriacetate hydrate, sodium L-ascorbate and sodium D-isoascorbate hydrate (Tokyo Kasei Kogyo, Co. Ltd., Tokyo). These complexes were recrystallized from aqueous solution.

Solvent complexes of the Na ions with 1,4-dioxane,[22] methanol,[23] acetone,[24] and *N*,*N*-dimethylformamide[25] were prepared by the procedure described in the literatures. The sodium complexes with 1,4-dioxane are efflorescent and easily turn into anhydrous powder. By contrast, the complexes with methanol, acetone or *N*,*N*-dimethylformamide were decomposed very rapidly in air because of lower melting points (25—27°). Accordingly, several kinds of preparations were used to achieve unambiguous assignment of ^{23}Na signals whose relative peak-intensities were varied from sample to sample. For example, the following three kinds of samples were prepared for the complexes of $NaClO_4$ with 1,4-dioxane. $NaClO_4$ dissolved in small amount of water was mixed with 1,4-dioxane (mole ratio 1:3) and allowed to evaporate in air. After separation from solution, sample 3 was obtained by placing the colorless crystals thus obtained in vacuo for 3 h. Plate-shaped crystals were obtained by heating the above-mentioned crystals up to 60° and were allowed to evaporate in air. Sample 1 was obtained by blotting the crystals with a filter paper. Sample 2 was obtained by placing the sample in vacuo for 3 h.

(Ethylene glycol)(1-phenyl-1,3-butanedionato)sodium was obtained from ethanol solution containing sodium 1-phenyl-1,3-butanedionate and 4% ethylene glycol and was crystallized from toluene solution.[26] Glycine-sodium iodide-water (2/1/1) was obtained as crystal from aqueous solution containing glycine and NaI (mole ratio 2:1).[27] In a similar manner, triethanolamine-sodium iodide (1/1) was crystallized from methanol-1-butanol solution containing equimolecular amount of individual components.[28] A solution of acetic acid and half an equivalent of sodium hydroxide in water was allowed to evaporate to give crystals of $NaH(CH_3COO)_2$.[29]

Sodium complexes of valinomycin (Sigma Chemical Company, MI, U.S.A), nonactin (Boehringer-Manheim GmbH, Germany) and tetranactin (Chugai Pharmaceutical Co. Ltd., Tokyo) were obtained from ethyl acetate solution containing 10% excess NaSCN.[30] Complex formation was confirmed by the characteristic change of the ^{13}C chemical shifts in the solid state as determined by cross polarization-magic angle spinning (CP-MAS) NMR.[30,31] Monensin (Na salt) and lasalocid (Na salt) were purchased from Sigma Chemical Company, MI, U.S.A. These compounds were recrystallized from diethyl ether-petroleum ether (1:1) containing small amount of acetone or methanol.

Cryptands [2.2.2], [2.2.1], and [2.2] were purchased from Merck Chemical Company, Germany. 18-Crown-6 was purchased from Aldrich Chemical Company, WI, U.S.A. Sodium complexes with these ligands were prepared by dissolving in methanol, which was allowed to evaporate in air.[32] Complex formation was checked by examination of the ^{13}C CP-MAS NMR spectra.[32]

^{23}Na NMR Spectra. ^{23}Na MAS NMR spectra were recorded on a Bruker CXP-300 spectrometer operating at 79.35 MHz with a Z32DR MAS probe. Solid samples were contained in an Andrew-Beams type rotor machined from Delrin and spun as fast as 2—3 kHz by compressed air. Spectra were accumulated usually less than 200 times. Spectral width was 30 kHz and data points were 4 K. 90° pulse and repetition time were 6 μs and 2 s, respectively. ^{23}Na chemical shifts were referred to the signal of 1 M NaCl in aqueous solution (1 M=1 mol dm^{-3}).

Static ^{23}Na NMR spectra were recorded on the same spectrometer with a Z32vHP high power probe. The spectral width used was up to 500 kHz with 2 K data points. The quadrupole coupling constant was evaluated from the displacement of the satellite lines caused by the first-order (f.o.) quadrupole interaction or from the second-order (s.o.) splitting of the central line.[33]

Ab Initio Molecular Orbital Calculation. We calculated the electronic energies and electron densities of sodium complexes either with solvent molecules or ionophores as a function of the Na-O distance (R), by an ab initio molecular orbital method utilizing the IMSPACK program system[34] with a 6—31 G basis set.[35] As a geometry of complex,[36] we postulated an octahedral arrangment of six H_2O or six $H_2C{=}O$ molecules around the central Na^+ ion, representing also an ether (OH) or a carbonyl moiety of these ligand molecules, respectively. For comparison, we also calculated the electronic structure of some sodium complexes containing a single H_2O molecule having various orientations with respect to the sodium ion.

Results

Inorganic Salts. Figure 1 illustrates a typical example of the static ^{23}Na NMR spectrum of $NaClO_3$ in the solid state. The quadrupole coupling constant (e^2qQ/h) 785±2 kHz was readily evaluated either by the

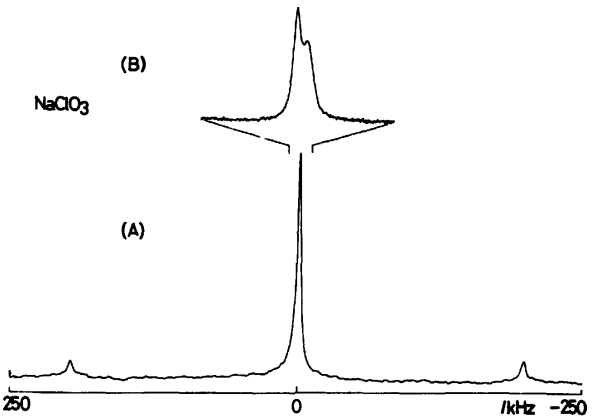

Fig. 1. 79.35 MHz static ^{23}Na NMR spectra of $NaClO_3$ in the solid state. (A) first-order split peaks (197 kHz from the central peak), spectral width 500 kHz. (B) second-order split central peaks (1.01 kHz), spectral width 20 kHz.

Table 1. ^{23}Na Chemical Shifts of Some Inorganic Salts in the Solid State (ppm from 1 M NaCl Soln)

	Static		MAS (ppm)			
	Type of spectrum[a]	$\frac{e^2qQ}{h}$ (kHz)	Obsd chemical shifts	Correction of chemical shifts by quadrupole interaction[b]	Corrected chemical shifts	Crystal structure
NaF	s	0	7.9±6	0	7.9±6	Cubic
NaCl	s	0	7.9±0.3	0	7.9±0.3	Cubic
NaBr	s	0	6.0±0.3	0	6.0±0.3	Cubic
NaHCOO	s	0	−0.2±0.7	0	−0.2±0.7

$NaClO_4$	o	0	−20.0±0.5	0	−20.0±0.5	Tetragonal
$NaBF_4$	s.o.	1200±100	−24.8±1.2	5.7±1	−19.1±2.5	Tetragonal
$NaBPh_4$	s	0	−51.7±1.6	0	−51.7±1.6	

a) s stands for single line; f.o. stands for the first-order split signal; s.o. stands for the second-order split central peak.
b) Estimated errors smaller than 0.1 ppm are not shown.

first-order or second-order quadrupole-split peaks.[33] The quadrupole coupling constants thus obtained are summarized in Table 1, although type of spectrum designated by s gave single lines without quadrupole interaction. In all cases, it was found that these static ^{23}Na NMR spectra were analyzed as being due to a symmetrical field gradient (η=0). In fact, the asymmetry parameter of $NaNO_3$ was reported to be exactly zero[37] and that of $NaBF_4$ was assumed to be negligible.[38] High resolution ^{23}Na MAS NMR spectra were obtained by MAS experiments which resulted in a considerable reduction of the linewidths.[39] The ^{23}Na chemical shifts are summarized in Table 1. The upfield displacements of the ^{23}Na signals by the quadrupole interaction were corrected by the following formula given by Lippmaa and coworkers.[21]

$$\delta = \frac{1}{40}(e^2qQ/h)^2/\omega_L \qquad (1)$$

where ω_L stands for the Larmor frequency.
